from Lisina together with natural and $NH_4$−Cp as an effective natural fertilizer mixture. Artificial neural network (ANN) models are recognized as a good modeling tool because they provide solutions to the problems from a set of experimental data and are capable of handling complex systems with nonlinearities and interactions between decision variables.[23,24] The main aim of this research was to determine how the processing time and changes in composition of the mixtures affect the PR dissolution and, further, whether the test mixtures have the potential to be adequate sources of nutrients required for plant growth. Using principal component analysis (PCA) and sensitivity analysis, solution concentrations of elements were tested against the impact of process variables. Empirical models of given systems were developed in the form of second-order polynomial (SOP) and ANN models. Characterization of the utilized minerals was also performed.

## MATERIAL AND METHODS

**Characterization of Materials.** The zeolite tuff (Cp), originating from deposit Baia Mare, Romania, and PR, apatite from ore deposit Lisina, near Bosilegrad, Serbia, were used in the experiment. Selected characteristics of the Cp and PR samples are presented in Tables 1 and 2. The CEC of the Cp using EPA method no. 9081 was 158.2 mequiv/100 g of zeolite (out of which $Ca^{2+}$ 92 mequiv, $K^+$ 51.5 mequiv, $Na^+$ 8.85 mequiv, and $Mg^{2+}$ 5.84 mequiv). To obtain $NH_4$−Cp, a partial saturation of Cp with $NH_4^+$ was performed according to the procedure described by Mihajlović et al.[25] at 1:7.5 ratios.

Powder X-ray diffraction (XRD) method was used to determine the phase composition of the Cp, $NH_4$−Cp, and PR. The XRD patterns of used natural Cp and $NH_4$−Cp were obtained on a Philips PW 1710 automated diffractometer using a Cu tube operated at 40 kV and 30 mA (for method details, see Mihajlović et al.[26]). Energy-dispersing spectroscopy (EDS) on scanning electron microscopy (JEOL JSM−6610LV SEM) was used to determine the composition of the starting materials.

**Experimental Procedure.** Two groups of several batch experiments were performed to investigate the solubility and ion-exchange relationships between Cp and PR. The purified Cp fraction (50−100 $\mu$m) and the PR coarse silt fractions (<37 $\mu$m) were used. The first group was composed of Cp/PR mixtures, and the second was composed of $NH_4$−Cp/PR mixtures. Both mixture groups were assembled in three different ratios of Cp and PR, 5:1, 10:1, and 15:1, and each system initially contained 4 g of PR. The mixtures in three replicates were placed in a 300 mL volumetric flask to which 200 mL of distilled water was added. Samples were shaken on a rotary shaker for 24, 48, and 72 h at 220 rpm After being drained, the resulting solutions were examined for contents of $Ca^{2+}$, $K^+$, $Na^+$, and $Mg^{2+}$ using the "Perkin Elmer AAS "703". Solution P concentration was determined by colorimetric method,[27] using SPEKOL 1300 UV VIS spectrophotometer.

**Exploratory Data Analysis.** Descriptive statistical analyses of the results were expressed as the mean ± standard deviation (SD). Analysis of variance (ANOVA) and the following posthoc Tukey's HSD were performed using StatSoft Statistica 10.0 software.

**Principal Component Analysis.** PCA is a multivariate analytical procedure extensively used in exploratory data analysis, in which the data are transformed into orthogonal components (principal components) that are linear combinations of the original variables.[28] This transformation is defined in such a way that the first principal component accounts for the largest variance in the data set. Consecutively, each of the following principal components accounts for the maximum of the remaining variance in the data set. In this research PCA analysis was used (i) to outline differences between the analyzed samples (mixture groups) by calculating score plots and (ii) to find correlations between the processes parameters (design variables) and measured solution concentrations of the cations (measured variables) by calculating correlation loading plots. All PCA calculations were performed by using The Unscrambler (version 10.1, CAMO Process AS, Oslo, Norway) and in-house developed routines written in MATLAB (version R2010a, The MathWorks, Natick, MA).

**Second-Order Polynomial Model.** The SOP model was used to estimate the main effect of the process parameters on the final concentrations of the investigated elements. The independent variables were processing time and composition of the fertilizer mixtures. All SOP models were fitted to data assembled by experimental measurements. The models of the following form were developed to relate 5 dependent outputs ($Y$) to 2 process variables ($X$):

$$Y_k = \beta_{k0} + \sum_{i=1}^{2} \beta_{ki} X_i + \sum_{i=1}^{2} \beta_{kii} X_i^2 + \beta_{k12} X_1 X_2, \quad k = 1, 2, 3, 4, 5 \tag{2}$$

where $\beta_{k0}$, $\beta_{ki}$, $\beta_{kii}$, and $\beta_{k12}$ are constant regression coefficients; $Y_k$ is the concentration of either P, $Ca^{2+}$, $K^+$, $Na^+$, or $Mg^{2+}$; and $X_i$ are either the processing time or the zeolite share in the mixture. Significant terms in the model were found using ANOVA for each dependent variable. The SOP models were obtained for each dependent variable, where factors were rejected when their significance level was $p > 0.05$. SOP modeling was performed by using StatSoft Statistica 10.0 software.

**Artificial Neural Network Modeling.** According to StatSoft Statistica's recommendations, the database was randomly divided into training data (60%), cross-validation data (20%), and testing data (20%). The cross-validation data set was used to test the performance of the network while training was in progress as an indicator of the level of generalization and the time at which the network has begun to overtrain. To improve the behavior of the ANN, the data set was normalized. To obtain good network behavior, it was necessary to make a trial-and-error procedure and to choose the number of hidden layers, together with the number of neurons within. The use of only one layer is advisible, because more layers worsens the problem of local minima.[29] According to Taylor,[30] multilayer perceptron models (MLPs) with three layers (input, hidden, and output) are the most flexible and general-purpose kind of ANN and, therefore, were used in this study. The MLP neural network learns using the "back-propagation" algorithm. The Levenberg−Marquardt algorithm was proved to be the fastest and suitable for networks of moderate size. The Broyden−Fletcher−Goldfarb−Shanno (BFGS) algorithm, implemented in StatSoft Statistica's evaluation routine, was used for ANN modeling.

**Training, Testing, and System Implementation.** After defining the architecture of ANN, the training step was initiated. Because of the high degree of parameters' variability, the training process was repeated several times to obtain the best performance of the ANN. It

was accepted that successful training was achieved when learning and cross-validation curves (sum of squares—SOS vs training cycles) approached zero. Testing was carried out with the best weights stored during the training step. Coefficient of determination ($r^2$) and SOS were used as parameters to check the performance (i.e., the accuracy) of the obtained ANNs. Finally, the best-behaved ANN was chosen and the model was implemented by using an algebraic system of equations to predict solution P, Ca, K, Na, and Mg concentrations in both fertilizer mixtures.

**Sensitivity Analysis.** ANNs were tested using sensitivity analysis to determine whether and under what circumstances the obtained models might result in an ill-conditioned system.[30] Sensitivity analysis is used for more precise defining of the influence of processing variables on the observed responses. The infinitesimal amount (+0.0001%) was added to each input variable in 10 equally spaced individual points encompassed by minimum and maximum of the training data, according to StatSoft Statistica's default. These signals were normally distributed with constant intensity and frequency.

## RESULTS AND DISCUSSIONS

**Mineral Characterization.** The XRD analyses confirmed that the major mineralogical component of the Cp and the $NH_4$−Cp was clinoptilolite (>75%) (Figures 1 and 2). The Cp

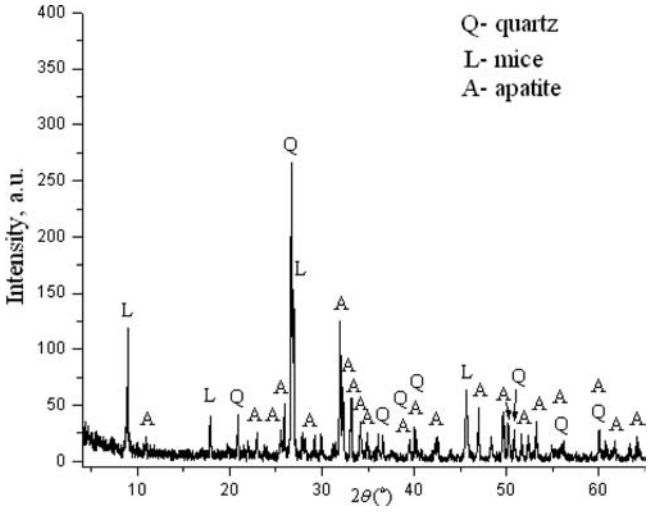

**Figure 1.** Diffractogram of the phosphate rock.

samples predominantly contained zeolite minerals from the group heulandites−clinoptilolites (HEUs) and feldspars, with smaller amounts of quartz, carbonates, and mica. The $NH_4$−Cp samples predominantly contained zeolite minerals from the group HEUs and smaller amounts of quartz and mica. A fraction of volcanic glass in both samples was significant, and the degree of crystallinity was very low. The XRD spectra of used natural Cp and $NH_4$−Cp could be found elsewhere.[26] The mineral composition of the analyzed PR sample mainly contained apatite and smaller amounts of quartz and mica (Figure 1).

Scanning electromicrographs illustrate the morphology of the analyzed zeolites and PR samples (Figure 2a, b, and c). The photomicrograph of the Cp sample shows that the crystal assemblage occurs as plates clustered closely together (Figure 2a). Clinoptilolite generally exists in the coffin-shaped crystals of monoclinic symmetry.[31] The flaky material coexisting with the crystals indicates the possible presence of mica and clay, which is consistent with the XRD analysis. The corresponding SEM energy-dispersive X-ray (EDX) spectrum shows that, apart from the gold (Au) peak, the main chemical elements (Al, Si, O, K, Mg, Ca, and Fe) are present in the Cp structure, which is in agreement with its chemical composition (Table 1). The SEM micrograph of the $NH_4$−Cp sample shows that the crystals maintained their original form after saturation, with a detectable content of impurities (Figure 2b). The matching SEM-EDX spectrum proved the presence of Si, Al, O, and K, but with smaller amounts of Ca and the absence of Mg compared to the untreated Cp EDX spectrum. The SEM micrograph of the PR particle is shown in Figure 2c, also with an obvious presence of flaky impurities. The matching EDX confirms the presence of the basic structural elements of the ore (P, Ca, and F) as well as the presence of Si and Al probably from quartz and mica, which is in agreement with the XRD spectra.

**Experimental Results.** *Reaction Time.* The reaction times in the present study were chosen on the basis of the proposed equilibrium times of similar batch experiments with zeolite and PR.[8,20,22] To assess the effect of mixture composition on nutrient availability, three ratios of Cp to PR, 5:1, 10:1, and 15:1, were used. The concentrations of P, $Ca^{2+}$, $K^+$, $Na^+$, and $Mg^{2+}$ in the solution, after shaking the Cp/PR and $NH_4$−Cp/PR mixtures for various durations of time, are shown in Tables 3 and 4, respectively. Obtained element concentrations were compared to the time-related concentrations liberated from PR alone.

In the Cp/PR mixtures a sudden increase in the concentration of all nutrients for the first 24 h of shaking was observed, followed by a significantly different but moderate increase up to 72 h for all three Cp/PR ratios (Table 3). Allen et al.[22] reported a similar small improvement in cation exchange in the Cp/PR mixture, after a rapid increase for the first 16 h. Also, after 72 h cation exchange has nearly ceased up to 96 h.[22] From Table 3 a gradual increase in concentrations of all nutrients as the ratio of the Cp/PR mixture increases can be observed. This finding is in accordance with previous results for P but in contrast to the behavior of $Ca^{2+}$ reported by Allen et al.[22] and Barbarick et al.[8] In the $NH_4$−Cp/PR mixtures, a rapid increase of solution P concentration in the first 24 h was followed by a slow increase up to 72 h (Table 4). This finding is also in accordance with the results of Allen et al.[32] where, after an initial phase of 6 h, the rate of P release decreased with time, despite the further PR dissolution. Solution P concentrations found in the $NH_4$−Cp/PR mixtures were about 2- to 3-fold higher than the P concentrations released from the correspondent Cp/PR mixtures. Similarly, three times higher P concentrations released from the $NH_4$−Cp/PR mixture compared to the Cp/PR mixture have been reported by Lai and Eberl.[20] Solution Ca concentrations after 24 h showed a tendency to decrease with time in the $NH_4$−Cp/PR mixtures and were 25 times higher than the $Ca^{2+}$ concentrations found in the respective Cp/PR mixtures. These results support the conclusions that have been previously published by Lai and Eberl,[20] where the released $Ca^{2+}$ from the PR, driven by cation exchange with $NH_4^+$, has been partially sequestered by the zeolite before equilibrium. The decrease in Ca promotes further dissolution of PR. Therefore, the $NH_4$−Cp contributes more to the dissolution of PR than the natural Cp. Solution Na and K concentrations increased by 2-fold with an increase of $NH_4$−Cp/PR ratio and varied over time around similar values. Solution Mg concentrations rapidly increased with time and with an increase of $NH_4$−Cp/PR ratio and were ∼70 times higher than the correspondent Mg concentrations released from the Cp/PR mixture. These results suggest a potentially

important role of $Mg^{2+}$ in the PR-dissolution process. Allen et al.[22] referred to the complex mechanism of $NH_4$−Cp−PR interaction, despite the fact that the simplified eq 1 describing the mechanism of PR dissolution was assumed to be sufficient.

**$NH_4^+$ in Soil Solution.** The typical range of $NH_4^+$ in soil solutions of agricultural soils varies between 0.36 and 3.60 mg $L^{-1}$.[33] According to numerous literature data points, the optimum N concentrations for maximum yield production of various plants ranges between 150 and 300 mg $L^{-1}$.[34−38] By applying chemical fertilizers, plants are supplied with inorganic N via two basic forms: inorganic nitrate nitrogen ($NO_3^{2-}$−N) and ammonium nitrogen ($NH_4^+$−N). A satisfactory plant yield

[a]Values printed in one column with the same letters (a−i) are not statistically different at the $p < 0.05$ level, 95% confidence limit, according to Tukey's HSD test.

may be achieved by a combination of both N types and sometimes with $NH_4^+$−N alone.[38] It was also demonstrated that plants adjust to acidic soils and that soils with low redox potential favor $NH_4^+$ ions.[39] When considering the degree of saturation of used Cp,[25,27] recalculated total contents of $NH_4^+$ from Cp-exchange sites in the $NH_4$−Cp/PR mixtures were 4, 8, and 12 g $L^{-1}$ for 5:1, 10:1, and 15:1 ratios, respectively. Thus, all three $NH_4$−Cp/PR mixtures that were used in this study have the potential to meet the necessity of plants for nitrogen even at a very low level of $NH_4^+$ discharge. This has already been confirmed by previous experiments with the $NH_4$−Cp/PR mixtures of similar composition.[8,21,22,32,40]

**Solution Cation Concentrations.** *Potassium.* As was shown by Tisdale et al.,[41] the optimum soil solution K concentrations are in the range between 8.6 and 60.0 mg $L^{-1}$. The concentration of $K^+$ found in the solution of the Cp/PR and $NH_4$−Cp/PR mixtures were near the lower and middle part of the range, giving further support to the ability of the test mixtures to provide K (Tables 3 and 4). The highest concentration of $K^+$ in the solution (41.07 mg $L^{-1}$) was detected in the $NH_4$−Cp/PR mixture with the maximum Cp abundance (Table 4).

*Phosphorus.* According to Tisdale et al.,[41] soil solution P concentrations adequate for a variety of crops range from 0.2 to 0.3 mg $L^{-1}$. Solution P concentrations in this study were between 0.15 and 0.28 mg $L^{-1}$ in the Cp/PR mixtures and between 0.36 and 0.82 mg $L^{-1}$ in the $NH_4$−Cp/PR mixtures (Tables 3 and 4). Allen et al.[22] reported that the Cp/PR mixtures of similar composition have provided between 0.465 and 12.1 mg $L^{-1}$ of P in the solution when reactive North Carolina (NC) and Tennessee (TN) PRs were used. Even though the solubility of PR from Lisina was lower compared to the NC and TN PRs, the prepared substrates have the potential to provide sufficient levels of P to support plant growth, especially the $NH_4$−Cp/PR mixtures.

*Calcium.* In well-balanced, flowing nutrient solutions, maximal growth rates of ryegrass and tomato were obtained at Ca concentrations of 0.1 and 4.0 mg $L^{-1}$, respectively.[38] According to Asher and Edwards,[42] the $Ca^{2+}$ concentrations required for plant growth have to be substantially higher in soil solutions than in balanced flowing nutrient solutions. Typical soil solution Ca concentrations necessary for a high yield of agricultural crops has been reported to be from 8 to 45 mg $L^{-1}$ and should not be lower than 14.8 mg $L^{-1}$.[41] Solution Ca concentrations in the Cp/PR substrates in this study ranged from 11.0 to 24.5 mg $L^{-1}$ (Table 3). In the $NH_4$−Cp/PR mixtures the intensities of Ca were between 112.5 and 700.5 mg $L^{-1}$ (Table 4). These results indicate that a sufficient amount of $Ca^{2+}$ can be supplied by the $NH_4$−Cp/PR test mixtures. Further, obtained solution Ca concentrations released from the $NH_4$−Cp/PR mixtures were substantially higher than previously reported.[22,40] This can be attributed to the difference in physicochemical composition of the raw materials, but also to the fact that in this experiment partially saturated $NH_4$−Cp was used, which preparation has been previously proposed.[25] Thus, obtained $NH_4$−Cp contains a sufficient amount of residual Ca that may be released in further ion-exchange reactions.

*Sodium.* In temperate regions, the typical Na concentration in soil solution is on average 2.3−23.0 mg $L^{-1}$. In semiarid and arid regions the concentrations of $Na^+$ in soil solution are 50-fold higher and may have a damaging effect on the growth of most crop plants due to saline stress. The growth response to $Na^+$ significantly varies among plant species as well as genotypes within a species.[37] The concentrations of $Na^+$ in the Cp/PR mixture solution in this study varied between 20.05 and 29.50 mg $L^{-1}$ and from 3.59 to 6.48 mg $L^{-1}$ in the $NH_4$−Cp/PR mixtures (Tables 1 and 2). Both substrates are therefore low in Na and do not induce saline stress in plants. In arid regions the $NH_4$−Cp/PR mixtures could prove to be good soil conditioners. Although $Na^+$ is essential for many, but not all, plant species, the conclusions on $Na^+$ as a beneficial nutrient are relatively scarce.[43]

*Magnesium.* The optimal concentration of $Mg^{2+}$ in soil equilibrium solutions is ∼0.94 mg $L^{-1}$.[37] Solution Mg concentrations in this study ranged from 0.33 to 0.95 mg $L^{-1}$ in the Cp/PR mixtures and from 11.25 to 61.69 mg $L^{-1}$ in the $NH_4$−Cp/PR mixtures, indicating that the ample Mg will be supplied by the test substrates even when the unsaturated zeolite is used (Tables 3 and 4).

*Solution pH Values.* In the Cp/PR mixtures the pH values ranged between 7.53 and 7.75 and were slightly increased compared to the pH values of the PR alone (Table 3). The same trend of solution pH values between natural Cp and PR alone has been reported in ref 20. Because the solution pH values of the $NH_4$−Cp/PR mixtures increase as the mixture ratio increases, the pH values of the measured mixtures increased from 8.53 to 8.75 (Table 4). According to Allen et

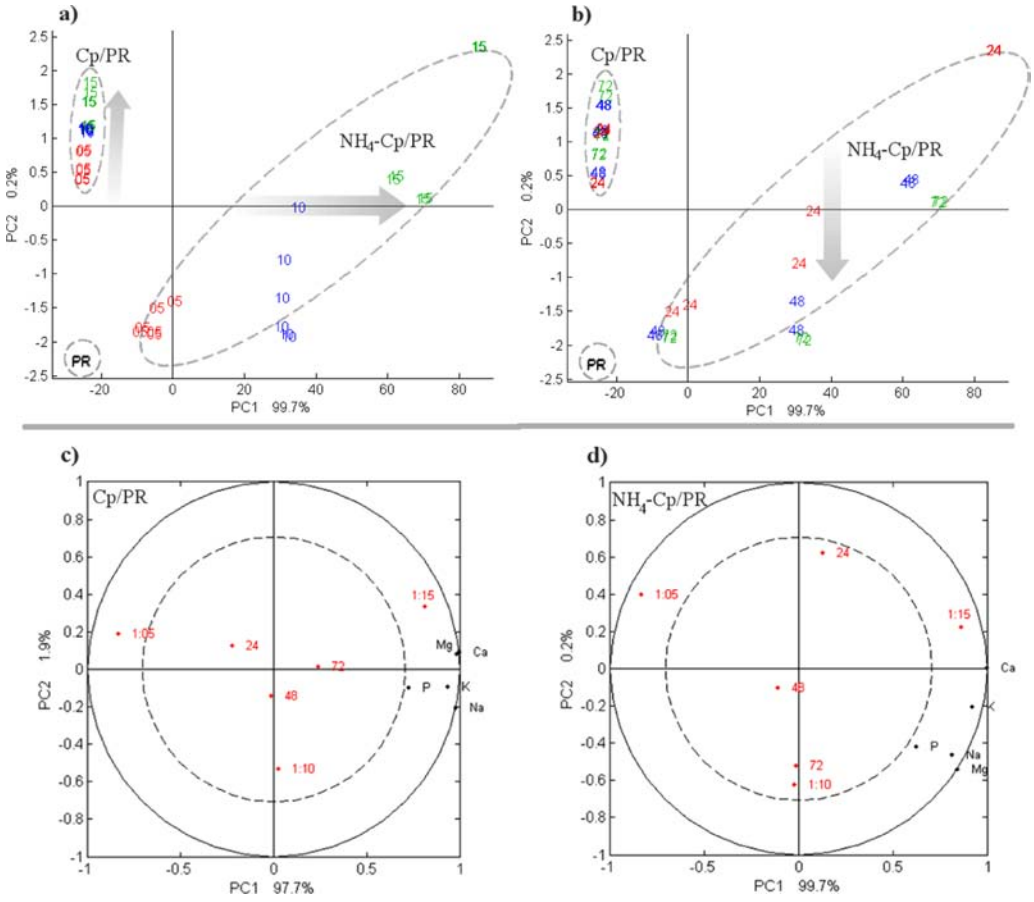

**Figure 3.** Score plots of the PCA model obtained on the whole data set with samples labeled in accordance with (a) the zeolite/PR ratio (where 05 designates 5:1, 10 designates 10:1, and 15 designates 15:1 ratio) and (b) the duration of mixing time (24, 48, and 72 h). Correlation loading plots of the PCA model for (c) the Cp/PR mixtures where design variables are presented in red and solution cation concentrations are presented in black color and (d) the $NH_4$−Cp/PR mixtures where variables are presented as in (c).

al.,[22] better dissolution of PR promoted by $NH_4$−Cp released more $OH^-$ into solution as the Cp/PR ratio increased (eq 1).

**Principal Component Analysis.** PCA was performed on the whole data set (Tables 3 and 4) to analyze the main variation patterns caused by the experimental design, and the results are presented as score plots in Figure 3a and b.[44] To obtain a better overview of the effects of mixing time and $NH_4$−Cp/PR ratio on solution cation concentrations in different substrates, two additional principal component analyses were performed on the subsets of data: one for Cp/PR substrate samples and one for $NH_4$−Cp/PR substrate samples (presented as correlation loading plots in Figure 3c and d).[44]

*Effect of Zeolite/PR Ratio.* The PCA score plot with samples labeled in accordance with the zeolite/PR ratio is presented in Figure 3a. The first two principal components account for 99.9% of the variation in the data set, and along these principal components the separation between substrates of different composition is observed: pure PR samples are separated in the farthest down-left part of the score plot, Cp/PR samples in the upper left, and the $NH_4$−Cp/PR substrate samples are separated in the right part of the score plot. Furthermore, a clear separation between the $NH_4$−Cp/PR substrates of different composition is visible along the first principal component. Along with that, the variance between the Cp/PR substrates of different composition is also observed along the second principal component but is significantly less pronounced than for the $NH_4$−Cp/PR substrates. This indicates that the composition of the mixture has a much stronger effect on the $NH_4$−Cp/PR mixture. Moreover, the highest zeolite share has the strongest influence on solution cation concentrations (Figure 3a).

*Effect of Mixing Time.* A PCA score plot with samples labeled in accordance with the duration of mixing time is presented in Figure 3b. A separation between the $NH_4$−Cp/PR substrates that were mixed for different durations of time can be observed along the second principal component (emphasized with gray downward arrow). It can also be seen that the influence of mixing time increases as the zeolite/PR ratio increases, meaning that the strongest effect of mixing time is observed for the substrates with 15:1 zeolite/PR ratio (e.g., these samples are more separated than the rest). Conversely, the influence of the mixing time has a very weak effect on the Cp/PR substrates and PR alone.

*Correlation Loading Plots.* From the correlation loading plots calculated for both substrates (Figure 3c and d), it can be observed that the highest zeolite/PR ratio exhibits the strongest influence on solution P, Ca, K, Na, and Mg concentrations. Moreover, the concentration of $Ca^{2+}$ in the solution is most affected by the $NH_4$−Cp/PR ratio of 15:1, while P is being the least affected by the same. In contrast to the Cp/PR mixture, a positive correlation between solution P concentrations, mixing time of 72 h, and $NH_4$−Cp/PR ratio of 10:1 was observed. Although these variables are positioned in the inner circle of the

[a]Significant at $p < 0.05$ level. [b]Significant at $p < 0.10$, level, 95% confidence limit, error terms were found statistically insignificant; df = degrees of freedom.

correlation loading plot (<50% of explained variance), the positive correlation found between them can be taken as an indication that the highest concentration of P in the solution can be achieved with longer mixing times and the moderate $NH_4$−Cp share in the mixture.

**ANOVA and SOP Models.** ANOVA was conducted for obtained SOP models, and solution P, Ca, K, Na, and Mg concentrations were tested against the impact of process variables (Tables 5 and 6). According to ANOVA of SOP models for Cp/PR mixtures, calculation of solution P, Ca, K, Na and Mg concentrations was mostly affected by the linear term of the Cp share in the mixture, which is statistically significant at $p < 0.05$ level, 95% confidence limit (Table 5). The quadratic term of the Cp share was also found to be very influential for the calculation of P, Ca, and K at $p < 0.05$ level. The linear term of t was found to be significant for calculation of P ($p < 0.05$).

**Table 6. ANOVA of the $NH_4$−Cp/PR Mixtures**

| | df | P | Ca | K | Na | Mg |
|---|---|---|---|---|---|---|
| t | 1 | 0.00 | 12.75[a] | 0.00 | 5.07 | 0.01[a] |
| $t^2$ | 1 | 0.00 | 0.05 | 0.01 | 0.01 | 0.00 |

| $r^2$ | | 0.905 | 0.992 | 0.988 | 0.946 | 0.997 |

[a]Significant at $p < 0.05$ level. [b]Significant at $p < 0.10$ level, 95% confidence limit, error terms were found to be statistically insignificant; df = degrees of freedom.

According to ANOVA of SOP models for $NH_4$−Cp/PR mixtures, calculation of solution P, Ca, K, Na, and Mg concentrations was mostly affected by the linear term of the $NH_4$−Cp share in the mixture, which is statistically significant at $p < 0.05$ level, 95% confidence limit (Table 6). The quadratic term of the $NH_4$−Cp share was also found to be very influential for the calculation of P, K, and Na, $p < 0.05$ level. The linear term of t was found to be significant for calculation of Ca (at $p < 0.05$ level).

The residual variance, marked as error in Tables 5 and 6, presents the model disagreement with the experimental values (contributions of other members that are not described in the SOP model). All developed models showed statistically insignificant deviation from the experimental values of the model, which confirmed their suitability. Analysis revealed that

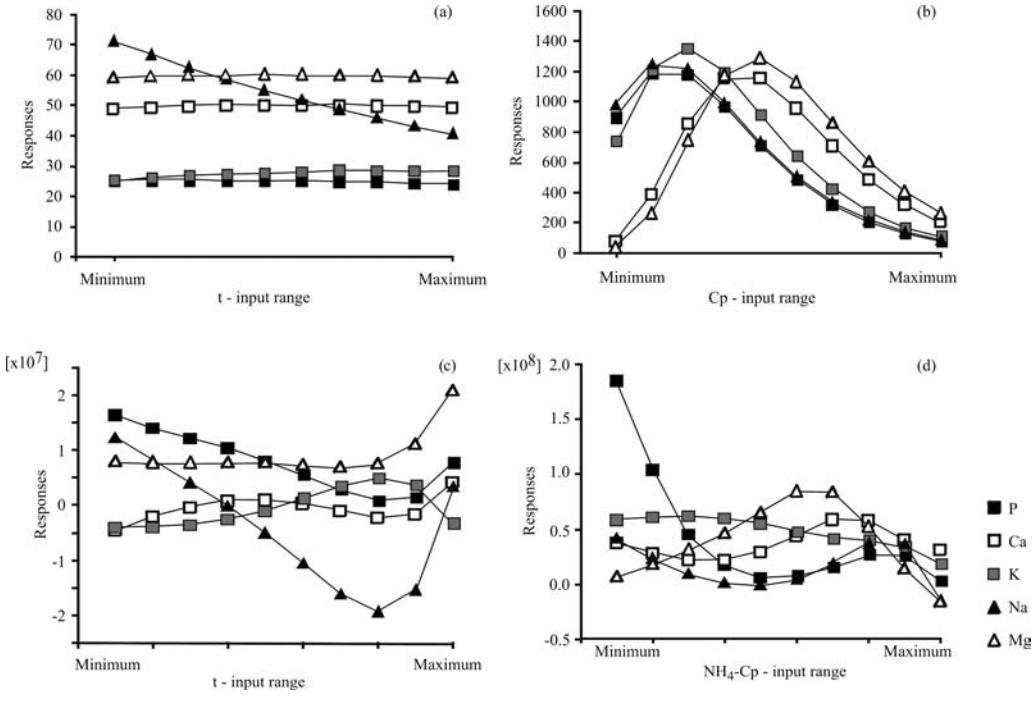

**Figure 4.** Sensitivity analysis for infinitesimal changes of process parameters in the Cp/PR mixtures (a, b) and the $NH_4$−Cp/PR mixtures (c, d).

linear, quadratic, as well as interchange terms considerably influenced forming SOP models. It is concluded that all of the obtained models were statistically significant and in agreement with the experimental results.

**Neurons in the ANN Hidden Layer.** All variables considered in the ANOVA analysis were also used for the ANN modeling. The optimum number of hidden neurons in this case was chosen upon minimizing the difference between the predicted ANN values and the measured solution concentrations of the elements, using SOS during testing as the performance indicator. According to ANN, the optimal number of neurons in the hidden layer was 3 (network MLP 2−3−5) for the Cp/PR mixture and 9 (network MLP 2−9−5) for the $NH_4$−Cp/PR mixture application, as well as when obtaining high values of $r^2$ and low values of SOS.

**Simulation of the ANNs.** ANN models were used to predict experimental variables (solution P, Ca, K, Na, and Mg concentrations). An optimal network, used for the Cp/PR mixture application, was able to predict all process outputs for a broad range of the process variables (coefficients of determination reached 0.986 for P; 0.993 for $Ca^{2+}$; 0.998 for $K^+$; 0.994 for $Na^+$; and 0.997 for $Mg^{2+}$) during the testing period. The accuracy of solution P, Ca, K, Na, and Mg concentrations' prediction of the $NH_4$−Cp/PR mixtures was also very good (0.998 for P; 0.999 for $Ca^{2+}$; 0.999 for $K^+$; 0.999 for $Na^+$; and 0.999 for $Mg^{2+}$ calculations). The predicted values were very close to the measured values in most cases, in terms of $r^2$ value. It is noteworthy that these coefficients of determination values are higher than those $r^2$ associated with the SOP model. Although ANN models are more complex (29−77 weight biases for the solution P, Ca, K, Na, and Mg concentration model of both the Cp/PR and $NH_4$−Cp/PR experimental mixtures) than SOPs; ANNs performed a bit better because of the high nonlinearity of the developed system. The mean of residuals for the Cp/PR mixture application model were 0.040 for P, 0.006 for $Ca^{2+}$, 0.019 for $K^+$, 0.015 for $Na^+$, and 0.010 for $Mg^{2+}$ content. The mean of residuals for the $NH_4$−Cp/PR mixture application model were 0.051 for P, 0.006 for $Ca^{2+}$, 0.028 for $K^+$, 0.025 for $Na^+$, and 0.012 for $Mg^{2+}$. These results showed a good approximation to normal distribution around zero with a probability of 95% (2 × SD), which delineates a good generalization ability of ANN model for the range of observed experimental values.

**Sensitivity Analysis.** For better access to the concentration changes of the elements, due to variations of process parameters, a sensitivity analysis was performed. The greater effect observed in outputs means greater sensitivity with respect to the process parameters.[45] Herein, the influence of the infinitesimal changes in process parameters (inputs) over solution P, Ca, K, Na, and Mg concentrations (outputs) was observed (Figure 4). The calculated changes in outputs corresponded to the level of experimental errors and showed how processing time and composition of the mixtures influence solution P, Ca, K, Na, and Mg concentrations.

Solution P, Ca, K, and Mg concentrations in the Cp/PR mixtures were not affected by the duration of the experiment, while prolongation of mixing negatively affects the Na concentration (Figure 4a). In contrast to this, in the $NH_4$−Cp/PR mixtures, solution P, Ca, K, Na, and Mg concentrations were affected by infinitesimal changes especially at a higher value of *t*. The concentrations of P, $Ca^{2+}$, $Na^+$, and $Mg^{2+}$ were increasing, while the concentration of $K^+$ in the solution was lowering at the upper input range limit (Figure 4c). In the Cp/PR mixtures all elemental concentrations in the solution were increased by small positive changes in Cp input between the minimum and medium input range (Figure 4b). The medium Cp input led to higher responses of P, Ca, K, Na, and Mg. The changes in $NH_4$−Cp share in the mixture led to complex phenomena, with it being most evident at the middle and upper limits of the input range, which is in accordance with PCA. Similar to $NH_4$−Cp system, responses to P, Ca, K, Na, and Mg concentration decrease with the Cp share increase, as the system approaches equilibrium. The highest response of P was observed close to the minimum of the Cp and $NH_4$−Cp input range, which is in accordance with PCA and ANOVA analysis, as well as with experimental findings.

soils in response to different environmental gradients, such as redox status, soil porosity, and water contents.[19] The changes in PLFAs also permit study of the mechanism of persistent organic pollutant biodegradation in soils.[20−22] Bardgett et al. reported that total PLFAs decreased with increasing soil depth in both grazed and ungrazed grasslands.[23] From the soil surface down to 2 m, the ratios of cyclopropyl/monoenoic precursors and total saturated/monounsaturated fatty acids increased with soil depth, suggesting that the microorganisms inhabiting the deeper soil horizons are more carbon limited than surface-dwelling microbes.[24] The focus of the present work is to study the influence of electron donors and acceptors on the PLFAs.

The aims of this study were (a) to study the dissipation of PCP and follow the evolution of its metabolites in vertical profiles of flooded paddy soil (0−50 mm); (b) to determine the effects of external electron donors and acceptors on the vertical profiles of PCP dissipation and microbial community structure; and (c) to establish a link between soil microbial community structures (PLFAs), PCP dissipation, and redox reaction.

## MATERIALS AND METHODS

**Soil.** The soil was taken from the surface layer (0−20 cm) of a paddy soil in Jiaxing city, Zhejiang province, China. After sampling, the soil was air-dried, ground, and sieved to <1 mm prior to use. The soil contained 22.2% clay, 53.1% silt, and 24.7% sand. The soil pH, organic carbon, and amorphous Fe were 5.8, 31.3 g $kg^{-1}$, and 6.1 g $kg^{-1}$, respectively.

**Chemicals.** Pentachlorophenol (PCP, >98% purity) and 3,4,5-trichlorophenol (3,4,5-TCP, >98% purity) were obtained from Sigma-Aldrich (St. Louis, MO, USA). Methanol (>99.9% purity) was obtained from Merck KGaAb (Darmstadt, Germany). The other analytical grade chemicals were obtained from Sinopharm Chemical Reagent Co., Ltd., Shanghai, China.

**Electron Acceptors and Donors.** $Na_2SO_4$ and $NaNO_3$ were used to supply $SO_4^{2-}$ and $NO_3^-$ as electron acceptors. The concentrations of $Na_2SO_4$ and $NaNO_3$ were 2.8 and 1.7 g $kg^{-1}$ soil. The concentrations adopted were those normally used to create $SO_4^{2-}$ and $NO_3^-$ reducing conditions in soil−water systems.[5,25]

Crop residues were used to supply electron donors. They were rice straw (*Oryza sativa* L.), wheat straw (*Triticum aestivum* L.), canola residue (*Brassica chinensis* L.), and Chinese milk vetch (*Astragalus sinicus* L.). They were collected from field sites, oven-dried at 65 °C for 24 h, and then ground to <1 mm. Some of the residues were used for determination of chemical composition, and the remainder were stored for incubation experiments. Their chemical compositions (including total C, N, S, TOC, $NH_4^+$-N, $NO_3^-$-N) were analyzed following previously described methods[26,27] and are shown in Table S1 of the Supporting Information (SI). Details can be found in the SI.

**Analytical Methods.** Soil pH was determined in a suspension of 1:2.5 soil/water ratio (w/v). Soil organic carbon (OC) was measured by dichromate digestion. Soil particle size was determined using a hydrometer method. Soil-dissolved organic carbon (DOC) was extracted by Milli-Q water (soil/water, 1:2.5, w/v), determined by a TOC Analyzer (Multi N/C 3100, Jena Analytical, Jena, Germany). Soil $NH_4^+$ extracted by 1 M KCl (shaking 1 h at 20 °C, soil/extractant, 1:10) was analyzed colorimetrically using a continuous colorimetric flow system (Skalar SAN$^{++}$System, Breda, The Netherlands). $SO_4^{2-}$ was determined by shaking soils (0.5 g, freeze-dried) with 5 mL of Milli-Q water for 15 min. The suspensions were filtered through 0.22 $\mu$m Millipore membranes followed by analysis using a Dionex ICS-2000 ion chromatography system (Dionex, Sunnyvale, CA, USA) equipped with an ASRS Ultra II self-regenerating suppressor. The column used was IonPac AS11-HC, and the mobile phase was 10 mM aqueous potassium hydroxide. $Na_2SO_4$ was used as the standard for $SO_4^{2-}$ detection. The average recovery ($n$ = 3) of the analytic method for $SO_4^{2-}$ was 89.0 ± 3.0%.

**Experiment Design.** To prepare xenobiotic spiked soil, PCP solution in methanol was mixed with a portion of soil. The spiked soil was thereafter vented for 24 h for the methanol to vaporize and then mixed thoroughly with a large portion of uncontaminated soil (1:19, w/w). Then, the $NaNO_3$, $Na_2SO_4$, and crop residues were added to the PCP-polluted soils at 1.7, 2.8, and 15 g $kg^{-1}$ soil, respectively, and mixed thoroughly to establish eight treatments: (A) PCP unspiked control (CK1); (B) PCP without other addition (CK2); (C) PCP + $NaNO_3$; (D) PCP + $Na_2SO_4$; (E) PCP + wheat; (F) PCP + rice; (G) PCP + canola; (H) PCP + vetch. Finally, both amended and unamended soils were transferred to 250 mL beakers to provide 7 cm thick soil depths and equilibrated in a greenhouse for 7 days; Milli-Q water was added to create a 2 mm thick water layer covering the soil surface. The daytime temperature was between 30 and 35 °C, the night-time temperature was between 25 and 30 °C; soils were sampled at 30, 60, and 120 days after incubation by sacrificing individual replicates. Four days before sampling, flooded water above the soil surface in three duplicate beakers was allowed to evaporate and then to reach almost soil saturation. A 20 mL syringe with the top cut off was used to take samples from four profiles (0−10, 10−20, 20−30, and 30−50 mm) separately. Evaporated water was refilled with Milli-Q water every 2 days.

**PCP and Intermediate Analyses.** The concentration of PCP in soils was determined by ultrasonic extraction and solid phase enrichment, followed by HPLC analysis.[5] Soil samples (2 g, freeze-dry weight) were adjusted to pH 4 with sulfuric acid and extracted in 10 mL of methanol by ultrasonics (60 kHz, 25 °C) for 15 min. After centrifugation at 3000 rpm for 10 min, the supernatants were collected. The soil residues were then extracted twice more, as above. The supernatant extracts from each soil sample were then combined and concentrated to 1 mL by rotary evaporation. The concentrated extracts were then transferred to an SPE C18 cartridge (6 mL, 500 mg) with 10 mL of Milli-Q water followed by elution with 10 mL of methanol and concentrated to 2 mL under $N_2$. Finally, each sample was filtered through a 0.22 $\mu$m Millipore membrane (ANPEL, 13 mm diameter) prior to analysis. Details of the HPLC analysis were described in our previous study.[5] All measurements were in triplicates with a variation generally <5%. Procedural blanks were determined by going through the same extraction and cleanup procedures for each series of samples. The average recovery ($n$ = 3) and the determined limits for PCP detection were 95.0 ± 2.1% and 0.01 mg $kg^{-1}$, respectively.

The sample preparation and the extractants used for intermediate analysis were as described earlier by Chen et al.[2] with small modifications. Briefly, soil (2 g, freeze-dry weight) was extracted with 10 mL of methanol followed by centrifuging, and the supernatants were collected. The procedure was performed three times, and the supernatants were combined. The supernatants were concentrated to 1 mL by rotary evaporation and $N_2$ and then derivatized by mixing with $K_2CO_3$ (10 mL, 0.2 M) and acetic anhydride (0.5 mL). The derivatizations were then extracted using 4 mL of hexane. The determination of intermediates was performed using a GC-MS (N6890/5975B, Agilent, Santa Clara, CA, USA) equipped with an HP-5MS capillary column of 30 m × 250 $\mu$m × 0.25 $\mu$m film thickness. The temperature ramp was as follows: 80 °C for 2 min, from 80 to 250 °C at 10 °C $min^{-1}$, held for 5 min.

**PLFA Extraction and Analysis.** The microbial community structure was determined by PLFA analysis. The PLFAs were extracted from soils using a single-phase chloroform−methanol−citrate buffer system.[28] Then, phospholipids were separated from neutral lipids and glycolipids on a solid-phase extraction column (Supelco, Inc., Bellefonte, PA, USA). Methyl myristate fatty acid (19:0) was added as internal standard, and PLFAs were subsequently derivatized by mild alkali methanolysis. The resulting fatty acid methyl esters were identified by GC (N6890, Agilent) fitted with a MIDI Sherlocks microbial identification system (version 4.5, MIDI, USA). Fatty acids are described according to the nomenclature of He et al.[21] Details can be found in the SI. Main taxa, including bacteria, Gram-positive bacteria, Gram-negative bacteria, fungi, actinomycetes, sulfate-reducing bacteria, aerobic bacteria, anaerobic bacteria, and cyanobacteria, were identified by their specific individual PLFA biomarkers.[29−31] PLFAs that contributed <1% of the total amount of extracted sample or PLFAs that were observed in only one sample were eliminated from the data set.

**Statistical Analysis.** Statistical analysis and principle component analysis (PCA) of soil PLFAs were conducted with the SPSS 16.0

correlate and factor procedures. Treatment effects were tested by one-way ANOVA. In addition, Pearson correlation analysis was applied to study the relationship between PCP/3,4,5-TCP and the microbial community. Correlation analysis was performed using SPSS 16.0 for windows. All values are the means of triplicate determinations.

## RESULTS

**PCP Dissipation in Soil Profiles.** The dissipation of PCP in soil profiles is shown in Figure 1. Changes in PCP concentrations varied widely following the addition of electron donors and acceptors but showed a general trend in the initial 30 days of incubation, in which PCP decreased with increasing soil depth in all treatments. However, electron donors and acceptors showed opposite influences on the PCP dissipation. The addition of $NO_3^-$ and $SO_4^{2-}$ significantly ($p < 0.05$) inhibited the dissipation of PCP in the deep layer (20–50 mm) with increasing incubation time (Figure 1b,c), whereas the crop residues (Figure 1d–g) enhanced PCP dissipation in all soil profiles. By the end of the incubation, the PCP concentrations were 0.5–13.3, 6.3–30.0, and 6.0–32.2% for the control, $NO_3^-$, and $SO_4^{2-}$ treatments, respectively. As with all of the crop residue treatments, the PCP concentrations were <0.01 mg $kg^{-1}$ in all soil profiles (Figure 1d–g). No significant differences were observed between the four crop residue treatments.

**Formation of Intermediates during Dissipation.** 3,4,5-TCP was produced as a major intermediate of PCP dissipation during the incubation (Table 1). During the initial 30 days of incubation, 3,4,5-TCP was produced in the electron donor treatments, whereas it was not found in the control or electron acceptor treatments. The 3,4,5-TCP concentration showed the same trend in all of the electron donor treatments, which decreased with increasing soil depth. After 60 days of incubation, 3,4,5-TCP could almost be found in all of the treatments, but the variation trends were markedly different. In the electron donor treatments, the concentration increased with increasing soil depth except the wheat residue treatment in which the 3,4,5-TCP concentration was too low to have any significant difference between soil profiles. The 3,4,5-TCP concentrations in the electron donor treatments remained unchanged until the end of incubation. At the end, 3,4,5-TCP was also found in the other treatments, especially the control treatment, in which approximately 12.9 mg $kg^{-1}$ of 3,4,5-TCP was found in the 10–20 mm soil layer.

**Variations of Electron Acceptors and Donors in Soil Profiles.** The variations of dissolved organic carbon (DOC), $SO_4^{2-}$, and $NH_4^+$ in soil profiles are shown in Figure 2. The addition of crop residues greatly increased the release of DOC in the order Chinese milk vetch > rice > wheat > canola (Figure 2A). The spatial variations of DOC in the soil profiles showed the same trend during the entire incubation. The main trend was that the DOC increased with increasing soil depth during the entire incubation period. In the crop residue treatments, DOC decreased sharply from 30 to 60 days and maintained a slow decline until the end of incubation. However, in the control and electron acceptor treatments, the DOC concentration showed a slow decline from 30 to 60 days and remained constant by the end of incubation at 120 days, especially in the deep layers.

The vertical distribution of $SO_4^{2-}$ increased with increasing soil depth during 30 days of incubation, but the trend was opposite by the end of incubation at 120 days (Figure 2B) except for the $SO_4^{2-}$ treatment (Figure 2Bc). The addition of $NO_3^-$ inhibited the $SO_4^{2-}$ reduction compared to the control treatment. In contrast, the dissipation of $SO_4^{2-}$ markedly increased with the

addition of wheat straw, rice straw, and canola residue, whereas the vetch residue increased the soil $SO_4^{2-}$ content. However, the final concentrations of $SO_4^{2-}$ were 10.5−46.8 and 7.6−36.8 mg $kg^{-1}$ for the electron donor treatments and control treatment, respectively.

The $NH_4^+$ in the soil profiles showed the same trend in all treatments during the entire incubation time and decreased with increasing soil depth (Figure 2C). In the electron acceptor treatments, the addition of $SO_4^{2-}$ (2.8 g $kg^{-1}$ soil) markedly increased the $NH_4^+$ formation, whereas the addition of $NO_3^-$ (1.7 g $kg^{-1}$) had no effect. The Chinese milk vetch also increased the soil $NH_4^+$ content, whereas the other electron donor treatments enhanced the dissipation of $NH_4^+$ during the incubation.

**Soil Microbial Community Structure.** PCA is a multivariate technique that analyzes a data table in which observations are described by several intercorrelated quantitative dependent variables. Its goal is to extract the important information from the table, to represent it as a set of new orthogonal variables called principal components, and to display the pattern of similarity of the observations and of the variables as points in maps.[32] In this study, PCA was used to analyze the changes in soil PLFA patterns in response to the addition of electron acceptors and donors and the variation of soil depth (Figure. 3). The PCA was conducted with 25 individual PLFAs that were present in all of the treatments (Table 2 of the Supporting Information). The first principal component (PC1) accounted for 56.2% of the variation, whereas the second principal component (PC2) accounted for 15.3% of variation in the data. It was found that PC1 was responsible for the variation of PLFA values versus the soil depth, whereas PC2 was responsible for the respective variation of PLFA values versus the addition of electron donors and acceptors (Figure 3A). All of the individual PLFAs had positive PC1 values, which indicated that the abundance of PLFA

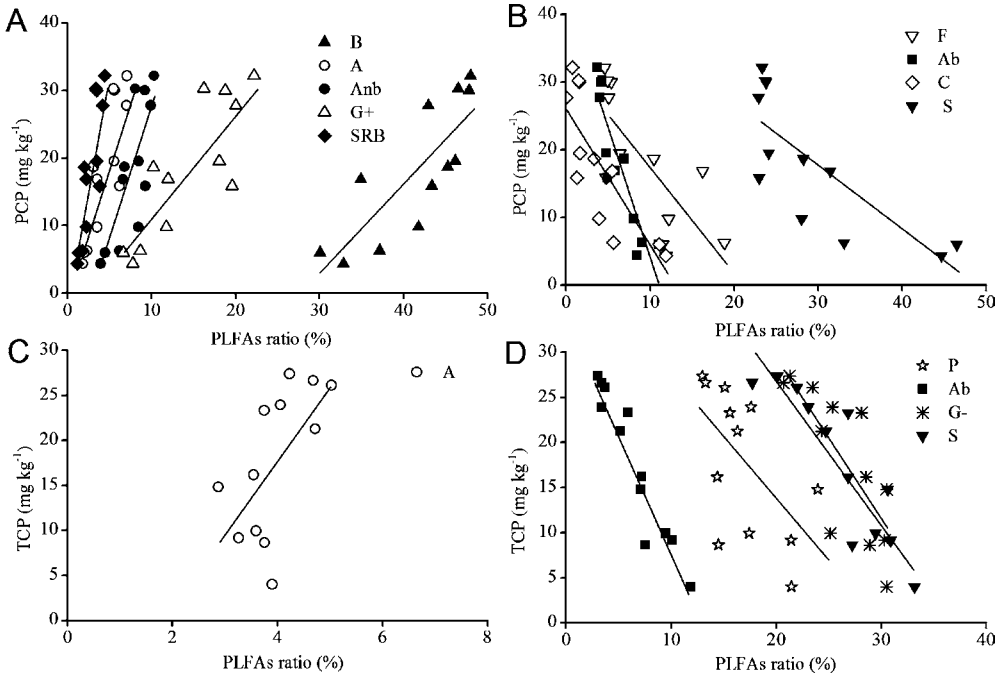

**Figure 4.** Correlation between PCP/3,4,5-TCP and microbial community: (A, B) relationship between PCP and ratio of PLFA signature groups to total PLFAs (%) in the electron acceptor and control treatments; (C, D) relationship between 3,4,5-TCP and ratio of PLFA signature group in the electron donor treatments. Symbols: B, bacteria; A, actinomycetes; Anb, anaerobic bacteria; G+, Gram-positive bacteria; SRB, sulfate reducing bacteria; F, fungi; Ab, aerobic bacteria; C, cyanobacteria; S, saturated PLFAs; P, precursors of cyclopropyl fatty acids; G-, Gram-negative bacteria.

decreased with increasing soil depth. The 17:1$\omega$8c and 17:0 had the highest PC1 values, which achieved 0.965 and 0.972, respectively (Figure 3B). The $NO_3^-$ and $SO_4^{2-}$ treatments clustered together and had much lower values in PC2 than the crop residue treatments. The order was electron acceptors, Chinese milk vetch, canola, rice, and wheat from negative to positive scores of PC2 (Figure 3A). cy19:0, 18:1$\omega$7c, and 17:1$\omega$8c represented aerobic bacteria clustered on the negative PC2, and i14:0, a15:0 and i16:0 represented anaerobic bacteria clustered on the positive PC2.

Ratios of particular PLFAs were changed with soil depth and varied significantly, with different responses to the addition of electron acceptors and donors (Table 2). In all treatments, the 30−50 mm soil layer had the highest cy/pre value, whereas the 0−10 mm soil layer had the highest i/a value. The S/M value increased with decreasing soil depth in the electron donor treatments, whereas no regularity could be found in the control and electron acceptor treatments.

**Correlation between PCP/3,4,5-TCP and Microbial Community.** Pearson correlation analysis is defined as a parametric linear correlation analysis based on Pearson's $r$ statistic and performed on raw data between two variables of observation.[33] The relationships between PCP/3,4,5-TCP and microbial community are shown in Figure 4. Pearson correlation analysis was used to demonstrate the relationship between PCP dissipation and PLFAs in the control, $NO_3^-$, and $SO_4^{2-}$ treatments because high residual PCP concentration was found in these treatments by the end of incubation. The results showed that PCP concentration was significantly and positively related ($p < 0.05$) to bacteria, actinomycetes, anaerobic bacteria, Gram-positive bacteria, and sulfate-reducing bacteria (Figure 4A), but negatively related to fungi, aerobic bacteria, cyanobacteria, and

saturated PLFAs (Figure 4B). In the crop residue treatments, PCP dissipated completely by the end and resulted in the production of 3,4,5-TCP. Therefore, here, we analyzed the correlation between 3,4,5-TCP and PLFAs. The 3,4,5-TCP concentration was significantly and positively correlated ($p < 0.05$) with actinomycetes (Figure 4C), but negatively correlated with the precursors of cyclopropyl fatty acids, anaerobic bacteria, Gram-negative bacteria, and saturated PLFAs (Figure 4D).

## DISCUSSION

**PCP Dissipation and 3,4,5-TCP Production.** The electron donors and acceptors showed significantly different effects on the dissipation of PCP in soil profiles (Figure 1). The inhibition of electron acceptors to PCP dissipation might be caused by competition for electron donors with PCP or increased soil redox potential, which finally inhibited PCP reduction. This was similar to other work.[5,25] The oxidation of electron donors was necessary for the anaerobic reduction of PCP, $SO_4^{2-}$, and $NO_3^-$. Dissolved organic carbon is an important complex electron donor that supports many redox reactions in flooded soils.[11,15] Hence, the PCP, $SO_4^{2-}$, and the DOC released from the decomposition of crop residues decreased with increasing incubation time (Figures 1 and 2). In addition, the decomposition of crop residues may also increase soil fertility, which might increase microbial activity involved in PCP dissipation.

The dissipation of PCP resulted in the accumulation of 3,4,5-TCP (Table 1). The inhibition of further 3,4,5-TCP dissipation might be due to the depletion of DOC (Figure 2A). Alletto et al.[34] found that isoxaflutole mineralization was significantly influenced by the nature of crop residues. The application of green manure to flooded soil resulted in the selective pathway of reductive dechlorination of DDT to DDD without enhanced formation of DDE.[35] In this study, 3,4,5-TCP was the major intermediate produced during the dissipation of PCP. The final accumulation of 3,4,5-TCP in soil profiles may be due to the deficiency of the meta and para positions of dehalogenase, which are both involved in the dechlorination of 3,4,5-TCP. Bouchard et al.[8] reported that the dechlorination of PCP by *Desulfitobacterium frappieri* resulted in the rapid production of 3,4,5-TCP, but further dechlorination was inhibited. However, 3,4,5-TCP showed greater toxicity than PCP.[8] In this study, the application of crop residues resulted in the accumulation of 3,4,5-TCP, a more toxic intermediate of PCP degradation. Hence, the accumulation of 3,4,5-TCP might inhibit bacterial growth.

Even though the addition of electron donors can increase the dissipation of PCP, it can also produce more toxic intermediate products. The decomposition of crop residues in soil can enrich soil fertility and simultaneously can also supply electron donors for redox reactions, including organic pollutants. Clearly, the negative effects should not be ignored.

**Soil Microbial Community Structure Response to External Electron Donors and Acceptors.** PLFA analysis is widely used to quantitatively assess the microbial community composition of soils.[29−31] In this study, the soil depth had the most effect on the PLFAs even in the small distance from 0 to 50 mm depth (Figure 3A). This significant difference in PLFA composition might be attributed to the flooded conditions. After flooding, oxygen could be consumed in a few hours followed by the reduction of $NO_3^-$, Fe(III), and $SO_4^{2-}$.[10] This might result in the formation of aerobic/anaerobic gradients from the surface to the deeper layers of soil profiles, possibly accounting for the difference in the PLFA composition. The PCA also showed that the composition of the microbial community was decreased with soil depth. Sundh et al.[36] reported that the total concentration of PLFAs decreased with depth in most profiles of both wet and dry boreal peat lands, but the decrease was steeper for wet sites than dry ones. This indicated a greater abundance of aerobic than anaerobic microorganisms. In this study, cyanobacteria were significantly and negatively related to PCP concentration (Figure 4B). Cyanobacteria could promote bacterial degradation of organic contaminants by increasing the oxygen supply or alternative organic substrates to promote bacterial growth.[37] In addition, cyanobacteria play an important role in the uptake and removal of insecticides.[37] Hence, in our study, the rapid dissipation of PCP (Figure 1) and 3,4,5-TCP (Table 1) in the surface layer might be partly caused by stimulation of the growth of cyanobacteria.

The predominant PLFAs differed significantly under different conditions (Figure 3). The monounsaturated PLFAs, such as cy19:0, 18:1$\omega$7c, and 17:1$\omega$8c, clustered on the negative PC2, which represented anaerobic bacteria, whereas the terminally branched PLFAs, i14:0, a15:0, and i16:0, clustered on the positive PC2, which represented aerobic bacteria (Figure 3B). The results indicated the successive shift from aerobic bacteria to anaerobic bacteria when electron acceptors were changed to electron donors. Among the Gram-negative bacteria, terminally branched PLFAs are more commonly found in anaerobes than in aerobes. Compared to wheat and rice treatments, the PCA clusters of vetch and canola treatments were much closer to the electron acceptor treatments (Figure 3A). This could be caused by the mineralization of S and N contained in vetch and canola residues (Table 1 of the Supporting Information; Figure 2Bg,Cg). The $SO_4^{2-}$ released during the decomposition of the crop residue also could be used as electron acceptors for soil microorganisms. The mineralization of organic N could release $NH_4^+$ under anaerobic condition and release $NO_3^-$ under aerobic conditions. Thus, both $SO_4^{2-}$ and $NO_3^-$ released from vetch and canola residues would have inhibited the formation of reducing environments due to a lack of electron donors.[5]

The ratios of specific PLFAs could be used to analyze the microbial stress response to substrate availability, water limitations, and contamination.[22,38] In this study, the values of cy/pre ratio were higher in the 30−50 mm layer, which might be caused by the higher DOC in the deep layer. As suggested by Feng and Simpson,[38] substrate availability has a large influence on the ratio of cy/pre. However, the cy/pre ratio decreased after the addition of electron donors. Similarly, Hammesfahr et al.[39] reported a decrease of cy/pre under manure addition. The decrease in S/M ratios indicated that the physiological and nutritional stress of the microbial community was relieved due to the increase in soluble substances.[40,41] However, our results were the opposite, in that the S/M ratios (Table 2) showed the same trend with DOC (Figure 2A) in soil profiles when amended with electron donors. A lower S/M ratio may be attributed to the higher rate of nutrient turnover.[29] 3,4,5-TCP is more toxic to bacteria and fungi than PCP.[42,43] In this study, the S/M ratio increased with soil depth, which probably implied that the nutrient turnover in soils declined after the accumulation of 3,4,5-TCP. In addition, the monounsaturated fatty acids also represent aerobic bacteria, which dominant in the surface and decrease with increasing soil depth.

In conclusion, this study provided an improved understanding of reductive dechlorination of PCP through investigating the dissipation of PCP and the variation in the microbial community in vertical soil profiles under flooded conditions with the

amendment of electron donors and acceptors. The addition of crop residues significantly enhanced PCP dissipation by supplying DOC as electron donors, whereas the addition of $NO_4^-$ and $SO_4^{2-}$ inhibited it by competition for electron donors with PCP or prevented the decrease in soil redox potential. The variety of PLFAs was decreased with increasing soil depth. Electron donors and acceptors showed significantly different effects on the soil microbial community. It shifted from aerobic to anaerobic bacteria when electron acceptors were changed to electron donors. Increases in the S/M ratio with soil depth probably implied that the nutrient turnover ability in soils declined after the accumulation of 3,4,5-TCP. However, further research is required to elucidate and exploit the links between electron donors/acceptors, PCP intermediates, and functional microorganisms involved.

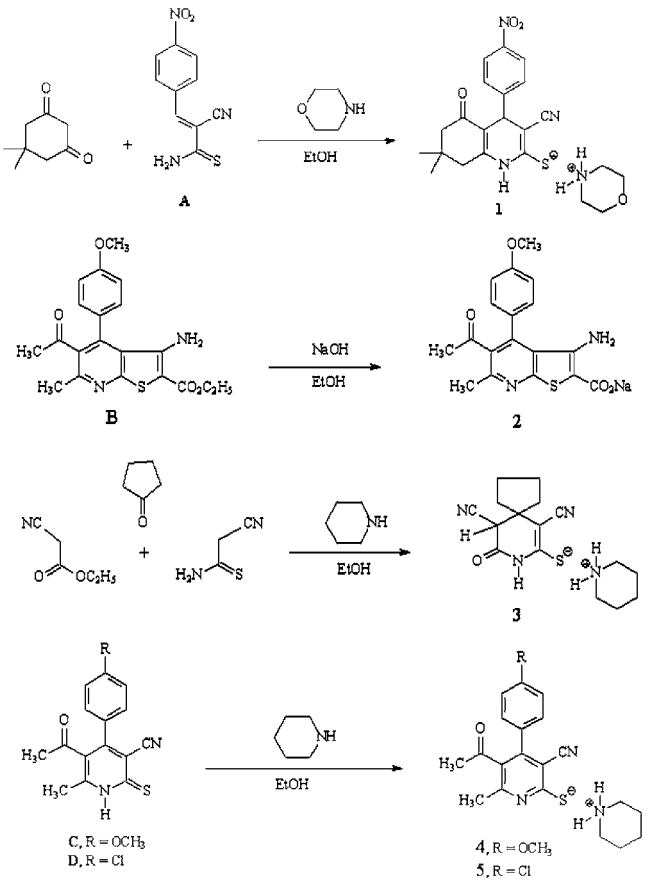
**Insect Field Strain.** The field strain of cowpea aphids, *A. craccivora*, was collected from fava bean, *Vicia faba*, fields of Assiut University Experimental Farm during the 2013/2014 season.

**Laboratory Bioassay.** The activities of insecticidal compounds against nymphs and adults of cowpea aphid were tested by the leaf dip bioassay method.[10] Reported here are the results of laboratory tests to determine the concentration of these chemical compounds that is required to kill 50% ($LC_{50}$) of nymphs and adults, with a modification in the toxicity tests. Six concentrations of aqueous solution of each compound plus 0.1% Triton X-100 as a surfactant were used. A total of 20 apterous adults and 20 nymphs, approximately of the same size, were dipped for 10 s in each concentration 3 times. The treated aphids were allowed to dry at room temperature for about 0.5 h. Control batches of aphids were similarly dipped in a solution of distilled water plus 0.1% Triton X-100. After the treated batches of aphids had dried, they were individually transferred to Petri dishes (9 cm diameter) and held for 24 h at 22 + 2 °C, 60 + 5% relative humidity, and photoperiod of 12:12 (light/dark). Aphid mortality was recorded 24 and 48 h after treatment with a binocular microscope. An aphid was considered dead if it was incapable of coordinated forward movement. The toxicity experiment of each compound was repeated twice, and the results were corrected by Abbott's formula.[11] Median lethal concentrations ($LC_{50}$) and slope values of chemical compounds were determined by the Probit regression analysis program and expressed in parts per million (ppm).[12]

## RESULTS AND DISCUSSION

**Synthesis.** The synthetic procedures for the title compounds are outlined in Scheme 1. The intermediate compounds **A**,[13] **B**,[14] **C**, and **D**[15] were prepared following the procedures reported previously.

**Scheme 1**



The structure of the synthesized compounds was elucidated and confirmed on the basis of their spectral and elemental analyses.

*Toxicity Test for the Cowpea Aphid Nymphs.* Insecticidal activities against the nymphs of cowpea aphid are shown in Table 1 and Figure 1. One of the tested compounds showed excellent insecticidal activities against nymphs of cowpea aphid, and others exhibit moderate to strong activities compared to acetamiprid. The $LC_{50}$ values of compounds **1**, **2**, **3**, **4**, and **5** were 0.004, 0.013, 0.180, 0.570, and 2.050 ppm, respectively, while that of acetamiprid was 0.010 ppm after 24 h of treatment. It was found that all compounds showed higher toxicity after 48 h treatment, with $LC_{50}$ values of 0.0001, 0.0030, 0.0100, 0.0100, and 0.0230, respectively, whereas that of acetamiprid was 0.0004 ppm. The above results revealed that the insecticidal activity of compound **1** against nymphs of cowpea aphid was 2.5- and 4.0-fold that of acetamiprid after 24 and 48 h of treatment.

*Toxicity Test for the Cowpea Aphid Adults.* Insecticidal activities against the adults of cowpea aphid are shown in Table 2 and Figure 2. All of the tested compounds showed low to excellent insecticidal activities against cowpea aphid adults after 24 h of treatment. Compound **1**, which has a $LC_{50}$ value of 0.010 ppm, was more active than acetamiprid itself, which

| compound | slope ± SE | $LC_{50}$ (ppm) | toxic ratio[a] | slope ± SE | $LC_{50}$ (ppm) | toxic ratio[a] |
| acetamiprid | 0.24 ± 0.02 | 0.010 | 1 | 0.36 ± 0.03 | 0.0004 | 1 |
| **1** | 0.37 ± 0.03 | 0.004 | 2.5 | 0.37 ± 0.04 | 0.0001 | 4 |
| **2** | 0.22 ± 0.02 | 0.013 | 0.76 | 0.29 ± 0.03 | 0.0030 | 0.13 |
| **3** | 0.19 ± 0.03 | 0.180 | 0.05 | 0.19 ± 0.03 | 0.0100 | 0.04 |
| **4** | 0.16 ± 0.03 | 0.570 | 0.02 | 0.24 ± 0.03 | 0.0100 | 0.04 |
| **5** | 0.16 ± 0.02 | 2.050 | 0.004 | 0.24 ± 0.03 | 0.0230 | 0.02 |

[a]The toxic ratio is defined as the ratio of the $LC_{50}$ value of acetamiprid for baseline toxicity and the $LC_{50}$ value of the compound.

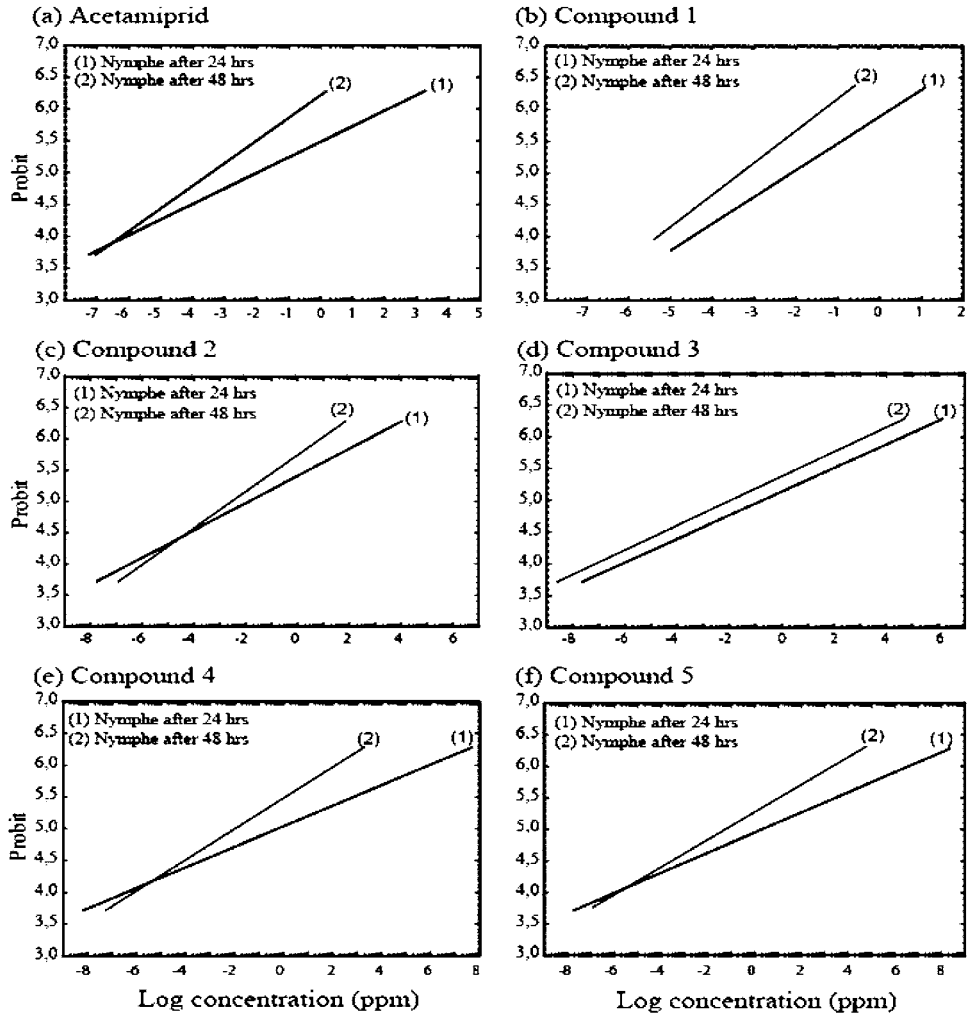

**Figure 1.** Insecticidal activities of acetamiprid and compounds **1**, **2**, **3**, **4**, and **5** against the nymphs of cowpea aphid, *A. craccivora*, after 24 and 48 h of treatment.

exhibits a $LC_{50}$ value of 0.041 ppm. The compounds **2**, **3**, **4**, and **5** showed low activity, with $LC_{50}$ values of 3.330, 2.270, 19.590, and 19.650 ppm, respectively. Compounds **1**, **2**, **3**, **4**, and **5** and acetamiprid showed higher toxicity after 48 h of treatment, with $LC_{50}$ values of 0.0005, 0.2300, 0.2900, 0.0800, 0.1340, and 0.0030, respectively. The Insecticidal activity of compound **1** against cowpea aphid adults was about 4.0- and 6.0-fold that of acetamiprid after 48 h of treatment.

Finally, It is interesting to note that (i) the highest activity associated with compound **1** may be due to the presence of the nitro group in its molecular structure because a number of neonicotinoids contain this group, (ii) the presence of the cyano group has no effect on the insecticidal activity of the tested compounds because compound **2**, which lack this cyano group, showed higher activity than each of compounds **3** (which possess two cyano groups), **4**, and/or **5**, (iii) the thienopyridine moiety in compound **2** may anticipate the insecticidal activity because this compound ranks second in the order of toxicity after compound **1**, and (iv) compound **4**, which contains the methoxyl group, showed relatively higher activity than its chloro analogue **5**, and this is an unexpected result, where the presence of the chlorine atom in the molecule often promoted the activity.

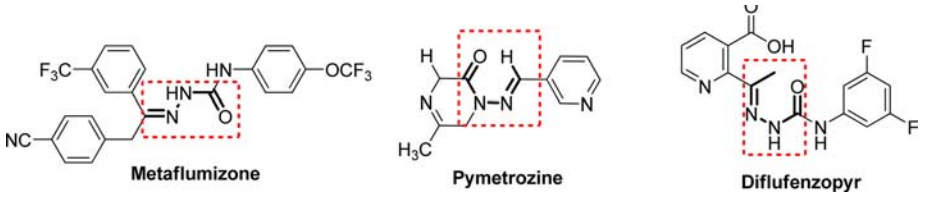

**Figure 1.** Acylhydrazone compounds.

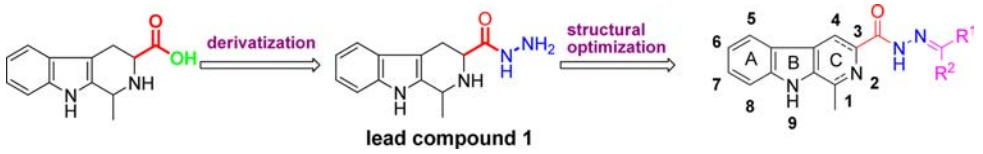

**Figure 2.** Design of target compounds.

**General Synthesis.** All anhydrous solvents were dried and purified by standard techniques. The synthetic routes are given in Scheme 2.

**Synthesis of (3*S*)-1-Methyl-2,3,4,9-tetrahydro-1*H*-pyrido-[3,4-*b*]indole-3-carbohydrazide (1).** This compound was synthesized by the method[17] reported in 99% yield: mp =100−103 °C; $^1$H NMR (400 MHz, $CDCl_3$) $\delta$ 8.15 (s, 1H, NH), 7.90 (s, 1H, NHCO), 7.50 (d, $^3J_{HH}$ = 7.6 Hz, 1H, Ar−H), 7.32 (d, $^3J_{HH}$ = 8.0 Hz, 1H, Ar−H), 7.17 (t, $^3J_{HH}$ = 7.2 Hz, 1H, Ar−H), 7.11 (t, $^3J_{HH}$ = 7.2 Hz, 1H, Ar−H), 4.18−4.23 (m, 1H, C**H**$CH_3$), 3.93 (br, 2H, $NH_2$), 3.65 (q, $^3J_{HH}$ = 8.4 Hz, 1H, C**H**CO), 3.26−3.32 (m, 1H, C$\mathbf{H}_2$), 2.71−2.78 (m, 1H, C$\mathbf{H}_2$), 1.48 (d, $^3J_{HH}$ = 6.8 Hz, 3H, C$\mathbf{H}_3$); $^{13}$C NMR (100 MHz, DMSO-$d_6$) $\delta$ 172.0, 137.9, 135.8, 126.9, 120.5, 118.3, 117.4, 110.9, 106.2, 56.1, 48.2, 25.4, 20.0; HRMS (ESI) calcd for $C_{13}H_{17}N_4O$ [M + H]$^+$ 245.1397, found 245.1398.

**Synthesis of 1-Methyl-9*H*-carbazole-3-carboxylic Acid Hydrazide (2).** A mixture of ethyl 1-methyl-9*H*-pyrido[3,4-*b*]indole-3-carboxylate[18] (2.00 g, 7.86 mmol) and hydrazine hydrate (80%) (3.15 g, 5.04 mmol) in a mixed solvent of alcohol (80 mL) and DMF (25 mL) was heated at reflux for 24 h; then the mixture was concentrated in vacuo. Solid was precipitated out and collected by filtration. The cake was extracted with boiling alcohol (each 30 mL) for several times until the filter cake did not dissolve in hot alcohol any more. The combined extract was concentrated to give **2** as a light-pink solid (0.90 g, 48%): mp =242−244 °C; $^1$H NMR (300 MHz, DMSO-$d_6$) $\delta$ 11.92 (s, 1H, NH), 9.51 (s, 1H, O═C-NH), 8.64 (s, 1H, Ar−H), 8.35 (d, $^3J_{HH}$ = 8.1 Hz, 1H, Ar−H)), 7.64 (d, $^3J_{HH}$ = 8.1 Hz, 1H, Ar−H), 7.57 (t, $^3J_{HH}$ = 7.2 Hz, 1H, Ar−H), 7.28 (t, $^3J_{HH}$ = 7.2 Hz, 1H, Ar−H), 4.55 (s, 2H, $NH_2$), 2.82 (s, 3H, C$\mathbf{H}_3$); $^{13}$C NMR (100 MHz, DMSO-$d_6$) $\delta$ 164.1, 141.0, 140.7, 138.7, 135.7, 128.3, 127.3, 122.2, 121.4, 119.9, 112.2, 111.9, 20.4; HRMS (ESI) calcd for $C_{13}H_{13}N_4O$ [M + H]$^+$ 241.1084, found 241.1084.

**Synthesis of *N*′-Benzylidene-(3*S*)-1-methyl-2,3,4,9-tetrahydro-1*H*-pyrido[3,4-*b*]indole-3-carbohydrazide (3).** To a slurry of compound **1** (0.50 g, 2.05 mmol) in toluene (35 mL) was added dropwise benzaldehyde (0.44 g, 4.10 mmol) at room temperature, Then the reaction mixture was heated to reflux. After 5 h, TLC analysis showed the complete consumption of compound **1**. The reaction solution was cooled to room temperature, and solid was precipitated out. The solid was filtrated and washed with toluene and then stirred in absolute ether for 1.5 h to remove the remaining toluene. Filtered once again to give **3** as a yellow solid (0.50 g, 74%): mp = 200−204 °C; $^1$H NMR (400 MHz, DMSO-$d_6$) $\delta$ 11.48 and 11.35 (s, 1H, NH), 10.84 and 10.81 (s, 1H, O═C-NH), 8.34 and 8.06 (s, 1H, N═CH), 7.71 and 7.61 (dd, $^3J_{HH}$ = 7.6 Hz, $^4J_{HH}$ = 1.6 Hz, 1H, Ph-H), 7.49−7.42 (m, 2H, Ph-H), 7.42−7.33 (m, 2H, Ph-H and Ar−H), 7.31 and 7.30 (d, $^3J_{HH}$ = 8.0 Hz, 1H, Ar−H), 7.03 (t, $^3J_{HH}$ = 7.2 Hz, 1H, Ar−H), 6.95 and 6.92 (t, $^3J_{HH}$ = 7.2 Hz, 1H, Ar−H), 4.48 and 3.61 (dd, $^3J_{HH}$ = 10.8 Hz, 3.6 Hz, 1H, C**H**), 4.15 (q, $^3J_{HH}$ = 8.0 Hz, 1H, C**H**), 2.98−2.89 (m, 1H, C$\mathbf{H}_2$), 2.71 and 2.62 (ddd, $^2J_{HH}$ = 14.4 Hz, $^3J_{HH}$ = 11.6 Hz, $^4J_{HH}$ = 2.0 Hz, 1H, C$\mathbf{H}_2$), 1.45 (d, $^3J_{HH}$ = 6.8 Hz, 3H, C$\mathbf{H}_3$); $^{13}$C NMR (100 MHz, DMSO-$d_6$) $\delta$ 174.6 and 169.1, 147.0 and 143.4, 137.9, 135.8, 134.4 and 134.1, 130.0 and 129.8, 128.9 and 128.8, 127.1 and 126.7, 126.9 and 126.9, 120.6, 118.4, 117.5, 111.0, 106.2 and 106.1, 56.7 and 53.3, 48.4 and 47.7, 25.5 and 25.4, 20.0; HRMS (ESI) calcd for $C_{20}H_{21}N_4O$ [M + H]$^+$ 333.1710, found 333.1715.

Compounds **4**−**26** were synthesized using the similar procedure as compound **3**.

*Data for 1-Methyl-9H-b-carboline-3-carboxylic Acid Benzylidene-hydrazide (**4**).* This compound was obtained as a yellow solid in 91% yield: mp = 303−306 °C; $^1$H NMR (300 MHz, DMSO-$d_6$) $\delta$ 12.05 (s, 1H, NH), 11.85 (s, 1H, O═C-NH), 8.82 (s, 1H, N═CH), 8.69 (s, 1H, Ar−H), 8.41 (d, $^3J_{HH}$ = 7.8 Hz, 1H, Ar−H), 7.77 (d, $^3J_{HH}$ = 6.3 Hz, 2H, Ph-H), 7.67 (d, $^3J_{HH}$ = 8.1 Hz, 1H, Ar−H), 7.60 (t, $^3J_{HH}$ = 7.2 Hz, 1H, Ar−H), 7.55−7.41 (m, 3H, Ph-H), 7.31 (t, $^3J_{HH}$ = 7.2 Hz, 1H, Ar−H), 2.92 (s, 3H, C$\mathbf{H}_3$); $^{13}$C NMR (100 MHz, DMSO-$d_6$) $\delta$ 161.2, 147.9, 141.1, 140.8, 138.2, 136.1, 134.6, 129.9, 128.9, 128.4, 127.5, 127.1, 122.3, 121.4, 120.1, 113.2, 112.3, 20.4; HRMS (ESI) calcd for $C_{20}H_{17}N_4O$ [M + H]$^+$ 329.1397, found 329.1402.

*Data for N′-Benzylidene-(3R)-1-methyl-2,3,4,9-tetrahydro-1H-pyrido[3,4-b]indole-3-carbohydrazide (**5**).* This compound was obtained as a light yellow solid in 76% yield: mp = 197−200 °C; $^1$H NMR (400 MHz, DMSO-$d_6$) $\delta$ 11.67 and 11.47 (s, 1H, NH), 10.98 and 10.86 (s, 1H, O═C−NH), 8.35 and 8.09 (s, 1H, N═CH), 7.75−7.69 (m, 1H, Ph-H), 7.66−7.60 (m, 1H, Ph-H), 7.50−7.41 (m, 2H, Ph-H), 7.41−7.36 (m, 2H, Ph-H and Ar−H), 7.33 and 7.31 (d, $^3J_{HH}$ = 8.8 Hz, 1H, Ph-H), 7.06 and 7.04 (t, $^3J_{HH}$ = 7.2 Hz, 1H, Ar−H), 7.00−6.92 (m, 1H, Ar−H), 4.70−4.61 and 3.69 (dd, $^3J_{HH}$ = 10.4 Hz, 3.6 Hz, 1H, C**H**), 4.42−4.14 (m, 1H, C**H**), 3.08 and 2.98 (dd, $^2J_{HH}$ = 14.8 Hz, $^3J_{HH}$ = 2.8 Hz, 1H, C**H**), 2.79−2.67 (m, 1H, C$\mathbf{H}_2$), 1.53 and 1.48 (d, $^3J_{HH}$ = 6.8 Hz, 3H, C$\mathbf{H}_3$); $^{13}$C NMR (100 MHz, DMSO-$d_6$) $\delta$ 173.4 and 168.8, 147.2 and 144.1, 137.2, 136.0 and 135.9, 134.3 and 134.0, 130.0 and 130.0, 128.8, 127.1, 126.8 and 126.6, 120.9 and 120.7, 118.6 and 118.5, 117.7 and 117.5, 111.1 and 111.1, 106.0 and 105.7, 56.6 and 53.6, 48.5 and 48.1, 25.3 and 24.7, 19.7 and 19.0; HRMS (ESI) calcd for $C_{20}H_{21}N_4O$ [M + H]$^+$ 333.1710, found 333.1708.

*Data for N′-(4-tert-Butylbenzylidene)-(3S)-1-methyl-2,3,4,9-tetrahydro-1H-pyrido[3,4-b]indole-3-carbohydrazide (**6**).* This compound was obtained as a yellow solid in 72% yield: mp = 139−143 °C; $^1$H NMR (400 MHz, DMSO-$d_6$) $\delta$ 11.47 and 11.32 (s, 1H, NH), 10.87 and 10.82 (s, 1H, O═C-NH), 8.31 and 8.03 (s, 1H, N═CH), 7.88 and 7.70−7.27 (m, 6H, Ph-H and Ar−H), 7.04 (t, $^3J_{HH}$ = 6.8 Hz, 1H, Ar−H), 6.96 (t, $^3J_{HH}$ = 7.2 Hz, 1H, Ar−H), 4.48 and 3.62 (dd, $^3J_{HH}$ = 10.4 Hz, 7.2 Hz, 1H, C**H**), 4.27−4.08 (m, 1H, C**H**), 3.02−2.88 (m, 1H, C$\mathbf{H}_2$), 2.77−2.59 (m, 1H, C$\mathbf{H}_2$), 1.52−1.35 (m, 3H, C$\mathbf{H}_3$), 1.30 and 1.24 (s, 9H, C$\mathbf{H}_3$); $^{13}$C NMR (100 MHz, DMSO-$d_6$) $\delta$ 174.3 and 168.9, 152.8 and 152.6, 147.0 and 143.3, 137.8, 135.8, 131.6 and 131.4, 129.2, 126.9 and 126.5, 125.7 and 125.6, 120.6 and 120.6, 118.4, 117.5 and 117.5, 111.0, 106.2 and 106.0, 56.7 and 53.5, 48.4 and 47.7, 34.6 and 34.5, 31.0 and 30.9, 25.5 and 25.2, 19.9 and 19.9; HRMS (ESI) calcd for $C_{24}H_{29}N_4O$ [M + H]$^+$ 389.2336, found 389.2338.

*Data for N′-(4-(Dimethylamino)benzylidene)-(3S)-1-methyl-2,3,4,9-tetrahydro-1H-pyrido[3,4-b]indole-3-carbohydrazide (**7**).*

dx.doi.org/10.1021/jf503794g | J. Agric. Food Chem. 2014, 62, 9987−9999

This compound was obtained as a yellow solid in 73% yield: mp = 215−220 °C; $^1$H NMR (400 MHz, DMSO-$d_6$) $\delta$ 11.20 and 11.05 (s, 1H, NH), 10.84 and 10.80 (s, 1H, O═C-NH), 8.16 and 7.92 (s, 1H, N═CH), 7.52 and 7.36 (d, $^3J_{HH}$ = 7.6 Hz, 2H, Ph-H), 7.44−7.38 (m, 1H, Ar−H), 7.30 (d, $^3J_{HH}$ = 6.4 Hz, 1H, Ar−H), 7.03 (t, $^3J_{HH}$ = 6.8 Hz, 1H, Ar−H), 6.95 (t, $^3J_{HH}$ = 6.8 Hz, 1H, Ar−H), 6.75 and 6.67 (d, $^3J_{HH}$ = 7.6 Hz, 2H, Ph-H), 4.44 and 3.57 (d, $^3J_{HH}$ = 8.8 Hz, 1H, C**H**), 4.23−4.08 (m, 1H, C**H**), 3.07−2.86 (m, 7H, N−C**H**$_3$ and C**H**$_2$), 2.74−2.56 (m, 1H, C**H**$_2$), 1.52−1.38 (m, 3H, C**H**$_3$); $^{13}$C NMR (100 MHz, DMSO-$d_6$) $\delta$ 173.8 and 168.5, 151.5 and 151.3, 147.8 and 144.2, 137.8, 135.8, 128.4 and 127.9, 126.9, 121.6 and 121.5, 120.6 and 120.5, 118.4, 117.5, 111.9 and 111.8, 111.0, 106.2 and 106.1, 56.6 and 53.5, 48.4 and 47.7, 39.8, 25.6 and 25.2, 19.9; HRMS (ESI) calcd for $C_{22}H_{26}N_5O$ [M + H]$^+$ 376.2132, found 376.2137.

*Data for N′-(4-Nitrobenzylidene)-(3S)-1-methyl-2,3,4,9-tetrahydro-1H-pyrido[3,4-b]indole-3-carbohydrazide (**8**).* This compound was obtained as a yellow solid in 74% yield: mp = 222−227 °C; $^1$H NMR (400 MHz, DMSO-$d_6$) $\delta$ 11.81 and 11.68 (s, 1H, NH), 10.87 and 10.82 (s, 1H, O═C-NH), 8.46 and 8.17 (s, 1H, N═CH), 8.31 and 8.22 (d, $^3J_{HH}$ = 8.4 Hz, 2H, Ph-H), 7.98 and 7.88 (d, $^3J_{HH}$ = 8.4 Hz, 2H, Ph-H), 7.41 and 7.36 (d, $^3J_{HH}$ = 7.6 Hz, 1H, Ar−H), 7.31 (d, $^3J_{HH}$ = 6.4 Hz, 1H, Ar−H), 7.04 (t, $^3J_{HH}$ = 7.2 Hz, 1H, Ar−H), 6.96 (t, $^3J_{HH}$ = 7.6 Hz, 1H, Ar−H), 4.55 and 3.67 (d, $^3J_{HH}$ = 8.8 Hz, 1H, C**H**), 4.25−4.10 (m, 1H, C**H**), 2.96 (d, $^2J_{HH}$ = 13.6 Hz, 1H, C**H**$_2$), 2.79−2.60 (m, 1H, C**H**$_2$), 1.47 (d, $^3J_{HH}$ = 6.4 Hz, 3H, C**H**$_3$); $^{13}$C NMR (100 MHz, DMSO-$d_6$) $\delta$ 174.8 and 169.6, 147.8 and 147.7, 144.6, 140.7 and 140.4, 137.8 and 137.5, 135.9, 128.0 and 127.7, 126.9, 124.1, 120.7 and 120.6, 118.5, 117.6 and 117.5, 111.0, 106.1 and 106.0, 56.8 and 53.2, 48.5 and 47.8, 25.4 and 25.4, 19.9 and 19.8; HRMS (ESI) calcd for $C_{20}H_{20}N_5O_3$ [M + H]$^+$ 378.1561, found 378.1563.

*Data for N′-(4-Chlorobenzylidene)-(3S)-1-methyl-2,3,4,9-tetrahydro-1H-pyrido[3,4-b]indole-3-carbohydrazide (**9**).* This compound was obtained as a yellow solid in 81% yield: mp = 140−145 °C; $^1$H NMR (400 MHz, DMSO-$d_6$) $\delta$ 11.62 and 11.51 (s, 1H, NH), 10.91 and 10.85 (s, 1H, O═C-NH), 8.35 and 8.07 (s, 1H, N═CH), 7.74 and 7.64 (d, $^3J_{HH}$ = 7.2 Hz, 2H, Ph-H), 7.58−7.35 (m, 3H, Ph-H and Ar−H), 7.35−7.28 (m, 1H, Ar−H), 7.10−7.00 (m, 1H, Ar−H), 7.00−6.90 (m, 1H, Ar−H), 4.56 and 3.66 (d, $^3J_{HH}$ = 9.6 Hz, 1H, C**H**), 4.30−4.12 (m, 1H, C**H**), 3.03−2.90 (m, 1H, C**H**$_2$), 2.79−2.62 (m, 1H, C**H**$_2$), 1.54−1.39 (m, 3H, C**H**$_3$); $^{13}$C NMR (100 MHz, DMSO-$d_6$) $\delta$ 174.2 and 169.1, 145.8 and 142.4, 137.6 and 135.9, 134.5 and 134.3, 133.3 and 133.0, 129.0, 128.7, 128.4, 126.9 and 126.8, 120.7 and 120.6, 118.5 and 118.4, 117.6 and 117.5, 111.0, 106.1 and 105.9, 56.7 and 53.3, 48.5 and 47.8, 25.4 and 25.1, 19.8 and 19.6; HRMS (ESI) calcd for $C_{20}H_{20}N_4OCl$ [M + H]$^+$ 367.1320, found 367.1323.

*Data for N′-(2,4-Dichlorobenzylidene)-(3S)-1-methyl-2,3,4,9-tetrahydro-1H-pyrido[3,4-b]indole-3-carbohydrazide (**10**).* This compound was obtained as a light yellow solid in 85% yield: mp = 211−213 °C; $^1$H NMR (400 MHz, DMSO-$d_6$) $\delta$ 11.82 and 11.77 (s, 1H, NH), 10.91 and 10.84 (s, 1H, O═C-NH), 8.71 and 8.42 (s, 1H, N═CH), 8.00 and 7.85 (d, $^3J_{HH}$ = 8.4 Hz, 1H, Ph-H), 7.73 and 7.71 (d, $^4J_{HH}$ = 2.0 Hz, 1H, Ph-H), 7.53 and 7.43−7.35 (dd, $^3J_{HH}$ = 8.4 Hz, $^4J_{HH}$ = 2.0 Hz, 1H, Ph-H), 7.41 and 7.37 (d, $^3J_{HH}$ = 8.0 Hz, 1H, Ar−H), 7.32 and 7.31 (d, $^3J_{HH}$ = 8.0 Hz, 1H, Ar−H), 7.04 (t, $^3J_{HH}$ = 7.2 Hz, 1H, Ar−H), 6.96 and 6.94 (t, $^3J_{HH}$ = 7.2 Hz, 1H, Ar−H), 4.65−4.56 and 3.66 (dd, $^3J_{HH}$ = 10.4 Hz, 3.6 Hz, 1H, C**H**), 4.35−4.13 (m, 1H, C**H**), 3.06−2.91 (m, 1H, C**H**$_2$), 2.78−2.64 (m, 1H, C**H**$_2$), 1.54−1.43 (m, 3H, C**H**$_3$); $^{13}$C NMR (100 MHz, DMSO-$d_6$) $\delta$ 174.0 and 169.2, 142.0 and 139.0, 137.5 and 137.5, 135.9, 135.0 and 134.9, 133.8 and 133.7, 130.8 and 130.4, 129.4 and 129.4, 128.1 and 128.1, 128.1 and 127.8, 126.8 and 126.7, 120.8 and 120.6, 118.5 and 118.5, 117.7 and 117.5, 111.1 and 111.0, 106.1 and 105.8, 56.7 and 53.4, 48.5 and 48.0, 25.3 and 25.0, 19.8 and 19.3; HRMS (ESI) calcd for $C_{20}H_{19}N_4OCl_2$ [M + H]$^+$ 401.0931, found 401.0929.

*Data for N′-(3,4-Dichlorobenzylidene)-(3S)-1-methyl-2,3,4,9-tetrahydro-1H-pyrido[3,4-b]indole-3-carbohydrazide (**11**).* This compound was obtained as a light yellow solid in 79% yield: mp = 189−193 °C; $^1$H NMR (400 MHz, DMSO-$d_6$) $\delta$ 11.84 and 11.67 (s, 1H, NH), 10.98 and 10.86 (s, 1H, O═C-NH), 8.34 and 8.07 (s, 1H, N═CH), 7.94 and 7.88 (s, 1H, Ph-H), 7.72 and 7.64 (s, 2H, Ph-H), 7.41 and 7.39 (d, $^3J_{HH}$ = 8.4 Hz, 1H, Ar−H), 7.33 and 7.31 (d, $^3J_{HH}$ = 8.4 Hz, 1H, Ar−H), 7.06 and 7.04 (t, $^3J_{HH}$ = 7.2 Hz, 1H, Ar−H), 6.96 and 6.96 (t, $^3J_{HH}$ = 7.2 Hz, 1H, Ar−H), 4.68 and 3.70 (dd, $^3J_{HH}$ = 10.4 Hz, 4.4 Hz, 1H, C**H**), 4.38 and 4.19 (q, $^3J_{HH}$ = 6.4 Hz, 1H, C**H**), 3.06 and 2.98 (dd, $^2J_{HH}$ = 14.4 Hz, $^3J_{HH}$ = 3.6 Hz, 1H, C**H**$_2$), 2.80−2.66 (m, 1H, C**H**$_2$), 1.53 and 1.48 (d, $^3J_{HH}$ = 6.4 Hz, 3H, CH$_3$); $^{13}$C NMR (100 MHz, DMSO-$d_6$) $\delta$ 173.5 and 169.0, 144.5 and 141.6, 137.2, 135.9 and 135.9, 135.2 and 134.8, 132.2 and 132.1, 131.7, 131.1, 128.6 and 128.5, 126.9 and 126.8, 126.6 and 126.4, 120.9 and 120.7, 118.6 and 118.5, 117.7 and 117.5, 111.1 and 111.0, 105.9 and 105.6, 56.6 and 53.5, 48.5 and 48.1, 25.3 and 24.7, 19.6 and 18.9; HRMS (ESI) calcd for $C_{20}H_{19}N_4OCl_2$ [M + H]$^+$ 401.0931, found 401.0934.

*Data for N′-(4-Methoxybenzylidene)-(3S)-1-methyl-2,3,4,9-tetrahydro-1H-pyrido[3,4-b]indole-3-carbohydrazide (**12**).* This compound was obtained as a yellow solid in 69% yield: mp = 138−143 °C; $^1$H NMR (400 MHz, DMSO-$d_6$) $\delta$ 11.35 and 11.22 (s, 1H, NH), 10.84 and 10.81 (s, 1H, O═C-NH), 8.27 and 8.00 (s, 1H, N═CH), 7.65 and 7.55 (d, $^3J_{HH}$ = 8.0 Hz, 2H, Ph-H), 7.40 and 7.36 (d, $^3J_{HH}$ = 7.6 Hz, 1H, Ar−H), 7.30 (d, $^3J_{HH}$ = 7.6 Hz, 1H, Ar−H), 7.08−6.89 (m, 4H, Ar−H and Ph-H), 4.45 and 3.59 (d, $^3J_{HH}$ = 8.8 Hz, 1H, C**H**), 4.20−4.08 (m, 1H, C**H**), 3.81 and 3.74 (s, 3H, O−C**H**$_3$), 2.93 (d, $^2J_{HH}$ = 14.4 Hz, 1H, C**H**$_2$), 2.76−2.56 (m, 1H, C**H**$_2$), 1.45 (d, $^3J_{HH}$ = 6.0 Hz, 3H, C**H**$_3$); $^{13}$C NMR (100 MHz, DMSO-$d_6$) $\delta$ 174.3 and 168.8, 160.8 and 160.6, 146.9 and 143.2, 137.9, 135.8 and 135.8, 128.6 and 128.2, 127.0 and 126.9, 126.7, 120.5, 118.4, 117.5, 114.3, 111.0, 106.2 and 106.1, 56.7 and 53.3, 55.3 and 55.2, 48.4 and 47.6, 25.5 and 25.4, 20.0 and 19.9; HRMS (ESI) calcd for $C_{21}H_{23}N_4O_2$ [M + H]$^+$ 363.1816, found 363.1819.

*Data for N′-(3-Methoxybenzylidene)-(3S)-1-methyl-2,3,4,9-tetrahydro-1H-pyrido[3,4-b]indole-3-carbohydrazide (**13**).* This compound was obtained as yellow solid in 63% yield: mp = 186−190 °C; $^1$H NMR (400 MHz, DMSO-$d_6$) $\delta$ 11.54 and 11.39 (s, 1H, NH), 10.87 and 10.83 (s, 1H, O═C-NH), 8.32 and 8.03 (s, 1H, N═CH), 7.45−7.11 (m, 5H, Ph-H and Ar−H), 7.08−6.89 (m, 3H, Ar−H and Ph-H), 4.48 and 3.63 (d, $^3J_{HH}$ = 8.0 Hz, 1H, C**H**), 4.25−4.10 (m, 1H, C**H**), 3.81 and 3.69 (s, 3H, O−C**H**$_3$), 3.02−2.89 (m, 1H, C**H**$_2$), 2.77−2.60 (m, 1H, C**H**$_2$), 1.46 (d, $^3J_{HH}$ = 5.2 Hz, 3H, C**H**$_3$); $^{13}$C NMR (100 MHz, DMSO-$d_6$) $\delta$ 174.3 and 169.2, 159.6, 147.1 and 143.4, 137.8 and 137.5, 135.9 and 135.8, 135.6, 130.0 and 130.0, 126.9, 120.7 and 120.6, 120.0 and 119.1, 118.4, 117.5, 116.2 and 115.4, 112.0 and 111.3, 111.0, 106.2 and 106.0, 56.7 and 53.6, 55.2 and 55.1, 48.5 and 47.8, 25.5 and 25.2, 19.9 and 19.8; HRMS (ESI) calcd for $C_{21}H_{23}N_4O_2$ [M + H]$^+$ 363.1816, found 363.1818.

*Data for N′-(2-Methoxybenzylidene)-(3S)-1-methyl-2,3,4,9-tetrahydro-1H-pyrido[3,4-b]indole-3-carbohydrazide (**14**).* This compound was obtained as yellow solid in 82% yield: mp = 180−183 °C; $^1$H NMR (400 MHz, DMSO-$d_6$) $\delta$ 11.52 and 11.46 (s, 1H, NH), 10.90 and 10.84 (s, 1H, O═C-NH), 8.66 and 8.41 (s, 1H, N═CH), 7.84 and 7.68 (d, $^3J_{HH}$ = 7.2 Hz, 1H, Ph-H), 7.41 (d, $^3J_{HH}$ = 7.6 Hz, 1H, Ar−H), 7.37 (d, $^3J_{HH}$ = 7.6 Hz, 1H, Ar−H), 7.31 (dd, $^3J_{HH}$ = 8.0 Hz, 4.0 Hz, 1H, Ph-H), 7.14−6.86 (m, 4H, Ph-H and Ar−H), 4.54 and 3.61 (dd, $^3J_{HH}$ = 10.0 Hz, 2.8 Hz, 1H, C**H**), 4.30−4.10 (m, 1H, C**H**), 3.86 and 3.84 (s, 3H, O−C**H**$_3$), 3.04−2.89 (m, 1H, C**H**$_2$), 2.77−2.60 (m, 1H, C**H**$_2$), 1.55−1.37 (m, 3H, C**H**$_3$); $^{13}$C NMR (100 MHz, DMSO-$d_6$) $\delta$ 173.9 and 168.9, 157.7 and 157.6, 142.5 and 139.3, 137.6, 135.8, 131.5 and 131.4, 126.9 and 126.8, 125.6 and 125.2, 122.3 and 122.1, 120.7 and 120.7, 120.6, 118.5 and 118.4, 117.6 and 117.5, 111.8, 111.0, 106.1 and 105.9, 56.6 and 53.5, 55.7, 48.4 and 47.8, 25.5 and 25.1, 19.9 and 19.6; HRMS (ESI) calcd for $C_{21}H_{23}N_4O_2$ [M + H]$^+$ 363.1816, found 363.1823.

*Data for N′-(3,4-Dimethoxybenzylidene)-(3S)-1-methyl-2,3,4,9-tetrahydro-1H-pyrido[3,4-b]indole-3-carbohydrazide (**15**).* This compound was obtained as light yellow solid in 91% yield: mp = 203−206 °C; $^1$H NMR (400 MHz, DMSO-$d_6$) $\delta$ 11.47 and 11.27 (s, 1H, NH), 10.89 and 10.83 (s, 1H, O═C-NH), 8.25 and 7.99 (s, 1H, N═CH), 7.43−7.36 (m, 1H, Ar−H), 7.34−7.27 and 7.22−7.15 (m, 3H, Ar−H and Ph-H), 7.07−6.91 (m, 3H, Ar−H and Ph-H), 4.49 and 3.67−3.59 (dd, $^3J_{HH}$ = 11.2 Hz, 3.6 Hz, 1H, C**H**), 4.33−4.11 (m, 1H, C**H**), 3.82 and 3.75 (s, 3H, O−C**H**$_3$), 3.81 and 3.64 (s, 3H, O−C**H**$_3$), 3.03 and 2.94 (dd, $^2J_{HH}$ = 14.8 Hz, $^3J_{HH}$ = 2.8 Hz, 1H, C**H**$_2$), 2.76−

2.65 (m, 1H, C$\mathbf{H}_2$), 1.48 and 1.46 (d, $^3J_{HH}$ = 6.8 Hz, 3H, C$\mathbf{H}_3$); $^{13}$C NMR (100 MHz, DMSO-$d_6$) $\delta$ 173.7 and 168.8, 150.7 and 150.5, 149.1 and 148.9, 147.4 and 143.7, 137.7, 135.9, 127.0, 126.9 and 126.9, 121.8 and 120.7, 120.6 and 120.4, 118.4, 117.5, 111.7 and 111.5, 111.0, 109.2 and 108.3, 106.1 and 106.0, 56.6 and 53.8, 55.6 and 55.5, 55.5 and 55.3, 48.4 and 48.0, 25.5 and 24.9, 19.9 and 19.6; HRMS (ESI) calcd for $C_{22}H_{25}N_4O_3$ $[M + H]^+$ 393.1921, found 393.1918.

*Data for N′-(Benzo[d][1,3]dioxol-5-ylmethylene)-(3S)-1-methyl-2,3,4,9-tetrahydro-1H-pyrido[3,4-b]indole-3-carbohydrazide (**16**).* This compound was obtained as yellow solid in 83% yield: mp = 199−203 °C; $^1$H NMR (400 MHz, DMSO-$d_6$) $\delta$ 11.41 and 11.26 (s, 1H, NH), 10.86 and 10.81 (s, 1H, O═C-NH), 8.24 and 7.96 (s, 1H, N═CH), 7.40 and 7.36 (d, $^3J_{HH}$ = 7.6 Hz, 1H, Ar−H), 7.31 and 7.30 (d, $^3J_{HH}$ = 8.0 Hz, 1H, Ar−H), 7.28 and 7.17 (s, 1H, Ph-H), 7.15 and 7.09 (d, $^3J_{HH}$ = 8.0 Hz, 1H, Ph-H), 7.06−6.96 (m, 2H, Ar−H and Ph-H), 6.94 (t, $^3J_{HH}$ = 7.6 Hz, 1H, Ar−H), 6.10 (s, 1H, O−C$\mathbf{H}_2$), 6.02 (d, $^2J_{HH}$ = 4.8 Hz, 1H, O−C$\mathbf{H}_2$), 4.49 and 3.60 (dd, $^3J_{HH}$ = 10.8 Hz, 3.6 Hz, 1H, C$\mathbf{H}$), 4.22 and 4.13 (m, 1H, C$\mathbf{H}$), 2.99−2.87 (m, 1H, C$\mathbf{H}_2$), 2.75−2.57 (m, 1H, C$\mathbf{H}_2$), 1.45 (d, $^3J_{HH}$ = 6.4 Hz, 3H, C$\mathbf{H}_3$); $^{13}$C NMR (100 MHz, DMSO-$d_6$) $\delta$ 174.2 and 168.9, 149.1 and 148.9, 148.0 and 147.9, 146.9 and 143.2, 137.8, 135.8, 128.8 and 128.6, 126.9, 123.3 and 122.8, 120.6 and 120.6, 118.4, 117.5, 111.0, 108.5, 106.2 and 106.0, 105.1 and 105.0, 101.6 and 101.5, 56.7 and 53.3, 48.4 and 47.7, 25.5 and 25.2, 19.9 and 19.8; HRMS (ESI) calcd for $C_{21}H_{21}N_4O_3$ $[M + H]^+$ 377.1608, found 377.1615.

*Data for N′-((2,3-Dihydrobenzo[b][1,4]dioxin-6-yl)methylene)-(3S)-1-methyl-2,3,4,9-tetrahydro-1H-pyrido[3,4-b]indole-3-carbohydrazide (**17**).* This compound was obtained as yellow solid in 81% yield: mp = 204−207 °C; $^1$H NMR (400 MHz, DMSO-$d_6$) $\delta$ 11.44 and 11.26 (s, 1H, NH), 10.89 and 10.82 (s, 1H, O═C-NH), 8.21 and 7.94 (s, 1H, N═CH), 7.40 and 7.36 (d, $^3J_{HH}$ = 7.6 Hz, 1H, Ar−H), 7.32 and 7.30 (d, $^3J_{HH}$ = 8.0 Hz, 1H, Ar−H), 7.20 and 7.10 (s, 1H, Ph-H), 7.19 and 7.09 (d, $^3J_{HH}$ = 7.6 Hz, 1H, Ph-H), 7.07−7.01 (m, 1H, Ar−H), 6.99−6.83 (m, 2H, Ar−H and Ph-H), 4.51 and 3.61 (dd, $^3J_{HH}$ = 10.8 Hz, 3.6 Hz, 1H, C$\mathbf{H}$), 4.35−4.09 (m, 5H, C$\mathbf{H}$ and O−C$\mathbf{H}_2$-C$\mathbf{H}_2$-O), 3.03−2.89 (m, 1H, C$\mathbf{H}_2$), 2.76−2.60 (m, 1H, C$\mathbf{H}_2$), 1.53−1.43 (m, 3H, C$\mathbf{H}_3$); $^{13}$C NMR (100 MHz, DMSO-$d_6$) $\delta$ 173.8 and 168.8, 146.8, 145.2 and 145.1, 143.6 and 143.6, 143.2, 137.7 and 137.1, 135.9 and 135.8, 127.7 and 127.5, 126.9 and 126.8, 120.7 and 120.7, 120.6 and 120.3, 118.5 and 118.4, 117.6 and 117.5, 115.3 and 114.9, 111.1 and 111.0, 106.2 and 105.9, 64.3 and 64.3, 64.1 and 64.0, 56.6 and 53.6, 48.5 and 47.9, 25.5 and 25.0, 19.9 and 19.6; HRMS (ESI) calcd for $C_{22}H_{23}N_4O_3$ $[M + H]^+$ 391.1765, found 391.1763.

*Data for N′-((6-Hydroxynaphthalen-2-yl)methylene)-(3S)-1-methyl-2,3,4,9-tetrahydro-1H-pyrido[3,4-b]indole-3-carbohydrazide (**18**).* This compound needed recrystallization from methanol to removed the remaining aldehyde. This compound was obtained as yellow solid in 70% yield: mp = 275−278 °C; $^1$H NMR (400 MHz, DMSO-$d_6$) $\delta$ 11.46 and 11.35 (s, 1H, NH), 10.85 and 10.81 (s, 1H, O═C-NH), 9.98 (s, 1H, OH), 8.42 and 8.16 (s, 1H, N═CH), 7.99 and 7.91 (s, 1H, Naphthalene-H), 7.85 (d, $^3J_{HH}$ = 9.2 Hz, 1H, Naphthalene-H), 7.80 and 7.61 (d, $^3J_{HH}$ = 8.8 Hz, 1H, Naphthalene-H), 7.74 and 7.70 (d, $^3J_{HH}$ = 8.8 Hz, 1H, Naphthalene-H), 7.42 and 7.37 (d, $^3J_{HH}$ = 7.6 Hz, 1H, Ar−H), 7.16 and 7.08 (s, 1H, Naphthalene-H), 7.15−7.09 (m, 1H, Naphthalene-H), 7.04 (t, $^3J_{HH}$ = 7.6 Hz, 1H, Ar−H), 7.00−6.90 (m, 1H, Ar−H), 4.52 and 3.63 (d, $^3J_{HH}$ = 8.4 Hz, 1H, C$\mathbf{H}$), 4.25−4.10 (m, 1H, C$\mathbf{H}$), 3.02−2.90 (m, 1H, C$\mathbf{H}_2$), 2.73 and 2.65 (t, $^2J_{HH}$ = 12.8 Hz, 1H, C$\mathbf{H}_2$), 1.47 (d, $^3J_{HH}$ = 6.0 Hz, 3H, C$\mathbf{H}_3$); $^{13}$C NMR (100 MHz, DMSO-$d_6$) $\delta$ 174.5 and 169.0, 156.5 and 156.5, 147.4 and 144.0, 137.9, 135.8 and 135.8, 135.6 and 135.4, 130.1 and 130.0, 129.0, 128.7 and 128.7, 127.3 and 127.3, 127.0 and 126.9, 126.9 and 126.8, 123.0 and 122.3, 120.6, 119.2 and 119.2, 118.4, 117.5, 111.0, 109.1, 106.1 and 106.0, 56.7 and 53.3, 48.4 and 47.7, 25.6 and 25.4, 20.0 and 20.0; HRMS (ESI) calcd for $C_{24}H_{23}N_4O_2$ $[M + H]^+$ 399.1816, found 399.1822.

*Data for N′-(Pyridin-4-ylmethylene)-(3S)-1-methyl-2,3,4,9-tetrahydro-1H-pyrido[3,4-b]indole-3-carbohydrazide (**19**).* This compound was obtained as yellow solid in 79% yield: mp = 235−239 °C; $^1$H NMR (400 MHz, DMSO-$d_6$) $\delta$ 11.84 and 11.69 (s, 1H, NH), 10.90 and 10.84 (s, 1H, O═C-NH), 8.65 and 8.57 (d, $^3J_{HH}$ = 5.6 Hz, 2H, Py-H), 8.35 and 8.05 (s, 1H, N═CH), 7.65 and 7.57 (d, $^3J_{HH}$ = 5.6 Hz, 2H, Py-H), 7.41 and 7.37 (d, $^3J_{HH}$ = 7.6 Hz, 1H, Ph-H), 7.34−7.29 (m, 1H, Ar−H), 7.04 (t, $^3J_{HH}$ = 7.6 Hz, 1H, Ar−H), 6.95 (t, $^3J_{HH}$ = 7.6 Hz, 1H, Ar−H), 4.58 and 3.67 (dd, $^3J_{HH}$ = 10.8 Hz, 3.6 Hz, 1H, C$\mathbf{H}$), 4.26 and 4.16 (q, $^3J_{HH}$ = 6.4 Hz, 1H, C$\mathbf{H}$), 3.05−2.91 (m, 1H, C$\mathbf{H}_2$), 2.80−2.62 (m, 1H, C$\mathbf{H}_2$), 1.48 (d, $^3J_{HH}$ = 6.4 Hz, 3H, $CH_3$); $^{13}$C NMR (100 MHz, DMSO-$d_6$) $\delta$ 174.5 and 169.4, 150.3, 144.7, 141.6, 141.3 and 141.2, 137.7 and 135.8, 126.9 and 126.8, 121.0, 120.7 and 120.6, 118.5 and 118.4, 117.6 and 117.5, 111.0, 106.0 and 105.9, 56.7 and 53.3, 48.5 and 47.9, 25.4 and 25.2, 19.8 and 19.6; HRMS (ESI) calcd for $C_{19}H_{20}N_5O$ $[M + H]^+$ 334.1662, found 334.1663.

*Data for N′-(pyridin-3-ylmethylene)-(3S)-1-methyl-2,3,4,9-tetrahydro-1H-pyrido[3,4-b]indole-3-carbohydrazide (**20**).* This compound was obtained as yellow solid in 72% yield: mp = 205−209 °C; $^1$H NMR (400 MHz, DMSO-$d_6$) $\delta$ 11.74 and 11.58 (s, 1H, NH), 10.91 and 10.84 (s, 1H, O═C-NH), 8.84 and 8.79 (s, 1H, Py-H), 8.62 and 8.55 (d, $^3J_{HH}$ = 4.0 Hz, 1H, Py-H), 8.41 and 8.12 (s, 1H, N═CH), 8.12 and 8.03 (d, $^3J_{HH}$ = 4.0 Hz, 1H, Py-H), 7.49 and 7.44−7.35 (m, 2H, Py-H and Ar−H), 7.33 and 7.31 (d, $^3J_{HH}$ = 7.6 Hz, 1H, Ph-H), 7.04 (t, $^3J_{HH}$ = 7.6 Hz, 1H, Ar−H), 6.96 (t, $^3J_{HH}$ = 7.6 Hz, 1H, Ar−H), 4.59 and 3.66 (dd, $^3J_{HH}$ = 10.8 Hz, 3.6 Hz, 1H, C$\mathbf{H}$), 4.32 and 4.12 (m, 1H, C$\mathbf{H}$), 3.05−2.92 (m, 1H, C$\mathbf{H}_2$), 2.78−2.63 (m, 1H, C$\mathbf{H}_2$), 1.53−1.39 (m, 3H, C$\mathbf{H}_3$); $^{13}$C NMR (100 MHz, DMSO-$d_6$) $\delta$ 169.1, 150.7 and 150.5, 148.7 and 148.5, 144.4 and 140.9, 137.6 and 135.8, 133.4 and 133.2, 130.3, 130.0, 126.9 and 126.8, 124.0 and 124.0, 120.7 and 120.6, 118.5 and 118.4, 117.6 and 117.5, 111.0, 106.0 and 105.9, 56.7 and 53.4, 48.5 and 47.9, 25.4 and 25.1, 19.8 and 19.5; HRMS (ESI) calcd for $C_{19}H_{20}N_5O$ $[M + H]^+$ 334.1662, found 334.1664.

**Biological Assay.** The anti-TMV and fungicidal and insecticidal activities of the synthesized compounds were tested using our previously reported methods.[21,22]

**Field Trials.** The experiments were carried out between June and July in 2014. The trial against TMV was performed in the trial area of Institute of Environment and Resources, Yunnan Provincial Academy of Agricultural Sciences, Kunming, Yunnan Province, China. The experimental design was a randomized complete block with three treatments. The untreated plots served as a blank control. The formulation of compounds **9** (1% EC) and **29** (1% ME) was prepared in our lab. They were diluted to 10, 50, or 100 g(ai)/ha (weight (gram) of active ingredient/hectare) before use. The formulation of moroxydine hydrochloride−cupric acetate (20% WP) and amino-oligosaccharins (5% aqueous solution) were obtained from Wansheng Biological Pesticide Co., Ltd. (Shandong, China) and Hainan zhengye zhong nong Co., Ltd. (Hainan, China) respectively. The incidence was surveyed 10 days after the third time spraying. The severity of the virus disease was divided into 0−4 grade. The disease index and control effect can be calculated by using the following formulas:

disease index

$$I\% = [\sum (N_n n)/(N4)] \times 100$$

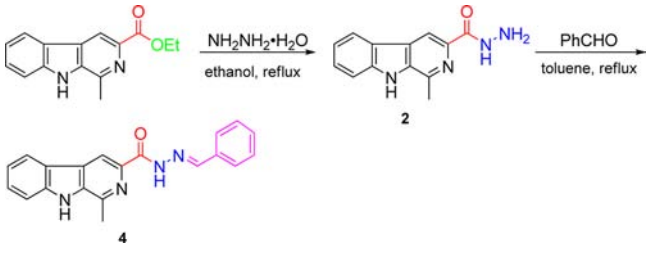
$$\text{control effect } (\%) = 1 - (I'_{bc}I)/(I_{bc}I') \times 100$$

where $N_n$ is the number of diseased plants of each relative level values, $n$ is the relative level values ($n$ = 0−4), $N$ is the total number of diseased plants, $I'_{bc}$ is the disease index of the blank control area before spraying, $I_{bc}$ is the disease index of the blank control area 10 days after the third time spraying, $I'$ is the disease index of the spraying area before spraying; and $I$ is the disease index of the spraying area 10 days after the third time spraying.

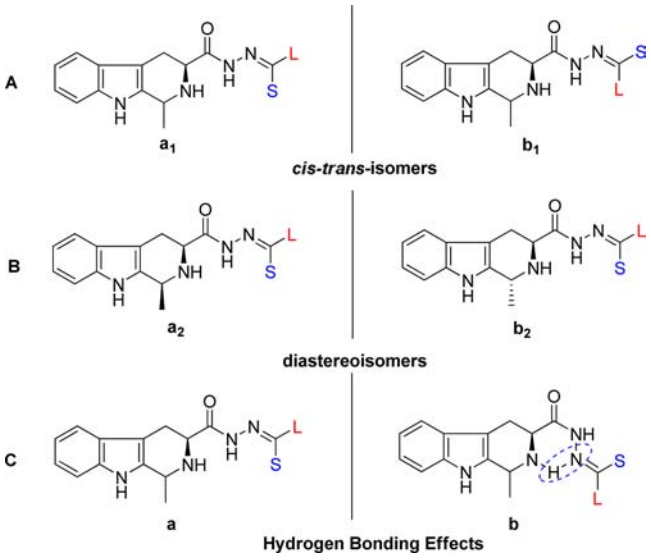
## RESULTS AND DISCUSSION

**Synthesis.** The synthesis of the lead compound **1** is shown in Scheme 1. Using L-tryptophan as starting material, the tetrahydrocarboline skeleton of **1** was constructed through Pictet−Spengler cyclization, and then the given carboxylic acid reacted with thionyl chloride and methanol to form methyl ester, which subsequently reacted with hydrazine hydrate to give compound **1**.

**Scheme 3. Synthesis of Compounds 2 and 4**



**Scheme 4. Prediction of the Configuration**



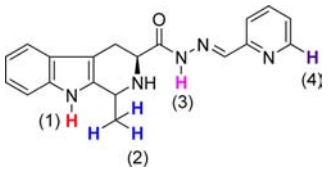


**Figure 3.** Compound **21**.

The compounds **3** and **6−33** containing the acylhydrazone fragment all can be synthesized from lead compound **1** by reaction with the corresponding aldehydes or ketones under different reaction conditions (Scheme 2). To be specific, when aromatic aldehydes were used as starting materials, the corresponding reactions were carried out in toluene under reflux conditions. When the reaction was complete, the reaction system was cooled to room temperature, and the solid products precipitated because of their poor solubility in toluene. By this approach, compounds **3** and **6−26** could be easily obtained in 60%−91% yields. When aliphatic aldehydes were used as starting materials, the corresponding reactions were carried out in tetrahydrofuran at room temperature. When the reaction was complete, compounds **27−30** could be obtained by column chromatography in 71%−95% yields. When ketones were used, these reactions were carried out in ethanol under reflux conditions. When the reaction was complete, compounds **31−33** could be obtained by column chromatography in 56%−63% yields.

In addition, 1-methyl-9*H*-carbazole-3-carboxylic acid hydrazide **2** could be prepared from ethyl 1-methyl-9*H*-pyrido[3,4-*b*]indole-3-carboxylate, which was synthesized from tryptophan through a literature protocol.[17] Compound **2** reacted with benzaldehyde using a similar procedure as the preparation of compound **3** to give **4** in 91% yield (Scheme 3).

**Configuration.** At room temperature, the $^1$H and $^{13}$C NMR spectra of most of target compounds exhibited two sets of signals, which aroused our attention. Initially, this phenomenon was thought to be due to the presence of *cis−trans* isomers (prediction A, Scheme 4); however, in the $^1$H NMR spectrum

dx.doi.org/10.1021/jf503794g | J. Agric. Food Chem. 2014, 62, 9987−9999

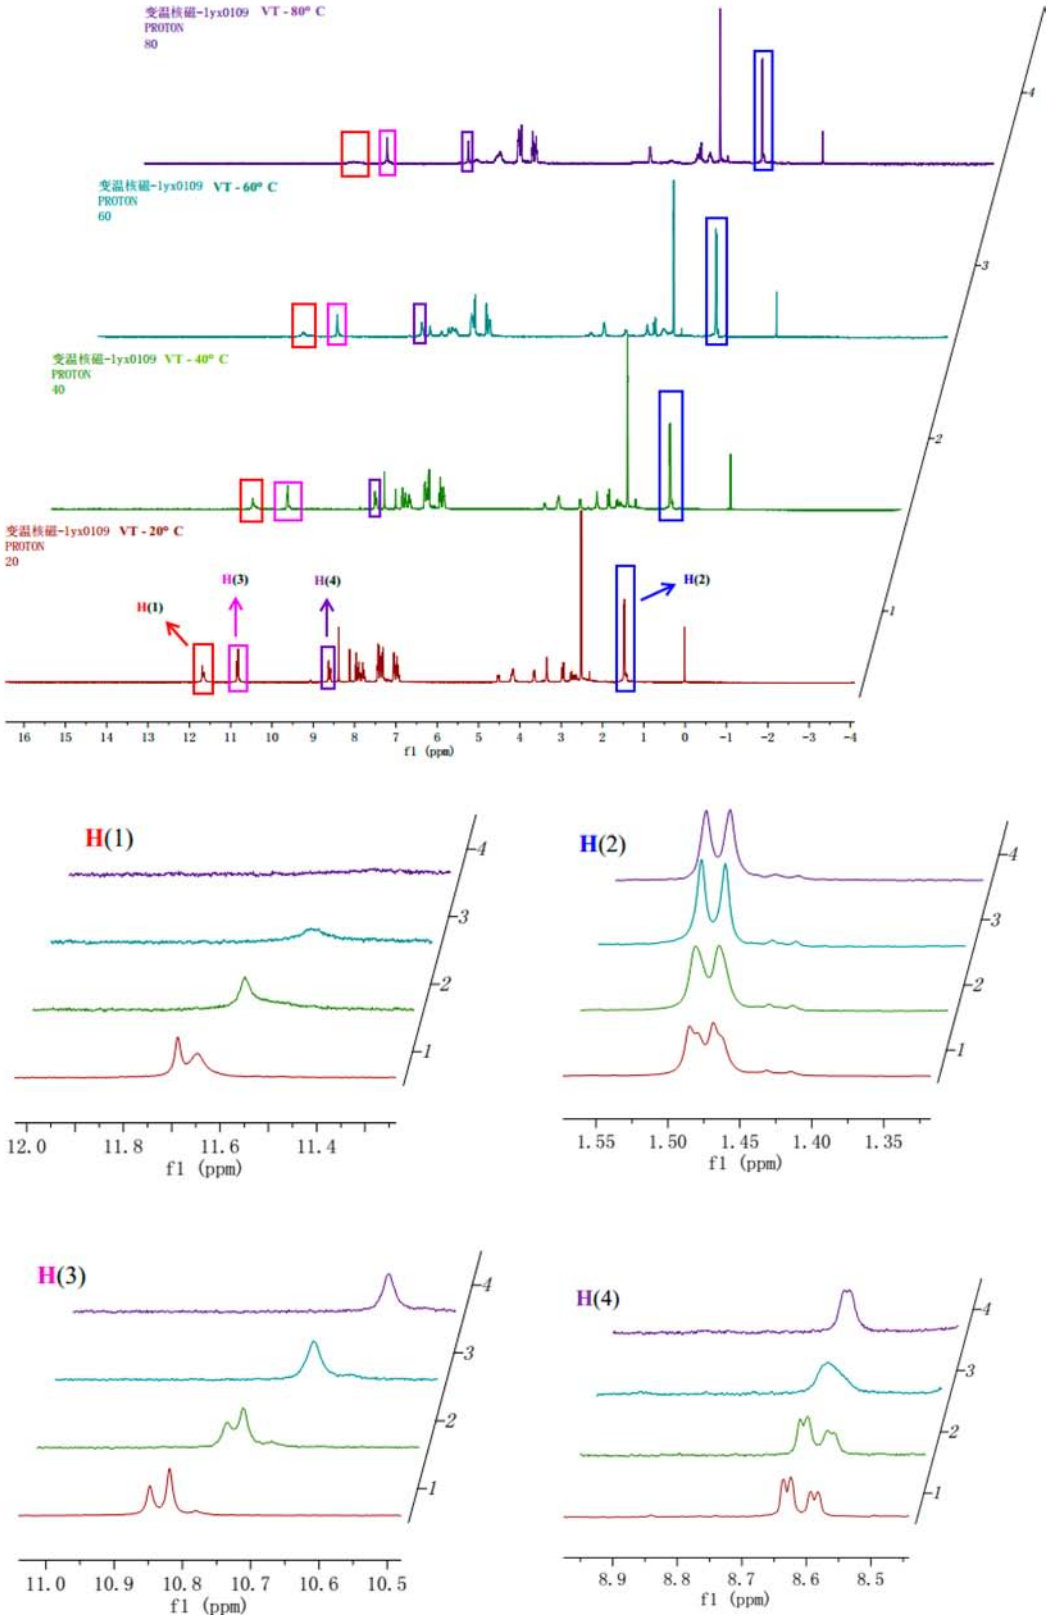

**Figure 4.** $^{1}$H NMR of Compound **21** at Different Temperatures.

of **4** only one set of signals was observed, which suggested such phenomenon resulted from other reasons. Meanwhile, the presence of diastereoisomers (prediction B, Scheme 4) as a possible reason was excluded (the $^{1}$H NMR spectra of precursor **1** as well as compound **21** (Figures 3, 4 and 5) clearly showed the presence of diastereoisomeric mixtures, and the ratio is 10:1). Eventually, hydrogen-bonding effects (prediction C, Scheme 4) was put forward, and variable-temperature (VT) $^{1}$H NMR studies (Figures 4 and 5) of compound **21** were performed in order to confirm this

dx.doi.org/10.1021/jf503794g | J. Agric. Food Chem. 2014, 62, 9987−9999

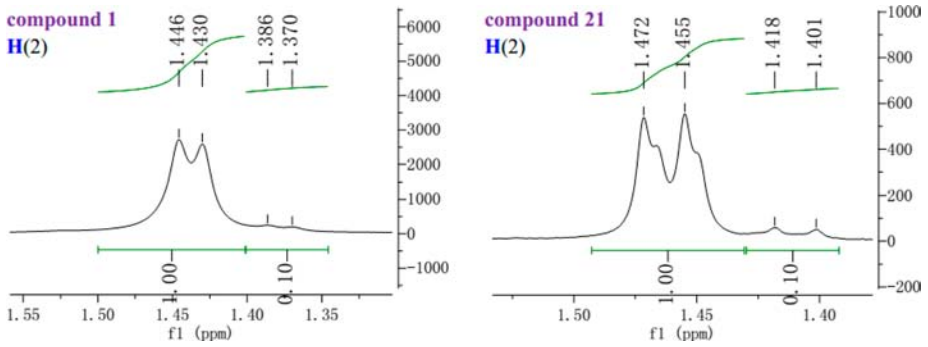

**Figure 5.** $^{1}$H NMR (H2) of compounds **1** and **21**.

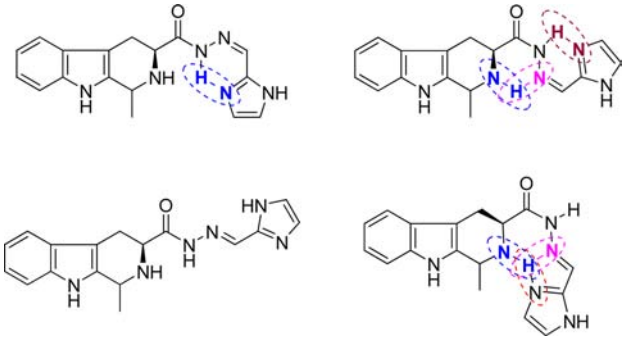

**Figure 6.** Hydrogen-bonding effects of compound **25**.

hypothesis. As we can see, the coalescence of signals was observed in the entire $^{1}$H NMR spectrum with the rise of the temperature (20 → 40 → 60 → 80 °C). Therefore, the VT $^{1}$H NMR studies indicated that the doubling of signals in the $^{1}$H and $^{13}$C NMR spectra was very likely due to hydrogen-bonding effects. In addition, it also could explain the appearance of four sets of signals in compound **25** (Figure 6).

**Antiviral Activities.** In our previous work, high antiviral lead compound **1** was found, on the basis of which, a series of derivatives containing acylhydrazone structure were synthesized to investigate the influence of the variation in the basic skeleton of **1**. The acylhydrazone compounds exhibited excellent antiviral activity. The antiviral results *in vitro* and *in vivo* (protection, inactivation, and curative) are listed in Tables 1 and 2. Overall, compared with ribavirin, most of the newly designed compounds exhibited desirable anti-TMV activity *in vitro*. Compounds **8**, **9**, **12**, **16**, **28**, **29**, and **30** showed much higher inhibition than that of ribavirin and their precursor **1** at 500 and 100 μg/mL. Especially, the activity of compound **16** was 36.9% at 100 μg/mL, which was very close to that of Ribavirin (40%) at 500 μg/mL.

When the C ring (Figure 3) was tetrahydropyridine, the in vitro activity of compound **1** (40.4%, 500 μg/mL) was a little lower than that of the β-carboline compound **2** (43.9%, 500 μg/mL); however, activity of compound **3** (55.8%, 500 μg/mL) was obviously higher than that of compound **4** (41.8%, 500 μg/mL). On the other hand, the activity of compound **1** (40.4%, 500 μg/mL) showed obviously lower inhibition than that of compound **3** (55.8%, 500 μg/mL), which proved that it is advantageous to improve the activity if the hydrazide structure at the 3-position of tetrahydrogen-β-carboline was changed to acylhydrazone. Hence, a representative set of compounds containing acylhydrazone structure were designed to search for better-activity compounds. Additionally, the

55.8%, 500 μg/mL) was slightly more active than compound **5** (3*R*, 49.6%, 500 μg/mL).

Furthermore, it was noteworthy that the substituents of the acylhydrazone moiety had a significant impact on anti-TMV activity.

When $R^2$ was hydrogen and $R^1$ was a benzene ring, it was universally advantageous to anti-TMV activity if substituents were introduced to the 4-position of the benzene ring such as **7** (56.8%, 500 μg/mL), **8** (62.8%, 500 μg/mL), **9** (67.3%, 500 μg/mL), and **12** (62.5%, 500 μg/mL). Monosubstitution or multisubstitution on the benzene ring affected anti-TMV activity to a certain extent, for instance, compared with compounds **10** (56.8%, 500 μg/mL) and **11** (50.7%, 500 μg/mL), the monosubstituted compound **9** exhibited significantly higher activity. In addition, the position of the substituent group also was favored to increase anti-TMV activity; the activity of compound **12** (62.5%, 500 μg/mL) was much better than that of **13** (53.2%, 500 μg/mL) and **14** (38.5%, 500 μg/mL), the order of their activities was para > meta > ortho. However, the activity was greatly reduced when the benzene ring was changed to a naphthalene ring, such as **18** (40.9%, 500 μg/mL).

Interestingly, compound **16** (72.6%, 500 μg/mL) exhibited excellent inhibitory effect; in contrast, compounds **15** (37.2%, 500 μg/mL) and **17** (46.5%, 500 μg/mL) were far less effective. We speculated it could be ascribed to the tension on the five-membered ring of **16**, which inhibited the conjugation of the lone-pair electrons of oxygen atoms with the benzene ring.

When $R^2$ was hydrogen and $R^1$ was a heterocyclic ring, the anti-TMV activities of these compounds (**19**−**25**) reduced obviously compared with those of compounds with substituted benzene (**3**, **5**−**18**).

When $R^2$ was hydrogen and $R^1$ was an aliphatic substituent, both the length of the aliphatic chain and the number of branched chains affected anti-TMV activity; the more branched and the longer was the aliphatic chain, the better was the

activity. For example, compound **26** containing an unsaturated aliphatic chain (35.2%, 500 μg/mL) and **27** (32.6%, 500 μg/mL) containing a saturated short-chain displayed lower anti-TMV activities than **28** (61.3%, 500 μg/mL), **29** (59.6%, 500 μg/mL), and **30** (64.4%, 500 μg/mL). When $R^2$ was methyl, the compounds **31** (30.2%, 500 μg/mL), **32** (58.1%, 500 μg/mL), and **33** (43.4%, 500 μg/mL) exhibited much lower antiviral activities than **3** (55.8%, 500 μg/mL), **30** (64.4%, 500 μg/mL), and **29** (59.6%, 500 μg/mL), which meant that the hydrogen-bond in N**H**═CH played an important role in the anti-TMV activity.

Further bioassay was conducted to investigate their inactivation, curative, and protection effect *in vivo* (Table 2). These results also showed that most of the compounds exhibited excellent antiviral activity and similar structure−activity relationship as the activities *in vitro*. Especially the activities of compounds **9** (70.4%, 71.5%, and 64.2% at 500 μg/mL), **12** (69.1%, 66.4%, and 70% at 500 μg/mL), **16** (74.5%, 69%, and 68.1% at 500 μg/mL), **28** (73.4%, 70.9%, and 59.6% at 500 μg/mL), **29** (75.8%, 62.8%, and 69.2% at 500 μg/mL), and **30** (63.7%, 68.2%, and 66.8% at 500 μg/mL) were much superior to ribavirin (37.6%, 39.4%, and 37.9% at 500 μg/mL). What is more, their anti-TMV activities (≥30%) at 100 μg/mL were close to ribavirin at 500 μg/mL.

**Fungicidal Activity.** The fungicidal results are listed in Table 3. Most of β-carboline, tetrahydrogen-β-carboline alkaloids, and their derivatives showed good fungicidal activities against 14 kinds of phytopathogens; especially compounds **6**, **9**, and **11** exhibited desirable fungicidal activities against each of the phytopathogens. Additionally, tetrahydrogen-β-carboline derivatives exhibited higher activities than β-carboline derivatives. When the skeleton was tetrahydrogen-β-carboline (C ring was tetrahydropyridine), the fungicidal activities were greatly affected by the substituents ($R^1$ and $R^2$) on the acylhydrozone. The compounds with one hydrogen and one aryl group (**3**, **5**−**25**) exhibited high activities against fungi; whereas the compounds with no hydrogen or with at least one alkyl group (**26**−**33**) exhibited relatively poor activities. Noteworthily, the compounds containing aryl groups exhibited fungicidal activities to certain fungi selectively; they showed apparently higher activities against *Physalospora piricola*, *Sclerotinia sclerotiorum*, *Phytophthora capsici*, *Rhizoctonia cerealis*, *Bipolaris maydi*, and *Botrytis cinerea* than the others.

**Table 5. Results of Anti-TMV Activities of Field Trial in 2014 after 10 Days of Application of 9, 29, Amino-oligosaccharins, and Moroxydine Hydrochloride−Cupric Acetate**

| compd[a] | concn (gai/ha) | $I'_{eq}$ [b] | $I_{eq}$ [c] | $E$[d] (%) |
|---|---|---|---|---|
| **9** (1% EC) | 10 | 1.14 | 1.52 | 65.28 |
| | 50 | 1.86 | 4.92 | 80.82 |
| | 100 | 0.00 | 0.00 | 100.00 |
| **29** (1% ME) | 10 | 1.10 | 1.52 | 70.91 |
| | 50 | 0.79 | 0.00 | 100.00 |
| | 100 | 0.00 | 0.00 | 100.00 |
| blank control | | 2.56 | 5.23 | |
| amino-oligosaccharins (5% aqueous solution) | 100 | 3.33 | 3.33 | 66.67 |
| moroxydine hydrochloride−cupric acetate (20% WP) | 600 | 1.23 | 2.67 | 66.67 |

[a]EC, emulsifiable concentrate; ME, microemulsion; WP, wettable powder. [b]$I'_{eq}$, the average disease index of the spraying area before spraying. [c]$I_{eq}$, the average disease index of the spraying area 10 days after the third time spraying. [d]$E$, the average control effect 10 days after the third time spraying.

**Figure 7.** Effect of anti-TMV activities in field trials of compounds **9** and **29**.

**Insecticidal Activity.** These derivatives also showed broad-spectrum insecticidal activities (Table 4). What is more, compounds **3** and **23**, which contain a phenyl group or a pyrryl group, respectively, exhibited moderate insecticidal activity against the four kinds of insects (*Mythimna separata*, *Helicoverpa armigera*, *Ostrinia nubilalis*, and *Culex pipiens pallens*).

**Field Trials.** Because compounds **9** and **29** exhibited excellent anti-TMV activity in laboratory, 1% EC of compound **9** and 1% ME of compound **29** were evaluated for their anti-TMV activities in Tengchong County, Yunnan Province, China. Their efficacy was compared with the amino-oligosaccharins, moroxydine hydrochloride−cupric acetate, and an untreated control. Table 5 presents part of the results of field trials. Compounds **9** and **29** (Figure 7) exhibited better activities than control plant virus inhibitors. The results showed that the series of compounds, especially compound **29**, are promising for plant virus control.

In summary, we designed and synthesized a series of novel tetrahydrogen-$\beta$-carboline and $\beta$-carboline derivatives containing an acylhydrazide or acylhydrazone moiety at the 3-position. The hydrogen bonding effect was verified via variable-temperature (VT) $^1$H NMR studies. What is more, the target compounds exhibited good anti-TMV activity in the laboratory; especially, *in vivo*, inactivation, curative, and protection activities of compounds **8**, **9**, **12**, **16**, **28**, **29**, and **30** were much higher (57.1−75.8% at 500 $\mu$g/mL) than that of ribavirin (37.6%, 37.6%, 39.4%, and 37.9% at 500 $\mu$g/mL) and the lead compound **1** (40.4%, 40.0%, 42.3%, and 39.6% at 500 $\mu$g/mL), and the relevant SAR was summarized. At the same time, field trials of compounds **9** and **29** further demonstrated the antiviral efficacy against TMV. In addition, we were pleased to find that these compounds also showed broad-spectrum of fungicidal activity and insecticidal activity. For instance, compounds **3**, **6**, **9**, and **11** exhibited good inhibition of the 14 kinds of phytopathogens; compounds **3** and **23** exhibited moderate insecticidal activity against four kinds of investigated insects. Further studies on structural optimization are in progress in our laboratory.

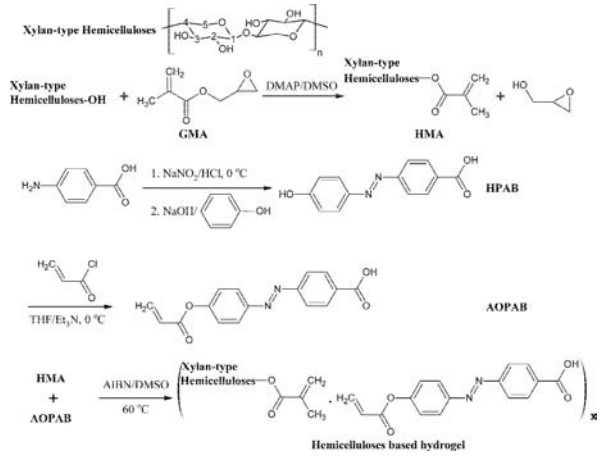
In this paper, modified hemicellulose-*graft*-carboxylic azobenzene hydrogels were prepared, which showed multiresponsive behaviors to light, pH, and water/ethanol alternating solutions. The chemical structures of the xylan-type hemicellulose derivative, azobenzene monomers, and the synthesized hydrogels were investigated using FT-IR and $^1$H and $^{13}$C NMR. The morphologies of the resulting hydrogels were characterized by using SEM. The water swelling ratios and swelling/deswelling behaviors of the hydrogels in different solvents were investigated. Furthermore, the in vitro drug release behaviors of the synthesized hydrogels were also studied by using vitamin $B_{12}$ ($VB_{12}$) as a model drug.

## MATERIALS AND METHODS

**Materials.** Xylan-type hemicelluloses were extracted from bamboo (*Dendrocalamus membranaceus* Munro, *Dm*M) according to our previous work.[29] The obtained xylan-type hemicelluloses mainly consisted of xylose (86.58%), arabinose (5.65%), glucose (1.97%), mannose (1.75%), galactose (0.69%), and glucuronic acid (2.80%). Glycidyl methacrylate (GMA), *p*-aminobenzoic acid, acryloyl chloride, 4-dimethylaminopyridine (DMAP), and azobis(isobutyronitrile) (AIBN) were purchased from Aladdin Reagent Co., Ltd., Shanghai, China. Other chemicals and solvents were of analytical reagent grade and used as received.

**Methods.** The scheme for the preparation of xylan-type hemicellulose-based hydrogel is illustrated in Scheme 1. The experimental details are given below.

**Scheme 1. Scheme for Preparation of Xylan-Type Hemicellulose-Based Hydrogel**



**Synthesis of Hemicellulose Methacrylate (HMA).** HMA was synthesized according to the method reported by De Smedt et al.[30] 10.0 g of dried xylan-type hemicelluloses was added into the flask with 90 mL of DMSO under magnetic stirring. The mixture was stirred vigorously at 90 °C for 0.5 h. After that, the temperature was adjusted to room temperature and 2.0 g of DMAP was added. Then 3.60 g of GMA was added to the solution corresponding to a ratio of 1 mol of GMA per 3 mol of anhydroxylose units. The reaction was carried out at room temperature for 48 h. At the end of the reaction, the mixture was added dropwise into 500 mL of ethanol under vigorous stirring. The separation, purification, and dehydration of HMA were performed according to the process reported in the literature.[30]

**Synthesis of 4-[(4′-Hydroxy)phenylazo]benzoic Acid (HPAB) and 4-[(4-Acryloyloxyphenyl)azo]benzoic Acid (AOPAB).** HPAB was synthesized according to the method reported by Chen et al.[28] A solution of $NaNO_2$ (4.14 g, 60 mmol) in 60 mL of $H_2O$ was added dropwise to a solution of 4-aminobenzoic acid (8.23 g, 60 mmol) in 24 mL of HCl (37%) in an ice water bath. The solution was stirred for 30 min and diluted with 300 mL of ice water. Then phenol (5.92 g, 63 mmol) and NaOH (2.52 g, 63 mmol) mixture in 30 mL of $H_2O$ was added dropwise at 0−5 °C. The mixture was stirred for 2 h, and the NaOH solution was added to precipitate the product, which was then washed with water and dried in a vacuum oven at 50 °C for 24 h. The structure of the orange product obtained was determined using $^1$H NMR. $^1$H NMR (DMSO-$d_6$): 7.01 (d, 2H), 7.85 (d, 2H), 7.89 (d, 2H), 8.12 (d, 2H). The $^1$H NMR spectrum of HPAB is illustrated in Figure S1 in the Supporting Information.

AOPAB was prepared by the reaction between acryloyl chloride and HPAB according to the method reported by Haitjema et al.[31] HPAB (3.63 g, 15 mmol) and triethylamine (5.06 g, 50 mmol) were dissolved in dry tetrahydrofuran (THF, 50 mL) and cooled in an ice water bath. A solution of acryloyl chloride (4.50 g, 50 mmol) in dry THF (15 mL) was added over 2 h, and the temperature was fixed at 0−5 °C and stirred for 48 h. At the end of reaction, the mixture was added dropwise to water. After filtration, the yellow precipitate was first dissolved in boiling acetic acid and subsequently crystallized during cooling down of the solution. The structure of the yellow product obtained was determined using $^1$H NMR. $^1$H NMR (DMSO-$d_6$): 6.22 (d, 1H), 6.46 (dd, 1H), 6.60 (d, 1H), 7.47 (d, 2H), 8.00 (dd, 4H), 8.16 (d, 2H). The $^1$H NMR spectrum of AOPAB is illustrated in Figure S2 in the Supporting Information.

**Preparation of Xylan-Type Hemicellulose-*graft*-photoisomeric Azobenzene Hydrogels.** HMA (1.0 g) and AOPAB (0.02, 0.04, 0.08, 0.12, and 0.16 g) were added into the test tube with 20 mL of DMSO, respectively. The mixture was shaken vigorously on a vortex mixer until completely homogeneous. Then AIBN (0.02 g) was added into the mixture as an initiator with nitrogen bubbling for 15 min. After mixing, the test tube was placed in a water bath at 60 °C for 24 h. The resultant hydrogels were cut into a single slice about 2 mm thick and first immersed in ethanol for 3 days and then dialyzed in deionized water for 1 week. The prepared hydrogels were freeze-dried in a freeze drier at −50 °C. The conditions of synthesizing the hydrogels are illustrated in Table 1.

**Table 1. Synthesis Conditions of the Prepared Hydrogels**

| samples | HMA/g | AOPAB/wt %[a] | AIBN/g |
|---|---|---|---|
| H1 | 1.0 | 2 | 0.02 |
| H2 | 1.0 | 4 | 0.02 |
| H3 | 1.0 | 8 | 0.02 |
| H4 | 1.0 | 12 | 0.02 |
| H5 | 1.0 | 16 | 0.02 |

[a]The mass ratio of AOPAB to HMA.

**Characterizations.** The composition of neutral sugars and uronic acids in the xylan-type hemicelluloses was detected by high-performance anion-exchange chromatography (HPAEC, Dionex ICS3000, U.S.) with pulsed amperometric detector, a Carbopac PA-20 column (4 × 250 mm, Dionex), and a guard PA-20 column (3 × 30 mm, Dionex). 18 mM NaOH was used as mobile phase at a flow rate of 0.4 mL/min.[32] FT-IR spectra of xylan-type hemicelluloses, HMA, and prepared hydrogels were recorded on a Bruker Tensor 27 spectrophotometer in the range of 4000−400 cm$^{-1}$ with a resolution of 4 cm$^{-1}$. A KBr disk containing 1% finely ground sample was used for measurement. $^1$H NMR spectra of HPAB and AOPAB and $^{13}$C NMR spectra of xylan-type hemicelluloses and HMA were carried out on a Bruker DRX-400 spectrometer operating at 400.12 MHz for $^1$H NMR and 100.62 MHz for $^{13}$C NMR. Xylan-type hemicelluloses in 1.0 mL of $D_2O$ and HPAB, AOPAB, HMA in 1.0 mL of DMSO-$d_6$ was used for NMR measurement (20 mg for $^1$H NMR, 80 mg for $^{13}$C NMR), respectively. A scanning electron microscope (ZEISS EVO 18, Germany) was used to record the morphologies of the hydrogels. The accelerating voltage of the instrument was maintained at 10.00 kV. Ultraviolet visible spectroscopy (S-3100, Scinco) was used to measure the time-dependent light sensitive behavior of the hydrogel and drug concentration in PBS.

**Measurement of Time- and pH-Dependent Swelling Ratios.** The swelling ratio of the hydrogel in distilled water as a function of

time was measured as follows. Preweighed dried hydrogel ($m_0$) was immersed into excessive distilled water, and the mass of the wet hydrogel ($m_t$) was determined at regular intervals after removal of the surface water with filter paper. The swelling experiments were performed twice to check the reproducibility. The swelling ratio (SR) was calculated by the following equation:

$$SR = (m_t - m_0)/m_0 \quad (1)$$

where $m_0$ and $m_t$ were the weights of dried and swollen hydrogels, respectively.

The pH sensitivity of the hydrogel was investigated by immersing about 1.0 g of sample into phosphate buffer solutions of pH 2.0, 4.0, 5.9, 7.4, 9.0, and 10.8 for 48 h at 37 °C to reach equilibrium. Since the SR of the hydrogel is also influenced by the ionic strength of the solution, the ionic strengths of these phosphate buffer solutions with various pH values were adjusted to 0.1 M with NaCl. The SR values of the hydrogels in various pH buffer solutions were measured using a similar method for water absorption and calculated according to eq 1.

**Swelling and Deswelling Behaviors of Hydrogel in Different Buffer Solutions.** The swelling and deswelling behaviors of the hydrogel in response to pH were carried out in different buffer solutions (pH 2.0 and 7.4). The swollen samples in water were first immersed in buffer solution of pH 7.4 for 30 min and weighed. Then the swollen samples were soaked in the buffer solution with pH 2.0 for another 30 min and weighed again. The procedure was repeated to record the swelling and deswelling performances of the hydrogel in buffer solutions of different pH values.

**Swelling and Deswelling Behaviors of Hydrogel in Water/Ethanol Alternating Solutions.** The swelling and deswelling behaviors of the hydrogel in response to water/ethanol alternating solutions were carried out as follows. The swollen samples in water were first immersed in ethanol and weighed per 100 s. After 10 min, the swollen samples were soaked in water and weighed per 100 s for another 10 min. The procedure was repeated to record the swelling and deswelling performances of the hydrogel in different solvents.

**Light Response Behavior of Hydrogel.** Dried hydrogel was first ground into a fine powder by using a Mikro-dismembrator S homogenizer (Sartorius, Goettingen, Germany) for light response test. Then it was transferred into plenty of distilled water for 48 h. The hydrogel was recovered by filtration and washed with plenty of distilled water. Next the hydrogel was dispersed into a certain amount of distilled water again. UV irradiation was carried out in an ultraviolet analyzer, which could emit UV light at 365 nm. The UV/vis spectra of the hydrogels as a function of irradiation time were recorded by ultraviolet visible spectroscopy (S-3100, Scinco).

**The Maximum Drug Release and in Vitro Drug Release Behavior of Hydrogel.** The maximum drug release was carried out by swelling the preweighed hydrogel in sufficient vitamin $B_{12}$ ($VB_{12}$) solution (0.5 mg/mL). After swelling in the solution for 48 h, the hydrogel was taken out and freeze-dried. To determine the maximum drug release, the hydrogel was first ground into fine powder. Then, the powder was put into a certain amount of water to maximize the drug release. The solution was filtered through a 0.22 $\mu$m filter, and the filtrate was determined by measuring its absorbance at 375 nm using a UV spectrophotometer to calculate the maximum drug release of the hydrogel. The drug concentrations were calculated based on the determined calibration curves.

In this work, $VB_{12}$ was used as a model hydrophilic drug to investigate the release behavior of the synthesized hydrogel in vitro. First, 20 mL of PBS (pH 7.4 or pH 2.2) was added into 50 mL of transparent tube and maintained in an incubator at 37 ± 0.3 °C with or without UV irradiation at 365 nm. Then, a certain amount of dried $VB_{12}$ loaded hydrogel was put into the PBS solution. The hydrogel was immersed in 20 mL of PBS (pH 7.4 or pH 2.2) and shaken at 100 rpm at 37 °C. At specific time intervals, 1.0 mL of PBS solution was removed and replaced by 1.0 mL of fresh PBS solution. After centrifugation at 10,000 rpm for 10 min, the supernatant of the PBS solution was collected and stored at −20 °C for further analysis. The collected supernatants were detected on a UV spectrophotometer at 375 nm to determine the concentration of $VB_{12}$. The drug cumulative release profiles were plotted as a function of time.

## RESULTS AND DISCUSSION

**FT-IR Analysis of Xylan-Type Hemicelluloses, HMA, and Prepared Hydrogels.** The FT-IR spectra of xylan-type hemicelluloses, HMA, and the prepared hydrogel (H3) were recorded and are illustrated in Figure 1. The strong and wide

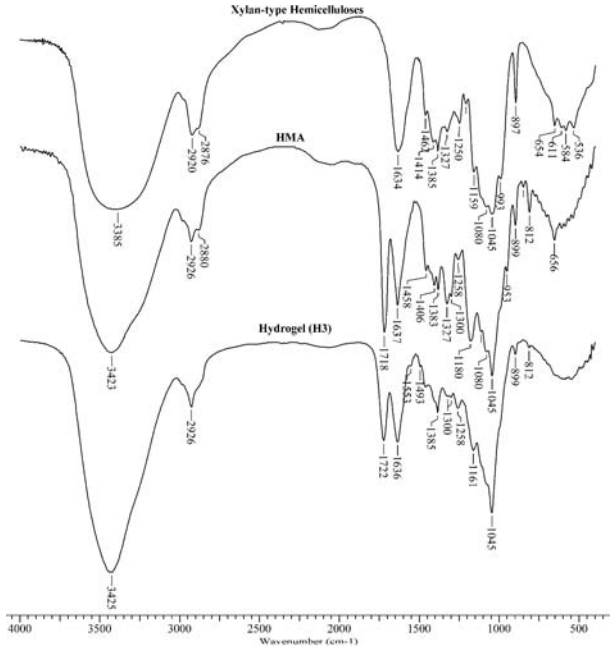


**Figure 1.** FT-IR spectra of xylan-type hemicelluloses, HMA, and the synthesized hydrogel (H3).

absorption at 3423 $cm^{-1}$ is attributed to the hydroxyl stretching vibration, and the bands at 2926 and 2880 $cm^{-1}$ are related to the C−H asymmetric and symmetrical vibrations of alkanes, respectively. These signals in the spectra are originated from the anhydrosugar unit of xylan-type hemicelluloses. The strong bands in the region 1200−1000 $cm^{-1}$ in xylan-type hemicelluloses are mainly from the ring vibrations and C−O−C glycosidic bond vibration overlapped with C−OH group stretching vibration.[33] The absorption band at 1634 $cm^{-1}$ in the spectrum of xylan-type hemicelluloses is assigned to the bending mode of the absorbed water. However, the band at 1637 $cm^{-1}$ in the spectrum of HMA is much sharper than that in xylan-type hemicelluloses. This is very likely related to the C═C in HMA, which shows the sharp C═C stretching signals at around 1630 $cm^{-1}$. Furthermore, HMA displays much stronger bands at 1327, 1300, and 1180 $cm^{-1}$ than xylan-type hemicelluloses, which originate from the C−H in-plane bending vibration of alkenes and C−O−C stretching of carboxylic esters. The small sharp band at 812 $cm^{-1}$ in HMA is related to the $CH_2$ out of plane bending of alkenes, and it can be seen that this band is absent in the xylan-type hemicelluloses. Two small absorption signals at 1553 and 1493 $cm^{-1}$ in the synthesized hydrogel originate from the aromatic skeletal vibration of aromatic structures. Signals at 1327, 1300, and 812 $cm^{-1}$ related to the C═C groups in hydrogel are much lower than those in HMA, suggesting that, during the preparation of the hydrogels, most C═C groups of HMA react with AOPAB by free radical reaction. These signal changes observed in the

FT-IR spectra preliminarily confirmed the successful synthesis of HMA and the target hydrogel.

**$^{13}$C NMR Analysis of Xylan-Type Hemicelluloses and HMA.** In this work, HMA is an important intermediate in the preparation of xylan-type hemicellulose-based hydrogel. The introduction of C═C groups into hemicelluloses makes HMA easy to polymerize with AOPAB. In order to ensure the accurate structure of HMA, $^{13}$C NMR spectra of xylan-type hemicelluloses and HMA were performed and are illustrated in Figure 2.

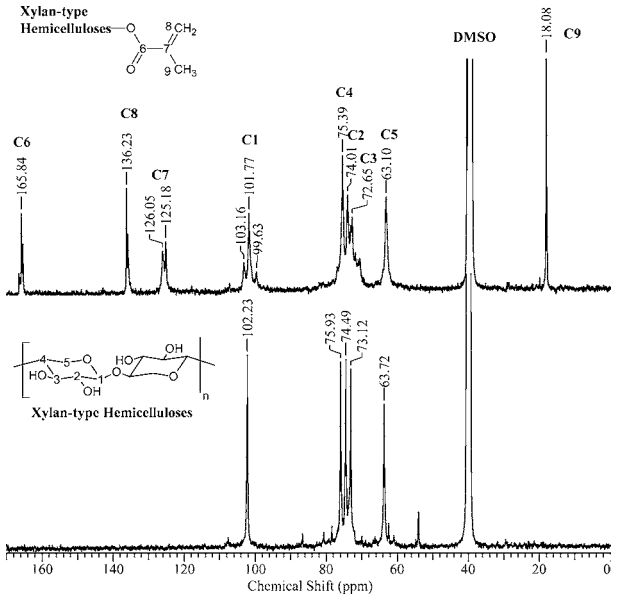

**Figure 2.** $^{13}$C NMR spectra of xylan-type hemicelluloses and HMA.

As seen in the $^{13}$C NMR spectrum of xylan-type hemicelluloses, five strong signals at 101.73, 76.43, 74.27, 68.25, and 63.02 ppm originating from the main 1,4-linked $\beta$-D-xylopyranosyl units can be observed apparently, which are assigned to the C1, C2, C3, C4, and C5 positions of the xylan backbone, respectively. In the $^{13}$C NMR spectrum of HMA, except the signals from xylan backbone, signals from acrylate groups also appear. Chemical shifts at 165.84, 136.23, 126.05 (125.18), and 18.08 ppm originate from C6, C8, C7, and C9 of HMA, respectively. These signals are all assigned and shown in Figure 2. In addition, the signal splitting of C7 (126.05 and 125.18 ppm) and C1 (103.16, 101.77, and 99.63) is likely caused by the substituted position difference of acrylate in the xylan backbone, and a similar phenomenon had been reported in other hemicelluloses derivatives.[34]

**Morphology of Hydrogels.** Figure 3 shows the SEM images of the cross section of the freeze-dried hydrogels with different contents of AOPAB. Honeycomb-like architecture could be observed in H1−H4, while cracklike structure can be found in H5 due to its high crossing density. Furthermore, as the content of AOPAB increased, the observed pore volume decreased significantly. The decrease of hydrogel pore volume was further confirmed by the swelling behavior later. This is likely related to the reactivity ratio of HMA and AOPAB. There are still visible residual C═C groups in the FT-IR spectrum of the hydrogel after reaction at 60 °C for 24 h, suggesting that the poor self-polymerization rate of HMA and AOPAB might be responsible for this phenomenon. It was assumed that the copolymerization between HMA and AOPAB could have led to an increase in cross-linking density and then caused the pore volume decrease.

**Time-Dependent Swelling Behaviors of Hydrogels.** The swelling ability is one of the most important factors of a hydrogel, which is correlated with many of its properties, such as permeability, drug loading, and mechanical characteristics.[35] Therefore, the swelling ability of the prepared hydrogels with different contents of AOPAB in deionized water was measured as a function of time and is illustrated in Figure 4.

The swelling ratios of the dried hydrogels increased at a fast rate during the first 3 h and then achieved a swelling equilibrium about 4 h later. The maximum swelling degrees of these hydrogels (from H1 to H5) were 9.8, 8.4, 6.7, 2.8, and 2.2 g/g in deionized water, respectively, which were in accordance with the pore volume decrease of hydrogels with the increase of AOPAB content, as observed in their SEM images. It indicated that AOPAB content showed a significant effect on the swelling process of the hydrogels. As the dried hydrogels were immersed in water, partial carboxylic groups (−COOH) originating from AOPAB were gradually ionized into carboxylate groups (−COO$^-$). The formation of anion−anion electrostatic repulsion forces within the three-dimensional polymer structure caused the hydrogel network sustained expansion. As the carboxylic group further reached its

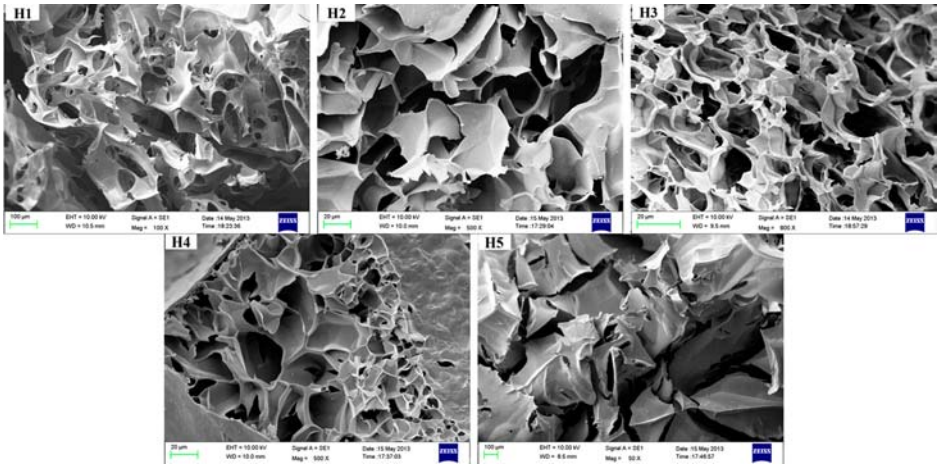

**Figure 3.** SEM images of the cross section of the freeze-dried hydrogels with different contents of AOPAB.

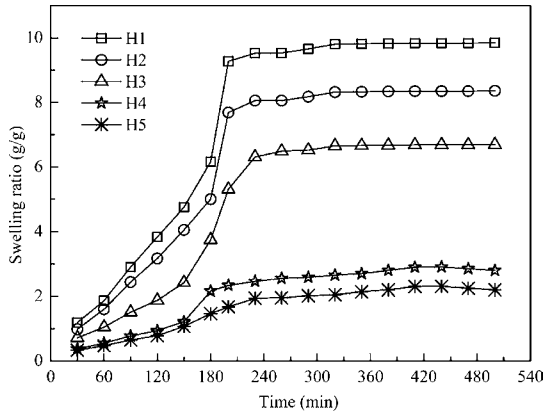

**Figure 4.** Swelling behavior of the hydrogels in water as a function of time.

ionization equilibrium, the swelling of the hydrogel also achieved a maximum.

**pH-Dependent Swelling Behaviors of Hydrogels.** Stimulus-responsive behavior is an important property of a hydrogel. Figure 5 illustrates the equilibrium swelling ratios

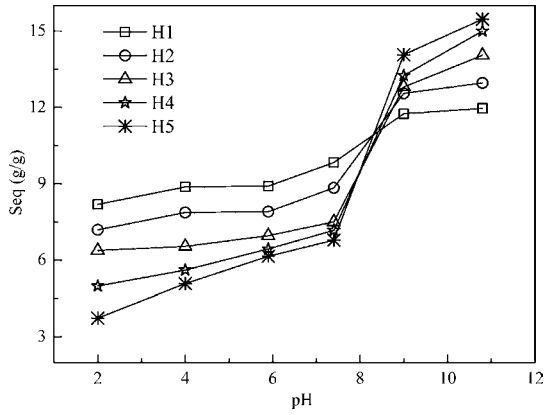

**Figure 5.** Equilibrium swelling ratios of the obtained hydrogels as a function of pH.

($S_{eq}$) of the obtained hydrogels with different amounts of AOPAB in solutions of different pH values. The equilibrium swelling ratio of all hydrogels increased with the pH of the initial solution. It was assumed that as the pH increased from 2.0 to 10.8, more −COOH groups in the hydrogel were ionized into $-COO^-$ groups. The anion−anion electrostatic repulsion forces were strengthened and the hydrogel networks were expanded gradually, thus resulting in the high swelling ratio of the hydrogel at the high pH value.

In the pH range of 2.0 to 7.4, the hydrogels containing a lower content of AOPAB showed higher $S_{eq}$ values. A similar result was found in their water absorption test. However, as compared with $S_{eq}$ in pH 2.0−7.4, the hydrogels showed opposite swelling capacities as the pH increased to 9.0 and 10.8. It was observed that in the solution of pH 9.0 and 10.8, the higher the AOPAB content was, the lower the $S_{eq}$ value was. The $S_{eq}$ value of H5 in pH 10.8 was 4.15 times higher than that in pH 2.0, while this value was only 1.46 for H1. It can be deduced that, at lower pH value, almost all carboxyl groups exist in the COOH form, and the solution absorption capacity mainly depends on the pore volume of the hydrogel. The $S_{eq}$ values are well in line with the pore changes observed in their SEM images. However, most carboxyl groups exist in the $-COO^-$ form in alkaline solution, thus the electrostatic repulsion forces will dominate the solution absorption capacity of the hydrogel. High AOPAB content will lead to high $S_{eq}$ value of hydrogel. Therefore, the hydrogel with a higher content of AOPAB showed a stronger pH responsive behavior.

**Swelling and Deswelling Behaviors of Hydrogel in Buffers.** Reusability is another important factor that is associated with the applications of hydrogel. In this study, the swelling and deswelling behaviors of the hydrogel (H5) in the buffer solutions with pH 2.0 and 7.4 at 37 °C are shown in Figure 6. When the swollen hydrogel in the buffer of pH 7.4

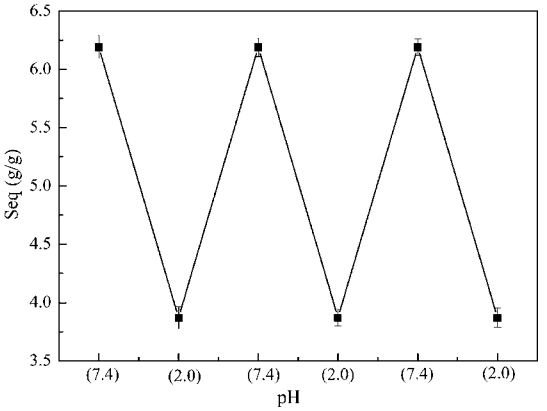

**Figure 6.** Swelling and deswelling ability of the hydrogel (H5) in the buffer solutions of pH 2.0 and 7.4.

was transferred into the solution of pH 2.0, the swelling ratio of H5 decreased from ∼6.2 g/g to ∼3.9 g/g. According to the results from pH-dependent swelling test, the carboxylates ($-COO^-$) would be generally protonated into carboxyl groups with the pH decrease and further resulted in the deswelling of the hydrogel. When the hydrogel was put into the solution of pH 7.4 again, these carboxyl groups would be ionized into $-COO^-$ again and the electrostatic repulsion forces induced the expansion of the hydrogel network and finally led to the reswelling of the hydrogel. After three swelling and deswelling cycles, no obvious decrease in swelling could be observed. A similar result was also reported in other hemicellulose-based poly(acrylic acid) hydrogel.[11]

**Swelling and Deswelling Behaviors of Hydrogel in Water and Ethanol Alternating Solutions.** To investigate the response behavior of the hydrogel in organic solvent and its recycle performance, the swelling and deswelling behaviors of the hydrogel (H1) in distilled water and ethanol alternating solutions are shown in Figure 7. As can be seen, the swollen hydrogel in distilled water rapidly deswelled in ethanol. When the shrunken hydrogel was put into distilled water again, it would expand again within a short period. It was reported that the swelling capacity of the hydrogel in organic solvents was closely related to the solubility parameter of the solvent and dielectric constant as well as the interaction between the polar groups of solvents and the ionic groups in the polymer network.[11,36,37] The Hildebrand solubility parameter and the relative dielectric constant of water and ethanol are 23.4 and 12.9 $cal^{1/2}$ $cm^{-3/2}$, respectively.[38] According to the Hildebrand equation, to dissolve a polymer in a solvent, the solubility parameter values must be close to each other.[37] To our best knowledge, almost all hydrogels with hydrophilic groups

dx.doi.org/10.1021/jf504040s | J. Agric. Food Chem. 2014, 62, 10000−10007

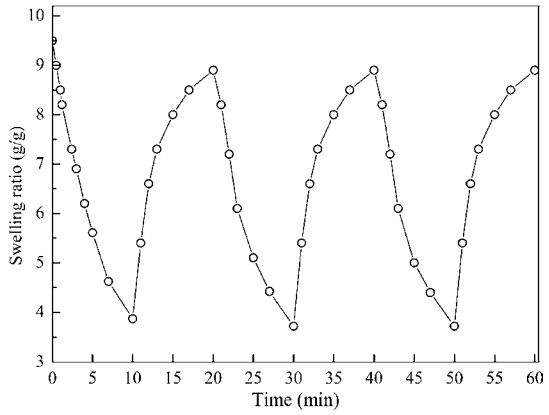

**Figure 7.** Swelling and deswelling behavior of the hydrogel (H1) in water/ethanol alternating solutions.

showed higher swelling ratios in water than in organic solvent,[11,36] suggesting that the solubility parameters of these hydrogels were much closer to that of water. Furthermore, ethanol possesses a much lower dielectric constant than water, which can significantly reduce the electrical double layer thickness and the dissociation abilities of the carboxyl groups.[39] Therefore, the synthesized hydrogel showed much lower swelling ratio in ethanol than in water. In addition, during the swelling and deswelling recycles, the adsorption and desorption process is reversible, which makes the repeated utilization of hydrogels possible.

**Time-Dependent Light Response Behavior of Hydrogel.** To investigate the light responsive behavior of hydrogel, finely ground hydrogel suspended in deionized water after being irradiated with UV light for different periods was subjected to UV/vis spectroscopy. The UV/vis spectra of the hydrogel solutions (H3) after UV irradiation were recorded and are illustrated in Figure 8. It was reported that the maximum

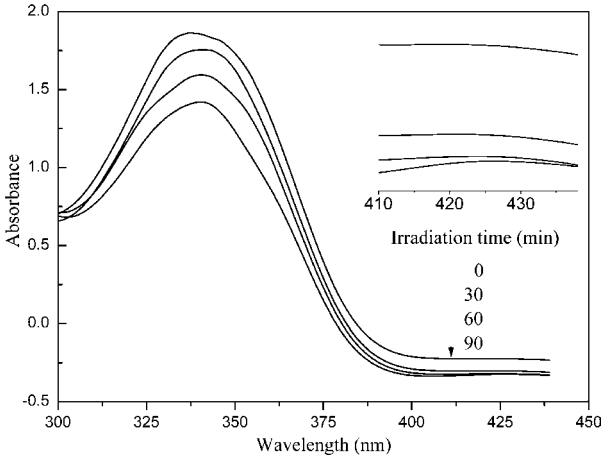

**Figure 8.** UV/vis spectra of the hydrogel (H3) solution after UV irradiation for 0, 30, 60, and 90 min, respectively (from the top down).

absorption peak of *trans*-azobenzene appeared at around 350 nm, which was associated with $\pi-\pi^*$ transition of *trans*-azobenzene, while *cis*-azobenzene showed a maximum absorption band near 440 nm, which was assigned to the $n-\pi^*$ transition of *cis*-azobenzene.[23,27] As seen in Figure 8, the absorption at around 340 nm originating from *trans*-azobenzene ($\pi-\pi^*$ transition) decreased with increasing UV irradiation time, while the absorption band at around 430 nm ($n-\pi^*$ transition of *cis*-azobenzene) appeared with very weak intensity, which can be observed in the top right corner of Figure 8. The signal change suggested the *trans*−*cis* photoisomerization of the azobenzene units in the synthesized hydrogel. Furthermore, a previous report showed that *trans*−*cis* photoisomerization of the azobenzene would change the hydrophilic/hydrophobic balance of material.[40] Therefore, the light response behavior of synthesized hydrogel might have potential in drug delivery application.

**Drug Release Behaviors of Hydrogel.** In order to investigate whether the synthesized hydrogel had special drug release behavior, vitamin $B_{12}$ ($VB_{12}$) was used as a model drug to record its in vitro release behavior at 37 °C. The influences of release medium pH and UV irradiation on the release behaviors of the prepared hydrogel were tested. The cumulative release data were summarized and are plotted in Figure 8. As seen in Figure 8, the initial release of $VB_{12}$ was very fast in the first 2 h, and then the release of $VB_{12}$ slowed down and moved toward release equilibrium. Additionally, pH value of medium and UV irradiation both had obvious effects on the release of $VB_{12}$. Over the releasing process, the cumulative release value of $VB_{12}$ in neutral medium was always higher than that in acidic medium. Without UV irradiation, the final cumulative release rates of the hydrogel in acidic medium and neutral medium were 78.2% and 89.3%, respectively. This is very likely related to the difference in swell ratios of the hydrogel in different mediums. Because the SR value of the hydrogel in neutral medium was much higher than that in acidic medium, the diffuse of drug was much faster.

As previously mentioned, the synthesized hydrogel showed a light response behavior under the UV irradiation. The thermodynamically stable *trans*-conformation of azobenzene structure would convert into the *cis*-conformation under UV irradiation.[23,40] However, as the *cis*-conformation of azobenzene was exposed to visible light or deposited in the dark, it would transfer into the *trans*-conformation again, resulting in a shift of the hydrophilic/hydrophobic balance arising from the *trans*−*cis* isomerization.[40] From Figure 9, it was found that the cumulative release of hydrophilic $VB_{12}$ from the hydrogel under UV irradiation was higher than that without UV irradiation. It can be explained by following reasoning. As the $VB_{12}$ loaded hydrogel was placed into the release medium, due to the

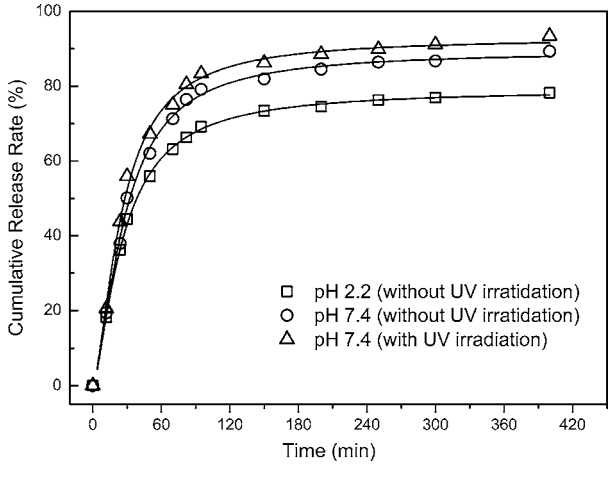

**Figure 9.** Vitamin $B_{12}$ ($VB_{12}$) in vitro cumulative release behavior of the synthesized hydrogel (H3) at 37 °C.

dx.doi.org/10.1021/jf504040s | J. Agric. Food Chem. 2014, 62, 10000−10007

different concentrations of $VB_{12}$ in the hydrogel and the release medium, the $VB_{12}$ started to gradually diffuse toward the release medium accompanied by the expansion of the hydrogel. However, the UV irradiation would change the hydrophilic/hydrophobic balance and make the hydrogel more hydrophobic, which would drive the hydrophilic $VB_{12}$ into the release medium and finally result in a higher cumulative release rate.

To conclude, a novel hemicellulose-based hydrogel with multiresponse behaviors to pH, solvent, and light was prepared by free radical copolymerization of xylan-type hemicellulose glycidyl methacrylate with 4-[(4-acryloyloxyphenyl)azo]-benzoic acid. The swelling ratio of the synthesized hydrogel ranged from 2.2 to 9.8 g/g in distilled water, which decreased generally with the increase of AOPAB content. The swelling capacity was closely associated with the strong electrostatic repulsion among carboxylic groups ($-COO^-$). The stimulus-response behaviors indicated that the hydrogel could be easily controlled by changing solvent pH and solvent type. Furthermore, the prepared hydrogel also showed good swelling and deswelling recycling performance. Results from light response test showed that the *trans*-conformation of azobenzene in hydrogel would generally convert into the *cis*-conformation under UV irradiation. Furthermore, this light response hydrogel was applied as a drug delivery device to monitor its drug release behavior, and results indicated that the hydrogel under UV irradiation showed higher drug cumulative release rate than that without UV irradiation.

subsequent settling or from grape cell walls prior to or during fermentation. Whereas polysaccharides have been shown to contribute to the perceived viscosity of model wine,[2,5] their role in the mouthfeel and taste of white wine, where they have the potential to form complex colloids with other macromolecules and phenolics, is less clear.

A variety of juice extraction and handling options are used in the production of white wines: whole bunch pressing, free run juice, pressing fraction juice, prefermentation skin contact, and juice hyperoxidation. A simultaneous comparison of the effects of these winemaking options on white wine composition and their effect on the broad range of mouthfeel attributes encountered in white wine has not been conducted to date. This study aimed first to investigate the effects of the commonly applied juice extraction and processing methods used in white winemaking on wine phenolic composition and, second, to examine the relationships between phenolic composition and other aspects of the wine matrix, pH, total polysaccharides, glycerol and alcohol concentrations, on the mouthfeel profile of white wine.

## MATERIALS AND METHODS

**Grape Sources and Winemaking.** Handpicked bunches (3 t) of Riesling from Eden Valley, South Australia (harvested February 25, 2010), Viognier from the Adelaide Hills, South Australia (harvested March 11, 2010), and Chardonnay from Lyndoch, South Australia (harvested February 11, 2010) were sourced (hereafter referred to as "grape sources"). Potassium metabisulfite was added at picking at 50 mg/L on the basis of an estimated yield of 700 L/t. The grapes were transported for a maximum of 2 h in 0.5 t bins before being chilled overnight. The grapes were subsequently destemmed and crushed using a Diemme 4t/h destemmer-crusher. An amount of 1.75 t of the resultant must from each grape source was pressed by a 2.5 t capacity Willmes membrane press (Willmes "Merlin", 1 t whole bunch and 2.5 t crushed capacity) to yield three fractions: free run juice (FR) at <0.5 bar pressure, light pressings (LP) at 0.5−1.0 bar, and hard pressings (HP) at 1.0−2.0 bar.

A portion of the FR juice was extensively hyperoxidized (HOX) by sparging with 100% oxygen at 8−10 L/min until reaching 40 mg/L free dissolved oxygen (Nomasense PSt3, Nomacorc LLC, Zebulon, NC, USA). Skin-contacted (SC) treatments were produced by blending free run and press fractions obtained from must held in press for 60 h at 5 °C and pressed as described above. Whole bunch pressed juice (WB) was also obtained by pressing 0.5 t of whole bunches at 1.0−2.0 bar.

The juices were cold settled with the aid of pectolytic enzymes (Novozyme, Vinoclear Classic, Dittingen, Switzerland) for 24−48 h and acid adjusted using tartaric acid. Duplicate 30 L fermentation vessels were filled with each juice and inoculated with *Saccharomyces cereviseae* strain EC1118. The ferments proceeded at 0.5−1.0 Baumé per day until dryness. Thereafter, 60 mg/L $SO_2$ was added, and the wines were cold stabilized by seeding with 4 g/L potassium bitartrate at 4 °C. Protein stability was achieved by adding 1 g/L sodium bentonite to the juice prior to fermentation and by adding additional sodium bentonite after cold stabilization at a rate determined by the 80 °C/2 h test.[14] The stabilized wines were sparged with nitrogen and argon to attain a dissolved oxygen level of <0.6 mg/L, bottled in 375 mL antique green bottles under Sarin-tin screw caps, and stored at 15 °C prior to analysis and sensory assessment.

**Sensory Assessment of Mouthfeel and Taste.** Eleven tasters (five males and six females) were used. All but one had experience in profiling the mouthfeel and tastes in white wine. Taster training was conducted over five sessions to generate and define mouthfeel and taste attributes appropriate to the wines and to identify attribute redundancies. Tasters were trained using a subset of the wines used in the study and a high-phenolic white wine made by fermenting juice in the presence of skins. The attribute descriptions agreed upon to represent the tastes and mouthfeel characteristics of the training wines were 'astringency (drying)', drying or mouth puckering; 'viscosity', body, weight, or thickness; 'hotness', warmth perceived after expectorating; 'acidity', sourness/tartness while in the mouth; 'sweet', sweetness while in the mouth; 'bitter', bitterness in the mouth. Bitterness and acidity after expectorating were also selected by the panel as relevant descriptors, but were subsequently found to correlate strongly with in-mouth sensations so they were deemed redundant.

Standards for 'astringency (drying)' (0.5 g/L aluminum potassium sulfate, Ajax Finechem, Sydney, NSW, Australia), 'viscosity' (3 g/L carboxymethyl cellulose, sodium salt, Sigma-Aldrich, St. Louis, MO, USA), "bitter" (15 mg/L quinine sulfate, Sigma-Aldrich), 'hotness' (20% v/v ethanol, Tarac Industries, Nuriootpa, SA, Australia), and 'acidity' (2 g/L tartaric acid, Ajax Finechem, Sydney, Australia) in water were also presented for discussion during training. The tasters were familiarized with the use of the unstructured line scale used in the formal assessment by rating six of the experimental wines in duplicate on the chosen attributes. The line scale was 15 cm long with "low" and "high" anchor points placed at 1.5 and 13.5 cm along the scale.

The perceived intensity of the taste and mouthfeel attributes of all wines (3 grape sources × 6 treatments × 2 fermentation replicates) were assessed in triplicate using the line scale used in training. Twenty wines were tasted per day over six sessions that extended over 14 days. Thirty milliliters of wine was tasted from clear ISO tasting glasses under natural lighting and at room temperature (22 ± 1 °C). The tasters were forced to rest for 1 min between wines and for 10 min after every fourth wine. Sensory assessment was conducted 1 month after bottling. Basic wine analysis was conducted at the time of bottling, and polysaccharide concentration and phenolic profiles were evaluated 4 months after bottling.

**Wine Analysis.** *Phenolics.* Total phenolics (TP) and total hydroxycinnamates (HCA) were determined on the basis of absorbance at 280 and 320 nm.[15] Absorbance at 370 nm ($A_{370}$) was also measured to assess the concentration of flavonol compounds. As the variation in TP, HCA, and $A_{370}$ between replicate ferments was low (CV < 2.5%), one fermentation replicate from each of the three grape sources was further analyzed for phenolic composition by HPLC with an Agilent 1100 chromatography system under the following conditions. Tandem (2×) Phenomenex Gemini C6-Phenyl columns (2.1 mm × 150 mm, 3 μm) were used with 20 μL injections of wine at 45 °C. Gradient composition and flow rates were as follows: 2% formic acid in water (v/v, solvent A) and 2% formic acid in methanol (v/v, solvent B); 0.5% B from 0 to 5 min, to 20% B from 5 to 70 min, to 98% B from 70 to 110 min (0−110 min, 0.16 mL/min), 98% B from 110 to 115 min (0.13 mL/min), and 0.5% B from 110 to 120 min (0.16 mL/min).

The phenolic compounds from a mixture of wines from the three grape sources were identified using HPLC-ESI-QTOF. Identification was made on the basis of accurate masses (mass difference <5 mDa) and isotope ratios (mSigma <20) of the respective $[M - H]^-$ ions to the assigned elemental composition as well as their MS/MS and UV spectra. The identities of some phenolic compounds were confirmed by comparison with the MS/MS and UV spectra of corresponding reference compounds (Supportying Information). For quanitification, benzoic acids and flavanols were expressed in gallic acid equivalents, hydroxycinnamates and GRP as ferulic acid equivalents, and flavones and flavanonols as quercetin-3-glucoside equivalents.

*Polysaccharides and Glycerol.* For polysaccharide determination, 240 mL of wine was reduced to 60 mL under vacuum at 30 °C (in triplicate) and 180 mL of ethanol added (96% v/v, Tarac Industries, Nuriootpa, SA, Australia). The precipitate was removed by centrifugation and washed twice with ethanol, dissolved in Milli-Q water, and extensively dialyzed at 23 °C against Milli-Q water for 36 h (3.5 kDa MW cutoff tubing, Thermo Scientific, Rockford, IL, USA) before being freeze-dried and weighed. Size exclusion chromatography (Phenomenex BioSep-SEC-S 2000, 300 × 7.8 mm, 40 μL injection, 40 °C, 0.1 M $NaNO_3$ as mobile phase, 1 mL/min. RI and UV−vis detection at 280 nm. MW estimated using Pullulan standards 100, 48, 23.7, and 12.2 kDa, Showa Denko, Japan) was used to confirm the

absence of low molecular weight carbohydrates and low molecular weight phenolic compounds in the lyophilized material. Glycerol concentration was determined by HPLC as previously described.[16]

**Statistical Analysis.** *Wine Composition.* The effects of juice extraction and handling methods (hereafter referred to as winemaking) on the concentrations of total polysaccharides, glycerol, TP, HCA, and $A_{370}$ were analyzed by ANOVA with winemaking as factors with fermentation replicates nested within them. Winemaking was considered fixed and fermentation replicates, random factors. Concentrations of phenolic classes, benzoic acids, tyrosol and resveratrols, hydroxycinnamic acids, GRP, flavanols, flavonols, flavononols, and flavanones, were analyzed by ANOVA with replications provided by grape sources.

*Sensory Attribute Ratings.* Taster ratings were analyzed by ANOVA with winemaking and assessors as factors, with fermentation replicates nested within winemaking treatments. Assessors and fermentation replicates were treated as random factors and winemaking as fixed factors.

*Relationships between Wine Composition and Sensory Ratings.* Mean sensory intensities were modeled on wine pH, titratable acidity, ethanol, total polysaccharides, glycerol, and glucose and fructose concentrations, on the concentrations of major phenolic classes, and on TP, HCA, and $A_{370}$ using orthogonal scores partial least-squares regression (PLS).

ANOVA were conducted using MINITAB 14 (Minitab Inc., State College, PA, USA). PLS regression analysis was conducted using Unscrambler 10.2 (CAMO Software AS, Oslo, Norway).

## RESULTS AND DISCUSSION

**Winemaking.** The experimental winemaking protocol produced wines with analytical parameters generally expected of white wine (Table 1). Although juices from press fractions are more likely to be selected for hyperoxidization in commercial practice than free run juices, the inclusion of a hyperoxidized free run treatment was produced in this study with the intention of producing wines with phenolic concentrations at the lower end that may be found in commercial practice. Conversely, the extended period of skin contact (60 h at 5 °C) was applied to produce phenolic concentrations typical of high-phenolic white wines. It should also be noted that as the juices were pH adjusted by tartaric acid addition, the differences in pH and TA among wines given in Table 1 and the perceived acidity and sweetness of the wines do not necessarily reflect the effect of the winemaking treatments applied.

**Phenolic Composition.** The free run (FR) treatment represents a logical "control" treatment because on a volume basis it is the most widely used method of white wine production. Juice extraction and handling significantly affected TP, HCA, and $A_{370}$ ($p < 0.05$) as well as benzoic acid, hydroxycinnamic acid, flavanol, flavanonol, flavonol, flavanone, and phenol concentrations ($P < 0.1$) (Figures 1 and 2).

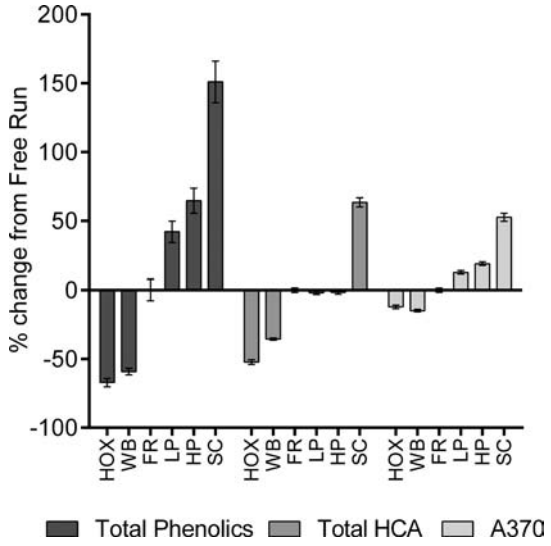

**Figure 1.** Difference in total phenolics, total hydroxycinnamates, and $A_{370}$ of wines as a percentage of wines made from free run juice. HOX, hyperoxidised free run; WB, whole bunch press; FR, free run; LP, light pressings; HP, hard pressings; SC, 60 h skin contact prefermentation. Error bars represent 2 standard errors.

The whole bunch pressed (WB) wines contained significantly lower TP than the free run wines (Figure 1), which resulted from lower concentrations of benzoic acids, hydroxycinnamic acids (Figure 2A), and flavanols (Figure 2B). Lower concentrations of flavanols were expected in the whole bunch pressed wines as the process results in less disruption to the berry than do crushing and draining. The lower HCA in the whole bunch pressed wines may be explained by less contact with the two possible sources of HCA, grape pulp solids and skins.[17]

The hard pressing (HP) wines in this study did not differ in their concentrations of either HCA or their oxidative products (GRP) (Figure 2A) compared with the free run wines, which suggests either that they were not released from the skins during pressing or that they were subsequently removed possibly via fining type actions of other macromolecules released during pressing or following other condensation reactions during fermentation.

Hyperoxidation of free run juice (HOX) resulted in significantly lower TP and HCA compared to the free run control[1] (Figure 1). The reduction in TP resulted from significantly reduced concentrations of hydroxycinnamic acids, flavanols, and flavanonols (Figure 2). The higher concentration of GRP (albeit not statistically significant) in the hyperoxidized wines relative to the free run wines suggests that some caftaric

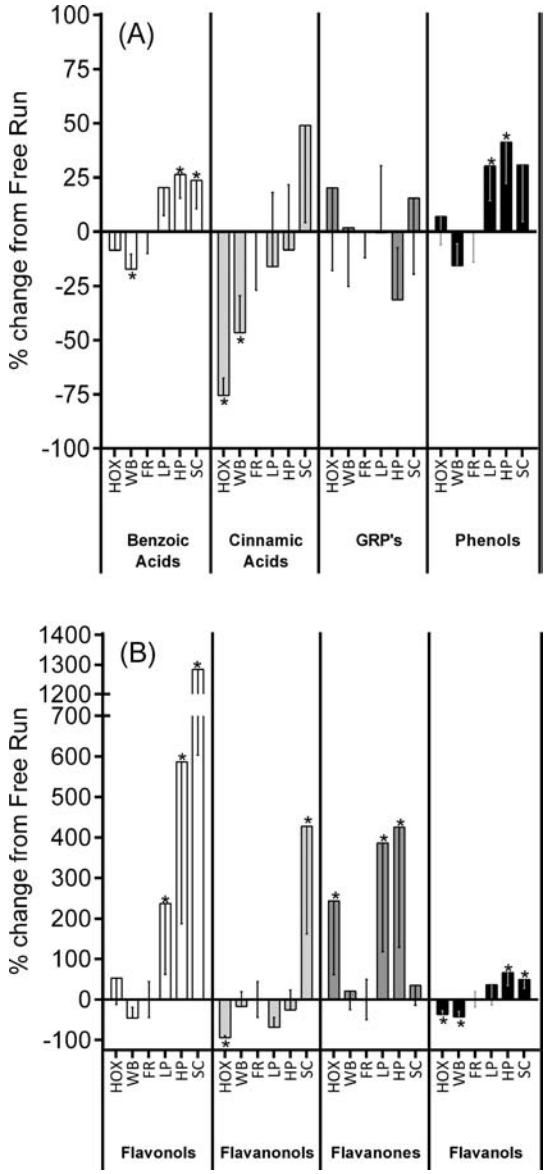

**Figure 2.** Difference in concentrations of major phenolic classes as a percentage of those in the corresponding free run wines: (A) nonflavonoids; (B) flavonoids. Error bars represent 2 standard errors. ∗ indicates significant difference from free run control.

acid was converted to GRP. Similarly, the significantly lower concentrations of flavanols in the hyperoxidized wines compared with the free run wines may be attributed to polyphenol oxidase catalyzed oxidation.[18] Reduced flavanonol concentration resulting from hyperoxidation has not previously been reported. However, given that flavanonols and flavanols both contain catechol 3′,4′-dihydroxyl electron-donating groups, their reduction may attributable to the same oxidative mechanism. The hyperoxidation regimen used in this study could be considered to be extreme in that the juice was extensively saturated using pure oxygen. Whether flavanonol concentration is similarly affected when a more commercially representative oxygenation regimen is applied is yet to be tested.

The wines made from pressings (LP and HP) and skin-contacted juice (SC) were higher in TP than those made from free run juices (Figure 1). The pressing and skin contact treatments were similar in that they both involved some form of interaction between juice and skins, and therefore both would be expected to result in greater extraction of phenolics from the skins.[19,20] However, the wines made from the juices produced from pressing skins and those made by skin contact had significantly different phenolic profiles (Figure 2). Specifically, extensive prefermentation skin contact resulted in wines with significantly higher flavanonol concentrations than the free run wines, but the light and hard pressing wines did not differ in this regard, whereas the pressing wines contained significantly higher concentrations of flavanones than did either the free run or skin contacted wines. The different phenolic profiles between the pressings and skin contact wines suggest that mechanisms other than simple extraction were involved during skin contact and pressing. The skin contact juices were in contact with skins for a substantially longer period than those of pressings juices, which may have favored enzymatically catalyzed oxidative processes such as the C-4 hydroxylation and dehydrogenation of flavanols into flavanonols.[21] The lower proportional increase in flavanones in the skin-contacted wines compared with that of the pressing wines is worthy of further investigation given that these compounds are known to be the primary contributors of bitterness in other foods and beverages.[22] In citrus, flavanones are enzymatically biotransformed to flavanonols via flavonol intermediates.[23] The concomitant lower concentrations of flavanones and higher concentrations of flavanonols and flavonols observed in the skin-contacted wines compared with the pressing wines may suggest that extensive skin contact could similarly involve enzymatic transformation of flavanones into flavononols. Keeping juice in contact with skins prior to fermentation has been shown to increase total hydroxycinnamates when done under conditions similar to those of this study, that is, at low temperature and under the action of pectolytic enzymes.[24,25] However, the contrasting effect of skin contact and pressing with respect to wine HCA concentration is worthy of further investigation.

The tyrosol concentration was higher in the pressings and wines than the free run wines. This was most likely the result of greater extraction of tyrosine from the skins, which is metabolized by yeast during primary fermentation to produce tyrosol.[26]

**Glycerol and Polysaccharide Concentration.** Wines made from pressings and skin-contacted juice had significantly higher ($p$ = 0.003) glycerol concentrations that those made from whole bunch pressed or free run juice (Table 1). However, the range in mean glycerol concentrations among treatments was <10% of the range of glycerol concentrations that have been reported in surveys of commercial dry white wines.[12,27] The small practical differences in glycerol concentration between wines from juices obtained from different juice extraction methods are expected as it is known that glycerol production depends primarily on yeast strain and fermentation conditions,[28] which were the same across all winemaking treatments.

The total polysaccharide concentrations of wine made primarily from juice deriving mostly from the grape pulp (whole bunch pressed, free run, and hyperoxidized free run) were similar. Skin-contacted wines were significantly higher in total polysaccharides, possibly due to skin-bound pectins being released during maceration, adding to the polysaccharides already present in the juice (Table 1). Wines made from hard pressings contained significantly lower polysaccharide concentrations than the other treatments, which suggest that

polysaccharides may form condensation products with phenolics under the action of hard pressing.

**Mouthfeel and Taste Effects of Juice Extraction and Relationships to Wine Composition.** The mean sensory attribute intensity ratings with treatments ordered from lowest to highest mean TP are given in Figure 3. 'Astringency (drying)' generally decreased with increasing TP. Under the classical protein−phenolic binding model of astringency, wines with higher phenolics should be more, rather than less, astringent. However, it may be that the monomeric phenolics in white wine may not have a sufficient number of hydrogen bonding sites that are required to extensively cross-link salivary proteins with phenolics and therefore elicit astringency. Analogously, chlorogenic acid, which is structurally similar to and contains the same number of hydrogen bonding sites as caftaric acid, was also found not to elicit astringency in model studies.[29] Organic acids are capable of producing drying astringent-like sensations in their own right with pH being a greater influence than titratable acidity.[30] The acidity parameters of pH and titratable acidity were very strongly correlated with 'astringency (drying)', with lower pH ($r$ = −0.87, $p$ < 0.001) and higher TA ($r$ = 0.53, $p$ < 0.001) wines being more 'astringent (drying)'. These correlations and PLS results (Figure 4) strongly suggest that the astringent (drying) sensation perceived in these wines resulted from acidity rather than phenolic concentration. Adding white wine phenolics to a white wine of pH 3.3 increased its astringency, but the same addition of phenolics did not increase the astringency of the same wine that had been previously been adjusted to pH 3.0.[31] However, consistent with the results of this study, lower pH wines were generally perceived to be more astringent than higher pH wines regardless of their phenolic content.[31]

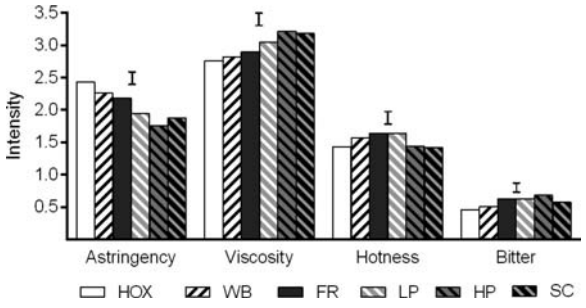

**Figure 3.** Mean ratings of mouthfeel and taste attribute ratings by juice extraction and handling treatment. Bars represent LSD 5%.

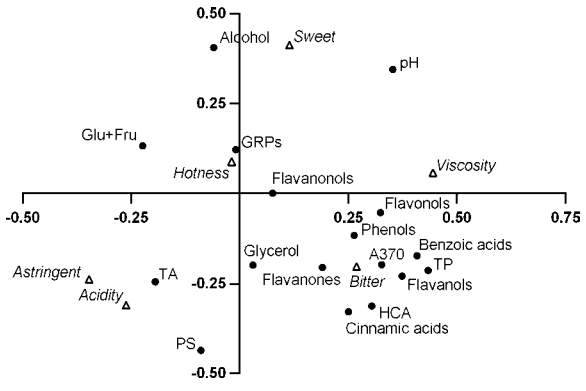

**Figure 4.** Partial least-squares regression correlation loadings of sensory attributes and total phenolics (TP), total hydroxycinnamates (HCA), $A_{370}$, total polysaccharides (PS), glucose and fructose (Glu +Fru), titratable acidity (TA), phenolic classes, pH, ethanol and glycerol concentrations.

Astringency can be modulated by viscosity,[32] which could explain why the wines perceived as more viscous were rated as less astringent (Figure 3). However, as perceived viscosity was positively correlated with total phenolic concentration, which under the classic protein−phenolic precipitation model would be expected to increase astringency, it is likely that variations in astringency/drying in these wines were due to factors other than total phenolic concentration.

Perceived viscosity was positively associated with TP, $A_{370}$, and pH ($p$ < 0.001, Table 2). PLS analysis also suggests that both pH and phenolics contribute to perceived viscosity (Figure 4). Oral perception of viscosity has previously been attributed to pH-induced changes in oral surface rheology.[33] Adding whole phenolics from white wine has also recently been shown to increase the perceived viscosity of white wine.[31] Perceived viscosity was most strongly correlated with benzoic acid ethyl ester ($r$ = 0.48, $p$ = 0.032), cinnamic acid ethyl ester ($r$ = 0.57, $p$ = 0.009), and flavonol ethyl ester ($r$ = 0.42, $p$ = 0.063) concentrations. Phenolic acid ethyl esters are formed during the course of alcoholic fermentation and are ubiquitous in alcohol beverages including wine,[34] but as both their formation through esterification and degradation by hydrolysis are pH dependent, their role in perceived viscosity remains speculative.

Despite the potential for glycerol and polysaccharides to increase the perceived viscosity by increasing physical viscosity,[13,35] neither glycerol nor polysaccharide concentrations were positively associated with perceived viscosity in these wines (Table 2; Figure 4). Whereas this may have been due to the small relative differences in glycerol and polysaccharide concentrations among treatments (Table 1), various studies have suggested that perceived viscosity in white wine or model wine is either unaffected or nominally affected by glycerol or polysaccharide concentrations within those typical of dry white wines[2,4,13,36]

'Hotness' was not significantly associated with any compositional variable, including ethanol concentration (Table 2). In other studies, adding either ethanol,[3] or phenolics[31] derived from white wines made white wine perceptively hotter. The lack of a correlation between 'hotness' and ethanol concentration may have resulted either from the narrow range of ethanol concentration among samples or by suppression by other wine components.

Juice extraction and handling had a significant effect on bitterness ($p$ = 0.013; Figure 3), with bitterness increasing with total phenolic concentration ($r$ = 0.460, $p$ = 0.034; Table 2). PLS analysis also suggested that phenolics contributed to bitterness in these wines (Figure 4). Bitterness was strongly associated with flavanol concentration ($r$ = 0.722, $p$ < 0.001). Flavanols have been shown to elicit bitterness,[37] and their role in bitterness perception has recently been confirmed following the discovery that they activate known bitter receptors on the tongue.[38] Benzoic acids and their derivatives were also positively associated with bitterness ($r$ = 0.417, $p$ = 0.034), which has been observed in red wines.[39] Flavanone concentrations were related to greater bitterness ($r$ = 0.470, $p$ = 0.018), which is consistent with findings related to other foodstuffs.[23] However, as flavanone concentration was strongly correlated with flavanol concentration ($r$ = 0.730, $p$ < 0.001),

Table 2. Correlations between Wine Composition and Mouthfeel and Taste Attributes[a]

| | Glu+Fru | pH | TA | ethanol | glycerol | PS | TP | HCA | $A_{370}$ |
|---|---|---|---|---|---|---|---|---|---|
| astringency(drying) | 0.29 | −0.87*** | 0.53*** | −0.21 | 0.16 | 0.39* | −0.39* | −0.09 | −0.15 |
| viscosity | −0.20 | 0.70*** | −0.34* | −0.02 | 0.02 | −0.34* | 0.55*** | 0.32* | 0.53*** |
| hotness | −0.07 | −0.03 | −0.07 | 0.25 | 0.24 | −0.14 | −0.11 | −0.06 | −0.02 |
| acidity | 0.25 | −0.74*** | 0.59*** | −0.10 | 0.23 | 0.39* | −0.27 | −0.06 | −0.13 |

| sweet | 0.02 | 0.73*** | −0.62*** | 0.39* | −0.29 | −0.53** | −0.03 | −0.24 | −0.12 |

[a]*, **, and *** indicate significance at $p < 0.05$, 0.01, and 0.001, respectively.

the interpretation that flavanones contribute to bitterness remains speculative. Hydroxycinnammic acids in white wine did not influence bitterness perception even when added to concentrations well above that found in white wines,[40] which is inconsistent with the positive association ($r = 0.417$, $p = 0.034$) between summed concentrations of hydroxycinnamic acids and their derivatives and bitterness observed in this study. One possible reason is that the previous studies assessed the effect of individual hydroxycinnamics, whereas in this study bitterness was equated to the summed presence of free hydroxycinnamic acids and their tartaric acid and ethyl esters.

