# Transamination Governs Nitrogen Isotope Heterogeneity of Amino Acids in Rats

Alexander Braun,[†] Armin Vikari,[‡] Wilhelm Windisch,[‡] and Karl Auerswald*[,†]

[†]Lehrstuhl für Grünlandlehre, Department of Plant Science and [‡]Fachgebiet für Tierernährung und Leistungsphysiologie, Technische Universität München, D-85350 Freising, Germany

**ABSTRACT:** The nitrogen isotope composition ($\delta^{15}N$) of different amino acids carries different dietary information. We hypothesized that transamination and de novo synthesis create three groups that largely explain their dietary information. Rats were fed with $^{15}N$-labeled amino acids. The redistribution of the dietary $^{15}N$ labels among the muscular amino acids was analyzed. Subsequently, the labeling was changed and the nitrogen isotope turnover was analyzed. The amino acids had a common nitrogen half-life of ∼20 d, but differed in $\delta^{15}N$. Nontransaminating and essential amino acids largely conserved the $\delta^{15}N$ of the source and, hence, trace the origin in heterogeneous diets. Nonessential and nontransaminating amino acids showed a nitrogen isotope composition between their dietary composition and that of their de novo synthesis pool, likely indicating their fraction of de novo synthesis. The bulk of amino acids, which are transaminating, derived their N from a common N pool and hence their $\delta^{15}N$ was similar.

**KEYWORDS:** *amino acid, $^{15}N$, transamination, isotopic scrambling*

## INTRODUCTION

The nitrogen isotope composition ($\delta^{15}N$) of organisms provides information on trophic systems.[1,2] While the bulk $\delta^{15}N$ of tissues indicates the trophic position of organisms,[3,4] the $\delta^{15}N$ of specific compounds has the potential to provide more detailed insights, because different compounds differ in biosynthetic pathways and thus may reveal isotope information from different (dietary) sources.[5] This is particularly true for amino acids, as they provide the main nitrogen reservoir of bulk materials, but have individual biosynthetic pathways.[6] Thus, alanine, aspartic acid, and glutamic acid (among others) reflect a similar trophic position as bulk tissues, whereas glycine and phenylalanine provide an accurate determination of the $\delta^{15}N$ at the base of the food web,[2,7] although reasons for this grouping, as well as the information that can be obtained from other amino acids, remain unknown. Understanding how the major biochemical mechanisms that govern nitrogen input and distribution, namely de novo synthesis and transamination, affect the $\delta^{15}N$ of amino acids would shed light on these knowledge gaps. Additionally, the time window through which such isotope information in amino acids is retained in organisms and differences between amino acids in such time windows are worthy of investigation.

For carbon isotope composition ($\delta^{13}C$), the amino acids' ability for de novo synthesis largely explained the information that can be retrieved from their $\delta^{13}C$.[2,7] Essential amino acids remain biochemically unmodified from diet to consumer and thus represent the $\delta^{13}C$ of the amino acids in the diet. For example, leucine (essential) was not enriched in $^{13}C$ between diet and consumer, whereas glutamic acid (nonessential) became enriched in $^{13}C$. Remarkably, both amino acids were enriched in $^{15}N$,[7] indicating that the classification into essential/nonessential only applies for the carbon backbone but not for $\delta^{15}N$, because a biochemical process interfered that regulates nitrogen exchange beyond de novo synthesis and thus alters the $\delta^{15}N$ even of (at least some) essential amino acids.

Transamination by aminotransferase transfers the amino nitrogen between an amino acid and an $\alpha$-keto acid; in turn, the $\alpha$-keto acid becomes an amino acid and vice versa.[6] Since most transamination reactions have equilibrium constants close to 1, the direction of a transamination reaction proceeds in large part as a function of the intracellular concentrations of the reactants.[8] Transaminations can also be chained, providing a "nitrogen shuttle" even between amino acids of different functional groups (e.g., essential and nonessential).[9,10] For example, L-serine:glyoxylate aminotransferase (transamination enzyme, EC 2.6.1.45) catalyzes the reversible amino transfer from serine to glycine and glycine:2-oxoglutarate aminotransferase (EC 2.6.1.4) catalyzes the reversible amino transfer from glycine to glutamate (Figure 1A). Glutamate, as the central amino acid in metabolism,[6] is in turn linked to other transamination chains, like the branched-chain amino acid metabolism that links the essential amino acids leucine, isoleucine, and valine.[12] Such chains provide continuous redistribution of amino nitrogen among transaminating amino acids beyond de novo synthesis.[8] Hence, amino acids, which are subject to transamination and which we term transaminating amino acids, virtually share one common amino nitrogen pool.[13] This should lead to a reduced heterogeneity in $\delta^{15}N$ among transaminating amino acids when the $\delta^{15}N$ of the diet is heterogeneous. However, since transamination implies an isotope effect, the $\delta^{15}N$ of transaminating amino acids is not completely equal.[14]

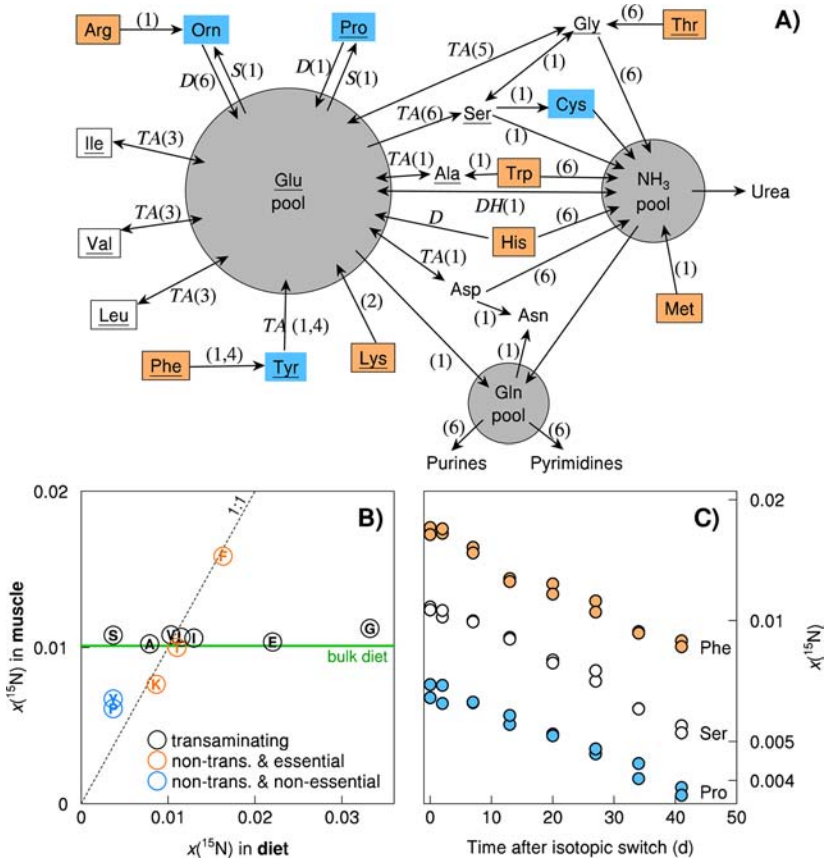

**Figure 1.** (A) Amino acid nitrogen pools and transfers in mammal metabolism. Amino acids (AAs) are given in the standard three-letter code (see Table 1); essential AAs are in boxes, and AAs analyzed in this study are underlined. A colored background, orange for essential and blue for nonessential AAs, means no transamination. The reactions are indicated in italics; they are succeeded by a number in parentheses indicating the reference (1, Berg et al.;[6] 2, Tomé and Bos;[16] 3, Hutson et al.;[12] 4, Matthews;[15] 5, Nakada;[10] 6, Voet and Voet[11]); TA = transamination (aminotransferation with $\alpha$KA = $\alpha$-keto acid) after AA1 + $\alpha$KA2 ↔ $\alpha$KA1 + AA2, in most cases dealing with Glu and $\alpha$-ketoglutaric acid; the double arrows indicate reversibility exclusively for this reaction. In this case, "equilibration" with the Glu pool is faster than any other reaction of the AAs or the $\alpha$KAs. Irreversible TAs, indicated by a one-pointed arrow, may occur, when the $\alpha$KA is rapidly further converted (Tyr) or when the TA does not concern the AS/$\alpha$KA itself but a derivative (Lys and Ser). D = degradation to Glu, S = synthesis from Glu (via different pathways), DH = Glu dehydrogenase. (B) The atom fraction $x(^{15}N)$ of amino acids in diet and in muscle before diet switch. Amino acids are indicated by their one-letter code (see Table 1). The 95% confidence intervals had a similar size as the markers. Note the different ranges of $x$ and $y$ axes. (C) Reaction progress of the atom fraction $x(^{15}N)$ for the amino acids phenylalanine (Phe), serine (Ser), and proline (Pro) after the diet switch. Each of these amino acids belongs to one of the three hypothesized groups (panel A). Since the $y$-axis is logarithmic, similar linear slopes indicate similar turnover rates.

Some amino acids differ in their ability to be transaminated. In mammals, tyrosine can be degraded but not synthesized by transamination, because the equivalent $\alpha$-keto acid that would accept nitrogen and turn into tyrosine is unavailable.[15] Hence, tyrosine can only be a nitrogen donor to the common nitrogen pool. The amino acids lysine,[16] threonine,[17] proline,[18] and phenylalanine (except for the dysfunction phenylkentonuria[6]) do not transaminate at all. Due to their disability of bidirectional transamination, these amino acids are termed "non-transaminating" in this study.

Since many diet reconstruction studies based on isotopes focus on feeding generalists (e.g., refs 2, 13) and feeding generalists likely have an isotopically heterogeneous diet, it should be investigated how the $\delta^{15}N$ of isotopically heterogeneous amino acids changes from diet to consumer, after nitrogen redistribution by de novo synthesis and transamination. We hypothesize that the joint consideration of transamination and de novo synthesis can largely explain the variation in $\delta^{15}N$ among amino acids in consumers. Since transamination is the final step in de novo synthesis, its effect on $\delta^{15}N$ of amino acids should be of a major priority, and hence, amino acids should in the present context be divided into three groups: (i) transaminating amino acids should eventually reach a rather homogeneous $\delta^{15}N$ irrespective of their isotope composition in the diet, because their amino nitrogen is exchanged with that of other transaminating amino acids (a common nitrogen pool); (ii) nontransaminating and essential amino acids should retain their $\delta^{15}N$ from diet, because nitrogen is not exchanged; and (iii) nontransaminating and nonessential amino acids should have a $\delta^{15}N$ that ranges between that of their dietary $\delta^{15}N$ and that of the $\delta^{15}N$ of the nitrogen donor pool that supplies de novo synthesis.

The exchange rate by transamination could determine the nitrogen isotope turnover and thus the time window through which isotope information can be perceived. If this were the case, the nitrogen isotope turnover must differ between amino acids, in particular between transaminating and nontransaminating amino acids. The effect of transamination on nitrogen isotope turnover could, however, be superimposed by the continuous release of amino acids from protein turnover, in particular by the degradation of proteins by proteolysis. In that

dx.doi.org/10.1021/jf502295f | J. Agric. Food Chem. 2014, 62, 8008−8013

case the nitrogen isotope turnover should be similar among all amino acids.

In order to examine the effect of dietary heterogeneity in $\delta^{15}N$ of amino acids on the $\delta^{15}N$ of amino acids in the consumer involving the nitrogen isotope turnover of amino acids, we fed rats a diet with $^{15}N$-labeled amino acids and analyzed the $\delta^{15}N$ of amino acids in muscle protein. Subsequently, we switched the $\delta^{15}N$ of the amino acids in the diet to quantify their nitrogen isotope turnover rate. This was necessary to evaluate potential differences in half-lives among amino acids that could induce differences in $\delta^{15}N$ due to different levels of labeling.

## MATERIALS AND METHODS

**Animals and $^{15}N$ Labeling.** Eighteen juvenile female Sprague–Dawley rats (*Rattus norvegicus*, Berkenhout) were assigned to cages and maintained at 25 °C ambient temperature, 60% relative humidity, and a 12 h day–12 h night cycle for 13 weeks. All rats had ad libitum access to deionized water supplemented with 0.014% NaCl and received a diet of 8 g $d^{-1}$ (dry mass), consisting of 2.2 g of sucrose, 0.6 g of coconut fat, 0.3 g of minerals, 0.2 g of cellulose, 0.1 g of sunflower oil, 0.02 g of vitamins, and 0.02 g of DL-methionine. Diets were supplemented with starch and casein depending on the nutritional requirements of the juvenile rats. During the first 7 weeks, termed the "isotope equilibration period", the supplement was 3.2 g $d^{-1}$ (days 1–17), 3.5 g $d^{-1}$ (days 18–34), and 3.7 g $d^{-1}$ (days 35–49) starch and 1.3, 1.0, and 0.8 g $d^{-1}$ casein, respectively. Digestibility of casein in young rats is close to 100%.[19] A mixture of 12 L-amino acids that was similar to the amino acid profile of casein but highly enriched in $^{15}N$ (atom fraction 0.95 or 0.99) was added, approximately at a ratio 1:100 to casein, which remained constant over time (Table 1). All amino acids were supplied by Chemotrade Chemiehandelsgesellschaft mbH, Leipzig, Germany, except for threonine, which was supplied by Campro Scientific, Veenendaal, The Netherlands. However, in the mixture, aspartic acid and serine were substituted isonitrogenously by glycine, cysteine was substituted by methionine, and tyrosine was substituted by phenylalanine. Proline was not added as a $^{15}N$-enriched amino acid. These modifications led to a large variation in labeling of the individual amino acids in the diet, with the atom fractions of $^{15}N$ ranging from 0.004 to 0.033 (Table 1). This pronounced labeling was chosen because any fractionation by the metabolism will be much smaller and can thus be neglected. For example, biosynthesis of glutamic acid by N transfer from aspartic acid to $\alpha$-keto glutaric acid is accompanied by N isotope fractionation,[14] but this will lower the atomic fraction only by ~0.004 and thus does not interfere with the labeling, which caused an atom fraction in the labeled diet of 0.022.

**Table 1. Amino Acid Profile in Dietary Casein and in the L-Amino Acid Labeling Mixture and Resulting Atom Fraction of $^{15}N$ [$x(^{15}N)$] in the Bulk Diet[a]**

| amino acid | | | content in bulk diet (g/100 g) | | |

[a]The $x(^{15}N)$ of amino acids in the bulk diet is calculated from mass balance and a $x(^{15}N)$ of 0.004 for casein and 0.950 for the enriched amino acids except for Tyr and Try, for which $x(^{15}N)$ was 0.990. The name of the amino acids is followed by their three and one letter codes, respectively. [b]This amino acid is essential for rats and most other mammals.

At day 50, the six-week "chase period" started and supplementation of the $^{15}N$-enriched amino acids was stopped in order to induce an exponential reaction progress in nitrogen isotope composition in the animals. To achieve reaction progress in less time, the protein content was increased to 2.4 g $d^{-1}$ (while starch was accordingly decreased to 2.1 g $d^{-1}$ [20]).

All procedures and protocols were approved by the Animal Care and Use Committee of Technische Universität München.

**Sampling.** Rats were sacrificed by decapitation under anesthesia (diethyl ether) in groups of four rats at day 39 of the equilibration period and on days 2, 7, 13, 20, 34, and 41 during the chase period to investigate the reaction progress of the isotope composition following the diet switch (Figure 1C). The animals were dissected to provide muscle tissue (musculus femoris and musculus quadriceps). The muscles were combined, homogenized with an Ultra-Turrax (IKA-Labortechnik Jahnke & Kunkel GmbH & Co KG, Staufen i. Br., Germany), rinsed with a solution of Hexane–2-propanol (3:2) to eliminate lipids, and filtrated. The fat-free muscle material was dried for 12 h at 70 °C and stored at −80 °C. The diet was collected daily, starting 5 days before the chase period to day 7 of the chase period and additionally on days 10, 13, 17, 22, 27, 34, and 41 of the chase period. For more details on the keeping and sampling, see the work of Braun et al.[20]

**Isotope Analyses of Amino Acids.** Isotope analysis was carried out at the Leibniz-Institut für Nutztierbiologie, Dummerstorf, Germany, following the method of Metges and Petzke.[21] In brief, samples of 2.5–3.5 mg of muscle lyophilizate were double-washed with 10% trichloroacetic acid, acetone, and ether. Washed samples were hydrolyzed for 24 h with 2 mL of 6 N HCl at 110 °C and derivatized to their N-pivaloyl-isopropyl esters. To this end, 2 mL of $CH_2Cl_2$ was added to 3–8 $\mu$mol of amino acids, and the solution was dried and solved in 100 $\mu$L of pyridine. An aliquot of 100 $\mu$L of pivalochloride was added, the solution was acetylated (30 min, 60 °C) and cooled, and 2 mL of $CH_2Cl_2$ was added. The mixture was then passed through a 4 cm silica gel (silica gel 60, 200–400 mesh) column (4 mm i.d.) and the filtrate was dried under a stream of $N_2$ before adding 100 $\mu$L of ethyl acetate. The samples were then analyzed for nitrogen isotope composition on a gas-chromatograph (HP 5890, Waldbronn, Deutschland), connected to a gas-isotope-ratio-mass spectrometer (Finnigan MAT, Bremen, Deutschland), via a GC combustion interface. The interface comprised a combustion furnace reactor filled with copper and nickel oxide and platinum (980 °C) and a reduction furnace filled with elemental copper (600 °C).

**Calculation of $x(^{15}N)$ of Dietary Amino Acids.** In the following, we denote isotope composition as the atom fraction [$x(^{15}N)$], because its use is preferred over the use of $\delta$ values for tracer and mixing calculations:[22]

$$x(^{15}N) = n(^{15}N)/(n(^{14}N) + n(^{15}N)) \quad (1)$$

where $n(^{14}N)$ and $n(^{15}N)$ are the amounts of isotope $^{14}N$ and $^{15}N$ of element N, respectively.

The $x(^{15}N)$ of the amino acids in the bulk diet was calculated according to the mass balance of an amino acid provided by casein and provided by the enriched amino acids of the labeling mixture as

$$x(^{15}N) = (m_{cas}x(^{15}N)_{cas} + m_{label}x(^{15}N)_{label})/(m_{cas} + m_{label}) \quad (2)$$

where $m_{cas}$ and $m_{label}$ are the masses of the specific amino acid provided by casein and by the labeled amino acid mixture, respectively, while $x(^{15}N)_{cas}$ and $x(^{15}N)_{label}$ are the corresponding $x(^{15}N)$ values.

**Turnover Estimation and Statistical Evaluation.** Turnover as quantified herein only applies for nitrogen but not for the carbon skeletons of the amino acids, which follow different pathways of recycling, degradation, and synthesis. A previous study that used the same animals had shown that the reaction progress of all organs including the muscle exhibited a common delay of 0.5 d following a diet switch, which likely was caused by the transit time in the digestive tract.[20] Since neglecting a delay would lead to an underestimate in isotope turnover, the delay (0.5 d) was subtracted from the sampling times to provide a delay-corrected reaction progress.

Since growth affects the apparent reaction progress[20,23] and the muscle from which the amino acids were sampled had a growth rate of ~0.7 g $d^{-1}$,[20] the effects of growth and turnover rate were disentangled from the delay-corrected reaction progress by fitting the function

$$x(^{15}N)_t = x(^{15}N)_\infty - (x(^{15}N)_\infty - x(^{15}N)_0)(1 - \Delta w/w_t)^{(1+r/g)} \quad (3)$$

where $x(^{15}N)_t$ is the atom fraction at time $t$, $x(^{15}N)_\infty$ is the atom fraction of the asymptote at the end of the reaction progress, and $x(^{15}N)_0$ is the atom fraction at time zero (time of isotope switch plus delay). The parameter $w_t$ is the dry mass of an amino acid at time $t$ and $\Delta w$ is $w_t - w_0$, where the subscript 0 denotes time zero. The growth rate constant is denoted $g$ and estimated for each amino acid specifically as $0.7/\gamma$ g $d^{-1}$, where $\gamma$ was the ratio of the mass of a specific amino acid to the mass of all amino acids in the muscle (0.7 g $d^{-1}$ was the growth rate of the entire muscle; see above and in Braun et al.[20]). The ratio $r/g$ gives the relative contribution of isotope turnover ($r$) and growth ($g$) to the apparent reaction progress. The half-life ($t_{1/2}$) is then given by $\ln(2)/r$. The parameter $x(^{15}N)_0$ was obtained by measuring the isotope composition at the end of the "equilibration period" (as described above), as this value characterizes the constant isotope composition during the delay and simultaneously the intercept of the following reaction progress model when delay time is subtracted. The standard errors of the fitting function for $x(^{15}N)_0$ and $t_{1/2}$ were then converted to confidence intervals for $p = 0.05$ and a two-sided error. All data analyses were done in R 2.15.1.

## RESULTS

**$x(^{15}N)$ of Amino Acids.** At the end of the equilibration period, the $x(^{15}N)$ of amino acids varied by about a factor of 2 in muscle tissue, ranging from 0.0067 in tyrosine to 0.0158 in phenylalanine. The $x(^{15}N)$ of dietary amino acids did not correlate significantly with the $x(^{15}N)$ of muscular amino acids ($p > 0.05$, $r^2 = 0.29$), but the following pattern was apparent (Figure 1B):

(i) The transaminating amino acids alanine, glutamic acid, glycine, isoleucine, leucine, serine, and valine had a common $x(^{15}N)$ of 0.0108 (SD 0.0007), which was not statistically different from the mean $x(^{15}N)$ of the diet (0.0101 ± 0.0001). Hence, their $x(^{15}N)$ had changed substantially, including depletion and enrichment in $^{15}N$. The change ranged from −0.0211 in glycine to 0.0071 in serine.

(ii) The $x(^{15}N)$ of nontransaminating and essential amino acids lysine, threonine, and phenylalanine was quite similar in diet and muscle; hence, they appeared on the 1:1 line (Figure 1 B).

(iii) The nontransaminating and nonessential amino acids proline and tyrosine had a $x(^{15}N)$ between their initial (dietary) $x(^{15}N)$ and the $x(^{15}N)$ of their specific nitrogen donor pools, glutamine and phenylanaline, respectively. The coefficient of variation was small among replicates for all amino acids (~2% of the respective mean), indicating equal labeling among rats.

**Turnover of Amino Acid $^{15}N$.** After the diet switch the $x(^{15}N)$ of all amino acids exponentially approached the $x(^{15}N)$ of the unlabeled diet (Figure 2). The mean half-life of the nitrogen in amino acids was 20 d (13−27 d), and the nitrogen half-lives were not significantly different among amino acids, and they were not statistically different from the nitrogen half-life of the entire muscle. In particular, turnover was not different for essential/nonessential and transaminating/nontransaminating amino acids (Figure 1C).

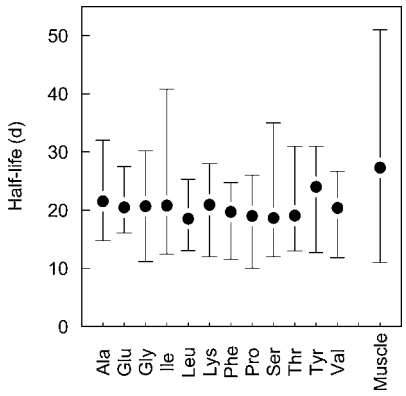

**Figure 2.** Half-lives of nitrogen in amino acids (quantified herein) and in muscle tissue (quantified in Braun et al.[20]), obtained from the same animals. The error bars indicate the 95% confidence intervals.

## DISCUSSION

We hypothesized that the joint consideration of transamination and de novo synthesis divides amino acids into three groups that largely explain the variation in $x(^{15}N)$ among amino acids in animals: (i) transaminating, (ii) nontransaminating and essential, and (iii) and nontransaminating and nonessential amino acids.

Transaminating amino acids had a homogeneous $x(^{15}N)$ value in consumer tissues, despite their $x(^{15}N)$ value in the diet varying by an order of magnitude (Figure 1B). For example, serine was not provided by the labeled amino acid mixture but had the same $x(^{15}N)$ value in the muscle tissue as the labeled amino acids (Table 1). The $x(^{15}N)$ value of transaminating amino acids was similar to the $x(^{15}N)$ of the bulk diet (plus an expectable isotope enrichment[24]), and it was similar to the mean of $x(^{15}N)$ of transaminating amino acids in the diet. This indicated that complete redistribution of amino nitrogen among transaminating amino acids in consumer tissues can be expected, because transamination is the most common reaction involving free amino acids.[17] However, the transaminations cause isotope fractionation[25,26] that appears herein only as minor variation around the homogenized $x(^{15}N)$, because of the very high labeling. Future research should gain detailed knowledge on the isotope fractionations of the specific transamination enzymes.

The harmonization of nitrogen isotope composition of transaminating amino acids seems to be consistent across trophic levels, environments, and diets, as similar nitrogen isotope compositions can be found for transaminating amino acids within herbivores, e.g., pig, and terrestrial and marine carnivores, e.g., lion and whale (see results of Hare et al.[13]). Thus, our results would be applicable to the many studies using

$^{15}N$ in mammals.[27−30] This finding is, however, in contrast to $x(^{15}N)$ values in a zooplankter,[7] indicating that the ability of transamination may differ between organisms that are more remote in their evolution and which do not share conserved biochemical pathways. This calls for the need to repeat such investigations in other animal groups that are in the focus of isotope animal ecology, e.g., birds or insects.

Homogeneous $x(^{15}N)$ in consumer but varying $x(^{15}N)$ in diet implies variation in trophic shifts among transaminating amino acids, including enrichment and depletion in $^{15}N$, as found herein (Figure 1B) and in other studies.[5,31] Amino acids become enriched in $^{15}N$ when their dietary $x(^{15}N)$ is below the homogenized $x(^{15}N)$ and vice versa; the height of the trophic shift will be defined by the difference between isotope composition of an amino acid and the homogenized $x(^{15}N)$. Hence, the trophic shift of a transaminating amino acid cannot indicate the trophic position of the consumer.

Nontransaminating and nonessential amino acids changed their $x(^{15}N)$ from diet to consumer to less extent. Considering their biochemical pathways, each amino acid of this group in consumer is either derived from its dietary amino acid pool (without nitrogen exchange by transamination) or synthesized de novo by the organism. Hence, the change in $x(^{15}N)$ should be a function of their dietary $x(^{15}N)$, the $x(^{15}N)$ of the donor pool supplying de novo synthesis, the fraction of de novo synthesized amino acids, and isotope fractionation during de novo synthesis:[14] Principally, the $x(^{15}N)$ of these amino acids may retain their dietary $x(^{15}N)$ in the case of no de novo synthesis (e.g., when dietary supply exceeds the need); the $x(^{15}N)$ of these amino acids should be equal to the $x(^{15}N)$ of the precursor pool (±isotope fractionation) in the case of the fraction of de novo synthesis being 100%; in cases where the fraction of de novo synthesis is between 0 and 100%, the $x(^{15}N)$ of the amino acid should be between the dietary $x(^{15}N)$ and $x(^{15}N)$ of the de novo synthesis pool (±isotope fractionation). When neglecting the relatively small isotope fractionation compared to the high labeling herein, the de novo synthesis fraction as calculated by mass balance was 25% for tyrosine and 40% for proline, despite their near identical $x(^{15}N)$ in consumer. This contrast resulted from differing nitrogen donor pools (tyrosine is supplied by phenylalanine, whereas proline is supplied by the common nitrogen pool, as glutamic acid is the precursor[32]) that also differed in $x(^{15}N)$ from the common nitrogen pool.

Nontransaminating and essential amino acids almost retained their dietary $x(^{15}N)$ value and hence provide highly conserved isotope information from the base of the food web. However, minor changes in isotope compositions might occur (e.g., small deviations from the 1:1 line in Figure 1B) due to isotope fractionation, e.g., caused by the deamination of threonine.[13]

The half-lives were rather constant among amino acids (Figure 2), indicating that the differences in $x(^{15}N)$ values among amino acids were not influenced by differences in isotope turnover rates that determine the kinetics of label incorporation. This also indicated that the common turnover was not an effect of transamination that differed between amino acids, but rather an effect of proteolysis that governs the degradation of whole proteins and thus affects nearly all amino acids at once. This is not surprising, as transamination is a kinetically perfect reaction, which is so efficient that it is only controlled by the provision of the substrate.

Amino acids had shorter half-lives than their bulk muscle tissue,[20] although statistically indistinguishable. This might result from the slower turnover of other nitrogen-containing components in bulk muscle, like nucleic acids.[33]

**ABSTRACT:** Producers of processed anchovies have developed hazard analysis and critical control points (HACCP) to guarantee the quality of their products. Nonetheless there is a lack of objective data to determine products' shelf life. The quality of a product is usually established on the basis of its safety and organoleptic properties. These parameters were assessed by monitoring the profiles of volatile compounds and quantitating six biogenic amines in samples of two types of processed anchovies during their shelf life. With regard to biogenic amines, quantities were below the regulatory limits throughout shelf life, except when a temperature abuse was applied for marinated samples. Moreover, this work highlights an optimum volatile profile at 5 and 6 months of storage for salted and marinated anchovies, respectively. This is the result of a higher content of six aldehyde and nine ketone compounds, mainly from lipid oxidation.

**KEYWORDS:** *anchovies, shelf life assessment, volatile compounds, biogenic amines, SPME-GC-MS*

## INTRODUCTION

Anchovies are one of the most caught fish species in the world with an estimated 3.5 million tons landed in 2010[1] and quantities consumed estimated at 369,000 tons in 2008. Anchovies can be processed using a wide range of techniques, such as salt ripening or marination in vinegar. Consumers are more and more aware of food quality and food safety. To manage such issues, the European Union has encouraged the application of good manufacturing practices and the development of hazard analysis and critical control points (HACCP). This approach has been developed in industry with specific applications for salted and marinated anchovies.

After their catch, anchovies can be ripened in salt or marinated in vinegar for a specified period and preserved until consumption. The shelf life of processed anchovies has only been empirically estimated, and there is a real lack of objective information on how the properties of products change during storage. The assessment of optimal shelf life will ensure consumers a safe product with good quality.

Numerous studies have described the microbial flora present in salted and marinated anchovies. *Lactobacillus* and *Micrococcus* genera have been identified as the main bacteria present in processed marinated anchovies,[2] and the presence of Enterobacteriaceae was also demonstrated.[3,4] In salted anchovies, potential histaminogenic floras, such as Enterobacteriaceae and *Staphylococcus*, have been reported.[3−5] In a study on brined anchovies,[6] halophilic and psychrophilic floras increased respectively at room temperature and in chilled conditions for samples conserved in low NaCl concentrations brines. A consensus is observed from previous authors to conclude that hygiene management provides a better control of these bacteria. In addition, a study on the ingredients added during the marination process showed that they have no impact on microbiological quality.[7]

Histamine is a biogenic amine resulting from the enzymatic decarboxylation of histidine. This molecule is responsible for many cases of food poisoning, with various symptoms.[8] Due to the high histidine content in their flesh, numerous fish families (Scombridae, Clupeidae, or Engraulidae) show a high histamine risk. This is the major food safety risk encountered in such products. European regulations (Commission Regulation (EC) No. 1441/2007 and Commission Regulation (EC) No. 1019/2013) have defined a limit of 400 mg $kg^{-1}$ of histamine for a single product having undergone enzymatic maturation treatment in brine.[9,10] Other biogenic amines have been reported, especially tyramine, putrescine, cadaverine, spermine, and spermidine.[11−13] Studies tracing biogenic amines during the storage period indicate changes in tyramine, histamine, and tryptamine.[11,13,14] Very few studies have been carried out on the storage of marinated samples and focus mainly on the marination step itself.[2,12] Furthermore, refrigeration limits the

biogenic amine content.[6,13,14] Analysis of volatile compounds in different food matrices has been increasing over the past decade.[15−17] The volatilome of a matrix can be analyzed by trapping volatiles on a solid phase microextraction (SPME) fiber, in the headspace of a vial.[18] Finally, volatiles can be quantitated thanks to a GC-MS device. To date, most studies on the volatile compounds of processed anchovies have been carried out to assess the maturation step of salted anchovies. Thus, indicators of maturation have been defined for salted anchovies as aldehydes, alkadienals, alcohols, and ketones.[19,20] Acetaldehyde, 2-methylbutanal, and 3-methylpropanal have been described as the most abundant odorant compounds in ripened anchovies.[21] On the basis of sensory analysis, the optimal maturation of salted anchovies has been estimated at close to 160 days.[22]

As anchovy processing is well documented, the goal of this study was focused on the less studied shelf life assessment of processed anchovies. To this end, both salt-ripened and marinated anchovies stored in different conditions, with and without temperature change, were studied. The first half of the study was focused on volatilome monitoring throughout storage, whereas the other half dealt with safety issues by quantitating biogenic amines.

## MATERIALS AND METHODS

**Chemicals.** NaCl used for the headspace analysis was obtained from Oxoid (Dardilly, France). An *n*-paraffin mix, $C_5$−$C_{15}$, used for the calculation of the linear retention index (LRI), was acquired from Sigma-Aldrich (St-Quentin-Fallavier, France). All pure compounds used to improve identification reliability including ethanol, dimethyl sulfide, 2-methylpropanal, 2,3-butanedione, butanal, 3-methylbutanal, 2-methylbutanal, 1-penten-3-ol, 2-ethylfuran, 1-pentanol, 2,3-hexanedione, hexanal, heptanal, benzaldehyde, 1-octen-3-ol, (*E*,*E*)-2,4-heptadienal, octanal, benzeneacetaldehyde, nonanal, (*E*,*Z*)-2,6-nonadienal, and decanal were purchased from Sigma-Aldrich. All chemicals used for quantitating biogenic amines were obtained from Sigma-Aldrich except perchloric acid, which was purchased from Carlo Erba (Val-de-Reuil, France), and toluene and acetonitrile, which were purchased from VWR (Fontenay-sous-Bois, France).

**Anchovy Processing and Preservation.** Samples of anchovies were provided by the Association of French Fish Processing Industries (*Confédération des Industries de Traitement des Produits de la Pêche Maritimes* (CITPPM − Paris)) and held at the innovation platform *PFI-Nouvelles Vagues* (Boulogne-sur-Mer, France). Samples of anchovy fillets (*Engraulis encrasicolus*) consisted of salted or marinated anchovies having been processed and packed.

For salted anchovies, samples were prepared by immersion in brine. Fish were gutted and beheaded and then transferred to vats, with alternating layers of salt and anchovies. Saturated brine was then added. Vats were covered, and pressure was applied to the lids to remove trapped air. Anchovies were ripened at room temperature for several months (a minimum of 3 months). After ripening, samples were packed in glass jars.

Marinated fish samples were produced from fresh anchovies that were cleaned, beheaded, gutted, and filleted. After 24 h of freezing to manage parasite risk, anchovies were then immersed in a vinegar solution. A marination period of a few days (with a minimum of 24 h) under refrigeration was carried out. Anchovies were then covered with oil and vacuum packed.

All storage times applied in this study were set to exceed the shelf life advocated by the guide to good hygiene practices. Two types of temperature of storage were applied to samples: with (wR) or without rupture (w/oR). Concerning marinated samples, storage without any change of temperature consisted of incubation at 4 °C. Storage with breaks in the temperature conditions consisted of one-third of the time at 4 °C and the remaining two-thirds at 8 °C. For the salted anchovies, storage without any change of temperature consisted of incubation at 15 °C, to ensure their inherent shelf stability. Rupture applied in the temperature conditions consisted of two-thirds of the time at 15 °C and the remaining one-third at 22 °C.

**Analysis of the Headspace by SPME-GC-MS.** Analysis of the headspace of vials containing anchovy samples was carried out as described by Duflos et al.[17] Briefly, 50 g of flesh was added to 100 mL of NaCl solution in ultrapure water at 300 g $kg^{-1}$ and then ground with a stomacher at 300 rpm for 2 min. Then, 45 g of filtrate was centrifuged at 10000*g* for 10 min at 4 °C. The supernatant (11 mL) was then distributed in 20 mL SPME vials and tightly sealed. SPME vials were placed at 4 °C on a refrigerated tray. The vials were handled using a combiPAL autosampler (CTC Analytics, Zwingen, Switzerland). The vial was placed for 10 min at 50 °C and shaken at 500 rpm. A 75 μm CAR/PDMS fiber (Supelco, Lyon, France) was introduced into the headspace of the vial to collect volatile compounds for 40 min at 50 °C under the same conditions. The fiber was then removed and placed for 1 min in splitless mode in a Merlin Microseal injector (at 250 °C) of a gas chromatograph GC-2010 equipped with a QP2010 Plus mass spectrometer (Shimadzu, Kyoto, Japan). The GC was equipped with an SLB-5 MS capillary column (60 m × 0.25 mm × 0.25 μm) from Supelco (St-Quentin-Fallavier, France), and helium was used as carrier gas at a flow of 1.78 mL/min. The temperature conditions applied in the oven were as follows: 5 min at 35 °C, increased to 100 °C at a rate of 10 °C/min, then increased to 280 °C at a rate of 20 °C/min, and maintained for 5 min. Spectrometric analysis was performed with the following conditions: interface temperature at 280 °C, ionization voltage at 70 eV, mass range from $m/z$ 33 to 200, and a scan frequency of 500 Hz. After each injection, the fiber was reconditioned at 300 °C with helium flow for 10 min. Volatile compounds were automatically integrated by GC-MS postrun analysis (Shimadzu), with a given retention time, a target ion, and reference ions for each volatile compound (Table 1). A normalization of each area (i.e., division of the area by the sum of areas of all compounds) was realized. Compounds were identified by comparing them with mass spectra in the NIST 08 library database and with LRI found in the literature,[23] calculated using the equation in van den Dool and Kratz.[24] The headspace analysis was performed in duplicate for all samples.

**Separation and Quantitation of Biogenic Amines.** Quantitative assay of biogenic amines was carried out using the method recommended by Commission Regulation (EC) No. 1441/2007 with high-performance liquid chromatography (HPLC).[25,26] Briefly, to extract biogenic amines, 5 g of anchovies was added to 100 μL of 1,3-diaminopropane used as internal standard and 10 mL of 0.2 M perchloric acid. The mix was blended with an Ultraturrax homogenizer and centrifuged at 7000*g* for 5 min at 4 °C. Then, 100 μL of supernatant was transferred in 300 μL of sodium carbonate and 400 μL of dansyl chloride, homogenized, and kept in the dark at 60 °C for 5 min. After derivatization, 100 μL of L-proline was added to remove excess dansyl chloride and kept in the dark at room temperature for 15 min. Then, 500 μL of toluene was added; after settling, the aqueous phase was frozen and the organic phase containing dansyl derivates was specifically recovered and evaporated under nitrogen flow for 5 min. The dry residue was dissolved in 200 μL of acetonitrile and then filtered at 0.2 μm and injected in a high-performance liquid chromatograph. Biogenic amines were separated on a Kromasil C18 reverse phase column (250 mm × 4.6 mm × 5 μm) from Alltech (Deerfield, IL, USA) with a water/acetonitrile gradient and a flow of 1 mL/min. After 30 min of separation, the chromatogram showed the peaks of the six biogenic amines, putrescine, cadaverine, histamine, tyramine, spermidine, and spermine, and the internal standard (1,3-diaminopropane). Quantitation of biogenic amines was performed by calculating each response factor against 1,3-diaminopropane and using a calibration curve.

**Experimental Design and Statistical Analysis.** For the analysis of volatile compounds, marinated samples were studied for 9 months and salted samples for 18 months, to reach or exceed the shelf life recommended by good manufacturing practices. Samples were irregularly supplied by producers, but a minimum of two samples was analyzed in duplicate each month for the duration of the tested

shelf life. A principal component analysis (PCA) was carried out on the data using open-source data-mining software Tanagra 1.4.[27] For each PCA, the two first principal components (PCs) were retained for interpretations. Correlations with PCs resulting from analysis determined which volatile compounds best characterized each group, as visualized by PCA.

Experiments on biogenic amines were designed as follows: for each pair of parameters (methods of preparation and storage conditions), five samples were taken for initial measurements (M0) and three samples for remaining months. Samples were analyzed every 2 months for 8 months (marinated samples) and 14 months (salted anchovies). For each analysis, measures were performed in duplicate. Comparisons of average results of assays, for biogenic amines, were carried out using nonparametric Kruskal–Wallis tests and post hoc pairwise Wilcoxon rank sum tests because the results did not follow a normal distribution and there was not homoscedasticity of variances. The tests were performed using the package "stats" from R software version 3.0.0. Kruskal–Wallis tests leading to significant results ($p$ value < 0.05) indicated that significant differences were observed for the concentration of the biogenic amines with respect to storage time. Pairwise Wilcoxon rank sum tests with $p$ values < 0.05 indicated that the two compared means were significantly different.

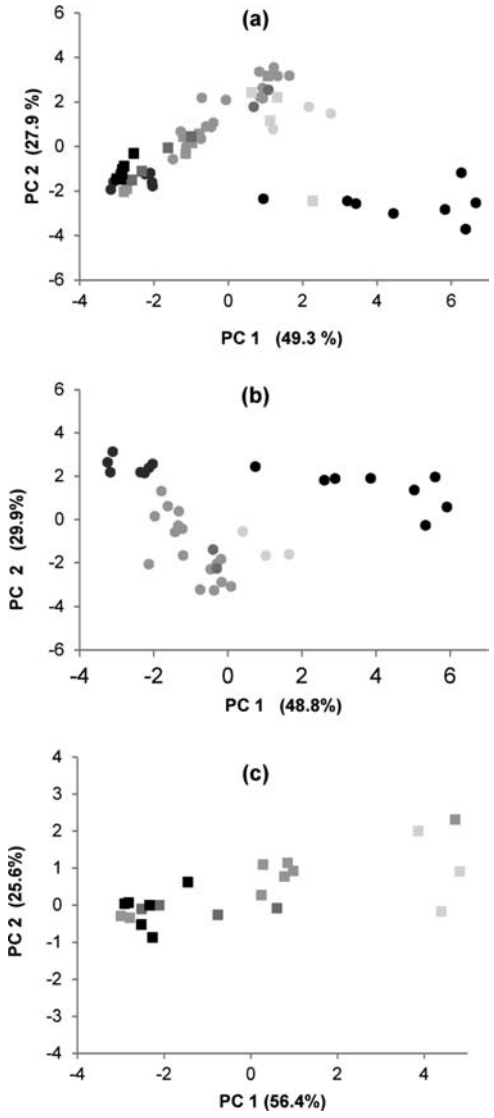

**Figure 1.** PCA obtained on the marinated anchovy samples for the whole data set (a), from the preoptimal phase (b), and from the postoptimal phase (c). Symbols indicate the tested month (M) of storage: M0, lightest gray circles; M2, medium gray circles; M3, dark gray circles; M4, darkest gray circles; M5, black circles; M6, lightest gray squares; M7, medium gray squares; M8, dark gray squares; M9, black squares.

## RESULTS

**Selection of the Volatile Compounds for PCA.** From the whole data set obtained by chromatogram integration, 36 compounds were selected as useful for our analysis (Table 1). These mostly included aldehydes, ketones, and alcohols and three compounds that do not belong to these chemical classes: 2-ethylfuran (furan), dimethyl sulfide (organosulfur), and trimethylamine (TMA) (amine).

[a]Three PCAs were carried out per maturation process. [b]Coefficient in parentheses corresponds to the correlation of the volatile compound with the PC concerned (row) for a given PCA (column). [c]Numbers in brackets correspond to identifiers of peaks when a double peak is recorded on chromatograms for one identified compound. [d]Percentage in parentheses corresponds to the inertia harbored by the PC concerned for a given PCA (e.g., 49.3% means that PC1 harbored 49.3% of the data set inertia in the PCA achieved on the marinated anchovies whole data set).

Among the compounds selected for statistical analysis, none allowed differentiation of storage conditions with or without rupture (data not shown). This study thus focused on the change in the volatilome with regard to each method of anchovy preparation.

**Volatile Compounds in Marinated Samples.** Integration failed to retrieve all of the volatile compounds for each sample. Compounds or sample duplicates with missing values were removed from the data set. Thus, of the 36 compounds, only 13 were analyzed, as shown in Table 1. Among the samples, only one sample was completely removed (i.e., both duplicates), a sample preserved for 9 months without any change in storage temperature. For the remaining samples, only four samples had data from only one duplicate.

Figure 1 illustrates the results of the PCA according to storage time. The global analysis (Figure 1a) showed that samples were relatively homogeneous, especially in the first months of storage (from M0 to M4). Groups of sample storage were differentiated primarily along the *x*-axis. The composition of volatile compounds appeared to change during the first 5 months of preservation, and the product appeared to stabilize in the following months. Table 2 shows that the samples of the fifth month stand out from the other months with higher proportions of (*E,E*)-2,4-heptadienal, (*E,Z*)-2,6-nonadienal, 2,3-octanedione, (*E*)-2-heptenal, hexanal, heptanal, benzeneacetaldehyde, and benzaldehyde. The fifth month may be designated as the month when the volatile compounds reach their optimum with regard to the storage of marinated anchovies.

On the basis of this 5 month optimum, the data set was then split into a preoptimal phase and a postoptimal phase. The preoptimal phase (Figure 1b) shows that months 0−4 are characterized by smaller proportions in the above-mentioned compounds compared to the fifth month, except for hexanal and

dx.doi.org/10.1021/jf5021736 | J. Agric. Food Chem. 2014, 62, 8014−8022

heptanal. Moreover, months 4 and 5 have higher proportions of 2-ethylfuran, (*E*)-2-hexenal, and (*E*)-2-pentenal than the other months. In the postoptimal phase (Figure 1c), groups were differentiated only along the *x*-axis. Thus, from month 6 to month 9, proportions of 2,3-octanedione, (*E*,*E*)-2,4-heptadienal, 2-ethylfuran, (*E*)-2-hexenal, (*E*)-2-pentenal, (*E*)-2-heptenal, hexanal, heptanal, and benzeneacetaldehyde decreased.

Splitting the data set into two phases according to this putative month 5 optimum showed an overall decrease in the proportions of 2-ethylfuran, (*E*)-2-hexenal, and (*E*)-2-pentenal throughout the study. However, for some compounds, proportions increased up until month 5 before decreasing, for example, 2,3-octanedione, 2,4-heptadienal, (*E*)-2-heptenal, and benzeneacetaldehyde.

**Volatile Compounds in Salted Samples.** For these samples also, integration failed to retrieve all of the volatile compounds for each duplicate. Samples with missing values were discarded. Ultimately, data from 24 compounds of the 36 were analyzed as shown in Table 1. Five duplicates were discarded due to missing data.

Figure 2 shows the results according to storage time. The storage month groups were differentiated mainly along the *x*-axis (Figure 2a). Groups were relatively homogeneous, especially during the first months of storage (from M0 to M4). This can be observed, in particular, for samples analyzed at the initial stage. A change in the profile of volatile compounds was recorded at 6 months. Month 6 thus appeared to correspond to the volatile compound optimum for salted anchovies. Table 2 shows that samples from month 2 stand out with higher proportions of 2-pentenal. Samples from month 6 differ from the other groups, probably due to higher relative quantities in the following compounds: (*E*,*E*)-2,4-heptadienal, (*Z*)-4-heptenal, (*E*)-2-heptenal, benzeneacetaldehyde, 2-nonanone, (*E*,*E*)-3,5-octadien-2-one, heptanal, hexanal, 2,3-octanedione, and benzaldehyde. Finally, samples corresponding to the last few months (10, 16, and 18) do not appear different from each other.

According to this putative optimum, the data set was divided into two phases, a preoptimal phase and a postoptimal phase. The PCA of the preoptimal phase (Figure 2b) shows that months 0, 2, and 6 were characterized by higher proportions of (*E*)-2-hexenal, 2-methylbutanal, and 3-methylbutanal compared to month 4. In the same phase, month 6 differs from the other months, showing higher levels for the compounds described for the overall data set and lower proportions of 1-penten-3-ol. The PCA of the postoptimal phase (Figure 2c) shows that month 8 stands out due to higher levels of 2,3-octanedione, (*E*,*E*)-2,4-heptadienal, (*E*)-2-pentenal, (*E*,*E*)-3,5-octadien-2-one, (*Z*)-4-heptenal, (*E*)-2-heptenal, benzeneacetaldehyde, heptanal, and hexanal. Moreover, months 10−16 show higher relative quantities in TMA. Lastly, there seem to be no differences between month 16 and month 18: they both show higher proportions of 2-methylbutanal, 3-methylbutanal, and 2-nonanone compared to previous months.

During the two phases, relative quantities of 2,3-octanedione, (*E*,*E*)-2,4-heptadienal, (*Z*)-4-heptenal, (*E*)-2-heptenal, (*E*,*E*)-3,5-octadien-2-one, hexanal, heptanal, and benzeneacetaldehyde appeared to increase until reaching the optimum level before decreasing. During the same period, a continuous increase of 2-nonanone was recorded.

**Changes in Biogenic Amines.** The overall results are summarized in Table 3. In the large majority of cases, no samples ever exceeded the limit defined by the regulation (Commission Regulation (EC) No. 1441/2007 and Commission

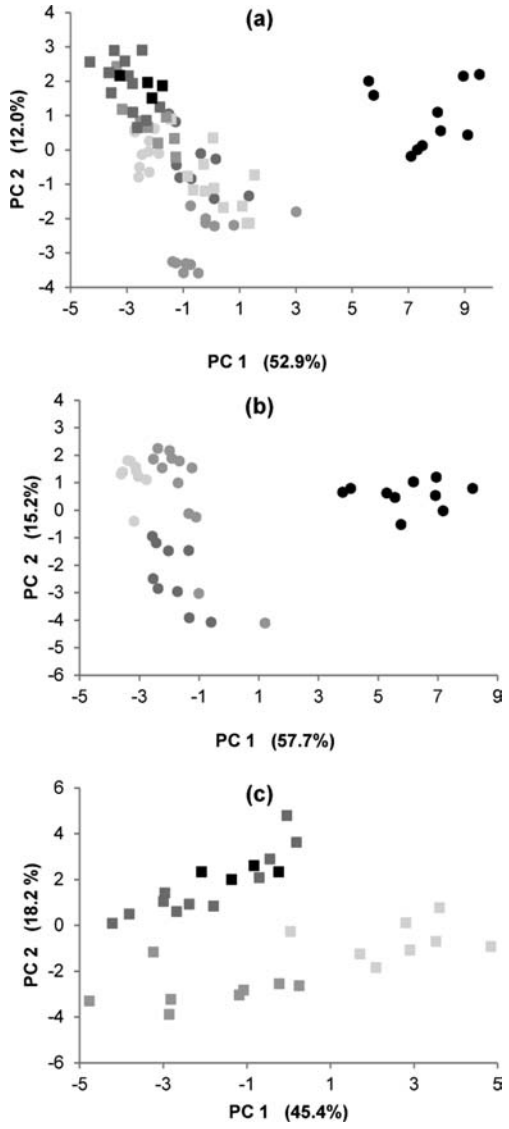

**Figure 2.** PCA obtained on the salted samples for the whole data set (a), from the preoptimal phase (b), and from the postoptimal phase (c). Regulation (EC) No. 1019/2013) during the study. Only marinated anchovies that underwent a break in the cold chain showed a significant change ($p$ value < 0.001) in the quantity of histamine, exceeding the prescribed limit from month 6. With regard to putrescine, cadaverine, and tyramine, a significant change ($p$ value ≤ 0.003) was also demonstrated with a maximum concentration of nearly 50 mg kg$^{-1}$ between months 4 and 6. Finally, a significant change ($p$ value < 0.001) in the concentrations of spermidine and spermine was recorded, although levels remained low, near 20 mg kg$^{-1}$. The experiment carried out on samples that did not undergo a break in the cold chain shows similar patterns, although all of the amine concentrations were lower. Thus, the concentrations of histamine, putrescine, cadaverine, tyramine, spermidine, and spermine did not exceed the threshold values of 40 mg kg$^{-1}$.

With regard to the salted anchovies, although significant changes were recorded throughout the storage of samples, the

threshold of 20 mg kg$^{-1}$ was never reached for any amine at any storage time or either storage condition.

## DISCUSSION

Principal component analysis helped to visualize a significant proportion of the variance contained in the data sets analyzed. For each analysis, principal components explained at least 64% of the variability in the whole data set, which is an acceptable level (Figures 1 and 2).

In these analyses, a difference in the volatile profile between marinated and salted samples was observed. Generally, it was found that the marinated samples did not show as many compounds as those identified for salted anchovy samples. As a result, multivariate statistical analysis could not be carried out on the same number of compounds for both types of processing methods. A significant amount of acetic acid in the headspace of marinated samples may explain the lower number of compounds recovered, possibly due to saturation of the SPME fiber.

With regard to the nature of compounds allowing the discrimination among samples, a large majority originated from the degradation of fatty acids of the $\omega$-3 and $\omega$-6 series (Table 4). This origin is consistent with observations of increased levels of free fatty acids throughout the maturation process of anchovies.[3,28] The presence of products of the catabolism of amino acids was also recorded as well as some products such as TMA or 2-ethylfuran, which are frequently observed in fish matrices. All compounds selected for the analysis of marinated samples were used in the statistical analysis of salted anchovy data set. Among the compounds included in the analysis of salted samples, five come from the degradation of fatty acids, three from the catabolism of amino acids, two from sugar degradation, and one from the degradation of trimethylamine *N*-oxide (TMAO) (Table 4).

The PCA traced the changes in the composition of the headspace over time. From those analyses, volatilome optima appear to occur at 6 months for salted anchovies and at 5 months for marinated anchovies. Only a small change in the

**Table 4. Compounds Used in the Multivariate Statistical Analysis of Anchovies and Their Assumed Origins**

| compound | assumed origin |
|---|---|
| ethanol | fermentation of sugar |

| (*E*,*Z*)-2,6-nonadienal | ω-3 fatty acid oxidation (ALA, EPA, DHA)[51] |

composition of volatile compounds was recorded after this period of storage.

The results of salted samples corroborate those of a study carried out on the selection of sensory attributes for the evaluation of the maturation of processed anchovies: the smell of Iberian ham is a reliable marker of maturation of salted anchovies.[22] SPME-GC-MS studies have specifically shown the presence of heptanal, with a maximum at the sixth month of storage. This compound is described in the literature as having a characteristic odor of ham, fat, even rancidity.[29,30] Moreover, higher proportions of 2,3-octanedione, 2-nonanone, (*Z*)-4-heptenal, (*E*)-2-heptenal, benzaldehyde, hexanal, benzeneacetaldehyde, (*E*,*E*)-2,4-heptadienal, and (*E*,*E*)-3,5-octadien-2-one were recorded for these samples. After 6 months, the proportions of all compounds decreased except for benzaldehyde. Among the above-mentioned compounds, only 2,3-octanedione and 2-nonanone have never been described in the total volatile profile in previous studies on ripened anchovy maturation.[19−21] On the basis of the aromatic qualifiers defined by Leduc et al.,[16] odors can be divided into the following classes: earthy/woody smell, vegetable odor, and floral smell.[30−32] Moreover, anchovy samples from the 10th to 18th months are characterized by higher proportions of TMA compared to the 8th month. This suggests that the increase in total volatile basic nitrogen (TVB-N), the chemical class to which TMA belongs,[33] recorded during the anchovy maturation process[3] continues during storage.

For marinated anchovies, the fifth month appears to mark the volatilome optimum of the product. These samples were characterized by a high proportion of benzeneacetaldehyde, (*E*,*E*)-2,4-heptadienal, (*E*)-2-heptenal, benzaldehyde, (*E*,*Z*)-2,6-nonadienal, and 2,3-octanedione compared with other months. Only 2,3-octanedione has never been described in other studies on salted anchovies[19−21] (there are no published studies on the volatilome of marinated anchovies). The proportion of the above-mentioned compounds decreased except benzaldehyde. These compounds are characterized by respective odors of moss/solvent,[32] fat/soap,[34,35] cardboard/fat,[30,31] almond/woody[29,30] and cucumber for the latter two.[31,34]

Five compounds were present in maximum amounts at the volatilome optimum of processed anchovies, whatever the method of preparation: (*E*,*E*)-2,4-heptadienal, benzeneacetaldehyde, (*E*)-2-heptenal, benzaldehyde, and 2,3-octanedione. To our knowledge, this is the first time that the latter compound has been identified, only by MS and LRI, as a component of volatile compounds in anchovies. 2-Nonanone, hexanal, and (*E*,*E*)-3,5-octadien-2-one appeared to be more specific to salt-ripened anchovies.

Analysis of biogenic amines showed high variability in quantities in similar samples principally in marinated anchovies stored with rupture in the temperature conditions. This probably reflects the heterogeneity of the fish that make up the samples. The initial microbiological load of the product, hygiene measures, and the presence of bruises are all factors that may influence the degradation of anchovies. Despite the high variability of two samples with rupture in the storage conditions, the lower quantities observed exceeded 50 mg $kg^{-1}$, the concentration at which the first allergic symptoms could be observed.

The type of anchovy processing has an impact on the quantity of biogenic amines, because marinated samples had higher concentrations of histamine, cadaverine, putrescine, and tyramine than salted anchovies. This fact can be explained by the bacteriostatic action of salt ripening, whereas the development of lactic flora, potential producers of biogenic amines, is still possible in acidic conditions.[2]

The major factor that determines the production of biogenic amines, as highlighted in our study and previous papers,[6,13,14] is storage temperature. If the cold chain is broken during storage of marinated anchovies, the regulatory threshold of 400 mg $kg^{-1}$ is exceeded. However, it should be noted that the producing process, mainly in salt-ripening treatment, limits the bacterial development at the origin of histamine production.[52]

The present work helps to visualize the changes in the profile of volatile compounds and safety for both types of anchovy processing techniques. It was shown that irregularities in temperatures of storage lead to the development of biogenic amines in marinated samples, whereas no risk was observed in salted samples. In contrast, the modification of temperature conditions did not affect the volatile profile of marinated or salted samples for which the volatilome optimum is respectively reached after 5 and 6 months. None of these results lead to the conclusion of a food safety risk caused by biogenic amines when anchovies are stored in good temperature conditions. However, the study of volatilomes suggests that marinated and salted anchovies should be consumed within 5−6 months after maturation, respectively, so as to guarantee a product with optimal flavor for consumers.

### Funding

Funds for this study, for which the CITPPM was project leader, were provided by FranceAgriMer, run by the French Ministry of Agriculture, as part of the program "*Soutien à l'innovation dans la filière des produits de la pêche et de l'aquaculture − Edition 2010*". A.D. is grateful to the Nord-Pas de Calais Regional

Council (France) and ANSES for providing financial support for his Ph.D. studies.

### Notes

The authors declare no competing financial interest.

## ■ ACKNOWLEDGMENTS

We thank Assi N'Guessan, Ossarath Kol, and Philippe Droin for their critical reviews of the manuscript and Ophélie Frottier and Paul Morieux for their kind technical assistance.

## ■ ABBREVIATIONS USED

ALA, $\alpha$-linolenic acid; CAR/PDMS, carboxen/polydimethylsiloxane; DHA, docosahexaenoic acid; EPA, eicosapentaenoic acid; GC, gaa chromatography; HACCP, hazard analysis critical control point; HPLC, high-performance liquid chromatography; LA, linoleic acid; LRI, linear retention index; MS, mass spectrometry; MUFA, monounsaturated fatty acid; PCA, principal component analysis; PUFA, polyunsaturated fatty acid; SPME, solid phase microextraction; TMA, trimethylamine; TMAO, trimethylamine *N*-oxide; TVB-N, total volatile basic nitrogen; wR, with rupture; w/oR, without rupture

# Control of Maillard-Type Off-Flavor Development in Ultrahigh-Temperature-Processed Bovine Milk by Phenolic Chemistry

Smaro Kokkinidou and Devin G. Peterson*

Department of Food Science and Nutrition, Food Science and Nutrition Building, 1334 Eckles Avenue, University of Minnesota, St. Paul, Minnesota 55108, United States

**ABSTRACT:** The application of phenolic compounds to suppress Maillard chemistry and off-flavor development in ultrahigh-termperature (UHT)-processed milk during processing and storage was investigated. Five phenolic compounds were examined for structure−reactivity relationships (catechin, genistein, daidzein, 1,2,3-trihydroxybenzene, and 1,3,5-trihydroxybenzene). The levels of key transient Maillard reaction (MR) intermediates (reactive carbonyl species) and select off-flavor markers (methional, 2-acetyl-2-thiazoline, 2-acetyl-1-pyrroline) were quantified by LC-MS/MS and GC-MS/ToF, respectively. The addition of phenolic compounds prior to UHT processing significantly reduced the concentration of MR intermediates and related off-flavor compounds compared to a control sample ($p < 0.05$). All phenolic compounds demonstrated unique structure reactivity and, notably, those with a more activated A-ring for aromatic electrophilic substitution (catechin, genistein, and 1,3,5-trihydroxybenzene) showed the strongest suppression effect on the off-flavor markers and reactive carbonyl species. Sensory studies were in agreement with the analytical data. The cooked flavor intensity was rated lower for the recombination model samples of the catechin-treated UHT milk compared to the control UHT milk. Additionally, consumer acceptability studies showed catechin-treated UHT milk to have significantly higher liking scores when compared the control sample (Fisher's LSD = 0.728).

**KEYWORDS:** *Maillard reaction, phenolic chemistry, reactive carbonyls species, thermal processing, UHT milk, off-flavor inhibition*

## INTRODUCTION

Milk, like many foods and commodities, is mandated to undergo thermal processing during production as stated in the Code of Federal Regulations[1] to improve microbial safety. Additional benefits of thermal processing are enhanced product stability and shelf life, which facilitates distribution and storage. For milk, a number of different pasteurization methods are available such as high temperature−short time (HTST), extended shelf life processing, and ultrahigh temperature (UHT) processing, each technology utilizing different time−temperature profiles. Aseptic UHT processing of milk yields a commercially sterile product, with the longest shelf life of 6 months to 1 year. It also allows for nonrefrigerated storage and transportation, widening distribution opportunities and reducing potential energy requirements. Despite the significant benefits of UHT products, high-temperature treatment also yields a product with reduced flavor and nutritional quality as well as undesirable color development, creating a barrier to consumer acceptance.[2−4] Pasteurized milk (typically consumed in the U.S. market) has as a slightly sweet flavor, weak aroma attributes, and a pleasant mouthfeel and aftertaste.[5] Any alteration to this "clean" flavor profile is considered a product defect. Research performed at Cornell University showed a direct correlation between the flavor quality of milk and the level of consumption.[6] Blake et al.[7] also reported UHT milk had a lower consumer liking compared to other less severe thermally processed samples (i.e., pasteurized milk).

The negative flavor changes in UHT milk previously reported to develop during heat treatment and ambient storage have been associated with the Maillard reaction (MR) and lipid oxidation (LO).[8,9] Recent work by Colahan-Sederstrom and Peterson[2] identified three important Maillard-derived off-flavor compounds that contributed to the "cooked" off-flavor of UHT milk, indicating that the MR is an important pathway of off-flavor development during thermal processing and a point of control to develop flavor improvement strategies for UHT milk and milk-based beverages. The MR is well-known to affect food flavor, color, toxicity, and nutritional value.[10−16] Additionally, it is known to play an important role in regulatory biology, diabetes, and cardiovascular and age-related pathology.[11,17] Therefore, a better understanding of the mechanisms that influence Maillard reaction product (MRP) generation in processed food systems would provide the food industry with the ability to more effectively control quality and also potentially improve the nutritional attributes of food.

Phenolic compounds have been previously shown to inhibit Maillard-type flavor generation pathways and reduce off-flavors.[2] Totlani and Peterson[18] have shown that flavan-3-ols function as trapping agents (via electrophilic aromatic substitution reactions, primarily on the A-ring) of key transient Maillard precursors (reactive carbonyl species (RCSs) C2, C3, C4, and C6 sugar fragments) and consequently suppress the generation of MRPs. Flavanols such as catechin are found in several plant products, most notably in tea, cocoa, and wine, and their antioxidant capacity has been extensively studied. High consumption of those phenols has been associated with decreased risk of cardiovascular disease and cancer, as well as metabolic regulation and weight loss.[19−24] Their use to control reactions that

negatively affect flavor and nutrition would additionally benefit the food industry as consumers are increasingly aware of food labels and there is a greater demand for natural products.

The objective of this study was to investigate phenolic structure−reactivity relationships on the mechanisms of off-flavor development in 1% UHT milk.

## MATERIALS AND METHODS

**Chemicals.** The following chemicals were obtained from the sources given: (+)-catechin ≥97% (TCI America); genistein ≥98% (Shaanxi Schipar Biotechnology Co. Ltd., China); daidzein ≥98% (Shaanxi Schipar Biotechnology Co. Ltd., China); phloroglucinol 97% (1,3,5-trihydroxybenzene) (Aldrich, St. Louis, MO, USA); pyrogallol (Fluka, St. Louis, MO); acetoin ≥96% FCC, food grade (FG) (Aldrich); acetol 90% (Aldrich); 2,3-butanedione 97% (Aldrich); 3-deoxyglucosone (TRC, Toronto Research Chemicals, Ontario, Canada); glyoxal 40% solution in water (Sigma, St. Louis, MO, USA); methylglyoxal 40% solution in water (Sigma); methional 97% FG (Aldrich); 2-acetyl-2-thiazoline ≥96% FG (Aldrich); *o*-phenylenediamine 99.5% (Aldrich); *o*-ethylhydroxylamine hydrochloride (Aldrich); and 99.9+% anhydrous diethyl ether (Fisher Chemicals). 2-Acetyl-1-pyrroline was not commercially available but was extracted from pandan leaves (*Pandanus amaryllifolius* Roxb.), obtained from a local market. The purification procedure is described below.

*Pilot Plant Scale UHT Milk Processing.* Raw skim and whole milk were obtained from the University of Minnesota Joseph Warthesen Food Processing Center (St. Paul, MN, USA) and mixed to yield raw milk with 1% fat content. Samples underwent aseptic UHT processing using a MicroThermics HTST/UHT Indirect Tubular Processing System with water final heat (DIP-W), a homogenizer, and aseptic filling station. Processing conditions were as follows: the unit was first sanitized while passing through a chlorine solution (100 ppm, sodium hypochlorite at pH 7.00) for 1 h at 40 °C followed by a clean water wash at 121.1 °C for 1 h. The milk was homogenized, then processed at final temperature of 140 °C, holding for 6 s to ensure commercial sterilization, immediately cooled to 15 °C, and filled in a sterilized laminar flow hood into previously sterilized 1 L amber bottles.

*Small-Scale Benchtop Simulated UHT Processing.* A simulated UHT method reported by Kokkinidou and Peterson[25] was used to process milk, utilizing small sample volumes for cost and time efficiency to monitor the development of off-flavor compounds in milk spiked with RCSs (Figure 9). Briefly, 5 mL of 1% raw milk in headspace vials was placed in a cooling vial holder held at 8 °C. Vials were transferred to an agitator (150 °C) and held for 265 s to allow the sample to reach a final temperature of 140−141 °C for 6 s and subsequently returned to the cooler.

*Characterization of Off-Flavor Generation in UHT Processed Milk.* Identification and quantitation of MR precursors methylglyoxal, glyoxal, 3-deoxyglucosone, and diacetyl (dicarbonyls) as well as glycolaldehyde, acetoin, and acetol (hydroxycarbonyls) were performed using the synthesized stable isotopes [$^{13}C_4$]-acetoin and [$^{13}C_4$]-diacetyl[26] as internal standards. Each internal standard (0.5 mM) was added to 5 mL of milk, followed by 500 μL of 10% trichloroacetic acid. The samples were then vortexed for 1 min and centrifuged at 3904*g* for 20 min at 4 °C (Beckman Coulter, Allegra X-22R), and the supernatant was collected. A solid phase extraction (SPE) method was used to isolate the compounds of interest and avoid interference from phenolic compounds and adducts according to the method of Kokkinidou and Peterson.[25] A derivatization method followed, and samples were analyzed using an Acquity UPLC system coupled with a Quattro Premier XE micromass mass spectrometer (Waters Co. Milford, MA, USA). An Acquity UPLC 2.1 × 100 mm BEH Phenyl 1.7 μm column with a VanGuard 2.1 × 5 mm BEH Phenyl 1.7 μm precolumn was used for separation, and all experiments were performed in triplicate. Analytes were detected using electrospray positive ionization−multiple reaction monitoring (MRM) using methods previously developed and reported by Kokkinidou and Peterson.[25]

*Generation of Phenolic−RCS Adduct Standards.* Model reactions were used to generate standards of Maillard−phenolic products as previously described by Totlani and Peterson.[27] A 50 mL saline phosphate buffer (pH 7.4, 137 mM NaCl, 2.7 mM KCl, 10 mM $Na_2HPO_4$, and 1.8 mM $KH_2PO_4$) reaction system containing 10 mM catechin and methylglyoxal, glyoxal, or 3-deoxyglucosone was incubated in a shaking water bath at 37 °C for 1 h. After incubation, 5 mL of the reaction mixture was spiked with an internal standard (5 μL of 2% solution of butyl paraben in methanol) and an SPE clean up and concentration step followed (DSC-18 cartridge; Supelco, Bellefonte, PA, USA).

Isolates were then purified using a 2D-RP-HPLC/MS-ESI fraction collection system coupled with a Varian Dynamax Pursuit 5 Diphenyl (250 × 10.0 mm) and a Dynamax Pursuit 5 C18 (250 × 10.0 mm). Chromatography was performed with a flow rate of 3.7 mL/min with the following linear gradient conditions (solvent A, 1 mM ammonium acetate, pH 5; solvent B, methanol): solvent B at 20% (0−15 min), increased to 55% (15−61 min), then to 80% (61−66 min), then to 100% (66−72 min), and finally reduced to 20% (72−81 min). Target analytes were collected by MS guided fractionation (*m*/*z* reported in Table 1).

**Table 1. Mass Fragmentation Ions of Main Detected Adducts between Catechin (CAT) and Glyoxal (GO), Methylglyoxal (MGO), and 3-Deoxyglucosone (3DG) in Model Systems[a]**

| adduct/phenolic | parent ion (*m*/*z*) | cone voltage (V) | collision energy (V) | daughter ion (*m*/*z*) |

| $CAT_2$−GO | 619 | 35 | 20 | 329 |
| CAT−MGO | 361 | 35 | 20 | 181 |
| CAT−$MGO_2$ | 433 | 35 | 27 | 235 |
| CAT−3DG | 451 | 32 | 22 | 289 |

[a]Optimum multiple-reaction monitoring (MRM) conditions used for their identification based on Mass Lynx (Waters, Milford, MA, USA).

Fragmentation spectra of the purified analytes were determined by LC-MS/MS techniques and are shown in Table 1. Fragmentation spectra were obtained to monitor these analytes in milk by MRM methods as well as to support the hypothesized structures of these adducts.

*Isolation and Quantitation of Off-Flavor Compounds in Milk.* Three off-flavor compounds previously identified in UHT milk[2] were monitored and included methional, 2-acetyl-2-thiazoline (2A2T), and 2-acetyl-1-pyrroline (2AP). Quantitation was conducted by stable isotope surrogate standards of each compound. The labeled compounds were synthesized as previously described [$^2H_3$]-methional,[28] [$^2H_3$]-2-acetyl-1-pyrroline,[29] and [$^2H_4$]-2-acetyl-2-thiazoline.[30] The identity and purity of each labeled standard were confirmed by MS analysis in both electron impact (EI, 70 eV) and chemical ionization (CI, at 115 eV with isobutane as reagent gas), analyzed with a Hewlett-Packard GC (HP 5890 series II) coupled with an MS detector (HP 5972). The concentration of each labeled standard was determined based on GC analysis in comparison to authentic compounds.

*Solvent-Assisted Flavor Evaporation.* Volatile isolates of the samples were prepared by solvent extraction that was adapted from the method of Colahan-Sederstrom and Peterson.[2] Prior to extraction [$^2H_4$]-2A2T, [$^2H_3$]-2AP, and [$^2H_3$]-methional were added as internal standards at levels of 5 μg standard/kg milk. The concentrated extract was then subjected to high-vacuum distillation using a solvent-assisted flavor evaporation (SAFE) apparatus.[31] The isolate was further fractionated into an acidic (A) and a neutral/basic (N/B) fraction as described by Colahan-Sederstrom.[2] The N/B fraction was prepared and stored at −80 °C prior to analysis by an Agilent 7890A GC (Agilent Technologies, Inc., Wilmington, DE, USA) coupled with a TruTOF HT time-of-flight mass spectrometer (Leco Co., St. Joseph, MI, USA) and a DB-5MS column (30 m × 0.250 mm × 0.25 μm, Agilent Technologies). The column heating profile was at 40 °C for 2.00 min, then ramped to 160 °C at 3 °C/min and ramped to 250 °C at 30 °C/min, and held for 5 min. Injection mode was splitless, and temperature was 250 °C.

*Dynamic Headspace GC-MS.* Off-flavor analysis of the milk samples spiked with RCSs (Figure 9) was performed using a 6890 GC coupled with a DB-5MS (30 m × 0.250 mm × 0.25 μm, Agilent Technologies)

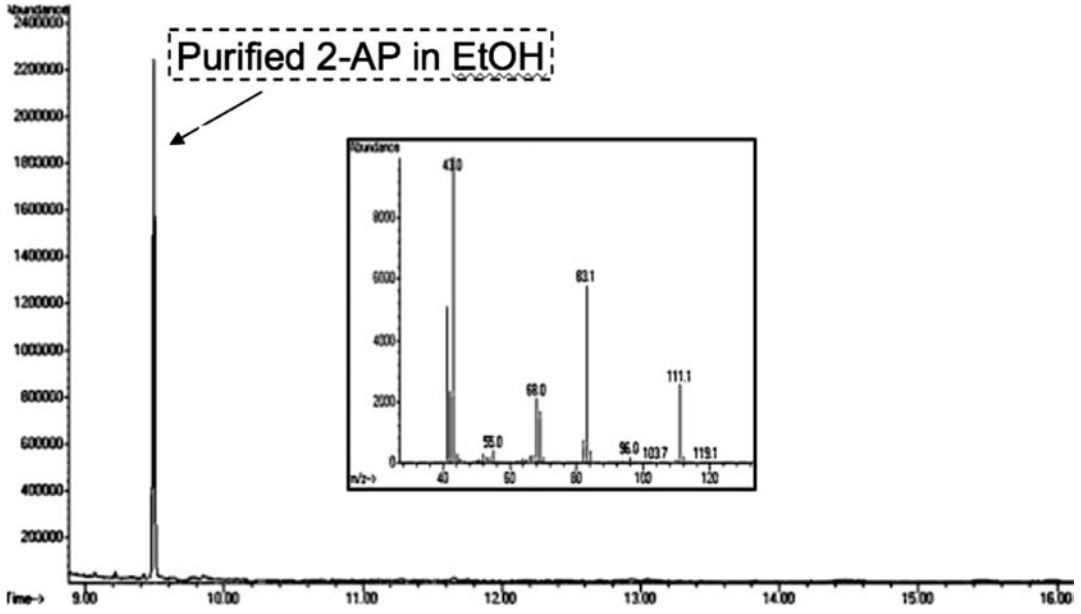

**Figure 1.** Example chromatogram and MS spectra of purified 2AP isolated from pandan leaf extract after multidimensional chromatography, heart-cutting, and fraction collection.

column and equipped with a 5973 mass selective detector (Agilent Technologies), thermal desorption unit (TDU, Gerstel), PTV inlet (CIS 3, Gerstel), and MPS 2 with headspace and dynamic headspace (DHS) option (Gerstel). Briefly, 5 mL of UHT processed milk was placed in headspace vials (20 mL) along with 1 mL of nanopure water and sodium chloride (1 M). Prior to dynamic headspace analysis, [$^2H_4$]-2A2T, [$^2H_3$]-2AP, and [$^2H_3$]-methional were added as internal standards at levels of 5 $\mu$g standard/kg milk. The headspace vials were then incubated at 40 °C for 10 min and subsequently purged with nitrogen at a rate of 40 mL/min for a total time of 12.5 min while agitated at 500 rpm to increase volatility. The trap (Tenax TA) was then dry purged for 4 min at a rate of 30 mL/min and transferred to a thermal desorption unit. The trapped volatiles were then desorbed, cryofocused at −125 °C, and injected in solvent vent mode. The column heating profile was at 40 °C for 2.00 min, ramped to 160 °C at 3 °C/min, then ramped to 250 °C at 30 °C/min, and held for 5 min.

*Identification of Odorants.* Positive identifications were made by linear retention indices (LRI) and mass spectra compared to authentic compounds analyzed under identical conditions.

*Generation of 2-Acetyl-1-pyrroline Standard.* A 2AP standard was prepared from an extract of pandan leaves (*P. amaryllifolius* Roxb.) as previously described by Colahan-Sederstrom and Peterson.[2] The reference compound was further purified using a two-dimensional GC system coupled with a fraction collector.

The analytical system consisted of an Agilent 6890N GC equipped with two Dean switch devices, two Gerstel modular accelerated column heaters (MACH), and an Agilent 7683 autosampler and injector and was additionally coupled with an Agilent 5973N MSD and a Gerstel preparative fraction collector (PFC). An RTX-5S ILMS (30 m × 0.25 mm × 0.25 $\mu$m) was used as a primary column, and a DB-Wax (30 m × 0.25 mm × 0.25 $\mu$m) was used as a secondary column. GC conditions for all runs were as follows: inlet temperature, 200 °C; 10 $\mu$L of sample injected in solvent vent mode (0 kPa, 0.15 min); helium carrier gas ramp pressure mode (initial pressure or 357 kPa held for 7.1 min and then ramped to 10 Pa at 999 kPa/min); and a total flow of 3.9 mL/min with a split 1:4 to MSD and 3:4 to PFC. MSD conditions were as follows: capillary direct interface temperature, 250 °C; mass range, 35−300 amu; The MACH heating profile for the RTX-5S ILMS capillary column was 40 °C for 1 min, then ramped to 280 °C at 10 °C/min, and held for 2.35 min, whereas for the DB-Wax the oven profile was 40 °C for 7.60 min, ramped to 230 °C at 10 °C/min, and held for 2 min. The valve-switching program for heart-cutting and isolation of 2AP was as follows: valve 1 switched on at 6.29 min, directing the flow to the secondary column, and switched off at 7.10 min; then valve two switched on at 15.4 min directing the flow to cryotrap of PFC for 2AP collection and switched off at 15.75 min. The PFC switching device was operated at 250 °C, and the trap was kept at −70 °C. 2AP was extracted from the trap using food grade ethanol and further quantified using vinylpyrrolidine as a standard using an HP 5890 series II GC coupled with an FID. An example chromatogram of 2AP is presented in Figure 1.

*Sensory Analysis of UHT Milk Samples.* Both consumer acceptability and descriptive analysis including off-flavor recombination models were conducted. For the consumer acceptability test, 49 panelists were recruited on the basis of regular milk consumption. Aseptically processed UHT milk samples with and without added 1.7 mM catechin and a commercial UHT milk (Parmalat, Agropur Inc., Division Natrel, USA) were evaluated for acceptability after storage at 30 °C for 1 month. The samples were presented at room temperature in coded 3 oz cups in randomized order. The panelists were asked to rate them on a nine-point hedonic scale (ranging from dislike extremely to like extremely). Differences among treatments were evaluated by analysis of variance (ANOVA) followed by Tukey's HSD pairwise comparison. All analyses were performed with Statistix software (version 9). Significance was established at $p < 0.05$.

For the descriptive analysis trained panelists evaluated the intensity of cooked off-flavor in milk samples. Seven graduate students from the Department of Food Science and Nutrition at the University of Minnesota were recruited for the analysis and were selected on the basis of availability and willingness to participate. They received eight 1 h training sessions focused on the cooked attribute of the milk samples. A cooked reference was prepared by heating 1% milk (Schroder Milk Co.) to 90 °C and holding for 45 min. This cooked reference was mixed with various amounts of pasteurized milk to create a range of cooked intensities. The panel agreed to use the following intensities as references: 100% cooked = 15; 75% cooked/25% pasteurized = 8; 50% cooked/50% pasteurized = 4; 30% cooked/70% pasteurized = 2. Samples were evaluated on a 15-point intensity scale, anchored on the left with "none" and on the right with "extreme".

Panelists participated in three evaluation sessions, occurring over the period of 1 day. The four samples were evaluated in triplicate in a randomized block design. The four samples evaluated were (1) pasteurized 1% milk (Schroder Milk Co.); (2) commercial 1% UHT milk (Parmalat); (3) off-flavor recombination model for simulation of control UHT milk prepared using pasteurized 1% milk (Schroder Milk Co.) spiked with 2AP (1.35 $\mu$g/kg), 2A2T (0.95 $\mu$g/kg), and methional (4.05 $\mu$g/kg); and (4) off-flavor recombination model for simulation of

UHT milk with added catechin prepared using pasteurized 1% milk (Schroder Milk Co.) spiked with 2A2T (0.41 μg/kg) and methional (0.88 μg/kg) to simulate UHT milk (Figure 3) . The spiked levels of off-flavor markers in recombination models were determined after quantitation in pasteurized 1% milk (Schroder Milk Co.) and addition of appropriate amounts for simulation of UHT processed milk samples.

Differences among treatments were evaluated by analysis of variance (ANOVA) followed by Tukey's HSD pairwise comparison. ANOVA was also used to monitor panelist performance. All analyses were performed with Statistix Software (version 9). Significance was established at $p < 0.05$.

*Microbial Testing.* Microbial analysis was conducted on both control and treatment samples using 3 M Petrifilm aerobic count (AC) plates and coliform count (CC) plates (3M Co., St. Paul, MN, USA) according to protocol. For counts in 3M AC and CC plates, 1 mL of each dilution 1:10, 1:100, and 1:1000 of milk samples was plated using phosphate buffer, $KH_2PO_4$ (0.0425 g/L, adjusted to pH 7.2, Butterfield's buffer; Weber Scientific, Hamilton, NJ, USA). Colonies were enumerated after incubation at 37 °C for 24 h for coliforms and at 35 °C after 48 h for aerobic bacteria.

## RESULTS AND DISCUSSION

Milk with 1% fat content was selected for evaluation, as it is the most consumed fluid milk product in the United States. Although overall fluid milk consumption has steadily decreased over the past three decades, consumption of low-fat milk has increased (in comparison to whole milk) as consumers become more aware of caloric intake and negative effects of saturated fat intake.[32] As previously reported[6,7] UHT milk receives significantly lower liking scores than pasteurized milk or other less severely thermally processed milk samples in the domestic marketplace. Consequently, the negative flavor attributes of aseptic UHT milk are a hurdle to utilization and product acceptability. Colahan-Sederstrom and Peterson[2] had previously reported the addition of a phenolic compound prior to UHT processing reduced the cooked flavor intensity of UHT milk suggesting an improved product quality. Therefore as an initial step, a consumer acceptability study was performed to assess the effectiveness of phenolic compound addition on consumer liking. UHT milk samples with and without catechin were stored at 30 °C for 30 days, for accelerated aging (estimated 2−3 months at ambient storage conditions), prior to evaluation. A commercial UHT sample was also included as an internal anchor. The results of the consumer panel are presented in Table 2. The UHT milk with catechin added prior to processing received a significantly higher liking score then both the control and commercial UHT milk samples, demonstrating the application of phenolic compounds to improve UHT milk quality.

**Table 2. Consumer Acceptability Rating of 1% UHT Milk Manufactured with and without Catechin Plus a Commercial UHT Sample**

| sample | mean liking (9-point hedonic scale) |
|---|---|
| 1% UHT-catechin containing (1.72 mM)[a] | 6.04a |
| 1% UHT milk[a] | 5.12b |
| commercial UHT (Parmalot) | 4.73b |

[a]Samples prepared and produced at University of Minnesota Joseph Warthensen Processing Center facilities (processed to 140 °C for 6 s) and stored at 30 °C for 1 month. Different letters indicate statistically significant differences. Fisher's LSD = 0.728 (5% significance level).

**Phenolic Structure Reactivity.** A mechanistic understanding of the reactivity of phenolic chemistry related to off-flavor suppression would be beneficial for the optimization of the dose response. For example, select phenolic structures might be more reactive (effective in suppressing off-flavor) during thermal processing (ca. 140 °C), whereas others could be more reactive during ambient storage.

Five phenolic compounds (see Figure 2) were selected to examine phenolic structure function reactivity on the MR pathways and off-flavor development in UHT processed milk, and the effectiveness of each structure on off-flavor suppression was evaluated immediately after processing as well as after storage. Three common food phenolic compounds, catechin (flavanol), genistein, and daidzein (isoflavones), along with two simple phenols, 1,2,3-trihydroxybenzene and 1,3,5-trihydroxybenzene, were selected.

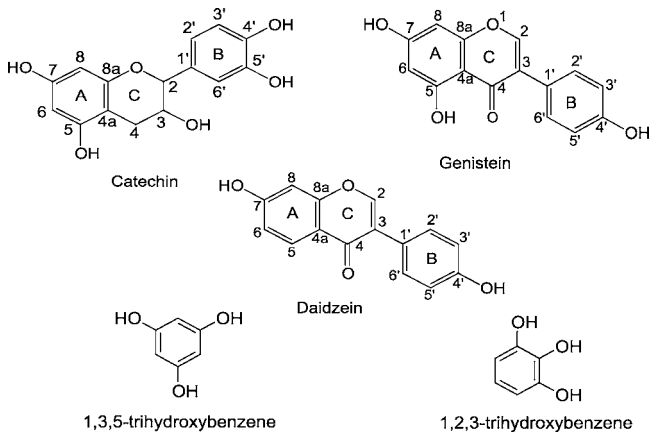

**Figure 2.** Select phenolic compounds evaluated in UHT milk.

The food phenolic compounds differ in the degree and position of hydroxyl substitution on rings A and B as well as the presence of a keto group on the C-ring (isoflavones). The simple phenols were used to simulate different ring chemistry, more redox reactive (123THB) or more "trapping" reactive of carbonyl compounds by electrophilic aromatic substitution reactions (135THB) to investigate the mechanisms by which phenolic compounds alter MR pathways. Among the food-derived phenolic compounds, catechin would have the highest trapping reactivity, followed by genistein and then daidzein, based on the position of the hydroxyl groups on the A-ring and electron-withdrawing groups on the neighboring C-ring (keto group). Phenolic compounds were added at dose levels of 1.7 mM, which was selected as this amount of epicatechin was reported[2] to be effective in suppressing off-flavor development and not result in a detectable bitterness (a sensory attribute associated with polyphenols).

**Sensory Recombination Analysis: Markers of UHT Cooked Flavor.** To quantitatively monitor off-flavor progression in UHT milk, the off-flavor compounds as well as reaction intermediates of these compounds were targeted. For target off-flavor compounds, Colahan-Sederstrom and Peterson[2] identified three Maillard-type reaction products related to the cooked off-flavor profile of 1% UHT milk. These included methional, 2-acetyl-1-pyrroline (2AP) and 2-acetyl-2-thiazoline (2A2T). In the current study the contribution of these off-flavor compounds to the "cooked" off-flavor attributes of UHT milk was further defined by sensory recombination analysis in milk systems.

The concentrations of methional, 2AP, and 2A2T were determined after 30 days of storage at 30 °C in UHT milk as well as in the UHT milk with catechin (see Figure 3). On the basis of

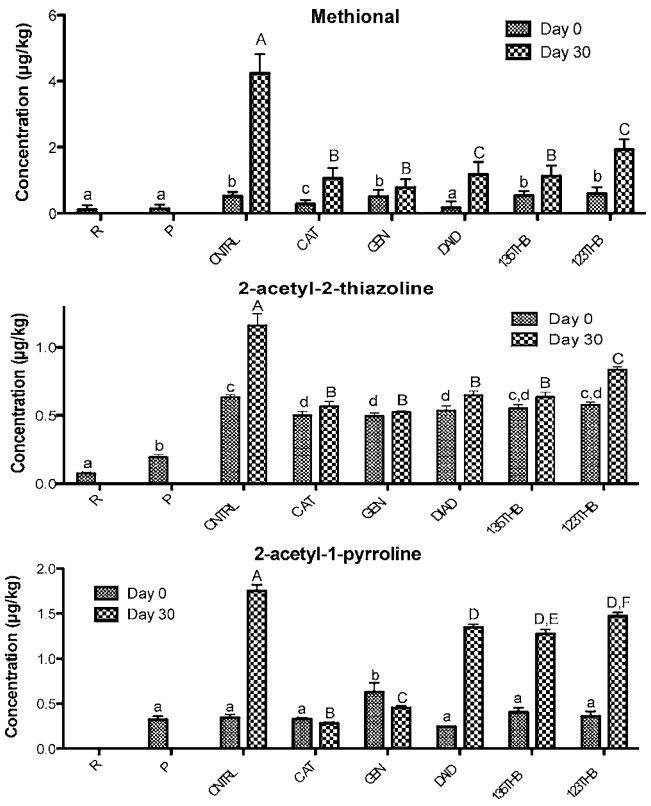

**Figure 3.** Concentration of off-flavor markers 2-acetyl-1-pyrroline (2AP), methional, and 2-acetyl-2-thiazoline (2A2T) in raw (R), pasteurized (P), control UHT milk (CNTRL), and UHT milk with added catechin (CAT), genistein (GEN), daidzein (DAID), 1,3,5-trihydroxybenzene (135THB), and 1,2,3-trihydroxybenzene (123THB) as determined right after UHT processing (day 0) and after 30 days of storage in 30 °C (day 30). The same letters indicate no statistical significant differences ($p < 0.05$). Lower case letters correspond to day 0 treatments, and upper case letters correspond to day 30 treatments.

these quantitative off-flavor fingerprints, the corresponding aroma recombination models of UHT and UHT with catechin samples were made in pasteurized (HTST) milk and evaluated for the cooked flavor intensity (see Table 3). The UHT aroma recombination model was not significantly different in cooked flavor intensity in comparison to commercial UHT milk and was significantly higher in cooked flavor intensity compared to both commercially pasteurized (HTST) milk and the model UHT milk that contained catechin. Overall these findings supported the utilization of these three Maillard-type off-flavor compounds as predictive chemical markers of cooked off-flavor associated with UHT processed milk.

**Table 3. Average Cooked Flavor Intensity of Commercial Milk and Off-Flavor Recombination Model Systems**

| sample | mean rating | homogenous groups[a] |
|---|---|---|
| commercial 1% UHT milk (Parmalat) | 5.5 | A |
| off-flavor recombination model of 1% UHT milk | 5.3 | A |
| commercial 1% pasteurized milk | 1.1 | B |
| off-flavor recombination model of UHT-catechin containing (1.72 mM) | 0.8 | B |

[a]Fisher's LSD = 0.319 (5% significance level), $n = 8$ in duplicate.

**Effect of Phenolic Compounds on Levels of Off-Flavor Markers.** The influence of different phenolic structures on the generation of cooked off-flavor both during thermal treatment (day 0) and after storage (30 days at 30 °C) is further illustrated in Figure 3; the concentration in the raw milk prior to UHT processing was also included for comparison. Overall, the concentration of all three marker compounds (methional, 2AP, and 2A2T) increased during UHT processing and storage at 30 °C in direct comparison to raw and pasteurized milk (Figure 3). Further comparison of the influence of phenolic addition on the suppression of off-flavor compounds indicated the effects reported were variable and dependent on the type of off-flavor compounds, the phenolic structure added, and the temperature of the system (UHT processing temperature, 140 °C, versus storage, 30 °C). For example, catechin and daidzein slightly inhibited the amount of methional generated during UHT processing, whereas the other three phenolics had no substantial effect. However, during storage, all phenolic compounds were reported to suppress its generation, with genistein and catechin being more effective, reducing methional by 80 and 75%, respectively. This observation indicated that catechin was more effective for suppressing the generation of methional during both processing and storage. However, for methional, daidzein is more reactive during processing, whereas genistein was more reactive during storage conditions.

For 2A2T, the addition of phenolic compounds had little impact on off-flavor development during processing temperatures as compared to control UHT, but all effectively suppressed generation during storage. Addition of catechin, genistein, or daidzein resulted in concentrations of 2A2T after storage 42–53% lower than the control, notably at concentrations below the odor threshold of this compound (1 µg/kg). Genistein was the most reactive phenolic compound for off-flavor suppression under storage conditions.

Finally for 2AP, most phenolic compounds had negligible influence on off-flavor development during processing. However, during storage, genistein and catechin were the most reactive and effective in suppressing off-flavor generation, whereas daidzein, 123THB, and 135THB had negligible effects.

In general 135THB, which is more activated toward aromatic electrophilic substitution, was more effective in reducing the concentration of off-flavor markers as compared to 123THB, supporting the idea that one of the mechanisms by which phenolic compounds inhibit MR pathways and off-flavor generation is reactive carbonyl trapping. On the basis of the observed unique structure reactivity of these phenolic compounds, utilizing mixtures of phenolic compounds as an off-flavor inhibition strategy was subsequently investigated in a further study.[25]

**Effect of Phenolic Compounds on RCS Levels.** To further elucidate the influence of the phenolic structure reactivity on the generation of the Maillard-type off-flavor compounds, the RCSs (key transient sugar fragments) were also quantified. The concentrations of dicarbonyl and hydroxycarbonyl sugar fragments as influenced by UHT processing, phenolic addition, and storage are illustrated in Figures 4 and 5, respectively. Overall, UHT processing resulted in increased concentrations of RCSs when compared to both raw and pasteurized milk. This was expected, as the UHT conditions would catalyze the MR and subsequently the generation of MR intermediates such as RCSs. Examination of the sugar fragments in the control UHT sample

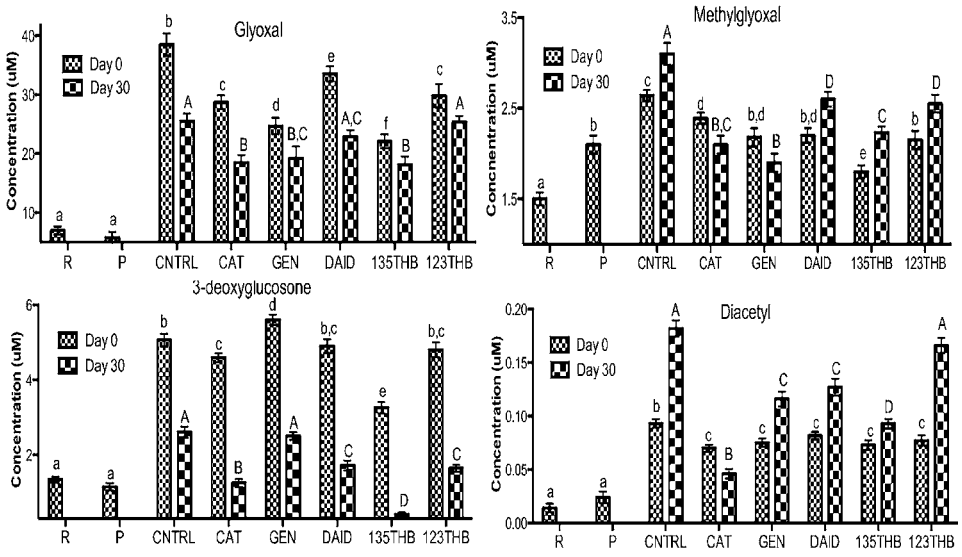

**Figure 4.** Concentrations of $\alpha$-diacarbonyls (glyoxal, methylglyoxal, 3-deoxyglucosone, and diacetyl) in raw (R), pasteurized (P), control UHT milk (CNTRL), and UHT milk with added catechin (CAT), genistein (GEN), daidzein (DAID), 1,3,5-trihydroxybenzene (135THB), and 1,2,3-trihydroxybenzene (123THB), as determined immediately after UHT processing (day 0) and after 30 days of storage in 30 °C (day 30). Each compound was monitored as quinoxaline derivatives and run in triplicate. The same letters indicate no statistical significant differences ($p < 0.05$)). Lower case letters correspond to day 0 treatments, and upper case letters correspond to day 30 treatments. All treatments were significantly different at day 30 when compared to day 0 ($p < 0.05$).

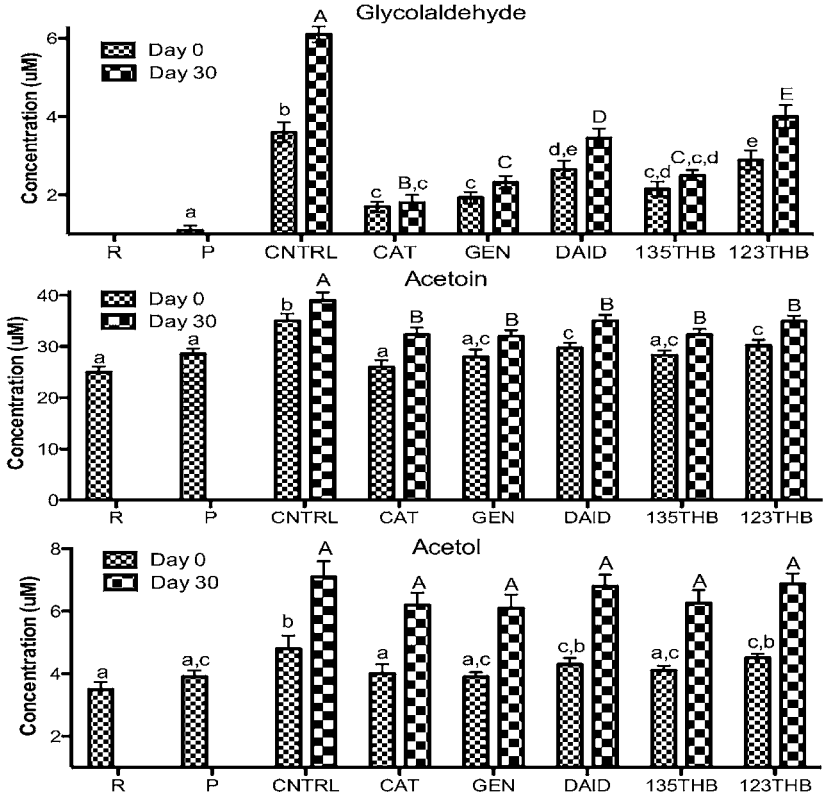

**Figure 5.** Concentration of $\alpha$-hydroxycarbonyls (glycolaldehyde, acetol, and acetoin) in raw (R), pasteurized (P), control UHT milk (CNTRL), and UHT milk with added catechin (CAT), genistein (GEN), daidzein (DAID), 1,3,5-trihydroxybenzene (135THB), and 1,2,3-trihydroxybenzene (123THB), as determined immediately after UHT processing (day 0) and after 30 days of storage in 30 °C (day 30). Each compound was monitored as ethoxylamine derivatives and run in triplicates. The same letters indicate no statistical significant differences ($p < 0.05$). Lower case letters correspond to day 0 treatments, and upper case letters correspond to day 30 treatments. Unless otherwise indicated, all treatments were significantly different at day 30 when compared to day 0 ($p < 0.05$).

after storage indicated that two of the dicarbonyl compounds, namely, methylglyoxal and diacetyl, increased, whereas glyoxal and 3-deoxylglucosone decreased; all hydroxylcarbonyls increased (glycolaldehyde and acetol) or maintained similar levels (acetoin). The observed reduction in the concentration of glyoxal and 3-deoxyglucosone could be indicative of the high

dx.doi.org/10.1021/jf501919y | J. Agric. Food Chem. 2014, 62, 8023−8033

reactivity of glyoxal entering several reaction pathways leading to off-flavor formation, and for 3-deoxyglucosone its further fragmentation to shorter chain sugar fragments further contributed to MRP generation.

In general, the addition of phenolic compounds prior to UHT processing resulted in reduced levels of these MR precursors (RCSs) compared to the control UHT milk samples. The influence of phenolic compounds on the reduction of RCSs indicated that the different structures have unique reactivity and was dependent on the structure of the dicarbonyl or hydroxycarbonyl compound, as well as on the temperature of the system (UHT processing temperature, 140 °C, or storage, 30 °C).

*Dicarbonyls.* Overall, all of the food phenolic compounds (catechin, genistein, and daidzein) reported a significant effect ($p < 0.05$) compared to control UHT milk on the levels of dicarbonyl compounds during processing and storage. Catechin, genistein, and 135THB were the most effective phenolic treatments in reducing the concentration of glyoxal after 30 days of storage followed by diadzein. These observations were expected on the basis of the reactivity of the phenolic structures toward aromatic electrophilic substitution (Figure 2). Genistein and 135THB were the most reactive phenolic compounds during UHT processing, demonstrating the highest reduction of glyoxal as compared to control UHT milk.

Similarly for methylglyoxal, addition of catechin, genistein, or 135THB significantly reduced the concentration of this RCS after 30 days of storage. Additionally, both catechin and genistein were effective in reducing the concentration of methylglyoxal during storage to concentrations lower than observed right after processing (day 0), and it is noteworthy these levels are not significantly different from concentrations found in pasteurized milk demonstrating unique reactivity as compared to other phenolic treatments. The most reactive phenolic compound for suppressing the levels of methylgloxyal during UHT processing was 135THB.

Similarly, 135THB was also the most reactive phenolic treatment in reducing the concentration of 3-deoxyglucosone during both UHT processing and storage, followed by catechin. Notably, these two phenolic treatments resulted in 3-deoxyglucosone levels that were not significantly different from or lower than those found in pasteurized and raw milk. The increased reactivity of 135THB as compared to catechin could also be explained by reduced steric hindrances. Overall, genistein had reduced reactivity toward C6 sugar fragments. The reduced reactivity of both genistein and diadzein as compared to catechin and 135THB was expected due to the presence of a keto group at the C-5 position on ring C that can decrease nucleophilicity of the activated ortho positions of ring A (C-8 and C-6) (Figure 2) and thus its sugar fragment trapping reactivity. The increased reactivity of daidzein as compared to genistein could potentially be attributed to reduced steric hindrance due to the absence of the hydroxyl group at the C-5 position of the A-ring (Figure 2).

Diacetyl was effectively reduced during UHT processing by all phenolic treatments except diadzein, which was not significantly different from the control UHT milk demonstrating negligible reactivity for this C4 sugar fragment. Catechin was the most reactive phenolic treatment in reducing the concentration of diacetyl during storage to levels below those observed at day 0. Findings again demonstrate unique phenolic structure reactivity. For all other phenolic treatments, the concentration of diacetyl continued to increase during storage, albeit at reduced rates when compared to the control.

*Hydroxycarbonyls.* The effect of phenolic treatment on the levels of hydroxycarbonyl compounds also reported unique structure reactivity, but the observed suppression effects were not as pronounced. All phenolic compounds significantly ($p < 0.05$) reduced the levels of glycolaldehyde with the more reactive phenols being catechin, genistein, and 1,3,5-trihydroxybenzene. Only catechin, genistein, and 1,3,5-trihydroxybenzene significantly reduced acetoin, and for acetol no significant ($p > 0.05$) changes were observed for the phenolic treatments when compared to control UHT milk. The overall noted reduction in phenolic reactivity for the hydroxycarbonyl compounds was anticipated. Hydroxylcarbonyl compounds are relatively weaker electrophiles and, thus, are less likely to be trapped by phenolic compounds. From the three hydroxycarbonyls investigated, glycolaldehyde is the most electrophilic and, as predicted, was the most influenced by phenolic addition.

**Phenolic Trapping Reactivity.** Overall, on the basis of the predicted reactivity of the selected phenolic compounds toward aromatic electrophilic substitution reactions and RCS trapping, catechin, as a flavanol, was expected to be significantly more reactive as compared to isoflavones such as genistein and daidzein. However, due to the complexity of food systems, phenolic-carbonyl reactions are anticipated to be influenced by multiple factors such as phenolic stability and competing reactions and hence why this general trend (based on aromatic electrophilic substitution reactions) was not always observed. In this study, genistein demonstrated overall similar reactivity toward trapping RCSs as compared to catechin. This observation could potentially be explained by the increased autoxidation reactivity of catechin resulting in the formation of quinones, thus leading to greater reactivity with milk proteins and other milk constituents and reduced RCS trapping reactivity.

Among the simple phenolic compounds, 135THB was more effective in reducing the levels of RCSs, which is in agreement with previously findings.[33] 1,3,5-Trihydroxybenzene would be expected to be a more reactive trapping agent of sugar fragments than 123THB on the basis of the polyhydroxyl ring configuration. 135THB has three electron-donating hydroxyl groups in the meta configuration on a benzene ring, which activate the ortho and para positions for electrophilic aromatic substitution reactions at the three substituted carbon sites (e.g., RCSs). Consequently, the noted higher reactivity of 135THB suggests that one of the mechanisms by which phenolic compounds alter the flavor generation pathways in UHT milk is the formation of adducts with these precursors as previously hypothesized by Totlani and Peterson.[34] In general, the observed reduction in the concentration of RCSs correlated with both analytical and sensorial data regarding the inhibition of off-flavor generation in UHT milk as influenced by the addition of phenolic compounds when compared with traditional UHT milk.

The noted improvement in the consumer acceptability of UHT milk treated with phenolic compounds (catechin) could also be due to, in part, the reduction in the concentrations of the RCS. Many of the RCS have unique (off)-flavor attributes. Diacetyl has been identified as a contributor to the heated, cooked, and fermented notes of UHT milk with a flavor threshold of 12 ppb (0.14 $\mu$M),[35−37] and notably diacetyl concentration in control UHT milk after 30 days of storage was above this flavor threshold value. Glyoxal and methyglyoxal have mild sour, pungent, and slightly nutty aromas. Acetol is characterized as sweet and roasted or as having a yogurt-like flavor in emulsions, and acetoin has a sweet, buttery, creamy aroma.[38−41]

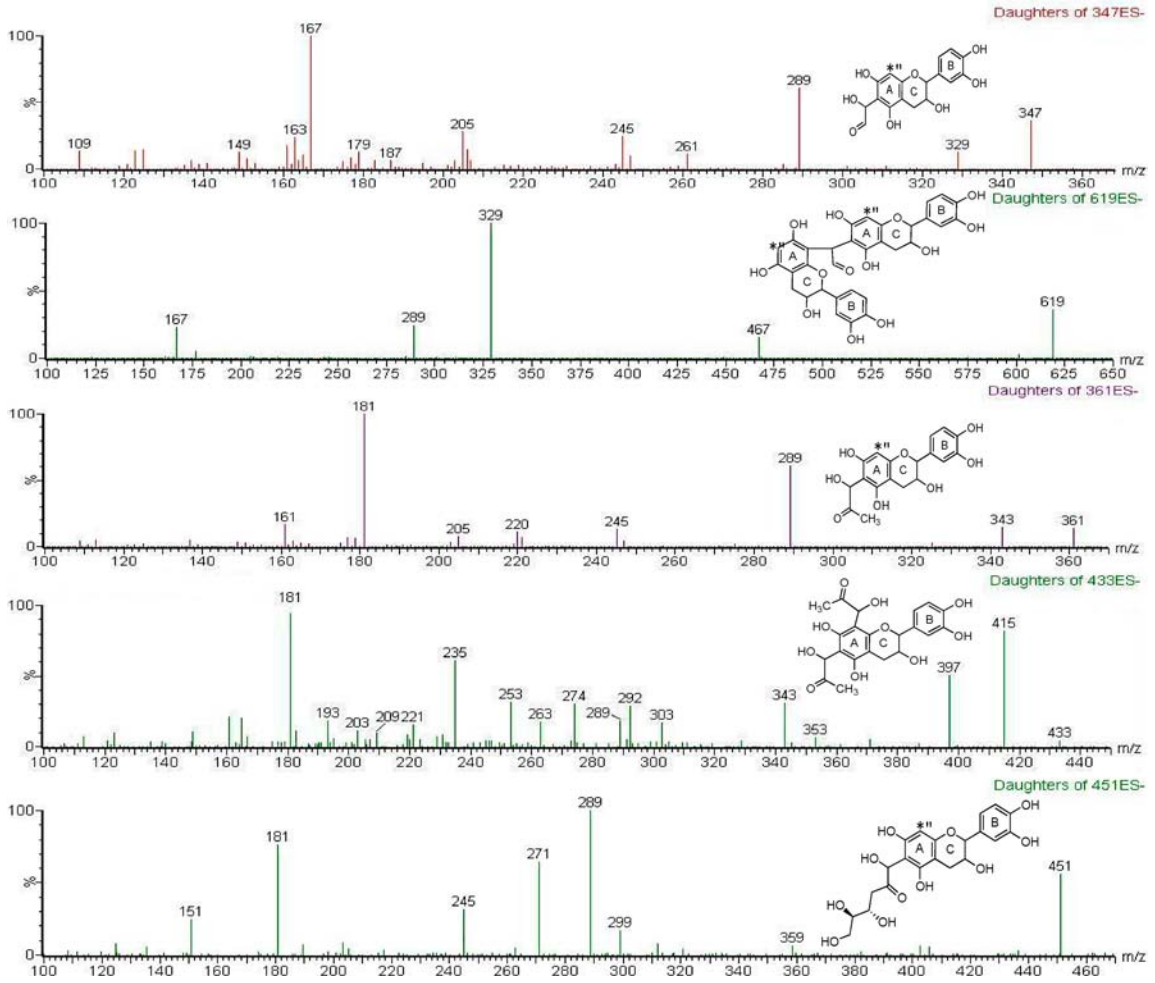

**Figure 6.** MS/MS fragmentation spectra for catechin−sugar fragment adduct reaction products. Spectra correspond to catechin−glyoxal, catechin−glyoxal−catechin, catechin−methylglyoxal, methylglyoxal−catechin−methylglyoxal, and catechin−3-deoxyglucosone adducts from top to bottom. ∗ denotes alternative position activated for aromatic electrophilic substitution. RCSs substitution can occur at either the C-6 or C-8 position of the A-ring. Only one structure is presented for simplicity.

**Phenolics−RCSs Adducts.** To further support the hypothesis of adduct formation as a mechanism for off-flavor inhibition, model reaction systems were prepared and adducts between catechin and glyoxal, methylglyoxal, and 3-deoxyglucosone were purified to develop analytical methods for their identification in UHT milk with added catechin. The most prominent products of these reactions were identified as catechin−glyoxal, catechin−glyoxal−catechin, catechin−methylglyoxal, methylglyoxal−catechin−methylglyoxal, and catechin−3-deoxyglucose adducts. The proposed reaction product structures shown in Figure 7 were based on prior literature[27,42,43] and MS/MS fragmentation patterns (Figure 6). The parent ions of all purified products/adducts generated daughter ions of $m/z$ 289, which corresponds to a catechin moiety along with fragments of $m/z$ 245, 205, and 179, which are characteristic daughter ions of catechin fragmentation[44] confirming its presence in these products. The $m/z$ 245 fragment may be generated after a neutral loss of $CO_2$, characteristic of negative ionization mode.[45] The $m/z$ 205 fragment is most likely generated by loss of rings B and C,[46] and $m/z$ 179 is produced after an A-ring loss. This particular fragmentation pattern (loss of A-ring) supports the adduct formation between catechin and RCSs via electrophilic aromatic substitution at C-8 or C-6 of ring A as well as the proposed adduct structures because fragments that correspond to a loss of ring A with RCS moieties were detected for all adducts. Namely, $m/z$ 167 (A-ring−glyoxal), $m/z$ 181 (A-ring−methylglyoxal), $m/z$ 253 (A-ring−methylglyoxal$_2$), and $m/z$ 271 (A-ring−3-deoxyglucosone) were detected as daughter ions of catechin−glyoxal and catechin−glyoxal−catechin, catechin−methylglyoxal, methylglyoxal−catechin−methylglyoxal, and catechin−3-deoxyglucosone adducts, respectively. MRM methods were developed, and the detection of all adducts in aseptically processed UHT milk with added catechin was achieved. An example chromatogram of the detection of catechin−glyoxal and catechin−methylglyoxal adducts is shown in Figure 8. Multiple peaks in chromatograms were anticipated to be due to four diastereoisomers of catechin forming during thermal processing reacting with RCSs. Catechin−methylglyoxal adducts resulted in more than four peaks as the addition of methylglyoxal added another chiral center to the molecule, thus increasing the number of possible products.

**RCSs and Off-Flavor Causality.** To demonstrate causality between increased levels of RCSs and off-flavor generation, RCSs were additionally added to milk prior to UHT processing and the levels of off-flavor volatiles were monitored. More specifically, pasteurized milk (control) and pasteurized milk spiked with levels of RCSs reported in UHT milk glyoxal (GO) 60 $\mu$M, methylglyoxal (MGO) 20 $\mu$M, diacetyl 0.4 $\mu$M, and 3-

dx.doi.org/10.1021/jf501919y | J. Agric. Food Chem. 2014, 62, 8023−8033

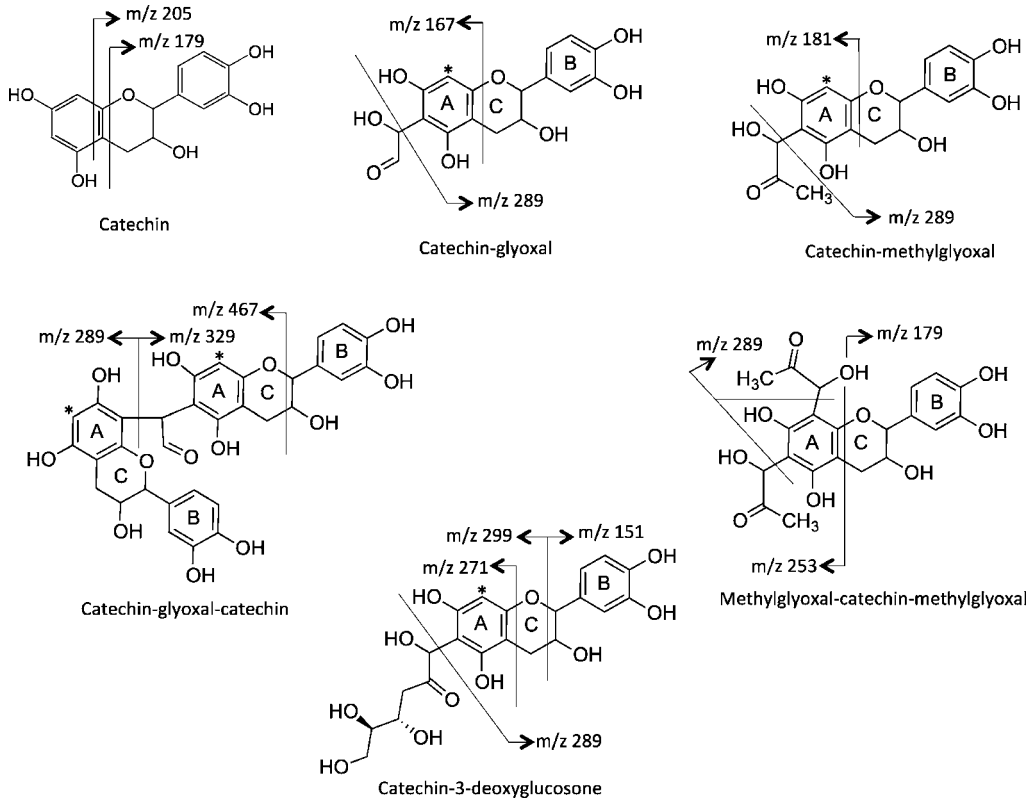

**Figure 7.** Hypothesized MS/MS fragmentation pattern of adducts between catechin and glyoxal, methylglyoxal, and 3-deoxyglucosone. ∗ denotes predicted main alternative position for aromatic electrophilic substitution based on prior literature.[27,42,43] RCSs substitution can occur at either the C-6 or C-8 position of the A-ring. Only one structure is presented for simplicity.

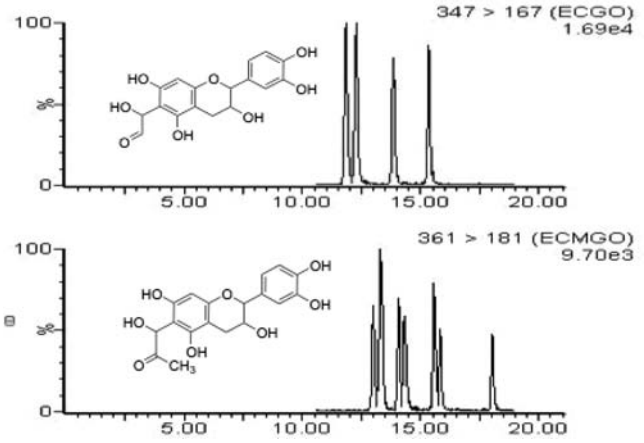

**Figure 8.** LC-MS/MS (ESI negative mode) chromatograms of detection catechin adducts with glyoxal (top,$m/z$ 347 → 167) and methylglyoxal (bottom, $m/z$ 361 → 181) in UHT milk with catechin. A suggested reaction product is illustrated.

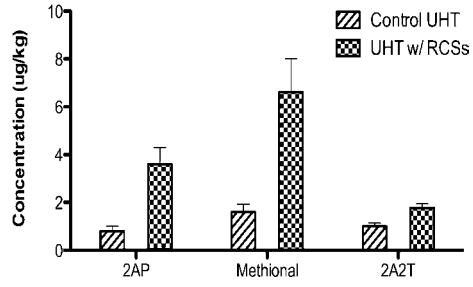

**Figure 9.** Concentration of off-flavor markers 2-acetyl-1-pyrroline (2AP), methional, and 2-acetyl-2-thiazoline (2A2T) in control UHT milk and UHT milk with added glyoxal (65 $\mu$M), methylglyoxal (20 $\mu$M), diacetyl (0.4 $\mu$M), and 3-deoxyglucosone (12 $\mu$M), as determined right after UHT processing (day 0).

deoxyglucosone (3DG) 10 $\mu$M) were subsequently UHT processed, and the concentrations of the selected off flavor markers were determined immediately after processing. The results are shown in Figure 9 and demonstrate that increased levels of RCSs resulted in significantly higher levels of off-flavor markers, as compared to the control. More specifically, 2AP, methional, and 2A2T were increased by 77.5, 74.2, and 42.1%, respectively, when milk was spiked with RCSs prior to UHT processing, thus demonstrating causality and further supporting the formation of phenolic−RCS adducts as one of the main mechanisms of phenolic off-flavor inhibition.

In summary, phenolic compounds were reported to significantly suppress MR off-flavor pathways in UHT milk during thermal processing and storage, resulting in a product with increased consumer acceptability. Furthermore, the results of this study support phenolic trapping reactions of Maillard-generated sugar fragments as an important mechanism of off-flavor suppression. This work further defined the interplay between phenolic chemistry and the mechanisms of the MR in foodstuffs. Unique phenolic−structure reactivity was also reported for the suppression of Maillard chemistry in UHT milk; different phenolic structures were more reactive during thermal processing versus storage in reducing both RCSs and off-flavor markers. Overall, these results support the potential of phenolic compound mixtures or food extracts rich in phenolic compounds (e.g., cocoa, tea, coffee, grape, soy) as treatments to

improve the flavor stability and nutritional value of thermally processed foods and in this case milk and milk-based beverages. Self-affirmed generally regarded as safe (GRAS) phenolic ingredients such as Teavigo (flavanol) and geniVida (isoflavone) are currently commercially available (DSM, NL).

# Identification of Bitter Peptides in Aged Cheddar Cheese

Konstantinia Karametsi, Smaro Kokkinidou, Ian Ronningen, and Devin G. Peterson*

Department of Food Science and Nutrition, University of Minnesota, 145 FScN Building, St. Paul, Minnesota 55108, United States

**ABSTRACT:** The compounds responsible for the bitter taste of aged "sharp" Cheddar cheese were characterized. Sensory-guided fractionation techniques using gel permeation chromatography and multi-dimension semi-preparative reversed-phase high-performance liquid chromatography revealed the presence of multiple bitter compounds. The compounds with the highest perceived bitterness intensity were identified by tandem mass spectrometry *de novo* peptide sequencing as GPVRGPFPIIV, YQEPVLGPVRGPFPI, MPFPKYPVEP, MAPKHKEMPFPKYPVEPF, and APHGKEMPFPKYPVEPF; all originated from *β*-casein. Subsequent quantitative liquid chromatography−tandem mass spectrometry analysis reported that the concentrations of GPVRGPFPIIV, YQEPVLGPVRGPFPI, and MPFPKYPVEP increased during maturation by 28.7-, 3.1-, and 1.8-fold, respectively. When directly compared to young "mild" Cheddar, APHGKEMPFPKYPVEPF was reported only in the sharp Cheddar cheese, whereas the concentration of MAPKHKEMPFPKYPVEPF did not change. Further taste re-engineering sensory experiments confirmed the importance of the identified peptides to the bitterness of sharp Cheddar. The bitter intensity of the aged "sharp" Cheddar model (mild Cheddar with equivalent concentrations of the five bitter peptides in the sharp sample) was rated as not significantly different from the authentic sharp Cheddar cheese. Among the five peptides, GPVRGPFPIIV was reported to be the main contributor to the bitterness intensity of sharp Cheddar. Furthermore, a difference from control sensory test also confirmed the significance of the bitter taste to the overall perception of aged Cheddar flavor. The sharp Cheddar model was reported to be significantly more similar to aged "sharp" Cheddar in comparison to the young "mild" Cheddar cheese sample.

**KEYWORDS:** *Cheddar cheese, aged, bitterness, peptides*

## INTRODUCTION

The chemical stimuli that invoke food flavor can be simplistically defined as a combination of aroma, taste, and chemesthetic compounds. Aroma compounds are volatile and perceived by the olfactory system, while taste compounds can be volatile or non-volatile and are detected by the gustatory system. Chemesthetic compounds are irritants of the pain nerves in the oral cavity. Historically, researchers have looked at food flavor as predominately being influenced by volatile aroma compounds, with minor contributions from taste. This assumption has turned out to be an oversimplification. Understanding the flavor compounds that contribute to the desirable flavor properties of foods provides a basis to develop manufacturing strategies to improve the acceptability of healthier options, such as reduced fat or salt.

Taste stimuli have been recognized as key aspects of the flavor properties of cheese.[1] A number of researchers have characterized the volatile flavor compounds from Cheddar cheese, resulting in an extensive list including a wide variety of compounds, such as acids, alcohols, esters, aldehydes, ketones, sulfur-containing compounds, and phenolics. On the contrary, only limited information is available on the characterization of the taste of most cheese varieties,[1−10] and none is characterized sufficiently to permit duplication of its complete flavor by mixtures of pure compounds.[11]

The degree of ripening of Cheddar cheese is known to affect the development of all aspects of flavor (taste, aroma, and texture). With regard to taste, over time, characteristic bitterness develops that has been associated with hydrophobic peptides. Although some bitterness is considered a normal component of Cheddar cheese taste and contributes to the desirable flavor of mature Cheddar,[12] excessive bitterness is generally regarded as a defect[2,13] and may limit consumer acceptance.

The development of bitterness during the maturation of Cheddar cheese is considered to be the result of the accumulation of hydrophobic peptides that consist of 2−23 amino acid residues in the molecular mass range of 500−3000 Da.[2,12,13] The isolation and characterization of the compounds that are responsible for bitterness in foodstuffs have been the subject of numerous studies over the years. Gouda has been analyzed by sensory-guided fractionation techniques, and 12 peptides were found to contribute to bitterness[8,9] as well as in whey protein and whey protein hydrolysates[14,15] and various kinds of cheeses.[3−5]

Very limited information is available about the taste active compounds in Cheddar cheese. Broadbent et al.[13] used two peptides [*β*-casein (*β*-CN) (f193−f209) and *α*(S1)-casein (*α*(S1)-CN) (f1−f9)] as indicators of excessive bitter development in Cheddar and model systems. However these peptides, or their breakdown products, have not been adequately characterized for their contribution to bitterness perception limiting the application of these data to better understand Cheddar flavor.

The goal of this study was therefore to identify bitter peptides in Cheddar cheese and characterize their sensory contribution to improve our understanding of Cheddar flavor.

dx.doi.org/10.1021/jf5020654 | *J. Agric. Food Chem.* 2014, 62, 8034−8041

The chemical nature of the identified taste compounds will provide insight as to whether the flavor compounds are produced during processing or during aging and will afford a basis to better understand flavor generation (precursors involved) and, thus, facilitate the development of strategies for control in related products for flavor improvement.

## MATERIALS AND METHODS

**Samples.** Sharp and mild Cheddar cheese samples were obtained from a local grocery store (Archer Farms, Target, Minneapolis, MN) and stored at −20 °C prior to analysis. Sharp Cheddar is representative of an aged cheese of 9−12 months, whereas mild Cheddar is representative of a young cheese of 2−3 months.

**Chemicals.** Trifluoroacetic acid, formic acid, and high-performance liquid chromatography (HPLC)-grade solvents were obtained from Sigma-Aldrich Co. Synthetic peptides YQEPVLGPVRGPFP, GPVRGPFPIIV, MAPKHKEMPFPKYPVEPF, QEPVLGPVREGPFP, APKHKEMPFPKYPVEPF, YQEPVLGPVRGPFPI, EPVLGPVRGPFP, QEPVLGPVRGPFPI, EMPFPKYPVEPF, LGPVRGPFP, PVLGPVRGPFP, and MPFPKYPVEPF were obtained from EZBiolab, Inc. at a purity of 98%.

**Preparation of the Methanol-Soluble Extract from Cheddar Cheese.** A total of 60 g of Cheddar cheese and 240 mL of water were homogenized for 5 min and, subsequently, centrifuged at 4000*g* for 20 min at 4 °C. The protein pellet as well as the fat layer were collected and re-extracted with 240 mL of methanol (overall analytical scheme is shown in Figure 1). The methanol layer was removed, filtered, and concentrated using a rotary evaporator. The resulting residue was subsequently diluted in water and freeze-dried twice to obtain the methanol-soluble extract (MSE), which was stored at −20 °C prior to further analysis.

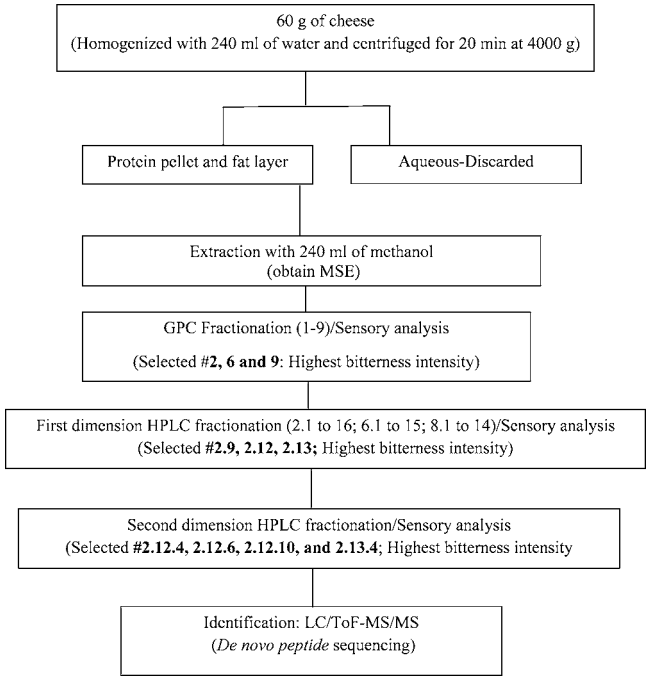

**Figure 1.** Sample preparation scheme and analytical techniques employed for identification of bitter peptides from Cheddar cheese.

**Gel Permeation Chromatography (GPC) Fractionation.** A total of 1 g of MSE was dissolved in 10 mL of nanopure water/methanol (1:1) and separated by size-extrusion gel permeation chromatography (100 × 2.6 cm). The GPC system consisted of a binary solvent delivery system (Shimadzu, LC-8A), a manual injector (SIL-10vp), a variable-wavelength ultraviolet−visible (UV−vis) detector (Shimadzu, SPD-10A), and a Sephadex G-15. Chromatographic separation was performed using isocratic elution, with a mobile phase comprising of 1:1 (50/50%) water and methanol and a flow rate of 5 mL/min. The effluent was collected into nine fractions, and the corresponding fractions (termed 1−9) obtained from several runs were pooled and liberated from solvent (freeze-dried 2×). The resulting residues obtained were then dissolved in water (10 mL) and evaluated for bitterness intensity by sensory analysis.

**First-Dimensional (1D) HPLC Fractionation.** Bitter fractions 2, 6, and 8 identified after the sensory screening of GPC isolates were selected and underwent further separation using a HPLC system coupled with a semi-preparative diphenyl column (250 × 10 mm, pursuit 5, Varian, Palo Alto, CA). The mobile phase comprised of water with 0.1% formic acid at pH 2.5 (A) and methanol (B) at a flow rate of 3 mL/min. The employed linear gradient was as follows: starting at 10% B in A (0−15 min), increasing to 20% B in A (15−25 min), increasing to 70% for 5 min (25−35 min), increasing to 100%, held for 5 min (35−40 min), and back to initial conditions. Total subfractions collected for fraction 2 were 16 (2.1−16); total subfractions collected for fraction 6 were 15 (6.1−15); and total subfractions collected for fraction 8 were 14 (8.1−14). All subfractions were liberated from solvent (freeze-dried 2×) and dissolved in distilled water (10 mL) for subsequent sensory analysis.

**Second-Dimensional (2D) HPLC Fractionation.** Bitter fractions 2.9, 2.12, and 2.13 were selected (had the highest perceived bitterness intensity from first-dimension HPLC fractionation) and were subjected to additional chromatography using a reverse-phase C18 column (250 × 10 mm, pursuit 5, Varian, Palo Alto, CA). The mobile phase was monitored at 220 nm and consisted of a series of linear gradients of solvent A (water with 0.1% formic acid) and solvent B (methanol) starting at 10% B (0−15 min), increasing to 20% B (15−25 min), increasing to 100% B (25−35 min), held for 5 min, and back to initial conditions. Total subfractions collected for 2.9 were 14 (2.9.1−2.9.14); total subfractions collected for 2.12 were 14 (2.12.1−2.12.14); and total subfractions collected for 2.13 were 14 (2.13.1−2.13.14). All subfractions were liberated from solvent (freeze-dried 2×) and dissolved in distilled water (10 mL) for subsequent sensory analysis.

**Liquid Chromatography−Mass Spectrometry/Quadrupole Time-of-Flight−Electrospray Ionization (LC−MS/Q-TOF−ESI) (*De Novo* Peptide Sequencing).** Peptide sequences were analyzed using an Acquity ultra-performance liquid chromatography (UPLC) system coupled with a Waters Q-TOF G2 mass spectrometer equipped with an ESI probe, run in positive mode. The UPLC system consisted of a degasser, binary pumping system, autosampler, column heater, and a reverse-phase C18 column (XBridge RP18 column, 2.5 $\mu$m, 50 × 2.1 mm). Mass spectrometric ionization conditions were as follows: desolvation temperature, 400 °C; source temperature, 120 °C; and capillary voltage, 3 kV. For scan mode, the range of $m/z$ was 100−2300, and for daughter ion analysis, a collision energy ramp was used, ramping from 40 to 120 eV.

**Purification of Synthetic Peptides.** Purchased synthetic peptides were purified prior to use for sensory analysis. The individual peptides were dissolved in water and purified by preparative HPLC. The preparative HPLC system (Shimadzu, Baltimore, MD) consisted of a binary solvent delivery system (LC-8A), a manual injector, and a variable-wavelength UV−vis detector (SPD-10A) coupled with a preparative reverse-phase C18 column (250 × 21.2 mm, pursuit 5, Varian, Palo Alto, CA). The mobile phase was monitored at 220 nm and consisted of a series of linear gradients of solvent A (water) and solvent B (methanol), starting at 10% B (0−5 min), increasing to 95% B (5−25 min), increasing to 100% B (25−26 min), held for 5 min, and back to initial conditions. The purified peptides were freeze-dried twice to remove all traces of solvent prior to use.

**Quantification of Peptides in Mild and Sharp Cheddar Cheese.** Analysis was performed on mild and sharp Cheddar cheese. The cheese sample (30 g) was combined with water (120 mL), and leucine enkephalin was added (5 mg/kg of cheese) as the internal standard (IS). The mixture was homogenized for 5 min and then centrifuged at 10000*g* for 20 min. The supernatant was collected, and the pH was adjusted by formic acid addition (pH ≤ 4.6). The sample

dx.doi.org/10.1021/jf5020654 | J. Agric. Food Chem. 2014, 62, 8034−8041

was recentrifuged at 10000*g* for 20 min, and the supernatant was again collected, pooled, and filtered through a paper filter (Whatman No. 4, Whatman, Ltd., Pittsburgh, PA). The filtrate was then concentrated and desalinized by solid-phase extraction prior to quantification. Briefly, 6 mL of extract was loaded onto a pre-conditioned C-18 SPE cartridge (500 mg of DSC-18 Supelco). The cartridge was then washed with 4 mL of a 98% water, 2% acetonitrile, and 0.1% formic acid solution to remove salt, and the peptides were then eluted using 1 mL of a 40% water, 60% acetonitrile, and 0.1% formic acid solution. Recovery studies were also performed to test the efficiency of the extraction protocol. Target peptides (YQEPVLGPVRGPFPI, GPVRGPFPIIV, MPFPKYPVEPF, PVLGPVRGPFP, MAPKHKEMPFPKYPVEPF, and APHGKEMPFPKYPVEPF) were added in cheese at appropriate concentrations along with water and an IS solution prior to homogenization, and the same extraction procedure was followed. Recovery extractions were performed in triplicate for each sample.

For quantification, the mass spectrometer was operated in positive-ion mode and the spectra were collected by multiple reaction monitoring (MRM). Six-point calibration curves (0.5−200 mg/L) were constructed from corresponding ion transitions of each peptide. Leucine enkephalin was used as an IS and monitored at an ion transition of 556 → 136. Quantitative analysis was performed in triplicate. MRM analysis was performed with Waters Acquity UPLC (column oven, binary solvent manager, sample manager, and a RP-C18 Acquity UPLC HSS T3 1.8 $\mu$m, 2.1 × 100 mm column) coupled with Waters triple-quadruple mass spectrometer (Quattro Premier XE) equipped with an ESI probe. Mass spectrometric ionization conditions were as follows: desolvation temperature, 350 °C; source temperature, 120 °C; and capillary voltage, 3 kV. MRM ion transitions were optimized for each peptide and were as follows: YQEPVLGPVRGPFPI, 835.10 → 136.04; GPVRGPFPIIV, 577.12 → 462.04; MPFPKYPVEPF, 677.05 → 263.31; PVLGPVRGPFP, 569.10 → 169.04; MAPKHKEMPFPKYPVEPF, 726.06 → 263.32; and APHGKEMPFPKYPVEPF, 658.72 → 263.32.

*Precaution Taken for Sensory Analysis of Food Fractions and Taste Compounds.* To remove solvent and buffer compound traces from all fractions isolated from Maillard−catechin reaction models and cocoa, prior to sensory testing, volatiles in each fraction were removed by rotary evaporation and, subsequently, freeze-dried twice. Gas chromatography/mass spectrometry (GC/MS), proton nuclear magnetic resonance ($^1$H NMR), and high-performance ion chromatography revealed that fractions treated by the above protocol are free of solvents and buffer compounds and suitable for sensory analysis.

*Sensory Analysis: Bitterness Intensity of Chromatographic Fractions (GPC, 1D HPLC, and 2D HPLC).* Panelists (five healthy adults, with no history of tasting problems) evaluated the bitterness of the fractions. Bitterness was rated on a 15-point line scale. Four references were provided to panelists [0.03, 0.08, and 0.15% (w/v) caffeine in water], corresponding to bitterness intensity ratings of 2, 5, and 10, respectively. Panelists were asked to avoid eating or drinking 2 h before sensory evaluation. Samples were presented in a randomized order at room temperature in coded 1 oz cups.

*Sensory Analysis: Cheese Samples and Taste Recombination Models.* A trained sensory panel consisting of eight panelists (ages 22−34) evaluated the bitterness intensity of mild and sharp commercial Cheddar cheese samples as well as a recombination "sharp Cheddar model" consisting of mild Cheddar with added purified peptides at levels quantified in sharp Cheddar cheese.

Cheddar cheese was weighted, cubed, and added to a food processor. The food processor was pulsed until cheese pieces were pea-sized. Water (control samples) or peptide solution was added at 1 mL/29 g of cheese, to make a 30 g sample. Cheese and water were mixed until the sample was homogeneous and smooth. A total of 5 g (±0.2) of this cheese was weighed and rolled into a ball, put into a coded sample cup, and covered immediately. All evaluations were conducted with nose clips. Panelists were trained to evaluate bitter taste intensity using caffeine solutions as references. Two reference levels were provided to panelists [0.05 and 0.08% (w/w) of caffeine in water], corresponding to bitterness intensity ratings of 2 and 5, respectively. The performance of a panelist was evaluated by analysis of variation (ANOVA, Statistix 9.0, Analytical Software, Tallahassee, FL). The bitterness and astringency intensity of each individual peptide and a peptide mixture were also evaluated at the corresponding concentrations in water solutions.

*Sensory Analysis: Difference from the Control.* Eight experienced sensory panelists, who regularly consumed Cheddar cheese, were asked to evaluate the size of the overall sensory difference between the commercial sharp Cheddar (control) compared to the sharp model and mild Cheddar cheese. The samples were evaluated in duplicate on a 15-point line scale anchored with "no difference" and "extremely different". The three sample evaluated were (1) the recombination "sharp Cheddar model" consisting of mild Cheddar with added purified peptides at levels quantified in sharp Cheddar cheese, (2) mild Cheddar cheese, and (3) blind control (sharp Cheddar). A Dunnett's test for multiple comparisons with a control was applied to the sample means. Statistix 9.0 (Analytical Software, Tallahassee, FL) was used for analysis.

## RESULTS AND DISCUSSION

A number of extraction protocols have been developed for the analysis of tastants and more specifically for extraction of bitter peptides from cheese matrixes,[1,6,8,9] with water being the most common solvent used. In the current study, the initial water-soluble extract obtained from sharp Cheddar cheese was excessively salty, thus masking the bitter taste attributes. Hence, an alternative extraction method using methanol was developed and implemented (Figure 1) to facilitate initial sensory screening and determine the bitterness profile of mild and sharp Cheddar cheese samples.

The MSE of Cheddar cheese was freeze-dried twice, redissolved at 10% (w/v), and then evaluated for bitterness by trained panelists. The mean bitterness rating of the MSE was 6 (slightly higher than a 0.08% caffeine solution). The MSE was subsequently separated by GPC (see Figure 2). Nine distinct

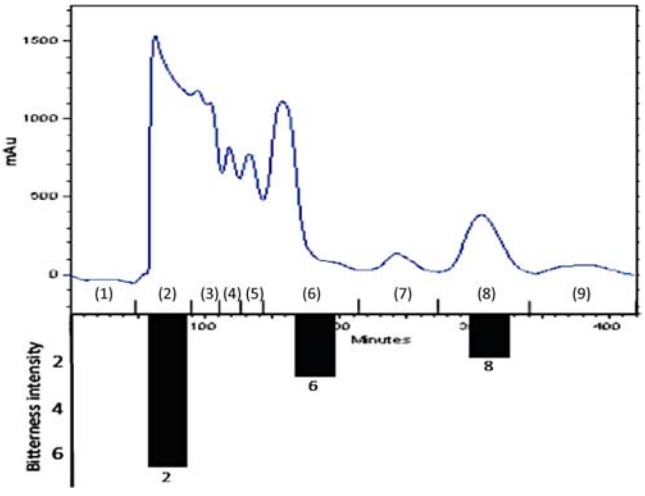

**Figure 2.** GPC chromatogram of Cheddar cheese isolate and the taste intensity chromatogram. Nine fractions were collected (shown in brackets); the fractions with the highest perceived bitter intensity (2, 6, and 8) are illustrated and selected for further investigation.

fractions were obtained and evaluated by a sensory panel. Fractions 2, 6, and 8 were identified as bitter, with average intensity ratings of 6, 2.5, and 1.5 and yields of 8, 12.5, and 15.8%, respectively (Figure 2). On the basis of the intensity of bitterness ratings of these fractions, fraction 2 was selected for further investigation.

dx.doi.org/10.1021/jf5020654 | J. Agric. Food Chem. 2014, 62, 8034−8041

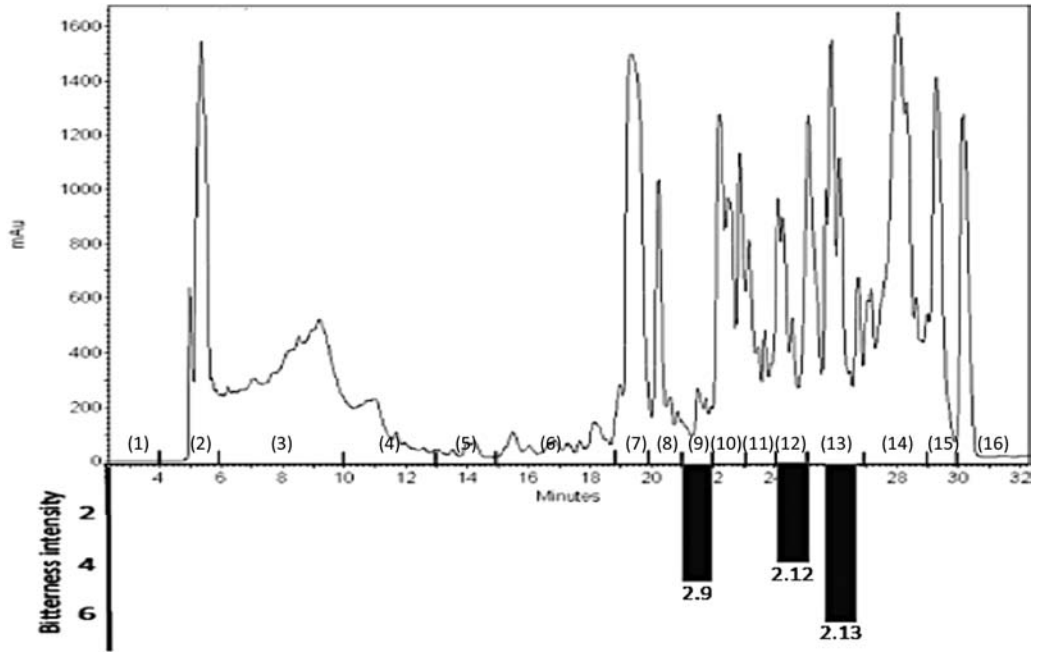

**Figure 3.** HPLC second-dimension chromatogram of fraction 2 obtained from GPC. A total of 16 subfractions of fraction 2 were collected (shown in parentheses); the fractions with the highest perceived bitter intensity (2.9, 2.12, and 2.13) are illustrated and selected for further investigation.

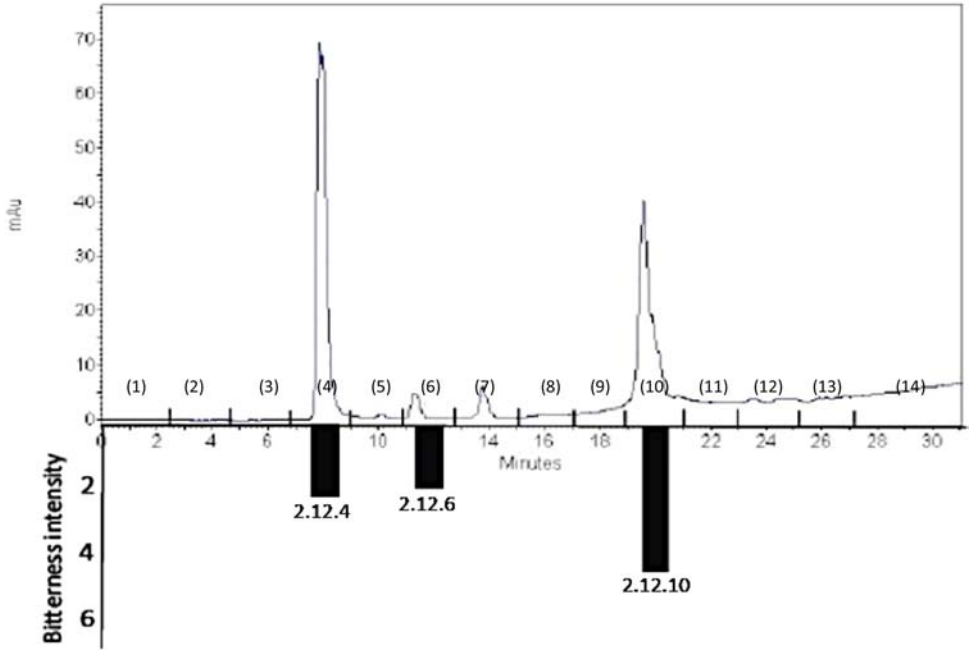

**Figure 4.** Third-dimension HPLC chromatogram of fraction 2.12 obtained from HPLC second-dimension chromatogram. A total of 14 subfractions of fraction 2.12 were collected (shown in parentheses); the fractions with the highest perceived bitter intensity (2.12.4, 2.12.6, and 2.12.10) are illustrated and selected for further investigation.

To decrease the complexity of the GPC isolated bitter-tasting fractions and facilitate identification of the underlying bitter compounds, fraction 2 was further separated using a HPLC system coupled with a diphenyl preparative column in 16 subfractions (see Figure 3). Six of the isolates (2.4, 2.9, 2.11, 2.12, 2.13, and 2.14) were identified as bitter. The fractions with the highest bitter intensity were 2.9, 2.12, and 2.13, corresponding to mean ratings of 4.5, 4, and 6. The remaining fractions (2.14, 2.11, and 2.4) were rated at 0.5 or threshold bitterness and, thus, were not selected for further investigation.

The three main bitter subfractions (2.9, 2.12, and 2.13) were subsequently analyzed by LC−MS, which revealed that more than one predominate peptide was present in each of the selected fractions. Consequently, the fractions were further purified by HPLC using a C-18 semi-preparative column. From this second HPLC separation, 16 fractions were obtained from fraction 2.9 (2.9.1−16) and 2 fractions were reported to be bitter (2.9.9 and 2.9.12). Similarly, 13 fractions were obtained from fraction 2.12 (2.12.1−13), and 12 fractions were obtained from 2.13 (2.13.1−12). Of those, 5 fractions (2.12.4, 2.12.5,

dx.doi.org/10.1021/jf5020654 | J. Agric. Food Chem. 2014, 62, 8034−8041

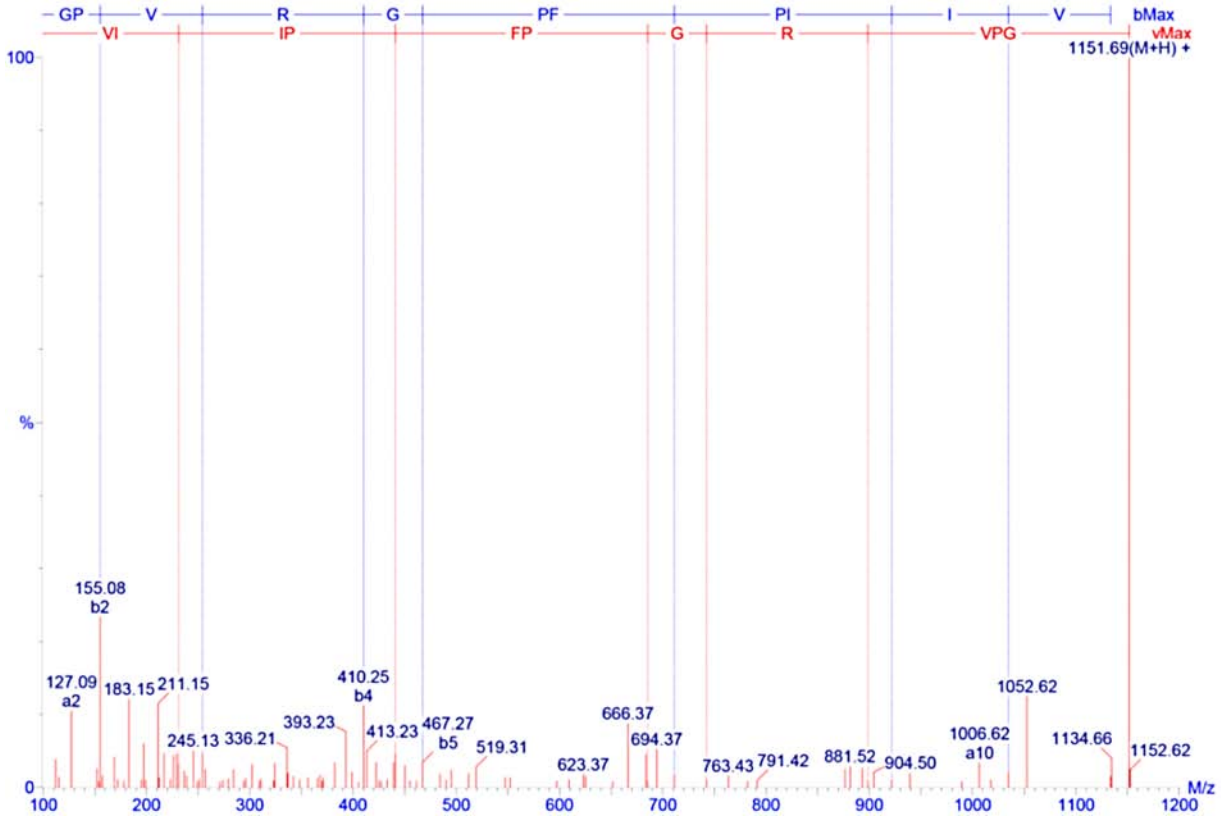

**Figure 5.** MS/MS ESI$^+$ spectra for *de novo* sequence determination of bitter peptide GPVRGPFPIIV.

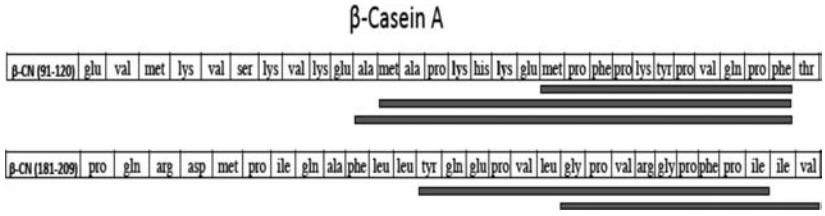

**Figure 6.** $\beta$-CN(91−120) and $\beta$-CN(181−209) sequences of bovine $\beta$-CN and assignment of bitter peptides (black lines) identified in sharp Cheddar cheese.

2.12.6, 2.12.9, and 2.12.10) and 4 fractions (2.13.3, 2.13.4, 2.13.8, and 2.13.9) were found to be bitter, respectively. An example chromatogram of fraction 2.12 is presented in Figure 4. The bitter intensity of the collective resultant fractions ranged from 4 to 0.5, with the highest ratings reported for 2.12.4, 2.12.6, 2.12.10, and 2.13.4.

These four fractions were subsequently analyzed by *de novo* peptide sequencing techniques by time-of-flight tandem mass spectrometry (TOF MS/MS). A total of 12 main peptide candidates were identified as YQEPVLGPVRGPFP, GPVRGPFPIIV, MAPKHKEMPFPKYPVEPF, QEPVLGPVREGPFP, APKHKEMPFPKYPVEPF, YQEPVLGPVRGPFPI, EPVLGPVRGPFP, QEPVLGPVRGPFPI, EMPFPKYPVEPF, LGPVRGPFP, PVLGPVRGPFP, and MPFPKYPVEPF. An example of MS/MS ESI$^+$ spectra of peptide GPVRGPFPIIV is shown in Figure 5. The sequence alignment of the above peptides identified in this study revealed that they originate from $\beta$-CN, as showed in Figure 6, which is in agreement with previous studies.[4,5,12]

Initial sensory screening of synthetic purified peptides revealed that GPVRGPFPIIV, YQEPVLGPVRGPFPI, MPFPKYPVEP, MAPKHKEMPFPKYPVEPF, and APHGKEMPFPKYPVEPF were bitter and, thus, were selected for further examination and taste recombination experiments to determine their overall sensory impact in Cheddar cheese. The five identified bitter peptides are hydrolysis products derived from the $\beta$-CN(91−120) and $\beta$-CN(181−209) sequence regions of bovine $\beta$-CN. Peptides YQEPVLGPVRGPFPI and GPVRGPFPIIV correspond to the following $\beta$-CN sequences, $\beta$-CN(193−207) and $\beta$-CN(199−209), and they are similar to bitter peptides previously identified in Gouda cheese.[8,9] The formation of $\beta$-CN(193−209) can be assigned to the hydrolytic action of chymosin that is responsible for the initial hydrolyisis of $\beta$-CN, yielding three peptides, $\beta$-I, $\beta$-II, and $\beta$-III, produced by cleavage of bonds 192−193 and/or 189−190, 163−164, and/or 165−166, and/or 167−168 and 139−140, respectively.[16−18] In addition to chymosin action, which mainly takes place during the initial stages of cheesemaking, the generation of $\beta$-CN(193−209) can be attributed to the hydrolytic action of the cell envelope proteinase (CEP) of *Lactobacillus* sp. because Leu192−Tyr193 is a known cleavage site of CEP in Cheddar cheese.[19] This peptide [$\beta$-CN(193−209)] has been

[a]Analysis conducted in triplicate; mean recovery ± standard error.

**Table 2. Mean Concentration of Select Bitter Peptides in Mild and Sharp Cheddar Cheese[a]**

| peptide | mild Cheddar (concentration ± error) (mg/kg) | sharp Cheddar (concentration ± error) (mg/kg) |
|---|---|---|
| MPFPKYPVEPF | 38.6 ± 2.9 | 69.8 ± 4.3 |
| GPVRGPFPIIV | 5.1 ± 0.4 | 146.4 ± 14.1 |
| MAPKHKEMPFPKYPVEPF | 37.9 ± 2.7 | 33.8 ± 2.7 |
| APHGKEMPFPKYPVEPF | ND | 1.7 ± 0.1 |
| YQEPVLGPVRGPFPI | 1.9 ± 0.2 | 5.8 ± 0.6 |

[a]Analysis conducted in triplicate; mean recovery ± standard error.

previously classified as extremely bitter, and studies have shown that fragments within that sequence exert significant bitterness as well. For example, fragment β-CN(202−209) has been reported to have a low bitterness threshold. Our findings support the contribution of the β-CN(193−209) region to perceived bitterness in aged Cheddar cheese. The formation of peptides MAPKHKEMPFPKYPVEPF [β-CN(102−119)] and APHGKEMPFPKYPVEPF [β-CN(103−119)] can likewise be attributed to chymosin action as well as the CEP of *Lactobacillus* sp. because $Ala^{101}$−$Met^{102}$ is a known cleavage site.[19] Moreover, peptide MPFPKYPVEPF [β-CN(109−119)] has also been previously identified in Gouda cheese,[20] and its formation can be attributed to plasmin, because $Lys^{108}$−$Gly^{109}$ has been identified as a cleavage site of this enzyme.[21]

For quantification, LC−MS/MS−ESI methods were developed for each peptide and ion transitions, and optimized conditions of MRM methods were determined. Six-point calibration curves for each peptide were constructed, exhibiting good linearity within a concentration range of 0.5−200 mg/kg and regression coefficients ranging from 0.960 to 0.999. On the basis of previous reports,[6,22] water extracts have typically been used for isolation and identification of taste components from Cheddar cheese. Thus, an aqueous extraction protocol was developed, and its efficiency was evaluated by performing recovery experiments. Results obtained from peptide spiking experiments and subsequent water extraction demonstrated that mean recovery was between 49.1 and 70.6% (±6.1−9.6%) depending upon the peptide (Table 1), suggesting that water extraction is not a quantitative method of extraction and can lead to underestimation of the levels of peptides present in cheese samples if percent recovery is not considered with the quantification method. Such an underestimation can lead to inaccurate construction of recombination models as well as incorrect conclusions regarding the sensory impact of identified taste active compounds.

The concentrations of the five bitter peptides were determined for both mild and sharp Cheddar cheese and are shown in Table 2. Overall results correlated well with the observed taste profile differences between mild and sharp Cheddar cheese (Table 2). Sharp Cheddar was rated as significantly higher in bitterness compared to mild Cheddar. That was depicted in the concentration of bitter peptides, as GPVRGPFPIIV, YQEPVLGPVRGPFPI, and MPFPKYPVEP increased during maturation by 28.7-, 3.1-, and 1.8-fold, respectively. Additionally, peptide APHGKEMPFPKYPVEPF was only found in quantifiable concentrations in the sharp Cheddar cheese sample, confirming that it was generated during the maturation process. The concentration of peptide MAPKHKEMPFPKYPVEPF was not statistically different between the two samples, indicating that maturation is not responsible for the generation of this bitter compound (Table 2).

To correlate analytical results with sensory impact of identified bitter peptides, taste re-engineering experiments were performed. A model sharp Cheddar was made by spiking appropriate concentrations of the identified peptides in mild Cheddar cheese, and a descriptive analysis study of the bitterness intensity of the samples was conducted. The results confirmed that the perceived bitterness of the sharp Cheddar recombination model was not significantly different [least significant difference (LSD) all-pairwise comparison of 0.46 at 5% significance level] when compared to a commercial sharp Cheddar sample with mean ratings of 1.89 and 1.58, respectively (Table 3). For comparison, the bitterness of the mild Cheddar was reported to be significantly lower than the sharp Cheddar as expected and indicated the importance of aging for the development of this taste attribute.

**Table 3. Mean Bitterness Intensity of Sharp and Mild Cheddar Cheese and a Sharp Cheddar Model Cheese[a]**

| sample | mean rating |
|---|---|
| sharp Cheddar (6 months) | 1.89 a |
| sharp Cheddar model | 1.58 a |
| mild Cheddar (3 months) | 1.07 b |

[a]Eight panelists in duplicate. Samples with different letters within a column are significantly different at $p < 0.05$.

To further evaluate the contribution of the individual peptides to the overall bitterness perception, the bitterness intensity of each peptide as well as a peptide mixture at levels found in sharp Cheddar were determined in water solutions (Table 4). Overall, each of the five peptides was reported to be above the bitter recognition taste threshold values. Peptide

**Table 4. Mean Bitterness Intensity of Each Peptide and the Peptide Mixture Dissolved in Water at Levels Quantified in Sharp Cheddar Cheese[a]**

| peptide | bitterness rating sharp |
|---|---|
| MPFPKYPVEPF | 0.5 ± 0.13 |
| GPVRGPFPIIV | 4.5 ± 0.61 |
| MAPKHKEMPFPKYPVEPF | 0.9 ± 0.20 |
| APHGKEMPFPKYPVEPF | 0.3 ± 0.23 |
| YQEPVLGPVRGPFPI | 0.5 ± 0.15 |

[a]Five panelists in duplicate; mean ± standard error.

GPVRGPFPIIV had the highest contribution to the bitter taste profile of sharp Cheddar cheese, with a mean bitter intensity rating of 4.5. Furthermore, the peptide mixture had a bitterness rating of 5.4 and accounted for 90% of the bitterness intensity of the initial methanol extract of sharp Cheddar. These findings support the relevance of the identified and characterized bitter peptides in the sharp Cheddar sample. This peptide (GPVRGPFPIIV) also provides a more targeted region to monitor bitterness development in Cheddar than the prior used sequences [$\beta$-CN (f193−f209) and $\alpha$(S1)-CN (f1−f9)].[13]

The role of the identified bitter peptides on the overall flavor profile of the sharp Cheddar cheese was also examined using a difference from the control test (see Table 5). The flavor of the

**Table 5. Difference from the Control Test Indicating the Overall Sensory Difference between the Commercial Sharp Cheddar (Control) Compared to the Sharp Cheddar Model (Mild Cheddar Spiked with Appropriate Levels of Bitter Peptides as Sharp Cheese) and Mild Cheddar Cheese[a]**

| sample | mean rating | difference from the control |
|---|---|---|
| sharp Cheddar (blind control) | 3.0 | |
| sharp Cheddar model | 6.2 | 3.3[b] |
| mild Cheddar | 9.4 | 6.5[b] |

[a]Eight panelist in duplicate rated the difference from the control using a 15-point line scale. Data were analyzed by ANOVA, followed by Dunnett's multiple comparisons to the control. [b]Significance at $p < 0.05$.

re-engineered sharp Cheddar cheese model (mild Cheddar cheese spiked with appropriate levels of bitter peptides) was reported to be significantly more similar to commercial sharp Cheddar than it was to mild Cheddar. This observation also indicated the importance of taste and, in this case, bitterness to recognize the characteristic flavor of an aged Cheddar cheese.

Interestingly, the peptides identified in the current study, such as GPVRGPFPIIV, YQEPVLGPVRGPFPI, and MPFPKYPVEPF, have been previously reported to have positive health bioactivities. Peptides GPVRGPFPIIV,[23,24] MPFPKYPVEPF,[20] and YQEPVLGPVRGPFPI[25,26] were found to have antihypertensive actions, with the later also exhibiting antimicrobial activity. This observation is another example of the interplay between bitter taste and beneficial bioactivity.

In summary, bitter peptides in Cheddar were identified and related to the flavor attributes of an aged product. Understanding the molecular drivers of flavor quality provides a basis to develop improved processing technology for flavor optimization.

Supporting Information

**ABSTRACT:** A previous study found that 1-phenylethanol (1PE) was a major endogenous volatile compound in tea (*Camellia sinensis*) flowers and can be transformed to glycosically conjugated 1PE (1PE-Gly). However, occurrences of 1PE-Gly in plants remain unknown. In this study, four 1PE-Glys have been isolated from tea flowers. Three of them were determined as (*R*)-1PE β-D-glucopyranoside ((*R*)-1PE-Glu), (*S*)-1PE-Glu, and (*S*)-1PE β-primeveroside ((*S*)-1PE-Pri), respectively, on the basis of NMR, MS, LC-MS, and GC-MS evidence. The other one was identified as (*R*)-1PE-Pri on the basis of LC-MS and GC-MS data. Moreover, these 1PE-Glys were chemically synthesized as the authentic standards to further confirm their occurrences in tea flowers. 1PE-Glu had a higher molar concentration than 1PE-Pri in each floral stage and organ. The ratio of (*R*) to (*S*) differed between 1PE-Glu and 1PE-Pri. In addition, a 1PE-Gly hydrolase β-primeverosidase recombinant protein produced in *Escherichia coli* exhibited high hydrolysis activity toward (*R*)-1PE-Pri. However, β-primeverosidase transcript level was not highly expressed in the anther part, which accumulated the highest contents of 1PE-Gly and 1PE. This suggests that 1PE-Gly may not be easily hydrolyzed to liberate 1PE in tea flowers. This study provides evidence of occurrences of 1PE-Glys in plants for the first time.

**KEYWORDS:** *glucopyranoside, 1-phenylethanol, primeveroside, primeverosidase, stereochemistry, tea flower*

## INTRODUCTION

Plants synthesize and emit a large variety of volatile organic compounds, which possess extremely important ecological functions. The volatile compounds can also be converted from free forms to glycosidically bound forms, which are more water-soluble and less reactive than their free aglycone counterparts.[1] Many glycosylated volatile compounds have been isolated and identified in various plant species or plant-derived foods. In many cases, alcoholic volatiles such as benzyl alcohol, 2-phenylethanol, methyl salicylate, (*Z*)-3-hexenol, linalool, linalool oxides, and geraniol can be transformed to glycosidically bound form.[2−6] Besides alcoholic volatile compounds, some nonalcoholic volatile compounds such as benzaldehyde, coumarin, and damascenone were found to occur as glycosidically bound form, and these glycosidically bound volatile compounds take more steps than the glycosidically bound alcoholic volatiles to release free volatile compounds.[7−9] The glycosylated volatile compounds are involved in diverse events in plants. For example, when plants are exposed to stresses or affected by environmental factors, the glycosylated volatile compounds can be hydrolyzed to release free volatile compounds, which are involved in the plant defense system.[10] Another example is that the glycosylated volatile compounds are related to regulation of emission of floral volatiles.[11] In our previous study, we found that 1-phenylethanol (1PE) was a major endogenous volatile compound in tea (*Camellia sinensis*) flowers, whereas only a little 1PE was emitted from the flowers.[12] This may be because 1PE was transformed to glycosically conjugated 1PE (1PE-Gly). However, occurrences of 1PE-Gly in plants remain unknown.

There is extensive literature on human health benefits of tea leaves and their bioactive compounds. Recently, tea flowers have attracted increasing interest of researchers. One reason is that tea flowers are an abundant and nonutilized resource; for example, over 1.8 billion kilograms of tea flowers are available annually in China.[13] Another reason is that tea flowers contain many bioactive compounds including catechins, caffeine,[14] floratheasaponins,[15−17] flavonol glycosides,[18] polysaccharides,[19] amino acids,[20] spermidine derivatives,[21] and volatile compounds.[12,22] In the present study, four glycosylated volatile compounds including (*R*)-1PE-β-D-glucopyranoside ((*R*)-1PE-Glu), (*S*)-1PE-Glu, (*R*)-1PE-β-primeveroside ((*R*)-1PE-Pri), and (*S*)-1PE-Pri were first identified in tea flowers. Moreover, the four 1PE-Glys were chemically synthesized for the first time to further confirm their occurrences in tea flowers, although the

enzymatic syntheses of 1PE-Gly by cultured plant cells have been reported previously.[23−25] In addition, β-primeverosidase, one of 1PE-Gly hydrolases, transcript level was not highly expressed in the anther part, which accumulated the highest contents of 1PE-Gly and 1PE. This suggests that 1PE-Gly may not be easily hydrolyzed to liberate 1PE in tea flowers.

## MATERIALS AND METHODS

**Chemicals.** D-Xylose and triphenylmethyl chloride were purchased from Tokyo Chemical Industries Co., Ltd., Japan. Ethyl *n*-decanoate, $CDCl_3$ (99.8 atom % D + 0.03% v/v tetramethylsilane (TMS)), and organic solvents used for chemical synthesis were purchased from Kanto Chemical Co. Inc., Japan. *N*-Methyl-*N*-(trimethylsilyl)-trifluoroacetamide (MSTFA) was purchased from Regis Chemical Co., USA. (*R*)-1PE, (*S*)-1PE, $CD_3OD$ (99.8 atom % D + 0.05% v/v TMS), $CD_3COCD_3$ (99.9 atom % D + 0.05% v/v TMS), and reagents used for chromatography analysis and chemical synthesis were purchased from Wako Pure Chemical Industries Ltd., Japan. Polyvinylpolypyrrolidone (PVPP), XAD-2, isopropyl-β-D-thiogalactopyranoside (IPTG), HBr/AcOH, β-glucosidase, and Spectrum Plant Total RNA Kit were purchased from Sigma-Aldrich Co. Ltd., USA. β-Primeverosidase was purchased from Amano Enzyme Inc., Japan. ODS-C18 was purchased from Chemco Scientific Co., Ltd., Japan. Sep-PakVac 6 $cm^3$ was purchased from Waters Corp., USA. Coomassie Blue R250, 30% acrylamide/Bis solution, *N*,*N*,*N*′,*N*′-tetramethylethylenediamine (TMEMD), sodium dodecyl sulfate (SDS), and 2× SYBR Green Universal PCR Mastermix were purchased from Bio-Rad Laboratories, USA. Ni-NTA resin was purchased from Qiagen Inc., USA. Enterokinase was purchased from Novagen, MERCK Eurolab, Germany. Quick RNA Isolation Kit was purchased from Huayueyang Biotechnology Co., Ltd., China. PD-10 desalting column was purchased from GE Healthcare Life Sciences, USA.

**Plant Materials.** The flowers of *C. sinensis* var. Jinxuan were obtained from tea fields at the South China Agricultural University (Guangzhou, China) between October and November 2012 and 2013. As described in our previous study,[12] flower development was divided into three stages: at stage 1 the flower buds are closed, at stage 2 the flower is half open, and at stage 3 the flower is fully open. In addition, the flowers at stage 3 were divided into four parts including petals, filaments, anthers, and other parts. The "other parts" comprise a mixture of carpels, receptacles, sepals, and pedicels.

**Isolation and Purification of 1PE-Gly from Tea Flowers.** Figure S1 (Supporting Information) shows a brief flowchart of the isolation and purification of 1PE-Gly from tea flowers. Eight hundred grams (fresh weight) of the flowers was extracted with 3 L of 80% ethanol overnight at 4 °C and then centrifuged at 17000*g* and 4 °C for 20 min. The supernatant was filtered, and the filtrate was concentrated to 500 mL by a rotary evaporation. Forty grams of PVPP was added to the concentrated filtrate to remove polyphenols. The mixture was stirred at 4 °C for 60 min and then centrifuged at 17000*g* and 4 °C for 20 min. Twenty grams PVPP was added to the supernatant, stirred at 4 °C for 30 min, and then centrifuged again at 17000*g* and 4 °C for 20 min. The resultant supernatant was extracted with 300 mL of $CHCl_3$ three times. The aqueous fraction was evaporated to remove $CHCl_3$ residue and diluted with Milli-Q water to 600 mL. The diluted solution was passed through an XAD-2 column (about 600 mL, i.d. 6 cm × 21 cm) and then eluted with 3 L of Milli-Q water and 3 L of methanol, successively. The methanolic eluate was concentrated to dryness and dissolved in 120 mL of 5% methanol. The 5% methanol-soluble solution was passed through an ODS-C18 open column (60 mL, i.d. 2.4 cm × 13.3 cm) and eluted with 120 mL of 25% methanol, 120 mL of 50% methanol, and 120 mL of 100% methanol, successively. The 50% MeOH/methanolic eluate was concentrated to dryness, dissolved in 1.5 mL of 16% MeCN, and then subjected to the first preparative HPLC (LC pump, Jasco PU-980; detector, 875-UV; solvent mixing module, Jasco LG-1580-02; degasser, Jasco DG-1580-53; column oven, Jasco CO-965; Jasco, Tokyo, Japan) isolation. The first preparative HPLC used a Capcell Pak C18 reversed-phase column (20 mm × 250 mm, 5 μm particle size, Shiseido Co. Ltd., Japan) with 16% MeCN as mobile phase, at 254 nm and a flow rate of 10 mL/min. The injection volume was 100 μL/isolation. Each collection volume was 10 mL/fraction. The obtained fractions 14 and 15 (RT 18−20 min) were subjected to the second preparative HPLC isolation, for which conditions were the same as for the first preparative HPLC isolation. The obtained fraction 6 (RT 17−18 min) was subjected to the third preparative HPLC isolation. The third preparative HPLC used a Capcell Pak C18 reversed-phase column (10 mm × 250 mm, 5 μm particle size, Shiseido Co. Ltd., Japan) with 16% MeCN as mobile phase, at 254 nm and a flow rate of 2.5 mL/min. The injection volume was 50 μL/isolation. The collection volume was 1.25 mL/fraction. The obtained fractions 4−8 were identified to have 1PE-Gly (Figure S2). Fractions 4 and 5 (RT 18.0−19.0 min) and fraction 6 (RT 19.0−19.5 min) were subjected to the recycle HPLC (LC pump, Jasco PU-9986; detector, Jasco 875-UV; Jasco) isolation, respectively. The recycle HPLC used a Capcell Pak C18 reversed-phase column (10 mm × 250 mm, 5 μm particle size, Shiseido Co. Ltd., Japan) with 18% MeCN as mobile phase, at 210 nm and a flow rate of 4.0 mL/min. The injection volume was 50 μL/isolation. Purified disaccharide of (*S*)-1PE and monosaccharide of (*S*)-1PE were obtained from fractions 4 and 5. The disaccharide of (*S*)-1PE and monosaccharide of (*R*)-1PE were obtained from fraction 6. Fractions 7 and 8 (RT 19.5−20.5 min) were subjected to the further preparative HPLC isolation to obtain the purified monosaccharide of (*R*)-1PE. The HPLC used a Capcell Pak C18 reversed-phase column (10 mm × 250 mm, 5 μm particle size, Shiseido Co. Ltd., Japan) with 18% MeCN as mobile phase, at 210 nm and a flow rate of 2.5 mL/min. The injection volume was 50 μL/isolation.

**Determination of 1PE-Gly Isolated from Tea Flowers.** *Determination of 1PE-Gly by Enzymatic Hydrolysis Combined with GC-MS Analysis during the Isolation.* The enzymatic hydrolysis combined with GC-MS analysis method is the same as described by Dong et al.[12] The isolated fraction (50 μL) as shown above was concentrated in a vacuum, dried under nitrogen gas, redissolved in 0.4 mL of 50 mM citric acid buffer (pH 6.0) containing 10 mg of β-primeverosidase (1.12 unit) and 0.6 mg β-glucosidase (from almonds, 3.12 unit), and allowed to react at 37 °C for 14 h. Sodium chloride (144 mg) was added to the reaction solution, which was allowed to stand for 15 min. Afterward, 5 nmol of ethyl *n*-decanoate as an internal standard was added. The solution was extracted with 0.4 mL of hexane/ethyl acetate (1:1) and centrifuged (16400*g*, 4 °C, 3 min), and the supernatant was dried over anhydrous sodium sulfate. The samples were then analyzed by GC-MS QP5000 (Shimadzu Corp.), which was controlled by a Class-5000 workstation. The temperature of the injector was 230 °C. The GC was equipped with a capillary SUPELCOWAX 10 column (30 m × 0.25 mm i.d., and 0.25 μm film thickness, Supelco Inc., Bellefonte, PA, USA). Helium was used as the carrier gas at a flow rate of 1.6 mL/min. The GC temperature was 60 °C for 3 min, ramped at 40 °C/min to 180 °C followed by 10 °C/min to 240 °C, and then held at 240 °C for 3 min. MS was performed in full scan mode (mass range $m/z$ 70−200).

*Determination of 1PE-Gly by LC-MS Analysis during the Isolation.* To further investigate the molecular weight of the isolated fractions containing 1PE-Gly, the isolated fractions were analyzed by a LCMS-2010 A system (Shimadzu Corp.) equipped with a UG120 C-18 reversed-phase column (2.0 mm × 150 mm i.d., 5 μm particle size, Shiseido Co. Ltd., Japan) with solvent A ($HCOOH/H_2O$, 0.05:99.95, v/v) and solvent B (MeCN), at a flow rate of 0.2 mL/min at 40 °C. A total of 5 μL of the sample solutions was analyzed using a gradient elution. Elution was started under isocratic conditions of 16% of solvent B for 5 min and followed by a linear increase of solvent B to 90% at 10 min and subsequently brought back within 0.5 min to 16% of solvent B and held for another 7.5 min to allow for column equilibration. UV−vis spectra were recorded between 190 and 370 nm for each chromatographic peak. Optimized electrospray operating conditions were as follows: dry gas, 1.5 L/min; capillary voltage, 1.5 kV; dry temperature, 250 °C. MS was performed in full scan mode (mass range $m/z$ 100−500) and SIM mode ($m/z$ 283, 329, 415, and 461).

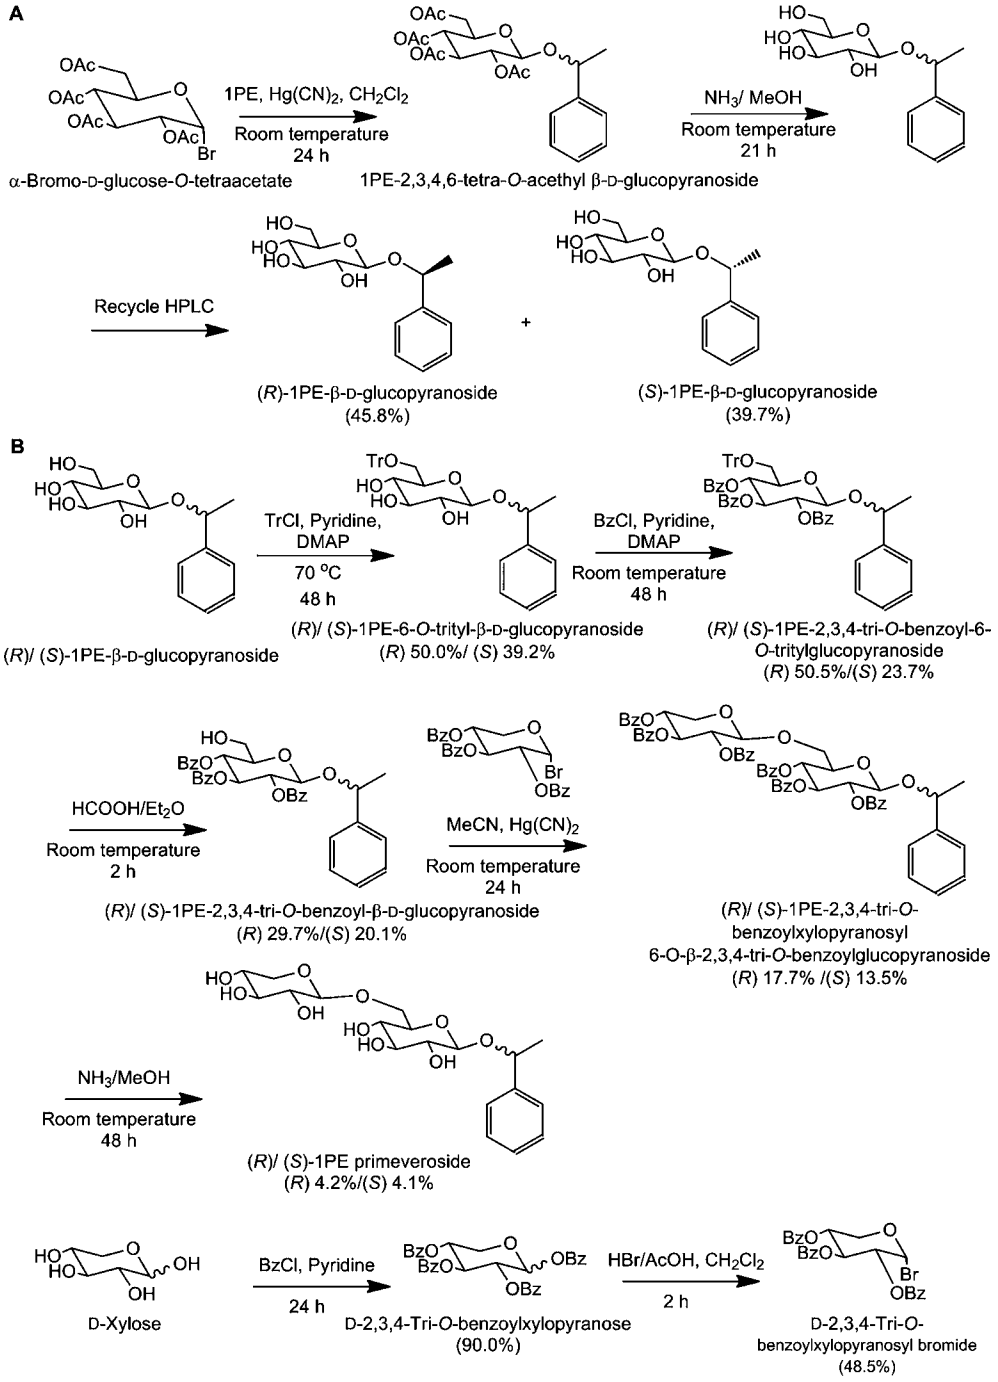

**Figure 1.** Schemes of chemical synthesis of (*R*)/(*S*)-1PE-Glu (A) and (*R*)/(*S*)-1PE-Pri (B).

*Determination of Stereochemistry of 1PE-Gly by LC-MS and GC-MS Analyses.* To determine the stereochemistry of 1PE-Gly, LC-MS was employed to analyze the 1PE-Gly in the crude extract of tea flowers (Supporting Information Figure S3) by comparison with the chemically synthesized authentic standards as shown below. The protocol of LC-MS analysis is shown under Quantitative Analysis of 1PE-Gly. Furthermore, the (*R*)- and (*S*)-1PE obtained from the enzymatic hydrolysis of the isolated fractions containing 1PE-Gly as described above were analyzed by using a GC-MS QP5000 (Shimadzu) equipped with an InertCap CHIRAMIX (30 m × 0.25 mm × 0.25 μm, GL Sciences, Inc., Torrence, CA, USA). Helium was used as the carrier gas at a flow rate of 1.8 mL/min. The temperatures were 40 °C for 5 min, a ramp of 3 °C/min to 180 °C, and then held at 180 °C for 10 min. MS was performed in full scan mode (mass range *m*/*z* 70−200) and SIM mode (*m*/*z* 77, 79, 107 and 122).

*Determination of Chemical Structures of 1PE-Gly by High-Resolution Mass Spectra (HRMS) and NMR.* The purified 1PE-Glys were identified by HRMS (JMS-T100LC AccuTOF mass spectrometer, JEOL, Tokyo, Japan) using polypropylene glycol as an internal standard and NMR (JNM-LA 500 FT-NMR, JEOL, Tokyo, Japan) using $^{1}H$, $^{13}C$, COSY, HSQC, and HMBC with TMS as an internal standard. The MS conditions were as follows: ionization, ESI (positive mode); scan at *m*/*z* 50−550.

As some $^{1}H$ NMR signals of the sugar moiety of the purified 1PE-Gly were overlapped, an acetylation reaction was employed to assign the $^{1}H$ NMR signal. One milligram of the purified 1PE-Gly was dissolved in 100 μL of dehydrated pyridine and 200 μL of dehydrated acetic anhydride. The solution was stirred for 17 h at room temperature. Afterward, toluene was added and then concentrated to

dx.doi.org/10.1021/jf5022658 | J. Agric. Food Chem. 2014, 62, 8042−8050

dryness. The acetylated product was dissolved in $CD_3OD$, and analyzed by $^1H$ NMR (500 MHz).