Prefermentation skin contact resulted in wines with significantly higher TP than the pressing wines, but they tended to be less bitter. This may have been the result of different phenolic profiles (Figure 2) as some phenolic classes may elicit more bitterness than others.[41] Alternatively, the lower bitterness in the skin-contacted wines may be the result of masking by acidity or polysaccharides (Table 1).

Sweetness perception and glucose and fructose concentraiond were unrelated, which could be due to the narrow range of concentrations (0.2−1.0 g/L) and masking by acidity ($r$ sweetness with TA = −0.62, $p < 0.001$). Whereas polysaccharide concentration was negatively associated with sweetness (Table 2; Figure 4), a direct effect cannot be attributed as polysaccharide concentration was correlated with pH ($r = 0.67$, $p < 0.001$). However, there is a potential for polysaccharides to act as sweetness antagonists as their extensive and complex structures provide the possibility that they have glycophores of size and shape similar to those of small molecular weight sweet compounds in white wine.

In conclusion, different methods of juice extraction and handling techniques resulted in significant differences in overall phenolic content and phenolic profiles, but only small differences in glycerol and polysaccharide concentrations. White wine bitterness was nominally affected by overall phenolic concentration and by the relative concentrations of phenolic compounds present. The perception of palate astringency or drying sensation could best be accounted for by pH differences rather than phenolics and, therefore, could be influenced by winemaking methods used to modify acidity. pH in combination with phenolic content influenced perceived viscosity, with higher pH and more phenolic wines having more apparent viscosity, which is an important attribute when fuller bodied styles of white wine are required.

wine oxidation and ultimately determining the specific aldehyde production rate of a given wine is therefore large. The list includes transition metals catalyzing the formation of quinones,[34−36] amino acids, alcohols, α-dicarbonyls, wine polyphenols,[32,37,38] and sulfur dioxide, known to act as antioxidant[39−41] and as a carbonyl binder.[42]

Reduction problems are associated with the accumulation of volatile sulfur compounds (VSCs),[43−45] particularly $H_2S$ and methanethiol (MeSH),[14] during bottle aging in conditions of minimum oxygen ingress through the bottle closure.[13,16,46−48] It is believed that the major source of VSCs in wine is yeast metabolism. The formation of small amounts of $H_2S$ are inherent to fermentation[49] and related to multiple factors.[50−52] The formation of MeSH and EtSH has been related to yeast catabolism of methionine and cysteine,[53] although it could be also related to amino acid synthesis.[54] The levels of these compounds are controlled by some treatments such as copper finning, aeration, and/or addition of lees.[9,55] The reasons why these molecules accumulate during bottle aging, more often in those wines suffering of high VSCs levels during fermentation, are not clearly known,[9] although several hypotheses such as the hydrolysis of thioacetates,[56] the reduction of disulfides,[57] the reaction between cysteine and wine α-dicarbonyls,[33] the transition-metal-catalyzed reduction of sulfate or sulfite,[58] or the hydrolysis of thioacetals[36] were formulated long time ago. The potential role of transition metal ions in amino acid transamination, racemization, and desulfhydration is well-documented in the classical chemistry literature,[59−61] but only a recent report has shown that wines spiked with transition metals can accumulate during storage in oxygen-free containers with higher levels of $H_2S$ and MeSH.[55] Therefore, the list of compounds potentially determining the wine tendency to form VSCs during wine bottle aging includes again transition metals, α-dicarbonyls, disulfides and thioacetates, sulfite and sulfate, and sulfur-containing amino acids.

The major aim of the present work is to search for relationships between some key chemical compositional parameters of the wines and the rates of production or depletion of oxidation- and reduction-related compounds along with bottling storage under different oxidation regimes.

## MATERIALS AND METHODS

**Wines, Reagents, Standards, and Materials.** *Wines.* Sixteen different commercial Spanish red wines from six different Spanish denominations of origin were used in the present study, as detailed in Table 1.

*Solvents.* Dichloromethane, methanol, pentane, hexane, and diethyl ether (gas chromatography quality) were purchased from Merck (Darmstadt, Germany). Ethanol was from Panreac (Barcelona, Spain). Water with resistance of 18.2 MΩ·cm at 25 °C was purified in a Milli-Q system from Millipore (Bedford, Germany).

*SPE Cartridge Materials.* LiChrolut EN resins (styrene/divinylbenzene copolymer) and 1 mL internal volume polypropylene cartridges were supplied by Merck. Carboxen-polydimethylsiloxane (CAR-PDMS) fibers were supplied by Supelco (Bellefonte, PA, U.S.A.). Semiautomated solid-phase extraction was carried out with a VAC ELUT 20 station system from Varian (Wallnut Creek, CA, U.S.A.) and automated solid-phase extraction was carried out with a GX-274 Liquid Handler from Gilson (Middleton, WI, U.S.A.).

*Chemical Standards.* The chemical standards used for the analytical characterization of wines were supplied by Merck (Darmstadt, Germany), Panreac (Barcelona, Spain), Lancaster (Eastgate, U.K.), Scharlau (Barcelona, Spain), SAFC (Steinheim, Germany), Aldrich (Madrid, Spain), Fluka (Madrid, Spain), ChemService (West Chester, PA, U.S.A.) and Oxford Chemicals (Hartlepool, U.K.). Purity of chemical standards is over 95% in all cases, and most of them are over 99%. Specific details can be obtained from method references.[15,62−73]

**Storage of Wine Samples under Different Oxygen Regimes.** The original wine bottles were opened inside a glovebox from Jacomex (Dagneux, France) in which oxygen was under 0.002%. The content of four bottles was mixed in a big beaker and stirred until the oxygen level in the wine dropped to 0.00 mg/L (in general, initial oxygen content for the recently opened bottle was under 0.01 mg $L^{-1}$), as measured with a fluorescence oxygen meter OptiOx SG-9 from Mettler Toledo (Barcelona, Spain). Then, 17 different samples of each wine (140 mL of wine with 8 mL of Argon headspace) were prepared in airtight amber vials (Aldrich Sure-Seal bottles) supplied by Sigma-Aldrich (Madrid, Spain). The vials were closed with an internal silicone septum, a strong crimp cap and an external screw cap. The internal septum of the bottles was intentionally pierced to different extents (in three bottles 0 times and in two 1, 2, 3, 4, 5, 6, and 8 times) in order to provoke different oxygen penetration rates. Vials were further sealed into plastic bags with known oxygen permeability (<9 cc/$m^2$ 24 h) supplied by Amcor (Barcelona, Spain). The efficiency of this procedure was assessed in preliminary trials in which solutions of 12% ethanol (v/v) in water were stored for 2 months, and the oxygen level was determined by measuring the dissolved oxygen as previously explained. The 272 vials (16 wines × 17 samples/wine) so prepared were stored at 25 °C in the dark for 6 months in an incubator Climas GROW 360 (Climas, Barcelona, Spain). In all cases, we were able to produce the same wine with quite different levels of oxidation after 6 months of storage. The total amount of oxygen taken by the samples was indirectly measured through the change in absorbance at 420 nm (from 2 to 60 mg $O_2$/L).

The relationship between absorbance at 420 nm and oxygen consumption was assessed in an independent experiment in which the wines were poured into a 60 mL screw-capped clear glass tubes containing PreSense Pst3 oxygen sensors from Presense (Regensburg, Germany). The wines were then saturated with atmospheric air until the measurement of dissolved oxygen reached 6 mg/L. Oxygen level was monitored with the Nomasense oxygen analyzer from Nomacorc S.A. (Aubel, Belgium). Wines were stored in the dark at 25 °C until the wine dissolved oxygen content dropped below 1 mg/L. Then the wine was saturated again with oxygen and the process was repeated along five saturation cycles. After each cycle, the wine absorbance at 420 nm was measured.

**Analytical Characterization of the 16 Original Samples and of the 17 Specimens Produced Per Wine Sample.** An extensive analytical characterization of the 16 original samples was carried out including basic enological chemical parameters, metallic elements, chemical astringency, amino acids, volatile carbonyls, VSCs, sotolon, general aroma composition, low molecular weight polyphenols, and polymeric pigments, as detailed below. In these samples, 2 (3 in the case of VSCs) analytical replicates were carried out per sample. In addition, absorbance at 420 nm, free and total $SO_2$, amino acids, volatile carbonyls, VSCs, and the general aroma composition were also analyzed in the 272 specimens derived from the 16 samples after the 6 months of storage. In these cases, a single analytical replicate was carried out in the analysis.

*Conventional Enological Parameters.* Conventional enological parameters of wines were determined in accordance with official OIV practices.[62] Total polyphenol index (TPI) was estimated as absorbance at 280 nm.[63] For all absorbance measurements the UV−vis spectrophotometer UV-17000 Pharma Spec from Shimadzu (Duisburg, Germany) was used.

*Determination of Free and Total Sulfur Dioxide.* Free and total sulfur dioxide was determined following the Rippert methodology (iodometry using starch as indicator). Wine, 15 mL, was titrated with $I_2$ 0.02 N until a bluish-violet tonality appeared. These procedures are described in ref 62. Combined sulfur dioxide levels have been calculated as the difference between total and free $SO_2$.

*Quantitative Analysis of Metallic Elements.* Microwave-assisted digestion in a closed vessel was used to mineralize wine samples. Samples were further analyzed by inductively coupled plasma optical emission spectrometry (ICP-OES), as described by Gonzalvez et al.[64] The elements analyzed are given in Table 2.

**Table 2. Ranges and Mean Concentrations in the Initial 16 Spanish Red Wines of Amino Acids and Alcohols Potentially Precursors for Oxidation Aldehydes and Some Trace Mineral Elements with Potential Catalytic Activity upon the Oxidation Processes**

| parameter | concentration range (mg/L) | average (mg/L) | median (mg/L) | SD |
|---|---|---|---|---|
| amino acid precursors | | | | |
| threonine | 27.3−390 | 146 | 108 | 97.7 |

*Chemical Astringency Determination.* The analysis was carried out by the method published by Llaudy et al.[65] using ovoalbumin as the precipitation agent and tannic acid solutions as standards.

*Quantitative Analysis of Amino Acids.* A precolumn derivatization procedure with aminoquinolyl-*N*-hydrosysuccinimidyl carbamate (AQC) for the determination of amino acids levels in wines using a quaternary high-performance liquid chromatography (HPLC) eluent system was followed as it is described in ref 66.

*Quantitative Analysis of Carbonyl Compounds.* Carbonyl compounds were extracted following an automated (GX-274 Liquid Handler from Gilson −Middleton WI, U.S.A.) solid-phase extraction (SPE) method and analyzed in a gas chromatography−mass spectrometry (GC-MS) system with negative chemical ionization (NCI), using a variation of the method described in the literature.[67] This method is based on the derivatization with *O*-(2,3,4,5,6-pentafluorobencyl)-hydroxylamine hydrochloride (PFBHA). Derivatives are formed in the SPE cartridge in which the analytes have been previously isolated. In our case, cartridges had 100 mg of LiChrolut EN resins, which implies that only half of wine, reagents, cleaning solvents, and derivatizating agent aqueous solution were necessary. Before the derivatization process, 20 μL of 5-chloro-2-pentanone 10 mg/L standard solution in ethanol, prepared daily, were loaded onto the wine. Derivatization reagent aqueous solution (5 mg/mL PFBHA) was prepared daily also. Derivatization was carried out at room temperature for 15 min. Derivatized analytes were eluted with 1 mL of 10% diethyl ether (v/v) in hexane and finally 30 μL of 2,3,6-trichloroanisole 17.5 mg/L were added as internal standard.

*Quantitative Analysis of Volatile Sulfur Compounds.* The quantitative determination of wine sulfur compounds is described in the method proposed by Lopez et al.[68] The method dilutes the sample in brine, and the sample headspace is preconcentrated with automated headspace solid-phase microextraction (HS-SPME) with a CAR-PDMS fiber and subsequently analyzed by gas chromatography-pulsed flame photometric detection (GC-PFPD)

*Quantitative Analysis of Sotolon.* This analyte was quantified by using SPE extraction coupled with a GC-MS analysis described in reference.[15] The instrumental conditions are described by Ferreira et al.[71]

*Quantitative Analysis of Major Aroma Compounds.* This analysis was carried out by the method published by Ortega et al.[69] The strategy followed a liquid−liquid microextraction with dichloromethane and the use of several internal standards to correct for matrix effects. The method is based on gas-chromatographic−flame ionization detection analysis of the dichloromethane microextracts.

*Quantitative Analysis of Minor and Trace Aroma Compounds.* The method is described in ref 70. The wine was extracted in a SPE cartridge filled with LiChrolut EN resins. The elution was carried out with dichloromethane containing 5% methanol (v/v). These extracts were directly analyzed by gas chromatography with ion trap mass spectrometry detection without further concentration.

*Quantification of Non-Volatile Compounds by UPLC-MS.* Individual nonvolatile compounds with low molecular weight (anthocyanin-derived pigments such as glycosylated, acylated, pyranoathocyanins or anthocyanin-flavonol dimers; flavonols; phenolic acids and esters; trans-resveratrol) were first isolated by preparative gel permeation chromatography (GPC). The preparative column was formed by TSK Toyopearl gel, which was packed in a HW-50F Millipore (Bedford, MA, U.S.A.) Vantage L column (120 mm × 12 mm i.d.) at atmospheric pressure as described elsewhere.[72] Two milliliters of wine were directly injected in the column and flow rate was regulated at 1 mL/min using a peristaltic pump. The first fraction containing the compounds of low molecular weight were eluted with 60 mL of ethanol/water/trifluoroacetic acid (55:45:0.05, v/v/v). This fraction was brought to dryness under vacuum, redissolved in 2 mL of formic acid/water (5:95, v/v), and further analyzed by UPLC-MS.

UPLC analyses were performed using a Waters Acquity Ultra Performance LC system (Milford, MA, U.S.A.) by direct injection of wine samples, previously filtered with 0.22 μm nylon discs. UPLC separation was achieved using an acquity BEH C18 column (100 mm × 2.1 mm, i.d., 1.7 μm particle size, Waters), kept at 40 °C. Mobile phase flow rate was 0.45 mL/min and the injection volume was 7.5 μL. Solvents were (A) water/formic acid (0.1%), and (B) acetonitrile/formic acid (0.1%). The gradient program employed was as follows: 0−4 min, 99−92% A; 4−11 min, 92−70% A; 11−13.5 min, 70−0% A; 13.5−14.5 min, 0−99% A. The UPLC system was coupled to a microTOF II high-resolution mass spectrometer (Bruker Daltonik, Germany) equipped with an Apollo II ESI (electrospray) source and controlled by Bruker Daltonics Data Analysis software. The ESI source was operated in negative mode recorded in the range of $m/z$ 150 and 1500. The optimized conditions of the ESI source were as follows: capillary voltage, 3.5 kV; ESI source temperature, 180 °C; desolvation temperature, 200 °C; cone gas flow, 9 L/min; the nebulizer gas was set at 3 bar and 25 °C. LC−MS was performed operating in both (continuum) MS mode and in MS/MS mode. The spectra were acquired at the speed of 2 scan/s. Fragmentor voltage for MS/MS acquisition mode was 35 eV.

The identity assignation of compounds was carried out by comparison of their retention time ($t_R$), MS and MS/MS spectra with those of their respective commercially available standards. Quantification was performed by UPLC-MS and using the response (peak area) ratio for each compound. The calibration curves were prepared by calculating the peak area of the different standards and were used to determine linearity and instrumental detection (LOD) and quantification (LOQ) limits. LOD and LOQ were calculated using 3 S/m and 10 S/m ($S$ is the standard deviation of the response; $m$ is the slope of the calibration curve), respectively. Calibration curves were prepared in methanol. The estimated concentrations of anthocyanin derivatives have been expressed as malvidin-3-*O*-glucosyde equivalents (mg/L of malvidin-3-*O*-glucosyde), Hydroxicinnamic acids and esters as caftaric acid equivalents (mg/L of caftaric acid).[72]

*Analysis of Polymeric Pigments.* The procedure for polymeric pigments determination was based on that developed by Habertson et al.[73] In accordance with the method, two tubes for each sample were required. The first tube was made up by dispensing 1 mL of an acetic/NaCl buffer (200 mM acetic acid and 170 mM adjusted to pH 3.3 with HCl) into the tube and then adding 500 μL of wine. One milliliter of the mixture was transferred to a cuvette. Then, 80 μL of 0.36 M potassium metabisulfite was added and the absorbance at 520 nm was determined after 10 min of incubation (reading A).

For the second tube, 1 mL of acetic/NaCl buffer containing bovin serum albumin (1 mg/L) was put into the tube together with 500 μL of wine. The mixture was allowed to incubate at room temperature for 15 min with slow agitation. After incubation, the sample was centrifuged 10 min at 2000 rpm to pellet the protein−tannin precipitate. One milliliter of the supernatant was put into the cuvette, then 80 μL of 0.36 M potassium metabisulfite was added, and after a 10 min incubation the absorbance was determined at 520 nm (reading B). The absorbance due to SPP (small polymeric pigments) and LPP (large polymeric pigments) is given as B and (A-B),

Table 3. Carbonyl Compounds and VSCs Concentration Ranges and Mean Concentrations of the Initial 16 Red Wines

| | concentration range (μg/L) | | average (μg/L) | median (μg/L) | odor threshold (μg/L) |

respectively. The sum of SPP and LPP was named "polymeric pigments" in the present manuscript.

**Statistical Analysis and Data Treatment.** *Determination of Carbonyl Formation Rates.* For each one of the 17 specimens derived from a single wine, the increments of a given carbonyl were determined by subtracting the carbonyl content of the original wine. Then, those 17 increments from that given carbonyl from that wine were represented versus the corresponding 420 nm absorbance increments, and a straight regression line was calculated using least-squares regression analysis. The slope of such regression line is the formation rate of such given carbonyl in that wine and the uncertainty of such slope is the uncertainty of the carbonyl formation rate. These calculations were carried out using Regression analysis of Excel 2013 (Microsoft). Comparison between carbonyl formation rates were carried out via *t* test analysis assuming dissimilar variances.

*Determination of VSCs Depletion Rates.* These were calculated as described for the carbonyls. Principal component analysis (PCA) was carried out using the statistical software The Unscrambler 9.7. from Camo (Norway).

## RESULTS AND DISCUSSION

**Characterization of the Initial Wines.** The basic enological parameters of the 16 original red wines used in the study are given in Table 1. Values of ethanol (12.5−14.2%), reducing sugars (below 4.35 g/L), pH (3.42−3.98), and titratable acidity (4.52−5.79 g/L are normal among Spanish red wines. Volatile acidity was mostly below 0.6 g/L, and only two samples (C11 and C12) have slightly higher values (0.86 and 0.73 g/L), which may be due to long storage in oak barrels (18 and 10 months, respectively).

Table 2 presents a summary of the wine contents in potential aroma precursors of carbonyls (amino acids and alcohols) and in trace mineral elements (the complete set of data is given as Supporting Information). As seen in the table, the amino acids with highest variation ranges (higher than 1 magnitude order) are threonine, γ-aminobutyric acid, and leucine, while the least variable is phenylalanine for which the highest level is just 4.2 times above the smallest. Alcohol levels are less variable, and in most cases, the ratios between the highest and the smallest are below 3. Exceptions are benzyl alcohol, methionol, and β-phenylethanol, for which such ratios are 16, 8.6, and 5.4, respectively. As for the trace elements, in all cases, their contents are low. The ubiquitous iron is in all cases below 5 mg/L, while copper levels only exceeded 1 mg/L in a single wine. The median content of this element was just 0.092 mg/L. Leaving aside aluminum and nickel, median levels were in all cases below 1 mg/L. Elemental sulfur was included in the list as a potential general precursor for VSCs.

Table 3 summarizes (the complete set of data is given as Supporting Information) the levels of carbonyls and VSCs measured in the original wines before the aging experiment. As can be seen, initial wines already contain Strecker aldehydes—methional, phenylacetaldehyde, 2-methylpropanal, 2-methylbutanal and 3-methylbutanal—at levels above their corresponding thresholds, as already noted in previous works,[15,22] while their contents in lipid-related alkenals are very low. The wines also contain small but suprathreshold amounts of 1-octen-3-one, which is a lipid-related aroma compound. It has been identified as a major contributor to the fungus type aroma observed in grape berries contaminated by mildew,[74] but it has been also identified in hydrolisates obtained from fractions of glycosidic aroma precursors extracted from noninfected grapes.[75] The wines also contained small amounts of sotolon, which can be formed by oxidation from threonine,[76] of benzaldeyde, a common grape and wine product usually found under its odor threshold, and of vanillin, which mostly comes from the oak used in winemaking.

As for VSCs, median contents in the set of wines are relatively low, as shown in Table 3. It is clear, however, that some wines contained hydrogen sulfide and methanethiol at

levels high enough to show "reduced" character. Results for $H_2S$ are comparable to those presented by Siebert et al.,[77] although 3 out of the 16 wines showed maxima levels (see Supporting Information). Similarly, concentration ranges of MeSH and DMS are similar to those reported previously.[68,78] EtSH, diethylsulfide (DES), dimethyldisulfide (DMDS), and diethyldisulfide (DEDS) were not detected, in accordance with data given in previous works.[77,78]

**Oxidation in Terms of Absorbance at 420 nm.** The present study involves the storage of wines in recipients with different oxygen permeabilities and requires a measurement of the total amount of oxygen consumed by the wine during the storage time. Due to limitations in the availability of standardized materials with different and known oxygen permeabilities, we decided to produce such recipients in a relatively rough way by piercing more or less the internal septa of our amber vials. The degree of oxygen consumed by of our samples was just indirectly controlled by the absorbance at 420 nm, which is commonly used to assess the degree of wine color oxidation. In order to validate this procedure, the 16 wines were oxidized (at 5 consecutive oxygen saturations) in clear glass tubes containing oxygen sensors (see methods) so that we could measure the real wine oxygen consumption and relate it with its change in absorbance at 420 nm. The 16 wine × 5 oxygen levels/wine = 80 pairs of points were graphically represented revealing a good linear relationship ($R^2$ = 0.81, significant at $P < 4.2 \times 10^{-30}$) and showing that on average, the consumption of 10 mg/L of oxygen implies an increase of 0.46 units of absorbance. This value is in relatively good agreement with the increase of 0.52 found by Ferreira et al. in white wines.[79] In the present experiment, and given that the maximum absorbance increments were around 2.6 absorbance units, we can conclude that our samples consumed along the 6 month period between nothing and around 56 mg of oxygen per liter.

**Rates of Production of Carbonyls upon Wine Oxidation.** For each one of the wines, the levels of carbonyls produced during the 6 months of storage increased in approximately a linear way with the amount of oxygen consumed, as shown in Figure 1 for the case of methional and three different samples (wines R2, B14, and C12). The ordinates of the figure are the increments of methional measured in the 17 different specimens obtained from the wines R2, B14, and C12 after the 6 months of storage under different oxygen regimes. Such increments are represented versus the measured increment in absorbance at 420 nm of the corresponding specimens. The existence of such linear relationships (significant in the three cases at $P < 0.008$, $<1.3 \times 10^{-8}$, and $<1.5 \times 10^{-8}$, respectively), makes it possible to determine the methional formation rate (MFR) of each wine as simply the slope of the regression line together with its uncertainty. As can be seen, these wines produced on average 26.3 ± 2.4, 11.2 ± 1.0, and 0.74 ± 0.24 μg/L of methional, per unit of increment of absorbance at 420 nm, respectively. The differences between those MFR are highly significant ($P < 1.8 \times 10^{-5}$ and $<2 \times 10^{-8}$ for the consecutive paired comparisons) and relevant, as will be later commented. Taking into account the relationship between absorbance and mg/L of oxygen consumed previously estimated, it can be estimated that these wines produced 1.21, 0.51, and 0.011 μg/L of methional per mg/L of oxygen consumed, respectively. In molar terms, this implies that per mol of oxygen consumed the wines produced 372, 158, and 10.4 μmol of methional, respectively.

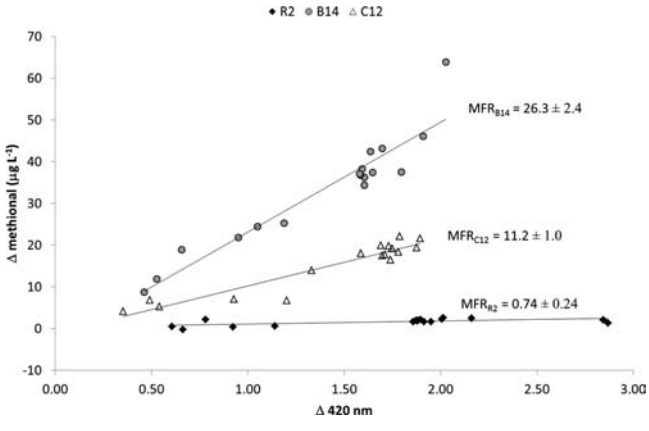

**Figure 1.** Linear relationships between the increments of methional measured in the 17 specimens obtained after the 6 month storage under different oxygen levels of wines B14, R2, and C12, vs the corresponding increments in absorbance at 420 nm of the specimens. The methional formation rates (MFR) are the slopes of the least-square regression lines.

As the linear pattern was observed for most wines and carbonyls, it is possible to estimate the specific rates of production of each aldehyde for each particular wine as shown before. Those data are summarized in Table 4, while more detailed data are given in the Supporting Information. Table 4 gives the ranges and medians of aldehyde formation rates per unit of oxygen consumed. For comparison purposes, the last column of the table gives the median increment in odor activity value (OAV) after the wine has consumed 25 mg/L of oxygen. Such parameter confirms previous findings about the utmost importance of methional and phenylacetaldehyde on the sensory characteristics of aged wines[15,22,80] and reveals that alkenals are rather unimportant oxidation compounds in the slow oxidation taking place during bottle aging, in contrast to what happened in an accidental oxidation with unlimited access to air.[22] The branched aldehydes, 2-methylpropanal, and 3-methylbutanal also have median increments of several units in OAV terms. Surprisingly, 1-octen-3-one and vanillin, which usually are not considered aging-related aroma compounds, showed consistent and potentially sensory relevant increases with the oxidation level. A recent work from Balboa-Lagunero et al.[80] reports an increase of vanillin levels upon oxidation as well. Benzaldehyde is also formed during oxidation but it is far from reaching the odor threshold. Another relevant observation is the absence of sotolon in the table, due to the fact that this compound was not found to increase with the oxidation level and hence it was not possible to estimate any sotolon formation rate, in agreement with the findings of Silva Ferreira et al.,[18,23] who found that this compound was readily formed only at 60 °C.

As ranges in Table 4 reveal, there are large differences in the aldehyde formation rates between wines. In the case of methional, for instance, the wine-forming maxima amounts of this aldehyde (1.57 μg/L per mg/L of $O_2$ consumed), forms it 57 times faster than the wine forming the minimum amount. Differences for phenylacetaldehyde are smaller (a factor 7), and for branched aldehydes difference factors lie between 11 and 27. Differences in the case of 1-octen-3-one are extreme (>600). These data indicate that the rate of production of carbonyls upon wine oxidation is an intrinsic characteristic of each wine. Aldehyde formation rates in the table would be

**Table 4. Minimum, Maximum, and Median Carbonyl Formation Rates Per Unit of Oxygen Consumed in the 16 Wines of the Study and Potential Sensory Significance[a]**

consistent with aldehyde contents of normal aged nonoxidized wines,[15,22] provided that they have taken up to 50 mg/L oxygen.

The pattern of carbonyl production upon wine oxidation during bottle aging is revealed in the principal component analysis shown in Figure 2. As shown in the figure, all carbonyls have positive loadings on the PC1, which means that this component arranges wines attending to their general ability to produce carbonyls upon oxidation. Samples C11 and R1 are the samples showing in all cases maxima carbonyl production rates. The second component separates wines attending to their individual ability to form alkenals on the one hand and vanillin, benzaldehyde and 1-octen-3-one on the other. Taking into account the large differences in aldehyde production rates, the plot tells us that wines on the left (samples V10, B15...) can undergo prolonged oxidative bottling aging periods without noticeable formation of aldehydes, while samples on the right of the plane, such as R1 and C11, will develop very quickly oxidation-related carbonyls, which will undoubtedly cause them to lose their freshness very soon.

**Formation from Precursors and Role of Intermediates and Catalysts.** As shown in Table 5a, the production rates of Strecker aldehydes are significantly correlated (except 2-methylbutanal) to the wine initial levels in the corresponding amino acid, but not to the wine initial levels in the corresponding alcohol. This suggests that wine amino acids act as primary active precursors for those aldehydes during wine oxidation, confirming previous hypotheses and observations.[21,30] Amino acid levels did not decrease significantly with oxidation, in agreement with a previous report[30] and with the low amount of aldehyde produced.

In the particular case of methional, however, the formation of the aldehyde from the alcohol, methionol, should not be ruled out, because as shown in Table 5b, the initial wine content of this aldehyde is strongly correlated to the wine initial level of methionol. The oxidation of methionol to methional seems, however, not to be the single oxidative degradation pathway of this molecule, because the levels of this alcohol were found to significantly decrease by oxidation (data not shown), while the concomitant increases of methional observed explained only between 4 and 14% of the decrease in methionol. Methionol could be also oxidized to its corresponding *S*-oxide, as recently suggested by Fedrizzi et al.[81]

Carbonyl production rates were significantly correlated to some metallic elements. Methional and phenylacetaldehyde production rates were significantly correlated to the wine content in Zn ($r = 0.51$, $p < 0.05$). The rates of formation of 2-methylpropanal and 2-methylbutanal were significantly correlated to the combined wine content in Fe, Zn, and Cu ($r = 0.58$ and 0.63; $p < 0.05$ and <0.01, respectively). Such correlations were not observed for 3-methylbutanal. In the case of (*E*)-2-alkenals, their production seems to be positively correlated with

Ni levels ($r$ = 0.59 and 0.57, both $p < 0.05$ for (*E*)-2-nonenal and (*E*)-2-octenal, respectively) and negatively with Mn ($r$ = −0.51 and $r$ = −0.51, both $p < 0.05$ for (*E*)-2-nonenal and (*E*)-2-heptenal, respectively). Carbonyl production rates were not correlated to the wine levels in the single dicarbonyl measured in the present study: diacetyl.

In the case of polyphenolic material, several correlations were found, as shown in Table 6. The rates of production of Strecker aldehydes are, in general, negatively correlated to pyroanthocyanidins, anthocyanin-flavanol adducts, flavonols, and *p*-coumaric acid, while they are positively correlated with the ethyl ester of caffeic acid. The rates of production of alkenals are even more strongly correlated to the wine phenolic composition. Negative correlations with TPI, polymeric pigments, flavonols, and ellagic acid and positive correlations with protocatechic acid, its ethyl ester, and *trans*-resveratrol were observed.

It is worth mentioning that anthocyanin pigments formed at the end of the alcoholic fermentation and during wine aging are negatively correlated to Strecker aldehyde and alkenal production rates. Despite their very different chemical structure, those anthocyanin-derived pigments have in common that the 4-position of the heterocycle is occupied, making them more stable and resistant to the action of the bisulfite ions than the anthocyanins from which they originate. An increase in the formation of these pigments is linked to a decrease of anthocyanins combined with $SO_2$, which would result in more color and more available $SO_2$, which could explain the negative correlation. Furthermore, Strecker aldehyde and alkenal production rates keep a negative correlation to flavonols, regardless of whether the determination of these polyphenols is carried out globally by molecular absorption spectroscopy or individually by UPLC-MS. These phenolic compounds are known to be the most effective antioxidant flavonoids,[82] due to the keto group and the OH at the 3-position of the heterocycle.

Benzaldehyde and vanillin mainly show a significant positive correlation with phenolic acids. Benzaldehyde is correlated with gallic acid, and vanillin with caftaric, ferulic, and ellagic acid. Caftaric and ferulic acid come from grapes, the source of ellagic acid is the aging barrel, and gallic acid comes from both sources.

In the case of pH, evidence suggests that less aldehyde (per unit of change in absorbance) is formed at higher pHs. This relationship only reaches the statistical significance level in the case of 2-methylbutanal ($p < 0.02$), but in all cases, the slopes were negative, suggesting that even if the wines oxidize faster at higher pHs, such oxidation is more efficiently producing carbonyls at acid pHs.

**Release from Bisulfite Adducts?** The rates of carbonyl formation during oxidation are in many instances significantly correlated with the combined $SO_2$ level of the original wine. This is the case of methional, phenylacetaldehyde, and 3-methylbutanal, as shown in Table 5, but these correlations were also observed in the cases of (*E*)-2-hexenal ($r$ = 0.530, $p < 0.05$), (*E*)-2-octenal ($r$ = 0.546, $p < 0.05$), (*E*)-2-nonenal ($r$ = 0.517, $p < 0.05$) and 1-octen-3-one ($r$ = 0.546, $p < 0.05$). Combined $SO_2$ includes all the different forms of sulfur dioxide that cannot be purged by a stream of air from an acidic portion of the sample at room temperature. In wine, carbonyls form relatively stable adducts with $SO_2$.[30,42] Those complexes would affect their liquid−gas transfer coefficients and hence their concentration in the headspaces above wine. The correlation between carbonyl formation rates and combined $SO_2$ make us hypothesize that a certain fraction of the oxidation-related carbonyls are in fact already formed in the initial wine trapped under the form of bisulfite adducts. From this point of view, then it follows that the observed formation of aldehydes upon oxidation would not be, at least in part, the direct result of the oxidation of precursor molecules but the simple result of the oxidation of sulfur dioxide itself that would provoke the liberation of the already present bisulfite-trapped aldehydes. In order to assess to what extent the observed formation of aldehydes is real formation from the direct oxidation of precursors, or just release from trapped forms upon depletion of sulfur dioxide, more refined analytical procedures, including the ability to separate between bonded and free forms of aldehydes, will be required.

**VSCs Production and Depletion.** VSCs have been measured by a previously developed method specifically designed for avoiding matrix effects by means of a strong dilution of the wine matrix in brine.[68] Therefore, VSCs measurements truly reflect levels of these compounds in wine rather than the free amounts present in the headspace, which is usually what is measured.[16,77,83] This difference should be taken into account in the interpretation of the results.

As it was previously done, the levels of the three relevant VSCs measured ($H_2S$, MeSH, and DMS) in each one of the 17 specimens produced from each wine sample have been plotted versus the absorbance at 420 nm, and regression lines have been estimated. Two different types of patterns emerge out of the data. In the case of hydrogen sulfide, in all the cases there is a clear decrease with respect to the original wines even in the samples whose oxidation level was very small; that is, in no single case could we appreciate any real accumulation of this molecule, and in all cases, the level of this molecule decreased concomitantly with the level of oxidation. In the cases of MeSH and DMS, on the contrary, we could detect an increment between the levels of the original wine and the levels of the wines after 6 months of storage with low level of oxidation. The effect of oxidation in these two cases was, generally speaking, also a decrease of the molecule with the level of oxidation. All these data are summarized in Table 7.

As shown in Table 7, degradation rates of hydrogen sulfide range from −0.25 to −2.3 μg/L per mg/L $O_2$ consumed (233 to 2160 μmol/L per mol/L oxygen consumed). Hydrogen sulfide degradation rates are strongly correlated to the own initial level of hydrogen sulfide ($r$ = −0.99), which basically suggests that the oxidation kinetics of this molecule follow a second-order kinetic model, according to which oxidation rate would be proportional to both the concentration of initial product ($H_2S$) and of reactant (a wine quinone, hydrogen peroxide, or other reactive oxygen species), being the kinetic constant very similar in all the wines. The strong correlation with the initial concentration of hydrogen sulfide is explained because what is measured in the present work is the degradation rate per oxidation unit, meaning that hydrogen sulfide is oxidized following the main wine oxidation pathway, which is consistent with its highest reaction rates to quinones, as recently measured.[31] Notwithstanding this affirmation, degradation rates are strongly correlated to copper ($r$ = −0.85, $p < 0.0001$) and iron ($r$ = −0.60; $p < 0.05$) levels. A closer look at these data revealed that the three wines with the highest levels of copper contained also the highest levels of hydrogen sulfide, which may just be the result of the industrial use of $Cu^{2+}$ to remove an excess of $H_2S$ caused by a problematic fermentation.[55] The fact that we could not observe

**Table 7. Degradation Rates of VSCs upon Oxidation and Increments (When Applicable) Consequence of Bottle Storage[a]**

[a]Degradation rates are μg/L of VSC degraded per mg/L of oxygen consumed, and increments are μg/L of VSC. [b]Not significant.

any increment on the levels of hydrogen sulfide even at the lowest oxygen levels, would suggest that there are no specific precursors for this molecule in these wines in apparent contrast to the increments very often observed along bottle aging.[14] As was mentioned previously, this disagreement could be related to the nature of our analytical method.

In the case of methanethiol, and in clear contrast to the case of hydrogen sulfide, a small but significant increment on the levels of this molecule has been measured in 12 out of the 16 wines, which suggests that this molecule can be formed from some precursor. Interestingly, methanethiol increments are positively correlated to the wine levels in several amino acids. Although the maximum degree of correlation has been found with the amino acid arginine ($r = 0.72$, $p < 0.01$), the most relevant is the one found with methionine ($r = 0.53$, $p < 0.05$), because this amino acid could be a specific precursor for methanethiol, as recently demonstrated for soy proteins[84] in a reaction mediated by hydroxyl radicals.[85] Furthermore, a negative correlation appears between methanethiol formation and resveratrol levels ($-0.58$, $p < 0.05$), whose activity as reactive oxygen species (ROSs) scavenger, in particular toward hydroxyl radicals, is well documented.[86] It is also worth mentioning the observed correlation between MeSH formation and total proanthocyanidin levels ($r = 0.60$, $p < 0.05$), which may suggest that these compounds compete by the quinones that react and destroy MeSH. A significant negative correlation with aluminum levels ($r = -0.59$, $p < 0.05$) has been also found, in contrast to the low effects found for this cation in methanethiol production.[55]

Methanethiol levels, as previously observed in the case of $H_2S$, decrease with oxidation. As no disulfide was detected in this study, the main degradation route should be the reaction of the mercaptan with a quinone produced along with oxidation.[31,39] Decreases are smaller than those observed for $H_2S$, because levels of methanethiol were in all cases smaller, in many instances close to the method detection limits, and because the reaction rate is smaller.[31] As in the $H_2S$ case, there is a significant negative correlation with copper ($r = -0.59$, $p < 0.05$) and iron levels ($r = -0.67$, $p < 0.01$), which is consistent with the central role played by these cations in wine oxidation.[39] The correlation, however, is strongly influenced by the single wine with the highest levels of these metals, which also had the maximum degradation rate. There is a sound correlation with Mn levels ($r = -0.67$, $p < 0.01$), suggesting that this cation also has a responsibility in the oxidative degradation of methanethiol. This should be further studied, because although the implication of Mn in wine oxidation was experimentally demonstrated in the past,[87] there are no recent reports addressing the role of this cation in wine oxidation.

Dimethylsulfide levels increase after 6 months of storage, as the most likely consequence of the hydrolysis of its known precursor, *S*-methylmethionine.[88] This precursor was not measured in this study. We should note a positive correlation with pH ($r = 0.73$, $p < 0.01$) consistent with the known higher speed of the hydrolytical process at higher pHs. Dimethylsulfide levels also decreased significantly in most cases upon wine oxidation as shown in Table 7, in contrast to what is stated in a recent review,[2] but in agreement with some other reports.[89] Further experiments would be required to clarify the fate of DMS upon oxidation.

**Table 1. Details of the Target Compounds**

| no. | analyte | CAS Registry No. | usage | SML[a] (mg kg$^{-1}$) | log$P^b$ |
|---|---|---|---|---|---|
| 1 | Cyasorb UV-1164 | 2725-22-6 | light stabilizer | 5 | 11.43 |
| 2 | Irgafos 168 | 31570-04-4 | antioxidant | 60 | 15.71 |
| 3 | Irganox 1010 | 6683-19-8 | antioxidant | 60 | 19.29 |
| 4 | Irganox 3114 | 27676-62-6 | antioxidant | 5 | 13.17 |
| 5 | Irganox 3790 | 40601-76-1 | antioxidant | 6 | 12.75 |
| 6 | Irganox 565 | 991-84-4 | antioxidant | 30 | 13.37 |
| 7 | Tinuvin 1577 | 147315-50-2 | light stabilizer | 0.05 | 8.59 |
| 8 | Tinuvin 234 | 70321-86-7 | light stabilizer | 2 | 8.41 |
| 9 | Tinuvin 326 | 3896-11-5 | light stabilizer | 30[c] | 5.33 |
| 10 | Tinuvin 327 | 3864-99-1 | light stabilizer | 30[c] | 6.49 |
| 11 | Tinuvin P | 2440-22-4 | light stabilizer | 30[c] | 3.19 |

[a]Specific migration limits of the target compounds according to 10/2011[1] [b]Values predicted by MarvinSketch. [c]The SMLs are given for the sum of these substances.

preparation techniques and the development of specific applications with these techniques are time-consuming and expensive ways to remove matrices or to enrich compounds. Liquid−liquid extraction with low-temperature purification is a practical technique for eliminating fat[38−40] as it freezes out while the target compounds remain dissolved in the organic phase.

The aim of this study was to develop and validate an LC-MS/MS method to measure the concentration of Cyasorb UV-1164, Tinuvin P, Tinuvin 234, Tinuvin 326, Tinuvin 327, and Tinuvin 1577 (UV stabilizers) and Irgafos 168, Irganox 1010, Irganox 3114, Irganox 3790, and Irganox 565 (antioxidants) in milk. To remove the fat content of the milk extracts liquid−liquid extraction with low-temperature purification was chosen because of its simplicity. In the course of method development different solvents, extraction volumes, and pH values were investigated to maximize recoveries. Injection volume was optimized to minimize the matrix effect. Because of the lack of isotope-labeled internal standards, both external and matrix calibrations were checked. During method development milk samples with low fat content were used. However, robustness was checked using fattier samples.

## MATERIALS AND METHODS

**Chemicals and Materials.** Irganox 565 (99%) was purchased from Chemos GmbH (RK Tech, Hungary); Tinuvin P (99.3%), Tinuvin 326 (98%), and Tinuvin 324 (98%) from Tokyo Chemical Indrustry Co. (RK Tech, Hungary); Cyasorb UV-1164 (97%), Irganox 3114 (97%), and Tinuvin 1577 (99%) from Toronto Research Chemicals Inc. (RK Tech, Hungary); and Tinuvin 327 (98%), Irganox 3790 (97%), Irgafos 168 (98%), and Irganox 1010 (98%) from Sigma-Aldrich Co. (Hungary).

2-Propanol (HPLC grade), tetrahydrofuran (HPLC grade), dichloromethane (GC grade), formic acid (Suprapur), acetic acid (Suprapur), NaCl, and ammonium acetate (ReagPhEur) were purchased from Merck Ltd. (Hungary). Acetonitrile (HPLC grade), methanol (HPLC grade), ethyl acetate (Picograde), and acetone (Picograde) were purchased from LGC Promochem Ltd. (Hungary). Ammonium solution (25%; Normapur) was obtained from VWR International, LLC. Ammonium formate (LC-MS grade) was bought from Fluka (Sigma-Aldrich Co., Hungary).

Mixed stock solution of the standards was prepared in dichloromethane at a concentration of 500 $\mu$g/mL for every target compound. The working solution was prepared by 10-fold dilution with tetrahydrofuran. One gram spiked milk samples were prepared by adding 100 $\mu$L of working solution.

UHT milk samples in Tetra Pak containers with fat contents of 1.5 and 3.5% were purchased in local food stores and, until analyzed, stored in a refrigerator at 5 °C.

**Instrumentation.** HPLC separation was performed on an Agilent 1100 HPLC equipped with a degasser (G1322A), a binary pump (G1312A), an autosampler (G1313A), a column thermostat (G1316A), and a variable-wavelength detector (G1314A). Mass spectrometric detection was carried out by using an Applied Biosytems API 2000 triple quadrupole. Data acquisition and evaluation were performed using Analyst version 1.6.1 software.

For centrifugation Z206A and Z230A Hermle centrifuges were used. HPLC grade water was prepared by a Direct-Q 5 (Millipore) system. A Julabo FT902 cryostat with acetone was used for liquid−liquid extraction with low-temperature purification. Dry residue weights of the extracts were measured with a Mettler Toledo AB135-S/FACT balance. To avoid contamination, only glass labware was allowed to come in contact with the sample.

**Recovery and Matrix Effect.** Recovery and matrix effect were optimized separately. Good recoveries are necessary for low limits of detection, yet good recoveries combined with high matrix effect indicate poor accuracy, especially for external calibration. Matrix effects (ME) and recoveries (RE) can be calculated by using eqs 1 and 2:[41]

$$\mathrm{ME}\ (\%) = \frac{B}{A} \times 100 \quad (1)$$

$$\mathrm{RE}\ (\%) = \frac{C}{B} \times 100 \quad (2)$$

$A$ is the peak area of the standard solution, $B$ is the peak area of the standard in the sample spiked after the extraction, and $C$ is the peak area of the standard in the sample spiked before the extraction. If ME is 100%, there is no matrix effect. If ME is >100%, there is a signal enhancement, and if ME is <100%, there is signal suppression. For all milk samples, A, B, and C samples were prepared with three parallel and mean values substituted into the above-described formulas.

After optimization of the sample preparation procedure based on recoveries, 1, 2, and 5 $\mu$L injection volumes were tested to minimize matrix effect.

**Chromatography and Mass Spectrometry Method Development.** Columns of different types, selectivities, and dimensions were tested to reach medium retention, acceptable peak symmetry, and narrow peaks. The tested columns were as follows: GL Sciences InertSustain C18 (100 mm × 2.1 mm × 3 $\mu$m); Phenomenex Synergi 4u Polar-RP 80A (150 mm × 2.0 mm × 4 $\mu$m); YMC-UltraHT Hydrosphere C18 (50 mm × 3.0 mm × s-2 $\mu$m); YMC-Triart C18 (100 mm × 2.1 mm × 3 $\mu$m); Thermo Hypersil Gold C18 (30 mm × 2.0 mm × 1.9 $\mu$m); Kinetex C18 (100 mm × 2.1 mm × 2.6 $\mu$m); Kinetex pentafluorophenyl (PFP) (100 mm × 2.1 mm × 2.6 $\mu$m). Gradient elution was performed during the studies of the columns with 0.25 mL/min flow. Water-based eluent was called "A" and the organic modifier, "B". Gradient was started at 90% A, held for 2 min.

Table 2. Ionization Mode and MRM Transitions of the Target UV Stabilizers and Antioxidants by LC-MS/MS

| | | precursor ion | | | | | | product ion | | |
|---|---|---|---|---|---|---|---|---|---|---|

[a]DP, declustering potential (V); FP, focusing potential (V); EP, entrance potential; CEP, collision entrance potential (V); CE, collision energy (eV); CXP, collision exit potential (V).

Linear gradient was applied to increase B to 90% in 8 min; 90% B was held for 10 min. Fourteen minutes was needed to equilibrate the system before the next injection. During optimization of chromatographic and mass spectrometric parameters, 5 $\mu$L was injected from a 500 ng/mL standard methanol solution onto the columns three times.

Different compositions of the mobile phase were tested. Formic acid (0.1 v/v %) both in Direct-Q water and in organic modifiers was used on every column. Both acetonitrile and methanol were tested as organic modifiers. Ammonium acetate (20 mmol/L; pH adjusted to 5.00) was also examined with both methanol and acetonitrile on all of the columns. On the Kinetex PFP column also the amount of buffer was tested with 1, 5, and 20 mmol/L ammonium formate (pH adjusted to 2.80 with formic acid). In these experiments 0.1 v/v % formic acid in methanol was used as organic eluent. Effects of the pH were studied on Kinetex PFP with pH 2.80 ammonium formate (20 mmol/L) and pH 5.00 ammonium acetate (20 mmol/L) in Direct-Q water. Methanol was used as the organic modifier in these experiments.

**Optimization of Sample Preparation.** In our method, liquid–liquid extraction was used to remove proteins and carbohydrates and low-temperature purification to remove fats from milk samples. The fat content of the extracts is usually removed by freezing for 12 h in a freezer at −20 °C.[38−40] The freezing process can be accelerated at lower temperature by liquid nitrogen, liquid nitrogen combined with an organic solvent, or a cryostat. We used a cryostat at −50 °C with acetone. Liquid–liquid extraction with low-temperature purification is usually combined with filtration. Even though syringe filtration would have been practical, we had to avoid any plastic tools. Thus, centrifugation, which is an easy and cheap way to remove particles from liquids, was used instead.

Optimization was started with a pretrial with extraction of the target compounds from 5 mL aqueous solutions into 5 mL of acetonitrile with three parallel samples to find out if basic or acidic conditions provide higher recoveries for the target compounds. Phase separation was obtained by adding 0.25 g of NaCl. For pH modification 0.1 v/v % formic acid and 0.1 v/v % ammonia solutions were used. Recoveries were tested without any pH modification as well. Because the alkaline media proved to be the best, the optimization of sample preparation was started with 25 $\mu$L of 25% ammonia solution for pH adjustment of the 1 g milk samples before extraction with 4 mL of solvent.

Acetonitrile, acetone, tetrahydrofuran, ethyl acetate, and 2-propanol were tested on milk samples using liquid–liquid extraction with low-temperature purification. After the extraction solvent, the extraction volume was optimized. One gram of milk was extracted with 2, 5, and 10 mL of the selected solvent.

The variety of functional groups contained by the target compounds necessitated a finer setting of the pH later: 50 $\mu$L of either 2 mol/L (pH ∼13), $2 \times 10^{-2}$ mol/L (pH ∼11), or $2 \times 10^{-4}$ mol/L (pH ∼9) NaOH solution was added to 1 g of spiked milk samples to determine the effects of the pH on recoveries.

Two microliters was injected from every sample during the development of sample preparation. Finally, the lipid-removing efficiency of low-temperature purification was tested using the validated sample preparation method, detailed in the next paragraph.

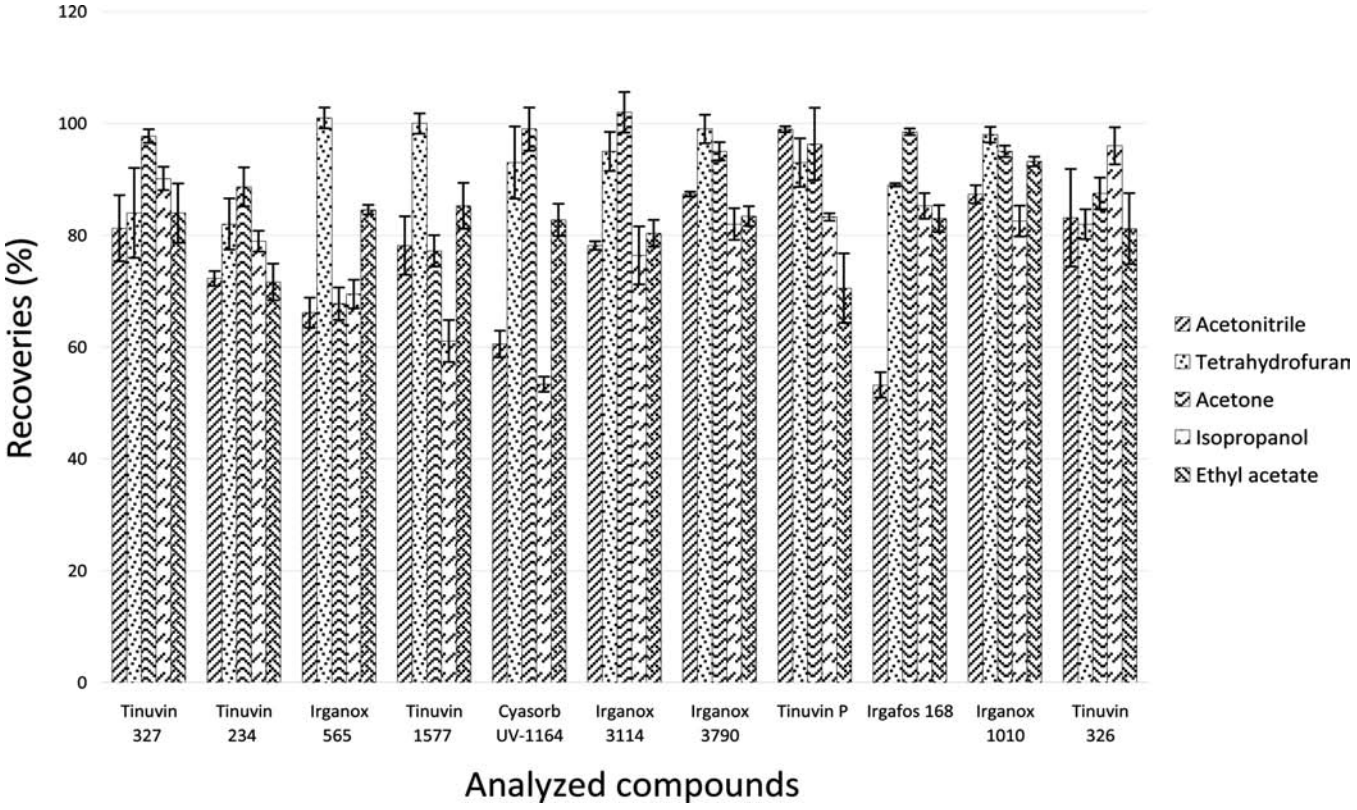

**Figure 1.** Recoveries for liquid−liquid extraction with low-temperature purification using different solvents on 1.5% fat milk. Error bars represent the mean ± standard deviation of recoveries calculated using average peak areas of the standard in the sample spiked after the extraction, $n = 3$.

For this purpose dry residue weights of 0.5 mL extracts were determined before and after low-temperature purification with five parallel samples. Measurements were performed from both 1.5 and 3.5% fat-containing milk. For the determination of dry residue weight, samples were dried to constant weight at 102 °C.

**Validated Method.** One gram of milk was weighed into a 40 mL vial. First, 50 μL $2 \times 10^{-2}$ mol/L NaOH (pH ∼11) solution was added to the sample. This was followed by 5 mL of tetrahydrofuran and 0.25 g of NaCl. The sample was vortexed for a minute and sonicated for a further 10 min. After the extraction, sample was centrifuged for 10 min at 410*g*. A 1.5 mL aliquot of the upper phase was transferred to a 2 mL HPLC vial that was sealed afterward. The vial was placed into a 15 mL centrifuge tube filled with 2.15 mL of −50 °C acetone then kept at −50 °C by cryostat for 30 min for the fat content to freeze out. In this centrifuge tube the sample was centrifuged for 2 min at 3300*g*. After centrifugation for 2 min, 0.5 mL of the fat-free supernatant was transferred to another HPLC vial from which the injection took place.

Gradient elution was carried out at a flow rate of 0.25 mL/min using 1 mmol/L ammonium formate (pH adjusted to 2.80 with formic acid) buffer in water as eluent A and 0.1 v/v % formic acid in methanol as eluent B. The gradient separation was started at 10% B, and then by a linear gradient B was increased to 95% within 3 min. This composition was held for 13 min, and then the eluent composition was lowered to 10% B immediately. Before the next run was begun, 14 min of equilibration time was necessary.

In the case of external calibration 1 μL, otherwise 5 μL, sample aliquots were injected with needle wash (vial wash in acetonitrile) onto a 100 mm × 2.1 mm × 2.6 μm PFP (Kinetex, Phenomenex, Hungary) core−shell column equipped with an in-line filter containing replacement frits (2 mm, 0.2 μm). The column temperature was kept at 30 °C during the analysis.

Electrospray ion source was used in positive mode. The sample was ionized and nebulized with 4500 V (IS voltage). The curtain gas, the nebulizer gas in the ion spray and the auxiliary gas, which helps to evaporate the spray droplets, were all nitrogen set to CUR 10, GS1 40, and GS2 60, respectively. The temperature of GS2 (TEM) was set to 550 °C. Nitrogen was used also as collision gas for collision-activated dissociation (CAD 7). Positive ions were acquired in multiple reaction monitoring (MRM) mode. For all compounds two transitions were monitored. Details of the MRM transitions are presented in Table 2. Dwell time was 50 ms for all transitions. Component-dependent parameters were acquired by measuring $NH_4^+$ adduct in the case of Irganox 1010, Irganox 3114, and Irganox 3790.

**Method Validation.** The method was validated with 1 g spiked negative milk samples (milk sample that did not contain any of the target polymer additives in detectable amount) with fat content of 1.5%. MDLs were determined with a series of spiked negative milk samples as the least detectable amount of analyte with a signal-to-noise ratio above 3. External standard calibration was performed from 125 μg/kg to 25 mg/kg concentration and matrix calibration between 25 μg/kg and 2.5 mg/kg. Because linear regression is suitable for only 1 order of magnitude, quadratic regression was applied. Accuracies and precisions were calculated at two concentration levels (500 μg/kg and 5 mg/kg) for external calibration for both 1.5 and 3.5% fat containing milk samples with three parallel samples. In the case of matrix calibration, accuracies and precisions were tested on all calibration levels with three parallels. Accuracies are given as percentages comparing the concentration calculated from the calibration curves with that of the spiked milk samples. To quantify intraday precision values relative standard deviation (RSD) was calculated from the average concentration and their standard deviation. To check the robustness of the method with regard to the fat content of the sample, accuracies and intraday precision values were determined also for fattier milk samples (3.5%) at 100 μg/kg and 1 mg/kg.

## RESULTS AND DISCUSSION

**Optimization of LC-MS/MS Conditions.** Most of the UV stabilizers can be protonated and measured by ESI.[25] Although atmospheric pressure chemical ionization (APCI)[6,8,9] or atmospheric pressure photoionization (APPI)[9] mode is

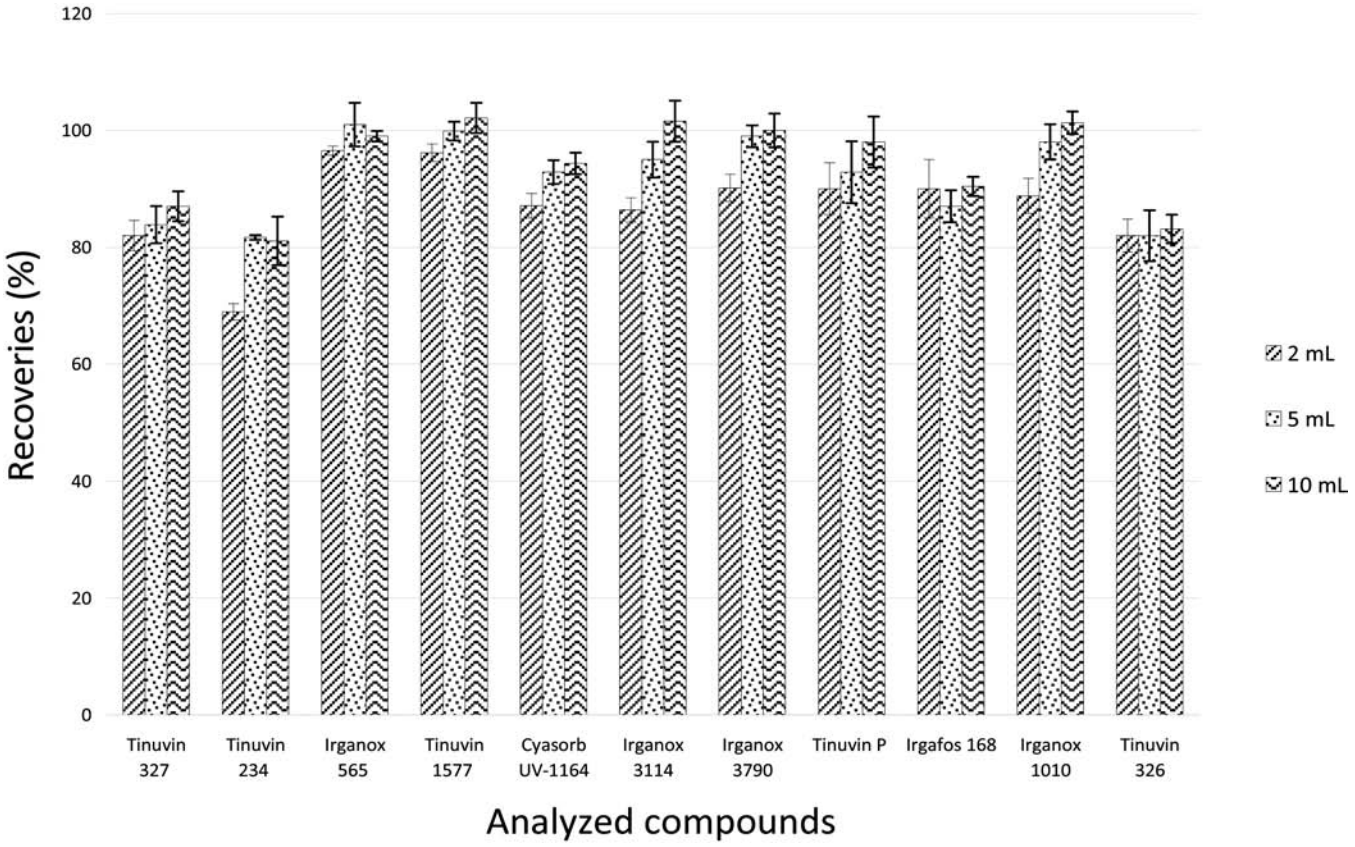

**Figure 2.** Recoveries for liquid–liquid extraction with low-temperature purification using different volumes of tetrahydrofuran on 1.5% fat milk. Error bars represent the mean ± standard deviation of recoveries calculated using average peak areas of the standard in the sample spiked after the extraction, $n = 3$.

advisable for some of the target compounds, mostly for the antioxidants, ESI was preferred in our method because it grants satisfying intensity for all compounds.

The first tests of columns and eluents showed that 0.1 v/v % formic acid in Direct-Q water and acetonitrile cannot elute Irganox 565 and Cyasorb UV-1164 from the GL Sciences InertSustain C18, YMC-UltraHT Hydrosphere C18, and YMC-Triart C18 columns. From the Kinetex C18 only Irganox 565 could not be eluted. Such problems did not occur with the Phenomenex Synergi 4u Polar-RP 80A, Thermo Hypersil Gold C18, and Kinetex PFP columns. On the Synergi 4u Polar-RP 80A and on the Thermo Hypersil Gold C18 the last peaks broadened severely compared to the Kinetex PFP. Kinetex PFP is made using core–shell technology that guaranteed high plate number and effective separation and therefore better signal-to-noise ratio compared to a fully porous column. Kintex PFP was chosen for further experiments. These initial experiments also revealed that with regard to sensitivity Tinuvin 327, Tinuvin 326, and Tinuvin P are the critical compounds.

Using methanol–water instead of acetonitrile–water granted higher abundance for most compounds but also higher back pressure and longer retention time. Methanol is a weaker eluent compared to acetonitrile, but it increased the signal so methanol was used for further experiments.

Effects of the pH of the eluent were studied with pH 2.80 ammonium formate (20 mmol/L) and pH 5.00 ammonium acetate (20 mmol/L) in water. Lower pH granted higher abundance for all of the compounds. The increment of the signal of Tinuvin P was the lowest: it gave only a 1.14 times bigger peak at pH 2.8 compared to that at pH 5.00. The highest increment was measured for Tinuvin 1577, giving a 3.9 ratio. (See the Supporting Information, Figure S1.)

Finally, the amount of ammonium formate was optimized. The abundance of the compounds measured as ammonium adduct increased with increasing amount of ammonium formate, but the three critical compounds suffered ion suppression. Ammonium formate (1 mmol/L) was chosen to minimize ion suppression and still provide enough ammonium ion for the sensitive and reproducible measurement of Irganox 1010, Irganox 3114, and Irganox 3790 peaks in the form of ammonium adduct. (See the Supporting Information, Figure S2.)

On the basis of these results and considerations, positive electrospray ion source (ESI) and a 100 mm × 2.1 mm × 2.6 $\mu$m PFP core–shell column with gradient elution using 1 mmol/L ammonium formate (pH 2.80) buffer and methanol with 0.1 v/v % formic acid as eluents was chosen.

**Optimization of Sample Preparation.** As potential extraction solvent, acetonitrile, acetone, 2-propanol, ethyl acetate, and tetrahydrofuran were tested on alkalinized milk samples. The observed recoveries are shown in Figure 1. Recoveries were >50% for all compounds with every solvent. The lowest recoveries were observed with acetonitrile and 2-propanol. Acetone, ethyl acetate, and tetrahydrofuran provided acceptable recoveries. Using acetone, the recoveries were >87% except for Irganox 565 (68%) and Tinuvin 1577 (77%). Extractions with ethyl acetate resulted <80% only for Tinuvin 234 (72%) and Tinuvin P (71%). Tetrahydrofuran provided >82% recoveries for all compounds. Thus, tetrahydrofuran was chosen for further studies.

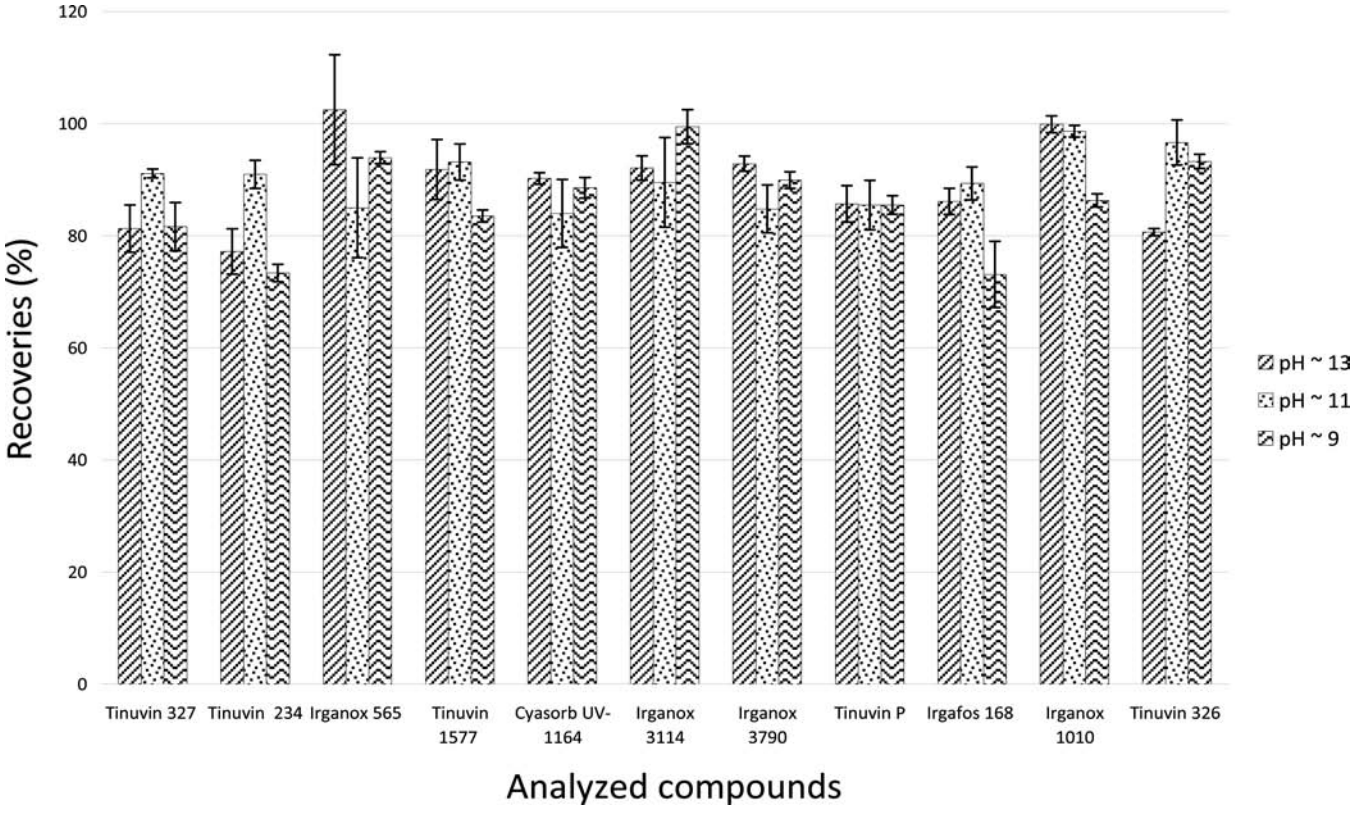

**Figure 3.** Recoveries for liquid−liquid extraction with low-temperature purification at different pH values using tetrahydrofuran on 1.5% fat milk. Error bars represent the mean ± standard deviation of recoveries calculated using average peak areas of the standard in the sample spiked after the extraction, $n = 3$.

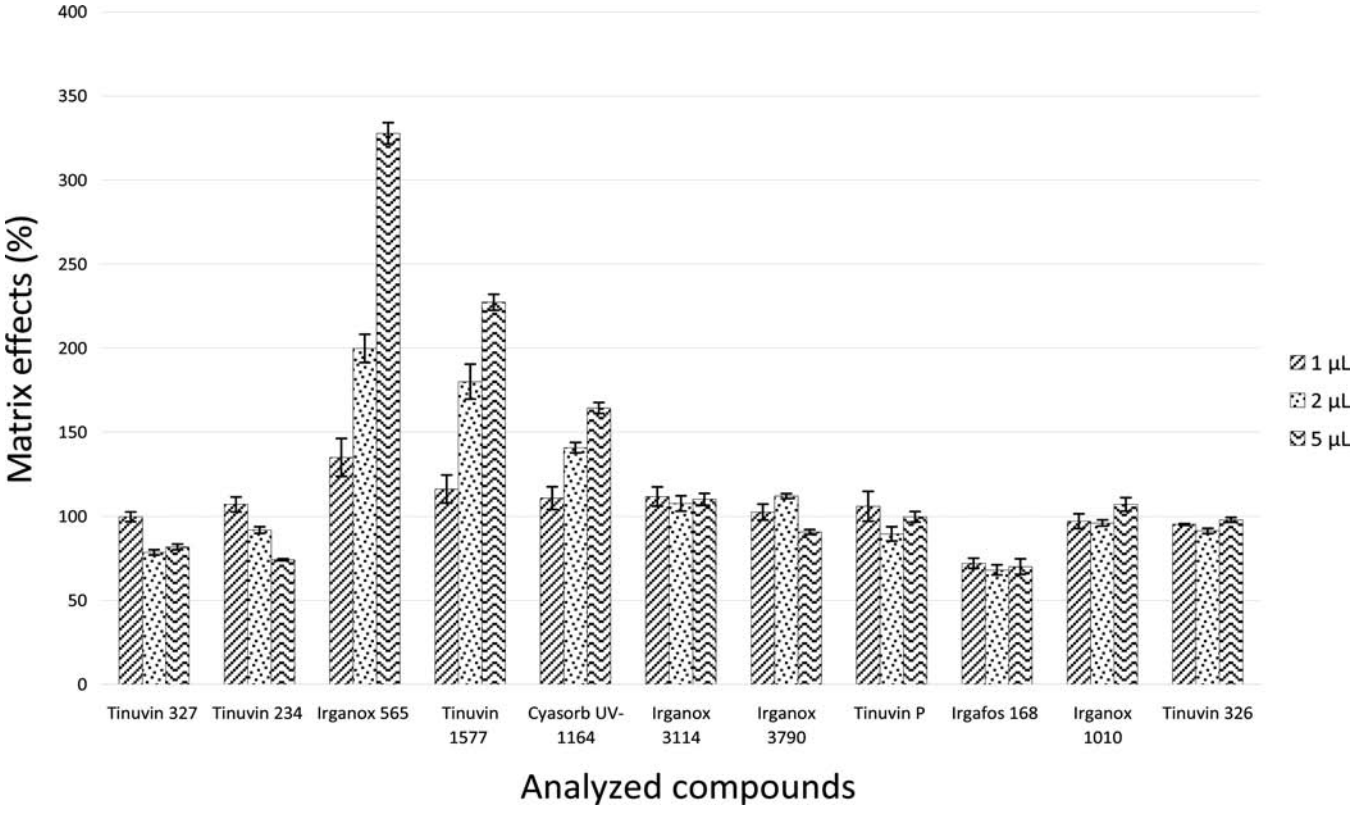

**Figure 4.** Matrix effects using liquid−liquid extraction with low-temperature purification on 1.5% fat milk with different injection volumes. Error bars represent the mean ± standard deviation of matrix effects calculated using average peak areas of the standard solution, $n = 3$.

[a]MDL, method detection limits.

The volume of tetrahydrofuran necessary for the extraction was tested at 2, 5, and 10 mL. Two milliliters of extraction solvent granted good recoveries for most of the compounds. (See Figure 2.) The recoveries were >80% except for Tinuvin 234. Increasing the extraction volume from 2 to 5 mL increased the recoveries, especially for Tinuvin 234, Cyanosorb-UV 1164, Irganox 3114, Irganox 1010, and Irganox 3790. With 5 mL of tetrahydrofuran the average recovery was 92%, and with 10 mL it was 94%. Anyhow, using 10 mL instead of 5 mL did not result in such a big increase in recoveries that it would be beneficial to use that much solvent with regard to environmental and financial reasons. Hence, 5 mL was used in the process of validation.

Because the target compounds have various functional groups, optimization of the pH of the extraction was indispensable. At first extraction from water, 0.1 v/v % formic acid, and 0.1 v/v % ammonia solutions to acetonitrile as the organic phase were tested. Without pH modification lower recoveries were reached than with either formic acid or ammonia solution. Acidic condition provided the best recoveries for Irganox 3790, Irganox 3114, and Tinuvin 326. In this medium recoveries were <70% for Irganox 565, Cyasorb UV-1164, and Irgafos 168. Recoveries were >75% with ammonia solution for every compound. Because an alkaline environment gave acceptable recoveries for the biggest number of target compounds, milk samples were set to pH 9, 11, and 13 with NaOH (Figure 3). At pH 13 recovery for Tinuvin 234 was 77%. At pH 9 it was 73% as well as for Irgafos 168. pH 11 was found to be the most suitable for the extraction of most analytes: it provided >84% recoveries for all of the compounds. For further studies pH 11 was applied.

On the basis of these results 50 μL of a $2 \times 10^{-2}$ mol/L NaOH solution was added to milk samples to adjust the pH for extraction. To reach the highest recoveries, 5 mL of tetrahydrofuran was used for the extraction.

The efficiency of low-temperature purification was tested by measuring the dry residue weight of the tetrahydrofuran extracts before and after the purification. In the case of 1.5% fat milk, the dry residue of a given amount of extract before low-temperature purification is 1.67 mg; that of the same amount of extract after low-temperature purification is 1.39, so the decrease (0.28) is 16.7% of the original dry residue weight (1.67).

**Matrix Effect.** Measurement error originating from ion suppression/enhancement can be eliminated by using internal standards or matrix calibration. Isotope-labeled internal standards offer an expensive way to decrease the matrix effects; moreover, for our target compounds we could not find any in commercial trade. Nonlabeled internal standards ought to resemble the corresponding target compound regarding ionization efficiency, functional groups, polarity, and retention time. Finding suitable nonlabeled internal standards that meet all of the mentioned criteria is almost impossible. On the other hand, matrix calibration is a time-consuming technique, so after minimization of the matrix effect, it is worthwhile to test external calibration first.

Instead of dilution lower matrix effect can be obtained by applying lower injection volumes; 1, 2, and 5 μL of injected volume were tested (Figure 4). Significant ion enhancement was experienced in the cases of Irganox 565, Cyasorb UV-1164, and Tinuvin 1577. By contrast, ion suppression took place in the case of Tinuvin 234. With 1 μL injection volume, the matrix effect could be decreased to 116% in the case of Tinuvin 1577, to 135% in the case of Irganox 565, and to 111% in the case of Cyasorb UV-1164. For the remaining compounds decreasing the matrix amount (i.e., injection volume) did not result in remarkable changes. One microliter injection volume was chosen.

**Method Validation.** Specificity was found to be satisfactory without any chromatographic interference at the retention time of the compounds. MRM chromatograms for negative milk and spiked negative milk samples are shown in the Supporting Information (Figures S3−S13).

**External Calibration.** Validation data obtained with external calibration are summarized in Table 3. Calibration curves ranged from 125 μg/kg to 25 mg/kg. The lowest determination coefficient was 0.9904 (Irganox 565). Parameters of the calibration curves are given in the Supporting Information (Table S1). The MDLs were in the range from 2.5 to 25 μg/kg. These detection limits are at least 1 order of magnitude lower than the corresponding SMLs.

Using external calibration, no significant effect of the fat content of the milk samples on accuracy and precision was observed. Good accuracy and precision values were obtained for Tinuvin P, Tinuvin 326, Irganox 3114, Irganox 3790, and Tinuvin 234 with both types of milk samples (1.5 and 3.5% fat contents). In this group the lowest accuracy was 89%, whereas

[a]MDL, method detection limits.

the highest was 100%. For these components the highest RSD was 12% (for Irganox 3114). For Tinuvin 327 the accuracies were between 75 and 81% and the RSD values between 10 and 12%. On the basis of the goal of the measurement, these values can also be acceptable.

For Irganox 565, Cyasorb UV-1164, Tinuvin 1577, and Irganox 1010 the accuracies were >110% due to matrix effects. For Irgafos 168 the accuracy was <70% due to ion suppression. Because of these unsatisfactory results external calibration is not applicable for the measurement of Irganox 565, Cyasorb UV-1164, Tinuvin 1577, Irganox 1010, and Irgafos 168. Anyhow, even for these compounds external calibration is suitable for screening of migration problems. On the other hand, the method was successfully validated for Tinuvin P, Tinuvin 234, Tinuvin 326, Tinuvin 327, Irganox 3114, and Irganox 3790 using external calibration and 1 μL injection volume. For these compounds MDLs were lower than the SML values in Regulation 10/2011/EC by 3 orders of magnitude.

**Matrix Calibration.** Validation data obtained with matrix calibration are summarized in Table 4. Calibration curves ranged from 25 μg/kg to 2.5 mg/kg. The lowest determination coefficient was 0.9914 (Irganox 3114) Parameters of the calibration curves are shown in the Supporting Information (Table S1). Due to the larger injection volume (and signal enhancement for some compounds) the MDLs were lower than in the case of external calibration.

Matrix calibration provided excellent accuracies and RSD values for milk samples containing 1.5% fat. Accuracies were between 93 and 109%, and RSD values were <13%. Using the matrix calibration on 3.5% fat milk at 100 μg/kg and 1 mg/kg concentrations, the accuracies were between 82 and 108% and the RSD values were <12% which are also acceptable.

Although liquid−liquid extraction combined with low-temperature purification provided good recoveries, the matrix effect still caused some difficulties regarding accuracy and precision. Because of the lack of isotope-labeled internal standards both external and matrix calibrations were tested. For Irganox 565, Cyasorb UV-1164, Tinuvin 1577, Irganox 1010, and Irgafos 168 acceptable accuracy and precision could be achieved only using matrix calibration. However, for all of the compounds MDLs were lower than the SML values in Regulation 10/2011/EC by 1−3 order(s) of magnitude. As a result, the presented analytical method using matrix calibration can be advised for determination of all targeted compounds (Cyasorb UV-1164, Irgafos 168, Irganox 1010, Irganox 3114, Irganox 3790, Irganox 565, Tinuvin 1577, Tinuvin 234, Tinuvin 326, Tinuvin 327, and Tinuvin P) in milk samples. With external calibration it can be used for the determination of Irganox 3114, Irganox 3790, Tinuvin 234, Tinuvin 326, Tinuvin 327, and Tinuvin P, whereas it can be used for the screening of Irganox 565, Cyasorb UV-1164, Tinuvin 1577, Irganox 1010, and Irgafos 168.

Millipore (Billerica, MA, USA). Trifluoroacetic acid, HPLC grade, was purchased from Sigma-Aldrich (St. Louis, MO, USA). MALDI matrix (sinapinic acid) was obtained from BrukerDaltonik GmbH (Bremen, Germany) (purity of 99%).

**Procyanidin B3 Synthesis.** Procyanidin B3 was obtained by hemisynthesis between (+)-taxifolin and (+)-catechin.[12] Taxifolin (100 mg, 0.986 mmol) and catechin (186 mg, 1.58 mmol) were dissolved in ethanol (20 mL), and this solution was degassed under Ar for 10 min. A sodium borohydrate solution previously degassed under argon was dropped under not oxidized conditions (Ar), and the solution was left for 15 min under magnetic agitation. After that, degassed (Ar) distilled water (13.5 mL) was added and the pH was adjusted to 4.5 using an acetic acid 5% v/v solution. Finally, procyanidin B3 was extracted with ethyl acetate and purified by Toyopearl gel column according to previous experiments.[13] The B3 obtained had a purity >90% determined by LC-MS.

**Saliva Collection and Treatment.** Saliva was collected from three healthy nonsmoking volunteers, and they were named saliva A, saliva B, and saliva C. Triplicates were collected for each saliva sample. The saliva samples were mixed with 10% TFA (final concentration = 0.1%) to precipitate several high molecular weight salivary proteins (such as $\alpha$-amylases, mucins, carbonic anhydrase, and lactoferrin) and to preserve sample protein composition (histatins, PRPs, and statherins), because TFA partially inhibits intrinsic protease activity. After centrifugation (8000$g$ for 5 min), supernatant was separated from the precipitate and used for the following experiments.

**HPLC-UV Saliva Analysis.** Saliva samples were analyzed by HPLC-DAD prior to mass spectrometry analysis according to previous studies.[11,14] An HPLC-DAD Elite Lachrom system (L-2130) equipped with a Vydac C8 column, with 5 $\mu$m particle diameter (column dimensions 150 × 2.1 mm), was used. Detection was carried out at 214−280 nm, using a diode array detector (L-2455). The HPLC solvents were (eluent A) 0.2% aqueous TFA and (eluent B) 0.2% TFA in ACN/water 80:20 (v/v). The gradient applied was linear from 10 to 40% (eluent B) in 60 min, at a flow rate of 0.30 mL/min. After this first elution program, the column was washed with 100% eluent B for 20 min to elute S-type cystatins and other late-eluting proteins. After washing, the column was stabilized in the initial conditions.

**Mass Spectrometry Analysis.** Mass spectrometry analysis was used to identify salivary proteins and to assess the tannin−protein aggregate formation. The method described as follows is based on that of a previous study.[17]

**ESI-MS Analysis.** An aliquot of each assay was injected by flow injection analysis (FIA) into an LTQ-OrbitrapXL mass spectrometer, from ThermoFisher Scientific (Waltham, MA, USA). Sample was pumped at 5 $\mu$L/min using nitrogen as sheath gas at a flow of 5 (arbitrary unit system). Electrospray conditions from 3 kV spray voltage, 270 °C capillary temperature, and tube lens are established at 100 V at optimal analysis conditions. Samples were diluted into a methanol/acetonitrile/TFA 0.01% (5:5:90 v/v) mixture 1:10 prior to analysis. Xcalibur 2.2 software was used to control the analysis and to interpret the data obtained. Because proteins acquire different charge states in the interface, after the mass spectrometry analysis, spectra were subjected to a deconvolution process using the charge ratio analysis method (CRAM) by MagTram 1.03 software.

**MALDI-TOF Analysis.** One microliter of saliva or tannin−saliva sample (dilution 1:10) was applied onto a stainless steel target plate (MTP 394 target plate Ground steel BC, BrukerDaltonik GmbH), overlaid with 1 $\mu$L of matrix solution containing 10 mg/mL sinapic acid in acetonitrile, water, and TFA (50:47.5:2.5, v/v), and finally air-dried. Samples were spotted in triplicates.

Mass spectra were automatically acquired on an UltrafleXtream MALDI-TOF-TOF mass spectrometer (BrukerDaltonics) operating in linear positive ion detection mode with laser SmartBeam-III and under FlexCompass 1.4 software control (BrukerDaltonics). For each sample the mass spectra (range from 500 to 50 000 Da) of 1000 laser shots were accumulated with 2000 Hz frequency.

**B3−Human Salivary Protein Aggregation.** Three different salivas (A, B, and C) were mixed with procyanidin B3. The differences in salivary protein profiles between samples were evaluated by HPLC. Further aggregation was studied by mass spectrometry (ESI-MS and MALDI-TOF). This experimental study was designed to establish differences in the aggregation process between salivas with different protein profiles and tannin at different concentrations. Differences in B3−salivary protein aggregates were established at two tannin concentrations (0.5 and 1 mg/mL procyanidin B3). Saliva A and saliva C were treated with 0.5 and 1 mg/mL B3, respectively, whereas saliva B was treated with both B3 concentrations. For all assays, 50 $\mu$L of B3 was added to 150 $\mu$L of saliva sample. After vortexing for 5 min, the samples were maintained for 30 min at room temperature prior to analysis.

**Kinetics Stability of Tannin−Protein Aggregates.** Fifty microliters of B3(1 mg/mL) was added to 150 $\mu$L of saliva C to study the aggregates tannin−salivary protein and follow their evolution in time after 1, 6, and 20 h.

All binding assays were analyzed in triplicates both by MALDI-TOF and by ESI-MS. Results obtained by FIA-ESI-MS were submitted to a deconvolution process. Blank subtraction with saliva control was made prior to the introduction of data into the MagTram software. Thus, the information obtained by ESI-MS was simplified, and the tannin−salivary protein complex deconvolution mass spectra became clearer.

Phyton is a program language that is used in a wide variety of application domains, often in mass spectrometry to compare or handle spectra.[15] It was employed as an identification bioinformatic tool to elucidate the structure of new tannin−protein aggregates. In this case, Phyton was used to reckon the different links between the different tannins assayed and the salivary proteins. This software works by matching the new $m/z$ values with the different protein $m/z$ values present in the control and each tannin added $m/z$ value. Adducts and loss of ions such as $H_3O^+$ or $NH_4^+$ as well as reduction or oxidation processes have been considered. After running Python, several matches were hypothesized for each assay. Only the aggregate identifications matched by the two analytical techniques used (MALDI-TOF and ESI-MS) were considered. MALDI-TOF sensitivity decreased as higher analysis ratios were used. When B3−salivary protein aggregate stability was evaluated over time, higher aggregates were formed; thus, this phenomenon was worsened. ESI-MS was, therefore, the main technique chosen to discern the evaluation of aggregates formed over time.

**Statistical Treatment.** All data values obtained empirically were treated statistically to observe significant differences. Graphpad Prism 6.1 was the software used in data statistical treatment. The Tukey test was used to establish differences in a single-step multiple comparison (it compares every mean with every other mean). The Tukey test gave a more precise value for scatter (mean square of residuals), which was reflected in more degrees of freedom. When mean A is compared to mean C, the test compares the difference between means to the amount of scatter, quantified using information from all of the groups, not just groups A and C. This gives more power to detect differences and made sense under the assumption that all of the data are sampled from populations with the same standard deviation, even if the means were different.

## RESULTS

The aggregation between procyanidin B3 and human saliva (A, B, C) with different protein profiles was studied by mass spectrometry.

Figure 1 shows the overlaid chromatographic protein profile (HPLC-DAD) of salivas A, B, and C. After HPLC-DAD analysis, some chromatographic differences were evident between the different salivas. The chromatographic protein profile was identified on the basis of previous studies.[14] The different groups of proteins appeared characterized in the chromatogram by different parts according to their elution times. The first eluted peaks constituted the bPRPs (20−30 min), the second eluted peaks corresponded to gPRPs (30−35 min), the third chromatographic zone corresponded to aPRPs (45−50 min), and the last one contained the statherins (Stath) (60−65 min). Histatins (His) eluted at different retention times along the chromatogram, but they are mainly embedded at times around 40 and 55 min.[12,14]

The salivary protein content is described in Table 1 for all samples analyzed. Several quantitative changes were observed between saliva samples. The salivary protein content was expressed as relative percentage area values. To compare the relative protein concentrations between saliva samples, saliva B was considered as being 100% due to its highest chromatographic peak area. Significant differences in the salivary proteins were observed between samples. Saliva A and saliva C have relative amounts of 10.25 and 75.44% of saliva B, respectively. In saliva A, the aPRPs comprised the group of salivary protein with higher area values followed by statherins, bPRPs, gPRPs, and histatins. However, in saliva B and C, the bPRPs was the salivary protein with higher area followed by gPRPs, aPRPs, statherins and histatins (Table 1).

**Table 1. Percent Area of Salivary Proteins (PRPs, Statherins, and Histatins) from Three Different Saliva Samples (A, B, and C)**

| | | saliva A | saliva B | saliva C |
|---|---|---|---|---|
| PRPs | bPRPs | 18.31 | 39.27 | 37.15 |
| | gPRPs | 14.75 | 31.93 | 31.97 |
| | aPRPs | 33.73 | 18.34 | 19.97 |
| histatins | | 9.66 | 2.73 | 1.59 |
| statherins | | 23.55 | 7.73 | 9.32 |
| total salivary proteins (referred to saliva B[a]) | | 10.25 | 100 | 75.44 |

[a]Saliva B was considered as being 100% due to its highest chromatographic area.

The soluble B3−salivary protein aggregates formed with these three saliva samples were characterized by mass spectrometry. MALDI-TOF was used to identify the B3−salivary protein spectra profile, and all data results were confirmed by ESI-MS.

Forty-eight soluble B3−protein aggregates were identified (Supporting Information Table S1). The major soluble B3−protein aggregates according to the MALDI-TOF spectrum profile for saliva B are shown in Figure 2. Twenty-three major B3−salivary protein aggregates and some adducts are shown in the mass spectra. The majority of B3−salivary protein aggregates are embedded in the $m/z$ 8000−16000 range (1−13 aggregates) and the $m/z$ 20000−22000 range (14−23 aggregates). The majority of aggregates had His in their composition (mass peaks 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 19, and 22). Mass peaks 1, 4, 7, 10, 14, 20, 22, and 23 had bPRPs in their composition, and mass peaks 5, 10, 12, 13, 15, 17, 19, and 23 were formed by Stath. aPRPs and gPRPs are supposed to be part of only two major aggregates, 18 and 21 and 2 and 23, respectively.

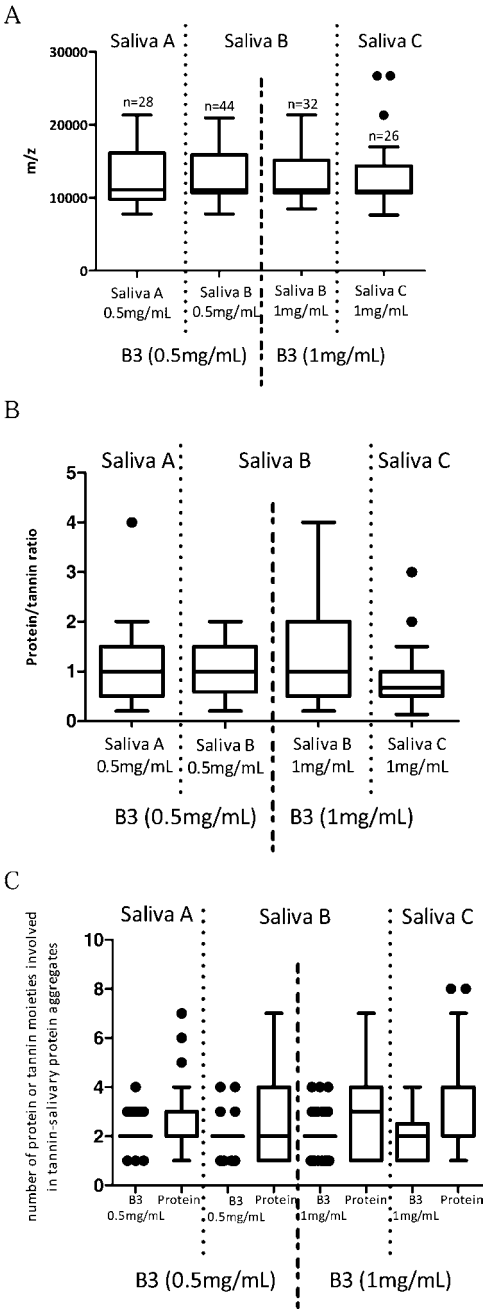

**Figure 3.** B3−salivary protein aggregates comparison between different salivas at different tannin concentrations: number and molecular mass of aggregates (A); protein/tannin ratio (B); number of proteins or tannins involved in aggregate formation (C).

Figure 3A shows the differences of number and molecular mass of all soluble B3−salivary protein aggregates identified after statistical data treatment. All aggregates had molecular masses in the range from 8000 to 25000 Da. The median molecular mass of soluble B3−salivary protein aggregates formed was the same regardless of the saliva sample and tannin concentration tested (≈11000 Da). Nevertheless, little differences can be observed. At higher B3 concentration, saliva B yielded B3−salivary protein aggregates with higher molecular weight mass range than saliva C except the three aggregates (symbolized by points)

dx.doi.org/10.1021/jf5033284 | J. Agric. Food Chem. 2014, 62, 10038−10045

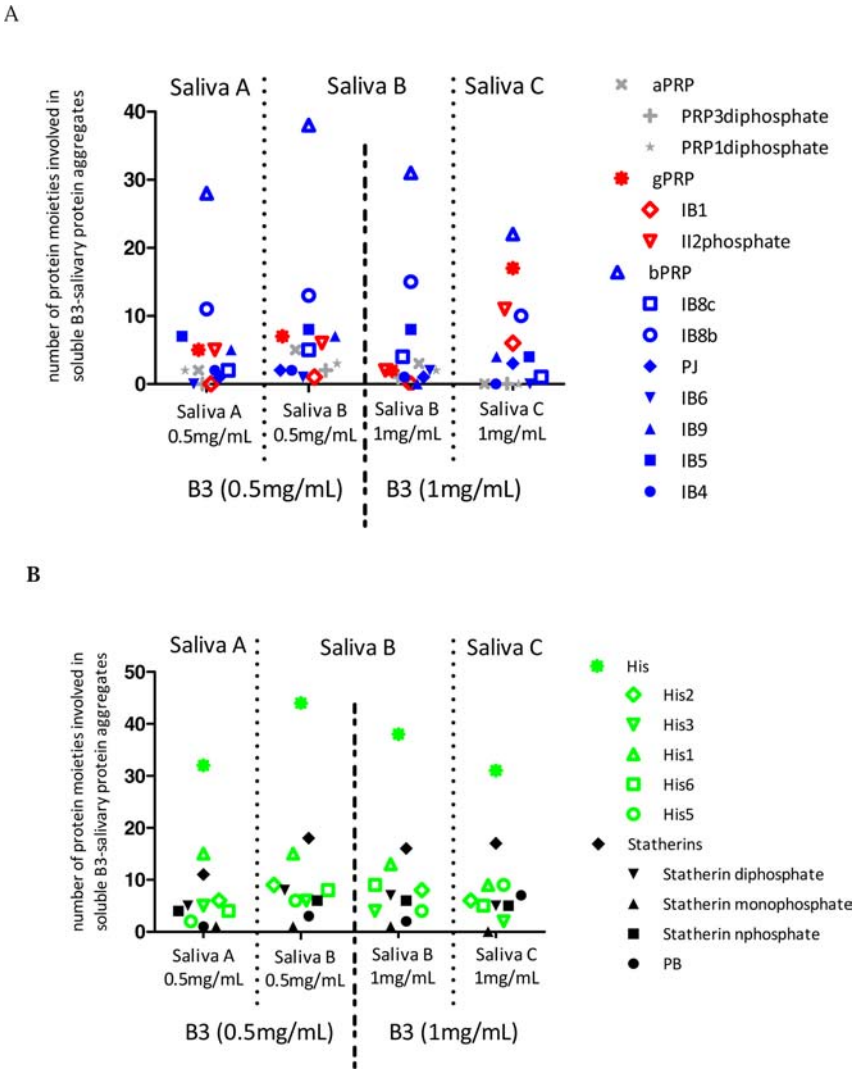

**Figure 4.** B3−salivary protein aggregates between different salivas at different tannin concentrations: occurrence of PRPs (A) and histatins and statherins (B). aPRP, acidic proline-rich protein; PRP3diphosphate, proline-rich protein 3 diphosphate; PRP1diphosphate, proline-rich protein 1 diphosphate; gPRP, acidic proline-rich protein; IB1, glucosidic proline-rich peptide IB1; II-2phosphate, glucosidic proline-rich peptide II-2phosphate; IB8c, basic proline-rich peptide IB8c; IB8b, basic proline-rich peptide IB8b; PJ, basic proline-rich peptide PJ; IB6, basic proline-rich peptide IB6; IB9, basic proline-rich peptide IB9; IB5, basic proline-rich peptide IB5; IB4, basic proline-rich peptide IB4; His, histatins; His2, histatin 2; His 3, histatin 3; His 1, histatin 1; His 6, histatin 6; His 5, histatin 5; PB, statherin peptide PB.

that appeared disperse with a molecular mass ≥20000. At lower B3 concentration, no differences were observed in the size of aggregates formed. Furthermore, no difference was observed in the molecular mass of the aggregates identified when two different tannin concentrations were tested (saliva B). Even though little or no differences were observed in the molecular mass, several differences were observed in the amount of aggregates identified. Forty-four aggregates were identified in saliva B, whereas saliva A yielded only 28 soluble B3−salivary protein aggregates at low tannin concentration. At higher tannin concentration, saliva B yielded 32 soluble B3−salivary protein aggregates and 26 were identified in saliva C.

The differences in protein/tannin ratio depending on the saliva or tannin concentration tested are shown in Figure 3B. At lower tannin concentration (0.5 mg/mL B3), there were no significant differences in protein/tannin ratio of soluble B3−salivary protein aggregates regardless of the saliva tested. Nevertheless, at higher tannin concentration (1 mg/mL B3) the median protein/tannin ratio of soluble B3−salivary protein aggregates yielded with saliva C was lower than those obtained with saliva B. Moreover, at higher B3 concentration, the range of protein/tannin ratio was higher for saliva B. The protein/tannin ratio reached values rounding 4, whereas saliva C did not achieve a value of 2. The protein/tannin ratio of soluble B3−salivary protein aggregates tended to be higher with higher tannin concentration when the same saliva was tested (Figure 3B).

As described in Figure 3C, the number of tannin and protein moieties involved in soluble B3−salivary protein aggregate formation at lower B3 concentration was almost the same. At higher tannin concentration (1 mg/mL), the number of protein moieties was higher than the number of B3 units in the aggregate formation either in different salivas or in the same saliva.

As aforementioned, the major aggregates had His in their composition, followed by bPRPs. Figure 4 shows the occurrence of salivary proteins in soluble B3−salivary protein aggregates depending on the saliva and/or tannin concentration used. No differences were found in salivary proteins that yielded the majority of soluble B3−salivary protein aggregates either with different

saliva or with different tannin concentrations. The protein group with higher occurrence in soluble B3−salivary protein aggregates was the His followed by bPRPs, Stath, gPRPs, and aPRPs.

**Time Stability of Soluble B3−Human Salivary Protein Aggregates.** Aggregation between B3 and salivary proteins was studied by mass spectrometry analysis (ESI-MS and MALDI-TOF) over time. MALDI-TOF and ESI-MS spectra showed trending for new mass peaks to appear at higher molecular mass range (data not shown). The aggregates formed during reaction time are described in Table S2 in the Supporting Information. Figure 5 shows the evolution over time in terms of number and molecular mass of the aggregates formed, protein/tannin ratio, and the scrutiny of proteins and tannin moieties involved in the formation of B3−human salivary protein aggregates. After 1 h of incubation time at room temperature, the number of aggregates found in saliva C increased from 26 to 42; it further increased exponentially after 6 h, leading to a maximum of 166 B3−human salivary protein aggregates, and it went down to 130 at 20 h. The median of molecular mass of aggregates also experienced some changes over time. Most of the aggregates decreased their size from 11000 to 7500 Da during the first hour of incubation time. At 6 h their size increased to a median of 18000 Da, and it further decreased to 13000 Da after 20 h of incubation. Although the median molecular mass followed a path first decreasing, increasing, and then decreasing once again, the trend was to form higher aggregates with time, but these aggregates appeared statistically scattered (symbolized by points) (Figure 5A).

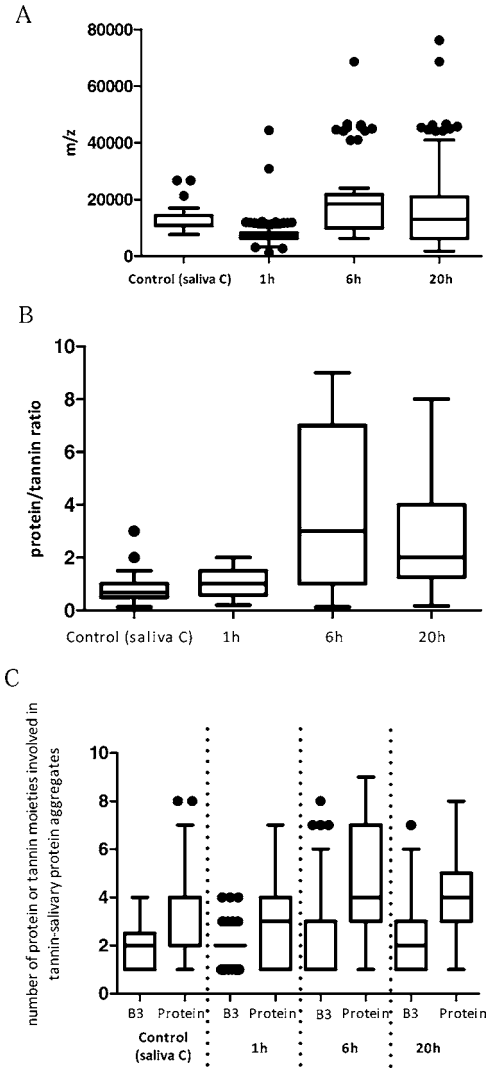

**Figure 5.** B3−salivary protein aggregate stability over time: number and molecular mass of aggregates (A); ratio protein/tannin (B); number of proteins or tannins involved in aggregate formation (C).

It should be noted that after 6 h, slight turbidity was observed in samples, probably resulting from the formation of insoluble complexes, and the homogeneity of samples was lost.

The number and molecular mass of aggregates has evolved over time, leading to new B3−human salivary protein aggregates, but some stable complexes were maintained over time. After 6 h of incubation time, six B3−salivary protein complexes did not evolve, appearing at the same signal spectra; they are the B3−statherin n-phosphate, 6B3−His6, B3−IB9, 3B3−statherin n-phosphate, 5B3−statherin monophosphate, and 4B3−PJ. At 20 h only two aggregates were maintained, the B3−IB9 ($m/z$ 6623) and 3B3−statherin n-phosphate ($m/z$ 6992).

On the other hand, the trend after 6 h was for major aggregates to be composed of more than five proteins and only one or two tannin moieties. The median protein/tannin ratio of B3−salivary protein aggregates was maintained from control to 1 h, then it increased to a maximum median value at 6 h, and finally decreased after 20 h of incubation (Figure 5B). These differences in protein/tannin ratio of B3−salivary protein aggregates are given by the change in protein moieties involved in B3−salivary protein aggregate formation among time (Figure 5C). As Figure 5C shows, the trend is to increase the number of protein moieties involved in aggregation process from control to 1 and 6 h, and then the number of protein moieties involved in B3−salivary protein aggregates was maintained until 20 h of incubation. On the other hand, the number of tannin moieties involved in aggregation changed only at 6 h, decreasing to a median value of 1 per soluble aggregate.

Figure 6 shows the scrutiny of proteins involved in aggregate formation. From control to 1 h no difference was observed in the scrutiny of proteins involved in the aggregate formation. The protein group with higher occurrence in B3−salivary protein aggregates was His, followed by bPRPs, Stath, gPRPs, and aPRPs. After 6 h, His are no longer the group of proteins with higher occurrence in the soluble B3−human salivary protein aggregates. The bPRPs became the group of proteins that yielded higher number of aggregates followed by Stath. Furthermore, most of the aggregates were only formed, in descending order, by IB8b, His6, PRP3diphosp, Stath monophosphate, Stath n-phosphate, IB9, peptide PB, and peptide PJ. After 20 h, most of the aggregates were formed by the same proteins but the order was altered. The proteins involved in higher number of aggregates after 20 h were, in descending order, PB, PJ, His6, IB9, Stath monophosphate, IB8b, Stath n-phosphate, and PRP3diphosp, respectively.

## ■ DISCUSSION

Individual chromatographic differences between samples were verified from salivas A, B, and C. This fact could influence differences in the B3−salivary protein aggregation process at the two tannin concentrations tested (0.5 and 1 mg/mL). The median molecular mass rounded 11000 Da regardless of the saliva or tannin concentration used. Several differences were found in the number of aggregates formed at different tannin concentrations and saliva samples tested. In general, it could be assumed that the number of soluble aggregates formed was higher at lower B3 concentration. On the other hand, a higher number of aggregates was observed at higher salivary protein

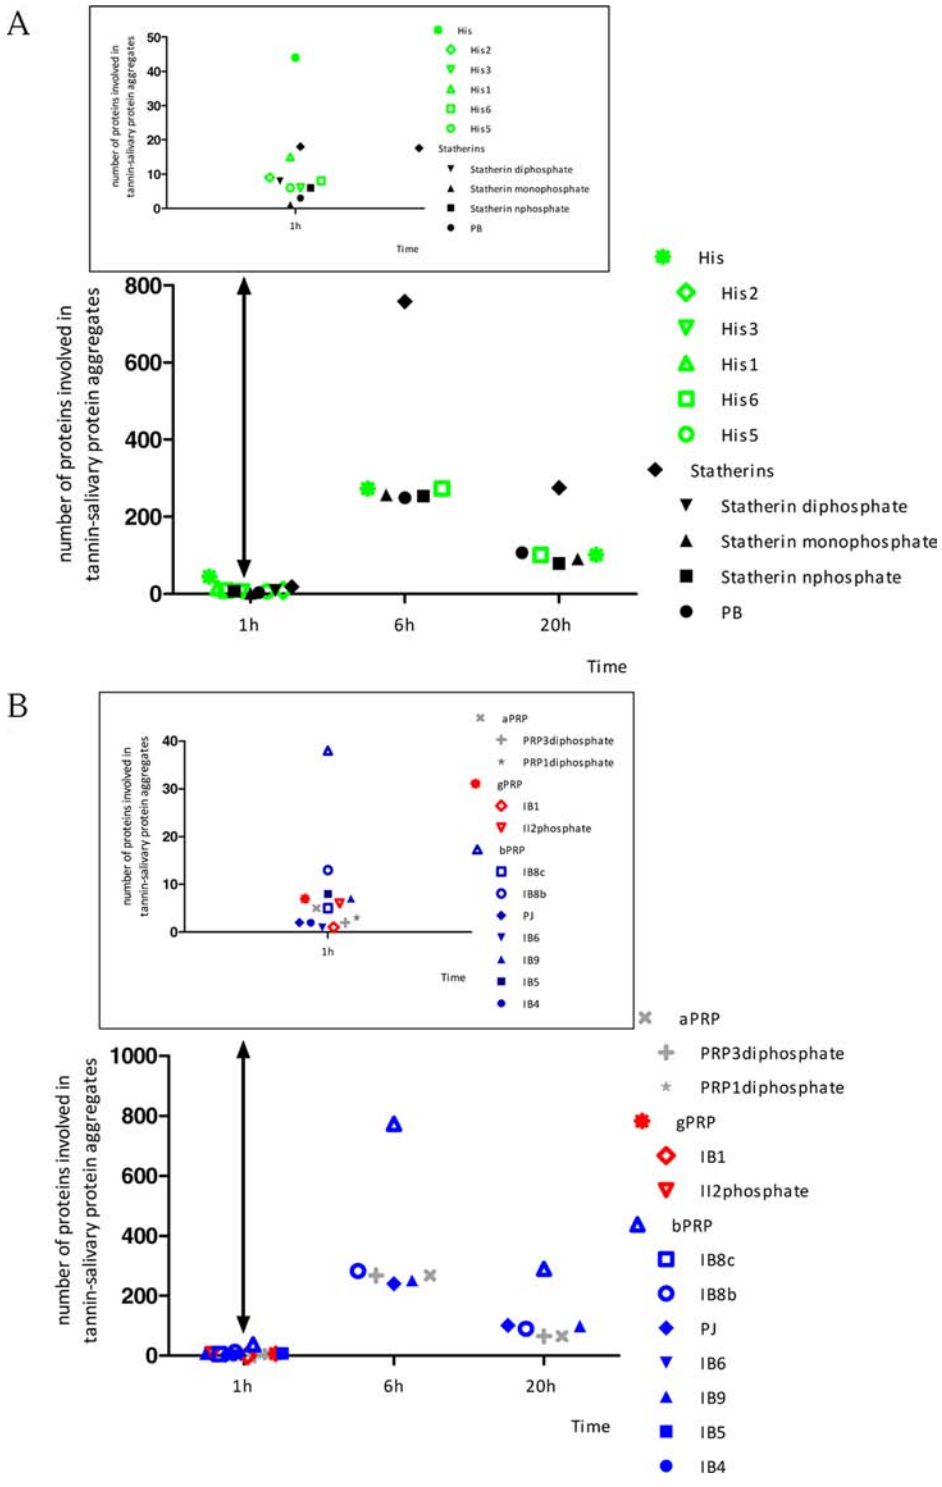

**Figure 6.** B3−salivary protein aggregates stability over time: occurrence of PRPs (A) and histatins and statherins (B). aPRP, acidic proline-rich protein; PRP3diphosphate, proline-rich protein 3 diphosphate; PRP1diphosphate, proline-rich protein 1 diphosphate; gPRP, acidic proline-rich protein; IB1, glucosidic proline-rich peptide IB1; II-2phosphate, glucosidic proline-rich peptide II-2phosphate; IB8c, basic proline-rich peptide IB8c; IB8b, basic proline-rich peptide IB8b; PJ, basic proline-rich peptide PJ; IB6, basic proline-rich peptide IB6; IB9, basic proline-rich peptide IB9; IB5, basic proline-rich peptide IB5; IB4, basic proline-rich peptide IB4; His, histatins; His2, histatin 2; His 3, histatin 3; His 1, histatin 1; His 6, histatin 6; His 5, histatin 5; PB, statherin peptide PB.

concentration (area values). The results presented herein also confirmed that for the same saliva sample at higher tannin concentration, the number of protein moieties involved in B3−salivary protein aggregate formation was also higher. These results are in agreement with previous studies. Cannon et al.[8] verified that at lower tannin concentrations at least, half of the protein added did not bind to tannin. According to Lorenz et al.,[16] increasing the tannin concentration decreases the protein solubility, so this fact could complicate the formation of a higher number of aggregates.

dx.doi.org/10.1021/jf5033284 | J. Agric. Food Chem. 2014, 62, 10038−10045

The protein and/or tannin selectivity was also verified regardless of the saliva samples and tannin concentration tested. The same group of salivary proteins yielded the higher number of aggregates despite some salivary protein chromatographic differences between samples. These results are in agreement with previous studies because His was the group of proteins that produced a higher number of aggregates when saliva was treated with B3.[17] Although His was the group of proteins that formed a higher number of soluble B3−salivary protein aggregates studied by mass spectrometry, it should be pointed out that Stath and aPRPs were the more reactive groups of proteins and led to a higher precipitation to form insoluble complexes.[14,18]

Stability over time was also studied showing that the B3−salivary protein aggregates evolved in time. After 1 h of incubation, the trend was to decrease the molecular mass of the B3−salivary protein aggregates. It is well-known that protein−tannin noncovalent aggregation is a reversible process in aqueous models.[19−21] After 1 h, new B3−salivary protein aggregates were formed, whereas the first B3−salivary protein aggregates were broken up. The trend after 6 h within the following 20 h was to increase the number of protein moieties involved in the aggregation process, and only a few aggregates were maintained. These results are in agreement with previous studies in which the number of protein moieties forming aggregates increased over time.[8] On the other hand, it should be noted that the group of proteins involved in aggregates changed over time. Whereas His was the protein group with higher selectivity from the initial aggregation process to 1 h, after 6 h, the bPRPs and Stath yielded the higher number of aggregates. Hence, the B3−salivary protein aggregates changed not only in number but also in the type of proteins involved in their composition. The results presented herein highlight the effect of the tannin concentration in the formation of different soluble B3−salivary protein aggregates. Furthermore, the individual effect of the different salivas has been exhibited. The differences in B3−salivary protein aggregates were based primarily in the number of complexes formed and hence not their molecular masses. Moreover, the protein/tannin ratio barely varied between different saliva samples or tannin concentration, but the number of tannin moieties involved in the aggregation process was higher at higher B3 concentrations.

On the other hand, the evolution of B3−salivary protein was revealed because a higher number with higher size was formed and their stoichiometry also changed over time.

more, the most abundant tea catechin, EGCG, has also been shown to exhibit hepatoprotective effects against liver injury by ethanol and carbon tetrachloride ($CCl_4$)-induced liver injury.[14,15] To the best of our knowledge, most studies on EGCG3″Me have focused on its antioxidant and inhibitory activities to allergies, and little information about the hepatoprotective effect of EGCG3″Me against alcohol-induced toxicity is available. Therefore, the main objective of the present study was to evaluate the hepatoprotective effects of EGCG3″Me. First, high-purity EGCG3″Me was prepared through extraction from Chinese oolong tea and simple purification procedures by using polyamide and Toyopearl HW-40S column chromatography. Then, the hepatoprotective effects of EGCG3″Me were evaluated by the antioxidant and hepatoprotective activity in alcohol-induced hepatotoxicity in the HepG2 cell line and mice.

## MATERIALS AND METHODS

**Chemicals.** Toyopearl HW-40S resin was purchased from Tosoh Corp. (Tokyo, Japan), and polyamide resin was obtained from Qingdao Ocean Chemical Co., Ltd. (Qingdao, China). 2,2-Diphenyl-1-picrylhydrazyl (DPPH) and 2,2′-azinobis(3-ethylbenzothiazoline-6-sulfonic acid) diammonium salts (ABTS) were obtained from Sigma Chemical Co. (St. Louis, MO, USA). 2,4,6-Tri(2-pyridyl)-*s*-triazine (TPTZ) was obtained from Fluka (Buchs, Swiltzerland). Standards of EGCG and EGCG3″Me were prepared according to our reported methods.[16,17] Human hepatic cancer HepG2 cells were obtained from the Cell Bank of Shanghai Institute of Cell Biology (Shanghai, China). 3-(4,5-Dimethylthiazol-2-yl)-2,5-diphenyl tetrazolium bromide (MTT), penicillin, and streptomycin were purchased from Sigma Chemical Co. Fetal bovine serum (FBS), trypsin, and RPMI-1640 media were purchased from Gibco/Invitrogen (Grand Island, NY, USA). Male Kunming mice were obtained from the Experimental Animal Centre of Academy of the Military Medical Sciences (Beijing, China). Analytical kits for aspartate aminotransferase (AST), alanine aminotransferase (ALT), glutathione peroxidase (GSH-Px), superoxide dismutase (SOD), and malondialdehyde (MDA) were obtained from Nanjing Jiancheng Bioengineering Research Institute (Nanjing, China). All other chemicals and reagents were of analytical grade.

**Tea Samples.** Oolong tea was purchased from a local market in Guangzhou, China. The fresh tea leaves picked were given a solar withering process for 2 h, followed by indoor withering for 4 h, and then 5 cycles of hand rolling for 20 min. The final steps consisted of 2 h of fermentation, followed by 5 min of killing, 5 min of kneading, and 5 h of roasting.[18] The oolong tea manufacturing process was replicated five times. After the manufacture, the water content of oolong tea is 4.05 ± 0.24%. The oolong tea sample was ground into powder using a milling machine, and the material that passed through a 40 mesh sieve was kept in sealed polyethylene bags at −20 °C until use.

**Preparation of Tea Catechins.** EGCG and EGCG3″Me were prepared from oolong tea according to the reported method with some modifications.[16,17] Briefly, 2 kg of tea powder was extracted with 32 L of distilled water at 96 °C for 40 min. Upon extraction, the extract was centrifuged at 4500*g* for 15 min, and the resulting insoluble residue was treated again as described above. The supernatants, which were extraction solutions of 2 times, were combined and concentrated by using rotary evaporators under vacuum. The resulting residue was dissolved, filtered, and applied to a column wet-packed polyamide resin. After reaching adsorptive saturation, the column was washed by distilled water and then eluted by 80% ethanol. The effluent of the ethanol solution was collected and concentrated, affording the crude extract for further purification.

The crude extract was dissolved and loaded onto a Toyopearl HW-40S column pre-equilibrated with 80% ethanol. The column was eluted with 80% ethanol, and the elution was monitored by measuring the absorbance at 280 nm and autocollected. The eluted fractions were analyzed by high-performance liquid chromatography with a diode array detector (HPLC-DAD), and the desired fractions were collected, concentrated, loaded onto the Toyopearl HW-40S column, respectively, and treated as described above. As results, the fractions containing EGCG and EGCG3″Me were concentrated and freeze-dried by a freeze-dry system respectively, affording EGCG and EGCG3″Me.

**Analysis and Characterization of EGCG3″Me.** The contents of tea catechins were determined according to the reported method using an Agilent 1100 series HPLC (Agilent, Santa Clara, CA, USA).[17] The separation was achieved on a TSKgel ODS-100Z column (4.6 × 150 mm, 5 μm; Tosoh). The mobile phase consisted of formic acid solution (pH 2.5, A) and methanol (B). Elution was performed with a linear gradient as follows: 0−15 min, A from 82 to 40%. The injection volume was 20 μL. The temperature of column oven was set at 40 °C, and the flow rate was set at 1.0 mL/min.

The structures of tea catechin monomers isolated from oolong tea were characterized by ESI-MS/MS and $^1$H NMR. ESI-MS/MS analysis was performed by using a TSQ Quantum Ultra triple -quadrupole mass spectrometer (Thermo Scientific) in positive mode. The operation parameters of the ESI ion source were as follows: drying gas, $N_2$; temperature, 270 °C; flow rate of drying gas, 4 L/min; pressure of nebulizer gas ($N_2$), 9.0 psi; and capillary voltage, 4 kV. ESI-TOF-MS spectra and $^1$H NMR spectrum were recorded on an Applied Biosystems mass spectrometer. $^1$H NMR spectrum was recorded by a Bruker DRX-500 spectrometer operated at 300 K with $D_2O$ as solvent. Chemical shifts ($\delta$) are given in parts per million, and $J$ values are given in hertz.

**DPPH Assay.** The DPPH free radical scavenging activity of each sample was determined according to the reported method.[19] The percentage of DPPH$^\bullet$ that was scavenged was calculated using

$$\text{scavenging activity (\%)} = (\text{Abs}_{\text{cont}} - \text{Abs}_{\text{samp}})/\text{Abs}_{\text{cont}} \times 100$$

where $\text{Abs}_{\text{cont}}$ is the absorbance of the control and $\text{Abs}_{\text{samp}}$ is the absorbance of the sample. The DPPH free radical scavenging activity was expressed by $IC_{50}$ value, which is the concentration of extract required to decrease the absorbance at 517 nm by 50%. Measurements were performed at least in triplicate.

**ABTS Assay.** The ABTS free radical scavenging activity of each sample was determined according to the method described by Stratil et al.[20] The radical cation ABTS$^{\bullet+}$ was generated by persulfate oxidation of ABTS, and the ABTS$^{\bullet+}$ scavenging rate was calculated to express the antioxidant ability of the sample. $IC_{50}$ values calculated denote the concentration of sample required to decrease the absorbance at 734 nm by 50%.

**FRAP Assay.** The ability to reduce ferric ions was measured using a modified version of the method described by Benzie and Strain.[21] The antioxidant capacity based on the ability to reduce ferric ions of sample was calculated from the linear calibration curve and expressed as millimoles of $FeSO_4$ equivalents per gram of sample (DW).

**Cell Culture.** The human hepatoma cell line HepG2 was cultured in the RPMI-1640 medium supplemented with FBS (10%), penicillin (100 U/mL), and streptomycin (100 μg/mL). This was incubated at 37 °C in a humidified 5% $CO_2$ incubator; cells were diluted to a density of 1 × $10^5$ cells/mL and fed every 2 days with fresh medium. Under these conditions the generation time of HepG2 cells was approximately 36 h. At subconfluence the Petri dishes were carefully washed with serum-free culture medium and treated for the following investigations.

**In Vitro Cytotoxicity Assay.** The $CTC_{50}$ (50% cytotoxic concentration) was determined by estimating mitochondrial synthesis using the tetrazolium assay.[22] Briefly, HepG2 cells were pipetted into a 96-well flat-bottom plate (100 μL/well) at a density of 1 × $10^5$ cells/mL. After 12 h of incubation at 37 °C in a humidified 5% $CO_2$ incubator, nonadherent cells were removed by washing with serum-free culture medium. Then, fresh medium (100 μL/well, control group) or test sample (100 μL/well, EGCG3″Me at a final concentration of 25, 50, 100, or 200 μg/mL) was added to each well, and the cells were incubated for 24, 48, and 72 h, respectively. After incubation, MTT solution (10 μL/well, 5 mg/mL) was added to each well, and the plate was incubated for an additional 4 h at 37 °C.

Finally, 100 μL of 10% sodium dodecyl sulfate (SDS) in 0.01 N HCl was added to each well, and the plate was kept overnight for the dissolution of formazan crystals. The absorbance of each well at 570 nm was measured. The inhibition rate was calculated according to the following formula:

$$\text{inhibition rate (\%)} = 100 - (\text{mean OD of individual test group} / \text{mean OD of control group}) \times 100$$

A concentration−response curve was generated using inhibition rate (%) and EGCG3″Me sample concentration (μg/mL). The $CTC_{50}$ value is calculated from the concentration−response curve.

**Alcohol-Induced Toxicity in HepG2 Cell Line.** To each well of the 96-well flat-bottom plate was added 100 μL of diluted HepG2 cell suspension ($1.0 \times 10^5$ cells/mL). After 12 h, when a partial monolayer was formed, the supernatant was removed and the monolayer was washed once with serum-free culture medium. Bifendate, a synthetic intermediate of schisandrin C with protective effect against drug-induced liver injury in rodents, is often used for the treatment of hepatitis as well as regarded as a positive control for exploring other hepatoprotective drugs.[23] Therefore, bifendate was adopted for the evaluation of the hepatoprotective effect of EGCG3″Me as positive control. The cells were treated with 100 μL of toxicant (medium containing 1% (v/v) alcohol), 100 μL of positive control (medium containing 1% (v/v) alcohol and bifendate (10, 20, and 40 μg/mL)), 100 μL of sample (medium containing 1% (v/v) alcohol and EGCG3″Me (10, 20, and 40 μg/mL)), and 100 μL of control (medium, medium and EGCG3″Me (40 μg/mL)), medium, and bifendate (40 μg/mL) for various time intervals of 3, 6, 12, and 24 h, and the following assays were carried out to observe time-dependent changes.

**Cell Viability.** Cell viability after alcohol treatment was evaluated by using a MTT-based colorimetric method as mentioned under in Vitro Cytotoxicity Assay. Briefly, after the cells were treated with 1% (v/v) alcohol for 24 h, MTT solution was added to each well, and the plate was incubated for an additional 4 h at 37 °C. Finally, 100 μL of 10% SDS in 0.01 M HCl was added to each well, and the plate was kept overnight for the dissolution of formazan crystals. The absorbance of each well at 570 nm was measured, and the viability rate was calculated according to the formula below:

$$\text{viability (\%)} = (\text{Abs}_{\text{samp}}/\text{Abs}_{\text{cont}}) \times 100\%$$

**Biochemical Assays of Alcohol-Induced Toxicity in HepG2 Cell Line.** The 96-well flat-bottom plates were centrifuged at 500*g* for 5 min at 4 °C, and the culture medium and cells were collected separately. The medium (0.2 mL) was used for measuring AST and ALT activities. AST and ALT activities in sera were measured using commercial reagent kits from Nanjing Jiancheng Bioengineering Institute. The level of MDA and activity of GSH-Px in HepG2 cells were also determined by using commercial reagent kits from the same institute according to the instruction manuals.

**Animals and Experimental Design.** The hepatoprotective effect of EGCG3″Me against alcohol-induced acute liver damage in mice was evaluated according to the reported method with proper modifications.[24] Furthermore, all procedures involving animals were conducted in strict accordance with Chinese legislation on the use and care of laboratory animals during the entire experimental period. Male Kunming mice (8 weeks old) with body weights (BW) of about 20 g were used in the present study. They were maintained in a room with a controlled temperature of 22 ± 0.5 °C and a normal day/night cycle and allowed free access to basal pellet diet and tap water.

After adapting to the environment for 7 days, these mice were randomly divided into six groups of eight each: (I) normal control group; (II) alcohol model control group; (III) positive control group; (IV−VI) EGCG3″Me treatment groups. Mice in the normal control group and alcohol model control group were given 1.0 mL of physiological saline and 50% alcohol solution, respectively, once daily. Bifendate and EGCG3″Me were both dissolved in physiological saline. Mice in the positive control group were given 0.5 mL of bifendate (10 mg/kg BW) per day. Mice in EGCG3″Me treatment groups were respectively fed 0.5 mL of EGCG3″Me solution in three different doses (25, 50, and 100 mg/kg BW) once daily. For positive control and EGCG3″Me treatment groups, they were fed 0.5 mL of 50% alcohol solution before given bifendate and EGCG3″Me, respectively. All administrations were conducted by gastric gavage for 14 consecutive days. After 10 h of fasting following the last administration, the mice were killed by decapitation. Blood samples were collected immediately and centrifuged at 3000 rpm for 10 min at 4 °C to afford the sera. The sera were stored at −70 °C until the determination of AST and ALT activities. The liver was excised and homogenized in 0.1 g/mL wet weight of ice-cold physiological saline. The homogenate was centrifuged at 3000 rpm for 10 min, and the supernatant was collected for determination of SOD and GSH-Px activities and the level of MDA.

**Biochemical Assays of Alcohol-Induced Toxicity in Mice.** The activities of AST and ALT in serum and the levels of MDA, SOD, and GSH-Px activities in liver were determined by using commercial reagent kits from Nanjing Jiancheng Bioengineering Institute according to the instruction manuals.

**Histopathological Evaluation.** Livers from mice in different groups were fixed in 10% neutral formalin solution, dehydrated in graded alcohol, and embedded in paraffin. Thin sections of 5 μm thickness of liver tissue were cut and mounted on glass slides and then were counter-stained with hematoxylin−eosin (H&E).[25] Then, thin sections of liver were made into permanent slides and were examined for possible histopathological changes under a high-resolution microscope with photographic facility.

**Statistical Analysis.** Data were analyzed by SPSS and expressed as mean ± standard deviation (SD) for at least three replicates. Significance was determined at $P < 0.05$ by ANOVA followed by Duncan's multiple-comparison tests.

## RESULTS

**Preparation of EGCG3″Me.** In the present study, EGCG3″Me was prepared from Chinese oolong tea by extraction and purification of column chromatography.[17] As shown in Figure 2, peaks 1−13 in the HPLC chromatogram of oolong tea infusion were identified to be gallic acid, (−)-gallocatechin, theobromine, (−)-epigallocatechin, (−)-catechin, theophylline, EGCG, caffeine, (−)-epicatechin, GCG

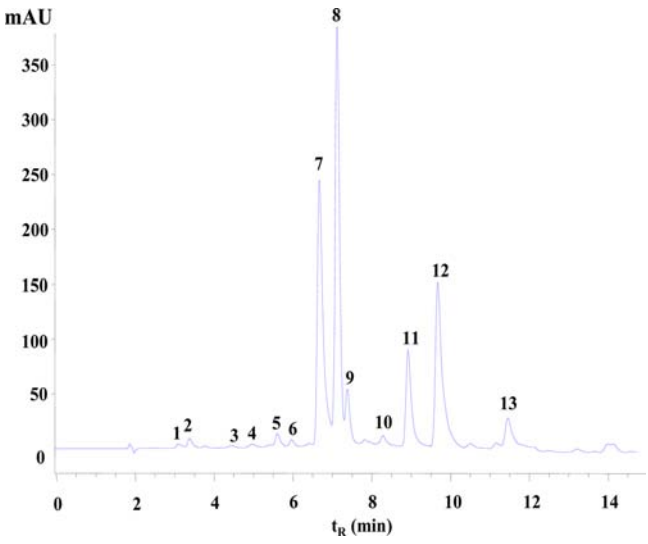

**Figure 2.** HPLC chromatograms of tea catechins, gallic acid, caffeine, theobromine, and theophylline from oolong tea (1, gallic acid; 2, (−)-gallocatechin; 3, theobromine; 4, (−)-epigallocatechin; 5, (−)-catechin; 6, theophylline; 7, EGCG; 8, caffeine; 9, (−)-epicatechin; 10, GCG; 11, EGCG3″Me; 12, (−)-epicatechin gallate; 13, (−)-catechin gallate).

dx.doi.org/10.1021/jf5016335 | J. Agric. Food Chem. 2014, 62, 10046−10054

((−)-gallocatechin gallate), EGCG3″Me, (−)-epicatechin gallate, and (−)-catechin gallate according to the retention times and online DAD spectra of authentic standards. In our previous study, EGCG3″Me as standard was obtained from Japanese green tea. Here, we found that Chinese oolong tea from Guangdong province contained relatively higher contents of EGCG, GCG, and EGCG3″Me. The contents of EGCG, GCG, and EGCG3″Me in Chinese oolong tea and Japanese green tea were 49.6 ± 0.82, 3.26 ± 0.23, and 11.9 ± 0.48 mg/g and 41.7 ± 0.91, 2.05 ± 0.12, and 8.07 ± 0.29 mg/g, respectively. Therefore, the infusion of oolong tea was loaded onto polyamide and Toyopearl HW-40S columns, respectively, affording high purity (>99%) of EGCG3″Me.

The structure of the resulting EGCG3″Me was characterized by ESI-TOF-MS and $^1$H NMR. Positive-mode MS for it gave molecular ion signals at $m/z$ 495.2 for $[M + Na]^+$ and at $m/z$ 473.2 for $[M + H]^+$. The results indicated that its molecular weight is 472.2, corresponding to that of EGCG3″Me.

$^1$H NMR data for EGCG3″Me: 7.01 (1 H, d, H-2″), 6.98 (1H, d, H-6″), 6.49 (2H, s, H-2′, H-6′), 5.87 (1H, d, H-8), 5.83 (1H, d, H-6), 5.56 (1H, s, H-2), 5.35 (1H, bs, 3-OH), 5.24 (1H, d, H-3), 3.82 (3H, s, $OCH_3$), 3.10 (1H, dd, H-4 ax), 2.85 (1H, dd, H-4 equiv).

The $^1$H NMR spectrum was similar to that of EGCG except for the presence of a methoxyl proton signal at $\delta$ 3.82 (3H, s) and two aromatic proton signals at $\delta$ 6.98 (1H, d) and 7.01 (1H, d).[26] On irradiation of the methoxyl proton signal, a nuclear Overhauser effect was observed at the aromatic proton signal at $\delta$ 6.98. From these data it was assumed to be EGCG3″Me and was assigned by comparison of the reported NMR data.[27]

**Determination of Antioxidant Activity of EGCG3″Me.** DPPH free radical scavenging activities of EGCG3″Me and EGCG are shown in Figue 3A. EGCG3″Me showed high scavenging activity on superoxide radical, and it increased with the increase of sample concentration. At concentrations ranging from 0.2 to 0.8 mg/mL, the scavenging activity increased rapidly with the increase of concentration; after that, it increased slowly. The EGCG3″Me showed DPPH radical scavenging activity with an $IC_{50}$ of 0.37 mg/mL. The free radical scavenging activity of EGCG3″Me was less than that of EGCG ($IC_{50}$ = 0.31 mg/mL), which exhibited high antioxidative property.

The antioxidant abilities of EGCG3″Me and EGCG determined by using the ABTS method are shown in Figure 3B. In our results, EGCG exhibited considerably higher activity than EGCG3″Me. In addition, the $ABTS^{\bullet+}$ scavenging rates of EGCG3″Me and EGCG increased with the increase of concentration in our study.

The trends for ferric ion reducing activities of EGCG3″Me and EGCG are shown in Figure 3C. For EGCG3″Me and EGCG, the absorbance increased clearly, due to the formation of the $Fe^{2+}$−TPTZ complex with increasing concentration. Similar to the results of the DPPH and ABTS assays, the reducing activity for EGCG was higher than that of EGCG3″Me.

**Determination of Hepatoprotective Activity of EGCG3″Me.** To ascertain the extent of toxicity caused by 1% of alcohol in HepG2 cells, we quantified the cell viability (Figure 4A) and AST (Figure 4B) and ALT (Figure 4C) levels at various time intervals of 3, 6, 12, and 24 h. MDA formed (Figure 4D) and GSH-Px content (Figure 4E) were also determined. It can be seen that no significant changes in cell

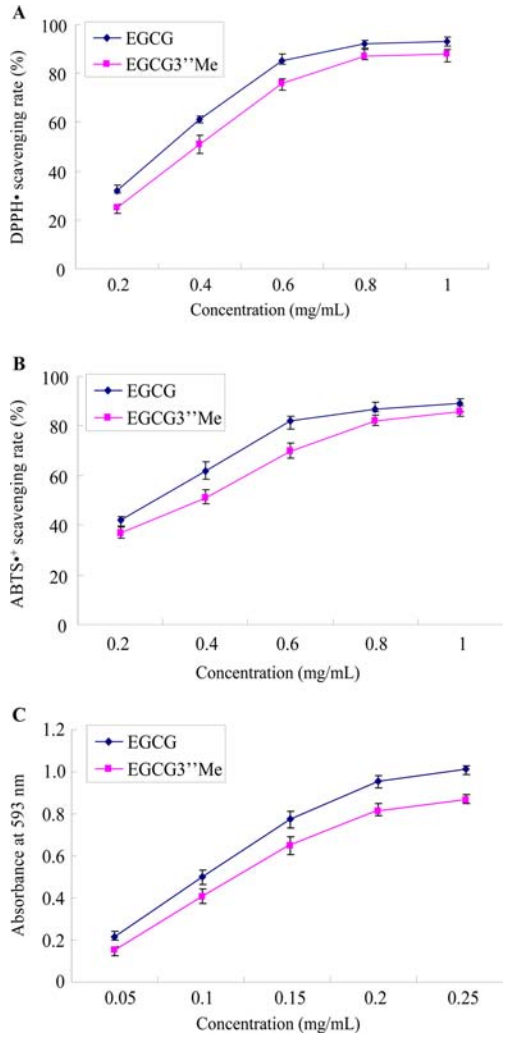

**Figure 3.** Antioxidant activities of EGCG and EGCG3″Me made from Chinese oolong tea determined by DPPH free radical-scavenging assay (A), ABTS assay (B), and FRAP assay (C).

viability, AST and ALT levels, lipid peroxidation, and glutathione depletion were observed until an exposure period of 3 h when compared with normal control, thus overruling any direct solvent-mediated damage by alcohol in HepG2 cells. Thereafter, a time-dependent significant ($P < 0.05$) increased leakage of AST and ALT and loss of cell viability were observed. Similarly, a significant ($P < 0.05$) increased lipid peroxidation with concurrent decrease in GSH-Px content was noted compared with normal control when cells were incubated for 6, 12, and 24 h.

The cytotoxicity of EGCG3″Me was studied by in vitro cytotoxicity assay, and it showed the $CTC_{50}$ value of EGCG3″Me was 94.2, 156, and 190 $\mu$g/mL for 24, 48, and 72 h, respectively, which showed EGCG3″Me had no cytotoxicity for the HepG2 cell line in this study.

Table 1 depicts the protective effect of EGCG3″ and bifendate on alcohol-induced toxicity in the HepG2 cell line. A significant decrease in cell viability and significant increases in AST and ALT levels were observed in HepG2 cells exposed to alcohol as compared with the normal control group. Both EGCG3″Me and bifendate treatments along with alcohol significantly increased the viability of cells. The middle concentration of bifendate (20 $\mu$g/mL) was more effective

[a]Results are expressed as mean ± SEM ($n$ = 5). No significant difference was noted between groups 1, 2, and 3. Data in the same column (group 4–10) with different letters are significantly different at $P < 0.05$ among different treatments.

dx.doi.org/10.1021/jf5016335 | J. Agric. Food Chem. 2014, 62, 10046–10054

when compared with all concentrations of EGCG3″Me. Increased release of intracellular enzymes AST and ALT was observed at >3 h exposure to alcohol. This indicated membrane damage and instability owing to oxidative injury created by alcohol. Likewise, alcohol caused an increase in the level of MDA with a concurrent decrease in GSH-Px content in HepG2 cells. The alcohol-induced changes in the HepG2 cells were ameliorated by cotreatment of the toxin along with both EGCG3″Me and bifendate. It was observed that when treated with different concentrations (10, 20, and 40 $\mu$g/mL) of EGCG3″Me, the cells showed a significant restoration of the altered biochemical parameters toward normal compared with the toxin-treated group in a concentration-dependent manner.

Effects of EGCG3″Me pretreatment on alcohol-induced alteration in body weight and relative organ weight in mice are shown in Table 2. It can be seen that body weights of mice were not affected by the treatment of alcohol, bifendate, or EGCG3″Me, for no differences were observed for body weights among different groups. However, significant increases of the relative weights of liver, spleen, and thymus were observed for the mice in the alcohol control group, indicating that alcohol induced hypertrophy of these organ tissues in mice. On the contrary, the pretreatment of bifendate showed a remarkable decrease in elevated relative organ weights when compared with the model control group. Moreover, the administration of EGCG3″Me significantly reduced the relative weight of liver and spleen and, notably, a similar effect was observed for the relative weight of thymus in mice pretreated with EGCG3″Me at a medium or high dose.

**Table 2. Effects of EGCG3″Me Pretreatment on Alcohol-Induced Alteration in Body Weight and Relative Organ Weight in Mice[a]**

| | | relative weight (g/g body weight, %) | | |
|---|---|---|---|---|
| group | body weight (g) | liver | spleen | thymus |
| I | 35.3 ± 2.04 | 4.38 ± 0.20a | 0.24 ± 0.02a | 0.21 ± 0.02a |
| II | 34.4 ± 1.28 | 5.62 ± 0.33e | 0.37 ± 0.04d | 0.28 ± 0.01c |
| III | 34.6 ± 1.39 | 4.39 ± 0.34a | 0.27 ± 0.03b | 0.20 ± 0.01a |
| IV | 35.2 ± 2.23 | 5.47 ± 0.27d | 0.34 ± 0.03c | 0.27 ± 0.02c |
| V | 36.3 ± 1.87 | 4.45 ± 0.16b | 0.26 ± 0.02b | 0.21 ± 0.02b |
| VI | 35.1 ± 2.08 | 4.58 ± 0.19c | 0.27 ± 0.02b | 0.22 ± 0.02b |

[a]Groups I, II, and III represent the normal control, model control, and positive control, respectively. Groups IV, V, and VI represent the groups pretreated with EGCG3″Me at doses of 25, 50, and 100 mg/kg BW per day, respectively. Each value is presented as the mean ± SD ($n$ = 8). Different lower case letters indicate significant difference from the model group at the level of $P < 0.05$.

Table 3 shows the effects of EGCG3″Me pretreatment on alcohol-induced alteration in serum enzyme activities of AST and ALT and hepatic SOD, GSH-Px, and MDA levels in mice. Apparently, significant increases in AST and ALT activities were observed in sera of the alcohol model group when compared with the normal control group, indicating that the alcohol-induced hepatotoxicity in mice was well-established. The elevated AST and ALT levels were reduced significantly in a concentration-dependent manner in mice pretreated with EGCG3″Me. Compared with those in the model control group, the levels of AST and ALT decreased 38.9 and 38.7%, respectively, at a dose of 100 mg/kg BW per day of EGCG3″Me. There was also a significant decrease in SOD and GSH-Px activities and an increase in MDA level in the alcohol model group when compared with the normal control group. As shown in Table 3, the administration of EGCG3″Me significantly enhanced SOD and GSH-Px activities but decreased MDA levels when compared with the model control group. At a high dose of EGCG3″Me, SOD and GSH-Px activities in the liver were restored by 5.67 and 32.4% in alcohol-induced liver injury mice. However, there was no significant difference of SOD activity for mice pretreated by EGCG3″Me at a medium or high dose. The level of MDA was significantly reduced in a concentration-dependent manner in the mice pretreated with EGCG3″Me. At a dose of 100 mg/kg BW per day of EGCG3″Me, the level of MDA in mice was 0.77 ± 0.03 nmol/mg protein, which was 32.5% lower than that of the alcohol model group.

The effects of EGCG3″Me and bifendate on liver histopathology of alcohol-treated mice are presented in Figure 5. In the normal control group (Figure 5I), the liver sections showed normal hepatic cells with well-preserved cytoplasm, prominent nucleus, and clear central vein (CV), whereas in the model control group, massive inflammation, infiltration, and many ballooned hepatocytes (blue arrow) were observed around the CV (Figure 5II). For the positive control group, bifendate (10 mg/kg) exhibited a significant protective effect evidenced by showing a clear CV and similar liver tissue compared with the normal group (Figure 5III). In addition, similar protection from alcohol-induced inflammation and infiltration in liver tissues was observed by the pretreatment with EGCG3″Me in a dose-dependent manner (Figure 5IV–VI). In Figure 5IV, a moderate inflammation area with color changes around the CV and fewer ballooned hepatocytes were observed; in Figure 5V, less inflammation and infiltration around CV and trace ballooned hepatocytes were presented, whereas Figure 5IV shows a clear CV and similar tissue structure when compared with the normal control group.

**Table 3. Effects of EGCG3″Me Pretreatment on Alcohol-Induced Alteration in Serum Enzyme Activities of AST and ALT and Hepatic SOD, GSH-Px, and MDA Levels in Mice[a]**

| group | AST (U/L) | ALT (U/L) | SOD (U/mg) | GSH-Px (nmol/mg protein) | MDA (nmol/mg protein) |
|---|---|---|---|---|---|

## DISCUSSION

Oolong tea is reported to have a wide range of health benefits, and its polyphenols have been considered as promising active ingredients responsible for the effects. However, previous studies have not connected the hepatoprotective effects to the phenolic constituents of oolong tea. In this study, we for the first time explored the hepatoprotective efficacy of EGCG3″Me from Chinese oolong tea.

EGCG3″Me is generally prepared from limited oolong tea or green tea by extraction with water and purification with HP-20 column chromatography and preparative HPLC.[26] In the present study, EGCG3″Me of high purity was successfully prepared from Chinese oolong tea through water extraction and simple purification procedures of polyamide and Toyopearl HW-40S column chromatography. Obviously, it is a simple and efficient procedure for the preparation of EGCG3″Me compared with reported methods.

In our study, we demonstrated that the in vitro antioxidant activity of EGCG is greater than that of EGCG3″Me. EGCG is the main component of tea polyphenols, which has been shown to have significant biological activity. However, for the low bioavailability, EGCG is rapidly metabolized to a variety of derivative products after absorption, including glycosylation, sulfation, and methylated derivatives.[28] These derivatives are likely to play an important role in vivo and show higher biological activity.[29,30] Currently, the function, mechanism, and biotransformation of these derivatives in vivo are still to be investigated and clarified. In this test, EGCG3″Me showed high antioxidant activity, which may also have excellent hepatoprotective ability as EGCG.

Recently, the in vitro cytotoxicity and hepatoprotective activity of plant extracts have gained importance for primary level screening. HepG2 cells possess many morphological and biochemical features of normal hepatocytes. Because it retains many of the phenotypic and genotypic characteristics of liver cells, this cell line has been used in various studies related to medicinal plants for their liver-protecting property.[31,32] Therefore, the present study was designed to ascertain the hepatoprotective activity of EGCG3″Me against alcohol in the HepG2 cell line.

Alcohol-mediated liver injury in vitro is reported in the literature to be caused by two components, a direct solvent effect or the generation of free radicals and subsequent lipid peroxidation depending on its concentration, the duration of exposure, and the sensitivity of the in vitro system to which it is added.[33,34] During alcohol exposure, superoxide radical is believed to play a central role in alcohol-induced liver injury. It can be produced readily by numerous processes and reacts through catalytic pathways in cells to form potent oxidants, including hydroxyl radical, hydrogen peroxide, and peroxynitrite.[35] In this study, our results in conjunction with other reports proved that hepatotoxin caused a time-dependent production of reactive oxygen species (ROS) and subsequent lipid peroxidation in HepG2 cells, which was found to be maximum after an incubation period of 24 h.[36] Therefore, HepG2 cells were incubated with alcohol for 24 h to study the protective effects of EGCG3″Me against alcohol-induced toxicity. Increased release of intracellular enzymes AST and ALT was observed at 24 h of exposure to alcohol. This indicated membrane damage and instability owing to oxidative injury created by the hepatotoxin. Likewise, alcohol treatment caused significant increase in the level of MDA, with a concurrent decrease in SOD and GSH-Px contents in HepG2 cells. When treated with different concentrations of EGCG3″Me, HepG2 cells showed a significant restoration of the altered biochemical parameters toward the normal compared with model control group. The possible underlying mechanism for the hepatoprotective effect of EGCG3″Me in a dose-dependent manner is its ability to inhibit lipid peroxidation and maintenance of GSH-Px and SOD by virtue of its antioxidative powers. Due to the nontoxic and hepatoprotective nature of EGCG3″Me, it was thought pertinent to assess its hepatoprotective potential in vivo using a mouse model.

Alcohol administration in animal models has been used as a test for potential hepatoprotective agents frequently. In the present study, a remarkably increased relative organ weight was observed in the model control group compared with the normal control group (Table 2). Furthermore, we found a dramatic elevation of AST and ALT activities in the model control group when compared with other groups (Table 3). The results indicated that alcohol induced hepatotoxicity in animal organs and disorders of enzyme activities. In recent times, much evidence has demonstrated that increases of serum AST and ALT activities caused by hepatotoxin are related to hepatic structural damage because these entities are normally localized to the cytoplasm and are released into the circulation after cellular damage occurred.[37,38] However, both relative organ weights and AST and ALT activities decreased dramatically in mice pretreated with bifendate when compared with those in the model control group (Table 2), and similar results have

been obtained by the pretreatment of EGCG3″Me. The results suggested that EGCG3″Me might have a protective effect against alcohol-induced liver injury in mice.

The accumulation of alcohol-induced radicals leads to a free radical mediated lipid peroxidation and cell necrosis, which causes liver injury, and the level of MDA provides an indirect index of lipid peroxidation. In the present study, the increase in MDA levels suggests enhanced lipid peroxidation leading to tissue damage and failure of antioxidant defense mechanisms to prevent formation of excessive free radicals. In our study, the pretreatment of EGCG3″Me inhibited alcohol-induced hepatotoxicity effectively by reducing the formation of MDA in the liver. At a dose of 100 mg/kg BW per day of EGCG3″Me, the MDA level reached the same level as the positive control group. This suggested that EGCG3″Me might have a hepatoprotective effect by decreasing oxidative stress in the liver of alcohol-induced mice. These results are also in good agreement with histopathological results. As shown in Figure 5, marked and widespread inflammation and infiltration areas were depicted in the model control group, whereas those of the bifendate treatment group and EGCG3″Me treatment group with a high dose reversed alcohol-induced liver injury, indicating that EGCG3″Me was effective against alcohol-induced hepatotoxic effect. In the model control group, SOD and GSH-Px activities were very low, whereas the mice of the positive control group showed higher activities when compared with the model control group. Notably, the activities of SOD and GSH-Px were also elevated markedly by the pretreatment of EGCG3″Me, especially at a dose of 100 mg/kg BW per day. It has been reported that the decrease in the activity of SOD, the increase in the lipid peroxidation, and the breakdown of the GSH-dependent antioxidant defense system are obviously seen along with the liver damage induced by hepatotoxin.[39] Oxidative stress has been considered as a major molecular mechanism involved in alcohol toxicity; in our study, EGCG3″Me showed excellent antioxidant and hepatoprotective activities in a dose-dependent manner, and the present results were in good agreement with other results.[37−39]

According to the results stated above, it is believed that the hepatoprotective effect of polyphenol is related to its antioxidant activity. Cui et al. reported the protective effects of polyphenol-enriched extract from green tea, including epigallocatechin, rutin, and epicatechin, against $CCl_4$-induced liver injury in mice, and emphasized the importance of a high content of polyphenols for guarding intact endogenous cellular antioxidant defense systems.[40] The most abundant tea catechin, EGCG, has also been shown to exhibit hepatoprotective effects against liver injury by ethanol and carbon tetrachloride.[14,15] Although EGCG has also been shown to exhibit hepatoprotective effects against liver injury, some studies demonstrated that high doses of EGCG can lead to mild liver injury.[41] During digestion and transfer across the small intestine, and in the liver, EGCG is rapidly metabolized by phase II enzymes to various *O*-sulfated, *O*-glucuronidated, and *O*-methylated forms, which may play an important role in vivo.[28] In the present study, the antioxidant and hepatoprotective effects of EGCG3″Me from Chinese oolong tea were confirmed.

In conclusion, high-purity EGCG3″Me was successfully prepared from Chinese oolong tea by extraction with hot water and simple purification procedures of polyamide and Toyopearl HW-40S column chromatography. In an in vitro antioxidant study, EGCG3″Me exhibited potential antioxidant activity. For hepatoprotective activity in vitro, it was observed that EGCG3″Me effectively alleviated the changes induced by alcohol in a concentration-dependent manner. On the basis of the in vivo alcohol-induced liver injury model, we demonstrated that the administration of EGCG3″Me significantly decreased AST and ALT levels in the serum and the liver level of MDA and remarkably restored the liver activities of SOD and GSH-Px in alcohol-induced liver injury mice. Accordingly, this suggested that EGCG3″Me had a significant hepatoprotective effect on alcohol-induced liver injury possibly via its antioxidant activity to protect biological systems against oxidative stress. These results provided evidence that EGCG3″Me might be an important active substance responsible for the hepatoprotective effect of Chinese oolong tea; therefore, EGCG3″Me could be developed as a potential functional food ingredient for liver injury and the maintenance of human health.

stability, bioaccessibility, and permeability of ginsenosides in WG and RG during in vitro digestion was conducted using a Caco-2 cell culture model coupled with an oral, gastric, and small intestinal simulated digestion. The overall design of the study is outlined in Figure S1 in the Supporting Information.

## MATERIALS AND METHODS

**Materials and Chemicals.** Standard ginsenosides, including the compounds Rg1, Re, Rf, Rg2 (20*S*), Rg2 (20*R*), Rb1, Rc, Rb2, Rd, Rg6, F4, Rk3, Rh4, Rg3 (20*S*), Rg3 (20*R*), Rk1, and Rg5, were purchased from the Ambo Institute (Daejeon, Korea). $\alpha$-Amylase, pepsin, pancreatin, pancreatic lipase, and bile extract were purchased from Sigma-Aldrich (St. Louis, MO, USA) for simulated digestion. All cell culture reagents including Dulbecco's modified Eagle's medium (DMEM), fetal bovine serum, 1 M 4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid (HEPES), phosphate buffer saline (PBS), 100× penicillin and streptomycin, and trypsin/EDTA were obtained from Gibco (Carlsbad, CA, USA). Hanks' balanced salt solution (HBSS) and 100× nonessential amino acids were purchased from Sigma-Aldrich. Transwell permeable polycarbonate inserts (0.4 $\mu$m) and 12-well cell culture plates were obtained from Corning Inc. The solvents used for ultraperformance liquid chromatography (UPLC) were purchased from Fisher Scientific (Springfield, NJ, USA). Unless indicated, all other chemicals were supplied by Sigma-Aldrich.

**Sample Preparation.** Freshly harvested 6-year-old Korean ginseng (*P. ginseng* C.A. Meyer) roots cultivated in Geumsan, South Korea, were selected for this study. They were washed and dried at 60 °C for 2 days using a forced airflow oven (WFO-400, EYELA, Japan) to produce WG. The RG was also prepared by steam cooking at 95 ± 5 °C for 18 h and dried under the same conditions as stated above for WG. Then, the dried WG and RG were pulverized and passed through a 350 $\mu$m screen (Chunggyesanggongsa, Korea) to prepare homogeneous powder samples, and the WG and RG powders were immediately stored at −20 °C until analysis.

**Simulated Digestion of WG and RG.** Simulated digestion was performed according to the method described by Garrett et al.[17] with minor modifications. Briefly, WG and RG powders (2 g) were homogenized in 10 mL of saline solution containing 120 mM NaCl, 5 mM KCl, and 6 mM $CaCl_2$. Then, 1000 units of $\alpha$-amylase was added, and the pH was adjusted to 6.5. After the addition of saline solution to a volume of 12.5 mL, the samples were incubated at 37 °C for 5 min in a shaking water bath (Lab Companion, Jeio Tech, Korea) at 95 rpm for the simulated oral phase of digestion. To mimic the gastric phase of human digestion, the pH of the sample was acidified to 2.5 with HCl and 0.5 mL of porcine pepsin solution (0.075 g/mL in 0.1 N HCl) was added. The samples were filled with saline solution to a volume of 15 mL and incubated at 37 °C for 2 h in a shaking water bath at 95 rpm. To simulate the intestinal phase more accurately and specifically, its phase was separated into three intestinal parts (duodenum, jejunum, and ileum). In the duodenum part, 250 mg of bile extract, 0.5 mL of pancreatic lipase (0.01 g/mL of 0.1 M sodium bicarbonate), and 0.5 mL of pancreatin (0.08 g/mL saline) were added, and the pH was increased to 4.5 by adding 1 M sodium bicarbonate. Samples were incubated for 30 min at 37 °C (final volume = 20 mL). In the jejunum part, the pH was adjusted to 5.5 and incubated for 90 min at 37 °C (final volume = 22.5 mL). Finally, the pH was adjusted to 6.5 and incubated for 300 min at 37 °C (final volume = 25 mL) to mimic the ileum part. At the end of each digestion, the aqueous supernatant, that is, the bioaccessible fraction (100 $\mu$L) was collected through a 0.2 $\mu$m PVDF syringe filter (Whatman, UK) for bioaccessibility measurement of ginsenosides. To measure the digestive stability of ginsenosides, the final digestates were added to ethanol (25 mL) and extracted by sonication for 1 h. After the ethanol mixtures of the aqueous fraction or digestate were centrifuged at 12300*g* for 10 min, their supernatants were recollected and filtered through a 0.2 $\mu$m filter prior to ultraperformance liquid chromatography−mass spectrometry (UPLC-MS) analysis. For the permeability test, the soluble fractions (5 mL) from ileum digestion of WG and RG were prepared through a 0.2 $\mu$m filter and immediately treated with a Caco-2 cell monolayer.

**Permeability of Micellar Ginsenosides by Caco-2 Human Intestinal Cells.** Caco-2 cells (HTB-37, American Type Culture Collection, Rockville, MD, USA) were maintained for cellular transport experiments, according to the method of Hubatsch et al.[25] For the experiments, cells were seeded at a density of $3 \times 10^5$ cells $cm^{-2}$ on the tissue culture-treated polycarbonate filter in 12-transwell plates. The cultures were grown for 21−29 days to obtain a differentiated intestinal cell monolayer. Transepithelial electrical resistance (TEERS) measurements were taken twice weekly using a Millipore Millicell-ERS system (Millipore Corp., Bedford, MA, USA) to ensure the monolayer was intact. Once the TEER values reached 600−1000 $\Omega/cm^2$, the monolayer was used for transport study.

To initiate the transport experiments, the culture media in the donor and receiving compartments were carefully aspirated, and the cells were rinsed with prewarmed transport medium (HBSS supplemented with 25 mM HEPES, pH 7.4). Following a 30 min equilibration with the transport medium at 37 °C, the cells were incubated with the ginsenoside-rich micellar solutions from simulated digestion, which were diluted 5 times with transport medium. The transport studies were performed in both directions for 2 h as follows. For apical-to-basolateral transport (a to b), 1.2 mL of transport medium was added in the basolateral part, and 0.45 mL of each diluted micellar solution was added into the apical part, and a 0.05 mL sample ($C_0$) was immediately withdrawn into a collection tube. After 2 h, 0.6 mL of basolateral transport medium was withdrawn for the analysis and replenished with an equal volume of fresh transport medium. For basolateral-to-apical transport (b to a), 1.25 mL of each diluted aqueous solution was added in the basolateral part and a 0.05 mL sample was immediately withdrawn, followed by 0.4 mL of transport medium being added into the apical part. Then, 0.2 mL of apical transport medium was withdrawn after 2 h and replenished with the same volume of fresh transport medium. The TEER values were measured after cell integrity was confirmed. All of the collected samples were added with the same volume of acetonitrile to increase the stability of ginsenosides prior to UPLC-MS analysis. The apparent permeability coefficient ($P_{app}$) was calculated as

$$P_{app} = \frac{\partial Q}{AC_0\partial t}$$

where $\partial Q \partial t$ is the permeability rate, $A$ is the surface area of the membrane filter, and $C_0$ is the initial concentration in the donor compartment (the apical compartment in the a to b transport study and basolateral compartment in the b to a transport study).

**UPLC-MS Analysis.** The quantitative analysis of ginsenosides in WG and RG was performed using the UPLC-MS (Thermofisher Scientific, Fremont, CA, USA) method according to a previous paper by Wang et al.[12] with a slight modification to avoid the overlay of each analyte. The UPLC system was equipped with an ACCELA pump, ACCELA autosampler, and ACCELA PDA detector. Chromatographic separation was carried out at 35 °C on a reversed-phase YMC-ultraHT Pro C18 column (50 × 2.0 mm, 2.0 $\mu$m, YMC Inc., USA). The mobile phase was acetonitrile (A) and 0.1% formic acid in water (B). Gradient elution started with 18% of solvent A and 82% of solvent B, which was changed to 22% A for 10 min, then to 35% A for 10 min, then to 45% A for 8 min, then to 65% A for 4 min, and held for 3 min; then it was changed to 90% A for 5 min. The flow rate was kept at 0.4 mL/min, and the sample volume to be injected was set at 1 $\mu$L. UPLC-ion trap-MS analysis was performed in full-scan mode with an LCQ FLEET ion trap mass spectrometer, which was equipped with an electrospray ionization (ESI) source. The mass spectra were acquired in negative mode using a scan range of the charge ratio ($m/z$) 100−1500. The conditions used for the ESI source were as follows: heater temperature, 200 °C; sheath gas flow rate, 40 bar; spray voltage, 5 kV; capillary temperature, 300 °C; capillary voltage, 45 V; and tube lens, 125 V. Data analysis was performed using Xcalibur 2.2 software (Thermofisher Scientific). Seventeen ginsenosides, Rg1, Re, Rf, Rg2 (20*S*), Rg2 (20*R*), Rb1, Rc, Rb2, Rd, Rg6, F4, Rk3, Rh4, Rg3 (20*S*), Rg3 (20*R*), Rk1, and Rg5, were identified by comparing the retention time with reference standards and the molecular weight with previous

[a]T-PPD, T-PPT, and T-G represent the sum quantities of protopanaxdiol type ginsenosides, protopanaxtriol type ginsenosides, and all ginsenosides, respectively. Data represent the mean ± SD from four independent experiments. Recovery (%) was calculated from percentage of the ginsenoside concentrations in digestates of each digestion phase on food material. Mean values in rows for each digestion phase show statistically significant differences in Tukey's test. *, $p < 0.05$ compared to food. [b]The ginsenoside content in food material was expressed as mg/g of dry weight.

**Figure 1.** Chemical structures of ginsenosides identified in white and red ginsengs. Glc, *β*-D-gluco-pyranosyl; Araf, *α*-L-arabino-furanosyl; Arap, *α*-L-arabino-pyranosyl; Rha, *α*-L-rhamno-pyranosyl.

published data[3,26] (Figures S2 and S3 and Table S1 in the Supporting Information). All calibration curves were plotted on the basis of linear regression analysis of the integrated peak areas in the total ion chromatogram (TIC) versus concentrations of the four different concentrations in a range from 2 to 200 *μ*g/mL. The regression equations and correlation coefficients for the analysis of the 17 marker constituents were obtained. A high linearity ($r^2 > 0.982$) was obtained for each standard curve (data not shown).

**Statistical Analysis.** All data are expressed as the mean ± standard deviation (SD). Statistical analysis was performed by a one-way analysis of variance (ANOVA) followed by Tukey's honestly significant difference (HSD) test using IBM SPSS statistics 21. *P* values < 0.05 were considered statistically significant.

## RESULTS AND DISCUSSION

**Stability of Ginsenosides during Simulated Digestion of WG and RG.** Information about the stability and bioaccessibility of ginsenosides from ginseng during transit through the gut is still limited. To assess the stability of ginsenosides during in vitro digestion of WG and RG, the ginsenosides present in the ingredients during simulated oral, gastric, and small intestinal digestion as well as food materials in

[a]Data represent the mean ± SD from four independent experiments. Mean values in rows for each digestion phase show statistically significant differences in Tukey's test. *, $p < 0.05$ compared to food; **, $p < 0.01$ compared to food. [b]The ginsenoside content in food material was expressed as mg/g of dry weight.

the WG and RG powders were identified and quantitated by UPLC-MS analysis. As shown in Figure S2 (Supporting Information), nine ginsenosides were detected in WG powder. The total ginsenoside content of WG was 6.47 ± 0.33 mg/g dry weight (Table 1). Ginsenoside Re (2.08 ± 0.27 mg/g) was most abundant, followed by Rb1, Rg1, Rb2, Rc, and Rf, and there were traces of Rg2 and Rd. The PPD/PPT ratio was 0.55. These results were similar to the total ginsenoside content (7.4 mg/g) and PPD/PPT ratio (0.46) of WG reported by Choi et al.[27] There were no differences in the composition of ginsenosides when compared to the results of Kim et al.[28] and Sun et al.,[8] but the total quantities of ginsenosides were somewhat different. The PPD/PPT ratio also differed as it ranged from 0.5 to 1.5. This is thought to be influenced by the cultivated areas, growth years, and harvest time of ginseng. Meanwhile, 17 ginsenosides were detected in RG powder (Figure S2 and Figure 1). The total ginsenoside content of RG was 11.82 ± 0.46 mg/g, 1.8-fold higher than that of WG (Table 2). Unlike WG, the main ginsenoside of RG was Rb1 (3.30 ± 0.27 mg/g). The levels of polar PPT type ginsenosides, such as Re and Rg1, decreased, and levels of all of the ginsenosides of the PPD type, such as Rb1, Rb2, Rc, Rd, Rg3 (*S*,*R*), Rk1, and Rg5, and the less polar ginsenosides of the PPT type, such as Rg2 (*S*,*R*), Rg6, F4, Rk3, and Rh4, increased. The mechanisms involved were deduced to be the demalonylation of malonyl ginsenosides in WG[27] and the loss of a glycosyl moiety at C-20−OH of dammarane type ginsenosides through thermal hydrolysis by steam processing.[3] Thus, the PPD/PPT ratio increased to 2.18. The formation of less polar ginsenosides (Rg2 (20*S*), Rg2 (20*R*), Rg3 (20*S*), Rg3 (20*R*), Rg5, Rg6, Rh1, Rh4, F4, Rk1, and Rk3) in steamed ginseng has been reported for Korean ginseng.[7,29] Recently, many studies had been conducted on the quantitative analysis of ginsenosides in RG. The ginsenoside contents varied by preparation method, such as the steaming temperature, steaming time, and number of steaming repetitions for RG,[3,27] and by the type of ginseng and its country of origin.[8] According to papers by Choi et al.[27] and Kim et al.,[28] the PPD/PPT ratio of RG ranged from 1.5 to 3.5. Our results are also within this range. However, the contents and profiles of the ginsenosides varied considerably compared to other studies.[3,4,8,28] These results suggest that the difference may be due to not only the steaming and drying conditions during RG preparation but also the contents and constituents present in WG itself.

Most of the ginsenosides in the WG powders in each digestion phase were stable with a >95% recovery rate (Table 1). In addition, the recoveries of ginsenosides Rb2 and Rc as well as Rg2 (20*S*) and Rg2 (20*R*) in the ileum phase were significantly increased to 113−114%. When the WG was incubated with a digestive fluid that did not contain enzymes, the results differed from those shown in Table 1 (data not shown). The increase of the recovery of ginsenosides Rb2, Rc, and Rg2 in the intestinal phase was thought to be due to the increase of extraction rate by intestinal enzymes during digestion. In contrast, the recovery of ginsenoside from the RG powders in each digestion phase was mostly >90%, except for ginsenoside Rk1 (Table 2). Thus, the recovery of ginsenosides Rb1, Rb2, and Rc was significantly decreased, whereas that of Rk1 was remarkably increased from the duodenum to the ileum. It was reported that PPD type ginsenosides such as Rb1, Rb2, and Rc were mainly converted to Rk1 and Rg5 through Rg3 (Figure 2).[26] In the above result, the change in the recovery rate was thought to be due to the conversion of Rb1, Rb2, and Rc to Rk1 during simulated digestion. Kim et al.[23] reported that stability of the ginsenosides in red ginseng extract was observed when they were placed in a 37 °C water bath for 4 h, and no significant changes in the ginsenoside composition were found. Moreover, the ginsenosides Rb1 and Rg1 added to serum samples in rats were stable as the recovery range was 90.13−105.66%.[16] Serventi et al.[19]

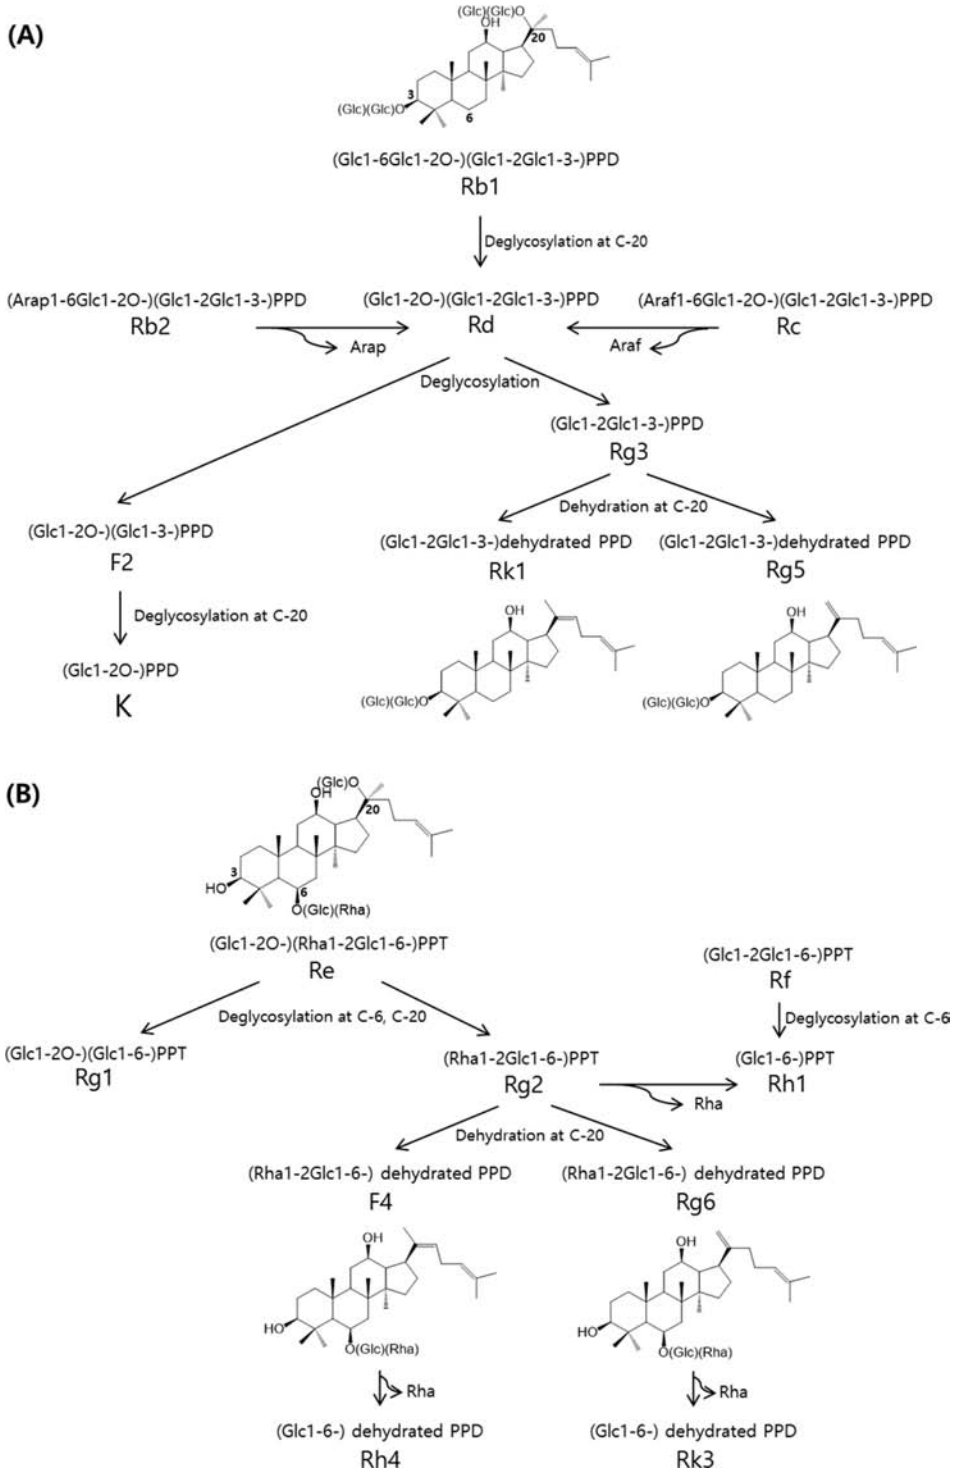

**Figure 2.** Possible enzymatic or chemical bioconversion of protopanaxadiol (A) and protopanaxatriol (B) type ginsenosides.

observed that the recovery of total saponins in soy bread was 83% during in vitro digestion, although recovery of saponins differed considerably by saponin type. In addition, the recovery of carotenoids in meals was >70% during in vitro digestion.[17] Therefore, these results indicate that most of the ginsenosides in RG and WG were relatively stable during in vitro digestion.

**Bioaccessibility of Ginsenosides during Simulated Digestion of WG and RG.** Bioaccessibility refers to the amount of a constituent in a food or supplement that is released from the matrix during digestion to a potentially absorbable form.[30] The aqueous or bioaccessible fractions from undigested material were separated through centrifugation from digestates in each phase generated during simulated digestion. The bioaccessibility of ginsenosides in the aqueous fraction from the food to the small intestinal phase of the simulated digestion of WG (Table 3) and RG (Table 4) generally increased. Among the nine ginsenosides in WG, the bioaccessibility of ginsenoside Re in the food phase (prior to the early stage of enzyme addition in the mouth) had the highest level, at 90% of the food matrix. The ginsenosides Rg1, Rg2 (20*S*), Rf, and Rg2 (20*R*)

[a]Bioaccessibility (%) was calculated from percentage of the ginsenoside concentrations in digestates of each digestion phase on red ginseng. Values represent mean ± SD from four independent experiments. Significant differences at digestion phase of individual ginsenosides as determined by Tukey's test ($p < 0.05$) are indicated by different letters.

ranged from 75 to 82%, and ginsenoside Rd constituted 71% of the matrix, whereas Rb1, Rc, and Rb2 had the lowest level at about 60%. The release percentages of total PPD (T-PPD) and PPT (T-PPT) were 60 and 85%, respectively. In the early phase, the bioaccessibility of ginseng saponins from the food matrix was higher for the PPT type, including Re, Rf, Rg1, and Rg2 (*S*,*R*) than for the PPD type, including Rb1, Rb2, Rc, and Rd. Moreover, the percentages of most of the ginsenosides transferred to the bioaccessible fraction after termination of the small intestinal phase (ileum = final stage) of simulated digestion increased to >85%, except for Rb1 (74%) and Rg2 (20*R*) (81%). The release percentages for T-PPD and T-PPT were 80 and 90%, respectively. The gap between the T-PPD and T-PPT types in the ileum phase (10%) was lower than that in the food phase (25%) during in vitro digestion. The ginsenosides are classified as belonging to the two major groups according to their structures. The PPD type had sugar moieties attached to the C-3 and/or C-20, and the PPT type has sugar moieties at C-6 and/or C-20 (Figure 1).[3] The polarity of PPT, having two hydrophilic tails (sugar moieties) and an additional hydroxyl group, is greater than that of PPD. Thus, the results implied that PPD ginsenosides were more slowly released during the digestion process than the PPT type.

Meanwhile, the release of ginsenosides in the aqueous fraction during simulated digestion of the RG increased, especially in the jejunum and ileum (Table 4). Among the 17 ginsenosides in RG, ginsenoside Re (85%) showed the highest bioaccessibility in the food phase as with the WG, followed by ginsenoside Rg1 (77%) > Rb1, Rb2, Rc, Rd, Rf, Rg2 (20*S*), and Rg2 (20*R*) (60%) > Rg3 (*S*,*R*), Rk1, Rg5, Rg6, F4, Rk3, and

Rh4 (30−40%), in decreasing order. Namely, the bioaccessibility of ginsenoside components present in WG itself was >60%, whereas the less polar RG ginsenosides exhibited low bioaccessibility at <40%. Ginsenosides Rg6 and F4 were presumed to be generated through deglycosylation of Re to Rg2 and a dehydration reaction at the C-20 (21) or C-20 (22) of Rg2 (20*S*). Subsequently, ginsenosides Rh4 and Rk3 were generated, respectively, through eliminating the terminal glycosyl moiety at the C-6 position of ginsenosides F4 and Rg6, whereas ginsenoside Rg3 was deduced to be generated through elimination of the terminal glycosyl moiety at the C-20−OH of Rb1, Rb2, and Rc to Rd and through removal of the remaining glycosyl moiety at the C-20 position of Rd. Next, ginsenosides Rg5 and Rk1 were generated, respectively, through a dehydration reaction at the C-20 (21) or C-20 (22) of Rg2 (20S), which was consistent with the findings reported by others (Figure 2).[3,7,24,26] The newly generated ginsenosides via deglycosylation and dehydration from Rb1, Rb2, Rc, Rd, Re, and Rg1 by WG steaming were less polar, and these unique, less polar RG ginsenosides were rapidly released after the jejunum phase. Bioaccessibility of ginsenoside Rk1 was increased only up to 131%. The results suggest that the particular ginsenosides in RG were greatly influenced by intestinal enzymes and bile extract compared with the polar ginsenosides in WG. Kim et al.[23] observed that the compositions of the red ginseng extracts remarkably changed after in vitro digestion; the proportions of the polar ginsenosides, such as ginsenosides Rg1, Re, Rb1, Rc, Rb2, Rb3, and Rd, decreased in contents, whereas the less polar ginsenosides, such as ginsenosides Rh1, Rg2, Rg3, Rk1, and Rg5, increased. These results suggested that ginsenosides are influenced only by gastric fluid and not by intestinal fluid. The bioaccessibility of total ginsenosides (T-G) in the food phase of RG (57%) was lower than that of WG (76%), but the bioaccessibility of RG (85%) was similar to that of WG (87%) in the final ileum phase of simulated digestion (Tables 3 and 4). These results suggest that the total RG ginsenosides were slowly liberated due to the generation of less polar ginsenosides and an increase in PPD ginsenosides. Therefore, these findings suggest that ginsenoside structure and the composition of WG and RG were influenced by the bioaccessibility of ginsenosides at each phase during in vitro digestion.

**Permeability of Ginsenosides by Caco-2 Cells.** A close correlation between the in vitro permeability across Caco-2 cell monolayers and the in vivo human absorption after oral administration has been obtained for several compounds.[31−33] Thus, the bidirectional permeability of ginsenosides in chyme generated by simulated digestion of WG and RG using Caco-2 cell monolayers was assessed. As shown in Table 5, the permeability coefficients of Rg1, Re, Rc, Rf, and Rb1 in the a to b direction for WG were determined as $5.17 \times 10^{-7}$, $3.60 \times 10^{-7}$, $3.02 \times 10^{-7}$, $3.00 \times 10^{-7}$, and $1.33 \times 10^{-7}$ cm/s in 2 h in descending order, respectively, whereas ginsenosides Rb2, Rd, and Rg2 (*S*,*R*) were not detected. It is well-known that compounds with $P_{app}$ values of $<1 \times 10^{-6}$ cm/s, between $1 \times 10^{-6}$ and $10 \times 10^{-6}$ cm/s, and $>10 \times 10^{-6}$ cm/s are considered to have low (<20%), moderate (20−70%), and high (70−100%) absorption respectively.[31,34] According to these criteria, the ginsenosides with a $P_{app}$ value of $<1 \times 10^{-6}$ cm/s in Caco-2 cell monolayers are likely to be poorly absorbed from the intestine in humans. The $P_{app}$ values in the b to a direction were >10-fold greater than those in the a to b direction, and the $P_{app}$ values for ginsenosides Rb2 and Rg2 (20*S*) in the b to a direction were only $10.6 \times 10^{-7}$ and $33.0 \times 10^{-7}$ cm/s, respectively. Subsequently, the permeability coefficients of Rg1, Re, Rf, Rc, and Rb1 in the a to b direction for RG were determined as $5.92 \times 10^{-7}$, $4.68 \times 10^{-7}$, $2.47 \times 10^{-7}$, $1.61 \times 10^{-7}$, and $0.91 \times 10^{-7}$ cm/s in descending order, respectively, indicating that most of the RG ginsenosides have a poor permeability and absorption rate in vivo. The other RG ginsenosides were not detected. The permeability in the b to a direction was more than 10-fold greater than that in the a to b direction, except for Rc. Overall, even though the bioavailability of the same ginsenosides in WG and RG was slightly different, it suggest that the permeability of several ginsenosides were influenced by some different components in food matrix of WG and RG powder. Both the PPD and PPT groups of ginsenosides exhibited low bioavailability at less than 5%, and but PPT ginsenosides, including Re, Rf, Rg1 and Rg2, had better bioavailability than PPD ginsenosides, including Rb1, Rb2 and Rc, perhaps because PPD ginsenosides degrade faster than PPT ginsenosides.[16] These results were similar to those found in previous studies.[9] Study with cultures of Caco-2 human intestinal cells on soy saponins showed that trans-epithelial transport of soy saponin Bb during a 4 h incubation were quite limited (<3% from medium with $P_{app}$ $<4 \times 10^{-6}$ cm/s).[19,36] Thus, the permeability of ginsenoside Rg1 (>3%) only was higher than that of soy saponin Bb, another ginsenosides were similar to soy saponin Bb. The permeability of ginsenosides such as Rb2, Rd, Rg3, Rk1, Rg5, Rg6, F4, Rk3, and Rh4 in WG and RG by Caco-2 cells was not detected because of the relatively small amounts of these components in WG and RG. Compound K, the main metabolite of the PPD ginsenosides, was detected mostly in the plasma and urine of

[a]Permeability coefficient ($P_{app}$) was calculated as $P_{app} = \partial Q/AC_0\partial t$, where $\partial Q\partial t$ is the permeability rate, $A$ is the surface area of the membrane filter, and $C_0$ is the initial concentration in the donor compartment (apical compartment in a to b transport study and basolateral compartment in b to a transport study). Permeability (%) was calculated from volume contrast percentage of the ginsenoside concentrations appeared in the receiver side on donor compartment. Data represent the means ± SD from four independent experiments. Different letters in columns for each compound show statistically significant differences in Tukey's test ($p < 0.05$).

humans after oral administration.[10,11] Compound K was not found in our results, and this was presumed to be because the in vitro digestion system excluded enterobacterium. Recent studies have reported that the polar ginsenosides exhibited poor bioavailability following oral administration in vivo, and less polar ginsenosides generated via internal metabolism exhibited potent anticancer, antiobesity, and anti-inflammatory bioactivities.[23,35] However, little is known about the comparative study of the bioavailability of various ginsenosides present in ginseng. This study is the first report on the wide bioavailability of ginsenoside components in WG and RG powders using a Caco-2 cell culture model coupled with in vitro digestion. However, as the main metabolism of ginsenosides in ginseng is reported to take place in the small and large intestines, future studies should evaluate the bioavailability of ginsenosides by intestinal microflora in the small and large intestine model and develop a method to improve the poor bioavailability of ginsenosides.

In conclusion, the results obtained in the present study demonstrate that all of the ginsenosides in WG and RG were highly stable during simulated digestion. In addition, the bioaccessibility of ginsenosides from WG and RG during oral, gastric, and small intestinal digestion gradually increased. Even though the bioaccessibility was different according to the ginsenoside compositions of WG and RG, it was comparatively good at 85% in the final ileum phase. However, all of the ginsenosides in WG and RG had poor absorption through the Caco-2 cell monolayers. Hence, a further study on the bioavailability of ginsenosides in an in vivo model system and a method for enhancing the absorption of ginsenosides are required.

nutrients,[9] and mycorrhization[2,34] on polyphenolics profile of basil have also been studied. These studies have been carried out using conventional pot (CP system) grown plants in the greenhouse[2,4,18,19,32,34] or in hydroponic systems.[6,7] Several studies also report collection of plants from wild or market bought samples for polyphenolics study.[2,3] For the screening of large and diverse collection of cultivars of *Ocimum basilicum*, use of a conventional pot system as a screening platform is a large, cumbersome, and voluminous technique requiring high cost and physical operations. Therefore, a system which can be managed in less space and observed throughout with visibility of the root system, as is not the case in a conventional pot system, is needed for screening studies of *Ocimum basilicum*.

For the selection of basil cultivars to be used for medicinal and food applications, determination of antioxidant potential also plays an important role. Conventionally, determination of antioxidant potential utilizes spectrophotometric assays based on 2,2-diphenyl-1-picrylhydrazyl radical ($DPPH^{\bullet}$) and 2,2′-azinobis(3-ethylbenzothioazoline-6-sulfonic acid) radical cation ($ABTS^{\bullet+}$) chromogens.[35] To increase the efficiency of detection these assays have been coupled with a HPLC postcolumn separation where the antioxidant potential of individual constituents can be assessed.[35−37] Postcolumn detection using the conventional chromogens has the disadvantage of long processing times, which results in poor resolution of the resulting chromatogram.[36] Chemiluminescence signals produced by the use of an acidic potassium permanganate assay overcome this issue due to the fast nature of the light producing reaction involved, and this technology has been used for polyphenolics analysis in many studies.[35−42]

Assays based on chemiluminescence offer selectivity to antioxidants, high sensitivity, ease of chemical preparation, long shelf life of the reagent, fast analysis time, and simple instrumentation. A positive correlation between the acidic potassium permanganate and the traditional DPPH assay has been also observed, making this technology an ideal replacement for the cumbersome online DPPH assay.[35] Further to this a direct correlation between acidic potassium permanganate chemiluminescnce signal and bioactive potential in muscle cell culture has been determined.[39] The distinct advantages of chemiluminescence based assays enable them to be used as a test for estimation of total antioxidant potential and for the assessment of individual chromatographically separated components.

This study developed a new "in vitro" true to type (as offspring plants raised are phenotypically and metabolically similar to the parent plant) system for plant growth in a controlled environment that allowed morphotyping, screening, and selection of the high yielding cultivars of *Ocimum basilicum* for three marker compounds rosmarinic, chicoric, and caffeic acids (referred to as polyphenolics in this study). Acidic potassium permanganate chemiluminescence detection was used to determine the antioxidant activity for whole extracts and key compounds of interest. We believe that the system has distinct advantages of uniformity, high reproducibility, and efficiency over the CP system approaches currently used in plant science for screening and selection studies.

## MATERIALS AND METHODS

**Plant Material.** Seeds of 15 different *Ocimum basilicum* cultivars from five different countries (India, Germany, Spain, United States of America, and Australia) were used in this study for representation of morphological variability and chemical diversity. Seeds were purchased from seed suppliers and research institutes. The seeds of each cultivar were tested for viability by first washing with 0.1% (v/v) Tween 20 for 3 min, then with tap water to remove excess detergent, followed by surface sterilization with 0.01% $HgCl_2$ two times for 2 min followed by washing with sterile distilled water three times. The surface sterilized seeds were placed on Murashige and Skoog (MS) medium within 90 mm diameter Petri plates (25 seeds in each plate). The plates were then incubated in the dark in a plant growth room at 25 ± 2 °C at 60% relative humidity. After 10−20 d the percentage germination for each seed lot was determined and seed lots were characterized on the basis of germination percentage as high (70−100%), medium (31−69%), low (21−30%), and very low or nil (0−20%).

**Chemicals.** Mercuric chloride ($HgCl_2$) and Tween 20 used for seed sterilization and standards of gallic acid, rosmarinic acid, chicoric acid, and caffeic acid were obtained from Sigma-Aldrich (Castle Hill, Australia), and Murashige and Skoog medium was prepared following the method of Murashige and Skoog.[43]

Ethanol and 85% *o*-phosphoric acid (AR grade) were obtained from Merck (Kilsyth, Australia). HPLC grade methanol was obtained from BDH Chemicals (Poole, England). Millipore Millex-HN (syringe filters; 0.45 μm) that were used for filtration of samples were obtained from Merck (Darmstadt, Germany).

For the chemiluminescence assays, potassium permanganate was obtained from Chem Supply (Gillman, Australia), sodium polyphosphate was obtained from Sigma-Aldrich (Castle Hill, Australia), and analytical grade sulfuric acid was from Merck (Kilsyth, Australia).

MS medium was prepared by dissolving $KNO_3$ (0.37 M), $NH_4NO_3$ (0.41 M), $MgSO_4{\cdot}7H_2O$ (0.06 M), $KH_2PO_4$ (0.02 M), $CaCl_2{\cdot}2H_2O$ (0.08 M), $MnSO_4{\cdot}4H_2O$ (0.01 M), $ZnSO_4{\cdot}4H_2O$ (0.04 M), $H_3BO_3$ (0.01 M), KI ($4.81 \times 10^{-4}$ M), $Na_2MoO_4$ ($1.21 \times 10^{-4}$ M), $CuSO_4{\cdot}5H_2O$ ($1.57 \times 10^{-5}$ M), $CoCl_2{\cdot}6H_2O$ ($1.93 \times 10^{-3}$ M), $Na_2EDTA$ (0.01 M), $FeSO_4{\cdot}7H_2O$ (0.01 M) (all from Merck), glycine (0.002 M), nicotinic acid ($4.06 \times 10^{-4}$ M), pyridoxine hydrochloride ($2.95 \times 10^{-4}$ M), thiamine hydrochloride ($2.96 \times 10^{-5}$ M), and myoinositol (0.05 M) in 1 L of distilled water with 2.5% phytagel (all from Sigma-Aldrich, St. Louis, MO), and the pH was maintained at 5.8. The prepared medium was then autoclaved at 121 °C, 15 psi for 15−20 min.

***In Vitro* System.** An *in vitro* [true to type] whole plant system was developed. A 90 mm diameter Petri dish containing MS medium was used as the plant growth substrate. To enable plant growth from the sterile substrate, a hole was made in the lid of the dish. A germinated seedling at the two leaf stage was transferred using forceps and inserted leaf first through the hole in the lid of the Petri plate that had been removed from the base. The lid containing the inserted seedling was then gently placed back on the base which contained the MS medium so that the root was in contact with the medium. After successful transfer any space around the stem was sealed with sterile silicone grease. The Petri dish containing a seedling was placed on a flat bench, and then the plate was covered with a black paper sheet that had a hole in the center from which the stem emerged (Figure 1A). The black sheet was used to minimize light incidence on the developing root system. The same steps were repeated for each of 15 cultivars that were arranged in a completely randomized block design with three replicates for each. The plants were grown under controlled conditions at 25 ± 2 °C under cool white fluorescent lights (Thermoline Scientific, Wetherill Park, NSW, Australia) that had a photosynthetic photon flux density of 100−120 $\mu M\ m^{-2}\ s^{-1}$ for a photoperiod of 16 h light and 8 h dark with 60% humidity.

**Conventional Plant System (CP System).** For comparison with the in vitro whole plant growth system, a conventional pot experimental system was also set up. For this purpose, seeds were surface sterilized using the procedure previously described and then sown in trays in sterilized commercially obtained soil (Loess soil) mixed with absorbent granules (TERRA-GREEN, Greenscape Aeration Company, Atascadero, CA) and kept in the dark. After germination one seedling at the two leaf stage was transferred to a 5 L black plastic pot containing the soil:granule mix. The experiment was set up with all cultivars with three replicates each in a completely randomized block design in a greenhouse at 25−28 °C. The plants

**Figure 1.** *Ocimum basilicum* cultivars grown in the *in vitro* setup developed in a 90 mm Petri dish. Four different morphotypes were observed in the study: (A) large (lettuce) leaf and robust type; (B) purple colored type; (C) tall and slender type; (D) dwarf leaf type. There were four types of flower found in the study: (E) light purple; (F) white flower; (G) dark purple flower; and (H) purple flower.

were watered to pot capacity on a daily basis and fertilized fortnightly with Hoagland solution.[44]

**Plant Harvesting, Morphotyping, and Lyophilization.** Plants were grown to maturity in both systems and examined for variation in aerial morphology. The morphology of each cultivar was classified according to the traits used by Carović-Stanko et al.,[21] who used the morphological traits developed by the International Union for the Protection of New Varieties of Plants for *Ocimum basilicum L* (UPOV 2003).[45] Plant height and internodal distance was measured on harvested plants from the base of the stem to the apical bud using a standard mm scale. After harvest, samples were lyophilized (Labconco lyophilizer, Kansas City, MO, United States of America) at −94.3 °C and 141 kPa for 48 h, and then the lyophilized weight was recorded (data not shown).

**Extraction for Total Phenolics, Individual Polyphenolics, and Antioxidant Potential Analysis.** For total phenolics, individual polyphenolics (rosmarinic chicoric and caffeic acids), total antioxidant, and individual antioxidant potential studies using postcolumn chemiluminescence assay, 50 mg of lyophilized plant material (aerial and root) was homogenized separately in 500 μL of 60% ethanol. To the homogenized mixture was added 14.5 mL of 60% ethanol, and the mixture was sonicated at 25 °C using an ultrasonicator (Branson Ultrasonics, Danbury, CT, United States of America) for 10 min. The sonicated extract was then centrifuged at 10,000 rpm for 5 min, the supernatant was collected in a 25 mL volumetric flask, and the leftover residue was re-extracted in 10 mL of 60% ethanol for 5 min and then centrifuged as previously. The supernatant was then pooled in volumetric flasks that contained the first fraction, and the final volume was made up to 25 mL with 60% ethanol. The extracts were then filtered and stored in the dark at −80 °C in HPLC vials for total phenolics, individual polyphenolics, and chemiluminescence studies.

**Determination of Total Phenolics.** For the determination of total phenolics, a modified Folin−Ciocalteau colorimetric assay[46] was used. Briefly, to 100 μL of the ethanolic extract were added 400 μL of distilled water, 250 μL of Folin−Ciocalteau reagent, and 1.25 mL of 2.1% aqueous sodium carbonate, the mixture was incubated in the dark for 30 min, and the absorbance of the resulting mixture was taken at 735 nm using a microplate reader (SPECTRAmax 340 PC$^{384}$ Microplate Spectrophotometer, Sunnyvale, CA, United States of America) against the same mixture without sample. The total phenolic concentration was quantified from a standard curve prepared for gallic acid within the range of 20−100 mg/L, and the final concentration of total phenolics in a sample is reported as gallic acid equilvalents (GAE mg/g DW).

**Determination of Rosmarinic, Chicoric, and Caffeic Acid Contents by HPLC Analysis.** Chromatographic analysis was carried out using HPLC (Agilent Technologies 1200 series liquid chromatography system), equipped with a quaternary pump, solvent degasser system, autosampler, and diode array detector (Agilent Technologies, Victoria, Australia). Inbuilt software (Hewlett-Packard Chemstation, Agilent Technologies) was used to control the HPLC pump and acquire data from the diode array, UV−vis absorbance, and chemiluminescence detectors. Separations were performed on an Apollo TM C 18 (150 mm × 4.60 mm × 5 μm particle diameter) column.

For separation of individual polyphenolics the mobile phase used was HPLC grade water + 0.1% OPA (mobile phase A) and methanol + 0.1% OPA (mobile phase B). A gradient program was developed for RA quantitation: 0−2 min isocratic 0% B, 2−5 min linear gradient to 40% B, 5−10 min a linear gradient to 50% B, 10−18 min isocratically maintained at 50% B, 18−23 min a decreasing gradient from 50% to 40%, and finally 23−25 min 0% B for column washing. The flow rate of the mobile phase was 1.0 mL/min, and the wavelength used for detection of all three acids was 280 nm with an injection volume of 20 μL. Unknown samples were identified by comparison of the retention times with those of commercial standard. For the sensitivity study of RA, ChA, and CA, 20 standard samples were prepared between $1 \times 10^{-3}$ M and $1 \times 10^{-12}$ M. Quantification of unknown samples was determined by comparison of integrated peak area for each sample with a standard calibration curve of rosmarinic, chicoric, and caffeic acids.

**Determination of Total Antioxidant Potential.** Total antioxidant potential was determined using acidic potassium permanganate chemiluminescence detection coupled to an Agilent 1200 HPLC system. The HPLC system (without a column in place) was coupled with a Minipuls 3 peristaltic pump, bridged PVC tubing, and custom built luminometer (which functions similarly to a conventional flow injection analysis system). Both the in vitro and CP system whole plant samples were diluted 100 times using deionized water before injection of 50 μL of the sample at flow rate of 3 mL min$^{-1}$ and merging with acidic potassium permanganate ($1 \times 10^{-3}$ M), and the peak area was recorded. The acidic potassium permanganate was prepared by dissolution of potassium permanganate in 1% sodium polyphosphate solution adjusted to pH 2 with sulfuric acid.

**Determination of Individual Antioxidant Potential by Chemiluminescence Assay.** In vitro grown plant sample extracts were subjected to postcolumn acidic potassium permanganate assay to assess the contribution of individual polyphenolic compounds. All polyphenolic standards ($1 \times 10^{-3}$ M to $1 \times 10^{-12}$ M) were prepared in 100% analytical grade methanol and appropriately diluted with the same solvent. Postcolumn acidic potassium permanganate assay was performed using the system previously described.[36] Postcolumn acidic potassium permanganate chemiluminescence was generated using an in house built manifold. The reagent, propelled at a flow rate of 3 mL min$^{-1}$ using a Gilson Minipuls 3 peristaltic pump (John Morris Scientific, Balwyn, Australia) with bridged PVC tubing (DKSH), merged with the HPLC eluate at a T-piece, and the light emitted from the reacting mixture was detected with a custom built flow-through

luminometer, which consisted of a coiled flow cell comprising 80 cm × 0.8 mm i.d., transparent PTFE-PFA tubing (DKSH), mounted flush against the window of an Electron Tubes photomultiplier tube (model 9828SB, ETP) set at a constant voltage of 900 V from a stable power supply (PM20D, ETP) via a voltage divider (C611, ETP). The flow cell photomultiplier tube and voltage divider were encased in a padded light-tight housing, and a Hewlett-Packard analogue to digital interface box (Agilent Technologies) was used to convert the signal from the chemiluminescence detector.

**Statistical Analysis.** All data presented in this study is expressed in terms of mean ± SEM. Raw data was analyzed using a commercial statistical package (GraphPad Prism 6). One-way analysis of variance with a Tukey HSD test of significance at $p < 0.05$ was used to determine the effect of cultivar on the quantified morphological traits, total phenolic content, individual polyphenolics content, and antioxidant potential for both systems.

Two-way ANOVA analysis using Sidak's multiple comparison test was used to examine the difference between the two growth systems for total phenolics, the individual polyphenolics, and total antioxidant potential. Correlation between total polyphenolics, total polyphenolic antioxidant potential, and rosmarinic acid antioxidant potential was tested using Pearson test at a significance level of 0.05.

Hierarchical cluster analysis was performed using IBM SPSS Statistics 22 to determine if there was a relationship between the cultivars grown in the in vitro system and their polyphenolic constituents. Data used was standardized using $Z$ score and between group linkages were analyzed using squared Euclidean distance and represented in the form of a dendrogram.

## RESULTS AND DISCUSSION

**Germination Rates of Seeds from Selected Cultivars.** Seeds were collected from different seed suppliers and research institutes from five countries. Of the 29 cultivars collected 14 showed no or very low germination and were not used further in this study. Thus, 15 cultivars were used for the analyses (Table 1).

**Morphotyping of Cultivars.** There are 27 traits mentioned in the UPOV guidelines for *Ocimum basilicum*.[45] They can be classified into four major groups, namely, plant type (habitat; height; density), stem type (color; pubescence; number of flowering shoots), leaf type (blade length; pubescence; color; margin; glossiness), and flower type (corolla color; bract hairiness; color of style). Collected cultivars were assessed against these major qualitative and quantitative traits (Table 2). The collected cultivars were broadly classified into large (lettuce) leaf and robust type, dwarf leaf type, purple colored type, or tall and slender type (Figure 1). All the cultivars grew successfully in both the in vitro and CP systems. Plants were healthy at maturity and progressed to flowering (approximately 90 days for the CP system grown plants). Flowering in the in vitro system was either accelerated, with some cultivars flowering at 60 days (for example B2, B8, and B10), or delayed, with flowering after 90 days. Plant height in the CP system was generally much greater than that in the in vitro system, with some cultivars grown in the CP system 20 times the height of those in the in vitro system (for example, B1 3.37 ± 0.44 cm in vitro and 74.83 ± 3.17 cm in the CP system). Height difference was reflected in the greater number of nodes, branches, and internodal distances found for the CP system grown plants. Traits shown in Table 2 align with other studies of *Ocimum basilicum*[18] where morphological diversity is reported.

**Table 1. Seed Collection and Screening of the *Ocimum basilicum* Cultivars for the Study Based on Their Germination Percentage[a]**

| code | cultivar | country |
|---|---|---|
| B1 | Cim Saumya | India |
| B2 | Turkmaniya Basil | India |
| B3 | Subja | India |
| B4 | Ban Tulsi | India |
| B5 | Basilicum Breitblattriges | Germany |
| B6 | Basil Genovese | India |
| B7 | Basil Genovese | Spain |
| B8 | Basil Minimum | Spain |
| B9 | Organic Cinnamon | Australia |
| B10 | Organic Thai Basil | Australia |
| B11 | Basil Stella | Australia |
| B12 | Holey Green | Australia |
| B13 | Red Rubin | Australia |
| B14 | Basil Genovese America | United States of America |
| B15 | Sweet Basil | United States of America |

[a]29 cultivars of *Ocimum basilicum* were collected for the study. B16−B29 (not shown in this table) showed no or very low germination (0−20%) and were not used in the study. B7, B8, B12, and B13 showed low germination percentage (21−30%); B1, B2, B3, B5, and B6 showed medium germination percentage (31−69%); and B3, B9, B14, and B15 showed high germination percentage (70−100%).

**Standardization of a Method for Extraction of Rosmarinic Acid.** Lyophilization of plant samples was determined, through preliminary analysis, to yield the highest concentration of polyphenolics (data not shown). This result concurs with that found previously[3] in a comparison of basil that was lyophilized with fresh, quick frozen or blanched and frozen samples. The removal of water concentrates polyphenolics in the dried plant samples. For *Ocimum basilicum,* RA is the major metabolite of interest, thus our extraction method was developed for its isolation. We tested a number of extraction protocols using ethanol, homogenization, and two forms of sonication (water bath assisted or ultrasonication) to optimize yields of RA from lyophilized samples. The highest yields of RA, 33.58 ± 0.95 mg/g DW and 31.45 ± 0.68 mg/g DW (Figure 2), were found when 80% v/v ethanol in water or 60% v/v ethanol in water respectively was used as the extraction solvent in combination with water bath sonication. Routinely, 60% v/v ethanol in water was used with the sonication processing of all samples. This protocol was found to be time efficient, required minimal resources, and was easy to perform.

**Comparison of the in Vitro and CP System.** *Total Phenolics.* The Folin−Ciocalteau phenolic assay was used to quantitate the total phenolic content of samples derived from the in vitro and CP growth systems for whole plant and was expressed in terms of gallic acid equivalents per gram (Figure 3). There was a significant difference ($p < 0.05$) found in total phenolic content between the two growth systems. It was also found that cultivars grown in the CP system had higher total phenolic contents; for example, the highest phenolic content was found in three of the cultivars, B12 (156.15 ± 6.19 mg/g GAE DW), B13 (127.41 ± 3.11 mg/g GAE DW), and B14 (126.41 ± 0.72 mg/g GAE DW), while the lowest was found for B10 (73.86 ± 1.29 mg/g GAE DW). The in vitro system showed a similar trend of phenolic content among cultivars, and the highest was found in B12 (69.69 ± 2.83 mg/g GAE DW), B13 (67.79 ± 0.82 mg/g GAE DW), and B7 (65.71 ± 2.14 mg/g GAE DW) while the significantly lowest level was found in B15 (41.78 ± 0.99 mg/g GAE DW). The highest

[a]Data represented as mean ± SEM of each of three replicates ($n = 3$). Different letters indicate significant differences ($p \leq 0.05$) according to Tukey's HSD. Plant habitat: All erect type except for B8, showing intermediate habitat. Plant density: Varies from loose (B1, B2, B4) to medium (B9, B10, B15) to dense (B3, B5, B6, B7, B8, B12, B13, B14). Stem type: Stem color in all cultivars was green except for B9 and B13, and hairs were present in all. Leaf type: Variants in leaf morphology including ovate/dark green/less hairy/serrated/flat (B1, B2, B4), ovate/green/hairy/serrated/undulate (B9), lanceolate/purple/serrated/flat (B13), broad ovate/green/hairy/serrated/undulate (B12), small ovate/dark green/serrated/flat/less hairy (B8), broad ovate/green/serrated/undulate/flat/glossy (B3, B5, B6, B7, B11, B14, B15) and lanceolate/green/serrated/less hairy (B15) were observed. Flower type: Four types of flower colors, light purple (B1, B2, B4, B10), white (B3, B5, B6, B7, B8, B11, B14, B15), dark purple (B9, B13), and purple type (B12), were found in this study.

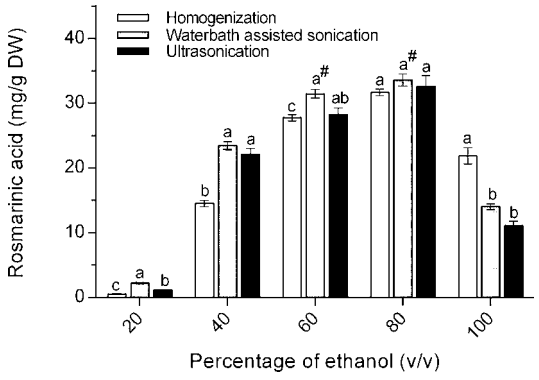

**Figure 2.** Comparison between homogenization, water bath sonication and ultrasonication at five different percentages of ethanol for standardization, and selection of extraction methodology for rosmarinic acid. Data are presented as the mean ± SEM of each of three replicates ($n$ = 3). Different letters indicate significant differences ($p \leq 0.05$) between methods, within percentage of ethanol according to Tukey's HSD. # shows no significant difference ($p \leq 0.05$) between 60% ethanol and 80% ethanol with water bath sonication.

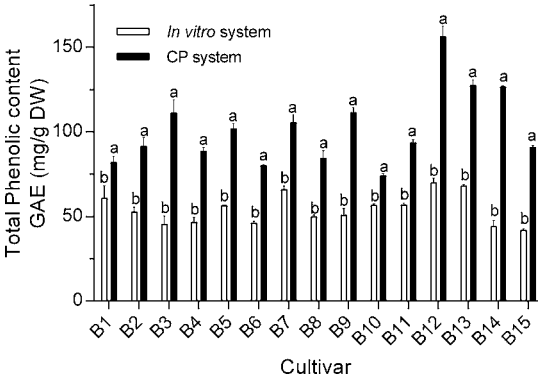

**Figure 3.** Total phenolic content for 15 *Ocimum basilicum* cultivars grown in the *in vitro* system and the CP system. Total phenolic content is reported in gallic acid equivalents, GAE (mg/g DW). Data are presented as mean ± SEM of each of three replicates ($n$ = 3) for the whole plant. Different letters indicate significant differences ($p \leq 0.05$) between the two growth systems, within cultivars according to Sidak's multiple comparison test.

phenolic content was thus found in B12 and B13 for both growth systems. This analysis clearly shows the effect of cultivar on the total phenolic content which correlates well with reports for this species and other studies.[4,47]

Our values for CP system grown samples are of the same magnitude as those reported by Jaysinghe et al.[19] for different fractions used by them. Total phenolic content is dependent on age and state of plant material (dry/fresh), and the contents found in mature plants in our study were much higher than those found for four week old plants (17.58 mg/g GAE DW) in the study reported by Kwee and Niemeyer[4] and Lee and Scagel.[2] Even though determination of total phenolics in plant cultivar samples is a useful comparative measure and may correlate well with antioxidant activity, it provides little indication of the responsible compounds.

*Individual Polyphenolic Content.* HPLC was used to determine the concentrations of RA, ChA, and CA in both the aerial parts and roots of the different cultivars of *Ocimum basilicum* grown in the in vitro and CP systems. A characteristic chromatogram (Figure 4) of extracts from the aerial part and

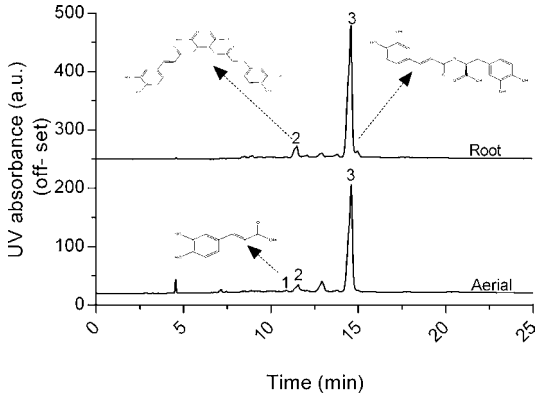

**Figure 4.** Typical HPLC chromatogram for the aerial and root samples of *Ocimum basilicum* using UV absorbance detection (280 nm). Peak 1: caffeic acid (10.6 min). Peak 2: chicoric acid (11.6 min). Peak 3: rosmarinic acid (14.5 min).

roots of B13 showed distinct peaks for RA (14.5 min), ChA (11.6 min), and CA (10.9 min). Analytical figures of merit for three polyphenolics are shown in Table 3. As reported by

**Table 3. Analytical Figures of Merit for Polyphenolics Found in This Study**

| | UV detection | | chemiluminescence | |
|---|---|---|---|---|
| polyphenolic | $R^2$ | LOD ($\mu$M) | $R^2$ | LOD ($\mu$M) |
| rosmarinic acid | 0.9988 | 0.5 | 0.9984 | 0.75 |
| chicoric acid | 0.9900 | 0.2 | 0.9870 | 0.1 |
| caffeic acid | 0.9922 | 10 | 0.9985 | 5 |

earlier studies, RA was found as the major polyphenolic in the ethanolic extract of these cultivars. The highest and lowest RA producing cultivars for whole plants were the same for both growth systems. No significant difference ($p < 0.05$) in RA content of whole plants was found for 11 out of the 15 cultivars grown in both systems. For four of the cultivars there was a significantly higher level of RA in CP system grown plants compared with those grown in vitro. B13, B12, and B7 were found to be high producing cultivars in both systems whereas B3, B5, and B11 emerged as low producing cultivars in both systems. RA content found in whole plants grown in the in vitro system ranged from as low as 24.20 ± 2.31 mg/g DW in B3 to 89.44 ± 1.49 mg/g DW in B13. B13 (89.44 ± 1.49 mg/g DW), B12 (78.00 ± 2.69 mg/g DW), and B7 (52.09 ± 6.38 mg/g DW) were the highest producing cultivars in the in vitro system while B3 (24.20 ± 2.31 mg/g DW), B14 (26.39 ± 0.82 mg/g DW), and B5 (28.46 ± 1.27 mg/g DW) were identified as the lowest producing cultivars (Figure 5A).

As shown in Tables 4 and 5 the aerial parts are found to be the major reserve of RA in both the in vitro system (10/15 cultivars) and the CP system (11/15 cultivars). The RA content found in the aerial parts is higher on a mg/g DW basis than that previously reported[2,4,9,32,34] while our results show similarity to the amounts reported (4–25 mg/g DW) by Kiferle[6] for leaves obtained from hydroponically grown plants.

The utility of the aerial parts of *Ocimum basilicum* and other plants belonging to the Lamiaceae family are well recognized for their RA content,[48] but to our knowledge only three studies, namely, Kiferle et al.,[6] Scagel and Lee,[34] and Toussaint et al.,[49] have studied roots as a source of RA. Interestingly, in our study roots of B13 in both systems showed an equal content of RA.

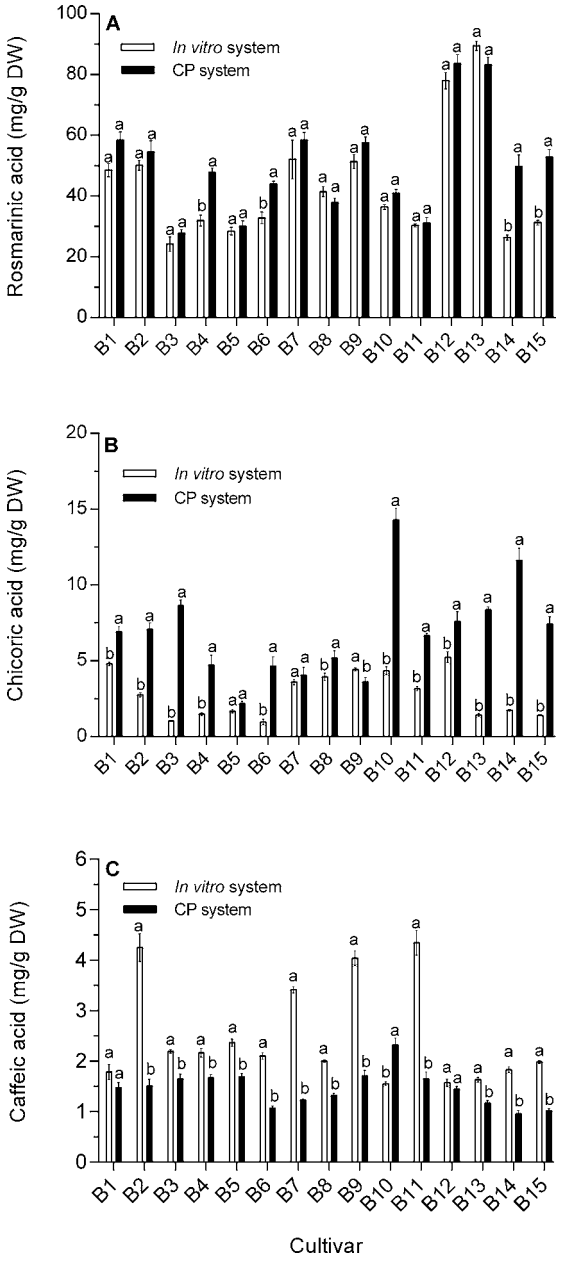

**Figure 5.** Concentrations of polyphenolics detected by HPLC analysis in the 15 *Ocimum basilicum* cultivars for the whole plant grown in the *in vitro* system and CP system. Comparison of (A) rosmarinic acid, (B) chicoric acid, and (C) caffeic acid (mg/g DW) content between the two growth systems. Data are presented as mean ± SEM of each of three replicates ($n$ = 3) for the whole plant. Different letters indicate significant differences ($p \leq 0.05$) between the two growth systems, within cultivars according to Sidak's multiple comparison test.

On the other hand, roots of cultivars such as B6, B3, B7, and B5 grown in the in vitro system produced up to three times more RA than in the CP system. Roots are clearly an alternative and rich source of RA. Kiferle et al.[6] reported high values of RA in roots of three cultivars at full bloom for plants growing in a hydroponic system and showed levels of RA similar to those found for two cultivars used in our study (B14, 27.32 ± 0.94 mg/g DW, and B7, 21.32 ± 0.85 mg/g DW). B13 in the in vitro system had RA content in the aerial parts of 45.33 ± 0.65 and in the roots of 44.11 ± 0.87 mg/g DW, showing that it has great potential as a source of RA and for selection studies. For all cultivars, similarity in RA profile for 11 cultivars between the CP system and the in vitro system shows that the in vitro system is very useful as a screening and selection tool for RA.

While the focus of this research was on quantification of RA in cultivars of *Ocimum basilicum*, the analysis of ChA and CA also offered insights into the contribution of other polyphenolics in the same cultivar and their antioxidant potential. Unlike RA, ChA content (Figure 5B) showed significant ($p < 0.05$) differences between both of the growth systems for all cultivars except for B5, B7, and B9. In the CP system B3 showed 8 times higher levels of ChA than in the in vitro growth system. The amount of ChA for the whole plant found in the in vitro growth system ranged from the highest level (5.24 ± 0.37 mg/g DW ChA) in B12 to the lowest level (0.98 ± 0.16 mg/g DW ChA) in B7. B12 (5.24 ± 0.37 mg/g DW ChA), B1 (4.80 ± 0.11 mg/g DW ChA), and B9 (4.44 ± 0.10 mg/g DW ChA) were found as high ChA producing cultivars in the in vitro system while B6 (0.98 ± 0.16 mg/g DW ChA), B3 (1.04 ± 0.04 mg/g DW ChA), and B15 (1.41 ± 0.04 mg/g DW ChA) were found as low producing cultivars. Similar to RA, aerial parts were found to be major sources of ChA in both systems (Tables 3 and 4). The amount of ChA (7.59 ± 0.37 mg/g DW ChA) found in B12 for the CP system and the amount found, 5.24 ± 0.37 mg/g ChA DW, in the in vitro system showed that this cultivar can be selected as a common high yielding cultivar.

The quantities of ChA reported in the in vitro and CP systems are higher than that reported in five studies to date on *Ocimum basilicum* and ChA.[2−4,9,34] Concentrations of ChA found in our study for B10 for the CP system are as much as 3.9 and 4.5 times higher than that reported in two previous studies.[29,4] Difference in growing conditions, age of harvest, extraction procedure, and analytical conditions can be defined as possible reasons for such a variable observation.[50] Although plants were grown for the same duration as in the studies conducted by Lee and Scagel[2] and Scagel and Lee,[34] the use of fresh samples and differences in cultivar type and extraction procedures may account for the differences of their values (0.114−0.885 mg/g FW and 0.05−0.01 mg/g FW) in comparison to our study. To the best of our knowledge, we have reported for the first time ChA in roots of *Ocimum basilicum.* No ChA was found in roots of B4, while the highest levels were found in B1 (2.45 ± 0.12 mg/g ChA) for plants grown in the in vitro system.

For CA in the in vitro system (Figure 5C) higher concentrations were found than in the CP system except for B10, which produced 1.4 times more CA. Cultivar type showed a significant effect on CA in both of the growth systems. The values found in this study ranged from 4.35 ± 0.25 mg/g CA DW in B11 to 1.55 ± 0.04 mg/g CA DW in B10. In the in vitro system high levels of CA were found in B11 (4.35 ± 0.25 mg/g CA DW), B2 (4.25 ± 0.27 mg/g CA DW), and B9 (4.04 ± 0.15 mg/g CA DW) while the lowest values were reported in B10 (1.55 ± 0.04 mg/g CA DW), B12 (1.58 ± 0.07 mg/g CA DW), and B13 (1.63 ± 0.04 mg/g CA DW). A low level of CA in B12 and B13 cultivars corresponds to the highest levels of RA in the same cultivars. As CA is a precursor to RA, low levels of CA compared to RA may indicate high biosynthetic turnover of CA. Similarly to RA and ChA, the aerial parts showed higher production of CA in 13 of the cultivars. Another possibility that may account for the higher levels of RA and ChA found compared with the levels of CA is that polyphenolic synthesis is altered during maturation and this may also account for the low

concentration of caffeic acid in comparison to RA and ChA as observed in our study.[18]

In the CP system plants were grown in the natural conditions and the light exposure was given equally and consistently to every unit by regular shifting. Similarly, in the in vitro system plants were grown under cool white fluorescent lights having qualities close to natural light and every unit was provided with uniform and consistent light conditions by regular shifting. Since the light conditions were consistent and the medium was consistent in each system, the polyphenolic response produced in the present study can be considered due to plant property in relation to the medium and light conditions. Additionally, the objective of the present work was to compare and find out whether an alternate system to the CP system can be evolved, and as the results have shown a similar trend for the major polyphenolic (RA), we presume that the developed technique is true to type to a greater extent.

Significant differences were found between the two growth systems for the four cultivars in RA and 13 out of 15 cultivars in ChA and CA profile. Conventional pot system was found to have higher amount of RA and ChA. Differences in the growth substrates, regular nutrient supplementation, and early flowering for all cultivars growing in conventional pot system can be hypothesized as the reasons for high RA and ChA content in the CP system and its significant difference from the in vitro system.[9,29,32] Additionally, as the extraction methodology was optimized for RA in the present study, it can be concluded that separate and targeted extraction of ChA and CA is needed to correlate the effects of growth substrate, growth parameters, and extraction methodology on their content in the two systems.

In the present study chicoric and caffeic acids are the minor polyphenolics found in the cultivars of *Ocimum basilicum*. The CP system is found as a better system for ChA while the in vitro system is found to be better for CA, clearly indicating that the amount of minor polyphenolic is differently affected by the growth substrate and growth parameters in basil in comparison to the major polyphenolics such as RA. The reasons for such an

observation can be studied in the future with extraction methodology optimized for these minor metabolites. It can be further postulated that parameters such as light quality, humidity, and temperature strongly affect the biosynthetic pathway for expression of minor polyphenolics in basil.

*Total Antioxidant Potential and Individual Polyphenolic Antioxidant Potential.* Antioxidant potential can be defined as the capacity of chemical moieties to act as inhibitors of free radicals, donators of hydrogen, quenchers of singlet oxygen, or molecules which can interrupt the oxidation process.[7] Thus, the identification of antioxidants from complex matrices is of significant importance to food, agriculture, and pharmaceutical industries. Detection of antioxidants by conventional antioxidant assays such as DPPH and FRAP assay is time-consuming. Acidic potassium permanganate reacts with potential antioxidant molecules to produce light due to excitation of manganese II species. The signals produced by the acidic potassium permanganate assay show good agreement with conventionally used assays thus its use has been advocated as an excellent alternative.[35]

Polyphenolics react with acidic potassium permanganate,[41] which is a distinct advantage of the chemiluminescence based assay over conventional assays. The method used in our study for total antioxidant assessment was as described by McDermott et al.[36] but modified and applied, for the first time to our knowledge, to *Ocimum basilicum* plant extracts. Total antioxidant content varied among the 15 cultivars for both growth systems. For the in vitro grown plant samples antioxidant potential was higher in comparison to CP grown plants. Similarly, in terms of total antioxidant content (Figure 6) no significant difference was found for the same 11 cultivars

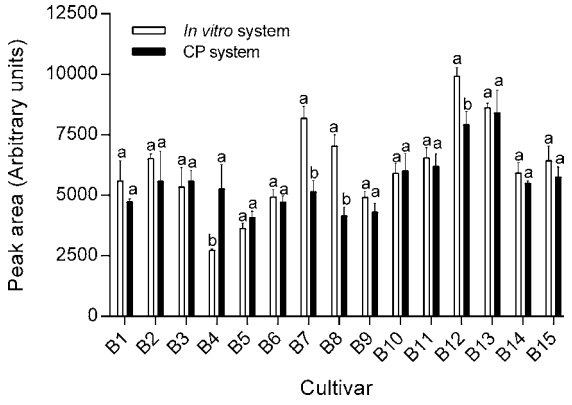

**Figure 6.** Total antioxidant potential found in 15 *Ocimum basilicum* cultivars grown in the *in vitro* system and the CP system by chemiluminescence analysis. Total antioxidant potential is expressed in terms of peak area. Data are presented as mean ± SEM of each of three replicates ($n$ = 3) for the whole plant. Different letters indicate significant differences ($p \leq 0.05$) between the two growth systems, within cultivars according to Sidak's multiple comparison test.

grown in both of the growth systems. B13 and B12 cultivars showed the highest chemiluminescence signals for plants growing in both growth systems.

It is important to identify individual polyphenolics within a complex matrix which may be responsible for antioxidant activity. To assess the contribution of individual polyphenolics, an enhanced acidic permanganate assay, a postcolumn technique, coupled with HPLC was performed on extracts from all cultivars growing in the in vitro growth system. RA antioxidant detection by the acidic potassium permanganate assay has been reported earlier by our group,[35,36] and in the present study its contribution to total antioxidant content was determined by comparing the peak area of RA with the peak area of total antioxidants. The highest antioxidant activity was found in association with RA for high yielding cutlivars such as B13 (Red Rubin), B12 (Holy Green), and B7 (Basil Genovese) cultivars growing in the in vitro system. RA associated antioxidant activity contributed to 44.7%, 44.4%, and 33.6% of the total antioxidant potential in these three cultivars while ChA (2.8%, 3.9%, and 5.8%) and CA (1.0%, 1.1%, and 1.7%) showed a lower percentage of total signal. RA is the major antioxidant compound detected in this study followed by ChA and CA. A positive correlation between the total polyphenolic content (RA + ChA + CA) detected by HPLC and the total polyphenolic antioxidant potential (RA + ChA + CA) and antioxidant potential of RA detected by chemiluminescence was found in this study (Figure 7). The presence of two catechol

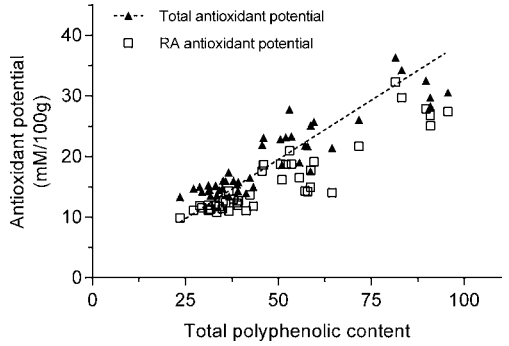

**Figure 7.** Correlation between antioxidant potential (total polyphenolic antioxidant potential and rosmarinic acid antioxidant potential) detected by chemiluminescence assay and total polyphenolic content detected by HPLC analysis for the 15 *Ocimum basilicum* cultivars grown in the in vitro system. The Pearson correlation coefficient ($r$) for antioxidant potential with total polyphenolic content response was 0.910 and 0.912 ($R^2$ = 0.828, 0.832) respectively. Antioxidant potential detected by chemiluminescence assay is expressed as mM/100 g. Data are presented as mean ± SEM of each of three replicates ($n$ = 3) for the whole plant.

rings with a carboxylic acid group gives rise to the antioxidant potential of RA.[5] The acidic potassium permanganate chemiluminescence detection and the subsequent determination of the antioxidant characteristics of ChA were observed for the first time in this study. The chemiluminescence assay is a sensitive and efficient method for determination of antioxidant activity that we propose as a tool for quick selection and screening of conventionally or in vitro grown samples. Our results indicated that polyphenolics content and antioxidant potential detected by chemiluminescence were positively correlated and significantly affected by cultivar type.

**Correlation between Morphotype and Individual Polyphenolic Content.** The contents of RA, ChA, and CA in aerial parts and roots of all cultivars were subjected to hierarchical cluster analysis to examine similarities and differences between the cultivars. Two distinct groups were generated based on the polyphenolic content analysis (Figure 8), and within the two main groups several subgroups were evident. Two main groups were primarily separated on flower color, which was highly correlated with plant morphology (leaf shape, leaf surface, stem type, plant habit) and RA content.

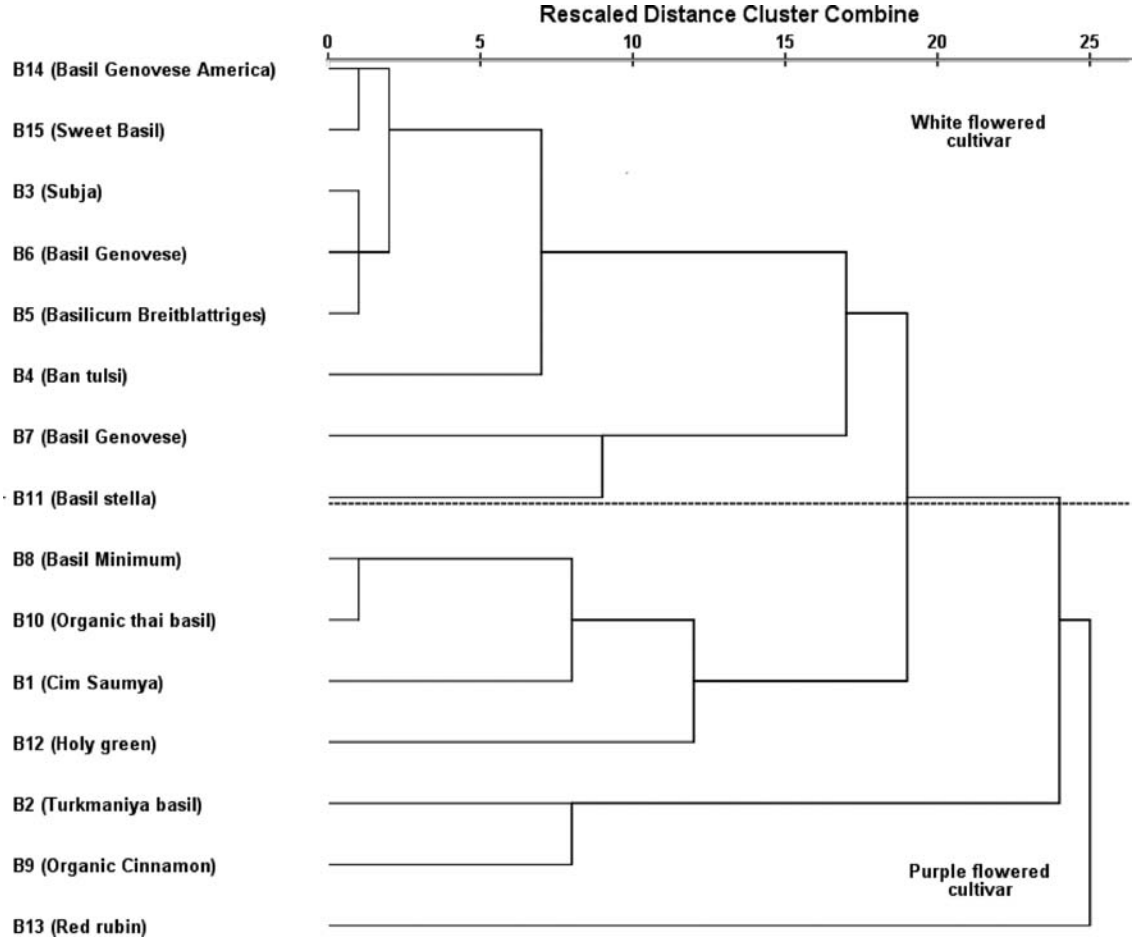

**Figure 8.** Clustering of 15 *Ocimum basilicum* cultivars grown in the *in vitro* system based on rosmarinic acid, chicoric acid, and caffeic acid content found in aerial parts and roots. Data used was standardized with *Z*-score using squared Euclidean distance, and dendrogram was drawn using SPSS 22 statistical computer package. Purple flowered cultivars showed higher contents of rosmarinic acid in comparison to white flowered cultivars. Dashed lines represent the division between the white and purple flowered cultivars.

Those cultivars with the highest RA content were purple flowered, and those with lower RA content were white flowered except for B4, which is a purple flowered cultivar that fell into the white flowered cluster.

**Merits of the in Vitro System.** The advantages of the developed in vitro screening system over conventional pot system include use of sterile, transparent (ease of observation), and precisely defined medium for root growth, no additional nutrient supplementation, and less labor and physical space requirement. These advantages allow for ease of downstream processing and nondestructive sampling for fast and reproducible screening of officinal plants. Additionally, the proposed in vitro system also shows advantages over hydroponics as a screening system as it does not requires use of specialized instrumentation, technical skills, labor, and energy.

Our study identified B13 (Red Rubin), B12 (Holy Green), and B7 (Basil Genovese) as high yielding cultivars in terms of high polyphenolic (RA) content and total polyphenolic antioxidant potential. Rosmarinic acid is the major metabolite found in the cultivars tested, and we have discovered that, in addition to its presence in the aerial parts of plants, roots are a viable and alternative source of RA. A distinct relationship in morphology and polyphenolic content was also revealed in this study, and purple flowered cultivars were found to be a rich source of RA compared with white flowered cultivars. We propose that the screening method described here will be applicable for the screening of a wide variety of secondary metabolites in a range of herbaceous annuals and that the method lends itself to the rapid determination of antioxidant activity in plant extracts.

**Fig Leaves.** Five fig varieties (Masui Dauphine, Horaishi, Kadota, Violette de Solies, and Negronne) cultivated in our orchard (Kawanishi, Hyogo, Japan) were used in this study. From the middle of June to early July, leaves at the nodes from the tip of the shoot to the fifth node were obtained. After a washing with water, the leaves were cut with a ceramic kitchen knife into 1.5 cm squares. The cut leaves were packaged in polyethylene bag with nitrogen gas and stored in an MDF-393AT freezer (Panasonic Healthcare, Tokyo, Japan) at −80 °C.

**Preparation of Leaf Extract.** The frozen leaves were freeze-dried by using an FDU-2100 freeze-dryer equipped with a DRC-3L dry chamber (Tokyo Rikakikai, Tokyo, Japan). Immediately after freeze-drying, leaves were pulverized to powder with a food mill (IFM-300SG, Iwatani, Osaka, Japan) four times for 10 s. Methanol or a mixture of water/methanol/acetone = 1:1:1 (v/v) was used as the extractant. Leaf powder (0.2 g) was placed in an Erlenmeyer flask, and 30 mL of extractant was added. The flask was shaken in a circular motion at 120 rpm using an NR-30 rotary shaker (Taitec, Saitama, Japan) for 3 h at room temperature. The atmosphere in the chamber of the food mill and in the flask was replaced by nitrogen. After centrifugation at 17000*g* for 10 min with a CR21G II centrifuge (Hitachi High-Technologies, Tokyo, Japan), the supernatant was collected. The residue was resuspended in 10 mL of extractant and centrifuged again under the same conditions. This process was repeated, and the collected supernatant was combined and made to be the volume of 50 mL by adding the extractant. The extract was filtered using a syringe filter (PTFE membrane, pore size = 0.45 μm) and stored at −20 °C.

**Identification of Phenylpropanoids.** *LC-DAD-MS/MS Analysis.* Analysis was carried out according to the method described by Kammerer et al.[25] with some modifications in equipment, column, and gradient program to reduce analysis time. An LC20ADXR HPLC with a diode array detector (DAD) system (Shimadzu, Kyoto, Japan) and a micrOTOF-Q II quadrupole-time-of-flight tandem mass spectrometer fitted with an ESI ion source (Bruker Daltonics, Billerica, MA, USA) were utilized. The UV−vis spectrum was recorded from 200 to 800 nm by DAD. A Synergi Hydro-RP column (particle size = 2.5 μm; 100 mm × 3 mm i.d., Phenomenex, Torrance, CA, USA) was employed for the separation of the phenylpropanoids. The mobile phase was (A) 2% acetic acid and (B) 0.5% acetic acid/acetonitrile = 1:1. The gradient began with 10% B and was varied to 24% B at 8 min, 30% B at 16 min, 55% B at 24 min, 100% B at 30 min, 100% B isocratic from 30 to 33.2 min, and 10% B from 34 to 36 min. The flow rate of the mobile phase was 0.4 mL/min. The temperature of the column oven was 40 °C, and the sample injection volume was 5 μL. Mass spectrometry was carried out using the following conditions: mass range, $m/z$ 50−1000; spectra rate, 1 Hz; nebulizing gas, nitrogen (1.6 bar); drying gas, nitrogen (180 °C, 7 L/min); capillary voltage, −4500 V for positive ion and +2800 V for negative ion; hexapole RF, 100 Vpp; quadrupole ion energy, 5 eV; collision gas, nitrogen (1.6 bar); collision energy, 10 eV; collision RF, 100 Vpp.

*Separation of HPLC Peak Fractions.* A semipreparative HPLC system equipped with a Delta 600 solvent pump (Waters, Milford, MA, USA) and AQUA C18 column (particle size = 5 μm; 250 × 10 mm i.d., Phenomenex) was used. The mobile phase was the same as that utilized for LC-DAD-MS/MS. The gradient started with 10% B and was varied to 24% B at 20 min, 30% B at 40 min, 55% B at 60 min, 100% B at 75 min, 100% B isocratic from 75 to 83 min, and 10% B from 84 to 90 min. The flow rate of the mobile phase was 4.7 mL/min. The temperature of the column oven was 30 °C. The extract was concentrated by evaporation, and 250 μL was injected into the system. The peaks that adsorbed at 320 nm were collected. The separated peak fractions were evaporated to remove the organic solvent. The dried fractions were dissolved in water and freeze-dried.

*NMR Measurements.* $^{1}$H NMR (400 MHz), $^{13}$C NMR (100 MHz), distortionless enhancement by polarization transfer (DEPT), double quantum filtered correlated spectroscopy (DQF-COSY), heteronuclear multiple-quantum coherence (HMQC), and heteronuclear multiple-bond connectivity (HMBC) NMR spectra were recorded with a JNM-ECA400 spectrometer (JEOL, Tokyo, Japan) in deuterated methanol ($CD_3OD$) using a 5 mm NMR tube. The chemical shifts were given on a $\delta$ (parts per million) scale with tetramethylsilane as an internal standard.

*Analysis of Sugar in Glycosides.* The freeze-dried HPLC peak fraction (1 mg) was dissolved in 5 mL of methanol, and HCl was added to reach 6 N. The mixture was heated at 90 °C for 4 h to hydrolyze the glycosides. After neutralization with NaOH, the sugar released from the glycoside was labeled by an ABEE (4-amino benzoic acid ethyl ester) labeling kit (J-oil mills, Tokyo, Japan) and was analyzed by HPLC. An LC-10A HPLC system (Shimadzu) and XBridge Phenyl (particle size = 5 μm; 150 mm × 4.6 mm i.d., Waters) were used for the analysis of the ABEE-labeled sugar. The mobile phase was 0.2 M potassium borate buffer (pH 8.9)/acetonitrile = 93:7 (v/v). The flow rate was 1.0 mL/min. The column oven temperature was 30 °C. The injection volume was 10−30 μL, and the peak was detected by monitoring the absorbance at 305 nm.

**Quantitative Determination of Phenylpropanoids.** An 1100 system HPLC-DAD (Agilent Technologies, Santa Clara, CA, USA) was used for determination of the phenylpropanoids. The column, mobile phase, and analytical conditions for HPLC were the same as those utilized for LC-DAD-MS/MS. Caffeoylmalic acid was detected by absorbance at 320 nm. Rutin, psoralen, bergapten, and psoralic acid glucoside were detected by absorbance at 250 nm. The calibration curves were made from standard chemicals, except for that of psoralic acid glucoside, which was made from the separated material from the fig leaves. All measurements were performed in triplicate.

**Evaluation of Antioxidative Activities.** *Superoxide Anion Radical ($O_2^{\bullet-}$) Scavenging Activity.* Following the method described by Saito et al.,[26] $O_2^{\bullet-}$ generated from the reaction of HPX and XOD was measured by ESR spin trapping with DMPO as the spin trapping agent. The ESR measurement conditions (JES-FA100, JEOL) were as follows: microwave power, 4 mW; field sweep, 330.5−340.5 mT; field modulation frequency, 100 kHz; field modulation width, 0.07 mT; sweep time, 2 min; time constant, 0.1 s. Fifty microliters of 2 mM HPX was placed in a test tube, and 30 μL of DMSO, 50 μL of sample, 20 μL of 4.45 M DMPO were added. The mixture was added to 50 μL of 0.4 U/mL XOD and vortexed for 20 s. The mixture was transferred to an ESR spectrometry liquid cell, and the DMPO−OOH spin adduct was quantified 100 s after the addition of XOD. The measurements were performed in duplicate. The $O_2^{\bullet-}$ scavenging activity was expressed as superoxide dismutase (SOD)-like activity from the calibration curve of standard SOD. Additionally, $IC_{50}$ values of samples were measured and the reaction rate constants with $O_2^{\bullet-}$ of samples ($k_2$) were calculated using eq 1, according to the method described by Mitsuta et al.[27]

$$k_2\ (\mathrm{M^{-1}\,s^{-1}}) = k_1 \times [\mathrm{DMPO}]/\mathrm{IC_{50}} \quad (1)$$

$k_1$ is the reaction rate constant with DMPO and $O_2^{\bullet-}$. The literature value used for the calculation was 15.7 $M^{-1}$ $s^{-1}$.[28] [DMPO] indicates the final concentration of DMPO, and the utilized value was 445 mM.

*Oxygen Radical Absorbance Capacity (ORAC).* The assay was carried out according to the method described by Dávalos et al.[29] with some modifications. In brief, 25 μL of the sample and 150 μL of phosphate buffer ($^1/_{15}$ M, pH 7.4) containing 100 nM fluorescein were placed in each well of a 96-well black, flat-bottom microwell plate (Thermo Fisher Scientific NUNC, Roskilde, Denmark). After preincubation at 37 °C for 30 min, 25 μL of 480 mM AAPH was added to the mixture using an onboard pipettor of plate reader (FLUOstar OPTIMA, BMG Labtech, Offenburg, Germany). From 270 s before the AAPH addition, the emission at 520 nm of each well was measured using a plate reader every 90 s for 60 intervals, with an excitation of 485 nm. The microwell plate was incubated at 37 °C during the measurements and was stirred prior to each measurement. The measurements were performed in triplicate. The area under the curve (AUC; calculated as an integral of the fluorescence intensity during measurement) of each sample was calculated, and activity was expressed as the trolox equivalent (μmol TE/g).

## RESULTS AND DISCUSSION

**Identification of Phenylpropanoids in Fig Leaves.** HPLC chromatograms of the MeOH and water/MeOH/acetone = 1:1:1 (v/v) extracts from Masui Dauphine leaves are shown as an example in Figure 1. The chromatogram profile

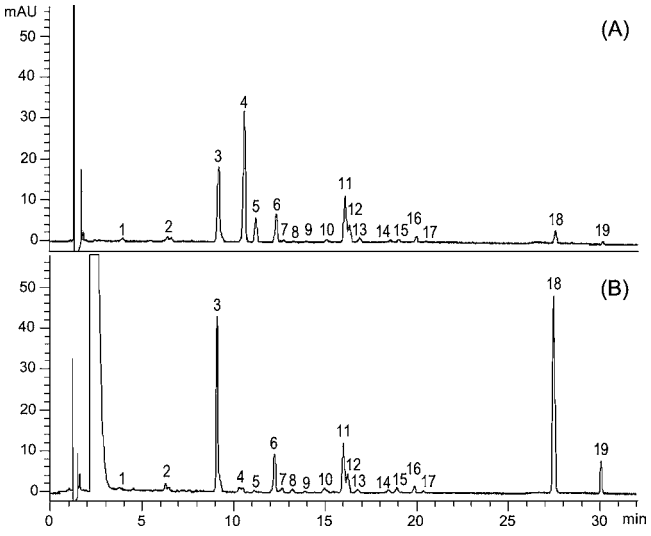

**Figure 1.** HPLC separation of phenylpropanoids from fig leaves: (A) MeOH extract; (B) water/MeOH/acetone = 1:1:1 extract of Masui Dauphine leaves. Peak detection was carried out at 280 nm. For peak assignment see Table 1.

differed depending on the extractant. Peaks 4 and 5 were reduced in the water/MeOH/acetone extract. Peaks 3, 18, and 19 of the water/MeOH/acetone extract were bigger than those in the MeOH extract. The LC-DAD-MS/MS results and corresponding identification of each peak are shown in Table 1. These peaks were detected from the five varieties examined. The intensities of the precursor ion (molecular ion) of peak 3, 4, and 5 detected in negative ion mode were >10 times than those detected in the positive ion mode. On the other hand, the intensities of the precursor ions of peaks 18 and 19 in the positive ion mode were about 30-fold higher than in the negative mode. In other peaks, the differences of the intensity of precursor ion were 0.7- to 1.2-fold between positive ion mode and negative ion mode.

Compound **2** showed a retention time (RT) of 6.5 min in HPLC, a molecular ion with $m/z$ 353 $[M - H]^-$, and a product ion with $m/z$ 191 in MS/MS. The formula of the molecular ion was calculated to be $C_{16}H_{17}O_9$. By matching the data with those of the standard chemical, compound **2** was identified as chlorogenic acid (Figure 2).

Compound **3** afforded a RT of 9.3 min in HPLC, a molecular ion with $m/z$ 295 $[M - H]^-$, and product ions with $m/z$ 133 (100%), 115 (85%), and 135 (75%) in MS/MS. The formula of the molecular ion was calculated to be $C_{13}H_{12}O_8$. These values matched with those of caffeoylmalic acid (CMA). Furthermore, NMR was used to confirm the planar structure (Figure 3; Table 2). Therefore, compound **3** was identified as CMA.

Compound **4** afforded a RT of 10.3 min in HPLC analysis, a molecular ion with $m/z$ 365 $[M - H]^-$, and a product ion with $m/z$ 159 in MS/MS. The formula of the molecular ion was calculated to be $C_{17}H_{17}O_9$. From the data obtained by NMR (Table 3), compound **4** was found to have the planar structure shown in Figure 4. Psoralen and sugar were generated by the

| | **Positive Ion Mode $[M + H]^+$** | | | |
| 18 | psoralen | 27.7 | 187 | 131 (100) |
| 19 | bergapten (5-methoxypsoralen) | 30.3 | 217 | 202 (100), 174 (45) |

hydrolysis of the compound **4** with hydrochloric acid. This sugar was identified as glucose by HPLC analysis using the ABEE labeling method. As such, compound **4** was determined to be (2*Z*)-3-[6-(β-D-glucopyranosyloxy)-1-benzofuranyl]-2-propenoic acid (psoralic acid-glucoside).

Compound **5** exhibited a RT of 11.3 min in HPLC, a molecular ion with $m/z$ 395 $[M - H]^-$, and product ions with $m/z$ 201 (100%) and 189 (65%) in MS/MS. The formula of the molecular ion was calculated to be $C_{18}H_{19}O_{10}$. The chemical composition was equivalent to psoralic acid glucoside (PAG) with an additional methoxy group ($CHO_3$−, FW 31.03). Furthermore, bergapten and glucose were generated by hydrolysis of the compound **5** fraction with hydrochloric acid. Thus, compound **5** was determined to be a PAG derivative with an additional methoxy group in the aglycone.

Compound **6** showed a RT of 12.4 min in HPLC, a molecular ion with $m/z$ 563 $[M - H]^-$, and product ions with $m/z$ 353 (100%), 383 (78%), and 443 (56%) in MS/MS. The formula of the molecular ion was calculated to be $C_{26}H_{27}O_{14}$. By matching the data to that of a standard chemical, compound **6** was identified as isoschaftoside (Figure 2). Schaftoside, the structural isomer of isoschaftoside, afforded a different product ion pattern ($m/z$ 353, 100%; 383, 83%; 443, 72%), but the

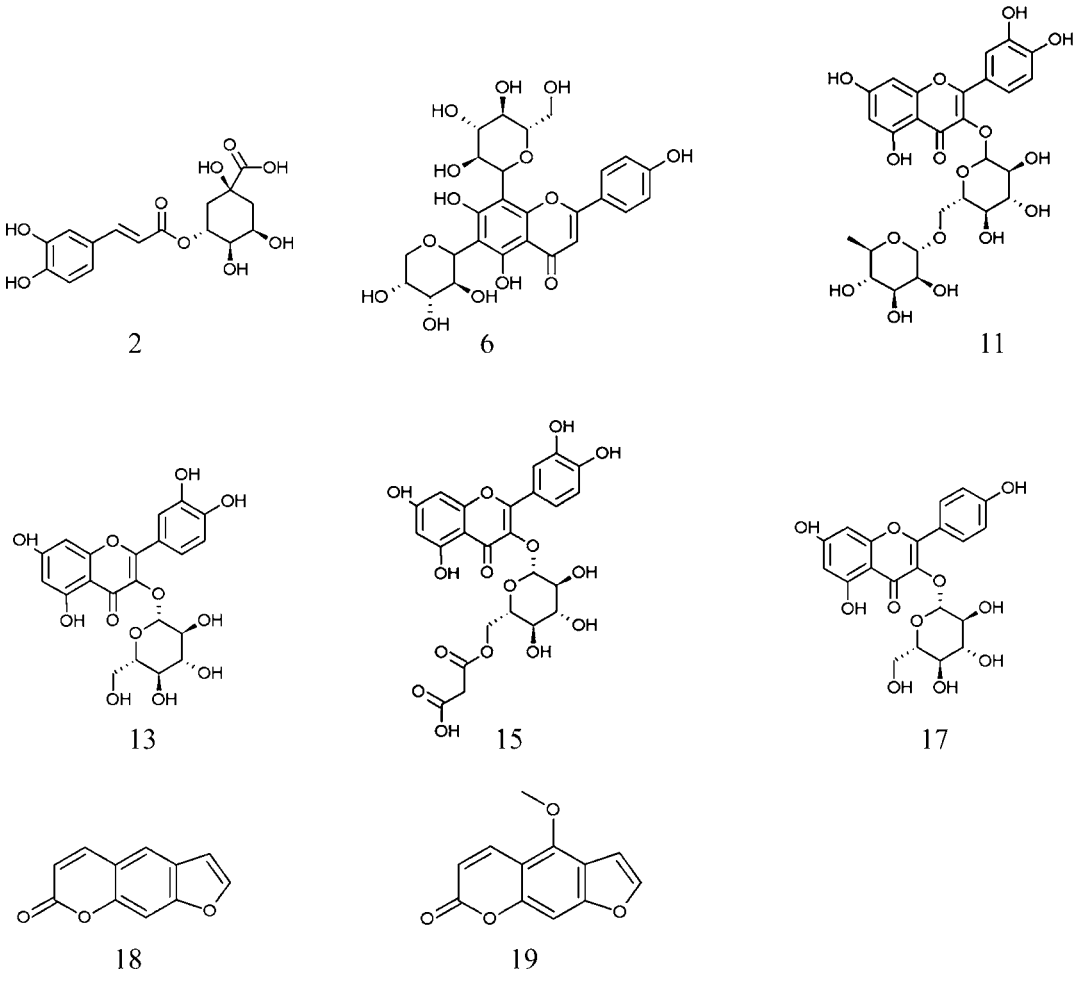

**Figure 2.** Identified compounds in fig leaf extract (except compounds **3** and **4**): compound **2**, chlorogenic acid; compound **6**, isoschaftoside; compound **11**, rutin; compound **13**, isoquercetin; compound **15**, quercetin 3-*O*-(6″-*O*-malonyl)-glucoside; compound **17**, astragalin; compound **18**, psoralen; compound **19**, bergapten.

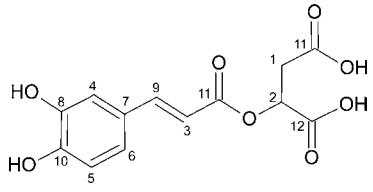

**Figure 3.** Chemical structure of compound **3**. For atom numbering see Table 2.

same RT. Thus, it is possible that a small amount of schaftoside was present in fig leaves.

Compound **11** showed a RT of 16.1 min in HPLC, a molecular ion with $m/z$ 609 $[M - H]^-$, and a product ion with $m/z$ 300 in MS/MS. The formula of the molecular ion was calculated to be $C_{27}H_{29}O_{16}$. By comparison to the standard, compound **11** was identified as rutin (quercetin 3-*O*-rutinoside, Figure 2).

Compound **12** showed a RT of 16.3 min in HPLC and the same molecular ion as PAG in MS/MS. The formula of the molecular ion was the same as that of PAG ($C_{18}H_{19}O_{10}$). Therefore, compound **12** was thought to be an isomeric form of PAG.

Compound **13** showed a RT of 16.9 min in HPLC, a molecular ion with $m/z$ 463 $[M - H]^-$, and a product ion with $m/z$ 300 in MS/MS. The formula of the molecular ion was calculated to be $C_{21}H_{19}O_{12}$. By comparison with the standard, compound **13** was identified as isoquercetin (quercetin 3-*O*-glucoside, Figure 2).

Compound **15** presented a RT of 19.1 min in HPLC, a molecular ion with $m/z$ 549 $[M - H]^-$, and product ions with $m/z$ 300 (100%) and 505 (30%) in MS/MS. The formula of the molecular ion was calculated to be $C_{24}H_{21}O_{15}$. Compound

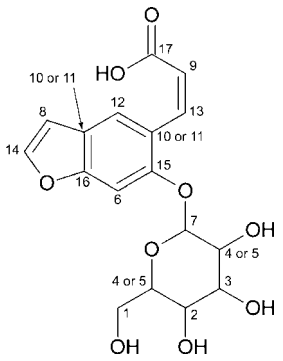

**Figure 4.** Chemical structure of compound **4**. For atom numbering see Table 3.

**15** was identified as quercetin 3-*O*-(6″-*O*-malonyl)-glucoside (Figure 2) by comparison with the standard.

Compound **17** exhibited a RT of 20.5 min in HPLC, a molecular ion with $m/z$ 447 $[M - H]^-$, and a product ion with $m/z$ 284 in MS/MS. The formula of the molecular ion was calculated to be $C_{21}H_{19}O_{11}$. By matching to the standard, compound **17** was identified as astragalin (kaempferol 3-*O*-glucoside, Figure 2).

Compound **18** presented a RT of 27.7 min in HPLC, a molecular ion with $m/z$ 187 $[M + H]^+$, and a product ion with $m/z$ 131 in MS/MS. The formula of the molecular ion was calculated to be $C_{11}H_7O_3$. Compound **18** was identified as psoralen (Figure 2) by comparison to the standard.

Compound **19** showed a RT of 30.3 min in HPLC, a molecular ion with $m/z$ 217 $[M + H]^+$, and product ions with $m/z$ 202 (100%) and 174 (45%) in MS/MS. The formula of the molecular ion was calculated to be $C_{12}H_9O_4$. By matching to the standard, compound **19** was identified as bergapten (5-methoxypsoralen, Figure 2).

**Phenylpropanoid Composition in Fig Leaves.** The amounts of some identified phenylpropanoids with comparatively large peak areas in the UV chromatograms were measured for five varieties including Masui Dauphine and Horaishi, the major varieties in Japan (Table 4).

Among the polyphenols, the CMA content ranged from 14.4 (Negronne) to 20.6 mg/g dry weight (DW) (Violette de Solies). The rutin content ranged from 7.2 (Negronne) to 11.4 mg/g DW (Violette de Solies), which was around 50−60% of the CMA content. CMA was the most abundant polyphenol in the fig leaves. CMA was reported to be found in plants such as *Chelidonium majus* L., *Corydalis lutea* L.,[30] lettuce (*Lactuca sativa* L.),[31] and nettle (*Urtica dioica* L.).[32] However, we found that fig leaves contained CMA for the first time. The second most abundant polyphenol, rutin, has been identified in many other plants. Additionally, some studies detected rutin in fig leaves.[17,18,20] Isoschaftoside was also previously identified in fig leaves,[33] and it was also considered a major polyphenol in addition to CMA and rutin. The HPLC-UV peak areas of other polyphenols were considerably small.

Among the furanocoumarins, the psoralen content ranged from 3.8 (Horaishi) to 23.0 mg/g DW (Violette de Solies). The bergapten content was only 12−22% of the psoralen content in the five varieties. The PAG content ranged from 6.7 (Horaishi) to 42.2 mg/g DW (Violette de Solies), which was approximately twice the psoralen content. Psoralen was regarded as the primary furanocoumarin in fig leaves. Because psoralen and glucose were generated in the hydrolysis of PAG, PAG may be a precursor of psoralen in fig leaves. PAG was identified in *Psoralea plicata* L.[34] and *Psoralea corylifolia* L.[35] We found that fig leaves contained PAG for the first time. One mole of psoralen (molecular weight (MW) 186) and glucose (MW 180) was generated by the hydrolysis of one mole of PAG (MW 366).[35] In fig leaves, the PAG content was approximately equivalent to the psoralen content by mole. Therefore, the potential psoralen content in fig leaves may be increased by approximately 2 times. Furthermore, a precursor of bergapten was also detected. Kasajima et al. reported a similar compound from methanol extracts of fig leaves.[18]

**Varietal Characteristics of Phenylpropanoid Composition.** Violette de Solies contained the greatest amounts of CMA, rutin, psoralen, bergapten, and PAG in the leaves among the five varieties of fig investigated in this study. The CMA and rutin contents differed between 1.4 and 1.6 times among the five fig varieties. Moreover, the furanocoumarin and PAG

**Table 4. Major Phenylpropanoid Content (Milligrams per Gram DW)[a] from Leaves of 5 Fig Varieties**

| variety | CMA[b] | PAG[b] | rutin | psoralen | bergapten |
|---|---|---|---|---|---|
| Masui Dauphine | 16.6 ± 0.6 | 18.0 ± 1.4 | 9.7 ± 0.4 | 10.2 ± 0.5 | 1.4 ± 0.1 |
| Horaishi | 17.6 ± 0.3 | 6.7 ± 0.2 | 11.3 ± 0.2 | 3.8 ± 0.0 | 0.8 ± 0.0 |
| Kadota | 18.7 ± 0.1 | 14.0 ± 0.6 | 8.7 ± 0.1 | 7.0 ± 0.1 | 1.1 ± 0.0 |

| Negronne | 14.4 ± 0.7 | 15.4 ± 0.6 | 7.2 ± 0.4 | 9.2 ± 0.3 | 1.1 ± 0.0 |

[a]Mean ± standard deviation ($n$ = 3). [b]CMA, caffeoylmalic acid, PAG, psoralic acid-glucoside.

contents of the Violette de Solies leaves were more than double those of Masui Dauphin.

It was reported that large doses (15 mg/person) of furanocoumarins administered orally induced photodermatitis in humans.[36] Therefore, caution should be exercised with oral ingestion of furanocoumarins from fig leaves. The leaves of Violette de Solies may have more risks for human health than other varieties with high concentrations of furanocoumarin and PAG. Horaishi is thought to be a low-risk variety because the leaves contain a lower amount of furanocoumarins and PAG.

There are a large number of fig varieties, so investigation of other varieties is necessary to elucidate the varietal characteristics of phenylpropanoid composition in fig leaves. If a variety with a low furanocoumarin-related compound content and high polyphenol content is found, it may be suitable for consumption.

**Antioxidant Activity of Phenylpropanoids in Fig Leaves.** Because CMA and PAG were the most abundant phenylpropanoids in the fig leaves, their $O_2^{\bullet-}$ scavenging activities were measured by ESR spin trapping. The SOD-like activities of CMA and PAG separated from fig leaves were 70604 and 3776 U/g, respectively.

The $O_2^{\bullet-}$ scavenging activities at various concentrations and $IC_{50}$ values were measured, and the reaction rate constants with $O_2^{\bullet-}$ ($k_2$) were calculated for CMA (standard chemical and separated material) and rutin (standard chemical) (Table 5).

**Table 5. $O_2^{\bullet-}$ Scavenging Activity and ORAC of CMA, Rutin, and PAG from Fig Leaves**

| | $O_2^{\bullet-}$ scavenging activity[a] | | ORAC[b] | |
|---|---|---|---|---|
| compound | $IC_{50}$ ($\mu$M) | $k_2$ ($M^{-1}s^{-1}$) | $\mu$mol TE[c]/g DW | $\mu$mol TE/$\mu$mol |
| CMA (standard) | 12.0 | $5.8 \times 10^5$ | 12043 ± 258 | 3.57 ± 0.08 |
| CMA (separated[d]) | 33.2 | $2.1 \times 10^5$ | 11130 ± 558 | 3.30 ± 0.17 |
| rutin (standard) | 17.4 | $4.0 \times 10^5$ | 14856 ± 2229 | 9.07 ± 0.36 |
| PAG (separated) | –[e] | – | 2156 ± 452 | 0.79 ± 0.17 |

[a]Mean ($n$ = 2). [b]Mean ± standard deviation ($n$ = 2). [c]Trolox equivalent. [d]Separated from fig leaves of Masui Dauphine variety. [e]Not measured because of low activity.

The $IC_{50}$ values of standard and separated CMA were 12 and 33.2 $\mu$M, respectively. The $k_2$ values of standard and separated CMA were $5.8 \times 10^5$ and $2.1 \times 10^5$ $M^{-1}$ $s^{-1}$, respectively. Impurities in the CMA separated from the fig leaves may have led to the lower $k_2$ value as compared to the standard compound. The $O_2^{\bullet-}$ scavenging activity of rutin (standard chemical; $IC_{50}$ = 17.4 $\mu$M and $k_2 = 4.0 \times 10^5$ $M^{-1}$ $s^{-1}$) was equivalent to that of CMA.

CMA is the compound that coupled with caffeic acid and malic acid. The $k_2$ values of caffeic acid and chlorogenic acid (caffeoylquinic acid) were reported to be $9.6 \times 10^5$ and $16.7 \times 10^5$ $M^{-1}$ $s^{-1}$, respectively.[37] Rutin is the glycoside of quercetin with rutinose. The $O_2^{\bullet-}$ scavenging activity of rutin is approximately equivalent to that of quercetin.[38] The $k_2$ values of catechin, epicatechin, epicatechin gallate, epigallocatechin and epigallocatechin gallate were reported to be $(0.4–0.6) \times 10^5$, $(0.5–0.7) \times 10^5$, $(3.8–4.3) \times 10^5$, $(4.1–7.7) \times 10^5$, and $(7.3–14.2) \times 10^5$ $M^{-1}$ $s^{-1}$, respectively.[38,39] Vitamin C has a high $O_2^{\bullet-}$ scavenging activity with a reported reaction rate constant of $(2.7–3.5) \times 10^5$ $M^{-1}$ $s^{-1}$.[40−42] Therefore, the $O_2^{\bullet-}$ scavenging activities of CMA and rutin were higher than or equivalent to those of other catechins and vitamin C, but lower than those of chlorogenic acid and epigallocatechin gallate.

ORAC is one method that is used to evaluate the suppression of peroxy radicals in vitro. The ORAC values by weight of CMA (standard chemical and separated material), rutin, and PAG were 12043, 11130, 14856, and 2156 $\mu$mol TE/g, respectively (Table 5). The ORAC values by mole of the aforementioned compounds were 3.57, 3.30, 9.07, and 0.79 $\mu$mol TE/$\mu$mol, respectively. The ORAC value of PAG was <25% that of CMA, and it was a tendency similar to the SOD-like activity.

The value of the separated CMA from fig leaves was moderately lower than that of the standard CMA. Impurities in the separated CMA may have led to the lower activity. CMA and rutin showed equivalent ORAC values per weight. However, rutin exhibited an ORAC value that was approximately 3 times higher than that of CMA per mole. The difference in molecular structure, including the number or placement of binding hydroxyl groups, may have led to a different affinity with the radical derived from AAPH among the compounds. Ou et al. reported the ORAC values of caffeic acid, chlorogenic acid, quercetin, rutin, and catechin to be 4.37, 3.14, 7.28, 6.01, and 6.76 $\mu$mol TE/$\mu$mol, respectively.[43] The ORAC level of CMA was equivalent to those of caffeic acid and chlorogenic acid and was moderately lower than those of quercetin, rutin, and catechin. The ORAC level of rutin was higher than those of caffeic acid and chlorogenic acid and was equivalent to those of quercetin and catechin.

In fig leaves, CMA and rutin were the major polyphenols and were found in relatively high concentrations. Therefore, both compounds are thought to contribute to the antioxidant activity. PAG is the most abundant phenylpropanoid in fig leaves, but the $O_2^{\bullet-}$ scavenging activity and ORAC of PAG were significantly lower in comparison with CMA and rutin. Isoschaftoside was the third most abundant compound, but the contribution to antioxidant activity was small because apigenin, the aglycon of isoschaftoside, showed low $O_2^{\bullet-}$ scavenging activity (data abbreviated). Similarly, because the contents of other polyphenols (chlorogenic acid and quercetin glycosides) were significantly less than that of CMA and rutin, the contribution to $O_2^{\bullet-}$ antioxidant activity was thought to be small.

**Potential of Fig Leaves as Functional Food Material.** Many papers have described the various physiological functions of polyphenols. The reduction effect of rheumatalgia was reported in CMA-rich nettle extracts.[44] Other caffeic acid derivatives, such as chlorogenic acid, were shown to reduce obesity, diabetes, and inflammation in animals.[45−48] The palliation of cerebral ischemia disorder in rats[49] and mitigation of convulsions induced by kainic acid in mice[50] were reported as effects of rutin. The fruit of *Psoralea corylifolia* L. containing PAG composes "Buguzhi", a euphoriant in Chinese medicine. Ossiferous promotion was reported with Buguzhi extracts,[51] but the exact effect of PAG on human health is unknown. When fig leaf extract is taken orally, the amount of furanocoumarins may increase in the stomach. When using fig leaves as food, it is necessary to examine how PAG will be hydrolyzed in the human body.

Fig leaf extracts exhibited high antioxidant activities, but the activity was less than that of green tea or coffee according to the

phenylpropanoid content found in this investigation. To elucidate the functionalities of fig leaves, further studies in the influence of CMA and PAG on human health are necessary. Moreover, a greater number of fig varieties should be evaluated in regard to phenylpropanoid content and antioxidant activity of the extracts. Similarly, the influence of various processing and extraction methods on the residual rate of the components in fig leaves should also be investigated.

concentrations higher than 95% in some orange varieties. For other citrus species, such as grapefruit, the proportion can be lower (between 80−90%), and in lemon, it can be even lower (bellow 75%). In the case of lemon, the presence of other monoterpene hydrocarbons, such as $\beta$-pinene and $\gamma$-terpinene, allows attainment of similar amounts of monoterpene hydrocarbons, as in orange. Other compounds, such as oxygenated monoterpenes (alcohols and aldehydes), also show interspecific variation.

The biological activity of citrus essential oils has been widely recognized.[30] For fruit flies, larval toxicity of some of their compounds has been reported for *C. capitata*,[26,31] and in general monoterpene hydrocarbons show less toxicity than oxygenated monoterpenes.[31] In addition, the proportions of monoterpenes and other compounds of the essential oils vary according to senescence of the fruit. These changes have been associated both with host acceptance[32] and with a reduction in peel extracts toxicity.[26]

The interaction of all the resistance mechanisms offered by the plant results in a variation between species and cultivars in their suitability as hosts. For example, lemon has been reported as the poorest host citrus for larval survival of *C. capitata*[24,23] and the Caribbean fruit fly, *Anastrepha suspensa* (Loew).[22] For *A. fraterculus* populations from Argentina, the absence of larval development allows proposing that lemon is not a host,[33] yet the mechanisms involved have not been investigated. In addition, the inability of the Mexican morphotype of *A. fraterculus* to successfully develop in the Valencia orange and the Ruby Red grapefruit renders the status of Mexican *A. fraterculus* as a pest of citrus in Mexico unsubstantiated.[34] In contrast, grapefruit has been reported as a good host for *A. suspensa*[22] and the Mexican fruit fly, *Anastrepha ludens* (Loew.),[35] and it was found naturally infested by *A. fraterculus* and *C. capitata* in Argentina.[17,18] For the case of *A. ludens*, it has been argued that its long ovipositor allows the females to lay the eggs in the albedo area of the peel, thus preventing the contact of the newly emerged larvae with the toxic compounds present in the essential oil glands from the flavedo on their way to the pulp.[36] Moreover, the susceptibility of citrus to *A. suspensa* was found to vary according to the senescence of the fruit.[22,37]

Given the relevance of understanding the resistance mechanisms of the plants that can affect host use in fruit flies, we investigated the role of peel extracts of lemon and grapefruit on the survival of the immature stages of *A. fraterculus*. We used an integrative approach and evaluated the insecticidal activity of the ether extracts obtained from the peel of the two citrus species as well as the toxicity of the major constituent of the essential oil (limonene) and one oxygenated monoterpene (citral). In addition, we evaluated the impact of the ripening stage of the fruit on the toxicity. We also evaluated another fruit fly species, *C. capitata,* from which extensive research has been done for comparison. Finally, we characterized the chemical composition of the extracts to allow identification of putative responsible compounds in case we found a differential mortality.

## MATERIALS AND METHODS

**Insects.** Eggs and first instar larvae of *A. fraterculus* and *C. capitata* were obtained from colonies established at the Agriculture Zoology laboratories of Estación Experimental Agroindustrial Obispo Colombres (EEAOC), Tucumán, Argentina. *Anastrepha fraterculus* colony was initiated in 1997 with pupae obtained from infested guavas, collected in the vicinity of Tafí Viejo, Tucumán province (northwest Argentina).[38] Wild individuals were introduced into the laboratory and were maintained following standard procedures.[38,39] *Ceratitis capitata* colony was initiated with wild individuals obtained from infested oranges collected at different localities in northwest Argentina (Salta and Jujuy provinces) and held under artificial rearing conditions using standard procedures. For the bioassays, eggs were collected from the rearing cages for 4 h. To evaluate the egg stage, eggs were used right after collection. For the larval stage, eggs were incubated for 48 to 72 h in a chamber at 25 ± 2 °C and 60 ± 20% relative humidity to obtain the larvae. All the experiments were conducted in the laboratory.

**Plant Material.** The citrus varieties used were lemon, *C. limon* var. Eureka, and grapefruit, *C. paradisi* var. Foster Seedless. Fruit were collected in May 2011 and in August 2012 from the experimental orchard at EEAOC (26°47′15,45″/65°11′23,72″) in Las Talitas, Tucumán, Argentina. These periods corresponded to two different ripening stages of the fruit; the fruit from May was at the stage in which it is harvested for its commercialization (the fruit is already ripening and is turning from green to yellow) while the fruit from August corresponded to the overripe stage. Fruits were randomly selected from different plants; however, special precaution was taken to avoid damaged fruit or with symptoms of illness or pests.

**Extraction of Ether Extracts.** One day after harvest, the fruits were washed with tap water and dried at room temperature. The flavedo was removed from the peel with a metal grater and placed in a glass Erlenmeyer. Peel compounds were extracted with ethyl ether by immersion. The flask was covered with a cotton plug and was placed on a shaker for 40 min. Ether extracts were filtered, and the solvent was evaporated using a rotary evaporator at room temperature.

**Chemical Compounds.** Two compounds were also evaluated. The monoterpene hydrocarbon limonene was selected, since it is the predominant compound of essential oil citrus extracts; the oxygenated monoterpene citral was selected because it is a component that exhibited high toxicity against *C. capitata* larvae.[26,31] (*R*)-Limonene (98%) and citral (mixture of neral and geranial) (95%) were purchased from Sigma-Aldrich, Buenos Aires, Argentina.

**Chemical Characterization of the Ether Extracts from the Peel.** The chemical characterization of the extracts was performed at the Laboratory for Research and Analytical Services (LISA) from Facultad de Bioquímica, Química y Farmacia, Universidad Nacional de Tucumán (FBQF-UNT) (Tucumán, Argentina). The ether extracts were analyzed by gas chromatography (GC) using an Ultra Trace gas chromatograph with DB-1 column-MS 25 mm × 0.25 mm ID, temperature ramp of 60 to 300 °C (3 °C/min), and an injection temperature of 270 °C. The mass spectrometer used was a Polaris Q, EI (+) 70 eV with an ion trap analyzer as detector. Individual peaks were identified by the retention time and retention rates. At least two independent analyses were performed for each extract. The results were processed to obtain the percentage of the area occupied by each compound, and this value was averaged in each extract. The components were identified by the comparison of their retention index (RI) with reference to a homologous series of *n*-alkanes (C9−C25), by comparing their mass spectra with those reported in the literature, and by computer matching with the Adams 31[40] library.

**Bioassays.** *Fumigant Toxicity Assessment. Eggs.* Fumigant toxicity was determined by exposing the eggs to the volatiles of the ether extracts or to the pure compounds. For each experimental unit, 20 eggs were deposited with the aid of a fine brush on a piece of black filter paper (2 cm × 2 cm) which was in turn placed over a dampened cloth (5 cm × 5 cm) inside a glass Petri dish of 10 cm diameter (90 $cm^3$ volume). The cloth was used to avoid the dehydration of the eggs. On the other side of the Petri dish, and without being in contact with the damp cloth, a square of filter paper (3 cm × 3 cm), previously impregnated with the extract or the corresponding compound, was placed. The Petri dish was sealed with parafilm and incubated at 25 °C for 24 h. Then the damp cloth and the filter paper with the eggs were placed in an untreated plastic Petri dish of 10 cm diameter and left for incubation. After 5 days, the number of chorions (corresponding to those individuals that survived the embryonic developmental stage)

and turgid eggs (corresponding to dead individuals) were quantified. In the controls, the filter paper was clean.

*Larvae.* The experimental design was similar to that used for eggs; each experimental unit consisted of 20 larvae that were placed on a black filter paper which, in this case, was placed over a pile of five pieces of white filter paper (2 cm × 3 cm) moistened with a sugar solution 10% (w/v). The extract or compound was applied on another piece of filter paper, placed at the opposite end of the Petri dish. The plate was sealed with parafilm and incubated for 24 h, the time at which larval mortality was registered (each larva was considered dead

when it remained immobile even after touching it gently with a brush). The control was performed similarly but without applying any extract or compound.

*Contact Toxicity Assessment. Eggs.* Contact toxicity was evaluated by incubating the eggs in an emulsion of water with a sodium salt of carboxymethylcellulose containing the extract or compound.[41] The eggs were obtained and manipulated as described previously. Once the black filter paper with the 20 eggs was placed in the damp cloth, 100 $\mu$L of the emulsion was applied with a micropipette (Eppendorf ). The Petri dish was sealed with parafilm and incubated at 25 °C for 5 days. The control was performed similarly, but the emulsion contained no extract or compound. Mortality was assessed as described for fumigant toxicity bioassays.

*Larvae.* Contact toxicity also involved the use of an emulsion which, in this case, contained sugar to provide food. Larvae were obtained and manipulated as described in the fumigant toxicity section. After applying the emulsion (100 $\mu$L), the Petri dish was sealed with parafilm. For the controls, the larvae were imbibed in the emulsion that lacked any extract or compound. Larval mortality was registered after 24 h of exposure. Both bioassays were performed in compliance with the appropriate laws and institutional guidelines to meet security standards and adequate animal handling.

**Experiments and Treatments.** *Experiment 1. Fumigant Toxicity of Lemon and Grapefruit Ether Extracts and Limonene and Citral on Egg and Larval Stages.* For the egg stage, the concentrations used were 0.07, 0.14, 0.28, 0.56, 1.11, and 2.22 $\mu$L extract/$cm^3$ air for the lemon and grapefruit extracts; 0.11, 0.21, 0.42, 0.83, and 1.11 $\mu L/cm^3$ air for limonene and 0.01, 0.11, 0.22, 0.44, and 0.89 $\mu L/cm^3$ air for citral. The number of individuals evaluated for each concentration ranged between 60 and 100, involving three to five independent repetitions. For the larval stage, the concentrations used were 0.014, 0.028, 0.056, 0.111, and 0.222 $\mu$L extract/$cm^3$ air. The number of individuals evaluated for each concentration ranged between 100 and 200, involving five to ten independent repetitions.

*Experiment 2. Fumigant Toxicity of Extracts Obtained at Different Ripening Stages from Lemon and Grapefruit on Egg Stage.* The concentrations used were 0.07, 0.14, and 0.28 $\mu$L extract/$cm^3$ air for the extracts of ripe lemon and grapefruit. The number of individuals evaluated for each concentration in each extract ranged between 60 and 100, involving three and five independent repetitions. The concentrations for overripe fruit were 0.07, 0.14, 0.28, and 0.55 $\mu$L extract/$cm^3$ air. The number of individuals evaluated for each concentration in each extract ranged between 60 and 100, involving three and five independent repetitions.

*Experiment 3. Comparative Analysis between A. fraterculus and C. capitata.* The comparative analysis between *A. fraterculus* and *C. capitata* involved peel extracts of lemon and grapefruit and limonene and citral. A contact assay for eggs and larvae was performed. For eggs, dilutions were performed at 50%, starting from an emulsion containing 100 $\mu$L of fruit extract or limonene, while for citral, they were performed starting from an emulsion containing 20 $\mu$L per mL. Eight concentrations were used: 1.56, 5, 6.25, 12.5, 25, 50, 75, and 100 $\mu$L per mL for extracts or compound in eggs of *A. fraterculus*, seven concentrations of lemon or grapefruit extract were evaluated on *C. capitata*: 6.25, 12.5, 25, 50, 100, 200, and 400 $\mu$L per mL for extracts. Dilutions for limonene started from an emulsion containing 100 $\mu$L per mL, and seven concentrations were used. One to four replicates were performed for each extract. For the larvae, dilutions were also performed at 50%, starting with an emulsion containing 20 $\mu$L of extract or compound per mL of solution. A total of nine concentrations were applied: 0.156, 0.3125, 0.625, 1.25, 2.5, 5, 6.25, 12.5, and 20 $\mu$L per mL.

**Data Analysis.** Data were analyzed by a probit analysis to obtain $LC_{50}$ and $LC_{90}$ values. Mortality was corrected in those cases in which the control cages had dead individuals (mortality attributable to a reason not related to the toxicity of the essential oil). The significance of the model was determined by a goodness of fit $\chi$-square test estimated with maximum likelihood. In all cases, the statistical package POLO Plus V1 (Software LeOra 2002−2003)[42] was used. Differences between $LC_{50}$ values were considered significant when the respective Confidence Intervals 95% (CI95%) did not overlap.

## RESULTS

**Chemical Characterization of the Ether Extracts from Lemon and Grapefruit.** The chemical characterization of the different extracts is presented in Table 1. For all extracts, the major chemical group was monoterpene hydrocarbons, and within this group, the major compound was D-limonene (higher than 70%), except in the extract from overripe lemon. The remaining chemicals ranged from 10.96% to 0.01%. The main constituents (more than 1% of the total area) of the extract of ripe lemon were D-limonene, $\gamma$-terpinene, $\beta$-pinene, geranial, myrcene, camphene, neral, and $\alpha$-pinene. In the case of grapefruit extract, the major compounds were limonene, oxypseucedanin, auraptene, and myrcene. The extract of the overripe lemon was characterized by D-limonene, $\gamma$-terpinene, $\beta$-pinene, $\beta$-bisabolene, geranial, neryl acetate, $\alpha$-*trans*-berga-

motene, neral, sabinene, and myrcene. Overripe grapefruit contained D-limonene, NI compound, myrcene, and β-caryophyllene.

**Fumigant Toxicity of Different Citrus Ether Extracts and Pure Compounds.** The volatile phases from lemon and grapefruit extracts were equally toxic to eggs of *A. fraterculus* ($p > 0.05$) (Table 2). Citral was four times more toxic than limonene, with their $LC_{50}$ values (0.04 and 0.16 μL/cm$^3$ air, respectively) being significantly different ($p < 0.05$). Additionally, limonene was significantly more toxic than both lemon and grapefruit extracts ($p < 0.05$). In agreement with what was found in eggs, larval mortality was equal for lemon and grapefruit extracts ($p > 0.05$) (Table 2).

**Fumigant Toxicity of Ether Extracts Obtained at Different Ripening Stages from Lemon and Grapefruit.** The extract from overripe lemon was slightly less toxic than the extract from ripe lemon, but the difference between their $LC_{50}$ values was not significant ($p > 0.05$). The extracts of ripe and overripe grapefruit were equally toxic ($p > 0.05$) (Table 3).

**Comparative Analysis between *A. fraterculus* and *C. capitata*.** *Eggs.* Lemon extract was six times more toxic to eggs of *A. fraterculus* than to eggs of *C. capitata* with their $LC_{50}$ values (18.12 and 113.46, respectively) being significantly different ($p < 0.05$) (Table 4). Grapefruit extract was also significantly more toxic to eggs of *A. fraterculus* than to eggs of *C. capitata* ($LC_{50}$ 26.25 and 72.94, respectively) (Table 4). Eggs of *A. fraterculus* were significantly more susceptible to limonene and citral than those of *C. capitata* ($p < 0.05$) (Table 4).

*Larvae.* Toxicity values of lemon and grapefruit extracts as well as of limonene and citral revealed no differences in sensitivity between *A. fraterculus* and *C. capitata* ($p > 0.05$) (Table 5). Contrary to what was found for eggs, citral was equally as toxic as limonene ($p > 0.05$).

## DISCUSSION

The presence of toxic compounds in the citrus essential oils from the citrus peel has been proposed as the main resistance mechanism of citrus species against fruit flies. Our integrative approach allowed us to evaluate the toxicity of lemon and grapefruit peel extracts in *A. fraterculus* eggs and larvae, the toxicity of limonene (the major compound of both citrus species essential oils) and citral (one highly toxic oxygenated monoterpene), and the effect of fruit ripening on the toxicity from the extracts of the citrus peel. Moreover, with this approach we were able to compare *A. fraterculus* susceptibility with that from *C. capitata*, from which host records in citrus and resistance mechanisms are better known.

Extracts from the peels of lemon and grapefruit proved toxic to *A. fraterculus* eggs and larvae. This is in agreement with what has been found for *A. suspensa*[22] and *C. capitata*[26,31] and confirms, by contact and fumigant bioassays, the occurrence of chemical resistance mechanisms. Other works extended the detrimental effects of several essential oils to the adult stage as an attempt to find organic insecticides.[7,30] Evaluations involved essential oils from citrus species such as *C. arantium* L. against *C. capitata* and the olive fly, *Bactrocera oleae* (Gmelin),[27] and from other plants such as *Hyptis suaveolens* (L.) Poiteau, *Rosmarinus officinalis* L., *Lavandula angustifolia* Miller and *Thuja occidentalis* L.,[41] and *Tagetes* spp.[43] in *C. capitata*. There is even one case of development of a novel packaging system controlling the release of essential oils from *Eugenia caryophyllata* Thumb against *C. capitata*.[44] Here, we did not explore if the extracts were toxic to the adult stage given that our main objective was to study insect−plant interaction and the role of chemical resistance mechanisms present in the fruit as a determinant of its status as a host of *A. fraterculus*. Our

results provide good evidence to sustain that lemon has chemically mediated resistance mechanisms.

Lemon and grapefruit extracts showed the same levels of toxicity within and between fruit fly species. This was confirmed in the fumigant (*A. fraterculus* only) and contact (*A. fraterculus* and *C. capitata*) bioassays and at both the egg and larval stages. Comparative studies between citrus species in *A. suspensa* larvae showed the same trend; grapefruit, orange, and lemon oils were equally toxic.[22] In contrast, studies conducted in *C. capitata* larvae showed that lemon oil from the variety Maglini was less toxic than the oil of three varieties of sweet orange (Merlin, Artas, and New Hall) and the oil of bitter orange (*Citrus aurantium L.* (Rootstock)).[31] The authors attributed this difference to the presence of $\alpha$- and $\beta$-pinene (less toxic than limonene) and to the low concentration of limonene in the lemon oil (less than 75%), while in the orange varieties evaluated, limonene was always above 95%. In our study, even when the amount of limonene in the extract from Eureka lemon (71%) was also lower when compared with the extract of Foster Seedless grapefruit (83%), the toxicity was similar. The chemical profiles of Maglini (Table 1)[31] and Eureka (this study, Table 1) lemons presented similar amounts of monoterpene hydrocarbons (91.7% and 91.9% for Papachristos et al.[31] and for our work, respectively) and oxygenated monoterpenes (6.4% and 5.2% for Papachristos et al.[31] and for our work, respectively). However, we did not evaluate extracts with limonene levels higher than 95%, whereas Papachristos et al.[31] evaluated different orange varieties that contained limonene levels higher than 95%. On the other hand, the work presented by Greany et al.[22] lacks information on oils chemical composition. In conclusion, more studies involving more citrus species are needed in order to assess different susceptibility among fruit fly species attributable to different limonene amounts.

The toxicities of limonene and citral were different and depended on the stage evaluated. For eggs, limonene was less toxic than citral, for both *A. fraterculus* (fumigant and contacts bioassays) and *C. capitata* (contact bioassays). For larvae, the confidence intervals of the $LC_{50}$ obtained for *A. fraterculus* and *C. capitata* had a great overlap, suggesting that limonene and citral were equally toxic. This is not in agreement with what was found by Papachristos et al.[31] for *C. capitata* larvae. One possible explanation could be the interaction of some compounds with the media in which they are presented. In the case of Papachristos et al.,[31] compounds were dispensed in the larval diet while in our case they were applied in a sugar solution.

Overripe lemon extract was marginally less toxic to *A. fraterculus* eggs than that from ripe lemon. This can be explained by the fact that, in overripe lemon, limonene showed values below 70% of the area. It could be proposed that mixtures containing less than 70% of limonene will be less toxic than mixtures with higher values of this compound. This could be one reason for the senescence-related susceptibility of grapefruit to *A. suspensa* infestation.[37] However, our inferences are based on tests that evaluated fumigant activity. The extract from overripe lemon had equal content of citroptene compared to that of ripen fruit. This compound, being less volatile than limonene, could have not been available at the same amounts in the fumigant tests as in the contact. In addition, our asseveration needs further confirmation, since the confidence intervals had a slight overlap. As for grapefruit, the chemical profile was similar to that from the lemon, and this may be the main reason for the similar toxicity.

Larvae were more sensitive than eggs. This was shown in both the fumigant and contact evaluations. In the fumigant tests, larvae were approximately three times more sensitive while, for the contact tests, the relationship was much higher (approximately 45 times more sensitive). A major susceptibility in larvae compared to eggs has been reported for *C. capitata* after topical application of *Fueniculum vulgarem* Mill. oil.[45] In a study that evaluated the effect of egg age on fumigant toxicity of the essential oil from *Lavandula hybrid* Rev., *Rosmarinus officinalis* L., and *Eucalyptus globules* Labill in the beetle *Acanthoscelides obtectus* (Say), it was demonstrated that as the eggs aged, and consequently the embryo developed, the susceptibility to the toxic compounds from the essential oils increased.[46] The authors attributed this to the fact that monoterpenes act against insects as neurotoxins; thus, the ovicidal activity could only be apparent when the nervous system begins to develop. In our case, the exposure to toxic compounds was done to fresh eggs, so embryonic development is expected to have been at an early stage. Therefore, it would be necessary to test older eggs to confirm this hypothesis. Another possible and nonmutually exclusive explanation could be the importance of the chorion as a barrier to penetration of toxic compounds.

The comparison between *A. fraterculus* and *C. capitata* revealed differences between the two species. Eggs of *A. fraterculus* were more sensitive than eggs of *C. capitata* to the effect not only of lemon and grapefruit extracts but also of limonene and citral. In contrast, for the larvae, the toxicities in both species were similar. The differences found in eggs could be explained by differences in the permeability of the egg shell or the susceptibility to certain compounds or chemical groups. It is worth wondering whether the differences in egg sensitivity between species had an impact on the immature performance of the fruit. To express this difference, it is necessary that eggs are exposed to the essential oils, and this can happen if the females lay their eggs in the glands of the flavedo. It has been proposed that females can adjust their oviposition behavior and prefer laying their eggs in the less toxic area of the albedo to avoid the toxic flavedo. However, this can be possible only on those species in which the female has a long ovipositor. Birke et al.[36] have already proposed this as an explanation why *A. ludens* can infest different citrus species. In the same line of evidence, it has been indicated that the resistance that lemon exhibits to the attack of *A. suspensa*[22] would be related to the thickness of the flavedo, the high concentration of oxygenated terpenoids, such as linalool, and the absolute amount of oil present in the peel. Under this hypothesis, we should expect that *A. fraterculus* will not survive or will have a poor performance in citrus with thin albedo such as lemon and oranges and will be able to develop better in fruits with a thicker albedo such as grapefruit and bitter orange, since it has a long ovipositor. Field infestation data[17−19] and laboratory experiments[47] seem to support this hypothesis.

Conclusively, we showed that extracts from the citrus peel are toxic to *A. fraterculus* immature stages and this contributes to the nonhost condition of lemon for *A. fraterculus*. It is probable that this condition is attained by a combination of the presence of chemical resistance mechanisms, as shown here, and the structure of the lemon peel that enhances the chances of the eggs or the larvae to enter in contact with the essential oil. Our results and those from Augier et al.,[48] with thorough

inspections of field and packing houses, as well as those of Gastaminza et al.,[33] with fruit-infestation laboratory and field experiments, provide good evidence and follow the guidelines to determine the host condition of a given species and variety of fruit to a given fruit fly species.[49,50] The recognition of the nonhost status of lemon will surely contribute to improve trade agreements.

The authors declare no competing financial interest.

## ACKNOWLEDGMENTS

We appreciate the valuable technical help of all the personnel from the Agriculture Zoology laboratories of Estación Experimental Agroindustrial Obispo Colombres (EEAOC) for their collaboration along the course of this study. We thank Dr. Nikos Papadopoulos for his valuable comments in an earlier version of the manuscript and three anonymous reviewers for all the constructive input during the revision process of the manuscript.

A characterization of food thermal damage can be achieved through the indirect measurement of the lysine APs such as lactulosyl-lysine or maltulosyl-lysine during acid hydrolysis by measuring furosine[27,28] or bound HMF.[29,30] More recently, some techniques allowed the direct measurement of the APs through LC/ESI-MS with or without labeled internal standard.[4,31−33] Other two routinely indicators of thermal damage are CML and CEL, which can be analyzed by MALDI-TOF/MS,[34] LC-MS/MS after acidic hydrolysis stable isotope dilution assay,[35,36] and GC-MS.[37] This last technique is commonly used for the determination and accurate quantification of MR volatile compounds such as hydroxycarbonyls, glycolaldehyde, acetol, and acetoin, or off-flavor compounds such as methional and 2-acetyl-2-thiazoline.[38−41] Last, but not least, a broad range of publications focuses on the determination of $\alpha$-dicarbonyls by using different derivatizing agents.[42,43]

The control of the MR in food using functional ingredients can promote the formation of compounds having the desired color and flavor, and it can reduce the concentration of off-flavors and potential toxic molecules. During the past years several approaches have been proposed to inhibit MR development in milk,[44] specifically by using green tea extract or catechins.[45,46] The mechanism behind the trapping activity of phenolic rings has been elucidated, and the chemical structure of the epicatechin−methylglyoxal adduct has been identified.[47,48] Recently, response surface methodology has been used to investigate the dose−response relationship of a catechin, genistein, and diadzein mixture as a prethermal processing technique to reduce the formation of reactive carbonyl species (RCSs) such as glyoxal, methylglyoxal, and 3-deoxyglucosone in ultrahigh-temperature (UHT) milk.[49] Twenty compounds having an aromatic ring substituted with at least one hydroxyl group have been reacted with methylglyoxal: results about the trapping efficiency can be transferred to milk product to verify the possibility of producing new better quality milk beverages.[50]

Olive mill wastewater is a byproduct of the olive oil production process and represents an abundant source of phenolic compounds.[51] olive mill wastewater typically contains 98% total phenols originally present in the olive, only a minor part being recovered in olive oil.[52] olive mill wastewater contains >60 phenolic compounds, among which the most relevant are secoiridoid derivatives, such as hydroxytyrosol and the dialdehydic form of decarboxymethyl oleuropein aglycone along with tyrosol and verbascoside.[53] The biological properties of its main components have been accurately reviewed;[52] olive mill wastewater has been proposed for a wide range of applications including the production of nutraceuticals,[54] the formulation of fish feed,[55] and stabilization during lard production;[56] however, its activity in preventing MR development in foods was never investigated.

In this paper, the ability of an ingredient obtained from olive mill wastewater through ultrafiltration and successive spray-drying in controlling the MR in UHT milk was examined. Olive mill wastewater activity was tested in laboratory-scale UHT milk to verify its effectiveness in the reduction of early-stage MR products, such as free APs, protein-bound APs, and RCSs, in the reduction of off-flavor formation and in the inhibition of CML formation.

## MATERIAL AND METHODS

**Chemicals.** Acetonitrile, methanol, and water for solid phase extraction (SPE) and LC-MS/MS determination were obtained from Merck (Darmstadt, Germany). The ion pairing agent perfluoropentanoic acid, trichloroacetic acid, hydrochloric acid (37%), sodium borohydride, sodium hydroxide, the analytical standards L-lysine hydrochloride, [4,4,5,5-$d_4$]-L-lysine hydrochloride ($d_4$-Lys), tyrosol (2-(4-hydroxyphenyl)ethanol, 98%), 3-hydroxytyrosol 98%, and verbascoside 98% along with glyoxal 40% solution in water, methylglyoxal 40% solution in water, and diacetyl (2,3-butanedione, 97%) as well as glycolaldehyde, acetoin, acetol, *o*-phenylenediamine (o-PD, 99.5%), and formic acid (MS grade 98%) were purchased from Sigma-Aldrich (St. Louis, MO, USA). Analytical standards *N*-$\varepsilon$-(2-furoylmethyl)-L-lysine (furosine), *N*-$\varepsilon$-(carboxymethyl)-L-lysine (CML), and its respective deuterated standard *N*-$\varepsilon$-(carboxy[$^2H_2$]-methyl)-L-lysine ($d_2$-CML) were obtained from Polypeptide Laboratories (Strasbourg, France), whereas 3-deoxyglucosone, $^{13}C_4$-acetoin, and $^{13}C_4$-diacetyl were obtained from TRC (Toronto Research Chemicals, Ontario, Canada).

**Formulation of OMW.** Olive oil mill wastewater polyphenol powders (OMW) were prepared from the water fraction resulting from olive oil production as follows. Olive water collected after olive paste centrifugation was treated with pectinases and fractionated by a filtration plant made up with three membranes at different cutoffs at 37 °C. Olive water was forced to pass through microfiltration (cutoff 25 kDa), ultrafiltration (cutoff 8 kDa), and nanofiltration (cutoff 0.3 kDa) membranes. At each stage a retentate containing the compounds not passing the membrane pores was collected. The ultrafiltration (UFR) retentate was concentrated by inverse osmosis (cutoff 0.1 kDa) up to 20% dry weight and spray-dried by adding maltodextrin and acacia fiber in a ratio 1:1 with the dry weight. A fine pale yellow powder with mild olive flavor was obtained and used in this study.

**OMW Characterization.** The phenolic profile of OMW was characterized by reversed phase HPLC-UV−vis to quantify the phenylethanoids: hydroxytyrosol, tyrosol, and verbascoside. Briefly, 100 mg of powder was dissolved in 10 mL of water, and after the complete melting of the coating material (5 min, room temperature under continuous stirring), 1 mL was purified on a preactivated C-18 cartridge (1 $cm^3$, 30 mg; Phenomenex, Torrance, CA, USA). Samples were eluted according to the method described by Kokkinidou and Peterson,[49] and after drying, they were reconstituted in a mixture of water/methanol 95:5 (v/v); 20 $\mu$L was injected onto a Prodigy ODS3 250 mm × 4.6 reversed phase C-18 (Phenomenex). The UPLC system consisted of two binary pumps (LC-20A, Shimadzu, Kyoto, Japan) equipped with an UV−vis detector (SPD20A, Shimadzu). The mobile phases were water/0.1% formic acid (A) and methanol (B). Hydroxytyrosol, tyrosol, and verbascoside were separated according to the gradient 0 min, 5% B; 5 min, 5% B; 40 min, 70% B; 42 min, 70% B; 45 min, 5% B; 50 min, 5% B; and the typical retention times were 20, 23, and 28 min, respectively. The three analytes were quantified by the external standard technique and the results reported as milligrams per gram of powder.

**Laboratory-Scale UHT Milk Treatment.** Raw milk (protein, 3.5%; fat, 1%) was obtained from a local market, and OMW was added to obtain final concentrations of 0.5 and 1 mg/mL. The three samples, one control and two samples with OMW, were homogenized, and after the complete dispersion of the powder (5 min, room temperature under continuous stirring) thermally treated in a laboratory-scale UHT milk system. It was constituted by three different tanks: two with oil, set at 180 and 140 °C, respectively, and another one with water at 6 °C. All of the samples were simultaneously treated, and one vial was used as reference. Along with 5 mL of milk, a thermocouple was inserted inside the reference headspace vial to control the time/temperature profile of each set. The high temperature of the first batch allowed a rapid increase of the temperature in the vial; instead, the second tank stabilized the temperature at 140 °C for 5 s. At the end of the thermal process the samples were rapidly moved into the last tank where the cooling phase blocked the extent of the MR. Finally, as soon as the samples reached 15 °C, they were rapidly frozen in dry ice in ethanol and stored at −20 °C until the analysis.

**CML, Total Lysine, and Furosine Analysis.** Total lysine and its derivatives *N*-$\varepsilon$-(carboxymethyl)lysine (CML) and *N*-$\varepsilon$-(2-furoylmethyl)-L-lysine (furosine) were analyzed according to the methods of

Fenaille et al., Delatour et al., and Troise et al. with some modifications.[35,36,57] Briefly, 100 μL of milk was mixed along with 0.45 mL of sodium borohydride (1 M in 0.1 N NaOH) and 0.5 mL of borate buffer (pH 9.2). The mixture was incubated for 4 h at room temperature to reduce the fructosyl-lysine in hexitol-lysine, and 1 mL of TCA (20% final concentradtion) was added to promote protein precipitation. Finally, 2 mL of 6 N HCl was added after careful removal of the supernatant. The mixture was incubated for 24 h at 110 °C in a forced-air circulating oven, and 400 μL was evaporated under a gentle flow of nitrogen. The samples were reconstituted in 380 μL of water, and 10 μL of the internal standard $d_2$-CML and 10 μL of $d_4$-lysine were added to obtain a final concentration of 50 ng/mL for both standards. Samples were loaded onto equilibrated Oasis HLB 1 $cm^3$ cartridges (Waters, Wexford, Ireland) and eluted according to the method previously described; finally, 5 μL was analyzed by ion pairing liquid chromatography coupled to MS/MS.[57] Furosine, CML, lysine, and the respective internal standard separation was achieved on a reversed phase core−shell column (Kinetex C18, 2.1 mm × 100 mm, Phenomenex) with a C-18 precolumn (3.0 × 4.0 mm, Phenomenex) using the following mobile phases: (A) 5 mM perfluoropentanoic acid and (B) acetonitrile/5 mM perfluoropentanoic acid. Compounds were eluted at 200 μL/min through the following gradient of solvent B: 0 min, 10% B; 2 min, 10% B; 5 min, 70% B; 7 min, 70% B; 9 min, 90% B; 10 min, 90% B; 12 min, 10% B; 15 min, 10% B. With the above-described chromatographic conditions, typical retention times for CML and $d_2$-CML were 6.8 min; for $d_4$-lysine and lysine, 7.03 min; and for furosine, 7.31 min. The MS/MS system was an API3000 (Applied Biosystems, Carlsbad, CA, USA); positive electrospray ionization was used for detection, and the source parameters were selected as follows: spray voltage, 5.0 kV; capillary temperature, 350 °C; dwell time, 100 ms. The chromatographic profile was recorded in multiple reaction monitoring mode, and the characteristic transitions were monitored to improve selectivity: for CML, furosine and lysine, the respective transitions of $m/z$ 205−84.1, $m/z$ 255.1−130.2, and $m/z$ 147.2−130.2 were used as quantifier, whereas $m/z$ 205−130.2, $m/z$ 255.1−84, and $m/z$ 147.2−84.1 were used as qualifier. CML was quantified using $d_2$-CML as internal standard ($m/z$ 207−144.1 and 207−84 for quantification and confirmation, respectively), whereas for furosine and lysine, $d_4$-lysine was used ($m/z$ 151.2−134.1 and 151.1−88 for quantification and confirmation, respectively).

**Free Amadori Products.** For the detection of free Amadori products (APs), each milk sample was diluted 10 times with water and ultracentrifuged (14800 rpm, 10 min, 4 °C), and then the supernatants were accurately filtered (RC 0.45 μm, Phenomenex) and injected. For the chromatographic separation a reversed phase core−shell column (Kinetex C18, 2.1 mm × 100 mm, Phenomenex) with a C-18 precolumn (3.0 × 4.0 mm, Phenomenex) was used. The mobile phases consisted of 5 mM NFPA in water (solvent A) and 5 mM NFPA in acetonitrile (solvent B). The following gradient of solvent B was used: 0 min, 10% B; 2 min, 10% B; 5 min, 50% B; 7 min, 50% B; 9 min, 10% B; 12 min, 10% B; 15 min, 10% B. The flow rate was set to 200 μL/min, and the injection volume was 5 μL. The U-HPLC was directly interfaced to an Exactive Orbitrap high-resolution mass spectrometer (HRMS) equipped with a heated electrospray interface (HESI). Mass spectrometer was operated in the full spectra positive ionization acquisition mode, in the mass range of $m/z$ 65−500; the mass spectrometry parameters were set up according to Troise et al.[58]

**Quantification of Reactive Carbonyl Species (RCSs).** Methylglyoxal, glyoxal, 3-deoxyglucosone, and diacetyl (2,3-butanedione) as well as glycolaldehyde, acetoin, and acetol were quantified using the synthesized stable isotopes $^{13}C_4$-acetoin and $^{13}C_4$-diacetyl as internal standards. Each internal standard (0.5 mM) was added to 5 mL of milk, followed by 500 μL of 10% trichloroacetic acid. The samples were then vortexed and centrifuged at 3904*g* for 20 min at 4 °C (Beckman Coulter, Allegra X-22R), and the supernatant was collected. Solid phase extraction (SPE) method was used to isolate the compounds of interest and avoid interference from phenolic compounds and adducts. A derivatization method followed, and samples were analyzed using an Acquity UPLC system interfaced with a Quattro Premier XE micromass mass spectrometer (Waters Co., Milford, MA, USA). An Acquity UPLC 2.1 × 100 mm BEH Phenyl 1.7 μm column with a VanGuard 2.1 × 5 mm BEH Phenyl 1.7 μm precolumn was used for separation, and all experiments were performed in triplicate. Analytes were detected using electrospray positive ionization−multiple reaction monitoring (MRM) using methods previously developed and reported by Kokkinidou and Peterson and specifically designed to avoid quantitative interference from phenolic compounds and adducts.[49]

**Quantification of Maillard Related Off-Flavor Volatiles.** A dynamic headspace method was developed for the quantification of off-flavor markers, namely, 2-acetyl-2-thiazoline and methional. Analysis was performed using a 6890 GC equipped with a 5973 mass selective detector (Agilent Technologies), thermal desorption unit (TDU, Gerstel), PTV inlet (CIS 4, Gerstel), and MPS 2 (Gerstel). Briefly, 2 mL of nanopure water and 1 M sodium chloride were added to 5 mL of UHT milk (control and treatments) spiked with deuterated standards. Sample was then purged with nitrogen, dry-purged to eliminate water, and then transferred to a thermal desorption unit. Measurements were performed 24 h after UHT processing using the analytical parameters summarized in Table 1.

**Table 1. Analysis Conditions Used for Identification and Quantification of Maillard-Related Off-Flavor Markers**

| | Analysis Conditions |
|---|---|
| PTV | solvent vent (20 mL/min) at 7.1 psi |
| | solvent vent (0.5 min), 20 °C (0.5 min); 10 °C/s; 290 °C (4 min) |
| column | DB5-MS, 30 m × 0.25 mm × 0.25 μm |
| | He, constant flow = 1 mL/min |
| oven | 40 °C (2 min); 4 °C/min; 160 °C |
| | 30 °C/min; 250 °C (5 min) |
| MSD | SIM, 104 + 48 (methional), 107 + 51 ($d_3$-methional), 129 (2-acetyl-2-thiazoline), 133 ($d_4$-2-acetyl-2-thiazoline) |
| | **Dynamic Headspace Component** |
| chemical trap | Tenax TA |
| DHS unit | trap temperature: ambient, 40 °C sample incubation temperature (10 min) |
| | 1000 mL purge volume, 50 mL/min purge flow |
| | 320 mL dry volume, 40 mL/min dry flow |
| TDU unit | solvent venting 20 °C (1 min); 720 °C/min; 290 °C (4 min) |

**Statistical Analysis.** Each thermal treatment was repeated twice to improve the reliability of the laboratory-scale UHT system, whereas each sample was analyzed twice and injected two times. Results were reported as nanograms per milliliter of milk for RCSs, milligrams per 100 g of protein for furosine, lysine, and CML, and percent inhibition toward the control samples for free APs. Data were analyzed by ANOVA, and means were compared by Tukey's test ($\alpha = 0.05$) using XLStat statistical software (Addinsoft, New York, NY, USA).

## RESULTS AND DISCUSSION

The use of a OMW ingredient obtained from ultrafiltered and spray-dried olive mill wastewater was evaluated for its ability to control the overall extent of the MR. The functional aspects of OMW were tested using a laboratory-scale UHT milk, and the selected outcomes were the MR aroma key odorants, the reduction of early-stage MRPs such as APs, the formation of protein-bound MRPs such as furosine and CML, and the ability to trap RCSs.

The first part of the work involved the production of OMW by four subsequent steps: the starting material was made by the water resulting after oil separation, which was treated with pectinases and fractionated by three different membranes to obtain three different retentate fractions.[59,60] The ultrafiltration

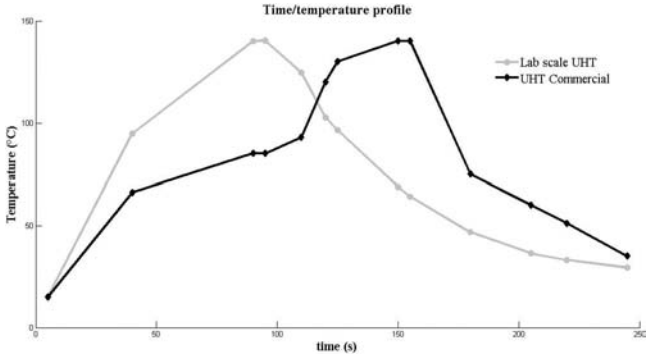

**Figure 1.** Comparison between laboratory-scale UHT system and commercial indirect tubular UHT system. The holding time used was the same for direct UHT processing and UHT plaque sterilization.

retentate was concentrated by inverse osmosis up to 67% dry matter and spray-dried with acacia fiber and maltodextrin in a molar ratio of 1:1 to obtain a fine pale yellow powder.[61] The phenolic profile of OMW was characterized by reversed phase UPLC-UV−vis to quantify the main constituents: hydroxytyrosol, tyrosol, and verbascoside. The concentrations of the three compounds in the OMW were 31 ± 0.2, 1.9 ± 0.1, and 2.8 ± 0.09 mg/g, respectively, in line with previous papers dealing with the composition of olive mill wastewater.[51,53,62]

Two different concentrations of OMW (0.05 and 0.1% w/v) were dissolved in raw cow's milk, and their impact on thermal damage was investigated by monitoring several intermediates and end-products of MR. A laboratory-scale UHT treatment was developed for this purpose: the thermal profile of the treatment confirmed that the thermal load closely simulated those of a commercial indirect tubular UHT processing method as highlighted in Figure 1. In the system here developed the time/temperature profile was similar to the ones previously reported for commercial indirect tubular UHT processing, direct UHT processing, and plaque UHT sterilization.[63,64] The sterilization factors were calculated according to Morales et al. using as reference temperature 127 °C and as $z$ value 30 °C.[65] They were 1.55 and 1.51 min for commercial UHT milk and laboratory-scale UHT milk, respectively. To compare the two concentrations of OMW, a control sample (without OMW) was simultaneously heated and several MRPs and RCSs were measured. In these conditions the final concentration of olive polyphenols reached a maximum of 36.1 mg/L without evident effects on milk sensory properties.

Off-flavor formation in UHT milk was already investigated in different papers.[12,66,67] According to the previous literature methional and 2-acetyl-2-thiazoline, commonly used as markers of off-flavor formation or aroma active compounds, were selected to verify the activity of OMW on this parameter. As shown in Figure 2 the concentration of methional was reduced from 4.08 ± 0.33 ng/mL for control UHT milk to 3.09 ± 0.26 and 2.15 ± 0.28 ng/mL for OMW 0.05% and OMW 0.1%, respectively. Furthermore, the concentration of 2-acetyl-2-thiazoline was reduced from 0.87 ± 0.09 ng/mL for control UHT milk to 0.74 ± 0.11 and 0.48 ± 0.08 ng/mL for OMW 0.05% and OMW 0.1%, respectively. This means that compared to control UHT milk, OMW 0.05% reduced by 24.3 and 16.9% the concentrations of methional and 2-acetyl-2-thiazoline, respectively, albeit those reductions were not statistically significant. Increasing the OMW concentration to 0.1% reduced the concentrations of methional and 2-acetyl-2-thiazoline by 47.3 and 46.1%, respectively, when compared to control UHT milk. This reduction was significant, indicating a concentration-dependent effectiveness of the phenolic mixture in reducing off-flavor generation during thermal processing. Data clearly showed that increasing the added OMW concentration prior to thermal processing can significantly decrease the concentration of off-flavor markers when compared to control UHT milk. These results were in line with those previously reported for the milk off-flavor and the potential role of added polyphenol.[67−69]

The trapping activity of OMW toward RCSs was evaluated by monitoring the concentrations of hydroxycarbonyl and dicarbonyl compounds in UHT milk with and without added OMW prior to thermal processing. The target RCSs monitored were glycoaldehyde, acetoin, and acetol for hydroxycarbonyls and glyoxal, methylglyoxal, 3-deoxyglucosone, and 2,3-butanedione for $\alpha$-dicarbonyls as they have been extensively studied for their contribution to AGE generation and carbonyl stress. Results are presented in Figures 3 and 4: the concentration of glycoaldehyde decreased from 246.03 ± 26.74 to 135.71 ± 30.63 and 105.36 ± 25.11 ng/mL for control UHT milk, OMW 0.05%, and OMW 0.1%, respectively, corresponding to reductions of 44.8 and 57.2% for samples containing OMW 0.05 and 0.1%. Similarly, OMW reduced the concentration of acetoin from 2293.73 ± 165.35 to 1897.91 ± 201.41 and 1321.86 ± 86.11 ng/mL for control UHT milk, OMW 0.05%, and OMW 0.1%, respectively, corresponding to reductions of 17.3 and 42.4% of acetoin for OMW 0.05 and 0.1% treatments. On the contrary, OMW did not show any reactivity toward acetol as no significant difference was observed between control UHT milk and OMW samples. These results can be explained on the basis of chemical reactivity as it follows the electophilicity of hydroxycarbonyl

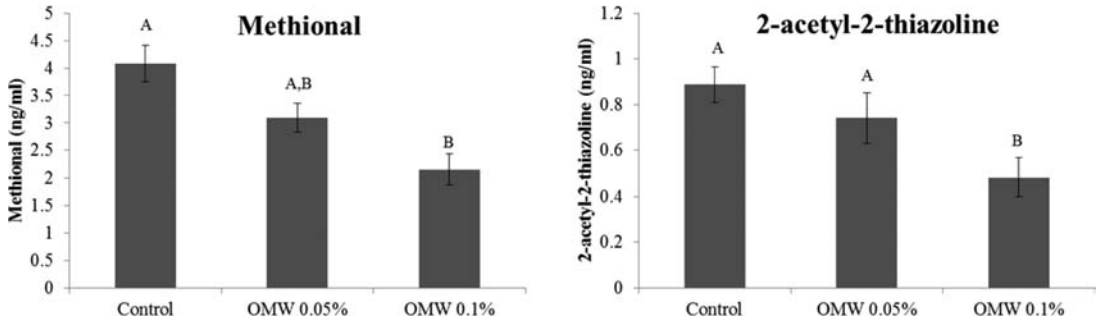

**Figure 2.** Methional and 2-acetyl-2-thiazoline concentration in control UHT milk, milk with 0.05% OMW, and milk with 0.1% OMW. Different letters correspond to significant differences (Tukey test, $\alpha$ = 0.05).

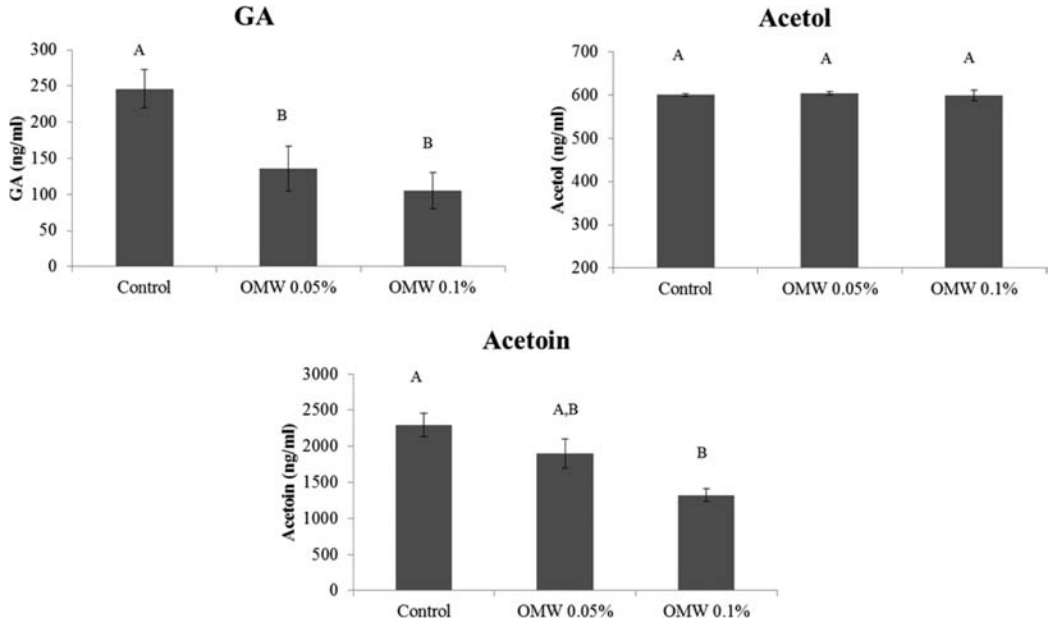

**Figure 3.** Hydroxycarbonyl concentration in control UHT milk, milk with 0.05% OMW, and milk with 0.1% OMW. Different letters correspond to significant differences (Tukey test, $\alpha = 0.05$). GA, glycoaldehyde.

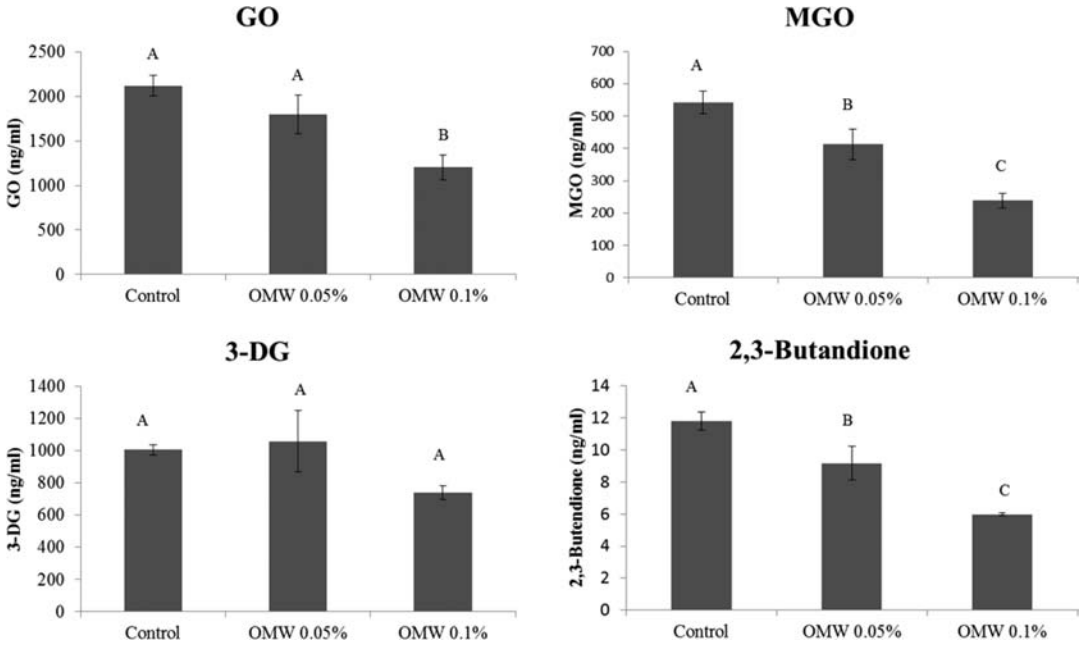

**Figure 4.** $\alpha$-Dicarbonyl concentration in control UHT milk, milk with 0.05% OMW, and milk with 0.1% OMW. Different letters correspond to significant differences (Tukey test, $\alpha = 0.05$).

compounds and thus the reactivity of phenolic compounds toward trapping them: the electron-rich phenols present in OMW can easily react with electrophilic hydroxycarbonyl compounds due to the presence of a hydroxyl group in position $\alpha$.

Slight differences in the concentration of $\alpha$-hydroxycarbonyls from previously reported papers can be ascribed to external factors such as microbial activity, starting material, and thermal treatments.[69−71]

The concentration of glyoxal was reduced from 2118.71 ± 113.94 ng/mL in control UHT milk to 1798.04 ± 218.49 and 1201.36 ± 136.73 ng/mL after the addition of OMW at 0.05 and 0.1%, respectively. This means reductions of 15.1 and 43.3% for glyoxal in samples with OMW 0.05 and 0.1% added, respectively. Methylglyoxal values were also reduced by 23.8 and 55.9% with OMW 0.05 and 0.1% addition, respectively. Both electrophilic dicarbonyls can give hydroxyalkylation of phenolic rings: Figure 4 suggests a higher activity of OMW toward methylglyoxal with respect to glyoxal, and this can be also due to the fact that the latter can polymerize in aqueous media, resulting in a lower affinity toward phenols.[72] For both compounds the observed reductions were in line with those previously reported.[49,50]

The concentration of 2,3-butanedione was reduced from 11.79 ± 0.55 ng/mL for control UHT milk to 9.16 ± 1.04 and 5.98 ± 0.09 ng/mL for OMW 0.05% and 0.1%, respectively,

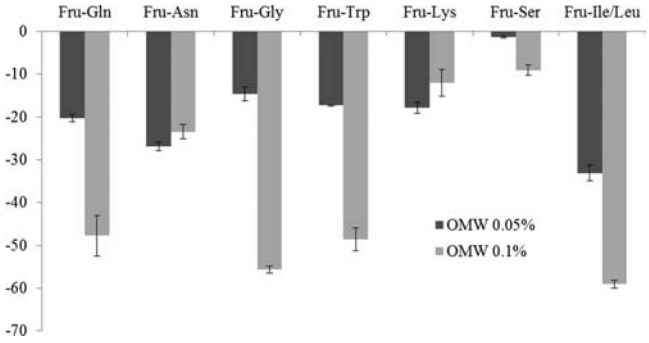

**Figure 5.** Amadori product mean percent inhibition in control UHT milk, milk with 0.05% OMW, and milk with 0.1% OMW.

and 3-deoxyglucosone was modified only by the addition of the higher concentration of OMW as no significant difference was observed between control UHT milk and milk treated with OMW 0.05%. It can be hypothesized that the trapping activity toward 3-deoxyglucosone is affected by the partial charge on the oxygen of the carbon carbonyl in position 2, by the presence of other carbons that can stabilize the structure, and by steric hindrance. From this first set of experiments it can be concluded that OMW treatment was not very effective in trapping C6 sugar fragments, whereas a significative reactivity of phenolic compounds in OMW mixture was observed toward methylglyoxal, diacetyl, and glycoladehyde.

All of the RCSs monitored are of interest not only for their contribution to MR pathways and carbonyl stress but also because they can contribute to the generation of off-flavor compounds; thus, their suppression can both directly and indirectly lead to a reduction in off-flavor generation.

The effect of OMW was tested also in the reduction of free APs, which can be measured without protein hydrolysis, thanks to the relatively high content of free amino acids in milk.[73] The formation of the AP was the central hub for the forthcoming steps of MR, so the presence of the phenolic rings favored the reduction of the AP formation and in turn of many MRPs via direct reaction with an amino group or via glyoxal trapping.

As shown in Figure 5, the reduction of AP formation was particularly evident for hydrophobic glycated amino acids, such as isoleucine/leucine and glycine. This can be explained by the high concentration of these amino acids and their APs and by the lower reactivity relative to that of other amino acids toward reducing sugars. The best known compounds are the Amadori products *N*-ε-fructosyl-lysine and furosine. The effect of OMW on free *N*-ε-fructosyl-lysine formation was significant at both concentrations: 12.1 and 17.8% over the control sample for OMW 0.1% and OMW 0.05%, respectively.

Finally the ability of OMW to reduce the formation of protein-bound CML and furosine was investigated. Results in Figure 6 show that after acidic hydrolysis the reduction of protein-bound MRPs was more pronounced for furosine; the reductions were 25.4 and 47.4% when OMW 0.05% and OMW 0.1% of phenolic powder were added, respectively. For CML the reductions were 11.2 and 16.2%, showing significant differences between the two phenolic powder concentrations and the control samples. Data on furosine showed that its concentration decreased from 10.962 ± 0.805 mg/100 g protein in the control UHT milk to 8.162 ± 0.794 and 5.761 ± 0.924 mg/100 g protein for OMW 0.05 and 0.1%, respectively.

The differences between CML and furosine reduction can be tentatively explained in two ways. First, the two MRPs could follow two different pathways. Furosine is formed by cyclization through the C-6 hydroxyl group and dehydration reaction, and it reflects the protein-bound Amadori products of lysine, because the free *N*-ε-fructosyl-lysine is destroyed by acidic hydrolysis.[4] CML can be formed by two mechanisms: the enediol form of the *N*-ε-fructosyl-lysine can undergo oxidative cleavage to produce CML and erythronic acid via free radical generation with simultaneous oxygen consumption, and glyoxal can easily block the amino group on the side chain via the Namiki pathway.[74] Second, as shown in Figure 7, the reduction of both protein-bound and free MRPs can be associated not

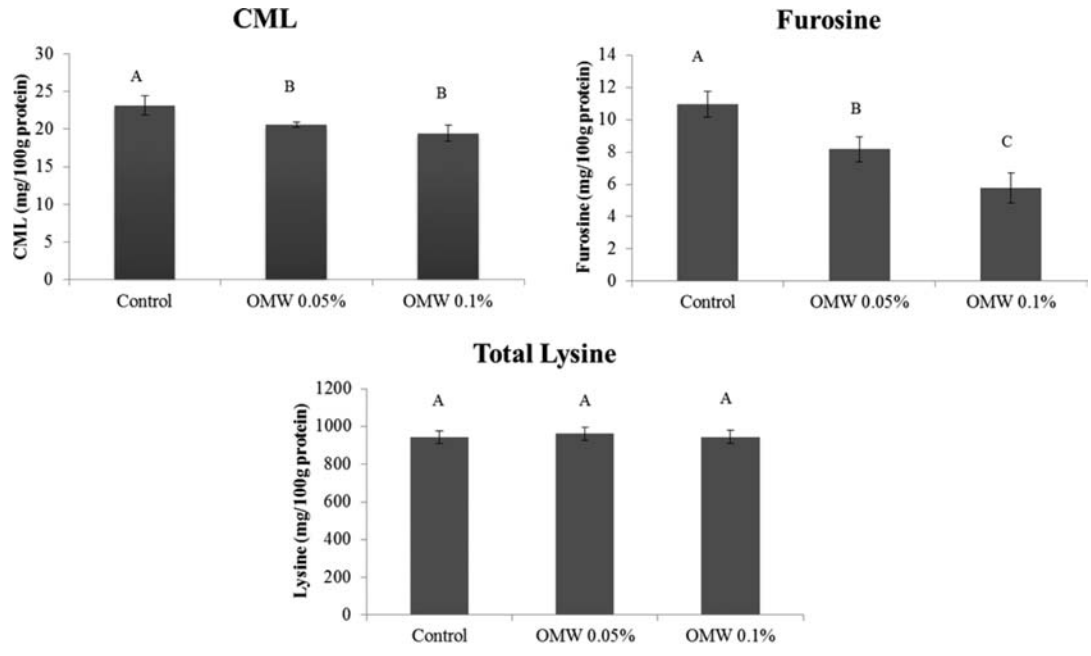

**Figure 6.** CML, furosine, and total lysine concentrations in control UHT milk, milk with 0.05% OMW, and milk with 0.1% OMW. Different letters correspond to significant differences (Tukey test, $\alpha = 0.05$).

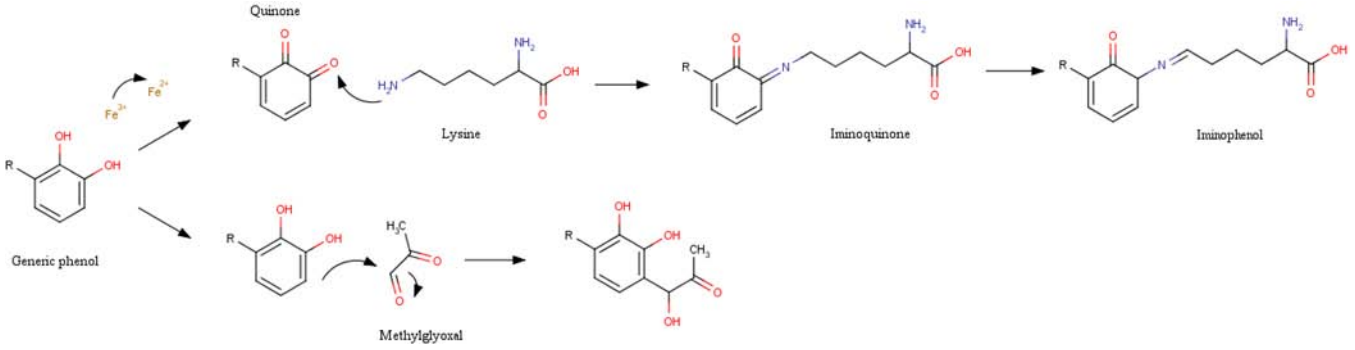

**Figure 7.** Proposed mechanism of MRP reduction by phenolic compounds adapted from Totlani and Peterson,[47] Estévez,[76] and Guerra and Yaylayan.[77]

only with the reduction of the Amadori product of lysine and glucose but also with the above-described trapping activity. A trisubstituted phenolic ring with an *o*-dihydroxy function can easily react with dicarbonyls by hydroxyalkylation and aromatic substitution reaction, thus showing trapping activity toward methylglyoxal and glyoxal.[47,48,75] Moreover, in the presence of reactants such as ascorbic acid or iron, the phenolic ring can be oxidized to quinone, whose reaction with side chain of lysine and other amino group can lead to the formation of iminoquinone and iminophenol via Schiff bases as highlighted by Estévez[76] and Guerra and Yaylayan.[77] The results on CML and furosine fully confirmed those previously obtained by other groups.[27,35,78]

In conclusion, in this paper it was demonstrated that OMW besides its potential nutritional functionality could also help in the production of superior quality food and can provide an effective strategy in the control of the MR. The result was achieved on a broad range of MRPs that contributed to the final chemical composition of the UHT milk. Interestingly, these results were obtained in conditions not leading to easily detectable modifications of either physical properties (viscosity or color) or sensory properties (bitterness, astringency, olive flavor). However, the sensory acceptability of the addition of OMW should be further investigated.

## NOTE ADDED AFTER ASAP PUBLICATION

This paper was published ASAP on October 3, 2014, with an error to Figure 4A. The corrected version was reposted on October 6, 2014.

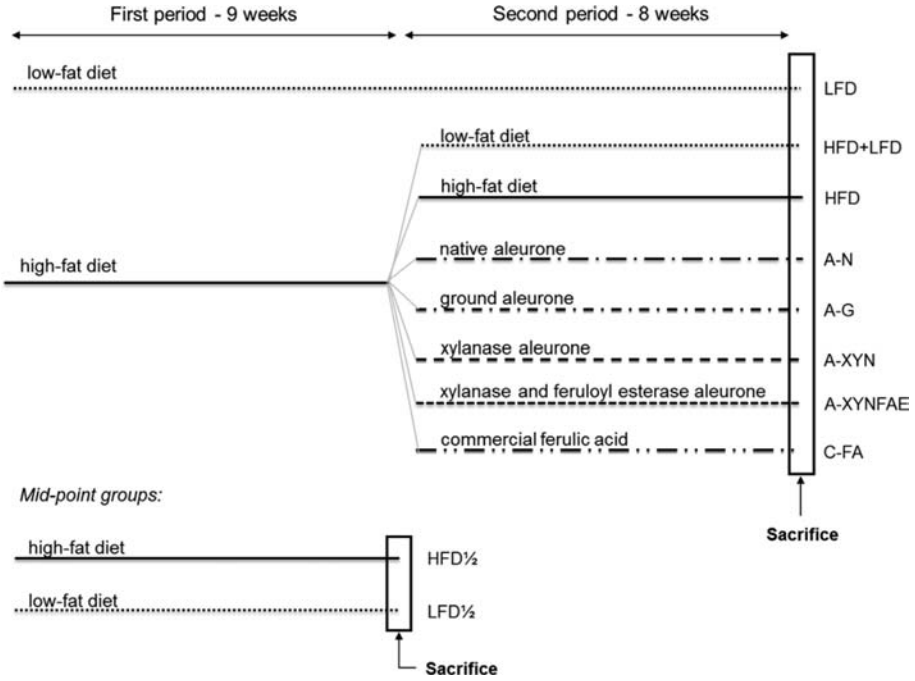

**Figure 1.** Experimental design of this study. Low-fat diet was provided during the whole period to the LFD group. High-fat diet was provided to the other groups during the first period (9 weeks), and during the second period (8 weeks) the diet was switched to the following diets: low-fat (HFD + LFD group), high-fat (HFD group), native aleurone (A-N group), ground aleurone (A-G group), xylanase treated aleurone (A-XYN group), xylanase and feruloyl esterase treated aleurone (A-XYNFAE), or commercial ferulic acid (C-FA group). Midpoint groups received either high-fat (HFD1/2) or low-fat (LFD1/2) diets and were sacrificed in the end of the first period (9 weeks).

**Table 1. Composition of the Diets: Carbohydrate, Fat, Protein, Cellulose, Mineral, Vitamin, Arabinoxylans (AX; Total, Insoluble, and Soluble), and Ferulic Acid (FA; Bound, Conjugated, and Free) Expressed as grams per 100 g[a]**

[a]The antioxidant capacity is expressed as mmol of TEAC/kg. Arabinoxylans, ferulic acid contents, and antioxidant capacity are reported as means ± SD. Amounts of carbohydrate, fat, protein, minerals, and vitamins in aleurone diets were added to match the energy content similar to that of the high-fat diet. For HFD-, A-N-, A-G-, A-XYN-, A-XYNFAE-, and C-FA-enriched diets: carbohydrate = corn starch (21%), maltodextrin (29%), and sucrose (50%); fat = soybean oil (12.3%) and lard (87.7%); protein = casein (98.5%) and L-cystine (1.5%). For LFD: carbohydrate = corn starch (45%), maltodextrin (5%), and sucrose (50%); fat = soybean oil (55.6%) and lard (44.4%); protein = casein (98.5%) and L-cystine (1.5%).

and wet processes to increase the bioaccessibility and bioavailability of bioactive compounds. Ultrafine dry grinding of the wheat bran and aleurone layer improved indeed their antioxidant capacity and fermentability and increased the bioavailability of their phenolic compounds.[17−21] The inner part of aleurone obtained by debranning and air classification also presented higher bioaccessibility of phenolic compounds and vitamins compared to the outer part of aleurone or the unfractionated bran.[22] Enzymatic treatment of aleurone improved to a larger extent its antioxidant capacity[19] and also allowed greater and faster metabolism of FA in an *in vitro* gut fermentation model.[20] Bioprocessed wheat bran had higher bioavailability of its phenolics *in vitro* and *ex vivo*.[23,24]

The aim of this work was to investigate the capacity of differently processed wheat aleurone fractions (native, finely ground, or enzymatically treated) to counteract metabolic disorders in a diet-induced-obesity mouse model. The design of this study consisted of first inducing obesity in mice (first

period, 9 weeks fed with high-fat diet) and then providing the processed aleurone fractions (second period −8 weeks fed with high-fat diet enriched with aleurone) (Figure 1). The aleurone was added in the diet of mice in order to provide 5% of the dietary fiber, which is a common level used in mice studies. Besides aleurone-enriched diets, high- and low-fat diets without aleurone were also provided during the whole experiment (first + second periods) as two control groups. The effects of the different aleurone-enriched diets were evaluated by recording obesity (body weight gain, adiposity), fasting blood glucose, fasting plasma insulin and leptin, pro- and anti-inflammation markers, and oxidative stress.

## MATERIALS AND METHODS

**Wheat Aleurone Layer Treatments.** The native aleurone-rich fraction (85% aleurone) was obtained by dry processing of bran provided by Bühler AG (Uzwil, Switzerland). Its chemical composition is described by Rosa et al.[19] (39.7 g of dietary fiber, 22.2 g of protein, 13.3 g of ash, 9.8 g of fat, and 5.8 g of starch in 100 g of wheat aleurone dry matter). The native aleurone had 192 $\mu$m mean particle size ($d_{50}$) and 24.3 and 0.6 g of total AX and total FA/(100 g), respectively. AX of native aleurone was present mainly in insoluble form (96.3%), and FA was mainly esterified to polysaccharides (98.5%). Three treatments were applied on the native aleurone to obtain three modified aleurone fractions: (i) finely ground aleurone, (ii) xylanase treated aleurone, and (iii) xylanase and feruloyl esterase treated aleurone.[20] The finely ground aleurone, which was obtained by ultrafine grinding with an impact mill in cryogenic conditions, had 65 $\mu$m mean particle size. The finely ground aleurone had amounts of insoluble AX and bound FA similar to that of the native one. Both enzymatic treated aleurones had amounts of total AX and total FA similar to that the native aleurone, but the proportions of soluble AX and free FA were higher in these treated fractions. The aleurone fractions were prepared in UMR IATE (Montpellier, France), and their total composition was described in our previous work.[20]

**Study Diets.** Each aleurone fraction was added at concentration 13% (w/w) in a commercial high-fat diet with 45% of energy from fat (D12451 high-fat diet; Research Diets Inc., New Brunswick, NJ, USA). High-fat diet ingredients and aleurone fraction were mixed and then extruded into pellets using a cold extrusion process. The pellets were manufactured by Research Diets. The total composition of each pellet is displayed in Table 1. Pellets will be called diet throughout this work. Based on the initial chemical composition of native aleurone, all of the aleurone-enriched diets were designed to match the commercial high-fat diet with calorie density, the amount of macronutrients, and the total fiber content (5%). The diets and study groups receiving the aleurone fractions, native, finely ground, xylanase treated, and xylanase plus feruloyl esterase treated, were named as A-N, A-G, A-XYN and A-XYNFAE, respectively. Commercial FA (Sigma, St. Louis, MO, USA) was also added into the high-fat diet (named as group C-FA) in the same concentration as the FA content of the AN diet. Phenolic acids (bound to polysaccharides, conjugated to mono- or oligosaccharides, and in the free form) and AX (insoluble and soluble forms) contents were determined in the pellets after the addition of aleurone fractions in order to check that these compounds were not lost or deconjugated during the extrusion process and to measure the exact amount of AX and FA consumed by mice in each diet. The total antioxidant capacity of the pellets was also determined. All of the methodologies used are described by Rosa et al.[18,20] The pellets were stocked into bags under vacuum at 4 °C and protected from light to avoid oxidation during the experiment.

**Animals and Experimental Design.** C57BL/6J male mice were obtained from the National Laboratory Animal Center (Kuopio, Finland) at the age of 9 weeks (initial weight = 23.8 ± 0.2 g). The mice were acclimatized for 1 week and housed 3−4 animals per cage during the weeks 1−12 and in single cages from week 13 until the end of the study (week 17). The conditions in the animal house were controlled: temperature, 22 ± 1 °C; relative air humidity, 55 ± 15%; 12 h/12 h light/dark cycle with lights on at 7 am. The experimental design is showed in Figure 1. After 1 week of acclimatization, mice ($n$ = 85) were fed ad libitum a commercial high-fat diet (D12451, Research Diets) for 9 weeks to induce obesity and related metabolic disorders. The control group ($n$ = 20) was fed ad libitum a commercial low-fat control diet (D12450B, Research Diets). After 9 weeks of prefeeding, 10 mice receiving high-fat diet and 10 mice receiving low-fat diet were sacrificed (midpoint groups HFD1/2 and LFD1/2). These midpoint groups were used in order to evaluate the metabolic status of mice in the end of the first period. The rest of the mice receiving high-fat diets were randomized into 7 study groups ($n$ = 9−14 per group) and were fed either with D12451 (high-fat diet control, HFD, $n$ = 14), D12450B (group switched from high- to low-fat diet, named as lifestyle control group HFD + LFD, $n$ = 9), the D12451 diets enriched with aleurone fractions (A-N, A-G, A-XYN, and A-XYNFAE diets, $n$ = 10, 11, 10, and 11, respectively) or commercial ferulic acid (C-FA diet, $n$ = 11) for 8 weeks. The group receiving the low-fat diet (LFD, $n$ = 10) remained on the same diet until the end of the study to serve as a "healthy control". The lifestyle control group (HFD + LFD) was used in order to compare the effects of the consumption of aleurone-enriched diets with a energy-restricted diet.

At the end of the experiment, the mice were fasted for 7.5−8.5 h and sacrificed by decapitation after being made unconscious by $CO_2$ gas. Venous blood was collected into ethylenediametetraacetic acid (EDTA) tubes (K2-EDTA Microtainer Tubes with BD Microgard Closure, Beckton Dickinson Oy) and centrifuged for 10 min × 16000g at room temperature. Plasma was frozen on dry ice and stored at −70 °C in smaller aliquots. Tissues including liver were dissected immediately after blood collection, rinsed with physiological saline, wrapped into aluminum foil, snap frozen in liquid nitrogen, and stored at −70 °C until further processing. The animal experiments were approved by the Institutional Animal Care and Use Committee of the Provincial Government of Finland (permission no. 041003).

**Monitoring of the Body Weight and Feed Intake.** The body weight of the mice was measured weekly. Feed intake was also monitored weekly (always on the same day of the week) by determining the difference between the pellets supplied and the amount of pellets left on the grid and taking the spillage of the pellets into account. The energy intake was calculated based on the feed intake and the energy density of the diet. The average feed intake was calculated based on the diet consumption of each mouse during the first (weeks 1−9) and second (weeks 10−17) periods of the experiment.

**Assays of Plasma Samples.** Blood glucose was measured by LifeScan OneTouch Ultra glucometer from the venous blood drops immediately after decapitation. The following analyses were performed in the frozen plasma which was thawed just before carrying out the experiments. C-reactive protein (CRP), pro-inflammatory cytokines (IL-6 and IL-1$\beta$), anti-inflammatory cytokines (IL-10), tumor necrosis factors $\alpha$ (TNF$\alpha$), leptin, and insulin were measured from the plasma using Multiplex Biomarker Immunoassays for Luminex xMAP technology (Millipore, Billerica, MA, USA) following the instructions of the manufacturer. The CRP was assessed by MAP2MAG-76K kit; cytokines IL-1$\beta$, IL-6, IL-10, and TNF$\alpha$ were measured by MCYTOMAG-70K kit, and leptin together with insulin, by MMHMAG-44K-02 kit. For measurement of the cytokines, the lowest concentration of the calibration curve was 3.2 mg/L. However, some plasma samples presented concentrations under this limit of detection, and an arbitrary medium value of 1.6 mg/L was attributed to them.

**Measurement of Liver Oxidative Stress Markers.** Livers were cryo-ground in 10 mL grinding steel jars with a stainless steel ball for 60 s with 15 Hz using TissueLyser II (Qiagen). The obtained liver powder was used for the oxidative stress marker analyses. The amounts of total (TGSH) and oxidized (GSSG) gluthathione were determined spectrophotometrically as described previously.[25] Lipid peroxidation level was evaluated by thiobarbituric acid−reactive substances (TBARS) and lipid hydroperoxydes (LPO), which were measured according to the method of Sunderman et al.[26] and Kinnunen et al.,[27] respectively. Sulfhydryl groups (SH) was measured according to Faure and Lafond[28] and protein carbonyls using the ELISA method as

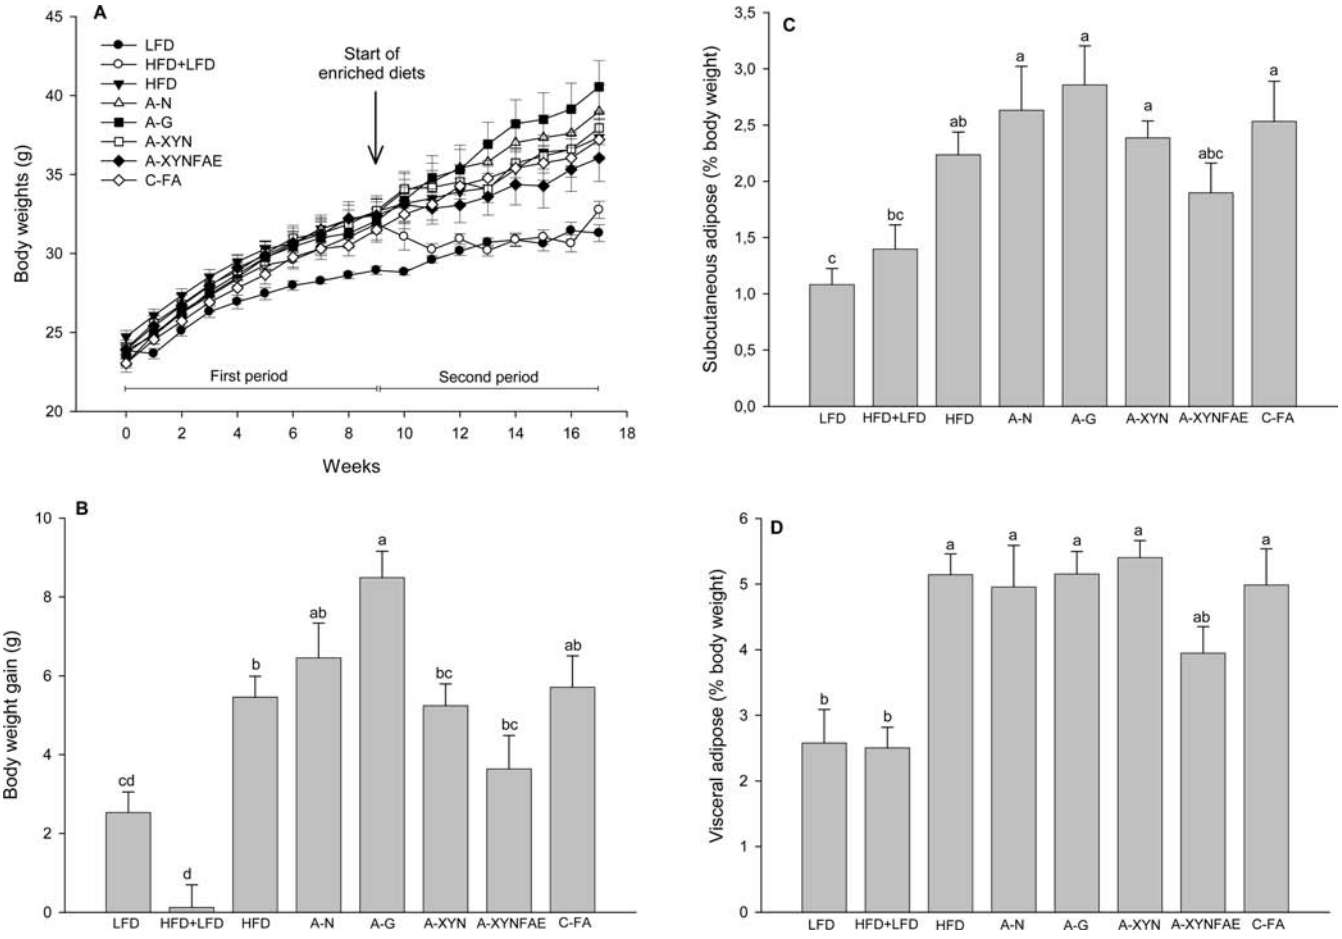

**Figure 2.** (A) Development of body weights of mice during the first (9 weeks) and second (8 weeks) periods. (B) Body weight gain during the second period (weeks 10−17). Weights for subcutaneous (C) and visceral (D) adipose tissues (percent body weight) at the end of the experiment (week 17). The values are reported as means ± SEM ($n$ = 10, 9, 14, 10, 11, 10, 11, and 11 for LFD, HFD + LFD, HFD, A-N, A-G, A-XYN, A-XYNFAE, and C-FA, respectively). Values not significantly different ($p > 0.05$) are designated by pairs of letters.

previously described by Oksala et al.[29] Oxygen radical absorbance capacity (ORAC) was used for the measurement of the antioxidant capacity, which was performed using a multiwell plate reader according to the methods described previously.[30] The activity of antioxidant enzymes catalase (CAT), glutathione peroxidase (GPx), and superoxide dismutase (SOD) was measured according to the method of Beers and Sizer,[31] Flohe and Gunzler,[32] and Marklund,[33] respectively. Protein carbonyls and ORAC measurements were performed in triplicate, and the other markers were measured in duplicates.

**Statistical Analysis.** Results were expressed as means ± standard error of the mean (SEM). Statistical analysis based on one-way ANOVA was applied followed by a Tukey−Kramer honest significant difference (HSD) posthoc test at 95% confidence level ($p < 0.05$) for the data following a normal distribution and having similar variance. The student's $t$-test at 95% confidence level ($p < 0.05$) was also applied in pairs between the HFD control group and each aleurone-enriched group. Correlation analyses were carried out by the Pearson's correlation method with a 95% confidence interval. For the analysis of the midpoint groups (HFD1/2 and LFD1/2), the student's $t$-test ($p < 0.05$) was applied.

## RESULTS

**Characterization of the Aleurone-Enriched Diets.** The total amounts of AX in the aleurone-enriched diets (A-N, A-G, A-XYN, and A-XYNFAE) were around 3.4−3.9 g/(100 g) (Table 1). Both diets A-N and A-G contained AX mainly in insoluble form (95%). The enzymatic process applied on aleurone efficiently solubilized AX, and thus the diets A-XYN and A-XYNFAE had higher proportion of AX in soluble form (39 and 75%, respectively). The total amount of FA in the aleurone-enriched diets was around 0.07−0.1 g/(100 g), which was equivalent to the amount of commercial FA in the C-FA diet (0.1 g/(100 g), mainly in free form). Both diets A-N and A-G had 95% of FA as bound to AX polysaccharides (Table 1). A-XYN and A-XYNFAE diets contained higher amounts of FA in both conjugated and free forms (41 and 84% for A-XYN and A-XYNFAE, respectively). The controls (HFD and LFD) and C-FA diets contained traces of AX, which came from the cellulose fraction added in these diets. Any traces of FA were detected in the control diets. The antioxidant capacity of the diets was measured and expressed in Trolox equivalent antioxidant capacity (TEAC). HFD and LFD had similar antioxidant capacity (10.8 mmol of TEAC/kg). Enrichment of the diets with either enzymatically treated aleurone fractions (A-XYN and A-XYNFAE diets) or free FA (C-FA diet) clearly increased the antioxidant capacity of the high-fat diets (2.5- and 2.1-fold for A-XYN and A-XYNFAE diets, respectively; Table 1). The diets A-N and A-G had slightly higher antioxidant capacity (1.3- and 1.4-fold, respectively) as compared to HFD alone (Table 1).

**Metabolic Status after 9 week High-Fat Feeding.** The high-fat diet resulted in significantly ($p < 0.05$) higher body weight after 9 weeks of feeding (31.4 ± 0.9 vs 28.2 ± 0.4 g for HFD1/2 and LFD1/2 groups, respectively; see the Supporting

Information Table S1). The adiposity index, i.e., the amount of adipose tissue (subcutaneous and visceral) in relation to the body weight, was significantly ($p < 0.05$) higher in the HFD1/2 group (4.8 vs 2.6% for HFD1/2 and LFD1/2, respectively) at the end of the first period. The plasma fasting insulin (1.7 ± 0.3 vs 0.9 ± 0.1 μg/mL for HFD1/2 and LFD1/2 groups, respectively) and leptin levels (14.9 ± 5 vs 3.9 ± 1 μg/mL for HFD1/2 and LFD1/2 groups, respectively) were also significantly ($p < 0.05$) increased in the HFD1/2 group, while no significant difference was observed in the fasting blood glucose concentration between the midpoint groups. Both groups presented similar levels of oxidative stress and inflammatory markers, except for the GSSG/TGSH ratio and IL-6 (pro-inflammatory) which were significantly ($p < 0.05$) higher in the HFD1/2 group (Supporting Information Table S1).

**Body Weight, Body Fat Content, and Intestinal Tissue Weight.** The development of body weights of mice during both periods of the study was displayed in Figure 2A. The body weight gain during the second period of the experiment (weeks 10−17), i.e., the difference of weight between week 17 and week 10, was calculated and shown in Figure 2B. The body weight gain of the HFD control group was significantly higher than that of the LFD group (Figure 2B). The HFD control group also had twice the weight of subcutaneous and visceral adipose tissues as compared to the LFD group (Figure 2C,D). The change from the high-fat diet to low-fat diet for the second period (HFD + LFD or "lifestyle" group) resulted in a rapid weight loss within the first 2 weeks after the dietary change (Figure 2A) and in the reduction of the weight of the adipose tissues (Figure 2C,D), reaching levels similar to the low-fat-diet control group (LFD).

The group receiving the high-fat diet enriched with the ultrafine ground wheat aleurone (A-G group) had the highest increase in body weight gain, which was significantly different ($p < 0.05$, ANOVA) from the body weight gain in the HFD control group (Figure 2B). Groups receiving high-fat diets enriched with native aleurone, enzymatically treated aleurone fractions, or commercial FA had body weight gain similar to that of the HFD control group (Figure 2B). In addition, there were no significant differences in the weights of the adipose tissues between the HFD control group and aleurone- or FA-enriched diets (Figure 2C,D). Although the group receiving aleurone treated with xylanase and feruloyl esterase (A-XYNFAE) had results statistically similar to those of HFD, a tendency toward reduced body weight gain (33% reduction, $p = 0.07$ $t$-test) and lower visceral adipose tissue amount (23% reduction, $p = 0.004$ $t$-test) was observed when comparing only these two groups (A-XYNFAE and HFD) by the $t$-test. Body weight gain and adipose tissue accumulation in the A-XYNFAE group was indeed found statistically similar to that of the LFD control (Figure 2B−D). All groups receiving high-fat diet had similar energy intake regardless of aleurone enrichment (Table 2). Only the low-fat-fed groups (LFD and lifestyle HFD + LFD group) had significantly lower energy intake ((kcal/mouse)/day) as compared to HFD groups (Table 2).

All diets enriched with wheat aleurone preparations produced intestinal tissue of similar weight of compared those from HFD, except A-XYNFAE which had significant ($p < 0.05$, ANOVA) higher weight of intestinal tissue than the HFD control (Table 2). Cecal and colon tissue weights were not significantly changed by enriched aleurone diets or free FA compared to the HFD control group.

**Table 2. Body Weight, Weights of Intestinal, Caecum, and Colon Tissues, and Fasting Plasma Glucose of Mice in the End of the Second Period[a]**

[a]Food intake and energy intake are the average consumption during the second period. The values are reported as means ± SEM. The values not significantly different ($p > 0.05$) are designated by the same letter.

dx.doi.org/10.1021/jf503314a | J. Agric. Food Chem. 2014, 62, 10101−10109

**Blood Plasma Parameters (Glucose, Insulin, and Leptin Levels).** The fasting blood glucose level was similar between all the groups (Table 2). The fasting insulin levels were doubled in the HFD group as compared to the LFD group (Figure 3A). The change from the high-fat diet to low-fat

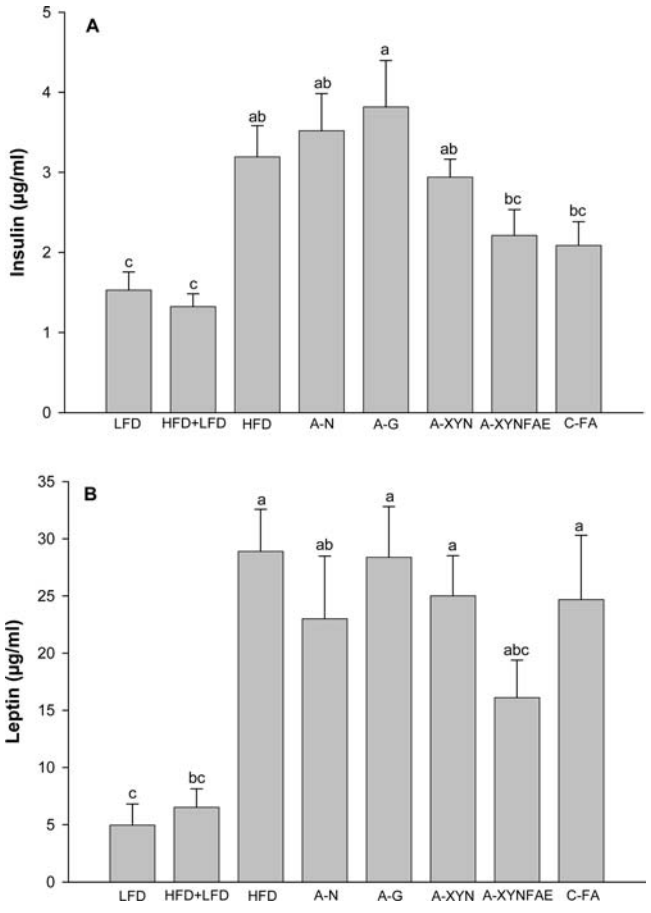

**Figure 3.** Plasma levels of (A) insulin and (B) leptin at the end of the experiment (week 17). The values are reported as means ± SEM. Values not significantly different ($p > 0.05$) are designated by pairs of letters.

diet (HFD + LFD lifestyle group) normalized the fasting insulin levels to the level observed in the LFD control group. Enrichment with aleurone preparations or commercial FA had no significant effect on insulin levels compared to the control HFD group (Figure 3A). However, A-XYNFAE had a tendency toward lowered fasting insulin levels (30% reduction, $p = 0.07$ *t*-test) compared to the HFD control group. A similar trend was observed for the C-FA group (35% reduction, $p = 0.03$ *t*-test) compared to the HFD control group.

The level of plasma leptin was 5.8-fold higher in the HFD group than in the LFD group (Figure 3B). The change from the high-fat diet to low-fat diet (HFD + LFD lifestyle group) resulted in reduction of leptin concentrations to the same level as in the LFD group. No significant differences in leptin levels were found between the HFD and aleurone-enriched groups. The group A-XYNFAE was the only one that had a tendency toward a reduced leptin level (44% reduction, $p = 0.02$ *t*-test) as compared to the HFD control group (Figure 3b). The level of leptin in all groups was positively correlated with the amount of adipose tissue in mice ($r = 0.98$ and 0.93 for visceral and subcutaneous, respectively).

**Oxidative Stress and Inflammation.** All of the data for oxidative and inflammatory markers are displayed in the Supporting Information (Table S2). High-fat diet feeding did not result in significant changes of the oxidative or inflammatory markers as compared to the LFD control group. Neither the aleurone-enriched diets nor C-FA-enriched diet had any beneficial impact on the levels of protein oxidation, the total antioxidant capacity, TBARS, TGSH, GSSG, GSSG/TGSH, CRP, pro (IL-1$\beta$, IL-6), or anti-inflammatory cytokines (IL-10) as compared to HFD. The only oxidative marker affected by the diets was the LPO. The aleurone-enriched diet A-XYN (LPO = 15.9 ± 1.9 nmol/g) and the C-FA (LPO = 16.4 ± 0.8 nmol/g) diet reduced the LPO levels significantly ($p < 0.05$, ANOVA) by 25% and 22%, respectively, as compared to the HFD control diet (LPO = 21.1 ± 0.8 nmol/g). The LPO levels did not change in the other groups (LPO = 18−20 nmol/g). Furthermore, no differences in the activity of the antioxidant enzymes catalase, GPx, and SOD were observed between the study groups.

## DISCUSSION

In the present work, the structure of the wheat aleurone was disrupted (by physical and enzymatic methods), and the effects of this disintegration on obesity and associated metabolic disorders in DIO mice were studied in a curative design. A curative design means that aleurone-enriched diets were provided to mice previously induced to develop obesity by feeding for 9 weeks with a high-fat diet. The amount of aleurone (13%) added in the high-fat diet provided a diet with 5% dietary fiber to mice, which is a common fiber (usually cellulose) level used in mice studies.

**Effects of Native and Processed Aleurone on Obese Mice.** Enrichment of the high-fat diet with 13% native wheat aleurone (group A-N) had no impact on the reversal of obesity in DIO mice. Other studies have also observed that high-fat diet supplemented with aleurone in corresponding amounts to those used in this study (10% for 3 weeks)[14] or wheat bran (16.5% for 12 weeks)[34] did not reduce the obesity of mice or rats in a preventive design. A preventive design means that no prefeeding period with high-fat diet was performed; i.e., the studied compound was added to the diet already in the beginning of the experiment. On the other hand, a recent study by Neyrinck et al.[12] showed that a high-fat diet (60E%) supplemented with purified AX from wheat (10% (w/w)) for 4 weeks in a preventive design decreased adiposity, body weight gain, serum and hepatic cholesterol accumulation, and insulin resistance in mice and that these effects were related to changes in the gut microbiota. The difference of the results obtained by Neyrinck et al.[12] as compared to the results found in our study could be attributed to the higher amount of purified AX (around 2.5-fold higher) and/or the preventive design of the study. If native aleurone had no impact on the reversal of obesity in DIO mice in our study, the ultrafine ground aleurone (group A-G) surprisingly increased ($p < 0.05$, Figure 2B) the body weight gain of mice as compared to the HFD control. The native and ground aleurones had a similar amount of insoluble AX and bound FA. Ultragrinding increased the aleurone particle surface area exposed to digestive enzymes, probably rendering the digestion more efficient. This could have led mice to increase their gain of weight when supplemented with ultraground aleurone instead of a native one or only a high-fat diet.

The disruption of aleurone by enzymatic treatment with the xylanase and feruloyl esterase (A-XYNFAE group) only showed a tendency ($p = 0.07$, *t*-test) toward reduced body weight gain as compared to the HFD group. A similar tendency toward lower visceral adipose tissue and secretion of leptin was observed when comparing only A-XYNFAE and HFD by *t*-test ($p = 0.004$ and $p = 0.02$ for visceral adipose tissue and leptin, repectively). A-XYNFAE diet had the highest proportion of soluble AX (75%) and conjugated and free forms of ferulic acid (85% of the total FA, respectively) in comparison to other aleurone fractions. Free and conjugated FA forms were reported to be bioavailable already in the upper part of the intestinal tract of humans and mice and beneficial against obesity in rodents.[35,36] Son et al.[37] observed that mice fed during 7 weeks with a free FA enriched high-fat diet in a preventive design reduced their body weight gain. In our work, however, mice fed the C-FA diet (100% free FA) did not have any significant reduction in the body weight gain or adiposity. This discrepancy between the two studies might be due to the 5-fold lower FA dose we administrated and to the curative design of our work. Since C-FA diet had no effect on the body weight gain of mice, the A-XYNFAE tendency could be more related to the high amount of soluble AX in this fraction. Soluble fiber can reduce the obesity by contributing to the viscosity of digesta in the small intestine delaying gastric emptying and decreasing the rate of lipid and carbohydrate absorption in the digestive tract.[38,39] Soluble AX fibers were also demonstrated to impact on the microbial metabolism (i.e., the formation of SCFA, gases, and phenolic metabolites) using an *in vitro* gut model with faecal microbiota as an inoculum.[20] However, the beneficial effects of the enzymatic solubilization of AX on mice obesity remained here as a minor trend, and it might be more pronounced adding the A-XYNFAE diet in a preventive way.

Obesity is associated with an increased risk of developing insulin resistance and type 2 diabetes. In our study the 17 weeks high-fat diet feeding tended to increase fasting blood glucose as compared to the low-fat control group ($p = 0.02$, *t*-test), but neither aleurone- nor FA-enriched diets had any effect on the fasting blood glucose. However, AXYNFAE and C-FA groups had a tendency toward lower fasting plasma insulin level compared to HFD ($p = 0.07$ for AXYNFAE and $p = 0.03$ for C-FA, *t*-test). This tendency to better insulin sensitivity might be related to the high amount of bioacessible FA in both groups rather than to their soluble AX fiber contents, as the C-FA diet contained only cellulose as fiber. Free FA has been previously shown to improve insulin sensitivity in diabetic rats,[40] suggesting that the different effects observed might be due the dose, longer feeding period (19 weeks), and preventive design.

**Effects of Native and Processed Aleurone on Oxidative Stress and Inflammatory Status.** There were no significant differences between the aleurone fractions, C-FA, and control groups for most of the markers for oxidative stress or inflammation. Similarly in healthy humans, the enrichment of the diet with aleurone (amount of aleurone corresponding to 1% of the diet, which provided around 15 g of dietary fiber from aleurone) during a 4 week period did not change the plasma antioxidant activity or markers of inflammation, CRP being the only one decreased after consuming aleurone.[16] In our study, the only marker significantly affected by the diets was the lipid peroxidation byproduct lipidhydroperoxides (LPO). The significant decrease in the LPO levels in A-XYN and C-FA groups ($p = 0.01$ and $p = 0.03$, respectively, ANOVA) may be related to the high antioxidant capacity of these diets due to the high amount of bioaccessible FA, which was shown to scavenge free radicals from the lipid phase and quench the lipid peroxides.[41] However, the fact that the A-XYNFAE diet did not reduce LPO levels despite its high antioxidant capacity remains unclear. Other studies have also shown that supplementation with free FA and feruloyl oligosaccharides from wheat bran decreases oxidative stress biomarkers in high-cholesterol, diabetic, and normal rats.[42−44]

Even though the HFD control group had higher levels of obesity, fasting plasma insulin and leptin compared to LFD throughout the experiment, HFD did not have any significant impact on the degree of oxidative stress or the inflammatory marker levels as compared to LFD. Similarly to our results, Hogan et al.[45] also observed that 12 weeks of a high fat diet feeding was not enough to induce oxidative stress in C57BL/6J mice when compared to a normal diet. It is noteworthy that despite the high amount of fat (45 E%), mainly saturated lard, present in the high-fat diet used in our study, the diet also contained adequate amounts of vitamins and minerals which can help the body metabolism to cope with potential oxidative stress. Therefore, more robust models of feeding trials such as cafeteria diets might be useful in future studies.[46]

In conclusion, this study showed that enrichment of diet with native aleurone reduced neither obesity nor oxidative stress and inflammatory status of DIO mice, but high-fat diets enriched with processed aleurone could impact some parameters of mice metabolism. Disruption of the physical structure of aleurone by ultrafine grinding was not beneficial, as it slightly increased the body weight gain of mice. Disintegration of aleurone at the molecular level showed some trends to reduce body weight gain, visceral adiposity, leptin level, and fasting insulin level in DIO mice, probably related to their higher content in soluble fiber, bioaccessible FA, and other phytochemicals. Considering the cost of aleurone milling and enzymatic treatments, it seems that the use of native or processed aleurone to counteract the metabolic disorders caused by obesity is limited. The lack of significant improvements was probably due to the curative design of this study, which aimed to reverse mice obesity by aleurone-enriched diets. The trends toward improvements of obesity observed by enzymatic treated aleurone indicates that it might be of interest to study the nutritional potential of processed aleurone on healthy mice fed with a high-fat diet in a preventive design.

is involved in TLR2 and TLR4 expression and MAPK/NF-κB signaling pathways.

## MATERIALS AND METHODS

**Animals.** Pathogen-free male BALB/c mice (8 weeks old; weight, 23 ± 2 g) were purchased from Orient Bio, Inc. (Seoul, Korea). The animals were acclimated for 1 week before the experiments. They were allowed free access to laboratory-standard food and water on a 12 h light/12 h dark cycle in a temperature (22 ± 2 °C) and humidity (50 ± 5%) controlled environment. All procedures and animal treatments were performed in a clean animal laboratory room according to the guidelines for laboratory animal experimentation specified by Chung-Ang University. This work was approved by the appropriate ethics committees for the use of laboratory animals at Chung-Ang University.

**Animal Treatment.** Con A was dissolved in pyrogen-free normal saline at a concentration of 25 mg/mL and intravenously injected at a dose of 20 mg/kg of body weight to induce hepatitis, as previously described.[25] EA was dissolved in 0.01 N NaOH[26] at concentrations of 5, 10, or 20 mg/mL and administered by gavage at doses of 50, 100, or 200 mg/kg of body weight.[27,28] The mice were randomized into five groups ($n$ = 4/group; total = 30) as follows: (i) sham group as the vehicle control, including oral administration of the phosphate-buffered saline (PBS) and a tail vein injection with the same volume of saline, (ii) Con A administration group that received no EA treatment, (iii) EA 50 (50 mg/kg) group, (iv) EA 100 (100 mg/kg) group, and (v) EA 200 (200 mg/kg) group. Mice, deprived of food 24 h before Con A treatment with free access to water, were administered with respective doses of EA at both 12 and 1 h before challenge with Con A. Liver samples were obtained 24 h after Con A injection.

**Serum Transaminase Activity Assays.** Blood was obtained from individual mice at 8 h after Con A injection. Serum levels of AST and ALT were used as markers of liver injury. Alanine aminotransaminase (ALT) and aspartate aminotransaminase (AST) concentrations were measured using an IDTox ALT color endpoint assay kit and an IDTox

AST color endpoint assay kit (ID Laboratories, Inc., London, Ontario, Canada), respectively, according to the instructions of the manufacturer, and absorbance was measured using a spectrophotometer.

**Histopathological Examination of the Liver.** The liver tissues were excised, fixed in 10% neutral buffered formalin, and embedded in paraffin. We prepared 4 $\mu$m thick slices stained with hematoxylin and eosin (H&E) according to standard procedures. The slides were examined using light microscopy.

**RNA Isolation, cDNA Synthesis, and Real-Time Quantitative Polymerase Chain Reaction (qPCR) Amplification.** Liver tissues were stored at −80 °C until required. RNA was extracted using Trizol reagent (Invitrogen, Carlsbad, CA). For real-time qPCR, 0.1 $\mu$g of total RNA was reverse-transcribed using a SuperScript III First-Strand Synthesis System for reverse transcription (RT)-PCR (Invitrogen). Real-time PCR was performed in triplicate using the MyiQ Single-Color Real-Time PCR Detection System and an iQ SYBR Green Supermix (Bio-Rad, Hercules, CA). Relative expression was normalized to glyceraldehyde 3-phosphate dehydrogenase (GAPDH) levels. The primer sequences used were as follows: GAPDH, forward, 5-TTC ACC ACC ATG GAG AAG GC-3 and reverse, 5-GGC ATG GAC TGT GGT CAT GA-3; TLR2, forward, 5-AAG ATG TCG TTC AAG GAG GTG CG-3 and reverse, 5-ATC CTC TGA GAT TTG ACG CTT TG-3; TLR4, forward, 5-GGT GTG AAA TTG AGA CAA TTG AAA AC-3 and reverse, 5-GTT TCC TGT CAG TAC CAA GGT TGA-3; tumor necrosis factor $\alpha$ (TNF-$\alpha$), forward, 5-GGC AGG TCT ACT TTG GAG TC-3 and reverse, ACA TTC GAG GCT CCA GTG AA-3; interleukin 6 (IL-6), forward, 5-ACC GCT ATG AAG TTC CTC TC-3 and reverse, 5-CCT CTG TGA AGT CTC CTC TC-3; and interleukin 1$\beta$ (IL-1$\beta$), forward, 5-TCA TGG GAT GAT GAT GAT AAC CTG CT-3 and reverse, 5-CCC ATA CTT TAG GAA GAC ACG GAT T-3. The thermal cycling conditions were as follows: pre-denaturation at 95 °C for 5 min, denaturation at 95 °C for 10 s, annealing at 58 °C for 15 s, and extension at 72 °C for 20 s.

**Isolation of Cytoplasmic and Nuclear Proteins and Immunoblotting.** Frozen liver tissues were weighed and homogenized in ice-cold hypotonic buffer [25 mM Tris (pH 7.5), 150 mM NaCl, 1 mM ethylenediaminetetraacetic acid (EDTA), 2 mM sodium orthovanadate, 50 mM sodium fluoride, 1 mM phenylmethylsulfonyl fluoride (PMSF), 0.1% Triton-X 100, phosphatase inhibitor cocktail tablets, and protease inhibitor cocktail tablets]. Homogenates were incubated for 10 min on ice and centrifuged (12500*g* for 10 min at 4 °C). Cytoplasmic proteins were collected from the supernatants, and nuclear proteins were collected from the pellets. Cytoplasmic fractions were stored at −70 °C. Nuclear proteins were released by dropwise addition of a high-salt buffer [25 mM Tris (pH 7.5), 500 mM NaCl, 10% glycerol, 1 mM EDTA, 2 mM sodium orthovanadate, 50 mM sodium fluoride, 1 mM PMSF, 0.2% Triton-X 100, phosphatase inhibitor cocktail tablets, and protease inhibitor cocktail tablets]. Samples were incubated on ice for 30 min with smooth shaking. The nuclei-containing suspension was then centrifuged (16000*g* for 30 min at 4 °C). The supernatant fraction was collected as the nuclear extract. This extract was stored in aliquots at −70 °C for the subsequent NF-$\kappa$B assay. Protein concentrations of the homogenate were determined using the BCA protein assay with bovine serum albumin as a standard. Equal amounts of whole protein extracts (50 $\mu$g) were separated on 10% acrylamide gels using sodium dodecyl sulfate−polyacrylamide gel electrophoresis. Then, the proteins were transferred onto polyvinylidene fluoride (PVDF) membranes and incubated overnight at 4 °C with specific primary antibodies, namely, rabbit polyclonal anti-TLR2 (Santa Cruz Biotechnology, Santa Cruz, CA) at a dilution of 1:500, rabbit polyclonal anti-TLR4 (Santa Cruz Biotechnology) at a dilution of 1:500, rabbit polyclonal anti-JNK and anti-p-JNK (Cell Signaling Technology, Beverly, MA) at a dilution of 1:2000, rabbit polyclonal anti-ERK and anti-p-ERK (Cell Signaling Technology) at a dilution of 1:2000, rabbit polyclonal anti-p38 and anti-p-p38 (Cell Signaling Technology) at a dilution of 1:2000, rabbit polyclonal anti-I$\kappa$B-$\alpha$ (Santa Cruz Biotechnology) at a dilution of 1:2000, rabbit polyclonal anti-p65 (Cell Signaling Technology) at a dilution of 1:2000, and rabbit polyclonal anti-inducible nitric oxide synthase (iNOS, Santa Cruz Biotechnology) at a dilution of 1:2000. Each filter was then washed 3 times for 10 min and incubated for 2 h at room temperature with horseradish peroxidase (HRP)-labeled secondary anti-rabbit antibody (Cell Signaling Technology) containing blocking solution. To ensure equal loading, the blots were analyzed for GAPDH expression using an anti-GAPDH antibody (Santa Cruz Biotechnology). Immunodetection was performed using Amersham ECL western blotting detection reagents (GE Healthcare, U.K.). Densitometric data were studied after normalization with the control (housekeeping gene). The signals were analyzed and quantified using ImageJ software [National Institutes of Health (NIH), Bethesda, MD].

**Liver Tissue Immunofluorescence.** The liver tissues were fixed in 4% paraformaldehyde, dehydrated, paraffin-embedded, and cut into 4−5 $\mu$m thick sections. After antigen retrieval, the slides were stained with primary TLR2 or TLR4 antibodies (Santa Cruz) and a fluorescently labeled secondary antibody and counterstained with 4′-6-diamidino-2-phenylindole (DAPI). Confocal images were collected in fluorescence mode followed by electronic image merging.

**Statistical Analysis.** Results are represented as the mean ± standard deviation (SD) and were analyzed statistically with analysis of variance (ANOVA), and differences between groups were determined with the Turkey method. Statistical significance was accepted when $p < 0.05$.

## RESULTS

**Hepatoprotective Effect of EA on Con A-Induced Hepatitis.** Acute hepatitis was induced in BALB/c mice by

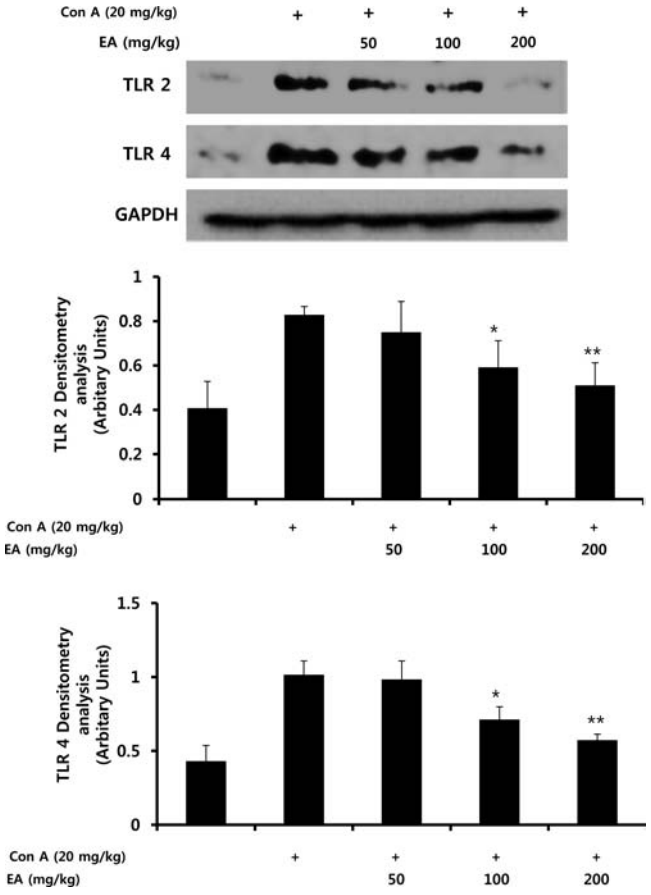

**Figure 2.** Effect of EA on the Con A-induced expression of TLR2 and TLR4 in mouse liver. Hepatic TLR2 and TLR4 protein levels were determined by immunoblotting. Densitometry was performed following normalization to the control (GADPH). Bar represents the mean ± SD ($n$ = 4 mice per group). (*) $p < 0.05$ versus Con A. (**) $p < 0.01$ versus Con A.

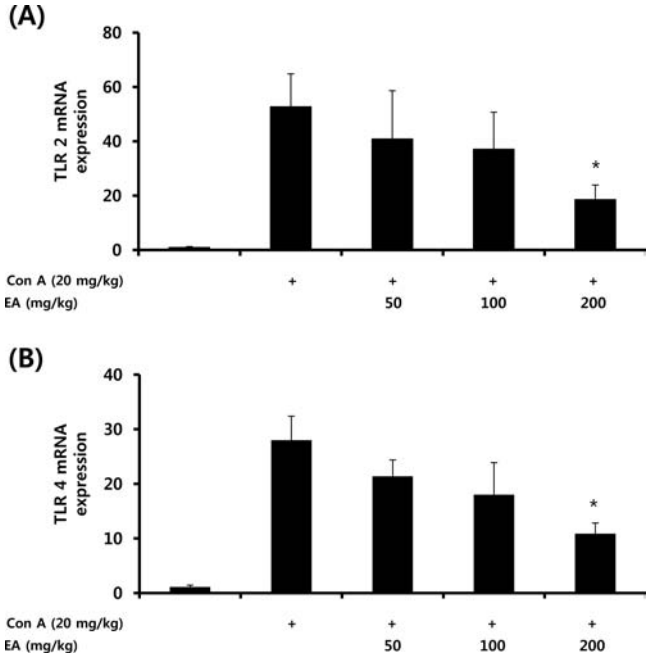

**Figure 3.** Effect of EA treatment on the expression of (A) TLR2 and (B) TLR4 mRNAs in the liver was examined by real-time qPCR. TLR2 and TLR4 mRNA levels were normalized to GAPDH expression in each sample. Bar represents the mean ± SD ($n$ = 4 mice per group). (*) $p < 0.05$ versus Con A.

intravenous injection of Con A. Plasma levels of AST and ALT were significantly increased at 8 h after injection of Con A (Figure 1). In comparison to the vehicle-treated group, the groups receiving oral administration of EA at doses of 50, 100, or 200 mg/kg at both 12 and 1 h before Con A injection showed a significant and dose-dependent decrease in the plasma levels of AST and ALT. Histopathological examination of the liver tissue was used to determine the effects of EA on Con A-induced liver injury. Light microscopy examination showed extensive inflammatory infiltration and large areas of necrosis in the livers of Con A-treated mice. In contrast, mice pretreated with EA showed dose-dependent reduction in liver damage (Figure 1C). This histopathologic evidence of liver damage was positively correlated with increased serum levels of liver enzymes. Taken together, pretreatment with EA showed a protective effect on Con A-induced hepatitis.

**Effects of EA on the TLR2 and TLR4 Expression in Con A-Induced Hepatitis.** We examined the effect of EA on the expression of TLR2 and TLR4 in Con A-induced hepatitis. We observed very low expression levels of TLR2 and TLR4 in the vehicle group. However, the Con A-treated group showed a significant increase of TLR2 and TLR4 expression levels (Figures 2 and 3). TLR2 and TLR4 were highly expressed, which suggested that both receptors were involved in the pathological sequelae of Con A-induced acute liver injury. EA-treated groups showed reduced expression levels of TLR2 and TLR4 in a dose-dependent manner (Figures 2 and 3). In immunofluorescence analysis, TLR2 and TLR4 were reduced in EA-treated groups in a dose-dependent manner (Figure 4).

**Effect of EA on the JNK, ERK1/2, and p38 Signaling Pathways in Con A-Induced Hepatitis.** TLR signaling pathways are involved in the activation of MAPKs. These molecules play a key role in inducing gene expression, which initiates inflammatory responses. We investigated the effect of EA on the Con A-induced hepatitis-associated activation of JNK, ERK1/2, and p38. We detected JNK, ERK1/2, and p38 MAPK protein phosphorylation using western blotting in the cytosolic extracts of liver tissues using phospho-specific MAPK antibodies. Con A treatment increases phosphorylation of JNK, ERK1/2, and p38; however, the EA treatment group showed a strong inhibition of phosphorylation of JNK, ERK1/2, and p38 (panels A–C of Figure 5). These results suggested that the activation of JNK, ERK1/2, and p38 could be induced at the acute stage of hepatitis caused by Con A and treatment with EA significantly decreased the phosphorylation levels of p38, JNK, and ERK1/2.

**EA Inhibits NF-κB Activation and IκB-α Degradation in Con A-Induced Hepatitis.** We further investigated the effect of EA on NF-κB activation and IκB degradation in a mouse model of Con A-induced hepatitis. EA pretreatment inhibits NF-κB activation and IκB-α degradation in an EA dose-dependent manner (panels A and B of Figure 6).

**EA Pretreatment Inhibits the Expression of Pro-inflammatory Cytokines and iNOS in Con A-Induced Hepatitis.** TNF-α, IL-6, and IL-1β have been shown to play critical roles in the progression of Con A-induced liver injury. To investigate whether EA influences the production of these cytokines, we measured the mRNA expression of TNF-α, IL-6, and IL-1β in Con A-induced hepatitis. The levels of TNF-α, IL-6, and IL-1β mRNA significantly increased in the control group

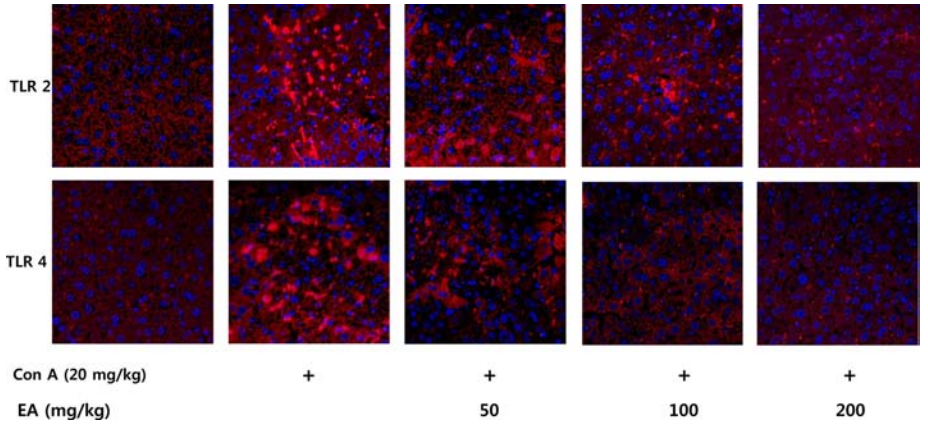

**Figure 4.** TLR2 and TLR4 localization in murine liver by immunofluorescence microscopy after administration of Con A for 24 h (original magnification and 300×).

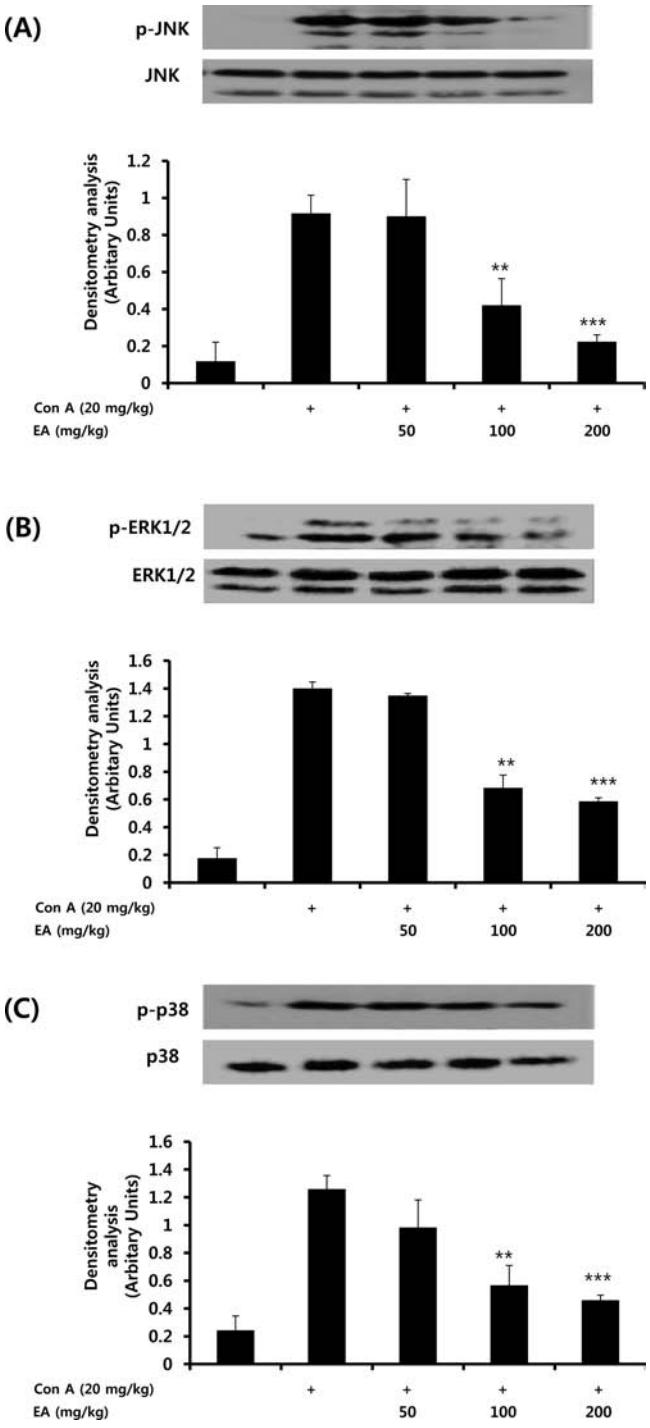

**Figure 5.** Hepatic (A) p-JNK, (B) p-ERK, and (C) p-p38 protein levels determined by immunoblotting. Densitometry was performed following normalization to the control (JNK, ERK, and p38 housekeeping genes, respectively). Bar represents the mean ± SD ($n$ = 4 mice per group) (∗) $p < 0.05$ versus Con A. (∗∗) $p < 0.01$ versus Con A. (∗∗∗) $p < 0.001$ versus Con A.

(panels A–C of Figure 7). EA pretreatment decreased the expression of TNF-$\alpha$, IL-6, and IL-1$\beta$ in the livers of Con A-treated groups. These data suggest that EA suppresses the expression of inflammatory cytokines in Con A-induced hepatitis. iNOS is a protein that is predominantly expressed on the sites of inflammation. We measured the cytosolic iNOS expression levels in the liver using western blotting. Exposure of

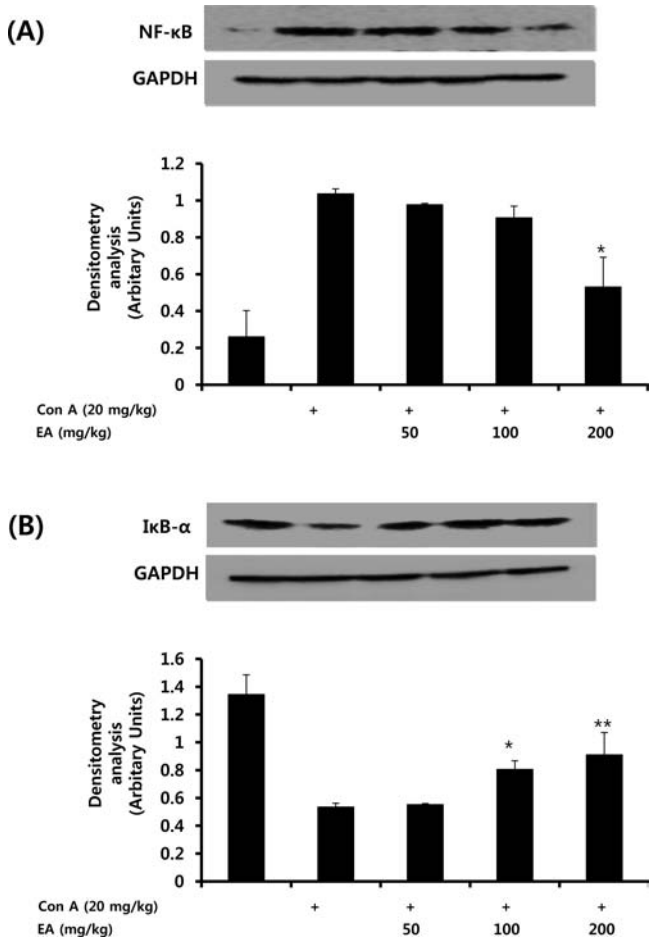

**Figure 6.** Effect of EA on the NF-κB pathway in Con A-induced liver injury. Hepatic (A) NF-κB and (B) IκB-$\alpha$ protein levels determined by immunoblotting. Densitometry was performed following normalization to the control (GADPH). Bar represents the mean ± SD ($n$ = 4 mice per group). (∗) $p < 0.05$ versus Con A. (∗∗) $p < 0.01$ versus Con A. (∗∗∗) $p < 0.001$ versus Con A.

the liver to Con A caused strong iNOS expression, which indicated that these proteins could be induced in the acute stage of hepatitis. Pretreatment of EA significantly decreased this upregulation of iNOS protein expression in a dose-dependent manner (Figure 7D).

## DISCUSSION

A recent study showed that the ALT and AST levels decreased after treatment with EA in Balb/C mice after Con A-induced fulminant liver failure.[24] However, the exact mechanism underlying this effect remains unclear. To determine the mechanisms underlying the protective effects of EA, we examined the TLR pathway. TLR expression may be associated with the production of proinflammatory cytokines because the activation of these receptors stimulates signaling pathways, which result in activation of NF-κB and MAPK phosphorylation (Figure 8).

Con A-induced hepatitis is an experimental model of immune-mediated liver disease in humans.[29] Con A was originally identified as a mitogen in T lymphocytes and activates macrophages and neutrophils.[30,31] The hepatitis induced by intravenous injection of Con A is mainly dependent upon T-cell activation.[2] Hepatic injury caused by Con A disrupts the hepatocellular plasma membrane, and the enzymes

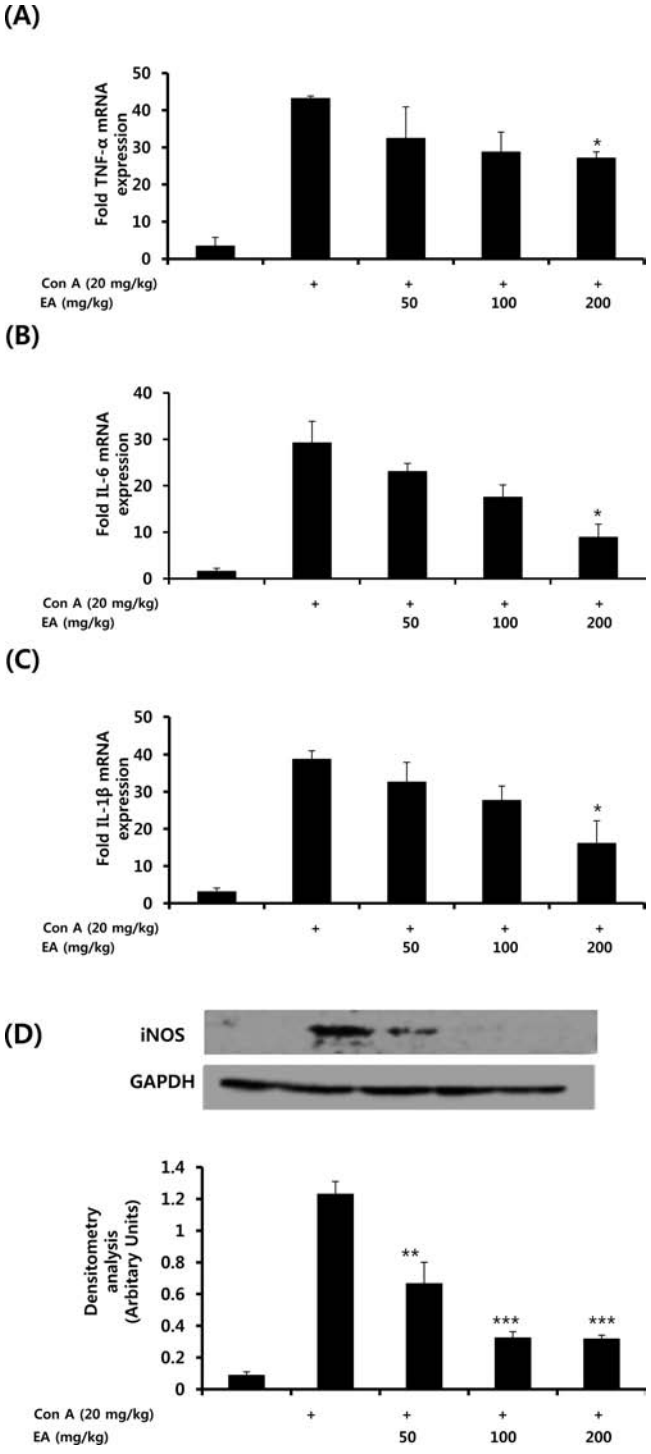

**Figure 7.** Effect of EA on the expression of proinflammatory cytokines and iNOS protein in the liver after Con A administration. Expression of (A) TNF-$\alpha$, (B) IL-6, and (C) IL-1$\beta$ mRNAs in the liver were examined by real-time qPCR. TNF-$\alpha$, IL-6, and IL-1$\beta$ mRNA levels were normalized to GAPDH expression in each sample. (D) iNOS protein levels determined by immunoblotting. Densitometry was performed following normalization to the control (GADPH). Bar represents the mean ± SD ($n$ = 4 mice per group). (*) $p < 0.05$ versus Con A.

normally present in the cytosol are released into the bloodstream.[32] In the present study, the ALT and AST levels in the Con A-treated mice returned to normal after pretreatment with EA, which showed the hepatoprotective

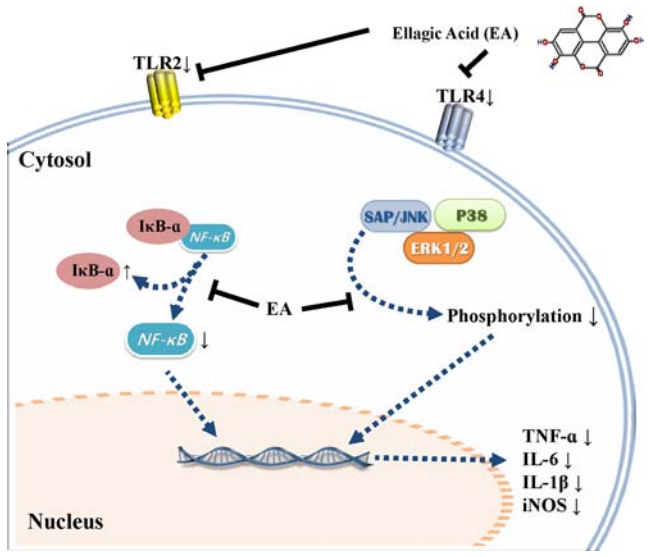

**Figure 8.** Hypothetic mechanism of the EA protective effect against hepatitis via TLR and MAPK/NF-$\kappa$B signaling pathways. EA decreased TLR2 and TLR4 levels (Figures 2–4). EA decreased the phosphorylation of JNK, ERK1/2, and p38 (Figure 5). EA suppressed NF-$\kappa$B and increased I$\kappa$B-$\alpha$ (Figure 6). EA suppressed inflammatory cytokines (Figure 7).

activity of EA. In the previous studies, EA was administered at doses of 50, 100, or 200 mg/kg of body weight.[27,28] In this study, we set the optimal dose range of the EA (0, 50, 100, or 200 mg/kg of body weight) and have shown the hepatoprotective effect of EA. Additionally, on the basis of previous studies,[33−38] we chose the optimal time points of EA treatment at 12 and 1 h prior to an injection of Con A. Soyasapogenol A, which has protective effects on a Con A-induced hepatitis model, was administered at 2 and 14 h prior to an intravenous injection of Con A. In other studies, therapeutic compounds, including allicin, Inchinko-to, and coumarin derivatives, were treated 1 h before Con A injection. Additionally, the Gal-3 inhibitor, which attenuates Con A-induced hepatitis, was intraperitoneally administered 2 h before and immediately after Con A injection.[33−38]

Previous studies indicated that the pathogenesis of Con A-induced hepatitis was mainly mediated by the release of inflammatory cytokines. TNF-$\alpha$, IL-6, and IL-1$\beta$ play crucial roles in the development of Con A-induced hepatitis.[39,40] These studies suggested that inhibition of TNF-$\alpha$, IL-6, and IL-1$\beta$ tended to alleviate liver injury. In the present study, we found that pretreatment with EA decreased the hepatic mRNA expression of TNF-$\alpha$, IL-6, and IL-1$\beta$ in Con A-induced liver injury. Therefore, we propose that EA exerts its hepatoprotective effects through the inhibition of TNF-$\alpha$, IL-6, and IL-1$\beta$ production.

In a recent study, the TLR signaling pathway was shown to be the predominant pathway in the early phase in a model of Con A-induced hepatitis.[4] The expression of TLR2 and TLR4 was increased in the liver during Con A-induced hepatitis.[1] Furthermore, TLR signaling stimulates the production of type I cytokines and, thus, recruits and activates T/NK cells. Activated T/NK cells exert cytotoxic effects on hepatocytes through induction of death receptor-mediated apoptosis, which results in liver injury.

Activation of TLR2 and TLR4 results in the recruitment of MyD88, an adaptor molecule, which subsequently facilitates the

activation of downstream signaling pathways. Two major kinase-mediated signaling pathways are activated after TLR stimulation, the MAPK and IκB kinase (IKK) complex pathways, which transduce various upstream signals to the activation of AP-1 and NF-κB transcription factors. Both of these are essential for the expression of activation-induced inflammatory mediators, including chemokines and cytokines.[17] Recent studies have shown that, in comparison to wild-type mice, TLR2 or TLR4 knockout mice are protected from Con A-induced hepatic injury.[9,41] Furthermore, MyD88-knockout mice develop less severe Con A-induced hepatitis with less production of proinflammatory cytokines.[42] These studies have provided evidence that TLR2 and TLR4 play an important role in Con A-induced hepatitis. Intervention via the regulation of TLR2 and TLR4 expression may therefore represent a therapeutic target for Con A-induced hepatitis.

In the present study, we showed that TLR2 and TLR4 expression in liver tissues, at the mRNA and protein levels, was significantly reduced by EA pretreatment (Figures 2−4). This might be attributed, at least in part, to the amelioration of liver injury and changes in cytokine production in mice. These data are new and relevant, because the effect of EA on these receptors has not been reported thus far. We propose that EA may have general anti-inflammatory effects in diseases associated with TLR signaling.

The liver is constantly exposed to bacterial peptidoglycans and LPS from the intestines via the hepatic portal vein.[16] After ligand binding, the TLRs activate downstream signaling pathways via recruitment of a group of intracellular TIR-domain-containing adaptors, including MyD88.[17] Recruitment of MyD88 leads to the activation of MAPKs, including ERK, JNK, and p38, and the transcription factor NF-κB, all of which regulate the expression of genes encoding the inflammatory cytokines.[14,18]

The transcription factor NF-κB consists of a heterodimer of p50 and p65, which is retained in the cytoplasm via the masking of a nuclear localization signal by the inhibitor IκB-α. Upon activation, IKK phosphorylates IκB-α, which promotes its translocation to the nucleus and results in the expression of various proinflammatory cytokines, including IL-2, IL-6, IL-8, IL-1β, and TNF-α.[43] In addition, NF-κB activation mediates the transcription of proinflammatory genes, such as *iNOS*. Many studies have suggested that NF-κB may be a key regulator of inflammation in liver injury.[44] Thus, inflammatory mechanisms play an important role in T-cell-mediated liver disease associated with increased activity of NF-κB. Inhibiting the activation of NF-κB exerts protective effects against liver injury; therefore, we propose that EA acts on NF-κB via the inhibition of IκB-α, which results in the prevention of NF-κB translocation into the nucleus in acute hepatitis. Furthermore, our findings show that EA can reduce the expression of the proinflammatory gene *iNOS*. Other important downstream signaling targets of TLRs are the MAPKs. The three major groups of MAPKs identified in mammalian cells are p38 MAPK, JNK kinase, and ERK.[45] MAPKs are key modulators of several target genes that ultimately regulate innate and adaptive immunity, cell motility, and cell proliferation.[46,47] Three different types of MAPKs contribute to the induction of AP-1 activity through phosphorylation of a different substrate. Activator protein (AP)-1 largely controls T-cell activation in the liver after binding of foreign antigens to the T-cell receptor, which leads to the secretion of cytokines, such as TNF-α, IL-6, and IL-1β.[46,47] ERK, JNK, and p38 MAPK pathways may therefore represent potential targets for inhibiting the progression of liver fibrosis. Similarly, inhibition of the phosphorylation of JNK, ERK, and p38 has protective effects in hepatitis. To our knowledge, this is the first study in which the protective effect of EA mediated by the inhibition of p38, JNK, and ERK MAPKs in hepatitis has been described.

In conclusion, we showed that EA attenuates Con A-induced hepatitis. One of the possible mechanisms underlying this effect is inhibition of TLR2 and TLR4 expression, which may decrease the expression of inflammatory cytokines and, in turn, inhibit the phosphorylation of MAPK and nuclear translocation NF-κB. This may account for a reduction in TNF-α, IL-6, and IL-1β expression by inhibition of NF-κB-mediated transcriptional activation and IκB-α degradation and prevention of p38, JNK, and ERK MAPK phosphorylation. Therefore, our findings suggest that TLR2, TLR4, NF-κB, and MAPK may be the specific molecular targets of EA in its protective effects against Con A-induced hepatitis.

China. Fruits were harvested when fully mature according to commercial practice and immediately transported to the laboratory. The clusters were selected on the basis of uniform color, size, and firmness, and blemished and diseased fruits were discarded. SA with a concentration of 1 mM was chosen for this experiment on the basis of a previous study.[7] Treatments were performed as follows: (i) grape berries immersed in sterile distilled water at 20 °C for 10 min were designated the control; (ii) grape berries immersed in 1 mM SA solution at 20 °C for 10 min were designated the SA treatment. Following treatments, fruits were placed on kraft paper and allowed to dry at 20 °C for 20 h. Both control and treated grape berries were then stored in a temperature-controlled chamber at 2 °C with a relative humidity of 95% for 45 days. At 0, 15, and 45 days of storage, three samples (30 grape berries for each) were taken randomly from each treatment for biochemical and proteomic analysis.

**Measurement of Weight Loss, Flesh Firmness, and Membrane Leakage.** Weight loss was recorded by subtracting final weight from the initial weight of the clusters and then expressed as percent weight loss with reference to the initial weight. Fruit firmness was determined using a TX-XT2i texture analyzer (Stable Micro Systems, Surrey, UK) with a 5 mm diameter probe at a speed of 1 mm/s and expressed in newtons (N). Measurements were carried out on two opposite sides of each individual fruit (15 grapes randomly selected from each treatment) after removal of the peel. Membrane leakage was determined according to the previously described method[21] using a digital conductivity meter (DDB-6200, Shanghai Leici Apparatus, Shanghai, China) and expressed as percentage of the conductivity of total tissue electrolyte.

**Protein Extraction.** Protein extraction was performed according to the method described by Yuan et al.[22] Deseeded grape berries tissues (approximately 10 g) taken from at least 15 fruits were ground to a fine powder in liquid nitrogen with a mortar and pestle. The ground tissue was suspended in 5 mL of extraction buffer containing 0.8 M sucrose, 0.1 M Tris-HCl, pH 7.5, 10 mM EDTA, 0.1 M KCl, 2 mM phenylmethanesulfonyl fluoride, and 2% $\beta$-mercaptoethanol, incubated by shaking for 1 h at 4 °C. Afterward, an equal volume of Tris-saturated phenol (pH 7.9) was added, and the mixture was incubated on a shaker for another 30 min at room temperature. Samples were then centrifuged for 10 min at 9000*g*. The resulting upper phenol phase was collected and washed twice with extraction buffer. The phenol phase was carefully transferred to a new centrifuge tube, and 5 volumes of ice-cold methanol containing 0.1 M ammonium acetate was added. Tubes were mixed by gentle inversion and then kept at −20 °C overnight. After that, samples were centrifuged at 9000*g* for 30 min, and the precipitated protein pellets were washed three times with cooled methanol containing 0.1 M ammonium acetate and finally twice with cooled acetone. The pellets were dried under vacuum at room temperature and resolubilized in lysis buffer containing 7 M urea, 2 M thiourea, 4% 3-[(3-cholamidopropyl)dimethylammonio]-1-propanesulfonate, 1% dithiothrietol (DTT), and 1% carrier ampholytes (pH 3−10).

**Two-Dimensional Gel Electrophoresis.** 2-DE was performed as described by Wang et al.[23] A Protean IEF Cell instrument (Bio-Rad, Hercules, CA, USA) was used for isoelectric focusing (IEF) with precast immobilized pH gradient (IPG) strips (pH 4−7, 17 cm). Samples of 300 $\mu$L containing 700 $\mu$g of protein were loaded by passive in-gel rehydration. The strips were subjected to IEF using the following program: at 500 V for 0.5 h, at 1000 V for 1 h, at 4000 V for 1 h, at 8000 V for 2 h, and focusing at 8000 V until a final volt-hours of 60000 was reached. After IEF, strips were equilibrated in 10 mL of SDS equilibration buffer (7 M urea, 2% SDS, 0.075 M Tris-HCl, pH 8.8, 30% glycerol), first with buffer containing 1% DTT for 15 min and afterward with buffer containing 2.5% iodoacetamide for 15 min. The second-dimensional electrophoresis was run on a 12% polyacrylamide gel in an Ettan DALT System (GE Healthcare, Piscataway, NJ, USA). Gel electrophoresis was first conducted at 5 W/gel for 0.5 h and then at 15 W/gel for 5.5 h. Proteins spots in 2-DE gels were visualized by Coomassie blue staining. Three replicate gels were run for each sample. Image analysis was performed with PDQuest software (version 7.2; Bio-Rad). Data were normalized as a percentage of the total density of all valid spots on the corresponding gel. Normalized spot volumes were compared between the control and treatment samples on each gel, and only those spots with an average fold change >1.5 at least at one time point after cold storage, as well as exhibiting the same expression pattern among the three replicates, were considered as differentially expressed proteins.[22]

**In-Gel Digestion and Mass Spectrometric Analysis.** Differentially expressed protein spots were manually excised from the gels and destained with 50 mM $NH_4HCO_3$ in 50% (v/v) acetonitrile. The gel pieces were then reduced in 10 mM DTT for 45 min at 55 °C and alkylated in 55 mM iodoacetamide for 45 min at room temperature. After washing with 0.025 mM $NH_4HCO_3$ in 50% (v/v) acetonitrile, the dried gels were incubated in 10 $\mu$L of 10 ng/mL trypsin (Sigma-Aldrich, Shanghai, China) at 37 °C overnight. The supernatant was collected for mass spectrometry analysis.

Mass spectrometry data were obtained using an ultraflex matrix-assisted laser desorption/ionization time-of-flight (MALDI-TOF) mass spectrometer (Bruker, Bremen, Germany). The resulting peptide mass fingerprinting (PMF) were queried against the NCBInr database using MASCOT software (http://www.matrixscience.com). The following parameters were used for database searches: taxonomy, Viridiplantae (green plant); cleavage specificity, trypsin with up to one missed cleavage; allowed modifications, carbamidomethylation of cysteine; peptide tolerance, ±0.2 Da; mass value, $MH^+$ and monoisotopic.