**Chemical Synthesis of 1PE-Gly.** To further confirm the chemical structures of the isolated 1PE-Gly, we chemically synthesized the (*R*)-1PE-Glu, (*S*)-1PE-Glu, (*R*)-1PE-Pri, and (*S*)-1PE-Pri as authentic standards, on the basis of the method described by Ma et al.[26] The schemes of chemical synthesis of these 1PE-Glys are shown in Figure 1. The detailed chemical synthesis protocol is described in the Supporting Information. The optical rotation of each compound is shown as (*R*)-1PE-Glu $[\alpha]^{29}_D$ +1.00° (*c* 1.0, $CH_3OH$), (*S*)-1PE-Glu $[\alpha]^{29}_D$ −18.01° (*c* 1.1, $CH_3OH$), (*R*)-1PE-Pri $[\alpha]^{21}_D$ −4.24° (*c* 1.3, $CH_3OH$), and (*S*)-1PE-Pri $[\alpha]^{21}_D$ −4.35° (*c* 0.2, $CH_3OH$). Figure S4 shows the UV spectra and HR-MS data.

**Quantitative Analysis of 1PE-Gly.** *Relative Quantitative Analysis of 1PE-Gly by MSTFA Derivatization and GC-MS Analysis.* The crude extract of 1PE-Gly was prepared by using the method described in refs 6 and 12 with a slight modification. Five hundred milligrams (fresh weight, finely powdered) of plant tissues was extracted with 2 mL of cold methanol by vortexing for 2 min followed by ultrasonic extraction in ice-cold water for 10 min. The extracts were mixed with 2 mL of cold chloroform and 0.8 mL of cold water for phase separation, and the resulting upper layer was dried and redissolved in 1 mL of water. The resulting solution was mixed with 30 mg of PVPP, allowed to stand for 90 min, and centrifuged (16400*g*, 4 °C, 10 min). The resultant supernatant was loaded on an Amberlite XAD-2 column and eluted successively with 3 mL of water, 3 mL of pentane/dichloromethane (2:1), and 5 mL of methanol. The methanol eluate was concentrated in a vacuum, dried under nitrogen gas, derivatized with 70 μL of MSTFA and 70 μL of pyridine at 37 °C for 60 min, and then centrifuged. The MSTFA derivates were then analyzed by a GC-MS QP2010 SE (Shimadzu Corp.) equipped with an HP-5 column (30 m × 0.25 mm × 0.25 μm, Agilent Technologies, Germany). The injector temperature was 240 °C, splitless mode was used with a splitless time of 1 min, and helium was the carrier gas with a velocity 1.0 mL/min. The GC temperatures were 80 °C for 2 min, ramp of 15 °C/min to 300 °C, then held at 300 °C for 10 min. The mass spectrometry was operated with full scan mode and SIM mode (see Table S1 in the Supporting Information). *m*/*z* 259 was used as quantifier ion.

*Quantitative Analysis of 1PE-Gly by LC-MS Analysis.* Two grams (fresh weight, finely powdered) of tea flowers at each stage was extracted with 36 mL of methanol containing 5 nmol of *p*-nitrophenyl-Glu (*p*NP-Glu) and 5 nmol of *p*NP-Pri as internal standards. Nine milliliters of methanol extracts was dried and redissolved in 4 mL of water. The solution was loaded on a Sep-PakVac 6 $cm^3$ (1 g) column and eluted successively with 20 mL of water, 60 mL of 25% methanol (in water), and 20 mL of methanol. The 25% methanol eluate was concentrated in a vacuum and dissolved in 500 μL of water. The resultant solution was analyzed by a LCMS-2010 A system (Shimadzu Corp.) equipped with a UG120 C-18 reversed-phase column (2.0 mm × 150 mm i.d., 5 μm particle size, Shiseido Co. Ltd., Japan) with solvent A ($HCOOH.H_2O$, 0.05:99.95, v/v) and solvent B (MeCN) at a flow rate of 0.2 mL/min at 40 °C. A total of 5 μL of the sample solution was analyzed using a gradient elution. Elution was started from a linear increase of solvent B from 5 to 7% at 60 min and held at 7% of solvent B for 15 min. MS was performed in SIM mode (*m*/*z* 329 and 461 for $[M + HCOOH]^-$ of 1PE-Glu and 1PE-Pri, respectively, and *m*/*z* 346 and 478 for $[M + HCOOH]^-$ of *p*NP-Glu and *p*NP-Pri, respectively) (Supporting Information Figure S3).

**Gene Cloning and Recombinant Protein Expression of β-Primeverosidase in *Escherichia coli*.** Finely powdered tea floral tissues (100 mg) were used to isolate RNA, and total RNA was isolated using a Spectrum Plant Total RNA Kit. The first-strand cDNA was synthesized using a Reverse Transcription System (Promega, Madison, WI, USA). The GenBank accession number of β-primeverosidase is AB088027.1. The cDNA coding was amplified by PCR with forward primer 5′-GATATCGCTCAAATCTCCTCCTTC-AAC-3′, containing an *Eco*RV site, and reverse primer 5′-GTCGAC-CTACTTGAGGAGGAATTTCTT-3′, containing a *Sal*I site.[27] The PCR conditions were adjusted as follows: denaturation at 94 °C for 5 min, followed by 35 cycles of 98 °C for 15 s, 54 °C for 15 s, 72 °C for 1 min 30 s, and a final extension at 72 °C for 10 min. The resulting PCR product was purified and subcloned into the pGEM-T vector (Promega) and sequenced to confirm the correctness of ORF. To obtain the mature form of a recombinant protein, the correct ORF was subcloned into pET32a vector (Novagen, Madison, WI, USA) to obtain the expression constructor (pET32a/PRD). After verification by sequencing, the expression constructor was transformed into *E. coli* Rosetta (Novagen) for inducible His-tagged protein expression. Freshly transformed Rosetta cells harboring pET32a/PRD vector were grown at 37 °C to an $OD_{600}$ = 0.6. After the addition of 0.05 mM IPTG, the cultures were grown at 20 °C for another 16 h to produce recombinant His-tagged protein. The cells were harvested at 4000*g* for 10 min and then disrupted by sonication in a 50 mM $NaH_2PO_4$ (pH 8.0) buffer containing 300 mM NaCl and 10 mM imidazole. After centrifugation at 10000*g* for 20 min, the supernatant was collected and purified by using affinity binding on Ni-NTA resin according to the manufacturer's instruction. The partially purified protein was passed through a PD-10 desalting column for further enzyme activity assay.

**SDS-PAGE Analysis.** The *E. coli*-expressed proteins were subjected to SDS-PAGE with the use of a separation gel (2.4 mL of 30% acrylamide/bis(acrylamide), 1.8 mL of Tris-HCl (pH 8.8), 0.07 mL of 10% SDS, 0.07 mL of 10% ammonium persulfate, 2.7 mL of $ddH_2O$, 0.003 mL of TMEMD) and a concentration gel (0.34 mL of 30% acrylamide/bis(acrylamide), 0.25 mL of Tris-HCl (pH 6.8), 0.02 mL of 10% SDS, 0.02 mL of 10% ammonium persulfate, 1.4 mL of $ddH_2O$, 0.002 mL of TMEMD). After completion of electrophoresis, the proteins were stained with Coomassie Blue R250 for at least 3 h and then decolored three times.

***E. coli*-Expressed β-Primeverosidase Assay.** To identify the *E. coli*-expressed β-primeverosidase activity, (*R*)-1PE-Glu, (*S*)-1PE-Glu, (*R*)-1PE-Pri, and (*S*)-1PE-Pri were selected as substrates. The reaction mixture contained 5 μg of substrate, 350 μL of 20 mM sodium citrate buffer (pH 5.0), and 10 μg of partially purified protein. The reactions were incubated at 37 °C for 10 h. After cooling to room temperature, the reaction mixture was extracted with 400 μL of hexane/ethyl acetate (1:1). The upper phase was dried over anhydrous sodium sulfate, and 1 μL of the extract was subjected to GC-MS analysis. Samples were analyzed using a GC-MS QP2010 SE (Shimadzu Corp.) equipped with a SUPELCOWAX 10 column (30 m × 0.25 mm × 0.25 μm, Supelco Inc.). The injector temperature was 240 °C, splitless mode was used with a splitless time of 1 min, and helium was the carrier gas with a velocity 1.0 mL/min. The GC temperatures were 60 °C for 3 min, ramp of 40 °C/min to 180 °C followed by 10 °C/min to 240 °C, and then held 240 °C for 5 min. The mass spectrometer was operated with SIM mode (*m*/*z* 77, 79, 107, 122). 1PE was identified by comparing its retention times and mass spectra with those of authentic compound.

**Transcript Expression Analysis of β-Primeverosidase.** Total RNA was isolated immediately after dissection (Fast Plant Total RNA Kit). Ten times-diluted reverse-transcribed cDNA was subjected to qRT-PCR analysis. The qPCR primers for β-primeverosidase were 5′-TGCCTCTTCTGCCTACC-3′ (sense) and 5′-TGTTCACTCCTC-CGCTAA-3′ (antisense). The qPCR primers for internal standard β-actin were 5′-GCCATATTTGATTGGAATGG-3′ and 5′-GGTGCC-ACAACCTTGATCTT-3′.[28] Each qPCR reaction (20 μL) was assembled in a 0.2 mL microtube by adding iTaq Universal SYBR Green Supermix (10 μL) (Bio-Rad, Hercules, CA, USA), 300 nM of each primer, 10 times-diluted cDNA (2 μL), and $ddH_2O$ (6 μL). The qRT-PCR was carried out on a Roach LightCycle 480 (Roach Applied Science, Mannheim, Germany) under conditions of one cycle of 95 °C for 60 s, 40 cycles of 95 °C for 15 s, and 60 °C for 30 s. A melt curve was performed at the end of each reaction to verify PCR product specificity. The $2^{-\Delta\Delta ct}$ method was used to calculate the relative expression level.[29] β-Actin was used as an internal reference. Change in mRNA level of β-primeverosidase for each treatment was normalized to that of β-actin.

## RESULTS AND DISCUSSION

**1PE-Glys in Tea Flowers Were Determined as (*R*)/(*S*)-1PE-Glu and 1PE-Pri.** 1PE-Gly may be involved in regulating the emission of 1PE from tea flowers.[12] To investigate the occurrence of 1PE-Gly in tea flowers, the 1PE-Gly compounds **1**, **2**, and **3** were isolated (Figure 2). On the basis of HR-MS

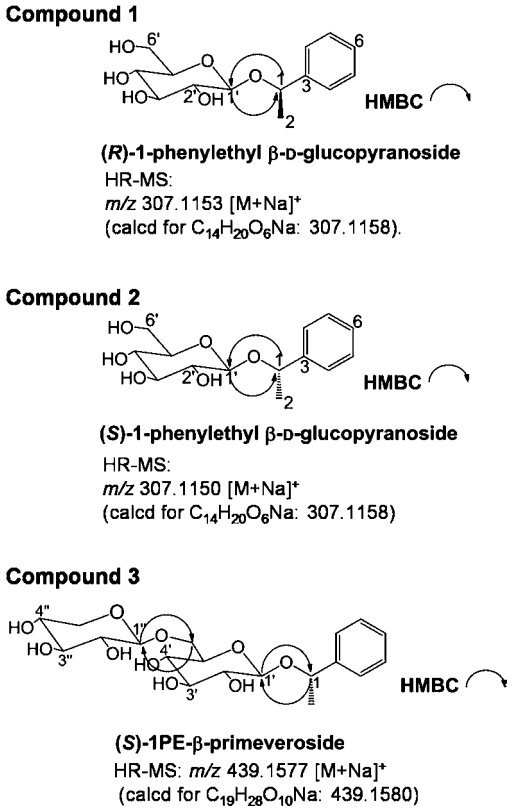

**Figure 2.** HR-MS data and chemical structures of 1PE-monosaccharides (compounds **1** and **2**) and 1PE-disaccharide (compound **3**) isolated from tea flowers.

data, the isolated compounds **1** and **2** are proposed as diastereomeric isomers of monoglycoside of 1PE (Figure 2). The $^{13}$C NMR data show that compounds **1** and **2** have 14 carbon signals (Supporting Information Table S2). $^{1}$H NMR showed that both compounds **1** and **2** have anomeric protons with $J$ = 7−8 Hz (Table S3). Moreover, the $\beta$-glucosidase could hydrolyze the glycoside to release 1PE (data not shown). These suggest that the glycoside moieties of compounds **1** and **2** have $\beta$-connectivity. The $^{1}$H chemical shifts of H-1′ significantly differ between (*R*)- and (*S*)-1PE glucopyranoside, and that of the (*R*) type is generally higher than that of the (*S*) type (Table S3). Moreover, after enzymatic hydrolysis, compounds **1** and **2** were hydrolyzed to release (*R*)-1PE and (*S*)-1PE, respectively. These indicate that compound **1** is (*R*) type and compound **2** is (*S*) type. The peracetate of compound **1** was obtained, and the structure of its glycosidic part was analyzed on the basis of the coupling patterns of each proton. As shown in Figure S5, from H-1′ to H-5′ all of the protons are *trans*-diaxial, suggesting that the C6 sugar moiety is $\beta$-glucopyranose. Therefore, compounds **1** and **2** were proposed as $\beta$-glucopyranose of (*R*)-1PE and (*S*)-1PE, respectively. On the HMBC, cross peaks between H-1′/C-1 and H-1/C-1′ revealed their connection between the aglycone and the sugar residue (Figure 2). To further confirm the proposed structures, $\beta$-D-glucopyranosides of (*R*)-1PE and (*S*)-1PE were chemically synthesized (Figure 1A and Supporting Information). On the basis of the $^{13}$C NMR data, the synthetic (*R*)-1PE and (*S*)-1PE $\beta$-D-glucopyranosides were coincided with those of compounds **1** and **2** (Table S2). The differences between (*R*)-1PE and (*S*)-1PE $\beta$-D-glucopyranosides were observed in the chemical shifts of C-1, C-2, C-1′, and C-3 (Table S2). On the basis of the above observations, compound **1** is identified as (*R*)-1PE-Glu and compound **2** as (*S*)-1PE-Glu.

On the basis of the HR-MS data and enzymatic hydrolysis to form (*S*)-1PE, compound **3** was proposed as a disaccharide of (*S*)-1PE, which has one additional $C_5$ sugar (Figure 2). The $^{1}$H NMR signal of H-1″ is 4.36 with $J$ = 7.6 Hz, suggesting that the sugar moiety with $C_5$ must be a pyranose form not in furanose form (5.10, $J$ = 6.0 Hz) (Supporting Information Table S4). We also need to determine if the disaccharide moiety is primeveroside or vicianoside. The differences between primeveroside and vicianoside are OH orientation at H-4″ (Figure S6A). Due to the differences, the coupling pattern for H-3″ should be different. The signal for H-3″ of primeveroside should have coupling with the same/similar values with H-2″ and H-4″, whereas the signal for H-3″ of vicianoside should have different coupling constants between H-2″ and H-4″ due to the *J*ax-ax and *J*ax-eq (Figure S6A). As the H-3″ $^{1}$H NMR signals were overlapped, we carried out acylated reaction of compound **3** and then analyzed its $^{1}$H NMR. We found that the $J$ H-3″ was a triplet with $J$ = 9.5 Hz (Figure S6B). To further confirm the proposed structures, $\beta$-primeverosides of (*R*)-1PE and (*S*)-1PE were chemically synthesized (Figure 1B and Supporting Information). The $^{13}$C NMR data of the synthetic (*S*)-1PE-Pri (Table S5) coincided with those of compound **3** (Table S4). On the basis of the above observations, compound **3** is identified as (*S*)-1PE-Pri. We did not obtain a sufficient purified amount for NMR identification of (*R*)-1PE-Pri. On the basis of LC-MS data on a column of ODS and the GC-MS equipped with a CHIRAMIX column after enzymatic hydrolysis (Figure S2), (*R*)-1PE-Pri was tentatively identified in tea flowers. By comparison with the GC-MS chromatogram of the MSTFA-derived product of synthesized (*R*)-1PE-Pri, tea flowers indeed contained (*R*)-1PE-Pri (Figure S7D). Moreover, LC-MS analysis by comparison with the chemically synthesized authentic standards also provided evidence that four 1PE-Glys, including (*R*)/(*S*)-1PE-Glu and (*R*)/(*S*)-1PE-Pri, occurred in the tea flowers at stages 1, 2, and 3 (Figure S3). In addition, the NMR data of the four 1PE-Glys from either tea flowers or chemical synthesis coincided with those from enzymatic syntheses by cultured plant cells that were reported previously.[23−25]

**1PE-Glu Was the Major 1PE-Gly Occurring in Tea Flowers.** To further characterize the occurrence of each 1PE-Gly, we quantified each 1PE-Gly in different floral stages and organs. MSTFA derivatization and GC-MS were employed to analyze the relative content of each 1PE-Gly. Figure S7 in the Supporting Information shows mass spectra and chromatograms of MSTFA-derived products of authentic 1PE-Gly standards and crude 1PE-Gly extract from tea flowers, suggesting the presences of the four 1PE-Glys in tea flowers. Table S1 shows the characteristic ions of MSTFA-derived products of each 1PE-Gly based on GC-MS and GC-TOFMS analyses. Relative quantitation results show that 1PE-Glu had higher molar concentration than 1PE-Pri in each floral stage and organ (Figure 3A,B). On the basis of the calculation of the

dx.doi.org/10.1021/jf5022658 | J. Agric. Food Chem. 2014, 62, 8042−8050

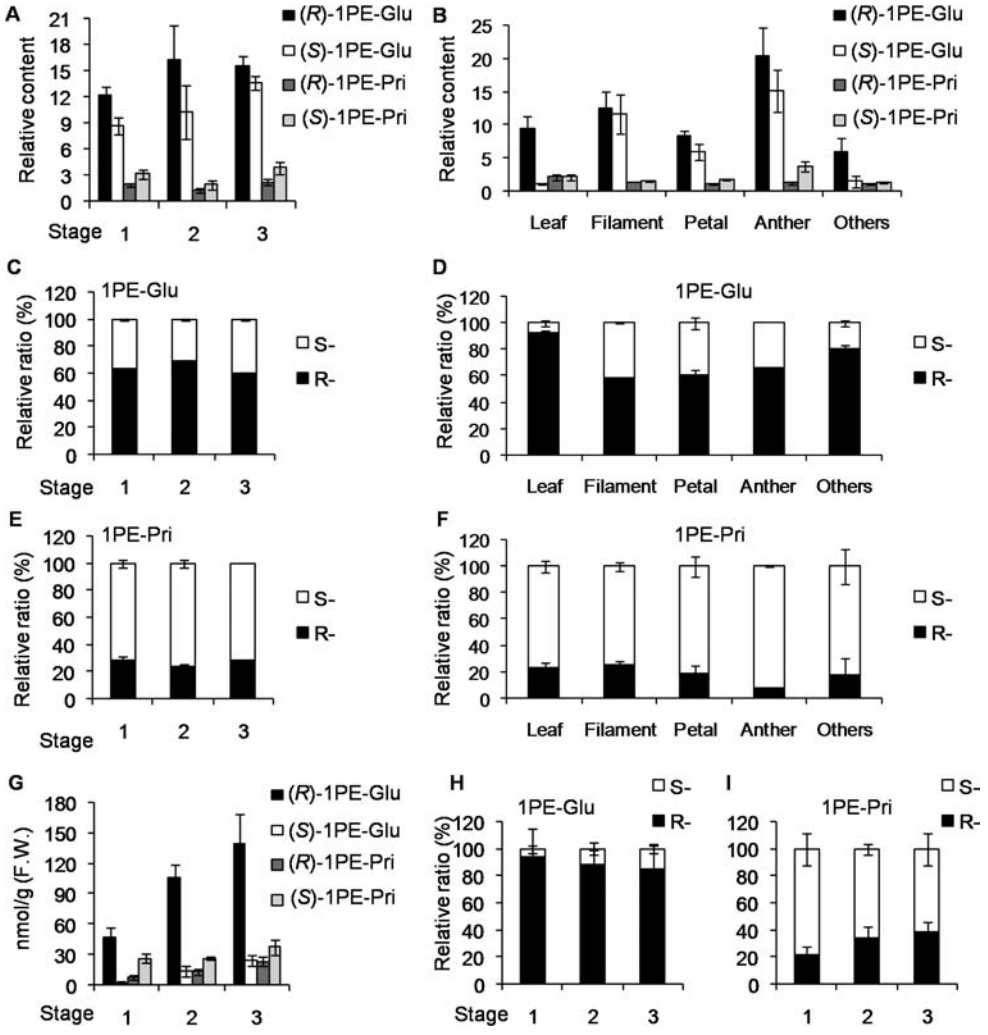

**Figure 3.** Distributions of 1PE-Gly in each floral stages and organ. (A, B) The relative quantitations of (*R*)-1PE-Glu, (*S*)-1PE-Glu, (*R*)-1PE-Pri, and (*S*)-1PE-Pri were performed using MSTFA derivatization and GC-MS. "Others" is a mixture of carpels, receptacles, sepals, and pedicels. (C–F) The relative ratio (%) of (*R*) and (*S*) was calculated on the basis of the peak area of characteristic ion *m*/*z* 259 from the MSTFA derivatization and GC-MS analysis. (G–I) The quantitations of (*R*)-1PE-Glu, (*S*)-1PE-Glu, (*R*)-1PE-Pri, and (*S*)-1PE-Pri were performed using LC-MS.

peak area of the characteristic ion *m*/*z* 259 (Table S1 and Figure S7), the relative ratio of (*R*) type of 1PE-Glu was higher than that of (*S*) type (Figure 3C,D), whereas the relative ratio of the (*S*) type of 1PE-Pri was higher than that of the (*R*) type (Figure 3E,F). Considering the possible effects of MSTFA derivatization reaction on the quantitation, we applied LC-MS to directly quantitate the content of each 1PE-Gly (Figure S3). The LC-MS analytical results (Figure 3H,I) show similar trends of ratio of *R* to *S* of 1PE-Gly with the GC-MS analytical results (Figure 3C,E), although concentrations of 1PE-Gly analyzed by LC-MS (Figure 3G) were higher than those analyzed by MSTFA derivatization and GC-MS (Figure 3A). In many cases, glycosylated alcoholic volatiles are found in tea leaves as $\beta$-primeverosides or glucopyranoside, and the $\beta$-primeverosides occur primarily in the glycosidically bound form.[30,31] Glucopyranoside was a major form of 1PE-Gly, although both glycosidic forms of 1PE were identified in tea flowers. Interestingly, the ratio of (*R*) to (*S*) differed between the 1PE-Glu and the 1PE-Pri. In our previous study, we used exogenous glycoside hydrolases to liberate free 1PE from the crude 1PE glycoside extract of tea flowers[12] and found that (*R*) type was the major hydrolyzed 1PE. In this study, we further demonstrated that (*R*)-1PE-Glu is the major 1PE-Gly in tea flowers.

**1PE-Gly Hydrolase $\beta$-Primeverosidase Transcript Level Was Not Highly Expressed in Floral Tissue.** To further clarify the hydrolysis of 1PE-Gly to liberate 1PE, we investigated the 1PE-Gly hydrolase $\beta$-primeverosidase. The recombinant $\beta$-primeverosidase expressed in *E. coli* (Figure S8 in the Supporting Information and Figure 4A,B) displayed strong enantioselectivity. Compared with (*S*)-1PE-Pri, the hydrolysis ability of $\beta$-primeverosidase toward (*R*)-1PE-Pri was significantly higher (Figure 4). On the other hand, neither (*S*)-1PE-Glu nor (*R*)-1PE-Glu was found to be hydrolyzed by $\beta$-primeverosidase. We attempted to express recombinant $\beta$-glucosidase in *E. coli* to verify its function. *E. coli* itself contained a high amount of its own $\beta$-glucosidase, which could hydrolyze 1PE-Glu to liberate 1PE. In contrast to the $\beta$-glucosidase occurring in *E. coli*, the expressed target $\beta$-glucosidase was very low. Therefore, it was very hard to distinguish if the expressed target $\beta$-glucosidase has a hydrolysis function of 1PE-Gly to form 1PE.

$\beta$-Primeverosidase transcript level showed a slight but nonsignificant decrease trend during floral development

dx.doi.org/10.1021/jf5022658 | J. Agric. Food Chem. 2014, 62, 8042–8050

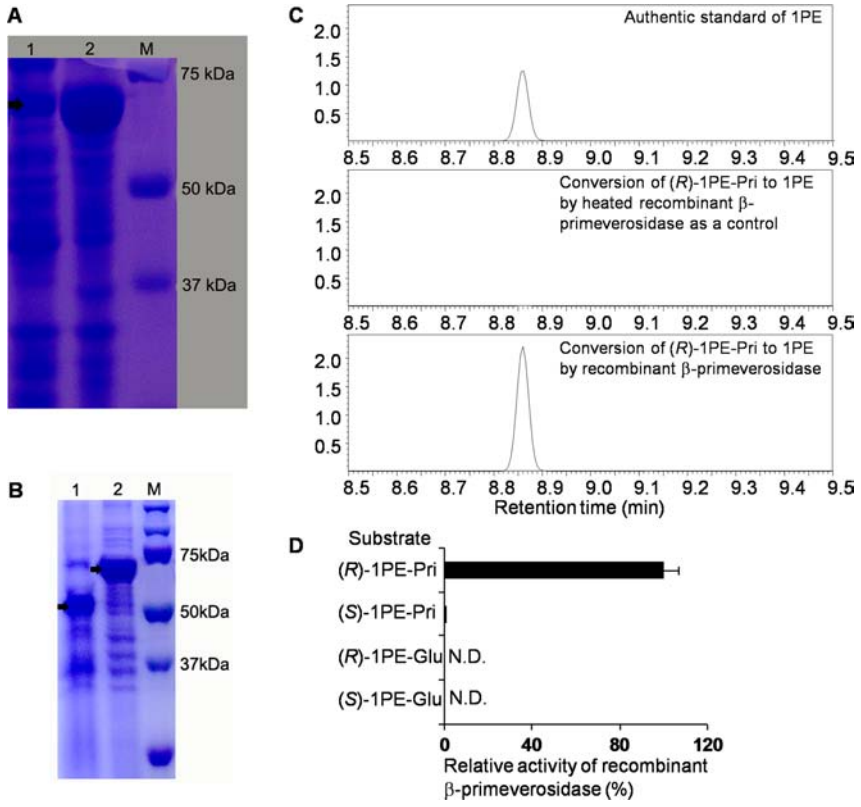

**Figure 4.** SDS-PAGE analysis of recombinant *β*-primeverosidase (A, B) and GC-MS identifications of formation of 1PE from (*R*)-1PE-Pri under the action of recombinant *β*-primeverosidase (C) and relative activities of recombinant *β*-primeverosidase toward different substrates (D). (A) Arrows indicate target protein. Proteins were resolved by SDS-PAGE on polyacrylamide gel and stained with Coomassie brilliant blue. Lanes: M, protein marker; 1, supernatant of crude extracts from *E. coli* cells with expression of vector pET32a/PRD; 2, pellet of crude extracts from *E. coli* cells with expression of vector pET32a/PRD. (B) Arrows indicate target protein. Lanes: M, protein marker; 1, enterokinase digested recombinant *β*-primeverosidase; 2, recombinant protein purified with Ni-NTA agarose from the supernatant of crude *E. coli* extracts. (C) 1PE product was identified by GC-MS. Total mass chromatography of characteristic ions of 1PE (*m*/*z* 77, 79, 107, and 122) is shown. (D) Activity toward (*R*)-1PE-Pri was highest and set as 100%. The activity toward other substrate was expressed as percent of maximum activity. N.D., not detected, which indicates that there were no differences between enzymatic reaction and control. The heated enzyme reaction was used as a control to exclude the possible effects of autodegradation of 1PE-Gly.

(Figure 5A). *β*-Primeverosidase was highly expressed in leaves, whereas it was not accumulated in floral tissues (Figure 5B). Furthermore, *β*-primeverosidase was lowly expressed in anthers, which accumulated the highest amounts of 1PE-Gly and 1PE (Figure 3B and ref 12). *β*-Primeverosidase has been purified from tea leaves, and its full amino acid sequence and function have been characterized.[27,32] *β*-Glucosidase was only partially characterized in tea leaves.[33] However, full the amino acid sequence of *β*-glucosidase has not been characterized, and its function has not been verified yet. In contrast to *β*-glucosidase, *β*-primeverosidase showed more involvement in the hydrolysis of glycosidically bound volatile compounds in tea leaves, because the *β*-primeverosides occur primarily in the glycosidically bound form.[27] The glycosidically bound volatile compounds occur in vacuoles. However, *β*-primeverosidase was observed to be localized in cell walls and the cavity areas among cells.[27] This compartmentation of substrates and enzymes in plant cells leads to the rare available evidence of hydrolysis of glycosidically bound volatile compounds in intact tea leaves.[34] In contrast, such enzymatic hydrolysis has mostly been investigated during the manufacturing process of tea leaves, which can have interactions between the enzyme and the substrate.[35,36] Investigations in flowers indicate that there is still evidence that the glycoconjugated volatile compounds can be hydrolyzed by endogenous glycosidases to liberate the volatile compounds from the plant. In *Rosa damascena* flowers, 2-phenylethanol is released from its precursor 2-phenylethyl *β*-D-glucoside during or after flower opening.[37] During flower development in *R. damascena*, *β*-glucosidase activity increases 5 times,[38] and *β*-glucosidase was suggested to be partly responsible for controlling the diurnal emission of 2-phenylethanol.[39] In *Gardenia jasmonoides* flowers, the formation of flower fragrance compounds was attributed to a glycosidase activity, reaching a maximum level at the flower opening stage.[40] In our present study, *β*-primeverosidase did not show an increase trend during the tea flower development and was relatively lowly expressed in tea flowers, suggesting that 1PE-Gly may not be easily hydrolyzed to liberate 1PE and be considered as transportable storage compounds.

Our previous study showed that tea flowers contained a high amount of endogenous 1PE.[12] 1PE is used as a fragrance in the food flavor and cosmetics industries because of its mild floral odor and as an intermediate in the pharmaceutical industry. This study provides detailed chemical evidence of occurrences of glycosidically conjugated 1PE in tea flowers for the first time. These results would contribute to our understanding of the formation of 1PE and provide essential information for future potential application of tea flowers in the food flavor and cosmetics industries.

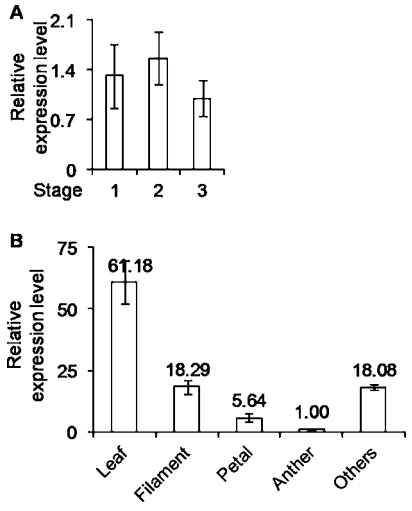

**Figure 5.** Stage-specific (A) and tissue-specific (B) expression profiles of $\beta$-primeverosidase. Transcript abundance was calculated on the basis of the difference in cycle threshold (Ct) values between $\beta$-primeverosidase and $\beta$-actin transcripts by the normalized relative quantitation $2^{-\Delta\Delta Ct}$ method. Data represent the mean value ± standard deviation of three independent experiments performed in triplicate. (B) Leaves were the first to third leaves. The fully open flowers were divided into four parts including petals, filaments, anthers, and other parts. "Others" is a mixture of carpels, receptacles, sepals, and pedicels.

# Eggshell Membrane-Based Biotemplating of Mixed Hemimicelle/Admicelle as a Solid-Phase Extraction Adsorbent for Carcinogenic Polycyclic Aromatic Hydrocarbons

Weidong Wang,[†,‡] Bo Chen,[†] and Yuming Huang*[,†]

[†]Key Laboratory of Luminescent and Real-Time Analytical Chemistry, Ministry of Education; College of Chemistry and Chemical Engineering, Southwest University, Chongqing 400715, China

[‡]Basic Department of Rongchang Campus, Southwest University, Chongqing 402460, China

Supporting Information

**ABSTRACT:** A new solid-phase extraction (SPE) format was demonstrated, based on eggshell membrane (ESM) templating of the mixed hemimicelle/admicelle of linear alkylbenzenesulfonates (LAS) as an adsorbent for the enrichment of carcinogenic polycyclic aromatic hydrocarbons (PAHs) in environmental aqueous samples. The LAS mixed hemimicelle/admicelle formation and SPE of the target PAHs were conducted simultaneously by adding the organic target and LAS through a column filled with 500 mg of ESM. The effect of various factors, including LAS concentration, solution pH, ionic strength, and humic acid concentration on the recoveries of PAHs were investigated and optimized. The results showed that LAS concentration and solution pH had obvious effect on extraction of PAHs, and the recoveries of PAHs compounds decreased in the presence of salt and humic acid. Under the optimized analytical conditions, the present method could respond down to 0.1−8.6 ng/L PAHs with a linear calibration ranging from 0.02 to 10 μg/L, showing a good PAHs enrichment ability with high sensitivity. The developed method was used satisfactorily for the detection of PAHs in environmental water samples. The mixed hemimicelle/admicelle adsorbent exhibited high extraction efficiency to PAHs and good selectivity with respect to natural organic matter and was advantageous over commercial $C_{18}$ adsorbent, for example, high extraction yield, high breakthrough volume, and easy regeneration.

**KEYWORDS:** *biomaterials, eggshell membrane, mixed hemimicelles, solid-phase extraction, polycyclic aromatic hydrocarbons*

## INTRODUCTION

Because of very low concentrations of the organic pollutants in the environment, it is in urgent need of an extraction procedure to enrich these targets before analysis. Among a great diversity of sample pretreatment methods, solid-phase extraction (SPE) is less time-consuming and solvent-consuming than liquid−liquid extraction. Nowadays, SPE has been widely applied in enrichment of various organic pollutants at trace level.[1−3] Although the commercial adsorbents including $C_8$, $C_{18}$, or Oasis HLB as SPE adsorbents have been widely utilized for sample pretreatment in environmental analysis,[4,5] the search for new extraction materials for SPE is still highly needed. This is because the silica-based materials present some shortcomings, such as pH instability and the possibility of discrepant results because of the unrestrained existence of free silanol groups.[6] In the past few years, a liquid−solid extraction system, based on hemimicelles (monolayers of the adsorbed surfactant aggregates at the solid−liquid interface) and admicelles (bilayers of the adsorbed surfactant aggregates at the solid−liquid interface), has been developed to extract organic pollutants from various environmental matrices.[7−11] The process of extracting analytes in hemimicelles and admicelles is defined as "adsolubilization", and it is suggested that both hemimicelles and admicelles regions are desirable for the SPE method.[7] Unlike the commercial adsorbents such as $C_8$, $C_{18}$, or Oasis HLB that can be directly used for extraction of analytes, in the SPE method based on hemimicelles and admicelles, the adsorbents are generated by the adsorption of ionic surfactants on the solid surface of mineral oxides.[7−13] Until now, almost all studies concentrated on the adsolubilization behavior of target analytes in the hemimicelle/admicelle aggregates formed on the surface of chemical structures, such as alumina, ferric oxyhydroxides, silica, and titanium dioxide.[7−18] There is no work yet on the hemimicelle/admicelle aggregates formation on the surface of biological material.

Eggshell membrane (ESM), existing between the egg white and the inner surface of the eggshell, is a worthless biomaterial after the production of egg derivatives in food industry. Its main components are biological molecules and protein fibers. ESM promises very good gas and water permeability and biocompatibility. Recently, ESM has been investigated as an efficient carrier of active components due to its cavity microstructure.[19] Importantly, due to the presence of amines, amides, and carboxylic groups on the surface of ESM,[20,21] ESM has been widely used in the removal of various pollutants, material preparation, catalysis, and organic synthesis.[22−25] On the basis of the principle of hard and soft acids and bases, hard-base groups such as amino groups and carboxylic groups on ESM favor binding to hard acid, such as $H^+$, through strong

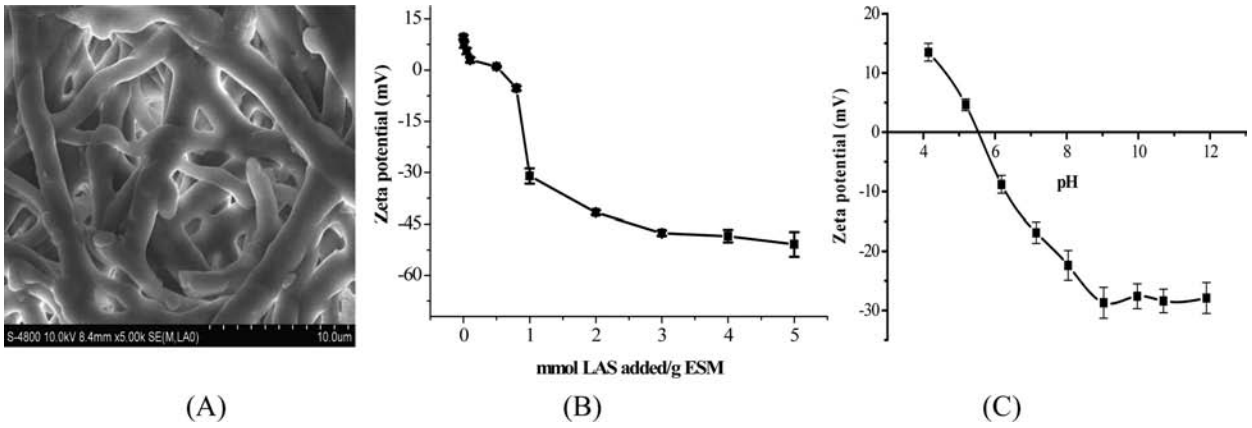

**Figure 1.** (A) Scanning electron microscopy image of the ESM. (B) $\zeta$ potential of ESM by adsorption of LAS at pH 4.97. (C) Effect of solution pH values on the $\zeta$ potential of ESM. Error bars denote standard deviations based on three measurements.

ionic interactions in solution, making ESM surface positively charged under acidic condition. If an anionic surfactant, such as linear alkylbenzenesulfonates (LAS), is added to ESM, the interaction via electrostatic attraction between negatively charged basic sulfonate groups of LAS and the positively charged acidic surface of ESM, results in the formation of hemimicelle/admicelle aggregates on the ESM, which can be used as adsorbents for the enrichment of polycyclic aromatic hydrocarbons (PAHs). On this basis, a new kind of adsorbents, namely, the biotemplating of hemimicelle/admicelle, is obtained. Hence, the objectives of this study were (1) to study the LAS surfactant adsorption onto ESM and mixed hemimicelle/admicelle formation on ESM biomaterial; (2) to investigate the feasibility of using ESM templating of the mixed hemimicelle/admicelle of LAS as new SPE adsorbent for the extraction of 10 PAHs, namely, naphthalene (Nap), acenaphthylene (Acy), fluorene (Flo), phenanthrene (Ph), anthracene (An), fluoranthene (Fl), pyrene (Py), benz[*a*]anthracene (BaA), benzo[*b*]fluoranthene (BbF), and benzo[*k*]fluoranthene (BkF), from environmental water samples. These target PAHs were considered because they are ubiquitous in our environment and are frequently found in rivers and wastewaters.[26,27] Thus, they always were chosen as the target PAH compounds in the analysis of environmental water samples;[26−30] (3) to optimize the predominant factors affecting the enrichment efficiency of this novel adsorbent for PAH target compounds.

## EXPERIMENTAL PROCEDURES

**Reagents and Chemicals.** The ESM was obtained from the eggshells of boiled eggs, which were provided by the local supermarket. After the obtained ESM was treated by 0.5% diluted hydrochloric acid[20] for 30 min, it was rinsed with proper ultrapure water, dried at 80 °C, and stored at 4 °C until use. Ten PAH standards of Nap, Acy, Flo, Ph, An, Fl, Py, BaA, BbF, and BkF were provided by Sigma−Aldrich (Shanghai, China). The stock PAH standard mixture was prepared in methanol media. The working solution of 10 PAHs was prepared every day by proper dilution of stock PAH solution using ultrapure water. Commercial LAS was supplied by Fluka Corporation, in a mixture containing a proportional composition of the different homologues as follows: $C_{10}$, 14.56%; $C_{11}$, 38.00%; $C_{12}$, 30.19%; and $C_{13}$, 17.25%. Acetonitrile and methanol (high-performance liquid chromatography (HPLC) grade) were purchased from Scharlau Chemie S.A. (Scharlau Chemie S.A., Spain). All other solvents and reagents were of analytical reagent grade and provided by the Chongqing Taixin Chemical Co. Ltd. (Beibei, Chongqing). The ultrapure water was used throughout.

**LAS Adsorption onto ESM.** To obtain the adsorption isotherm of LAS on ESM, a series of 100 mL of 0.05−50 mmol/L LAS aqueous solutions (pH 5.0) was prepared and transferred into conical flasks containing 100 mg of ESM. Then, all flasks were placed vertically on a flat surface in a water bath at 25 °C and shaken at 100 rpm for 1 h to ensure the equilibrium between LAS aqueous solution and ESM. The free LAS concentration in solution was analyzed by HPLC−UV (see the Supporting Information).

**SPE Procedure.** Before adsorption of LAS, ESM was cut into small pieces (about 0.5 mm × 0.5 mm). An ESM-packed cartridge was organized by amending a $C_{18}$ cartridge (1 g, 6 mL, polypropylene) from SUPELCO Corporation, USA. The 500 mg of the as-prepared ESM was filled into the emptied cartridge. Because ESM is a complex biomaterial probably containing various impurities such as inorganic cations and organic matters,[22,31] in order to remove these possible impurities, the homemade ESM column was washed consecutively with $CH_2Cl_2$, hexane, $CH_3OH$, $CH_3CN$, and ultrapure water, 5 mL for each. Before sample loading, the ESM-packed column was pretreated by 5 mL of acetone and 5 mL of ultrapure water. Extraction of 10 PAHs was fulfilled by passing 500 mL of the PAH standard solution in water or 100−500 mL of the different water samples (500 mL for the tap water sample, the Jialingjiang water sample and the Changjiang water sample, 100 mL for wastewater from the effluent of a constructed wetland treatment system) containing LAS surfactants (the amount of LAS added was kept 0.5 mmol/g ESM) through the 0.5 g ESM-packed cartridge (for 500 mL sample) or 0.1 g ESM-packed cartridge (for 100 mL sample) at 6 mL/min flow rate. After extraction, 10 mL of ultrapure water was used to wash the homemade ESM column. Then, the column was dried under the negative pressure of 20 mmHg for 15 min, and the enriched 10 PAHs were eluted with 5 mL of acetone. Finally, a volume of 20 $\mu$L was used for HPLC−UV analysis of 10 PAHs. The recovery of the target PAHs was used as the criterion for optimizing the parameter for the proposed SPE method, which was obtained based on the ratio of the obtained content of PAHs to the expected content of PAHs, displayed as a percentage.

**Instrumental Analysis.** The HPLC instrument (JASCO Corporation, Japan) consisted of two inert pumps, a column thermostat, and a UV detector. The PAHs were separated on a $C_{18}$ column (250 mm × 4.6 mm, 5 $\mu$m). The mobile phase was a mixture of acetonitrile and water at a ratio of 80−20% (v/v), and its flow rate was set at 1 mL/min. The column temperature was 25 °C. The chromatographic data were recorded at the wavelength of 254 nm. The HPLC−UV system was controlled by the JASCO Chrompass (JASCO Corporation, Japan). Analytical method for LAS determination was based our previous work,[32] and the detailed procedure is provided in the Supporting Information under "LAS Determination by HPLC−UV" (see the Supporting Information). The $\zeta$ potential was measured on a Zetasizer Nano ZS90 apparatus (Malvern, U.K.).

**Analysis of Environmental Water Samples and Comparative Study.** In this study, river water, tap water, and wastewater samples

were used for the detection of 10 PAHs by the proposed method. The river water samples were collected from the Chongqing sections of the Jialingjiang River (Beibei, Chongqing, China) and the Changjiang River (Jiulongpo, Chongqing, China), respectively. Tap water and wastewater samples were sampled from our lab and an effluent of a wastewater treatment system in Yongchuan (Chongqing, China). Prior to sample pretreatment, all of the aqueous samples were filtered through a 0.45 μm mixed fiber membrane (Shanghai Xinya Purification Device Factory, Shanghai, China); then, the pH value of the resulting filtrate was regulated to 5.0 by dilute HCl.

For a comparison, water sample preconcentration by $C_{18}$ was conducted following the published procedures.[33,34] Briefly, the $C_{18}$ SPE cartridge (0.5 g, 3 mL, polypropylene, SUPELCO Corporation, USA) was preconditioned by 5 mL of methanol and 5 mL of ultrapure water. Then, 100−500 mL of water sample spiked with the target PAHs was pumped through the cartridge at 6 mL/min, followed by a rinsing procedure by 10 mL of ultrapure water. After the column was dried for 15 min, the enriched 10 PAHs were eluted with 5 mL of acetonitrile. Finally, 20 μL of the obtained acetonitrile solution was used for HPLC−UV analysis of 10 PAHs.

## RESULTS AND DISCUSSION

**LAS Adsorption on ESM.** It is essential to obtain the adsorption isotherms of LAS on ESM because this is important to locating the ranges where different aggregates form and to interpreting the SPE behavior of the selected analytes when using the mixed hemimicelle/admicelle-based SPE.[13,17] The Fourier transform (FT) IR spectrum of ESM exhibits significant peaks at 3300−3500 $cm^{-1}$ (ascribed to N−H stretching mode), 1630 $cm^{-1}$ (ascribed to N−H bending mode), and 1350−1385 $cm^{-1}$ (ascribed to C−N stretching mode) (see Figure S1, Supporting Information), proving the presence of amines and amides in ESM.[21] In addition, ESM contains macroporous network structure (Figure 1A), consisting of highly cross-linked protein fibers (about 1−3 μm in diameter). The presence of macropores benefits mass transfer as an adsorbent. Figure 1B depicts the ζ potential change of ESM by adsorption of LAS at pH 4.97. The isotherm is similar to those in previous works.[8,17] Generally, the ionic surfactant adsorption isotherms can be classified into three areas, namely, hemimicelles, mixed hemimicelles, and admicelles.[35,36] In the first area, the ζ potential of ESM at pH 4.97 (below the point of zero charge of ESM, about 5.50, see Figure 1C) is positive, and LAS anionic surfactants are sparsely adsorbed onto the positively charged ESM surface. In such a case, adsorption of surfactants occurs primarily via the electrostatic attraction between the positive surface charges of ESM and the negative sulfonate surfactant head groups, resulting in a single-layer coverage (hemimicelles). Hence, the ζ potential decreased from positive to zero. In the area of the mixed hemimicelles, with increase in the amount of LAS, the surface charge of ESM turned to negative due to charge neutralization. For example, the ζ potential gradually decreased from about 1.0 to −41.7 mV when the amount of LAS added increased from 0.5 to 2.0 mmol/g ESM (Figure 1B). This is because the lateral hydrophobic interactions among surfactant tails results in the aggregation of the surfactant molecules at the solid−liquid interface, leading to the formation of bilayers called admicelles. Both hemimicelles and admicelles areas are suitable for the SPE method.[7,17] From the ξ potential isotherm (Figure 1B), the range 0.1−0.8 mmol/g ESM is in the mixed hemimicelles regions, which is suitable for SPE. In the third region, further increases in the amount of LAS caused no obvious change of the surface charge; thus, the ζ potential of ESM remained almost constant. For example, the ζ potential shifted from −47.6 to −50.9 mV when the amount of LAS added increased from 3.0 to 5.0 mmol/g ESM. This suggests that additional increase in the amount of surfactant did not significantly increase LAS adsorption on ESM. In such a case, the LAS surfactant begins to form micelles in solution, and the aqueous LAS micelles are in equilibrium with LAS admicelles. This results in a distribution of target analytes in two kinds of LAS aggregates, which is unsuitable for SPE application.[17] In a word, previous works proved that adsorption of surfactant on inorganic oxides resulted in formation of hemimicelle, hemimicelle/admicelle mixture, as well as admicelle.[7−9,11,12,15] Similarly, the adsorption phenomenon of LAS on ESM under acidic conditions also led to formation of hemimicelle, hemimicelle/admicelle mixture, as well as admicelle.

Figure S2 (Supporting Information) depicts the adsorption isotherms of LAS homologues on ESM. As can be seen, the $C_{10}$ to $C_{13}$ LAS isotherms showed a similar trend (see Figure S2, Supporting Information). The representative fitting parameters by Langmuir[37] and Freundlich[38] adsorption equations proved that the Langmuir equation ideally described the adsorption data ($r^2$ > 0.99, see Table S1, Supporting Information), suggesting the Langmuir isotherm as a better fit with the experimental data than the Freundlich isotherm. This confirms the monolayer adsorption of LAS onto ESM surface.

**Optimization of SPE Procedure for PAHs Extraction.** *Effect of the Amount of LAS Surfactant.* The extraction performance of the mixed hemimicell/admicelle adsorbent to PAHs was investigated, and a HPLC−UV instrument was used for the detection of 10 PAHs in aqueous samples after preconentration by the adsorbent. During the extraction process, the amount of LAS is one of the important factors in the present method because the formation of the mixed hemimicelle/admicelle depends on this condition directly.[7,11,17,18] Thus, the effect of the LAS amount on extraction of 10 PAH compounds was investigated in detail. As shown in Figure 2, when there was no LAS in aqueous solution, the recoveries of 10 PAHs were rather low, showing that PAHs in aqueous media were hardly adsorbed on ESM in the absence of LAS. With increase in the amount of LAS, the recoveries of PAHs increased. This indicated that the mixed hemimicelle/

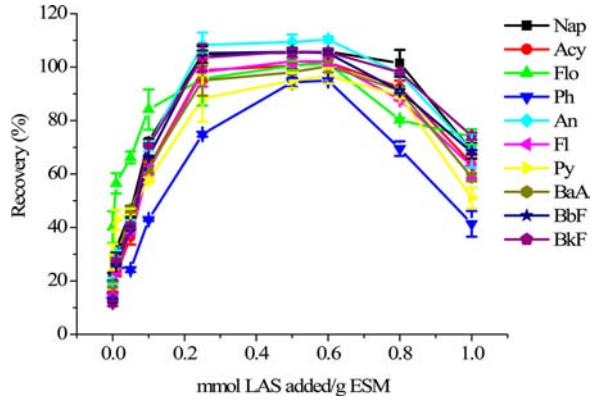

**Figure 2.** Effect of the amount of LAS on recoveries of PAHs. Error bars denote standard deviations based on three measurements.

dx.doi.org/10.1021/jf501877k | J. Agric. Food Chem. 2014, 62, 8051−8059

admicelle began to form on the surface of ESM in the presence of LAS, which obviously enhanced the retention of the target PAH compounds. The PAH adsolubilization increased with the amount of LAS surfactants rising up to 0.50 mmol/g ESM, then remained stable until 0.60 mmol/g ESM, and decreased above 0.60 mmol/g ESM. Hence, 0.50 mmol of LAS/g ESM was selected as the optimal addition of surfactant in this investigation, corresponding to 0.5 mmol/L LAS concentration in aqueous solution. This concentration was lower than the critical micelle concentration (CMC) of LAS ranging from 1.8 to 4 mmol/L depending on the solution chemistry and homologues.[39,40] This interesting phenomenon suggested that this novel hemimicelle could occupy the highest adsorptive capacity for PAHs when LAS was self-organized on ESM in a specified pattern of saturated monolayer. The formation of anionic hemimicellar/admicelles was conductive to the generation of analyte−adsorbent mixed aggregates. As expected, the adsolubilization of PAHs gradually reduced for free LAS concentrations close to critical micelle concentration.

*Desorption Condition.* Several organic solvents ($CH_3CN$ and $CH_3OH$, acetone, $CH_2Cl_2$ and hexane) were selected for elution of analytes from ESM templating of hemimicelle/admicelle adsorbents. The effects of the kind and the volume of eluent on desorption were further investigated from 1 to 5 mL. The obtained results proved that desorption ability of acetone was better than that of $CH_3CN$, $CH_3OH$, hexane and $CH_2Cl_2$ (see the Figure S3 of the Supporting Information). Hence, acetone was selected in this work. The effect of volume of acetone as an eluent was investigated in the range of 1−5 mL. The results demonstrated that the recoveries of PAHs increased with volume of acetone as an eluent to 4 mL and then remained stable ranging from 93.8 to 116.9%. Finally, 5 mL of acetone was chosen as an optimized eluent to get the quantitative results.

*Effect of Sample pH and Ion Strength.* The influence of solution pH in extraction of PAHs was examined in the range from 1.0 to 9.0. The retention of all analytes on ESM showed no significant change with solution pH from 1.0 to 5.0 (Figure 3). It is interesting that, for the studied analytes, the adsorption decreased sharply when solution pH was above 5.0. Thus, for practical aqueous samples, pH adjustment is necessary to guarantee quantitative retention of the target PAHs on ESM. This is because solution pH determines both the surface charge of ESM and the existing state of LAS surfactant in aqueous solution. Finally, pH of 5.0 was adopted in this work. The pH effect can be attributed to the fact that ESM contains some functional groups such as $-NH_2$, $-CONH_2$, and $-COOH$ groups, which can be protonated or deprotonated relying on pH value of the sample solution.[35,41] As indicated previously, the $pH_{pzc}$ of ESM is about 5.5 (Figure 1C). Hence, the positively charged sites would form on the ESM surface under acidic media. In the acidic solution ($pH \leq 5.5$), the quantitative recoveries of PAHs were obtained (Figure 3), suggesting that the electrostatic attraction may play a key role in hemimicellar/admicelle formation derived from LAS retained on ESM. At a pH greater than 5.5, the ESM surface became neutral or negatively charged, leading to the decrease of LAS assembled onto ESM and finally leading to the decrease of the target PAH recoveries. The LAS retention decreased at a pH of above 5. This may be caused by the competition effect between the hydroxyl group and the sulfonic group at the identical sorption site of ESM. In fact, it has been found that the adsorption of anions on the positively charged surface decreased by increasing solution pH.[42] In addition, the electrostatic repulsion between the negatively charged ESM surface and the negatively charged sulfonic groups will increase at higher pH. Figure 1C shows that the surface potential of ESM was negatively charged at higher pH values. It became more negative at pH from about 5.5 to 9.0, making electrostatic repulsion between the negatively charged basic sulfonic groups of LAS and ESM stronger at higher pH values than that at more acid pH values. Thus, the LAS adsorption on the surface of ESM decreased at higher pH values, leading to low recoveries of PAHs. The result further indicated the importance of the mixed hemimicelle/admicelle formation arising from LAS for the extraction of PAHs.

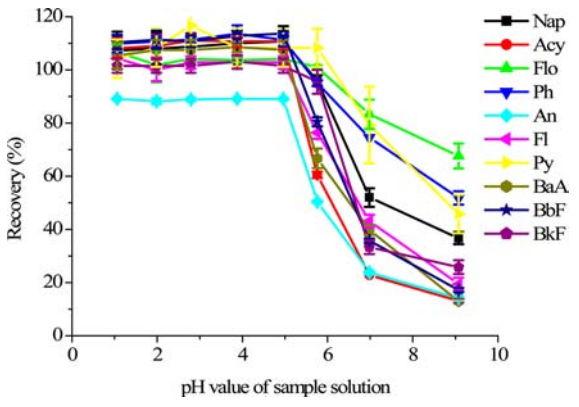

**Figure 3.** Effect of solution pH on recoveries of PAHs. The amount of LAS: 0.5 mmol/g ESM; other conditions were the same as those in Figure 2. Error bars denote standard deviations based on three measurements.

Another experiment was performed to examine the influence of ionic strength on the extraction of PAHs in the presence of sodium chloride. The experimental results indicated that the addition of NaCl reduced the retention of 10 PAH compounds on ESM templating of hemimicelle/admicelle adsorbents (see Figure S4, Supporting Information). For example, the recoveries of 10 PAHs decreased by about 10% to about 25%, as the NaCl was increased from 0% to 2.0% (w/v). A similar result has been observed in the literatures on the solvent microextraction of nitroaromatic explosives in water samples[43] and ion-pair hollow fiber-protected liquid-phase microextraction of acidic herbicides.[44] However, it is noteworthy that the quantitative recovery (recovery >95%) of the target PAHs could be obtained when NaCl concentration was ≤1.0% (w/v). This suggested that the fresh water matrix had a minor effect on extraction of 10 PAH compounds in terms of ion strength. In general, the addition can cause a decrease in the solubility of analytes in an aqueous media,[45] which benefits the extraction of target analytes. However, in our case, the recovery of 10 PAHs decreased in the presence of salt. One possible reason for this finding is the reduced electrostatic pull between negatively charged LAS and the positively charged surface of ESM. In order to confirm this hypothesis, the effect of NaCl addition on the $\zeta$ potential of LAS solution was studied. It is evident that the $\zeta$ potential of LAS solution increased with an increasing concentration of NaCl (see Figure S5, Supporting Information). This would lead to the reduced sorption affinity between negatively charged LAS and the positively charged surface of ESM, which would cause a reduced sorption of PAHs and hence a decrease in recovery. On the basis of the above result,

NaCl was not used in the coming experiments. In addition, in order to clarify the effect of water-structure making or water-structure breaking characters of the added salts on the extraction of 10 PAHs, the effects of KCl and KSCN as water-structure breaking salts[23] on the extraction of PAHs were examined. On the basis of the results shown in Figure S4 (Supporting Information), similar variation trends could be observed for KCl and KSCN, namely, the recoveries of 10 PAHs declined as concentrations of KCl and KSCN increased. Also, they showed a similar trend with NaCl as water-structure making salt[23] (see Figure S4, Supporting Information). The result indicated that both water-structure making salt and water-structure breaking salt had similar effect on the adsorption of PAHs. This is probably because PAHs are hydrophobic compounds; the hydrogen bonds in water have little influence on the solvation pattern of 10 PAHs. Hence, the water-structure making or water-structure breaking characters of the added salts had minor effect on the interaction between ESM and PAHs.

*Breaking through Volume and Flow Rate.* In the present study, LAS hemimicelle/admicelle formation and the target extraction occurred simultaneously. Thus, experiments for determining the sample breaking through volume were realized by passing sample solution through a column filled with 500 mg of ESM. The volume of the aqueous sample was varied from 100 to 1000 mL with the spiked concentration of a 0.2−4 μg/L for the PAH aqueous solution, in which the amount of LAS added was kept 0.25 mmol. The experimental results are shown in Figure 4. As can be seen, when the sample solution volume

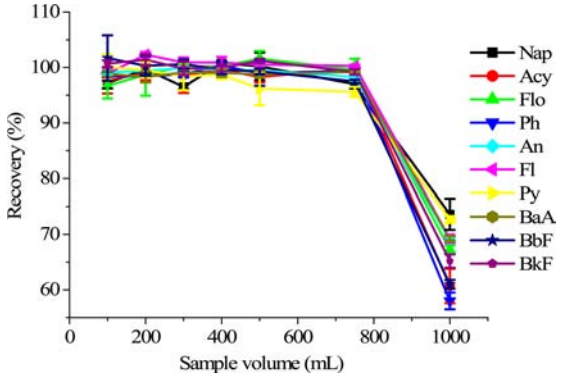

**Figure 4.** Effect of sample volume on recoveries of PAHs. The amount of LAS: 0.5 mmol/g ESM; other conditions were the same as those in Figure 2. Error bars denote standard deviations based on three measurements.

increased from 100 to 750 mL, the quantitative recoveries of PAHs were obtained. Whereas, as the volume of sample solution was increased to 1000 mL, the recoveries of the 10 PAHs decreased. Finally, the sample volume of 500 mL was adopted for further study. It should be indicated that additional experiments were also performed to determine the sample breaking through volume by a common way to work with hemimicelles and/or admicelles. In order to do this, first, 0.25 mmol of LAS in 50 mL of water solution was loaded to 0.5 g of ESM-packed cartridge, then 100−1000 mL of sample solutions spiked with a 0.2−4 μg/L PAH standard solution was loaded to the cartridge. The results demonstrated that, when the sample solution volume increased from 100 to 750 mL, the quantitative recoveries of PAHs were obtained (see Figure S6, Supporting Information). However, the recoveries of the BbF and BkF (86% and 89%, respectively) at 750 mL of sample volume were a little bit lower than those in Figure 4. This indicated that, if the amount of LAS interacting with the ESM adsorbent was kept constant and large enough (0.5 mmol/g ESM in present study) to form the mixed hemimicelle/admicelle onto ESM, the manner for loading LAS surfactant had no obvious effect on the enrichment ability of the mixed hemimicelles/admicelles-based adsorbent for PAHs. However, direct addition of LAS into the water sample before SPE adopted in our study can simplify the experimental separation procedure as compared to a common way to work with hemimicelles and/or admicelles.

The effect of the sample flow rate was studied in the 3−10 mL/min range. The satisfactory recoveries of PAHs (82.4−116.7%) were obtained in the studied range of flow rate, thus allowing the fast pretreatment of the practical samples. Finally, 6 mL/min was chosen for further experiment.

*Effect of Humic Acid.* The natural organic matter (NOM) in the aqueous samples may cause a matrix interference with extraction of the organic pollutants (e.g., PAHs). In this work, the influence of NOM on the extraction of PAHs was studied by using humic acid (HA) as a model of NOM. As shown in Figure S7 (Supporting Information), the recoveries of PAH compounds reduced in the presence of HA. However, HA did not cause obvious effect on the extraction of 10 PAHs when the concentration of HA changed from 0 to 10 mg/L dissolved total organic carbon (TOC). This can be explained based on the property of HA. HA is a weak acid and contains phenolic and carboxylic groups in its structure.[46] The p$K_a$ values of humic substances range from 3 to 7.[46] At pH 5.0, a portion of −COOH groups is deprotonated via ionization of HA. The degree of HA ionization increased with the increasing of HA concentration, leading to the competitive adsorption between LAS and HA on ESM. This phenomenon could result in the decline of recoveries of 10 PAHs by weakening the formation of hemimicelle and admicelle on the surface of ESM, which was further confirmed by the significant reduction of extraction recoveries of 10 PAH compounds at a concentration of HA above 10 mg/L. The concentration of TOC in river water samples used in this work ranges from 3.44 to 3.50 mg/L. Thus, it can be concluded that HA had minor effect on the detection of PAHs in river water. This suggested that the proposed SPE format showed good selectivity with respect to natural organic matter.

*Analytical Performance.* The above-selected experimental conditions were employed to measure the analytical performance, in order to determine whether the developed method could be used to the analysis of PAHs in aqueous samples. The analytical data, including linear range, correlation coefficients, detection limits, and precision, are shown in Table 1. As can be seen, good linear relationships could be obtained for different analytes in the 0.02−10 μg/L range. Detection limits (S/N = 3) of 10 PAH compounds were in the range 0.1−8.6 ng/L under the above-mentioned extraction conditions, proving that the developed method was highly sensitive for the detection of PAHs. The relative standard deviations (RSDs) were from 1.3% to 3.8% ($n$ = 6) for 10 PAHs at concentration levels of 0.2−2 μg/L on the same column on the same day. In addition, the RSD of intercolumn and intracolumn was below 9% ($n$ = 3, Table 2), showing that the reproducibility among the ESM cartridges was desirable.

*Analysis of Environmental Water Samples and Comparative Study.* The developed method was applied to detecting PAHs in several aqueous samples. Also, a comparison of the

mixed hemimicelle/admicelle-based SPE adsorbent and conventional SPE $C_{18}$ adsorbent for the extraction of 10 PAH compounds was made. Figure 5 and Figure S8 (Supporting Information) present the chromatograms of the Changjiang River water sample, wastewater sample, PAH-spiked ultrapure water, PAH-spiked Changjiang River water sample, and PAH-spiked wastewater sample, enriched using LAS hemimicelle/admicelle as adsorbent. The satisfactory recoveries of PAHs were obtained (77.8−112.7%) for all the tested water samples (see Table 3 and Table S2, Supporting Information), although the relatively low recoveries of PAHs were obtained for the wastewater sample (77.8−95.7%) (see Table S2, Supporting Information). This suggests that competitive adsorption processes might occur between the wastewater sample matrix and LAS onto ESM. This may be due to the enhancement of the coextraction of humic substances in the present study. In fact, we determined TOC content in the studied water samples in this work, and the concentration levels (mg/L) are as follows: 3.44−3.50 for river water samples, and 12.04 for the constructed wetland water sample. The NOM in the wastewater was 3 times higher than that in the river water sample. Higher TOC content would cause lower recovery, which was consistent with the result in Figure S7 (Supporting Information). The comparative experiments were performed to obtain comprehensive data of $C_{18}$ and hemimicelle/admicelle adsorbent, using several practical aqueous samples such as tap water, river water, and wastewater. The experiments on water sample preconcentration by $C_{18}$ were conducted following published procedures.[33,34] For $C_{18}$ SPE adsorbent, the recoveries of 10 PAHs varied from 45.6% to 101.0% for tap water and river water (Table 3 and Table S2, Supporting Information), and the recoveries of 10 PAHs varied from 50.8% to 75.2% for wastewater (see Table S2, Supporting Information). Hence, compared with traditional $C_{18}$ SPE adsorbents, LAS hemimicelle/admicelle adsorbent exhibited higher extraction recoveries for PAHs in various aqueous samples.

In conclusion, this work has well illustrated the potential of ESM templating of the mixed hemimicelle/admicelle as a novel SPE adsorbent for the preconcentration of PAHs in environmental aqueous samples. This method provided highly sensitive analysis of PAHs with a LOD of 0.1−8.6 ng/L, linearity of the response from 0.02 to 10 $\mu$g/L, and good selectivity with respect to NOM. The proposed SPE protocol was effective for the concentration of trace PAHs in environmental water sample before HPLC−UV analysis. Compared with commercially available $C_{18}$ materials, the design of ESM templated hemimicelle/admicelle adsorbent for PAHs extraction has advantages as follows: (1) ESM is a biocompatible material and ESM degrades readily; thus, it can be used as a green biomaterial with little secondary contamination; (2) the peculiar macroporous network of eggshell membrane consisting of cross-linking protein fibers benefits mass transfer as a adsorbent; (3) ESM is low-cost and can be obtained in a massive amount as an waste product of food industry. It is believed that the ESM templating of the mixed hemimicelle/admicelle may be a valuable adsorbent for other micropollutants.

Supporting Information

**ABSTRACT:** Forty-one samples of skim milk powder (SMP) and nonfat dry milk (NFDM) from 8 suppliers, 13 production sites, and 3 processing temperatures were analyzed by NIR diffuse reflectance spectrometry over a period of 3 days. NIR reflectance spectra (1700−2500 nm) were converted to pseudoabsorbance and examined using (a) analysis of variance-principal component analysis (ANOVA-PCA), (b) pooled-ANOVA based on data submatrices, and (c) partial least-squares regression (PLSR) coupled with pooled-ANOVA. ANOVA-PCA score plots showed clear separation of the samples with respect to milk class (SMP or NFDM), day of analysis, production site, processing temperature, and individual samples. Pooled-ANOVA provided statistical levels of significance for the separation of the averages, some of which were many orders of magnitude below $10^{-3}$. PLSR showed that the correlation with Certificate of Analysis (COA) concentrations varied from a weak coefficient of determination ($R^2$) of 0.32 for moisture to moderate $R^2$ values of 0.61 for fat and 0.78 for protein for this multinational study. In this study, pooled-ANOVA was applied for the first time to PLS modeling and demonstrated that even though the calibration models may not be precise, the contribution of the protein peaks in the NIR spectra accounted for the largest proportion of the variation despite the inherent imprecision of the COA values.

**KEYWORDS:** *pooled-ANOVA, milk powder, near-infrared spectroscopy, partial least-squares regression, ANOVA-PCA*

## INTRODUCTION

Skim milk powder (SMP) and nonfat dry milk (NFDM) are important foods/ingredients in the international food supply.[1] In 2011, the United States Pharmacopeial Convention (USP) initiated a project to characterize compositional and functional variations of these powders and develop nontargeted methods for detection of adulteration. One phase of this project analyzed 41 samples collected from 8 national and 3 international suppliers at 13 production sites (Table 1) using diffuse reflectance NIR.[1] The variance of the data was initially characterized using principal component analysis and varimax rotation[2] of the principal components. This Article provides the second step of the analysis by characterizing the NIR variance using analysis of variance-principal components analysis (ANOVA-PCA),[3] pooled-ANOVA,[4,5] and partial least-squares regression (PLSR).[6]

It has become customary to use chemometric methods to simplify and glean information from complex data sets. However, classical statistical methods, such as ANOVA, can also be applied to complex data. ANOVA can be used to compare the difference among the means of multiple groups, and in a factorial mode to isolate and quantify the variance associated with different experimental factors and their interactions. Pooled-ANOVA extends ANOVA from a single dependent variable to a pooled set of multiple variables.[4,5] Thus, ANOVA tests the differences of means among groups, and pooled-ANOVA tests the differences among two or more vectors of means by comparing the pooled variance of the variables.

Harrington et al.[3] used ANOVA to decompose the original sample matrix of mass spectrometry (MS) data into a series of

[a]Eight suppliers. [b]Production site per supplier in the United States (US), internationally (I), or unknown (?). [c]N = nonfat dry milk and S = skim milk powder. [d]Number of samples collected from each production site. [e]Process type: L = low, M = medium, H = high, or ? = unknown heat. [f]Six subsamples per sample (two subsamples/sample/day for 3 days).

submatrices, each associated with the means of different experimental factors. The final residual matrix was then added to each means matrix and analyzed by principal component analysis (PCA). This combined approach of ANOVA-PCA provides a scores plot for each experimental factor. The separation of scores of the different levels of the factor indicates significance. The separations are defined by 95% confidence ellipses derived from the Hotelling $T^2$ statistic. ANOVA-PCA provides information about the separation of the groups of objects with respect to the experimental factors.

Harnly[4,5] showed that the sum of the squared residuals of the variables of these submatrices derived from ANOVA-PCA could be pooled into a single scalar value and the mean squared statistic could be tested as it is done with ANOVA. The submatrices allowed computation of the percentage of the total variance for each experimental factor, the level of significance of the variance, and the variance associated with the interaction of the factors. The number of variables is omitted from calculation because it is difficult to determine the true rank or degrees of freedom from underdetermined data sets. Thus, the sum of squares across the number of variables is treated as a single squared variable, and the F statistic will underestimate significant differences. If a significant difference is observed, it will indeed be significant. Pooled-ANOVA provides a conservative test for differences among the level averages for each factor.

In this study, the previously reported NIR data for SMP and NFDM[1] are subjected to analysis by ANOVA-PCA, pooled-ANOVA, and PLSR coupled with pooled-ANOVA. The percentages of the total variance according to day of analysis, supplier, production site, milk class, process type, between sample variation, and instrumental variation were determined. A third aspect of the study examined the correlation of the NIR spectra with the protein, moisture, and fat content of the samples. Because this study was large with milk powders collected from many sources, it was difficult to achieve a balanced experimental design, and some of the data with respect to the experimental factors were missing, which prevented interaction from being studied for several factors. A more systematic study would attempt to collect an equal number of milk samples with respect to each experimental factor. Collecting milk powders from different sources produced on the same date and using the same process may be impossible because of limitations of the facility and production schedule.

## MATERIALS AND METHODS

**Milk Powders.** As previously reported,[1] 41 milk powders (19 skim milk and 22 nonfat dry milk) produced between August 2008 and May 2012 were acquired from eight suppliers. Certificates of analysis (COA) indicated product origin details including production sites, lot numbers, process type (labeled as high, medium, and low heat), and weight/weight concentrations of moisture, fat, and protein. The sample information is summarized in Table 1.

The data were analyzed with respect to four sample variables, that is, sample class, production site, process type, and individual samples. The supplier was not treated as a variable because the majority of the suppliers (6 out of 8) only had one production site. A fifth instrumental variable was the day of analysis because the samples were each analyzed on three different days.

**NIR Analysis.** The NIR analysis methodology was previously reported.[1] In brief, Fourier transform (FT) near-infrared spectra were acquired at the U.S. Food and Drug Administration (Center for Food Safety and Applied Nutrition, Division of Food Processing Science and Technology) with a PerkinElmer Frontier FT-NIR system (Waltham, MA) fitted with the NIRA reflectance accessory. Data were acquired from 4000 to 10 000 $cm^{-1}$ (1000−2500 nm). A 99% Spectralon diffuse reflectance standard (Labsphere, cat. no. AS-01160-060, North Sutton, NH) was used to acquire 84 background scans throughout the experiment. NIR spectra of six subsamples for each of the 41 milk powder samples were acquired in a randomized order on three consecutive days of analysis with two subsamples per milk powder being acquired on each day. In addition, on each day of analysis, six replicate measurements were acquired for randomly selected subsamples with the sample remaining on the sampling interface between replicates. Thus, spectral acquisition included 246 unique subsample spectra, 105 additional replicate spectra, and 84 background spectra, yielding a total of 435 spectra.

**Data Processing.** Raw data files consisted of 6001 reflected intensities (1000−2500 nm) for each of the 435 samples. As previously described,[1] the 84 spectra of the diffuse reflectance standard were used to convert reflectance intensities of the samples to pseudoabsorbance ($A_s$):

$$A_s = \log_{10}(I_{standard}/I_{sample}) \quad (1)$$

for which $I_{sample}$ is the diffuse reflectance intensity of the samples, and $I_{standard}$ is the reflected intensity of the 99% reflectance standard. In the current study, only 228 of the 246 unique subsample spectra were used. The 105 replicate spectra were not included, and another 18 spectra (3 samples) were omitted due to provision of incomplete information, that is, missing information regarding process type (Table 1). Initial analysis by PCA showed little variation for the variable loadings of the first and second principal components in the region between 1000 and 1700 nm.[1] Consequently, only the region from 1700 to 2500 nm was used in this study.

Preprocessing of the pseudoabsorbance data prior to PCA transformed the data to the first derivative using a cubic polynomial fit of 35 points followed by standard normal variate (SNV) correction. The 20 points from the 2500 nm end of the wavelength range were removed so that the spectra would range from 1700 to 2480 nm. The derivative was calculated before the shorter wavelengths were excised from the data set so that no points were lost from the shorter wavelength ends of the derivatized spectra. Each derivatized spectrum comprised 1850 data points.

Outliers were detected by calculating the residual data matrix produced by subtracting the sample means from the corresponding spectra. Using a confidence interval defined by the Hotelling distribution at a 99.99% confidence interval applied to the $T^2$ statistic obtained from the first 10 principal component scores, three spectra

dx.doi.org/10.1021/jf5013727 | J. Agric. Food Chem. 2014, 62, 8060−8067

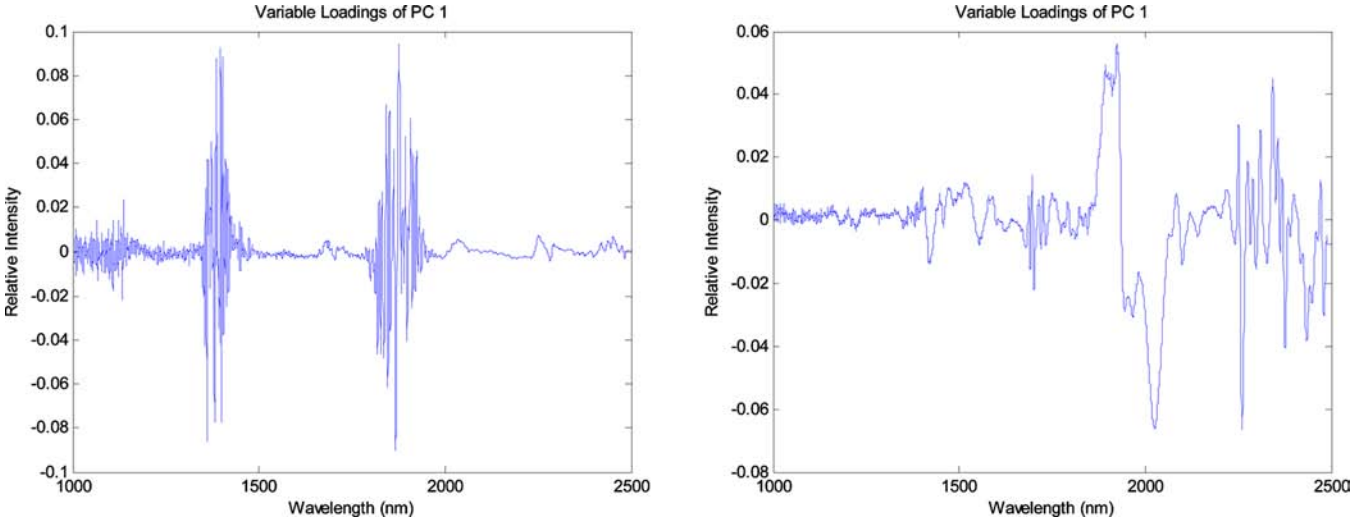

**Figure 1.** First principal component variable loadings of the SNV corrected first derivative spectra obtained from the single beam spectra (left) and pseudoabsorbance spectra (right).

were rejected because they had scores outside this interval. The number of spectra was reduced using this method from 228 to 225. Consequently, the derivatized and SNV corrected data matrix for the current study consisted of 1850 variables (1700−2480 nm) for 225 spectra (6 subsamples of 38 samples less the 3 outlier spectra). These 225 spectra were subjected to ANOVA-PCA, pooled-ANOVA, and PLSR.

PLSR used the NIPALS algorithm implemented in PLS2 mode (i.e., three dependent variables, moisture, fat, and protein). PLSR used a data set further reduced in size because some of the spectra were incomplete with respect to the COA for moisture, fat, and protein. This data set comprised 144 spectra from 24 samples and 7 production sites.

**ANOVA-PCA and Pooled-ANOVA.** Both approaches have been previously described.[2−5] In summary, submatrices are constructed for each experimental factor, for experimental factor interaction, and for the factor residuals. For ANOVA-PCA, the final residual matrix is added back to the means matrices for each factor and then subjected to PCA. For pooled-ANOVA, the residuals matrix for each factor and factor interaction is squared and summed to provide a pooled variance. A more detailed description of the calculation is given in Supporting Information Appendix A.

**PLSR for Protein, Moisture, and Fat.** COA concentrations for moisture, fat, and protein were only available for 24 of the 41 samples, which yielded 144 spectra. The data were preprocessed as described in the Materials and Methods, although it is worthwhile noting that the spectra without numerical derivatization yielded better PLSR prediction results. These results are not included. The PLS-2 nonlinear iterative partial least-squares (NIPALS) algorithm was used as described.[6] The optimum number of principal components was determined by the leave-one-spectrum-out cross validation and the minimum total sum of squared prediction error. Note that the 6 replicates per sample were run at two different times for three sequential days of analysis, so the replicates characterize uncontrolled sources of variation (e.g., instrumental drift with time).

**Pooled-ANOVA PLS Regression.** The pooled-ANOVA can be applied to the PLS calibration to determine the contribution to the X-block (NIR spectra) of each Y-block property (concentration of moisture, fat, and protein). The procedure is quite simple. For each latent variable or component, the pooled sum of squares for the NIR block of the PLS calculation was apportioned by the squared values of the concentration loadings vector (usually designated as $\boldsymbol{q}$). This calculation allows the variation contributions of each property (i.e., moisture, fat, and protein concentration) to be attributed to the NIR spectra.

A PLS model comprises a set of components that span the covariance of the X- and Y-blocks of data. Prediction is accomplished by iteratively removing the contribution of each PLS component or latent variable to the X-block and adding the contribution to the Y-block for the number of components chosen in the model.

$$t_{i,j} = \boldsymbol{x_{i,j-1}} \boldsymbol{w_j} \tag{2}$$

for which $x_{i,j}$ is the NIR spectrum of object $i$ that has been centered with respect to the mean of the calibration set of data. The spectrum is modified for each iteration $j$ of the PLS calculation, and $\boldsymbol{w}_j$ is the $j$th PLS component. The contribution to the NIR spectrum is calculated as

$$\hat{\boldsymbol{x}}_{i,j} = t_{i,j} \boldsymbol{p_j} \tag{3}$$

for which $\hat{\boldsymbol{x}}_{i,j}$ is a component of the reconstructed NIR spectrum $i$ and $p_j$ is a row vector from the PLS regression for component $j$. This contribution is iteratively removed or peeled from the NIR spectrum as follows.

$$\boldsymbol{x_{i,j}} = \boldsymbol{x_{i,j-1}} - \hat{\mathbf{x}}_{i,j} \tag{4}$$

The properties are iteratively estimated as

$$\hat{\boldsymbol{y}}_{i,j} = \hat{\boldsymbol{y}}_{i,j-1} + t_{i,j} b_j \boldsymbol{q_j} \tag{5}$$

for $\hat{\boldsymbol{y}}_{i,0}$ is the average of the properties and the estimate is built up with respect to PLS component number. The $b_j$ is the inner relation, which can be considered a correlation coefficient between the X- and Y-blocks for each component. The property loadings $\boldsymbol{q}_j$ for component $j$ are a row vector.

The pooled sums of squares of the X-block or NIR spectra with respect to the properties of the Y-block or concentrations are calculated as follows:

$$\boldsymbol{ss_{x_{i,j}}} = \boldsymbol{q_j^2} \sum_{k=1}^{n} \hat{\mathrm{x}}_{i,j,k}{}^2 \tag{6}$$

The sum of squares for the reconstructed component is calculated across the $n$ variables of the spectrum or object $i$. The $\boldsymbol{ss}_{\boldsymbol{x}_{i,j}}$ is a row vector that contains the sums of squares of the X-block variance with respect to the PLS component $j$ and the properties for the calibration, in this case, the concentrations of moisture, fat, and protein.

$$\boldsymbol{SS_x} = \sum_{i=1}^{m} \sum_{j=1}^{r} \boldsymbol{ss_{x_{i,j}}} \tag{7}$$

dx.doi.org/10.1021/jf5013727 | J. Agric. Food Chem. 2014, 62, 8060−8067

**Table 2. Pooled-ANOVA of NIR Pseudo-Absorbance Data**

| treatment | df | SS | MS | F | *p*-value | RSS |
|---|---|---|---|---|---|---|
| milk class | 1 | 221 | 221 | 130 | $\ll 10^{-3}$ | 8.7% |
| day | 2 | 21 | 11 | 6.2 | $3 \times 10^{-3}$ | 0.8% |
| processing type | 2 | 223 | 111 | 65 | $\ll 10^{-3}$ | 8.8% |
| production site | 10 | 980 | 98.0 | 57 | $\ll 10^{-3}$ | 38.8% |
| sample | 37 | 665 | 18.0 | 10 | $\ll 10^{-3}$ | 26.3% |
| milk × processing | 2 | 108 | 54.2 | 31 | $\ll 10^{-3}$ | 4.3% |
| processing × day | 4 | 5 | 1 | 0.7 | 0.59 | 0.2% |
| milk × day | 2 | 2 | 1 | 0.7 | 0.51 | 0.1% |
| site × day | 20 | 53 | 2.7 | 1.5 | 0.07 | 2.1% |
| residual error | 144 | 247 | 1.7 | 9.8% | | |

The $ss_{x_{i,j}}$ is summed across the $m$ objects and $r$ PLS components that were used for calibration, and then the pooled-ANOVA is applied to the total $ss_x$ as described previously.

## RESULTS AND DISCUSSION

**Selection of Spectral Region.** The SNV corrected spectra, first derivative with SNV spectra, and variable loadings of the first principal component for both diffuse reflectance and pseudoabsorbance modes are given in Figure 1S of the Supporting Information. Figure 1 gives the variable loadings obtained from the diffuse reflectance spectra, which have two major water bands at 1340−1440 and 1800−1950 nm. The variable loadings obtained from the pseudoabsorbance spectra are given on the right. The water bands of these variable loadings are attenuated when compared to those of the diffuse reflectance spectra. However, the pseudoabsorbance calculation did not completely remove the moisture bands as will become apparent later in the subsequent results. The reference standards were only run every sixth analysis and did not account for any moisture in the milk powder but only for ambient moisture in the NIR beam path. There was no attempt to interpolate a reference spectrum for the spectra acquired between the two reference spectra. Thus, depending on the direction of the drift, the reference standards may have over- or under-corrected the sample pseudoabsorbance spectra.

**Pooled-ANOVA.** Table 2 reports the pooled-ANOVA results for the analysis of the NIR pseudoabsorbance data matrix comprising 38 samples (i.e., 225 spectra) each with 1850 variables (1700−2500 nm). The residuals matrix for each experimental factor and factor interaction were squared to provide the factor variance (see Supporting Information Appendix A). Numbers in bold designate cases associated with significant differences (i.e., less than $10^{-2}$ of a type I error). In other words, bold designees indicate if the average levels of the experimental factors came from the same distribution, which is the Null Hypothesis. The likelihood of obtaining this result would be equal to or less than the corresponding *p*-value. The relative sum of squares (RSS) gives the relative contribution of each factor with respect to the total sum of squares. The sample residuals account for 10% of the RSS as indicated by the residual error (bottom row) of Table 2. The sum of the pairwise factor interactions accounted for less than 7% of the RSS. Rows 6−9 of Table 2 list the interactions between pairs of factors.

At the 99% confidence level, there are significant differences for milk class, day of analysis, production site, process type, and samples (Table 2). It should be noted that pooled-ANOVA, and ANOVA in general, tests for a difference among the averages of each level. Thus, significant differences for factors reported in Table 2 do not indicate that all of these averages are different, but that at least one average of a level differs from the other averages. Further matrix calculations can provide information for specific levels. However, visual methods such as ANOVA-PCA are easier to interpret.

**ANOVA-PCA.** The submatrices used for the pooled-ANOVA calculations in the previous section were also used to compute reconstituted matrices for each factor prior to PCA (see Appendix A in the Supporting Information). The same experimental factors evaluated by pooled-ANOVA in Table 2 are described by ANOVA-PCA in the PCA scores and variable loadings given in Figure 2. However, pooled-ANOVA takes advantage of the power of the Central Limit Theorem to determine if the average spectra are varying, while ANOVA-PCA compares the separation of data points with respect to the individual spectra.

In the top row of Figure 2, the effect of milk class is clearly significant. Skim milk powder (SMP) is compared to nonfat dry milk (NFDM). The RSS reported in Table 2 for milk type accounted for 8.7% of the variation in the data set. The two milk types were significantly different (i.e., *p*-value $\ll 10^{-3}$), and this estimate underestimates the significance because the degrees of freedom from the 1850 NIR spectral variables are neglected.

The second row of Figure 2 gives plots for the effect of the day to day variation. In the score plots, the 95% confidence ellipses for the 3 days of the analysis all overlap with respect to the residual error. However, the third day of analysis, C, clearly has a different mean that is characterized by a shift with respect to the second principal component. The variable loadings for this component indicate that moisture peaks are primarily responsible for the difference. The pooled-ANOVA result (Table 2) is at a level of significance of 0.003, indicating that the averages are different even though the fraction of variance explained by the RSS is a relatively small 0.8%.

The third row corresponds to the three process types labeled as low (LH), medium (MH), and high (HH) heat. The medium and high temperature processes are more different from each other with the low temperature appearing between the two. This trend can be explained by the process differences that arise in milk condensation and dehydration. The pooled-ANOVA results indicate a RSS of 8.8% and similar *p*-value that was far below $10^{-3}$.

The fourth row corresponds to the production site's geographical location, which accounts for the largest source of variation with an RSS of 38.8% and a *p*-value also far less than $10^{-3}$. The score plots indicate that the production sites form nicely defined clusters in the data space.

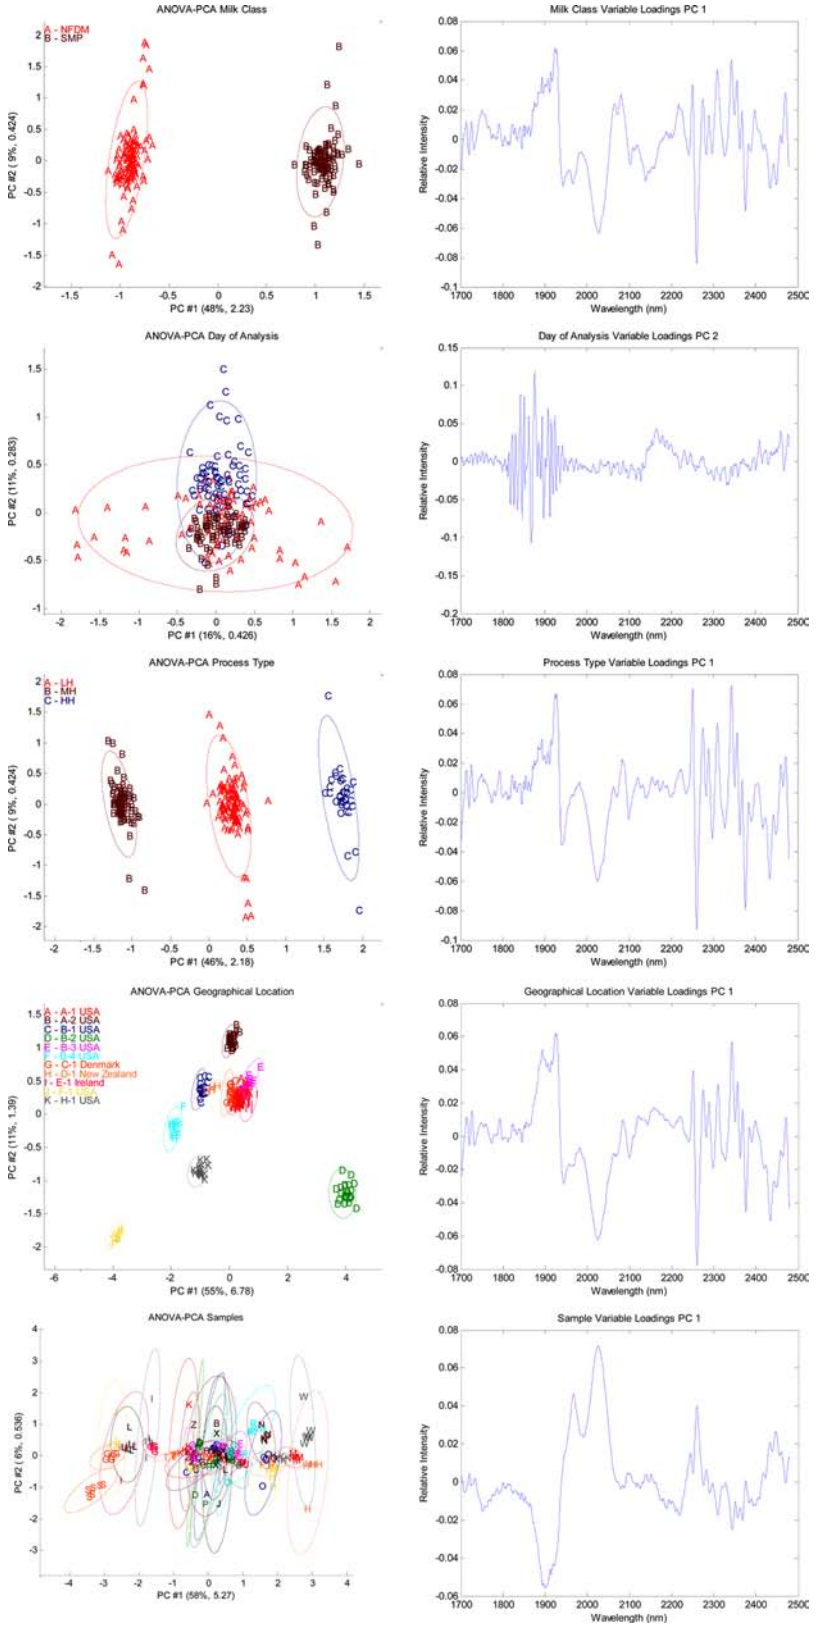

**Figure 2.** (Left) ANOVA-PCA score plots with 95% confidence ellipses. (Right) Corresponding variable loadings. (Row 1) Skim milk (SMP) and nonfat dry milk (NFDM). (Row 2) Day of analysis; for this case, the variable loading for the second principal component is plotted. (Row 3) Low, medium, and high processing temperatures. (Row 4) Production site of milk supplier. (Row 5) Thirty-eight samples.

Each sample was taken from a different lot of milk powders. The fifth row of Figure 2 corresponds to the individual sample level, and, according to its RSS, the samples contribute 26.3% of the variance in the data set, making it the second largest contributor. The sample scores that form tight clusters indicate that NIR spectroscopy of the dried milk powders has the

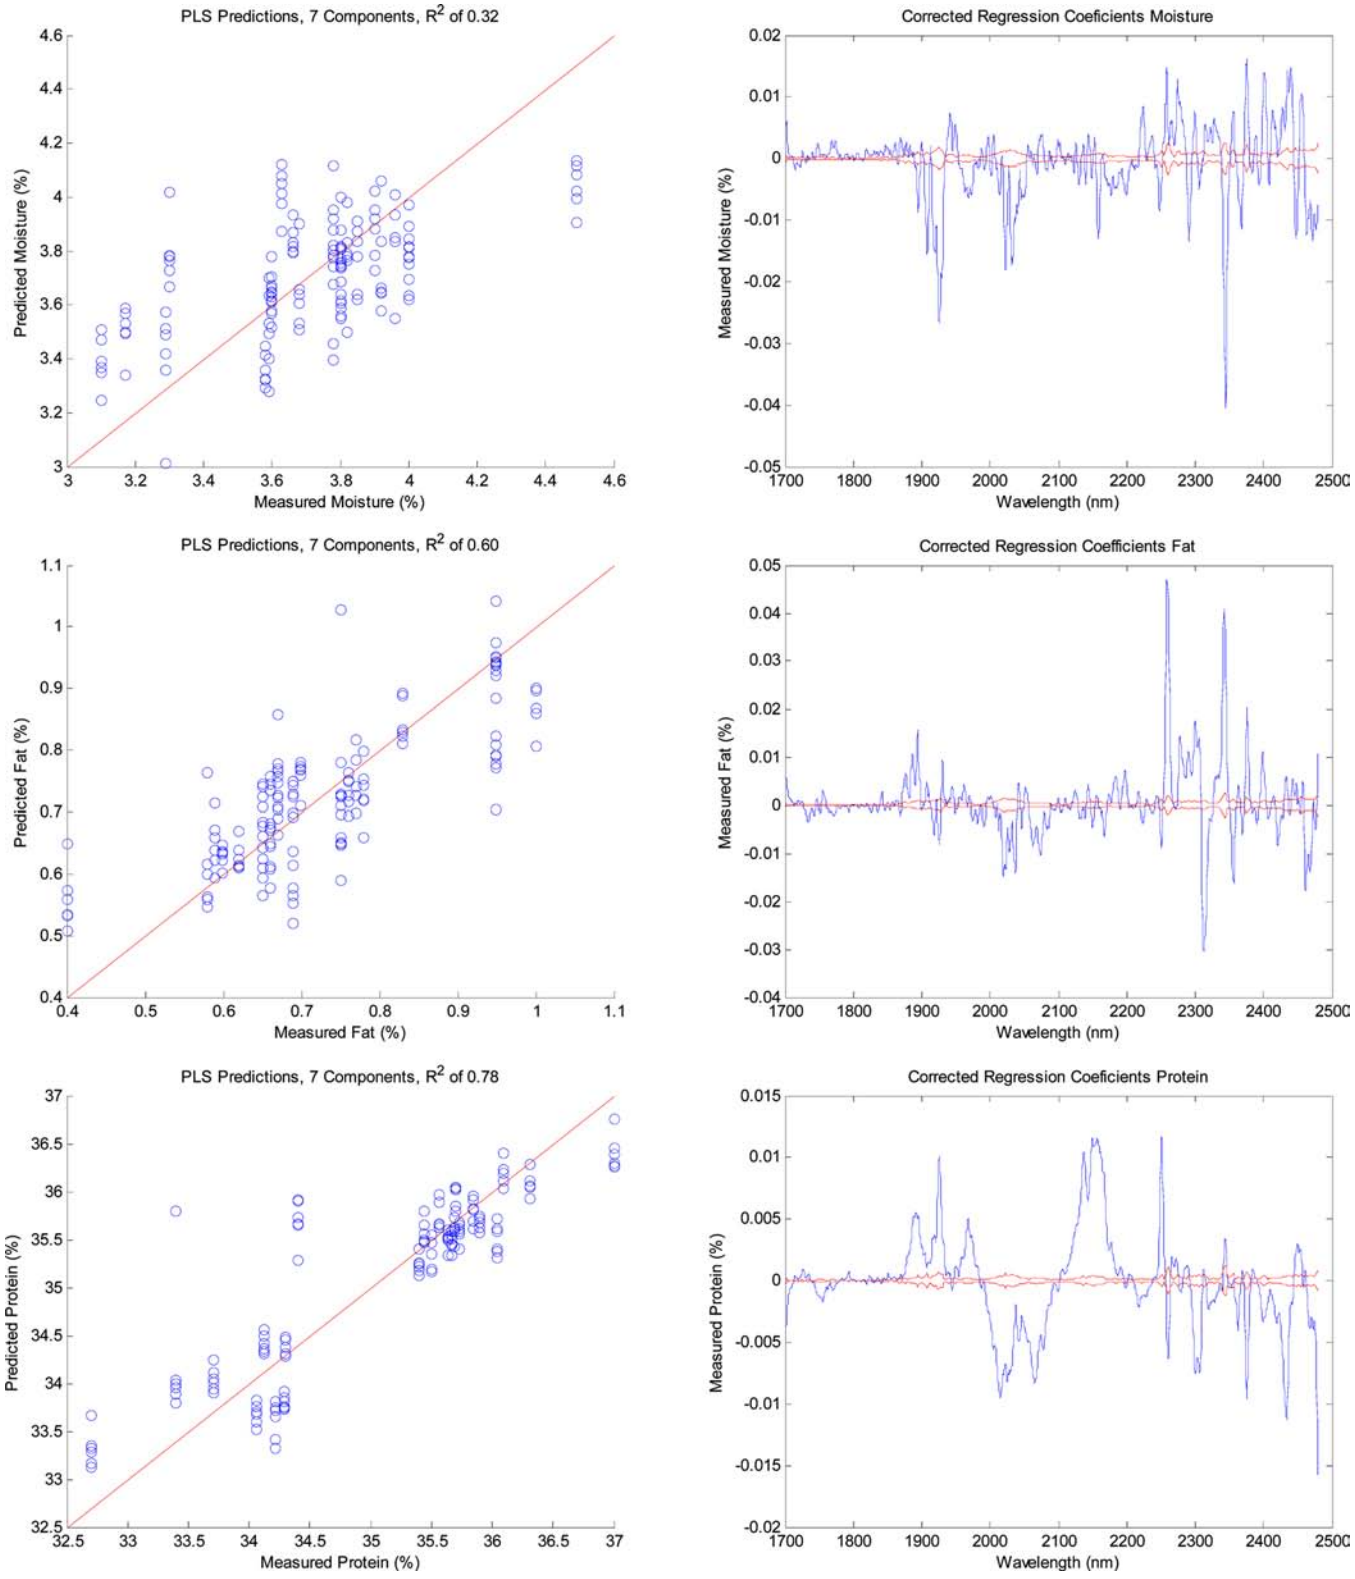

**Figure 3.** Partial least-squares regression cross-validation prediction results using seven latent variables (left). The corresponding corrected average regression coefficients and their 95% confidence intervals (right) for moisture (top), fat (middle), and protein (bottom).

potential to discriminate among the different lots of milk powders.

Interaction between factors was also examined; the figures are available in the Supporting Information (Figure 2S). However, not all interactions could be studied because the experimental design had confounded some of these factors. When plotting the interaction scores, the main effect averages were added back to the data as well as the interaction means for the ANOVA-PCA. The addition of the main effect averages to the interaction averages allows the interplay of factors to be displayed in Supporting Information Figure 2S. The top row/left side of Supporting Information Figure 2S gives the scores

dx.doi.org/10.1021/jf5013727 | J. Agric. Food Chem. 2014, 62, 8060−8067

for the interaction of process type with milk class. One can see that six subgroups are all resolved. On the right side of the top row, the variable loadings for the first principal component are given, which indicate the features of the NIR spectrum that are prominent for this interaction.

However, for the pooled-ANOVA results reported in Table 2, the main effect averages were not included in the sum of squares calculation. The RSS is smaller than those of the main effects with a value of 4.3%; yet this interaction is significant with a $p$-value far less than $10^{-3}$. This result is expected because the process type should affect the milk classes differently since the milk classes differ in chemical and physical composition. NIR spectrometry is affected by the powder morphology, particle size, and chemical composition, all of which may differ among the milk classes, processes, and production sites.

The interactions between milk class and process type with the day of analysis are illustrated by the ANOVA-PCA score plots in the second row of Supporting Information Figure 2S. The confidence intervals of the days are not resolved, although we can see the third day is shifted a bit off center. The respective RSS values for the interaction between day and milk class and between day and process type are 0.2% and 0.1%, respectively. For these cases, the pooled-ANOVA did not detect a significant difference among the means as reported in Table 2.

The bottom row of Supporting Information Figure 2S gives the ANOVA-PCA score plots of the interaction of production site with day of analysis. Because of the large number ($3 \times 11$) of labels for this interaction, the same set of scores is plotted with the day label (left) and the production site label (right). In Table 2, the corresponding RSS is 2.1%, which was not significant at a 95% level of confidence. For this interaction term, the $p$-value was 7%. This result occurs because different samples may have various interactions with moisture because of their varied chemical and physical compositions.

**Influence of Fat, Protein, and Moisture.** An earlier report by this team of investigators implicated the involvement of fats, proteins, and moisture as an influence on the sample variability.[1] Varimax rotations provided variable loadings that correlated with the bands of all three families of compounds. For the partial least-squares regression (PLSR) study, spectra from the 24 samples that had complete COA concentrations for moisture, fat, and protein were used. The concentrations were weight to weight percentages. No spectra from this set of samples were detected as outliers using the same method that was applied to the ANOVA-PCA, so 144 spectra (24 samples × 6 replicates) were available for calibration by PLS regression. Because the two replicates on each day of analysis were blocked with respect to time, a leave one spectrum out cross-validation was used for model building. Each replicate characterized variations with respect to time and sampling by the NIR spectrometer. The squared prediction errors were summed across the fat, moisture, and protein concentrations and plotted with respect to the number of latent variables used by the PLS model. A minimum total prediction error was obtained with seven latent variables or PLS components, so this model was used for the subsequent calculations and figures. Data are not shown.

The prediction results using cross validation of the seven-component PLS model are given in Figure 3. During the cross-validation procedure, each PLS model was converted to a linear set of regression coefficients. These regression coefficients were stored and used to calculate average regression coefficients with 95% confidence intervals that are also given in Figure 3. The coefficient of determination ($R^2$) values were calculated with respect to the cross-validated prediction results and are included with each figure along with a red reference line indicating ideal behavior.

Table 3 reports the pooled-ANOVA results derived from the PLS model. The sum of squares for the NIR (X-Block) are calculated for each component as described by eqs 2−7. From the PLS calibration, the contributions of each concentration can be calculated as a sum of squares for the NIR spectra. In addition, the residual sum of squares (i.e., variation that is not accounted for by the calibration model) can also be calculated for in the spectra. These sums of squares were totaled for the seven components to furnish the top half of Table 3.

**Table 3. Pooled-ANOVA Partial Least-Squares Regression Analysis**

| Near-Infrared Spectra Block | | | | | | | |
|---|---|---|---|---|---|---|---|
| treatment | df | SS | MS | F | $p$-value | | RSS |
| moisture | 6 | 438 | 72.7 | 52 | $\ll 10^{-3}$ | | 25.7% |
| fat | 6 | 178 | 29.7 | 21 | $\ll 10^{-3}$ | | 10.5% |
| protein | 6 | 897 | 149.5 | 107 | $\ll 10^{-3}$ | | 52.6% |
| residuals | 137 | 192 | 1.4 | | | | 11.2% |
| Concentration Block | | | | | | | |
| treatment | df | SS | MS | F | $p$-value | RMSEP | $R^2$ |
| moisture | 6 | 46 | 17.7 | 10.8 | $\ll 10^{-3}$ | 0.24% | 0.32 |
| residual | 137 | 97 | 0.7 | | | | |
| fat | 6 | 87 | 14.4 | 35.0 | $\ll 10^{-3}$ | 0.09% | 0.61 |
| residual | 137 | 97 | 0.4 | | | | |
| protein | 6 | 112 | 18.7 | 82.2 | $\ll 10^{-3}$ | 0.48% | 0.78 |
| residual | 137 | 97 | 0.2 | | | | |

The lower half of Table 3 was obtained from the moisture, fat, and protein concentration predictions using the leave-one-spectrum-out cross validation. The sum of squares of the regression was obtained by subtracting the sum of the squared errors from the sum of the squared mean-centered measured concentrations for moisture, fat, or protein.

Although the coefficients of variation ($R^2$) are not large, it is important to remember that the calibration did not comprise prepared standards over a wide range of concentrations; instead, the concentration ranges used for the calibration were those that were measured from each lot of milk powder, which happened to vary over a narrow range.

Note that, although the contribution to the NIR data for moisture is relatively large as compared to fat, the $R^2$ value of 0.32 is quite low. This trend indicates that the moisture bands in the spectra do not correlate well with the COA moisture concentrations. The samples were stored under ambient conditions, and the moisture content most likely varied during storage. In addition, the COA moisture concentration was measured for the lot of milk powder and not for the individual sample. Last, the range of moisture values was relatively small at 1.8−4.5%, which typically can result in smaller coefficients of determination. NIR spectrometry is sensitive to moisture, and variations of ambient moisture during the measurement may not have been sufficiently corrected by the reference spectrum. According to the RSS, moisture was responsible for one-quarter of the total variation of the NIR spectral data. However, it is important to remember that these data were obtained from a multinational study of many diverse milk powder samples, so the lack of correlation with the moisture concentrations could

be attributed to the different chemical and physical properties of this diverse set of samples.

Fat had the smallest contribution to the NIR data, but its $R^2$ of 0.61 is more than twice that of the moisture. The range of fat concentrations was 0.01−1.05%. The RSS of fat was 10.5%, which indicates that, although the concentration of fat was less than moisture, it still contributed a significant source of variation to the NIR spectra. Although fat is nonvolatile and fairly inert, it could also be affected by ambient storage; for example, lipid oxidation may alter the spectral profile.

Protein was the largest contributor to the variation of the NIR data and gave the best $R^2$ of 0.78. The COA protein concentration range was 32.7−37.0%. The results were encouraging when one considers the wide range of milk powder samples and that the concentration values were determined by lot and not by sample. Typically, calibration models would be devised from a single milk source across a controlled range of concentrations.

Supporting Information Figure 3S gives the production sites with respect to the predicted fat and protein concentrations. These predictions are from the cross-validation of the seven-component PLS regression model. This plot suggests that milk samples processed in the different production sites have different fat and protein concentrations. The 95% confidence ellipses indicate that some sites are statistically different.

In this study, the 38 samples analyzed by NIR showed statistically significant variability with respect to the day of analysis, production site, milk class, process type, and individual samples. NIR spectrometry is very sensitive to chemical composition and physical properties of milk powder products and is an excellent tool for judging the quality of product. The lot to lot variation was not studied. However, the individual samples were precisely determined, which indicates that for targeted or untargeted analysis of milk powders, the models would have to be specific for each sample or lot of milk. Perhaps a future study will examine the lot to lot variations of the milk powders.

Significant correlations were found with the COA concentration values even though some of the coefficients of determination $R^2$ indicated rather weak predictability of models. Many effects could be responsible for the weak PLS models. The range of concentrations was relatively narrow because the observed concentration range was used as opposed to using a standard range of concentrations that would presumably be wider. In addition, the concentrations of fat, moisture, and protein may have changed during storage of the samples. Because these concentrations are relative to the total weight, a change in any one component could also affect the concentration of the others; for example, the adsorption of moisture by the dried milk sample would lower its relative concentrations of protein and fat.

Pooled-ANOVA was combined with PLS regression for the first time. Although the PLS calibration models were not impressively accurate, the pooled-ANOVA applied to PLS regression models demonstrated that the correlated peaks of the NIR spectra were important contributors to the variances of the data set with the protein bands accounting for more than the majority and the moisture bands one-quarter of the total variation of the data set.

This study indicates that for targeted or untargeted analysis of adulterants in milk powders by near-infrared spectrometry, a global model will probably not succeed because the variations arising from milk class, process type, and production site were all significant. Instead localized models that are specific for milk class, process type, and production site would be expected to have a better opportunity for success. Furthermore, local standardization of moisture, fat, and protein would improve calibration models for these important properties. The significance of the variation with respect to the day of analysis indicates that a better approach for collecting reference spectra may be beneficial, especially with respect to controlling variations that arise from ambient moisture.

**ABSTRACT:** The aim of this work was to propose a high-performance liquid chromatography with diode array detection (HPLC−DAD) method for determining the three main compounds responsible for determining the quality of saffron (crocetin esters, picrocrocin, and safranal) by preparing an aqueous extract according to the ISO 3632 standard to solve the difficulty that this standard has for aroma and taste determination by ultraviolet−visible spectroscopy. Toward this aim, laboratory-isolated picrocrocin, a safranal standard with a purity of ≥88%, *trans*-crocetin di(β-D-gentiobiosyl) ester (*trans*-4-GG) and *trans*-crocetin (β-D-glucosyl)-(β-D-gentiobiosyl) ester (*trans*-3-Gg) standards, both with a purity of ≥99%, and 50 different saffron spice samples from Italy, Iran, Greece, and Spain were used in the intralaboratory validation of the HPLC method. The analytical method proposed was adequate in terms of linearity, selectivity, sensitivity, and accuracy for determining the three foremost parameters that define the quality of saffron using only a saffron solution prepared according to the ISO 3632 standard.

**KEYWORDS:** *Crocus sativus L., aqueous extract, trans-4-GG, trans-3-Gg, picrocrocin, safranal, HPLC−DAD*

## INTRODUCTION

Few spices are able to provide the combination of color, taste, and aroma to the foods and beverages to which they are added. The most popular of these is saffron.[1,2] To hydrophilic foods, saffron leads to a yellow color because of its high crocin content (also called crocetin esters, which are glycosylated carotenoids derived from crocetin), bitter taste because of picrocrocin, and pleasant and unmistakable aroma owing to safranal.

The first reference to crocin [crocetin di(β-gentiobiosyl) ester] was made in 1818 by Aschoff,[3] who gave it its name. Pfander et al.[4] were the first to isolate six glycosides of crocetin in saffron. In 1984, Speranza et al.[5] identified their *trans* and *cis* isomers by high-performance liquid chromatography with ultraviolet−visible spectroscopy (HPLC−UV−vis). Tarantilis et al.[6] identified a greater number of crocetin esters and their *trans* and *cis* isomers by high-performance liquid chromatography with diode array detection and mass spectrometry (HPLC−DAD−MS), and Carmona et al.[7] identified four more by HPLC−DAD−MS. Thus far, the quantification of crocetin esters by HPLC has been carried out without high precision,[8−10] and the use of commercial standards in calibration curves gives low correlation coefficients, owing to the phenomenon of aggregation that some authors have demonstrated that happens in highly concentrated aqueous solutions of crocetin esters.[11,12] The kinetics of individual crocetin ester degradation in aqueous extracts of saffron were studied by Sánchez et al.[8] to determine their stability.

Picrocrocin [4-(β-D-glucopyranosyloxy)-2,6,6-trimethyl-1-cyclohexene-1-carboxaldehyde] has been identified only in the genus *Crocus*, of which the only edible species is *Crocus sativus* L. For this reason, picrocrocin is a molecular marker of this spice that is able to give a unique taste that cannot be imitated from other spices or seasonings. This compound was isolated for the first time in the stigmas of *C. sativus* by Winterstein et al.[13] Its molecular structure was defined in 1934 by Kuhn et al.[14] Glycosidic compounds that are structurally related to picrocrocin have been identified. Tarantilis et al.[6] identified three glycosidic compounds in 1995; the Winterhalter group[15,16] recognized eight other glycosidic compounds between 1997 and 1998; and Carmona et al.[17] identified four more by HPLC−DAD−MS in 2006, which were found in considerably lower amounts than picrocrocin. The picrocrocin stability was determined by Sánchez et al.,[18] and picrocrocin is more stable than the crocetin esters.

More than 40 related compounds with a saffron aroma have been identified,[19−24] with the major aromatic compound being safranal (2,6,6-trimethyl-1,3-cyclohexadiene-1- carboxaldehyde). In the saffron with the highest quality in the world "Azafrán de La Mancha", safranal represents over 65% of the

total aroma, as determined by gas chromatography (GC).[25] Safranal is a nonpolar compound, but its solubility in water has not been studied. Different analytical techniques have been developed for its quantification, such as gas chromatography−olfactometry (GC−O),[26] gas chromatography/mass spectrometry (GC/MS),[27] high-performance liquid chromatography (HPLC),[28] or ultrasound-assisted extraction/ultraviolet−visible spectroscopy (USAE/UV−vis).[29] The results obtained are quite different between these various methods.

The first references related to the use of saffron regarded their therapeutic properties.[30] In the first century, Dioscórides described a great number of therapeutic properties;[30] in the tenth century, new properties were described by Avicena.[31] The therapeutic uses of saffron declined greatly over the past decade. However, saffron has received much attention by scientists in recent years.[32] Most of these properties are ascribed to the *trans* isomers[33−35] and safranal.[36−38]

The quality of saffron in international commercial agreements is determined according to the ISO 3632[39] standard, which classifies it into three categories depending upon their physical and chemical characteristics. The three foremost parameters used to define the quality of saffron are color, taste, and aroma.[17,28] These parameters are determined by UV−vis based on the study by Corradi et al.,[40] that is, the $E^{1\%}_{1\ cm}$ at 440 nm (coloring strength), the $E^{1\%}_{1\ cm}$ at 257 nm (the wavelength of picrocrocin maximum absorbance), and the $E^{1\%}_{1\ cm}$ at 330 nm (the wavelength of safranal maximum absorbance). While the $E^{1\%}_{1\ cm}$ at 440 nm is directly correlated with the ability to transmit color to foodstuffs to which it is added, the $E^{1\%}_{1\ cm}$ at 257 nm and $E^{1\%}_{1\ cm}$ at 330 nm do not give an accurate measurement of picrocrocin and safranal because the *trans* isomers of the crocetin esters also absorb at 250 nm and the *cis* isomers of the crocetin esters absorb at 250 and 330 nm as well, causing interference in the measurements.[7,28] Moreover, the UV−vis spectrophotometry does not provide the ratio between the *trans* and *cis* isomers of crocetin esters, which is important for their therapeutic use.[33−35]

Therefore, the purpose of this work was to validate a HPLC method for the independent determination of the crocetin esters, picrocrocin, and safranal using only a saffron solution prepared according to the ISO 3632.[39]

## MATERIALS AND METHODS

**Samples and Reagents.** *Samples.* A total of 50 samples of saffron from different countries were used during the same year of their harvest. These were obtained directly from the producers and packers with a guarantee of their origin and freedom from fraud. The samples were from Italy, Iran, Greece, and Spain. All of the samples were of Category I according to ISO 3632.[39]

*Standards.* Safranal with a purity of ≥88% was obtained from Sigma-Aldrich (Madrid, Spain), and crocetin esters, *trans*-crocetin di(β-D-gentiobiosyl) ester (*trans*-4-GG) and *trans*-crocetin (β-D-glucosyl)-(β-D-gentiobiosyl) ester (*trans*-3-Gg), with a purity of ≥99%, were obtained from Phytolab GmbH & Co. KG (Vestenbergsgreuth, Bavaria, Germany).

*Solvents.* Acetonitrile was obtained from Panreac (Barcelona, Spain), while water was purified through a Milli-Q system (Millipore, Bedford, MA).

**Safranal Water Solubility.** To prepare a saturated safranal aqueous solution, increasing aliquots of safranal standard were added to a known volume of water until it was observed that the aqueous solution was saturated with safranal. A volume of 20 μL of the safranal standard in 10 mL of Milli-Q water was enough to obtain a saturated safranal aqueous solution. This solution was stirred using a magnetic stir bar at 1000 rpm for 1 h while being kept away from light. Then, it was allowed to stand to separate the aqueous phase from the safranal, with the saturated aqueous solution of safranal on top of the flask. An aliquot of this saturated solution was taken, *s*, and five dilutions were carried out: *s*/2, *s*/4, *s*/8, *s*/16, and *s*/32. These were then analyzed by UV−vis. The water solubility was calculated as the mean of the concentration values at which the absorbance obeyed the Lambert−Beer law. These analyses were carried out in triplicate at 20 ± 2 °C.

The safranal standard solutions were monitored by scanning from 200 to 400 nm using a PerkinElmer Lambda 25 spectrophotometer (Norwalk, CT) with UV WinLab 2.85.04 software (PerkinElmer). Their absorbance was determined at 330 nm. For the safranal quantification, two series of safranal standard solutions in water with concentrations of 3, 10, 20, 30, and 32 mg/L were prepared and analyzed in duplicate by UV−vis. A calibration curve was constructed for the safranal concentration, *c* (mg/L) as a function of its absorbance *a*, at 440 nm with the equation $c = 22.899a - 0.3027$ and a $R$ value = 0.999.

**Saffron Extract Preparation.** The saffron aqueous extracts were prepared according to ISO 3632.[39] A total of 500 mg of powdered saffron, previously passed through a sieve of 0.5 mm pore diameter, was placed in a 1 L volumetric flask, and 900 mL of Milli-Q water as added. The solution was stirred using a magnetic stir bar at 1000 rpm for 1 h while being kept away from light. The flask was filled to the 1 L mark, and the solution was homogenized through agitation. The solution was filtered through a filter made of hydrophilic polytetrafluoroethylene (PTFE) with a pore size of 0.45 μm (Millipore, Bedford, MA). It was then transferred into a vial for HPLC−DAD analysis. The saffron extraction was checked by doing a second extraction of the vegetable material obtained by filtration of the first extraction of three different saffron extracts prepared according to ISO 3632.[39]

**HPLC−DAD Analysis.** A total of 20 μL of each sample (saffron aqueous extracts) were injected into an Agilent 1200 HPLC chromatograph (Palo Alto, CA) equipped with a 150 × 4.6 mm inner diameter, 5 μm Phenomenex (Le Pecq Cedex, France) Luna $C_{18}$ column that was equilibrated at 30 °C. The eluents were water (A) and acetonitrile (B) with the following gradient: 20% B, 0−5 min; 20−80% B, 5−15 min; and 80% B, 15−20 min. The flow rate was 0.8 mL/min. The DAD detector (Hewlett-Packard, Waldbronn, Germany) was set at 250, 330, and 440 nm for picrocrocin, safranal, and crocetin ester detection, respectively. All of the analyses were performed in duplicate, and two measurements were taken for each replicate.

The identifications of *trans*-4-GG and *trans*-3-Gg were carried out using the UV−vis spectrum, and the retention time was carried out by the HPLC−DAD method at 440 nm and the parameter %III/II[41] of their standards. Their quantification was based on calibration curves.

With the aim of avoiding the phenomenon of aggregation that some authors have described in carotenoids, such as crocetin,[12,42] *trans*-4-GG, and *trans*-3-Gg standard solutions, 10, 20, 30, 40, 50, 60 and 70% acetonitrile/water (v/v) solutions were prepared and analyzed in duplicate by UV−vis at 440 nm.

Two series of *trans*-4-GG standard solutions in water and two other series in 50% acetonitrile/water (v/v) with concentrations of 100, 50, 25, 12.5, 6.25, 3.125, 1.6, and 0.8 mg/L were prepared and analyzed in duplicate by HPLC−DAD.

Two series of *trans*-3-Gg standard solutions in water and two other series in 50% acetonitrile/water (v/v) with concentrations of 50, 25, 12.5, 6.25, 3.125, 1.6, and 0.8 mg/L concentration were prepared and analyzed in duplicate by HPLC−DAD.

Isomeric standards for the *cis*-crocetin esters are not available on the market; therefore, they were identified using the UV−vis spectrum. The retention time by HPLC−DAD−MS at 440 nm was determined by this group[7] and in other works by the parameter %III/II.[41] Isomeric *cis*-crocetin ester quantification was performed by the molecular coefficient absorbance value (63 350), obtained by Speranza et al.[5]

Picrocrocin identification was carried out by combination of its UV−vis spectrum and its retention time by HPLC−DAD at 250 nm. For its quantification, picrocrocin was isolated as described by Sánchez et al.[8] Two series of isolated picrocrocin solutions in water from 2 to 315 mg/L were prepared and analyzed in duplicate by HPLC−DAD.

dx.doi.org/10.1021/jf5019356 | J. Agric. Food Chem. 2014, 62, 8068−8074

Safranal identification was carried out using the UV−vis spectrum and the retention time of the safranal standard by HPLC−DAD at 330 nm. Two series of safranal standard solutions in water with concentrations of 4, 2, 1, 0.5, 0.25, 0.125, 0.06, and 0.03 mg/L were prepared and analyzed in duplicate by HPLC−DAD.

**Ultrasound-Assisted Extraction Followed by Gas Chromatography/Mass Spectrometry (USAE/GC/MS).** Safranal determination by USAE/GC/MS was carried out as described by Maggi et al.[27] USAE was performed in a Super RK 255H ultrasound water bath (Sonorex, Berlin, Germany) at a fixed frequency of 35 kHz. The temperature of the sonicated water bath was 25 °C. The sample flask was charged with 4 g of saffron. The solvent system extractant was 40 mL of diethyl ether. Each saffron sample was sonicated twice for 15 min (two fractions per saffron sample). For each sonication, a new volume of the solvent system extractant was added to the sample flask. The organic extract (80 mL) was concentrated using a Laborata 4000 efficient rotary evaporator (Heidolph Instruments GmbH & Co. KG, Schwabach, Germany). The volume of the final aromatic extract in diethyl ether was 4 mL. The collected diethyl ether was analyzed by GC to check if there was a loss of saffron volatiles during the evaporation procedure, but no saffron volatiles were detected. A HP 5890 series II chromatograph (Hewlett-Packard, Palo Alto, CA) equipped with a HP 5972 mass-selective detector in electron impact mode (70 eV) and a HP-5 MSM capillary column (30 m, 0.25 mm inner diameter, and 0.25 $\mu$m film thickness) with helium as the carrier gas at a flow rate of 1 mL/min was used for the analysis of safranal. The column temperature was initially held for 3 min at 50 °C, then increased to 180 °C at a rate of 3 °C $min^{-1}$, and finally increased to 250 °C at a rate of 15 °C $min^{-1}$. The injector and detector temperatures were set at 200 and 290 °C, respectively. Aliquots of 1 $\mu$L were manually injected in the splitless mode. For the safranal quantification, the external standard method was applied. The calibration curve was established for the series of safranal standard solutions in diethyl ether, with eq 1.

$$\text{mg of safranal/kg of saffron} = 86.6\text{area}_{\text{safranal}} \quad (R = 0.999) \qquad (1)$$

**Analytical Method Validation.** An intralaboratory method validation was carried out according to the Eurachem guideline.[43] For the linearity study, calibration graphs were performed by injecting standard solutions of saffron components (*trans*-4-GG, *trans*-3-Gg, picrocrocin, and safranal) at different concentrations. Each level of concentration was analyzed in duplicate, and two measurements for each one were carried out, with a total of four replicates.

The selectivity was determined by comparing the chromatograms obtained from the saffron samples to those of the standard solutions analyzed by HPLC−DAD.

The sensitivity of the method was determined with regard to the limit of detection (LOD) and limit of quantification (LOQ), comparing the height of a sample peak and the height of a noise peak. The LOD was reached at a signal-to-noise ratio greater than 3, and the LOQ was reached at a signal-to-noise ratio greater than 10.[44] The detection and quantification limits were determined by the empirical examination of the chromatograms from 50 saffron samples.

The accuracy of the method was evaluated with the 50 samples of saffron from different countries. Each sample was analyzed in duplicate, and two measurements were also taken for each replicate. The standard deviation (square root of the arithmetic mean of the variances) was calculated to obtain the repeatability [percent relative standard deviation (% RSD)]. The standard deviation multiplied by the square root of 3 was taken as the reproducibility value if this value was higher than the repeatability. If not, this last value was also taken as the reproducibility.[45]

## RESULTS AND DISCUSSION

**Safranal Water Solubility.** Saffron contains metabolites of different polarity because crocetin esters and picrocrocin are highly water-soluble polar compounds and safranal is a nonpolar constituent that has low solubility in polar solvents. The solubility of safranal in water has not been determined previously.

The water solubility of safranal was calculated from the saturated safranal aqueous solutions and was found to be 673.07 ± 0.01 mg/L at 20 ± 2 °C. An aqueous extract prepared according to ISO 3632[39] contains 500 mg of saffron dissolved in 1 L of water, and its safranal content will be less than the solubility (673.07 mg/L); hence, safranal will be completely dissolved. This result suggests that a saffron aqueous extract according to ISO 3632[39] could be used for safranal determination by HPLC, with the same solution used for determining the crocetin esters and picrocrocin. GC−O,[26] GC/MS,[27] HPLC,[28] or USAE/UV−vis[29] have been used to quantify safranal, with the results between these methods being quite different. HPLC is considered the most efficient analytical technique for the analysis of sensitive compounds in complex extracts of natural products.[46] Some authors have used HPLC for determining safranal,[47−49] but these authors carried out the extraction with organic solvents, such as ethanol or methanol, because of the nonpolar character of safranal and the ignorance of its water solubility.

**Calibration Graphs.** Table 1 shows the calibration curves of the saffron components (*trans*-4-GG, *trans*-3-Gg, picrocrocin, and safranal) calculated by the least-squares method.

**Table 1. Linearity Data for Analysis by HPLC−DAD of *trans*-4-GG, *trans*-3-Gg, Picrocrocin, and Safranal**

| | linear range of concentration (mg/L) | slope | intercept | correlation coefficient ($R^2$) |
|---|---|---|---|---|
| *trans*-4-GG | 0.8−100 | 0.0094 | 2.4861 | 0.976 |
| *trans*-3-Gg | 0.8−50 | 0.0079 | 0.6682 | 0.996 |
| picrocrocin | 2−315 | 0.0290 | 0.5194 | 0.999 |
| safranal | 0.03−4 | 0.0323 | 0.0510 | 0.998 |

The absorbance at 440 nm of the *trans*-4-GG and *trans*-3-Gg standard solutions at different percentages of acetonitrile/water (v/v) increased until a ratio of 40% acetonitrile/water (v/v). From a ratio of 50% acetonitrile/water (v/v) and greater, the absorbance at 440 nm of the *trans*-4-GG and *trans*-3-Gg standard solutions remained stable. This result suggests that, in highly concentrated aqueous solutions of *trans*-4-GG and *trans*-3-Gg standard in 40−50% acetonitrile/water (v/v) or greater, molecular aggregation does not occur.

The calibration curves of *trans*-4-GG and *trans*-3-Gg in water gave correlation coefficients lower than those of the calibration curves of *trans*-4-GG and *trans*-3-Gg in 50% acetonitrile/water (v/v), probably because of the phenomenon of aggregation;[12,42] hence, the calibration curves in 50% acetonitrile/water (v/v) were used. The chromatographic purity of the *trans*-4-GG was 99.43%. The calibration curve for the concentration of *trans*-4-GG, $d$ (mg/L), as a function of its HPLC peak area, $b$, exhibited good linear regression in the range from 0.8 to 50 mg/L with the equation $d = 0.0075b - 0.008$ and a $R$ value = 0.999 for a total of seven data points. The calibration curve of the *trans*-3-Gg concentration, $f$ (mg/L), as a function of its HPLC peak area, $g$, showed good linear regression in the range from 0.8 to 25 mg/L with the equation $f = 0.0071g - 0.0047$ and a $R$ value = 0.999 for a total of six data points. Its chromatographic purity was 99.19%.

The molecular coefficient absorbance values for *trans*-4-GG and *trans*-3-Gg in 50% acetonitrile/water (v/v) were 106

dx.doi.org/10.1021/jf5019356 | J. Agric. Food Chem. 2014, 62, 8068−8074

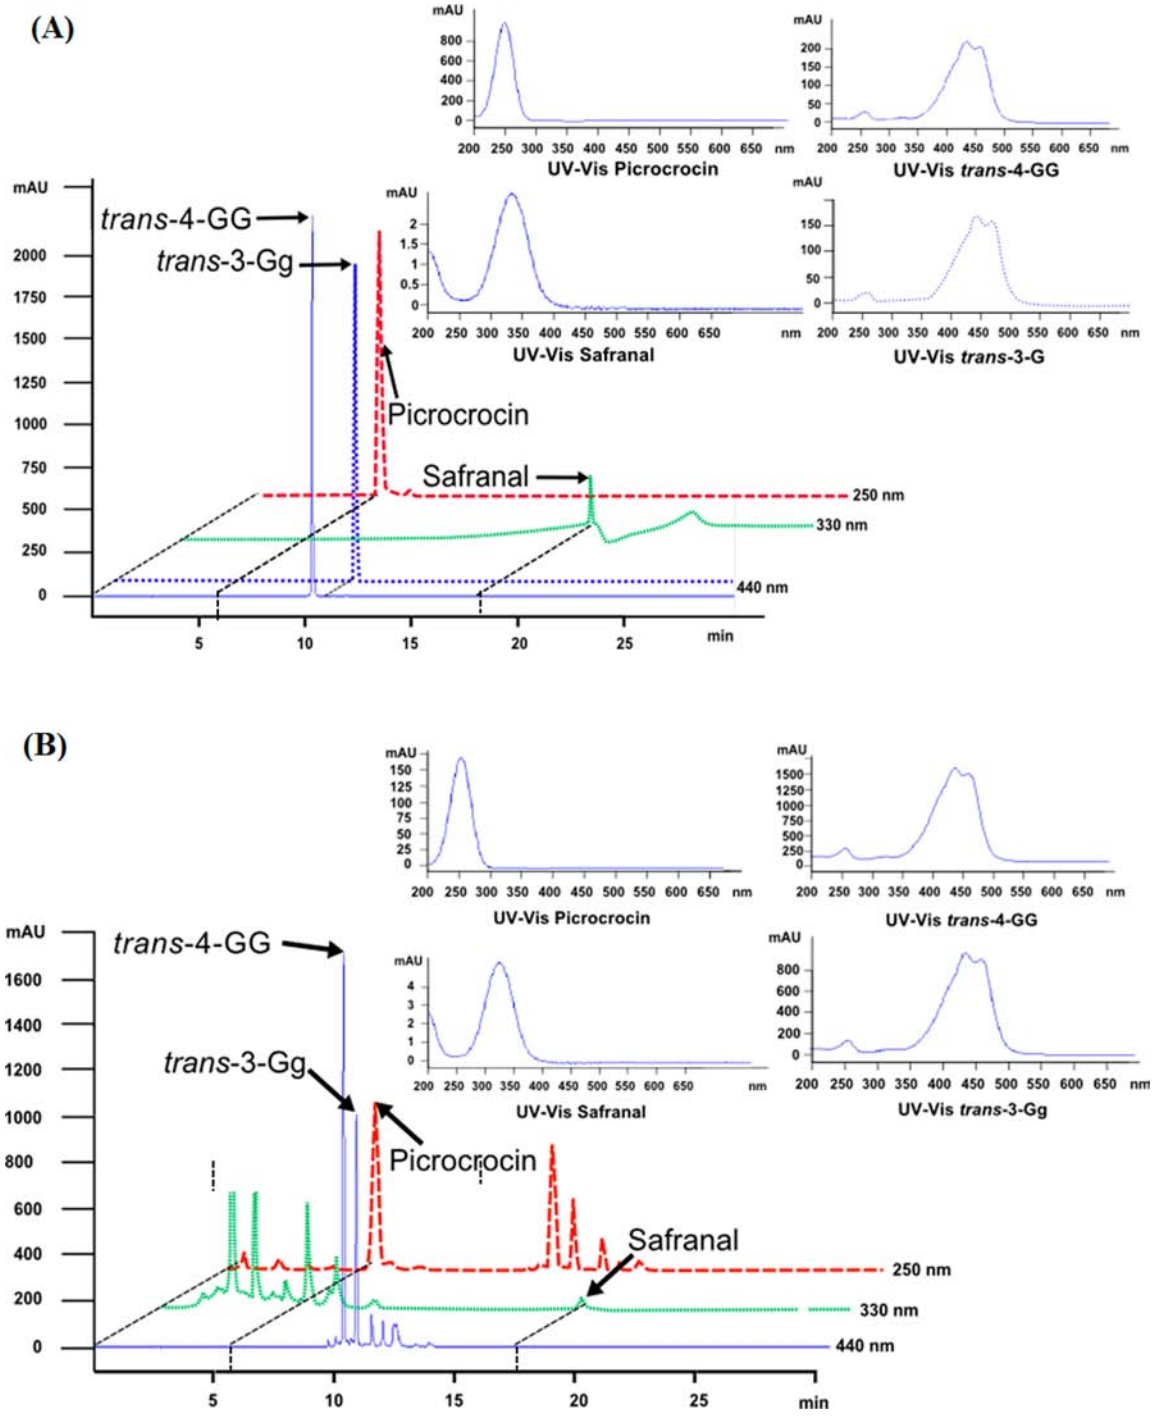

**Figure 1.** (A) Chromatograms of the commercial *trans*-4-GG (440 nm), *trans*-3-Gg (440 nm), and safranal (330 nm) standards and the laboratory-isolated picrocrocina (250 nm) and their UV−vis spectrum. (B) Chromatograms of the saffron sample (440, 330, and 250 nm) and their UV−vis spectrum.

922.75 and 92 781.76 $M^{-1}$ $cm^{-1}$ (440 nm), respectively, which were close to the values obtained by other authors for *trans*-4-GG: 89 000 $M^{-1}$ $cm^{-1}$,[5] 132 200 $M^{-1}$ $cm^{-1}$,[50] 133 750 $M^{-1}$ $cm^{-1}$,[51] and 133 500 $M^{-1}$ $cm^{-1}$;[52] these differences may be due to the use of different solvents. The quantification of the *cis* isomers was based on eq 2

$$C_{cis} = \left(m_{trans} \times \frac{\epsilon cis}{\epsilon trans}\right)\text{area}_{cis} + \left(n_{trans} \times \frac{\epsilon cis}{\epsilon trans}\right) \quad (2)$$

where $C_{cis}$ is the concentration of the *cis*-crocetin esters in mg/L, $m_{trans}$ is the slope of the *trans*-crocetin ester, $\epsilon cis/\epsilon trans$ is the ratio *cis*/*trans* obtained by Speranza et al.,[5] $\text{area}_{cis}$ is the *cis*-crocetin ester peak area, and $n_{trans}$ is the intercept of the *trans*-crocetin ester.

The calibration curve of the picrocrocin concentration, $j$ (mg/L), as a function of the picrocrocin peak area, $k$, showed good linear regression in the range from 2 to 315 mg/L with the equation $j = 0.0290k + 0.5194$ and a $R$ value = 0.999 for a total of six data points. Its chromatographic purity was 96%.

dx.doi.org/10.1021/jf5019356 | J. Agric. Food Chem. 2014, 62, 8068−8074

The chromatographic purity of safranal was 92.99%. The calibration curve of the safranal concentration, $h$ (mg/L), as a function of the peak area for safranal, $i$, revealed good linear regression in the range from 0.03 to 4 mg/L with the equation $h = 0.0323i + 0.051$ and a $R$ value = 0.998 for a total of eight data points.

**Saffron Extraction Conditions.** Saffron extraction was carried out according to ISO 3632.[39] Other authors[40] showed that this method is suitable. In this work, these extraction conditions were checked again, and the results showed that the coloring strength in the second extraction was less than 2%; therefore, it is an efficient and eco-friendly extraction method.

**HPLC−DAD Conditions.** For the HPLC method, we relied on the method proposed by the identification and quantification of the crocetin esters and picrocrocin.[8,53] This method had not been validated previously. For the crocetin ester quantification, an approximate equation was used[8,53] on the basis of the molecular weight of the crocetin ester, the coloring strength of the sample determined by UV−vis according to ISO 3632,[39] the percentage peak area of the crocetin ester by HPLC−DAD at 440 nm, and the molecular coefficient absorbance value determined by Speranza et al.[5] In this work, the quantification of the crocetin esters was carried out using the calibration curves of the standards of *trans*-4-GG and *trans*-3-Gg. Figure 2 represents the comparison of the *trans*-4-GG and *trans*-3-Gg contents, respectively, obtained for 50 saffron samples using the approximate equation[8] and their respective calibration curves. Pearson's correlation ($r$) was 0.953 for *trans*-4-GG and 0.766 for *trans*-3-Gg; thus, in both cases, there was a positive correlation between both methods. The *trans*-3-Gg correlation is lower, possibly because of the use in the approximate equation of the molecular coefficient absorbance value calculated by Speranza et al.[5] for *trans*-4-GG. In this work, we have demonstrated that there is a difference between the molecular absorbance coefficients for *trans*-4-GG and *trans*-3-Gg.

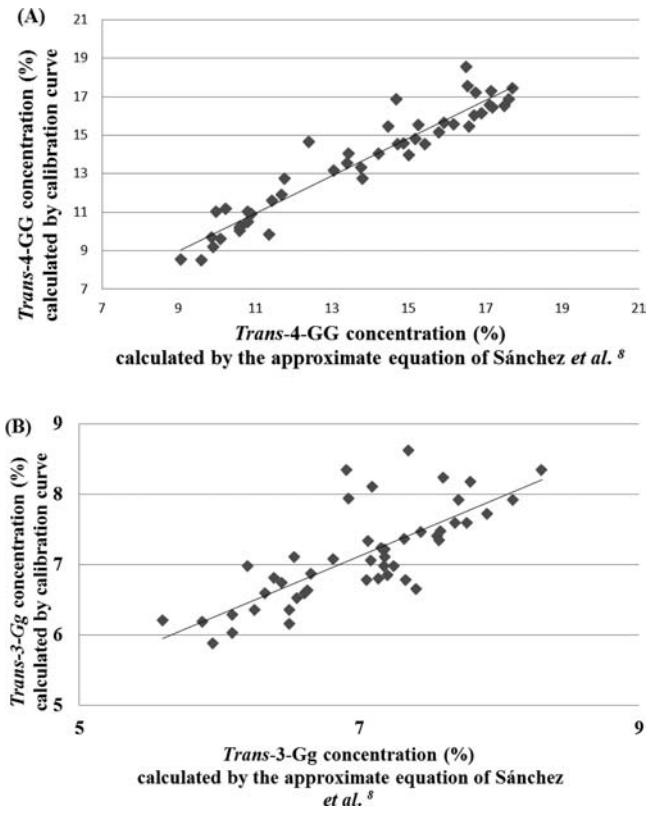

**Figure 2.** Graphical representation of the (A) *trans*-4-GG and (B) *trans*-3-Gg concentrations calculated by the approximate equation of Sánchez et al.[8] versus the (A) *trans*-4-GG and (B) *trans*-3-Gg concentrations calculated by the calibration curve for 50 saffron samples.

In summary, 50 saffron samples were analyzed by HPLC. The values obtained ranged from 182.648 to 82.827 g of *trans*-4-GG/kg of saffron, from 84.093 to 58.819 g of *trans*-3-Gg/kg of saffron, from 73.501 to 36.802 g of picrocrocin/kg of saffron, and from 1.142 to 4.346 g of safranal/kg of saffron.

The evaluation of the method, described in terms of its linearity, selectivity, sensitivity, and accuracy, showed that it was adequate for our objectives. In Table 1, we can see the linearity of the proposed method by means of the calibration graphs for the saffron components *trans*-4-GG, *trans*-3-Gg, picrocrocin, and safranal. The excellent linearity of this HPLC method is demonstrated by taking into account that the correlation coefficients were higher than 0.99 in the majority of the cases.

The proposed method showed a good selectivity because the retention times of their corresponding peaks were practically the same for the standards and the saffron samples analyzed (Figure 1).

The values of the detection and quantification limits, calculated as the concentration, gave a peak height 3 or 10 times the signal-to-noise ratio, as shown in Table 2.

The accuracy of the experimental procedure was also evaluated by studying the reproducibility and repeatability (% RSD). To consider the reproducibility of a method to be acceptable, its value should be lower than 20%. As seen in the results, summarized in Table 2, this parameter ranged from 0.06% (safranal) to 3.33% (*trans*-3-Gg). The same limit (20%) was taken to represent good repeatability, which, in this case, ranged from 0.04% (safranal) to 1.93% (*trans*-3-Gg). Therefore, the method proposed showed very good repeatability and reproducibility parameters.

**Comparison of HPLC−DAD and USAE/GC/MS Methods for Determining Safranal.** The safranal content of the 50 saffron samples was determined by USAE/GC/MS and HPLC−DAD from an aqueous extract to compare the results obtained with both analytical techniques. USAE/GC/MS is a method that has already been validated and published. The values obtained with this method were from 2.367 to 4.945 g of safranal/kg of saffron. The same sample analyzed by HPLC from a saffron aqueous extract gave values from 1.142 to 4.346 g of safranal/kg of saffron. The graph shown in Figure 3 represents the comparison of the safranal content obtained for the 50 saffron samples using HPLC−DAD and USAE/GC/MS. Pearson's correlation coefficient ($r$) was 0.788, showing a positive correlation between both methods.

In conclusion, the proposed HPLC−DAD method allows for the quantification of the three main compounds of saffron in an easy and fast way, using only a water solution,[39] with good linearity, selectivity, sensitivity, and accuracy. This methodology is adequate for determining the three foremost parameters that define the quality of saffron by preparing an aqueous extract according to ISO 3632.[39] Because HPLC−DAD is common in laboratories certified for the quality control of saffron, this method could even be included in the present ISO 3632.[39]

Table 2. Precision of the Experimental Procedure for Analysis by HPLC−DAD of *trans*-4-GG, *trans*-3-Gg, Picrocrocin, and Safranal ($n$ = 4)

| | LOD (g/kg of saffron) | LOQ (g/kg of saffron) | reproducibility (%) | RSD (%) |
|---|---|---|---|---|
| *trans*-4-GG | 0.33 | 0.95 | 3.07 | 1.77 |
| *trans*-3-Gg | 0.38 | 1.02 | 3.33 | 1.93 |
| picrocrocin | 0.60 | 1.01 | 1.34 | 0.77 |
| safranal | 0.105 | 0.28 | 0.06 | 0.04 |

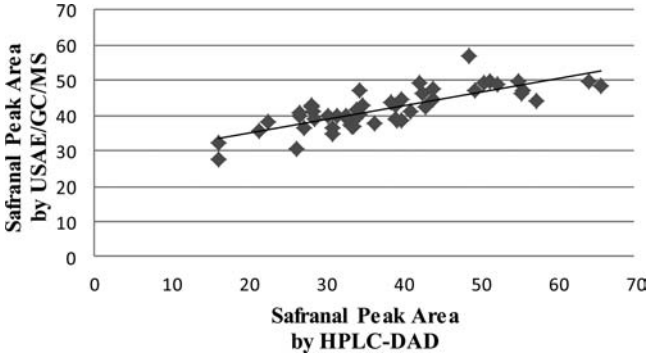

Figure 3. Graphical representation of the safranal content obtained by HPLC−DAD versus the safranal content obtained by USAE/GC/MS for 50 saffron samples.

**ABSTRACT:** Ultraperformance liquid chromatography mass spectrometry (UPLC-MS), flow injection mass spectrometry (FIMS), and headspace gas chromatography (headspace-GC) combined with multivariate data analysis techniques were examined and compared in differentiating organically grown oregano from that grown conventionally. It is the first time that headspace-GC fingerprinting technology is reported in differentiating organically and conventionally grown spice samples. The results also indicated that UPLC-MS, FIMS, and headspace-GC-FID fingerprints with OPLS-DA were able to effectively distinguish oreganos under different growing conditions, whereas with PCA, only FIMS fingerprint could differentiate the organically and conventionally grown oregano samples. UPLC fingerprinting provided detailed information about the chemical composition of oregano with a longer analysis time, whereas FIMS finished a sample analysis within 1 min. On the other hand, headspace GC-FID fingerprinting required no sample pretreatment, suggesting its potential as a high-throughput method in distinguishing organically and conventionally grown oregano samples. In addition, chemical components in oregano were identified by their molecular weight using QTOF-MS and headspace-GC-MS.

**KEYWORDS:** *UPLC-MS, QTOF-MS, headspace-GC, multivariate data analysis, oregano (Origanum vulgare)*

## INTRODUCTION

Organic food has attracted more consumers in the past decades, especially in the past 5 years. A survey indicated that in 2012, U.S. consumers spent $31.5 billion on organic food, with an annual growth of 10.3% compared with that in 2011.[1] The survey also indicated that private label and contract manufacturing keep increasing in the organic field, which results in a higher demand for analytical technologies to differentiate organic foods from conventionally grown foods. The development of novel methods might prevent food adulteration and protect both consumers and the organic food market.

Oregano (*Origanum vulgare*) is a widely used culinary spice. Besides daily use as a cooking spice, oregano may also be recognized as a functional food because of its bioactivities.[2−19] Previous research indicated that oregano extracts have many beneficial effects, including anti-inflammatory,[2] antibacterial,[3] lipid oxidation reducing,[4,5] antimalarial,[6] antimicrobial,[7−10] and antioxidant[10−19] activities. Both conventional and organic oreganos are commercially available and differ significantly in their prices. Therefore, analytical methods for differentiating oregano samples from different growing conditions are in high demand to detect possible adulteration.

Previous research indicated that both LC-UV and flow injection electrospray ionization with ion trap mass spectrometry (FIMS) fingerprints are effective in differentiating organically and conventionally grown spices.[20−23] Since 2012, conventionally and organically grown peppermint, sage, and basil samples have been differentiated using both HPLC-UV and flow injection electrospray ionization with ion trap mass spectrometry (FIMS) fingerprinting techniques combined with principal component analysis (PCA) in our laboratory.[22−24] As a continuation of our effort in detecting food adulteration, this study examined whether headspace-GC, UPLC-MS, and FIMS fingerprinting combined with statistical approaches could effectively differentiate organically and conventionally grown oregano samples. This was the first effort to distinguish organically and conventionally grown spices by headspace-GC fingerprints of the nonpolar volatile components.

## MATERIALS AND METHODS

**Standard Compounds and Other Chemicals.** LC-MS grade acetonitrile, methanol, and formic acid were purchased from Sigma-Aldrich (St. Louis, MO, USA). LC-MS grade water was obtained from a Milli-Q 10 ultrapure water system (Billerica, MA, USA). All other chemical reagents were of analytical grade purchased from Sigma-Aldrich (St. Louis, MO, USA) and used without further purification.

**Plant Materials and Sample Preparation.** Ten USDA certified organic oregano leaf samples and 10 conventional oregano leaf samples were gifts from the Frontier Natural Products Co-op (Norway, IA, USA). Dry botanical samples were ground to 20 mesh powder using an IKA A11 laboratory grinder (IKA, Staufen, Baden-

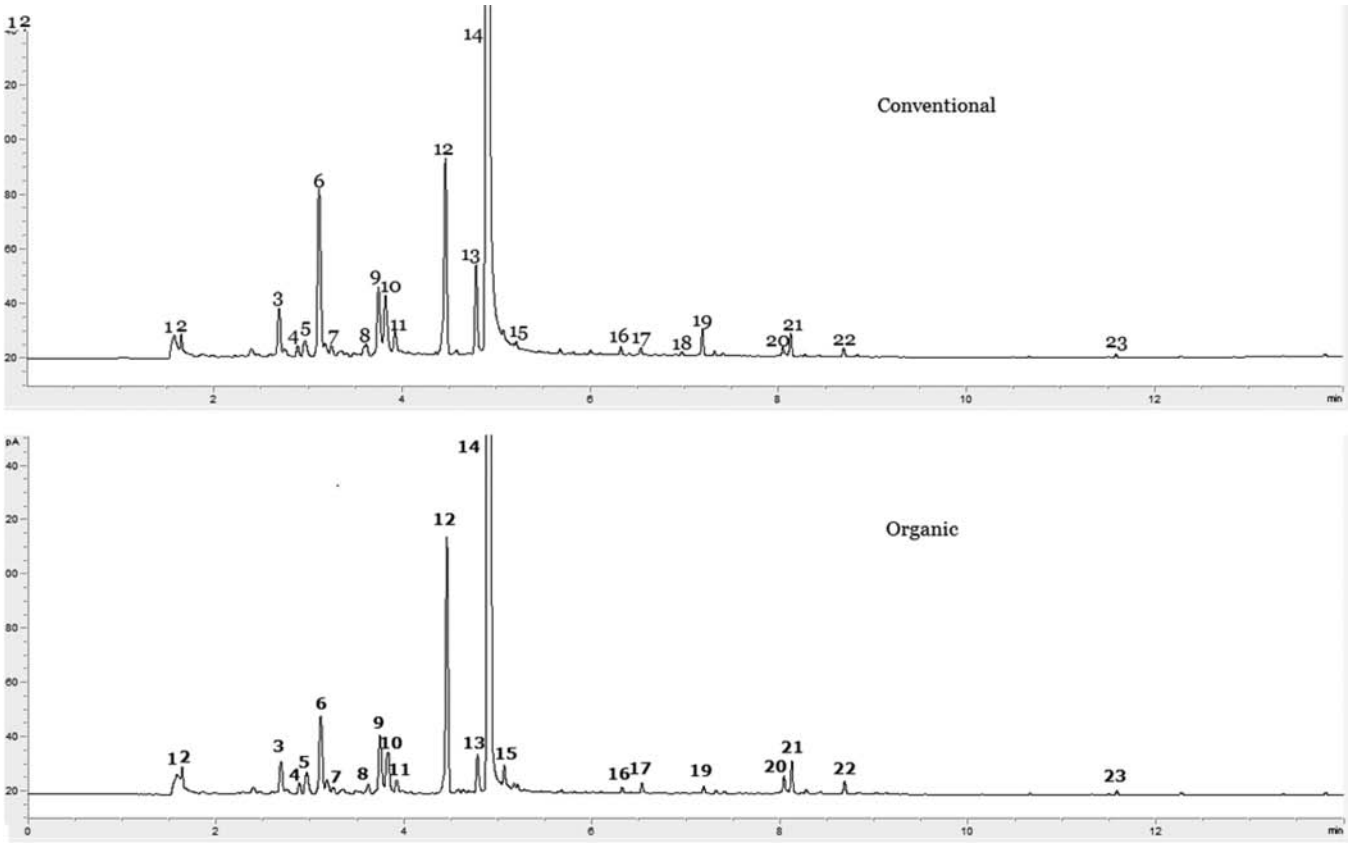

**Figure 1.** Representative headspace-GC fingerprints for commercial conventional and organic oregano samples.

Württemberg, Germany) and stored at −20 °C before analysis. One hundred milligrams of every sample powder was accurately weighed and extracted with 10 mL of water/MeOH (1:1, v/v) with ultrasonication at ambient temperature for 30 min. The extracts were filtered with a 0.22 μm GHP syringe filter (Waters, Milford, MA, USA) and ready for LC-MS and FIMS fingerprinting analyses. One hundred milligrams of oregano samples was accurately weighed and directly sealed into headspace sample bottles and ready for GC analyses. Each sample was analyzed in triplicate.

**Headspace GC and GC-MS Conditions.** An Agilent 7890A GC with an Agilent 7697A headspace sampler and an FID was used for GC fingerprinting analysis (Agilent, Loveland, CO, USA). Carrier gas was helium at a flow rate of 2.5 mL/min. An HP-5 phenyl methyl siloxane column (30 m × 320 μm with a 0.25 μm film thickness) from Agilent was used. The injection volume was 1 μL at a split ratio of 10/1. FID temperature was 300 °C. The initial oven temperature was 100 °C, which was increased at 10 °C/min to 250 °C and held for 5 min. Headspace oven, loop, and transfer line temperatures were 100, 110, and 120 °C, respectively.

An Agilent 7890A/5973N headspace-GC−single-quadruple MS system was selected for the identification of volatile substances. The temperature programming was the same as that for headspace-GC fingerprinting. Quadruple temperature was 150 °C, source temperature was 230 °C, and cone voltage was 70 eV. The mass range was set from 30 to 450 Da.

Individual substances were tentatively identified through the molecular weight of substances and the material information in the database. Quantification was based on the area under each substance peak as absolute peak area, and peak area was compared to the reference peak (peak 14) as relative peak area.

**UPLC-MS and FIMS Conditions.** A Waters Acuity UPLC-Xevo G2 QTOF MS system was selected for both UPLC-MS and FIMS analyses. Mobile phase A consisted of 0.1% formic acid in water, and mobile phase B consisted of 0.1% formic acid in acetonitrile for both UPLC-MS and FIMS analyses. For UPLC-MS, a Waters BEH C18 column (2.1 mm i.d. × 100 mm, 1.7 μm) was used at 40 °C; the elution gradient started with 5% phase B, changed linearly to 50% in 10 min, increased linearly to 90% B at 15 min, was maintained for 2 min and then returned to its initial conditions for 2 min to re-equilibrate the column for the next injection. The flow rate was 0.4 mL/min with an injection volume of 2 μL. The MS detector conditions were as follows: capillary voltage, 2.50 kV; sampling cone voltage, 60 V; extraction cone voltage, 4.0 V; source temperature, 120 °C; and desolvation temperature, 450 °C. The cone gas flow rate was 100 L/h, and the desolvation gas was 800 L/h. An $MS^E$ method was used with a mass range from $m/z$ 100 to 1000 in ESI negative mode, scan time was 0.3 s, and the ramp collision energy was 30 eV.

For FIMS, the mobile phase of methanol/water in a ratio of 1:1 (v/v) was used, and the flow rate was 0.2 mL/min. Oregano extracts were diluted 10 times before injection, and the injection volume was 2 μL. MS spectra were collected from 0.05 to 0.55 min, and MS conditions were the same as those used in UPLC-MS analysis. Masslynx 4.1 software (Waters) was used for alignment of peaks and accurate mass weight calculation and identification.

**Data Processing.** Thirty-seven major chromatographic peaks were detected in the UPLC-MS fingerprints in both organically and conventionally grown oregano samples. Their absolute and relative peak areas were used for orthogonal partial least-squares discriminant analysis (OPLS-DA). For absolute peak area analyses, 37 peak areas in all of the UPLC-MS chromatograms were analyzed with OPLS-DA directly. For relative peak area analyses, peak 36 was selected as a reference peak, and other peak areas were divided to the reference peak in each chromatogram to obtain the relative peak area. Peaks with areas of >5% of the reference peak area were recognized as major peaks and taken into account for calculation. For FIMS fingerprints, one-dimensional spectra ranging from $m/z$ 100 to 1000 were collected for analysis. For headspace-GC fingerprints, both absolute and relative peak areas were selected for analyses. Peak 14, as the largest peak in headspace-GC, was selected as a reference peak, and other peak areas were divided by the reference peak area in each chromatogram to

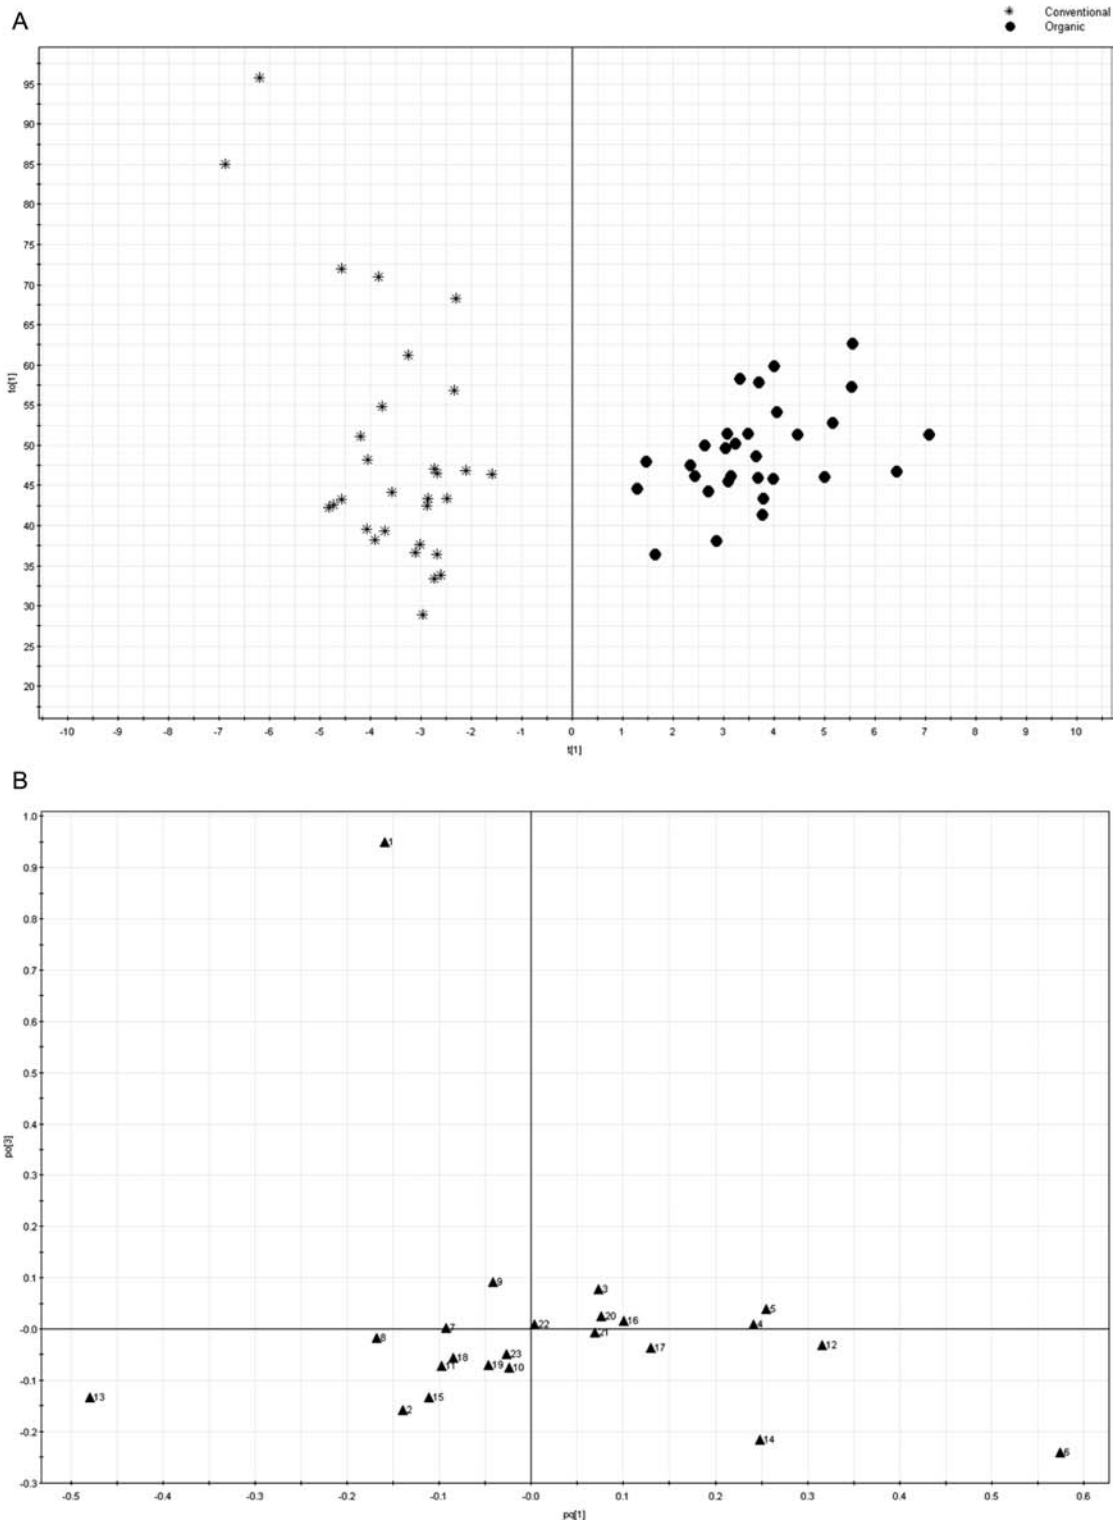

**Figure 2.** Orthogonal partial least-squares discriminant analysis (OPLS-DA) (A) scores plot and (B) loading plot for headspace-GC absolute peak areas of the organically and conventionally grown oregano samples.

obtain the relative peak area. PCA and OPLS-DA were performed using SIMCA-P software (Umetrics, Malmo, Skånelän, Sweden) to analyze all of the data: containing 37 absolute peak areas in all 60 chromatograms and 36 relative peak areas in all 60 chromatograms (20 samples with triplicate analyses each) in UPLC-MS fingerprints; 23 absolute peak areas in all 60 chromatograms and 22 relative peak areas in all 60 chromatograms in headspace-GC fingerprints. PCA was also performed for one-dimensional FIMS fingerprints obtained from $m/z$ 100 to 1000 using the Markerlynx software (Waters).

## RESULTS AND DISCUSSION

**Headspace-GC Fingerprinting Analysis.** This was the first time that headspace-GC fingerprints were examined for their possible application to differentiate organically and

dx.doi.org/10.1021/jf502419y | J. Agric. Food Chem. 2014, 62, 8075−8084

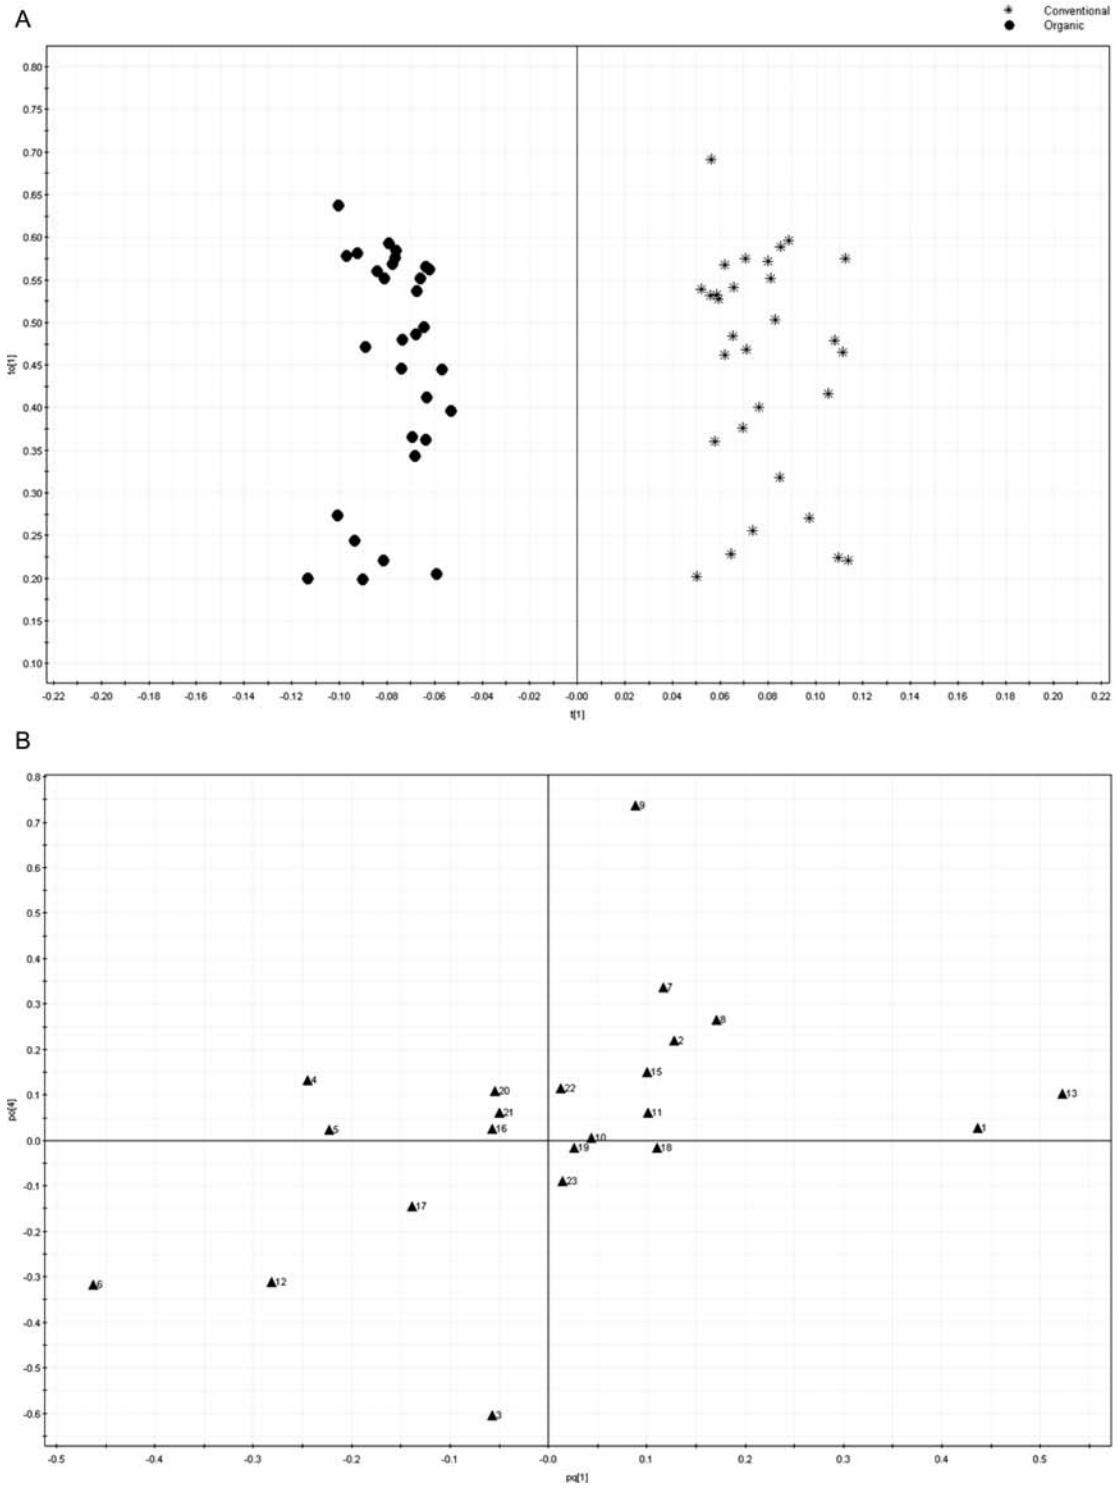

**Figure 3.** Orthogonal partial least-squares discriminant analysis (OPLS-DA) (A) scores plot and (B) loading plot for headspace-GC relative peak areas of the organically and conventionally grown oregano samples. All peak areas were divided by the area of peak 14 in each sample, and the results were used for OPLS-DA.

conventionally grown spices. A total of 23 peaks were detected in a gas chromatograph (Figure 1). As shown in Figure 1, there was no characteristic component or deterministic large peak to separate the conventional and organic oregano samples by manual observation.

OPLS-DA is a statistical method that finds a linear regression model by projecting the predictor and observation variables to a new space. It can be used to find the fundamental relationships between two matrices to model the covariance structures in these two spaces. Headspace-GC fingerprinting is an effective method in the analysis of volatiles. It has been widely used because it requires less sample pretreatment and has high sensitivity. The OPLS-DA scores plot and loading plot of the headspace-GC fingerprints for absolute peak area are provided in panels A and B, respectively, of Figure 2. As shown in Figure 2A, the conventional oregano samples are all on the left side of

dx.doi.org/10.1021/jf502419y | J. Agric. Food Chem. 2014, 62, 8075−8084

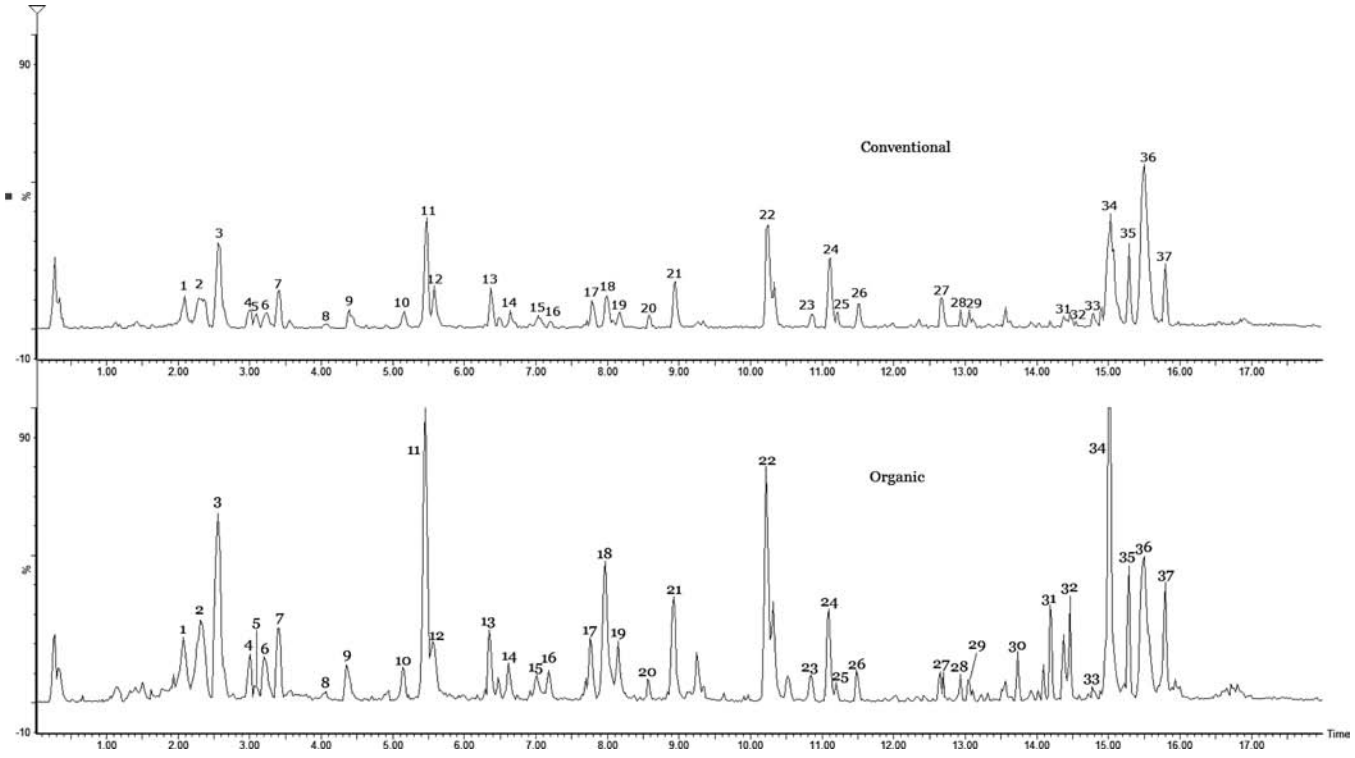

**Figure 4.** Representative UPLC-MS fingerprints for commercial conventionally and organically grown oregano samples.

the scores of latent variable (LV) 1, whereas all of the organic samples are located on the right. The scores plot indicated that headspace-GC combined with OPLS-DA could effectively differentiate the organically and conventionally grown oregano samples by determining their volatile components. This is the first report on the potential application of headspace-GC fingerprints combined with OPLS-DA in differentiating commercial organically and conventionally grown botanicals.

In the loading plot of the headspace-GC absolute peak areas (Figure 2B), peaks 13, 1, and 8 contributed significantly to the separation of conventional samples, whereas peaks 6, 12, 5, and 4 contributed significantly to the separation of organic oregano samples (Figure 2B). In addition, GC-MS analysis was performed, and 10 compounds were tentatively characterized by comparing their MS result with that in the database, including *p*-cymene (peak 3), $\gamma$-terpinene (peak 5), 3,7-dimethyl-1,6-octadien-3-ol (peak 6), 5-methyl-2-(1-methylethyl)cyclohexanone (peak 8), isoborneol (peak 9), thymoquinone (peak 12), thymol (peak 13), 1-(*N*-methylcarbamate), 3-methyl-5-(1-methylethyl)phenol (peak 14), caryophyllene (peak 19), and $\beta$-bisabolene (peak 21).

Relative peak area represents the relative amount of each component against a selected base peak. Previous studies showed the different degrees of effectiveness in differentiating organically and conventionally grown botanicals using the absolute peak area and the relative peak area.[22,23] Therefore, the relative peak areas for the headspace-GC fingerprints were also analyzed using OPLS-DA in the present study, and Figure 3 shows the scores plot and loading plot of the relative peak areas for the organic and conventional oreganos. Among the 23 peaks, peak 14 showed the highest peak area and was selected as the reference peak (RP) for calculating the relative peak area. Other major peaks were defined as at least 1% of the area of the RP. In Figure 3A, all of the conventional oregano samples are clustered on the right side of the OPLS-DA scores plot, whereas all of the organic samples are located on the left side of the scores plot, separating well the LV1. In the loading plot for the headspace-GC relative peak areas (Figure 3B), peaks 13 (thymol) and 1 were on the right side of loading scatter plot, indicating that these two substances had higher concentrations in the conventional oregano samples, and peaks 6 (3,7-dimethyl-1,6-octadien-3-ol), 12 (thymoquinone), 4, and 5 ($\gamma$-terpinene) were greater in the organic oregano samples. Because peak 14 was the RP, the results indicated that the levels of peak 13 (thymol), 6 (3,7-dimethyl-1,6-octadien-3-ol), 12 (thymoquinone), 4, and 5 ($\gamma$-terpinene) might be important in determining if an oregano sample was organically or conventionally produced according to its headspace-GC fingerprints.

**LC-MS Fingerprinting Analysis.** The 50% MeOH extract of oregano samples were analyzed with UPLC-QTOF-MS. As shown in Figure 4, organic oregano samples had the same peak numbers as their conventional counterparts, but relative peak areas were visually different in these two groups, especially for peaks 3, 11, 22, and 34. The OPLS-DA scores plot and loading plot of the UPLC-MS chromatographic absolute peak areas are provided in Figure 5, panels A and B, respectively. The conventional oregano samples are all on the left side of the OPLS-DA scores plot, whereas all of the organic oregano samples are located on the right side. OPLS-DA in LC fingerprints was able to visualize the results and made the comparison of the chromatographic fingerprints easy to read and understand without subjective decisions.

In the loading plot of the OPLS-DA absolute peak areas (Figure 5B), peak 34 (ursolic acid) contributed most to separate the organic samples from their conventional counterparts, followed by peaks 11 (catechin 7-xyloside), 18 (luteolin), 32 (6-methylscutellarein), and 3 (baicalin). On the other hand, peaks 36 (methylgalangin) and 23 (thymol) showed significant contribution to the separation of conventional oregano

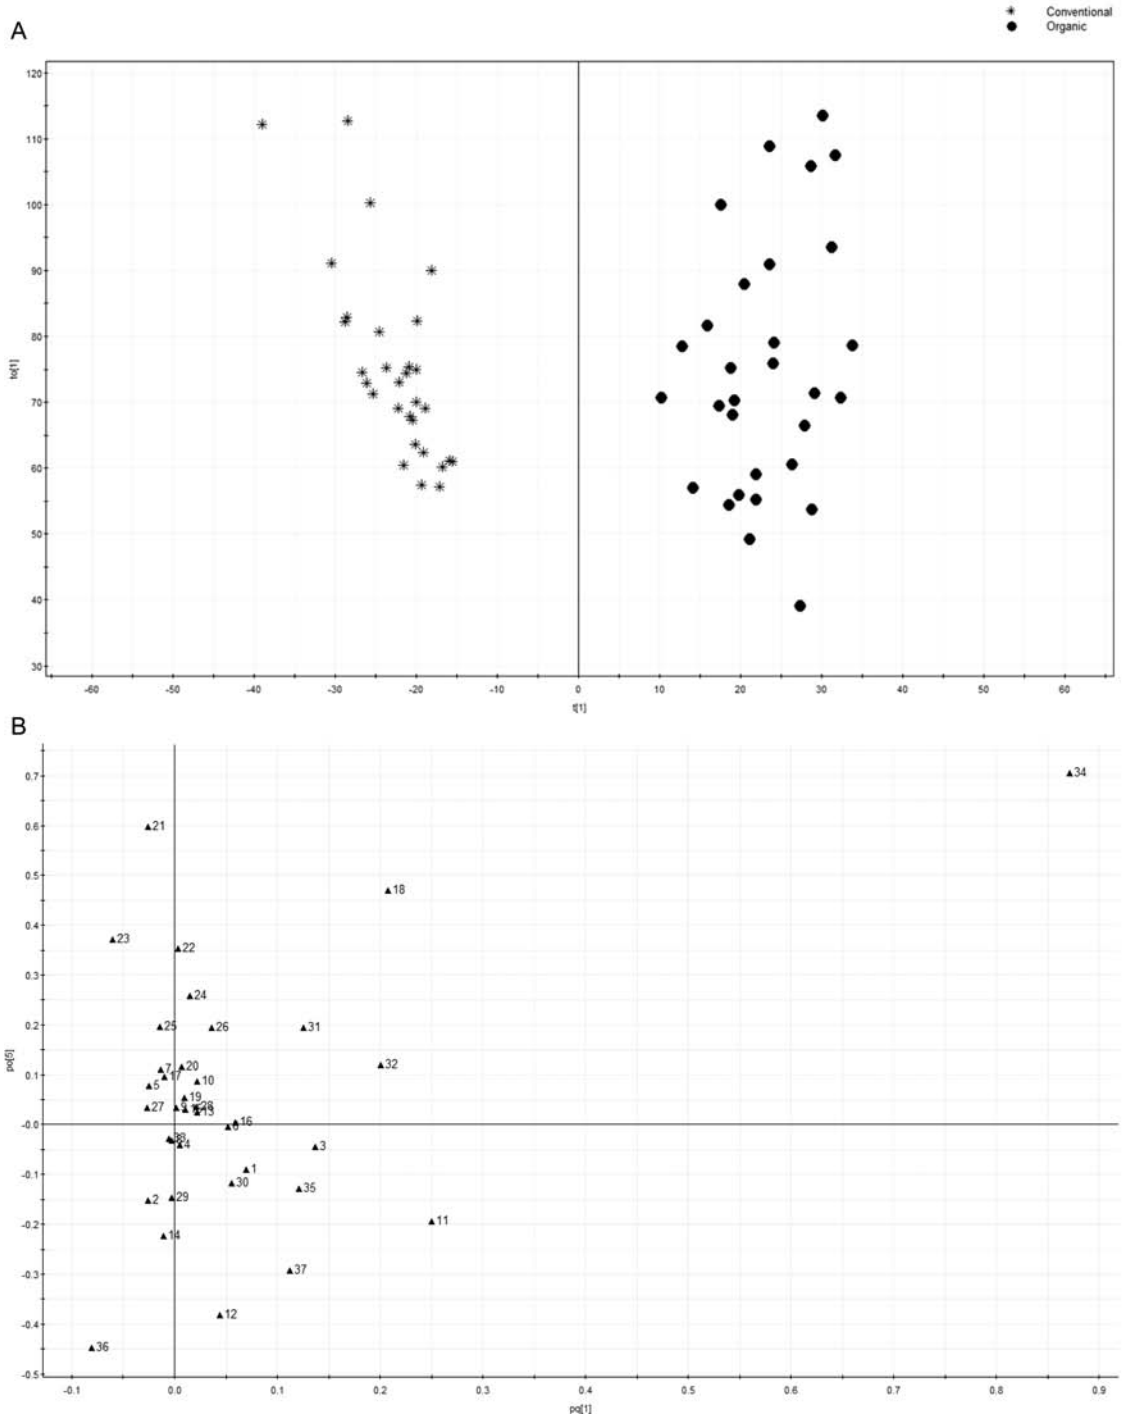

**Figure 5.** Orthogonal partial least-squares discriminant analysis (OPLS-DA) (A) scores plot and (B) loading plot for UPLC-MS absolute peak areas of the organically and conventionally grown oregano samples.

samples. With the UPLC-MS chromatographic fingerprint taken into account, the result also confirmed the fact that organic oregano samples contained higher levels of ursolic acid, catechin 7-xyloside, luteloin, and 6-methylscutellarein. Including the peaks mentioned above, there were a total of 33 identified substances in oregano according to their accurate mass weight and previous research results.[25−28] Peaks were identified as scutellarein (peak 1), baicalin (peak 3), catechin 7-xyloside isomer (peak 4), catechin 7-xyloside isomer (peak 5), catechin 7-xyloside isomer (peak 7), acacetin (peak 9), aromadendrin/eriodictyol (peak 10), catechin 7-xyloside (peak 11), luteolin-7-*O*-glucoside (peak 12), apigenin-7-*O*-glucoside (peak 13), thujene (peak 14), kaempferol 3-xyloside (peak 15), kaempferol 3-*O*-(*β*-D-xylopyranosyl-(1→2)-*α*-D-ribopyranoside) (peak 16), apigenin (peak 17), luteolin (peak 18), fortunellin (peak 19), cassiaoccidentalin B (peak 21), rehin (peak 22), thymol (peak 23), 6,7-dimethylscutellarein (peak 24), 3,3′,4-tri-omethlellagic acid (peak 25), acacetin isomer (peak 26), tricalysioside I (peak 27), hederagenin isomer (peak 28), hederagenin isomer (peak 29), hederagenin (peak 30), 6-methylscutellarein isomer (peak 31), 6-methylscutellarein (peak 32), oleanolic acid (peak 33), ursolic acid (peak 34),

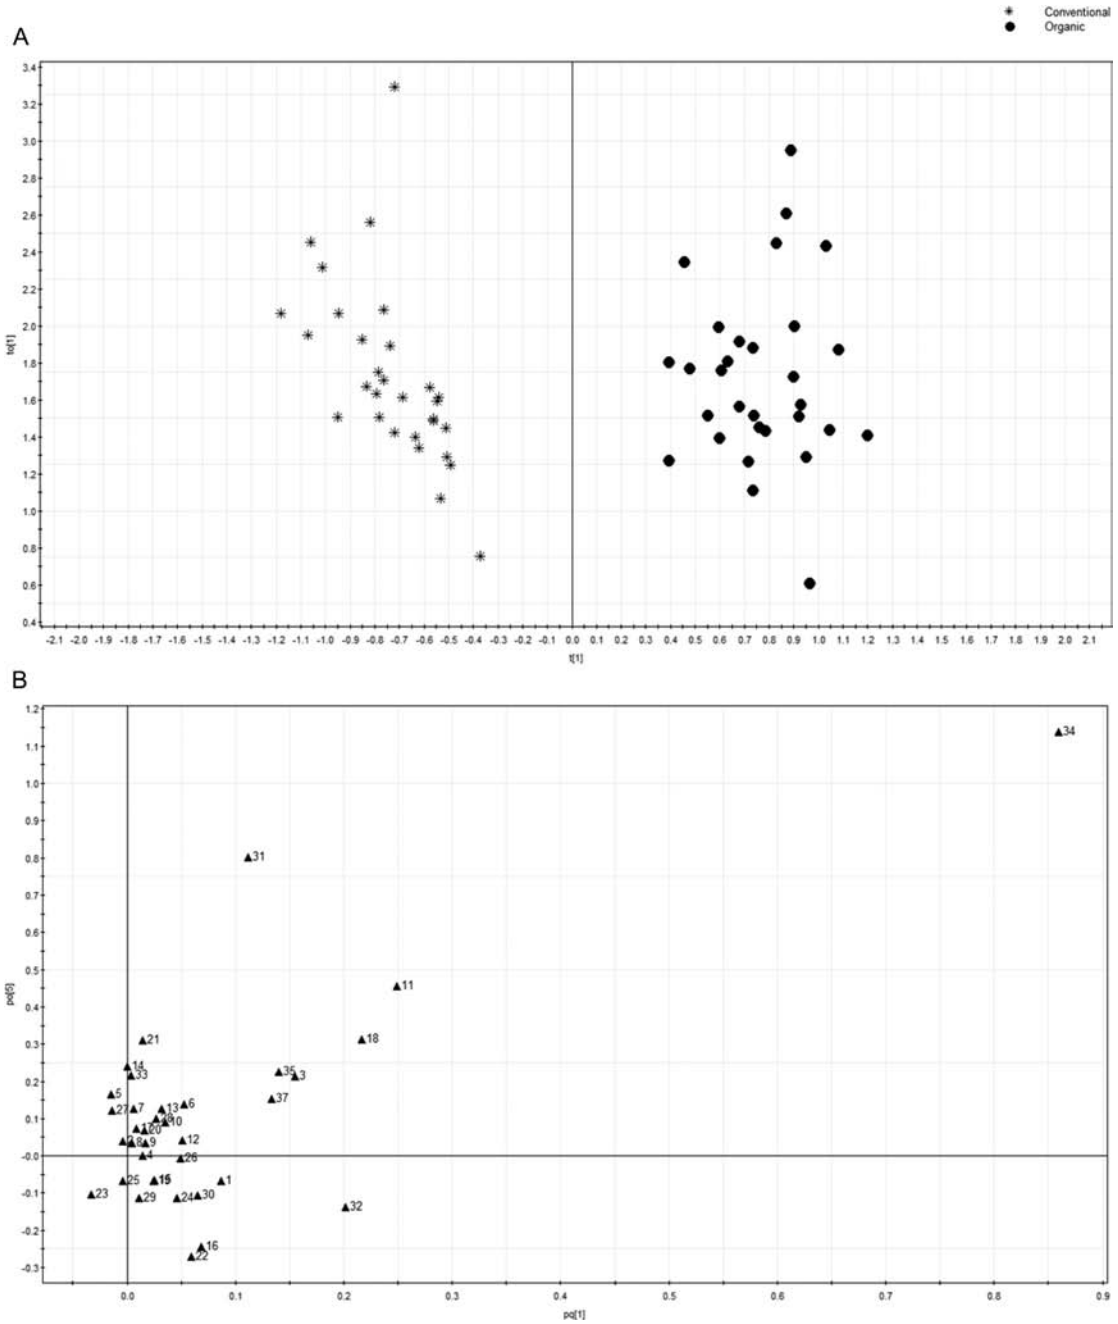

**Figure 6.** Orthogonal partial least-squares discriminant analysis (OPLS-DA) (A) scores plot and (B) loading plot for UPLC-MS relative peak areas of the organically and conventionally grown oregano samples. All peak areas were divided by the area of peak 36 in each sample, and the results were used for OPLS-DA.

pinocembrin (peak 35), methylgalangin (peak 36), and methylgalangin isomer (peak 37). The major peaks that have been detected and identified in oregano by UPLC-MS were flavonoids, flavonoid glycosides, and pentacyclic triterpene acids. The results also confirmed the fact that UPLC-MS is an effective tool in analyzing the polar components in botanicals.