**Sugar Measurement.** GC-MS analyses of sugar contents were performed according to the method of Yun et al.,[24] with minor modification. Briefly, grape berry (10 g) tissue taken from at least 15 fruits was ground in a mortar with liquid $N_2$, and 600 mg of the resulting powder was suspended in 8.4 mL of cooled methanol. A total of 600 $\mu$L of 0.2 mg/mL ribitol was added as a quantification internal standard. The resulting extract was incubated in 90 $\mu$L of methoxamine hydrochloride (20 mg/mL in pyridine) by shaking at 50 °C for 45 min, followed by a 30 min treatment at 60 °C using 100 $\mu$L of *N*-methyl-*N*-trimethylsilyl-trifluoroacetamide containing 1% trimethylchlorosilane. The derivatized samples were analyzed by a Thermo Scientific TRACE GC Ultra system (Waltham, MA, USA) equipped with a fused-silica capillary column (30 m × 0.25 mm, Thermo Scientific) chemically bonded with 0.25 $\mu$m TR-5MS stationary phase. The injector temperature was 250 °C with a carrier helium gas flow rate of 1 mL/min. The column temperature was initially kept at 100 °C for 1 min and then increased to 184 °C at a rate of 3 °C/min, increased to 190 °C at a rate of 0.5 °C/min, and increased to 280 °C at a rate of 15 °C/min, at which it was held for 5 min. The column effluent was introduced into the ion source of a Thermo Scientific ITQ 1100 MS. Ions were generated by a 70 eV electron, and ion source temperature was set at 250 °C. Total ion current spectra were recorded from $m/z$ 45 to 600 in scanning mode. The compound was identified by comparing the mass spectrum with that in the NIST library 2005. The quantitative results were processed into Microsoft Word using the toolbox in Thermo Xcalibur. For comparative purposes, within each chromatogram the peak areas of the compounds were normalized by the sample fresh weight and by the peak area from the internal ribitol standard, resulting in a relative response ratio for each compound.

**Determination of Energy Charge.** Extraction and measurement of ATP, ADP, and AMP contents were conducted according to the previously described method.[25] Flesh tissue (2 g) of grape berries was homogenized with 5 mL of 0.6 mol/L perchloric acid. After centrifugation at 20000*g* for 15 min, a volume of 3 mL of supernatant was taken and quickly adjusted to pH 6.5 using KOH solution and passed through a 0.45 $\mu$m filter. Liquid assays of ATP, ADP, and AMP contents were performed on a Shimadzu SPD-M20A HPLC system (Kyoto, Japan) equipped with a DAD detector and a Shim-pack VP-ODS column (250 mm × 4.6 mm, Shimadzu). Mobile phases consisted of A (0.06 mol/L $K_2HPO_4$ and 0.04 mol/L $KH_2PO_4$ solution, pH 7.0) and B (acetonitrile) with a flow rate of 1.2 mL/min. The gradient program was as follows: 0−2 min, 2% B; 2−4 min, 5% B; 4−5 min, 20% B; 5−6 min, 25% B; 6−9 min, 2% B. The injection volume was 20 $\mu$L, and the detection wavelength was 254

nm. Standard curves of each reference compound were used to quantify ATP, ADP, and AMP concentrations. Energy charge was calculated as [ATP + $^1/_2$ ADP]/[ATP + ADP + AMP].

**Statistical Analysis.** One-way analysis of variance (ANOVA) was carried out to estimate differences using the software package SPSS version 17.0, and minimum significant differences were calculated by using Duncan's test ($\alpha$ = 0.05). Data presented were expressed as means ± standard deviation (SD).

## RESULTS

**Evaluation of Postharvest Quality of SA-Treated Grape Berries.** Weight loss was effectively reduced by SA treatment with values of 4.1 ± 0.1 and 2.5 ± 0.0% for control and treated fruits after 45 days of storage, respectively (Figure 1a). The same behavior was also found for fruit firmness

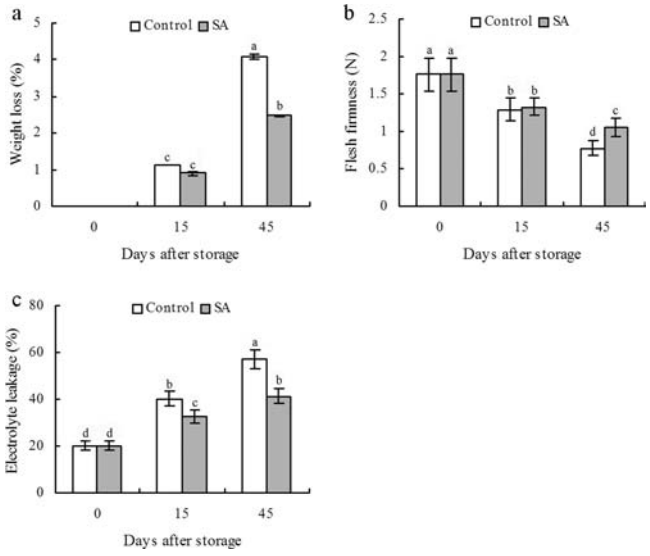

**Figure 1.** Changes of weight loss (a), flesh firmness (b), and electrolyte leakage (c) of control and 1 mM SA-treated grape berries during 45 days of storage at 2 °C. Values are the mean ± SD of three biological replicates. In the case of flesh firmness estimation, determinations were carried out independently using 15 different fruits. Different letters within each parameter indicate statistically significant differences ($p$ < 0.05).

(Figure 1b), for which SA-treated fruit exhibited significantly ($p$ < 0.05) higher flesh firmness (1.1 ± 0.1 N) after 45 days of storage as compared to the control (0.8 ± 0.1 N). In addition, as expected, chilling injury evaluated by ion leakage increased during storage, although it was affected by treatment (Figure 1c). At the end of storage, relative membrane leakage of SA-treated grape berries was 41.3 ± 3.2%, which was significantly ($p$ < 0.05) lower than that of control fruit (57.3 ± 4.0%).

**Changes in Protein Expression Profiles of Grape Berries after SA Treatment.** Our preliminary study indicated that phenol extraction procedure produced a better protein extraction and fewer interfering compounds as compared with the TCA/acetone extraction method. A similar conclusion was reported in an analysis of the proteome of grape and orange tissues.[26,27] 2-DE analysis was conducted using pH 4−7 strips and 12% SDS-PAGE, and about 500 protein spots were reproducibly detected in CBB-stained gel (Figure 2). After normalization for the total density of all spots on the corresponding gel, quantitative analysis indicated that 91 protein spots showed a fold change >1.5 at least at one time point as compared between the control and SA-treated samples.

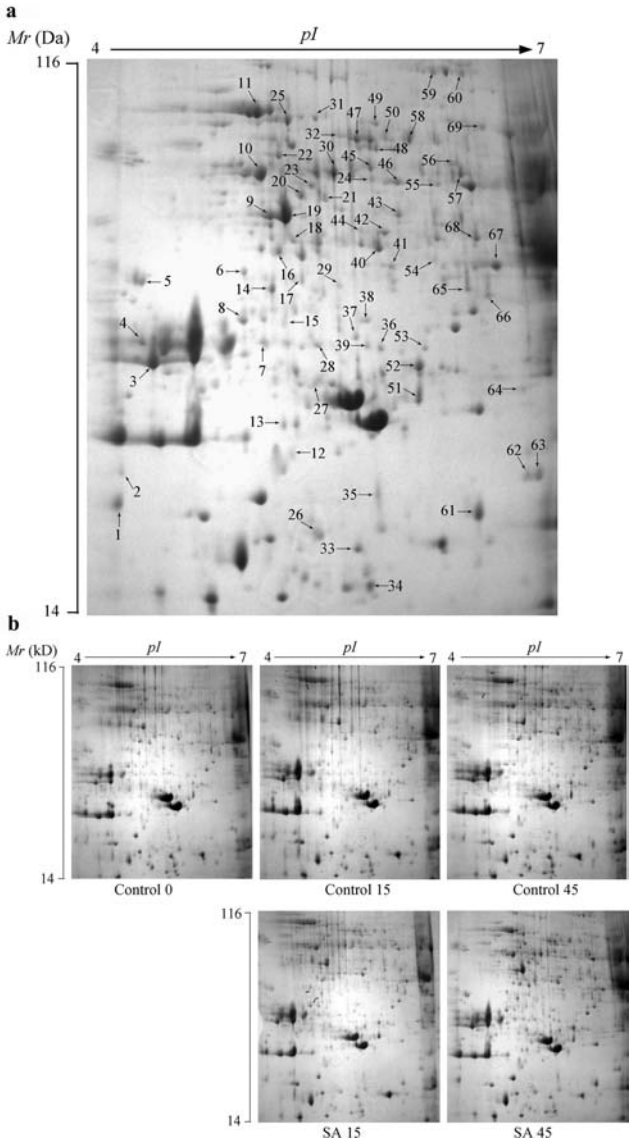

**Figure 2.** Two-dimensional gel electrophoresis of total proteins from grape berries during postharvest storage: (a) 69 differentially expressed protein spots subjected to SA treatment; (b) representative 2-DE profiles of proteins from SA-treated grape berries and respective control at different time points during postharvest storage.

MALDI-TOF MS analysis was carried out for the differentially expressed proteins, and 69 proteins were unambiguously identified by searching against the NCBInr viridiplantae protein database using the PMF data (Table 1), representing an identification rate of 75.8%.

These 69 proteins were classified into 8 functional groups on the basis of their putative roles in biological processes, including carbohydrate and energy metabolism, response to storage environmental stimuli, protein biosynthesis and degradation, amino acid and fatty acid metabolism, signal transduction, cytoskeleton, secondary metabolism, and unclassified (Figure 3). Accordingly, the major categories found to be affected by SA treatment were carbohydrate and energy metabolism and response to storage environmental stimuli, which might provide a clue to understanding the effectiveness of SA treatment to protect against environmental stresses while maintaining fruit quality.

**Table 1. Identification of SA-Regulated Proteins in Grape Berries during Postharvest Storage at 2 °C for 45 Days**

| | | | observed | | theoretical | | | | | ratio[a] | |

[a]Ratio of relative abundance of corresponding spot in samples treated by SA versus the control. Data are the mean values ± SD of three replicates.

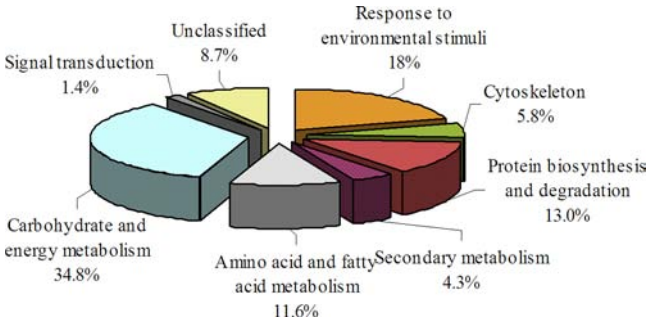

**Figure 3.** Pie chart showing functional classes of identified proteins. This classification is based on MIPS functional catalogue database (http://mips.helmholtz-muenchen.de/proj/funcatDB/) and related literature data.

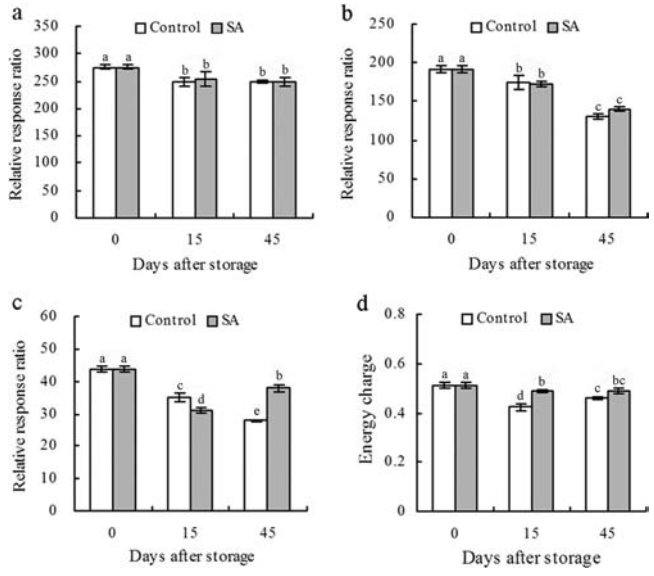

**Figure 4.** Changes of fructose (a), glucose (b), sucrose (c), and energy charge (d) in control and 1 mM SA-treated grape berries during 45 days of storage at 2 °C. Variation of levels of sugars are expressed as the relative response ratio with respect to the ribitol internal standard and normalized to the fresh weight of the sample. Data are the mean ± SD of three biological replicates. Different letters within each parameter indicate statistically significant differences ($p < 0.05$).

**Changes of Sugars Contents and Energy Charge.** Both the control and SA-treated grape berries showed a continual decline in fructose and glucose levels during the full experiment period, and no significant difference was observed between SA-treated and control samples (Figure 4a,b). However, the contents of sucrose in SA-treated grape berries decreased dramatically after 15 days of storage and exhibited a lower sucrose level as compared to that in the control (Figure 4c). At the later storage, fruits treated with SA showed pronounced higher levels of sucrose than in the control.

Distinct changes of energy charge were also observed in SA-treated and the control grape berries during storage (Figure 4d). The energy charge in control fruit decreased significantly after 15 days of storage and increased slightly at the later storage stage. SA treatment maintained the obvious higher energy charge in comparison with the control fruit.

## DISCUSSION

In the present study, SA treatment effectively reduced postharvest loss and chilling injury of grape berries during subsequent cold storage, which was manifested by decreased weight loss, softening, and membrane damage as compared to control fruit. The effect of SA on increasing resistance to environmental stress and preserving fruit quality has been reported for other fruit such as pomegranate,[11] sweet cherry,[7,28] and peach.[12,29] However, little information related to SA treatment is available at a systemic biological level. Further proteomic analyses allowed for a total of 69 SA-responsive proteins to be identified by MS. Functional analysis revealed that the major categories found to be affected by SA treatment were carbohydrate and energy metabolism and response to storage environmental stimuli, which accounted for 34.8 and 18.0% of the total identified proteins, respectively, and were higher than the 22.5 and 11.5% predicted for the whole genome of plant species.[30] For harvested grape berries, storage conditions and natural maturation were the primary factors affecting fruit quality and, therefore, it can be expected that carbohydrate metabolism and response to storage environmental stimuli may dominate the cellular processes and participate in combination or separately in regulating the responses to SA treatment.

In terms of fruit under postharvest conditions, carbohydrate metabolism and energy supply not only affect fruit quality but also are closely related to chilling tolerance during cold storage.[31,32] On the basis of proteomic analysis, a number of proteins with known roles in glycolysis and tricarboxylic acid cycle, such as pyruvate dehydrogenase (spot 6), enolase (spots 30, 46, 54, 55, and 57), 2,3-bisphosphoglycerate-independent phosphoglycerate mutase (spot 32), phosphoglycerate kinase (spots 44 and 68), succinate dehydrogenase (spot 49), aconitate hydratase (spot 59), trisphosphate isomerase (spot 64), and malate dehydrogenase (spot 67), and four proteins associated with energy metabolism, including ATP synthase subunit $\beta$ (spot 10), ATP synthase CF1 $\alpha$ subunit (spot 22), V-type proton ATPase (spot 24), and soluble inorganic pyrophosphatase (spot 27), were found to be up-regulated in stored grape berries after SA treatment. Enhanced expression of these enzymes may result in activation of carbohydrate catabolism and increasing energy supply. As a result, increased sucrose consumption and energy charge were observed in SA-treated fruit in comparison with the control, especially during the first 15 days of cold storage. Recently, increasing evidence has shown that development of chilling injury in several types of fruit is partially attributed to limited availability of energy or low energy production, whereas maintenance of higher levels of energy status alleviates chilling damage. For example, pretreatments with methyl jasmonate[25] and oxalic acid[33,34] enhance chilling tolerance of peach and mango fruit by inducing enzyme activities related to energy metabolism and maintaining high levels of ATP and energy charge. Therefore, increased expression of these enzymes associated with carbohydrate metabolism and energy production could provide sufficient energy supply, thereby reducing chilling injury of grape berries during cold storage.

There is evidence that chilling may impose oxidative stress on plant tissues,[35] and the alleviation of chilling damaging in resistant plants may be related to their ability to reduce and to scavenge free radicals through activated antioxidant system.[36] In this study, SA treatment increased the abundances of several antioxidant enzymes, such as ascorbate peroxidase (spots 15 and 52), glutathione *S*-transferase (spot 51), and oxidoreductase (spot 37). Other studies have also indicated that the activities of antioxidant enzymes appear to be increased by SA treatment and, as a result, may play a major role in responses to chilling damage-induced oxidative stress.[7,12,29]

Heat shock proteins (HSPs) are one of the major classes of chaperone molecules in higher plants and play a crucial role in protecting plants against stresses by re-establishing normal protein configuration and thus helping to maintain cellular homostasis.[37] Abiotic stresses usually caused protein dysfunction, so maintaining proteins in their functional configuration and preventing the aggregation of non-native proteins are particularly important for cell survival under chilling stress conditions.[38] In the present study, several HSPs including HSP 18.2 (spot 33), HSP 60 (spot 25), HSP 70 (spots 11 and 31), and HSP STI-like (spot 69) as well as translationally controlled tumor protein (spot 1), which was recently designated a novel heat shock protein,[39] were also up-regulated in SA-treated grape berries compared to the control during postharvest cold storage. Similarly, treatments with SA or methyl salicylate prior to cold storage increase the synthesis of HSPs and, at the same time, prevent chilling injury in tomato[40] and peach.[28] Moreover, spots 62 and 63 exhibited increased expression after SA treatment and were identified as temperature-induced lipocalin; this protein has been supposed to be associated with abiotic stress response and is correlated with the plant's capacity to develop chilling tolerance.[41,42]

The present work profiles the biochemical and proteomic changes in postharvest grape berries subjected to SA treatment and provides an overview regarding the crucial response components and subsequent processes during the subsequent cold storage. In SA-treated grape berries, fruit quality loss is reduced and chilling damage is inhibited, with decreased flesh firmness and weight loss and membrane leakage. Comparative proteomic analysis reveals that the induction of HSPs, antioxidant enzymes, and proteins involved in carbohydrate catabolism and energy production in SA-treated fruit may constitute the molecular basis for the protection against chilling injury and reduced postharvest loss. Many areas of research remain open after all of these findings, for instance, the elucidation of the changes in specific enzymes involved in carbohydrate metabolism as well as metabolomic studies during postharvest storage and how these are affected by SA treatment.

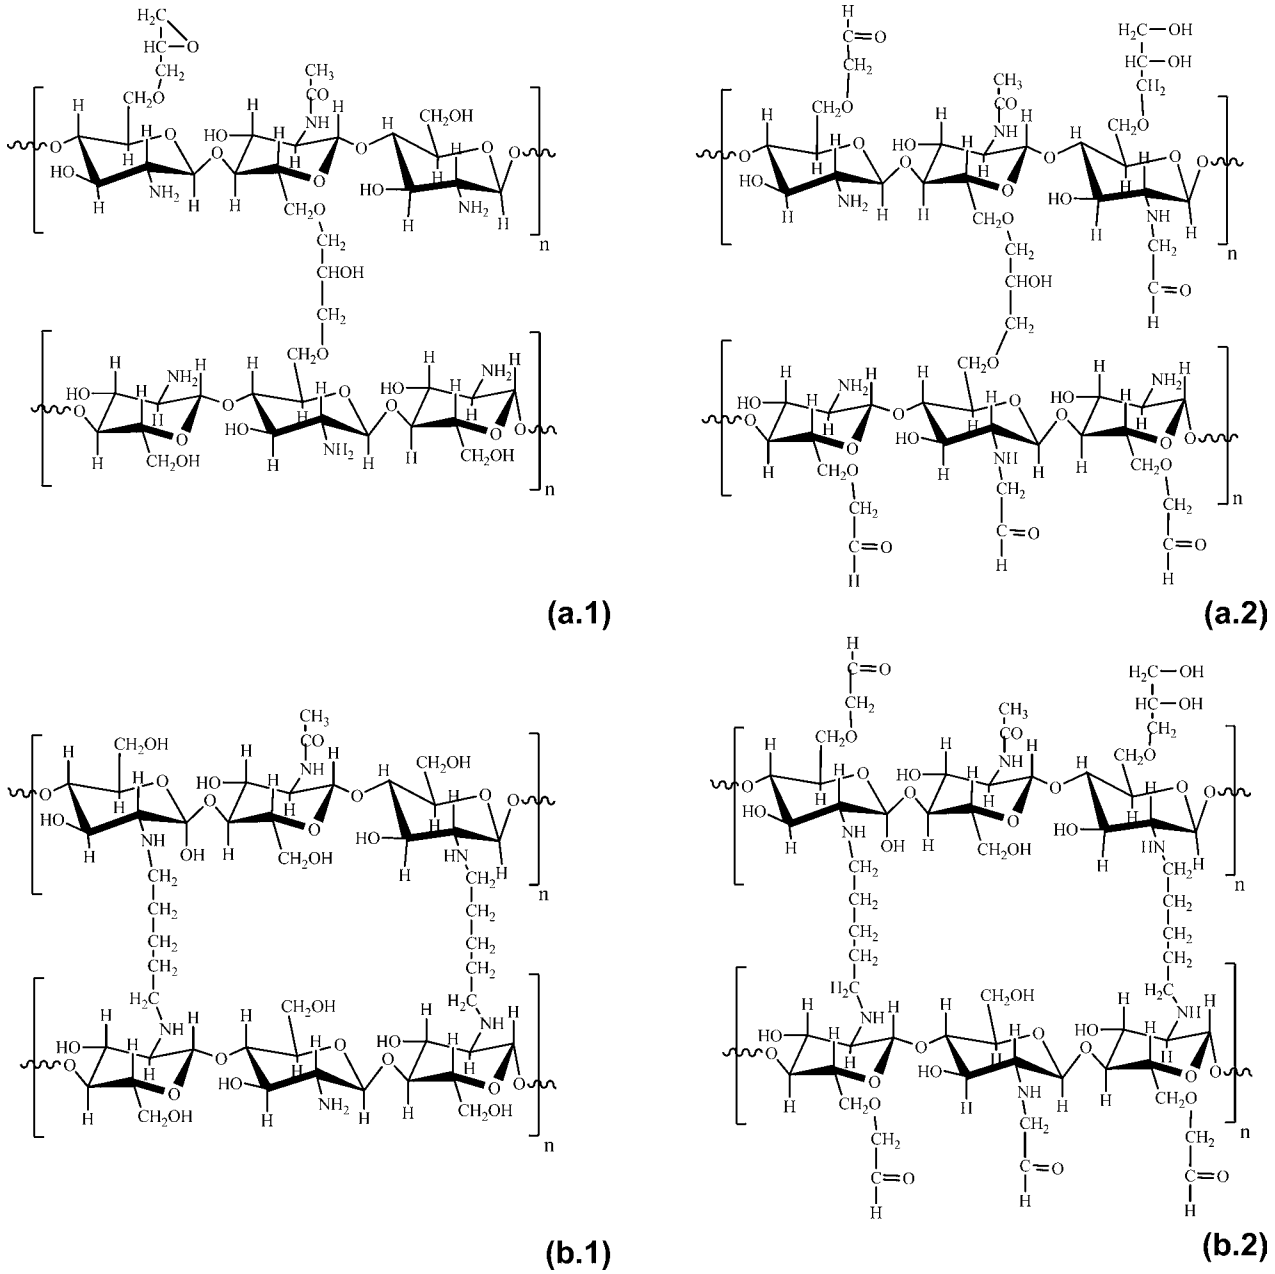

**Figure 1.** Possible structures after cross-linking (1) and activation (2) of C-EPI-EPI (a) and C-GA-EPI (b).

usually offers the highest degree of rigidification[25] and, consequently, enzyme stabilization, being normally selected when the objective is to improve the enzyme stability and/or when the immobilized biocatalyst will be used in an aqueous media where immobilization by adsorption is in most cases precluded.[26] However, the strength of the enzyme−support linkage makes it difficult or impossible to recover the support after enzyme inactivation; therefore, support cost may have a high impact on the economics of the process employing the immobilized biocatalyst.

Chitosan is a natural biopolymer outstanding for its relatively low cost, innocuousness, biocompatibility, antimicrobial activity, and the presence of functional groups that may be chemically modified.[27,28] It is a linear polysaccharide composed of $\beta$-(1−4)-linked D-glucosamine and *N*-acetyl-D-glucosamine units, which is produced by partial deacetylation of chitin that is obtained from the exoskeletons of crustaceans, particularly from wastes of the seafood-processing industry.[29] The use of chitosan as a carrier for the covalent immobilization of enzymes requires the introduction of functional groups that can react with the amino acid residues of the protein surface. Additionally, polymer chains must be cross-linked to improve the support mechanical resistance and avoid its solubilization in aqueous acidic media due to its cationic nature ($pK_a$ of the amino groups $\sim$ 6.5).[27] One typical derivatization method is the cross-linking and activation of chitosan with the bifunctional reagent glutaraldehyde (GA). The chemistry of the reaction between GA and amino groups is not fully understood, and according to the pH, the reaction mechanism may involve Schiff bases, nucleophilic substitution of amino groups, and Michael addition.[30,31] The reaction of GA with chitosan allows the cross-linking of different polymer chains and the activation of the support with aldehyde groups that may react with the enzyme through its amino groups (lysine residues and terminal

dx.doi.org/10.1021/jf500351j | J. Agric. Food Chem. 2014, 62, 10126−10135

amino group)[32,33] and eventually with other surface functional groups (thiols, phenols, and imidazoles).[30] Epichlorohydrin (EPI) has been also utilized in the derivatization of chitosan because it may react with amino and hydroxyl groups of the polymer, cross-linking different chitosan chains and activating the support with epoxide groups. The reaction occurs mainly through the chitosan hydroxyl groups when high temperature and alkaline media are utilized.[34,35] Because part of the residual epoxy groups may be spontaneously hydrolyzed, a heterofunctional support is obtained, presenting epoxide, diols, and amino groups. The residual epoxy groups may be also hydrolyzed, and diols could be then oxidized with periodate to aldehyde groups that form Schiff bases with the $\varepsilon$-amino group of protein lysine residues. To avoid the opening of the chitosan pyranosidic rings due to the oxidation of vicinal diols with periodate,[36] a limited quantity of periodate should be added and chitosan chains should be previously cross-linked. This final step of support modification presents the advantage of obtaining a more homogeneous support, and aldehydes may favor a more intense multipoint covalent attachment than when epoxy groups are utilized because the instability of Schiff bases should favor immobilization through the enzyme surface area with the highest density of lysine residues.[37]

It has been reported that according to the methodology utilized for chitosan derivatization, the immobilization yield and thermal stability of the biocatalyst may be modified.[33,38,39] These results may be related to the modification of chitosan functional groups, the activation degree, and/or the modification of the structure of the support by varying the cross-linking process. The objective of this investigation was to design a methodology for chitosan derivatization that offers the best compromise of expressed activity and thermal stability of an immobilized biocatalyst of *B. circulans* $\beta$-galactosidase for its further application in GOS synthesis in repeated batch operation.

## MATERIALS AND METHODS

**Materials.** A commercial preparation of $\beta$-galactosidase from *B. circulans* (Biolactasa-NTL CONC X2) in the form of a liquid solution was purchased from BIOCON (Barcelona, Spain), presenting 31.3 ± 0.5 mg of protein per mL and 1353 ± 11 IU per mL (determination of enzyme activity is in section Analysis). *o*-Nitrophenyl-$\beta$-D-galactopyranoside (*o*-NPG) was from Carbosynth Limited (Bershire, UK). Lactose monohydrate was from Quimatic S.A. (Santiago, Chile). Sodium metaperiodate and glycerol were purchased from Merck (Darmstadt, Germany). EPI, GA, sodium borohydride, *o*-nitrophenol (*o*-NP), and chitosan (≥75% deacetylated; MW 190,000−375,000; batch 061M0046 V) were from Sigma-Aldrich (St. Louis, MO, USA). All other reagents were of the highest available purity and used as purchased.

**Analysis.** Enzymatic activity of $\beta$-galactosidase was assessed spectrophotometrically by measuring the production of *o*-NP at 420 nm. The reaction was initiated by adding 50 $\mu$L of $\beta$-galactosidase solution or suspension to 2 mL of 45 mM *o*-NPG solution, using a temperature-controlled cell with constant magnetic stirring. One international unit of $\beta$-galactosidase activity (IU) was defined as the amount of enzyme producing 1 $\mu$mol of *o*-NP per minute from a 45 mM *o*-NPG solution in 0.1 M citrate−phosphate buffer, pH 6, at 25 °C. The extinction molar coefficient of *o*-NP under the assay conditions was 560 $M^{-1}$ $cm^{-1}$.

Protein concentration was determined according to the Bradford methodology, using bovine serum albumin as standard.[40]

Lactose and products of GOS synthesis (galactose, glucose, and GOS) were measured as previously reported, using a Jasco RI 2031 HPLC delivery system, provided with a refractive index detector, an isocratic pump (Jasco PU2080), an autosampler (Jasco AS 2055), and BP-100 Ag columns (300 mm × 7.8 mm) for carbohydrate analysis (Benson Polymerics, Reno, NV, USA).[41]

**Support Preparation.** Chitosan particles were produced as previously reported.[39] Chitosan was solubilized in acetic acid solution (3% v/v) to achieve a concentration of 1.5% (w/v) and stirred for 12 h. This solution was fed by gravity and sprayed into 1 M NaOH in 40% (v/v) ethanol solution under stirring. The particles were recovered and washed with distilled water and phosphate buffer (0.05 M, pH 7.0). The particles were derivatized by two different methodologies, and the possible chemistry involved after cross-linking and activation of chitosan is presented in Figure 1.

*Cross-Linking with Glutaraldehyde and Activation with Epichlorohydrin (C-GA-EPI).* Chitosan particles were cross-linked with GA as previously reported,[39,42] modifying the quantity of GA utilized. To favor the polymer cross-linking, 1 mol of GA was added per 4 equiv mol of chitosan amino groups, assuming 75% deacetylation. The imines formed by the reaction of GA with the amino groups of chitosan were reduced to secondary amines with $NaBH_4$ to form stable bonds. Finally, the cross-linked chitosan was activated with excess EPI to favor chitosan activation. A typical cross-linking and activation process was performed as follows: 1 g of chitosan particles was suspended in 10 mL of a solution of 0.78 g/L of GA prepared in 5 mM phosphate buffer, pH 7, and maintained under stirring for 30 min at 4 °C. The cross-linked particles were washed with distilled water. For the reduction of imines, 1 g of cross-linked particles was suspended in 10 mL of a solution of 3.8 g/L of $NaBH_4$ in 0.1 M bicarbonate buffer, pH 10, and maintained under stirring for 2 h at 25 °C. Afterward, the particles were washed with distilled water. The support was activated by suspending 1 g of support in 6 mL of an aqueous solution containing 40 g/L of NaOH, 37% (v/v) acetone, and 3.8 g/L of $NaBH_4$ at 4 °C. Then, EPI was added to reach a final concentration of 185 g/L. The mixture was stirred at 25 °C for 18 h, and the support was carefully washed with 20% (v/v) aqueous acetone solution, with distilled water, and finally with 50 mM phosphate buffer, pH 7.0. The support was finally contacted with a 0.5 M $H_2SO_4$ solution during 1 h to hydrolyze all unreacted epoxy groups, and then the diol groups were oxidized during 2 h with an aqueous solution containing $NaIO_4$ (a ratio of 1 g of support per 10 mL of solution was used in both steps). Because 1 mol of $NaIO_4$ oxidizes 1 equiv mol of diol, the activation degree (moles of aldehyde groups per gram of support) was modified by varying the concentration of $NaIO_4$ utilized during the oxidation step (10−25 mM).

*Cross-Linking and Activation with Epichlorohydrin (C-EPI-EPI).* Chitosan particles were derivatized in a two-step process with EPI as previously reported.[24] For support cross-linking, 1 mol of EPI was contacted per 4 equiv mol of primary hydroxyl groups of chitosan, assuming a 75% deacetylation. For this process, the chitosan particles (1 g) were resuspended in 2 mL of mixture with 4.8 g/L of EPI and 2.7 g/L of NaOH at 45 °C during 2 h. The cross-linked support was then activated with EPI following the same procedure as the activation of C-GA-EPI. For both supports the quantification of aldehyde groups was done spectrophotometrically by back-titration with $NaHCO_3$/KI.[38]

**Enzyme Immobilization.** The enzyme was immobilized in C-GA-EPI and C-EPI-EPI contacting 10 mL of the enzyme solution per 1 g of support at 25 °C. The $\beta$-galactosidase solution was prepared in 0.1 M bicarbonate buffer, pH 10, with 20% (v/v) of glycerol, which was used to avoid enzyme inactivation during immobilization. Finally, to obtain stable bonds between the enzyme and the support, the Schiff bases formed were reduced by adding $NaBH_4$ to reach a final concentration of 1 mg/mL. The suspension was maintained under stirring during 30 min at 25 °C, and the biocatalyst was thoroughly washed with distilled water.

Immobilization was followed by measuring the enzyme activity in the suspension and in the supernatant. The activity of the suspension was determined according to the same methodology utilized for the soluble enzyme. Immobilization yield in terms of the bound protein ($IY_P$) was defined as the mass ratio of immobilized protein (difference between contacted protein and unbound protein in the supernatant) to contacted protein. Immobilization yield in terms of expressed

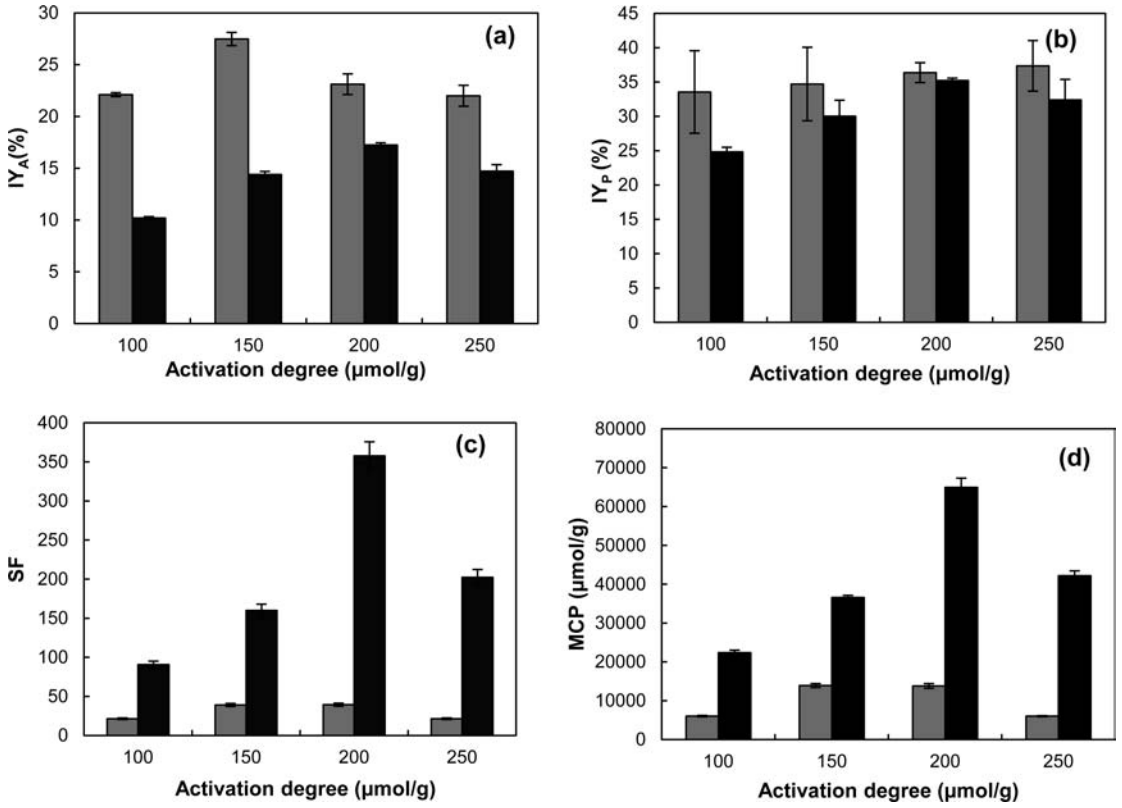

**Figure 2.** Effect of the activation degree of C-GA-EPI (gray bars) and C-EPI-EPI (black bars) on the performance of immobilized *B. circulans* β-galactosidase: (a) immobilization yield in terms of expressed activity ($IY_A$); (b) immobilization yield in terms of protein ($IY_P$); (c) stability factor (SF); (d) maximum catalytic potential (MCP). Immobilization conditions: 0.1 M citrate−phosphate buffer, pH 10, 20% glycerol, and 25 °C. Inactivation conditions: 60 °C and 0.1 M citrate−phosphate buffer, pH 6.

activity ($IY_A$) was defined as the ratio of the activity expressed by the immobilized biocatalyst to the contacted activity.

**Selection of the Methodology of Chitosan Derivatization and Optimization of Immobilization Conditions.** To select a methodology of chitosan derivatization, an enzymatic solution of 1.3 mg protein/mL was immobilized in C-GA-EPI and C-EPI-EPI with different activation degrees for 10 h, under the conditions previously mentioned. The performance of the biocatalysts was evaluated in terms of their immobilization yield and thermal stability. The thermal stability was evaluated through the stability factor (SF), defined as the ratio of the half-lives of immobilized and soluble biocatalyst at 60 °C and pH 6 (0.1 M citrate−phosphate buffer). Half-life was calculated after modeling biocatalyst inactivation kinetics by a biphasic mechanism:

$$\frac{A_I}{A_{I0}} = \left[1 + \alpha \times \frac{k_1}{k_2 - k_1}\right] \times \exp(-k_1 \times t) - \left[\alpha \times \frac{k_1}{k_2 - k_1}\right] \times \exp(-k_2 \times t) \quad (1)$$

$A_I/A_{I0}$ represents the residual activity at time $t$, $\alpha$ is the specific activity ratio of the intermediate species with respect to the native enzyme species, and $k_1$ and $k_2$ are the transition rate constants from the native to the intermediate and from the intermediate to the final enzyme species, respectively.

To consider both the activity of the immobilized biocatalyst and its thermal stability, the lumped parameter maximum catalytic potential (MCP) was also utilized for selecting a chitosan derivatization methodology.[39,41] MCP integrates the variation of expressed activity ($A_I$) along biocatalyst inactivation (eq 2), considering the time of biocatalyst utilization ($t_f$) as the one at which residual activity is 35%.

$$\mathrm{MCP} = \int_0^{t_f} A_I \, dt \quad (2)$$

After selecting the chitosan derivatization methodology, the contacted protein and immobilization time were optimized using a central composite rotatable design of two variables at two levels with five replicas at the central point.

**Galacto-oligosaccharide Synthesis.** GOS synthesis with the soluble and immobilized β-galactosidase was carried out using 50% (w/w) lactose solution at pH 6 (0.1 M citrate−phosphate buffer) and 60 °C. β-Galactosidase activity in the reaction mixture was adjusted to 40 IU/g lactose, as previously reported.[41] To evaluate the impact of reusing the immobilized enzyme on GOS synthesis and measure the biocatalyst thermal stability under reactive conditions, sequential batches of GOS synthesis were carried out. In this case, the ratio of biocatalyst mass to lactose mass was maintained constant and equal to the one used in the first batch.

The following parameters were used for evaluating GOS synthesis:

Yield ($Y_{GOS}$): maximum GOS mass ($M_{GOS}$) per unit mass of initial lactose mass ($M_{L0}$)

$$Y_{GOS} = \frac{M_{GOS}}{M_{L0}} \times 100 \quad (3)$$

Volumetric productivity ($\pi$): total GOS mass per unit of reaction volume ($V$) and unit of reaction time ($t$). For the purposes of this work, $\pi$ was evaluated at the time when maximum GOS concentration was achieved.

$$\pi = \frac{M_{GOS}}{V \times t} \quad (4)$$

Cumulative specific productivity ($\pi_C$): total GOS mass obtained over the whole operation of sequential batches ($n$ batches) per unit mass of biocatalyst protein ($M_{BP}$) and unit of reaction time. For the purposes of this work, total GOS mass of each batch was evaluated at the moment when maximum GOS concentration was achieved.

dx.doi.org/10.1021/jf500351j | J. Agric. Food Chem. 2014, 62, 10126−10135

$$\pi_C = \frac{\sum_{batch1}^{batchn} M_{GOS}}{M_{BP} \times \sum_{batch1}^{batchn} t} \quad (5)$$

In the case of the immobilized enzyme, $\pi_C$ is expressed in terms of the mass of protein that was contacted with the support for biocatalyst immobilization. $M_B$ represents the mass of biocatalyst utilized in the first batch of GOS synthesis.

$$\pi_C = \frac{\sum_{batch1}^{batchn} M_{GOS}}{M_B \times P_c \times \sum_{batch1}^{batchn} t} \quad (6)$$

## RESULTS AND DISCUSSION

**Selection of Chitosan Derivatization Method.** Chitosan particles were derivatized either using glutaraldehyde for cross-linking and epichlorohydrin for support activation (C-GA-EPI) or else using epichlorohydrin for both cross-linking and activation (C-EPI-EPI). The derivatization of chitosan with epichlorohydrin was done in a two-step process because it was previously reported[39] that this methodology allows a higher degree of activation than when chitosan is derivatized in just one step.[38] This difference may be related to the fact that the first step of cross-linking should produce some steric hindrances that limit the additional cross-linking of chitosan chains when a high concentration of epichlorohydrin is contacted during the second step of derivatization, favoring the support activation. The characterization of C-GA-EPI is presented as Supporting Information. In the case of C-EPI-EPI, its physical and chemical characterization was reported previously,[39] showing that the used methodology allows the modification of the amino and hydroxyl groups of chitosan. In the case of C-GA-EPI, the modification was tested with FTIR, showing that the GA and EPI groups have reacted with the chitosan matrix and new aldehyde groups were introduced as reflected by the best resolution bands related with the vibration of C—N of amine and C═O of aldehydes (1570 and 1650 $cm^{-1}$, respectively) (Figure SM3, Supporting Information).

The concentration of aldehyde groups of C-GA-EPI and C-EPI-EPI was modified by varying the concentration of $NaIO_4$ utilized for the oxidation of the support. After oxidation, all $NaIO_4$ was reacted, obtaining supports with activation degrees in the range from 100 to 250 $\mu$mol of aldehyde per gram. The effect of chitosan derivatization method over $IY_A$, $IY_P$, SF, and MCP of the immobilized enzyme is presented in Figure 2. The inactivation kinetics of each biocatalyst was modeled by a biphasic mechanism (eq 1), and the values of the corresponding inactivation parameters are summarized in Table 1.

The activation degree of both supports affected the biocatalysts' expressed activity; however, immobilized protein varied significantly only in the case of C-EPI-EPI. In general, C-GA-EPI produced the higher values of $IY_A$ and $IY_P$ independent of the aldehyde concentration in the support. With both supports $IY_P$ was higher than $IY_A$, which is explained by the immobilization of proteins different from the $\beta$-galactosidase (the commercial enzyme preparation is not pure) and also by the presence of diffusional restrictions and/or inactivation of the catalyst due to the immobilization process. The stability (SF) of the biocatalysts immobilized in both supports also varied according to the activation degree. The maximum values of $IY_A$ and SF were obtained when the C-GA-EPI and C-EPI-EPI were activated with 150 and 200 $\mu$mol of aldehyde per gram of support, respectively. The increase in the concentration of aldehyde groups in the support should allow the immobilization of a higher proportion of the contacted enzyme and favor multipoint interaction between the protein and the support, which may explain the increase of expressed activity and stability until 150 and 200 $\mu$mol of aldehyde per gram of C-GA-EPI and C-EPI-EPI, respectively. On the other hand, the decrease of $IY_A$ in the supports with a higher activation degree may be explained by the formation of covalent bonds close to the active site or by an excessive stiffening of the protein, reducing mobility below the minimum level required for catalysis. In the case of SF, an excessive stiffening of the protein may expose areas more prone to denaturation, explaining the lower thermal stability of the biocatalysts. In general, independent of the activation degree, best results were obtained with C-GA-EPI in terms of $IY_A$: in the case of C-GA-$EPI_{150}$ $IY_A$ was almost twice that obtained with C-EPI-$EPI_{150}$. The opposite effect was observed for SF, a better performance being obtained with the $\beta$-galactosidase immobilized in C-EPI-EPI, irrespective of the activation degree. The highest stability was obtained with C-EPI-$EPI_{200}$, for which the SF was 4 times the value reported for the biocatalyst of *B. circulans* $\beta$-galactosidase immobilized in glyoxyl-agarose under optimized conditions and 7 times the value reported for the enzyme immobilized in silica support.[41,43] Because C-GA-EPI and C-EPI-EPI were activated using the same methodology, the different performance obtained with both supports may be explained by a difference in support structure as a consequence of their cross-linking process. When the combined effect of activity and stability was assessed using MCP as lumped parameter, the support C-EPI-$EPI_{200}$ offered the best performance due to the prevalence of the effect of thermal stabilization. This support was selected for the further optimization of protein loading and immobilization time.

**Table 1. Inactivation Parameters of *B. circulans* $\beta$-Galactosidase Immobilized in Different Chitosan Supports, Determined According to a Series Biphasic Model (Equation 1)[a]**

| support | $k_1$ ($h^{-1}$) | $k_2$ ($h^{-1}$) | $\alpha$ | $R^2$ |
|---|---|---|---|---|
| C-GA-$EPI_{100}$ | 1.35 | 0.03 | 0.28 | 0.998 |
| C-GA-$EPI_{150}$ | 0.77 | 0.02 | 0.29 | 0.988 |
| C-GA-$EPI_{200}$ | 0.94 | 0.03 | 0.37 | 0.999 |
| C-GA-$EPI_{250}$ | 1.37 | 0.05 | 0.28 | 0.996 |
| C-EPI-$EPI_{100}$ | 1.14 | 0.03 | 0.53 | 0.996 |
| C-EPI-$EPI_{150}$ | 1.83 | 0.03 | 0.60 | 0.999 |
| C-EPI-$EPI_{200}$ | 0.63 | 0.02 | 0.58 | 0.996 |
| C-EPI-$EPI_{250}$ | 2.54 | 0.03 | 0.63 | 0.993 |

[a] $R^2$, coefficient of determination.

The leaching of $\beta$-galactosidase from the derivatized supports was not evaluated in this work because Bernal et al.[44] showed that the covalent immobilization of this enzyme in a support activated with aldehyde groups avoids the leaching of the enzyme.

**Optimization of Immobilization Conditions.** Biocatalyst specific activity and thermal stability are important parameters for the industrial application of immobilized enzymes because the first one will define the quantity of catalyst required for a specific reaction and the latter will determine its lifespan. Biocatalyst specific activity varies according to the quantity of enzyme contacted during the immobilization process, whereas it has been reported that the thermal stability of an immobilized enzyme may be improved through the increase of immobiliza-

tion time.[45] To set the range of contacted protein to be considered in the optimization of immobilization conditions, the maximum protein loading capacity of C-EPI-EPI was assessed (Figure 3), obtaining a maximum of 23.8 mg of

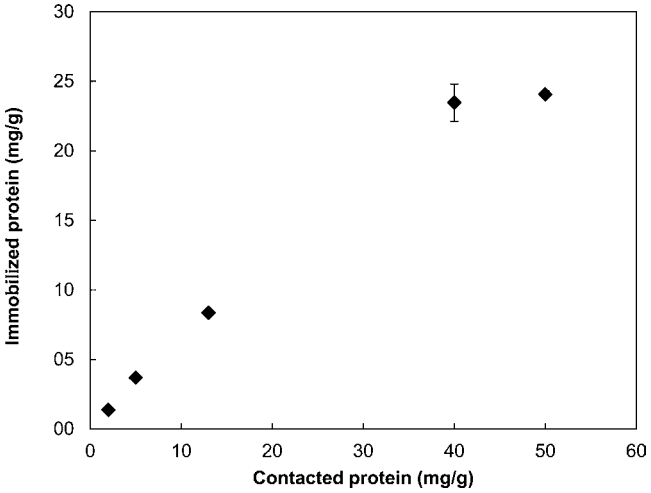

**Figure 3.** Loading capacity of C-EPI-EPI$_{200}$ expressed in terms of *B. circulans* $\beta$-galactosidase protein content.

immobilized protein per gram of support. This maximum loading capacity was 45 and 20% lower than the values reported for the immobilization of *B. circulans* $\beta$-galactosidase in glyoxyl-agarose[41] and acrylic resins,[46] respectively. Such a difference may be due to the lower total surface area. The range of immobilization time considered for the optimization of the immobilization process was established after evaluating the stability of the biocatalysts at maximum protein loading and at 10% of that maximum. Two different immobilization times were considered: the minimum time required for obtaining a constant activity in the supernatant ($t_{min}$) and $t_{min}$ plus 24 h. As shown in Figure 4, thermal stability of the biocatalyst loaded with the maximum quantity of protein was independent of immobilization time, in contrast to the biocatalyst loaded with a lower quantity of protein. This effect may be explained by a difference in the multipoint interaction between the enzyme and support due to the nonhomogeneous surface of the support, obtaining higher interaction intensity when the enzyme is first linked to the most reactive areas and a lower interaction intensity when the enzyme is immobilized in the less reactive areas. This effect was also reported for glyoxyl-agarose.[41]

Considering the interaction observed between the quantity of protein contacted and the immobilization time, both variables were optimized by a central composite design, using MCP as response parameter (Figure 5). The response surface was modeled by a second-order polynomial equation (eq 7), obtaining the maximum value of MPC when 25.8 mg/g was contacted for $t_{min}$ plus 14.1 h (total immobilization time = 38.1 h).

$$\mathrm{MCP} = P_c \times 35010.8 + t_{add} \times 17136.5 - t_{add} \times P_c \times 127.9 - P_c^2 \times 640.5 - t_{add}^2 \times 491.4 - 190011 \quad (7)$$

The ANOVA test was performed, obtaining a $p$ value of 0.0005, an $R^2$ value of 0.9366, and an adjusted $R$ value of 0.8913. The optimized conditions were validated experimentally, obtaining a MCP of 367,032 $\mu$mol/g (4.5% lower than the predicted value). The optimized biocatalyst expressed 280 ± 7 IU/g, with an IY$_A$ of 17.3 ± 0.4% and an IY$_P$ of 61.5 ± 3.9%. The expressed activity was 53% lower than the value reported for the enzyme immobilized under optimized conditions in glyoxyl-agarose.[41] However, the SF obtained with the enzyme immobilized in chitosan was 450% higher than the corresponding value obtained with the agarose biocatalyst.[41] Additionally, the use of chitosan presents an economic advantage, because one of the limiting factors in the use of agarose is its high cost.[47]

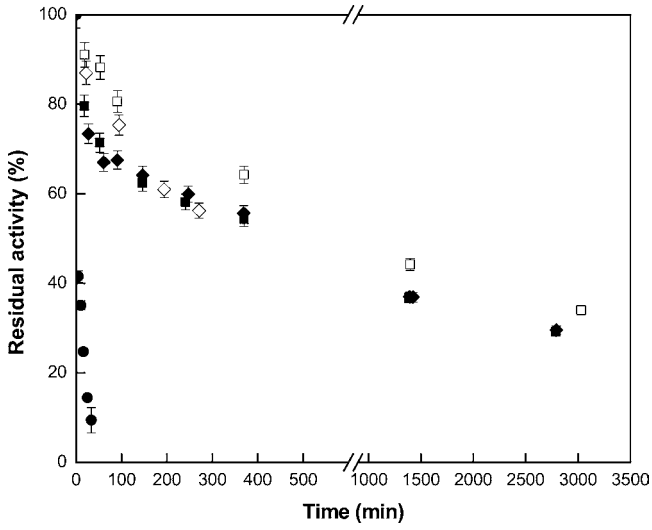

**Figure 4.** Thermal inactivation at 60 °C and pH 6 (0.1 M citrate–phosphate buffer) of the soluble enzyme (closed circles) and derivatives of $\beta$-galactosidase immobilized in C-EPI-EPI$_{200}$ at maximum protein loading capacity (solid symbols) and at 10% of that maximum (open symbols) at different immobilization times: (rhombuses) $t_{min}$; (squares) $t_{min}$ + 48 h. $t_{min}$ is the minimum time required to obtain a constant activity in the supernatant.

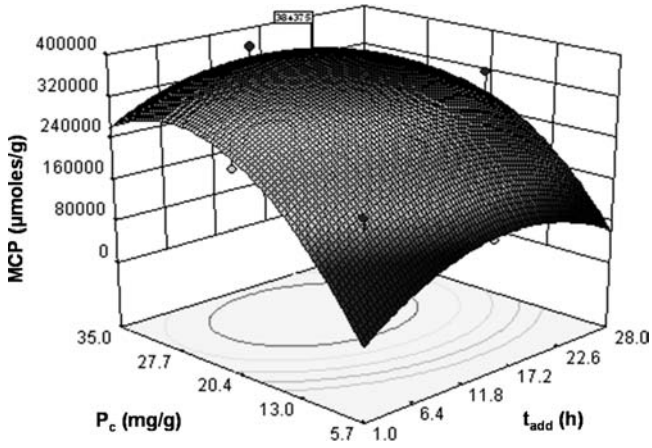

**Figure 5.** Optimization of *B. circulans* $\beta$-galactosidase immobilization in C-EPI-EPI$_{200}$, considering additional immobilization time ($t_{add}$) and contacted protein as variables and maximum catalytic potential (MCP) as objective function. Immobilization conditions: 0.1 M citrate–phosphate buffer, pH 10, 20% glycerol, and 25 °C.

**Galacto-oligosaccharide Synthesis.** The optimized biocatalyst was utilized in the synthesis of GOS in repeated batch operation. A comparison of Y$_{GOS}$ and $\pi$ values obtained in one batch of GOS synthesis catalyzed by the soluble and immobilized $\beta$-galactosidase is presented in Table 2. The

**Table 2. Comparison of Synthesis of GOS with Soluble β-Galactosidase and β-Galactosidase Immobilized in C-EPI-EPI$_{200}$[a]**

| parameter | soluble β-gal | β-gal/C-EPI-EPI$_{200}$ |
|---|---|---|
| $Y_{GOS}$ (%) | 38.3 | 39.1 |
| $\pi$ ($g_{GOS}$/h·L) | 462.2 | 473.7 |

[a] $Y_{GOS}$, GOS yield; $\pi$, volumetric productivity.

production of GOS was not affected by the immobilization of the enzyme, as reflected by the lack of a significant variation in $Y_{GOS}$ and $\pi$. These results indicate that diffusional restrictions in the immobilized enzyme are not significant and the immobilization process did not produce conformational changes or steric hindrances that affect the activity of the biocatalyst. In contrast, Huerta et al.[42] and Sheu et al.[48] reported that the synthesis of GOS with *Aspergillus oryzae* β-galactosidase immobilized in chitosan derivatized with glutaraldehyde resulted in a lower $Y_{GOS}$ than the one obtained with the soluble enzyme, a result explained by the presence of diffusional restrictions. The insignificant effect of diffusional restrictions in the biocatalyst of *B. circulans* β-galactosidase immobilized in C-EPI-EPI$_{200}$ may be explained by the use of a lower enzyme loading and/or by differences in the support size and structure. Considering that several isoenzymes of *B. circulans* β-galactosidase have been identified in the commercial soluble enzyme preparation,[18−20] the absence of variation in $Y_{GOS}$ and $\pi$ also indicates that the relative activity of each isoform was not significantly altered upon immobilization. The profile of GOS obtained with β-galactosidase immobilized in C-EPI-EPI$_{200}$ was similar to the one obtained with the soluble enzyme (Figure 6). This pattern remained unchanged along 10 repeated batches, as may be observed in Figure 7.

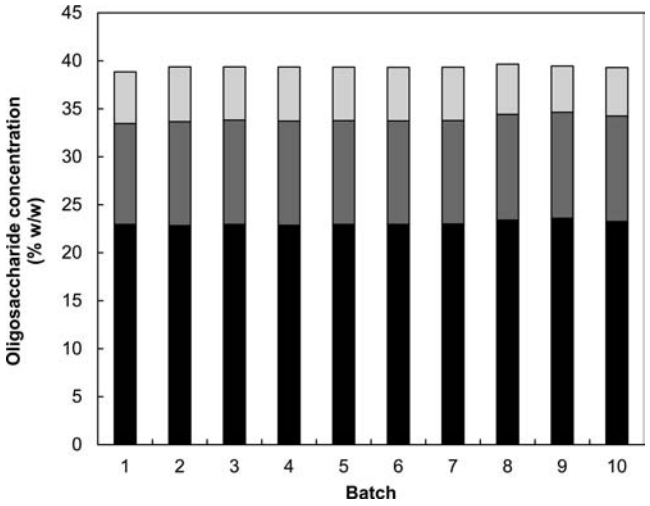

**Figure 7.** Product distribution of GOS synthesized by the β-galactosidase from *B. circulans* immobilized in C-EPI-EPI$_{200}$ along batches in repeated batch operation: (black bars) trisaccharides; (gray bars) tetrasaccharides; (white bars) penta- and hexasaccharides. Reaction conditions: 50% (w/w) initial lactose concentration, 0.1 M citrate−phosphate buffer, pH 6, and 60 °C. Biocatalyst added in the first batch was adjusted to 40 IU/g initial lactose, and for the subsequent batches the ratio of biocatalyst mass to lactose mass was maintained constant and equal to the one used in the first batch.

To make a fair comparison between the soluble and immobilized β-galactosidase, the parameters cumulative specific productivity ($\pi_c$) and total mass of GOS per mass of contacted protein ($R_{GOS}$) were evaluated. The expression of each parameter in terms of the contacted protein takes into consideration the immobilization yield; therefore, both the soluble and immobilized enzymes are compared considering

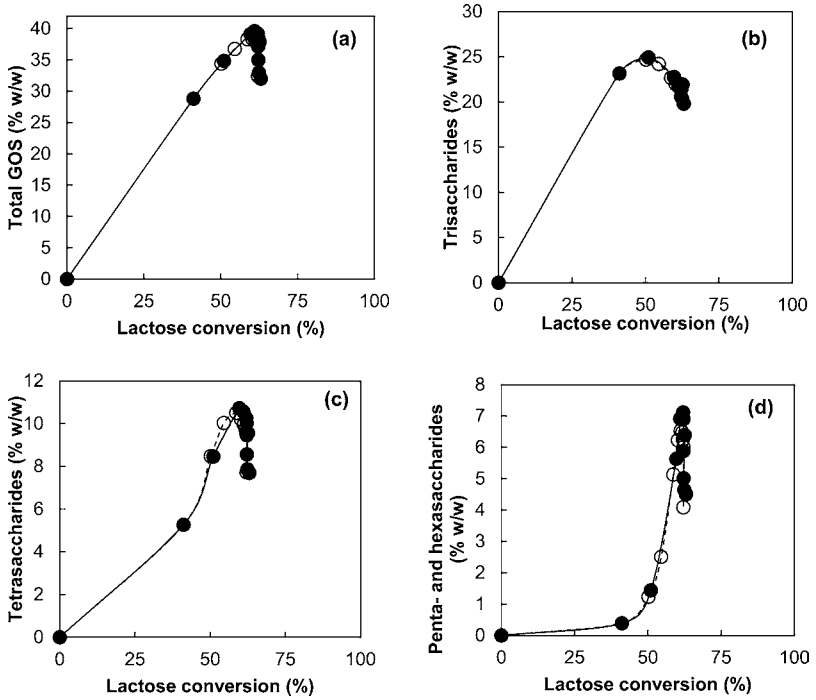

**Figure 6.** Profiles of GOS synthesized by *B. circulans* β-galactosidase: (a) total GOS; (b) trisaccharides; (c) tetrasaccharides; (d) penta- and hexasaccharides; (solid symbols) soluble enzyme; (open symbols) enzyme immobilized under optimized conditions in C-EPI-EPI$_{200}$. Reaction conditions: 50% (w/w) initial lactose concentration, 0.1 M citrate−phosphate buffer, pH 6, 60 °C, and 40 IU/g initial lactose.

the total mass of protein expended for the production of GOS. The values of $\pi_c$ along 10 successive batches are presented in Figure 8a. The $\pi_C$ of the first batch of synthesis was lower for the immobilized enzyme due to the loss of activity during immobilization; however, the reutilization of the biocatalyst compensates for the loss of activity, requiring only four sequential batches to surpass the $\pi_C$ of the soluble enzyme. After 10 successive batches, the $\pi_C$ of the immobilized enzyme was 2.9 times the value obtained with the soluble enzyme. This value is lower than the $\pi_C$ reported for the enzyme immobilized in glyoxyl-agarose[41] due to the lower expressed activity of the biocatalyst. The advantage associated with the high thermal stability of the enzyme immobilized in C-EPI-EPI$_{200}$ should be observed with a higher number of batches or extending the time of each batch. Values of $R_{GOS}$ are presented in Figure 8b, observing that after 10 batches almost 1 kg of GOS per gram of contacted protein is produced when the immobilized biocatalyst is utilized. The thermal stability of the immobilized enzyme was compared under reactive and nonreactive conditions (Figure 9), observing a positive modulation by the reaction media. Under reactive conditions, <10% of the initial biocatalyst hydrolytic activity was lost after 10 successive batches.

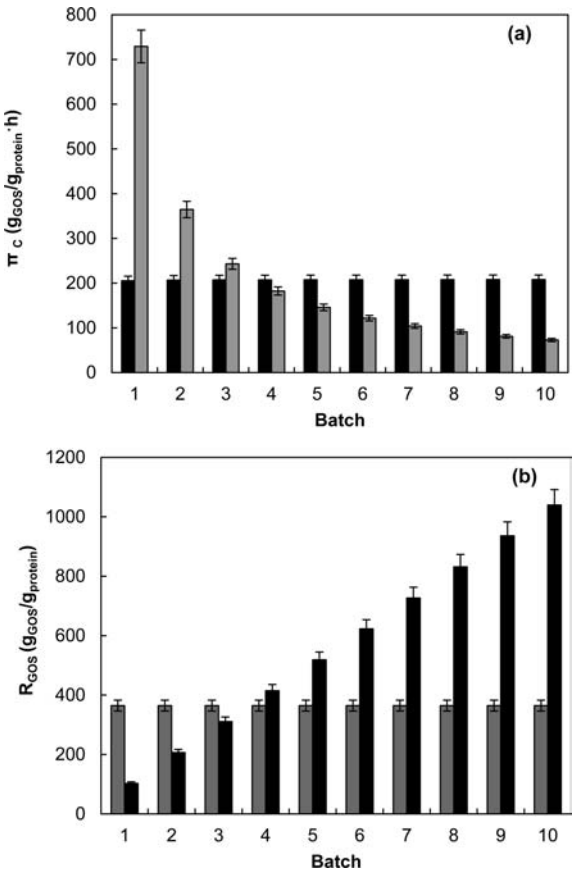

**Figure 8.** Comparison of soluble $\beta$-galactosidase (gray bars) and $\beta$-galactosidase immobilized under optimized conditions in C-EPI-EPI$_{200}$ (black bars): (a) cumulative GOS productivity in terms of contacted protein ($\pi_c$); (b) accumulated mass of GOS per unit mass of contacted protein ($R_{GOS}$). Reaction conditions: 50% (w/w) initial lactose concentration, 0.1 M citrate−phosphate buffer, pH 6, and 60 °C. Biocatalyst added in the first batch was adjusted to 40 IU/g initial lactose, and for the subsequent batches the ratio of biocatalyst mass to lactose mass was maintained constant and equal to the one used in the first batch.

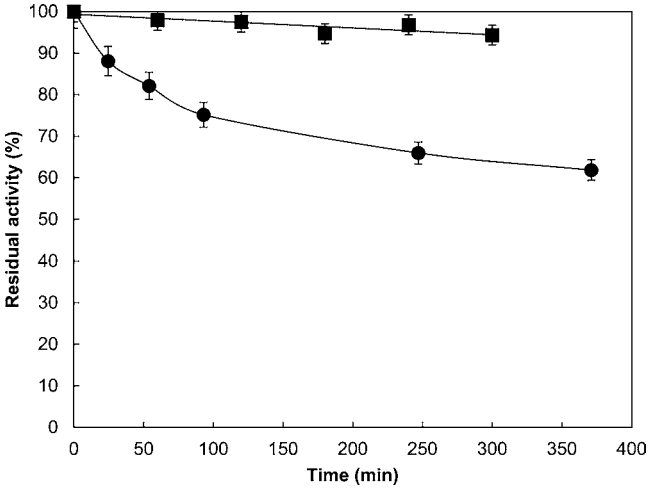

**Figure 9.** Comparison of thermal stability of $\beta$-galactosidase immobilized under optimized conditions in C-EPI-EPI$_{200}$ under nonreactive (circles) and reactive (squares) conditions. Nonreactive conditions: 0.1 M citrate−phosphate buffer, pH 6, 60 °C. Reactive conditions: 50% (w/w) initial lactose concentration, 0.1 M citrate−phosphate buffer, pH 6, 60 °C.

In conclusion, the cross-linking agent utilized for chitosan derivatization and the activation degree of the support had a high impact on the performance of the immobilized *B. circulans* $\beta$-galactosidase. The best compromise between expressed activity and thermal stability was obtained with the enzyme immobilized in cross-linked chitosan and activated with epichlorohydrin at a degree of activation of 200 $\mu$mol of aldehydes per gram of support. The optimization of immobilization conditions (protein load and immobilization time) increased biocatalyst expressed activity and thermal stability. The optimized biocatalyst was applied to the synthesis of GOS, without affecting the product profile obtained with the soluble enzyme. Four successive batches were required for obtaining a cumulative specific productivity higher than the one obtained with the soluble enzyme. The appropriate design of a low-cost support, such as chitosan, is a good strategy for the development of a highly stable biocatalyst adequate for GOS synthesis.

The geographical origin[26,27] and the manufacturing process, including fermentation,[28] need to be highlighted as key factors that might greatly influence polyphenolic distribution.

To develop an efficient calibration model using NIRS, a solid database representative of the chemical variability of the product[29,30] and a reliable reference analysis were prerequisites. To achieve this goal, we first built a large database of samples (with different geographical origins, phenotypes, and fermentation conditions). Second, different flavan-3-ol extraction procedures were studied to choose the one allowing a quick and reliable analysis to be applied on a large cocoa sample for NIRS calibration purposes. In addition to the already known extraction techniques involving sonication or Ultra-Turax homogenization,[10,17,18,31,32] a Fast-Prep (FP) device was used for the first time for cocoa flavan-3-ol extraction.

With the large and robust database we generated and with the optimized extraction protocols, we set out to build a quantitative and efficient model for predicting flavan-3-ol content. The changes occurring within the beans were correlated with the sum of temperatures (ST)[33] during fermentation for different cocoa origins, and the changes in flavan-3-ols monitored by NIRS were studied.

## MATERIALS AND METHODS

**Chemicals.** Hexane, acetone, methanol, and acetonitrile were of HPLC grade, purchased from Carlo Erba (Val de Reuil, France). Formic acid was also purchased from Carlo Erba. The reference compounds (−)-epicatechin and proanthocyanidin dimers $B_1$ and $B_2$ were obtained from Sigma Chemical Co. (St. Louis, MO, USA).

**Cocoa Bean Sampling.** Thirty microfermentation trials were carried out in three different countries (Ecuador, Madagascar, and Dominican Republic), in line with producers' usual practices. A microfermented sample was composed of about 700 g of fresh cocoa beans placed in nets and positioned in fermentation boxes at three different defined levels (close to the top, in the middle, close to the bottom).[34] The temperature of each microfermented sample was recorded every 15 min by sensors (Thermo-boutons IP65 40/+85 +/−0.5, Laboratoires Humeau, France) placed in the nets. The nets were surrounded by the mass of fresh cocoa beans to ensure a sufficient volume of cocoa for fermentation to proceed. Fermentation was carried out for 6 days with mixing every 2 days (48 and 96 h). One sample per position and per fermentation was taken each day and then sun-dried to a final moisture content close to 7%. In addition, the cocoa mass was sampled every 2 days during mixing for each fermentation trial and then sun-dried like the microfermented samples.

The experimental design led to 635 samples: 524 microfermented samples and 111 cocoa mass samples. This sampling was completed with 83 samples from Cameroon, Ghana, Indonesia, and Trinidad and Tobago. Those samples, used in other projects, were prepared and handled in the same way as the others, but no survey of the temperature was carried out. The total number of samples used for this study was 718. In addition to that, for the 524 microfermented samples, the ST was calculated by using the integral of the curve of temperatures from the beginning of fermentation to the time of sampling with a baseline fixed at 20 °C, as described previously.[33]

About 100 g of unshelled dried cocoa was ground in a "Valentin" blender (SEB, France) under liquid nitrogen, sifted to 0.5 mm, and stored at −20 °C prior to analysis.

**Flavan-3-ol Extraction and Quantification.** To investigate the phenolic content, and for NIR calibration, wet chemistry was carried out on 193 samples selected from the set of 718 samples. The 193 samples were randomly selected under the constraint of having the same sample percentage per class (fermentation time, origin, position in the box). The 193 samples were analyzed in the laboratory and were used for NIR model development.

*Fast-Prep Extraction (FPE).* A Fast-Prep-24 device (MP Biomedicals, Eschwege, Germany) at 6.5 m $s^{-1}$ was used with a garnet matrix and 1/4 ceramic sphere as the lysing matrix. Cocoa powder (100.0 ± 0.1 mg) was defatted two times for 1 min with 1 mL of hexane. Following centrifugation (5 min, 21400*g*, 4 °C), the upper organic phase was discarded to remove lipids. The solid phase (defatted cocoa powder) was then extracted for 1 min with 1 mL of acetone/water/formic acid (70:30:0.1, v/v/v). After centrifugation (21400*g*, 5 min, 4 °C), the upper phase was collected and the solid phase was re-extracted using the same conditions. The two fractions were then gathered, and the solvent was eliminated by a rotavapor (50 °C). Flavan-3-ols were thereafter extracted with methanol/water (50:50 v/v) and injected into HPLC. The analysis was carried out in duplicate. Replicates were consolidated using the Student *t* test at 95%, based on the standard deviation of samples.

*Ultra-Turax Extraction.* One gram of cocoa powder was added to 20 mL of hexane and finely ground for 2 min at 2000 rpm with an Ultra-Turax T25 digital (Staufen, Germany). After centrifugation (10 min, 21400*g*, 4 °C), the hexane phase was discarded. The defatted powder was then extracted with the blender for 2 min with 20 mL of acetone/water/formic acid (70:30:0.1, v/v/v). The organic phase was then recovered by evaporation (same conditions as above) and injected into HPLC.

*Pressurized Liquid Extraction (PLE).* PLEs were carried out on an ASE350 automated sample extractor (Dionex, Idstein, Germany) using 10 mL stainless steel extraction cells. One gram of cocoa powder was mixed with 5 g of diatomaceous earth. The mixture was loaded into the cartridge. The remaining free space of the cell was filled with diatomaceous earth. Cocoa powder was first defatted with four cycles of hexane for 5 min each (60 °C, 1500 psi). The hexane phase was eliminated by a rotavapor (50 °C). Flavan-3-ols were thereafter extracted with one cycle (5 min) of an acetone/water/formic acid (70:30:0.1, v/v/v) mixture at 70 °C and 1451 psi. The organic phase was then recovered by evaporation (same conditions as above) and injected into HPLC. The volume flush was 20 mL of acetone/water/formic acid (70:30:0.1 v/v/v).

*HPLC-DAD Analysis.* Prior to injection, all of the samples were filtered through a 0.45 μm syringe filter. The HPLC analysis was performed on an HPLC system from the Agilent Technologies 1200 series (Agilent Technologies, Santa Clara, CA, USA). Separation was achieved at 30 °C using a 250 mm × 4.6 mm i.d., 5 μm, end-capped reversed-phase Lichrospher ODS-2 (Interchim, Montluçon, France). The mobile phase was water/acetonitrile/formic acid (99:0.8:0.2, v/v/v) (solvent A) and acetonitrile (solvent B). Proanthocyanidins were eluted using the following gradient: 5% of B for 4 min, then from 5 to 35% B in 41 min and from 35 to 100% B in 15 min. At the end, the column was equilibrated to its initial state. The injection volume was 20 μL, and detection was carried out between 200 and 600 nm.

*Quantification.* Quantification of flavan-3-ols was achieved through external calibration curves established at 280 nm with epicatechin, proanthocyanidin $B_1$, and proanthocyanidin $B_2$ standards (0−120 mg/L), leading to $R^2$ = 0.93, 0.92, and 0.99, respectively.

*HPLC-MS Analysis.* After passing through the flow cell of the diode array detector, the column eluate was split and at 0.25 mL/min was directed to an LCQ ion trap mass spectrometer fitted with an electrospray interface (Thermo Finnigan, San Jose, CA, USA). Experiments were performed in both negative and positive ion modes. The scan range was 100−2000 and scan rate, 1 scan/s. The desolvation temperatures were 250 and 300 °C in the positive and negative ion modes, respectively. The high spray voltage was set at 5000 V. Nitrogen was used as the dry gas at a flow rate of 75 mL/min. Identification was achieved on the basis of the ion molecular mass, MS, and UV−visible spectra. The identifications of catechin, epicatechin, proanthocyanidin $B_1$, and proanthocyanidin $B_2$ were confirmed by direct injection of authentic standards. Total flavan-3-ols were quantified as the sum of individual compounds.

**NIRS Prediction.** NIRS acquisitions were obtained on a Foss 6500 monochromator (Foss, Silver Spring, MD, USA) using a spin cell sample module. About 3 g of cocoa powder was analyzed by diffuse reflectance from 400 to 2500 nm in 2 nm steps. Data were saved as the average of 32 scans and stored as $\log(1/R)$, where $R$ was the

reflectance at each wavelength. Spectra were acquired in a random order.

Statistical analyses were performed using Win-ISI II software (Infrasoft International, Port Matilda, PA, USA) and XLstat software (Addinsoft, Paris, France).

*Spectrum Pretreatment.* Different pretreatments were tested. The one adopted was a mathematical correction for light scattering, using the standard normal variate and detrend correction.[35] Then, the second derivative was calculated on five data points and smoothed using Savitzky and Golay polynomial smoothing on five data points on the whole data set including visible and near-infrared wavelengths.

*Principal Component Analysis (PCA).* Prior to calibration development, a PCA was used to extract relevant information from the spectral matrix ($n$ = 193). The generalized Mahalanobis distance ($H$) was calculated on the extracted PCs for each sample. This statistical distance is useful for defining boundaries of the population and a similarity index between spectra. No sample displayed a Mahalanobis distance greater than the distance limit (3), so all of the samples were kept in the database.

*NIR Calibration Development.* To optimize the model parameters and assess the performance of the predictive model, the 193 samples analyzed in the laboratory were separated into two groups, one for calibration and one for validation. The validation subset comprised 30 samples: 14 samples corresponding to two independent geographical origins (Ghana and Indonesia) and 16 randomly selected samples. The calibration subset comprised the remaining 163 samples. The calibration equations for the phenolic content were constructed with the calibration subset using the modified partial least-squares regression (mPLS) algorithm of WinISI software.[30] Calibration statistics included the following parameters: standard deviation (SD), coefficient of determination ($R^2$), standard error of calibration (SEC), and standard error of cross-validation (SECV).

Cross-validation was used during calibration development to select the optimum number of latent variables and to minimize overfitting of the equations. For SECV estimation, 25% of the samples were predicted using a calibration model developed with the other 75%. SECV estimation was repeated four times and the average calculated. In addition to $R^2$, the ratio of performance to deviation (RPD = SD/SECV) was used to evaluate the general quality of the fit obtained for each equation. Unlike SEC and SECV, RPD has no units and can therefore be compared between parameters.[36] The Student $t$ test was used to identify $t$-outlier samples during calibration development. Outlier detection was based on the standardized residuals (= error/SECV) with a cutoff of 2.5. Two passes of outlier elimination were used.[37] The standard error of prediction (SEP), corresponding to the standard deviation of residuals, was estimated by predicting the validation subset using a model developed on the calibration subset. The ratio of performance to deviation of prediction (RPDp) was also calculated as RPDp = SDval/SEP (where SDval was the standard deviation of validation samples). The quality of the fit between flavan-3-ol values from HPLC-DAD analysis and flavan-3-ol NIRS-predicted values was evaluated from the linear regression slope, the $R^2$p, and the bias.

On the basis of these results, the final NIRS calibration was developed using the 193 samples and applied to the 635 samples for which the ST was calculated to predict the polyphenolic content. The predicted values were studied as a function of fermentation time and the ST.

## RESULTS AND DISCUSSION

**Comparison of Flavan-3-ol Extraction Techniques.** The three extraction methods were compared for their flavan-3-ol extraction yield and their relative repeatability. It clearly appeared that epicatechin required two cycles to be extracted at >95% using Fast-Prep, whereas only one cycle was needed for PLE proanthocyanidin extraction (>95%) (results not shown).

A three-way ANOVA was performed on the total flavan-3-ol content with fermentation time, repetition, and extraction type as factors. A strong effect of fermentation time ($F$ = 1773.4; $p$ < 0.0001) and a lesser effect of extraction type ($F$ = 14.5; $p$ = 0.001) appeared. The Newman−Keuls test ($\alpha$ = 5%) showed that Fast-Prep enabled the extraction of a significantly higher content (21.3 mg/g of dried cocoa) than PLE (20.5 mg/g of dried cocoa). The lowest level of flavan-3-ols was obtained with the Ultra-Turax technique (19.7 mg/g of dried cocoa).

Seven samples covering the range of flavan-3-ol contents were extracted twice with the three different extraction methods to express the repeatability of (−)-epicatechin extraction yield. For total flavan-3-ol quantification, the smallest coefficient of variation was obtained with Fast-Prep extraction (0.75%); it was close to that achieved with PLE (1.27%), with the highest being for the Ultra-Turax method (2.67%), but remained very low whatever extraction device was used. The coefficients of variation were not significantly different for proanthocyanidin $B_1$ and proanthocyanidin $B_2$ (results not shown).

The Fast-Prep extraction procedure was preferred considering that the repeatability of this device was greater than for the other devices, with the advantage of its rapidity and easy-handling.

**Determination of Polyphenolic Content.** For the 193 samples selected, the flavan-3-ols were extracted by Fast-Prep and quantified by HPLC-DAD.

The most abundant component was (−)-epicatechin, with an average of 9.4 mg/g of cocoa powder and a standard deviation of 6.3 mg/g. The values were regularly distributed between the

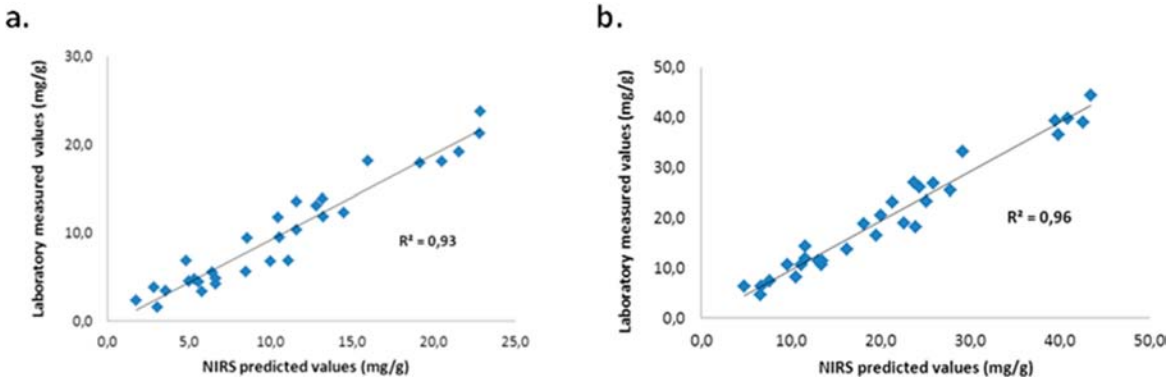

**Figure 1.** Scatter plot of NIRS-predicted values versus laboratory values for the validation set: (a) (−)-epicatechin; (b) total flavan-3-ols.

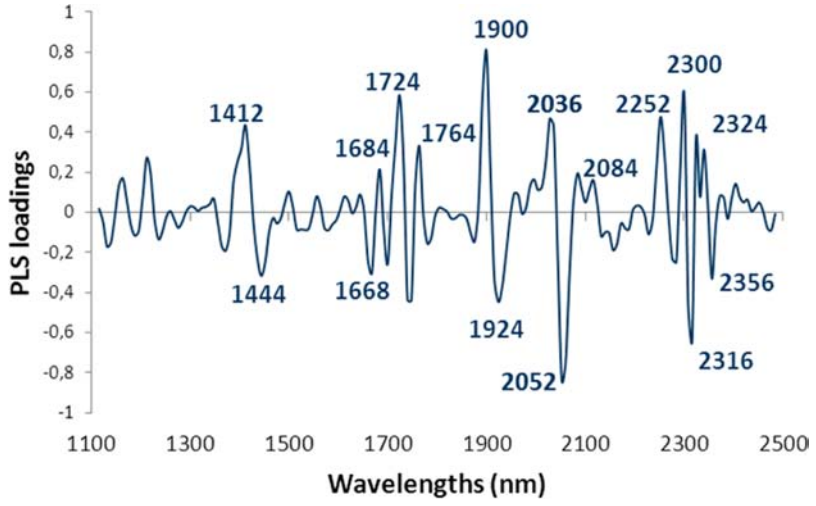

**Figure 2.** First PLS loadings as a function of the wavelengths observed for (−)-epicatechin calibration.

minimum and maximum values. This distribution reflected the experimental design assuming the hypothesis that flavan-3-ol content is linked to the fermentation time. The distribution was then considered optimum for developing NIR calibration.[30]

**NIRS Models and Validation.** The models developed for each individual component were efficient; the number of latent variables (PLS terms) introduced in the models ranged from 6 to 10 (Table 1). The $R^2$ values were between 0.95 and 0.98, and five to eight outliers ($t$ test) were removed during calibration.

These models were applied to estimate the SEP by predicting the validation set. The SEP values were between 0.24 mg/g (for proanthocyanidin $B_2$) and 2.33 mg/g (for total flavan-3-ols). The regression between predicted values and laboratory values led to $R^2$p values between 0.93 and 0.96 with nonsignificant bias and slope. The RPDp values were >3, reflecting the efficiency and the robustness of the models.

The scatter plot of NIRS-predicted values versus laboratory (Figure 1) values for the validation set highlighted the quality of the calibration for the whole range of the component concentration.

This accuracy was not expected due to NIR sensitivity, which is known to be around 0.1% for quantification. We put forward the hypothesis that NIRS was mainly calibrated on an indirect strong correlation due to the changes occurring during fermentation and the interactions of flavan-3-ols with some major components such as proteins. The amount of proteins in cocoa (10−15% of dry bean weight),[38] their hydrolysis, and their complexation with flavan-3-ols during fermentation, probably by surface contact and hydrogen-bonding,[39] lead to regression models computed on a correlation between proteins and flavan-3-ols. Those kinds of correlations make it difficult to interpret the size and the sign of the regression coefficients.[40] The contribution of flavan-3-ols in NIR spectra patterns is difficult to interpret, even on pure components. As an example, some of the absorption bands of pure (−)-epicatechin (data not shown) could also be assigned to N−H bond vibrations from proteins, polypeptides, amino acids, and amides: 1458, 1986, 2014, 2062, 2302, and 2474 nm.[41] However, the interpretation of PLS loadings (generated from raw or derivative spectra) could efficiently help to bring out such correlations. The observation of the loadings associated with the first PLS term (Figure 2) for (−)-epicatechin calibration revealed high coefficients[41] in the NIR region associated with (1) NH bonds at 2052 nm (proteins) and 2300 nm (amino acids); (2) C═O bonds at 1900 nm (second overtone stretching) from $-CO_2H-$ (acids), at 2036 nm (C═O stretching second overtone of $CONH_2$), and at 1924 nm (stretching, second overtone of CONH); (3) CH bond of aromatics at 1444 nm (and phenolic group) and 1684 nm; and (4) O−H bonds at 1412 nm, 2084 nm (R−OH), and 2252 nm (starch).

The remaining coefficients were associated with CH bonds from $CH_2$ and $CH_3$; a coefficient at 1668 nm could be assigned to CH from *cis*-RCH═CHR[1].

These patterns in PLS loadings were similar for proanthocyanidins and total flavan-3-ols. The relationship between bands related to proteins and bands related to O−H and

aromatic groups confirmed the close and strong relationship between proteins and flavan-3-ols. The evolution of these two compounds is dependent on fermentation conditions and follows similar kinetics. The accuracy of the model, despite low concentration levels, was directly linked to this strong relationship between proteins and flavan-3-ol compounds that occurs during fermentation and drastically changes spectrum profiles.

**Changes in Phenolic Compounds during Fermentation.** The phenolic compounds of the 718 samples were predicted by NIRS using the model developed. The values ranged from 0 to 46.6 mg/g for total flavan-3-ols, 5.4 mg/g for proanthocyanidin $B_1$, 4.3 mg/g for proanthocyanidin $B_2$, and 25.5 mg/g for (−)-epicatechin, with standard deviations of 10.6, 1.3, 1.0, and 5.7 mg/g, respectively. As expected, and whatever the origin, the phenolic content decreased significantly with fermentation time: total flavan-3-ol concentration fell from an average of 33.3 mg/g for unfermented samples to an average of 6.2 mg/g at the end of fermentation (Figure 3). A similar decrease was observed in previous studies.[12,15,42,43]

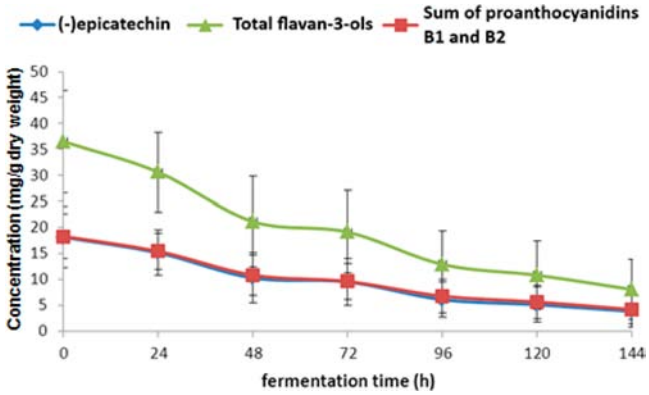

**Figure 3.** Evolution of (−)-epicatechin, sum of proanthocyanidins $B_1$ and $B_2$, and total flavan-3-ol concentration during fermentation.

Each compound was highly correlated to the others, enabling us to focus only on the evolution of the total flavan-3-ol content during fermentation.

A two-way ANOVA was performed to test the influence of cocoa origins and fermentation time on the total flavan-3-ol content. The ANOVA highlighted the strongest significant effect of the fermentation time ($F$ = 96.3; $p$ < 0.0001) compared to the origin ($F$ = 52.5; $p$ < 0.0001). According to the ANOVA-SNK (Newman−Keuls) test ($\alpha$ = 5%), for the fermentation time, the total flavan-3-ol concentration values were not significantly different for 120 and 144 h only.

As for the origin, the Dominican Republic, Madagascar, and Indonesia samples had significantly lower flavan-3-ol content values than those from Trinidad and Tobago, Ecuador, and Ghana. Samples from Cameroon were not significantly different from Ghana, but different from the others. Those variations could be explained by differences in the cocoa varieties used, endogenous microflora, fermentation conditions (size and material of boxes, harvest and pod opening delays, etc.), environmental conditions, etc.

The interaction between origin and fermentation time was also significant (Figure 4) and was due to differences in the kinetics of flavan-3-ol degradation depending on the origin. Samples from Indonesia displayed particular kinetics because no variation in flavan-3-ol content was observed after 48 h. This

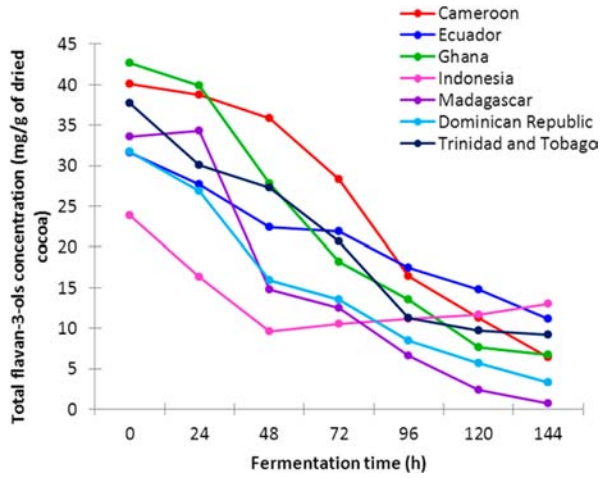

**Figure 4.** Total flavan-3-ol content predicted values versus fermentation times per geographical origin.

behavior was similar for other constituents measured on those samples, such as ammonia nitrogen or free amino acids (data not shown). One hypothesis is that no fermentation occurred after 48 h, probably due to poor fermentation conditions.

**Fermentation Monitoring and Relationship with Phenolic Content.** Temperatures were recorded at the exact place where samples in the net were located. The temperature profiles measured for the 30 microfermentations were similar to those in the literature with an average of 33 °C after 24 h, a rise to 40 °C at 96 h, and ending up close to 44 °C at the end of fermentation.

To better understand the effect of temperature on cocoa fermentation, the ST was calculated for each microfermented sample. For the 524 microfermented samples, the calculated values of the ST ranged from 0 to 3662 °C. They were regularly distributed. At 24 h the ST was relatively uniform with an average value equal to 265 ± 51 °C. The dispersion increased after 72 h, whereas at 144 h, the average ST was close to 2811 ± 387 °C. Unsurprisingly, the dispersion of ST was greater with the progression of fermentation and reflected the high heterogeneity of the batches. On this basis, we investigated the usefulness of ST for keeping track of flavan-3-ol changes (Figure 5).

There was a significant correlation ($r$ = 0.80) between both parameters, which could be described as a logarithmic equation. Each fermentation batch analyzed separately led to a high correlation between total flavan-3-ol concentration and the ST (e.g., $R^2$ = 0.87 for a particular batch randomly selected from the whole set). The minimum $R^2$ observed per batch was 0.44 and the highest, 0.92, for an average value of 0.74. This result was expected and confirmed the correlation between ST and flavan-3-ol concentration.

The ST factor explained changes occurring in the flavan-3-ol content more accurately than the fermentation time, whatever the geographical origin, phenotype, or position in the box studied. Flavan-3-ol derivatives and ST could be used by farmers and chocolate manufacturers to check fermentation levels.

In conclusion, this study, based on a large collection of samples and a robust experimental design, confirmed the effect of fermentation on the polyphenolic content of cocoa beans and the feasibility of using it as a marker of fermentation time. The Fast-Prep technique, a repeatable, easy-to-use, and quick

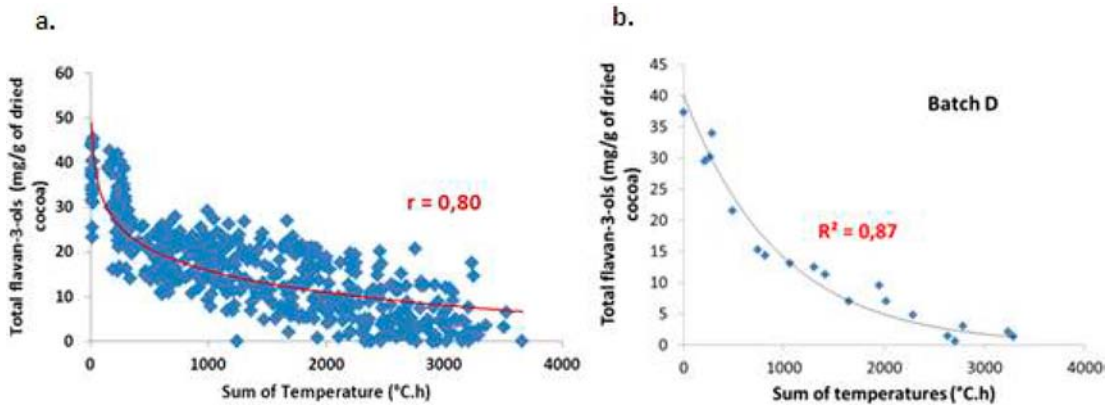

**Figure 5.** Scatter plot of total flavan-3-ol concentration versus the sum of temperatures for the whole database (a) and for a particular batch (b).

extraction method, was tested and used to calibrate the NIRS. This made it possible to effectively enlarge the database. Chocolate manufacturers could use the NIRS model on dry cocoa sample to predict fermentation levels by estimating the polyphenolic content. To complete this study, a specific study on tanning occurring with flavan-3-ols and proteins would give more information on reactions taking place during fermentation and on the specificity of the NIRS response. In addition, samples from other geographical origins (such as Ivory Coast or Brazil) need to be analyzed to enhance the robustness of the model.

In the present study, we aim to use various microscopy techniques to characterize the structure of morphologically different starch granules isolated from TRS mature kernels. The mature kernels will be mapped in situ using light microscopy to identify the spatial distribution of morphologically different granules in the endosperm. This study could increase our understanding of heterogeneous starch granules from high-amylose cereal and would provide important information on the formation of heterogeneous starch granules resulting from kernel development.

## MATERIALS AND METHODS

**Plant Materials.** An *indica* rice cultivar Te-qing (TQ) and its transgenic line (TRS) with high amylose and RS contents were used in this study. TRS was generated from TQ after transgenic inhibition of both SBE I and SBE IIb through an antisense RNA technique and was homozygous for the transgene.[6] TQ and TRS were cultivated in the transgenic close experiment field of Yangzhou University, Yangzhou, China.

**Starch Isolation.** Starches were isolated from TQ and TRS mature kernels according to the method of Wei et al.[16] with some modifications. Brown rice seeds were steeped in distilled water at 4 °C overnight and homogenized with ice-cold water in a home blender. The homogenate was squeezed through five layers of cotton cloth. The residue was homogenized and squeezed twice more in a mortar with a pestle to facilitate the release of starch granules. The combined extract was filtered with 100-, 200-, and 400-mesh sieves and centrifuged at 3000*g* for 10 min. The yellow gel-like layer on top of the packed white starch granule pellet was carefully scraped off and discarded. The process of centrifugation separation was repeated several times until no dirty material existed. The precipitated starch was further washed with anhydrous ethanol two times, dried at 40 °C, ground into powders, and passed through a 100-mesh sieve.

**Light Microscopy.** A starch suspension (1%, w/v) was prepared with 50% glycerol. 10 $\mu$L of starch suspension was placed on the microscope slide and covered with a coverslip. The starch granule shape and Maltese cross were viewed with an Olympus BX53 polarized light microscope equipped with a CCD camera under normal and polarized light. Iodine-stained starches were prepared and observed according to the method of Evans et al.[18] with some modifications. 5 mg of starch was stained in 0.5 mL of iodine solution (0.5% NaAc buffer, pH4.5, 25% glycerol, 0.04% $I_2$, 0.06% KI) for 30 min in darkness. 10 $\mu$L of iodine-stained starch suspension was first viewed under normal light, and then the same field was viewed under polarized light. All the iodine-stained starch granules were photographed under the same conditions in order to compare the polarization colors. Iodine-stained starches had four kinds of polarization colors: blue, fuchsia, red, and interior dark blue and exterior brown. For one type of heterogeneous starch granules, 50 granules were randomly chosen to be analyzed for polarization color for one experiment. The experiments were performed in triplicate.

**Confocal Laser Scanning Microscopy.** Starch granules were stained with the fluorophore APTS (8-amino-1,3,6-pyrenetrisulfonic acid) and prepared for confocal laser scanning microscope (CLSM) essentially as previously described by Blennow et al.[19] Images were recorded on a CLSM (LSM 710, Carl Zeiss MicroImaging GmbH) using a 488 nm laser line for excitation, and light was detected in the interval from 500 to 535 nm. For morphology observation, laser power capacity and master gain were adjusted to maximum saturation. To compare the fluorescence intensity, the laser power was kept constant at 1%, and images were recorded at the master gain of 620 for all starch granules. The conditions allowed all granules to have no saturation of the detector for every dot in all granules. For every type of heterogeneous starch granules, 60 granules were randomly chosen to be recorded. Image analysis was performed using the Carl Zeiss ZEN 2010 software.

**Hot Stage Microscopy.** Starch suspension was prepared by suspending about 10 mg of starch in 1.0 mL of double distilled water by using a vortex mixer. The suspension was transferred onto a slide, covered with a coverslip, and sealed with nail polish to prevent moisture loss during heating. The sealed specimen was then mounted on a Kitazato hot stage apparatus and observed under a long focus M Plan Semi Apochromat objective (50× magnification) using an Olympus polarized microscope during heating. The hot stage was heated from 25 to 50 °C at a heating rate of 5 °C/min and from 50 to 100 °C at a heating rate of 1 °C/min.

The gelatinization temperatures were measured according to the method of Konik-Rose et al.[20] with some modifications. The starch slurry was photographed under polarized light using an Olympus DP72 CCD camera during heating from 50 to 100 °C at 1 °C intervals. Three group experiments were carried out for every type of starch granule. For every group experiment, more than 100 granules of every type of heterogeneous starch granules were analyzed from 10 to 30 photographs. For every granule, the temperature at which the granule lost birefringence was recorded. The granule number was counted at the lost birefringence temperature. Plotting the granule number percentage of birefringence loss against the temperature produced a gelatinization curve. The initial, middle, and end gelatinization temperatures were obtained from the gelatinization curve when 5%, 50%, and 95% of granules had lost their birefringence.

The swelling of starch granule during heating was viewed under normal light and photographed using an Olympus DP72 CCD camera from 40 to 95 °C at 5 °C intervals. The area of starch granule was analyzed from the micrograph with a JEDA 801D morphological image analysis system (Jiangsu JEDA Science-Technology Development Co., Ltd., Nanjing, China). Fifty starch granules were measured for every type of heterogeneous starch granule. The starch granule swelling was presented as area swelling percentage (ASP) from ungelatinized granule at 40 °C and calculated by the equation ASP (%) = $A_t/A_i \times 100$, where $A_i$ and $A_t$ represented the area of starch granule at initial (40 °C) and specific testing temperature, respectively.

**Kernel Sections for Light Microscopy.** In order to soften the kernels, mature kernels were first fixed in a fixation solution (2.5% glutaraldehyde and 4% paraformaldehyde in 0.1 M phosphate buffer at pH 7.2) for 2 h at room temperature and then held overnight at 4 °C. The softened kernels were transversely cut with a razor blade at the midregion of the kernel to obtain thin tissue blocks. The tissue blocks were then fixed in the same fixation solution again for 48 h at 4 °C. After fixation, the blocks were washed 3 times with phosphate buffer, successively dehydrated in gradient ethanol, and embedded in LR White Resin. The semithin sections of 2 $\mu$m thickness were cut with a glass knife on a Leica Ultrathin Microtome (EM UC7), stained with iodine solution (25% glycerol, 0.07% $I_2$, 0.14% KI) for 10 min in darkness, and observed with an Olympus BX53 light microscope equipped with a CCD camera.

**Statistical Analysis.** One-way analysis of variance (ANOVA) and Tukey's test ($p < 0.05$) were used for statistical analysis of the difference of properties of TQ starch granule, TRS starch individual granule, TRS starch aggregate granule, TRS starch elongated granule, and TRS starch interior hollow granule using the SPSS 16.0 Statistical Software Program. All the replications were technical replicates.

## RESULTS AND DISCUSSION

**Morphology of Heterogeneous Starch Granules.** Starch granules isolated from TQ and TRS mature kernels were observed under normal and polarized light (Figure 1). Most TQ starch granules were regular and polygonal (Figure 1A,C) with all of them showing one central hilum and one typical Maltese cross (Figure 1a,c). Therefore, TQ starch granules were morphologically homogeneous. TQ starch is a compound starch that separates during isolation into many subgranules.[17] In the present study, the TQ starch granules isolated were the subgranules of compound starch that appeared as individual granules.

As found previously,[17] TRS starch granules showed significantly different morphologies (Figure 1B,b). These

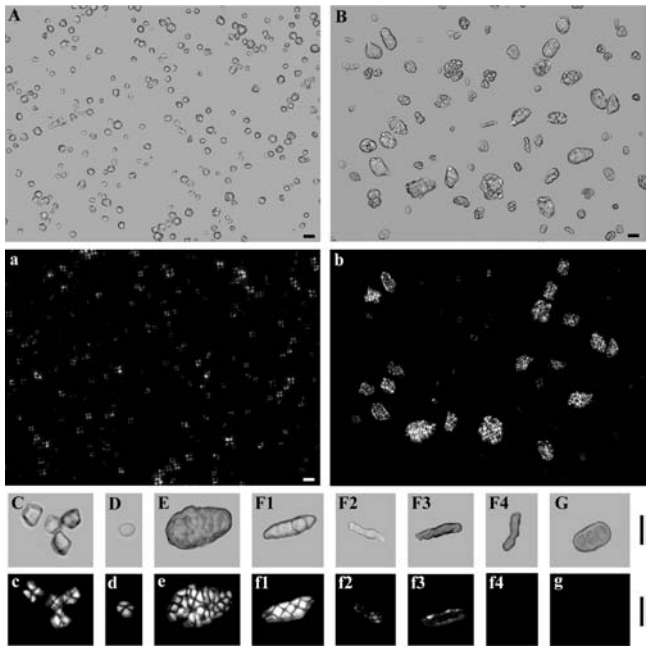

**Figure 1.** Microphotographs of starch granules under normal (A−G) and polarized (a−g) light. (A, C, a, c) TQ starch, (B, D−G, b, d−g) TRS starch, (C, D, c, d) individual granule, (E, e) aggregate granule, (F, f) elongated granule, (G, g) interior hollow granule. Scale bar = 10 $\mu$m.

granules could be divided into four types: individual, aggregate, elongated, and interior hollow granules according to their morphologies and Maltese crosses (Figure 1D−G,d−g). The individual granules of TRS and TQ starches all had the central hila and one typical Maltese cross on one granule, but there were significant differences in morphology and size. The TRS individual granules were spherical and smaller than the polygonal-shaped TQ individual granules (Figure 1D,d). The TRS aggregate granules were large and voluminous with nonangular rounded bodies and numerous bright Maltese crosses within granules (Figure 1E,e). Under transmission electron microscopy, the large voluminous and nonangular rounded body was observed to consist of many small subgranules. Some of these subgranules at the periphery of the starch fuse together and form a thick band or wall encircling the entire exterior of the starch granule, which prevents the release of subgranules during starch isolation.[17] Therefore, the large voluminous and nonangular rounded bodies were called aggregate granules, which were observed to have numerous Maltese crosses (Figure 1e). This agrees with the findings of Wei and his colleagues that the aggregate granule consisted of many subgranules and each subgranule contained a hilum and a Maltese cross.[17] The TRS elongated granules displayed different shapes including rods and filaments and could be further classified into three types: full birefringence, partial birefringence, and no birefringence according to their birefringence patterns (Figure 1F,f). The elongated granules with full birefringence patterns had three or more clear Maltese crosses within granules (Figure 1f1). Some of the elongated granules with partial birefringence showed only weak birefringence along the edge of the granules, while others displayed a birefringence pattern consisting of combinations of one or more Maltese crosses and weak to no birefringence on other parts of the granule (Figure 1f2,f3). The third type of elongated granule exhibited no birefringence (Figure 1f4). This phenomenon has also been reported elsewhere in high-amylose maize starch granules.[15,21] The percentage of elongated starch granules increases with the increasing amylose content in high-amylose maize.[10] The TRS interior hollow granules were mostly irregular and deformed, and exhibited extremely weak to no birefringence (Figure 1g), which was the same as interior hollow starch granules from high-amylose SGP-1 null wheat.[22]

Aggregate, elongated, and interior hollow starch granules have been observed in high-amylose rice,[12,17] maize,[10,15] wheat,[5,9] and barley.[11] However, the mode of formation of interior hollow granules is not clear at present. Birefringence patterns are the result of orderly aligned polymers or crystallites. Different birefringence patterns show various radial orientations and alignments of the crystallites' regions within the granules.[23,24] In the present study, the TQ and TRS individual starch granules and the subgranules of TRS aggregate starch granule had a typical Maltese cross in the hilum, indicating that the starch molecules were aligned in a radial order centered at the hilum and perpendicular to the granule surface.[21] In high-amylose maize, about 36% and 55% of elongated granules have partial birefringence and no birefringence, respectively.[15] In high-amylose wheat and barley, over 90% of interior hollow starch granules are not birefringent.[5,11] In the present study, the TRS elongated and interior hollow starch granules had weak or no birefringence, indicating that the starch molecules of granules were not radially aligned, which might result from the high amylose concentrations in these granules. The amylose molecules of granules are not expected to be specifically uniformly oriented.[19] The significantly different birefringence patterns of TRS starch granules indicated that the arrangement of starch molecules varied between heterogeneous granules and within the same granule.

**Polarization Colors of Iodine-Stained Heterogeneous Starch Granules.** Iodine staining in combination with polarized light microscopy has been used to reveal the structural heterogeneity of starch granules.[15,18] The color of iodine-stained starch under polarized light is termed the polarization color.[25] TQ and TRS starch granules stained with iodine solution (0.04% $I_2$ and 0.06% KI) were viewed under normal and polarized light (Figure 2). The TQ starch showed a homogeneous blue polarization color at the Maltese cross (Figure 2a,c), while the TRS starch granules exhibited significantly heterogeneous polarization colors. There were three types of polarization colors for TRS individual granules: blue (Figure 2d1), dark red (Figure 2d2), and a dark blue interior with brown exterior (Figure 2d3). The TRS aggregate granules displayed four types of polarization colors: blue (Figure 2e1), fuchsia (Figure 2e2), dark red (Figure 2e3), and a dark blue interior with brown exterior (Figure 2e4). Both the TRS elongated and interior hollow granules exhibited two types of polarization colors: dark red (Figure 2f1,g1) and a dark blue interior with brown exterior (Figure 2f2,g2). Table 1 summarizes the percentages of iodine-stained starch granules with different polarization colors. The TRS starch granules showed significant heterogeneity in polarization color between heterogeneous granules and within the same granule. Most of the TRS individual granules showed a blue polarization color, aggregate granules a dark red polarization color, and elongated and interior hollow granules a dark blue interior with brown exterior polarization color. The present results agree with previous reports that the polarization color of iodine-stained

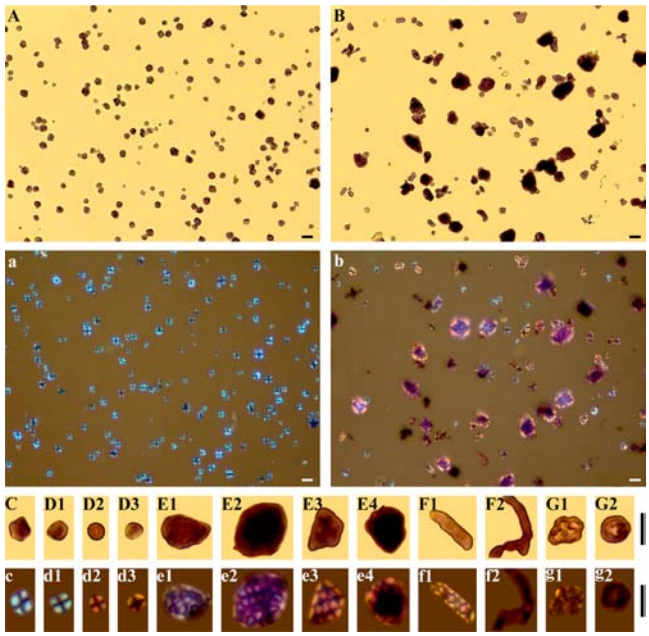

**Figure 2.** Microphotographs of iodine-stained starch granules under normal (A–G) and polarized (a–g) light. (A, C, a, c) TQ starch, (B, D–G, b, d–g) TRS starch, (C, D, c, d) individual granule, (E, e) aggregate granule, (F, f) elongated granule, (G, g) interior hollow granule, (c, d1, e1) showing the blue color, (e2) showing the fuchsia color, (d2, e3, f1, g1) showing the dark red color, (d3, e4, f2, g2) showing the dark blue interior with brown exterior. Scale bar = 10 $\mu$m.

starch is similar to that observed under normal light for waxy and normal starch and different from that observed under normal light for high-amylose starch. The *ae* single mutant high-amylose maize starch appears blue under normal light and pink under polarized light.[18,25]

The explanation of polarization color is based on absorption effects in combination with birefringence.[26] It is generally known that the amylose–iodine complex normally shows blue under normal light, but, in fact, the color of the complex depends on the degree of polymerization (DP) of the amylose helix. The color of the amylose–iodine complex changes from brown (DP 21–24) to red (DP 25–29), red–violet (DP 30–38), blue–violet (DP 37–46), and finally blue (DP > 47).[27] In the same manner as amylose, the linear branches of amylopectin, which form a helix, can also develop a red or orange amylopectin–iodine complex. The external chain length is equally important for iodine staining of amylopectin.[27−29] It is believed that the radially ordered alignment of starch molecules results in birefringence and the random orientation in no birefringence.[30] The intensity of birefringence is not in proportion to the amylopectin content but is positively correlated with the proportion of symmetrically and radially oriented amylopectin molecules.[18] When starch molecules (amylose and amylopectin) are completely radially oriented, iodine-stained starch granules will exhibit a blue polarization color because the amylose–iodine complex generates a stronger color than the amylopectin–iodine complex. When only the amylopectin is oriented radially, the intensity of birefringence will be slightly reduced and iodine-stained starch granules will display a pink polarization color resulting from the amylopectin–iodine complex. When only the amylose is oriented radially, the intensity of birefringence will be markedly diminished and iodine-stained starch granules will display a blue polarization color resulting from the amylose–iodine complex.[18] In the present study, all TQ starch granules and most of the TRS individual granules showed a blue polarization color, indicating that these granules contained radially oriented starch molecules. Some TRS aggregate granules exhibited a fuchsia polarization color, indicating that both the amylopectin and amylose were partly radially oriented. As a result of the less symmetrical radial orientation of amylopectin and the randomly oriented amylose, a dark red polarization color was observed in some TRS individual, aggregate, elongated, and interior hollow granules. The dark reddish polarization color has also been observed in some maize amylose-extender (*ae*) mutant starch granules.[18] The polarization colors of a dark blue interior with brown exterior were also observed in TRS starch granules (Figure 2d3,e4,f2,g2). The different colors within a granule indicated that its structure was heterogeneous. This structural heterogeneity within a granule has been also reported in high-amylose maize starches.[13−15,18] The significantly different polarization colors of the TRS starch granules indicated that heterogeneity in the orientations of amylose and amylopectin existed between heterogeneous granules and within the same granule.

**Fluorescence Intensities of APTS-Stained Heterogeneous Starch Granules.** CLSM photographs of APTS-stained starch granules provide information about the internal structure of starch granules.[31] The reducing end of the starch molecule is reacted specifically with APTS leading to a 1:1 stoichiometric ratio for starch molecule labeling. Owing to its smaller size, amylose contains a much higher molar ratio of reducing ends per glucose residue than amylopectin, which leads to a higher by-weight labeling of amylose when constructing a detailed map of the distribution of amylose and amylopectin within starch granules.[19] The distribution of amylose and amylopectin within the TQ and TRS starch granules stained with APTS are shown in Figure 3. TQ starch granules showed a strong fluorescent dot in the central hilum (Figure 3A), indicating a high density of amylose in the center of the granule. This phenomenon has also been reported in normal cereal starch granules.[17,31] Because of the high content of amylose, the TRS starch granules exhibited a fluorescence too strong for observing the

microstructure under the same conditions of laser power and master gain as the TQ starch (data not shown). Figure 3B–E shows the microstructure and fluorescence distribution of TRS starch granules at a lower laser power. For the TRS individual granules, there were three types of amylose distribution pattern (Figure 3B). For the first type, some TRS individual granules had a slightly smaller size than the TQ starch granules with a bright fluorescent dot in the hilum (Figure 3B1). This type of amylose distribution was similar to that of the individual TQ granule. Starch granules with this type of amylose distribution might display a blue polarization color (Figure 2d1). The second type of TRS individual granule exhibited strong fluorescence evenly over the whole granule (Figure 3B2), indicating a high level of amylose distribution in the whole granule, and might display a dark blue interior with brown exterior polarization colors (Figure 2d3). The third type of TRS individual granule had a significantly smaller size and a larger central strongly fluorescent dot compared with the individual TQ granules. This type of starch also had an intense fluorescence around the granule's circumference (Figure 3B3), indicating that the amylose was concentrated mainly around the central hilum and the circumference of granule and might result in the dark red polarization color (Figure 2d2).

For TRS aggregate granules, the CLSM optical sections clearly revealed that the large voluminous and nonangular rounded bodies consisted of many subgranules and a band encircled the entire circumference of the granule (Figure 3C). There were two types of amylose distribution patterns in the TRS aggregate granules. The first type, consisting of most of the aggregate granules, showed intense fluorescent dots in the hila of subgranules and a bright fluorescence around the circumference of the granules and the subgranules (Figure 3C1), indicating that the amylose was distributed mainly in the central hilum regions of the subgranules and the circumference of the granules and subgranules. This type of aggregate granule might display the blue and fuchsia polarization colors (Figure 2e1,e2). The second type of aggregate granule had such strong fluorescence on the subgranules that the microstructure of the granule could not be clearly viewed under the same viewing conditions as the first type of aggregate granule (data not shown). Figure 3C2 shows the amylose distribution of the second type of aggregate granule using a lower laser power than the first type of aggregate granule. The interior of the subgranules exhibited a uniformly intense fluorescence and the band encircling the entire circumference of granules a weak fluorescence. This result suggests that the amylose content, which was largely distributed in the subgranules, was very high in the second type of aggregate granule and would result in a dark red polarization color (Figure 2e3) or a dark blue interior with brown exterior polarization colors (Figure 2e4). The internal structure and amylose distribution of TRS aggregate granules agreed with previous reports on high-amylose rice and maize starch aggregate granules.[15,17]

For TRS elongated granules, there were three types of amylose distribution (Figure 3D). The first type consisted of three or more regular and polyhedral subgranules. These subgranules were arranged in a line and encircled by a band with the hila of subgranules showing strong fluorescence (Figure 3D1). This type of elongated granule had many clear Maltese crosses (Figure 1f1) and showed a dark red polarization color (Figure 2f1). The second type had no clear subgranule inside, but three or more highly fluorescent clear round dots were arranged in a line inside the granule, which might result from the aberrant formation of subgranules (Figure 3D2). This type of elongated granule had some Maltese crosses (Figure 1f1) and might display a dark red polarization color (Figure 2f1). The third type had an intensely fluorescent interior (Figure 3D3). This type of elongated granule might have only a weak birefringence along the edge of the granule or no birefringence (Figure 1f2–f4) and resulted in a dark blue interior with brown exterior polarization colors (Figure 2f2). The different amylose distribution patterns in elongated starch granules have been reported in high-amylose maize.[15,21]

For TRS interior hollow granules, irregular granule shapes could be observed and there were three types of amylose distribution (Figure 3E). Some TRS interior hollow granules had a few subgranules adjacent to the encircling band. These subgranules were polyhedral and had central hila. The hila of subgranules and the encircling band of the granule displayed highly strong fluorescence (Figure 3E1). The second type of interior hollow granule showed a brightly fluorescent band encircling the entire circumference and a weakly fluorescent interior that consisted of very small starch molecules (Figure 3E2). The third type of interior hollow granule exhibited a weakly fluorescent band encircling the entire circumference, but the interior of the band displayed very strong fluorescence (Figure 3E3). These results revealed that the formation of the subgranules inside the TRS interior hollow granules was aberrant, which resulted in no birefringence or very weak birefringence in the encircling band (Figure 1g). The strongly fluorescent band indicated a very high amylose content, which resulted in a dark red polarization color (Figure 2g1) or a dark blue interior with brown exterior polarization colors (Figure 2g2).

These amylose and amylopectin distributions within the TQ and TRS starch granules (Figure 3) indicate that heterogeneity in amylose and amylopectin distribution existed in all starch granules, which agreed with previous reports.[17,19,31] The distribution patterns of amylose and amylopectin (Figure 3) showed that the TQ starch granules were homogeneous, and the TRS starch granules were highly heterogeneous, which agreed with results on high-amylose maize starch.[15]

As previously reported, the fluorescence intensity of APTS-stained starch granules as imaged by CLSM was positively correlated with amylose content.[19,32] To compare the difference in amylose content between heterogeneous starch granules, the fluorescence intensities of the optical sections

**Table 2. Fluorescence Intensities and Gelatinization Temperatures of Starch Granules[a]**

| starches | fluorescence int (arbitrary units)[b] | gelatinization temp (°C)[c] | | |
|---|---|---|---|---|
| | | $T_i$ | $T_m$ | $T_e$ |

| interior hollow granule | 63.1 ± 16.2 d | –[d] | – | – |

[a]Data (mean ± SD) in the same column with different lowercase letters were significantly different ($p < 0.05$, $n = 60$ for fluorescence intensity and 3 for gelatinization temperature). [b]The intensity of fluorescence was measured in CLSM optical sections of starch granules. [c]Gelatinization temperatures ($T_i$, initial temperature; $T_m$, middle temperature; $T_e$, end temperature) were measured by hot stage microscopy. [d]Data were not detected.

were analyzed under the same photographic conditions, which provided no saturation of the detector for every dot in all starch granules in the present study (Table 2). Compared with the TQ starches, TRS starches showed a significantly higher fluorescence intensity, which corresponded with a higher amylose content.[6,16] For the TRS heterogeneous starch granules, interior hollow granules and individual granules had the highest and lowest fluorescence intensity, respectively. These results indicated that a significant heterogeneity in amylose content existed between TRS heterogeneous starch granules and that the interior hollow granule and individual granule had the highest and lowest amylose content, respectively.

**Gelatinization Properties of Heterogeneous Starch Granules.** Hot stage microscopy is a sensitive in situ method to investigate the simultaneous behaviors of granule swelling, gelatinization temperature, and crystallinity disruption.[20,33,34] The behaviors during TQ and TRS starch gelatinization were investigated using hot-stage microscopy in the present study, and the results are presented in Figure 4. Before gelatinization, the starch granule retained its intact morphology as observed under normal light and showed a bright and clear Maltese cross pattern under polarized light. During gelatinization, the birefringence intensity of the granule faded away when the heating temperature rose above the initial gelatinization temperature, and this loss of birefringence was accompanied by granule swelling. Although TQ and TRS starches had different morphologies, their crystallinity disruption patterns were similar. During heating, the crystallinity disruption started in the hilum region and was accompanied by a small amount of swelling. With increasing heating temperature, the crystallinity disruption and swelling propagated from the inner hilum to the outer region of the starch granule. At this stage, the crystal structure of the outer area of the granule was still undisrupted. During the last stage of the gelatinization process, the crystallinity of the outer region of the granule was disrupted. These crystallinity disruption patterns for TQ and TRS starches were similar to those of various starches with central hila.[34]

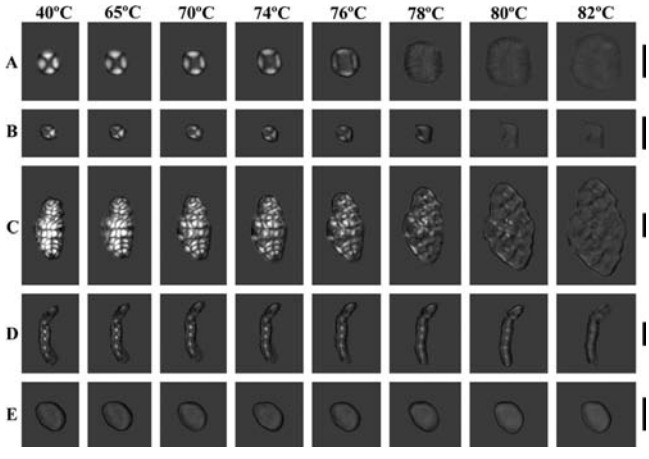

**Figure 4.** Gelatinization of starch granules under polarized light at different temperatures. (A) TQ individual starch granule; (B, C, D, E) TRS individual, aggregate, elongated, and interior hollow starch granule, respectively. Scale bar = 10 μm.

The gelatinization temperatures of TQ and TRS starch granules with the associated changes in birefringence are presented in Table 2.[20] The TRS starches showed significantly higher gelatinization temperatures than the TQ starch. Among the TRS heterogeneous starches, the individual and elongated starch granules had the lowest and highest gelatinization temperatures, respectively. The TRS interior hollow granules exhibited extremely weak or no birefringence, therefore their gelatinization temperature could not be detected in the present study. The gelatinization temperature of starch is related to a variety of factors including granule morphology and size, amylose content, amylopectin structure, and crystallinity type.[35,36] In high-amylose starches, the amylose double helices and the amylose–lipid complex require a high temperature and energy to disrupt and therefore give rise to a high gelatinization temperature.[37] High-amylose maize starch consists of aggregate and elongated granules. The amylose molecules interact and form antiparallel double helices between the adjacent two subgranules, and the continuous outer layer of these fused granules is composed of more amylose.[21] In the present study, the TRS elongated and aggregate granules had higher gelatinization temperatures than the TRS individual granules, indicating that the elongated and aggregate granules had a higher amylose content and gelatinization resistance than the TRS individual granules. These results agreed with the fluorescence intensity of APTS-stained starch granules (Table 2).

The swelling of granules was investigated continuously in situ at 5 °C intervals from 40 to 85 °C during heating (Figure 4) and was calculated as the sectional area swelling percentage compared with ungelatinized granules at 40 °C in Table 3. Compared with that at 40 °C, the granule size of TQ and TRS starch did not significantly change at 50 °C and the size started to increase above 55 °C. Below 75 °C, the granule swelling was not significantly different between TQ and TRS starches. The swelling of TQ starch granules increased markedly above 75 °C

and was significantly higher than that of the TRS starches. Above 75 °C, the swelling of TRS starch granules exhibited significant differences between heterogeneous granules at the same temperature. The swelling of individual and interior hollow granules was the highest and lowest, respectively. Swelling was not measured above 80 °C for TQ starch and TRS individual starch granules and above 85 °C for TRS aggregate, elongated, and interior hollow starch granules because of the deformation, folding, and disruption of the swollen granules at high temperatures. Amylose is considered to contribute to the inhibition of the water absorption and swelling of starch, whereas amylopectin tends to promote these processes. Owing to the decrease of amylopectin content, in high-amylose starch granules, a small quantity of amylose forms the double helical structure through self-interactions. Furthermore, the amylose double helices and the amylose–lipid complex, which only disrupt at high temperature, will strongly inhibit the swelling of high-amylose starch.[37] During gelatinization, the starch chains interact in the crystalline and amorphous regions of the high-amylose starch granule. The interactions of amylose chains (involving amylose–lipid and amylose–amylose) may result in the formation of new crystallites with varying stability in the amorphous and crystalline regions of the granule. In contrast, the interactions of amylopectin chains do not lead to the formation of new crystallites.[38] It has been reported that swelling power is significantly negatively correlated with the amylose content.[39,40] In the present study, TRS starch had a significantly lower level of granule swelling than TQ starch above 75 °C, which might result from the high amylose content, the high level of amylose–lipid complex chains, and the interactions of amylose chains that formed the most stable new crystallites in TRS starch. The granule swelling showed significant differences between TRS heterogeneous starch granules. The individual and interior hollow granules had the highest and lowest granule swelling, respectively, which might have resulted from significantly different morphology, amylose content, and amylose distribution.

**Spatial Distribution of Heterogeneous Starch Granules in Endosperm.** The combined use of resin semithin sections in which starch is retained within cells and KI/$I_2$ staining is a powerful in situ technique to observe the kernel shape, starch morphology, and spatial distribution of granules in the endosperm. On the basis of the visual examination of transverse sections at the midregion of 10 mature kernels of TQ and TRS, there was a clear difference in the kernel shape, starch granule morphology, and spatial distribution of starch granules in the endosperm between TQ and TRS (Figures 5 and 6). For kernel shape, the thickness of kernel was significantly lower in TRS than in TQ, which agreed with the mature kernel appearance.[6] The sections were stained with iodine so that starch granules were specifically stained blue. The degree of filling of the starch was significantly higher in the TQ endosperm than in the TRS endosperm, resulting in the decrease of kernel weight of TRS.[6]

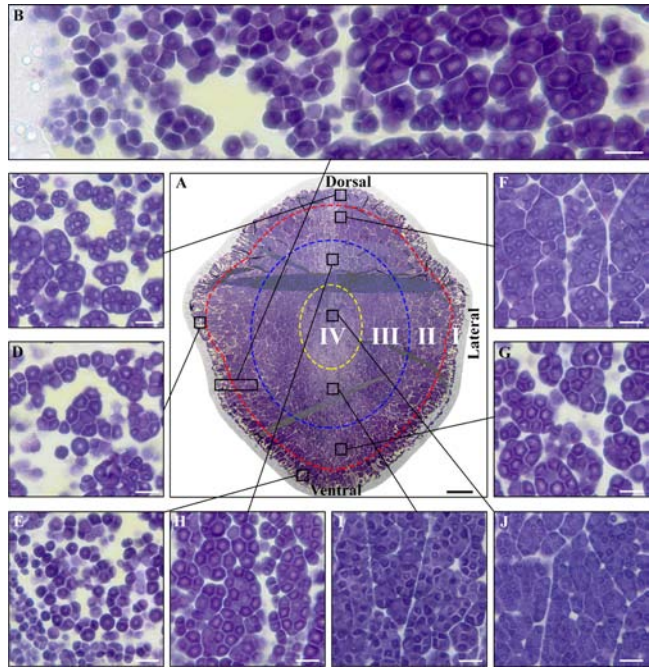

**Figure 5.** Microphotographs of iodine-stained transverse sections at the midregion of TQ mature kernel. (B–J) Showing starch granule morphology in different regions of endosperm. Scale bar = 200 μm for A and 10 μm for B–J.

Regarding the starch granule morphology, TQ showed typical compound starch structure and was homogeneous. The compound starch was composed of many separate subgranules, formed simultaneously within a single amyloplast, but each separate granule had a central hilum (Figure 5). During grain isolation, the compound starch can be ground into separate individual granules. TRS starch showed significant heterogeneity in its morphology as compound, aggregate, elongated, and interior hollow starches. The compound starch can be broken up into individual starch granules, while aggregate granules can remain intact with the surrounding band (Figure 6).

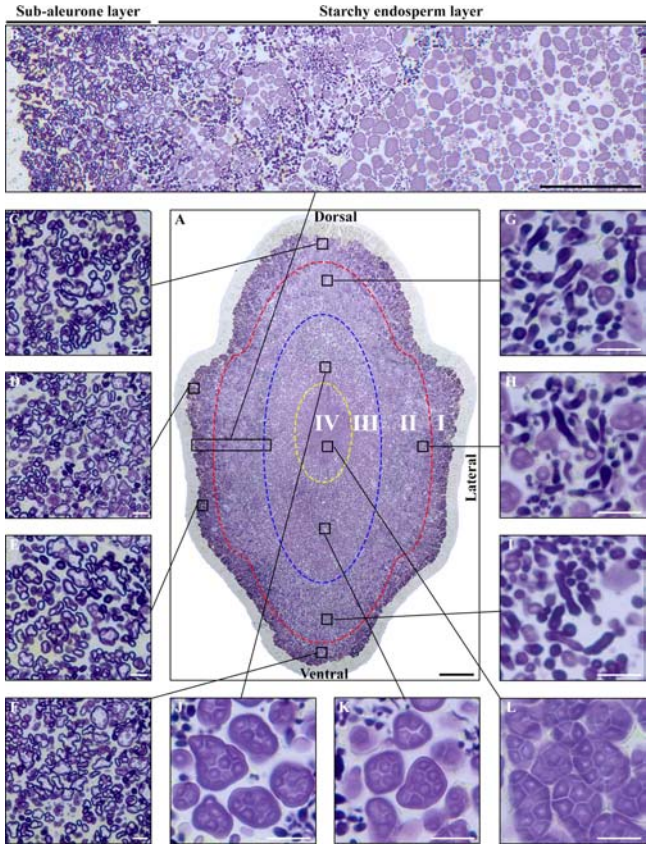

**Figure 6.** Microphotographs of iodine-stained transverse sections at the midregion of TRS mature kernel. (B) Showing the distribution of heterogeneous starch granules in subaleurone layer and starchy endosperm cells, (C–F) showing interior hollow starch granule in region I of endosperm, (G–I) showing elongated starch granule in region II of endosperm, (J, K) showing aggregate starch granule in region III of endosperm, (L) showing individual starch granule in region IV of endosperm. Scale bar = 200 $\mu$m for A, 100 $\mu$m for B, and 10 $\mu$m for C–L.

Regarding the spatial distribution of starch, the compound starch was homogeneously distributed in the whole TQ endosperm, except that the central endosperm cells were packed more tightly than the surrounding endosperm cells (Figure 5). TRS heterogeneous starch granules had a significant regional distribution in the endosperm (Figure 6). The interior hollow starch granules (Figure 6C–F) were mainly distributed in the subaleurone layer (Figure 6, region I), the elongated granules (Figure 6G–I) in the peripheral starchy endosperm cells adjacent to the subaleurone layer (Figure 6, region II), the aggregate granules (Figure 6J,K) in the starchy endosperm cells between the subaleurone layer and the central region of kernel (Figure 6, regions II and III), and the compound starch (Figure 6L) in the central regional of the kernel (Figure 6, region IV).

The spatial distribution of starch granules was mapped within the kernel. The present study suggests that the level of heterogeneity of the TRS starch granules in the endosperm varied remarkably between different regions of the endosperm and became more heterogeneous from the inner to the outer endosperm. The highest level of heterogeneity was observed in the peripheral starchy endosperm adjacent to the subaleurone layer (Figure 6, region II). It is necessary to explain the reason for this spatial distribution of heterogeneous starch granules in the endosperm. In rice, the formation of starch granules starts at the central region of the endosperm and propagates outward to the outer endosperm cells. Consequently, the peripheral endosperm cells are the final parts of the endosperm to be filled with starch granules. This process is completed about 1 month after the initiation of starch granule formation in the central region of the endosperm.[41] This would imply that the greatest level of heterogeneity occurred in TRS starch granules that were deposited late during the development of the kernel, and that the level of heterogeneity was less in granules formed during the early development of the kernel. Cereal storage starches are semicrystalline granules consisting of the two main components: amylose and amylopectin. Their biosynthesis is a complex system involving four classes of enzyme: ADP-glucose pyrophosphorylase, starch synthase, SBE, and starch debranching enzyme. The granule-bound starch synthase is essential for amylose biosynthesis, while amylopectin is synthesized by the combined actions of several isoforms of starch synthase, SBE, and starch debranching enzyme.[42] The SBEs play a pivotal role in amylopectin biosynthesis and occur in cereals in three classes: SBE I, IIa, and IIb.[8] SBE I plays a role in the formation of long chains of amylopectin, SBE IIb generates short chains, and SBE IIa partially, but not fully, supports the functions of SBE I and IIb.[6] The expression of starch-related enzymes varies dramatically between the early and late stages of endosperm development.[43] The granule-bound starch synthase I (GBSS I) is the most important enzyme for amylose biosynthesis in the endosperm. The mRNA of GBSS I increases with the development of rice endosperm,[44] and the activities of both SBE I and IIb are inhibited in the middle and late stages of TRS kernel development.[6] The inhibition of SBE I/IIb not only increases amylose content but also changes the structure of starch granules, leading to a broad population of morphological types. The spatial distribution of heterogeneous starch granules has suggested that the individual granule (compound starch) was synthesized at the early stage of endosperm development, the aggregate and elongated granules at the middle stage, and the interior hollow granules at the late stage. The formation and spatial distribution of these heterogeneous starch granules result from changes in the activities of SBEs during kernel development.

In conclusion, a range of microscopic techniques have been used to observe and characterize the morphology and structure of starch granules isolated from the mature kernels of high-amylose rice (TRS) and its wild-type rice (TQ). The mature kernels have been mapped in situ using light microscopy to identify the spatial distribution of starch granules in the endosperm. These studies have revealed that TQ starch granules were homogeneous in their morphology, structure, and spatial distribution in the endosperm. In contrast, TRS starch showed significant heterogeneity in morphology consisting of individual, aggregate, elongated, and interior hollow granules. The polarization colors of iodine-stained starch granules and fluorescence intensities of APTS-stained starch granules indicated that the individual and interior hollow granules had the lowest and highest amylose contents, respectively, among the TRS heterogeneous starch granules. The results of hot-stage microscopy showed that the individual and interior hollow granules had the lowest and highest resistance to heating, respectively. The kernel sections revealed that the individual granules existed mainly in the middle of the endosperm, the interior hollow granules in the subaleurone layer cells, the elongated granules in the peripheral starchy endosperm cells adjacent to the subaleurone layer, and the

aggregate granules in the starchy endosperm cells between the subaleurone layer and the middle of the endosperm. These results suggest that the morphology and structure of TRS starch granules and their spatial distribution in endosperm were all heterogeneous. This heterogeneity might have resulted during kernel development.

erythrocytes and lower plasma α-tocopherol contents with LC-PUFA enriched formulas.[7,11] Preterm infants are most likely more susceptible to peroxidation, therefore these findings cannot be extrapolated to term infants. Moreover, other studies in preterm infants showed no effect of LC-PUFA enrichment on vitamin E levels or markers of oxidative stress (i.e., total plasma antioxidant capacity (PAC), serum malondialdehyde (MDA), total peroxides and total antioxidant capacity (TAC)).[9,10] Interestingly, even antioxidant effects of n-3 fatty acids or LC-PUFA were reported in preterm infants receiving parenteral nutrition enriched with n-3 LC-PUFA plus added vitamin E, compared to a standard soybean-oil-based lipid emulsion or getting LC-PUFA enriched compared to not-enriched formulas.[8,14]

The aim of this study was to assess the ratio of vitamin E content to estimated need. Our findings were based on the unsatured fatty acid content in a large sample of commercially available formulas on the German market ($n$ = 31 LC-PUFA enriched; $n$ = 29 not LC-PUFA enriched). This ratio was then set as a risk indicator for oxidative damage primarily in the formulas themselves and which, theoretically, might have consequences for the antioxidant status of the infants. For risk assessment, we deemed the whole spectrum of vitamin E as an important antioxidant with respect to the prevention of lipid peroxidation. The whole spectrum of fatty acids (the potential oxidants) was weighed with regard to the number of double bonds, and this represented the estimated vitamin E need.

In addition, to figure out potential differences between LC-PUFA enriched formulas and not enriched formulas, we used breast milk and its ratio of vitamin E content to vitamin E need as a reference.

The present analysis was conducted in the context of the nutritional intervention trial on complementary feeding (i.e., PINGU), which is entitled "Poly unsaturated fatty acids in child nutrition—A German multimodal optimization study".

## MATERIALS AND METHODS

**PINGU Study Design and Milk Sampling.** The current investigation is part of the PINGU-study, a double-blinded randomized controlled intervention trial conducted in 2010—2013 in the region of Dortmund, Germany. The primary objective of PINGU was to examine the effects of an optimization of the n-3 PUFA supply in commercial complementary food via rapeseed oil rich in ALA, the precursor of endogenous DHA synthesis, or DHA-rich fish (salmon) on infant DHA status and functional outcomes in the second 6 months of life. The PINGU study was partially double blinded; that is, in the corn oil (control) and rapeseed oil group, the affiliation was blinded, whereas the ingredient fish can be identified olfactorily.[15]

In total, 214 women (median age: 33 yrs) and their infants were enrolled, of which 205 kept the first study appointment (T0) at the end of the child's eighth week of life. The aim was to mirror the early period of exclusively milk feeding. T0 appointments took place from June 2011 to January 2013. From the age of 8 weeks onward, infants' nutrition was assessed by daily weighed dietary records kept by mothers who also collected formula packages. Nine formula brands were reported to be used. Upon request, producers provided product samples of almost their entire assortments of formulas for term infants offered on the German market. A total of $n$ = 60 different formula were supplied, of which $n$ = 31 were LC-PUFA enriched (FM(+)) and $n$ = 29 were not LC-PUFA enriched (FM(−)).

Exclusively and partially breastfeeding mothers ($n$ = 150) were instructed to take three milk samples during one nursing (at the beginning, in the middle, and at the end; 2—3 mL at each point) on the day before the T0 appointment. They then stored the samples in their household freezer overnight before transporting them on ice to the FKE. Samples were stored at −80 °C and shipped on dry ice for further analyses (fatty acids: Dr. von Hauner'sches Kinderspital, Ludwig-Maximilians-University Munich, Germany; vitamin E: Institute of Nutrition, Friedrich Schiller University Jena, Jena, Germany). Valid analyses of both fatty acids and vitamin E were available in 118 breast milk (BM) samples.

**Chemicals.** For fatty acid analysis: The standard mixture of fatty acid methyl esters was provided by GLC569, Nuchek (Elysian, U.S.A.). Methanolic hydrogen chloride (HCl) was purchased from Sigma-Aldrich (Deisenhofen, Germany) and diluted with methanol from J.T Baker (via CLN, Freising, Germany) (0.6 M). Hexan was also provided by J.T. Baker (via CLN, Freising, Germany). Butylated hydroxytoluene was purchased from Fluka (Deisenhofen, Germany) and tripentadecanoin was provided by Avanti Polar Lipids (Alabaster, U.S.A.).

For vitamin E analysis: Stock solutions of α-, β-, γ-, δ-tocopherol were obtained from Calbiochem, Merck (Darmstadt, Germany) ($c$ = 1 mg/mL), α-, β-, γ-, δ-tocotrienol were from Davos Life Sciences (Singapore, Singapore) ($c$ = 1 mg/mL) and α-tocopherol acetate was from Sigma-Aldrich (Taufkirchen, Germany) ($c$ = 2 mg/mL). Absolute ethanol was purchased from Merck KGaA (Darmstadt, Germany) and $n$-hexane from VWR International GmbH (Darmstadt, Germany). Methyl-*tert*-butyl ether was provided by Th. Geyer GmbH & Co KG (Renningen, Germany).

**Fatty Acid Analysis.** The procedure for milk fatty acid analysis was adapted from the method described by Lepage and Roy for various matrices.[16] Mixtures of BM (a combination of equal measures of fore milk and hind milk) as well as ready-to-feed solutions of formulas were prepared by shaking at room temperature. Twenty microliters of the prepared samples was then transferred into a 4 mL brown glass vial and dissolved in a mixture of 1.9 mL methanolic HCl (0.6 M) and 0.3 mL hexane (containing 200 mg/L butylated hydroxytoluene and 104 mg/L tripentadecanoin as radical scavenger and internal standard, respectively).

The closed vial was heated to 100 °C for 60 min to transfer fatty acids into their methyl esters. After cooling, 0.5 mL water was added, and after mixing, the reaction vial was centrifuged (5 min, 1500 g) to achieve separation between a lower methanol/water phase and an upper hexane phase containing the methyl esters. A 0.1 mL aliquot of the hexane phase was diluted with 0.5 mL hexane and stored at −20 °C until gas chromatographic analysis. For gas chromatography (GC), an Agilent 7890 GC (Agilent, Waldbronn, Germany) equipped with a programmable temperature vaporizer (Gerstel, Mühlhein, Germany), a BPX-70 column (length 50 m, inner diameter 0.25 mm, SGE, Milton Keynes, U.K.), and a flame ionization detector was used. The gas chromatograph was operated under Agilent ChemStation Rev B.04 software, which was also used for chromatographic data evaluation. The injection volume and injector temperature were set to 3 μL and 30 °C, respectively. The sample was vaporized by increasing the injector temperature to 300 °C at a rate of 12°/s. The temperature program of the gas

Table 1. $\alpha$-D-Tocopherol Equivalent Calculation[13,15]

| | | milk type | | |

x = included, n. c. = not contained, d. l. = detection limit. [a]Allowed vitamin E isomers in formulas.

chromatography started at 50 °C and increased after a 0.5 min delay with a rate of 40°/min to 150 °C, 6°/min to 180 °C, and 1.8°/min to 215 °C. The initial flow of the carrier gas, helium, was set to 1.5 mL/min. After 23 min of chromatography, the flow was increased to 1.7 mL/min.

Fatty acid methyl esters were identified by comparing retention times of sample peaks with the retention times of a methyl ester standard mixture. This standard was also used to determine response factors of individual fatty acids relative to pentadecanoic acid methyl ester. The experimental setup enabled estimation of the fat content (weight/volume) by summation of the analyzed fatty acids and determination of percentage contributions (% weight/weight) of fatty acids with chain lengths from 8 to 24 carbon atoms to total milk fatty acids.

**Vitamin E Analysis.** Simultaneously, we determined $\alpha$-tocopherol acetate, tocopherols, and tocotrienols from breast milk and infant formulas. The second human milk sample collected (in the middle of one nursing) was used for vitamin E analyses by HPLC (high-performance liquid chromatography) according to the modified method reported by Moltó-Puigmartí et al.[17] After thawing the breast milk samples in a water bath at 30 °C and homogenization in an ultrasonic bath for 1 min, 100 $\mu$L of ethanolic solution containing $\alpha$-tocopherol acetate (0.1 mg/mL) was added as internal standard to 500 $\mu$L of milk. Absolute ethanol (1000 $\mu$L) was added for deproteinization. After vortexing for 1 min, samples were left to rest for 10 min and then mixed with 1000 $\mu$L of *n*-hexane, followed by another 5 min incubation, and again 1 min of vortex-mixing. After centrifugation for 5 min (3700g) at room temperature, the hexanoic layer was removed. The remaining lower layer was extracted again twice. The combined extracts were evaporated under nitrogen at 30 °C until dry. The residue was then resuspended in 500 $\mu$L *n*-hexane/methyl-*tert*-butyl ether (98 + 2 v/m), vortex-mixed for 30 s, and centrifuged (14 000 rpm) at room temperature 2 min. An aliquot of this solution (150 $\mu$L) was transferred into an amber vial, and 20 $\mu$L was injected into the HPLC system.

For infant formula analysis, 500 $\mu$L of the formula prepared as ready-to-feed was used following the analogous procedure as for breast milk. The following steps were different to the breast milk preparation: the extraction was conducted only once; the residue was redissolved in 1000 $\mu$L *n*-hexane/methyl-*tert*-butyl ether (98 + 2 v/m). As the internal standard $\alpha$-tocopherol acetate (used for breast milk) is a common food additive in formulas, in these cases, $\alpha$-tocopherol acetate was measured separately assuming a loss of 3% and then used as an additive internal standard in the main measurement.

HPLC was performed according to a procedure modified from that of Balz et al. with a normal phase HPLC column, Eurospher 100 DIOL; 250 × 4.0 mm; 5 $\mu$m (Knauer, Berlin, Germany), and *n*-hexane/methyl-*tert*-butyl ether (98 + 2 v/m) as mobile phase (isocratic).[18] The vitamin E forms are eluted in the order: $\alpha$-tocopherol acetate, $\alpha$-tocopherol, $\alpha$-tocotrienol, $\beta$-tocopherol, $\gamma$-tocopherol, $\beta$-tocotrienol, $\gamma$-tocotrienol, $\delta$-tocopherol, and $\delta$-tocotrienol. The temperature and flow were set at 35 °C and 1.5 mL/min, respectively. The whole separation procedure took 45 min. For fluorescence detection (Merck-Hitachi, Darmstadt, Germany), the wavelengths $\lambda_{EX}$ = 292 nm and $\lambda_{EM}$ = 330 nm were used. A triple determination was conducted.

For vitamin E quantification, five dilutions of stock solutions of $\alpha$-, $\beta$-, $\gamma$-, $\delta$-tocopherol, $\alpha$-, $\beta$-, $\gamma$-, $\delta$-tocotrienol ($c$ = 1 mg/mL) and $\alpha$-tocopherol acetate (c = 2 mg/mL) were prepared to obtain the calibration curves. Dilutions ranged from 1:100 for $\alpha$-tocopherol acetate to 1:20 000 for $\delta$-tocotrienol. The mean recovery rate was 87% in breast milk and 92% in formulas.

The limits of detection (LOD) ranged from 0.28 $\mu$g of $\alpha$-tocopherol in 100 mL of breast milk to 6.01 $\mu$g of $\alpha$-tocopherol acetate in 100 mL of formula. The limit of quantification (LOQ) amounted to 3.3-fold of the respective LOD values.

**Pentaenoic Fatty Acid Equivalents (PE) and Arachidonic Acid Equivalents (AE).** It is suggested that the vitamin E demand to protect fatty acids from oxidation is related to their degree of unsaturation, that is, 0.06, 0.4, 0.6, 0.8, 1.0, 1.2 mg of $\alpha$-D-tocopherol equivalents ($\alpha$-TE) per gram of monoenoic, dienoic, trienoic, tetraenoic, pentaenoic, and hexaenoic fatty acids, respectively.[19,20] As 1 mg $\alpha$-TE is required for 1 g pentaenoic fatty acids, we calculated "pentaenoic fatty acid equivalents" (PE) on the basis of the whole analyzed fatty acid spectrum to express the individual oxidative potential of formula and breast milk samples.

The Commission Directive 2006/141/EC on infant formulas and follow-on formulas and amending Directive 1999/21/EC stated a calculation for an optimal $\alpha$-TE/unsaturated fatty acid ratio based on the main polyunsaturated fatty acids: 0.5, 0.75, 1.0, 1.25, and 1.5 mg $\alpha$-TE per g linoleic (18:2 n-6), $\alpha$-linolenic (18:3 n-3), arachidonic (20:4 n-6), eicosapentaenoic (20:5 n-3), and docosahexaenoic acid (22:6 n-3) respectively.[2] We refer to the results of this approach to calculating vitamin E needs as "arachidonic acid equivalents (AE)".

**α-D-Tocopherol Equivalents (α-TE).** In accordance with the conversion factors of the German Nutrition Society (DGE), we expressed vitamin E activity of the vitamin E isomers as α-D-tocopherol equivalent (α-TE).[19] Each of the analyzed formulas contained added vitamin E. Four forms are allowed by law: 2 α-tocopherol forms (α-**D**-tocopherol—also naturally occurring, e.g., in plant oils—and α-**D,L**-(= *all-rac)* tocopherol) and 2 α-tocopherol **acetate** forms (α-**D**-tocopherol acetate and α-**D,L**-(= *all-rac)* tocopherol acetate).[2] As the list of ingredients provided no information about the exact vitamin E variants and our method of vitamin E analysis allowed no distinction between D- and D,L-isomers, we calculated two scenarios on the basis of the different antioxidant activities of the vitamin E isomers. The naturally occurring α-D-forms (RRR) have higher biological activity than the *all-rac* forms. This is because gut absorption of naturally occurring α-D-forms is highest among all eight possible isomers resulting from the three chiralic C-atoms. In contrast, the *all-rac* forms are a racemic mixture of all eight possible isomers in equimolar concentrations.[21,22] Scenario 1 (best antioxidant scenario) included α-D-tocopherol acetate and α-D-tocopherol, scenario 2 (worst antioxidant scenario) included the *all-rac* forms (α-D,L-tocopherol acetate and α-D,L-tocopherol) (see Table 1). Conversion factors of the *all-rac* forms were taken from Belitz et al. 2001.[23]

**Statistical Analysis.** All statistical tests were performed using SAS procedures (version 9.2, Statistical Analysis Systems, Cary, NC, U.S.A.). As most variables were not normally distributed, Wilcoxon tests were generally used to identify differences between LC-PUFA-enriched formulas (FM(+)) and standard formulas (FM(−)), between FM(+) and breast milk (BM) and between FM(−) and BM concerning the three topics: fatty acid composition, vitamin E content, and α-TE/unsaturated fatty acid index ratios.

## RESULTS AND DISCUSSION

**Formulas and Mothers' Characteristics.** The formulas tested comprised a balanced proportion of infant formulas and follow-on formulas, and of LC-PUFA enriched ($n$ = 31) and not enriched ($n$ = 29) formulas (Figure 1). Infant formulas were more often LC-PUFA enriched than follow-on formulas, using fish oil and, in 8 cases, also fungal oil (*Mortierella alpine*).

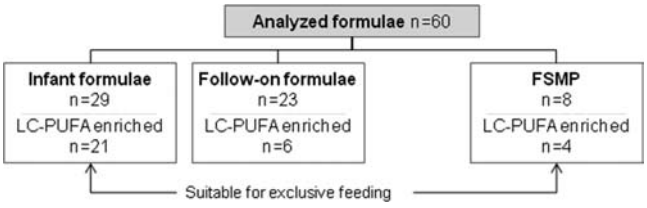

**Figure 1.** Specification of the analyzed formulas ($n$ = 60), LC-PUFA = long chain polyunsaturated fatty acids, FSMP = foods for special medical purposes (e.g., in the case of diarrhea).

Maternal characteristics of PINGU participants, of which breast milk samples were available and analyzed ($n$ = 118), are shown in Table 2.

**Unsaturated Fatty Acid Equivalents (PE, AE) and Fatty Acids Profile.** Interestingly, our results showed that PE and AE (i.e., the calculated relative vitamin E need) did not differ between FM(+) and FM(−) (Table 3), although one might assume higher values resulting from use of fish and fungal oil in the recipes for FM(+) by the producers. This finding can be explained by our consideration of the whole fatty acid profile. In fact, n-3 LC-PUFA (i.e., EPA and DHA) were markedly higher in FM(+), but total n-3 PUFA was only moderately higher, because ALA, the main n-3 fatty acid, was similar in both kinds of formulas. Similarly applicable for n-6 fatty acids, FM(+) showed higher values of n-6 LC-PUFA (AA in particular (Table 3)) but lower total n-6 PUFA values as a result of lower LA values (the main n-6 fatty acid in formulas). Thus, total PUFA tends to be higher in FM(−) (which is significant for percentage values). Total fatty acids, SFA, and MUFA contents, indeed, did not differ between FM(+) and FM(−).

**Table 2. Maternal Characteristics of PINGU Participants of Which Breast Milk Samples Were Available and Analyzed ($n$ = 118)**

| maternal characteristic | mean | SD |
|---|---|---|
| age (years) | 33 | 5 |
| gestational age (weeks) | 40 | 4 |
| body mass index ($n$ = 117, 2 months *pp*) | 26 | 5 |
| primiparous (%, yes/no) | 57/43 | |
| university entrance diploma (%, yes/no) | 59/41 | |
| SES (%, low/medium/high, $n$ = 113)[a] | 3/34/64 | |
| smoker (%, yes/no)[b] | 5/95 | |

[a]SES = Socioeconomic status, defined according to maternal level of school education, maternal level of professional education, and household income before pregnancy. [b]At least 1 cigarette/d.

In BM, higher values for SFA and lower values for both n-6 and n-3 PUFA, LA, and ALA were found than in FM(+) or FM(−) (Table 3). In contrast, the sums of n-6 LC-PUFA and n-3 LC-PUFA were markedly higher in BM, which was only partly explained by differences in AA and EPA. DHA values were similar in FM(+) and BM. Main reason for differences in LC-PUFA was the contribution of further LC-PUFA in BM, for example, 20:3 n-6 LC-PUFA and 22:5 n-3 LC-PUFA (data not shown). Ratios of LA/ALA were lower in both types of formulas compared with BM, the ratio of n-6/n-3 PUFA of BM was located in between the two types of formulas, and n-6/n-3 LC-PUFA ratio was similar in FM(−) and BM, and about twice as high as in FM(+). PE and AE were generally higher in both of the FM types than in BM (Table 3).

**α-Tocopherol Equivalents (α-TE) and Vitamin E Profile.** FM(−) showed higher α-TE and total vitamin E (sum of all vitamers) values than FM(+) in both vitamin E scenarios (Table 4), that is, even when assuming exclusively the *all-rac* vitamin E forms were used for supplementation. Obviously, and in contrast to what could be expected, producers used less α-tocopherol acetate on average in their recipes for FM(+) than for FM(−). However, the amounts of vitamin E content in all formulas were in accordance with the European legislation. Nonetheless, most analyzed values were below the values indicated by label declaration.[2]

Formulas contained the whole spectrum of naturally occurring vitamin E forms (Table 4) (predominantly α- and γ-tocopherol), without differences between FM(+) and FM(−). In BM, only tocopherols were detected—mainly α-tocopherol—in similar proportions as in FM. Compared to BM, both formulas showed markedly higher vitamin E contents caused by the supplementation with the synthetic α-tocopherol acetate.

In fact, BM as a natural "product" is individually composed and depends on the mother's diet. Although no clear

association exists between the vitamin E content of maternal nutrition and vitamin E content of BM, there is at least evidence for the roles of fat quantity and quality of mothers' diets on BM.[24−27]

Published data on analyzed vitamin E contents in commercially available infant formulas in Europe are scarce, and reported values differ between studies (Table 5).[26,28,29] Our results were in the range reported by Balz et al., Martysiak-Zurowska et al., Chavez-Servin et al., and Miquel et al.[18,26,28,30] Lower values reported by Sziklai-Lásló et al. 2009 might have resulted from not considering the added α-tocopherol acetate.[29] Kaempf-Rotzoll et al. observed higher values of vitamin E in preterm formulas.[14] In agreement with our results, all studies except one (Sziklai-Lásló et al. 2009) found higher α-TE in formulas than in human milk (Table 5).

**α-Tocopherol Equivalent/Unsaturated Fatty Acids Index Ratios (α-TE/PE, α-TE/AE).** According to absolute fatty acid concentration analysis (mg/100 mL), α-TE/PE and α-TE/AE (i.e., the ratios between vitamin E content and need of individual products) ranged from 1.6 to 4.3 (mean value of 2.8 in Table 6) and 1.6 to 4.7 (mean value of 3.0 in Table 6), respectively, in FM(+) in scenario 1 (assuming the high vitamin E values). Similar values were calculated for FM(−), excluding one upper outlier (α-TE/PE: 7.6, α-TE/AE: 8.0). As expected, the ratios were lower in scenario 2 (Table 6), but still above 1. In other words, vitamin E content was higher than the estimated relative vitamin E need in all formulas, and as such, were in accordance with legal regulations.[2] Based on absolute FA amounts, α-TE/PE and α-TE/AE did not differ between FM(+) and FM(−). However, using relative (%-) values for the unsaturated fatty acids, α-TE/PE and α-TE/AE tended to be higher in FM(−) ($0.1 > p > 0.05$) (Table 6).

In BM, α-TE/PE and α-TE/AE showed a wider interindividual variability, ranging from 0.7 to 11.32 (mean value of 2.5 in Table 5) and 0.9 to 14.5 (mean value of 3.5 in Table 6) respectively, including five upper outliers. However, the highest values within the normal range (i.e., within the whiskers) were 5.0 and 6.4.

The comparison of FM with BM showed inconsistent results. When BM was used as the reference, FM(−) showed (in both vitamin E scenarios) similar or higher vitamin E need to vitamin E content ratios than BM. This applied also for FM(+) compared to BM, except for the calculation with arachidonic acid equivalents (AE) in scenario 2 where BM showed higher vitamin E need to vitamin E content ratios than FM(+).

There are no generally agreed upon approaches to calculate an adequate ratio of α-tocopherol equivalents relative to unsaturated fatty acid contents in infant formulas. A simplified parameter to assess antioxidant protection is the vitamin E/PUFA ratio, irrespective of PUFA composition.[6] Based on manufacturers' data, values of 6.6 and 3.92 mg vitamin E/g PUFA in LC-PUFA enriched and not-enriched formulas, respectively, and in another study, 2.8 mg vitamin E/g PUFA for both kinds of formulas were stated.[11,12] Calculation of this ratio (i.e., vitamin E as α-tocopherol equivalents, see "α-TE" in Table 4; and PUFA as sum of all PUFA without consideration of the degree of unsaturation, see "total PUFA" in Table 3) in our formulas samples resulted in mean values of 1.24 (range 0.67−1.92) in FM(+) and 1.39 (0.57−3.21), in FM(−), when the worst α-TE calculation was used (scenario 2). However, excepting 4 formulas in scenario 2 (2 formulas in scenario 1 with higher vitamin E values), all samples were in line with the ESPGHAN recommendation of at least 0.9 mg vitamin E/g PUFA.[6] Kaempf-Rotzoll et al. observed that the ratio of total tocopherol to fatty acid double bonds did not differ between LC-PUFA enriched and not-enriched formulas but were markedly higher than in BM.[14]

**Strengths and Limitations.** Our study analyzed the vitamin E and unsaturated fatty acid content in a large sample of commercial infant and follow-on formulas. The relative vitamin E need to prevent lipid peroxidation could only be calculated based on two models proposed by the current European food legislation (AE) or the whole fatty acid spectrum (PE).[2,19] A further limitation is the lack of consensus with respect to conversion factors for calculation of alpha tocopherol equivalents.[19,23,31] Moreover, the label declaration on formula packages did not reveal which one of the four vitamin E forms permitted by EU legislation was added, and in which proportions. Therefore, we calculated a lowest and a highest value scenario to reflect a possible range.

Regarding our analytical methods, the calculation of total fat contents from fatty acid analysis is expected to underestimate fat content by about 5% because glycerol and other lipid components such as cholesterol are not included. This may contribute to the observed lower mean fat contents calculated from our analyses (2.7 g/100 mL) as compared to label declarations (3.3 g/100 mL).

Breast milk analysis was based on a mixed sample of fore and hind milk, while vitamin E was analyzed in a milk sample from the midpoint of nursing. We assume that the fat content of the mixture of fore and hind milk would be representative of the

midpoint milk sample given that milk fat content increases from fore to hind milk.[32] However, a certain range of variation needs to be considered.

Our results indicate an adequate vitamin E content relative to unsaturated fatty acid content in present-day commercial infant and follow-on formulas. On average, the vitamin E content was more than twice as high as the estimated vitamin E need (based on absolute fatty acid values). Our findings show that breast milk tends to contain higher ratios of vitamin E to unsaturated fatty acids than LC-PUFA-enriched formulas (at least in a worst-case scenario). Therefore, the potential effects of increasing vitamin E content in LC-PUFA enriched formulas should be explored in further investigations concerning composition of relevant ingredients in infant formulas.

a prototype designed in the Lima University laboratories, which consists of a cylinder with holes of 1/16 in. in which the seeds were loaded and then pressed by a piston actuated by a hydraulic system assisted by a motor of 1 horsepower (HP). An average amount of 2 kg of shelled seeds was used for each sample in order to obtain enough oil for complete characterization. After the extraction the oil was filtered with a centrifugal filter (30 min, 3600 rpm). Crude oil samples were stored in dark bottles at 4 °C until analysis.

**Reagents and Solutions.** Acetone, diethyl ether, hexane, propionitrile, and THF were supplied by VWR International (West Chester, PA, USA). The Si-SPE cartridges were from Varian (EA Middelburg, The Netherlands). Standards of 5-$\alpha$-cholestan-3$\beta$-ol and trilinolenin (LnLnLn) were from Sigma-Adrich Co. (St. Louis, MO, USA). Hexamethyldisilazane, pyridine, trimethylchloroxilane, and standards of eicosane and tocopherols were from Merck-España (Merck Group, Darmstadt, Germany). All chemical reagents were analytical grade.

**Physical−Chemical Determinations.** The physical−chemical parameters included in the current legislation for Sacha inchi oils and other regulations for other edible oils were determined in the crude oils.[10]

*Free Fatty Acids and Peroxide Values.* AOCS Official Methods were followed to determine FFA and peroxide indexes.[15,16]

*UV Evaluation.* Specific extinction at 270 nm (K270) was evaluated according to the European Union Standard Methods.[17]

*Oxidative Stability.* The induction time was evaluated using a Rancimat equipment (743 Rancimat Metrohm Co., Basel, Switzerland), following the standard Official Method Cd 12-b-92,[18,19] with an air flow of 20 L·h$^{-1}$ and 100 ± 1 °C.

*Other Physical Parameters.* Parameters such as viscosity and density were measured using a Stabinger SVM 3000 viscometer (Anton Paar GmbH Graz, Austria). The refractive index was determined with a temperature-controlled Abbe refractometer (Hilger & Watts Ltd., London, U.K.).[3,20]

**Major Components.** *Triacylglycerol Composition.* The TG composition was obtained as follows: oil samples at a concentration of 50 mg·mL$^{-1}$ in acetone were analyzed by RP-HPLC. The separations were done on a Merck Li-Chrospher 100 RP-18 column (250 mm × 4 mm i.d.; 4 $\mu$m particle size) thermostated at 20 °C. The liquid chromatograph (Beckman-Coulter, Fullerton, CA, USA) was equipped with a pumping unit (118 solvent module) and used propionitrile as the mobile phase at a flow rate of 0.6 mL·min$^{-1}$. Oil solutions in acetone (10 $\mu$L) were injected using an autosampler (508 system). Detection was done with a PerkinElmer 200 RI detector.[21]

*Polar Glyceridic Compounds.* PC were assessed with small modifications of the already published method, by separating the oils in two fractions by Si-SPE using 1 g cartridges.[22,23] Thus, 200 mg of oil samples were weighed in 10 mL volumetric flasks and dissolved in hexane. On each case an aliquot of this solution (2 mL) was introduced into the cartridge and then eluted with 15 mL of the hexane:diethyl ether 87:13 (v/v) admixture. The fraction containing the nonaltered TG was rejected. A second fraction was collected eluting with 15 mL of diethyl ether. The latter fraction was evaporated until dryness, re-dissolved in 1 mL of THF and injected onto the HPLC (Hewlett-Packard 1050 series). The HPSEC system is equipped with an Agilent PL gel of 5 $\mu$m, a 100 Å column, and a Merck La Chrom RI Detector L-7490. THF was used as eluent at a flow rate of 0.7 mL·min$^{-1}$. The injection volume was 20 $\mu$L. The compounds eluted from the columns according to their molecular size, so those with the largest molecular sizes were eluted earlier and were quantified as individual percentages of the total eluted compounds and also as absolute quantities using an external standard of pure TG in THF at concentrations of 5−10 mg·mL$^{-1}$.

*Fatty Acid Composition.* The FFA composition was determined as the composition of FAME by GC after transesterification of the oils with 2 N KOH in methanol, according to the IUPAC Standard Method.[20,24] The chromatographic analysis was done using an Agilent 5890 GC system (Palo Alto, CA, USA) equipped with a split injector (1:50 split ratio), a polar capillary column (poly(90% biscyanopropyl−10% cyanopropylphenyl)siloxane, 60 m × 0.25 mm i.d.; 0.20 $\mu$m film thickness) and a FID. Hydrogen was used as the carrier gas at a flow rate of 1.0 mL·min$^{-1}$. The detector and injector temperatures were 225 and 250 °C, respectively. The initial oven temperature was 180 °C, and a temperature gradient from 180 to 220 °C at 3 °C min$^{-1}$ was applied. Injections of 1 $\mu$L each were performed automatically.

**Minor Unsaponifiable Compounds.** The percentage of the total unsaponifiable fraction was calculated gravimetrically after subjecting the oil samples to a saponification procedure carried out according to the IUPAC 2401 Official Method.[25]

*Tocopherols.* Tocopherols were determined according to the IUPAC Standard Method 2432.[26] An oil solution in hexane at a concentration of 10 mg·mL$^{-1}$ was prepared and analyzed by HPLC fitted with a Si-column (250 mm × 4 mm i.d.; 4 $\mu$m particle size). The elution solvent was a hexane:2-propanol (99:1, v/v) mixture at a flow rate of 1 mL·min$^{-1}$. Detection was done by fluorescence (RF-10AXL Shimadzu fluorescence detector), setting excitation and emission at $\lambda$ = 290 and $\lambda$ = 330 nm, respectively. For quantitative determinations standards of tocopherols in hexane at concentrations of 4−6 $\mu$g·mL$^{-1}$ were prepared and injected.

*Sterol Composition.* The sterol fraction was isolated from the unsaponifiable matter by silica TLC using plates impregnated with potassium hydroxide with the purpose of retaining the remaining saponified compounds. The plate was developed twice with a mixture of petroleum ether:diethyl ether (87:13, v/v). The isolated fraction was scratched off and extracted with hot chloroform and diethyl ether. The solution was evaporated until dryness, derivatized with 500 $\mu$L of the 1:3:9 (v/v/v) trimethylchloroxilane:hexamethyldisilazane:pyridine admixture and analyzed by GC. The gas chromatograph (Agilent 6890N) was equipped with a fused silica low-polarity capillary column (poly(5% diphenyl−95% dimethyl)siloxane, 30 m × 0.25 mm i.d. × 0.25 $\mu$m film thickness), and FID. The oven program was isothermal at 260 °C with a split ratio of 1:50. Hydrogen was used as carrier gas at a flow rate of 1 mL·min$^{-1}$. The temperatures of the injector and detector were 300 °C. The quantitative determination was done using $\alpha$-cholestanol as internal standard.

*Aliphatic Saturated Hydrocarbons.* HC were isolated by low-pressure column chromatography filled with 15 g of silica gel (Si-60) impregnated with $AgNO_3$.[27] A sample of 0.5 g of oil was introduced into the column, and the fraction containing the aliphatic hydrocarbons was eluted with 80 mL of petroleum ether. This fraction was evaporated until dryness, re-dissolved in 0.5 mL of hexane, and analyzed by GC. The gas chromatograph was equipped with a low-polarity capillary column (poly-5% diphenyl−95% dimethylsiloxane, 12 m × 0.32 mm i.d. × 0.1 $\mu$m film thickness) and an on-column injection

[a]Data are the average of 14 samples and are expressed as the mean ± SD. The same letter (a) represents no significant differences.

system. The initial oven temperature was set at 80 °C for 2 min, and the rate was established at 12 °C·min$^{-1}$ up to 280 °C, then at 7 °C·min$^{-1}$, and then up to 340 °C. The injector temperature was 80 °C and was allowed to follow the oven temperature program. The FID temperature was 350 °C. Eicosane (C20:0) at a concentration of 0.05 mg·mL$^{-1}$ was used as internal standard.

*Statistical Analysis.* Each sample was analyzed in triplicate, and data were presented as the average of the 14 data obtained in each crop. The statistical analyses were run using the GraphPad Prism version 5.01 for Windows software. The crops were compared by ANOVA. When significance was observed, the Tukey test was applied. Significant differences ($p > 0.05$) are specified with different letters.

## RESULTS AND DISCUSSION

**Oil Yield.** Compared to Sacha inchi *P. volubilis*, currently the most widely used cultivar for oil extraction and commercialization, the *P. huayllabambana* species is almost twice its size (1.7−4.1 cm$^3$ vs 4.1−8.0 cm$^3$) and weight, having an oil yield after pressing and filtration in the range of 30.3−41.2% with respect to the shelled seeds.

**Analytical Indexes and Oxidative Stability.** The values of the indexes commonly used to evaluate the initial quality of vegetable oils, i.e., FA, PV, and $K_{270}$, were found within the expected ranges for crude oils of good quality, with some remarkable exceptions. Regulation for extra virgin and virgin Sacha inchi oils establishes a maximum of 1.0 and 2.0 (expressed as a percent of oleic acid) of FA, respectively. Table 1 shows the results of the quality parameters, and it can be observed that the average value obtained for the 28 oil

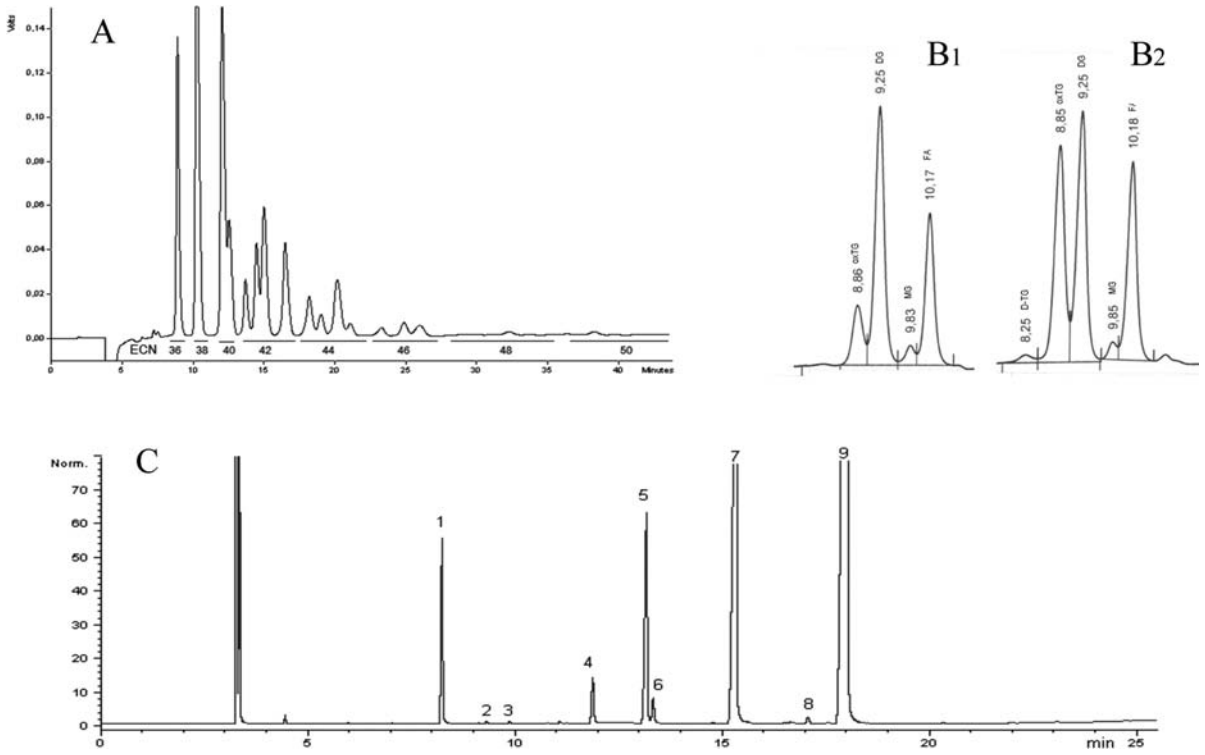

**Figure 1.** Chromatogram profiles of the major compounds of Sacha inchi *P. huayllabambana* oils, where panels are described as follows: (A) HPLC-RI of triglycerides with ECN 36−50; (B1 and B2) HPSEC-RI of polar compounds and dimers of tryglicerides (D-TG), oxidized triglycerides (oxTG), diglycerides (DG), monoglycerides (MG), free fatty acids (FFA); (C) HRGC of FA for (1) palmitic C16:0, (2) palmitoleic C16:1, (3) margaric C17:0, (4) estearic C18:0; (5) oleic $\omega$9-C18:1, (6) vacenic $\omega$7-C18:1, (7) linoleic $\omega$6-C18:2, (8) arachidic C20:0, and (9) linolenic $\omega$3-C18:3 acids.

samples from the two harvests under study is within the established ranges for virgin oils. Half of the samples can be classified as extra virgin, 29% as virgin, and 21% are neither extra virgin nor virgin oils. These results are indicating that Sacha inchi *P. huayllabambana* seeds are highly susceptible to hydrolysis, yielding oils with acidity over the established limits. The high hydrolyzation level showed is not an exclusive characteristic of *P. huayllabambana* oil samples. Actually some published data on *P. volubilis* also present acidity values over the limits established in the regulations.[28,29]

Regarding the oxidation state of the oils, the mean values were shown to be within the limits included in the regulations, although three of the samples overpassed the 10 meq $O_2 \cdot kg^{-1}$ maximum established in the NTP.

Concerning the absorbance at 270 nm, there is not a limit established in the NTP Regulation. Olive oil regulation includes a limit of 0.22 for extra virgin and 0.25 for virgin olive oils. The results on the analyzed Sacha inchi oils drove us to categorize a high number of samples (24) as extra virgin, and 3 as virgin, whereas only one dropped out of both categories.

Most of the PV data reported for *P. huayllabambana* were within the limits established by the regulations. It can be observed that some of the samples from the first harvest yielded oils with PV over the limit, but that the oils obtained from the second harvest showed a significantly lower value, which means lower oxidation level, undoubtedly due to a more suitable storage period in the second repetition of the study. Nevertheless their absorbance at 270 nm is higher, although with no meaningful differences.

The oxidative stability determined by Rancimat gave IP of 2.0−3.4 h, at 100 °C. These values are rather low compared to those of other edible oils such as olive or sunflower oils, but they are similar or even higher than those of oils with similar unsaturation level, such as safflower or flax oils.[30] No significant differences are found between the two harvests under study.

We have to consider that these oils were obtained from raw seeds. In the case of carrying out a previous seed roasted process, an increase of the oil stability is to be expected, as occurred with argan seeds.[2,3] These kinds of processes have been recently carried out with Sacha inchi (*P. volubilis*).[31]

Density, refractive index, and viscosity are physical parameters determined to differentiate and to characterize the oils and mainly are used for commercial purposes. The density values at 20 °C were in the 0.920−0.930 $g \cdot cm^{-3}$ range and were within the requirements of the NTP. These values are slightly higher than those reported at the same temperature for other vegetable oils such as sunflower or olive (0.898−0.906).[3]

The refractive index at 20 °C for the first harvest ranged from 1.480 to 1.482 and is within the ranges set in the NTP. For the second harvest the average of the 14 samples under study was over the limit established in the NTP. These results were also higher than those reported for other vegetable oils (1.461 to 1.474).[32]

The kinematic viscosity data at 20 °C were in the 38.9−44.0 $mm^2 \cdot s^{-1}$ range, the averages being 42.8 and 41.1 $mm^2 \cdot s^{-1}$ for the first and second harvests, respectively. These values are higher than those reported at the same temperature for *P. volubilis*.[8]

**Major Saponifiable Compounds.** *Triglyceride Molecular Species.* A detailed study of the TG was carried out by means of RP-HPLC-RI, and it is summarized in Table 2. The eluting order of each TG molecular species can be determined using

[a]Data are the average of 14 samples and are expressed as the mean ± SD. Different letters (a, b) represent significant differences. n.c., not quantified, <1%; n.d.: not detected.

the standard of LnLnLn, which elutes as the first TG peak. One should take into account that under the isocratic conditions used in this work the retention times for TG are directly proportional to the number of carbon atoms and inversely proportional to the total number of double bonds in the three fatty acyl chains. TG molecular species can be grouped according to their ECN, defined as the total acyl-carbon number in the molecule minus twice the total number of double bonds of the fatty acids comprising the TG.[21]

As one can observe in Figure 1A the ECN of the main TG identified are within the range from 36 to 42, normally with combinations of Ln and L. Thus, the four main TG are LnLnLn, LnLnL, LnLL, and LLL (ECN 36, 38, 40, and 42, respectively). Also TG with ECN 44, 46, 48, and 50 are found, but in minor proportions. Fanali and co-workers[6] reported the TG composition of Sacha inchi *P. volubilis* oils from Peruvian producers for the first time. Remarkable differences can be found with the *P. huayllabambana* species presently studied. Thus, although in both species LnLnL (ECN 38) is the major TG, for *P. huayllabambana* this TG is higher than the whole group of TG with ECN 40 (26% vs 21%), which is the main TG group reported for *P. volubilis* (28.7%).[6]

*Glyceridic Polar Compounds.* The quantitative determination of glyceridic polar compounds gives a direct evaluation of all the compounds having polarity higher than that of the TG, the major compounds in edible fats and oils. The composition and profile of the PC is the most valuable and common methodology utilized for evaluating the alteration in heated oils. The fraction isolated by Si-SPE was quantified using HPSEC, separating the compounds according to their molecular size: D-TG, oxTG, DG, MG, and FFA (Figure 1B1 and 1B2). Quantitative PC data (Table 2), which include values between 2.3 and 7.5% for Sacha inchi *P. huayllabambana* oils, show percentages below 5−6% in most of the samples studied, which is indicative of good quality oils.[34] No comparison can be done with other Sacha inchi species since no PC data have been reported. As can be observed, the PC fraction is mainly composed of DG and FFA in a ratio of 2:1 approximately. It is noteworthy the presence of MG in proportions around 0.6−3.3% in all analyzed samples, confirming that the susceptibility of the seed to hydrolization goes beyond the DG formation. Some of the evaluated samples exhibited a high level of compounds related to hydrolization such as DG and FA, and also important quantities of oxTG and D-TG (Figure 1B2).

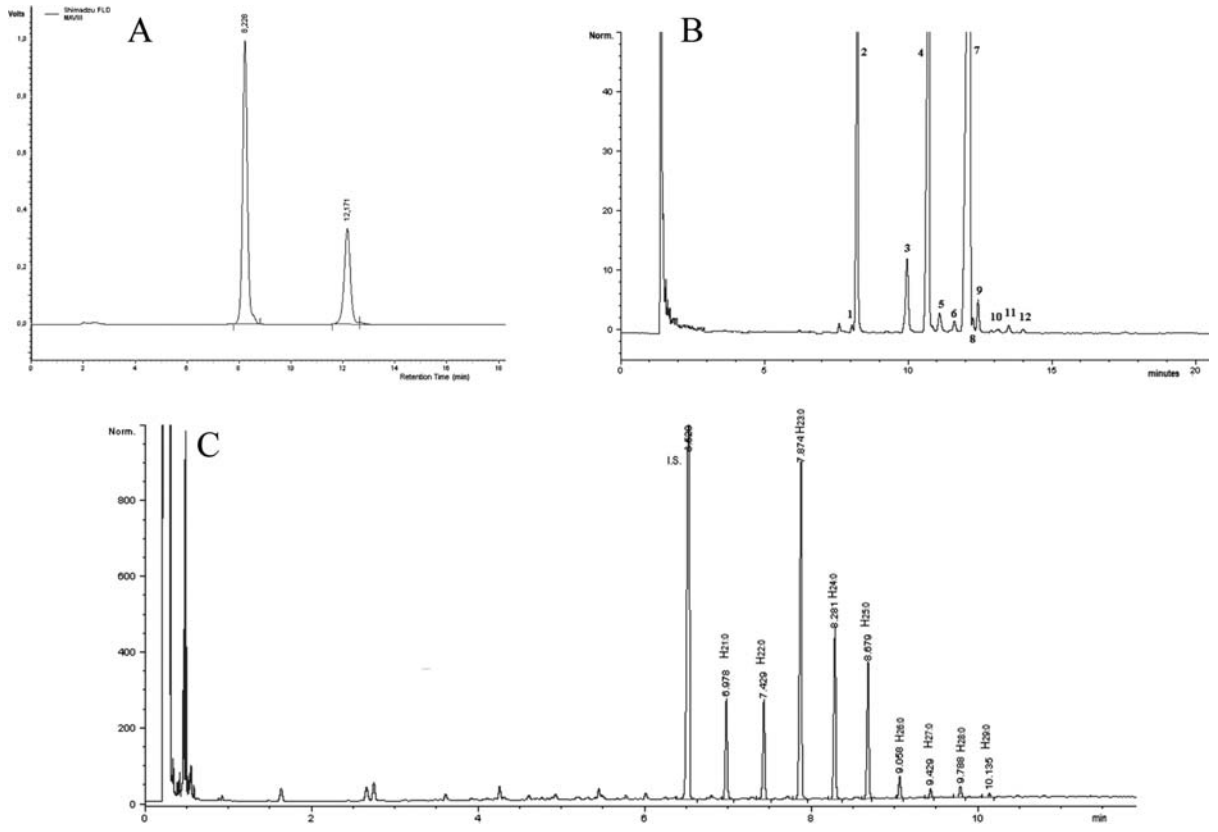

**Figure 2.** Chromatogram profiles of the main unsaponifiable compounds of the Sacha inchi *P. huayllabambana* oils: (A) tocopherols HPLC-FL profile (Rt 8.22, $\gamma$-tocopherol; Rt 12.17, $\delta$-tocopherol); (B) sterol GC profile for (1) cholesterol, (2) I.S (Internal Standard: $\alpha$-cholestanol), (3) campesterol, (4) stigmasterol, (5) Δ7-campesterol, (6) clerosterol, (7) $\beta$-sitosterol, (8) sitostanol, (9) Δ5-avenasterol, (10) Δ5,24-stigmastadienol, (11) Δ7-stigmastenol, and (12) Δ7-avenasterol; (C) aliphatic saturated hydrocarbon on-column GC profile. I.S: Internal Standard, H20.

The PC method, designed in the beginning for oils subjected to frying processes, gives us valuable information on the alteration of the Sacha inchi seeds due to hydrolysis. Moreover, all oil samples contain oxTG as has been seen in other edible oils but an important number of them also have high quantities of minor glyceridic components, which indicates the facility of Sacha inchi oils to oxidative alteration, which is expected due to their high unsaturation degree.

*Fatty Acid Composition.* A representative chromatogram of the FAME of Sacha inchi *P. huayllabambana* oil is presented in Figure 1C. There we can observe the high percentage of Ln, as well as the presence of $\omega$7-C18:1 and the absence of C20:1. The results (Table 2) indicate no significant differences between the two studied harvests. The high contents of Ln (55.5−60.7%) and L (25.0−27.3%) stand out. These values are slightly different from those reported for Sacha inchi *P. volubilis*.[28,35] The $\omega$6:$\omega$3 ratio determined in this work for Sacha inchi *P. huayllabambana* is 0.45:1, which is lower than those reported for Sacha inchi *P. volubilis* (0.75:1), since for the commercial species the Ln content is low (47−50%).

**Main Unsaponifiable Components.** We have studied the total quantity of the unsaponifiable matter as well as the sterol, tocopherols, and aliphatic hydrocarbons profiles and contents.

The total unsaponifiable matter (Table 3) differs for both harvests and in some samples is out of the limits established in the regulations (0.36%). At this point it is important to highlight that the limit established in the regulation is not really reasonable since just the addition of the values regarding valuable unsaponifiable components such as sterols and tocopherols exceeds it.

Figure 2 represents the chromatograms of the main unsaponifiable compounds of Sacha inchi *P. huayllabambana* oils studied here.

*Tocopherols.* $\gamma$-Tocopherol and $\delta$-tocopherol are the main species that can be directly separated and quantified by HPLC using fluorescence detector (Figure 2A). In a few number of samples also $\alpha$-tocopherol is present, but with percentages lower than 0.1. $\gamma$-Tocopherol was the major tocopherol with percentages above 65% in most of the samples. High variability is found in their total quantities not only between harvests but also among samples within the same harvest (Table 3). This fact can be explained by taking into account that these compounds, specially $\delta$-tocopherol, are powerful antioxidants and protect the highly unsaturated TG of Sacha inchi oils against oxidation, resulting in their degradation. The results obtained regarding the tocopherol content of the Sacha inchi *P. huayllabambana* are slightly higher than data published for *P. volubilis* species.[6,28] However, they are above the maximum limit established in the most recent Peruvian Regulations for Sacha inchi *P. volubilis* oils.[36] This recent regulation concerning only *P. volubilis* species establishes a maximum limit of 0.7, 0.29, 136.7, and 85.6 mg·kg$^{-1}$ for $\alpha$, $\beta$, $\gamma$, and $\delta$, respectively, which is at the least strange.

*Sterols.* Related to the sterols GC profile (Figure 2B), 12 peaks can be separated including $\alpha$-cholestanol, which is added as an internal standard for quantitation purposes. The major peak corresponds to $\beta$-sitosterol (peak 7), as in the majority of

dx.doi.org/10.1021/jf5028697 | J. Agric. Food Chem. 2014, 62, 10162−10169

vegetable oils, with percentages above 60%. Stigmasterol (peak 4) is the second most important sterol in Sacha inchi oils, which is in agreement with recent data reported by Muñoz Jáuregui and co-workers[13] where sterols were determined by HPLC. In rare cases, as occur in Sacha inchi oils, including the *P. volubilis* species, the stigmasterol content is higher than the campesterol concentration.[5] For most edible oils, the ratio campesterol/stigmasterol is higher than 1.[37] This is the case of olive oil, where its regulation establishes explicitly that the stigmasterol content must be lower than that of campesterol.[17] The campesterol/stigmasterol ratios calculated in this work are within the 0.14−0.21 range, the stigmasterol concentration being six times that of campesterol. This high stigmasterol content can provide interesting properties to Sacha inchi oils since this phytosterol plays an important role in reducing the inflammatory processes.

*Aliphatic Saturated Hydrocarbons.* HC form a remarkable group of minor unsaponifiable compounds present in edible fats and oils. At present, they are considered as intermediate metabolites in the formation of other minor compounds, such as aliphatic alcohols, with specific roles. Figure 2C shows an on-column gas chromatogram corresponding to the aliphatic saturated hydrocabons of Sacha inchi *P. huayllabambana* oil. The main peaks correspond to H21 heneicosane; H22 docosane; H23 tricosane; H24 tetracosane, and H25 pentacosane. A minor amount of H19 nonadecane; H26 hexacosane, H27 heptacosane, H28 octacosane, and H29 nonacosane are also present. Surprisingly both the odd and even series were present. The procedure was applied using impregnated silver nitrate silica to ensure that only saturated hydrocarbons eluted from the silica column. Results of the mean concentrations of the main aliphatic saturated hydrocarbons and also their total quantities evaluated using as standard a solution of heneicosane (*n*-H20:0) at concentration of 0.05 $mg \cdot mL^{-1}$ are included in Table 3. The high concentrations of the H23:0 hydrocarbon with values of 36−38%, followed by those of H24 (17−19%) and H25 (13−15%), are remarkable. As can be observed, the area relation between hydrocarbons with even and odd carbon-atom number is around 2, although the odd series is the most abundant one, as in the main edible vegetable oils. However, the even carbon number series is present in important concentrations. This fact must be pointed out as distinctive of Sacha inchi oils when compared with other vegetable oils.[37] Data on hydrocarbons and their relative concentrations in edible oils have been scarcely studied with regard to their usefulness. In this sense it has been proposed as a good parameter for beeswaxes authentication, allowing one to discriminate in the adulterations with paraffin[33] and also to distinguish among olive oil varieties.[38]

To summarize, we will conclude as follows: The concentration ranges of minor and major components of cold-pressing Sacha inchi *P. huayllabambana* oils studied can serve as a valuable guide in forthcoming enlargement of the regulations. Changes and extension in the normative are necessary as it would ensure better control of these oils avoiding the presence of adulteration with other seeds of lower prices. It also serves to encompass analytical parameters of other Sacha inchi species since there are almost no studies concerning this. It should be pointed out that some objective analytical determinations can help to characterize Sacha inchi oils both *P. volubilis* and *P. huayllabambana*. Such is the case of their characteristic sterol profile with its particular campesterol/stigmasterol ratio. Determinations of FAME and TG compositions indicate that *P. huayllabambana* oils are more unsaturated than *P. volubilis*, which affects to the presence of TG molecular species with lower ECN for the first of the species. Results demonstrate that the studied species have a seasonal stable composition, not influenced by the harvest year significantly.

Finally, their high susceptibility to oxidative and hydrolytic alterations is another common characteristic of these valuable oils. At this point it is convenient to emphasize the need to protect the product from the time of seed harvest, passing by the oil extraction up to their marketing, in order to guarantee their unique and valuable properties.

**Table 1. Film Formulations**

| formulation | PLA (wt %) | PHB (wt %) | ATBC (wt %) | I168 (wt %) | CAT (wt %) |
|---|---|---|---|---|---|
| PLA (control) | 99.8 | | | 0.2 | |
| PLA−ATBC | 84.8 | | 15 | 0.2 | |
| PLA−CAT | 94.8 | | | 0.2 | 5 |
| PLA−ATBC−CAT | 79.8 | | 15 | 0.2 | 5 |
| PLA−PHB | 74.85 | 24.95 | | 0.2 | |
| PLA−PHB−ATBC | 63.6 | 21.2 | 15 | 0.2 | |
| PLA−PHB−CAT | 71.1 | 23.7 | | 0.2 | 5 |
| PLA−PHB−ATBC−CAT | 59.85 | 19.95 | 15 | 0.2 | 5 |

On the other hand, current worldwide trends to reduce the use of food additives have given way to investigations of incorporating additives, such as antimicrobial or antioxidant compounds, into food packaging. These systems are known as active food packaging and offer the opportunity to provide continuous release of active compound from packaging material to the foodstuffs, having an important effect on the shelf life extension without the need of direct incorporation of additives into the final food product. However, active agents could show higher affinity for the polymer matrix than the foodstuffs. Consequently, the design of active packaging systems is aimed to obtain an effective release capacity of active agent from the polymer matrix. It is known that the plasticizer presence increases the polymer chain mobility in PLA−PHB blends,[7,8] and for this reason it is expected that the mass transport of the active agent should be modified,[16] resulting in an effective way to improve the release of the active substance from the polymer matrix.[17] One of the main drawbacks of polymer modifiers is the negative effect of the additives on the thermal stability. Thermal degradation is responsible for serious damage to many polymeric materials during processing.[11] In this sense, antioxidants are chosen as active substances not only to protect food deterioration and extend its shelf life[17,18] but also to protect the polymer matrices from thermo-oxidative degradation during processing[18,19] because antioxidants are able to act with the free radicals formed during thermo-oxidation, blocking further polymer degradation.[20]

Currently, synthetic additives are being replaced by natural preservatives due to safety[16] and environmental concern. Most of the common natural antioxidants are phenolic compounds derived from flavonoids,[18,20] which are sourced primarily from renewable resources and have been in use for centuries. For instance, catechins are flavonoids with multiple biological effects[18] that have gained considerable attention due to their potential benefits on human health[21] related to antimutagenic, antidiabetic, anti-inflammatory, and prevention activities against several kinds of cancer.[22] From a technological aspect, catechins have been suggested as effective natural antioxidants in many polyolefins for active food-packaging applications.[16,18,21] Catechin, one of the major active constituents of green tea, represents a natural food-grade additive that inhibits lipid oxidation, increasing the shelf life of foods,[23] and has a positive acceptance among consumers owing its well-known healthy properties. With regard to the polymers' transformation, the extrusion process is one of the most widely used processing technologies in the packaging industry.[24] Because PLA−PHB blends should be processed in the region from at least 160 °C to below 200 °C,[3] catechin, which is a nonvolatile compound, is optimal for melt processing to avoid or reduce its loss during polymer processing.[18]

The main objective of this work was to develop a biodegradable active packaging based on PLA−PHB blends with added catechin, as antioxidant agent, intended for fatty food-packaging application. These systems were plasticized with ATBC with the dual objective of overcoming ductility required for film manufacturing and uses as well as improving the kinetics of release of catechin from the polymer matrix to the foodstuff. The developed materials were characterized with regard to their structure and nanomechanical and thermal properties. The release capacity of catechin into a fatty food simulant after the release process was tested, as well as its antioxidant effectiveness, and the morphological, structural, and nanomechanical properties were also followed during the material exposure to the selected food simulant.

## MATERIALS AND METHODS

**Materials and Chemicals.** Poly(lactic acid) (PLA 2003D, $M_n$ = 98000 g mol$^{-1}$, 4 wt % D-isomer) was supplied by NatureWorks (USA), and poly(hydroxybutyrate) (PHB, under the trade name PHI) was acquired from NaturePlast (France). Catechin dehydrate (CAT), (−)-epicatechin (EC), Irgafos 168 [tris(2,4-di*tert*-butylphenyl)-phosphate] (I168), acetyl tri-*n*-butyl citrate (ATBC) ($M$ = 402 g mol$^{-1}$, $T_m$ = −80 °C, 98% purity), and 2,2-diphenyl-1-picrylhydrazyl (DPPH) 95% free radical were purchased from Sigma-Aldrich (Madrid, Spain). Methanol (MeOH) and ethanol (EtOH) of HPLC grade were supplied by Merck (Darmstadt, Germany). Water was purified by means of a Milli-Q ultrapure water purification system (Millipore, Bedford, MA, USA).

**Sample Preparation.** Samples were prepared by melt-blending the materials in a microextruder equipped with twin conical corotating screws (MiniLab Haake Rheomex CTW5, Thermo Scientific) with a capacity of 7 cm$^3$. A screw rotation rate of 40 rpm, temperature of 190 °C, and residence time of 1 min were used. Irgafos 168 was incorporated in all cases at 0.2% to protect the polymer during processing steps. The concentration ratios of the obtained films are summarized in Table 1.

**Sample Characterization.** *Field Emission Scanning Electron Microscopy (FESEM).* The film cross sections performed in liquid nitrogen were coated with a thin palladium−gold layer to be observed by FESEM (Supra 25-Zeiss).

*Thermogravimetric Analysis (TGA).* TGA was performed with a thermogravimetric analyzer TGA/SDTA-851e Mettler Toledo (Schwarzenbach, Switzerland). Tests were run under dynamic mode from 30 to 600 °C at 10 °C min$^{-1}$ in air (50 mL min$^{-1}$). The initial degradation temperatures ($T_0$) were determined at 5% mass loss, whereas temperatures at the maximum degradation rate ($T_{max}$) were calculated from the first derivative of the TGA curves (DTG).

*Differential Scanning Calorimetry (DSC).* Dynamic DSC experiments were performed in a Mettler Toledo calorimeter by using two different atmospheres of air (250 mL/min) and nitrogen (50 mL/min) with sample weight about 4 mg in hermetic aluminum pans.

Samples analyzed under air conditions were heated from 30 to 350 °C at a heating rate of 10 °C min$^{-1}$ to determine the maximum temperature at which the polymers degrade (onset oxidation temperature, OOT). OOT values were calculated as the intersection

point between the baseline and the tangent to the degradation peak. Meanwhile, samples analyzed under nitrogen conditions were subjected to a cycle program consisting of a first heating stage from 30 to 180 °C at a heating rate of 10 °C $min^{-1}$, followed by a cooling process to 30 °C at 30 °C $min^{-1}$ and subsequent heating to 250 °C to erase the materials' thermal history. The glass transition temperature ($T_g$) was taken at the midpoint of heat capacity changes. The melting temperature ($T_m$) and cold crystallization temperature ($T_{cc}$) were obtained from the second heating, and the degree of crystallinity ($\chi_c$) was calculated through eq 1

$$\chi_c = 100\% \times \left[\frac{\Delta H_m - \Delta H_c}{\Delta H_m^c}\right] \times \frac{1}{W_{PLA}} \quad (1)$$

where $\Delta H_m$ is the melting enthalpy, $\Delta H_{cc}$ is the cold crystallization enthalpy, and $\Delta H_m^c$ is the melting heat associated with pure crystalline PLA (93 J $g^{-1}$) and WPLA is the proportion of PLA in the blend.[25]

*X-ray Diffraction (XRD).* The crystalline phases of the nanocomposite films were studied by using XRD equipment (Bruker AXS D5005, SCSIE Universitat de València).

Scanning was performed on square film surfaces (15 mm × 15 mm) mounted in an appropriate sample holder. The patterns for profile fitting were obtained from a diffractometer using Cu K$\alpha$ radiation with a scanning step of 0.02° between 2.5° and 40° in 2$\theta$ with a collection time of 10 s per step, and the voltage was held at 40 kV.

*Wettability.* The surface wettability of films was evaluated by measuring the water contact angle with an Easy-Drop Standard goniometer FM140 (Krüss GmbH, Hamburg, Germany) equipped with a camera and analysis software (Drop Shape Analysis SW21; DSA1). Samples for wettability measurements were prepared as disk films with an average thickness between 180 and 230 $\mu$m by a compression molding process at 180 °C in a hot press (Mini C 3850, Caver, Inc., Wabash, IN, USA). The contact angle was calculated by randomly adding 5 drops of distilled water (2 $\mu$L) with a syringe onto the film surface at room temperature, and the average values of 10 measurements for each drop were used.

*Release Studies.* Release studies of the antioxidant flavonoid catechin were conducted by the determination of the specific migration into a solution of 50% ethanol as a fatty food simulant (simulant D1)[26] at 40 °C.

Release tests were performed by total immersion of preweighed rectangular strip film pieces (80 ± 0.099 mm × 3.40 ± 0.26 mm × 1.20 ± 0.14 mm) in 10 mL of food simulant contained in glass-stoppered tubes with PTFE closures at 40 °C. For fatty food products that will be stored at ambient conditions (temperatures between 20 and 40 °C) during not more than 30 days, legislation orders that food packaging materials should be assayed at contact temperature in worst foreseeable use of 40 °C for 10 days. In this work, the release test was conducted during 20 days. Thus, samples were taken at 1, 5, 10, and 20 days. Working standard catechin solution in the food simulant and pure simulant were run simultaneously with the release test to check for interferences, and all samples were performed in triplicate.

*Measurement of Released Antioxidant.* The released catechin was measured after the contact period; an aliquot of each simulant was filtered through an Acrodisc PTFE CR 13 mm, 0.2 $\mu$m filter (Waters, Milford, MA, USA) and quantified by HPLC-PDA-FL. A Waters 2695 HPLC system with a gradient pump and automatic injector was used for high-performance liquid chromatography (HPLC) analysis equipped with a stainless steel column packed with SunFire C18 (150 mm × 3.0 mm, 3.5 $\mu$m) (Waters) kept at 35 °C following the methodology described by Castro López et al.[16] The method consisted of a two-solvent gradient elution at a flow rate of 0.5 mL $min^{-1}$. Mobile phase was composed by water (A) and methanol (B). The following gradient elution profile was used: Mobile phase composition started at 25% B and was maintained for 0.5 min. Then, it was linearly increased to 40% B in 4.5 min, to 60% B in 1 min, and to 100% B in 2 min. Finally, it was maintained for 3 min and brought back to recover the initial chromatographic conditions. Detection was performed on a photodiode array detector (PDA, model 996 UV) set in the range of 200−400 nm (277 nm output signal as a quantification wavelength) coupled in series with a fluorescence detector (FL, model 2475, Waters) with an excitation wavelength of 280 nm and an emission wavelength of 310 nm.[21] Output signals were monitored and processed with a personal computer operated under Empower software (Waters). Catechin and epicatechin were identified by means of retention time and UV spectrum. Release data were expressed as the percentage of catechin released into the food simulant after the contact period: amount of catechin released per kilogram of film with reference to the initial amount of catechin loaded per kilogram of film formulation.

The stability of catechin was also evaluated in the simulant under selected exposure conditions by storing a solution of the additive in the simulant in parallel with the release tests and quantified using the same procedure as for the samples.[17]

The release process is normally described by the kinetics of the diffusion of the antioxidant in the film and is expressed by the diffusion coefficient ($D$). $D$ is usually estimated using the Fickian diffusion law.[16,17] When the release of antioxidant reached equilibrium, a rigorous model for describing the migration controlled by Fickian diffusion in a packaging film is used as explained in eq 2:

$$\frac{M_t}{M_{F,\infty}} = 1 - \sum_{n=0}^{\infty} \frac{8}{(2n+1)^2\pi^2} \exp\left[\frac{-D(2n+1)^2\pi^2 t}{L_p^2}\right] \quad (2)$$

$M_t$ is the mass of the migrant in the food simulant at a particular time $t$ (s), $M_{F,\infty}$ is the mass of the migrant in the food at equilibrium, $L_p$ is the film thickness (cm), $D$ is the diffusion coefficient ($cm^2$ $s^{-1}$), and $t$ (s) is time.

Nevertheless, when release is slow and equilibrium is not reached at the end of the experiment, with the boundary condition of $M_t/M_p < 0.6$, eq 3 can be used:

$$\frac{M_t}{M_p} = \frac{4}{L_p}\left(\frac{Dt}{\pi}\right)^{1/2} \quad (3)$$

$M_p$ is the initial loading of antioxidants in the film, $D$ is estimated from the slope of the plot of $M_t/M_p$ versus $t^{1/2}$, and the intersection with the $x$-axis represents the time lag.

*Antioxidant Activity.* The antioxidant effectiveness of development materials was measured according to the DPPH method by determining the absorbance of release medium at different times by means of a UV−vis spectrophotometer at 517 nm. The antioxidant activity was obtained according to eq 4

$$I\ (\%) = \left(\frac{Abs_{control} - Abs_{sample}}{Abs_{control}}\right) \times 100\% \quad (4)$$

where $I$ (%) is the percentage of inhibition. The results were calculated in percent of inhibition as the mean of three replicates, and they were expressed as the equivalent of gallic acid (GA) concentration (ppm) by using a calibrated curve of gallic acid concentration versus $I$ (%).

*Nanomechanical Analysis.* The mechanical hardness ($H$) and elastic modulus ($E$) properties of films before release studies and after 10 days of contact with food simulant D1 were determined by a nanoindenter machine G-200 (Agilent Technologies, Santa Clara, CA, USA). All samples were indented in the same experiment. All samples before release studies and those after 10 days in food simulant were indented during the same test. Indentations were performed at maximum 2000 nm constant depth using a Berkovich diamond tip. An array of 16 indentations was performed for each sample. The area function that is used to estimate the contact area at low depths was previously calibrated in fused silica. The stiffness required to calculate the contact area beyond indenter and elastic modulus was obtained by means of the continuous stiffness measurement (CSM) technique.[27,28] The CSM technique provides in-depth profiles of the stiffness response and, subsequently, in-depth profiles of $H$ and $E$.

*Statistical Analysis.* Experimental data were statistically analyzed with OriginPro 8 software. One-way analysis of variance (ANOVA) was carried out, and significant differences among formulations were

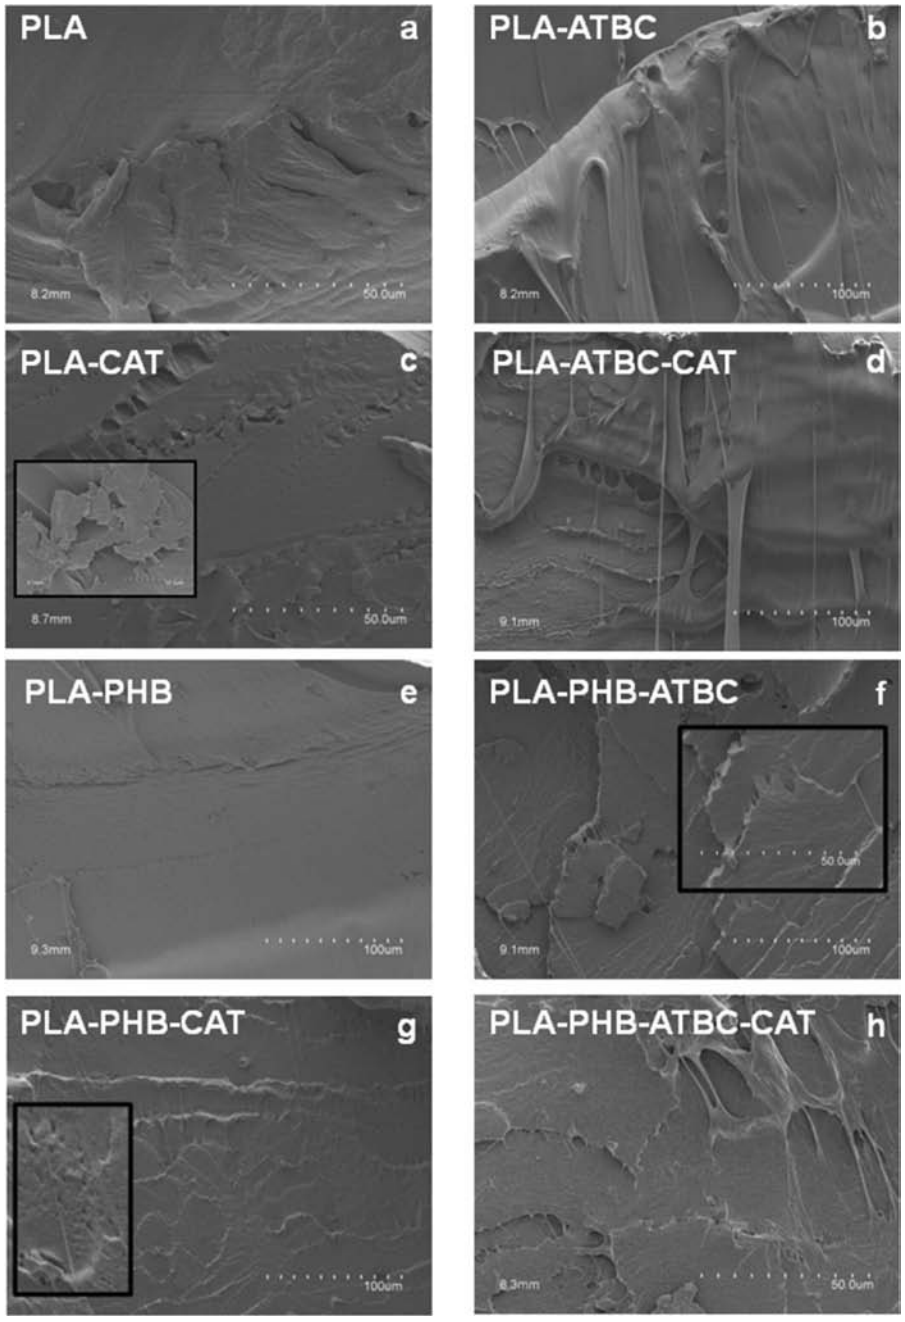

**Figure 1.** Microstructure of fracture surface of unplasticized (left side) and plasticized films (right side).

recorded at the 95% confidence level according to Tukey's post hoc test.

## RESULTS AND DISCUSSION

**Morphological Characterization.** Figure 1 shows FESEM images of cryofractured surfaces of unplasticized (left side) and plasticized films (right side). Whereas unplasticized films showed a smooth fracture, plasticized samples showed a clear plastic behavior with no apparent phase separation. These results show that ATBC is well incorporated into the PLA and PLA−PHB matrices in agreement with previous observations.[8] The characteristic plastic behavior was more evident in PLA−ATBC (Figure 1b) and PLA−ATBC−CAT (Figure 1d) than in plasticized PLA−PHB counterparts (Figure 1f ,h). The PLA and PLA−PHB films incorporated with CAT appear to be more porous without a plain smoothness (Figure 1c,g).

**Thermal Characterization.** *Thermogravimetric Analysis.* The thermal decomposition was studied by TGA and DTG (Figure 2). Stabilized with catechin and unstabilized PLA and plasticized PLA materials decomposed in a one-step process (Figure 2a), whereas PLA−PHB blend counterparts decomposition took place in two well-separated steps. In the first degradation process the total weight loss is close to 25% and corresponds to the degradation of PHB, and the second stage is related with the degradation of PLA. Figure 2b shows that PHB decreases the thermal stability of the final formulation in accordance with previous results.[7,8]

Table 2 also summarizes the main thermal parameters obtained by TGA and DTG. Whereas ATBC shifted the $T_0$ to

dx.doi.org/10.1021/jf5029812 | J. Agric. Food Chem. 2014, 62, 10170−10180

| PLA−PHB−ATBC−CAT | 275.1 | 289.5 | 309.6 | 281.2 | 57.7 | 126.0 | 152.5 | 5.3 | 8.1 | 5.1 |

lower degradation temperatures, catechin led to an increment in $T_0$, delaying the beginning of the thermal decomposition process in all cases indicative of an effective stabilizing effect. As well, catechin presence leads to a displacement of the $T_{max}$ of PLA toward slightly higher values in PLA and plasticized PLA samples (PLA−CAT and PLA−ATBC−CAT). However, in PLA−PHB blends at the same time as the $T_{max}$ corresponding to the degradation of PHB showed a considerable increment of about 10 °C with catechin addition, the $T_{max}$ of PLA was shifted to lower values, and this behavior was particularly noticeable in PLA−PHB−ATBC−CAT, where the reduction was about 14 °C. The antioxidant capacity of catechin protects the polymer thermal degradation at the first stage leading the $T_{max}$ of the blends to higher values, and then the degradation at higher temperatures is accelerated.

*Differential Scanning Calorimetry.* The OOT was used to evaluate the effectiveness of catechin to increase the polymer stability under oxidative atmosphere, and results are summarized in Table 2. OOT values clearly increased with the addition of catechin in all cases, showing its effectiveness to protect PLA, PLA−PHB, plasticized PLA, and plasticized PLA−PHB against oxidation, as was already commented for TGA results above. However, PLA-based materials stabilized with catechin showed higher values of OOT than PLA−PHB counterparts, in good accordance with $T_0$ values. It must be noted that whereas ATBC decreases the thermal stability of PLA, it slightly increases the thermal stability of PLA−PHB blend due to the fact ATBC improves the interaction between both polymers.[8] Consequently, catechin could be considered as a natural stabilizer for PLA, PLA−PHB, and their plasticized systems.

Panels a and b of Figure 3 show the thermograms for the DSC second heating where it is possible to observe the glass transition temperature ($T_g$), the cold crystallization exotherm ($T_{cc}$), and the melting endotherm ($T_m$) of the PLA-based (Figure 3a) and PLA−PHB-based (Figure 3b) films, showing that the cooling conditions applied did not produce the crystallization of PLA. DSC thermal properties are also summarized in Table 2. ATBC induced the depression in $T_g$ of all samples, confirming its plasticizing effect also reported and discussed in a previous study.[8] Moreover, the lowest $T_g$ values were presented by PLA−ATBC followed by PLA−ATBC−CAT due to their higher plastic behavior, in good

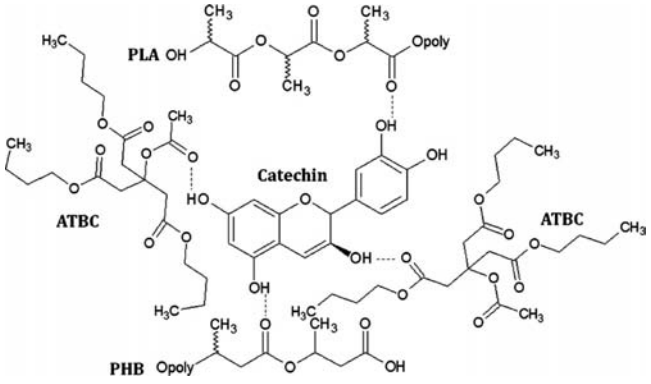

**Figure 4.** Proposed molecular interaction between PLA, PHB, ATBC, and catechin.

accordance with FESEM micrographs. ATBC also shifted the $T_{cc}$ to lower values, whereas catechin shifted the $T_{cc}$ to higher temperatures probably as a result of increased crystal nuclei density, which requires more thermal energy to crystallize PLA. Catechin presence also promoted faster crystallization of PLA and PLA−PHB and the plasticized systems, most likely due to hydrogen-bonding interactions between catechin hydroxyl groups and carbonyl groups of PLA and PHB. Figure 4 shows the proposed molecular interaction. Similar findings were previously reported by López de Dicastillo et al., who found an induction effect of catechin on the crystal nucleation of maleic anhydride modified poly(propylene) (MAPP) and also the formation of intermolecular hydrogen bonds between catechin and poly(propylene) (PP).[18]

PHB slightly increased $T_m$ temperature with respect to the neat PLA,[7] suggesting miscibility between both polymers ascribed to a transesterification reaction between PLA and PHB chains during melt blending.[4] Although PLA can crystallize showing different polymorphisms, namely, the alpha ($\alpha$), beta ($\beta$), and gamma ($\gamma$) forms, from the melt PLA crystallizes in the $\alpha$ form.[29] Neat PLA showed the $T_m$ corresponding to the melt of stable $\alpha$ homocrystals developed during the heating process. Meanwhile, plasticized PLA systems (PLA−ATBC and PLA−ATBC−CAT) showed a multimelting behavior ascribed to the presence of different PLA crystals. Disordered $\alpha'$ crystals are formed when the $T_{cc}$ is below 110 °C.[30] PLA is known for its slow crystallization rate.[31,32] However, the crystallization rate of PLA is higher at temperatures between 100 and 118 °C,[33] at which disorder-to-order phase transition ($\alpha'$ to $\alpha$) takes place.[30] Similar findings were observed in PLA plasticized with oligomeric lactic acid (OLA).[34] On the other hand, the presence of multimelting temperatures in PLA−PHB blends, after the PLA melting peak, at around 175 and 185 °C corresponds to the as-formed PHB crystals during blending process and recrystallized PHB crystals formed during DSC heating, respectively.[3,5] Different behavior was observed in plasticized PLA−PHB blends (PLA−PHB−ATBC and PLA−PHB−ATBC−CAT). PLA−PHB−ATBC showed the $T_{cc}$ below 110 °C and as a consequence the multimelting PLA peak as well as the as-formed and recrystallized PHB crystals, whereas the multimelting behavior was not detected for PLA−PHB−ATBC−CAT. The CAT presence considerably shifted the $T_{cc}$ from 106.3 °C in PLA−PHB−ATBC to 126.0 °C in PLA−PHB−ATBC−CAT, avoiding the formation of disordered PLA $\alpha'$ crystals. The nonappearance of as-formed and recrystallized PHB crystals

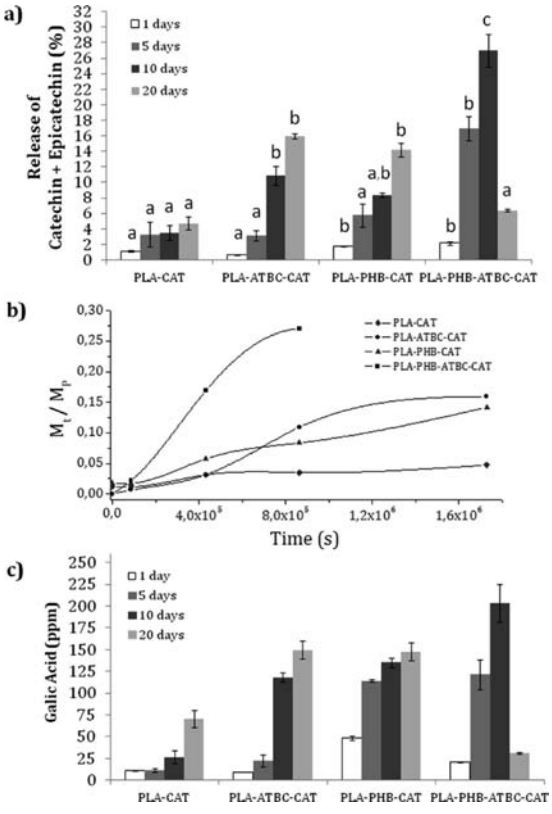

**Figure 5.** (a) Catechin (%) released from PLA-based and PLA−PHB-based materials calculated by means of HPLC-PDA. (b) Diffusion kinetics of catechin from PLA-based and PLA−PHB-based materials. (c) Antioxidant activity of catechin expressed as gallic acid concentration (ppm) measured by DPPH radical scavengers. Different letters on the bars within the same day indicate significant differences between formulations ($p < 0.05$).

could be related with an improvement in the interfacial adhesion between PLA, PHB, and ATBC due to CAT presence.

*X-ray Diffraction.* Figure 3c shows a comparative plot of the crystalline profiles of films. PLA had one broad diffraction peak centered at $2\theta = 15°$ and a smaller one centered at $2\theta = 31°$. The X-ray patterns of PLA−ATBC, PLA−CAT, and PLA−ATBC−CAT are very similar to that of neat PLA. The presence of crystalline PHB showed an increase in the crystallinity of PLA in the PLA−PHB blend, in good accordance with the increase of the degree of crystallinity calculated by DSC (Table 2). The characteristic reflection peaks of PHB at $2\theta = 13.5°$ and $2\theta = 16.9°$, as well as the weak peaks at higher $2\theta$, are observed because the crystal growth rate of PHB is higher and faster than that of PLA.[35]

*Wettability.* The surface hydrophobicity is an important issue in materials intended for food-packaging applications because they are required to protect foodstuffs from humidity during transport, handling, and storage.[9] Thus, water contact angle measurements were conducted to study the water absorption of these material surfaces (Figure 3d). The line at 65 $\theta°$ represents the limit value between a hydrophilic surface ($\theta° < 65°$) and a hydrophobic surface ($\theta° > 65°$). All studied formulations showed values higher than 65°, showing a poor affinity of the water to the material surfaces and highlighting their potential use for packaging applications. The addition of 15 wt % ATBC and 25 wt % of PHB significantly increased the water resistance of PLA ($p < 0.05$). Meanwhile, the wettability of PLA and PLA−PHB remained practically unchanged ($p > 0.05$) with the addition of 5 wt % of catechin in PLA−CAT and PLA−PHB−CAT.

PLA−PHB−ATBC−CAT film resulted in material with a surface hydrophobicity increased ($p < 0.05$) with respect of those of PLA−PHB−ATBC and PLA−PHB−CAT. One possible explanation for this behavior could be that there is a strong interaction of catechin hydroxyl groups with PLA and PHB chains and the interaction is also improved with the presence of ATBC. As a consequence, catechin hydroxyl groups did not show surface orientation affecting the surface chemical properties, leading to an increase in the surface hydrophobicity.

*Catechin Release.* The release of the catechin from PLA-based and PLA−PHB-based developed materials expressed as the percentage of catechin and epicatechin released into food simulant D1 at 1, 5, 10, and 20 days and their diffusion kinetics obtained by HPLC-PDA are shown in Figure 5, panels a and b, respectively. The incorporation of ATBC showed a significant increase of the release capacity from PLA and PLA−PHB matrices. After 10 contact days, levels of released catechin increased about 3 times in both PLA and PLA−PHB with respect to the corresponding films without plasticizer. Castro-Lopez et al. also showed an improvement in the release of antioxidants from a polypropylene matrix due to the use of plasticizers in the formulations with increased diffusion coefficients between 1 and 2 orders of magnitude.[16] Diffusion coefficients were estimated from Figure 5b and from the slope of the curve obtained by eq 3, and they also showed the positive effect of the presence of plasticizer on the release of catechin from PLA-based and PLA−PHB-based materials. Increased values from $1.9 \times 10^{-12}$ cm$^2$ s$^{-1}$ in PLA−CAT to $8.3 \times 10^{-11}$ cm$^2$ s$^{-1}$ in PLA−CAT−ATBC and from $2.6 \times 10^{-11}$ cm$^2$ s$^{-1}$ in PLA−PHB−CAT to $3.5 \times 10^{-10}$ cm$^2$ s$^{-1}$ in PLA−PHB−CAT−ATBC were observed due to the ability of plasticizer to increase the polymer chain mobility and, thus, the release of catechin.

It is expected that the higher amount of crystalline regions of PLA−PHB blends slowed the diffusion of catechin. However, the addition of PHB showed somewhat an increment in the release of active compound in comparison with those formulations without PHB, particularly noticeable in PLA−PHB−ATBC−CAT film (Figure 5a). The incorporation of PHB produced only an induction period in the diffusion process, due to the limited polymer chain mobility in PLA−PHB-based blends, leading to an increase in time lag from 30 s in PLA−CAT to 209 s and to 252 s in PLA−PHB−CAT and PLA−PHB−ATBC−CAT, respectively. This increase in the time lag can be justified by the increase of interactions between catechin and the PLA−PHB blend matrix. However, once the diffusion process started, the release of catechin became faster in PHB-added samples as shown by the increment in 1 order of magnitude of the diffusion coefficient with respect to PLA-based material counterparts. This behavior could be ascribed to the higher affinity of the simulant D1 with less polar catechin-added PLA−PHB blends in comparison with catechin-added PLA equivalents, as was already commented for the wettability test. Thus, the higher penetration capacity of simulant D1 in the PLA−PHB matrix than in PLA matrix, after the required time lag, accelerated the catechin release process as a function of time.

Additionally, after the 10 contact days, enhanced crystallinity of all tested materials was observed by XRD (Figure 6). The diffraction patterns clearly show an increased intensity of the

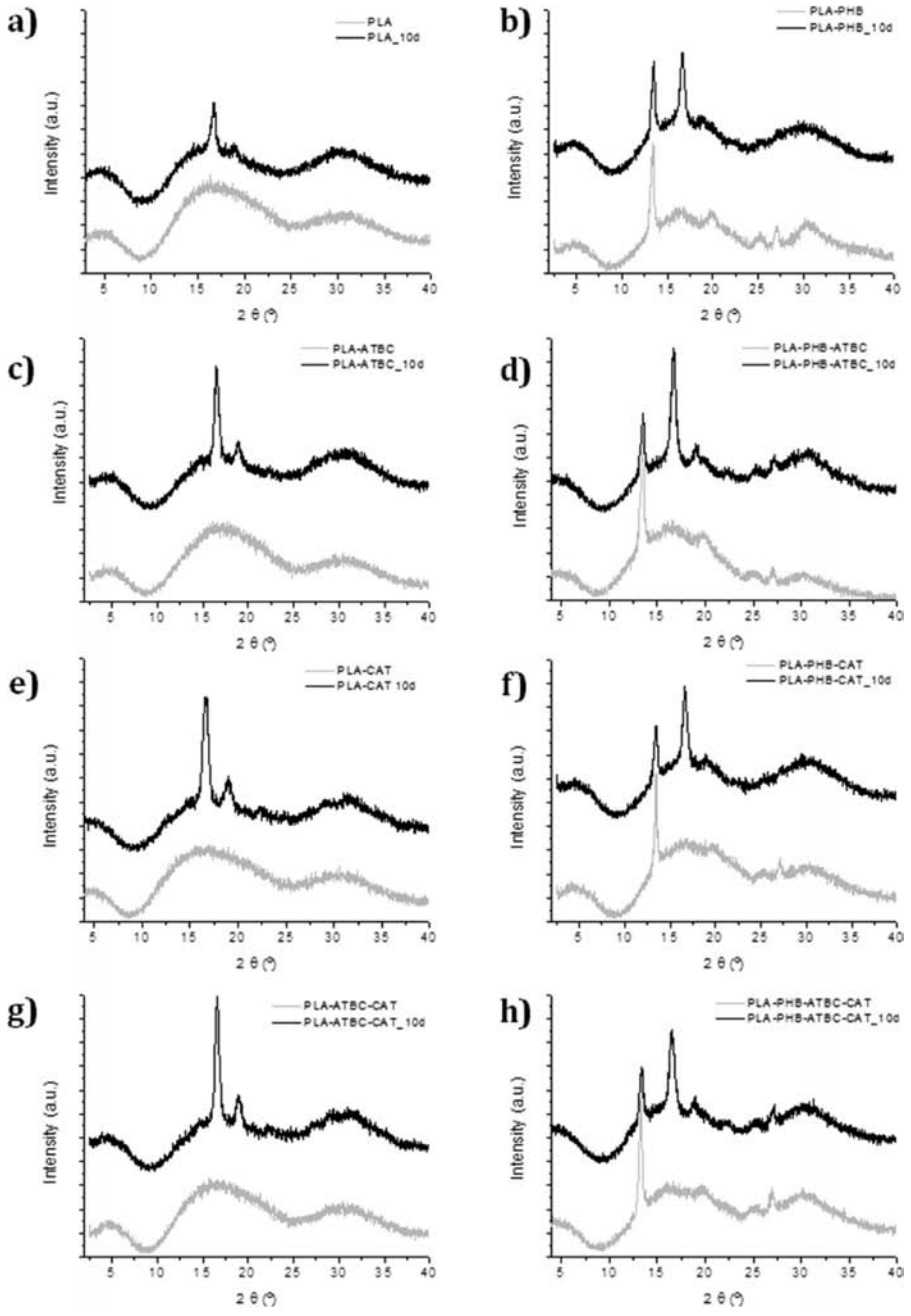

**Figure 6.** X-ray diffraction patterns of PLA-based and PLA−PHB-based films before and after 10 days of contact with simulant D1.

peak at $2\theta = 16.5°$ for all formulations, attributed to the typical $\alpha$ crystal form of the crystalline phase of PLA,[34] showing the highest intensity in plasticized samples. Thus, the higher penetration capacity of simulant D1 in PLA−PHB blends at the same time as the increase of crystallinity of amorphous PLA based materials led to comparable catechin release profiles for PLA−ATBC−CAT and PLA−PHB−CAT at 5, 10, and 20 contact days in simulant D1.

The highest diffusion process was observed for PLA−PHB−ATBC−CAT samples between 0 and 10 days. However, at the highest period of contact time studied here of 20 days, a reduction of catechin concentration occurred, showing the not possible lower value than those obtained at 5 and 10 days. This unexpected result could be explained by the feasible interaction between the free catechin molecules in the food simulant, possible forming dimers or oligomers, which cannot be quantified by the experimental methodology used here. In fact, in a food simulant the released compound is dispersed in the food simulant where no oxidation processes are happening, as can occur in a real packaged food environment. The molecules of catechin released from the packaging are expected to interact with food components, jamming oxidation processes.

It should be taken into account that the inherent biodegradability of PLA-based materials could be a drawback in food packaging, where the material structure needs to be guaranteed at least during the food's shelf life.[36] For this reason, the morphology of cross sections of the films after 10 and 20 days exposed to simulant D1 was also studied by FESEM (Figure 7). PLA-based and PLA−PHB-based materials preserved their structure at 10 days of the migration test. Meanwhile, PLA, PLA−ATBC (Figure 7a), and PLA−PHB and

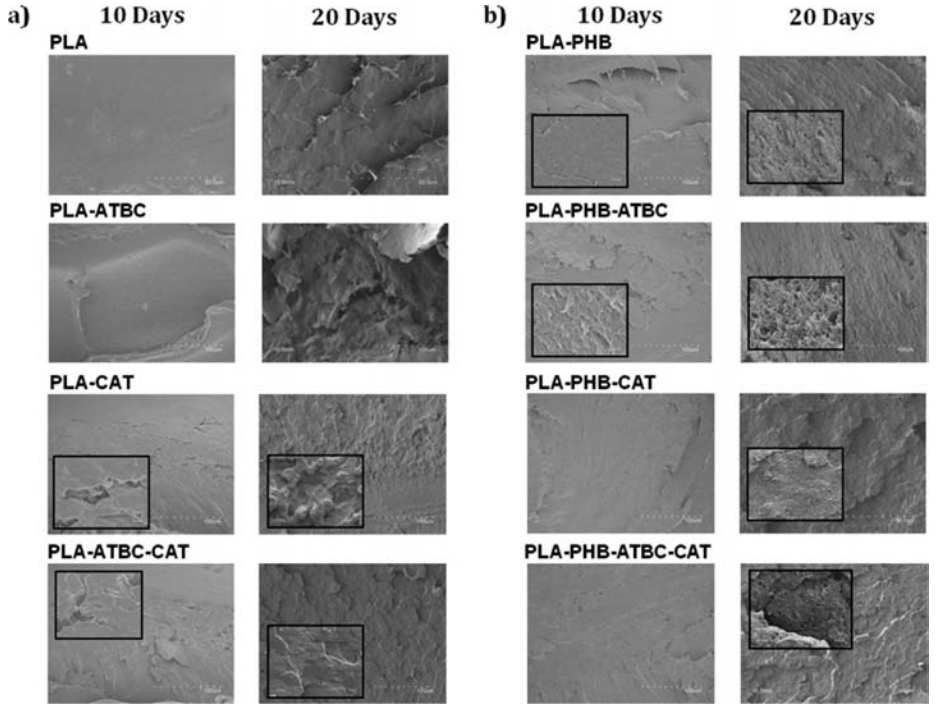

**Figure 7.** FESEM images of (a) PLA-based materials and (b) PLA−PHB-based materials after 10 and 20 days of exposure to simulant D1.

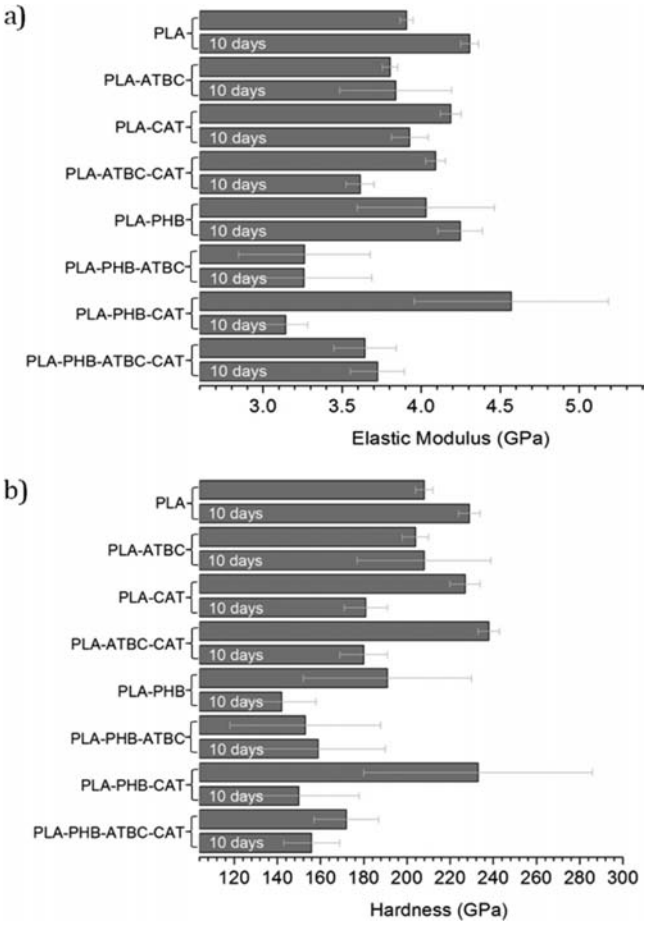

**Figure 8.** Nanomechanical results of materials essayed before and after 10 days in contact with simulant D1: (a) elastic modulus ($E$); (b) nanohardness ($H$).

PLA−PHB−ATBC (Figure 7b) showed increased plastic behavior at 20 days caused by the plasticization effect produced by the simulant dispersion into the polymer matrix. In most cases, the materials become rougher with increasing time in contact with food simulant. As well, at 20 days some cavities were formed in PLA catechin-incorporated samples (Figure 7a), whereas many cavities were observed in PLA−PHB catechin incorporated samples (Figure 7b) as a result of the higher loss of catechin in those samples. This observation supported our conclusion that higher levels of catechin than those obtained here should be released from PLA−PHB−ATBC−CAT sample after 20 days in contact with food simulant.

All catechin-incorporated materials showed an effective release of catechin in worst foreseeable use conditions between 0 and 10 days as indicated by current legislation for fatty food intended to be transported, handled, and stored at ambient conditions.

*Antioxidant Activity.* The effectiveness of the developed materials as antioxidant packaging systems was demonstrated by the reduction of stable free radical DPPH caused by catechin presence in the food simulant, and the obtained results are expressed as gallic acid (GA) concentration (Figure 5c). As expected, the antioxidant activity shows comparative tendency to the catechin release. It is known that the solubility characteristics of the antioxidant can determine its effectiveness.[37] Catechin shows high solubility in ethanol (50 g $L^{-1}$),[18] and consequently catechin-incorporated materials usually show high activity in ethanol-containing simulants.[16,18,22,38,39] Thus, the high affinity of catechin for fatty food simulants and its high antioxidant activity give good reasons for its addition in plasticized PLA and PLA−PHB materials for fatty foodstuff.

*Mechanical Features of the Films.* The mechanical behavior of all samples before and after 10 days in contact with food simulant D1 was assayed by means of a nanoindenter test. The mean of elastic modulus ($E$) and hardness ($H$) values for each

sample was calculated in the range from 500 to 1000 nm. The obtained values are shown in Figure 8. As expected, plasticized samples before release studies showed lower $H$ and $E$ values than unplasticized ones, showing the effectiveness of ATBC to plasticize PLA and PLA−PHB systems.[8,10] On the other hand, catechin-added samples showed increased $H$ and $E$ values with respect to their counterparts without catechin. This result confirms that catechin produced a somewhat reinforcing effect blocking the elastic and plastic deformation mechanisms owing to the enhancement of the materials' interfacial adhesion in the blend, in accordance with DSC experiments (see Differential Scanning Calorimetry). An increase in PLA and PLA−PHB modulus was also observed in PLA−PHB blends reinforced with cellulose nanocrystals[9] ascribed to an enhancement in the interface interaction between PLA and PHB due to nanocellulose presence.[3]

The nanomechanical results of assayed samples after release studies showed scattered values, probably due to residues of simulant D1 and/or released components from the polymer matrices on their surfaces. This activated surface is able to affect the short distance forces between the surface and nanoindenter tip. After 10 days in contact with simulant D1, catechin-added materials revealed in general a drastic diminution of $E$ and $H$ values as a result of the release of catechin to the food simulant, with the exception of PLA−PHB−ATBC−CAT, which mainly maintained the mechanical properties without significant changes. This result highlights an additional positive effect of catechin incorporation to plasticized PLA−PHB systems.

expression of the small-intestinal glucose transporter SGLT1.[16] Our group has shown that oligomeric cocoa procyanidins offer improved protective effects against obesity, insulin resistance, and impaired glucose tolerance than monomeric and polymeric cocoa procyanidins during high-fat feeding in mice.[17]

Cider production volume continues to increase across the U.S. and has become a viable value-added processing option in regions such as Virginia that have traditionally been large apple producers but only recently have become major cider producers. As the cider industry expands into new regions, so does demand for apple cultivars with relatively high concentrations of endogenous phenolic compounds. Polyphenol composition and concentration is highly variable across apple cultivar, growing locations, and harvest year.[18] This variability has also been observed in many other fruits, including grape-derived products,[19] and can be exacerbated when the oxidation products of the native polyphenols that may be formed during storage and processing are taken into consideration.[20]

While cider apple polyphenols have been the subject of ongoing research programs in Europe, most notably in Spain,[18,21] the U.K.,[8,22] and France,[23] only a few studies on cider apples have been conducted in the U.S. in apple growing regions of New York[24,25] and Michigan.[26] To date, no work has been published regarding polyphenol composition of cider apples grown in Mid-Atlantic or Southeastern states in the U.S., despite the rapid increase of cider production in this region.

Currently, the U.S. apple industry is dominated by culinary apples that contain lower malic acid and polyphenol levels[27] than preferred for cider production. In order to utilize widely available cultivars, commercial production practice often involves addition of food-grade acids and polyphenols to obtain the target sensory character for cider. Exogenous polyphenols can be added to improve astringency, bitterness, and mouthfeel. In red grape wines, exogenous polyphenol-based products added at the manufacturers' recommended rates may actually have negative sensory impacts,[28] suggesting the practical limitations of this common production strategy.

In order to support the burgeoning cider industry in Virginia by identifying apple cultivars for cider production, we selected widely grown dessert (e.g., Fuji, Golden Delicious, Granny Smith, Jonagold, Pink Lady, and Red Delicious) cultivars, generally consumed fresh, and processing (e.g., Enterprise, GoldRush, Idared Rome, and York) cultivars, generally processed into juice or sauce, for this study. A few cultivars in our study (e.g., Arkansas Black, Black Twig, Stayman, and Winesap) are found in older orchards throughout the Mid-Atlantic region, while others (e.g., Harrison, Newtown Pippin, Suncrisp, and Virginia Gold) are currently preferred for cider production in Virginia.

In the current study, we quantified the chemical composition, including 21 individual phenolic compounds of interest from 20 apple cultivars with the aim of identifying suitable cultivars for cider production. The purposes for this analysis was to compare apple cultivars and identify cultivars grown in Virginia that contain sufficient endogenous polyphenols to meet consumer sensory expectation, thus precluding or reducing the need for additions of commercial polyphenol adjuncts. In addition, we aim to inform cultivar selection for future studies involving apple polyphenols and human health.

## MATERIALS AND METHODS

**Chemicals and Standards.** Catechin monomers [(+)-catechin (C), (−)-epicatechin (EC), (−)-epicatechin gallate (ECG), (−)-epigallocatechin (EGC), and (−)-epigallocatechin gallate (EGCG)], chlorogenic acid (3-caffeoylquinic acid), phloretin, phloridzin (phloretin 2′-$\beta$-D-glucoside), quercetin, isoquercitrin (quercetin-3-$\beta$-D-glucoside), hyperin (quercetin-3-D-galactoside), and ascorbic acid were purchased from Sigma-Aldrich (St. Louis, MO, U.S.A.). Procyanidin (PC) dimer $B_2$ and trimer $C_1$ were obtained from ChromaDex (Irvine, CA, U.S.A.). Purified procyanidin dimer $B_1$, dimer $B_2$-gallate, dimer $B_5$, trimer $T_2$, tetramer cinnamtannin $A_2$ ($CinnA_2$), and procyanidin pentamer and hexamer fractions were obtained from Planta Analytica (Danbury, CT, U.S.A.). Solvents for sample preparation and extraction were ACS grade or better (Fisher, Pittsburgh, PA, U.S.A. or VWR, Radnor, PA, U.S.A.). Solvents for UPLC-MS/MS were LC-MS grade (VWR).

**Apple Cultivars.** A total of 600 apple samples belonging to 20 cultivars [Black Twig, Enterprise, Fuji (BC2), Golden Delicious, GoldRush, Granny Smith, Idared, Jonagold, Newtown Pippin, Pilot, Cripps Pink (Pink Lady), Red Delicious (Bisbee), Rome (Taylor), Stayman, Suncrisp, Virginia Gold, Winesap, and York (Red Yorking)] were harvested from the Alson H. Smith, Jr. Agricultural Research and Extension Center (AREC, Winchester, VA, U.S.A.) and (Arkansas Black and Harrison) from Albermarle CiderWorks (North Garden, VA, U.S.A.) in September and October 2013. Fruit were harvested from the exterior part of the tree canopy from a height between 1 to 1.5 m from the ground, placed into cardboard bushel (80 fruit) boxes, and brought to the AREC, where they were stored for 1 to 3 weeks at 4 °C until the time of analysis. Photographs of the 20 cultivars are shown in Supporting Information, Figure S1. These cultivars were selected from 40+ potential Virginia-grown cultivars and represent those of greatest interest to the Virginia cider industry based on current availability in Virginia, desirability as historically significant cider apples, and acceptable horticultural performance.

**Fruit Chemistry and Maturity Parameters.** Fruit weight, peel color, flesh firmness, starch index, pH, soluble solid content (SSC), and titratable acidity (TA) were measured at the AREC in Winchester, VA. Juice samples for total polyphenol concentration measurement by the Folin−Ciocalteu (FC) method were also collected from these apple samples. The remaining fruit were brought to a commercial storage facility in Winchester, VA and stored at 1 °C, 90% relative humidity, under ambient atmospheric gases (i.e., no active adjustments were made to the oxygen, carbon dioxide, nitrogen, or other gas concentrations) for 1−3 weeks before fruit maturity analysis (conducted at the AREC in Winchester, VA) and 4−6 weeks until transferred to the Virginia Tech main campus (Blacksburg, VA) for UPLC-MS/MS analysis.

Fifteen apples from each cultivar were weighed and visually assessed for percent red blush (0−100%) or green background color (1 = green, 2 = light green, 3 = yellowish green, 4 = yellow). Flesh firmness was measured on the same 15 samples, after removing part of the peel at two locations along the equator of each apple, with a Fruit Texture Analyzer penetrometer [Güss Manufacturing (Pty) Ltd.; Strand, S.A.] fitted with a cylindrical 11.1 mm diameter Effegi tip. Starch index was determined by staining the stem-side of an equatorial cross-section of the apples with iodine solution (0.22% w/v iodine, 0.88% w/v potassium iodine) and visual rating, where 1

Table 1. MRM[a] Settings for Detecting and Quantifying Phenolic Compounds by ESI-MS/MS[b] in Twenty Cultivars of Apples Grown in Virginia

[a]MRM: multireaction monitoring. [b]ESI-MS/MS: electrospray ionization tandem mass spectrometry. [c]$[M - H]^-$: deprotonated, negatively charged pseudomolecular parent (precursor) ion; MRMs employed singly charged parent ions except for cinnamtannin tetramer $A_2$, pentamers, hexamers, heptamers, octamers, which were doubly charged ($[M - 2H]^{2-}$). [d]Likely procyanidin dimers B3, B4, B6, B7, or B8.

= 100% staining and 8 = 0% staining[29] Three pooled samples each containing five apples were used to measure SSC, TA, pH, and total polyphenols by FC. The calyx half of each apple was juiced in a Champion Juicer (Lodi, CA), and SSC was measured using a digital PAL-1 refractometer (Atago U.S.A., Inc., Bellevue, WA) and reported as °Brix. TA was measured by titrating a 5 mL juice aliquot against a standardized 0.1 N NaOH solution to an end-point of pH 8.1 with a 848 Titrino Plus autotitrator (Herisau, CH). A 50 mL aliquot of the juiced apples was shipped overnight in a Styrofoam cooler with ice packs to the Virginia Tech Enology Service Lab (Blacksburg, VA) for total polyphenol concentration analysis.

**Total Polyphenols.** All chemical reagents were from Fisher Scientific (Suwanne, GA) unless otherwise noted. Absorbance measurements were made using a BioTek Epoch Microplate Spectrophotometer (Winooski, VT) and Corning Costar UV-Transparent Microplates (Corning, NY). Juice samples were centrifuged for 15 min at 3500*g* to remove nonsoluble solids. The supernatant fraction was diluted 10:1 in 10% glucose solution, and the 280 nm absorbance was read. Using the obtained absorbance value fresh supernatant was diluted with water to yield an approximate $OD_{280\ nm}$ of 1 AU. The diluted supernatants were analyzed for total polyphenols by the FC method.[30] Standards for the total polyphenols were generated using gallic acid from 0 mg/L to 500 mg/L in steps of 50 mg/L. The reaction was carried out in a 96-well, 2.2 mL storage block (Thermo Fisher, Suwanee, GA). The reaction mixture consists of 10 $\mu$L of standard or sample, 790 $\mu$L of water, and 50 $\mu$L of FC reagent (MP Biomedicals, Solon, OH). Three min after the addition of the FC reagent, 150 $\mu$L of 2 M sodium carbonate solution was added. The reaction mixture was incubated for 2 h at 21 °C. The 765 nm absorbance was measured by transferring 300 $\mu$L of the reaction mix to a 96-well microplate. Total polyphenol content was determined by linear regression from the standard curve plot and multiplying by the dilution factor.

**Sample Storage and Preparation for UPLC-MS/MS Analysis.** Immediately before analysis, apples to be analyzed by UPLC-MS/MS were transferred from the commercial cold storage facility to the Virginia Tech Main Campus (Blacksburg, VA), where they were stored in a walk-in cooler at 4 °C for 2−4 weeks prior to sample preparation. For each apple variety, peel and flesh samples from 15 individual apples were prepared. A consumer-grade apple peeler was used to remove the peel from each apple. Peel samples (1−2 g) were immediately weighed and placed and into a preservative solution (0.83 M acetic acid and 0.02% w/v ascorbic acid) to inhibit polyphenol oxidation. Flesh samples (~1 g) were immediately weighed and placed and into preservative solution. Peel and flesh samples were stored at −80 °C until extraction and analysis. Samples were thawed at 25 °C prior to extraction, and the preservative solution was decanted and discarded. Peel and flesh samples from five individual apples were pooled, resulting in $n = 3$ pooled replicates for each cultivar. Pooled samples were homogenized in 100 mL of acetone/water/acetic acid (70:28:2 v/v/v), sonicated (5 min), and centrifuged (10 min, 4 °C, 8000*g*). An aliquot of the supernatant was filtered (13 mm nylon syringe filter, 0.22 $\mu$m, VWR). Samples were prepared for UPLC-MS/MS analysis by combining 25 $\mu$L of filtered sample with 500 $\mu$L of 95:5 phase A/phase B (see UPLC-MS/MS Analysis Section, to follow, for phase compositions) in certified LCMS vials (Waters, Milford, MA).

**UPLC-MS/MS Analysis.** The polyphenolic composition of the apple cultivars was quantified by UPLC-MS/MS. UPLC was performed on a Waters Acquity H-class UPLC module with an Acquity UPLC HSS T3 column (2.1 mm × 100 mm, 1.8 $\mu$m particle size) maintained at 40 °C. Binary gradient

[a]Measurements were made on uncut whole fruit for fruit weight, red color, green background color, fruit firmness; bottom half of fruits were used for starch; pressed juice was used for soluble solids, pH, TA, and total polyphenols. Values are means, followed by standard errors in parentheses. [b]TA: titratable acidity, expressed as malic acid equivalents. [c]FC method was used.

dx.doi.org/10.1021/jf503379t | J. Agric. Food Chem. 2014, 62, 10181−10191

elution was carried out with 0.1% formic acid in water (phase A) and 0.1% formic acid in acetonitrile (ACN, phase B). Linear gradient elution was performed at a flow rate of 0.6 mL/min as follows: 95% A (0−0.5 min), 65% A (6.5 min), 20% A (7.5−8.6 min), 95% A (8.7−10.5 min). Sample temperature was maintained at 10 °C. UPLC effluent was analyzed by (−)-electrospray ionization (ESI) coupled to tandem mass spectrometry (MS/MS) on a Waters Acquity triple quadrupole (TQD) MS. Ionization was performed in (−) mode to generate pseudomolecular parent ions $[M - H]^-$ of compounds to be quantified (with the exception of cinnamtannin $A_2$, pentamers and hexamers, for which $[M - 2H]^{2-}$ was the most abundant pseudomolecular parent ion). ESI was performed with a capillary voltage of −4.25 kV, cone voltage of 30.0 V, extractor voltage of 3.0 V, and source and desolvation temperatures of 150 and 400 °C, respectively. Cone and desolvation gases were $N_2$ at flow rates 75 and 900 L/h, respectively. MS/MS was performed using Ar as the collision gas at 0.25 mL/min in the collision cell. Multireaction monitoring (MRM) was performed on pseudomolecular parent (precursor) ions and signature daughter (product) ions following collision-induced dissociation (CID). MS data collection was set to 10 points/peak with an average peak width of 6 s. The autodwell setting was used to automatically calculate dwell time based on an interscan delay time of 0.02 s for each transition. The TQD was operated in quantitation mode, with the mass resolution of the first and second quadrupoles set at 1.0 and 0.75, respectively. The Intellistart function of MassLynx was used to develop and optimize MRM parameters for each compound of interest. Compound solutions were directly infused into the ESI source in combination with a background flow of 50% phase A/50% phase B at 0.6 mL min. Intellistart automatically generated a single MRM transition for each compound centered on the exact monoisotopic mass of the parent (precursor) and daughter (product) ions, with a mass window of 0.2 amu (i.e., exact monoisotopic mass determined by Intellistart ±0.1). Refer to Table 1 for MRM parameters for each compound of interest. Refer to Supporting Information, Figure S2 for structures of quantified compounds. All compound peaks were processed and quantified using the QuanLynx function of MassLynx software. Peaks were smoothed using a mean smoothing method with 2−3 smoothing iterations and a smoothing width of 1. Compounds were quantified based on external standard curves of authentic standards in 0.1% formic acid in water: 0.1% formic acid in ACN (95:5 v/v). Calibration and method validation parameters are presented in Supporting Information, Table S1.

**Statistical Analysis.** Data were expressed as mean ± SEM for $n = 3$ replicate sets of five apples for UPLC-MS/MS analyses, pH, SSC, TA, and FC, and $n = 15$ replicates for fruit size, peel color, flesh firmness, and starch data. Statistical analyses were performed using Prism v6.0e (GraphPad Software, Inc., La Jolla, CA). Data for total catechin, total PC, total flavan-3-ol, total quercetin derivatives, total phloretin derivatives, chlorogenic acid, and total of measured polyphenols in both peel and flesh were analyzed by one-way ANOVA followed by all possible pairwise comparisons using Tukey's HSD posthoc test. Significance was defined as $P < 0.05$.

**Safety.** We report no unique safety considerations for the present research.

## RESULTS

Fruit size, peel color, and flesh firmness varied among cultivars, but all were within commercially acceptable ranges[31] (Table 2). With the exception of some of the later-maturing cultivars (Newtown Pippin, Stayman, and York), the apples had starch indices greater than 5, indicating that most of the stored starch had converted to sugar. GoldRush, Harrison, and Pilot all had SSC values greater than 15°Brix, which would result in a higher than average alcohol content in the resulting cider. Starch and SSC contents were not significantly correlated ($r^2 = 0.471$, $P = 0.3583$). Fuji, Golden Delicious, Jonagold, and Red Delicious had pH values greater than 3.8 (a threshold above which microbial control becomes more difficult in the fermentation process). Above pH 3.8, the standard recommendation is to add exogenous organic acid to the juice to bring the pH below 3.8. Black Twig, GoldRush, Harrison, and Newtown Pippin had the highest concentrations of titratable acidity, whereas Red Delicious had the lowest titratable acidity. For most cultivars in this study, total polyphenol content in juice pressed from whole fruits during the maturity assessment ranged from 211 and 415 mg GAE/L. With a total polyphenol content of 926 mg GAE/L in juice pressed from whole fruits, Harrison had more than twice the total polyphenol concentration in juice pressed from whole fruits as determined by FC than any other apple cultivar in this study.

Peel and flesh concentrations (mean ± SEM) for all individual polyphenols measured in apple cultivars are presented in Supporting Information, Tables S2−S5. Summary data for total catechins, total procyanidins (PCs), and total flavan-3-ols (catechins + procyanidins) in peel and flesh of apple cultivars are shown in Figure 1. There were extreme variations in the levels of catechins, PCs, and total flavan-3-ols between cultivars. Mean levels of total catechins varied from 0.000381 to 1.22 μg/g and 0.0530 to 4.17 μg/g for flesh and peel, respectively. In all cases, mean total catechin levels in peel were greater than those in flesh. The predominant catechins in both peel and flesh were EC followed by C (Supporting Information, Tables S2, S4). Mean levels of total PCs varied from 0.805 to 65.2 and 3.34 to 122 μg/g for flesh and peel, respectively. Similar to total catechins, mean total PC levels in peel were greater than those in flesh. PC $B_1$ was by far the predominant PC in both peel and flesh (Supporting Information, Tables S2, S4). Mean levels of total flavan-3-ols (catechins + PCs) ranged from 0.806 to 66.5 and 3.60 to 124 μg/g for flesh and peel, respectively. The majority of the flavan-3-ols in both peel and flesh were PCs; catechins made up just 0.0474 to 4.28 and 0.814 to 7.05% of the total flavanols by weight in flesh and peel, respectively. As the mean total PC and catechin levels were both greater in peel than those in flesh for all cultivars, this was also reflected in total flavan-3-ol levels.

Summary data for chlorogenic acid, total quercetin derivatives, and total phloretin derivatives in peel and flesh of apple cultivars are shown in Figure 2. Mean levels of total quercetin derivatives ranged from 0.00131 to 0.0186 and 0.144 to 3.24 μg/g for flesh and peel, respectively. Mean levels of total quercetin derivatives were higher in peel compared to flesh for all cultivars. Hyperin and isoquercitrin were the predominant quercetin derivatives in both flesh and peel; quercitin aglycone was much less abundant (Supporting Information, Tables S3, S5). Mean levels of total phloretin derivatives ranged from ND (not detected) to 63.5 and ND to 414 μg/g for flesh and peel, respectively (refer to Supporting Information, Table 1 for lower

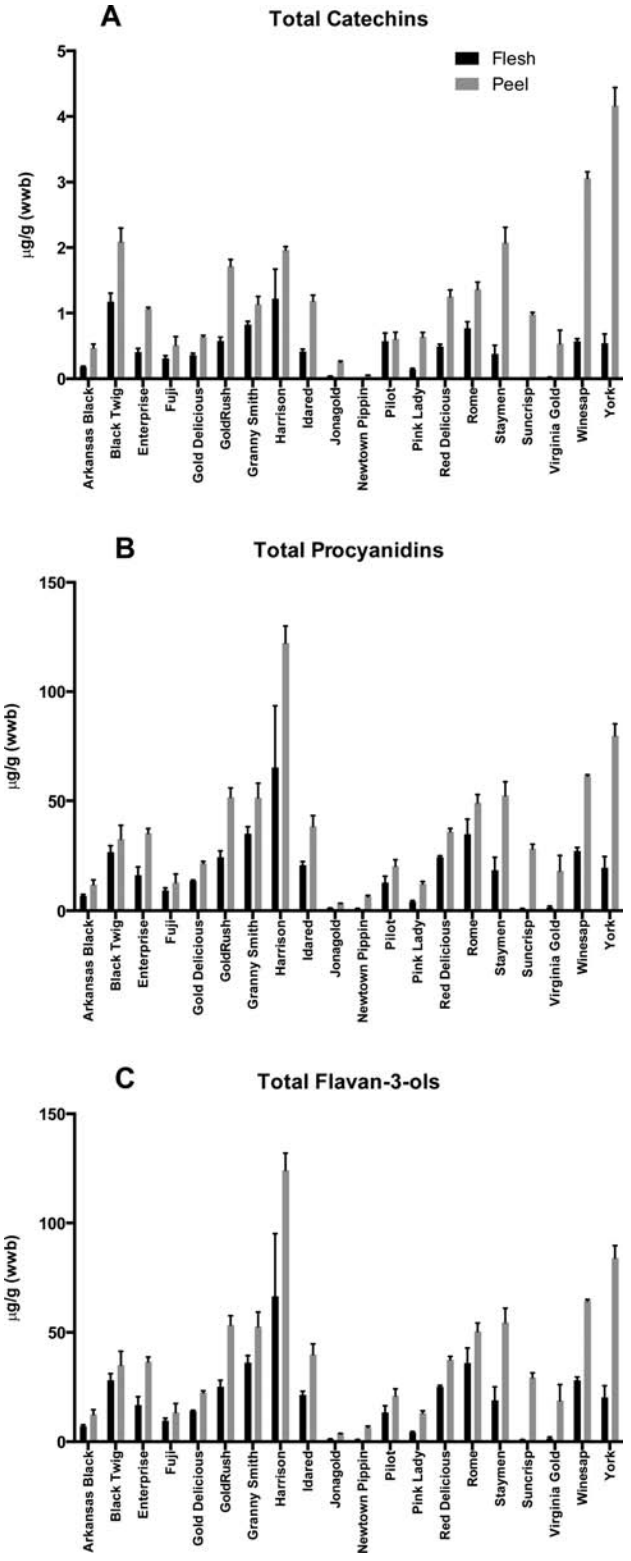

**Figure 1.** Peel and flesh concentrations of total measured catechins (A), total measured procyanidins (B), and total measured flavan-3-ols (C) in apple cultivars. Values are expressed on a wet weight basis (wwb). Values represent the mean ± SEM for $n = 3$ replicates (except for Harrison, flesh where $n = 2$). Total catechins = Σ[(−)-EGC, (+)-C, (−)-EC, (−) ECG], total procyanidins = Σ[PC $B_1$, PC $B_2$, PC $B_5$, 3 unidentified PC dimers, PC $C_1$, PC $T_2$, Cin$A_2$, PC pentamers, PC hexamers], total flavan-3-ols = total catechins + total procyanidins. Note that not all possible flavonoid glycosides were quantified by this analysis.

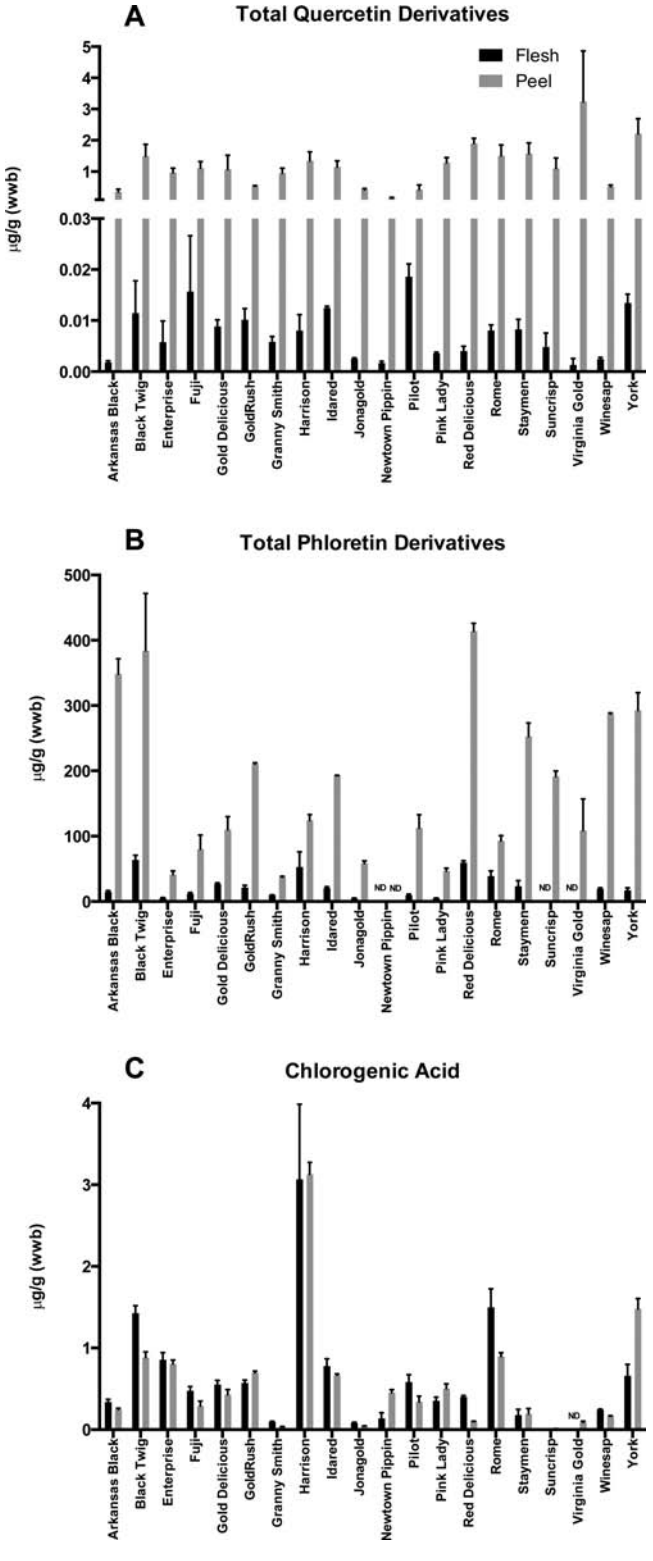

**Figure 2.** Peel and flesh concentrations of total measured quercetin derivatives (A), total measured phloretin derivatives (B), and chlorogenic acid (C) in apple cultivars. Values are expressed on a wet weight basis (wwb). Values represent the mean ± SEM for $n = 3$ replicates (except for Harrison, flesh where $n = 2$). ND = not detected. Total quercetin derivatives = Σ[hyperin, isoquercitrin, quercetin] and total phloretin derivatives= Σ[phloridzin, phloretin]. Note that not all possible flavonoid glycosides were quantified by this analysis.

limits of quantification and detection). Mean levels of total phloretin derivatives were higher in peel compared to flesh for all cultivars. No phloretin derivatives were detected in flesh or peel of Newtown Pippin, flesh of Suncrisp, or flesh of Virginia Gold. Phloridzin was by far the predominant phloretin derivative in peel; phloretin aglycone was only present in trace amount (5−7 orders of magnitude lower than phloridzin) (Supporting Information, Tables S3, S5). In flesh, phloridzin was the only phloretin derivative detected; no phloretin aglycone was detected in any flesh sample (Supporting Information, Tables S3, S5).

Mean chlorogenic acid levels ranged from ND to 3.07 and 0.00661 to 3.13 μg/g for flesh and peel, respectively. In contrast to values for all other measured compounds, mean chlorogenic acid levels were higher in flesh than peel for many cultivars (Arkansas Black, Black Twig, Enterprise, Fuji, Gold Delicious, Granny Smith, Ida Red, Jonagold, Pilot, Red Delicious, Rome, and Winesap).

The differences between peel and flesh concentrations of total quercetin and phloretin derivatives (Figure 2A,B) were much more pronounced than for total catechins, total PCs, or total flavan-3-ols (Figure 1), whereas the concentrations of chlorogenic acid in peel and flesh were very similar (Figure 2C). Overall, PC $B_1$ and phloridzin were clearly the most abundant individual compounds in both peel and flesh for most cultivars, although individual variations did occur (Supporting Information, Tables S2−S5). As mentioned previously, Newtown Pippin had no phloridzin in peel or flesh. Newtown Pippin also had little PC $B_1$ in either peel or flesh. VA Gold had no PC $B_1$ in flesh. Neither Virginia Gold nor Suncrisp had detectable phloridzin in flesh, as mentioned previously.

The sums of all individual compounds (catechins, PCs, chlorogenic acid, quercetin derivatives, and phloretin derivatives) in peel and flesh of apple cultivars are shown in Figure 3. Mean levels of all compounds measured varied from 0.943 to 122 and 7.11 to 453 μg/g for flesh and peel, respectively. For all cultivars, the total concentration of all individual compounds was greater in peel than flesh. However, extreme variation was observed in the ratio of total compounds in peel versus flesh: the concentration of total compounds in peel ranged from 1.9-fold to 222-fold greater than the concentration in flesh. The majority of the cultivars had a 1.9−7.9 fold difference between peel and flesh. York, Jonagold, and Arkansas Black had differences of 10.0, 10.8, and 16.2-fold, respectively. VA Gold and Suncrisp were extreme outliers, with differences of 87.3 and 222-fold, respectively.

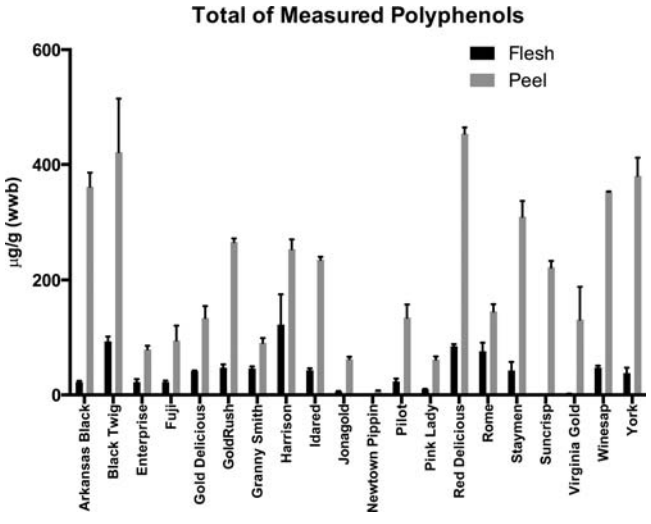

**Figure 3.** Peel and flesh concentrations of total measured polyphenols in apple cultivars. Values are expressed on a wet weight basis (wwb). Values represent the mean ± SEM for $n$ = 3 replicates (except for Harrison, flesh where $n$ = 2). Total measured polyphenols = Σ[total measured catechins, total measured procyanidins, total measured quercetin derivatives, total measured phloretin derivatives, chlorogenic acid]. Note that not all possible flavonoid glycosides were quantified by this analysis.

Linear regression analyses relating the sums of all individual compounds in peel with the sums of all individual compounds in flesh of apple cultivars are shown in Figure 4A. There appeared to be a moderate linear relationship between the sums of all individual compounds in flesh and peel ($r^2$ = 0.306, 95% CI for slope: 0.0347−0.238, slope is significantly different from 0, $P$ = 0.0114). Linear regression analyses relating the sums of all individual compounds in peel and flesh with the total polyphenol concentration in pressed juice (measured by the FC assay) of apple cultivars are shown in Figure 4B,C. There appeared to be no linear relationship between the sum of all individual compounds in peel and the total polyphenol levels in pressed juice ($r^2$ = 0.01667, 95% CI for slope: −0.419−0.718, slope is not significantly different from 0, $P$ = 0.59). There was a moderate linear relationship between the sum of all individual compounds in flesh and the total polyphenol concentration in pressed juice ($r^2$ = 0.430, 95% CI for slope: 1.33−4.83, slope is significantly different from 0, $P$ = 0.0017).

The overall effect of cultivar on the quantitative profile of the various classes of polyphenols measured is presented in Table 3. For all classes of compounds, cultivar had a statistically significant effect ($P$ < 0.05) on the amounts present in both flesh and peel, and this effect was highly significant ($P$ < 0.0001 for all compounds except total quercetin derivatives in both peel and flesh). Pairwise comparisons between all cultivars for each class of polyphenol measured in flesh and peel are shown in Supporting Information.

## DISCUSSION

Qualitative and quantitative polyphenol profiles vary widely across apple cultivars grown in Virginia. We observed significant differences across cultivar for concentration in both peel and flesh for catechins, procyanidins, total flavan-3-ols, total quercetin derivatives, total phloretin derivatives, and chlorogenic acid, as well as total measured polyphenols. Differences in fruit chemistry across cultivars were previously reported for cider apples grown in Spain, France, the U.K., New York, and other regions.[18,21,23,24,32] The total concentration of polyphenols measured by UPLC observed in fruit from Virginia (ranging from 7 μg/g wwb in peel for Newtown Pippin to 453 μg/g wwb in peel for Red Delicious) is low compared to similar surveys conducted in other cider-producing regions. This may be due to the fact that only select flavonoid aglycones were quantified in this study, and thus our total level of polyphenols does not account for some glycosides which may make up a significant fraction of the total flavonoids in apple. This study was designed to profile differences in select compounds rather than quantify all major flavonoid glycosides in apples. This may also be due to the fact that flesh and peel samples were stored in a preservative solution, which was decanted and discarded prior to extraction. Therefore, some polyphenols, particularly the most water-soluble compounds, may have leached into the solution and been discarded prior to extraction. However, it

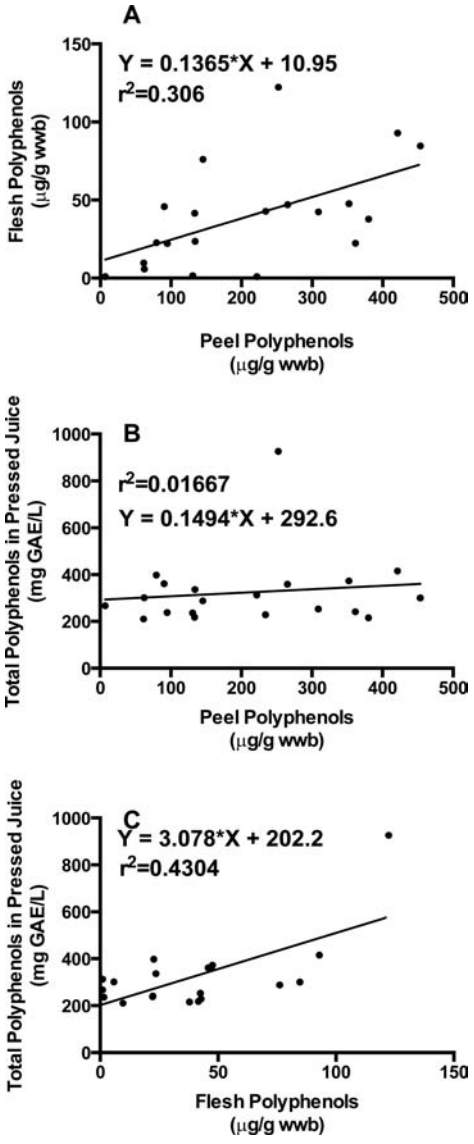

**Figure 4.** Linear regression analysis of peel and flesh concentrations of total polyphenols measured by UPLC-MS/MS (A), peel concentrations of total measured polyphenols measured by UPLC-MS/MS and total polyphenolic content of juice pressed from whole apples (B), and peel concentrations of total measured polyphenols measured by UPLC-MS/MS and total polyphenolic content of juice pressed from whole apples (C). The polyphenolic concentrations of juice pressed from whole apples were measured using the FC assay, and are expressed as mg gallic acid equivalents (GAE)/L juice. Data points represent the mean for $n = 3$ replicates (except for Harrison flesh, where $n = 2$). Note that not all possible flavonoid glycosides were quantified by this analysis.

should be noted that samples were frozen at −80 °C immediately following immersion in the preservative, and the preservative was immediately decanted after thawing. Therefore, the exposure time of the samples to the liquid preservative was minimal. Furthermore, all samples were treated equally, and thus this approach does not affect our primary objective of comparing differences in polyphenol levels between cultivars. Furthermore, a search of the literature and Phenol-Explorer reveal extreme variation in all compounds, including some reports of undetected flavonols, including quercetin and its derivatives.[33] In addition to analytical methodological differences, variations in genotype, climate, orchard management practices, and fruit maturity are expected to result in tremendous variation in polyphenol content. English cider apples contained 546 to 6306 μg/g fresh weight total polyphenols in peel, and 485 to 4920 μg/g in flesh.[32] Juice pressed from milled Spanish cider apples contained 67 to 927 mg/L total polyphenols, expressed as tannic acid equivalents. This may reflect the desired characteristics for cider in each of these regions.

**Table 3. Overall Statistical Significance of the Effect of Cultivar on Various Classes of Polyphenols in Both Apple Flesh and Peel**

| | *P*-values[a] | |
|---|---|---|
| measure | flesh | peel |
| catechins | <0.0001 | <0.0001 |
| procyanidins | <0.0001 | <0.0001 |
| total flavan-3-ols | <0.0001 | <0.0001 |
| total quercetin derivatives | 0.0154 | 0.0035 |
| total phloretin derivatives | <0.0001 | <0.0001 |
| chlorogenic acid | <0.0001 | <0.0001 |
| total of measured polyphenols | <0.0001 | <0.0001 |

[a] *P*-values from one-way ANOVA analysis.

It should be noted that no standardized conditions exist for extraction of polyphenols from apples. Recently reported conditions include a wide array of extraction solvent, including: methanol (MeOH)/0.1% formic acid, MeOH/water/acetic acid (70:29:1), MeOH/water (70:30), acetone/water (80:20), ethanol (EtOH)/water/formic acid (80:20:1), and aqueous buffer solutions (or no extraction, i.e., direct analysis of pressed and filtered juice).[34−39] The observed qualitative and quantitative profiles of polyphenols likely differ greatly depending upon the chosen extraction conditions. Our conditions were chosen to maximize extraction of the flavan-3-ols, particularly the PCs, due to our interest in the sensory implications of monomeric catechins and oligomerized PCs (the "hard" vs "soft" tannins) as well as the chemistry and health benefits of these compounds.[40] Furthermore, flavonoids such as quercetin, kaempferol, and phloretin are typically present in various glucoside forms, which complicate accurate determination of the total levels of these compounds. Although we have measured the aglycones and a few glycosides, the compounds measured in this study do not fully represent the compendium of glycosides of compounds such as quercetin, kaempferol, and phloretin. Therefore, these data should not be interpreted as exhaustive, rather as representative of the differences in flavonoid compositions between these cultivars. Analytical strategies to better quantify these compounds have included measurement of as many glycosides as possible,[41] as well as hydrolysis of the glycosides to yield the aglycone form.[36] We plan to employ glycoside hydrolysis in future studies to more accurately quantify total flavonoid levels. As with extraction conditions, the chosen analytical strategy likely influences the observed results. For example, for total polyphenol concentration in pressed juice from whole fruits presented with maturity parameters in Table 2, Harrison showed the highest total polyphenol concentration by the FC method, whereas Harrison showed intermediate values for total polyphenol concentration in peel in Figure 3, compared to other cultivars in the study. These differences are due to differences in both sample processing methods and analytical methods employed for maturity assessment, wherein juice was

pressed from whole fruit and analyzed by the FC method, and the individual polyphenol determination wherein peel and flesh were analyzed separately via UPLC-MS. Although the results are certainly influenced by the sample preparation and analytical methods, the results of this study indicate that there is a correlation between total polyphenols in flesh by UPLC-MS and total polyphenols in juice pressed from whole fruits (such as is used in cider production) by FC. In Figure 4B,C, the correlation coefficient for total polyphenols in pressed juice by FC with total polyphenols in peel, $r^2 = 0.02$, is much lower than the correlation coefficient of total polyphenols in pressed juice by FC with total polyphenols in flesh by UPLC-MS at $r^2 = 0.43$. Despite the variability imparted by differences in analytical approach, advancements in food analytical chemistry over the past decade have provided new perspectives on the extent of diversity in polyphenol composition across plant materials. Coupled with the increasingly sophisticated understanding of the impact of specific classes of polyphenols on physiology and health outcomes,[10,17,40,42] information on polyphenol composition observed across fruit genotypes and growing conditions[21,23,24,32,43−45] can be utilized to make informed selections of sources of fruit juice, extracts, and byproducts for use in future investigations of bioactivity and bioavailability of polyphenols. Phenol-Explorer is a useful online database which compiles results from thousands of studies on polyphenol content in a wide range of foods.[46]

Our results are consistent with previous studies showing that polyphenols are concentrated in the peel compared to the flesh of apples on a $\mu$g/g basis.[41,47] However, the much larger total mass of flesh than peel per fruit may result in larger total masses of specific compounds in the flesh versus peel.[38] The sum of the concentrations of compounds measured by UPLC ranged from 1.9- to 222-fold greater in peel versus flesh with high variability across cultivars. This variability is expected to impact extraction efficiency of polyphenols from milled apples into juice during processing.[48] For example, mechanical pressing parameters could be adjusted to allow for increased extraction of polyphenols from the peel in cultivars with very high peel/flesh polyphenol concentration ratios like Virginia Gold and Suncrisp, whereas these techniques would be less useful in cultivars like Harrison and Rome where flesh polyphenol concentration is relatively high. Future work is needed to examine the impact of processing parameters on the fate of polyphenols through the cider production process, from fruit to juice to fermented finished product.

In Virginia, the cultivars Harrison, Granny Smith, Rome, Winesap, and Black Twig had the highest concentration of total flavan-3-ols in flesh, indicating the highest potential for imparting desired sensory character from polyphenols to cider under current processing conditions where extraction of polyphenols from peel is minimal.[48] The highest concentrations of total flavan-3-ols in peel were found in Harrison, York, Winesap, Staymen, and GoldRush. These results indicate that further experimental work on improvement of polyphenol extraction from peel to pressed juice could increase total flavan-3-ol concentration in juice from cultivars such as York.

Phloridzin, a compound with a bittersweet taste, was found in highest concentration in the flesh of Black Twig, Red Delicious, Harrison, Rome, and Golden Delicious, and in the peel of Red Delicious, Black Twig, Arkansas Black, York, and Winesap. Phloretin, which can mask bitter taste,[49] was found in only very low concentrations of <0.01 $\mu$g/g wwb across cultivars and tissues in our study. Highest total polyphenol concentrations in flesh were found in Harrison, Black Twig, Red Delicious, Rome, and Winesap, and in the peel of Red Delicious, Black Twig, York, Arkansas Black, and Winesap. The sensory impact of phloridzin and flavan-3-ols would be expected to vary depending on sugar, alcohol, and acid concentration in cider; therefore, it is useful to consider the concentration of these categories of polyphenols in addition to total polyphenol concentration when selecting cultivars for cider production.

In addition to variation across cultivars, cultural practices and orchard maturity have been demonstrated to impact polyphenol concentration in cider apples.[44] Understanding how polyphenol composition and concentration change as orchards mature and respond to different climates and cultural practices will be important in achieving consistent production of fruit with optimal polyphenol concentration and composition to support the growth of the cider industry in Virginia. Based on the results of this study, the cultivars Harrison, Granny Smith, Rome, Winesap, and Black Twig show the highest potential for imparting desired polyphenol character to cider under current growing and processing conditions.

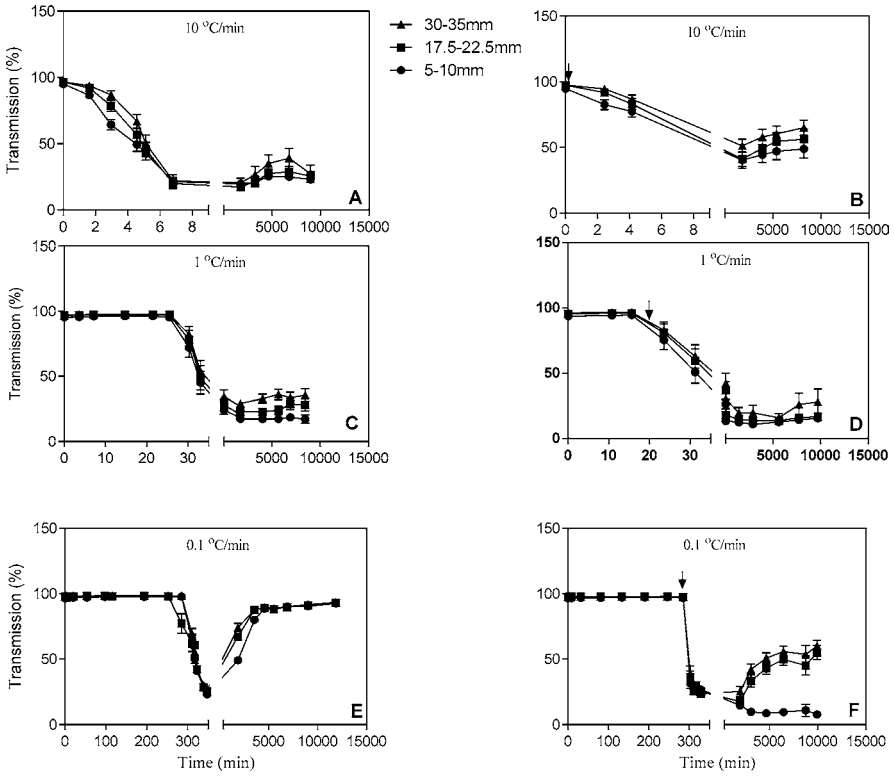

**Figure 1.** Transmission measurements of 0.5% BW in soybean oil crystallized at 25 °C for 7 days using different cooling rates (0.1, 1, and 10 °C/min) without (left column) and with (right column) HIU: (A, B) 10 °C/min; (C, D) 1 °C/min; (E, F) 0.1 °C/min. Transmission measurements were performed at the bottom of the tube (5−10 mm from the bottom, solid circles), at the middle of the tube (17.5−22.5 mm, solid squares), and at the top of the tube (30−35 mm, solid triangles). The arrow (right column) indicates the moment at which HIU was applied. One hundred percent transmission of light indicates there is no turbidity, and 0% transmission indicates that the contents of the assay tubes are completely turbid.

pure corn oil, Great Value pure olive oil, high-oleic All Natural Louana pure safflower oil, high-oleic Antoine & Muse imported pure sunflower oil, and Pure Wesson soybean oil were used in our experiments. Beeswax was supplied by Koster Keunen, Inc. BW is composed of wax esters (35%, mainly C50), hydroxyl esters (24%, mainly ester of 15-hydroxypalmitic acid and C24−C34 alcohols), hydrocarbon (14%), diesters (12%), free acids (12%), and unidentified compounds (6%).[14] Samples of 0.5 and 1% BW in vegetable oils were used. Three different cooling rates were evaluated (0.1, 1, and 10 °C/min) to represent slow, medium, and fast cooling rates. BW was mixed with the oils and heated to 100 °C in an oven to allow for complete melting and dissolution of the wax in the oil. Samples were kept at 100 °C for at least 30 min, and then 5 g of the melted samples was placed in customized tubes for transmission measurements (see section below) and placed again in the oven to ensure that no wax crystallized during the filling of the tubes.

**Fatty Acid Compositions in Different Oils.** Fatty acid compositions of the oils were determined as described by Ye et al.[20] using a gas chromatograph (Shimadzu 2010) equipped with a flame ionization detector (Shimadzu, Columbia, MD, USA).

**Cooling Rate Measurement.** After the samples had bee kept in the oven for 30 min, samples were cooled from 60 to 25 °C using the three different cooling rates previously mentioned. Slower cooling rates (0.1 and 1 °C/min) were achieved using a programmable water bath (Lauda Ecoline Staredition (Delran, NJ, USA). The fast cooling rate (10 °C/min) was achieved by placing the hot samples in a water bath (VWR, model 1160S (Buffalo Grove, IL, USA), that was preset at the crystallization temperature (25 °C).

**High-Intensity Ultrasound (HIU).** HIU operating at a frequency of 20 kHz was applied to the samples using a 2 mm probe (part 4423, Qsonica Sonicators, Newtown, CT, USA) with a vibration amplitude of 180 $\mu$m for 10 s, which resulted in a power level of 10 W. To achieve maximum efficiency of the ultrasound waves, HIU was applied in the presence of crystals;[20] therefore, HIU was applied at 300, 20, and 1.5 min for the 0.5% BW samples cooled at 0.1, 1, and 10 °C/min cooling rates, respectively. HIU was applied at 300, 15, and 1.5 min for 1% BW cooled at 0.1, 1, and 10 °C/min cooling rates, respectively.

**Transmission Measurement.** The crystallization behavior of the samples was followed by measuring the transmission of light through the samples. When samples crystallize, they create a certain amount of turbidity, showing a decrease in the transmission of light. Transmission of light through the samples was taken with TurbiScan equipment (Turbiscan Classic, MA2000, L'Union, France), and data were analyzed using computer software (Turbisoft version 1.2.1). Melted samples (5 g) were placed in the TurbiScan tubes reaching a height of 40 ± 0.5 mm, and transmission was measured as a function of time. Transmission of the tubes was measured at three different levels, 5−10 mm (bottom), 17.5−22.5 mm (middle), and 30−35 mm (top), respectively, from the bottom of the tubes. TurbiScan data were taken on a daily basis for 7 days, from the start of the experiment. Details regarding the operation of TurbiScan can be found in Martini and Tippetts.[21]

**Crystal Morphology.** After 1 week of storage in an incubator at 25 °C, crystals present in the samples were evaluated. Samples were taken from the middle of the tube when no phase separation was observed and from the bottom when phase separation was observed. Crystal morphology was analyzed at different cooling rates at different concentrations of BW in different oils crystallized with and without the use of HIU. The crystals were observed using a polarized light microscope (Olympus BX41, Olympus Optical Co., Tokyo, Japan). A small amount of sample containing crystals was placed on a glass microscope slide and covered gently with a glass cover slip. Digital images of the polarized specimens were captured using Lumenera's Infinity 2 (Lumenera Corp., Nepean, Canada). Approximately 10 pictures of each sample and crystallization run were taken to obtain approximately 200 crystals. These pictures were used to measure crystal sizes using ImageJ 1.42q (Wayne Rasband, National Institutes of Health, USA).

**Differential Scanning Calorimetry (DSC).** The melting profile of the different samples crystallized at 25 °C for 7 days was measured using DSC (TA Instruments DSC model Q20 1963 with RCS cooling system, New Castle, DE, USA). Samples were centrifuged at 25 °C at 3000*g* for 30 min to separate the crystals from the oil and achieve higher resolution in the DSC. The DSC baseline and temperature were calibrated with a pure indium standard. Approximately 10 mg of crystals was placed in Tzero aluminum pans, covered and sealed with Tzero aluminum lids. The samples were heated from 25 to 100 °C with a ramp of 5 °C/min to analyze the melting profile of the samples. TA Universal Analysis software was used to analyze the onset and peak temperatures.

**Statistics.** Samples were crystallized in triplicate. From each crystallization run, transmission measurements were taken in quintuplicate and DSC measurements were taken in duplicate. TurbiScan data were reported using GraphPad Prism6 software (Graphpad Software, San Diego, CA, USA). Crystal sizes were analyzed using Microsoft Office Excel 2010 (Microsoft Corp., Redmond, WA, USA). Statistical analysis was performed using two-way ANOVA test using GraphPad Prism6 software.

## RESULTS AND DISCUSSION

**Effect of Cooling Rate, Wax Concentration, and HIU on BW Crystallization.** Figure 1 shows transmission measurements of 0.5% BW in soybean oil crystallized to 25 °C for 7 days using three different cooling rates (0.1, 1, and 10 °C/min). The *x*-axis denotes time of storage at 25 °C, and the *y*-axis is the percentage of transmission through the wax/oil sample. Transmission counts were taken at the bottom, middle, and top of the tube to evaluate if crystallization occurs in a homogeneous manner throughout the tube. As expected, samples crystallized more quickly when cooled at the fast cooling rate (10 °C/min) and reached a minimum value of approximately 25% transmission after 7 h (Figure 1A) at 25 °C. When samples were crystallized at 1 °C/min (Figure 1C), values of transmission similar to the ones observed for the sample crystallized at 10 °C/min were obtained. However, when the sample was crystallized at 1 °C/min, slighter higher values of transmission were observed after 1 day (1440 min) at 25 °C at the middle and top of the tube compared to the transmission values obtained at the bottom of the tube. This indicates that some degree of phase separation occurs under these conditions when the sample gets less turbid over time due to crystal sedimentation. This effect is even more significant when samples are cooled at 0.1 °C/min (Figure 1E), when a significant phase separation is observed after the first day of storage at 25 °C (note the significant increase in transmission in Figure 1E), and a high transmission value (∼100%) is observed after 3 days (4320 min), suggesting that the tube is completely clear after 3 days of storage and that the crystals have sedimented at the bottom of the tube (lower than 5 mm from the bottom). Therefore, it is evident that the cooling rate has a direct influence on the phase separation of the wax in oil mixture.

HIU was used in these samples to evaluate if this processing tool could help in stabilizing crystal networks and therefore delay phase separation. When HIU was applied in samples crystallized at the fast cooling rate, higher transmission values (27 ± 7 and 65 ± 6% for samples crystallized without and with HIU, respectively) were observed (Figure 1B), suggesting that HIU delays wax crystallization under these conditions. Figure 1D shows that HIU slightly delays phase separation when samples were cooled at 1 °C/min because transmission values obtained at the bottom, middle, and top of the tube are similar. This can be observed by comparing transmission values reported in panels C and D of Figure 1 at 30−35 mm (35 ± 5 and 28 ± 10%, respectively). A significant delay in phase separation is observed for samples crystallized at the slow cooling rate and with HIU application. No phase separation was observed at the bottom of the tube, and significantly lower transmission values were observed in the middle and top of the tubes (Figure 1F) compared to the same sample crystallized without the use of HIU (Figure 1E). These data suggest that HIU can help in the stabilization of a crystalline network to avoid phase separation, especially when samples are processed using slow cooling rates.

To understand the results reported in Figure 1, the morphology of the crystals was evaluated using polarized light microscopy after storage. Figure 2 shows the morphology

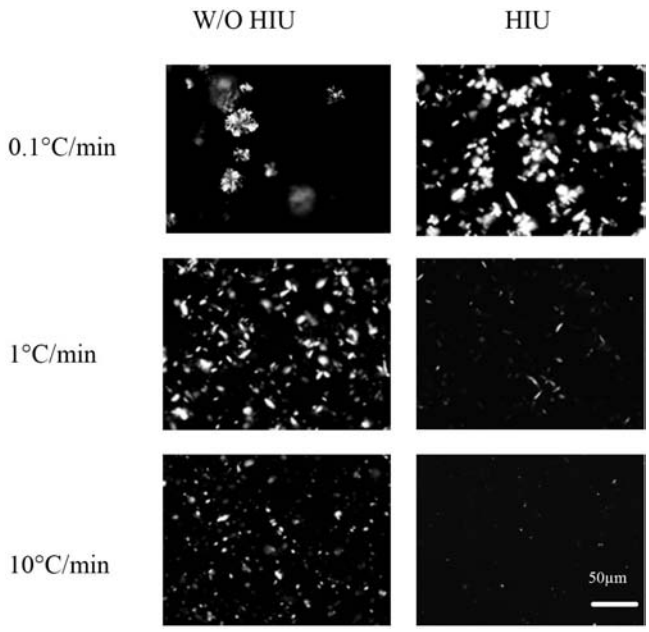

**Figure 2.** Morphology of crystals obtained when 0.5% BW in SBO is crystallized at 25 °C for 7 days at different cooling rates (0.1, 1, and 10 °C/min) without (left column) and with (right column) HIU. Crystal pictures were taken at 20× magnification under polarized light microscopy. The white bar corresponds to 50 μm.

of crystals obtained for the 0.5% BW samples crystallized in soybean oil at different cooling rates (0.1, 1, and 10 °C/min) with and without the use of HIU. As expected, bigger crystals where obtained when samples were crystallized at slow cooling rates. Previous research has reported the increase in crystal size when lipids are crystallized using slow cooling rates.[22] In addition, this figure shows that HIU reduced crystal sizes and morphologies, especially for the BW crystallized at slow cooling rates: big spherulites are observed in the sample crystallized without the use of HIU, and smaller crystals are observed when HIU was used.

The experiments performed in Figures 1 and 2 were repeated using a BW concentration of 1% to evaluate the effect of cooling rate and sonication when a higher wax concentration is used. Figure 3 shows the transmission measurements for these samples. All of the crystallization conditions remained constant except the timing of the ultrasound application. HIU was applied at 5 h, 15 min, and 1.5 min for 0.1, 1, and 10 °C/min, respectively. This change was performed so that HIU could be applied at the moment when the first crystals appeared. The

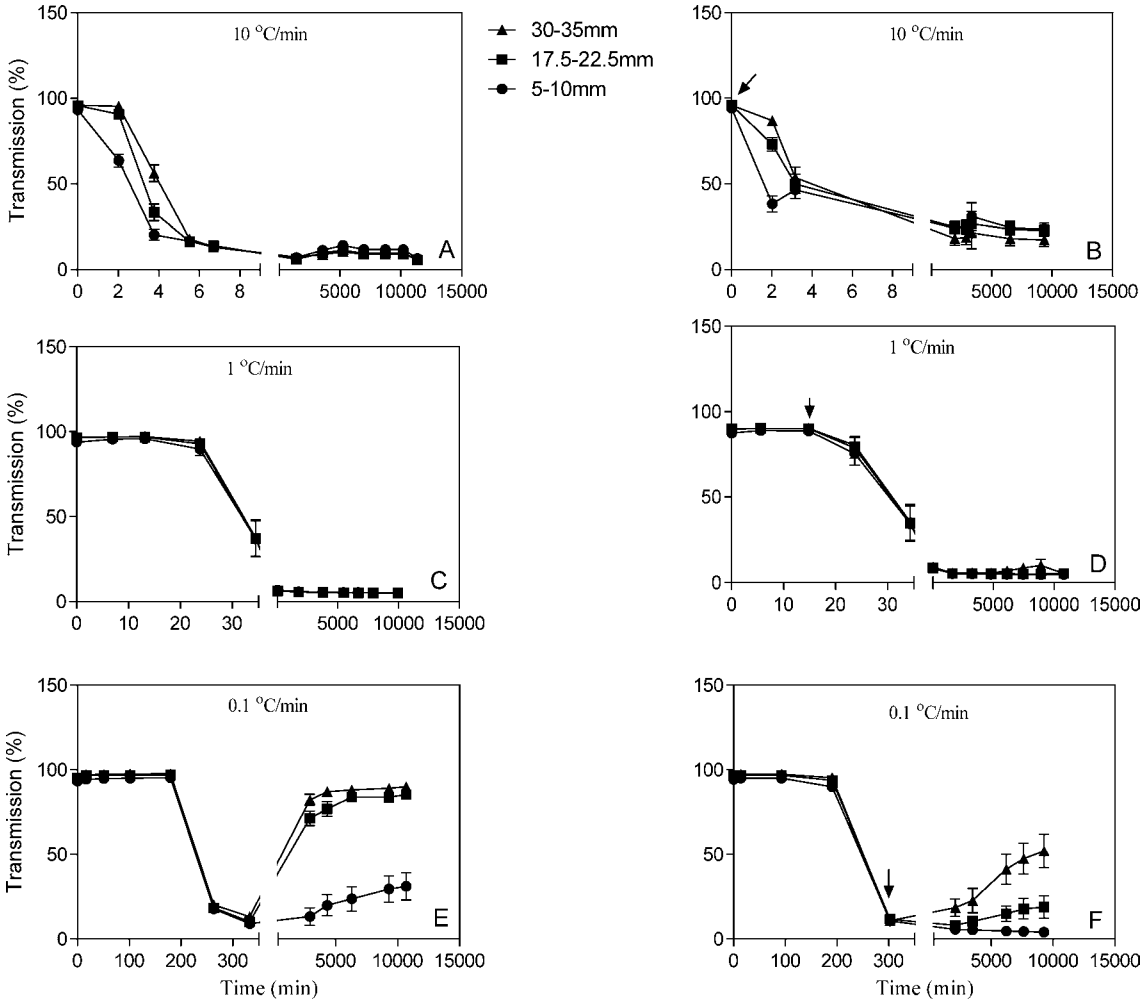

**Figure 3.** Transmission measurements of 1% BW in soybean oil crystallized at 25 °C for 7 days using different cooling rates (0.1, 1, and 10 °C/min) without (left column) and with (right column) HIU: (A, B) 10 °C/min; (C, D) 1 °C/min; (E, F) 0.1 °C/min. Transmission measurements were performed at the bottom of the tube (5−10 mm from the bottom, solid circles), at the middle of the tube (17.5−22.5 mm, solid squares), and at the top of the tube (30−35 mm, solid triangles). The arrow (right column) indicates the moment at which HIU was applied. One hundred percent transmission of light indicates there is no turbidity, and 0% transmission indicates that the contents of the assay tubes are completely turbid.

higher concentration of BW (1 vs 0.5%) induced crystallization, and therefore HIU was applied sooner. Figure 3 shows that no phase separation was observed in the samples crystallized at intermediate (1 °C/min) and fast cooling rates (10 °C/min) with transmission values of 5 ± 0 and 7 ± 2%, respectively (Figure 3, panels A and C, respectively). Some degree of phase separation was observed in samples crystallized at the slow cooling rate with transmission values of 90 ± 2% at the top of the tube and 31 ± 8% at the bottom of the tube (Figure 3F). The use of HIU did not affect the final transmission value of the samples crystallized at 1 and 10 °C/min (Figure 3B,D) but significantly affected transmission values and therefore phase separation of samples crystallized at slow cooling rates (Figure 3F). The transmission values for these samples decreased to 52 ± 10% at the top of the tube and 19 ± 7% at the bottom of the tube. Similarly to the results reported for the 0.5% samples, these results show that HIU delayed phase separation during storage.

Figure 4 shows the morphology of crystals obtained for the samples discussed in Figure 3 after 7 days of storage at 25 °C. Even though a slight decrease in the crystal size is observed as a consequence of sonication, the effects are not as evident as the ones observed for the 0.5% BW in soybean oil samples (Figure 2). Figure 4 shows that the morphology of the BW crystals cooled at 0.1 °C/min is not changed as a consequence of sonication as reported for the 0.5% BW samples.

Results reported in Figures 1−4 suggest that a significant phase separation occurs when 0.5 and 1% of BW is crystallized at the slow cooling rate (0.1 °C/min) in soybean oil and that this phase separation can be delayed using HIU. Previous research on natural waxes with soybean oil was done by Hwang et al.[14,15] and suggested that sunflower wax works best toward crystallization and cooling rate in a concentration range of 0.5−10%. Dassanayake et al.[12] evaluated the crystallization behavior of rice bran, carnauba, and candelilla wax in olive oil and salad oil (50% canola + 50% soybean oil) and suggested that the long, thin, needle-shaped crystal structures formed by rice bran wax in the above oils might be responsible for the good gelling properties of this wax. Similar to our data, Toro-Vazquez et al.[5] showed that 1% candelilla wax crystallized in safflower oil showed phase separation during storage for 3 months. Even though some wax/oil combinations have been studied as discussed above, it is not clear how the type of oil affects the crystallization of waxes. However, the existing literature and our

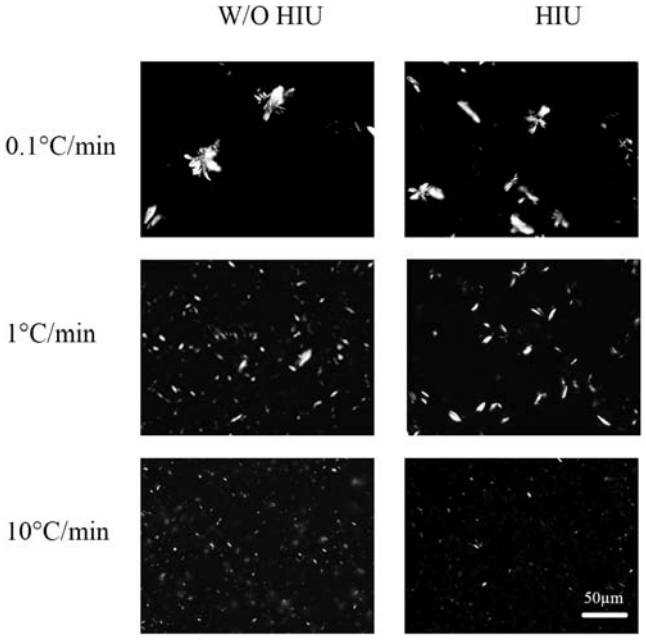

**Figure 4.** Morphology of crystals obtained when 1% BW in SBO is crystallized at 25 °C for 7 days at different cooling rates (0.1, 1, and 10 °C/min) without (left column) and with (right column) HIU. Crystal pictures were taken at 20× magnification under polarized light microscopy. The white bar corresponds to 50 $\mu$m.

data agree on the fact that wax concentration and cooling rate have a direct impact on wax crystallization. Therefore, the next step in our research is to evaluate if the crystallization of BW is affected by the type of oil used when crystallized at 0.1 °C/min.

**Effect of Oil Type and Sonication on BW Crystallization.** Table 1 shows the fatty acid composition of the oils used in this research. These oils were chosen to include different and typical chemical compositions found in vegetable oils. For example, canola and sunflower oils have approximately 62% of oleic acid (C18:1), whereas olive and safflower oils have higher contents of oleic acid (approximately 73 and 76%, respectively). On the other hand, corn and soybean oils have lower contents of oleic acid with values of approximately 29 and 23%, respectively.

Figure 5 shows the crystallization behavior of 0.5% BW in different vegetable oils cooled at 0.1 °C/min. Phase separation was observed in 0.5% BW samples crystallized in all of the oils tested (canola, corn, olive, safflower, and sunflower) when stored. It is interesting to note that the crystallization behavior of the 0.5% BW solutions is significantly affected by the type of oils used. For example, when BW is crystallized in soybean oil, the sample starts crystallizing at approximately 300 min (Figure 1E). The onset of crystallization is lower for canola, corn, olive, safflower, and sunflower with an onset of crystallization of approximately 200 min for canola and sunflower and 250 min for corn, olive, and safflower (Figure 5A,C,E,G,I). As previously discussed, phase separation was very marked when 0.5% BW was crystallized in soybean oil (Figure 1E). Phase separation was observed in all the other samples but to a lower degree. When 0.5% BW was crystallized in canola oil (Figure 5A), the sample remained turbid at the bottom of the tube even after 5000 min (~3.5 days) of storage with transmission values of 22 ± 1%. However, some degree of phase separation is present after the first day of storage, which is evidenced by higher transmission values observed at the top of the tube (50 ± 4%). This phase separation becomes more evident at approximately 3500 min (~2.5 days), when the transmission increased to 61 ± 5% at the top of the tube and to 33 ± 3% in the middle of the tube. The use of HIU in this sample inhibited crystallization, and lower values of transmission were observed (60 ± 15% at the bottom of the tube at 1500 min). These transmission values remained constant during storage, indicating that phase separation was delayed due to the use of HIU. When 0.5% BW was crystallized in corn oil (Figure 5C), the sample shows more turbidity (24 ± 7%) at the bottom after 5000 min of storage compared to the middle (39.6 ± 5.3%) and top (51 ± 7%) of the tube. HIU application (Figure 5D) made the transmission values approximately similar at the bottom (29 ± 10%), middle (32 ± 11%), and top (32 ± 11%) of the tube, suggesting the lack of phase separation. The transmission at the bottom part of 0.5% olive oil (Figure 5E) was low (42 ± 7%) up to 4200 min and then increased over time. Similar results were observed at the middle (65 ± 5%) and top (73 ± 2%) of the tube. When HIU was used (Figure 5F), transmission levels were lower at the bottom (22 ± 6%), middle (45 ± 9%), and top (46 ± 8%) part of the tube after 4700 min. When 0.5% BW was crystallized in safflower oil (Figure 5G), the contents at the bottom part (38 ± 2%) of the tube were more turbid than the middle (53 ± 2%) and top (60 ± 2%), but no changes in transmission values were observed when HIU was applied (Figure 5H) with approximately the same turbidity obtained throughout all levels of the tube (transmission at bottom, 63 ±

[a]Mean values and standard deviation of two replicates are reported. Fatty acids present at levels below 0.5% are not reported.

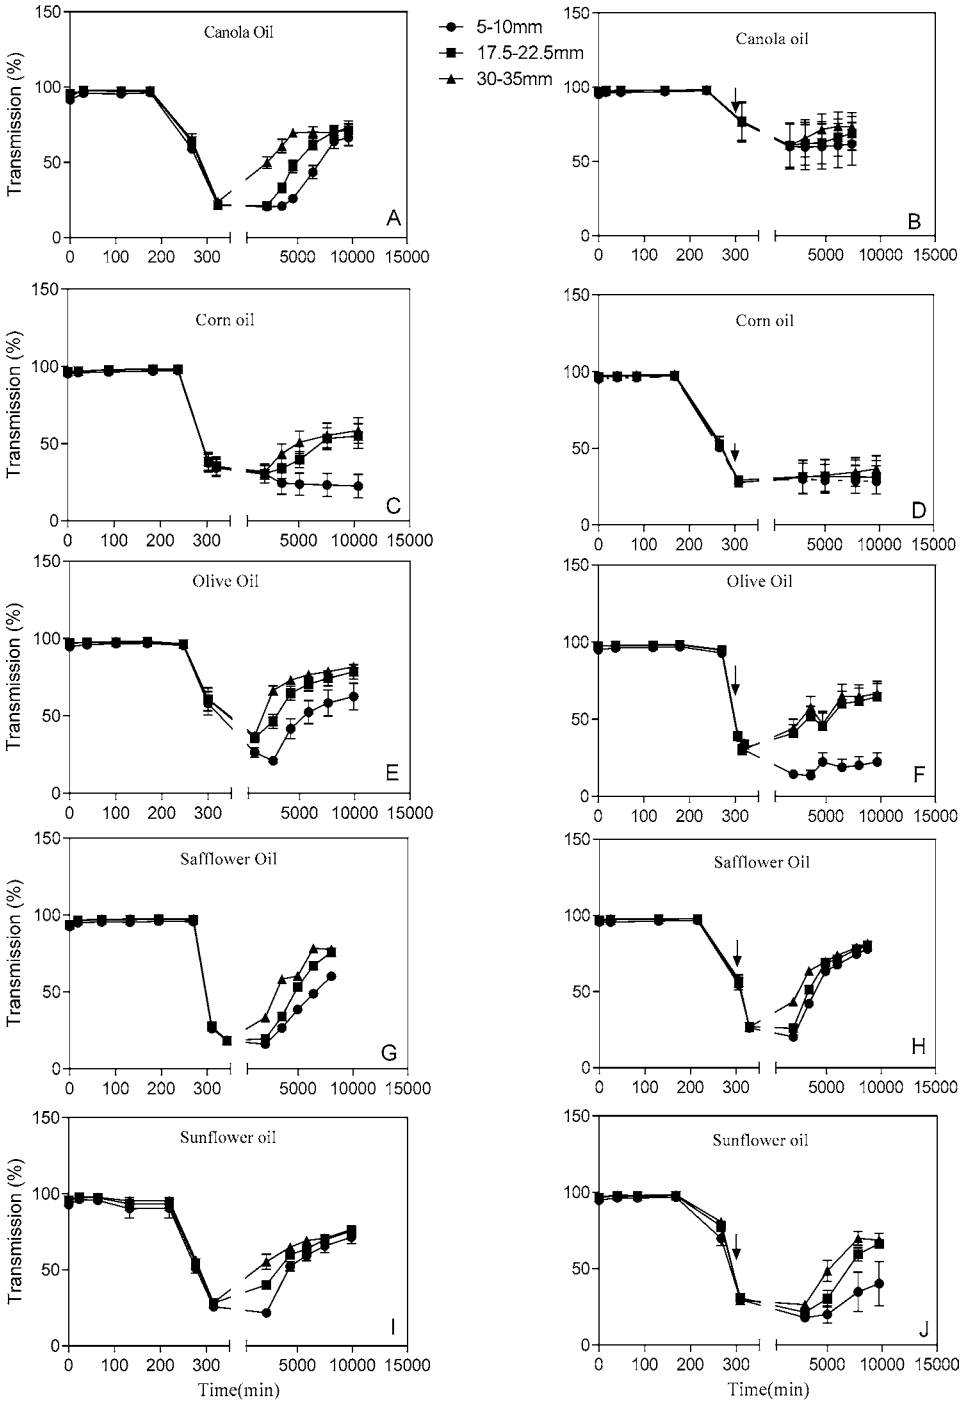

**Figure 5.** Transmission measurements of 0.5% BW in different edible oils crystallized at 25 °C for 7 days using a slow cooling rate of 0.1 °C/min without (left column) and with (right column) HIU: (A, B) canola oil; (C, D) corn oil; (E, F) olive oil; (G, H) safflower oil; (I, J) sunflower oil. The arrow shows the time of HIU application, that is, 300 min after the start of the experiment.

2%; middle, 69 ± 1%; and top, 70 ± 1.6%) after 5000 min. When 0.5% BW was crystallized in sunflower oil, the transmission at the bottom after 5000 min was 59 ± 3% and the transmissions in the middle and top portions were 64 ± 3 and 69 ± 3%, respectively. The transmission through sunflower oil (Figure 5J) shows more turbidity with HIU application after 5000 min at all levels of the tube. The bottom part reached a transmission value of 20 ± 6%, and the middle and top reached 30 ± 6 and 49 ± 7%, respectively. Overall, the stability toward phase separation increased in the order soybean oil < olive oil < sunflower oil < canola oil < safflower oil < corn oil. These results suggest that (a) for the same type and amount of wax, the type of oil used affects the degree of phase separation and (b) HIU can help in the delay of phase separation to different degrees depending on the oil used. However, it is not clear how the type of oil affects BW crystallization. For example, corn oil and soybean oil have both very similar fatty acid compositions (Table 1, 29.9 vs 23.9% of oleic acid), and the crystallization behavior of BW and phase separation observed are significantly different (Figures 1E and 5C) where more phase separation is observed in the soybean oil samples and a greater effect of sonication is observed in the corn oil samples (Figures 1F and

dx.doi.org/10.1021/jf503393h | J. Agric. Food Chem. 2014, 62, 10192−10202

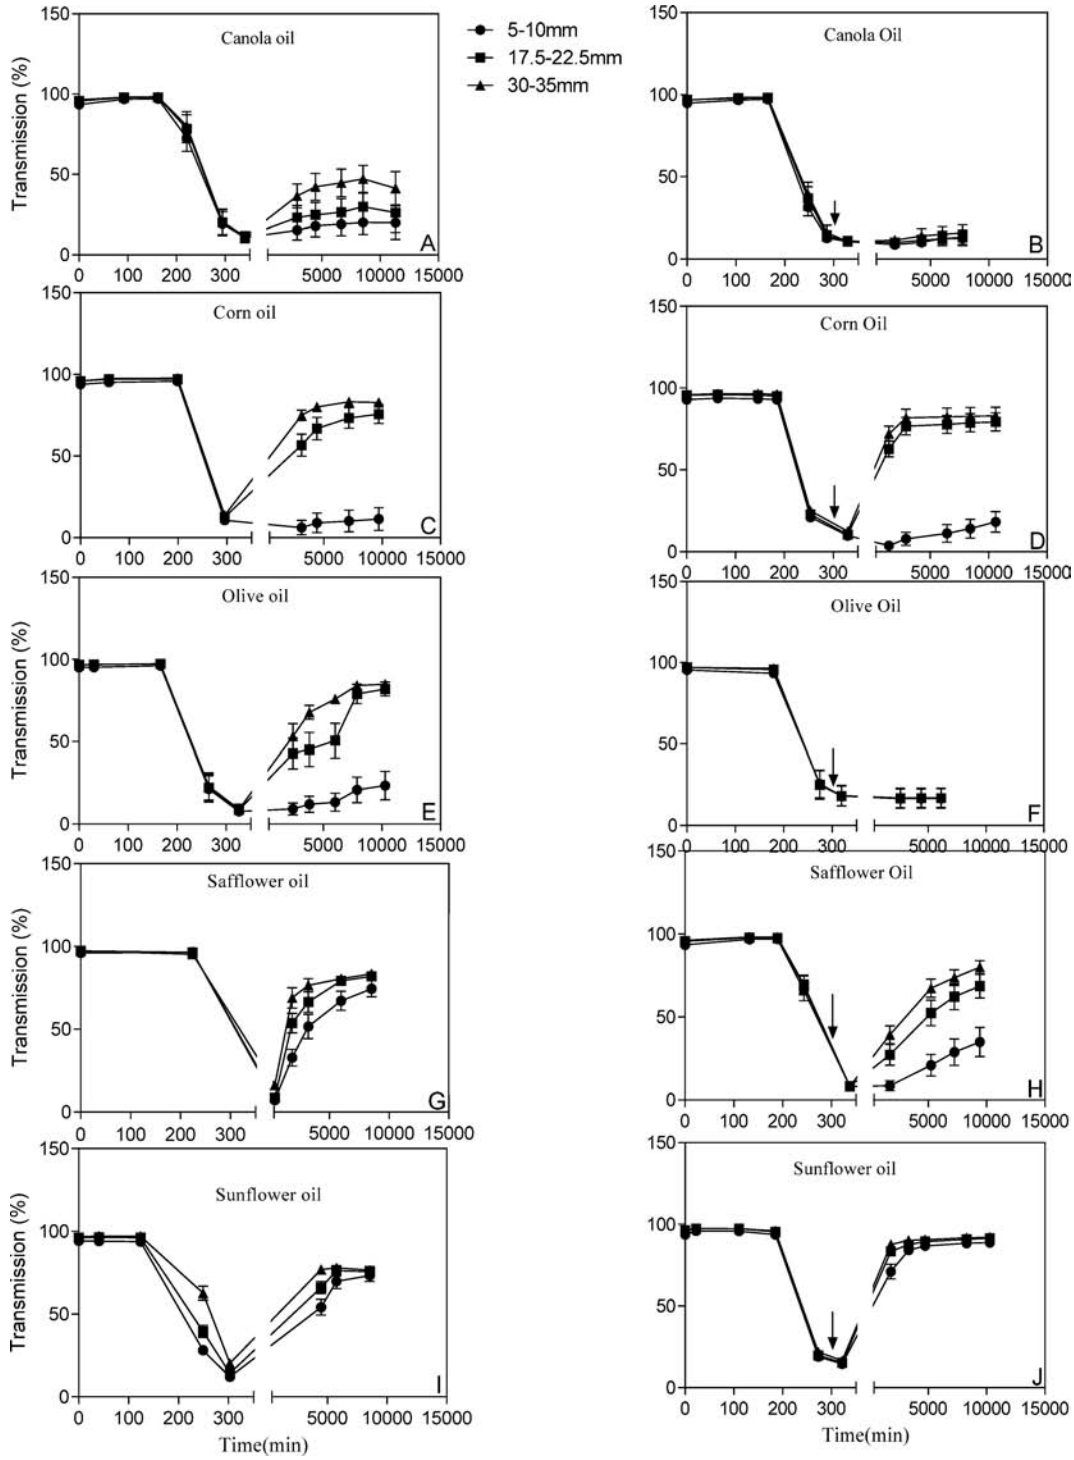

**Figure 6.** Transmission measurements of 1% BW in different edible oils crystallized at 25 °C for 7 days using a slow cooling rate of 0.1 °C/min without (left column) and with (right column) HIU: (A, B) canola oil; (C, D) corn oil; (E, F) olive oil; (G, H) safflower oil; (I, J) sunflower oil. The arrow shows the time of HIU application, that is, 300 min after the start of the experiment.

5D). It is possible that the differences observed are a consequence of the C18:3 content because the value observed in soybean oil is approximately 87% higher than in corn oil.

Similarly, Figure 6 shows the crystallization behavior of 1% BW in different vegetable oils cooled at 0.1 °C/min. Phase separation was observed in 1% BW samples crystallized in all of the oils tested (canola, corn, olive, safflower, and sunflower) when stored and was affected by the type of oil used. When 1% BW samples were crystallized in canola oil (Figure 6A), the sample remains more turbid at the bottom (18 ± 7%) after 5000 min and the transmissions at the middle and top parts were 25 ± 8 and 42 ± 8%, respectively. At 340 min the transmissions in all three levels were the same for 1% BW samples in canola oil (almost 11%). When HIU (Figure 6B) was applied in 1% BW in canola oil sample, the transmission at the top level after 6000 min was 15 ± 5% and the transmissions at bottom and middle of the tube after 6000 min were 12 ± 4 and 12 ± 4%, respectively. This low value of transmission

dx.doi.org/10.1021/jf503393h | J. Agric. Food Chem. 2014, 62, 10192−10202

suggests that HIU decreases phase separation of 1% BW in canola oil. When 1% BW samples were crystallized in corn oil (Figure 6C), the contents at the top (80 ± 3%) and middle (67 ± 7%) of the tube were more transparent than that at the bottom part after 4500 min kept at 25 °C. Data collected from 1% BW sample with HIU application (Figure 6D) show no different transmission pattern (top level, 82 ± 5%; middle, 78 ± 6%; and bottom, 11 ± 5.4%) in all levels of transmission after 6500 min of storage at 25 °C compared to the sample crystallized without HIU (Figure 6C). Previous research in our laboratory in anhydrous milk fat showed that the effect of HIU is less effective in samples crystallized under high driving forces.[19] In this case, the higher concentration of wax (1 vs 0.5%) might create a high enough driving force that inhibits the effect of sonication to some degree. When 1% BW is crystallized in olive oil (Figure 6E), more turbidity at the bottom of the tube (13 ± 6%) is observed compared to the turbidity at the middle and top (50 ± 10.5 and 76 ± 3%, respectively). The transmissions obtained for 1% BW samples crystallized with HIU (Figure 6F) were similar for the entire tube length. The bottom part shows 17 ± 6% transmission, the middle part shows 17 ± 6% transmission, and the top part shows 17 ± 6% transmission. Similar to the results shown for 1% BW crystallized in canola oil, HIU inhibited phase separation for a period of 7 days. When 1% BW samples were crystallized in safflower oil (Figure 6G), phase separation was observed with transmission values of 80 ± 2% at the top, 79 ± 3% in the middle, and 67 ± 6% at the bottom after 6000 min of storage. When HIU was applied (Figure 6H), the transmission after 5200 min at the bottom was 21 ± 6.5%. Lower transmission values were also obtained in sonicated samples in the middle (52 ± 8%) and in the top (67 ± 6%) sections of the tube. These results suggest that HIU helped delay phase separation in 1% BW crystallized in safflower oil. When 1% BW was crystallized in sunflower oil (Figure 6I), there was a difference in transmission in the three sections of the tube after 4500 min; the contents in the bottom section are more turbid (54 ± 5% transmission) than those in the middle (66 ± 4%) and top (77 ± 3%) sections. When HIU was applied in that sample (Figure 6J), transmission values through all sections of the tubes remained almost similar to the ones obtained without the use of HIU. Transmission values were 87 ± 2% at the bottom, 90 ± 2% in the middle, and 91 ± 1% at the top.

Figures 5 and 6 show that the degree of phase separation is not related to wax concentration and that the effect of HIU toward the delay of phase separation at both wax concentrations (0.5 and 1%) highly depends on the type of oil used. The stability toward phase separation observed at 0.5% BW does not correlate with stability observed at 1% BW. For example, BW/corn oil samples are the most stable toward phase separation when used at a 0.5% level, whereas BW/canola oil is the most stable when used at 1%. Data reported in Figure 6 show that the stability toward phase separation increases in the following order: safflower oil < sunflower oil < soybean oil < corn oil < olive oil < canola oil. These data suggest that phase separation is probably related to the content of saturated fatty acids (SFA), where a higher content of SFA in the vegetable oil results in less phase separation. Table 1 shows that soybean, corn, and olive oils have a higher amount of SFA (15.5, 13.7, and 14.3%, respectively), and these oils show the least phase separation (Figures 1 and 6). On the other hand, sunflower and safflower oils have lower SFA contents of 7.8 and 6.4%, respectively, and show more phase separation (Figure 6). The mixture of canola oil/BW seems to be an exception to this hypothesis because this sample is the most stable toward phase separation and has a low content of SFA (Figure 6; Table 1). It is possible that for a similar content of SFA a higher content of PUFA contributes to the higher stability toward phase separation. This could explain the different behaviors observed for canola oil and safflower oil samples and also for olive oil and corn oil (Table 1).

As suggested by Dassanayake et al.,[12,13] it is likely that the physical characteristics (oleogel formation, phase separation) of the crystallized material are affected by the type of crystalline network formed. Therefore, to better understand the different crystallization behaviors observed in BW samples crystallized in different oils with and without HIU, we analyzed the morphology of the crystals obtained after 7 days of storage. Figures 7 and 8 show the morphology of crystals obtained in 0.5 and 1% BW, respectively, crystallized in different oils with and without HIU at 0.1 °C/min and stored at 25 °C for 7 days. Crystal morphology significantly changed depending on the type of oil used. When 0.5% BW was crystallized in canola oil without the use of HIU, big spherulites similar to the ones found in soybean oil were observed (Figures 2 and 7). This

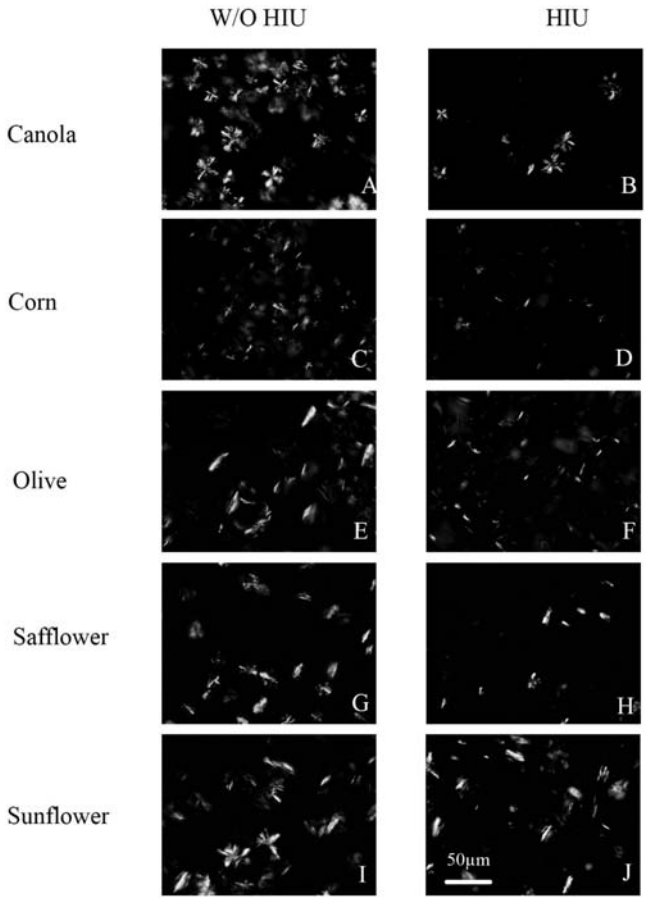

**Figure 7.** Morphology of crystals obtained when 0.5% BW is crystallized in different edible oils at a slow cooling rate (0.1 °C/min) without (left column) and with (right column) HIU after 7 days of storage at 25 °C: (A, B) canola oil; (C, D) corn oil; (E, F) olive oil; (G, H) safflower oil; (I, J) sunflower oil. Crystal pictures were taken at 20× magnification under polarized light microscopy. The white bar corresponds to 50 $\mu$m.

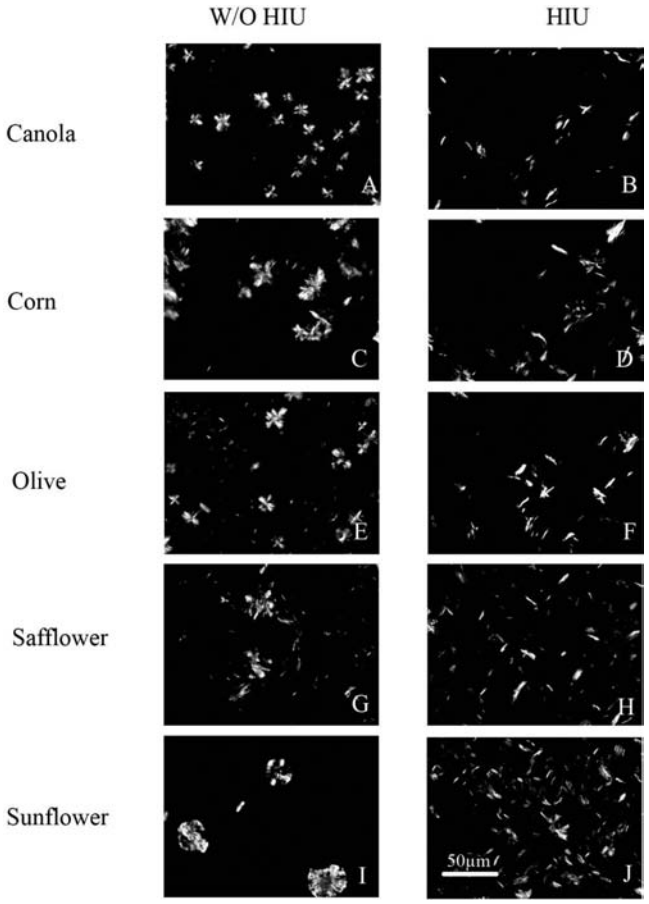

**Figure 8.** Morphology of crystals obtained when 1% BW is crystallized in different edible oils at a slow cooling rate (0.1 °C/min) without (left column) and with (right column) HIU after 7 days of storage at 25 °C: (A, B ) canola oil; (C, D) corn oil; (E, F) olive oil; (G, H) safflower oil; (I, J) sunflower oil. Crystal pictures were taken at 20× magnification under polarized light microscopy. The white bar corresponds to 50 $\mu$m.

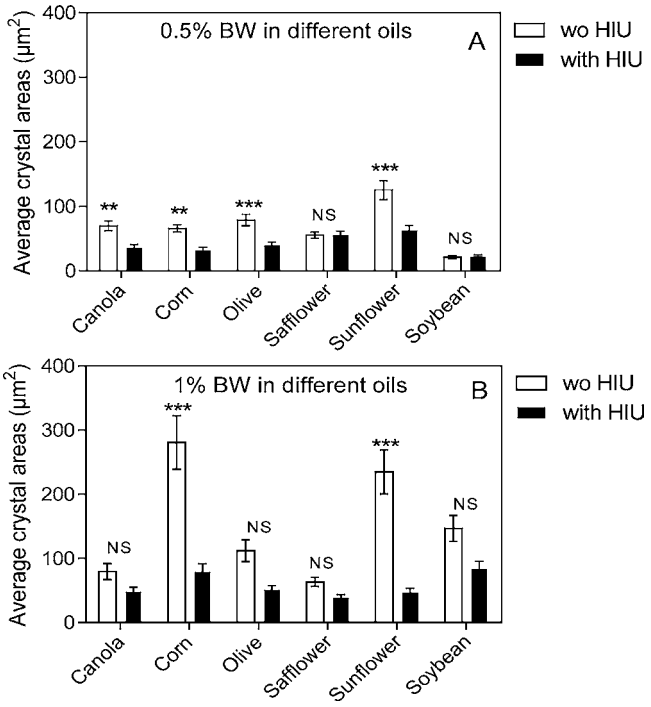

**Figure 9.** Mean crystal area ($\mu$m$^2$) of crystals obtained when 0.5% (A) or 1% (B) BW is crystallized in different vegetable oils (canola, corn, olive, safflower, sunflower, and soybean) at 0.1 °C/min after 7 days of storage at 25 °C. Mean values and standard errors are reported. (*) $p < 0.05$, (**) $p < 0.01$, (***) $p < 0.001$; NS means nonsignificant ($\alpha = 0.05$). Minimum count of the crystals taken was 200 in all cases.

type of morphology was also observed in the BW crystallized in sunflower oil, although the spherulites were not as well formed as the ones observed in canola and soybean oils. Spherulite morphologies were maintained in BW crystallized in canola oil with the use of HIU but were not observed in BW crystallized in soybean and sunflower oils with HIU. Spherulites were also observed when 1% BW was crystallized in all of the vegetable oils but were not present when BW was crystallized in the presence of HIU. Crystal morphology does not seem to explain the differences found in phase separation as a function of type of oil used; however, spherulites seem to be more often associated with phase separation. In general, HIU breaks down the spherulites, and small needle-like crystals are observed. We hypothesize that these needle-like crystals can interact more readily with each other, allowing for more oil entrapment and therefore delaying phase separation.

Figure 9 shows crystal average areas of samples crystallized with and without the use of HIU. It can be observed that HIU generated significantly smaller ($\alpha = 0.05$) crystals in 0.5% BW in all oils with the exception of safflower and soybean oils (Figure 9A). These two oils were the ones on which HIU had the least effects on decreasing the degree of phase separation (Figure 5G–J). The effect of HIU in reducing crystal size in the 1% BW solutions was not as evident as the one observed in the 0.5% BW solutions. HIU reduced crystal areas in 1% BW in corn and sunflower oils ($p < 0.05$), whereas no significant effect was observed in the other oils (Figure 9B). It is interesting to note that even though no significant differences were found in crystal areas in some of these samples, HIU was still effective at delaying phase separation. These results suggest that the effect of crystal area is less important in stabilizing the crystalline network at higher concentrations.

Further analysis on the characteristics of the crystals formed in BW/vegetable oil systems was performed using DSC. Table 2 illustrates onset and peak temperatures of crystals obtained from 0.5 and 1% BW crystallized in different oils (canola, corn, olive, safflower, sunflower, and soybean) at 0.1 °C/min with and without HIU application after 7 days of storage. The melting behavior of the wax crystals obtained from the different wax/oil combinations was very similar to $T_{on}$ values between 38 and 41 °C for the 0.5% samples and between 38 and 45 °C for the 1% samples. In general, the use of HIU resulted in a narrower melting profile as evidenced by either higher $T_{on}$ values or lower $T_p$ values in the sonicated samples. It is likely that the effect of HIU in delaying phase separation is related to the generation of a less fractionated crystalline network where similar molecules can interact strongly among them, entrapping more oil.

Overall, this study shows that several processing conditions can affect phase separation in wax/oil systems. Cooling rate, wax concentration, and type of oil play important roles in the crystallization behavior of waxes, which can also be controlled by using HIU. It is still not clear how the different types of oils affect the crystallization of waxes, but this research suggests that crystal morphology might play an important role in phase separation. Other factors such as the presence of minor

Table 2. Onset ($T_{on}$) and Peak ($T_p$) Temperatures of Crystals Obtained from 0.5 and 1% BW Crystallized in Different Edible Oils (Canola, Corn, Olive, Safflower, Sunflower, And Soybean) at 0.1 °C/min without and with HIU after 7 Days at 25 °C[a]

[a]Mean values and standard deviation of two independent runs are reported. NS means that $T_{on}$ or $T_p$ within each BW/oil samples is not significantly different ($\alpha = 0.05$). (*) $p < 0.05$; (**) $p < 0.01$; (***) $p < 0.001$.

components and the solubility of wax in the different oils might also play an important role in the crystallization behavior of these molecular entities and therefore on the phase separation observed during storage. Results presented in this study suggest that HIU can be used to delay phase separation in wax/oil systems that have the potential to be used as *trans*-fat replacements in food products.

may be a more potent singlet oxygen quencher than $\beta$-carotene, due to its longer polyene chain.

The emerging foodomics trend uses a mass spectrophotometry (MS) based approach to advance food science and nutrition, for its fast and high-throughput nature.[18] Under the foodomics field, untargeted metabolomics is an analytical strategy to identify all metabolites in an organism under a given set of conditions.[19] This use of metabolomics ranges from analyzing wine profiles for the development of a predictive model to aid wine development by nontargeted GC-MS[20] to studying microbial metabolism[21] and is also used to identify the main compound in strawberry responsible for its anti-inflammatory benefits.[22]

The ability of *R. toruloides* to use glycerol as a substrate for fermentation has been well explored.[6,23,24] Its proteomic profile has also been studied in lipid-accumulating conditions using LC-MS-based metabolomic technology.[11] However, studies on the metabolism of this unique yeast on glycerol, and its mechanism to convert glycerol into carotenoids are lacking. In this study we analyze the potential of carotenoid production from three strains grown on glycerol using HPLC and their metabolic changes at four different growth phases via GC-MS. The differential metabolite profile would also be useful to understand the differences in carotenoid production between the strains.

## MATERIALS AND METHODS

**Fermentation of *R. toruloides*.** Over the past years, many studies have shown that the yeast *R. toruloides* can use glycerol as the sole carbon source for fermentation. From over a decade of work on this species, we have chosen three strains: *R. toruloides* ATCC 10788 (AC) is from the American Type Culture Collection ane was one of the first strains to be investigated for its lipid-producing ability.[25] AS 2.1389 (AS) is from the China General Microbiological Culture Collection Center and its genome was recently sequenced, which enables future genetic work.[11] To both of these strains we added CBS 5490 (CBS), which was purchased from the largest fungal culture collection worldwide (Central Bureau voor Schimmelcultures, Utrecht, The Netherlands); it is a novel strain that has not yet been studied. All strains were maintained on YPG agar plates containing (per liter) 20 g of glycerol, 20 g of peptone, 10 g of yeast extract, and 20 g of agar. Overnight culture was used to inoculate each 250 mL Erlenmeyer flask at an optical density (OD) of 0.2 containing 50 mL of fermentation media. Fermentation media contained (per liter) 20 g of peptone, 10 g of yeast extract, and 60 g of glycerol, purity = 99% (Sigma, St. Louis, MO, USA). Fermentation was carried out in an incubator for 12 days in 250 mL Erlenmeyer flasks at 30 °C, with shaking at 250 rpm. Three biological replicates were carried out for each strain.

**Growth and Carotenoid Extraction.** To measure the growth of the yeasts, the OD of the culture media was measured at a wavelength of 600 nm, using a Nano Drop 2000 UV spectrophotometer (Thermo Scientific, Waltham, MA, USA). Dry cell weight was quantitated by drying 1 mL of washed culture supernatant in an oven set at 70 °C until constant dry cell weight (DCW). Biomass was quantitated by using a standard curve correlating OD at 600 nm to dry cell weight. To analyze the intracellular carotenoid content of the cells, 1 mL of culture media was taken. The cells were centrifuged at 10000*g*, washed with Milli-Q water, and broken with glass beads using a Fast Prep bead grinder (MP Biomedicals, Solon, OH, USA). Carotenoids were extracted with acetone until the cell pellet was colorless. Carotenoids were measured and quantitated using standards from CaroteNature (Ostermundigen, Switzerland). The spectrophotometric measurement of carotenoids was according to their absorption maxima peak ($\lambda_{max}$), which is the middle maximum of their UV−vis spectra in acetone. They were measured as follows: torularhodin, **1**, at 495 nm; torulene, **2**, at 485 nm; and $\beta$-carotene, **3**, at 455 nm.

**Carotenoid Characterization and Quantitation.** To confirm the quantitation and characterization of carotenoids extracted in acetone in each strain, high-performance liquid chromatography (HPLC) equipped with a photodiode array detector was used as it is a validated method.[26] The carotenoids torularhodin (**1**), torulene (**2**), and $\beta$-carotene (**3**) were identified on the basis of their retention times using standards from CaroteNature. An Agilent 1100 series instrument was employed, and the column used was a 250 mm × 4.6 mm i.d., 5 $\mu$m, Li-Chrospher 100 RP-18, with a 4 mm × 4 mm i.d. guard column of the same material (Merck, Rahway, NJ, USA). A gradient from 70 to 100% acetone in Milli-Q water at a flow rate of 0.5 mL/min was used as the mobile phase. Detection was performed at 450 nm, and the UV−vis absorption spectra were recorded online with the photodiode array detection system.

**Extracellular Glycerol Analysis.** To analyze extracellular glycerol levels in the culture media, 1 mL of culture medium was taken every 24 h and filtered. Glycerol was quantitated using HPLC equipped with a refractive index detector using a standard of purity of 99% (Sigma). The column used was an Aminex HPX-87H column (Bio-Rad, Hercules, CA, USA). Milli-Q water was used as the mobile phase at a

flow rate of 0.6 mL/min, with temperature controlled at 65 °C, and detection was performed at 210 nm.

**Metabolic Profile of Each Strain at Different Growth Phases and GC-MS Analysis.** The intracellular metabolites were extracted from all three strains at four different time points: early log growth phase on day 1, middle of log growth phase on day 4, as cells enter stationary phase on day 7, and during death phase at the end of fermentation on day 12. Cell suspensions with an OD of 10 were lysed and quenched in 800 μL of ice-cold methanol using glass beads and a bead grinder. Ten microliters of 2 mg/mL ribitol dissolved in Milli-Q water was added to each sample as an internal standard to correct for any loss of metabolite during the extraction process. The supernatant was extracted and then air-dried using a heat block set at 30 °C overnight. Next, 50 μL of 20 mg/mL solution of methoxyamine hydrochloride in pyridine was added to protect the carbonyl groups and incubated at 37 °C for 1 h. Silylation was then carried out by adding 99 μL of *N*-methyl-*N*-(trimethylsilyl)trifluoroacetamide (MSTFA) with 1 μL of trimethylchlorosilane (TMCS) and incubated for 30 min at 70 °C.

Samples were then shaken vigorously for 2 h at room temperature before they were transferred to sample vials and covered with Parafilm to prevent evaporation. Metabolite analysis was carried out using gas chromatography coupled with a mass spectrophotometer (GC-MS). All samples for GC-MS were run within 24 h. One microliter of sample was injected using a Shimadzu QP 2010 Plus GC-MS system. The oven temperature was kept at 75 °C for 4 min, raised at 4 °C/min to a final temperature of 280 °C, and held for 2 min. Mass spectra were recorded from $m/z$ 35 to 600 with a scan time of 0.2 s.[27] The total elution time for mass spectra collected for each sample was 58 min. Data processing and metabolite identification were carried out accordingly.[28]

## RESULTS AND DISCUSSION

**Growth of Three *R. toruloides* Strains on Glycerol.** We have found 60 g/L to be the optimized glycerol concentration to ensure growth and carotenoid production in the three strains (data not shown). Glycerol is able to enter the cell through diffusion and/or active transport.[29] Extracellular glycerol in the culture media was depleted from the culture media by day 3 for strains AC and AS and by day 4 for strain CBS. This showed that the three strains could assimilate glycerol and grew comparatively well (Figure 2). From the biomass curve of the three strains in Figure 2, we define that all three strains were in the logarithmic (log) phase of growth from days 1 and 6, entered stationary phase on day 7, and were in the death phase by day 12. Cells underwent division and replication by obtaining energy from glycerol through glycolysis. The best strain to use glycerol as a substrate for cell growth was CBS. The cells produced the highest concentration of biomass (42.3 g/L) during late stationary phase, as compared to 37.2 g/L by AC and 38.4 g/L by AS (Figure 2).

**Carotenoid Quantitation by UV Spectrophotometer.** *Rhodosporidium* yeasts are known to produce the carotenoids torularhodin, **1**; torulene, **2**; and β-carotene, **3**.[14] In the three strains, carotenoid concentration reached a plateau during stationary growth phase (Figure 2). The strain CBS was the highest carotenoid producer of all strains for the three types of carotenoids: torularhodin, **1**; torulene, **2**; and β-carotene, **3**.

**Characterization and Quantitation of Carotenoids by HPLC.** To our knowledge, there has been no report of the characterization of carotenoids in these strains. It was found that the carotenoid values obtained by spectrophotometry and HPLC greatly differed, so the values quantitated by HPLC were taken as it is a more accurate method.[30] The milli-absorbance units (mAU) obtained from the HPLC profile were quantitated using carotene standards. Our analysis showed that all strains produced torularhodin (**1**), torulene (**2**), and β-carotene (**3**) in different percentages (Figure 3), although torularhodin (**1**) was

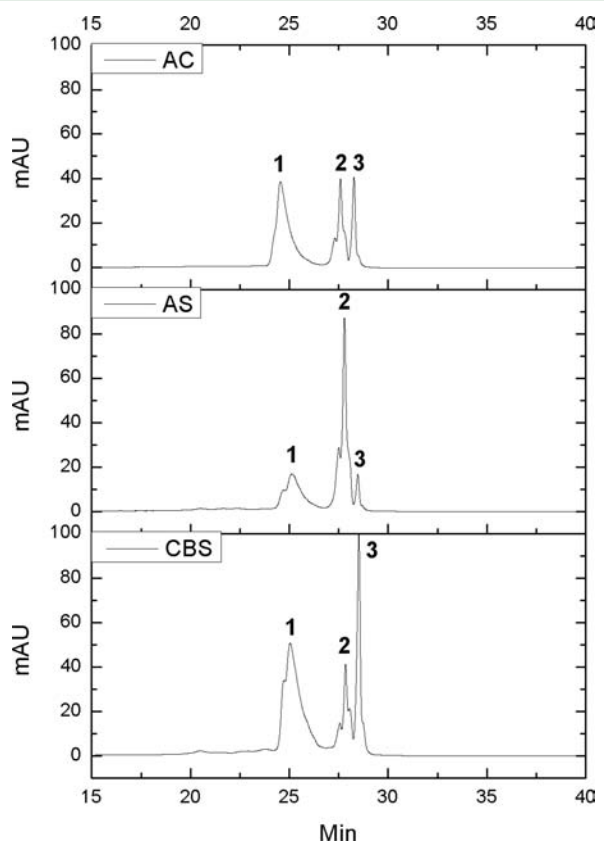

**Figure 3.** Representative HPLC profile of carotenoids in the three strains, AC, AS, and CBS. In each HPLC profile the following carotenoids were identified: torularhodin, **1**; torulene, **2**; β-carotene, **3**.

the most abundant carotenoid in all three strains. All of the carotenoids eluted within 24−28 min as shown in Table 1. The HPLC results confirmed the UV spectrophotometer findings that CBS was the highest carotenoid producer. As quantitated from HPLC, at the end of fermentation on day 12, it produced 28.5 mg/L, as compared to 18 mg/L by AC and 19.3 mg/L by AS. It also produced the highest amount of the industrially relevant compound β-carotene, **3** (Figure 3).

**Comparison of the Metabolite Profiles during Different Growth Phases.** Metabolomics was used to investigate and shed light onto the differences in carotenoid accumulation in the three strains on a metabolic level. The changes in intermediates would help to explain the cellular metabolism accounting for the different carotenoid productions in the three strains. In total, 13 important differential metabolites were identified, and the changes in their levels are shown in Figures 5 and 6. The metabolites could be classified into carbohydrates, TCA cycle intermediates, fatty acids, and amino acids. To apply the knowledge of metabolomic changes seen in the cell, we have mapped the changes in relation to biochemical pathways, as depicted in Figure 4. This gives a view of the metabolite changes in comparison to the other strains AC and AS, which could help us to understand the reason for higher carotenoid accumulation in strain CBS.

**Carbohydrate Metabolites.** Glycerol was used as the sole carbon source in this study. In the cell, glycolysis is the pathway that supplies the cells with energy, by breaking down sugars

**Table 1. Production of Carotenoids by the Three Strains Quantitated by HPLC**

| | | strain | | | | | |
|---|---|---|---|---|---|---|---|
| | | AC | | AS | | CBS | |
| carotenoid | ret time (min) | mg/L | % of total carotenoids | mg/L | % of total carotenoids | mg/L | % of total carotenoids |
| torularhodin, **1** | 24.5−25.1 | 7.4 | 41 | 12.5 | 65 | 19.7 | 69 |
| torulene, **2** | 27.3−27.9 | 7 | 39 | 2.5 | 13 | 2.0 | 7 |
| $\beta$-carotene, **3** | 28.0−28.5 | 3.6 | 20 | 4.3 | 22 | 6.8 | 24 |
| total | | 18 | | 19.3 | | 28.5 | |

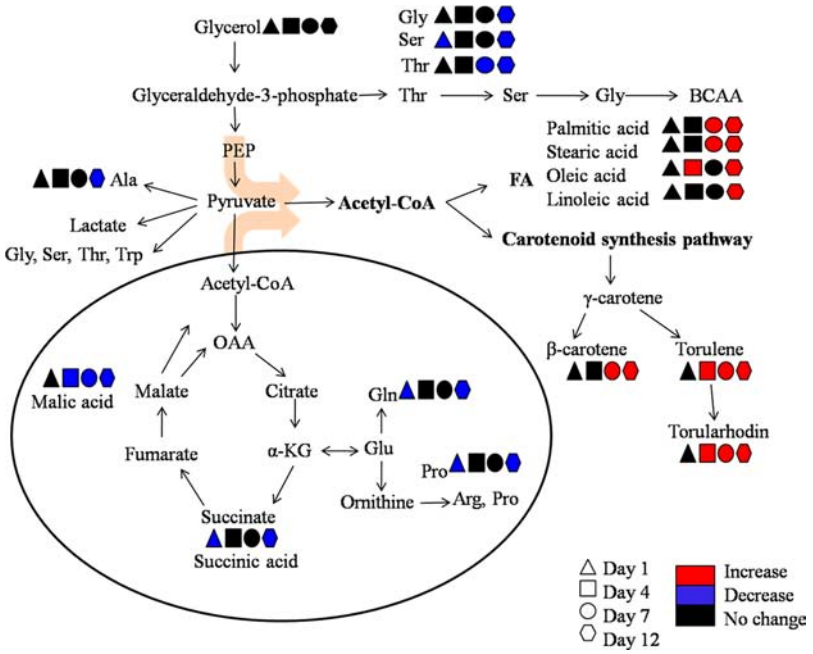

**Figure 4.** Metabolic changes in strain CBS mapped onto metabolic pathways during the four different growth phases on days 1, 4, 7, and 12. Colored symbols represent an increase, decrease, or no change in the level of the metabolite at each time point, as compared to the other strains AC and AS. Orange arrows represent the general flow of metabolic flux in strain CBS.

such as glycerol, to form the final pyruvate molecule. During glycolysis, glycerol is converted into glyceraldehyde-3-phosphate, transformed into phosphoenolpyruvate (PEP), and finally into pyruvate (Figure 4). Pyruvate may enter the mitochondria and is converted into acetyl-CoA, which enters the citric acid cycle (TCA). Acetyl-CoA is an important molecule as it is the precursor of the fatty acid and carotenoid synthesis pathway.[31] In Figure 5, the intracellular metabolite glycerol was found to decrease in all three strains in comparatively the same manner as glycolysis took place.

**Amino Acid Metabolites.** Amino acids can be synthesized from compounds in the glycolysis pathway and TCA cycle. The glycolysis pathway provides the substrate glyceraldehyde-3-phosphate for the synthesis of threonine, serine, and glycine, which are used to form branched-chain amino acids (Figure 4). The amino acid alanine is synthesized from the pyruvate molecule provided by the glycolysis pathway. Glutamate and proline are synthesized from the intermediate of the TCA cycle, $\alpha$-ketoglutarate ($\alpha$-KG).

Interestingly, we observe that the strain CBS demonstrated a unique amino acid metabolic profile. In comparison to AC and AS strains, all of the amino acids were generally synthesized in lower amounts (Figure 5). This might suggest that the cellular mechanism of the CBS strain preferably synthesized less amino acids, which resulted in more available acetyl-CoA to enter the carotenoid and fatty acid synthesis pathways. This could contribute to the higher levels of carotenoids and total intracellular fatty acids observed in strain CBS.

**TCA Cycle Intermediate Metabolites.** The TCA cycle is a key metabolic pathway in all cells. After glycolysis, pyruvate enters the mitochondria and is converted into acetyl-CoA, which undergoes oxidative phosphorylation to provide energy for the cell in the form of NADH and NADPH. The TCA cycle contains intermediates such as succinic acid and malic acid.

In strain CBS we also observed a general down-regulation in production of the TCA cycle intermediates, malic acid and succinic acid, as compared to strains AC and AS (Figure 6). Therefore, we propose that the TCA cycle was down-regulated to enable more acetyl-CoA from glycolysis to enter the carotenoids and fatty acid synthesis pathway. This contributes to higher carotenoid production in strain CBS. This is also seen in a previous study in which the decrease of the TCA cycle intermediate malic acid enhanced $\beta$-carotene production in the yeast *Blakeslea trispora*.[32]

**Fatty Acid Metabolites.** *R. toruloides* is an oleaginous yeast that has been studied for its ability to accumulate high amounts of lipids. The total intracellular fatty acids synthesized by all three strains was palmitic acid, oleic acid, linoleic acid, and stearic acid, which is in accordance with previous results.[23] The highest carotenoid-producing strain, CBS, was also the highest

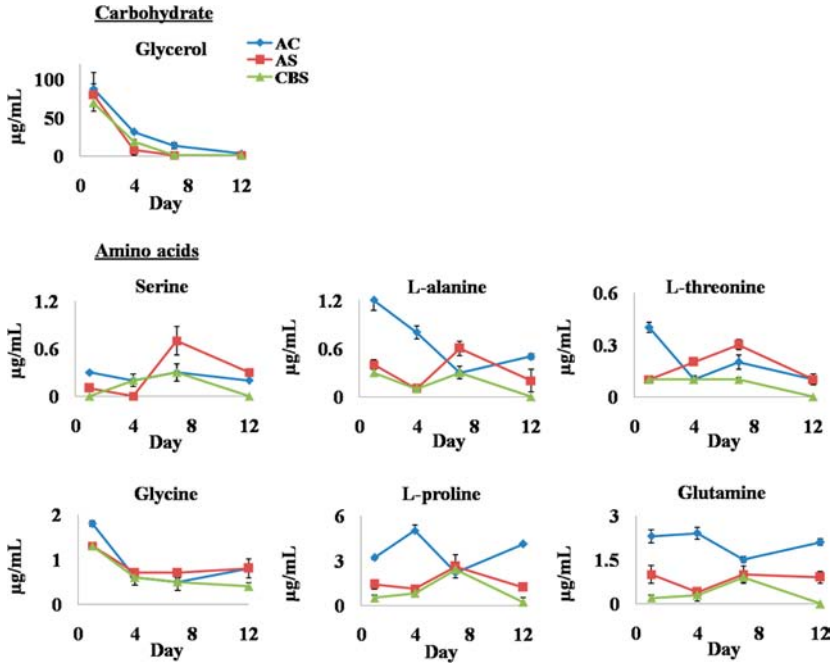

**Figure 5.** Quantitated metabolite profiling in the three strains AC, AS, and CBS during different growth phases by GC-MS: changes in the carbohydrate metabolite glycerol and amino acid levels of serine, glycine, threonine, alanine, glutamine, and proline. The error bar indicates the SD of three biological replicates.

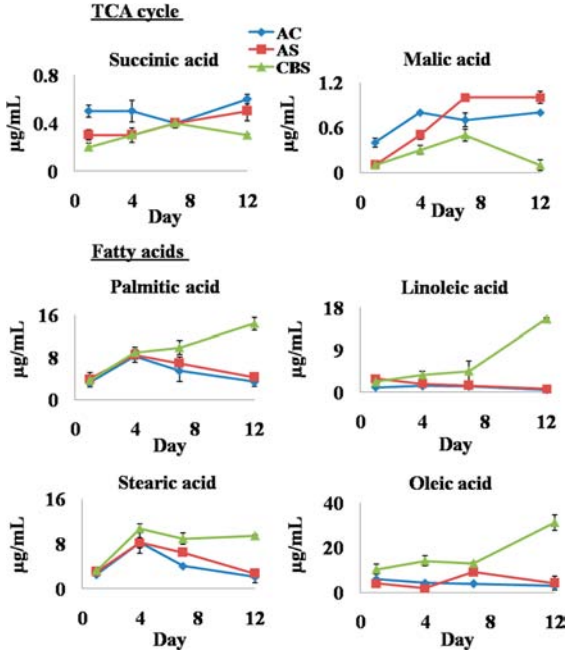

**Figure 6.** Quantitated metabolite profiling in the three strains AC, AS, and CBS during different growth phases by GC-MS: changes in the TCA cycle intermediate metabolites malic acid and succinic acid, and levels of the total intracellular fatty acids metabolites (oleic acid, stearic acid, linoleic acid, and palmitic acid). The error bar indicates the SD of three biological replicates.

fatty acid producer, especially the unsaturated oleic acid and linoleic acid (Figure 6).

The cell membrane is made up of a phospholipid bilayer where many biochemical processes take place. Both fatty acids and carotenoids are localized in the lipid bilayer membrane. Carotenoid–lipid interactions play a role in the regulation of membrane fluidity and integrity. $\beta$-Carotene molecules are randomly integrated in the hydrophobic interior of the lipid bilayer. Its ability to penetrate deeper into the membrane is dependent on the fluidity of the membrane. Higher amounts of unsaturated fatty acids in the bilayer result in increased membrane fluidity, thereby allowing more $\beta$-carotene to accumulate deeper into the interior of the bilayer.[33] Therefore, the high content of the unsaturated fatty acids, oleic acid and linoleic acid, in strain CBS may have served not to increase the membrane stability but to improve the cell membrane fluidity to enhance the accumulation of all three carotenoids. In support of this, a study by Li et al.[34] has also shown that oleic acid could help increase membrane fluidity to overcome ethanol stress in *Saccharomyces cerevisiae*.

In addition, intracellular fatty acids form TAG and sterol esters, which are stored inside lipid bodies.[35] The increased synthesis of total intracellular fatty acid metabolites observed in strain CBS means more lipid bodies can be formed. Oleic acid has been suggested to be the main constituent in the formation of lipid bodies in *Dunaliella*.[36] It has been proposed that formation of lipid bodies was the driving force of $\beta$-carotene synthesis. This is because lipid bodies have the ability to sequester $\beta$-carotene molecules, stimulating more $\beta$-carotene production.[37] In light of our results it is possible that the higher production of fatty acids, especially the oleic acid levels in strain CBS, resulted in more lipid bodies formed, which can sequester all three carotenoids including torularhodin, **1**; torulene, **2**; and $\beta$-carotene, **3**. The sequestering by lipid bodies thus promoted an increase for overall total carotenoid accumulation which was not reported previously. Therefore, our study found a strong correlation between fatty acid production and carotenoid biosynthesis, especially in the unsaturated fatty acids oleic acid, which could help increase membrane fluidity and lipid body formation.

**Carotenoid Synthesis Pathway.** Isoprenoids such as carotenoids are secondary metabolites produced at highest

levels during late log phase to early stationary phase,[38] which is consistent with our observations. As seen in Figure 4, in the carotenoid synthesis pathway, γ-carotene is the metabolic branch point for β-carotene and the torulene/torularhodin pathway. From γ-carotene, cyclization forms the dicyclic carotenoid β-carotene, whereas oxidation takes place to form the monocyclic carotenoid torulene, **2**, and further oxidation into torularhodin, **1**.[39] In all strains the highly oxidized end product torularhodin, **1**, was the major carotenoid formed (Table 1). The regulatory mechanisms controlling the carotenoid synthesis pathways are not well understood, and further studies are required.

In summary, the use of a metabolomics strategy to study the metabolic profile at different time points has allowed us to gain insight into the metabolism and biochemical pathways of *R. toruloides*. Also, it helped us understand the underlying differences in carotenoid-producing ability between strains. The results suggested that fatty acid synthesis was beneficial to increase carotenoid production. However, more studies on the relationship between fatty acids and carotenoid synthesis is needed. Knowledge from this study could aid future work to increase carotenoid yields by metabolic engineering in microorganisms, for example, to down-regulate the TCA cycle and amino acid synthesis and increase the unsaturated fatty acid production such as oleic acid.

for foods, only a few studies have focused on feed-processing effects on pesticide persistence.

The pellet feeds that originate from cereals are the most frequently used feedstuffs for ducks and other poultry.[19] Therefore, chlorpyrifos residual behaviors in field crops (i.e., rice, maize, and soybean) were determined according to the "Guideline on Pesticide Residue Trials" of China, and in the results of field trials, processing steps of duck pellet feed were mimicked to investigate chlorpyrifos persistence in these steps. Finally, the potential exposure risks of chlorpyrifos in duck feeding were evaluated, under the conditions of domestic ducks fed processed pellet feeds that originated from the heaviest contaminated raw materials of this study.

## MATERIALS AND METHODS

**Materials.** Commercial seeds of rice, maize, and soybean for field trials were purchased from Zhejiang Wuwangnong Seeds Co., Ltd. (Hangzhou, China). Stock solution of chlorpyrifos (100 μg/mL in acetonitrile) was obtained from the Agro-Environmental Protection Institute, Ministry of Agriculture (Beijing, China). Commercial 40% chlorpyrifos emulsifiable concentrate (EC, w/v) was the product of Zhejiang Xinnong Chemical Co., Ltd. (Hangzhou, China). *N*-Propylethylenediamine (PSA) and graphitized carbon black (GCB) were provided by Bonna-Agela Technologies, Inc. (Tianjin, China). Analytical grade acetonitrile, ethyl acetate, $MgSO_4$, and NaCl were obtained from East China Pharmaceutical Group Co., Ltd. (Hangzhou, China). Chromatography grade acetonitrile and methanol were products of Honeywell International Inc. (Morris Plains, NJ, USA). Ultrapure water was the product of a Milli-Q system (Bedford, MA, USA). A paddy husker machine and a cereal grain milling machine were products of Tianyang Co., Ltd. (Shangdong, China). A poultry pellet miller was purchased from Gemco Machinery Co., Ltd. (Henan, China). A screw oil press machine was the product of Weichang Machinery Co., Ltd. (Rizhao, China).

**Field Trials.** The field trials for chlorpyrifos residual behaviors on rice, maize, and soybean were performed in Danzhou (109.5 E, 19.5 N), Hangzhou (102.1 E, 30.2 N), and Haerbin (126.3 E, 45.5 N), and the field trials strictly complied with the "Guideline on Pesticide Residue Trials" (NY/T788-2004) in China.[20] Each field trial consisted of triplicate test plots and a control plot (30 $m^2$ for each plot), and each plot was separated by a buffer area. Chlorpyrifos 40% EC (w/v) was selected as the tested formulation in field residue trials. The recommended dosages (0.864 kg ai $ha^{-1}$ for rice, 0.720 kg ai $ha^{-1}$ for maize, and 0.240 kg ai $ha^{-1}$ for soybean) and 1.5 times recommended dosages (1.296 kg ai $ha^{-1}$ for rice, 1.080 kg ai $ha^{-1}$ for maize, and 0.360 kg ai $ha^{-1}$ for soybean) were chosen for field trials. The pesticide was sprayed on fields of mid- and late-planting periods two or three times at intervals of 7−14 days (7 days for rice, 10 days for maize, and 14 days for soybean) for each time during 2011 and 2012. Pesticide was sprayed on fields by a knap-sack hand sprayer (product of Shandong Shenglu machine works, Shandong, China), and there was no precipitation during the spraying period. Field samples were collected from each plot on days 7 and 14 for rice, days 10 and 20 for maize, and days 14 and 28 for soybean after the last chlorpyrifos spraying. After harvest, all samples were dried in the shade under ambient conditions. Afterward, the samples were transported at 4 °C in darkness by labeled polyethylene bags to the laboratory and stored at −20 °C until analysis.

**Feed Processing for Chlorpyrifos Persistent.** As we know, pellet feeds are the most used feedstuff for poultry (e.g., ducks and goose) feeding.[19] Generally, pellet feed processing steps include paddy rice hulling, milling, grinding, shelled corn grinding, soybean seed squashing, and granulating (Figure 1). In this study, the raw crop materials (paddy rice, shelled corn, and soybean seed) with the highest chlorpyrifos residues obtained from field trials were selected for pellet feed processing works to evaluate the chlorpyrifos persistent. Rice grain was hulled to yield brown rice and hull, and the brown rice was further milled to polishing rice and rice bran. The soybean seed was roasted at 120 °C for 0.5 h to remove moisture. The dried soybean seed was squashed to produce soybean meal and soybean oil by screw press. As ingredients of duck pellet feeds, brown rice, rice bran, shelled corn, and soybean meal were further ground to powder, mixed, and granulated to pellet feeds. During the feed processing, raw materials and intermediate products (i.e., rice grain, rice hulls, rice bran, brown rice powder, rice bran powder, maize seed, maize powder, soybean seed, soybean meal, and soybean meal powder) in each step were collected, and the chlorpyrifos residues were determined. On the basis of the residual results of each step, chlorpyrifos persistence in feed processing works was evaluated, and final residues in different duck pellet feeds were calculated on the basis of two typical duck feed formulas in southern China (Table 1).

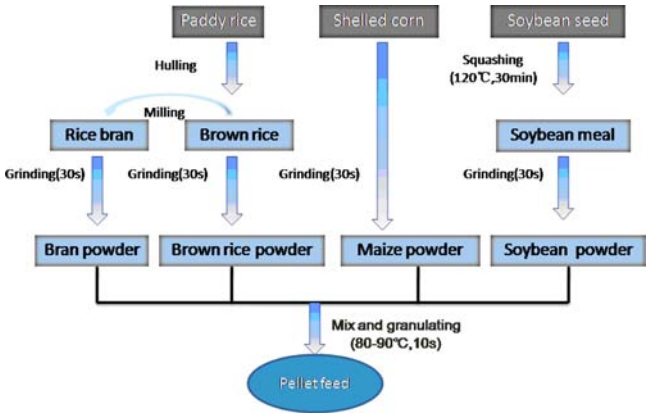

**Figure 1.** Flowchart of duck pellet feed processing in southern China.

**Table 1. Formula Ingredients of Two Typical Duck Pellet Feeds in Southern China**

| feed A | | feed B | |
|---|---|---|---|
| ingredient | content (%) | ingredient | content (%) |
| maize | 59.50 | brown rice | 60.00 |
| rice bran | 10.00 | rice bran | 5.00 |
| soybean meal | 21.30 | soybean meal | 25.00 |
| fish meal | 7.20 | fish meal | 8.00 |
| tricalcium phospahte | 0.35 | tricalcium phospahte | 0.35 |
| limestone | 0.40 | limestone | 0.40 |
| salt | 0.25 | salt | 0.25 |
| DL-methionine | 0.07 | DL-methionine | 0.07 |
| trace mineral premix | 0.50 | trace mineral premix | 0.50 |
| vitamin premix | 0.43 | vitamin premix | 0.43 |

**Sample Preparation and Chlorpyrifos Determination.** Extraction and cleaning procedures of chlorpyrifos from raw materials and the intermediate products were performed according to the methods of Qu et al. with minor modifications.[21] An aliquot of 5.0 g of homogenized sample was transferred to a 50 mL Teflon centrifuge tube with 10 mL of ultrapure water and immersed for 30 min. Afterward, 25 mL of acetonitrile acidified with 1 M HCl (99:1, v/v) was added and shaken for 15 min by an oscillator, followed by centrifugation for 5 min at 966*g* (room temperature). The supernatant was transferred into a 100 mL glass measuring cylinder with a graduated stopper. The extraction steps were repeated again, the extracts were pooled, and then 8 g of NaCl was added. The extracted mixture was shaken vigorously for 1 min and left to stand for 30 min. An aliquot of 10 mL of organic extract was concentrated using a rotary vacuum evaporator at 40 °C and dried with a gentle stream of nitrogen. The residue was redissolved with 1.0 mL of ethyl acetate in a 2.5 mL microcentrifuge tube with a mixture of 150 mg of $MgSO_4$, 25 mg of GCB, and 50 mg of PSA. The tube was shaken vigorously for 1 min and centrifuged for 5 min at 9030*g* (room temperature). The

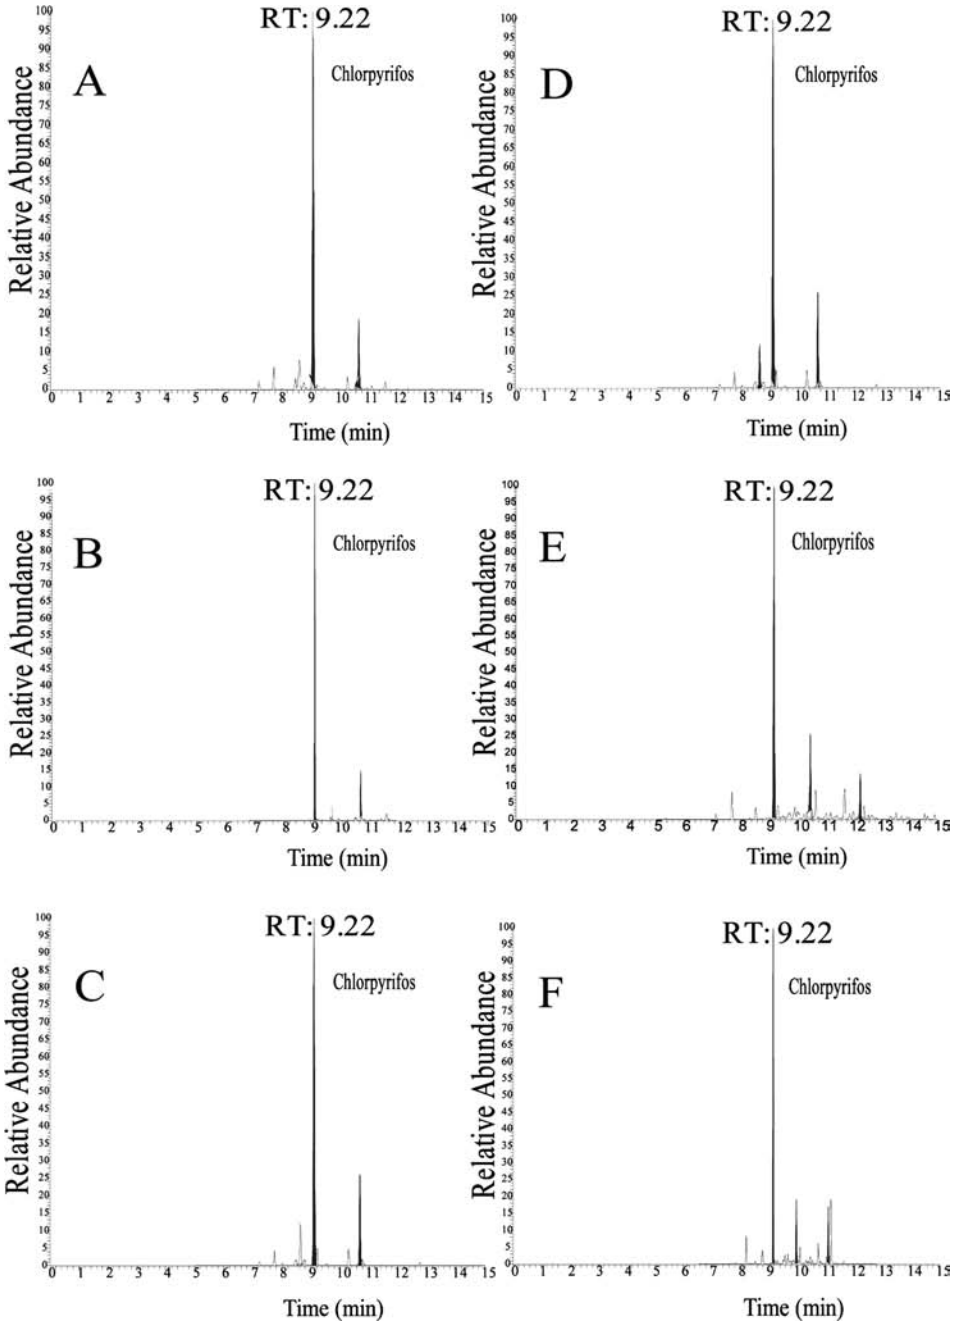

**Figure 2.** Total ion chromatograms obtained from fortified samples of paddy rice (A), brown rice (B), rice bran (C), shelled corn (D), soybean seed (E), and soybean meal (F).

extract was filtered through a 0.22 $\mu$m PVDF filter before analysis. Chlorpyrifos determination by GC-MS/MS was performed following the method of Zhao et al.[15] TSQ Quantum gas chromatography (GC, Thermo Fisher Scientific, USA) with a GC system TRACE GC Ultra and a triple-quadrupole mass spectrometer Quantum (mass range from $m/z$ 10 to 3000) was used throughout the determination. Samples were injected with an AS3000 autosampler into a split/splitless injector. The Zebron ZB-MultiResidue-2 capillary column (30 m × 0.25 mm i.d, 0.25 $\mu$m film thickness, Guangzhou FLM Scientific Instrument Co., Ltd., Guangzhou, China) was applied for analyte separation. The precursor ion was selected by analyzing the 20 $\mu$g/L chlorpyrifos standard solution under the full scan mode in the GC-MS system, and the highest intensity ion ($m/z$ 314) was used for subsequent fragmentation to create product ions ($m/z$ 286 and 258). The retention time of chlorpyrifos was approximately 9.22 min.

Recoveries of the analytical method were evaluated by spiked blank samples at three chlorpyrifos concentrations with six replicates. The spiked samples were kept at room temperature for 2 h to allow solvent evaporation before analysis. Matrix effects were evaluated by comparing the slopes of solvent and matrix calibration sets. Series 1 was prepared by diluting the stock standard solution in solvent at three concentrations of 5, 50, and 500 $\mu$g/kg and series 2 by diluting the stock standard solution in matrix extract that was obtained from pesticide-free sample.

**Statistical Analysis.** Unless otherwise indicated, all tests were performed in three replicates, and the values are presented as means ± standard deviation (SD). Data were statistically evaluated by one-way ANOVA analysis with SPSS base 11.0 software. Once a significant difference was observed, the least significant difference (LSD) test was applied to validate the differences among means.

## RESULTS AND DISSUSSION

**Analytical Method Validation.** The GC-MS analytical results of chlorpyrifos extracted from fortified samples indicated that no interference peak was observed that might affect the analysis accuracy of the pesticide (Figure 2). At three fortified concentrations (0.01, 0.1, and 0.5 mg/kg), the chlorpyrifos recoveries ranged from 81.8 to 110.7% in different raw materials and intermediate products, and the relative standard deviations (RSDs) were from 3.2 to 11.6% (Table 2). The

**Table 2. Chlorpyrifos Analytical Recoveries and RSDs in Different Fortification Samples**

| matrix | fortification level (mg/kg) | mean recovery (%) | RSD (%) |
|---|---|---|---|
| rice grain | 0.5 | 93.6 | 4.6 |
| | 0.1 | 94.2 | 5.3 |
| | 0.01 | 89.3 | 6.8 |
| brown rice | 0.5 | 95.8 | 4.3 |
| | 0.1 | 93.6 | 5.6 |
| | 0.01 | 81.8 | 7.9 |
| rice bran | 0.5 | 90.8 | 3.2 |
| | 0.1 | 83.5 | 4.6 |
| | 0.01 | 90.2 | 8.8 |
| shelled corn | 0.5 | 91.5 | 3.5 |
| | 0.1 | 86.4 | 6.5 |
| | 0.01 | 82.6 | 4.9 |
| soybean seed | 0.5 | 85.3 | 4.8 |
| | 0.1 | 108.6 | 5.6 |
| | 0.01 | 93.2 | 9.5 |
| soybean meal | 0.5 | 91.2 | 4.6 |
| | 0.1 | 96.4 | 10.5 |
| | 0.01 | 110.7 | 11.6 |

LODs and LOQs of the determination were calculated on the basis of signal-to-noise ratios (S/N) of 3 (3:1) and 10 times (10:1) the background chromatographic noise, respectively. The LOD and LOQ were estimated to be 0.0006 and 0.002 mg/kg for paddy rice, brown rice, rice bran, and shelled corn, respectively. For the substrates of soybean seed and soybean meal, the LOD and LOQ were estimated to be 0.0009 and 0.003 mg/kg, respectively. Recoveries slightly greater than 100% were observed for some substrates (i.e., soybean seed and soybean meal), and this result indicated that the matrices may affect the pesticide recovery.[22] Matrix effects of chlorpyrifos ranged from 92 to 118%, which indicated that the matrix effect was acceptable for quantitative analysis.

**Chlorpyrifos Final Residues in Field Trials.** In China, chlorpyrifos is registered for rice at the recommended dosage of 0.864 kg ai $ha^{-1}$ with a preharvest interval (PHI) of at least 7 days, followed by good agricultural practice (GAP) conditions. In the six field trials, which were performed following the "Guideline on Pesticide Residue Trials" in China at 1× (0.864 kg ai $ha^{-1}$) and 1.5× (1.296 kg ai $ha^{-1}$) the recommended dosage, the chlorpyrifos residues of harvest paddy rice treated two or three times with chlorpyrifos all exceed the MRL of rice grain in China (0.5 mg/kg, GB 2763-2012).[23] (Figure 3A,B), and the results are consistent with the previous study.[10] The highest chlorpyrifos residue in paddy rice is 12.0 mg/kg, which was much higher than the MRL on corn forage and fodder set by the U.S. Environment Protection Agency (8.0 mg/kg).[24] The chlorpyrifos residues of paddy rice showed positive correlations to the pesticide applied dosage and spraying times. The results indicated that chlorpyrifos residues were relatively high if the rice crops were treated at the recommended dosage more than two times, and the residues of this study definitely pose serious health risks in foods for human consumption and even as feed material for animal production. The chlorpyrifos residues based on "Guideline on Pesticide Residue Trials" in rice suggest that the pesticide (chlorpyrifos EC, 40%) should be applied fewer than two times at the recommended dosage (≤0.864 kg ai $ha^{-1}$), and the harvest interval (from the last spraying to crop harvest) should be >14 days.

Unlike rice, chlorpyrifos is not officially registered for maize and soybean by means of spraying in China, but dosages of 0.720 kg ai $ha^{-1}$ with a PHI of 10 days for maize and 0.240 kg ai $ha^{-1}$ with a PHI of 14 days for soybeans are recommended by the product (chlorpyrifos EC, 40%) handling instructions. In the 1.5× dosage trials, chlorpyrifos residues in shelled corn with three treatments and 10 days PHI all exceed the maize MRL of China (0.05 mg/kg, GB 2763-2012)[23] (Figure 3C,D). About half of the shelled corn in two years' field trials exceed the maize MRL of China, and the highest residue is 0.605 mg/kg. Similarly to paddy rice, chlorpyrifos residues of shelled corn showed positive correlations to pesticide applied dosage and spraying times. The field trial results by means of spraying indicated that the recommended dosage of 0.720 kg ai $ha^{-1}$ (chlorpyrifos EC, 40%) should be applied on maize crop fewer than two times or with a PHI of longer than 20 days. In soybean trials, five soybean seeds (about 20.8%) exceed the soybean MRL of China (0.1 mg/kg, GB 2763-2012),[23] and the highest residue was 0.220 mg/kg (Figure 3E,F). The residual results of soybean trials were obviously better than those of rice and maize crops, but under the recommended spraying conditions of this study, some residues still exceeded the soybean MRL of China. Field trials of soybean by means of spraying indicated that the recommended dosage of 0.240 kg ai $ha^{-1}$ (chlorpyrifos EC, 40%) applied on soybean crops under the conditions of this study was slightly high, fewer treatments or a longer PHI being obligatory. Field trials of three crops indicated that the chlorpyrifos recommended dosages appeared to be high for rice, maize, and soybean application, and a revised GAP is required for crop production. For each crop, residual levels were moderately different from location to location and from year to year. These results were consistent with the previous study that pesticide residues were affected significantly by various environmental factors (e.g., temperature, humidity, soil characteristics, and climate), which are always diverse from different locations or years.[25]

**Chlorpyrifos Transfers during Pellet Feed Processing.** Chlorpyrifos residue of the raw rice grain selected for pellet feed processing was 12.0 mg/kg. After hulling, the chlorpyrifos residue in brown rice was 7.42 mg/kg and the transfer rate from rice grain to brown rice was 61.8%. Chlorpyrifos residue in rice bran was 12.7 mg/kg after milling processing (Figure 4A,B). The processing results showed that a considerable proportion of chlorpyrifos deposited on the skin of the rice grain, and the finding was similar to chlorpyrifos residual behaviors on vegetables and fruits.[13,26] Brown rice and rice bran were manufactured to powder by grinding for approximately 30 s under a temperature lower than 50 °C, and the chlorpyrifos

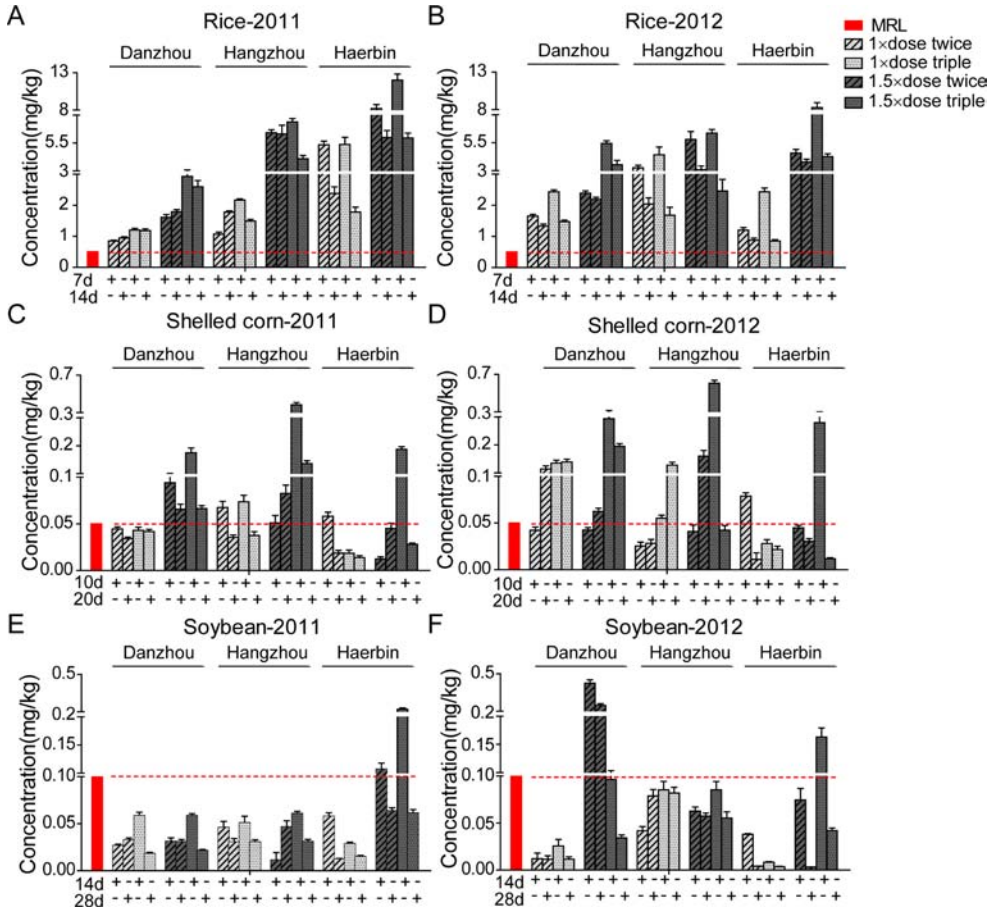

**Figure 3.** Chlorpyrifos residues of rice grain, shelled corn, and soybean seed produced from six field trials.

removal by grinding step was <10%. The grinding process showed only limited influence on chlorpyrifos removal for intermediate product of rice, and the result was consistent with the study of the grinding process during honey production.[27] After granulating, chlorpyrifos residue in rice bran pellet feed reduced to 7.58 mg/kg and the transfer rate was similar to the process step from wheat flour to baking bread.[28] In the granulating step, high temperature is considered as the most important factor for chlorpyrifos breakdown, and the pesticide loss is normally ascribed to physicochemical processes (e.g., evaporation, codistillation, and thermal degradation). During the rice processing steps, chlorpyrifos residues in the processed products of brown rice, rice bran, and pellet feeds ranged from 4.68 to 12.7 mg/kg, which were much higher than the American regulation limit (3.0 mg/kg) on alfalfa forage used as animal feed commodities set by the U.S. Environment Protection Agency.[24] After the processing steps, rice intermediate products and pellet feeds were unsafe as animal feed if the raw rice grain was contaminated by chlorpyrifos at 12.0 mg/kg.

Grinding and granulating are the main steps of shelled corn processing. After grinding, the mean loss of chlorpyrifos was 4.13%, which also proved that chlorpyrifos was stable at low temperature. After granulating, chlorpyrifos residue was 0.0414 mg/kg with a removal rate of 28.6% (Figure 4A,B). The final chlorpyrifos residue in processed maize pellet feed was much lower than that of rice pellet feeds, but the transfer rate from shelled corn to maize pellet feed (68.4%) was higher than those of rice grain to rice pellet feeds (63.2% for pellet feed of rice bran; 39.0% for pellet feed of brown rice).

The chlorpyrifos reduction in soybean meal was 73.8% during the squashing process, indicating that hot squashing led to a significant chlorpyrifos removal. In the grinding process, the loss of chlorpyrifos in soybean meal was 7.12%. The chlorpyrifos reduction of soybean pellet feed is 81.5% after several conventional processing steps. This might be attributed to the physical−chemical properties of chlorpyrifos including the solubility in oils. The high fat-soluble characteristic of chlorpyrifos (logarithm of partition coefficient $P$ is 5.1) makes the pesticide transfer from soybean to the oil layer easy during the squashing processing.[29] Chlorpyrifos residue was 0.0408 mg/kg after soybean meal manufactured to pellet feed by granulating, and the reduction was 23.7%, which was slightly lower than that of processed products of brown rice (30.9%) and maize (28.6%). Similar to the previous study, reduction of chlorpyrifos was significantly enhanced if the processing steps involved heat treatment.[30] Chlorpyrifos residues in soybean intermediate product and pellet feed were reduced more significantly than those of rice and maize because the soybean processing steps involved two heating procedures (soybean roasting and pellet feed granulating) and oil pressing.

**Processing Factors and Feed Safety Assessment.** Processing factors (PFs, pesticide concentration in processed product/pesticide concentration in preprocessing material) are usually adopted to assist dietary assessment of pesticide intake from processed commodities.[31] On the basis of the residues and processing transfer rates in three cereal products in this

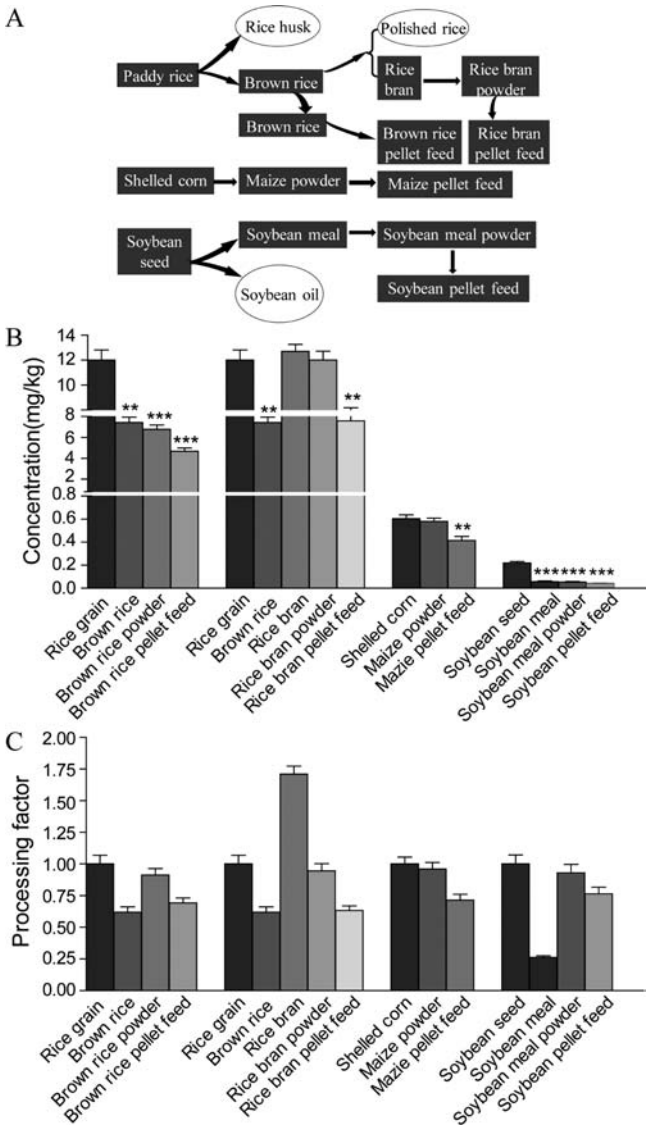

**Figure 4.** Three cereal-processing products, chlorpyrifos residues, and processing factors during duck pellet feed manufacture: (A) intermediate and processing products; (B) chlorpyrifos residues; (C) processing factors. (**) $P < 0.01$; (***) $P < 0.001$.

study, PFs were calculated and evaluated according to Joint Meeting on Pesticide Residues (JMPR).[32] PF values <1.0 indicate a chemical residue reduction in the processed commodity, whereas a value >1.0 indicates a chemical residue rise in the processed products.[33] Results of this study showed that the three cereals' PF values in each processing step were generally <1.0, except for the milling process of brown rice (Figure 4C), and these results were consistent with previous studies.[13,34] The grinding process exhibited only a slight effect on chlorpyrifos reduction (PFs, 0.912−0.959). Compared to other processing steps (e.g., hulling, milling, and granulating), chlorpyrifos was stable in grinding processing at low temperature. The PF value of soybean squashing showed a dramatic chlorpyrifos reduction from soybean seed to soybean meals (PF, 0.262), and the result was also supported by the transfer rate discussed above (a great amount of chlorpyrifos was transferred to soybean oil). This finding was similar to the study of Holland et al.,[30] in which the lipophilic pesticides used for postharvest pests led to serious residues in oil products. High-temperature processing was involved in pellet feeds, for final pellet forming, and this was one of the most important factors contributing to pesticide reduction in each feed material (PFs, 0.632−0.763).

Two duck pellet feeds (feeds A and B) in southern China were consistent for final chlorpyrifos residues based on the feed formula ingredients in Table 1 and the chlorpyrifos concentrations of processed products (Figure 4B). On the basis of the raw material residues, the processing PFs, and the duck pellet feed ingredients, the final residues in two duck pellet feeds were 1.01 mg/kg for feed A and 3.20 mg/kg for feed B. Obviously, the feed using rice as energy resource was more seriously contaminated than that using maize as energy resource. The residues calculated here should be a little higher than those of industrial productions, because material storage was not considered, although previous study indicated that postharvest storage showed only limited effects on pesticide removal.[1] Generally, animal toxicological testing is not obligatory as part of chlorpyrifos official registration, but is intensively recommended when the residue of animal diet is >0.1 mg/kg.[3] For healthy aquaculture and food safety, the duck pellet feeds (feeds A and B) of this study definitely required further toxicological evaluation.

sampled). We will apply headspace SPME for the sampling and concentration of surface volatiles followed by GCMS for separation, detection, and identification. Principal component analysis (PCA) will be applied to the chromatograms to characterize surface volatile peak patterns that differentiate PTD from non-PTD coffee. This study is the first both to characterize the volatile organics *on the surface* of green coffee beans and to utilize SPME−GCMS for the study of potato taste defect. Parts of this research were presented at the Coffee Research Symposium, convened by the Rwandan Ministry of Agriculture[24] and the Global Knowledge Initiative,[25] March 17−18, 2014, Kigali, Rwanda.

## MATERIALS AND METHODS

**Chemicals.** Standard compounds were obtained from Fisher Scientific Co. or Sigma/Aldrich Co., U.S.A. ($C_{11}$−$C_{18}$ standard alkane mixture, hexanal, 2-pentylfuran, nonanal, 1-octen-3-ol, 2-ethyl-1-hexanol, benzaldehyde, 3-methylbutanoic acid, heptanal, 2-*E*-hexenal, pentanol, octanal, 6-methyl-5-hepten-2-one, decanal, hexanoic acid, 2-isopropyl-3-methoxypyrazine, 2-isobutyl-3-methoxypyrazine, 1-hexanol, limonene, octanoic acid, phenol, octyl acetate, 1-dodecene, 2,6-dimethylpyridine, methylsalicylate, 1-tetradecene). Note that 1-methoxy-4-propylbenzene, phenylethylalcohol, 2,6,10,14-tetramethylpentadecane, hexadecanoic acid, and dodecanal were identified by mass spectral match but not confirmed by standard.

**Samples and Characterization.** Fifty-two samples (Arabica coffee, varietal Bourbon) were sent directly from the coffee growing regions of Rwanda in the 2012 and 2013 harvest seasons to the Rogers Family Company laboratory in Lincoln, California, where they were characterized by physical and sensorial analysis. All samples were conventionally grown in the sun at 5000−8000 feet elevation on small farms. Physical characteristics included moisture content (%), screen size distribution, sorting, and counting defects. Sensorial analysis consisted of standard cupping of a medium roasted sample by four experienced cuppers, which for our purposes classified the samples as either "PTD" or "non-PTD". PTD samples tested positive at rates from 1 in 6 cups to 1 in 20 cups. Green coffee samples from each batch were forwarded to Seattle University along with the characterization data. For the purpose of this study, the detailed origins of the samples were not included. The samples varied in size from 100 to 400 g and were stored as received in plastic bags at room temperature until analyzed.

**Sample Preparation.** The SPME sampling conditions used here were previously validated and applied in studies of green and roasted coffee.[12−15] Whole bean green coffee (70.0 g, approximately 400 beans, randomly selected) was placed in a headspace bottle (125 mL) with a PFTE/silicone septum cap (Supelco, U.S.A., 27236). The SPME fiber used was triple phase 50/30 $\mu$m DVB/Carboxen/PDMS coated (Supelco, U.S.A., 57328-U). Prior to first use, the fiber was preconditioned at 250 °C in the injection port of the GCMS for 30 min. The fiber was exposed in the headspace above the coffee beans for 60 min while the assembly was immersed in a 60 °C water bath. The headspace-to-volume ratio was approximately 1:10. The fiber was desorbed in the GC injection port for 5 min at 250 °C in the splitless mode using a Supelco specific SPME injection insert of 0.75 mm i.d.

**Organization of Study.** Samples selected randomly were subjected to GCMS analysis in batches of three to five per day. Blank samples were run once per day under the bean analysis conditions and provided negligible response. One to four replicates of each sample were analyzed, depending on size of coffee sample received. Usually, replicates were not run on the same day. In all there were 52 samples that resulted in 115 GCMS runs.

**Gas Chromatographic and Mass Spectrometric Analysis.** The GCMS conditions here were previously validated in several studies of green and roasted coffee.[16,17] An Agilent 5890 gas chromatograph was used as equipped with a 60 m × 0.25 mm i.d., 0.25 $\mu$m film thickness Stabilwax capillary column (Restek, 10641, Supelco, U.S.A.), an Agilent 5972 mass-selective detector, and Agilent ChemStation software. Analyses were done in the splitless mode using helium gas carrier at 1.0 mL/min flow. Column temperature was maintained at 40 °C for 11 min, then raised to 190 °C at 3 °C/min, held at 190 °C for 10 min, and finally raised from 190 to 250 °C at 15 °C/min. Mass spectra were recorded following electronic impact ionization at 70 eV. The mass range for data collection was 40−400 Da with 0.3 s scan interval. The data were collected and analyzed by GCMS Agilent ChemStation software (GCMSD1 operating software with Enhanced Data Analysis) using the NIST-05 and Wiley FFNSC-2 mass spectral databases. Peak assignments were made using dual criteria of mass spectral database and linear retention index[26,27] match. Retention indices of the eluted compounds were calculated on the basis of the standard alkane mixture ($C_{11}$−$C_{18}$). By comparing the retention indices and unique mass spectra with the reference library matches and literature retention indices,[28] tentative assignments were obtained, and they were confirmed by running known standards under the bean analysis conditions.

**Chromatographic Analysis of Ground Bean Samples.** Green coffee samples were frozen to −70 °C and then ground in a blender (Waring Commercial, model 51BL30, Fisher Sci., U.S.A.), with the size fraction less than 2 mm (U.S.A. Standard Test Sieve, No. 10, 2 mm, Fisher Sci., U.S.A.) being considered representative of the interior of the beans and analyzed for volatiles. A 3.5 g ground sample in a 40 mL sample vial was heated to 60 °C, sampled by SPME, and analyzed chromatographically by the procedure as described above in the Chromatographic and Mass Spectrometric Analysis section.

**Statistical Analyses.** Principal component analysis (PCA) allows comparison and classification of complex samples using their entire gas chromatographic (GC) profiles, avoiding selection and identification of individual peaks and peak-area integrations, while taking into account the large number of minor peaks and peak shape information. Due to minor drifts in retention times, data alignment is required prior to applying PCA to GC data. This approach, utilizing the entire instrument output, has been applied successfully to chromatographic[29,30] and spectral[31] analysis of complex systems. The PCA was accomplished using software within the PLS Toolbox v. 7.5.2[32] running on the Matlab platform v.R2013b.[33] See Chapter 4 of Brereton[34] for a general discussion of PCA in the chemometric context.

The GC/MS signal, total ion current (TIC) as a function of time, was collected every 0.4 s, yielding approximately 11 132 observations for each 75 min run. Visual inspection revealed that all useful data had retention times in the range 17.2−70.9 min, and the GC data sets were truncated accordingly, yielding data objects of 7951 variables corresponding to points in the chromatogram. Prior to analysis, the GC data objects were aligned using correlation-optimized warping (COW) according to the procedures of Tomasi et al.[35] The reference chromatogram (pt 61a) was selected as having the maximum cumulative product of correlation coefficients for a subset of 52 chromatograms collected in midstudy.[36] Parameters used in the alignment (segment = 100, slack = 15) were determined by their systematic variation with graphical assessment of the resulting aligned chromatograms. After alignment, further preprocessing included baseline correction using the Eilers and Boelens[37] method with Whittaker[38] filter ($p$ = 0.001, lambda = 100), followed by mean-centering.

The resulting principal component model was then subjected to the VARIMAX rotation[39] in order to facilitate the interpretation of the potato taste samples in terms of the loadings on a single factor.

## RESULTS AND DISCUSSION

**Chromatograms of Whole Bean Samples.** In all, 115 chromatographic runs of surface volatiles were performed on 52 characterized whole bean samples. One to four replicates were collected, depending on availability of sample, and in all cases they were reproducible. Six of the samples in the study were confirmed with PTD by the taste testers. Visual inspection of the chromatograms revealed obvious differences between the potato taste (PTD) and nonpotato taste (non-PTD) samples. Typical non-PTD and PTD surface volatile chromatograms are

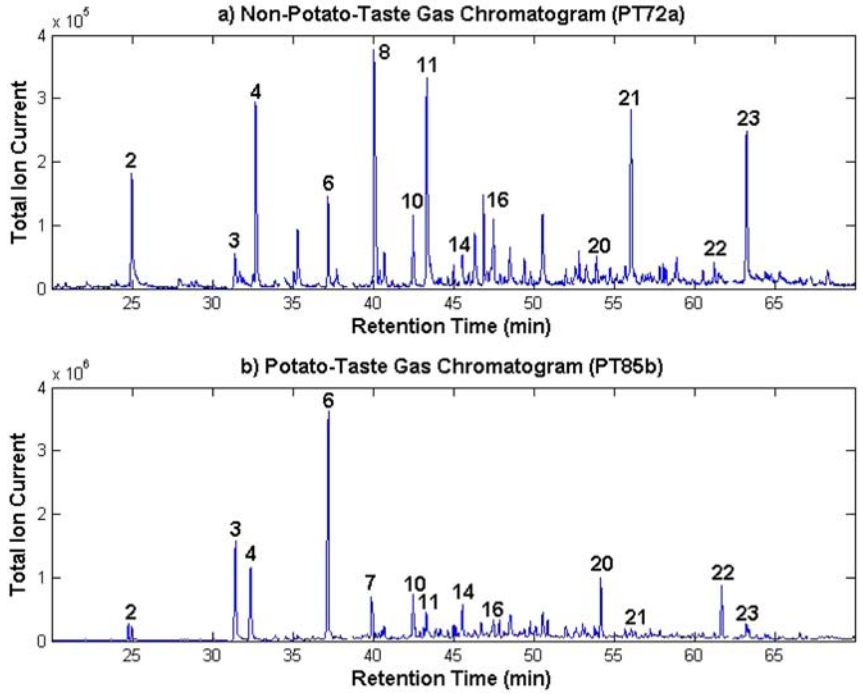

**Figure 1.** Gas chromatograms for whole bean green coffee samples: (a) non-potato-taste (Pt 72a) and (b) potato-taste (Pt 85b). Compounds are labeled according to Table 1.

shown in Figures 1a and 1b, respectively. The sample analyses are labeled in the figures with a number designating their index in our laboratory records and a letter indicating the replication. For example, "Pt 85b" refers to second analysis ("b") of the sample designated "85". Note the difference in scale for the ordinate axes: the total ion current scale is 10 times greater (to $4.0 \times 10^6$) in the PTD chromatogram as compared to the non-PTD chromatogram ($4.0 \times 10^5$) The retention times and compound identifications for the major peaks are given in Table 1.

Peaks occurring at 31.1, 38.5, 45.4, 62.2, and 67.2 min corresponded to silyl esters originating from the SPME sampling conditions and were eliminated from further analysis. These assignments were confirmed through a blank sampling experiment. A peak of widely varying intensity at 34.3 min was identified as 1-dodecene. The intensity of this peak correlated strongly with the elapsed time between processing of the coffee beans in the field and their analysis in the lab. This is consistent with 1-dodecene being a product of on-the-shelf oxidation of unsaturated plant oils, and the development of a cardboard-like odor.[40] Having no significance in the present context, the 1-dodecene peak was eliminated from further analysis. The peaks labeled "8" at 40.1 min (Figure 1a) and "7" at 39.9 min (Figure 1b) are "unidentified" by the MS analysis.

Peaks corresponding to tridecane (6), dodecane (3), tetradecane (10), and methylsalicylate (22) are observed to have much larger intensities in the PTD chromatograms than in the non-PTD ones (note the different ordinate scales). Peak "20" at 54.3 min corresponding to 1-methoxy-4-propylbenzene is variable among the PTD chromatograms and observed only at reduced intensity in the non-PTD chromatograms. This pattern of relatively intense alkane peaks in PTD samples is denoted in this study as a "PTD profile."

Two samples (Pts 77a and 80a) that were characterized as "non-PTD" by the taste testers were found to have the PTD profile (i.e., high alkane concentrations) in their surface volatile chromatograms. The PCA (see below) also characterized them as "PTD." These samples were from farms adjacent to those

**Table 1. Selected Observed Peaks for Whole Bean and Ground Samples (non-PTD and PTD)**

| label | retention time (min) | linear retention index | compound |

[a]Identified by mass spectral match, but not confirmed by standard.

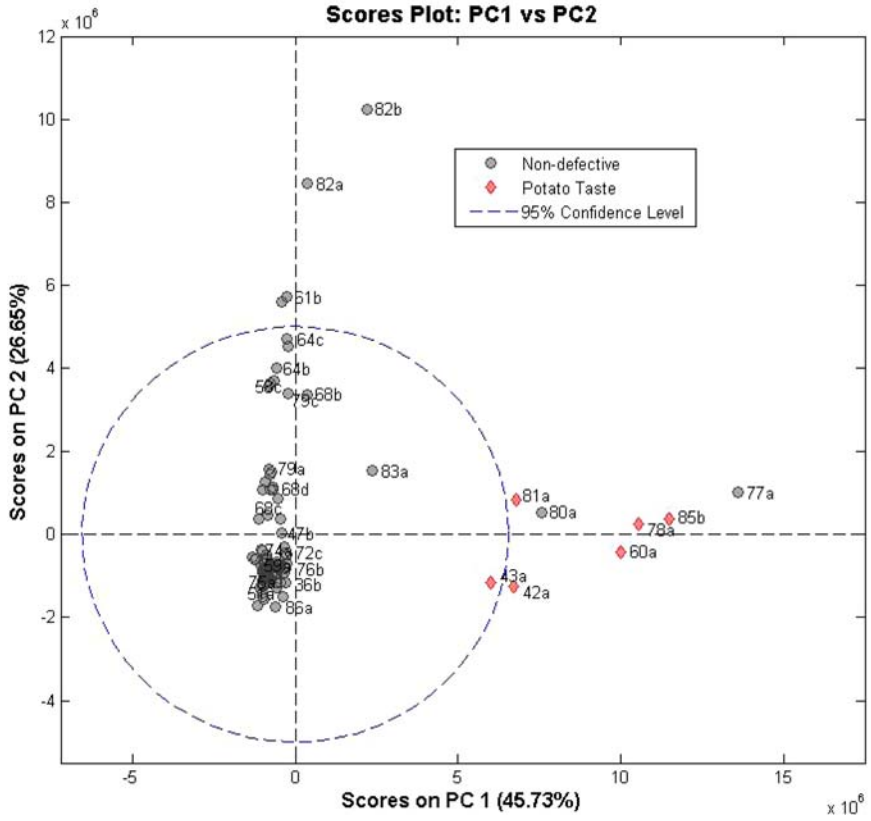

**Figure 2.** PCA scores biplot (PC1 vs PC2) for 115 whole bean green coffee samples (after VARIMAX rotation).

that had PTD, which suggested PTD could possibly be verified by further taste testing of these samples. However, due to limited sample availability, further testing was not possible.

Surprisingly, neither IPMP nor IBMP was observed in any of the PTD or the non-PTD chromatograms of surface volatiles when the samples were heated at 60 °C. Standards of IPMP and IBMP showed them to be found at 45.2 and 49.7 min, respectively. To determine if a higher temperature would release these pyrazines, PTD and non-PTD samples were heated to 90 or 100 °C, but still no IPMP or IBMP was observed among the surface volatiles. Samples could not be heated over 100 °C because roasting chemistry begins above 100 °C, producing new compounds.

**PCA of Chromatograms.** Principal component analysis (PCA) was utilized to classify the 115 samples as either PTD or non-PTD. In general, a model with two principal components was found to be satisfactory, accounting for 72% of the variance in the data sets. In Figure 2 is the scores biplot (PC1 versus PC2) for the 115 data objects. A VARIMAX rotation has been applied to the component axes to bring the cluster of PTD samples into good alignment with the PC1 axis, facilitating interpretation in terms of the PC1 loadings. Note first that all samples identified as PTD by the taste testers (red diamonds) appear in a cluster well separated from the much larger number of non-PTD samples (black circles). As already noted above from the visual inspection of the chromatograms, Pts 77a and 80a appear firmly within the PTD cluster, strongly suggesting that they would be likely to reveal PTD character upon further sensorial testing. The remaining 107 non-PTD points exhibit very little spread along the PC1 axis as would be indicative of PTD chromatograms.

In Figure 3 is presented a plot of the loadings for PC1. Since the PTD cluster of data lies close to the positive PC1 axis in the scores biplot, we can interpret the loadings as characteristic of the chemical "profile" that classifies these points as PTD and separates them from the other samples. This indicates that compared to the non-PTD samples, PTD samples have strongly increased levels of dodecane and tridecane; moderately increased levels of tetradecane, 1-octene-3-ol, 2-ethyl-1-hexanol, and limonene; slightly increased levels of 1-methoxy-4-propylbenzene and methylsalicylate, and *decreased* levels of 3-methylbutanoic acid. The strongest features of this PTD profile are increased levels of several alkanes and a decreased level of 3-methylbutanoic acid. Of interest is the observation of increased methylsalicylate (oil of wintergreen) in the PTD profile. Methylsalicylate is derived from salicylic acid, a plant hormone, and is known to increase in response to insect attacks.[41] This compound has not been reported among the volatiles of "normal" green coffee[15,17,19] but has been reported among the volatiles in defective moldy/earthy coffee.[8] Consistent with the previous visual observations, no evidence of IPMP or IBMP is found in the loadings for PC1.

In Figure 2, the spread within the non-PTD samples is along PC2, with the two replicates of Pt 82 having the largest displacements. Examination of the PC2 loadings and the GC's for Pt 82 indicates that those samples have relatively large concentrations of nonanal ("11") and an unidentified compound ("7").

**Chromatograms of Ground Samples.** The surface volatiles observed in chromatograms of whole bean samples (above) revealed differences between PTD and non-PTD coffees that serve to classify the coffees but were not the same as the reported differences in the literature[1] in that the whole bean chromatograms did not include IPMP or IBMP. However, the previous observations[1] were based on finely ground samples that were solvent-extracted and put through a multistep process

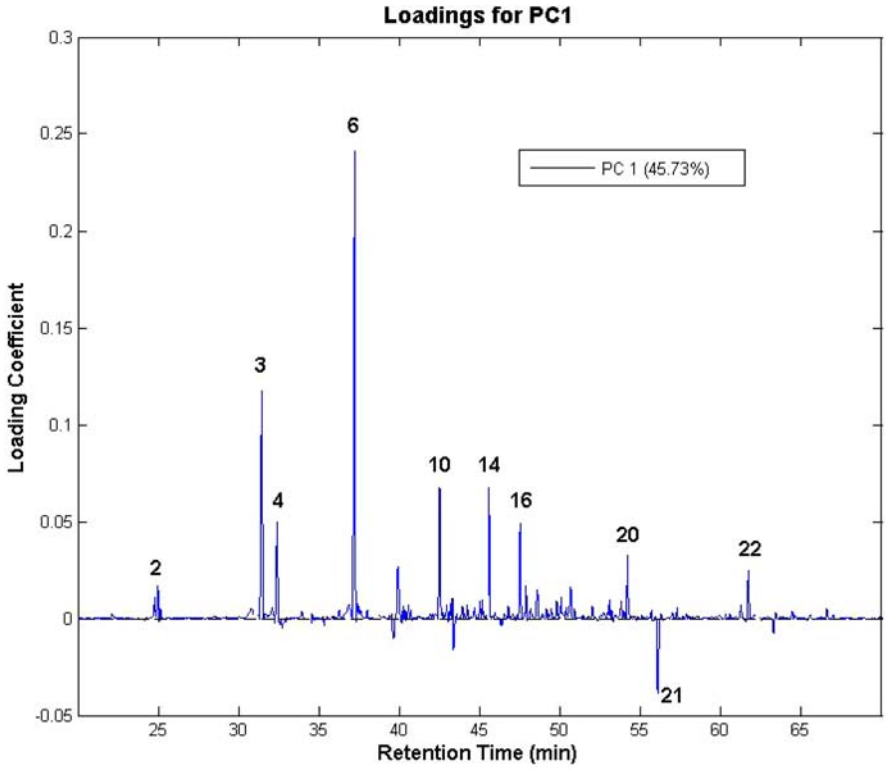

**Figure 3.** PCA loadings plot for PC1. Compounds are labeled according to Table 1.

before chromatography. When using ground samples previously, the volatiles were extracted from the interior of the coffee beans and the concentration of surface volatiles would be insignificant in the mixture. Since in our research (above), IPMP and IBMP, which were assumed to bring about PTD, were not observed in the surface volatiles of PTD coffee, they must have been in the interior of the PTD beans. Thus, further experiments were designed to measure the interior volatiles of the beans. PTD and non-PTD green coffee samples were frozen to −70 °C, ground in a blender with the size fraction less than 2 mm being considered representative of the interior of the beans, and analyzed for volatiles. A 3.5 g ground sample was sampled and analyzed chromatographically by the PSPME−GCMS procedure as described above in the Materials and Methods Section.