The OPLS-DA scores plots of the relative UPLC-MS peak areas for the organic and conventional oreganos are shown in Figure 6, panels A and B, respectively. In all 37 chromatographic peaks, all of the other 36 peaks were taken into OPLS-DA analysis except peak 36 (methylgalangin) was selected as the reference peak (RP) for calculating the relative peak area. As shown in Figure 6A, the conventional oregano samples are located on the left side of the scores plot, whereas the organic oregano samples are all on the right side of the scores plot. The same trend of scores plot between the absolute peak areas and relative peak areas indicated that all of the oregano samples had a uniformal chemical profile regardless of their growing condition. In the loading plot of UPLC-MS relative peak areas (Figure 6B), the same trend was observed in both organically and conventionally oregano samples. Peak 36 was selected as RP and not taken into account, and peak 23 (thymol) was on the left side of loading scatter plot, indicating that the relative area of thymol was greater in conventional samples, whereas peaks 34 (ursolic acid), 11 (catechin 7-xyloside), 18 (luteolin), 32 (6-methylscutellarein), and 3

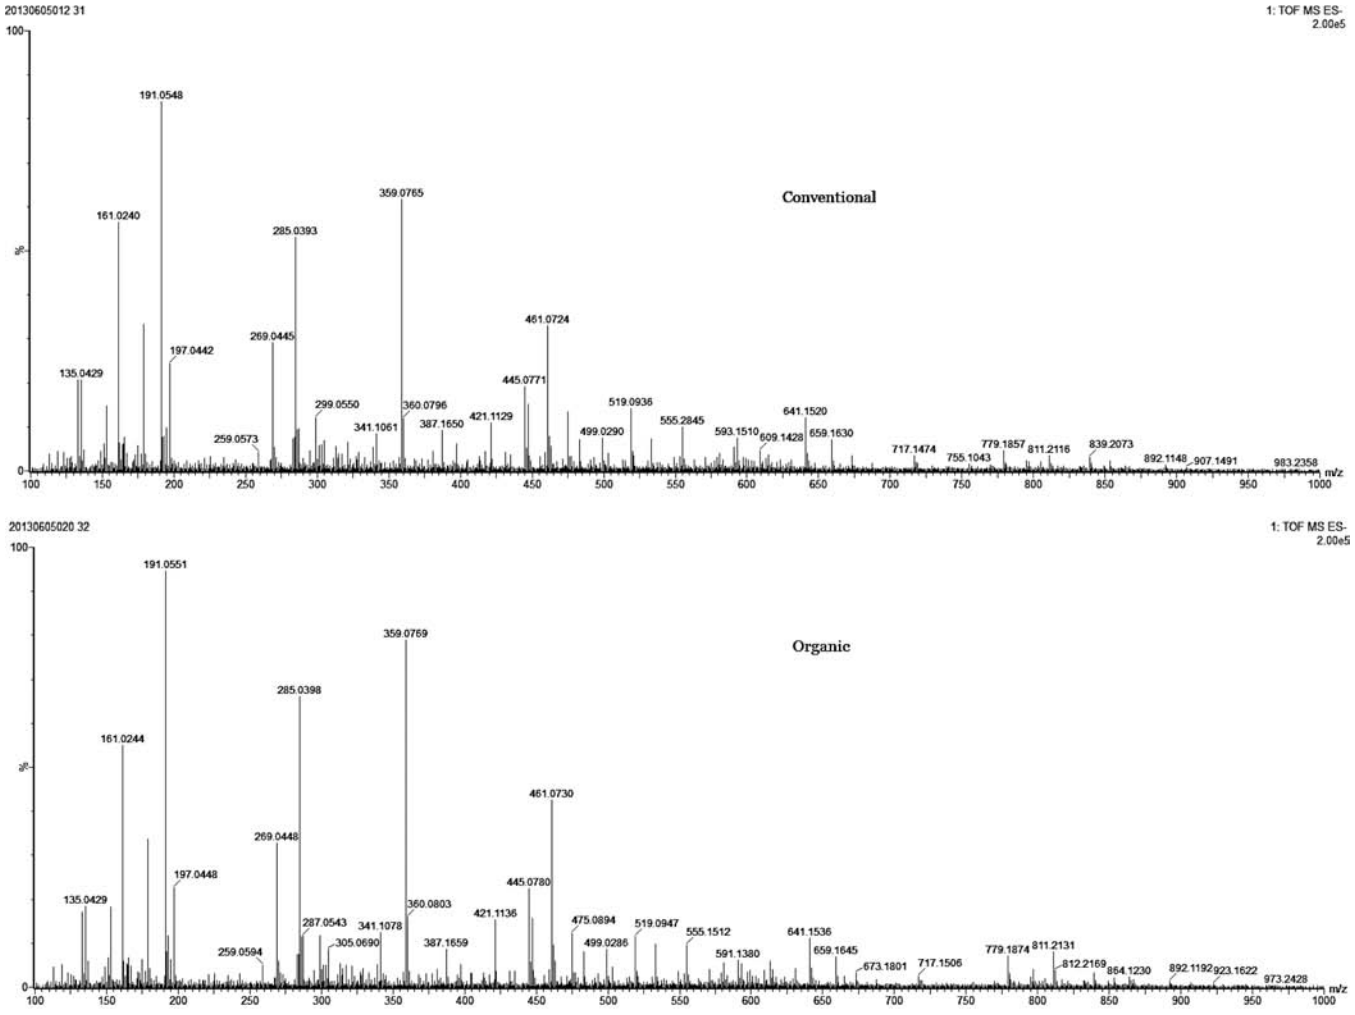

**Figure 7.** Representative FIMS fingerprints for commercial conventionally and organically grown oregano samples.

(baicalin) showed higher relative peak areas in organic oregano samples and are located on the right side of the loading scatter plot.

**FIMS Fingerprint Analysis.** Typical FIMS fingerprints for both organically and conventionally grown oregano samples are shown in Figure 7. The highest natural abundant peak in both conventional and organic oregano spectra is $m/z$ 191.0548, followed by $m/z$ 359.0765, 161.0240, 285.0393, and 461.0724. All of these peaks are not the molecular ion peaks of chemical substances identified in oregano, indicating that these spectral peaks might be the major fragment ion peaks.

The FIMS PCA scores plot and loading plot are shown in Figure 8. As one of the most widely used data analysis methods, PCA is a mathematical approach transforming a large number of correlated variables into a small group of uncorrelated variables, the principal components (PCs). In the PCA scores plot of oregano FIMS fingerprints, all of the conventional samples were on the lower side, whereas all of the organic samples were on the upper side (Figure 8A). The scores plot indicated that FIMS fingerprints could effectively differentiate conventionally and organically grown oregano samples in a 1 min analytical time.

In the loading plot of FIMS fingerprints (Figure 8B), most of the ions were clustered near the abscissa, but there were still a few ions dispersed far away from the center, indicating that these ions and their natural abundance might be more important in differentiating the growth conditions of oregano. In the upper side of the loading plot, ions $m/z$ 200.9919, 127.9888, 290.0744, 230.9881, 199.9843, 154.9736, and 156.9659 yielded higher scores and would lead to positions in the upper side of the PCA scores plot. On the other hand, the most important ions that contributed positively to conventional oregano samples were ions at $m/z$ 867.1962, 614.1596, 798.1968, and 572.1494. All of the ions mentioned above were not the major chemical substances detected in UPLC-MS analysis, indicating that some trace chemical materials or the fragment ions of major chemical materials played the most important role in differentiating organic oreganos from conventional ones in FIMS fingerprints.

In conclusion, headspace-GC, UPLC-MS, and FIMS fingerprints combined with multivariate data analysis tools may have potential application in effectively differentiating commercial organically and conventionally grown oregano and other botanical samples. This was the first study in which headspace-GC fingerprinting showed potential in rapidly differentiating organically and conventionally grown oregano samples. UPLC-MS fingerprinting may obtain detailed chemical composition information about the samples, but requires a longer analysis time. FIMS fingerprinting may provide a rapid and accurate test and has the potential for high-throughput applications. In addition, the results from UPLC-MS fingerprints and GC-MS analyses suggested that thymol might play

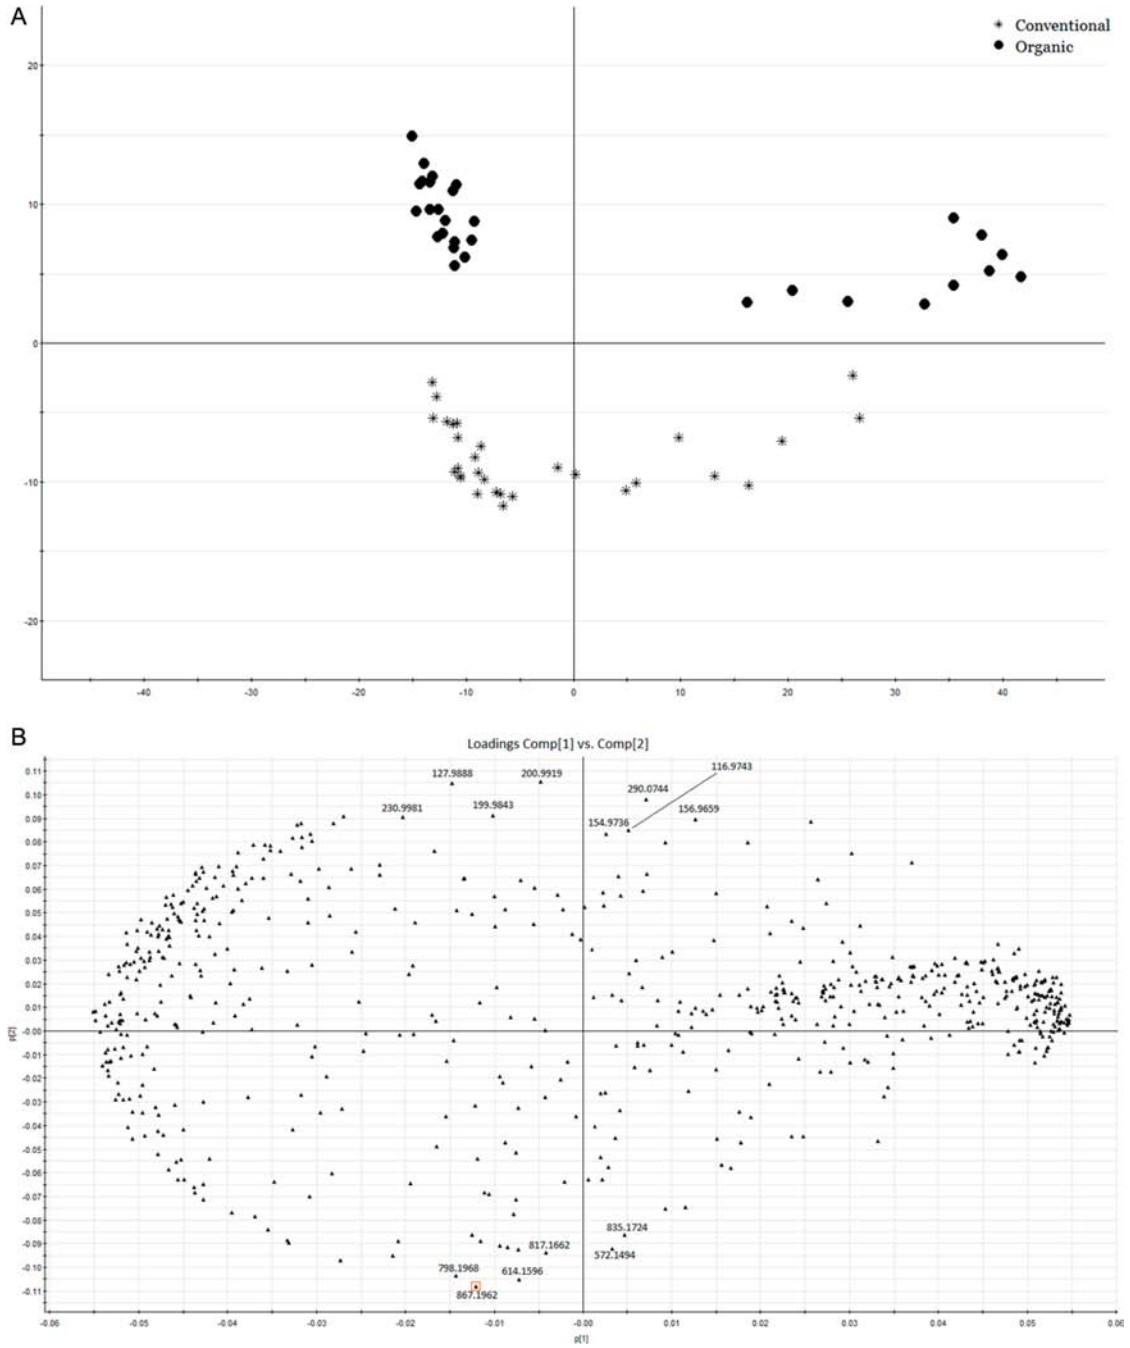

**Figure 8.** Principal component analysis (PCA) (A) scores plot and (B) loading plot for FIMS fingerprints of the organically and conventionally grown oregano samples.

the most important role in separating the conventionally grown oregano samples from the organically grown ones, and the concentration difference of thymol might be due to the different growth condition, genotype, and the interactions between genotype and growing environment. In practical application, headspace-GC fingerprints and FIMS combined with multivariate data analysis may be selected first for unknown spice samples, and additional UPLC-MS and GC-MS identifications may be performed if necessary. Besides, the results also indicated that, compared with PCA, other multivariate data analysis methods such as OPLS-DA may also be utilized for differentiating organically and conventionally grown oregano samples. These data analysis methods and chemical analysis techniques might be used in combination for distinguishing botanical samples.

**ABSTRACT:** Labile zinc, a tiny fraction of total intracellular zinc that is loosely bound to proteins and easily interchangeable, modulates the activity of numerous signaling and metabolic pathways. Dietary plant polyphenols such as the flavonoids quercetin (QCT) and epigallocatechin-gallate act as antioxidants and as signaling molecules. Remarkably, the activities of numerous enzymes that are targeted by polyphenols are dependent on zinc. We have previously shown that these polyphenols chelate zinc cations and hypothesized that these flavonoids might be also acting as zinc ionophores, transporting zinc cations through the plasma membrane. To prove this hypothesis, herein, we have demonstrated the capacity of QCT and epigallocatechin-gallate to rapidly increase labile zinc in mouse hepatocarcinoma Hepa 1-6 cells as well as, for the first time, in liposomes. In order to confirm that the polyphenols transport zinc cations across the plasma membrane independently of plasma membrane zinc transporters, QCT, epigallocatechin-gallate, or clioquinol (CQ), alone and combined with zinc, were added to unilamellar dipalmitoylphosphocholine/cholesterol liposomes loaded with membrane-impermeant FluoZin-3. Only the combinations of the chelators with zinc triggered a rapid increase of FluoZin-3 fluorescence within the liposomes, thus demonstrating the ionophore action of QCT, epigallocatechin-gallate, and CQ on lipid membrane systems. The ionophore activity of dietary polyphenols may underlay the raising of labile zinc levels triggered in cells by polyphenols and thus many of their biological actions.

**KEYWORDS:** *clioquinol, epigallocatechin-gallate, flavonoids, liposomes, quercetin, zinc ionophores*

## 1. INTRODUCTION

Quercetin (QCT), a water-insoluble flavonoid present in onions, nuts, and many other vegetables, and epigallocatechin-3-gallate (EGCG), a water-soluble flavonoid present in green tea, are among the most consumed and most studied polyphenols present in the human diet.[1] Flavonoids are considered bioactive micronutrients whose regular consumption, either as food components, or as dietary supplements and nutraceuticals,[2] entails benefits for human health, including prevention and amelioration of cancers,[3] diabetes, and cardiovascular[4] and neurodegenerative[5] diseases. Many of the health benefits of flavonoids have historically been ascribed to their antioxidant activity, which they exert directly by scavenging reactive oxygen species (ROS) and by chelating the redox-active transition metals iron and copper, which may act as ROS generators in biological systems.[6] Flavonoids also act as antioxidants indirectly by inhibiting redox-sensitive transcription factors and pro-oxidant enzymes as well as through induction of phase II and antioxidant enzymes.[7] However, it is currently believed that the levels of polyphenols achieved through ingestion are not enough to justify their wide array of biological actions. Beyond their antioxidant actions, flavonoids are also known to act as signaling molecules that, either directly or indirectly, interact with proteins and nucleic acids, thus modulating multiple cell signaling pathways, gene transcription, metabolic fluxes, and cell fate including apoptosis.[8,9]

Diverse polyphenols have been shown able to form complexes with the redox-inactive transition metal zinc.[10] Zinc is an essential micronutrient for humans, the deficiency of which causes multiple dysfunctions, including alterations of glucidic and lipidic metabolisms.[11] Within cells, the vast majority of zinc cations (in concentrations usually ranging from 100 to 300 $\mu$M for most cells) are tightly bound to proteins, functioning as a catalytic or structural component of an estimated 3000 mammalian proteins involved in virtually all cellular processes.[12] A minor fraction of intracellular zinc, termed labile zinc, exists in its free ionic form (picomolar concentrations) or loosely bound to proteins (in nanomolar concentrations). This pool of zinc is detectable by specific fluorophores with very high affinities for zinc cations at neutral pH such as Zinquin and FluoZin-3. Zinc ionophores such as pyrithione and clioquinol (CQ) have been used to increment labile zinc within cells and determine the fundamental roles that this zinc pool plays in cellular biology. Thus, free and labile zinc acts as second messenger molecule, which modulates the

activity of many enzymes and thus signaling and metabolic pathways and cellular processes, including cell fate and apoptosis.[13,14] While many enzymes are inhibited by small elevations of zinc concentrations, others are activated.[15,16] Mammalian cells tightly control the subcellular distribution of zinc cations and the levels of labile zinc through the coordinated action of dedicated transmembrane zinc transporters and zinc-chelating metallothioneins.

Zinc from the extracellular milieu and from intracellular compartments enters the cytoplasm through 14 specialized transmembrane proteins of the ZIP/SLC39 family, whereas cytoplasmic extrusion of zinc toward organelles or the extracellular environment is performed by 10 transporters of the ZnT/SLC30 family, being ZnT1, located at the plasma membrane, the main regulator of cellular zinc efflux and export of excess zinc in most cells.[17] Within the cytoplasm, zinc may bind to metal free apo-metallothionein (apo-MT) to generate Zn−MT complexes. The apo-MT/Zn−MT ratio controls free and labile zinc concentrations. MT also serves as a ROS scavenger and heavy metal chelator, and the transcription of MT responds, in addition to zinc, to stress stimuli such as ROS, heavy metals, and proinflammatory cytokines.[18] In response to elevations of intracellular zinc, the zinc-sensor transcription factor MTF1 coordinately upregulates the expression of MT and ZnT1,[19] thus keeping zinc levels within a functional range. Excessively high levels of labile zinc are associated with cellular death through apoptosis.[20] Dysfunctions of MT and zinc transporters are promoting factors in cardiovascular diseases,[21] diabetes,[22] Alzheimer's disease,[23] and cancer.[24]

Several studies have shown that flavonoids affect zinc metabolism. For instance, rats fed during long periods with bicalain and rutin showed reduced hepatic levels of total zinc, as well as iron and copper, implying that flavonoids may sequester these metals and render them unavailable for absorption in a similar way as phytate.[25] Consistent with this, feeding obese rats with proanthocyanidins reverse dyslipidemia and lower protein levels of ZnT1 in the liver, reflecting lower levels of hepatic zinc.[26] Early in vitro studies showed that, in human intestinal Caco-2 cells, genistein enhanced the expression of MT, here regarded as an antioxidant enzyme,[27] while QCT increased the copper-induced expression of MT.[28] More recently, QCT was shown to enhance zinc uptake by Caco-2 cells, increasing total zinc accumulation and MT expression.[29] In contrast, grape seed flavonoids, produced a reduction in apical zinc uptake in Caco-2 cells, similar to that produced by phytate, whereas EGCG did not alter zinc absorption.[30] In prostate cancer cells, EGCG accelerated the accumulation of total zinc in the cytosol and mitochondria.[31] Two reports have shown that polyphenols may produce an increase of intracellular labile zinc. A water-soluble glycoside of the isoflavone genistin enhanced MT expression in human hepatocarcinoma HepG2 cells concomitantly increasing labile zinc and cellular death.[32] Furthermore, the stilbene resveratrol was shown to enhance total and labile zinc in normal human prostate epithelial cells, while not significantly affecting MT expression, and this was accompanied by increased cellular death. These authors suggested that the increment of labile zinc elicited by resveratrol might be due to the uptake of resveratrol−zinc complexes, followed by the dissociation of the complexes in the cytoplasm.[33]

Conversely, zinc may affect the bioactivity of flavonoids, as detailed in a few reports, including one that outlines the stimulating effect of zinc on the apoptotic effect of genistein in osteoclastic cells.[34] Zinc also yields EGCG effective in protecting cultured rat hepatocytes against hepatotoxin-induced cell injury[35] and enhances the antiproliferative, proapoptotic effects of EGCG on various lines of prostate cancer cells.[36] Zinc was also shown to affect the uptake of EGCG by prostate carcinoma cells, where Zn−EGCG chelates were less internalized by cells than EGCG alone, while mixtures of EGCG with zinc enhanced the transport of EGCG into the cells. These authors also showed that zinc enhances the incorporation of EGCG into liposomes.[37]

We have previously reported that the water-soluble flavonoid EGCG and the water-insoluble flavonoid QCT profoundly alter zinc homeostasis in cultured human and mouse hepatocarcinoma cells. Whereas EGCG reduced the levels of total intracellular zinc and the expression of MT and ZnT1,[38] QCT enhanced total zinc accumulation as well as MT and ZnT1 expression (M. Bustos, personal communication, 2011, Universitat Rovira i Virgili). However, both QCT and EGCG dose-dependently prevented zinc-induced toxicity, suggesting that most zinc cations in the culture medium are rendered unavailable to cells due to their chelation by flavonoids and the formation of flavonoid−zinc concatemers, as shown for iron and copper complexed with diverse polyphenols.[39] In addition, both polyphenols enhanced cytoplasmic levels of Zinquin-detectable labile zinc, suggesting that a fraction of the flavonoid molecules in the culture medium formed complexes with zinc that cross the plasma membrane; that is, the flavonoids may also act as zinc ionophores, transporting zinc cations across the plasma membrane independently from zinc transporters.

The aim of this work was to evaluate the capacity of QCT and EGCG to act as zinc ionophores. Clioquinol (CQ) was also tested in this study as it is a synthetic antitumor drug recently reported to induce apoptosis in diverse cells lines by enhancing intracellular labile zinc and therefore inferred to act as a water-soluble zinc ionophore.[40] We evaluated the ability of QCT, EGCG, and CQ to chelate zinc cations and the subsequent formation of a complex with FluoZin-3, a fluorophore that displays a very high affinity for zinc cations ($K_d$ = 15 nM).[41] The uptake of zinc by mouse hepatocarcinoma cells was measured fluorescently using FluoZin-3 in the presence and absence of QCT, EGCG, and CQ. This study was repeated using unilamellar liposomes with encapsulated FluoZin-3 to investigate whether the transport of the zinc cations across the cytoplasmic membrane to form a complex with FluoZin-3 was indeed enhanced by the presence of QCT, EGCG, or CQ or was simply due to the activity of cellular zinc transporters.

## 2. MATERIALS AND METHODS

**2.1. Chemicals.** The lipid 1,2-dipalmitoyl-*sn*-glycero-3-phosphocholine (DPPC), cholesterol, zinc chloride ($ZnCl_2$), QCT, EGCG, CQ, dimethyl sulfoxide (DMSO), ethanol, and phosphate-buffered saline (0.01 M PBS, pH 7.4) were bought from Sigma−Aldrich. Cell-impermeant FluoZin-3 tetrapotassium salt and cell permeant FluoZin-3 AM were bought from Molecular Probes. A Simplicity 185 Millipore water system was used to obtain Milli-Q water (18.2 mΩ·cm$^{-1}$) for the preparation of buffers and liposomes. The compounds QCT, EGCG, and CQ were dissolved as 100 μM solutions in 100% DMSO, aliquoted, and stored at −20 °C. $ZnCl_2$ was stored as 1 M solution in ethanol/PBS (50%/50% v/v). FluoZin-3 indicators were used at 10 μM in 100% DMSO.

**2.2. Cell Cultures and Treatments.** The mouse hepatoma cell line Hepa 1-6 was obtained from the European Collection of Cell Cultures (BW7756 ECACC) and propagated in Dulbecco's Modified Eagle medium (DMEM; BioWittaker) supplemented with 10% fetal

bovine serum (BioWittaker), 2 mM glutamine in 0.85% NaCl, 1000 U/mL penicillin/streptomycin, and 1.25 M HEPES. This medium contains 4.9 ± 0.2 $\mu$M zinc, as determined by flame atomic absorption spectroscopy (FAAS). Cells were cultured at 37 °C in a humidified, 5% $CO_2$-enriched atmosphere and routinely split every 3−4 days at a 1:5 ratio upon reaching approximately 80% confluence. For treatments, cells at 80% confluence were detached with Accutase (Sigma−Aldrich) and resuspended at a density of $5 \times 10^5$ cells/mL; 500 $\mu$L of this cell suspension ($25 \times 10^4$ cells) was then seeded per well in 24-well plates (Orange Scientific). Twenty four hours after plating, medium was removed, and the cells were treated by adding 100 $\mu$L of fresh medium containing either 50 $\mu$M $ZnCl_2$, 100 $\mu$M QCT, 100 $\mu$M EGCG, 100 $\mu$M CQ, or the combination of 50 $\mu$M $ZnCl_2$ with each chelator for 1 and 4 h, respectively. As a control experiment, untreated cells were incubated just with medium and vehicle (final 0.1% DMSO and 0.05% ethanol).

**2.3. Measurements of Cytoplasmic Labile Zinc in Hepa 1-6 Cells.** The intracellular levels of free and labile zinc cations were measured as the fluorescence emission of cells upon loading them with the membrane-permeant zinc specific detector FluoZin-3, using fluorescence microscopy as described.[42] Briefly, following cell treatment (Section 2.2), culture media were replaced with a fresh one containing 1.5 $\mu$M FluoZin-3 (AM, cell permeant) and incubated for 30 min at 37 °C. This medium was then removed, and the cells were washed three times with PBS, and the zinc-dependent FluoZin-3 fluorescence within cells was measured using a Nikon Eclipse TE2000-S microscope, with excitation set at 494 nm and emission at 516 nm. Fluorescent intensities were quantified using the NIS-Elements AR software (Nikon Instruments) and the software ImageJ, a Java-based image processing program developed at the NIH (National Institutes of Health).[43]

**2.4. Liposomes as Cell Membrane Models.** Homogeneous populations of liposomes were prepared using a previously reported method.[44] FluoZin-3 in a final concentration of 3 $\mu$M was mixed with 5 mL of PBS (0.01 M, pH 7.4) in a glass reactor protected from light-induced degradation, under stirring conditions and a blanket of argon gas. After 15 min, a mixture of DPPC and cholesterol (9:1 molar ratio) was added and maintained under stirring conditions and argon at 25 °C for another 15 min. The homogeneous mixture was then treated with a rapid pH jump from pH 7.4 to pH 11 and then back to pH 7.4 within a 3 s frame, followed by an equilibration step of 25 min where lipid clusters curl into FluoZin-3 encapsulating liposomes. The resulting FluoZin-3-loaded liposomes were purified using a Sephadex G-100 size-separation column and used immediately.

Liposomes with encapsulated FluoZin-3 were separately incubated with 10 $\mu$M QCT, EGCG, or CQ, in the presence and absence of 10 $\mu$M $ZnCl_2$. All the solutions were allowed to incubate at 25 °C for 30 min before measuring their fluorescence. For the kinetic experiment, liposomes loaded with FluoZin-3 were added to three different cuvettes, the fluorescence was measured for 15 min, followed by addition of $ZnCl_2$ (final 10 $\mu$M) to each cuvette, and the fluorescence emission was measured for another 15 min. Finally, QCT, EGCG, or CQ was added (final 10 $\mu$M) to each sample, and fluorescence emission was monitored over the duration of 1 h until the fluorescent intensity reached a plateau.

## 3. RESULTS

**3.1. QCT, EGCG, and CQ Increase the Cytoplasmic Labile Zinc in Hepa 1-6 Cells.** The increase of cytoplasmic labile zinc is modulated by the cellular zinc transporters, where the zinc ions are transported to the cytoplasm through specific channels of the ZIP family, bound to ionophore molecules that independently cross the lipid bilayer, or liberated from zinc-binding proteins such as metallothioneins (Figure 1).

In order to assess the effect of QCT, EGCG, CQ and zinc on cytoplasmic labile zinc, Hepa 1-6 cells were treated for 1 and 4 h with the chelators and supplemental zinc, and variations in the intracellular levels of labile zinc were measured as changes

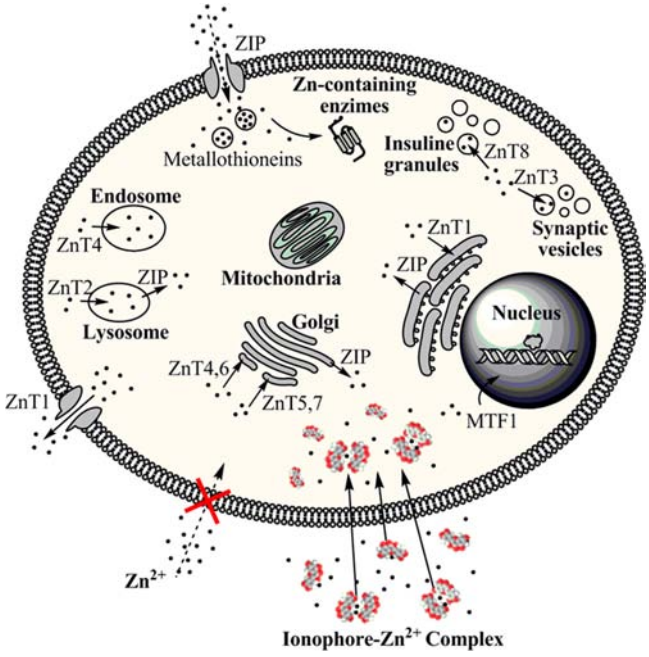

**Figure 1.** Schematic representation of zinc homeostasis. Intracellular labile zinc is modulated by the coordinated activity of a large family of zinc transporters (ZnT and ZIP) and zinc-binding proteins, such as metallothionein or ionophore molecules.

in the FluoZin-3 fluorescence intensity as described in Section 2.3. Figure 2 shows the fluorescent images of the Hepa 1-6 cells after 1 and 4 h of treatment. No significant increase in fluorescence was obtained when QCT or EGCG were added to the culture medium without additional zinc. Only CQ insignificantly enhanced the fluorescence in these conditions, that is, with basal zinc concentration in the culture medium, which is roughly 5 $\mu$M.

However, when 50 $\mu$M $ZnCl_2$ was added, both QCT and EGCG doubled the amount of FluoZin-3-detectable zinc after 1 h, and CQ increased this pool of zinc 10-fold with respect to the control (50 $\mu$M $ZnCl_2$ in the absence of any of QCT, EGCG, or CQ) (Figure 3), suggesting a slower ionophore action of the flavonoids as compared to CQ. After 4 h treatment with additional 50 $\mu$M $ZnCl_2$, all treatments triggered a significant increase in fluorescence intensity. In the case of the control, the increase of the cytoplasmic labile zinc is associated with the plasma membrane ZIP transporters, whereby zinc ions are transported into the cell. QCT doubled the amount of labile zinc attained with only 50 $\mu$M zinc, EGCG quadrupled this value, and CQ increased it 7-fold.

A closer view of intracellular distribution of FluoZin-3 fluorescence (Figure 4) after 4 h of treatment shows a similar punctuated pattern of labile zinc for CQ, EGCG, and QCT, suggesting similar ways of action for the three compounds.

**3.2. Zinc Ionophore Activity of QCT, EGCG, and CQ Using Liposomes as Membrane Models.** Increases of cytoplasmic labile zinc levels triggered by CQ and pyrithione in a variety of cell lines have been attributed to their ionophore activity, that is, to the capacity of CQ−zinc and pyrithione−zinc complexes to cross the plasma membrane. To our knowledge, however, the classification of CQ and pyrithione as zinc ionophores is based on their functional effect in cells, that is, the rapid increase in Zinquin-detectable or Fluozin-3-detectable intracellular zinc, but no direct biochemical assay has

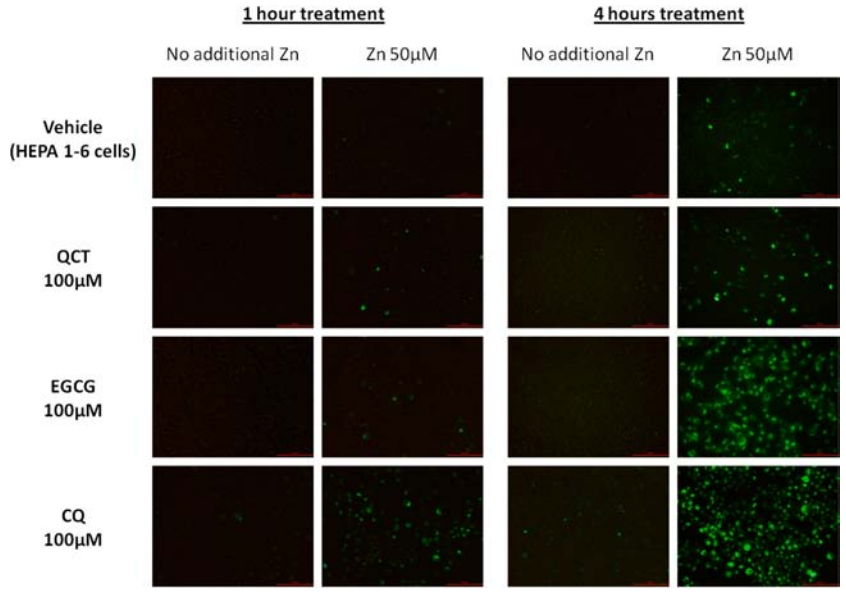

**Figure 2.** Effect of QCT, EGCG, and CQ on the cytoplasmic pool of labile zinc in Hepa 1-6 cells. Hepa 1-6 cells were first treated with 100 $\mu$M QCT, EGCG, or CQ, in the presence or absence of 50 $\mu$M $ZnCl_2$ for 1 and 4 h. The medium was then removed, and 3 $\mu$M FluoZin-3 (AM, cell permeant) was added. After 30 min incubation, cells were washed and examined using a confocal fluorescence microscope. Control cells were treated with vehicle (final 0.05% ethanol, 0.1% DMSO). Scale bars are 50 $\mu$m.

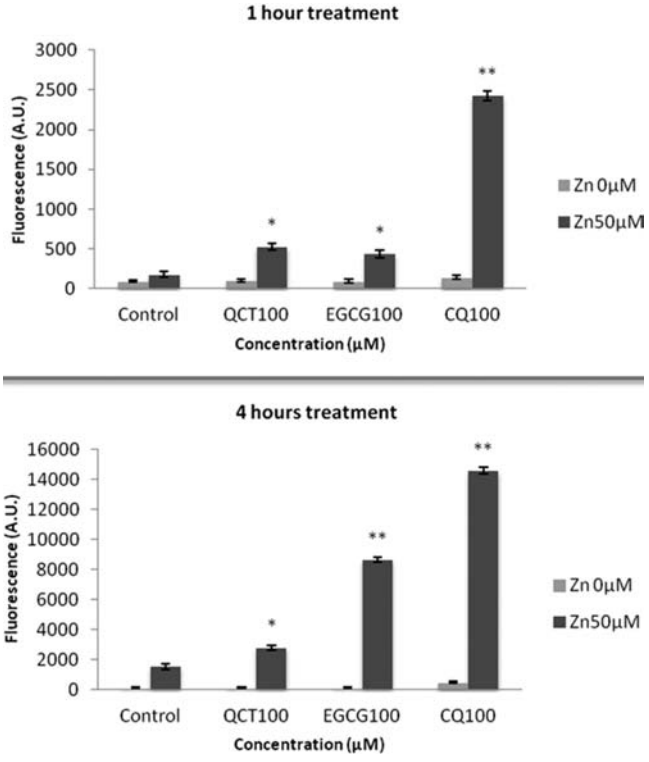

**Figure 3.** Intensity of FluoZin-3 fluorescence signal from images in Figure 2 was quantified using quanta program and considering an equal number of cells in each field. All values are mean ± SEM of three independent experiments. Significant differences between treatments were determined using one-way ANOVA (Tukey test). *$P \leq 0.05$; **$P \leq 0.01$.

been performed to discard the involvement of plasma membrane zinc importers or the origin of labile zinc from intracellular components on this effect. Furthermore, there is no report confirming that polyphenols are able to transport zinc across the plasma membrane independently of cell transport mechanisms, such as zinc transporters or endocytosis. To directly prove the ionophore action of the flavonoids and CQ, we tested their capacity to transport zinc cations across the lipid bilayer of protein-free liposomes as a model system that mimics a cell membrane devoid of protein and polysaccharide fractions. Taking advantage of our previously reported method for the rapid preparation of liposomes,[44] 3 $\mu$M concentration of cell-impermeant FluoZin-3 was encapsulated within unilamellar liposomes composed of DPPC/cholesterol in a 9:1 molar ratio. The resulting FluoZin-3-loaded liposomes were purified by passing the sample through a Sephadex G-100 size-separation column to remove the unencapsulated FluoZin-3 molecules. Dynamic light scattering (DLS) and $\zeta$ potential analysis were performed to clearly confirm the presence of stable liposomes within a size range 1−2 $\mu$m and surface charge around zero (Table 1).

The zinc ionophore activity of polyphenols was then tested as their capacity to transport zinc cations into the liposome cavity, interacting with the encapsulated zinc-dependent FluoZin-3 and consequently increasing the fluorescence signal within the liposomes (Figure 5). $ZnCl_2$ (10 $\mu$M) was added to the liposomal suspension in the absence and presence of 10 $\mu$M QCT, EGCG, and CQ, respectively, and zinc-dependent fluorescence intensity was measured over time. Following the addition of QCT, EGCG, or CQ, the Zn−polyphenol chelation complex is formed and transported across the bilayer, followed by interaction with the encapsulated FluoZin-3 probe, resulting in a significant and immediate increase in the fluorescence intensity.

Following the addition of 10 $\mu$M $ZnCl_2$ to the liposomes, a very small increase in the fluorescence appears due to the presence of a few free FluoZin-3 molecules that were not removed during the purification process and represent the background fluorescent signal. Even so, the fluorescent signal remains very low as zinc ions alone cannot cross the liposome membrane. The results from the kinetic experiment demon-

strate that QCT, EGCG, and CQ present different ionophore properties. CQ showed the strongest ionophore activity, producing a 35-fold increase in the zinc-dependent FluoZin-3 fluorescence intensity. Moreover, the maximum fluorescence is achieved rapidly after reaching the equilibrium in less than 15 min. QCT and EGCG also display a high ionophore activity in the system, although to a lesser extent as compared to the strong ionophore CQ, with 8- and 16-fold increases in fluorescence signal observed for QCT and EGCG, respectively. It can also be observed that both QCT and EGCG required more time (>60 min) to achieve the plateau phase, displaying slower chelation and transport kinetics (Figure 6).

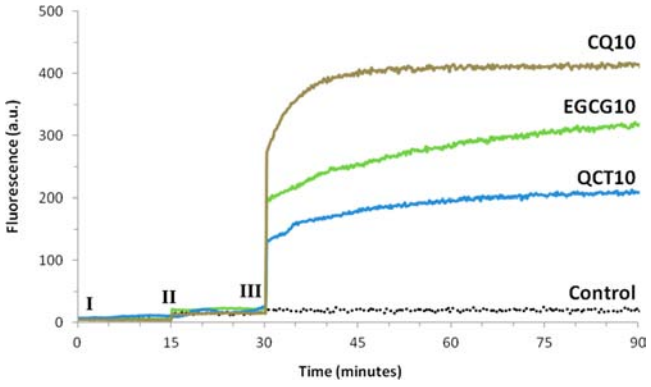

**Figure 6.** Effect of QCT, EGCG, and CQ on the uptake of zinc cations by liposomes. Zinc-dependent fluorescence emission of FluoZin-3 encapsulated within liposomes treated with zinc cations, polyphenols, and CQ. The fluorescence emission ($\lambda_{ex}$ = 494 nm; $\lambda_{em}$ = 516 nm) of purified FluoZin-3-loaded liposomes was recorded continuously. Background fluorescence (0−15 min) was negligible (I). Upon the addition of 10 $\mu$M $ZnCl_2$ to the liposomal suspensions (II), a small fluorescence signal was detected, presumably due to the presence of trace amounts of unencapsulated FluoZin-3 in the liposomal solutions. At time point 30 min, 10 $\mu$M quercetin (QCT10), epigallocatechin-3-gallate (EGCG10), clioquinol (CQ10), or vehicle (control, final 0.1% DMSO) were added to the liposomal solutions, and the fluorescence was monitored for one additional hour (III).

Confocal microscopy analysis was also performed in order to visualize and corroborate that the fluorescence produced by the interaction between zinc and FluoZin-3 was atributable to fluorescence in the inner part of the liposomes. As can be seen in Figure 7, fluorescence is only observed when the combination of $ZnCl_2$ with QCT, EGCG, or CQ is present, and the fluorescent signal comes from the inside part of the liposomes and not from the lipid membrane or the background

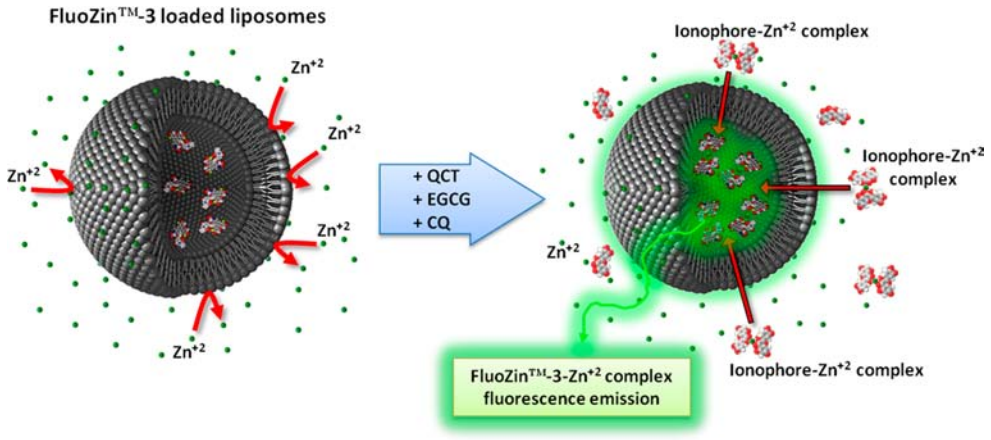

**Figure 5.** Schematic design of the FluoZin-3-loaded liposomes and the ionophore-like effect interpretation.

solution. To further support this, stability studies were carried out in order to check whether the QCT, EGCG, or CQ can destabilize and break the lipid vesicles. All the liposomes were characterized using transmission electron microscopy (TEM), DLS, and $\zeta$ potential to check that their stability was maintained following exposure.

As shown in Figure 8, TEM images of the liposomes before and after treatments clearly demonstrate that liposome stability was not affected with the morphology and mean size (1−2 $\mu$m) being maintained. Moreover, the DLS and $\zeta$ potential results presented in Table 1, confirmed that the size of the liposomes and their surface charge were not significantly affected by the addition of zinc and/or the ionophores, thus demonstrating that FluoZin-3-loaded liposomes were not destabilized and their around-zero charge, due to the zwitterionic nature of main lipid component DPPC, was maintained, thus confirming that the fluorescence signal is due to transport of the Zn−QCT/EGCG/CQ complex across the lipid membrane.

## 4. DISCUSSION

The consequences that zinc chelation by flavonoids may have on zinc availability to the cells may in principle be dual: sequestering or ionophore, as shown for other well-characterized zinc-binding compounds.[45] On the one hand, the formation of zinc−flavonoid complexes may render zinc unavailable for cells, as do other dietary phytochemicals such as phytatesc[46] and zinc-chelator drugs such as TPEN that induce zinc deficiency in vitro and in vivo.[47] Metal chelating therapy using CQ has been proposed for neurodegenerative disorders that course with high levels of metal accumulation such as Alzheimer's and Parkinson.[48] On the other hand, flavonoids may form water-insoluble membrane-permeant complexes with zinc that cross the plasma membrane, and thereby act as zinc ionophores. The ionophore effect of zinc-binding compounds has been characterized for pyrithione and CQ. Both drugs chelate zinc cations and, when applied to cells, trigger a rapid increase of the intracellular pool of zinc that is detectable with different fluorophores such as Zinquin or FluoZin-3. Thereafter, it is assumed that these chelators form membrane-permeable complexes that are transported into the cell and that, once within the cell, chelator−zinc complexes dissociate into the single compounds due to the low concentration of intracellular free and labile zinc, thus providing labile zinc cations. Although FluoZin-3 has been widely accepted as a fluorophore that specifically interacts with zinc,[49−52] a recent report has indicated that this marker may in fact suffer from a lack of specificity.[53] However, this has no impact on the proof-of-concept study reported here as zinc is the only ion present and studied and thus no interfering effect from other ions will occur. We have shown here that treatment of Hepa1-6 cells with zinc together with QCT, EGCG, or CQ elicits a rapid and drastic increase in FluoZin-3-detectable intracellular zinc. The same effect was previously observed using Zinquin upon treatments of HepG2 cells with combinations of zinc and EGCG or zinc and QCT.[38] In these cells, the upregulation of MT and ZnT1 by zinc was

dx.doi.org/10.1021/jf5014633 | J. Agric. Food Chem. 2014, 62, 8085−8093

enhanced by QCT. In contrast, EGCG decreased the intracellular zinc accumulation. Similar to QCT, the stilbene resveratrol efficiently chelates zinc in solution and enhances total and Zinquin-detectable cytoplasmic zinc in cultured human prostate epithelial cells, and this correlated with the antiproliferative action of resveratrol on cells.[33]

While an increasing effort has been made to understand the interaction of flavonoids with lipid bilayers,[54] no report has been published reporting the use of liposomes to demonstrate the zinc ionophore activity of polyphenols. Liposomes have been widely used as the simplest cell membrane systems in order to study the ionophore activity of molecules across the lipidic bilayer.[55] We have herein used a liposomal system to prove that zinc can transverse lipid bilayers when combined with flavonoids. It is not necessary to evoke the intervention of zinc transporters in the plasma membrane or the mobilization of zinc from intracellular compartments to account for the elevation of intracellular zinc levels in cells treated with flavonoids. The flavonoid-dependent transport of zinc cations into the liposomal cavity also implies that polyphenols may cross biological membranes when conjugated with metal cations. The mechanisms by which polyphenols enter the cells are largely unknown, but our results imply that complexation with metals may increase the bioavailability of polyphenols to cells.

There are several reports that strongly suggest that the demonstrated zinc ionophore effect on polyphenols will be observed in real physiological conditions if studied in vivo. Lee et al.[56] in 2002 has reported that a minor part of the EGCG found in plasma conserved its native form, and it has also been reported that the polyphenol metabolites still maintain their ability to chelate and form complexes with metal ions[30] and furthermore that nanomolar concentrations of polyphenols or their metabolites are able to modulate some metabolic pathways,[5,57,58] as does labile zinc in a picomolar to nanomolar concentration range.[14] While all these reports point toward the same ionophore effect being observed under physiological conditions, in a recent report by Oyama et al.,[59] the authors suggest the dual effect of CQ depending on the extracellular zinc concentration, where the known ionophore effect of CQ was only observed when extracellular zinc was available, and when zinc was not available in the extracellular environment, CQ could cross the membrane and chelate the intracellular zinc ions. To this end, ongoing work is looking at extending the proof-of-concept reported and demonstrated here with both liposomes and cellular models to true physiological conditions exploring the interactions between a range of polyphenols and polyphenol metabolites and zinc in a lower concentration range of picomolar to micromolar.

In conclusion, we have demonstrated that QCT, EGCG, and CQ rapidly increase intracellular labile zinc in Hepa 1-6 cells and that they function as ionophores for zinc in a liposomal system. Thus, natural flavonoids can be added to an arsenal of drugs that may be used to modulate zinc homeostasis and regulate zinc-dependent biological pathways.

Supporting Information

**ABSTRACT:** Isothiocyanates, generated from the hydrolysis of glucosinolates in plants of the Brassicaceae family, promote health, including anticancer bioactivity. Hydrolysis requires the plant enzyme myrosinase, giving myrosinase a key role in health promotion by brassica vegetables. Myrosinase measurement typically involves isolating crude protein, potentially underestimating activity in whole foods. Myrosinase activity was estimated using unextracted fresh tissues of five broccoli and three kale cultivars, measuring the formation of allyl isothiocyanate (AITC) and/or glucose from exogenous sinigrin. A correlation between AITC and glucose formation was found, although activity was substantially lower measured as glucose release. Using exogenous sinigrin or endogenous glucoraphanin, concentrations of the hydrolysis products AITC and sulforaphane correlated ($r$ = 0.859; $p$ = 0.006), suggesting that broccoli shows no myrosinase selectivity among sinigrin and glucoraphanin. Measurement of AITC formation provides a novel, reliable estimation of myrosinase-dependent isothiocyanate formation suitable for use with whole vegetable food samples.

**KEYWORDS:** *broccoli, kale, myrosinase activity, sulforaphane, isothiocyanates*

## INTRODUCTION

Brassica vegetable crops contain diverse health-promoting compounds including glucosinolates (GSL), flavonoids, carotenoids, and vitamins. Glucosinolates themselves are not bioactive but are converted into multiple hydrolysis products, including isothiocyanates and nitriles, through the action of the endogenous enzyme myrosinase.[1] The health benefits of broccoli are strongly associated with isothiocyanates including sulforaphane (SF), phenethyl isothiocyanate (PEITC), and allyl isothiocyanate (AITC). The chemical structure of hydrolysis products depends on the structure of the GSL side chain and reaction conditions, including the presence of myrosinase cofactors such as epithiospecifier protein (ESP). Abundance of ESP favors formation of nitriles, which not only lack anticancer activity, but are alternative hydrolysis products to bioactive isothiocyanates, thus lowering isothiocyanate levels.[1,2]

Recent studies report that destruction of myrosinase during processing of commercially available frozen broccoli products was the probable cause for little to no formation of the anticancer compound SF upon crushing the material.[3,4] We and others find that in the absence of myrosinase, only about 10% of the glucoraphanin present in a supplement or processed broccoli product appears as SF and its metabolites in plasma and urine.[5,6] A larger study found that SF absorption from a broccoli product lacking myrosinase may vary between <1% and approximately 40% of the starting dose of glucoraphanin.[7] Therefore, if consumers are to gain the full health benefit of brassica foods, research is needed to find ways to enhance GSL hydrolysis in brassica vegetable produce. A first step in such an endeavor is the accurate measurement of myrosinase activity contained within a whole brassica vegetable sample.

There are many excellent studies of myrosinase focused on the biochemistry of the purified or semipurified enzyme, rather than measurement in unextracted food samples.[1] Current methods for analyzing myrosinase activity measure either substrate disappearance or product (glucose) formation, following addition of an exogenous substrate, sinigrin. A less common measure of myrosinase activity is by the measurement of the acid release rate, by titrating the sample with 1 mM NaOH, using a dedicated pH meter coupled with a dispenser in a thermostatically controlled cell.[8]

Myrosinase activity is typically reported in terms of the hydrolysis of sinigrin, for which a unit of activity is defined as that which hydrolyzes 1 $\mu$mol of sinigrin per minute, and is measured by either sinigrin disappearance or glucose release. Each has benefits as well as limitations, affecting the calculated enzymatic activity. Disappearance of exogenous sinigrin, measured at 227 nm, suffers from interference from other components in the plant sample, including ascorbic acid, endogenous GSL, and proteins.[9] Quantitative analysis of glucosinolates is most commonly carried out by HPLC-UV detection following stabilization by desulfation; indole glucosinolates such as desulfo-neoglucobrassicin are found to have very different response factors compared to desulfo-sinigrin: 0.2 compared to 1, when measured at 227 nm.[10] It is likely that complete, sulfated, glucosinolates will also vary in their molar absorption at 227 nm. Concern for interference from endogenous GSL with differing absorbances has been overcome by hydrolysis of endogenous GSL prior to HPLC measurement of exogenous sinigrin disappearance.[11] A second and major advantage of endogenous GSL hydrolysis followed by HPLC for sinigrin disappearance is the lack of dependence on real-time enzyme analysis using spectrophotometry and, thus, the ability to measure activity in a whole homogenate rather than a clear solution.[11] Glucose release during GSL

hydrolysis is typically measured as a coupled enzyme assay, either glucose oxidase-peroxidase with a chromophore such as 2,2′-azinobis(3-ethylbenzothiazoline-6-sulfonic acid) (ABTS) and 4-hydroxybenzoic acid or hexokinase-glucose-6-phosphate dehydrogenase measuring NADPH at 340 nm. Whereas the glucose release method is sensitive and reliably measures myrosinase activity in a purified system, in the whole vegetable matrix it can suffer from interference from endogenous glucose and antioxidant compounds including ascorbic acid and polyphenolics.[9,12] Hexokinase-glucose-6-phosphate dehydrogenase similarly suffers from interference by endogenous glucose, flavonoids, and decomposition products of ascorbate.[9,12]

To overcome interference, endogenous glucose and GSL are typically removed by aqueous extraction, followed by semi-purification of the crude myrosinase protein, which is time-consuming and alters the protein content and, thus, the reported myrosinase specific activity. Additionally, myrosinase exists in both soluble and insoluble forms in plant material, so extraction could lead to loss of insoluble myrosinase, due to the pellet being discarded following aqueous extraction, and even loss of some soluble myrosinase, due to multiple rinses.[13,14] Therefore, it appears that the myrosinase activity estimated in purified protein, although useful for mechanistic studies, may not directly reflect the myrosinase present in unextracted brassica vegetable tissue samples.

There is only one reported method for myrosinase activity, developed using red cabbage and since applied to other vegetables, which uses a whole vegetable homogenate.[11] The homogenate is sieved to remove larger particles and then incubated for 2 h to hydrolyze potentially interfering GSL and estimates myrosinase as the disappearance of exogenous sinigrin using HPLC.[11,15] This paper offers an alternative method to evaluate total myrosinase activity in whole brassica vegetable homogenates, on the basis of isothiocyanate formation, and compares this to measures of myrosinase activity using a modified glucose release assay.

## MATERIALS AND METHODS

**Sample Collection and Preparation.** Broccoli florets, leaves, and roots (*Brassica oleracea* L. cv. 'Sultan', 'Marathon', 'Patron', 'Pirate', 'Maximo') and kale leaves and roots (*B. oleracea* L. cv. 'Red Winter', 'Red Russian', 'Dwarf Blue Curled Vates') were grown at the University of Illinois in 2013, harvested at commercial maturity, frozen in the field using liquid nitrogen, and transported to the laboratory on dry ice for further processing. Samples were freeze-dried for later analysis of myrosinase activity. In previous work, freeze-drying was shown not to affect the content of glucosinolates or sulforaphane formation during hydrolysis.[16] GSL were measured as previously described.[17]

**Myrosinase Activity Using Allyl Isothiocyanate and Sulforaphane Formation.** Myrosinase activity is traditionally measured as sinigrin hydrolysis.[18] However, broccoli contains little or no sinigrin,[17,19] so we developed an assay that could compare the hydrolysis of exogenous sinigrin with that of endogenous glucoraphanin, by monitoring the concomitant formation of AITC and SF. Myrosinase activity was initiated by the addition of sinigrin (final concentration = 2 mM; Sigma, St. Louis, MO, USA) to 100 mg of freeze-dried broccoli or kale tissue in 5.0 mL of water followed by incubation at 25 °C. Samples (0.5 mL) were removed at 5 min, spiked with an internal standard of benzyl isothiocyanate (Sigma), then immediately extracted into dichloromethane (0.5 mL), centrifuged for 1 min at 16000*g*, and analyzed for AITC and SF content (see below). In later studies, samples were removed from the incubation at different times, as shown in the figures. For calculation of myrosinase activity, the first 3 min was used on the basis of the linearity of isothiocyanate generation.

**Allyl Isothiocyanate and Sulforaphane Measurement.** Using an Agilent model 7683B series autosampler, 1 μL of dichloromethane extract was injected onto an Agilent 6890N gas chromatography system equipped with a single flame ionization detector (Agilent Technologies, Santa Clara, CA, USA). Samples were separated using a 30 m × 0.32 mm J&W HP-5 capillary column (Agilent Technologies). After an initial hold at 40 °C for 2 min, the oven temperature was increased by 10 °C/min to 260 °C and held for 10 min. Injector temperature was 200 °C; detector temperature was 280 °C. Helium carrier gas flow rate was 25 mL/min. Results were quantitated against standards of SF (LKT Laboratories, St. Paul, MN, USA) and AITC (Sigma).

**Determination of Myrosinase Activity Using Glucose Release.** The glucose release assay has traditionally utilized an aqueous extract of plant material. Because we were interested in the activity in the whole food, we chose to run the assay using freeze-dried plant material, which was subjected to extraction only after the hydrolysis was complete. In other aspects, the assay was similar to published methods.[18,20] Briefly, freeze-dried, powdered plant material (50 mg) was weighed in duplicate into 2 mL tubes, and 1 mL of sinigrin (10 mM) was added to each tube. After 10 s of vigorous vortexing, one of the paired samples was put directly into a heating block (95 °C) for 10 min to inactivate the myrosinase enzyme (zero time blank). The second sample was incubated at 40 °C for 30 min and then inactivated as outlined above. After inactivation, samples were cooled on ice for 5 min and then centrifuged at 16000*g* for 2 min. The supernatants were diluted 96-fold, and aliquots (30 μL) or glucose standard was added in a 96-well plate, followed by the addition of 200 μL of an ABTS−glucose solution [2.7 mM ABTS, 1000 units of peroxidase (Type VI-A, Sigma), and 1000 units of glucose oxidase in 100 mL] and incubation for 20 min; absorbance was measured at 630 nm in a μQuant plate reader (Bio-Tek instruments, Winooski, VT, USA). Myrosinase activity was also measured for different incubation times, as shown in the figures. In another study, myrosinase activity was measured by adding water in place of sinigrin to compare myrosinase activity in the presence of exogenous GSL (sinigrin) and endogenous GSL.

**Soluble and Insoluble Myrosinase Activity.** Because we chose to measure myrosinase activity in unextracted plant material, we were interested in comparing myrosinase activity between freeze-dried brassica vegetable tissue and a crude protein plant extract more typical of published measurements: aqueous extracts were generated by extracting plant material into solutions containing ice-cold 10 mM sinigrin, followed by centrifugation at 16000*g* for 1 min. Supernatants containing soluble myrosinase were transferred to new tubes, brought to a final volume of 1 mL using sinigrin in water (10 mM), and either immediately heated (zero time blank) or incubated at 40 °C for 30 min. The myrosinase activity of the centrifugal pellet after crude protein extraction containing insoluble or bound myrosinase was also evaluated by adding 1 mL of 10 mM sinigrin, vortexing, and then heating immediately (zero time blank) or incubating at 40 °C for 30 min and then heating.

**Determination of Interference by Antioxidant Compounds in the Glucose Assay.** To measure interference to the ABTS−glucose assay by endogenous antioxidant compounds from plant samples, eight different concentrations of gallic acid ranging from 1.17 to 150 μM were incubated with glucose (5 μg fixed concentration), and the ABTS−glucose assay was conducted. Interference of glucose measurement by endogenous antioxidant compounds in the plant extracts ('Marathon' root, leaf, or floret) was also measured using the ABTS antioxidant assay.[21] Briefly, plant tissue extracts (30 μL of 50 mg/mL or 96-fold diluted samples) were added to 200 μL of ABTS in 96-well plates (absorption at 630 nm = 1.0), and absorbance was measured after 6 min.

**Statistical Analysis.** Statistical analysis was conducted using JMP 10 software (SAS Institute Inc., Cary, NC, USA). Student's *t* tests were used for comparing treatment groups. Fisher's least significant difference (LSD) test was conducted to compare means; $p < 0.05$

was accepted as significant. Pearson's correlation was conducted whereby pairs of myrosinase activities were compared.

## RESULTS AND DISCUSSION

As shown in Figure 1, myrosinase activity of whole freeze-dried broccoli floret tissue, measured as glucose release, is 63%

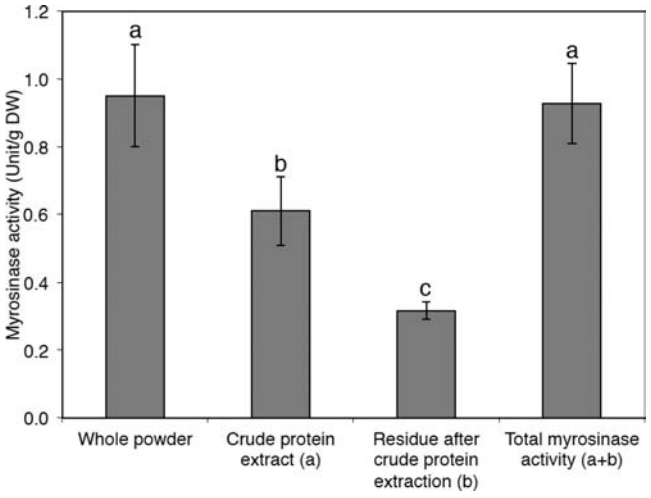

**Figure 1.** Myrosinase activity in whole freeze-dried 'Marathon' broccoli floret samples, crude protein extract (soluble myrosinase), centrifugal pellet after crude protein extraction (insoluble myrosinase), and total myrosinase activity (soluble + insoluble measures), measured as glucose appearance after 30 min of incubation. Mean ± SD ($n$ = 3). Different letters indicate significantly different values based on LSD test ($p < 0.05$). A unit is defined here as 1 $\mu$mol of glucose formed per minute, using 10 mM sinigrin as substrate.

greater than that of the corresponding aqueous extract. The freeze-dried broccoli floret powder best represents total myrosinase activity in a serving of broccoli. Interestingly, when the value for the crude protein extract (soluble myrosinase) was added to the value for myrosinase remaining in the pellet (insoluble myrosinase), this equaled the value obtained for the unextracted plant tissue, suggesting that this was a reasonable measure of soluble plus insoluble myrosinase activity. In a previous study measuring insoluble myrosinase from *Sinapis alba* seeds, the authors found that after three extractions, when the centrifugal pellet was resuspended and assayed for activity, it was highly active, in agreement with our present results for floret tissue.[14] This suggests that measurement of myrosinase activity in an aqueous extract could greatly underestimate the activity of whole, unextracted tissues.

Aqueous extraction can be expected to affect myrosinase activity measurement in several additional ways. For example, isolating crude protein is often preceded by defatting, which could alter myrosinase activity by changing its structure.[22] Protein extraction buffers often contain EDTA, which is known to chelate iron, as well as many other cations. In the simplified matrix of an extract, the iron at the active center of ESP was found to be relatively labile, such that EDTA treatment completely inhibited ESP-dependent nitrile formation in favor of the generation of isothiocyanate.[23] Whereas redirecting away from nitrile formation would not alter measurement of myrosinase activity by sinigrin disappearance or glucose appearance, a drawback of the use of AITC as a measurement of myrosinase activity is that nitriles are alternative products to isothiocyanates, and any nitrile formed would detract from total myrosinase activity measured as AITC formation. Yet because isothiocyanate formation relates directly to any health impact, the measurement of myrosinase-dependent isothiocynate formation may be of significant interest. Inhibition of nitrile production would be expected to increase isothiocyanate production.[24] It would be interesting to include EDTA in our system to determine if so doing increased myrosinase activity measured as isothiocyanate appearance. Furthermore, use of a buffer with or without EDTA, rather than water, to form the homogenate might improve the stability of the enzyme in our system.

Endogenous ascorbic acid and magnesium chloride may be removed during extraction, particularly if extraction is followed by fractionation for semipurification of the enzyme away from endogenous glucose.[18] The use of unextracted plant tissue when total myrosinase activity is measured reduces the risk of excluding insoluble myrosinase and of discarding important cofactors. Alternatively, methods that use semipurified myrosinase often add cofactors at levels chosen to optimize activity, rather than to reflect the content of the food.[13,25]

The results shown in Table 1 are comparisons of myrosinase activity in five broccoli and three kale varieties measured

**Table 1. Comparison of Myrosinase Activity Assays**

| cultivar | tissue | glucose assay, mean ± SD (units/g DW) | AITC assay, mean ± SD (units/g DW) |
|---|---|---|---|
| Sultan | floret | 1.75 ± 0.08 | 15.62 ± 2.43 |
| Sultan | root | 0.83 ± 0.05 | 4.44 ± 0.53 |
| Sultan | leaf | 1.85 ± 0.11 | 20.60 ± 2.27 |
| Marathon | floret | 0.69 ± 0.12 | 13.64 ± 1.25 |
| Marathon | root | 0.73 ± 0.01 | 10.68 ± 0.44 |
| Marathon | leaf | 1.53 ± 0.12 | 19.01 ± 1.94 |
| Patron | floret | 2.04 ± 0.16 | 13.31 ± 1.49 |
| Patron | root | 0.86 ± 0.08 | 9.13 ± 0.25 |
| Patron | leaf | 1.27 ± 0.11 | 15.49 ± 2.68 |
| Pirate | floret | 1.63 ± 0.24 | 14.46 ± 1.10 |
| Pirate | root | 0.56 ± 0.03 | 3.62 ± 0.20 |
| Pirate | leaf | 1.66 ± 0.11 | 14.72 ± 2.39 |

| Dwarf Blue Curled Vates | leaf | 2.39 ± 0.14 | 14.70 ± 0.94 |

independently using either glucose release or the proposed method of AITC formation. The myrosinase activities from the glucose release assay are much lower values than those from the AITC formation-based assay. Furthermore, although the two assays were in relatively good agreement in ranking activity across plant parts (leaf, floret, root) within a cultivar, there were several striking inconsistencies between assays. For example, 'Red Russian' kale root tissue had only 85% of the activity found in the leaf tissue as measured by the glucose assay, although the same kale root tissue had 145% of the activity found in leaves when measured by the AITC assay. Conversely, for 'Red Winter' kale, root tissue had only 50% of the activity of

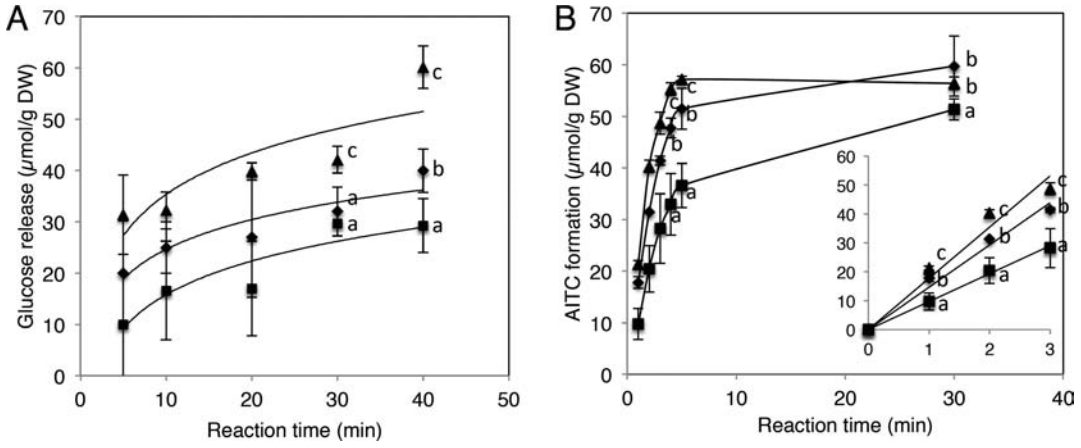

**Figure 2.** Glucose and allyl isothiocyanate (AITC) time-dependent formation from 'Marathon' broccoli floret (solid diamond), root (solid square), or leaf (solid triangle) tissue samples supplemented with sinigrin: (A) glucose release; (B) AITC formation (inset, early time points of AITC formation used for myrosinase activity calculations). Values are means ± SD ($n$ = 3). Different letters indicate significantly different values based on LSD test for the same time point ($p < 0.05$).

leaf samples, measured by either glucose or AITC assays. In all, when myrosinase activity from all tissues was compared across the two assays, although it was not strong, there was a significant, positive correlation between glucose appearance and AITC formation ($r$ = 0.488, $n$ = 21, $p$ = 0.0252). This suggests that the two assays measure the same activity, although not optimally. Therefore, we chose to determine if data were more similar between the two assays at earlier time points.

In reviewing change in enzyme rates over time, Figure 2 shows that rates were initially linear, but no longer linear by 5 min, whether using appearance of glucose (Figure 2A) or formation of AITC (Figure 2B). Background glucose levels are low in semipurified myrosinse preparations but greatly confounded the glucose appearance assay in homogenates at short time points (Figure 2A). For example, at 5 min, there was insufficient glucose formed to differentiate glucose production from background glucose present in the whole tissue sample, causing great variability in repeat measures (Figure 2A). Thus, it was not until 30 min that leaf samples showed significantly greater activity than root samples, and not until 40 min that floret samples showed significantly greater activity than root samples (Figure 2A). Both assays identified leaf as having the greatest myrosinase activity per gram DW of tissue and root the least, even though *under the conditions used*, linearity was possibly only present for the first 3 min of incubation. In leaf tissue, neither glucose nor AITC appearance at 5 min was significantly different from their appearance at 30 min, showing that the reaction had almost stopped by 5 min under these conditions.

In the literature the glucose release or sinigrin disappearance assays are often run for 5 min or more[9,11,18,20,23] and assume linearity of glucose formation during the entire assay,[18] which is likely true for these simplified systems using extracted myrosinase but could greatly underestimate myrosinase activity and not accurately reflect the real-time activity of myrosinase if the reaction slows as we observed in the unextracted tissue. We considered the possibility that substrate loss, when sinigrin is converted to hydrolysis products, could be responsible in part for the change seen in linearity of myrosinase activity. However, on the basis of product formation at 30 min, >40% substrate remained in samples from the AITC method. A previous study suggested that AITC can react with protein, resulting in inhibition of enzymatic activity due to modification of amino acid profile.[26] This could also explain part of the decrease in myrosinase activity that occurred over the 30 min measurement period. We further considered whether the steep decline in rate from 5 to 30 min for the AITC assay (Figure 2B) could be due to reaching the limit of water solubility for AITC. However, AITC solubility is 1.3 mg/mL, and the 30 min values for AITC were an order of magnitude less than this (0.118 mg/mL).[27]

Use of the AITC formation assay (Figure 2B) gave a value closer to linear, particularly when shorter incubation times were used (3 min), an option that is not possible for the glucose appearance assay, if using unextracted plant tissue samples, because of variation due to the high glucose background interference (Figure 2A). However, use of AITC formation could also underestimate myrosinase activity by ignoring nitriles formed due to the presence of ESP.[1] The inclusion of EDTA in the reaction solution could possibly prevent the formation of nitriles, channeling hydrolysis toward isothiocyanate formation.[23] However, this would actually overestimate the formation of isothiocyanates during food consumption, which is important when the role for myrosinase-dependent isothiocyanate release in health-promoting bioactivity is considered.

We considered that antioxidant compounds naturally present in plant tissues might also interfere with glucose estimation in the glucose appearance assay[9,12] because the ABTS-glucose assay is dependent on the oxidation of ABTS (Figure 3). When increasing concentrations of gallic acid were added to the assay medium in the presence of 5 μg of glucose, the appearance of oxidized ABTS was inhibited in a dose-dependent manner, with 150 μM gallic acid causing a >93% inhibition (Figure 4A). To avoid this interference for the ABTS-glucose assay, after

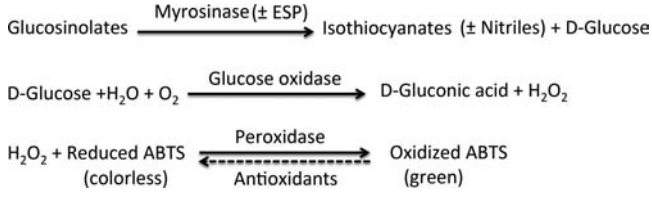

**Figure 3.** Scheme of ABTS-glucose assay showing site of potential risk of antioxidant interference.

dx.doi.org/10.1021/jf501692c | J. Agric. Food Chem. 2014, 62, 8094−8100

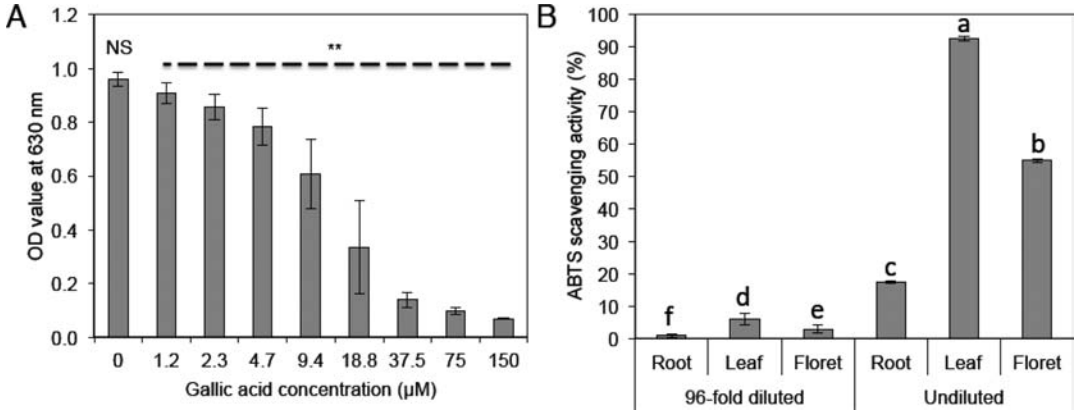

**Figure 4.** Endogenous antioxidant interference of glucose measurement, when using the ABTS-glucose assay: (A) interference of gallic acid (1.17−150 $\mu$M) on measurement of glucose (fixed at 5 $\mu$g); (B) percent interference by endogenous antioxidant compounds in 'Marathon' root, leaf, or floret broccoli tissues. Extracts generated following incubation were either undiluted or diluted 96-fold. Values are means ± SD ($n$ = 3). (**) Significantly different from no gallic acid, $p < 0.01$. Different letters indicate significantly different values based on LSD test ($p < 0.05$).

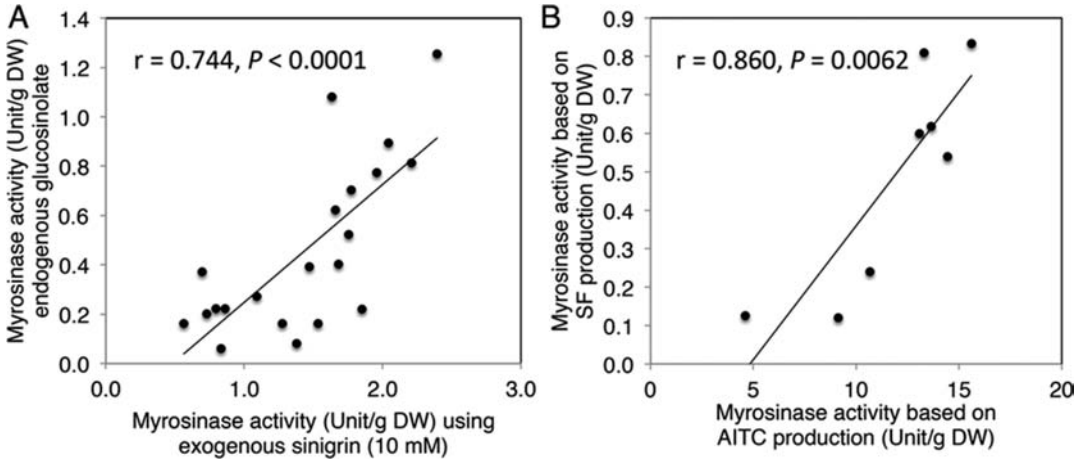

**Figure 5.** Correlation between myrosinase measurements using exogenous (singirin) or endogenous glucosinolate in 21 broccoli and kale tissue samples: (A) sinigrin (10 mM) or no glucosinolate addition, glucose assay; (B) sinigrin (2 mM) or no glucosinolate addition, AITC and SF assay. Pearson's correlation was calculated on the basis of the mean activity for each assay; $n$ = 3.

myrosinase-dependent glucose formation was complete, we evaluated the use of 96-fold diluted sample extracts to estimate glucose. At this dilution, plant endogenous antioxidant compounds interfered with glucose generation less than 1, 6, and 3% for root, leaf, and floret tissues, respectively (Figure 4B). This dilution not only allows us to minimize the potential interference from antioxidant compounds but also to decrease the concentration of endogenous glucose within the capacity range of the ABTS-glucose assay.

Published myrosinase activity assays typically use the addition of excess exogenous GSL; in most cases sinigrin is used and activity is reported in terms of sinigrin hydrolysis.[23] Often, however, myrosinase activity is being measured in samples in which other GSL or isothiocyanates are the compounds of interest. The use of a GSL not endogenous or not found in high concentrations in a cruciferous vegetable may skew results, particularly if substrate specificity exists between myrosinase and endogenous GSL, as previously shown for *Crambe abyssinica* seeds.[28] In this respect we hypothesized that using endogenous GSL to measure myrosinase activity should also be possible if the sample contains sufficient endogenous substrate to ensure that myrosinase (and not substrate) is rate limiting. Hydrolysis of endogenous GSL was measured as the appearance of glucose in 21 test samples. The tissue total GSL concentrations ranged from 1.86 to 70.9 $\mu$mol/g (concentration during the assay, 0.093−3.54 mM, Supporting Information Table S1). There was a highly significant correlation between myrosinase activity using endogenous GSL and exogenous GSL (10 mM sinigrin) measured as glucose appearance ($r$ = 0.744, $n$ = 21, $p < 0.0001$; Figure 5A). This shows that myrosinase activity can be measured using endogenous GSL over this naturally occurring GSL concentration range. The GSL concentration varied significantly from tissue to tissue; averaged values of total broccoli floret and root GSL concentration from five cultivars were 16.2 and 14.8 $\mu$mol/g DW, respectively which were considerably higher concentrations than those observed in leaf tissue (4.0 $\mu$mol/g DW, Supporting Information). Averaged values of kale root and leaf tissue GSL concentrations were 44.3 and 10.0 $\mu$mol/g DW, respectively (Supporting Information). However, this method is only feasible to use for short time measurements and for screening plant tissues that contain sufficient GSL. Because glucoraphanin is usually the predominant GSL found in broccoli, we hypothesized that its hydrolysis would correlate to the myrosinase activity determined previously. We found myrosinase activity using the formation of either AITC or SF to

be significantly correlated ($r = 0.860$, $n = 8$, $p = 0.0062$; Figure 5B). This suggests that the ITC formation-based myrosinase assay described here can be utilized to measure myrosinase activity using endogenous, as well as exogenous, GSL. For example, myrosinase activity in broccoli, watercress, and horseradish might be measured by SF, PEITC, and AITC formation, respectively. However, it is necessary to remember that whereas this may provide an accurate measure for ingested foods, the presence of ESP, and possibly other myrosinase protein cofactors, will cause underestimation of absolute myrosinase activity. Because in vivo formation and bioavailability of ITC from GSL in broccoli is affected by processing conditions,[29] more study should be conducted using foods after the cooking process.

In conclusion, evaluating myrosinase activity from multiple broccoli varieties, we find that leaf and floret tissues have relatively greater activity than root tissue, on a per gram DW basis. Kale varieties exhibited the same trend, with leaf tissues possessing greater myrosinase activity than root. Myrosinase activity based on the formation of AITC can be useful in determining short-term enzymatic rates of myrosinase, with incubation times limited to 1−3 min. Samples can be run and hydrolysis products extracted rapidly, allowing a quick turnaround time for a few activity estimations. When using brassica vegetable tissues, the glucose release assay cannot be run for such short times, due to high baseline interference by endogenous glucose: on average, 30 min was required to reliably measure glucose formation. For limited sampling, the glucose assay also takes longer to perform, with multiple steps and incubations. However, if there are a large number of samples, performance time per sample is reduced radically, making glucose release a better high-throughput method, as long as samples are prepared in such a way that background glucose does not interfere, such as the use of a crude protein extract in place of tissue samples. However, we found that up to 36% of myrosinase activity was discarded in the pellet during generation of the crude protein extract. Whether soluble and insoluble myrosinases are similar with regard to activity or even substrate specificity is not known, although we found that changing substrates from sinigrin to the endogenous substrate glucoraphanin did not alter myrosinase measurements using the AITC method.

The proposed AITC formation assay can measure activity during the short-term linear phase of total myrosinase activity (~3 min) when used for whole brassica vegetable samples. It also has the capacity to evaluate hydrolysis of endogenous glucoraphanin. Whereas this assay appears most relevant for estimating myrosinase activity in terms of food consumption, further studies are needed to understand the impact of cooking on myrosinase activity in whole homogenates, particularly to determine how soluble and insoluble myrosinase enzymes are affected by postharvest processing.

Supporting Information

**ABSTRACT:** Measurements of aroxyl radical (ArO•)-scavenging rate constants ($k_s^{AOH}$) of antioxidants (AOHs) [α-, β-, γ-, and δ-tocopherols (TocHs) and -tocotrienols (Toc-3Hs)] were performed in ethanol solution via stopped-flow spectrophotometry. $k_s^{AOH}$ values of α-, β-, γ-, and δ-Toc-3Hs showed good agreement with those of the corresponding α-, β-, γ-, and δ- TocHs. $k_s^{AOH}$ values were measured not only for each antioxidant but also for mixtures of two antioxidants: (i) α-TocH with β-, γ-, or δ-TocH and (ii) α-TocH with α-, β-, γ-, or δ-Toc-3H. A synergistic effect in which the $k_s^{AOH}$ value increases by 12% for γ-TocH (or by 12% for γ-Toc-3H) was observed for solutions including α-TocH and γ-TocH (or γ-Toc-3H). On the other hand, a cancel effect in which the $k_s^{AOH}$ value decreases (a) by 7% for β-TocH (or 11% for β-Toc-3H) and (b) by 24% for δ-TocH (or 25% for δ-Toc-3H) was observed for solutions including two kinds of antioxidants. However, only a synergistic effect may function in edible oils, because contents of β- and δ-TocHs (and β- and δ-Toc-3Hs) are much less than those of α- and γ-TocHs (and α- and γ-Toc-3Hs) in many edible oils. UV−vis absorption of α-Toc•, which was produced by reaction of α-TocH with ArO•, decreased remarkably for coexistence of α-TocH with β-, γ-, or δ-TocH (or β-, γ-, or δ-Toc-3H), indicating that the prooxidant effect of α-Toc• is suppressed by the coexistence of other TocHs and Toc-3Hs.

**KEYWORDS:** *free radicals, vitamin E, tocopherols, tocotrienols, antioxidant activity, reaction rate, stopped-flow spectrophotometry, coexistence of antioixidants, synergistic and cancel effects*

## INTRODUCTION

α-Tocopherol (α-TocH) is well-known as one of the most important lipophilic antioxidants (AOHs) in foods and biological systems.[1−3] The antioxidant action of α-TocH has been ascribed to the scavenging reaction of lipid peroxyl (LOO•) radical, producing the corresponding α-tocopheroxyl (α-Toc•) radical (reaction 1).[1] On the other hand, if α-TocH exists in edible oils and biomembranes, α-Toc• radicals may react with unsaturated lipids (LHs) (reaction 2). Reaction 2 is known as a prooxidant reaction, which induces degradation of unsaturated lipids.[4−8]

$$\text{LOO}^\bullet + \text{α-TocH} \xrightarrow{k_{inh}} \text{LOOH} + \text{α-Toc}^\bullet \quad (1)$$

$$\text{α-Toc}^\bullet + \text{LH} \xrightarrow{k_p} \text{α-TocH} + \text{L}^\bullet \quad (2)$$

Ubiquinol-10 ($UQ_{10}H_2$) is also well-known as a representative lipophilic antioxidant.[9,10] $UQ_{10}H_2$ functions as an antioxidant by (i) scavenging LOO• (reaction 3) and (ii) regenerating α-Toc• to α-TocH (reaction 4):[1,9,10]

$$\text{LOO}^\bullet + UQ_{10}H_2 \xrightarrow{k_{inh}} \text{LOOH} + UQ_{10}H^\bullet \quad (3)$$

$$\text{α-Toc}^\bullet + UQ_{10}H_2 \xrightarrow{k_r} \text{α-TocH} + UQ_{10}H^\bullet \quad (4)$$

where $UQ_{10}H^\bullet$ denotes the ubisemiquinone radical. The results of kinetic studies for reactions 3 and 4 indicated that both reactions are important for the antioxidant actions of $UQ_{10}H_2$.[11−15]

On the other hand, vitamin C (ascorbate monoanion, $AsH^-$) is a representative water-soluble antioxidant. Hydrophilic $AsH^-$ also enhances the antioxidant activity of α-TocH by regenerating α-Toc• to α-TocH (reaction 5):[15−18]

$$\text{α-Toc}^\bullet + \text{AsH}^- \xrightarrow{k_r} \text{α-TocH} + \text{As}^{-\bullet} \quad (5)$$

where $As^{-\bullet}$ is an ascorbate free radical. As described above, α-Toc• is an important key radical, which appears in the process of antioxidant and prooxidant actions of α-TocH (see reactions 1, 2, 4, and 5).

In previous works, we measured the second-order reaction rates ($k_s^{AOH}$) of many kinds of natural antioxidants, such as α-, β-, γ-, and δ-TocHs,[19,20] biological hydroquinones including $UQ_{10}H_2$,[20] vitamin C (or sodium ascorbate),[21] and many polyphenols including catechins and flavone derivatives,[21,22]

**Figure 1.** Molecular structures of *α*-, *β*-, *γ*-, and *δ*-tocopherols (TocHs); *α*-, *β*-, *γ*-, and *δ*-tocotrienols (Toc-3Hs); and aroxyl radical (ArO•).

stopped-flow spectrophotometry. ArO• can be regarded as a model for active oxygen radicals (LOO• and others) in biological systems, as described in previous works.[19,20,23]

$$\mathrm{ArO^{\bullet}} + \mathrm{AOH} \xrightarrow{k_s^{\mathrm{AOH}}} \mathrm{ArOH} + \mathrm{AO^{\bullet}} \quad (6)$$

As described above, *α*-TocH, $UQ_{10}H_2$, and vitamin C are the most important natural antioxidants in biological systems. These antioxidants coexist in relatively high concentrations in human (and rat) plasma and various tissues.[24−27] Furthermore, it is well-known that various antioxidants coexist in many foods.[2] However, a detailed kinetic study has not been performed for mixtures of these antioxidants.

Therefore, recently, measurements of ArO•-scavenging rate constants ($k_s^{\mathrm{AOH}}$) of antioxidants [*α*-TocH, $UQ_{10}H_2$, and sodium ascorbate ($Na^+AsH^-$)] were performed in 2-propanol/water (5/1 v/v) solution by stopped-flow spectrophotometry. $k_s^{\mathrm{AOH}}$ values were measured not only for each antioxidant but also for mixtures of two antioxidants: (i) *α*-TocH with $UQ_{10}H_2$ and (ii) *α*-TocH with $Na^+AsH^-$.[28] A notable synergistic effect in which $k_s^{\mathrm{AOH}}$ values increase 1.6, 2.5, and 6.8 times for *α*-TocH, $UQ_{10}H_2$, and $Na^+AsH^-$, respectively, was observed for solutions including two kinds of antioxidants. Furthermore, formation of *α*-Toc• radical was suppressed remarkably for coexistence of *α*-TocH with $UQ_{10}H_2$ (or $Na^+AsH^-$). The result suggests that the prooxidant effect induced by the reaction between *α*-Toc• radical and LH (reaction 2) may be suppressed by the coexistence of *α*-TocH with $UQ_{10}H_2$ (or $Na^+AsH^-$).

*α*-, *β*-, *γ*-, and *δ*-Tocopherols and -tocotrienols (*α*-, *β*-, *γ*-, and *δ*-TocH and -Toc-3H; see Figure 1) are well-known as vitamin E homologues. As described above, ArO•-scavenging rates ($k_s^{\mathrm{AOH}}$) of *α*-, *β*-, *γ*-, and *δ*-tocopherols have been investigated in previous works.[19,20] However, a detailed kinetic study has not been performed for *α*-, *β*-, *γ*-, and *δ*-tocotrienols, as far as we know.

In the present work, first, measurements of the rate constants ($k_s^{\mathrm{AOH}}$) were performed for eight vitamin E homologues in ethanol solution at 25 °C by stopped-flow spectrophotometry, to investigate the effect of alkyl side chain of *α*-, *β*-, *γ*-, and *δ*-TocHs and -Toc-3Hs on the scavenging rate. Second, measurements of the $k_s^{\mathrm{AOH}}$ value were performed for solutions including two kinds of antioxidants, (i) *α*-TocH with *β*-, *γ*-, and *δ*-TocHs and (ii) *α*-TocH with *α*-, *β*-, *γ*-, and *δ*-Toc-3Hs, to investigate the synergistic and cancel effects of antioxidants on the ArO•-scavenging rate. Third, the effect of coexistence of *α*-TocH and other TocHs (or Toc-3Hs) on the prooxidant action of *α*-TocH has been studied. Vitamin E homologues are included in many kinds of edible oils such as rapeseed, soybean, peanut, rice bran, palm oils, etc.[29−33] Consequently, it will be of interest to study the effect of coexistence of *α*-TocH with other TocHs (or Toc-3Hs) on the antioxidant and prooxidant actions of *α*-TocH.

## MATERIALS AND METHODS

**Materials.** D-*α*-, *β*-, *γ*-, and *δ*-Tocopherols and -tocotrienols were kindly supplied from Eisai Food & Chemical, Co. Ltd., Japan. The purities of tocopherols and tocotrienols used were as follows; *α*-, *β*-, *γ*-, and *δ*-TocHs (99.9%, 99.8%, 100.0%, and 99.5%) and *α*-, *β*-, *γ*-, and *δ*-Toc-3Hs (99.4%, 99.4%, 98.7%, and 98.7%), respectively. ArO• radical was prepared according to the method of Rieker and Scheffler.[34]

**Measurements.** Measurement of the second-order rate constant ($k_s^{\mathrm{AOH}}$) for reaction of ArO• with AOH (reaction 6) was performed on a Unisoku single-mixing stopped-flow spectrophotometer (Model RSP-1000) by mixing equal volumes of ethanol solutions of ArO• and AOH under nitrogen atmosphere.[20,21] The time between mixing the two solutions and recording the first data point (that is, dead time) was 10−20 ms. The reaction was monitored with either single-wavelength detection (Figure 2B) or photodiode-array detection (Figure 2A) attached to the stopped-flow spectrophotometer. All measurements were performed at 25.0 ± 0.5 °C. Experimental errors in the rate constants ($k_s^{\mathrm{AOH}}$) were estimated to be about 5% in ethanol solution.

## RESULTS

**Measurements of Aroxyl Radical-Scavenging Rates for *α*-, *β*-, *γ*-, and *δ*-Tocopherols and -Tocotrienols in Ethanol Solution.** Measurement of the rate constant ($k_s^{\alpha\text{-TocH}}$) for reaction of ArO• radical with *α*-TocH was performed in ethanol solution (reaction 6). Upon reaction of *α*-TocH with ArO• radical, the absorbance at 376 and 580 nm of ArO• decreases and the absorbance at 428 nm of *α*-Toc• radical increases, as shown in Figure 2A. The scavenging rate of ArO• was measured by following the decrease in absorbance at 376 or 580 nm of the ArO• radical, as shown in Figure 2B.[28] The pseudo-first-order rate constants ($k_{obsd}$) at 376 or 580 nm were linearly dependent on the concentration of *α*-TocH [*α*-TocH], and thus, the rate equation is expressed as

$$-\mathrm{d}[\mathrm{ArO^{\bullet}}]/\mathrm{d}t = k_{\mathrm{obsd}}[\mathrm{ArO^{\bullet}}] = k_s^{\alpha\text{-TocH}}[\alpha\text{-TocH}][\mathrm{ArO^{\bullet}}] \quad (7)$$

where $k_s^{\alpha\text{-TocH}}$ is the second-order rate constant for oxidation of *α*-TocH by ArO• radical. $k_s^{\alpha\text{-TocH}}$ was obtained by plotting $k_{obsd}$ against [*α*-TocH], as shown in Figure 2C. The $k_s^{\alpha\text{-TocH}}$(alone) value obtained is $5.14 \times 10^3$ $M^{-1}\cdot s^{-1}$ (see Table 1), where $k_s^{\alpha\text{-TocH}}$(alone) means the ArO• radical-scavenging rate constant obtained in solution including only one antioxidant (*α*-TocH). As described above, upon reaction of *α*-TocH with ArO• in

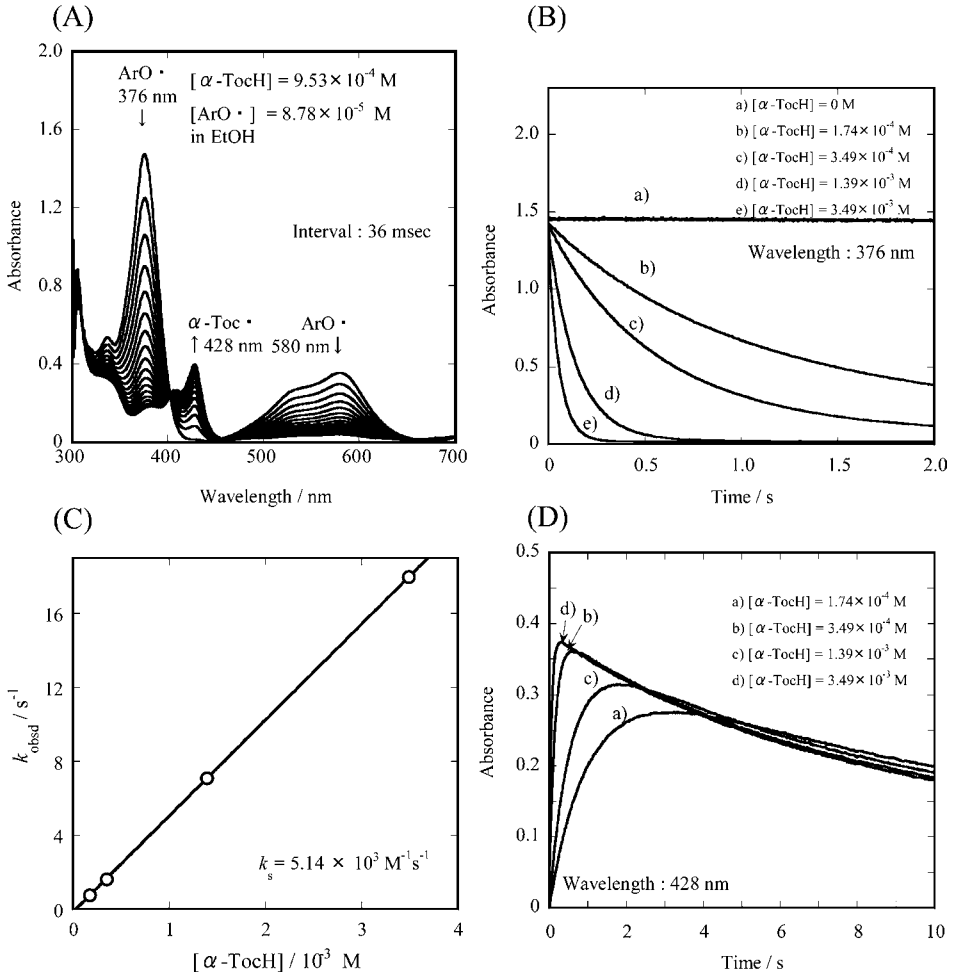

**Figure 2.** (A) Change in electronic absorption spectra of ArO• and α-Toc• radicals during reaction of ArO• with α-TocH in ethanol solution at 25.0 °C. Initial concentrations were $[ArO^{\bullet}] = 8.78 \times 10^{-5}$ M and $[\alpha\text{-TocH}] = 9.53 \times 10^{-4}$ M. Spectra were recorded at 36 ms intervals. Arrow indicates a decrease (ArO•) and an increase (α-Toc•) in absorbance with time. Also shown is the time dependence of absorbance of (B) ArO• radical (at 376 nm) and (D) α-Toc• radical (at 428 nm) in solutions including five and four different concentrations of α-TocH at 25.0 °C, respectively. (C) Pseudo-first-order rate constant ($k_{obsd}$) versus [α-TocH] plot.

ethanol, α-Toc• is produced rapidly. α-Toc• is unstable at 25.0 °C and its absorption peak decreases gradually after passing through the maximum (see Figure 2D).[28,35]

Similar measurements were performed for reaction of ArO• with β-, γ-, and δ-tocopherols and -tocotrienols in ethanol solution. For example, the result obtained for γ-TocH is shown in Figure 3. Upon reaction of γ-TocH with ArO• radical, the absorbance at 376 nm of ArO• decreases rapidly, and an absorption spectrum due to γ-Toc• radical appears at $\lambda_{max}$ = 432 nm, as shown in Figure 3A. However, the absorption observed for γ-Toc• is very weak; its absorption peak (at 432 nm) decreases rapidly after passing through the maximum and disappears almost at 10 s, differing from the case of α-Toc• (see Figures 2D and 3D).[35] The rate constant, $k_s^{\gamma\text{-TocH}}$(alone), was obtained by plotting $k_{obsd}$ against [γ-TocH] (see Figure 3C).

In the present work, measurements of $k_s^{AOH}$(alone) values were repeated three or four times for each α-, β-, γ-, and δ-TocH and -Toc-3H to obtain reliable $k_s^{AOH}$(alone) values, to compare the values of α-, β-, γ-, and δ-tocotrienols with those of α-, β-, γ-, and δ-tocopherols. Each measured $k_s^{AOH}$(alone) value and the average $k_s^{AOH}$(alone) values obtained are summarized in Table 1. As is clear from the $k_s^{AOH}$(alone) values listed in Table 1, the ArO•-scavenging activity in ethanol increases in the order shown in eq 8:

$$\begin{aligned} &\delta\text{-TocH} \sim \delta\text{-Toc-3H} \\ &< \gamma\text{-TocH} \sim \gamma\text{-Toc-3H} \sim \beta\text{-TocH} \sim \beta\text{-Toc-3H} \\ &< \alpha\text{-TocH} \sim \alpha\text{-Toc-3H} \end{aligned} \quad (8)$$

**Measurements of Aroxyl Radical-Scavenging Rates ($k_s^{AOH}$) for Mixtures of α-Tocopherol with β-, γ-, or δ-Tocopherol in Ethanol.** Measurements of $k_s^{\beta,\gamma,\delta\text{-TocH}}$(+α-TocH) values were performed for solutions including α-TocH and β-, γ-, or δ-TocH, respectively. The notation $k_s^{\beta,\gamma,\delta\text{-TocH}}$(+α-TocH) indicates the rate constant obtained in solution including two tocopherol components. First, measurement of $k_s^{\gamma\text{-TocH}}$(+α-TocH) was performed by keeping [α-TocH] constant at 2.88 × $10^{-4}$ M and varying [γ-TocH] from 0 to 1.21 × $10^{-3}$ M (denoted measurement 1 in Table 2).

Upon mixing the solution of ArO• radical with the solution including α-TocH and γ-TocH, absorption of the ArO• at 376 and 580 nm decreases rapidly, as shown in Figure 4. Absorption due to α-Toc• and γ-Toc• was observed at 428 nm, but absorption intensity decreased with increasing [γ-TocH]. By

[a]Measurement of $k_s^{\alpha\text{-TocH}}$(alone) for α-TocH was performed many times in ethanol. Average value is $5.12 \times 10^3$ $M^{-1}\cdot s^{-1}$.

analyzing the decay curves of ArO• at 376 nm, $k_{obsd}$ values were determined. Figure 5B (●) shows the $k_{obsd}$ versus [γ-TocH] plot.

If α-TocH and γ-TocH coexist in solution, reactions 9 and 10 will occur competitively in solution, because the difference in $k_s^{\alpha\text{-TocH}}$(alone) and $k_s^{\gamma\text{-TocH}}$(alone) values is not too large, as listed in Table 1.

$$\text{ArO}^\bullet + \alpha\text{-TocH} + \gamma\text{-TocH} \xrightarrow{k_s^{\alpha\text{-TocH}}} \text{ArOH} + \alpha\text{-Toc}^\bullet + \gamma\text{-TocH} \quad (9)$$

$$\text{ArO}^\bullet + \alpha\text{-TocH} + \gamma\text{-TocH} \xrightarrow{k_s^{\gamma\text{-TocH}}} \text{ArOH} + \alpha\text{-TocH} + \gamma\text{-Toc}^\bullet \quad (10)$$

In such a case, we can expect that the $k_{obsd}$ value depends on eq 11, if the interaction among α-TocH, γ-TocH, and their radicals is negligible.

$$k_{obsd} = k_s^{\alpha\text{-TocH}}(\text{alone})[\alpha\text{-TocH}] + k_s^{\gamma\text{-TocH}}(\text{alone})[\gamma\text{-TocH}] \quad (11)$$

Next we will assume that a synergistic effect is present. By substituting $k_s^{\alpha\text{-TocH}}$(alone) and $k_s^{\gamma\text{-TocH}}$(alone) values and the value of [α-TocH] ($2.88 \times 10^{-4}$ M) used for measurement 1 (see Table 2) into eq 11, $k_{obsd}$ was plotted against [γ-TocH] (see dotted line in Figure 5B). Furthermore, the result of the $k_{obsd}$ versus [γ-TocH] plot (○) obtained for the solution including only γ-TocH (see eq 7) is also shown in Figure 5B. As described above, measurement 1 was performed by keeping α-TocH at a constant concentration and varying [γ-TocH]. Consequently, the $k_s^{\gamma\text{-TocH}}$(+α-TocH) value was determined from the gradient of the $k_{obsd}$ versus [γ-TocH] plot (●) in Figure 5B, by use of eq 12:

$$k_{obsd} = k_s^{\alpha\text{-TocH}}(\text{alone})[\alpha\text{-TocH}] + k_s^{\gamma\text{-TocH}}(+\alpha\text{-TocH})[\gamma\text{-TocH}] \quad (12)$$

As expected from the gradient in Figure 5B, the $k_s^{\gamma\text{-TocH}}$(+α-TocH) value ($3.25 \times 10^3$ $M^{-1}\cdot s^{-1}$) is 1.15 times larger than $k_s^{\gamma\text{-TocH}}$(alone) (average $2.82 \times 10^3$ $M^{-1}\cdot s^{-1}$) obtained for the solution including only γ-TocH. A synergistic effect due to the coexistence of α-TocH and γ-TocH in solution was observed for the rate constant $k_s^{\gamma\text{-TocH}}$(+α-TocH). Measurement was repeated twice to ascertain the result obtained above (see measurement 2 in Table 2). The $k_s^{\gamma\text{-TocH}}$(+α-TocH) value ($3.08 \times 10^3$ $M^{-1}\cdot s^{-1}$) obtained showed good agreement with that ($3.25 \times 10^3$ $M^{-1}\cdot s^{-1}$) for measurement 1, indicating a similar synergistic effect.

As an effect of the coexistence of α-TocH and γ-TocH was observed for the rate constants $k_s^{\gamma\text{-TocH}}$(+α-TocH), similar measurements were performed for the solutions including α-TocH and β-TocH (or δ-TocH), by keeping [α-TocH] constant and varying [β-TocH] (or [δ-TocH]) (see measurements 1 and 2 in Table 2), respectively. Figure 5A,C shows the plots for $k_{obsd}$ versus [β-TocH] and [δ-TocH], respectively. As we may see clearly from the above plots (●), both the rate constants$k_s^{\beta\text{-TocH}}$(+α-TocH) and $k_s^{\delta\text{-TocH}}$(+α-TocH) decrease by 11% and 24% compared with the corresponding values of $k_s^{\beta\text{-TocH}}$(alone) and $k_s^{\delta\text{-TocH}}$(alone). Measurements were repeated twice to ascertain the results obtained above (see measurements 1 and 2 in Table 2). The average rate constants are listed in Table 2, indicating a cancel effect due to the coexistence of α-TocH and β-TocH (or δ-TocH).

As observed for the reaction of the solution of ArO• with the solution including α-TocH and γ-TocH (see Figure 4A–C), the absorption due to α-Toc• and β-Toc• (or δ-Toc•) at 428 nm decreased with increasing concentration of β-TocH (or δ-TocH), as shown in Figure 6A,C. The reason will be discussed in the Discussion section.

**Measurements of Aroxyl Radical-Scavenging Rates ($k_s^{AOH}$) for Mixtures of α-Tocopherol with α-, β-, γ-, or δ-Tocotrienol in Ethanol.** As a clear effect of the coexistence of α-TocH and β-, γ-, or δ-TocH was observed for rate constants $k_s^{\beta,\gamma,\delta\text{-TocH}}$(+α-TocH), similar measurements were performed for solutions including α-TocH and α-, β-, γ-, or δ-Toc-3H by

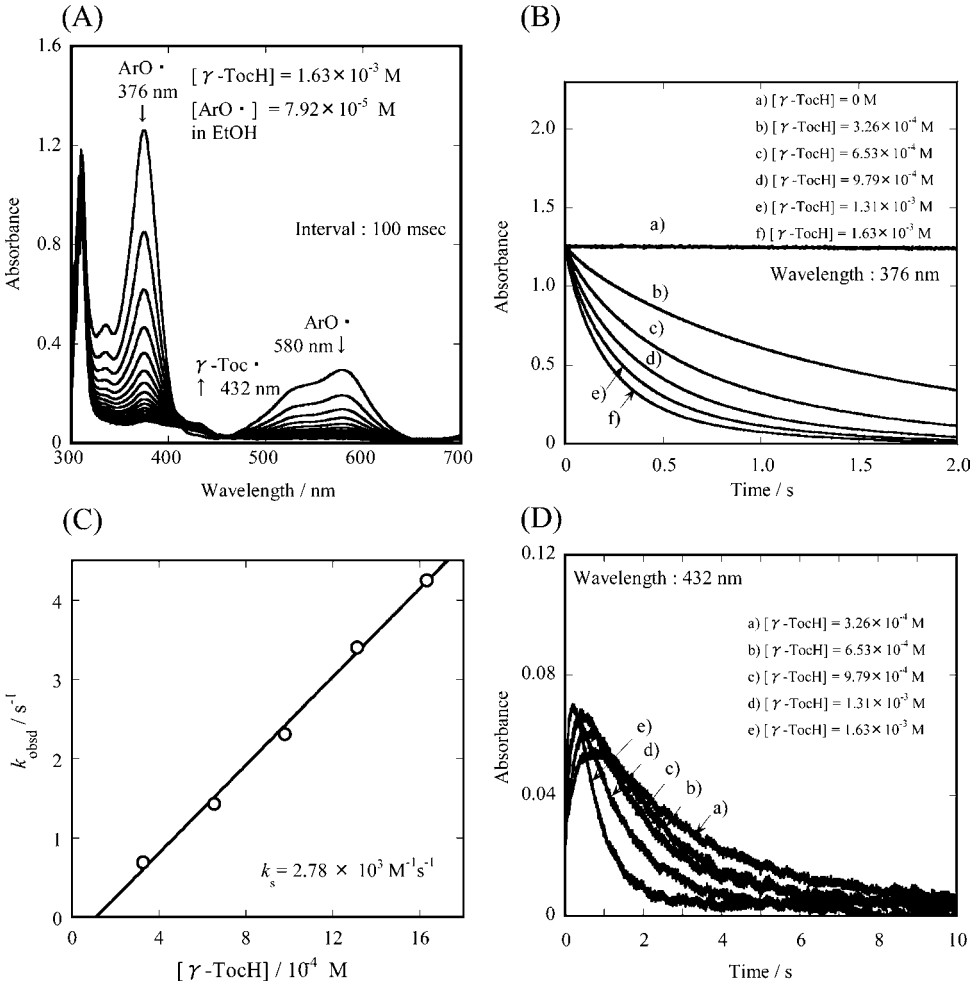

**Figure 3.** (A) Change in electronic absorption spectra of ArO$^{\bullet}$ and $\gamma$-Toc$^{\bullet}$ radicals during reaction of ArO$^{\bullet}$ with $\gamma$-TocH in ethanol solution at 25.0 °C. Initial concentrations were [ArO$^{\bullet}$] = 7.92 × 10$^{-5}$ M and [$\gamma$-TocH] = 1.63 × 10$^{-3}$ M. Spectra were recorded at 100 ms intervals. Arrow indicates a decrease (ArO$^{\bullet}$) and an increase ($\gamma$-Toc$^{\bullet}$) in absorbance with time. Also shown is time dependence of the absorbance of (B) ArO$^{\bullet}$ radical (at 376 nm) and (D) $\gamma$-Toc$^{\bullet}$ radical (at 432 nm) in solutions including six and five different concentrations of $\gamma$-TocH at 25.0 °C, respectively. (C) Plot of $k_{obsd}$ versus [$\gamma$-TocH].

[a]Measurements were performed by keeping [$\alpha$-TocH] constant and varying [TocH] and were repeated twice to ascertain the results.

keeping [$\alpha$-TocH] constant and varying the concentration of $\alpha$-, $\beta$-, $\gamma$-, or $\delta$-Toc-3H. The $k_{obsd}$ versus [Toc-3H] plots (●) for $\alpha$-, $\beta$-, $\gamma$-, and $\delta$-Toc-3H, respectively, are shown in Figure S1A−D, Supporting Information. Analysis of the rate constant $k_s^{\alpha,\beta,\gamma,\delta\text{-Toc-3H}}$($+\alpha$-TocH) was performed by use of eq 12. The $k_s^{\alpha,\beta,\gamma,\delta\text{-Toc-3H}}$($+\alpha$-TocH) values and ratios of the rate constants $k_s^{\alpha,\beta,\gamma,\delta\text{-Toc-3H}}$($+\alpha$-TocH)/$k_s^{\alpha,\beta,\gamma,\delta\text{-Toc-3H}}$(alone) obtained are listed in Table 3.

To investigate the effect of concentration of $\alpha$-, $\beta$-, $\gamma$-, and $\delta$-Toc-3Hs on the reaction rates $k_s^{\alpha,\beta,\gamma,\delta\text{-Toc-3H}}$($+\alpha$-TocH), similar

dx.doi.org/10.1021/jf502049k | J. Agric. Food Chem. 2014, 62, 8101−8113

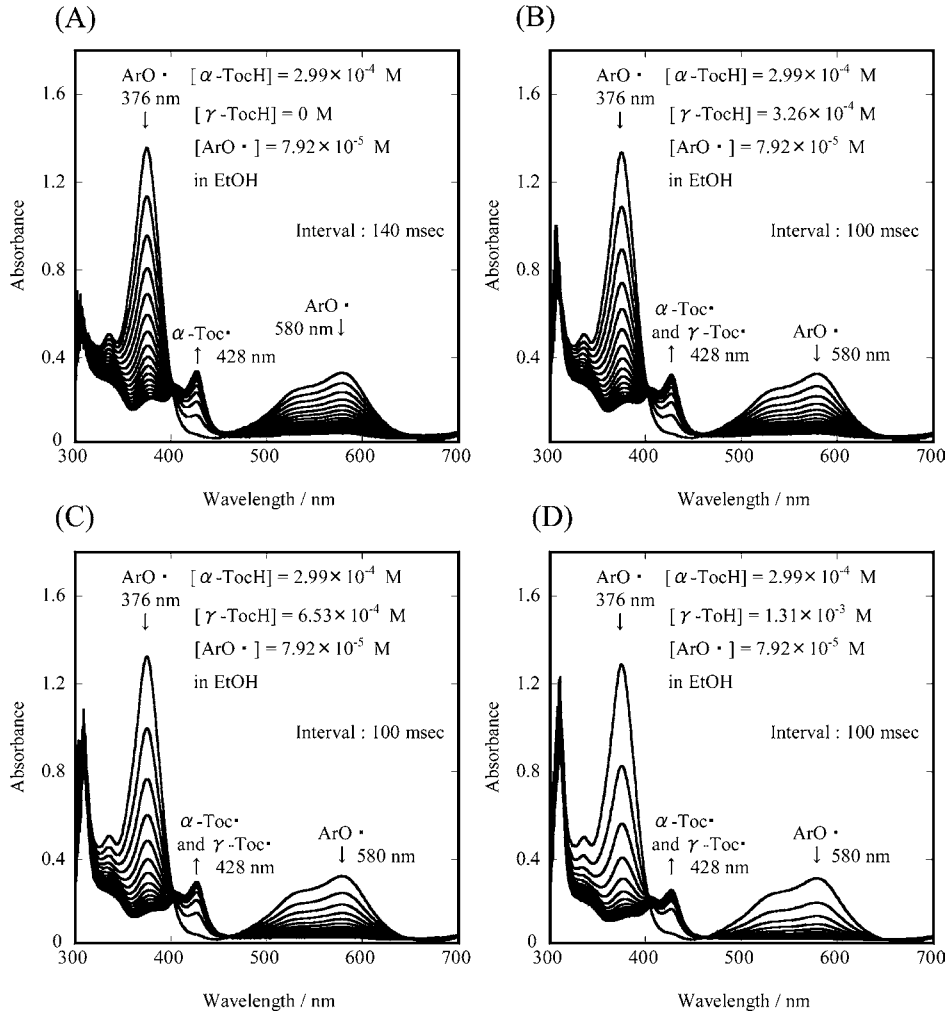

**Figure 4.** Change in electronic absorption spectra of ArO$^\bullet$ and $\alpha$-Toc$^\bullet$ (and $\gamma$-Toc$^\bullet$) radicals during reaction of ArO$^\bullet$ with a mixture of $\alpha$-TocH and $\gamma$-TocH in ethanol at 25.0 °C. [ArO$^\bullet$] = $7.92 \times 10^{-5}$ and [$\alpha$-TocH] = $2.99 \times 10^{-4}$ M. Spectra were recorded at 140 or 100 ms intervals. Absorption of $\alpha$-Toc$^\bullet$ (and $\gamma$-Toc$^\bullet$) decreased with increasing concentrations of $\gamma$-TocH. [$\gamma$-TocH] = (A) 0 M, (B) $3.26 \times 10^{-4}$ M, (C) $6.53 \times 10^{-4}$ M, and (D) $1.31 \times 10^{-3}$ M.

measurements were repeated for the mixture including different concentrations of $\alpha$-, $\beta$-, $\gamma$-, and $\delta$-Toc-3H. $k_s^{\alpha,\beta,\gamma,\delta\text{-Toc-3H}}$(+$\alpha$-TocH) values for measurements 1, 2, and 3 and average values are also summarized in Table 3. As listed in Table 3, $k_s^{\gamma\text{-Toc-3H}}$(+$\alpha$-TocH) values obtained for measurements 1, 2, and 3 showed good accordance with each other. Similar results were obtained for $\alpha$-, $\beta$-, and $\delta$-Toc-3Hs.

As listed in Table 3, a synergistic effect was observed for $\gamma$-Toc-3H, and a cancel effect was observed for $\beta$- and $\delta$-Toc-3H. Furthermore, the degree of increase (average +12%) of the rate constant $k_s^{\gamma\text{-Toc-3H}}$(+$\alpha$-TocH) is similar to that (average +12%) of $k_s^{\gamma\text{-TocH}}$(+$\alpha$-TocH). The degrees of decrease (average −13% and −25%) of $k_s^{\beta\text{-Toc-3H}}$(+$\alpha$-TocH) and $k_s^{\delta\text{-Toc-3H}}$(+$\alpha$-TocH) are also similar to those (average −7% and −24%) of $k_s^{\beta\text{-TocH}}$(+$\alpha$-TocH) and $k_s^{\delta\text{-TocH}}$(+$\alpha$-TocH), respectively.

Similar measurements were performed for solutions including $\alpha$-TocH and $\alpha$-, $\beta$-, $\gamma$-, or $\delta$-Toc-3H by keeping the concentration of $\alpha$-, $\beta$-, $\gamma$-, or $\delta$-Toc-3H constant and varying [$\alpha$-TocH] (see Table 4). The $k_{obsd}$ versus [$\alpha$-TocH] plots (for constant concentrations of $\alpha$-, $\beta$-, $\gamma$-, or $\delta$-Toc-3H) are shown in Figure S2A−D in Supporting Information. The rate constants $k_s^{\alpha\text{-TocH}}$(+$\alpha$-, $\beta$-, $\gamma$-, and $\delta$-Toc-3H) obtained are summarized in Table 4. Although a synergistic effect was observed for $\gamma$-Toc-3H and a cancel effect was observed for $\beta$- and $\delta$-Toc-3H, effects of the coexistence were smaller: 7% increase for $\gamma$-Toc-3H, 6% decrease for $\beta$-Toc-3H, and 7% decrease for $\delta$-Toc-3H. Effect of the coexistence of $\alpha$-TocH and $\alpha$-Toc-3H was small and negligible.

**UV−Visible Absorption Spectra of $\alpha$-, $\beta$-, $\gamma$-, and $\delta$-Tocopheroxyl and -Tocotrienoxyl Radicals in Ethanol Solution.** Measurements of wavelengths of absorption maxima ($\lambda_{max}$) and molar extinction coefficients ($\varepsilon_{max}$) were performed for $\alpha$-, $\beta$-, $\gamma$-, and $\delta$-Toc$^\bullet$ radicals in ethanol in a previous work.[35] By reacting ArO$^\bullet$ with $\alpha$-TocH in ethanol, absorption of $\alpha$-Toc$^\bullet$ is observed, as shown in Figure 2A. $\lambda_{max}^{\ i}$ ($i$ = 1−4) values of $\alpha$-Toc$^\bullet$ are easily determined from absorption peaks of the spectrum. The example for $\gamma$-Toc$^\bullet$ is also shown in Figure 3A. As the stability of $\gamma$-Toc$^\bullet$ is low compared to that of $\alpha$-Toc$^\bullet$, weak absorption was observed. Similarly, $\lambda_{max}^{\ i}$ values for $\alpha$-, $\beta$-, and $\gamma$-Toc-3$^\bullet$ were determined. However, as $\delta$-Toc-3$^\bullet$ is unstable, we could not observe absorption, even if we use high concentration of $\delta$-Toc-3H. The results obtained are summarized in Table 5.

As described above, upon reaction of $\alpha$-TocH with ArO$^\bullet$ in ethanol, $\alpha$-Toc$^\bullet$ is produced rapidly. $\alpha$-Toc$^\bullet$ is unstable at 25.0 °C; its absorption peak decreases gradually after passing through

dx.doi.org/10.1021/jf502049k | J. Agric. Food Chem. 2014, 62, 8101−8113

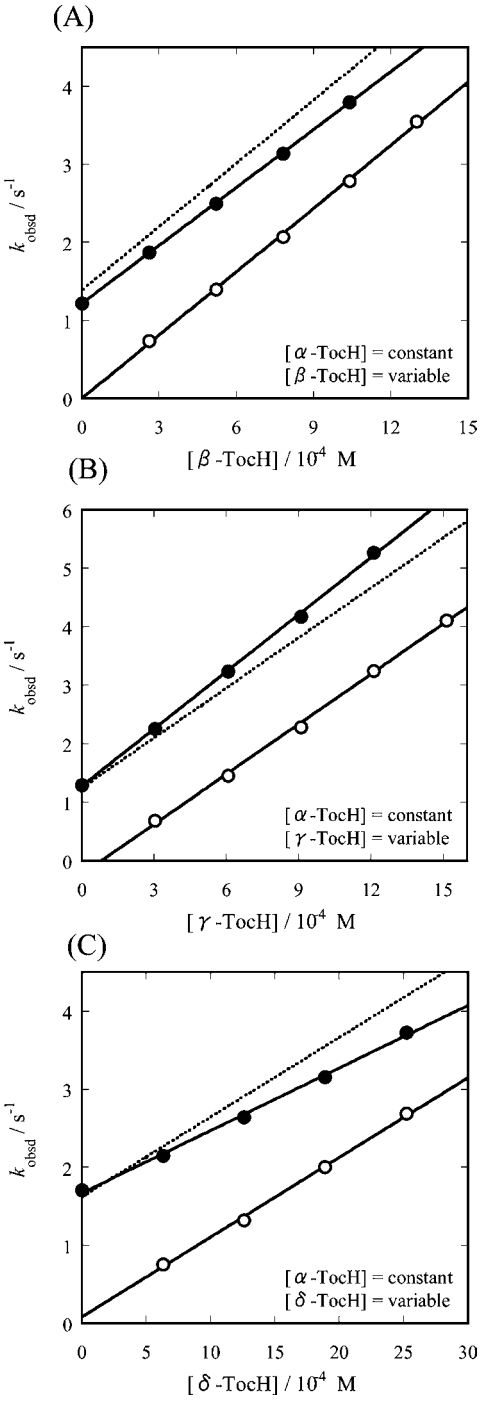

**Figure 5.** Plots of $k_{obsd}$ versus [AOH] for reactions of ArO• radical with (i) AOH only (○) and (ii) mixture of α-TocH and AOH (●). AOH = (A) β-TocH (measurement 1), (B) γ-TocH (measurement 1), and (C) δ-TocH (measurement 2) (see Table 2 and text). Dotted lines show the plots for which any synergistic effect is absent between α-TocH and β-, γ-, or δ-TocHs.

the maximum and disappears by a bimolecular reaction (reaction 13).[15,35]

$$\text{α-Toc}^{\bullet} + \text{α-Toc}^{\bullet} \xrightarrow{2k_d} \text{nonradical products (NRP)} \qquad (13)$$

As shown in Figure 2D, the maximum absorbance (that is, the concentration) of α-Toc• observed at $t_{max}$ increases with increasing [α-TocH] and approaches a constant value, because at high [α-TocH], α-Toc• appears rapidly and the decay of α-Toc• is very small and negligible. Therefore, we can estimate the $\varepsilon_1$ value of α-Toc• radical at $\lambda_{max}^{1}$ = 428 nm by use of the relationship Abs(α-Toc• at $t_{max}$) = $\varepsilon_1$[ArO•]$_{t=0}$, as reported in a previous work.[35] The $\varepsilon_1$ value of α-Toc• radical obtained was 4370 $M^{-1}\cdot cm^{-1}$ in ethanol solution.

Similarly, upon reaction of γ-TocH with ArO• in ethanol, γ-Toc• is produced, and its absorption peak decreases rapidly after passing through the maximum (see Figure 3D). As shown in Figure 3D, the maximum absorbance at 432 nm of γ-Toc• observed at $t_{max}$ increases with increasing [γ-TocH] and approaches a constant value. Therefore, we can tentatively estimate the $\varepsilon_1$ value of γ-Toc• radical at $\lambda_{max}^{1}$ = 432 nm, by use of the relationship Abs(γ-Toc• at $t_{max}$) = $\varepsilon_1$[ArO•]$_{t=0}$.[35] The $\varepsilon_1$ value of γ-Toc• radical obtained was 820 $M^{-1}\cdot cm^{-1}$ in ethanol solution. Similarly, the $\varepsilon_1$ values of β- and δ-Toc• and α-, β-, and γ-Toc-3• radicals were determined (see Table 5).

The $\lambda_{max}^{1}$ and $\varepsilon_1$ values for α-, β-, and γ-Toc-3• show good agreement with those of the corresponding α-, β-, and γ-Toc• in ethanol. The $\lambda_{max}^{1}$ value increases in the order α- < β- ≤ γ- < δ-Toc• (and α- < β- ≤ γ-Toc-3•), although the difference in $\lambda_{max}^{1}$ value among α-, β-, γ-, and δ-Toc• (and -Toc-3•) is comparatively small. On the other hand, the $\varepsilon_1$ value decreases remarkably in the order α- > β- > γ- > δ-Toc• (and α- > β- > γ- > δ-Toc-3•) in ethanol. The reason will be discussed in the Discussion section.

**Decrease in UV−Visible Absorption of α-Tocopheroxyl Radical for Coexistence of α-Tocopherol with β-, γ-, or δ-Tocopherol (or -Tocotrienol).** Upon reaction of ArO• radical with α-TocH, absorption of α-Toc• radical at $\lambda_{max}^{1}$ (= 428 nm) appears rapidly and decreases gradually, as shown in Figure 2D. The concentration of α-Toc• radical produced by reaction with ArO• ([ArO•] = 8.78 × $10^{-5}$ M) is similar to that of ArO• if a high concentration of α-TocH is used for the reaction, as described in a previous section.[35]

On the other hand, if γ-TocH coexists in the above solution, absorption of α-Toc• radical (for [γ-TocH] = 0 M) decreases with increasing [γ-TocH], as shown in Figure 4. The time dependence of absorption observed at 428 nm is shown in Figure 6C, where absorption at 428 nm is due to the sum of α-Toc• and γ-Toc•, although the contribution of the latter is much smaller than that of the former (see Figures 2A and 3A and Table 5). The contribution of γ-Toc• is almost negligible at 10 s, as shown in Figure 3D. Consequently, [α-Toc•] at 10 s was calculated from absorbance of α-Toc•, by use of the relationship Abs = $\varepsilon_1$[α-Toc•], where $\varepsilon_1$ = 4370 $M^{-1}\cdot cm^{-1}$). Figure 6D shows the plot of [α-Toc•], at 10 s (●) in Figure 6C, versus [γ-TocH]. The [α-Toc•] decreases remarkably with increasing [γ-TocH], suggesting that the prooxidant effect induced by α-Toc• is suppressed by the coexistence of γ-TocH. The reason for the decrease of [α-Toc•] due to the coexistence of γ-TocH will be discussed in the Discussion section.

Similar measurements were performed for solutions including α-TocH and β-TocH (or δ-TocH). The time dependence of absorption observed at 428 nm for the coexistence of (i) α-TocH and β-TocH and (ii) α-TocH and δ-TocH is shown in Figure 6A,E, indicating that absorption of Toc• radicals at 428 nm decreases with increasing [β-TocH] or [δ-TocH]. In the case of δ-TocH, δ-Toc• is very unstable, and the contribution of δ-Toc• to absorption is almost negligible at 10 s. The plot of [α-Toc•], at 10 s in Figure 6E, versus [δ-TocH] is shown in Figure 6F. On the other hand, β-Toc• is not so unstable, and its absorption overlaps with that of α-Toc• at the first stage of reactions 9 and 10.

The decrease of [α-Toc•] (at 10 s) due to the coexistence of β-, γ-, or δ-TocH—that is, the ratio of [α-Toc•] with β-, γ-, or δ-

dx.doi.org/10.1021/jf502049k | J. Agric. Food Chem. 2014, 62, 8101−8113

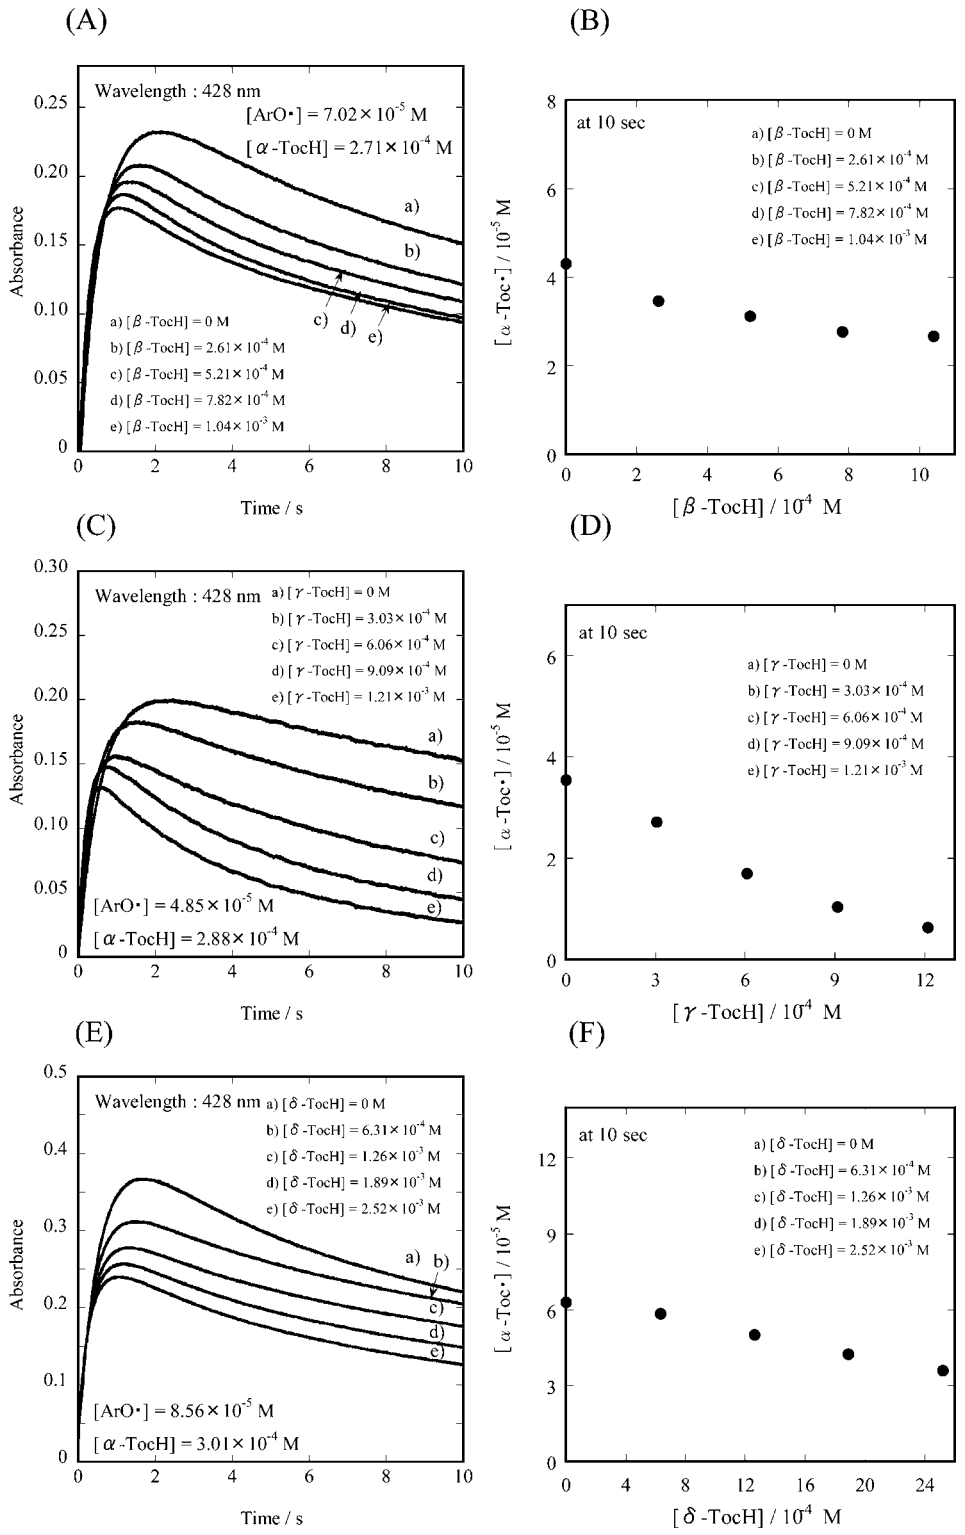

**Figure 6.** (Left panels) Time dependence of absorbance of Toc• radicals (at 428 nm) in ethanol solutions including five different concentrations of (A) $\beta$-, (C) $\gamma$-, and (E) $\delta$-TocH at 25.0 °C. (Right panels) Plots of [$\alpha$-Toc•], at 10 s in corresponding left panels, versus (B) [$\beta$-TocH], (D) [$\gamma$-TocH], and (F) [$\delta$-TocH].

TocH to [$\alpha$-Toc•] without $\beta$-, $\gamma$-, or $\delta$-TocHs—is 0.62 at [$\beta$-TocH] = $1.04 \times 10^{-3}$, 0.18 at [$\gamma$-TocH] = $1.21 \times 10^{-3}$, and 0.57 at [$\delta$-TocH] = $2.52 \times 10^{-3}$ M, which are the maximum concentrations of $\beta$-, $\gamma$-, and $\delta$-TocHs used for measurements.

Similar measurements were performed for solutions including $\alpha$-TocH and $\alpha$-, $\beta$-, $\gamma$-, or $\delta$-Toc-3H. The time dependence of absorption observed at 428 nm for the coexistence of $\alpha$-TocH and $\beta$-, $\gamma$-, or $\delta$-Toc-3H is shown in Figure 7panels A, C, and E, respectively. The decrease of [$\alpha$-Toc•] (at 10 s)—that is, the ratio of [$\alpha$-Toc•] (with $\beta$-, $\gamma$-, or $\delta$-Toc-3H) to [$\alpha$-Toc•] without $\beta$-, $\gamma$-, or $\delta$-Toc-3Hs—is 0.74 at [$\beta$-Toc-3H] = $1.28 \times 10^{-4}$, 0.16 at [$\gamma$-Toc-3H] = $1.45 \times 10^{-3}$, and 0.55 at [$\delta$-Toc-3H] = $2.37 \times$

**Table 5. Values of UV−Visible Absorption Maxima and Molar Extinction Coefficients of α-, β-, γ-, and δ-Tocopheroxyls and -Tocotrienoxyls in Ethanol**

| $Toc^•$ or Toc-$3^•$ | $\lambda_{max}{}^1$, nm ($\varepsilon_1$, $M^{-1}\cdot cm^{-1}$) | $\lambda_{max}{}^2$, nm ($\varepsilon_2$, $M^{-1}\cdot cm^{-1}$) | $\lambda_{max}{}^3$, nm ($\varepsilon_3$, $M^{-1}\cdot cm^{-1}$) | $\lambda_{max}{}^4$, nm ($\varepsilon_4$, $M^{-1}\cdot cm^{-1}$) |
|---|---|---|---|---|
| α-$Toc^•$ | 428 (4370)[a] | 408 (3010) | 387 sh[b] (1630) | 340 sh (3790) |
| α-Toc-$3^•$ | 428 (4280) | 407 (3220) | 387 sh (2120) | 340 sh (3720) |
| β-$Toc^•$ | 431 (1500)[a] | 409 (1200) | | |
| β-Toc-$3^•$ | 430 (1620) | | | |
| γ-$Toc^•$ | 432 (820)[a] | | | |
| γ-Toc-$3^•$ | 432 (745) | | | |
| δ- $Toc^•$ | 434 (380)[a] | | | |
| δ- Toc-$3^•$ | | | | |

[a]See ref 35. [b]Shoulder.

$10^{-3}$ M. The decrease of [α-$Toc^•$] (+[α-Toc-$3^•$]) due to coexistence of α-TocH and α-Toc-3H was negligible, as expected (data not shown). The degree of decrease of [α-$Toc^•$] (at 10 s) increases in the order shown in eq 14:

$$\begin{aligned} \text{α-Toc-3H} &\ll \text{β-TocH} \sim \text{β-Toc-3H} \\ &< \text{δ-TocH} \sim \text{δ-Toc-3H} \\ &< \text{γ-TocH} \sim \text{γ-Toc-3H} \end{aligned} \quad (14)$$

As described above, [α-$Toc^•$] decreases notably with increasing concentration of β-, γ-, or δ-TocH. This result suggests that the prooxidant effect induced by α-$Toc^•$ may be suppressed by the coexistence of β-, γ-, or δ-TocH (or β-, γ-, or δ-Toc-3H). The reason will be discussed in the Discussion section.

## DISCUSSION

**Comparison of Aroxyl Radical-Scavenging Rates ($k_s^{AOH}$) of Tocotrienols with Those of Tocopherols in Ethanol Solution.** α-, β-, γ-, and δ-TocHs and -Toc-3Hs are well-known as vitamin E homologues. Toc-3Hs have received much attention in recent years.[36] Yoshida et al.[37] reported that the reactivities of α-, β-, γ-, and δ-Toc-3Hs toward peroxyl radicals are the same as those of the corresponding α-, β-, γ-, and δ-TocHs in acetonitrile solution. On the other hand, Serbinova et al.[38] reported that α-Toc-3H has more potent antioxidant activity than α-TocH for lipid peroxidation in rat liver microsomal membranes. Moreover, some biological functions such as cholesterol-lowering,[39−41] anti-cancer,[42,43] anti-inflammatory,[44,45] anti-angiogenic,[46,47] and neuroprotection[48] effects

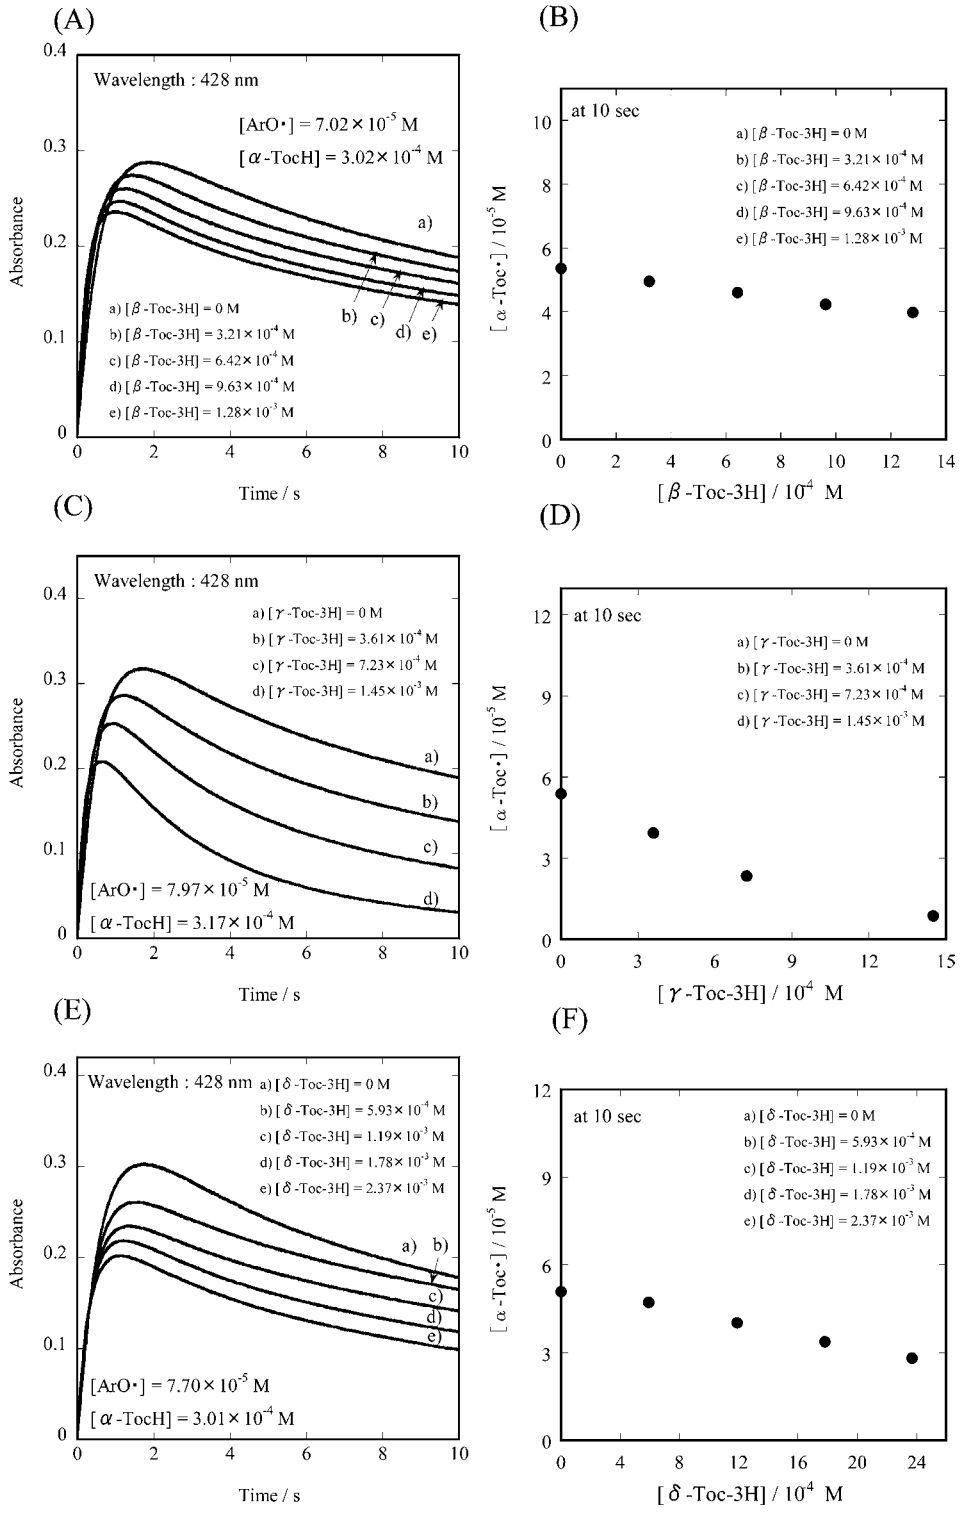

**Figure 7.** (Left panels) Time dependence of absorbance of Toc• radicals (at 428 nm) in ethanol solutions including five (or four) different concentrations of (A) $\beta$-, (C) $\gamma$-, and (E) $\delta$-Toc-3H at 25.0 °C. (Right panels) Plots of [$\alpha$-Toc•], at 10 s in corresponding left panels, versus (B) [$\beta$-Toc-3H], (D) [$\gamma$-Toc-3H], and (F) [$\delta$-Toc-3H].

have been reported for Toc-3Hs. These findings suggest that Toc-3Hs have a wide variety of health benefits.

In the present work, measurements of ArO•-scavenging rate constants, $k_s^{AOH}$(alone), of antioxidants ($\alpha$-, $\beta$-, $\gamma$-, and $\delta$-TocHs and -Toc-3Hs) were performed in ethanol solution via stopped-flow spectrophotometry. As listed in Table 1, the $k_s^{AOH}$(alone) values of $\alpha$-, $\beta$-, $\gamma$-, and $\delta$-Toc-3Hs show good agreement with those of the corresponding TocHs in ethanol, indicating that the difference of the alkyl side chains in tocopherols and tocotrienols does not have a significant effect on the reaction rates. Furthermore, $\lambda_{max}^1$ and $\varepsilon_1$ values of $\alpha$-, $\beta$-, $\gamma$-, and $\delta$-Toc-3• radicals also agree well with the corresponding values of $\alpha$-, $\beta$-, $\gamma$-, and $\delta$-Toc• radicals in ethanol (see Table 5). The result also indicates that the electronic states of the chroman ring in $\alpha$-, $\beta$-,

dx.doi.org/10.1021/jf502049k | J. Agric. Food Chem. 2014, 62, 8101−8113

γ-, and δ-Toc$^{\bullet}$ and -Toc-3$^{\bullet}$ radicals are similar to one another, being independent of the difference in alkyl side chain.

**Finding of Synergistic and Cancel Effects on the Aroxyl Radical-Scavenging Rates ($k_s$) for the Coexistence of α-Tocopherol with β-, γ-, or δ-Tocopherol (or -Tocotrienol.).** It is well-known that various antioxidants coexist in many foods and plants[2] and biological systems.[24−27] However, examples of measurement of free radical-scavenging rates for the coexistence of two antioxidants are very limited.[49] Recently, it has been found that the ArO$^{\bullet}$ radical-scavenging rates ($k_s^{AOH}$) increase notably for the coexistence of two antioxidants, (i) α-TocH and vitamin C and (ii) α-TocH and $UQ_{10}H_2$, in 2-propanol/water (5:1 v/v) solution.[28]

In the present work, measurements of $k_s^{AOH}$ for α-, β-, γ-, δ-TocHs and -Toc-3Hs were performed in ethanol solution. The $k_s^{AOH}$ values were measured not only for each antioxidant but also for the mixtures of two antioxidants, (i) α-TocH and β-, γ-, or δ-TocH and (ii) α-TocH and α-, β-, γ-, or δ-Toc-3H. A clear synergistic effect in which $k_s^{\gamma\text{-TocH}}$(+α-TocH) values increase by 12% was observed for solutions including α-TocH and γ-TocH. On the other hand, a cancel effect in which (i) $k_s^{\beta\text{-TocH}}$(+α-TocH) and (ii) $k_s^{\delta\text{-TocH}}$(+α-TocH) decrease by 7% and 24%, respectively, was observed for the solutions including (i) α-TocH with β-TocH and (ii) α-TocH with δ-TocH. Similar results were observed for the solutions including two kinds of antioxidants (α-TocH with β-, γ-, or δ-Toc-3H).

It is important to know the concentrations of α-, β-, γ-, and δ-TocHs and -Toc-3Hs included in foods and plants (especially in edible oils). The contents of α-, β-, γ-, and δ-TocHs in rapeseed, soybean, peanut, pumpkin, sunflower, canola, corn, wheat germ, and almond oils have been determined by an HPLC method, showing that α- and γ-TocHs are mainly included in edible oils.[29−31] For example, the contents in edible oils are as follows: (i) in peanut oil, concentrations of α-, β-, γ-, and δ-TocH = 73.2, nd, 312.0, and 13.4 mg/kg, respectively; (ii) in sunflower oil, concentrations are 494.2, nd, 131.0, and 9.2 mg/kg, respectively; and (iii) in rapeseed oil, concentrations are 90.9, nd, 527.6, and 6.1 mg/kg, respectively, as reported by Tuberoso et al.[30] Here, nd denotes not detected. Contents of β- and δ-TocHs are much less than those of α- and γ-TocHs. The result suggests that a synergistic effect observed for the reaction rate constant $k_s^{\gamma\text{-TocH}}$(+α-TocH) for the coexistence of α- and γ-TocHs functions mainly in edible oils, to protect the degradation of edible oils. Furthermore, high concentrations of α- and γ-TocHs and -Toc-3Hs are included in rice bran and palm oil.[32,33] Contents of β- and δ-TocHs (and -Toc-3Hs) are much less than those of α- and γ-TocHs (and -TocH-3s), suggesting that a synergistic effect functions in rice bran and palm oils. However, the reason why a synergistic effect functions between α- and γ-TocHs (or γ-TocH-3s) and a cancel effect functions between (i) α-TocH and β-TocH (or β-Toc-3H) and (ii) α-TocH and δ-TocH (or δ-Toc-3H) is not clear at present.

**Scheme for Suppression of Prooxidant Effect of α-Tocopherol for Coexistence of α-Tocopherol with β-, γ-, or δ-Tocopherol (or -Tocotrienol).** As described in the Introduction, α-Toc$^{\bullet}$ is an important key radical, which appears in the process of antioxidant and prooxidant actions of α-TocH. As shown in Figures 4, 6, and 7, we could directly ascertain that the [α-Toc$^{\bullet}$] produced by the reaction with ArO$^{\bullet}$ radical decreases remarkably with the coexistence of β-, γ-, or δ-TocH (or -Toc-3H), by observing the decrease of UV−vis absorption of α-Toc$^{\bullet}$ radical. The result clearly indicates that the prooxidant effect of α-Toc$^{\bullet}$ (see reaction 2) may be suppressed by the coexistence of α-TocH and another TocH (or Toc-3H).

In previous studies, the scheme of the decay reaction of α-, β-, γ-, and δ- Toc$^{\bullet}$ radicals in organic solvents has been investigated.[15,35] In polar ethanol, acetonitrile, and chloroform solvents, α-Toc$^{\bullet}$ decays by a simple bimolecular reaction without dimer formation, suggesting the production of α-TocH and α-tocopherol-*o*-quinonemethide (α-Toc-QM) by disproportionation (reaction 15):

$$\text{α-Toc}^{\bullet} + \text{α-Toc}^{\bullet} \xrightarrow{2k_d} \text{α-TocH} + \text{α-Toc-QM} \quad (15)$$

On the other hand, in nonpolar *n*-hexane, *n*-heptane, and diethyl ether solvents, bimolecular radical decay of α-Toc$^{\bullet}$ radical involves dimerization (recombination) and disproportionation (reaction 16):[35]

$$\text{dimer (α-Toc} - \text{α-Toc)} \underset{2k_{16}}{\overset{2k_{-16}}{\rightleftharpoons}} \text{α-Toc}^{\bullet} + \text{α-Toc}^{\bullet} \xrightarrow{2k_d} \text{α-TocH} + \text{α-Toc-QM} \quad (16)$$

where dimer is quinol ether (see Figure 9d in ref 35), although it is unstable and has not been isolated. $k_{16}$ and $k_{-16}$ represent the rate constants for formation and breakdown of dimer, respectively. Dimerization reactions of phenoxyl radicals (including α-Toc$^{\bullet}$) are fast reactions and are characterized by large rate constants ($k \approx 10^7-10^9$ $M^{-1}\cdot s^{-1}$) in nonviscous solvents at room temperature.[50]

As described in the Results section, the absorbances of α-, β-, γ-, and δ-Toc$^{\bullet}$ radicals produced by reaction with ArO$^{\bullet}$ decrease remarkably in the order α-Toc$^{\bullet}$ > β-Toc$^{\bullet}$ > γ-Toc$^{\bullet}$ > δ-Toc$^{\bullet}$ in ethanol solvent. The smaller absorbance obtained for β-, γ-, and δ-Toc$^{\bullet}$ radicals will be due to the fast formation of dimer (fast equilibrium with the dimer) (reaction 17) in these Toc$^{\bullet}$ radical molecules. The steric repulsion due to two ortho-methyl groups on the α-Toc$^{\bullet}$ radical molecule will hinder the formation of quinol-ether-type dimer in polar ethanol solvent. However, dimer formation will become easier with decreasing number of ortho-methyl groups.

$$\text{dimer (γ-Toc} - \text{γ-Toc)} \underset{2k_{17}}{\overset{2k_{-17}}{\rightleftharpoons}} \text{γ-Toc}^{\bullet} + \text{γ-Toc}^{\bullet} \xrightarrow{2k_d} \text{γ-TocH} + \text{γ-Toc-QM} \quad (17)$$

As described above, if α-TocH and γ-TocH coexist in ethanol and react with ArO$^{\bullet}$, reactions 9 and 10 will occur competitively. The α-Toc$^{\bullet}$ and γ-Toc$^{\bullet}$ radicals produced will disappear following reactions 15 and 17 in ethanol, respectively. In addition to these reactions, α-Toc$^{\bullet}$ radical will react with γ-Toc$^{\bullet}$ and disappear following reactions 18a and 18b:

$$\text{dimer (α-Toc} - \text{γ-Toc)} \underset{2k_{18}}{\overset{2k_{-18}}{\rightleftharpoons}} \text{α-Toc}^{\bullet} + \text{γ-Toc}^{\bullet} \quad (18a)$$

$$2\text{α-Toc}^{\bullet} + 2\text{γ-Toc}^{\bullet} \xrightarrow{2k_d} \text{α-TocH} + \text{γ-Toc-QM} + \text{γ-TocH} + \text{α-Toc-QM} \quad (18b)$$

where $2k_d$ includes three types of bimolecular reaction rates between (i) α-Toc$^{\bullet}$ + α-Toc$^{\bullet}$, (ii) γ-Toc$^{\bullet}$ + γ-Toc$^{\bullet}$, and (iii) α-

Toc$^{\bullet}$ + $\gamma$-Toc$^{\bullet}$, and the reaction produces four kinds of products ($\alpha$-TocH, $\alpha$-Toc-QM, $\gamma$-TocH, and $\gamma$-Toc-QM). Formation of dimer ($\alpha$-Toc−$\gamma$-Toc) will proceed rapidly, because steric hindrance for the reaction between $\alpha$-Toc$^{\bullet}$ and $\gamma$-Toc$^{\bullet}$ is smaller than that between $\alpha$-Toc$^{\bullet}$ and $\alpha$-Toc$^{\bullet}$.

As the electron-donating character of $\alpha$-TocH is larger than that of $\beta$-, $\gamma$-, and $\delta$-TocHs, we may expect that reaction 19 will proceed if $\alpha$-TocH coexists with $\beta$-, $\gamma$-, or $\delta$-Toc$^{\bullet}$ in solution.[19] In fact, Niki et al.[51] ascertained that $\alpha$-TocH reacts quite rapidly with $\beta$-, $\gamma$-, and $\delta$-Toc$^{\bullet}$ radicals to give $\alpha$-Toc$^{\bullet}$ radical and $\beta$-, $\gamma$-, and $\delta$-TocHs, respectively, by electron spin resonance (ESR) measurement.

$$\alpha\text{-TocH} + \beta\text{-, }\gamma\text{-, or }\delta\text{-Toc}^{\bullet} \xrightarrow{k_{19}} \alpha\text{-Toc}^{\bullet} + \beta\text{-, }\gamma\text{-, or }\delta\text{-TocH} \quad (19)$$

Consequently, if ArO$^{\bullet}$ radical reacts with $\alpha$-TocH and $\gamma$-TocH in a solution, $\alpha$-Toc$^{\bullet}$ and $\gamma$-Toc$^{\bullet}$ are produced, and reactions 15, 17, 18a, 18b, and 19 proceed competitively in the solution. On the other hand, even if ArO$^{\bullet}$ radical reacts with $\alpha$-TocH and $\delta$-TocH in a solution, dimer ($\alpha$-Toc−$\delta$-Toc) formation between $\alpha$-Toc$^{\bullet}$ and $\delta$-Toc$^{\bullet}$ (see reactions 18a and 18b) does not occur, because $\delta$-Toc$^{\bullet}$ produced is very unstable and disappears rapidly by forming the dimer $\delta$-Toc−$\delta$-Toc. Consequently, only $\alpha$-Toc$^{\bullet}$ remains in solution and disappears gradually, as shown in Figure 6E. This will be a reason why larger [$\alpha$-Toc$^{\bullet}$] remains in solution at 10 s, compared to the case of coexistence of $\alpha$-TocH and $\gamma$-TocH. In the case of coexistence of $\alpha$-TocH and $\beta$-TocH, reactions 15, 17, 18a, and 18b will proceed competitively in solution. Furthermore, as $\beta$-Toc$^{\bullet}$ is comparatively stable, $\beta$-Toc$^{\bullet}$ disappears and $\alpha$-Toc$^{\bullet}$ is formed by reaction 19, and the $\alpha$-Toc$^{\bullet}$ produced disappears gradually (see Figure 6A) as observed for the case of coexistence of $\alpha$-TocH and $\delta$-TocH.

Similar results were obtained for solution including $\alpha$-TocH and $\beta$-, $\gamma$-, or $\delta$-Toc-3H, as shown in Figure 7, indicating that the difference in alkyl side chain does not have a significant effect on the bimolecular radical decay of Toc$^{\bullet}$ and Toc-3$^{\bullet}$ radical.

As described above, $\alpha$-TocH and the other TocHs and Toc-3Hs (especially $\gamma$-TocH and $\gamma$-Toc-3H) coexist in edible oils.[29−33] Consequently, the above synergistic effect—that is, suppression of the prooxidant reaction— may function in edible oils.

In the present work, a kinetic study of the ArO$^{\bullet}$ radical-scavenging activity of eight vitamin E homologues ($\alpha$-, $\beta$-, $\gamma$-, and $\delta$-tocopherols and -tocotrienols) has been performed in ethanol solution, by use of stopped-flow spectrophotometry. The ArO$^{\bullet}$ radical-scavenging rates ($k_s^{AOH}$) of $\alpha$-, $\beta$-, $\gamma$-, and $\delta$-Toc-3Hs showed good agreement with those of the corresponding $\alpha$-, $\beta$-, $\gamma$-, and $\delta$-TocHs, indicating that the difference of the alkyl side chains in tocopherols and tocotrienols does not have a significant effect on the reaction rates. The $k_s^{AOH}$ values were measured not only for each antioxidant but also for mixtures of two antioxidants: (i) $\alpha$-TocH with $\beta$-, $\gamma$-, or $\delta$-TocH and (ii) $\alpha$-TocH with $\alpha$-, $\beta$-, $\gamma$-, or $\delta$-Toc-3H. Synergistic and cancel effects in which the $k_s^{AOH}$ values increase by 12% and decrease by 7% (or 24%) were observed for the solutions including two kinds of antioxidants, (i) $\alpha$-TocH and $\gamma$-TocH and (ii) $\alpha$-TocH and $\beta$-TocH (or $\alpha$-TocH and $\delta$-TocH). As contents of $\alpha$- and $\gamma$-TocHs included in general edible oils are much higher than those of $\beta$- and $\delta$-TocHs, only a synergistic effect may function in edible oils. Furthermore, UV−vis absorption of $\alpha$-Toc$^{\bullet}$ (at $\lambda_{max}$ = 428 nm), which had been produced by reaction of $\alpha$-TocH with ArO$^{\bullet}$, decreased remarkably for coexistence of $\alpha$-TocH with $\beta$-, $\gamma$-, or $\delta$-TocH (or -Toc-3H). This result indicates that the prooxidant effect of $\alpha$-Toc$^{\bullet}$ may be suppressed by coexistence with another TocH or Toc-3H. The scheme for the decrease of [$\alpha$-Toc$^{\bullet}$] due to coexistence of $\alpha$-TocH with another TocH (or Toc-3H) was discussed on the basis of the results obtained.

**ABSTRACT:** The effects of granule swelling on enzymatic saccharification of normal corn starch by granular starch hydrolyzing enzyme were investigated. After swelling, $K_m$ values for the saccharification of granular starch decreased compared with native granular starch, indicating that granule swelling caused granular starch hydrolyzing enzyme to have higher affinity for starch granules. The partial swelling of starch granules enhanced starch saccharification. Furthermore, the enhancement at an earlier stage of enzymatic reaction was much more significant than that at later stages. For granular starch pretreated at 67.5 °C for 30 min, conversions to glucose after incubation with the enzyme at 32 °C for 4 and 24 h were approximately 3-fold and 26% higher than for native granular starch, respectively. As a result, proper heat pretreatment of granular starch before simultaneous saccharification and fermentation has great potential to facilitate industrial production of ethanol by use of granular starch hydrolyzing enzyme.

**KEYWORDS:** *corn starch, granule swelling, granular starch hydrolyzing enzyme, saccharification, enhancement*

## INTRODUCTION

Ethanol is the primary renewable liquid transportation fuel, with a long history of good performance, and it can be used in over 80% of automobiles and other light-duty transportation vehicles.[1] The basic procedures for large-scale production of fuel ethanol from starch are enzymatic conversion of starch into fermentable sugars, microbial fermentation of sugars to ethanol, distillation, dehydration, and denaturing (optional).[2] The conventional process for enzymatic hydrolysis of starch into sugars prior to fermentation is to cook a starch slurry of approximately 30% (w/v) in the presence of thermostable α-amylase at above 100 °C, hold it at 90 °C for 1−3 h, and then cool it further to 60 °C with added glucoamylase.[3] This process has considerable economic drawbacks, mainly due to high energy-consuming cooking and liquefaction steps.[4]

An alternative process in which granular starch hydrolyzing enzymes are applied to convert granular or uncooked starch to glucose and other fermentable sugars has been suggested.[5−7] This process does not require high temperatures during cooking and liquefaction, which could reduce the energy requirements of ethanol production[3] and decrease the formation of undesirable byproducts of the Maillard reaction.[8] In addition, the process could simplify the operation and eliminate the cooking and cooling equipment required to handle high-viscosity starch slurries. Granular starch hydrolyzing enzymes are commercially available and have been applied in a simultaneous saccharification and fermentation process for ethanol production.[9−11]

Enzymatic hydrolysis of granular starch is a solid-solution two-phase reaction in which the enzymes need to first diffuse toward and bind to the solid substrate and then cleave the glycosidic linkages.[12] Enzyme adsorption onto starch granules is the initial stage for enzymatic hydrolysis of granular starch;[13−15] consequently, the initial rate of granular starch hydrolysis is related to the morphology, porosity, particle size, and surface area of the starch granules.[15−19] α-Amylase and glucoamylase are relatively large, several nanometers in size.[20−22] Because of their relatively large size, these enzymes have limited access to starch granules. Granule swelling could increase the specific surface area of starch granules (surface area per unit mass of of dry starch) and open up the surface. We postulated that even slight granule swelling would have a great positive impact on enzymatic hydrolysis of granular starch. Thus, the objective of this study was to determine the effects of granule swelling of normal corn starch, the most commonly used starch material in ethanol production, on enzymatic saccharification by a granular starch hydrolyzing enzyme.

## MATERIALS AND METHODS

**Materials.** Normal corn starch was obtained from National Starch LLC (Bridgewater, NJ). Stargen 001, a granular starch hydrolyzing enzyme, was obtained from Genencor International (Palo Alto, CA). Blue dextran, which was prepared from dextran with an average molecular weight of approximately $2.0 \times 10^6$, was purchased from Sigma (St. Louis, MO). Other chemicals were purchased from Fisher Scientific (Santa Clara, CA).

**Determination of Swelling Factor.** The swelling factor of the starches was measured according to the blue dextran dye exclusion method of Tester and Morrison.[23] Normal corn starch (100 mg, dry basis) was weighed into a 10 mL screw-cap tube, 5.0 mL of water was added, and the sealed tubes were incubated with constant shaking in a water bath at a specific temperature for 30 min. Then 0.5 mL of blue dextran solution (5 mg/mL) was added, and the contents were mixed by gently inverting the closed tubes several times. After centrifugation at 5000*g* for 5 min, the absorbance of the supernatant was measured at 620 nm. The absorbance of reference tubes that contained no starch

was also measured. The swelling factor was reported as a ratio of the volume of swollen granules to the volume of dry starch.

**Light Microscopy.** Normal corn starch (100 mg, dry basis) was slurried in water (1.0 mL) and heated in a water bath at a specific temperature for 30 min with constant shaking. The starch slurry without heat pretreatment was used as a control. Starch samples were promptly viewed with an optical microscope with a digital camera (Model BX51, Olympus Co., Japan) and observed under normal visible light by use of a 40× objective.

**Assay for Glucose-Forming Activity.** Glucose-forming activity was measured by incubating 0.05 mL of 100-fold diluted enzyme with 0.95 mL of 1% (dry basis, w/v) normal corn starch slurry in 50 mM citrate buffer (pH 4.2) at 32 °C for 10 min. The reaction was stopped by boiling the mixture for 10 min. Glucose released was measured by high-performance anionic-exchange chromatography (HPAEC) on a Dionex ICS 3000 system equipped with a CarboPac PA-1 column and pulse amperometric detector (PAD, Dionex, Sunnyvale, CA). The mobile phase was 150 mM NaOH at a flow rate of 1 mL/min. One unit of activity was defined as the amount of enzyme that released 1 μmol of glucose/min. Enzyme activity was expressed as units per milliliter of enzyme solution.

**Enzyme Kinetic Studies.** First, normal corn starch slurry in 50 mM citrate buffer (pH 4.2) was heated in a water bath at a specific temperature for 30 min with constant shaking. The starch slurry without heat pretreatment was used as a control. Then 0.05 mL of 100-fold diluted enzyme (Stargen 001) was incubated with 0.95 mL of the preheated starch slurry at 32 °C for 10 min. Kinetic studies were performed by measuring the initial rate of glucose formation at normal corn starch concentrations ranging from 0.05% to 1.0%. The SigmaPlot program (Systat Software Inc., version 10.0 for Windows) was used for curve-fitting of the data to the standard Michaelis–Menten formula: $v = V_{max}[S]/(K_m + [S])$, where $v$ is the rate of glucose formation, $[S]$ is the substrate concentration, $V_{max}$ is the maximal velocity of the reaction, and $K_m$ is the Michaelis–Menten constant.

**Saccharification Process of Granular Starch.** Before enzymatic saccharification, normal corn starch slurry (30%, dry basis, w/v) in 50 mM citrate buffer (pH 4.2) was heated in a water bath at a specific temperature for 30 min with constant shaking. The starch slurry (30%, dry basis, w/v) without heat pretreatment was used as a control. The starch slurry was incubated with Stargen 001 (2.5 units/g dry starch) at 32 °C for 72 h. At regular time intervals, samples were taken and boiled for 10 min to terminate the reaction. Glucose released was measured by HPAEC-PAD.

**Morphology of the Starch Granule.** Starch granule morphology was studied by scanning electron microscopy (SEM). Normal corn starch slurry (30%, dry basis, w/v) in 50 mM citrate buffer (pH 4.2) was heated at 55 or 65 °C for 30 min with constant shaking. The starch slurry (30%, dry basis, w/v) without heat pretreatment was used as a control. Then the above starch slurries were incubated with Stargen 001 (2.5 units/g dry starch) at 32 °C. After 0, 4, or 24 h of incubation, samples were taken, washed with anhydrous ethanol, and dried in a forced-air oven at 30 °C for 24 h. The dried samples were coated with gold–palladium by a sputter coater (Denton Vacuum, LLC, Moorestown, NJ) and viewed at 2000× magnification by SEM (S-3500N, Hitachi Science Systems, Ltd., Japan) operating at an accelerating voltage of 20 kV.

**Statistical Analysis.** Experiments were conducted in triplicate, and average values are reported. Statistical analyses were carried out by SPSS software (SPSS Inc., Chicago, IL). Significant differences ($p < 0.05$) between means were identified by one-way analysis of variance (ANOVA) using the Student–Newman–Keuls (SNK) procedure.

## RESULTS AND DISCUSSION

**Swelling of Starch Granules.** The swelling factors of normal corn starch granules were investigated in the 40–90 °C temperature range. Very little swelling was observed from 40 to 50 °C; the swelling factor increased only slightly at 50–60 °C but greatly at temperatures above 60 °C (Figure 1). It is known

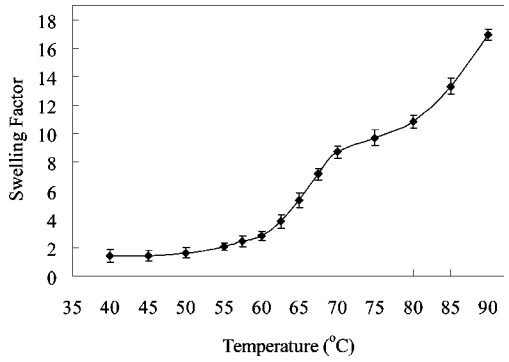

**Figure 1.** Swelling curve of normal corn starch granules heated at different temperatures. Each value represents the mean of three independent measurements.

that normal corn starch has an onset gelatinization temperature of about 58 °C.[17] Starch granules swell significantly above that temperature, resulting in the loss of crystalline order and birefringence. The swelling factor curve reached a plateau value at 70–80 °C with a swelling factor of 9–11. The swelling factor further increased significantly at temperatures above 80 °C and reached approximately 17 at 90 °C. A similar trend has been observed for waxy corn starch at temperatures below 80 °C; compared with normal corn starch, waxy corn starch showed a higher swelling curve.[23,24] The swelling factors of waxy corn starch granules at 75–80 °C reached above 30, which was approximately 2-fold higher than normal corn starch. Previous studies have also shown that the other waxy cereal starches had higher swelling capacities than corresponding normal starches.[23,25] The main reason might be that amylose–lipid complexes in normal starches inhibit granule swelling.[23] Swelling of starch granules is mainly a property of amylopectin.

In addition, when normal corn starch was incubated at 65 or 70 °C for various durations, the period of rapid swelling lasted approximately 10 min (Figure 2). After that, the swelling factor almost plateaued. Thus, incubation at a specific temperature for 30 min could reach a steady state for the swelling of starch granule.

The size and shape of normal corn starch with or without heat pretreatment at a specific temperature for 30 min are shown in Figure 3. Normal corn starch granules without heat pretreatment had polygonal and round shapes. After treatment

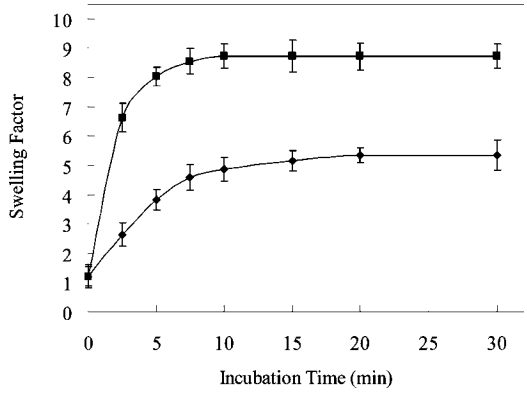

**Figure 2.** Effects of different incubation time durations on granule swelling of normal corn starch (2% solids) preheated in a water bath at (◆) 65 or (■) 70 °C with constant shaking. Each value represents the mean of three independent measurements.

dx.doi.org/10.1021/jf500814g | J. Agric. Food Chem. 2014, 62, 8114–8119

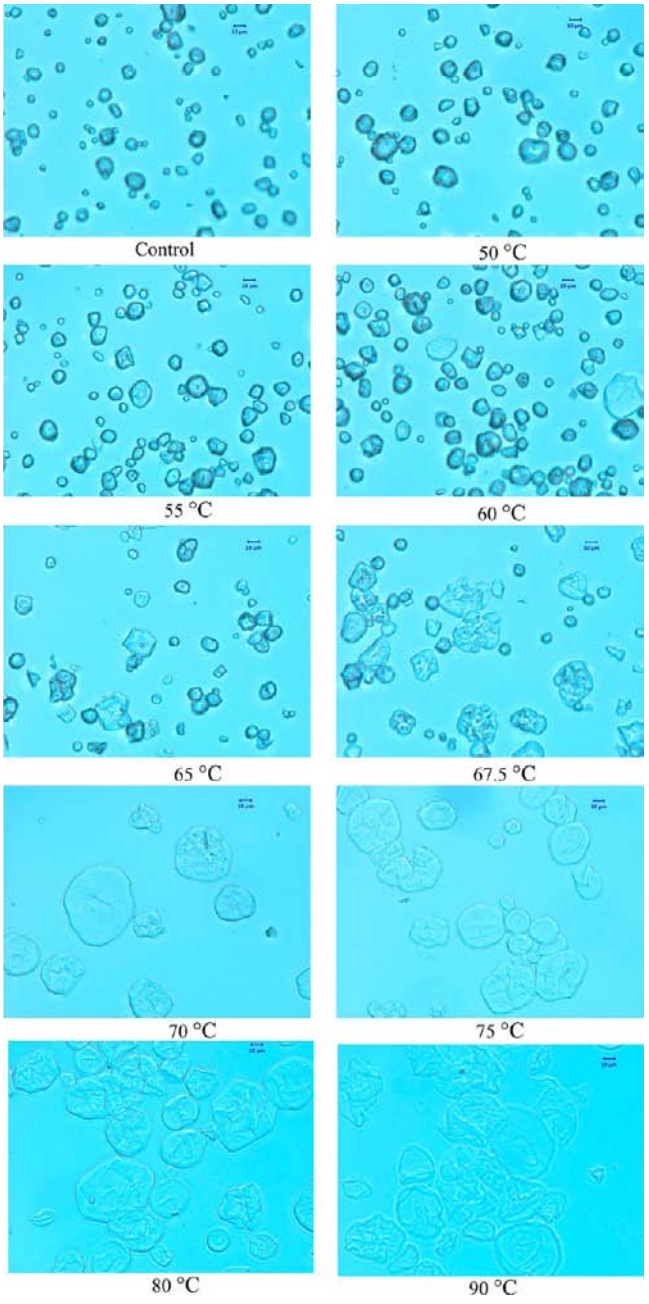

**Figure 3.** Light microscopic images of normal corn starch granules heat-treated at a specific temperature for 30 min with constant shaking. The number below each panel represents the treatment temperature. Starch granules without heat pretreatment were used as a control. Starch samples were observed under normal visible light by use of a 40× objective.

at 50−60 °C, the granules began to swell slightly, whereas granule swelling was obvious only at temperatures above 60 °C. Large starch granules appeared to swell first at around 50−60 °C; small granules did not begin to swell obviously until 65 °C. Few starch granules began to be disrupted at 65 or 67.5 °C. More starch granules were disrupted, and the rest swelled at 70−80 °C, indicating partial gelatinization of starch samples. Almost all granules were irreversibly disrupted at 90 °C, indicating complete gelatinization of starch samples. The swelling trend of normal corn starch granules obtained by optical microscopy agreed with results of swelling factors of normal corn starch granules (Figure 2).

**Kinetic Parameters.** Heat pretreatment of normal corn starch granules at different temperatures greatly affected the kinetic properties of the granular starch hydrolyzing enzyme. After heat pretreatment, $K_m$ values for the saccharification of granular starch decreased compared with those for granular starch without heat pretreatment (Table 1), indicating that granule swelling resulted in higher affinity of the granular starch hydrolyzing enzyme for starch granules. Furthermore, the significant decrease in $K_m$ value was not observed until starch granules swelled almost completely, at 70 °C or above (Figure 3). On the other hand, after heat pretreatment at 50−60 °C, $V_{max}$ values for the saccharification of granular starch increased only slightly compared with those for granular starch without heat pretreatment (Table 1). After the starch granules began to swell at temperatures above 60 °C, however, the increase in $V_{max}$ was significant. Even if the starch granules were pretreated only at 65 or 67.5 °C, at which temperature the starch granules were partly swollen, $V_{max}$ values were more than 1.5-fold higher than those of granular starch without heat pretreatment.

Catalytic efficiency as expressed by $k_{cat}/K_m$ ratios (Table 1) indicated that granular corn starch with heat pretreatment was a better substrate than that without heat pretreatment. It is noteworthy that $k_{cat}/K_m$ values for granular starch preheated at temperatures above 60 °C were much higher than those for granular starch without heat pretreatment (Table 1). For granular starch preheated at 65 or 67.5 °C, the value was more than 2-fold higher than for granular starch without heat pretreatment.

**Saccharification Process of Granular Starch.** Because heat pretreatment of 30% normal corn starch slurry (dry basis, w/v) at 70 °C or above resulted in a high slurry viscosity, temperatures below 70 °C (50−67.5 °C) were chosen to treat the normal corn starch granules before enzymatic saccharification. The pretreatment of normal corn starch granules at 50−67.5 °C enhanced starch saccharification by granular starch hydrolyzing enzyme under conditions resembling the industrial yeast fermentation process for ethanol production (Figure 4). The higher the pretreatment temperature, the more significantly starch saccharification was enhanced. In addition, enhancement of starch saccharification at an earlier stage of the enzymatic reaction was much more significant than at later stages. For granular corn starch pretreated at 65 or 67.5 °C before enzymatic saccharification, conversion to glucose after incubation with the enzyme at 32 °C for 4 h was approximately 2- or 3-fold higher, respectively, than for granular starch without heat pretreatment (Figure 4). In contrast, after incubation for 24 h, pretreatment at 65 or 67.5 °C resulted in approximately 18% or 26% increases in starch conversion into glucose, respectively (Figure 4).

The significant enhancement in saccharification of heat-pretreated granular corn starch at earlier stages might be attributed to the looser surface structure and higher specific surface area of partially swelled starch granules, which give the enzyme greater access to the substrate and allow the enzyme to degrade granular starch more easily and extensively.[26] As the sizes of active α-amylase and glucoamylase are several nanometers,[20−22] the enzymes can enter into the interior of native starch granule only through the limited number of pores to degrade starch, but granule swelling provides greater enzyme access to the granule interior. However, at later stages of the enzymatic reaction, reduced availability of starch to the enzyme

Before enzymatic saccharification, normal corn starch slurry (30%, dry basis, w/v) in 50 mM citrate buffer (pH 4.2) was heated in a water bath at (■) 50, (▲) 55, (×) 60, (*) 65, or (●) 67.5 °C for 30 min with constant shaking. The starch slurry without heat pretreatment (◆) was used as a control. During enzymatic saccharification, the formation of glucose was measured by incubation of Stargen 001 (2.5 units/g dry starch) with a starch sample at 32 °C for 24 h and expressed as starch conversion (percent, dry basis). Each value represents the mean of three independent measurements.

might result in a decreased glucose formation rate, especially in the rigid or tight crystalline region of the starch. Because $\alpha$-amylase binds more slowly to crystalline material,[27] the residual starch granules with high crystallinity were resistant to enzymatic hydrolysis. After pretreatment of normal corn starch granules at 55−67.5 °C, which was close to or above the gelatinization temperature, a small portion of the semicrystalline region would be converted into amorphous material,[28,29] which is more readily hydrolyzed,[30] but the crystalline portion of the starch would not be significantly changed. Thus, partial swelling of starch granules would not significantly enhance starch saccharification at later stages of the enzymatic reaction.