Due to limited quantity of samples, two non-PTD and four PTD samples were used to collect nine chromatograms of ground samples (two non-PTD and seven PTD). In addition to these samples a large Burundian sample (see section below) was used to collect 13 more chromatograms. In contrast to the surface volatile case, the intense PTD profile (mainly alkanes) was not observed in the interior of either PTD or non-PTD samples. Among the interior volatiles, hexanal, hexanol, nonanal, 3-methylbutanoic acid, and hexanoic acid were prominent and similar in intensity in both the PTD and non-PTD chromatograms. These compounds have been previously observed in studies of ground green coffee beans.[14−16,19,20] IBMP was found in both types of sample at approximately the same amount, but IPMP was detected *only* in the PTD sample, in agreement with the previous findings of Becker[1] that IPMP was found at increased levels in PTD coffee. Further, the lack of IPMP or IBMP among the surface volatiles shows that these compounds are found only inside the beans. Our results are consistent with a hypothesis that the IPMP was produced *in the seeds* and not deposited on the seed surface by a bacterial growth in the fruit, as had been suggested by Bouyjou.[4]

**Chromatograms of Insect Damaged PT Coffee Beans.** Given that the IPMP occurs inside the beans, it would be illustrative to determine if its level is the same throughout a PTD sample or is concentrated in specific beans, for example, those exhibiting visible signs of insect damage. Further, if the elevated IPMP level is associated with *antestia* activity, then coffee with known *antestia* damage should exhibit the PTD profile in the whole beans and the PTD-associated pyrazines in the ground coffee. To test these hypotheses, a large (several kilogram) sample of PTD coffee was needed so that it could be sorted into the defect categories. None of the Rwandan samples was large enough, but we were fortunate to receive a large donated sample of Burundian coffee that had very weak PTD (1 cup in 120 confirmed by a tasting panel). This sample was sorted into the following fractions: insect-damaged (brown spots indicative of *antestia* activity), UV fluorescent (presumably from the presence of a fluorescent microbe on the bean surface), broken (during removal of the parchment and silverskin), withered (characteristic of poor cultivation conditions), and bulk (no defects, after the other fractions were removed).

SPME−GCMS analysis of the bulk fraction gave results indicative of non-PTD coffee, i.e., no prominent alkane PTD profile in the whole bean chromatogram and IBMP with only a trace of IPMP in the ground bulk chromatogram. In contrast, the chromatogram of the whole bean insect-damaged fraction did feature a prominent tridecane peak with accompanying dodecane and tetradecane peaks, similar to the profile that characterized PTD whole bean coffee. The chromatogram of the whole-bean insect-damaged fraction (Figure 4a) did not have peaks attributed to IPMP or IBMP, whereas chromatogram of the ground-bean insect-damaged fraction (Figure 4b) exhibited both. Comparing the chromatograms of the sorted fractions

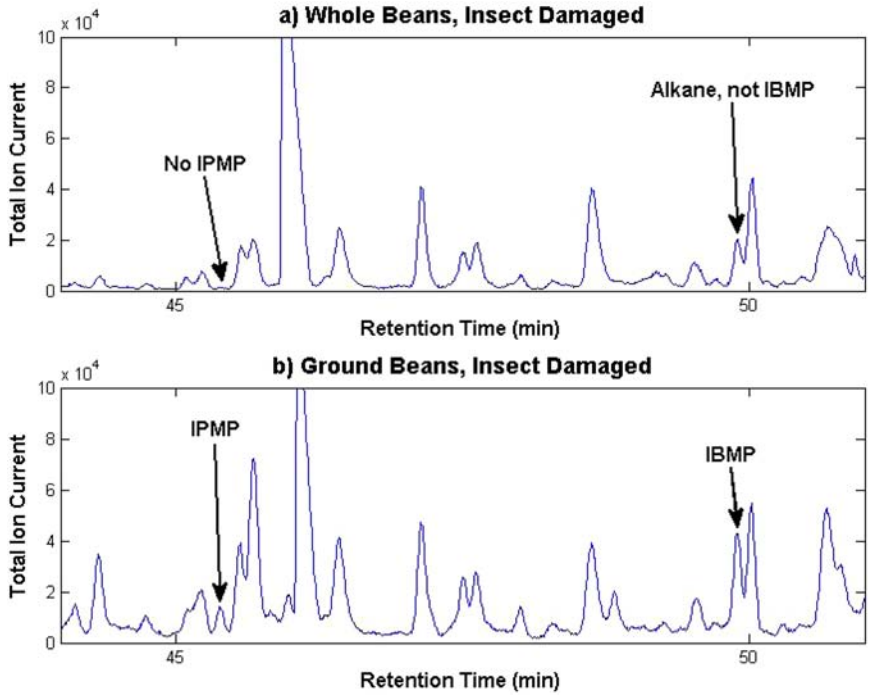

**Figure 4.** Expanded GC region from insect damaged sample: (a) whole beans and (b) ground beans.

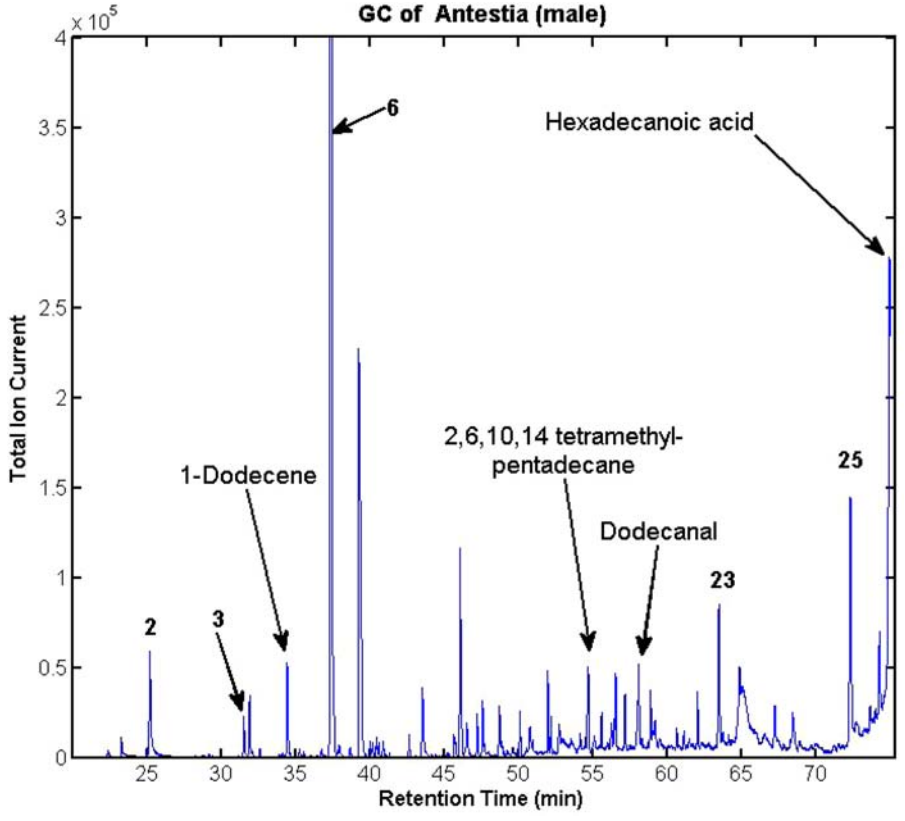

**Figure 5.** GC analysis of a whole, male *Antestia* bug. Peaks without labels are unidentified.

revealed that the IBMP peak was about the same size in all the fractions whereas the IPMP/IBMP peak ratio varied from 0 in the bulk fraction to 0.08, 0.11, and 0.32 in the broken, UV fluorescent, and insect-damaged fractions, respectively. The presence of the PTD profile in the whole-bean insect-damaged fraction, along with the IPMP and IBMP presence in the ground-bean insect-damaged fraction (and only trace IPMP in the bulk sample), is the first direct evidence observed to date for the association of *antestia* activity with both the surface alkane and interior pyrazine PTD profiles. Lower levels of IPMP were observed in the UV fluorescent and broken bean samples. Future experiments will focus on establishing a more

quantitative relationship between interior IPMP level and surface alkane levels.

**Chromatograms of Whole Desiccated *Antestia* Bugs.** In order to test the hypothesis that the PTD surface profile, consisting mainly of tridecane, dodecane, and tetradecane, is associated with volatile compounds possibly deposited by the *antestia* bug, specimens of *antestia* were obtained from Rwanda and chromatograms of whole bug volatiles were collected. Male and female *antestia* were collected, kept separately, killed by freezing, and then dried before transport to the U.S. The specimens were frozen at −15 °C immediately upon arrival, and when needed, a single whole bug was transferred to a 40 mL sample vial, sealed with a septum cap, heated to 60 °C, and then sampled by headspace SPME for 5 min and subjected to chromatographic analysis by the same procedure described in the Materials and Methods section.

Male and female specimens each were analyzed in triplicate and gave very similar chromatograms with the same set of volatiles, including hexanal, dodecane, 1-dodecene, tridecane, 2,6,10,14-tetramethylpentadecane, hexanoic acid, and phenol (see Figure 5). The three major compounds of the *antestia* chromatograms, tridecane (largest), dodecane, and tetradecane, were also detected as the three major compounds in the PTD profile of the surface volatiles of green coffee. The pheromones of *antestia orbitalis* have not been studied; however, in the literature, tridecane, dodecane, and tetradecane are prominent among the pheromones identified as defensive compounds in pentadomidae species related to *antestia*, such as *Agroecus griseus,*[42] *Cosmopepla bimaculata,*[43] and *Nezara viridula*.[44]

In summary, the results of the analysis of surface volatile compounds on green coffee indicate a clear pattern of distinction between PTD and non-PTD coffees. The four prominent identifiable compounds found at higher levels in PTD coffee surface were dodecane, tridecane, tetradecane, and 2-ethyl-1-hexanol, while 3-methylbutanoic acid was found at decreased levels. Long-chain alkanes have not previously been associated with volatile compounds of ground green coffee.[6−9,20,23] However, long-chain alkyl compounds are frequently found as constituents of plants and insects, for example, on leaf surfaces and seed surfaces, and are used as pheromones by insects. Several studies include alkanes such as tridecane, dodecane, tetradecane, and undecane on lists of defensive pheromones secreted by stink bugs related to *antestia*.[42−44] These results support the hypotheses that PTD is associated with *antestia* feeding activity and that IPMP, which imparts potato taste in roasted coffee, is produced inside the coffee beans, possibly in response to the stress of *antestia* damage.

different cleavage sites that can be used as substrate. In addition, each cleavage site can be present in different peptides formed during hydrolysis. For this reason, the selectivity has recently been defined as the relative rate at which the enzyme cleaves each individual cleavage site compared to the total rate of hydrolysis of all cleavage sites in the protein.[9]

Furthermore, it has already been shown that there were large differences in terms of selectivity toward cleavage sites after the same type of amino acid for the hydrolysis by *Bacillus licheniformis* protease (BLP) of a 1% (w/v) WPI solution.[9] In the present study, the same specific enzyme (BLP) was used for the hydrolysis of 0.1−10% (w/v) whey protein isolate (WPI) at constant enzyme/substrate ratio. The molar concentration of most of the peptides (i.e., >90% of the total $UV_{214}$ signal) in the hydrolysates was determined at different points during the hydrolysis. From the kinetics of formation of the peptides, the influence of substrate concentration on the selectivity of the enzyme was determined.

## MATERIALS AND METHODS

**Materials.** Bipro, a commercial whey protein isolate (WPI), was obtained from Davisco Foods International Inc. (Le Sueur, MN, USA). It contained (by weight) 74.0% $\beta$-lactoglobulin, 12.5% $\alpha$-lactalbumin, 5.5% bovine serum albumin, and 5.5% immunoglobulin, according to specifications of the supplier. The protein content (N × 6.32)[4] of the powder was 93.4% (w/w) as determined by Dumas.[10] BLP, specific for Glu−X bonds and for Asp−X bonds,[11] was obtained from Novozymes (NS-37005) (Bagsvaerd, Denmark). BLP (4.5% protein, N × 6.25, 0.3 AU/mg/min as determined by the azocasein assay[12]) was partly insoluble and was fractionated as described before.[9] The freeze-dried material was found to contain 60% protein (N × 6.25) from which 78% is the enzyme BLP (23.6 kDa) and 14% is the pro-peptide (6.9 kDa) based on $UV_{214}$, as determined by RP-UPLC-MS.[9] An activity of 3.9 AU/mg/min was determined by the azocasein assay. All other chemicals were of analytical grade and purchased from Sigma or Merck.

**Hydrolysis.** Protein solutions were prepared by dispersing WPI powder at a concentration of 45% (w/v) in Milli-Q water (18.2 MΩ·cm), followed by stirring overnight at 4 °C. Insoluble parts were removed by centrifugation (30 min, 4000*g*, 20 °C), and the supernatant obtained (30% (w/v)) was diluted to the required final concentrations 0.1−10% (w/v) as determined by $UV_{280}$.[4] Hydrolyses were performed using a pH-stat at pH 8, which is described to be the optimum pH for the enzyme BLP.[13] Solutions of WPI at 0.1, 0.25, 0.5, 1, 5, and 10% (w/v) were hydrolyzed at 40 °C and pH 8 using NaOH at concentrations of 0.02, 0.05, 0.1, 0.2, 1, and 2 M, respectively, to keep the pH constant. Protein solutions (10 mL) were equilibrated for at least 15 min at 40 °C and adjusted to pH 8.0 before addition of BLP dissolved at 5% (w/v) in Milli-Q water (0.30 $\mu$L of enzyme/mg of protein). The DH was calculated on the basis of the added volume of NaOH with $\alpha$, the average degree of dissociation of the $\alpha$-NH groups ($1/\alpha$ = 1.20 at 40 °C and pH 8.0) and $h_{total}$, the total number of peptide bonds per gram protein substrate ($h_{total}$(WPI) = 8.5) as described before.[4,14]

The overall rate of hydrolysis $k_{hydr}$ was calculated using eq 1

$$\mathrm{DH} = \frac{1}{a}\ln(1 + k_{hydr}t) \quad (1)$$

in which $k_{hydr}$ and $a$ are fitting parameters for the overall hydrolysis rate ($s^{-1}$) and an inactivation parameter, respectively, and $t$ is the time in seconds.[15] The overall relative rate of hydrolysis was determined using the highest value of overall hydrolysis rate as 100%. The overall hydrolysis rates of BLP were compared with previous results obtained with Alcalase.[4]

Samples were taken during the hydrolysis of 0.1, 0.5, 1, 5, and 10% (w/v) protein solutions at different degrees of hydrolysis (1.5, 3, 4.5, 6, and 7%). These samples were then centrifuged (5 min, 19000*g*, 15 °C). Supernatant and pellet were separated, and the supernatants were inactivated by adjusting the pH to 2 with 5 M HCl. The pH was set back to 8.0 after at least 10 min of inactivation before storage of the samples at −20 °C. Centrifugation was performed before the pH adjustment to 2, to avoid losses of material resulting from the pH adjustment. It has indeed been noted that there was formation of insoluble aggregates at pH 2. These aggregates were resolubilized at pH 8.

Separate experiments were performed to confirm that no inactivation of enzyme took place during hydrolysis and that the inactivation at low pH was irreversible.

To confirm that the enzyme does not autohydrolyze under these conditions, 30 $\mu$L of BLP dissolved to a concentration of 5% (w/v) was added to 9 mL of Milli-Q water and incubated at 40 °C and pH 8 for 1 h. After this incubation, a concentrated solution of WPI (10% (w/v)) was added to the enzyme at a final concentration of 1% (w/v) WPI. The hydrolysis was followed with the pH-stat for 1 h. The same experiment was performed with fresh enzyme, and it was concluded that no significant enzyme inactivation occurs.

As previously described for Alcalase,[4] the inactivation was verified by hydrolyzing a sample of 1% WPI for 10 min using the pH-stat. The pH was brought to pH 2 to inactivate the enzyme and readjusted to pH 8 after 10 min. After readjustment of the pH to 8, the pH remained constant (for 1 h), indicating that the enzyme had indeed lost its activity.

Samples obtained during the hydrolysis of 0.1 and 0.5% (w/v) WPI were freeze-dried after the pH was readjusted to pH 8.0 and redissolved to a concentration of 1% (w/v) to have the same concentration for all samples for analysis on RP-UPLC-ESI-MS.

**Solubility.** The protein and peptide contents in the supernatants of the samples taken at different DH values were determined using Dumas (N × 6.32)[4] using a Flash EA 1112 NC Analyzer (Thermo Fisher Scientific, Waltham, MA, USA). The proportion of soluble protein was calculated by dividing the concentration of protein of the supernatants by the concentration of protein in the solution before centrifugation (5 min, 19000*g*, 15 °C) at DH = 0.

**Reverse Phase Ultrahigh-Performance Liquid Chromatography (RP-UHPLC).** Samples obtained during hydrolysis were analyzed on an Acquity UPLC System (Waters, Milford, MA, USA) using an Acquity UPLC BEH 300 C18 column (2.1 × 150 mm, 1.7 $\mu$m particle size) with an Acquity BEH C18 Vanguard precolumn (2.1 × 50 mm, 1.7 $\mu$m particle size). Eluent A was 1% (v/v) acetonitrile (ACN) containing 0.1% (v/v) trifluoroacetic acid (TFA) in Milli-Q water, and eluent B was 100% ACN containing 0.1% (v/v) TFA. To reduce disulfide bridges and to facilitate peptide annotation, samples were first incubated for 2 h with 100 mM dithiothreitol (DTT) in 50 mM Tris·HCl, pH 8.0, at a concentration of 0.5% (w/v). After incubation, samples were further diluted in eluent A to a final concentration of 0.1% (w/v) and centrifuged (10 min, 19000*g*, 20 °C). Samples (4 $\mu$L) were injected into the column thermostated at 40 °C.[9]

The amount of remaining intact proteins ($\beta$-lactoglobulins A and B and $\alpha$-lactalbumin) was determined using the following elution profile: 0−2 min, isocratic on 30% B; 2−12 min, linear gradient from 30 to 50% B; 12−15 min, linear gradient from 50 to 100% B; 15−20 min, isocratic on 100% B; 20−21 min, from 100 to 30% B; and 21−30 min, isocratic on 30% B. The flow rate was 350 $\mu$L $min^{-1}$. The proportion of remaining intact $\alpha$-lactalbumin and $\beta$-lactoglobulin was determined by dividing the area of the $UV_{214}$ peak obtained for each protein at different DH values by the peak area obtained for each intact protein before hydrolysis. The proportion of $\beta$-lactoglobulin takes into account the proportions of both A and B variants.

For separation of the peptides a different elution profile was used: 0−2 min, isocratic on 3% B; 2−10 min, linear gradient from 3 to 22% B; 10−16 min, linear gradient from 22 to 30% B; 16−19 min, linear gradient from 30 to 100% B; 19−24 min, isocratic on 100% B; 24−26 min, linear gradient from 100 to 3% B; and 26−30 min, isocratic on 3% B. The flow rate was 350 $\mu$L $min^{-1}$. Detection was performed using a PDA, which scanned the absorbance from 200 to 400 nm at a 1.2 nm resolution with 20 points per second.

**Electron Spray Ionization Time-of-Flight Mass Spectrometry (ESI-Q-TOF-MS).** The mass spectra of the hydrolysates were determined with an online Synapt high-definition mass spectrometer (Waters), coupled to the RP-UPLC system, equipped with a z-spray electrospray ionization (ESI) source, a hybrid quadrupole, and an orthogonal time-of-flight (Q-TOF). The system was calibrated using the peptide Glu-1-Fibrinopeptide B ($m/z$ 1570.6 in positive mode). The capillary voltage was set to 3 kV with the source operation in positive ion mode and the source temperature at 120 °C. The sample cone was operated at 35 V. Nitrogen was used as desolvation gas (250 °C, 800 L/h) and cone gas (200 L/h). The trap gas was set at 1.5 mL/min. MS and MS/MS (MSe method) were performed between $m/z$ 100 and 2000 with a scan time of 0.3 s. The trap collision energy was set at 6 V in single MS mode and ramped from 20 to 30 V in MSe mode. The transfer collision energy was set at 4 V in MS and switched between 4 and 10 V in the MSe mode. UV and MS data were acquired using MassLynx v4.1 (Waters).

**Peptide Identification and Quantification.** For peptide identification, internal lock mass was applied on every chromatogram for MS and MS/MS data with two previously identified masses chosen among the most abundant masses, of which the sequences were identified manually. The identification of MS and MSe ion peaks was done by Biopharmalynx software (v 1.3) with the parameters described before.[9] The annotation was first done using a method to identify peptides cleaved after Glu and Asp residues. Next, a generic method was used in which no enzyme specificity was selected. For UV peaks where the automatic annotation did not yield a peptide sequence, a manual analysis of the MS and MS/MS data was used to assign the peptide sequence. For the total peptide quantification, peaks in the $UV_{214}$ chromatogram were included until 90−95% of the total $UV_{214}$ area was included. Peptides from $\beta$-lactoglobulin and $\alpha$-lactalbumin as well as the intact protein were quantified using the $UV_{214}$. In the case of coeluting peptides, the UV peak area was divided over the coeluting peptides based on the MS intensity (based on the assumption that coeluting peptides have comparable overall properties, i.e., charge, size, and hydrophobicity). For the further determination of the selectivity, only peptides from $\beta$-lactoglobulin were considered.

The quantification of the peptides was based on the UV signal at 214 nm, using eq 2

$$C_{\text{peptide}} = 1 \times 10^6 \left( \frac{A_{214}}{\varepsilon_{214} l V_{\text{inj}} k_{\text{cell}}} \right) Q \tag{2}$$

in which $C_{\text{peptide}}$ ($\mu$M) is the concentration of peptide, $A_{214}$ (AU·min) is the UV peak area at 214 nm, $V_{\text{inj}}$ ($\mu$L) is the volume of sample injected, $Q$ is the flow rate in $\mu$L min$^{-1}$, and $l$ is the path length of the UV cell, which is 1 cm according to the manufacturer. The value for the cell constant $k_{\text{cell}}$ was previously determined to be 0.66 using pure peptides, but depends on the geometry of the UV detector used.[16] The molar extinction coefficient at 214 nm of each peptide ($\varepsilon_{214}$) was calculated as described before.[17] Peak areas were annotated up to 150,000 $\mu$AU·min, and the linearity range of detection has been established for peak areas up to 350,000 $\mu$AU·min.

**Quality of the Annotation and Quantification.** For each hydrolysate, the quality of the peptide identification and of the quantification was described by three different parameters. First, the amino sequence coverage was determined by calculating the number (#) of unique annotated amino acids divided by the total number (#) of amino acids present in the parental protein sequence.[18]

$$\text{amino acid sequence coverage} = \frac{\text{\# of unique annotated amino acids}}{\text{\# of amino acids in protein sequence}} \times 100 \tag{3}$$

The amino acid sequence coverage was 100% for most samples. Only for samples DH 6 and 7% at 5 and 10% (w/v) WPI was an amino acid sequence coverage of 95% obtained. To take into account the fact that each part of the sequence was covered by several peptides, the peptide sequence coverage was determined as a second quality parameter on the peptide annotation.[9] It is defined as the number of amino acids (# AA) in annotated peptides divided by the total number of amino acids (# AA) present in all peptides (annotated peptides and missing peptides) as in eq 4:

$$\text{peptide sequence coverage} = \frac{\text{\# AA (annotated peptides)}}{\text{\# AA (annotated peptides)} + \text{\# AA (missing peptides)}} \times 100 \tag{4}$$

The peptide sequence coverage was found to be on average 95 ± 3% for all hydrolysates. No distinction between variants can be made for the calculation of the peptide sequence coverage. It was indeed not possible to assign the peptides to a variant, except for the peptides containing the mutant amino acids (positions 64 and 118).

To determine the completeness of the quantification, the molar sequence coverage was calculated. For that, the concentration of each amino acid $C_n$ ($\mu$M) was calculated using the molar concentration of each individual (annotated) peptide $C_{\text{peptide}}$ ($\mu$M). With this, each individual amino acid of the primary sequence of $\beta$-lactoglobulin has been quantified in the hydrolysate. The molar sequence coverage was calculated using eq 5

$$\text{molar sequence coverage} = \left( 1 - \frac{\sqrt{\frac{\sum (C_n - C_0)^2}{(\text{\# AA} - 1)}}}{C_0} \right) \times 100 \tag{5}$$

where $C_n$ is the concentration ($\mu$M) of each amino acid $n$ in the protein and $C_0$ is the initial concentration of the protein ($\mu$M). # AA is the number of amino acid residues in the sequence.

**Determination of Enzyme Selectivity.** To describe the selectivity of the enzyme, the rate at which individual peptide bonds are hydrolyzed (e.g., between Glu-45 and Leu-46) was determined. To do this, first, the concentrations of all peptides originating from hydrolysis of the same peptide bond ($C_{i,t}$) in the parent molecule were calculated using eq 6:

$$C_{i,t} = \sum \{ C_{\text{peptide}}[x - y]_t | i = x - 1 \cup i = y \} \tag{6}$$

In other words, the concentration of cleavage products formed at each time point $t$, after hydrolyzing peptide bond $i$, equals the sum of all peptides of the sequence $[x{-}y]$, for which $i = (x - 1)$ (i.e., starts on position P1′) or $i = y$ (i.e., ends on position P1). This means that the number of cleaved bonds is equal to the concentration of cleavage site products $C_{i,t}$ divided by 2. This also means the peptides that are formed from hydrolysis after the amino acid $i$ or which end by the amino acid $i$.

For each cleavage site the apparent cleavage rate ($k_{i,\text{app}}$ in s$^{-1}$) was then calculated by fitting eq 7 to the experimental data

$$C_{i,t} = 2(C_0 - C_0 \, e^{-k_{i,\text{app}} t}) \tag{7}$$

in which $C_{i,t}$ ($\mu$M) is the concentration of cleavage products determined for each time point $t$ and $C_0$ is the initial concentration of protein ($\mu$M).

Because one peptide can be formed through different pathways during the hydrolysis, there is no definite mechanistic equation (at the current moment) that can be used to fit the curves of the concentration of cleavage site products as a function of time. For most of the curves (e.g., 85 of 95) the first-order fit was satisfactory (e.g., $R^2 > 0.8$). However, the fit was not as good for cleavage sites hydrolyzed at a later stage of the hydrolysis. Still, using a different fit would only introduce more fitting parameters and inaccuracies. Hence, the first-order kinetics fit was the most efficient.

The rate of selective hydrolysis $k_i$ (s$^{-1}$ mg$^{-1}_{\text{enzyme}}$) was defined as

$$k_i = \frac{k_{i,\text{app}}}{m_{\text{E}}} \tag{8}$$

in which $m_{\text{E}}$ is the mass of enzyme added for the hydrolysis (in mg). Subsequently, the selectivity$_{\beta\text{-lg}}$ (%) was calculated by dividing the rate of selective hydrolysis ($k_i$) of each individual cleavage site by the sum

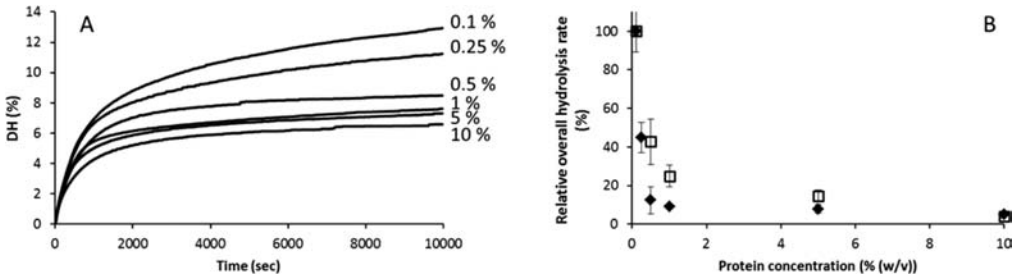

**Figure 1.** (A) DH curves of 0.1−10% (w/v) WPI hydrolyzed by BLP at constant E/S and (B) relative overall hydrolysis rate $k_{hydr}$ for hydrolysis of WPI by BLP (◆) and by Alcalase (□) as a function of the initial WPI concentration at constant E/S.

of the rate of selective hydrolysis of all cleavage sites at each protein concentration as in eq 9:

$$\text{selectivity}_{\beta\text{-lg}}\,(\%) = \frac{k_i}{\sum k_j} \times 100 \tag{9}$$

It should be noted that in this definition of selectivity, the final value depends on the total number of cleavage sites. As such, it may be difficult to compare this value with values determined for different substrates. The benefit of the current definition is that the total selectivity (in one experiment) adds up to 100%. Therefore, the value represents which fraction of the enzyme total activity corresponds to the cleavage of a particular site. In addition, all cleavage sites, even those with low selectivity, were hydrolyzed, which indicates that the enzyme tries all possible locations. Therefore, we assumed that the number of times the enzyme attacks a certain cleavage site (per unit time) does not depend on the rate of cleavage of other cleavage sites. It should only be considered that the attack of the enzyme on a cleavage site does not directly lead to hydrolysis or that for some cleavage sites the hydrolysis takes more time. Consequently, the rate of cleavage of site $i$ does not depend on the rate of cleavage of all sites $j$ ($j \neq (i)$.

**Reproducibility of the Analysis.** The relative overall hydrolysis was calculated from three repeated hydrolysis experiments, and the standard deviation was calculated for each condition.

To test the reproducibility of the UPLC-$UV_{214}$ quantification method, one sample (1% WPI, DH 4.5%) was injected three times. The concentration determined for individual peptides showed a typical standard error of 6%. In addition, the reproducibility of the complete analysis was tested. For this, two separate hydrolysis experiments were performed at the same protein concentration (0.5% (w/v) WPI). During each hydrolysis, samples were taken at DH 1.5, 3, and 6%. Peptides were annotated (i.e., assigned to a sequence) and quantified for all hydrolysates. The error of peptide sequence coverage and molar sequence coverage was calculated for the hydrolysate at each DH. The values of standard errors (standard deviation/mean × 100) were averaged to determine the analysis error. The quality of the annotation as described by the peptide sequence coverage showed a standard error of 2.5%. The molar sequence coverage showed a standard error of 18%. Finally, the determined selectivity showed a typical standard error of 15%.

## RESULTS AND DISCUSSION

**Protein Hydrolysis at Different Substrate Concentrations.** The DH of WPI hydrolyzed by BLP at constant enzyme/substrate ratio reached after 10000 s decreases with increasing initial protein concentration from DH = 14% for 0.1% (w/v) WPI to DH = 6% for 10% (w/v) WPI (Figure 1A). The effect of concentration observed here for WPI hydrolyzed by BLP was compared to previous results obtained for hydrolysis of WPI by Alcalase, an enzyme mixture that mostly contains the a-specific enzyme subtilisin.[4] In both cases the rate of hydrolysis as seen, for instance, in the initial slope of the DH versus time curve and quantified by the overall hydrolysis rate $k_{hydr}$, decreased with increasing substrate concentration (Figure 1B).

The solubility of all the hydrolysates was determined to be 96 ± 5%. This result shows that the effect of the initial substrate concentration on the overall hydrolysis rate is not due to the formation of insoluble aggregates. It also indicates that the peptides identified represent the complete sample. On this basis, the pellet was not analyzed for peptides. The hydrolysates obtained at different concentrations can thus be compared for detailed analysis of the hydrolysates and peptides formed as a function of initial protein concentration. It has also been shown that even at high protein concentrations, such as 30% (w/v) WPI, no aggregation or oligomerization was measured by size exclusion chromatography.[4] In addition, it was previously shown that the increase in protein concentration does not result in a significant increase in viscosity (2.0 mPa·s at 10% (w/v) WPI and 27 mPa·s at 30% (w/v) WPI).[4] Moreover, as described in a previous study,[14] the substrate concentrations used here (0.1−10% (w/v) WPI equivalent to 36 μM−3.6 mM) are above the reported threshold for substrate inhibition (<350 μM). Above the reported threshold, the substrate inhibition curve tends to reach a plateau. In that study,[14] it was concluded that substrate inhibition could not explain the decrease in hydrolysis rate with increasing substrate concentration.

The hydrolysis was also characterized by the decrease of intact proteins as a function of the DH. Changes in this curve indicate changes in the preference for the hydrolysis of intact protein versus the hydrolysis of intermediate peptides formed. These curves are found to be similar for all initial protein concentrations (0.1−10% (w/v) WPI), with no remaining intact β-lactoglobulin above DH 4.5% (Figure 2). In other words, the accessibility toward the intact protein relative to the accessibility toward the peptides was not affected by the initial

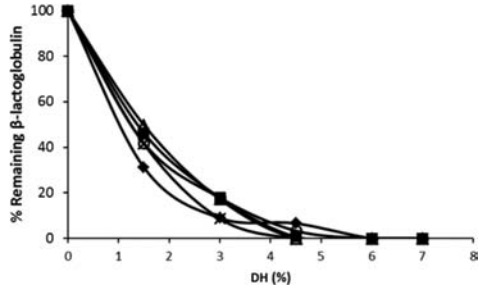

**Figure 2.** Remaining intact β-lactoglobulin as a function of DH for different initial substrate concentrations of (◆) 0.1%, (■) 0.5%, (△) 1%, (×) 5%, and (○) 10% (w/v) WPI (0.1% WPI corresponds to a concentration of 37 μM β-lactoglobulin).

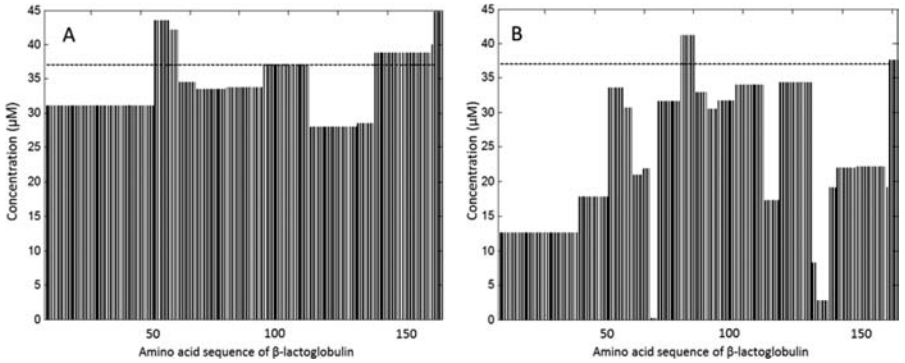

**Figure 3.** Concentration of all amino acids ($C_n$) for (A) 1% (w/v) WPI at DH 1.5% and (B) 5% (w/v) WPI at DH 6%. The dotted line (···) indicates the initial protein concentration. Hydrolysates were diluted to 0.1% (w/v) prior to analysis.

**Table 1. A-specific Peptides Annotated during Enzymatic Protein Hydrolysis of 0.1−10% (w/v) WPI by BLP and the Parental Peptides**

| parental peptide | sequence | a-specific peptides annotated |
|---|---|---|
| [56−62] | ILLQ−KWE | [56−59]−[60−62] |
| [75−89] | KTKIP −VFKIDALNE | [75−80]−[81−89] |
| [135−157] | KFDKALK−ALPMHIRLSFNPTQLE | [135−141]−[142−157] |
| [135−158] | KFDKALK−ALPMHIRLSFNPTQLEE | [135−141]−[142−158] |
| [138−157] | KALKALPM−HIRLS−FNPTQLE | [138−145]−[146−157] and [146−150]−[151−157] |
| [138−158] | KALKALPM−HIRLS−FNPTQLEE | [138−145]−[146−158] and [146−150]−[151−158] |

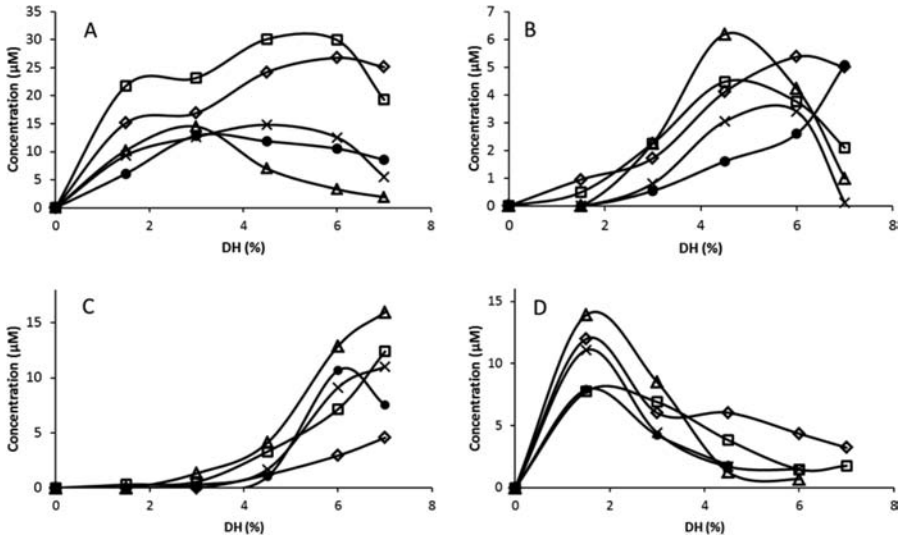

**Figure 4.** Concentration ($\mu$M) of different peptides as a function of DH for different initial protein concentrations (◇) 0.1%, (□) 0.5%, (△) 1%, (×) 5%, and (●) 10% (w/v) WPI. All hydrolysates were diluted to 0.1% (w/v) prior to analysis.

substrate concentration. The onset temperature of denaturation of $\beta$-lactoglobulin, as determined by DSC, is 60 °C, and the midpoint of unfolding is at 77 °C.[19] In addition, no intact $\beta$-lactoglobulin was present at DH 4.5%, which corresponds to a maximum incubation time of 30 min (at the highest protein concentration). On this basis, it was assumed that there is no significant effect of denaturation of the intact $\beta$-lactoglobulin on the observed behavior.

Both the solubility of the hydrolysates and the difference in accessibility of the intact protein relative to that of peptides are independent of the initial protein concentration, whereas the overall hydrolysis rate is affected by the initial protein concentration at constant enzyme/substrate ratio. To determine if the mechanism of hydrolysis depends on the initial substrate concentration, the peptides formed during the hydrolysis were identified.

**Identification and Quantification of the Peptides.** For all samples at different DH and different initial substrate concentrations, a total of 77 peptides were identified and quantified. The quality of the quantification was determined by calculating the molar sequence coverage. The molar sequence coverage provides an indication of the concentration of each amino acid of the parental protein sequence found in the peptides identified compared to the initial protein concentration (eq 5). The molar sequence coverage was 70 ± 10%, indicating a quite complete annotation and quantification. Still, for some amino acids, a concentration higher than expected is obtained and for others a concentration lower than expected is

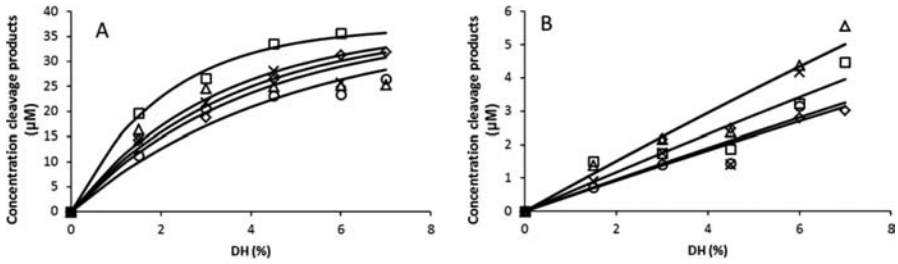

**Figure 5.** Concentration of cleavage products as a function of DH for (A) cleavage site 45 and (B) cleavage site 157 for different initial protein concentrations of (◇) 0.1%, (□) 0.5%, (△) 1%, (×) 5%, and (○) 10% (w/v) WPI. Symbols indicate experimental data, and solid lines show the fits from eq 7.

determined (Figure 3). At increasing DH, in some parts of the sequence not all amino acids were present at the expected concentration. Some amino acids were not annotated at all (Figure 3B). This finding is most likely due to the formation of free amino acids or short peptides, which are not annotated in RP-UPLC. In total, 5 free amino acids can theoretically be obtained during hydrolysis of $\beta$-lactoglobulin by BLP (45-E, 65-E, 130-D, 131-E, 158-E). Over all hydrolysates, 13 of the 77 peptides annotated are so-called a-specific peptides. These peptides were the result of cleavage of previously formed (specific) peptides. For instance, the formation of $\beta$-lg[56−59] and $\beta$-lg[60−62] results from the cleavage of the specific peptide $\beta$-lg[56−62] (Table 1). The formation of a-specific peptides was actually increased with increasing substrate concentration and DH, whereas the overall hydrolysis rate decreased (data not shown). It was assumed that certain peptides formed as a result of the enzyme action are not stable in solution. These peptides autohydrolyze to form the a-specific peptides mentioned (Table 1). Similar instability of peptides has been described for several isolated cases such as the vasoactive intestinal peptide[20] or for RNA splicing.[21]

The formation and further breakdown of all peptides were monitored as a function of the DH for the different initial protein concentrations. Different types of peptide release kinetics were observed as a function of the initial protein concentration (Figure 4). For some peptides no clear effect (i.e., larger than the experimental error) of substrate concentration on their formation and subsequent hydrolysis was observed, for example, peptide $\beta$-lg[135−162] (Figure 4D). For this peptide, at each DH, there was no clear trend of the peptide concentration as a function of initial substrate concentration. Others, such as peptide $\beta$-lg[1−45], showed two types of kinetics for low (0.1−0.5% (w/v) WPI) and for high initial substrate concentrations (1−10% (w/v) WPI) (Figure 4A). For peptides such as $\beta$-lg[1−45], a higher peptide concentration (25−30 $\mu$M) was reached at low substrate concentrations (<1% WPI) than at high substrate concentrations (12 $\mu$M). This fact indicated a faster rate of formation than degradation at low substrate concentrations and a comparable rate of formation and degradation at high substrate concentrations. In other words, the maximum concentration of peptide reached during hydrolysis was lower at high initial substrate concentrations (Figure 4A). Peptide $\beta$-lg(A)[90−127] is an intermediate peptide formed from at least two cleavages on the intact protein (Figure 4B). For this peptide different formation and further hydrolysis behavior were observed for the different initial concentrations. For the final peptide $\beta$-lg(A)[115−127], no large effect of initial substrate concentration on its formation was observed up to DH 4.5% (Figure 4C), and large effects were observed at DH 7% with concentration varying from 4 to 15 $\mu$M.

**Influence of Substrate Concentration on Selectivity.** *Kinetics of Hydrolysis.* On the basis of the peptide identification and quantification, the concentration of cleavage products $C_{i,t}$ was determined (eq 6). The concentration of cleavage products, for example, for residues 45 and 157, as a function of DH can be compared for the different initial substrate concentrations (Figure 5). The concentration of cleavage products was comparable for all initial substrate concentrations. The concentration was higher for cleavage site 45 than for cleavage site 157. The apparent cleavage rate $k_{i,\mathrm{app}}$ (Supporting Information) and rate of selective hydrolysis $k_i$ of each cleavage site were determined on the basis of the concentration of cleavage products as a function of time (eqs 7 and 8). Large differences in the rate of selective hydrolysis were observed for all cleavage sites for all protein concentrations with rates varying from $2.5 \times 10^{-2}$ to $1.0 \times 10^{-7}$ $s^{-1}$ $mg^{-1}{}_{enzyme}$ and even 0 for some of the cleavage sites (Figure 6).

On the basis of the rate of selective hydrolysis of 1% (w/v) WPI, the cleavage sites were divided into five groups. The first group consists of four Glu residues with a rate of selective hydrolysis of $6.5 \times 10^{-3}$ $s^{-1}$ $mg^{-1}{}_{enzyme}$. The second group consists of five Glu residues with a rate of selective hydrolysis of $2.4 \times 10^{-3}$ $s^{-1}$ $mg^{-1}{}_{enzyme}$ (Figure 6A). The third group consists of four Glu residues for which the rate of selective hydrolysis is 10 times lower than that for the first two groups, $4.3 \times 10^{-4}$ $s^{-1}$ $mg^{-1}{}_{enzyme}$ (Figure 6B). Two Glu residues have a rate comparable to that of the Asp residues ($9.5 \times 10^{-6}$ $s^{-1}$ $mg^{-1}{}_{enzyme}$), forming a fourth group (Figure 6C). Finally, one Glu residue (44) and four Asp residues (53, (A)-64, 98, and 130) are not hydrolyzed at all, constituting the fifth group.

Whereas the overall division of the cleavage sites into five groups was comparable for all initial substrate concentrations, for a few of these cleavage sites a clear effect of initial substrate concentration was observed. For the nine Glu residues for which the enzyme had a high or intermediate rate of selective hydrolysis, a decrease in the rate of selective hydrolysis was observed with increasing substrate concentration (from $1.3 \times 10^{-3}$ $s^{-1}$ $mg^{-1}{}_{enzyme}$ for 0.1% (w/v) WPI to $2.3 \times 10^{-4}$ $s^{-1}$ $mg^{-1}{}_{enzyme}$ for 10% (w/v) WPI (Figure 6A). This was expected because the overall hydrolysis rate determined from the DH versus time curves was decreased (Figure 1B).

*Nonannotated Cleavage Sites.* For 5 of 27 potential cleavage sites, no rate of hydrolysis was determined, because no peptides were annotated starting or ending at these cleavage sites. There are two reasons for this. First, cleavage sites 53-D and 130-D are surrounded by other cleavage sites (51-E and 55-E and 129-D and 131-E, respectively), for which cleavages were observed. The cleavages occurring on 53-D and 130-D

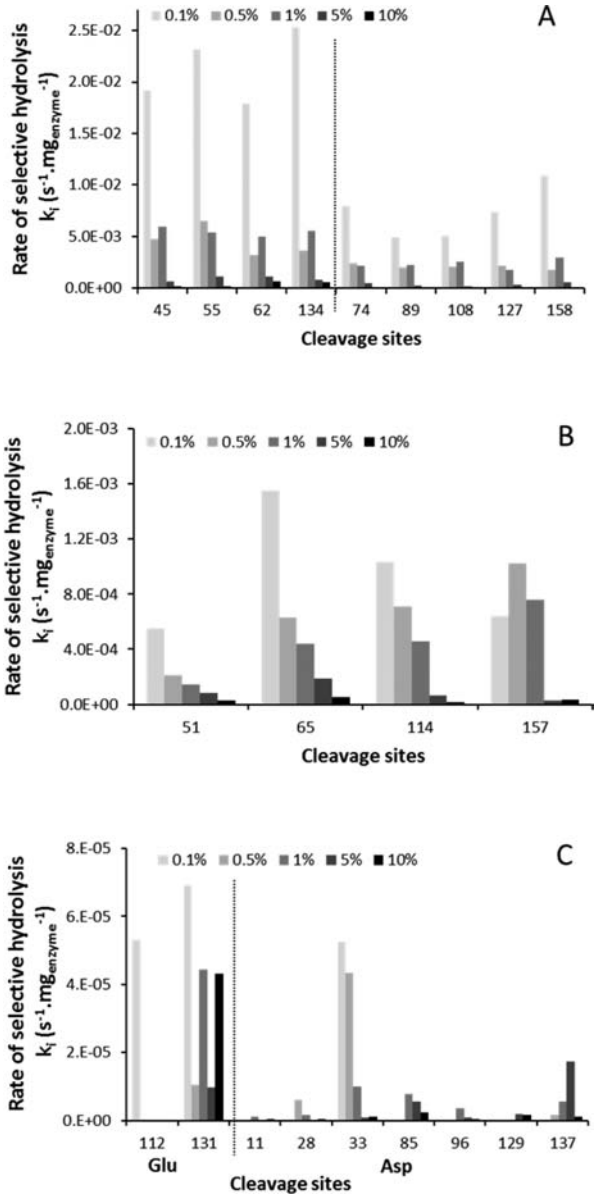

**Figure 6.** Rate of selective hydrolysis $k_i$ of the enzyme toward glutamic acid and aspartic acid residues divided in three groups with (A) Glu with high and intermediate rates of selective hydrolysis, (B) Glu with low rate of selective hydrolysis, and (C) Glu with very low rate of selective hydrolysis and Asp for the different initial protein concentrations (0.1−10% (w/v) WPI).

might lead to the formation of single amino acids or dipeptides. The short peptides and free amino acids are generally not detected during LC-MS analysis. The difficulty of annotating short peptides and free amino acids in RP-HPLC has been mentioned before.[22] This could be solved by analyzing the free amino acids, using a different gradient or a different type of column than reversed phase. Second, for cleavage sites 44-E and 64-E, a glutamic acid on the P1′ position is found: 45-E and 65-E. It has been previously suggested that the presence of a negative charge on position P1′ hinders the hydrolysis by BLP.[11]

*Determination of the Selectivity.* The selectivity was determined for all cleavage sites identified for all protein concentrations (0.1−10% (w/v) WPI). The selectivity is determined as the rate of selective hydrolysis of each cleavage site divided by the rate of selective hydrolysis of all cleavage sites for each substrate concentration (eq 9; Table 2). The selectivity showed a typical standard error (standard deviation/mean × 100) of 15%. Large differences are observed over all cleavage sites for each initial substrate concentration from 17 to 0.001%. The cleavage sites are divided into five groups, based on the groups defined for the rate of selective hydrolysis (Figure 6). The enzyme selectivity toward the first four Glu residues is on average ∼16%. The selectivity toward the second group (five Glu) is ∼6%, and toward the third group (four Glu) the average selectivity is ∼1.4%. The fourth group contains two Glu and seven Asp, for which the enzyme has a selectivity of ∼0.027%. The fifth group contains the cleavage sites for which no hydrolysis was observed (Table 2). Enzyme selectivity has never been studied in this way. There are no studies describing the kinetics of formation of all peptides present in the hydrolysates. Peptide annotation and quantification have been done at a single DH point, for example, for $\beta$-lactoglobulin hydrolyzed by BLP.[16] In that study, cleavage sites 44, 53, and 98 were, for example, observed not to be cleaved by BLP. This corresponds to the same cleavage sites as in the current study. The observation that not all cleavage sites are used was made for $\beta$-casein hydrolyzed by the same enzyme, for which the peptides were annotated at different time points. In that study, 5 (of 19) Glu residues were found not to be hydrolyzed by the enzyme.[23]

*Influence of Substrate Concentration.* The large differences in selectivity toward all cleavage sites are quite similar for all substrate concentrations. Still, two main effects of protein concentration are observed on the selectivity, first in the group with the highest selectivity and second on the group with aspartic acid residues. First, in the group of cleavage sites for which the enzyme has the highest selectivity, the selectivity toward cleavage sites 62 and 134 is 2 times higher at 10% (w/v) WPI than at the other protein concentrations (Figure 7). The selectivity toward cleavage sites 45 and 55, on the other hand, is 2 times lower at 10% (w/v) WPI than at the other concentrations (Figure 7). As shown in Figure 3, especially in the N-terminal part of the sequence, there are amino acids that were not annotated/quantified to the expected concentration. Over the total UV area, at higher DH values only 50−70% of the total (at DH = 0) UV signal is recovered. However, this effect is similar for all concentrations. Therefore, it was concluded that a change in selectivity as a function of original substrate concentration can still be identified as a significant effect. It may be expected that at higher concentrations differences occur as a result of peptide aggregation, or shuffling of disulfide bridges. Aggregation was shown to increase with DH,[24] and disulfide shuffling was shown to occur during hydrolysis at pH 8.[25] However, the difference in selectivity between 45/55 and 62/134 is already apparent from an early point in the hydrolysis and thus cannot be attributed to differences in these effects.

Reasons for the changes in selectivity for these four cleavage sites can be sought in the primary, secondary, tertiary, and quaternary structures of the protein. Different amino acids were found on the neighboring positions of the four cleavage sites for which the largest effects of the substrate concentration were observed (45, 55, 62, and 134). Therefore, it was concluded that there is no clear indication that neighboring amino acids had a specific influence on the enzyme selectivity. In addition, all four cleavage sites are present at the solvent-exposed surface of the protein (Figure 8). Therefore, the cleavage sites would

[a]Typical standard errors (standard deviation/mean × 100) < 15%. The sum of selectivities of all cleavage sites at each substrate concentration is 100%. To allow recalculation of absolute values of rates (eqs 6 and 7), the sum of apparent cleavage rate is indicated for each substrate concentration. [b]Cleavage sites for which the $R^2$ of the first-order fit (eq 7) was <0.8. [c]Peptides were analyzed until a DH of 7%; for certain cleavage sites no corresponding peptides were found, indicating that the selectivity is <0.001% (nd).

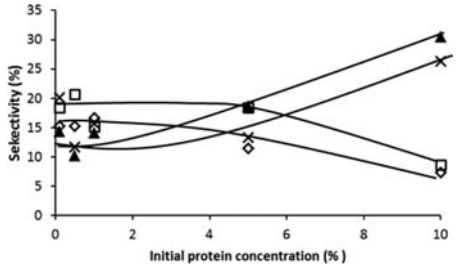

**Figure 7.** Enzyme selectivity toward four cleavage sites, (◇) 45, (□) 55, (▲) 62, and (×) (134), as a function of the initial substrate concentration.

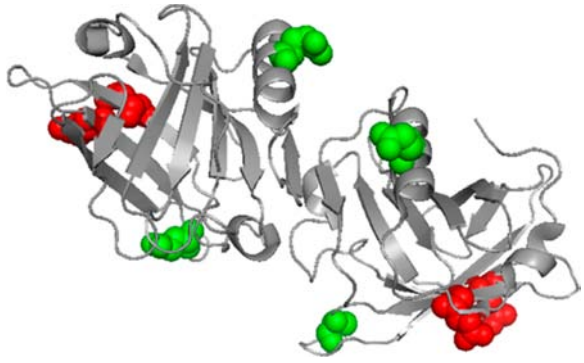

**Figure 8.** Three-dimensional structure of $\beta$-lactoglobulin as dimer (pdb entry 2q39). Cleavage sites 45 and 55 are highlighted in red, and cleavage sites 62 and 134 are highlighted in green.

be expected to be equally accessible for the enzyme. The accessibility may be influenced by the fact that the protein occurs as a dimer at pH 8. Moreover, the fraction of $\beta$-lactoglobulin dimers increases with increasing concentration.[26] This was expected to reduce the accessibility of cleavage sites 62 and 134, because they are in close proximity to the dimer interface (Figure 8). In contrast to expectation, the enzyme has an increased selectivity for these cleavage sites at increased substrate concentration. With respect to secondary structure, it has been described for trypsin that $\alpha$-helices hinder the physical approach of the enzyme,[27] but for BLP such information is not available. However, cleavage sites 45 and 55 are both found on $\beta$-sheets, whereas cleavage sites 62 and 134 are not. This might

dx.doi.org/10.1021/jf503151f | J. Agric. Food Chem. 2014, 62, 10230−10239

be an indication that β-sheets are more difficult for the enzyme to approach. Currently there is no clear argument to explain the significant change in selectivity toward these four cleavages sites as a function of protein concentration.

For other cleavage sites after Glu residues, some influence of the concentration is observed. For instance, cleavage site 51 has a higher selectivity at high initial substrate concentrations (5 and 10% (w/v) WPI) than at low substrate concentrations (0.1−1% (w/v) WPI). Cleavage sites such as 51 have a lower selectivity than cleavage sites 45, 55, 62, and 134. Consequently, their influence on the composition of the hydrolysates is smaller.

Second, the enzyme selectivity toward the cleavage sites after Asp residues is higher at high initial substrate concentrations (>1% (w/v)) than at the low concentrations (0.1−1% (w/v) WPI). The average selectivity toward Asp residues is 0.01% for low concentrations (0.1−1% (w/v) WPI) and 0.06% for high concentrations (5 and 10% (w/v) WPI) (Table 2).

By increasing the substrate concentration at constant enzyme/substrate ratio during enzymatic protein hydrolysis, the overall hydrolysis rate is decreased and a lower DH is reached. For the cleavage sites Glu-62 and Glu-134 and Glu-45 and Glu-55, for which the enzyme has a very high selectivity, a 2 times higher or lower selectivity, respectively, is observed at 10% (w/v) WPI than at the other substrate concentrations. In addition, the enzyme selectivity toward Asp residues is higher at high initial substrate concentrations (≥5% (w/v) WPI) than at low substrate concentrations. This finding shows that changing the substrate concentration influences both the overall hydrolysis rate and the mechanism of hydrolysis.

(1 h in a 90 °C water bath). Other HS−solid phase microextraction (SPME)[20] or purge-and-trap[21] GC methods require the dilution or centrifugation of beverages, which produces a loss of the species through volatilization. More recently, an HS-SPME method has been applied to determine four THMs in soft drinks[22] and beer.[23] In general, these methods require manual sample manipulation with low sensitivity because they are adapted from water methodologies.

The aims of this work were (i) to develop a solventless SHS-GC−mass spectrometric method with enough sensitivity to determine target analytes at nanogram per liter levels in beverages; (ii) to include six emerging iodinated THMs for the first time, in addition to the four common THMs and four VOCs regulated in treated water; and (iii) to discriminate the source of these species through treated water employed for beverage preparation or by contamination through the industrial process (i.e., washing, bottling line, etc.).

## MATERIALS AND METHODS

**Chemicals and Standards.** The 14 species included in this study with their corresponding acronyms are indicated in Table 1. The majority of standards and the internal standard, 1,2-dibromopropane, were supplied from Sigma-Aldrich (Madrid, Spain). Iodinated THM (DCIM, BCIM, DBIM, CDIM, and BDIM) standards were supplied by Cansyn (Toronto, Canada). Methanol, sulfuric acid, and salts were supplied from Merck (Darmstadt, Germany). Stock standard solutions containing 1 g/L of each compound were prepared in methanol and stored in amber glass vials at −20 °C. Working-standard solutions were prepared on a daily basis by dilution at the microgram per liter level in mineral water (untreated water and free of DBPs).

**Static Headspace and Gas Chromatographic Conditions.** The experimental setup for the SHS-GC-MS determination of VOCs and THMs consisted of an SHS autosampler G1888 and an HP 6890N gas chromatograph (Agilent Technologies, Palo Alto, CA, USA) equipped with an HP 5973N mass selective detector. The operating conditions for the HS autosampler were as follows: vial equilibration time, 15 min; oven temperature, 80 °C; vial pressurization time, 30 s; loop fill time, 3 s; valve/loop temperature, 100 °C. Helium (6.0 grade purity, Air Liquid, Seville, Spain) was used both to pressurize vials and to drive the headspace formed to the injection port of the chromatograph via a transfer line at 110 °C. Injection was done in the split mode (split ratio 1:20) for 1 min with an inlet temperature of 250 °C; flow rate of carrier gas (He) was fixed at 1 mL/min. The gas chromatographic separation was achieved on an HP-5MS UI fused silica capillary column (30 m × 0.25 mm × 0.25 μm film thickness) coated with a stationary phase consisting of 5% phenyl−95% methylpolysiloxane supplied by Agilent. Oven temperature was programmed as follows: 40 °C for 5 min, raised to 100 °C at 25 °C/min, held for 2 min, ramped at 30 °C/min to 250 °C, and finally held for 3 min. The MS was operated in the electron impact ionization mode at 70 eV, and ion source and quadrupole temperatures were set at 250 and 150 °C, respectively. Optimization experiments were conducted in total ion chromatography mode between $m/z$ 25 and 400 at 3.5 scans/s. The ions selected for identification and quantification of VOCs and THMs (SIM mode) are listed in Table 1; $m/z$ values for 1,2-dibromopropane (IS) were 42, 121 (base peak), 123.

**Sample Preparation.** The commercial beverages (soft drinks and juices) used in this study were purchased at local markets in Spain (one of the largest producers of fruits and derivatives in Europe). Several brands with different packaging types and different flavors were selected. In the laboratory, samples were stored refrigerated or at room temperature, depending on the manufacturer's instructions, and the seal of each bottle was broken right before its analysis. Freshly squeezed orange juice (blank) was used to optimize the analytical parameters of the method. For the preparation of the blank, fresh oranges were hand-peeled and homogenized with a laboratory squeezer. Food utensils were always washed with mineral water to ensure the prevention of DBP contamination.

**Analytical Procedure.** Beverages were mixed in their own container for 1 min by manual shaking. Ten milliliters of beverage or standard solution containing between 0.03 and 100 μg/L of each target analytes and 5 μg/L of 1,2-dibromopropane (IS) was placed in a 20 mL glass vial containing 4 g of NaCl. For carbonated soft drink analyses, 300 μL of a 6 mol/L NaOH solution was also added to eliminate the carbonic acid present. Then, the vial was immediately sealed and vortexed for 1 min for mixing purposes and placed in the autosampler carousel. Samples were analyzed by SHS-GC-MS, using the operating conditions mentioned above.

## RESULTS AND DISCUSSION

**Evaluation of Chemical Parameters.** First, the SHS variables were studied using 10 mL of freshly squeezed orange juice containing 10 μg/L of each VOC and THM, 5 μg/L of the IS, and 3 g of NaCl in a 20 mL glass vial. The most relevant parameters were oven temperature (60−80 °C) and vial equilibration time (5−20 min), providing the best results at 80 °C and 15 min, respectively. Other instrumental parameters did not present significant changes in the abundance signals for the

compounds, and a pressurization time of 30 s and a venting time of 12 s were selected as the working values.

Salting-out increases the ionic strength of the aqueous solution; this can decrease the solubility of organic species, improving their distribution from the aqueous solution to the headspace. Hence, the addition of NaCl was studied between 0 and 5 g. The analytical signal of the compounds increased with increases in the amounts of salt up to 4 g; therefore, this amount was selected per 10 mL of sample. The effect of the sample pH on the extraction of the 14 species was studied in the 2.5−9.0 range by adjusting the fortified juice with diluted $H_2SO_4$ or NaOH as required. As the peak area ratio of all species remained constant throughout this range, beverage samples were analyzed without pH adjustment. Fruit juices did not present any problem for their analyses by SHS, but carbonated soft drinks can have certain problems due to the presence of $CO_2$. When a soft drink bottle is opened, the pressure is reduced to atmospheric pressure, causing decomposition of the carbonic acid, releasing $CO_2$. This loss of $CO_2$ originates a sweep of the most volatile compounds into the atmosphere. Moreover, the $CO_2$ could be competing with the analytes for the headspace in the vial. To solve this problem, different procedures have been proposed, such as nitrogen bubbling, agitation, or ultrasonication.[24] However, these decarbonation methods can remove the volatile compounds from the matrix, so the best alternative can be the addition of NaOH to eliminate carbonic acid, which does not involve the volatilization of the analytes. With the wide pH range of the proposed method (2.5−9.0) taken into account, the addition of NaOH up to pH 8−9 is possible. For this purpose, the recovery of the 14 species was studied by adding various volumes (0−350 $\mu$L) of a 6 mol/L NaOH solution to 10 mL of a representative carbonated soda. As can be seen in Figure 1 (for nine representative analytes),

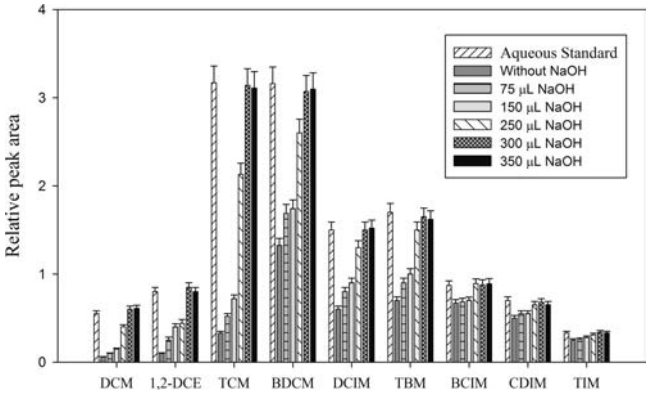

**Figure 1.** Influence of the addition of variable volumes of a 6 mol/L NaOH solution to 10 mL of fortified natural orange juice on the recoveries of nine representative analytes versus an aqueous standard. Concentration: 10 $\mu$g/L of each compound. Error bars are the standard deviation for five measurements.

the relative peak areas were extremely low for the most volatile compounds (DCM, 1,2-DCE, CTC, and TCM) without NaOH, whereas the addition of NaOH solution to the carbonated sample reduced the loss of these compounds. The recovery (versus an aqueous standard solution) for all analytes improved as the volume of NaOH increased to 300 $\mu$L (pH ∼8.4). This improvement was more noticeable for the most volatile analytes, which underwent an increase of ∼90% as compared to the aqueous standard. For 1,2-DBE, BDCM, DBCM, DCIM, and TBM, recoveries increased ∼40−50%, whereas for the majority of iodinated THMs (BCIM, CDIM, DBIM, BDIM, and TIM), this increase was only ∼10−20%. The final volume selected was 300 $\mu$L of a 6 mol/L NaOH solution added to 10 mL of carbonated soft drink because it provided a sample pH of ∼8.4 (the prevalent species is $HCO_3^-$; $pK_a$ = 6.1).

Finally, the efficiency percentage of the whole process for the 14 compounds in a fresh orange juice (blank) was calculated in quintuplicate by a second SHS extraction of the remaining liquid phase to check the absence of any compound. For this purpose, 10 mL of the blank was fortified with 10 $\mu$g/L of each compound and salt according to the procedure. The average yield of the whole analytical process was ≥95% for all analytes, showing that the method is adequate for the determination of these species.

**Sensitivity and Validation of the Method.** Linear range, analyte detectability, and precision of the proposed method were studied under optimal experimental conditions (see Table 1). Calibration curves were constructed by using fresh orange juice fortified with 0.03−100 $\mu$g/L of each compound and processed as described under Analytical Procedure. The equations for the standard curves were obtained by plotting the analyte to internal standard peak area ratios against the amount of the analytes. Regression coefficients were >0.995 in all cases. Limits of detection (LODs) were determined as the analyte concentration that provides a chromatographic peak equal to 3 times the regression standard deviation, $S_{y/x}$, divided by the slope of each calibration graph. The lower limit of the linear range corresponds to the limit of quantification, which is 3.3 × LOD.[25] The precision was calculated by measuring 11 fresh orange juices on the same day and different days. The results obtained were satisfactory, with average RSD values ranging from 5.0 ± 0.2 to 5.9 ± 0.3% for intra- and interdays, respectively, which indicates that the method is absolutely repeatable and reproducible.

In the bibliography, different solventless techniques have been employed for the determination of several VOCs and THMs in beverages and foods. All of these methodologies have been proposed only for the four common THMs and do not reach the sensitivity of the proposed method.[4,17−23] In addition, some of these methodologies involve the manipulation of the beverages by dilution[20]/centrifugation[21]/heating in water baths,[4] etc., with the consequent loss of volatile compounds. More recently, the four THMs have been determined in soft drinks[21] and beers,[22] but the method is ca. 10 times less sensitive than the present alternative.

To validate the proposed method, a recovery study was conducted by analyzing several representative soft drinks and fruit juices fortified with 5 and 20 $\mu$g/L of each compound ($n$ = 5). The analytical responses (taking into account the genuine concentration of the analytes) from all samples were compared to similar standard additions to mineral water. Good recoveries (93−95% for apple, 94−96% for pineapple, 92−96% for orange, and 90−92% for peach juices; 94−96% for tonic; and 95−97% for soda) were obtained for all compounds.

**Analysis of Beverage Samples.** VOCs and THMs can occur in beverages through multiple pathways, namely, (i) inclusion of drinking water as an ingredient in the production of the beverages; (ii) accumulation and sorption from retained water in beverage packaging and wrapping that had been disinfected/washed with chlorinated sanitizers; (iii) contamination by contact with cleaners/disinfectants used in beverage processing equipment, rinses with water in beverage processing, storage, and/or marketing; and (iv) formation during beverage preparation due to reactions between residual chlorine and

precursors present in food, for example, carbohydrates, lipids, and proteins. The samples selected for analysis, soft drinks and fruit juices, are products that contain water as an ingredient and that are frequently consumed every day.

The proposed SHS-GC-MS method was applied to determine 4 VOCs and 10 THMs in 100 types of samples: 40 soft drinks (teas, isotonics, fruit beverages, tonics, and sodas) and 60 fruit juices (natural juices 100%, reconstituted juices, and nectars). All samples gave positive results containing up to five THMs including DCIM, in different distributions and levels; none of the four VOCs studied were present in these beverages. Tables 2 and 3 list the concentrations of the THMs found at detectable concentrations in soft drinks (ca. 90% water) and fruit juices (up to 70% water), respectively. The analytes not shown were either not contained or present at levels below their LODs. The species TCM, BDCM, and DBCM were present in practically all samples and at higher concentrations, whereas TBM and DCIM were found in lower proportions. This could be explained because the water used in food applications is frequently disinfected with chlorine due to its economic impact and simple use.

Table 2 lists the levels of each THM found in soft drinks as well as the total concentration of trihalomethanes (TTHMs). There are two levels of TTHM concentrations: soft drinks A for concentrations <15 μg/L ($n = 15$; average value of 5.5 ± 2.8 μg/L) and soft drinks B containing ≥15 μg/L ($n = 25$; average value of 28.8 ± 9.1 μg/L). From Table 2 it can be concluded that (i) there were no significant differences in either TTHM concentrations in each kind of soft drink (tea, tonic, soda, etc.) or in the species of THMs; (ii) there were no differences between flavors (lemon, orange, cola, etc.) in the same kind of soft drinks; and (iii) the presence of THMs in these beverages should be ascribed to the type of treated water employed in their preparation. One factor that influenced the TTHM concentrations was the factory that bottled the samples. Each factory has a different source of water, and the levels of

[a] ± standard deviation, $n = 5$. [b] Total THMs. [c] Not detected. [d] <LOQ.

THMs depend on the disinfection process. However, in this case, no differences were found between TTHM concentrations, presumably because the samples manufactured came from only four different factories, so there was not great variability. By way of example, tea 2 and soda 7 contain 30 and 1.4 μg/L, respectively, and both were manufactured in the same factory. Thus, the differences between the two groups of soft drinks (A and B) could be associated with the type of treated water used in their manufacturing at each moment. No sample exceeded the limits established for the concentration of TTHMs, so the soft drinks were prepared with water from the distribution network or treated water prepared in the same factory following EU normatives.[10] This has been corroborated by analyzing five soft drinks elaborated with mineral water (free of DBPs), which was negative for the species studied or contained chloroform only at very low levels (<1 μg/L). Figure 2 shows the chromatogram for

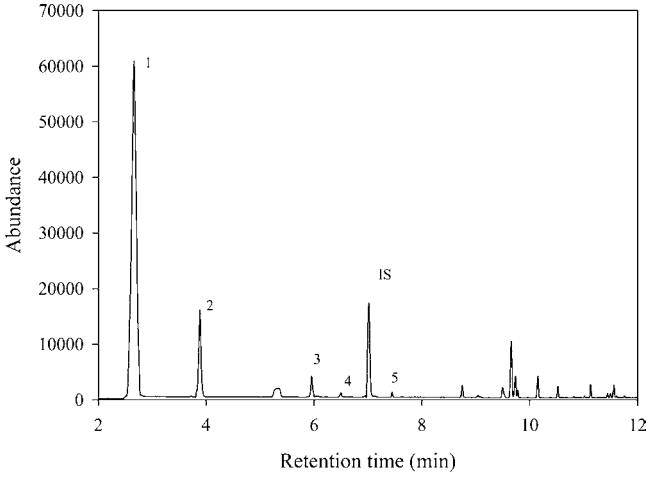

**Figure 2.** GC-MS chromatogram in SIM mode obtained in the analysis of soda 18. Peaks: (1) TCM; (2) BDCM; (3) DBCM; (4) DCIM; (5) TBM; (IS) internal standard. For compound abbreviations, see Table 1.

soda 18, which shows the peaks corresponding to the five species of THMs detected. After a retention time of 9 min, some peaks appeared in the chromatogram that correspond to flavors or other volatile compounds present in the beverage; these compounds did not interfere with the target analytes, so there was no matrix interference.

Table 3 shows the results obtained in the analysis of 60 fruit juices and nectars. In this case, only the four common THMs were found in these samples. DCIM was not detected because its level is associated with the amount of treated water in the beverage, and fruit juices contain a lower volume of water than soft drinks. The average TTHM concentrations in 100% natural juices were always <1 μg/L, and the predominant species was chloroform (TCM) followed by BDCM. As these juices do not contain treated water, the presence of these species at such a low level can be ascribed to contamination from the use of chlorinated sanitizers in the industry. In contrast, reconstituted juices can contain up to four THMs, and there are two distinctive groups as in soft drinks; reconstituted juices A with TTHM concentrations <1 μg/L and reconstituted juices B containing >2 μg/L. The average value for groups A and B were 0.5 ± 0.2 ($n$ = 10) and 6.2 ± 3.6 ($n$ = 11) μg/L, respectively. Moreover, the kind of fruit was not a relevant parameter because the same fruit was present in both groups. On the other hand, the average values of reconstituted juices A were similar to those of natural juice, but there was a significant difference because brominated species were present in reconstituted juices due only to the addition of treated water. With regard to nectar (ca. 50−75% of water), the average TTHM concentration was higher than that obtained in reconstituted juices, depending on the higher water volume.[26] Hence, there were noticeable variations in concentrations of TTHMs for natural juices, 100%, reconstituted juices, nectars, and soft drinks with average values of 0.47, 3.5, 8.3, and 20 μg/L, respectively, according to the volume of treated water included.

Figure 3 shows the distribution of the total trihalomethane concentrations as box plots in the beverages studied. The

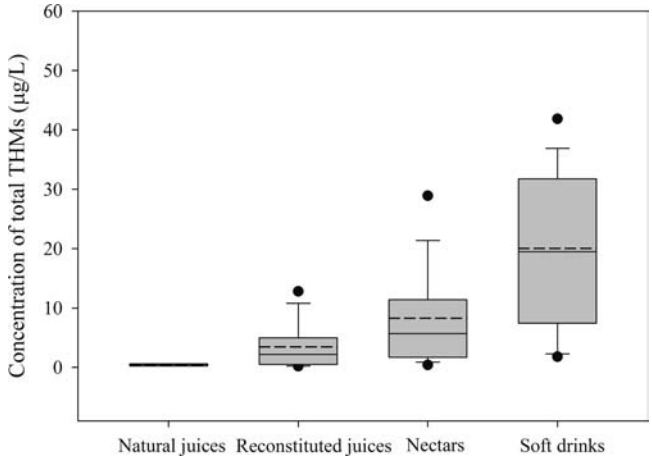

**Figure 3.** Representation of the total trihalomethane concentrations distributed as box plots in the beverages. The box plots indicate the mean concentration (dashed line) and the 10th, 25th, 50th, 75th, and 90th percentiles (points denote the 5th and 95th percentiles).

bottom and top of the box correspond to the 25th and 75th percentiles, whereas the band (median) inside the box is related to the 50th. The ends of the whiskers represent the lowest and highest observations, and the spacing between the different parts of the box give an indication of the degree of spread and skewedness in the data. There are again two different groups, nectars A with TTHM concentrations <6 μg/L ($n$ = 17; average value of 2.6 ± 1.9 μg/L) and nectars B with concentrations >6 μg/L ($n$ = 15; average value of 14.7 ± 8.7 μg/L). As occurred in the previous case, these variations cannot be attributed to the kind of fruit but rather to the difference between the qualities of the treated water used in their production. Moreover, this deduction was consolidated by comparison to the same product (nectar) manufactured in different bottling factories ($n$ = 12) shown in Table 3 following a word code. Thus, the average TTHM concentrations in nectars produced by A (nectars 1, 5, 28, and 30) or L (nectars 10, 11, 21, 23, and 24) bottling factories were 6.1 or 22.2 μg/L, respectively. Thus, in our study, the juices from factory L always provided the highest concentrations of THMs. These variations in the concentration of THMs in the same product can be explained on the basis of the type of treated water employed at each moment. Figure 4 shows the chromatograms obtained from the analysis of natural juice 7 (A), reconstituted juice 2 (B), and nectar 21 (C). Finally, for comparison purposes, several reconstituted juices of various flavors were analyzed from different European countries. As can be seen in Table 4, no sample presented TTHM concentrations above the levels allowed by EPA or EU for drinking water (80 or 100 μg/L).[9,10] Once again, two differentiated groups existed: one

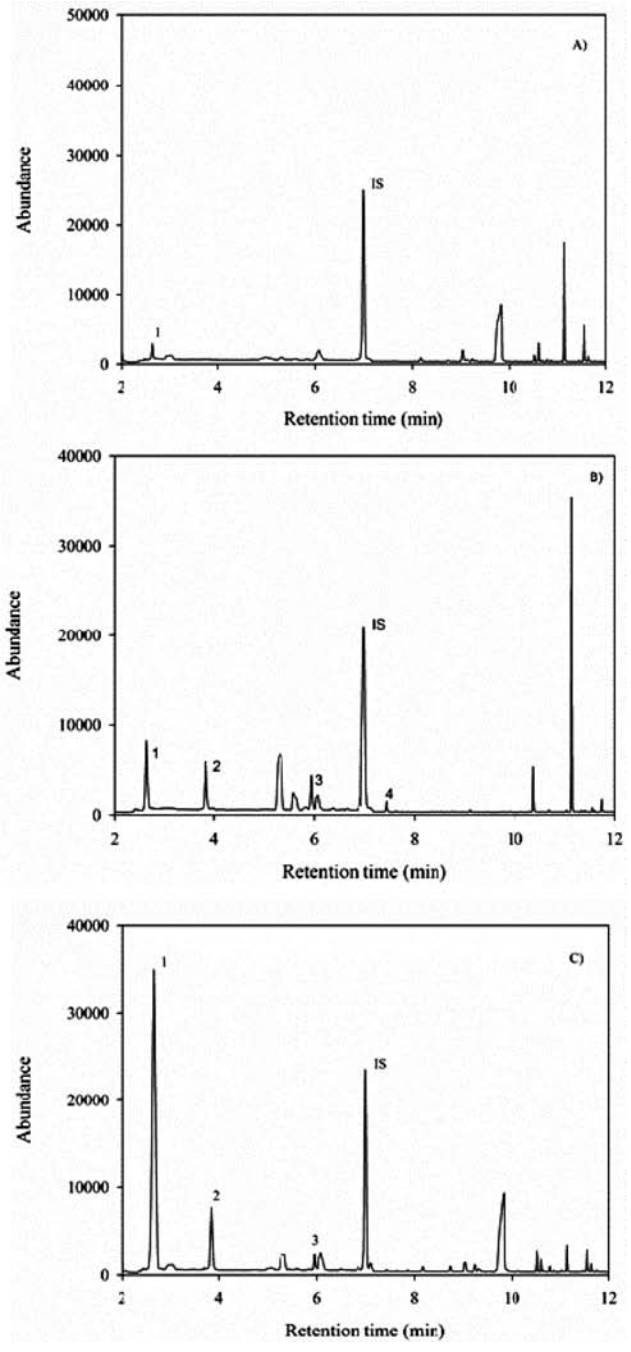

**Figure 4.** GC-MS chromatograms in SIM mode obtained in the analysis of natural juice 7 (A), reconstituted juice 2 (B), and nectar 21 (C) samples. Peaks: (1) TCM; (2) BDCM; (3) DBCM; (4) TBM; (IS) internal standard. For compound abbreviations, see Table 1.

for TTHM concentrations of 0.4 ± 0.2 μg/L ($n$ = 8) and the other for 9.9 ± 8.2 μg/L ($n$ = 6), similar to Spanish juices.

This study has revealed that chloroform can appear at concentrations <1 μg/L in beverages without treated water as a consequence of contamination due to the chlorinated sanitizers usually employed in the food industry. The treated water included as an ingredient is the main source of the presence of THMs, and the concentration and speciation of these compounds depend on the volume of treated water as well as the water-quality employed. Moreover, brominated THMs and one iodinated one (DCIM) appeared in these samples, which can be used as an indicator of the presence of treated water.

[a]Not detected. [b]<LOQ. [c]Total THMs.

dx.doi.org/10.1021/jf503431q | J. Agric. Food Chem. 2014, 62, 10240−10247

The proposed method could be adopted by public laboratories to perform routine controls of VOCs and THMs in beverages.

On the other hand, if it is estimated that a person can consume 2 L per day of drinking water (this includes drinking water consumed in the form of juices and other beverages containing tap water)[27] and taking into account that the most contaminated sample (soda 18 in Table 2) contained 52 $\mu$g/L of total THMs, a person could ingest >100 $\mu$g/L of THMs each day (MCL 80−100 $\mu$g/L).[9,10] This problem is aggravated because the default assumption of 2 L per day is not always appropriate or conservative with respect to populations, climates, and physical activity; thus, variations between 3.8 and 4.8 L have been referenced.[28] On the other hand, although chlorinated THMs were the common THMs present in beverages, some samples contained high concentrations of brominated compounds (reconstituted juice 5 and nectar 5 in Table 3) and one iodinated compound (sodas 18 and 20 in Table 2), these compounds being more cytotoxic and genotoxic when compared to their chlorinated analogues. In our opinion, the contribution of human exposure through beverages such as fruit juices and soft drinks per day is significant, taking into account that there are other sources of exposure through foods during the day. Thus, it is deemed acceptable to include these compounds as emergent pollutants in beverages because they have been already established as such for drinking water in several countries.

on GCE modified with AFc/CB/PVB has not been reported so far.

Additionally, to differentiate free and total sulfite, different sample pretreatment procedures are used. Kim[7] reported that free and total sulfite in three dehydrated foods were analyzed by extraction of the sulfite at pH 2.0 and 8.9, respectively, and ion chromatography (IC) with electrochemical detection was used. Warner[23] found that the rate of dissociation of the reversibly bound sulfite in wine and other foods was relatively slow at pH 3.0 but very rapid at pH 7.0. This difference in kinetics was exploited to develop a procedure to detect free and reversibly bound sulfite in food. Koch[24] investigated the influence of the pH on the efficiency of bound sulfite release. Hydroxymethylsulfonate (HMS) was chosen as a model substance for bound sulfite and was spiked in blank wine. It was found that at pH 6.0 only <20% of bound sulfite was recovered, while in alkaline solution (pH 11.0) an average recovery of about 90% was yielded. From the above publications, we can see that it still is a controversial issue as to how to extract sulfite from foods, and some of the current extraction methods might not be suitable for electrochemical analysis because they detect sulfite in the form of sulfate[24] or HMS,[23] which do not respond on the electrode via the above proposed eletrocatalytic oxidation process. Therefore, the second aim of this work was to examine appropriate extraction pH to differentiate free and total sulfite, matching the following measurement by the above-mentioned electrochemical method using an AFc/CB/PVB modified electrode, and to apply this method in muscle foods.

## 2. MATERIALS AND METHODS

**Chemicals and Reagents.** Chemical standards including sodium sulfite (Acros, Belgium), sodium metabisulfite (Aladdin, China), HMS (Aladdin, China), and AFc (J&K Scientific Ltd., China) were used as purchased without further purification. Reagents including pyrophosphate, tripolyphosphate, sodium chloride, citric acid, nitrate, phosphate, sulfuric acid, hydrochloric acid, sodium hydroxide, anhydrous ethanol, propyl alcohol, and PVB, poly(vinylidene fluoride) (PVDF) were of analytical grade and obtained from Aladdin, China. Nafion perfluorinated ion-exchange resin (5 wt %) was purchased from Sigma-Aldrich Chemical Co. (U.S.A.). Carbon black (Super-P-Li) was obtained from Timcal, Belgium. The supporting electrolyte used for all experiments was a 0.2 mol $L^{-1}$ sodium chloride solution. The working standard solutions of sodium sulfite and sodium metabisulfite were prepared daily in supporting electrolyte.

**Apparatus.** All cyclic voltammetric experiments were performed on a computer-controlled LK2005A Electrochemistry Workstation (Lanlike, China) with a conventional three-electrode configuration. A platinum electrode served as the counter electrode, and the saturated calomel electrode (SCE) was used as a reference in all electrochemical experiments. The working electrode (3 mm diameter) was GCE or GCE modified with appropriate chemicals including PVB, PVB/CB, PVB/AFc, PVB/CB/AFc, AFc/Nafion, and CB/AFc/Nafion. The working electrode for cyclic voltammogram scanning was operated within a potential range of 0−0.8 V (vs SCE) at scan rate of 50 mV $s^{-1}$. All tests were conducted at room temperature. The pH was measured using a Sartorius pH meter, model PB-10, employing a combined glass electrode with a SCE as external reference electrode.

**Preparation of Working Electrodes.** The GCE was polished with metallographic sandpaper polishing (5 $\mu$m) and then with 0.3 $\mu$m alumina powders ($\alpha$-$Al_2O_3$) on a wet polishing cloth to a mirror finish. Afterward, the electrode was successively cleaned using 1:1 (v/v) nitrate solution and anhydrous ethanol and rinsed with distilled water (4−5 min) with the aid of ultrasonic leaching. The freshly polished GCE was pretreated by cycling the potential several times between −0.2 and 1.2 V vs SCE, at a scan rate of 50 mV $s^{-1}$ in 0.5 mol $L^{-1}$ sulfuric acid solution until a steady signal was obtained (about 10−13 cycles). To prepare the modified electrode, a well-dispersed suspension was first prepared by perfect hand mixing of 5.0 mg of AFc and 100.0 mg of PVB; for AFc to be well dissolved, 5 mL of anhydrous ethanol was added. Subsequently, 125.0 mg of CB was added to the mixture, which was then diluted to 10 mL with anhydrous ethanol. For modifying GCE, 3.0 $\mu$L of the suspension was carefully dropped on the clean surface of the GCE using a micropipette, and it was left to dry at room temperature. Other modified electrodes (GCE/PVB, GCE/CB/PVB, GCE/CB/AFc, and GCE/CB/AFc/PVB) were prepared according the same procedure described above by dropping their corresponding chemical suspensions on the surface of GCE. The GCE/AFc/Nafion and GCE/CB/AFc/Nafion electrodes were made using Nafion instead of PVB.

**Sample Preparation.** Raw iced shrimps were purchased from the local markets and delivered to the lab in half an hour. Once delivered to the lab, the shell of the shrimps was peeled and homogenized using a JYL-350 food processor (Joyoung, China) and kept in a refrigerator for further use. Prior to analysis, muscle food was weighed accurately (10 g) into a 50 mL centrifuge tube, and 35 mL of propyl alcohol (2%, v/v) solution was added to stabilize sulfite inhibiting oxidation to their sulfate constituents.[25] Afterward, the sample was adjusted to the appropriate pH values using 0.5 mol $L^{-1}$ hydrochloric acid or 0.5 mol $L^{-1}$ sodium hydroxide (pH 8.4 for the extraction of free sulfite, pH 11.0 for the total sulfite) and then extracted with the aid of ultrasonic leaching for 10 min and centrifuged (3K15 model, Sigma, Gemany) at 8000 g for 15 min at 4 °C. The suspension was vacuumed filtered and transferred to a volumetric flask and then diluted to 50 mL with 2% (v/v) propyl alcohol for the following electrochemical measurement. The quantification of sulfite was carried out by using an external standard calibration curve based on the cyclic voltammograms.

For comparison study, an IC method was used for the determination of splitting samples, and the detailed description of sample preparation procedure has already been reported elsewhere.[8] In the current work, for the extraction of total sulfite the same procedure was followed, and for the extraction of free sulfite pH 8.4 was used.

## 3. RESULTS AND DISCUSSION

**Electrochemical Behavior of Sulfite at GCE/CB/AFc/PVB.** Figure 1A shows the typical cyclic voltammograms of 2.0 mmol $L^{-1}$ sulfite (0.2 mol $L^{-1}$ sodium chloride as supporting solution, pH 8.0 without adjustment) at bare GCE (a), GCE/PVB (b), GCE/PVB/AFc (c), GCE/PVB/CB (d), and GCE/CB/AFc/PVB (e). As seen in Figure 1A-a, the use of a bare GCE yielded a cyclic voltammogram with one anodic peak at 0.601 V, showing a small current value around 6.0 $\mu$A. When PVB was coated on the surface of GCE (Figure 1A-b), it was observed that the anodic peak disappeared, indicating that the electron transfer may be cut off by PVB film due its insulating property. When CB was coated within PVB membrane (Figure 1A-d), it was observed that the peak showed up at around 0.60 V with a small current value of about 7.0 $\mu$A, a little bit higher than that at bare electrode (Figure 1A-a), indicating that CB can effectively improve the electron-transfer kinetics, which can be attributed to its excellent electric conductivity. To improve this result in terms of sensitivity and selectivity, a modified GCE with PVB/CB/AFc was evaluated (Figure 1A-e). As seen in Figure 1A-e, a much improved and sharp electrochemical peak of sulfite was observed at the GCE/CB/AFc/PVB occurring at a much lower potential of about 0.50 V with much higher current of 14.5 $\mu$A, which shifted negatively by about 0.1 V. At a given level of AFc concentration, the anodic peak current increased with the increase of the sulfite concentration, and when the concentration of AFc changed, the concentration range of sulfite changed accordingly, indicating a typical electrochemical behavior for electrocatalytic oxidation by a mediator. Furthermore, it was observed that the

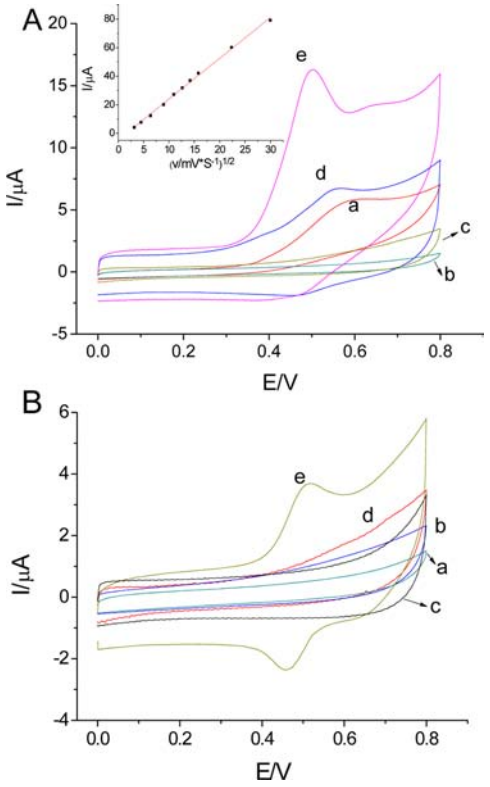

**Figure 1.** Cyclic voltammograms of 2.0 mmol $L^{-1}$ sulfite (A) (0.2 mol $L^{-1}$ NaCl as supporting solution) and 0.2 mol $L^{-1}$ NaCl (B) at bare GCE (a), GCE/PVB (b), GCE/AFc/PVB (c), GCE/CB/PVB (d), and GCE/CB/AFc/PVB (e). Inset of (A): the linear relationship between the oxidation peak currents and the square root of the scan rate. All tests were conducted at a scan rate of 50 mV $s^{-1}$.

sulfite oxidation peak current was proportional to the square root of the scan rate in the range of 10−900 mV $s^{-1}$ (Figure 1A, inset), which suggested that the reaction system of sulfite was controlled by diffusion. Similar results were found at bare electrode with the presence of AFc in sulfite aqueous solution.[15] However, the electrocatalysis of AFc could not take effect with the absence of CB at the GCE/PVB/AFc (Figure 1A-c), which further proved that CB improved the electron-transfer kinetics.

Figure 1B shows the typical cyclic voltammograms of supporting solution of 0.2 mol $L^{-1}$ sodium chloride (pH 8.0) at the corresponding electrodes the same as used in Figure 1A. As seen in Figure 1B, no peak showed up when using bare GCE, GCE/PVB, GCE/PVB/AFc, and GCE/PVB/CB. When GCE/CB/AFc/PVB (Figure 1B-e) was used, a quasi-reversible redox peak appeared at the potential of 0.511 V (anodic) and 0.447 V (cathodic) with $\Delta E_p \sim 64$ mV and $I_{pa}/I_{pc} \sim 1$, which was attributed to the AFc itself, indicating the electrode itself responded in the sodium chloride supporting solution. Fortunately, the peak current was much lower compared to that in sulfite solution, indicating that the interface caused by AFc was acceptable.

**Optimization Studies for Modification of GCE.** As a solid powder mediator, AFc is difficult to be modified on the smooth surface of GCE as to be mounted in a tube toward fabrication of a carbon paste electrode. In this work, several polymer films such as Nafion, PVDF, and PVB were tried to immobilize AFc onto the surface of the GCE. Nafion, as a sulfonated tetrafluoroethylene based fluoropolymer-copolymer, is widely used in the chemical modified electrodes because of its excellent film-forming, dissolving dispersing ability, stability, and ion-exchange properties.[26] The responses of both 2.0 mmol $L^{-1}$ sulfite and 0.2 mol $L^{-1}$ sodium chloride solution at GCE/CB/AFc/Nafion and GCE/AFc/Nafion were investigated. A pair of reversible redox peaks was observed in aqueous 0.2 mol $L^{-1}$ sodium chloride solution at GCE/CB/AFc/Nafion at potentials of 0.420 V (anodic) and 0.370 V (cathodic) with $\Delta E_p \sim 15$ mV and $I_{pa}/I_{pc} \sim 1$, which was apparently the redox peak of AFc. Another pair of almost equally high redox peaks at nearly the same potential was observed in aqueous 0.2 mmol $L^{-1}$ sulfite solution using the same electrode, which was also thought to be the redox peaks of AFc itself, showing that the anodic peak generated by the AFc catalytic oxidation of sulfite was absent. The same phenomena were observed at GCE/AFc/Nafion. This could be explained by the fact that the surface of GCE/CB/AFc/Nafion was electronegative charged and accordingly electrostatic repulsion of $SO_3^{2-}$ was generated, which made it hard for sulfite to approach the surface of the electrode. Also, when PVDF was used, film coating was difficult to be formed on the surface of GCE. As for PVB, it worked well in terms of stability and film-forming performance; moreover, no electrostatic repulsion of $SO_3^{2-}$ was observed, so PVB was chosen as the membrane matrix of the modified electrode.

The effects of the content of CB in the range of 3−60 $\mu$g on the detection of the aqueous 2.0 mmol $L^{-1}$ sulfite at GCE/CB/AFc/PVB were studied and are shown in Figure 2A. As seen, the sulfite oxidation peak increased with the increase of the content of CB from 3 to 35 $\mu$g. For content higher than 35 $\mu$g, the anodic peak current did not change much anymore, probably due to a saturation of the conductive area at the surface of the electrode. It was thought that CB in the

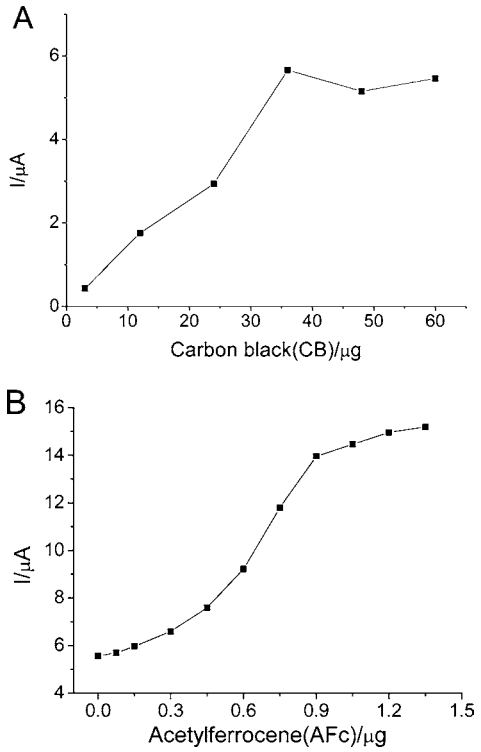

**Figure 2.** Effects of the content of CB (A) and AFc (B) on the current generated by the oxidation of 2.0 mmol $L^{-1}$ sulfite at GCE/CB/AFc/PVB.

dx.doi.org/10.1021/jf503339v | J. Agric. Food Chem. 2014, 62, 10248−10253

membrane structure of modified electrodes can affect electron transfer in the process of electrode reaction. Moreover, CB might create plenty of electroactive sites for analytes by increasing the effective area of modified electrode surface. In this way, 35 $\mu$g of CB was selected when modifying the CGE.

Figure 2B shows the effects of the content of AFc in the range of 0−1.3 $\mu$g on the current generated by the oxidation of 2.0 mmol $L^{-1}$ sulfite in 0.2 mol $L^{-1}$ sodium chloride solution at GCE/CB/AFc/PVB. As seen, the response of sulfite increased with increase of AFc; when the content was higher than 0.9 $\mu$g, the response current of sulfite became almost constant, suggesting that the sulfite response at a given concentration could not keep increasing by the sustained increase of the amount of catalyst. Therefore, AFc content at about 0.9 $\mu$g was chosen as optimal for the determination of sulfite.

**Electrochemical Responses of Sulfites under Different pH Conditions.** The proposed electrochemical method measures the current generated by direct oxidation of sulfite at electrodes. Moreover, the relative concentration of oxosulfur species is determined by the pH of the sample solution. At basic pH, $SO_3^{2-}$ is the predominant sulfur oxoanion, and at acidic pH, $HSO_3^-$ and $SO_3^{2-}$ exist in equilibrium.[7,27] It is necessary to optimize the extraction pH for the differentiation purpose of free and total sulfite as well as for the optimization of electrochemical signal of $SO_3^{2-}$. In this work, the electrochemical responses of sodium metabisulfite and HMS in aqueous solutions under different pH values were investigated. For comparison study, sodium sulfite was used as a contrast (Figure 3). Sodium metabisulfite and HMS were chosen to be studied because the former one is the most commonly used source of sulfur dioxide for seafood applications,[28,29] and the latter one can be regarded as a model substance for bound sulfite and can resolve into bisulfite and formaldehyde at basic conditions.[24] As shown in Figure 3A, no significant sulfite current was detected when pH < 6.0 in 2.0 mmol $L^{-1}$ sodium metabisulfite solution, possibly due to the absence of $SO_3^{2-}$, while $HSO_3^-$ was the predominant ion. With the increase of pH from 6.0 to 8.4, the sulfite oxidation peak response increased dramatically. When pH was higher than 8.4, the response approached constant. This phenomenon could be explained by the fact that the concentration of $SO_3^{2-}$ increased with the increase of pH in aqueous sodium metabisulfite. When pH > 8.4, the concentration of $SO_3^{2-}$ no longer increased. When it comes to sodium sulfite, the current response has a similar change trend as sodium metabisulfite with the change of pH (Figure 3C). As for HMS shown in Figure 3B, no significant peak current was detected at pH < 11.0, and a much improved and significant sulfite oxidation peak current response at the pH > 11.0 was detected. When pH > 11.0, the response leveled out, indicating that HMS no longer released sulfite at pH > 11.0. However, even at pH > 11.0, the response of HMS was about 60−70% of those signals of the same molar concentration of both sodium sulfite and sodium metabisulfite, probably because the HMS may present partly as irreversible bound form under this condition. As for the potential, it was hardly affected by the pH and was in the range of 0.45−0.5 V throughout the whole studied pH ranges for both HMS and sodium metabisulfite. Figure 3A−C may also indicate that pH above 11.0 is the optimum pH for the extraction of total sulfite, while pH around 8.4 is suitable to extract free sulfite, which well matches the electrochemical detection.

**Calibration Curve, Limit of Detection, and Repeatability of GCE/CB/AFc/PVB.** The optimized cyclic voltammetric (CV) experimental parameters were employed to acquire the analytical curve for sulfite. Cyclic voltammograms obtained after successive additions of the sulfite standard solution at GCE/CB/AFc/PVB are shown in Figure 4 with the concentration ranging from 0.03 to 4.0 mmol $L^{-1}$ in 0.2 mol $L^{-1}$ sodium chloride solution (pH 8.4). The inset in this figure depicted the analytical curve obtained for sulfite with the corresponding regression equation $I_{ap}$ ($\mu$A) = 2.899 + 6.935 × $10^{-3}$ C $SO_3^{2-}$ (mol $L^{-1}$) and correlation coefficient ($R^2$) 0.9994. The limit of detection (LOD), based on a signal-to-noise ratio of three (S/N = 3), was found to be 15 $\mu$M (calculated as $SO_2$), which is comparable to the previous reports using AFc modified carbon paste electrode to detect sulfite,[30] and was in the approximate order of magnitude compared with other electrochemical sensors modified with sensing material such as copper-salen[31] and iron-hexacyanoferrate.[32]

The intraday repeatability of the peak current was determined by successive measurements ($n$ = 7) of a 2.0 mmol $L^{-1}$ sulfite solution, and the relative standard deviation

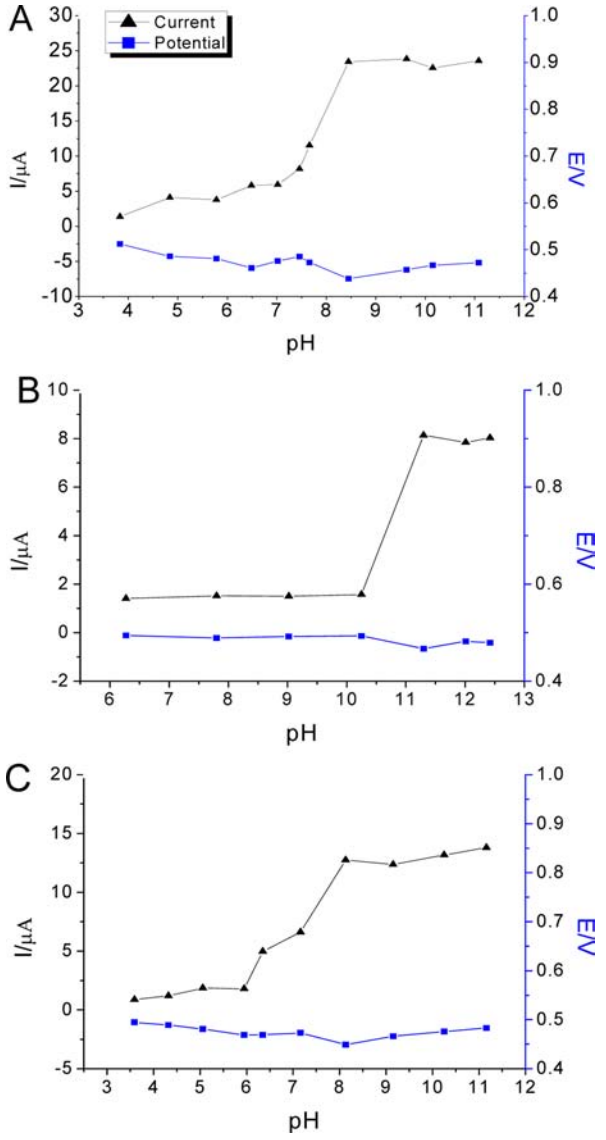

**Figure 3.** Electrochemical responses of 2.0 mmol $L^{-1}$ sodium sulfite (A), sodium metabisulfite (B), and HMS (C) at GCE/CB/AFc/PVB under different pH conditions.

dx.doi.org/10.1021/jf503339v | J. Agric. Food Chem. 2014, 62, 10248−10253

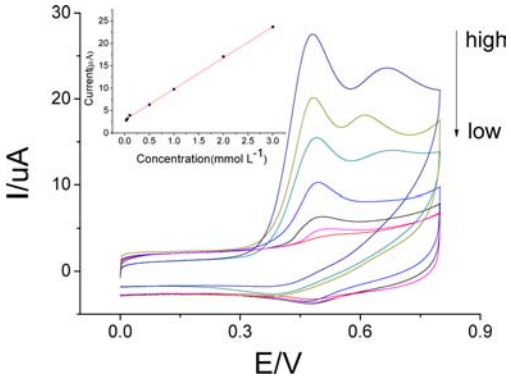

**Figure 4.** Cyclic voltammograms of sulfite concentration ranging from 0.03 to 4.0 mmol $L^{-1}$ at GCE/CB/AFc/PVB in 0.2 mol $L^{-1}$ NaCl (pH 8.4) as electrolyte with a scan rate of 50 mV $s^{-1}$; the inset is the calibration curve constructed by plotting current response vs sulfite concentration.

(RSD) of 2.4% was obtained. After a total of 15 successive measurements, compared with the first run, the peak current decreased around 5.0%, suggesting it is better to reprepare the electrode. In addition, five GCE/CB/AFc/PVB electrodes made in three successive days exhibited very stable responses (RSD = 7.2%, $n$ = 5) in the same 2.0 mmol $L^{-1}$ sulfite solution, showing thus the good repeatability of the electrode.

**Interference Study.** The suitability of the developed electrochemical sensor mainly depends on the influence of interfering species presented in real samples along with sulfite.[33] In order to apply the developed sensor for real sample analysis, the influence of interferences presented in seafood samples was studied by spiking these species in their proper forms in the muscle food matrices. No interferences could be found when including up to 100-fold of $Na^+$, $K^+$, $SO_4^{2-}$, and $Cl^-$, and 25-fold of pyrophosphate, tripolyphosphate, citric acid, nitrate, and phosphate in the standard solution of 2.0 mmol $L^{-1}$ sulfite. The largest tolerance yielded an error of less than ±5% of the analytical signal of sulfite.

**Sample Analysis and Comparison with IC Method.** Homogenized raw shrimp muscle foods spiked with sulfite at three levels (10, 30, and 100 mg $kg^{-1}$, calculated as $SO_2$) were used to evaluate the precision and recovery of the proposed method, at the same time, compared with a modified IC method using the splitting samples. Free or total sulfite was selectively extracted from matrix using pH 8.4 for extracting free sulfite and pH 11.0 for total sulfite as described above, and the results are summarized in Table 1. As shown, recovery values of 90.8, 88.6, and 88.1% were obtained at three fortified levels of 10, 30, and 100 mg $kg^{-1}$, respectively, with corresponding RSD of 2.2, 6.4, and 2.8% using the proposed method. When IC method was used, recovery values of 86.0, 83.0, and 87.7% were achieved respectively with corresponding RSD of 5.8, 3.2, and 1.5%. Moreover, Table 1 also demonstrates that free sulfite is the major form of sulfite in shrimp muscle foods with free/total ratio varying from 0.75 to 0.85 at three fortified levels using the proposed method and from 0.80 to 0.88 using the IC method, which is in accordance with other reports.[34] Additionally, the deviations between the two methods were in the range of −2.8−2.9 for free sulfite and 0.4−6.8 for total sulfite. Overall, no significant differences were observed between the two methods in terms of recovery, RSD, and free/total ratio.

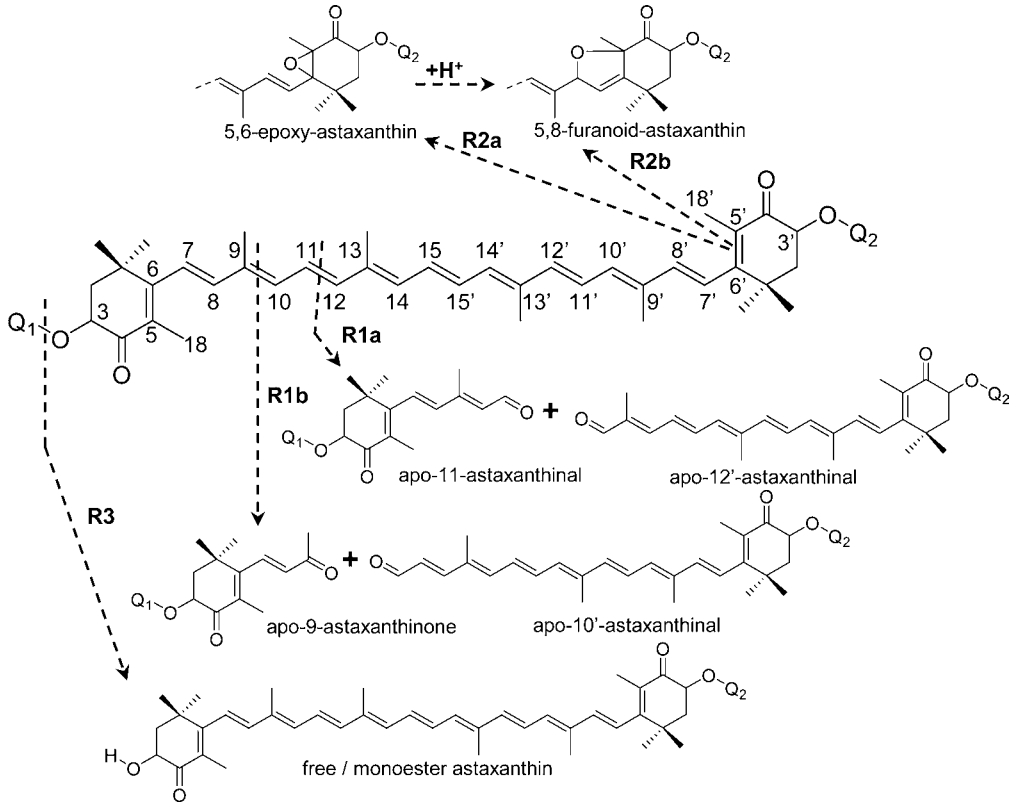

**Figure 1.** Chemical structures of astaxanthin and examples of degradation reactions and products. Reaction 1 (R1a and R1b) CDB cleavage; reaction 2 (R2a and R2b), 5,6-epoxide and 5,8-furanoid formation; reaction 3 (R3), de-esterification. Free astaxanthin, $Q_1 = Q_2 = H$; astaxanthin monopalmitate, $Q_1 = (C{=}O){-}C_{15}H_{31}$ and $Q_2 = H$; astaxanthin dipalmitate, $Q_1 = Q_2 = (C{=}O){-}C_{15}H_{31}$.

hypochlorite. The reaction products formed from *β,β*-carotene by hypochlorite bleaching were *β*-apo-13-carotenone, *β*-apo-15-carotenal, and *β*-apo-14′-carotenal. Furthermore, smaller volatiles derived from C7−C8 (e.g., *β*-cyclocitral) and C9−10 (e.g., *β*-ionone, dihydroactinidiolide) cleavages were found.[17,18]

Unlike *β,β*-carotene, xanthophylls (oxygenated carotenoids), comprising, among others, astaxanthin, canthaxanthin, lutein, and zeaxanthin, have not gained much attention, with respect to neither autoxidation nor hypochlorite bleaching. Furthermore, the fate of the fatty acid ester has not been assessed. For hypochlorite bleaching, it has been reported that the xanthophylls lutein, zeaxanthin, *α*-cryptoxanthin, (*β*-)-cryptoxanthin, and anhydrolutein were degraded, but no reaction products were described.[19] Upon oxidation of canthaxanthin by nickel peroxide, mainly apo-canthaxanthinals and canthaxanthinones were found.[20] It was also shown that upon autoxidation of free astaxanthin a series of apo-astaxanthinals and -astaxanthinones were found with apo-13-astaxanthinone as the main reaction product.[21] Treatment by peroxynitrite resulted in a mixture of apo-astaxanthins and nitro-astaxanthins.[22] The stability of the ester bond connecting astaxanthin and a fatty acid has never been assessed using light-accelerated autoxidation or hypochlorite bleaching, although the deliberate removal of the fatty acid by means of methanolic saponification and lipases has been reported.[23,24]

As a consequence of esterfication with fatty acids, the number of potential xanthophyll oxidative degradation products is expected to be larger than that for nonesterified xanthophylls. Therefore, this study reports on the analysis of apo-astaxanthin mixtures using a new method comprising reversed phase ultrahigh-performance liquid chromatography (RP-UHPLC) in combination with in-line electrospray ionization mass spectrometry (ESI-MS). For triggering the formation of reaction products through the various routes R1a, R1b, R2a, R2b and R3, light-accelerated autoxidation and hypochlorite bleaching were performed on astaxanthin, astaxanthin monopalmitate ester, and astaxanthin dipalmitate ester. The experiments were performed in pure solvent to minimize matrix effects.

## MATERIALS AND METHODS

**Materials.** (3*RS*)-Apo-12′-astaxanthinal (>98% w/w), (3*RS*,3′*RS*)-astaxanthin (97% w/w), (3*RS*,3′*RS*)-astaxanthin monopalmitate (97% w/w), and (3*RS*,3′*RS*)-astaxanthin dipalmitate (98% w/w) were purchased from CaroteNature (Lupsingen, Switzerland). ULC-MS grade methanol absolute (≥99.9% w/w), acetonitrile (≥99.9% w/w), water and formic acid (99% w/w), AR grade ethyl acetate (99.8% w/w), and HPLC grade chloroform (≥99.9% v/v, corrected for stabilizer, stabilized by 0.5−1.5% (w/v) ethanol) were purchased from Biosolve (Valkenswaard, The Netherlands). Sodium hypochlorite solution (active Cl 12.3−14.9% w/v) in $H_2O$ was purchased from Carl Roth (Karlsruhe, Germany).

**Preparation of Carotenoid Stock Solutions.** Apo-12′-astaxanthinal, free astaxanthin, astaxanthin monopalmitate, and astaxanthin dipalmitate were separately dissolved in chloroform. All stock solution concentrations were determined spectrophotometrically in hexane/chloroform (minimum 98% (v/v) *n*-hexane). Astaxanthin concentrations were determined at 470 nm using the absorption coefficient $A^{1\%}_{1\ cm}$ of 2100 L $g^{-1}$ $cm^{-1}$.[25] For astaxanthin monopalmitate and dipalmitate, concentrations were subsequently corrected for the difference in molecular weight, assuming that the fatty acid moiety did not contribute to absorption, yielding values of $A^{1\%}_{1\ cm}$ of 1501 and 1167 L $g^{-1}$ $cm^{-1}$, respectively. For apo-12′-astaxanthinal, concentrations were determined at 421 nm using $A^{1\%}_{1\ cm}$ of 2276 L $g^{-1}$ $cm^{-1}$.[26]

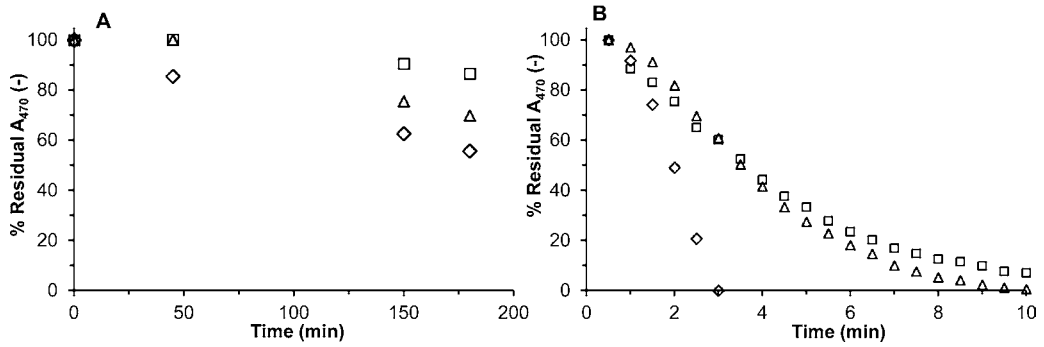

**Figure 2.** Decrease in visible absorption of various astaxanthins subjected to (A) light-accelerated autoxidation and (B) hypochlorite bleaching over time at 470 nm followed by spectrophotometry: free astaxanthin (□); astaxanthin monopalmitate (△); astaxanthin dipalmitate (◇).

**Light-Accelerated Autoxidation.** Free astaxanthin, astaxanthin monopalmitate, and astaxanthin dipalmitate were separately diluted in methanol to concentrations of 18.0, 19.6, and 24.0 $\mu$M, respectively. Aliquots (1.5 mL) were transferred to quartz cuvettes (type 114-QS, Hellma Analytics, Müllheim, Germany) closed with stoppers. A headspace of approximately 50 $\mu$L was left, filled with atmospheric air. Three cuvettes for each type of astaxanthin were irradiated for 3 h in a Suntest XLS+ (Atlas MTS, Chicago, IL, USA) equipped with a 1700 W xenon arc lamp and window glass filter. Irradiation energy was set to 30 W $m^{-2}$, and black standard temperature was maintained at 79 °C, which corresponded to a methanol sample temperature of 55 °C. The triplicates were pooled per type of astaxanthin and evaporated to dryness under a stream of nitrogen. Next, samples were redissolved in ethyl acetate and subsequently supplemented with acetonitrile to reach a ratio of ethyl acetate/acetonitrile 1:3 (v/v). Prior to UHPLC injection, samples were filtered using Whatman Rezist 13 0.45 $\mu$m PTFE syringe filters (GE Life Sciences, Fairfield, CT, USA).

**Hypochlorite Bleaching.** Bleaching of astaxanthin with hypochlorite was adapted from ref 15. Free astaxanthin, astaxanthin monopalmitate, and astaxanthin dipalmitate were diluted in 900 $\mu$L of methanol to concentrations of 30.3, 32.9, and 40.4 $\mu$M, respectively. Subsequently, degradation was carried out by the addition of 65 $\mu$L of approximately 12% (w/v) NaOCl solution and incubation for 10 min at room temperature in daylight. Estimation of the decrease in absorbance at 470 nm in time was made by comparison with a methanol/hypochlorite blank. Subsequently, the methanol layer was extracted three times using 900 $\mu$L of *n*-hexane each time. The *n*-hexane layers were pooled and evaporated to dryness under a stream of nitrogen in the dark. Rearrangement of 5,6-epoxides into 5,8-furanoids was performed by dissolving the evaporated hexane layer in 2.0 mL of 100% (v/v) ethanol. Eight hundred microliters of the ethanol-resolved degradation products was acidified with 50 $\mu$L of 0.1 M HCl.[27,28] Prior to UHPLC analysis, samples were prepared as for light-accelerated autoxidation.

**RP-UHPLC-PDA-ESI-MS Analysis of Degradation Products.** Separation and identification of carotenoid degradation products were carried out using a Thermo Accela UHPLC system (Thermo Scientific, San Jose, CA, USA) equipped with a pump, degasser, autosampler, and photodiode array (PDA) detector and coupled in-line to a LTQ-Velos double ion trap mass spectrometer equipped with a heated ESI probe (Thermo Scientific). Samples were injected onto an Acquity UPLC BEH Shield RP18 column (2.1 × 150 mm, 1.7 $\mu$m particle size; Waters, Milford, MA, USA) fitted to a Vanguard precolumn (2.1 × 5 mm, 1.7 $\mu$m particle size; Waters). The flow rate was 300 $\mu$L $min^{-1}$, operated at 23 °C. The eluents used were the following: 1% (v/v) acetonitrile in Millipore water (A), acetonitrile (B), and ethyl acetate (C), all containing 0.10% (v/v) formic acid as a mobile phase modifier. The elution program was started from 95% (v/v) A/5% (v/v) B and followed by 0−20 min linear gradient to 100% (v/v) B, 20−25 min isocratic at 100% (v/v) B, 25−32 min linear gradient to 100% (v/v) C, and 32−35 min isocratic at 100% (v/v) C. The eluent was adjusted to its initial composition in 10 min, followed by equilibration for 5 min. Detection wavelengths for UV−vis were set at 280 ± 0.5, 370 ± 0.5, and 450 ± 0.5 nm. Data were recorded at 10 Hz.

Mass spectrometric data were recorded in positive ion mode. Nitrogen was used as both sheath (30 arbitrary units) and auxiliary gas (10 arbitrary units). Settings of the mass spectrometer were tuned by 3 $\mu$L $min^{-1}$ direct injection of apo-12′-astaxanthinal in a mixture of ethyl acetate/acetonitrile 1:3 (v/v). Most settings were optimized via automatic tuning by using LTQ Tune Plus 2.7 (Thermo Scientific). The temperature of the ion transfer tube was 450 °C and the source voltage, 3.5 kV. Data were recorded over the $m/z$ segments 150−350 (0.50−10.00 min), 250−500 (10.00−15.40 min), 350−500 (15.40−19.00 min), 420−680 (19.00−23.00 min), 400−575 (23.00−24.40 min), 400−590 (24.40−24.95 min), 542−650 (24.95−26.80 min), 615−720 (26.80−29.30 min), and 615−1250 (29.30−37.00 min). Within these segments dynamic data-dependent $MS^2$ fragmentation was performed on the most intense parent ion ($x$ = 1) and subsequently on the second most intense parent ($x$ = 2). Dynamic exclusion was used to identify coeluting apo-astaxanthins. Also, it served the purpose of fragmenting both $[M + H]^+$ and $[M + Na]^+$ spectra within one chromatographic peak. A repeat count of two $MS^2$ spectra per parent ion and a maximum of $x$ = 25 or within a time frame of 5.0 s were used as settings. The collision-induced dissociation was set to 35%. Data acquisition and reprocessing were done with Xcalibur 2.2 (Thermo Scientific).

## RESULTS AND DISCUSSION

**Time Course of Color Loss of Various Astaxanthins.** The astaxanthin degradation was performed by light-accelerated autoxidation via exposure to high-intensity light conditions and elevated temperatures. Conventional autoxidation in darkness at lower temperatures could take up to several weeks.[29] Exposure of the parental *all-trans* forms of the three types of astaxanthin to light-accelerated autoxidation decreased the absorption at 470 nm (Figure 2A). After 180 min of exposure, a decrease of 13% for the free astaxanthin was observed, 30% of the monoester, and 44% of the diester. Subsequently, UHPLC-PDA-ESI-MS was used to assess the degradation products formed. As it is known that $\beta,\beta$-carotene forms small volatile compounds upon extensive degradation,[8,9] our degradation experiments were terminated with a high proportion of residual parent material, so that an overview of intermediate degradation products would be obtained. After 45 min, the absorption of the free astaxanthin and monoester was not reduced (Figure 2A). Their absorption spectra showed only a hypsochromic shift of 3−5 nm (data not shown). In contrast, the diester already showed a decrease in $A_{470}$ of 14% within 45 min. This indicated that esterification can influence color stability, which has also been reported before.[30,31]

The three types of astaxanthin were also exposed to bleaching with astaxanthin/HOCl ratios in the range of 1:3.5

and 1:5.0 (mol/mol). These ratios were reported to occur (locally) in inflamed tissues in the body.[18] The three types of astaxanthins all showed a ~100% decrease in $A_{470}$ upon bleaching, within 10 min (Figure 2B). This indicated that the reaction approached the end-point. No noticeable differences in stability between the free and monopalmitate astaxanthin degradation were observed, whereas the dipalmitate astaxanthin showed a more rapid degradation, as was also observed with light-accelerated autoxidation. No plausible explanation for this difference could be provided. Due to the different nature of the light-accelerated autoxidation and hypochlorite bleaching, they resulted in different sets of degradation products, which were used to design the LC-MS analysis method.

**Free Apo-astaxanthinals and Apo-astaxanthinones (R1a, R1b).** The absorbance maxima of the various degradation products of astaxanthin (esters) are expected to be related to the number of CDBs present in the molecules. To detect the widest array of apo-astaxanthins possible by PDA, detection wavelengths were set at 450, 370, and 280 nm. Using these three wavelengths, upon light-accelerated autoxidation a plethora of peaks was found, of which 44 could be tentatively annotated (Figure 3 and Table 1). Free apo-astaxanthinals and -astaxanthinones were found at different detection wavelengths and eluted between approximately 7.0 and 18.0 min. For the astaxanthin dipalmitate samples no PDA response was observed, indicating that no free apo-astaxanthinals and -astaxanthinones were formed. A first ascertainment of the apo-astaxanthinals and -astaxanthinones was done by locating their predicted $m/z$ values with the full scan MS data accompanying a chromatographic peak (Table 1). Using this approach, the matching protonated parent masses ($[M + H]^+$) for apo-9- and apo-13-astaxanthinone and apo-11-, apo-15-, apo-14′-, apo-12′-, and apo-10′-astaxanthinal were found upon treatment of both free and monopalmitate astaxanthin. The accompanying absorption spectra of these apo-astaxanthins had increasing $\lambda_{max}$ values from apo-9-astaxanthinone (260−270 nm) to apo-10′-astaxanthinal (452 nm). The smallest aldehyde, apo-7-astaxanthinal, was probably also formed. However, our approach will not visualize this compound due to its limited conjugated system or likely volatile properties. Nevertheless, the MS trace showed $[M + H]^+$ ($m/z$ 183) values that could potentially be associated with apo-7-astaxanthinal, but no diagnostic $MS^2$ fragments could be obtained for a reliable annotation.

The identification was further verified by analyzing $MS^2$ fragmentation of all $[M + H]^+$ parents annotated and comparison with the $MS^2$ spectrum of the apo-12′-astaxanthinal standard, which had retention time, parent mass, and $MS^2$ fragmentation similar to those of the apo-12′-astaxanthinal formed (peak 12) in our degradation study. The $MS^2$ spectra of the apo-astaxanthinals and -astaxanthinones all showed similar fragmentation behavior upon CID fragmentation (Supporting Information Table S1). In Figure 4A fragmentation of apo-12′-astaxanthinal is displayed as an example. The most intense neutral loss in the $MS^2$ spectra of the free apo-astaxanthinals and -astaxanthinones was 18 Da, yielding the fragment $m/z$ 363.2. The loss originates from the hydroxyl group at C3, analogous to water neutral loss with the (native) astaxanthin molecule.[32] The second water loss, yielding the fragment with $m/z$ 345.1, might have originated from the loss of the aldehyde group at C12′. An exception to this dominant water loss was found for apo-11-astaxanthinal, which showed a neutral loss of 42 Da ($m/z$ 205) as the main fragment. This preference for

ejecting 42 Da instead of 18 Da could not be explained. CID fragmentation of $[M + H]^+$ apo-12′-astaxanthinal, and all of the other free apo-astaxanthin aldehydes and ketones described, resulted in a multitude of smaller fragments, typical for carotenoids.[7] In our study, these smaller mass fragments at, for example, $m/z$ 201, 187, 185, 173, 161, 157, 147, 145, 135, 133, and 119 could be interpreted similarly as for apo-carotenals and -carotenones derived from $\beta,\beta$-carotene upon EI-MS, in which a saturated carbon−carbon bond is fragmented and the molecular ion is rearranged. A series of polyene fragmentations and tandem rearrangements resulted in multiple

ejections of $CH_4$ and $CH_2$, giving rise to this wide array of smaller $MS^2$ fragment ions.[7] Fragments resulting from toluene and xylene polyene elimination products were low in abundance and could in the case of apo-12′ astaxanthinal be annotated to $m/z$ 289.1 and 275.1. Other fragment ions could not be rerouted to a fragmentation of the parent ion.

**Apo-astaxanthinal and Apo-astaxanthinone Palmitate Esters (R1a, R1b).** When astaxanthin monopalmitate and dipalmitate were subjected to light-accelerated autoxidation, additional peaks appeared in the hydrophobic region of the chromatogram (21.5−30 min) (Figure 3). Again, a first annotation was performed by tracing their respective parent masses (Table 1). Upon assessment of the UV−vis absorption spectra of the peaks, a similar trend was observed as for the free apo-astaxanthinals and -astaxanthinones (Figure 5). The absorption maxima slightly deviated from previously reported $\lambda_{max}$ values of purified free apo-astaxanthinals and -astaxanthinones (1−14 nm), possibly due to the use of the different LC solvents and coelution with other reaction products.[21] This led to the conclusion that a series of apo-9- to apo-8′-astaxanthinals and -astaxanthinones palmitate esters were formed.

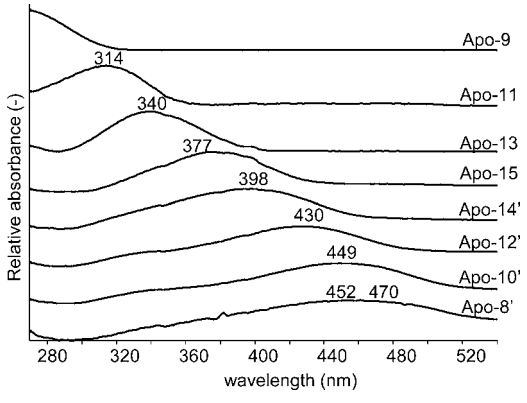

**Figure 5.** Overlay of UV−vis absorbance spectra of several apo-astaxanthin palmitate ester ketones and aldehydes.

dx.doi.org/10.1021/jf503520q | J. Agric. Food Chem. 2014, 62, 10254−10263

Similar to the astaxanthin esters, $MS^2$ spectra were used to identify the apo-astaxanthin backbone and the esterified fatty acid (Supporting Information Table S2).[32] As an example, the fragmentation of $[M + H]^+$ apo-12′-astaxanthinal palmitate (peak 40) is explained (Figure 4B). Again, water loss, yielding fragment $m/z$ 601.4 (**I**) was observed, but this time resulting from the aldehyde or ketone group. Most abundant were the fragments at $m/z$ 381.2 (**II**), representing the apo-12′-astaxanthinal backbone, and $m/z$ 363.2 (**III**), which represented the apo-astaxanthin that ejected C16:0. The typical polyene elimination products toluene (92 Da) and xylene (106 Da) were found at $m/z$ 527.3 and 513.4, respectively, albeit in low intensities. Toluene and xylene neutral losses were formed only for apo-12′-astaxanthins and larger apo-astaxanthins and not for the smaller ones. Furthermore, tandem losses of water and palmitate yielded the fragment at $m/z$ 345.2 (**IV**). Also, tandem losses of palmitate ketene and toluene (yielding $m/z$ 289.1) and palmitate and toluene (yielding $m/z$ 271.1) were observed. Contrary to the free apo-7-astaxanthinal, molecular ions of the palmitate ester of apo-7-astaxanthinal (peak 20) could be detected between Rt values of 21.8 and 22.4 min. Upon fragmentation of both the $[M + H]^+$ and $[M + Na]^+$ parents ($m/z$ 421.2 and 443.1, respectively), diagnostic fragments **I**, **II**, and **III** could be annotated (Supporting Information Table S2).

As an additional confirmation of the apo-astaxanthinal and -astaxanthinone palmitoyl structures, esterified astaxanthin sodium adducts $[M + Na]^+$ were analyzed. It has been shown that upon fragmentation, the $MS^2$ of sodiated ions strongly deviated from the protonated $MS^2$ fragmentation.[32,33] This was also the case for apo-astaxanthin palmitate esters as shown in Figure 4C. No fragments similar to **II** were found in this case; only the palmitate loss **III** is visible at $m/z$ 385.2 (for apo-7-astaxanthinal and apo-9-astaxanthinone a neutral loss of 238 Da was visible). The main fragment at $m/z$ 465.3 represented a sodiated benzonium ion and could be explained, similarly as for astaxanthin esters, by ring closure at C18 to C9 after electron rearrangement at C5−C6 (Figure 4C inset).[33,34] Remarkably, the formation of this benzonium ion was dominant over the other fragments and could already be observed with apo-9-astaxanthinone. As the sodiated parent mass of apo-9-astaxanthinone is $m/z$ 483.3, one might argue that the $m/z$ 465.4 fragment represents a simple water loss.

**Other Apo-astaxanthins and *cis*-Apo-astaxanthins (R1a, R1b).** Besides aldehyde and keto functional groups, we also screened for apo-astaxanthinols and apo-astaxanthinoic acids. Only one apo-astaxanthinol could be annotated. Instead of the parent mass of apo-8′-astaxanthinal, an $m/z$ of 449.2 was detected, suggestive for apo-8′-astaxanthinol (peak 16, Table 1 and Figure 3C). The presence of a C7−C8 CDB apo-8′-degradation product indicated that probably the corresponding apo-7-astaxanthin was also formed.

In Table 1, it can be observed that similar apo-astaxanthinal or -astaxanthinone structures were annotated to multiple chromatographic peaks (e.g., peaks 4/5, 7/8, 9/10, 14/15, and 39/43). Probably these represented different *cis*-apo-astaxanthin geometrical isomers. As also *cis*-isomers were formed from *all-trans*-astaxanthin (results not shown), this conclusion seems plausible. Assignment of the geometrical isomers using blue shifts in $\lambda_{max}$ compared to the *all-trans* isomer is common practice. As these compounds were present in trace amounts, and because it was not always possible to baseline separate degradation products to obtain a spectrum representing a single compound, *cis* and *all-trans* annotations were not pursued.

**Epoxy-astaxanthins (R2a, R2b).** The formation of epoxides was observed for intact astaxanthin (esters) upon light-accelerated degradation (Table 1). For the free astaxanthin, parent masses associated with mono-, di-, and triepoxides (e.g., epoxides on the C5−C6, C5′-C6′, and C15−C15′ positions) were found (peaks 17−19), eluting together with a plethora of other components just before the free astaxanthin peak F at 370 nm (Figure 3B). Presumably, the astaxanthin epoxides were also visible at 450 nm (Figure 3C), because epoxides normally show a small hypsochromic shift compared to astaxanthin, as will be elaborated later. Fragmentation of the epoxides showed two consecutive water losses and again a multitude of smaller fragments, the most intense of which were annotated in Tables S1 and S2 of the Supporting Information. Most likely, the epoxide groups were in the 5,6-epoxide or the 5,8-furanoid position, reported predominant in autoxidation of $\beta,\beta$-carotene.[5,9] When the carotenoid's C5−C6 and C5′-C6′ positions are occupied with epoxides, a third epoxide group might, for example, be located at the 15−15′ position.[9] Similarly, mono-, di-, and triepoxides were found for astaxanthin monopalmitate (peaks 46−48) and dipalmitate (peaks 49−51) (Table 1; Figure 3B,C). Also for the monopalmitate, the formation of intact astaxanthin epoxides upon autoxidation was observed as a large hump, which made it difficult to pinpoint exact retention times.

**Epoxy-apo-astaxanthinones and -astaxanthinals (R1a, R1b, R2a, R2b).** Two abundant free apo-astaxanthins, which were found upon hypochlorite degradation of free astaxanthin, its monopalmitate, and its dipalmitate, had parent masses of $m/z$ 239.1 and 305.1. These corresponded to the masses of epoxy-apo-9-astaxanthinone (peak 2) and epoxy-apo-13-astaxanthinone (peak 6), respectively (Table 1; Figure 6). Furthermore, for the astaxanthin monopalmitate and dipalmitate, the esterified forms of the epoxy-apo-9-astaxanthinone with $m/z$ 477.3 (peak 26) and epoxy-apo-13-astaxanthinone with $m/z$ 543.4 (peak 29) were annotated. Following the identification strategy used throughout this study, the epoxy palmitate ester species were identified by fragments **II** and **III** (Figure 4B), similar to apo-12′-astaxanthinal palmitate.

$MS^2$ fragmentation could not clarify the position of the epoxide groups, as both parent ions would result in similar fragment ions.[5,35] Therefore, further evidence for the identification of the apo-9 and apo-13 epoxide ketones was provided by the UV−vis absorption spectra. First, the epoxy-apo-13-astaxanthinone (peak 6) and its palmitate ester (peak 29) showed a blue shift of approximately 5 nm in the UV−vis absorption spectrum compared to apo-13-astaxanthinone (palmitate ester) (Figure 7A). This indicated that the conjugated system was only slightly shortened. The magnitude of the hypsochromic shift is dependent on the position of the epoxide group. Typically, a 5,6-epoxide group shortens the conjugated system with only a single double bond, whereas with a 5,8-furanoid group two double bonds are sacrificed. For intact carotenoids, epoxidation results in blue shifts of 4−13 nm for 5,6-epoxides (e.g., zeaxanthin−antheraxanthin) and blue shifts of 23−28 nm for 5,8-furanoids (e.g., zeaxanthin−mutatoxanthin).[36] For the apo-9 epoxide ketones a blue shift could not be detected due to the detection limits of the PDA detector. Although the influence of a shortened carbon skeleton of apo-astaxanthins on the magnitude of the hypsochromic shift has never been reported, the observed blue shift indicated the

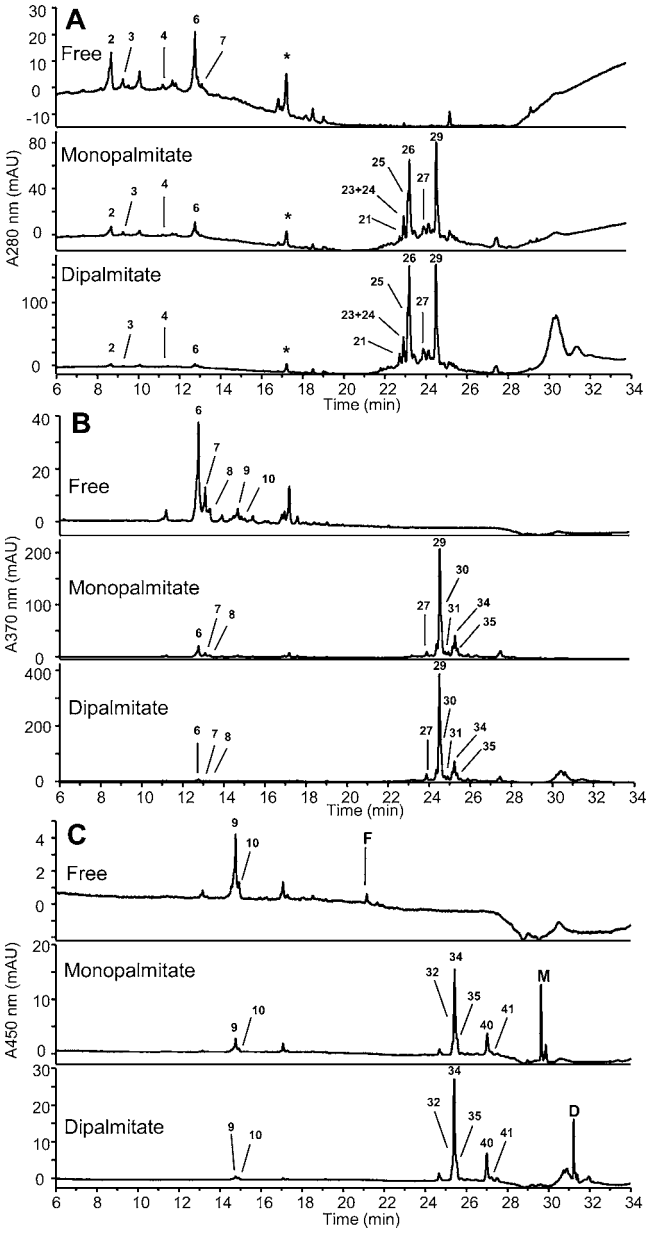

**Figure 6.** RP-UHPLC-UV profiles of hypochlorite-degraded free, monoester, and diester astaxanthin in methanol: (A) 280 nm; (B) 370 nm; (C) 450 nm. presence of a 5,6-epoxide rather than a 5,8-furanoid group for the apo-13 epoxide (peak 29).

Acidification of the apo-astaxanthin degradation products in ethanol with 0.1 M hydrochloric acid, followed by RP-UHPLC analysis, did not lead to unambiguous annotation of the 5,6 or 5,8 configuration of the epoxide group (Figure 7B).[28] Peaks 21 and 26 (apo-9) remained intact, hinting at a 5,8-configuration. Peak 29 (apo-13) only partially disappeared, and no ketone-related new peaks appeared, hinting at either a 5,6-epoxide or a 5,8-furanoid configuration. However, for peak 29 the hypsochromic shift after acidification was only 9 nm, which might be attributed to the disappearance of apo-15-astaxanthinal palmitate (peak 30) (Figure 7B). This small hypsochromic shift would argue in favor of the 5,6-epoxide. The acidification protocol was originally designed for intact carotenoids, thus without the presence of reactive aldehyde and ketone groups as in apo-astaxanthins. All apo-astaxanthin aldehydes disappeared upon acidification, whereas the less reactive ketones partially remained. Therefore, acidification seems less suitable for distinguishing 5,6-epoxides and 5,8-furanoids in the more reactive apocarotenoids.

Epoxidation of carotenoids with HOCl might proceed as has been described for unsaturated fatty acids and cholesterol.[37] In Figure 7C this reaction is visualized as follows: the electrophilic addition of HOCl to the 5−6 CDB results in intermediate **1**. The remaining $OH^-$ is added to either C5 or C6, resulting in chlorohydrin carotenoids (**2**). The 5,6-epoxide (**3**) or 5,8-furanoid (**4**) is subsequently formed by dehydrochlorination of **2**.[38] Additionally, the released HCl from **2** might trigger the conversion of **3** into **4**. Chlorohydrins might also be an end-point in this type of reaction,[37] but this was not the case here, as indicated by the isotope ratio of parent mass $m/z$ 305.1 (Figure 7D). The presence of a chlorohydrin structure would have resulted in a relative intensity of 32% for the third parent mass isotope ($m/z$ 307.1), for which only a relative intensity of 3.8% was found. This supported the formation of 5,6-epoxides or 5,8-furanoids and excluded the presence of a chlorohydrin structure.

Epoxy-apo-astaxanthinals and -astaxanthinones were also found in conjunction with reaction 1 upon light-accelerated degradation. For free astaxanthin and astaxanthin monopalmitate epoxy-apo-12′-astaxanthinal (peak 13) was annotated (Table 1). The absorbance maximum of the epoxy-apo-12′-astaxanthinal had a hypsochromic shift of approximately 20 nm compared to apo-12′-astaxanthinal. Besides apo-astaxanthins esterified with palmitate, also their epoxidized forms were found upon degradation of astaxanthin monopalmitate and dipalmitate. The palmitoyl esters of epoxy-apo-9-astaxanthinone (peak 21), epoxy-apo-15-astaxanthinal (peaks 32, 36, and 38), epoxy-apo-12′-astaxanthinal (peaks 39 and 43), and epoxy-apo-15-astaxanthinoic acid (peak 33) were all traced. The occurrence of multiple epoxides can be explained by either isomerization of the polyene backbone (*all-trans* to *cis* conversion), or the variation in 5,6-epoxide or 5,8-furanoid, or a combination thereof.

**Degradation of the Fatty Acid Ester (R3).** Upon examination of the diester chromatograms (Figures 3C and 6C), de-esterification was observed with especially the hypochlorite bleaching treatment, as free apo-astaxanthins (e.g., peaks 2−4 and 6−10) were formed. The de-esterification did not lead to the annotation of any new compounds and proceeded in conjunction with reaction 1 and, occasionally, reaction 2. Most probably, the de-esterification proceeded via a base-induced hydrolysis with the apo-astaxanthin as the leaving group. The reactive nucleophile in this case is likely a hypochlorite anion ($OCl^-$) or a hydroxide ($OH^-$) resulting from the HOCl. As the degradation was performed in methanol, also a methoxide anion ($MeO^-$) might have served as nucleophile, resulting in a fatty acid methyl ester.

For light-accelerated autoxidation, trace amounts of free astaxanthin (peak F) and astaxanthin monopalmitate (peak M) were found (Figure 3C). When the degradation was continued to 7 h, also no accumulation of free astaxanthin and astaxanthin monopalmitate was observed (data not shown). Observation of the trace amounts of de-esterification products upon light-accelerated autoxidation (e.g., a system that does not favor de-esterification) underscores the sensitivity of the analysis method employed.

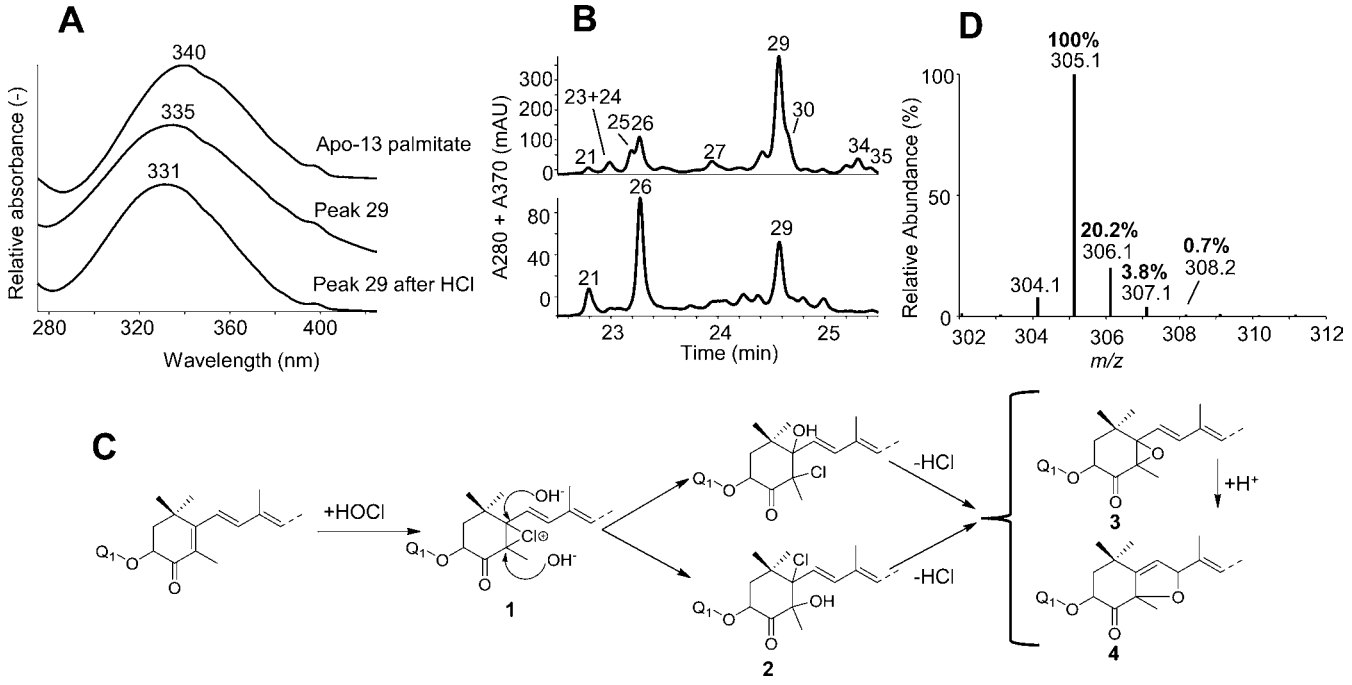

**Figure 7.** (A) Overlay of UV−vis absorption spectra of apo-13-astaxanthinone palmitate ester (top), epoxy-apo-13-astaxanthinone palmitate ester (middle), and epoxy-apo-13-astaxanthinone palmitate ester after acidification with HCl (bottom); (B) RP-UHPLC-UV profiles (sum of detection wavelengths 280 and 370 nm) of hypochlorite-degraded astaxanthin dipalmitate (top) and 0.1 M HCl acidified hypochlorite degraded astaxanthin dipalmitate (bottom) Numbers refer to Table 1. (C) Reaction scheme for the formation of chlorohydrins (**2**) via intermediate cloronium ion **1** and conversion to 5,6-epoxy-apo-astaxanthin (**3**) or 5,8-furanoid-apo-astaxanthin (**4**) by dehydrochlorination. $Q_1$ is either H or (C═O)-$C_{15}H_{31}$, (D) Full MS spectrum of epoxy-apo-13-astaxanthinone (peak 6), average of 31 spectra.

and AnaeroGen sachets for generating $CO_2$ and BR55 anaerobic indicators were obtained from Oxoid Ltd. (Basingstoke, UK).

**Source of Walnuts.** California walnuts (Sweet Valley brand) were purchased from a local supermarket.

**Study Design.** Four healthy volunteers were entered into the study. No restriction with regard to general diet was enforced, only ingestion of supplements or medication and walnuts was forbidden for 3 weeks prior to the study. The volunteers consumed peeled walnuts (200 g) starting at 9:00 a.m. on day 1 and completed ingestion within 4 h. Morning urine samples were collected 1 day later.

On the basis of urine urolithin excretion data, one volunteer (V-1) displaying the most dynamic profile of ellagitannin metabolites was selected for a further in-depth study of blood, feces, and urine.

V-1 was female, aged 43, a nonsmoker and nonvegetarian, without a history of gastrointestinal or any other chronic diseases, and was not involved in a weight-reducing dietary regimen. On day 1, 24 h urine and fecal samples were collected. On day 2 of the study, 200 g of commercially available peeled walnuts was consumed over the course of the morning between 9:00 a.m. and 12:00 p.m. Successive urine and fecal samples were collected separately over the following 7 days. Additionally, plasma samples were collected on days 2, 3, and 4 of the study in 2−4 h periods. On day 8, the ingestion of 200 g of peeled walnuts was repeated, and successive urine and fecal samples were again collected up to day 13 of the study.

**Collection and Storage of Urine, Blood, and Fecal Samples for V-1.** *Urine.* Following ingestion of a further 200 g of walnuts by V-1, all subsequent urine samples were collected in measuring cylinders, noting the time and volume. Aliquots of 2 and 10 mL were pipetted into plastic test tubes (15 mL), and the rest was discarded. During the day, samples were placed immediately at −80 °C, whereas outside working hours, samples were placed at −20 °C overnight before transport to the laboratory and subsequent storage at −80 °C.

*Feces.* For V-1, all fecal samples were collected throughout the two intervention phases, in preweighed round plastic containers of 10 cm diameter. The plastic containers plus feces were reweighed for wet weight calculations. During the day, samples were placed immediately at −80 °C, whereas after working hours samples were placed at −20 °C overnight before transport to the laboratory and subsequent storage at −80 °C. The samples were freeze-dried within 8 days of collection to obtain dry weights and were pulverized to a fine homogeneous powder prior to Soxhlet extraction.

dx.doi.org/10.1021/jf5040652 | J. Agric. Food Chem. 2014, 62, 10264−10273

*Plasma.* During the first intervention period of the two-stage intervention study with V-1, blood samples (4−5 mL) were taken from the basilic vein into heparin prepared tubes at different time points; five samples on day 2 (ingestion of walnuts), five samples on days 3 and, and four samples on day 4 of the study. The blood samples were centrifuged (13000 rpm) at 5 °C for 10 min, and plasma was frozen at −80 °C.

**Column Chromatography on Sephadex LH-20.** Dried urine extraction residues, after suspension in absolute ethanol, were adsorbed on Sephadex LH-20 by freeze-drying, prior to addition to the free volume at the head of glass columns (38 cm × 4.5 cm i.d.) filled to ca. 5 cm from the top with Sephadex LH-20 in ethanol. After bedding down of the gel material, fractionation was conducted by successive elution with ethanol followed by increasing concentrations of methanol (5−50%) in ethanol followed by 100% methanol (250 mL of each solvent). Fractions (250 mL) were collected, and the solvent was removed by rotary evaporation in vacuo at 40 °C.

**Column Chromatography on C18.** The dried fractions obtained by Sephadex LH-20 chromatography were dissolved in 2% acetic acid (2.0 mL) and applied to C18 columns for subfractionation. The columns were preconditioned with methanol (4.0 mL) and 2% acetic acid (4.0 mL) and were not allowed to dry. Elution was performed with solvent mixtures containing increasing concentrations of methanol (5−50%) in 2% acetic acid followed by 100% methanol. The solvent was removed on a SpeedVac (Bachhofer, Reutlingen, Germany). Individual phenolic compounds, in relevant fractions, were purified by semipreparative HPLC for structure elucidation by spectroscopic analysis.

**Isolation of Urolithin Glucuronides from Urine.** A week later, three of the healthy volunteers again consumed 200 g of walnuts, acccording to the same protocol as before. The following morning, first-pass urine was collected, and the volume of urine was reduced in vacuo on a rotary evaporator. The samples were all worked up separately. Sephadex LH-20 was added, and the remaining urine was adsorbed on this substrate by freeze-drying prior to addition to the free volume at the head of individual glass columns (38 cm × 4.5 cm i.d.), filled to ca. 5 cm from the top, with Sephadex LH-20 in ethanol and fractionated as described above. The dried fractions were dissolved in methanol (5.0 mL) prior to analyses by analytical reverse-phase HPLC and HPLC-ESI-MS. The fractions obtained from the Sephadex column were subfractionated on C18 columns as described above. Dried subfractions were suspended in methanol (2 mL) and diluted when necessary prior to reverse-phase analytical HPLC and HPLC-ESI-MS. Phenolic compounds were purified by semipreparative HPLC for spectroscopic analysis.

**Generation of Free Urolithins by Fermentation of Ellagic Acid in Vitro.** Reference-free urolithins were unavailable commercially and therefore were produced by bacterial fermentation according to the following protocol. Urolithins were produced by adding ellagic acid (50.0 mg) in ethanol (5.0 mL) to BHI broth (100 mL) in Duran bottles (100 mL) fortified with the reducing agents, sodium formaldehyde sulfoxylate (300 mg/L) and L-cysteine HCl (500 mg/L), to a final concentration of 1 mg/mL. After previous sterilization at 120 °C for 20 min, the medium was steamed for 30 min, immediately prior to use, to remove residual oxygen, and allowed to cool before inoculation with freshly voided fecal matrix (100 mg) from three of the volunteers. The bottles with open caps were placed in an anaerobic churn (neoLAB, Heidelberg, Germany) containing an indicator of anaerobiosis (Anaerobic indicator, BR55), which turned from pink to white on generation of an anaerobic atmostphere, by two freshly opened sachets of ascorbic acid (AnaeroGen).

The fermentation broths were centrifuged and metabolites extracted on two C18 (5 g) (octadecyl-modified silica, Chromabond) columns. The columns were preconditioned with methanol (50 mL) and 2% acetic acid (50 mL). The fermentation solutions were eluted, and the columns were washed twice with distilled water (50 mL). The columns were allowed to dry and eluted with methanol (50 mL). Solvent from the combined eluants was removed by rotary evaporation, and the dried extracts were dissolved in methanol (2.0 mL). The metabolites were analyzed by analytical HPLC and HPLC-ESI-MS and purified by semipreparative HPLC prior to spectroscopic analyses.

**Semipreparative HPLC.** Semipreparative HPLC was conducted on a HP 1100 liquid chromatograph (Agilent Technologies, Waldbronn, Germany) fitted with a C18 column (10 mm i.d.) similar to that used for analytical HPLC. For the separation of individual compounds in the extracts, the mobile phase (3 mL/min) consisted of 0.2% acetic acid in distilled water (solvent A) and acetonitrile (solvent B), utilizing the following solvent gradient profile over a total run time of 50 min: initially 95% A for 1 min; reduced to 90% A over 9 min; to 85% A over 10 min; to 80% A over 10 min; to 0% A over 5 min; and continuing at 0% A until completion of the run. Peaks eluting from the column were collected on a HP 220 microplate sampler and subsequently lyophilized.

**Electrospray Ionization Mass Spectrometry (ESI-MS).** HPLC-ESI-MS was conducted on an Agilent 1100 HPLC, coupled to a HP 1101 single-quadrupole, mass-selective detector (Agilent Technologies). The column used was a 250 mm × 4.5 mm i.d., 5 μm, RP-18 with a 4 mm × 4 mm i.d. guard column of the same material (Latek, Eppelheim, Germany). The mobile phase consisted of 2% acetic acid in water (solvent A) and acetonitrile (solvent B) with the following gradient profile: initially 95% A for 10 min; reduced to 90% A over 1 min; to 60% A over 9 min; to 80% A over 10 min; to 60% A over 10 min; to 0% A over 5 min; and continuing at 0% A until completion of the run. Volumes (10 μL) were injected into the HPLC, and phenolic compounds in the eluant were detected at 278 and 340 nm with a diode array UV detector (HP 1040M). Mass spectra in negative-ion selected ion monitoring (SIM) mode were generated under the following conditions: fragmentor voltage, 100 V; capillary voltage, 2500 V; nebulizer pressure, 30 psi; drying gas temperature, 350 °C; mass range, 100−1500 Da. The ions used for the detection of glucuronidated and free urolithins are listed in Table 1. Instrument control and data handling were performed with the same software as for analytical HPLC.

**Table 1. Details of the Parameters Used for Detection of the Urolithins by HPLC-ESI-MS in Negative Ion Selected Ion Monitoring Mode**

| | phenolic compound | formula | exact mass *M* (calcd) | selected $[M-H]^-$ ion | HPLC-MS ret time (min) |
|---|---|---|---|---|---|
| 1 | urolithin B glucuronide | $C_{19}H_{16}O_9$ | 388.079 | 387 | 33.74 |
| 2 | urolithin A glucuronide | $C_{19}H_{16}O_{10}$ | 404.074 | 403 | 25.82, 26.18, 27.11, 27.42 |
| 3 | urolithin C glucuronide | $C_{19}H_{16}O_{11}$ | 420.069 | 419 | 27.77 |
| 4 | urolithin D glucuronide | $C_{19}H_{16}O_{12}$ | 436.064 | 435 | 23.37, 25.57, 29.34, 33.64 |
| 5 | urolithin B | $C_{13}H_8O_3$ | 212.047 | 211 | 42.68 |
| 6 | urolithin A | $C_{13}H_8O_4$ | 228.042 | 227 | 41.94 |
| 7 | urolithin C | $C_{13}H_8O_5$ | 244.037 | 243 | 37.84, 39.67 |
| 8 | urolithin D | $C_{13}H_8O_6$ | 260.032 | 259 | 36.24, 37.74 |
| 9 | urolithin E | $C_{13}H_8O_7$ | 276.027 | 275 | 27.98 |

**Total Polyphenol Content of Walnuts Evaluated by the Folin−Ciocalteu Assay.** Preparation of a cold walnut extract was conducted according to the method of Anderson et al.,[14] whereby 50 g of powdered walnuts (frozen for 24 h) was incubated in a solution of 75% aqueous acetone containing sodium metabisulfite (10 mg/L) at 4 °C for 4 days. The acetone was decanted and evaporated under reduced pressure, and methanol (50% aqueous, v/v) was added. The solution was extracted three times with *n*-hexane. The defatted solution was freeze-dried and dissolved in 100 mL of 10% aqueous dimethyl sulfoxide and used for the analysis of total polyphenols.

To evaluate the total polyphenol content of walnuts, 20 μL of gallic acid standard solution or walnut extract was mixed with 1.58 mL of double-distilled water and 100 μL of Folin−Ciocalteu phenol reagent

N2 (Sigma-Aldrich, Deisenhof, Germany) in a 2 mL cuvette. After 8.5 min, 300 μL of sodium carbonate solution (200 g/L) was added, and the solution was stirred and incubated for 30 min at 40 °C, following the procedure of Waterhouse.[15] The absorbance was measured at 765 nm on a spectrophotometer (Pharmacia Biotech, Ultraspec 3000) against a blank. Different concentrations of gallic acid (0.5−10 mM) in 10% aqueous dimethyl sulfoxide were used to generate a standard curve with a slope of 0.1534 (SD = 0.00329, $P < 0.0001$). The total polyphenol content was calculated as gallic acid equivalents (GAE).

**Total and Individual Content of Phenolic Compounds in Walnuts As Evaluated by Soxhlet Extraction and HPLC-ESI-MS.** Freeze-dried walnuts (5 g) were delipidated by extraction with hexane (3 × 150 mL) for 3 h. The walnut cake was dried under a stream of nitrogen and further extracted with methanol (3 × 150 mL) for 3 h. The methanol extracts were combined, and solvent was removed by rotary evaporation. The dried residue was immobilized on Sephadex LH-20 and fractionated by successive elution with increasing concentrations of methanol in ethanol as described. Phenolic compounds in the fractions were identified by HPLC-ESI-MS and quantitated against standard curves of the purified metabolites.

**Sample Analyses.** *Urine.* Urine samples (20 μL) were analyzed for urolithin metabolites of ellagitannins by HPLC-ESI-MS operating in negative ion SIM mode, using the ions listed in Table 1. Calculation of the amounts of individual metabolites were conducted with the relevant standard curves listed in Table 2.

**Table 2. Standard Curves of Purified Glucuronidated Urolithins, Free Urolithins, and Uric Acid Generated by HPLC-ESI-MS in Selected Ion Monitoring Negative Ion Mode**

| substance with mass | slope | *R* | *P* |
|---|---|---|---|
| urolithin B glucuronide | 5791 | 0.999 | <0.0001 |
| urolithin A glucuronide | 9101 | 0.999 | <0.0001 |
| urolithin C glucuronide | 738 | 0.999 | <0.0001 |
| urolithin D glucuronide | 7418 | 0.998 | <0.001 |
| urolithin B | 4318 | 0.999 | <0.0001 |
| urolithin A | 12035 | 0.996 | <0.0001 |
| urolithin C | 657 | 0.997 | <0.001 |
| urolithin D | 9618 | 0.999 | <0.0001 |
| uric acid | 7.710 | 0.999 | <0.0001 |

*Plasma.* Prior to analysis, blood samples were defrosted and centrifuged. To plasma samples (500 μL) were added 0.2 M hydrochloric acid (100 μL) and ethanol (2.0 mL), and the mixture was vortexed vigorously for 2 min and centrifuged at 13000 rpm for 15 min. The ethanol layer was aspirated and the procedure repeated twice. The combined ethanol extracts (6.0 mL) were evaporated to dryness under a stream of nitrogen and suspended in 200 μL of phosphate buffer (pH 6.6) prior to analysis (20 μL) by HPLC-ESI-MS under the conditions described for the analysis of urine samples. Calculations of the amounts of individual metabolites were conducted with the relevant standard curves listed in Table 2.

*Feces.* Homogenized dried fecal powders (2.5 g) were extracted in a Soxhlet apparatus with *n*-hexane for 3 h to remove lipids. Residual powders, after drying under a stream of nitrogen, were extracted with methanol (3 h), and solvent was removed by rotary evaporation at 35 °C.

The extracts were dried, weighed, and suspended in 10 mL of methanol. Of the homogenized solutions, 1.0 mL was transferred to an Eppendorf microfuge tube and centrifuged at 3500*g* for 5 min. The upper methanol layer was aspirated and analyzed (20 μL) by HPLC-ESI-MS, operating in the SIM mode using the ions listed in Table 1. The residue was dissolved in DMSO (1.0 mL) and likewise analyzed (20 μL) by HPLC-ESI-MS. Calculation of the amount of metabolites was conducted using the relevant standard curves listed in Table 2.

**Antioxidant Assays.** *DPPH Assay.* The DPPH assay was conducted as previously described.[16] Raw urine and fecal extracts were diluted 1:10 and 1:100 with methanol, respectively. Plasma samples (100 μL) were added to 100 μL of perchloric acid. The samples were centrifuged at 13000 rpm for 5 min, and the supernatants (150 μL) were neutralized with 10 M sodium hydroxide (5 μL), and 20 μL of this solution was used in the assay. Each batch of samples was measured simultaneously with Trolox at concentrations of 50−1000 μM. Using the percentage degradation of DPPH, at the different Trolox concentrations, a standard curve was constructed, which was always exponential. To obtain linear regression curves, the data points were subdivided into two parts. With Trolox concentrations of 250−1000 μM, a linear regression curve was calculated and used for the calulation of all Trolox equivalents for all data points ≥10% DPPH value. With Trolox concentrations of 50−250 μM a linear regression curve was calculated and used for the calulation of all Trolox equivalents for all data points ≤10% DDPH. The Trolox equivalents calculated were corrected for dilution factors and, in the case of urine and feces, calculated in relation to the amount of urine or fecal extracts.

*FRAP Assay.* The FRAP assay was conducted as previously described.[16] Raw urine and fecal extracts were diluted 1:10 and 1:100 with acetate buffer (300 mM sodium acetate, pH, 3.6). Plasma samples were prepared as described for the DPPH assay. Each batch of samples was measured simultaneously with Trolox at concentrations of 50−1000 μM to obtain a linear regression curve. Using this linear regression curve, the Trolox equivalents for each sample of fecal extracts, plasma, and urine were calculated and corrected for dilution factors.

*ORAC Assay.* The ORAC assay was conducted as described previously.[16] To precipitate proteins, plasma samples (100 μL) were mixed with 0.5 M perchloric acid (100 μL) and centrifuged. Of the upper layer, 100 μL was mixed with 10 M sodium hydroxide solution (2 μL). The plasma extracts, diluted 1:100 or 1:200 with ORAC buffer, and aliquots (10 μL) were placed in quadruplicate in a 96-well plate to measure peroxy radical scavenging capacity. Raw urine and fecal extracts were diluted 1:50 and 1:200, respectively, with ORAC buffer prior to analysis.

**Statistics.** The Trolox equivalent values of pure compounds and biospecimens in the DPPH assay were correlated with the Tablecurve program (Jandel Scientific, Chicago, IL, USA). Correlations between urolithin and uric acid concentrations and antioxidant capacity in the biospecimens were evaluated by linear regression using the Origin program (version 7.5).

## RESULTS AND DISCUSSION

**Concentration of Total Phenolic Compounds in Walnuts.** On the basis of the Folin−Ciocalteu assay, the total amount of polyphenol compounds ingested after intervention with 200 g of walnuts equated to 3.11 g calculated as gallic acid equivalents. This is almost identical to that reported by Anderson et al.,[14] at 3.2 g pf polyphenol/200 g of walnuts. However, the total amount of polyphenolic compounds detected in the same batch of walnuts following Soxhlet extraction, column chomatography, and identification[17] and quantitation by HPLC-ESI-MS equated to 5.013 g of ellagitannins alone, of which 3.228 g was ellagic acid moieties (Table 3).

**Identification of Urolithin Glucuronides and Free Urolithins Isolated and Purified from Urine and Fermentation Experiments, Respectively.** A range of glucuronidated urolithins were isolated and purified from large-scale extractions of urine samples from the volunteers. The basic structures were elucidated by HPLC-ESI-MS (Table 1). These (Figure 1) were urolithin B glucuronide, **1**; urolithin A glucuronide (four isomers), **2**; urolithin C glucuronide (two isomers), **3**; and urolithin D glucuronide (four isomers), **4**. From the fecal extracts and fermentation experiments the following free urolithins were characterized (Figure 1), namely,

**Concentration of Glucuronidated Urolithins in Urine of the Volunteers.** A wide interindividual variation (Figure 2) in gastrointestinal ellagitannin metabolism was apparent among the four volunteers, as judged by the profiles in urine 1 day after ingestion: volunteer 1, excreted mainly urolithin A, C, and D glucuronides (5.67 mM); volunteer 2, mainly urolithin A and B glucuronides (1.75 mM); volunteer 3, mainly urolithin A, B, and C glucuronides (0.72 mM); and volunteer 4, only urolithin A glucuronides (4.0 mM).

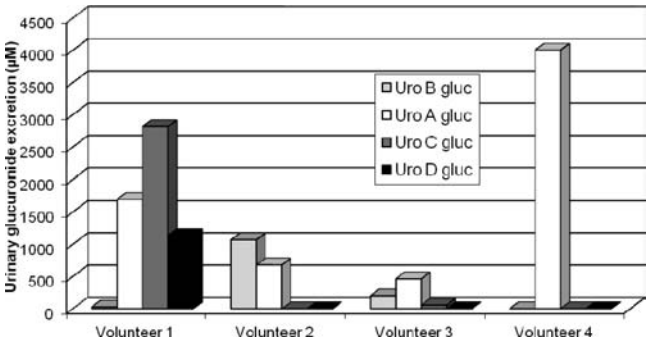

**Figure 2.** Profile of glucuronidated urolithins in the urine of the four volunteers following intervention with walnuts (200 g).

**Concentration of Urolithins in Sequential Urine, Plasma, and Fecal Samples in Volunteer 1.** *Urine.* The concentration of total glucuronidated urolithins in successive urine samples of V-1 is depicted in Figure 3A, whereas the contribution by the major individual glucuronides is shown in Figure 4A.

As shown in Figure 3A, maximal excretion (4.6 mM) of glucuronidated urolithins in urine, during intervention phase 1, was attained 2 days after ingestion of walnuts, whereas during phase 2, it attained 8.0 mM somewhat earlier at 1 day after ingestion. Appreciable levels were also detected for as long as 4 days after ingestion. Overall, the ingestion of 200 g of walnuts by V-1 (equivalent to 3.228 g of ellagic acid moieties) led to total excretions of 2.02 and 2.24 g of urolithin glucuronides in

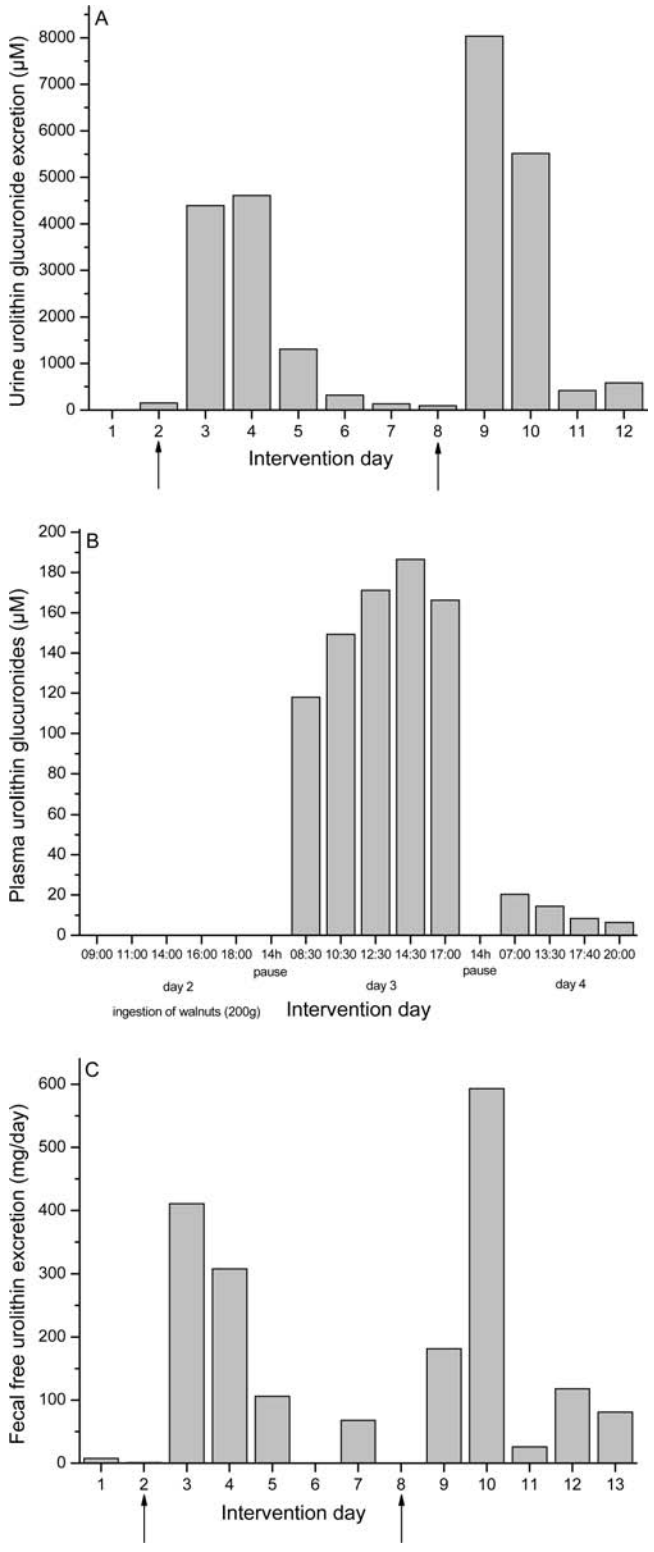

**Figure 3.** (A) Total glucuronidated urolithins in urine of volunteer 1 following intervention with walnuts (200 g), on days 2 and 8 as indicated by the arrows. (B) Total glucuronidated urolithins in plasma of volunteer 1 following intervention with walnuts (200 g) during phase 1 of the study. (C) Total free urolithins in feces of volunteer 1 following intervention with walnuts on days 2 and 8 as indicated by the arrows.

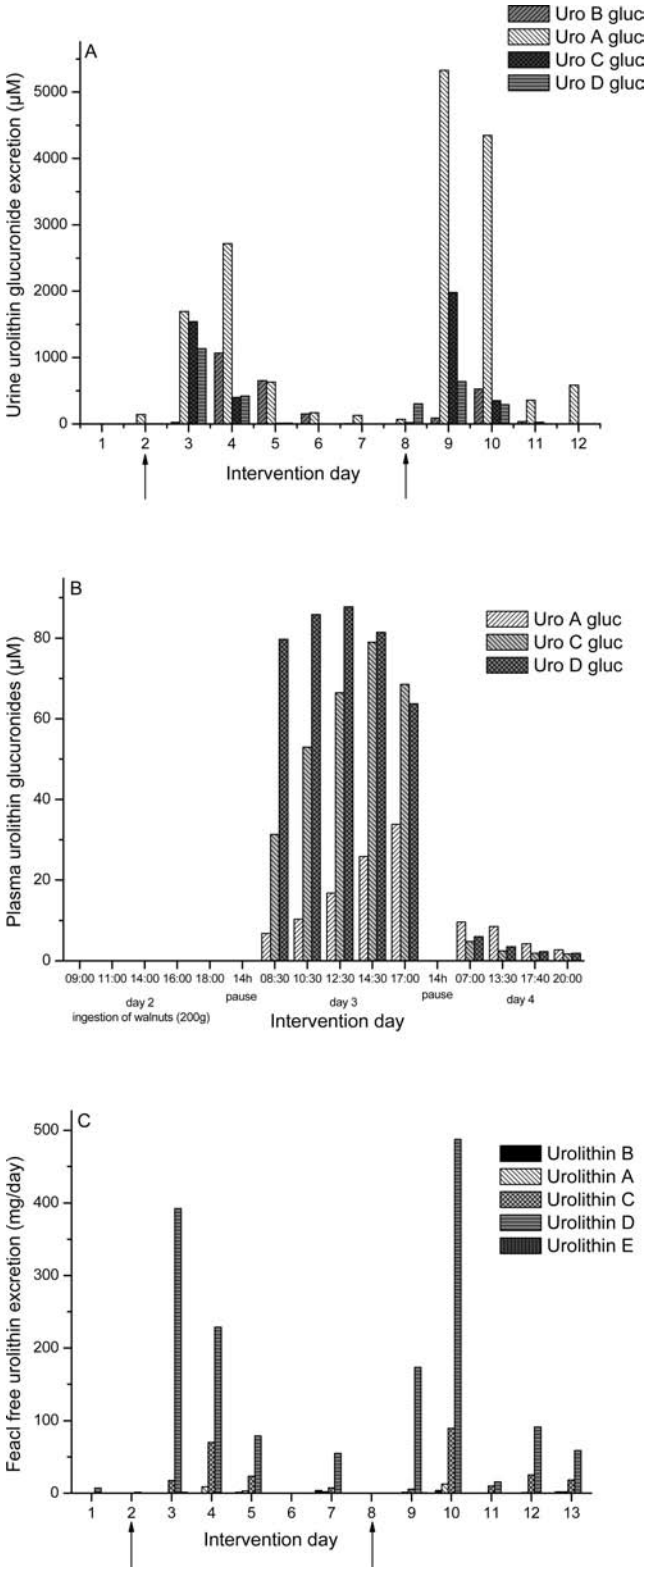

**Figure 4.** (A) Distribution of individual glucuronidated urolithins in the urine of volunteer 1 following intervention with walnuts (200 g) on days 2 and 8 as indicated by the arrows. (B) Distribution of individual glucuronidated urolithins in the plasma of volunteer1 following intervention with walnuts (200 g) during phase 1 of the study. (C) Distribution of free urolithins in the feces of volunteer1 following intervention with walnuts on days 2 and 8 as indicated by the arrows.

urine after phases 1 and 2, respectively, which means that 63 and 69% were excreted via this route. The major metabolites identified in the urine of V-1, during intervention phase 1, were urolithin A glucuronides at 2.72 mM on day 3 (2 days later) and during phase 2 also urolithin A glucuronides at 5.33 mM on day 9 (1 day later). Appreciable levels of urolithin B glucuronide appeared in the urine 2 days later (Figure 4B) after ingestion, during both intervention phases, confirming that metabolism proceeds from polyhydroxylated to monohydroxylated metabolites.[15,17]

*Plasma.* Consecutive 2−4 h plasma samples, over 3 days, were analyzed, showing that the concentration of total urolithin glucuronides rose over 32 h in plasma to a maximum of 185 $\mu$M following walnut ingestion and declined rapidly over the next 12 h. The distribution in plasma displayed a Gaussian curve taking into account the 14 h breaks during nonworking hours. The concentration of total glucuronidated urolithins in successive plasma samples of V-1 is depicted in Figure 3B, whereas the contribution by the major individual glucuronides is shown in Figure 4B. Three major glucuronidated urolithins were detected in plasma samples, namely, urolithin A, C, and D glucuronides. Because the degradation of ellagitannins proceeds from higher to lower hydroxylated forms,[18] the concentration of urolithin D glucuronide (up to 87 $\mu$M) and urolithin C glucuronide (up to 79 $\mu$M) in blood rose in the first 14 h after ingestion and represented the highest concentrations detected in plasma. Maximal levels of urolithin A glucuronide (35 $\mu$M) were apparent 6 h later, 20 h after ingestion.

*Feces.* The number of fecal samples produced per day was variable; for example, on day 2 of the study, fecal samples were not produced (days 6 and 8), sometimes two or more, so on day 9 and 12 two samples and three on day 7. The excretion of total free urolithins in successive fecal extracts of V-1 is depicted in Figure 3C, whereas the contribution by the major individual urolithins (mg/day) is shown in Figure 4C. The urolithins detected were mainly urolithins A, B, C, and D along with minor amounts of urolithin E. After phase 1 ingestion of 200 g of walnuts by V-1, 893 mg of urolithins was excreted in feces over 6 days, and after phase 2 ingestion, a similar amount of 919 mg was excreted in 5 days. This indicates that, on average, 28% of ingested ellagitannins was excreted via this route after the intervention phases. The major urolithins excreted in feces were urolithin D isomers, with the highest excretion at 392 mg/day on day 3 during phase 1 and 488 mg/day on day 10 during phase 2, respectively. Urolithin C was excreted at concentrations of 70 mg/day on day 4 (2 days after ingestion) and 89 mg/day on day 10 (again 2 days after ingestion) during phase 2.

**Antioxidant Capacity of Pure Urolithin Glucuronides and Free Urolithins.** Urolithin glucuronides (Table 4), purified by semipreparative HPLC and examined in the DPPH assay, were very ineffective. The highest concentration of the three urolithin glucuronides tested (1.0 mM) led to a reduction of the DPPH radical of between 5 and 22% only. Free monohydroxylated (urolithin B) and dihydroxylated (urolithin A) urolithins (Table 4) also displayed negligible activity in the DPPH assay, with reductions of the DPPH radical, at a concentration of 1.0 mM, of only 13 and 25%, respectively. The other free urolithins examined, urolithins C and D, displayed much higher activity, with $IC_{50}$ values of 142 and 57 $\mu$M, respectively.

The urolithin glucuronides and free urolithins were also very weak in the FRAP assay (Table 4), with concentrations in the

**Table 4. Antioxidant Capacity of Purified Glucuronidated and Free Urolithins and Reference Compounds**

| | DPPH assay ($IC_{50}$)[a] or $M_1$[b] at 1.0 mM | FRAP ($EC_1$)[c] ($\mu$M) | ORAC units[d] |
|---|---|---|---|
| urolithin B glucuronide | 5%* | 6340 | 0.33 ± 0.02 |
| urolithin A glucuronide | 22%* | 2483 | 1.89 ± 0.08 |
| urolithin C glucuronide | 7%* | 7138 | 1.48 ± 0.01 |
| urolithin B | 15%* | 7922 | 0.65 ± 0.04 |
| urolithin A | 13%* | 1291 | 1.84 ± 0.03 |
| urolithin C | 141.6 $\mu$M | 2683 | 1.23 ± 0.05 |
| urolithin D | 56.7 $\mu$M | 1803 | 0.57 ± 0.07 |
| Trolox | 65.96 $\mu$M | 527 | 1.0 |

| ellagic acid | 13.11 $\mu$M | 139 | 1.85 ± 0.05 |

[a]$IC_{50}$, concentration of substance ($\mu$M) at which 50% of the DPPH radical is scavenged. [b]Percent reduction of DPPH at a concentration of 1.0 mM. [c]$EC_1$, concentration of substance ($\mu$M) giving an absorbance increase equivalent to 1 mM Fe $2^+$ solution. [d]One ORAC unit equals the inhibition of the declining fluorescence produced by 1 $\mu$M Trolox.

ranges of 2.5−7.1 and 1.3−7.9 mM, respectively, required to reduce 1 mM $Fe_3^+$ as compared to the standard compounds tested, namely, ellagic acid, gallic acid, uric acid, and Trolox with $EC_1$ values of 139, 170, 379, and 527 $\mu$M.

In contrast to the FRAP and DPPH assays, both glucuronidated and free urolithins A and C show much higher activity in the ORAC assay (Table 4). Of the pure urolithins tested, activity increases in the order urolithin B glucuronide (0.33 ± 0.02) < urolithin C glucuronide (1.48 ± 0.01) < urolithin A glucuronide (1.89 ± 0.08), whereas of the free urolithins tested, activity increases in the order urolithin D (0.57 ± 0.07) < urolithin B (0.65 ± 0.04) < urolithin C (1.23 ± 0.05) < urolithin A (1.84 ± 0.03) in comparison to Trolox were evident.

**Antioxidant Capacity of Raw Urine, Plasma, and Fecal Methanol Extracts in the DPPH, FRAP, and ORAC Assays.** *Raw Urine.* As shown in Table 5, the antioxidant capacity of raw urine samples did not correlate with the concentration of total glucuronidated urolithins (mean, 555 ± 92 $\mu$M; range, 6−2761 $\mu$M) as determined by HPLC-ESI-MS across the assays. However, strong positive correlations between the concentration of uric acid (mean, 3.01 ± 0.19 mM; range, 0.87−7.89 mM) in the raw urine were evident in all of the assays (DPPH, $R = 0.61$, $P < 0.0001$; FRAP, $R = 0.62$, $P < 0.0001$; ORAC, $R = 0.53$, $P < 0.0001$).

**Table 5. Antioxidant Capacity of Total Urolithin Glucuronides and Uric Acid in Urine Samples of Volunteer 1**

| | correlation | slope | *P* | *R* | *n* |
|---|---|---|---|---|---|
| DPPH | total urolithin glucuronides ($\mu$M) | 0.03562 | 0.50 | 0.09 | 56[a] |
| | uric acid ($\mu$M) | 0.52273 | <0.0001 | 0.61 | 67[b] |
| FRAP | total urolithin glucuronides ($\mu$M) | 0.008 | 0.79 | −0.04 | 56 |
| | uric acid ($\mu$M) | 0.5202 | <0.0001 | 0.62 | 67 |
| ORAC | total urolithin glucuronides ($\mu$M) | 0.22778 | 0.80 | 0.03 | 56 |
| | uric acid ($\mu$M) | 0.94501 | <0.0001 | 0.53 | 67 |

[a]Correlation based on urine samples that contained urolithin glucuronides ($n = 56$); urine samples on day 1 of ingestion did not contain urolithins. [b]Correlation based on all urine samples ($n = 67$).

*Plasma.* As shown in Table 6, the antioxidant capacity of protein-free plasma was negatively correlated with the concentration of both total glucuronidated urolithins and uric acid, respectively, in all assays. Possibly, the urolithin data are compromised by dilution (inherent in the assay) and matrix effects, but with the relatively constant levels of uric acid (317 ± 10 $\mu$M; range, 283−393 $\mu$M) a positive correlation would not be expected.

**Table 6. Antioxidant Capacity of Total Urolithin Glucuronides and Uric Acid in Plasma Samples of Volunteer 1**

| | correlation | slope | *P* | *R* | *n* |
|---|---|---|---|---|---|
| DPPH | total urolithin glucuronides ($\mu$M) | −1.012 | 0.13 | −0.54 | 9[a] |
| | uric acid ($\mu$M) | −0.176 | 0.28 | −0.31 | 14[b] |
| FRAP | total urolithin glucuronides ($\mu$M) | −0.69442 | 0.02 | −0.74 | 9 |
| | uric acid ($\mu$M) | 0.11387 | 0.23 | 0.34 | 14 |
| ORAC | total urolithin glucuronides ($\mu$M) | −1.36116 | 0.004 | −0.85 | 9 |
| | uric acid ($\mu$M) | 0.11531 | 0.58 | 0.16 | 14 |

[a]Correlation based on urine samples that contained urolithin glucuronides ($n = 9$); plasma samples on day 1 of ingestion did not contain urolithins. [b]Correlation based on all plasma samples ($n = 14$).

*Fecal Extracts.* As shown in Table 7, the antioxidant capacity of fecal extracts correlated positively with the concentration of total urolithins as determined by HPLC-ESI-MS in both the DPPH ($R = 0.81$, $P < 0.01$) and FRAP ($R = 0.80$, $P < 0.01$) assays. However, the association in the ORAC assay was negative ($R = -0.40$, $P > 0.05$). The positive correlation in the DPPH and FRAP assays can be mainly attributed to the high concentrations of urolithin D ($R = 0.67$, $P < 0.05$; $R = 0.76$, $P < 0.05$, respectively) in the fecal extracts, which supports the data for the pure compound (Table 4). The negative correlation in the ORAC assay is readily explained by the low antioxidant capacity of pure urolithin D in this assay (Table 4).

**Table 7. Antioxidant Capacity of Total Free Urolithins and Urolithin D in Fecal Extracts of Volunteer 1**

| | correlation | slope | *P* | *R* | *n* |
|---|---|---|---|---|---|
| DPPH | total free urolithins ($\mu$M) | 3461.2 | <0.01 | 0.81 | 10 |
| | urolithin D ($\mu$M) | 985.73 | <0.05 | 0.67 | 10 |
| FRAP | total free urolithins ($\mu$M) | 2315.9 | <0.01 | 0.80 | 10 |
| | urolithin D ($\mu$M) | 751.7 | <0.05 | 0.76 | 10 |
| ORAC | total free urolithins ($\mu$M) | 23.37 | 0.23 | −0.40 | 10 |
| | urolithin D ($\mu$M) | 4.99 | 0.51 | 0.24 | 10 |

The urolithin glucuronides present in the urine of the four volunteers, intervened with walnuts, were very different in terms of their profiles and concentrations and reflect the

variable capacity of the human intestinal flora to metabolize ellagitannins as shown previously.[19]

In the detailed two-stage walnut (200 g; equivalent to 3.228 g of ellagic acid moieties) intervention study with V-1, a very high proportion of the ellagitannins they contain was metabolized to urolithins, as demonstrated by excretions, on average, of 66% in urine and 28% in feces, which attained a maximum of 11% in blood during phase 1 of the study. Over the two intervention phases, 94% of ellagitannins (based on ellagic acid moieties) ingested was detected in urine and feces. This indicates highly efficient degradation of ellagitannins to urolithins by the gastrointestinal flora in this subject. Excretion of 66% urolithins in urine also reflects the high bioavailability of urolithins in humans. Maximal excretion during phases 1 and 2 attained 4.6 and 8.0 mM, respectively.

In addition, walnut ingestion led to maximal plasma concentrations of up to 35 $\mu$M urolithin A glucuronides, up to 79 $\mu$M urolithin C glucuronides, and up to 87 $\mu$M urolithin D glucuronides. Calculating the maximal value of urolithin glucuronides in this volunteer shows that 25% of the ingested ellagitannins from walnuts is present in blood in the form of urolithins within the first 24 h after ingestion.

The urine excretion data are fairly consistent with those of Cerda et al.,[20] who reported a mean total excretion of 11.17 mM (urolithin A + urolithin B) in 15 patients after a daily intake of pomegranate juice (400 mL) equivalent to 2.66 g of ellagitannin precursors. In addition, Gonzalez-Barrio et al.[21] reported maximal values of 44 $\mu$M urolithin glucuronides in urine after a challenge in humans with raspberries (300 g) containing much lower levels of ellagitannins and ellagic acid, at a combined concentration of 140 $\mu$M. This represents an excretion rate of 31% in urine based on ellagitannins ingested.

With regard to urolithin concentration in blood samples, our data, however, are in stark contrast to other reports. Surprisingly, Gonzalez-Barrio et al.[21] were unable to detect urolithins in plasma samples. In another study by Gonzalez-Sarrias et al.,[22] walnuts were fed (3 × 35 g) to human volunteers and led to a concentration of only 0.11 ± 0.05 $\mu$M urolithin A glucuronide in blood.

The negative antioxidant capacity of purified urolithin glucuronides in the DPPH and FRAP assays is in agreement with previous studies.[3] By contrast, they were far more effective in the ORAC assay, urolithin A glucuronide (1.89 ± 0.08) > urolithin C glucuronide (1.48 ± 0.01) > urolithin B glucuronide (0.33 ± 0.02), in comparison to Trolox. Sufficient urolithin D glucuronide isomer could not be purified for comparison.

The free compounds urolithins A and B were not very effective in the DPPH and FRAP assays, as was also the case for urolithins C and D in the FRAP assay. By contrast, urolithin C and, especially, urolithin D were effective antioxidants in the DPPH assay. In the ORAC assay, the data mirrored strongly the data for the glucuronidated metabolites, urolithin A (1.84 ± 0.03) > urolithin C (1.23 ± 0.05) > urolithin B (0.65 ± 0.04) > urolithin D (0.57 ± 0.07).

These data contradict several reported studies[3,23] which have shown that free urolithins do not display antioxidant activity in a range of assays. However, this represents the first report of antioxidant capacity by pure urolithins tested in the ORAC assay and underscores the need to evaluate compounds in a minimum of three assays.

With regard to the content of metabolites in urine, urolithin glucuronide concentration was negative, whereas uric acid concentration was positive across the antioxidant assays ($P < 0.0001$). A correlation between urolithin glucuronide concentration and antioxidant capacity in plasma was also not observed. By contrast, the data pertaining to the free urolithins in the fecal extracts closely reflected the data for the purified compounds. A strong association ($P < 0.01$) for total urolithin concentration was observed in both the DPPH and FRAP assays, with the major contribution from urolithin D ($P < 0.05$). However, the very weak associations in the ORAC assay with regard to total urolithins ($P > 0.2$) and urolithin D ($P > 0.5$) concentration reflect the data obtained with pure urolithin D (ORAC value, 0.57 ± 0.07), which was the major metabolite in fecal extracts.

The strong association between the high levels of uric acid detected in urine and antioxidant capacity is consistent with previous reports.[24−26] However, with regard to the ORAC assay, it is difficult to explain the discrepancy between urine urolithin levels given that the majority of the final concentrations of the urolithins in the assay were far above the effective concentrations of the pure compounds (Table 4). For plasma biospecimens, perhaps this is not the case because levels were close to, or below, the effective concentrations of the pure compounds (Table 4). Nevertheless, the plasma data are consistent with the ORAC and FRAP data of McKay et al.,[27] who also demonstrated nonsignificant changes, following intervention with albeit lower doses of either 21 or 42 g of walnuts per day. It is interesting to note that in contrast to our data and those of McKay et al.[27] with regard to plasma antioxidant capacity over the long term, short-term studies indicate rapid increases in plasma antioxidant capacity following walnut ingestion.[28] We are of the opinion that this has little relevance to the urolithins, which are produced only by bacterial metabolism of ellagitannins in the large intestine.

With regard to urolithins (in terms of comparing pure compounds with biospecimen concentration), consistent data were obtained for urolithin D in the fecal biospecimen extracts and the pure compound. Possibly, this is due to semi-purification and concentration of urolithin D in the Soxhlet extraction step. The inconsistencies in the correlations with regard to urolithin glucuronide concentration in urine and plasma biospecimens (the latter may be due to dilution effects), compared to the data generated with pure compounds, need to be clarified in the future by solid/liquid phase extraction methods to exclude possible matrix effects. In this sudy, although the data for the antioxidant capacity of urolithins in urine and possibly plasma biospecimens, in comparison to pure compounds, are equivocal, the results for the fecal extracts are not. The positive antioxidant capacities of the fecal extracts, rich in urolithin D, in the DPPH and FRAP assays, but negative in the ORAC assay, mirror exactly the data for the purified compounds and confirm the cell-based assay of Bialonska et al.[6] This points to a potential chemopreventive effect, with regard to colorectal cancer, given that urolithins also inhibit cell proliferation and induce apoptosis in HT-29 cells,[29] exhibit anti-inflammatory effects,[30] and inhibit Wnt signaling[31] in a human 293T cell line. Finally, although the number of subjects entered into the study was low ($n = 4$), they served the purpose of this pilot study to a certain extent. However, given the data generated from successive biospecimens from V-1, it would have been helpful had a similar protocol been possible for the other three volunteers. Unfortunately, due to logistic problems, this was not the case.

In summary, the data in this pilot study show that the metabolism of ellagitannins in four volunteers gave rise to a diverse profile and a highly variable concentration of urolithins in urine. The concentration of glucuronidated urolithins in urine, surprisingly, did not correlate with antioxidant capacity, in contrast to data generated with purified individual urolithins. This discrepancy warrants further investigation. However, the antioxidant capacity of urine biospecimens was highly correlated with uric acid concentration. The antioxidant capacity of fecal extracts correlated positively with the concentration of urolithin D, in both the DPPH and FRAP assays, but not in the ORAC assay, which was entirely consistent with the in vitro assays for pure urolithin D.

activity of calcium-binding peptides may be used as one kind of food additive that prevents bone disorders.

## MATERIALS AND METHODS

**Materials.** Whey protein (WPC80, containing 80.5% protein) was kindly provided by Hilmar Corporation (Batch 20111107, Hilmar, CA). The commercial proteases, Flavourzyme (EC. 3.4.11.1, $2 \times 10^6$ units/g) and Protamex (EC. 3.4.24.28, $1.5 \times 10^6$ units/g), were purchased from Novo (Novozymes, Denmark). Toyopearl DEAE-650M and Sephadex G-25 were offered by Amersham Pharmacia (Amersham Pharmacia Co., Uppsala, Sweden). All of the other chemicals and solvents were of analytical grade.

**Hydrolysis of Whey Protein.** A total of 5% (w/v) whey protein solution was denatured in 80 °C for 20 min, and the pH was adjusted to 7.0. The sample was hydrolyzed using Flavourzyme and Protamex (2:1, w/w) with a substrate/enzyme ratio of 25:1 (w/w) at 49 °C for 7 h. Hydrolysate was heated at boiling water for 10 min to inactive the enzyme and cooled to room temperature. The mixture was subsequently centrifuged at 16000*g* for 20 min, and then the supernatant named whey protein hydrolysate (WPH) was lyophilized and stored at −20 °C for subsequent investigation.

**Purification and Identification of Calcium-Binding Peptide.** *Ion-Exchange Chromatography on Diethylaminoethyl (DEAE).* The peptide that could bind with calcium and form peptide−calcium chelate was defined as the calcium-binding peptide. The slurry of Toyopearl DEAE-650M was packed in a column (20 × 2.5 cm) and then equilibrated at 5 column volume (CV) of 20 mM Tris-HCl buffer (pH 9.0) as the equilibrating buffer. Afterward, 100 mg of the lyophilized hydrolysates that had been through 0.45 μm filter film was dissolved in 10 mL of the same buffer (pH 9.0) and loaded on the column. Then, after washing with the equilibrating buffer, the collected peak was labeled as the non-absorbed fraction. The bond peptides were eluted by a gradient elution with the same buffer containing 0−0.5 M NaCl. The flow rate was 0.5 mL/min; fraction volume was 5 mL/tube; elution was monitored at 214 nm; all peaks were collected; and calcium-binding capacities of the fractions were determined.

*Gel Filtration on Sephadex G-25.* The fraction with the highest calcium-binding capacity was pooled and lyophilized; 200 mg of the sample was dissolved in 5 mL of deionized water and loaded onto a Sephadex G-25 column (100 × 2.0 cm), which had previously been equilibrated with deionized water, and then eluted with deionized water at a flow rate of 0.3 mL/min. The eluate was monitored by measuring the absorbance at 214 nm. After calcium-binding capacity was determined, the fraction with the highest activity was pooled and lyophilized.

*High-Performance Liquid Chromatography (HPLC) on C18.* The lyophilized sample collected from G-25 was dissolved in distilled water approximately equivalent to 30 mg/mL and purified by semi-preparative reversed-phase high-performance liquid chromatography (RP-HPLC) on C18 reversed silica gel chromatography (Gemini 5 μm C18, 250 × 10 mm, Phenomenex, Inc., Torrance, CA). Elution was performed on solution A [0.05% trifluoroacetic acid (TFA) in water] and solution B (0.05% TFA in acetonitrile) with a gradient of 0−30% B at 1.0 mL/min for 50 min. The elution was monitored at 214 nm, and the absorption peaks were fractionated for measuring the calcium-binding activity. The injection volume was generally 200 μL.

*Identification of the Purified Calcium-Binding Peptide.* The molecular mass and amino acid sequence of the purified calcium-binding peptide were determined using liquid chromatography−electrospray ionization/mass spectrometry (LC−ESI/MS, Delta Prep 4000, Waters Co., Milford, MA) over the $m/z$ range of 300−3000.

*Calcium-Binding Capacity Assay.* The calcium-binding capacity was defined as the content of calcium (μg) bound with peptide (mg) after the chelating reaction. Lyophilized whey protein hydrolysate was dissolved in deionized water to be 1.0 mg/mL and mixed with 5 mM $CaCl_2$ in 0.2 M sodium phosphate buffer (pH 8.0). The solution was stirred at 37 °C for 2 h, and pH was maintained at 8.0 with a pH meter. The reaction mixture was centrifuged at 10000*g* at room temperature for 10 min to remove insoluble calcium phosphate salts. Sodium phosphate was used as the calcium-binding buffer, which could react with calcium ion and peptide, separately, and show obviously different reactions. Calcium ion could combine with phosphate to form calcium phosphate precipitation, while peptide could take calcium ion from precipitation. As a result, peptide−Ca chelate was a water-soluble substance, and a soluble calcium content in the supernatant represented the calcium content associated with the peptide.[16] The calcium contents in the supernatant were determined using a colorimetric method with *ortho*-cresolphthalein complexone reagent.[17] The absorbance at 570 nm was determined after adding the working solution to the sample. The experiments were performed in triplicate, and values were expressed as the mean ± standard deviation (SD).

**Characterization of the Purified Calcium-Binding Peptide.** *Formation of the Peptide−Calcium Chelate.* Peptide−calcium chelate was the chelating component of the reaction between dipeptide Gly-Tyr and calcium ion. The calcium-binding chelate was prepared by adding 5 mL of 1% (w/v) $CaCl_2$ into 20 mL of 2.5% (w/v) calcium-binding peptide solution. The reaction was placed in a controlled water bath with constant agitation (100 rpm) at 37 °C for 2 h after the pH of the solution was adjusted to 7.0 by the addition of 0.1 M NaOH. Then, the mixture was added with absolute ethanol (9 times of solution volume) to remove free calcium and centrifuged at 10000*g* for 10 min, and the precipitates was lyophilized for analysis.

*Ultraviolet (UV) Absorption Spectroscopy Assay.* The UV spectra of the calcium-binding peptide and peptide−calcium chelate were recorded over the wavelength range from 190 to 400 nm by a UV−vis spectrophotometer (UV-2600, UNICO Instrument Co., Ltd., Shanghai, China) as the method described by Chen et al.[18] The calcium-binding peptide of 0.2 mg/mL was prepared. The peptide−calcium chelate was prepared by adding 0, 2, 4, 6, 8, and 10 μM $CaCl_2$ to 0.2 mg/mL calcium-binding peptide solution, separately. The mixed solution reacted at room temperature for 30 min.

*Fluorescence Spectra Analysis.* Fluorescence spectra were measured to monitor conformational changes in the peptide induced by calcium chelation using the F-4600 fluorescence spectrophotometer (Hitachi Co., Japan). The excitation wavelength was 280 nm, and emission wavelengths between 290 and 360 nm were recorded.

*Fourier Transform Infrared Spectroscopy (FTIR) Measurement.* A total of 1 mg of calcium-binding peptide powder or peptide−calcium chelate was ground evenly with 100 mg of dry KBr under infrared light to the size below 2.5 μm. Then, the transparent KBr piece was made at 60 MPa. To examine whether the variation in pellet thickness causes significant interference in the measured spectra, three different pellets were prepared from the same sample and their FTIR spectra were compared. The average of these three spectra was then used for analysis. The FTIR spectra were recorded using an infrared spectrophotometer (360 Intelligent, Thermo Nicolet Co., Waltham, MA) over a wavenumber region between 4000 and 400 $cm^{-1}$ at a resolution of 4 $cm^{-1}$, and the sample spectra were background-subtracted using a spectrum collected in the absence of a peptide−calcium chelate sample. Therefore, the physical variation in the FTIR spectra caused by the KBr technique had been removed prior to the FTIR spectra analysis. A total of 64 scans were recorded per sample in the FTIR spectra, and the peak signals in the spectra were analyzed using OMNIC 8.2 software (Thermo Nicolet Co., Madison, WI).

*$^1$H Nuclear Magnetic Resonance (NMR) Spectroscopy Assay.* The peptide−calcium chelate and calcium-binding peptide (0.5 mg) were dissolved in 500 μL of deionized water, separately. A total of 50 μL of deuterium oxide ($D_2O$) was added after the pH of the solution was adjusted to 6.5. The samples were transferred into 5 mm NMR tubes and subjected to NMR analysis with a Bruker Avance III spectrometer (Bruker Biospin, Rheinstetten, Germany).

*Differential Scanning Calorimetry (DSC) Analysis.* Thermogravimetry (TG)−DSC simultaneous thermal analyzer (STA449C, NETZSCH, Germany) was employed to measure the thermal property. Hermetic pans with lyophilized powder samples (5 mg) were heated from 50 to 600 °C at a programmed heating rate of 10 °C/min in a argon atmosphere. An empty pan was used as a reference.

*ζ Potential Measurement.* A Malvern Nano ZS Zetasizer based on dynamic light scattering was employed to measure the ζ potential. The system works according to the phase analysis light scattering (PALS) principle. The volume of all samples (3 mg) was 15 mL with autotitration by 0.25 M NaOH or HCl. The samples were equilibrated for 30 s before titration.

*Calcium-Releasing Percentage Experiment.* The calcium-releasing percentage determination of peptide−calcium chelate and $CaCl_2$ was examined according to the method described by Wang et al.[19] Peptide−calcium chelate and $CaCl_2$ were dissolved in deionized water, separately, equivalent to 10 μg/mL. The pH of these solutions was adjusted to 2.0, 3.0, 4.0, 5.0, 6.0, 7.0, and 8.0. After incubation in a shaking water bath for 2 h at 37 °C, the solutions were centrifuged in a refrigerated centrifuge at 10000*g* for 10 min. The calcium amount in the supernatant and the total calcium in the whole solution were determined by the colorimetric method with an *ortho*-cresolphthalein complexone reagent. The calcium releasing percentage was calculated as follows:

$$\text{calcium-releasing percentage (\%)} = \text{Ca amount in supernatant (g)/total Ca in solution (g)} \times 100$$

**Statistical Analyses.** All data were presented as means (SDs) conducted with three replicates. The statistical analysis was performed using SPSS 16.0 software (SPSS, Inc., Chicago, IL). Analysis of variance (ANOVA) was performed to determine the significance of the main effects. A value of $p < 0.05$ was considered statistically significant.