During the simultaneous saccharification and fermentation process for ethanol production, improved saccharification of heat-pretreated granular corn starch could reduce the necessary amount of granular starch hydrolyzing enzyme. Granular starch hydrolyzing enzyme is more expensive than conventional enzymes,[31] so the amount of granular starch hydrolyzing enzyme is an important factor in the economics of ethanol production. Although heat pretreatment of granular corn starch resulted in consumption of a small amount of energy, a reduction in the amount of granular starch hydrolyzing enzyme might significantly lower the production cost of ethanol. Heat pretreatment could also result in significant enhancement of the conversion of granular starch into glucose at earlier stages of the enzymatic reaction, which might be beneficial to yeast fermentation for ethanol production because the rapid growth of yeast at the early stage of fermentation (especially the logarithmic growth phase) needs much more glucose as a carbon source than at the later stage of fermentation.

**Morphology of Starch Granules.** During enzymatic saccharification, the morphology of granular corn starch with or without heat pretreatment was observed by SEM (Figure 5A−C). Changes in morphology of normal corn starch before and after digestion by $\alpha$-amylase alone, glucoamylase alone, and a mixture of $\alpha$-amylase and glucoamylase have been reported.[17] In this study, normal corn starch granules pretreated at 55 or 65 °C were larger and had more irregular shapes and rougher surfaces than starch granules without heat pretreatment (Figure 5A−C), further confirming that larger particle size and corresponding higher specific surface area resulted from heat pretreatment. Enzymatic erosion occurred mainly at the surface of starch granules at earlier stages of the enzymatic reaction (Figure 5D−F). After incubation with granular starch hydrolyzing enzyme at 32 °C for 4 h, the surface of starch granules pretreated at 55 °C, especially relatively large granules (Figure 5E), appeared to have a greater number of small pores than granules without heat pretreatment, which could permit more enzyme penetration.[32] As a result, when the external part of the granule was corroded, the enzyme could more easily act internally.[33] For starch granules pretreated at a higher temperature (65 °C), many granules swelled to a higher degree. As a result, starches in external parts of the granule could be corroded more easily by the enzyme, and even internal parts of the granule were hydrolyzed and removed (Figure 5F). In contrast, for the normal corn starch granules without pretreatment, only micropores were observed but not the interior of the granules (Figure 5D). After incubation for 24 h, starch granules without heat pretreatment showed more large pores in the surface than those incubated for 4 h, and the internal part of some granules was corroded (Figure 5G). The greater portion of many starch granules, however, was still not hydrolyzed, and some small granules were almost intact. In contrast, starch granules subjected to heat pretreatment

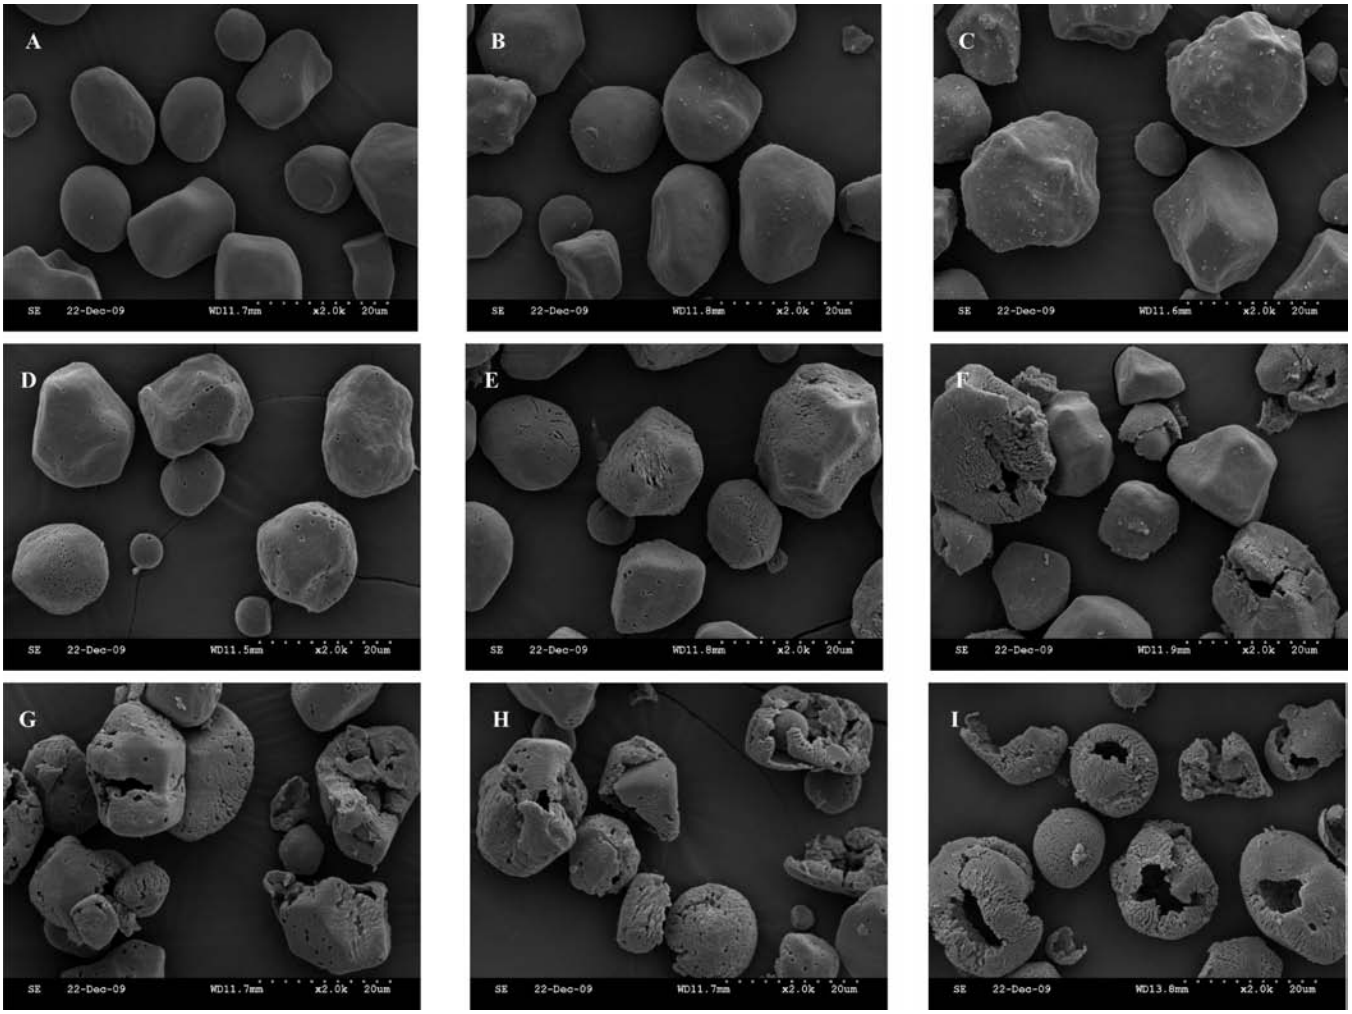

**Figure 5.** Scanning electron micrographs of normal corn starch granules during enzymatic saccharification. Normal corn starch slurry (30%, dry basis, w/v) without heat pretreatment or pretreated at 55 or 65 °C for 30 min was incubated with Stargen 001 (2.5 units/g dry starch) at 32 °C for (A–C) 0, (D–F) 4, or (G–I) 24 h, respectively.

exhibited a higher degree of external and internal starch hydrolysis that resulted in the almost complete collapse of large starch granules (Figure 5H,I). For starch granules heat-pretreated at 65 °C, the residual portion of large granules was very small, and even small ones were also corroded, resulting in a rough porous surface or collapse of the granule (Figure 5I). Both $\alpha$-amylase and glucoamylase are able to hydrolyze crystalline as well as amorphous regions of normal corn starch granules, and a synergetic action was observed when both enzymes were used together.[17] A side-by-side mechanism has been proposed to explain the enzymatic digestion of amylose and amylopectin, as well as crystalline and amorphous regions in normal corn starch granules.[19]

In conclusion, the partial swelling of normal corn starch granules greatly enhanced starch saccharification by granular starch hydrolyzing enzymes. Furthermore, enhancement of starch saccharification at an earlier stage of the enzymatic reaction was much more significant than at later stages. Thus, proper heat pretreatment of granular starch before simultaneous saccharification and fermentation has great potential to facilitate industrial production of ethanol by use of granular starch hydrolyzing enzyme.

# Structural Elucidation of Sorghum Lignins from an Integrated Biorefinery Process Based on Hydrothermal and Alkaline Treatments

Shao-Long Sun,[†] Jia-Long Wen,[†] Ming-Guo Ma,[†] and Run-Cang Sun*[,†,‡]

[†]Beijing Key Laboratory of Lignocellulosic Chemistry, Beijing Forestry University, Beijing 100083, China

[‡]State Key Laboratory of Pulp and Paper Engineering, South China University of Technology, Guangzhou 510640, China

**ABSTRACT:** An integrated process based on hydrothermal pretreatment (HTP) (i.e., 110−230 °C, 0.5−2.0 h) and alkaline post-treatment (2% NaOH at 90 °C for 2.0 h) has been performed for the production of xylooligosaccharide, lignin, and digestible substrate from sweet sorghum stems. The yield, purity, dissociation mechanisms, structural features, and structural transformations of alkali lignins obtained from the integrated process were investigated. It was found that the HTP process facilitated the subsequent alkaline delignification, releasing lignin with the highest yield (79.3%) and purity from the HTP residue obtained at 190 °C for 0.5 h. All of the results indicated that the cleavage of the *β*-*O*-4 linkages and degradation of *β*-*β* and *β*-5 linkages occurred under the harsh HTP conditions. Depolymerization and condensation reactions simultaneously occurred at higher temperatures (≥170 °C). Moreover, the thermostability of lignin was positively related to its molecular weight, but was also affected by the inherent structures, such as *β*-*O*-4 linkages and condensed units. These findings will enhance the understanding of structural transformations of the lignins during the integrated process and maximize the potential utilizations of the lignins in a current biorefinery process.

## INTRODUCTION

The ultimate goal of lignocellulosic biomass separation according to the biorefinery was to attain the fractionation of the three primary components (cellulose, hemicelluloses, and lignin) via an effective method, in which the fractions obtained can be converted into different biobased products. Currently, most research has focused on the applications of cellulose in biomass, such as papermaking and cellulosic ethanol production. However, research and development activities directed toward commercial production of cellulosic ethanol have created the opportunity to dramatically increase the transformation of lignin to value-added products.[1] Meanwhile, to maximize the utilization of underlying values of lignocelluloses, it is very important to fractionate them into their main compositions and then transform them into value-added products.[2]

To investigate the utilization of potential values of lignocelluloses, a series of lignocellulosic biorefinery technologies including steam explosion, extrusion process, dilute acid, and hydrothermal treatment have been investigated.[3−6] Among them, hydrothermal pretreatment, a process that disposes of lignocelluloses in a chemical-free, water-only medium, provides a low-cost, handy, and environmentally friendly biorefinery technology.[6] Moreover, physical changes induced by hydrothermal pretreatment that improve enzymatic hydrolysis of cellulose are well-known and include an increase in pore size to enhance enzyme penetration and an increase in accessible cellulose by decreasing its crystallinity and association with lignin.[7,8] Simultaneously, a hydrothermal pretreatment process can produce some chemicals, such as oligosaccharides, furfural, formic acid, acetic acid, and levulinic acid.[9] More importantly, hydrothermal pretreatment accelerates the subsequent delignification. For instance, it has been demonstrated that hydrothermal pretreatment facilitated kraft pulping of hardwood and the subsequent alkaline extraction of lignin.[10] Some integrated biorefinery technologies based on liquid hot water and $H_2SO_4$ catalysis were also proposed.[11] These technologies cause structural changes of lignin and cellulose as well as solubilization of hemicellulose, which in turn contribute to the reduction of biomass recalcitrance. However, the delignification in this process was performed under acidic conditions, which normally needs appropriate acid-resistant equipment. This undoubtedly increases the cost of the entire process.

Sweet sorghum is considered a potential renewable source of energy for economic development and environmental sustainability, owing to its wide adaptability and high photosynthesis.[10] On the basis of previous investigations,[11,12] a combination of hydrothermal pretreatment (i.e., 110−230 °C, 0.5−2.0 h) and sodium hydroxide delignification was proposed in this study. In this integrated process, alkaline treatment has been implemented to disrupt the dense cellular structure in lignocelluloses.[13] It contains many types of chemical reactions in the complex network of lignocelluloses, such as cleavage of ether linkages in lignin units along with peeling reaction of carbohydrates.[14] As a biorefinery process, lignin should receive wide attention due to its potential value in developing biobased materials and chemicals. Although the lignin polymers formed during the hydrothermal pretreatment process were structurally

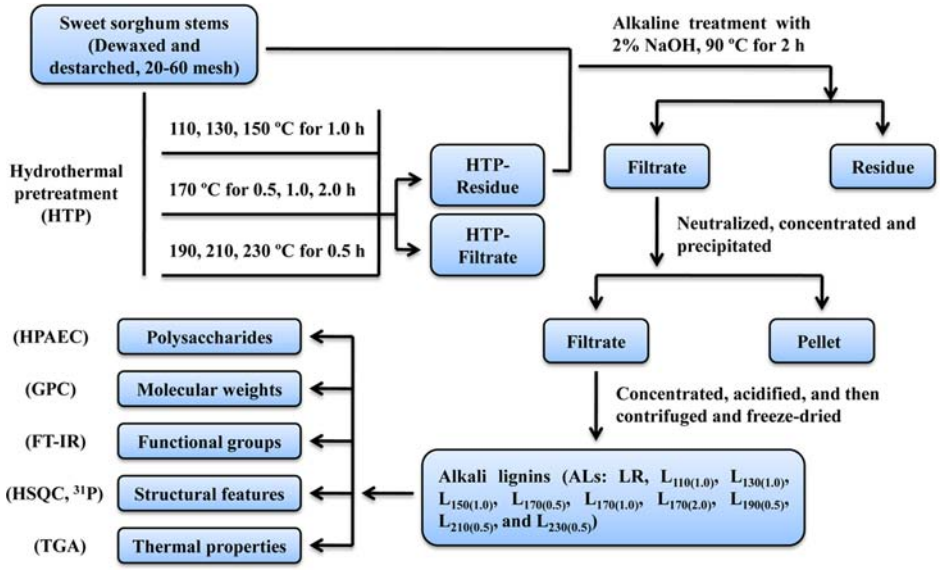

**Figure 1.** Schematic diagram of the lignin extracted from the integrated process.

analyzed previously, some aspects about lignin yield, purity, dissociation mechanisms, and structural features as well as the structural changes during the integrated process should be clarified in the current integrated process.[15] Moreover, these aspects will be conducive for developing renewability, availability, and value-added lignin-based products, such as sustainable construction materials for replacing petroleum-based products.[16−18]

In the present study, the structural features and chemical reactivity of the lignin fractions obtained from the integrated process were thoroughly investigated by high-performance anion exchange chromatography (HPAEC), gel permeation chromatography (GPC), and Fourier transform infrared (FT-IR), quantitative two-dimensional heteronuclear single-quantum coherence (2D-HSQC), and $^{31}$P NMR spectroscopy. In addition, to unveil the relationship between structural features and thermal behaviors, thermogravimetric analysis (TGA) was also performed. It is believed that all of the investigations will increase the availability of these integrated techniques in the current biorefinery industry.

## MATERIALS AND METHODS

**Materials.** Sweet sorghum stems (SSS) were obtained from the experimental farm of the North-Western University of Agricultural and Forest Sciences and Technology (Yangling, People's Republic of China). The dried SSS were cut into small pieces and then ground, and the fractions passing 20−60 mesh were collected. The powder was extracted with toluene/ethanol (2:1, v/v) in a Soxhlet instrument for 6 h, followed by a hot water treatment at 80 °C for 2 h to remove starch. The composition of SSS was 2.3% arabinan, 0.7% galactan, 41.1% glucan, 25.9% xylan, and 21.4% lignin (19.5% Klason lignin and 1.9% acid-soluble lignin), which was determined by using National Renewable Energy Laboratory's (NREL) standard analytical procedure.[19] All experiments were performed in duplicate under the same conditions.

**Hydrothermal Pretreatment (HTP).** The HTP processes were implemented in a 1000 mL stainless steel autoclave (Parr, USA) with a magnetic stirrer at a solid to liquid ratio of 1:10 (g/mL) by a PID controller (Parr 4848, USA). A total of 15.0 g of raw material was mixed with 150 mL of deionized water and then heated at 110, 130, and 150 °C for 1.0 h, at 170 °C for 0.5, 1.0, and 2.0 h, and at 190, 210, and 230 °C for 0.5 h, respectively. At the end of HTP, the mixtures were cooled to room temperature. The solid residues were collected with a Buchner funnel, washed thoroughly with distilled water, and further dried in an oven at 60 °C for 16 h.

**Alkaline Post-treatment.** The unpretreated and hydrothermally pretreated SSS meal was utilized as starting material for the fractionation process (Figure 1). Specifically, the fractionation (5.0 g HTP residue) was operated in 2% NaOH aqueous solution at 90 °C for 2 h under a solid to liquid ratio of 1:20 (g/mL). The collected liquid fractions were neutralized to pH 5.5−6.0 with 6 M HCl and were further concentrated to 40 mL under vacuum. Subsequently, each concentrated solution was poured into 95% ethanol (120 mL) with vigorous stirring, and the hemicellulosic pellet was obtained by filtering, washing with 70% aqueous ethanol, and freeze-drying. The residual supernatants were concentrated to 30 mL and poured in 150 mL of acidic water (pH 2.0, adjusted by HCl) to precipitate the lignins (i.e., alkali lignins, ALs). The notation of the nine ALs ($L_{110(1.0)}$, $L_{130(1.0)}$, $L_{150(1.0)}$, $L_{170(0.5)}$, $L_{170(1.0)}$, $L_{170(2.0)}$, $L_{190(0.5)}$, $L_{210(0.5)}$, and $L_{230(0.5)}$) was according to the increasing pretreatment conditions (i.e., 110−230 °C, 0.5−2.0 h). Raw lignin (LR) was also separated from the unpretreated SSS under the same alkaline treatment condition.

**Analysis Procedures.** The associated polysaccharides in the ALs were calculated by using HPAEC as reported previously.[20] Molecular weights of the ALs were determined by GPC with an ultraviolet detector (UV) at 240 nm. The column used was a PL-gel 10 mm mixed-B 7.5 mm i.d. column, which was calibrated with PL polystyrene standards. Four milligrams of the ALs was dissolved in 2 mL of tetrahydrofuran (THF), and 20 $\mu$L lignin solutions were injected. The column was operated at ambient temperature and eluted with THF at a flow rate of 1.0 mL/min. FT-IR spectra of the ALs were recorded on a Bruker spectrophotometer in the range of 800−2000 cm$^{-1}$ with a resolution of 4 cm$^{-1}$. A KBr disk containing 1% finely ground ALs was used for determination. The solution-state NMR spectra of the ALs were acquired on a Bruker AVIII 400 MHz spectrometer at 25 °C. For 2D HSQC spectroscopic experiments, the data were acquired in HSQC experiment mode using 60 mg of lignin in 0.5 mL of DMSO-$d_6$. Functional groups (phenolic hydroxyl, aliphatic hydroxyl, and carboxyl groups) of the ALs were determined by $^{31}$P NMR spectra according to recent publications.[21,22] Thermal properties of the ALs were measured by using TGA and differential thermogravimetric (DTG) analysis on a simultaneous thermal analyzer (TGA Q500, USA). About 4−8 mg of the AL samples was heated in a platinum crucible from room temperature to 700 °C at a heating rate of 20 °C/min under nitrogen atmosphere. Provision was made for electronic differentiation of the weight signal to give the rate of weight loss.[20]

## RESULTS AND DISCUSSION

**Solid Yields, Yields, and Associated Polysaccharides of the Lignins.** Table 1 shows that the solid yields decreased from 92.4 to 51.5 g/100 g oven-dried SSS as the pretreatment severity increased. This is mainly due to the degradation and solubilization of hemicelluloses. According to the NREL procedure, the Klason lignin contents in respective HTP residues obtained from the different pretreatment conditions (110, 130, 150 °C for 1.0 h; 170 °C for 0.5, 1.0, 2.0 h; and 190, 210, 230 °C for 0.5 h) were 16.5, 19.2, 20.7, 24.1, 24.7, 25.7, 28.0, 33.6, and 43.9%, respectively. The yields of the ALs were calculated on the basis of the Klason lignin in respective SSS and are shown in Table1. In the integrated process, the yields of the ALs were 52.3, 53.4, 54.9, 59.6, 64.7, 61.6, 79.3, 54.8, and 39.9%, corresponding to the HTP conditions at 110, 130, 150 °C for 1.0 h; 170 °C for 0.5, 1.0, 2.0 h; and 190, 210, 230 °C for 0.5 h, respectively. Particularly, only 30.7% of the alkali lignin (LR) from the unpretreated SSS was obtained. All data indicated that the HTP process facilitated more original lignin (40.9−68.6%) release with alkaline treatment as compared with direct alkaline delignification (30.7%) without the HTP process. In other words, the HTP was a promising pretreatment for efficiently loosening the tight cell wall structure and then facilitating the release of lignin from the plant cell wall with the assist of alkaline treatment. Apparently, the increase of pretreatment temperature from 110 to 170 °C for 1.0 h resulted in a notable increase of the AL yield from 52.3 to 64.7%. The increasing trend was probably related to the HTP process, which cleaved the chemical bonds between lignin and hemicelluloses to some extent (e.g., ester and ether bonds).[23] The partly dissociated components facilitated the following alkaline extraction under the conditions given. However, when the pretreatment temperature was further increased to 230 °C, the yield of the AL distinctly decreased to 39.9%. Meanwhile, when the pretreatment period was further prolonged from 1.0 to 2.0 h at 170 °C, the yields of the ALs decreased from 64.7 to 61.6%. The reduced yield was due to the fact that the lignin content in the HTP residues was overestimated by the klason method because the HTP process under the harsh conditions induced some recondensation reactions between polysaccharides (or polysaccharide degradation products) and lignin, which was also called "'pseudolignin"'.[24] Interestingly, the yield of the AL reached a plateau ($L_{190(0.5)}$, 79.3%) at the pretreatment condition of 190 °C for 0.5 h, demonstrating that the optimized condition for isolating lignin was achieved at this HTP condition. To verify the purity of the extracted ALs, the associated polysaccharides of the ALs were detected by HPAEC (Table 1). As can be seen, all of the ALs contained a rather low amount of associated polysaccharides (<1.80%). In detail, xylose was the major monosaccharide in the ALs, suggesting that the associated polysaccharides in the ALs originated from xylans. Especially, polysaccharides were not detected in $L_{210(0.5)}$ and $L_{230(0.5)}$, suggesting that the hemicellulosic polymer was thoroughly destroyed and degraded under the harsh conditions.

**Molecular Weight Determination.** Changes in molecular weights of the ALs indirectly provided valuable insights into lignin's fragmentation and recondensation reactions during the HTP process. To determine the effect of the HTP on the molecular weight of the ALs obtained, the LR and pretreated lignin fractions ($L_{110(1.0)}$−$L_{230(0.5)}$) were analyzed by GPC. Table 2 lists the changes in molecular weight of the ALs with respect to the HTP temperature and time. As shown in Table 2, the molecular weight ($M_w$) of LR was 1360 g $mol^{-1}$, and its polydispersity ($M_w/M_n$) was 1.24. After the HTP, it was observed that the $M_w$ of the ALs decreased (530−1320 g $mol^{-1}$) as compared to LR. This suggested that the ALs underwent depolymerization with increasing HTP temperature and time.[23,25] It was noted that the depolymerization reaction became more evident under the harsh pretreatment conditions (HTP temperature was higher than 170 °C and/or time exceeded 1.0 h at 170 °C), which resulted in a reduced $M_w$ of

dx.doi.org/10.1021/jf501669r | J. Agric. Food Chem. 2014, 62, 8120−8128

the ALs ($L_{170(2.0)}$, $L_{190(0.5)}$, $L_{210(0.5)}$, and $L_{230(0.5)}$). Furthermore, the content of $\beta$-*O*-4 was positively related to the $M_w$ of the lignin under the conditions given.[26] Especially, the higher the $\beta$-*O*-4 content, the higher the molecular weight of the lignin, which was further confirmed by the subsequent quantitative 2D-HSQC results. Moreover, the polydispersity index of LR obtained from the unpretreated material was 1.24. After the HTP under various processing conditions, the polydispersity indices of the ALs were slightly increased (1.29−1.58) to some extent, suggesting that some inhomogeneous lignin fragments, which were probably originated from HTP and alkaline treatments, occurred and collected after the integrated process.

**FT-IR Spectral Analysis.** Figure 2 exhibits the fingerprint region of FT-IR spectra of the ALs obtained from the integrated process, and the bands were assigned according to the literature.[20,27,28] Specifically, the 1701 $cm^{-1}$ band is attributed to the conjugated/unconjugated carboxyl acid/ester groups or unconjugated $\beta$-ketone carbonyl groups. The bands at 1630−1649 $cm^{-1}$ originate from stretching of conjugated C═O groups, which were prominent in the LR, $L_{110(1.0)}$, and $L_{130(1.0)}$, suggesting that more conjugated C═O appeared at the mild conditions (below 150 °C). The intense bands at 1605, 1514, and 1427 $cm^{-1}$ correspond to aromatic skeletal vibrations and the C−H deformation combined with aromatic ring vibration at 1462 $cm^{-1}$. This suggested that the increase of the pretreatment temperature from 110 to 230 °C and/or time from 0.5 to 2.0 h at 170 °C had no evident influence on the basic lignin structure. A small band at 1153 $cm^{-1}$ (antisymmetric C−O stretching of ester groups) was observed in the spectra of the ALs (LR-$L_{190(0.5)}$), implying that some ester bonds remained under the condition given. However, this band was inconspicuous in the ALs ($L_{210(0.5)}$ and $L_{230(0.5)}$), suggesting that the ester bonds in the lignin macromolecules were significantly cleaved when the HTP temperature reached 210 and 230 °C. The intensity of bands at 1329, 1269, and 1032 $cm^{-1}$ decreased with increasing pretreatment severity, and the bands are assigned to the characteristic of syringyl and condensed guaiacyl units, the ring breathing with C−O stretching in uncondensed guaiacyl units, and aromatic C−H in-plane deformation, respectively. The 1217 $cm^{-1}$ band originates from the C—C, C—O, and C═O stretching. In addition, the band at 1117 $cm^{-1}$, which was ascribed to aromatic C−H in-plane deformation (typical for S units), decreased in $L_{210(0.5)}$ and $L_{230(0.5)}$, suggesting that the proportion of S-type lignin units was decreased as a result of demethoxylation reactions under the harsh pretreatment conditions.[27,29]

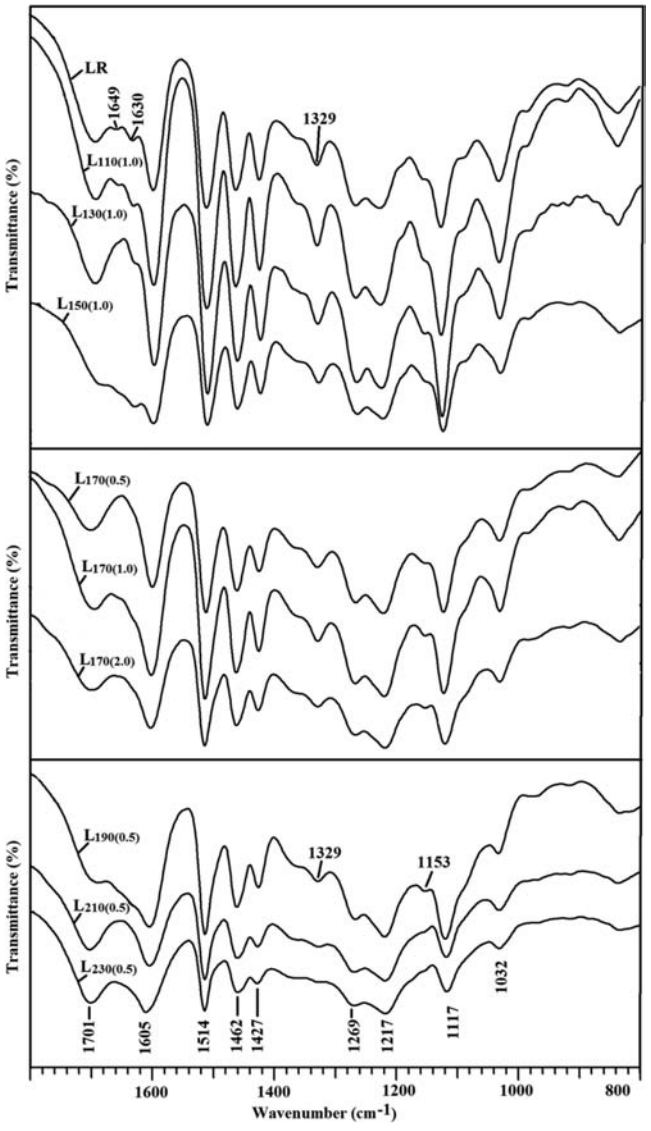

**Figure 2.** FT-IR spectra of the lignins obtained from the integrated process under various processing conditions.

**2D-HSQC NMR Spectral Analysis.** 2D-HSQC NMR was used to obtain important structural information on the ALs to accelerate the understanding of the fundamental chemistry of the ALs obtained from the integrated process. The 2D-HSQC spectra and main linkages of these ALs are shown in Figures 3 and 4, and the signals were assigned (Table 3) on the basis of previous literature.[20,21,23,28−38] In the side-chain region of the AL spectra (Figure 3), cross-peaks of different interunit linkages of the ALs were identified, such as $\beta$-aryl-ether ($\beta$-*O*-4, A), resinol ($\beta$-$\beta$, B), phenylcoumaran ($\beta$-5, C), $\alpha$,$\beta$-diaryl ethers (E), and *p*-hydroxycinnamyl alcohol end groups (F). As can be seen, the cross-peaks of methoxy groups (−$OCH_3$, $\delta_C/\delta_H$ 55.7/3.74) and side chains in $\beta$-*O*-4 substructures (A/A′) were the main substructures. In the integrated process, the relative content of different linkages was changed. For instance, the content of $\beta$-*O*-4 linkages was decreased, whereas the content of $\beta$-5 linkages was increased, suggesting that the $\beta$-*O*-4 linkages were cleaved as a result of the HTP process. In addition, the cleaved $\beta$-*O*-4 linkages were probably recondensed to form $\beta$-5 linkages. Furthermore, it was also noted that lignin−carbohydrate complex (LCC), such as benzyl ether (BE) structure, occurred in the ALs at HTP temperature below 210 °C, implying that the BE structure was more stable during the integrated delignification process. However, no signal of the BE was detected in the $L_{210(0.5)}$ and $L_{230(0.5)}$, implying that the BE was completely cleaved when the HTP temperature was >190 °C.[29]

In the aromatic region of 2D-HSQC spectra (Figure 4) of the ALs, the correlated signals of the ALs from syringyl (S/S′), guaiacyl (G/G′), and *p*-hydroxyphenyl (H) units clearly appeared. Specifically, the S and the $C_\alpha$-oxidized S units (S′) signals for $C_{2,6}$−$H_{2,6}$ correlation were observed at $\delta_C/\delta_H$ 104.1/6.72 and 106.2/7.26, respectively. The G units showed various correlations for $C_2$−$H_2$ ($\delta_C/\delta_H$ 110.8/6.99), $C_5$−$H_5$ ($\delta_C/\delta_H$ 114.9/6.71), and $C_6$−$H_6$ ($\delta_C/\delta_H$ 119.1/6.82), respectively. Moreover, the oxidized G units with a $C_\alpha$ ketone (G′) exhibited

| $B_\alpha$ | 84.8/4.63 | $C_\alpha-H_\alpha$ in $\beta$-$\beta$ resinol substructures (B) |
| $A_{\beta(S)}$ | 85.9/4.10 | $C_\beta-H_\beta$ in $\beta$-$O$-4 linked to a S unit (A) |
| $C_\alpha$ | 87.4/5.56 | $C_\alpha-H_\alpha$ in phenylcoumaran substructures (C) |
| $S_{2,6}$ | 104.1/6.72 | $C_{2,6}-H_{2,6}$ in syringyl units (S) |
| $S'_{2,6}$ | 106.2/7.26 | $C_{2,6}-H_{2,6}$ in oxidized S units (S′) |
| $G_2$ | 110.8/6.99 | $C_2-H_2$ in guaiacyl units (G) |
| $G'_2$ | 117.6/7.22 | $C_2-H_2$ in oxidized G units (G′) |
| $G_5$ | 114.9/6.71 | $C_5-H_5$ in guaiacyl units (G) |
| $G_6$ | 119.1/6.82 | $C_6-H_6$ in guaiacyl units (G) |
| $H_{2,6}$ | 127.7/7.17 | $C_{2,6}-H_{2,6}$ in H units (H) |
| $PCA_{3,5}$ | 115.2/6.92 | $C_{3,5}-H_{3,5}$ in $p$-coumaric acid (PCA) |
| $PCA_{2,6}$ | 129.8/7.51 | $C_{2,6}-H_{2,6}$ in $p$-coumaric acid (PCA) |
| $PCA_7$ | 143.9/7.48 | $C_7-H_7$ in $p$-coumaric acid (PCA) |
| $PCA_8$ | 115.2/6.29 | $C_8-H_8$ in $p$-coumaric acid (PCA) |
| $FA_2$ | 110.9/7.23 | $C_2-H_2$ in ferulic acid (FA) |
| $FA_6$ | 122.1/7.09 | $C_6-H_6$ in ferulic acid (FA) |
| $FA_7$ | 143.9/7.48 | $C_7-H_7$ in ferulic acid (FA) |
| $FA_8$ | 116.5/6.39 | $C_8-H_8$ in ferulic acid (FA) |

correlation for $C_2-H_2$ ($\delta_C/\delta_H$ 117.6/7.22) when the HTP temperature was <170 °C or the HTP time was <1.0 h at 170 °C. However, with further increase of the pretreatment temperature from 170 to 230 °C or increase of the pretreatment time from 1.0 to 2.0 h at 170 °C, no signal of G′ was detected in these corresponding ALs, implying the oxidized G units occurred in a relatively low temperature and time. Furthermore, the $C_{2,6}-H_{2,6}$ correlation signal from H units was found at $\delta_C/\delta_H$ 127.7/7.17. As the temperature increased, the content of H units increased in the ALs, which was mainly as a result of the demethoxylation reactions occurring in G and/or S units, especially at higher temperatures. Besides the normal signals for aromatic rings of the ALs, some condensed S and G units occurred in the 2D HSQC spectra of the ALs.[36] Increasing the pretreatment temperature from 170 to 230 °C or prolonging the pretreatment time from 0.5 to 2.0 h at 170 °C resulted in an obvious increase of the contents of condensed S and G units. The ALs obtained from these processes appeared to contain large amounts of $p$-hydroxycinnamates (PCA and FA). After the same alkaline post-treatment, the lignin obtained (LR-$L_{230(0.5)}$) presented obvious signals of free $p$-coumaric acid correlations ($PCA_8$, $\delta_C/\delta_H$ 115.2/6.29) but not for $PCA_8$ ($\delta_C/\delta_H$ 113.5/6.24), suggesting that the acylated $p$-coumarate (PCE) were significantly cleaved, appeared as free PCA, and coprecipitated with the alkali lignins, which has been discussed in detail in a previous publication.[26] The PCA was characterized by relatively intense correlations at $\delta_C/\delta_H$ 129.8/7.51 ($PCA_{2,6}$), 115.2/6.92 ($PCA_{3,5}$), 115.2/6.29 ($PCA_8$), and 143.9/7.48 ($PCA_7$), whereas ferulic acid (FA) was found at $\delta_C/\delta_H$ 110.9/7.23 ($FA_2$), 122.1/7.09 ($FA_6$), and 116.5/6.39 ($FA_8$).

**Quantitative Analysis of Lignin Structures Based on 2D-HSQC Spectra.** The 2D-HSQC spectra of the pretreated lignins illustrated the relative degradation of the lignin side chains and the aromatic units with increasing pretreatment temperature and time as compared to that of the LR. According to the computing method of the literature,[34,37] the different linkages could be expressed by a comparative mode (Table 4).

The content of $\beta$-$O$-4 aryl ether in the ALs obtained at the mild conditions was higher than that of the LR, suggesting that some condensed reactions rather than depolymerization reactions occurred under the mild conditions. The condensation reactions led to the decrease of the protonated aromatic carbon and the elevation the content of $\beta$-$O$-4.[29] However, as the pretreatment temperature further increased (150−230 °C), the content of $\beta$-$O$-4 aryl ether in the ALs was sharply decreased, suggesting that the cleavage of $\beta$-$O$-4 aryl ether (depolymerization) was the predominant reaction during the HTP at higher temperatures.

Besides $\beta$-$O$-4 aryl ether linkage cleavage and carbon−carbon linkage degradation or condensation, changes of the S/G and PCA/FA ratios in the ALs were also prominent structural alterations observed after HTP.[29,38] The S/G and PCA/FA ratios in the ALs had no obvious changes ($L_{110(1.0)}$ and $L_{130(1.0)}$) at pretreatment temperature <150 °C as compared to that of the LR. The S/G and PCA/FA ratios gradually increased as the pretreatment temperature rose and time prolonged and reached a maximum ratio (S/G = 3.76; PCA/FA = 4.53) in $L_{170(2.0)}$. The increased S/G ratio suggested that the G-type lignin was more easily degraded during the HTP process, in agreement with a previous study.[29] Meanwhile, the increased PCA/FA ratio suggested that most of the etherified FA was removed during the HTP process. However, with the pretreatment temperature further increased from 190 to 230 °C, the S/G and PCA/FA ratios gradually decreased (S/G = 1.19; PCA/FA = 0.94) at the same time in $L_{230(0.5)}$.

**$^{31}$P NMR Spectral Analysis.** To further investigate the fundamental chemistry of the ALs obtained from the integrated process, a quantitative $^{31}$P NMR technique was also applied (Figure 5).[39,40] Table 5 shows the quantitative data on the distribution of the different OH groups of the ALs. The content of aliphatic OH of the ALs gradually reduced as the pretreatment temperature and time increased during the integrated process, suggesting that the aliphatic OH groups were gradually oxidized and modified under the harsh conditions.[29] The contents of S- and G-type phenolic OH groups were greatly increased from LR to $L_{230(0.5)}$ as a result of the cleavage of the *β*-*O*-4 aryl ether linkages, and the increasing rate of S-type lignin was faster than that of the corresponding G units. Additionally, the gradually increased condensed S and G phenolic OH implied that increasing the pretreatment temperature and time also resulted in more condensation reactions during the HTP process, as shown in the 2D HSQC NMR section aforementioned. The total content of PCA and *p*-hydroxyphenyl OH (H-type lignin unit) could be also revealed by $^{31}$P NMR spectra. The total content in LR was 0.32 mmol/g, whereas it decreased to 0.27 mmol/g in $L_{110(1.0)}$ and it increased from 0.32 to 0.73 mmol/g in the ALs ($L_{130(1.0)}$–$L_{230(0.5)}$) as the pretreatment temperature increased from 130 to 230 °C, suggesting that the demethoxylation reactions probably occurred at G and/or S units, especially at higher temperatures, as revealed by the intensive signals of H units in the 2D HSQC spectra.

**Thermal Analysis.** The thermal behaviors of lignin are extremely important for its utilization in thermochemical conversion into energy and chemicals, for example, thermolysis. The decomposition of lignin is a complex reaction and occurred by diverse bond fissions within the lignin macromolecule. The maximum decomposition temperature ($T_M$) is the corresponding temperature of the maximum decomposition rate ($V_M$).[41] In principle, the different thermal behaviors are not only influenced by the inherent structures and different functional groups of lignin molecule but condensation of the lignin macromolecule also associated with specific chemical features. To investigate the potential relationship between structural features and thermal behaviors, the TGA of the ALs (A, LR and $L_{150(1.0)}$; B, $L_{170(0.5)}$ and $L_{170(2.0)}$; C, $L_{190(0.5)}$ and $L_{230(0.5)}$) were comparatively investigated in this experiment (Figure 6).

dx.doi.org/10.1021/jf501669r | J. Agric. Food Chem. 2014, 62, 8120−8128

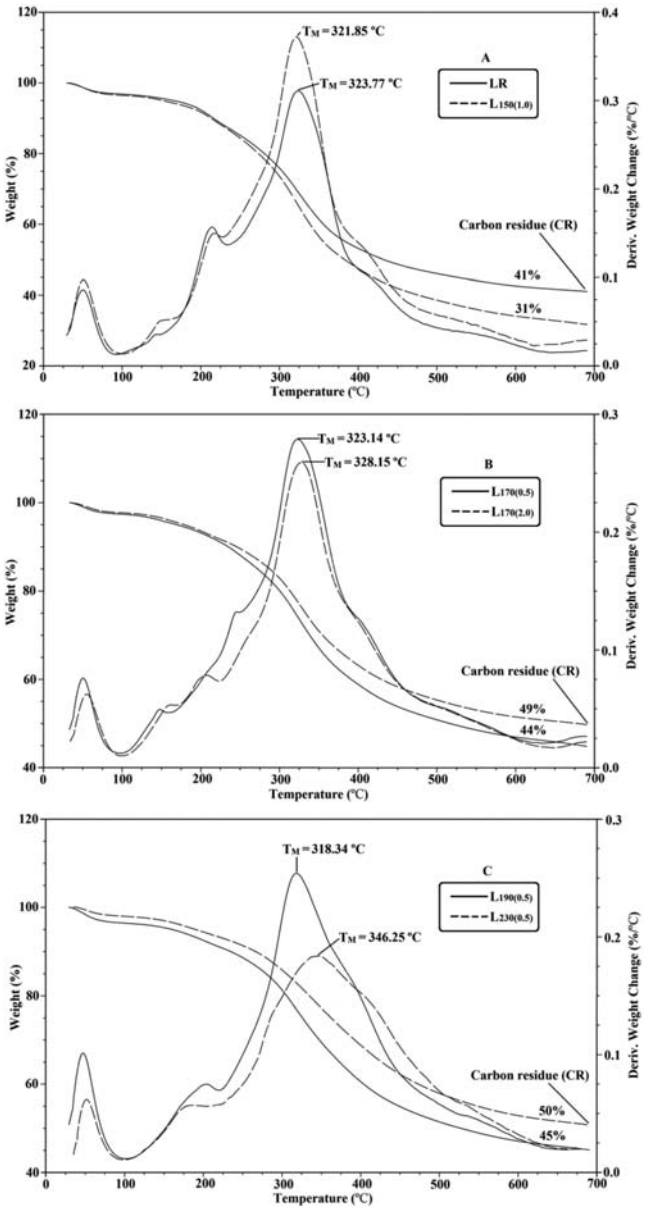

**Figure 6.** Thermogram of the lignins obtained from the integrated process under various processing conditions.

The $T_M$ of the six ALs obtained from the integrated process existed in the higher $T_M$ range from 318.34 to 346.25 °C. A previous study demonstrated that the $T_M$ is positively correlated with the corresponding molecular weight, suggesting that the initial reaction contained the deformation of the weaker C−O bond in the *β-O*-4 unit during the lignin decomposition.[42] In this study, the relationship between $T_M$ and molecular weight reflected only in the ALs extracted from the HTP residue at the mild conditions; however, when the HTP condition became harsh, the lignin extracted contained more condensed units, which in turn affected the corresponding $T_M$. In addition, "condensed lignin" was also reported to be correlated to "carbon residue (CR)".[36] As shown in Figure 6, the CRs were 44% for $L_{170(0.5)}$ and 49% for $L_{170(2.0)}$ at 700 °C as the HTP time increased from 0.5 to 2.0 h at 170 °C (Figure 6B). Similarly, when the HTP temperature further increased from 190 to 230 °C for 0.5 h (Figure 6C), the higher CR was found in $L_{230(0.5)}$ (50%) than in $L_{190(0.5)}$ (45%). That is, the CR was positively related to the "condensed lignin" of the ALs, which was revealed by the $^{31}$P NMR results aforementioned. These facts suggested that lignin with high CR was produced at the harsh HTP conditions.[36] However, only a small amount of condensed structures was observed in the ALs at the mild conditions (HTP temperature <170 °C). Therefore, besides the factor of "condensed structures", the CR in LR was also affected by other factors, such as ash and inorganic salt in plant cell wall.[43] This was why the CR in the LR was higher than that of $L_{150(1.0)}$, which even contained a slightly high content of condensed structures.

In summary, the present study demonstrated that the hydrothermally pretreated conditions had significant effects on the subsequent alkali lignin isolation and their chemical structures and properties. It was found that the alkali lignin with a high yield and purity could be obtained from the HTP residue under a high temperature and a short time (190 °C, 0.5 h). Meanwhile, NMR and molecular weight analysis suggested that the cleavage of the *β-O*-4 linkages and the degradation of *β-β* and *β*-5 linkages occurred during the integrated process, especially at the harsh conditions. Depolymerization and condensation reactions mainly occurred at higher temperatures. In addition, the thermostability was positively related to its molecular weight but also affected by the inherent structures, such as *β-O*-4 linkages and condensed units. However, as an integrated biorefinery process for XOS, high-purity lignin, and bioethanol, the optimal condition for the integrated process should be balanced along with some other aspects, such as cost, operability, and target product, to achieve overall goals. In short, an enhanced understanding of lignin structure features during the integrated process will be beneficial to value-added applications of abundant lignin fractions in a biorefinery process.

# Quantitation of Sugar Content in Pyrolysis Liquids after Acid Hydrolysis Using High-Performance Liquid Chromatography without Neutralization

Patrick A. Johnston[†] and Robert C. Brown*[,†,‡]

[†]Bioeconomy Institute and [‡]Department of Mechanical Engineering, Iowa State University, Ames, Iowa 50011, United States

**ABSTRACT:** A rapid method for the quantitation of total sugars in pyrolysis liquids using high-performance liquid chromatography (HPLC) was developed. The method avoids the tedious and time-consuming sample preparation required by current analytical methods. It is possible to directly analyze hydrolyzed pyrolysis liquids, bypassing the neutralization step usually required in determination of total sugars. A comparison with traditional methods was used to determine the validity of the results. The calibration curve coefficient of determination on all standard compounds was >0.999 using a refractive index detector. The relative standard deviation for the new method was 1.13%. The spiked sugar recoveries on the pyrolysis liquid samples were between 104 and 105%. The research demonstrates that it is possible to obtain excellent accuracy and efficiency using HPLC to quantitate glucose after acid hydrolysis of polymeric and oligomeric sugars found in fast pyrolysis bio-oils without neutralization.

**KEYWORDS:** *HPLC, biomass, bio-oil, acid hydrolysis, levoglucosan, fast pyrolysis, carbohydrates*

## INTRODUCTION

Direct liquefaction is the thermal decomposition of solid organic material into condensable vapors, liquids, or solutions of organic compounds. Examples include fast pyrolysis, solvent liquefaction, and hydrothermal processing. Under appropriate conditions, direct liquefaction can depolymerize lignocellulosic biomass into monosaccharides or disaccharides.[1] Sugars have not received much attention because they have not traditionally been thought to be an important product of direct liquefaction and the difficulty of measuring them in the complex matrix of the liquid products of direct liquefaction.

We are developing analytical methods for measuring sugars in the products of direct liquefaction with a particular focus on bio-oil, the liquid product from the fast pyrolysis of lignocellulosic biomass. Fast pyrolysis is the thermal decomposition of organic compounds in the absence of oxygen at temperatures in the range of 400−600 °C.[2,3] Products include liquids (55−60 wt %), gases (12−22 wt %), and char (16−20 wt %).[4−6] The liquids are a complex mixture of organic acids, alcohols, aldehydes, ketones, phenols, carbohydrates, esters, lignin oligomers, and water.[3] The carbohydrates include monosaccharides and anhydrosugars, most prominently levoglucosan. Usually the yield of levoglucosan from the pyrolysis of lignocellulosic biomass is only a few percent, but Kuzhiyil et al.[1] found that infusing biomass with a weak mineral acid solution prior to pyrolysis increased levoglucosan yields from the cellulose fraction to as much as 59 wt %. These sugars can be upgraded into transportation fuels and chemicals via fermentation to alcohols, catalytic synthesis to hydrocarbons, dehydration to heterocyclic aldehydes (furfurals) and aromatics (furans), and aqueous-phase re-forming to produce alkanes as building blocks of gasoline.[3,7]

Analytical techniques such as high-performance liquid chromatography (HPLC) are commonly used to identify and quantitate sugar concentrations by hydrolyzing oligosaccharides and levoglucosan to glucose.[8,9] However, these traditional HPLC methods can be cumbersome. Methods such as ASTM E1758 "Standard Method for the Determination of Carbohydrates by HPLC" and the National Renewable Energy Laboratory's (NREL) "Determination of Structural Carbohydrates in Biomass" require a neutralization step after hydrolyzing polysaccharides and oligosaccharides to glucose.[10,11] Researchers analyzing wood sugar using other liquid chromatography techniques have been successful in performing analysis without neutralization. Petterson et al.[12] performed wood sugar analysis using anion-exchange chromatography with a pulsed amperometric detector (PAD) after hydrolysis without neutralization. The main problem with the conventional methods of analysis using neutralization is the loss of sugars if the pH is not carefully monitored. The NREL methodology states: "Samples should never be allowed to exceed a pH of 9, as this will result in a loss of sugars".[10] Miller[13] showed spectrophotometer evidence that a significant reduction of glucose was observed with increasing concentrations of sodium hydroxide. Rover et al.[14] determined that a 7% decrease of sugar was observed when the pH was increased to 11. A new HPLC method recently established at Iowa State University (ISU) enables researchers to avoid the neutralization step. Hence, total sugar in lignocellulosic fast pyrolysis oils can be analyzed more rapidly. The new method also helps to prevent degradation and loss of sugars that can sometimes result from neutralization if the pH is not carefully monitored.[10]

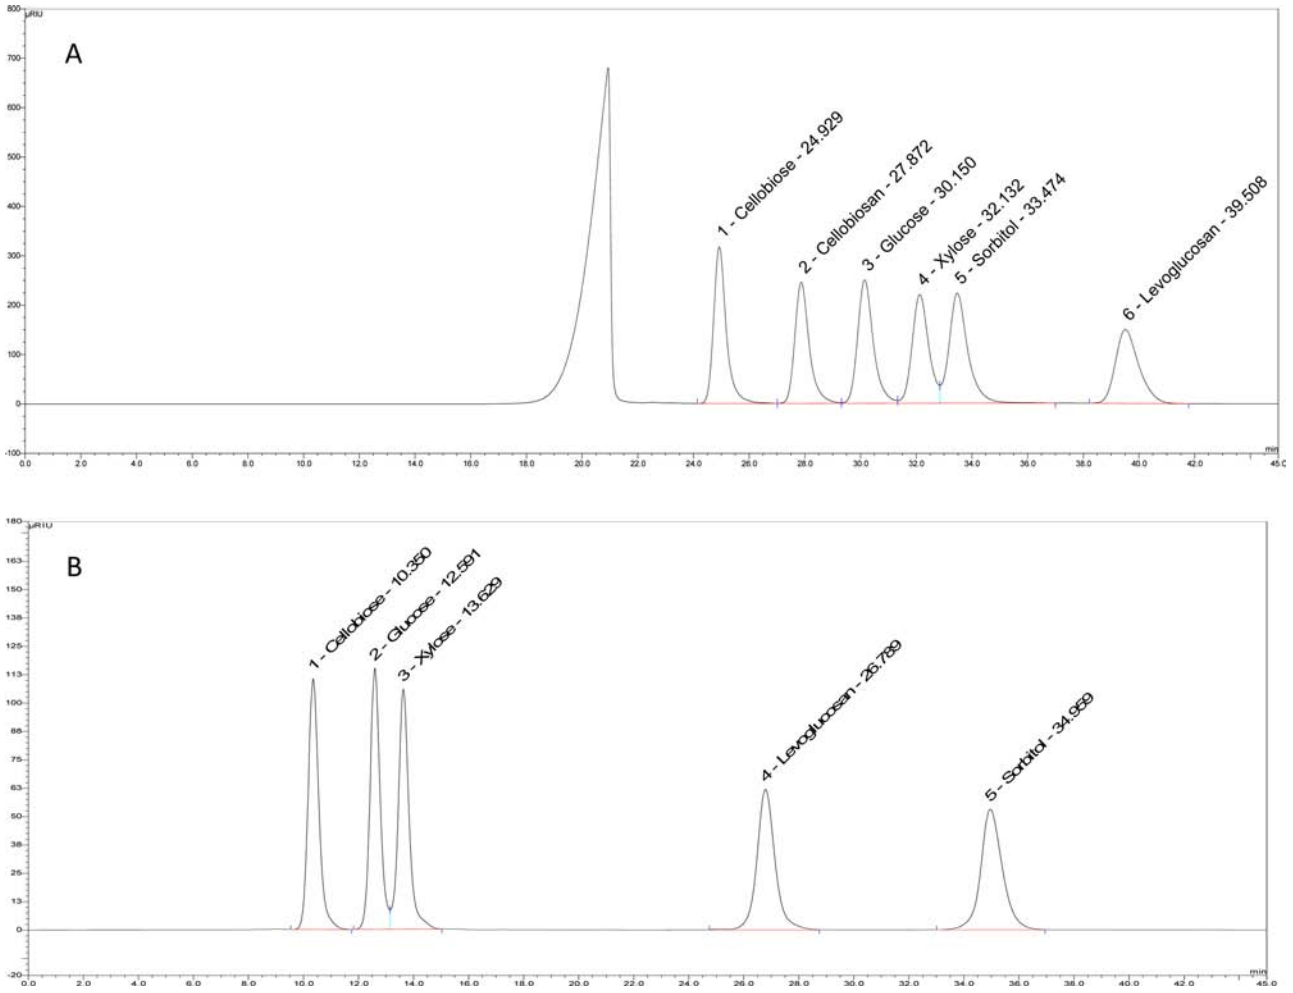

**Figure 1.** Comparison of standard compounds using HPLC: (A) acidic hydrolysate (new method); (B) neutralized hydrolysate (traditional method).

## MATERIALS AND METHODS

**Reagents and Standards.** Levoglucosan and cellobiosan were purchased from Carbosynth (Compton, Berkshire, UK) and had purities of ≥99.0%. Glucose and xylose were purchased from Thermo Fisher Scientific (Waltham, MA, USA) and had purities ≥98.0%. Cellobiose and sorbitol were purchased from Acrōs Organics (Thermo Fisher Scientific) and had purities of ≥99.0 and ≥98.5%, respectively. All samples and standards solutions were prepared using ultrapure 18.2 MΩ deionized water from a Barnstead E-Pure system (Thermo Fisher Scientific). The sulfuric acid used in all experiments was certified 10 N with an assay of 9.95−10.05 (Thermo Fisher Scientific).

**Pyrolysis Liquid Samples.** The pyrolysis liquid used in this study was produced using a fast pyrolysis auger reactor and switchgrass feedstock.[15,16] The reactor was a benchtop 2 kg/h screw (auger) type fast pyrolysis reactor. The feedstock is first mixed with the heat carrier media in the reactor. After the biomass has been thermochemically processed, the particulate matter (char) is removed from the gas by two cyclones. In the final stages the gases are condensed out at different temperatures to produce four fractions of bio-oil. The polysaccharide-rich portion was found mainly in the first two condensers and electrostatic precipitator (ESP) stage fractions.

**Acid Hydrolysis of Bio-Oil Samples.** The anhydro and other polymeric/oligomeric sugars in the fast pyrolysis bio-oil were acid hydrolyzed with 400 mM $H_2SO_4$ at 125 °C for 44 min to glucose.[17] Hydrolysis conditions were based on the previous work of Bennett et al.[17] Aliquots of 6 mL of 400 mM $H_2SO_4$ and 60 mg of bio-oil were added to sealed glass vials. Pure compounds of levoglucosan and cellobiosan were used as check standards to determine complete hydrolysis. These standards were hydrolyzed under the same conditions as the samples to establish complete hydrolysis to glucose and used as reference standards. The reference standards had purities of ≥99.0%. After hydrolysis, all samples were filtered with a 0.45 μm glass microfiber (GMF) syringe filter (Whatman, Pittsburgh, PA, USA) before HPLC analysis. With the traditional method an extra neutralization step was completed before the filtration. The neutralization step was completed as per ASTM E1748 by adding calcium carbonate slowly until a pH of between 5 and 6 was attained. The samples were filtered with a 0.45 μm GMF syringe filter before HPLC analysis.

**Instrumentation.** The HPLC system used for the experiments was a Dionex Ultimate 3000 LC system (Sunnyvale, CA, USA) with a quaternary analytical pump and a Shodex refractive index (RI) detector (New York, NY, USA). Two different types of columns were used in the experiments. The analytical columns used were either a 300 mm × 7.7 mm i.d, 8 μm, HyperRez XP Carbohydrate (Thermo Fisher Scientific) or a 300 mm × 7.8 mm i.d., 9 μm, Aminex 87P (Bio-Rad, Hercules, CA, USA). The guard column for the Aminex was a Micro-Guard de-ashing cartridge with a de-ashing holder (Bio-Rad). The guard column for the HyperRez was a Carbohydrate $H^+$ cartridge with a guard holder (Thermo Fisher Scientific). The guard columns were used to eliminate possible interferences caused by anions and cations. The instrument parameters for the HyperRez were as follows: The mobile phase was ultrapure 18.2 MΩ deionized water with a flow rate of 0.2 mL/min, and the column temperature was set at 55 °C. The instrument parameters for the Aminex column were as follows: The mobile phase was ultrapure 18.2 MΩ deionized water with a flow rate of 0.6 mL/min, and the column temperature was set at 80 °C. The

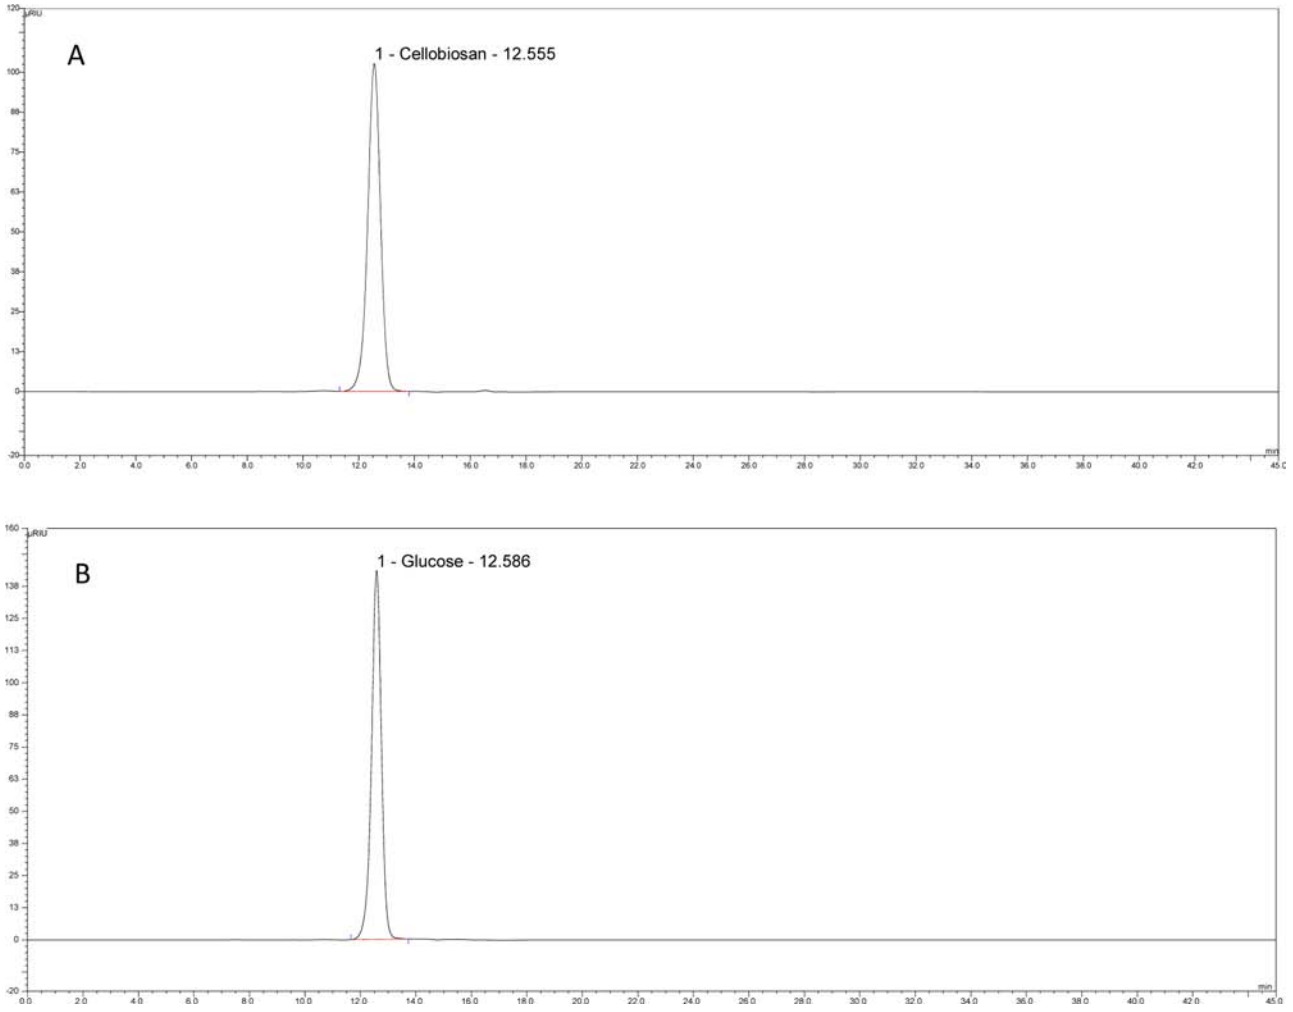

**Figure 2.** Comparison of equivalent retention times of standard compounds (A) cellobiosan and (B) glucose with the traditional method.

injection amount for the HyperRez column was 25 $\mu$L and the Aminex column was 20 $\mu$L.

## RESULTS AND DISCUSSION

A comparison of glucose, cellobiosan, cellobiose, levoglucosan, sorbitol, and xylose standard compounds using both the Aminex 87P and the HyperRez columns is displayed in Figure 1. The concentration of the standard was approximately 10 mg/mL.

A complete set of calibration standards using glucose, cellobiosan, cellobiose, levoglucosan, sorbitol, and xylose was performed in duplicate on the HPLC using the HyperRez column. The same sugars, with the exception of cellobiosan, were measured on HPLC with the Aminex column. Cellobiosan has almost the exact same retention time as glucose (Figure 2). Because the acid hydrolysis reaction will convert the cellobiosan to glucose, this compound is not necessarily needed in the calibration standard. Its absence would, however, be an issue with the conventional column because incomplete hydrolysis of cellobiosan could give falsely high readings for glucose. The calibration curves had 12 points (same concentration in duplicate) in the range of approximately 0.5−10 mg/mL. The coefficient of determination for all standard compounds on both the HyperRez and Aminex columns was >0.999. Check standards were tested after each set of samples was complete. All samples were hydrolyzed in duplicate, and triplicate injections were performed on each sample. The results displayed are based on total polymeric/oligomeric sugars that are converted to glucose after acid hydrolysis. Figure 3 displays the sample chromatograms for both methods after hydrolysis. The sugar yield in milligrams per milliliter was calculated as percent (w/w) using the density of the solution used in the sample preparation. The result for the traditional method was 11.3% (w/w) and that for the new method was 11.2% (w/w). The two methods displayed equivalent results.

Verification standards were tested before and after each set of tests. Reference standards of pure levoglucosan and cellobiosan were hydrolyzed with each set of samples to ensure complete hydrolysis conditions. All samples were tested in duplicate with triplicate injections. The percent RSD for the Aminex column was 1.03% and that for the HyperRez column was 1.13%.

Levoglucosan was added to each bio-oil sample and hydrolyzed in duplicate and analyzed in triplicate. The average recovery yields of the two levoglucosan-spiked samples with a 95% confidence interval were 105 ± 0.20 and 104 ± 0.49%. Levoglucosan recovery yields were very representative of the total amount of sample spiked in the solution.

Both columns had very good linearity and were able to resolve and separate the compounds of interest in the bio-oil samples. The new method produced total sugar results comparable to the traditional method. The HyperRez column,

dx.doi.org/10.1021/jf502250n | J. Agric. Food Chem. 2014, 62, 8129−8133

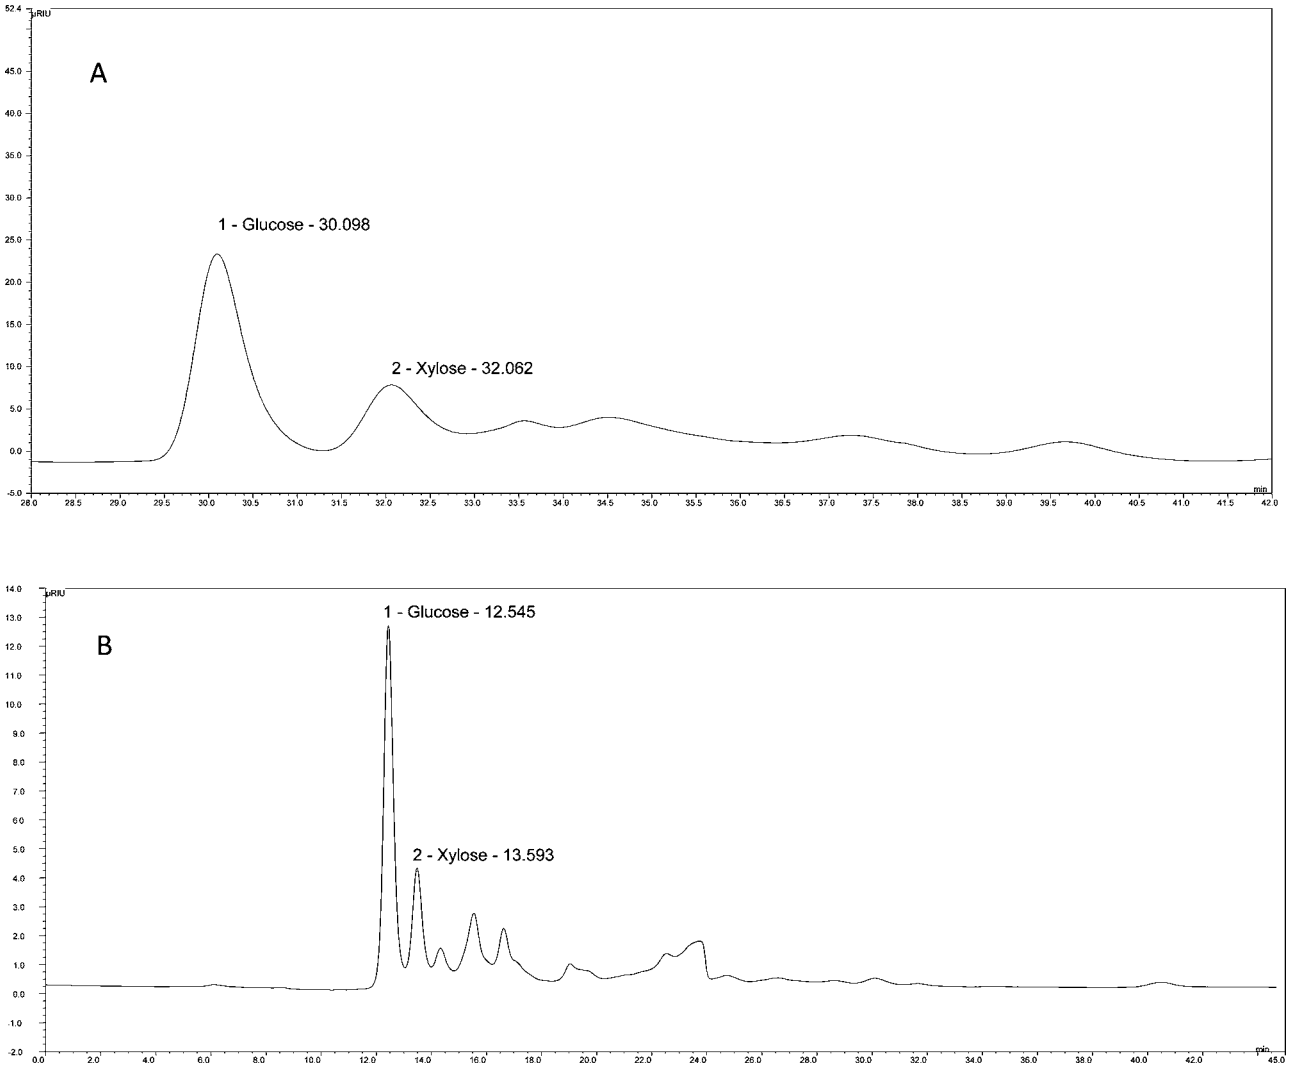

**Figure 3.** Comparison of samples using HPLC: (A) acidic hydrolysate (new method); (B) neutralized hydrolysate (traditional method).

however, offers two distinct advantages. It enables researchers and refineries to quickly analyze hydrolyzed sugar samples, bypassing the time-consuming and tedious neutralization step. The HyperRez column also eliminates possible degradation of sugars that can occur during the conventional neutralization step if pH levels are not closely monitored. Our research demonstrated that it is possible to obtain excellent accuracy and efficiency using HPLC to quantitate glucose after acid hydrolysis of polymeric and oligomeric sugars found in fast pyrolysis bio-oils without neutralization.

Supporting Information

**ABSTRACT:** The evolution of glyphosate-resistant weeds has recently increased dramatically. Six suspected glyphosate-resistant *Amaranthus tuberculatus* populations were studied to confirm resistance and determine the resistance mechanism. Resistance was confirmed in greenhouse for all six populations with glyphosate resistance factors (R/S) between 5.2 and 7.5. No difference in glyphosate absorption or translocation was observed between resistant and susceptible individuals. No mutation at amino acid positions G101, T102, or P106 was detected in the *EPSPS* gene coding sequence, the target enzyme of glyphosate. Analysis of *EPSPS* gene copy number revealed that all glyphosate-resistant populations possessed increased *EPSPS* gene copy number, and this correlated with increased expression at both RNA and protein levels. EPSPS $V_{max}$ and $K_{cat}$ values were more than doubled in resistant plants, indicating higher levels of catalytically active expressed EPSPS protein. *EPSPS* gene amplification is the main mechanism contributing to glyphosate resistance in the *A. tuberculatus* populations analyzed.

**KEYWORDS:** *glyphosate absorption, glyphosate translocation, EPSPS gene amplification, EPSPS gene expression, gene duplication, EPSPS enzyme activity, herbicide resistance*

## INTRODUCTION

*Amaranthus tuberculatus* (Moq.) Sauer var. *rudis* (Sauer) Costea & Tardif (common waterhemp) is a dioecious C4 weed that can grow up to 3 m in height with roots reaching a depth of 70 cm. It can occupy a radial area of 2 m with a growing rate of 0.11−0.16 cm per growing degree day.[1−3] The reported growth rate of *A. tuberculatus* is less than that for *Amaranthus palmeri*, but still higher than the values reported for other *Amaranthus* species.[4] The female plant can produce between 35,000 and 1,200,000 seeds during the growing season.[5] It prefers well-drained and nutrient-rich soils also well suited for agricultural production. Therefore, *A. tuberculatus* is an important weed, especially under drought stress conditions, and can vigorously compete with corn and soybean for water and nitrogen.[5,6] *A. tuberculatus* has also evolved resistance to several herbicide modes of action either separately or in combination, including inhibitors of (1) aromatic amino acid biosynthesis, (2) photosystem II, (3) branched-chain amino acid biosynthesis, (4) chlorophyll biosynthesis, and (5) carotenoid biosynthesis.[7−13]

Glyphosate, a broad-spectrum herbicide, acts on enolpyruvyl-5-shikimate-3-phosphate-synthase (EPSPS), the sixth enzyme in the plant shikimic acid pathway. It converts shikimate-3-phosphate (S-3-P) together with phosphoenolpyruvate (PEP) into enolpyruvalshikimate-3-phosphate (EPSP), a precursor in the formation of aromatic amino acids and many secondary aromatic plant metabolites.[14−16] Due to a missing feedback inhibition at this step, the S-3-P concentration in plants increases continuously after glyphosate treatment.[17] With its high-energy bonds, the phosphate group of S-3-P is unstable in plant cells and degrades into shikimic acid, which can be used as an early indicator of the inhibitory activity of glyphosate in plants.[18−21] EPSPS is most active in young, actively growing plant tissue; therefore, the highest shikimic acid can be measured in these tissues, and particularly in the meristems, after glyphosate treatment.[22,23]

Both target- and non-target-site-based resistance mechanisms are responsible for glyphosate resistance.[24] Alterations in the *EPSPS* gene sequence, specifically at the amino acid P106, have been reported in several glyphosate-resistant weeds, including *Eleusine indica* and *Lolium rigidum*.[25,26] Differences in glyphosate translocation have been found in other populations of *L. rigidum* and in *Lolium multiflorum*, *Sorghum halepense*, and *Conyza canadensis*.[27−30] Glyphosate translocation in these populations is mostly restricted within the treated leaves, resulting in significantly less translocation throughout the whole plant. In *C. canadensis* the reduced translocation is based on rapid glyphosate sequestration into vacuoles.[31] In a population of *L. multiflorum* found in Chile, the resistance is based on differences in the spray solution retention and foliar absorption.[32] Both a P106S mutation and reduced translocation were identified in a glyphosate-resistant *A. tuberculatus* population from Mississippi.[13]

Although many different glyphosate resistance mechanisms have been reported, new mechanisms continue to be identified, such as the *EPSPS* gene amplification in *A. palmeri* populations from Georgia and Mississippi, USA.[33−35] In these plants the *EPSPS* gene was amplified from 40- to >100-fold. The importance of gene amplification in conferring, for example, insecticide resistance has been well established;[36] however, the amplification of the *EPSPS* gene in a single *A. palmeri* population was the first case of herbicide resistance induced by this mechanism.[34] The *EPSPS* transcript abundance in untreated resistant plants was positively correlated with the genomic *EPSPS* gene copy number, suggesting no significant gene silencing of amplified genes. Amplified *EPSPS* genes were also translated into higher enzyme content.[34,35] Glyphosate resistance based on gene amplification or increased EPSPS activity in vitro also occurred in cell cultures reared on glyphosate containing media, in *Daucus carota* L., *Petunia hybrida*, *Nicotiana tabacum*, *Glycine max*, *Corydalis sempervirens*, and *Medicago sativa*.[37−41] However, plants derived from these cell cultures did not ultimately yield field-level glyphosate resistance.

The scope of the present work is to characterize the glyphosate resistance mechanism(s) in *A. tuberculatus* and compare the role of gene amplification between two related species, *A. tuberculatus* and *A. palmeri*. Populations collected from the field and described as being either susceptible or resistant to glyphosate were characterized without further inbreeding of resistance using biological (greenhouse dose response), physiological (glyphosate absorption and translocation), biochemical (shikimic acid content and EPSPS enzyme activity), and molecular (EPSPS gene copy number and expression) analyses to determine the glyphosate resistance mechanism.

## MATERIALS AND METHODS

Six different and still segregating *A. tuberculatus* populations collected between 2005 and 2009 from different fields in Missouri (MO) and Illinois (IL) (Supporting Information Table SI1) were assessed for their response to glyphosate. Previous results and the glyphosate resistance status of the field populations are described in Table SI1 of the Supporting Information. Six populations (IL-R, MO-R1, MO-R2, MO-R3, MO-R4, and MO-R5) were difficult to control in field, whereas the susceptible population, MO-S, was controlled by the recommended field rate of glyphosate.

The *A. tuberculatus* populations were sown in Petri dishes containing 0.7% agar type A (Sigma-Aldrich Inc., St. Louis, MO, USA). The plates were stored in the dark for 2 days at 4 °C to induce germination and were then transferred to the greenhouse at a photoperiod of 16 h light, 28 °C/8 h dark, 15 °C. At the cotyledon developmental stage, single seedlings were transplanted into a 2 cm diameter pot system and grown for about 3 weeks, before 200−250 uniform plants from each population were transplanted as single plants into 8 cm diameter plastic pots containing a peat/vermiculite mixture (Fafard 2B Mix, Agawam MA, USA). *A. tuberculatus* used for all further experiments was similarly cultivated using 4.5 cm Fertilpots containing a peat/loam 1:1 soil mixture. Plants were grown in the greenhouse at a photoperiod of 16 h light, 22 °C/8 h dark, 14 °C, with a light intensity of at least 220 $\mu$mol $m^{-2}$ $s^{-1}$ (Phillips Son-T AGRO). Watering and fertilization with 0.4% Wuxal Super solution (Wilhelm Haug GmbH & Co. KG, Ammerbuch, Germany) were performed as necessary to maintain vigorous plant growth.

**Response to Glyphosate.** A dose response study was performed to verify the previous reports of glyphosate resistance of the different *A. tuberculatus* populations. The dose response relationship was established according to described methods.[42−45] For each population plants of uniform size and appearance were selected, and nine plants were treated with each glyphosate dose. All populations were treated together when they reached the growth stage defined as BBCH 16[46] to allow unbiased comparisons. Thirteen increasing doses of glyphosate [0, 22.5, 45, 90, 180, 360, 540, 720, 1080, 1440, 2880, 5760, 11520 g ae $ha^{-1}$ formulated as Roundup Weathermax, 660 g ae $L^{-1}$ glyphosate (Monsanto Co., St. Louis, MO, USA)] containing additional nonionic surfactant (0.5% v/v Activator 90, Loveland Industries Inc., Greeley, CO, USA) were applied using a stationary sprayer outfitted with Teejet 8001 nozzles at 280 kPa and a spray volume of 200 L $ha^{-1}$. The fresh weight of the above-ground plant material of each plant was determined 19 days after treatment (DAT).

Dose response curves based on fresh weight and shikimic acid assays were determined using the statistical program R and the drc package to calculate the four-parameter sigmoidal log−logistic dose−response model.[42,47] The calculated upper and lower limits were used in a second step to normalize raw data, allowing unbiased comparisons of dose response curves. The doses causing 50 and 90% effect on fresh weight reduction ($ED_{50}$ and $ED_{90}$, respectively) were calculated for each population. The resistance factor (R/S) for each population was calculated as the ratio between $ED_{50}$ value of the putative resistant population and the susceptible *A. tuberculatus* control population.

Shikimic acid content after glyphosate treatment is an early indicator for glyphosate-mediated plant injury,[17,23] so a shikimic acid accumulation dose response model was evaluated as a potential method to characterize the *A. tuberculatus* populations. Therefore, shikimic acid accumulation was determined 4 DAT in leaf disks from plants used to establish the glyphosate dose response experiments. Four 0.4 cm diameter leaf disks of the youngest fully expanded leaf of each plant were harvested, except for plants treated with 11520 g ae $ha^{-1}$ as these were severely stunted. The color reaction was measured at 380 nm on a 96-well plate reader (Biotek Synergy 4, Winooski, VT, USA) using previously described methods.[18,19]

**Glyphosate Absorption and Translocation.** Alterations in glyphosate absorption and translocation were evaluated in nine plants per population and time point in the *A. tuberculatus* populations MO-S, MO-R1, and IL-R. The application solution was adjusted to a final rate of 720 g ae $ha^{-1}$ glyphosate (Roundup Ultramax; 450 g ae $L^{-1}$ glyphosate; Monsanto Co., St. Louis, MO, USA) and radiolabeled glyphosate (phosphonomethyl-[$^{14}$C]) solution (50 mCi $mmol^{-1}$, American Radiolabeled Chemicals, St. Louis, MO, USA). Twelve 0.5 $\mu$L droplets, each containing 1000 Bq $\mu L^{-1}$, were spotted onto the youngest fully expanded leaf. The treated plants were moved to a growth chamber (model 1401, Rubarth Apparate GmbH, Laatzen, Germany) with a photoperiod of 16 h light and a light intensity of 120 $\mu$mol $m^{-2}$ $s^{-1}$ (Iwasaki Eye MT150D, Middlesex, UK) at a temperature of 25/18 °C day/night and a constant relative humidity of 70%.

To determine the glyphosate absorption, treated leaves were removed from the plant 0, 8, 24, 48, 72, and 96 h after treatment (HAT). They were rinsed for 20 s in 3 mL of 0.1% Triton X-100 and 4% methanol, and radioactivity was measured using a scintillation counter (the scintillation liquid was Rotiszint Eco Plus, Carl Roth GmbH + Co. KG, Karlsruhe, Germany; the scintillation counter was a Packard 2000CA TriCarb Liquid Scintilation counter, Downers Grove, IL, USA).

Glyphosate translocation was quantitatively measured by combusting different plant parts. The harvest time points were set at 0, 8, 24, 48, 72, and 96 HAT for the populations MO-S and MO-R1. The IL-R population had the same harvest time points except for 96 HAT, which could not be collected due to technical problems. Soil was washed off the roots at harvest, and plants were sectioned into roots, shoot above treated leaf, treated leaf, and remaining shoot material. The sectioned plant material was dried at 60 °C and oxidized using a biological sample oxidizer (OX-500, R. J. Harvey Instrument Corp., Hillsdale, NJ, USA) and released $^{14}CO_2$ was determined (Packard 2000CA TriCarb liquid scintillation counter). Values for absorption and translocation were calculated as percent of total applied radioactivity. Glyphosate absorption and translocation were analyzed using nonlinear regression in the R statistical program.[48]

Table 1. $ED_{50}$ and $ED_{90}$ Values and R/S Ratios of *A. tuberculatus* Populations ($n$ = 9) to Glyphosate; Dose Response Relationship in Shikimic Acid Concentration 4 DAT and Fresh Weight Assessment 19 DAT[a]

[a]Means with the same letter are not statistically different ($P$ = 0.05).

To visualize differences in glyphosate transport, autoradiographs were obtained at 8, 18, 48, and 96 HAT. Treated plants of each population and at each time point including the washed leaf and rinsed root were fixed on a paper sheet (20 × 40 cm) and pressed until complete dryness. The dry plants were exposed to a phosphoimaging film (Fujifilm BAS-MS-2040) for 48 h before image detection (BAS-reader 1000, Fujix, Japan). Background reduction and image evaluation were performed with AIDA Image Analyzer software 4.19 (Raytest, Germany).

***EPSPS* Target-Site Detection.** Pyrosequencing was used to detect target-site mutations at G101, T102, or P106 in the *A. tuberculatus* *EPSPS* gene sequence with modifications.[49] The DNA was purified with the Qiagen DNeasy Plant mini kit in eight biological and three technical replicates each. For the sequencing reactions a 195 bp long DNA fragment was amplified using the forward primer gly.a.3f (5′ ATGTTGGACGCTCTCAGAACTCTTGGT 3′) and the 5′-biotinylated reverse primer gly.a.4r (BT - 5′ TGAATTTCCTCCAGCAACGGCAA 3′) in a polymerase chain reaction (PCR). The PCR conditions were 15 min of preincubation at 95 °C, followed by 45 cycles at 94 °C denaturating step (30 s), 55 °C annealing temperature (40 s), 70 °C elongation (40 s)m and a final extension step for 10 min at 70 °C (Eppendorf Mastercycler ep Thermal Cyclers, Hamburg, Germany). The primer gly.pyro.a1.1 (5′ GGAAATGC(AT)GGAACAGCGATGCG 3′) was used to sequence the coding sites G101 and T102, whereas the primer gly.pyro.a1.2 (5′ CAACTTTT(CT)CTTGGAAATGC 3′) was used to sequence the coding site P106 in a Pyromark PSQ 96 device. Evaluation was in all cases done with the manufacturer's software (Qiagen, Hilden, Germany).

**Relative Genomic *EPSPS* Gene Copy Number.** The *EPSPS* gene copy number in the *A. tuberculatus* genomic DNA was determined as previously described with minor modifications.[34] Due to the high homology of *EPSPS* and *ALS* genes of both closely related species, the same quantitative PCR (qPCR) method was used to determine the relative *EPSPS* gene copy number in 16 *A. tuberculatus* plants of each population. The DNA was purified using the Promega Wizard Magnetic 96 DNA Plant system kit (Madison, WI, USA) according to manufacturer's instructions. The comparison was done at a level of 12 times the standard deviation of the background by using the model of crossing points with the manufacturer's software (Roche LightCycler 480 1.5, Mannheim, Germany). The difference between the *ALS* gene and the *EPSPS* gene was expressed as relative *EPSPS* gene amount in relation to the *ALS* reference gene ($2^{\Delta Cp}$).[34,50,51] A calibration curve was performed using increasing DNA concentrations to determine the amplification efficacy of each primer combination.

***EPSPS* Expression Characteristics.** Plants at four-leaf stage, BBCH 14, were sprayed with 720 g ae $ha^{-1}$ glyphosate (Roundup Ultramax, 450 g ae $L^{-1}$ glyphosate) using a single-nozzle overhead track sprayer outfitted with Teejet 8001 nozzle at 280 kPA and a spray volume of 200 L $ha^{-1}$. Plant samples from the shoot tip were taken directly before treatment and at 4, 8, 24, and 48 HAT from both treated and untreated plants maintained under identical conditions.[52] RNA was purified with a RNeasy mini kit (Qiagen, Hilden, Germany) according to the manufacturer's instruction, followed by DNase I (Invitrogen, Carlsbad, CA, USA) treatment. The cDNA synthesis was performed using the Superscript kit (Invitrogen). The expression of *EPSPS* and *ALS* mRNA was determined using the previously described method.[34] A 242 bp long fragment from the *Actin* gene was used as an additional reference gene. The *Actin* gene fragment was amplified with the primer pair act.a.1f (5′ GACTCTGGTGATGGTGTGAGTC 3′) and act.a.2r (5′ GAGCTGCTCTTGGCAGTCTC 3′). Evaluation was done as previously described with the manufacturer's software (Roche LightCycler 480 1.5). The obtained crossing points of the *Actin* fragment were tested for statistical differences in all time points with a $t$ test ($P$ = 0.05) for the populations MO-S, MO-R1, and IL-R and for all time points. Because no changes in expression were observed, the *Actin* gene was used as a stably expressed reference gene. The values obtained for the *Actin* gene were tested for their homogeneity by ANOVA ($t$ test). The relative expression values of the *EPSPS* and *ALS* genes were given by the ratio of their respective absolute values with those obtained for the *Actin* gene. Significant differences between the relative *ALS* and *EPSPS* gene expression values at different time points were tested by ANOVA at a probability value of $P$ = 0.05 (Sigmaplot 11.0, Erkrath, Germany).

**EPSPS Enzyme Activity.** The EPSPS enzyme activity was measured in crude extracts prepared from the youngest leaves and shoot tip of actively growing plants according to previously described methods with minor modifications.[53] The final extract was mixed with 20% glycerol (v/v) and stored at −20 °C. The protein concentration was determined in a Bradford assay (Bio-Rad, Hercules, CA, USA), and bovine serum albumin (BSA) (Sigma-Aldrich Inc., St. Louis, MO, USA) was used to establish the calibration curve.[54] Results are given as micrograms of BSA equivalent protein. The EPSPS activity was measured by monitoring the $P_i$ release of the crude protein extract.[34] The color reaction was continuously measured at 360 nm in a Fluostar Optima 96-well plate reader to determine EPSPS enzyme parameters. The S-3-P concentration was held constant at 0.5 mM while the PEP concentration was varied (0, 0.016, 0.031, 0.0625, 0.125, 0.25, and 0.5 mM PEP). The experiments were conducted with two technical and at least two biological replicates of each population (IL-R and MO-S). A calibration curve was used to express the enzyme activity as micromoles $P_i$ released. Enzyme kinetic parameters were determined using the linear Lineweaver−Burk model[55] and Sigmaplot 11.0. A probability value of $P < 0.05$ was chosen to determine significant differences in a $t$ test between populations (SigmaPlot 11.0).

## RESULTS

**Response to Glyphosate.** The fresh weight of treated plants of *A. tuberculatus* populations IL-R, MO-R1, MO-R2, MO-R3, MO-R4, and MO-R5 assessed 19 DAT (Supporting Information Figure SI1) showed $ED_{50}$ values between 317 and 460 g ae $ha^{-1}$, whereas the $ED_{50}$ of the susceptible population MO-S was 61 g ae $ha^{-1}$ (Table 1). None of the susceptible plants would survive labeled glyphosate rates, as their $ED_{90}$ values were below 300 g ae $ha^{-1}$ glyphosate (Table 1). The resistant populations were clustered together with average $ED_{50}$ values of 396 g ae $ha^{-1}$ and a resistance factor of >5-fold. Some

[a]Data fitted to the rectangular hyperbolic model. No significant statistical differences (ns) were observed between MO-R1 and IL-R compared to MO-S. NA = not applicable.

plants within these populations survived dose rates of 720 g ae $ha^{-1}$ glyphosate, as their $ED_{90}$ values were between 1350 and 3000 g ae $ha^{-1}$ glyphosate.

**Glyphosate Absorption and Translocation.** Total average recovery of applied radioactivity was 90% in the glyphosate absorption and translocation experiments. Approximately 62.2 ± 2.2% of the total applied radioactivity was the maximum absorption of the *A. tuberculatus* populations MO-S, MO-R1, and IL-R (Table 2; Supporting Information Figure SI2). On average 46.4 ± 7.5 h was necessary to absorb 50% of the maximum amount of radioactivity. No significant differences in absorption were observed between glyphosate-susceptible and -resistant populations at any time points analyzed.

Radioactivity was detected in all plant parts 8 HAT, and concentration increased with time (Supporting Information Figure SI3). Translocation occurred at a nearly constant rate over the 96 h time frame, especially into the root. There were no differences between populations in total amount of glyphosate translocated to the different plant tissues among the investigated populations MO-S, MO-R1, and IL-R (Table 2; Supporting Information Figure SI3). The average maximum amounts of translocation into the root, shoot, and shoot tip and in the applied leaf were 0.65 ± 0.1, 4.8 ± 0.6, 3.1 ± 0.7, and 40 ± 2.1% of total applied radioactivity, respectively. There were also no significant differences in the rate of translocation. The times to reach 50% of the maximum amount of radioactivity ($T_{50}$) in the root, shoot, shoot tip, and applied leaf were 0.55 ± 7.1, 104 ± 43, 242 ± 113.3, and 52 ± 11.7 h after application, respectively. Significant differences among populations were solely obtained from the calculation of the time needed to reach 90% of the maximum translocated amount ($T_{90}$) in the shoot tip. The glyphosate-resistant populations MO-R1 and IL-R absorbed significantly more radioactivity in the shoot tip 72 HAT (2.6 ± 0.6 and 2.3 ± 0.3%, respectively) than the glyphosate-susceptible population MO-S (1.5 ± 0.4%). At $T_{50}$ no significant differences between resistant and susceptible populations were found in translocation to the shoot tip (Table 2).

The autoradiographs in Figure 1 revealed no differences in the translocation of $^{14}$C-labeled glyphosate throughout susceptible and resistant plants. Radioactivity was distributed throughout the plant by 8 HAT, with the highest radioactivity found in the youngest and most actively growing plant parts. The amount of radioactivity in older and less active plant parts and the overall amount in each tissue increased with time. Additionally, no localized differences in directed translocation into leaf margins or into any specific plant organs were observed in these glyphosate-resistant *A. tuberculatus* populations.

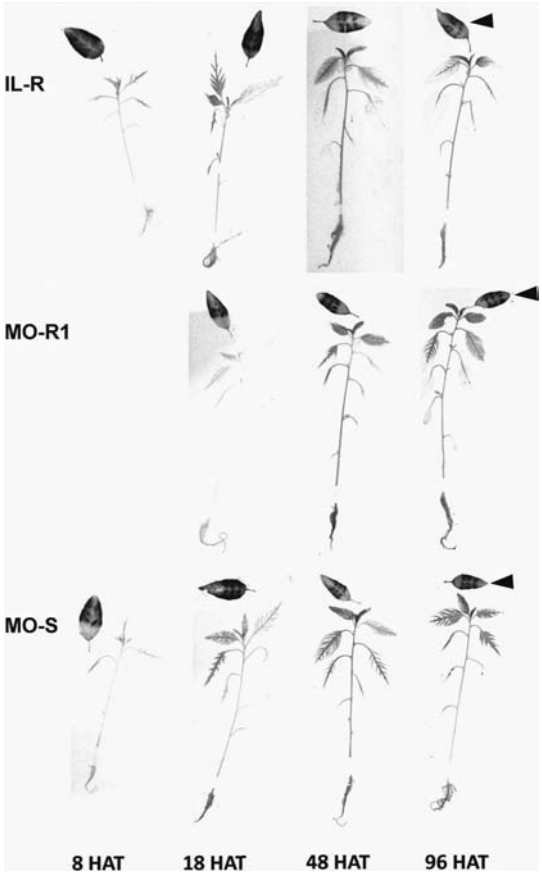

**Figure 1.** Phosphorimaging visualization of $^{14}$C-glyphosate translocation in *A. tuberculatus* populations IL-R, MO-R1, and MO-S at 8, 18, 48, and 96 HAT. Arrow heads indicate the treated leaves at 96 HAT, rinsed at harvest time and dried separately. Each plant is representative of five plants tested at each time point. Increasing color intensity indicates a higher amount of radioactivity within the plant material.

**Mutations in the *EPSPS* Coding Sequence.** Using pyrosequencing to genotype multiple individuals from each glyphosate-resistant *A. tuberculatus* population, no DNA sequence mutations were found in any individual that altered the predicted EPSPS amino acid sequence at position G101, T102, or P106 (data not shown).

***EPSPS* Gene Amplification.** Comparable amounts of *EPSPS* and *ALS* genes in the genome of the susceptible *A. tuberculatus* population MO-S were measured with 1.1 ± 0.4 relative *EPSPS* gene copies (Figure 2). The glyphosate-resistant plants had on average a higher amount of *EPSPS* genes in their genome, from 2- to 8-fold (Figure 2). IL-R had the highest *EPSPS* gene amplification with on average 7.1 ± 0.84 relative *EPSPS* genes. The populations collected in Missouri had on average 2.4 ± 0.11 relative *EPSPS* genes in the genome. The highest gene amplification found in a single resistant plant of the Missouri populations was 6 times the *ALS* gene, but each population also contained some individuals bearing an equal *EPSPS* and *ALS* copy number.

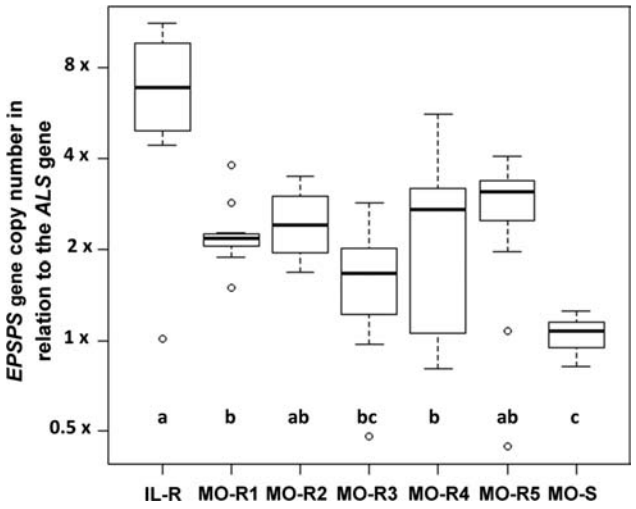

**Figure 2.** Genomic *EPSPS* gene copy number in *A. tuberculatus* populations IL-R, MO-R1, MO-R2, MO-R3, MO-R4, MO-R5, and MO-S relative to the *ALS* gene. Individual plants were not selected for their glyphosate resistance before *EPSPS* gene copy number measurement ($n$ = 16); IL-R = 7.1 ± 0.84 relative *EPSPS* genes; MO-R1 = 2.3 ± 0.15; MO-R2 = 2.5 ± 17; MO-R3 = 1.7 ± 0.15; MO-R4 = 2.7 ± 0.4; MO-R5 = 2.9 ± 0.23; and MO-S = 1.1 ± 0.04. Different letters indicate significant differences among populations ($P$ = 0.05).

To study whether amplified *EPSPS* genes were expressed differently after glyphosate application, the *EPSPS* mRNA expression in untreated plants was compared to those of plants treated with the recommended field rate of 720 g ae ha$^{-1}$ glyphosate. The *Actin* gene and the *ALS* gene were tested for their stable expression among time points and individual plants and found to be suitable as stably expressed reference genes. The *EPSPS* mRNA expression was significantly higher in both *A. tuberculatus* populations MO-R1 and IL-R compared to MO-S ($P$ = 0.05), but there were no significant *EPSPS* expression changes at any time point within a population (Table 3).

**EPSPS Enzyme Activity.** The EPSPS $K_m$ (app) (PEP) values of MO-S and IL-R were 58.49 and 59.92 μM PEP, respectively (Table 4). The lack of difference suggests that no alterations in the EPSPS amino acid sequence influencing the enzyme activity occur in the IL-R population. Significant differences were found in the $V_{max}$ values with a 2.4 times higher $P_i$ release in IL-R ($V_{max}$ of 0.15 μmol $P_i$ s$^{-1}$) than in MO-S ($V_{max}$ of 0.64 μmol $P_i$ s$^{-1}$). Differences were also obtained in the total EPSPS activity per equivalent total protein present in crude extracts. The $K_{cat}$ value of the resistant population IL-R was 3.7 times higher than the $K_{cat}$ value of the susceptible population MO-S, whereas the $K_{cat}$ values of MO-R1, MO-R3, and MO-R4 were about 2 times higher (Table 4). These differences are due to the higher EPSPS enzyme quantity present in the total extract.

## DISCUSSION

**Glyphosate Resistance of the *A. tuberculatus* Populations.** Glyphosate resistance was confirmed in the tested *A. tuberculatus* populations IL-R, MO-R1, MO-R2, MO-R3, MO-R4, and MO-R5 with an average RF of 6.5 ± 0.33, which is at a lower level than found in other glyphosate-resistant *A. tuberculatus* or *A. palmeri* populations.[10,13,33] The 2-fold higher sensitivity of the susceptible population MO-S in comparison to previous results for the same population[10] might explain part of this difference and shows also the impact of environmental conditions on plant susceptibility to herbicides, including glyphosate. Nevertheless, with an $ED_{90}$ value of 1096−2969 g ae ha$^{-1}$ several plants of the populations MO-R1, MO-R2, MO-R3, MO-R4, MO-R5, and IL-R will survive the recommended field rate of 720 g ae ha$^{-1}$ glyphosate and will be able to set viable seeds. Ongoing glyphosate selection pressure will most probably enable the further evolution of higher resistance factors in *A. tuberculatus*.

The accumulation of shikimic acid in plant tissue after glyphosate treatment can be used for an early determination of glyphosate efficacy.[17,23] In the present work shikimic acid content indicated the populations could be grouped according to their response to glyphosate into two different groups. The susceptible and resistant populations were clearly separated by the $ED_{50}$ values, with all resistant populations at least 2.8-fold more resistant than the susceptible population MO-S. This method is suitable to distinguish between resistant and susceptible plants. Also, the $ED_{50}$ values and the R/S factors calculated from the shikimic acid levels of the population MO-S and the different MO-R populations provide a reasonable correlation with the fresh weight data assessed 19 DAT. In comparison, the weaker correlation between the shikimic acid response after glyphosate treatment and the fresh weight data

**Table 3. *EPSPS* Gene Expression Expressed as Fold-Change Relative to the *ALS* Gene (Standard Error in Parentheses) in Individuals ($n$ = 4) of the *A. tuberculatus* Populations IL-R, MO-R1, and MO-S at Different Time Points after Glyphosate Treatment (720 g ae ha$^{-1}$)[a]**

[a]Individuals were not selected for glyphosate resistance prior to *EPSPS* expression measurement.

Table 4. Native EPSPS Protein Activity of Plants of the *A. tuberculatus* Populations MO-S, IL-R, MO-R1, MO-R3, and MO-R4[a]

| | MO-S | IL-R | MO-R1 | MO-R3 | MO-R4 |
|---|---|---|---|---|---|
| $K_M$(app) (PEP) ($\mu$M) | 58.49 ns | 59.92 ns | nd | nd | nd |
| $V_{max}$($\mu$mol $P_i$ $s^{-1}$) | 0.064 a | 0.15 b | nd | nd | nd |
| $K_{cat}$ ($\mu$mol $P_i$ $\mu g^{-1}$ protein) | 11.43 a | 41.25 b | 22.5 c | 22.75 c | 21.75 c |

[a]Plants used for the enzyme extraction were not selected for their glyphosate resistance. Values are the mean of two biological replications with two technical replicates each. Samples with different letters are significantly different ($P = 0.05$); ns, not significant; nd, not determined. Crude protein is given in $\mu$g BSA equivalent.

for the IL-R population is probably reflecting bigger genetic differences to the susceptible population MO-S. Determining shikimic acid levels using a dose response provides an early separation of resistant and susceptible individuals, but this approach is not suitable for early and exact prediction of $ED_{50}$ values or of R/S ratios between different resistant *A. tuberculatus* populations. The exact accumulation of shikimate is known to vary between species and populations with different resistance mechanisms.[13,56,57]

**Absorption and Translocation of $^{14}$C-Glyphosate.** Because altered glyphosate translocation is a common glyphosate resistance mechanism in some weeds, translocation patterns were evaluated to clarify whether this mechanism contributes to glyphosate resistance of *A. tuberculatus* populations.[58] No spatial or temporal differences in glyphosate translocation were observed in the *A. tuberculatus* populations analyzed. Slightly higher glyphosate translocation to the shoot tip occurred in glyphosate-resistant populations; however, the higher translocation is likely due to herbicide injury in the susceptible biotype, resulting in what is known as self-limiting translocation.[59] Previous research reported similar absorption during the first 50 HAT in a glyphosate-susceptible *A. tuberculatus* population,[60] which is comparable to data reported here. Glyphosate absorption is within the common range for other species, such as *C. canadensis*.[61] Glyphosate translocation observed in these *A. tuberculatus* populations was similar to more typical patterns of glyphosate translocation,[22,60,62] and differences in absorption or translocation like those described in glyphosate-resistant *C. canadensis*, *S. halepense*, *L. multiflorum*, and *L. rigidum* populations were not found.[26−30] Although reduced translocation has been reported in an *A. tuberculatus* population from Mississippi,[13] our data clearly demonstrated that glyphosate resistance in these *A. tuberculatus* populations is not based on reduced absorption. This diversity in resistance mechanisms among different populations of the same species has been frequently described.[24]

***EPSPS* Gene Amplification.** The *A. tuberculatus* populations MO-R1, MO-R2, MO-R3, MO-R4, MO-R5, and IL-R were resistant to glyphosate in the dose response study; however, on the basis of R/S values resistance was lower than the glyphosate-resistant *A. palmeri* population from Georgia, USA.[33,63] Because *A. palmeri* and *A. tuberculatus* are closely related species and are able to produce fertile crosses, *EPSPS* gene amplification was also evaluated in these populations.[64−66] We found evidence that the glyphosate-resistant *A. tuberculatus* populations evolved *EPSPS* gene amplification, similar to previous reports for multiple species with *EPSPS* gene copy increases from 2−10-fold up to 40−100-fold.[3,34,35,57,67−69] Despite differences in *EPSPS* copy number, all glyphosate-resistant *A. tuberculatus* populations had similar glyphosate resistance based on fresh weight assessment 19 DAT. *EPSPS* expression in IL-R, MO-R1, or MO-S was not induced or silenced by glyphosate treatment, but the *EPSPS* transcript levels showed the same differences between the resistant and susceptible populations as found in genomic DNA. A previous paper hypothesized that glyphosate resistance in *A. tuberculatus* could be determined by a polygenic event.[70] A positive correlation between *EPSPS* gene copy number and increasing glyphosate resistance level has been reported in *A. palmeri*[35,71] and *L. multiflorum*,[57] consistent with the current results showing gene dosage effects of additional *EPSPS* gene copies.

***EPSPS* Enzyme Kinetics.** Previous results showed higher EPSPS protein content in a glyphosate-resistant *A. palmeri* population by immunoblotting and a higher EPSPS activity during the determination of $IC_{50}$ values for glyphosate.[34,35] The EPSPS enzyme activity was measured to test resistant *A. tuberculatus* plants for a higher EPSPS enzyme content relative to susceptible. Glyphosate inhibits EPSPS as a competitive inhibitor of PEP.[72] Higher $K_m$(app) (PEP) values indicate a lower enzyme affinity to its substrate PEP and decreases EPSPS activity at lower PEP concentrations.[72] Glyphosate-resistant plant EPSPS enzymes with target-site mutations typically have increased $K_m$(app) (PEP) values in comparison to wild-type enzymes.[72] The $K_m$(app) (PEP) values were determined in the *A. tuberculatus* populations MO-S and IL-R. The values, although measured in a crude enzyme extract, are comparable to published values (e.g., *Corydalis sempervirens* and *Zea mays*).[41,73] They are about 10-fold higher than those published for *Sorghum bicolor*, *Escherichia coli*, and *Pseudomonas aeruginosa* and also for the EPSPS of *Eleusine indica* and *Zea mays* expressed in *E. coli*.[25,74,75] As the $K_m$ values between the protein extracts IL-R and MO-S plants were not significantly different, it can be hypothesized that the EPSPS enzyme sequence therefore contained no mutations influencing affinity to PEP, the competitive substrate of glyphosate. In addition, no known resistance-endowing EPSPS mutations[76] were found using pyrosequencing. A different *A. tuberculatus* population was reported with a P106S mutation,[13] again demonstrating that different populations of the same species may have different resistance mechanisms.[24]

Whereas no significant differences were obtained between the $K_m$(app) (PEP) values between resistant and susceptible populations, the $V_{max}$ and $K_{cat}$ values were significantly different between resistant and susceptible individuals. Because the $V_{max}$ and $K_{cat}$ values were measured at an equal protein concentration, but not at an equal EPSPS concentration, among populations, the higher $V_{max}$ and $K_{cat}$ values indicate a higher proportion of EPSPS in the protein pool of resistant plants. Increases of 2.3 and 3.7 times in $V_{max}$ and $K_{cat}$ values, respectively, were measured between resistant and susceptible *A. tuberculatus* plants. These values, from a naturally evolved plant population, are lower than those reported for the same mechanism selected in cell culture experiments, for example, a 40-fold increase in EPSPS activity in *C. sempervirens*.[41] However, the obtained values are already high enough to mediate plant glyphosate resistance in the field. The R/S ratio

of $V_{max}$ and $K_{cat}$ values is slightly lower than the R/S ratio of *EPSPS* gene expression results. This slight reduction could be caused by regulatory mechanisms of protein translation or turnover.

In plants, the variability of protein levels in relation to the genome or the transcriptome is unknown.[77,78] In mouse cells, mRNA levels can explain about 40% of the variability in the protein level.[77] In *A. tuberculatus* this relationship is unknown. Nevertheless, the different $V_{max}$ and $K_{cat}$ values indicate an increased amount of active EPSPS in the protein pool of resistant plants and emphasize gene amplification as the glyphosate resistance mechanism in *A. tuberculatus* populations. The results of this work strongly suggest that *EPSPS* gene amplification and the higher content and activity of the EPSPS enzyme in glyphosate-resistant plants are the main mechanisms involved in the glyphosate resistance in the tested *A. tuberculatus* populations.

In conclusion, we have compared glyphosate susceptibility of several *A. tuberculatus* populations from Missouri and Illinois, USA. Glyphosate resistance was observed in each population, either confirming previous reports[10] or reported for the first time. Physiological, biochemical, and molecular approaches showed that the resistance mechanisms of altered glyphosate absorption and translocation and target-site mutations in the *EPSPS* coding sequence could be excluded as the cause of the observed glyphosate resistance in these populations. We showed that *EPSPS* gene amplification occurred in several of these *A. tuberculatus* populations from the areas most affected by resistance, and the amplified *EPSPS* genes resulted in higher *EPSPS* mRNA expression and higher EPSPS protein activity. On the basis of these results we propose that glyphosate resistance in these *A. tuberculatus* populations is mainly based on amplification of the *EPSPS* gene.

Supporting Information

**ABSTRACT:** Oil palm is one of the most productive oil-producing crops and can store up to 90% oil in its fruit mesocarp. Oil palm fruit is a sessile drupe consisting of a fleshy mesocarp from which palm oil is extracted. Biochemical changes in the mesocarp cell walls, polyamines, and hormones at different ripening stages of oil palm fruits were studied, and the relationship between the structural and the biochemical metabolism of oil palm fruits during ripening is discussed. Time-course analysis of the changes in expression of polyamines, hormones, and cell-wall-related genes and metabolites provided insights into the complex processes and interactions involved in fruit development. Overall, a strong reduction in auxin-responsive gene expression was observed from 18 to 22 weeks after pollination. High polyamine concentrations coincided with fruit enlargement during lipid accumulation and latter stages of maturation. The trend of abscisic acid (ABA) concentration was concordant with $GA_4$ but opposite to the $GA_3$ profile such that as ABA levels increase the resulting elevated $ABA/GA_3$ ratio clearly coincides with maturation. Polygalacturonase, expansin, and actin gene expressions were also observed to increase during fruit maturation. The identification of the master regulators of these coordinated processes may allow screening for oil palm variants with altered ripening profiles.

**KEYWORDS:** *oil palm, Elaeis guineensis, polyamines, hormones, cell wall metabolism*

## INTRODUCTION

Fruit development is a complex process, being a combination of events in physiology, gene and protein expression, and biochemical changes toward maturation. To date, metabolite profiling of soft fleshy fruits such as strawberry,[1] peach,[2] and tomatoes[3] during ripening is more widely studied compared to oil fruits such as olive, avocado, and oil palm. This is partly because soft fruits are metabolite rich but also because of their importance to the human diet.[1−3] Studies reported on soft fruit start from the fertilized ovary through to the mature fruit stage. These studies have suggested cross-talk between hormones, polyamines, and cell wall metabolism in fruits during development and ripening.[4] The fruit of the oil palm (*Elaeis guineensis* Jacq.) is a source of two edible oils and is currently the most productive oil crop with average annual yields above 4 ton/ha. Unlike most temperate oil-bearing crops where oil is stored in the seed, the majority of palm oil is produced in the fleshy mesocarp of the fruit, with relatively less as kernel oil. The oil palm fruit consists of the exocarp-outer skin, mesocarp-outer oily fibrous layer, the endocarp layer covering the kernel seed, and the kernel itself. During the later phase of fruit development, most fruit will accumulate high levels of carbohydrates in the form of starch or sugars, whereas oil palm fruits accumulate oil, almost exclusively. Oil palm fruit is considered to be nonclimacteric since no significant ethylene synthesis occurs during the fruit ripening period, i.e., from about 120 to about 150 days post pollination.[5] The study of metabolites involved in ripening, such as phytohormones, polyamines, as well as cell wall metabolism in oil palm mesocarp, may provide useful insights into why it is so productive and lead to the development of varieties that ripen faster through the identification of key controlling genes.

Plant hormones are key regulators of many seed processes, including TAG accumulation. It is known that plant phytohormones are also involved in the control of fruit growth, which is demonstrated by the fact that these chemical compounds help to enhance cell division and promote cell expansion or enlargement during different stages of development. Fruit size is due more to cell division than cell enlargement, hence any factors that contribute to cell division will have an influence on fruit growth and final fruit size.[6] Many recent studies have shown that the phytohormone abscisic acid (ABA) plays an important role in the regulation of fruit development and ripening,[7] and gibberellic acid ($GA_3$) has been proposed as a possible trigger to increase fruit set and fruit size of numerous vine and fruit crops.[8] To date in oil palm, hormone analysis has been reported in sap exudate from stumps of preanthesis inflorescences,[9] wild-type and truncated leaves,[10] and fruit mesocarp.[11] In addition to plant hormones, other natural substances, such as the polyamines (PAs), may be involved in controlling fruit growth and ripening. (Spd), spermine (Spm), putrescine (Put), and ornithine are the most commonly found polyamines in plants with several studies reported on tomatoes,[12] mango,[13] strawberry,[14] and peach.[15] Exogenous applications of PAs have also been reported to increase the endogenous levels of PAs and fruit size.[16] However, biosynthesis and distribution of PAs in relation to oil palm fruit mesocarp growth and development have not been reported to date.

In the context of studying fruit maturation and ripening, hormones, polyamines, and cell wall metabolism have interrelated roles. Mesocarp tissue is composed of thin-walled storage parenchymatous cells that are characterized by a prominent cell wall consisting of a complex network of polysaccharides and proteins giving mechanical strength to the tissues. A wide range of hydrolases that catalyze the process of softening are activated at transcriptional and translational levels. Softening is further enhanced by expansins that break down the multiple polysaccharide networks, thus increasing the accessibility of hydrolases, such as polygalacturonase (PG) or cellulase, to the cell wall polymers.[17] Tomato PG has been the most widely studied cell wall hydrolase in relation to ripening, while pectin degradation during ripening has been reported in avocado mesocarp.[18] We were also interested in studying hormone levels since they are well-known to play important roles in lipid biosynthesis regulation.[19] On the basis of our previous work,[20] we had identified several key biosynthetic pathways that are important to the synthesis of lipids and that the study of hormones may provide insights into the regulation of these networks.

For this study, hormones and polyamines in oil palm mesocarp were analyzed from 12 to 22 weeks after pollination, representing the main stages of lipid accumulation and ripening. Tandem HPLC and mass spectrometry (MS) with multiple reaction monitoring (MRM) were used, in which several plant hormones (IAA, CKs, ABA, and their metabolites) were quantified using deuterated internal standards. We also extracted RNA from mesocarp tissue to determine gene expression changes during ripening. Transcript levels of the cell wall metabolism genes, pectin, polygalacturonase, cellulose, and expansin, were analyzed using an oil palm mesocarp transcriptome microarray. Further understanding of the biological and physiological mechanisms underlying oil palm fruit ripening may be useful for optimizing harvesting as well as lead to the breeding of palms with improved ripening profiles.

## MATERIALS AND METHODS

**Plant Material.** Oil palm fruits were derived from commercial crosses of Serdang Avenue dura and AVROS pisifera to yield hybrid tenera progeny. The fruit bunches were sampled from a commercial estate in Carey Island, Malaysia, at different developmental stages preceding, during, and after the major oil biosynthesis period, namely, 12, 14, 16, 18, 20, and 22 WAP. All fruitlets were separated from the bunches, and then 20 were randomly selected from each without bias to location in the bunch. Mesocarp tissues were harvested and snap frozen in liquid $N_2$ to quench the metabolism of the plant tissues and enzyme activity and then stored in the dark at −80 °C for metabolite analysis and mRNA extraction. Prior to extraction, plant material (100 mg) was ground to a fine powder using a pestle and mortar under liquid nitrogen.

**Chemicals.** Zeatin, gibberellins ($GA_3$ and $GA_4$), ICA, IAA, BA, ABA, MeIAA, SA, CA, MeBA, IBA, JA, MeSA, MeCA, MeJA, and OPDA were purchased from either Aldrich or Sigma Chemical Co. (St Louis, USA). Isotopically labeled internal standards including [$^2H_5$]IAA and [$^2H_6$]ABA and [$^2H_5$] *trans*-zeatin riboside were purchased from OlChemim Ltd. (Olomouc, Czech Republic).

**Metabolite Extraction.** The extraction of polar and lipid metabolites from oil palm tissues was carried out in a single integrated procedure according to a previously published method.[20a] For hormone extraction, ground tissue (100 mg) was extracted with a mixture of 1-propanol:$H_2O$:conc HCl (2:1:0.002, v/v; 500 μL) with internal standards, [$^2H_5$]ABA and [$^2H_5$] *trans*-zeatin riboside (50 ng), added, followed by agitation for 30 min at 4 °C. $CH_2Cl_2$ (1 mL) was then added, followed by agitation for another 30 min and then centrifugation for 5 min at 4 °C, 13 000*g*. After centrifugation, two phases formed with plant debris suspended between the layers. An aliquot of the lower layer (1 mL) was concentrated and resolubilized in MeOH for analysis. All extracts were kept dry at −80 °C until further use. The analysis was comprised of targeted and untargeted LC-MS, GC-MS, and CE-MS analysis.

**Analysis Methods.** *Targeted Profiling of Hormone Metabolites Using LC-MS.* LC-MS data were acquired using UPLC-triplequad MS (Waters, USA). The Waters Acquity UPLC system (Waters Corporation, Milford, MA) was run in gradient mode, as per a previously published method.[21] The column used was reversed-phase C18 (1.8 μm, 2.1 × 100 mm; Waters) set at 30 °C. Solvent A was $H_2O$ (0.1% formic acid v/v), and solvent B was MeOH (0.1% formic acid v/v); the flow rate was 0.3 mL/min. The gradient was as follows: 30% B (0−2.0 min), linearly increased to 100% B at 20 min. The autosampler temperature was set at 4 °C with a 3.0 μL injection volume. MS analysis was performed on a Xevo TQs triple quadrupole mass spectrometer (Waters Corporation, Milford, MA). MS analysis was carried out in positive and negative ion electrospray ionization (ESI) modes of detection. The electrospray ionization capillary voltage on both modes was set at 2.5 kV, with the cone gas flow set at 150 L/h, and desolvation temperature of 350 °C. The collision gas flow was set at 0.15 mL/min. The MRM settings in the MS/MS function with corresponding cone voltage and collision energy were optimized for each standard compound. The total acquisition duration for both UPLC and MS was set at 15 and 5 min, respectively. Data were acquired and processed using MassLynx V4.1 and TargetLynx, respectively. [$^2H_5$] *trans*-zeatin riboside was used as an internal standard for positive mode and [$^2H_6$] ABA for negative mode.

*Targeted Profiling of Polyamine Metabolites Using CE-MS.* Targeted profiling of 108 primary metabolites using CE-MS was carried out by Human Metabolome Technologies, Inc. (HMT), Japan, as per a previously published method.[22]

**RNA Extraction.** Total RNA was extracted according to the San et al. method.[23] The extraction buffer contained 0.1 M Tris-HCl, pH 7.6, 0.1 M NaCl, 6% *p*-aminosalicylic acid, 1% SDS, 0.35% β-mercaptoethanol, and 5% phenol. The buffer was added at a rate of 4 mL/g of plant tissue, vortexed, and extracted with phenol:chloroform. The supernatant was precipitated twice using 3 M LiCl followed by ethanol precipitation. The pellet was then redissolved in DEPC-treated distilled water and again precipitated with 3 M LiCl followed by ethanol. The precipitate was finally dissolved in DEPC-treated distilled water and stored at −80 °C.

**Synthesis of cRNA, Microarray Hybridization, and Scanning.** Expression microarray analysis was performed using Agilent's one color method (Agilent Technologies, Palo Alto, CA, USA).[24] Total RNA samples from mesocarp were individually treated and labeled with a one-color Cy3 dye according to the Low Input Quick Amp Labeling protocol version 6.0, December 2009, provided by Agilent. Briefly, a total of 100 ng of total RNA was used to synthesize cRNA labeled with Cy3 dye. Labeled cRNAs were then purified using Qiagen's RNeasy mini kit as recommended by the manufacturer, and quality and quantity were assessed using the Spectrophotometer ND-1000(NanoDrop). The purified labeled cRNA was hybridized onto the *Arabidopsis*, rice, and custom oil palm mesocarp array at 65 °C for 16 h. After hybridization, 2 steps of washing were performed with wash buffer 1 and 2 for 1 min each. The array was then air-dried for a few seconds before proceeding with image scanning using the Agilent microarray slide scanner (SG11350602). A blank control without RNA, put through the entire hybridization and scanning processes, was also used to provide an estimate of the array background noise when no labeled probe is present.

**Data Extraction, Normalization, and Comparisons.** Raw microarray data were extracted from scanned images by using the Feature Extraction software (version 10.7.31; Agilent). The extracted microarray data were normalized using the Quantile normalization algorithm and analyzed using R (version 2.13.1). After normalization, comparisons of selected candidates between oil palm mesocarp microarray were carried out based on the normalized signal intensity produced.

## RESULTS AND DISCUSSION

**Hormone Metabolism during Oil Palm Development.** Fruit ripening in oil palm is accompanied by lipid and carotenoid accumulation along with chlorophyll degradation.[25] To determine the association of specific hormones with the timing of key ripening events, the major classes of plant hormones (ABA, auxins, cytokinins, and GA) in the mesocarp were profiled during the final stages of fruit development. Endogenous phytohormones occur only in a trace amount in plants. Consequently, for their analysis, sensitive mass spectrometric methods were combined with chromatographic separation techniques such as gas chromatography and high performance liquid chromatography. Unigenes also known to be involved in metabolism and response of multiple hormones including auxin, ethylene, gibberellins (GA), brassinosteroid (BR), jasmonic acid (JA), abscisic acid (ABA), and cytokinins (CK) were identified during mesocarp maturation from microarray expression data. Oil palm mesocarp tissue also had detectable levels of IAA, *trans*-zeatin, *trans*-zeatin glucoside, $GA_3$, $GA_4$, ABA, MeJA, and cinnamic acid. Changes in endogenous concentrations of GA, ABA, and cinnamic acid in mesocarp tissues during fruit growth and development are shown in Figure 1.

**Gibberellins.** Gibberellins (GAs) are plant growth regulators that are known to stimulate physiological responses during plant development, such as shoot growth, flower development, dormancy release, and seed germination, as well as alter the source−sink metabolism through their effect on photosynthesis and sink formation.[26] GA is also important in controlling seed maturation, germination, and seedling growth. While only trace amounts of $GA_3$ were detected, interestingly $GA_3$ and $GA_4$ exhibited clear opposite trends during oil palm mesocarp development. $GA_3$ appeared to be higher at Week 12 and decreased to almost undetectable levels at ripening.[11] However, $GA_4$ exhibited an opposite trend to $GA_3$ as its concentration increased during fruit development and peaked at Week 18, followed by a gradual decline to Week 22. $GA_4$ is the main bioactive hormone in cucumber[27] and *Arabidopsis*[28] and is also clearly important in oil palm fruit ripening. Several unigenes with annotated functions in gibberellin biosynthesis and responses were identified in the oil palm mesocarp transcriptome. Three genes that encode "DELLA proteins", the repressor of GA responses, were identified and showed down-regulated expression patterns toward maturation (Figure 2A). Unigenes encoding proteins homologous to GA20ox and GA3ox that convert the inactive precursors to bioactive GAs also showed mostly down-regulated expression patterns in mesocarp during fruit development after peaking at 18 WAP, concordant with the peak concentration of $GA_4$ observed followed by a decline (Figure 1A in the Supporting Information). In particular, GA20ox exhibited much lower expression at 22 WAP. Interestingly GA2ox, which is involved in the catabolic pathway of $GA_4$, exhibits a similar expression trend, peaking at 14−18 WAP and declining thereafter,

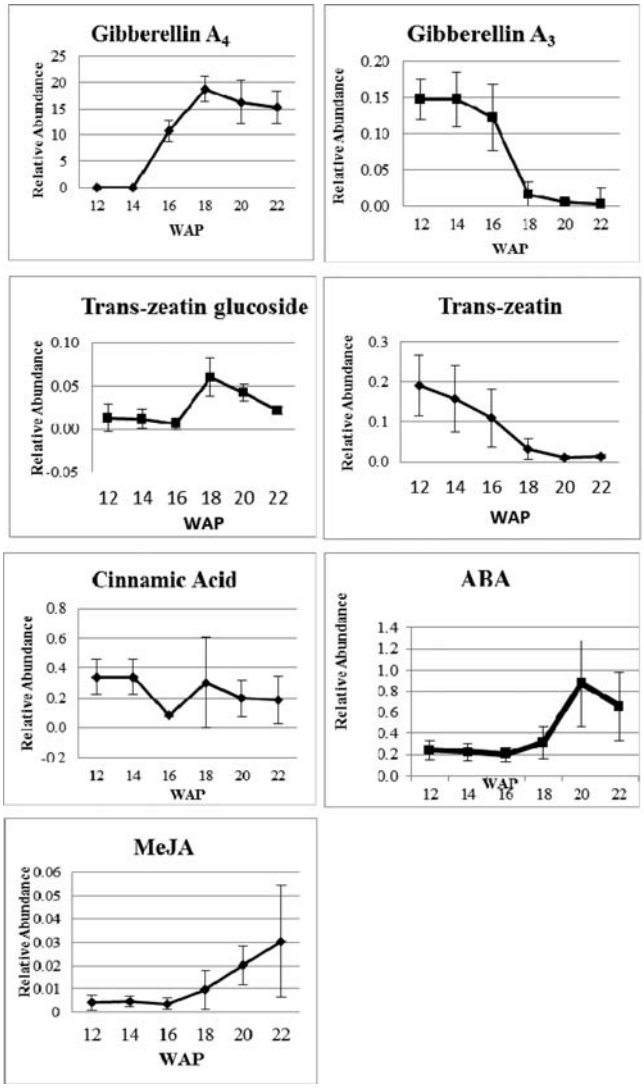

**Figure 1.** Hormone profiles during mesocarp development.

concordant with the lower levels of $GA_3$ observed. The combination of lower expression of GA20ox and GA3ox resulting in less provision of $GA_4$, combined with lower expression of GA2ox after week 18, may contribute to the dramatic lowering of $GA_3$ concentrations at the last stage of ripening.

**Abscisic Acid.** Liu et al. reported that high levels of endogenous ABA occur concurrently with rapid increases in the rate of fresh and dry weight accumulation in soybean seeds and coincide with the maximum rate of cell division.[29] Several studies report an increase in free ABA levels during grape ripening concomitant with sugar accumulation and color changes.[30] In oil palm, mesocarp also contained higher levels of ABA as lipid accumulated during ripening. ABA has been proposed as a possible trigger of ripening in some fruits as well.[31] The specific role of ABA during fruit ripening remains obscure although ABA accumulation appears to be critical and participates in the regulation of ripening of both climacteric and nonclimacteric fruit. Transcription levels of 9-*cis*-epoxycarotenoid dioxygenase 1 gene, *NCED1*, in oil palm mesocarp were also found to be congruent with ABA content clearly indicating its importance to the ripening process of oil palm (Figure 1 and Figure 2B). It was previously observed by Chernys et al. that

dx.doi.org/10.1021/jf500975h | J. Agric. Food Chem. 2014, 62, 8143−8152

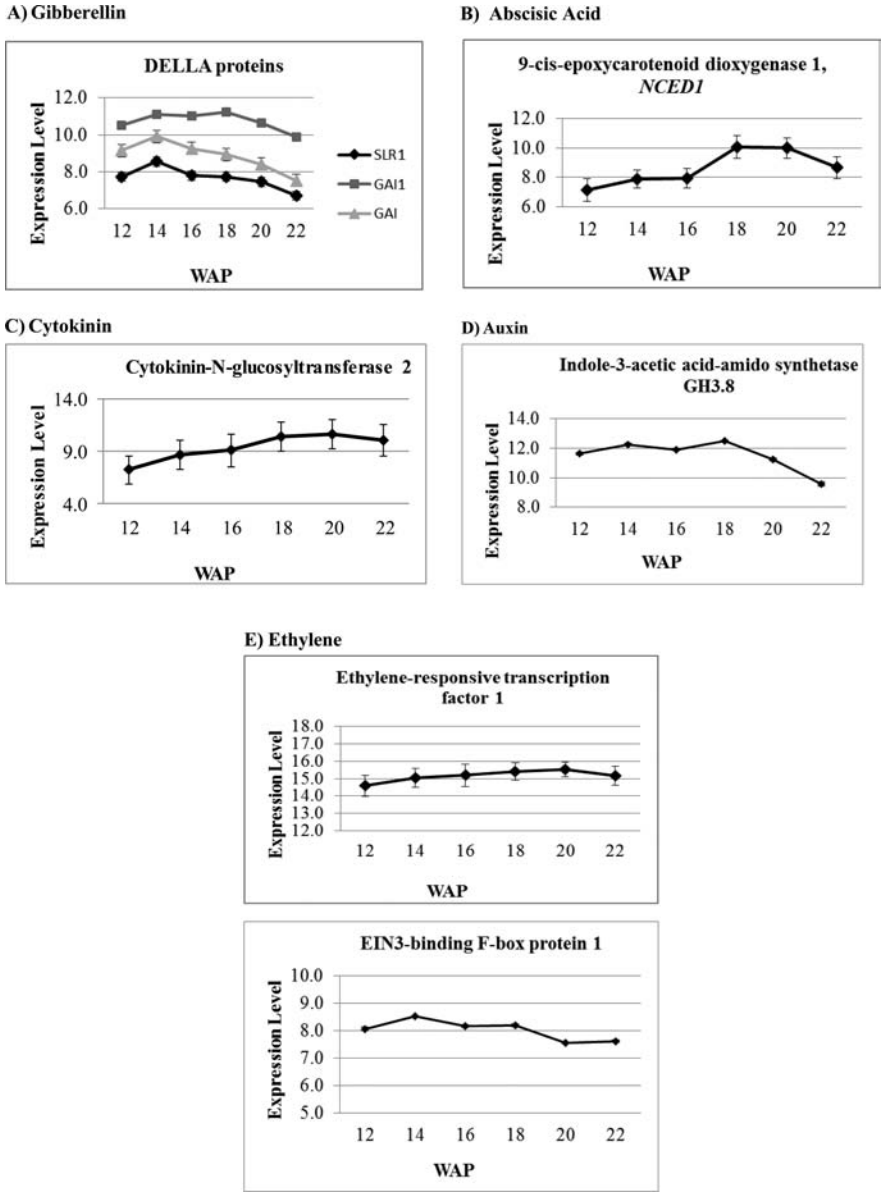

**Figure 2.** (A) Gibberellin, (B) abscisic acid, (C) cytokinin, (D) auxin, (E) ethylene.

*NCED1*, a key enzyme involved in ABA biosynthesis, is up-regulated during the ripening of several fruits, including avocado.[32] In addition, two unigenes for 'abscisic acid 8'-hydroxylase were clearly down-regulated in mesocarp at 20−22 weeks, possibly leading to a decrease in ABA degradation (Supporting Information) allowing accumulation.

The interaction between GA and ABA can have antagonistic effects according to Gao et al.[33] Seed maturation and germination are not determined by ABA alone but instead by the ABA/GA ratio. ABA content increases in *Arabidopsis* seed as the embryo enters the maturation stage, and the resulting high ABA/GA ratio promotes maturation, induces dormancy, and inhibits cell-cycle progression, embryo growth, and germination.[34] While in maize, it also appears to be the ABA/GA ratio and not the absolute hormone concentration that controls germination.[35] For oil palm mesocarp, at the beginning of the maturation phase, ABA levels increase in fruits, while $GA_3$ decreases, the resulting elevated ABA/$GA_3$ ratio clearly coinciding with maturation (Figure 3).

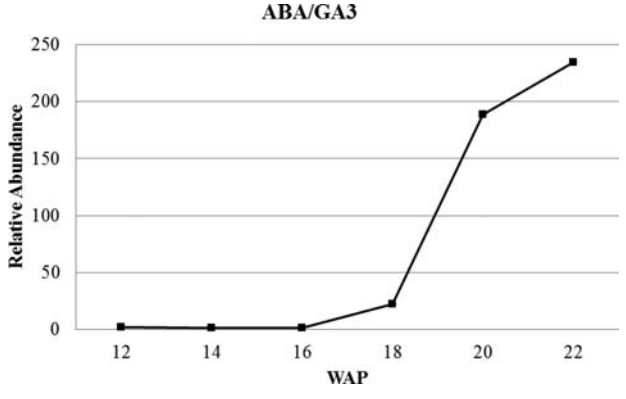

**Figure 3.** ABA/$GA_3$ ratio of palm mesocarp samples during 12−22 WAP. Data obtained from LC-MS-triplequad analysis.

**Cytokinins.** Cytokinins also have an important regulatory role in plant development and growth. They improve seed germination, release bud from apical dominance, and stimulate

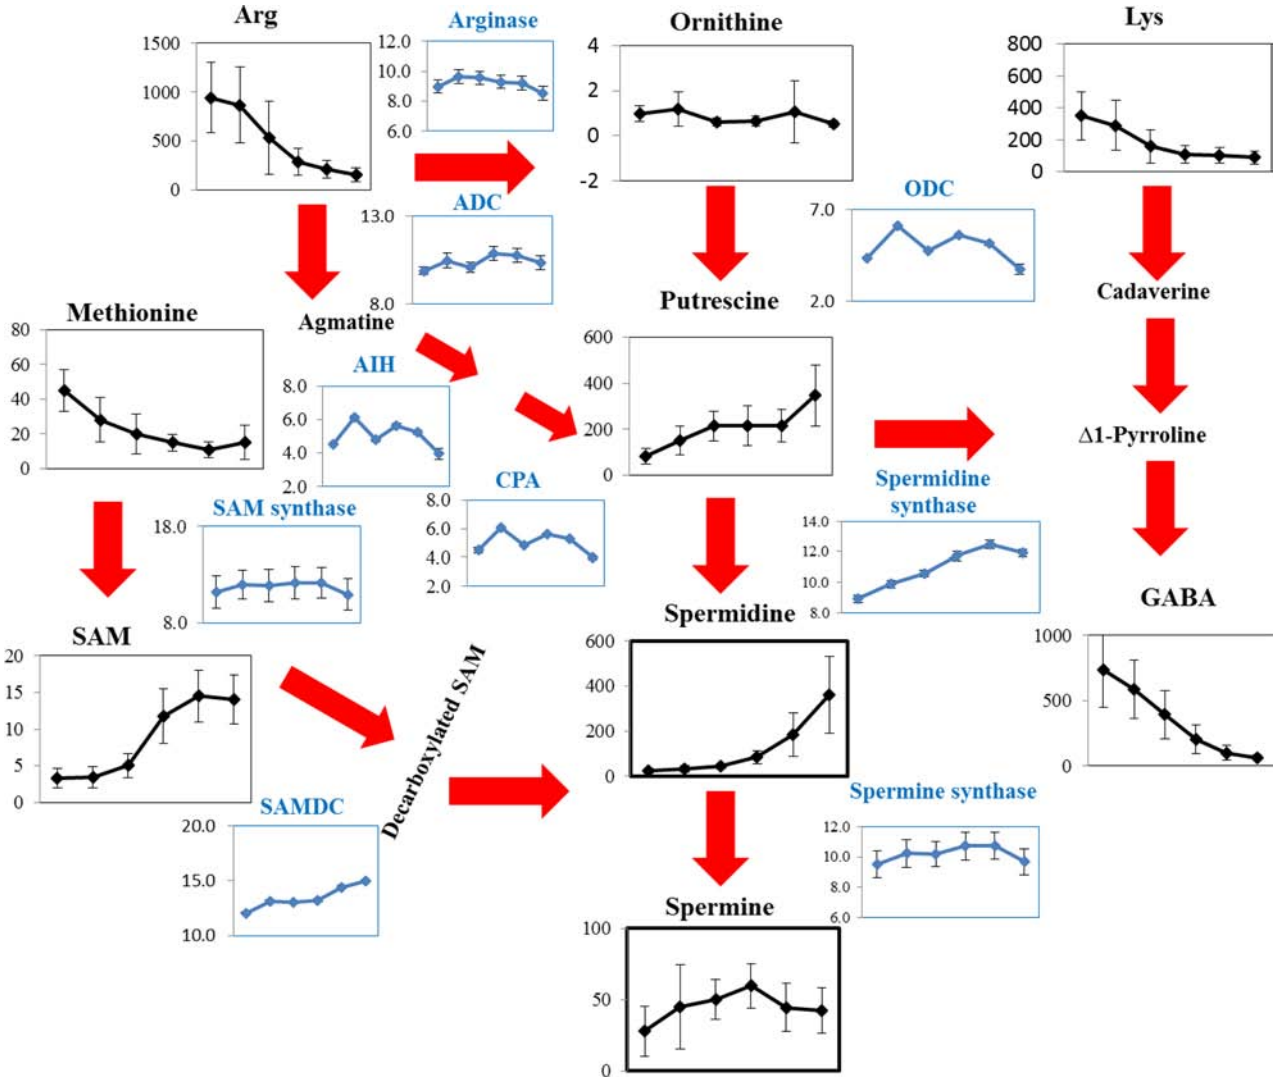

**Figure 4.** Changes in polyamine levels and transcript expression in mesocarp across 6 time points.

leaf expansion and development of reproductive organs and retardation of senescence.[36] Cytokinins have been reported to increase the number of pods/plant and seed weight in soybean. *trans*-Zeatin was the predominant cytokinin detected in oil palm mesocarp, followed by *trans*-zeatin glucoside. Contrary to ABA, the levels of *trans*-zeatin are high early in fruit development but decrease to very low or undetectable levels at maturation (Figure 1). *trans*-Zeatin glucoside exhibited different behavior, being detected at low concentration at weeks 12−16, peaking at week 18, followed by a decline until week 22 (Figure 1). Cytokinins are thought to be involved in berry set and in growth promotion and tend to inhibit fruit ripening.[37] The levels of zeatin are high early in grape development but decrease rapidly to be low at around the time of ripening.[37] Three unigenes encoding proteins homologous to "cytokinin dehydrogenase" and three unigenes for cytokinin-*N*-(or *O*-)glucosyltransferase, which regulate homeostasis by deactivating cytokinin were identified in mesocarp. Of these, only cytokinin-*N*-glucosyltransferase 2 exhibited increased expression towards ripening (Figure 2). Hormonal analysis by Habib et al. revealed that various cytokinin derivatives such as *trans*-zeatin, *trans*-zeatin riboside, *trans*-zeatin *O*-glucoside, and *trans*-zeatin riboside 5′-monophosphate were significantly higher in truncated oil palm leaf syndrome leaves compared to wild-type oil palm leaves.[38]

**Jasmonic Acid.** Jasmonic acid (JA) has been demonstrated to be involved in cross talk with ethylene signaling components in *Arabidopsis* and has been associated with fruit maturation. In climacteric and nonclimacteric fruits, jasmonate levels increase during early fruit developmental stages, suggesting that jasmonate could be involved in cell division and other early fruit expansion processes. Generally, jasmonates and salicylates contribute to local and systemic defenses against pathogens, wounding, and stress responses and are involved in pollen and embryo development, seed germination, senescence, fruit ripening, and allelopathy.[39] To our knowledge jasmonate has not been previously reported in the context of oil fruit ripening. Methyl jasmonic acid (MeJA) was found to increase after oil biosynthesis commences until ripeness in oil palm (Figure 1). JA and MeJA have been reported to retard cell division in soybean callus [*Glycine max* (L.) Merr.].[40] We observed that 12-oxophytodienoate reductase 3, lipoxygenase 7, jasmonate-induced protein, and allene oxide synthase 1 and 2 are expressed at a higher level as compared to other jasmonic acid biosynthesis genes (Figure 1D in the Supporting Information).

dx.doi.org/10.1021/jf500975h | *J. Agric. Food Chem.* 2014, 62, 8143−8152

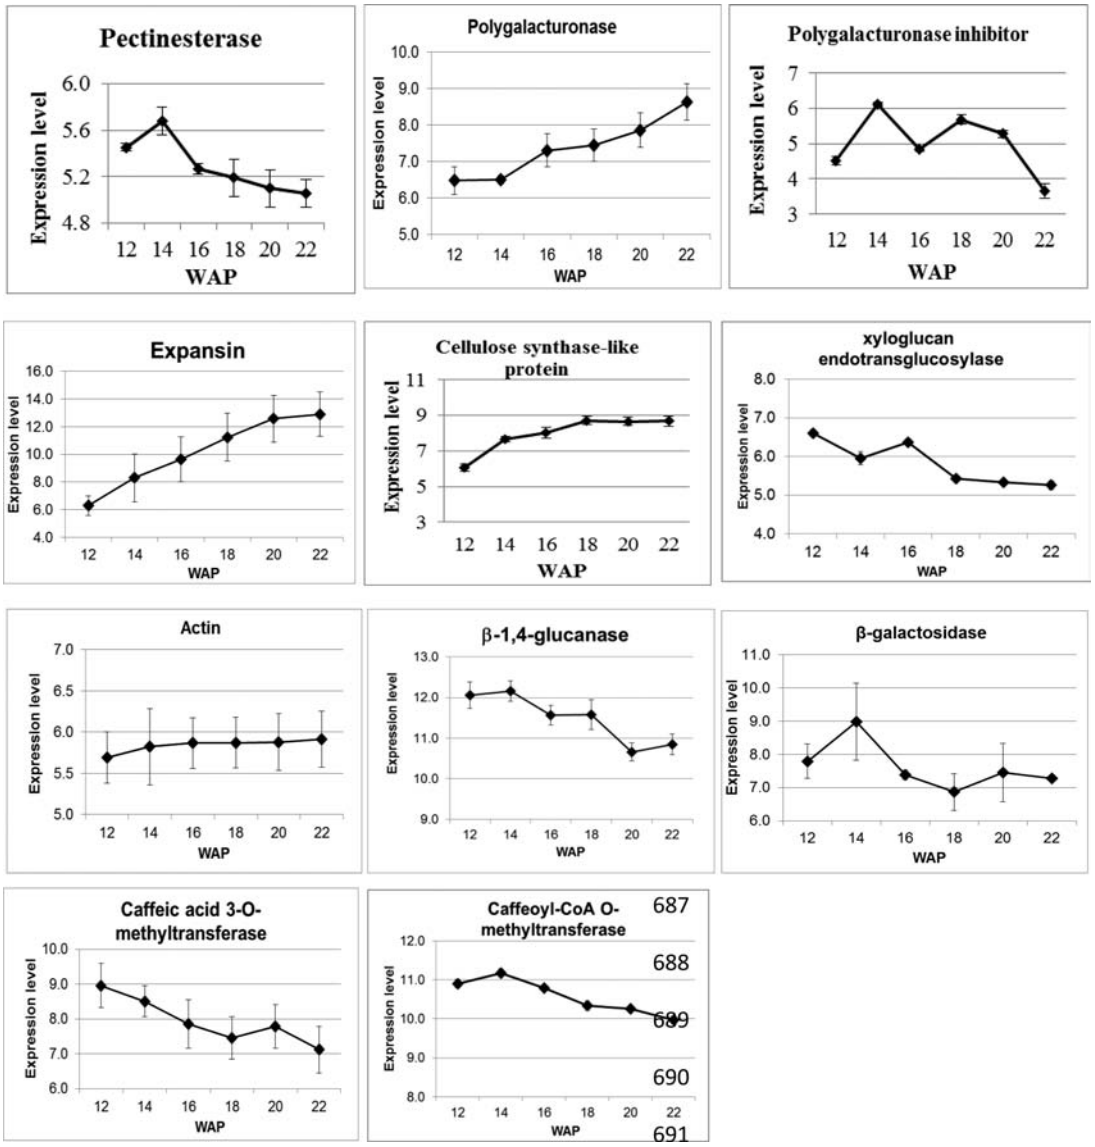

**Figure 5.** Expression microarray data for genes which are involved in cell wall metabolism.

**Auxin.** In oil palm mesocarp it was reported that indole-3-acetic acid (IAA) levels peak after pollination and then decline to very low levels in the ripe fruit.[11] IAA was also found to be undetectable in this study of mesocarp after week 12. However, auxin biosynthesis genes were detected using expression microarray. A gene coding for an indole-3-acetic acid-amido synthetase GH3.8 exhibited the highest expression at week 18 but declined in expression toward ripeness (Figure 2D). Many genes coding for auxin and IAA proteins were down-regulated at week 22 suggesting that auxin levels are indeed lowered toward ripening. A transcript encoding IAA-amino acid hydrolase 1 (ILR1, 5, 6, and 7), which is putatively involved in IAA homeostasis, was down-regulated during fruit development (S1E). Auxin-response factors bind auxin-response elements of auxin-responsive genes and thus seem to act as regulators of gene transcription.[41] In this study, several auxin response factors (ARFs 1, 2, 4, 6, 7, 9, 11, 12, 15, 16, 18, 19, 23) were down-regulated during the maturation stages except ARF 7, 17, and 23 (Figure 1E in the Supporting Information). The majority of transcripts related to auxin transport and perception displayed decreased abundance in mesocarp (Supporting Information).

**Ethylene.** Consistent with the critical roles of ethylene during fruit maturation and ripening, the majority of unigenes related to ethylene functions showed up-regulated expression patterns as maturation progressed. We found that one unigene encoding the EIN3-binding F-box protein in oil palm mesocarp samples, a negative regulator of ethylene action, exhibited down-regulated expression patterns (Figure 2E) along with up-regulated expression patterns for most ethylene function related unigenes. Ethylene-responsive transcription factor 1 is found to be expressed highest among other genes related to ethylene pathways. Recent research reported by Tranbarger et al. shows that oil palm mesocarp exhibits characteristics of a climacteric fruit with an autocatalytic burst of ethylene coordinated transcriptional activity.[11]

**Brassinosteroids.** Lastly, brassinosteroids also regulate various aspects of plant growth and development, including cell elongation, photomorphogenesis, xylem differentiation, and seed germination as well as adaptation to abiotic and biotic environmental stresses.[42] Brassinosteroid insentive 1-associated

receptor kinase 1, brassinosteroid-regulated protein, and brassinosteroid LRR receptor kinase genes were detected in oil palm mesocarp (Figure 1F in the Supporting Information) and decreased from week 12 to 22.

**Polyamine Metabolism during Oil Palm Development.** Polyamines, generally putrescine (Put), spermidine (Spd), and spermine (Spm), are polycationic compounds of low molecular weight that are present in living organisms. In plants, polyamines are present from micromolar (~10 $\mu$M) to millimolar concentrations.[43] They distribute differently among tissues and developmental stages, with Put and Spd being more abundant than Spm and cadeverine (Cad). Plant polyamines are considered as growth regulators, as they play fundamental roles in a wide range of growth, differentiation, and morphogenetic processes during the course of plant ontogeny. They have been shown to be involved in fruit enlargement, maturation, and ripening.[15] Thus, the changes in endogenous free polyamines (Put, Spd, Spm, and ornithine) were monitored to examine their role during mesocarp development. Figure 4 shows the changes in polyamine levels and related gene expression in the oil palm mesocarp across the six time points. The concentrations of both ornithine and Spm remained relatively low compared to Spd and Put. Spd was higher than Put across time points, both increasing toward ripeness. Spermidine synthase (SpdSyn) is a key enzyme in polyamine biosynthesis and is responsible for Spd accumulation as also seen in Figure 4. The concentration profile of Spm also followed the expression levels of spermine synthase (SpmSyn). Along with accumulation of polyamines, arginine showed steady consumption after week 12. The pathway to Spd from methionine also revealed similar coordination with ripening. The increase in polyamines during oil palm fruit ripening suggests that endogenous polyamines may be involved in response to ethylene production.[13] Quinet et al. found that a high level of Put concentration played an active role in triggering biosynthesis of ethylene.[44] For oil palm mesocarp, Put, Spd, and Spm concentrations increased toward maturation along with ethylene.[11] Contrary to oil palm, higher levels of polyamines are found in the initial fruit growth period, progressively declining toward maturation in several fruits including apple,[16] grapes,[45] tomato,[12] mango,[13] and peach.[46] Polyamines are reported to be abundant during the cell division stage and decrease during the subsequent cell enlargement phase, ripening, and postharvest.[47] However, the opposite trend seen in oil palm fruit in this study has been reported in mandarins and rambutans.[48] In addition, Maria et al. recently reviewed that mature olive fruit abscission is associated with up-regulation of polyamine metabolism.[49]

**Cell Wall Metabolism.** Plant cell wall metabolism, particularly cell wall degradation and modification, has long been associated with fruit ripening and softening. The complexity of the cell wall is encoded by multigene families that likely contribute to fruit cell wall metabolism including multiple steps such as substrate generation, synthesis and glycosyl transferase activities, secretory pathways, wall assembly, wall dynamics, and wall disassembly. Genes encoding for cell wall metabolism have been studied for their potential roles in fruit ripening and postharvest fruit softening. During oil palm mesocarp development, the cells continue to grow as they accumulate lipid.[50] Actin gene expression seemed to increase between week 12 and week 14, remaining high thereafter (Figure 5). This may be related to cell expansion during lipid accumulation as actin is involved in a number of cellular processes such as cytoplasmic streaming, cell shape determination, organelle movement, and extension growth.[51] We have also noted that amino acid levels are increased in high yielding fruits at weeks 12−14.[20a]

Identified unigenes with annotated functions in cell wall metabolism represent another major transcriptomics change during mesocarp maturation. Fruit softening during ripening is associated with depolymerization and solubilization of cellulose microfibrils, hemicellulose, and pectins in the cell wall.[52] Fruit softening during ripening results from the hydrolytic breakdown of cell wall polymers (e.g., celluloses, hemicelluloses, pectins) by hydrolases (e.g., polygalacturonase [PG], pectin methyl esterase, pectate lyase, rhamnogalacturonase, $\beta$-galactosidase).[53] Pectolytic enzymes constitute a unique group of enzymes that are responsible for the degradation of pectin and pectic substances in plant cell walls. In peach, high levels of polygalacturonase and low levels of cellulose have been reported for the fruit ripening stage.[54] Much research has focused on pectin degradation, resulting from the action of the ripening-related enzyme polygalacturonase, as the key element underlying the softening process. Expansin gene A-8, cellulose synthase-like protein, and polygalacturonase genes have the similar pattern of gene expression level in mesocarp fruits across the six time points in oil palm mesocarp (Figure 5). Our results also showed that the expression level of polygalacturonase inhibitor transcript exhibited an opposite trend to polygalacturonase. Polygalacturonase gene family members have been studied in fleshy oil palm fruit ripening and abscission recently by Roongsattham et al.[55] They identified the expression level of five transcripts that encode PGs increased during ethylene treatments that induce cell separation. During avocado ripening the amount of high and intermediate sized polymers in the pectin fraction have been reported to decrease.[18] $\beta$-Galactosidase expression decreased during ripening in oil palm mesocarp (Figure 5). $\beta$-Galactosidase may be involved in releasing stored energy for rapid growth, degrading cell wall components during senescence, and releasing free galactose during metabolic recycling of galactolipids, glycoproteins, and cell wall components.[56] Caffeic acid 3-*O*-methyltransferase (COMT) decreased gradually from week 12 to 22 (Figure 5). Caffeoyl CoA 3-*O*-methyltransferase (CCOMT) also peaked at week 14 and decreased gradually thereafter (Figure 5). Strong down-regulation of COMT and CCOMT has been shown to result in decreased lignin content.[57]

Expansins are plant cell wall proteins proposed to disrupt hydrogen bonds within the cell wall polymer matrix so that cell wall hydrolase enzymes can access, thus enhancing softening of, tissues.[58] Expansins are encoded by a super family of genes that are divided into four families, namely, expansin A, expansin B, expansin like A, and expansin like B.[58,59] Expression of specific expansin genes has been observed in tomato (*Lycopersicon esculentum*) meristems, expanding tissues, and ripening fruit. It has been proposed that a tomato-ripening-regulated expansin might contribute to cell wall polymer disassembly and fruit softening by increasing the accessibility of specific cell wall polymers to hydrolase action. We found nine forms of expansin genes expressed during oil palm mesocarp development (Expansin B5, A2, A7, A8, A10, A15, like-A1, like-A2, and like-B1). In particular, expression levels of expansin gene-A8 increased significantly (Figure 5). Xie et al. found that expression and enzyme activity of cell wall hydrolases including

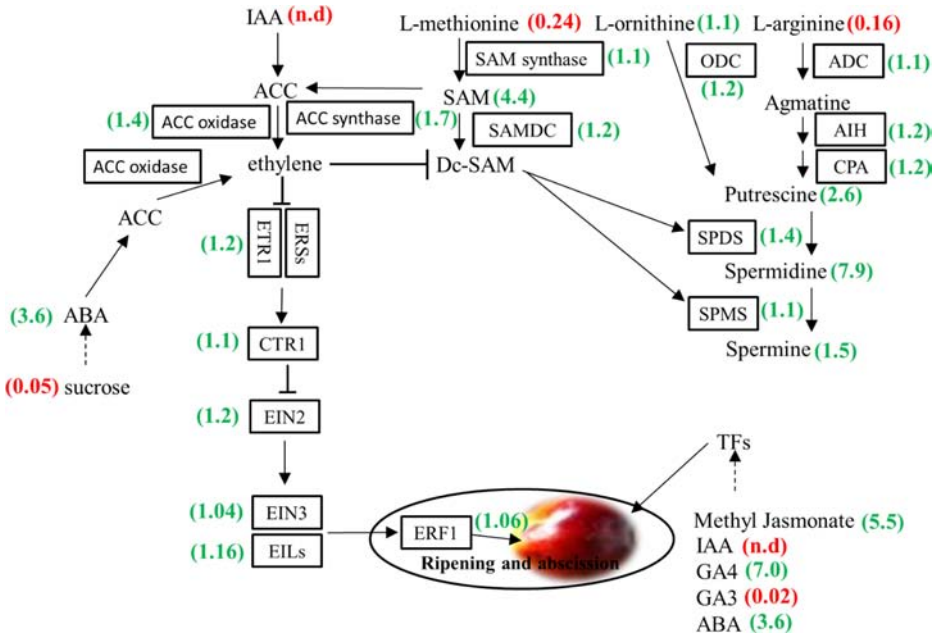

**Figure 6.** Schematic representation of the integration of polyamines, hormones, and their respective genes in mesocarp fruit ripening and abscission events. The numbers between brackets correspond to a gene/metabolite expression ratio of week 20 to week 12. Abbreviations: SAMDC, *S*-adenosylmethionine decarboxylase; SPDS, spermindine synthase; SPMS, spermine synthase; ODC, ornithine decarboxylase; AIH, agmatine iminohydrolase; ADC, arginine decarboxylase; CPA, *N*-carbamoylputrescine amidohydrolase; ACC, 1-aminocyclopropane-1-carboxylic acid; Dc-SAM, decarboxylated *S*-adenosyl methionine; ROS, reactive oxygen species; TFs, transcription factors; EIN, ethylene-insensitive; ERF, ethylene-responsive transcription factor; EIL, EIN3-Like.

expansin and polygalacturonase were increased during the final stages of fruit development and abscission.[4]

Figure 6 shows the temporal expression patterns of hormones and polyamines between weeks 12 and 20. Almost all the polyamines and hormones exhibited increased expression, except $GA_3$, sucrose, arginine, and L-methionine. The ratio of genes coordinated in regulation of these hormones and polyamines was found to be concordant with the ratio value of their metabolites in most cases. Among the hormones and polyamines metabolites, a few were evident as the most critical for ripening in oil palm: Spd (7.9) (driven by SAM (4.4)) and $GA_4$ (7.0) showing the most differential, followed by methyl jasmonate (5.5) and ABA (3.6). As discussed earlier, the effect of ABA may be more pronounced by its ratio with $GA_3$ increasing even more markedly at 20 WAP. Xie et al. reported cross-talk among the hormones, saccharides, and polyamines in apple, mango, and citrus.[4] It can be seen that their levels in oil palm can be related to lipid biosynthesis commencement first and later to fruit maturation (softening and abscsission).

In summary, this work describes the combined analysis of transcripts and metabolites contributing to the involvement of hormones, polyamines, and cell wall metabolism during oil palm fruit ripening from 12 weeks after pollination (WAP). Figure 7 summarizes the changes in total oil content, amino acids, organic acids, polyamines, and hormones in the three main stages of development: lag phase (12−14 WAP), maturation (16−18 WAP), and finally ripening (20−22 WAP). Lag phase (12−14 WAP) occurs after cell division and cell expansion, where peak lipid biosynthesis starts during maturation (16−18 WAP), reaching maximum lipid concentrations at ripening (20−22 WAP). Figure 7 clearly shows the key developmental changes related to oil biosynthesis at weeks 14−16 and then ripening at weeks 20−22 and indicates how hormones and polyamines are coordinated. Some are

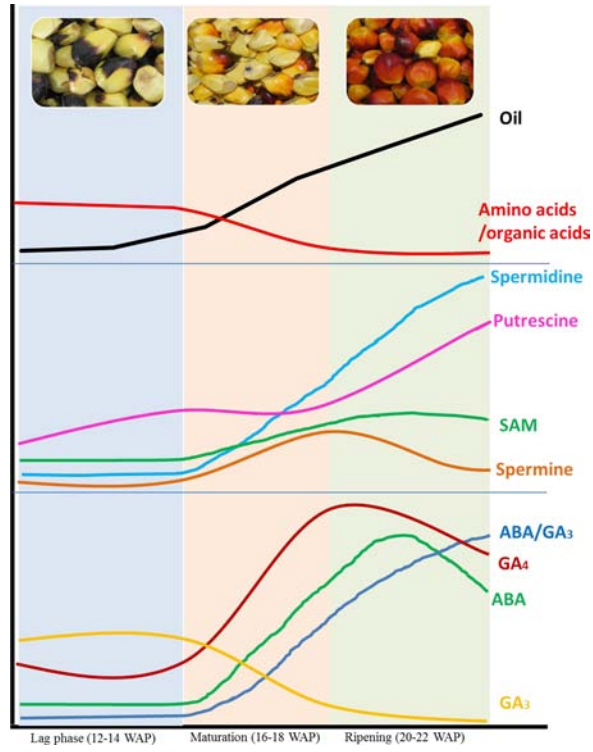

**Figure 7.** Summary of total oil, amino acids, organic acids, polyamines, and hormones in the mesocarp tissue during oil palm fruit development.

concordant with the onset of lipid biosynthesis at 16 WAP, such as $GA_4$ concentration, while others are concordant with the final stages of ripening (fruit softening and abscission), most notably ABA and the ABA/$GA_3$ ratio as well as

dx.doi.org/10.1021/jf500975h | J. Agric. Food Chem. 2014, 62, 8143−8152

polyamines. These results provide a valuable contribution for the understanding of key genes and expression timing changes related to the regulation of the complex process of mesocarp ripening, in particular the initiation of peak oil biosynthesis and final ripening before harvesting. In summary, we conclude that (1) high polyamine concentrations coincide with lipid accumulation and maturation; (2) ABA is concordant with $GA_4$ but not $GA_3$ during fruit development, and the resulting elevated ABA/$GA_3$ ratio appears to promote maturation; (3) ethylene-responsive transcription factor 1,9-*cis*-epoxycarotenoid dioxygenase 1 (NCED1), cytokinin-*N*-glucosyltransferase 2, and ethylene-responsive transcription factor 1 were all expressed higher in up-related pattern until week 20; (4) polygalacturonase, expansin A-8, cellulose synthase-like protein, and actin genes clearly increase toward ripening. The elucidation of the specific promoter binding sites and transcription factors that are in common between genes that exhibit related expression profiles during ripening or transcription factors modulated by hormone concentrations may lead to the identification of important timing regulators of oil biosynthesis and ripening. These will in turn assist in the development of fruit that ripens faster and/or produces more oil.

Supporting Information

**ABSTRACT:** Lentinan from *Lentinula edodes* fruiting bodies (shiitake mushrooms) is a valuable *β*-glucan for medical purposes based on its anticancer activity and immunomodulating activity. However, lentinan content in fruiting bodies decreases after harvesting and storage due to an increase in glucanase activity. In this study, we downregulated the expression of an *exo*-*β*-1,3-glucanase, *exg2*, in *L. edodes* using RNA interference. In the wild-type strain, *β*-1,3-glucanase activity in fruiting bodies remarkably increased after harvesting, and 41.7% of the lentinan content was lost after 4 days of preservation. The EXG2 downregulated strain showed significantly lower lentinan degrading activity (60−70% of the wild-type strain) in the fruiting bodies 2−4 days after harvesting. The lentinan content of fresh fruiting bodies was similar in the wild-type and EXG2 downregulated strains, but in the downregulated strain, only 25.4% of the lentinan was lost after 4 days, indicating that downregulation of EXG2 enables keeping the lentinan content high longer.

**KEYWORDS:** *shiitake mushroom, lentinan, β-glucan, β-glucanase*

## INTRODUCTION

The cell wall of fungi is typically composed of chitin, *β*-1,3-, and *β*-1,6-glucans. Among these cell-wall polysaccharides, several *β*-glucans from basidiomycetes have been reported to possess physiological activities.[1−3] *Lentinula edodes* (shiitake mushroom) is one of the most widely cultivated edible mushrooms and is highly valued for its medical applications. The water-soluble *β*-1,3-/1,6-glucans from *L. edodes* fruiting bodies are called lentinan[4] and have been reported to have anticancer and immunomodulating activity.[5−8] Lentinan is used clinically as an antitumor and antiallergy agent. Lentinan has a high molecular weight (degree of polymerization range 5400−8900) and a chemical structure of linear *β*-1,3-glucans with two *β*-1,6-glucosyl side chains every five residues.[9,10] It has been suggested that these features of lentinan, the main chain length and the extent of side chains, contribute to its physiological activities.[11]

Basidiomycetes such as *L. edodes* form fruiting bodies for sporulation, and the cell wall components of fruiting bodies undergo autolysis after sporulation or artificial harvesting.[12−15] Although lentinan can be purified from fresh *L. edodes* fruiting bodies, it is rapidly degraded during storage as a result of an increase in glucanase activity.[16,17] Minato et al. (1999) have reported that lentinan content decreases to less than half of the original during 5 days of storage at 20 °C. Previously, we isolated four *β*-glucanases, an *exo*-*β*-1,3-glucanase, EXG2, an *endo*-*β*-1,3-glucanase, TLG1, an *endo*-*β*-1,3-glucanase, GLU1, and an *endo*-*β*-1,6-glucanase, LePus30A, from *L. edodes* fruiting bodies 4 days after harvest.[13,18−20] These enzymes are produced in particular during fruiting body senescence and have the ability to degrade the cell-wall *β*-glucans in *L. edodes* fruiting bodies, suggesting they are involved in fruiting body autolysis.[14]

Among these *β*-glucanases, EXG2 shows the highest activity in vitro toward lentinan in reaction tests.[13] The complementary DNA of EXG2, *exg2*, includes an open reading frame of 2343 bp encoding a 21 amino acid signal peptide and a 759 amino acid mature protein. Sequence analysis indicated that EXG2 is a member of glycoside hydrolase (GH) family 55, and GH 55 *exo*-*β*-1,3-glucanases are found only in filamentous fungi (CAZy: http://www.cazy.org). The expression of *exg2* increases after harvesting, and this pattern correlates with a decrease in lentinan in *L. edodes* fruiting bodies. From these characteristics of EXG2, we deduced that the enzyme strongly enhances lentinan degradation in *L. edodes* fruiting bodies after harvesting.

Downregulation of gene expression in fruiting bodies has been reported in some basidiomycetes such as *Agaricus bisporus* and *Pleurotus ostreatus*.[21,22] Previously, we showed that RNA interference (RNAi) could be used for gene silencing in *L. edodes*.[23] RNAi is a post-transcriptional gene silencing phenomenon in which double-stranded RNA (dsRNA) triggers degradation of cognate mRNA in a sequence-specific manner. In this study, we downregulated the expression of the *exg2* gene in an *L. edodes* strain using RNAi and raised fruiting bodies of the *exg2* downregulated transformant (ivr-exg2#51). Analysis of

the phenotype of ivr-exg2#51 indicated that EXG2 is a key enzyme in lentinan degradation in *L. edodes* fruiting bodies after harvest.

## MATERIALS AND METHODS

**Strains and Culture Conditions.** A dikaryotic strain of *L. edodes* SR-1 was used as the recipient host in all transformation experiments. Mycelia were maintained on 0.25 × MYPG medium containing 0.25% Bacto malt extract (Difco, Detroit, MI, USA), 0.1% Bacto yeast extract (Difco), 0.1% tryptone peptone (Difco), and 0.5% glucose.

For postharvest preservation, fruiting bodies were prepared following a previously described method.[13] The harvested mature fruiting bodies were immediately transferred to a room at 25 °C with 80% humidity.[24] After harvest, fruiting bodies were sampled every day for 4 days, with day 0 being defined as corresponding to a fresh mature fruiting body just prior to postharvest preservation. After postharvest preservation, stipes were removed from samples and then immediately frozen in liquid nitrogen. For following enzymatic activity and lentinan content assays, three separate samples were prepared per data.

**Construction of the pChG′ and pChG′-ivrexg2 Vectors.** The pChG′-Gateway vector containing a multicloning site was constructed by Nakade et al. from vector pChG.[23,25] pChG′ was digested by *EheI*, and the Gateway cassette (Gateway Vector Conversion System; Invitrogen, CA, USA) was ligated into the digested pChG′ vector (pChG′-Gateway), then used to transform *Escherichia coli* competent cells (One Shot ccdB Survival cells, Invitrogen).

To construct the RNAi vectors, we synthesized the 250-bp short homologous hairpin dsRNA sequences of the *exg2*,[13] separated by a 60-bp spacer sequence of *lcc1* intron 2 (Figure S1, Supporting Information) (MediBIC Group, Co., Ltd., Tokyo, Japan). Synthesized DNA was inserted into vector pDONR221 (Invitrogen) and then transformed into pChG′-Gateway by an LR reaction (Invitrogen).

***L. edodes* Transformation.** The SR-1 strain was transformed with 2.5 μg of DNA of the above vectors by the restriction enzyme-mediated integration (REMI) method using 5.0 U *SphI*.[26] Transformants were selected on 0.25 × MYPG containing 20 μg mL$^{-1}$ of hygromycin B.

**Protein Extraction.** The frozen pileus and gill parts of the fruiting bodies (0−4 days after harvest, 2 g) were suspended in 0.5 mL of 100 mM sodium acetate buffer (pH 4.2) and mixed for 60 min at room temperature. The extracts containing protein were collected by centrifugation (10 000*g*, 20 min) and filtration (Ultrafree MC HV 0.45 μm filter, Merck Millipore, Darmstadt, Germany). The extracts were desalted and concentrated using an Amicon Ultra 10,000 NMWL filter (Merck Millipore), and 2 μg of the samples was used for Western blotting as described below.

**Protein Assays.** Protein concentration was measured by the Bradford method using the Bio-Rad Protein Assay kit (Bio-Rad Laboratory, CA USA) with a bovine serum albumin (BSA) (Pierce, Rockford, IL, USA) standard. Protein concentration was monitored by absorbance at 595 nm.

**Western Blotting.** For Western blot analysis, fruiting bodies after postharvest preservation and aging fruiting bodies were sampled as described above. Samples were frozen and crushed in liquid nitrogen, suspended in extraction buffer (200 mM sodium acetate, pH 4.2), and incubated by rotation for 15 min at room temperature. Electrophoresis and blotting were performed as described previously.[24] For Western blot analysis, EXG2 antiserum was used as the primary antibody, and antirabbit Ig conjugated with horseradish peroxidase was used as the secondary antibody. ECL detection reagents were used for detection (GE Healthcare, Little Chalfont, UK).[13]

**Measurement of Enzymatic Activity.** To measure enzymatic activity in the fruiting bodies, extracts prepared as above were assayed using lentinan (0.5%), pustulan (0.5%), Curdlan (1%), and *p*-nitrophenyl-*N*-acetyl-β-D-glucosaminide (pNP-GlcNAc, 0.5 mM, Sigma-Aldrich Inc., St. Louis, MO, USA) as substrates in 50 mM sodium acetate buffer (pH 4.2) at 37 °C. Reducing sugars liberated from lentinan, pustulan, and Curdlan were analyzed according to the Somogyi−Nelson method.[27] To assay pNP-GlcNAc, the amount of pNP was determined spectrophotometrically at 405 nm. The extinction coefficient of pNP was assumed to be 17 100 M$^{-1}$ cm$^{-1}$.[28] One unit (U) of enzyme activity was defined as the amount of enzyme that produces 1 μmol of reducing sugar per minute.

**Measurement of Lentinan Content in Fruiting Bodies.** The *L. edodes* fruiting body samples prepared as above (approximately 15 g) were freeze-dried and crushed. A water-soluble cell wall polysaccharide mixture was extracted by autoclaving in 20 mL of water (120 °C, 20 min). The hot-water extract was recovered from the supernatant by ethanol precipitation, and the dried precipitate was used for measurement of lentinan content. The lentinan content of the samples was determined by an ELISA inhibition assay with antilentinan antibodies prepared previously.[16,29]

## RESULTS AND DISCUSSION

**Constructing Downregulated Transformants of *exg2*.** An *exg2* homologous hairpin dsRNA expression vector (pChG′-ivr-exg2) was constructed (Figure S1, Supporting Information) and introduced to *L. edodes* using REMI-based transformation, allowing integration in the genome.[23,26] We obtained 67 transformants of pChG′-ivr-exg2; 6 transformants were selected and tested for EXG2 expression after harvesting of fruiting bodies. Expression of EXG2 in wild type increased after harvesting.[13] Expression of EXG2 in ivr-exg2#7 was higher, but its expression in #26, #39, and #51 was significantly suppressed (Figure 1). Expression of the β-glucanase TLG1

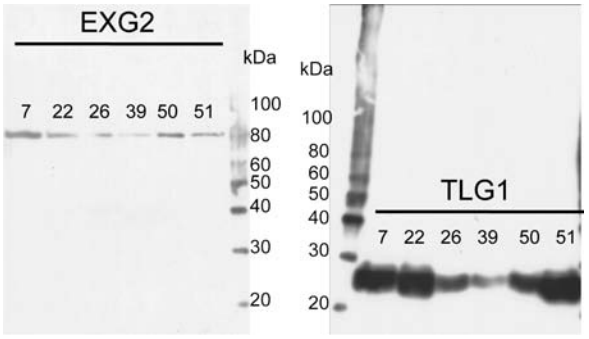

**Figure 1.** Western blot analysis of the crude enzyme from fruiting bodies 4 days after harvest. Selected transformants of pChG′-ivr-exg2 (ivr-exg2 #7, #22, #26, #39,#50, #51) were tested. Western blot analysis was performed using (A) EXG2 antiserum and (B) TLG1 antiserum.

was also suppressed in #26 and #39 for unknown reasons but was similar to wild-type levels in #51.[18] These results suggest that expression of *exg2* is specifically suppressed in ivr-exg2#51.

**Analyzing the Phenotype of ivr-exg2#51.** Fruiting bodies of the EXG2 downregulated transformant (ivr-exg2#51), the pChG′ vector transformant (pChG′), and the control (SR-1) were cultivated, harvested, and preserved for 4 days (Figure S2, Supporting Information). As shown in Figure 2, EXG2 production of ivr-exg2#51 in fruiting bodies preserved for 2−4 days was significantly suppressed compared to pChG′ and SR-1. The EXG2 suppression was also observed in the transcription level (Figure S3, Supporting Information).

Sakamoto et al. reported that EXG2 is involved in self-degradation of cell-wall β-1,3-glucans, causing lentinan degradation during postharvest preservation.[13] To analyze enzyme activity in the fruiting bodies after harvest, crude enzymes were extracted from fruiting bodies and tested for activity on substrates related to fungal cell-wall components. As shown in Figure 3A and 3B, β-1,3-glucanase activities of pChG′

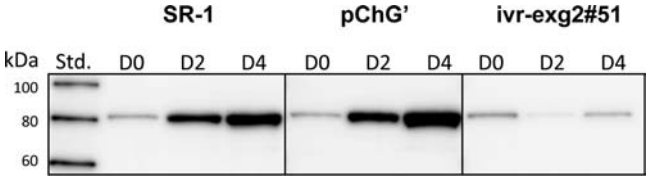

**Figure 2.** Western blotting pattern of extracts from the fruiting bodies of SR-1 (original strain), PchG′ (control strain), and an EXG2 downregulated strain (ivr-exg2#51) using EXG2 antibody. Fruiting bodies were preserved for 0−4 days after harvesting, and the extracts (2 $\mu$g of protein) were separated by SDS-PAGE.

and SR-1 remarkably increased after harvesting of fruiting bodies, whereas the activity of ivr-exg2#51 toward a water-soluble $\beta$-1,3/1,6-glucan (lentinan) was approximately 60−70% lower than that of pChG′ and SR-1. Moreover, the enzymatic activity against a water-insoluble $\beta$-1,3-glucan (Curdlan) was also decreased in the EXG2 downregulated strain; the activity of ivr-exg2#51 at day 2 was approximately 80% lower than that of SR-1 and pChG′, and the activity at day 4 was approximately 60−75% lower (Figure 3B). When $\beta$-1,6-glucan (pustulan) and artificial chitin oligosaccharide (pNP-GlcNAc) were used as substrates, no significant difference was observed in enzymatic activity (Figure 3C and 3D). These results indicate that downregulation of EXG2 specifically caused the reduction of $\beta$-1,3-glucanase activity in the fruiting bodies after harvest.

The lentinan content of hot-water extracts prepared from *L. edodes* fruiting bodies was determined using antibody-based detection.[16,29] The lentinan content of fresh fruiting bodies (D0) was almost similar, 4.1−5.5 mg/g dry weight (dw) in SR-1, pChG′, and ivr-exg2#51. Table 1 shows the changes in lentinan content in the fruiting bodies after harvest; 60.6% of the lentinan content was lost in SR-1, and 61.9% was lost in pChG′ after 4 days of preservation. However, the loss in lentinan content of ivr-exg2#51 after 4 days of preservation was only 27.5%, demonstrating that ivr-exg2#51 preserves the lentinan content over a longer time than the original strain.

**Table 1. Changes in Lentinan Content in the Fruiting Bodies of SR-1 (Original Strain), pChG′ (Control Strain), and an EXG2 Downregulated Strain (ivr-exg2#51) after Harvesting[a]**

| | D0 (mg/g dw) | D4 (mg/g dw) | residual ratio (%) |
|---|---|---|---|
| SR-1 | 4.16 ± 0.69 | 1.64 ± 1.07 | 39.4 |
| pChG′ | 4.70 ± 0.89 | 1.80 ± 1.00 | 38.1 |
| ivr-exg2#51 | 5.45 ± 0.35 | 3.95 ± 1.30 | 72.5 |

Previously, we purified two other $\beta$-1,3-glucanases, TLG1 and GLU1, next to EXG2 from harvested *L. edodes* fruiting bodies.[18,19] These two enzymes are also expressed in fruiting bodies after harvest, suggesting that they are involved in fruiting body senescence. The $\beta$-1,3-glucanase activity and the decrease in lentinan content in harvested ivr-exg2#51 fruiting bodies might be caused primarily by the actions of TLG1 and GLU1. However, their $\beta$-1,3-glucanase activities are weaker than that of EXG2. Moreover, TLG1 and GLU1 have been suggested to have strict substrate specificity for $\beta$-1,3-glucan polymers; $\beta$-1,6-linkages within $\beta$-1,3/1,6-glucan would prevent hydrolysis of the $\beta$-1,3-linkages, and the enzymes showed low activity toward $\beta$-1,3-glucan oligomers. Therefore, TLG1 and GLU1 might only perform a partial degradation of cell-wall $\beta$-1,3-glucans at the fruiting body senescence stage. On the other hand, EXG2 can cleave almost all $\beta$-1,3-linkages within $\beta$-1,3-glucans and $\beta$-1,3/1,6-glucans regardless of their length and branching structure.[30] Indeed, lentinan is completely degraded to glucose and gentiobiose by the exotype manner of action of EXG2.[15] EXG2 belongs to GH 55, and the crystal structure of a GH 55 *exo*-$\beta$-1,3-glucanase from the basidiomycete *Phanerochaete chrysosporium*, homologous to EXG2 from *L. edodes*, has been reported.[30] This *P. chrysosporium* enzyme appears to be able to accept a gentiobiose unit in the cleavage site owing to its substrate-binding pocket structure, suggesting that GH 55 *exo*-

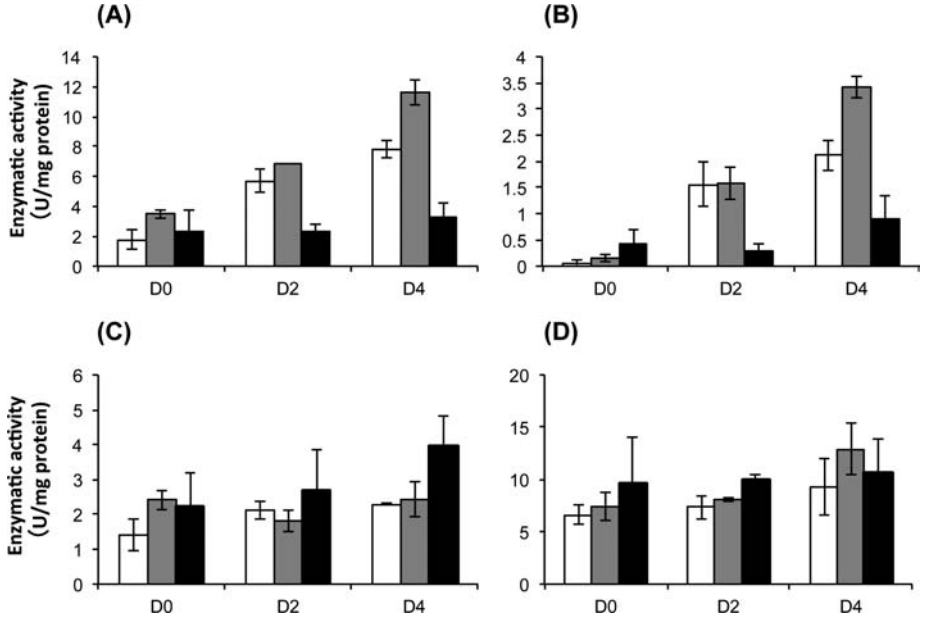

**Figure 3.** Changes in enzymatic activities in the fruiting bodies of SR-1 (original strain, white), pChG′ (control strain, gray), and an EXG2 downregulated strain (ivr-exg2#51, black) after harvesting. Lentinan (A), Curdlan (B), pustulan (C), and pNP-GlcNAc (D) were used as substrates. The data indicate means ± SD ($n$ = 3 samples).

$\beta$-1,3-glucanases can bypass the $\beta$-1,6-glucosyl side chains in lentinan. In this study, approximately 75% of the lentinan content in *L. edodes* was preserved for 4 days by the downregulation of only EXG2. This suggests that EXG2 is the most effective $\beta$-1,3-glucanase in cell-wall autolysis of fruiting bodies after artificial harvesting. Lentinan from *L. edodes* fruiting bodies is a very valuable polysaccharide for medical applications because of its anticancer activity and immunomodulating activity. Lentinan is obtained only from fresh fruiting bodies and decreases rapidly during postharvest storage due to the actions of $\beta$-1,3-glucanases. This study indicates that a knockout or downregulation of EXG2 in *L. edodes* enables a significantly more stable supply of lentinan.

Supporting Information

**ABSTRACT:** The production of neutralizing immunoglobulin A (IgA) in edible fruits as a means of oral passive immunization is a promising strategy for the inexpensive treatment of mucosal diseases. This approach is based on the assumption that the edible status remains unaltered in the immunoglobulin-expressing fruit, and therefore extensive purification is not required for mucosal delivery. However, unintended effects associated with IgA expression such as toxic secondary metabolites and protein allergens cannot be dismissed a priori and need to be investigated. This paper describes a collection of independent transgenic tomato lines expressing a neutralizing human IgA against rotavirus, a mucosal pathogen producing severe diarrhea episodes. This collection was used to evaluate possible unintended effects associated with recombinant IgA expression. A comparative analysis of protein and secondary metabolite profiles using wild type lines and other commercial varieties failed to find unsafe features significantly associated with IgA expression. Preliminary, the data indicate that formulations derived from IgA tomatoes are as safe for consumption as equivalent formulations derived from wild type tomatoes.

**KEYWORDS:** *tomato, IgA, antibody, rotavirus, unintended effects, metabolomics, proteomics*

## INTRODUCTION

Antibody-based treatments for mucosal passive immunization (MPI) have great potential in human and veterinary medicine for the prevention of infection diseases. MPI is particularly advantageous for the treatment of enteric diseases.[1−3] Generally, passive antibody-based treatments require large amounts of antibodies to be delivered to the target mucosa to ensure protection.[4] The high specificity of recombinant monoclonal antibodies makes them excellent candidates for MPI; however, the increasing costs of producing recombinant antibodies in the preferred mammalian cell platforms has hampered their use in MPI.

As an alternative, neutralizing recombinant antibodies aimed at MPI can be inexpensively produced in edible plant organs. Many seeds, fruits, leaves, tubers, and roots are considered safe and palatable for human consumption in minimally processed formulations without heat treatment;[5] therefore, it has been proposed that antibodies produced in plant organs with generally regarded as safe (GRAS) status could be delivered as dose-controlled ingredients in partially processed formulations without the need for exhaustive purification.[4] This would certainly reduce the manufacturing costs, as plant platforms are reportedly easier to scale up than other platforms, for example, those based on fermentation.[5]

The lack of exhaustive purification can, on the other hand, become a drawback when the composition of the final product ultimately results from an event of genetic modification. It could be argued that, besides producing a recombinant antibody, transgenesis could eventually lead to unintended effects in the final fruit composition.[6,7] Such unintended effects could be derived from the integration of the transgene, from biological interactions caused by transgene-encoding proteins, or from spurious somaclonal mutations. Unintended effects have become one of the most controversial issues in biological safety debates.[8] Despite the evidence accumulated during the past 20 years indicating that transgenesis could be even less disruptive of food composition than traditional breeding,[8−10] the absence of unintended, deleterious effects in the composition of genetically modified edible plants organs expressing recombinant antibodies has never been assessed.

Recently, our group reported a model human immunoglobulin A (IgA) for passive protection against the enteric pathogen rotavirus, produced in transgenic tomato fruits. Dry formulations suitable for oral intake and compatible with long-term storage presented a high concentration of active antibodies (≈0.7 mg/g DW), which were shown to inhibit virus infections in an in vitro virus neutralization assay. Thus, minimally processed fruit-derived formulations containing recombinant IgA were proposed as potential vehicles for low-cost MPI treatments.[11] The availability of IgA-producing fruits provides an opportunity to test for the possible unintended effects that the expression of a human antibody could have on the final composition of the fruit and to infer the possible deleterious effects on human health that such unintended effects could have.

Safety concerns in tomato fruit composition arise fundamentally from two sources: proteins (allergens) and secondary metabolites (toxicants). So far, only three tomato protein allergens, Lyc e 1 (profilin), Lyc e 2 (invertase), and Lyc e 3

(nonspecific lipid transfer protein), are listed in the official International Union of Immunological Societies (IUIS) allergen database, although additional potential allergens have been reported.[12−16] To investigate the changes in the fruit protein profile associated with the overexpression of recombinant proteins, a proteomic analysis is required. Proteomics is a powerful nontargeted tool that can be used to detect unintended differences derived from genetic manipulation. Proteomics-based approaches have been used a number of times to compare protein profiles of transgenic maize,[17] tomato,[18] or potato[19,20] with their nontransgenic counterparts.[8]

A second possible source of concern is the presence of toxic metabolites. Fruits are rich in chemically diverse compounds, which can be present in a wide range of different concentrations. The most important toxicants in tomatoes are the steroidal glycoalkaloids $\alpha$-tomatine and dehydrotomatine. Tomato glycoalkaloids are synthesized in tomato fruits during early development and then degraded during fruit maturation.[21−24] There is no analytical method capable of extracting and detecting all metabolites; however, in the past two decades, several methods have been established for large-scale analysis and comparison of metabolites in plant extracts.[8,25] Among them, ultraperformance liquid chromatography−mass spectrometry (UPLC-MS) specifically allows the detection and quantification of semipolar secondary metabolites, which is the major source of potential toxicants.

The goal of this work was to examine a broad set of components in the fruit to search for unintended effects produced by the expression of a human IgA, which could eventually affect the safety of minimally processed formulations derived from IgA tomatoes. First, a protein profile analysis was performed to detect possible changes associated with the production of human IgA in the fruit. Next, the metabolomic profile of IgA tomatoes was compared to that of nontransgenic tomatoes to detect possible unintended effects in the semipolar secondary metabolite pool.

## MATERIALS AND METHODS

**Plant Material.** Seven transgenic lines (A, B, D, F, G, H, and I) of tomato (*Solanum lycopersicum* cv. Moneymaker) expressing human IgA were used in this study along with the parental line, K, used for genetic transformation. Lines A, B, and D were obtained by *Agrobacterium*-mediated transformation of a plasmid carrying the heavy (HC) and light chains (LC) of human IgA under the cauliflower mosaic virus 35s constitutive promoter and the tomato NH fruit promoter,[26] respectively. Lines F, G, H, and I were obtained by cotransformation with two *Agrobacterium* cultures, one carrying a plasmid with the 35s:IgA_HC and the second carrying a plasmid with the 35s:IgA_LC construct. A detailed description of the generation of these transgenic lines can be found in Juarez et al.[11] Additionally, two nullizygote segregant lines, C and E, from the 35S:IgA_HC/NH:IgA_LC transformation, and one wild type moneymaker line, J, obtained from a different laboratory were also included as additional controls. Finally, fruits from three widely consumed tomato varieties, plum (L), round (M), and cherry (N), purchased from a local grocery completed the experimental data set. Tomato seeds (excluding commercial lines L, M, and N) were grown in pots in a greenhouse with a light/dark cycle of 16/8 h. Fruits were harvested 15 days postbreaker. Five independent samples from each plant line were collected. After removal of the gel and seeds, tomato pericarp (with the peel) was ground to a fine powder in liquid nitrogen and stored at −80 °C for further analysis.

**Protein Analysis.** For antibody analysis, frozen tomato powder samples from each group were pooled together. Total soluble protein (TSP) extraction, Western blots, and ELISA tests for IgA quantification were developed as previously described.[11] Proteomic profiling, protein precipitation, fluorescent labeling, 2D electrophoresis, and protein identification by mass spectrometry (MALDI, LC-MS/MS) were developed as previously described.[27] To identify differentially regulated proteins, each 2D gel was loaded with three samples: a transgenic line, a nontransgenic line, and an internal standard (Figure 2a, blue). The internal standard was composed of a pool of all the transgenic and nontransgenic samples used in the analysis. Each of the three samples in a gel was labeled with a different CyDye (Cy2, Cy3, and Cy5). 2D gels were scanned using a Typhoon Trio (GE Healthcare). The three different images corresponding to each fluorophore were overlapped, and the spots from the different gels were matched. Gel image analysis was performed with DeCyder 2D software v. 6.5. Principal component analysis (PCA) was performed with the software package SIMCA-P 11 (Umetrics, Sweden). Sample J was not included in the PCA plot to improve visualization. The PCA plot with the complete set of samples is shown in Supplementay Figure 1 in the Supporting Information.

**UPLC-QTOF and Data Processing.** Ultraperformance liquid chromatography−quadrupole time of flight (UPLC-QTOF) analysis of tomato powder was performed as previously described,[28] with minor modifications. Following extraction in 3 volumes of cold (−20 °C) methanol acidified with 0.125% formic acid, the supernatant was dried (in two separate 750 $\mu$L aliquots) in a Speed-Vac and stored at −80 °C. Prior to analysis, dry extracts were solubilized in 150 $\mu$L of methanol−0.1% formic acid and filtered through a 0.2 $\mu$m Anotop 10 membrane filter (Whatman, Kent, UK). Samples were analyzed by UPLC-MS using an ACQUITYUPLC-PDA system coupled to a Q-Tof micro mass spectrometer (Waters Corp., Milford, MA, USA).[28] Mass spectrometry analysis was performed by electrospray ionization (ESI) in positive and negative modes (using one of the extract aliquots for each ionization mode). A reference sample (made by pooling equal amounts of all biological samples) was injected four times (at regular intervals) in each injection series. MassLynx raw files converted to netCDF format with DataBridge (Waters Corp.) were processed with XCMS package v. 1.34.0 (http://bioc.ism.ac.jp/2.11/bioc/html/xcms.html) run under R v. 2.15.2 (http://www.r-project.org/). The centWave algorithm[29] was used for feature detection; peak grouping and retention time correction were performed with the density and peakgroups algorithms,[30] respectively. Mass features were grouped using the CAMERA algorithm.[31] The area of each extracted mass feature was first normalized to the total chromatogram area; the reference sample was then used to normalize the data between different runs (for each mass feature, the test sample area is divided by the mean area of the reference samples included in that run). Preprocessing of the data generated two discrete data files, one for each ionization mode: ESI− (electrospray ionization in negative mode) and ESI+ (electrospray ionization in positive mode). The ESI− data set contained 386 mass variables, whereas 835 peaks were initially identified in the ESI+ mass profile. To remove low-quality data, a first filtering step was done by imposing two different conditions: (i) a mass feature should be detectable in a minimum of three biological replicates in at least one of the tomato lines, and (ii) the average-day coefficient of variation for the reference sample (computed on normalized data) should not be greater than 40%. Mass peaks that did not fulfill these requirements were considered unreliable and were excluded from the study. A second filtering step was accomplished by removing the redundant isotopic features, which were identified by the package CAMERA (a collection of algorithms for metabolite profile annotation with the primary purpose of annotation and evaluation of isotope peaks, adducts, and fragments in peak lists).[31] The final ESI− and ESI+ data sets, with 107 and 246 peaks, respectively, were joined together in a single matrix for further analysis.

**Statistical Data Analysis.** PCA and OPLS-DA of the protein and metabolite profiles of tomato fruits were performed with the software package SIMCA-P 11 (Umetrics). Variables were log-transformed, mean centered, and scaled to unit variance prior to analysis. Two-sample *t* tests on log transform data were performed using MeV v4.9 (http://www.tm4.org/mev.html), an application of the TM4Microarray Software Suite.[32] Safety thresholds in the proof-of-safety analysis

were defined by the symmetric maximum boundaries of the nonparametric 90% confidence intervals for the ratio to WT of the commercial variety farthest away from the WT. Safety was concluded when the confidence intervals for the ratio to control of the transgenic lines were within the safety limits. For the calculations of the confidence intervals the R package pairwise CI was used.

## RESULTS

**Evaluation of IgA Content in the Fruit.** To detect unintended changes in fruit composition, two types of IgA-producing plants were selected for analysis. The first group was generated in cotransformation experiments (referred to as 35S_IgA) in which tomato explants were simultaneously cotransformed with two *Agrobacterium* cultures carrying HC and LC antibody chains, respectively, both of them expressed under the control of constitutive 35S promoter. In the second group (referred to as NH_IgA), both HC and LC were linked in the same T-DNA, with LC placed under the control of the tomato NH promoter.[26] In the second generation (T2), different segregating lines were obtained. Some NH_IgA segregant lines lacking the transgene (nullizygotes) were selected to serve as appropriate negative controls in subsequent assays. All cotransformed 35s-IgA segregants showed at least one of the two antibody chains. As a consequence, no 35S_IgA nullizygote could be included in the analysis. In total, seven independent transgenic lines from both groups (NH_IgA and 35s_IgA) showing a broad range of IgA levels were used in the different comparative analyses (see Table 1). This includes an

"elite" T4 homozygous IgA line (line I) previously selected from the 35S_IgA group for its high antibody levels. A number of IgA-free control lines were also included, which comprised (i) the above-mentioned nullizygote plants from the segregating NH_IgA lines, (ii) two wild type Moneymaker lines from different seed batches, and (iii) three commercial tomato varieties purchased from a local supermarket (L, M, and N).

Tomato plants of all noncommercial lines were grown in the same greenhouse conditions. Fruits were collected 15 days after breaker stage, and frozen tomato powder of each fruit was prepared. The first analytical step consisted on the determination of the antibody content of the different lines. For this, frozen tomato powder samples were extracted in PBS buffer, and the IgA content in the resulting crude extracts was quantified by means of ELISA. As expected, the "elite" homozygous 35S_IgA line (line I) showed the highest IgA levels, with an average content of 37.5 $\mu$g/g FW. The IgA content of the remaining transgenic lines ranged from 25.5 to 1.9 $\mu$g IgA/g FW (see Table 1). To check the integrity of the IgA in the powder samples, 20 transgenic fruits (4 pools of 5 fruits) were analyzed by Western blot. As expected, specific bands corresponding to the HC (55 kDa) and the LC (28 kDa) were detected in all of the transgenic samples analyzed. A major degradation HC fragment band of 28 kDa HC was also observed in blots developed with anti-HC antibody. This degradation corresponds to the HC domains of reduced fragment antigen-binding (Fab) fragments and was earlier characterized by Juarez et al.[11] In all cases the relative expression levels observed in Western blots were consistent with the ELISA quantification. Neither HC nor LC bands were detected in nontransgenic control samples (Figure 1).

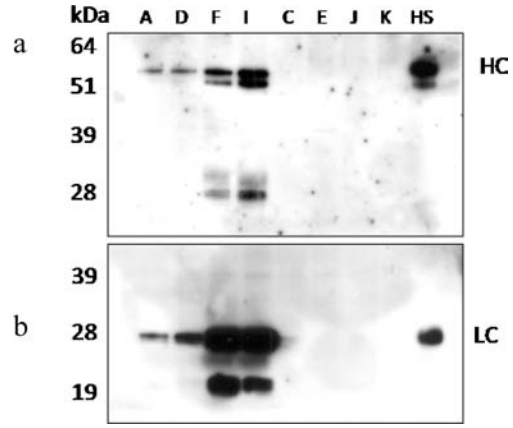

**Figure 1.** Western blot analysis of IgA expression in tomato fruit: (a) Western blot under reducing conditions, developed with anti-heavy chain antibody (HC); (b) Western blot under reducing conditions developed with anti-light chain antibody (LC). Lanes: A and D, NH_IgA lines; F and I, 35S_IgA lines; C and E, nullizygote; J and K, wild type Moneymaker samples from two different seed batches; HS, human serum sample.

**Identification of Differentially Expressed Proteins in IgA Tomatoes by 2D-DIGE and LC-MSMS.** The first assessment of the fruit content was directed to the analysis of the protein composition by 2D-DIGE. A total of eight tomato lines were included in the analysis: four selected IgA lines covering the whole IgA expression range were paired with samples from four nontransgenic lines, which included two in-house-grown Moneymaker plants as well as two NH_IgA nullizygote plants. The NH_IgA tomato samples (A and D from Table 1) were paired with their corresponding nullizygote samples (C and E), in two gels. The other two gels were loaded with 35s_IgA samples (F and I), each one in combination with a different wild type sample (J and K). A total of 1001 spots were located in the four gels. Differential proteins are shown as green spots (with higher levels in transgenic line) or red spots (with higher levels in the control line) (Figure 2). All spots were quantified, and the resulting data were used for the comparative analysis between the composition of the different samples.

A principal component analysis (PCA) was performed with the quantitative data extracted from the quantification of protein spots in the gels (Figure 3). The first two principal components of this PCA model explain 28 and 23% of the total

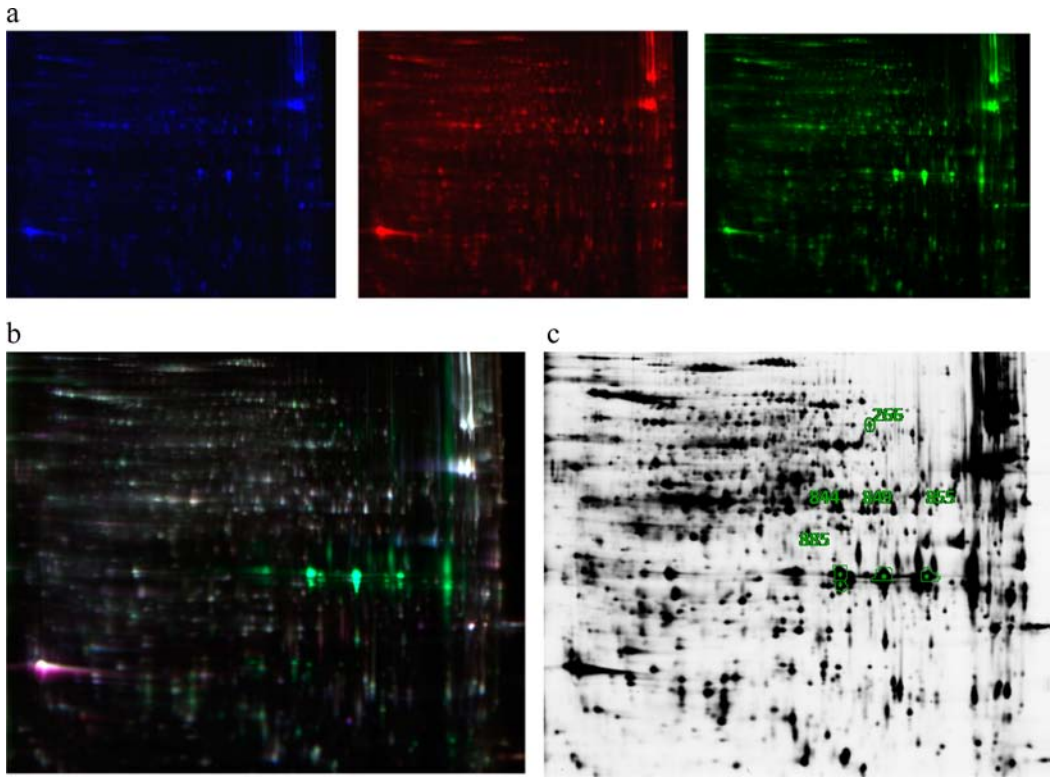

**Figure 2.** Representative 2D DIGE gel of tomato fruit proteins: (a) fluorescence images of gel loaded with equal amounts (50 $\mu$g) of the reference sample (Cy2-labeled, blue), nontransgenic samples (Cy5-labeled, red), and transgenic samples (Cy3-labeled, green); (b) overlay of the three fluorescence images (differential proteins appear in green or red; unaffected proteins appear in white); (c) silver-stained 2D DIGE gel (spots showing significant differences between transgenic and nontransgenic samples are outlined in green).

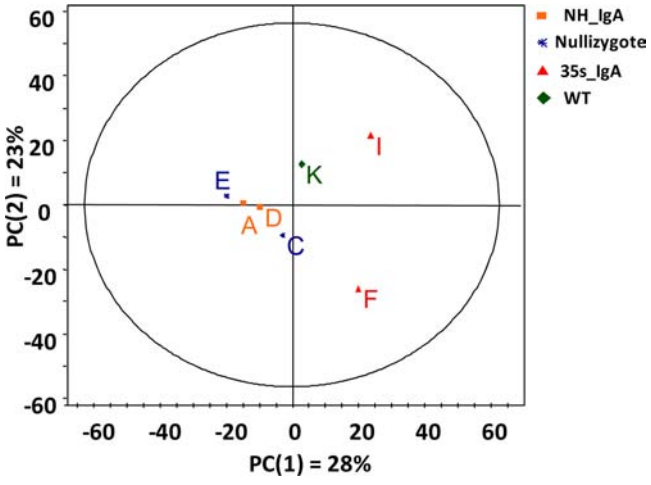

**Figure 3.** PCA of proteomic data of transgenic and nontransgenic tomato lines. Capital letters represent the different tomato lines as described in Table 1. Sample J, which behaves as an outlier, is not included in the plot to improve visualization.

variance, respectively. PC1 slightly separates 35s_IgA lines (F and I) from the rest of the group, which remain together in the scores space. PC2 further discriminates between both 35s_IgA lines (F and I). Interestingly, all samples derived from NH_IgA transformation events (both transgenic and nullizygote) remain closely grouped in the PCA model.

To identify those spots that are the main contributors for class separation, a quantitative comparison between transgenic and nontransgenic lines was performed. From a total of 37 spots showing average ratio higher than 2 (|ratio| > 2), only 19 of them showed an increase in both 35s_IgA and NH_IgA lines when considered separately, and only 5 of these 19 were found statistically significant ($P < 0.05$) (Figure 2c, outlined in green). The identification of all 19 selected spots by LC-MS/MS is shown in Table 2. All spots were identified as HC or LC with the exception of spot 783, which corresponded to a mix of human HC and tomato ACC oxidase.

**Metabolic Profiling by UPLC-MS for the Evaluation of Unintended GM Effects.** Unintended effects on the metabolome of transgenic tomato fruits generated by the expression of human IgA were also evaluated by nontargeted metabolomics. Tomato methanol extracts were used for the analysis, which was carried out by means of reverse-phase UPLC coupled to mass spectrometry (UPLC-QTOF). This technology is especially suited for the detection of semipolar secondary metabolites, primarily tomato polyphenols and alkaloids.[33] Four or five ripe fruits from seven transgenic lines containing different levels of IgA, two nullizygote plants, two wild type Moneymaker lines, and three commercial varieties (L, M, and N) were analyzed.

The mass profile obtained was first processed with XCMS, an integrated metabolomics analysis platform for the determination of metabolic profile differences and metabolite identification.[30] Data processing and filtering generated a total of 356 reliable peaks, which were introduced in a single matrix for analysis. A PCA was performed as the first step in data exploration to examine the relationship between the different sample classes. The first two components of the PCA model explained 30 and 17% of the total variance, respectively. As can be seen in the scores scatter plot depicted in Figure 4a,

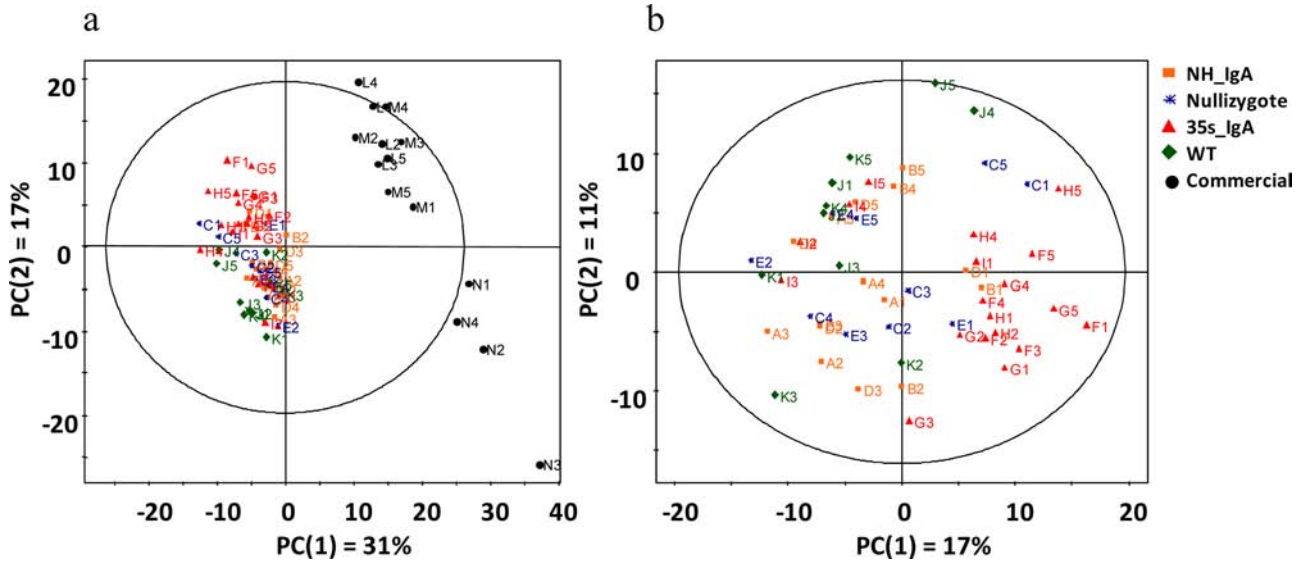

**Figure 4.** PCA scores plots of LC-MS spectra: (a) complete data set of tomato cultivars including transgenic lines expressing IgA, nullizygote lines, wild type lines, and commercial lines; (b) PCA including only Moneymaker lines grown in-house. Each point represents a biological replicate (pool of two to three different fruits). Capital letters represent the different tomato lines as described in Table 1.

PC1 clearly separated the commercial varieties from the remaining samples, whereas PC2 allowed further discrimination within the commercial group between N and L and M lines. The samples from IgA-producing lines and control nullizygote and Moneymaker wild type lines, however, grouped together in the scores space, not being separated by any of the components of the PCA model. As the largest variance in the data set was observed between commercial lines purchased in a supermarket and Moneymaker lines, a new PCA was performed in which commercial lines were excluded from the analysis to thus better explore the differences associated with IgA production. The obtained PCA model (Figure 4b) did not reveal any clear group structure in the data set; only 35S_IgA lines F, G, and H slightly separated from the remaining samples, whereas significant confusion occurred between the homozygous 35S_IgA line I, NH_IgA lines, and the control lines.

To directly search for specific metabolites that discriminate between IgA and control lines, an orthogonal partial least-squares discriminate analysis (OPLS-DA) was set. OPLS-DA makes use of a priori information on class membership (e.g., IgA content) to extract class-related variance in a predictive component and class-uncorrelated variation in one or more orthogonal components. Thus, even in the presence of uncontrolled covariates, OPLS-DA allows a direct identification of class-discriminant variables. As 35s_IgA lines and NH_IgA lines contain very different IgA levels,[11] they were treated separately so that each transgenic group could be compared with its closest control (non-IgA) group. Thus, three separate

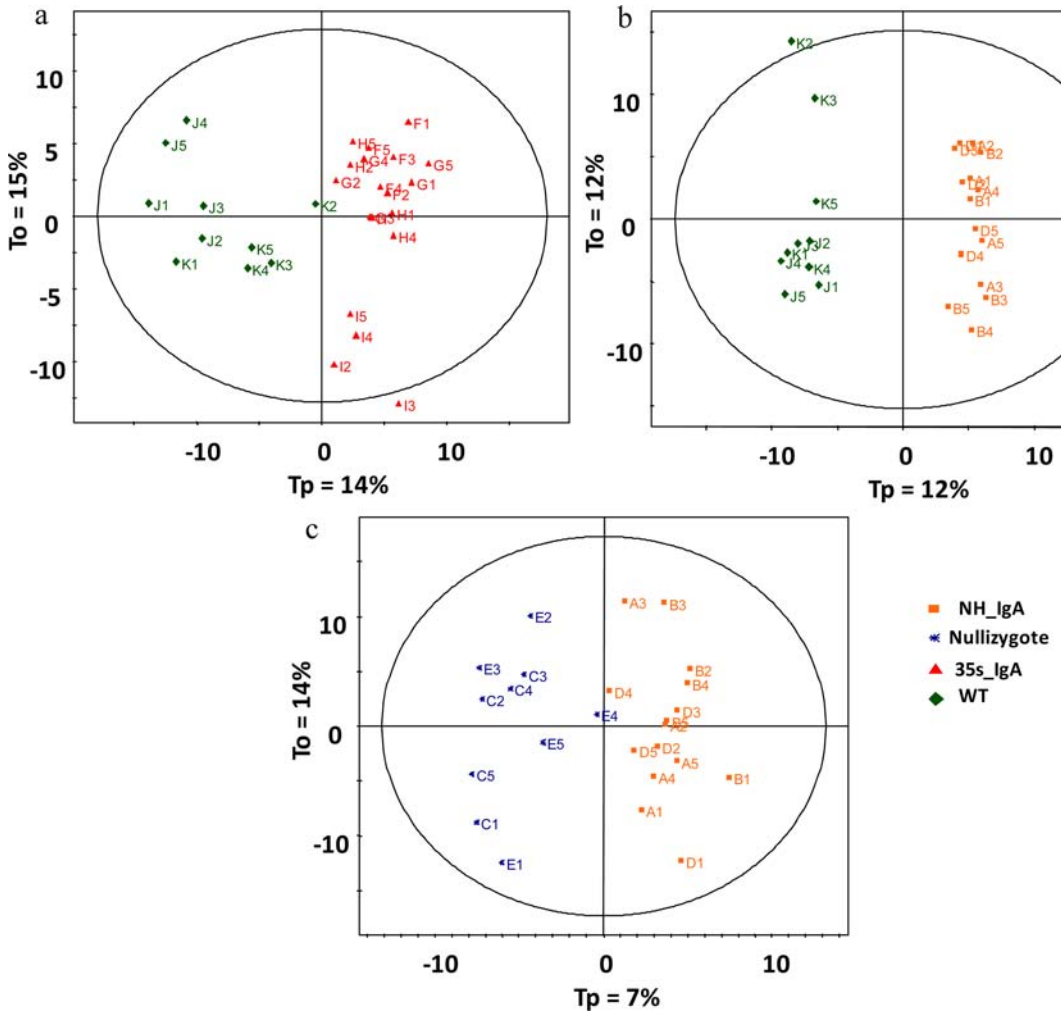

**Figure 5.** OPLS-DA score plots of LC-MS spectra: (a) 35S_IgA versus WT; (b) NH_IgA versus WT; (c) NH_IgA versus nullizygote. Each point represents a biological replicate (pool of two to three different fruits). Capital letters represent the different tomato lines as described in Table 1.

comparisons were made involving 35s_IgA versus WT, NH_IgA versus WT, and NH_IgA versus nullizygote lines (Figure 5). The fitted models comprised one predictive (IgA content) plus one, two, and one orthogonal components, respectively. The variance related to class separation explained by the models was 82, 98, and 84% with a cross-validated predictive ability $Q^2(Y)$ = 0.31, 0.84, and 0.40, indicating a higher uncertainty in the 35s_IgA versus WT and NH_IgA versus nullizygote models regarding class separation. The homozygous line I formed a separate subgroup within the 35s lines as revealed by the first orthogonal component of the model.

The most relevant metabolite ions for class discrimination were selected, according to the following rules: the selected ions should present a high variable influence on projection (VIP ≥ 1), a high correlation with IgA content ($|p(\text{corr})| \geq 0.5$), and narrow jack-knifed 95% confidence intervals of the variable coefficient (confidence interval not crossing zero). Totals of 41, 39, and 27 discriminating mass peaks (counting 91 different masses) were chosen according to these criteria from the 35s_IgA versus WT, NH_IgA versus WT, and NH_IgA versus nullizygote models, respectively. A large proportion of these peaks, however, showed a very modest variation between the transgenic lines and their counterpart controls with <50%, 42 masses, reaching fold ratios ≥2. The complete list of 91 masses is provided in Table S1 as Supporting Information. The three models were then compared by means of shared and unique structures (SUS) plots, an analysis that combines the $p$(corr) profiles from two models, constructed with all of the selected variables (Figure 6). The first SUS plot showed the correlation between models 35s_IgA versus WT and NH_IgA versus WT (Figure 6a). The second SUS plot correlated models 35s_IgA versus WT and NH_IgA versus nullizygote (Figure 6b). The last SUS plot showed the correlation between models NH_IgA versus WT and NH_IgA versus nullizygote (Figure 6c). Only two discriminating ion masses were shared by the three models, namely, masses Mp232 and Mn44. In general, there was little overlap between the 35s_IgA versus WT and NH_IgA versus nullizygote models, except the two mentioned masses, Mp232 and Mn44, sharing high correlation loadings and covariance. Comparison of 35s_IgA versus WT/NH_IgA versus WT and NH_IgA versus WT/NH_IgA versus nullizygote demonstrated greater correspondence, with nine and six common discriminating features, respectively (Figure 6d).

To determine the statistical significance of the differences in the metabolic profiles observed in the OPLS-DA, a univariate analysis was also carried out. A $t$ test was performed for the comparison between NH_IgA versus WT, NH_IgA versus nullizygote, and 35s_IgA versus WT. Seventeen masses, 4.8%

[a]Comparisons in which each mass is significant (FDR < 0.05) are indicated with an asterisk. Mass features showing an uptrend in the transgenic lines are in bold. Contribution to class separation in an OPLS-DA model is indicated by an underscore. [b]Mp, mass detected in ESI+ mode; Mn, mass detected in ESI− mode. [c]$t_R$, retention time.

of the total number of variables, proved to be significant (FDR < 0.05) in at least one of the comparisons (Table 3). All of these metabolic features, which included the ion masses Mp232 and Mn44 above-mentioned, were among the 91 masses selected as major contributors to class separation in the OPLS-DA model. Among the 17 masses, only nine peaks showed an uptrend in the transgenic lines when compared to the WT, which could represent a potential concern regarding the safety of the final product (Supporting Information Supplementary Table 1). These nine mass features, with an average fold variation ranging from 1.6 to 3.4, showed similar tendency in both 35s and NH lines, with the only exception of Mp173,

dx.doi.org/10.1021/jf502292g | J. Agric. Food Chem. 2014, 62, 8158−8168

which remained unaltered in NH lines. However, in all nine cases the same uptrend was observed for the nullizygote lines when compared to the WT. It is also worth noting that no significant differences between the NH_IgA lines and their nullizygote controls were found.

In addition to the assessment of the statistical significance of the differences in the metabolic profiles between the transgenic lines and their counterpart control lines (proof of difference), the safety of the metabolic changes in IgA-producing fruits was also evaluated following a proof-of-safety approach. According to this test, differences will be regarded as safe if the metabolite levels fall within an established safety range.[10,34] When a priori defined safety thresholds are not available, as is necessarily the case for untargeted metabolomic studies, these can be derived from the metabolite levels found in commercial varieties. Thus, following the approach of Kusano et al.,[10] symmetric safety limits were defined as the 90% confidence interval for the ratio to control (WT) of the commercial variety farthest away from the WT. When, for any given metabolite, the confidence interval for the ratio of the transgenic fruits to the WT control is within this safety range, the levels of the metabolite can be regarded as safe. This analysis was performed following three different approaches: in the first one, all 35s lines were analyzed as a group; in the second one, all NH lines were analyzed as a group; and in the third one, the homozygous line was analyzed separately. When these analyses were performed, a single mass, Mn52, showed a ratio to WT outside the acceptable limits in the 35s group. No mass was found to exceed the upper boundary of the safety range in the NH group and, most importantly, all metabolites showed confidence intervals within the acceptable limits when the homozygous line was evaluated separately (Supporting Information Supplementary Table 2). Moreover, it should be noted that Mn52 also exceeds the upper boundary of the safety range when the nullizygote group is analyzed (data not shown).

## DISCUSSION

Plant organs are considered GRAS when at their ripe stage they contain no toxicants, allergens, or antinutrients that could be harmful for the consumer. It is expected that recombinant production of IgA in edible tomatoes does not compromise fruit composition and, consequently, its edibility. However, this hypothesis had never been corroborated experimentally before; the most important compounds concerning edibility in tomato are proteins (allergens) and secondary metabolites (alkaloids).[13] Here, we analyzed proteomic and metabolomic profiles of IgA tomatoes and compared them with those of nontransgenic fruits as a way to evaluate the changes in tomato composition introduced by IgA production. The whole proteome was analyzed by means of 2D-DIGE gels, and UPLC-qTOF was used to analyze secondary metabolites. The changes or similarities are taken as an indication of the safety of minimally processed IgA tomato products.

Four representative transgenic lines paired with four nontransgenic lines were chosen for the proteomic analysis by means of 2D-DIGE. These included NH_IgA compared with their corresponding nullizygote fruits as well as 35s_IgA paired with WT samples. To quantify the magnitude of the changes between transgenic and nontransgenic groups, mean ratios were calculated for each spot between IgA and non-IgA samples. In a first arbitrary cut only spots with ratio >2.0 were selected, as only a high increase in the abundance of a protein can be considered a potential thread. As a result, a total of 19 protein spots were selected for identification by LC-MS/MS, with only 5 of them showing significant increase in a *t* test analysis ($P$ value <0.05). All of the sequenced proteins matched human IgA chains except for spot 783, which showed an overlap between human IgA HC and tomato ACC oxidase, an ethylene-forming enzyme involved in climacteric fruit ripening.[35] ACC oxidase is a common enzyme in climacteric fruits with no allergenic properties reported; thus, a slight increase in this protein probably does not represent a threat for human consumption. Therefore, it can be deduced from this analysis that no other protein apart from IgA is substantially changing the composition of the transgenic tomato.

With regard to the analysis of secondary metabolites, PCA including the commercial varieties L, M, and N showed a clear separation between them and the Moneymaker samples collected from the laboratory greenhouse. This separation could be due to several reasons. It is possible that inherent variety differences are sufficient to separate the samples, but other possible explanations are the cultivation conditions of each tomato batch and the postharvesting conditions to which they have been subjected, for example, refrigeration.[36] These variables seem to mask any differences in semipolar compound levels that could be generated by the production of an immunoglobulin. For this reason, another PCA was made after removal of the commercial samples from the data set. This second PCA showed no separation between IgA lines and IgA-free lines. Both groups showed a similar distribution, meaning that any environmental effect on metabolite composition seems more relevant than putative differences generated by the production of IgA.

Subsequently, OPLS-DA models were set to search for specific unintended effects between transgenic and nontransgenic lines directly related with IgA production. As NH_IgA lines and 35s_IgA lines presented strong differences in IgA levels, they were treated separately. All three OPLS-DA models were able to separate transgenic and nontransgenic lines. However, with the exception of the model set for NH_IgA versus WT comparison, they presented a low predictive power with values of $Q^2 < 0.5$.

In principle, the masses correlating with IgA levels that are common within the three models are expected to be truly related with the IgA production. Only two masses, namely, Mn44 and Mp232, were found to fulfill this criterion. In addition, only Mp232 showed an uptrend in transgenic lines, although this uptrend was significant only when NH_IgA samples were compared with WT but not in the two remaining comparisons. The fact that the Mp232 uptrend is significant in only one of the group comparisons indicates that it has only minor effects in fruit composition. Moreover, the average increase ratio is 3.38-fold, an increase that would be a concern only if high daily doses of tomato-derived products were required. An additional proof-of-safety approach was performed according to the method of Kusano et al.[10] to evaluate if the levels of Mn232 fell outside the safety limits defined by the variability observed among commercial cultivars. In this analysis, all of the measured variables fell within the acceptable limits except for Mn52, which fell outside the safety range when the 35s group was analyzed. However, this mass remained in acceptable safety limits when the NH group and the homozygous line itself were analyzed. It should also be noted that the levels of Mn52 also fell outside the safety range when the nullizygote group was analyzed. These observations, together with the fact that Mn52 was not among the masses

which significantly separated the transgenic from the nontransgenic lines in the OPLS-DA analysis, suggests a lack of association with the IgA production. Most importantly, the levels of mass Mn232 remained within the safety limits in all three approaches. Taken together, these results suggest that no substantial differences beyond natural variation associated with IgA production are found in IgA tomatoes.

It is a common mistake to expect that the composition of a transgenic crop is identical to that of its nontransgenic reference.[37−40] As shown here in PCA and OPLS-DA models, IgA expression leaves an associated footprint in the fruit composition, which can be detected and partially described using proteomic and metabolomic profiling. Similarly, a metabolic signature introduced by the recombinant overexpression of the taste-modifying protein miraculin was found before in tomato fruits using a multiplatform approach, in the context of a substantial equivalence assessment.[10] Other examples pointing out the necessity of assessing the unintended effects in transgenic crops are the transgenic rice lines expressing *sck* and *cry1Ac* genes for insect resistance, which presented slight changes in metabolite concentrations that were caused by gene modification,[41] or the proteome changes found in tomato lines transformed with phytoene synthase-1.[42] There are also a number of remarkable works which point out that transgenesis does not significantly change the metabolic composition of crops.[43−45] As an example, a hierarchical metabolomics approach showed that metabolic changes caused through conventional breeding techniques were at least of a magnitude comparable to those resulting as an unintended effect of genetically modified potato lines expressing inulins.[43] However, to our knowledge, the metabolic signature of a therapeutic protein produced in an edible plant organ was not analyzed before. The overexpression of xenoproteins in the plant cell can induce sequence-specific responses in the host, which range from the suppression of the expression of the foreign gene via post-transcriptional gene silencing to the triggering of a general stress response or the induction of a program of cell death (see Orzaez et al.[46] and references cited therein). Therefore, the accumulation of harmful compounds in response to IgA expression in fruits could not be initially dismissed. By incorporating several independent transformation events leading to different IgA expression levels, this work aimed at evaluating unintended effects associated with producing IgA-based preparations in tomato. However, this work alone cannot rule out the possibility of harmful unintended effects associated with any strategy involving IgA production in fruits. At least three potential sources of uncertainty remain. First, the unexpected accumulation of harmful compounds other than the proteins and semipolar secondary metabolites cannot be dismissed with the methodology used here. A single method enabling complete metabolome analysis does not exist, and therefore additional comprehensive profiling methods should be considered.[7] Second, any new transgenic event involving IgA production in fruits should evaluate possible unintended effects associated specifically with the site of insertion, which can only be evaluated on a case-by-case basis. Finally, as observed in the protein profile, the antibody itself accumulates in the form of different polypeptides with distinct electrophoretic mobilities, probably arising from partial proteolytic degradation and/or different glycosylation patterns. Certainly, the pool of IgA-related polypeptides present in the fruit is different from that occurring in a natural oral passive immunization (OPI), and therefore the safety of the plant-made IgA itself and in the context of the fruit matrix needs to be thoroughly evaluated. All in all, the data shown here constitute a first step for confirming the safety of fruit-based IgA production strategy.

Supporting Information

**ABSTRACT:** Barley husks, rye bran, and a fiber residue from oat milk production were processed by heat pretreatment, various separation steps, and treatment with an endoxylanase in order to improve the prebiotic potential of these cereal byproducts. Metabolic functions were intended to improve along with improved microbial activity. The products obtained were included in a high-fat mouse diet so that all diets contained 5% dietary fiber. In addition, high-fat and low-fat controls as well as partially hydrolyzed guar gum were included in the study. The soluble fiber product obtained from rye bran caused a significant increase in the bifidobacteria (log copies of 16S rRNA genes; median (25−75 percentile): 6.38 (6.04−6.66) and 7.47 (7.30−7.74), respectively; $p < 0.001$) in parallel with a tendency of increased production of propionic acid and indications of improved metabolic function compared with high-fat fed control mice. The oat-derived product caused an increase in the pool of cecal propionic (from 0.62 ± 0.12 to 0.94 ± 0.08) and butyric acid (from 0.38 ± 0.04 to 0.60 ± 0.04) compared with the high-fat control, and it caused a significant increase in lactobacilli (log copies of 16S rRNA genes; median (25−75 percentile): 6.83 (6.65−7.53) and 8.04 (7.86−8.33), respectively; $p < 0.01$) in the cecal mucosa. However, no changes in measured metabolic parameters were observed by either oat or barley products.

## INTRODUCTION

Dietary fiber is a collective term for carbohydrates in plants with three or more monomeric units that are resistant to digestion by human gastrointestinal enzymes. Health benefits of dietary fiber in the human diet, such as reduced risk for developing obesity, diabetes, coronary heart disease, hypertension, and gastrointestinal disorders such as colorectal cancer are well-known.[1,2] In this respect, the viscosity of the dietary fiber seems to play an important role and the higher the viscosity the higher the beneficial effect.[3] However, in recent years, the effect of short-chain fatty acids (SCFA), produced from soluble fiber during colonic fermentation, has been more emphasized. This means that also nonviscous indigestible carbohydrates of lower molecular weight may contribute to reduce the risk of cardiovascular disease and type 2-diabetes.

Cereals such as wheat, rye, barley, and oats are important sources of dietary fiber in the human diet. The hemicelluloses, which have structural functions in the plant cell walls, constitute major components in the fiber fraction. Cereals contain a variety of hemicelluloses with arabinoxylan as an important example. In obese mice, wheat arabinoxylan has been shown to counteract the high-fat-induced change of the gut microbiota in parallel with decreased body weight gain and insulin resistance.[4]

Dietary fiber, which is fermented by the colonic microorganisms, may be an important modulator of the gut microbiota, which in turn is essential for the metabolic function of the host. A beneficial microbiota may inhibit pathogen colonization, modulate the immune system, and metabolize otherwise indigestible carbohydrates.[5] Indigestible carbohydrates can be regarded as prebiotic if they selectively stimulate the growth and activity of intestinal bacteria with health promoting effects for the host. Mostly oligosaccharides such as fructo-oligosaccharides and galacto-oligosaccharides are included in this concept, but in fact all dietary fiber that are fermented in the colon are potential prebiotic components.[6] Also the formation of bacterial metabolites, formed as a consequence of oligosaccharide fermentation, such as SCFA, may be important. Of the SCFA, propionic acid and butyric acid have mostly been associated with beneficial metabolic effects.[7] Interestingly, the monomeric composition and chain length of the oligosaccharides are of utmost importance in this respect. Thus, FOS of higher chain length gave higher formation of propionic acid in rats than FOS of lower chain length, which instead gave higher amounts of butyric acid.[8]

In addition to FOS, several other types of oligosaccharides have promising properties. These include mannooligosaccharides (MOS), xylooligosaccharides (XOS), and arabinoxylooli-

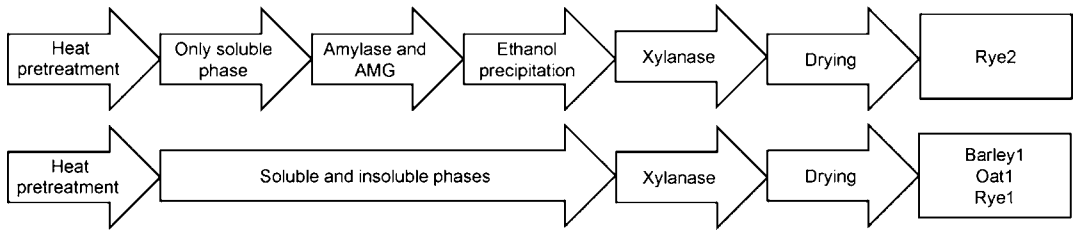

**Figure 1.** Schematic flowchart of the processes used to produce the different products. AMG = amyloglucosidase.

gosaccharides (AXOS). MOS produced from guar gum has been shown to increase the number of bifidobacteria in faeces of humans when incorporated into biscuits.[9] Furthermore, there is now overwhelming evidence that XOS and AXOS are prebiotics.[10] XOS have been shown to be fermented by certain groups of lactobacilli and bifidobacteria present in the human gut microbiota[11,12] XOS have been shown to be fermented by certain strains of the genus *Weissella*, which are putative probiotic bacteria.[13] FOS and XOS were found to stimulate bifidobacteria and lactobacilli, but the stimulation pattern was different.[14]

It should be emphasized that the size and structure of the oligosaccharides are important for their properties in general and for their digestibility by bacteria. Short AXOS have been shown to stimulate digestion by bifidobacteria, while longer ones were shown to decrease protein fermentation (branched SCFA), and it has been suggested that an average degree of polymerization of 5 was optimal for the overall effect on gut health characteristics.[15] It has also been shown that the selectivity for lactobacilli and bifidobacteria, i.e., the prebiotic effect, increased with decreasing size of wheat arabinoxylan.[16]

In the present study, byproducts from industrially processed barley, oats, and rye were treated in different ways, including selective hydrolysis catalyzed by a xylanase for the generation of XOS and AXOS, in order to improve the products' prebiotic potential. The products were evaluated in high-fat fed C57BL/6 mice, a model of obesity and insulin resistance associated with microbial dysbiosis,[17] with special attention on effects on the gut microbiota and generation of SCFA as an improved gut microbial activity was hypothesized to improve metabolic functions of the host. This model was chosen rather than healthy animals in order to get faster effects on physiological parameters and gut microbiota.

## MATERIALS AND METHODS

**Chemicals.** Thermostable amylase (*Bacillus licheniformis*) and amyloglucosidase (*Aspergillus niger*) were purchased from Megazyme (Wicklow, Ireland). Xylanase was from the thermophilic bacterium *Rhodothermus marinus* (*Rm*Xyn10A, catalytic domain[18]) and was produced and purified in-house as described elsewhere.[19] All other chemicals were of analytical grade unless stated otherwise.

**Materials.** Milled barley husks (Lyckeby Stärkelsen, Kristianstad, Sweden), oat fiber residue (Oatly, Landskrona, Sweden), and rye bran (Farina, Kävlinge, Sweden) were included in the study. Partially hydrolyzed guar gum (Guar) was obtained under the trade name Sunfiber R (lot no. 002141) (Taiyo Lucid Pvt. Ltd., Mumbai, India). The Sunfiber has been shown to be polydispersed with an average weight of 20 kDa.[20]

**Processing Steps.** *Heat Pretreatment.* The products Barley1, Oat1, and Rye1 were made from 150 g of dry barley husks (Barley0), oat fiber residue (Oat0), and rye bran (Rye0), respectively (Figure 1). The more refined product Rye2 was made from 1.62 kg of rye bran (Rye0) (Figure 1). The products were mixed with deionized water with a weight ratio of 1:9 and autoclaved in glass bottles at 121 °C for 15 h.

*Treatments of Products Barley1, Oat1, and Rye1.* The autoclaved products were adjusted to pH 6 using NaOH and then heated under stirring to 70 °C. Thereafter, 900 U of the thermostable xylanase was added to the samples. The reaction mixture was maintained at 70 °C for 23 h under constant stirring, and the reaction was terminated by autoclaving at 121 °C for 15 min and the product was freeze-dried (Figure 1).

*Treatments of Soluble Fibers for Product Rye2.* After heat pretreatment of rye bran, the extract was first filtered through a textile cloth and then the filtrate was centrifuged at 10 000 rpm for 30 min to separate the soluble extract from insoluble particles. The soluble extract was concentrated by vacuum evaporation down to 4 L. The extract was treated with 15 kU of amylase at 85 °C. The extract was cooled to 50 °C, 33 kU amyloglucosidase was added, and the reaction mixture was stirred for 60 min. The extract was then precipitated under stirring with ethanol to a final concentration of 80% (v/v), and the precipitate was collected by filtration and air-dried (Figure 1).

The ethanol precipitate was dissolved in 3 L of deionized water and heated under stirring to 70 °C, and the pH was adjusted to 6.5. Then 1.2 kU of xylanase was added. The reaction mixture was maintained at 70 °C for 7 h under stirring, and the reaction was stopped by boiling for 20 min and thereafter the product was freeze-dried.

**Analysis of Final Products.** Protein was analyzed according to Kjeldahl on a FIASTAR 5000 system (FOSS TECATOR). Available starch and total starch contents were analyzed as previously described.[21,22]

Monosaccharide analysis of starting materials and final products was done using a 10 mg sample with 5 mL of 4% sulfuric acid at 100 °C for 3 h according to a modified method by Sluiter et al.[23] After hydrolysis, the hydrolysate was neutralized with 0.1 M $Ba(OH)_2$. Released monosaccharides were analyzed by high-performance anion exchange chromatography with pulsed amperiometric detection (HPAEC-PAD) (DIONEX, California, USA) using a 250 mm × 4 mm i.d., 8.5 $\mu$m CarboPac PA10 column and guard column 50 mm × 4 mm of the same material and an isocratic mobile phase of 1 mM NaOH at 1 mL/min.

Oligosaccharides present in the final products were analyzed using a 250 mm × 3 mm i.d., 5.5 $\mu$m CarboPac PA200 and a guard column 50 mm × 3 mm of the same material and a mobile phase of 100 mM NaOH and a gradient of sodium acetate of 0−50 mM between 0−20 min at 0.5 mL/min.

Dietary fibers were analyzed according to Asp.[24] The fat content was determined using the Schmid−Bondzynsky−Ratzlaff method (SBR) (NMKL Method no. 88, 1974). The water content of the samples was analyzed by NREL/TP-510-42621 and ash by NREL/TP-510-42622 (http://www.nrel.gov/publications/).

**Mouse Study Procedure.** Male 4 week old C57BL/6JBomTac mice (Taconic, Skensved, Denmark) were housed 10 mice per cage in 10 cages from arrival throughout the study. During acclimatization, they were all fed the low-fat diet (LFD) for 12 days. The animals were maintained in a temperature-controlled room with 12 h light−dark cycle. The study was approved by the local animal ethics committee (M185-11, Lund, Sweden), and the principles of laboratory animal care were followed.[46] After acclimatization, the mice were fed either one of the eight experimental diets with supplement or a control diet without supplement. The mice were fed the different diets ad libitum

[c]Mainly glucose.

with free access to drinking water for 5 weeks. Body weight and food intake were registered once a week. At the time of sacrifice, mice were fasted for 4 h and thereafter anesthetized with an intraperitoneal injection of midazolam (Midazolam Panpharma 5 mg/mL, Panpharma SA, France) and a mixture of fluanison 10 mg/mL and fentanyl citrate 0.315 mg/mL (Hypnorm, VetPharma, U.K). The mice were weighed, and body fat content and lean body mass were analyzed using dual-energy X-ray absorptiometry (DEXA) technique with a Lunar PIXImus densitometer (GE Medical Systems). Blood was drawn by intraorbital puncture followed by cervical dislocation. The ceca were weighed, content collected and snap frozen for SCFA analysis, and the cecum tissues were rinsed in sterile phosphate buffered saline (PBS; Oxoid, England) and weighed, liquid was thoroughly soaked up by sterile compress, and tissues were snap frozen. All samples were stored at −80 °C until analysis.

*Experimental Diets.* The supplemented cereal byproducts were prepared as described above and analyzed for nutritional content (Table 1). In the eight experimental diets and the high-fat control diet (HFD), 60% of the energy originated from fat while the energy from fat was 10% in the low-fat control diet (LFD). All diets were manufactured by Research Diets (NB, USA). The supplemented products were included in levels so that each product contributed with 5 g/100 g dietary fiber (dry weight basis, dwb, Supporting Information, Table S1), i.e., cellulose was only added in the control HFD and LFD (5 g/100 g, dwb). One of the diets contained guar gum and used as a positive control. All high-fat diets were balanced to contain equal amounts of protein, carbohydrates (starch, maltodextrin, and mono/disaccharides), and fat.

*Plasma Samples.* Blood samples were drawn by intraorbital puncture using an EDTA-coated glass pipet. After immediate centrifugation plasma was collected and stored at −20 °C until analysis. Glucose, total cholesterol, triglycerides, HDL (all from Infinity, Thermo Electron Melbourne, Australia), fructosamine (VetSpec, Catachem Inc., Oxford, CT, USA), and alanine aminotransferase (ALT) (DiscretePak, Catachem Inc.) were measured enzymatically with colorimetric methods. LDL was calculated using Freiwalds formula: LDL = total cholesterol − (triglycerides/2.2 + HDL).[25] Insulin was measured with ELISA (Mercodia, Uppsala, Sweden).

*DNA Extraction from Cecum Tissue.* DNA from cecum tissue was isolated and purified in BioRobot EZ1 (EZ1 DNA Tissue Kit and tissue card; Qiagen, Hilden, Germany). Tissue samples were incubated with 380 μL of Buffer G2 and 30 μL of Proteinase K (Qiagen, Germany) in 56 °C for 6 h. Then 12 glass beads (2 mm in diameter) were added to each sample, which were shaken at 4 °C for 45 min to disintegrate the bacterial cell walls. Then 100 μL of the supernatant and 100 μL sterile PBS were used for extraction in the BioRobot EZ1.

*Microbial Analyses.* The amount of 16S rRNA genes of bacteria belonging to *Lactobacillus*, *Bifidobacterium*, *Enterobacteriaceae*, and *Clostridium leptum* groups and *Akkermansia muciniphila*-like bacteria were estimated using separate quantitative real-time PCR (qPCR) assays as previously described,[26] with previously published primers.[26−28] Detection limit was $10^2$ genes/reaction for *Lactobacillus*, *Bifidobacterium*, and *A. muciniphila*-like bacteria, while the limit for the *Enterobacteriaceae* assay was $10^4$ genes/reaction. For standard curves, 10-fold dilution series of the target DNA were made in TE buffer (10 mM Tris, 1 mM EDTA, pH 8.0). Number of bacteria was expressed as log 16S rRNA genes/g cecum tissue.

*SCFA in Cecum.* The SCFA (acetic, propionic, iso-butyric, butyric, iso-valeric, valeric, caproic, and heptanoic acids) in cecum were analyzed using a GLC method.[29] The intestinal content was homogenized with an Ultra Turrax T25 basic (IKA-Werke, Staufen, Germany) after adding hydrochloric acid (to protonise the SCFA) and 2-ethylbutyric acid (internal standard). The samples were centrifuged (MSE Super Minor, Hugo Tillquist AB, Solna, Sweden) and the supernatant injected on to a fused-silica capillary column with a free fatty acid phase (DB-FFAP 125-3237; J&W Scientific, Agilent Technologies Inc., Folsom, CA, USA). GC ChemStation software (Agilent Technologies Inc., Wilmington, DE, USA) was used for the evaluation. The concentration of each SCFA (μmol/g) was multiplied by the amount of cecal content to obtain the cecal pool (μmol).

**Statistics.** All groups were compared with HFD control. One-way analysis of variance (ANOVA) with Dunnet's multiple comparison post-test was used when the data was Gaussian distributed according to D'Agostino and Pearson omnibus normality test. When not normally distributed, Kruskal−Wallis nonparametric test with Dunn's multiple comparison post-test was used (GraphPad Prism 6.0, GraphPad Software, San Diego, CA, USA or Minitab software, release 16). To find significances between the different oat products and also the three rye products, the general linear model of ANOVA followed by Tukey's procedure was used. These data are not shown in any table but reported in the text under Results and Discussion.

**Principal Component Analysis.** Principal component analysis (PCA) was performed using the software SIMCA (version 13.0.3, Umetrics, Umeå, Sweden) to visualize the relationship between the analyzed bacterial groups, cecal SCFA production, and some physiological parameters in relation to each other and to the various diets.

## RESULTS AND DISCUSSION

In the present study, processed cereal byproducts were used as dietary fiber additives in a high-fat diet (HFD) and their affects were evaluated in a mouse model for human obesity and prediabetes. Three byproducts from industrials processing of cereals were used as raw materials: a fiber-rich residue from the production of oat milk, barley husks, and rye bran. The materials are rich sources of dietary fiber, antioxidants, and possibly also other potentially health-promoting substances. In an attempt to improve their health promoting properties further, the materials were subjected to selective hydrolysis by a thermostable xylanase to generate xylooligosaccharides (XOS) and arabinoxylooligosaccharides (AXOS). A heat pretreatment step was used as pretreatment to solubilize the fibers and make the materials more accessible to the enzymes.

Because no separation steps were included in the processing of three of the four products, the starting materials (Oat0, Barley0, and Rye0) and the xylanase-treated products (Oat1,

Barley1, and Rye1) had similar overall chemical composition (Tables 1 and 2).

**Table 2. Content of Carbohydrates of the Barley, Oat and Rye Products**

| | sugars[a] (mg/g dry weight material) | | | | |
|---|---|---|---|---|---|
| products | Ara | Gal | Glc | Xyl | total |
| Oats0 | 41 | 4 | 190 | 70 | 300 |
| Oats1 | 31 | 4 | 150 | 60 | 240 |
| Barley0 | 35 | 10 | 300 | 180 | 530 |
| Barley1 | 29 | 7 | 280 | 180 | 500 |
| Rye0 | 64 | 9 | 270 | 150 | 490 |
| Rye1 | 54 | 8 | 270 | 140 | 470 |
| Rye2 | 85 | 9 | 240 | 280 | 610 |

[a]Fructose is not included in the analysis because it is degraded to a large extent by sulfuric acid. Values are means, $n$ = 3. SD not more than 3%.

Rye bran was selected as starting material for production of the fourth product (Rye2, Tables 1 and 2), which is a material rich in XOS and AXOS. After heat pretreatment, only the soluble fraction was recovered and further processed. To improve the purity, starch was degraded enzymatically using a combination of $\alpha$-amylase and amyloglucosidase. Precipitation of soluble oligo- and polysaccharides to remove glucose and other small molecular impurities was carried out using ethanol. After redissolving the precipitate, xylanase-catalyzed hydrolysis was carried out. The resulting product (Rye2) had a dietary fiber content of 71% (Table 1) and high amounts of polymeric xylose and arabinose (Table 2). Similar processing has successfully been done with wheat bran to make short chain XOS and AXOS.[30]

The xylanase treatment produced xylobiose from all three tested raw materials, and in most cases longer XOS were formed as well (Figure 2). The xylanase is expected to produce XOS from xylan and from parts of AX without arabinose substituents, and it is thus less efficient in hydrolyzing highly substituted AX.[19] The smallest amount of xylobiose was found in Barley1, although Barley0 was the starting material having the highest content of xylose (Table 2). The main reason was probably the tough, highly cross-linked structure of the barley husk material. In Rye1, the distribution of different XOS was shifted toward the shorter ones, mainly xylobiose and xylotriose, which indicates that the xylanase-catalyzed hydrolysis had proceeded further in this case than in the preparation of Rye2. It has previously been shown that relatively short XOS are efficiently consumed by bifidobacteria and some strains of *Lactobacillus* in vitro.[19] More complex oligosaccharides, tentatively identified as AXOS, were detected in Oat1, Rye1, and in the highest amounts in Rye2.

To assess the effects of the different products in vivo, C57BL/6 mice were fed high-fat diets supplemented with the cereal byproducts. The different diets were evaluated for their effect on metabolic parameters, abundance of selected bacterial groups in the intestinal microbiota, and production of SCFA. The mean body weight of the test diet groups did not differ compared with the HFD control. There were no differences in energy intake, weight gain per energy intake, or body fat mass between the mice fed HFD with or without cereal supplementation. In addition, the measured plasma parameters glucose, insulin, triglycerides, total cholesterol, HDL cholesterol, LDL cholesterol, as well as HOMA-IR did not differ

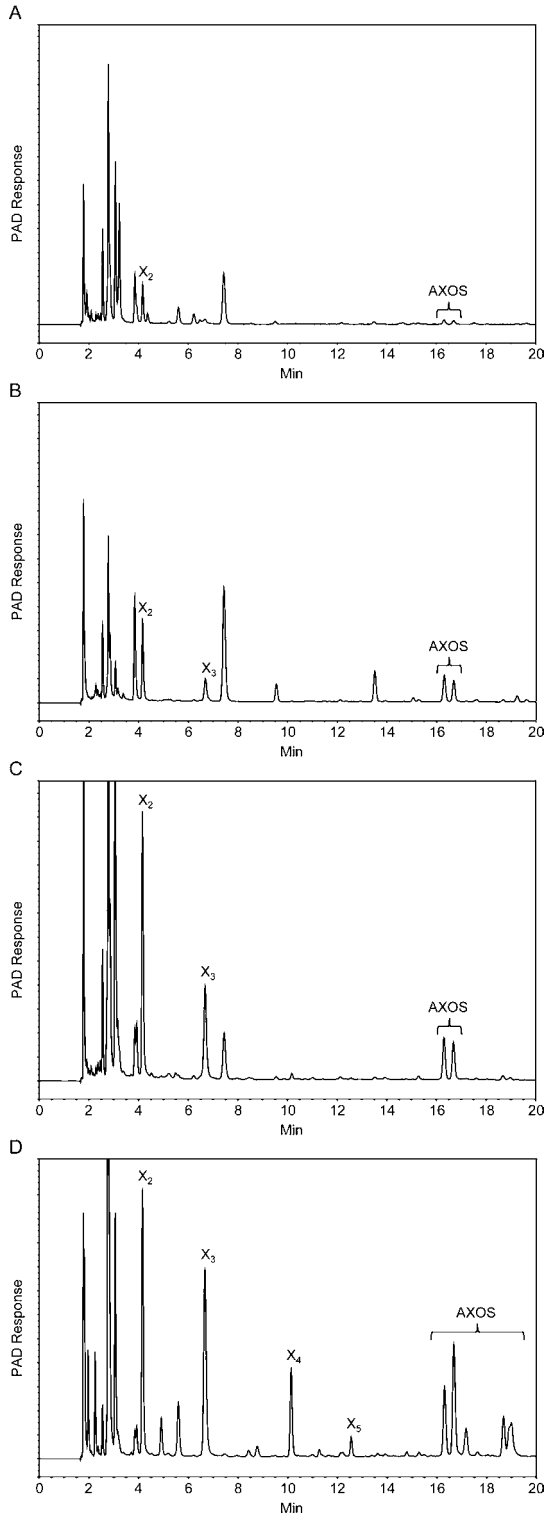

**Figure 2.** HPAEC-PAD analysis of oligosaccharides present in fiber products (A) Barley1, (B) Oat1, (C) Rye1, and (D) Rye2. $M_2$ = maltose; $X_n$ = XOS having $n$ xylose residues.

significantly between the groups fed with fiber-supplemented high-fat diet, compared with the HFD control (Table 4). Mice receiving a diet supplemented with guar gum hydrolysate (Guar, positive control[31]) showed reduced body weight after 5 weeks compared with the HFD control mice group (Table 3). Some minor metabolic changes were observed in mice fed the Rye2 diet. In plasma from Rye2-fed mice, the level of alanine

[a]Values are means ± SEM, $n = 10$. [b]Indicating significant difference ($p < 0.05$) compared to HFD. [c]$p < 0.001$.

aminotransferase (ALT) was decreased ($p = 0.006$) compared with the HFD control (Table 4), which indicates that Rye2 can counteract HFD-induced liver dysfunction. Also, the Rye2 group had a tendency of lower fructosamine ($p = 0.13$ using ANOVA multiple comparison test and $p = 0.012$ using unpaired $t$ test), which mirrors the blood glucose over the last 2 weeks, indicating an improved glucose control compared to HFD control. As expected, mice fed a low-fat diet (LFD), which was used as an additional control, showed reduced body weight ($p < 0.001$), energy intake ($p < 0.001$), and adiposity ($p < 0.001$) compared with the HFD control.

In a previous study in rats fed a high-fat diet, inclusion of XOS was shown to reduce blood glucose significantly.[32] A few of the differences compared to the present study were that the rat study was somewhat longer (6 weeks), used a pure XOS preparation (obtained from wheat bran), and that the XOS replaced corn starch in the diet, which made the dietary fiber content different in the different groups. In a human study, 4 g/day of XOS for 8 weeks reduced glucose, HbA1c, fructosamine, and blood lipids in type 2 diabetic patients.[33] With these results in mind, there seems to be good reasons to study antidiabetic effects of cereal byproducts enriched in XOS further, although no effects on some of the risk parameters could be seen, and it seems likely that both the dosage and the length of the intake period influence the observed response.

Propionic acid and butyric acid, formed from microbial fermentation of dietary fiber in colon, have been suggested to have positive metabolic effects due to their capacity to modulate pro- and anti-inflammatory markers present in the gut.[3] With this background, it is interesting to see that the cecal amount of SCFA in the mice decreased to almost the half when fed the HFD diet compared with the LFD. When the cellulose in the HFD was replaced by the dietary fiber in the different diets, the cecal amount of total SCFA formed increased in the mice, but it was only significant in mice fed the diet with Oat0 ($p < 0.01$) and guar gum ($p < 0.05$) (Table 5). More significance was seen with the individual SCFA. Guar gum, which was used as a positive control in the experiment, more than doubled the yield of propionic ($p < 0.001$) and butyric acids ($p < 0.01$) compared with the HFD control. Increased amounts of propionic ($p < 0.01$) and butyric ($p < 0.001$) acids could be seen as an effect of Oat0 and Oat1. Interestingly, if comparing the butyric acid formation before and after enzymatic treatment of oats (Oat0 with Oat1) and rye (Rye0 with Rye 1 and Rye2, respectively) there was a lower formation ($p < 0.01$–$p < 0.05$) of butyric acid after enzymatic treatment. However, Rye0 increased the amount of butyric acid ($p < 0.05$) in the cecum of mice compared with the HFD. Enzymatic treatment caused changes in the physicochemical properties of the products. When the insoluble fibers were removed (Rye2), there was an increase of propionic acid in the cecum of mice ($p < 0.05$) compared with Rye0. Similar findings, with an increased amount of propionic acid, have been seen in wheat enzyme-treated in a similar way.[34] None of the barley products had any effects on the amounts of SCFA formed in the cecum of mice compared with the HFD, and the specific SCFA formed were very similar to those formed with the high-fat control diet. The SCFA usually detected in rather low amounts; valeric, iso-valeric, and iso-butyric acid were significantly higher in mice fed the two oat products (Oat0, $p < 0.05$, and Oat1, $p < 0.001$) and with guar gum ($p < 0.001$) compared with the HFD control. Iso-valeric acid was also significantly higher ($p < 0.01$) with Rye2. The physiological impact of this is not known, but higher

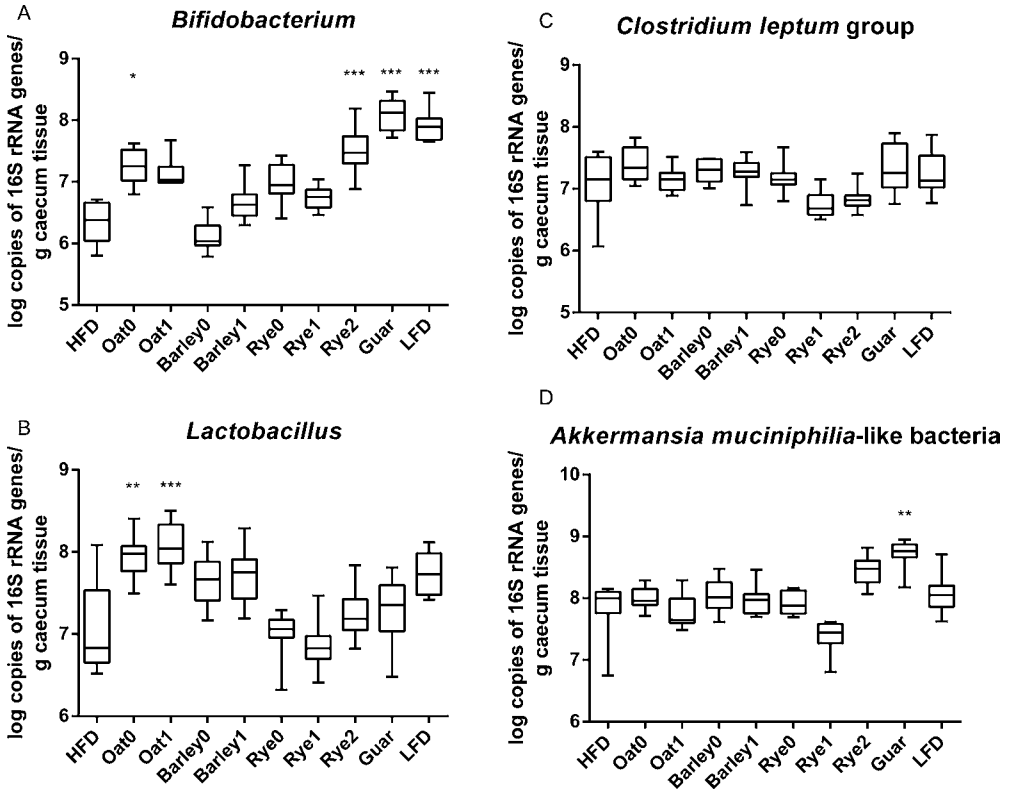

**Figure 3.** Box plots presenting the median, 10th, 25th, 75th, and 90th percentiles of the concentrations of 16S rRNA genes from (A) *Bifidobacterium*, (B) *Lactobacillus*, (C) *Clostridium leptum* group, and (D) *Akkermansia muciniphila*-like bacteria in the cecum tissue of mice on the test diets ($n$ = 7–10 animals/group, * $p < 0.05$, ** $p < 0.01$, *** $p < 0.001$).

amounts of valeric acid in blood have been seen in microscopic colitis patients, who usually have a low dietary fiber intake compared with healthy controls.[35]

*Lactobacillus* and *Bifidobacterium* are bacterial genera considered beneficial for host health.

The abundance of *Lactobacillus* and *Bifidobacterium* was assumed to be stimulated by the supplemented nondigestible carbohydrates that were used in the diets of the present experimental study. Members of the *C. leptum* group are abundant in the gastrointestinal tract and known to contribute to the intestinal butyrate production and so of interest in the present study.[36] *Akkermansia* is a commensal bacterial genus known to degrade mucin and is commonly found in the gastrointestinal tract and has been negatively correlated to obesity and metabolic disorders.[37,38] *Enterobacteriaceae* is a Gram-negative family with pro-inflammatory lipopolysaccharides in its outer cell membrane. Abundance of *Enterobacteriaceae* can be regarded as an indicator if the microbiota is in balance or if dysbiosis occurs.

In the experimental data, prebiotic potential was shown by diets LFD, Oat0, Rye2, and guar gum because animals on these diets had increased amount of *Bifidobacterium* in cecum mucosa compared to animals on HFD ($p < 0.001$, 0.05, 0.001, and 0.001, respectively) (Figure 3A). Furthermore, the number of 16S rRNA genes of *Lactobacillus* were significantly higher in animals on diets Oat0 and Oat1 compared with HFD ($p < 0.01$ and <0.001, respectively) (Figure 3B). The number of 16S rRNA genes from the *C. leptum* group did not differ significantly between the groups (Figure 3C). The number of 16S rRNA genes corresponding to *Akkermansia muciniphila*-like bacteria was increased in animals on a diet supplemented with guar gum compared to animals on HFD ($p < 0.01$) (Figure 3D), possibly indicating a prebiotic potential by enhancing the gut integrity through mucin production.[37] The amount of *Enterobacteriaceae* was below detection limit for all diet groups, so no significant differences between the diet groups could be obtained.

It is obvious that the different diets produced quite different effects on the mucosal bacterial groups quantified in this study. Because the total content of dietary fiber was the same in all cases, it seems that the composition of the fiber had a major influence although other components of the products likely contributed to the observed effects. However, Rye2 and guar gum contained mainly oligosaccharides, so at least in these cases those can be expected to have been of major importance.

The stimulation of bifidobacteria by Rye2 was likely due to its content of XOS and AXOS, which have been shown to have this effect in several other studies. For example, it has been reported that 10% XOS in the diet caused the most efficient stimulation of bifidobacteria in streptozotocin induced diabetic rats.[39] Likewise, XOS caused an increase in bifidobacteria in rats given a Western human diet.[15] In vitro experiments have also shown that XOS are indeed fermented by many intestinal bifidobacteria.[40] The mechanism for XOS utilization has been studied in the strain *Bifidobacterium animalis* subsp. *lactis* BB-12.[41] XOS/AXOS are supposed to be transported into the bacterial cells using an ABC transporter, and they are subsequently degraded intracellularly by xylanolytic enzymes. It is likely that rye fructooligosaccharides also contributed to the stimulation of bifidobacteria, as observed previously.[42] The positive effect of Oat0 on bifidobacteria agrees with previous observations of bifidobacteria stimulation by oat-based

dx.doi.org/10.1021/jf502343v | J. Agric. Food Chem. 2014, 62, 8169–8178

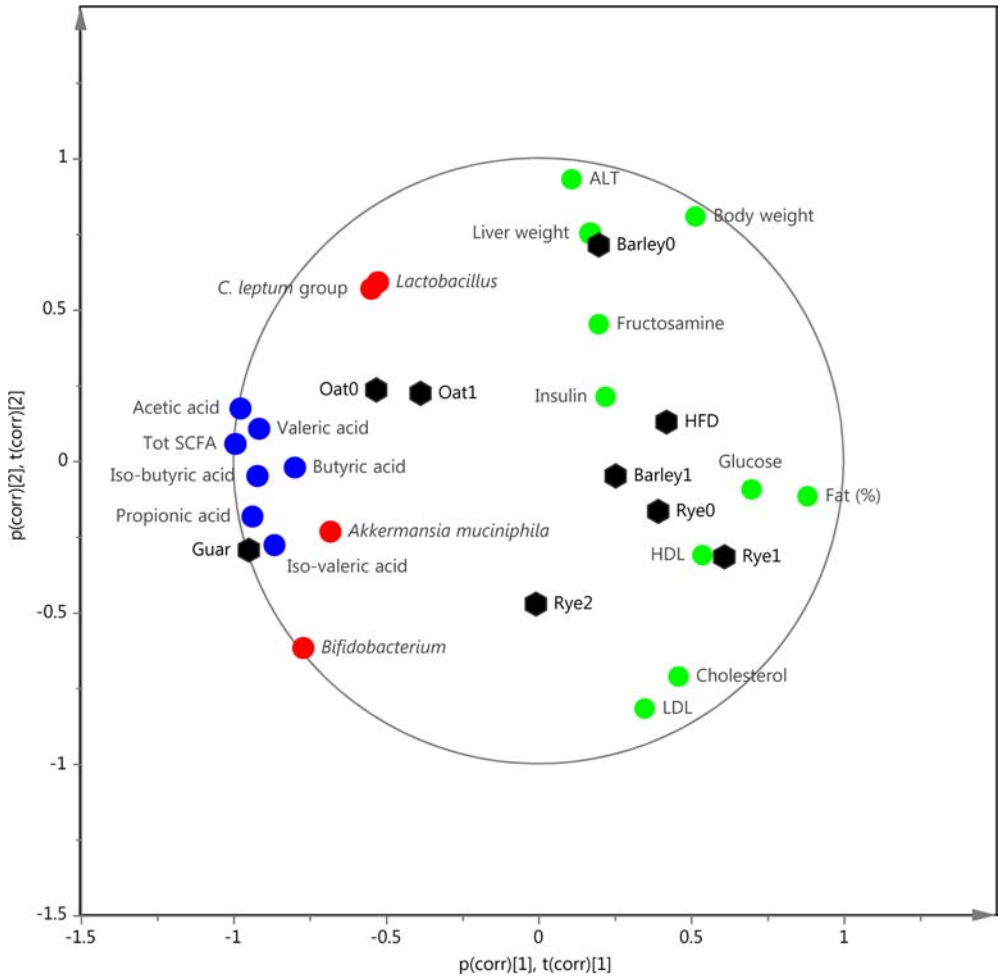

**Figure 4.** To visualize patterns and relationship in the data, a PCA was performed. Data is displayed in a biplot of analyzed bacterial groups, SCFAs, and some physiological parameters in relation to the diet groups. PC1 explained 46.6% and PC2 23.3% of the variation. Blue dots represent mean of cecal pool of analyzed SCFA or total SCFA, red dots represent the mean of the 16S rRNA expression of the analyzed microbial groups, green dots represent mean of the physiological parameters, and black hexagons represent the different diets.

products.[43] It has been reported that $\beta$-glucans from both oats and barley stimulate growth of lactobacilli and bifidobacteria,[44] so that might be at least part of the reason. The third product that caused a significant increase in bifidobacteria compared to HFD was the guar hydrolysate, which is in agreement with results reported by Giannini and co-workers.[45]

The best stimulation of lactobacilli was achieved with the oat-based products. As in the case with bifidobacteria, the stimulation was probably partly due to $\beta$-glucans,[44] but at least some lactobacilli (e.g., *L. brevis* and *L. fermentum*) grow very well on XOS as well.[40] It is interesting that the products composed mainly of oligosaccharides (Rye2 and Guar) favored bifidobacteria, while those based on oats were more efficient for lactobacilli. Notably, the abundance of the *C. leptum* group appeared similar, indicating no major change in this group of butyrate producing bacteria, although some changes of butyrate concentration in cecum content was observed in mice on different diets. Everard et al.[37] suggested *Akkermansia muciniphila* to have extensive prebiotic effects. In the present study, animals on the Guar diet was the only group with significantly higher abundance of *Akkermansia muciniphila*-like bacteria compared to HFD. The Guar group had lower body weight, but no changes of other metabolic parameters could be observed.

Multivariate statistical analysis was performed using PCA to visualize the relationship between SCFA, analyzed microbial groups, and some metabolic parameters (Figure 4). In a biplot, PC1 and PC2 were shown to explain 46.6% and 23.3% of the variation, respectively. The PCA biplot illustrates the fact that the diets supplemented with Guar and Oats (Oat0 and Oat1) cluster with the beneficial bacterial groups and SCFA in cecum but have inverse impact on, for example, body weight, body fat, and blood glucose (Figure 4).

In conclusion, the diet supplemented with Rye2, containing the highest amount of XOS and AXOS, induced bifidobacteria and there was also a tendency to an increased amount of propionic acid in the cecum as compared with the HFD control, indicating a prebiotic effect. Rye2 also significantly reduced the plasma concentration of ALT, indicating that the altered microbiota, with higher amounts of bifidobacteria, had beneficial effects on liver function. In addition, a tendency of reduced fructosamine was observed in the Rye2 group, indicative of improved glucose control compared to HFD control. The lack of other statistically proven beneficial metabolic changes might be due to the relatively short duration of the study. Also, both fractions of oat were shown to increase the amount of lactobacilli and the amounts of propionic and butyric acids in cecum, however, only the nonhydrolyzed Oat0-

dx.doi.org/10.1021/jf502343v | J. Agric. Food Chem. 2014, 62, 8169−8178

supplement increased the bifidobacteria. The present study demonstrated that underutilized byproducts from industrial processing of cereals have a potential to be used as raw materials for production of valuable prebiotic food ingredients.

# Inert and Oxidative Subcritical Water Hydrolysis of Insoluble Egg Yolk Granular Protein, Functional Properties, and Comparison to Enzymatic Hydrolysis

Ismael Marcet, Carlos Álvarez, Benjamín Paredes, and Mario Díaz*

Department of Chemical and Environmental Engineering, University of Oviedo, C/Julián Clavería 8, 33006 Oviedo, Spain

**ABSTRACT:** The use of enzymes to recover soluble peptides with functional properties from insoluble proteins could prove to be very expensive, implying high reaction times and low yields. In this study, the insoluble granular protein, previously delipidated, was hydrolyzed using enzymes (trypsin) as a comparison to the proposed alternative method: subcritical water hydrolysis (SWH) using both nitrogen and oxygen streams. The result of the hydrolysis was characterized in terms of the yield and peptide size distribution as well as different functional properties. The SWH of the delipidated granules resulted in a higher recovery yield than that obtained by enzymatic hydrolysis in half of the time. The foaming capacity of the peptides obtained by SWH was higher than that obtained by trypsin hydrolysis, although the foam stability was lower. Slight differences were detected between these peptides in terms of their emulsifying properties.

**KEYWORDS:** *egg yolk, functional properties, insoluble protein, subcritical water hydrolysis, trypsin hydrolysis*

## 1. INTRODUCTION

The use of proteins in the food industry is important, not only because of their nutritional value but also because proteins are capable of interacting among themselves and with other biopolymers in the food matrix, altering their organoleptic and functional properties.

Proteins used in the preparation of a food product can be from animal sources, such as the albumen of egg white, milk casein, or gelatin obtained from the connective tissue of cows and pigs. Vegetable proteins, such as soy protein, are used as well.

While all of these proteins are used to alter the features of food, their resultant peptides can extend these protein-dependent properties or produce other alterations that may be useful and profitable for the food industry. Protein hydrolysis has been broadly studied by Adler-Nissen,[1] and an extensive bibliography on a great variety of proteins has been published. Changes in the functional properties, protein recovery from food industry wastes, and others have been documented.[2−6] The main advantage of enzymatic over non-enzymatic hydrolysis is that the enzymatic reactions require mild conditions that prevent chemical alterations in the processed proteins. Furthermore, the size of the peptides can be adjusted by taking into account the hydrolysis time. This is important because the average size of the peptides is related to their functional properties. However, enzyme use can be considered expensive, and the targeted proteins must be accessible to enzymatic action.

In addition to enzymatic hydrolysis, other hydrolysis reactions can be considered, such as water hydrolysis under subcritical conditions. Water is considered to be subcritical when its temperature varies in the range from 100 to 370 °C, and it is maintained in a liquid state by application of high pressures. In this state, noticeable changes occur in its properties, increasing the ion concentration product ($K_w$) at 250 °C to $10^{-11}$, as well as its decreasing dielectric constant at elevated temperatures, thereby exhibiting higher solvation behavior.[7] In fact, subcritical water has been used previously to recover phenolic compounds[8] and amino acids from biomass discards.[9−11] Furthermore, this method can be used in the hydrolysis of soluble proteins, allowing, with adjustment of the treatment parameters, the control of the end products.[12]

Egg yolk can be easily separated into plasma and granular fractions. The first one is the lipid-rich fraction, and it is mainly composed of lipoproteins. It has been described as having emulsion[13] and gelation properties,[14,15] similar to those found in the whole egg yolk. On the other hand, the second one is the protein-rich fraction, and it requires an ionic strength ≥0.3 M NaCl to solubilize its protein constituent. Below 0.3 M NaCl, the granules from egg yolk show a low solubility[16] and, therefore, decreased functional properties, which reduces their applications.

In this work, the hydrolysis of non-soluble egg yolk proteins has been studied using enzymes and the subcritical water method. For that purpose and because it has a high protein content and limited utility, the egg yolk granular fraction was obtained, delipidated, and hydrolyzed. The hydrolysis yield, average size of the peptides, and their functional properties were evaluated and compared in this study.

## 2. MATERIALS AND METHODS

**2.1. Production of Delipidated Granules.** The egg yolk granules were obtained using the Laca et al.[17] method. Egg yolk was separated from the albumen manually, and the vitelline membrane was discarded using tweezers. The egg yolk was diluted (1:1.5, v/v) with water, and the pH was adjusted to 7. Finally, the diluted egg yolk was kept overnight at 4 °C and centrifuged at 4 °C and 10000*g* for 45 min to obtain the granules in the sediment. Granules were lyophilized and mixed with ethanol (96%, 1:12.5, w/v) at 40 °C for 2 h with gentle agitation. Finally, the granules were recovered using a vacuum pump and Whatman No. 1

filter paper. The delipidated egg yolk granules were then washed with 200 mL of fresh ethanol and dried overnight in a heater at 50 °C to obtain a dehydrated and ethanol-free powder.

**2.2. Enzymatic Hydrolysis.** The hydrolysis was carried out in a 400 mL bioreactor with a pH-STAT automatic titration (pH-Buret 24 2S, Crison) connected to an isothermal shaker. Delipidated egg yolk granules were mixed with water (1:20, w/v) and preheated at 90 °C for 7 min to enhance the dispersion of the granules. Two enzyme−substrate ratios were tested, 1:50 and 1:25, using trypsin from porcine pancreas EC 3.4.21.4 (93610, Sigma-Aldrich), 18 136 U/mg. The dispersed granules were heated at 37 °C, and the pH was adjusted to 7.5 using 0.1 M sodium hydroxide solution. Finally, the enzyme was added to the reactor, and after 6 h, the enzymatic reaction was stopped by heating the hydrolysate for 15 min in a water bath at 90 °C.

The degree of hydrolysis (DH) was evaluated using the pH-STAT method according to Adler-Nissen.[1] In this method, the amount of base solution consumed along the reaction is proportional to the amino groups liberated during the enzymatic hydrolysis. The DH was calculated using the Adler-Nissen equation (eq 1)

$$\mathrm{DH}\ (\%) = \frac{100 V_B N_B}{\alpha M_p h_{tot}} \tag{1}$$

where $\alpha$ is the degree of dissociation of the $\alpha$ amino group calculated by following eq 2, $M_p$ is the amount of protein in the assay (g), and $h_{tot}$ is the total number of peptide bonds in the protein (mequiv $g^{-1}$ of protein). The value of $h_{tot}$ for egg yolk protein was assumed to be 8 based on a suggestion found in ref 18, which perfectly fits with the $h_{tot}$ values reported by Nielsen et al. for raw materials.[19] $V_B$ is the volume (mL) of the base (NaOH) added during the course of the enzymatic reaction, and $N_B$ is the normality of the base.

$$\alpha = \frac{10^{\mathrm{pH}-\mathrm{p}K}}{1 + 10^{\mathrm{pH}-\mathrm{p}K}} \tag{2}$$

The p$K$ value used for the hydrolysis procedure is calculated approximately using the equation by Guadix et al.[20] (eq 3).

$$\mathrm{p}K = 3.80 + 0.45\mathrm{pH} \tag{3}$$

*2.2.1. Subcritical Water Hydrolysis (SWH).* The delipidated granules were dispersed in water (1:20, w/v) to obtain 400 mL of solution and placed in the jacketed reactor shown in Figure 1. Different hydrolysis temperatures were tested, and the lowest temperature tested with a good peptide recovery in 4 h was 180 °C. At each tested temperature, a pressure of 40 bar was achieved using a non-reactive (nitrogen) or an oxidizing (oxygen) gas stream of 1 L/min. A back-pressure valve (Brooks mass flow controller 5850) allowed for pressure control in the system. The injected gas was previously saturated with water to avoid sample evaporation and heated to keep the reactor temperature constant. In this study, the reaction time specified in each case includes the heating time. This heating time was short in each case; therefore, its influence on the overall process is negligible.

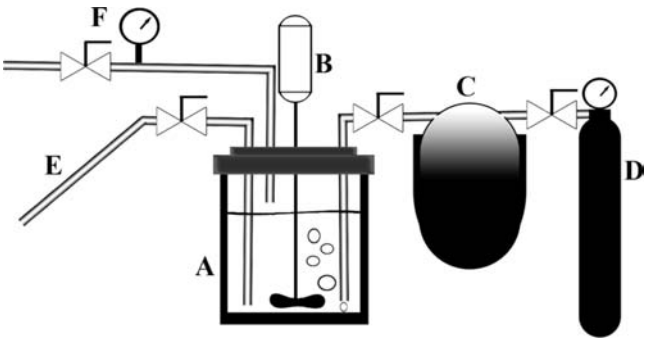

**Figure 1.** Setup of the SWH reactor: (A) pressure reactor, (B) agitation, (C) humidifier, (D) nitrogen or oxygen gas bottle, (E) sample taker, and (F) back-pressure valve.

**2.3. Size-Exclusion Chromatography.** An AKTA fast protein liquid chromatography (FPLC) system (GE Healthcare, Sweden) was employed to determine the peptide size distribution using a size-exclusion column (Superdex Peptide 10/300 GL), which can separate peptides from 100 to 7000 Da. The buffer used was composed of 0.1 M Tris at pH 7.6. The elution flow was adjusted to 1 mL/min. The FPLC system used was dotted with an ultraviolet (UV) detector, and the wavelength employed was 214 nm. Previously, the column was calibrated with weight markers supplied by Sigma-Aldrich: lysozyme (14 307 Da), cytochrome *c* (12 384 Da), aprotinin (6512 Da), cianocobalamin (1355 Da), and tryptophan (204 Da) ($R^2$ = 0.99). The molecular size distribution and the average molecular size of the obtained peptides were analyzed to determine the total concentration. Subsequently, the area of the chromatograms obtained was divided into ranges of molecular size, according to previous calibration. The area of each zone was measured, employing the Unicorn 5.1 analysis software, and transformed into protein concentration. The frequency of each molecular weight range was calculated with regard to the total amount of soluble peptides.

**2.4. Amino Acid Quantification.** The amounts of amino acids produced during the SWH and the enzymatic hydrolysis were calculated by the Rosen method.[21] This method is based on the interaction of ninhydrin with the amino groups, resulting in a colored compound.

**2.5. Functional Properties.** To test the functional properties, after the hydrolysis processes, the solutions were centrifuged at 10000*g* for 30 min. After that, the supernatants were separated from the sediments by decantation. Immediately, the supernatants were lyophilized, and the sediments were discarded. The protein content of the lyophilized product was determined using the Dumas combustion method.[22] For that purpose, the nitrogen content was calculated using a CNHS/O Elementar Vario EL analyzer (Elementar, Germany). The conversion factor employed was 6.25 mg of protein/mg of N.

*2.5.1. Solubility.* The solubility of the hydrolyzed and non-hydrolyzed delipidated egg yolk granules was determined using a modified method by Wang et al.[18] Briefly, they were diluted in distilled water to obtain a protein concentration of 1 mg/mL. The pH of these solutions was adjusted with 1 N HCl or 1 N NaOH and equilibrated at room temperature for 60 min. The pH values were readjusted at 30 and 60 min to correct possible variations. Finally, the diluted samples were centrifuged at 10000*g* and 30 min, and the sediment was discarded. The protein content of the samples was determined according to Markwell et al.,[23] both before centrifugation and in the resulting supernatant. A calibration curve was carried out using bovine serum albumin. The protein solubility was calculated using the following equation:

$$\mathrm{PS}\ (\%) = \frac{\text{protein in supernatant (mg)}}{\text{protein in the initial solution (mg)}} \times 100 \tag{4}$$

*2.5.2. Foaming Capacity (FC) and Foam Stability (FS).* FC and FS were determined according to ref 24, with slight modifications. Peptide solutions of 5 mg/mL protein in water were prepared, and the pH was adjusted to 7 using 1 N NaOH or 1 N HCl. After 30 min of equilibration at room temperature, 30 mL of the solutions were taken and stirred at 15 000 rpm using a Heidolph SilentCrusher for 1 min. The volume of the foam formed was immediately calculated using a cylinder measure, and the FC was determined. To calculate the FS, foam volume changes in the cylinder measure were recorded at 30 min of storage.

$$\mathrm{FC}\ (\%) = \frac{\text{foam volume after whipping (mL)}}{\text{initial liquid volume (mL)}} \times 100 \tag{5}$$

$$\mathrm{FS}\ (\%) = \frac{\text{foam volume after 30 min(mL)}}{\text{foam volume after whipping (mL)}} \times 100 \tag{6}$$

*2.5.3. Emulsifying Properties.* Emulsifying properties were measured according to the study by Pinciroli et al.[25], with slight modifications. Peptides were diluted in a NaCl solution (0.075%, w/v) to obtain a final concentration of 10 mg/mL protein. The pH of these solutions was adjusted to pH 7 using 1 N HCl or 1 N NaOH and equilibrated for 30 min with continuous stirring at room temperature. A total of 15 mL of these solutions were mixed with 10 mL of cottonseed oil at 15 000 rpm

using a Heidolph SilentCrusher (Heidolph, Germany). Immediately, the emulsions were put into a glass measurement cell, and the stability against creaming was measured using a Turbiscan apparatus (Formulaction, France). Backscattered light was monitored every 2 min for 1 h as a function of the sample height. Clarification was measured at the bottom of the measured cell from 0 to 25 mm ($B\%_{0-25\ mm}$), and creaming was determined at the top of the cell ($B\%_{25-40\ mm}$). Furthermore, the initial backscattering value in the medium zone of the measurement cell ($B\%_{ini}$), stability parameter ($t_{0.1}$), and kinetic constant ($K_{0.1}$) were determined too. The stability parameter $t_{0.1}$ was calculated as the time in which the backscattering in the bottom of the measured cell decreased to 10% of its initial value. The kinetic constant $K_{0.1}$ was calculated according to the following equation:

$$K_{0.1}\ (h^{-1}) = (B\%_{ini,0-25\ mm} t_{0.1})^{-1} \quad (7)$$

**2.6. Statistical Analysis.** The assays shown in this work were carried out in triplicate. Mean and standard deviation are shown in each case.

## 3. RESULTS AND DISCUSSION

**3.1. Enzymatic Hydrolysis Characterization.** The DH is a parameter used with respect to enzymatic hydrolysis that is frequently referred to in the literature.[26−29] The DH is directly related to the solubility of the peptides obtained from the insoluble proteins.[30] Figure 2 shows DH versus enzymatic reaction time. It can be seen that, as one would expect, an increase in the hydrolysis time and enzyme concentration lead to an increase in the DH.

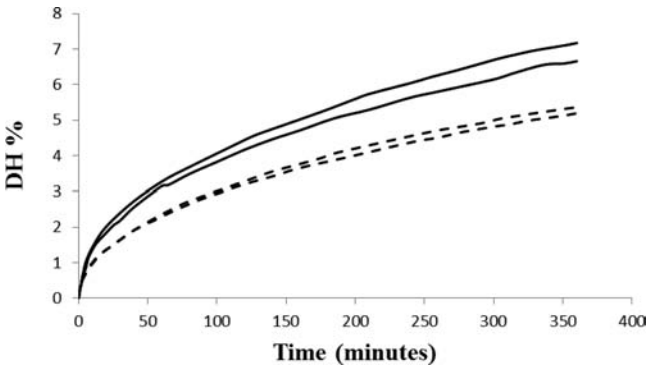

**Figure 2.** DH (%) of delipidated egg yolk granules treated with trypsin. Continuous lines correspond to a 1:25 enzyme/substrate ratio, and discontinuous lines correspond to a 1:50 enzyme/substrate ratio. Reproducibility is shown in each case.

As expected, the low solubility of the delipidated egg yolk granules at any pH impedes the cleavage of the peptide bond by the enzyme. This can be observed in Figure 2, where after 360 min of operation, the DH values reached 5.2 ± 0.12% (enzyme/substrate ratio of 1:50) and 6.9 ± 0.3% (enzyme/substrate ratio of 1:25).

According to the hydrolysis time, these DH values can be considered low compared to others found in the bibliography. In previous studies,[3] the non-delipidated granules were dissolved in a 0.55 M NaCl solution. In this NaCl solution, the phosphocalcic bridges between the granular proteins are disrupted and these proteins became soluble. In this case, the enzyme can interact with the peptide bonds efficiently and the DH increases to 12.0 ± 0.5% after 90 min. In other studies and using different enzymes, the hydrolysis of ethanol-delipidated whole egg yolk resulted in a DH of 6% in 80 or 100 min as a function of the enzyme tested.[18] However, the comparison of the results presented in this work to those obtained by these authors is difficult given the methodology differences. In any case, the trypsin hydrolysis of delipidated egg yolk granules resulted in a significantly longer reaction time compared to those reported by other authors.

The DH is an indication of the peptide sizes obtained; therefore, the higher the DH, the lower the size of these peptides. To calculate their average size with more precision, aliquots obtained at different times during the enzymatic hydrolysis were analyzed by size-exclusion chromatography (SEC). The chromatogram is shown in Figure 3A, and the peaks identified in this figure are detailed in Table 1.

In the hydrolysis using trypsin, five peaks were detected (Figure 3A), which maintain their relative importance during the period of hydrolysis. The main peak identified is number 4, which corresponds to peptides with an average size of 3500 Da (Table 1). Furthermore, in Table 2, the peptides were analyzed according to their size at each hydrolysis time. In enzymatic hydrolysis, the average peptide size was similar at each time tested, with no significant variations during the process.

**3.2. SWH.** In the SWH method, the aliquots obtained at different times were analyzed by SEC. In these non-enzymatic hydrolyses, the peptide size profiles vary according to the reaction time, with their sizes decreasing progressively from 23 000 Da in the initial stages to around 1000 Da at longer times. This can be observed in panels B and C of Figure 3, where at short reaction times, the main peak obtained is the number 1, while at longer reaction times, the SEC chromatograms obtained were progressively moving to the right, with the main peak appearing around the 1000 Da in these cases (peak numbers 3 and 4 in panels B and C of Figure 3). Therefore, in this type of hydrolysis, the temperature and reaction time that are chosen are important to obtain the greatest amount of soluble peptides, because the reaction progression leads to full protein breakdown. According to Abdelmoez et al.,[31] some amino acids are sensitive to temperatures around 230 °C. This can be observed in Table 2, where in both nitrogen and oxygen SWH, the population of peptides of more than 6 kDa decreases with the time of hydrolysis and those peptides of less than 6 kDa increase in a similar way.

**3.3. Process Yield.** The process yield in each case was calculated and shown in Figure 4. For enzymatic hydrolysis, the yield obtained rises with the reaction time. After 360 min of operation, the recovery of soluble peptides corresponds to 50% of the original protein when an enzyme−substrate ratio of 1:25 is used.

In the SWH under nitrogen stream, the maximum yield was obtained at 240 min. After that, the yield decreased slowly until it reached 70% at 580 min. According to ref 32, some additives, such as sodium bicarbonate, can be used to enhance the protein hydrolysis, although it produces a decrement in the molecular weight of final peptides. With regard to the SWH under oxygen stream, the yield rose quickly until 120 min and then decreased quickly too. Using these gas streams, the yield obtained was around 95%, almost doubling the value obtained by the enzymatic hydrolysis and with significantly shorter operation times as well. Between the nitrogen and oxygen treatments, the latter was more efficient, reaching the maximum recovery rate in half of the time required to achieve that value in the hydrolysis under a nitrogen stream. This is because, in the SWH under nitrogen stream, the non-reactive nitrogen has no effect on peptide breakdown, with hydrolysis being possible thanks to the increase in the amount of hydrogen and hydroxide ions in the subcritical water. However, using oxygen, in addition to the

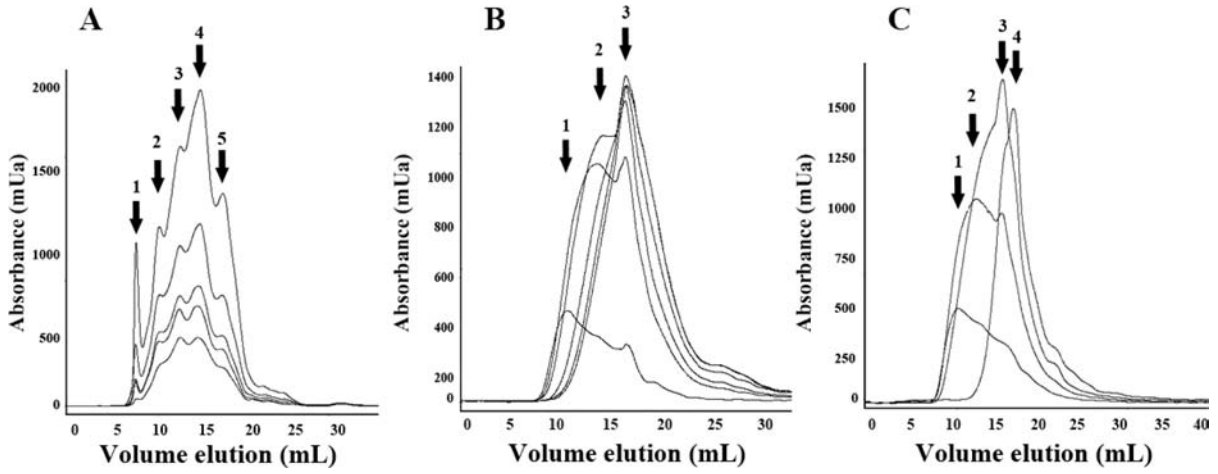

**Figure 3.** SEC chromatograms of the peptides obtained during hydrolysis: (A) peptides obtained from enzymatic hydrolysis, (B) peptides obtained from SWH under nitrogen stream, and (C) peptides obtained from SWH under oxygen stream.

increase in the ion concentration product of the water, the dissolved oxygen produces a rise in the oxidization of the organic matter. According to the study by Kelvin et al.,[33] the exposure of proteins to the hydroxyl radical and the superoxide anion radical promotes changes in their structure. This could increase their susceptibility to proteolytic action and lead to the rise in peptide bond cleavage that was detected.

During the SWH reaction, loss of protein in the form of amino acids, ammonium compounds, and other volatile products was expected.[34] Amino acids are considered to be the main decomposition compound in both enzymatic and SWH. For this reason, amino acids were measured in the reaction medium at each hydrolysis time (Figure 5). In the enzymatic hydrolysis (Figure 5A), the production of amino acids was the lowest, and after 360 min of reaction, the loss of protein was around 2% (w/w). In the SWH under nitrogen stream, the rise in amino acid production was more noticeable and continuous as the reaction proceeded. However, at the minute of optimum peptide yield (240 min), the loss of protein was 6%, owing to the formation of amino acids. The progression was similar in the SWH under oxygen stream, but because of the fact that the maximum yield was obtained at 120 min, the production of amino acids was reduced to 3%. According to these results, in every hydrolysis method, the loss of protein in the form of amino acids and in the maximum yield times was not relevant.

**3.4. Functional Properties.** For the functional properties assays, the highest yields in each case were chosen according to section 3.3.

*3.4.1. Solubility Profile.* The solubility profiles of the peptides obtained by hydrolysis are shown in Figure 6. The ethanol-delipidated egg yolk granules were used as a reference for the improvement in solubility obtained. Solubility could be considered as the most important functional property of proteins, because other functional properties, such as, for example, their water holding, gelling, foaming, and emulsifying capacities, are dependent upon it.

The low solubility of the delipidated egg yolk granules at any tested pH was expected because of the ethanol treatment that they had undergone, which produces the protein denaturation. In food proteins, denaturation is usually associated with protein insolubilization and loss of other functional properties.[35] An increase in the solubility properties of the resultant peptides is expected after the hydrolysis process.[27,36]

In the case of the enzymatic hydrolysis, the peptides obtained were highly soluble. However, in this type of hydrolysis, it is very difficult to recover all of the initial insoluble protein in the form of soluble peptides. In previous studies using soy protein, a DH of 8% or higher was required and the 100% conversion from protein to soluble peptides was not achieved.[37] As previously commented, in this work, a DH of 7% was obtained and only 50% of the protein was recovered as soluble peptides. This is explained by the remaining hydrophobic protein aggregations that cannot be hydrolyzed by the enzymes.

In nitrogen and oxygen SWH and also in the enzymatic hydrolysis, in the tested pH range, the isoelectric point of the peptides was not detected and their solubility maintains a relative flat profile, instead of the characteristic U-shaped profile expected. In the two SWH tested, in addition to the high solubility of the peptides obtained, 95% of the protein was recovered.

*3.4.2. Foaming Properties.* The FC of the peptides is shown in Figure 7. The FC of the delipidated egg yolk granules was tested too, and it was considered to be 0 because of their low solubility.

As observed in Figure 7, all of the peptides showed foaming properties but differences in the FC and FS were found. Peptides obtained by enzymatic hydrolysis had the lowest values for FC, but their FS was the highest. In comparison, the peptides obtained by SWH under nitrogen and oxygen streams showed a higher FC, but their FS was poor compared to that obtained with the peptides derived from enzymatic hydrolysis.

These differences could be explained by the differences in the average size of the peptides that have been described previously. According to Sijtsma et al.[38] and Addler-Nilsen and Olsen,[37] the optimum peptide size varies from 1650 to 3850 Da. In enzymatic

hydrolysis, the average peptide size obtained was around 7 kDa, while in SWH, the average size was around 4 kDa. In this case, it is likely that the lower size peptides obtained by SWH diffuse rapidly and adsorb at the interface.[39] However, the number of interactions at the air−water interface will be larger in the case of bigger proteins, and therefore, although SWH leads to more FC, the bigger size of the peptides derived from enzymatic hydrolysis gives greater FS.[40]

In addition to the peptide size, the adequate distribution of the hydrophobic groups and the charged nuclei in the peptide structure are another important feature for obtaining good interfacial qualities.[35] They are important for creating interactions with the interface and providing the electrostatic repulsions that give FS. The size distribution of the peptides obtained by SWH in oxygen and nitrogen was similar; however, the FC and FS were higher in the peptides obtained under the nitrogen stream than those obtained in the oxygen stream. This could be because, although the oxygen promotes protein hydrolysis, the oxidizing conditions provided could be altering the amino acid residues. According to Stadtman and Levine,[41] the oxidation of proteins leads to the hydroxylation of aromatic groups and aliphatic amino acid side chains, nitration of aromatic amino acid residues, nitrosylation of sulfydryl groups, sulfoxidation of methionine residues, chlorination of aromatic groups and primary amino groups, and conversion of some amino acid residues to carbonyl derivates. It could be interesting to further investigate if these amino acid residue modifications affect the ability of the peptides to interact with the air−water interface and, in particular, to stabilize the foams produced.

*3.4.3. Emulsifying Properties.* The emulsifying properties of the peptides obtained are shown in Figure 8. Figure 8A shows the variation in backscattering at the bottom of the measurement cell, which was measured to study the emulsion creaming. The peptides obtained by enzymatic hydrolysis showed a lower decrease in emulsion backscattering with time when compared to the values obtained for the SWH peptides. In fact, according to the values shown in Table 3, enzymatic hydrolysis produced the peptides whose emulsions were the most stable, with the highest $t_{0.1}$ and the lowest $K_{0.1}$ values. Peptides obtained by SWH under a nitrogen stream showed values closer to those found in the enzymatic hydrolysis, although their creaming was more noticeable. On the other hand, peptides obtained by SWH under an oxygen stream showed the poorest emulsifying properties.

This was confirmed by the $B\%_{ini}$ values. Higher initial values of backscattering are related to emulsions that contain a high number of oil droplets and low size. Therefore, a high value in this parameter is considered indicative of good emulsifying properties.

With regard to stabilization in the cream phase (Figure 8B), the decrease in the backscattering profile detected in the emulsions elaborated using peptides from the two SWH processes showed that coalescence is the main component in the destabilization, reversing the expected rise in backscattering caused by the creaming process.[25] However, the emulsion elaborated using peptides from enzymatic hydrolysis was more stable, which indicates that it is likely that coalescence is not the main cause of emulsion destabilization in this case.

According to the study by Wang et al.,[18] hydrolyzed ethanol-delipidated whole egg yolk protein resulted in improved emulsifying capacity and stability, in particular with the hydrolysates obtained at the highest DH tested (DH = 6%). In our study for delipidated egg yolk granular protein, the

hydrolysates obtained after the enzymatic hydrolysis, with DH of 7%, had the better emulsifying properties. The SWH method

**Table 3. Parameters Obtained from the Backscattering Variations Shown in Figure 8**

| | trypsin | SWH nitrogen | SWH oxygen |
|---|---|---|---|
| $t_{0.1}$ (min) | 17.5 ± 0.6 | 12.25 ± 0.4 | 5.9 ± 0.11 |
| $K_{0.1}$ ($h^{-1}$) | 0.06 ± 0.002 | 0.08 ± 0.002 | 0.19 ± 0.003 |
| $B\%_{ini}$ | 57 ± 1.5 | 58.3 ± 2 | 52 ± 1 |

resulted in significantly smaller peptides, and they gave less stable emulsions. Therefore, as with foaming properties, the emulsifying properties were highly dependent upon the peptide size. This result is consistent with another study, which suggest that extensive hydrolysis of whey proteins reduces the emulsifying activity of the obtained products.[39]

Finally, the results suggest that the modifications caused by SWH under an oxygen stream had a negative effect on the interfacial properties of the peptides, while SWH under a nitrogen stream resulted in hydrolysates with foaming and emulsifying properties close to those obtained by enzymatic hydrolysis.

In conclusion, the delipidated and non-hydrolyzed egg yolk granular protein used as a control was highly insoluble at any tested pH. Using enzymatic hydrolysis (trypsin), 50% of the initial protein content was recovered in the form of soluble peptides in 360 min of reaction. However, using the SWH method, the yield increased until 95% and the reaction time decreased significantly. The functional properties of the peptides obtained using trypsin and those using SWH under a nitrogen stream showed slight differences in their foam and emulsifying capacities. Furthermore, when a SWH under oxygen pressure was carried out, probably because of the protein modifications caused by the oxidizing gas stream, a decrement in the functional properties of the peptides was detected.

According to these results, the use of SWH to obtain peptides from insoluble proteins can be considered as a good alternative to the enzymatic hydrolysis, being a faster and reactive-free method.

Supporting Information

**ABSTRACT:** Thermal treatment of meat proteins induces a range of observable and molecular-level changes. In order to understand and track these heat-induced modifications at the amino acid level, various analytical techniques were used. Changes were observed both in the soluble and in the insoluble fractions after hydrothermal treatment of minced beef samples. Redox proteomics clearly indicated increasing oxidative modification of proteins with increased heat exposure. Collagens in the soluble fraction and myosin in the insoluble fraction were found to be highly susceptible to such modifications. Maillard reaction products in the insoluble and pyrrolidone formation in the soluble fraction steadily increased with increased heat exposure. Fluorescence studies indicated a rapid increase in fluorescence with heat, suggesting the formation of advanced glycation end products. Overall these results provide a deeper understanding of the effect of cooking on meat proteins and the possible relationship to processing conditions in meat-derived food.

**KEYWORDS:** *meat proteins, amino acids, heat-induced modifications, microspectroscopy, fluorescence*

## INTRODUCTION

Cooking or hydrothermal treatment of food proteins induces a range of changes observable both at the whole food level (for example color, taste, tenderness, and moisture holding capacity) and at the molecular level, such as changes in the amino acid profile. This is a particularly important consideration for meat-based foods, which generally have some form of heat treatment prior to consumption. To understand and control the properties of meat-derived products, it is essential to understand and map these modifications.

Cooking causes a cascade of chemical reactions; some of these are beneficial while others have undesirable effects on meat proteins. Cooking-induced changes in protein composition and functional properties affect the sensory, textural, and the nutritional quality of meat products.[1,2]

One of the determining factors of nutritional quality is the bioavailability of proteins. The quality of proteins may be compromised if there are modifications to essential amino acids when food is cooked. For example, heat treatment of food may cause the formation of cross-linked amino acids such as lysinoalanine, lanthionine, and histidinoalanines. Bioavailability is also linked to digestibility, and food processing using heat and alkali treatment either reduces or increases the digestibility of proteins.[3−6] Alkaline treatment in the presence of heat may contribute to reduced nutritive quality of proteins due to amino acid racemization. Bioavailability of the amino acid lysine is reported to be reduced as a result of lysinoalanine formation, under such conditions.[7] Digestibility is aided by the hydrolysis of proteins into amino acids and peptides which is an essential step for absorption of food proteins by enterocytes.[8,9] Reduced bioavailability due to the destruction of arginine and lysine (which are proteolytic enzyme substrates) and also due to racemization of L-amino acids to their less utilizable D-form has been reported earlier.[10,11] Enhanced bioavailability on the other hand, is brought about by the inactivation of tannins, phytates, and protease inhibitors and from the release of bound vitamins.[12] It is a complex trade-off, of which a full understanding can only be gained through tracking of modifications to proteins. Unfortunately tracking residue-level modification is particularly difficult due to the complex nature of food which is confounded by various processing conditions. However, understanding these changes can lead to process improvements resulting in improvements in the final product.

Since cooked meat is composed primarily of protein, its functional properties are influenced by changes to constituent amino acids. Oxidative modification can reduce the bioavailability of basic and aromatic amino acids.[13] Oxidation of basic amino acids often leads to the formation of highly reactive carbonyl groups resulting in protein cross-links.[14] Free radicals produced during meat cooking reduces bioavailability of amino acids such as cysteines and tyrosines by the formation of disulfides and dityrosine bridges, respectively.[15] These cross-links may form protein aggregates, which are substrates for proteases, reducing digestibility and nutritional quality. Subsequent fermentation by the colonic microflora of non-hydrolyzed proteins can then lead to the formation of mutagenic products, resulting in detrimental effects on human health.[16] Changes in color, flavor, digestibility, and nutritional value of food, as a result of cooking, are partly due to

the Maillard reaction, a form of nonenzymatic browning. Maillard chemistry encompasses a complex array of reactions starting with the glycation of proteins and progressing to sugar-derived protein adducts and cross-links also known as advanced glycation end products (AGEs). Impaired nutritional value as a result of changes in protein integrity and function through protein cross-linking mediated by AGEs is an undesirable effect of Maillard reactions.[17] On the positive side, an increased antioxidant activity in food has also been attributed to these reactions.[18] Maillard reaction also remains a major contributor toward the development of the most recognized flavor compounds during the process of cooking meat.[19] Prolonged cooking time and high temperature have been shown to produce high levels of heterocyclic aromatic amines (HAA), which are mutagenic in nature.[20,21] HAA formation in meat during heat exposure has been previously demonstrated to be dependent on the type of meat and the cooking method used.[21]

The challenging task of detecting modifications of proteins and peptides in food substrates and tracking molecular changes is possible using advanced proteomic techniques, including mass spectrometry combined with bioinformatics. The evaluation of protein modification pathways is now possible and can provide valuable information on food processing conditions.[22] The aim of this study was to use several different approaches to profile protein modifications introduced during cooking of meat. We were able to identify the level and sites of amino acid modifications which has provided a deeper understanding of the factors affecting heat-induced changes in meat proteins.

## MATERIALS AND METHODS

**Materials.** TPCK-trypsin was obtained from Promega Corp. (Madison, WI, USA). Tris(2-carboxyethyl)phosphine (TCEP) was obtained from Fluka Chemie (Buchs, Germany). Acetonitrile (ACN) and HPLC grade water were obtained from Mallinckrodt (Phillipsburg, NJ, USA). Tris, dithiothreitol (DTT), and formic acid (FA) were obtained from Merck (Darmstadt, Germany). *o*-Phthalaldehyde (OPA) and triethylamine were obtained from Sigma-Aldrich (St. Louis, MO, USA)

**Methods.** *Sample Preparation.* A 500 g amount of beef sample (biceps femoris), obtained from an animal aged 18 months at the time of slaughter, was minced for 2 min. Subsamples (15 g wet weight) were individually weighed out in round-bottomed flasks and dispersed in water at a meat to water ratio of 1:3. An equilibration time of 20 min each was given before the individual samples were boiled under reflux for 0, 15, 30, 60, or 240 min. Samples were constantly stirred for even heat distribution. Afterward, flasks were immediately cooled in an ice bath for 5 min. Samples were centrifuged (Avanti J-30 I, Beckman) at 38400*g* for 10 min at 4 °C to obtain soluble and insoluble fractions. These were individually freeze-dried (Dura-Dry $\mu$P freeze-dryer, FTS Systems) and stored at −80 °C until analyzed.

*Total Fat Analysis.* Approximately 5 g of raw meat sample was finely minced and boiled gently for 30 min using 50 mL of 6 M hydrochloric acid. The hydrolyzate was then filtered using a Whatman 54 filter paper and the residue rinsed with water until a neutral pH was reached. The filter paper containing the residue was then dried and Soxhlet extracted to determine the total fat content.[23] The total fat content was determined to be 2.8%.

*Determination of pH.* The pH of the raw meat was measured using a pH meter (Mettler-Toledo, Columbus, OH, USA) at ambient temperature. The pH was determined to be 5.58.

*OPA Assay.* Free amines were quantified in the soluble fractions from all time points using an OPA assay.[24] Approximately 10 mg of each lyophilized soluble fraction was dissolved in 1 mL of double distilled water which was then further diluted 2-fold. A 100 $\mu$L aliquot of the diluted sample solution was added to 1 mL of OPA reagent prepared as described,[24] briefly vortexed, incubated for 2 min, and the absorbance measured at 340 nm using an Ultrospec II spectrophotometer (LKB, GE Healthcare, Cleveland, OH, USA). Absorbance readings, averaged from three technical repeats, were compared to the serine standard (1.367 mequiv/L) to determine the $\alpha$-$NH_2$ equivalents generated during hydrolysis. The degree of hydrolysis (DH) was calculated according to the method described by Nielsen et al.[24]

*Amino Acid Analysis.* The lyophilized soluble and insoluble fractions were subjected to amino acid analysis after hydrolysis using HCl vapor at 110 °C for 24 h followed by phenylisothiocyanate derivatization.[25]

An Ultimate 3000 HPLC system (Dionex, Thermo Fisher Scientific Inc., Sunnyvale, CA, USA) was used. A 10 mm aliquot of each derivatized sample was injected onto a Zorbax SB-C18, 5 $\mu$m, 250 × 4.6 $mm^2$ column (Agilent Technologies, Santa Clara, CA, USA) protected with a C18 guard column. The separation was performed at 40 °C using a gradient from 2 to 40% mobile phase B over 31 min. Mobile phase A contained sodium acetate (140 mM), sodium azide (7.5 mM), disodium ethylenediaminetetraacetic acid (EDTA; 0.26 mM) and triethylamine (20 mM) in water and was titrated to pH 5.9 with acetic acid. Mobile phase B was 100% acetonitrile. The eluting peaks were monitored at 254 nm using a photodiode array detector (Ultimate 3000 PDA). At the end of each run the column was washed with 100% B for 10 min followed by reequilibration with 1% B for 20 min.

The level of tryptophan, which is also an essential amino acid, cannot be determined by this method because the indole ring of this amino acid is highly sensitive to the acidic conditions. Cysteines and methionines were quantified using performic acid oxidation followed by HCl vapor hydrolysis.

*Gel Filtration Chromatography.* Gel filtration chromatography was performed on a HPLC system (Knauer, Berlin, Germany) equipped with an A 3800 auto sampler and a S 2600 photodiode array detector.

The soluble fraction from each sample was lyophilized, dissolved in HPLC grade water at 5 mg/mL, and injected (50 $\mu$L) onto a Superdex Peptide HR 10/30 column (GE Healthcare), having an exclusion limit of 20000 Da and optimum separation range of 100−7000 Da. Elution was performed at a flow rate of 0.75 mL/min with 0.05 M phosphate buffer (pH 6.9) containing 0.3 M sodium chloride as the mobile phase. Under these conditions, carbonic anhydrase (29 kDa) eluted at 10.0 min, cytochrome C (12.4 kDa) at 11.3 min, aprotinin (6.5 kDa) at 13.3 min, and sodium azide at 28.2 min. A standard curve was established from the elution times of these standards. The column eluate was monitored at 230, 260, and 280 nm.

*LC-MS/MS Analysis.* The freeze-dried samples from the insoluble fractions, approximately 10 mg in weight, were extracted in a buffer consisting of 7 M urea, 2 M thiourea, and 50 mM DTT, at a ratio of 1:2 (w/v). The proteins were then precipitated using methanol/chloroform precipitation.[26] Proteins from both the insoluble and the soluble fractions were reduced with 50 mM TCEP, alkylated with 360 mM acrylamide, and finally digested with sequencing grade trypsin.

Nanoflow LC-MS/MS was performed on a LC-Packings (Amsterdam, Holland) HPLC, consisting of a Famos autosampler, a Switchos column-switching module, and an Ultimate nanoflow pump. Samples were loaded at 8 $\mu$L/min onto a 0.5 cm × 300 $\mu$m trap column (Varian MicroSorb C18, 5 $\mu$m, 300 Å) which was then switched in-line with 20 cm × 75 $\mu$m analytical column (Varian MicroSorb C18, 5 $\mu$m, 300 Å). Both the trap column and the analytical column were packed in-house. Elution was performed at 150 nL/min, using a linear gradient from 5% to 70% acetonitrile (with 0.2% FA) over 45 min. The column outlet was directly interfaced to a QSTAR Pulsar *i* mass spectrometer (AB Sciex) using a stainless steel electrospray needle (Proxeon, Thermo Fisher). Automated information-dependent acquisition (IDA) was performed using Analyst QS 1.1 software, with a MS survey scan over the range $m/z$ 400−1200 followed by three MS/MS spectra from $m/z$ 40−1600 accumulating three cycles, each with 1.3 s duration.

*Data Analysis.* After each LC-MS/MS run, the raw data file was submitted to Mascot Daemon software (Matrix Science, London, U.K.) for peak list extraction. Peak lists were queried against *Bos taurus*

sequences in the NCBInr database (release date, Sept. 14, 2011) using the Mascot search engine (v2.2.03, Matrix Science) maintained on an in-house server. The following Mascot search parameters were used: "semitrypsin" as the proteolytic enzyme with two missed cleavages permitted; 200 ppm error tolerance for MS and 0.3 Da for MS/MS. Search results were compiled and analyzed using ProteinScape 2.1 (Bruker) using the ProteinExtractor function. At least one peptide with a score indicating identity, calculated by the search engine, was required for protein identification and results assessed as true matches were used for further analysis.

For the evaluation of heat-induced peptide modifications, Mascot searches were conducted using a combination of up to four of the target modifications listed in Table 1 as variable amino acid modifications at any given time. Error-tolerant searches were performed to account for combinations of modifications that are not in the same group. There were no additional meaningful combinations of modifications found using error-tolerant searches that were not included in the combinations reported.

Modifications between samples were compared using an in-house-developed scoring system. For each modification, the score was calculated by dividing the number of amino acids bearing the modification by the total number of susceptible amino acids in the identified peptides. Modifications 1−7 were categorized as oxidative, 8−15 as other modifications ,and 16−17 as Maillard modifications (Table 1).

For the oxidative modifications, the scores were multiplied by weighing factors associated with damage hierarchies that reflected the relative severities of the modifications relative to the native unmodified amino acid residue.[27] A total oxidative weighted score was then obtained by summing the individual weighted modification scores as shown in the following equation:

$$S_w = \sum_{n}^{i=1} \left( \frac{aa_{mod_i}}{aa_{tot_i}} f_{mod_i} \right)$$

where $S_w$ = total weighted modification score, $aa_{mod_i}$ = count of amino acids affected by the $i$th modification, $aa_{tot_i}$ = total number of amino acids that could be affected by the $i$th modification, and $f_{mod_i}$ = the weighing factor for the $i$th modification.

A similar approach was used for calculating the total scores for Maillard and other heat-induced modifications, but without any weighting factors.

*Microspectroscopic and Fluorescence Studies.* Lyophilized fractions, resuspended in water (15 μL), were transferred by micropipette into 96-well plates for examination (bright field or fluorescence) using a Leica DM6000B microscope (Leica, Wetzlar, Germany) with 200 W Hg lamp. Soluble fractions were examined with UV (340−380 nm)/blue (>425 nm long pass) and blue (450−490 nm)/green (>515 nm long pass) filter sets. Reproducibility (sample transfer accuracy and sample homogeneity) was validated using replicates.

Samples in wells were centered on the microscope stage to standardize the fluid volume being imaged. Microscope and camera (DC500, Leica) settings were standardized to prevent overexposure at the highest sample brightness. Black standard (with shutter in place) and white standard (ultrapure water in well plates) images were taken just before imaging. All images were in sRGB color space and stored as 8 and 16 bit per channel RGB TIFF files.

Mean red, green, and blue values were measured from a central line across each image (AnalySIS 5.0, Olympus, Tokyo, Japan), and these data (900 samples per channel) were transferred to a spreadsheet for analysis. Conversion from sRGB to CIEXYZ and xyY space was achieved by a matrix transform to a 2° Observer, D65 illumination standard.

Insoluble fractions were observed by bright field and fluorescence. In addition to the filters described previously, a multispectral band-pass filter (Leica B/G/R) was used with excitation regions in UV (420 ± 30 nm), blue (495 ± 15 nm), and green/yellow (570 ± 20 nm), and emission in blue (465 ± 20 nm), green (530 ± 30 nm) and red (640 ± 40 nm).

**Statistical Analysis.** All values are reported as the mean ± standard error of the mean from three individual measurements for the OPA and amino acid analysis.

In order to assess the effect of heat exposure time, heat-induced weighted modification scores (oxidative or other) were analyzed using one-sample $t$ test (Minitab v. 16). The first $t$ test compared the oxidative scores of heat-exposed samples ($n$ = 4; i.e., samples with exposure times of 15, 30, 60, and 240 min combined) in the insoluble fraction against the score of the baseline sample (i.e., sample with exposure time of 0 min). The second $t$ test similarly compared the oxidative scores of heat-exposed samples ($n$ = 4) in the soluble fraction against the baseline score. These two $t$ tests were then repeated on the scores other than oxidative ($n$ = 4 each in insoluble or soluble fraction). The statistical significance was set at $p < 0.05$.

## RESULTS

Minced beef samples were exposed to boiling water under reflux for various time periods. Minced meat was used to increase the meat surface area of exposure to the designated temperature as quickly as possible without the formation of a temperature gradient from the surface to the core, as would be expected if bigger meat pieces are used. Individual samples were

then centrifuged to obtain a soluble and an insoluble fraction and subsequently investigated for protein denaturation and amino acid modifications.

**OPA Assay.** Figure 1 shows the amount of free amino groups present in the soluble fraction obtained from the various

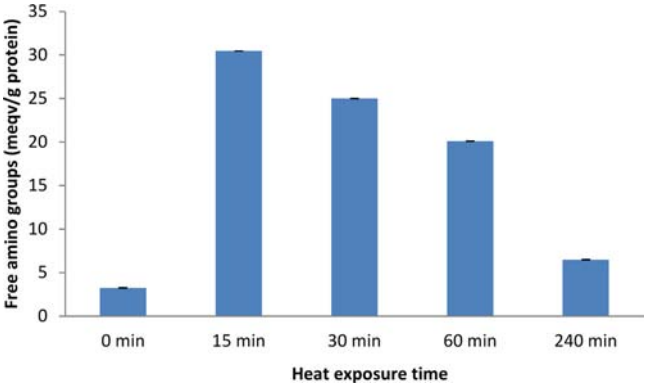

**Figure 1.** Amount of free amines expressed as milliequivalents per gram of protein in the soluble fraction after 0, 15, 30, 60, and 240 min exposure to heat. The error bars represent standard errors of the means.

heat exposure time points. There was an 8-fold increase in the level of free amines within the first 15 min of heat exposure followed by a steady reduction to about double the starting amount on further exposure to heat over the following 210 min.

**Amino Acid Analysis.** The weights of the individual freeze-dried soluble and of the insoluble fractions and their total protein contents at each time point, as determined by quantitative amino acid analysis, are shown in Table 2.

The amount of protein in the soluble fraction was highest in the baseline sample before exposure to heat and was then markedly reduced in the 15, 30, and 60 min samples before being partially restored in the final sample after 240 min heat treatment. In the insoluble fractions, little variation was observed in the protein content. The levels of essential amino acids, expressed as percentages of the total protein amounts in the soluble fractions and in the insoluble fractions, are shown in Figures 2 and 3, respectively.

In the soluble fractions all the essential amino acids, except methionine and histidine, were determined to be highest in the baseline (0 min) fraction. These levels decreased by about half after 15 min heat exposure after which they were relatively stable. The level of methionine however increased to a plateau between 15 and 30 min but then decreased progressively upon longer heat exposure. The level of histidine in the soluble fraction was the lowest as compared to the rest of the essential amino acids. There was no definite trend observed in the changes in histidine level even after 240 min heat exposure.

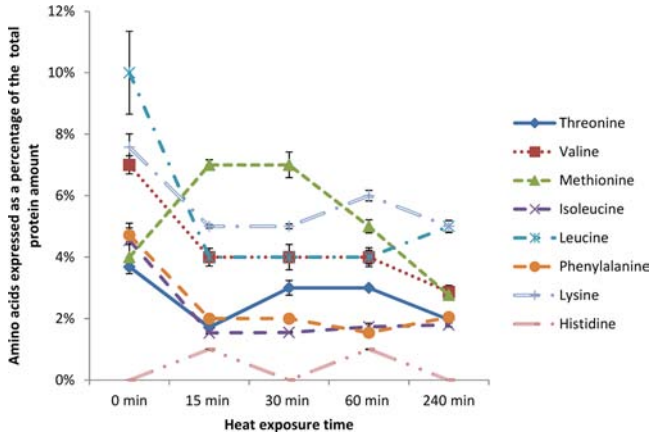

**Figure 2.** Essential amino acids of the soluble fractions after 0, 15, 30, 60, and 240 min exposure to heat, expressed as percentages of the total protein contents. The error bars represent standard errors of the means.

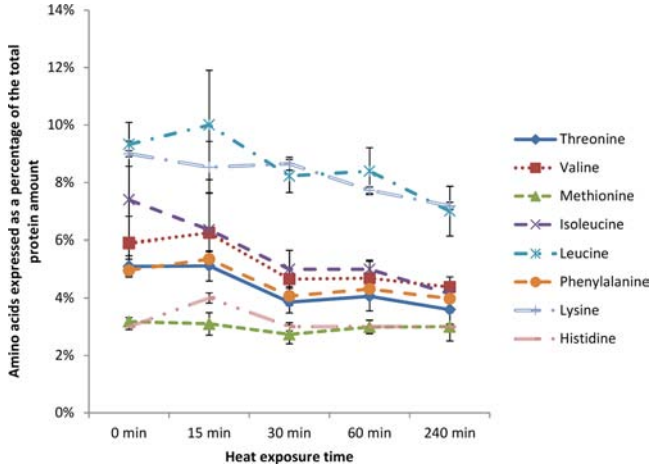

**Figure 3.** Essential amino acids of the total protein contents of the insoluble fractions after 0, 15, 30, 60, and 240 min exposure to heat, expressed as percentages. The error bars represent standard errors of the means.

In the insoluble fraction, the levels of all of the essential amino acids were stable up to 15 min heat exposure. None of the essential amino acids, except isoleucine, showed any marked changes beyond the 15 min exposure time, although slight decreases in the levels of a number of them, in particular leucine, lysine, isoleucine, valine, phenylalanine, and threonine, were observed. The isoleucine level decreased progressively with increased heat exposure time up to 30 min after which it stabilized.

**Gel Filtration Chromatography.** Protein profiling by gel filtration chromatography (GFC) provided an indication of the

**Table 2. Weight and the Total Protein Contents of the Soluble Fractions and of the Insoluble Fractions after 0, 15, 30, 60, and 240 min Exposure to Heat, As Determined by Quantitative Amino Acid Analysis[a]**

molecular mass distribution of proteins and polypeptides in the soluble fraction and also revealed the presence of highly hydrophobic peptides that were retained on the column for longer than expected based on their molecular weights (Figure 4). The distribution of peptides and proteins across the high

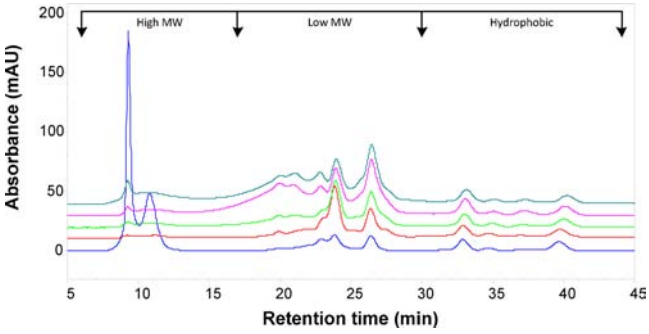

**Figure 4.** Overlaid GFC profiles of the soluble fractions after 0, 15, 30, 60, and 240 min exposure to heat, from bottom to top, respectively.

molecular weight (greater than 2.2 kDa), low molecular weight (less than 2.2 kDa), and the hydrophobic (eluting after the position of the salt peak) ranges is given in Figure 5.

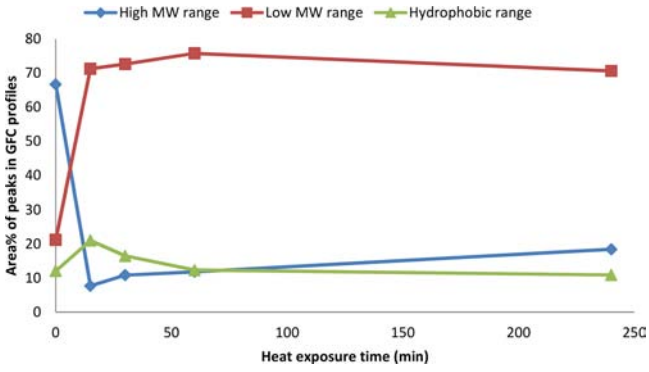

**Figure 5.** Peak area percentages of the high and low molecular weight peptides and hydrophobic peptides in the GFC profiles of the soluble fractions after 0, 15, 30, 60, and 240 min exposure to heat.

A 9-fold decrease in the percentage peak areas of the high molecular weight compounds was observed shortly after 15 min heat exposure. However, with increased heat exposure a gradual increase was noticed, with the 240 min heat-exposed sample showing only a 4-fold decrease in these compounds from the unexposed sample. A 3-fold increase in the area percentage of low molecular weight peaks was obtained after 15 min, the level of which remained constant in the remaining samples up to 240 min. The percentage peak areas of hydrophobic peptides increased 2-fold after 15 min but gradually decreased to slightly less than starting level with increased heat exposure time (Figure 5).

**LC-MS/MS Analysis and Heat-Induced Modification Scoring.** The total number of proteins identified in each fraction, along with the total number of identified peptides, based on the search criteria is listed in Table 3.

The relative scores for oxidative and other heat-induced modifications were calculated using a redox proteomic approach.

Oxidative modifications were observed and scored in the insoluble fraction of the sample without any heat exposure.

**Table 3. List Showing the Number of Proteins Identified from Each Sample and the Total Number of MS/MS Spectra along with the Number of Identified Peptides**

| sample | proteins identified | total no. of MS/MS spectra | total no. of identified peptides |
|---|---|---|---|
| supernatant 0 min | 9 | 595 | 15 |
| supernatant 15 min | 61 | 711 | 219 |
| supernatant 30 min | 63 | 737 | 237 |
| supernatant 60 min | 61 | 979 | 191 |
| supernatant 240 min | 55 | 991 | 172 |
| pellet 0 min | 46 | 764 | 226 |
| pellet 15 min | 33 | 647 | 176 |
| pellet 30 min | 31 | 713 | 120 |
| pellet 60 min | 32 | 645 | 91 |
| pellet 240 min | 22 | 649 | 68 |

These scores gradually showed a slight increase through the exposure times, such that there was an approximate 1.4-fold increase between the 0 and 240 min samples. In contrast, no modifications were detected in the soluble fraction without heat exposure. However, a steep increase of almost 4-fold in the modification score was observed from 30 to 240 min of heat exposure (Figure 6a).

Heat-induced modifications, other than oxidative (Table 1), were also monitored in both the insoluble and the soluble fractions. Here too, a baseline level of these modifications was observed only in the insoluble fraction. A 1.5-fold increase in the score of the insoluble fraction and a slightly higher increase in that of the soluble fraction were detectable from 15 to 240 min heat exposure (Figure 6b). Maillard modifications, monitored separately, could not be initially detected in the soluble fraction. However, after 15 min heat exposure the formation of these products could be detected that remained constant for up to 60 min but decreased thereafter. In the insoluble fraction, a baseline level of these modifications was seen that showed a steady increase with longer heat exposure time (Figure 6c).

The detailed database search results are provided as Supporting Information (Table 1s).

One-sample *t* tests were used to assess the statistical significance of the differences between the baseline sample scores and heat-exposed sample scores (i.e., 15, 30, 60, and 240 min samples combined), for each combination of modification score (oxidative or other) and sample type (insoluble fraction or soluble fraction).

The mean oxidative modification scores of the four heat-treated insoluble fractions (0.16) and of the four heat-treated soluble fractions (0.13) were both significantly higher than their respective baseline scores of 0.13 and 0.00. The scores for the insoluble fraction and the soluble fraction were not significantly different from baseline scores but tended to be higher than their respective unexposed control scores. The mean scores for modifications other than oxidative, in the insoluble fractions, although tending to be higher than the baseline score, were not significantly different. In contrast, in the soluble fractions, the mean score for these modifications was significantly lower for the four samples (0.80) than for the baseline sample (1.28).

**Microspectroscopic and Fluorescence Studies.** A distinct color change was observed in the soluble fraction

from pink to clear to brown during the first 15 min of cooking, as reflected in measurements of hue (Figure 7a). No further large changes in hue were observed, but there was a clear and prospectively linear decrease in the luminosity of the sample (Figure 7b). This rapid initial change, followed by a smaller change during the last 180 min of cooking, was also seen with fluorescence studies with filter sets chosen to fit with expected AGEs (advanced glycation end products) excitation and emission wavelengths (Figure 7c). A similar pattern of events was observed in bright-field and fluorescence micrographs of the insoluble fraction (Figure 8). Color changes and gradual darkening of solid material were observed in bright field, while fluorescence microscopy using UV excitation revealed gradual increases in fluorescence as cooking progressed. However, we also observed a nonhomogeneous increase in red fluorescence during cooking that included excitation well outside that previously reported for AGEs.

## DISCUSSION

In order to minimize nutritional loss during cooking of meat, reliable monitoring parameters are required to check the severity of hydrothermal exposure.[28] Changes in the functional attributes of food proteins can be inferred from information on site specificity and the extent of amino acid modification. Heat induces oxidative modifications in muscle foods, which is of major concern as it contributes to loss of nutritional quality and changes to sensory perceptions. Models that mimic the protein composition in meat and their physicochemical state have been used in previous studies to eliminate the effect of biological variability in meat samples. Models are also useful to independently assess the effect of various processing parameters.[29] However, in meat, the complex nature of heat-induced oxidative changes at the molecular level, the interdependence of the various oxidation pathways, and their effect on bioavailability require further investigations. Once profiled, these changes can ultimately be correlated to information on the nutritional quality as well as functionality of muscle foods.[30]

**Amino Acid Analysis.** Modifications induced at the amino acid level can influence the shelf life, digestibility, and the nutritional value of food proteins.[31,32] Amino acid analysis showed that the percentages of essential amino acids determined in the soluble fraction, except methionine and histidine, decreased with an increase in heat exposure time. Most of the decreases in these levels were evident after 15 min heat exposure, beyond which the changes were minimal. Phenylalanine and tyrosine have previously been reported to be highly sensitive to the oxidative process.[33] Also, model studies on free amino acid oxidation revealed that the aromatic amino acids were most susceptible to oxidation in solution.[34] These amino acids are essential for humans, although tyrosine is not always directly required from the diet. Since tyrosine is synthesized in the body from phenylalanine, deficiency of phenylalanine in the diet can affect the levels of tyrosine. The decrease in the proportions of the essential amino acids, except methionine, in the soluble fraction observed after just 15 min of heat exposure could also be due to heat-induced protein aggregation and the subsequent removal of the precipitated proteins from the solution. In contrast to the soluble fraction, amino acid analysis of the insoluble fraction did not reveal any marked changes with increased exposure to heat. A slight and gradual decrease after 15 min heat exposure indicated a higher stability of the amino acids in the insoluble fraction to heat. A contributory factor to this apparent stability could be due to protein aggregation, leading to a protective effect. A rapid decrease in the total protein content was observed in the soluble fraction with increased heat exposure time, possibly due to an increase in protein aggregation with increasing heat, whereas no such changes were detected in the insoluble

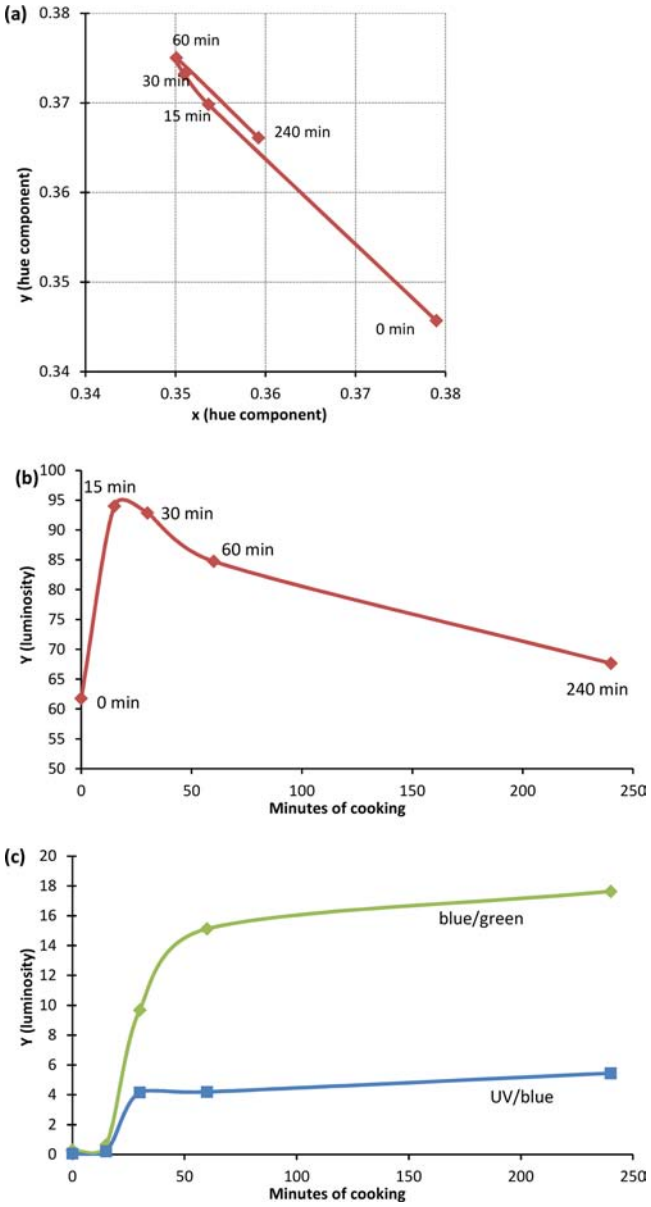

**Figure 7.** Color measurements showing the changes in (a) hue, (b) luminosity, and (c) fluorescence in the soluble fraction after 0, 15, 30, 60, and 240 min exposure to heat. See text for details.

fraction. Thus, it is apparent that the bioavailability of the essential amino acids especially in the soluble fraction is highly dependent on the duration of heat exposure, whereas in the insoluble fraction which contained the bulk of the protein, the effect of heat on these amino acids is reduced.

Cross-linking reactions between amino acid side chains may be a consequence of heat exposure, the most common being the formation of lysinoalanine and lanthionine. Cysteine can degrade in the presence of heat to form dehydroalanine, probably through a $\beta$-elimination reaction, which can then react with the $\varepsilon$-amino group of lysine to form lysinoalanine or with the thiol group of cysteine to form lanthionine. Both lysinoalanine and lanthionine can introduce enzyme-resistant cross-links in proteins, reducing bioavailability of these proteins. Lysinoalanine has been implicated in renal toxicity in rats and is found both in home-cooked as well as commercially processed foods. Although lysinoalanine is usually observed following alkali treatment of food, it is now reported to be present in nonalkali-treated food as well.[35] In the present study, lysinoalanine and lanthionine formation were found to be negligible in both the insoluble fraction as well as in the soluble fraction, suggesting that such cross-links may not be easily formed even after extensive boiling of meat. Determining the cooking temperatures and conditions under which these cross-links form would be a fruitful area for further study.

**Peptide Molecular Weight Profiling.** Peptide molecular weight profiling can provide a useful way of determining the amount of degradation and aggregation of meat peptides and also the generation of peptides with hydrophobic characteristics. From the GFC profiles of the soluble fractions, it was evident that the peptides in the low molecular mass range increased as a result of exposure to heat. A shift from the high molecular weight proteins, seen in the baseline sample, to the low molecular mass region within 15 min heat exposure is indicative of a combination of both hydrolysis and aggregation. Heat-induced hydrolysis of proteins generating a mixture of peptides would contribute to an increase in low molecular weight compounds whereas the formation of heat-induced insoluble protein aggregates would result in an overall decrease in the levels of high molecular weight compounds. Peptides eluting from the Superdex column between 22 and 24 min would be expected to have molecular weights around 1 kDa as determined by a standard curve generated using pure proteins. The size of these peptides provides them with the ability to aggregate in the presence of heat. The results from the OPA assay provided some evidence supporting this hypothesis because, after a substantial initial increase in the free amines, a progressive decrease is noticed with increased heat exposure time. We suspect that this decrease in the amount of free amines is due to an aggregation of peptides which prevents the free amines from the lysine side chains or from the free amino termini of peptides from reacting with the OPA reagent. Although results from the amino acid analysis showed an initial

dx.doi.org/10.1021/jf502668w | J. Agric. Food Chem. 2014, 62, 8187−8196

decrease in the level of lysine residues, after 15 min heat exposure these changes were minimal. These results further indicate that this decrease in free amines, as seen with the OPA assay, were not due to the loss of lysine residues but possibly due to aggregation.

Peaks in the GFC profiles that eluted after 29 min were suggestive of the presence of highly hydrophobic peptides in the hydrolyzates, which were not fully separated based on their molecular size but were selectively retained by hydrophobic interactions with the chromatography matrix.[36] Hydrophobicity in protein hydrolyzates, along with several other factors such as size, primary sequence, and spatial structure of peptides can contribute toward the perception of bitter taste thus affecting product quality.[37] Peptides with hydrophobic characteristics were seen in all the samples including the sample without any heat exposure. An initial increase in the peak areas in this region of the chromatogram followed by a steady decline suggested that hydrophobic peptides initially formed were destroyed or aggregated with other peptides as a consequence of prolonged heat exposure.

**Tracking and Scoring Heat-Induced Damage in Meat Proteins.** We have reported here an advanced application of a scoring system that can be used to characterize oxidative and other heat-induced modifications occurring in meat during cooking. Using this scoring system, we measured a steady increase in the oxidative modification score in both the insoluble fraction and in the soluble fraction with increased heat exposure time. From the results (Table 3) it was evident that the number of proteins identified in the soluble fractions increased almost 7-fold after just 15 min of heat exposure, compared to the unexposed sample. A slight decrease in this number was noticed in the soluble fraction of the sample exposed to heat for the longest period (240 min), possibly due to protein aggregation. A steady decrease in the number of identified proteins in the insoluble fractions was seen with increasing time of heat exposure (Table 3), again possibly due to aggregation. Analysis of the peptides modified by heat indicated that oxidized aromatic amino acids made major contributions to the overall oxidative damage scores (Supporting Information Table 1s). Aromatic amino acids are well-distributed in meat proteins but are also particularly prone to oxidative damage during the cooking process.[15] An increase in the levels of phenylalanine oxidation and the formation of quinone from tyrosine with increasing heat were the major contributors. We suspect that the cause of the measured oxidation lies in another effect; cooking also disrupts muscle tissue releasing iron from the heme molecule. The iron from the heme and nonheme pigments aids in the formation of free radicals which can then react with aromatic amino acid rings forming hydroxylation products.[38−41] Superoxide radicals formed during the cooking process due to autooxidation of myoglobin can attack the aromatic rings of tryptophan forming *N*-formylkynurenine. Oxidation of phenylalanine can form *o*- or *m*-tyrosine and dimers of hydroxylated aromatic amino acids, and tyrosine oxidation can lead to dihydroxyphenylalanine and trihydroxyphenylalanine formation.[42,43]

The results clearly indicated that the proteins extracted in the soluble fraction were more susceptible to heat-induced modifications. Theory would suggest that hydrophilic proteins should be more susceptible to modifications due to their increased solubility and that in meat many of these proteins would be collagens. Our results have confirmed this, and the identities of scored peptides confirm that collagens make up the majority of hydrophilic peptides.

Scores for modifications other than oxidative showed a similar trend. Further study with a larger sample size may resolve further details of these trends. An increase in Maillard reaction products was detected in the insoluble fraction just after 30 min heat exposure. Such an increase was however not observed in the soluble fraction. Myosin was found to be the protein most susceptible to Maillard reactions. Previous reports have shown that a clear correlation exists between decreased rehydrability and protein extractability from freeze-dried meat due to glucose-mediated cross-linking between the heavy chains of myosin through a Maillard type reaction.[44] Our results clearly indicate that myosin is prone to reactions with reducing sugars in the presence of heat.

An interesting observation within the heat-induced modifications other than oxidative was the formation of pyroglutamic acid. A significant increase in the pyroglutamic acid content in the soluble fraction was observed with increased heat exposure. Pyroglutamic acid formation is not related to glycation or oxidation of proteins but is hypothesized to be a heat-induced nonenzymatic cyclization reaction in which the free amino group of glutamic acid or glutamine forms a lactam. This type of modification has been previously reported to increase in milk proteins such as $\alpha$-lactalbumin exposed to heat.[45] Bitterness resulting from the formation of pyrrolidone carboxylic acid at the N-terminus of hydrophobic peptides, during proteolysis of casein, has also been reported.[46] An overall increase in the level of pyrrolidone formation in the soluble fraction with increasing heat exposure indicated that meat proteins/peptides in their soluble form were more susceptible to such modifications. A possible explanation for this could be that hydrolysis of soluble proteins during the cooking process produces an increasing number of peptides with glutamine or glutamic acid residues at their N-termini. These are then readily available for the cyclization process forming pyrrolidones. However, it is also possible that this increase could result due to the method used for sample preparation for the LC-MS studies. Particularly during the trypsin hydrolysis step, an alkaline pH and an elevated temperature of 37 °C may favor the decomposition of the glutamine/glutamic acid residue to pyrrolidone-carboxylic acid,[47] if the tryptic peptide had a glutamine/glutamic acid preceded by a lysine or an arginine residue. A steady increase in the levels of longer peptides with a trypsin cleavage site adjacent to a glutamic acid or glutamine residue was observed in the soluble fraction with increasing heat exposure.

**Microspectroscopic and Fluorescence Studies.** Spectral changes in meat hydrolyzates were of two distinct types: color changes during the first 15 min of cooking, after which the hue remained similar; and reducing luminosity over the following hours. Together with the GFC and oxidative damage data, this suggests a considerable diversity in the processes, substrates, and end products occurring during the initial few minutes of cooking, followed by a less-diverse buildup of particular types of product subsequently.

Fluorescence data clarify these visual color changes in terms of chemistry because we have chosen filter sets with excitation and emission wavelength ranges that cover the spectrum previously published for AGEs.[48,49] Results from the UV/blue and blue/green filter sets suggest that changes in the sample following the first 60 min of cooking are probably gradual and approximately linear. We interpret this as resulting from the

initial formation of condensation products of sugar- and lysine-derived amino acids, during the first 15 min, followed by a gradual build-up over an extended period of heat exposure.

Our microscopy method allowed for direct comparison of the spectral and fluorescence characteristics of both the soluble fraction and the insoluble fraction under the same conditions. We conclude that the changes in the soluble fraction are generally also seen in the insoluble fraction. However, within the insoluble fraction there is considerable spatial variation in buildup of product with some structures showing higher fluorescence than others. While the fluorescence seen with UV and blue light excitation (assumed AGEs) increased in a way similar to that of the soluble fraction, there were also additional fluorescent species that increased in abundance in the later stages of cooking which were excited by longer wavelengths (e.g., yellow/green) and fluoresced red with a multispectral band-pass filter. These appeared to mostly be associated with dense regions of structure that appeared the deepest brown in the visible spectrum. Whether this heterogeneity is due to the difference in the rate of AGE formation is yet to be determined. AGEs have been reported earlier to be dynamic in nature and constantly undergoing rearrangements as they continue to cross-link with other proteins.[49]

Overall the results from amino acid analysis, modification scoring, protein/peptide profiling, and microscopic and fluorescence studies provided a deeper understanding of the changes at the amino acid levels of meat proteins brought about though a series of reactions aided by heat. Essential amino acids were determined to be more susceptible to heat in their soluble form, although heat-induced cross-links such as the formation of lanthionine and lysinoalanine were not detected even after prolonged heat exposure. Meat proteins were also found to be susceptible to aggregation in their soluble form. An increase in the amino acid oxidative modifications was seen especially in the soluble collagen proteins, whereas myosin in the insoluble fraction was most susceptible to other heat-induced modifications such as Maillard reactions. Also most of these changes at the amino acid level were determined to take place quite rapidly in the presence of heat. Further work will however help to elucidate the functional importance and potential effects on bioavailability of these cooking-induced changes.

Supporting Information

**ABSTRACT:** In this paper, we investigate whether the analysis of stable isotope ratios D/H and $^{13}C/^{12}C$ in ethanol and acetic acid and of $^{18}O/^{16}O$ in water can be applied to the ingredients of "aceto balsamico di Modena IGP" (ABM) to evaluate their authenticity. We found that impurities in the extraction solution do not affect the $^{13}C/^{12}C$ of acetic acid and the D/H values of acetic acid are not affected under a composite NMR experiment. The standard deviation of repeatability and standard deviation of reproducibility are comparable in wine vinegar and ABM and generally lower than those quoted in the official methods. This means that the validation parameters quoted in the official methods can also be applied to the ingredients of ABM. In addition, we found no changes in the isotopic values from wine to vinegar and to ABM, and from the original must to the ABM must, providing experimental evidence that reference data from wine databanks can also be used to evaluate the authenticity of vinegar and ABM.

**KEYWORDS:** *D/H, $\delta^{13}C$, $\delta^{18}O$, isotope ratio mass spectrometry, SNIF-NMR, vinegar authenticity*

## INTRODUCTION

Wine vinegar is defined by EC Regulations 479/2008 (Annex IV, sections 1 and 17) as a product obtained from the acetous fermentation of wine, which is in turn defined as a product obtained exclusively from the alcoholic fermentation of fresh grapes, whether crushed or not, or from grape must. According to this definition, wine vinegar cannot contain acetic acids obtained from either petroleum derivatives or pyrolysis of wood (synthetic acetic acid) or from the fermentation of nongrape sugars (e.g., from beet or cane). Moreover, wine and wine vinegar cannot be produced from dried grapes diluted with water; therefore, the so-called "raisin vinegar", commonly produced in some Mediterranean countries by fermenting dried grapes and rehydrating with tap water, cannot be considered wine vinegar.[1]

This also applies to "aceto balsamico di Modena IGP" (ABM), a PGI (Protected Geographical Indication) vinegar now renowned throughout the world, obtained from cooked and/or concentrated grape must (at least 20% of the volume), with the addition of at least 10% of wine vinegar and a maximum 2% of caramel for color stability (EU Reg. 583/2009). The geographical origin of ABM ingredients is not specified.

In the case of must and wine, since 1991 the addition of water and exogenous sugars has been detected by analyzing the isotopic ratios of hydrogen (D/H) and carbon ($^{13}C/^{12}C$) in ethanol and of oxygen ($^{18}O/^{16}O$) in water. OIV (International Organization of Vine and Wine) methods are currently adopted: OIV-MA-AS311-05 for site-specific analysis of the D/H ratio using $^{2}H$-site-specific natural isotope fractionation NMR ($^{2}H$-SNIF-NMR), OIV-MA-AS312-06 for analysis of the $^{13}C/^{12}C$ ratio (expressed as $\delta^{13}C$ ‰) using isotope ratio mass spectrometry (IRMS), OIV-MA-AS2-12 for analysis of the $^{18}O/^{16}O$ ratio (expressed as $\delta^{18}O$ ‰) using IRMS. Addition is detected by comparing the results against an appropriate databank, such as the official databank set up in 1991 (EU Regulations 2347 and 2348/91) by the European Union for all wine-producing countries within its territory. According to current regulations (EU Regulation 555/2008), a number of samples representing the wine production of each member state are officially collected every year and analyzed using the above-mentioned OIV methods. The isotope data bank makes available reference data on a yearly basis, thus allowing legal limits to be defined on the basis of isotopic data for each country, each subarea (e.g., region), and each protected denomination (PDO-IGP), as well as general limits[2] when origin and year of production are not declared.

Very recently, isotopic methods have been recognized by the European Committee for Standardization (CEN) and in part by OIV as a means of detecting the presence of exogenous acetic acid and tap water in wine vinegar. The methods are EN 16466-1 for D/H in the methyl site of acetic acid using $^{2}H$-SNIF-NMR, EN 16466-2 and OIV 510/2013 for analysis of $^{13}C/^{12}C$ in acetic acid using IRMS, and EN 16466-3 and OIV 511/2013 for analysis of $^{18}O/^{16}O$ in water using IRMS.

Moreover, a recent paper[1] showed that the legal limits set on the basis of the wine isotope databank can be used as reference for $\delta^{18}O$ analysis to detect the authenticity of wine vinegar.

As yet, no studies have investigated application of these techniques to the ingredients of ABM (wine vinegar and must) or the possibility of using the wine databank as reference for vinegar and ABM for the isotopic ratios D/H and $\delta^{13}C$.

In this work, we aim to fill these gaps by investigating whether official isotopic methods recognized by OIV and CEN for must and wine vinegar can be used to analyze ABM. To do this, we verified and quantified the presence of impurities in solutions extracted from wine vinegar and ABM, determined the validation parameters of the methods applied to the ingredients of AMB, and compared them with those quoted in the CEN and OIV standards. We also evaluated the variation of D/H and $^{13}C/^{12}C$ between wine ethanol and acetic acid in wine vinegar and ABM in order to determine whether the wine isotope databank can also be used as reference for D/H and $\delta^{13}C$ of acetic acid in order to monitor the authenticity of vinegar and ABM.

## MATERIALS AND METHODS

**Samples.** To assess variation in isotopic parameters along the production chain (Table 1), 13 production chains were considered (Table 1). Nine of them consisted of wine, the corresponding wine vinegar, grape must (100% concentrated must or 100% cooked must or mixtures of the two types), and the corresponding ABM. The other four were obtained directly from vinegar rather than starting from wine. Cane sugar acetic acid was added to two of these vinegar samples (chains 11 and 12).

Table 1. Summary of the Production Chain Samples[a]

| chain | wine | vinegar | cooked must | concentrated must | ABM |
|---|---|---|---|---|---|
| 1 | × | × | × (100%) | | × |
| 2 | × | × | × (52%) | × (48%) | × |
| 3 | × | × | × (20%) | × (80%) | × |
| 4 | × | × | × (20%) | × (80%) | × |
| 5 | × | × | × (50%) | × (50%) | × |
| 6 | × | × | × (50%) | × (50%) | × |
| 7 | × | × | × (50%) | × (50%) | × |
| 8 | × | × | | × (100%) | × |
| 9 | × | × | | × (100%) | × |
| 10 | | × | × (54%) | × (46%) | × |
| 11 | | × | × (50%) | × (50%) | × |
| 12 | | × | × (50%) | × (50%) | × |
| 13 | | × | | × (100%) | × |

[a]Crosses indicate samples from each chain. The first nine chains were started from wine, the other four from vinegar. Cooked grape must or concentrated must or a mixture of the two in different percentages (in parentheses) were used to produce the ABM.

To evaluate the effects of adulteration with exogenous sugars, one sample of wine was divided into seven parts to which were added increasing percentages of alcohol from cane sugar (from 0% to 42%) before being fermented into vinegar. Two of these vinegars (with 10% and 42% cane alcohol added) were used to make ABMs. In addition, two samples of ABM were adulterated with different percentages of synthetic vinegar (20% and 40%).

In the production of ABM, a maximum 2% of caramel can be added for color stability, tangential filtering is usual, and the product may be concentrated to increase its density. To evaluate the effects of these processes, one sample of vinegar was divided into three parts: one was used to produce ABM without filtration, another underwent tangential filtration but no caramel was added, while the third underwent filtration and addition of caramel (1.79%). Another sample of vinegar was divided into three parts, and ABM was produced without concentration from one subsample, and at two different degrees of concentration (45°Brix and 57°Brix) from the other subsamples.

**Pilot Production of Vinegar and ABM.** Wines were transformed into vinegars using a couple of fully automated pilot fermenters (each with a capacity of 8 L) and a continuous fermentation process (at least 10 days per sample) identical to the industrial process with respect to time, temperature, and concentration of alcohol and acetic acid (40 h to entirely transform the alcohol into acetic acid, 34−36 °C, 10.0−10.4% of alcohol in wine, transformation efficiency 95−97%). Oxidation of ethanol was performed by means of *Acetobacter* spp. bacteria.

The ABM was produced according to EU Reg. 583/2009.

When evaluating the effects of adulteration with exogenous sugars, in order to correctly measure the percentages of the different raw materials in each fermentation process, lithium (30 ppm) was added to the wine as a marker; the concentration of each new raw material was calculated on the basis of the lithium concentration in the product (measured using atomic absorption spectrometry).

Tangential filtration was carried out by passing the vinegar through a polysulphone membrane with a porosity of 0.6 $\mu$m; the maximum temperature throughout the process was below 37 °C.

ABM concentration was carried out in batches using pilot vacuum equipment normally used for jam production. The samples were collected at different times during a single concentration process.

**Methods of Isotopic Analysis.** Ethanol was distilled from wine samples following the official OIV method (MA-AS-311-05). Acetic acid was extracted from the vinegars and ABMs according to OIV method 510/2013. Briefly, acetic acid was extracted with diethyl ether or *tert*-butyl methyl ether by liquid−liquid extraction for at least 5 h, and the solvent was then eliminated by distillation using a column that prevents isotopic fractionation of acetic acid. The samples of must and of ABM residue after acetic acid extraction underwent alcoholic fermentation. Before fermentation, the ABM residue was heated to 40° for at least 6 h to remove residual ether. Each sample was inoculated with a fresh culture of *Saccharomyces cerevisiae* (strain ATCC 9763) without added water. Fermentation was carried out in glass bottles with a bubbler valve in the cap; each bottle contained 0.7 L of sample, and the temperature was adjusted to 25 °C. At the end of fermentation, the ethanol was extracted by distillation, according to the procedure described in the OIV MA-AS-311-05 method. The Brix degree of must was measured following the OIV-MA-AS2−02 R2009 method.

**SNIF-NMR Analysis.** The D/H of ethanol from wine and must fermentation (cooked and concentrated as well as the ABM residue after acetic acid extraction) and of acetic acid from vinegar and ABM was determined by SNIF-NMR (FT-NMR AVANCE III 400, Bruker BioSpin GmbH, Karlsruhe, Germany). An NMR spectrometer fitted with a selective 10 mm "deuterium" probe tuned to a frequency Vo characteristic of channel Bo (e.g., Bo = 9.4 T, $\nu o$ = 61.4 MHz) with a decoupling channel (B2) and a field-frequency stabilization channel (lock) at the fluorine frequency. The second channel B2 was also used in the $^1H$ NMR experiment for acetic acid analysis. The resolution measured on the $^2H$-SNIF-NMR spectrum, transformed without exponential multiplication (i.e., LB = 0) and expressed by the width at the half-height of the methyl signal of acetic acid and the methyl signal of TMU (see below for definition) was less than 0.5 Hz. Sensitivity (signal-to-noise ratio) measured when the FID was exponentially weighted by a factor equal to 2 Hz line B broadening (LB), was greater than or equal to 150 for the methyl signal of acetic acid containing less than 25% of water.

Site-specific D/H values were measured in the methyl and methylene sites of ethanol ($(D/H)_I$ or $(D/H)_{CH3}$ and $(D/H)_{II}$) and in the methyl site of acetic acid ($(D/H)_{CH3}$) and expressed in parts per million (ppm). The method described in OIV MA-AS-311-05 was used for wine and must, while for vinegar, we followed the method described in EN 16466-1 with certain modifications that took into account the fact that impurities can be extracted at the organic phase together with acetic acid (see the Results and Discussion section).

3.25 gr of the extract containing acetic acid after filtration was placed in a 10 mm NMR tube together with 1.1 g of the internal standard tetramethylurea (TMU, certified reference material, STA-003m, EC-JRC, Geel, Belgium), as described in EN 16466-1, and a sufficient quantity of lock substance (for example: 50 $\mu$L of hexafluorobenzene or 150 $\mu$L of a homogenized mixture of hexafluorobenzene ($C_6F_6$)/trifluoroacetic acid (TFA) 90/10 v/v). This sample was then measured in the NMR tube by $^1$H NMR and $^2$H-SNIF-NMR by means of a composite NMR experiment.[3,4]

Typical conditions for obtaining $^2$H-SNIF-NMR spectra are as follows: constant probe temperature (e.g., 303 K); rotation of the sample (e.g., 15−20 Hz); acquisition time of at least 5.5 s for 1200 Hz spectral width (i.e., about 20 × $10^{-6}$ at 46.1 MHz); 90° pulse; quadrature detection, fix the offset O1 between the OD and $CH_2D$ reference signals for acetic acid; and determination of the value of the decoupling offset O2 from the $^1$H NMR spectrum measured by the decoupling coil on the same tube. Good decoupling is obtained when O2 is located in the middle of the frequency interval lying between the $CH_3$ and TMU groups. Use of broad band decoupling sequence WALTZ-16.

Typical conditions for obtaining $^1$H NMR spectra are as follows: constant probe temperature (e.g., 303 K); rotation of the sample (e.g., 15−20 Hz); acquisition time of at least 4.1 s for 8000 Hz spectral width (i.e., about 20 × 10−6 at 400 MHz); 30° pulse or less; D1 = 7s at least; parabolic detection, fix the offset O1 between the OH and $CH_3$ reference signals for acetic acid; and no decoupling.

For each spectrum, a number of accumulations sufficient to obtain the signal-to-noise ratio given above were carried out.

Appropriate software based on a complex least-squares curve fitting algorithm should be used to determine the signal area (first-order phasing and baseline correction are sensitive parameters for the proper evaluation of signal areas and have to be correctly adjusted). When larger errors in phasing and baseline distortions can safely be excluded (e.g., by applying suitable spectrometer routines for phasing and baseline correction) software based on the real part of the complex NMR data can be used instead.

For each $^1$H NMR spectrum, we calculated the ratio $S_{TMU}/S_{acetic\ acid}$, where $S$ is the $^1$H NMR signal area, integrated by data processing software after Fourier transform of the free induction decay, with an appropriate line-broadening factor of 0.5 Hz.

For each $^2$H-SNIF-NMR spectrum, we calculated the ratio $S'_{acetic\ acid}/S'_{TMU}$, where $S'$ is the $^2$H NMR signal area, integrated by data processing software after Fourier transform of the free induction decay, with a line-broadening factor of 2 Hz.

The ratio $(D/H)_{CH3}$ is calculated as follows:

$$(D/H)_{CH3} = S'_{acetic\ acid}/S'_{TMU} \times S_{TMU}/S_{acetic\ acid} \times (D/H)_{TMU}$$

where $(D/H)_{TMU}$ is the certified deuterium content in parts per million of the TMU provided by the supplier of the reference product.

Appropriate software enabled these three successive calculations to be made.

The standard deviation of repeatability (sr) of $(D/H)_{CH3}$ quoted in the methods (OIV AS311-05, EN 16466-1) is 0.3 for wine and must and 0.6 ppm for vinegar, whereas the standard deviation of reproducibility (sR) is 0.4 for wine and must and 0.6 ppm for vinegar.

**IRMS Analysis.** The $^{13}C/^{12}C$ of ethanol and acetic acid was measured using IRMS (SIRA II-VG ISOGAS, FISIONS, Rodano, Milano, Italy, or DELTA V, Thermo Scientific, Germany) interfaced with an elemental analyzer (Flash 1112, Carlo Erba, Milano, Italy, or EA Flash 1112, Thermo Scientific), according to the procedures described in OIV-MA-AS312-06, OIV 510/2013 and EN 16466-2.

To evaluate the impact of the impurities present in the extraction solution of acetic acid, we measured the $^{13}C/^{12}C$ in pure acetic acid using gas chromatography combustion (GC-C; Trace GC Ultra, Thermo Scientific) interfaced with an IRMS (DELTA V, Thermo Scientific) through an open split interface. A ZB-FFAP capillary column (30 m × 0.25 mm i.d. × 0.25 $\mu$m film thickness; Phenomenex) with He as carrier gas (at a flow rate of 2.7 mL/min) was used. A volume of 1.5 $\mu$L of a solution of acetic acid/diethyl ether (1:5) was injected in split mode by an autosampler (Triplus, Thermo Scientific). The injector temperature was set at 250 °C, and the oven temperature of the GC set at an initial 50 °C where it was held for 2.5 min before heating at 70 °C/min to 150 °C and held for 20 min. The eluted compound was combusted into $CO_2$ and $H_2O$ in a combustion furnace reactor at 1000 °C and composed of a ceramic tube (320 mm in length) containing an NiO tube in combination with NiO and CuO wires (0.125 mm diameter, 240 mm identical length) braided and centered end-to-end within the tube. Water vapor was removed with a water-removing trap consisting of a Nafion membrane.

The $^{18}O/^{16}O$ analyses of wine, must, vinegar, and ABM were performed using an isotope ratio mass spectrometer (SIRA II, VG Fisons, Middlewich, UK, or Isoprime, Cheadle, UK) connected to a water/$CO_2$ equilibration system (Isoprep 18, VG Fisons or Isoprime Multiflow) according to the procedures described in the OIV-MA-AS2-12, OIV 511/2013, and EN 16466-3 methods for wine, must, and vinegar.

The $^{13}C/^{12}C$ and $^{18}O/^{16}O$ values are expressed on the $\delta$ ‰ scale against international standards V-PDB (Vienna-Pee Dee Belemnite, IAEA, Vienna) and V-SMOW (Vienna-Standard Mean Ocean Water) normalized to the VSMOW−SLAP (Standard Light Antarctic Precipitation) scale, respectively, according to the equation: $\delta‰ = ((R_{sample} - R_{standard})/(R_{standard}))\cdot 1000$ where $R$ is the ratio of the heavy to light stable isotope in the sample ($R_{sample}$) and the international reference material ($R_{standard}$).

The sr of $\delta^{18}O$ quoted in the OIV and EN methods is 0.1 ‰ for wine, must, and vinegar, while the sr of $\delta^{13}C$ is 0.1 ‰ for wine and must and 0.2 ‰ for vinegar. The sR of $\delta^{18}O$ is 0.2 ‰ for wine, must, and vinegar, while the sR of $\delta^{13}C$ is 0.2 ‰ for wine and must and 0.3 ‰ for vinegar.

**GC-MS/MS Analysis.** The solutions after vinegar and ABM vinegar extraction were filtrated with a 0.22 $\mu$m filter and then diluted 5 times with 80% acetic acid (LC/MS grade), and for analysis of acetic acid, 2000 times with water (Milli-Q).

GC analysis was performed using a Trace GC Ultra gas chromatograph coupled with a TSQ Quantum tandem mass spectrometer upgraded to the XLS configuration. A DuraBrite IRIS ion source with prefilter was installed to improve performance of the spectrometer. The system was fitted with a Triplus autosampler (Thermo Electron Corporation, Waltham, MA, USA). The injection volume was 1 $\mu$L, postinjection dwell time was 4 s, and tray temperature was 5 °C. GC separation was performed on a 30 m VF-WAXms capillary column with an internal diameter of 0.25 mm and a film thickness of 0.25 $\mu$m (Varian, Inc., Palo Alto, CA, USA). The temperature program was as follows: 40 °C hold for 2 min after injection, 10 °C/min up to 50 °C, 1.4 °C/min up to 60 °C, hold for 2 min, 1.6 °C/min up to 70 °C, hold for 1 min, 2.2 °C/min up to 100 °C, hold for 0.5 min, 3.1 °C/min up to 140 °C, 4.4 °C/min up to 200 °C, 12 °C/min up to 250 °C, hold for 6 min. Injection parameters were as follows: split injection, split ratio 150 (split flow 120 mL/min), inlet temperature 250 °C, carrier gas was helium 5.5, programmed flow: 0.8 mL/min hold for 62.50 min, 0.8 mL/min up to 1.2 mL/min in 0.5 min, hold for 7 min. The mass spectrometer was operated in electron impact (EI) ionization mode at 70 eV. The temperature of the transfer line was 220 °C. Mass spectrometer parameters were EI ionization mode at 70 eV. Full scan acquisition from $m/z$ 40 to $m/z$ 400 using the third quadripole with a scan time of 0.200 s. Source temperature was 250 °C, and filament emission current was 50 $\mu$A. The mass spectrometer was tuned and calibrated using FC-43 (perfluorotributylamine (PFTBA)). Data acquisition and analyses were performed using Xcalibur Workstation software supplied by the manufacturer. Quantification was performed using Trace finder EFS 3.0 software (Thermo Scientific).

**Statistical Analysis.** The data were analyzed using Statistica v.9 software (StatSoft Italia srl, Padua, Italy). A paired $t$-test was carried out on the data set to identify differences between samples within the production chains.

ANOVA, honestly significant difference (HSD) Tukey, Kruskall−Wallis, and U-Mann−Whitney tests were carried out on the data set to identify differences between the various groups.

## RESULTS AND DISCUSSION

**Impurities in the Extraction Solution from Wine Vinegar and ABM.** First of all, we checked for the presence of impurities in the solution extracted by diethyl ether along with acetic acid from wine vinegar and ABM and whether they affect the isotopic data of acetic acid. We analyzed 11 samples of ABM and 10 of wine vinegar and used GC-MS/MS for quantification (Table 2).

The percentage of impurities was found to be on average 6% in the extraction solution of ABM and 4% in that of wine vinegar. The main impurities (higher than 1%) are the extraction solvent, ethyl acetate, acetoin (= 3-hydroxybutanone) and butanoic acid. Comparison of the ABM and vinegar solutions showed 5-acetoxymethyl-2-furaldehyde (= 5-formylfurfuryl acetate), levulinic acid, and 5-(hydroxymethyl)furfural (= 5-hydroxymethyl-2-furaldehyde), mostly originating from the heating of the grape must and caramel, to be significantly higher in ABM ($p$ < 0.001, Tukey, Kruskall–Wallis and U-Mann–Whitney tests).

In the case of D/H analysis, the presence of impurities was overcome by carrying out a composite NMR experiment on acetic acid, as described in the Materials and Methods section. As for $\delta^{13}C$, we compared the values obtained for the extracted purified solution using EA-IRMS with those for pure acetic acid analyzed by GC/c-IRMS. We did not find any significant differences ($p$ < 0.001) in the 18 vinegar and 21 ABM samples, the mean difference being 0.06 ‰ and the maximum difference 0.3 ‰.

We can conclude that, even if impurities are extracted along with acetic acid from wine vinegar and ABM, the isotopic data of acetic acid are not affected when the methods here described are adopted.

**Validation of the Isotopic Methods for ABM.** There exist official validated isotopic methods for acetic acid and water in wine vinegar and for ethanol in grape must. To ascertain whether the same methods can also be used for analyzing the ingredients of AMB, we assessed the repeatability and reproducibility of SNIF-NMR and IRMS analyses of acetic acid, ethanol, and water in ABM and compared these values with those obtained in vinegar and must and with those reported in the corresponding official methods.

To assess repeatability, we analyzed the same vinegar and ABM samples 10 times. The repeatability values (sr < 0.4 ppm) for $(D/H)_{CH3}$ are comparable for vinegar and ABM and are lower than the repeatability mean value of the EN 16466-1 method (sr = 0.6 ppm). The sr for $\delta^{13}C$ and $\delta^{18}O$ for both vinegar and ABM (≤0.2 ‰) are consistent with those for

[a]Maximum difference between laboratories found in this study.

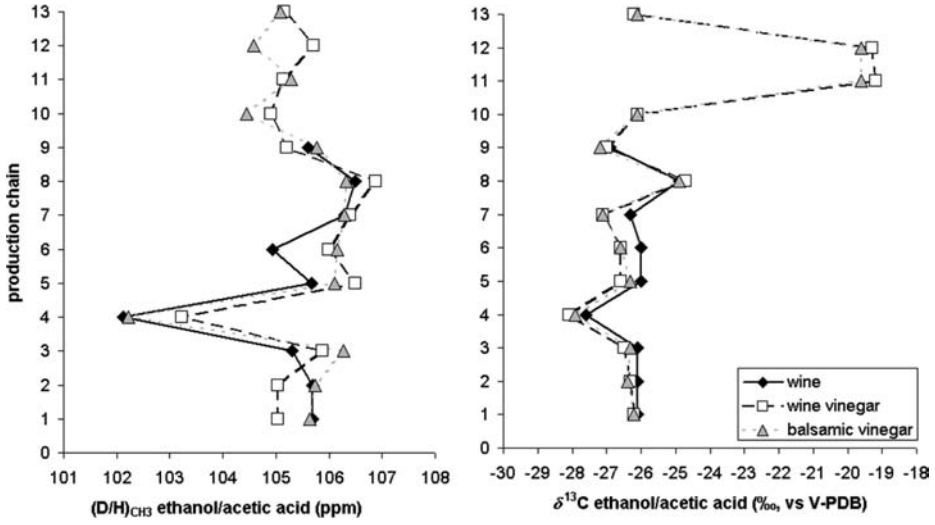

**Figure 1.** Variations in ethanol/acetic acid $(D/H)_I$ and $\delta^{13}C$ values between wine, wine vinegar, and ABM.

vinegar reported in the OIV and EN methods (≤0.2 ‰). The sr for $(D/H)_{CH3}$ (0.5 ppm) and $\delta^{13}C$ (0.2 ‰) of alcohol from must contained in the ABM (residue after acetic acid extraction) are also comparable to those of the OIV-MA-AS311-05 (average sr = 0.3 ppm) and OIV-MA-AS312-06 (average sr = 0.2 ‰) methods, although they were slightly higher for $(D/H)_{CH3}$.

To determine method reproducibility, 10 samples of vinegar (cane sugar acetic acid was added to some of the samples) and 5 of ABM were analyzed in 3 different laboratories, which used as solvent, diethyl ether or tert-butyl methyl ether and as lock substance, $C_6H_6$ or TFA. Table 3 reports a summary of the sr and sR values of the OIV and EN methods compared with those found in this study. Also shown is the repeatability limit (r), that is, the value less than or equal to which the absolute difference between two results obtained under repeatability conditions may be expected to be with a probability of 95% (calculated as 2.8 × sr)[5], and the reproducibility limit (R), that is, the value less than or equal to which the absolute difference between two results obtained under reproducibility conditions may be expected to be with a probability of 95% (2.8 × sR)[5]. The reproducibility values for $(D/H)_{CH3}$ for vinegar and ABM are comparable to each other and to the values of the EN 16466-1 method. The sR values of authentic and adulterated samples are not different. The same was found with $\delta^{13}C$ of acetic acid and $\delta^{18}O$ of water and with $(D/H)_{CH3}$ and $\delta^{13}C$ of ethanol from ABM must fermentation, which were measured only in two laboratories, the differences being always lower than the reproducibility limits for all the isotopic parameters (Table 3).

We conclude that the isotopic methods for analyzing $(D/H)_{CH3}$, $\delta^{13}C$, and $\delta^{18}O$ in grape must and vinegar can also be applied to the ingredients of ABM. The same validation data apply, except for the repeatability values of ethanol $(D/H)_{CH3}$, which are here slightly higher.

**Variations between $(D/H)_{CH3}$ and $\delta^{13}C$ Values in Wine and Must and Those in the Ingredients of ABM.** Figure 1 reports the $(D/H)_{CH3}$ and $\delta^{13}C$ values of ethanol obtained from wine (solid black diamonds connected by black lines), acetic acid extracted from vinegar (open squares connected by dashed lines), and balsamic vinegar (solid gray triangles connected by dotted lines) for the 13 chains, reported along the *y* axis. The mean difference for $(D/H)_{CH3}$ between wine and both vinegar and ABM was +0.3 ppm with a range of −0.7 to 1.1 ppm and therefore below the repeatability limits of the official methods reported in Table 3. The difference was not significant according to a paired *t*-test ($p < 0.001$), in line with previous findings.[6] The wine samples had different $(D/H)_I$ values, ranging from 102.1 to 106.3 ppm, and covered a large part of the typical variability of a grape product.[2]

The $\delta^{13}C$ of ethanol obtained from wine also appears not to differ from that of acetic acid after extraction from both vinegar and ABM (Figure 1), in line with previous findings.[6] The mean differences between wine and vinegar and wine and ABM are 0.4 ‰ and 0.3 ‰, respectively, with a range of −0.8 to 0.2 ‰, averagely lower than the official repeatability limits shown in Table 3. Moreover, the differences were not significant according to a paired *t*-test ($p < 0.001$). The $\delta^{13}C$ values of chains 11 and 12 for both products are very high (on average

dx.doi.org/10.1021/jf5013538 | J. Agric. Food Chem. 2014, 62, 8197−8203

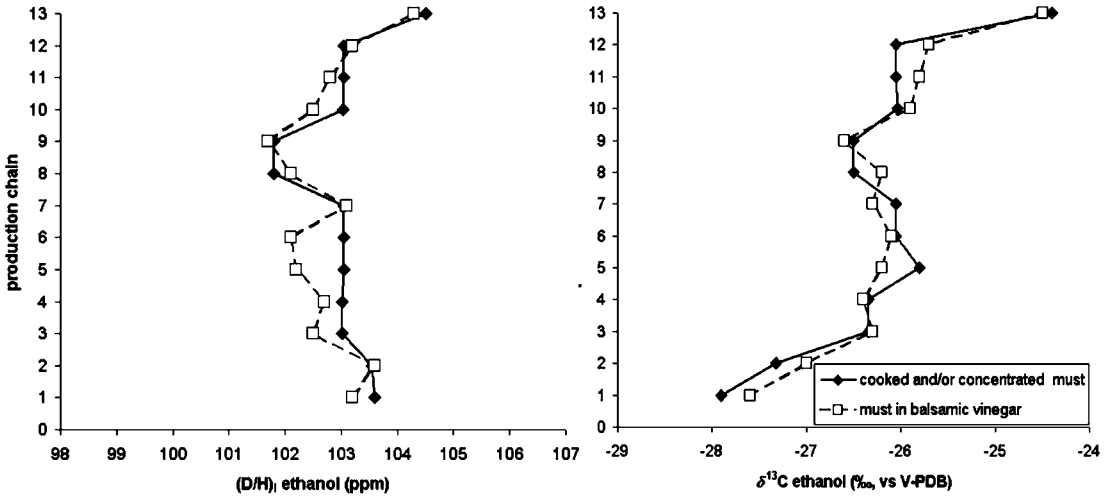

**Figure 2.** Variations in ethanol $(D/H)_I$ and $\delta^{13}C$ between the mixtures of concentrated and cooked must (calculated values) and the corresponding mixture in the ABM.

| ABM (45°Brix) | 1.206 38 | 6.31 | 105.3 | −26.1 | | |
| ABM (57°Brix) | 1.278 19 | 5.71 | 105.6 | −26.1 | | |

−19.5 ‰) due to the addition of cane sugar acetic acid to the vinegar.