## RESULTS AND DISCUSSION

**Purification and Identification of the Calcium-Binding Peptide.** Bioactive peptides are usually purified using a combination of chromatographic techniques.[20] Throughout the purification process, calcium-binding activity of WPH was assessed using the colorimetric method with an *ortho*-cresolphthalein complexone reagent.[17] Three fractions (F1, F2, and F3) of the WPHs were divided on a DEAE anion-exchange chromatography column (Figure 1). The calcium-binding capacity was noticeably higher in F2 and F3 compared to F1 (Figure 1). Moreover, in comparison to WPH (33.92 μg/mg), the calcium-binding capacity of F2 was significantly improved (57.02 μg/mg).

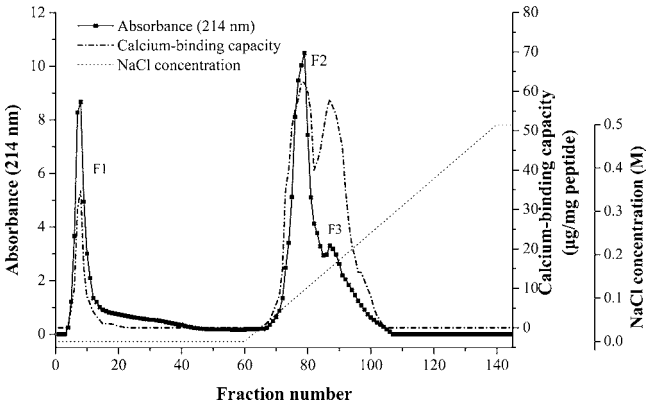

**Figure 1.** Fractionation on a DEAE anion-exchange chromatography column and the calcium-binding capacity of the three fractions separated from the DEAE column. The peptide was washed with the binding buffer (0.02 M Tris−HCl buffer at pH 9.0) and eluted with a linear gradient of 0−0.5 M NaCl in the same buffer.

Fraction F2 with the highest calcium-binding capacity was further separated using size-dependent Sephadex G-25 gel filtration chromatography resulting in four major fractions, named F21, F22, F23, and F24 (Figure 2). F23 exerted the most excellent calcium-binding capacity (Figure 2). The result was consistent with some previous reports, which showed that a lower molecular mass peptide exhibited a tendency to combine with calcium ion.[21,23] It is reported that the lowest molecular weight peptide fraction (<1 kDa) had the higher calcium-binding activity through ultrafiltration and small molecular peptide fractions purified on a G-25 column possessed higher calcium-binding capacity.[21,22]

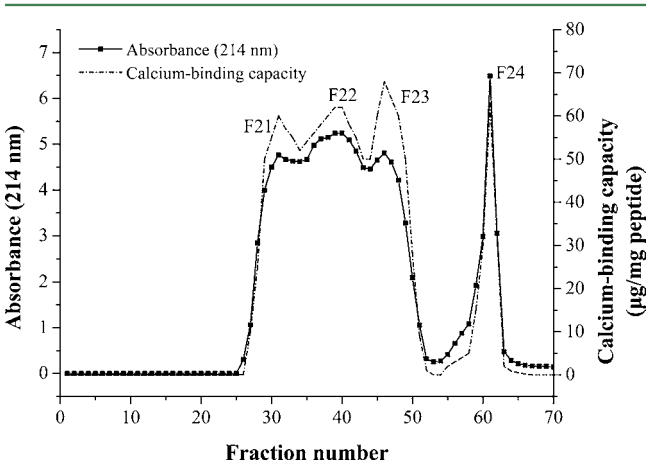

**Figure 2.** Fractionation of the fraction F2 with the highest calcium-binding activity from DEAE chromatography on a Sephadex G-25 gel filtration chromatography column and the calcium-binding capacity of the fractions F21−F24 separated from a Sephadex G-25 column.

The active peak F23 was pooled, dissolved in distilled water, and loaded onto semi-preparative C18 RP-HPLC. The fraction F23 was separated into 13 major distinct fractions (Figure 3A). Each fraction was pooled, and calcium-binding capacity was determined subsequently (Figure 3B). Among 13 distinct fractions, fraction 7 showed the highest calcium-binding ability, and then it was further fractionated by RP-HPLC on a C18 column. The elution profile showed that fraction 7 was composed of five peaks, and fraction 2 (Figure 4A), one of the eluted peaks, was the purifed peptide. The calcium-binding capacity of fraction 2 reached 75.38 μg/mg (Figure 4B). The chromatographic profile of fraction 2 on analytic C18 RP-HPLC (Figure 5) showed only a single peak called WPH-A, indicating the high purity of the isolated peptide.

The amino acid sequence of WPH-A eluted from RP-HPLC chromatography was identified by LC−ESI/MS (Figure 6). According to the mass/charge ratio ($m/z$) of 238.99 Da of the molecular ion peak ($[M + H]^+$), the molecular mass of WPH-A was confirmed to be 237.99 Da. The $m/z$ of fragment ion y1 was 181.99 Da, which resulted from the relative molecular mass of tyrosine in addition with one hydrogen atom. On the basis of calculation in ESI ion molecular mass, one residue in WPH-A was Tyr and the other one was Gly. Therefore, the animo acid sequence was determined to be Gly-Tyr. The result was confirmed by comparison to data from the National Center for Biotechnology Information (NCBI) database.

Not only could the differences in the net charge and length of peptides influence the extent of chelate formation with metal ion, but also the different amino acid residues of peptides affected their activities,[14,24] including the amino acid composition and sequence of the peptides.[25] Chaud et al.[14] reported that tyrosine seemed to bind with divalent metal

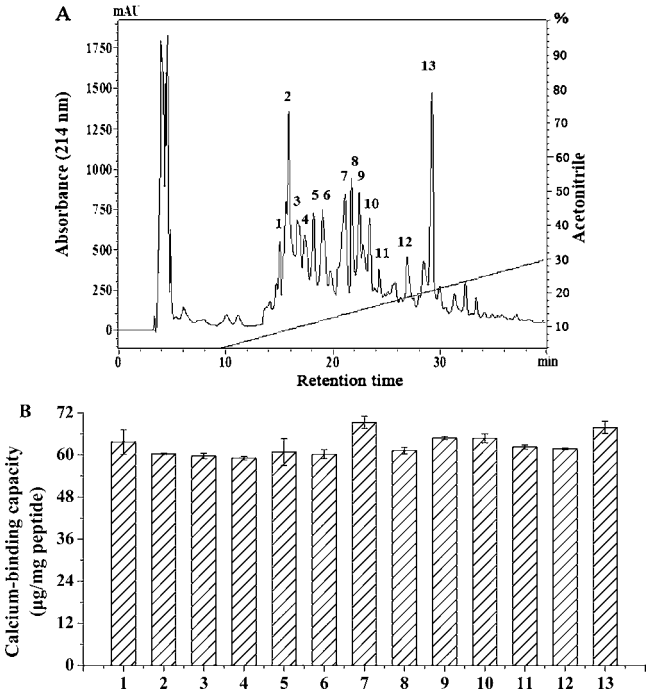

**Figure 3.** (A) Fraction F23 from a Sephadex G-25 column and then applied to a semi-preparative C18 RP-HPLC column. The column was then washed with a linear gradient of 0−30% acetonitrile containing 0.05% TFA. (B) Calcium-binding capacity for the fractions 1−13 of F23 separated from semi-preparative HPLC.

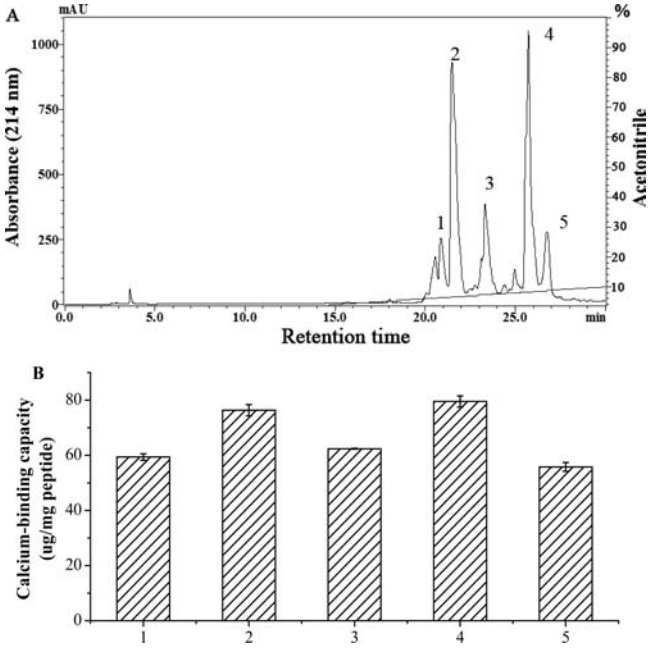

**Figure 4.** (A) RP-HPLC of fraction 7 derived from preparative HPLC. The column was then washed with a linear gradient of 0−10% acetonitrile containing 0.05% TFA. (B) Calcium-binding capacity of fractions 1−5 from RP-HPLC.

cations through oxygen of the phenolic hydroxyl group. The phosphorylation of tyrosine and serine residues could provided suitable binding sites for positively charged metals, such as calcium, iron, or zinc.[26] Moreover, the animo acid glycine was considered as an organic ligand having the metal ion binding function. Jung et al.[27] purified a calcium-binding peptide from

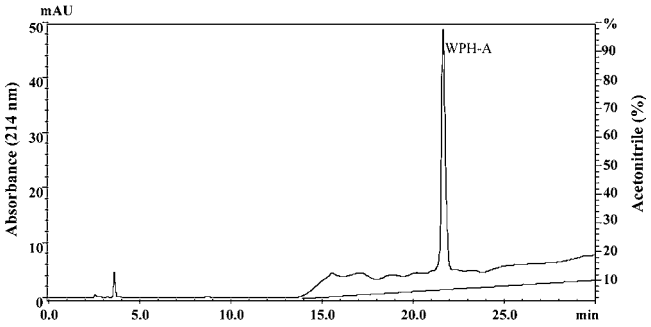

**Figure 5.** Analytic RP-HPLC of the peak WPH-A for purify identification. The column was washed with a linear gradient of 0−10% acetonitrile containing 0.05% TFA.

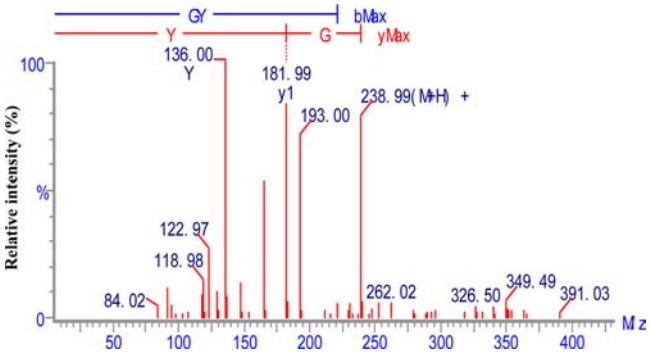

**Figure 6.** Identification of the amino acid sequence of the calcium-binding peptide using LC−ESI/MS.

Alaska pollack containing Gly, Ser, and Val. Hoki bone hydrolysates had a high affinity to calcium, and the major animo acid composition of the peptide included Gly, Asp, and Glu.[28] An iron-chelating peptide with multi-glycine residues was also purified from anchovy muscle protein.[29] In this study, a calcium-binding peptide was identified to contain Gly and Tyr residues; both of them contributed to combine with divalent minerals.

**Characterization of the Purified Calcium-Binding Peptide.** *UV Absorption Spectroscopy Assay.* The UV spectra of calcium-binding peptide Gly-Tyr showed an obvious difference from that of the Gly-Tyr−Ca chelate (Figure 7). A strong absorption band was observed at about 200 nm, which could be regarded as the characteristics of the amide bond in peptide. Another absorption peak at around 280 nm appeared in both Gly-Tyr and Gly-Tyr−Ca chelate, resulting from the characteristic UV absorption of Tyr. With the addition of calcium ion to dipeptide Gly-Tyr, the intensity of the absorption band of the amide bond became higher than that of dipeptide alone. In the magnified UV spectra image, the red shifts of the band, such as the red curve in Figure 7, could be clearly observed and a small peak arose in the dipeptide−calcium chelate.

Through observing the shifts and intensity changes of UV bands, the UV absorption situation of the amide bond in peptide and the side group in Tyr could be analyzed. The UV spectra phenomenon was consistent with some other studies, which demonstrated that the spatial structure with the chirality of the chromospheres (C═O and −COOH) and auxochromes (−OH and $-NH_2$) of peptides changed after incorporating with the calcium ion.[30,31] The main reason for the intensity changes of the band indicated that the oxygen atom of the

dx.doi.org/10.1021/jf502412f | J. Agric. Food Chem. 2014, 62, 10274−10282

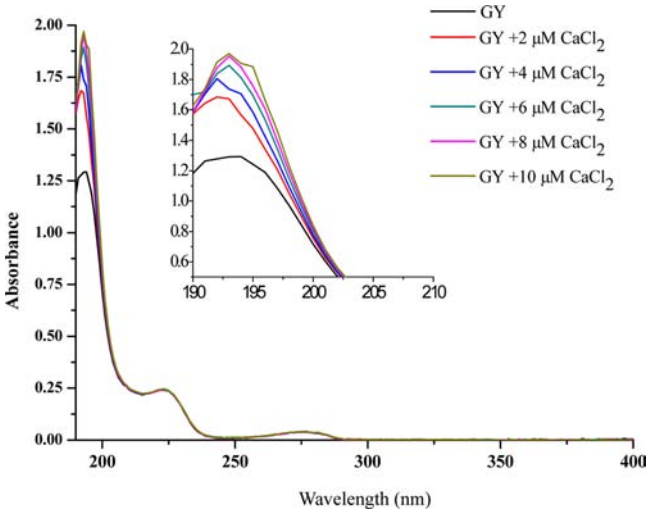

**Figure 7.** UV spectra of Gly-Tyr and Gly-Tyr−Ca chelate over the wavelength range from 190 to 400 nm.

carbonyl group and nitrogen of the amino group in the peptide bond with calcium.[32] The appearance of a small peak reflected the difference of relevant valence electron transition when more calcium ion reacted with Gly-Tyr. All of these band changes suggest that Gly-Tyr could bind with calcium ion and form the Gly-Tyr−Ca chelate.

*Fluorescence Spectra Analysis.* The purified calcium-binding dipeptide Gly-Tyr contained aromatic amino acid Tyr, which could generate endogenous fluorescent at a proper excitation wavelength. The fluorescence emission spectra of Gly-Tyr was examined to monitor its structural modification with $CaCl_2$ treatment. Through fluorescence quenching, the calcium binding sites could be speculated. The fluorescence spectra of Gly-Tyr and Gly-Tyr−Ca chelate are shown in Figure 8. When excited at 280 nm, Tyr in Gly-Tyr exhibited an intrinsic fluorescence emission maximum at 310 nm. With the increased calcium ion concentration, the endogenous fluorescence decreased dramatically, which meant that calcium ion had a significant effect on the Gly-Tyr structure. Especially, apparent folding and conformation modification of Gly-Tyr happened at the beginning of the addition with 5 $\mu$M $CaCl_2$.

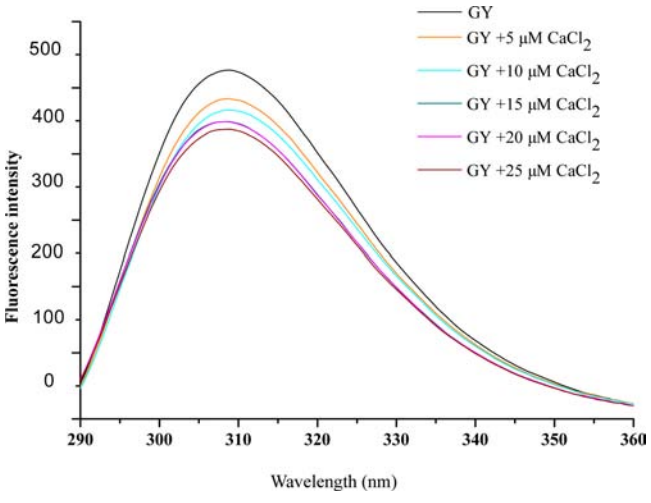

**Figure 8.** Fluorescence emission spectra of the peptide Gly-Tyr at various concentrations of $Ca^{2+}$.

This result is consistent with that of the iron-chelating peptides from anchovy (*Engraulis japonicus*) muscle protein.[29] Reddi et al.[33] demonstrated that the $Zn^{II}$ binding energy was used to fold the peptide in the zinc-binding reaction of a zinc-finger peptide. As the concentration of $CaCl_2$ increased, fluorescence quenching became weaker than before. It meant that there were not any spared binding sites in Gly-Tyr for the calcium ion. This experimental evidence suggested that the structure of functional binding sites in Gly-Tyr changed, resulting in the formation of the Gly-Tyr−Ca chelate when $CaCl_2$ reacted with Gly-Tyr. The addition of metal ion induced the intrinsic fluorescence quenching of protein or peptide, especially for the oligo-peptide without thermodynamic structure stability.[34] Generally, the calcium ion could cause fluorescence quenching of the calcium-binding peptide, which likely contributed to the decrease in the fluorescence intensity.[19]

*FTIR Measurement.* Changes in the characteristic FTIR absorption peaks of some functional binding sites in peptide could reflect the interaction of metal ion with organic ligand groups in the peptide. To analyze calcium-ion-induced changes in the structure of the calcium-binding peptide Gly-Tyr, the FTIR technique was employed.

Figure 9 depicted the infrared spectrum of Gly-Tyr in the absence and presence of calcium. There were significant

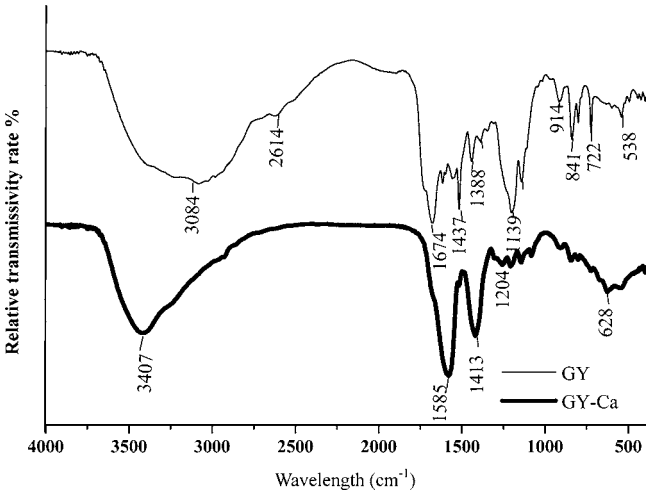

**Figure 9.** FTIR spectra of Gly-Tyr and Gly-Tyr−Ca chelate in the regions from 4000 to 400 $cm^{-1}$.

differences between Gly-Tyr and Gly-Tyr−Ca chelate. The results implied that the wavenumbers (1674 and 1437 $cm^{-1}$) of the amide I band were shifted to lower frequencies (1585 and 1413 $cm^{-1}$) after the addition of calcium, which stood for infrared absorption of the carbanyl group caused by the antisymmetric stretching vibration $\upsilon_{as}$ ($COO^-$) and the symmetric stretching vibration $\upsilon_s$ ($COO^-$) of carboxylic acid ions. Upon coordination with the Gly-Tyr−Ca chelate, the C bands corresponding to the carboxyl groups at 1204 and 1139 $cm^{-1}$ exhibited two weaker peaks in the fingerprint region. It is reported that ferric chloride could bind with casein enzymatic hydrolysates to form the $Fe^{3+}$−peptide complex, and the chief iron-binding site relates to the amide and carboxylate groups.[14] When metal ions combined with ligand atoms, such as O, N, and S, of organic compounds to form the chelate, the absorption peaks because of vibration of the coordinate bonds were typically located in the far-infrared region. The

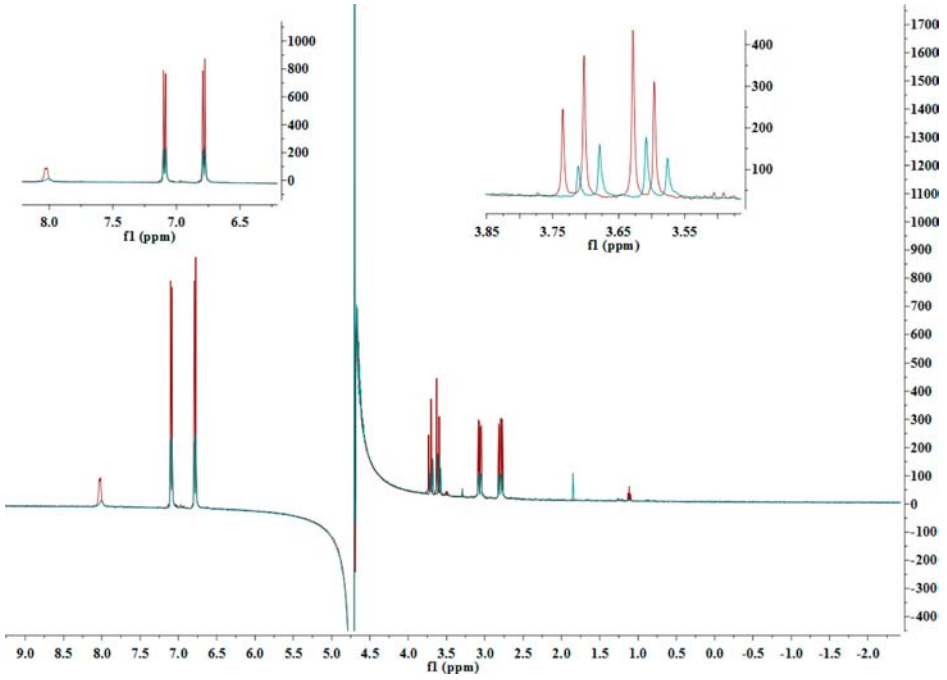

**Figure 10.** [1]H NMR spectral region from −0.30 to 10.00 ppm of Gly-Tyr and Gly-Tyr−Ca chelate (the red line means Gly-Tyr, and the green line means Gly-Tyr−Ca).

Ca−O vibration band was located between 500 and 800 $cm^{-1}$, while the interaction between the peptide and calcium ion resulted in a broadening and decreased intensity of the peaks; even some band absorptions disappeared, which was in agreement with the report by Chen et al.[18] Absorption of a high frequency at 3084 $cm^{-1}$ referred to the antisymmetric stretching vibration $\upsilon_{as}$ (N−H) and the symmetric stretching vibration $\upsilon_{s}$ (N−H) of the N−H bond in the Gly-Tyr spectrum. Absorption of a high frequency at 3200−3600 $cm^{-1}$ referred to the possible Ph−O-H strech and H bonds of hydration in the Gly-Tyr spectrum. With the coordination of the calcium−peptide complex, the waveform and the absorbance values had greatly changed. After the addition of calcium, the chelation reaction resulted in a shift to a higher wavenumber (3407 $cm^{-1}$), which indicated that the electron cloud density of N−H in Gly-Tyr became stronger because of the inductive effect or dipole field effect.

These phenomena indicated that the interaction between Gly-Tyr and calcium occurred via the carboxyl oxygen atoms and amino group nitrogen atoms in the peptide, which were similar to the calcium-binding peptides derived from soybean protein hydrolysates.[35]

*[1]H NMR Spectroscopy Assay.* The low-field region, from 6.75 to 8.00 ppm, of the Gly-Tyr and Gly-Tyr−Ca NMR spectrum (Figure 10) contained signals from aromatic group tyrosine (6.75 and 7.10 ppm) and N−H of the amide bond (8.00 ppm). The symmetric doublet in the region of 3.55−3.75 ppm corresponded to H spin coupling cracking in $\alpha$-H of Gly and Tyr. The signals at 3.00 and 2.75 ppm arose from two $\beta$-H atoms of tyrosine. With the addition of the calcium ion, the symmetric doublet signals of $\alpha$-H in Gly-Tyr shifted to lower parts per million (ppm) values, whose chemical shift was approximately 0.025 ppm. The change in hydrogen atom spin coupling cracking resonance signal peaks was caused by the combination of Gly-Tyr and calcium, thereby the electron density around the hydrogen nucleus in Gly-Tyr was affected.

The chemical shift information on [1]H NMR could explain the distribution of the electron cloud density around the hydrogen nucleus among different substances; consequently, the reaction situation between the purified calcium-binding dipeptide Gly-Tyr and calcium ion could be revealed. A declined electron cloud density along with a decreased shielding effect and intensive resonant frequency led to the movement of resonance signal peaks to a lower field region.

*TG−DSC Analysis.* The thermostability of samples was investigated through DSC and TG thermal analysis. There were remarkable differences of peak temperatures between dipeptide Gly-Tyr and Gly-Tyr−Ca chelate (Figure 11). The TG−DSC curve of Figure 11A showed that the thermal decomposition reaction of Gly-Tyr was not single in the whole process of weight loss. The thermal transitions at 179.40, 269.15, 359.99, and 530.51 °C were accompanied by weight loss of 25.74, 14.23, 15.15, and 14.32%, respectively. These endothermic peaks were caused by the C−N bond in Gly-Tyr. Whereas, obviously high shift endothermic peaks were observed at 428.77, 462.05, 504.07, and 550.93 °C after calcium ion treatment (Figure 11B). Meanwhile, TG of Gly-Tyr−Ca showed a flat and decline curve with a mass loss of 80%, which demonstrated that calcium-ion-processed Gly-Tyr resulted in a great increase in the DSC peak temperature accompanied by less and reduced weight loss, indicating that the Gly-Tyr−Ca chelate exhibited distinct thermal stability. This result suggested that Ca-processed dipeptide Gly-Tyr was less sensitive to heat denaturation with a higher peak temperature because of the formation of the Gly-Tyr−Ca chelate compound and the thermal stability of Gly-Tyr−Ca chelate was higher than that of Gly-Tyr alone.

*$\zeta$ Potential.* The principal of $\zeta$ potential was polarization of the water that occurred in the interface of two phases and then inducing that potential difference that existed in the phases. Figure 12 presented the $\zeta$ potential values of the Gly-Tyr−Ca chelate compared to Gly-Tyr without the calcium ion. The

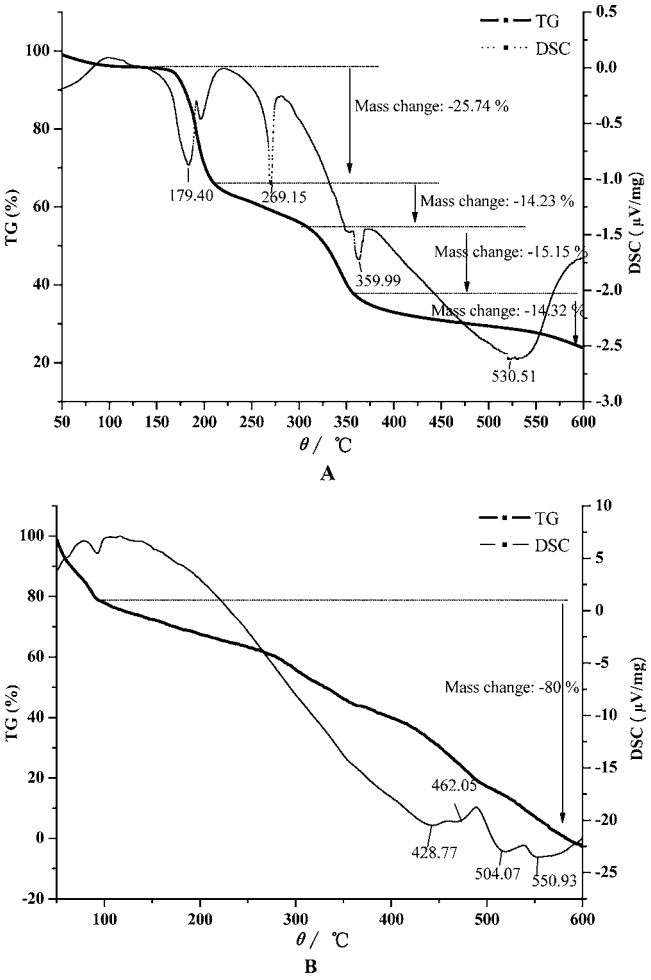

**Figure 11.** Typical DSC thermograms of (A) Gly-Tyr and (B) Gly-Tyr−Ca chelate.

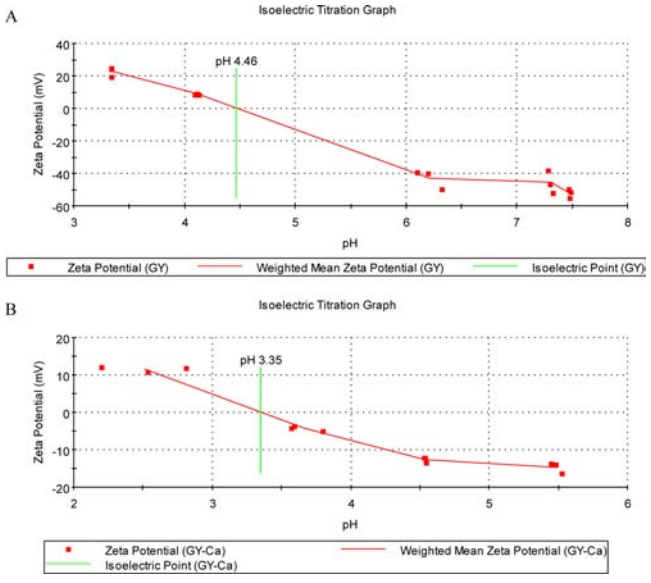

**Figure 12.** ζ potential of (A) Gly-Tyr and (B) Gly-Tyr−Ca chelate.

initial pH of Gly-Tyr in aqueous solution was measured to be 3.34 (Figure 12A). It meant that dipeptide Gly-Tyr in aqueous solution exhibited acid property. While in the Gly-Tyr−Ca chelate, the initial pH 5.45 approached neutral pH 7.0, which indicated that the addition of calcium improved the pH value of Gly-Tyr, inducing a weaker charge, and made it prone to be an neutral molecule (Figure 12B). Besides, the ζ potential ranged from positive charge (19.3 mV) to negative charge (−13.8 mV) when the calcium ion was added to dipeptide Gly-Tyr. Figure 12A also showed that the pI of Gly-Tyr was 4.46, while that of Gly-Tyr−Ca was 3.35. The pI decreased with the calcium ion treated on Gly-Tyr. In addition, the pH 3.34 of Gly-Tyr in aqueous solution was closer to its pI 4.46 than that of Gly-Tyr−Ca, which suggested that Gly-Tyr−Ca was more stable than Gly-Tyr alone. In the same pH value range, the changes of the ζ potential absolute value of Gly-Tyr−Ca were less than those of Gly-Tyr and Gly-Tyr−Ca possessed a lower ζ potential absolute value. The result indicated that Gly-Tyr−Ca existed as a molecular structure in aqueous solution without two different phases or double electrode layers. Through this experimental evidence, it could be speculated that the calcium ion was surrounded by the functional binding sites, such as the carboxyl and amino groups, of Gly-Tyr by a coordinate bond exhibiting an neutral molecule without being a form of inorganic calcium, to enhance its stability in the gastrointestinal tract.

*Calcium-Releasing Percentage Assay.* The calcium-releasing percentage of the Gly-Tyr−Ca chelate and $CaCl_2$ at different pH values is shown in Figure 13. The solubility

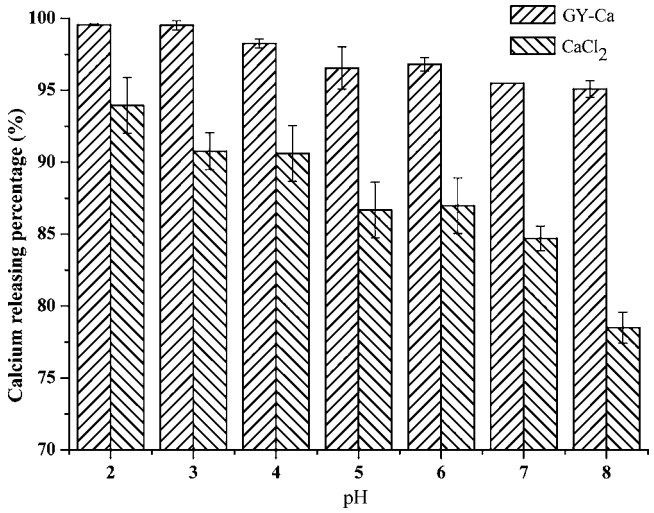

**Figure 13.** Calcium-releasing percentage of the Gly-Tyr−Ca chelate and $CaCl_2$ at pH values of 2.0, 3.0, 4.0, 5.0, 6.0, 7.0, and 8.0, separately.

between Gly-Tyr−Ca and $CaCl_2$ was apparently different. For both of them, the calcium-releasing percentage reduced with the increase of pH. While at any pH value, the calcium-releasing percentage of Gly-Tyr−Ca was obviously higher than that of $CaCl_2$. The calcium-releasing amount in the Gly-Tyr−Ca chelate was relatively stable in the pH that ranged from 2.0 to 8.0, maintaining above 95%, whereas that of $CaCl_2$ decreased significantly from 93.94% at pH 2.0 to 78.48% at pH 8.0. The result implied that calcium in Gly-Tyr−Ca had good solubility whether at pH 2.0 or 8.0, which was similar to the pH values of the human stomach or gastric environment; consequently, precipitation could not form.[36]

It is essential to discuss the dissolved status of the peptide−calcium chelate in the human gastrointestinal tract because the calcium ion probably reacted with phytic or oxalic acid to become insoluble in the stomach and form $Ca(OH)_2$ in the

dx.doi.org/10.1021/jf502412f | J. Agric. Food Chem. 2014, 62, 10274−10282

intestinal tract. The finding of our study suggested that the purified dipeptide Gly-Tyr contributed to improve the solubility of Ca under gastrointestinal tract pH values and was effectively absorbed by intestinal epithelial cells. The result suggests that it is feasible to produce natural calcium-chelating peptide as functional food additives.

*Hypothetical Molecular Structural Formula of the Gly-Tyr−Ca Chelate.* According to the results of frontal structural characterizations, including UV absorption spectroscopy, FTIR, fluorescence spectra, and $^1$H NMR spectroscopy, the functional binding sites of Gly-Tyr contained an oxygen atom of the carbonyl group and nitrogen of the amino or imino group in the peptide bond. Futhermore, the $\zeta$ potential experiment indicated that the calcium ion was surrounded by these functional binding bonds in Gly-Tyr through a coordinate bond. Therefore, the molecular structural formula of the Gly-Tyr−Ca chelate was speculated in Figure 14.

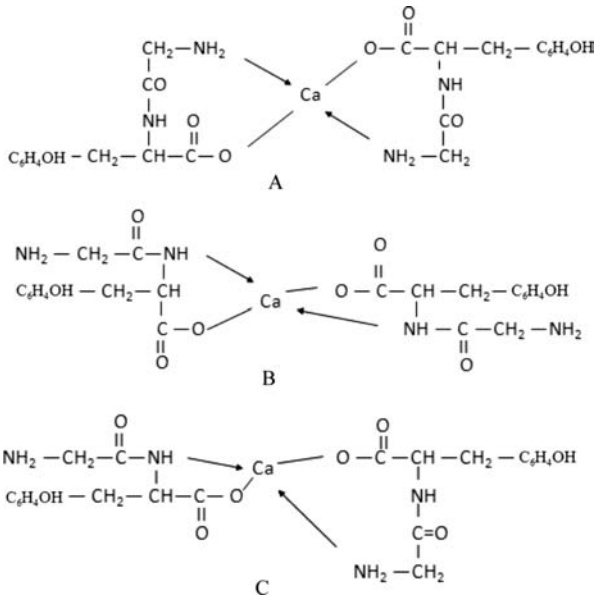

**Figure 14.** Hypothetical molecular structural formula of the Gly-Tyr−Ca chelate.

the chemical composition, instrumental taste profile measured by an electronic tongue, and antioxidant and metal chelating activities of mixtures of green, yellow, and red teas. Furthermore, a simultaneous optimization of the tea mixture was carried out to render the best combination of teas with maximized in vitro antioxidant activities as well as instrumental taste profile.

## MATERIAL AND METHODS

**Chemicals.** Gallic acid, (−)-epicatechin, (+)-catechin, chlorogenic acid, caffeine, epigallocatechin gallate, Folin−Ciocalteu reagent, 6-hydroxy-2,5,7,8-tetramethylchroman-2-carboxylic acid (Trolox), 2,4,6-tripyridyl-*s*-triazine (TPTZ), ferrozine (3-(2-pyridyl)-5,6-di(2-furyl)-1,2,4-triazine-5′,5″-disulfonic acid disodium salt), 2,2-diphenyl-1-picrylhydrazyl (DPPH), neocuproine (2,9-dimethyl-1,10-phenanthroline), sodium molybdate dihydrate, and pyrocatechol violet (3,3′,4′-trihydroxyfuchsone-2″-sulfonic acid) were purchased from Sigma-Aldrich (Zwijndrecht, The Netherlands). Procyanidin primer A2 was obtained from Extrasynthese (Genay, France). Butanol, ammonium acetate, copper(II) chloride, copper sulfate pentahydrate, hydrochloric acid, methanol, phosphoric acid, ethanol, acetic acid, aluminum chloride hexahydrate, sodium acetate anhydrous, iron(II) chloride tetrahydrate, iron(II) sulfate heptahydrate, and sodium carbonate were purchased from Merck (Darmstadt, Germany).

**Tea Samples.** Authentic dried leaves of red, green, and yellow teas, all from *C. sinensis* var. *sinensis*, cultivated and manufactured in China, were kindly donated by Herbaflora (São Paulo, Brazil). The particle sizes of samples were between 20 and 40 mesh. A certificate of botanical authenticity of these vegetable materials can be obtained directly from the producer and authors.

**Experimental Design and Tea Preparation.** To assess the effects of binary and ternary mixtures of green, yellow, and red teas on chemical composition, instrumental taste profile, and antioxidant/metal chelating activities, a three-component simplex-centroid mixture design composed of 10 experimental assays was employed, in which the independent variables (factors) were green, yellow, and red teas. All batches of tea infusions were prepared according to the mixture design layout presented in Table 1. The sequence of experiments was performed randomly.

To prepare the tea samples, tea leaves were ground using a pestle and mortar to obtain a homogeneous fine powder. Then, each tea infusion was prepared by pouring 100 mL of ultrapure water at 80 °C on a flask containing 2.0 g of leaves and brewed for 8.5 min under magnetic stirring and covered with a lid. Brewed tea samples were then filtered through Whatman no. 1 qualitative paper and centrifuged for 10 min at 2000 rpm, and the supernatant was aliquoted into eppendorfs and stored at −25 °C until analysis. Part of each infusion ($v$ = 70 mL) was allowed to cool until 25 °C, and teas were immediately used for assessing the instrumental taste profile.

**Instrumental Taste Profile (e-Tongue).** The instrumental taste profile of tea samples was assessed by measuring the sourness, bitterness, umami, richness (aftertaste umami), astringency, saltiness, and the aftertaste due to astringency using a commercial taste sensing system (model SA402B, Intelligent Sensor Technology Inc., Atsugi-shi, Japan). Artificial lipid-based membranes (similar to that of the human tongue) that detect the signs via potential measurements were used in the measurements. The taste sensor unit approximates and translates molecular information into simple and understandable human information (taste quality traits). Briefly, an aliquot of about 30 mL of each sample was placed in 50 mL plastic glasses for electronic tongue (e-tongue) detection, and analyses were conducted at 20 °C. The measuring time was set to 30 s for each sample, and the sensors were rinsed lightly for 6 s using a standard solution (30 mM KCl + 0.30 mM tartaric acid; conductivity between 4.0 and 4.2 mS/cm and pH in the range of 3.5−3.6) to measure the aftertaste. After that, sensors were rinsed in an alcoholic solution (28.5 mL/100 mL ethanol) for 90 s to remove adsorbed compounds from the lipid membrane, and sensors were again rinsed in the cleaning solution (30 mM KCl + 0.30 mM tartaric acid) for another 240 s to remove the

alcohol and re-establish the sensors. The rinsing procedure is important to reach stable potential readings before analysis of the next sample. A total of four replicated measurements were run on each sample, whereas the first cycle was discarded due to instability, and the other three responses were averaged. The sensor outputs of the samples (electric potential) were converted into taste intensity values on a scale where one unit is the sensor output difference corresponding to a 20% concentration difference in the standard substance solution.[15] In the current research, these taste intensities are designated estimated intensity of taste (EIT) values.

**Chemical Composition.** The Folin−Ciocalteu reducing power (total phenolic compounds) of teas was assessed in triplicate using the method proposed by Singleton and Rossi[16] with modifications. For this purpose, a standard curve of gallic acid (0−150 mg/L) was built, and absorbance was read at $\lambda$ = 725 nm. Results were expressed as milligrams of gallic acid equivalents per liter of tea (mg GAE/L).

The content of flavan-3-ols (tannins) of teas was assessed in triplicate by oxidative depolymerization in HCl/*n*-butanol at 90 °C for 20 min.[17] A calibration curve was built using procyanidin primer A2 (0−125 mg/L), and absorbance was read at $\lambda$ = 540 nm. The results were expressed as milligrams of procyanidin primer A2 equivalents per liter of tea (mg PCY/L).

The *o*-diphenols content was estimated by using the sodium molybdate method,[18] with modifications to microplates. Briefly, a 50 $\mu$L aliquot of tea (1:5) was mixed with 200 $\mu$L of a 5 g/100 mL sodium molybdate dihydrate solution (ethanol in water at a proportion of 1:1 v/v) and allowed to react for 25 min. The absorbance was recorded at $\lambda$ = 370 nm against a blank (EtOH/water 1:1 v/v). A standard curve of chlorogenic acid (0−160 mg/L) was plotted, and results were expressed as milligrams of chlorogenic acid equivalents per liter of tea (mg CAE/L).

Gallic acid, (+)-catechin, caffeine, (−)-epicatechin, chlorogenic acid, and epigallocatechin gallate (EGCG) were quantified by high-performance liquid chromatography by means of a chromatograph (HPLC) coupled with a diode array detector (DAD) from Agilent Technologies 1100 series equipment containing a quaternary pump and an automated injector. The chromatographic separation was carried out on a Luna $C_{18}$ column (250 × 4.6 mm, 5 $\mu$m; Phenomenex, Torrance, CA, USA) maintained at 35 °C. The DAD was set up at 210 nm for all compounds except for chlorogenic acid that was monitored at 320 nm. A volume of 20 $\mu$L was injected after filtration of tea using a 0.45 $\mu$m pore size polyvinylidene difluoride membrane (Millipore, Tullagreen, Ireland). The mobile phase was composed of solvent A (acetonitrile) and solvent B (0.05% v/v phosphoric acid solution) with a gradient program as follows: 0−8 min, linear gradient 5−8% A; 8−28 min, linear gradient 8−10% A; 28−40 min, 10% A isocratic elution; 40−55 min, linear gradient 10−14% A; 55−80 min, linear gradient 14−24% A; and 80−90 min, 24% A isocratic elution at a flow rate of 1 mL/min, as described elsewhere.[10] The quantification of each compound was performed by comparing the peak area with calibration curves ($n$ = 5 evenly spaced concentrations) of chemical standards. The limit of detection (LOD) and limit of quantification (LOQ) were calculated as the concentration giving signals equal to 3 and 10 times, respectively, the signal-to-noise ratio. The regression parameters, retention time, LOD, and LOQ of all compounds measured are presented in Table 1 of the Supporting Information, and typical chromatograms of standards are presented in Figure 1 of the Supporting Information.

**Antioxidant and Metal Chelation Activities.** The cupric reducing antioxidant activity (CUPRAC) of teas measures the ability of an extract to reduce substances by electron transfer, at a physiological pH. CUPRAC was evaluated in triplicate by the colorimetric method employing neocuproine as outlined by Apak et al.[19] Trolox standard solutions were prepared at a concentration ranging from 90 to 3000 $\mu$mol/L, and absorbance was read at $\lambda$ = 450 nm. The results were expressed as millimoles of trolox equivalents per liter of tea (mmol TE/L).

The ferric reducing antioxidant power (FRAP) of teas is a direct test that measures the total antioxidant levels in a given sample as no activity-changing interactions between antioxidants occur in the system. FRAP was measured four times according to the method by Benzie and Strains,[20] with modifications to microplates. An aliquot of 300 $\mu$L of the freshly prepared FRAP reagent and 10 $\mu$L of diluted tea (1:25) were added to each well, and the absorbance was recorded at $\lambda$ = 593 nm after 30 min of reaction. The FRAP reagent was prepared by mixing sodium acetate buffer (300 mM, pH 3.6), a solution of TPTZ (10 mM) in 40 mM HCl, and 20 mM $FeCl_3{\cdot}6H_2O$ using the proportion 10:1:1 (v/v/v). A standard curve of trolox (100−1000 $\mu$mol/L) was plotted to quantify the reducing power of teas. The results were expressed in millimoles of trolox equivalents per liter (mmol TE/L).

The free radical scavenging activity toward 2, 2-diphenyl-1-picrylhydrazyl (DPPH) of each tea measures the sequential proton loss electron transfer from the antioxidants to the DPPH radical. DPPH was performed four times according to a method reported elsewhere,[21] with modifications to microplates. An aliquot of 5 $\mu$L of dilute tea (1:11) or methanol (blank) was mixed with 195 $\mu$L of a 125 $\mu$mol/L methanolic solution of DPPH and left to react for 30 min at room temperature, and the absorbance was read at $\lambda$ = 517 nm. The antioxidant activity (% of inhibition) was calculated as $[1 - (A_{517}\ \text{sample}/A_{517}\ \text{blank})] \times 100$.

Ferrous ion chelating ability was determined in triplicate by measuring the formation of the $Fe^{2+}$−ferrozine complex according to the method proposed by Carter,[22] with modifications to microplates. For this purpose, to an aliquot of 50 $\mu$L of diluted tea (1:5), 160 $\mu$L of ultrapure water and 15 $\mu$L of a 0.30 mM $FeCl_2{\cdot}4H_2O$ solution were added in a microtiter plate. After 5 min of incubation, the reaction was initiated by adding 30 $\mu$L of a 0.80 mM ferrozine solution, and the final mixture was incubated for 15 min at room temperature. Distilled water (30 $\mu$L) instead of ferrozine solution was used as a blank, which was used to correct for unequal color of the sample solutions. The formed magenta complex was measured at $\lambda$ = 562 nm. Water was used as a negative control. The percentage of $Fe^{2+}$−ferrozine complex formation was calculated as $Fe^{2+}$ chelating rate (%) = $[1 - (\text{Abs}_{\text{sample}} - A_{\text{solution without ferrozine}})/A_{\text{control}}] \times 100$.

Copper ion-chelating activity of tea mixtures was determined using a previous method.[23] Briefly, an aliquot of 200 $\mu$L of sodium acetate buffer at 50 mM, pH 5.7, was mixed with 8.5 $\mu$L of a 2 mM pyrocatechol violet solution and 25 $\mu$L of a 0.1 mg/mL (w/v) $CuSo_4{\cdot}5H_2O$ solution and 30 $\mu$L of diluted tea (1:5) or water (blank). The 96 wells were shaken for 15 s and allowed to react for 20 min at room temperature. Then, absorbance at $\lambda$ = 632 nm was measured using a microplate reader (Synergy-BIOTEK, Winooski, VT, USA). The percentage of inhibition of pyrocatechol violet−$Cu^{2+}$ complex formation was calculated as $Cu^{2+}$ chelating activity (%) = $[(\text{Abs}_{\text{control}} - \text{Abs}_{\text{sample}})/\text{Abs}_{\text{control}}] \times 100$.

**Statistical Analysis and Response Surface Methodology.** Data are presented as means and standard deviations. To apply RSM, significant statistical differences were investigated by one-way analysis of variances (ANOVA) for parametric and homoscedastic data or Welch-ANOVA for parametric nonhomoscedastic data. For this purpose, normality of data was checked by Shapiro−Wilk's test and homoscedasticity was tested by Brown−Forsythe's test. When data did not conform to a normal distribution, results were transformed using the Box−Cox approach. Differences among means were analyzed by Duncan's multiple-comparison test taking on $p < 0.05$. Linear correlation analysis was performed to verify the degree of association between responses, and regression analysis, based on the ordinary least-squares regression, was applied to some of the responses to explain the correlation through a mathematical function.[24] The instrumental taste profile and the chemical compounds quantified by HPLC and UV−vis spectrophotometry were also correlated by using principal component analysis aiming at a more comprehensive and broader understanding of experimental data.[25]

When differences among tea samples were verified by one-way ANOVA ($p < 0.05$), RSM was applied to model the analytical measurements as a function of the factors (tea types).[26] The regression model equation of three-component mixtures to estimate the coefficients is presented in eq 1

[a]Different letters in the same column represent statistically different results according to Duncan's multiple-comparison test ($p < 0.05$). [b]Aftertaste due to astringency.

$$Y = b_1x_1 + b_2x_2 + b_3x_3 + b_{12}x_1x_2 + b_{13}x_1x_3 + b_{23}x_2x_3 + b_{123}x_1x_2x_3 \quad (1)$$

where $Y$ is the predicted response; $b_1$, $b_2$, and $b_3$ are the regression coefficients for linear effects; $b_{12}$, $b_{13}$, and $b_{23}$ represent the binary interaction coefficients; and $b_{123}$ is the ternary regression coefficient. In the same sense, $x_1$, $x_2$, and $x_3$ represent the fractions of green, red, and yellow teas, respectively.

The analysis of variance of the above equation was calculated, and the effects and regression coefficients of individual linear, quadratic, and cubic terms were determined. Nonsignificant regression coefficients ($p < 0.10$) were discarded, and data were refitted to obtain the final model for each parameter. Then, the regression coefficients were used to generate two-dimensional contour plots for each response variable. The adequacy and goodness of fitting were assessed by calculating the coefficient of determination ($R^2$) and adjusted $R^2$.[27] For all regression models, the residuals plots were examined for obvious patterns (predicted vs experimental data) and formally tested for normality using Shapiro−Wilk's test.

After modeling of the responses, the following variables were used to optimize the extraction of antioxidants and instrumental taste profile of the *C. sinensis* tea mixtures: the main objective was to maximize the CUPRAC, iron-chelating activity, and DPPH activities and the flavan-3-ols content and to balance the instrumental bitterness of the tea, about which consumers often complain. For this purpose, the desirability function proposed by Derringer and Suich[28] was employed, and the $d$ value, which is a measure of how much the proposed formulation conforms to the main objective of optimization, was obtained. All statistical analysis was performed by Action v. 2.6 (Statcamp, Brazil) and Statistica v. 7 (StatSoft, Tulsa, OK, USA) software.

## RESULTS AND DISCUSSION

**Chemical Composition, Instrumental Taste Profile, and Antioxidant/Metal Chelating Activities.** The chemical composition data are listed in Table 1, whereas the antioxidant/metal chelating activities and the instrumental taste profile of tea mixtures are presented in Tables 2, and 3, respectively. The contents of flavan-3-ols and total phenolic substances varied from 104.46 to 154.59 mg/L (median = 138.46 mg/L) and from 374.11 to 668.49 mg/L (median = 545.47 mg/L), whereas the content of *o*-diphenols varied from 336.11 to 586.27 mg/L (median = 463.01 mg/L). The antioxidant activity presented a higher variation: although DPPH data were comprehended between 22.93 and 56.40% inhibition (median = 43.45% inhibition), FRAP and CUPRAC were in the ranges of 5.55−11.42 mmol TE/L (median = 9.16 mmol TE/L) and 10.16−25.02 mmol TE/L (median =15.39 mmol TE/L). The

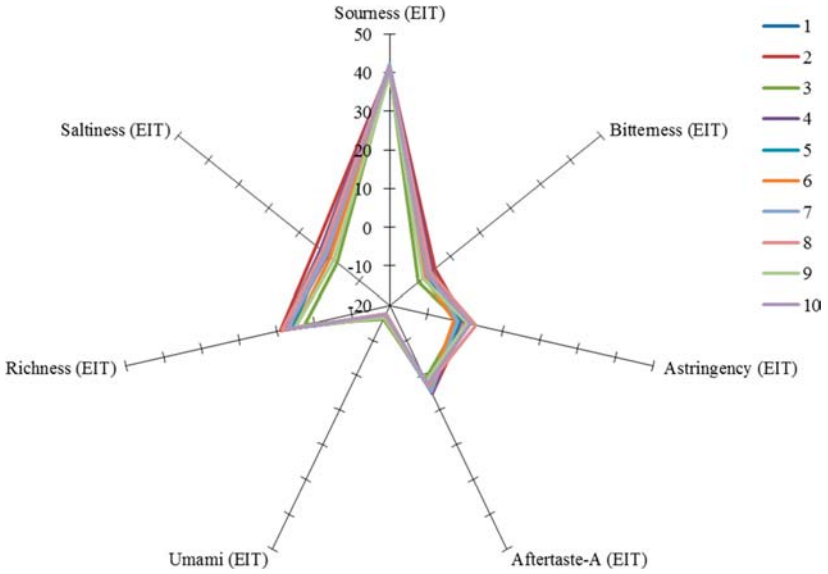

**Figure 1.** Instrumental taste profile of *Camellia sinensis* teas obtained by an electronic tongue. See Table 1 for sample codes.

iron chelating activity ranged from 28.68 to 41.93% of complex formation (median = 36.13% of complex formation), and copper chelating activity ranged from 43.27 to 55.39% inhibition (median = 52.10% inhibition). Overall, when Duncan's multiple comparison of means was performed, red tea presented the highest content of total phenolic compounds, caffeine, and gallic acid, the lowest content of chlorogenic acid, (+)-catechin, (−)-epicatechin, and epigallocatechin gallate, and the highest antioxidant power as measured by FRAP, CUPRAC, DPPH, and copper chelating activity. Green tea presented the highest content of flavan-3-ols, (+)-catechin, and (−)-epicatechin and the lowest caffeine content (Tables 1 and 2). On the other hand, yellow tea presented higher levels of epigallocatechin gallate and *o*-diphenols, the lowest levels of flavan-3-ols and total phenolic compounds, and intermediate levels of other phenolic compounds as measured by HPLC. All of these results are in accordance with those obtained by Zhang et al.[10,11] Likewise, Wang et al.[29] evaluated 87 *C. sinensis* teas marketed in China and verified that the (+)-catechin, epigallocatechin gallate, and (−)-epicatechin contents decreased in the following order: green tea > oolong tea > white tea > black tea. The results observed in the current study corroborate the idea that fermentation and oxidation processes used to manufacture different types of teas lead to a decrease in the content of catechin components.

With regard to the chemical composition and antioxidant effects of *C. sinensis* teas, many studies have shown contradictory results: Some authors state that green tea presents the best chemical profile and antioxidant power as compared to other *C. sinensis* teas. Fernàndez et al.[30] verified that the content of catechins in nonfermented *C. sinensis* teas (green and white) is higher than in fermented teas (black, oolong, red). Likewise, Karori et al.[31] concluded that the antioxidant activities of green and white teas, measured by the DPPH assay, are comparable and higher than the values observed for black tea. Carloni et al.[14] evaluated the phenolic compounds and antioxidant activity (ABTS, ORAC, LDL-oxidation) and iron chelating activity of white, black, and green teas and verified that green tea presented the highest antioxidant power and lowest iron-chelating activity. Conversely, in our study, green tea also presented the lowest inhibition of pyrocatechol violet−$Cu^{2+}$ complex formation and the highest percentage of $Fe^{2+}$−ferrozine complex formation. Once no phenolic compound was correlated with copper and iron chelating activities, it is hypothesized that the presence of compounds that present hydroxyl and carbonyl functions may play a role in copper ion chelating activity rather than only phenolic compounds.[14]

The taste of teas is the most important sensory factor for assessing their quality, and although it is common practice to evaluate the taste profile and acceptance by means of a taste panel (trained or not), the use of electronic tongues is advantageous over human responses as their use eliminates the subjectivity and individual preferences. In this regard, red tea presented the highest instrumental bitterness, aftertaste due to astringency, saltiness, and richness (umami aftertaste), whereas yellow tea showed the opposite behavior (Figure 1 and Table 3). Indeed, bitterness, aftertaste, and astringency are limitation factors of tea consumption in Western countries. Binary and ternary mixtures of *C. sinensis* teas presented higher astringency and sourness as compared to green, red, or yellow teas alone (Table 3). Astringency is a tactile sensation perceived as drying of the epithelium of the oral cavity due to the content of tannins (flavan-3-ols) and other phenolic compounds in the matrix. Sourness, which is related to the content of acidic compounds in tea, presented statistical differences among teas, but a low variation was observed. Herein, sourness was correlated to the total content of flavan-3-ols ($r$ = 0.669, $p$ = 0.034). According to Kim et al.,[32] the teas are available in many different fermentation levels for consumption ranging from green to black, and during the oxidative process the flavan-3-ols are transformed to theaflavin, thearubigin, and other high molecular mass pigments; decreased bitterness, astringency, and flavor are derived during the fermentation process.

**Correlation Analysis.** When multiple analytical variables are analyzed, it is often interesting to analyze how they are interconnected with each other. From a chemical standpoint, the correlation between sensory properties and chemical composition with antioxidant and metal chelating activity can be used by food companies to develop potentially functional products as well as to monitor the quality of *C. sinensis* teas. In the current study, Pearson's correlation coefficient was used to express the degree of association between variables, and results

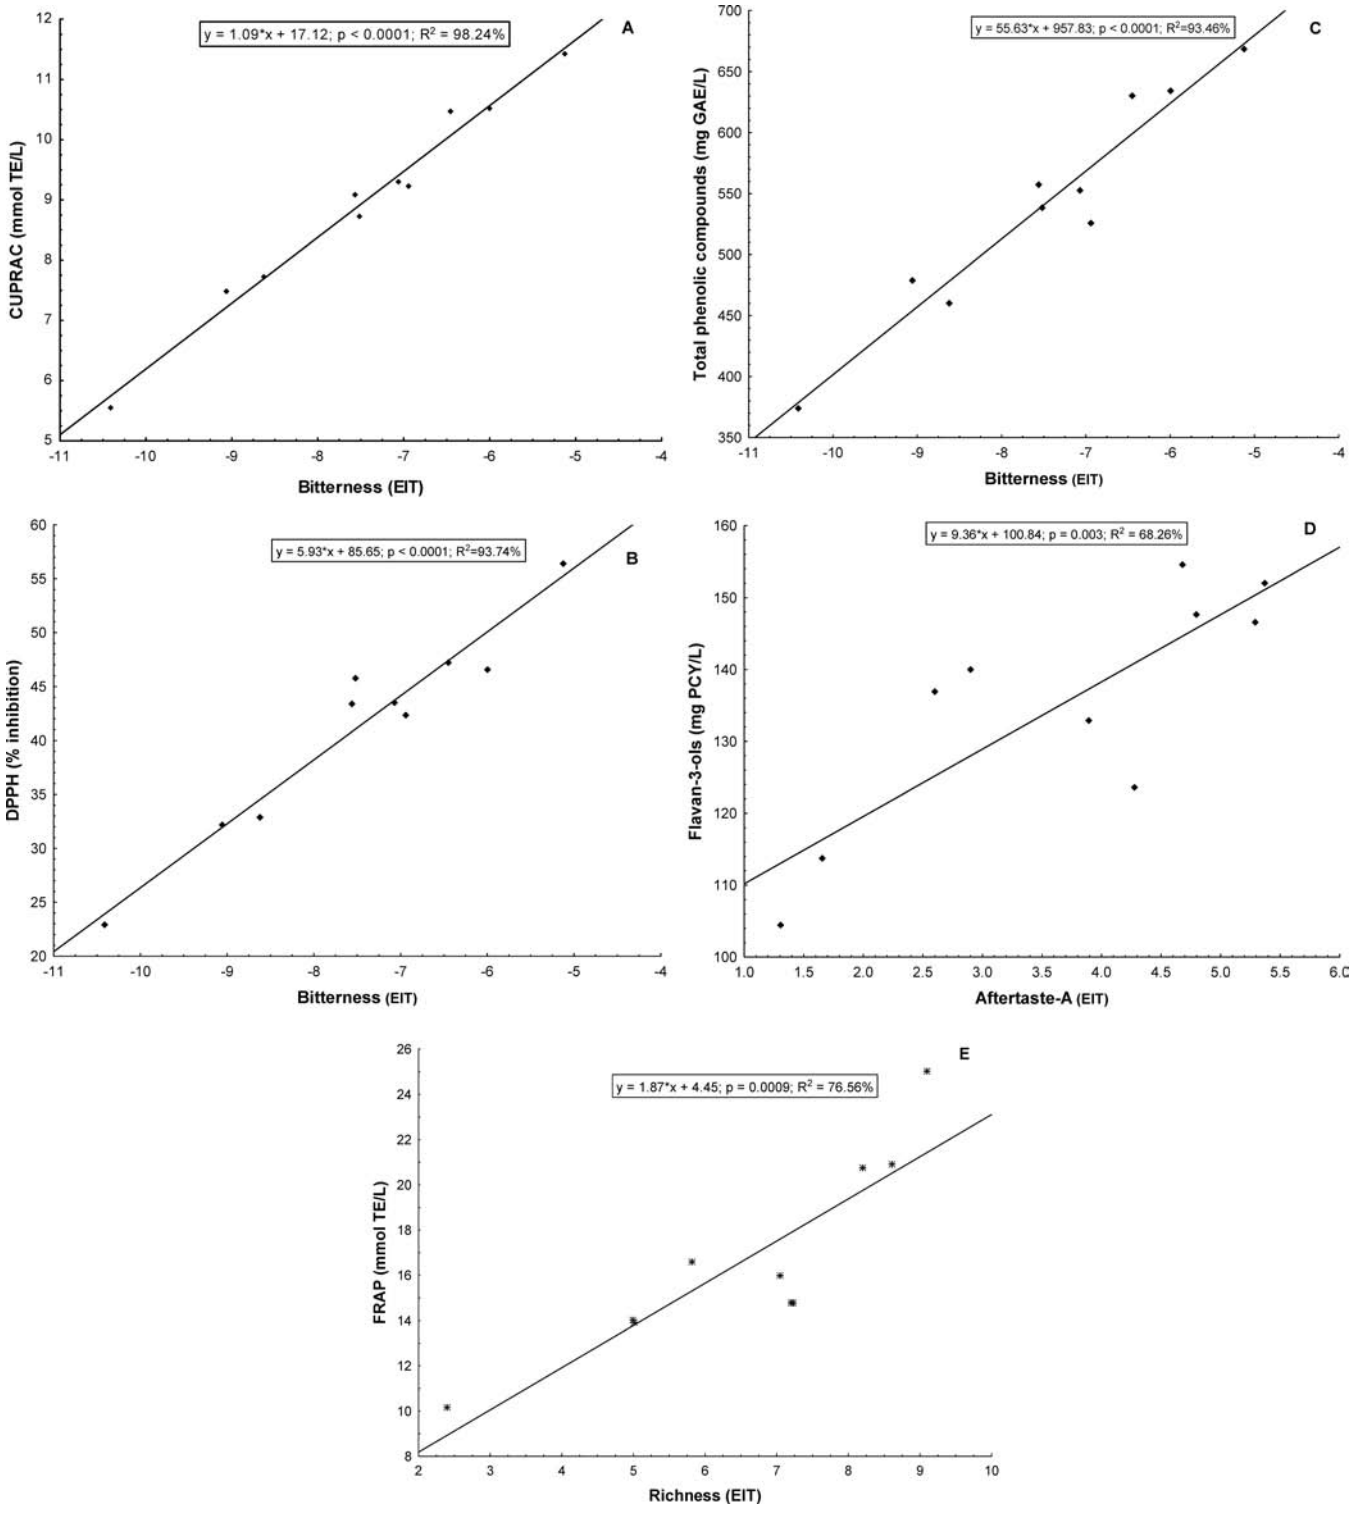

**Figure 2.** Regression analysis coupled to analysis of variances to explain the relationship between bitterness and CUPRAC (A), between bitterness and DPPH (B), between bitterness and total phenolic compounds (C), between aftertaste due to astringency and flavan-3-ols content (D), and between richness and FRAP (E) of *C. sinensis* teas.

showed that CUPRAC, DPPH, and FRAP were significantly ($p < 0.05$) correlated to the content of flavan-3-ols ($r = 0.829$, $r = 0.747$, $r = 0.613$), total phenolic compounds ($r = 0.989$, $r = 0.955$, $r = 0.944$), bitterness ($r = 0.991$, $r = 0.968$, $r = 0.915$), aftertaste due to astringency ($r = 0.732$, $r = 0.735$, $r = 0.636$), richness ($r = 0.988$, $r = 0.936$, $r = 0.875$), and saltiness ($r = 0.960$, $r = 0.971$, $r = 0.937$). In the same sense, iron chelating activity was correlated to the content of flavan-3-ols ($r = 0.747$, $p = 0.013$), total phenolic compounds ($r = 0.724$, $p = 0.018$), bitterness ($r = 0.737$, $p = 0.015$), richness ($r = 0.750$, $p = 0.012$), and saltiness ($r = 0.642$, $p = 0.045$). It is important to note this is the first report in the literature that correlates the intensity of instrumental taste attributes with chemical

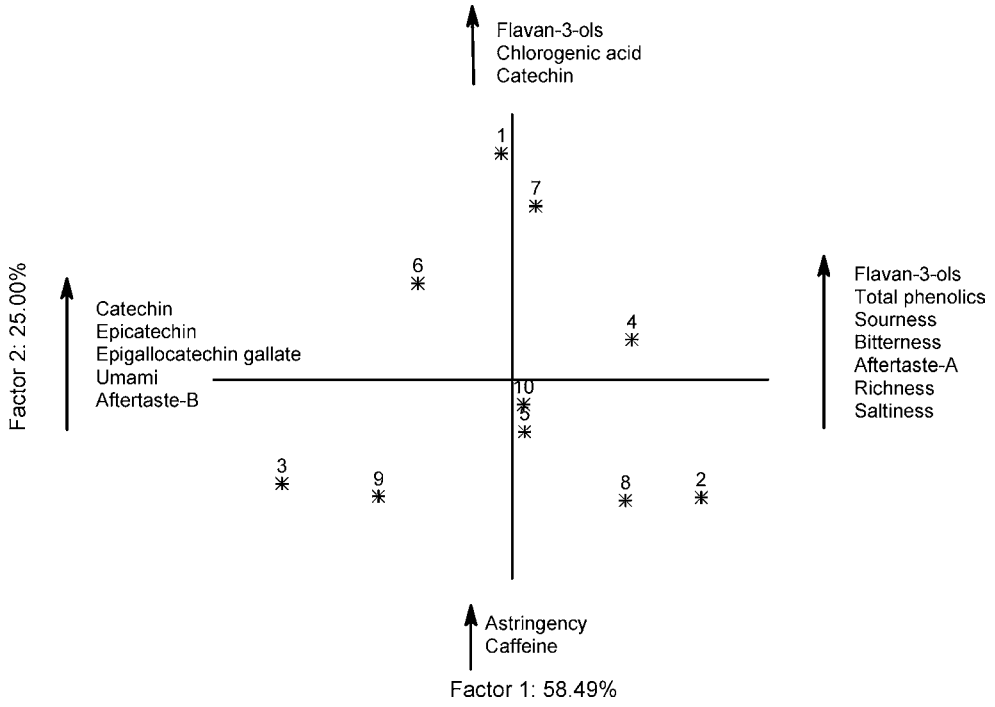

**Figure 3.** Principal component analysis showing the correlation between instrumental taste profile and chemical composition of mixtures of green, red, and yellow teas. See Table 1 for sample codes.

composition and antioxidant activity of *C. sinensis* tea mixtures (Figure 2).

Although green and yellow teas undergo very similar technological production operations, the flavan-3-ols, total phenolic compounds, and *o*-diphenols varied significantly between them. From a chemical standpoint, red tea (fully oxidized and partially fermented) presented the lowest *o*-diphenols content besides having the highest total phenolic compounds, whereas yellow tea (less processed as compared to red teas) had the highest *o*-diphenols content besides presenting the lowest total phenolic compounds content, corroborating the results obtained by Cabrera et al.[33] Indeed, it is plausible that the during fermentation of leaves, mono-, di-, and some trihydroxy phenolic compounds are either polymerized or oxidized to theaflavins and thearubigins and, therefore, the higher the oxidation and fermentation time that *C. sinensis* leaves undergo, the lower the *o*-diphenols content is. This trend can also be observed by linear correlation analysis: total phenolic compounds were inversely correlated to *o*-diphenols ($r = -0.884$, $p < 0.001$) and by the lower concentration of gallic acid in red tea (Table 2). In addition, it is known that total phenolic compounds and, specifically, *o*-diphenols display a high and significant correlation with in vitro antioxidant activity assays in many food and beverage matrices. The total phenolic compounds content was higher in fermented and fully oxidized tea (red tea), with consequently lower *o*-diphenols content, and a significant and strong correlation was observed between *o*-diphenols and DPPH ($r = -0.877$, $p = 0.001$), FRAP ($r = -0.858$, $p = 0.001$), and CUPRAC ($r = -0.835$, $p = 0.003$), whereas a low-intensity and nonsignificant correlation was observed with copper chelating activity ($r = -0.342$, $p = 0.334$) and iron chelating activity ($r = -0.516$, $p = 0.126$). These results indicate that *o*-diphenols alone do not play an important role in chelating transition metal ions, and perhaps interactions among all reducing materials are responsible for the metal chelating effect of tea.

With regard to the individual phenolic compounds measured by HPLC, correlation analysis revealed that chlorogenic acid was correlated to copper chelating activity ($r = 0.617$, $p = 0.050$), whereas gallic acid was not correlated to any antioxidant activity assay. Similarly to what was observed for *o*-diphenols, red tea (fully oxidized and fermented) presented the lowest content of chlorogenic acid, (+)-catechin, (−)-epicatechin, and epigallocatechin, and an inverse correlation was observed for these compounds and the antioxidant activity: (+)-catechin versus CUPRAC ($r = -0.548$), DPPH ($r = -0.618$), and FRAP ($r = -0.741$); (−)-epicatechin versus CUPRAC ($r = -0.573$), DPPH ($r = -0.583$), and FRAP ($r = -0.792$); and epigallocatechin gallate versus CUPRAC ($r = -0.876$), DPPH ($r = -0.908$), iron chelating activity ($r = -0.676$), and FRAP ($r = -0.852$). These results also clearly indicated that the oxidation and fermentation processes that *C. sinensis* undergo influence the antioxidant power of teas. Additionally, future works should focus on the quantification of theaflavins and thearubigins and how these substances (alone and in combination to other phenolic compounds) affect the bioactivity of tea mixtures. Our data corroborate the findings of Cao et al.,[34] who concluded that phenolic compounds with higher numbers of −OH substitutions on the B ring display considerably more effectiveness against free radicals and by binding transition metals, which means that epigallocatechin gallate presents a higher antioxidant power as compared to (+)-catechin and (−)-epicatechin. In the same way, Zhang et al.[10] analyzed different *C. sinensis* teas (white, oolong, and green teas) and verified that epigallocatechin gallate contributed between 67 and 79% of the total antioxidant activity as measured by the DPPH assay.

To facilitate the interpretation of correlation analysis between phenolic composition determined by HPLC, UV−vis

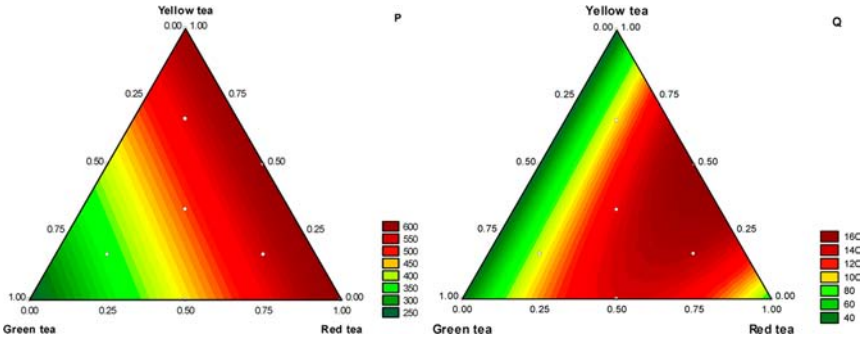

**Figure 4.** Response surface plots to show the effects of green, red, and yellow teas on the content of flavan-3-ols (mg PCY/L) (A), cupric ion reducing antioxidant power (mmol TE/L) (B), total phenolic compounds (mg GAE/L) (C), free radical scavenging activity toward DPPH (% inhibition) (D), ferric reducing antioxidant power (mmol TE/L) (E), bitterness (EIT) (F), aftertaste due to astringency (EIT) (G), umami (EIT) (H), richness (EIT) (I), saltiness (EIT) (J), *o*-diphenols (mg CAE/L) (K), chlorogenic acid (L), (+)-catechin (M), (−)-epicatechin (N), epigallocatechin gallate (O), caffeine (P), and gallic acid (Q) of *C. sinensis* tea mixtures.

spectrophotometry, and instrumental taste profile, a two-dimensional projection of samples was made using principal component analysis, and results are presented in Figure 3. Data showed that samples 2 (red tea), 3 (yellow tea), 8 (67% red + 17% green + 17% yellow), and 9 (17% red + 17% green + 67% yellow) presented the highest EIT for astringency, whereas samples 3, 6 (50% green + 50% yellow), and 9, which presented the highest content of (+)-catechin, (−)-epicatechin, and epigallocatechin gallate, had the highest EIT values for umami and aftertaste due to bitterness. Samples 2, 4 (50% red + 50% green), and 8, which have the highest values of flavan-3-ols and total phenolic materials, seemed to be more sour, bitter, rich, and salty and had a stronger aftertaste due to astringency as compared to the other teas. This two-dimensional projection (principal component 1 vs principal component 2) explained up to 83.5% of data variability.

**Response Surface Methodology and Optimization.** The effects of green, red, and yellow teas and their binary and ternary mixtures on chemical composition, objective taste profile, and antioxidant and metal chelation activities of teas as well as the mathematical models obtained by RSM and the statistical parameters of such models are presented in Figure 4 and Table 4. Astringency and sourness could not be modeled using RSM as the $R^2$ values (parameter that indicates how well experimental data fit a statistical model) were much lower than 30% (data not shown) and no significant effect of factors was observed, which means that the cubic model was not effective in representing the experimental data suitably.

It is possible to observe that there was a significant ($p < 0.05$) effect of each type of tea on all response variables measured in the study. However, binary mixtures of either green/red, green/yellow, or red/yellow teas were only statistically significant for CUPRAC, total phenolic compounds, DPPH, and extraction of all compounds measured by HPLC. In these cases, binary mixtures of teas enhanced the extraction of phenolic compounds and antioxidant capacity of tea. Ternary mixtures of green, red, and yellow teas seemed to have a significant effect on aftertaste due to astringency, umami taste, and tea sensory richness. For example, the binary combination of green/red, green/yellow, and red/yellow teas had a positive and significant effect on CUPRAC, whereas the mixture of green and red teas enhanced the extraction of total phenolic compounds, and the mixture of red and yellow teas increased the free radical scavenging activity toward DPPH.

Using ANOVA, the significance and suitability of the RSM models (Table 4) could be evaluated, and for all cases $p$ values below 0.05 were attained, indicating that the mathematical equation proposed to explain each response variable was satisfactory. Additionally, the $R^2$ values were >60%, which means that most of the variability in experimental data could be explained by the second-order mathematical models. For the iron and copper chelating activities, the $R^2$ values were slightly lower (63.95 and 61.71%, respectively) than the ones obtained for the instrumental taste profile, antioxidant activity, and phenolic composition of tea samples. From a practical standpoint, high $R^2$ values are not always easy to be obtained when a biochemical reaction needs to be fit into a mathematical equation, once a more robust model is required or even no modeling is possible for certain responses. The main idea of multiple regression obtained by RSM is to compress the data into an equation relating the independent factors (tea type, for example) in a way to comprehensively explain the phenomena under investigation, to try to explain as much information as possible and test the suitability of these models in predicting future observations.

When a RSM model is proposed, not only do the equation and $R^2$ values need to be taken into consideration to make inferences about the statistical quality (goodness of fitting) of the model but the residues (alignment between observed and predicted values) and adjusted $R^2$ (calculates the proportion of the variation in the dependent variable accounted by the explanatory variables) also need to be calculated and discussed. In the current study, in addition to the significance ($p$ value) and $R^2$ values, the normality of residues was formally evaluated by Shapiro−Wilk's test, which revealed that for all models the observed versus the expected (predicted) values were closely related and the residues followed a normal distribution ($p_{\text{Shapiro−Wilk}} > 0.05$). The adjusted $R^2$ was also provided, and results evidence the closeness between adjusted and "raw" $R^2$ values, indicating the models could describe satisfactorily the instrumental taste profile, chemical composition, antioxidant, and metal chelating activity of *C. sinensis* tea samples.

The simultaneous optimization of the tea mixture using the CUPRAC, DPPH, and iron chelating activities, flavan-3-ols content, and instrumental bitterness led to a formulation containing 14.81% green tea, 28.33% red tea, and 56.86% yellow tea, with a desirability function of 0.9441, which means that this formulation is, theoretically, the best option to obtain a mixture with maximized antioxidant capacity (DPPH and

**Table 5. Predicted and Experimental Values for the Optimized Ternary Mixture of Green (14.81%), Yellow (56.86%), and Red Teas (28.33%)**

| response variable | goal | predicted mean value | −95% prediction | +95% prediction | experimental value | relative absolute error[a] (%) |
|---|---|---|---|---|---|---|
| bitterness (EIT) | intermediate value | −8.38 | −8.72 | −8.05 | −8.30 ± 0.00 | 0.95 |
| flavan-3-ols content (mg PCY/L) | maximize | 122.88 | 114.64 | 131.12 | 125.90 ± 4.38 | 2.46 |
| cupric ion reducing antioxidant power (mmol TE/L) | maximize | 8.10 | 7.68 | 8.52 | 7.96 ± 0.06 | 1.74 |
| iron-chelating activity (%) | maximize | 34.12 | 26.17 | 42.07 | 41.89 ± 0.64 | 22.77 |
| free radical scavenging activity (% inhibition) | maximize | 37.12 | 29.35 | 44.89 | 42.26 ± 0.13 | 13.84 |

[a]Relative absolute error (RAE) was calculated as RAE (%) = [(experimental mean value − predicted mean value)/predicted mean value] × 100 as outlined by Granato et al.[27]

CUPRAC), iron chelating activity, and flavan-3-ols and a balanced bitterness. This formulation was prepared and analyzed using the same experimental assays, and the obtained results were compared with the values predicted by each final regression model (Table 5). All experimental data were within the ±95% prediction interval, meaning the regression models can be regarded as significant and predictive. Therefore, to obtain a maximized antioxidant/metal chelating power, higher content of flavan-3-ols, and mild bitterness, a sample containing 14.81% green tea, 28.33% red tea, and 56.86% yellow tea should be produced. This sample presented 0.44 ± 0.02 mg/L chlorogenic acid, 50.66 ± 6.66 mg/L gallic acid, 251.90 ± 0.06 mg/L epigallocatechin gallate, 9.65 ± 0.01 mg/L (+)-catechin, 73.84 ± 0.18 mg/L (−)-epicatechin, and 533.18 ± 0.15 mg/L caffeine.

In conclusion, response surface methodology was successful in modeling the extraction of phenolic compounds, instrumental taste profile, and antioxidant and metal chelating properties of mixtures of green, yellow, and red *C. sinensis* teas, and the regression equations developed can be used for prediction purposes. The system was subjected to a multiresponse optimization, and the best formulation to obtain a tea with intermediate level of bitterness and maximized antioxidant activity is by mixing 14.81% green tea, 28.33% red tea, and 56.86% yellow tea. Overall, our results clearly corroborate the fact that the oxidation and fermentation processes that *C. sinensis* undergoes highly influence the chemical composition and antioxidant capacity of teas.

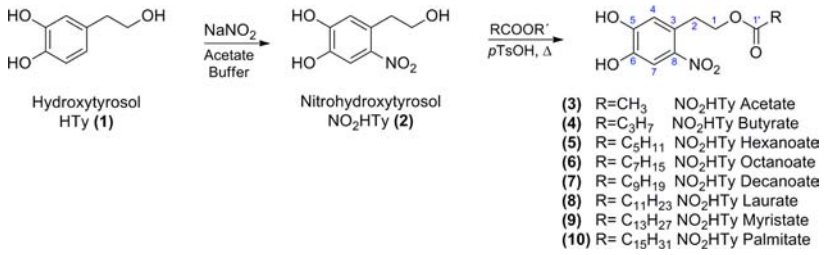

**Figure 1.** Chemical structures of hydroxytyrosol (**1**), nitrohydroxytyrosol (**2**), and nitrohydroxytyrosyl esters (acetate (**3**), butyrate (**4**), hexanoate (**5**), octanoate (**6**), decanoate (**7**), laurate (**8**), myristate (**9**), and palmitate (**10**)).

methanol, acetone, sodium nitrite, hydrogen chloride, iron(III) chloride hexahydrate, sodium hydrogen phosphate, potassium dihydrogen phosphate, acetic acid, sodium acetate trihydrate, hexadeuterated dimethyl sulfoxide (DMSO-$d_6$), ethyl acetate, and methyl esters (butyrate, hexanoate, octanoate, decanoate, laurate, myristate, and palmitate) were from Aldrich (Madrid, Spain).

Fluorescein, methylated $\beta$-cyclodextrin (RMCD), 2,2′-azinobis(3-ethylbenzothiazoline-6-sulfonic acid) diammonium salt (98%) (ABTS), 2,2′-azobis(2-amidinopropane) dihydrochloride (AAPH), and 2,4,6-tri-(2-pyridyl)-1,3,5-triazine (TPTZ) were from Sigma (Madrid, Spain).

HTy was recovered with 95% purity from olive oil wastewaters[16] and further purified by column chromatography.

NMR spectra were recorded on a Bruker AVANCE 500 spectrophotometer operating at 500.13 MHz ($^1$H) and 125.75 MHz ($^{13}$C). Chemical shifts are given in parts per million, with the residual solvent signals (2.49 ppm for $^1$H and 39.5 ppm for $^{13}$C) as references. Samples were dissolved (10−20 mg/mL) in DMSO-$d_6$, and spectra were recorded at 303 K. High-resolution CI or FAB mass spectra (HRMS) were obtained on a Micromass AUTOSPECQ spectrometer.

**Synthesis Procedures.** *Synthesis of Nitrohydroxytyrosol (2).* HTy (**1**, 154 mg, 1 mmol) was added to 0.1 M acetate buffer (pH 3.8) (200 mL) followed by sodium nitrite (138 mg, 2 mmol). After 30 min at room temperature, the mixture was extracted with ethyl acetate (6 × 50 mL), and the combined organic layers were dried over anhydrous sodium sulfate and taken to dryness to give a yellow residue (180 mg). The resulting residue was purified by column chromatography (ethyl acetate/hexane 3:1) to obtain pure nitrohydroxytyrosol (**2**) (160.2 mg, 80.5% yield) as a yellow solid, previously described by Napolitano et al.:[17] mp 197 °C (dec); $^1$H NMR (500 MHz, DMSO-$d_6$) $\delta$ 10.05 (bs, 2H, phenolic OHs), 7.43 (s, 1H, $H_7$), 6.75 (s, 1H, $H_4$), 4.65 (bs, 1H, alcoholic OH), 3.56 (t, $J$ = 6.8 Hz, 2H, $H_1$), 2.90 (t, 2H, $H_2$); $^{13}$C NMR (125 MHz, DMSO-$d_6$) $\delta$ 150.9 ($C_5$), 143.7 ($C_6$), 139.7 ($C_8$), 127.8 ($C_3$), 118.5 ($C_4$), 112.0 ($C_7$), 61.0 ($C_1$), 36.0 ($C_2$); HRMS (CI) $m/z$ calcd for $C_8H_{10}NO_5$ $[M + H]^+$ 200.0559, found 200.0566 (3.5 ppm).

*General Method for Esterification.* $p$-Toluenesulfonic acid (10 mg) was added to a solution of nitrohydroxytyrosol (**2**, 199 mg, 1 mmol) in 16 mL of a 1:1 mixture of THF and the corresponding alkyl ester (acetate, butyrate, hexanoate, octanoate, decanoate, laurate, myristate, or palmitate). The resulting mixture was stirred at 60−65 °C until completion of the reaction (TLC). The solvent was evaporated, and the resulting residue was purified by column chromatography using silica gel as stationary phase and different hexane/diethyl ether mixtures as eluent to yield pure nitrohydroxytyrosyl ester derivatives (**3**−**10**), the chemical structures of which are depicted in Figure 1.

*Data for Nitrohydroxytyrosyl Acetate (3):* 96% yield; obtained as a white solid; mp 107−109 °C; $^1$H NMR (500 MHz, DMSO-$d_6$) $\delta$ 10.11 (bs, 2H, phenolic OHs), 7.46 (s, 1H, $H_7$), 6.74 (s, 1H, $H_4$), 4.18 (t, $J$ = 6.6 Hz, 2H, $H_1$), 3.06 (t, 2H, $H_2$), 1.94 (s, 3H, $H_{2'}$);$^{13}$C NMR (125 MHz, DMSO-$d_6$) $\delta$ 170.2 ($C_{1'}$), 151.2 ($C_5$), 144.2 ($C_6$), 139.8 ($C_8$), 126.2 ($C_3$), 118.4 ($C_4$), 112.2 ($C_7$), 63.4 ($C_1$), 31.8 ($C_2$), 20.6 ($C_{2'}$); HRMS (CI) $m/z$ calcd for $C_{10}H_{11}NO_6$ $[M]^{\bullet+}$ 241.0586, found 241.0591 (1.9 ppm).

*Data for Nitrohydroxytyrosyl Butyrate (4):* 70% yield; obtained as a syrup; $^1$H NMR (500 MHz, DMSO-$d_6$) $\delta$ 10.34 and 9.85 (2 bs, 2H, phenolic OHs), 7.46 (s, 1H, $H_7$), 6.73 (s, 1H, $H_4$), 4.20 (t, $J$ = 6.5 Hz, 2H, $H_1$), 3.07 (t, 2H, $H_2$), 2.20 (t, $J$ = 7.2 Hz, 2H, $H_{2'}$), 1.48 (m, 2H, $H_{3'}$), 0.81 (t, $J$ = 7.4 Hz, 3H, $H_{4'}$); $^{13}$C NMR (125 MHz, DMSO-$d_6$) $\delta$ 172.5 ($C_{1'}$), 151.2 ($C_5$), 144.2 ($C_6$), 139.7 ($C_8$), 126.3 ($C_3$), 118.5 ($C_4$), 112.2 ($C_7$), 63.2 ($C_1$), 35.3 ($C_{2'}$), 31.9 ($C_2$), 17.8 ($C_{3'}$), 13.3 ($C_{4'}$); HRMS (FAB) $m/z$ calcd for $C_{12}H_{15}NO_6Na$ $[M + Na]^+$ 292.0797, found 292.0796 (0.4 ppm).

*Data for Nitrohydroxytyrosyl Hexanoate (5):* 80% yield; obtained as a syrup; $^1$H NMR (500 MHz, DMSO-$d_6$) $\delta$ 10.10 (bs, 2H, phenolic OHs), 7.46 (s, 1H, $H_7$), 6.73 (s, 1H, $H_4$), 4.20 (t, $J$ = 6.5 Hz, 2H, $H_1$), 3.07 (t, 2H, $H_2$), 2.20 (t, $J$ = 7.4 Hz, 2H, $H_{2'}$), 1.45 (m, 2H, $H_{3'}$), 1.21 (m, 4H, $H_{4'}$ and $H_{5'}$), 0.82 (t, $J$ = 7.4 Hz, 3H, $H_{6'}$); $^{13}$C NMR (125 MHz, DMSO-$d_6$) $\delta$ 172.7 ($C_{1'}$), 151.2 ($C_5$), 144.1 ($C_6$), 139.7 ($C_8$), 126.2 ($C_3$), 118.4 ($C_4$), 112.2 ($C_7$), 63.2 ($C_1$), 33.4 ($C_{2'}$), 31.8 ($C_2$), 30.5 ($C_{4'}$), 24.0 ($C_{3'}$), 21.7 ($C_{5'}$), 13.7 ($C_{6'}$); HRMS (FAB) $m/z$ calcd for $C_{14}H_{19}NO_6Na$ $[M + Na]^+$ 320.1110, found 320.1107 (1.0 ppm).

*Data for Nitrohydroxytyrosyl Octanoate (6):* 72% yield; obtained as a colorless liquid; $^1$H NMR (500 MHz, DMSO-$d_6$) $\delta$ 10.10 (bs, 2H, phenolic OHs), 7.47 (s, 1H, $H_7$), 6.73 (s, 1H, $H_4$), 4.20 (t, $J$ = 6.5 Hz, 2H, $H_1$), 3.07 (t, 2H, $H_2$), 2.20 (t, $J$ = 7.4 Hz, 2H, $H_{2'}$), 1.44 (m, 2H, $H_{3'}$), 1.21 (m, 8H, $H_{4'}$−$H_{7'}$), 0.82 (t, $J$ = 7.4 Hz, 3H, $H_{8'}$); $^{13}$C NMR (125 MHz, DMSO-$d_6$) $\delta$ 172.7 ($C_{1'}$), 151.2 ($C_5$), 144.2 ($C_6$), 139.7 ($C_8$), 126.3 ($C_3$), 118.4 ($C_4$), 112.2 ($C_7$), 63.2 ($C_1$), 33.5 ($C_{2'}$), 31.9 ($C_2$), 31.1 ($C_{6'}$), 28.4−28.3 ($C_{4'}$ and $C_{5'}$), 24.4 ($C_{3'}$), 22.0 ($C_{7'}$), 13.9 ($C_{8'}$); HRMS (CI) $m/z$ calcd for $C_{16}H_{24}NO_6$ $[M + H]^+$ 326.1604, found 326.1601 (0.8 ppm).

*Data for Nitrohydroxytyrosyl Decanoate (7):* 81% yield; obtained as a white solid; mp 65−66 °C; $^1$H NMR (500 MHz, DMSO-$d_6$) $\delta$ 10.33 and 9.84 (2 bs, 2H, phenolic OHs), 7.47 (s, 1H, $H_7$), 6.74 (s, 1H, $H_4$), 4.20 (t, $J$ = 6.5 Hz, 2H, $H_1$), 3.07 (t, 2H, $H_2$), 2.21 (t, $J$ = 7.4 Hz, 2H, $H_{2'}$), 1.45 (m, 2H, $H_{3'}$), 1.22 (m, 12H, $H_{4'}$−$H_{9'}$), 0.84 (t, $J$ = 6.9 Hz, 3H, $H_{10'}$); $^{13}$C NMR (125 MHz, DMSO-$d_6$) $\delta$ 172.6 ($C_{1'}$), 151.1 ($C_5$), 144.1 ($C_6$), 139.7 ($C_8$), 126.2 ($C_3$), 118.4 ($C_4$), 112.2 ($C_7$), 63.2 ($C_1$), 33.4 ($C_{2'}$), 31.8 ($C_2$), 31.2 ($C_{8'}$), 28.7−28.3 ($C_{4'}$−$C_{7'}$), 24.2 ($C_{3'}$), 22.0 ($C_{9'}$), 13.8 ($C_{10'}$); HRMS (FAB) $m/z$ calcd for $C_{18}H_{27}NO_6Na$ $[M + Na]^+$ 376.1736, found 376.1736 (0.0 ppm).

*Data for Nitrohydroxytyrosyl Laurate (8):* 58% yield; obtained as a white solid; mp 76−77 °C; $^1$H NMR (500 MHz, DMSO-$d_6$) $\delta$ 10.10 (bs, 2H, phenolic OHs), 7.47 (s, 1H, $H_7$), 6.73 (s, 1H, $H_4$), 4.20 (t, $J$ = 6.5 Hz, 2H, $H_1$), 3.07 (t, 2H, $H_2$), 2.21 (t, $J$ = 7.4 Hz, 2H, $H_{2'}$), 1.44 (m, 2H, $H_{3'}$), 1.22 (m, 16H, $H_{4'}$−$H_{11'}$), 0.84 (t, $J$ = 6.9 Hz, 3H, $H_{12'}$); $^{13}$C NMR (125 MHz, DMSO-$d_6$) $\delta$ 172.6 ($C_{1'}$), 151.2 ($C_5$), 144.1 ($C_6$), 139.7 ($C_8$), 126.2 ($C_3$), 118.4 ($C_4$), 112.2 ($C_7$), 63.2 ($C_1$), 33.4 ($C_{2'}$), 31.8 ($C_2$), 31.2 ($C_{10'}$), 28.9−28.3 ($C_{4'}$−$C_{9'}$), 24.3 ($C_{3'}$), 22.0 ($C_{11'}$), 13.9 ($C_{12'}$); HRMS (FAB) $m/z$ calcd for $C_{20}H_{31}NO_6Na$ $[M + Na]^+$ 404.2049, found 404.2045 (1.0 ppm).

*Data for Nitrohydroxytyrosyl Palmitate (**10**):* 55% yield; obtained as a white solid; mp 90−91 °C; $^1$H NMR (500 MHz, DMSO-$d_6$) $\delta$ 10.12 (bs, 2H, phenolic OHs), 7.47 (s, 1H, $H_7$), 6.73 (s, 1H, $H_4$), 4.20 (t, $J$ = 6.5 Hz, 2H, $H_1$), 3.07 (t, 2H, $H_2$), 2.20 (t, $J$ = 7.4 Hz, 2H, $H_{2'}$), 1.44 (m, 2H, $H_{3'}$), 1.22 (m, 24H, $H_{4'}$−$H_{15'}$), 0.84 (t, $J$ = 6.9 Hz, 3H, $H_{16'}$); $^{13}$C NMR (125 MHz, DMSO-$d_6$) $\delta$ 172.6 ($C_{1'}$), 151.2 ($C_5$), 144.1 ($C_6$), 139.7 ($C_8$), 126.2 ($C_3$), 118.4 ($C_4$), 112.2 ($C_7$), 63.2 ($C_1$), 33.4 ($C_{2'}$), 31.8 ($C_2$), 31.2 ($C_{14'}$), 29.0−28.3 ($C_{4'}$−$C_{13'}$), 24.3 ($C_{3'}$), 22.0 ($C_{15'}$), 13.9 ($C_{16'}$); HRMS (FAB) $m/z$ calcd for $C_{24}H_{39}NO_6Na$ $[M + Na]^+$ 460.2675, found 460.2689 (3.0 ppm).

**Ferric Reducing Antioxidant Power (FRAP) Assay.** The FRAP assay was carried out according to the procedure described by Pulido et al.[18] The antioxidant potential of the synthesized compounds was estimated from their ability to reduce the ferric tripyridyltriazine (TPTZ−Fe(III)) complex to its stable ferrous form (TPTZ−Fe(II)). Briefly, the FRAP reagent contained 2.5 mL of a 10 mM TPTZ solution in 40 mM HCl, plus 2.5 mL of 20 mM $FeCl_3{\cdot}6H_2O$ and 25 mL of 0.3 M acetate buffer to a final pH of 3.6. This reagent was freshly prepared and warmed to 37 °C prior to use. Nine hundred microliters of FRAP reagent was mixed with 90 $\mu$L of distilled water and 30 $\mu$L of either a standard, methanol (as appropriate reagent blank), or a test sample (ranging from 50 to 400 $\mu$M for esters with shorter acyl chain (≤6) and from 100 to 1000 $\mu$M for esters with longer acyl chain (≥8)). All compounds were dissolved in methanol. Once the mixture was shaken, readings at the absorption maximum at 595 nm were taken every 20 s, and the reaction was monitored up to 30 min at 37 °C, using a UV−visible Varian (Cary 50 BIO) spectrophotometer equipped with a thermostated autocell-holder. The reading at 30 min was selected in each case for the calculation of FRAP values. Methanolic solutions of Trolox were used for calibration. The FRAP values are expressed as millimolar TEAC (Trolox equivalent). All analyses were run in triplicate.

**ABTS Assay.** The free radical scavenging capacity was measured using the ABTS decoloration method[19] with some modifications. The method is based on the capacity of different components to scavenge the ABTS radical cation ($ABTS^{\bullet+}$) compared to a standard antioxidant (Trolox). Briefly, ABTS was dissolved in a 2.45 mM potassium persulfate solution and stored in the dark at room temperature for 12−16 h, to set a 7 mM concentration of ABTS radical cation ($ABTS^{\bullet+}$) solution. The $ABTS^{\bullet+}$ stock solution was diluted with methanol to get an absorbance of 0.70 ± 0.02 at 730 nm. After the addition of 0.1 mL of sample dissolved in methanol (ranging from 50 to 400 $\mu$M for esters up to butyrate and from 100 to 500 $\mu$M for the rest of the compounds), methanol as a blank, or Trolox standard to 3.9 mL of diluted $ABTS^{\bullet+}$ solution, absorbance readings were taken every 20 s at 30 °C over 6 min, using a UV−visible spectrophotometer. The percentage inhibition of absorbance was plotted against time, and the area under the curve (0−360 s) was calculated. Methanolic solutions of known concentrations of Trolox were used for calibration. Results are expressed in millimolar TEAC (Trolox equivalent). Each value is the average of three determinations.

**Oxygen Radical Scavenging Capacity (ORAC) Assay.** The oxygen radical scavenging capacity was measured by the lipophilic ORAC assay according to the method developed by Huang et al.[20] with some modifications. The assay is based on the fluorescence decay of a reference substance (fluorescein) after the addition of a peroxyl radical (AAPH), which acts as an initiator of the oxidative reaction. Nitrohydroxytyrosol (**2**) and its derivatives (**3**−**10**) from 5 to 25 $\mu$M

and Trolox standard (6.25, 12.5, 25, 50, 75, and 100 $\mu$M) were dissolved in 7% methylated $\beta$-cyclodextrin (RMCD) in acetone/water (1:1, v/v) solution. Then, 25 $\mu$L of either Trolox, test sample, or solvent as blank was added to a 96-well microplate followed by the addition of 150 $\mu$L of fluorescein work solution ($8.5 \times 10^{-5}$ mM) prepared in 75 mM phosphate buffer (pH 7.4). The microplate reader (Bio-Tek, Winooski, VT, USA) was programmed to record every 2 min for 120 min at 485 and 528 nm excitation and emission wavelengths, respectively, the fluorescence after the addition of 30 $\mu$L of AAPH (153 mM) as peroxyl radical generator, which was also prepared in 75 mM phosphate buffer (pH 7.4). Trolox was used for calibration, and values are expressed as millimolar TEAC (Trolox equivalent). All analyses were run in quadruplicate.

**Statistical Analysis.** Results are expressed as means ± standard deviation (SD) of three measurements for the ABTS and FRAP assays and of four measurements for the ORAC assay. The data were subjected to a one-way analysis of variance (ANOVA) using the program SPSS 19.0. The level of significance was set at $p < 0.05$.

## RESULTS

**Preparation and Characterization of Nitrohydroxytyrosyl Esters (3−10).** Hydroxytyrosol recovered from olive oil wastewaters (OOWW) was used as starting material for the synthesis of new compounds. Slight modifications to the procedure described by Napolitano et al.[17] allowed increased yield of nitrohydroxytyrosol (**2**) formation from 60 to 80%. These modifications consisted in the use of a higher concentration of reactants and a shorter reaction time. Nitrohydroxytyrosol (**2**) was obtained as a yellow solid and further esterified following the procedure described by our research group[21,22] to directly obtain the nitroester derivatives **3−10** (Figure 1) with moderate to excellent yields. Synthetic nitrohydroxytyrosyl esters (**3−10**) were characterized by NMR and HR-MS spectroscopy. $^1H$ and $^{13}C$ NMR chemical shifts (Tables 1 and 2, respectively) were unequivocally assigned for each derivative by 2D heteronuclear correlation experiments (HSQC and HMBC spectra) and were in good agreement with the proposed structures. In addition, the study by HRMS spectrometry of the molecular ion for compounds **3−10** confirmed their calculated molecular masses and elemental compositions, with a mass deviation ranging between 0.0 and 3.0 ppm (see Materials and Methods).

**Antioxidant Activity Evaluation of Nitrohydroxytyrosol (2) and Its Acyl Derivatives (3−10).** Results of the reducing power by the FRAP assay and the radical scavenging activity using ABTS and ORAC assays of nitrohydroxytyrosol (**2**) and its acyl derivatives (**3−10**) are summarized in Figure 2 and Table 3, expressed as millimolar TEAC (Trolox equivalent).

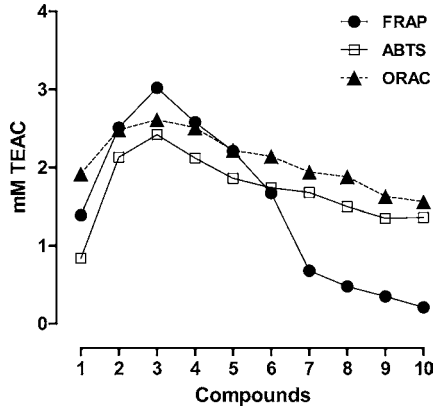

**Figure 2.** Graphical representation of data from FRAP, ABTS, and ORAC assays of hydroxytyrosol (**1**), nitrohydroxytyrosol (**2**), and nitrohydroxytyrosyl esters (**3−10**).

[a]The data represent the mean ± standard deviation of three determinations for FRAP and ABTS assays and four determinations for ORAC assay. Results are expressed as mM Trolox equivalent (TEAC, mM). All values within a column with different letters are significantly different, $p < 0.05$. [b]FRAP and ABTS values of HTy (1) have been previously published by Mateos et al.[8] and are included for comparative purposes.

**FRAP Assay.** Nitrohydroxytyrosol (2) exhibited higher reducing activity than HTy (1). The antioxidant activity of the new nitrohydroxytyrosyl esters (3−10) in comparison with their precursor nitrohydroxytyrosol (2) varied depending on the length of the acyl side chain. Thus, nitrohydroxytyrosyl acetate (3) presented significantly higher antioxidant activity than nitrohydroxytryrosol (2), whereas nitrohydroxytyrosyl butyrate (4) showed similar activity, but the more lipophilic compounds hexanoate (5) and octanoate (6) presented lower activity and decanoate, laurate, myristate, and palmitate (7−10) presented activity even lower than that of HTy (1).

**ABTS Assay.** The radical scavenging activities of nitrohydroxytyrosol (2) and its acyl derivatives, nitrohydroxytyrosyl esters (3−10), showed a tendency similar to the reducing activity. The nitro functional group induced a positive effect on antioxidant activity because nitrohydroxytyrosol (2) as its acyl derivatives (3−10) showed higher antioxidant activity than their precursor HTy (1). Within the nitro derivatives, nitrohydroxytyrosol (2) showed lower activity than nitrohydroxytyrosyl acetate (3), similar to that of butyrate derivative (4) and higher than the rest of the tested ester derivatives (5−10).

**ORAC Assay.** The oxygen radical scavenging capacities of nitrohydroxytyrosyl esters (3−10) and their precursors, nitrohydroxytyrosol (2) and HTy (1), were in agreement with the results from the FRAP and ABTS analyses. Nitrohydroxytyrosol (2) showed higher antioxidant capacity than HTy (1), whereas its acyl derivatives (3−10) showed different behaviors related to the side-chain length; that is, the shorter chain of nitrohydroxytyrosyl acetate (3) and butyrate (4) was associated with higher and similar activity, respectively, whereas the longer acyl chains (5−10) were related with significantly lower antioxidant capacities with respect to the nitro derivative precursor (2). Almost all nitro derivatives (2−7) showed potency higher than or equal to that of HTy (1) except laurate (8), myristate (9), and palmitate (10) derivatives.

## DISCUSSION

Natural dietary antioxidants have the potential to be therapeutic and/or preventative agents against free radicals by combating oxidative stress. Reactive oxygen species accumulation in cellular components is the major factor causing molecular injury, which ultimately leads to cell aging as well as other age-related degenerative diseases.[23] Phenolic compounds in virgin olive oil have been widely studied, focusing on their antioxidant activity.[24] Among these compounds, there is evidence that HTy (1) presents relevant bioactivity, which highlights its potential preventing oxidative stress.[25] Recently, another compound also naturally present in virgin olive oil, hydroxytyrosyl acetate, is gaining interest due to its higher bioavailability,[6,7] biological activity, and particularly antioxidant activity compared to HTy.[8−12] Olive oil phenols have also shown neuroprotective properties,[1,4,12] which prompted the hypothesis that nitrocatechol derivatives of HTy might present interesting biological activities with potential as effective and safer therapeutic alternatives to the nitrocatechols currently used in the treatment of Parkinson's disease.[13−15] In the present work, the synthesis of nitrohydroxytyrosol and up to eight derivatives is presented together with the characterization of their antioxidant activity.

After nitrohydroxytyrosol (2) was obtained, a chemoselective transesterification procedure[21,22] was applied to esterify it, yielding nitrohydroxytyrosyl acetate (3) as well as other more lipophilic nitrohydroxytyrosyl ester derivatives such as butyrate, hexanoate, octanoate, decanoate, laurate, myristate, and palmitate, labeled 4, 5, 6, 7, 8, 9, and 10, respectively (Figure 1). Subsequently, in the present work the antioxidant activity characterization of nitrohydroxytyrosol (2) and its acyl derivatives (3−10) was evaluated using complementary methods (FRAP, ABTS, and ORAC) and comparatively studied against results previously published for free HTy.[8]

As expected, the synthesis of nitroester derivatives (3−10) took place in good to excellent yield. The esterification reaction used to obtain the nitroester derivatives (3−10) had been previously set up[21,22] and presented significant advantages with respect to other methods used to synthesize lipophilic ester phenolic derivatives.[26,27]

According to the results obtained, the antioxidant activity of nitro derivatives of HTy (2−10) depended on the length of the acyl side chain. The addition of a nitro functional group to the HTy chemical structure, yielding nitrohydroxytyrosol (2), induced a positive, significant increase in the antioxidant activity (Table 3). The enhanced antioxidant capacity of nitrohydroxytyrosol (2) is in accordance with the stabilization of the phenoxyl radical by ortho substitutions with electron-donating groups described by other authors.[28,29]

As mentioned, the length of the linear acyl side chain of nitroester derivatives (3−10) induced variable effects on antioxidant activity. The shorter acyl side chains (from two to four carbon atoms) stabilized the phenoxyl radical, thus enhancing or maintaining the antioxidant activity of their precursor (2), whereas longer acyl side chains (six or more carbon atoms) induced a negative effect on the antioxidant activity, probably due to steric hindrance. These results disagree with the polar paradox that assumes that there is a linear relationship between the hydrophobic character and antioxidant capacity of a compound.[30] Nevertheless, they are in accordance with results previously reported for hydroxytyrosyl esters,[8] homovanillyl esters,[31] chlorogenate esters,[32] rosmarinate

esters,[33] and other lipophilic HTy derivatives such as alkyl hydroxytyrosyl ethers.[34] In fact, this nonlinear phenomenon called the *cutoff effect*, coined by Laguerre et al.,[32] has been observed in both biological and physicochemical systems.[35] Three possible mechanisms of actions have been proposed to explain this effect: the *reduced mobility*, *internalization*, and *self-aggregation* hypotheses,[36] but no definitive conclusions have been yet reached.[37]

Moreover, a nonlinear association between biological activity and the lipophilic nature of homologous series of molecules has already been described. Ester derivatives of gallic acid were cytotoxic to L1210 leukemia cells,[38] whereas hydroxytyrosyl ethers showed antiplatelet effects in blood from healthy human volunteers[39] and after oral administration to rats.[40] Additionally, cytotoxic activity of hydroxytyrosol alkyl ether derivatives against A549 lung cancer cells and MRC5 nonmalignant lung fibroblasts was recently described.[41] In all of the aforementioned studies, biological activity increased up to medium length of the acyl or alkyl side chain, whereas the most lipophilic compounds showed lower biological activities.

In conclusion, a series of nitroderivatives has been synthesized from natural olive oil phenols to increase the assortment of compounds with a putative effect against Parkinson's disease. Compounds with shorter acyl side lengths showed higher antioxidant activities compared to HTy, whereas this activity progressively decreased further with the length of the acyl side chain in good accordance with the cutoff theory. Experiments to test their neuroprotective potential will follow.

[a]The chemical shifts are in $\delta$ values (ppm) from TMS. 2D $^{1}H,^{1}H$ (COSY) and 2D $^{13}C,^{1}H$ (HSQC) NMR experiments delineated the correlations of all protons and the corresponding carbons. [b]Multiplicities were assigned by DEPT spectra. [c]These signals are allylic coupled. [d]These signals are overlapped.

(HMBC), and nuclear Overhauser enhancement spectroscopy (NOESY) experiments[11] were performed using Varian microprograms. HRESI MS were recorded on an Agilent Technologies 6120 quadrupole LC/MS (Santa Clara, CA, USA) instrument. Analytical and preparative TLC were performed on silica gel (Kieselgel 60, $F_{254}$ plates, 0.25 and 0.5 mm) (Merck, Darmstadt, Germany). The spots were visualized by exposure to UV radiation (254 nm) and/or by spraying first with 10% $H_2SO_4$ in MeOH and then with 5% phosphomolybdic acid in EtOH, followed by heating at 110 °C for 10 min. Column chromatography was performed on a silica gel column (Kieselgel 60, 0.063−0.200 mm) (Merck).

**Fungal Strain.** The *P. semeniperda* strain WRK10-22 used in this study was obtained from a *B. tectorum* seed bank sample collected from the Whiterocks exclosure (−112.7780 longitude 40.3282 latitude, 1446 m elevation) in Skull Valley, Tooele County, Utah, USA, in November 2010. For details see Masi et al.[8]

**Production, Extraction, and Purification of Phytotoxins.** To produce solid culture on *B. tectorum* seeds, 6.6 mg of WRK10-22 conidia suspended in sterile $H_2O$ were added to 200 g of soaked, autoclaved *B. tectorum* seeds, and the mixture was placed in a sterile 1 L Erlenmeyer flask with an aluminum foil cap at 22 °C. The flask was hand-shaken periodically during the 4-week incubation period to prevent caking together of the grains. The culture was then spread in pans and air-dried for at least several weeks prior to extraction. The dried material was then minced using a laboratory mill and extracted with 500 mL of MeOH/$H_2O$ (1% NaCl) (55:45, v/v). The mixture was centrifuged for 1 h at 10,000 rpm. The pellet was extracted again with the same solvent mixture in the same conditions, and the two supernatants were then pooled (pH 5.5), defatted by *n*-hexane (2 × 500 mL), and extracted with $CH_2Cl_2$ (3 × 500 mL). The resulting aqueous phase was acidified to pH 2 with formic acid and extracted with EtOAc (3 × 500 mL).

The EtOAc organic extracts were combined, dried ($Na_2SO_4$), and evaporated under reduced pressure to yield a brown solid residue (193.4 mg) that showed significant phytotoxic activity in a *B. tectorum* coleoptile bioassay. It was then subjected to bioassay-guided fractionation through column chromatography (750 mm × 30 mm) on silica gel, eluted with 1 L of EtOAc/MeOH/$H_2O$ (75:20:5, v/v/v), affording six groups of homogeneous fractions. The residue (16.4 mg) of the second fraction was further purified by TLC on silica gel, eluted with $CH_2Cl_2$/MeOH (9:1, v/v), yielding pyrenophoric acid, **3** ($R_f$ 0.36, 10.2 mg), as a homogeneous amorphous solid. The residue (14.6 mg) of the third fraction was further purified by TLC on silica gel, eluted with $CH_2Cl_2$/MeOH (9:1, v/v), yielding abscisic acid, **4** ($R_f$ 0.30, 3.2 mg, 16 mg/kg), as a white crystal powder and a mixture of two compounds. The mixture was further purified by TLC on silica gel, eluted with EtOAc/MeOH/$H_2O$ (9.5:0.3:0.2, v/v/v), yielding pyrenophoric acid B, **1** ($R_f$ 0.62, 1.8 mg, 9 mg/kg), and pyrenophoric acid C, **2** ($R_f$ 0.72, 1.6 mg, 8 mg/kg), both as homogeneous amorphous solids.

The $CH_2Cl_2$ organic extracts were combined, dried ($Na_2SO_4$), and evaporated under reduced pressure to yield a brown solid residue (694.4 mg), which essentially contained cytochalasin B (**7**) as shown by TLC analysis carried out in comparison with an authentic sample of the toxin. The mixture was washed with small aliquots (5 × 1 mL) of MeOH, and **7** was crystallized twice from EtOAc−*n*-hexane (1:5, v/v), giving white needles (223.2 mg). The mother liquors of cytochalasin B crystallization (155.3 mg) were combined with the initial MeOH washing (for a residual total extract of 470.1 mg) and fractionated by different steps of column chromatography and TLC on silica gel, affording a further amount of **7** (118.6 mg, for a total of 341.8 mg, 1025.4 mg/kg) and pyrenophoric acid (**3**, 6.3 mg, for a total of 16.5 mg, 82.5 mg/kg) as well as cytochalasin A (**5**, 12.3 mg, 61.5 mg/kg), cytochalasin F (**9**, 7.9 mg, 23.7 mg/kg), cytochalasin Z3 (**8**, 0.8 mg, 4.0 mg/kg), and deoxaphomin (**6**, 18.3 mg, 91.5 mg/kg).

*Pyrenophoric Acid B (**1**).* $[\alpha]_D^{25}$: +21.3 ($c$ = 0.18); IR $\nu_{max}$ 3394, 1727, 1670, 1554, 1260 $cm^{-1}$; UV $\lambda_{max}$ nm (log $\varepsilon$) 256 (4.75); $^{1}H$ and $^{13}C$ NMR spectra, see Table 1; HRESI MS (+) spectrum $m/z$ 286.1979 [$C_{15}H_{28}NO_4$, calcd 286.2018, M + $NH_4$]$^+$; HRESI MS (−) spectrum $m/z$ 267.5917 [$C_{15}H_{23}O_4$, calcd 267.1596, M − H]$^-$.

**Cheatgrass Seedling Bioassay.** Pyrenophoric acids B, **1**, and C, **2**, pyrenophoric acid, **3**, abscisic acid, **4**, cytochalasin A, **5**, deoxaphomin, **6**, cytochalasin B, **7**, and cytochalasin F, **9**, were first

dissolved in DMSO, and then brought up to the assay concentration of $10^{-3}$ M or $10^{-4}$ M with distilled water (the final content of DMSO was 2%). Pyrenophoric acid, **3**, and cytochalasins **5**, **6**, **7**, and **9** were also assayed in mixture (1:1 molar ratio) at $10^{-4}$ M with the same procedure. For each sample and concentration, 1.33 mL of the solution was pipetted into each of three 6 cm Petri dishes onto the surface of one filter paper. Seeds were incubated in 2% DMSO in the control treatment.

Six host seeds were arranged onto the surface of each filter paper in a pattern that made it possible to track individual seeds. Petri dishes were sealed with Parafilm to retard moisture loss and incubated at 20 °C with a 12/12 light/dark photoperiod. Germination was scored each day, and germination day was tracked individually for each seed. Five days after germination, the coleoptile and radicle length of each seedling was measured and recorded using electronic calipers. Most seeds germinated within 3 days. Seeds that did not germinate within 7 days (<5%) were excluded from analysis, while seeds that produced a radicle but no coleoptile were scored with a coleoptile length of zero. Cytochalasin Z3, **8**, was not tested because of the small amount obtained.

**Statistical Analysis.** Three separate experiments were performed, each with its own control. The first included the four cytochalasins, **5**, **6**, **7**, and **9**, at two concentrations ($10^{-3}$ and $10^{-4}$ M), while the second included the three pyrenophoric acids, **1**, **2**, and **3**, and abscisic acid, **4**, at the same two concentrations. The third experiment included each additive pairwise combination of cytochalasins **5**, **6**, **7**, and **9** (6 pairs) and pairwise combinations of each cytochalasin with pyrenophoric acid, **3**, at $10^{-4}$ M (4 pairs). Pyrenophoric acids B, **1**, and C, **2**, could not be included in this last experiment because of the small amounts obtained. The objective of the pairwise tests was to determine whether the combined effects of the different toxins were additive, less than additive, or synergistic.

Data from the first two experiments were analyzed using two-way analysis of variance (ANOVA; SAS Proc GLM) with compound and concentration as fixed effects and day-5 coleoptile length, day-5 radicle length, and germination time as the response variables. Data from the third experiment were combined with data from the pure compound bioassays at $10^{-4}$ M to permit comparisons between pure compounds and pairs of compounds and were then subjected to a similar analysis. LSMeans comparisons from the ANOVAs were used to test the statistical significance of differences between treatment means ($P < 0.05$). Coleoptile and radicle length data were log-transformed to improve homogeneity of variance prior to analysis. Germination percentage was also included in the data presentation but was not analyzed statistically because of inadequate replication.

Coleoptile and radicle length data are presented as reductions relative to the control, i.e., 1 − (treatment/control), while germination time data are presented as germination delay, i.e., treatment germination time − control germination time, in order to make the data comparable across experiments with different control treatments. A separate test confirmed that the DMSO controls did not differ significantly across experiments for any response variable.

## RESULTS AND DISCUSSION

When a *P. semeniperda* strain (WRK10-22) was cultured for the first time on host cheatgrass seeds (*B. tectorum*) and the culture was extracted, pyrenophoric acid, **3** (Figure 1), and a large quantity of cytochalasin B (**7**, Figure 1) were isolated from the $CH_2Cl_2$ extract, together with cytochalasin A, **5**, deoxaphomin, **6**, cytochalasin Z3, **8**, and cytochalasin F, **9** (Figure 1). The physical and spectroscopic properties of these compounds were identical to those previously reported,[7,9] confirming that the fungus is able to produce these metabolites when grown on host seeds (*B. tectorum*).[8,9]

The aqueous phase remaining after $CH_2Cl_2$ extraction was acidified (pH 2) and extracted with EtOAc. From the purification of this organic extract two additional polar metabolites were isolated together with the known abscisic

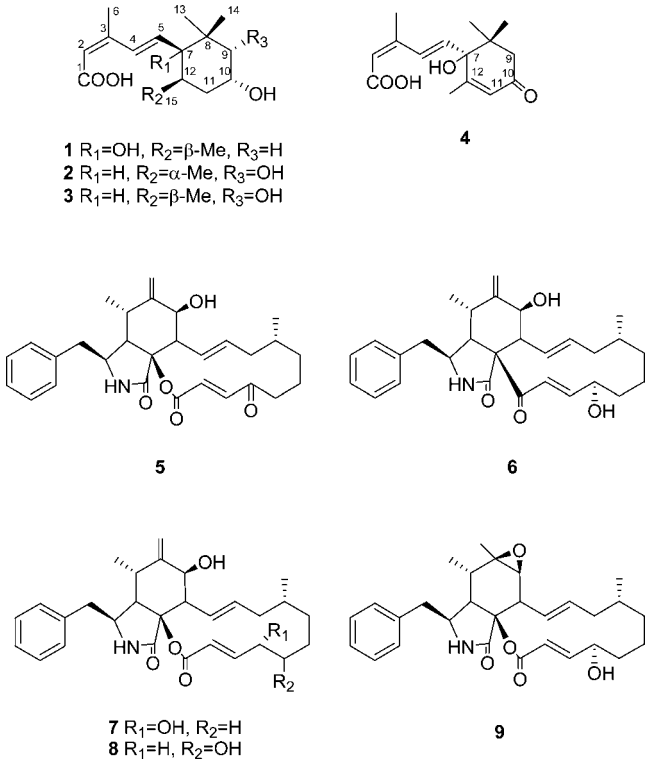

**Figure 1.** Structures of pyrenophoric acid B, **1**, pyrenophoric acid C, **2**, pyrenophoric acid, **3**, abscisic acid, **4**, cytochalasin A, **5**, deoxaphomin, **6**, cytochalasin B, **7**, cytochalasin Z3, **8**, and cytochalasin F, **9**.

acid, **4** (Figure 1), and a further amount of pyrenophoric acid, **3** (Figure 1). Both polar metabolites showed a molecular formula of $C_{15}H_{24}O_4$ as deduced from their HRESI MS, consistent with four hydrogen deficiencies. The preliminary investigation of their $^1H$ and $^{13}C$ NMR spectra, carried out in comparison with those of pyrenophoric acid, **3**,[9] showed that they are very closely related to **3**, and, being new, they were named pyrenophoric acids B, **1**, and C, **2** (Figure 1).

The $^1H$ and $^{13}C$ NMR spectra of **1** and **2** showed the signal pattern of a 3-methylpenta-2,4-dienoic acid, linked at C-7 with the same stereochemistry as in **3**, also confirmed on the basis of the couplings observed in their COSY, HSQC, and HMBC spectra.[11] However, they differed significantly for the cyclohexyl moiety system.

The $^1H$ NMR of **1** (Table 1) differed from that of **3** essentially by the absence of the double doublet of H-7 while H-5 was a doublet ($J$ = 15.9 Hz) at $\delta$ 6.32 instead of the expected double doublet as in **3**. H-5 in the COSY spectrum[11] was *trans* coupled with H-4, which showed a doublet ($J$ = 15.9 Hz) at $\delta$ 7.78. As expected, the COSY spectrum also showed the absence of the coupling between H-7 with H-12, which appeared as a multiplet at $\delta$ 2.36. These results and the molecular formula suggested the presence of a tertiary hydroxy group bonded at C-7. This was confirmed by the corresponding signal observed in the $^{13}C$ NMR spectrum (Table 1) at the typical chemical shift value of $\delta$ 79.6.[14] This carbon (C-7) significantly coupled in the HMBC spectrum with H-5 and both Me-13 and Me-14. A further significant difference, observed comparing the $^1H$ and $^{13}C$ NMR spectra of **1** to those of **3**, was the absence of the signals due to the hydroxylated secondary carbon C-9 and the presence of the signals of a further methylene group ($H_2C$-9) at $\delta$ 1.73 (2H)

dx.doi.org/10.1021/jf5035515 | J. Agric. Food Chem. 2014, 62, 10304−10311

m/44.7 $CH_2$.[14,15] $H_2$-9, in the COSY spectrum, coupled with the proton of the adjacent secondary hydroxylated carbon (CH-10), which resonated as a quintet ($J$ = 3.2 Hz) at $\delta$ 4.13, being also coupled with both protons of the other adjacent methylene group ($H_2$C-11) appearing as a broad doublet ($J$ = 15.1) and a doublet of double doublets ($J$ = 15.1, 13.0, and 3.2 Hz) at $\delta$ 1.76 and 1.51. The latter protons ($H_2$-11) were also coupled with the multiplet of H-12, and this was coupled in turn with the geminal methyl group (Me-15) appearing as a doublet ($J$ = 6.8 Hz) at $\delta$ 0.84. The other two methyl groups resonated as singlets at $\delta$ 1.27 and 1.25 (Me-13 and Me-14). The couplings observed in the HSQC spectrum allowed us to assign the chemical shifts at $\delta$ 138.0, 128.7, 116.0, 66.9, 30.4, 29.1, 25.1, 20.6, and 15.6 to C-5, C-4, C-2, C-10, C-11, C-14, C-13, C-12 and C-15. Those observed in the HMBC spectrum between C-3 with Me-6 and C-8 with Me-13 and Me-15 allowed us to attribute to these two quaternary carbons the chemical shifts of $\delta$ 152.1 and 38.7. The remaining signal at the typical chemical shift value for a carboxylic group at $\delta$ 169.1 was assigned to C-1.[14] Thus, the chemical shifts were assigned to all the protons and corresponding carbons as reported in Table 1, and **1** could be formulated as 5-(1,4-dihydroxy-2,2,6-trimethylcyclohexyl)-3-methylpenta-2,4-dienoic acid.

This structure was confirmed by the other couplings observed in the HMBC spectrum (Table 1) and by the HRESI MS data, which showed the ammonium cluster $[M + NH_4]^+$ at $m/z$ 286.1979. When the same spectrum was recorded in negative ion mode, the pseudomolecular ion $[M - H]^-$ was recorded at $m/z$ 267.5917.

The relative stereochemistry of **1**, as depicted in Figure 1, was deduced from the coupling constants measured in the $^1$H NMR spectrum. In particular, also by comparison with the value observed in **3**, the values measured for the coupling constants between H-12 and both protons of $H_2$-11 and those for the coupling of H-10 and $H_2$-11 and H-9 allowed us to locate H-10 and H-12 as $\beta$-equatorial and $\alpha$-axial as in **3**. The comparison of the chemical shifts of protons and carbons (essentially HC-5, C-8 and HC-12) surrounding C-7 with those of **3** allowed us to locate its hydroxy group $\alpha$-equatorial. The relative stereochemistry of **1** was also confirmed by the inspection of its Drieding model.

Therefore, **1** could be formulated as (2*Z*,4*E*)-5-[(1*R**,4*R**,6*R**)-1,4-dihydroxy-2,2,6-trimethylcyclohexyl]-3-methylpenta-2,4-dienoic acid. Comparing the $^1$H and $^{13}$C NMR spectra (Table 1) of **2** with those of **3,** the cyclohexyl moiety present in both compounds appeared very similar. In fact, H-7 was observed in the $^1$H NMR spectrum as a double doublet ($J$ = 9.9 and 5.1 Hz) at $\delta$ 2.20 and was coupled in the COSY spectrum with H-5 and H-12. H-12, a multiplet at $\delta$ 2.06 (overlapped to the signal of Me-6), coupled with its geminal methyl group (Me-15) and with both protons of the adjacent methylene group $H_2$C-11, which resonated, respectively, as a doublet ($J$ = 7.6 Hz), a double triplet ($J$ = 12.7 and 4.4 Hz), and a quintet ($J$ = 7.0 Hz) at $\delta$ 1.05, 1.91, and 1.71. The latter two protons ($H_2$-11) coupled with the proton of the adjacent hydroxylated secondary carbon (HC-10) resonating as a quintet ($J$ = 4.4 Hz) at $\delta$ 3.77, and this latter (H-10) was also coupled with the proton of the other hydroxylated secondary carbon (HC-9), appearing as multiplet at $\delta$ 4.38. The two methyl groups (Me-13 and Me-14) gave an overlapped signal integrating for six protons at $\delta$ 1.25. The couplings observed in the HSQC spectrum allowed us to assign the signals at $\delta$ 136.7, 132.0, 114.9, 69.2, 69.0, 53.4, 38.5, 29.4, 21.4, and 18.5 to C-5, C-4, C-2, C-9, C-10, C-7, C-11, Me-13 and Me-14 (overlapped signals), C-12 and Me-6 (overlapped signals), and Me-15. The couplings observed in the HMBC spectrum between C-3 with Me-6 and C-8 with Me-15 allowed the signal at $\delta$ 153.2 and 38.9 to be assigned to these two quaternary carbons. Thus, the remaining signal present at the typical chemical shift for a carboxylic group at $\delta$ 169.0 was assigned to C-1.[14]

On the basis of these results pyrenophoric acid C (**2**) could be formulated as 5-(3,4-dihydroxy-2,2,6-trimethylcyclohexyl)-3-methylpenta-2,4-dienoic acid, the same structural formula obtained for **3**. This structure was confirmed by the other couplings observed in the HMBC spectrum (Table 1) and by the data of the HRESI MS spectra. These latter recorded in positive ion mode showed the ammonium cluster $[M + NH_4]^+$ at $m/z$, 286.2026, while in negative ion mode they showed the pseudomolecular ion $[M - H]^-$ at $m/z$ 267.6075.

The only difference between **2** and **3** is in the stereochemistry of the cyclohexyl ring. H-12 was located $\beta$-equatorial (opposite that in **3**), and H-11a and H-11b were located $\beta$-axial and $\alpha$-equatorial as in **3**. This was deduced by measuring the values of the coupling constants in the $^1$H NMR spectrum, between H-12 and H-7 and also between H-12 and both $H_2$-11 and comparing these to the coupling constant values of **3**. Similarly the values recorded for the coupling of H-10 with both $H_2$-11 and H-9 allowed us to locate this proton (H-10) as $\beta$-equatorial and H-9 as $\beta$-axial as in **3**. The correlation observed between H-9 and H-10 in the NOESY spectrum allowed us to confirm this last proton (H-9) as $\beta$-axial. The comparison of the chemical shifts of protons and carbons (essentially HC-5, C-8, and HC-12) surrounding C-7 with those of **3** allowed us to locate its hydrogen group $\alpha$-equatorial. The relative stereochemistry of **2** as depicted in Figure 1 was also confirmed by the inspection of its Drieding model.

Thus, pyrenophoric acid C (**2**) could be formulated as (2*Z*,4*E*)-5-[(1*S**,3*S**,4*R**,6*S**)-3,4-dihydroxy-2,2,6-trimethylcyclohexyl]-3-methylpenta-2,4-dienoic acid. Both **1** and **2**, as well as **3**, are sesquiterpenoids closely related to the well-known (+)-abscisic acid (**4**). This latter is a plant hormone with roles in environmental stress response, stomatal control of plant water balance, leaf senescence promotion, and growth inhibition. **4** also regulates other important physiological processes in plants including seed development, storage product deposition, and dormancy.[16] The biosynthesis and the metabolism of **4** have been extensively studied,[17−19] and several abscisic acid derivatives have been synthesized.[20,21] However, **4** is not a plant-specific compound but one found in organisms across kingdoms from bacteria to animals, suggesting that it is a ubiquitous and versatile substance that can modulate the physiological functions of various organisms.[22] **4** has also been previously reported as a fungal metabolite.[23,24] Natural abscisic acid analogues have also been isolated from fungi during recent years.[9,25]

The compound **1** was previously reported, in racemic mixture, as a synthetic product (named PBI-175) in a patent regarding the use of abscisic acid derivatives to enhance synchrony of germination and emergence in plants.[21] This racemic mixture was prepared starting from the compound (±)-(8*R**,10*S**)-8-acetoxymethyl-1,5-dioxaspiro[5,5]undecan-9-one, following the procedure previously reported.[26] Only the $^1$H NMR and HRMS data were shown, and no results of biological activity were highlighted. In this paper **1** is described for the first time as a phytotoxic natural product isolated in its

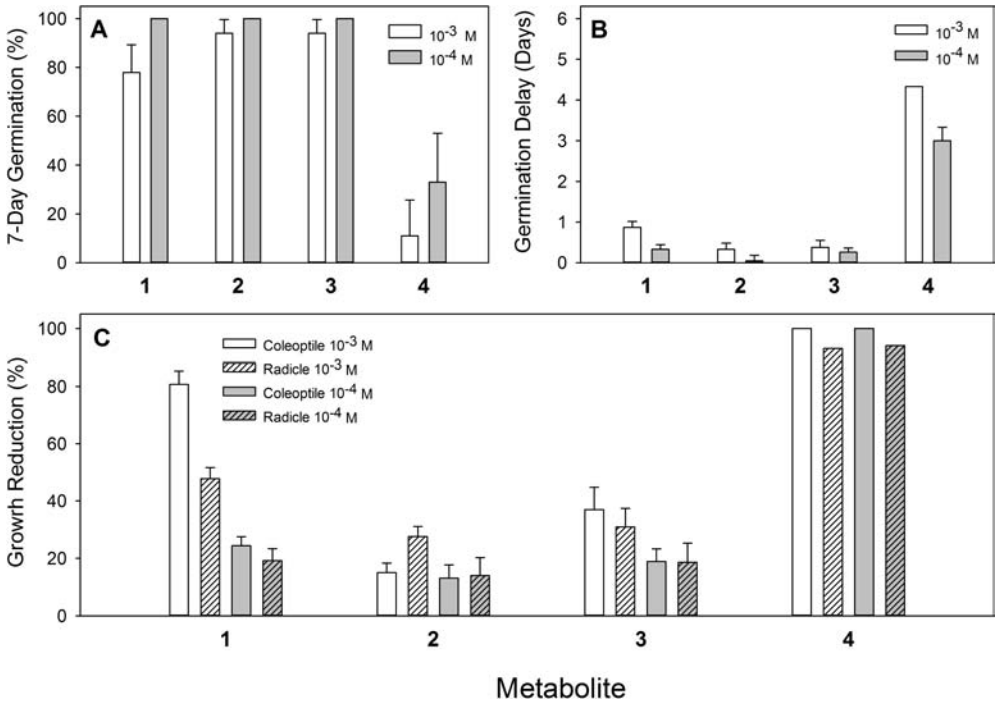

**Figure 2.** Results of host (*Bromus tectorum*) seedling bioassays with abscisic acid, **4**, and the related compounds pyrenophoric acid, **3**, pyrenophoric acid B, **1**, and pyrenophoric acid C, **2**, produced by the seed pathogen *Pyrenophora semeniperda*, at two concentrations ($10^{-3}$ and $10^{-4}$ M) (A) Seed germination percentage after 7 days. (B) Seed germination delay relative to the 2% DMSO control. (C) % coleoptile and radicle 5-day length reduction relative to the 2% DMSO control. Error bars represent standard error of the mean.

pure enantiomeric form from the cheatgrass seed culture of the fungus *P. semeniperda*. Other synthetic analogues related to pyrenophoric acid B were reported in the previously cited patent and in a related paper on the metabolism of biologically active abscisic acid analogues.[21,27]

Seedling bioassays with pyrenophoric acid (**3**), absisic acid (**4**) produced by the fungus, and the two new related compounds pyrenophoric acids B and C (**1** and **2**) demonstrated a hierarchical order of toxicity. All four compounds caused significant 5-day coleoptile and radicle length reductions relative to the control even at the lower concentration, demonstrating their potential role as phytotoxins (Figures 2 and 3). Not surprisingly, **4** was by far the most active compound, and was able to suppress most germination, delay the germination of seeds which did germinate, completely suppress coleoptile elongation, and greatly reduce radicle length relative to the control (Figures 2A, 2B, and 2C). We obtained a similar result in an earlier study with a synthetically produced (±)-abscisic acid, which completely suppressed germination of *B. tectorum* seeds.[9]

Among pyrenophoric acid analogs (**1** and **2**), only pyrenophoric acid B (**1**) was able to reduce 7-day germination and cause significant germination delay relative to the control (Figures 2A and2B). It also caused significantly more coleoptile and radicle growth reduction than the other two compounds at $10^{-3}$ M (Figure 2C). None of these effects were significant at the lower concentration. Pyrenophoric acid (**3**) caused more coleoptile growth suppression than pyrenophoric acid C (**2**), but only at the higher concentration. The relative toxicity ranking of the four compounds was therefore abscisic acid ≫ pyrenophoric acid B > pyrenophoric acid > pyrenophoric acid C (**4** ≫ **1** > **3** > **2**). These results allow us to consider structure−activity relationships between abscisic acid (**4**) and the related pyrenophoric acids (**1**−**3**). The presence at C-10 of

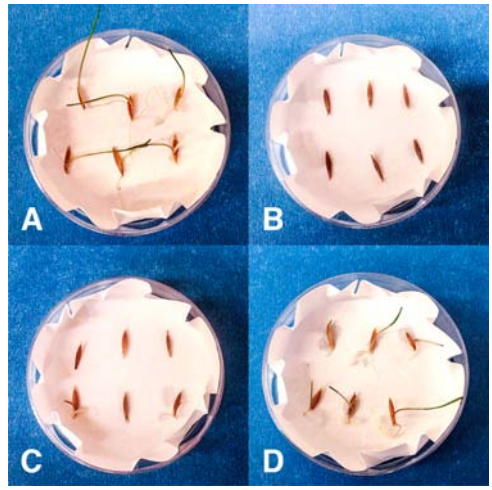

**Figure 3.** Host (*Bromus tectorum*) seedlings 5 days after germination for (A) the 2% DMSO control treatment, (B) abscisic acid, **4**, at $10^{-4}$ M (showing lack of germination), (C) pyrenophoric acid B, **1**, at $10^{-4}$ M, and (D) pyrenophoric acid, **3**, at $10^{-4}$ M.

the $\alpha,\beta$-unsaturated ketone in **4** seems to play a central role in the strong germination-inhibiting activity of this compound. The absence of this moiety in **1**, **2**, and **3** causes a noticeable activity reduction. The hydroxy group at C-7 in **4** and **1** also seems to be involved, as it is absent in the less active **2** and **3**. Furthermore, the stereochemistry of the chiral C-7 in **4**, compared with that of **1**−**3**, could be important in increasing activity, while the difference between **2** and **3** at C-12 should be unimportant. To better understand the potential mode of action of pyrenophoric acids and which structural features are involved, suitable semisynthetic derivatives should be prepared from **1**−**3** and tested in seedling bioassays.

dx.doi.org/10.1021/jf5035515 | *J. Agric. Food Chem.* 2014, 62, 10304−10311

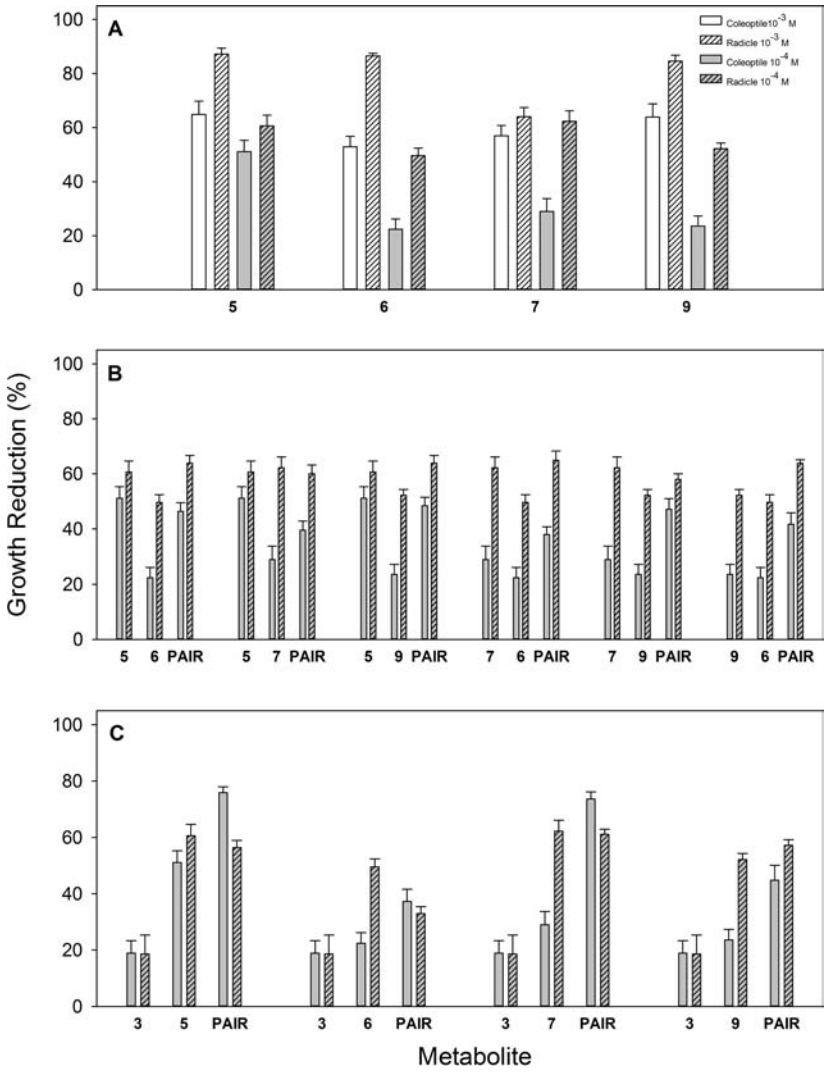

**Figure 4.** Results of host (*Bromus tectorum*) seedling bioassays showing the reduction in 5-day radicle and coleoptile length relative to the 2% DMSO control for four cytochalasins [cytochalasin A, **5**, cytochalasin B, **7**, cytochalasin F, **9**, and deoxaphomin, **6**] produced by the seed pathogen *Pyrenophora semeniperda*: (A) applied singly at two concentrations ($10^{-3}$ and $10^{-4}$ M), (B) applied in pairwise additive combination with each other at $10^{-4}$ M, and (C) applied in pairwise additive combination with pyrenophoric acid, **3**, at $10^{-4}$ M. Error bars represent standard error of the mean.

In the bioassay with pure cytochalasins, all four compounds significantly reduced 5-day coleoptile and radicle length at both concentrations relative to the control, clearly demonstrating their toxicity on this host (Figure 4A). Toxicity was consistently higher at $10^{-3}$ concentration (except for the effect of **7** on radicle growth, which was similar at the two concentrations). The growth-suppressive effect was far from additive, however, suggesting some form of saturation at higher concentrations. The negative effect on radicle growth was generally greater than the effect on coleoptile growth. There was little difference among the compounds in their impact on seedling growth at high concentration, but at low concentration, **5** caused significantly more coleoptile growth reduction than the other three compounds. In contrast with their strong toxicity to seedlings, cytochalasins had no significant effect on germination time or percentage (data not shown).

When the cytochalasins were combined additively in pairwise combinations at $10^{-4}$ M, there was no sign of an additive effect on radicle growth suppression in five of six pairs, with suppression caused by the most toxic compound (**5** or **7**) not significantly less than the effect of the combined compounds (Figure 4B). Only the combination of cytochalasin F and deoxyphomin (**9** and **6**) resulted in a significant radicle growth suppression increase relative to either compound alone. For coleoptile growth suppression, combinations that included **5** resulted in no significant increase in suppression relative to this compound applied singly. Combinations that included **7** but not **5** resulted in increased suppression relative to the pure compounds, while the combination of **9** and **6** resulted in a nearly additive effect. These results suggest that when more toxic cytochalasins are included in the pairwise combination, the apparent saturation effect observed at higher concentrations of pure compounds is also evident.

When cytochalasins were combined in pairwise combinations with pyrenophoric acid, there was again little indication of an additive effect on radicle growth suppression, with no significant increase in suppression beyond that achieved by cytochalasins applied as pure compounds (Figure 4C). There was actually a significant decrease in toxicity to radicles when pyrenophoric acid (**3**) was combined with deoxaphomin (**6**). In contrast to the effect on radicles, the effect of pyrenophoric acid−cytochalasin combinations on coleoptile growth suppres-

sion was at least additive or nearly so. When **7** was combined with **3**, the toxicity effect on coleoptiles was clearly synergistic, with a growth reduction of 74%, or 1.54 times the reduction predicted by a strictly additive effect (19% + 29% = 48%).

In conclusion, the structures of two new sesquiterpenoids, named pyrenophoric acids B and C and isolated from *B. tectorum* culture of *P. semeniperda*, were reported. They are closely related to pyrenophoric acid, previously isolated from the same fungus, being the 7-dehydro-7-hydroxy and the 12-epimer of this acid. They are structurally related to abscisic acid, which was also isolated from the fungus in this study.

As is true for most of the secondary metabolites produced by fungi, the biological functions of phytotoxic metabolites produced by *P. semeniperda* in pathogenesis on *B. tectorum* seeds are still largely unknown. We have demonstrated here that these metabolites are produced by the fungus on seeds of the host of origin and not just in standard wheat seed culture. This makes it more likely that they have some function in pathogenesis. As cytochalasin B is produced in quantities orders of magnitude greater than other secondary metabolites known to be produced by this fungus, it seems likely that it is important in terms of pathogenesis. The detection of a series of closely related cytochalasins could suggest that they represent sequential steps in biosynthesis of the principal compound or possibly degradation products.[28] Cytochalasin B is well-known to interfere with cytokinesis through its action on the actin skeleton of cells, making it a logical candidate as a compound that could facilitate pathogenesis on seeds by interfering with germinant development. Similarly, abscisic acid is the most likely of the sesquiterpenoid group of compounds produced by *P. semeniperda* to play a direct role in pathogenesis on seeds because of its ability to delay or halt germination. This compound and related pyrenophoric acids were detected in very small quantities, however. The failure to detect abscisic acid and related compounds in biologically significant amounts could be an artifact of cultural conditions on autoclaved seeds. The synergistic effect of pyrenophoric acid and cytochalasin B on coleoptile growth suppression suggests that they may play complementary roles in pathogenesis, especially if the effect of cytochalasin B is saturating at relatively low concentrations, making the large disparity in production levels less important. However, this begs the question of why the fungus produces such large quantities of cytochalasin B.

An annotated genome assembly for *P. semeniperda* is now available, and the putative gene cluster for cytochalasin biosynthesis in this fungus has been identified.[29] Gene silencing studies to directly determine how cytochalasin B and other phytotoxins produced by *P. semeniperda* function in pathogenesis provide the most promising approach for understanding the activities in vivo of the diverse array of phytotoxic metabolites produced.

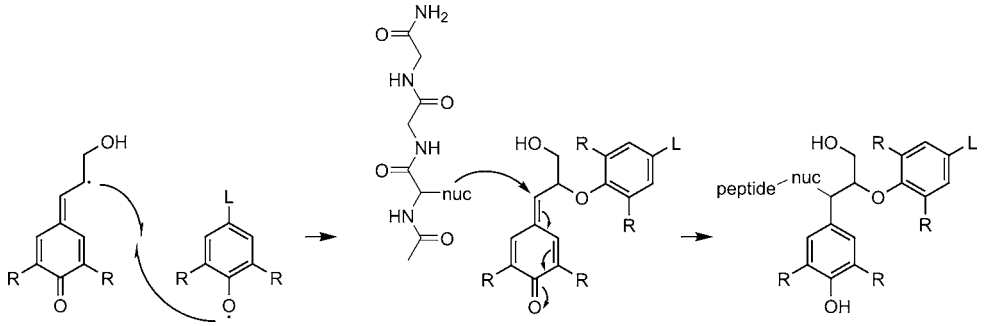

**Figure 1.** Lignin−peptide cross-linking pathway. Lignin−peptide cross-links form when nucleophilic side chains of amino acids react with quinone methides formed during lignin $\beta$-ether coupling. R = H or OMe, L = lignin.

To investigate the propensity for lignin−peptide cross-linking under biomimetic conditions, lignin dehydrogenation polymer (DHP) was prepared in aqueous solutions containing tripeptides. Each tripeptide had the general structure X−glycine−glycine (XGG), with X being cysteine (C), lysine (K), histidine (H), aspartic acid (D), glutamic acid (E), serine (S), tyrosine (Y), threonine (T), or hydroxyproline (Hyp). These amino acids were previously identified as being reactive (or potentially reactive in the case of T and Hyp) toward lignin QMs.[17] The general peptide structure and predicted mode of lignin−peptide cross-linking are shown in Figure 1. The C-termini and N-termini of the peptides were blocked via amidation and acetylation, respectively, to ensure that the amino acid of interest (i.e., residue X) contained the only nucleophilic moiety. Glycine was chosen as the "place holder" residue due to its expected lack of reactivity toward lignin. The lengths of the peptides were limited to three residues because in vitro reactions of large peptides with DHPs result in the formation of lignin−peptide complexes that are insoluble and thus difficult to characterize (e.g., liquid state NMR becomes impractical) (results not shown). Tripeptides were added in 25% mol/mol ratio to the lignin monomer (coniferyl alcohol) because it was previously reported that lignin DHPs contain between 20 and 30% $\beta$-ether linkages.[19] Thus, the ratio of nucleophilic amino acids to lignin $\beta$-ether QMs was expected to be approximately 1:1 over the course of the polymerization reaction.

Fourier-transform infrared spectroscopy (FT-IR), scanning electron microscopy (SEM), energy dispersive X-ray spectroscopy (EDS), and nuclear magnetic resonance spectroscopy (NMR) were used to characterize the lignin−peptide adducts. FT-IR and, more recently, NMR, have become staples of lignin characterization.[20−22] Multidimensional NMR techniques (e.g., heteronuclear single quantum coherence (HSQC)) are particularly useful because the shift degeneracies observed in 1D spectra are largely eliminated. Furthermore, diagnostic NMR shifts of lignin−peptide model compounds have previously been assigned.[17] SEM imaging of synthetic and native lignins has not garnered much research attention,[23,24] but the technique was employed here to visualize morphological differences between neat DHP and the lignin−peptide adducts. It was useful to also collect EDS elemental analysis data while the lignin−peptide samples were in the SEM instrument, with the presence of nitrogen suggesting peptide incorporation. Through the use of these techniques this study provides new insights into the propensities and mechanisms of lignin−peptide linkage formation. It is expected that this will be useful toward the continued study of lignin formation in both native and mutant plant lines.

## MATERIALS AND METHODS

**Materials.** All chemicals necessary for DHP preparation were purchased from Sigma with the exception of the peptides (>95% purity), which were purchased from Peptide 2.0 (www.peptide2.com). The peptides acquired were of the sequence XGG, where X represents one of the following: cysteine (C), lysine (K), histidine (H), aspartic acid (D), glutamic acid (E), serine (S), tyrosine (Y), threonine (T), or hydroxyproline (Hyp).

**Synthesis of Lignin DHP and Lignin−Peptide Adducts.** Guaiacyl-based DHP was synthesized in sodium phosphate buffer (pH 6.5) using coniferyl alcohol as the sole lignin monomer.[18] The DHP crude product was centrifuged (10000*g*, 20 min, 4 °C) and the pellet washed four times with distilled water. The DHP product was then lyophilized to yield dry DHP (typical yields 60−70%), which was characterized via NMR as described below and was found to contain shifts typical of G−DHP.[20,22]

Lignin−peptide adducts were prepared as above, with the exception that 25% peptide to coniferyl alcohol (mol/mol basis, all tripeptides were freely water-soluble at the concentrations employed) was added to the flask containing coniferyl alcohol prior to the start of the reaction. The crude reaction products were centrifuged, washed four times, and lyophilized as described above to yield tan powders. Products were stored at −40 °C and characterized using FT-IR, SEM, EDS, and NMR.

**Scanning Electron Microscopy and Energy Dispersive X-ray Spectroscopy.** SEM images were collected on a field emission SEM (FESEM-FEI NanoSEM 630) at 2 or 3 kV under high vacuum ($1.7 \times 10^{-6}$ Torr). Samples were not sputter-coated prior to imaging. Characteristic X-rays were collected with an X-Max silicon drift detector (Oxford Instruments) at 10 kV under low-vacuum conditions (0.6 Torr) to prevent sample charging. Elements were selected and quantified using Aztec Energy Analyzer Software (Oxford Instruments). Three locations were analyzed per adduct, and average atomic percentages and standard deviations are reported under Results and Discussion.

**Nuclear Magnetic Resonance Spectroscopy.** The neat peptides (25 mg) were dissolved in DMSO-$d_6$/pyridine-$d_5$ (4:1 v/v, 500 $\mu$L), and proton (16 scans), carbon (4000 scans), HMQC (64 scans), and HMBC (32 scans) spectra were collected using standard Bruker pulse programs on a Bruker DRX-400 (400 MHz $^1$H resonance frequency) using the central solvent peak [$\delta_H/\delta_C$, dimethyl sulfoxide (DMSO), 2.50/39.50 ppm] as internal standard. In the case of DHP and the lignin−peptide adducts, NMR spectra were acquired on a Bruker Biospin (Billerica, MA, USA) AVANCE 500 (500 MHz $^1$H resonance frequency) spectrometer fitted with a cryogenically cooled gradient probe having inverse geometry, that is, with the proton coils closest to the sample. Spectra were processed with Bruker's Topspin 3.1 software, using the central solvent peak as internal reference [$\delta_H/\delta_C$, dimethyl sulfoxide (DMSO), 2.50/39.5 ppm]. The DHP or lignin−peptide adducts (~45 mg) were placed in an NMR tube (i.d. =

4.1 mm), dissolved in DMSO-$d_6$/pyridine-$d_5$ (4:1 v/v, 500 $\mu$L), and subjected to adiabatic HSQC ('hsqcetgpsisp2.2') experiment. In the case of DHP−YGG, HMBC ("hmbcgpndqf"), COSY ("cosygpqf"), and NOESY ("noesyesgpph") experiments were also conducted to attempt to determine the lignin−tyrosine cross-linking mechanism. Processing used typical matched Gaussian apodization in F2 (LB = −0.3, GB = 0.001), squared cosine-bell, and one level of linear prediction (32 coefficients) in F1.[25] For an estimation of the various interunit linkage types in DHP and lignin−peptide adducts, the well-resolved $C_\alpha$−$H_\alpha$ contours were integrated; no correction factors were used.

**Fourier-Transform Infrared Spectroscopy.** Lignin DHP, neat peptides, and lignin−peptide adducts were analyzed using a Bruker Vertex V70 spectrometer (Bruker Optics) equipped with an MVP-Pro diamond single reflection ATR accessory (Harrick Scientific), and 100 scans at 6 $cm^{-1}$ resolution were averaged for each sample using a DTGS detector and a scan frequency of 5 kHz. In all cases, the spectrum of the clean diamond crystal was used as the reference spectrum. All spectral manipulations were performed using OPUS 6.0 (Bruker Optics).

## RESULTS AND DISCUSSION

**Preparation and Yields of the Lignin−Peptide Adducts.** Lignin DHP was prepared in aqueous solutions containing water-soluble tripeptides (25% peptide/coniferyl alcohol mol/mol basis). Each tripeptide contained one nucleophilic amino acid and blocked N- and C-termini to mimic inclusion within a larger protein and to prohibit potential side reactions. The lignin−peptide adducts were collected via centrifugation, washed, and characterized via FT-IR, SEM, EDS, and NMR. Water-soluble residues that remained in the supernatants following centrifugation and adduct collection were not analyzed. The results, detailed below, indicate covalent incorporation of CGG and YGG peptides into the lignin polymer, whereas other peptides did not show significant reactivity.

Yields for the DHP and lignin−peptide adducts are shown in Table 1. Yields were determined by dividing the mass of recovered solids by the total starting mass (i.e., combined mass of lignin monomer and peptide). The yield of the DHP control was typical.[18] In the cases of CGG and YGG (which we show below to be considerably reactive toward lignin), the yields of recoverable DHP were depressed. In these cases, the authors perceived that a portion of the lignin−peptide adducts may have been aqueous soluble and thus held in solution during the centrifugation process. Characterizations of these aqueous-soluble fractions was not carried out.

**Table 1. Yield Data for the DHP and Lignin−Peptide Adducts**

| | CA[a] (mg) | peptide (mg) | yield (mg) | yield (%) |
|---|---|---|---|---|
| DHP | 200.0 | 0.0 | 130.0 | 65.0 |
| DHP−CGG | 200.0 | 88.4 | 100.0 | 34.7 |
| DHP−KGG | 200.0 | 83.6 | 174.5 | 61.5 |
| DHP−HGG | 200.0 | 86.1 | 176.0 | 61.5 |
| DHP−DGG | 200.0 | 80.0 | 180.0 | 64.3 |
| DHP−EGG | 200.0 | 83.9 | 197.9 | 69.7 |
| DHP−SGG | 200.0 | 72.2 | 172.8 | 63.5 |
| DHP−YGG | 200.0 | 93.3 | 114.2 | 38.9 |
| DHP−TGG | 200.0 | 76.1 | 179.1 | 64.9 |
| DHP−HypGG | 200.0 | 79.4 | 177.4 | 63.5 |

[a]CA, coniferyl alcohol

**Lignin−Peptide Morphology.** SEM was used to compare the morphologies of neat DHP and the lignin−peptide coproducts (Figure 2). The neat DHP particles clumped together to form nearly perfect spheres, as reported previously.[23,26] Comparatively, spheres of lignin−peptide adducts tended to form large, aggregate domains. This alteration of morphology was observed regardless of whether the peptide in question was covalently incorporated into the lignin (e.g., see DHP−DGG in Figure 2 and in Figure S2 in the Supporting Information). This change in morphology was most likely the result of favorable interactions with water; that is, the more hydrophilic tripeptides surrounded the more hydrophobic lignin particles, as would be expected in a heterogeneous polymerization. Further research is necessary to determine the influence of noncovalent interpolymer interactions during lignin polymerization.

**Lignin−Peptide Linkage Identification.** Figure 3 shows the heteronuclear single-quantum coherence (HSQC) spectrum of DHP−CGG. This 2D NMR technique is particularly useful for lignin analysis because the shift degeneracy observed in 1D NMR spectra is largely avoided. Novel shifts are shown in green, red, and blue, whereas standard lignin shifts are shown in black.[20,21] Reference shifts of neat CGG (purple) were added to the spectrum during processing; these shifts were not observed in the DHP−CGG spectrum. Some peptide shifts migrated as a result of DHP−CGG cross-linking. For example, the cys-$^{13}C/^{1}H_\alpha$ shift (originally at 4.5/56.0 ppm in neat CGG) migrated to 4.6/52.8 ppm and the cys-$^{13}C/^{1}H_\beta$ shift (originally at 2.8/26.6 ppm in neat CGG) migrated to 2.8/32.9 ppm in the DHP−CGG adduct. These shifts migrated upon lignin−peptide cross-linking due to their proximity to the thiol group, which is the reactive center of the CGG peptide. Shifts of proton and carbon atoms located far from the reactive thiol were largely unaffected by cross-linking (e.g., shifts at 3.9/42.8 and 3.8/42.5 ppm).

Two novel lignin shifts, found at 4.4/50.1 ppm (Figure 4, red peak) and 4.8/81.3 ppm (Figure 4, blue peak), confirmed covalent cross-linking of DHP with CGG. Similar lignin $\alpha$-shifts (4.3/50.4 ppm) and $\beta$-shifts (4.7/81.7 ppm) were previously reported in a model compound study wherein a single cysteine residue was reacted with a lignin model quinone methide.[17] The minute differences in shift locations can be attributed to changes in chemical environment between a small lignin model compound and a high molecular weight lignin. Volume integration of the HSQC contours showed that approximately 33% of the $\beta$-ether linkages in DHP−CGG exhibited cysteine functionality at the $\alpha$-carbon, whereas the remaining $\beta$-ether linkages exhibited typical $\alpha$-hydroxyl functionality and a minor fraction of $\alpha$-aryl ether ($\alpha$-*O*-aryl) moieties. This indicated that cysteine was an efficient trapper of lignin QMs under biomimetic conditions.

Figure 4 shows the HSQC spectrum of DHP−YGG. As with the DHP−CGG adduct, incorporation of YGG peptide into lignin was evidenced by the appearance of diagnostic chemical shifts (Figure 4, green and orange contours). Reference shifts of neat YGG (purple, solid yellow, and solid orange contours) were added during processing.

Several factors confound evidence for cross-linking between tyrosine-based peptide (YGG) with lignin. The structural similarity of tyrosine and the lignin monomer, coniferyl alcohol, led to substantial degeneracy in the NMR spectra, as discussed in greater detail below. In addition, the cross-linking of YGG with DHP may have occurred via two mechanisms. The first

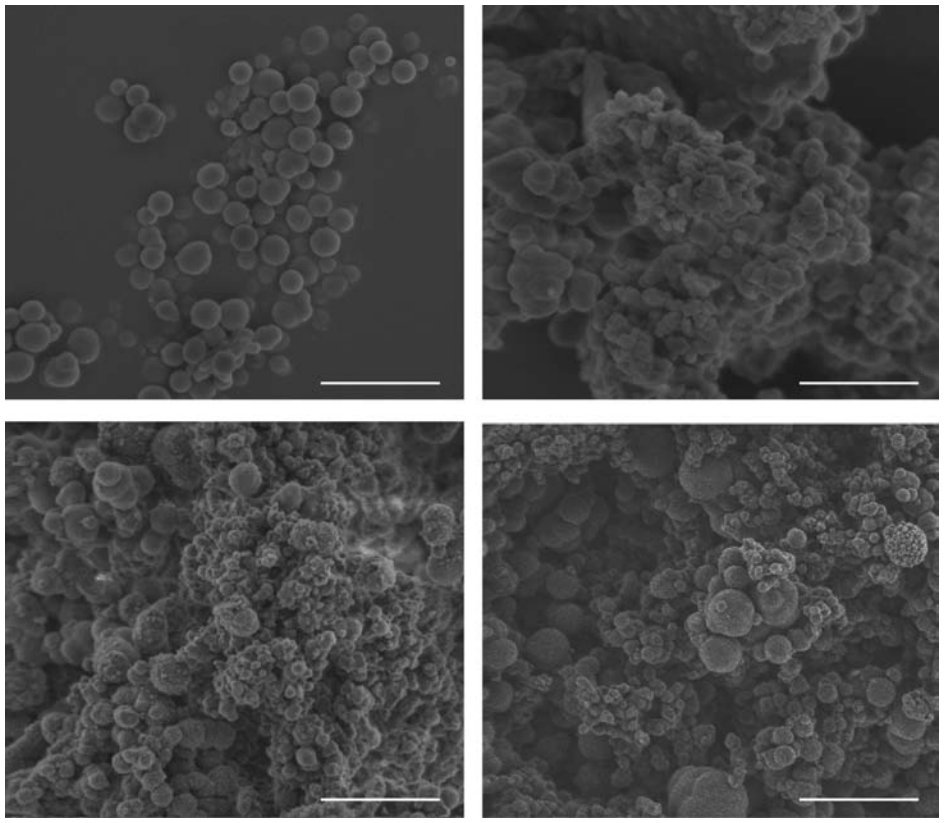

**Figure 2.** SEM images of DHP (top left), DHP−CGG (top right), DHP−YGG (bottom left), and DHP−DGG (bottom right). Scale bar = 2 $\mu$m. Refer to the Supporting Information for SEM images of other lignin−peptide adducts, which displayed morphologies similar to those of the DHP−DGG adduct.

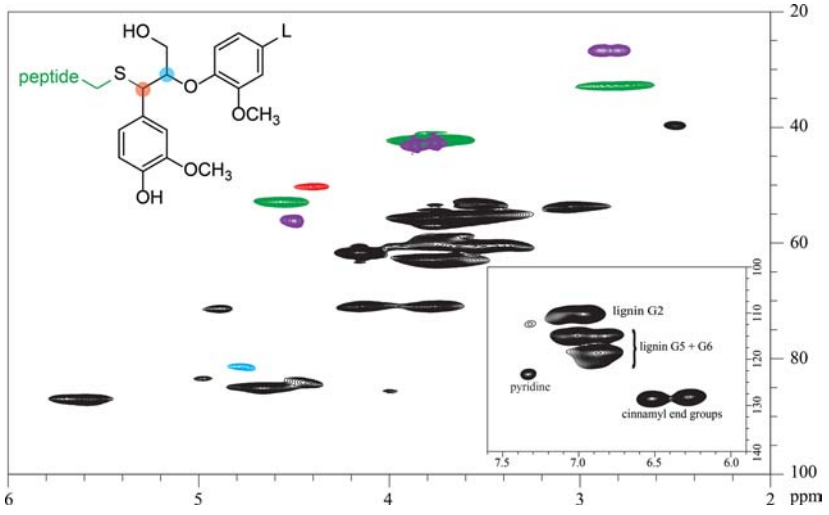

**Figure 3.** Side-chain and aromatic regions (inset) of the HSQC NMR spectrum of DHP−CGG. Black shifts are typical of G−DHPs, green shifts correspond to peptide $\alpha$- and $\beta$-signals, and red and blue shifts correspond to lignin $\alpha$- and $\beta$-signals in $\beta$-ether/$\alpha$-cysteine structures (top left). Purple shifts were added during processing to indicate shifts of neat CGG peptide.

potential mechanism involves oxidation of the phenolic hydroxyl of tyrosine by horseradish peroxidase, followed by recombination of the tyrosine radical with a radical on the lignin polymer. Previous work relied upon stop-flow kinetics to show that this mechanism is probably unfavorable.[16] Still, we investigated the possibility of this compound forming by conducting heteronuclear multiple bond correlation (HMBC), correlation spectroscopy (COSY), and nuclear Overhauser effect spectroscopy (NOESY) (data not shown). However, we were unable to conclusively assign NMR shifts of lignin−tyrosine linkages formed in this manner. Either the mechanism is not valid under our experimental conditions and/or the shift degeneracy between lignin−tyrosine linkages and typical lignin shifts is too great to allow necessary spectral resolution.

A second cross-linking mechanism between lignin and tyrosine is also possible if the phenolic hydroxyl of tyrosine quenches the lignin quinone methide to form the $\alpha$-aryl ether structure shown in Figure 4. Importantly, phenolic hydroxyls of

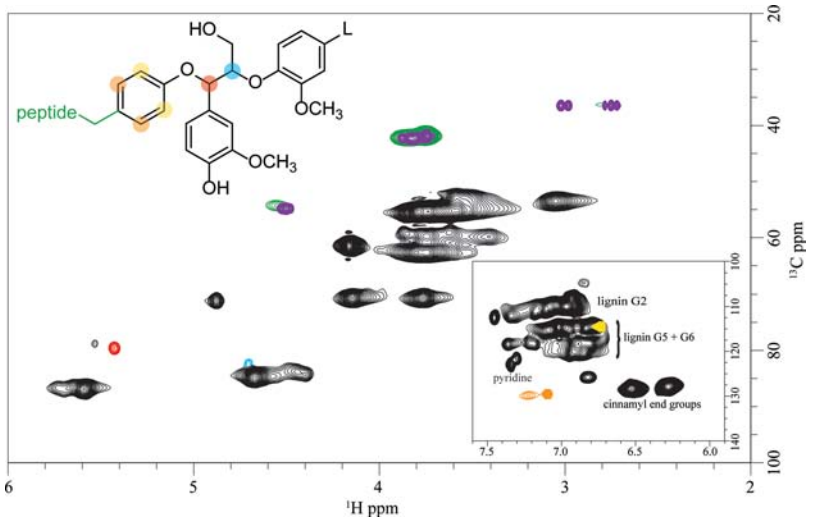

**Figure 4.** Side-chain and aromatic regions (inset) of the HSQC NMR spectrum of DHP−YGG. Black shifts are typical of G−DHPs, green shifts correspond to peptide $\alpha$- and $\beta$-signals, and red and blue shifts correspond to lignin $\alpha$- and $\beta$-signals in $\beta$-ether/$\alpha$-tyrosine structures (top left) and/or lignin−lignin $\alpha$-*O*-aryl structures. Purple shifts were added during processing to indicate shifts of neat YGG peptide. Within the aromatic region, solid yellow and orange shifts (added during processing) were assigned to the aromatic ring of tyrosine in neat YGG.

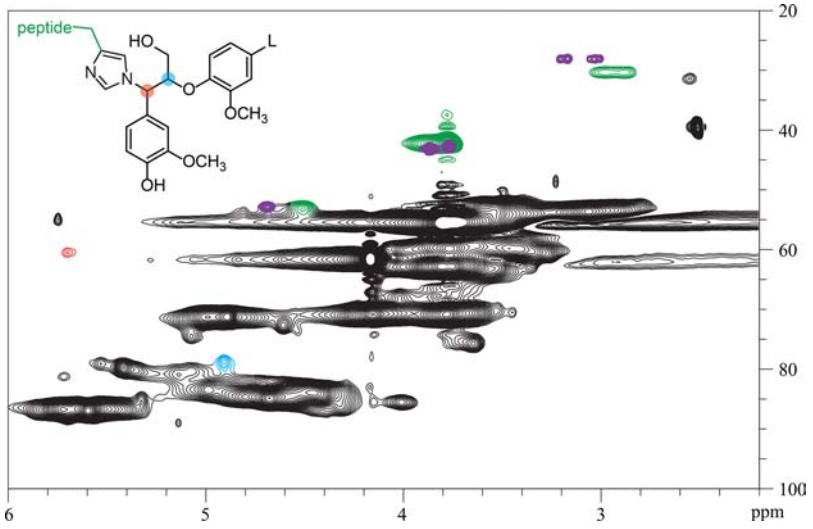

**Figure 5.** Side-chain region of the HSQC NMR spectrum of DHP−HGG. Black shifts are typical of G−DHPs, green shifts correspond to peptide $\alpha$- and $\beta$-signals, and red and blue shifts correspond to lignin $\alpha$- and $\beta$-signals in $\beta$-ether/$\alpha$-histidine structures (top left). Purple shifts were added during processing to indicate shifts of neat HGG peptide.

the monolignols could participate in the same reaction. Given the similarity of these structures, shift degeneracy again complicates the investigation of the mechanism, as a lignin−tyrosine model compound exhibited similar NMR shifts ($\alpha$-$^{1}$H/$^{13}$C, 5.5/78.3 ppm in DMSO/pyridine) to $\alpha$-aryl ether linkages known to occur in neat coniferyl alcohol-based DHPs ($\alpha$-$^{13}$C, 79.01 ppm in DMSO).[17,27]

In an attempt to overcome this issue, the well-resolved HSQC $\alpha$-signals of neat DHP and DHP−YGG adduct were integrated. It was observed that $\alpha$-aryl ether shifts comprised approximately 4.2% of the total $\alpha$-signal in DHP−YGG but only 1.9% in neat DHP synthesized under similar conditions. This increase could be due to cross-linking, but other factors exist as well, such as imprecision in the HSQC volume integration or random variation among DHP syntheses (other lignin−peptide adducts displayed similarly high $\alpha$-aryl ether signals), making it unclear if the structure shown in Figure 4 formed in the DHP−YGG adduct. In summary, previous work,[16] as well as the NMR, IR, and EDS data (shown below), strongly suggests that the YGG peptide cross-linked with lignin DHP via quenching the quinone methide; however, diagnostic evidence supporting this remains elusive.

Peptide peaks could always be observed when the HSQC contours were viewed quite low (i.e., near the signal-to-noise limit), even for lignin−peptide adducts other than DHP−CGG and DHP−YGG. Figure 5 shows the HSQC spectrum of DHP−HGG. This sample showed the highest concentration of peptide after DHP−CGG and DHP−YGG. A putative lignin−$\alpha$-histidine cross-link was observed at 5.7/60.4 ppm, in good agreement with the $\alpha$-shift of a lignin−histidine model compound (5.7/60.2 ppm).[17] Volume integration showed that the lignin−$\alpha$-histidine shift accounted for only ∼0.1% of the total lignin $\alpha$-signal. It is noteworthy that this low abundance of peptide was detected by HSQC NMR but not readily detected by IR or EDS, thus illustrating the sensitivity of multidimensional NMR toward investigating lignin−protein linkages.

**Table 2. Interunit Linkage Ratios of the DHP and Lignin−Peptide Adducts[a]**

| | HSQC signal ratios | | | | | |
|---|---|---|---|---|---|---|
| | $\beta$-ether/$\alpha$-OH | $\beta$-ether/$\alpha$-$O$-aryl | $\beta$-ether/$\alpha$-peptide | $\beta$-5 | $\beta$-$\beta$ | dibenz |
| DHP | 27.3 | 1.9 | | 50.3 | 19.2 | 1.2 |
| DHP−CGG | 8.6 | 1.5 | 5.1 | 50.8 | 32.4 | 1.6 |
| DHP−DGG | 10.1 | 5.5 | 0.1 | 54.1 | 30.2 | tr |
| DHP−EGG | 13.1 | 4.6 | 0.1 | 54.1 | 27.2 | 0.9 |
| DHP−KGG | 4.7 | 3.1 | tr | 62.3 | 29.9 | tr |
| DHP−HGG | 20.4 | 0.9 | 0.1 | 57.7 | 20.3 | 0.6 |
| DHP−SGG | 11.1 | 2.3 | tr | 52.5 | 34.1 | tr |
| DHP−YGG | 11.5 | | 4.2 | 51.7 | 32.5 | tr |
| DHP−TGG | 21.8 | 0.9 | tr | 54.1 | 22.2 | 1.0 |
| DHP−HypGG | 17.7 | 2.7 | tr | 53.2 | 26.2 | 0.2 |

[a]The table shows lignin interunit linkage ratios (as percentage of total $\alpha$-signal) for DHP and lignin−peptide adducts. In the case of DHP−YGG the DHP−$\alpha$-peptide shift was degenerate with standard lignin $\alpha$-$O$-aryl shifts; thus, the $\beta$-ether/$\alpha$-$O$-aryl and $\beta$-ether/$\alpha$-peptide quantities were combined. tr, trace (<0.1%).

Other lignin−peptide adducts exhibited less abundant (<0.1%) NMR peptide shifts than DHP−HGG.

Volume integration of the HSQC contour signals allowed for comparison of the various lignin interunit linkages among DHP and lignin−peptide adducts (Table 2). The column "$\beta$-ether/$\alpha$-peptide" documents the evidence for those tripeptides that covalently reacted. The neat DHP contained typical linkage ratios.[18,19,28] Linkage ratios varied among the lignin−peptide adducts, but decreased $\beta$-ether content with increased pinoresinol ($\beta$-$\beta$) content was generally observed. This occurred regardless of covalent reactivity toward the lignin DHP, demonstrating the ability of a matrix material (in this case peptides) to influence lignin structure during polymerization.

**Supporting Techniques for Lignin−Peptide Characterization.** In addition to NMR, which can provide direct evidence of covalent cross-linking, other techniques were used to show peptide incorporation into lignin. Figure 6 shows FT-IR spectra of DHP−CGG, DHP−YGG, and neat DHP. Infrared spectra of other lignin−peptide adducts can be found in the Supporting Information (Figure S1). The DHP IR spectrum exhibited bands typical of lignin DHPs.[22] The DHP−CGG and DHP−YGG spectra exhibited three peaks indicative of peptide incorporation into the lignin. The shoulder near 3200 $cm^{-1}$ was attributed to N−H stretching in amide functional groups, the peak at 1658 $cm^{-1}$ increased dramatically and was attributed to increased C═O stretching due to the incorporation of amide functional groups, and the shoulder at 1540 $cm^{-1}$ was attributed to N−H deformation with C−N stretching, again indicating incorporation of amide functionalities.[29] It is notable that these shifts displayed greater intensity in the DHP−CGG adduct compared to the DHP−YGG adduct, suggesting greater incorporation of CGG peptide over YGG peptide. These peaks were not observed in the IR spectra of other lignin−peptide adducts, suggesting a lack of peptide incorporation (see Figure S1). In the case of DHP−CGG and DHP−YGG, incorporation of peptide into the lignin polymer caused an increase in the band at 1505 $cm^{-1}$, which was previously assigned to aromatic skeletal vibrations.[22] This increase in peak height was not observed in other lignin−peptide products, and the origin of this increased peak intensity is unclear. Although the IR results suggested incorporation of CGG and YGG peptides into lignin DHP, peaks directly attributable to lignin−peptide linkages were not identified.

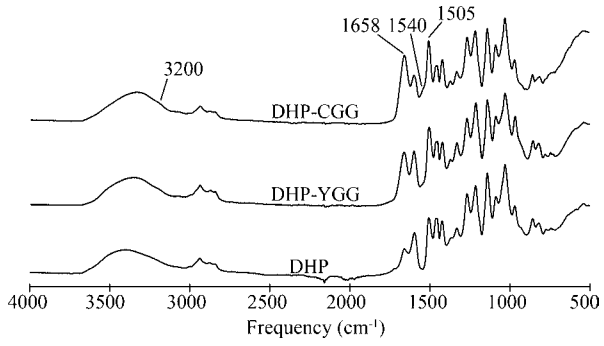

**Figure 6.** FT-IR spectra of (top to bottom) DHP−CGG, DHP−YGG, and neat DHP.

EDS was used to determine elemental compositions of neat DHP and the lignin−peptide adducts. The DHP and most lignin−peptide adducts contained 0% nitrogen (Table 3), indicating no detectable incorporation of peptide into the lignin. In comparison, DHP−CGG and DHP−YGG contained 3.5 and 2.0% nitrogen, respectively. This provided compelling evidence for incorporation of cysteine- and tyrosine-containing peptides into the lignin DHP and suggested that cysteine reacted more readily with lignin compared to tyrosine, in agreement with the IR data.

**Table 3. EDS Elemental Analysis Data for DHP and the Lignin−Peptide Adducts[a]**

| | average atomic % (SD) | | | |
|---|---|---|---|---|
| | carbon | oxygen | nitrogen | sulfur |
| DHP | 78.8 (2.8) | 21.2 (2.9) | 0.0 (0.0) | 0.0 (0.0) |
| DHP−CGG | 76.5 (2.0) | 18.9 (1.2) | 3.5 (0.7) | 1.2 (0.3) |
| DHP−KGG | 86.8 (2.5) | 13.2 (2.5) | 0.0 (0.0) | 0.0 (0.0) |
| DHP−HGG | 90.5 (2.1) | 9.5 (2.5) | 0.0 (0.0) | 0.0 (0.1) |
| DHP−DGG | 82.8 (3.8) | 17.2 (3.8) | 0.0 (0.0) | 0.0 (0.0) |
| DHP−EGG | 83.7 (2.0) | 15.4 (1.1) | 0.0 (0.0) | 0.6 (0.8) |
| DHP−SGG | 86.3 (2.9) | 13.7 (2.9) | 0.0 (0.0) | 0.0 (0.0) |
| DHP−YGG | 84.0 (2.7) | 14.0 (1.1) | 2.0 (1.7) | 0.0 (0.0) |
| DHP−TGG | 85.8 (1.1) | 14.2 (1.1) | 0.0 (0.0) | 0.0 (0.0) |
| DHP−HypGG | 84.4 (0.2) | 15.6 (0.2) | 0.0 (0.0) | 0.0 (0.0) |

[a]Atomic percentages are reported as averages of three sampling locations. Standard deviations are shown in parentheses. Trace levels of calcium account for the balance in the case of DHP−EGG.

**Conclusions.** Individual amino acids bearing nucleophilic side chains were previously shown to react with a lignin model quinone methide in dichloromethane, yielding adducts at the lignin $\alpha$-position.[17] In the present study, we extended this work by introducing nucleophilic tripeptides during lignin DHP synthesis under biomimetic conditions.

Lignin DHP was prepared using coniferyl alcohol as the sole lignin monomer, and peptides were added having the general structure XGG, in which X was an amino acid residue with a nucleophilic side chain (i.e., C, K, H, D, E, S, Y, T, and Hyp). The lignin was precipitated via centrifugation and washed to yield lignin−peptide adducts. Analysis using FT-IR, EDS, and NMR showed that CGG and YGG were reactive toward lignin, whereas other peptides were not. In the case of DHP−CGG, HSQC NMR showed that cross-linking occurred at the lignin $\alpha$-position (Figures 3 and 4). The cross-linking pathway of DHP with YGG could not be conclusively elucidated. SEM imaging showed that lignin−peptide adducts exhibited a unique morphology compared to neat DHP, regardless of peptide incorporation into the lignin. With regard to lignin interunit linkage ratios, the quantity of $\beta$-ether linkages was typically depressed in DHPs synthesized in the presence of peptides, whereas the quantity of pinoresinol structures increased. The yields of DHP−CGG and DHP−YGG were depressed compared to neat DHP yields.

We have shown that cysteine cross-links with lignin under biomimetic conditions and that tyrosine most likely follows a similar cross-linking pathway. This suggests that cross-linking may occur in the cell walls of both native and transgenic plant lines. Further research is needed to investigate whether this cross-linking does occur and to discover how the plant might control and benefit from such cross-linking (i.e., does it help stiffen the wall, assist water conduction, provide protection from pathogens, etc.). In addition, a better understanding of lignin−protein linkages could lead to novel strategies for manipulating lignin biosynthesis and improving lignin extractability, as previously explored.[14,15] This could reduce lignin recalcitrance, which is currently a barrier to using lignocellulosic materials in developing industries such as biofuels. It is anticipated that this work will lead to future studies of lignin−protein linkages in planta and a more thorough understanding of how such linkages could be tailored and modified.

white flour fraction in Rialto and Riband, respectively. In the whole grain, Fe-NA/DMA accounted for 5.3 and 7.3% of the total iron in Rialto and Riband, respectively. Our method did not allow a separation of Fe−NA from Fe−DMA as the two complexes are very similar. Therefore, increasing NA and/or DMA is another strategy for increasing bioavailable iron in plant foods, but this requires the use of transgenic technologies.

The aim of this research was to investigate whether there are differences in iron availability between unleavened bread made from wholegrain and white flours from two commercial wheat cultivars differing in the total iron concentration (Rialto, a hard wheat used for bread, which is high in iron; and Riband, a soft wheat used for biscuits and cakes, which is low in iron). Caco-2 cells are widely used as an in vitro model to study iron bioavailability,[25−27] and previous studies have shown good agreement between in vitro results (using this particular cell line) and in vivo determination of iron bioavailability from food in the presence of enhancers and inhibitors[28,29] (e.g., ascorbic acid (AA) and calcium[30,31]). We have therefore used Caco-2 cells, in combination with simulated gastrointestinal digestion of unleavened bread, to determine the availability of iron from MFP, iron(II) chloride, and iron(II) sulfate and the effects of NA, DMA, and AA on iron uptake into the cells.

## MATERIALS AND METHODS

**Preparation of Grain Materials and Unleavened Bread.** Two commercial wheat cultivars (Rialto and Riband) that accumulate different levels of iron in their grain[10] were grown in field trials at Rothamsted Research in 2010, as described by Shewry et al.[32] Grains were milled in a Buhler mill (MLU-202) at Campden BRI, Gloucestershire, UK, to obtain whole wheat (100% extraction) and white flour (Riband, 38 ± 2.1% extraction; Rialto, 41 ± 3.4% extraction). Unleavened bread was made on a small scale: 20 g of flour was placed in a silica crucible, 5.76 mL of deionized water and 0.4 g of salt were added, and the mixture was kneaded into dough. The dough was left to proof at 30 °C for 30 min before being baked at 200 °C for 15 min. The breads were then broken up by hand into smaller pieces, approximately 0.5 $cm^3$, before flash freezing in liquid nitrogen and freeze-drying for 72 h. Samples were then homogenized and ground to a fine flour in an agate ball mill (Retsch PM400, Düsseldorf, Germany). The characteristics of the flours and unleavened bread samples are summarized in Table 1.

**Table 1. Iron and Phytate Content of Rialto and Riband Flours and Unleavened Breads**

| flour type | iron (mg/kg) in flour[a] | phytate (g/kg dry wt) in unleavened bread[b] | phytic acid/iron molar ratio |
|---|---|---|---|
| Rialto white | 11.9 ± 0.8 | 1.0 ± 0.1 | 7.13 |
| Rialto wholegrain | 46.7 ± 4.3 | 6.4 ± 0.2 | 11.60 |
| Riband white | 6.7 ± 0.5 | 0.4 ± 0.01 | 5.08 |
| Riband wholegrain | 30.3 ± 1.7 | 4.5 ± 0.2 | 12.57 |

[a]Total Fe (±SE, $n$ = 3) determined by ICP-MS. [b]Analysis of phytate was performed using a commercially available kit (K-PHYT 12/12 Megazyme, Ireland), as per the manufacturer's instructions. Eiither 0.5 of 1.0 g of sample was extracted with 10 mL of HCl followed by an enzymatic dephosphorylation step with phytase and alkaline phosphatase and precipitation using a color reagent prepared from AA in sulfuric and ammonium molybdate. The absorbance (655 nm) of free phosphorus and total phosphorus (±SE, $n$ = 3) was compared to phosphorus standards using a Varioskan spectrometer (Thermo, Finland).

**Solutions of Ascorbic Acid, Monoferric Phytate, Nicotianamine, and 2′-Deoxymugineic Acid for Caco-2 Cell Studies.** In Caco-2 cell studies, it is common practice to add AA to give an AA/Fe molar ratio in the range of 10−20:1, the amount being calculated on the basis of the concentration of iron in the samples.[26,33] However, as there was wide variation in total iron in the unleavened bread samples, ranging from 6.65 to 46.7 mg/kg, a standard amount of AA (880 μM, AA dissolved in Milli-Q water) was added to each gram of unleavened bread. Although this meant that some samples had a higher AA/Fe ratio than others (Table 2), the amount of AA added was high enough to ensure that it achieved maximal effect on iron uptake into Caco-2 cells, as observed in previous studies.[34]

**Table 2. Iron and Ascorbic Acid (AA) Concentrations of Unleavened Bread Digests**

| unleavened bread (1 g) | Fe content (μg) | Fe content (μmol/L) | AA (μmol/L) | Fe/AA molar ratio |
|---|---|---|---|---|
| Riband white | 6.7 | 8.0 | 880 | 1:110 |
| Rialto white | 11.9 | 14.2 | 880 | 1:62 |
| Riband wholegrain | 30.3 | 36.2 | 880 | 1:24 |
| Rialto wholegrain | 46.7 | 55.7 | 880 | 1:16 |
| Riband white fortified | 36.7 | 43.8 | 880 | 1:20 |
| Rialto white fortified | 41.9 | 50.0 | 880 | 1:18 |
| Riband wholegrain fortified | 60.3 | 72.0 | 880 | 1:12 |
| Rialto wholegrain fortified | 76.7 | 91.6 | 880 | 1:10 |

Monoferric phytate (MFP) was prepared from a solution of 100 mL of 0.5 M acetic acid, 10 g of sodium phytate, and 1 g of ferric chloride. The mixture was stirred for 2 h until all of the sodium phytate was completely dissolved, 100 mL of 95% (v/v) ethanol was added, and the solution was left overnight. The precipitate was then collected by centrifugation (5000$g$ for 10 min) (Medowrose Scientific Ltd., Oxford, UK), washed three times with acetone, allowed to air-dry, and stored in a desiccator.[35] The final product was analyzed by inductively coupled plasma atomic emission spectroscopy after digestion in ultrapure $HNO_3$ and $HClO_4$ (87:13% v/v).

Commercial sources of DMA and NA, with certified chemical composition (see TOC graphic), were purchased from Toronto Research Chemicals Inc. (Toronto, Canada). Both DMA and NA form 1:1 molar complexes with Fe. The F (II)−NA solution was prepared from ferrous sulphate (Sigma-Aldrich, Vienna, Austria), and Fe(III)−DMA was prepared from ferric chloride (Sigma-Aldrich). Each of the compounds was dissolved separately in Milli-Q water, and appropriate solutions were then mixed immediately to avoid oxidation. The molar concentrations are given in the captions of the figures.

**Cell Culture Procedures.** Caco-2 cells were grown in collagen-coated six-well plates (Greiner, Dungannon, UK) at a density of 4.75 × $10^4$ in 2 mL of Dulbecco's modified Eagle's medium (DMEM) (LGC, Teddington, UK) supplemented with 10% fetal bovine serum, 2 mM L-glutamine, 5 mL of 5000 u/mL penicillin/streptomycillin solution (Gibco, Paisley, UK), and 5 mL of 100× nonessential amino acids (Sigma, Dorset, UK). Media were replaced every 2 days. Cells between passages 27 and 34 were used for experiments at 13 days post seeding, and 24 h prior to experimentation, cells were switched to serum-free medium (minimum essential medium, MEM)[37] supplemented as above with the exception of fetal bovine serum. Experiments without a simulated digestion phase were initiated by the addition of fresh serum-free medium containing the appropriate treatment. After 24 h, the treatment medium was aspirated from the six-well plates, and the cells were washed twice with 2 mL of PBS. Deionized water was then applied to each well, and the Caco-2 cells were scraped off using an inverted 10 μL pipet tip. The cell suspension from each well was sonicated on ice, three times for 5 s, using a probe sonicator and stored at −20 °C.

Initially, the simulated digestion procedures were identical to those reported by Glahn et al.[27,38] However, due to the low iron content of the flour samples, the sample volume was increased from 0.5 to 1 g and subsequently to 3 g, which produced a thick digestate, so the duodenal phase of the simulated digestion was performed in a test tube for 2 h and not above the Caco-2 monolayer (the usual procedure in Glahn's assay). Experiments with unleavened bread were initiated with iron deprivation of the cells by switching from supplemented DMEM to MEM. Twenty-four hours of simulated digestion[27,37] was then carried out with the following modification: the duodenal phase of digestion was continued for 2 h in test tubes (rather than over the cells) at 37 °C on a rotating table, and once completed all samples were centrifuged at 21000*g* for 10 min to remove any sample residue, which could have resulted in physical blockage of the dialysis membrane. After centrifugation, 10% of the resulting supernatant from each treatment was applied to the dialysis membranes and placed over the appropriate wells. Cells were incubated for 1 h with the supernatant at 37 °C on a rotating table at a speed of 20 oscillations per minute, after which time the digests were removed and the cells were incubated for a further 23 h. Then they were harvested, sonicated, and frozen at −20 °C. For the analysis sonicated cell lysates were defrosted at room temperature and kept on ice, and a spectroferritin ELISA assay (Ramco Laboratories, Stafford, TX, USA) was carried out 24 h post sonication, according to the manufacturer's instructions. Total protein was quantified using a BCA protein assay (Pierce, Rockford, IL, USA), and iron availability assessed from the ferritin content (expressed as ng/mg protein), a surrogate measure of iron bioavailability.[38,39]

**Experiments Using Ascorbic Acid, Monoferric Phytate, Nicotianamine, and 2-Deoxymugineic Acid.** A series of experiments were also performed without a simulated digestion. Solutions containing NA, DMA, and MFP were prepared in Milli-Q water. When appropriate, AA was added either at 1:9 molar ratio (Figure 4) or various ratios (Figure 5). The pH was adjusted to 2, and the samples were incubated for 1 h at 37 °C. The samples were diluted with MEM to the desired iron concentrations (1.6 or 3.11 $\mu$g Fe/mL) and incubated in a water bath at 37 °C for 1 h. Because small concentrated volumes of NA, DMA, or MFP solutions were used (600 $\mu$L were diluted in 6 mL), they did not markedly affect the pH of the treatment solutions (the final pH was 6.9−7.0). Before addition to the cell monolayers, all treatment solutions were filtered with 0.22 $\mu$m syringe filters (Merck Millipore, Watford, UK). The cells were incubated for 24 h and then harvested, sonicated, and analyzed as described above.

**Statistical Analysis.** Unless otherwise stated, all statistical analyses were performed using SPSS Inc. (Chicago, IL, USA; version 16.0.0). One-way ANOVA with Tukey's post hoc was used to examine pairwise differences on power-transformed data. Data are presented as the mean ± SD. Differences were considered significant at $p < 0.05$.

## RESULTS

**Caco-2 Ferritin Response to Unleavened Flat Bread Samples: Simulated Digestion Experiments.** Data obtained from 1 g samples of unleavened breads (Figure 1) showed that significantly more ferritin was produced with white Riband flour than with wholegrain Riband and Rialto flours, in the presence of AA ($p < 0.005$ and $p = 0.004$, respectively). There were no significant differences in ferritin formation between the wholegrain and white flour breads from the two cultivars. When 3 g samples were used (Figure 2), the cells exposed to white unleavened bread (Rialto and Riband) produced significantly more ferritin protein than cells exposed to wholegrain breads ($p < 0.0005$ in both cases). Cells exposed to white bread from Riband produced significantly more ferritin than cells exposed to the other breads ($p < 0.0005$ in all comparisons).

To increase the cell response further, all flour samples were supplemented with ferrous sulfate with 30 mg Fe/kg prior to the production of the bread (Figure 3). There was a significantly higher cell ferritin response to unleavened bread made from white than from wholegrain flour, for both Rialto and Riband ($p < 0.0005$ for all comparisons). Cells exposed to Riband wholegrain bread produced significantly more ferritin than cells exposed to Rialto wholegrain bread ($p = 0.001$). The cell ferritin response to the positive control (53.54 $\mu$M $FeSO_4$) was not significantly different from the cell response to Riband white bread, but was significantly higher than the response to Rialto white and wholegrain and to Riband wholegrain breads ($p = 0.049$, $p < 0.0005$, and $p < 0.0005$, respectively). The cell response to unleavened bread made from Rialto wholegrain flour was not significantly different from the blank (17.7 ± 2.5 ng/mg total protein).

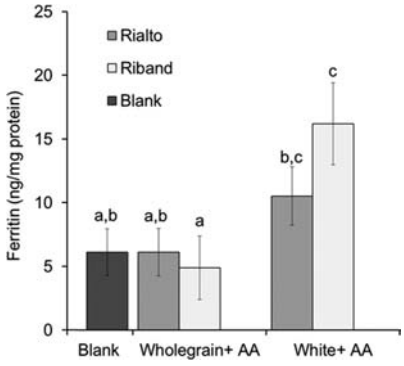

**Figure 1.** Ferritin concentration in Caco-2 cells exposed to digests prepared from 1 g of unleavened bread made from Rialto and Riband white and wholegrain flours in the presence of 880 $\mu$mol/L ascorbic acid (AA), expressed as ferritin concentration (ng/mg total protein). Data represent the mean ± SD ($n = 6$). Bars without a common letter (a−c) are significantly different, $p < 0.05$.

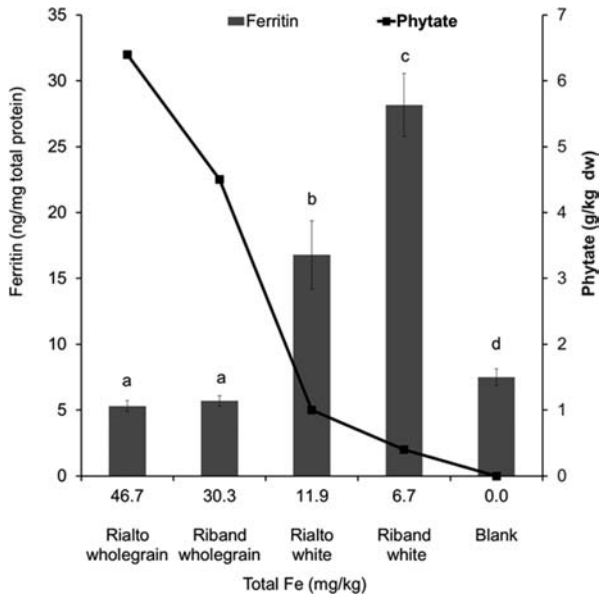

**Figure 2.** Ferritin concentration in Caco-2 cells exposed to digests prepared from 3 g of unleavened bread made from Rialto and Riband white and wholegrain flours in the presence of 880 $\mu$mol/L ascorbic acid (AA) expressed as ferritin concentration (ng/mg total protein, gray bars, *y*-axis). The phytate content (g/kg dry weight) of the unleavened bread is shown on the second *y*-axis and the iron content (mg/kg) on the *x*-axis. Data represent the mean ± SD ($n = 6$). Bars without a common letter (a−c) are significantly different, $p < 0.05$.

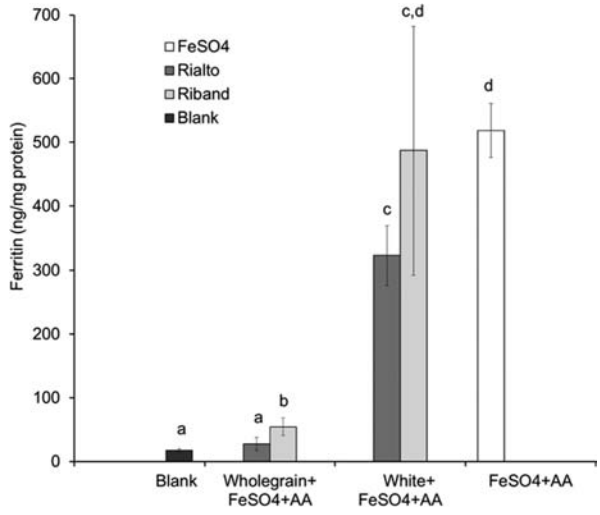

**Figure 3.** Ferritin concentration (ng/mg protein) in Caco-2 cells exposed to digests prepared from unleavened bread made from Rialto and Riband white and wholegrain flours in the presence of 880 $\mu$mol/L ascorbic acid (AA) and 53.54 $\mu$M ferrous sulfate ($FeSO_4$). Data represent the mean ± SD ($n$ = 6). Bars without a common letter (a–d) are significantly different, $p < 0.05$.

**Cell Ferritin Response to Iron(II), Iron(III), or MFP Treatments with Nicotianamine, Ascorbic Acid, 2-Deoxymugineic Acid, or Nicotianamine plus Ascorbic Acid.** AA was present in the treatments (Figure 4) at a ratio of approximately 1:9 (Fe/AA), whereas DMA or NA was present at a ratio of 1:1 (Fe/NA or DMA). The cell ferritin response to iron with NA (Figure 4) was significantly higher than to iron with DMA ($p < 0.0005$), suggesting that NA is a more potent enhancer of iron uptake than DMA (at the tested molar ratio). The response was also significantly increased when AA was added to the iron with DMA ($p < 0.0005$), but further addition of NA had no extra effect.

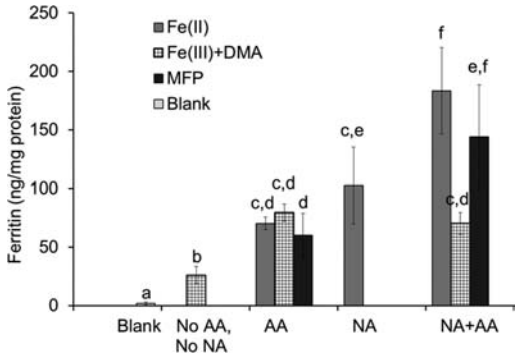

**Figure 4.** Ferritin concentration (ng/mg protein) in Caco-2 cells exposed to 1.6 $\mu$g of ferrous chloride (Fe(II)), ferric chloride (Fe(III))–DMA, or MFP in the presence of NA (at 1:1 Fe to NA ratio) or AA (at 1:9 Fe to AA ratio). Cell response is expressed as ferritin concentration (ng/mg total protein). Data represent the mean ± SD ($n$ = 6). Bars without a common letter (a–d) are significantly different, $p < 0.05$.

The cell ferritin responses to MFP plus AA and iron(II) chloride plus AA were not significantly different, suggesting that the availabilities are similar. Also, further addition of NA to MFP plus AA or to iron(II) chloride plus AA significantly increased ferritin formation in cells ($p < 0.0005$ in both comparisons).

An experiment (Figure 5) was also designed to determine whether there was a dose–response effect of NA and to compare it with AA, the most potent known enhancer of iron uptake. Cells exposed to iron in the presence of increasing NA concentrations (from 1:0.25 Fe/NA molar ratio through 1:0.5 to 1:1 molar ratio) produced significantly more ferritin with increasing NA ($p < 0.0005$, $p = 0.001$, and $p = 0.004$, respectively). When a higher Fe/NA molar ratio of 1:4 was used, the ferritin levels were not significantly different from those in cells exposed to a 1:0.5 Fe/NA molar ratio. The cell ferritin response was positively related to AA concentration (from 1:0.25 Fe/AA molar ratio through 1:4 and 1:10 molar ratio; $p = 0.002$, $p < 0.0005$, and $p < 0.0005$, respectively). Cells exposed to the highest molar ratio of Fe to AA (1:10) produced ferritin at similar levels to cells exposed to the lowest molar ratio of Fe to NA (1:0.25), indicating that NA is a more potent enhancer of iron bioavailability than AA and evoked the highest ferritin response.

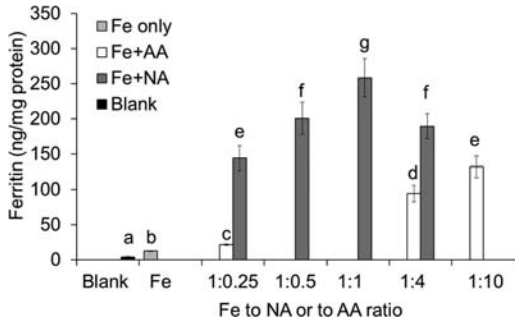

**Figure 5.** Ferritin concentration in Caco-2 cells exposed to 3.11 $\mu$g (13.88 $\mu$M) of ferrous sulfate ($FeSO_4$) with or without NA at Fe/NA ratios of 1:0.25, 1:0.5, 1:1, and 1:4 or AA at Fe/AA ratios of 1:0.25, 1:4, or 1:10. Cell response is expressed as ferritin concentration (ng/mg total protein). Data represent the mean ± SD ($n$ = 6). Bars without a common letter (a–f) are significantly different, $p < 0.05$.

## DISCUSSION

Unleavened bread made with white flour from the wheat cultivar Riband contained more available iron (when in the presence of AA) than the other breads tested, despite having the lowest iron content of all samples. A likely explanation for this is that it contained the lowest phytate content and lowest phytic acid/iron molar ratio (Table 1); there was an inverse relationship between cell ferritin response and phytate content (Figure 2). When unleavened bread was supplemented with iron (30 $\mu$g/g), together with AA (Figure 3), the same trend was observed.

Another contributory factor to the difference in iron availability between bread made from white and wholegrain flour may be the content of phenolic acids. Although not analyzed in our samples, limited data in the literature suggest that white flour has a much lower concentration of phenolic acids[40] as they are found primarily in the bran fraction.[41] Nevertheless, the difference observed between bread made from Riband and Rialto white flour is unlikely to be explained by their content of phenolic acids. Fernandez-Orozco et al.[42] analyzed flour from a number of locations and years and found no differences in the content of free phenolic acids between Riband and Rialto wholegrain flours (both contained 12 ± 7

μg/g), but Riband (990 ± 87 μg/g) had a significantly higher total phenolic acids content ($p = 0.026$) than Rialto (833 ± 118 μg/g). As the ferritin response was higher in Riband, assuming typical phenolic acids concentrations in the wheat samples used in these experiments, this indicates that phytate is the main determinant of iron bioavailability.