ABM is made with a mix of concentrated and cooked grape must. In this work, we produced ABM with different percentages of these two ingredients (Table 1). We analyzed the raw must and calculated the values of ethanol $(D/H)_I$ and $\delta^{13}C$ for each mix containing different quantities of concentrated and cooked must (see Table 1). Figure 2 shows a comparison between these values and the values for the ethanol obtained from fermentation of the residual solution of the corresponding ABM after acetic acid extraction. The mean differences were 0.3 ppm for $(D/H)_I$ and 0.1 ‰ for $\delta^{13}C$, ranging from −0.3 to 1 ppm and from −0.4 to +0.4 ‰, respectively. In both cases, the mean values are below the official limits of repeatability (Table 3).

Effects of technological processing stages, such as addition of caramel, tangential filtration, and concentration, were found to be nonsignificant for isotopic ratios of both acetic acid and must ethanol (Table 4): indeed, the maximum difference between values from the same experiment was always below the corresponding repeatability limit (Table 3). As for caramel, we have found by experiment that it does not ferment in the conditions adopted here, which is why its presence does not affect the isotopic values of ethanol. Anyway its low presence (maximum addition allowed 2%) should not influence the data.

The absence of any effect of concentration is not consistent with what is found in the literature,[8] where it has been shown that concentration under vacuum evaporation, as in this case, can change significantly the $\delta^{18}O$ of must water, the $(D/H)_{II}$ of must ethanol and also, but to a lesser extent, $(D/H)_I$.

We conclude that there are no changes in isotopic values $(D/H)_I$ and $\delta^{13}C$ from wine to vinegar and to ABM and from the original must to ABM must, independently of concentration, filtration, and addition of caramel. This supports the suggestion that the methods recognized for vinegar and must using a composite NMR experiment for D/H can also be adopted for analysis of the ingredients in ABM. Moreover, it provides experimental evidence that the reference data of wine databanks can also be used to evaluate the authenticity of vinegar and ABM.

**Detection of Adulteration of Vinegar and ABM.** Previous studies have shown that C and H stable isotope ratios have a marked capacity to identify synthetic vinegars and distinguish C3 and C4 derived products, allowing the adulteration of vinegars with raw fermentation materials cheaper than those declared on the label to be detected.[9−11] Here, we investigated the ability of isotopic analysis to detect the fraudulent addition of increasing percentages of cane sugar ethanol to wine from which vinegar is derived and of synthetic vinegar to ABM. The general reference of wine, as reported by

dx.doi.org/10.1021/jf5013538 | J. Agric. Food Chem. 2014, 62, 8197−8203

Dordevic et al. (98.8 to 106 ppm for $(D/H)_{CH3}$ and −29.3 ‰ to −24.3 ‰),[2] can be adopted for products such as vinegar and ABM, where origin and year of production are generally not known.

Table 5 shows that the addition of more than 20% of cane sugar ethanol to the source wine can be detected because the

**Table 5. Isotopic Values of Nonauthentic Vinegar and ABM**

| | % grape | % cane | $(D/H)_{CH3}$ | $\delta^{13}C/‰$ |
|---|---|---|---|---|
| vinegar 1 | 90% | 10% | 106.7 | −25.3 |
| vinegar 2 | 86% | 14% | 107.3 | −24.1 |

| vinegar 4 | 67% | 33% | 108.5 | −22.6 |
| vinegar 5 | 60% | 40% | 109.3 | −21.5 |
| vinegar 6 | 58% | 42% | 109.1 | −21.2 |
| ABM from vinegar 1 | 90% | 10% | 106.9 | −25.1 |
| ABM from vinegar 6 | 58% | 42% | 108.3 | −21.3 |
| | % grape | % synthetic | $(D/H)_{CH3}$ | $\delta^{13}C/‰$ |
| ABM 1 | 60% | 40% | 112.4 | −27.8 |
| ABM 2 | 80% | 20% | 110.7 | −27.3 |

isotopic parameters fall outside of the limits, taking into account the measurement uncertainty. In addition, the presence of 20% of synthetic acetic acid (and potentially less, since the synthetic sources cover a very wide range)[7] can be detected. In all cases, the actual detection limit depends on the isotopic values of the starting materials (wine vinegar and added substitutes).[2,12] Moreover, detection of adulteration is more efficient if the exact origin of the grapes is known, because the limits are more narrow.

**ABSTRACT:** Previously developed radical-scavenging pea protein hydrolysates (PPHs) prepared with Flavourzyme (Fla-PPH) and Protamex (Pro-PPH) were used as cosurfactants with Tween 20 to produce soybean oil-in-water (O/W) emulsions, and the suppression of lipid oxidation was investigated. Both PPHs significantly retarded oxidation ($P < 0.05$) of the emulsions when stored at 37 °C for 14 days. Electron microscopy revealed an interfacial peptidyl membrane around oil droplets, which afforded steric restrictions to oxidation initiators. When licorice extract (LE) was also used in emulsion preparation, a remarkable synergistic oxidation inhibition was observed with both PPHs. LE adsorbed onto oil droplets either directly or through associating with PPH to produce a thick and compact interfacial membrane enabling the defense against oxygen species. Liquiritin apioside, neolicuroside, glabrene, and 18$\beta$-glycyrrhetic acid were the predominant phenolic derivatives partitioning at the interface and most likely the major contributors to the notable synergistic antioxidant activity when coupled with PPHs.

**KEYWORDS:** *antioxidant, pea protein hydrolysate, licorice extract, emulsion, oxidative stability, synergism*

## INTRODUCTION

A wide array of natural and processed foods exist as emulsions, such as milk, cream, mayonnaise, and salad dressings. Due to the large contact surface between oxidizable fatty acids and water-soluble oxidants (oxygen and transition metal ions), emulsified oil is much more susceptible to oxidation than bulk oil.[1] Peptides and protein hydrolysates as potential alternatives to traditional antioxidants have been widely reported to be inhibitory of lipid oxidation in biphasic (O/W) systems through scavenging free radicals, sequestrating pro-oxidative metal ions, or forming physical (shielding) barrier around oil droplets.[2−4] Unlike small-molecule antioxidants, protein hydrolysates may also act as stabilizing agents to improve the physical stability of emulsion systems.[5,6]

Phenolic compounds extracted from plants and spices are also recognized for their strong antioxidant activity in food systems due to radical-scavenging activity and chelation of transition metal ions.[7,8] Many polyphenols and their plant extracts are effective against both lipid peroxidation and protein oxidative changes in model systems and in complex food matrices, such as processed meats.[9,10]

The effectiveness of an antioxidant in retarding lipid oxidation in food emulsions depends not only on its chemical reactivity with oxidation initiators and propagators but also on its location, which is dictated by its polarity and affinity for other constituents.[11,12] Due to the size reduction and increased charges, peptides are distributed preferentially in the aqueous phase and can partition at the oil−water interface, thereby preventing the initiation of lipid oxidation induced by water-soluble oxidants. On the other hand, as polyhydroxyl phenol derivatives with both polar and nonpolar moieties, phenolic compounds have the propensity to concentrate at the oil−water interface and are dispersible in the lipid phase (where hydroperoxides and peroxide radicals are generated) to curtail the propagation of lipid radical chain reactions.

Because of their complementary processes in inhibiting lipid oxidation, peptides (protein) and phenolic compounds when used in combination have been found to function synergistically in several biphasic systems, such as O/W emulsions[7,13,14] and a liposome suspension.[15] However, it should be noted that similar to Tween, Span, and monoglycerides, phenolic molecules as surface active compounds might influence the adsorption of peptides at the interface either indirectly by competing for the oil droplets or directly by binding to peptides through hydrophobic interaction and hydrogen bonds.[16] Therefore, the existence of phenolics in a peptide-stabilized emulsion can affect the overall oxidative stability, and possibly also the physical stability, of the emulsion system. Indeed, there have been reports that peptides could suppress the antioxidative action of phenolic compounds.[17,18]

In our previous study, we have reported that radical-scavenging pea protein hydrolysates (PPHs) prepared with Flavourzyme (Fla-PPH) and Protamex (Pro-PPH) exhibit remarkable synergistic antioxidative effect with licorice extract (LE) (an ethanol extract from the herb *Glycyrrhiza glabra*) in a liposomal model system.[15] However, it is not known whether there exists a similar cooperative inhibitory effect of PPH with LE on lipid oxidation in an O/W emulsion and, if so, how they would partition and interact at the oil−water interface. Therefore, the present study was conducted to investigate the influence of LE on the antioxidant activity of Fla-PPH and Pro-

PPH in a soybean O/W emulsion. To elucidate the reaction mechanism, the adsorption of PPH and LE at the emulsion interface and the interfacial properties were examined.

## MATERIALS AND METHODS

**Materials.** Pea protein isolate (PPI) was extracted from pulverized yellow peas (*Pisum sativum* L.) using the isoelectric precipitation method that involved initial extraction at pH 8.0 followed by precipitation at pH 4.5.[19] After neutralization (pH 7.0), the PPI suspension was lyophilized to yield a dry powder with 92% protein. Flavourzyme and Protamex were donated by Novozymes North America Inc. (Franklinton, NC, USA). Soybean oil was purchased from a local supermarket (Lexington, KY, USA). Licresse, a licorice (*G. glabra*) root ethanol extract (LE) powder with a 23% total phenolic content and <1% glycyrrhizic acid, was obtained from ICL Performance Products LP (St. Louis, MO, USA). All other chemicals were purchased from Fisher Scientific (Fair Lawn, NJ, USA). Nanopure deionized water was used for the preparation of all solutions.

**PPH Preparation.** Antioxidative pea protein hydrolysates Fla-PPH and Pro-PPH were prepared with Flavourzyme and Protamex, respectively, as described previously.[15] Briefly, a preheated (90 °C, 5 min) 2% (w/v) protein solution of PPI was hydrolyzed for 0.5 h with Flavourzyme and Protamex at 50 °C. The enzyme−protein ratio was 1/100, and the hydrolysis pH was 6.0. After inactivating proteases (80 °C, 15 min), solutions were neutralized to pH 7.0, followed by centrifugation at 9000*g* for 10 min to remove insoluble particles. Samples were freeze-dried and stored at 4 °C before use. This hydrolysis condition was found to produce antioxidative Fla-PPH and Pro-PPH that, when combined with LE, also acted concertedly to inhibit lipid oxidation in a liposome suspension.[15] Therefore, it was used in the present study to produce the protein hydrolysates for the testing of synergism with LE in O/W emulsions.

**Emulsion Preparation.** The O/W emulsions were prepared by homogenizing 10% (w/w) soybean oil and 90% (w/w) aqueous phase (10 mM phosphate buffer, pH 7.0) containing different emulsifiers. For emulsifying capacity tests, different concentrations of PPHs (2.5, 5, 10, or 20 mg/mL, final concentrations) were added to the aqueous phase before blending with soybean oil using an Ultra-Turrax homogenizer (Ika T18 Basic, Staufen, Germany) at 13500 rpm for 2 min, followed by passage through a two-stage high-pressure homogenizer (ATS Engineering Inc., Shanghai, China) at a pressure of 30 MPa for two cycles. To investigate the influence of LE on the antioxidant activity of PPHs in emulsion systems, the same ingredient composition and homogenization conditions as mentioned above were used except that 10 mg/mL Tween 20 and different levels of LE (0, 50, 100, and 200 $\mu$g/mL, final concentrations) were added prior to blending. These concentration levels of LE were chosen on the basis of our previous study in which the antiradical activity of LE against $^{\bullet}$OH was found to increase rapidly until about 200 $\mu$g/mL.[20] For comparison, a control emulsion consisting of 10 mg/mL Tween 20 was prepared using the same emulsifying conditions as given above. To prevent microbial growth, 3 mM sodium azide was added to all emulsions.

**Emulsifying Capacity of PPH.** Freshly prepared emulsions were immediately transferred into 25 mL beakers and allowed to stand at room temperature for 1 min (for emulsifying activity testing) and 12 h (for emulsion stability testing). Emulsifying activity index (EAI) and emulsion stability index (ESI) were measured according to the turbidometric method of Pearce and Kinsella.[21] The emulsions were also placed in tightly sealed screw-cap test tubes and set at room temperature for 5 days to monitor their physical stability during storage.

**Emulsion Oxidative Stability.** To evaluate oxidative stability, emulsions were placed in tightly sealed screw-cap test tubes and incubated at 37 °C in the dark for up to 14 days to allow lipid autoxidation. Peroxide values (POVs) and 2-thiobarbituric acid-reactive substances (TBARS) were used to assess the degree of lipid oxidation. POVs were determined according to the AOCS[22] standard procedure using sodium thiosulfate ($Na_2S_2O_3$) titration. TBARS were tested according to the method of Mei et al.[23] and calculated from the standard curve prepared by 1,1,3,3-tetraethoxypropane. Synergism of PPHs and LE in inhibiting peroxides or TBARS formation was expressed and calculated as

$$\text{synergism (\%)} = \frac{(C - M) - [(C - H) + (C - L)]}{C - M} \times 100$$

where *C*, *H*, *L*, and *M* represent the formation of peroxides or TBARS in emulsions containing no antioxidant (control), PPH, LE, and mixed PPH and LE, respectively.

**Partition Coefficient of PPH in the O/W Emulsions.** Partitioning of Fla-PPH and Pro-PPH in the aqueous phase and at the oil−water interface of the emulsions was estimated according to the method of Huang et al.[11] as detailed by Cheng et al.[4] Protein concentrations in the aqueous phases were determined using the Bradford method.[24] The partition coefficient (PC) for PPH in the aqueous phase was calculated as

$$\text{PC} = \frac{V_w}{V_l} \times \left(\frac{W_t}{W_w} - 1\right)$$

where $V_w$ is the volume of the aqueous phase, $V_l$ is the volume of the oil phase, $W_t$ is the total amount of protein, and $W_w$ is the amount of protein in the aqueous phase. The density (g/mL) of oil used for calculating its volume was 0.922. Percentage of PPH in the aqueous phase was calculated as $(W_w/W_t) \times 100$, and that at the interface was calculated by subtraction.

**Characteristics of Emulsion Droplets.** Transmission electron microscopy (TEM) was used to visualize the microstructure of emulsion droplets, which were of different interfacial compositions. Emulsion samples were diluted (1:10, v/v) with 10 mM phosphate buffer (pH 7.0). One drop of the dilute samples and one drop of staining solution (2% phosphotungstic acid, v/v) were applied onto a copper grid with 200 meshes and allowed to stabilize for 10 min to dry out. Images of emulsion droplets were captured using an ES500W Erlangshen CCD camera (Gatan, Inc., Pleasanton, CA, USA) mounted to a JEM-2100 electron microscope (JEOL, Tokyo, Japan).

Zeta-potential and size distribution of emulsion droplets were also determined. The emulsions were diluted to an oil droplet concentration of approximately 0.05% (w/w) using 10 mM phosphate buffer (pH 7.0) and stirred continuously to ensure the samples were homogeneous. The zeta-potential of diluted oil droplets was examined using a particle electrophoresis instrument (Nanosizer, Malvern Instruments, Worcestershire, UK) and reported as the average and standard deviation of measurements. Droplet size distribution of the emulsions was measured using a dynamic light scattering instrument (Nanosizer, Malvern Instruments). The measured droplet sizes were expressed as the *Z*-average diameter and standard deviation of measurements.

**Separation and Characterization of Peptides at the Oil−Water Interface and in the Aqueous Phase.** The emulsions prepared with both PPH and LE were centrifuged at 15000*g* for 30 min to create a cream layer and a serum layer.[4] The cream layer was washed with 10 mM phosphate buffer (pH 7.0), followed by centrifugation at the same condition. After washing for a total of three times, the resultant cream was mixed with chloroform/methanol (2:1, v/v) to eliminate the interference of lipid. The mixture was centrifuged at 10000*g* for 10 min, and the upper methanol phase, which contained interface-located peptides, was subjected to a rotary evaporator to remove the solvent. The recovered cream phase peptide samples were stored at 4 °C before analysis. To recover peptides from the aqueous phase, the serum layer was centrifuged at 15000*g* for 30 min, then filtered through a 0.22 $\mu$m filter membrane, and stored at 4 °C before use. To collect a sufficient amount of peptide samples, a total of 50 mL of emulsions was used. Sodium dodecyl sulfate−polyacrylamide gel electrophoresis (SDS-PAGE) was conducted as described by Liu et al.[25] under nonreducing conditions to characterize the peptide samples.

**Isolation and Identification of LE Compounds at the Oil–Water Interface and in the Aqueous Phase.** The upper methanol phase obtained from the above interfacial peptide recovery step contained both peptides and LE compounds. The peptides were removed by precipitation with 4 volumes of cold acetone added to the methanol extract, and the mixture was stored at −20 °C overnight. After centrifugation at 10000*g* for 10 min at 4 °C, the supernatant (containing LE compounds only) was saved, and the precipitate was washed two times with cold acetone to recover additional LE compounds. The supernatants were combined and then concentrated by rotary evaporation. The recovered cream phase LE compounds were redissolved in methanol and stored at 4 °C before analysis.

To recover LE compounds remaining in the aqueous phase, 4 volumes of cold acetone was added to a portion of the final serum layer collected from the above peptide preparation step. The mixture was kept at −20 °C overnight and then centrifuged at 10000*g* for 10 min at 4 °C. The supernatant was saved, and the precipitate was washed two times with cold acetone. The supernatants were combined, and the solvents were removed by a rotary evaporator. The recovered LE compounds were redissolved in methanol and stored at 4 °C before use. Compound identification was carried out using LC-MS as described previously.[15]

**Statistical Analysis.** All experiments were repeated three times each with a freshly prepared emulsion. Data were expressed as mean ± standard deviation and processed using the general linear model procedure of the Statistix software 9.0 (Analytical Software, Tallahassee, FL, USA). Significant differences ($P < 0.05$) between means were identified by the least significance difference (LSD) procedure.

## RESULTS AND DISCUSSION

**Emulsion Properties.** The emulsifying activity (EAI) of the protein hydrolysates increased in a concentration-dependent manner (Figure 1), suggesting that within the tested protein concentration range (2.5–20 mg/mL), the surface coverage of oil droplets by peptides and the resulting interfacial tension reduction were more effective at high protein concentration levels. Indeed, preliminary interfacial tension measurement revealed a slight drop of the value from 12.3 to 10.1 mN/m ($P < 0.05$) with increasing hydrolysate concentration from 2.5 to 10 mg/mL. The emulsion stability was improved with increasing protein concentrations due to greater interfacial coating and possibly increased viscosity; yet, none of the emulsions was considered stable because the ESI values were well below 100% (Figure 1, inset), reflecting an overall weak surface tension reduction capability of the PPH. This was particularly true for the emulsions prepared with Fla-PPH. After 5 days of storage at room temperature, all Fla-PPH emulsions were separated into two phases, whereas creaming was less obvious for emulsions prepared with ≥5 mg/mL Pro-PPH (data not shown).

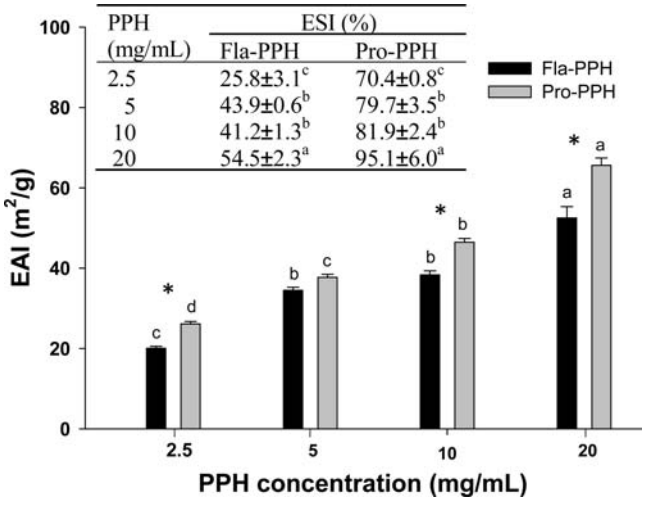

**Figure 1.** Emulsifying capacity of Fla-PPH and Pro-PPH (2.5, 5, 10, and 20 mg/mL) in soybean O/W emulsions. The inset table shows the emulsion stability. Means ± standard deviations ($n = 3$) for the same emulsion type without a common letter differ significantly ($P < 0.05$). (*) Significant difference ($P < 0.05$) between emulsion types at the same protein concentration.

Because PPH alone could not produce a satisfactorily stable O/W emulsion, the subsequent evaluation of antioxidant efficacy of PPH was carried out with emulsions costabilized by Tween 20 (10 mg/mL) and PPH. The strong surface activity of Tween 20 provided a reasonable justification for its use in the PPH emulsion system. For example, under the present experimental conditions, 10 mg/mL Tween 20 had an interfacial tension of 2.7 mN/m, and the Tween 20–5 mg/mL PPH blend had an interfacial tension of 4.7 mN/m, a substantial reduction ($P < 0.05$) from the PPH alone (11.5 mN/m). The Tween 20–PPH costabilized emulsions were remarkably stable and remained homogeneous even after 14 days when stored at room temperature or at 37 °C (data not shown).

**Oxidative Stability.** The efficacy of PPH in inhibiting lipid autoxidation in the Tween 20-aided O/W emulsions was evaluated by means of POV and TBARS analyses. Results showed a remarkable suppression of both primary (peroxides) and secondary (TBARS) product formation upon storage at 37 °C, namely, reductions up to 56 and 62% from the control ($P < 0.05$), respectively, by day 14 (Figure 2). However, the degree of POV or TBARS inhibition was independent of protein concentration, and the percentage of TBARS reduction was more pronounced with increasing storage time. Hence, both PPHs were effective antioxidants even at low concentrations, and peptides present in the continuous phase appeared to play a dominant role in deterring reactive oxygen species.

The oxidation inhibitory effect can be attributed to strong radical-scavenging activity of pea peptides and their affinity for oxidized lipids. As reported previously, peptides present in PPHs that are rich in leucine, lysine, glutamic acid, glutamine, valine, and proline are mostly responsible for the antioxidative protection of liposomes.[15] Ten peptides had been identified by mass spectrometry, of which, LQEEDNVISQ (Leu-Gln-Glu-Glu-Asp-Asn-Val-Ile-Ser-Gln), ITPERTLQLQDLDIFVN (Ile-Thr-Pro-Glu-Arg-Thr-Leu-Gln-Leu-Gln-Asp-Leu-Asp-Ile-Phe-Val-Asn), and LANRDDNEDLVGVL (Leu-Ala-Asn-Arg-Asp-Asp-Asn-Glu-Asp-Leu-Val-Gly-Val-Leu) matched the sequence of pea vicilin. On the other hand, steric hindrances of adsorbed interfacial proteins at low concentrations (e.g., 50 mg/m$^2$ of interfacial protein coverage) can reinforce the oxidative protection of O/W emulsions.[26] Because the greatest oxidation inhibition was already achieved at 5 mg/mL PPH, this dosage was chosen for the subsequent investigation of cooperative effects of PPH and LE for the inhibition of lipid oxidation in O/W emulsions during storage.

The results presented in Figure 3 display stronger suppressions of oxidation with the inclusion of LE than with PPHs alone. As widely reported, LE is capable of stabilizing oxidants due to the presence of radical-scavenging phenolic compounds in the herb extract.[15,27] When PPH and LE were applied together, a remarkable synergistic effect was observed,

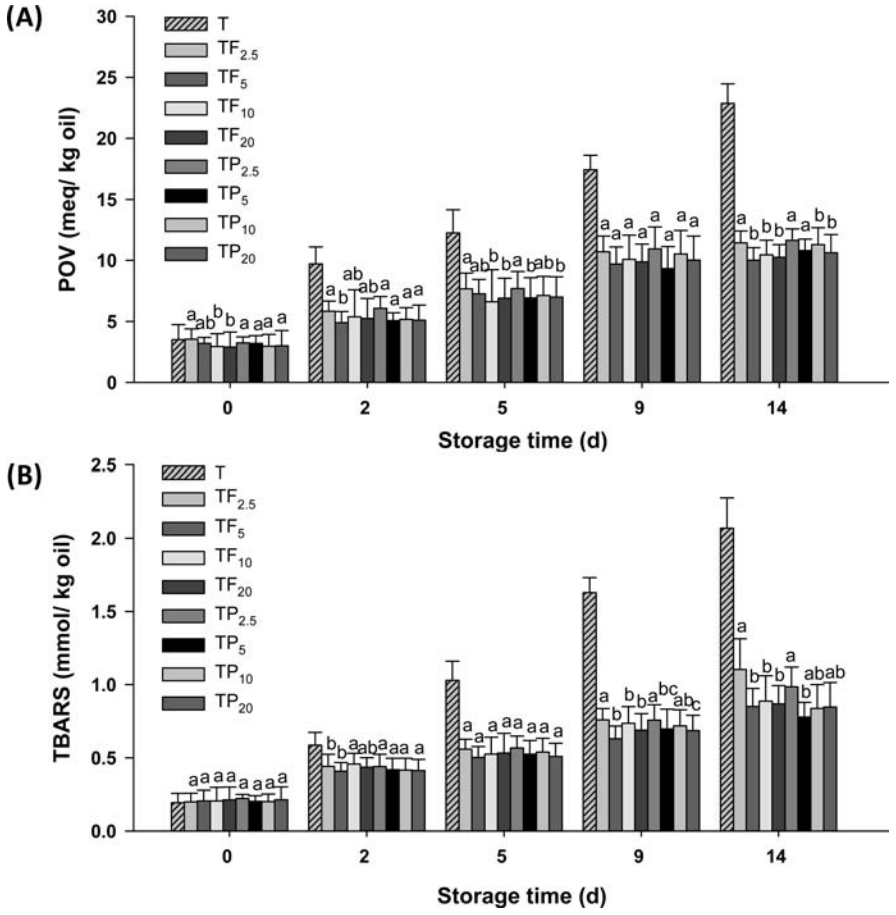

**Figure 2.** Formation of peroxides (A) and TBARS (B) during storage (37 °C) of soybean O/W emulsions prepared with Tween 20 + Fla-PPH (or + Pro-PPH) at various concentrations. T, $TF_x$ (or $TP_x$): emulsions prepared with Tween 20 and with Tween 20 + Fla-PPH (or + Pro-PPH) at the indicated concentrations (mg/mL). Tween 20: 10 mg/mL. Means ± standard deviations ($n$ = 3) for the same emulsion parameter with different letters differ significantly ($P$ < 0.05).

most notably for the inhibition of TBARS. The finding was consistent with our previous result that, when used in combination with LE, PPH provided superior protection of phospholipid-based liposome against radical-initiated oxidation over their separate uses.[15]

From day 9 to day 14, there was a slight reduction in the synergy (Table 1), which could be caused by the consumption of antioxidants or the gradual desorption of antioxidants from the interface during storage.[28] The synergy declined with increasing LE from 100 to 200 μg/mL. This may be explained by the accumulation of LE at the interface that can induce bridging association through phenolic compounds adsorbed onto neighboring oil droplets,[7] thereby promoting droplet aggregation and lipid radical chain propagation. The most remarkable synergy was displayed by Pro-PPH when used together with 100 μg/mL LE, up to 30.9 and 40.8%, for POV and TBARS, respectively. It should be noted that the extent of synergistic inhibition by PPH and LE on lipid oxidation in O/W emulsions was less than that in liposomal model systems.[15] A similar finding has been reported by Medina et al.[29] This result could be due to the differences in lipid chemical structure and interfacial chemical composition, which apparently favored phenolic antioxidant association with phospholipids (liposomes) over that with triacylglycerols (O/W emulsions).

**Distribution of PPH and LE in O/W Emulsions.** The specific location of antioxidants in an O/W emulsion is believed to affect the rate of lipid oxidation.[11] As indicated in Table 2, the bulk of PPH was present in the aqueous phase, and <15% was distributed at the interface. The percentage of interfacial PPH tended to decrease with the addition of LE, although such numerical differences were nonsignificant. It seems reasonable to suggest that LE and PPH adsorbed onto oil droplets in a competitive manner; driven by the concentration gradient, previously adsorbed peptides might be partially displaced by high-concentration LE. Alternatively, LE could bind to PPH through noncovalent interaction to participate in the interfacial layer indirectly. This latter contribution is in line with the finding that BSA and phenols could form protein−phenol "complexes" that accumulate at the oil−water interface due to the surface-active nature of the protein.[14]

A large variety of peptides in the aqueous phase are capable of scavenging free radicals, hence, neutralizing water-soluble oxidants.[2,30] Although much less abundant (<15%) at the interface, PPH located on or immediately above the emulsion droplets would play a crucial role in inhibiting lipid oxidation. In O/W emulsions, the oxidation reaction occurs principally at the oil−water interface.[2] Moreover, the generated lipid hydroperoxides and peroxide radicals are preferentially concentrated at the interface.[1] Furthermore, peptides that accumulate at the interface and phenolics that partition both at the interface and in the interior of oil droplets can reduce the mobility of lipid molecules and the diffusion of radicals within

the lipid phase.[31] In particular, the physical location and effective concentration of LE at the oil−water interface played a concerted role with PPH to curtail lipid oxidation and produce the observed synergistic antioxidative actions.

Interestingly, if LE was added to PPH emulsions immediately after homogenization instead of during homogenization, it elicited negligible protection of the emulsions (data not shown). Due to different affinities of peptides and phenolics for oil droplets, the combination of PPH and LE not only delayed the initiation but also suppressed the propagation of lipid radical chain reactions, consequently providing the superior antioxidative protection. It has been shown that the synergism observed between some natural phenolic compounds and antioxidative lactoferrin lies in their different affinities toward O/W emulsions.[29] Besides, the association of PPH and LE at the oil−water interface would generate a structural barrier around the oil droplet to hinder the penetration and diffusion

[a]Means ± standard deviations ($n$ = 3) in the same column do not differ statistically ($P$ > 0.05). TF (or TP) and TF-$L_x$ (or TP-$L_x$): emulsions prepared with Tween 20 + Fla-PPH (or + Pro-PPH) without or with LE at the indicated concentrations ($\mu$g/mL). PPH: 5 mg/mL. Tween 20: 10 mg/mL.

of lipid oxidation initiators, thereby providing the observed synergistic effects beyond their individual actions.

It is noteworthy that small surfactants, such as Tween and sucrose ester micelles, can potentially influence the physical location of antioxidants in O/W emulsions by promoting the solubilization of lipophilic antioxidants in the aqueous phase.[32,33] Therefore, phenolic compounds in LE, which are less polar and have the propensity to accumulate at the interface, are likely to be removed from the oil droplets by Tween 20 micelles, resulting in a reduced antioxidative efficiency. This premise can be applied to explain the unexpected decrease of synergism between PPH and the high-concentration LE (200 $\mu$g/mL) (Table 1). Phenolic antioxidants that reside in the Tween 20 micelles would still be effective because they can scavenge radicals present in the aqueous phase.

**Microstructure of Emulsion Droplets.** The biophysical properties of the oil droplet interface can significantly influence the rate of lipid oxidation due to the nature of the interface that connects two immiscible phases and closely contacts antioxidants, pro-oxidants, and oxidizable substrates.[34] Apart from the aforementioned interfacial composition, the morphology, thickness, and rheology of the interfacial structure are important for the oxidative stability of O/W emulsions.[26,35]

TEM, by virtue of its high resolution, was applied to visualize the interfacial structure of emulsion droplets, and the micrographs are displayed in Figure 4. Emulsion droplets stabilized by Tween 20 did not show a typical definitive membrane structure but, rather, small spherical micelles adsorbing onto the surface (A). In comparison, an interfacial membrane made up of peptides was formed around oil droplets in the emulsion containing PPH (B). Nevertheless, the membrane appeared to be thin and discontinuous, which may arise from the loose and unfolded structure of the peptides and the competitive adsorption of Tween 20, which breaks down protein–protein interactions at the interfacial layer.[36] As a result, the oxidative process was difficult to avoid. On the other hand, when PPH and LE were homogenized together, a thick and compact interfacial membrane was observed (C), which corresponded to the lowest lipid oxidation rate (or the highest synergism). The enhanced steric restrictions of the interface enabled a strong defense mechanism against oxygen species.

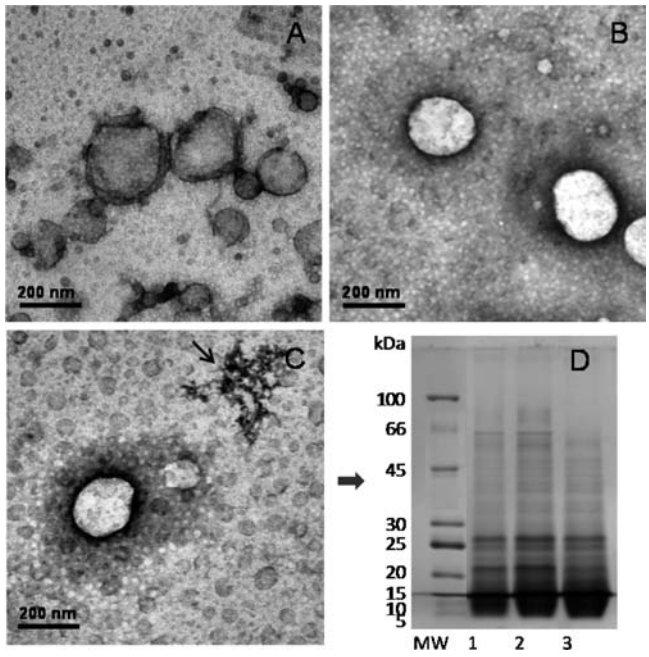

**Figure 4.** TEM micrographs of soybean O/W emulsions prepared with Tween 20 (A), Tween 20 + Pro-PPH (B), and Tween 20 + Pro-PPH + LE (C). SDS-PAGE (D) shows the peptides extracted from different regions of the emulsion prepared with (C), namely, lane 1, native Pro-PPH; lane 2, peptides distributed in the aqueous phase; and lane 3, peptides partitioning at the oil–water interface. MW: molecular weight marker. Tween 20: 10 mg/mL. PPH and LE concentrations were 5 mg/mL and 100 $\mu$g/mL, respectively. Arrow in (C) points to large networks of Pro-PPH and LE.

The complementary chemical and physical mechanisms exerted by PPH and LE for the antioxidative protection of O/W emulsions support the findings of Jiang et al.[26] that steric deterrence is a critical contributor to an emulsion's oxidative stability. Hu et al.[37] and Ogawa et al.[38] also stated the critical role of interfacial membrane thickness in maintaining the oxidative stability of O/W emulsions.

The cooperativity of PPH and LE at the oil–water interface was a primary reason for the formation of a thick and compact interfacial membrane. Atarés et al.[39] reported that the adsorbed layer of rutin molecules can aid in the formation of a thicker droplet interface in emulsions stabilized by whey protein. Moreover, phenolic compounds could modify the structure of polypeptides to a more unfolded and unordered state,[40] allowing a fast adsorption and tight packing of these molecules onto the droplet surface. Meanwhile, as a result of structural changes, reactive amino acid side-chain groups that are capable of neutralizing radicals are increasingly exposed, leading to an increase in the antioxidative protection.[41] Besides, phenolic compounds could act as cross-linkers of these adsorbed peptides, thereby enhancing the protein–protein interaction at the interfacial layer.[36]

The association of PPH with LE could be another important reason for the formation of thick interfacial membranes as proteins and phenolics can attach to each other through noncovalent interactions.[17] Such "complexes" might possess greater interfacial activity and a balanced hydrophilicity–hydrophobicity as well as an increased size relative to individual molecules.[7] Consequently, there is an increased affinity for the interface, and higher amounts of PPH and LE would accumulate at the oil–water boundary to produce a thick and

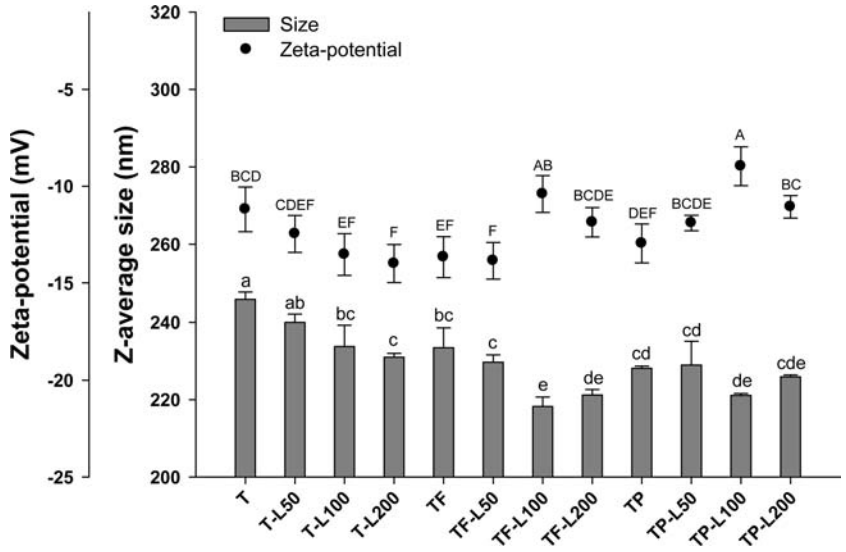

**Figure 5.** Zeta-potential and *Z*-average size of emulsions prepared with Tween 20 + Fla-PPH (or + Pro-PPH) coupled with licorice extract (LE). T, T-Lx, TF (or TP), TF-Lx (or TP-Lx): emulsions prepared with Tween 20, Tween 20 + LE, Tween 20 + Fla-PPH (or + Pro-PPH), and Tween 20 + Fla-PPH (or + Pro-PPH) + LE, respectively. $L_x$: three levels of LE (50, 100, 200 $\mu$g/mL). Tween 20: 10 mg/mL. PPH: 5 mg/mL. Means ± standard deviations ($n$ = 3) for the same emulsion parameter with different letters differ significantly ($P < 0.05$).

compact interfacial membrane. It is noteworthy that PPH can form a self-assembled network.[15] Such a structure may be triggered by $\beta$-sheet conformation transition[42] that provides a solid support for the formation of more interactive PPH−LE units conducive to the thickness and the compactness of droplet interface. The physical filling effect of LE or LE aggregates by self-association[17] can also be a contributor to the enhancement of the membrane thickness and firmness.

Hence, the presence of LE modified the peptidyl interfacial membrane from a mobile and heterogeneous unit into a steady and homogeneous entity. With this resistant interfacial membrane, it was difficult for water-soluble oxidants (e.g., $^{\bullet}$OH) to gain access to the oil droplets to initiate and accelerate lipid peroxidation. Meanwhile, the mobility and diffusion of hydroperoxides and peroxide radicals within oil droplets were restricted, so that they could not easily transfer to other droplets to sustain the radical chain reactions. It should be taken into account that the complexes present in the aqueous phase can associate with each other and finally form large networks (one was captured in Figure 4C and is indicated by an arrow), and they can act as free radical scavengers as well as stabilizers, contributing to the oxidative stability.

The electrophoretic pattern shown in Figure 4 supports the notion that PPH−LE "complexes" were formed as intensive and broad peptide bands were observed in lane 2 (peptides in the aqueous phase) and lane 3 (peptides at the interface) when compared to native PPH (lane 1), indicating the migration of LE into the gel by associating with PPH. Newly formed high-molecular-weight bands ranging from 60 to 80 kDa are visible in lane 2, yet some high-molecular-weight bands were missing in lane 3, which might be due to the loose attraction of these large molecules to the interface so that they were separated and not retained in the prepared interfacial protein samples. It is also plausible that these large peptides were firmly anchored into the lipid phase and remained in the chloroform phase after extraction with methanol.

**Zeta-Potential and Size Distribution.** Measurement of electrical charges on the droplet surface can provide valuable information about interactions between ionizable surfactants and emulsion droplets.[43] As shown in Figure 5, emulsion droplets stabilized by Tween 20 carried negative charges (about −11.5 mV), which can be ascribed to phosphate (buffer). The addition of LE increased the negative potential, indicating the accumulation of negatively charged compounds such as 18$\beta$-glycyrrhetic acid onto the surface of oil droplets.

When LE was incorporated into emulsions containing PPH, the zeta-potential increased to a less negative value, suggesting the displacement of peptides from the interface or the interaction of PPH, and LE shielded the charged groups in peptides that oriented toward the outer layer of the droplet surface.[38] When a droplet surface has a low net charge, there will be less electrostatic repulsion between the interfacial layer and a more compact interfacial membrane tends to be formed. Hence, the reduced surface charge on oil droplets caused by the combination of PPH and LE also favored the formation of a thick and continuous interfacial membrane and contributed to the remarkable synergistic inhibition. The lowest surface potential was displayed at 100 $\mu$g/mL LE, indicating the highest amount of LE being involved at the interface, which correlated well with the greatest synergism. On the other hand, the relatively weak synergism observed at 200 $\mu$g/mL LE was ostensibly due to insufficient adsorption at the interface, which might be caused by the solubilization by Tween 20 micelles or the bridging flocculation.

The combination of PPH and LE also endowed the emulsion with small size distribution, which could be interpreted as an increased coverage of surface active compounds and the enhanced steric hindrance between oil droplets.[7,39] It has been reported that oxidative stability increased with decreasing oil droplet size as on an oil volume basis more emulsifiers were adsorbed onto the droplet surface.[26] Moreover, the "wedge effect" of hydrophobic portion of emulsifiers can more efficiently suppress the mobility of lipid molecules and radicals in small droplets than in large droplets.[44] Hence, the effect of the combination of PPH and LE on decreasing the size distribution of emulsion droplets also contributed to the notable synergistic oxidation inhibition.

**Figure 6.** UPLC profiles of licorice extract (LE) by photodiode array and ESI-MS detectors: (A) standard LE; (B) compounds in LE present in the aqueous phase of the emulsion prepared with Tween 20 + Pro-PPH + LE; (C) compounds in LE partitioning at the oil−water interface of the same emulsion, and compounds identified in standard LE (lower table). Tween 20: 10 mg/mL. PPH and LE concentrations were 5 mg/mL and 100 $\mu$g/mL, respectively. The structures of major active compounds partitioning at the oil−water interface are shown on the right.

**Identification of Active Compounds in LE at the Oil−Water Interface.** As displayed in Figure 6, 15 compounds were identified in LE, which were predominantly flavonoids. Most of these compounds were detected at the oil−water interface (C) but with different proportions when compared to standard LE (A). As expected, the amount of glycyrrhic acid was negligible because the LE was prepared to remove this compound. Liquiritin apioside, neolicuroside, glabrene, and 18$\beta$-glycyrrhetic acid were the predominant compounds in LE partitioning at the interface and were likely responsible for the strong antioxidant activity of LE in O/W emulsions and the notable synergism when coupled with PPH.

18$\beta$-Glycyrrhetic acid is known as one of the most effective antioxidants in licorice extract.[45] Glabrene, having a strong conjugation of double bonds in hydroperoxides, can produce a more stable phenoxyl radical formation after the donation of an electron and, therefore, effectively suppresses the oxidative process.[46] Glabridin, the most abundant compound in LE, barely adsorbed at the interface, which can be interpreted as its having a strong affinity for the lipid molecules and dispersing into the interior of oil droplets, so that methanol cannot extract it from the chloroform phase after centrifugation. However, it has to be taken into consideration that both the competitive adsorption and the formation of PPH−LE "complexes" might weaken the partitioning of LE at the oil−water interface. There are also some compounds present in the aqueous phase (B). Some of them can be the detached molecules from the interface due to the loose attraction, and some can be ascribed to the solubilization by Tween 20 micelle from the oil droplets. This result is consistent with that in SDS-PAGE (Figure 4D), as some high-molecular-weight bands were missing from the interface (lane 3).

In conclusion, pea protein hydrolysates prepared with Flavourzyme and Protamex, when used in combination with

dx.doi.org/10.1021/jf5016126 | J. Agric. Food Chem. 2014, 62, 8204−8213

licorice extract, produced a synergistic inhibition on lipid oxidation in soybean O/W emulsions. The physical location and effective concentration of LE at the oil−water interface determined the degree of synergism. The combination of PPH and LE, on the one hand, allowed the efficient removal of radicals in both aqueous and lipid phases and, on the other hand, reduced the surface charge and particle size of oil droplets, thereby facilitating the formation of a thick and compact interfacial membrane, which offered superior defense against oxidative stress. Liquiritin apioside, neolicuroside, glabrene, and 18$\beta$-glycyrrhetic acid were the predominant compounds in LE partitioning at the oil−water interface and were likely responsible for the strong antioxidant activity of LE in O/W emulsions and the notable synergism when coupled with PPHs. Hence, enzymatic pea protein hydrolysates and licorice extract when applied together could help maximize the stability of emulsion-type food products, both physically and chemically.

# Preparation of Starch Nanoparticles in a Water-in-Ionic Liquid Microemulsion System and Their Drug Loading and Releasing Properties

Gang Zhou, Zhigang Luo,* and Xiong Fu*

Carbohydrate Laboratory, College of Light Industry and Food Science, South China University of Technology, Guangzhou 510640, China

**ABSTRACT:** An ionic liquid microemulsion consisting of 1-butyl-3-methylimidazolium hexafluorophosphate ([Bmim]$PF_6$), surfactant TX-100, 1-butanol, and water was prepared. The water-in-[Bmim]$PF_6$ (W/IL), bicontinuous, and [Bmim]$PF_6$-in-water (IL/W) microregions of the microemulsion were identified by conductivity measurements. Starch nanoparticles with a mean diameter of 91.4 nm were synthesized with epichlorohydrin as cross-linker through W/IL microemulsion cross-linking reaction at 50 °C for 4 h. Fourier transform infrared spectroscopy (FTIR) data demonstrated the formation of cross-linking bonds in starch molecules. Scanning electron microscopy (SEM) revealed that starch nanoparticles were spherical and that some particles showed aggregation formation. Furthermore, drug loading and releasing properties of starch nanoparticles were investigated with mitoxantrone hydrochloride as a drug model. This work provides an efficient and environmentally friendly approach for the preparation of starch nanoparticles, which is beneficial to their further application.

**KEYWORDS:** *ionic liquid microemulsion, cross-linking, starch nanoparticles, drug loading, drug release*

## INTRODUCTION

Starch, one of the most abundant natural polymers, is renewable, biodegradable, and modifiable. However, native starches have limitations such as poor processability and solubility, which limit their industrial application. Therefore, starches have been modified for many years through physical, chemical, or enzymatic processes to improve their properties.[1,2] Among various modifications, cross-linked starch microspheres show good properties, such as high stability toward swelling, high shear, high temperature, and acidic conditions.[3] Besides, cross-linked starch microspheres possess good performance in biodegradability, nontoxicity, stability during storage, and cost-effectiveness as well as simple fabrication method.[4] In view of the good properties, cross-linked starch microspheres can be used in many areas, especially in drug delivery systems as a drug carrier.[5] Several years ago, Malafaya et al.[6] prepared cross-linked starch microspheres and studied their loading properties to biologically active agents. Some researchers found that cross-linked starch microspheres are promising vehicles in the intranasal drug delivery system.[7,8] In addition, starch microspheres have also been used as drug carriers for the treatment of liver cancer or arterial embolism via parenteral route.[9−12] As we know, the applications of starch microspheres in drug delivery systems are influenced by their particle size and administration route. However, the literature about the preparation of cross-linked starch microspheres shows that they possess relatively large size and broad size distribution.[13] Therefore, the quality of starch microspheres is desperately expected to be improved for better application.

Starch microspheres have been synthesized through several approaches, among which the water-in-oil (W/O) emulsion cross-linking technique has been widely used because of the defined and simple preparation steps with mild processing conditions.[14] However, the W/O emulsion cross-linking technique requires a lot of toxic organic reagents, which will influence the quality of starch microspheres and lead to pollution, and starch microspheres obtained from this approach still appear relatively big in size and have a wide size distribution range.[15] Heretofore, there are few reports of the synthesis of starch nanoparticles by the emulsion cross-linking method. Shi et al.[14] prepared starch nanoparticles in a traditional W/O microemulsion system with a volume ratio of oil to water at 15:2. In view of the fact that a lot of toxic organic reagents are used in this traditional microemulsion, it is essential to develop an environmentally friendly emulsion cross-linking method for the synthesis of starch nanoparticles.

Room temperature ionic liquids (ILs) have become more and more important as desirable green solvents and reaction media due to their recyclability and designability.[16] Recently, many documents have shown that ILs can substitute polar phase, nonpolar phase, or surfactant to prepare ionic liquid microemulsions, and some inorganic nanomaterials can be prepared in this kind of system.[17−21] However, only Zhou et al.[22] performed the synthesis of starch nanoparticles through an ionic liquid-in-oil (IL/O) microemulsion technique, and the achieved starch nanoparticles possessed an average diameter of 96.9 nm. In this paper, ionic liquid 1-octyl-3-methylimidazolium acetate substituted for the water phase and cyclohexane served as oil phase. Therefore, this IL/O microemulsion system was not environmentally friendly because of the use of toxic organic reagents such as cyclohexane.

To explore an efficient and environmentally friendly approach for the preparation of starch nanoparticles, we

substituted the oil phase with [Bmim]$PF_6$ and prepared a water-in-ionic liquid (W/IL) microemulsion. Furthermore, the oil phase substituted by [Bmim]$PF_6$ in the W/IL microemulsion was much less than that in the W/O microemulsion and IL/O microemulsion, suggesting that the W/IL microemulsion was a green system. In this work, we investigated the synthesis of starch nanoparticles in a W/IL microemulsion system. Starch nanoparticles with small size and narrow size distribution were successfully obtained and characterized by Fourier transform infrared spectroscopy (FTIR), scanning electron microscopy (SEM), and dynamic light scattering (DLS). Moreover, drug loading and releasing properties of starch nanoparticles were investigated with mitoxantrone hydrochloride as a drug model. This work provided an efficient and environmentally friendly approach for the preparation of starch nanoparticles and may be beneficial to the further applications of starch nanoparticles in many fields.

## MATERIALS AND METHODS

**Materials.** Acid-treated granular starch was obtained from Guangzhou Chemical Reagent Factory (Guangzhou, China). 1-Butyl-3-methylimidazolium hexafluorophosphate ([Bmim]$PF_6$, >99%) was purchased from Lanzhou Institute of Chemical Physics (Lanzhou, China). Mitoxantrone hydrochloride was provided by Hubei Jianyuan Chemical Co., Ltd. (Wuhan, China). All other chemicals were of analytical grade.

**Preparation of Ionic Liquid Microemulsions.** The preparation of a water/Triton X-100 (TX-100) + 1-butanol/[Bmim]$PF_6$ system was conducted by direct visual observation. First, certain amounts of water and [Bmim]$PF_6$ were added into a small beaker, and their masses were determined by an FA1104N analytical balance (Shanghai Balance Instrument Co., Shanghai, China) with a resolution of 0.0001 g. The temperature was controlled by a DF-II thermostatic magnetic stirring apparatus (Shanghai Yuzheng Instrument Co., Shanghai, China). After thermal equilibrium, the mixture of TX-100 and 1-butanol with the mass ratio of TX-100 to 1-butanol at 3:1 was added into the solution until the hierarchical and hazy liquid solution became transparent, which was indicative of the formation of the single phase.

**Phase Diagram Determination.** The pseudoternary phase diagram of the microemulsion was determined at 25 °C as described above. A series of microemulsions were prepared through changing the mass ratio of [Bmim]$PF_6$/water at 9:1, 8:2, 7:3, 6:4, 5:5, 4:6, 3:7, 2:8, and 1:9, respectively. The corresponding composition of the solution was noted as the phase boundary.

**Conductivity Measurements.** Conductivity measurements were taken with a model DDSJ-308A conductometer (Shanghai Precision Scientific Instrument Co., Shanghai, China) at 1 kHz using a dip-type cell of cell constant 0.971 $cm^{-1}$. The errors in the conductance measurements were ±0.5%. The water was progressively added to the mixture of [Bmim]$PF_6$, TX-100, and 1-butanol, and the conductance was measured after thorough mixing and temperature equilibration.

**Dynamic Light Scattering.** DLS is used to determine the size distribution of microemulsions and further demonstrate the formation of W/IL microemulsions. Measurements were conducted using a Malvern Nano-Zetasizer particle size analyzer (Malvern Instrument Ltd., Worcestershire, UK) at a wavelength of 633 nm. The scattering angle was set at 90°. Samples were maintained at 25.0 °C during the experiments.

**Preparation of Starch Nanoparticles.** Starch nanoparticles were prepared according to the W/IL microemulsion cross-linking method with epichlorohydrin as a cross-linker. This method combined the ionic liquid microemulsion with cross-linking reaction of starch nanoparticles. The solidification of the starch molecules and cross-linking reaction took place during the stable W/IL microemulsion. The reaction scheme for cross-linked starch nanoparticles is depicted in Figure 1. First, the aqueous phase was prepared by dissolving acid-treated granular starch (0.5 g) in 9.5 g of NaOH solution (NaOH/$H_2O$ = 1:50, w/w) and then poured into [Bmim]$PF_6$ (40 g) to form

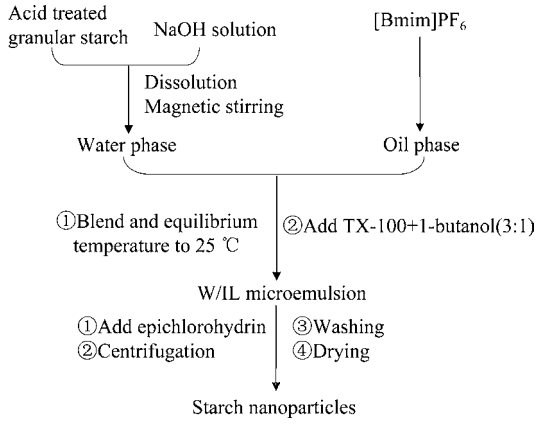

**Figure 1.** Scheme of microemulsion cross-linking reaction of starch.

the W/IL microemulsion with the aid of 40 g of a mixture of surfactant TX-100 and cosurfactant 1-butanol (TX-100/1-butanol = 3:1, w/w). After several minutes of magnetic stirring, epichlorohydrin (1.84 g) was added to the above microemulsion as a cross-linker. In this stage, the mixture was stirred by a DF-II thermostatic magnetic stirring apparatus at the speed of 1200 rpm at 50 °C for 4 h. Subsequently, the reaction solution was cooled to room temperature, and starch nanoparticles were precipitated with methanol under vigorous stirring followed by centrifugation. The precipitate was washed thoroughly with sufficient methanol and ethanol to eliminate [Bmim]$PF_6$, unreacted epichlorohydrin, 1-butanol, and TX-100. Finally, the solid was centrifuged and dried in a vacuum at 45 °C for 24 h.

**Characterization of Starch Nanoparticles.** The structure character of acid-treated granular starch and starch nanoparticles was analyzed by a Nicolet 510 spectrophotometer (Thermo Electron Corp., Waltham, MA, USA) using the KBr disk technique. For FTIR measurement, the samples were mixed with anhydrous KBr and then compressed into thin disk-shaped pellets. The spectra were obtained with a resolution of 2 $cm^{-1}$ over a wavenumber range of 400−4000 $cm^{-1}$. SEM images of acid-treated granular starch and starch nanoparticles were examined by means of a model 430 scanning electron microscope (FEI Corp., Hillsboro, OR, USA). The samples were mounted on an aluminum stub with double sticky tape, followed by coating with gold in a vacuum before examination. The accelerating voltage was 5 kV. The size distribution of starch nanoparticles was determined by DLS. Before measuring, 0.1 g of starch nanoparticles was added to 100 mL of distilled water and treated by ultrasound for 30 min to disperse sufficiently.

**Standard Curves of Mitoxantrone Hydrochloride.** Standard curves of mitoxantrone hydrochloride in phosphate-buffered saline (PBS, 0.2 mol/L, pH 7.4) were obtained using the following approaches: 0.01 mg/mL of mitoxantrone hydrochloride in PBS solution was scanned at wavelengths between 360 and 760 nm with a model TU-1810 ultraviolet−visible spectrophotometer (Beijing Puxi General Apparatus Co., Ltd., Shanghai, China). The wavelength at which mitoxantrone hydrochloride absorbed the most was selected as the testing wavelength for later experiments. Then, 0.0025, 0.005, 0.01, 0.02, 0.03, and 0.04 mg/mL of mitoxantrone hydrochloride in PBS solution were measured at the corresponding testing wavelengths to obtain the standard curve of mitoxantrone hydrochloride absorbance to concentration.

**Drug Loading Analysis.** About 50 mg of starch nanoparticles with diameters of 64, 176, and 255 nm were weighed and suspended in 10 mL of PBS solution with 0.0221, 0.0442, 0.0884, and 0.1326 mg/mL mitoxantrone hydrochloride each. The resulting suspensions were gently stirred at the desired temperature of 17, 27, 37, and 47 °C for 0.5, 1, 1.5, 2, 2.5, and 3 h. Subsequently, the solutions were centrifuged, and each supernatant was extracted to determine the drug loading and encapsulation efficiency with an ultraviolet−visible spectrophotometer according to the standard curve of mitoxantrone hydrochloride absorbance to concentration. The drug loading ($A$) and

dx.doi.org/10.1021/jf5018725 | J. Agric. Food Chem. 2014, 62, 8214−8220

encapsulation efficiency ($B$) were calculated with eqs 1 and 2, respectively.

$$A = (C_0 - nC_1)V_0/W \quad (1)$$

$$B = C_0 - nC_1/C_0 \quad (2)$$

$C_0$ means initial concentration of mitoxantrone hydrochloride in PBS, $C_1$ means diluted concentration of mitoxantrone hydrochloride in PBS, $n$ means dilution multiple of extracted supernatant, $V_0$ means initial volume of mitoxantrone hydrochloride in PBS, and $W$ means the weight of starch nanoparticles dissolved in PBS.

**Drug Release Analysis.** About 90 mg of drug-loaded starch nanoparticles that possess the most drug loading (1.5587 mg/g) under the experimental conditions above was weighed and added to the dialysis tube. Then, 10 mL of PBS solution was added to the dialysis tube. Subsequently, the drug-loaded starch nanoparticles and dialysis tube were placed in a beaker containing 80 mL of PBS solution and slowly stirred in magnetic stirring apparatus at 37 °C. At appropriate time intervals, 5 mL of solution was taken out and replaced by the same volume of fresh PBS solution. The cumulative release rate was determined according to the standard curve of mitoxantrone hydrochloride absorbance to concentration and eq 3.

$$R = M_1/M_0 \quad (3)$$

$M_1$ is the cumulative mass of mitoxantrone hydrochloride released from drug-loaded starch nanoparticles at a given time, and $M_0$ is the total drug loading in starch nanoparticles.

## RESULTS AND DISCUSSION

**Phase Diagram.** A phase diagram is useful for further characterizing the microemulsions and choosing the proper cross-linking reaction system. The phase diagram of the water/TX-100 + 1-butanol/[Bmim]$PF_6$ system at room temperature is shown in Figure 2. Apparently, two different regions, a two-phase region and a one-phase region, could be observed. A continuous stable single-phase microemulsion region could always be observed in the range of the water or [Bmim]$PF_6$ content from 0 to 100% (wt). It could be seen that the phase behavior of the water/TX-100 + 1-butanol/[Bmim]$PF_6$ system was similar to that of the traditional W/O microemulsions and the IL microemulsions reported recently.[23]

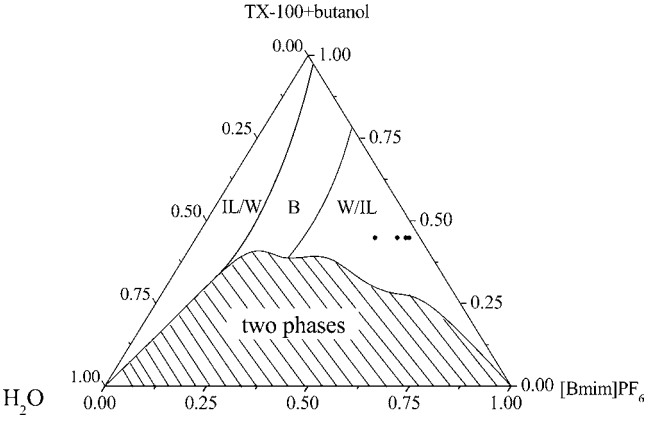

**Figure 2.** Phase diagram of the water/TX-100 + 1-butanol/[Bmim]$PF_6$ (in weight fraction) at 25 °C.

**Conductivity.** Conductivity is frequently used to investigate the structural changes in microemulsions and can provide a basis for the determination of the cross-linking reaction system.[19] The one-phase region could be divided into different subregions, such as the water-in-IL (or oil) microemulsion region, the IL (or oil)-in-water microemulsion region, and the bicontinuous region.[17,24] In our research, the W/IL microemulsion was chosen as the cross-linking reaction system. Therefore, it is essential to investigate the structure of this kind of microemulsion. Conductivity measurement is commonly used to locate the subregions of microemulsions.[24] Figure 3 illustrates the dependence of the conductivity on the weight fraction of water with the mass ratio of [Bmim]$PF_6$ to TX-100 + 1-butanol at 1:4. Obviously, it could be seen that the conductivity increased first and then decreased with an increase in water content, representing the subregion structure transition from W/IL to IL/W after passing through a bicontinuous region (B), indicative of the existence of three subregions. A similar phenomenon could also be seen in ethylene glycol/TX-100/[Bmim]$PF_6$ microemulsions.[25]

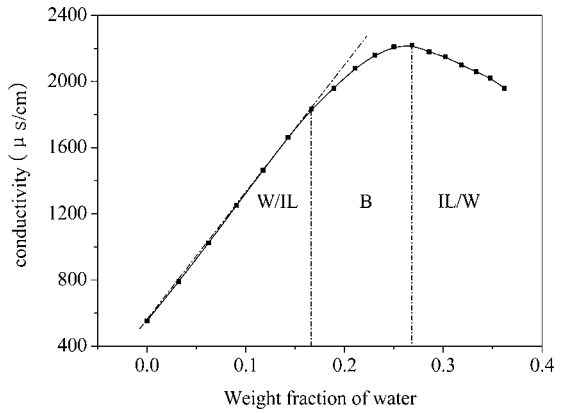

**Figure 3.** Conductivity as a function of weight fraction of water in the microemulsions at 25 °C with the mass ratio of [Bmim]$PF_6$ to TX-100 + 1-butanol at 1:4.

**Size Distribution of Microemulsions.** The size distribution of the droplets in the W/IL microemulsions was characterized by DLS. In this work, several kinds of W/IL microemulsions were chosen for DLS analysis because of their applications in the preparation of starch nanoparticles. The compositions of selected microemulsions are as follows: the weight fraction of mixture of TX-100 and 1-butanol in the microemulsions was 0.45, and the mass ratios of [Bmim]$PF_6$ to water ($R$) are 4:1, 9:1, 15:1, and 20:1, respectively. As shown in Figure 4, the sizes of microemulsions increased from about

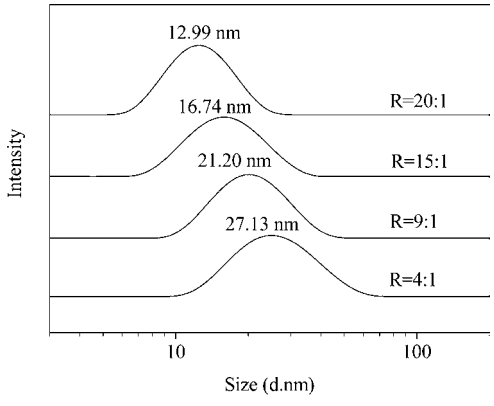

**Figure 4.** Size distribution of the droplets in the water/TX-100 + 1-butanol/[Bmim]$PF_6$ microemulsions at 25.0 °C. $R$ represents the mass ratio of [Bmim]$PF_6$ to water.

dx.doi.org/10.1021/jf5018725 | J. Agric. Food Chem. 2014, 62, 8214−8220

12.99 to 27.13 nm with the increase of water. The microemulsions showed regular swelling behavior with the addition of water, which demonstrated the formation of W/IL microemulsion according to the study by Pramanik et al.[26]

**FTIR Analysis of Acid-Treated Granular Starch and Starch Nanoparticles.** Figure 5 shows the comparative FTIR spectra of acid-treated granular starch (Figure 5a) and starch nanoparticles (Figure 5b). In the case of acid-treated granular starch, the O−H stretching and the C−H stretching vibration give strong signalsat 3389 and 2928 $cm^{-1}$, respectively.[27] The absorption peak at 1651 $cm^{-1}$ belonged to O−H bending vibration.[28] The bands at 1160, 1084, and 1024 $cm^{-1}$ were due to C−O stretching vibrations.[29] In comparison with acid-treated granular starch, FTIR spectra of starch nanoparticles showed some difference. The absorption peaks at 3389 nd 1651 $cm^{-1}$ clearly became narrowed and weaker than that of acid-treated granular starch,which demonstrates the occurrence of cross-linking reaction. The band shape between 900 and 1160 $cm^{-1}$ in starch nanoparticles had changed, and the band intensity became a little stronger compared with acid-treated granular starch. The results suggested that a cross-linking reaction took place between starch molecules. Similar results were also observed in previous literature.[4,29]

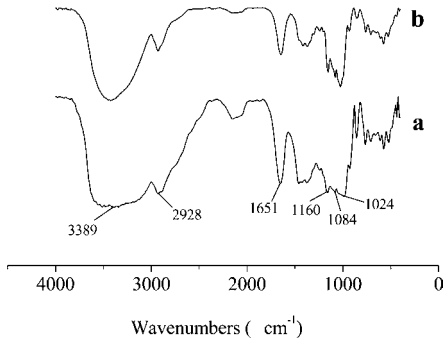

**Figure 5.** FTIR spectra of acid-treated granular starch (a) and starch nanoparticles (b).

**SEM Analysis of Acid-Treated Granular Starch and Starch Nanoparticles.** SEM was used to investigate the morphology of acid-treated granular starch and starch nanoparticles. As shown in Figure 6, acid-treated granular starch showed round or oval shapes with various sizes ranging from about 10 to 30 $\mu$m. In comparison with the acid-treated granular starch, starch nanoparticles exhibited good sphericity and particle sizes ranged from about 100 to 300 nm, but some of the particles showed aggregation formation mainly due to strong van der Waals force and electrostatic attraction.[22]

**Size Distribution of Starch Nanoparticles.** The size distribution of starch nanoparticles was measured using DLS. As observed in Figure 7, the result showed that the size distribution of starch nanoparticles was relatively concentrated, and the mean diameter was 91.4 nm, which is much smaller than that of starch microspheres prepared by the traditional W/O emulsion cross-linking method.[30] From the result, it could be concluded that starch nanoparticles with a relatively concentrated size distribution could be obtained by using the W/IL microemulsion cross-linking approach.

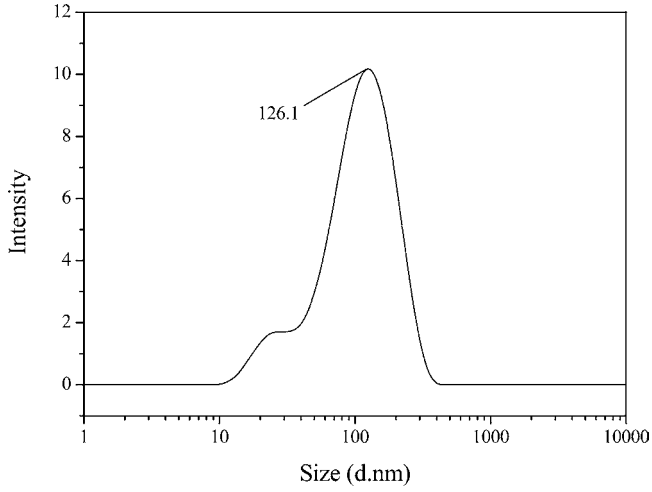

**Figure 7.** Size distribution of starch nanoparticles.

**Drug Loading Analysis.** According to the scanning result, the testing wavelength of PBS solution containing mitoxantrone hydrochloride was 608 nm. Besides, the standard curve of mitoxantrone hydrochloride absorbance to concentration (from 0.0025 to 0.04 mg/mL) was $A = 0.0424 + 24.38C$ ($R^2$ = 0.9982).

The influence of loading time on drug loading property is shown in Figure 8A. The drug loading and encapsulation efficiency increased first and then decreased as time went on. To be exact, the drug loading increased from 0.5102 to 0.7317 mg/g as the time was prolonged from 0.5 to 1.5 h and then decreased to 0.5513 mg/g when the time was extended to 3 h. The encapsulation efficiency increased from 11.54 to 16.55% and then reduced to 12.47% correspondingly. From the result, it could be concluded that the drug loading and encapsulation

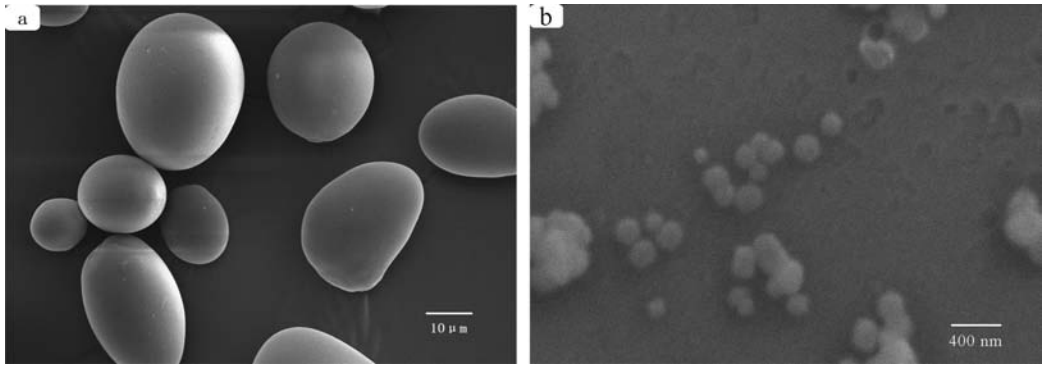

**Figure 6.** SEM images of acid-treated granular starch (a) and starch nanoparticles (b).

dx.doi.org/10.1021/jf5018725 | J. Agric. Food Chem. 2014, 62, 8214−8220

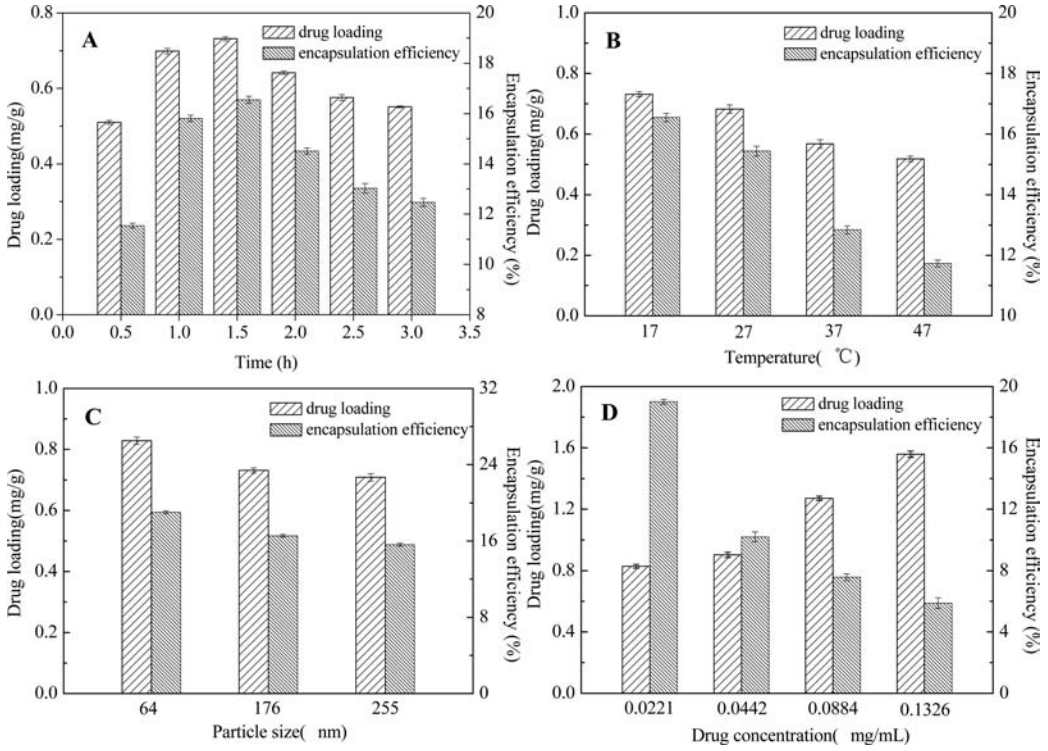

**Figure 8.** Effect of loading time (A), loading temperature (B), particle size (C), and drug concentration (D) on drug loading property. Other conditions: (A) loading temperature, 17 °C; particle size, 176 nm; drug concentration, 0.0221 mg/mL. (B) loading time, 1.5 h; particle size, 176 nm; drug concentration, 0.0221 mg/mL. (C) loading time, 1.5 h; loading temperature, 17 °C; drug concentration, 0.0221 mg/mL; (D) loading time, 1.5 h; loading temperature, 17 °C; particle size, 64 nm.

efficiency of starch nanoparticles on mitoxantrone hydrochloride presented an appropriate time value.

The effect of temperature on drug loading property is observed in Figure 8B. It was obvious that different loading temperatures resulted in significant changes in drug loading and encapsulation efficiency. At a temperature of 17 °C, starch nanoparticles loaded with more mitoxantrone hydrochloride, and encapsulation efficiency showed the same trend. The reason for this phenomenon may be that the adsorption of mitoxantrone hydrochloride was mainly attributed to the existence of opposite charges and high affinity. This adsorption process would be hindered by high temperature; thus, the drug loading reduced at higher temperature.[15]

Starch nanoparticles with different particle sizes (64, 176, and 255 nm) were obtained through changing the reaction conditions such as reaction time, reaction temperature, and starch concentration to investigate the effect of particle size on drug loading property. As shown in Figure 8C, drug loading and encapsulation efficiency decreased with increasing particle size of starch nanoparticles. The reason for this phenomenon may be that starch nanoparticles of smaller particle size have greater specific surface area and stronger adhesion ability.

As shown in Figure 8D, drug loading ascended significantly from 0.7317 to 1.5587 mg/g as the concentration of mitoxantrone hydrochloride rose from 0.0221 to 0.1326 mg/mL. However, the increase of drug concentration caused a decline in encapsulation efficiency. Therefore, higher drug concentration does not necessarily result in better drug loading property.

**Drug Release Analysis.** Drug release experiments were performed in PBS solution. As presented in Figure 9, an initial burst release was observed in the first hour after the drug-loaded starch nanoparticles were immersed into release medium. The high release rate of 32.15% in the first hour was associated with the immediate dispersion of the mitoxantrone hydrochloride close to the surfaces of starch nanoparticles. In the following 9 h, the starch nanoparticles presented a swelling-controlled and sustained release, in which the release rate tailed off, and 79.95% of mitoxantrone hydrochloride contained in the starch nanoparticles was released in the 10th hour. This may be explained by increasing swelling causing a great number of mitoxantrone hydrochloride molecules to diffuse out of the starch nanoparticles and pass into the release medium. This observed phenomenon was consistent with the results of Fang et al.[15]

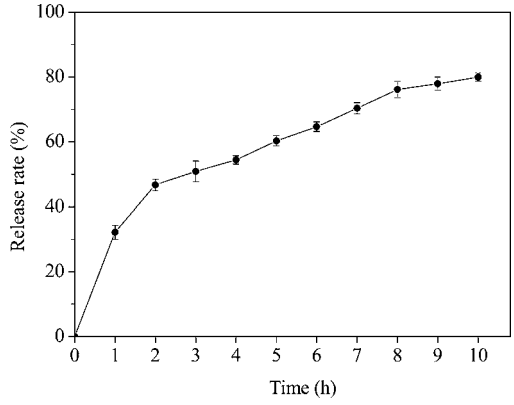

**Figure 9.** Mitoxantrone hydrochloride release of starch nanoparticles in PBS solution.

This paper describes an exploratory study on the preparation of starch nanoparticles by a novel ionic liquid microemulsion

dx.doi.org/10.1021/jf5018725 | J. Agric. Food Chem. 2014, 62, 8214−8220

and drug loading and releasing properties of starch nanoparticles. Water/TX-100 + 1-butanol/[Bmim]$PF_6$ microemulsions were prepared, and the pseudoternary phase diagram was drawn to investigate the phase behavior. The W/IL, bicontinuous, and IL/W microregions of the microemulsions were identified by conductivity measurements. DLS analysis of microemulsions demonstrated the formation of a W/IL microemulsion. Cross-linked starch nanoparticles were prepared with epichlorohydrin as cross-linker through a W/IL microemulsion cross-linking approach. The formation of cross-linking bonds in starch molecules was demonstrated by FTIR spectra. SEM and DLS of starch nanoparticles intuitively suggested the formation of starch nanoparticles. In terms of drug loading property of starch nanoparticles, it was found that the drug loading and encapsulation efficiency were influenced by loading time, loading temperature, and particle size as well as drug concentration. The release curve of drug-loaded starch nanoparticles contained two phases: an initial burst release phase and a sustained release phase depending on the swelling and degradation of starch nanoparticles.

**ABSTRACT:** Magnetic molecular imprinted polymers (MMIPs) have been prepared as solid phase material to selectively extract protocatechuic acid (PCA) from fruit juices with high capacity and fast binding kinetics. The resulting MMIPs were characterized by TEM, FT-IR, TGA, and VSM. The adsorption process between PCA and MMIPs followed Langumuir adsorption isotherm with maximum adsorption capacity at 7.5 mg/g and pseudo-second-order reaction kinetics with fast binding kinetics (equilibrium time at 40 min). In addition, the prepared MMIPs showed rapid magnetic separation (10 s) and reusability (retained 94.9% after six cycles). Subsequently, MMIPs were successfully applied for selective enrichment and determination of PCA from fruit juices (0.45 $\mu$g/mL in grape juice but not detected in apple juice, pineapple juice, orange juice, and peach juice) with satisfactory recoveries (92−107%). The results indicated that synthesized MMIPs can be used for efficient and selective extraction of PCA from complex matrices.

**KEYWORDS:** *protocatechuic acid, fruit juice, molecular imprinted polymer, magnetic solid phase extraction, HPLC analysis*

## INTRODUCTION

Protocatechuic acid (PCA), a phenolic compound, is widely distributed in commonly consumed foods, fruits, juices, and traditional Chinese medicine. At the same time, PCA is the major human metabolite of cyanidin-glucosides, flavonoids widely existing in fruit.[1,2] Pharmaceutical investigations indicate that PCA exhibits a wide variety of bioactivities, such as strong antioxidant,[3] wide anticancer,[4,5] anti-inflammatory,[6] and anticarcinogenic[7] properties. Moreover, PCA has been studied in ongoing clinical trials.[8] Nowadays, PCA has attracted increasing interest as a dietary supplement in an expanding health food market. However, the qualitative and quantitative analyses of polar PCA in a complex matrix (e.g., fruit juice, food, natural product, and biological sample) are difficult because of the low concentration of PCA (e.g., <1 $\mu$g/mL in fruit juices) and the coelution with some other polar interferences in usual high-performance liquid chromatography (HPLC) analysis.[9] Therefore, it is necessary to develop an efficient and selective extraction method for the recovery and purification of PCA from complex matrices.

Molecularly imprinted polymers (MIPs) are selective materials that contain specific recognition sites in synthesized polymers with the memory of templates and their analogues due to shape, size, and functionality recognition.[10,11] Other powerful features of MIPs are mechanical/chemical stability, low cost, easy preparation, and reversible adsorption/desorption procedure, as indicated by Haupt and Mosbach in a review.[12] Recently, it has attracted wide attention and attained significant application in effective and selective separation/determination of small bioactive components or macromolecules (e.g., proteins) from real complex samples.[13−16]

In most cases, MIPs show specific adsorption of target components at very low concentrations.[13−16] However, MIPs prepared by conventional method, such as bulk polymerization and precipitation polymerization, embed most binding sites, which leads to poor binding capacities and low binding kinetics of templates on MIPs.[17] Karasová et al. prepared PCA-imprinted polymers by bulk polymerization, and the best specific binding capacity of MIPs for PCA was found in porogen solvent; however, it was just 34.7 $\mu$g/g.[18] After that, Chen and co-workers declared that they achieved PCA-imprinted polymers with good adsorption capacity by conventional precipitation polymerization, whereas the binding capacity of MIPs for PCA was only about 0.16 mg/g.[19] Recently, various forms of surface-imprinting techniques, imprinting MIPs on the surface of nano/micro solid supports (e.g., silica,[20] carbon nanotube,[21] polymer support,[22] and magnetic nanoparticle[10,11]), have been successfully and widely used with promising results to address this problem. The results suggest that the surface-imprinted MIPs increase binding capacity obviously because of the high surface area of solid support, leading to more imprinted cavities within the polymer network, and shorten equilibrium time largely from 12−24 h in conventional MIPs to <2 h for the surface recognition sites.[10,11] Notably, magnetic solid supports (e.g, $Fe_3O_4$) have been considered as ideal ones and received increasing attention because they possess significant advantages including but not limited to unique magnetic property for easy and rapid separation from the matrix under external magnetic field after adsorption, which will avoid the column-packing procedure or centrifugation procedure, and then make the pretreatment step

simple.[10,11,23] However, to our best knowledge, no paper has reported the preparation of magnetic MIPs (MMIPs) using PCA as template to efficiently and selectively extract and determine PCA from complex matrices.

Herein, we attempted to prepare and characterize MMIPs using PCA as template and investigate adsorption isotherms and kinetics, competitive adsorption, reusability analysis, and application in selective extraction and determination of PCA in fruit juices. The results suggested that the prepared MMIPs possessed high binding capacity, fast binding kinetics, excellent selectivity, quick separation ability, and good reusability because of the combination of the advantage of surface-imprinted MIPs and magnetic $Fe_3O_4$.

## MATERIALS AND METHODS

**Chemicals and Reagents.** Iron(III) chloride hexahydrate ($FeCl_3 \cdot 6H_2O$), polyethylene glycol 6000 (PEG 6000), 2,2-azobis-(isobutyronitrile) (AIBN), tetraethyl orthosilicate (TEOS), and HPLC grade methanol were obtained from Sinopharm Chemical Reagent Co., Ltd. (Shanghai, China). Ethylene glycol dimethacrylate (EGDMA), 4-vinylpyridine (4-VP), acrylamide (AM), methacrylamide (MAM), and 3-(trimethoxysilyl)propyl methacrylate (MPS) were acquired from Shaen Chemical Technology Co., Ltd. (Shanghai, China). 4-Hydroxybenzoic acid (4-HBA), salicylic acid (SA), caffeic acid (CA), gallic acid (GA), and PCA with purities >99% were purchased from National Institute for the Control of Pharmaceutical and Biological Products (Beijing, China). Ultrapure water was collected from a Milli-Q gradient ultrapure water system (Millipore, MA, USA). The other reagents were of analytical grade and supplied from Kemiou Chemical Reagent Co., Ltd. (Tianjin, China).

**Procedures for Preparation of MMIPs.** PCA-imprinted polymers were prepared by a surface-imprinted polymerization method using magnetic microparticles as solid support according to our previous work with minor modifications.[10,11] At first, $Fe_3O_4$ microspheres were synthesized by solvothermal reaction as previously reported.[24,25] Then, $Fe_3O_4$ microspheres were coated with a $SiO_2$ layer by hydrolysis of TEOS catalyzed by NaOH.[26] Typically, as-prepared $Fe_3O_4$ microspheres (50.0 mg) were dispersed in deionized water and ultrasonicated for 30 min. Then the resultant homogeneous solution was diluted with 1.0 mM NaOH aqueous solution (450.0 mL) and ultrasonically treated for another 5 min. Subsequently, the obtained basic dispersion was mechanically stirred at 60 °C for 30 min and injected with TEOS/ethanol (1:4, v/v) solution (2.5 mL) for stirring about 1 min and then allowed to stand for 12 h. The $Fe_3O_4$@$SiO_2$ microspheres were collected magnetically, repeatedly washed by deionized water, and dried in a vacuum. After that, $Fe_3O_4$@$SiO_2$ was modified by vinyl groups. Briefly, $Fe_3O_4$@$SiO_2$ (250.0 mg) was dissolved in MPS solution (150.0 μL of MPS dispersed in 40.0 mL of water containing 10% acetic acid). After stirring for 5 h at 60 °C, the vinyl-modified $Fe_3O_4$@$SiO_2$ was magnetically gathered, repeatedly washed with water, and dried in a vacuum.[10,11] Finally, MMIPs were prepared in anhydrous acetonitrile via the surface-imprinted polymerization method. PCA (0.25 mmol) and 4-VP (1.0 mmol) were dissolved in anhydrous acetonitrile (6.0 mL), purged with $N_2$, and then stored in a refrigerator at 4 °C for 12 h to prepare preassembly solution. Then, vinyl-modified $Fe_3O_4$@$SiO_2$ (50.0 mg), EGDMA (5.0 mmol), and AIBN (20.0 mg) were dissolved in acetonitrile (15.0 mL) and added into the above solution, purged with $N_2$ on ice, and then allowed to proceed for 24 h at 60 °C under constant stirring. After polymerization, MMIPs were collected magnetically, rinsed with acetonitrile until the supernatant was clear, and then eluted with methanol/acetic acid (9:1, v/v) to remove the template absolutely, which was monitored by HPLC. Finally, the MMIPs were washed with methanol to neutral pH and dried overnight under vacuum at 50 °C.

As a control, the same procedures were applied for the preparation of magnetic nonmolecularly imprinted polymers (MNIPs) in the absence of PCA.

**Characterization.** The morphology of microspheres was observed by transmission electron microscopy (TEM) (JEM-2100F, JEOL, Japan). The infrared spectra (4000−400 $cm^{-1}$) were recorded on a Fourier transform infrared spectrometer (FT-IR) (Nicolet 6700, Thermo Nicolet Co., Waltham, MA, USA). The encapsulation efficiency of microspheres was determined by thermogravimetric analysis (TGA SDTQ600, TA, USA). Magnetization was measured at room temperature in a vibration sample magnetometer (VSM7407, Lake Shore Cryotronics, Westerville, OH, USA).

**HPLC Analysis.** Chromatographic separation was performed on a Zorbax SB-$C_{18}$ column (150 mm × 4.6 mm, 5 μm, Agilent, Santa Clara, CA, USA) in tandem with a Phenomenex $C_{18}$ guard cartridge (4.0 mm × 3.0 mm, Phenomenex, Torrance, CA, USA). The eluent was delivered from an Agilent 1260 HPLC quaternary pump (Agilent Technologies) equipped with an online vacuum degasser, an autosampler, a thermostated column compartment, and a diode array detector. The mobile phase consisted of A (0.4% acetic acid in water) and B (0.4% acetic acid in methanol), which was programmed as follows: 0−30 min, 20−50% B. The flow rate was 0.8 mL/min, the temperature was controlled at 25 °C, and UV detection was operated at 260 nm.

**Adsorption Experiments.** For equilibrium experiments, 10.0 mg of MMIPs/MNIPs was suspended in 3.0 mL of a series of PCA acetonitrile solutions with initial concentrations ranging from 0.05 to 6.0 mg/mL. The series of mixtures were shaken for 40 min at 298, 308, and 318 K, and then the equilibrium concentrations of PCA were detected by HPLC. The equilibrium adsorption capacity $Q_e$ (mg/g) was calculated according to the equation

$$Q_e = (C_0 - C_e)V/m \quad (1a)$$

where $C_0$ (μg/mL) represents the initial concentration of PCA and $C_e$ (μg/mL) is the equilibrium concentrations of PCA. $V$ (mL) is the volume of PCA solution, whereas $m$ means the mass of MMIPs/MNIPs (g).

Similarly, for kinetic experiments, 10.0 mg of MMIPs/MNIPs was suspended in 3.0 mL of a 1.0 mg/mL PCA acetonitrile solution. The mixtures were then continuously shaken at 298 K, and the concentrations of PCA in the supernatant at certain intervals (5, 10, 20, 30, 40, 50, 70, 100, 140, 180, and 220 min) were analyzed by HPLC; then the adsorption capacity $Q_t$ (μg/g) at different contact times $t$ was calculated as

$$Q_t = (C_0 - C_t)V/m \quad (1)$$

where $C_t$ (mg/mL) is the concentration of PCA at different contact times.

Selectivity adsorption was performed using PCA and its four structurally similar compounds (4-HBA, SA, CA,and GA) in individual standard solutions with the same initial concentrations of 1 mg/mL.

**Regeneration and Reuse Experiments.** MMIPs with loaded PCA were separated magnetically, rinsed with acetonitrile to reduce the nonspecific adsorption, and then eluted with 1.0 mL of methanol/cetic acid (9:1, v/v) for 30 min for PCA desorption, and then the regenerated MMIPs were reused for the next adsorption experiment.

**Extraction and Determination of PCA in Fruit Juices.** Grape juice, apple juice, pineapple juice, orange juice, and peach juice (Huiyuan Juice, Beijing Huiyuan Beverage and Food Co., Ltd., China) were purchased from a local market in Changsha. All kinds of fruit juices (50 mL) were first centrifugated at 8000 rpm for 20 min, and then the supernatants were adjusted to pH 7.0 by 1.0 mM NaOH aqueous solution and submitted to liquid−liquid extraction twice using an equivalent volume of ethyl acetate. The ethyl acetate extraction was concentrated on a rotary evaporator (Shanghai Yarong Biochemical Instrument Factory, Shanghai, China) under reduced pressure at 40 °C to yield dried residue. The residue was dissolved in 10 mL of acetonitrile and stored at 4 °C for further experiments.

MMIPs/MNIPs (10.0 mg) were suspended in 3.0 mL of fruit juice extract. After 40 min of shaking at 298 K, MMIPs/MNIPs were collected by a magnet and then washed with acetonitrile followed by

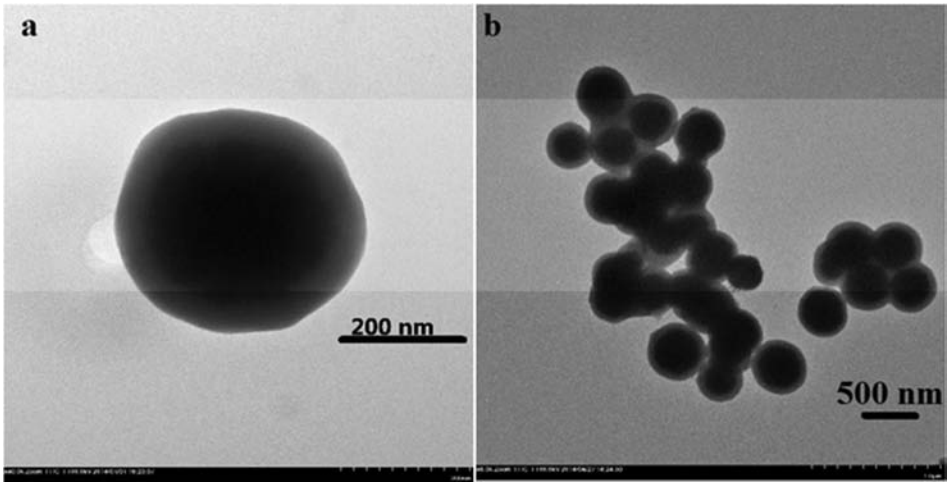

**Figure 1.** TEM images of $Fe_3O_4$@$SiO_2$ (a) and MMIPs (b).

3.0 mL of methanol/acetic acid (9:1, v/v) at 298 K for 30 min to release PCA. The eluates were analyzed by HPLC.

## RESULTS AND DISCUSSION

**Preparation of MMIPs.** MMIPs are prepared by surface-imprinted polymerization technology. The micro size of solid support has a large surface to volume ratio to provide abundant reaction sites for surface imprinting. Furthermore, the thin layer of MIPs is prepared on the surface of the solid support, which benefits the complete removal of template and the enhancement of mass transfer.[27] At the beginning, $Fe_3O_4$ microspheres were synthesized by solvothermal reaction, which have higher magnetic response than those prepared by coprecipitation method.[10,11] Then, well-dispersed $Fe_3O_4$@$SiO_2$ microparticles with magnetic core and silica shell were synthesized. Notably, our previous research indicated that the encapsulation of $Fe_3O_4$ with $SiO_2$ will improve their dispersion in water, reduce agglomeration phenomenon in repetitious magnetic separation, and then increase their reusability.[28] Moreover, a silica-like surface is easily modified with various groups through covalent reaction. After that, vinyl groups were introduced onto the surface of $Fe_3O_4$@$SiO_2$ with MPS for reaction with EDGMA to initiate the copolymerization of 4-VP and PCA in the presence of AIBN. Finally, MMIPs with surface binding sites were achieved by removal of templates.

The binding properties of MMIPs depend on various factors. To achieve high adsorption capacity with efficient recognition, some essential factors were investigated during the preparation procedures. Functional monomer is a key factor for the powerful molecular recognition of MIPs because the molecular recognition is based on the intermolecular interaction between the template and the functional monomer.[29] Templates containing phenolic substructures have been templated in the past, using both acidic and basic functional monomers; however, basic functional monomers associate more strongly with phenol derivatives, through hydrogen bonding between the basic nitrogen atom of the monomer and the phenolic proton.[30] Previous papers have reported the preparation of MIPs for PCA by bulk/precipitation polymerization, and basic AM has been selected as functional monomer.[18,19] Here, three kinds of basic functional monomers (4-VP, AM, and MAM) were selected to evaluate the specific recognition ability of MMIPs for PCA. Finally, 4-VP was considered as the optimum functional monomer because of the existence of strong electrostatic bonds and hydrogen-bonding interactions between pyridyl group of 4-VP and PCA as well as of the $\pi-\pi$ interactions between aromatic rings.[31] Thus, a more stable template−monomer complex between PCA and 4-VP can be formed in the imprinting process, which will lead to the formation of well-defined specific binding sites in MMIPs for high selectivity. Acetonitrile was selected as porogen, in which PCA and 4-VP was dissolved well. Moreover, the weak polarity solvent of acetonitrile was suitable for noncovalent molecular recognition of MIPs for strong polar molecule without any hydrophobic functional group.[32] The molar ratio of template−functional monomer−cross-linker was a critical factor in a successful imprinting protocol due to their effect on the number of recognition sites in synthesized MIPs and the quality of MIPs. Then different molar ratios of template−functional monomer−cross-linker (1:3:20, 1:4:20, 1:5:20, 1:4:16, 1:4:30, and 1:5:30) were evaluated and optimized. The results indicated that PCA−4-VP−EDGMA at 1:4:20 achieved highest adsorption capacity and molecular recognition ability of MMIPs. In addition, there is a competition between surface and bulk polymerization, which could affect the homogeneity of the MIP coating and then affect the binding capacity of MMIPs. Different quantities of $Fe_3O_4$@$SiO_2$ (25, 50, 75, and 100 mg) were used when the concentration of PCA was set at 0.25 mmol. Eventually, 50 mg of $Fe_3O_4$@$SiO_2$ was evaluated as the best choice.

**Characterization of MMIPs.** The particle size and morphology of $Fe_3O_4$@$SiO_2$ and MMIPs can be obviously observed by TEM (Figure 1). It can be seen that the core−shell structure of $Fe_3O_4$@$SiO_2$ microspheres with diameters of approximately at 400 nm were successfully prepared with regular spherical shape, relatively narrow size distribution, and good dispersity. About 50 nm thick $SiO_2$ shell was clearly seen to be uniformly coated on $Fe_3O_4$ dark core (Figure 1a). After the imprinting process, an external imprinted polymer layer of about 40 nm was clearly observed around $Fe_3O_4$@$SiO_2$ microparticles (Figure 1b), which suggested that the MIP layer had been successfully grafted on the surface of $Fe_3O_4$@$SiO_2$ microparticles. There were hardly any free $Fe_3O_4$, $SiO_2$, and MIPs microspheres in the TEM view. It was noted that the surface recognition sites could improve the mass transfer rate for adsorption and desorption of the template quickly.

In FT-IR spectra, the strong absorption peak at about 580 $cm^{-1}$ was characteristic of Fe−O vibration (Figure 2a), and the

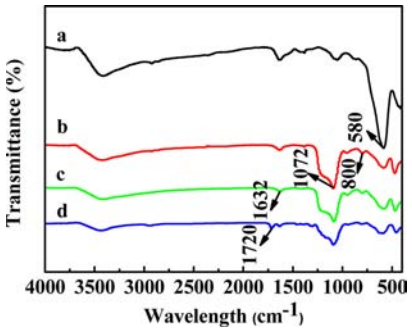

**Figure 2.** FT-IR spectra of $Fe_3O_4$ (a), $Fe_3O_4$@$SiO_2$ (b), vinyl-modified $Fe_3O_4$@$SiO_2$ (c), and MMIPs (d).

strong peaks around 1072 $cm^{-1}$ (Si−O asymmetric strenching vibration) and 800 $cm^{-1}$ (Si−O symmetric strenching vibration) displayed that $SiO_2$ was successfully encapsulated onto the surface of $Fe_3O_4$ microspheres (Figure 2b). The stretching vibration of C═C bonds at 1632 $cm^{-1}$ was attributed to the successful functionalization with vinyl groups (Figure 2c). The new adsorption peak of the C═O stretching band at 1720 $cm^{-1}$ for EDGMA showed that the MIPs were successfully coated on the surface of $Fe_3O_4$@$SiO_2$. The existence of C═C vibration indicated that not all of the EDGMA was cross-linked.[33]

TGA was performed to quantify the encapsulation. As shown in Figure 3, the small weight loss of about 5% at a temperature

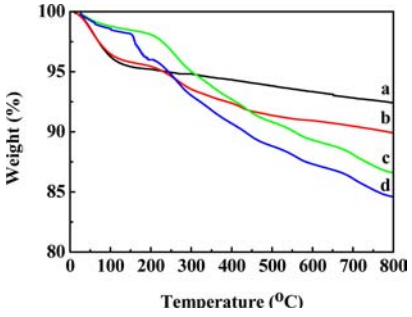

**Figure 3.** TGA curves of $Fe_3O_4$@$SiO_2$ (a), vinyl-modified $Fe_3O_4$@$SiO_2$ (b), MMIPs (c), and MNIPs (d).

of <200 °C was attributed to the elimination of water in samples. After that, $Fe_3O_4$@$SiO_2$ showed a weight loss of about 2% when heated to 800 °C, probably due to some contaminations. About 4% more weight loss was observed for vinyl-modified $Fe_3O_4$@$SiO_2$ because of the decomposition of grafted MPS. Significant weight loss of MMIPs (11%) and MNIPs (14%) could be observed. The slight difference may be come from the different grafting density caused by the template.

The magnetic saturation of MMIPs was about 20 emu/g, which was lower than that of $Fe_3O_4$ microspheres (56 emu/g) (Figure 4). This might be related to the magnetic inactive layer containing $SiO_2$ and imprinted polymer layers. However, the decrease did not seriously affect the magnetic separation of MMIPs, and they remained strongly magnetic and could be accumulated within 10 s in solution under a conventional magnet and dispersed quickly with a slight shake once the magnetic field was removed, which indicated that MMIPs were successfully synthesized with high magnetic responsivity. No

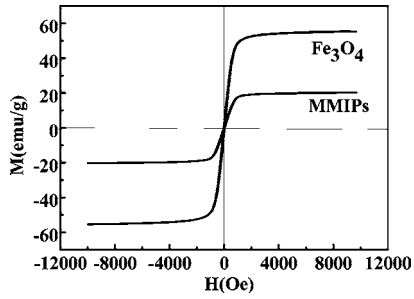

**Figure 4.** Magnetization curves of $Fe_3O_4$ and MMIPs.

remanence was detected after removal of the applied magnetic field, revealing that MMIPs was superparamagnetic.

**Adsorption Isotherms.** Figure 5a shows characteristic adsorption isotherms at 298 K. It was obvious that the equilibrium adsorption capacity of PCA on MMIPs/MNIPs increased first and then became saturated when the concentration reached 0.4 mg/mL. The equilibrium adsorption capacity of PCA on MMIPs was 7.5 mg/g, 1.5 times that on MNIPs (5.3 mg/g), which might result from the imprinting effect. That is to say, MMIPs had a significantly specific adsorption to PCA for the existence of imprinting phenomenon, and MNIPs showed low adsorption ability because of the randomly distributed functional groups on the surface. Therefore, MMIPs can selectively extract PCA from complex matrices. It was noted that equilibrium adsorption capacity of PCA on MMIPs (calculated to be 68.7 mg/(g, MIPs)) was largely higher than that for previously reported traditional MIPs (34.7 $\mu$g/g and 0.16 mg/g).[18,19] We have previously prepared MMIPs using benzoic acid/4-HBA as template, 4-VP as functional monomer, and acetonitrile as porogenic solvent;[10] their equilibrium adsorption capacities of PCA were a little lower (<65 mg/(g, MIPs)) because of the complementary specific sites for template. Clearly, MIPs grafted on microparticles can take measure to ensure almost all of the imprinting sites on surface and then increase the accessibility of template to the recognition sites for high binding capacity.

Figure 5b shows adsorption isotherms of PCA on MMIPs with the temperature at 298, 308, and 318 K. The equilibrium adsorption capacities of PCA increased with the increment of temperature, which corresponded with previous investigation that MIPs prepared at higher temperature tend to work better at higher temperature because of the similar 3D structures.[34] Moreover, lower viscosity and surface tension of the solvent at higher temperature improved wetting of the MMIPs, which was then to a certain extent led to higher binding capacity. To further estimate the binding properties of MMIPs and MNIPs, two classical isotherm models, Langmuir and Freundlich equations, were selected to fit the experimental data. The Langmuir equation $[1/Q_e = 1/(K_L C_e Q_m) + 1/Q_m$, where $Q_m$ is the maximum adsorption capacity (mg/g) and $K_L$ is a characteristic constant (mL/mg)] can be used to describe a monolayer adsorption, whereas the Freundlich equation $[\log Q_e = (\log C_e)/n + \log K_F$, where $n$ and $K_F$ are Freundlich constants] can be used to describe a monolayer adsorption as well as a multilayer adsorption. Table 1 summarizes the fitted parameters $Q_m$, $K_L$, $K_F$, $n$, and $R^2$ (correlation coefficient), which revealed that the Langmuir equation with $R^2 > 0.99$ was found to better fit the isotherm data. Moreover, the saturated adsorption capacities of MMIPs for PCA at different temperatures were

| | 318 | 2.39 | 7.75 | 0.995 | 2.14 | 4.02 | 0.971 |

greatly higher than those of MNIPs, which indicated that MMIPs showed higher binding affinity for PCA than MNIPs.

**Adsorption Kinetics.** The kinetic curves of PCA adsorption on MMIPs/MNIPs at 298 K are illustrated in Figure 6. As we can see, the adsorption capacity of PCA

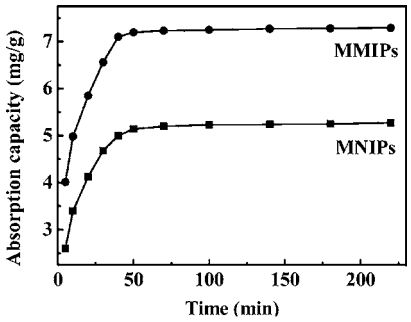

**Figure 6.** Kinetic adsorption curves of MMIPs/MNIPs for PCA at 298 K.

increased with the increment of adsorption time. The adsorption of PCA on MMIPs reached adsorption equilibrium at 40 min, suggesting that the adsorption is a fast process, and then 40 min was chosen as optimal extraction time. In comparison, traditionally imprinted materials would take 12–24 h to reach adsorption equilibrium.[17] Therefore, surface imprinting technology provided binding sites at the surface of microparticles, which then showed the advantage of faster mass transfer and binding kinetics.

The Lagergren pseudo-first-order equation [$\ln(Q_e - Q_t) = \ln Q_e - K_1 t$), where $K_1$ is the pseudo-first-order rate constant ($min^{-1}$)] and pseudo-second-order equation [$t/Q_t = t/Q_e + 1/(Q_e^2 K_2)$, where $K_2$ is the pseudo-second-order rate constant] were used to analyze the kinetic data according to our previous report to determine the rate-controlling and mass transfer mechanisms.[10] The corresponding parameters by two kinetic models were calculated and are displayed in Table 2. It could be concluded that the pseudo-second-order rate equation was considered as the better-fit model from high $R^2$ (>0.99) and close data between calculated $Q_e$ and experimental data suggested. Similar results were reported for adsorption of hydrobenzoic acids on MMIPs.[10]

**Selectivity Adsorption for PCA.** Molecular recognition ability of MMIPs was mainly dependent on the bonding between MMIPs and adsorbed components, and then the binding ability was related to similarity between template and adsorbed components in functional groups, size, and shape. It is obvious in Figure 7 that adsorption capacities of five components (PCA, 4-HBA, SA, GA, and CA) on MNIPs (nonspecific adsorption) had no significant difference. In comparison, the adsorption capacities of five selected components on MMIPs were much higher than those on MNIPs. The difference results illustrated the success of the imprinting process. Although five selected components had close structural homology, the adsorption capacity of PCA was about 1.21, 1.79, 1.48, and 1.81 times that for 4-HBA, SA, GA,

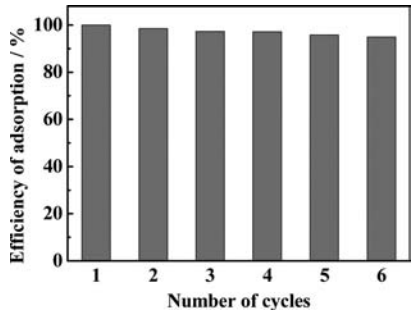

**Figure 8.** Reusability of MMIPs (mean values of five batch samples).

and CA, which was because the specific sites in MMIPs were complementary in shape, size, and spatial distribution to match PCA. The selectivity of MMIPs was further evaluated using three parameters: the distribution coefficient ($K_d$), selectivity coefficient ($K$), and relative selectivity coefficient ($K'$). As shown in Table 3, $K'$ values were >1, which showed a higher binding selectivity of MMIPs than MNIPs for PCA than other tested similar compounds. However, in our previously prepared MMIPs using benzoic acid/4-HBA as template, the $K'$ values ($K' = K_{MMIPs}/K_{MNIPs}$, $K' = K_{d(template)}/K_{d(PCA)}$) for PCA were <1.[10] This could be attributed to the imprinting effect. The comparison result of the adsorption capacity was attributed to the molecular analogue degree of detected compounds to the template molecule. Although 4-HBA, SA, and GA had close structural homology with PCA, except for the numbers and positions of phenolic hydroxyl groups, the lower adsorption capacity was probably because there were no specific imprinted sites for compounds with different molecular size and stereochemistry. For CA, the steric effect of the acrylic group presumably prevented it from entering into the binding cavities, and as a result, weak binding capacity was detected. These data indicated the imprinting effect of MMIPs could make sense for selective extraction of PCA from real complex samples, so the characteristics of MMIPs were superior to those of traditional inefficient selective adsorbents.

**Reusability of MMIPs.** Our previous paper indicated that methanol/acetic acid (9:1, v/v) could weaken the noncovalent interactions between hydroxybenzoic acids and MIPs and then was considered as the optimum desorption solvent to recover template and regenerate MIPs.[11] The optimum desorption time was selected as 30 min according to the desorption ratio (about 96%). The reusability of MMIPs was investigated by monitoring the efficiency of adsorption of five batch samples for great cost benefit on extending its applications. As shown in Figure 8, after six consecutive adsorption−desorption cycles under the same conditions, the efficiency of adsorption was still as high as 94.9% of the first one. The results manifested that MMIPs were stable and six cycles had little influence on its efficiency of adsorption.

**Method Validation.** The MMIPs as adsorbent for extraction and enrichment of PCA and the HPLC-UV method for analysis of PCA had been established. Then the application of the method was evaluated by determining its performance characteristics regarding linearity, reproducibility, accuracy, precision, limit of detection, ruggedness, and robustness. Using the standard curve based method, the ratios of the HPLC peak areas ($A$) with respect to the corresponding concentrations of PCA ($C$) were found to be linear from 1 to 100 $\mu$g/mL with $R^2$ value at 0.9996. The regression equation was $A = 62.6C + 22.7$. The limit of detection (S/N = 3) for PCA was 0.5 $\mu$g/mL, which was sufficient for PCA determination in real samples.

The intraday and interday precisions were investigated by extraction and analysis of PCA-spiked reference standard in grape juice at low, medium, and high concentration levels five times per day and for six consecutive days. The RSD values of intraday precisions ranged from 1.0 to 5.0% ($n = 6$), which were indicative of high reproducibility, and the RSD values of interday precisions over a six-day span were all <6.0%. Indeed, acceptable recovery values, ranging from 92 to 107% with RSD <5%, were obtained for PCA. The results showed that the proposed MMIP extraction and HPLC analysis method was sufficiently accurate, selective, and practical for the determination of PCA from complex matrices.

**Analysis of Fruit Juices.** Fruit juices produced from fruit are very complex matrices, which subsequently can cause matrix effects during the extraction process. For this reason, it was necessary to apply a selective pretreatment step to isolate target components from complex matrices before HPLC analysis. PCA is a polar component with retention time at 5.60 min, and from 3D UV−vis spectra, we can see interferences that had almost the same retention time as PCA in grape juice (Figure

**Table 3. Selectivity Parameters of MMIPs/MNIPs[a] ($n = 3$)**

| | | PCA | 4-HBA | SA | GA | CA |
|---|---|---|---|---|---|---|
| MMIPs | Q (mg/g) | 7.56 ± 0.5 | 6.23 ± 0.4 | 4.22 ± 0.3 | 5.12 ± 0.4 | 4.17 ± 0.2 |
| | $K_d$ (mL/g) | 7.71 | 6.32 | 4.25 | 5.19 | 4.18 |
| | $K$ | | 1.22 | 1.81 | 1.48 | 1.84 |
| MNIPs | Q (mg/g) | 5.22 ± 0.3 | 4.92 ± 0.4 | 3.11 ± 0.2 | 4.31 ± 0.3 | 3.18 ± 0.2 |
| | $K_d$ (mL/g) | 5.29 | 4.98 | 3.23 | 4.37 | 3.21 |
| | $K$ | | 1.06 | 1.64 | 1.21 | 1.65 |
| | $K'$ | | 1.15 | 1.10 | 1.22 | 1.11 |

[a] $K_d$ = binding amount/equilibrium concentration, $K = K_{d(PCA)}/K_{d(similar\ components)}$, $K' = K_{MMIPs}/K_{MNIPs}$.

9a). Therefore, quantitative analysis results of PCA in grape juice by HPLC-UV method without selective pretreatment

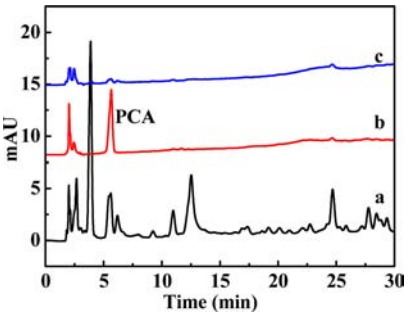

**Figure 9.** Chromatograms of grape juice (a) and the elutions with methanol/acetic acid (9:1, v/v) from MMIPs (b) and MNIPs (c).

process were sometimes imprecise. PCA was then selectively adsorbed and enriched onto MMIPs (Figure 9b), and the peak of PCA appeared distinctly, whereas no obvious PCA peak was observed in the eluted solution MNIPs (Figure 9c), which also demonstrated the selectivity of MMIPs. Therefore, the content of PCA in grape juice was easily found to be 0.45 $\mu$g/mL. However, PCA was not detected in apple juice, pineapple juice, orange juice, and peach juice, which agreed well with values reported in the literature.[35] The results indicated that the prepared MMIPs were very suitable to be directly exploited in efficient and selective enrichment and determination of trace PCA in complex matrices (e.g., juices, foods, natural products, biological samples).

Supporting Information

**ABSTRACT:** The baking activity of two different lipases was evaluated by a microbaking test on a 10 g flour basis, and the altered lipid composition of lipase-treated wheat lipids was quantitated. To identify and quantitate the various lipid classes, pure glycolipids and phospholipids were isolated from a wheat flour lipid extract by a silica gel batch procedure and silica gel column chromatography. These reference compounds were used to establish a high-performance liquid chromatographic method with evaporative light scattering detection, which was able to separate all of the wheat lipid classes and lipase reaction products. Wheat lipids, dough lipids, and dough lipids after lipase addition were quantitated using cholesterol as an internal standard. Especially digalactosyl diglycerides (−0.9 mmol/kg flour), monogalactosyl diglycerides (−0.4 mmol/kg), and *N*-acyl-phosphatidyl ethanolamine (−0.3 mmol/kg) were hydrolyzed, and a concomitant formation of digalactosyl monoglycerides (+0.6 mmol/kg), monogalactosyl monoglycerides (+0.6 mmol/kg), and *N*-acyl-lysophosphatidyl ethanolamine (+0.5 mmol/kg) was found. The lipase-induced changes of the lipid fraction caused increases in bread volume of 56−58%, depending on the type and concentration of the added lipase. The current results confirm the important relationship between the lipid fraction composition and the baking performance of flour.

**KEYWORDS:** *lipase, wheat lipids, HPLC-ELSD, microbaking test*

## INTRODUCTION

The lipid content of wheat is considered of utmost importance for the baking performance of wheat flour. Wheat grain usually contains 3−4% lipid depending on genetics and growth conditions, while wheat flour contains 1−2.5% lipid depending on the raw materials and milling conditions. Wheat flour lipids are divided into two major groups based on their location and functionality. Two-thirds are nonstarch-bound lipids and one-third is starch-bound lipids.[1] Starch lipids are primarily composed of lysophospholipids, which form inclusion complexes with amylose helices in native starch.[2] Only the nonstarch lipids are considered to be active in baking.[3] Nonstarch lipids are extractable at room temperature (RT) and can be further subdivided into free and bound lipids according to the solvent used for their extraction.

Although lipids are present in wheat in considerably lower levels than are starch and protein, they exhibit important functional properties in breadmaking. Several studies have examined the functionality of endogenous wheat flour lipids in breadmaking based on fractionation and reconstitution methods, as reviewed in detail by Pareyt et al.[4] It was also shown that the improved bread properties were mainly due to the polar wheat lipids,[5,6] and glycolipids are considered more active than phospholipids as suggested by De Stefanis and Ponte.[7]

In the past few decades, demands for consistent quality in baked goods led to the application of a wide range of additives in the baking industry. Beside synthetic emulsifiers such as diacetyl tartaric esters of mono- and diglycerides (DATEM) or sodium stearoyl-2-lactylate (SSL), lipases along with other enzymes are being used to improve the baking quality of wheat flour. Currently available lipases for baking applications hydrolyze a number of different lipid structures in flour and lead to improved surface activity of these endogenous lipids, thus resulting in the significant increase in bread volume after baking.[10] The specific improving effect of individual lipases is mainly considered to be due to their preference for certain lipid classes, resulting in the formation of a lipase-specific range of products.[8] In particular, this has been shown by Gerits et al.,[9,10] who also suggested theories on the mechanism of action. Altogether, information about lipase-generated lipids is known to some extent for single components, but in-depth understanding of lipase-mediated reaction products is missing, and especially information regarding the function of lipid mixtures generated by the action of lipases is still very scarce.

The aim of this study was to quantitate lipids from wheat flour and wheat dough after the addition of two different commercial lipases. Therefore, the generation of lipase reaction products and the consumption of the lipase substrates were quantitatively analyzed. Different lipase concentrations as well as two different lipid extraction procedures were used. The functional effects of lipases in baking were demonstrated by microscale baking tests using 10 g of flour, and classical surfactants such as DATEM and SSL were used as benchmarks. Quantitation of wheat lipids required obtaining reference compounds either by isolation from wheat lipids or by lipase-aided hydrolysis from isolated compounds and fractions. High

performance liquid chromatography coupled to an evaporative light scattering detector (HPLC-ELSD) based on a method published by Gerits et al.[9,10] was applied for lipid analysis with the aim to separate all polar and nonpolar wheat lipid classes, as well as the lipase reaction products, in a single HPLC run. In contrast to Gerits et al.,[10] absolute concentrations of lipid classes were determined.

## MATERIALS AND METHODS

**Wheat Flour.** 'Kolibri' flour, a commercial flour obtained from a mixture of wheat cultivars (Meneba, Rotterdam, The Netherlands, 2012 harvest), was characterized as follows. The moisture and ash contents of the flour were determined according to ICC Standards 110[12] and 104,[13] respectively. Nitrogen contents were determined by means of the method of Dumas on a TruSpec N nitrogen analyzer (Leco, Kirchheim, Germany). A conversion factor of 5.7 was used to calculate the crude protein content from the nitrogen content. Analytical characteristics of the flour were 13.3% moisture, 10.7% protein (dry mass), and 0.52% ash (dry mass).

**Chemicals and Reagents.** Fresh baker's yeast was obtained from Wieninger GmbH (Passau, Germany). All solvents used were HPLC or LC−MS grade and from Sigma-Aldrich (Steinheim, Germany). The following reagents were purchased from the sources given in squared brackets: L-α-phosphatidic acid sodium salt from chicken egg (PA), L-α-phosphatidyl ethanolamine from chicken egg (PE), L-α-phosphatidyl choline (95%) from chicken egg (PC), L-α-phosphatidyl serine sodium salt from soy (PS), L-α-phosphatidyl inositol sodium salt from soy (PI), monogalactosyl diglyceride (MGDG), digalactosyl diglyceride (DGDG), 1-oleoyl-2-hydroxy-*sn*-glycero-3-phosphate sodium salt (LPA), L-α-lysophosphatidyl choline from soy (LPC), 1-oleoyl-2-hydroxy-*sn*-glycero-3-phospho ethanolamine (LPE), L-α-phosphatidyl glycerol sodium salt from soy (PG), 1-oleoyl-2-hydroxy-*sn*-glycero-3-phospho-(1′-rac-glycerol) sodium salt (LPG), 1-oleoyl-2-hydroxy-*sn*-glycero-3-phospho-L-serine sodium salt (LPS), L-α-lysophosphatidyl inositol sodium salt from soy (LPI) [Avanti Polar Lipid through Otto Nordwald GmbH, Hamburg, Germany]; steryl glucosides (SG), acylated steryl glucosides (ASG), ceramides (*N*-acyl-sphingosine) (CER), glucocerebrosides (cerebroside) (CBR) [Matreya LLC through Bio Trend, Cologne, Germany]; Monomuls 90−35 (monoglycerides containing 75% stearic and 35% palmitic acid, monoglyceride content 90%), Lametop 300 (80% DATEM, 20% calcium carbonate as anticaking reagent); Prefera SSL 6000 [BASF, Illertissen, Germany]; glyceryl-1,3-distearate, glyceryl trioleate, ethanolamine (>99%), acetic acid eluent additive for LC−MS [Sigma-Aldrich, Steinheim, Germany]; silica gel G 60 (0.04−0.063 mm), silica gel (0.063−0.200 mm), concentrating zone-high performance thin layer chromatography (HPTLC) plates (20 × 10 $cm^2$) coated with silica gel G 60 on glass, concentrating zone-HPTLC plates (20 × 20 $cm^2$) coated with silica gel G 60 on glass [VWR Merck, Darmstadt, Germany]; commercial enzyme granulate Lipopan F-BG (25.0 KLU/g), commercial enzyme granulate Lipopan Xtra-BG (7.2 KLU/g) [Novozymes A/S, Bagsvaerd, Denmark]. *N*-acyl phosphatidyl ethanolamine and monogalactosyl monoglyceride were obtained from Novozymes (Bagsvaerd, Denmark).

**Lipid Extraction from Flour.** Two different lipid extraction methods were compared regarding the extracted lipid composition. Lipids were extracted from flour using water-saturated 1-butanol (WSB) or 2-propanol at 75 °C. WSB was obtained when HCl (1 L; 80 mmol/L) and 1-butanol (2.5 L) were stirred for 15 min. Subsequently, the water phase was removed using a separating funnel. For each extraction, flour (1000 g) and WSB (3.5 L) were stirred at RT for 16 h. After centrifugation (20 min, 4 °C, 3550 g), the solvent was removed and collected by filtration on a glass filter (porosity 3, pore size 16−40 μm). The combined extracts were evaporated to dryness on a rotary evaporator (Büchi, Rotavapor R-210). The defatted flour was spread out on a flat glass tray in a fume hood for one week. The second extraction method used 2-propanol at 75 °C as the extraction solvent according to Chung et al.[14] The defatted flour was dried as described for the WSB-defatted flour.

**Lipid Extraction from Dough.** The dough was prepared from 50 g of flour by upscaling the recipe for 10 g of flour used by Köhler and Grosch.[15] The ingredients were as follows: flour (50 g), water (27.2 mL), NaCl (1.0 g), sucrose (0.5 g), fresh baker's yeast (3.5 g), L-*threo* ascorbic acid (20 mg/kg flour), and lipase (0−170 mg/kg flour; Lipopan F-BG or Lipopan Xtra-BG, Novozymes, Bagsvaerd, Denmark). The flour, NaCl, sucrose, baker's yeast, and lipase were premixed dry for 1 min in a Farinograph (50 g Z-blade mixer, Brabender, Duisburg, Germany) at 22 °C. Ascorbic acid solution (1.5 mL, 0.67 g/L) and water (27.2 mL) were added within 25 s and mixing was continued until the optimum consistency of the dough (550 Brabender units at 7 min) was reached. The dough was divided into two equal pieces, one was immediately frozen with liquid $N_2$, and the other one was allowed to rest (20 min, 30 °C, water-saturated atmosphere). The dough was then reshaped on a dough rounder (Type 440, Brabender, Duisburg, Germany) for 10 cycles, and the resulting spherical dough piece was rolled (PTFE cylinder; diameter, 5 cm; length, 30 cm) to yield an oval dough piece of 5 mm thickness. The dough piece was folded twice to $^1/_4$ of its original size and was reshaped on the dough rounder for 20 cycles. After proofing (30 °C, water-saturated atmosphere, 38 min), the dough was also frozen in liquid $N_2$. Both dough pieces were freeze-dried and milled using an ultracentrifugal mill ZM 200 (200 μm mesh size, Retsch, Haan, Germany).

Lipids were extracted from the freeze-dried dough powder (10.0 g) by the powder being stirred with WSB (40 mL, 16 h, RT) or 2-propanol (80 mL, 2 h, 75 °C). After centrifugation (5 min, 4 °C, 3550 g), the supernatant was filtered (0.45 μm), and the solvent was evaporated to dryness using a rotational vacuum concentrator (Christ, Osterode, Germany) and stored under an Ar atmosphere at −75 °C until further analysis.

**Isolation of Lipid Reference Compounds.** Reference compounds for the identification and quantitation of lipid classes by HPTLC and HPLC-ELSD were isolated from wheat flour by WSB-extraction. The lipids (6 g) were prefractionated using a preparative solid-phase extraction protocol for complex lipid mixtures ("batch procedure") according to Selmair and Koehler,[6] and all batches were examined by thin layer chromatography.[6] A crude glycolipid fraction was obtained, which was further separated by column chromatography to obtain three pure glycolipid classes, ASG, MGDG, and DGDG, as reported by Selmair and Koehler[6] and three further fractions containing mixtures of lipid classes. The latter three fractions (mixtures of SG/MGDG, NAPE/DGDG, and NAPE/NALPE/PC/DGMG) were further purified by column chromatography. The separation of the fraction containing SG and MGDG was performed by column chromatography using activated silica gel. The silica gel (G 60, 0.040−0.063 mm) was activated as follows: 200 g of silica gel were dried overnight at 105 °C and left to cool in a desiccator. After the addition of water (10 mL), the material was shaken for 20 min. The activated silica gel was dispersed in dichloromethane/acetone/2-propanol (60/39/1, v/v/v), poured into a glass column, and packed to a height of 38 cm (diameter 2 cm). The sample was dissolved in 2 mL of chloroform and applied to the column. The lipids were eluted with 1 L of dichloromethane/acetone/2-propanol (60/39/1, v/v/v). Each fraction was evaporated and examined by HPTLC (see above). Fractions comprising the same pure lipid class were recombined, evaporated to dryness, and weighed.

The fraction containing NAPE and DGDG was separated by silica gel chromatography (35 × 2 $cm^2$) in the same manner as described above using the eluent dichloromethane/methanol (87/13, v/v; 600 mL) and dichloromethane/methanol (83/17, v/v; 400 mL).

To obtain pure NALPE, the fraction containing NAPE, NALPE, PC, and DGMG was separated using column chromatography in the same manner as described above. The eluents were dichloromethane/methanol (87/13, v/v; 1 L), dichloromethane/methanol (80/20, v/v; 500 mL), and methanol (200 mL).

**Synthesis of Digalactosyl Monoglyceride (DGMG).** Isolated DGDG (105 mg) was emulsified in phosphate buffer (5 mL, pH 6.9, 50 mmol/L) with a T8 Ultra-Turrax (IKA Labortechnik, Staufen) and Lipopan F (5.0 mg) was added. The suspension was incubated for 2 h

dx.doi.org/10.1021/jf5022434 | J. Agric. Food Chem. 2014, 62, 8229−8237

at 30 °C in a thermo shaker (HLC BioTech, Bovenden, Germany). The lipids were extracted with chloroform (4 × 5 mL) and separated by activated silica gel column chromatography (3 × 27 $cm^2$) using dichloromethane/methanol (500 mL 84/16, v/v; 500 mL 82/18, v/v; 500 mL 77/23, v/v; 200 mL methanol) as the mobile phase. Each fraction was evaporated and examined by HPTLC (see above). Fractions containing DGMG were combined and evaporated to dryness.

**Nuclear Magnetic Resonance (NMR) Spectroscopy.** The $^1H$ and two-dimensional NMR spectra ($^1H$, COSY ($^1H^1H$, correlated spectroscopy), HMQC ($^1H^{13}C$, heteronuclear multiple quantum coherence), and HMBC ($^1H^{13}C$, heteronuclear multiple bond correlation)) of NALPE and DGMG were recorded on a Bruker AMX 400 II Ultrashield spectrometer (400 MHz, Bruker Biospin, Rheinstetten, Germany) and the $^{13}C$ NMR spectra were recorded on a Bruker AMX 360 spectrometer (360 MHz, Bruker Biospin, Rheinstetten, Germany). All of the experiments were conducted at a temperature of 25 °C. Chemical shift values $\delta$ (in ppm) are given relative to the signal for internal tetramethylsilane (TMS, $\delta = 0$). The values for coupling constants $J$ are given in Hz (see Supporting Information).

**HPLC-ELSD Analysis of Lipid Mixtures.** A HPLC-ELSD analysis was conducted on a 100 × 2 mm Chromolith Performance Si column with a 5 × 4.6 mm security guard Chromolith precolumn (Merck, Darmstadt, Germany). A Jasco HPLC (PU-1580; Gross-Umstadt, Germany) was used in combination with a Jasco autosampler (AS-2057 Plus), a Jasco HPLC Pump (PU-1580), a Jasco Ternary Gradient Unit (LG-1580−02), and a ThermaSphere TS-130 column oven (Phenomenex, Aschaffenburg, Germany) set at 40 °C. The detector was a Sedex 85 ELSD (Sedere, Alfortville, France). The carrier gas used was compressed air with a pressure of 0.35 MPa. The evaporation chamber was kept at 40 °C, the gain was set at 3 or 8, and for the computerized analysis, the software KromaSystem 2000 (Version 1.60) was used.

The gradient of the HPLC solvent was based on the method of Graeve and Janssen[11] for marine lipids. Gerits et al.[9] adapted the procedure for wheat flour lipids to improve the separation of the polar lipid classes; however, further optimization was carried out to separate all wheat flour lipids and lipase reaction products. Table 1 lists the mobile phase solvent gradient. The composition of the three solvent mixtures and the gradient were adapted to improve the separation of glycolipids and phospholipids since not all lipid classes were separated with the gradient of Gertis et al.[9] With the optimized procedure, all nonpolar lipids, glycolipids, and phospholipids were separated in one single run, but for quantitation, two runs at different gain settings were necessary to get signals suitable for calculation. Calibration curves were generated from the isolated or purchased lipid reference compounds, respectively. Two standard mixtures with concentrations of 0.05 μg/μL, 0.1 μg/μL, 0.2 μg/μL, and 0.3 μg/μL of each reference compound were prepared. The solvent was chloroform/methanol (50/50, v/v) containing cholesterol as the internal standard (250 mg/L) as suggested by Gerits et al.[10] The first standard mixture consisted of FFA, MG, CER, SG, NAPE, NALPE, and DGMG; the second mixture contained DG, CBR, ASG, MGDG, MGMG, PC, and LPC. The calibration curves for the lipid classes were obtained by injecting the standard mixtures (10 μL) and monitoring the ELSD-signal at gain 8. The calibration curves of TG and DGDG, which were present in high concentrations, were acquired at a low sensitivity (gain 3) with absolute amounts of TG and DGDG of 5, 10, 15, and 20 μg. The calibration curves were plotted as the peak area ratio (sample/cholesterol) versus the amount of each sample. In all of the calibration and quantitative separations, the inject volume was 10 μL, thus cholesterol was always present in the same amount while the amounts of the analytes varied.

The extracted lipids from flour or dough were dissolved (5 mg lipid extract/mL) in chloroform/methanol (50/50, v/v) containing cholesterol as an internal standard (0.25 mg/mL). The samples (10 μL) were injected into the HPLC column (10 μL) and analyzed by HPLC-ELSD. The ELSD-signal was monitored at gain 3 for TG and DGDG and at gain 8 for all other lipid classes (one run per gain setting).

**Microbaking Test (MBT).** The microbaking test using 10 g of flour was conducted as described by Köhler and Grosch.[15] The appropriate amount of water was determined by a modification of the ICC standard procedure 115 (22 °C instead of 30 °C).[16] Flour (10 g), NaCl (0.2 g), sucrose (0.1 g), baker's yeast (0.7 g), and different amounts of lipases (30−170 mg/kg) or surfactants (0.2−0.8%) were premixed dry for 1 min in a microfarinograph (10 g Z-blade mixer, Brabender, Duisburg, Germany) at 22 °C. An L-*threo*-ascorbic acid solution (0.3 mL, 0.67 g/L) and water (5.44 mL) were added within 25 s and the mixing was continued until the optimum consistency of the dough (550 BU at 7 min) was reached. After removal from the mixer, the dough was fermented (20 min, 30 °C, water-saturated atmosphere). The dough was then reshaped on a dough rounder (custom-made) for 10 cycles. The resulting dough ball passed through the rolls (3 mm roll-gap) of an AMPIA-pasta machine (model 150 mm—Deluxe, Marcato, Italy) to form an oval dough piece. This piece was folded twice to $^1/_4$ of its original size and reshaped on the dough rounder for 20 cycles. The dough was then proofed (30 °C, water-saturated atmosphere, 38 min) and baked (180 °C increasing to 250 °C, 10 min) on an automatic proofing−baking line.[5] The volume of the bread was determined using a benchtop laser-based device (VolScan Profiler, Stable Micro Systems, Godalming, U.K.).

**Micro-Rapid-Mix Test (MRMT).** The dough was microbaked with 10 g of flour and mixed at high-speed for 1 min according to Köhler and Grosch[15] except that the proofing and baking was done in-line with an automatic proofing-baking device. The recipe and additives were the same as described for the MBT.

**Statistical Analysis.** Triplicate determinations were carried out for each control bread and each concentration of additive. The data was statistically evaluated using Microsoft Office Excel 2010 (Microsoft Corporation, Seattle, WA). The following values were used to rate the levels of significance: $p > 0.05$, not significant; $p < 0.05$, statistically significant; $p < 0.01$, significant; and $p < 0.001$, highly significant. The statistical evaluation of all quantitative data was carried out via one-way analysis of variance (ANOVA) using the software Sigma Plot 11.0 (Systat, San José, CA).

## RESULTS AND DISCUSSION

**Reference Compounds for the Quantitation of Wheat Lipid Classes.** Quantitative methods require reference

dx.doi.org/10.1021/jf5022434 | J. Agric. Food Chem. 2014, 62, 8229−8237

compounds for calibration and all relevant lipid classes from wheat are to be available. For this purpose, pure lipid classes were isolated from wheat flour lipids to obtain reference compounds for HPLC-ELSD analysis. WSB-extracted wheat lipids were prefractionated by a batch procedure into a nonpolar lipid fraction and two polar fractions.[6] The latter were a crude glycolipid and a phospholipid fraction. The glycolipid fraction was further separated by column chromatography into pure fractions of ASG (yield: 4.7%, 103 mg), MGDG (yield: 8.3%, 182 mg), and DGDG (yield: 29%, 650 mg). However, further fractions contained mixtures of lipid classes; therefore, SG, CBR, MGMG, NAPE, NALPE, and DGMG could not be isolated with this column. Thus, mixtures of these compounds had to be further purified by column chromatography.

Nonstarch wheat lipids contain an average of 3% DGMG, but the isolated amount was not sufficient for subsequent purification. Hence, the isolated DGDG was hydrolyzed to DGMG by incubation with Lipopan F at 30 °C in a phosphate buffer. After purification by silica gel column chromatography, DGMG was obtained in a yield of 30% (32 mg). The byproduct MGMG was also isolated with a yield of 8% (9 mg) because impurities of MGDG present in the initial DGDG-fraction were also hydrolyzed by the lipase. These pure glycolipid classes were identified by HPTLC[5] and HPLC-ELSD having used authentic reference compounds commercially available in small amounts. The identity of DGMG and NALPE were verified by NMR because no reference compounds were commercially available. NMR data and structures of DGMG and NALPE are given in the Supporting Information.

**HPLC-ELSD Method to Quantitate Wheat Lipid Classes.** For wheat lipid analysis, an optimized HPLC-ELSD procedure with a ternary gradient of the mobile phase was used. The gradient was optimized in numerous steps to be able to separate all relevant lipid classes that were considered (Table 1). A typical chromatogram of wheat lipids is shown in Figure 1. Only the separation of LPC was complicated because of the irregular baseline at this part of the chromatogram. This affected the accuracy of the quantitative determination of this compound. Table 2 shows the retention times of the 27 reference compounds that were separated in one single run. The different classes of wheat lipids were present in a wide range of concentrations (e.g., ~40% TG vs ~3% PC based on total wheat lipids) so that two different sensitivities of the ELSD (separate runs for gain 3 and gain 8) were necessary to get peaks suitable for quantitation of all of the wheat lipid classes. The relative responses (i.e., signal intensity per mass unit of lipid) of the different lipid classes varied according to the lipid type and the injected amount so that nonlinear relationships between the ratio of the signal intensities (sample/internal standard) and the ratio of the quantities (sample/internal standard) were obtained. Depending on the lipid class, different polynomial calibration curves were fitted from as many calibrators as possible (0.5–3.0 $\mu$g (gain 8), 5–20 $\mu$g (gain 3)).

**Lipid Composition of Flour and Dough Lipids without Lipase Addition.** Table 3 shows the quantitated lipid classes of wheat lipids extracted from 'Kolibri' flour and fermented dough as affected by the solvent used for lipid isolation. On one hand, wheat flour lipids were extracted using 2-propanol at 75 °C (yield: 1.57 ± 0.03% dm) to minimize flour damage and to maximize lipid extraction. On the other hand, WSB was used at RT with a yield of 1.67 ± 0.05% dm. The quantitated lipid composition of wheat flour is in accordance with the literature,[1,17] with TG as the major component of nonpolar

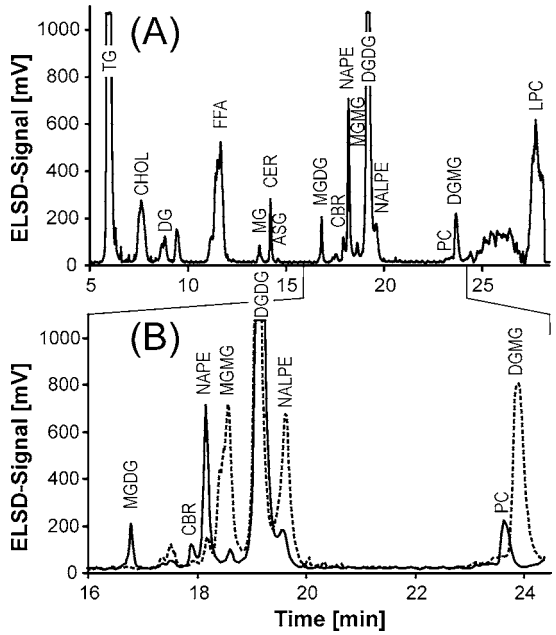

**Figure 1.** HPLC chromatograms of wheat flour lipids (solid line) and dough lipids after mixing and fermentation in the presence of lipase (Lipopan Xtra 130 mg/kg) (dashed line). (A) Retention time of 5–29 min and (B) retention time of 16–24.5 min with details of the relevant lipid classes. Lipid classes are designated as defined in Table 2. Lipids were extracted with WSB at RT.

**Table 2. Retention Times of Lipid Classes from Wheat after Separation by HPLC**

| abbreviation | lipid class | retention time (min) |
|---|---|---|
| TG | triglycerides | 5.1 |
| CHOL | cholesterol | 7.6 |
| DG | diglycerides | 8.6 |
| FFA | free fatty acids | 11.4 |
| MG | monoglycerides | 13.5 |
| CER | ceramides | 13.7 |
| ASG | acylated sterol glucosides | 14.5 |
| SG | sterol glucosides | 16.6 |
| MGDG | monoglactosyl diglycerides | 16.8 |
| CBR | cerebrosides | 17.5 |
| NAPE | *N*-acyl phosphatidyl ethanolamine | 18.1 |

[a]Mean values ± standard deviations of triplicate determinations. Mean values associated with different capital letters are significantly different within each lipid class (one-way ANOVA, Tukey test, $p \leq 0.05$) [b]Lipid classes are designated as defined in Table 2.

lipids, DGDG of glycolipids, and NAPE of phospholipids. As mentioned before, natural fluctuations of the lipid composition of wheat depend on the individual genetic predisposition (cultivar), the agricultural practices used during cultivation, the environmental effects to which the plant was exposed, and the age of the milled flour.

The lipid compositions per kilogram of dry flour extracted with different solvents differed mainly in the polar lipid composition. More glycolipids and phospholipids were extracted using WSB than using 2-propanol (75 °C). It is known that beside free lipids, bound lipids are also extracted almost completely with WSB,[4] which is possibly due to the "bipolar" character of this solvent. WSB is a combination of a nonpolar and a very polar compound, which is more similar to polar lipids than it is to (water-free) 2-propanol, and thus, dissolves these compounds more effectively. This might explain the higher polar lipid portion in the WSB compared to the 2-propanol-extracted lipids, because bound lipids are more efficiently detached from their binding sites.[4,9] The amount of each lipid class was lower in the dough lipids than in the flour lipids when 2-propanol was used as the extraction solvent. In contrast, the compositions of flour and dough lipids were not significantly different in the lipid extracts obtained with WSB. Our results are in line with the phenomenon of "lipid binding".[4,14] This means that when flour is wetted and mixed into dough, around 70% of the total flour lipids become bound to or are entrapped by the gluten network.[9] Because of the binding of lipids during mixing, fewer lipids were extracted with 2-propanol from dough than were extracted from flour. These results suggest WSB as the preferred solvent for total lipid extraction from wheat flour and dough.

**Baking Performance as Affected by the Addition of Lipase.** To reveal the maximum bread volume increase caused by the addition of lipases and their dose/volume increase dependency, two versions of a microscale baking test based on 10 g of flour differing in the time and intensity of mixing were applied.[18] In the micro-rapid-mix test (MRMT), the dough was mixed for 2 min with a high-speed mixer (1250 rpm), whereas in the microbaking test (MBT), the dough was mixed in a Microfarinograph (63 rpm) until the optimum consistency of the dough was reached (7 min). All other steps were identical. To take dough losses during breadmaking into account, the loaf volumes were based on the dough weight (mL/g dough) before the second proofing session. The bread volume was expressed

dx.doi.org/10.1021/jf5022434 | J. Agric. Food Chem. 2014, 62, 8229−8237

in relation to the respective mean value of the control breads in the individual test series, taking into account both climatic and technical fluctuations.

The breads were baked using the MRMT to study the lipase-dependent volume increase after the addition of Lipopan Xtra (10−70 mg/kg). The lipase was applied as a solid or as a watery suspension; the latter procedure was used to get a more homogeneous distribution of the enzyme. However, both application forms did not cause a significant increase of the bread volume. Even after the application of 700 and 1400 mg of Lipopan Xtra per kilogram of flour, no volume increase was obtained. Similar results were obtained for Lipopan F (50 and 500 mg/kg). Also, for the Lipopan F addition, no significant increase in the loaf volume was obtained after the proofing time was extended from 37 to 54 min. Recent studies[8,19] show that Lipopan F and Lipopan Xtra caused a significant volume increase when a normal scale baking test (300 g of flour) with dough mixing in the Farinograph was used. Consequently, the MBT was used to demonstrate the effect of added lipases. It is known that a rather high-volume increase is typical of the microscale setup when compared to conventional baking. Previous studies on the effect of DATEM have shown that the volume increases were higher in the microscale baking test (40−60% volume increase) than in a normal-scale test with 300 g of flour (10−20% volume increase).[20] However, the correlation between the micro- and normal-scale baking tests was high because the same trend of the loaf volumes was obtained with both setups.[18,20] As shown in Figure 2, significant

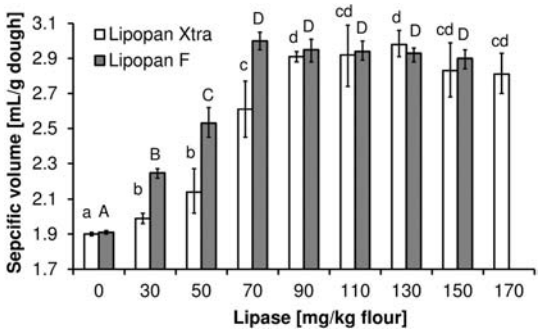

**Figure 2.** MBTs with 10 g of flour. Change of the bread volume as affected by the increasing concentrations of the lipases Lipopan Xtra and Lipopan F. Error bars represent the mean standard deviations of triplicate determinations. Mean values associated with different letters are significantly different within each lipase concentration (one-way ANOVA, Tukey test, $p \leq 0.05$).

volume increases were obtained for both Lipopan Xtra and Lipopan F. The volume increase was found to correlate to the enzyme dosage until a plateau was reached. Lipopan F was found to reach a plateau at a lower dosage (70 mg granulate/kg flour) than did Lipopan Xtra (90 mg granulate/kg flour). A further increase in the enzyme dosage did not cause statistically significant differences in the obtained bread volumes.

These results strongly suggest the MBT as the preferred test to assess the effects of lipase addition. It can only be speculated as to why the MRMT was not suited to study the functional effect of lipases. One explanation would be that the enzymes were shear sensitive and were inactivated by the high mechanical input during mixing.

The commercial synthetic surfactants DATEM and SSL were chosen as reference surfactants to evaluate the potential of lipases and lipase-treated lipids in breadmaking. To determine the concentration of surfactants for a maximum increase in the bread volume, concentrations of 0.2−0.8% were applied. DATEM was applied as a solid or as a watery suspension. There were no significant differences between the two application forms, and a maximum volume increase of 58% at a concentration of 0.6% was obtained. The typical plateau phase was seen at DATEM concentrations between 0.4 and 0.8%, comparable with the plateau phase after lipase application. SSL showed the same phenomenon and caused a maximum bread volume increase of 47% at a concentration of 0.4%. In summary, the functional effects of lipases (volume increase of 56−58%) were comparable to those of DATEM (58%) and superior to those of SSL (47%). Furthermore, the amount of commercial lipase product added, concentration of lipase required for this effect, was approximately 1/50 of the amount of surfactants added.

**Changes of Lipid Composition as Affected by Lipase Addition.** Figure 1 shows an overlay of the chromatograms of the wheat flour lipids and lipase-treated dough lipids. It can be clearly seen that especially certain polar lipid classes (retention time 15−25 min) were hydrolyzed after lipase addition. The quantitative data of the lipase-treated dough lipids are given in Tables 3 and 4. In the following sections, the lipid classes TG, DGDG, NAPE, and DGMG are used as examples to discuss the effect of lipases in more detail. Lipase-treated (Lipopan F and Lipopan Xtra) dough lipids differed significantly from the untreated dough lipids and the flour lipids. The results also confirmed that WSB was more effective in extracting the relevant lipid classes than was 2-propanol. With an increase in the amount of lipases, a decrease of TG, DGDG, NAPE, and MGDG occurred, in particular after proofing. This went hand in hand with the increased concentrations of the hydrolysis products FFA, MGMG, NALPE, and DGMG.

Upon review of the composition of WSB extracted lipids, TG were hydrolyzed by lower concentrations of Lipopan F than of Lipopon Xtra, and the concomitant formation of FFA was observed. This corresponds to Lipopan Xtra having a higher affinity toward phospholipids than does Lipopan F. Furthermore, a larger decrease of DGDG (2043 → 1148 mg/kg flour) and the corresponding increase of DGMG (180 → 540 mg/kg) were detected after proofing with Lipopan F than with Lipopan Xtra (DGDG, 2043 → 1350 mg/kg; DGMG, 180 → 265 mg/kg). However, the changes of the DGDG and DGMG concentrations (Tables 3 and 4) revealed that the formation of DGMG did not compensate for the decrease of the DGDG concentration. An explanation could be that DGMG is a transient intermediate and is subjected to further hydrolysis by the lipase. In contrast to DGDG, the addition of Lipopan Xtra resulted in a significantly stronger hydrolysis of MGDG (498 → 26 mg/kg) and NAPE (1013 → 661 mg/kg) after proofing than did the addition of Lipopan F (MGDG, 498 → 158 mg/kg; NAPE, 1013 → 742 mg/kg). Lipid concentrations before fermentation are given in the Supporting Information (Tables S3 and S4) and show the same trends as the concentrations after proofing.

To get a closer overview of the degradation and formation of lipase substrates and products, mass concentrations were converted into molar concentrations. This was done exemplarily for the addition of Lipopan F and for WSB as a lipid extraction solvent (Table 3). Molar masses of the lipid classes were calculated by the use of linoleic acid ($M$ = 280.5 g/mol) as the default fatty acid. The results for the relevant lipid classes

[a]Mean values ± standard deviations of triplicate determinations. Mean values associated with different capital letters are significantly different within each lipid class (one-way ANOVA, Tukey test, $p \leq 0.05$). [b]Lipid classes are designated as defined in Table 2.

are shown in Figure 3. The dough without added lipase contained almost equal molar concentrations of TG and FFA (5.5−6 mmol/kg flour). Upon the addition of Lipopan F, TG decreased by 2.5 mmol/kg flour to a minimum value of 3.5 mmol/kg flour (Figure 3A). The corresponding product FFA strongly increased by 4.5 mmol/kg flour to a final concentration of 10 mmol/kg flour as the lipase concentration increased. Thus, hydrolysis of TG only explained 56% of the FFA formation, clearly showing that other substrates such as glyco- and phospho-lipids also contributed to FFA formation.[10] The hydrolysis of NAPE and the concurrent formation of NALPE (Figure 3B) were approximately in the same range (−0.3 vs +0.5 mmol/kg flour, respectively). Comparable results were obtained from the hydrolysis of MGDG (−0.4 mmol/kg flour) and the formation of MGMG (+0.6 mmol/kg flour) (Figure 3D). The situation was somewhat different for DGDG and DGMG (Figure 3C). The decrease of DGDG (−1 mmol/kg flour) was twice as high as the increase of DGMG (+0.5 mmol/kg flour). A possible reason was given above. The calculation of the balance of the reactions on a molar basis showed that the total increase of FFA after lipase addition (+4.5 mmol/kg flour) was almost equaled by the decreases of the lipase substrates DGDG, MGDG, NAPE, and TG. Hydrolysis of these substrates explained 93% of the lipase-mediated formation of FFA (4.2 of 4.5 mmol/kg flour).

**Relevance of the Modified Lipid Composition for the Baking Performance.** Nonpolar lipids and NAPE have a negative influence on baking performance, whereas all glycolipids show positive baking potential.[6] Consequently, the hydrolysis of NAPE to NALPE can be regarded as positive for the baking performance. The formation of MGMG from MGDG is also desirable because it was found that the latter has the proper ratio between hydrophilic and lipophilic moieties in the molecular structure to yield good functionality.[6]

Glycoglycerolipids containing two carbohydrate moieties show different behavior compared to one carbohydrate moiety glycoglycerolipids. Previous studies have shown that DGDG and MGMG have comparable positive effects in baking.[6] Thus, the second acyl residue in DGDG must be essential for a high functionality of this lipid class in baking, while a weaker effect has been shown for purified DGMG.[6] Moreover, these studies have shown that DGDG had the best functional effects of all glycolipids. As a consequence, the degradation of DGDG found here (Tables 3 and 4) can be considered unfavorable because

dx.doi.org/10.1021/jf5022434 | J. Agric. Food Chem. 2014, 62, 8229−8237

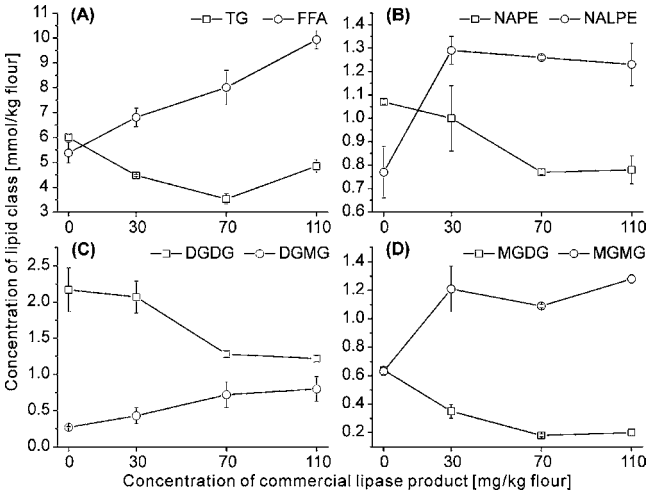

**Figure 3.** Decrease of selected lipase substrates and increase of the corresponding products as affected by the addition of Lipopan F. Mass concentrations given in Table 3 were converted into molar concentrations [mmol/kg flour] using linoleic acid as the default fatty acid. Lipid classes are designated as defined in Table 2. Lipids were extracted with WSB at RT.

the functional effects of DGDG are much stronger than those of DGMG. Generally, the increased concentration of FFA from lipolytic action is considered to decrease the positive effect of the addition of lipases. Experiments in which free linoleic acid (0.1%, 3.6 mmol/kg) was added, show a considerable decrease in the loaf volume (data not shown).

A comparison of the quantitative data of the lipase-modified lipids (Tables 3 and 4) with bread volumes (Figure 2) as affected by lipases shows that the highest amount of polar hydrolysis products obtained at the highest levels of Lipopan F (110 mg/kg) and Lipopan Xtra (170 mg/kg) did not match the concentrations that caused maximum bread volumes (70 and 130 mg/kg, respectively). Accordingly, a higher concentration of polar lipids did not automatically cause a higher bread volume, although the bread volume remained on a high level compared to the bread volume obtained without the addition of lipase. This effect can be explained by the increased amounts of FFA and DGMG, which have a negative (FFA) or at least a less positive effect (DGMG) on the baking performance. Therefore, the type and concentration of the added lipase appears to be of major importance. Evidence for this hypothesis is given in the work of Gerits et al.,[10] who showed that the specificity of the added lipase clearly affects its technological effect.

Finally, synergistic effects between glycolipids and phospholipids must also be considered. Tables 3 and 4 as well as Figure 2 show that PC was also hydrolyzed to LPC. It is generally accepted that lysophospholipids exhibit stronger functional effects than do phospholipids.[21,22] Furthermore, Wilde et al.[23] indicated that the complex of LPC with the lipid-binding protein puroindoline A is more surface active than is LPC or puroindoline A alone, suggesting a synergistic effect in breadmaking. In addition, already very low concentrations of glycolipids are able to enhance the functionality of phospholipids significantly. Selmair[24] showed that a small amount of MGMG added to the phospholipids of lecithin resulted in an improved baking performance of the flour.

# Controlled Release Properties of Zein−Fatty Acid Blend Films for Multiple Bioactive Compounds

Iskender Arcan and Ahmet Yemenicioğlu*

Department of Food Engineering, Faculty of Engineering, Izmir Institute of Technology, 35430, Gülbahçe Köyü, Urla, Izmir, Turkey

Supporting Information

**ABSTRACT:** To develop edible films having controlled release properties for multiple bioactive compounds, hydrophobicity and morphology of zein films were modified by blending zein with oleic ($C_{18:1}$)$\Delta^9$, linoleic ($C_{18:2}$)$\Delta^{9,12}$, or lauric ($C_{12}$) acids in the presence of lecithin. The blend zein films showed 2−8.5- and 1.6−2.9-fold lower initial release rates for the model active compounds, lysozyme (LYS) and (+)-catechin (CAT), than the zein control films, respectively. The change of fatty acid chain length affected both CAT and LYS release rates while the change of fatty acid double bond number affected only the CAT release rate. The film morphologies suggested that the blend films owe their controlled release properties mainly to the microspheres formed within their matrix and encapsulation of active compounds. The blend films showed antilisterial activity and antioxidant activity up to 81 $\mu$mol Trolox/cm$^2$. The controlled release of multiple bioactive compounds from a single film showed the possibility of combining application of active and bioactive packaging technologies and improving not only safety and quality but also health benefits of packed food.

**KEYWORDS:** *active packaging, bioactive packaging, edible film, blend film, lysozyme, CAT*

## INTRODUCTION

In recent years, continuous efforts have been spent to improve safety and quality of food or to increase their shelf life by using novel packaging technologies. Active packaging containing antimicrobials (antimicrobial packaging) or antioxidants (antioxidant packaging) is among the most promising packaging technologies, since its application can inhibit pathogenic and spoilage microorganisms and lipid oxidation in food, respectively.[1] The addition of bioactive compounds into packaging materials has also initiated bioactive packaging, a novel packaging concept that targets enriching packed food with bioactive compounds and improving their potential health benefits.[2]

Because of the health concerns of the consumers and environmental problems, there is an increasing trend to use natural active compounds and edible films in active packaging. Therefore, antimicrobial enzymes including lysozyme (LYS), lactoperoxidase and glucose oxidase, bacteriocins, and natural antimicrobial and antioxidants such as plant phenolics and essential oils have been extensively tested in different edible packaging materials.[3−5] The use of natural phenolic compounds in active packaging attracts a particular interest, since these compounds show antimicrobial and antioxidant activity in food systems and increase health benefits of food because of their potential bioactive effects.[2,6] (+)-Catechins (CATs), a group of flavonoids ($C_6C_3C_6$), are frequently employed in foods, since it is economically feasible to extract these compounds from abundant sources such as green tea[7] and they show well documented bioactive effects such as antioxidant, anticancerogenic, antidiabetic, and antihypertensive activities.[8] LYS obtained from hen egg white is also among the most potential candidates for antimicrobial packaging, since it has a GRAS status and it shows good stability and activity in different films and food systems under refrigerated storage temperature.[9,10] This enzyme is effective mainly on Gram-positive bacteria and shows its antimicrobial activity by splitting the bonds between *N*-acetylmuramic acid and *N*-acetylglucosamine of the peptidoglycan layer in the bacterial cell wall. Thus, the application of LYS in active packaging targets mainly inhibition of critical Gram-positive pathogenic bacteria such as *Listeria monocytogenes* that might cause deadly infections.[10−12] LYS has recently been tested extensively in different plastic materials such as cellulose acetate, nylon, and PVOH[4,13] and biopolymeric materials from zein, soy protein, carrageenan, whey protein, chitosan, alginate, and pullulan[4,14] to develop antimicrobial packaging materials.

Antioxidant and antimicrobial packaging targets mainly the food surface on which oxidative and microbiological changes occur most intensively.[15] A sufficient preservation effect could not be achieved unless the release rate of active compounds from the packaging materials to the food surface is adjusted considering the physical and chemical properties of food, lipid oxidation rate, growth kinetics of target pathogenic or spoilage microorganisms, and expected food shelf life.[15,16] Different studies have been conducted to control the release rate of LYS in different plastic films from cellulose acetate, poly(vinyl alcohol), and glycerol/poly butylenes trephthalate and in different edible films from caseinate, zein, and chitosan.[13,17−20] On the other hand, although the controlled release of CAT had been studied from polypropylene films,[21,22] no studies are determined related to controlled release of CAT from edible films.

The incorporation of LYS into zein films or zein particles has recently gained an increasing interest, since (1) zein is the major coproduct of the oil and rapidly growing bioethanol industries, (2) it is one of the rare film forming proteins soluble in various organic solvents including ethanol, and (3) it provides an effective delivery system for LYS.[9,23−29] The effectiveness of zein-based LYS delivery systems is due to the highly hydrophobic nature of the zein film matrix that contains very limited charges to cause binding and immobilization of LYS that is positively charged in food systems due to its high pI at 11.35.[30] The LYS activity is also highly stable during zein film making and during cold storage of precast zein films.[9] Moreover, LYS release profiles of zein films could be changed effectively by modifying film morphology and hydrophobicity using composite and blend film making technologies. Gucbilmez et al.[23] sustained LYS release from zein films by forming composites of these films with chickpea proteins. Arcan and Yemenicioğlu[24] controlled LYS release from zein films by preparing composites of zein with different waxes. These authors reported that the LYS release profiles of zein−wax composites could be effectively modified by using different types of waxes that create different film morphologies and increase film tortuosity depending on their melting points. Ünalan et al.[15] employed LYS with a mixture of CAT and gallic acid and showed the benefits of using controlled release technology in zein−wax composites applied for antimicrobial and antioxidant packaging of cheese. Not only composite films, but also blend films of zein prepared by forming emulsions of zein with the fatty acid oleic acid (OLE) in the presence of lecithin (LEC) have also been applied for controlled release of LYS.[24] The preparation of zein blend films with OLE causes the formation of microspheres within the film matrix, and this increases barriers against diffusion of encapsulated LYS.[24] The aim of the current work is to investigate the effects of using different fatty acids, OLE ($C_{18:1}$)Δ,[9] linoleic (LIN) ($C_{18:2}$)Δ,[9,12] and lauric (LAU) ($C_{12}$), in zein blend film making to obtain different release profiles for LYS and CAT at the same film system. It was proposed that the use of fatty acids with different chain length, conformation, and saturation level could create different types of zein microspheres and morphologies and this could be exploited to obtain films with different release profiles for LYS and CAT. The use of LAU in blend film making could contribute not only to the controlled release properties of active compounds, but it could also provide an additional antimicrobial effect to films, since it is an active fatty acid with potent antimicrobial activity.[31] This is one of the first studies that aimed in developing a scientific basis for edible packaging materials having controlled release properties for multiple active compounds capable of showing antimicrobial and antioxidant effects not only in packed food (active packaging) but also in the human physiological system after consumption of the enriched packed food (bioactive packaging).

## MATERIALS AND METHODS

**Materials.** Maize zein (batch number: 058 K0093), (+)-CAT hydrate (≥98%), *Micrococcus lysodeikticus*, OLE (tech. 90%), LIN (minimum 99%), and LAU (≥98%) were from Sigma−Aldrich Chem. Co. (St. Louis, MO, USA). Soybean L-α-LEC and glycerol were from Merck (Darmsdadt, Germany). All other chemicals were reagent grade. Fresh hen eggs used in production of LYS were obtained from a supermarket in Izmir (Turkey).

**LYSs Used in the Study.** The partially pure (PP) LYS was produced by the selective precipitation of egg white proteins other than this enzyme according to the method described by Mecitoglu et al.[9] The enzyme was lyophilized by using a freeze drier (Labconco, FreeZone, 6 L, Kansas City, MO, USA) and stored at −18 °C until it was used in film-making. The pure commercial (PC) LYS (protein and specific activity values specified in the manual are ≥90% and ≥40 000 units/mg protein, respectively) was obtained from Sigma−Aldrich Chem. Co. (St. Louis, MO, USA). The specific activities of PP LYS and PC LYS determined by the method described in this study were 40477 and 78984 U/mg protein, respectively. The protein content of the LYS preparations was tested by the classical Bradford method by using bovine serum albumin as the standard. The impurities in the PP LYS and the purity of PC LYS were tested by sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) according to the method of Laemmli[32] using a 12% separating gel and a 4% stacking gel. Proteins bands were stained with silver salts described by Blum et al.[33]

**Preparations of Zein Films.** The films were produced by modifying the methods described in Padgett et al.[34] and Arcan and Yemenicioglu.[33] Briefly, 1.4 g of zein was dissolved with 8.1 mL of ethanol (96%) by mixing slowly with a magnetic stirrer for 25 min, and 0.4 mL of glycerol was then added to the medium as plasticizer. The mixture was then heated under continuous mixing until it started to boil. The boiling was conducted for 5 min, and the film-making solution was cooled to room temperature. CAT (100 mg/g film-forming solution) and PC LYS (Sigma−Aldrich Chem. Co.) or PP LYS obtained according to Mecitoglu et al.[9] were then added into film-forming solutions. PC LYS (78984 U/mg protein) and PP LYS (40477 U/mg protein) were used at the concentrations of 11.7 and 23.4 mg lyophilized powder/g of film-forming solution, respectively (the final PC LYS, PP LYS, and CAT concentrations in cast and dried films were 0.7, 1.4, and 6 mg/cm$^2$, respectively). The PP LYS concentration used in film making is 2-fold higher than that used in zein films successfully applied to control microbial development in actively packed ground beef patties.[10] After addition of CAT and LYS, the mixtures were homogenized (Heidolph, Germany, rotor Φ = 6.6 mm tip) at 10 000 rpm for 4 min. Then, 4.3 g portions of the homogenized film-forming solutions were cast into the glass templates (W × L × H: 8.5 × 8.5 × 0.4 cm$^3$) and dried for 19 ± 2 h at 25 °C in an incubator unless otherwise was stated. This homogenization and casting procedure was also used to obtain zein−fatty acid blend films by adding fatty acids (LAU, OLE, and LIN) and emulsifier LEC into film-forming solutions at 5−20% (w/w) and 10% (w/w) of zein, respectively. The fatty acids and LEC were added after the boiling step following cooling of zein film-forming solution to room temperature.

**LYS Release Profiles of Films.** For the release tests, film samples (4.5 × 4.5 cm$^2$) were placed between two glass frames (dimensions: inside, 4 × 4 cm$^2$; outside, 6 × 6 cm$^2$). The edges of the glass frames were carefully sealed with paraffin film, and the glass apparatus containing the film was placed horizontally at the bottom of a 500 mL glass beaker containing 150 mL of distilled water at 4 °C. Four 0.5 cm diameter glass rods were placed below the frame at the corners to increase water circulation, and the overall apparatus (the 500 mL beaker) was placed onto an orbital shaker working at 80 rpm in an incubator at 4 °C. The LYS activity released from the films was monitored by taking 0.25 mL (×3) aliquots from the release test solution at different time intervals. The release tests were conducted until equilibrium was reached for release of LYS or an insignificant increase was observed in the activity of released LYS. The LYS activities of collected aliquots were determined spectrophotometrically at 660 nm by using a Shimadzu spectrophotometer (Model 2450, Tokyo, Japan) equipped with a constant temperature cell holder working at 30 °C. The *Micrococcus lysodeikticus* solution prepared in 0.05 M, pH 7.0 Na phosphate buffer (0.26 mg/mL) was used as substrate during activity determination. The reaction mixture was formed by mixing 0.1 or 0.25 mL of release test medium (depending on LYS activity) and 2.4 or 2.25 mL of substrate solution to reach a final reaction volume of 2.5 mL. The enzyme activities were calculated from the slopes of initial linear portions of absorbance versus time curves and were expressed as unit (U) that was defined as the number of 0.001 changes in absorbance in 1 min. All calculations were corrected by considering the activity removed by collected aliquots

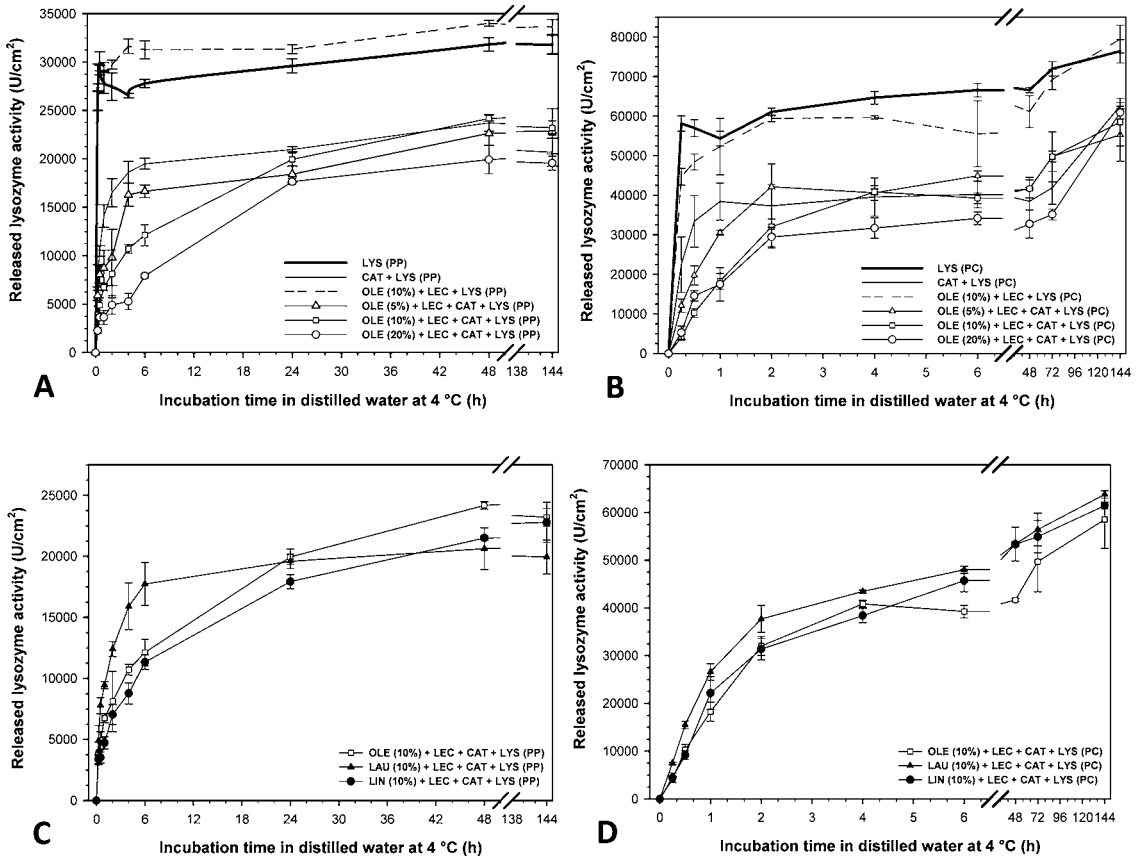

**Figure 1.** Effect of CAT and blend film making on release profiles of (A, C) PP LYS and (B, D) PC LYS. CAT: catechin; LYS: lysozyme; OLE: oleic acid; LAU: lauric acid; LIN: linoleic acid; LEC: lecithin.

during sampling. The total LYS activity released from each film corresponded to maximum units released per centimeter squared of the films (U/cm$^2$) at the equilibrium. All activity measurements were conducted three times. The release curves were formed by plotting calculated released activities (U/cm$^2$) versus incubation time (h). The initial release rates of LYS were determined from the slope of the initial linear portion of the release curve. The release rates were expressed as units per centimeters squared per hour (U/(cm$^2$ h)).

**CAT Release Profiles and Antioxidant Capacity of Films.** To determine the CAT release profiles of films, the release tests were conducted in water as described in the LYS Release Profiles of Films section. The soluble CAT content of the collected samples was determined spectrophotometerically at 510 nm according to the colorimetric method of Meyers et al.[35] used for quantification of flavonoids. The total soluble CAT contents released from the films were expressed as milligrams of CAT per centimeter squared of the films (mg/cm$^2$) using the calibration curve prepared by CAT. All concentration measurements were conducted three times. The release curves were formed by plotting the calculated released phenolic contents (mg/cm$^2$) versus time (h). The initial CAT release rates were determined from the slope of the initial linear portion of release curve. The release rates were expressed as milligrams per centimeter squared per hour (mg/(cm$^2$ h)). The antioxidant capacity of the films was based on calculating the Trolox equivalent antioxidant capacity (TEAC) of their total released CAT content at the equilibrium. The percentage of free soluble CAT in the films was determined by the formula of (total released CAT/initial CAT added) × 100. The TEAC of CAT was determined by using the spectrophotometric ABTS radical cation decolourization assay conducted at 734 nm.[36] The results were expressed as micromoles of Trolox equivalents released per centimeter squared of films ($\mu$mol Trolox/cm$^2$).

**Antimicrobial Potential of Films.** The antimicrobial potentials of films were tested by using *Listeria innocua* (NRRL B-33314; supplied from USDA, Microbial Genomics and Bioprocessing Research Unit, Peoria, IL, USA) as a test microorganism. During antimicrobial tests, 18 discs (1.3 cm in diameter) were prepared from each film by a cork borer. Total of 15 discs were selected randomly, and 3 discs were placed into each Petri dish containing nutrient agar previously inoculated with 0.1 mL of bacterial culture. The inocula were prepared in peptone water (0.1%) by using 48 h culture grown in nutrient agar. The cell concentration was set to 1.0 McFarland unit that corresponded to 13 × 10$^7$ CFU/mL. The Petri dishes containing discs of films were incubated first at 4 °C for 4 h to prevent rapid diffusion of the LYS, and then, second they were incubated at 37 °C for 36 h for microbial growth. The diameter of the zones formed around the discs was measured by using a calliper, and the results were expressed as average zone areas (mm$^2$).

**Scanning Electron Microscopy (SEM) of Films.** The cross sections and surfaces of selected films were monitored by using SEM (Philips XL 30S FEG, FEI Company, Netherlands) under high vacuum mode at an operating voltage at 3 kV. The film cross sections were obtained by crushing films following freezing in liquid nitrogen. The samples were then gold coated with a sputter coater (Emitech K550X, Quorum Technologies Inc., UK) under 15 mA for 60 s. The thickness of the films was measured from SEM cross-sectional views of films by using Scandium software (Olympus Soft Imaging Solutions GmbH, Münster, Germany).

**Mechanical Properties of Films.** Tensile strength at break, elongation at break, and elastic modulus were determined using a Texture Analyzer TA-XT2 (Stable Microsystems, Godalming, UK) according to ASTM standard method D 882-02.[37] The films used in mechanical tests were conditioned by extending the standard drying period from 19 to 48 h at 25 °C and conducting drying at 50% RH using a controlled test cabinet (TK 120, Nüve, Turkey). Films were cut into 5 mm wide and 80 mm length strips, initial grip distance was

[c]Time periods of data used in best fitting curves were between 0 and 0.5 h. $r^2$ values of curves were between 0.6825−0.9994. [d]Different letters (a−c; A−C) in each column show the significant difference at $P < 0.05$. Small letters indicate the differences within each enzyme type. Capital letters indicate the differences within all given results at the column. [e]Not included in statistical analysis.

50 mm, and crosshead speed was 50 mm/min. At least seven replicates of each film were tested.

**Statistical Analysis.** For the determination of effects of film compositions on antimicrobial potentials and mechanical properties of films analysis of variance (ANOVA) was applied using Minitab 15 (Minitab Inc., State College, PA, USA). Multiple comparisons of means were performed using Fisher's least significant difference (LSD) method with a significance threshold of $P < 0.05$.

## RESULTS AND DISCUSSION

**Effect of CAT and Blend Film Making with OLE on LYS Release Profiles.** In the zein film system, the phenolic compounds including CAT not only serve as an active component but they also affect film morphology, since they interact with the film matrix via hydrogen bonding to available zein carbonyl groups.[24] The morphological changes in zein films caused by CAT are particularly important, since they affect the film porosity, thus the controlled release properties of films.[24,38] Arcan and Yemenicioğlu[24] clearly showed the concentration-dependent contribution of CAT in sustained release of LYS form zein and zein−carnauba wax composite films. In the current work, the contribution of CAT in LYS release properties of zein films and zein−OLE (10%) blend films are seen in Figure 1A, B. The control zein films and control zein−OLE (10%) blend films lacking CAT showed 2.9- and 8.5-fold higher release rates for PP LYS, and 1.9- and 7.5-fold higher release rates for PC LYS than CAT-containing zein films and zein−OLE (10%) blend films, respectively (Table 1). The SEM photos for cross sections (Figure 2A−D) and surfaces (Supporting Information, Figure S1) of zein films and zein−OLE (10%) blend films containing and lacking CAT clearly showed the reduced film porosity by incorporation of CAT into films. Thus, it is clear that the CAT used as active compound also contributed to the sustained LYS release rates of zein films. On the other hand, the 2.1- and 3.6-fold lower release rates of CAT-containing zein−OLE (10%) blend films for PP and PC LYS than CAT-containing zein films could be related with the differences in morphological properties of these films. The morphological changes of zein film structure when it is mixed with OLE without use of an emulsifier was recently explained by Wang et al.[39] According to these authors, the morphological changes in the zein−OLE film system occurred at three steps: (1) formation of large numbers of OLE-coated zein microspheres, (2) partial melting of the microspheres by means of OLE, and (3) transformation of a sponge-like morphology by interconnection of microspheres with channels and tunnels. Arcan and Yemenicioğlu[24] who employed the zein−OLE blend films for controlled release of LYS also reported the presence of microspheres within the zein−OLE films and attributed the sustained release properties of these blend films to encapsulation of LYS within the microspheres. However, different from Wang et al.,[39] these workers conducted the blending process by using LEC emulsifier, and they did not observe the presence of interconnections among the formed self-standing microspheres. In this work, the presence of self-standing microspheres was also observed in the SEM photos of both CAT-containing and -lacking zein−OLE blend films that were prepared by using emulsifier LEC (Figure 2C, D). These results suggest that the repulsion formed by negative charges of LEC that interacted with the OLE-coating formed around zein microspheres. This might prevent the interaction and melting down of the microspheres and enables the formation of self-standing microspheres different from the spongelike structure observed by Wang et al.[39] It is also worth to note that the CAT reduced the sizes of microspheres and caused an increase in the number of microspheres. On the other hand, it is important to report that the total released PC or PP LYS activity from CAT-containing zein and zein−OLE (10%) films at the equilibrium

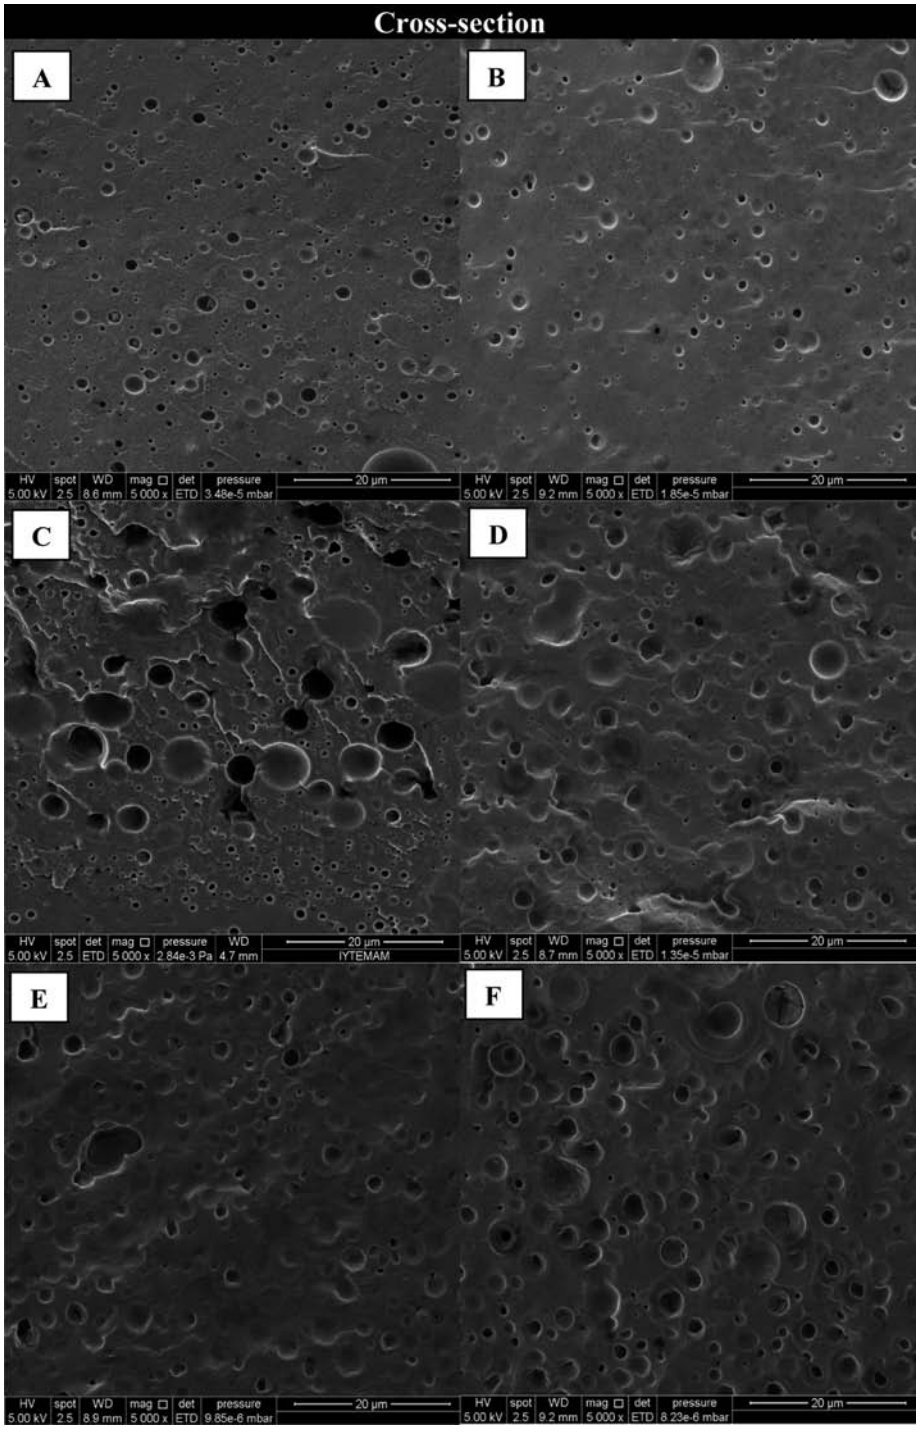

**Figure 2.** Cross-sectional SEM images of developed films: (A) zein film containing PP LYS (1.4 mg/cm$^2$); (B) zein film containing CAT (6 mg/cm$^2$) and PP LYS (1.4 mg/cm$^2$); (C) blend film containing OLE (10%) and PP LYS (1.4 mg/cm$^2$); (D) blend film containing OLE (10%), CAT (6 mg/cm$^2$), and PP LYS (1.4 mg/cm$^2$); (E) blend film containing LAU (10%), CAT (6 mg/cm$^2$), and PP LYS (1.4 mg/cm$^2$); (F) blend film containing LIN (10%), CAT (6 mg/cm$^2$), and PP LYS (1.4 mg/cm$^2$). CAT: catechin; LYS: lysozyme; OLE: oleic acid; LAU: lauric acid; LIN: linoleic acid; LEC: lecithin.

is 18−27% lower than those of their CAT-lacking controls. This result suggests the trapping or immobilization of part of LYS within zein and zein−OLE (10%) films when CAT was incorporated into films. On the other hand, there are no significant differences in total released PC or PP LYS activities from control zein films and zein−OLE (10%) films lacking CAT ($P > 0.05$). Thus, it also appeared that the blend film making with OLE and the formation of microspheres within films did not cause considerable LYS trapping and immobilization.

**Effect of OLE Concentration on LYS Release Profiles of Blend Films.** In order to determine the effect of fatty acid concentration in release profiles of blend films, the OLE concentration of 10% was changed as 5% and 20% (Figure 1A, B). The results clearly showed that the increase of OLE fraction within blend films caused a reduction in release rates for both

[a]Concentrations of fatty acids and LEC as % of zein (w/w). [b]Time periods (h) of data used in best fitting curves were between 0 and 1 h. $r^2$ values of curves were between 0.6110 and 0.7491. [c]Different letters in each column show significant difference $P < 0.05$.

PC and PP LYS. The initial release rate of PP LYS reduced 1.4- to 1.6-fold as a concentration-dependent manner when OLE concentration in blend films increased between 5% and 20%. On the other hand, the increase of OLE concentration within blend films from 5% to 10% caused almost 2-fold reduction in initial release rate of PC LYS, but further increase of OLE concentration did not affect the initial release rate of PC LYS (Table 1). These results clearly showed the possibility of controlling LYS release rate of CAT-containing zein−OLE blend films by changing fatty acid concentration within the films.

**Effect of Different Fatty Acids on LYS Release Profiles of Blend Films.** To determine the effects of different fatty acids on LYS release profiles of CAT-containing blend films, LIN and LAU at 10% (w/w) of zein were also used in film making. The selected fatty acids enabled determining the possible effects of carbon chain length ($C_{12}$ or $C_{18}$), number of double bonds ($C_{18:1}$ or $C_{18:2}$), and fatty acid tail conformation (LIN has more bent tail than OLE) in LYS release properties (Supporting Information, Figure S2). The LYS release curves of films clearly showed the more different release profiles of LAU-containing blend films than LIN- and OLE-containing blend films (Figure 1C, D). In fact, the initial PP LYS and PC LYS release rates of LAU-containing blend films were 1.6- to 2.0-fold higher than those of OLE- and LIN-containing blend films (Table 1). These results clearly showed the reduced diffusion barriers for LYS when fatty acid chain length was reduced from $C_{18}$ to $C_{12}$. On the other hand, the similar release profiles of LIN- and OLE-containing blend films also showed that the presence of one or two double bonds and the resulting conformational differences at the fatty acid aliphatic tails has no contribution in LYS release properties of blend films. The SEM photos of blend films obtained with LIN and LAU also showed the presence of self-standing microspheres in these films (Figure 2E, F). Thus, it is once more conformed that different fatty acids emulsified with LEC in the zein film system caused self-standing microspheres within the blend films. Moreover, it was also observed that microspheres in OLE- and LIN-containing blend films were larger and more intensive than those observed for LAU-containing films. Thus, it appeared that the higher LYS release rate of zein−LAU blend films than zein−OLE and zein−LIN films is related with the reduced fraction of LYS encapsulated within the microspheres. This result supported our hypothesis that the microspheres formed in zein−fatty acid blend films play a very important role in controlling LYS release rates.

**Effect of Enzyme Purity on LYS Release Profiles of Zein and Blend Films.** In this work, the use of LYS preparations at different purities aimed to test the magnitude of potential variations in the effectiveness of formed controlled release mechanisms. The comparison of the overall results for release tests clearly showed the higher release rates obtained for PC LYS than PP LYS. Almost 2-fold (78984 U/mg PC protein/40477 U/mg PP protein = 1.95) higher purity of PC LYS than PP LYS resulted with 1.6−3-fold higher release rates of PC LYS than the PP LYS from similar films. The results of SDS-PAGE clearly showed the quite similar moleculare weights (MWs) of PP and PC LYS centered around 12 kDa (Supporting Information, Figure S3). The SDS-PAGE profiles of PC LYS did not indicate any considerable protein impurities within this preparation except a thin band appeared at 11 kDa. On the other hand, as expected, the electrophoresis results showed the presence of different protein impurities in the PP LYS. The protein bands observed as impurities in PP LYS between 43 and 65 kDa concentrate around 46−47 kDa that might correspond to the ovalbumin fraction reported to have a MW of 45 kDa.[40] Dense bands observed in PP LYS between 34 and 43 kDa might be ovoglobulins ($G_2$ and $G_3$) and flavoprotein that have reported MWs between 30 and 45 kDa[41] while the dense band centered at 26 kDa might be ovomucoid and ovoglycoproteins that have reported MWs at 28 and 24 kDa, respectively.[41] Thus, it is possible that the PP LYS might form complexes with the impurities present in egg white, and this affected its release profiles. The interaction of PP LYS with egg white protein impurities might modify its diffusion properties due to changes in its molecular weight and affinity (by hydrophobic or charge−charge interactions) to film matrix. However, the results of this work clearly showed the possibility of controlling release rates of LYS at different purities by using blend film technology in the presence of CAT.

**CAT Release Profiles and Antioxidant Potential of Blend Films.** The results of release tests conducted to determine release profiles of CAT showed that 72−84% of CAT existed in soluble form in films (Table 2) while remaining CAT was bound by the film matrix, since this phenolic compound is capable to form H bonds with zein film matrix.[42] Thus, the soluble CAT in films formed a significant antioxidant potential that varies between 69 and 81 $\mu$mol Trolox/cm$^2$. On the other hand, the release curves clearly showed the effectiveness of the formed blend film structures to reduce release rates of CAT (Figure 3). The zein−fatty acid blend films showed 1.6−2.9-fold lower initial CAT release rates than the control zein film. The highest CAT release rate among blend films was observed for that of zein−LAU films while zein−OLE blend films had the lowest CAT release rates and zein−LIN blend films had intermediate CAT release rates. These results clearly proved that the change of chain length of fatty acids during blend film making could be employed as a highly effective tool to control release rates of both CAT and LYS. Moreover, it is also evident that the $C_{18}$ fatty acids' number of double bonds and tail conformation (LIN has more bent tail than OLE) that did not affect release rates of LYS is

dx.doi.org/10.1021/jf500666w | J. Agric. Food Chem. 2014, 62, 8238−8246

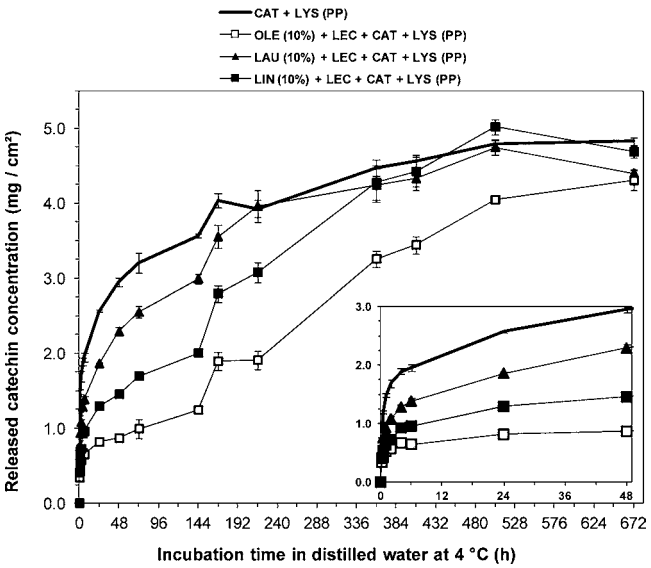

**Figure 3.** Release profiles of CAT from zein-based films containing PP LYS. CAT: catechin; LYS: lysozyme; OLE: oleic acid; LAU: lauric acid; LIN: linoleic acid; LEC: lecithin.

effective on release rates of CAT. The CAT has a significantly lower molecular weight (MW: 290.3 g/mol) than LYS (MW: 14 300 g/mol). However, it is an amphiphilic molecule, and its diffusion properties might change due to its hydrophobic affinity on the aliphatic chains of fatty acids. It appeared that the CAT showed higher hydrophobic affinity to microspheres formed by single double bonded OLE that has a slightly bent tail than those microspheres of double bonded LIN that has an apparently bent tail. In contrast, LYS is a hydrophilic protein, and this might limit its interactions with the hydrophobic tails of fatty acids. These results proved that the developed controlled release mechanism by blend film formation could be employed for delivery of multiple active compounds. Moreover, it is once more proved that the use of fatty acids having different molecular properties could be employed as an effective tool in controlling release profiles of blend films.

**Antimicrobial Potential of Films.** The results of antimicrobial tests on *L. innocua* are given in Table 1. The control zein film without LYS and CAT did not form any inhibition zones. In contrast, all other films containing PC or PP LYS showed antimicrobial effect on *L. innocua* and formed clear zones. Although PC LYS preparation has higher enzyme activity than the PP LYS preparation, there are no significant differences among the clear zone sizes of control zein films containing these enzymes ($P > 0.05$). However, the addition of CAT into films and reduction in their LYS release rate decreased the antimicrobial activity of PC LYS-containing zein control films significantly ($P < 0.05$) while this caused only an insignificant reduction in antimicrobial activity of PP LYS-containing zein control films ($P > 0.05$). Although the CAT-containing blend films with OLE and LIN showed lower LYS release rates than CAT-containing zein control films, there are no significant differences among the antimicrobial activities of these films containing CAT and PC or PP LYS ($P > 0.05$). On the other hand, the CAT-containing zein−OLE and zein−LIN films with sustained LYS release rates had significantly lower antimicrobial activity than PC or PP LYS-containing, but CAT-lacking zein control films showed the highest LYS release rates. In contrast, blend film making with the potent antimicrobial fatty acid LAU gave films with the highest antimicrobial activity. This result was quite expected, since Hoffman et al.[43] previously showed the high antimicrobial activity of LAU-containing zein films against *L. monocytogenes.* Although the results of this work did not indicate antilisterial activity originated from OLE and LIN in zein films, the OLE and LIN solubilized properly in broth medium were reported to have a limited antimicrobial activity on *L. monocytogenes*.[44] However, LAU has reported to have a 6-fold lower minimum inhibitory concentration on *L. monocytogenes* than OLE and LIN solubilized in broth medium.[44] The overall results of antimicrobial tests conducted with the classical zone inhibition test could not reflect the effectiveness of developed films in a food system, but they clearly showed the presence of in vitro antimicrobial activity of blend films with sustained LYS release rates and beneficial effects of using antimicrobial fatty acid LAU in blend film making.

**Mechanical Properties of Films.** In order to analyze their mechanical properties, tensile strength at break, elongation at break, and Young's modulus values of films were determined (Table 3). The control zein films lacking LYS were quite brittle and showed the lowest elongation, but the average tensile strength of these films (17.67 MPa) was significantly higher

**Table 3. Mechanical Properties of Zein-Based Blend Films**

| film composition | | | | | | |
|---|---|---|---|---|---|---|
| CAT (mg/cm$^2$) | fatty acid[a] (%) | LEC[a] (%) | tensile strength at break (MPa) | elongation at break (%) | Young's modulus (MPa) | film thickness ($\mu$m) |
| – | – | – | 17.67 ± 0.93a[b] | 4 ± 1a | 775 ± 44a | 113 ± 1 |
| | | | PP LYS (1.4 mg/cm$^2$) | | | |
| – | – | – | 10.98 ± 0.96b | 3 ± 1a | 530 ± 32c | 143 ± 1 |
| 6.0 | – | – | 0.98 ± 0.14c | 61 ± 18b | 55 ± 12d | 167 ± 1 |
| 6.0 | 10(OLE) | 10 | 1.17 ± 0.26c | 53 ± 9b | 55 ± 19d | 160 ± 2 |
| 6.0 | 10(LAU) | 10 | 0.88 ± 0.10c | 70 ± 10b | 37 ± 9d | 159 ± 2 |
| 6.0 | 10(LIN) | 10 | 1.23 ± 0.10c | 71 ± 15b | 63 ± 9d | 192 ± 5 |
| | | | PC LYS (0.7 mg/cm$^2$) | | | |
| – | – | – | 11.02 ± 0.67b | 3 ± 1a | 611 ± 22b | 119 ± 3 |
| 6.0 | – | – | 0.61 ± 0.06c | 161 ± 18c | 28 ± 5d | 160 ± 5 |
| 6.0 | 10(OLE) | 10 | 0.52 ± 0.02c | 164 ± 17c | 23 ± 4d | 162 ± 8 |
| 6.0 | 10(LAU) | 10 | 0.45 ± 0.04c | 166 ± 10c | 22 ± 4d | 184 ± 12 |
| 6.0 | 10(LIN) | 10 | 0.49 ± 0.08c | 131 ± 25c | 22 ± 6d | 173 ± 2 |

[a]Concentrations of fatty acids and LEC as % of zein (w/w). [b]Different letters in each column show significant difference at $P < 0.05$.

than those of the CAT-containing zein films (0.61−0.98 MPa) and zein−fatty acid blend films (0.45−1.23 MPa) ($P < 0.05$). The addition of LYS reduced the tensile strength and Young's modulus of zein films significantly ($P < 0.05$), but it did not cause any significant change in film elongation ($P > 0.05$). In contrast, the addition of CAT effectively plasticized the zein films and increased their elongation 20−50-fold of that for controls depending on the use of PC or PP LYS. The use of PC or PP LYS did not considerably affect the tensile strength and Young's modulus values of films, but CAT- and PC LYS-containing films showed significantly higher elongation than those containing CAT and PP LYS ($P < 0.05$). The negative effects of PP LYS in flexibility of the plasticized films could be due to its protein impurities that could bind part of the CAT or could cause some local disruptions within the film matrix. However, the CAT-containing films containing PP LYS were not brittle, and they are still much more flexible than the PP LYS-containing but CAT-lacking zein control films. On the other hand, the results of mechanical tests clearly showed that, in the presence of CAT, the blend film making with fatty acids had no considerable additional effect on mechanical properties of films. This result contradicts with those of Santosa and Padua[45] who reported the plasticizing effects of OLE and LIN on zein. However, these workers produced films from zein−fatty acid resins aggregated in cold water and used OLE and LIN in film composition at 50−100% (w/w) of zein.

The factors causing the classical brittleness and flexibility problems of zein films and possibility of using phenolic compounds including CAT in zein film plasticization has been studied recently. Zein films consist of a meshwork that is composed of doughnut structures formed by asymmetric rods joined to each other.[46] The hydrophobic interactions among asymmetric rods is the primary force that keeps them together and maintains the film integrity,[46] but these interactions are also responsible for the brittleness and lack of flexibility in zein films. It was recently shown that the phenolic compounds such as CAT and gallic acid could be used effectively for plasticization of zein films and zein-based films such as zein−wax composite and zein−fatty acid blend films.[24,38,47] It was reported that the zein plasticizing effect of phenolic compounds is due to the formation of H bonds between the hydroxyl groups of phenolic compounds and the carbonyl group of zein as well as the increased hydrophilicity of films due to increased number of −OH groups.[24,47] However, further characterization studies are needed to understand the exact factors effective on mechanical properties and morphologies of zein films.

This work clearly showed the possibility of controlling release rates of both LYS and CAT by using the blend film making technique. The sustained LYS and CAT release mechanisms of developed films were attributed to the encapsulation of a fraction of active compound in microspheres formed within the zein film matrix by blend film making, reduced film porosity caused by CAT and changed affinities of active compounds to modified hydrophilic/hydrophobic balance of film matrix. It was clearly shown that the LYS and CAT release rates of blend films could be changed by changing type and concentration of fatty acid used in blend films. The increase in fatty acid concentration of blend films reduces the LYS release rates. The increased fatty acid chain length is a highly effective factor causing sustained release of both LYS and CAT form the blend films. The formation of blends with $C_{18:1}$ more effectively sustained release rates of CAT than blends formed by $C_{18:2}$. The release tests also showed the presence of differences in LYS release profiles depending on the purity of the enzyme used in film making. The use of antimicrobial fatty acids like LAU in blend film making served not only to improve the controlled release properties of films but also to support the antimicrobial effect of films. This work showed the possibility of obtaining flexible edible films for controlled release of multiple active compounds. The use of LYS and CAT as active compounds could provide highly functional edible films suitable both for active (antimicrobial and antioxidant) packaging and bioactive packaging. Thus, it is possible to employ such multifunctional films not only to increase safety and quality of food but also to improve the potential health benefits of food.

**ABSTRACT:** Soyasaponins are a group of structurally complex oleanane triterpenoids primarily found in soybeans and have diverse biological properties. The recent investigations and findings (since 2000) regarding the biological functions of soyasaponins and their aglycones, including their anti-inflammatory, antimutagenic, anticarcinogenic, antimicrobial, and hepato- and cardiovascular-protective activities, are herein summarized. The primary conclusion is that the use of soyasaponins and soyasapogenols in functional foods should be considered.

**KEYWORDS:** *soyasaponin, soyasapogenol, anti-inflammatory, anticarcinogenic, hepatoprotective, cardiovascular*

## INTRODUCTION

Soyasaponins are found in soybeans (*Glycine max*) and other legumes, such as lentils (*Lens culinaris*) and green peas (*Pisum sativum* L). Soyasaponins are amphiphilic oleanane triterpenoid glycosides with polar sugar chains conjugated to a nonpolar pentacyclic ring[1] and are generally classified into four major groups according to their aglycones (soyasapogenols): groups A, B, E, and DDMP (2,3-dihydro-2,5-dihydroxy-6-methyl-4*H*-pyran-4-one). Group A soyasaponins are characterized as having a hydroxyl group at C-21 and two sugar moieties separately attached at the C-3 and C-22 positions of soyasapogenol A,[2] with an exceptional compound, A3, that contains one sugar moiety at C-3.[3] In addition to a starting glucoronyl residue, the C-3 side chain has one or two more sugar residues, and the C-22 sugar moiety contains two sugar residues: a starting arabinosyl and an ending xylosyl or glycosyl residue.[4] Group A soyasaponins can be further grouped into acetylated and deacetylated forms.[1] Group B soyasaponins differ from those in group A by the presence of a hydrogen atom at C-21 and only one sugar moiety at the C-3 position of soyasapogenol B,[2] with the exception of three soyasaponins that, in addition to the C-3 sugar chain, contain a sugar moiety at C-22.[5,6] Additionally, soyasaponin Bh, which has a unique five-membered ring exhibiting hemiacetal activity, has been identified.[7] With a DDMP group connected to group B at C-22, DDMP soyasaponins are sometimes categorized as B-type soyasaponins.[1] Unlike DDMP soyasaponins, group E soyasaponins have a carbonyl group at C-22 that may be produced by the photo-oxidation of group B. Approximately 36 soyasaponins have been found in soybean.[2,4] As aglycones of soyasaponins, soyasapogenols A, B, and E do not occur in soybean naturally but can be formed by the acid or alkaline hydrolysis of soyasaponins and therefore may exist in processed soy products. Soyasapogenols C and D may result from the acid hydrolysis of soyasapogenol B and are not genuine aglycones of soyasaponins.[2,4]

The physiological effects of soyasaponins are dependent on their metabolism and absorption.[8] The anaerobic incubation of soyasaponin Ab with human fecal specimens produced two main metabolites, soyasapogenol A and soyasapogenol A 3-$\beta$-D-glucuronide, despite the different metabolic activities and pathways among individuals.[9] When group B soyasaponins were digested by healthy women, the metabolite was soyasapogenol B and was excreted in the feces.[10] In particular, soyasaponin I was metabolized to soyasapogenol B by human fecal microorganisms via soyasaponin III or, alternatively, via soyasaponin III and soyasapogenol B 3-$\beta$-D-glucuronide with apparent first-order kinetics.[8,11] The transepithelial transfer of soyasaponin I across a human colon cancer Caco-2 cell monolayer was concentration independent and saturable with an intermediate apparent permeability coefficient ($P_{app}$) of $(0.9-3.6) \times 10^{-6}$ cm/s, whereas soyasapogenol B was transported across Caco-2 cells in a concentration-dependent manner with a low $P_{app}$ of $(0.3-0.6) \times 10^{-6}$ cm/s.[10] Due to its tighter paracellular route, the Caco-2 model often underestimates the permeability of compounds in the human intestine.[12]

With diverse chemical structures, soyasaponins and soyasapogenols have been reported to possess a wide range of health benefits, including anticancer, antivirus, and antioxidant activities, as well as hepatoprotective and cardiovascular-protective effects.[2,4] In this review, recent studies (since 2000) concerning the biological functions of these compounds have been summarized (Table 1).

## ANTI-INFLAMMATORY EFFECTS

A crude extract of soyasaponins significantly inhibited the production of the pro-inflammatory cytokine tumor necrosis factor (TNF)-$\alpha$ and chemokine monocyte chemoattractant protein (MCP)-1, the inflammatory mediators prostaglandin E2 (PGE2) and nitric oxide (NO), and the inflammatory enzymes cyclooxygenase (COX)-2 and inducible nitric oxide

**Table 1. Biological Effects of Soyasaponins and Soyasapogenols**

| material | effect | in vitro/in vivo | mechanism | ref |
|---|---|---|---|---|
| total soyasaponins | anti-inflammatory | LPS-stimulated macrophages | inhibit TNF-$\alpha$, MCP-1, PGE2, NO, COX-2, and iNOS production and I$\kappa$B-$\alpha$ degradation | 13 |
| | | helper T cells | increase $p27^{KIP1}$ expression and stability; inhibit cyclin D and cyclin E expression, cell cycle transition and proliferation, and secretion of IL-2 and IFN-$\gamma$ | 17 |
| | antimutagenic | *S. typhimurium* | inhibit aflatoxin $B_1$-induced mutagenicity by scavenging electrophiles | 20 |
| | | Hep-G2 cells | inhibit the formation of aflatoxin $B_1$-induced DNA adducts by changing membrane permeability | 20 |
| | anticarcinogenic | colon cancer HT-29 cells | alter membrane structure; inhibit cell growth and migration, I$\kappa$B-$\alpha$ degradation, COX-2 and PKC expressions, and PKC activity; increase AP activity and CEA levels; induce autophagic death | 22−25 |
| | | colon cancer DLD-1 cells | elicit cell cycle arrest at the G2 phase along with early apoptosis | 27 |
| | | mice injected with colon carcinoma CT-26 cells | decrease the incidence of metastatic tumor colonization in lungs | 23 |
| | | fibrosarcoma HT-1080 cells | inhibit the expression and secretion of MMP-2 and MMP-9; increase TIMP-2 secretion; suppress cell migration | 23 |
| | hepatoprotective | mice | decrease lipid peroxidation in the liver by increasing the secretion of thyroid hormones | 44 |
| | | mice with acute alcohol-induced liver damage | protect plasma membrane integrity; increase liver regenerative capacity; decrease serum levels of hepatic marker enzymes and hepatic TG, TC, and MDA contents; activate the hepatic antioxidant system; prevent hepatic steatosis necrosis, inflammation, and swelling | 45 |
| | lung-protective | rats with silicotic pulmonary fibrosis | decrease serum NO and ROS contents and pulmonary MDA level; increase serum SOD level; inhibit Fas/FasL expression and lung cell apoptosis | 59, 60 |
| soyasaponins with no soyasapogenols | anticarcinogenic | hepatocarcinoma Hep-G2 cells | inhibit proliferation; induce a sub-G1 buildup of apoptotic cells and morphological changes | 33 |
| soyasaponins $A_2$ + I + II + III + V + Be | anticarcinogenic | cervical carcinoma HeLa cells | cytotoxic; change cell cycle distribution; increase NO content, the activities of NOS, and iNOS and intracellular $Ca^{2+}$ levels; cause a loss of mitochondrial transmembrane potential; induce apoptosis | 34, 35 |
| soyasaponin Ab | anti-inflammatory | LPS-stimulated macrophages | inhibit TNF-$\alpha$, PGE2, NO, and IL-1$\beta$ production, I$\kappa$B-$\alpha$ degradation and binding of LPS to TLR4 | 14 |

synthase (iNOS) and the degradation of IκB-α, an inhibitor of nuclear transcription factor kappa B (NF-κB), in lipopolysaccharide (LPS)-stimulated macrophages.[13] The phosphorylation and degradation of IκB-α allowed NF-κB to translocate to the nucleus, bind to specific promoter sequences, and induce the expression of inflammatory genes. Thus, it may be through the inhibition of NF-κB activation that soyasaponins exert their anti-inflammatory effects. Soyasaponins Ab, $A_1$, $A_2$, and I were confirmed to contribute to these anti-inflammatory properties.[14−16] Furthermore, soyasaponins $A_1$, $A_2$, and I were found to inhibit iNOS enzyme activity and NF-κB transcriptional activity in LPS-stimulated murine RAW 264.7 macrophages.[15] Soyasaponins Ab and I also suppressed the release of the pro-inflammatory cytokine interleukin (IL)-1β in LPS-stimulated mouse peritoneal macrophages.[14,16] The $IC_{50}$ values of soyasaponin Ab for inhibiting the production of PGE2 and NO and the expression of TNF-α and IL-1β were 2.0 ng/mL, 1.6 μM, 1.3 ng/mL, and 1.5 pg/mL, respectively. In addition, soyasaponin Ab prevented the binding of LPS and Alexa-Fluor-594-conjugated LPS to Toll-like receptor 4 (TLR4),[14] a receptor on macrophages that is linked to the NF-κB pathway via IL-1 receptor-associated kinases (IRAKs) and that recognizes pathogen-associated molecular patterns such as LPS. In contrast to soyasaponins $A_1$, $A_2$, and I, soyasapogenols A and B exhibited no inhibitory effect on the production of NO, iNOS, and TNF-α or on the iNOS enzyme activity in LPS-stimulated macrophages,[15] indicating that the sugar chains in the structures of soyasaponins are critical to their anti-inflammatory activities. Excessive helper T (Th) cell activity occurs during severe inflammation. Soyasaponins were found to enhance the expression and increase the stability of the negative regulator of cyclin-dependent kinases (CDKs) $p27^{KIP1}$ and to decrease the expression of the positive CDK regulators cyclin D and cyclin E in Th cells. CDKs are key molecules for cell cycle progression. Soyasaponins were thus confirmed to block the G1-to-S phase cell cycle transition and inhibit the proliferation of Th cells, leading to the decreased mRNA transcription and secretion of cytokine IL-2 and interferon (IFN)-γ in Th cells.[17] As a member of the immunoglobulin family of adhesion molecules, intercellular adhesion molecule (ICAM)-1 appears to cause acute and chronic inflammatory disease. Soyasaponin $A_3$ mildly inhibited the TNF-α-induced expression of ICAM-1 on THP-1 human monocytic leukemia cells, soyasapogenols B and C exhibited strong inhibitory activities, and soyasapogenol A slightly activated ICAM-1 expression. These results indicate that the hydroxyl group at C-21 and the glycosyl group at C-3 influence the inhibition of ICAM-1.[18] The excessively activated complement system acts fatally on organ transplantation, and its modulation is important in the treatment of inflammatory diseases. Soyasaponin III showed a stronger anticomplementary activity than did soyasaponin I, and their activities were influenced by the nature of glucuronic acid; the free acid forms (−COOH) displayed much more potent activity than did the sodium salt forms ($-COO-Na^+$), methyl ester forms ($-COOCH_3$), or reduced forms ($-CH_2OH$).[19]

In addition to down-regulating the expression of TNF-α, IL-1β, COX-2, and iNOS, orally administered soyasaponins Ab and I potently ameliorated body weight reduction, colon shortening, macroscopic score, and myeloperoxidase activity in the colon of 2,4,6-trinitrobenzenesulfonic acid (TNBS)-induced colitic mice.[14,16] Soyasaponin I also suppressed the expression of PGE2 and another potent pleiotropic inflammatory cytokine, IL-6, and suppressed the activation of NF-κB, reducing the levels of the lipid peroxides malondialdehyde (MDA) and 4-hydroxy-2-nonenal and increasing the glutathione content as well as the superoxide dismutase (SOD) and catalase activities.[16] These results indicate that soyasaponin I may ameliorate colitis by inhibiting NF-κB activation and consequently diminishing its ability to scavenge the lipid peroxides produced by TNBS. Soyasaponin Ab increased the expression of IL-10, an immunosuppressive and anti-inflammatory cytokine that inhibits NF-κB activation and consequently suppresses the production of pro-inflammatory cytokines. Soyasaponin Ab also inhibited the expression of TLR4 and the phosphorylation of IRAK1, the inhibitor of NF-κB kinase (IKK)-β, and the NF-κB subunit p65 in the colon of TNBS-induced colitic mice.[14] Phosphorylated IRAK1 activates a multimeric protein complex, and the activated subunit, transforming growth factor-β activated kinase-1, phosphorylates IKKs. IKKs phosphorylate IκB-α, leading to its ubiquitination and subsequent degradation by the proteasome.[14]

## ANTI-MUTAGENIC AND ANTI-CARCINOGENIC EFFECTS

Crude soyasaponins strongly inhibited aflatoxin $B_1$-induced mutagenicity and blocked the initiation step of carcinogenesis by inhibiting the formation of aflatoxin $B_1$-induced DNA adducts.[20] Additionally, an ethanol extract consisting of group B, E, and DDMP soyasaponins, as well as the purified soyasapogenol B, both repressed 2-acetoxyacetylaminofluorene (2AAAF)-induced DNA damage in Chinese hamster ovary cells and thus exhibited antigenotoxic activity against 2AAAF.[21]

Crude soyasaponins changed the membrane structure and inhibited the growth of WiDr human colon cancer cells (the same cell line as HT-29) by reducing the activity of protein kinase C (PKC) while increasing the activity of alkaline phosphatase (AP) at lower concentrations or by inducing autophagic death at higher concentrations.[22] PKC activity increases as cells undergo the proliferation process, and AP activity is a marker of cell differentiation. For the HT-29 cell line, crude soyasaponins were additionally found to inhibit cell migration and increase the level of another differentiation marker, carcinoembryonic antigen (CEA).[23,24] In addition, crude soyasaponins suppressed the degradation of IκB-α and down-regulated the expression of COX-2 and PKC in HT-29 cells,[25] indicating that the anti-inflammatory activity of soyasaponins is involved in their anticarcinogenic function. Soyasapogenols A and B were found to inhibit the growth of HT-29 cells more strongly than did soyasaponin III.[26] For DLD-1 colon cancer cells, treatment with soyasaponins also elicited cell cycle arrest at the G2 phase and early apoptosis.[27] Group B soyasaponins, at physiologically relevant doses, increased the protein content of the CDK inhibitor $p27^{KIP1}$ and the inhibitory phosphorylation of CDK-2 at $Tyr^{15}$ and decreased the activity of CDK-2, leading to an accumulation of HCT-15 colon cancer cells in S phase and, through this delay, suppressed cell proliferation. Group B soyasaponins also induced type II nonapoptotic programmed cell death or macroautophagy in the HCT-15 cell line, as indicated by the elevated concentration of microtubule-associated protein light chain-3 I and II, by the increased incorporation of monodansylcadaverine into autophagic vacuoles, and by morphological alterations, including reduced cytoplasmic density and prominent vacuolization.[28] The autophagy-inducing action in HCT-15 cells was due to the suppression of Akt activity by reducing the Akt phosphorylation at $Ser^{473}$

dx.doi.org/10.1021/jf503047a | J. Agric. Food Chem. 2014, 62, 8247−8255

and the activation of ERK 1/2, in part modulated by enhanced raf-1 activity.[29] Soyasapogenol B was found to inhibit the proliferation and reduce the viability of Caco-2 cells.[10,30] Feeding with dietary soyasaponins also decreased the incidence of metastatic tumor colonization in the lungs of mice injected with colon carcinoma CT-26 cells.[23]

A reflux extract consisting of group B soyasaponins was cytotoxic to hepatocarcinoma Hep-G2 cells with an $LC_{50}$ value of 0.55 mg/mL and produced a significant accumulation of sub-G1 apoptotic cells, and a room temperature extract containing a greater amount of DDMP soyasaponins induced differentiation and morphological changes.[31] Another extract containing a majority of soyasaponins I and III inhibited Hep-G2 growth with an $LC_{50}$ value of 0.39 mg/mL. The significant accumulation of sub-G1 cells, mid- and late-apoptotic cells, and dead cells confirmed the apoptosis-inducing effects of soyasaponins I and III, with the cellular protein expression of the caspase family of enzymes being a main trigger of the apoptotic pathway.[32] Soyasapogenols A and B more strongly inhibited Hep-G2 proliferation than did a soyasaponin extract containing no soyasapogenols, with $LC_{50}$ values of 0.052, 0.128, and 0.594 mg/mL, respectively, and induced a greater sub-G1 buildup of apoptotic cells.[8,33] All three compounds also induced morphological changes in Hep-G2 cells, such as nuclear condensation and fragmentation.[33]

The treatment of human fibrosarcoma HT-1080 cells with crude soyasaponins inhibited the mRNA expression and secretion of matrix metalloproteinase (MMP)-2 and MMP-9, increased the secretion of tissue inhibitor of metalloproteinase (TIMP)-2, and reduced cell migration.[23] TIMP-2 contributes to the inhibition of pro-MMP-2 and acts as a specific inhibitor of MMP-2, and MMP-2 and MMP-9 degrade extracellular matrix components and contribute to the invasion and metastasis of cancer cells.

A mixture containing soyasaponins $A_2$, I, II, III, V, and Be had obvious cytotoxic effects on human cervical carcinoma HeLa cells, changing the cell cycle distribution and inducing apoptotic features, including nuclear fragmentation, cytoplasm shrinkage, and decreased cell volume.[34] The apoptosis of HeLa cells might be due to the increased NO content and the activities of NOS and iNOS, the loss of mitochondrial transmembrane potential, or the increase in intracellular $Ca^{2+}$ induced by the fraction released through the mitochondrial pathway.[35] Soyasapogenol B also inhibited the proliferation of HeLa cells.[8]

For the SNB19 human glioblastoma cell line, group B soyasaponins inhibited cell growth and invasion and decreased the S phase of the cell cycle with a concomitant increase in the G0/G1 phase. The apoptosis of SNB19 cells induced by group B soyasaponins was due to the loss of mitochondrial transmembrane potential, the release of mitochondrial cytochrome *c* into the cytosol, and the subsequent up-regulation of Apaf-1, the activation of caspase-9 and caspase-3, and the specific cleavage of poly-ADP-ribose polymerase.[36]

Sialyltransferases catalyze the transfer of sialic acids to the nonreducing terminal positions on the sugar chains of glycoconjugates, and the increased sialylation is associated with oncogenic transformation and metastasis. Soyasaponin I, a sialyltransferase inhibitor,[37] was predicted to inhibit the $\alpha$2,3-sialyltransferase activity of nonmetastatic MCF-7 breast cancer cells and depressed the mRNA expression of ST3Gal IV sialyltransferase and the secretion of cell surface $\alpha$2,3-sialic acids. Soyasaponin I also stimulated MCF-7 cell adhesion to collagen I and the Matrigel matrix. Soyasaponin I showed no effect on the migration of MCF-7, but it did significantly decrease the migration ability of highly metastatic MDA-MB-231 breast cancer cells.[38] Soyasapogenol B reduced the proliferation of both estrogen-responsive MCF-7 cells[8,39] and estrogen-insensitive MDA-MB-231, and soyasapogenol A inhibited the growth of MDA-MB-231 but stimulated MCF-7 cell proliferation. Soyasapogenol A also increased estrogen-induced pS2 mRNA expression and activated the estrogen receptor in MCF-7 cells,[39] indicating an estrogen-like activity of soyasapogenol A that might have the same in vivo anticarcinogenic and health-promoting functions as those reported for the soybean phytoestrogen genistein.

Soyasaponin I inhibited the expression of $\alpha$2,3-sialic acids on the surface of highly metastatic B16F10 melanoma cells; increased cell adhesion to the extracellular matrix proteins collagen IV, fibronectin, and laminin; and reduced cell migration. Additionally, soyasaponin I-treated B16F10 cells showed a markedly decreased ability to grow into tumors in the lungs of experimental mice that had harbored the cells for a 2 week period after tail-vein delivery.[40] Soyasapogenol B exhibited potent cytotoxicity against A549 lung cancer cells.[8]

## HEPATOPROTECTIVE EFFECTS

Soyasaponin I exhibited protective activity toward immunological liver injury in primary cultured rat hepatocytes as measured by the reduced alanine aminotransferase (ALT) activity in the medium.[41] The immunological liver injury was considered to be caused by complement-mediated cell damage.[19] Soyasaponin III and soyasapogenol B exerted weak protective effects against the cytotoxicity of *tert*-butyl hydroperoxide to human liver-derived cells.[42] Soyasapogenols A and B were found to protect against aflatoxin $B_1$-induced cytotoxicity to liver cells and, furthermore, soyasapogenol B protected against actinomycin D-TNF-$\alpha$-induced apoptosis and increased the mixed lymphocyte reaction (MLR) in cultured cells. The marked decrease in MLR is proportional to the decrease in immune system function in patients and therefore increases the chance of infectious diseases; thus, soyasapogenol B may be a candidate therapeutic agent for chronic hepatitis.[43]

When total soyasaponins were administered to mice orally and intraperitoneally, significantly decreased lipid peroxidation was observed in the liver, with the effect of the intraperitoneally injected soyasaponins being comparable to that of $\alpha$-tocopherol. Soyasaponins increased the levels of serum thyroid hormones, which then restrained NADPH-dependent lipid peroxidation in vitro in liver microsomes more strongly than did $\alpha$-tocopherol. Propylthiouracil, an antithyroid drug, decreased the effect of the soyasaponins, suggesting that the in vivo inhibition of lipid peroxidation by soyasaponins might be mediated through the secretion of thyroid hormones. Constituent group B soyasaponins (I, II, and III) showed much stronger in vivo reducing effects on hepatic lipid peroxidation than did group A soyasaponins ($A_1$ and $A_2$), and only group B soyasaponins induced a significant increase in thyroid hormones.[44] The administration of crude soyasaponins in mice with acute alcohol-induced liver damage decreased the serum levels of the hepatic marker enzymes aspartate transaminase (AST), ALT, AP, and lactate dehydrogenase by stabilizing the plasma membrane and repairing the hepatic tissue damage as well as the hepatic triglyceride (TG), total cholesterol (TC), and MDA contents. A better profile of the antioxidant system with normal SOD, glutathione *S*-transferase,

and glutathione peroxidase activities was also observed, which was associated with an increase in the hepatic glutathione level. In addition, crude soyasaponins prevented hepatic steatosis necrosis, inflammation, and swelling in acutely alcohol-treated mice.[45] Concanavalin (Con) A injection into mice can lead to autoimmune or viral hepatitis. Soyasapogenol A reduced the number of infiltrating inflammatory cells in the liver and the elevated level of plasma TNF-$\alpha$ and then reduced the elevated plasma ALT activity and the number of apoptotic bodies in the liver parenchymal cells, resulting in the prevention of liver damage in the Con A-induced hepatitis mouse model.[46] Similarly, soyasapogenol B lowered the elevated plasma ALT level in a mouse model, with two hydroxyl groups on the A ring of soyasapogenol B required for the amelioration.[47]

## CARDIOVASCULAR PROTECTIVE EFFECTS

$\alpha$-Glucosidase is involved in the development of diabetes. Group B, E, and DDMP soyasaponins showed strong inhibitory activities against this enzyme in vitro, with $IC_{50}$ values of 10−40 $\mu$M.[48] Renin is the rate-limiting enzyme in the renin−angiotensin system, and its overactivation leads to hypertension. A soybean embryo extract showed approximately 3-fold higher human renin inhibitory activity than did a soybean cotyledon extract, and the active compound was shown to be soyasaponin I. Kinetic analysis indicated partial noncompetitive inhibition, with a $K_i$ value comparable to that of synthetic tetradecanoyl acetal sodium sulfate, an analogue of sodium houttuynin.[49,50] Following a simple structure and activity analysis of 14 saponins and sapogenols, the 3-*O*-$\beta$-D-glucopyranosiduronic moiety in saponins was found to be essential for renin inhibition. In addition to soyasaponin I, soyasaponin II contains such a structure and has a similar human renin inhibitory activity.[51]

Due to the bile acid- or cholesterol-binding ability in the digestive tract,[52] group B soyasaponins increased the fecal excretion of total bile acid, primarily including cholic acid, and neutral sterols, including cholestane, coprostanol, lathosterol, and campesterol, and therefore improved the plasma cholesterol status by lowering the TC, non-high-density-lipoprotein cholesterol (HDLC), and TG concentrations as well as the TC-to-HDLC ratio in hamsters. Greater production of group B soyasaponin metabolites was associated with better plasma cholesterol status in hamsters, indicating that gut microbial variation in soyasaponin metabolism influences the health effect of group B soyasaponins.[53] The oral administration of commercially purified soyasaponin I in spontaneously hypertensive rats (SHRs) significantly decreased their blood pressure and led to reductions in the plasma levels of low-density lipoprotein cholesterol (LDLC), AST, ALT, and blood urea nitrogen, indicating that soyasaponin I may exert its liver and kidney protective functions by lowering blood pressure.[54]

## ANTIMICROBIAL AND ANTIVIRAL EFFECTS

Soyasaponin I was found to have moderate activities against *Escherichia coli* and *Candida albicans*, whereas soyasaponin III showed only weak activity against *E. coli*.[55] Soyasaponin II showed much higher in vitro anti-herpes simplex virus type I (HSV-1) activity than did soyasaponin I, indicating the contribution of the glucosyl unit in the central sugar moiety to the antiviral activity.[56] The activities of soyasapogenols A and E were less than $^1/_{20}$ and $^1/_{10}$ that of soyasapogenol B, respectively; thus, the hydroxyl group at C-21 and the carbonyl group at C-22 seem to reduce anti-HSV-1 activity; soyasapogenol C, with a double bond at C-21 and C-22 instead of the hydroxyl group in soyasapogenol A, showed moderate anti-HSV-1 activity.[56,57]

## ADDITIONAL EFFECTS

Soyasaponin I showed 1,1-diphenyl-2-picrylhydrazyl (DPPH) radical-scavenging activity with a 50% inhibitory concentration of 70.2 $\mu$M, which is comparable to that of $\alpha$-tocopherol ($IC_{50}$ = 52.1 $\mu$M). Soyasaponin I also suppressed lipid peroxidation in liposomes prepared from L-$\alpha$-phosphatidylcholine, with an $IC_{50}$ of 19.5 $\mu$M.[16] Soyasaponin $\beta$g at 1 mM showed an 8% $O_2^-$ scavenging activity and at 25 $\mu$M exhibited a 20.9% DPPH radical-scavenging activity ($IC_{50}$ = 63.8 $\mu$M), which is comparable to that of *tert*-butylhydroxytoluene (21%; $IC_{50}$ = 67.5 $\mu$M). When a low concentration of gallic acid was added, a synergistic effect was observed, with an unpaired electron located on the carbons at C-4 and C-6 and on the ketone group at C-4 of the DDMP moiety of soyasaponin $\beta$g and a two-electron reduction from gallic acid related to the synergistic scavenging action toward $O_2^-$ and DPPH radicals.[58]

The treatment of rats with silicotic pulmonary fibrosis with soyasaponins decreased the serum NO and reactive oxygen species (ROS) contents as well as the MDA level in pulmonary tissue, increased the serum SOD level, and inhibited the expression of Fas and FasL and the apoptosis of lung cells, which thus retarded the progress of $SiO_2$-induced pulmonary fibrosis.[59,60] Soyasaponins bearing sugar chain(s) showed strong adjuvant activities and stimulated anti-chicken ovalbumin total-IgG and IgG1 antibody responses in mice.[61] Among the bisdesmosidic soyasaponins, soyasaponin $A_1$, with a long sugar side chain, induced stronger total IgG and IgG1 antibody responses than did soyasaponin $A_2$. For the monodesmosidic soyasaponins, the antibody response decreased in the order soyasaponin I > II > III. The adjuvant activity of these soyasaponins increased with the ratio of hydrophilic sugar side chain(s) to lipophilic aglycone (HLB). Therefore, the number, length, and composition of sugar side chains affecting the HLB value would indicate the overall conformation of each saponin molecule, and the amphipathic structure would define the fundamental adjuvanticity of soyasaponins.[62] Soyasaponin I also impeded kidney enlargement and cyst growth in the *pyc* mouse model of polycystic kidney disease (PKD), as indicated by the reduced kidney weight, water content, and plasma creatinine and urea levels.[63]

Human beings have consumed soybeans as a source of high-quality protein and other nutrients for hundreds of years. This review summarizes recent findings regarding the health effects of soyasaponins and soyasapogenols. Clearly, the biological functionality of these compounds largely depends on the testing materials, methodology, and dose. Before they are used as components of functional foods, further studies of the in vivo and clinical effects of soyasaponins and soyasapogenols are necessary.

# Simultaneous Degradation of Cypermethrin and Its Metabolite, 3-Phenoxybenzoic Acid, by the Cooperation of *Bacillus licheniformis* B-1 and *Sphingomonas* sp. SC-1

Fangfang Liu, Yuanlong Chi, Shuang Wu, Dongying Jia, and Kai Yao*

College of Light Industry and Food Engineering, Sichuan University, 610065 Chengdu, Sichuan, People's Republic of China

**ABSTRACT:** Cypermethrin (CY) and its metabolite, 3-phenoxybenzoic acid (3-PBA), generally coexist in agricultural soil and cause a toxic effect on the human body. In this study, CY and its metabolite 3-PBA were simultaneously degraded by the cooperation of *Bacillus licheniformis* B-1 and *Sphingomonas* sp. SC-1. The effects of the inoculation proportion and inoculation method of these two strains, cultivation time, and initial CY content on the degradation of CY and 3-PBA were investigated. Furthermore, the degradation of CY and 3-PBA in soil environment by using the cooperation of these two strains was also determined. When the inoculation proportion of the biomass of strain B-1/strain SC-1 was 3.3:6.7, strain B-1 was inoculated first, and strain SC-1 was inoculated after 24 h of cultivation, 75.60% CY (100 mg $L^{-1}$) was degraded at 72 h and the 3-PBA content was 10.31 mg $L^{-1}$. Compared with those by using only strain B-1, the half-life of CY by using these two strains was shortened from 71.90 to 35.71 h, and the yield coefficient of 3-PBA was decreased from 0.8938 to 0.2651. As in the soil environment, the CY content by using these two strains within a period of 25 days declined from 22.71 to 5.33 mg $kg^{-1}$ and the 3-PBA content was 1.84 mg $kg^{-1}$. Compared with those by using only strain B-1, the half-life of CY by using these two strains was shortened from 19.86 to 11.34 days and the yield coefficient of 3-PBA was decreased from 0.5302 to 0.2056. This work could develop a promising approach for the simultaneous degradation of CY and its metabolite 3-PBA in agricultural soil.

**KEYWORDS:** *cypermethrin, 3-phenoxybenzoic acid, simultaneous degradation, Bacillus licheniformis B-1, Sphingomonas sp. SC-1, cooperation*

## INTRODUCTION

Cypermethrin (CY), used as an important pyrethroid pesticide, has been extensively used for pest control in fruits and vegetables or as grain protectant against stored-product insect pests,[1−3] especially when the use of organophosphate and organochlorine is restricted due to their high toxicity.[2] However, CY often remains in agricultural soil and agricultural products owing to excess spraying,[4,5] and CY residues would be accumulated in human or mammal bodies through frequent contact or the food chain,[6] which might cause toxic effects on the reproductive system,[5] immune system,[7] and nervous system.[8] Therefore, to remediate CY-contaminated regions, biodegradation is generally considered as an effective method to remove CY residues, owing to its characteristics of high efficiency, easy application, and environmental friendliness.[9−11]

As reported, most CY-degrading organisms could not mineralize CY, but transformed it into 3-phenoxybenzoic acid (3-PBA).[12] 3-PBA could disrupt the normal secretion of reproductive hormones[13] and lead to sperm DNA fracture and sperm concentration decrease in the male body.[14] Moreover, 3-PBA is more likely to spread in the environment due to its stronger hydrophilicity compared with CY[15] and thus could cause some food safety problems.[16,17] Therefore, the biodegradation of 3-PBA has also attracted increasing attention.[15]

To the best of our knowledge, there are many research sutdies focused on the degradation of either CY[18,19] or 3-PBA[20,21] separately. Jilani et al. found that *Pseudomonas* IES-Ps-1 had a good degradation ability on CY and could degrade 51% of CY (80 mg $L^{-1}$) in 48 h.[22] Chen et al. reported that *Stenotrophomonas* sp. ZS-S-01 could degrade 82.9% of 3-PBA (250 mg $L^{-1}$) in 9 days.[23] However, no information about the simultaneous degradation of CY and 3-PBA is available. In fact, CY and 3-PBA generally coexisted in the CY degradation process. Therefore, the simultaneous degradation of these two compounds would be of important practical application value. Our previous studies proved that *Bacillus licheniformis* B-1 (strain B-1) and *Sphingomonas* sp. SC-1 (strain SC-1) had good degradation capacities on CY and 3-PBA, respectively.[21,24] In this study, these two strains were used for the cooperative degradation of CY and 3-PBA. The purpose is to enhance CY degradation and remove the metabolite 3-PBA simultaneously. Figure 1 shows the proposed degradation pathway of CY and 3-PBA by using strains B-1 and SC-1. CY is first degraded into 3-PBA through hydrolysis by strain B-1,[12] and then the 3-PBA is converted into muconic acid through benzene ring cleavage by strain SC-1.[21] The metabolite of muconic acid has been proved to be of no harm to the human body.[25]

## MATERIALS AND METHODS

**Materials.** Cypermethrin (CY, 99.7%) was purchased from the National Standard Substances Center (Beijing, China). 3-Phenoxybenzoic acid (3-PBA, 98%) was purchased from Sigma-Aldrich Chemical Co. (Shanghai, China). Chromatographic grade acetonitrile was purchased from Meridian Medical Technologies (Beijing, China). Acetonitrile, ethyl acetate, ethyl alcohol, $KH_2PO_4$, $K_2HPO_4$, $MgSO_4$,

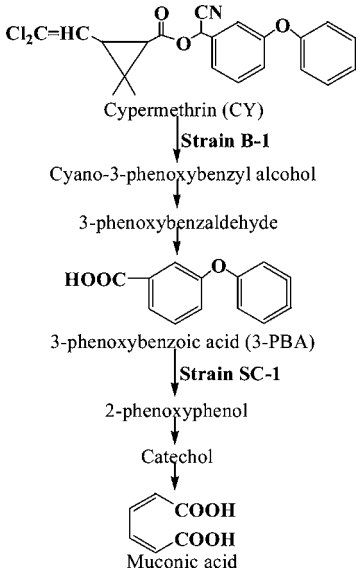

**Figure 1.** Proposed degradation pathway of CY and its metabolite 3-PBA by the cooperation of *Bacillus licheniformis* B-1 and *Sphingomonas* sp. SC-1.

NaCl, NaOH, $Na_2SO_4$, $(NH_4)_2SO_4$, and Tween 80 were of analytical grade and purchased from Kelong Chemical Co. (Chengdu, China).

**Microorganisms and Media.** The CY-degrading strain B-1 and the 3-PBA-degrading strain SC-1 were obtained from the soil in a tea garden (Ya'an, China) and from the sludge in a pesticide factory (Chengdu, China), respectively. Both were transferred to the laboratory by using sterile paper bags and domesticated by using enrichment culture technique. After several enrichment cultures, they were isolated by diluting the final cultures serially and spreading them on enrichment medium agar plates. On the basis of the analysis of morphological, physiological, and biochemical characteristics and 16S rDNA sequence (GenBank accession no.: strain B-1, HQ009796; strain SC-1, JN857975), strains B-1 and SC-1 were identified as *B. licheniformis*[24] and *Sphingomonas* sp.,[21] respectively. Both were stored in a 15% glycerol solution at −80 °C before experiments.

Several kinds of media were prepared. Luria−Bertani (LB) medium, containing 5.0 g $L^{-1}$ yeast extract, 10.0 g $L^{-1}$ peptone, and 10.0 g $L^{-1}$ NaCl, was used for CY degradation tests. Mineral salt (MS) medium, containing 0.2 g $L^{-1}$ $MgSO_4$, 0.5 g $L^{-1}$ $KH_2PO_4$, 0.5 g $L^{-1}$ NaCl, 1.5 g $L^{-1}$ $(NH_4)_2SO_4$, and 1.5 g $L^{-1}$ $K_2HPO_4$ was used for 3-PBA degradation tests. LB-MS medium, containing both LB and MS, was used for CY+3-PBA degradation tests. All media were adjusted to pH 7.0−7.5, and 0.2% Tween 80 (v/v) was added as an emulsifying agent before sterilization at 121 °C for 20 min.

**Inoculum Preparation.** Strain B-1 (or strain SC-1) was thawed and inoculated into a 100 mL Erlenmeyer flask, which contained 30 mL of LB-MS medium with 100 mg $L^{-1}$ CY (or 3-PBA). Then the flask was placed in a rotary shaker (Multitron-Pro, Infors, Switzerland) at 180 rpm and 30 °C, and the activated strain was obtained at 16 h of cultivation. After being centrifuged (ST40R, Thermo, German) at 10000 rpm and 4 °C for 10 min, the strain was collected and suspended in sterile *N*-saline (0.9% NaCl) to achieve a cell density of about $1.0 \times 10^8$ cells $mL^{-1}$. Then, the bacterial suspension was used as inoculum.

**Determination of the Content of CY and 3-PBA by HPLC.** *Pretreatment.* The broth culture was shaken by a vortex mixer for 30 s first, and 5 mL of broth culture was transferred to a 100 mL flask. Then, 5 mL of acetonitrile was added into the flask, and the flask was shaken by a vortex mixer for 30 s. The CY or 3-PBA in broth culture was extracted under ultrasonic (40 kHz and 300 W; B-3510E, Branson, America) for 30 min.[26] After centrifugation at 8000 rpm and 25 °C for 20 min, the supernatant was collected and filtered through a 0.22 μm membrane filter. Then, the collected filtrate was used for the determination of CY and/or 3-PBA contents.

*Determination of CY Content.* The content of CY was determined by an LC-20AT high-performance liquid chromatograph (HPLC, Shimadzu, Kyoto, Japan) equipped with an LC-20AT pump (Shimadzu), a CTO-20A column oven (Shimadzu), a Kromasil C18 column (250 mm × 4.60 mm, 5.0 μm; Sweden), and an SPD-M20A UV detector (Shimadzu). A series of CY acetonitrile solutions were prepared, and their contents ranged from 2.5 to 500 mg $L^{-1}$. After pretreatment as described under Pretreatment, 20 μL of the solution was injected manually, and elution was performed at 35 °C using 90% (v/v) aqueous acetonitrile solution with a flow rate of 1.0 mL $min^{-1}$. The detection wavelength was 210 nm.[26] Linear regression was taken between CY contents ($X$, mg $L^{-1}$) and their corresponding peak areas ($Y$), and then the calibration curve equation of CY was obtained as follows: $Y = 57585X + 99879$, $R^2 = 0.9996$, which was used for the calculation of CY content.

*Determination of 3-PBA Content.* The content of 3-PBA was determined by HPLC. A series of 3-PBA acetonitrile solutions with contents ranging from 1.0 to 200 mg $L^{-1}$ were prepared. HPLC detection was performed with a mobile phase of 60% (v/v) aqueous acetonitrile solution and a flow rate of 0.6 mL $min^{-1}$. Other chromatographic conditions were the same as those used for the determination of CY content. The calibration curve equation of 3-PBA was obtained as follows: $Y = 127025X + 84767$, $R^2 = 0.9998$, where $X$ and $Y$ represent the 3-PBA content (mg $L^{-1}$) and its corresponding peak area, respectively. It was used for the calculation of 3-PBA content.

**Degradation of CY by *B. licheniformis* B-1.** CY-degrading tests by using *B. licheniformis* B-1 were conducted in 250 mL Erlenmeyer flasks, which contained 30 mL of LB medium with 100 mg $L^{-1}$ CY. Strain B-1 inoculum was first shaken by a vortex mixer for 30 s, and then 1.5 mL of the inoculum was transferred into the medium (inoculated). The flask was shaken at 180 rpm and 30 °C. Uninoculated LB medium with 100 mg $L^{-1}$ CY served as control. Microbial biomass, CY degradation (%), and 3-PBA content (mg $L^{-1}$) in media were measured every 12 h. Microbial biomass was expressed by the optical density value measured at 600 nm ($OD_{600}$), and CY degradation was calculated according to eq 1, where $C$ is the content of CY in inoculated medium and $C_k$ is the content of CY in control.

$$\text{CY degradation (\%)} = (1 - C/C_k) \times 100 \quad (1)$$

**Degradation of 3-PBA by *Sphingomonas* sp. SC-1.** 3-PBA-degrading tests by using *Sphingomonas* sp. SC-1 were done in 250 mL Erlenmeyer flasks, which contained 30 mL of MS medium with 300 mg $L^{-1}$ 3-PBA. Strain SC-1 inoculum (1.5 mL) was inoculated to the medium, and the flask was shaken at 180 rpm and 30 °C. Uninoculated MS medium with 300 mg $L^{-1}$ 3-PBA was used as control. Microbial biomass and 3-PBA degradation (%) in media were measured every 2 h. 3-PBA degradation was calculated according to eq 2, where $C_1$ is the content of 3-PBA in inoculated medium and $C_{k1}$ is the content of 3-PBA in control.

$$\text{3-PBA degradation (\%)} = (1 - C_1/C_{k1}) \times 100 \quad (2)$$

**Degradation of CY and 3-PBA by Cooperation of Strains B-1 and SC-1.** *Effect of Inoculation Proportion of Strains B-1 and SC-1.* Mixed inocula of strains B-1 and SC-1 at different biomass ratios (10:0, 8:2, 7.5:2.5, 6.7:3.3, 5:5, 4:6, 3.3:6.7, 2.9:7.1, 2.5:7.5, 2:8, 0:10) were prepared, and the cell density of the mixed inocula were all $1.0 \times 10^8$ cells $mL^{-1}$. Each inoculum (1.5 mL) was separately inoculated to 30 mL of LB-MS media with 100 mg $L^{-1}$ CY. Uninoculated LB-MS medium with 100 mg $L^{-1}$ CY served as control. All of them were cultivated by shaker at 30 °C and 180 rpm for 72 h. Then, the CY degradation (%) and 3-PBA content (mg $L^{-1}$) in media were measured.

*Effect of Inoculation Method.* Strains B-1 and SC-1 at the biomass ratio of 3.3:6.7 were inoculated into 30 mL LB-MS medium with 100 mg $L^{-1}$ CY by using three different methods described below. Uninoculated LB-MS medium with 100 mg $L^{-1}$ CY served as control.

CY degradation (%) and 3-PBA content (mg $L^{-1}$) in media were measured after 72 h of cultivation.

Method 1: Strains B-1 and SC-1 were inoculated to the medium, simultaneously.

Method 2: Strain B-1 was first inoculated to the medium. At 24 h of cultivation, its biomass was determined as $N_0$. Strain SC-1 at the biomass of $6.7N_0/3.3$ was inoculated to the medium and cultivated for a further 48 h.

Method 3: Strain SC-1 was first inoculated to the medium. At 24 h of cultivation, its biomass was determined as $N_1$. Strain B-1 at the biomass of $3.3N_1/6.7$ was inoculated to the medium and cultivated for a further 48 h.

*Effect of Cultivation Time.* Degradation tests for a cultivation period of 96 h were done in 30 mL of LB-MS medium with 100 mg $L^{-1}$ CY. Strain B-1 was first inoculated to the medium. At 24 h of cultivation, its biomass was determined as $N$, and strain SC-1 at the biomass of $6.7N/3.3$ was inoculated and cultivated for a further 72 h. Uninoculated LB-MS medium containing 100 mg $L^{-1}$ CY served as control. Microbial biomass, CY degradation (%), and 3-PBA content (mg $L^{-1}$) in media were measured every 12 h.

*Effect of Initial CY Content.* Degradation tests at different initial CY contents (10, 25, 50, 100, 150 mg $L^{-1}$) in LB-MS media were conducted. Strain B-1 was first inoculated to the medium. At 24 h of cultivation, its biomass was determined as $N$, and strain SC-1 at the biomass of $6.7N/3.3$ was inoculated and cultivated for a further 48 h. Then the CY degradation (%) and 3-PBA content (mg $L^{-1}$) in media were measured. Uninoculated LB-MS medium containing a certain content of CY served as control.

**Degradation of CY and Its Metabolite 3-PBA in Soil Environment.** The soil was collected from the top 0−10 cm of a vegetable farmland in Sichuan University. The soil was sieved (mesh size = 2 mm) and air-dried overnight. The characteristics of the soil ($g^{-1}$, dry weight) were detected as follows: organic matter, 54.9 mg; total bacteria, $4.58 \times 10^8$ CFU; total actinomycetes, $1.33 \times 10^8$ CFU; total fungi, $1.67 \times 10^7$ CFU; and pH 7.86. A certain amount of CY was added to the soil to achieve a final content of 20 mg $kg^{-1}$, and then the soil was placed overnight.

Three soil samples with a weight of about 1000 g were used. One sample was inoculated with strain B-1 ($1.0 \times 10^8$ cells $g^{-1}$ soil, dry weight) and called B sample. Another sample was first inoculated with strain B-1 ($3.3 \times 10^7$ cells $g^{-1}$ soil, dry weight). At 24 h of cultivation, strain SC-1 ($6.7 \times 10^7$ cells $g^{-1}$ soil, dry weight) was inoculated and called BS sample. The third sample was uninoculated and used as control. The moisture contents of these three soil samples were kept at 40.0 ± 5.0% (w/w) by supplying water manually, and the average temperature was 22 °C. The contents (mg $L^{-1}$) of CY and 3-PBA in soil were measured every 2 days.

As for the extraction of CY and 3-PBA in the soil, the soil was dried to constant weight, and 5.0 g of soil was mixed with 10 mL of acetonitrile in a 100 mL flask under ultrasonic (40 kHz and 300 W) for 60 min. Ten milliliters of ethyl acetate was then added, and the supernatant was collected. The supernatant was purified by passing through an anhydrous $Na_2SO_4$ column.[26] After recovery of the organic solvent at 50 °C in a vacuum, the CY and 3-PBA solution was obtained by redissolving into 1 mL of acetonitrile. It was filtered through a 0.22 $\mu$m membrane filter and used for the determination of CY and 3-PBA contents.

## RESULTS AND DISCUSSION

**Degradation of CY by *B. licheniformis* B-1.** Microbial biomass ($OD_{600}$), CY degradation, and 3-PBA content in the CY degradation process by *B. licheniformis* B-1 are shown in Figure 2. In the initial cultivation phase (0−24 h), the $OD_{600}$ value and CY degradation all exhibited rapid increase trends, and the CY degradation reached 23.35% at 24 h, whereas only 0.72 mg $L^{-1}$ 3-PBA was detected. This might be due to the fact that CY was first degraded into cyano-3-phenoxybenzyl alcohol by esterase produced by strain B-1,[12] and only a very small

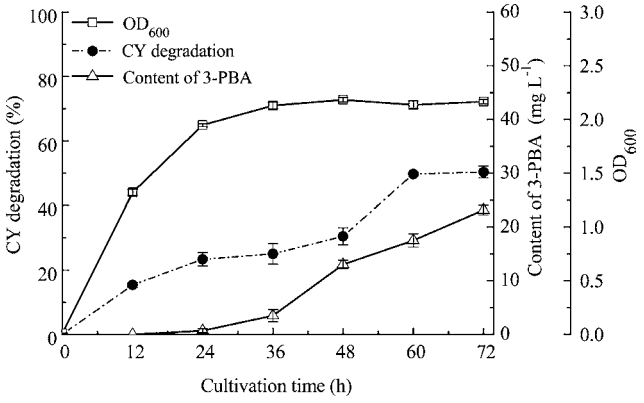

**Figure 2.** Microbial biomass ($OD_{600}$), CY degradation, and 3-PBA content in the CY degradation by *B. licheniformis* B-1. Results are expressed as the average and standard deviation of three parallel samples.

amount of cyano-3-phenoxybenzyl alcohol was transformed to 3-PBA. From 24 to 72 h, the CY degradation continued to increase, and the 3-PBA content began to increase quickly. These might be because cyano-3-phenoxybenzyl alcohol was gradually oxidized to 3-phenoxybenzaldehyde and then to 3-PBA.[12] At 72 h, CY degradation and 3-PBA content reached 50.36% and 23.16 mg $L^{-1}$, respectively. Compared with other CY-degrading organisms, such as *Pseudomonas* IES-Ps-1 isolated by Jilani and Khan that could degrade 51% CY (80 mg $L^{-1}$) in 48 h[22] and *Bacillus* sp. ISTDS2 reported by Sundaram and co-workers that could completely degrade CY (50 mg $L^{-1}$) in 180 h,[27] strain B-1 exhibited similar degradation ability on CY. However, the metabolite 3-PBA would be accumulated in the CY degradation process, and strain B-1 possessed poor degradation of 3-PBA.

**Degradation of 3-PBA by *Sphingomonas* sp. SC-1.** Microbial biomass ($OD_{600}$) and 3-PBA degradation in the 3-PBA degradation process by *Sphingomonas* sp. SC-1 were determined, and the results are shown in Figure 3. From 0 to 6

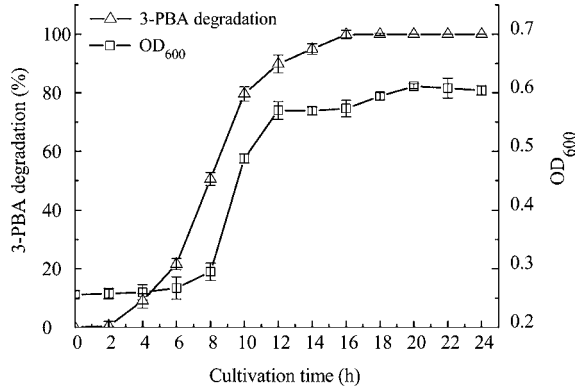

**Figure 3.** Microbial biomass ($OD_{600}$) and 3-PBA degradation in the 3-PBA degradation by *Sphingomonas* sp. SC-1. Results are expressed as the average and standard deviation of three parallel samples.

h, strain SC-1 could be in the lag growth phase, so its $OD_{600}$ value remained constant. Low 3-PBA degradation was found. From 6 to 16 h, 3-PBA was degraded rapidly and could be completely degraded at 16 h. The possible mechanism of 3-PBA degradation by strain SC-1 was described as follows. 3-PBA was first degraded to 2-phenoxyphenol under the effects of

dx.doi.org/10.1021/jf502835n | J. Agric. Food Chem. 2014, 62, 8256−8262

decarboxylase and hydroxylase produced from strain SC-1. Then 2-phenoxyphenol was converted into catechol owing to cleavage of the ether linkage and further degraded into muconic acid by the role of dioxygenase.[21] Chen et al. reported that *Stenotrophomonas* sp. ZS-S-01 could achieve 82.9% degradation of 3-PBA (250 mg $L^{-1}$) in 9 days,[23] and *Ochrobactrum lupine* DG-S-01 could completely degrade 100 mg $L^{-1}$ 3-PBA in 14 days.[28] Compared with these two strains, strain SC-1 exhibited a stronger degradation capacity on 3-PBA and could completely degrade 300 mg $L^{-1}$ 3-PBA in 16 h.

**Simultaneous Degradation of CY and Its Metabolite 3-PBA by Cooperation of Strains B-1 and SC-1.** *Effect of Inoculation Proportion of Strains B-1 and SC-1.* Strains B-1 and SC-1 have been proved to possess good degradation performance on CY and 3-PBA, respectively. Therefore, to improve the degradation of CY and decrease the metabolite 3-PBA content, simultaneously, the cooperation of these two strains was used in a CY degradation process.

The simultaneous degradation of CY and its metabolite 3-PBA was performed under different inoculation proportions of strains B-1 and SC-1, as the results show in Figure 4. When

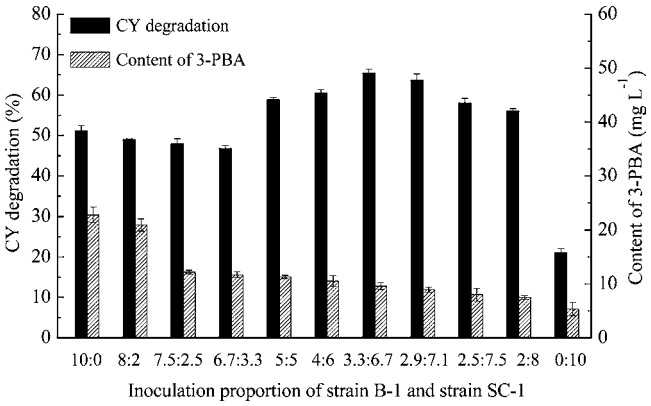

**Figure 4.** CY degradation and 3-PBA content by using different inoculation proportions of strains B-1 and SC-1. Results are expressed as the average and standard deviation of three parallel samples.

only strain B-1 was inoculated to the media (B-1/SC-1 = 10:0), 51.08% CY was degraded and 22.81 mg $L^{-1}$ 3-PBA was accumulated. As the inoculation proportion of strains B-1 and SC-1 ranged from 8:2 to 2:8, the 3-PBA content gradually decreased, which indicated that strain SC-1 can effectively degrade 3-PBA even in the coexistence of strain B-1 and CY. When the inoculation proportion was 3.3:6.7, the maximum CY degradation (65.36%) and only 9.6 mg $L^{-1}$ 3-PBA was observed. When only strain SC-1 was used (B-1/SC-1 = 0:10), only 21.08% CY could be degraded, indicating that strain SC-1 possessed poor degradation performance on CY. Therefore, strains B-1 and SC-1 used in a cooperative way can degrade CY and 3-PBA, simultaneously, and the proportion of 3.3:6.7 was appropriate and used in the following experiments.

*Effect of Inoculation Method.* The CY degradation and 3-PBA content by using three inoculation methods are shown in Figure 5. The CY degradations by using methods 1, 2, and 3 were 64.78, 75.60, and 53.89%, respectively. There was a statistically significant difference ($t$ test, $P < 0.05$) among the three methods. The 3-PBA contents by using these three methods were all about 10 mg $L^{-1}$. Therefore, method 2, in which strain B-1 was first inoculated and then strain SC-1 was

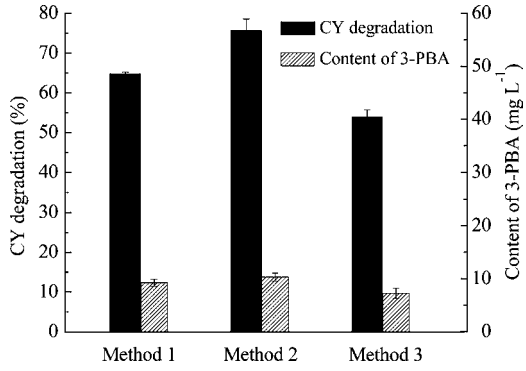

**Figure 5.** CY degradation and 3-PBA content by using three different inoculation methods. Results are expressed as the average and standard deviation of three parallel samples.

inoculated, was the most effective inoculation method for degrading CY and 3-PBA, simultaneously. It was presumably because (i) the antagonism and competition between strains B-1 and SC-1 might be minor[29] and (ii) CY was first degraded into 3-PBA by strain B-1 and then the 3-PBA was further degraded by strain SC-1, in accordance with the proposed degradation process of CY shown in Figure 1. Therefore, method 2 was used as the inoculation method in the following experiments.

*Effect of Cultivation Time.* Microbial biomass ($OD_{600}$), CY degradation, and 3-PBA content in the cultivation period of 96 h were investigated, and the results are shown in Figure 6. In

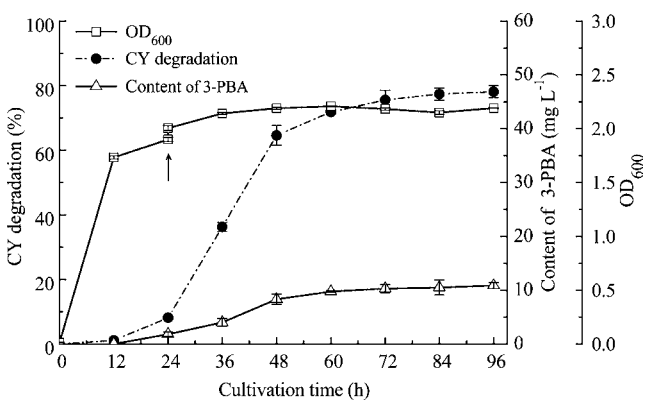

**Figure 6.** Microbial biomass ($OD_{600}$), CY degradation, and 3-PBA content in the cultivation period. ↑ represents addition of strain SC-1. Results are expressed as the average and standard deviation of three parallel samples.

the initial cultivation period (0–24 h, only strain B-1 was inoculated to the media), the $OD_{600}$ value increased quickly and reached 1.899 at 24 h, but only 8.13% CY was degraded. This was presumably because strain B-1 mainly utilized the nutrients in medium except CY to achieve fast growth in the initial phase. After the addition of strain SC-1 (24–96 h), CY degradation began to increase rapidly and reached 78.13% at 96 h, and only 10.87 mg $L^{-1}$ 3-PBA was detected. The possible mechanism of CY degradation by the cooperation of these two strains was as follows: CY was first degraded into 3-PBA by strain B-1, then 3-PBA was further degraded by strain SC-1. Meanwhile, the degradation of metabolite 3-PBA contributed to accelerate CY degradation. Compared with those by using only strain B-1 as described under Degradation of CY by *B. licheniformis* B-1, CY

dx.doi.org/10.1021/jf502835n | J. Agric. Food Chem. 2014, 62, 8256–8262

degradation by the cooperation of strains B-1 and SC-1 was improved from 50.36 to 75.60%, and the 3-PBA content declined from 23.16 to 10.31 mg $L^{-1}$ at 72 h of cultivation.

To further quantify the degradation efficiency of CY and 3-PBA by only strain B-1 or by the cooperation of strains B-1 and SC-1, the degradation rate constant ($k$) (eq 3) and half-life ($t_{1/2}$) (eq 4) of CY from a first-order degradation kinetic model and the yield coefficient ($Y$) of 3-PBA (eq 5) were calculated.[30]

$$C_t = C_0 \times e^{-kt} \quad (3)$$

$$t_{1/2} = \ln 2/k \quad (4)$$

$$Y = (P_t - P_0)/(S_0 - S_t) \quad (5)$$

$C_0$ is the initial content of CY, and $C_t$ is the content of CY at time $t$ (mg $L^{-1}$). $k$ and $t$ are the degradation rate constant ($h^{-1}$) and cultivation time (h), respectively. $P_0$ is the initial molar content of 3-PBA, and $P_t$ is the molar content of 3-PBA at time $t$ (mmol $L^{-1}$). $S_0$ is the initial molar content of CY, and $S_t$ is the molar content of CY at time $t$ (mmol $L^{-1}$). The molar masses of CY and 3-PBA are 416.32 and 214.2 g $mol^{-1}$, respectively.

The degradation rate constant and half-life of CY and the yield coefficient of 3-PBA at 72 h are shown in Table 1.

**Table 1. Degradation Rate Constant ($k$), Half-Life ($t_{1/2}$), and Correlation Coefficient ($R^2$) of CY and Yield Coefficient ($Y$) of 3-PBA after 72 h of Cultivation by Using Strain B-1 or a Cooperation of Strains B-1 and SC-1 in Media**

| treatment | regression eq | $k$ ($h^{-1}$) | $t_{1/2}$ (h) | $R^2$ | $Y$ |
|---|---|---|---|---|---|
| strain B-1 | $C_t = 99.3948\ e^{-0.0096t}$ | 0.0096 | 71.90 | 0.9143 | 0.8938 |
| strains B-1 and SC-1 | $C_t = 113.1823\ e^{-0.0194t}$ | 0.0194 | 35.71 | 0.9101 | 0.2651 |

Compared with those by using only strain B-1, the half-life ($t_{1/2}$) of CY by a cooperation of strains B-1 and SC-1 was shortened from 71.90 to 35.71 h, and the yield coefficient of 3-PBA was decreased from 0.8938 to 0.2651. Therefore, these results could further confirm that the cooperation of strains B-1 and SC-1 was an effective way to achieve the simultaneous degradation of CY and its metabolite 3-PBA.

*Effect of Initial CY Content.* The CY degradation and 3-PBA content by using different initial CY contents are shown in Figure 7. When the initial CY content was 10 mg $L^{-1}$, CY and its metabolite 3-PBA were completely degraded. When the initial CY content increased from 25 to 100 mg $L^{-1}$, the CY degradations were all >75% and the 3-PBA contents were ≤10 mg $L^{-1}$. When the initial CY content reached 150 mg $L^{-1}$, only 37.13% CY was degraded, and the 3-PBA content was still about 10 mg $L^{-1}$. This might be because when the CY reach a high content, it could produce a toxic effect on the voltage-sensitive $Na^+$ channels of strains B-1 and SC-1,[1] prolonging the lag growth phase of these two strains,[22] and so their degradation activity on CY or 3-PBA declined. These results indicated that the simultaneous degradation of CY and its metabolite 3-PBA by these two strains could be well achieved when the initial CY content was <100 mg $L^{-1}$. In fact, the CY content in the natural environment is at a very low level. For example, the content of CY in vegetables was from 0.02 to 0.19 mg $kg^{-1}$,[4] and the content of pyrethroid pesticide in soil is not more than 0.129 mg $kg^{-1}$.[31] Therefore, the cooperation of strains B-1 and SC-1 might be a promising method for the degradation of CY and its metabolite 3-PBA in agricultural soil, and this proposed method would be verified in the following.

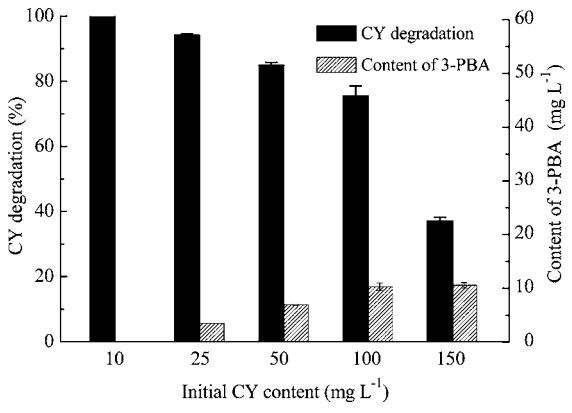

**Figure 7.** CY degradation and 3-PBA content by using different initial CY contents. Results are expressed as the average and standard deviation of three parallel samples.

**Degradation of CY and Its Metabolite 3-PBA in Soil Environment.** The contents of CY and its metabolite 3-PBA in the period of 25 days by using only strain B-1 or a cooperation of strains B-1 and SC-1 are shown in Figure 8. After incubation for 25 days, the CY content was 5.33 mg $L^{-1}$ in the soil inoculated with both strains B-1 and SC-1 (BS sample), whereas those in the soil inoculated with strain B-1 (B

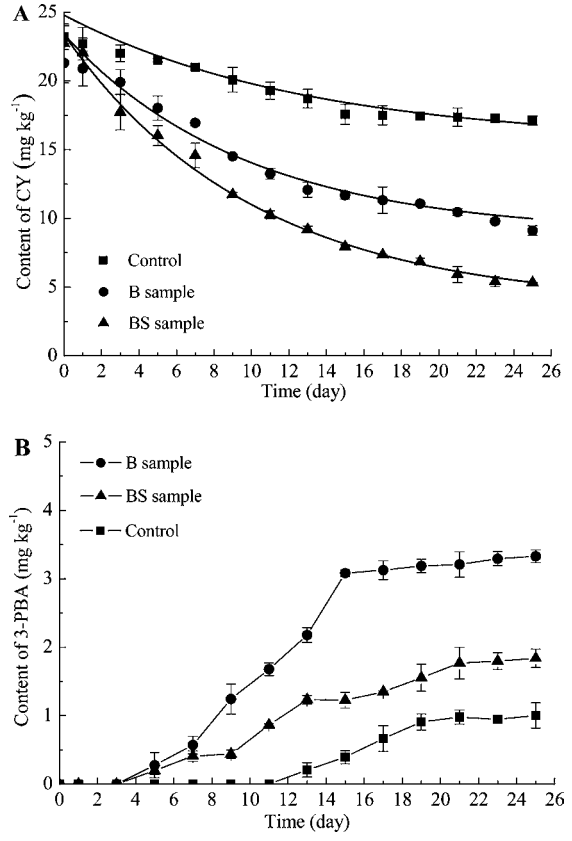

**Figure 8.** CY content (A) and 3-PBA content (B) in the soil by using only strain B-1 (B sample), in the soil by using the cooperation of strains B-1 and SC-1 (BS sample), and in the uninoculated soil (control). Results are expressed as the average and standard deviation of three parallel samples.

dx.doi.org/10.1021/jf502835n | J. Agric. Food Chem. 2014, 62, 8256−8262

sample) and the uninoculated soil (control) were 9.11 and 17.11 mg $L^{-1}$, respectively. As for the 3-PBA content, those in BS sample, B sample, and control were 1.84, 3.33, and 1.00 mg $L^{-1}$, respectively. These results indicated that the degradation of CY and its metabolite 3-PBA by a cooperation of strains B-1 and SC-1 was still much better than that by using only strain B-1 in the soil environment.

Furthermore, the degradation rate constant ($k$) and half-life ($t_{1/2}$) of CY from a first-order degradation kinetic model and the yield coefficient of 3-PBA ($Y$) at incubation on the 25th day were calculated and are summarized in Table 2. The half-lives

**Table 2. Degradation Rate Constant ($k$), Half-Life ($t_{1/2}$), and Correlation Coefficient ($R^2$) of CY and Yield Coefficient ($Y$) of 3-PBA after Incubation for 25 Days in the Uninoculated Soil (Control), in the Soil Inoculated with Strain B-1 (B Sample), or in the Soil Inoculated with both Strains B-1 and SC-1 (BS Sample)**

| treatment | regression eq | $k$ ($days^{-1}$) | $t_{1/2}$ (days) | $R^2$ | $Y$ |
|---|---|---|---|---|---|
| control | $C_t = 22.7303\, e^{-0.0133t}$ | 0.0133 | 52.12 | 0.9392 | 0.3200 |
| B sample | $C_t = 20.9596\, e^{-0.0349t}$ | 0.0349 | 19.86 | 0.9703 | 0.5302 |
| BS sample | $C_t = 21.5829\, e^{-0.0611t}$ | 0.0611 | 11.34 | 0.9853 | 0.2056 |

of CY in control, B sample, and BS sample were 52.12, 19.86, and 11.34 days, respectively. The B or BS sample has a longer half-life of CY than that in media, which might be because the soil environment has less nutrients and poor oxygen dissolving ability for the growth of strains B-1 and SC-1. The yield coefficients of 3-PBA in control, B sample, and BS sample were 0.3200, 0.5302, and 0.2056, respectively. A lower yield coefficient of 3-PBA in B or BS sample was observed as compared with that in media, which might be because part of the generated 3-PBA was degraded by the indigenous organisms in soil. From the above results, it could be further confirmed that the cooperation of strains B-1 and SC-1 could effectively remove the CY and its metabolite 3-PBA in agricultural soil.

Supporting Information

**ABSTRACT:** This study evaluated the effect of thermal processing on the estimated metabolizable protein (MP) supply to dairy cattle from camelina seeds (*Camelina sativa* L. Crantz) and determined the relationship between heat-induced changes in protein molecular structural characteristics and the MP supply. Seeds from two camelina varieties were sampled in two consecutive years and were either kept raw or were heated in an autoclave (moist heating) or in an air-draft oven (dry heating) at 120 °C for 1 h. The MP supply to dairy cattle was modeled by three commonly used protein evaluation systems. The protein molecular structures were analyzed by Fourier transform/infrared-attenuated total reflectance molecular spectroscopy. The results showed that both the dry and moist heating increased the contents of truly absorbable rumen-undegraded protein (ARUP) and total MP and decreased the degraded protein balance (DPB). However, the moist-heated camelina seeds had a significantly higher ($P < 0.05$) content of ARUP and total MP and a significantly lower ($P < 0.05$) content of DPB than did the dry-heated camelina seeds. The regression equations showed that intensities of the protein molecular structural bands can be used to estimate the contents of ARUP, MP, and DPB with high accuracy ($R^2 > 0.70$). These results show that protein molecular structural characteristics can be used to rapidly assess the MP supply to dairy cattle from raw and heat-treated camelina seeds.

**KEYWORDS:** *camelina seed, protein metabolic characteristics, protein molecular structure, protein evaluation system*

## INTRODUCTION

Camelina (*Camelina sativa* L. Crantz), commonly known as gold-of-pleasure or false flax, is an unexploited, short-seasoned oilseed crop in the family of Brassicaceae. Over the past few years, the demand for camelina seeds has increased because of its increased use in biodiesel and bio-oil production, and in animal feed.[1,2] Moreover, because of its early maturity and adaptability to diverse soil and environmental conditions, the crop grows well in the cold, semiarid, and marginal lands of North America. As a result, the cultivated area of camelina was estimated to reach 0.607 million hectares by 2013 in North America.[3] Camelina seeds contain over 35% oil,[3] with a remarkably high content (>37%) of C18:3n-3,[2,4] which makes it a valuable alternative source of omega-3 fatty acids in human and animal diets.[5] Moreover, it is well-known that camelina seeds are relatively rich in crude protein (CP, >25%) and essential amino acids,[3,6] indicating the potential of this oilseed as a high quality protein and oil supplement for dairy cattle, particularly during early lactation. The beneficial effects of feeding camelina-derived oil on animal health and the fatty acid profiles of meat and milk have been extensively evaluated;[7−13] however, to the author's knowledge, the metabolizable protein (MP) supply to dairy cattle from camelina seeds has not been evaluated.

Excessive degradation of oilseed-derived protein in the rumen decreases the efficiency of protein utilization and increases feed cost and N losses to the environment.[14,15] Thermal processing has been used widely to decrease the rumen degradation of protein; however, the establishment of optimal heating conditions is vital to optimize protein utilization in ruminants. Recent research has demonstrated that thermal processing alters protein digestive behavior by changing protein molecular structures.[16] Therefore, quantifying the heat-induced changes in protein molecular structures in relation to changes in protein digestive behavior in the rumen and intestines of dairy cattle can help to establish optimal heating conditions.[17,18] However, such studies are extremely rare, partly because of the lack of appropriate analytical techniques. Recent research has revealed that Fourier transform/infrared-attenuated total reflectance (FT/IR-ATR) molecular spectroscopy can be used as a fast, nondestructive, and noninvasive bioanalytical technique to detect protein molecular structural changes in feed tissues.[16,18,19]

Over the past few decades, various protein evaluation models such as the National Research Council (NRC)-2001 model,[20] the DVE/OEB system[21] (DVE, truly absorbed protein in the small intestine; OEB, degraded protein balance), and the PDI[22] (protein truly digestible in the small intestine) system have been developed, which estimate the MP supply to dairy cattle using in situ ruminal and intestinal protein digestibility data. So far, the MP content and feed milk value (FMV) of camelina seeds have not been investigated by employing and comparing different protein evaluation models. Therefore, the first objective

of the present study was to evaluate the metabolic characteristics of the protein in the rumen and intestines of dairy cattle and to estimate the MP supply to dairy cattle from raw and heat-treated camelina seeds. The second objective was to establish the relationship between the protein molecular structural characteristics and the MP supply to dairy cattle as predicted by three evaluation systems in order to provide a new tool for the rapid evaluation of protein nutritive value. We hypothesized that some specific protein structural characteristics can be used to estimate the MP content, degraded protein balance (DPB), and FMV of camelina seeds.

## MATERIALS AND METHODS

**Camelina Seeds, Heat Treatment and Processing.** Seeds of Blaine Creek and Celine varieties of camelina were sampled from three replicate plots in two different years (2010 and 2011) by the Feeds Innovation Institute (FII), University of Saskatchewan (Saskatoon, Canada). The seeds were used as a model for camelina-derived feed protein. The seeds (1 kg) of each camelina variety were spread (2 cm thin layer) in aluminum pans (23 cm × 33 cm × 5 cm high) and heated in an air-draft oven (dry heating) or an autoclave (Amsco Eagle SG-3031, Steris Corp., Mentor, OH) under 15 pounds per square inch pressure (moist heating) for 1 h at 120 °C. The heat processing was carried out in two replicate runs. After heat treatment, the seeds were immediately removed from the oven or autoclave, cooled at room temperature (22 ± 2 °C), and stored at 4 °C for further processing and analysis. The raw seeds were used as a control.

The seeds were ground through a 2 mm screen (Retsch ZM-1, Brinkmann Instruments Ltd., Mississauga, ON, Canada) for in situ incubation studies. For chemical analysis, the seeds were ground through a 1 mm screen, whereas for molecular spectral analyses, the seeds were finely ground through a 0.25 mm screen. For the fine grinding, the seeds were kept cool and were slowly fed into the grinder to avoid extrusion.

**Molecular Spectroscopy.** The protein molecular structural bands of the raw and heat-treated camelina seeds were analyzed using FT/IR-ATR microspectroscopy (Jasco-4200, Jasco Inc., Easton, MD) at the molecular spectroscopy laboratory of the Department of Animal and Poultry Science, University of Saskatchewan (Saskatoon, Canada). The FT/IR-ATR was equipped with a deuterated L-alanine-doped triglycine sulfate detector (JASCO Corp., Tokyo, Japan) and a ceramic infrared light source, and was outfitted with a MIRacle ATR accessory module and a ZnSe crystal and pressure clamp (Pike Technologies, Madison, WI, U.S.A.). For each sample, 128 scans were generated in the mid-infrared (ca. 4000−800 $cm^{-1}$) and fingerprint (ca. 1800−800 $cm^{-1}$) regions in a transmission mode at a spectral resolution of 4 $cm^{-1}$. Each sample was run five times. The spectra were collected with Jasco Spectra Manager II software, and the molecular structural features were quantified by Ominic 7.2 software (Spectra-Tech Inc., Madison, WI, U.S.A.). The specific spectral bands associated with protein functional groups, such as amide I and amide II, and protein secondary structures, such as $\alpha$-helix and $\beta$-sheet, were identified and quantified as reported by Peng et al.[3]

**In Situ Rumen Incubation.** Four nonlactating Holstein cows, fitted with flexible rumen cannula with an internal diameter of 10 cm (Bar Diamond Inc., Parma, ID, U.S.A.), were used for the in situ incubation. The cows were handled and cared for according to the guidelines of the Canadian Council on Animal Care.[23] The cows had free access to fresh drinking water and were individually fed twice each day with a balanced total mixed ration, containing 805 g barley silage and 195 g concentrate per kg DM, according to NRC maintenance requirements.[20] The detailed chemical composition of the concentrate and barley silage is reported earlier.[19] The rumen degradation kinetics of raw and heat-treated camelina seeds were determined according to the standard in situ method as described by Yan et al.[24]

**Rumen Degradation Characteristics.** The rumen degradation characteristics of protein were computed according to the first-order kinetics equation of Ørskov and McDonald[25] with a modification for lag time by Robinson et al:[26]

$$\mathrm{CP}\ (t) = U + (100 - S - U) \times \mathrm{e}^{-K_\mathrm{d}(t-T_0)}$$

where CP ($t$) is the CP (g/kg) present in the residues at time h incubation; $S$ is the soluble CP fraction (g/kg); $U$ is the rumen nondegradable CP fraction (g/kg); $K_\mathrm{d}$ is the degradation rate/h; and $T_0$ is the lag time (h). The results were analyzed using the PROC NLIN (nonlinear) procedure of Statistical Analysis System (SAS, 2009)[27] with an iterative least-squares regression (Gauss−Newton method). Rumen-degraded feed protein (RDP) and rumen-undegraded protein (RUP) were calculated according to the NRC-2001[20] model as

$$\mathrm{RDP\ (g/kg)} = S + D\left[\frac{K_\mathrm{d}}{(K_\mathrm{d} + K_\mathrm{p})}\right]$$

$$\mathrm{RUP\ (g/kg)} = U + D\left[\frac{K_\mathrm{p}}{(K_\mathrm{d} + K_\mathrm{p})}\right]$$

where $D$ is the potential degradable protein (g/kg) and was calculated as $D = 100 - S - U$, and $K_\mathrm{p}$ is the estimated outflow rate of digesta from rumen, which was assumed to be 6%/h for the three evaluation systems.

**Intestinal Protein Digestion Determination.** The intestinal digestibility of RUP was determined using the three-steps in vitro method of Calsamiglia and Stern[28] with slight modifications as described in our previous study by Peng et al.[3]

**Estimating Metabolizable Protein Supply to Dairy Cattle: NRC-2001 Model.** The detailed framework, concepts, and formulas of the NRC-2001 dairy model are provided by the NRC.[20] Briefly, the MP supply from raw and heat-treated camelina seeds to the small intestine of dairy cattle was calculated from (1) truly absorbable RUP ($\mathrm{ARUP_{NRC}}$), (2) truly absorbable ruminally synthesized microbial protein (microbial protein, MCP) ($\mathrm{AMCP_{NRC}}$), and (3) truly absorbable rumen endogenous protein ($\mathrm{AECP_{NRC}}$). The MP was calculated as follows:

$$\mathrm{MP\ (g/kg\,DM)} = \mathrm{ARUP_{NRC}\ (g/kg)} + \mathrm{AMCP_{NRC}\ (g/kg)} + \mathrm{AECP_{NRC}\ (g/kg)}$$

The $\mathrm{ARUP_{NRC}}$ content was estimated as follows:

$$\mathrm{ARUP_{NRC}\ (g/kg\,DM)} = \frac{\mathrm{dRUP\ (\%RUP)}}{100} \times \mathrm{RUP_{NRC}\ (g/kg\,DM)}$$

where, dRUP was the intestinal digestibility of RUP, determined according to the three-step in vitro procedure of Calsamiglia and Stern.[28] The RUP content was calculated as

$$\mathrm{RUP_{NRC}\ (g/kg\,DM)} = \mathrm{CP\ (g/kg\,DM)} \times \frac{\mathrm{RUP\ (\%CP)}}{100}$$

The $\mathrm{AMCP_{NRC}}$ was estimated from the predicted MCP synthesized in the rumen. The NRC (2001) assumes that the MCP contributed by bacteria and protozoa contains 80% true protein while the other 20% CP is contributed by nucleic acids, which are not available to dairy cattle. Moreover, it also assumes that the digestibility of true MCP is 80%. Thus,

$$\mathrm{AMCP_{NRC}} = \mathrm{MCP} \times 0.8 \times 0.8$$

According to the NRC-2001 model, the MCP was estimated from the total digestible nutrients (TDN). The model assumes that the yield of MCP from 1 kg TDN is 130 g. The $\mathrm{MCP_{TDN}}$ was calculated as follows:

$$\mathrm{MCP_{TDN}\ (g/kg\,DM)} = 0.130 \times \mathrm{TDN}$$

However, if RDP in the feed is less than $1.18 \times \mathrm{MCP_{TDN}}$, then MCP is calculated from RDP as follows:

$$\mathrm{MCP_{RDP}\ (g/kg\,DM)} = 0.85 \times \mathrm{RDP\ (g/kg\,DM)}$$

dx.doi.org/10.1021/jf5013049 | J. Agric. Food Chem. 2014, 62, 8263−8273

where the NRC (2001) assumes that 85% of the RDP is converted to MCP, and 1.18 results from 1.00/0.85.

The supply of endogenous crude protein (ECP) to the small intestine was calculated as

$$ECP_{NRC}\ (g/kg\,DM) = 6.25 \times 1.9 \times DM$$

The number 6.25 represents the protein−N conversion factor, and 1.9 indicates that 1.9 g of endogenous N was originated from 1 kg of DM. The NRC assumes that 50% of the $ECP_{NRC}$ passes to the duodenum, and 80% of the rumen ECP is true protein. The truly absorbed ECP in the small intestine ($AECP_{NRC}$) was estimated as

$$AECP_{NRC} = 0.50 \times 0.80 \times ECP_{NRC}$$

The $DPB_{NRC}$ was calculated as the difference between the potential $MCP_{RDP}$ and $MCP_{TDN}$, as follows:

$$DPB_{NRC}\ (g/kg\,DM) = MCP_{RDP}\ (g/kg\,DM) - 1.18 \times MCP_{TDN}\ (g/kg\,DM)$$

**Nutrient Supply Evaluated Using DVE/OEB System.** The calculation for estimating the MP supply using the DVE/OEB system[21] is summarized here. The MP (DVE) value of feed comprises truly absorbable RUP ($ARUP_{DVE}$), truly absorbable rumen-synthesized MCP ($AMCP_{DVE}$), and a correction for endogenous $ECP_{DVE}$ losses ($ENDP_{DVE}$). The $MP_{DVE}$ value was calculated as

$$MP_{DVE}\ (g/kg\,DM) = ARUP_{DVE} + AMCP_{DVE} - ENDP_{DVE}$$

The $ARUP_{DVE}$ was calculated on the basis of the content and digestibility of $RUP_{DVE}$. The $ARUP_{DVE}$ was calculated as

$$ARUP_{DVE}\ (g/kg\,DM) = \frac{dRUP\ (\%RUP)}{100} \times RUP_{DVE}\ (g/kg\,DM)$$

where dRUP was determined according to Calsamiglia and Stern.[28] The content of $RUP_{DVE}$ was calculated from the CP content of the feeds and RUP contents of the CP as follows:

$$RUP_{DVE}\ (g/kg\,DM) = 1.11 \times \left[CP\ (g/kg\,DM) \times \frac{RUP\ (\%CP)}{100}\right]$$

where 1.11 is the correction of the in situ data from the in vivo results.[21] The $AMCP_{DVE}$ was calculated as follows:

$$AMCP_{DVE}\ (g/kg\,DM) = 0.75 \times 0.85 \times MCP_{FOM}\ (g/kg\,DM)$$

where 0.75 is the assumed amount of true protein in the MCP, and 0.85 is the digestibility of $MCP_{FOM}$. The $MCP_{FOM}$ was calculated as

$$MCP_{FOM} = 0.15 \times FOM$$

where the factor 0.15 represents the assumption of the DVE system that for 1 kg of fermentable organic matter (FOM), 150 g of $MCP_{FOM}$ is synthesized in the rumen. The FOM was calculated as

$$FOM\ (g/kg\,DM) = DOM - Cfat - RUP - RUST - FP$$

where DOM is the digestible organic matter (OM); Cfat is the ether extract; RUST is the ruminally undegraded feed starch; and FP is fermentation products for conserved forages. For camelina seeds, FP and RUST were assumed to be zero.

The DVE/OEB system assumes that the ECP losses ($ENDP_{DVE}$) in the digestive tract are associated with the passage of the undigested DM (UDM). The $ECP_{DVE}$ was calculated as

$$ENDP_{DVE}\ (g/kg\,DM) = 0.075 \times UDM\ (g/kg\,DM)$$

where the DVE/OEB system assumed that 75 g of protein would be excreted per kilogram of UDM. The UDM was calculated as

$$UDM\ (g/kg\,DM) = (0.35 \times ash) + OM - \left[\frac{OM \times dOM}{100}\right]$$

where 0.35 is the constant utilized by CVB,[29] which indicates that 35% of the ash is not digested, and dOM is the degradability of OM after 120 h of rumen incubation.

The degraded protein balance ($DPB_{DVE}$) was calculated from the difference between the $MCP_{RDP}$ and the potential MCP based on the energy extracted during the anaerobic fermentation of FOM ($MCP_{FOM}$) in the rumen:

$$DPP_{DVE} = MCP_{RDP} - MCP_{FOM}$$

where $MCP_{RDP}$ was determined as follows:

$$MCP_{RDP} = CP\ (g/kg\,DM) \times \left[1 - \left(1.11 \times \frac{RUP\ (\%CP)}{100}\right)\right]$$

**Nutrient Supply Evaluated Using PDI System.** The principles and calculations of the PDI system[22,30] were used to calculate the supply of truly digestible protein (PDI) to the small intestine of dairy cattle from the raw and heat-treated camelina seeds. The PDI of feed comprises the truly absorbable RUP ($ARUP_{PDI}$) and the truly absorbable rumen-synthesized MCP ($AMCP_{PDI}$):

$$PDI\ (g/kg\,DM) = ARUP_{PDI} + AMCP_{PDI}$$

The $ARUP_{PDI}$ was calculated from the $RDP_{PDI}$ as

$$ARUP_{PDI}\ (g/kg\,DM) = CP\ (g/kg\,DM) \times (1.11 \times (1 - RDP)) \times TId$$

The PDI system assumes that 1.11 is a correction factor for the rumen bypass protein ($RUP_{PDI} = 1.11 \times (1 - RDP_{PDI})$ based on in vivo experiments. The RDP was calculated from the disappearance of protein from nylon bags during 48 h, assuming a rumen particle outflow rate of 6%/h. The TId is the true intestinal digestibility of RUP. TId was calculated as

$$TId\ (g/kg\,DM) = 88.3 + 0.371 \times CP - 0.0037 \times CP^2 - 1.07 \times ADL - 0.313 \times UDOM$$

where CP, acid detergent lignin (ADL), and undigested OM (UDOM) are expressed in (g/kg DM).

The $AMCP_{PDI}$ was calculated from (1) the MCP synthesized based on the available energy ($MCP_{ME}$), assuming that the degraded CP and other nutrients are not limiting, and (2) the MCP synthesized based on RDP ($MCP_{RDP}$), assuming that energy and other nutrients are not limiting. The $MCP_{ME}$ was estimated from the FOM and was calculated as follows:

$$MCP_{ME} = FOM \times 0.145 \times 0.8 \times 0.8$$

where 0.145 represents the yield of MCP that is assumed to be 145 g CP/kg FOM, and its true protein content and true digestibility in the small intestine are assumed to be 0.80 each. The FOM was calculated as follows:

$$FOM = DOM - EE - RUP_{PDI}$$

The DOM was calculated as

$$DOM = 87.75 - 0.314 \times CF\ (\%of\,DM) + \alpha$$

where $\alpha = 6.2$ for oilseeds. The $MCP_{RDP}$ was calculated as

$$MCP_{RDP} = 0.80 \times 0.80 \times RDP_{PDI}$$

as mentioned before, the true protein content of MCP and the true digestibility in the small intestine are 0.80 each. The $RDP_{PDI}$ was calculated as

$$RDP_{PDI}\ (g/kg\,DM) = 0.90 \times CP\ (g/kg\,DM) \times (1.11(1 - RDP))$$

where 0.90 is the efficiency of conversion of degraded N to rumen microbial N. The truly absorbable rumen-synthesized MCP in the small intestine ($AMCP_{PDI}$) was calculated as

$$AMCP_{PDI}\ (g/kgDM) = CP \times \frac{RDP_{PDI}}{DOM}$$

The degraded protein balance ($DPB_{PDI}$) was calculated as

$$DPB_{PDI}\ (g/kg\,DM) = (ARUP_{PDI} + MCP_{RDP}) - (ARUP_{PDI} + MCP_{ME})$$

dx.doi.org/10.1021/jf5013049 | J. Agric. Food Chem. 2014, 62, 8263−8273

**Feed Milk Value.** The FMVs of raw and heat-treated camelina seeds were calculated using the estimated MP supply as obtained with the NRC-2001, DVE/OEB, and PDI systems. The FMV was calculated as

$$FMV = MP \times 0.67 \times 0.033$$

Where, 0.67 is the efficiency of MP for milk production, and 0.033 is the protein content (g/g) of milk.

**Statistical Analysis.** The PROC MIXED procedure of the Statistical Analysis System (SAS)[27] was used to analyze the data on modeled protein supply, DPB, and FMV. The model used for analysis was

$$Y_{ij} = \mu + T_i + e_{ij}$$

where $Y_{ij}$ is an observation on the dependent variable $ij$; $\mu$ is the overall population mean; $T_i$ is the fixed effect of heat treatment (i = control, moist heating, and dry heating), and $e_{ij}$ is the random error associated with the observation $ij$. The plots were used as experimental replicates.

Comparisons among the three protein evaluation models were performed using the PROC MIXED procedure of SAS,[27] using the following model:

$$Y_{ij} = \mu + M_i + e_{ij}$$

where $Y_{ij}$ is an observation on the dependent variable $ij$; $\mu$ is the overall population mean; $M_i$ is the fixed effect of the protein evaluation model (i = NRC-2001, DVE/OEB, PDI); and $e_{ij}$ is the random error associated with the observation $ij$. The different treatments (control, dry heating, and moist heating) were used as replications. For variables with significant ($P < 0.05$) differences, posthoc analyses were carried out using the Tukey Test to compute pairwise differences in the means.

Stepwise, multiple-regression analyses were performed using the PROC REG procedure of SAS[27] to determine which of the protein molecular structural features can be used to estimate the modeled protein nutrient supply to dairy cattle from raw and heat-treated camelina seeds. The independent variables tested in the model were the $\alpha$-helix height, $\beta$-sheet height, amide-I area, amide-II area, ratio of the $\alpha$-helix to $\beta$-sheet height, and ratio of the amide I to amide II area. Only variables contributing significantly ($P < 0{\cdot}05$) to the estimation of the dependent variable were left in the final model. Collinearity among the independent variables was detected and avoided by the use of the variance inflation factor (VIF) option of SAS.[27]

## RESULTS

**Estimating Protein Supply to Dairy Cattle Using the NRC-2001 Model.** Heat processing increased the contents of $MCP_{TDN}$, $AMCP_{NRC}$, $ARUP_{NRC}$, and total MP, with the increase being significant ($P < 0.05$) for moist heating (Table 1). The FMV and $RUP_{NRC}$ contents increased ($P < 0.05$) with both dry and moist heating, and the highest ($P < 0.05$) values were estimated for moist heating. In contrast, the $MCP_{RDP}$ and $DPB_{NRC}$ contents decreased ($P = 0.01$) with heat processing, and the lowest value was computed for moist heating.

**Protein Supply to Dairy Cattle Using the DVE/OEB System.** Heat processing decreased the contents of $MCP_{FOM}$ and $DPB_{DVE}$, and the decrease was significant ($P < 0.05$) for moist heating (Table 2). Both the dry and moist heating significantly ($P < 0.05$) decreased the contents of $MCP_{RDP}$ and $AMCP_{DVE}$, and the lowest values were estimated for moist heating. In contrast, the contents of $RUP_{DVE}$, $ARUP_{DVE}$, $MP_{DVE}$, and $FMV_{DVE}$ increased ($P < 0.05$) with both dry and moist heating; however, the highest ($P < 0.05$) values were obtained with moist heating.

**Protein Supply to Dairy Cattle Using the PDI System.** Both dry and moist heating decreased ($P < 0.01$) the contents of $MCP_{ME}$, $MCP_{RDP}$, $AMCP_{PDI}$ and $DPB_{PDI}$, and the lowest values ($P < 0.05$) were obtained with moist heating (Table 3).

| $FMV_{NRC}$ | 2.92c | 3.98a | 3.25b | 0.146 | 0.001 | 0.002 |

[a]Means within a row with different letters differ at the $P < 0.05$ level. [b]HT-1, moist-heated in an autoclave at 120 °C for 1 h; HT-2, dry-heated in an air-draft oven at 120 °C for 1 h. [c]SEM, standard error of mean. [d]$MCP_{TDN}$, MCP synthesized in the rumen based on available energy; $MCP_{RDP}$, MCP synthesized in the rumen based on available protein, calculated as 0.85 of rumen-degraded protein; $AMCP_{NRC}$, truly absorbable rumen-synthesized MCP in the small intestine. [e]ECP, rumen endogenous crude protein; AECP, truly absorbable endogenous protein in the small intestine. [f]$RUP_{NRC}$, ruminally undegraded crude protein; $ARUP_{NRC}$, truly absorbable rumen-undegraded feed protein in the small intestine. [g]MP, total metabolizable protein contributed by $ARUP_{NRC}$, $AMCP_{NRC}$, and AECP. [h]$DPB_{NRC}$, degraded protein balance, which reflects the difference between the potential MCP synthesis based on ruminally degraded feed protein and that based on energy (TDN) available for microbial fermentation in the rumen. $FMV_{NRC}$, feed milk value. The efficiency of use of the metabolizable protein for lactation is assumed to be 0.67,[19] and the protein content of milk is assumed to be 33 g/kg milk.

The contents of $RUP_{PDI}$ and FMV increased ($P < 0.05$) for both dry and moist heating; however, the highest ($P < 0.05$) values were obtained with moist heating. The contents of PDIE ($ARUP_{PDI}$ + $MCP_{ME}$) and PDIN ($ARUP_{PDI}$ + $MCP_{RDP}$) increased with heat processing with significant ($P < 0.05$) increase being observed with moist heating.

**Comparison of Estimated Protein Supply to Dairy Cattle by the NRC-2001 Model, DVE/OEB System, and PDI System.** Comparison of the estimated contents of protein nutrient supply and FMV of camelina seeds by the NRC-2001 model, DVE/OEB system, and PDI system are presented in Table 4. The estimated content (g/kg DM) of rumen-synthesized MCP on the basis of available energy was significantly higher ($P < 0.05$) in the NRC-2001 model (149.40) than that estimated by the DVE/OEB (59.51) and PDI (37.32) systems. Subsequently, the estimated content of truly absorbable rumen-synthesized MCP was substantially higher ($P < 0.05$) in the NRC-2001 model than those obtained with the DVE/OEB and PDI systems. In contrast, the rumen-synthesized MCP based on RDP was higher ($P < 0.05$) in the DVE/OEB and PDI systems than that in the NRC-2001 model. Moreover, the estimated content of truly absorbed rumen-synthesized MCP was higher ($P < 0.05$) in the DVE/OEB system than that in the PDI system.

| $FMV_{PDI}$ | 2.26c | 3.03a | 2.66b | 0.060 | 0.001 | 0.001 |

[a]Means within a row with different letters differ at the $P < 0.05$ level. [b]HT-1, moist-heated in an autoclave at 120 °C for 1 h; HT-2, dry-heated in an air-draft oven at 120 °C for 1 h. [c]SEM, standard error of mean. [d]$MCP_{ME}$, amount of MCP that could be synthesized from the available energy in the rumen, when degraded nitrogen (N) is not limiting; $MCP_{RDP}$, amount of MCP that could be synthesized in the rumen from the degraded dietary N when energy is not limiting; $AMCP_{PDI}$, truly absorbable rumen-synthesized MCP in the small intestine. [e]$RUP_{PDI}$, ruminally undegraded feed protein; $ARUP_{PDI}$, truly absorbable ruminally undegraded feed protein. [f]PDIN, digestible proteins in the small intestine where N is the limiting factor for rumen microbial activity; PDIE, digestible proteins in the small intestine where energy is the limiting factor for rumen microbial activity; $DPB_{PDI}$, the difference between MCP synthesis based on rumen-degraded feed crude protein and that based on energy from anaerobic fermentation in the rumen. The efficiency of use of the metabolizable protein for lactation is assumed to be 0.67,[19] and the protein content of milk is assumed to be 33 g/kg milk.

The contents of ARUP did not differ significantly among the three evaluation systems. The MP content obtained with the NRC-2001 model was higher ($P < 0.05$; 152.97 vs 84.33) than that of the DVE/OEB system. The DPB was different ($P < 0.01$) among the three evaluation systems, and the highest ($P < 0.05$) value was obtained with the DVE/OEB system. The PDI system had a higher ($P < 0.05$) DPB value than did the NRC-2001 model. The FMV of camelina seeds differed among the three protein evaluation systems, and the highest ($P < 0.05$) value was recorded for the NRC-2001 model, followed by the PDI and DVE/OEB systems, respectively.

**Using Protein Molecular Structural Spectra to Predict the Estimated Protein Supply to Dairy Cattle.** The multiple-regression equations in Table 5 show that the protein secondary structure ($\alpha$-helix height) can be used to predict $ECP_{NRC}$ ($R^2$ = 0.73), $AECP_{NRC}$ ($R^2$ = 0.75), $ARUP_{NRC}$ ($R^2$ = 0.84),

| Feed Milk Value[h] | | | | |
| $FMV_{DVE}$ | $Y = 4.74 - 44.65 \times \alpha$-helix | 0.808 | 19.57 | 0.012 |

[a]Protein molecular structural characteristics measured with FT/IR-ATR molecular spectroscopy: amide I area and amide II area intensity with the baseline at about 1,715−1,485 $cm^{-1}$, $\alpha$-helix height centered at about 1,653 $cm^{-1}$, and $\beta$-sheet centered at about 1,630 $cm^{-1}$. [b]RSD, residual standard deviation. [c]$MCP_{FOM}$, MCP synthesized in the rumen based on available energy; $MCP_{RDP}$, MCP synthesized in the rumen based on rumen-degraded protein; $AMCP_{DVE}$, truly absorbable rumen-synthesized MCP in the small intestine. [d]$ECP_{DVE}$, endogenous protein losses in the digestive tract. [e]$RUP_{DVE}$, ruminally undegraded feed protein calculated according to the DVE/OEB model; $ARUP_{DVE}$, truly absorbable rumen-undegraded feed protein in the small intestine. [f]$MP_{DVE}$, truly absorbable protein in the small intestine contributed by $RUP_{DVE}$, $MCP_{FOM}$, and a correction for ENDP. [g]$DPB_{DVE}$ reflects the difference between the potential MCP synthesis based on rumen-degraded feed crude protein and that based on energy (FOM) available for microbial fermentation in the rumen. [h]$FMV_{DVE}$, feed milk value, the efficiency of use of the metabolizable protein for lactation is assumed to be 0.67,[19] and the protein content of milk is assumed to be 33 g/kg milk.

$MP_{NRC}$ ($R^2$ = 0.80), and $FMV_{NRC}$ ($R^2$ = 0.81) with high accuracy. Similarly, the $\alpha$-helix height and the ratio of amide I to amide II area can be used to predict $MCP_{RDP}$ ($R^2$ = 0.98) and $DPB_{NRC}$ ($R^2$ = 0.99). However, no protein molecular peak intensities were left in the model to predict $MCP_{TDN}$, $AMCP_{NRC}$, and $RUP_{NRC}$.

The regression equations and their predictive power for the estimation of the protein nutrient supply and FMV obtained with the DVE/OEB system from protein molecular spectral characteristics are shown in Table 6. These equations demonstrated that the data on $\alpha$-helix height can be used to predict the supply of $MCP_{FOM}$ ($R^2$ = 0.74), $AMCP_{DVE}$ ($R^2$ = 0.74), $ECP_{DVE}$ ($R^2$ = 0.86), $ARUP_{DVE}$ ($R^2$ = 0.84), $MP_{DVE}$ ($R^2$ = 0.83), $DPB_{DVE}$ ($R^2$ = 0.97), and $FMV_{DVE}$ ($R^2$ = 0.81) with high accuracy. The $\alpha$-helix height and the ratio of amide I to amide II area provided a high prediction power for $MCP_{RDP}$ ($R^2$ = 0.98).

Equations in Table 7 show that the $\alpha$-helix height can be used to predict $ARUP_{PDI}$ ($R^2$ = 0.84), PDIA ($R^2$ = 0.70), and PDIE ($R^2$ = 0.87) with high accuracy. The amide I area can be used to predict $DPB_{PDI}$ ($R^2$ = 0.70), and the $\alpha$-helix height and the ratio of amide I to amide II area can be used to predict $MCP_{RDP}$ ($R^2$ = 0.98) and $AMCP_{PDI}$ ($R^2$ = 0.97). No protein spectral bands were left in the model to predict the supply of $MCP_{ME}$, $RUP^{PDI}$, or $FMV^{PDI}$.

## DISCUSSION

An accurate measurement of the feed protein degradation and MCP synthesis in the rumen and the intestinal digestibility of feed undegraded and MCP is required to optimize the efficiency of oilseed-derived protein utilization in dairy cattle, reduce feed costs, and reduce $NH_3$−N losses to the environment.[14,15] With the recent advances in the understating of protein metabolism in ruminants, various protein evaluation systems have been developed, which estimate the MP supply to dairy cattle from feeds. This study provides the first data set on the MP supply to dairy cattle from raw and heat-treated camelina seeds by employing and comparing three different protein evaluation systems. This study also provides information on the relationship between the protein molecular structural characteristics and the estimated MP supply to dairy cattle. This information will strengthen the current knowledge on the evaluation of feed protein nutritive value for dairy cattle and can also be used as an alternative tool for the rapid assessment of protein nutritive value.

**Heat-Induced Changes in the Metabolic Characteristics of Protein in Camelina Seeds.** The protein evaluation models estimated that both dry and moist heating (1 h at 120 °C) of camelina seeds increased the content of MP and improved the FMV. A similar increase in the supply of MP, estimated from the data obtained with in situ and mobile nylon techniques, from the toasting of whole-fat rapeseed[31] and lupine seeds[32] was reported earlier. The increase in MP supply with thermal processing was predominantly caused by the substantial increase in the supply of digestible RUP. This shift in protein degradation from the rumen to the small intestine of dairy cattle could be related to heat-induced changes in protein molecular structures and secondary chemical reactions, such as the Maillard reaction, between protein molecules and other compounds.[3,16] These structural and chemical changes decrease the protein degradation in the rumen by decreasing the protein solubility[3,17,18] and the access of microbes and proteolytic enzymes to protein molecules.[33−35] The improvement in MP supply was much higher with moist heating (>36%) than it was with dry heating (~11%). This could be related to a larger decrease in protein degradation in the rumen and an increase in the intestinal digestibility of the RUP with the moist heating of oilseeds compared to dry heating.[3,17] It is pertinent to mention that the validation of in situ-derived ruminal degradation data and the estimated MP content with in vivo results has been limited. However, several in vivo studies have shown a lower range in the RUP supply to the small intestine between raw and thermal processed protein feeds than in the large differences estimated by

**Table 7. Regression Equations To Predict the PDI Model Estimated Protein Supply to Dairy Cattle from Protein Structural Characteristics Data[a]**

| predicted variable ($Y$) | prediction equations | $R^2$ | RSD[b] | $P$ value |
|---|---|---|---|---|
| Absorbable Microbial Protein Synthesis in the Rumen[c] | | | | |
| $MCP_{ME}$ | No variables met the 0.05 significance level for entry into the model | | | |
| $MCP_{RDP}$ | $Y = -109.36 + 1450.18 \times \alpha$-helix + 46.30 × ratio of amide I to II area | 0.983 | 35.38 | 0.010 |
| $AMCP_{PDI}$ | $Y = -28.19 + 436.27 \times \alpha$-helix + 13.37 × ratio of amide I to II area | 0.967 | 16.19 | 0.028 |
| Truly Absorbable Rumen-Undegraded Protein in Small Intestine[d] | | | | |
| $RUP_{PDI}$ | No variables met the 0.05 significance level for entry into the model | | | |
| $ARUP_{PDI}$ | $Y = 203.37 - 2351.18 \times \alpha$-helix | 0.842 | 21.35 | 0.010 |
| Degraded Protein Balance[e] | | | | |
| PDIN ($ARUP_{PDI}$ + $MCP_{RDP}$) | $Y = 253.01 - 1595.17 \times \alpha$-helix | 0.696 | 9.17 | 0.039 |
| PDIE ($ARUP_{PDI}$ + $MCP_{ME}$) | $Y = 237.05 - 2259.33 \times \alpha$-helix | 0.865 | 25.59 | 0.007 |
| $DPB^{PDI}$ (PDIN−PDIE) | $Y = -2.05 + 12.00 \times$ amid I area | 0.704 | 9.52 | 0.037 |
| Feed Milk Value[f] | | | | |
| $FMV_{PDI}$ | No variables met the 0.05 significance level for entry into the model | | | |

[a]Protein molecular structural characteristics measured with FT/IR-ATR molecular spectroscopy: amide I area and amide II area intensity with the baseline at about 1,715−1,485 $cm^{-1}$, $\alpha$-helix height centered at about 1,653 $cm^{-1}$, and $\beta$-sheet centered at about 1,630 $cm^{-1}$. [b]RSD, residual standard deviation. [c]$MCP_{ME}$, amount of MCP that could be synthesized from the available energy in the rumen when degraded N is not limiting; $MCP_{RDP}$, the amount of MCP that could be synthesized in the rumen from the degraded dietary N when energy is not limiting; MPS, truly absorbed rumen-synthesized MCP in the small intestine. [d]$RUP_{PDI}$, ruminally undegraded feed crude protein; $ARUP_{PDI}$, truly absorbable ruminally undegraded feed protein. [e]PDIN, digestible proteins in the small intestine where N is the limiting factor for rumen microbial activity; PDIE, digestible proteins in the small intestine where energy is the limiting factor for rumen microbial activity; $DPB_{PDI}$, the balance between MCP synthesis based on rumen-degraded feed crude protein and that based on energy from anaerobic fermentation in the rumen. [f]$FMV_{PDI}$, feed milk value, the efficiency of use of the metabolizable protein for lactation is assumed to be 0.67,[19] and the protein content of milk is assumed to be 33 g/kg milk.

the in situ method, which could be related to the over estimation of RUP by the in situ method.[36]

The NRC-2001 model showed that heat processing caused a small increase (<3 g/kg DM), and the DVE/OEB and PDI systems showed that heat processing caused a small decrease (<8 g/kg DM) in the contents of truly absorbed MCP synthesis in the rumen. This discrepancy among the models is due to the energy inputs that these models use for the estimation of MCP synthesis. In the NRC-2001 model, the MCP synthesis is based on the energy extracted from the TDN, hence the increase in fat availability with heating[3] increased the TDN content and the estimated microbial biomass production from TDN. While in the DVE/OEB and PDI systems, the MCP syntheses are based on the FOM (FOM = DOM − fat − RUP), and the increase in fat and RUP contents[3] with heating would synergistically decrease the contents of FOM and the estimated MCP synthesis from FOM.

The DPB shows the difference between MCP syntheses that are potentially possible from the available RDP and those potentially possible from the energy extracted from anaerobic fermentation in the rumen. A positive DPB value indicates $NH_3$ (N) loss from the rumen, and a negative DPB value indicates a shortage of N in the rumen, which can impair MCP synthesis. The optimum DPB value for a dairy ration is, therefore, zero or slightly above.[21] The three protein evaluation models showed high positive values (>36 g/kg DM) of DBP for raw camelina seeds. In agreement with our findings, high DPB values have been reported for full fat oilseeds such as rapeseeds and lupine seeds.[31,32] The high DPB values and N loss in the rumen could be related to the high contents of rapidly degradable soluble protein (523.7 g/kg CP) and the extensive degradation of protein (754.5 g/kg CP) in the raw camelina seeds. The decrease in DPB values with heating, particularly with moist heating, improved feed protein utilization in the rumen, and the DPB values of the heated camelina seeds were still positive. The decrease in DPB values with heat processing could be related to the subsequent decrease in the soluble protein content and overall protein degradation in the rumen.

**Comparison of the Three Protein Evaluation Models in Predicting Protein Nutrient Supply to Dairy Cattle from Camelina Seeds.** The three models selected in the present study are prevalently used in the feed industry and in scientific research work in North America and Europe. The basic framework and principles of these protein evaluation systems are similar; however, some concepts and factors used to compute the MP contents of feedstuffs are different. Each evaluation system has its strengths and weaknesses for different types of feed ingredients.[33,34] For example, the three models adopted a similar concept of predicting MCP synthesis from the potentially available energy supply to the rumen; however, the three models differ in their sources of available energy, and they use different conversion factors in the calculations. The NRC-2001 model uses the available TDN as the energy source, whereas the DVE/OEB and PDI systems use the rumen FOM as the energy source. The FOM does not include fat as an energy source, while TDN does. For forages and other low fat containing feeds, the differences in the available energy and the MCP syntheses from FOM and TDN were not large.[35,37,38] However, our results showed that for high fat (381.7 g/kg DM) containing camelina seeds, the difference in energy inputs (TDN vs FOM) caused a substantial difference in the predicted energy supply to the rumen and MCP synthesis. In the present study, $MCP_{TDN}$ was markedly higher than were $MCP_{FOM}$ (>89 g/kg DM; 60%) and $MCP_{ME}$ (>112 g/kg DM; 75%). With the recent advances in fat metabolism in the rumen and on the basis of previous recommendations of other studies,[38] the concept of energy inputs adopted by the three models needs to be further standardized for different feed types. The RUP does not provide energy for MCP synthesis, which is taken into account by the DVE/OEB and PDI systems. However, the TDN used for MCP synthesis in the NRC-2001 model needs to be corrected for this RUP content. Fermented protein provides much less energy to rumen microbes than do

carbohydrates, but all of the protein evaluation systems ignore this concept.[39] The three systems assume a constant value for the efficiency of MCP synthesis and do not account for the decrease in digestibility with an increase in the feeding level, which may lead to an overestimation of MCP with increased feed intake. Secondly, the constants used by the three models are different. The NRC-2001 model assumes that 130 g of MCP is synthesized from 1 kg of energy substrate (TDN); the DVE/OEB system assumes that 150 g of MCP is synthesized from 1 kg of energy substrate (FOM); and the PDI system assumes that 145 g of MCP is synthesized from 1 kg of energy substrate (FOM). The three models use different conversion factors to compute the digestibility and amino acid N contents of the rumen-synthesized MCP. The DVE/OEB system assumes that the digestibility of MCP is 85% and that 75% of the MCP is presented in the form of amino acids. In the NRC-2001 and PDI models, the digestibility and amino acid N contents of MCP are assumed to be 80%, each. However, the combined value of these conversion factors (0.64; 0.85 × 0.75 vs 0.80 × 0.80) for the estimation of truly absorbable MCP is more or less similar.

The three models calculated the contents of truly absorbable RUP as the product of the RUP and the intestinal digestibility of RUP; however, the estimation of the RUP differs among the three models. The PDI and DVE/OEB systems use a coefficient of 1.11 to correct the in situ degradation data on in vivo results, whereas in the NRC-2001 model, no correction factor is used. On the basis of these differences, the content of truly absorbable RUP was 11% higher in the PDI and DVE/OEB systems than it was in the NRC-2001 model. However, these calculations only caused numerical differences among the contents of the truly absorbable RUP predicted by the three models. Our results are in agreement with literature values.[40]

In the three models, the protein degradation characteristics were determined by the in situ method, which contains several inherent limitations.[40] These limitations include the assumption that proteins in the soluble-fraction are completely degraded in the rumen; however, recent studies[41,42] have shown that dietary CP can escape from the rumen as nonammonia and nonmicrobial N. Moreover, small feed particles can escape the bags without being degraded. On the other hand, the physical restriction of feeds within the nylon bag and microbial contamination of the undigested residues can results in the under estimation of CP degradability. The model used for the estimation of the rumen degradation parameter assumes that the particles escaping the system are independent of factors such as particle size, specific gravity, and body size. In vivo studies, however, clearly showed a selective retention of forage particles in the rumen.[39] For concentrates, such as the camelina seed, with smaller particle sizes, the differences in retention time may not be very large.

The three systems differ in the concepts and calculations of the ECP. In the NRC-2001 model, the ECP (digestive enzymes, desquamated rumen epithelial cells, bile, and mucus) excretion in the gastrointestinal tract is considered as a contribution to the total MP, and its value is added to the requirements rather than subtracted from the supply. In contrast, in the DVE/OEB system, the ECPs are subtracted from the total truly MP. Although the ECP originates from the animal, the DVE/OEB system assumes that these losses are more related to the characteristics of the feed than to the animal. Moreover, the calculations of ECP also differ between the DVE/OEB and NRC-2001 models. The DVE/OEB system assumes that with the excretion of 1 kg of UDM, 75 g of truly absorbed $ECP_{DVE}$ is lost; therefore, the total truly absorbable MP is corrected ($ECP_{DVE}$ = 0.075 × UDM) for the endogenous losses, whereas the NRC-2001 model assumes that with the intake of 1 kg of DM, 4.75 g of truly absorbable ECP is added to the total truly MP supply. In our study, the $ECP_{DVE}$ content predicted by the DVE/OEB system was over two times higher than that obtained with the NRC-2001 model (12.38 g/kg DM vs 4.47 g/kg DM). Our results are in line with those of Yu et al.[40] Nevertheless, this was in contrast with the findings of Theodoridou and Yu[40] and Yu et al.[38] who reported higher values of $AECP_{NRC}$ than $ECP_{DVE}$. The discrepancy among these studies could be attributed to the intrinsic differences in the digestibility of the different feed types. Because no ECP excretion or losses are available for the PDI system, no comparison could be made with the NRC-2001 and DVE/OEB models. Consequently, no total truly MP was estimated for the PDI system.

The three models use different efficiencies for MCP synthesis based on the RDP. The NRC-2001 model assumes that the turnover efficiency of RDP into MCP is 85%.[19] The DVE/OEB system[21] assumes that 100% of the RDP could be potentially converted into MCP if enough energy is provided, whereas, the PDI system[22] assumes that 90% of the RDP is converted into MCP. The lower values of MCP synthesized from RDP in the NRC-2001 model than in the DVE/OEB and PDI systems are consistent with earlier studies[41,43,44] and could be related to lower turnover efficiency.

The DPB represents the difference between MCP synthesis potentially possible from the available RDP and the MCP synthesis potentially possible from the available energy. The DPB value of of the NRC-2001 model (18.49 g/kg DM) was much lower than the values estimated by the DVE/OEB (98.10 g/kg DM) and PDI (54.72 g/kg DM) systems. As discussed earlier, these large differences in DPB values among the three systems mainly originated from differences in the energy inputs (TDN vs FOM) between these systems. Similarly, the high MP and FMV values predicted by the NRC-2001 model compared to those by the DVE/OEB and PDI systems were predominantly associated with the higher predicted MCP synthesis based on a higher energy input (TDN vs FOM). Our results are consistent with those of Theodoridou and Yu.[35]

**Relationship between Protein Molecular Structural Characteristics and Predicted Metabolizable Protein Supply to Dairy Cattle.** Recent research has demonstrated that rumen degradation and the intestinal digestibility of feed protein is strongly related to protein intrinsic molecular structures.[3,17,44] Moreover, if feeds contain similar protein and amino acid contents, their nutritive values may be different if their protein molecular structures are different.[3] In addition, the heat-induced changes in the inherent molecular structure of proteins alter its degradation in the rumen[16] by changing the protein solubility[3,17,18] and the access of microbes and proteolytic enzymes to protein molecules in the gastrointestinal tract of dairy cattle.[33−35] This study provides information on the relationship between the protein molecular structures and MP supply to dairy cattle as predicted by three different protein evaluation systems and may provide an approach for the prediction of the protein value of feeds.

The large variation in the nutritive value of protein feeds highlights the need for a rapid and accurate assay to determine the quality of individual feedstuff in terms of their MP content. The traditional wet chemical analysis in combination with in situ protein degradation data and the intestinal digestibility

of RUP can be modeled to estimate the truly MP content of feed protein.[15] However, these procedures are time-consuming and expensive and could not be applied for routine analysis. Alternatively, FT/IR-ATR molecular spectroscopy is a noninvasive and nondestructive technique that can rapidly analyze a large number of feed samples. Our results demonstrate that the spectral bands intensities, such as the $\alpha$-helix height and the ratio of amide I to amide II area, can be used to quantitatively estimate the protein supply to the small intestine of dairy cattle with good accuracy.

Our results showed that dry and moist heating of camelina seeds increased the content of truly absorbable RUP, total MP, and FMV and decreased the DPB in dairy cattle. However, moist-heated camelina seeds had a significantly higher ($P < 0.05$) content of truly absorbable RUP, total MP, and FMV and a significantly lower ($P < 0.05$) content of DPB than did the dry-heated camelina seeds. Because of difference in energy inputs (TDN vs FOM), the NRC-2001 model predicted a significantly higher energy supply to the rumen microbes, which resulted in significantly higher contents of the predicted MCP, total truly MP, and FMV and lower contents of DPB than those predicted by the DVE/OEB and PDI systems. The regression equations showed that the protein molecular structural bands intensities, such as the $\alpha$-helix height and the ratio of amide I to amide II area, can be used to quantitatively estimate the contents of truly absorbable RUP, total MP, DPB, and FMV with good accuracy ($R^2 > 0.70$).

Supporting Information

**ABSTRACT:** The aim of this work was to determine the role of saliva in wine aroma release by using static and dynamic headspace conditions. In the latter conditions, two different sampling points ($t$ = 0 and $t$ = 10 min) corresponding with oral (25.5 °C) and postoral phases (36 °C) were monitored. Both methodologies were applied to reconstituted dearomatized white and red wines with different nonvolatile wine matrix compositions and a synthetic wine (without matrix effect). All of the wines had the same ethanol concentration and were spiked with a mixture of 45 aroma compounds covering a wide range of physicochemical characteristics at typical wine concentrations. Two types of saliva (human and artificial) or control samples (water) were added to the wines. The adequacy of the two headspace methodologies for the purposes of the study (repeatability, linear ranges, determination coefficients, etc.) was previously determined. After application of different chemometric analysis (ANOVA, LSD, PCA), results showed a significant effect of saliva on aroma release dependent on saliva type (differences between artificial and human) and on wine matrix using static headspace conditions. Red wines were more affected than white and synthetic wines by saliva, specifically human saliva, which provoked a reduction in aroma release for most of the assayed aroma compounds independent of their chemical structure. The application of dynamic headspace conditions using a saliva bioreactor at the two different sampling points ($t$ = 0 and $t$ = 10 min) showed a lesser but significant effect of saliva than matrix composition and a high influence of temperature (oral and postoral phases) on aroma release.

**KEYWORDS:** *saliva, wine, aroma release, static HS-SPME-GC/MS, dynamic HS-SPME-GC/MS*

## INTRODUCTION

Aroma is one of the most outstanding aspects related to food preferences and choices, especially in the case of wine, in which consumption is mainly triggered by a hedonic motivation. Therefore, aroma represents a relevant aspect in wine research, and many interesting works have focused on the characterization of aroma impact compounds of different wine types.[1−3] However, the retronasal aroma profile of a food during consumption might better represent the aroma fraction involved in the interaction with the olfactory receptors than the orthonasal aroma profile; therefore, it should be more closely related with aroma perception.[4]

In the case of the consumption of liquid foods, such as wine, retronasal aroma is produced by the breathing airflow after swallowing, sweeping the aroma molecules retained in the oral or throat cavities traveling via the nasopharynx from the mouth or throat to the nose.[5−7] It has been shown that orthonasal (odor sense when smelling a food) and retronasal aroma perceptions can be different.[8−10] Different factors involved in the intraoral release of aroma compounds during consumption (saliva, interaction with mucosa, temperature, breathing flows, in-mouth air cavity volumes, change, etc.) seem to be related to these differences[7,11−15,16]

Saliva is a complex dilute aqueous solution; its composition varies depending on the respective physiological status, type of food consumed, oral hygiene, etc.[17] Saliva contains numerous inorganic salts (sodium, calcium, potassium, chloride, phosphate, and bicarbonate)[18] and organic components such as enzymes (amylase, lipases, proteases, etc.)[17,19,20] and proteins (mucins, proline rich proteins, histidine rich proteins, etc.).[21,22] Previous studies have shown that saliva might exert an important role in aroma release through different physicochemical (dilution of aroma due to the aqueous phase of saliva, changes in the pH of the food, hydration of the food, which favors aroma release, interaction with salts causing a salting-out effect, interaction with proteins), chemical (degradation of odorants), biochemical (degradation of odorant or release from aroma precursors), or even physiological effects (impact on velum−tongue seal formation and swallowing performance), which form part of many previous works performed on this topic.[19,20,23−25]

Nonetheless, many of the studies performed on the saliva effect on aroma release in simple and real food systems seem to be contradictory. Some studies have shown that saliva reduces aroma release, for example, in pectin gels,[26] bell peppers,[25] or French beans,[24] whereas others have shown an increase in volatiles released from model gels[27] or primary and multilayer oil/water emulsions.[28]There are also other works showing the

lack of effect of saliva on aroma release, for example, in model cheeses[29] and from starch and water liquid systems.[30]

Undoubtedly, the physicochemical characteristics of the volatile compounds are outstanding parameters in determining the degree of interaction with saliva components.[22] In addition, saliva might induce an array of processes with sometimes opposite effects on aroma release and perception. Therefore, the overall impact of saliva needs to be specifically studied for each food system and aroma composition. Moreover, in many of the above-mentioned works, different types of saliva had been used (human, artificial saliva with different compositions); therefore, a comparison of the effect of saliva performed in such different conditions is not straightforward.

As stated in a recent review on wine aroma analysis, studies regarding aroma release during wine consumption using in vitro or in vivo approaches are scarce,[31] and research on the role of different intraoral factors (such as saliva) that might be involved in aroma release during wine drinking is still incipient. The effect of saliva has been mainly studied because of its involvement in wine astringency.[32−37] However, there are very few studies focused on the role of saliva in wine aroma release.[38,39] Although the relatively short intraoral period of consumption of liquid foods could indicate a limited effect of saliva on aroma release, the formation of an intraoral (and pharyngeal) aroma reservoir[5] and the fact that natural swallowing of saliva is continuously performed make the idea that saliva might exert an important role in the perception of wine aroma during consumption perfectly viable and also affect the persistence of aroma perception during the postoral phase of wine consumption. Very recently, using in vivo conditions, it was shown that enzymatic degradation of palm wine odorants due to saliva was not noticeable among pyrazines, pyrrolines, and most alcohols but was quite pronounced among aldehydes, esters, and thiols.[40]

Likewise, in other food systems, the few studies concerning the effect of saliva on aroma release from wines are contradictory. In the work of Genovese and collaborators,[38] saliva induced, in general, a decrease on aroma release for most of the wine volatiles, and this effect seemed to be more important in white than in red wines. On the contrary, Mitropoulou and co-workers[39] observed an enhancement in the release of hydrophobic compounds from model wines and a decrease in the release of the most hydrophilic compounds in the presence of saliva, although this effect was dependent on the concentration of tannins and polysaccharides. Both works were, however, performed in very different conditions: by using dynamic conditions in the work by Genovese et al.[38] and by using a static headspace approach in the work of Mitropoulou et al.[39] The dynamic conditions are advisible to achieve conditions more realistic to those during food consumption; however, the static conditions have been shown to be better suited for the study of interacting effects that otherwise might be underestimated with the first approach.[23,41]

Therefore, the aim of this work was to determine the role of saliva in wine aroma release by using both static and dynamic headspace conditions. In an attempt to follow a systematic study, avoiding the influence of different factors other than those of interest in this work (saliva effect and wine type), both methodologies were applied to reconstituted wines (with different nonvolatile wine matrix compositions) and a synthetic wine (with no matrix effect), keeping the concentrations of ethanol and aroma compounds the same. In addition, two types of saliva (human and artificial) and control samples (with water) were used to better understand the different mechanisms that saliva might induce in the release of aroma compounds from wine.

## MATERIALS AND METHODS

**Wine Samples.** Two commercial Spanish wines representative of different wine matrix compositions were selected for this study: a young Verdejo white wine (W-wine) and a young Tempranillo red wine (R-wine).

**Reconstituted Wines.** *Deodorization Procedure.* Wines were deodorized with Amberlite XAD-2 (Supelco, Bellefonte, PA, USA). Two 25 cm length glass columns (Pobel, Madrid, Spain), one for each wine type, filled with 100 g of Amberlite XAD-2 were prepared by sequential conditioning with 250 mL of dichloromethane, then methanol, and finally 375 mL of a 12% (v/v) hydroethanolic solution. After this, wine samples were filtered through glass wool and loaded into the column by slowly passing 750 mL of each wine.

Deodorized wines (750 mL of each) were transferred to 250 mL vials and were completely dried in a lyophilizer (Labconco, Kansas City, MO, USA). Five samples per wine type were prepared using this procedure. To replace the oxygen from the samples, all of the dry samples were exposed to a nitrogen atmosphere and stored at 4 °C until sample preparation. This procedure practically ensured the complete elimination of the original aroma compounds in the wines as was confirmed by HS-SPME-GC/MS analysis.

*Wine Reconstitution.* Deodorized wines were reconstituted with a hydroalcoholic solution and spiked with a volatile mixture to a final ethanol concentration of 12%. This aroma mixture is composed of 45 aroma compounds (manufacturers: Aldrich, Fluka, Merck, Firmenich, Lancaster, and Scharlau) representative of a typical wine aroma profile to produce the final concentration of each aroma compound shown in Table 1. This table also shows some of the typical gas chromatography and physicochemical properties of these compounds.

As well as the two types of reconstituted wine matrix, a synthetic wine (S-wine) representing a sample with "no matrix effect" was prepared by mixing a hydroalcoholic solution with 4 g/L tartaric acid (Panreac, Barcelona, Spain) and adjusting the pH to 3.5 with NaOH (Panreac).

The influence of ethanol on the volatility of aroma compounds was not considered in this study, because it has been extensively demonstrated.[42−45] Therefore, ethanol was kept at the same concentration in all reconstituted and synthetic wines.

**Human Saliva.** Stimulated human saliva was collected from 20 volunteers as described before.[46] Participants could not consume food or water for 1 h before sampling. To stimulate production, volunteers chewed a little piece of Parafilm and spat out as much saliva in a bottle as they could. Sodium azide ($NaN_3$, Sigma-Aldrich, Saint Quentin Fallavier, France) was added at a final concentration of 0.02% to avoid bacterial and fungal contamination and development. To obtain the most representative salivary composition, the different saliva samples were pooled, mixed, and centrifuged at 15000*g* for 15 min. After that, the saliva pool was filtered through a 0.22 $\mu$m Sartorius device under vacuum at 4 °C to remove saliva bacteria. Finally, saliva was sampled into pots of 20 mL and stored at −80 °C until use.

**Artificial Saliva.** Artificial saliva was prepared as previously described[24] by dissolving in 1 L of water (purified by a Milli-Q system) 5.028 g of $NaHCO_3$, 1.369 g of $K_2HPO_4{\cdot}3H_2O$, 0.877 g of NaCl, 0.477 g of KCl, 0.441 g of $CaCl_2{\cdot}2H_2O$, and 2.16 g of mucin (type 1-S from bovine submaxillary glands) from Sigma (Milan, Italy). The artificial saliva was stored at 4 °C until use.

**Static Headspace-SPME Sampling Procedure.** In the human mouth, the average ratio of liquid food/saliva had previously been shown to be 5:1 w/v.[38] Therefore, blends containing the reconstituted white and red wines (W-wine, R-wine) or the synthetic wine (S-wine) were prepared by adding 10 mL of the wines spiked with the volatile mixture in a 20 mL vial (Agilent Technologies, Palo Alto, CA, USA). After that, 2 mL of water or human or artificial saliva was added. The headspace vials were immediately closed with a screw cap and polytetrafluoroethylene (PTFE)/silicone septum (Supelco, Bellefonte, PA, USA) and were placed in the incubator of an automatic headspace sampling device (GERSTEL MPS 2, Gerstel Inc., Mülheim an der Ruhr, Germany) at 11 °C. The wine/saliva mixture was previously preincubated for 12 min at 36 °C. In the control wine, the extraction was performed in the headspace of each vial at different incubation times (5, 15, 30, and 45 min) to follow the kinetic of aroma release and to determine the equilibrium time, using a DVB/CAR/PDMS (divinylbenzene/carboxen/polydimethylsiloxane 50/30 $\mu$m thickness, 2 cm length) coated SPME fiber (Supelco). After the incubation time, the fiber was exposed to the headspace above the sample for 2 min, and the vial was maintained at 36 °C. Desorption was performed in the injector of the GC system (Agilent 6890N) in splitless mode for 1.5 min at 270 °C. After each injection, the fiber was cleaned for 30 min to avoid any memory effect. Each analysis was performed in triplicate (one injection per sample vial). Linearity and reproducibility of the

procedure were previously determined by using a synthetic wine spiked with different amounts of the aroma solution (75, 150, and 300 μL) covering as closely as possible the wine aroma concentration expected in wines.[47]

The results of this study are shown in supplementary Table 1 in the Supporting Information. Herein, satisfactory values for the regression coefficients for most of the aroma compounds were obtained, which ranged from 0.910 to 1.000, and the regression RSDs were also acceptable, with values lower than 20% (except for γ-butyrolactone and ethyl dodecanoate). These results confirmed the lack of interactions between individual volatile aroma compounds in the mixture at the concentrations used,[48] confirming the adequacy of the technique to perform this study.

**Dynamic Headspace-SPME Sampling Procedure.** A saliva bioreactor cell was used for these assays.[49] This device was specifically designed to evaluate the particular role of saliva during liquid and semisolid food consumption. It was composed of a water-jacketed glass flask (100 mL), which allowed a temperature control of the sample set at 36 °C. This device has five orifices. The first permits clean air to enter the flask to purge the sample (100 mL/min), therefore reproducing the dynamic conditions of the breathing phenomena. A second orifice is the purge gas outlet, which is connected through a heated transfer line to a flowmeter. In the third orifice the SPME fiber is inserted, and the fourth opening is where the sample is introduced. Finally, to mix the sample as might occur in the mouth, a fifth orifice allowed the introduction of a stir bar with digital speed control. An agitation rate of 150 rpm was employed. This last orifice was firmly sealed around the stir bar shaft with a septum to avoid leaks from the flask. During the experiment setup, the sample was added to the apparatus using a glass funnel.

Following the above-mentioned 5:1 average ratio liquid food/saliva in the human mouth, 10 mL of water, human saliva, or artificial saliva was transferred into the sample flask (100 mL), which was kept at 36 °C, and then 50 mL of wine was then added. The headspace was continuously flushed with purified nitrogen gas (100 mL/min). Even if the experimental conditions were not directly comparable with conditions in the mouth, two sampling points were assayed to analyze the aroma release resulting from the incubation of control, red, and white wines in contact with water, human saliva, or artificial saliva (Figure 1). The first one, corresponding to an initial sampling time ($t$ = 0 min), in which the saliva/wine mixture temperature was raised from 25.5 to 32.3 °C that might correspond with the introduction of the sample in the mouth (oral phase). The second sampling point ($t$ = 10 min at 36 °C) was more related to the postoral phase in which aroma from the remaining wine sample could be released within the oral cavity at physiological temperature. In both cases, extraction was performed for 2 min. Two or three replicates for each sample type were analyzed depending on the experiment.

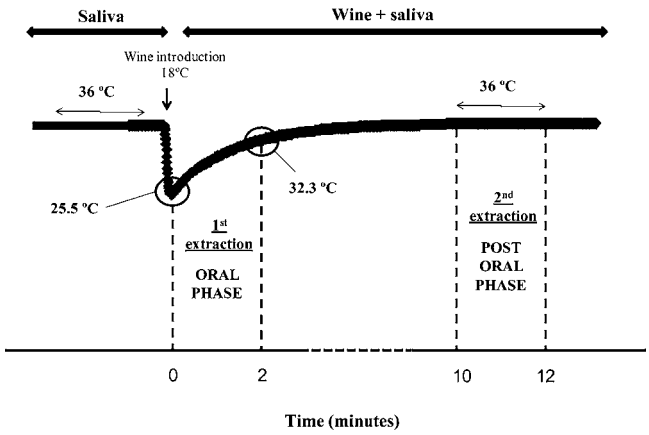

**Figure 1.** Representation of the sampling procedure employed during the dynamic HS-SPME-GC/MS analysis.

It has been shown that interfiber repeatability is lower than the intrafiber accuracy.[50−52] Therefore, a preliminary interfiber repeatability study was performed to select the most similar fibers to complete the study. For this study 9 SPME fibers were used to recover the 45 aroma compounds of the aroma mixture added to synthetic wines, and the 2 SPME fibers exhibiting the lowest variation (<10% RSDs for the extraction of the same aroma compound) were selected and used for the complete set of experiments.

In addition, because the dynamic HS-SPME sampling approach is based on a nonequilibrium situation, a linearity study was carried out to seek the relationship between the adsorbed amount of volatiles on the fiber and their initial concentration in the sample. To do so, a synthetic wine spiked with four different amounts of the aroma mixture was submitted to the dynamic HS extraction conditions as explained above. These results are shown in supplementary Table 1 in the Supporting Information. As can be seen, there is good linearity, high coefficients of determination ($R^2$) (>0.9 in the assayed concentration range, except for γ-butyrolactone), and adequate regression RSDs for most of the assayed compounds independent of the time at which sampling was performed (0 and 10 min). The lack of fit test also showed the adequacy of the proposed regression models ($p$ values > 0.01 for most of the aroma compounds) (data not shown). Therefore, the adsorbed amount of aroma compounds in the SPME was linearly proportional to their initial concentration in the sample matrix, highlighting the adequacy of the technique for quantification purposes, which is in agreement with other theoretical and experimental studies performed in simpler aroma systems.[53]

**GC/MS Analysis.** The identification of volatile compounds was carried out with an Agilent 6890N gas chromatograph coupled to an Agilent 5973 quadrupole mass detector. After desorption of the SPME fiber (270 °C, splitless), volatile compounds were separated on a DB-Wax polar capillary column (60 m × 0.25 mm i.d. × 0.50 μm film thickness) from Agilent (J&W Scientific, Folsom, CA, USA). Helium was the carrier gas at a flow rate of 1 mL/min. The oven temperature was initially held at 40 °C for 5 min, then increased at 4 °C/min to 240 °C, and held for 20 min.

For the MS system (Agilent 5973N), the temperatures of the transfer line, quadrupole, and ion source were 250, 150, and 230 °C, respectively. Electron impact mass spectra were recorded at 70 eV ionization voltages, and the ionization current was 10 μA. The acquisitions were performed in scan (from 35 to 350 amu) and SIM modes for some specific compounds as indicated in Table 1.

The identification of compounds was based on their retention indices (RIs) and comparison of retention times and mass spectra. RIs were calculated from the retention times of $n$-alkanes (C5−C30) on the same column. The mass spectra were compared with those from three databases: NIST 2.0, WILEY 138, and INRAMASS (internal database achieved using standard compounds).

To avoid possible wine matrix interaction phenomena,[47] instead of using an internal standard compound, release data were referred to absolute peak area, once the precision of the data was proven.

**Chemical Wine Matrix Composition.** Total acidity and pH, total polyphenols, neutral polysaccharides, residual sugar, and nitrogen compounds (total nitrogen, free amino acids, and peptides) were determined following previously described analytical procedures.[47]

**Saliva Biochemical Analysis.** *Protein Concentration.* The protein concentration was determined using the Bradford protein assay Quick Start (Bio-Rad, France) with γ-globulin as the standard for calibration.

*Enzymatic Activities.* Lipolysis, proteolysis, lysozyme, and amylase activities were measured as previously described.[17,46]

**Statistical Analysis.** Aroma release data (absolute peak area) were submitted to two-way ANOVA to determine significant effects of the studied factors (saliva type and wine type). In addition, for each aroma compound and wine type (red, white, and synthetic) differences between medium type (with human saliva, artificial saliva, and water) were subsequently examined by least significant difference (LSD) test. The significance level was $p$ = 0.05 throughout the study. Principal component analysis (PCA) was also applied to examine the relationship between aroma release data and wine samples. The

STATISTICA program for Windows version 7.1 was used for data processing (StatSoft, Inc., 2005; www.statsoft.com). Linear regression analysis to establish the calibration curves of each aroma compound and the lack of fit test to judge the adequacy of the models were performed by using the Statgraphics Centurion XV version 15.2 (Manugistics, Rockville, MD, USA).

## RESULTS AND DISCUSSION

To understand the effect of saliva composition on the release of aroma compounds, two types of wines, a white and a red wine, were previously deodorized, reconstituted to the same ethanol content, and aromatized at the same concentration with the aroma mixture (Table 1). With this procedure, it was guaranteed that ethanol did not affect the partition of volatile compounds into the headspace and that both wine matrices had the same concentration of aroma compounds. Therefore, the main differences between both wines were exclusively due to their matrix composition. Table 2 shows the chemical compositions of both reconstituted wines. The percentage of nonvolatile residue and the pH values were very similar. The nonvolatile residues were 2.17 and 2.99% (w/w) and the pH values were 3.23 and 3.79 for the white and red wines, respectively. Total acidity was slightly lower for the red wine (4.29 mg tartaric acid/L) compared to 5.66 mg tartaric acid/L in the case of white wine. The major differences were, however, in the total polyphenol content, neutral polysaccharides, residual sugars, and nitrogen-containing compounds (amino acids and peptides) that were significantly higher in the red wine. These differences in matrix composition have been previously shown to affect the release of aroma compounds in static conditions.[47] In addition to this, a synthetic wine with the same ethanol concentration and pH 3.5 that could be considered as a wine with "no matrix" effect was also prepared.

**Table 2. Chemical Composition of the Red and White Wines Employed in This Study**[a]

| | white wine | | red wine | |
|---|---|---|---|---|
| | mean | SD | mean | SD |
| nonvolatile residue (% w/w) | 2.17 | 0.11 | 2.99 | 0.08 |
| pH | 3.23 | 0.01 | 3.79 | 0.01 |
| total acidity (mg tartaric acid/L) | 5.66 | 0.1 | 4.29 | 0.2 |
| total polyphenols (mg gallic acid/L) | 269.95 | 17.2 | 1647.98 | 292.8 |
| neutral polysaccharides (g mannose/L) | 1.67 | 0.5 | 2.50 | 0.9 |

| peptides[b] (mg N/L) | 18.87 | | 79.94 | |

[a]Values are the average of two determinations except for pH (average of three determinations). [b]This value is indirectly determined as the difference between the analytical determination of amino acids plus peptides and free amino acids; therefore, standard deviation (SD) values are not included.

For the saliva experiments, two types of saliva were used: artificial saliva with mucin prepared in agreement with the recipe previously described and human saliva collected from different volunteers and mixed together to form a single pool. The composition, regarding total protein content and enzymes (amylase, lipase, lysozyme, and protease) was analyzed. The major enzymatic activity detected in the human saliva was lysozyme (698.06 U/mL) followed by proteolysis (16.77 U/mL) and amylase (8.01 U/mL) and, to a lesser extent, lipase (0.95 mU/mL). These values are in the same order of magnitude as those previously published[17,46,54] except for proteolysis activity, which was higher in our study. In addition to the two types of saliva, control experiments were also performed by adding the same amount of water instead of saliva. With this control, we also eliminated the dilution effect exerted by saliva on volatile release, which has also been described.[28,55] In addition, this type of experiment could provide us important information regarding whether saliva enzymes might have an impact on aroma release from wine as has been previously shown in simple aroma/saliva mixtures.[19,20,56]

**Effect of Saliva on Aroma Release Using Static Headspace Conditions.** Although static headspace conditions do not mimic the dynamic conditions during drinking or eating, this technique has been largely used to study aroma interactions with food matrix components to determine their effect on aroma release.[23,39,47,57] Even so, different authors have shown that this is a reliable approach to investigate partitioning in more controlled and simple conditions, which allows us to envisage this subtle phenomena with importance on aroma release that otherwise might be underestimated by using dynamic HS methods.[23,41]

In this work, the aroma release behavior of a mixture of 45 volatile compounds characteristic of the wine aroma profile and with very different physicochemical characteristics (Table 1) was evaluated in the presence and absence of human and artificial saliva by using a previously validated static HS-SPME approach (see Table 1 in Supporting Information). Preliminary experiments were performed to determine the equilibration time (5, 15, 30, 45 min) for most volatiles of the aroma mixture. From the analysis of the kinetic profiles it was found that 5 min of incubation was enough for the equilibration of most of the aroma compounds of the mixture. Only 10 of them (ethyl propanoate, isobutyl acetate, isobutanol, isoamyl acetate, 1-butanol, ethyl octanoate, furfuryl alcohol, $\alpha$-terpineol, benzyl alcohol, and decanoic acid) were not equilibrated after 5 min. Nonetheless, because the main objective of this work was to compare wine samples performed under identical experimental conditions, this should not be a constraint for the validity of the data, and 5 min was adopted as the sampling time to perform the experiment, which are conditions closer to real physiological situations.

Data corresponding to absolute peak areas of the aroma compounds determined by HS-SPME-GC/MS analysis in the three types of wines (white, red, and synthetic) incubated with the two types of saliva (artificial and human) and water were submitted to a two-factorial ANOVA to determine the magnitude of the effect of matrix composition and type of saliva on aroma release. Results of this analysis showed that both effects and the interactions (matrix composition × type of saliva) significantly affected the majority of aroma compounds. From a total of 45 aroma compounds, 37 were affected by the type of saliva and 33 by matrix composition (data not shown). This showed the similar importance of both factors in aroma release in static headspace conditions.

To gain insight into the impact of saliva on aroma release depending on wine matrix composition, a LSD test was also carried out for each type of wine and for each aroma compound. Table 3 shows these results taking into consideration the different aroma chemical families assayed. As can be seen, in general, the addition of saliva (artificial or

human) provoked a significant decrease (or higher retention) on the aroma release for most of the aroma compounds assayed. However, the extent of this effect was dependent on the type of wine and also on the type of aroma chemical class. In this sense, it is important to highlight that human saliva exerted a high impact on the aroma release from red wines, and

dx.doi.org/10.1021/jf503503b | J. Agric. Food Chem. 2014, 62, 8274–8288

practically all of the aroma compounds assayed were less released when human saliva was added to the wine. However, in the case of white wines this effect was more dependent on the type of aroma compound. For example, the addition of human or artificial saliva did not affect the release of any of the alcohols of the aroma mixture. As can be seen in the table, the effect of saliva seemed to be much lower in the case of synthetic wines.

To better understand the way in which both factors (type of saliva and wine matrix) affected the aroma release behavior, a PCA was also performed taking into consideration all of the aroma release data. Two principal components, PC1 and PC2, explaining 68.8% of data variations were obtained (Figure 2a). As can be seen in the graph, PC1 was mainly involved in the separation of the samples depending on the type of medium (with human saliva, artificial saliva, or water). In agreement with previous results, the clearest separation (or differences) among wine samples were obtained for red wines. As can be seen, red wines with human saliva showed positive values for PC1, whereas red wines with water showed high and negative values for this component. Red wines with artificial saliva showed an intermediate behavior and were placed between the other two types of wine samples (with human saliva and water). PC1 was negatively correlated with many volatile compounds (25 volatile compounds showed loadings lower than 0.8 and 15 of them, lower than 0.9). Among them, the variable projection (Figure 2b) showed that some aroma compounds such as limonene (11), hexyl acetate (14), *cis*-3-hexen-1-ol (17), linalool (20), or 5-methylfurfural (21), among others, were strongly correlated with PC1. On the contrary, PC2 separated wines as a function of wine type. Red wines exhibited negative values for this component, whereas white and synthetic wines appeared on the half top of the graph showing positive values for PC2.

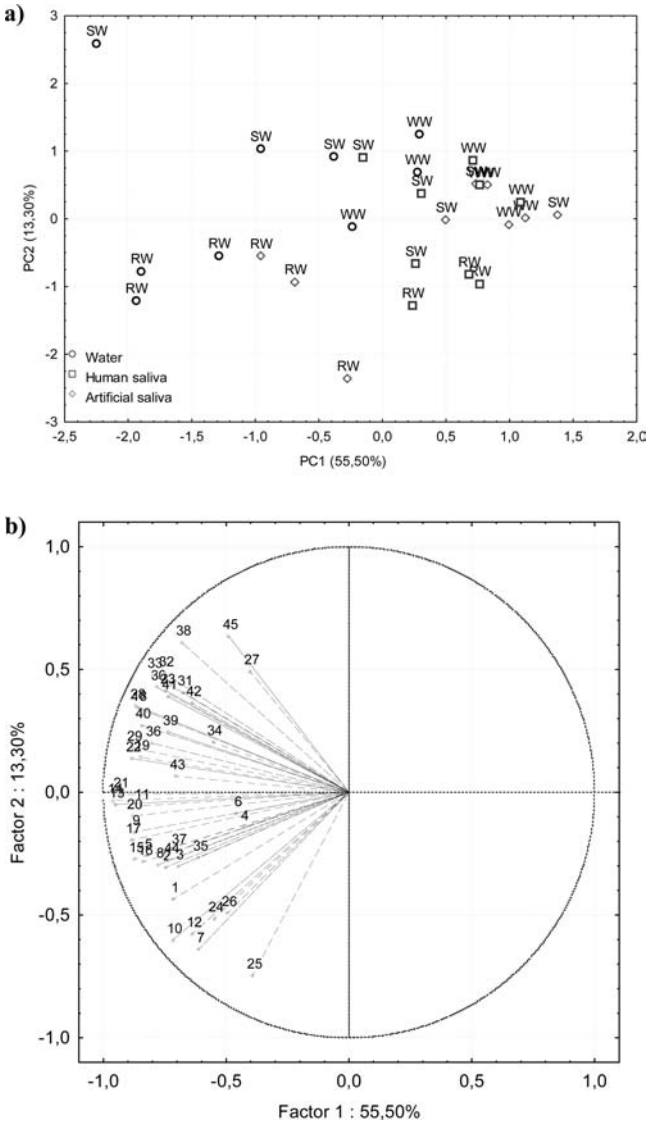

**Figure 2.** Graphic representation of the wine samples (a) and of the variables (b) obtained using PCA with the aroma release data from the static HS-SPME-GC/MS. Numbers of the variables in panel b correspond to the compounds listed in Table 1. RW, SW, and WW mean red, synthetic, and white wines, respectively.

These results emphasized an effect of saliva on aroma release dependent on wine matrix composition. Even more interestingly, red wines seemed to be more affected than white and synthetic wines. The most outstanding effect provoked by human saliva was a reduction in the aroma release of most of the aroma compounds independent of their chemical structure. This global effect could be the result of the combination of single effects that could be differently affecting the volatile compounds employed in this study.

For instance, it is already known that wine polyphenols, which are more abundant and structurally different in red than in white wines, might interact with aroma compounds through different mechanisms depending on polyphenol structure decreasing the amount of aroma release.[47,58−60] In addition to this effect, wine polyphenols (such as procyanidins) might form insoluble complexes with saliva proteins with colloidal structures[39] modifying the viscosity of the sample and, therefore, affecting aroma release. To check this hypothesis, the viscosity values of white and red wines with the two types of saliva and water were also determined. Table 4 shows that the viscosity values determined in all of the wines were very similar, ranging from 6.9 mPa·s for the white wine with water to 7.4 mPa·s for the white wine with artificial saliva. Therefore, there were no substantial differences between red and white wines. Although an increase in viscosity induced by saliva has been proposed to explain the lower aroma release observed in oil/water emulsions,[12,28] the low volume of saliva compared to the wine (1:5) employed in this study might not be enough to provoke a clear effect, at least in static headspace conditions as used here. Therefore, this factor did not seem a determinant parameter responsible for the higher retention of aroma compounds determined in red wines and specifically in those with human saliva.

The buffering capacity of saliva might be another important factor to explain aroma release, because this property might induce changes in the pH of the food matrix.[12,22] In fact, this factor has been pointed out, because it might influence the overall perception of aroma compounds during the in vivo consumption of palm wine.[61] To check this hypothesis, the pH values of the human and artificial saliva and the pH values of the wine/saliva mixtures were determined, and they are also shown in Table 4. The original pH value for the artificial saliva was a little bit higher (8.4) than the pH of the human saliva (8.2). As expected and for both white and red wines, the addition of water practically did not change the pH, whereas it increased with the addition of saliva. Artificial saliva seemed to induce higher changes in pH than human saliva, and this could

Table 4. Viscosity and pH Values Determined for the Saliva Samples and Wine/Saliva Mixtures ($n$ = 3)

| | viscosity (mPa·s) | | | pH | | |
|---|---|---|---|---|---|---|
| | water mean (SD) | human saliva mean (SD) | artificial saliva mean (SD) | water mean (SD) | human saliva mean (SD) | artificial saliva mean (SD) |
| salivas | | 7.0 (0.1) | 7.9 (0.2) | | 8.2 (0.1) | 8.4 (0.2) |
| red wine | 7.2 (0.1) | 7.3 (0.1) | 7.1 (0.1) | 3.8 (0) | 4.0 (0.1) | 4.2 (0.1) |
| white wine | 6.9 (0.0) | 7.3 (0.3) | 7.4 (0.5) | 3.1 (0) | 3.3 (0.1) | 3.7 (0.1) |

be due to its higher original pH compared to the human saliva. Therefore, differences induced by changes in pH did not seem relevant to explain the differences in the behavior of the aroma compounds in both wines whatever the matrix and type of medium.

To explain the retention effect induced by saliva, mainly in red wines, we have to propose an additional hypothesis. Previous works using static headspace conditions but with other food matrices have shown the ability of the saliva protein mucin to bind aroma compounds via hydrophobic interactions, leading to a reduction in aroma release into the headspace.[23] Moreover, this hypothesis has already been proposed to explain the lower release of a wide range of volatile compounds (e.g., esters, acetates, alcohols) from red and white wines.[38] However, in the present study, red wine with human saliva released lower amounts of aroma than the same wine with artificial saliva. The final amount of mucin in the wine/artificial saliva vial was 4.32 mg, whereas the amount of total protein (including mucin) in the wines samples with added human saliva was lower, 0.98 mg. Therefore, wines spiked with human saliva should have a minor interaction effect with mucin (and therefore higher aroma release) than wines spiked with artificial saliva, which does not explain our results. However, it is important to bear in mind that human saliva contains other proteins different from mucin, for instance, proline-rich proteins (PRPs), histidine-rich proteins (histatins or HRPs), lactoferrine, and enzymes ($\alpha$-amylase, lipase, etc.),[21] which could be also involved in specific interactions with aroma compounds explaining the lower aroma release of wines with human saliva. In particular, PRPs, which represent up to 70% of proteins originated from the parotid gland, are known to interact with tannins, leading to the formation of some aggregates.[62] Moreover, it has been shown that depending on the protein and tannin concentrations, dense aggregates might coexist with nonaggregated proteins, the latter also showing a significant number of bound tannin molecules.[62] We could hypothesize that the formation of this second type of aggregate might interact with aroma molecules without substantially changing the viscosity of the solution, as was observed in the present study in the case of red wines with added human saliva.

Moreover, besides tannins, other wine matrix components might be also involved in the formation of these types of aggregates. Mitropoulou et al.[39] have suggested, at least in reconstituted model wines, the possible formation of saliva protein−polyphenol−carbohydrate complexes able to encapsulate hydrophobic aroma molecules. In this sense, in addition to the higher concentration of polyphenols determined in the red wine employed in this study, the polysaccharide content was also higher (2502 mg mannose/L) compared to the white wines (1667 mg mannose/L) (see Table 2). The formation of these type of complexes involving saliva proteins and specific wine polyphenols (tannins) and polysaccharides, both at higher concentrations in red than in white wines, might explain why red wines, and specifically those with human saliva, retained more aroma molecules. Moreover, the fact that the very high hydrophobic aroma compounds (log $P$ > 2) of the aroma mixture showed higher retention (lower aroma release) in red wines with saliva than in the white wines might be in agreement with this hypothesis. The formation of these structures (protein−polyphenol−carbohydrate complexes) might, however, represent a reservoir of aroma molecules ready to be released by the exhalation breath during the in vivo red wine consumption, as has been recently proposed.[63]

Finally, the salivary metabolic activity might have also affected the release of certain aroma compounds. In this regard, a reduction of aldehydes to the corresponding alcohols and/or partial hydrolysis of certain aroma compounds such as esters might be expected.[19,20] In the case of the aldehydes employed in the aroma mixture (furfural and 5-methylfurfural), the release of these compounds was lower in red wines with human saliva, which could be in agreement with a possible transformation by an NADP-linked aldehyde reductase.[19] However, the increase of the corresponding alcohol (furfuryl alcohol in the case of furfural) was not significant in these samples. In addition, the involvement of aldehydes in the formation of condensation products such as Schiff bases (e.g., with salivary proteins) or other chemical reactions might be also possible.[19]

On the other hand, a reduction of esters in the HS of white but mainly red wines with saliva has been also shown in this work. However, this seems to be more related to the interaction of these compounds with the protein−polyphenol−carbohydrate complex than related to the esterase activity of saliva. Although the decrease in the release of some esters (ethyl butanoate, hexanoate, octanoate, etc.) in wines with human saliva compared to control wines (without saliva) has been attributed to the esterase activity,[38] the activity of these enzymes has been proven only in a very different environment (specifically, in an aqueous system at pH 5)[20] from that in wine (12% ethanolic system at pH 3.5). Therefore, it seems difficult to obtain straightforward relationships between the decrease in ester release and saliva esterase activity.

**Effect of Saliva on Aroma Release Using Dynamic Headspace Conditions.** In the present work, aroma release from different wine matrices in dynamic conditions was determined by using a bioreactor cell with controlled temperature and agitation conditions at two different sampling times (initial $t$ = 0 and final $t$ = 10 min) (Figure 1). The initial sampling time ($t$ = 0) might be related to the oral phase, in which the mixture of wine (generally cold) and saliva is at lower temperature (25.5 °C) than physiological temperature (36 °C). The final sampling time ($t$ = 10 min) could be more representative of the postoral phase, in which some volatiles could be released from the liquid sample remaining in the oral cavity after drinking[5] at oral temperature (36 °C).

Aroma release data collected from $t$ = 0 and $t$ = 10 min are shown in Tables 5 and 6, respectively. These data were submitted to two independent two-way ANOVA (one for each sampling time), considering the global effect of saliva type (artificial, human, water) and type of wine matrix (red, white,

[a]All values (area: arbitrary units) are divided by a factor of 10000. Different letters (a–c) for the same aroma compound in the same wine type (synthetic, white, red) denote statistical differences among saliva types after application of LSD test.

factor. In the case of the postoral phase ($t$ = 10 min) the application of the same statistical treatment also showed a higher influence of wine matrix composition (22 compounds significantly affected) compared to the saliva effect (7

dx.doi.org/10.1021/jf503503b | J. Agric. Food Chem. 2014, 62, 8274–8288

compounds) and the interaction (5 compounds) (data not shown).

Compared to results from the previous static headspace analysis, the influence of saliva on aroma release seemed to be lower. The minor effect of saliva addition by using the dynamic approach compared to the static headspace analysis could have been due to a displacement of the equilibrium, which might reduce the retention effect produced by proteins[41] or by other nonvolatile wine matrix molecules, such as the above-mentioned protein−polyphenol−polysaccharide complexes. These findings are not surprising taking into consideration that several authors have already suggested that despite dynamic conditions might better simulate the consumption situation, static measurements are better suited for determining thermodynamic and kinetic parameters with good precision.[64]

In terms of amount of aroma release, it is interesting to note that higher releases for most of the aroma compounds were found during the postoral release step ($t$ = 10 min) (Table 6) compared to the oral phase (Table 5). This could be due to the higher extraction temperature in the postoral phase (36 °C) compared to the oral phase (25.5 °C). Previously, the effect of temperature (4, 23, 60 °C) on volatile release from oil/water emulsions using an artificial mouth system had been pointed out.[28] These authors showed a similar effect between 4 and 23 °C (release less pronounced), compared to 60 °C. In the present work, using more realistic temperatures closer to what was expected during wine consumption (25.5 and 36 °C), most of the volatile compounds showed higher release when the temperature was raised about 12 °C independent of the wine type. The increase in sampling temperature increases the partitioning of the volatiles into the gas phase following the van't Hoff law.[65] In addition, in ethanol solutions (as wine) and using dynamic headspace conditions, Tsachaki et al.[66] showed that the evaporation of ethanol at the solution vapor interface might create a surface tension gradient, making new ethanol molecules move from the bulk phase to replenish the depleted surface areas, carrying along an appreciable volume of underlying liquid with aroma compounds. This phenomenon, called the Marangoni effect,[67] might also explain the higher aroma release for most of the volatile compounds in the wines with a moderate increase in temperature.

To extract more conclusions on the role of saliva in aroma release using dynamic conditions, a LSD test for mean comparison was also performed for each type of wine (red, white, and artificial) in the oral and postoral phases. These results are also shown in Tables 5 and 6. Results show that during the oral phase ($t$ = 0), only three terpenes ($\alpha$- and $\beta$-pinenes, limonene) showed significantly lower release in the three types of wines with saliva (human and artificial) (Table 5). The same compounds were significantly less released in white and red wines with saliva during the postoral phase ($t$ = 10 min) (Table 6). These compounds are characterized by high log $P$ values, which seem to be in agreement with their involvement in the formation of hydrophobic interactions with wine polyphenols[58] or with their involvement in the formation of complexes with salivary proteins, polyphenols, and polysaccharides.

Surprisingly, and mainly during the oral phase, a relatively high number of aroma compounds were highly released in the wines with saliva, which seems to contradict results from the previous experiment performed in static conditions. This could be due to the higher sensitivity of the dynamic HS conditions over the static HS, which might have improved the detection of some aroma compounds.[41] For instance, some lactones (*cis*- and *trans*-whiskylactones, $\gamma$-nonalactone), furanic compounds (furfural, 5-methylfurfural), volatile phenols (eugenol, ethylphenol), C13 norisoprenoids ($\beta$-damascenone, $\alpha$-ionone, $\beta$-ionone), and terpene alcohols (linalool, terpinen-4-ol, $\alpha$-terpineol, $\beta$-citronellol, nerol) were more highly released in red wines with human saliva (Table 5). Some of these compounds, such as terpene alcohols, could have originated de novo from the corresponding grape glycosidic precursor that might have remained in the wine matrix after the desaromatization step. The existence of saliva glycoside activity has been recently shown.[68]

To better understand the impact of saliva on aroma release in the three types of wine matrices, aroma release data (peak area) taken at $t$ = 0 and $t$ = 10 min were independently submitted to PCA. Figure 3a shows the representation of the first two

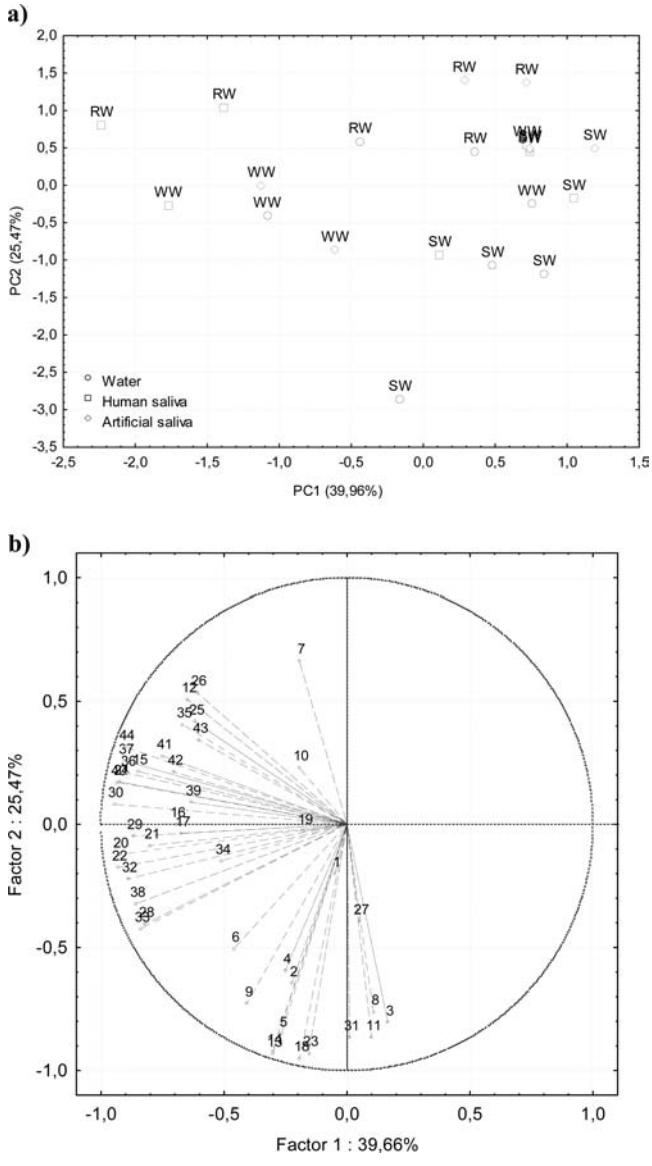

**Figure 3.** Graphic representation of the wine samples (a) and of the variables (b) obtained using PCA with the aroma release data from the dynamic HS-SPME-GC/MS analysis at $t$ = 0 (oral phase). Numbers of the variables in panel b correspond to the compounds listed in Table 1.

dx.doi.org/10.1021/jf503503b | J. Agric. Food Chem. 2014, 62, 8274−8288

principal components obtained after the application of this test to aroma release data collected from the wines at $t$ = 0. Both PCs explained >65% of data variation. As can be seen (Figure 3), similar to what happens in static conditions, the main differences among wine samples were found in the case of red wines. PC1 clearly separated red wines with water and artificial saliva from red wines with human saliva. The latter exhibited high and negative values for this component. The representation of the variables on the basis of the two first components (Figure 3b) shows how some variables such as *trans*- and *cis*-hexenol (16, 17), linalool (20), 5-methylfurfural (21), terpinen-4-ol (22), nerol (29), $\beta$-phenylethyl acetate (30), $\beta$-damascenone (32), and $\beta$-ionone (38), among others, were strongly and negatively correlated with PC1. Most of these compounds match those previously shown in the LSD test (Table 5) as significantly more released in red wines with saliva, which is the same conclusion obtained by PCA. In Figure 3a, PC2 also shows a separation of the samples depending on wine matrix composition. Red wines appeared on the top of the graph showing high values for this component, whereas white and mainly synthetic wines appeared in the low part of the graph with lower and even negative values for this component, especially in the water medium. As can be seen (Figure 3b), the most correlated (negatively) variables were, in general, ethyl esters such as ethyl octanoate (18), ethyl decanoate (23), and ethyl dodecanoate (31) and some nonalcoholic terpenes such $\alpha$-pinene (3), $\beta$-pinene (8), and limonene (11). It seems that these compounds (with high log $P$ values) might interact more with saliva protein and wine matrix than with synthetic wine. In the case of these three terpene compounds, this result was the same as previously shown in the LSD test.

Similar to the results found in the previous ANOVA and LSD tests, results from the PCA performed with release data collected during the postoral phase ($t$ = 10 min) did not show a clear grouping of wine samples depending on the medium composition (with human saliva, artificial saliva, or water) (Figure 4a). However, an influence on the wine matrix composition was indeed manifested. As can be seen, PC1 separates between red on the positive side of the graph and white and synthetic wines on the other side (Figure 4a), showing differences in their aroma release behaviors. Red wines exhibited higher values for this component than white wines. The projection of the variables on the plane defined by the first and second components (Figure 4b) shows that PC1 was highly correlated (negatively) with some aroma compounds such as terpinen-4-ol (22), $\beta$-citronellol (28), $\alpha$-ionone (33), $\beta$-phenylethyl alcohol (37), 4-ethylguaicol (40), and 4-ethylphenol (44), among others. In addition, PC2 also allowed a separation between synthetic wines with positive values for this component and white and red wines with negative values for it. In this case, PC2 was strongly and negatively correlated with some alcohols such as 1-butanol (10) or isoamylic alcohols (12) but positively with some nonalcoholic terpenes such as $\alpha$- and $\beta$-pinene (3, 8) and limonene (11).

In conclusion, the main finding of this work is that saliva has an important effect on aroma release from wine and this effect was different depending on wine matrix composition. In addition, we found differences depending on using human or artificial saliva, therefore proving that proteins other than mucins seem to have an important role in aroma release. Moreover, it has been shown that the effect of saliva on wine aroma release is more evident when using static than dynamic headspace conditions. In general, human saliva produces lower

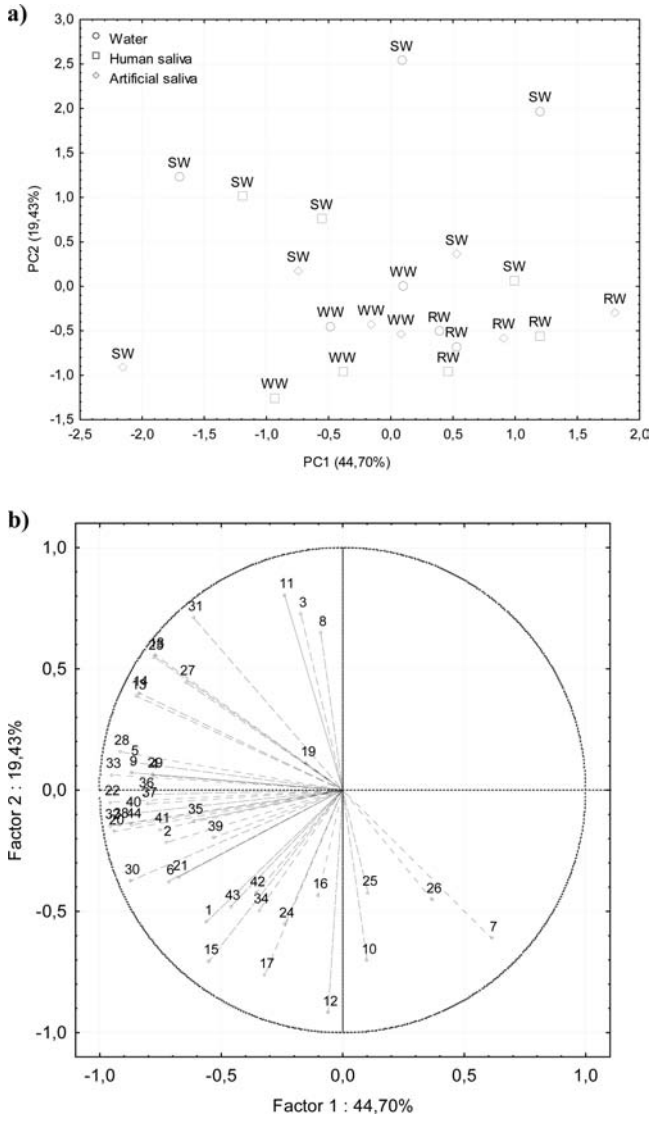

**Figure 4.** PCA of the graphic representation of the wine samples (a) and of the variables (b) obtained using PCA with the aroma release data from the dynamic HS-SPME-GC/MS analysis at $t$ = 10 min (post oral phase). Numbers of the variables in panel b correspond to the compounds listed in Table 1.

release for most of the wine volatile compounds, and this effect was more important in red than white wines. The interaction of aroma compounds with other proteins different from mucin or the formation of complexes involving saliva glycoproteins−wine polyphenols−wine polysaccharides and aroma compounds, preferentially for those aroma compounds with high log $P$ values (hydrophobic), seems to be responsible for the observed effect. In addition, large differences in the amount of aroma released depending on sampling temperature during the oral and postoral phases invite us to think about the importance of this second step of wine consumption as a mechanism in releasing aroma compounds from oral or throat wine reservoirs influencing long-lasting perception of aroma after swallowing. Finally, despite the minor impact of saliva observed in dynamic conditions, it is important to bear in mind that in vivo consumption conditions could represent a more dynamic process than that used in the present work, in which saliva is continuously produced and replenished (incorporating more proteins to interact with aroma compounds or enzymes) and

dx.doi.org/10.1021/jf503503b | J. Agric. Food Chem. 2014, 62, 8274−8288

also that "fresh" sample is continuously being provided. Therefore, the extent of its effect could be higher than that determined with the experimental in vitro dynamic headspace conditions used in this study. Overall, this work will contribute to insights into the role of oral physiology on wine aroma perception, which should be taken into consideration in the production of high-quality wines for targeted groups of consumers.