The cell ferritin response was inversely proportional to the concentrations of phytate and iron in the breads tested. However, because the iron contents of the samples were not the same, the AA/Fe molar ratios in the samples differed (Table 2), with the highest AA/Fe ratio being present in the sample with the lowest iron content (Riband white unleavened bread). The rationale for using the same amount of AA for all samples is that when AA is used in excess/ it should have a similar effect across all iron concentrations.[34]

Since 1953, it has been mandatory in the United Kingdom to add iron to white and brown flours to restore the content to the levels found in wholegrain flour (16.5 mg $kg^{-1}$).[43,44] The iron present in wholegrain products is not bioavailable due to the presence of inositol phophates $IP_6$, $IP_5$, $IP_4$, and $IP_3$, which bind iron tightly. However, iron present in monoferric phytate, found in wheat,[35] appears to be more bioavailable (Figure 4). In dogs, monoferric phytate has been shown to be about 50% as available as ferrous sulfate at a low dose of iron (1.5 mg), although only one-seventh as available at a higher dose of iron (15 mg).[36]

NA had a clear enhancing effect on iron availability, being a more potent enhancer of iron uptake than DMA (Figure 4) and AA (Figure 5) (as also reported by Zheng et al.[21] for rice flour). The lowest molar ratio of Fe/NA that was tested (1:0.25) had an effect similar to that of AA at a 1:10 Fe/AA molar ratio (Figure 5).The most effective Fe/NA molar ratios observed in this study were 1:1 to 1:4 (Figure 5). Zheng et al.[21] also reported that a 1:1 Fe/NA molar ratio was the most effective for wild type rice and that a 1:4 Fe/NA molar ratio was most effective for a transgenic rice grain expressing an additional nicotianamine synthase (*NAS*) gene. However, these results cannot be directly compared with those presented here as the iron compounds were examined in the absence of a food matrix and the test materials were not subjected to a simulated digestion procedure.

In the samples studied the phytate levels had more influence on iron bioavailability than total iron, a finding that should be taken into account in the development of biofortification strategies to reduce iron deficiency anemia. Our results also demonstrated that MFP with AA provoked a similar cell ferritin response to iron(II) chloride plus AA, whereas endogenous phytate (mainly $IP_6$ and $IP_5$) in wheat flour prevented iron from being taken up into Caco-2 cells.

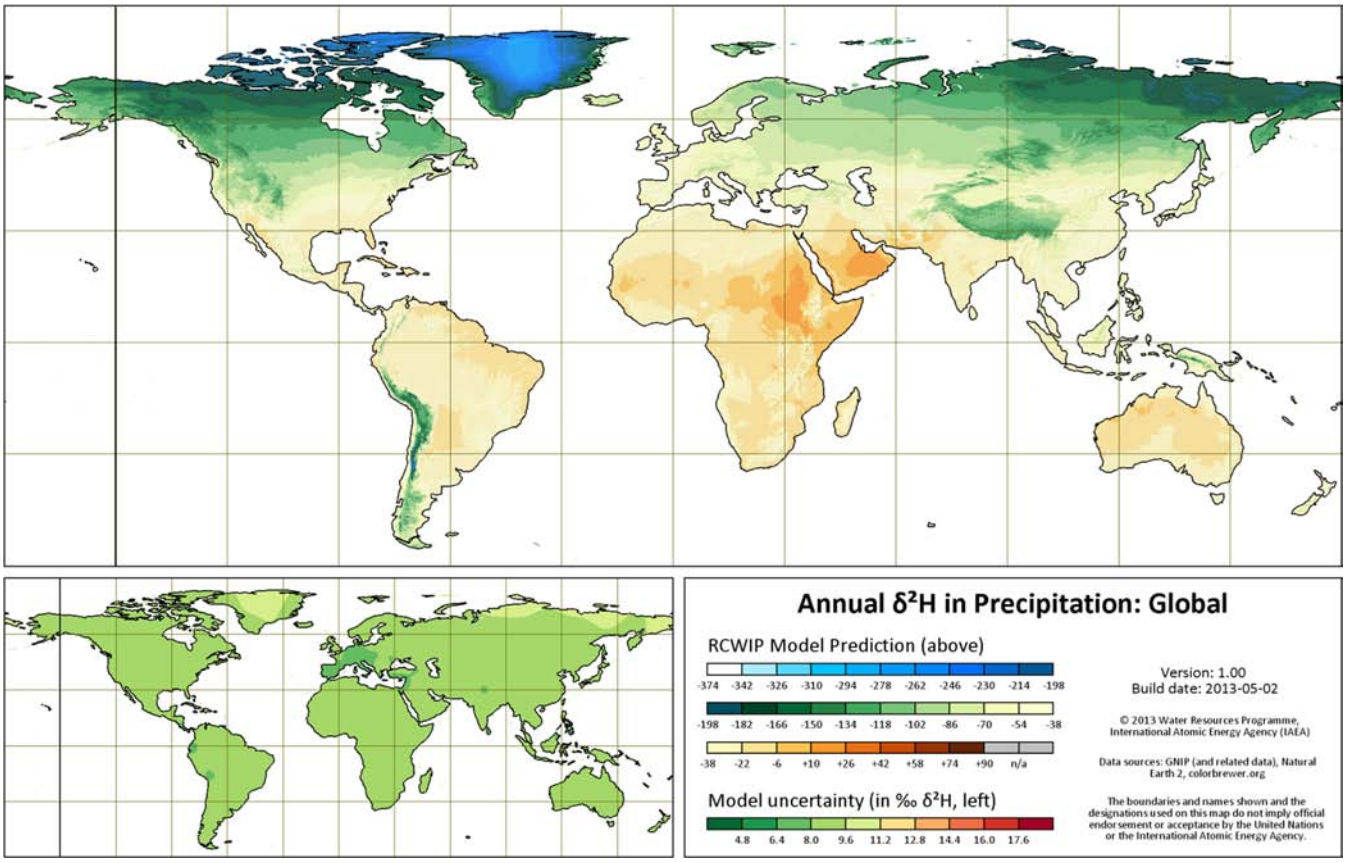

**Figure 1.** Regionalized cluster-based water isotope prediction model of $\delta^2$H in precipitation, developed by the International Atomic Energy Agency (IAEA).[22−24]

the location of its habitat. Because the plant absorbs water and uses it for biosynthesis of metabolites, the values of $\delta^2$H in the local precipitation will be reflected in these secondary metabolites, for example, vanillin from the vanilla orchid.[11−13]

The values of $\delta^{13}$C and $\delta^2$H can be measured by isotope ratio mass spectrometry (IRMS). IRMS is capable of measuring the natural abundance of stable isotopes.[14] Previous studies have investigated the authenticity of vanilla flavor using either elemental analyzer−IRMS (EA−IRMS) or gas chromatography−IRMS (GC−IRMS).[15−17] In these studies, it was shown that GC can be used to separate vanillin from the other components of a vanilla extract and that compound-specific data can be measured.

In this study, three types of vanillin were analyzed by gas chromatography−combustion−isotope ratio mass spectrometry (GC−C−IRMS) to investigate if the $\delta^{13}$C values differed enough to assign each group with a specific $\delta^{13}$C interval. In this way, an unknown sample of vanillin can be categorized by measuring its $\delta^{13}$C value. Additionally, gas chromatography pyrolysis isotope ratio mass spectrometry (GC−P−IRMS) was used for determining $\delta^2$H of vanillin from vanilla pods from various locations to test if it is possible to assign a $\delta^2$H interval to a specific geographic area. To the knowledge of the authors, this is the first time measurements of $\delta^2$H of vanilla pods from more than three different geographical origins have been characterized.

## MATERIALS AND METHODS

**Samples.** A total of 82 vanilla flavors of different origin were analyzed: 2 produced synthetically by Sigma-Aldrich (Brondby, Denmark), 1 sample produced by fermentation of natural eugenol by Rhodia (www.rhodia.com), and 79 natural vanilla pods of different types and geographical origin: 54 pods of the type *V. planifolia*, 15 pods of *V. tahitensis*, and 10 pods of unknown species. The geographical origin was known for 71 of the vanilla pods. The vanilla pods analyzed, originated from Madagascar, French Polynesia, India, New Caledonia, Tonga, Vanuatu, Mexico, Africa (Congo and Uganda), Indonesia, and New Guinea (including Papua New Guinea).

**Chemicals.** Ethanol used for extraction was of 96% purity and purchased from CCS Healthcare AB (Borlänge, Sweden). Ethyl acetate and cyclohexane used for extraction were purchased from Rathburn Chemicals, Ltd. (Walkerburn, U.K.), and anhydrous sodium sulfate was purchased from Merck (Darmstadt, Germany). A mixture of $C_{11}$, $C_{15}$, and $C_{20}$ alkanes (Chiron, Trondheim, Norway) with known values of $\delta^{13}$C (−26.11, −30.02, and −33.06‰) were used for sample calibration against the reference standard: Vienna-Pee Dee Belemnite (V-PDB). Two samples of caffeine (1 and 2) with different $\delta$ values (91.4 and −152.8‰), purchased from Arndt Schimmelmann (Indiana University, Bloomington, IN), were used for $\delta^2$H calibration against the reference standard: Vienna-Standard Mean Ocean Water (V-SMOW).

**Sample Preparation.** Vanilla pods were cut lengthwise; the seeds were scraped out; and the rest of the pod was cut in pieces less than 5 mm. Vanilla seeds and pods were placed in a closed flask, and for every 15 g of vanilla, 46 g of water and 54 g of 96% ethanol were added and macerated at ambient temperature for approximately 72 h during constant stirring with a stir bar (500 rpm). The flask was protected against sunlight. Afterward, the mixture was filtered, and the filter cake was pressed. This method extracted most of the vanillin because a second extraction resulted in less than 10% vanillin content compared to the first extraction. A total of 3 mL of the ethanol/water extract was further extracted with 3 mL of ethyl acetate/cyclohexane (1:1) and dried with anhydrous sodium sulfate. Samples were diluted 4 times

with ethyl acetate/cyclohexane (1:1) prior to GC−C−IRMS analyses, while no dilution was used before GC−P−IRMS analyses. One extraction was made for each vanilla pod. Synthetic vanillin and vanillin from eugenol were dissolved in ethyl acetate/cyclohexane (1:1). Each sample was analyzed 3 times by GC−C−IRMS and GC−P−IRMS, and results are given as a mean of the 3 determinations.

**GC Analyses.** Separation of the samples was performed on a Trace GC Ultra (Thermo Scientific, Bremen, Germany) fitted with a DB-5 capillary column (Agilent Technologies, Böblingen, Germany) (30 m × 0.250 mm inner diameter, with $d_f$ of 0.25 $\mu$m). The following GC conditions were employed: splitless injection, injector temperature of 230 °C, initial oven temperature of 40 °C, ramp at 4 °C/min to 150 °C, and ramp at 7 °C/min to 260 °C for 1 min. Helium was used as the carrier gas at 1.4 mL/min for GC−C−IRMS analysis and 1.2 mL/min for GC−P−IRMS; otherwise, the GC parameters were the same for the determination of $\delta^{13}$C and $\delta^{2}$H.

**IRMS Analysis.** For the determination of $\delta^{13}$C, compounds eluting from GC were combusted in an oxidation reactor (NiO tube with NiO/CuO/Pt) operated at 1000 °C, purchased from Thermo Scientific (Bremen, Germany). For $\delta^{2}$H determinations, compounds eluting from GC were converted in a high-temperature pyrolysis reactor (HTC reactor), consisting of a ceramic tube with no catalyst and operated at 1420 °C. The HTC reactor was purchased from Thermo Scientific (Bremen, Germany). The converted compounds from either the combustion reactor or the HTC reactor were analyzed on a Delta V Advantage isotope ratio mass spectrometer from Thermo Scientific (Bremen, Germany).

**Standardization against Primary Standards.** The standards of known isotopic values were analyzed in every sequence together with vanilla samples. The measured isotopic values for the standards were used to create an isotopic calibration of the samples, to express the final results in delta notation with the unit "per mille" versus V-SMOW and V-PDB, separately: $\delta = (R_{sample} - R_{standard})/R_{standard} \times 1000‰$, where $R$ is the ratio of the heavy/light isotopes.

**Statistical Analysis.** $t$ tests have been used for comparison of means between two groups. Variance homogeneity have been established preliminary using $F$ tests. One-way analysis of variation (ANOVA) has been used when more than two groups are compared. Afterward, Tukey's test is used to establish the correlation between the groups.

## RESULTS AND DISCUSSION

Vanillin is the main contributing compound to the vanilla flavor. The molecule is identical in its elemental composition regardless of the production method: natural, synthetic, or biovanillin. We determined the ratios of stable carbon isotopes by GC−C−IRMS of 82 vanillin samples to test if these results could be used to differentiate between the three production methods. A total of 2 samples of synthetic vanillin, 1 sample of biovanillin, and vanillin extracted from 79 vanilla pods were analyzed. Figure 2 shows a partial GC−C−IRMS chromatogram of mass 44 for a vanilla extract.

**Authenticity of Vanillin: Plant Species.** There was a significant difference in the $\delta^{13}$C between vanillin extracted from *V. planifolia* compared to vanillin from *V. tahitensis* (Figure 3) ($t$ test; $p < 0.001$). The range of $\delta^{13}$C values was from −21.8 to −17.8‰ for *V. planifolia* ($n$ = 54) and from −19.1 to −15.5‰ for *V. tahitensis* ($n$ = 15). The results show that *V. tahitensis* is more enriched in the heavy carbon isotope than *V. planifolia*. These findings are consistent with the results obtained by Scharrer et al. and Greule et al.[16,18]

**Authenticity of Vanillin: Production Method.** Synthetic vanillin from two different productions was found to have values of $\delta^{13}$C at −27.4 and −31.7‰, while biovanillin was measured to −30.9‰ (Figure 3). Because the $\delta^{13}$C value of biovanillin is within the range found for synthetic vanillin, the stable isotope analysis of carbon is not sufficient to differentiate

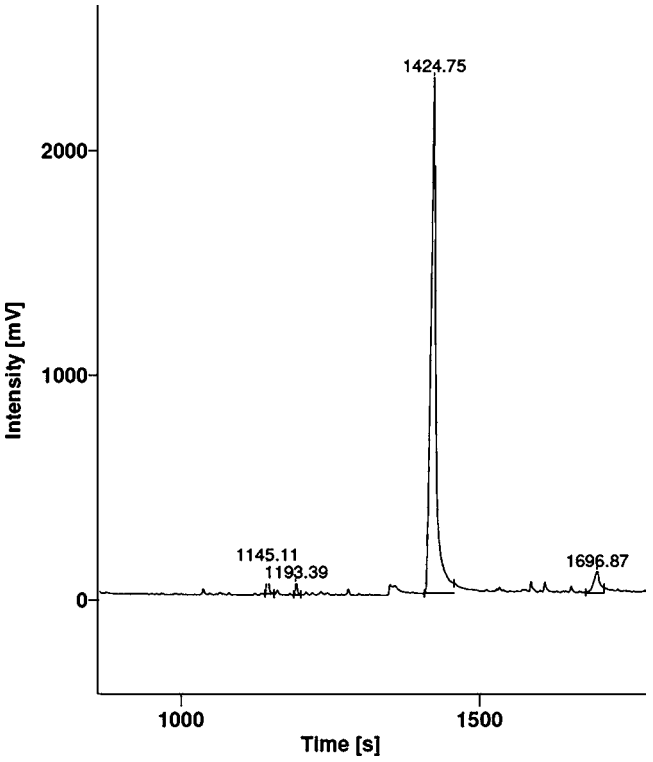

**Figure 2.** Partial GC−C−IRMS chromatogram showing the ion current of mass 44. The large peak with the retention time at 1424 is vanillin.

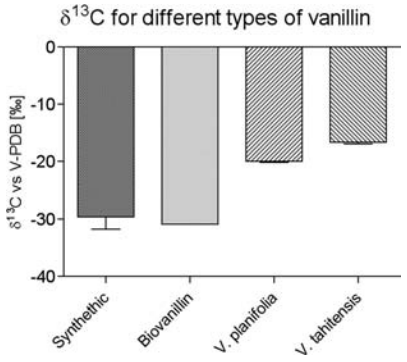

**Figure 3.** $\delta^{13}$C versus V-PDB for vanillin of known authenticity: obtained from chemical synthesis ($n$ = 2), fermentation of eugenol ($n$ = 1), and vanilla pods of the types *V. planifolia* ($n$ = 54) and *V. tahitensis* ($n$ = 15). Error bars equal standard errors of the means within the sample group.

the two groups and other methods have to be considered for authentification, i.e., measurements of site-specific isotopic ratios.[19] The $\delta^{13}$C value of the sample of biovanillin was −30.9‰, which is within the interval for $C_3$ plant material. Stable isotope analyses of synthetic and natural eugenol showed values of $\delta^{13}$C similar to biovanillin from eugenol (results not shown) and indicate that the isotope ratio of carbon does not change significantly when converted from eugenol to vanillin during fermentation.

Precursors used for the production of synthetic vanillin are generally derived from petrochemicals, with a $\delta^{13}$C similar or lower than $C_3$ plants.[20] In the case of biovanillin made by the fermentation of eugenol, the $\delta^{13}$C values found are similar to the values of synthetic vanillin in this study. However, Scharrer

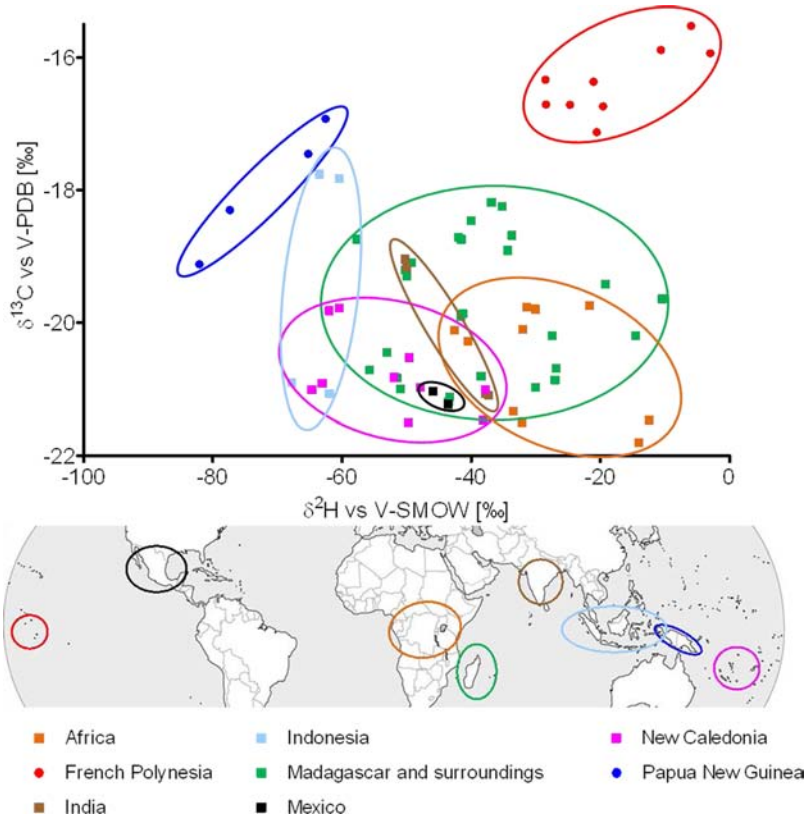

**Figure 4.** Results of $\delta^2$H versus V-SMOW and $\delta^{13}$C versus V-PDB for vanillin extracted from vanilla pods. Points are labeled with geographic origin. The geographical origins are separated by colors, with *V. tahitensis* represented by circles and *V. planifolia* represented by squares. The large circles in the scatter plot are color-correlated to the circles in the world map, showing the regions from where the samples originate.

**Table 1. Measured Values of $\delta^{13}$C versus V-PDB and $\delta^2$H versus V-SMOW for Vanilla Pods Originating from New Caledonia, French Polynesia, Mexico, Africa, Madagascar, India, Indonesia, and New Guinea**

| | | $\delta^{13}$C versus V-PDB (‰) | | | | $\delta^2$H versus V-SMOW (‰) | | | |
|---|---|---|---|---|---|---|---|---|---|
| | *n* | $\bar{x}$ | *s* | minimum | maximum | $\bar{x}$ | *s* | minimum | maximum |
| New Caledonia, Tonga, and Vanuatu | 10 | −20.8 | 0.6 | −21.5 | −19.8 | −52.5 | 9.8 | −64.6 | −37.8 |
| French Polynesia | 9 | −16.4 | 0.5 | −17.1 | −15.5 | −18.0 | 9.4 | −28.5 | −3.0 |
| Mexico | 2 | −21.1 | 0.1 | −21.2 | −21.0 | −44.7 | 1.6 | −45.9 | −43.6 |
| Africa (Congo and Uganda) | 10 | −20.6 | 0.8 | −21.8 | −19.7 | −29.0 | 10.1 | −42.6 | −12.4 |
| Madagascar | 28 | −19.8 | 1.0 | −21.3 | −18.2 | −38.9 | 12.1 | −57.7 | −10.4 |
| India | 4 | −20.1 | 1.2 | −21.1 | −19.0 | −43.8 | 7.3 | −50.2 | −37.3 |
| Indonesia | 4 | −19.4 | 1.9 | −21.1 | −17.8 | −63.4 | 3.2 | −67.8 | −60.4 |
| New Guinea | 4 | −18.0 | 1.0 | −19.1 | −16.9 | −71.8 | 9.4 | −82.1 | −62.5 |

et al. found that biovanillin could be differentiated from synthetic vanillin using GC−C−IRMS. The precursor for the biovanillin used by Scharrer et al. was not specified.[18] Therefore, it might be possible to authenticate biovanillin made from $C_3$ plant material other than eugenol using the measurement of $\delta^{13}$C.

Values of $\delta^{13}$C for natural vanillin extracted from vanilla pods were in the range from −21.8 to −15.5‰, while vanillin from other sources had values of $\delta^{13}$C between −31.7 and −27.4‰. Thus, natural vanillin is more enriched in the heavy carbon isotope compared to vanillin originating from fermentations or chemical synthesis. This difference was expected because natural vanillin is extracted from CAM plants, which have higher values of $\delta^{13}$C than $C_3$ plant materials used for the production of biovanillin by fermentations. O'Leary found that CAM plants often have values of $\delta^{13}$C between −20 and −10‰, while $\delta^{13}$C for molecules from $C_3$ plants have values between −33 and −24‰.[9] The results from this study are consistent with the findings by O'Leary.

To differentiate between vanillin from vanilla pods and vanillin made otherwise, the values of synthetic vanillin and biovanillin are tested against values of $\delta^{13}$C for vanillin extracted from vanilla pods. Because the two species of vanilla pods are found to have significant different means, the non-natural vanillin has to be tested against both species separately. This results in three groups: one containing synthetic and biovanillin, a second containing all vanillin results for *V. planifolia*, and a third group with vanillin results for *V. tahitensis*. A one-way ANOVA followed by a Tukey's test showed significant difference between the three groups ($p < 0.001$). Values of $\delta^{13}$C versus V-PDB can therefore be used to determine if vanillin originates from a vanilla pod or is produced otherwise.

**Traceability of Vanillin.** Ratios of the heavy/light stable isotopes of hydrogen differ around the world primarily as a result of longitudinal, altitudinal, and continental effects. Because plants take up water from their surroundings, the ratio of stable hydrogen isotopes in plants will resemble the ratio of their specific geographic location.[13] In this study, natural vanillin was analyzed for $\delta^2$H by GC−P−IRMS to investigate whether the differences in $\delta^2$H values are large enough to differentiate between the geographic origins of growth.

Figure 4 shows results of $\delta^{13}$C plotted against results of $\delta^2$H for vanillin extracted from vanilla pods. The average, standard deviation, maximum, and minimum values of $\delta^{13}$C and $\delta^2$H for each geographic origin are shown in Table 1. Samples from French Polynesia and New Guinea are all of the species *V. tahitensis*, while the rest of the vanilla samples are *V. planifolia*. Samples of *V. tahitensis* from New Guinea are more depleted in the heavy carbon isotope than samples of *V. tahitensis* from French Polynesia. Growth conditions may be a possible explanation for the differences in values of $\delta^{13}$C between these two countries. West et al. describes how marijuana grown in an indoor environment has significant lower values of $\delta^{13}$C than plants grown outdoors. The respired $CO_2$ has lower values of $\delta^{13}$C than atmospheric $CO_2$. Therefore, in a closed environment, with poor ventilation, the respired $CO_2$ will not mix well with the atmosphere and, thereby, decrease the values of $\delta^{13}$C.[21] In places with intensive sunlight, it is necessary to protect the vanilla orchid, either in the form of support trees or by covering the plants.[5] In the last-mentioned case, the cover could cause poor ventilation and, consequently, lower the values of $\delta^{13}$C in the vanilla plants.

Figure 4 shows results of $\delta^{13}$C versus $\delta^2$H for natural vanillin, and it is seen that adjacent geographic locations are grouped together. Vanillin extracted from vanilla pods originating from French Polynesia differ from the other samples. Because vanilla pods from French Polynesia are solely of the species *V. tahitensis*, which are more enriched in the heavy carbon atom than *V. planifolia*, they can be separated from other geographic origins growing *V. planifolia* based on their values of $\delta^{13}$C. Even within samples of *V. tahitensis*, the two different locations, French Polynesia and New Guinea, are easily separated ($p < 0.001$) because their values of $\delta^2$H differ by more than 30‰.

The lowest $\delta^2$H values were found for vanillin extracted from vanilla pods from New Guinea and Indonesia, with mean values of $-71.8 \pm 9.4$ and $-63.4 \pm 3.2$‰, respectively. India and New Caledonia samples are more enriched in deuterium than New Guinea and Indonesia. $\delta^2$H mean values are $-43.8 \pm 7.3$‰ for India and $-52.5 \pm 9.8$‰ for New Caledonia. Values of $\delta^2$H for vanillin from Madagascar and surrounding islands show more variation than the other origins analyzed (Figure 4). The mean $\delta^2$H value of vanillin samples from Madagascar is $-38.9 \pm 12.1$‰. The highest values of $\delta^2$H are found for French Polynesia and Africa, with a mean value of $-18.0 \pm 9.4$ and $-29.0 \pm 10.1$‰, respectively.

One of the highest values of $\delta^2$H is found for vanilla grown in Africa (Uganda and Congo). From Africa, there is a tendency toward decreasing values of $\delta^2$H moving east. This trend can also be seen in the regionalized cluster-based water isotope prediction (RCWIP) model developed by IAEA,[22−24] which shows the predicted annual $\delta^2$H in precipitation (Figure 1). The agreement between the measured $\delta^2$H values of vanillin and the RCWIP model supports that the plants incorporate water from its surroundings without significant isotopic fractionation.[13]

Tests showed that values of $\delta^{13}$C versus V-PDB for *V. planifolia* are significantly different from those of *V. tahitensis*, To use this knowledge about vanilla species, the geographical origins are separated into two groups: one group for origins growing only *V. planifolia* (Madagascar, Mexico, India, Africa, Indonesia, and New Caledonia) and a second group growing only *V. tahitensis* (French Polynesia and New Guinea). Values of $\delta^2$H versus V-SMOW for the geographical origins in the group of *V. planifolia* are tested using one-way ANOVA followed by a Tukey's post-test. This test shows that values of $\delta^2$H for vanillin originating from Indonesia can be separated from vanillin from Africa ($p < 0.001$) and Madagascar ($p < 0.01$). Furthermore, vanillin from New Caledonia can be separated from vanillin originating from Africa ($p < 0.001$) and Madagascar ($p < 0.05$). Values of $\delta^2$H versus V-SMOW for vanilla pods originating from French Polynesia and New Guinea are tested using a $t$ test and found to be significantly different ($p < 0.001$).

The combined use of results of $\delta^{13}$C and $\delta^2$H analyses for vanillin, extracted from vanilla pods, shows a relatively close clustering pending upon species as well as geographic location of growth. Analysis of $\delta$ values of carbon and hydrogen by compound-specific IRMS is a useful tool in the verification of the authenticity and traceability of vanilla pods.

## MATERIALS AND METHODS

**Flower Collection Sites.** Flower collection sites were selected with the assistance of local beekeepers. The sites were spread across New Zealand between latitudes 34° and 41° S and between longitudes 171° and 179° E. The sites recommended by beekeepers were those regarded as yielding mānuka honey with measurable NPA; the Whanganui site was chosen to provide contrast as it yielded "bush" honey rather than mānuka honey with measurable NPA, and the Northland survey was undertaken because the variety of *L. scoparium* in Northland differs from the rest of New Zealand. The range of sites also afforded the opportunity for comparison with the study of honeys by Stephens.[12] Sampling at the Coromandel, East Cape, Waikato, Wairarapa, Whanganui, and Nelson sites was carried out during the flowering seasons (November−December) in 2009 and 2010 and for the East Cape and Waikato sites also in 2011. A separate collection of samples from the Northland region was made in 2010 and 2011. Most site visits in remote locations occurred once each year, and only specimens that were flowering on the day of the visit were sampled; this was an unavoidable bias. More accessible cultivated trees around the University of Waikato campus were used for testing of the effect of sampling methods, floral gender, and age on nectar quality.

**Sampling Protocol.** The trees sampled in 2009 were resampled in 2010 except for those that had died in the interim. In 2011 additional trees located within 50 m of the existing test trees at the East Cape sites were sampled. Further samples were collected in the Auckland and Waikato regions in 2012, both cultivars and wild accessions. The trees were sampled, whenever possible, on a fine day. Entire flowers were picked off individually or scraped off between two fingers drawn from the base toward the apex of the shoot. In addition to collection of flower samples in 2009, soil was collected (with a small trowel at 2 m from the trunk of each tree, samples approximately 15 × 10 × 20 cm in dimension), and foliage was collected for leaf oil analyses. All samples were stored in airtight bags and chilled with ice while transported, until they could be transferred to a freezer (−20 °C) for storage until analysis.

**Herbarium Depository.** Accessions collected from the wild were assigned to one of the two varieties recognized for *L. scoparium*: either var. *scoparium* or var. *incanum*.[13] Voucher specimens for each tree were deposited in the University of Waikato Herbarium (WAIK).

**Materials.** *o*-(2,3,4,5,6-Pentafluorobenzyl)hydroxylamine hydrochloride (PFBHA) (derivatization grade) and methylglyoxal (43.2%) were obtained from Fluka Analytical (Buchs, Germany). Dihydroxyacetone (97%), hydroxyacetone (technical grade 90%), sucrose (99+%), D-(−)-fructose (99+%), D-mannitol (98+%), and citric acid (99.5%) were obtained from Sigma-Aldrich (Sydney, Australia). 1-(Trimethylsilyl)imidazole (TMSI) was obtained from Thermo Scientific (Scoresby, Australia). D-(+)-Glucose (AR) grade was obtained from BDH Laboratory (Murarrie, Australia). Deionized water was obtained from a Barnstead Epure water system at 17.9 MΩ. Dichloromethane (analytical grade) was obtained from Ajax Finechem (Sydney Australia) or purified using a Pure Solv solvent purification system model PS-SD-5 (Innovative Technology, Amesbury, MA, USA).

**Extraction of Nectar.** The methodology was based upon that of Morrant et al.[14] Frozen flowers were removed from the sample bag, giving preference whenever possible to open flowers in good condition. Either 20 (20F), 10 (10F), or 1 (1F) flower(s) was placed in 4, 2, or 1 mL of water, respectively, and kept for 20 min. After standing, the flowers were removed and the nectar/water solution was frozen if analysis was not performed immediately. Ten replicates of the 20F or 10F method were carried out for each bag/tree when there was sufficient material.

**Single-Flower Test.** Some of the trees, especially the Northland and East Cape samples collected in 2011, yielded insufficient flowers for the 10F or 20F test. Comparison of the 1F and 20F tests was carried out using replicates ($n$ = 10) from three *L. scoparium* 'Martinii' (*L.* 'Martinii') trees sampled on the University of Waikato campus.

**Preparation of Nectar for Dihydroxyacetone Detection.** To a vial containing hydroxyacetone (internal standard, 10 μL, 0.5 mg/mL) and nectar extract (20F, 200 μL; 10F, 200 μL; 1F, 400 μL) was added and mixed PFBHA (50 μL, 20 mg/mL in a pH 4 citric buffer), and the mixture was kept for 1 h. Dichloromethane (20F, 2 mL; 10F, 2 mL; 1F, 1 mL) was added and mixed. The vial was then placed in a freezer (0 °C) until the aqueous layer froze to aid extraction. An aliquot (1 mL) of the dichloromethane layer was withdrawn into a GC vial (1.5 mL). TMSI (50 μL) was added, mixed, and allowed to stand (1 h) before analysis by GC-FID.

**Preparation of Nectar for Sugar Detection.** To a vial containing mannitol (internal standard, 5 μL, 5 mg/mL) was added nectar extract (20F, 20 μL; 10F, 20 μL; 1F, 50 μL), and the vial contents were freeze-dried. To the dry sample was added and mixed TMSI (50 μL), and the mixture was kept at room temperature. Heptane (1 mL) was added with mixing before analysis by GC-FID.

**GC-FID Parameters.** The column used was a 0.32 mm × 0.25 μm i.d., 30 m, Zebron ZB-5 capillary GC column (Agilent Technologies, Santa Clara, CA, USA). For all methods a 2 μL injection into a splitless inlet with a 2 mL/min purge flow was used, with the FID held at 300 °C. $H_2$ flow was 30 mL/min; air flow, 400 mL/min; and $N_2$ makeup flow, 10 mL/min.

For the detection of dihydroxyacetone, the inlet was set to 250 °C and used a $H_2$ carrier gas flow of 2 mL/min. The temperature program was 130 °C held for 5 min, increased at 10 °C/min to 250 °C, and then held at that temperature for 6 min. Dihydroxyacetone was quantitated against hydroxyacetone as an internal standard and used a calibration curve constructed over the range of 0.003−0.015 mg/mL. The limits of detection for dihydroxyacetone and methylglyoxal were $3.00 \times 10^{-8}$ and $4.58 \times 10^{-7}$ g/mL, respectively. The limits of quantitation for dihydroxyacetone and methylglyoxal were $1.00 \times 10^{-7}$ and $1.53 \times 10^{-6}$ g/mL, respectively.

For the detection of sugars, the inlet was set to 280 °C with a $H_2$ carrier gas flow of 4 mL/min. The temperature program was 100 °C held for 1 min, increased at 30 °C/min to 200 °C, increased at 10 °C/min to 250 °C, and finally increased at 30 °C/min to 300 °C. The sugars were quantitated against D-mannitol as an internal standard with a response factor found for each sugar. The response was measured over the range of 50−150 mg/mL and gave fructose, 0.5335; glucose, 0.8217; and sucrose, 0.7126. Fructose, glucose, and sucrose were summed to give total sugars.

**Expression of Results for Dihydroxyacetone Content.** Dihydroxyacetone content is expressed as a ratio of DHA/total nectar sugar (Tsugar). The assumption was made that all of the sugars in honey derive ultimately from the nectar and that the ratio for dihydroxyacetone to total sugar would be indicative of the expected ratio in the early honey before maturation because dihydroxyacetone might be expected to have volatility similar to that of the sugars. Ten replicates for each tree were assayed and after outliers were determined (single outlier and largest/smallest or two largest/smallest tests);[17] results are expressed as the mean and 95% standard error.

**Measurement of Nectar DHA/Tsugar in Australian Species.** The nectars of some Australian species (*L. juniperinum* Sm., *L. liversidgei* R.T.Baker & H.G.Sm., *L. laevigatum* (Gaertn.) F.Muell.) were analyzed at the University of the Sunshine Coast in southern Queensland. Sampling from wild populations occurred principally in the coastal region of northern New South Wales. Sample preparation was as above, but GC-MS was utilized.

**GC-MS Parameters.** The column used was a 30 m × 0.25 mm × 0.25 μm i.d. Elite 5MS gas capillary column (PerkinElmer, Melbourne, Australia). Analyses were carried out using a PerkinElmer Clarus 580 gas chromatograph coupled to a PerkinElmer Clarus SQ85 mass spectrometer (all PerkinElmer instruments were supplied by PerkinElmer, Melbourne, Australia). The carrier gas (helium) flow was set to 1 mL/min for both the sugar and dihydroxyacetone analyses. For the sugar analysis the inlet was configured to shut the split from 0.20 to 1.00 min and open with a 50:1 ratio; it was maintained at 280 °C. The oven program was the same as described for the New Zealand samples. Compound ionization was at 70 eV electron impact, analyzing $m/z$ 70−440 over 4.50−11.00 min. For the dihydroxyacetone analysis, the inlet was configured as for the sugar analysis except the temperature was maintained at 250 °C. The oven

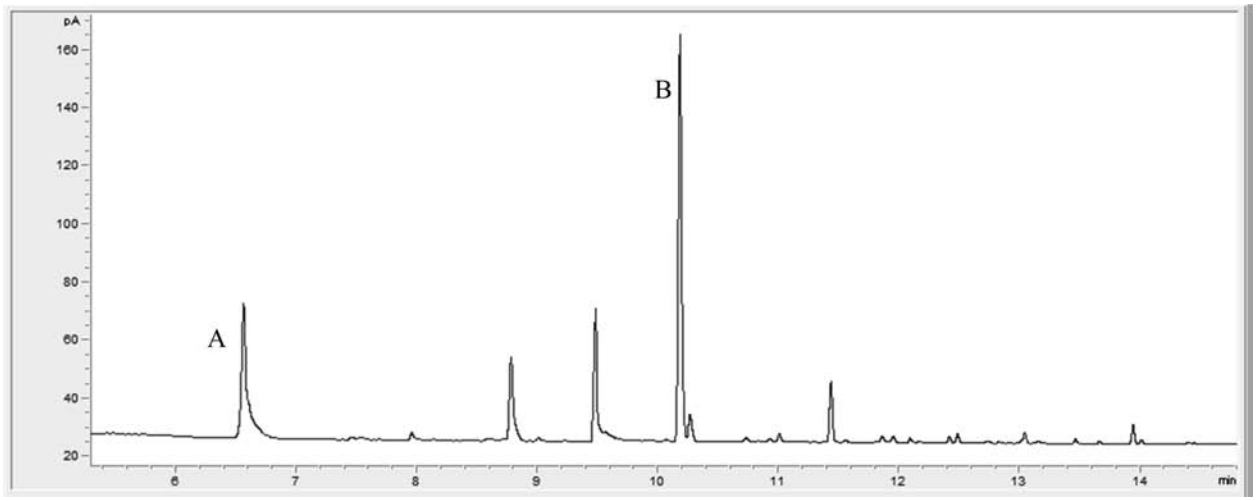

**Figure 1.** GC-FID chromatogram of a nectar sample used for dihydroxyacetone quantitation: (A) hydroxyacetone used as internal standard; (B) dihydroxyacetone.

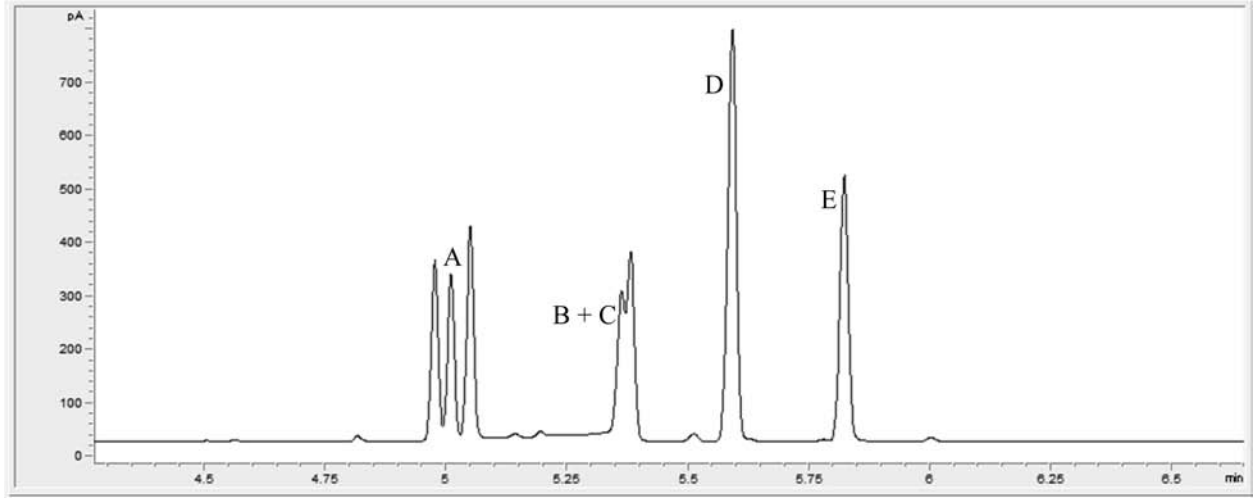

**Figure 2.** GC-FID chromatogram of a nectar sample used for sugar quantitation. The peaks at (A) are fructose, those at (C) and (E) are glucose, and that at (D) is mannitol used as an internal standard. (B) arises from an organic acid and was not included in the glucose peak area.

program was the same as that outlined for the New Zealand specimens. Compound ionization was at 70 eV electron impact, analyzing $m/z$ 45−440 over 4.50−23.00 min.

**Statistical Analyses.** Statistical analyses were carried out using Microsoft Excel or Minitab 16.

## RESULTS AND DISCUSSION

To simplify discussion, nectar DHA/Tsugar has been divided into three classifications: low (<0.001 mg/mg), moderate (0.001−0.002 mg/mg), and high (>0.002 mg/mg).

**Choice of Methodology for Nectar Sampling and Extraction.** Stephens et al.[15] analyzed nectar of *L. scoparium* ($n$ = 6) for phenolics and for methylglyoxal; the methodology employed by those authors was to use direct sampling by pipet.[15] For the current study this method was considered, but it was decided that it was far too time-consuming for this broad-based preliminary survey, which was often carried out in isolated areas, accessed only with difficulty and often under inclement conditions. This view is supported by the conclusions of Morrant et al.,[14] who have reviewed methods of nectar collection.

Two methods of extracting nectar from the previously collected flowers were compared: washing (20 min) and individual dipping (three times). Each method was repeated eight times using 20 flowers per sample for flowers from the same tree, and the absolute dihydroxyacetone content was analyzed; mean and %RSD were respectively 0.0056 mg (26%) and 0.00020 mg (90%). Washing was therefore used in this survey. Morrant et al.[14] also recommended washing of cut flowers as the most practical method and, indeed, found this to be preferable to and more reproducible than the use of micropipets.[14]

Stephens et al.[15] did not assay dihydroxyacetone; methylglyoxal was assayed but only reported as a trace, so no numerical comparison between methods in that study and the current study is possible.

**Method Validation.** *Gas Chromatography Methodology for Analysis of Dihydroxyacetone and Methylglyoxal with PFBHA Derivatization.* PFBHA derivatization with analysis by reversed phase HPLC has been used previously to assay dihydroxyacetone and methylglyoxal simultaneously in honey;[4] it was decided that GC-FID would supply the requisite sensitivity for nectar samples. The derivatization and GC-FID

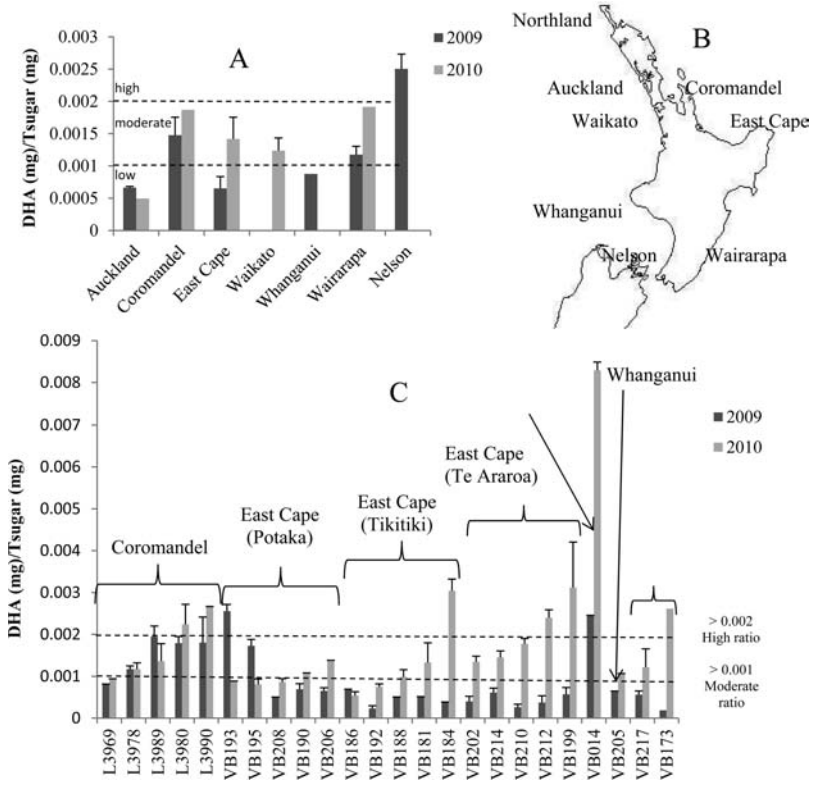

**Figure 3.** (A) Plot of the mean nectar DHA/Tsugar of all wild trees for each region for the two flowering seasons 2009 and 2010 (error bars are standard error values). (B) Map of locations across the North Island and upper South Island of New Zealand. (C) Plot of nectar DHA/Tsugar values for all trees that were sampled in both 2009 and 2010, grouped into regions and then ascending order of 2010 value. The only tree from Waikato that was tested in both years was a cultivar growing in a suburban garden (not included in panel A; error bars are standard error values).

analysis of samples was optimized using standards of hydroxyacetone, dihydroxyacetone, and methylglyoxal. Nectar samples spiked with these standards were used to ensure that the derivatizing agent PFBHA was present in sufficient excess. Under the conditions used, hydroxyacetone (internal standard), dihydroxyacetone, and methylglyoxal eluted at 6.6, 10.1, and 13.1 min, respectively. Responses for dihydroxyacetone and methylglyoxal (measured as analyte/internal standard versus analyte) were linear from 0 to 0.0016 mg ($R^2$ = 0.9998) and from 0 to 0.015 mg ($R^2$ = 0.9815), respectively. The LOQ for dihydroxyacetone corresponded to a minimum detectable mass of 20.5 ng and that for methylglyoxal to 313 ng. The LODs were respectively 6.16 and 93.8 ng. Methylglyoxal was never detected at a level that allowed quantitation in any nectar samples in this study (Figure 1); the presence of methylglyoxal in nectar samples assayed by others[15] might be because the methodology employed was more sensitive than that used here or might indicate that the flowers or nectar samples had been exposed to elevated temperatures or stored for prolonged periods at room temperature prior to analysis.[16]

*Gas Chromatography Methodology for Analysis of Sugars with TMS Derivatization.* Response factors of sucrose, glucose, and fructose relative to the internal standard mannitol were ascertained by varying weight ratios and comparing area ratios and were 0.7126, 0.8217, and 0.5335, respectively. Varying the quantity of derivatization agent from 50 to 200 μL demonstrated that 50 μL was sufficient excess. As sugars were always readily observed, LOD and LOQ were not required. Under the chromatographic conditions used for the analysis, fructose (multiple furanose and pyranose anomers) eluted at 4.9−5.1 min, glucose (pyranose anomers) at 5.6 and 5.8 min, and mannitol at 5.7 min (Figure 2).

*Duration of Washing for Nectar Extraction.* The duration of washing was based upon the method of Morrant et al.,[14] who found no difference between 1 and 20 min but a significant difference between 20 and 60 min. In this study extended washing of the flowers (230 min) resulted in a ∼25% decrease in DHA/Tsugar, presumably because sugar was leaching from other parts of the flower.

*Reproducibility Tests.* To ascertain day-to-day reproducibility of the method, samples from eight trees were assayed (20F, $n$ = 10) on two different days. Statistically, three of the trees gave significantly different results between days ($p$ = 0.0010, 0.0007, and 0.000), whereas five did not ($p$ = 0.1597, 0.8899, 1.000, 1.000, and 1.000), but in only one case did a tree change its DHA/Tsugar classification. The weather conditions on each day of sampling may have had an influence on these results as rain and wind can remove nectar from the open bowl of the mānuka flower, as can visits by pollinators.

*Stability of Nectar Extract.* The stability of the nectar extract was ascertained for samples from three trees in which replicates ($n$ = 10) were stored frozen and others ($n$ = 5) were left to stand at room temperature overnight before analysis. The samples that were left to stand darkened in color overnight, but a $z$ test for two sample means showed that there was no change in the DHA/Tsugar ratio. To test the stability of the derivatized samples, duplicates from one tree were prepared for both dihydroxyacetone and sugar assays and injected into the GC at the beginning and the end of the sequence; the time lapse for the sugar assay was ∼315 min and for the dihydroxyacetone

assay, ~702 min. The results for DHA/Tsugar were identical to two significant figures.

*Comparison of 10-Flower (10F) and 20-Flower (20F) Tests.* The 10F test was compared with the 20F test using replicates ($n$ = 10) from three different trees; the difference between the two tests was insignificant at the 95% confidence level. The percentage relative standard deviation was higher for the 10F than for the 20F test but did not exceed 25%.

*Comparison of the Single-Flower Test (1F) and the 20F Test.* Some of the trees, especially the Northland samples and the East Cape samples collected in 2011, yielded insufficient flowers for the 20 or 10 flower test. Comparison of the 1F and 20F tests was carried out using replicates ($n$ = 10) from three trees. The ranges of percentage difference between the two tests for the two ratios, DHA/Tsugar and fructose/glucose, were 5.52−20.21 and 1.83−17.44, respectively. The percentage relative standard deviation for the 1F test was much higher than for the 20F test and also much higher than the percentage difference between the two methods. This indicates, as might be expected, that there is variability between individual flowers on the same tree. To confirm that biological variation exceeded experimental variation, replicates ($n$ = 5) of a single extraction (20F) were compared to multiple extractions (20F, $n$ = 10) for three different trees. For the single extraction percentage relative standard deviations were 1.20, 2.54, and 3.13 for the three trees, and the corresponding values for the multiple extractions were 14.36, 9.06, and 25.80. This confirms that the greatest source of variation is that within a single tree, the cause of which is not yet established but may include active removal by pollinators and variation related to the different stages of flower maturity.

*Transference of Nectar.* The residue from an empty sample bag was rinsed out and assayed, and dihydroxyacetone equivalent to about half that found in 20 flowers was measured (a bag typically contained ~500 flowers). This confirms that transfer of nectar between flowers and the bag and presumably also between flowers is occurring; this may partially account for the variation observed in the single-flower test.

**Variation of Nectar DHA/Tsugar between Regions and Years and within Regions.** *Variation of Nectar DHA/Tsugar between Regions and Years.* Regional and annual variation in nectar DHA/Tsugar was observed (Figure 3). Only the Coromandel and East Cape regions had sufficient samples in both years for a statistical test of the effect of sampling year. A balanced ANOVA showed that the mean DHA/Tsugar for the East Cape region was significantly different ($p$ = 0.02) between 2009 and 2010, whereas the Coromandel region did not differ between years ($p$ = 0.5). The change observed in the East Cape samples was sufficient to alter the classification from low in 2009 to moderate in 2010.

Only the Coromandel, East Cape, and Wairarapa regions had sufficient samples for a test of effect of region on DHA/Tsugar. A one-way ANOVA test followed by mean separation using Tukey's method detected an overall region effect ($p$ = 0.05). Mean nectar DHA/Tsugar did not differ between the Coromandel and Wairarapa samples, but the East Cape values were lower in both 2009 and 2010.

*Variation within Regions.* Significant differences in nectar DHA/Tsugar were observed between trees within the Coromandel sampling site (Figure 3). All trees were located within a radius of 100 m, but a range of classifications from low to high was observed. There were three soil orders present at this Coromandel site, but no relationship between soil order and DHA/Tsugar could be found. To further investigate variation within a region, an additional collection was made in the East Cape region in 2011. From eight sites, one or more trees of various classifications (low−high), which had been sampled previously, were selected, and other trees within a 50 m radius were also sampled. Even within a narrow radius individual trees differed significantly in their nectar DHA/Tsugar (Table 1), in some cases ranging from high to low classifications.

The Northland/Auckland region was surveyed in 2010 and 2011 (Figure 4). For this survey the region was divided into two zones: Northland, encompassing the area from Cape Reinga to 36.3° S (zone 1) and the Auckland/Coromandel regions south of 36.3° S (zone 2). In zone 1 *L. scoparium* var. *incanum* Cockayne predominates,[18] whereas in zone 2 and the rest of New Zealand most wild mānuka honeys are considered to be *L. scoparium* var. *scoparium*. The individual tree returning an exceptionally high value belonged to *L. scoparium* var. *incanum* located in a maintained area. The individual with a midmoderate result was also from *L. scoparium* var. *incanum*. The only other individual demonstrating a high classification belonged to *L. scoparium* var. *scoparium* as did the two specimens with low−moderate results. The remaining individuals consisted of a mixture of var. *scoparium* ($n$ = 23) and var. *incanum* ($n$ = 16), all of which scored in the low classification. No apparent trend exists relating either of these varieties to high nectar DHA/Tsugar.

Stephens[12] grouped 463 mānuka honey samples (from a single season, 2001−2002 and supplied by apiarists) by region and by mean "unique mānuka factor" (UMF), a measure of nonperoxide antibacterial activity. Waikato ($n$ = 6) and Coromandel ($n$ = 23) returned high values of activity (>14 UMF), although other Coromandel honeys returned intermediate levels ($n$ = 16; 12.6 UMF) and low levels ($n$ = 63; 10.5 UMF). Some East Coast honeys returned intermediate levels of activity ($n$ = 22, 12.5 UMF), whereas others returned lower levels ($n$ = 17; 10.9 UMF). Wairarapa honeys returned low levels of activity ($n$ = 12; 9.4 UMF) as did samples from the northern South Island ($n$ = 41; 9.1 UMF), whereas Northland demonstrated high levels of activity ($n$ = 35; 14.8 UMF). These findings concur with the variability observed in the current study in both the Coromandel region and the East Cape and, to some extent, the finding that the East Cape values were lower than those for the Coromandel. However, the Wairarapa, Northland, and northern South Island results are in contrast. The Waikato result, with the exclusion of the garden cultivar, is somewhat lower than expected from Stephens's results, which relate to honeys originating from wild mānuka in swamplands, but in the current study the trees were sampled from drier locations, which might possibly account for the observed difference.

Caution should be exercised when these two studies are compared because variability of classification of dihydroxyacetone content between seasons was observed in the current study at one location, and further work (unpublished data) indicated that the conditions of storage by the apiarist strongly influence the efficiency of conversion of dihydroxyacetone to methylglyoxal in maturing mānuka honey and hence the final UMF value.

**Nectar DHA/Tsugar in Commercial New Zealand Originated Cultivars.** The specimen used to first illustrate the presence of dihydroxyacetone in nectar was a red-pink-flowered cultivar *L.* 'Martinii', which is widely available from

[a]The trees (and the corresponding DHA/Tsugar value) originally sampled in 2010 are shown in bold. [b]Tree with a significantly different DHA/Tsugar from the original tree at that site. [c]Dihydroxyacetone was below the level of quantitation.

plant nurseries and which was growing in a suburban garden in Hamilton. This cultivar consistently gave substantially higher nectar DHA/Tsugar values than any of the wild specimens tested (Figure 3).

*L.* 'Martinii' is believed to be a cross between the pink-flowered, *L. scoparium* 'Keatleyi' and the red-flowered *L. scoparium* 'Nichollsii' (*L.* 'Nichollsii'),[19] which is no longer found in New Zealand, but *L. scoparium* 'Red Ensign' (*L.* 'Red Ensign') is thought to be a newer name for *L.* 'Nichollsii Improved'.[19] The nectar DHA/Tsugar for several *L.* 'Martinii' and *L.* 'Red Ensign' plants from which flowers were collected in 2011 and 2012 (including VB014 from the original survey) was classified as high or very high (Table 2). When compared to regional variation between wild plants, only the Nelson region had a mean DHA/Tsugar approaching that of *L.* 'Martinii' and *L.* 'Red Ensign' (between 0.002 and 0.003 in 2009); all other regions had means <0.002 (Figure 3).

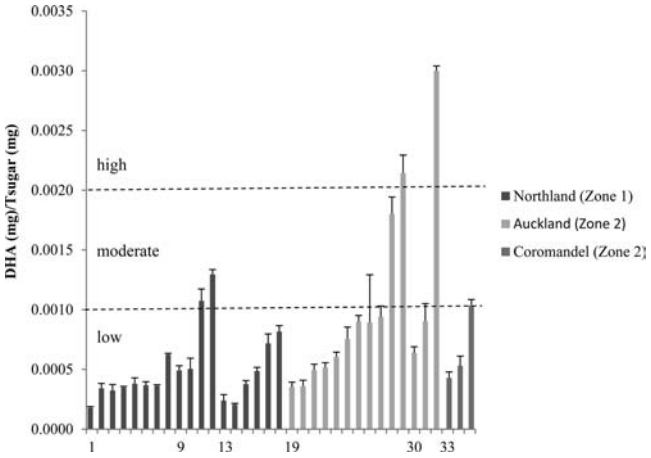

**Figure 4.** Nectar DHA/Tsugar values for Northland, Auckland, and Coromandel trees sampled between 2010 and 2011 (error bars are standard error values). The numbers on the *x*-axis indicate the first tree in each zone of sampling. Trees 1–8 were from upper Northland, trees 9–12 from upper East Northland, trees 13–18 from lower East Northland, trees 19–29 from North Auckland, trees 30–32 from South Auckland, and trees 33–35 from the Coromandel region.

In addition to the aforementioned pink- and red-flowered garden cultivars, >150 cultivars have been named. These have been obtained from the wild and also selected in cultivation.[5,19−21]

To further examine the possibility that some garden cultivars may exhibit unusually high nectar DHA/Tsugar, a collection of cultivars was made at the Auckland Botanic Gardens in a single day (10F, 10 replicates) (Table 3). All cultivars with levels of dihydroxyacetone below the limit of quantitation were still producing nectar sugars; that is, the Tsugar values were readily measured. From this small, preliminary survey it would appear that red or pink coloration in a cultivar is often associated with high nectar DHA/Tsugar but that this is also often suppressed to moderate or low when a double flower is present; the only

[a]Cultivars are presented in groups, with the putative original seed parents of each group in bold.[4,19] [b]Cultivars not available for testing in this survey, but known to belong within the same group. [c]Dihydroxyacetone was below the level of quantitation.

exception to this is *L. scoparium* 'Burgundy Queen', a red double that was classified as high. High nectar DHA/Tsugar values are observed in *L. scoparium* 'Nanum Tui' (*L.* 'Nanum Tui'), a single-flowered dwarf ,and in pink single-flowered cultivars also derived from *L. scoparium* 'Nanum'.

**Nectar DHA/Tsugar in Australian Species of *Leptospermum*.** Australia has 87 species of *Leptospermum* inhabiting various ranges.[21] Honey from *L. polygalifolium* has also been shown to contain dihydroxyacetone and methylglyoxal,[4] indicating that production of dihydroxyacetone in the nectar is found elsewhere in the genus. To confirm this, a limited survey of Australian species was carried out in southern Queensland at the University of the Sunshine Coast. Samples were obtained from wild populations in southern Queensland or northern New South Wales, which abuts southern Queensland. *Leptospermum scoparium* 'Merinda' (*L.* 'Merinda'), which is a complex cross between two interspecific hybrids of Australian species, was also included in this survey, but the plant sampled was growing in New Zealand. Some of the Australian *Leptospermum* species contained dihydroxyacetone (in two cases being nonquantatible), and DHA/Tsugar differed both between and within species (Table 4). This confirms that

**Table 4. DHA/Tsugar Ratios in Australian Species of *Leptospermum***

[a]Dihydroxyacetone was below the level of quantitation.

production of high levels of dihydroxyacetone in the nectar is a characteristic of the genus *Leptospermum* and that the same degree of variation in DHA/Tsugar seen in *L. scoparium* probably occurs in other *Leptospermum* species as well.

**Other Factors That Might Relate to DHA/Tsugar.** *Composition of Leaf Oil.* Some degree of correlation occurred between leaf oil and nectar DHA/Tsugar in some regions (East Cape and Wairarapa regions; adjusted $R^2$ values of 80.7 and 88.9%, respectively) with multivariate analysis of different leaf oils in different areas. This agrees with recently published findings[22] that FT-Raman spectroscopy of leaf material can be used as a predictive model for dihydroxyacetone levels in floral nectar of mānuka.

*Sex of the Flower.* *L. scoparium* is andromonecious, that is, it bears both hermaphrodite and male-only flowers.[23] A significant difference was observed between flowers of different sexes with male flowers having higher DHA/Tsugar due to elevated levels of dihydroxyacetone.

*Age of the Flower.* The hypanthium is initially green in new flowers and as a general rule turns dark red with age. Both dihydroxyacetone and Tsugar values were higher in flowers with red hypanthia.

*Soil Composition.* No correlation could be found with soil order or soil quantifiable components. This is similar to the observation that soil properties had no discernible effect upon leaf oil[10] or the activity of honey derived from a certain area.[12]

*Coverage with Sooty Mold.* Sooty mold indicates a scale insect infestation, which is a potential stressor for the plant and which might affect dihydroxyacetone production, but no correlation was found between DHA/Tsugar and coverage with sooty mold.

**Nectar Sugars.** Dihydroxyacetone in nectar could be produced by the plant or by microbes present in the flower.[24,25] Sucrose was not detected in any of the *L. scoparium* nectars

assayed, indicating a hexose-dominant nectar of the type associated with pollination by small, unspecialized insects.[26] This concurs with classification of the dish-shaped mānuka flower as open-access and visited by a variety of insect feeders/pollinators.[27] The ratio of fructose to glucose in the 2009 and 2010 North Island nectar samples was 1.65:1 ($R^2$ = 0.9164), clearly differing from the 1:1 ratio expected if the nectar was solely derived from the hydrolysis of sucrose. The predominance of fructose found in the nectars of *L. scoparium* in the field may indicate the effect of a microorganism, specifically yeast, transported by visiting insects such as ants.[24,25]

An ongoing study of fructose/glucose ratios in mānuka honeys of various NPA found a mean of 1.29 and a range from 0.98 to 1.67 ($n$ = 1483, $s$ = 0.10) (P. Bray, personal communication). There is no obvious explanation for the difference between the honeys and the nectar as it seems unlikely that the nectar extraction procedure utilized here is selective for fructose. Given that visitation by insects and colonization by microbes are essentially random, it is possible that this particular set of trees simply fell to the high end of the range expressed by the honeys.

This method was developed and validated for assaying DHA/Tsugar in floral nectar from cut flowers and was applied to a survey of wild *L. scoparium* and also for a survey of cultivars and a limited survey of Australian species. Within the wild populations, variation in DHA/Tsugar within and between regions and, in some cases, between seasons was observed although no relationship to soil composition could be elucidated. Results were partially aligned with a previous survey of honeys from these regions[12] with the reservation that levels of dihydroxyacetone in nectar do not always accurately reflect methylglyoxal in honey because of the effects of storage conditions. In some regions leaf oil composition could be correlated to DHA/Tsugar, and this is corroborated by a study demonstrating that spectroscopy of leaf material can be used to predict dihydroxyacetone content of nectar.[22] Nectar sugars indicate that the flower is pollinated by small nonspecialized insects and that sugar composition is likely to be affected by microbial species transferred from a variety of pollinators. Horticultural cultivars frequently exhibited very high nectar DHA/Tsugar, and this is likely to indicate a genetic predisposition. Australian species also exhibited elevated nectar DHA/Tsugar, and variation within and between species was observed; this confirms that the phenomenon operates at the genus level. This was, however, a limited survey, and a larger survey needs to be undertaken of further species and cultivars in Australia and extended to other wild populations in New Zealand. There were indications that the age and the sex of the flower may influence DHA/Tsugar, and more detailed studies under controlled conditions will be reported separately.

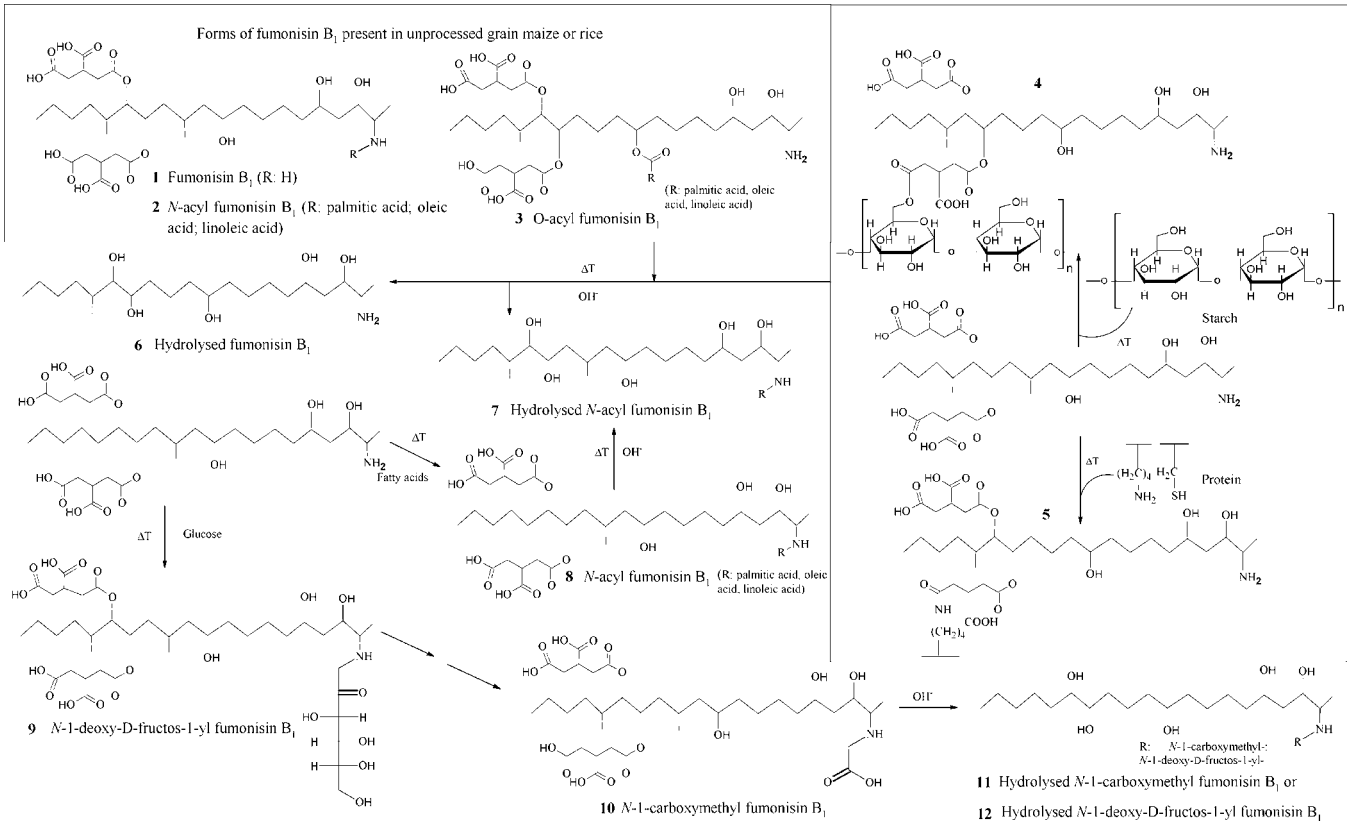

**Figure 1.** Various forms of fumonisins and their transformation paths during technological processes.[8,10,16,19,20]

tolerance to gluten are particularly vulnerable to fumonisins because maize products are the basis of a gluten-free diet in developed countries.[22,23] Free, hidden, and fumonisins esterified with fatty acids hydrolyze in alkaline medium into hydrolyzed fumonisin molecules, for example, **6** (Figure 1).[10,21] The concentrations of fumonisin $B_1$ in the total bound form and in the protein form detected in alkali-processed corn-based foods were higher by about 1.3 and 0.9 times, respectively, than fumonisin $B_1$ concentrations determined by traditional methods.[22] There has been some indirect evidence reported in the literature that formation of selected types of masked fumonisins with corn constituents might be promoted in the alkaline medium during grain nixtamalization.[24]

Due to the lack of literature data concerning thermal stability of the hidden fumonisins, in this work an attempt was made to assess the influence of the baking process on the reduction of the content of free and hidden fumonisins in gluten-free bread.

## MATERIALS AND METHODS

**Chemicals.** Both native and $^{13}C$-labeled fumonisin $B_1$, $B_2$, and $B_3$ analytical standards used in this study were supplied by Biopure (Tulln, Austria). The concentration of all native standards was 50 $\mu$g/mL; those of $^{13}C_{34}$-fumonisin $B_1/B_2/B_3$ standards were 25, 10, and 10 $\mu$g/mL, respectively. The purities of the used labeled fumonisin standards were as follows: $^{13}C$-fumonisin $B_1$ ($^{13}C_{34}$-fumonisin $B_1$), 76.2%; $^{13}C_{33}$-fumonisin $B_1$, 19.8%; $^{13}C_{32}$-fumonisin $B_1$, 4%); $^{13}C$-fumonisin $B_2$ ($^{13}C_{34}$-fumonisin $B_2$, 85.6%; $^{13}C_{33}$-fumonisin $B_2$, 13%; $^{13}C_{32}$-fumonisin $B_2$, 1.3%); $^{13}C$-fumonisin $B_3$ ($^{13}C_{34}$-fumonisin $B_3$, 78.2%; $^{13}C_{33}$-fumonisin $B_3$, 16.8%; $^{13}C_{32}$-fumonisin $B_3$, 3.3%; and $^{13}C_{31}$-fumonisin $B_3$, 1.8%). All of the HPLC grade solvents were supplied by Rathburn Chemicals (Walkerburn, UK). Formic acid, acetic acid, and potassium hydroxide of p.a. grade were supplied by POCH (Gliwice, Poland). The FumoZON AFFINIMIP molecularly imprinted polymeric (MIPs) solid phase extraction cartridges were supplied by Polyintell (Val de Reuil, France).

**Samples.** Gluten-free maize flour of particle size <1 mm naturally contaminated with fumonisins (a courtesy of Silesian Grain, Ziębice, Poland) was used to prepare dough by the direct method and by the sourdough-based method. The flour was produced from grain that was not approved for marketing or use as food/feed. The breads were produced with two methods in two parallel series for each method. In each series three loaves of bread were produced. Two samples from each bread were taken and analyzed in triplicate.

**Dough Processing: Direct Method.** All of the ingredients listed (see the Supporting Information), except sourdough and oil, were mixed and kneaded using a KitchenAid kneader (Benton Harbor, MI, USA) set to a low speed for 6 min. Subsequently, oil was added to the trough and the dough was kneaded for another 4 min. The dough temperature after kneading was 32 °C. In a preliminary experiment several dough pieces containing different amounts of added water were baked in parallel to find the optimum dough yield (mass of dough obtained from 100 g of flour) and the dough producing the highest quality bread. The bread for analyses was baked from the optimal dough in triplicates.

**Dough Processing: Sourdough Method.** Sourdough was prepared from corn flour (600 g) and water (900 mL) with an addition of a starter culture Saf Levain LV2 (Cérences, France) (3 g) and subsequently fermented at 30 °C for 20 h. Saf Levain LV2 fermentation starter supplied by Lesafree was used. That composition of lyophilized lactic acid bacteria and yeast allows bakery sourdough yo be produced in a single-step process in <20 h. The used LV2 starter contains strains of *Lactobacillus brevis* and heterofermentative lactic acid bacteria that produce organic acids (including high quantities of acetic acid) during the fermentation process. The LV2 starter features a higher acetic acid/lactic acid concentration ratio than another fermentation starter offered by the same supplier (LV1). The produced maize bread has a clear and rich flavor.

The dough was prepared from matured sourdough plus ingredients given in the Supporting Information and kneaded as described in the

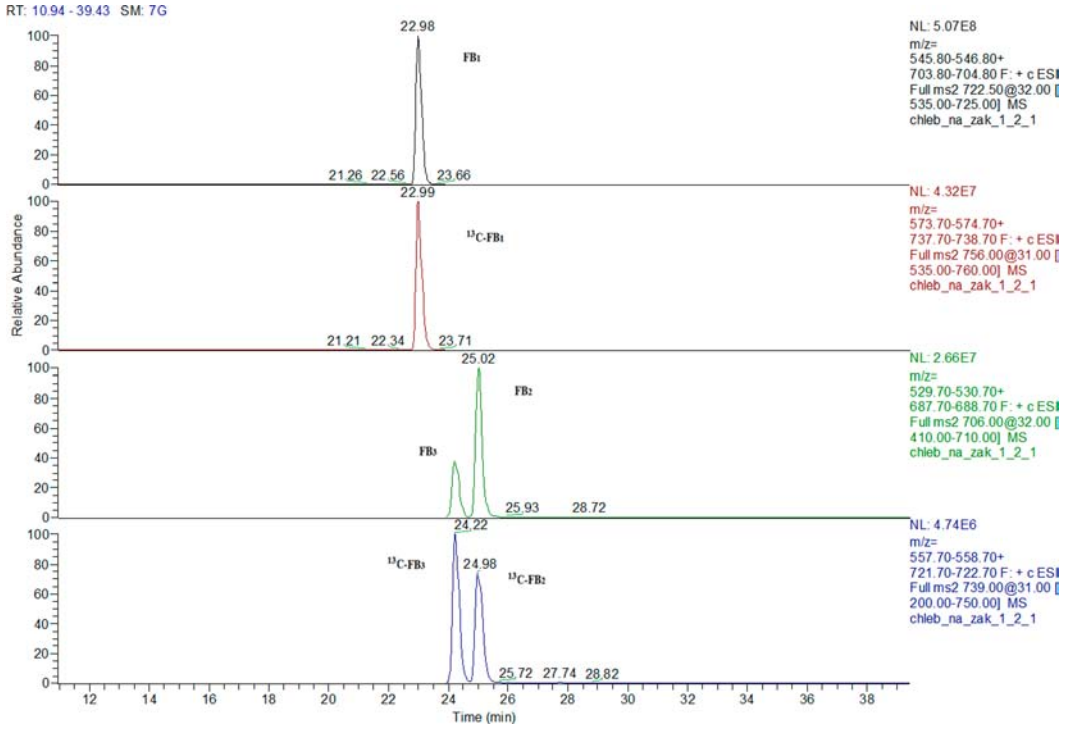

**Figure 2.** CID-MS/MS chromatograms of free fumonisins extracted from maize bread (prepared with sourdough).

previous section until the mixture became homogeneous. The optimum dough yield was evaluated as described above. Immediately after the preparation, the dough pieces were loaded into molds each holding 150 g and grown inside a fermentation chamber at 40 °C and 75% relative air humidity.

The dough grown to an optimal volume was then baked inside a Piccolo Wachtel Winkler shelf oven for 38 min at 260 °C lowered to 210 °C. Baking was initially carried out with steaming.

**Preparation of Samples for Analysis of Free Fumonisins.** The sample preparation procedure previously proposed by Bryła et al.[25] with some major modifications was used to assess levels of free fumonisins. Briefly, 2.5 g of sample (flour or bread) was placed in a 50 mL glass beaker and spiked with 10 $\mu$L of internal standard mixture ($^{13}C_{34}$-fumonisins $B_1$, $B_2$, and $B_3$). The sample was subsequently homogenized with 10 mL of a methanol/acetonitrile/water (25:25:50 v/v/v) mixture for 3 min. The mixture was centrifuged at 10730*g* for 10 min. Five milliliters of the supernatant was diluted with 5 mL of water. Eight milliliters (4 mL × 2) of the diluted solution was loaded on a MIP cartridge previously conditioned with acetonitrile and water (2 mL each). The flow rate was 3−4 drops/s. The cartridge was washed with 6 mL of an acetonitrile/water mixture (40:60 v/v) and subsequently eluted with 4 mL of formic acid/methanol mixture (2:98 v/v). The eluate was evaporated to dryness using a rotary evaporator operated at 40 °C and then redissolved in 1 mL of methanol/water/formic acid mixture (10:89.9:0.1 v/v/v). Each sample was sonicated for 13 s in an ultrasonic bath to ensure complete dissolution of analytes, filtered through a PTFE 0.2 $\mu$m syringe filter into an autosampler vial, and injected into the LC-MS/MS system. Calibration curves were plotted using matrix-matched calibration standards prepared in the same way as the samples. Dry residues were dissolved in standard solution instead of pure solvent mixture.

**Preparation of Samples for Analysis of Total Fumonisins.** The total concentration of free and hidden/bound fumonisins was determined in alkaline-digested samples, in which free, hidden, and some bound fumonisins undergo hydrolysis to hydrolyzed fumonisins. Briefly, 0.5 g of a well-ground sample (flour or bread) was placed in a 50 mL Falcon-type PP centrifuge tube and spiked with 10 $\mu$L of fumonisin $B_1$, $B_2$, and $B_3$ $^{13}C_{34}$-labeled internal standard solutions. Subsequently, 10 mL of 2 M KOH was added. The hydrolysis was conducted for 24 h at room temperature. The analytes were extracted into 12.5 mL of dichloromethane by shaking. The samples were centrifuged at 10730*g*. Five milliliters of supernatant was transferred into a round-bottom flask and evaporated using a rotary evaporator operated at 40 °C. The dry residues were redissolved in 1 mL of 30:69.9:0.1 methanol/water/acetic acid mixture, filtered through a 0.2 $\mu$m nylon syringe filter, and transferred into autosampler vials.

The labeled internal standards were used to monitor analyte recovery rates, to adjust the analyte concentrations by the rates calculated for the corresponding internal standards, and to eliminate the errors resulting from incomplete hydrolysis. The accuracy of the analytical procedure was thus substantially improved.

The quotient of molar masses was used as a conversion factor for calculation of analyte concentration before the hydrolysis. The results were expressed as concentration of free fumonisins. The calibration solutions of hydrolyzed fumonisins $B_1$, $B_2$, and $B_3$ were prepared from fumonisin $B_1$, $B_2$, and $B_3$ standards, each of 5 $\mu$g/mL concentration. Matrix-matched calibration was applied. To prepare the solutions, 0.5 g portions of fumonisin-free flour were spiked with 10 $\mu$L of each labeled internal standard (of analyte concentration like in the samples) and with an appropriate amount of native standard and then processed as for samples. The spiked samples, the calibration standards, and the QA/QC samples were prepared and processed simultaneously to maintain identical hydrolysis conditions (time and temperature).

**Hidden Fumonisin Assessment.** The hidden fumonisin concentration was calculated by subtraction of two measured values: suitably corrected concentration of sum of free plus hidden forms after hydrolysis minus concentration of free forms before hydrolysis. It was assumed that the concentrations of all fumonisins in the analyzed samples were proportional to the determined concentrations of hydrolyzed forms with the quotient of molar masses of compounds present before the hydrolysis and after it as the proportionality factor.

**Analytical Method Performance.** The basic statistical parameters of the analytical method (including analyte recovery and recovery repeatability) were assessed using some laboratory-made spiked samples prepared from fumonisin-free maize grain. The samples were prepared at three different concentration levels and analyzed in triplicate. The developed method performed satisfactorily. Average recovery rates of free fumonisins from samples spiked at 200 ($n$ = 4),

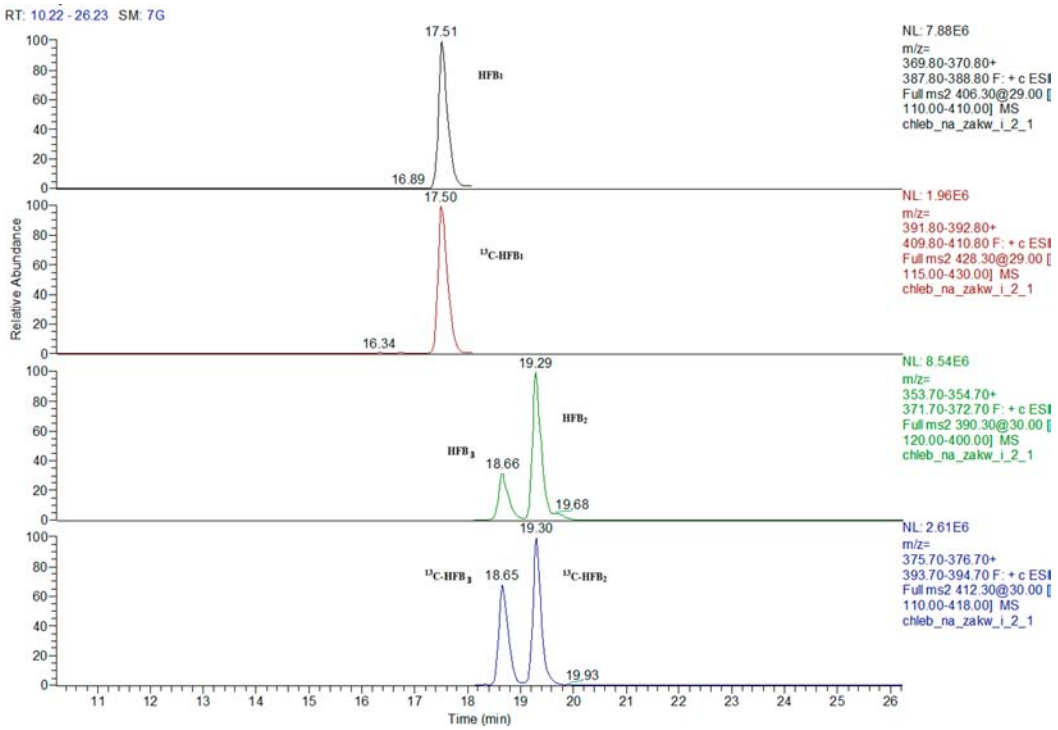

**Figure 3.** CID-MS/MS chromatograms of fumonisins extracted from maize bread (prepared with sourdough) hydrolyzed under alkaline medium.

500 ($n$ = 4), and 800 $\mu$g/kg ($n$ = 4) were 102 ± 11.5, 106 ± 12.3, and 97 ± 11.5% for fumonisins $B_1$, $B_2$, and $B_3$, respectively (mean recovery values calculated for three fortification levels). The average recovery rates of hydrolyzed fumonisins from the samples spiked at 280 ($n$ = 5), 560 ($n$ = 5), and 1120 $\mu$g/kg ($n$ = 5) for hydrolyzed fumonisin $B_1$ or at 275 ($n$ = 5), 550 ($n$ = 5), and 1100 $\mu$g/kg ($n$ = 5) for hydrolyzed fumonisins $B_2$ and fumonisin $B_3$ were 94 ± 10.9, 99 ± 11.5, and 98 ± 12% for hydrolyzed fumonisins $B_1$, $B_2$, and $B_3$, respectively. The calibration curves plotted against matrix-matched calibration standards were linear (coefficient of determination $R^2 > 0.99$) within the 13−1200 $\mu$g/kg range for fumonisins $B_1$, $B_2$, and $B_3$, within the 22−5040 $\mu$g/kg range for hydrolyzed fumonisin $B_1$, and within the 22−4950 $\mu$g/kg range for hydrolyzed fumonisins $B_2$ and $B_3$. The lowest points of calibration curves, 13 $\mu$g/kg for fumonisins $B_1$, $B_2$, and $B_3$ and 22 $\mu$g/kg for hydrolyzed fumonisins $B_1$, $B_2$, and $B_3$, were taken as the limit of quantification (LOQ). The signal-to-noise ratio at these concentrations was not less than 10:1.

The method was also validated within the framework of an interlaboratory proficiency test performed between September and November 2013 on a test sample provided under the FAPAS program (Food Analysis Performance Assessment Scheme), Report 2297. The concentration of free fumonisins $B_1$ and $B_2$ in maize was evaluated. The results expressed as $Z$ score were 0.3 and 0.6, respectively, for fumonisins $B_1$ and $B_2$. They were considered satisfactory.

**LC-MS/MS Analysis.** A high-performance liquid chromatograph, coupled to an LTQ ion trap mass spectrometer (Thermo Finnigan, Austin, TX, USA), was used for this study. The chromatographic system was equipped with an autosampler, a column thermostat, a degasser, and a quaternary gradient pump. The chromatographic separations were performed on pentafluorophenyl (PFP) and octadecyl (C18) silica-based reversed-phase columns. The free fumonisins were separated on a 100 mm × 2.1 mm, 2.6 $\mu$m pore size, PFP Kinetex core−shell column, whereas the hydrolyzed fumonisins were separated on a 150 mm × 2.0 mm, 3 $\mu$m pore size, C18 Luna column (both supplied by Phenomenex, Torrance, CA, USA). The mobile phase flow rate was in all cases set at 0.15 mL/min. The following mobile phase gradient was used in analyses of free fumonisins (A = water, B = methanol, C = 2% acetic acid/water mixture): 0−4 min (initial), 60% A + 30% B + 10% C; 14−28 min, 10% A + 80% B + 10% C; 32−55 min, back to the initial conditions. A representative chromatogram of fumonisins extracted from maize bread prepared with sourdough is shown in Figure 2. The following mobile phase gradient was used in the analyses of hydrolyzed fumonisins (A = water, B = methanol; both phases contained 0.1% acetic acid): initial 0−3 min, 70% A; 7−20 min, 35% A; 21−31 min, 100% B; 33−48 min, 70% A. A chromatogram of fumonisins extracted from maize bread prepared with sourdough and hydrolyzed under alkaline medium is shown in Figure 3.

The compounds were analyzed charged in an electrospray ionization (ESI) source. The nebulizing/auxiliary gas ($N_2$) flow rates were set constant at 20/10 AU, respectively. Helium was used as the dumping gas. Values ($m/z$) corresponding to pseudo molecular ions $[M + H]^+$ of fumonisins $B_1$, $B_2$, and $B_3$ and hydrolyzed fumonisins $B_1$, $B_2$, and $B_3$ were used as precursors in all CID experiments. The mass spectrometer scanning windows in the CID mode were set according to the main produced daughter ions from the selected precursor: 722 (fumonisin $B_1$) − 535 − 725; 706 (fumonisins $B_2$ and $B_3$) − 410 − 710; 406 (hydrolyzed fumonisin $B_1$) − 120 − 410; and 390 (hydrolyzed fumonisins $B_2$ and $B_3$) − 120 − 400. The data were acquired and analyzed using Xcalibur 1.2 software. The optimized CID parameters are given in the Supporting Information.

**Statistical Analysis.** Statistical evaluations of the data were performed using Statgraphics 4.1. (Graphics Software System, STCC, Inc., Rockville, MD, USA) computer software. The significance of the differences between determined concentrations were assessed using a one-way ANOVA statistical test. To evaluate the significance of the differences between the only two variables (concentrations), a Tukey's test at $\alpha$ = 0.05 was applied.

## RESULTS AND DISCUSSION

Because hidden fumonisins in food products could not be directly determined in this study, their concentration was assessed on the basis of the concentration of hydrolyzed fumonisins formed during alkaline digestion of samples. A strong basic medium can break noncovalent interactions that prevent extraction of fumonisins bound as inclusion complexes, degrade spatial structure of macromolecules, denaturize

proteins, and cause starch swelling and saponification of lipids in cereals. In effect, free, hidden, and O-acylated fumonisins are all hydrolyzed into hydrolyzed fumonisins $B_1$, $B_2$, and $B_3$.

The concentrations of both free and hidden fumonisins found in the studied bread samples are listed in Table 1 and shown in Figure 4. The concentrations in bread have been calculated on the basis of flour mass used for baking.

**Measured Concentrations (Free and Freeplus Hidden Fumonisins).** The single-factor analysis of variance of data shown in Table 1 and charted in Figure 4 revealed statistically significant ($p$ value $\leq 0.05$) differences between concentrations of free fumonisins in flour and bread: the sum of fumonisins dropped from 5101 ± 564 μg/kg in flour to 3569 ± 184 μg/kg in bread prepared with sourdough (i.e., by 30%) and to 3470 ± 325 μg/kg in bread prepared without sourdough (i.e., by 32%). The differences between both bread values are too small to be statistically significant. The sourdough addition did not influence the concentration of free fumonisins in baked breads.

The literature data on fumonisin behavior during baking are scarce. Jackson et al.[26] reported a 16−28% decrease in fumonisin $B_1$ concentration (initial = 5 mg/kg) during baking of maize muffins at 175 and 200 °C for 20 min. The highest drop was observed in near-surface layers of the muffins, whereas the reduction was lower in the crumb. Castelo et al.[27] did not find any significant drop in the initial 5 mg/kg fumonisin $B_1$ concentration during baking of maize muffins at 204 °C for 20 min, but found that the toxin concentration dropped by 48% during baking at 232 °C. Avantaggiato et al.[28] baked maize muffins spiked with native and $^{14}$C-labeled fumonisin $B_1$ (15 μg per muffin) at 210 °C for 25 min and observed a 52−57% decrease in fumonisin $B_1$ concentration. The same authors repeated their experiments using maize flour spiked with $^{14}$C-labeled fumonisin $B_1$, synthesized by fungi from $^{14}$C-labeled sodium acetate, at 1.56 μg per muffin and observed a 51% reduction. Such diversity of results might have different roots: different baking conditions (temperature, time of the process), different sizes of the used dough portions, different dough pH values. Jackson et al.[29] reported that the thermal stability of fumonisins is pH-dependent. Their model studies on buffered solutions showed that <27% of fumonisin $B_1$ should degrade at temperatures ≤125 °C applied for 60 min, whereas an 18−90% degradation level (depending on pH of the reaction medium) is to be expected at a temperature of 150 °C applied for 60 min. The highest degradations were observed at pH 4 and 10. More than 90% of fumonisin $B_1$ degraded at temperatures above 175 °C regardless of pH. In this context it must be pointed out that distribution of temperature inside a baking bread is usually not uniform, temperatures in the crumb being significantly lower than those in the crust. Normally, the temperature in the crumb center does not exceed 100 °C. In this study the dough prepared with sourdough had pH 4.6, whereas dough prepared without sourdough had pH 5.5. Despite this, that no statistically significant difference between the fumonisin concentrations in breads baked from both types of dough was observed.

Thus, several studies proved that fumonisins may undergo degradation as a result of heat treatment. Some of the results indicate also that fumonisin $B_1$ might be present in thermally processed complex food matrix in various forms bound to proteins (**5**, Figure 1), sugars (**9**, **10**), including starch (**4**) or fatty acids (**8**).[8,20,22] Dough additives such as monohydrates (glucose, fructose) or milk (containing lactose) might increase the rate of nonenzymatic browning reaction occurring between

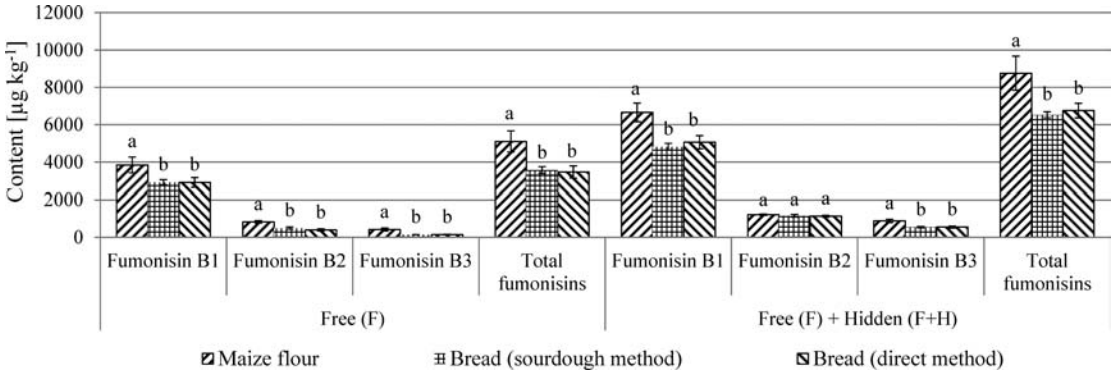

**Figure 4.** Determined mean (±SD) concentrations of free and free plus hidden fumonisins in maize flour and bread (related to mass of flour used to prepare dough). Statistically homologous groups have been marked with identical letters.

the fumonisin amine group and the carbohydrate carbonyl group. In effect, they could reduce fumonisin concentration.[26,30] Due to the structural changes resulting from reactions of fumonisin molecules with food components,[8,22] in such a way that functional groups in the fumonisin molecule necessary for its identification are blocked or unavailable, it is in fact impossible to apply conventional analytical methods for its analysis. In this respect bound fumonisins will be considered degraded. In this study an indirect method based on alkaline digestion of samples was utilized to quantitate masked fumonisins. In such a case the analytical procedure involved quantification of fumonisin degradation products formed during hydrolysis. However, some N-acylated (**7**, Figure 1) and N-alkylated (**11**, **12**) derivatives are not quantified because such bonds are not susceptible to the alkaline-catalyzed hydrolysis.[10,20] The resulting total fumonisin contents is a sum of free fumonisins and fumonisins both covalently[8] and noncovalently bonded to biopolymers[24] as well as *O*-esters of fatty acids. The latter were identified in small quantities in *F. verticllioides* cultures grown in vitro on rice or corn.[16−19] Therefore, it is expected that the group of masked fumonisins quantified in the unprocessed corn covers mainly the hidden forms that covalently or noncovalently interact with macroconstitutive food compounds.[31]

The baking process reduced the sum of free plus hidden fumonisins from 8756 ± 913 μg/kg in flour to 6531 ± 161 μg/kg in bread made with sourdough (by 25%) and to 6756 ± 392 μg/kg in bread made without sourdough (by 23%) (Table 1). The performed statistical assessment using the single-factor analysis of variance technique did not reveal any significant differences between type breads (Figure 4).

**Calculated Concentrations (Hidden Fumonisins).** The concentrations of hidden fumonisins were calculated as the differences between free plus hidden and free fumonisins. The baking process reduced hidden fumonisin contents from 3655 μg/kg in flour to 2962 μg/kg in bread made with sourdough (by 19%) and to 3286 μg/kg in bread made without sourdough (by 10%) (Table 1).

The observed lower degradation rate of the masked fumonisins compared to their free forms during baking of bread might be explained by the co-occurrence of the opposite types of reactions. It is possible that simultaneously covalent bonds between fumonisins and biopolymers are being formed or degraded. Nonetheless, the rates of the hidden fumonisin synthesis and degradation might be significantly different. The results of some studies performed in model systems indicate the formation of covalent bounds between carboxyl groups of fumonisins and a hydroxyl group present in the starch molecule or amine groups of proteins.[8] Burns et al.[24] introduced some indirect evidence indicating the possible interactions of fumonisins with corn components during cooking in the nixtamalization process. The authors suggest that the alkaline medium might promote such types of reactions.

It might be also concluded that the observed lower reduction levels of hidden forms than of free forms mean that hidden fumonisins in maize flour are simply more thermally stable than free fumonisins. The average hidden/free ratio increased as a result of the baking process from an initial 0.72 in flour to 0.83 in bread produced with sourdough and to 0.95 in bread made without sourdough. Literature data on the thermal stability of free fumonisins are scarce, and data on the stability of hidden forms are practically unavailable. Therefore, it is difficult to compare the results of this study with other reports.

The results of this study revealed that hidden fumonisins may have a higher thermal stability compared to their native forms. Natural biopolymers (such as starch or proteins) capable of noncovalently interacting with fumonisins can stabilize their structure and consequently increase their thermal stability. Assuming that concentrations of both hidden and native fumonisins in maize and maize milling products are comparable, thermal processing would increase a relative share of hidden forms in total concentration. Considering other published reports that hidden fumonisins (covalently or noncovalently bound) might be released to form free (native) molecules in the digestive tract,[10,31] it seems that further studies on the stability of hidden fumonisins during thermal processing at different pH values are needed to assess toxicological hazards for consumers.

## MATERIALS AND METHODS

**Chemicals and Reagents.** The analytical standards of **1**−**6** (98% purity) were obtained from the Institute of Veterinary Pharmaceuticals (Huazhong Agricultural University, Wuhan, People's Republic of China). Individual stock standard solutions (1000 μg/mL) of all analytes were prepared by dissolving each pure standard in methanol (MeOH). A mixed standard fortification solution [20 μg/mL (10 μg/mL for **1** and **2**)] was prepared by combining 2.0 mL (1.0 mL for **1** and **2**) of each stock standard and diluting with MeOH to obtain a final volume of 100 mL. The stock solutions were stored in amber vials at −20 °C and stabilized for 3 months. The mixed fortification solution was also stored in an amber vial at −20 °C and then stabilized for 1 month. Distilled water was further purified by passing it through a Milli-Q Plus apparatus (Millipore, Bedford, MA, USA). HPLC grade MeOH and acetonitrile (MeCN) were purchased from Tedia (Fairfield, OH, USA). Other chemicals, including formic acid, metaphosphoric acid, and zinc acetate, were of analytical reagent grade.

**Feed.** The feed used in this study was purchased from Wuhan Lvhong Bioscience and Technology Co., Ltd. (Wuhan, People's Republic of China). The feed formula was strictly in accordance with the recommended formula of the U.S. National Research Council. Premix (4%; 2.5 g/kg quinocetone concentration) and complete feed (100 mg/kg quinocetone concentration) were initially prepared. The blank feed and the medicated feed were analyzed using the HPLC method described by Wu et al.[17] to determine drug content. The results indicated that no quinoxaline compound was detected in the blank feed, and only quinocetone (98 ± 6 mg/kg feed, $n$ = 9) was found in the medicated feed.

**Animals and Sampling.** The study was performed in accordance with the guidelines of the Committee on the Care and Use of Laboratory Animals of China (permit SYXK 2007-0044). Thirty healthy castrated crossbred (large white × landrace) pigs (50−65 kg) were purchased from the Breeding Pig Testing Center (Wuhan, People's Republic of China); these pigs were housed in six 8 m × 10 m pigpens, which were cleaned daily. Thirty-six 1-day-old healthy Cobb500 broilers were purchased from Charoen Pokphand Group (Wuhan, People's Republic of China); these broilers were kept in stainless steel cages. Sixty healthy carp (400−600 g) were purchased from the Wuhan Fish Breeding Farm (Wuhan, People's Republic of China); these carp were placed in a fish tank with circulating water. The animal houses were maintained at 25 ± 2 °C room temperature with 45−65% relative humidity. All of the animals were allowed a 7 day acclimation period before our experiments were conducted; a standard ration based on corn and soybean was fed twice a day and tap water was available ad libitum. The animals were randomly divided into a control group ($n$ = 5, 6, and 10 for pigs, broilers, and carp, respectively) and a test group ($n$ = 25, 30, and 50 for pigs, broilers, and carp, respectively). The control groups were fed the standard ration without quinoxaline compounds. The test groups were provided with medicated feed for 90, 42, and 60 consecutive days for pigs, broilers, and carp, respectively. The medicated feed contained a standard ration premixed with quinocetone at a level of 100 mg/kg diet, which was slightly higher than the recommended level of quinocetone preparations.[1]

At different time points [6 h, 1, 3, 7, and 14 days (6 h, 1, 3, 5, and 7 days for broilers, and 6 h, 1, 3, 5, and 10 days for carp)], 1 control and 5 medicated pigs (6 medicated broilers and 10 medicated carp) were anesthetized and sacrificed. The pigs and broilers were slaughtered using captive bolt stunning equipment and exsanguinated in accordance with the guidelines provided by the American Veterinary Medical Association for euthanasia,[23] the carp were euthanized in a MS-222/water (1:10000) bath. Liver, kidney, muscle, and fat (skin) specimens were collected. All of the samples were placed in labeled plastic bags in an ice bath, immediately homogenized, and frozen at −20 °C until these samples were analyzed.

**Analysis of Analytes.** *Sample Preparation.* Samples (2 ± 0.1 g) were transferred into a 50 mL centrifuge tube, and 8 mL of 1% metaphosphoric acid in MeOH/MeCN/water (50:20:30, v/v/v) was added to the sample. The mixtures were shaken using a vortex system for 5 min, ultrasonicated for 10 min at room temperature, and centrifuged at 2160$g$ for 10 min. The supernatant was then transferred into a 50 mL centrifuge tube. The same extraction procedure was repeated. The two supernatants were combined, and 1 mL of 10% aqueous zinc acetate was added to the extracts. These extracts were mixed by vortexing for 2 min and centrifuged at 13500$g$ for 10 min; afterward, the supernatant was transferred and diluted with 1% metaphosphoric acid to obtain a final volume of 64 mL, which was ready for the cleanup procedure.

The HLB cartridge (60 mg, 3 mL) (Waters Corp., Milford, MA, USA) was preconditioned with 3 mL of MeOH and 3 mL of water. Flow rates for conditioning and washing were set at 3 mL/min. The entire extracts were loaded onto the SPE column at a flow rate of 1 mL/min. The column was washed with 3 mL of water and 3 mL of 10% MeOH and dried by purging air at a rate of 10 mL/min for 5 min. The analytes were eluted with 3 mL of MeCN at a flow rate of 1.0 mL/min into a 10 mL tube and evaporated to dryness under a stream of nitrogen at 45 °C. The dry residue was dissolved in 1 mL of 20% MeCN, vortexed for 1 min, and centrifuged at 16600$g$ for 10 min. The resulting solution was then filtered using a 0.22 μm nylon Millipore chromatographic filter, and a 20 μL aliquot was analyzed by HPLC.

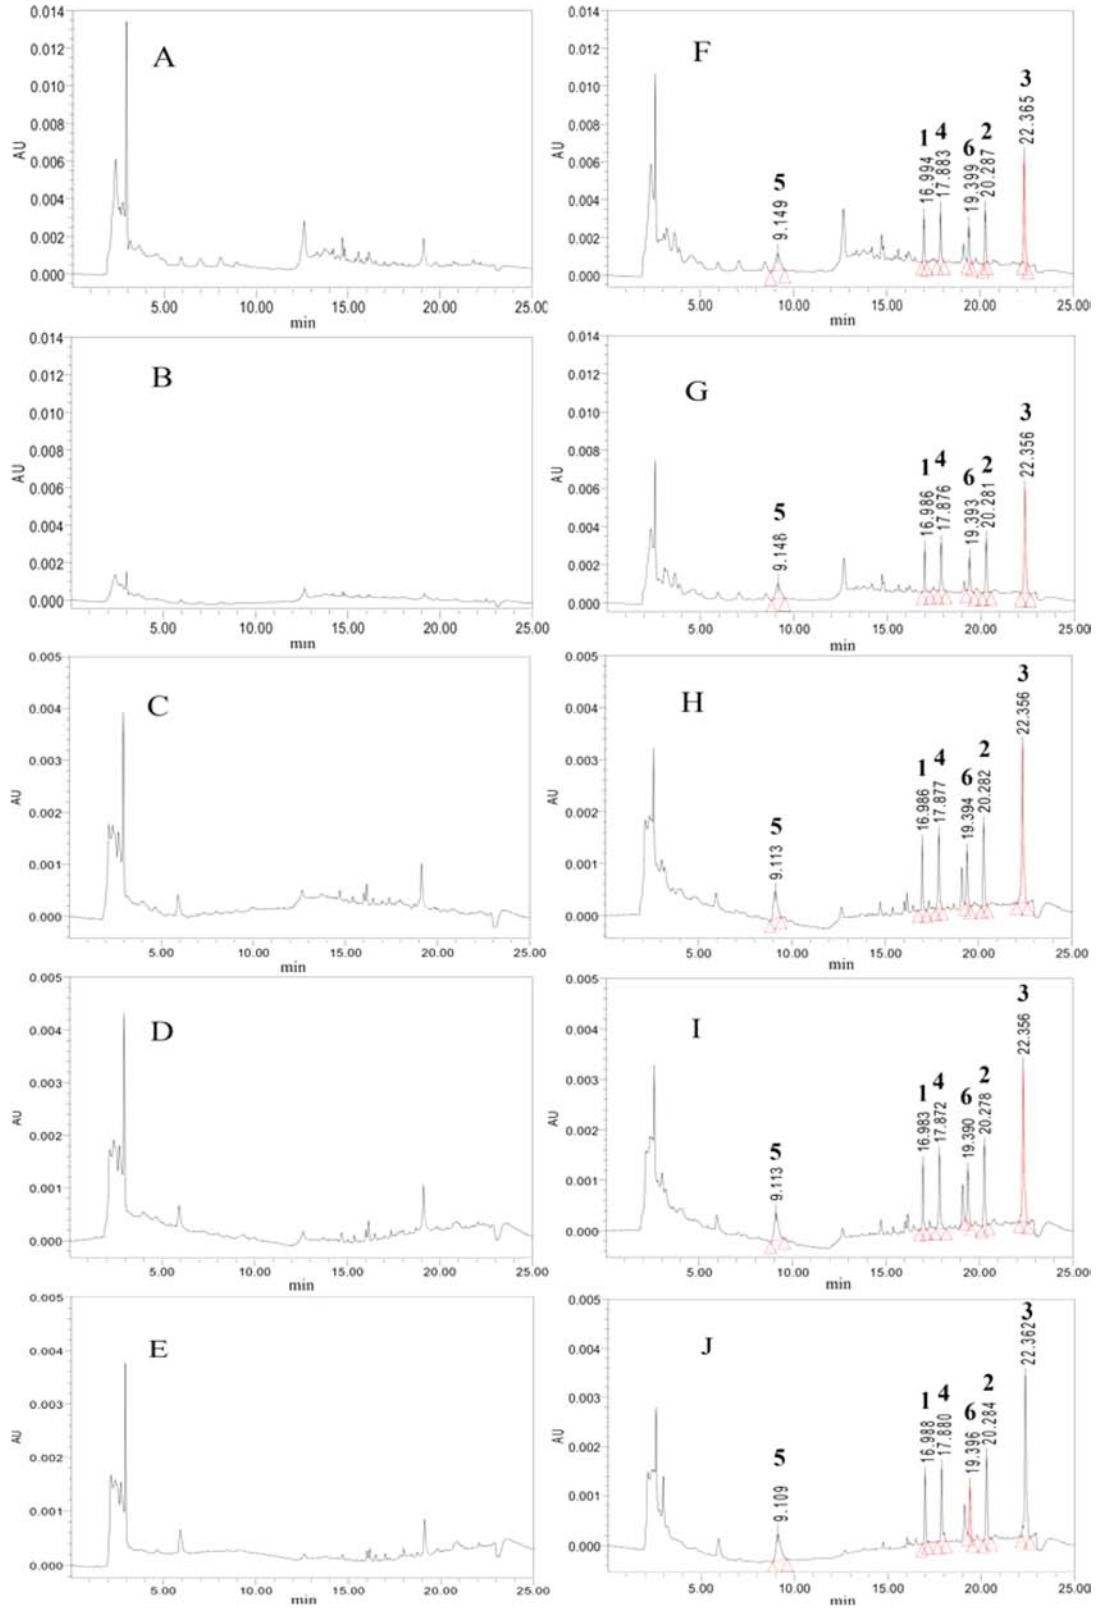

**Figure 2.** Chromatograms of (A) blank pig liver, (B) kidney, (C) broiler muscle, (D) sebum, and (E) carp skin sample, (F) blank pig liver, (G) kidney, (H) broiler muscle, (I) sebum, and (J) carp skin sample spiked with quinocetone and its main metabolites.

The other tested cartridges were an Oasis MAX (60 mg, 3 mL) (Waters Corp.) and an SCX (500 mg, 3 mL) (Agilent, Santa Clara, CA, USA).

*HPLC Analysis.* HPLC analysis was performed using a Waters 2695 HPLC system coupled with a UV detector. Chromatographic separation was conducted using a ZORBAX SB-$C_{18}$ column (250 mm × 4.6 mm i.d., 5 $\mu$m; Agilent Technology, USA) coupled with a 2 mm $C_{18}$ guard column at a flow rate of 1.0 mL/min at 30 °C in a column oven. Mobile phase component A was 1% formic acid, and component B was MeCN. The mobile phase gradient profile was as

dx.doi.org/10.1021/jf5042867 | J. Agric. Food Chem. 2014, 62, 10348−10356

follows: 0 min, 80% A; 8 min, 80% A; 15 min, 35% A; 20 min, 10% A; 20.1 min, 80% A; 25 min, 80% A. The UV detector was set at a wavelength of 320 nm for all of the compounds. The developed method was validated with reference to the implemented validation procedure for residues in food animal products, as described in EU Commission Decision 2002/657/EC under Council Directive 96/23/EC.[24]

*Calibration Curve and Linearity.* The standard mixture calibration curves were generated on five different days at seven concentration levels from 2 to 500 μg/L for **1** and **2** and from 4 to 500 μg/L for **3**−**6**. The analyses were performed in triplicate. The method was further tested by matrix-matched calibration curves, which were obtained by fortification with the six compounds at each of the six concentrations from 2 to 200 μg/kg. The calibration curves constructed on five separate days were analyzed to evaluate the linearity of each curve. Slope, intercept, and correlation coefficient were calculated for each standard curve. Unknown concentrations were calculated from the equation of the calibration curve.

*Limits of Detection (LOD) and Limits of Quantification (LOQ).* LOD was calculated by comparing the 3-fold variation of signal-to-noise ratio (S/N = 3:1) obtained from the extract analysis of the blank samples; LOQ was calculated using S/N = 10:1.

*Accuracy and Precision.* Blank samples were fortified at three different levels (1, 2, and 4 times the LOQ). For the intraday experiment, six sets of each concentration were run. Six replicates of the three concentrations were analyzed on five different days for the interday experiment. Accuracy was defined by the mean absolute recovery, which was calculated by comparing the peak area of the extracted sample with that of the standard working solution. Precision was defined by relative standard deviation (RSD).

*Specificity.* Method specificity was verified by analyzing blank samples and observing residue-interfering peaks. The results were evaluated by the presence of interfering substances at the specified retention time.

*Stability.* Stability experiments were conducted to investigate the stability of quinocetone and its metabolites in incurred samples stored at −20 °C within 6 months. The incurred samples were extracted, thawed, and analyzed every week. The measured values were compared with those in freshly incurred samples in triplicate. The results indicated that quinocetone and its metabolites were stable for 4 months in the incurred samples during storage at −20 °C.

**Data Analysis.** To determine the tissue depletion profile, we analyzed the concentrations of quinocetone and its metabolites by using a linear regression model of natural log-transformed average concentration of quinocetone and its metabolites (ln *C*) against time. The last three time-point data were fit to the first-order rate equation $C = C_0\ e^{-kt}$, where *C* is the concentration of quinocetone and its metabolites on day *t*, $C_0$ is the initial concentration, elimination rate constant ($k$) is the slope of the linear regression equation for the log-transformed residue concentration (ln *C*) against time, and the half-life of elimination ($t_{1/2k}$) is calculated from the equation $t_{1/2k} = \ln 2/k$ for each tissue.

The withdrawal time (WDT) was estimated by the Statistical Tool for Data Analysis of Draft Maximum Residue Limits for Veterinary Drugs (MRLVDs) in Edible Tissues.[25] The approach is primarily based on linear regression analysis and statistical estimation of one-sided upper tolerance limits for the marker residue depletion in the individual target tissues. An iterative procedure is then used to calculate for different time points on the depletion curve the intake of residues of concern in the food basket. The calculated intake of residues is compared with the acceptable daily intake (ADI), and the time point of depletion below the ADI is selected to determine the MRLs.

The estimated daily intake (EDI) was adopted to calculate the quantity of residues of toxic concern for a food basket that includes 300 g of muscle, 100 g of liver, 50 g of kidney, and 50 g of fat. The concentration of residues was calculated using the median of the residue distribution, expressed as the marker residue **3**, with inclusion of factors (when required) to convert the marker residue concentration to total residues. For each food commodity, the highest species-specific median residue value is used in the calculation. The global estimated chronic dietary exposure (GECDE) to quinocetone residue for the population group of interest is "the highest exposure calculated using the 97.5th percentile consumption figure for a single food selected from all the foods plus the mean dietary exposure from all the other relevant foods" and is calculated as

$$\text{GECDE} = \text{highest exposure from one animal product} + \text{total mean exposure from all other products}$$

Descriptive statistical parameters, such as mean, standard deviation (SD), and coefficient of variation (CV), were calculated. Data were statistically analyzed using Microsoft Excel 2007.

## RESULTS AND DISCUSSION

**Sample Pretreatment.** Low recoveries of all six analytes were obtained when MeOH or MeCN was used alone as an extraction solvent. However, almost all of the analytes were extracted when 30% water was added to MeOH and MeCN, but the recovery of **5** was low. All of the compounds were extracted with recoveries of >80% when 1% metaphosphoric was added to MeOH/MeCN/water (50:20:30, v/v/v). On the basis of the properties of the six compounds and the sample/matrix composition, we used the following test cartridges: Oasis HLB, Oasis MAX, and SCX cartridges. With SCX, the recovery was low, and interferences were observed at the same retention time as **5**. Sin et al.[26] recommended the SPE cleanup on Oasis MAX for **5**, but the method was not suitable for other compounds. Comparative studies indicated that Oasis HLB was superior to the other cartridges in terms of good recovery (>90%) and low matrix interference. During the elution steps of Oasis HLB, MeCN and MeOH were selected because of their good extraction efficiencies. MeCN showed high elution power to acquire high recoveries and low interference. The techniques were improved, thereby reducing the total time of sample pretreatment to <2 h.

**HPLC Method Validation.** *Linearity.* The linearity of the standard mixtures was good for all of the analytes at tested concentrations, as indicated by correlation coefficients >0.9999 for all of the curves. Matrix-matched calibration standard curves were used to quantitate the target analytes in animal tissues and to ensure that the method was as accurate as possible. The correlation coefficient values of the analytes within the range from 2 to 200 μg/kg were >0.99.

*Specificity.* On the basis of the comparison of background noise with various matrices, our results showed that no interference peak was detected at the retention time of the tested compounds (Figure 2).

*LOD and LOQ.* The LODs of **1** and **2** were 5 μg/kg in liver and kidney tissues and 3 μg/kg in muscle and fat tissues. The LODs of **3**−**6** were 10 μg/kg in liver and kidney tissues and 6 μg/kg in muscle and fat tissues. The LOQs of **1** and **2** were 20 μg/kg in liver and kidney tissues and 10 μg/kg in muscle and fat tissues. The LOQs of **3**−**6** were 40 μg/kg in liver and kidney tissues and 20 μg/kg in muscle and fat tissues.

*Accuracy and Precision.* The results of recovery and reproducibility of the method at the specified concentration range on five separate days were calculated. The mean recoveries ranged from 61.5 to 81.5%. The interday values were <11.7%, indicating that the proposed method could precisely and accurately determine quinocetone and its metabolites in animal tissues.

[a]Samples were below the LOQ of analysis method.

its metabolites in pig, broiler, and carp edible tissues for each time point were averaged, and the SD of each was calculated (Table 1). The highest concentrations of all of the related compounds in all of the edible tissues were obtained at 6 h after the last dosing. At all time points, the highest concentrations were detected in the liver, and the lowest concentrations were measured in the muscle or fat (skin).

*Pigs.* After the drugs were consecutively administered for 3 months, **1**−**6** were detected in the liver at 6 h postmedication, and the residual concentrations ranged between 42.2 and 173.5 $\mu$g/kg. **1**−**3** and **5** were detected in the kidney and muscle at

**Table 2. Comparison of Chronic Dietary Exposure Assessments for Quinocetone for the General Population**

| | food consumption (g/day) | | | | | | | exposure from each food (μg/day) | | |
|---|---|---|---|---|---|---|---|---|---|---|
| food category | model diet | mean chronic | high chronic | median residue (μg/kg) | M:T | analytical method recovery (%) | EDI (μg/day) | high consumers | mean total population | ADI (%) |
| pork muscle[a] | 300 | 114 | 415 | 40 | 0.30 | 62.1 | **64.4** | 89.1 | **24.5** | |
| mammalian trimmed fat, skin, and added fat | 50 | 14 | 125 | 10 | 0.31 | 64.3 | 2.5 | 6.3 | **0.7** | |
| mammalian liver | 100 | 2 | 237 | 173 | 0.29 | 62.3 | **95.8** | **226.9** | 1.9 | |
| mammalian kidney | 50 | 0.5 | 166 | 164 | 0.29 | 68.5 | **41.3** | 137.0 | **0.4** | |
| poultry muscle | 300 | 118 | 352 | 45 | 0.34 | 68.4 | 58.0 | 68.1 | **22.8** | |
| poultry fat and skin | 50 | 1 | 23 | 30 | 0.36 | 64.4 | **6.5** | 3.0 | **0.1** | |
| poultry offal (kidney) | 150 | 5 | 188 | 134 | 0.31 | 62.8 | 103.2 | 129.4 | **3.4** | |
| fish | 300 | 27 | 655 | 39 | 0.38 | 64.8 | 47.5 | 103.7 | **4.3** | |
| EDI | | | | | | | 208[b] | | | 69 |
| mean exposure from all foods | | | | | | | | | 58 μg/day | |
| mean exposure for adult of 60 kg body weight | | | | | | | | | 1.0 μg/kg bw/day | 19 |
| GECDE | | | | | | | | | 283[c] μg/day | |
| GECDE for adult of 60 kg body weight | | | | | | | | | 4.7 μg/kg bw/day | 94 |

[a]Total residue = marker residue/ratio (M:T)/analytical method recovery. [b]For each food commodity, the highest species-specific median residue value is used in the calculation of EDI. [c]The GECDE is the sum of the bold values for high consumer exposure and mean total population exposure.

the withdrawal time of 6 h, and the residual concentrations ranged between 19.5 and 167.5 μg/kg. **1** and **3**−**5** were detected in the liver after 1 day. **3** was detected in the liver and kidney after 7 days and in the muscle after 3 days. Low amounts of **1**, **2**, and **5** were detected in the fat at the withdrawal time of 6 h, and the residual concentrations ranged between 11.6 and 33.0 μg/kg; residues were found at values approximately equal to the LOQ of the method after a withdrawal time of 1 day. The linear regression analysis results between the natural log of the concentration of **3** and the withdrawal time in the liver, kidney, and muscle are listed as follows: $C_{\text{liver-3}} = 205.0\ e^{-0.232t}$, $C_{\text{kidney-3}} = 233.2\ e^{-0.244t}$, $C_{\text{muscle-3}} = 42.2\ e^{-0.248t}$. Hence, $t_{1/2ke}$ values of **3** in the liver, kidney, and muscle of pigs were 2.99, 2.84, and 2.79 days, respectively.

*Broilers.* **2**−**5** were detected in the liver at the withdrawal time of 6 h, and the residual concentrations ranged between 41.4 and 142.7 μg/kg. **2** and **4** were detected in the liver after 1 day. **1**−**3** were detected in the kidney and fat at the withdrawal time of 6 h, and the residual concentrations were between 26.6 and 130.6 μg/kg. **2** and **5** were detected for 1 day in the kidney. Quinocetone was detected in the muscle and fat at 1 day at very low concentrations of 10.3 and 17.3 μg/kg, respectively, slightly higher than the LOQ of the method. **3** was detected in the liver and kidney for 5 days, in the muscle for 3 days, and in the fat for 1 day. The elimination equations of **3** in the liver, kidney, and muscle of broiler were calculated using the regression curves, which were $C_{\text{liver-3}} = 133.9\ e^{-0.257t}$, $C_{\text{kidney-3}} = 137.7\ e^{-0.276t}$, and $C_{\text{muscle-3}} = 46.6\ e^{-0.285t}$. Hence, the $t_{1/2ke}$ values of **3** in the liver, kidney, and muscle of the broiler were 2.70, 2.51, and 2.43 days, respectively.

*Carp.* **5** and **6** were not detected in the tissues of carp. **1**−**3** were detected in the liver at withdrawal times of 6 h and 1 days, and the residual concentrations ranged between 20.6 and 74.9 μg/kg. **1**−**4** were detected in the kidney at the withdrawal time of 6 h, and the residual concentrations ranged between 27.9 and 77.6 μg/kg. **1** was detected in the kidney for 1 day. **1** and **3** were detected in the muscle and skin at the withdrawal time of 6 h, **4** was detected in the muscle at the withdrawal time of 6 h, and the residual concentration was 26.8 μg/kg. **3** was detected in the liver and kidney for 3 days and in the muscle and skin for 1 day. The linear regression analysis results between the natural log of the concentration of **3** and the withdrawal time in the liver and the kidney are listed as follows: $C_{\text{liver-3}} = 64.6\ e^{-0.181t}$ and $C_{\text{kidney-3}} = 80.7\ e^{-0.235t}$. The elimination half-lives of **3** in the liver and kidney of carp calculated from the elimination equations were 3.83 days for liver and 2.95 days for kidney.

In this study, depletion of quinocetone residues in three food animals was investigated. The results showed that quinocetone was eliminated rapidly in pigs, broilers, and carp; no metabolites could be detected after the withdrawal time of 7 days.

The present residue depletion study showed the same residual marker, the same target tissue, and the same tendency in elimination rate as the radioactive tracer studies,[12] but these results differed from those in previous studies, suggesting that **5** is the marker residue.[13,21] **5** likely conjugates with glycine in vivo. In previous studies, sodium hydroxide or hydrochloric acid is applied to hydrolyze the samples, showing that **5** is released from **5**-glycine; other compounds are also degraded to **5**; thus, the concentration of **5** is very high and can be detected for a long time.[13,21] In our study, a method previously reported[18,22] was modified using 1% metaphosphoric acid in MeOH/MeCN/water (50:20:30, v/v/v) to ensure the stability of the compounds in tissues. In this case, the real **5** (free **5** and **5** released from **5**-glycine) was extracted; hence, the results were different from those in previous reports.

The depletion rate of quinocetone-related residues in pig, broiler, and carp tissues was found in the following order: fat (skin) > muscle > kidney > liver. This result indicated that the liver is the key organ of quinocetone residues. According to the principle of pharmacokinetics, the distributions of compounds in the body depend on organ blood flow and compound affinity to tissues. Blood supply to the liver and kidney is higher than that to muscle and fat. Therefore, a comparatively higher level of **3** was found in the liver and kidney than in other organs or tissues.

The depletion rate of the six compounds in the liver was observed in the order **6** > **2** > **1** > **5** > **4** > **3**. This result

indicated that **3** is the main compound that produces residues in pigs, broilers, and carp for the longest time when quinocetone was administered consecutively to these animals. Therefore, **3** could be the key compound for quinocetone residue monitoring compared with other compounds. The long half-lives of **3** in tissues may be attributed to the following reasons. **3** (didesoxyquinocetone) is one of the reduced metabolites of quinocetone. The polarity of **3** is much lower than that of other metabolites. As a result, **3** may be easily retained in organs and tissues.

Although the residue marker of quinocetone in the three animals was possibly **3**, certain differences were found in the residue characteristics of different animals. **6** could be detected only in pig liver. **5** could not be detected in carp tissues. Our results showed that the differences in metabolic processes could be accounted for the differences in distribution. In addition, $t_{1/2\ ke\text{-}3}$ in the liver was detected in the following order: carp > pigs > broilers. This result could be attributed to the differences in the metabolic absorption and metabolic enzymes of different animals.

**Acceptable Daily Intake (ADI).** On the basis of the toxicology results, the no observed effect level (NOEL) of quinocetone is 5 mg/kg bw/day.[27] The safety factor usually chosen is 100 in the situation where a NOEL is derived from a long-term animal study on the assumption that humans are 10 times as sensitive as the test animals used in such studies and that a 10-fold range of sensitivity within the human population may exist, but genotoxicity of quinocetone was noted in previous studies,[2] so a higher safety factor of 1000 was employed.[28] Then the ADI is 5 μg/kg bw/day.

**Dietary Exposure Assessment.** *Estimated Daily Intake (EDI).* Results below the LOQ are assigned a value of half of the LOQ when the median residue concentration is calculated. On the basis of the established model diet, the exposure to quinocetone expressed as the EDI, and calculated from the M:T and analytical method recovery adjusted median residue, was 208 μg/person/day. Dietary exposure was estimated to be 69% of the ADI (Table 2).

*Assumptions for Dietary Exposure Assessment.* The following assumptions were used in dietary exposure estimates: residues are found in pork, poultry, and fish; residues are found in muscle, liver, kidney, skin, and fat; all poultry offal is assumed to be kidney (worst-case scenario).

*Global Estimated Chronic Dietary Exposure (GECDE).* For the general population group, mammalian liver was the major contributor to estimated exposure from quinocetone residue (Table 2). Mammalian fat and kidney and poultry fat and skin contributed only negligible amounts to overall exposure estimates. Using the median residue as input, GECDE was 4.7 μg/kg bw/day, 94% of the ADI of 5 μg/kg bw/day (Table 2), and did not exceed the ADI.

*Comparison to EDI Estimates.* The calculations based on the model diet found that the median residue resulted in exposure estimated below the ADI for the general population. Similarly, the GECDE calculations found that exposure estimates were below the ADI for the general population, but they were higher than the EDI. Mammalian liver was the major contributor to chronic exposure estimates. In summary, none of the chronic exposure estimates resulted in exceeding the ADI.

**Withdrawal Time (WDT).** The EDI chart reveals that the EDI was below the ADI at zero withdrawal intervals in pigs and carp and at the withdrawal time of 72 h in broilers (Figure 3); therefore, it is recommended that the WDT of quinocetone is 0 days in pigs and carp and 3 days in broilers.

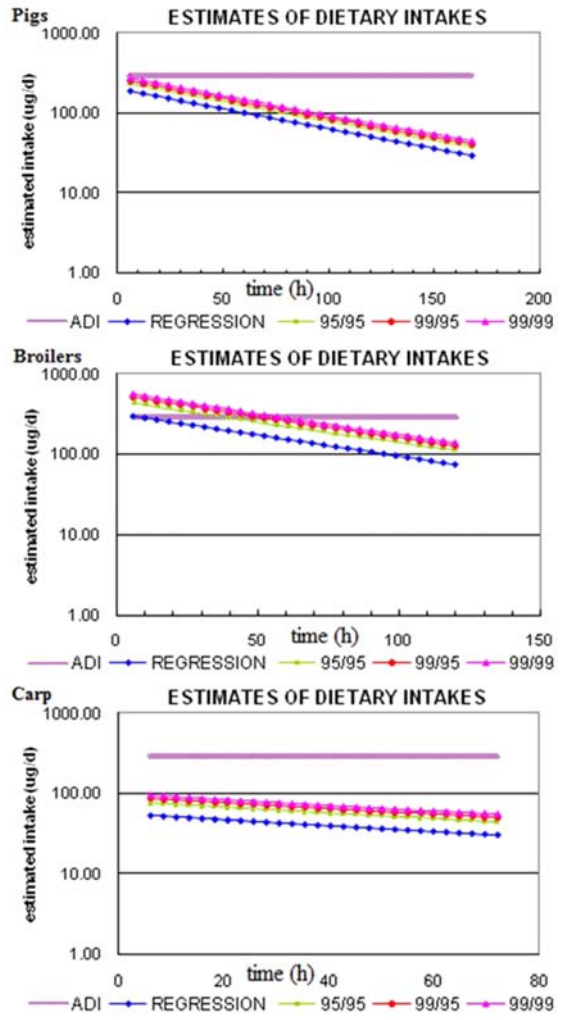

**Figure 3.** Estimated intakes (μg/person/day) versus time in pigs, broilers, and carp.

The prolonged presence of quinocetone-related residues in edible tissues is a potential risk for consumers. Considering that the established WDT was based on dietary exposure assessment, we could use the proposed WDT for residue monitoring of quinocetone in food-producing animals. In contrast to LC-MS/MS, HPLC-UV is probably more suitable for routine quinocetone residue monitoring analyses. HPLC-UV could be efficiently applied in a quinocetone monitoring program. The application of this technology could significantly improve the monitoring procedures for the illegal use of quinocetone to ensure food safety.

Our results provided the residue profile of quinocetone and its metabolites in edible tissues. On the basis of these residue data in edible tissues, our conclusion is that the liver is the target tissue and **3** is the residual marker of quinocetone in food animals. A withdrawal period of 0 days was estimated for quinocetone in pigs and carp, and 3 days was the estimated WDT in broilers. In addition, an HPLC-UV method was established to simultaneously and quantitatively determine quinocetone and its five major metabolites in edible tissues of pig, broiler, and carp. The recoveries in edible tissues spiked at

10−160 μg/kg ranged from 61.5 to 81.5% with interday RSD < 11.7%. These results also provided scientific evidence for the routine residue monitoring of quinocetone in food-producing animals.

**ABSTRACT:** Refined olive, corn, soybean, and sunflower oils were used as cooking oils for deep-frying at two different temperatures, 160 and 190 °C, and for pan-frying of potatoes at 180 °C for 10 successive sessions under the usual domestic practice. Several chemical parameters were assayed during frying operations to evaluate the status of the frying oils. Refined olive oil, as frying oil, was found to be more stable than the refined seed oils. In fact, this oil has proven the greatest resistance to oxidative deterioration, and its *trans*-fatty acid contents and percentages of total polar compounds were found to be lower at 160 °C during deep-frying. Finally, chemometric analysis has demonstrated that the lowest deterioration of the quality of all refined oils occurred in the refined olive oil during deep-frying at 160 °C and the highest deterioration occurred in the refined sunflower oil during pan-frying at 180 °C.

**KEYWORDS:** refined oils, deep-frying, pan-frying, frying temperatures, oil quality, Fourier-transformed near-infrared spectroscopy

## INTRODUCTION

Frying is one of the most popular methods of food processing, in which a foodstuff is submerged into heated oil exposed to atmospheric oxygen, moisture from the foodstuff, and high temperature with simultaneous heat and mass transfer.[1]

The selection of new industrial frying oils should satisfy many requirements. First of all, the product should be easy to use and keep good quality standards during prolonged exposure to high temperatures. Stability to oxidation during a prolonged exposure to high temperatures is one of the main characteristics that an industrial frying oil should possess, as its physical, chemical, and nutritional properties may undergo significant modifications during thermoxidation.[2] When lipids are subjected to a frying process, a wide range of complex chemical reactions such as oxidation, hydrolysis, isomerization, cyclization, and polymerization take place, which can degrade the oil. Undesirable constituents and off-flavors are developed in frying oil due to these chemical reactions.[3] Indeed, these reactions are influenced by the type and quality of the oil, the food properties, and the food/oil ratio, among other parameters,[4] altogether determining the frying oil performance.[5] Each vegetable oil is characterized by a typical stability against oxidation, which is dependent on the fatty acid composition, particularly the unsaturation degree and the content and composition of minor compounds. As a consequence, there is a need to define the point at which the fat or oil ought to be replaced. This is linked to the percentage of total polar compounds (TPC) formed during fryings. Today, it is well-known that when its TPC percentage is >25%, a fat or an oil for frying purposes must be discarded.[6]

A previous method described by Waltking and Wessels[7] was based on the separation by column chromatography on silica gel of two fractions. In fact, the first fraction contains the unaltered part or nonpolar compounds of the fat, which are unaltered triglycerides, and the second is composed of the altered products or polar compounds of frying fats. These decomposition products, also known as polar contaminant materials (PCM), tend to remain liquid and cannot be filtered out of the oil. They are also deposited on the surfaces of the fryer and absorbed by food. The PCM fraction is thought to include most of the potential toxic products produced in frying oils. In the biological tests conducted by López-Varela et al.,[8] rats fed used frying oil were found to exhibit liver damage. According to Andrikopoulos et al.,[9] the presence of byproducts of lipid peroxidation in food is undesirable because the nutritional value of food decreases with the destruction of unsaturated fatty acids (UFAs) and other essential food constituents with an unsaturated lipid structure such as vitamin E during the deep- and pan-frying of potatoes.

To obtain further information about polymerization changes that occur during frying, polar fractions that were previously obtained by column chromatography were analyzed by high-performance size exclusion chromatography (HPSEC).[10] These traditional chemical methods of oil analysis are commonly time-consuming and/or need substantial amounts of solvents.

[a] ROO, refined olive oil; RCO, refined corn oil; RSO, refined soybean oil; RSfO, refined sunflower oil; $K_{232}$ and $K_{270}$, spectrophotometric indices. Each value represents the mean of three determinations ($n = 3$) ± standard deviation. Different lower case letters (a, b, c, and d) within the same row indicate significant differences ($p < 0.05$) between the fresh and refined oil sample groups.

The development of a simple and rapid test is needed to proficiently monitor oil quality.

Fourier-transformed near-infrared spectroscopy (FT-NIRS) is an important tool used for quality control and process monitoring in the food industry because it is s less expensive, relatively fast, and nondestructive technique to analyze fats and oils. It is also considered as the optimal tool to describe all aspects of fat degradation.[11] FT-NIRS is used for quantitative and qualitative measurements of edible oils and fats as a result of the development of instrumental macroprogramming for automated routine operations and the application of chemometrical techniques for multicomponent analysis.[12−14]

The purpose of the present research study is to investigate and compare the deterioration effect of successive deep-fryings at two different temperatures, 160 and 190 °C, and pan-frying sessions of potatoes at 180 °C on the quality of four refined vegetable oils, namely, refined olive, corn, soybean, and sunflower oils, under the real household practice of frying. Indeed, after frying, each sample of refined oil was examined for free acidity (FA), absorption coefficients $K_{232}$ and $K_{270}$, TPC, dimeric and polymeric triacylglycerols (DPTG), anisidine value (AnV), fatty acid compositions, and *trans*-fatty acid (TFA) contents as well as oxidative stability (through a Rancimat apparatus).

## MATERIALS AND METHODS

**Chemicals and Reagents.** Ethanol (≥99.9%) and *n*-heptane (99.0%) were obtained from Riedel-de Haën (Steinheim, Germany). Cyclohexane (99.5%), *n*-hexane (99.0%), and diethyl ether (≥99.7%) were purchased from Merck KGaA (Darmstadt, Germany). Potassium hydroxide (85.0%) was obtained from CDM (Karlsruhe, Germany), and potassium iodide (>99.0%) was purchased from Chem-Lab (Zedelgem, Belgium). Sodium hydroxide (>99.0%) was supplied by Scharlau Chemie S.A. (Barcelona, Spain). Acetic acid (100.0%) and chloroform (>99.1%) were obtained from AnalaR NORMAPUR (La Chapelle-sur-Erdre cedex, France). Folin−Ciocalteu reagent was obtained from Fluka (Buchs, Switzerland). FAMEs multistandards (>99.0%) were purchased from Sigma Chemical Co. (St. Louis, MO, USA).

**Oil Samples.** The studied oils during the successive pan- and deep-frying sessions were refined olive oil (ROO), refined corn oil (RCO), refined soybean oil (RSO), and refined sunflower oil (RSfO). These oil samples were obtained from the National Oil Office of Sfax, Tunisia.

**Frying Process.** Spunta variety potatoes from Tunisia were peeled, cut uniformly (0.5 cm thick, 2 cm × 5 cm pieces, on average), washed, and wiped before the frying experiments, which were conducted in the same manner as the actual household cooking process.[15]

Pan-frying was performed in an uncovered stainless steel pan fryer (5.5 cm in height, 20.5 cm in diameter). Five hundred grams of potatoes was pan-fried each time in 0.3 L of refined oil, at 180 °C for 6 min, using an electric plate of a conventional electric kitchen cooker equipped with a thermostat. The oil temperature was monitored with a digital thermometer attached to a steel probe.

For deep-frying, a common domestic-type electric fryer was used. It is equipped with a thermostat (160 and 190 °C) and supplied with an inert cross-linked steel wire mesh that allows the food to be dipped into the oil without coming in contact with the fryer's inner surface. In every frying session, 400 g of potatoes was deep-fried for 8−9 and 11−12 min at 190 and 160 °C, respectively, in 2.0 L of refined oil, without replenishment. For the deep-frying experiments, the fryer's lid was closed when the cooling started. The same thing applied to the pan-frying experiments. It is to be noted that the stainless steel pan fryer was completely covered when cooling. After cooling (≈30 min), the frying process was repeated 10 times using new potatoes in the same oil. Samples of the fresh refined oils together with those sampled after each two successive pan- and deep-frying sessions were stored in sealed dark glass bottles at −20 °C until examination.

**Determination of Standard Quality and Composition Parameters.** Free acidity (FA) was determined according to International Norm ISO 660 "Determination of acid value and acidity",[16] peroxide value (PV) was determined according to International Norm ISO 3690 "Determination of peroxide value",[17] and the coefficients of specific extinction at 232 and 270 nm ($K_{232}$ and $K_{270}$) were determined according to the COI "Spectrophotometric investigation in the ultraviolet".[18] FA, given as a percentage of major fatty acid (% of oleic acid for the ROO and % of linoleic acid for the refined seed oils), was determined by the titration of a solution of oil dissolved in ethanol/diethyl ether (1:1, v/v) with ethanolic potash (0.1 N). PV, expressed in milliequivalents of active oxygen per kilogram of oil (mequiv $O_2$/kg of oil), was determined as follows: a mixture of oil and chloroform/acetic acid (2:3, v/v) was left to react with a saturated solution of potassium iodide in the dark; the free iodine was then titrated with a sodium thiosulfate solution (0.01 N). $K_{232}$ and $K_{270}$ were calculated from absorption at 232 and 270 nm, respectively, with a spectrophotometer (UNICO, SQ-2800, USA), using pure cyclohexane as a blank. The total phenols were evaluated colorimetrically at 725 nm with the Folin−Ciocalteu reagent.[15]

**Determination of Total Polar Compounds, Dimeric and Polymeric Triacylglycerols, and Anisidine Value.** TPC, DPTG, and AnV were determined by FT-NIRS following the DGF standard method C-VI 21a (13).[11] An MPA multipurpose FT-NIR analyzer equipped with an OPUS LAB spectroscopy software interface (Bruker Optik GmbH, Ettlingen, Germany) was used for data acquisition and analysis.

**Determination of Fatty Acids Composition.** The methyl esters for the determination of the *cis*- and *trans*-fatty acids by the use of capillary column gas chromatography (GC) were prepared according to a standard protocol (vigorous shaking of the solution of oil in *n*-heptane (0.1 g in 2 mL) with 0.2 mL of 2 N methanolic potassium hydroxide).[19,20] The GC analysis of FAMEs was performed on an

AutoSystem gas chromatograph equipped with a flame ionization detector (FID) (HP 6890N, Agilent, Palo Alto, CA, USA). The column used was a capillary Agilent CP-Sil88 (length = 50 m, i.d. = 0.25 mm, and film thickness = 0.20 $\mu$m), and the analysis conditions were as follows: the initial column temperature was settled at 165 °C for 25 min, then raised at a gradient of 5 °C/min to 195 °C; the temperature of the injector and detector was set at 250 °C; helium was used as the carrier gas at a flow rate of 1 mL/min and 1:100 split ratio; the injection volume was 1 $\mu$L.

*cis*- and *trans*-FAMEs were identified through a comparison of their retention times versus pure standards analyzed under the same conditions. They were quantified according to their percentage area, obtained by the integration of the peaks. The results were expressed as the percentages of individual fatty acids in the lipid fraction. The 10 fatty acids (*cis*) considered in this study were palmitic (C16:0), hypogeic (C16:1n-9) + palmitoleic (C16:1n-7), margaric (C17:0), margaroleic (C17:1), stearic (C18:0), oleic (C18:1n-9) + *Z*-vaccenic (C18:1n-7), linoleic (C18:2), linolenic (C18:3), arachidic (C20:0), and gondoic (C20:1n-9) acids. The TFAs considered in this study included *trans*-octadecenoic (tC18:1), *trans*,*trans*-octadecadienoic (tt C18:2), *cis*,*trans*- and *trans*,*cis*-octadecadienoic [(ct + tc) C18:2], and *trans*,*cis*,*trans*-, *cis*,*cis*,*trans*-, *cis*,*trans*,*cis*-, and *trans*,*cis*,*cis*-octadecatrienoic [(tct + cct + ctc + tcc) C18:3] acids expressed as percentages of fatty acid methyl esters.

**Determination of Oxidative Stability by Rancimat Apparatus.** The oxidative stability was evaluated by a Metrohm Rancimat model 743 (Herisau, Switzerland) following AOCS Official Method Cd 12b-92.[21] The oil samples (5.0 g) were heated at 120 °C, with a continuous air flow of 20 L/h passing through the samples. The conductivity cells were filled with 60 mL of deionized water. The time needed for the appearance of a sudden water conductivity rise, caused by the adsorption of volatiles derived from oil oxidation, was registered as the induction time in hours.

**Statistical Analysis.** The results were expressed as the mean ± standard deviation (SD) of three measurements for the analytical determination. Significant differences between the values of all parameters were determined at $p < 0.05$ according to the one-way ANOVA: post hoc comparisons (Student−Newman−Keuls test).

Nonstandardized principal component analysis (PCA) was applied to characterize the effect of the frying method and distinct temperatures on the quality and stability characteristics and compositions of ROO, RCO, RSO, and RSfO before and after 10 successive frying sessions according to all of the parameters investigated without any rotation type. The PCA type was Pearson ($n$), the biplot type was correlation biplot, and the coefficient was automatic. The Pearson correlation matrix and the PCA plots were performed using XLSTAT software for Windows (v. 2014.1.08, Addinsoft, New York, NY, USA).

The estimated marginal means are the means for each factor, adjusted for any other factor or covariate in the model. These means can be obtained by SPSS (general linear model, GLM) which corresponds to the means of $Y$ for each level of the factor at the mean value of the covariate. If the factor is independent, the marginal means are equal to the means of levels for each factor considered alone. The repeated measures analysis of variance (ANOVA) was applied to confirm the PCA results according to all of the parameters investigated during both frying methods at distinct temperatures. The Student−Newman−Keuls test and the repeated measures analysis were performed using SPSS Statistics 17.0 for Windows (SPSS Inc., 2008).

## RESULTS AND DISCUSSION

The results of the analytical indices based on the chemical changes obtained from the studied fresh oils and their corresponding ones after different fryings are given in Tables 1 and 2.

**Changes in Free Acidity during Frying.** The free fatty acids (FFAs) content results from the hydrolysis of triacylglycerol (TAG) as well as the further decomposition of hydroperoxides. The released fatty acids are more susceptible to thermal oxidation under frying temperatures. The oxidized products of fatty acids give the off-flavors and odors (hydrolytic rancidity) to the frying medium and fried foods.[22,23] Therefore, controlling the level of FFA within a reasonable range would prevent the breakdown of fats.

During titration, it is not possible to differentiate between acids formed by hydrolysis and those formed by oxidation or thermal oxidation. Therefore, the effect of heating on FA cannot be exactly described. Furthermore, the volatility of FFAs and their degradation to more volatile products affect the FFA levels obtained as the sum of the FFAs initially present and those formed by treatments.

The changes in the FFA percentages of the studied oils during 10 successive frying sessions with both frying methods at distinct temperatures are given in Table 2. Slow but significant ($p < 0.05$) increases of FFAs were shown for all refined oils. Besides, the highest percentage of FFAs was detected after pan-frying at 180 °C, followed by deep-frying at 190 and 160 °C, in decreasing order.

Indeed, the pan-fried refined sunflower oil at 180 °C (RSfO P-F) and deep-fried refined olive oil at 160 °C (ROO 160 °C) show the highest and lowest susceptibilities to the hydrolysis of fatty acids, respectively. Our previous study[15] has shown that the ROO has the lowest content in FFAs when compared with the RSO after five successive pan-frying sessions at 180 °C. Generally, low amounts of FFA were formed during frying, and this parameter is not suitable to be used as a quality indicator for frying oils.[15,24,25] Newly developed frying oils usually form smaller amounts of FFA than frying fats used commonly for this process.[26]

**Changes in the Specific Extinction Coefficients during Frying.** The lower solubility of oxygen at high frying temperatures promotes thermal reactions. The main products of thermal degradation are isomerization products such as *trans*-isomers, cyclization products such as cyclic monomeric TAGs, and polymerization products such as nonpolar dimeric and oligomeric TAGs.[27]

Cooling from 180 °C to room temperature slightly increased the oxygen content of oil in a short period. During the next frying session, the decrease in oxygen content was observed again.[28] It is important to note that both the oxygen absorbed in oil during cooling and the high temperature play an important role in the deterioration of the oil during frying.[28−30] Under ambient conditions, autoxidation occurs by free radical mechanism where hydroperoxides play a primary role.[31] Hydroperoxides do not accumulate due to their instability at frying temperature, but rather spontaneously decompose to form dimers and volatile products.[32]

The oxidation of polyunsaturated fatty acids (PUFAs) is accompanied by the increase in ultraviolet (UV) absorption. In fact, the UV absorption at 232 and 270 increases with the formation of the conjugated dienes and trienes. The resulting conjugated dienes exhibit an intense absorption at 232 nm; similarly, the conjugated trienes absorb at 270 nm.

The changes in $K_{232}$ and $K_{270}$ of the studied oils during 10 successive frying sessions with both frying methods at distinct temperatures are shown in Table 2. In this study, the ROO had the lowest level of conjugated dienes and trienes compared with

the other frying oils, followed by the RCO after deep-frying at 160 and 190 °C. However, the RSO and RSfO frying oils showed high levels in the absorption coefficient recorded at 232 and 270 nm in increasing order, especially after 10 pan-frying sessions at 180 °C. In this context, $K_{232}$ increased highly and significantly ($p < 0.05$) from 3.66 and 4.57 to 10.27 and 17.69 and $K_{270}$ augmented significantly ($p < 0.05$) from 2.03 and 3.53 to 3.22 and 4.89 for RSO and RSfO, respectively. This indicates that higher amounts of conjugated dienes and trienes are formed during frying (Table 2). Like dienes, the trienes could also form polymers during the frying process.[30]

These results are in good agreement with those reported by Marinova et al.[33] In fact, with respect to the conjugated diene and triene accumulations, ROO is the most stable oil. Moreover, for the polyunsaturated oils, although RCO is less stable than ROO, it is more stable than RSO.

**Changes in Total Polar Compounds during Frying.** The measurement of TPC is recognized as one of the most accurate assessments of the oxidative degradation of frying oils.[34−36] Many countries have established regulatory limits for TPC in frying oils and considered 25% as a limit.[26,28]

The changes in the TPC percentages of the studied oils after 10 frying sessions with both frying methods at distinct temperatures are shown in Figure 1a. High and significant ($p < 0.05$) increases of TPC were illustrated especially after pan-frying at 180 °C for the polyunsaturated oils from 4.39, 5.54, and 7.52% to 17.19, 17.08, and 17.75% for RCO, RSO, and RSfO, respectively, whereas small but significant increases ($p < 0.05$) were observed for the ROO after deep-frying at 160 and 190 °C from 3.45 to 5.11 and 5.74%, respectively, followed by RCO, RSO, and RSfO in increasing order. These results show that the oils containing higher percentages of UFAs provide more polar compounds compared to the more saturated ones. As can be seen from Figure 1a, whereas the RSfO P-F proves the highest TPC percentage at 180 °C, ROO D-F at 160 °C showed the lowest level of TPC at the end of the frying process. This indicates that the high stability of ROO to changes in TAGs that occurred during the frying experiments can be explained by considering that the ROO is rich in monounsaturated fatty acids (MUFAs), especially in oleic acid.[37]

In a related study, Matthäus[38] has determined the frying stability of high-oleic rapeseed oils and found that high-oleic rapeseed oils have lower TPC levels after 72 h of frying when compared with other commonly used edible oils. Warner and Knowlton[39] reported that genetically modified corn oils, which contain 65% oleic acid, have remarkably lower TPC levels after 20 h of frying at 190 °C as compared with normal corn oils. Similar findings were also seen in Abdulkarim's work, which has demonstrated that high-oleic *Moringa oleifera* seed oils show a lower TPC level after 30 h of frying at 185 °C as compared with other vegetable oils.[40]

The TPC results of this research study are in good agreement with those reported by Marinova et al.,[33] which have proven that ROO contains the lowest level of TPC followed by RCO, RSO, and RSfO in increasing order.

**Changes in Dimeric and Polymeric Triacylglycerols during Frying.** As a consequence of prolonged oxidation, ether, peroxy, or carbon−carbon bridged dimers and oligomers of TAG are formed. Because of their high molecular weight, these components remain in the oil and can provide reliable indications of the performance of oils/fats under frying conditions.[41]

The changes in the DPTG of the studied oils after 10 frying sessions with both frying methods at distinct temperatures are shown in Figure 1b. Indeed, high and significant ($p < 0.05$) increases of DPTG were illustrated especially after pan-frying at 180 °C for the polyunsaturated oils from 0.54, 0.65, and 0.82% to 8.40, 10.57, and 9.34% for RCO, RSO, and RSfO, respectively, whereas after pan-frying at 180 °C, ROO showed the lowest DPTG percentage ranging from 0.69 to 6.37%.

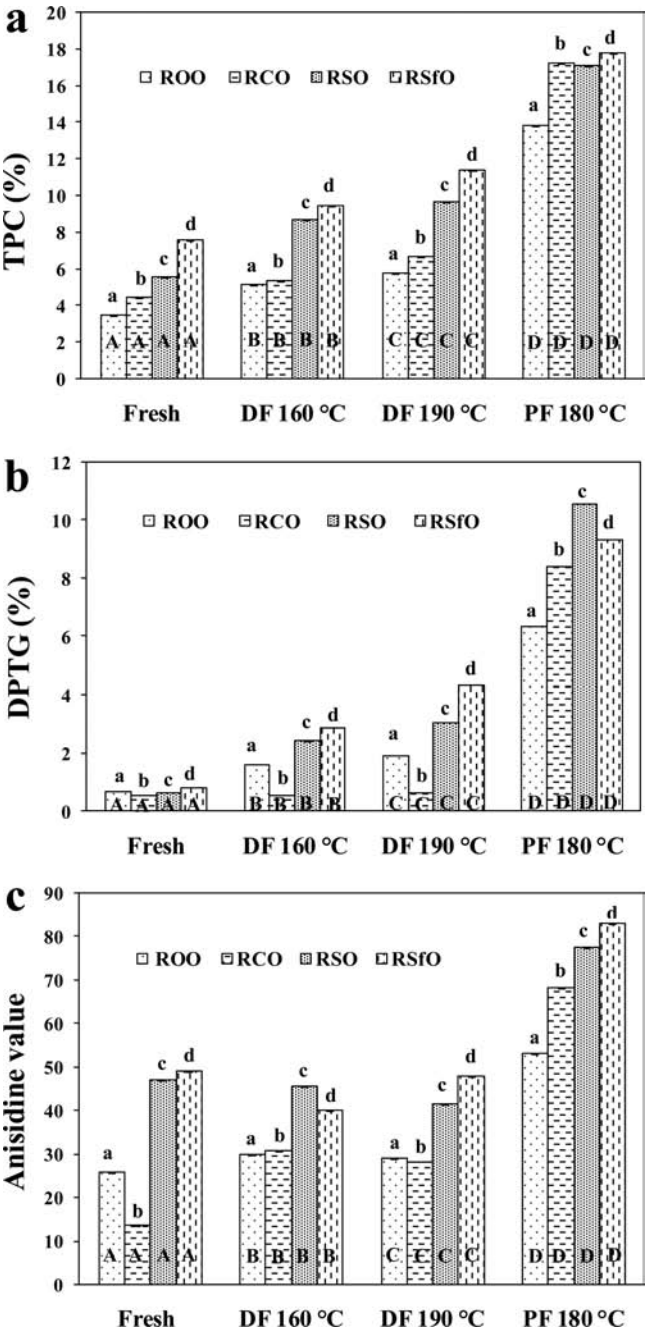

**Figure 1.** Changes in the composition of total polar compounds (a), dimeric and polymeric triacylglycerols (b), and anisidine value (c) before and after 10 pan- and deep-frying sessions at distinct temperatures (each value represents the mean of three determinations ($n = 3$); standard deviation <0.10%). Different upper case letters (A, B, C, and D) indicate significant differences ($p < 0.05$) for the same refined oil at distinct temperatures with different frying methods. Different lower case letters (a, b, c, and d) indicate significant differences ($p < 0.05$) between refined oil sample groups at the same temperature with the same frying method.

Slow but significant ($p < 0.05$) increases of DPTG were shown after deep-frying at 160 and 190 °C, especially for RCO and ROO from 0.54 and 0.69% to 0.57 and 1.62%, and to 0.66 and 1.93%. Yet RSO and RSfO revealed the highest levels of DPTG, which varied from 0.65 and 0.82% to 2.43 and 2.88% and to 3.05 and 4.35% after deep-frying at 160 and 190 °C, respectively. Thus, the highest percentage of DPTG was observed after pan-frying at 180 °C, followed by the deep-frying at 190 and 160 °C, in decreasing order.

The increase in DPTG is due to the formation of higher molecular weight substances by polymerization occurring at elevated frying temperature.[42] The oil containing a higher percentage of PUFAs exhibits a great tendency to form polymeric compounds rather than a highly saturated fatty acid-containing oil.

**Changes in Anisidine Value (AnV) during Frying.** The *p*-anisidine value is a measurement of nonvolatile aldehyde content in an oil, principally 2-alkenals and 2,4-dienals, formed as secondary degradation products from fatty acid hydroperoxides.[43] A *p*-anisidine value is, therefore, a measure of the oxidative state of an oil. A lower *p*-anisidine value in an oil indicates a lower oxidation level in that oil.

The changes in the AnV of the studied refined oils after 10 frying sessions with both frying methods at distinct temperatures are shown in Figure 1c. A clear variation was observed during deep-frying at both temperatures, 160 and 190 °C. Significant ($p < 0.05$) increases of AnV for ROO and RCO ranged from 25.71 and 13.52 to 29.63 and 30.47 and to 28.98 and 28.13 after frying at 160 and 190 °C, respectively. Nevertheless, significant ($p < 0.05$) decreases of AnV for RSO and RSfO were observed from 46.78 and 48.94 to 45.39 and 39.81 and to 41.31 and 47.87 after frying at 160 and 190 °C, respectively. This is presumably due to the participation of the target carbonyls in the further deteriorative reactions, principally, polymerization. It is noteworthy that these two oils (RSO and RSfO) contain the highest level of initial AnV (Figure 1c).

High and significant ($p < 0.05$) increases in the AnV of all refined oils were observed after 10 pan-frying sessions at 180 °C, especially for the RSfO with 82.92, followed by the RSO with 77.29, RCO with 68.15, and ROO with 53.10 in decreasing order compared to that of fresh oils: 48.94 for RSfO, 46.78 for RSO, 13.52 for RCO, and 25.71 for ROO. The highest values were found for RSfO and RSO, indicating extensive degradation of oxidized UFAs. These results have confirmed that RSfO and RSO are more susceptible to oxidation at high frying temperature than the other frying oils during pan-frying. This could be due to the presence of a high concentration of PUFAs, especially in RSfO followed by RSO. The latter are found to be more susceptible to oxidation when compared to the other frying oils, especially the monounsaturated oil as ROO.

The higher *p*-anisidine levels in the polyunsaturated oils, especially RSfO and RSO after 10 deep- and pan-frying sessions, being related with the formation of oxidation products, can also give some insight into the higher TPC observed in these samples. These results have proven that these vegetable oils present minor resistance to oxidation under frying conditions when compared to ROO, which is in good agreement with those reported by Casal et al.[44]

**Changes in Fatty Acid Compositions during Frying.** Being the main oils constituent, and by nature, the most important factor determining the oxidative stability, fatty acids are evaluated in detail in the current study. Olive oil, as expected, is characterized by a high degree of MUFAs, particularly oleic acid, thus contributing to the beneficial cardiovascular health effects.[45]

The fatty acid compositions of the studied oils are shown in Table 3. For all fresh frying oils, the most predominant fatty acids are palmitic (6.78−17.53%), oleic (25.84−58.29%), and linoleic (18.09−63.21%) acids.

RSfO is characterized by a dominant polyunsaturated fraction, particularly linoleic acid (63.21%), and a comparatively low amount of oleic acid (25.84%). When the relative percentages of fatty acids of all studied oils were compared after 10 frying sessions, a slight decrease (not significant, $p > 0.05$) of UFAs was observed, with the consequent increase (not significant, $p > 0.05$) in the percentages of saturated fatty acids (SFAs) (Table 3). The decrease is particularly noticeable ($p < 0.05$) in the PUFAs, presumably by oxidation, with the linoleic and linolenic acids. Despite the remarkable amount of PUFAs in RSfO, the lowest reduction in the amount of PUFAs was observed in ROO during the frying process. Indeed, the amount of C16:0 slightly increased but not significantly ($p > 0.05$) for all of the oils under investigation. As shown in Table 3, the amount of C18:1 is found to slightly increase in all studied oils during frying. These results are in accordance with those of Enríquez-Fernández et al.[46] and Romero et al.,[47] which suggest that the increase in oleic acid might be attributed to the linoleic and linolenic acid degradation.

The ratios of C18:2/C16:0 are shown in Table 3. For all studied oils, these ratios highly declined after 10 successive frying sessions, especially for RSfO followed by RSO, RCO, and ROO, and during pan-frying at 180 °C, deep-frying at 190 °C, and deep-frying at 160 °C, in decreasing order. Indeed, linoleic and palmitic acids are usually used as indicators of the extent of fat deterioration because linoleic acid is more susceptible to oxidation, whereas palmitic acid is more stable against oxidation. Therefore, the ratio of C18:2/C16:0 is also used to indicate the degree of oxidative deterioration of frying oil.[15,33,36,42]

**Changes in *trans*-Fatty Acid Compositions during Frying.** Elaidic acid, a *trans*-fatty acid from oleic acid, was present in all studied oils in small amounts even after 10 successive frying sessions. A high temperature (190 °C) can increase the amount of *trans*-isomers during deep-frying (Figure 2; Table 3). For all refined seed oils, the *trans* PUFA contents showed significant increases ($p < 0.05$) after 10 successive pan- and deep-frying sessions (Table 3). Indeed, the high increase of the *trans* PUFA contents was detected in RSfO followed by RSO and RCO, in decreasing order. However, a very small increase of these compounds was detected in ROO. In all studied oils and especially the seed oils, the higher deteriorations occurred during pan-frying at 180 °C, followed by deep-frying at 190 and 160 °C, in decreasing order. Published results reported by Zribi et al.[15] showed that a high increase of the *trans* PUFA contents was detected in RSO and a very small increase was detected in ROO after five successive pan-frying sessions.

Moreno et al.[48] reported that the intensive heating of oils caused an increase in the *trans* PUFA contents. For instance, the TFA content increased from 0.23 to 1.10% when sunflower oil was heated at 200 °C for 40 min and increased to 3.20% when heated at 250 °C for the same duration.

**Changes in Oxidative Stability during Frying.** The Rancimat method is frequently used for evaluating or predicting oxidative stabilities under heating conditions, known as induction time. Despite being an important tool for comparison of

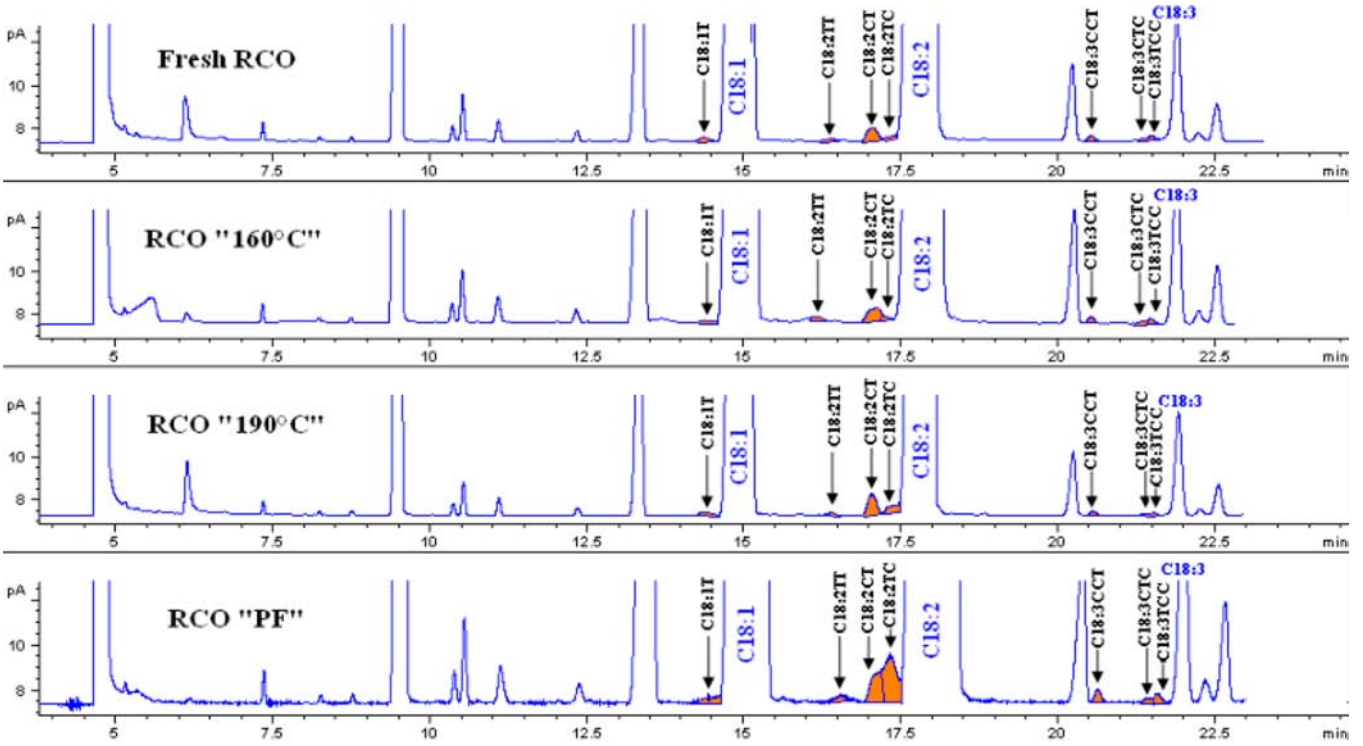

**Figure 2.** Gas chromatograms of *cis*/*trans* refined corn oil (RCO) before and after 10 successive pan- and deep-frying sessions at distinct temperatures. PF, pan-frying.

[a] ROO, refined olive oil; RCO, refined corn oil; RSO, refined soybean oil; RSfO, refined sunflower oil; IT, induction time; P-F, pan-frying. Each value represents the mean of three determinations ($n = 3$) ± standard deviation. Different upper case letters (A, B, C, D, and E) within the same column indicate significant differences ($p < 0.05$) for the same refined oil at distinct temperatures and different frying methods. Different lower case letters (a, b, c, and d) within the same row indicate significant differences ($p < 0.05$) between refined oil sample groups at the same temperature with the same frying method.

different vegetable oils, the results are not directly transposable to real frying conditions.

Clearly distinct results are observed for all oil samples (Table 4). The highest oxidative stability is depicted for ROO at 4.39 h, followed by RCO at 3.55 h and RSO at 3.34 h. The RSfO presents a clearly reduced stability at only 2.18 h.

The oxidative resistance of all studied refined oils decreased significantly ($p < 0.05$) after 5 deep-frying sessions and then declined to 0 h after 10 deep-frying sessions. The most resistant oil during deep-frying at 160 and 190 °C was ROO at 1.93 and 0.98 h, respectively, which had the lowest percentage of TPC after deep-frying at both temperatures, followed by RCO at 1.59 and 0.77 h and RSO at 1.25 and 0.65 h. However, the less resistant oil during deep-frying at 160 and 190 °C was the RSfO with 0.88 and 0.49 h, respectively, which had the highest percentage of TPC after deep-frying at both temperatures. Furthermore, as already mentioned above, the high stability of the ROO can be explained by its richness in MUFAs, especially in oleic acid.

With regard to the pan-fried refined oils, their oxidative resistance still decreased significantly ($p < 0.05$) after 5 pan-frying sessions at 180 °C and then declined to 0 h after 10 pan-frying sessions. The highest stability value was registered for ROO at 0.25 h, which had the lowest percentage of TPC after pan-frying, followed by RCO at 0.17 h and RSO at 0.13 h, whereas the lowest stability value was registered for RSfO at 0.06 h, which had the highest percentage of TPC after pan-frying.

Similar results reported by Casal et al.[44] showed that for the refined oils, ROO presented a high oxidative resistance during deep-frying when compared with a refined seed oil such as RSfO, which presented the lowest resistance to oxidation.

**Chemometric Analysis.** PCA was applied to the data set of all analyses performed for ROO, RCO, RSO, and RSfO before and

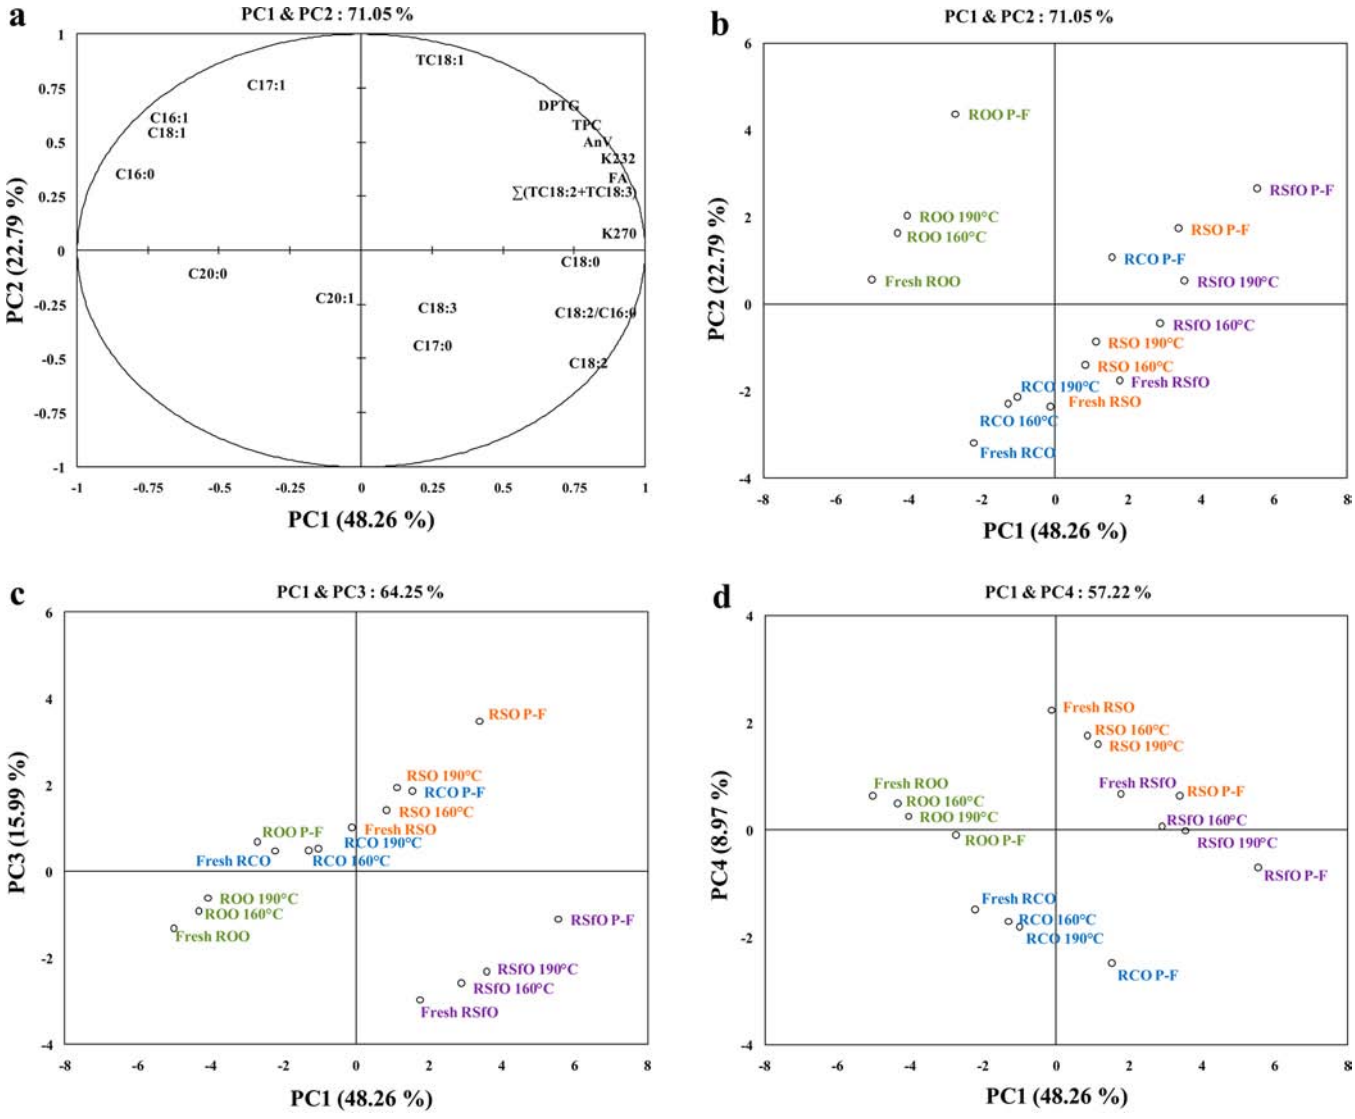

**Figure 3.** Principal component analysis applied to all samples analyzed before and after 10 pan- and deep-frying sessions at distinct temperatures considering 19 variables presented in the loading plot (a) and 16 observations shown in the score plots (b, c, and d). FA, free acidity; $K_{232}$ and $K_{270}$, spectrophotometric indices; TPC, total polar compounds; DPTG, dimeric and polymeric triacylglycerols; AnV, anisidine value; ROO, refined olive oil; RCO, refined corn oil; RSO, refined soybean oil; RSfO, refined sunflower oil.

after 10 successive pan- and deep-frying sessions at distinct temperatures, and four factors were selected justifying 96.01% of total variance (PC1, 48.26%; PC2, 22.79%; PC3, 15.99%; and PC4, 8.97%). With regard to these factors, all fresh and frying oils could be differentiated on the PCA diagram (Figure 3).

First, the first principal component (PC1) was mainly correlated by the following parameters: free acidity, $K_{232}$, $K_{270}$, ∑(TC18:2 + TC18:3), C16:0, C16:1, C18:1, C18:2, C20:0, C18:2/C16:0, TPC, and AnV. It can therefore be considered as a stability axis. Second, the second principal component (PC2) was dominated by the following parameters: TC18:1, C17:1, and DPTG (Figure 3a). The third and fourth principal components (PC3) and (PC4) were mainly correlated to C17:0, C18:3, and C20:1 and to C18:0, respectively.

PC1 clearly separates the most stable frying oil ROO from the other oils (RCO, RSO, and RSfO), with the least stable frying oil being RSfO. PC2 has proven that deep-frying at 160 °C is the best frying method for all refined oils, followed by deep-frying at 190 °C, and the worst is pan-frying at 180 °C (Figure 3b). More precisely, PC1 opposes ROO (in the negative side) to RSfO (in the positive side), whereas PC2 separates each fresh oil, deep-frying oil at 160 and 190 °C, and pan-frying oil at 180 °C. Besides, PC3 further separates RSfO (in the negative side) from all other oils and mainly RSO and RCO (Figure 3c). The two groups RCO and RSO are well separated by PC4, where RSO was found in the positive side and RCO in the negative side (Figure 3d).

According to the PCA, the least deteriorated oil is ROO during deep-frying, especially at 160 °C, and the highest is RSfO during pan-frying at 180 °C. Indeed, fresh ROO, ROO at 160 °C, and ROO at 190 °C are highly and negatively related to PC1, which are characterized by their highest C18:1 and C16:0 percentages and very lowest TC18:1 contents, whereas ROO P-F is related positively to PC2, which is correlated with the increase in TC18:1. Moreover, RSfO P-F is highly related to PC1, which is correlated positively with the slight increase of the free acidity

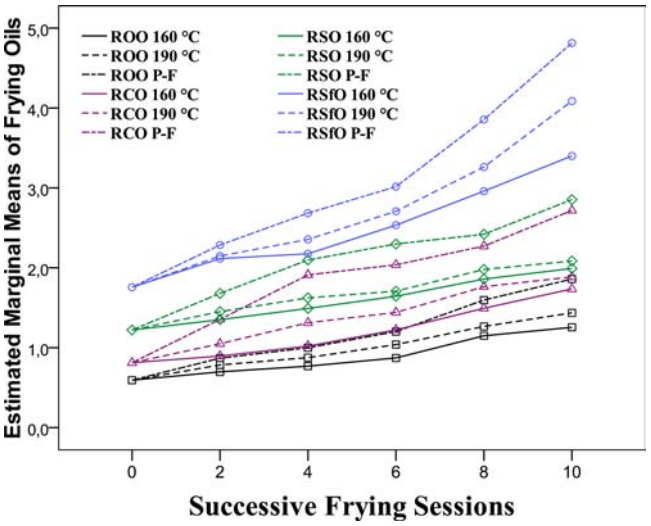

**Figure 4.** Repeated measures analysis of variance (ANOVA) of some parameters [free acidity, $K_{232}$, $K_{270}$, TC18:1, and Σ(TC18:2 + TC18:3)] analyzed after each two successive pan- and deep-frying sessions. ROO, refined olive oil (□); RCO, refined corn oil (△); RSO, refined soybean oil (◇); RSfO, refined sunflower oil (○); P-F, pan-frying.

and significant increases of the $K_{232}$, $K_{270}$, AnV, TPC, and Σ(TC18:2 + TC18:3) percentages.

The analysis of variance of some parameters of the refined oils such as free acidity, $K_{232}$, $K_{270}$, TC18:1, and Σ(TC18:2 + TC18:3) obtained after each two successive pan- and deep-frying sessions at distinct temperatures is shown in Figure 4. Indeed, the repeated measures analysis of variance indicates that the quality of ROO, followed by RCO, shows better chemical characteristics than those of RSO and RSfO after 10 successive frying sessions, especially during deep-frying at 160 °C.

In conclusion, changes in the characteristics and compositions of the studied oils have shown that ROO is the most stable oil during deep-frying at 160 °C, whereas RSfO is the least stable during pan-frying at 180 °C. Therefore, ROO appears to be a good substitute for the refined seed oils in domestic frying applications. Thus, the choice of a stable frying oil having a good quality and adequate frying temperature and frying method is of great importance to maintain a low deterioration during frying operations and hence obtain high-quality fried foods.

involve complex chemical reactions to immobilize the targets and their analogues onto the matrixes but also alter the inherent structure of the target molecules, possibly leading to a reduction in aptamer affinity toward their original targets. Although Yang and Bowser reported that they screened aptamers for *N*-methyl mesoporphyrin IX (MW = 580 g/mol) by capillary electrophoresis (CE)−SELEX, allowing for the binding and separation steps to occur in free solution without steric hindrance,[22] CE−SELEX employs expensive capillary electrophoresis as an instrumental platform for SELEX, which limits its application in aptamer selection. Recently, Park et al. reported an immobilization-free method for screening aptamers against insulin assisted by graphene oxide (GO)[23] as well as against whole bovine viral diarrhea virus type 1 via a similar method.[24] GO is a well-known graphene derivative; one of its important properties is that ssDNA can be strongly adsorbed on its surface because of hydrophobic and $\pi-\pi$ stacking interactions between the nucleobases and GO, whereas dsDNA adsorption on GO is very weak because of the shielding of nucleobases by the phosphate backbone.[25,26]

In the present study, we used GO for screening aptamers against the small-molecule target T-2. Measures were taken during SELEX to generate high-quality aptamers for T-2. The incubation system throughout the selection process contained 1.0% (volume ratio) of methanol to increase the compatibility of T-2 and the oligonucleotides. Because T-2 is relatively insoluble in water,[6] the toxin was dissolved in methanol, a common extraction solvent used in current detection, which enabled T-2 to gain full access to the ssDNAs in free solution. In addition, common mycotoxins that are potentially found in combination with T-2 were added, starting at the sixth round of SELEX to increase the specificity of the generated aptamers for T-2. The presented methodology eliminates the necessity of solid-phase attachment, avoids structural changes in the target molecule, reduces the potential for non-specific interactions, and does not rely on expensive instrumentation. Therefore, our proposed method is believed to be a more versatile technique than previously reported methods to a certain extent.

## MATERIALS AND METHODS

**Chemicals and Reagents.** The initial ssDNA library and primers for amplification were synthesized by Integrated DNA Technologies (Coralville, IA). T-2, fumonisin $B_1$ ($FB_1$), and ochratoxin A (OTA) were obtained from Fermentek, Ltd. (Jerusalem, Israel); zearalenone (ZEN), aflatoxin $B_1$ ($AFB_1$), and acrylamide/bis-acrylamide (30% solution) were purchased from Sigma-Aldrich (St. Louis, MO). The operators were required to wear gloves and masks to avoid exposure to the above toxins. GO was prepared from graphite powder using a modified Hummer's method,[27] as described previously by our group.[28] A homogeneous suspension of GO (approximately 5.0 mg/mL) was prepared by ultrasonic vibration and used throughout the experiment. The reagents for polymerase chain reaction (PCR) amplification and 5′-carboxyfluorescein (FAM)-labeled aptamers were obtained from Sangon Biotech. Co., Ltd. (Shanghai, China). Lambda exonuclease enzyme (5000 units/mL) and 10× lambda exonuclease reaction buffer were purchased from New England BioLabs (Ipswich, MA). Chromatographically pure methanol and other unspecified chemicals and reagents of analytical grade were purchased from Sinopharm Chemical Reagent Co., Ltd. (Shanghai, China). Solutions were prepared with ultrapure water processed with a Millipore Direct-Q3 ultrapure water system (Billerica, MA).

**Apparatus.** All PCRs were performed in a C1000 thermocycler (Hercules, CA). The observation of polyacrylamide gel was carried out using a Chemi Doc XRS+ imaging system with Image Lab software (Hercules, CA). A ND-1000 spectrophotometer (Wilmington, DE) was used to measure the nucleic acid concentration. Fluorescent detection was performed using a F-7000 fluorescence spectrophotometer (Tokyo, Japan). Circular dichroism (CD) spectroscopy was performed on a MOS-450/AF-CD (Claix, France) spectropolarimeter interfaced with a computer with Biokine V4.51 software installed.

**Generation of ssDNA Library.** An 80 nucleotide oligonucleotide ssDNA library consisting of a central 40 nucleotide randomized region flanked by two 20 nucleotide primer binding sites was used as the initial library (5′-CAGCTCAGAAGCTTGATCCT-N40-GACTC-GAAGTCGTGCATCTG-3′) on the basis of the study by Tang et al.[29] The ssDNA library and subsequent aptamer pools were amplified by symmetric PCR with a forward primer (5′-CAGCTCAGAAGCTT-GATCCT-3′) and phosphorylated reverse primer (5′-P-CAGATG-CACGACTTCGAGTC-3′) under the following conditions: 5 min at 94 °C, repeated cycles of 30 s at 94 °C, 30 s at 53 °C, and 30 s at 72 °C, followed by 5 min at 72 °C. The PCR cycles were optimized in each round of SELEX to obtain the intended 80 base pair products. The PCR products were analyzed using 8% native PAGE and purified by a PCR Product Purification Kit (Generay Biotech. Co., Ltd., Shanghai, China). Subsequently, the concentrations of recovered products were measured using a ND-1000 spectrophotometer to estimate the amount of lambda exonuclease needed. The phosphorylated antisense strands were digested by lambda exonuclease according to the instructions of the supplier (New England BioLabs). After identification using 8% denaturing PAGE with 7 M urea, the digestion products were purified, precipitated, and subsequently used as the ssDNA library.

***In Vitro* Selection.** The GO−SELEX process is illustrated in Scheme 1. Prior to being mixed with target mycotoxin T-2, the ssDNA library dissolved in binding buffer (BB; 10 mM Tris-HCl, 150 mM NaCl, 10 mM KCl, and 2.5 mM $MgCl_2$ at pH 7.4)[30] was heated at 94 °C for 5 min, immediately cooled on ice for 15 min, and placed at 25 °C for 10 min. In the first round, folded ssDNA (1 nmol) was incubated with T-2 (100 nmol) in 400 $\mu$L of special binding buffer, which contained 1.0% methanol, for 2 h at 25 °C with tilting and rotation. Subsequently, 10.0 mg of GO (mass ratio of GO/ssDNA is 400:1) from the above-mentioned GO suspension by centrifugation were added to the mixture of potential aptamers and unbound ssDNA, and the solution was incubated at 25 °C for 40 min. This mixture containing GO was centrifuged at 13 000 rpm/min for 10 min, and the supernatant containing ssDNAs bound to T-2 was collected, while the deposit with unbound ssDNAs adsorbed onto GO was discarded. The collected potential aptamer pool was amplified by PCR, and the ssDNA products were generated by lambda exonuclease digestion of the phosphorylated strands from dsDNA products. The subsequent round of GO−SELEX was performed with the purified library.

Counter GO−SELEX was performed starting from the sixth round to improve the specificity of the aptamers against T-2. The ssDNA library (200 pmol) was first incubated with a mixture of $FB_1$, ZEN, $AFB_1$, or OTA (5 nmol, individually) in 400 $\mu$L of incubation buffer for 60 min, and then GO (2.0 mg) was added and incubated for 40 min. During this process, the oligonucleotides that did not bind to the counter-targets were adsorbed onto the GO surface by $\pi-\pi$ stacking

[a]The affinity and $K_d$ of the underlined sequences were characterized using binding assays.

interactions, while those bound to the counter-targets remained suspended in the buffer. After separation by centrifugation, GO on which oligonucleotides were adsorbed was resuspended and washed with BB 5 times for harsher conditions. Subsequently, target T-2 (20 nmol) was mixed with the GO−ssDNAs and incubated further for 2 h in 400 μL of buffer, to recover the aptamers from the GO surface. The mixture solution was centrifuged, and the supernatant containing potential aptamers was collected. This obtained library pool was amplified by PCR, and ssDNA was again generated by lambda exonuclease digestion and purification.

**Cloning and Sequencing of the Enriched Pool.** Following 10 rounds of selection, the enriched ssDNA pool was amplified by unmodified primers. The purified PCR product was cloned using the pMD-19T cloning vector (Takara Biotech.Co., Ltd., Dalian, China) and transformed into *Escherichia coli* DH5α. Through blue−white spot screening, 30 white positive clones were randomly selected and cultured in LB medium containing 50 μg/mL ampicillin, followed by plasmid DNA extraction using a Plasmid MiniPrep Kit (Generay Biotech. Co., Ltd., Shanghai, China). Finally, the extracted plasmid DNA with inserted aptamer candidates were sequenced by Sangon Biotech. Co., Ltd. (Shanghai, China). Multiple sequence alignment of the obtained sequences was analyzed using DNAMAN software,[31] and the secondary structure of each sequence was predicted using RNAstructure 4.6 software (http://rna.urmc.rochester.edu/RNAstructure.html) with paraments of maximum percent energy difference of 10 and maximum number of structures of 20.

**Binding Assays.** The aptamers were heat-denatured and cooled on ice, using the same procedure as for the *in vitro* selection, prior to use. To identify individual aptamer candidates, binding assays for each FAM-labeled representative sequence and its truncated sequence (without the primer-binding regions) were conducted by incubating a fixed amount of T-2 (1 μM) with various concentrations of the synthetic sequences, ranging from 5 to 200 nM, in 500 μL of BB in the dark for 2 h. Then, GO proportional to the amount of ssDNA present was added to each tube, and the mixture was incubated in the dark for 40 min. After centrifugation, the fluorescence intensity of the T-2/aptamer complexes in the supernatant was measured using a F-7000 fluorescence spectrophotometer with excitation at 490 nm. Negative controls without T-2 added were used to determine non-specific binding. All of the binding assay experiments were repeated 3 times. The equilibrium dissociation constant ($K_d$) of aptamer/T-2 binding was determined using GraphPad Prism 5.0 software based on a nonlinear fit of the T-2/aptamer complex fluorescence intensities for a range of aptamer concentrations.

**Evaluation of Specificity.** Three sequences with lower $K_d$ values were selected to evaluate the specificity of the aptamers against T-2 based on the binding assay results. The specificity test was performed as follows: GO (0.3 mg/mL) in the special binding buffer was incubated with the aptamers (100 nM), along with T-2 or $FB_1$, ZEN, $AFB_1$, or OTA (10 μM, individually), for 2 h in the dark. The negative control for each sequence was mixed with BB instead of any mycotoxin targets. Subsequently, each of the mixtures was centrifuged at 13 000 revolutions per minute (rpm) for 10 min, and the supernatant was collected and kept in the dark. Finally, the fluorescence of each supernatant was measured using a F-7000 fluorescence spectrophotometer with excitation at 490 nm.

**CD Spectroscopy Assay.** To further investigate the mechanism of binding between the preferred aptamer Seq.16 and target T-2, CD spectroscopy was used to study the conformation of the ssDNA aptamer before and after binding with free T-2 in free solution. Aptamer Seq.16 (1 μM) was incubated with or without target T-2 (20 μM) for 2 h in special binding buffer as well as a tube of pure T-2 (20 μM) in the vibration oven (total volume of each was 400 μL). Subsequently, these samples were analyzed on a MOS-450/AF-CD (France) spectropolarimeter with recording of the CD spectra from 230 to 320 nm.

**Aptamer-Based Fluorescent Bioassay.** The potential application of aptamer Seq.16 for the detection of T-2 in beer was explored by a fluorescent bioassay. Canned beer purchased from a local supermarket (50 mL) was completely degassed by sonication, and then the $CO_2$-free beer was filtered through a 13 mm, 0.22 μm nylon syringe filter. Prior to being used in the study, the beer sample was analyzed by mass spectrometry to make sure that T-2 was undetectable. The beer was spiked with the stock solution of T-2 to obtain a final concentration of 1 mM T-2. From this spiked sample, several dilutions from 0.05 to 500 μM T-2 were prepared with non-spiked beer. Then, 400 μL of folded 5′-FAM-labeled Seq.16 (125 nM) in 5× BB was mixed with 100 μL of beer sample at a final concentration of T-2 ranging from 0.01 to 100.0 μM, along with GO (150 μg). The control group was set similarly but without T-2 added. The mixtures (500 μL) were incubated in the dark for 2 h with gentle shaking. Subsequently, each of the mixtures was centrifuged at 14 000 rpm for 10 min, and the fluorescent intensity of the supernatant collected was measured using a F-7000 fluorescence spectrophotometer with excitation at 490 nm.

## RESULTS AND DISCUSSION

**Screening of Aptamers against T-2.** Several preliminary experiments were conducted before the screening of aptamers against T-2. The critical point at which approximately 500 μg of GO could adsorb 100 pmol of the ssDNA pool was first determined by an adsorption test using the initial library pool. The double ratio of GO/ssDNA was maintained throughout the selection process to ensure that the ssDNAs not bound to T-2 were completely adsorbed. Next, a series of PCRs containing 0, 0.1, 1.0, or 10.0% (volume ratio) methanol in the PCR system was performed to study the effect of the methanol content in the special binding buffer on PCR amplification (see the Supporting Information). Finally, 1.0% methanol was selected for use in the incubation system during *in vitro* selection, enabling the T-2 toxin full access to ssDNAs in free solution. A balance was achieved between control of the selection conditions and PCR amplification, which greatly contributed to the screening of aptamers against T-2.

During the formal SELEX process, T-2 was used as the target, and several common mycotoxins, including $FB_1$, ZEN, $AFB_1$, and OTA, were treated as counter-targets. The counter-targets are known to be produced by the same fungus species or to likely coexist with the target mycotoxin in a heterogeneous environment. Five rounds of counter selection following five

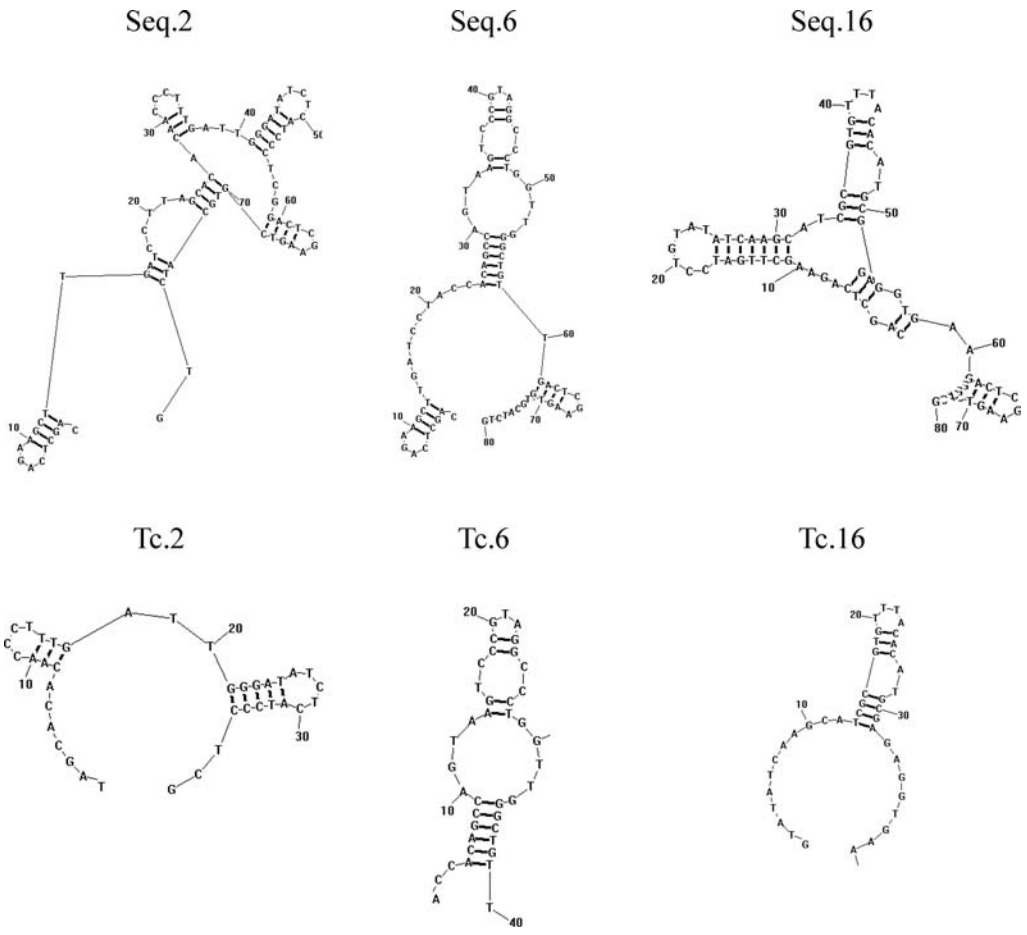

**Figure 1.** Secondary structure models of representative aptamers and their truncated sequences predicted by software RNAstructure 4.6.

rounds of positive selection increased the specificity of aptamers by the efficient removal of non-specific sequences in each round. The recovery amount of ssDNA bound to T-2 was measured by a ND-1000 spectrophotometer, and selection was finished in the 10th round when we observed that the recovery ratio of it was much higher than that of the first round. The above-mentioned GO−SELEX procedure eliminated the necessity for solid-phase attachment, thus avoiding structural changes in the target molecule, reducing the potential for non-specific interactions, and not relying on expensive instrumentation.

**Preliminary Identification of Aptamers.** After the 10th round of immobilization-free SELEX, a total 30 recombinant plasmids were sent for sequencing. Finally, 27 sequences of aptamer candidates were successfully obtained from Sangon Biotech. Co., Ltd., and they were grouped into three families, as presented in Table 1. The aptamer candidate termed Seq.2 was the sequence with the highest abundance in the enriched library, but two bases were missing in the variable N40 region. As Viswanathan et al. reported, GC-rich regions in the templates can cause the formation of stem-loop secondary structures that have been known to promote polymerase jumping during PCR amplification.[32] This polymerase jumping produces smaller PCR products with missing sequences for the template stem-loop region.[33] Similar cases have been reported for the study by McKeague et al. of fumonisin $B_1$ aptamers[34] and the study by Kiani et al. of digoxin aptamers.[35] However, these missing bases would not matter if Seq.2 exhibited high affinity and specificity toward target T-2.

Representative aptamers from each family were selected on the basis of DNA homology, as analyzed using DNAMAN software, and the lowest predicted free energy of formation $\Delta G$, as calculated using RNAstructure 4.6 software. The sequences that occurred twice or more in the cloning results were chosen because these sequences may be present in higher abundance. Meanwhile, aptamers with lower $\Delta G$ were also chosen, because these sequences should possess more stable secondary structures, which help to maintain the stability of the target/aptamer complexes. The secondary structures of the representative aptamers Seq.2, Seq.6, and Seq.16 and their truncated sequences Tc.2, Tc.6, and Tc.16 predicted by RNAstructure 4.6 software are shown in Figure 1. Unique stems, loops, bulges, hairpins, triplexes, and pseudo-knots assembled in the aptamers may have contributed to the specific binding of these aptamers to target T-2.

**Affinity of DNA Aptamers to T-2.** The binding saturation curves of the measured fluorescence intensity of the T-2/aptamer complexes (after deduction of the blank background) plotted against the aptamer concentration (5, 10, 25, 50, 100, or 200 nM) were generated, and the $K_d$ values for the aptamer sequences were calculated by nonlinear regression analysis using GraphPad Prism 5.0 (Figure 2). Among the tested sequences, the $K_d$ values of Seq.2 (62.4 ± 12.1 nM), Seq.6 (37.2 ± 8.4 nM), and Seq.16 (20.8 ± 3.1 nM) were relatively lower than that of Tc.6 (81.3 ± 21.7 nM), indicating higher affinities to T-2. The binding of the aptamers to their targets typically resulted from structure compatibility, stacking of aromatic rings, electrostatic interactions, van der Waals forces,

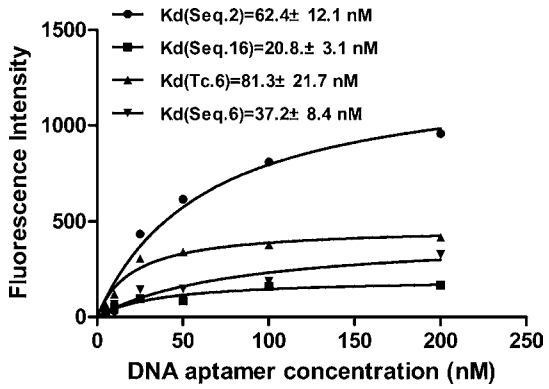

**Figure 2.** Binding saturation curves and determination of the dissociation constants ($K_d$) of aptamers against T-2 by nonlinear regression analysis using GraphPad Prism 5.0.

and hydrogen-bond interactions or a combination of these effects.[36] As seen in Figure 1, the secondary structure of the short sequence Tc.6 is similar to that of Seq.6 but the secondary structures of Tc.2 and Tc.16 remarkably differed from those of their full-length sequences. This difference might be the reason for the lack of affinity of sequence Tc.2 and Tc.16 to target T-2, which was most likely caused by the truncation of primer-binding regions that resulted in a failure to form the three-dimensional structures essential for binding.

**Specificity of Aptamers.** On the basis of the results of the affinity assays, three aptamers (Seq.2, Seq.6, and Seq.16) with lower $K_d$ values for T-2 were selected for specificity testing. The specificity tests were performed using a competitive binding method inspired by the report by Lu et al.[37] GO was mixed with each FAM-labeled aptamer, along with the target molecule T-2 or with $FB_1$, ZEN, $AFB_1$, or OTA. In the presence of T-2, the binding between the FAM-labeled DNA and target molecules should alter the conformation of the FAM-labeled DNA and disturb the interaction between the ssDNA and GO, thus shifting the FAM-labeled DNA into the supernatant.[37] From Figure 3, all of the three aptamer candidates (Seq.2, Seq.6, and Seq.16) exhibited obviously higher corrected

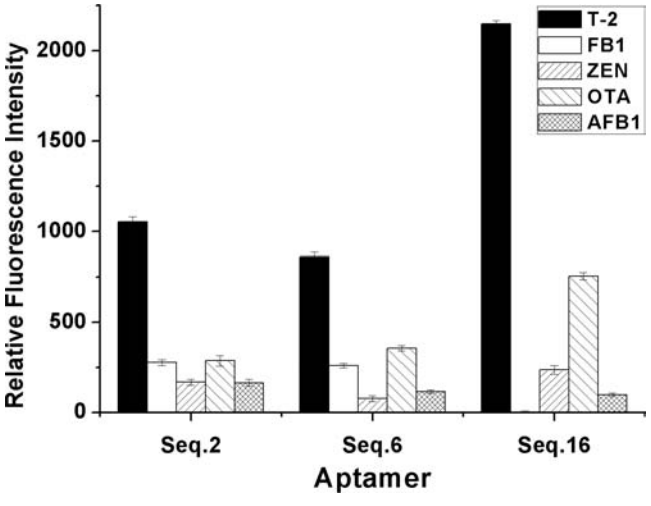

**Figure 3.** Characterization of the specificity of aptamers Seq.2, Seq.6, and Seq.16 by a competitive binding assay. The data shown are corrected values with the negative control signal value deducted. Each data point represents the mean ± standard deviation of three replicates.

fluorescence intensities in the presence of T-2, in comparison to incubation with the counter-targets, and aptamer Seq.16 was found to be significantly more specific to target T-2.

**Study of the Interaction Mode between T-2 and Aptamer.** The CD spectroscopy assay is a powerful and sensitive technology to study the interaction mode between small molecules and DNA aptamers. For further study of conformational information on Seq.16, CD spectra were recorded before and after binding with T-2 in special binding solution. As shown in Figure 4, the CD spectrum of pure T-2 is

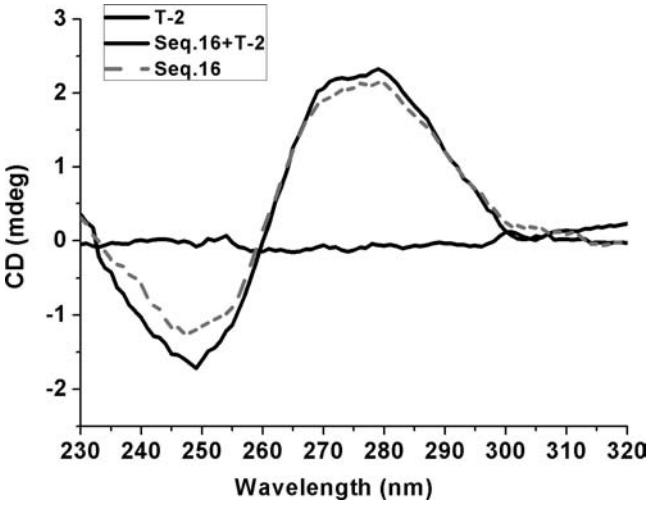

**Figure 4.** CD spectra of T-2 and aptamer Seq.16 in the absence or presence of T-2. The final concentration of T-2 is 20 $\mu$M, and that of the aptamer is 1 $\mu$M.

near the baseline, almost zero signal. The CD spectrum of pure aptamer Seq.16 displays a negative band at 249 nm and a positive band at 280 nm, indicating that the aptamer may have an A-form duplex of the hairpin structure.[38] The addition of T-2 caused a slight increase of the positive band around 280 nm and an apparent decrease of the negative band around 250 nm, suggesting that the binding of T-2 to Seq.16 could promote the formation of the A-form duplex of the hairpin structure.

**Application of Aptamer Seq.16.** To demonstrate the potential application of aptamer Seq.16, we performed a fluorescent bioassay for the detection of T-2 in beer samples. Matrix background interference from beer was reduced by diluting the sample 5 times with BB. Because of the high affinity and specificity of Seq.16 against the target T-2, the binding events between the aptamers and targets disturb the interaction between the ssDNA and GO, thus reserving the FAM-labeled aptamers in the supernatant. In the absence of T-2, the fluorescent intensity of the diluted beer sample was at a minimum; in the presence of different concentrations of T-2, the fluorescent intensity varied. A calibration curve of aptamer-based detection of T-2 in beer was created by plotting the relative fluorescence intensity ($\Delta I$) against the T-2 concentration of undiluted beer (Figure 5), in which $\Delta I$ represents the difference of fluorescence intensity in the presence and absence of T-2. A linear correlation ($R^2$ = 0.988) was obtained between 0.5 and 37.5 $\mu$M (0.1 and 7.5 $\mu$M in the diluted beer sample). The sensitivity of the developed bioasssay was investigated, and the limit of detection (LOD) for T-2 was found to be 0.4 $\mu$M in the real beer sample. Recovery tests were performed for evaluation of the accuracy of the developed method for T-2

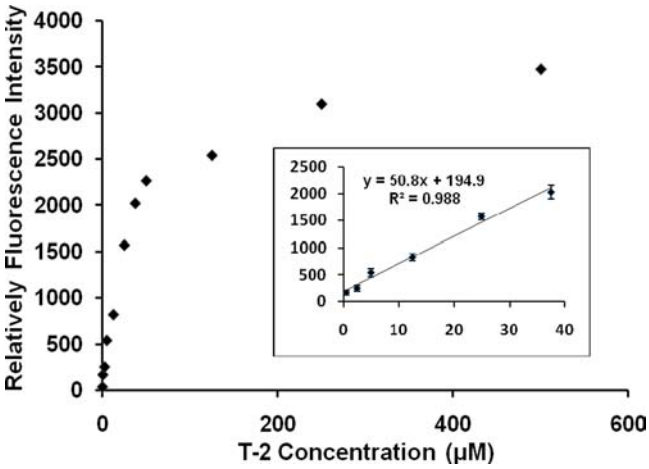

**Figure 5.** Calibration curve for T-2 in beer measured by the aptamer-based fluorescent bioassay.

determination in beer. A good assay recovery for spiked real beer samples was obtained, as listed in Table 2. The preliminary study in the work shows potential application of the selected aptamer in the detection of T-2 in real samples. A further study is ongoing in our laboratory to develop advanced biosensors for T-2 detection, with an increased sensitivity and a decreased detection limit, by means of the signal amplification technique.

**Table 2. Recovery of T-2 in Spiked Beer by the Aptamer-Based Fluorescent Bioassay**

| T-2 added ($\mu$M) | T-2 detected ($\mu$M) ($n$ = 3) | recovery (%) |
|---|---|---|
| 2.5 | 2.34 ± 0.14 | 93.6 |
| 12.5 | 12.6 ± 0.12 | 100.8 |
| 25.0 | 26.5 ± 0.12 | 106.0 |