Supporting Information

**ABSTRACT:** Among the soybean germplasm in Japan, two varieties, Nishiyamahitashi 98-5 (NH) and Shinanokurakake (SKK), have an intense seaweed-like flavor after cooking. Gas−liquid chromatography with mass spectrometry (GC-MS) indicated that a significant amount (11.5 ± 3.46 $\mu$g g$^{-1}$ for NH and 6.66 ± 0.91 $\mu$g g$^{-1}$ for SKK) of dimethyl sulfide (DMS) was formed after heat treatment. DMS is formed from *S*-methylmethionine (SMM, vitamin U). SMM was detected in all soybean varieties examined here, but its concentration in NH and SKK seeds was >100-fold higher than in the other varieties and ranged from 75 to 290 $\mu$g g$^{-1}$. The SMM content and the ability to form DMS upon heat treatment correlated among them. The plumes and radicles contained SMM exclusively. This is the first report of soybean varieties containing SMM at a level equivalent to or higher than that in vegetables known to contain high levels of SMM, for example, turnip, cabbage, and celery.

**KEYWORDS:** *soybean, flavor, dimethyl sulfide, S-methylmethionine*

## INTRODUCTION

Soybean, *Glycine max* (L.) Merr., is the most important legume plant and the fifth most important crop in the world in terms of quantity of production after maize, rice, wheat, and potato (FAOSTAT, 2012, http://faostat3.fao.org/faostat-gateway/go/to/home/E). Soybean seeds contain large amounts of oils (18−20%) and proteins (40%−45%);[1] accordingly, they are widely used as a source of nutritious foods for humans and livestock. Recently, a variety of claims about health benefits of soy products increased the consumption of soybeans. Because of its importance, the soybean is regarded as a model legume crop, and in 2010, a whole-genome sequence of the representative variety Williams 82 was published.[2] At the same time, a wide diversity of agronomic and food-related chemical properties such as the level of proteins, lipids, isoflavones, and saponins as well as flavor properties have been reported for different varieties of soybean;[1,3,4] therefore, a lot of effort has been devoted to the establishment of germplasm collections worldwide. For example, approximately 11300 soybean-related accession numbers are available in the National Institute of Agrobiological Sciences Genebank, Japan (https://www.gene.affrc.go.jp/index_en.php). Each entry has a distinct color, shape, size, and other agronomic traits.[4] During our effort to identify new traits in the Japanese germplasm, we noticed a unique seaweed-like flavor in some of the traditional varieties locally cultivated and consumed in the central part of Japan (around Nagano prefecture). In these regions, soybean seeds with seed coat colors of green and black are widely consumed. The colored soybean seeds with the seaweed-like flavor are consumed after boiling of water-soaked seeds with a modicum of soy sauce and sugar. Colored soybeans such as black and green soybeans have high isoflavone and anthocyanin contents, respectively;[5] thus, their use as a functional food is to be expected.

Dimethyl sulfide (DMS) is a typical volatile organic sulfur compound with a characteristic seaweed-like and boiled cabbage-like odor. DMS is formed enzymatically in a lyase reaction involving dimethylsulfoniopropionate in a wide variety of seaweed species.[6] DMS is considered a key flavor constituent in cooked vegetables, such as tomato, cabbage, and asparagus.[7−9] DMS is one of the markers that differentiate black truffle (*Tuber melanosporum*) and Chinese truffle (*Tuber indicum*), with stronger aromatic contribution to the former.[10] Formation of DMS was also reported in soy milk prepared using heat treatment at 90 °C for 10 min.[11] DMS has a disagreeable odor at high concentrations but is beneficial to the aroma of lager types of beer at a concentration between 30 and 100 $\mu$g L$^{-1}$[12] and some types of red wine at a concentration of 100 $\mu$g L$^{-1}$.[13,14]

In vegetables and green malts, DMS is formed via thermal degradation of its precursor, *S*-methylmethionine (SMM).[9] The latter was originally called vitamin U because it has an antiulcerogenic activity, and it reduces gastric mucosal damage induced by ethanol in rats.[15] It is an active ingredient in an over-the-counter gastrointestinal drug widely used in Japan (Cabagin Kowa, Kowa Co., Ltd.). Furthermore, SMM has been shown to have a choline-sparing activity in poultry.[16] It is also reported that SMM inhibits adipocyte differentiation via down-regulation of adipogenic factors and up-regulation of AMP-

activated protein kinase.[17] Such beneficial biological activities of SMM should make food products containing it attractive to consumers.

Until now, soybeans have not been recognized as food products containing high concentrations of SMM. The traditional soybean varieties that show an intense seaweed-like flavor especially after boiling are believed to contain a relatively high concentration of SMM, which would be degraded to DMS upon heating. We examined the SMM contents of several soybean varieties and compared them with those of other soybean varieties. Because of the unique flavor resulting from DMS and the possible pharmaceutical properties of SMM, identification of varieties that contain a substantial concentration of SMM should open up opportunities for novel uses of soybeans.

## MATERIALS AND METHODS

**Plant Materials.** Seeds of a leading Japanese cultivar, Fukuyutaka (FK), widely used for tofu in Japan,[18] were harvested at Saga City (E 130° 18′, N 33° 14′; annual mean temperature, 17 °C), Saga, Japan, in 2011 (provided by Dr. Toyoaki Anai, Saga University, Japan). The other varieties, Shinanomidori (SM), Shinanokuro (SK), Nakasennari (NS), Gankui (GK), Shinanokurakake (SKK), and Nishiyamahitashi 98-5 (NH; Figure 1), are traditional varieties in the Nagano prefecture

**Figure 1.** Seven varieties of soybean used in this study.

(central Japan) and were harvested in 2011 in an experimental field at the Nagano Vegetable and Ornamental Crops Experimental Station, Shiojiri City (E 137° 57′, N 36° 06′; annual mean temperature, 11 °C), Nagano, Japan. SKK and NH have a green color with a black patch and are known to produce a seaweed-like flavor. The seaweed-like flavor is enhanced after boiling. The seaweed-like flavor is hardly detected in the other varieties used here even after boiling. SM is a green soybean without a black patch, and SK and GK are black soybeans. NS is a yellow soybean and is used as a control similar to FK but grown in the same field with the other colored soybeans. The seeds were kept at 4 °C under dry conditions until use.

**Chemicals.** L-Methionine-*S*-methyl-$d_6$ sulfonium chloride ($d_6$-SMM) was purchased from Toronto Research Chemicals Inc. (Toronto, Ontario, Canada) via the distributor Funakoshi Co., Ltd. (Tokyo, Japan). DL-SMM sulfonium chloride was purchased from Tokyo Chemical Industry Co. (Tokyo, Japan). 1-Octen-3-ol was from Alfa Aesar (Lancashire, UK), and isobutanol, *n*-hexanal, *n*-hexan-1-ol, and dimethyl sulfide were purchased from Wako Pure Chemicals (Osaka, Japan).

**Analysis of Volatiles.** We collected volatiles at 25 °C to avoid any further changes that might happen at higher temperatures. The volatiles from intact soaked seeds, with and without heat treatment, were collected to analyze the way the colored seeds were consumed in the region where they were popular. The seeds (1 g, corresponding to 2−5 seeds depending on the seed size) were soaked in 8 mL of distilled water for 8 h at 4 °C in a glass vial (22 mL, PerkinElmer, Waltham, MA, USA). The vial was kept open during the soaking period. Thereafter, the vial was sealed tightly with a butyl rubber stopper and a crimp top seal (National Scientific, Rockwood, TN, USA). Heat treatment of soybean seeds was carried out at 80 °C for 30 min, keeping the vial sealed. This temperature was chosen because it is often used to prepare various types of soy milk.[19,20] Volatiles from the soaked seeds were collected without heat treatment. After chilling of the seeds to 25 °C, we collected the volatiles by using the solid-phase microextraction (SPME) fiber (50/30 μm DVB/Carboxen/PDMS, Supelco, Bellefonte, PA, USA; preconditioned immediately prior to use at 240 °C for 37 min) by exposing the fiber to the headspace for 30 min at 25 °C. The fiber was inserted into the insertion port of a gas chromatography−mass spectrometry (GC-MS) system (QP-5050, Shimadzu, Kyoto, Japan) equipped with a Stabilwax column (30 m × 0.25 mm i.d. × 0.25 μm film thickness, Restek, Bellefonte, PA, USA). The column temperature was programmed as follows: 40 °C for 5 min followed by an increase of 5 °C $min^{-1}$ to 200 °C. The carrier gas (He) was delivered at 86.1 kPa. The glass insert was an SPME sleeve (Supelco). Splitless injection with a sampling time of 1 min was used. The fiber was held in the injection port for 10 min to remove completely any compounds from the matrix. The temperature of the injector and interface was 240 °C. The mass detector was operated in the electron impact mode with ionization energy of 70 eV. Full-scan acquisition was used in the 40−350 atomic mass unit range of masses. To identify each compound, we used retention time and an MS profile of corresponding standard samples. The corresponding MS profiles in the NIST08 database (Shimadzu) were also used. For quantitation, an aqueous solution (10 mg $mL^{-1}$) of each compound was prepared in 10 mg $mL^{-1}$ Tween 20. The solutions were mixed at different ratios, and then water was added to 8 mL in a glass vial. Immediately after mixing of the solutions, the vial was tightly sealed, and the volatiles in the headspace were collected using the SPME fiber at 25 °C for 30 min. A calibration curve for each compound was constructed, and the area was calculated using integration software (GC-MS Solution, Shimadzu; Supporting Information Figure S1). The limit of detection for DMS, *n*-hexanal, *n*-hexan-1-ol, or 1-octen-3-ol was 30, 10, 20, or 20 ng $g^{-1}$, respectively. All measurements were performed in triplicate for each sample. The precision of the GC-MS method was determined by injecting a mixture of standards five times: dimethyl sulfide (5 μg), *n*-hexanal (0.1 μg), *n*-hexan-1-ol (0.1 μg), and 1-octen-3-ol (0.2 μg) suspended in 8 mL of $H_2O$. The relative standard errors (RSEs) for dimethyl sulfide, *n*-hexanal, *n*-hexan-1-ol, and 1-octen-3-ol were 3.08, 2.14, 1.03, and 2.46%, respectively. When the volatiles formed after treatment of NH seeds at 80 °C for 30 min were analyzed five times, RSEs for dimethyl sulfide, *n*-hexanal, *n*-hexan-1-ol, and 1-octen-3-ol were 5.15, 23.2, 10.2, and 14.4%, respectively.

**Quantitation of *S*-Methylmethionine.** This procedure was carried out essentially as per the procedure reported by Scherb et al.[9] The seeds were powdered using a force mill (Osaka Chemical Co., Ltd., Osaka, Japan). The powder (1 g) was suspended in 20 mL of 0.1 M sodium acetate buffer (pH 4.4). A portion (0.2 mL) of the suspension was mixed with 20 μL of 0.05 mg $mL^{-1}$ $d_6$-SMM in water as the internal standard and then mixed with 2 mL of MeOH/water (7:3, v/v). The mixture was shaken on a reciprocal shaker at 25 °C for 30 min. Thereafter, the mixture was centrifuged at 1500 rpm (Kubota 8100 centrifuge with RS 3000/6 rotor; Kubota Co., Tokyo, Japan) for 10 min at room temperature, and the resultant supernatant was collected. After removal of MeOH with $N_2$ gas flow, 1 mL of ethyl acetate was added, vigorously mixed, and centrifuged at 1500 rpm (same centrifuge) for 5 min. The lower aqueous phase was collected and cleared using Ekicrodisc 3 (0.45 μm, 3 mm, Wako Pure Chemicals). The cleared solution was mixed with acetonitrile/water (1:1, v/v) to the total volume of 2.5 mL.

Liquid chromatography with tandem mass spectrometry (LC-MS/MS) was performed on an AB Sciex (Framingham, MA, USA) 3200 Q-TRAP LS-MS/MS system equipped with a Prominence UFLC (Shimadzu). Chromatography was carried out on a Discovery HS F5 column (15 cm × 2.1 mm, 3 μm; Supelco) using 20% acetonitrile in water supplemented with 0.1% formic acid at a flow rate of 0.1 mL $min^{-1}$. The injection volume was 5 μL. The column temperature was set to 40 °C. The compound was detected using electrospray ionization (ESI) in the positive ion mode [ion spray voltage, 5500 V; nitrogen as the curtain gas (set to 35 arbitrary units)] with the multiple reaction monitoring (MRM) mode (Q1/Q3 mass, 164.113/102.000 for SMM and 170.113/102.000 for $d_6$-SMM; declustering potential, 16 V; energy potential, 5 V; collision energy potential, 10 V; collision

energy, 13 V). A calibration curve for SMM was constructed, and the area was calculated using integration software (Analyst, ABSciex; Supporting Information Figure S2). On the basis of the calibration curve, a response factor of 0.863 was calculated.

The precision of the LC-MS/MS method was determined by injecting a 1 $\mu$g mL$^{-1}$ solution of $d_6$-SMM four times. The RSE was found to be 0.84%. When SMM in NH seed powder was analyzed four times, the RSE for SMM was 2.22%. The recovery was validated by spiking the heat-treated NH seeds with a known amount of $d_6$-SMM. The results showed that 52.7% of the theoretical amount of $d_6$-SMM was recovered.

**Statistical Analysis.** All of the experiments were conducted at least in triplicate. The differences were evaluated using one-way analysis of variance (ANOVA) with Tukey's test in Excel Toukei (Social Survey Research Information Co., Ltd., Tokyo, Japan).

## RESULTS AND DISCUSSION

We collected six varieties of soybeans that are grown in the local area in the central part of Japan and one variety that is widely grown throughout Japan (Figure 1). Fukuyutaka (FK) is a strain widely grown in Japan as an ingredient of tofu and was used as a control in this study. Nakasennari (NS) is also a soybean variety that is widely grown (for tofu production) in the central part of Japan. Shinanokurakake (SKK) and Nishiyamahitashi 98-5 (NH) are the traditional varieties in the Nagano prefecture (central Japan). These soybean seeds are usually eaten after boiling with a modicum of soy sauce and sugar, and they are known to produce a seaweed-like flavor, especially after boiling. Their seed coat color is green with a black patch that resembles a saddle on horseback; therefore, they are sometimes called "saddle-bearing" soybeans (*Kurakakemame* in Japanese). Shinanomidori (SM) is also a traditional variety in Nagano prefecture and is consumed after boiling, but it does not smell like seaweed. It has a green seed coat without the black "saddle". Shinanokuro (SK) and Gankui (GK) are black soybeans. SM, SK, and GK were used as controls to evaluate the effect of the seed coat color on the flavor. To identify the compound responsible for the seaweed-like flavor after boiling, we examined volatiles formed before and after heat treatment in whole seeds.

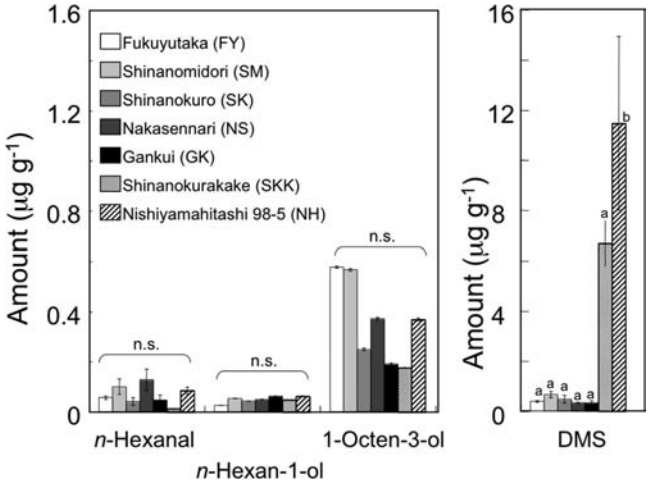

**Figure 2.** Concentration of volatile compounds formed in heat-treated soybean seeds. The concentrations of *n*-hexanal, *n*-hexan-1-ol, and 1-octen-3-ol (left panel) and dimethyl sulfide (DMS; right panel) detected in the headspace of heat-treated soybean seeds were determined using solid phase microextraction with gas–liquid chromatography and mass spectrometry. Means ± standard error (error bars) are shown ($n$ = 3). Different letters indicate significant differences, and n.s. means that there is no significant difference (analysis of variance, Tukey's test, $p < 0.05$).

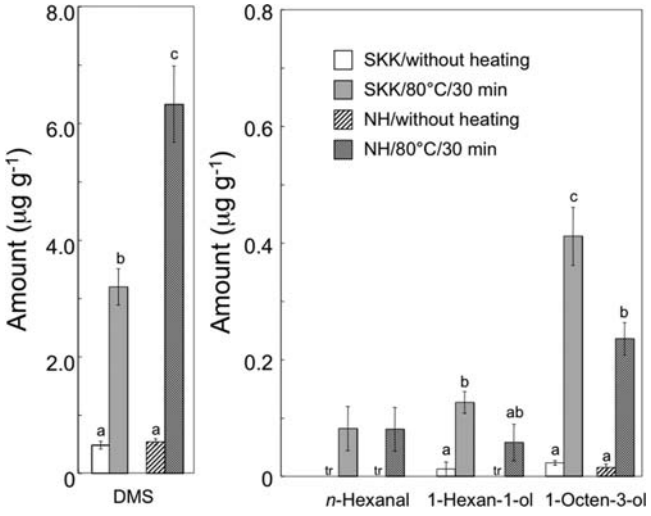

**Figure 3.** Effect of heat treatment on the concentration of dimethyl sulfide (DMS) in the headspace of Sinanokurakake (SKK) and Nishiyamahitashi (NH) soybean seeds. The seeds were soaked in 8 mL of water, and immediately, or after heating at 80 °C for 30 min, the concentration of DMS was determined. Means ± standard error (error bars) are shown ($n$ = 3). Different letters indicate significant differences (analysis of variance, Tukey's test, $p < 0.05$).

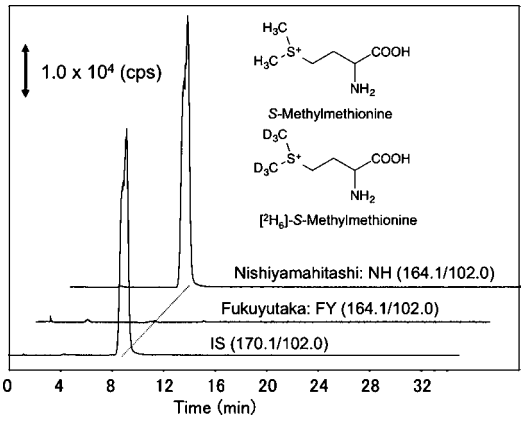

**Figure 4.** Detection of *S*-methylmethionine (SMM) in the multiple reaction monitoring (MRM) mode of liquid chromatography with tandem mass spectrometry (LC-MS/MS). We performed LC-MS/MS analyses of the extracts from Nishiyamahitashi (NH) and Fukuyutaka (FY) by following the signal of 164.113 (Q1)/102.000 (Q3) as well as the analysis of a standard sample of L-methionine-*S*-methyl-$d_6$ sulfonium chloride ($d_6$-SMM) by following the signal of 170.113 (Q1)/102.000 (Q3) (top, middle, and bottom chromatograms, respectively). The structures of SMM and $d_6$-SMM are shown.

After overnight soaking and heat treatment of the intact seeds, *n*-hexanal, *n*-hexan-1-ol, and 1-octen-3-ol were detected in all seven varieties (Figure 2; Supporting Information Figure S3). These were the typical volatile compounds most abundant in homogenized soybean seeds.[21,22] Even though the content of *n*-hexanal, *n*-hexan-1-ol, and 1-octen-3-ol somehow varied depending on the variety analyzed, the differences in their concentrations in the seven soybean varieties were insignificant (Figure 2). The concentrations of *n*-hexanal detected in heat-treated soybean seeds in this study (ranging from 0.01 to 0.13

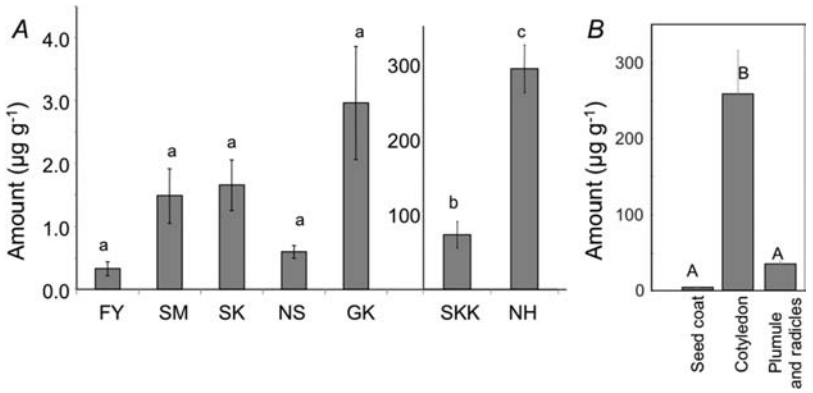

**Figure 5.** Concentration of SMM in whole seeds of each variety of soybean (A) and that in seed coats, cotyledons, and plumules with radicles in Nishiyamahitashi (NH) soybean seeds (B). Means ± standard error (error bars) are shown ($n$ = 3). Different letters indicate significant differences (analysis of variance, Tukey's test, $p < 0.05$).

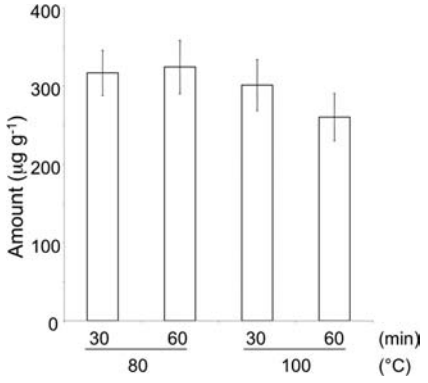

**Figure 6.** Effects of heating temperature and duration on the concentration of *S*-methylmethionine (SMM) remaining in the soaked soybean seeds (Nishiyamahitashi, NH). The seeds were soaked in 8 mL of water at 4 °C and were then heated at 80 or 100 °C for 30 or 60 min. After the seeds had chilled to room temperature, we quantified SMM using liquid chromatography with tandem mass spectrometry (LC-MS/MS). Means ± standard error (error bars) are shown ($n$ = 3). Statistical analysis by using analysis of variance and Tukey's test indicated no statistically significant differences among the treatments.

$\mu$g g$^{-1}$) were 7−500-fold lower than those in soy milk (ranging from 1 to 5.4 $\mu$g g$^{-1}$).[11,19−21] The difference might be attributable to the differences in processing procedures such as the method of heating and whether the seeds were homogenized. *n*-Hexan-1-ol was generally undetectable in soy milk prepared through homogenization of seeds with hot water (80 °C),[11,22] whereas a substantial level of *n*-hexan-1-ol was found here (ranging from 0.025 to 0.063 $\mu$g g$^{-1}$). Again, this effect might be explained by differences in the processing procedures, for example, rapid homogenization of seeds with hot water in the study by Lozano et al.[11] and a gradual temperature increase to 80 °C with intact seeds in the present study. The level of 1-octen-3-ol detected in the heat-treated soybean seeds used in this study was comparable to that reported for soy milk regardless of the differences in processing procedures. This is probably because the formation of 1-octen-3-ol is independent of disruption of soybean tissues.[21,23]

A low but substantial concentration of DMS was detected in FY, SM, SK, NS, and GK, whereas this concentration in SKK and NH was quite high and reached 6−11 $\mu$g g$^{-1}$ of seeds. The concentrations are roughly equivalent to the levels found in cooked vegetables: from 1.1 $\mu$g g$^{-1}$ (tomato) to 25 $\mu$g g$^{-1}$ (celery).[9] It was apparent that the ability to form DMS in soybean seeds was independent of the ability to form volatile oxylipins examined here.

The concentrations of *n*-hexanal, *n*-hexan-1-ol, 1-octen-3-ol, and DMS were low in SKK and NH seeds soaked for 8 h; however, these concentrations significantly increased after we heated the soaked seeds at 80 °C for 30 min (Figure 3). It was assumed that DMS was formed from an endogenous substrate. DMS is formed in large amounts by algae and bacteria, especially in marine environments through the action of a lyase enzyme on dimethylsulfoniopropionate.[6] On the contrary, it is known that DMS is formed as a result of thermal degradation of SMM in angiosperms including vegetables and green malt.[9]

SMM has been found in various vegetables such as cabbage, tomato, celery, and spinach.[9] Soybean has the ability to form SMM from methionine,[24] and SMM at 1.65 mg g$^{-1}$ was detected after acid hydrolysis (at 105 °C for 24 h in HCl) of dehulled-soybean meal.[16] We used a stable isotope dilution assay involving LC-MS/MS to measure the concentration of SMM, essentially as per the procedure developed by Scherb et al.[9] With the modified assay system, SMM was eluted at a retention time of 8.1 min and was detected with the limit of detection of 0.1 $\mu$g g$^{-1}$ with a signal/noise ratio >3 (Figure 4).

We quantified the concentration of SMM in soaked soybean seeds (Figure 5). The soybean varieties showing a low ability to form DMS, that is, FY, SM, SK, NS, and GK, contained SMM in the range between 0.5 and 3.0 $\mu$g g$^{-1}$ without any significant differences among these varieties. In contrast, the concentrations in SKK and NH were 75 and 290 $\mu$g g$^{-1}$: 30−600-fold higher than those in the other soybeans. The level found in SKK and NH was comparable to or even higher than that found in vegetables reported to contain a high concentration of SMM such as celery (176.0 $\mu$g g$^{-1}$), turnip cabbage (124.0 $\mu$g g$^{-1}$), leek (94.0 $\mu$g g$^{-1}$), beetroot (89.0 $\mu$g g$^{-1}$), and cabbage (81.0 $\mu$g g$^{-1}$).[9] Nonetheless, the concentration in SKK and NH was still much lower than that found in acid-hydrolyzed soybean meal (1.65 mg g$^{-1}$).[16] Because we estimated the concentration of SMM in its free form without acid hydrolysis, a large proportion of SMM might exist as its bound form as a component of a protein, as in the LaeA protein in *Aspergillus nidulans*.[25]

Most plant seeds have the biosynthetic pathway that produces SMM in seeds;[26] however, no studies have been reported to examine its distribution in seeds. When the seed of the NH soybean was dissected into the seed coat, cotyledon,

and plumules with radicles, the cotyledons accounted for ~87% of the total SMM found in the whole seeds, followed by the plumules and radicles, which comprised ~12% of the total SMM (Figure 6B). On the basis of the weight of each part, the plumules and radicles accounted for only 1.8% of the total weight of soaked soybean seeds, whereas the cotyledons accounted for 89%. Thus, the plumules and radicles contain the highest concentration of SMM (1071 ± 179 $\mu g\ g^{-1}$) followed by the cotyledons (159 ± 36.0 $\mu g\ g^{-1}$).

The concentration of SMM tended to decrease depending on the heating temperature and heating time, even though there was no statistically significant difference among the treatments (Figure 6). At low pH (pH 2−5), DMS is formed as a result of a nucleophilic substitution of the dimethyl sulfonium group by water, whereas at higher pH values (pH >7), an intramolecular nucleophilic substitution caused by the carboxyl group of SMM takes place.[27] Because the pH of the homogenate prepared from soybean seeds after soaking or after heat treatment was 5.7−6.0, both mechanisms might be possible. Under the experimental conditions used here, where soybean seeds (NH) are heated without disruption, ~90% of SMM found in intact seeds was retained even after heat treatment at 100 °C for 60 min. This yield was expected because the concentration of DMS (10−12 $\mu g\ g^{-1}$, see Figure 2) after heating of the NH seeds accounted for only 3−4% of the initial concentration of SMM found in intact seeds before heat treatment (Figure 5). The thermal stability of SMM is dependent on the pH value of the solution and on the matrix; therefore, its degradation in tomato or orange juice is higher than that in an aqueous buffer at the same pH.[9]

This seems to be the first study on soybean varieties that contain SMM at a level (75−290 $\mu g\ g^{-1}$) equivalent to or even higher than that in vegetables that are known to contain high concentrations of SMM such as cabbage and celery (80−180 $\mu g\ g^{-1}$).[9] It was reported that the biosynthetic pathway that produces SMM (SMM cycle) is widespread among angiosperms[28] and is active during seed development in alfalfa (*Medicago truncatula*)[29] and flax (*Linum usitatissimum*).[30] In fact, all of the soybean seeds examined here, except for the two that showed extraordinarily high SMM content, exhibited a low but substantial concentration of SMM. These findings suggest that a mutation in the metabolic pathway results in the high SMM concentration in the seeds of NH and SKK. The SMM cycle partly accounts for the methionine level, which is an important nutritional parameter of soybeans.[31] Therefore, deciphering the cause of the high SMM content of the two varieties at the molecular level would be worthwhile. Currently, we are trying to locate genetic loci responsible for the accumulation of SMM.

Supporting Information

**ABSTRACT:** The oxidative stability of oleoyl and linoleoyl residues esterified in the form of triglyceride (TAG) and phosphatidylcholine (PC) during thermal treatment was investigated. Headspace solid-phase microextraction (HS-SPME) followed by gas chromatography−mass spectrometry (GC−MS) analysis was used to determine the volatile compounds from oxidized PL and TAG molecular species. The results showed that aldehydes were the major volatile oxidized compounds (VOCs) of 1-stearoyl-2-oleoyl-*sn*-glycero-3-phosphocholine (SOPC), 1-stearoyl-2-linoleoyl-*sn*-glycero-3-phosphocholine (SLPC), and 1,3-distearoyl-2-linoleoyl-glycerol (SLS), while ketones, especially saturated methyl ketones, were the major VOCs of 1,3-distearoyl-2-oleoyl-glycerol (SOS). The monitoring of the oxidative degradation using liquid chromatography−electrospray ionization−mass spectrometry (LC−ESI−MS) showed that either monounsaturated or diunsaturated fatty acyl groups were less oxidized when in the form of PCs than when in the form of TAGs. This finding demonstrated that the choline group in the form of PCs could increase the stability of fatty acyl groups to oxidation in comparison to TAGs.

**KEYWORDS:** *phosphatidylcholine, triglycerides, oxidative stability, volatile oxidized compound, oleic acid, linoleic acid*

## INTRODUCTION

Polyunsaturated fatty acids (PUFAs) play very important roles in human health, in particular, in protecting the liver,[1,2] in improving memory and learning,[3,4] and in protecting the cardiovascular system.[5−7] Phospholipids (PLs) are rich in PUFAs and are an important source of PUFAs.[8] Supplementation of food products with PUFA-rich PLs has recently emerged as an interesting way of increasing the daily intake of PUFA and, thereby, received more and more attention. Another important source of PUFA is triglycerides (TAGs), which are the major carriers of fatty acids (FAs), with 50−100 g/day for an adult, followed by PLs, with 2−10 g/day.[9,10] However, according to the bioavailability of FAs, PLs are much more efficient than TAGs.[11−13] Moreover, cellular permeability to PUFA and their intracellular level were indeed much higher when linked to PL than to TAG,[10,14] which suggests that food supplementation with PUFA-rich PL could enhance essential FA assimilation.

The bioavailability of PUFA in the form of PL or TAG is an important factor that should be considered, but their stabilities in food sources are also as important. The information on the evaluation of relative stability of TAG and PL is limited. Most of the studies were contributed on the comparison of the stability of oil-enriched PLs to that of oils containing few or no PLs at all.[13,15,16]

Lipid oxidation is a major cause of quality deterioration of many natural and processed foods.[17,18] It leads to the development of undesirable off-flavors and potentially toxic compounds. Our previous studies have investigated the formation mechanism of non-volatiles of PLs.[19,20] As for volatile compounds, there are also major decomposition products of lipids.[21] We have identified the volatile compounds from oxidized phosphatidylcholine (PC) and figured out their origin.[22] However, to our knowledge, no studies have been carried out in detail on the comparison of volatiles by oxidation of PC to TAG.

Several methods are available to measure the progress of lipid oxidation. Conventional measurements for the assessment of lipid oxidation are usually determined by simple spectroscopic techniques, such as thiobarbituric acid reactive substances (TBARS), carbonyl group, and diene conjugate methods. However, these photometric assays could only roughly reflect the level of lipid oxidation, and their sensitivities are limited, while chromatographic techniques (gas chromatography and/or high-performance liquid chromatography together with different detectors, including mass spectroscopy) are useful for a more detailed description of the reaction products.

The aim of this study was to compare the oxidative stability of PC to TAG. As a model system, oleyol and linoleoyl residues in the form of PC and TAG were chosen, because they exist widely in food matrices, such as soybean, egg yolk, and ox liver, which were identified in our previous study.[4,19] The comparison of the oxidative stability of PC and TAG was made in terms of the kinetics of the formation of volatile oxidized compounds (VOCs), which was monitored by headspace solid-phase microextraction and gas chromatography−mass spectrometry (HS-SPME−GC−MS), and the kinetics of degradation of the starting material, which was

monitored using liquid chromatography−electrospray ionization−mass spectrometry (LC−ESI−MS).

## MATERIALS AND METHODS

**Materials.** The following standards (>95%) were used to identify the volatile compounds, including pentanal, hexanal, heptanal, octanal, nonanal, (*E*)-2-hexenal, (*E*)-2-heptenal, (*E*)-2-octenal, (*E*)-2-decenal, (*E*,*E*)-2,4-decadienal, 1-pentanol, 1-hexanol, 1-octen-3-ol, 1-heptanol, 1-octanol, 2-decanone, 2-undecanone, 1-octen-3-one, 2-pentyl-furan, (*E*)-2-undecenal, (*E*)-3-octen-2-one, 5-ethyldihydro-2(3*H*)-furanone, and dihydro-5-propyl-2(3*H*)-furanone. They were purchased from Sigma-Aldrich (St. Louis, MO).

1-Stearoyl-2-oleoyl-*sn*-glycero-3-phosphocholine (SOPC) (99.9%) and 1-stearoyl-2-linoleoyl-*sn*-glycero-3-phosphocholine (SLPC) (99.9%) were purchased from Avanti Polar Lipids (Alabaster, AL). 1,3-Distearoyl-2-oleoyl-glycerol (SOS) (99.9%) and 1,3-distearoyl-2-linoleoyl-glycerol (SLS) (99.9%) were obtained from Larodan (Malmö, Sweden). High-performance liquid chromatography (HPLC)-grade methanol and ammonium formate were purchased from VWR (Strasbourg, France). Chloroform of analytical grade was purchased from Riedel de Haën (Sigma-Aldrich, Seelze, Germany).

The SPME fiber tested in this study was 65 $\mu$m of polydimethylsiloxane/divinylbenzene (PDMS/DVB), purchased from Sigma-Aldrich (St. Louis, MO).

**Sample Preparation.** Stock solutions of 10 mg mL$^{-1}$ were prepared by weighing standards (SOPC, SLPC, SOS, and SLS) in a 5 mL amber vial and dissolving them in chloroform. A total of 100 $\mu$L of these solutions (1.0 mg of sample) were placed in a 20 mL dark glass injection vial previously desorbed, uncapped by a heating treatment at 200 °C during 2 h in an oven. After evaporation of chloroform at room temperature in the fume chamber, each injection vial was sealed with an aluminum crimp cap provided with a polytetrafluoroethylene/silicone septum (Agilent Technologies, Massy, France) and kept at −20 °C until oxidative treatment.

**Oxidative Treatments.** The samples were heated in an oven at a specified temperature comprised between 100 and 200 °C for a duration ranging from 0 to 180 min. After oxidation, samples were cooled quickly in ice for 5 min, then left at room temperature for 5 min, and finally injected in HS-SPME−GC−MS for analysis. A total of 1.0 mL of methanol was added in the vial; then a $^{1}/_{50}$ dilution was performed to obtain 0.02 mg/mL; and 10 $\mu$L was injected in the LC−ESI−MS system. All samples were analyzed in triplicate.

**HS-SPME.** Prior to analysis, the PDMS/DVB fiber was preconditioned (at 250 °C for 30 min) in the bakeout oven of the CombiPAL injector with the temperature and duration suggested by the manufacturers. The extraction was carried out for 25 min at 50 °C,[22] and each measurement was repeated 3 times.

**GC−MS Analysis of Volatiles.** GC−MS analysis was performed in a 450 Varian gas chromatograph fitted with a CombiPAL (CTC Analytics AG, Switzerland) automatic HS-SPME injector. Helium was used as the carrier gas at a constant flow rate of 1 mL min$^{-1}$. The injector operated in the splitless mode, and its temperature was set at 250 °C. The separation of VOCs was performed on a DB-wax column (60 m × 0.25 mm, 0.15 $\mu$m, Agilent, Santa Clara, CA). The oven temperature program started at 40 °C, was raised at a rate of 4 °C min$^{-1}$ to 220 °C (held for 5 min), and then was raised at a rate of 4 °C min$^{-1}$ to 240 °C (held for 17 min). The detection was performed by an Agilent 240 mass selective detector (ion trap) set in positive electron impact (+EI) mode with 70 eV of electron energy. The electron multiplier was set by the autotune procedure. MS data were collected with the daughter ion scan mode over the $m/z$ range from 50 to 315. Transfer line temperature, trap temperature, and ion source temperature were 110, 150, and 150 °C, respectively.

VOCs were tentatively identified by matching the experimental mass spectra with the reference mass spectra in the National Institute of Standards and Technology (NIST) mass spectral library. Most VOCs identified in this way were then confirmed by comparing their mass spectra and retention times to those obtained from authentic reference compound (STD) under the same analytical conditions. In addition, retention indices (RIs) were calculated on the basis of a series of *n*-alkanes with a chain length from $C_5$ to $C_{20}$. They were compared to literature values to support tentative identification.[23−25]

**LC−ESI−MS Analysis.** After oxidative treatment of the samples, the remaining PCs and TAGs were evaluated using a Varian Prostar HPLC system made of two 210 solvent delivery modules, a 410 autosampler, and a 1200 L triple quadrupole mass spectrometer with ESI operated in positive-ion mode (Agilent, Les Ulis, France). High-purity nitrogen (99.99%, Domnik Hunter) was used as the nebulizing gas, set at 317 kPa, and as the drying gas, set at 300 °C. Separation was performed on a Zorbax column C8 (250 × 4.6 mm, 5 $\mu$m, Agilent) using an isocratic elution of 100% $CH_3OH$ containing 5 mM ammonium formate at a flow rate of 1 mL min$^{-1}$. A total of 20 $\mu$L of each diluted oxidized sample was injected. A split system allowed for the HPLC effluent to enter the mass spectrometer at a flow rate of 0.2 mL min$^{-1}$. The injection volume was performed in positive mode in a mass range between $m/z$ 500 and 1000 and in selected ion monitoring (SIM) mode by extracting ion $[M + H]^+$ $m/z$ 788.6 for SOPC, $m/z$ 786.6 for SLPC, $m/z$ 889.8 for SOS, and $m/z$ 887.8 for SLS.

The percentage of the remaining precursors was determined as follows:

$$\% = \frac{(\text{area})_t}{(\text{area})_{t^\circ}} \times 100$$

where $(\text{area})_t$ is the area of the peak corresponding to the ion $m/z$ of the starting material (PC or TAG) after oxidation and $(\text{area})_{t^\circ}$ is the area of the same ion $m/z$ without oxidative treatment. All samples were analyzed in triplicate, and results are given as the mean ± standard deviation (SD).

## RESULTS

**Determination of Optimal Oxidation Temperatures.** To determine the optimal oxidation conditions of SOPC and SLPC, the total areas of VOCs generated at several temperatures was determined. The temperatures allowing for the highest yield of total VOCs were different for thermally oxidized SOPC and SLPC. According to our previous study,[22] the highest production of total VOCs was 175 and 125 °C for SOPC and SLPC, respectively, in the same oxidation time. This was in accordance with a previous report showing that free linoleic acid was more sensitive to oxidation than free oleic

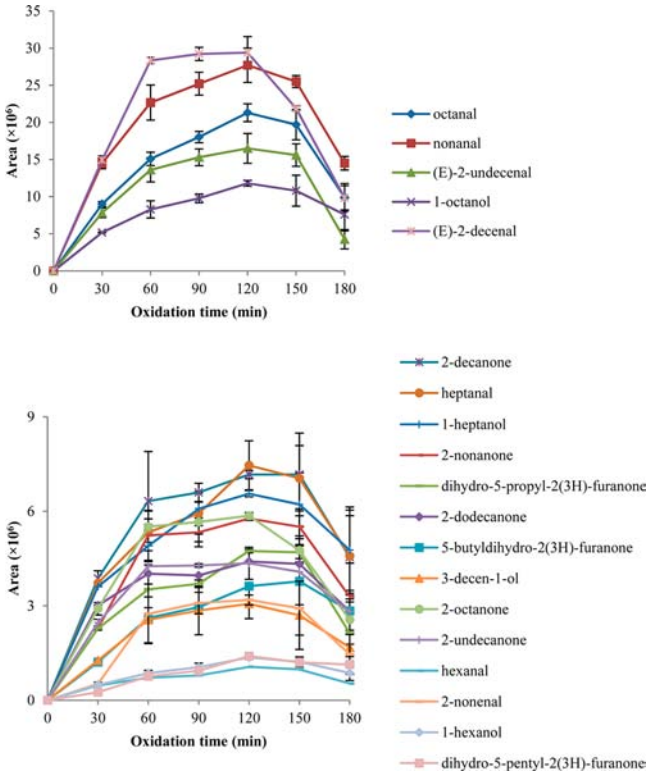

**Figure 1.** Kinetics of VOCs produced from oxidized SOPC during heat treatment at 175 °C monitored from 0 to 180 min.

acid.[9] To compare to the oxidative stability of TAG, 175 and 125 °C were chosen for SOS and SLS, respectively.

**Identification of VOCs.** A variety of volatile and nonvolatile secondary products are formed from hydroperoxides when lipid oxidation is carried out at elevated temperatures. The mechanism suggested for the formation of oxidized products involves the homolytic cleavage of the hydroperoxide group to yield an alkoxyl radical and a hydroxyl radical.[26] The further decomposition of an alkoxyl radical involving carbon−carbon bond scission is a major pathway for the formation of volatile products.[27] The $\alpha$-scission and $\beta$-scission of an alkoxyl radical lead to different decomposition products (Scheme 1).

Oxidation was performed in the solid state because chloroform was evaporated before oxidation. Because of the selectivity of the HS-SPME procedure, identified compounds were those that were present in the sample and were extracted by the PDMS/DVB fiber. Besides, there might be other VOCs that were present in the sample but not extracted by the fiber.

Table 1 gives the VOCs of SOPC and SOS at 175 °C with 120 min. A total of 19 VOCs were detected from oxidized SOPC. The major VOCs of SOPC were aldehydes, such as nonanal, (*E*)-2-decenal, octanal, and (*E*)-2-undecenal. However, ketones were the predominant group of VOCs formed from oxidized SOS. Among them, saturated methyl ketones, such as 2-octanone, 2-nonanone, 2-decanone, 2-undecanone, and 2-dodecanone, accounted for a large proportion of total VOCs. It was well-known from our previous study that these saturated methyl ketones were formed from the stearic acid chain of SOPC or SOS.[22] Three reactions, degradation, $\beta$-oxidation, and decarboxylation, occurring simultaneously were proposed to account for the homologous series of methyl ketones.[29] Furthermore, the results indicated that the total peak areas of saturated methyl ketones from oxidized SOS were

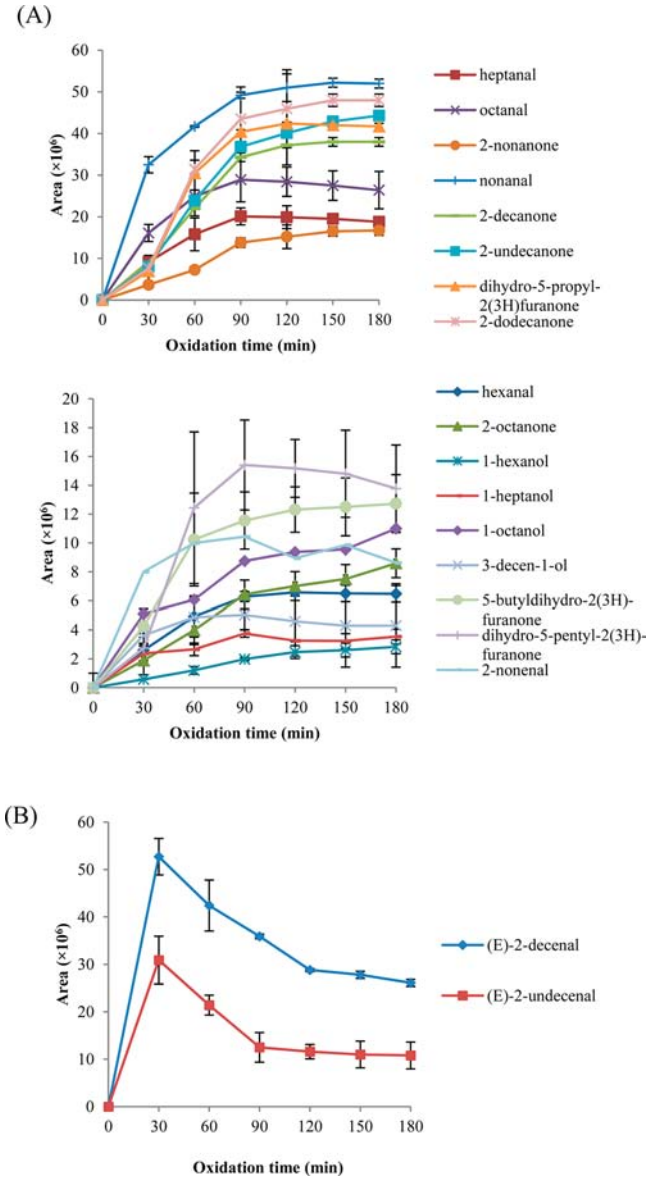

**Figure 2.** Kinetics of VOCs produced from oxidized SOS during heat treatment at 175 °C monitored from 0 to 180 min: (A) VOCs increased gradually until 90 min and then stabilized or increased slightly, and (B) VOCs increased in a sharp way before 30 min and decreased rapidly until 90 or 120 min.

obviously higher than that from oxidized SOPC. That was in agreement with the fact that SOS contained two stearic acid chains, while SOPC contained only one stearic acid chain.

A total of 18 VOCs were detected from oxidized SLPC and SLS (Table 2). Among them, aldehydes were also the major VOCs. In contrast to SOPC/SOS, oxidation of SLPC and SLS produced rather unsaturated ketones, such as (*E*)-3-octen-2-one, formed from linoleic acid chains, with saturated methyl ketones being only in trace amounts because only one (2-heptanone) was detected. Up to now, it is quite difficult to explain why SOPC/SOS and SLPC/SLS did not produce the same kind of ketones because they contain both the same C18:0 saturated FA. Perhaps the competitive oxidation equilibrium between *sn*-1 and *sn*-2 FA chains of PC/TAG may give information. The competition between stearoyl residues and oleoyl residues for VOC formation is relatively

dx.doi.org/10.1021/jf501934w | J. Agric. Food Chem. 2014, 62, 8295−8301

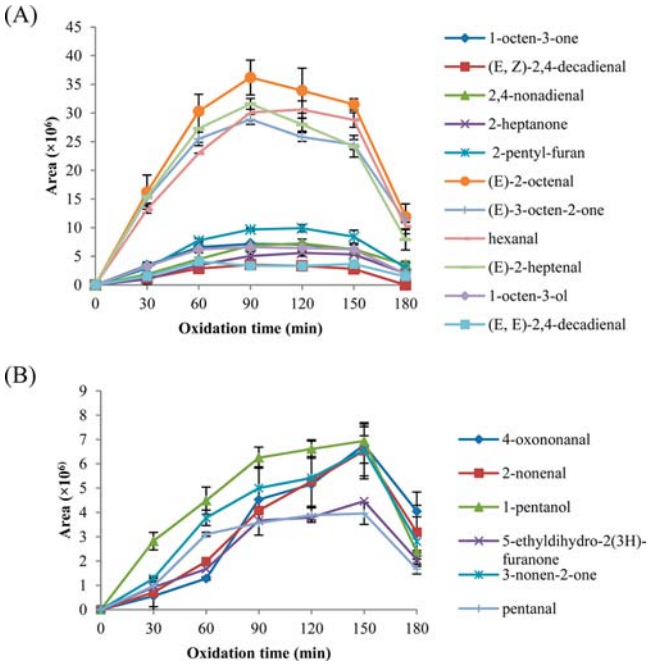

**Figure 3.** Kinetics of VOCs produced from oxidized SLPC during heat treatment at 125 °C monitored from 0 to 180 min: (A) VOCs increased until 90 min and then decreased, and (B) VOCs increased continuously until 150 °C and then decreased.

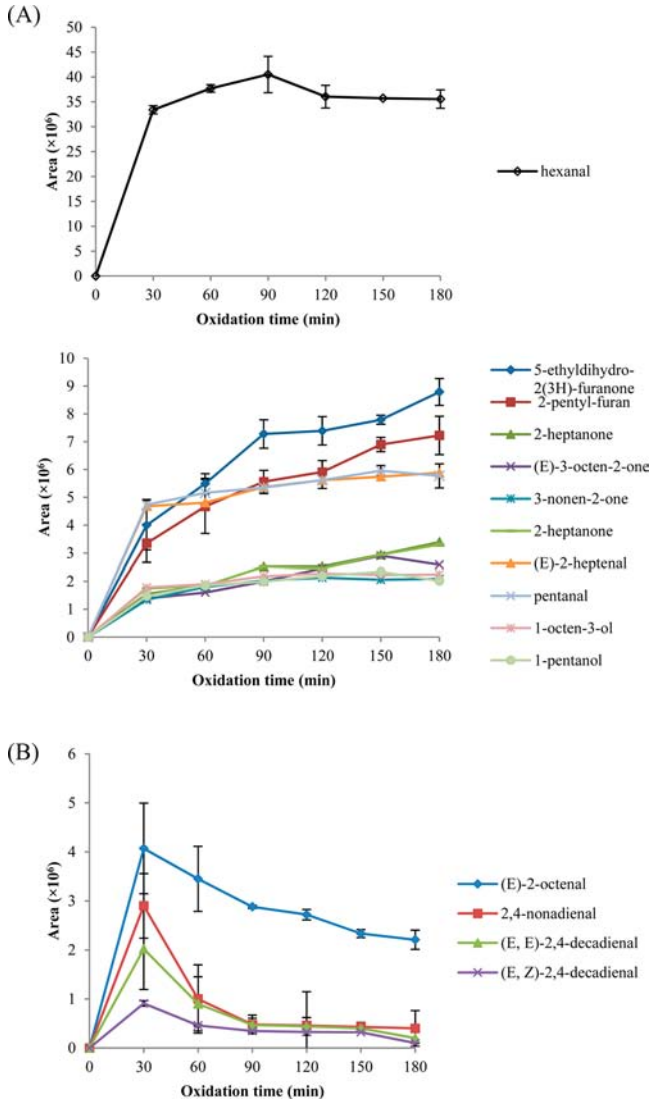

**Figure 4.** Kinetics of VOCs produced from oxidized SLS during heat treatment at 125 °C monitored from 0 to 180 min: (A) VOCs increased gradually with the increase of the oxidation time or increased to reach a maximum and then were kept stable, and (B) VOCs increased in a sharp way in the first 30 min and then decreased.

weak by comparison to stearoyl residues and linoleoyl residues. In other words, the *sn*-1 FA chains of SOPC/SOS and SLPC/SLS are stearic acids, but *sn*-2 FA chains of SOPC/SOS and SLPC/SLS are oleic and linoleic acids, respectively. Because linoleic acid is more sensitive to oxidation than oleic acid, it is easier to be oxidized. That is probably why more ketones tend to be formed from the linoleic acid chains of SLPC/SLS and less from the stearic acid chains. In comparison, more ketones, especially methyl ketones, were derived from the stearic acid chain of SOPC/SOS. It thereby showed that a higher amount of total saturated methyl ketones was formed from SOPC/SOS than that from SLPC/SLS.

**Oxidative Kinetics.** The oxidative kinetics of PLs and TAGs were investigated by analyzing HS-SPME−GC−MS peak areas of all VOCs produced as a function of the oxidation time. Some VOCs had relatively high occurrences in one chemical group. To let the low-content VOCs appear clearly, the curves of relatively high-content and low-content VOCs were divided into two separate figures.

The major VOCs of oxidized SOPC were (*E*)-2-decenal, nonanal, octanal, 2-undecenal, and 1-octanol (Figure 1). Almost all of the VOCs increased rapidly during 0−60 min and reached their maximum at 120 min, then were kept stable or decreased slowly until 150 min, but decreased rapidly after 150 min.

As for SOS (Figure 2), the VOCs can be separated into two groups: one group included the products that increased gradually until 90 min and then stabilized or increased slightly (Figure 2A), and the other group included (*E*)-2-decenal and (*E*)-2-undecenal, which increased in a sharp way before 30 min, decreased rapidly until 120 and 90 min, respectively, and then reached equilibrium or decreased slightly (Figure 2B).

Figure 3 shows kinetics of production of VOCs from oxidized SLPC. Two groups were obtained: one group (Figure 3A) reached their maximum rapidly at 90 min of oxidation, then were kept stable or decreased slowly until 150 min, and decreased sharply after 150 min, and the other group (Figure 3B) increased gradually until 150 min and then decreased rapidly.

As far as the VOCs of SLS were concerned, 18 VOCs were detected (Table 2). Hexanal was most abundant among the VOCs. It increased in a sharp way in the first 30 min, reached its maximum at 90 min, then decreased, and stabilized (Figure 4A). The amount of (*E*)-2-octenal, 2,4-nonadienal, (*E*,*Z*)-2,4-decadienal, and (*E*,*E*)-2,4-decadienal reached a maximum after 30 min of oxidation and then decreased (Figure 4B). Other VOCs increased gradually with the increase of the oxidation time (Figure 4A).

SOS is more sensitive to oxidation than SOPC. Two major VOCs of SOS identified, (*E*)-decenal and (*E*)-2-undecenal, reached their maximum after only 30 min of oxidative treatment and then decreased (Figure 2B), while most VOCs of SOPC reached their maximum after 120 min (Figure 1). Similarly, four VOCs, which were (*E*)-2-octenal, 2,4-non-

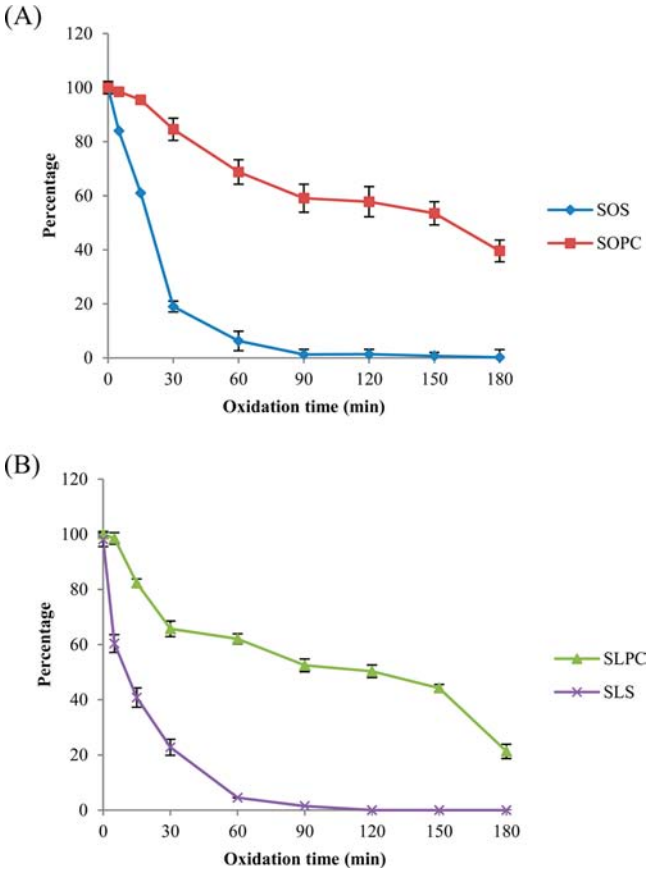

**Figure 5.** (A) Oxidative kinetics of SOPC and SOS was monitored over time of thermal treatment at 175 °C, and (B) oxidative kinetics of SLPC and SLS was monitored over time of thermal treatment at 125 °C.

adienal, (*E*,*E*)-2,4-decadienal, and (*E*,*Z*)-2,4-decadienal, reached a maximum at 30 min and then decreased (Figure 4B). While all of the VOCs of SLPC reached their maximum after 90 min, even some VOCs reached their maximum after 150 min (Figure 3B). That shows that SLS is also more sensitive to oxidation than SLPC.

**Degradation of Starting Material.** The quantities of the starting materials SOPC and SOS (SLPC and SLS), expressed as recovery percentages, were monitored by LC−ESI−MS as a function of the oxidation duration. An example of mass spectra of SOPC (A) and SLPC (B) were shown in Figure S1 of the Supporting Information. The percentage of SOPC decreased gradually over time of oxidation; SOPC was not completely decomposed at the end of 180 min; and the remaining percentage of SOPC was 39.6%. While in the case of SOS, the remaining percentage decreased rapidly (by 81%) during the first 30 min and then decreased slightly until an almost total loss of the precursor during 90 min of oxidation (Figure 5A).

Figure 5B shows the evolution of the relative amounts of SLPC and SLS over time at 125 °C. The trend of curves was similar to Figure 5A. The amounts of SLS decreased immediately and were significantly sharper than SLPC ($p < 0.05$). It also showed that SLS disappeared within 90 min of oxidation, while SLPC decreased gently down to 21.3% after 180 min of oxidation.

The kinetics of the loss of the precursors of SLS and SLPC followed the same trend as that of SOS and SOPC. PC species thereby appeared more resistant to thermal oxidation than TAG species. Our results were consistent with the results by Song et al.,[16] who demonstrated that docosahexaenoic acid (DHA) in the form of PLs was more resistant to oxidative degradation than DHA in the form of TAGs or ethyl esters. Results obtained by Lyberg et al.[30] followed the same trend that DHA was protected against hydroperoxide formation when it was incorporated at *sn*-1 and *sn*-2 positions of PC, while incorporation of DHA at any positions of a TAG was not an appropriate solution for protecting DHA. Therefore, the result suggests that the polar moiety of PC has a role to play in their stability to oxidation. This hypothesis was proposed by Yoshimoto et al.,[31] who supposed that PC can lead to the polarization of the oxygen−oxygen bond in the hydrogen peroxide, which allowed for a nucleophilic attack of an oxygen atom of another peroxide group. That can reduce the proparation phase of the oxidation process.

In this study, the results showed that PC species are more resistant to thermal oxidation than their corresponding TAG species, which supported a hypothesis that polar head groups affect oxidative kinetics of glycerol-based lipids. Therefore, concerning FA bioavailability and oxidative stability, supplementation with PUFA PLs was a more potential and interesting way than PUFA TAGs for food development.

# Lichenysin, a Cyclooctapeptide Occurring in Chinese Liquor *Jiannanchun* Reduced the Headspace Concentration of Phenolic Off-Flavors via Hydrogen-Bond Interactions

Rong Zhang, Qun Wu, and Yan Xu*

State Key Laboratory of Food Science and Technology, Synergetic Innovation Center of Food Safety and Nutrition, Key Laboratory of Industrial Biotechnology of Ministry of Education, School of Biotechnology, Jiangnan University, 1800 Lihu Avenue, Wuxi, Jiangsu 214122, China

**ABSTRACT:** Nonvolatile compounds play important roles in the quality of alcoholic beverages. In our previous work, a type of cyclooctapeptide lichenysin was newly identified in Chinese strong-aroma type liquor. In this work, it was found that lichenysin could selectively affect aroma volatility in strong-aroma type (*Jiannanchun*) liquor. Interaction of lichenysin and volatile phenolic compounds (off-odors in strong-aroma type liquor) was characterized using headspace solid-phase microextraction coupled with gas chromatography−mass spectrometry (HS-SPME-GC-MS). HS-SPME results indicated that lichenysin very efficiently suppressed the volatility of phenolic compounds by 36−48% ($P < 0.05$). Thermodynamic analysis showed that the binding process was mainly mediated by hydrogen bonding. Furthermore, the mixture of lichenysin and 4-ethylguaiacol revealed intermolecular cross peaks between the *a*H (Val) of lichenysin and the 1H of 4-ethylguaiacol, by using nuclear Overhauser effect spectroscopy. This study will help to further understand the interaction mechanisms between flavor and nonvolatile matrix components in Chinese liquors.

**KEYWORDS:** *lichenysin, phenolic off-flavors, aroma volatility, hydrogen-bond interaction*

## INTRODUCTION

Chinese liquor is a traditionally indigenous and famous distilled beverage in China.[1] The various aroma profiles of Chinese liquors result from their complexity in manufacturing practices. During the production, Chinese liquor is typically distilled from fermented sorghum. The sorghum used for liquor fermentation is cooked and then mixed with a fermentation starter (Daqu powder). Daqu made from wheat is rich in various microorganisms including bacteria, yeast, and fungi. They are typically carried out at 28−32 °C under anaerobic conditions in the solid-state fermentation. After fermentation, the liquor is distilled out with steam from fermented sorghum by the means of traditional solid distillation. Then, it is aged in a china jar (sealed tightly) for more than 3 years at 15−25 °C.[1]

The quality of Chinese liquor depends on the volatile and nonvolatile compounds. In Chinese strong-aroma type liquors, a sum of 132 aroma compounds was detected using gas chromatography olfactometry (GC-O) coupled with mass spectrometry (MS).[2,3] Besides the volatile compounds, nonvolatile compounds also play important roles in the liquor quality. In past research, we isolated and identified a cyclooctapeptide lichenysin in many different Chinese liquors as a nonvolatile compound, using preparative high-performance liquid chromatography (HPLC) coupled with a quadrupole-time-of-flight (Q-TOF) mass spectrometer. Lichenysin is produced by *Bacillus licheniformis* in the fermented sorghum and is most likely to be distilled into the liquor with steam by means of traditional solid distillation. The concentration of this nonvolatile compound is the highest to reach 112 μg/L in the *Dongjiu* liquor (unpublished data). However, little information has been reported about the nonvolatile compounds affecting aroma perception in Chinese liquors, especially their interaction mechanism with aroma compounds.

The nature of interactions between odor and nonvolatile matrix components may depend on the physicochemical properties of the aroma compound and the binding mechanisms. The most frequent method to measure the interactions that occur between aroma compounds and other food or beverage constituents is headspace analysis, the headspace solid-phase microextraction (HS-SPME) method.[4−6] Aronson and Ebeler[7] have shown that gallic acid (in 1% ethanol solution) significantly decreased the volatility of 2-methylpyrazine by HS-SPME. To further explore the nature of the interactions between aroma compounds and nonvolatile wine compounds, NMR spectroscopy has been proven as one of the most powerful techniques. It was found that the interactions between the galloyl ring of gallic acid and the aromatic ring of methylpyrazine were stabilized by hydrogen bonds, using NMR techniques.[8] β-Cyclodextrin (β-CD) is usually used for the microencapsulation of aroma compounds in food processes. The binding nature of β-CD with benzyl alcohol and 2-methylbutyric acid was studied by using $^{1}H$ and $^{13}C$ NMR experiments.[9] Up to now, there is no report about the interaction mechanism between nonvolatile compounds and aroma compounds in Chinese liquor.

In this study, we characterized that the cyclooctapeptide lichenysin reduced the headspace concentration of phenolic off-

flavors in strong-aroma type liquor and the model solution, using HS-SPME-GC-MS and sensory evaluation. Furthermore, we used thermodynamic analysis and nuclear Overhauser effect spectroscopy (NOESY) to elucidate the nature of binding between lichenysin and phenolic compounds.

## MATERIALS AND METHODS

**Chemicals.** DMSO-$d_6$ and tetramethylsilane (TMS) were purchased from Sigma Technology (St. Louis, MO, USA). The chemical standards of all the aroma compounds and internal standards (hexyl formate and 2-octanol) were purchased from Acros Organics (Fair Lawn, NJ, USA). Formic acid was purchased from Acros Organics. Methanol and absolute alcohol were purchased from Tedia (Fairfield, OH, USA). The reference standards were prepared in an ethanol solvent. All standard solutions were flushed with nitrogen to avoid oxidation of the phenols and kept in the freezer at −20 °C in the dark. We got the $C_{15}$–lichenysin from the Chinese liquor sample *Dongjiu* liquor, from the Dongjiu distilleries. The compound was isolated from the fractions by means of preparative HPLC (autopurity system, Waters, Milford, MA, USA) material, by using an Xbridge Prep $C_{18}$ (250 mm × 19 mm, 10 μm) reversed-phase Xbridge steel column. The solvents were water containing 0.1% formic acid as solvent A and methanol as solvent B. The program was conducted by means of gradient elution, and the detection was selected at wavelength of 210 nm. The structure of $C_{15}$–lichenysin was confirmed by the Waters Synapt Q-TOF system. It is built from a heptapeptide and a β-hydroxy fatty acid with a chain of 15 carbon atoms. The purity of $C_{15}$–lichenysin that we got from the liquor can reach 99%. The Chinese liquor sample *Jiannanchun* liquor was purchased from the market. *Jiannanchun* is one of the most famous strong-aroma type liquors, which typically have strong fruity, pineapple-like, and banana-like aromas.[1] This liquor is the typical representatives of strong-aroma type.

**Sample Preparation for SPME Extraction and SPME Conditions.** An aliquot of $C_{15}$–lichenysin was dissolved in Chinese liquor (strong-aroma type liquor) and model solution. Phenol, 4-methylphenol (4-MP), 4-ethylphenol (4-EP), guaiacol, and 4-ethylguaiacol (4-EG) (Figure 1) were respectively dissolved in the model

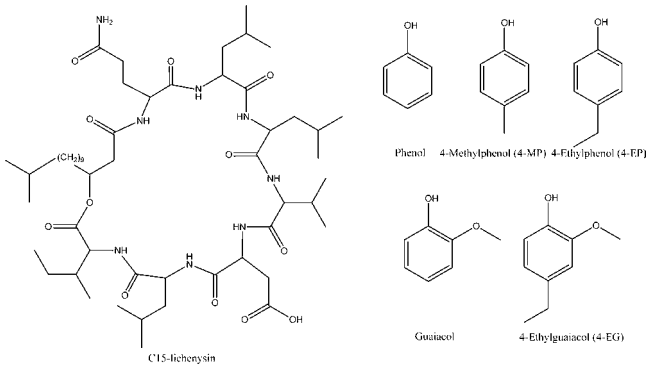

**Figure 1.** Chemical structures of $C_{15}$-Lichenysin and five phenolic compounds.

solution (46% ethanol/water solution, v/v). The phenol concentration was 1.28 mg/L, the 4-MP concentration was 3.20 mg/L, the 4-EP concentration was 0.38 mg/L, the guaiacol concentration was 0.38 mg/L, and the 4-EG concentration was 1.54 mg/L. The concentration of phenolic compound in the model solution reached close to the strong aroma type *Jiannanchun* liquor determined by HS-SPME-GC-MS.[10] The $C_{15}$–lichenysin is the highest to reach 75% of the total in Chinese liquor. Therefore, the effect of $C_{15}$–lichenysin on aroma compounds release was evaluated by HS-SPME-GC-MS.

For the SPME, an automatic headspace sampling system (Multi Purpose Sample MPS 2 with a SPME adapter, from GERSTEL Inc., Baltimore, MD, USA) with a 50/30 μm DVB/CAR/PDMS fiber (2 cm, Supelco Inc., Bellefonte, PA, USA) was used for analyte extraction. A total of 8 mL of sample was spiked with 10 μL of internal standard (hexyl formate for nonpolar compounds, 760 μg/L in ethanol, 2-octanol for polar compounds, 810 μg/L in ethanol). The sample was transferred to a screw-capped, straight-sided headspace vial with a 15 mL volume. The vial was tightly capped with a Teflon-faced silicone septum. The samples were equilibrated at 30 °C for 5 min and extracted for 45 min at the same temperature[6,7] under stirring (500 rpm, on for 20 s, off for 0 s). After extraction, the fiber was inserted into the injection port of the gas chromatograph (250 °C) for 5 min to desorb the analytes. All analyses were made in triplicate, using a modified HS-SPME method.[6,7]

**GC-MS Analysis and GC-MS Data Analysis.** For the GC-MS analysis, an Agilent 6890N gas chromatograph coupled to an Agilent 5975 mass selective detector (MSD) was used. The capillary column used was a DB-Wax column (30 m length × 0.25 mm i.d., 0.25 μm film thickness; Phenomenex, Torrance, CA, USA). The injector temperature was 250 °C, and the splitless mode was used. The conditions were as follows: starting temperature 50 °C (holding 2 min), then raised to 230 °C at the rate of 6 °C/min, and held at 230 °C for 30 min. The column carrier gas was helium with a purity of 99.9995% at a constant flow rate of 2 mL/min. The electron impact energy was 70 eV, and the ion source temperature was set at 230 °C. Full-scan acquisition was used in the ranges of masses (30−350 amu).

Identification of aroma compounds in Chinese liquor has been carried out on a DB-Wax column and a DB-5 column (30 m × 0.25 mm i.d., 0.25 μm film thickness, J&W Scientific, Folsom, CA, USA). It was based on the following criteria: comparing determined mass spectra and retention indices (RIs) with those of reference compounds. RIs were determined using a series of standard linear alkanes $C_5$–$C_{23}$ in accordance with a modified Kovats method.[11] Peak area integration of unique masses was conducted using MSD Chemstation (G1701-90057, Agilent, Santa Clara, CA, USA).

We compared the peak areas of aroma compounds in the control group (the liquor sample) with that of experiment group (the liquor sample added with lichenysin) by the means of HS-SPME-GC-MS. The net changes in peak areas were obtained by dividing the peak area of the control group subtracted from that of experiment group by the control. To eliminate the effect of other factors, we kept the control group and the experiment group at the same condition. From the net changes in peak areas, we studied about the effect of lichenysin on the volatility of different aroma compounds in the Chinese liquor. The use of peak area data to express aroma release was sufficient for the purpose of studying about aroma volatility in this work.

**Sensory Evaluation of Model Solutions.** The model solutions were presented to 10 panelists (China Distilled Spirit Appraisal Commissioner) at room temperature of 25 °C. According to Aronson's method,[7] the judges were trained in three test sessions and then carried up the experiment. They learned how to use the intensity scales by practicing with a number of samples. They familiarized themselves with the aroma and the low (zero) and high (the following concentrations) standards for each flavor compound. The model solution is 46% ethanol/water solution by volume, in which the phenol concentration is 1.28 mg/L, the 4-MP concentration is 3.20 mg/L, the 4-EP concentration is 0.38 mg/L, the guaiacol concentration is 0.38 mg/L, and the 4-EG concentration is 1.54 mg/L. Each flavor compound was evaluated respectively for two weeks. Samples of 30 mL were randomly presented in coded clear white wine glasses covered by tinfoil plates. The samples consisted of five controls and five phenolic/lichenysin solutions. The five phenolic compounds were respectively dissolved in the model solutions. Standards were used to anchor the ends of the scale for the judges.

The aroma intensity of the samples was marked on a 10 cm line scale in terms of deviation. The line scale was labeled "less than reference" and "more than reference" at the two ends. Judges were asked not to swirl the samples so as not to disturb the equilibrium. Lastly, they were allowed to resniff samples as long as they waited approximately 1 min before smelling the same sample a second time. All evaluations were conducted in a well-ventilated room. Each phenol and lichenysin combination was replicated during the triangle tests.

[a]Odor descriptors of the aroma compounds were from refs 2 and 3. [b]Identification based on comparing determined MS and RI with that of reference compounds. [c]Different letters within a row denote significantly different means at $p \leq 0.05$.

Three samples include one control and two experiment groups. Judges periodically took some time to rest during the experiment to minimize fatigue. The responses for the test were decoded manually in centimeters and entered into an Excel spreadsheet.

**NMR Procedures.** NMR measurements were performed on a Bruker Avance 500 MHz spectrometer at 25 °C. Samples were prepared in DMSO-$d_6$; tetramethylsilane (TMS) were added to the DMSO-$d_6$ at a level of 0.05%. To investigate the concentration dependence of chemical shift changes, a 2.5 mM phenolic compound solution (0.5 mL) was mixed with various amounts of lichenysin covering molar ratios of 1:4, 1:2, 3:4, 1:1, 2:1, and 2.5:1 in DMSO-$d_6$ and observed by the single-pulse method. The chemical shift changes of protons were measured relative to the reference chemical shift. The experiments were carried out at 25, 45, and 60 °C, from which equilibrium association constants ($K_a$) and thermodynamic parameters ($\Delta H$ and $\Delta S$) were obtained using a nonlinear estimation program, ORIGIN (Microcal Software Co. Inc., Northampton, MA, USA). Then, a 2.5 mM lichenysin solution (0.5 mL) was mixed with various amounts of 4-EG to cover molar ratios of 1:0, 4:1, 4:2, 1:1, and 1:2 in DMSO-$d_6$. The NOESY spectrum was observed by the mean of NOESY measurement. The NOESY spectra were acquired with a spectral width of 7 kHz in 2K data points using 16 scans for each of the 512 $t_1$ increments. The spin lock power level and mixing time were set to 29 dB and 60 ms, respectively.

Data processing was performed by using Topspin NMR software (version 2.1; Bruker, Rheinstetten, Germany).

**Statistical Analysis Software.** Each sample was analyzed in triplicate for each analysis. Results presented in the tables were shown with standard deviations and the arithmetic means. All data were statistically assessed using SPSS version 19.0 for Windows statistical package (SPSS Inc.; Chicago, IL, USA). The significance of differences between mean values obtained was determined using a one-way ANOVA ($P < 0.05$).

## RESULTS AND DISCUSSION

**Interaction between $C_{15}$−Lichenysin and Aroma Compounds in Chinese Liquor by HS-SPME-GC-MS.** The study examined the effect of lichenysin on the volatility of aroma compounds in Chinese liquor (strong-aroma type liquor). In this study, a sum of 22 volatile compounds in Chinese liquor was identified and quantitated by using the HS-SPME method (Table 1). These following compounds were eight esters, two alcohols, three acids, two aldehydes, two aromatic compounds, and five phenolic compounds.

Addition of lichenysin (at concentration of 160 μg/L) to the liquor sample resulted in significant but variable suppressing effects on headspace concentration (HS-GC peak area) depending on the nature of flavor compound examined (Table 1). For esters, the headspace concentrations were influenced little by lichenysin, where the volatility of esters decreased by 1−5% in the liquor sample. For alcohols and aldehydes, the volatility of these compounds was affected the least by 1−15%. For volatile acids, the headspace concentrations were influenced by 1−7%. The most pronounced effects were interactions between lichenysin and phenolic compounds (phenol, 4-MP, 4-EP, guaiacol, and 4-EG). It might be because the phenolic hydroxyl group of these compounds formed hydrogen bonds with the carboxyl group of the lichenysin. The headspace concentration of phenol, 4-MP, 4-EP, guaiacol, and 4-EG significantly decreased by 77%, 59%, 48%, 63%, and 55%, respectively, in the liquor sample. The volatilities of esters, alcohols, aldehydes, and volatile acids were affected little. Thus, lichenysin selectively affected aroma volatility in Chinese liquor.

**Interaction between $C_{15}$−Lichenysin and Phenolic Compounds in Model Solutions by HS-SPME-GC-MS and Sensory Evaluation.** Volatile phenolic compounds in Chinese liquor are considered as off-odors,[10] in which 4-MP and 4-EG, respectively, give horsy and medical smells. We chose phenol, 4-MP, 4-EP, guaiacol, and 4-EG as aroma compounds. Interactions between lichenysin and phenolic

dx.doi.org/10.1021/jf502053g | J. Agric. Food Chem. 2014, 62, 8302−8307

compounds were studied in model solution by using the HS-SPME-GC-MS method. In Figure 2, lichenysin significantly

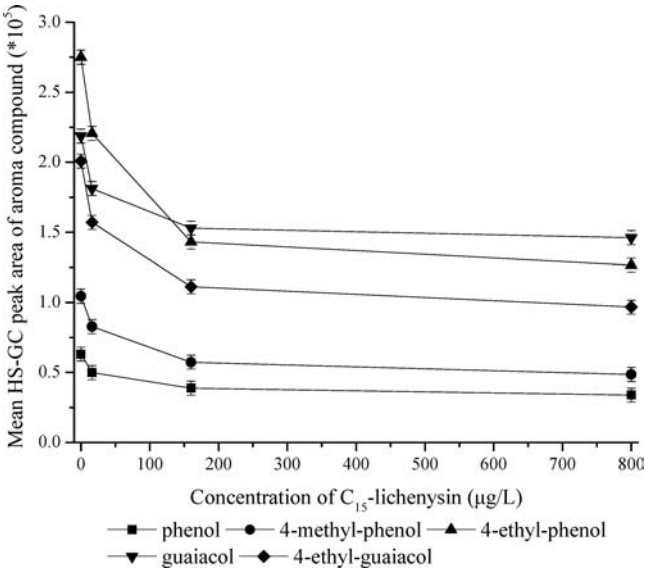

**Figure 2.** Effect of $C_{15}$–lichenysin concentration on mean HS-GC peak area for phenolic compounds in model solution (46%, ethanol/water solution, $n = 3$).

decreased the headspace concentration (HS-GC peak area) of the whole phenolic compounds relative to control group (without the addition of lichenysin), and the effect was the most pronounced when the concentration of lichenysin was 160 $\mu$g/L. The headspace concentrations of phenol, 4-MP, and 4-EP decreased by 39%, 45%, and 48%, respectively, ($p < 0.05$). The volatility of guaiacol and 4-EG in model solution decreased by 30% and 45% ($p < 0.05$). Later from that concentration, the effect of lichenysin on the volatility of phenolic compounds tended to reach an equilibrium state. When the concentration of lichenysin was 16 $\mu$g/L, the headspace concentrations of phenolic compounds decreased by 17−22%.

Ten trained sensory panelists were asked to test the aroma intensity scores of the model solution and also the one with lichenysin addition. Lichenysin (160 $\mu$g/L in model solution) significantly suppressed aroma perception of phenolic compounds ($p < 0.05$, Table 2). Thus, lichenysin could efficiently suppress the volatility of phenolic off-flavors in Chinese liquor.

**Thermodynamic Parameters and Acting Forces between Lichenysin and Phenolic Compounds.** To further study the nature of the phenolic/lichenysin interaction, the changes in the chemical shifts of protons in the phenolic compounds were evaluated by using $^1$H NMR, upon complexation with lichenysin in DMSO-$d_6$. Exchangeable protons such as those in carboxylic acids or alcohols do not give separate resonances in $D_2O$ or ethanol-$d_6$. Therefore, the solvent (DMSO-$d_6$) was chosen in which exchange is so slow that coupling between OH and adjacent protons can be observed. A titration process was then used to determine the concentration equilibrium constant, $K_a$, based on the chemical shift changes of phenolic protons. The 1H proton of each phenolic compound, which was most significantly affected by lichenysin complexation (Figure 3), was selected to obtain the association

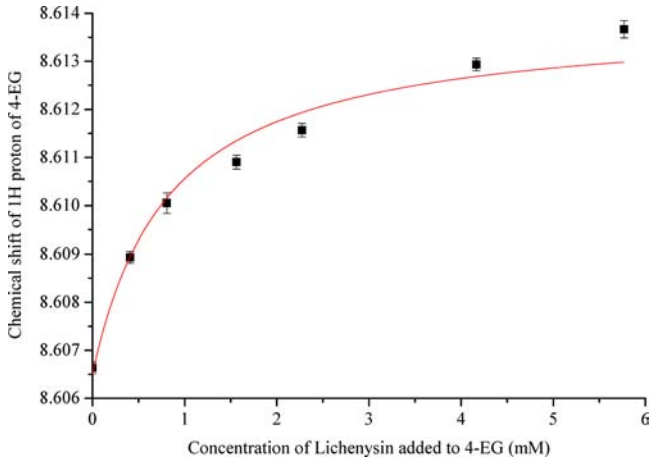

**Figure 3.** Nonlinear curve fitting of chemical shift data for mixtures of 4-EG (2.5 mM) and lichenysin in DMSO-$d_6$ at 25 °C.

constant, $K_a$, assuming a 1:1 stoichiometry between phenolic compound (2.5 mM) and lichenysin:

$$K_a = \frac{LP}{L \times P} \quad (1)$$

.In eq1, L, P, and LP represent the mole fractions of the free lichenysin, the free phenolic compound, and the bound form of the phenolic compounds, respectively. When fast exchange processes take place, the NMR spectrum for each proton shows a single signal, averaged in the proportions of the partial mole fractions of the complexed and free molecules. Therefore, the observed chemical shift ($\delta_{obs}$) of a signal is a weighted average of the chemical shifts in two possible environments—the chemical shift for the free flavor ($\delta_P$) and the chemical shift for the bound flavor ($\delta_{LP}$):

$$\delta_{obs} = \delta_P + (\delta_{LP} - \delta_P)\frac{LP}{P_0} \quad (2)$$

,where $P_0$ represents the total mole fraction of the phenolic compound. Values of $K_a$, $\delta_P$, and $\delta_{LP}$ leading to a best fit of the proton chemical shift changes were estimated by a nonlinear curve fitting program, and theoretical curves were derived from eq2. The curve fit of a 4-EG (2.5 mM) and lichenysin mixture is shown in Figure 3. Quantitative analysis of NMR spectra recorded at 25, 45, and 60 °C yielded association constants ($K_a$) for the interaction of the five phenolic compounds with lichenysin (Table 3).

The interaction forces between phenolic compounds and lichenysin mainly include four types: hydrogen bonding, hydrophobic interaction, electrostatic interaction, and van der Waals force. The thermodynamic parameters free energy change ($\Delta G$), enthalpy change ($\Delta H$), and entropy change

dx.doi.org/10.1021/jf502053g | J. Agric. Food Chem. 2014, 62, 8302−8307

**Table 3. Thermodynamic Parameters for Association between Lichenysin and Five Phenolic Compounds**

| | $K_{25°C}$ ($M^{-1}$) | $K_{45°C}$ ($M^{-1}$) | $K_{60°C}$ ($M^{-1}$) | $\Delta H$ (kJ/mol) | $\Delta S$ (J/(mol·K)) |
|---|---|---|---|---|---|
| phenol | 327.09 | 302.21 | 193.73 | −11.63 | 9.62 |
| 4-MP | 1243.47 | 927.66 | 888.49 | −8.20 | 31.51 |
| 4-EP | 1601.28 | 1081.24 | 559.39 | −24.07 | −19.55 |
| guaiacol | 2913.92 | 1344.43 | 438.00 | −43.57 | −79.09 |
| 4-EG | 1219.65 | 340.65 | 46.68 | −74.85 | −192.46 |

($\Delta S$) of the binding reaction can provide evidence for clarifying interaction modes. If $\Delta H$ does not change significantly over the temperature range studied, it can be regarded as a constant, and then, the values of $\Delta H$, $\Delta S$, and $\Delta G$ are estimated from the Van't Hoff equation:

$$\ln K_a = -\Delta H/RT + \Delta S/R \quad (3)$$

$$\Delta G = \Delta H - T \times \Delta S \quad (4)$$

where $K_a$ is the association constant at temperature $T$ and $R$ is the universal gas constant.

The signs and magnitudes of the thermodynamic parameters associated with various individual kinds of interaction that might take place in the protein association processes.[12] That is, for $\Delta H > 0$ and $\Delta S > 0$, the contributions to these changes mainly arise from hydrophobic interactions; for $\Delta H < 0$ and $\Delta S < 0$, van der Waals forces and hydrogen-bond formation play major roles; for $\Delta H \approx 0$ and $\Delta S > 0$, electrostatic forces are suggested as more important. The calculated $\Delta H$ and $\Delta S$ are summarized in Table 3. For 4-EP, guaiacol, and 4-EG, the values of both $\Delta H$ and $\Delta S$ were negative, which suggested the main acting force would be hydrogen bonding and/or van der Waals force. The carbonyl group of the amino acid residues of lichenysin is a neutral acceptor group for hydrogen bonding. For phenol and 4-MP, $\Delta S$ values were found to be positive, whereas $\Delta H$ values were negative. The positive $\Delta S$ values are supposed to provide evidence for hydrophobic interactions in the binding phenomenon between lichenysin and these two phenolic compounds. Meanwhile, the negative $\Delta H$ values may account for the involvement of hydrogen bonding in this interaction, as 1H atoms on the phenolic compounds can easily form hydrogen bonds with amino acid residues of lichenysin. Thus, the main acting force between lichenysin and phenolic compounds was hydrogen-bond interaction.

**$^1$H NMR and Two-Dimensional NOESY in the Complexes of Lichenysin and 4-EG.** To better evaluate the binding site of the interactions and determine the spatial proximity of interacting protons, we chose $^1$H NMR and two-dimensional (2D) NOESY for the complexes of lichenysin and 4-EG. When passing from the free to the complex state, the $^1$H NMR chemical shifts change for individual molecules in the complex. By using $^1$H NMR, the changes in the chemical shifts of protons in the lichenysin were evaluated, upon complexation with 4-EG in DMSO-$d_6$. For complexes of lichenysin and 4-EG, the special proton of both compounds underwent chemical shift changes compared to those of their free state. When the 4-EG molar concentration was onefold with respect to that of lichenysin, a gentle downfield shift (4.10 ppm) of *a*H (Val) of lichenysin is observed in Figure 4, as compared with that (4.07 ppm) of its free state. Lichenysin has a potential of hydrogen bonding to 4-EG, as it has some acyl groups.

The lichenysin/4-EG interactions were further evaluated using 2D NOESY. The cross peaks indicate spatial proximity among the peaks (<5 Å) in the NOESY spectra. As shown in Figure 5, the NOESY spectrum of a lichenysin and 4-EG mixture in DMSO-$d_6$ reveals intermolecular cross peaks between the *a*H (Val) of lichenysin and the 1H of 4-EG. The NOESY effect observed by means of 2D experiments suggests that, in the spatial geometry, the carbonyl oxygen of the acyl group (Val) of lichenysin can very easily form a hydrogen bond with the hydroxyl groups of 4-EG.

This study was the first one to characterize that the cyclooctapeptide lichenysin reduced the headspace concentration of phenolic off-flavors in the Chinese liquor

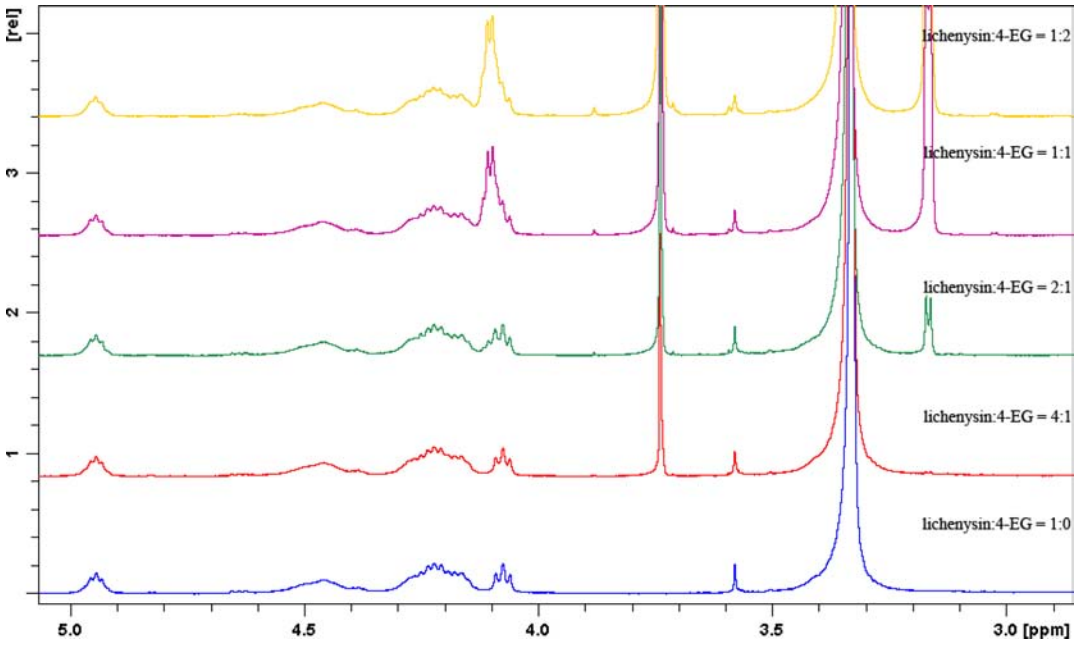

**Figure 4.** Change values of the chemical shift of lichenysin (2.5 mM) in DMSO-$d_6$ solution at 25 °C following the addition of 4-EG at the ratio of mole.

# Characterization of the Potent Odorants Contributing to the Characteristic Aroma of Chinese Green Tea Infusions by Aroma Extract Dilution Analysis

Ryoko Baba* and Kenji Kumazawa

Ogawa & Company, Ltd., 15-7 Chidori Urayasushi, Chiba 279-0032, Japan

Supporting Information

**ABSTRACT:** The volatile fractions of three famous Chinese green tea cultivar infusions (Longjing, Maofeng, and Biluochun) were prepared by a combination of the adsorptive column method and the SAFE techniques. The aroma extract dilution analysis (AEDA) applied to the volatile fractions revealed 58 odor-active peaks with flavor dilution (FD) factors between $4^1$ and $4^7$. Forty-six of the odorants, which included six odorants that have not been reported in the literature in Chinese green tea (2-isopropyl-3-methoxypyrazine, 2-ethenyl-3,5-dimethylpyrazine, *cis*-4,5-epoxy-(*E*)-2-decenal, 4-ethylguaiacol, (*E*)-isoeugenol, and 3-phenylpropionic acid), were identified or tentatively identified by GC-MS and GC-O. Among the perceived odorants, 4-hydroxy-2,5-dimethyl-3(2*H*)-furanone, 3-hydroxy-4,5-dimethyl-2(5*H*)-furanone, coumarin, vanillin, geraniol, (*E*)-isoeugenol, and 2-methoxyphenol showed high FD factors in all of the cultivars, irrespective of the cultivar or harvesting season, suggesting that these seven odorants are essential for the aroma of Chinese green tea. On the other hand, the contents of the odorants, FD factors of which were uneven between the cultivars, were suggested to influence the characteristic aroma of each cultivar. In addition, the formation mechanism of (*E*)-isoeugenol, one of the odorants which have not been reported in the literature with a high FD factor common to all the cultivars, was investigated, and it was suggested that the (*E*)-isoeugenol content of the tea products has a close correlation with the manufacturing process of the tea leaves.

**KEYWORDS:** *Chinese green tea, flavor, aroma, AEDA, isoeugenol, coniferyl alcohol*

## INTRODUCTION

Tea is one of the most widely consumed beverages in the world. Being differentiated by the degrees of fermentation by the endogenous enzymes in the leaves, three main types of teas are produced; i.e., fermented tea (black tea), semifermented tea (oolong tea), and unfermented tea (green tea). Each of them has its own characteristic aroma, despite being made from the same plant (*Camellia sinensis*). Among them, green tea, the leaves of which are immediately heated after being plucked to inactivate the endogenous enzymes, is the most popular tea in China, Japan, and other East Asian countries.

The manufacturing process of green tea is mainly divided into two types according to the heating process to inactivate the endogenous enzymes in the leaves, i.e., pan-firing and steaming, which are common in China and Japan, respectively. The difference in the heating process is said to be one of the factors which influences the aromas of the tea products; the steamed tea (Sen-cha), which is not affected by the enzymes because they are immediately inactivated, has a green, marine aroma. On the other hand, pan-fired tea, affected by the enzymatic reactions because the temperature of the leaves slowly rises and the enzymes are not immediately inactivated, has a sweet, floral aroma like fermented teas, besides the characteristic pan-fired aroma. Furthermore, in China, the leaves are generally withered before being pan-fired, during which the leaves are affected by the enzymes. In addition, there are numerous Chinese green tea cultivars classified by the subtle differences in the producing area, varieties of tea, and/or the manufacturing process (withering, heating, etc.), and each of them has its own characteristic aroma.

A number of volatile compounds in Chinese green tea have been identified by gas chromatography (GC) and GC/mass spectrometry (MS).[1−6] A number of potent odorants in green tea have also been identified (Japanese green tea,[4,7] Darjeeling green tea,[8] and Chinese green tea[4−6]). However, the investigations of Chinese green tea were only intended for some of the cultivars, despite there being many.[4−6] Therefore, they cannot fully explain the characteristic aroma of Chinese green tea in general.

In this investigation, in order to elucidate the potent odorants common to Chinese green tea in general, the three famous Chinese green tea cultivar infusions (Longjing, Maofeng, and Biluochun) were investigated by aroma extract dilution analysis (AEDA). Simultaneously, the characteristic odorants of each cultivar were also investigated. In addition, the formation mechanism of (*E*)-isoeugenol, which has not been reported in the literature in Chinese green tea, was studied.

## MATERIALS AND METHODS

**Materials.** Tea samples: Chinese green tea products, Longjing, Maofeng, and Biluochun (spring and summer crops), were produced in the Zhejiang, Anhui, and Jiangsu provinces (China) in 2012. Sen-cha was produced in the Shizuoka prefecture (Japan) in 2008 and

ACS Publications © 2014 American Chemical Society

2012. The oolong tea products, Pouchong tea, Dongding oolong tea, Oriental Beauty tea, Tie Guan Yin tea, Golden Cassia, and Robe tea, were produced in Taiwan or China in 2001. The black tea products, Dimbura, Java tea, Kenyan tea, and Assam tea, produced in 2005, were purchased from Mitsui Norin Co., Ltd. (Tokyo, Japan). All of these products were of high grade based on the market price and stored at −80 °C until needed.

**Chemicals.** The following compounds were synthesized according to the literature procedures: 2-acetyl-1-pyrroline;[9] (*Z*)-1,5-octadien-3-one;[10] 4-mercapto-4-methyl-2-pentanone;[11] 2-ethenyl-3,5-dimethylpyrazine;[12] 3-methyl-2,4-nonanedione;[13] 2-acetyl-2-thiazoline;[14] and *cis*- and *trans*-4,5-epoxy-(*E*)-2-decenal.[15] Compounds (Table 2) **3**, **6**, **12**, **14**, **16**−**19**, **21**, **23**−**26**, **29**, **32**, **33**, **35**, **38**, **40**, **41**, **43**, **47**, **48**, **52**−**55**, **57**, and **58** were purchased from Tokyo Chemical Industry Co., Ltd. (Tokyo, Japan); compounds **4**, **15**, **30**, **45**, **46**, and **56** were purchased from Sigma-Aldrich Japan (Tokyo, Japan); **39**, **44**, and coniferyl alcohol were purchased from Wako Pure Chemical Industries (Osaka, Japan); **50** was purchased from the Zeon Corporation (Tokyo, Japan); cellulose and cinnamyl alcohol were purchased from Nacalai Tesque (Kyoto, Japan); and pectriase was purchased from the Shinnihon Chemicals Corporation (Chiba, Japan).

**Isolation of the Volatiles from Chinese Green Tea Infusion.** Distilled water (90 °C, 1500 g) was added to 75 g of Chinese green tea, and the leaves were filtered after standing for 5 min. The filtrate (1000 g) was immediately cooled in tap water and passed through a column packed with 20 mL of SP700 (Mitsubishi Chemical Corporation).[16] The adsorbed compounds were eluted with methylene chloride (100 mL). As the internal standard solution, 0.1% 2-octanol in methylene chloride (100 μL) was added to the eluate. The eluate was dried over anhydrous sodium sulfate and distilled under reduced pressure (<4.0 × $10^{-3}$ Pa, 40 °C) using the SAFE technique.[17] The solvent in the distillate was removed by rotary evaporation (35 °C, 550 mmHg) to about 5 mL in volume. Further concentration to approximately 100 μL was conducted using a nitrogen stream. The concentrate was used as the sample for the AEDA and the GC-MS analysis (*a*).

**Gas Chromatography−Olfactometry (GC-O).** An Agilent 6850 series gas chromatograph equipped with a thermal conductivity detector (TCD) (Agilent Technologies, Santa Clara, CA, USA) and fused silica column (30 m × 0.25 mm i.d., coated with a 0.25 μm film of DB-Wax; Agilent Technologies) was used in splitless injection mode from 40 to 210 °C at the rate of 5 °C/min for all runs. The injector and detector temperatures were both 250 °C. Helium was used as the carrier gas at a flow rate of 1 mL/min. A glass sniffing port was connected to the outlet of the TCD and heated by a ribbon heater along with moist air being pumped into the sniffing port at about 100 mL/min to quickly remove the odorant from the sniffing port that had been eluted from the TCD.

**Aroma Extract Dilution Analysis (AEDA).** The original odor concentrates of the Chinese green tea infusion were stepwise diluted with methylene chloride to $4^n$ ($n$ = 0−8), and aliquots (1 μL) of each sample were analyzed by capillary GC using a DB-Wax column. The odorants were then detected by GC eluate sniffing (GC-O). The flavor dilution (FD) factors of the odorants were determined by AEDA.[18] Prior to the FD factor measurement, two panelists repeatedly confirmed the retention time and the odor quality of the odorants using each diluted sample ($4^0$ and $4^1$), and then the FD factors of the odorants were defined as the dilution step that both panelists detected. For the purpose of selecting the potent odorants common to all of the cultivars or characteristics of each cultivar, the mean values and the relative standard deviations (RSD) of exponents of the FD factors ($\log_4$ (FD factor)) of all the samples were calculated; a compound with a high mean value and low RSD was considered to be a potent odorant common to all of the cultivars.

**Semi-Quantitative Analysis of Isoeugenol and Coniferyl Alcohol in the Various Teas.** Various tea infusions (three Japanese green teas, six Chinese green teas, six oolong teas, and four black teas) prepared by the same method as that described above (200 g) were passed through a column packed with 5 mL of SP700. The adsorbed compounds were eluted with a mixed solvent (diethyl ether: *n*-pentane (8:2), 50 mL). The internal standard solution, 0.1% 2-octanol in methylene chloride (20 μL), was added to the eluate. The eluate was dried over anhydrous sodium sulfate, and the solvent in the distillate was removed by rotary evaporation (35 °C, 550 mmHg) to about 1 mL in volume. Further concentration to approximately 100 μL was conducted using a nitrogen stream. The concentrates were used as the samples for the GC-MS analysis (*b*).

**Model Experiment for (*E*)-Isoeugenol Formation by Heating.** Coniferyl alcohol or cinnamyl alcohol mixed with cellulose in distilled water was lyophilized and placed in a 20 mL vial. After being sealed by a silicon septum, the vial was heated in the GC column oven (150 °C, 30 min) and analyzed by the GC-MS using the solid phase microextraction (SPME) method (*c*). As a control experiment, a nonheated sample was also analyzed.

**Model Experiment for Coniferyl Alcohol Formation by Enzymatic Reaction.** Japanese green tea infusion prepared by the same method as described above (200 g) was passed through a column packed with 5 mL of SP700. After the adsorbed compounds were eluted with the mixed solvent (diethyl ether/*n*-pentane (8:2), 50 mL), the nonvolatile compounds were eluted with methanol (50 mL). Methanol in the eluate was removed by rotary evaporation (35 °C, 120 mmHg), and then the nonvolatile fraction was lyophilized. The nonvolatile fraction (0.4 g) was put into a 10 mL glass vial and dissolved in the citrate phosphate buffer (pH 4.5, 7 mL). After pectriase (Shinnihon Chemicals, 2 mg) was added, the vial was capped and incubated in a water bath (40 °C, 3 h). The volatile compounds in the reaction liquid were extracted with 2 mL of a mixed solvent (diethyl ether/*n*-pentane (8:2)), then the extract was concentrated to approximately 100 μL by a nitrogen stream, and used as the sample for the GC-MS analysis (*d*).

**Gas Chromatography−Mass Spectrometry.** (*a*) An Agilent 7890A gas chromatograph coupled to an Agilent 5975C *inert* XL series mass spectrometer (Agilent Technologies) was used. The column was a 60 m × 0.25 mm i.d., fused silica capillary type, coated with a 0.25 μm film of DB-Wax (Agilent Technologies). The column temperature was programmed from 80 to 230 °C at the rate of 3 °C/min. The injector temperature was 250 °C, and the flow rate of the helium carrier gas was 1 mL/min. An injection volume of 1 μL was applied using the split mode (the split ratio was 1:30). The mass spectrometer was used with an ionization voltage of 70 eV (EI) and ion source temperature of 150 °C. (*b*) The conditions of the GC-MS were same as those in *a*. The semiquantitative contents of isoeugenol and coniferyl alcohol in the tea infusions were determined by the internal standard method from the total ion or the selected ion peak areas obtained by mass chromatography. The GC-MS was operated in the selected ion monitoring and scan (SIM-SCAN) mode, and the selected ions of 115 and 164 were monitored for 2-octanol (internal standard) and (*E*)-isoeugenol, respectively. The semiquantitative contents of these compounds in the tea infusions were calculated from the ratio of the total ion peak areas of the internal standard and those of the analytes. On the basis of the ratio of the selected ion versus the overall ions of the mass spectra for each authentic compound, the total ion peak area of each compound was converted from the selected ion peak area; total ion peak area = selected ion peak area × conversion factor. The conversion factors were 63.4 and 4.2 for 2-octanol and (*E*)-isoeugenol, respectively. The response factor of each odorant versus the internal standard was defined as 1. (*c*) The volatile compounds in the headspace were extracted by the SPME fiber, 50/30 μm StableFlex DVB/Carboxen/PDMS (Sigma-Aldrich), and analyzed by an Agilent 6850N gas chromatograph coupled to an Agilent 5973N series mass spectrometer (Agilent Technologies), equipped with the CycleComposer autosampler system (AMR Inc., Tokyo, Japan): CycleComposer with macro editor software, a sample tray, a temperature controlled agitator tray, and a fiber conditioning device system. All of the setup parameters of the autosampler are as follows: the agitator was 60 °C, 500 rpm (on for 5 s. and off for 2 s.), the pre-extraction equibration time was 10 min, the extraction time was 15 min, and the desorption time was 1 min. The column and its temperature, the injector temperature, and the flow rate of the helium

carrier gas were the same as those in *a*. (*d*) The conditions of the GC-MS were the same as those in *a*.

**Identification of the Components.** Each component was identified by comparing its Kovats GC retention index (RI), mass spectrum, and odor quality to those of the authentic compounds.

## RESULTS AND DISCUSSION

**Potent Odorants in Chinese Green Tea Infusions.** The three famous Chinese green tea cultivars, Longjing, Maofeng, and Biluochun, the spring crops and summer crops of each, were used. The shapes of the tea leaves differ with the cultivars, depending on the manufacturing process of pan-firing and drying. The leaves of Longjing had flat shapes because the leaves were pressed against the pans. Those of Maofeng, which were dried in baskets over charcoal fires, had big, twisted shapes. On the other hand, those of Biluochun had small, twisted shapes and white fluff on them because they were plucked early by their shoots and stirred in the pans. The characteristic aromas of the infusions evaluated by four panelists are shown in Table 1. The infusions of the spring crops had better and more characteristic aromas from each cultivar than those of the summer crops.

**Table 1. Characteristic Aromas of the Chinese Green Tea Infusions**

| cultivar | crop | characteristic aroma of infusion |
|---|---|---|
| Longjing | spring | roast, green sweet |
| Longjing | summer | roast, green |
| Maofeng | spring | roast, metallic |
| Maofeng | summer | soybean-like |
| Biluochun | spring | floral, japanese apricot-like |
| Biluochun | summer | roast |

The volatile concentrates of these Chinese green tea infusions were prepared by the combination of the adsorptive column method and the SAFE techniques, which makes it possible to efficiently and reproducibly extract the aroma components from a large volume of samples. The volatile concentrates obtained by this preparation without excessive heating well-reproduced the characteristic aroma of the infusions. Thus, it was regarded as the most preferable analytical sample for the screening of the potent odorants by GC-O. The AEDA applied to the volatile concentrates of the six Chinese green tea infusions revealed 58 odor-active peaks with FD factors between $4^1$ and $4^7$ (Table 2). Forty-six of the odorants, which included six odorants that have not been reported in the literature in Chinese green tea, were identified or tentatively identified by GC-MS and GC-O. Among the perceived odorants, 4-hydroxy-2,5-dimethyl-3(2*H*)-furanone (**40**: sweet, caramel-like), 3-hydroxy-4,5-dimethyl-2(5*H*)-furanone (**45**: seasoning-like, caramel-like), coumarin (**55**: sweet), vanillin (**57**: vanilla-like), geraniol (**32**: floral, green), (*E*)-isoeugenol (**52**: floral, spicy), and 2-methoxyphenol (**33**: burnt, rubber-like) showed high FD factors in all of the cultivars, irrespective of the cultivars or the harvesting seasons (the mean of $\log_4$ (FD factor) >4 and RSD <20%), suggesting that these odorants are essential for Chinese green tea aroma. Although most of the odorants in Table 2 are consistent with those reported in previous studies,[4−6] some compounds have not been reported. This is assumed to be due to the raw materials and/or analytical procedures; it is noteworthy that steam distillation was not applied in this investigation.

On the other hand, to elucidate the potent odorants responsible for the characteristic aroma of each cultivar, the FD factors of the compounds in the spring crops of the three cultivars were compared since the aromas of the spring crops were more characteristic than those of the summer crops. Among the odorants, except for the seven odorants mentioned above, the odorants, which had FD factors more than $4^3$ and higher by $4^2$ or more from the other cultivars, were selected. In Longjing and Maofeng, the FD factors of 2-isopropyl-3-methoxypyrazine (**12**: pea-like) and 3-methyl-2,4-nonanedione (**27**: green) were higher than those in Biluochun. Furthermore, in Maofeng, (*E*,*E*)-2,4-nonadienal (**26**: fatty) and *trans*-4,5-epoxy-(*E*)-2-decenal (**37**: sweet, juicy, metallic) also showed significantly high FD factors. These results did not contradict the characteristic aromas of each infusion, suggesting that the contents of these odorants are responsible for the characteristic aroma of each cultivar. It was assumed that various factors, such as the contents of the precursors in the tea leaves and the conditions during the manufacturing process, influence the contents of these odorants since most of the volatile compounds in tea are known to be generated during the enzymatic reaction or the heating reaction from various precursors, i.e., fatty acids, amino acids, sugar, and glycosides.[19]

On the basis of these results, it was suggested that sweet, floral, and burnt aromas are essential for the aroma of Chinese green tea, and some odorants influence the characteristic aroma of each cultivar. However, it is necessary to investigate more samples to confirm this hypothesis since there are an enormous number of Chinese green teas. Furthermore, since highly volatile compounds might be lost during the concentration by rotary evaporation or nitrogen stream, it is necessary to apply some other methods such as static headspace olfactometry to detect them.

**Proposed Formation Mechanism of (*E*)-Isoeugenol.** (*E*)-Isoeugenol (**52**: floral, spicy), which was newly identified in Chinese green tea and showed high FD factors in all of the cultivars, was suggested to play an important role in the characteristic flowery aroma of Chinese green tea. On the other hand, the **52** content of the tea leaves is reported to increase during the withering process.[20] Therefore, to elucidate the relationship between the **52** contents and the enzymatic reaction during the tea manufacturing process, the **52** contents of various tea infusions were semiquantified. As a result, the **52** contents of Chinese green tea (generally withered) infusions showed a tendency to be higher than those of the Sen-cha (not withered) infusions (Figure 1A). Furthermore, the **52** contents of six semifermented tea (Pouchong tea, Dongding oolong tea, Oriental Beauty tea, Tie Guan Yin tea, Golden Cassia, and Robe tea) and four black tea infusions (Dimbura, Java tea, Kenyan tea, and Assam tea) were extremely higher than those of the green tea infusions (Figure 1B). These results suggested that the enzymatic reaction during the tea manufacturing process has a close relationship with the formation of **52**.

There are some reports about the generation of **52** in plants. In the petunia flower, **52** is reported to be biosynthesized from coniferyl alcohol via coniferyl acetate by an enzymatic reaction.[21] On the other hand, in wood, **52** is reported to be generated from coniferyl alcohol by heat during delignification.[22] This information suggests that coniferyl alcohol is an important intermediate in the formation of **52** in plants. Thus, the coniferyl alcohol in the various tea infusions was analyzed by GC-MS. As a result, coniferyl alcohol was detected in all of the infusions (green tea, oolong tea, and black tea), and its

**Table 2. continued**

[a]Retention index on DB-Wax column (30 m × 0.25 mm i. d.; coated with a 0.25 μm film) observed for GC-O. [b]The compound was identified by comparison with the reference substance on the basis of the following criteria: retention index (R.I.) on stationary phase DB-Wax, mass spectra, and odor quality. [c]The MS signals were too weak for unequivocal interpretation. The compound was tentatively identified by comparison with the reference substance on the basis of the following criteria: retention index (R.I.) on stationary phase DB-Wax and odor quality. [d]The compound has not been reported in the literature in Chinese green tea. [e]Odor quality assigned during AEDA.

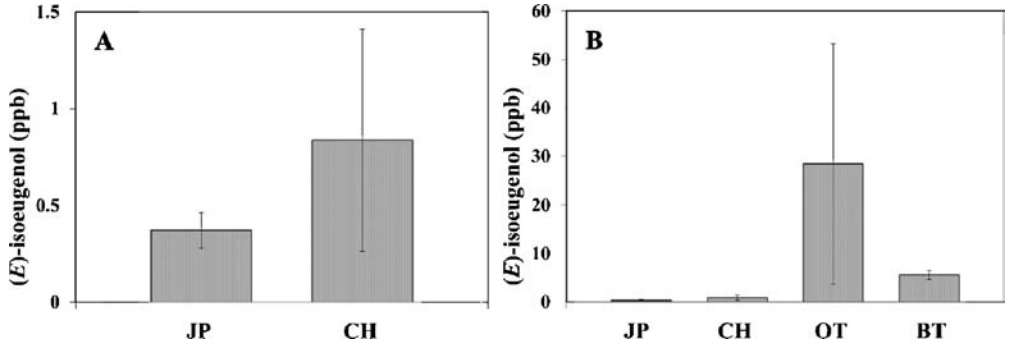

**Figure 1.** Semiquantified (*E*)-isoeugenol content of various tea (three Japanese green teas, six Chinese green teas, six oolong teas, and four black teas) infusions. Error bars show standard deviations. (JP, Japanese green tea (Sen-cha); CH, Chinese green tea; OT, oolong tea; BT, black tea.)

contents were correlated with those of **52**, suggesting that coniferyl alcohol might be an important intermediate in the formation of **52**, also in the tea leaves. The formation of **52** from coniferyl alcohol was assumed to be caused by heating during the manufacturing process, not by an enzymatic reaction, since coniferyl acetate was not detected in the tea infusions, and **52** was reported to be generated from coniferyl alcohol by heating. To confirm this assumption, coniferyl alcohol mixed with cellulose was heated under the same conditions as the pan-firing and drying process of the tea leaves (150 °C, 30 min), and then **52** and eugenol (**43**) were generated. It was assumed that **52** is formed from coniferyl alcohol during the reducing dehydration reaction. The mechanism presumed for this reaction includes the corresponding quinone methide intermediate since coniferyl alcohol has a hydroxyl group at the C-4 position on the benzene ring. To confirm this, the requirement of the hydroxyl group at the C-4 position on the benzene ring for this reaction was indirectly tested, i.e., cinnamyl alcohol, which has no hydroxyl group on the benzene ring like coniferyl alcohol, was heated (150 °C, 30 min). As a result, the corresponding product, 3-phenylpropene, was not generated, indicating that the hydroxyl group on the benzene ring is required for this dehydration reaction. Therefore, it was suggested that this reaction includes a quinone methide intermediate which is relatively stable, and thus this reaction would proceed under such moderate heating conditions (Figure 2).

On the other hand, coniferyl alcohol is known as a precursor of lignin, an essential substance of plants, and known to be accumulated as a glycoside called coniferin in plants because of its instability. In addition, coniferin is found in *Camellia taliensis*, a close relative of *Camellia sinensis*.[23] Considering that most of the alcohols in tea aroma are known to be generated from glycosides by enzymatic reactions during the manufacturing process,[19] a glycoside like coniferin is assumed to be involved in the formation of coniferyl alcohol. To confirm this assumption, a hydrolysis enzyme, pectriase, was added to the nonvolatile fraction of the Sen-cha infusion, in which glycosides were assumed to be included. As a result, coniferyl alcohol was generated.

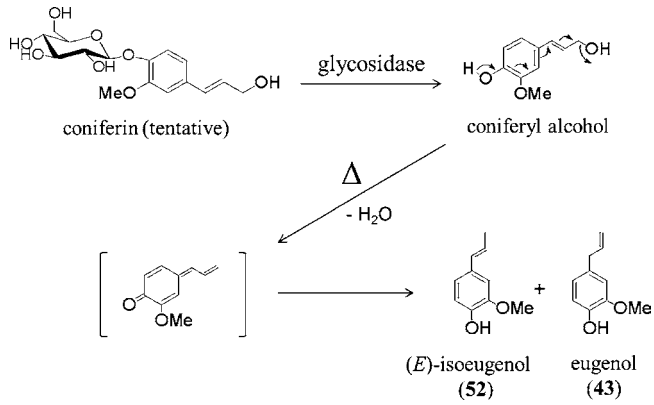

**Figure 2.** Proposed pathway for the formation of (*E*)-isoeugenol in tea leaves during the manufacturing process of Chinese green tea.

On the basis of these results, the formation mechanism of **52** in tea leaves during the manufacturing process was indirectly suggested as follows: first, coniferyl alcohol is generated from its glycoside like coniferin by an enzymatic reaction, and then **52** is formed from coniferyl alcohol by heating. In other words, it was suggested that coniferyl alcohol is generated from the precursor like coniferin by the endogenous enzymatic reaction during the withering and pan-firing processes and that then **52** is formed from coniferyl alcohol via the quinone methide intermediate by heating during the pan-firing and drying processes in tea leaves during the manufacturing process (Figure 2). These results indicated that the formation of **52**, which is assumed to be the important compound for the characteristic floral aroma of Chinese green tea, is closely correlated to the specific manufacturing process of Chinese green tea: withering the plucked leaves and slowly inactivating the endogenous enzymes in the leaves by pan-firing. However, the coniferyl alcohol content showed a tendency to be higher in the semifermented tea (oolong tea) than in the fermented tea (black tea), suggesting that the coniferyl alcohol content is not necessarily in proportion to the degree of fermentation. It seems possible that coniferyl alcohol once generated in the tea leaves by fermentation changes into other compounds as the

fermentation proceeds because coniferyl alcohol is an unstable compound. Therefore, further studies and elucidation of the precursor of coniferyl alcohol in tea leaves are necessary to clarify the relationship between the **52** contents of the tea leaves and the tea manufacturing process.

In this study, the essential volatile compounds and characteristics of the aroma of three famous cultivars of Chinese green tea were identified. It is assumed that the contents of these compounds are affected by the precursor contents of the tea leaves or their manufacturing process. However, the details about the formation mechanism of these compounds have not been clarified. Now that green tea has become increasingly popular around the world, it would be important to elucidate the potent odorants, their formation mechanism, and the effect of the manufacturing process on their contents to produce better-smelling and highly palatable green tea.

# Quantitation of *trans*-Aconitic Acid in Different Stages of the Sugar-Manufacturing Process

Guillermo Montoya,*[,†] July Londono,[†] Paola Cortes,[†] and Olga Izquierdo[§]

[†]Facultad de Ciencias Naturales, Grupo Natura, Universidad ICESI, Cali, Colombia

[§]Manuelita Sugarmill Km 7 vía Palmira-Cerrito, Palmira, Colombia

**ABSTRACT:** The sugar cane industry has seen how biomass production in sugar mills would be converted to a readily available source of molecules besides sugar. Properly managed, byproducts would be transformed into a sustainable source of renewable and environmentally friendly chemical products.[1] As a principal and more abundant organic acid in sugar cane juice, *trans*-aconitic acid (TAA) has been studied for use as a plasticizer in the polymer industry.[2] However, up to now no industrial-scale application has been reported. As a reasonable approach to recover TAA from a sugar mill, first, an analytical method to determine its presence in all stages of the sugar-manufacturing process is needed. A new modern method was developed to measure TAA in seven stages in a sugar mill located in Valle del Cauca, Colombia. The stages with higher content of TAA were syrup, with 3363.6 ± 589.3 mg/L, and honey (molasses), with 6110.05 ± 139.5 mg/L.

**KEYWORDS:** *sugar cane, trans-aconitic acid, solid phase extraction, UPLC-ESLD, byproducts, sugar mill*

## INTRODUCTION

Sugar from sugar cane is produced in around 120 countries worldwide, and Brazil is the biggest producer with an average annual production of 34 million tons per year.[3] Additional byproducts obtained in the Brazilian sugar cane industry are the bioelectricity commonly used by manufacturing plants and biopolymers (as raw materials for the production of packaging, bags, and bottles obtained from sugar, ethanol, and bagasse).[4,5] Whereas the use of byproducts in some countries is well established, others have not determined how to take advantage of these residuals. Exploratory work has been carried out to recover byproducts from the production process, and *trans*-aconitic acid is no exception; its industrial retrieval has been suggested by means of easy scaled-up techniques.[6] There is no consistent flowchart of a specific pathway to discover a recoverable molecule from industrial waste. However, the first step of a reasonable approach is an analytical evaluation of the target into the matrix where it is contained.

Colombia processes >20 million tons of sugar cane per year, obtaining around 2.4 million tons of sugar;[7] its residues are mainly employed for bioelectricity, in the paper industry, and to fertilize the sugar cane crops. Sugar cane is also one of the country's most widespread crops and therefore has an important impact in gross domestic product. Conversely, the economic progress of this agro-industrial business during the course of the lpast few decades has been stagnant; Colombia does not appear in the top 10 of the world's biggest producers. Another well-known issue in the sugar cane industry is the unpredictable volatile nature of the price of raw sugar,[8] which supports the idea that taking advantage of byproducts in sugar mills would be a rational alternative to increase the industry's economic value.

**Aconitic Acid and Special Considerations.** Aconitic acid is a tricarboxylic acid and the most abundant acid produced by sugar cane. The predominant form is the *trans*-aconitic acid isomer (TAA), which in Australian molasses averages 19.4 g/kg of the total dry solids[9] and in North American molasses averages 9−55 g/kg in dry solid bases. Several techniques have been used to try to recover TAA from molasses; two of the most popular are liquid−liquid extraction[10] and supported liquid membranes.[9] However, bioethanol plants operate with discarded molasses from sugar mills, and the scientific community is making enormous efforts to use bagasse as a source of second-generation alcohols.[11−13] Scientists are also trying to find the best matrix in the sugar-manufacturing stages to establish an industrial TAA extraction for the food, cosmetics, and chemical industries.

With regard to analytical methods, TAA is an organic acid with a low molar absorptivity coefficient and high hydrosolubility (Log $P = -1$); therefore, it is inadequately retained in hydrophobic chromatographic columns. The oldest methodologies described the use of octadecylsilane columns with an ion pair reagent; however, ion pair reagents make the column spoil quickly, so this practice is no longer used. Another option was to use amino columns under low-pH normal phase condition, which become weak anion exchangers capable of separating negatively charged molecules. Recently, polar embedded groups in reverse phase columns are gaining more attention for their rising hydrophilic interaction, capable of interacting with polar compounds such as carbohydrates and small organic acids.[14] Amide columns also offer a wider set of possibilities to separate very highly hydrophilic molecules.[15] This hydrophilic interaction chromatography is available in sub-2 $\mu$m particles, offering acceptable separation of molecules with physicochemical properties such as those described above, in short retention times and good peak shapes.

After good separation is achieved, properly detecting small organic aliphatic acids using chromatography is one of the biggest concerns. Generally, academics describe mass spectrometry as the perfect choice to couple with a separation technique; however, in most commercial industries, it is not always chosen because of its high cost. The lack of light absorption of organic acids and carbohydrates makes them unsuitable for UV detection (at least with high sensitivity and without derivatization), but other options are available to detect them, such as refractive index and conductivity. Recently, evaporative light-scattering detectors (ELSD) and charged aerosol detectors (CAD) have undergone some improvements that allow them to replace the refractive index in many applications. ELSD has the advantage of having a response independent of the solvent gradient, and despite the fact that the ELSD response is not necessarily linear, the selection of the appropriate concentration for calibration standards and the best fitted equation allow the analyst to quantify a wide range of analyte concentrations.

On the basis of these aspects, we decided to develop a method to measure the quantities of TAA in different stages of the sugar-manufacturing process. We suggest additional matrices from which TAA could be recovered. It is important to systematically identify the best stages in the sugar-manufacturing process where this byproduct is wasted and, consequently, promote its industrial recovery. The new methodology includes a sample treatment using ion exchange cartridges in solid phase extraction coupled with a faster LC analysis with an evaporative light-scattering detector (SPE-UPLC-ELSD).

## MATERIALS AND METHODS

**Materials.** The *trans*-aconitic and formic acids were purchased from Sigma-Aldrich. Methanol and acetonitrile of HPLC grade were obtained from Merck (Darmstadt, Germany). The sugar cane juices were obtained from the analytical laboratory of the Manuelita sugar cane mill (Km 7, Vía Palmira, Valle del Cauca, Colombia). Ultrapure water was obtained from a Sartorius ASTM ultrapure water system (total organic carbon < 5 ppb, conductivity at 0.05 $\mu$S/cm$^3$, and filtered using 0.22 $\mu$m pore size).

**Selection of Different Sugar-Manufacturing Process Stages.** In the pipelines of several sugar mills, the stage names would differ. Nevertheless, the sequence of steps remains the same. Briefly, the processing of sugar cane begins with crushing the stalk to obtain the juice (extraction); then the bagasse is re-extracted with water to contribute better sucrose extraction (dilution). Once extracted, the juice is transferred to an alkalization tank where the pH is controlled by adding lime (alkalization). After that, the juice is clarified, precipitating proteins, fats, and waxes to make a sludge (clarification). To make the process more efficient, the sludge is squeezed and filtered (filtration). The clarified juice is then transferred to multieffect evaporators, where almost 80% of the water content is eliminated to obtain the syrup; then the process is repeated twice to obtain honey. Thus, the stages of production are extraction, dilution, alkalization, clarification, and filtration, producing syrup and two final products: refined white sugar (ultrapure) and brown sugar. The juices were collected during the last week of October 2013 during four consecutive days in triplicate. A schematic flowchart of sugar cane manufacturing is shown in Figure 1.

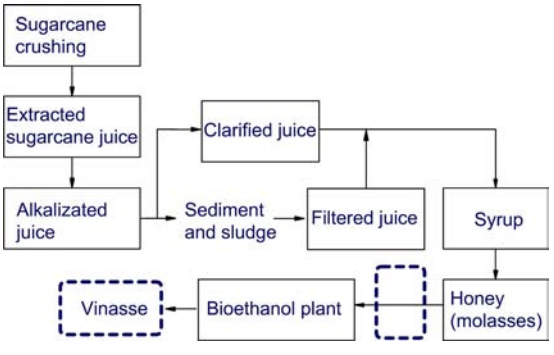

**Figure 1.** Flowchart of the sugar-manufacturing process. The arrows follow the workflow, and the solid line boxes show the stages sampled. Dashed boxes show the stages where TAA would be recovered.

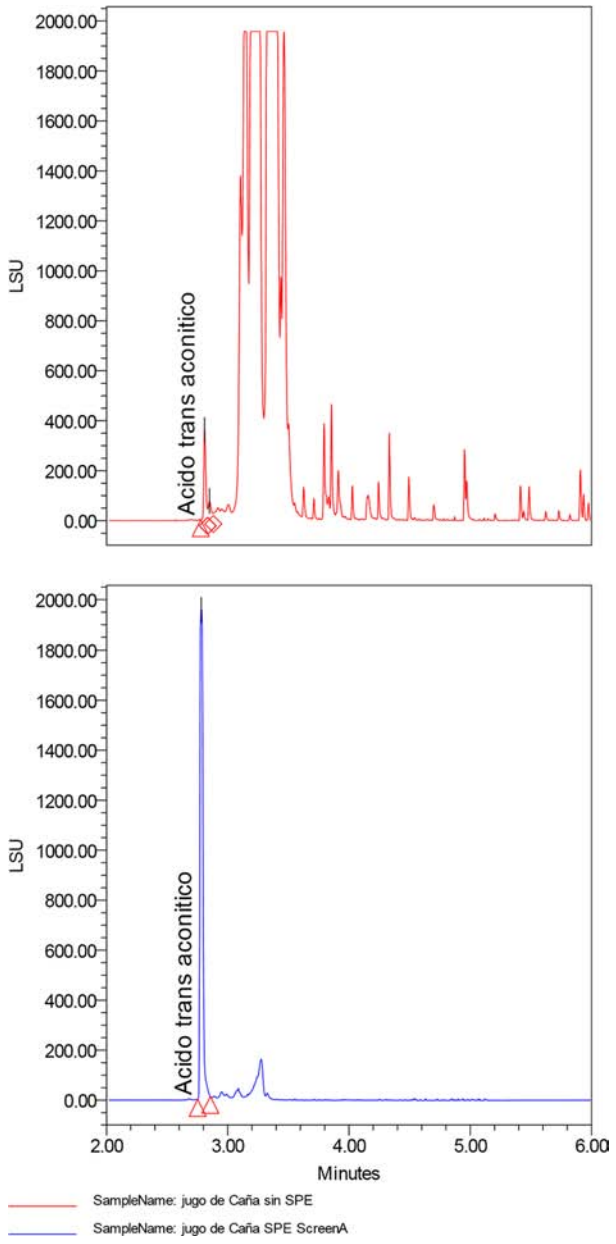

**Figure 2.** Comparison of chromatograms obtained with and without solid phase extraction: (top) sugar cane juice containing high levels of impurities; (bottom) well sample subjected to the SPE procedure. Both samples were diluted at equal volumes to manage the same concentration of solids, suggesting TAA was concentrated after SPE [by comparing light-scattering units (LSU)].

**Sample Treatment by Solid Phase Extraction.** Sugar cane liquors and standards were injected onto a Strata Screen-A cartridge (sorbent with C8 and anion exchange quaternary propylamine) conditioned with methanol and water. The loading of samples and

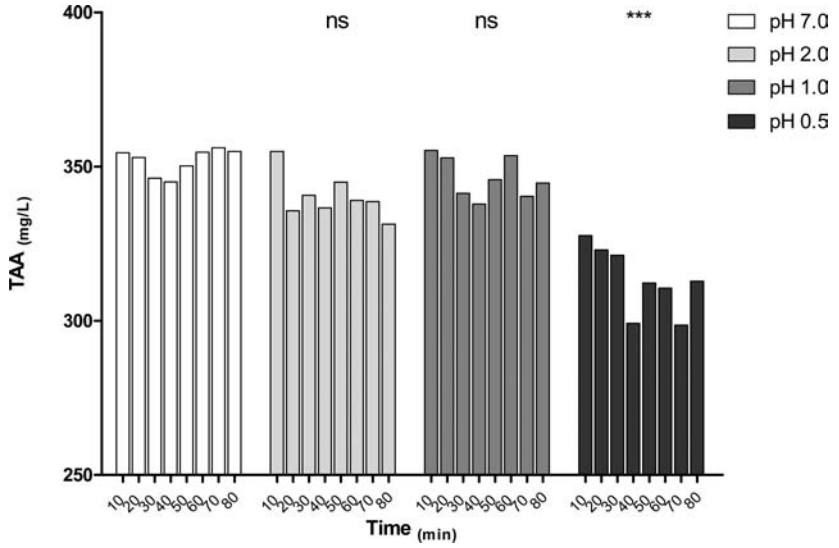

**Figure 3.** Stability test of TAA at 350 mg/L in different pH values over 80 min. Injections were made every 10 min. A Kruskal–Wallis test showed a significant difference ($p < 0.05$) between 8.0 and 0.5 pH values. No significant differences were found between 8.0 value and either the 2.0 or 1.0 pH value.

standards was performed on a solution at pH 7.0, and the washing stage was carried out with 90:10 methanol/water preserving the same pH value as the loading stage. The elution was performed with 20:80 methanol/water at pH 1.5 with diluted hydrochloric acid. All of the pH values as well as organic/water proportions were obtained by experimental design not shown. The stability of *trans*-aconitic acid at various pH values is discussed below.

**Equipment.** The UPLC system consisted of a Waters Acquity H-class equipped with a quaternary pump, degasser, and preheater modules. Detection was performed with an ELSD using gas pressure at 40 psi, gain set at 25, the nebulizer on cooling mode, and drift tube temperature set at 40 °C.

Chromatographic separation analysis was carried out on an amide BEH (2.1 mm × 100 mm, 1.7 $\mu$m particle size) column (Waters, USA). The mobile phase was a mixture of (A) deionized water/formic acid (FA) (99.9:0.1% v/v) and (B) acetonitrile/formic acid (FA) (99.9:0.1% v/v), and the flow rate was 0.5 mL/min in linear gradient without temperature control of the column.

**Statistical Analysis and Validation of the SPE-UPLC-ELSD Method.** All data processing was carried out with Empower 3.0. Calibration curves were analyzed by quadratic equation (second-order polynomial), and the coefficient correlations were always >0.9990 from a six-level curve ranging from 100 to 700 mg/L and relative standard deviation (RSD) <5% by quadruplicate. To validate the method, we used the logarithm of response (light-scattering units).[16] Limits of detection (LOD) and limits of quantitation (LOQ) were determined as 3 and 10 times the signal-to-noise ratio. LOD was 4 mg/L, and LOQ was 55 mg/L. The precision of intraday variation was determined by analyzing five standard solutions in triplicate within 1 day by two analysts. The recovery was determined in water and matrix (1 g of ultrapure sugar in 10 mL of pure water) at two concentrations, 200 and 500 mg/L. The results showed that the recovery of both water and matrix-spiked standard solutions ranged from 90 to 105% with RSDs <7%. Statistical analyses were performed by using GraphPad Prism 5.0 for Windows. A Kruskal–Wallis test was used to assess the significance of the differences of TAA concentration among pH values. All data were grouped by pH and compared against pH 7.0 (control group). $p < 0.05$ was considered statistically significant.

## RESULTS AND DISCUSSION

**Recovery of Aconitic Acid by Ion Exchange SPE.** We needed to develop analytical methods that were as simple as possible; sugar cane juice represents a complex matrix that contains fat, waxes, organic acids, polyphenols, and high concentrations of sugars. The average concentration of organic acids is estimated in the range of 0.5–2%. Taking this into consideration, we used a sample treatment method that would extend column lifetime. Figure 2 shows the differences between raw sugar cane juice and juice after SPE ion exchange preparation on separate UPLC runs. Despite the natural concentration of TAA being high enough to be quantified, we found that SPE not only concentrates the analytes but also prevents impurities such as waxes and long-chain alcohols from entering the column.

**Stability of TAA at pH Conditions.** As low pH is needed to elute the TAA from cartridges, we verified the stability of TAA at different pH values. Figure 3 shows a stability test of TAA at 350 mg/L under different pH values (from 0.5 to 7.0) over 80 min. TAA has three p$K_a$ values at 2.8, 4.6, and 6.3, and we selected pH 1.5 due to the observed stability in combination with the fact that it is >1 unit lower than the p$K_a$ value.

**Content of TAA in Different Sugar-Manufacturing Process Stages.** As shown in Figure 1, the main goal of a sugar mill is to whiten sugar cane juice and then crystallize sucrose. Most sugar mill engineers suggested that we evaluate primarily the sludge produced by alkalization tanks, because this stage eliminates most of the acidic metabolites from the juice, which precipitate under high pH value. These engineers were wrong, because we proved that TAA remains in all stages of the sugar-manufacturing process as shown in Figure 4. A large amount of TAA was found in syrup and honey, obeying the phenomenon of increasing concentration as water content evaporates and also because the sucrose is extracted. That is the same reason why honey TAA content is almost twice that of syrup, as shown in Figure 4. Ultrapure sugar lacks TAA, but brown sugar maintains around 158 mg/L TAA. The final molasses that does not crystallize into additional sugar is then used in bioethanol plants, making it off-limits for TAA recovery, unless an intermediate stage is proposed that depletes TAA from honey and preserves the sugar content needed in a biorefinery. One feasible matrix that contains TAA is vinasses (resulting after alcohol distillation of molasses); however, the matrix becomes more complex due to the high contents of tannins and colored compounds. TAA is most likely to be

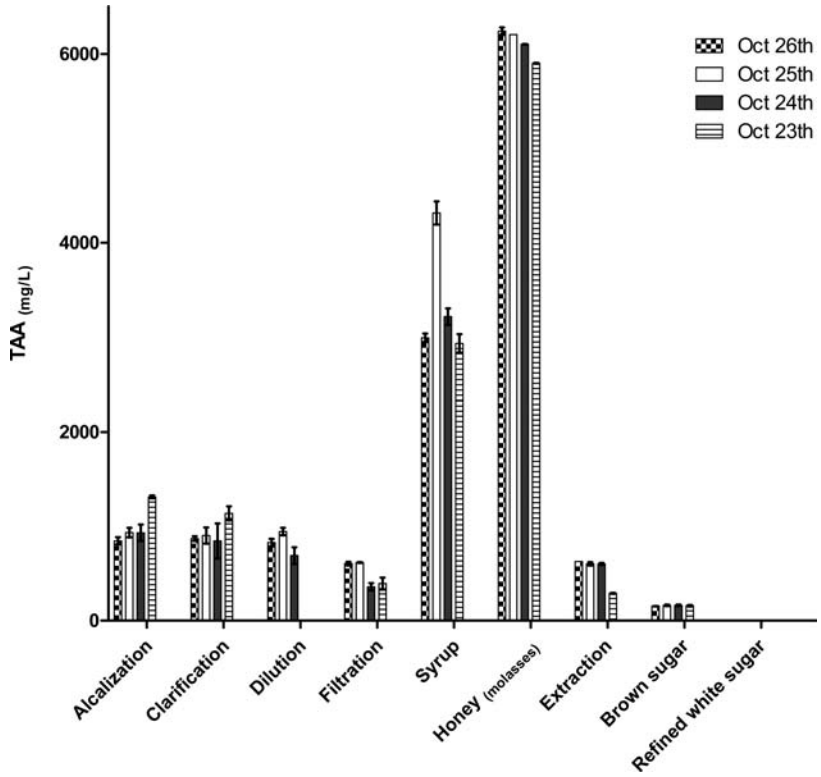

**Figure 4.** Quantification of *trans*-aconitic acid in seven stages of the sugar-manufacturing process. Samples were taken in triplicate over four consecutive days. Bars are plotted with a standard deviation bar between each day. The concentration of TAA decreased from alkalized to filtered. Brown sugar contains 158.45 ± 6.7 mg/L TAA, whereas refined white sugar (ultrapure sugar) does not have quantifiable amounts of TAA. Honey contains 6110.05 ± 139.5 mg/L TAA. The rest of the TAA contents were 1006.4 ± 193.5 mg/L alkalized, 938.5 ± 152.9 mg/L clarified, 820.8 ± 122.2 mg/L diluted, 492.6 ± 127.5 mg/L filtered, 3363.6 ± 589.3 mg/L syrup, and 547.5 ± 136.6 mg/L extract, respectively.

recovered in the dashed-line boxes in Figure 1. Decades ago, some scientists were dealing with the recovery of TAA from molasses,[9,17,18] but up to now, no commercial production has been carried out.

The chromatographic conditions prove that hydrophilic interaction by amide column represents a simple alternative to retain highly hydrophilic compounds instead of using a complex mix of solvents. Although light-scattering detectors have less sensitivity compared to ultraviolet ones, it is the best simple alternative for analytes with low absorptivity coefficients and simultaneously uses solvents with additives well adapted to the chemistry of the column. The honey (molasses) contains a high concentration of TAA, but a method that does not affect sugar and alcohol production is required to be feasible at a commercial level. Future research should explore the economic viability of these processes.

# A Simple Method for Simultaneous Quantification of Total Arabinoxylans and Fructans in Wheat Flour

Zhiqian Liu[†] and Simone Rochfort*[,†,‡]

[†]Department of Primary Industries, Biosciences Research Division, Bundoora, Victoria 3083, Australia

[‡]La Trobe University, Bundoora, Victoria 3086, Australia

Supporting Information

**ABSTRACT:** Current methods for measuring fructan and arabinoxylan concentrations in wheat flour are time-consuming, and each type of the polymers requires a separate method. Here, we report the development of a new method that allows simultaneous determination of arabinoxylan and fructan contents in wheat flour. The new method is based on a single hydrolysis procedure for both arabinoxylans and fructans and an optimized separation technique for all monomers released. Owing to the use of milder hydrolysis conditions that afforded higher recovery of pentoses, the level of arabinoxylans in wheat flour determined by this new method is slightly higher than that measured with the widely used hydrolysis protocol. On the basis of the finding that, for a given flour sample, the total fructose concentration after hydrolysis is highly correlated with its total fructan concentration, the fructan content of a wheat flour sample can thus be estimated directly by the total fructose content. By simplifying and combining the two separate methods used for arabonoxylan and fructan analysis, this new method enables the quantification of arabinoxylans and fructans in wheat flour using a single acid hydrolysis step and a single high-performance liquid chromatography run.

**KEYWORDS:** *arabinoxylans, fructans, quantification, HPLC, wheat flour*

## INTRODUCTION

Fructans are linear or branched polymers of fructose molecules, with or without a single internal or terminal glucose molecule. Fructans are present in approximately 15% of the angiosperm flora.[1] Arabinoxylans, consisting of a linear xylan backbone to which mostly single arabinose units are linked as side residues, are one of the major polysaccharides in all major cereal cell walls.[2] In white wheat flour, fructan content is below 3%,[3] whereas arabinoxylan content ranges from 1.5% to 2.5%.[4] Despite being a minor component of wheat flour, fructans and arabinoxylans are soluble dietary fiber and are claimed to have beneficial effects on human health by selectively promoting certain bacterial species of the gut flora (prebiotic effect).[5−7] For this reason, fructans are increasingly being used as functional additives to foods.[8] In addition to conferring health benefits when included in human diets,[9] arabinoxylans play an important role in the rheological properties of dough and bread-making quality of wheat flours.[10,11] Since wheat is a staple food crop, increasing its fructan and arabinoxylan levels could increase the intake of these nonstarch carbohydrates for a large number of people. As significant genotypic variation has been reported for fructan and arabinoxylan concentrations in wheat grain,[3,12] developing higher fructan and arabinoxylan wheat cultivars can be envisaged.[3,13] Therefore, a high-throughput yet reliable method for evaluating fructan and arabinoxylan concentrations in wheat flour samples has the potential to facilitate both genetic mapping of loci responsible for controlling fructan and arabinoxylan accumulation in grain and rapid and accurate screening for the identification of elite or improved germplasm.

Although various high-performance anion-exchange chromatography (HPAEC) based methods have been reported for quantification of fructans in plant tissues,[14−16] they may not be suitable for wheat flour samples that contain only a small amount of fructans.[3] Recently, specific methods for determination of fructan content in wheat flour have been developed.[17,18] These methods are accurate but complex and time-consuming because they involve two steps in sample treatment (extraction of fructans from flour samples using hot water followed by acid or enzymatic hydrolysis of fructans into hexoses), and two high-performance liquid chromatography (HPLC) runs are required to determine the level of total fructans.[17,18] Therefore, the current methods are low throughput and not suited for processing a large number of samples.

Different methods can also be found in the literature for determination of arabinoxylan content in wheat flour.[19−23] As colorimetric methods cannot provide information on pentose composition and gas chromatography based methods require an additional derivatization step following hydrolysis,[24,25] HPAEC is increasingly being used for arabinoxylan quantification. Similarly, the amount of arabinoxylans can be determined by quantifying the level of arabinose and xylose released after hydrolysis of the pentose polymers. A detailed method comprising optimization of the acid hydrolysis condition and HPAEC separation of released monomers was reported by Houben et al.,[22] and the hydrolysis protocol has been widely used since.[13,26] However, a recovery of about 85% for arabinose and about 75% for xylose was observed under these hydrolysis

conditions (i.e., 90 min in 2 M HCl at 100 °C),[22] which could lead to underestimation of arabinoxylan content.

Although separate methods are available for the determination of fructans and arabinoxylans in wheat flour, to our knowledge, no attempt has been made to develop a comprehensive method that enables simultaneous quantification of both fructans and arabinoxylans in wheat flour. Here, we report on the development and validation of a new method for the quantitative analysis of fructans and arabinoxylans in wheat flour based on a direct acid hydrolysis of both types of polymers and a single HPLC run to quantify all monomers released.

## MATERIALS AND METHODS

**Wheat Flour.** Wet-milled white flour samples (150 in total) were prepared from different bread wheat cultivars and/or locations throughout Australia.

**Chemicals.** Standards of glucose, fructose, sucrose, arabinose, xylose, and raffinose were purchased from Sigma (USA). Sodium hydroxide (50% solution) and sodium acetate anhydrous used in the mobile phase were obtained from Fluka (Germany).

**Hydrolysis of Arabinoxylans.** Arabinoxylan content in wheat flour was determined by measuring the amount of arabinose and xylose released after hydrolysis of arabinoxylans. The method of direct acid hydrolysis of wheat flour was adopted in this work. Briefly, 10 mg of flour samples was accurately weighed out into 2 mL screw-cap tubes, and 1 mL of HCl of an appropriate concentration (as detailed below) was added to each tube. The hydrolysis was accomplished by incubating the tubes in heating blocks (90 °C) for 60 min. Following hydrolysis, the sample was neutralized by adding NaOH, and the amount of arabinose and xylose released was determined by HPAEC. The amount of arabinoxylans in a sample is calculated as the sum of arabinose and xylose, multiplied by 0.88 to correct for water uptake during hydrolysis.[22]

**Extraction and Hydrolysis of Fructans.** Fructan content in wheat flour was determined by measuring the amount of fructose and glucose released after hydrolysis of the fructose polymers. Two hydrolysis methods were used in this work: (1) extraction of fructans from wheat flour by hot water, followed by acid hydrolysis of the extracted fructans; (2) direct acid hydrolysis of fructans from wheat flour. The first method was adapted from that of Verspreet at al.[18] and is referred to as the 2-step method in this paper. Briefly, the extraction of fructans by hot water was performed in heating blocks (90 °C) for 60 min (step 1), followed by hydrolysis of an aliquot of the extract with 30 mM HCl in heating blocks (70 °C) for 90 min (step 2). The amount of free glucose, fructose, sucrose, and raffinose present in the aqueous extract before hydrolysis as well as that of total glucose and fructose after hydrolysis was determined by HPAEC. Fructan content was then calculated as described by Liu et al.[16] For the second method, the hydrolysis was performed by adding 1 mL of HCl of various concentrations into 2 mL screw-cap tubes containing 10 mg of a flour sample, followed by incubating the tubes in heating blocks (90 °C) for 30−120 min. The amount of fructose released from the flour sample was measured by HPAEC.

**HPAEC Analysis.** Carbohydrate analysis was performed using an ICS-5000 HPLC system (Dionex) equipped with a CarboPac PA100 column (4 × 250 mm) and an electrochemical detector working in pulsed amperometric mode using a gold working electrode and a combined pH−Ag/AgCl reference electrode. A standard quadruple-potential waveform for carbohydrates was used for all analyses (Supporting Information, Table S-1). Two elution programs were used in this work (Supporting Information, Tables S-2 and S-3): one for the quantification of arabinose, xylose, and fructose after hydrolysis, and the other for measuring free glucose, fructose, sucrose, and raffinose content before hydrolysis.

## RESULTS

**Correlation of the Total Fructose Content (after Hydrolysis) and the Fructan Content.** Rhamnose was used as an internal standard in our preliminary analysis, and comparable results were obtained with and without the internal standard. So, no internal standards were used in subsequent experiments. By using the 2-step method, the fructan content of a flour sample can be calculated based on the amount of glucose and fructose liberated from fructan molecules. To deduce the portion of fructose and glucose derived solely from fructans, two separate analyses are needed to quantify, respectively, total fructose and glucose after hydrolysis and free glucose, fructose, sucrose, and raffinose before hydrolysis, as both sucrose and raffinose also contain glucose and fructose units.

The analysis of the aqueous extract of 54 random flour samples indicates that free glucose, fructose, and raffinose are present in very small amount in wheat flour (Supporting Information, Table S-4). Consequently, only the amount of fructose and glucose derived from sucrose needs to be subtracted from the total fructose and glucose to calculate the fructan content. This implies that the concentration of fructan in a wheat flour sample can be calculated using only three values (total glucose and total fructose content after hydrolysis and free sucrose content before hydrolysis), as the amount of glucose and fructose released from sucrose hydrolysis can be directly calculated from sucrose content.

Table 1 shows the fructan content of 12 random flour samples as calculated using the three values determined by two separate HPLC analyses.

A close examination of the data in Table 1 reveals that the fructan content of the 12 samples is very close to their total fructose content after hydrolysis. The strong correlation between these two data series is clearly seen in Figure S-1 (Supporting Information). This suggests that the concentration of total fructose after hydrolysis can be potentially used to estimate the content of fructans in a flour sample. This will greatly simplify the fructan analysis procedure, as the total fructose content after hydrolysis can be determined by one single HPLC run.

**Simplification of the 2-Step Method in Fructan Analysis.** All the current methods for fructan analysis involve two steps: a hot water extraction step and a hydrolysis step.[16−18] Given the fact that, in the case of wheat flour, fructan content could be estimated directly by the total fructose content after hydrolysis, the 2-step method in fructan quantification can also be simplified into one single step, that is, direct hydrolysis of fructans from wheat flour under the same hydrolysis conditions. Indeed, the total fructose contents of 24 random flour samples determined after direct hydrolysis are very close to those measured using the 2-step method (Figure 1).

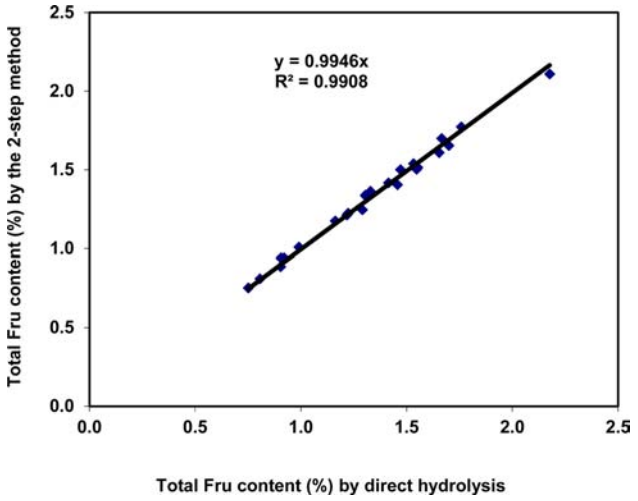

**Figure 1.** Correlation of the total fructose content of 24 wheat flour samples, as determined by the direct hydrolysis method and by the 2-step method. The direct hydrolysis was performed by incubating flour samples with 30 mM HCl at 70 °C for 90 min.

**Optimization of HPLC Separation for All Fructan and Arabinoxylan Monomers.** In order to develop a method allowing simultaneous quantification of fructans and arabinoxylans in wheat flour, chromatographic separation of all monomers (i.e., arabinose, xylose, glucose, and fructose) contained in these two types of carbohydrate polymers is required. A systematic evaluation of the performance of various columns and mobile phase concentrations allowed us to achieve baseline resolution of the four monomer in a standard mix as well as in a wheat flour hydrolysate, in which a large amount of glucose (derived from starch) is present (Figure 2). The optimum chromatographic conditions consist of a Carbopac PA100 ion-exchange column (Dionex) and a mobile phase containing 40 mM NaOH.

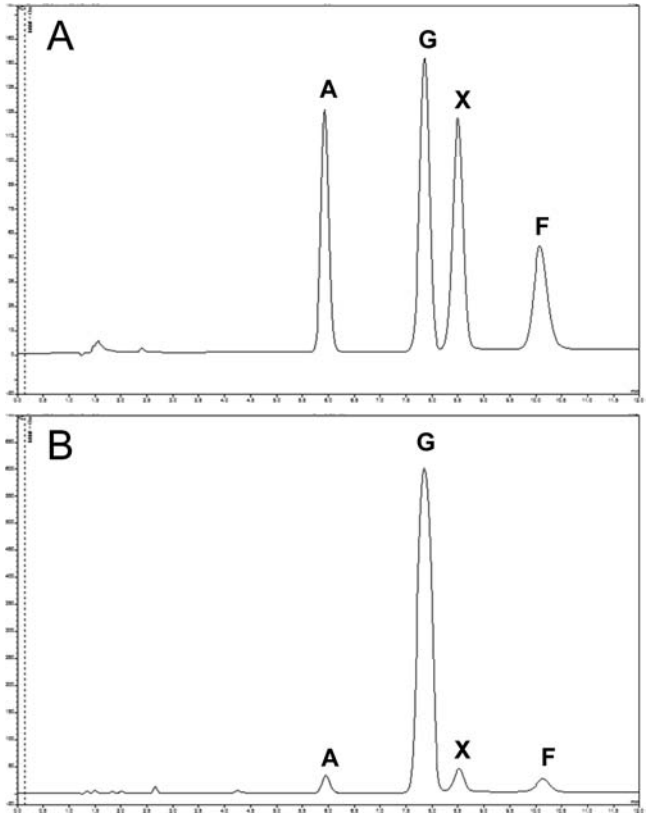

**Figure 2.** HPAEC separation of the four monomers (A) from a standard mix and (B) from the hydrolysate of a wheat flour sample. Peak annotations: A, arabinose; G, glucose; X, xylose; F, fructose. The hydrolysis of wheat flour was performed with 1 M HCl at 90 °C for 60 min.

**Optimization of Acid Hydrolysis for Arabinoxylans and Fructans.** Having demonstrated that fructan and arabinoxylan monomers can be quantified by a single HPLC analysis, a unified acid hydrolysis protocol for both types of polymers is needed in order to develop a higher throughput method. The yield of arabinose, xylose, and fructose was compared when one random flour sample was subjected to various hydrolysis conditions (by varying HCl concentrations, incubation time, and temperatures). Figure 3 shows the yield of arabinose, xylose, and fructose as a function of HCl concentration and incubation time at a fixed incubation temperature (90 °C). Clearly, the hydrolysis rate of arabinoxylans and fructans, as reflected by the yield of arabinose/xylose and fructose, respectively, is influenced by both the HCl concentration and the incubation time. It is also observed that the xylan backbone of arabinoxylans is more resistant to acid hydrolysis than the arabinose branches, whereas fructans can be depolymerised readily. Lowering the incubation temperature to 70 or 80 °C significantly prolongs the time required for complete hydrolysis of arabinoxylans (results not shown).

A combination of HCl concentration of 1 M, incubation time of 60 min, and incubation temperature of 90 °C appears to be the best compromise for the hydrolysis of both types of carbohydrate polymers in wheat flour. This unified hydrolysis protocol and the one-step HPAEC analysis of all monomers form our new method for simultaneous quantification of fructans and arabinoxylans in wheat flour.

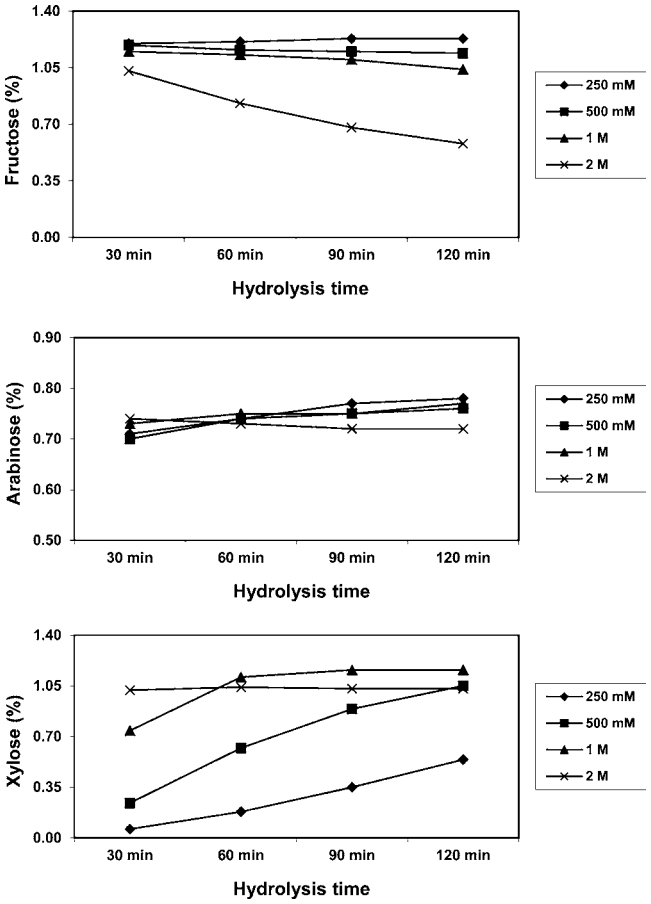

**Figure 3.** Yield of monomers as a function of HCl concentration and incubation time. All hydrolyses were performed at 90 °C, and all data points are the means of three replicates.

**Stability of Arabinose, Xylose, and Fructose under Acidic Conditions.** Having found the unified hydrolysis conditions for the two types of polymers, the stability of the monomers under these hydrolysis conditions needs to be assessed, as the content of the polymers is calculated based on the concentrations of the monomers. The stability of arabinose, xylose, and fructose was assessed by measuring the recovery of standard compounds (applied at 0.01%) after incubation in 1 M HCl at 90 °C for 30–90 min. Figure 4 shows that both arabinose and xylose are stable under the hydrolysis conditions, with a recovery rate close to 100% even after 90 min. By contrast, a slight degradation (or transformation) was observed for fructose (92% recovery after 60 min) (Figure 4).

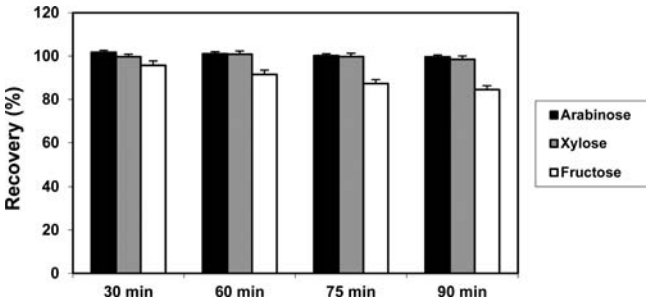

**Figure 4.** Recovery (%) of arabinose, xylose, and fructose after incubation in 1 M HCl at 90 °C. All values in this figure are the means of two replicates.

**Comparison between the New Method and the Standard Method for Arabinoxylan Quantification.** Ten randomly selected flour samples were used to compare our new method with the standard hydrolysis method in quantitative analysis of arabinoxylans. Overall, our new method produced similar results compared to the currently widely used direct hydrolysis method. However, owing to the improved recovery of arabinose and xylose, a slightly higher arabinxylan content was obtained with our new method for nearly all samples (Table 2).

**Table 2. Comparison of Arabinoxylan Content of 10 Flour Samples, as Determined by the New Method and by the Standard Method**

| | mean content[a] (%) ± SD | |
|---|---|---|
| sample | new method | standard method |
| A | 2.33 ± 0.06 | 2.24 ± 0.07 |
| B | 2.13 ± 0.04 | 1.99 ± 0.08 |
| C | 2.22 ± 0.04 | 2.15 ± 0.04 |
| D | 2.46 ± 0.02 | 2.40 ± 0.04 |
| E | 2.36 ± 0 | 2.20 ± 0.10 |
| F | 2.81 ± 0.02 | 2.68 ± 0.07 |
| G | 2.74 ± 0.01 | 2.59 ± 0.10 |
| H | 2.56 ± 0.03 | 2.42 ± 0.08 |
| I | 1.94 ± 0.02 | 1.77 ± 0.10 |
| J | 2.08 ± 0.05 | 1.96 ± 0.05 |

[a]Mean and SD values are calculated from two replicates.

**Comparison between the New Method and the 2-Step Method in Fructan Quantification.** To confirm the reliability of the new method in fructan quantification, a further set of 24 randomly selected samples was analyzed in parallel by the new method and the standard 2-step method. Fructan contents determined by the new method were highly correlated with those determined by the standard 2-step method (Figure 5). However, the overall fructan content measured by our new method is about 95% that determined by the 2-step method. As a result, a correction factor of 1.05 should be applied when using this new method for fructan quantification in wheat flour.

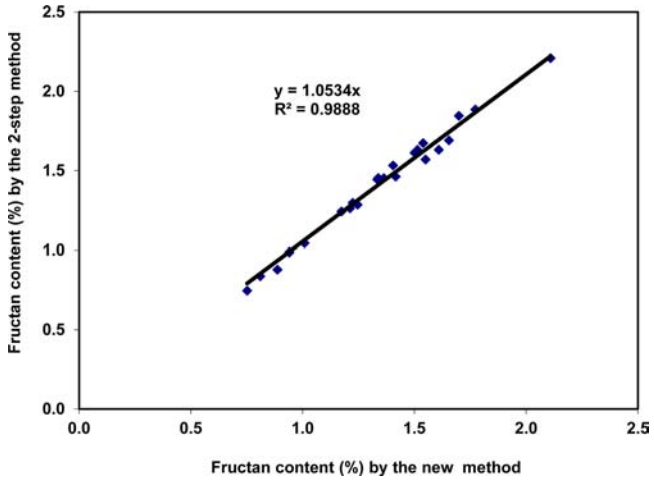

**Figure 5.** Correlation of fructan content of 24 random flour samples, as determined by the new method and by the standard 2-step method.

dx.doi.org/10.1021/jf501198k | J. Agric. Food Chem. 2014, 62, 8319–8324

Indeed, a recovery of about 94% and 99% before and after correction, respectively, was obtained with this new method when wheat flour was spiked with commercial fructan at two different concentrations (1% and 2% fructan of the flour wheat).

**Reproducibility of the New Method in Arabinoxylan and Fructan Quantification.** The reproducibility of the method in the quantification of fructans and arabinoxylans in wheat flour was assessed by the variation of measurement results between technical replicates taken from one single flour sample (Table 3). The content of both arabinoxylans and fructans shows very small variation between replicates, demonstrating the excellent repeatability of the method in fructan and arabinoxylan quantification.

**Table 3. Reproducibility of the Method in Arabinoxylan and Fructan Analysis[a]**

| carbohydrate | rep | content (%) | mean | SD | RSD (%) |
|---|---|---|---|---|---|
| arabinoxylans | 1 | 2.12 | 2.13 | 0.04 | 1.88 |
| | 2 | 2.16 | | | |
| | 3 | 2.16 | | | |
| | 4 | 2.07 | | | |
| fructans | 1 | 1.97 | 1.97 | 0.02 | 1.02 |
| | 2 | 1.98 | | | |
| | 3 | 1.94 | | | |
| | 4 | 1.97 | | | |

[a]Arabinoxylan content is calculated as the sum of arabinose and xylose multiplied by 0.88 to correct for water uptake. Fructan content is calculated using the total fructose content (after direct hydrolysis) multiplied by 1.05. SD, standard deviation. RSD, relative standard deviation.

## DISCUSSION

Quantitative analysis of arabinoxylans and fructans in grains is an important step in the understanding of the genetic control mechanisms for the accumulation of these carbohydrates and in research programs aiming to develop high arabinoxylan and/or fructan germplasm.

Currently, separate methods are available for the determination of total arabinoxylan and fructan contents in wheat flour. A systematic method development for arabinoxylan analysis was reported by Houben et al.,[22] in which a direct hydrolysis of the flour sample was adopted, resulting in significant simplification of the sample pretreatment procedure. However, an extra step was needed in this method to convert glucose into gluconic acid to prevent its interference in xylose quantification. Nguyen et al.[13] further simplified this method by a direct quantification of xylose and arabinose in the hydrolysate. We also found it unnecessary to convert or remove glucose (derived from starch) after hydrolysis, as the use of a CarboPac PA100 column together with an optimized mobile phase allowed complete separation of the four monomeric sugars. In addition, by fine-tuning the parameters used in hydrolysis (reducing the HCl concentration from 2 to 1 M and decreasing the incubation temperature from 100 to 90 °C), we have improved slightly the recovery of the pentoses while achieving complete breakdown of arabinoxylans.

In the case of fructan analysis in wheat flour, an excellent method was published by Verspreet et al.,[18] in which a mild acid hydrolysis (60 mM) was used to breakdown fructan polymers with no degradation of starch. By avoiding starch breakdown during acid hydrolysis, this method allowed accurate estimation of wheat flour fructans. However, this method involved two steps, that is, hot water extraction and acid hydrolysis, and is thus low throughput.

We have found that, in the case of wheat flour, the total fructose content after hydrolysis can be used directly to estimate the content of fructans. This is an important finding for simplifying the fructan analysis procedure. The possibility of using direct hydrolysis of flour to measure the total fructose content is a key step toward a unified hydrolysis protocol for both arabinoxylans and fructans. However, the easy breakdown of fructan molecules and the relative instability of fructose under acidic conditions imply that mild conditions would be preferred for fructan hydrolysis, whereas the backbone of arabinoxylans is much harder to break. Considerable effort was made to find a three-way combination (HCl concentration, incubation time, and temperature) of hydrolysis conditions that ensure complete conversion of arabinoxylans (into arabinose and xylose) and at the same time minimum degradation of fructose liberated from fructans. Under the optimized hydrolysis conditions, the content of arabinoxylans measured is slightly higher compared to the widely used hydrolysis protocol, and the content of fructan is about 95% that measured by the 2-step method. A correction factor of 1.05 is thus needed when using this method for fructan quantification in wheat flour. The reproducibility of the new method in the quantification of both arabinoxylans and fructans was finally confirmed by replicate analyses of the same sample.

In conclusion, a combined method for arabinoxylan and fructan quantification in wheat flour has been developed. This method, requiring one single sample preparation step and one single HPLC run, is simple and reliable and thus particularly suited for screening a large number of samples. Although it has been validated in wheat flour, this method should be applicable to other cereal species.

# Highly Sensitive Detection of Zearalenone in Feed Samples Using Competitive Surface-Enhanced Raman Scattering Immunoassay

Jianzhi Liu, Yongjun Hu,* Guichi Zhu, Xiaoming Zhou, Li Jia, and Tao Zhang

Ministry of Education Key Laboratory of Laser Life Science & Institute of Laser Life Science, College of Biophotonics, South China Normal University, Guangzhou 510631, People's Republic of China

**ABSTRACT:** Accurate and quantitative analysis of mycotoxin (such as zearalenone) is particularly imperative in the field of food safety and animal husbandry. Here, we develop a sensitive and specific method for zearalenone detection using competitive surface-enhanced Raman scattering (SERS) immunoassay. In this assay, a functional gold nanoparticle was labeled with the Raman reporter and the zearalenone antibody, and a modified substrate was assembled with the zearalenone−bovine serum albumin. With the addition of free zearalenone, the competitive immune reaction between free zearalenone and zearalenone−bovine serum albumin was initiated for binding with zearalenone antibody labeled on gold nanoparticle, resulting in the change of SERS signal intensity. The proposed method exhibits high sensitivity with a detection limit of 1 pg/mL and a wide dynamic range from 1 to 1000 pg/mL. Furthermore, this method can be further applied to analyze the multiple natural feed samples contaminated with zearalenone, holding great potential for real sample detection.

**KEYWORDS:** *Zearalenone, mycotoxin, surface-enhanced Raman scattering, competitive, immunoassay, quantitative detection*

## INTRODUCTION

Contamination of agricultural commodities by mycotoxins is a serious problem worldwide due to their high toxicity and biological persistence. Zearalenone is one of the most important mycotoxins and results from the secondary metabolite of several Fusarium species.[1] Because of unusual weather conditions or improper storage, zearalenone contamination is frequent in agricultural commodities and cereal products such as flour, malt, soybeans, and beer.[2] Global trade also facilitates the occurrence of zearalenone contamination in food, feed, and feed raw materials.[3] Evidence suggests that the consumption of contaminated products might cause various toxic effects on humans and animals, including teratogenesis, carcinogenicity, neurotoxicity, abortion, and estrogenic effect.[4−9] Consequently, accurate and quantitative analysis of zearalenone in agricultural commodities is critical for food safety and animal husbandry.

Because of the adverse effects and the universal existence of zearalenone, a variety of methods such as chemical, physical, and biological processing approaches have been used to lower its level, and it is necessary to develop effective methods to detect and monitor the trace amount of residual zearalenone.[10,11] The traditional analytical methods used for zearalenone detection include high-performance liquid chromatography and ultra high performance liquid chromatography coupled with tandem mass spectrometry, but they usually require expensive instrumentation and complicated sample preparation processes, which might limit their applications in the routine monitoring of zearalenone.[12,13] To avoid this limitation, the immunoassay- and aptamer-based methods have been developed with the advantages of simplicity and low cost, but most of them are difficult to reach a satisfactory sensitivity.[14−20] Therefore, a simple and sensitive method is highly desirable for zearalenone detection in the real samples.

Surface-enhanced Raman scattering (SERS) is an emerging and powerful optical technology that can provide a nondestructive and ultrasensitive detection even down to a single molecular level.[21,22] With several characteristics of tremendous signal enhancement, narrow band widths, and alleviated photobleaching, SERS immunoassay has been widely applied for sensitive detection of nucleic acids, proteins, and microbes.[22−27] In SERS immunoassay, a novel labeling technique is employed. Herein, a SERS nanoprobe that relies on gold nanoparticle is labeled by dye molecules (Raman reporter, e.g., 4,4′-dipyridyl) and antibodies, respectively; thus, Raman signal of the reporter molecules can act as the tracer signal.[23] However, the conventional SERS immunoassay depends on the formation of a sandwich structure of "antibody−antigen−antibody", which demands the antigen with multiple recognition sites for binding antibody. For the detection of small molecules with small size and nonmultiple recognition sites, like zearalenone, this sandwich structure is unsuitable. To overcome this defect, the introduction of competitive concept into SERS immunoassay has gained attention.[23,28] Dufek et al.[29] first applied the competitive SERS immunoassay for the detection of 1,25-dihydroxy metabolite of vitamin $D_3$, but the antibody was chosen to attach to the substrate instead of antigen, which would increase the cost of the assay. Afterward, our group designed a low-cost competitive SERS immunoassay for the detection of adrenergic agonist of clenbuterol in pig urine;[30] nevertheless, the analysis of spiked clenbuterol samples could not confirm its presence in real samples.

Herein, we developed a new method based on a competitive SERS immunoassay, which was carried out between free zearalenone and zearalenone−bovine serum albumin fixed on the substrate, competitively binding with zearalenone antibody conjugated on the gold nanoparticles. In the present report, this method was used to detect the zearalenone in natural feed samples.

## MATERIALS AND METHODS

**Materials.** Zearalenone monoclonal antibody, zearalenone−bovine serum albumin, and zearalenone standard solution were purchased from Beijing Huaan Magnech Bio-Tech Co., Ltd. (Beijing, China). Aflatoxin $B_1$ standard solution and diethylstilbestrol standard solution were from Guangzhou Analysis Center Keli Technology Co., Ltd. (Guangzhou, China). 4,4′-Dipyridyl, bovine serum albumin, and trisodium citrate were purchased from Sigma Chemical (St. Louis). 3-Aminopropyl trimethoxysilane and glutaraldehyde were purchased from Aladdin China Ltd. (Shanghai, China). Chloroauric acid ($HAuCl_4$) was received from Sinopharm Chemical Reagent Co., Ltd. (Shanghai, China). The blank feed samples were obtained from Guangdong Medical Laboratory Animal Center (Guangdong, China). Sulfuric acid, nitric acid, 30% hydrogen peroxide, sodium chloride (NaCl), boric acid, borax, potassium dihydrogen phosphate, disodium hydrogen phosphate, and potassium chloride were from Guangzhou Chemical Regent Factory (Guangzhou, China).The following buffer solutions were used: borate buffer (pH 8.2) and phosphate-buffered saline (pH 7.4). The washing buffer was prepared by adding 0.05% Tween-20 to the phosphate-buffered saline. All these reagents were analytical grade or better and all aqueous solutions were prepared with ultrapure water processed by an ultrapure water system (ELGA, London).

**Equipment.** A microscopic Raman spectrometer (Nippon Optical System Co., Tokyo) was used to measure the Raman spectra. The excitation source was a He−Ne laser (Melles Griot, Carlsbad, CA) with a 632.8 nm excitation wavelength and a power of 1 mW was obtained. All spectra were calibrated referring to the 520 $cm^{-1}$ line of silicon. The typical accumulation time used in this study was 30 s. The Raman spectrum was collected by WinSpec/32 software and could be converted into digital data. Those data were processed with Origin 7.0 software. Thereafter, only a baseline calibration on the spectra was performed to remove the intense fluorescence, which came from the capture substrate. A UV/vis spectrometer (Perkin-Elmer, Waltham, MA) was used to determine the diameter of gold nanoparticles.

**Preparation of Gold Nanoparticles and SERS Nanoprobes.** The gold nanoparticles were prepared according to Frens' method,[31] with slight modification.[32] Generally, 100 mL of 1 mM $HAuCl_4$ aqueous solution was heated to boiling, and then 6.0 mL of freshly prepared 38.8 mM trisodium citrate solution was added rapidly. The solution turned deep red quickly and was boiled for another 20 min. Then the solution was allowed to cool down to room temperature with continuous stirring. The resulting red gold nanoparticles were obtained with a diameter of 30 nm and the diameter of the nanoparticles was determined by the UV/vis spectrometer.

The SERS nanoprobes were prepared by the procedure reported by Gu and co-workers with slight modification.[33,34] It was prepared in a typical two-step process: first, 4,4′-dipyridyl molecules were located on the gold nanoparticles through the spontaneous adsorption on gold nanoparticles surface. A total of 30 μL of 0.01 mM 4,4′-dipyridyl was added to 1.0 mL of uncoated gold nanoparticles and the resultant mixture was allowed to react for 10 min. The gold nanoparticles labeled with 4,4′-dipyridyl molecules were then separated from the solution by centrifugation at 12 000 rpm for 5 min and dispersed with 1.0 mL of borate buffer (pH 8.2). Second, zearalenone antibody was immobilized on the 4,4′-dipyridyl-labeled gold nanoparticles. Five microliters of 0.5 mg/mL zearalenone antibody was added to 1.0 mL of 4,4′-dipyridyl-labeled gold nanoparticles. The mixture was incubated at room temperature for 2 h. Then the SERS nanoprobes were purified by centrifugation for 10 min and resuspension with 1.0 mL of borate buffer (pH 8.2). Finally, 20 μL of 2.5% bovine serum albumin was added into the above SERS nanoprobes to block sites bare of 4,4′-dipyridyl and the mixture was incubated for 1 h at room temperature. After centrifugation and resuspension with 1.0 mL of phosphate-buffered saline (pH 7.4), the SERS nanoprobes were finally obtained and the nanoprobes are usually stable for 2−3 days when stored at 4 °C.

**Preparation of Capture Substrates.** The substrates that we used were concave glass slides and five steps were needed to modify them, which meant that the substrates were modified by piranha solution, 3-aminopropyl trimethoxysilane, glutaraldehyde,[35−38] zearalenone−bovine serum albumin, and bovine serum albumin. In the first step, the glass slides were immersed in piranha solution ($H_2SO_4$:$H_2O_2$, 7:3, v/v) for 30 min to yield hydroxyl on the surface. In the second step, after ultrasonic cleaning, the substrates were dipped in methanol solution containing 5% 3-aminopropyl trimethoxysilane for 12 h at room temperature. In the third step, 2.5% glutaraldehyde was added onto the 3-aminopropyl trimethoxysilane silanized substrates to form an 3-aminopropyl trimethoxysilane−glutaraldehyde surface. The slides were allowed to react for 4 h at room temperature, and the amino groups on the 3-aminopropyl trimethoxysilane silanized substrates reacted with the aldehyde groups of glutaraldehyde, thus yielding the 3-aminopropyl trimethoxysilane−glutaraldehyde surface. In the fourth step, 100 μL of 50 μg/mL zearalenone−bovine serum albumin were dropped onto the concave surface of the modified substrates. In the last step, the substrates were incubated in 2.5% bovine serum albumin for 1 h to block active sites on the modified substrates. After they were rinsed with ultrapure water and dried under a stream of nitrogen, the capture substrates were eventually obtained.

**Sample Preparation.** Zearalenone-free feed sample was spiked by adding zearalenone standard solution and the mixture was stored overnight at 4 °C. The concentrations of the spiked samples used in the experiment were 0, 1, 10, 100, and 1000 pg/mL for zearalenone.

A new extraction method, dispersive liquid−liquid extraction, for SERS immunoassay was investigated. Specifically, 5 g of the spiked ground sample was extracted with 30 mL of methanol and 20 mL of 50 g/L NaCl solution where methanol was used as extractant and NaCl was used to avoid emulsification. The mixture was first shaken for 10 min and then ultrasonically for 30 min. After filtering, the filtrate was placed in the separatory funnel and chloroform was used to extract zearalenone from the mixture. The zearalenone chloroform solution was evaporated to dryness before diluting 30-fold with phosphate-buffered saline (pH 7.4) containing 10% methanol (v/v) and 0.05% Tween 20 (v/v). Three natural feed samples contaminated with zearalenone were also handled according to the procedure above.

**Test Procedure.** The SERS procedure has been described previously,[30] with minor modification, as shown in Figure 1. In

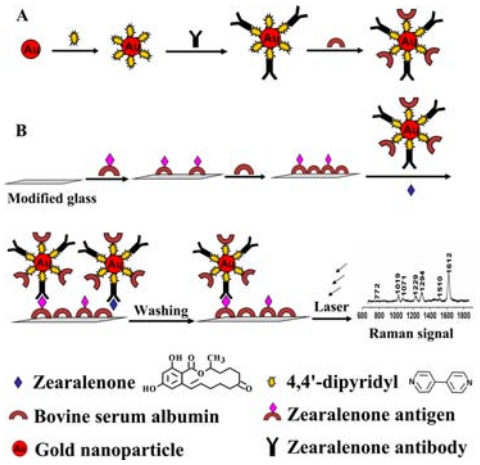

**Figure 1.** (A) Preparation of SERS nanoprobes. (B) Competitive SERS immunoassay for zearalenone.

the first step, the SERS nanoprobes were prepared as above. In the second step, the competitive SERS immunoassay was carried out. Zearalenone standard solution and SERS nanoprobes in the same volume were simultaneously dropped on the concave surface of the capture substrate, during which zearalenone–bovine serum albumin fixed on the capture substrate and zearalenone antigen suspending in the standard solution competitively conjugated with the zearalenone antibody labeled on the SERS nanoprobes. Finally, the 4,4′-dipyridyl Raman signal was obtained from the substrate with a microscopic Raman spectrometer if there are nanoprobes conjugating on the capture substrate. The control experiment was carried out to confirm the antibody and bovine serum albumin were actually labeled on the gold nanoprobes.

## RESULTS AND DISCUSSION

**Optimization of the SERS Nanoprobes.** 4,4′-Dipyridyl is a typical bifunctional Raman reporter, with two nitrogen atoms on both ends of the molecule (Figure 2). One can interact with the gold nanoparticles and the other conjugates with the

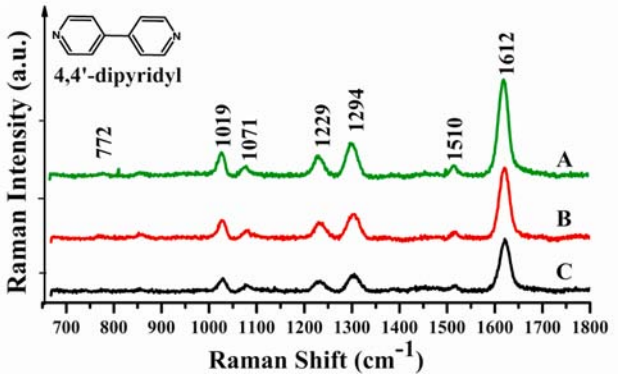

**Figure 2.** (A) SERS spectra of the 4,4′-dipyridyl labeled on gold nanoparticles. (B) SERS nanoprobes labeled with 4,4′-dipyridyl and antibody. (C) SERS nanoprobes labeled with 4,4′-dipyridyl and antibody, and then bovine serum albumin blocking the surplus 4,4′-dipyridyl on the gold nanoparticles surface.

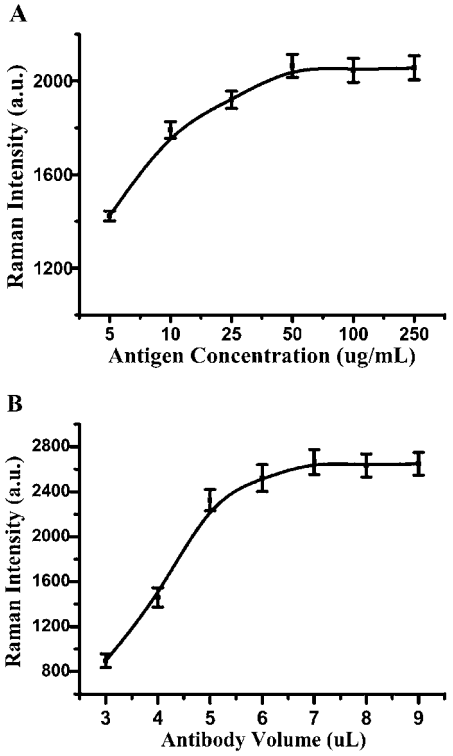

**Figure 3.** (A) SERS signal intensity with different concentrations of zearalenone–bovine serum albumin. (B) SERS signal intensity with different volumes of zearalenone antibody. The Raman intensities are those of the bands at 1612 $cm^{-1}$ of 4,4′-dipyridyl. Error bars indicate the standard deviations of three independent measurements.

zearalenone antibody or bovine serum albumin. A previous study showed bovine serum albumin could be used to block the surplus active sites of the 4,4′-dipyridyl.[33] 4,4′-Dipyridyl is able to be perpendicularly adsorbed on the surface of the gold nanoparticles, which makes the amount of the antibodies labeled on gold nanoparticles as large as possible.[39,40] Its fast-labeled and nontoxic properties make it an excellent Raman reporter. The characteristic peaks of 4,4′-dipyridyl are at 1612, 1510, 1984, 1229, 1071, 1019, and 772 $cm^{-1}$, respectively. The characteristic peak at 772 $cm^{-1}$ is assigned to ring breathing vibrational mode, $B_1$, and the characteristic peak at 1019 $cm^{-1}$ is related to ring breathing vibrational mode, $A_1$. The characteristic peak at 1071 $cm^{-1}$ is assigned to ring in-plane deformation vibrational mode and C–H bend vibrational mode, $A_1$. The band at 1229 $cm^{-1}$ is attributed to C–H in-plane bending vibrational mode, $A_1$. The band at 1294 $cm^{-1}$ is attributed to inter-ring stretching Ω, $B_1$. The band at 1510 $cm^{-1}$ is assigned to C–H in-plane bending vibrational mode and ring stretching, $A_1$. The band at 1612 $cm^{-1}$ is assigned to ring stretching vibrational mode, $A_1$.[39]

From Figure 2, we can see that the number and the locations of the 4,4′-dipyridyl peaks remain invariable, which means that the additions of zearalenone antibody and bovine serum albumin have no effect on 4,4′-dipyridyl adsorption and the 4,4′-dipyridyl is steadily adsorbed on the gold nanoparticles. Because of the long distance between the gold nanoparticles and the zearalenone antibody or bovine serum albumin, no SERS signal of zearalenone antibody or bovine serum albumin was observed. Hence, we chose 4,4′-dipyridyl as the Raman reporter for our experiment. To achieve the optimal Raman spectrum, we carried out a series of experiments to optimize the

4,4′-dipyridyl amount and the reaction time of 4,4′-dipyridyl and gold nanoparticles. The results indicate that the proper amount is ca. 30 μL of 0.01 mM 4,4′-dipyridyl and the proper incubation time is ca. 10 min, which corresponds with our previous work.[30]

**Optimization of the Concentrations of the Zearalenone−Bovine Serum Albumin and the Zearalenone Antibody.** For the sake of the optimal experimental results, determining the proper concentration of zearalenone−bovine serum albumin antigen is very important. As a high-cost reagent, we need to avoid unnecessary waste while making it detectable, so it is important to determine the proper concentration while meeting our experiment demands. To obtain the proper concentration, the same volume of zearalenone−bovine serum albumin antigens with the concentrations of 5, 10, 25, 50, 100, and 250 μg/mL were dropped respectively on the glass slides to incubate for 2 h and the antibody used in this test was sufficient. After 2 h incubation, the SERS calibration curves of different concentrations were obtained as shown in Figure 3A. It is found that the Raman intensity increases with the concentration when the concentrations are lower than 50 μg/mL. At 50 μg/mL, the Raman intensity reaches the maximum and when the concentration is over 50 μg/mL, the Raman intensity is unchanged. This indicates that the glass slide has not been completely occupied by the antigen when the concentrations are lower than 50 μg/mL, and when the concentration is beyond 50 μg/mL, zearalenone−bovine serum albumin antigens are excessive. Therefore, the optimal concentration of zearalenone−bovine serum albumin antigen used in our experiment is 50 μg/mL.

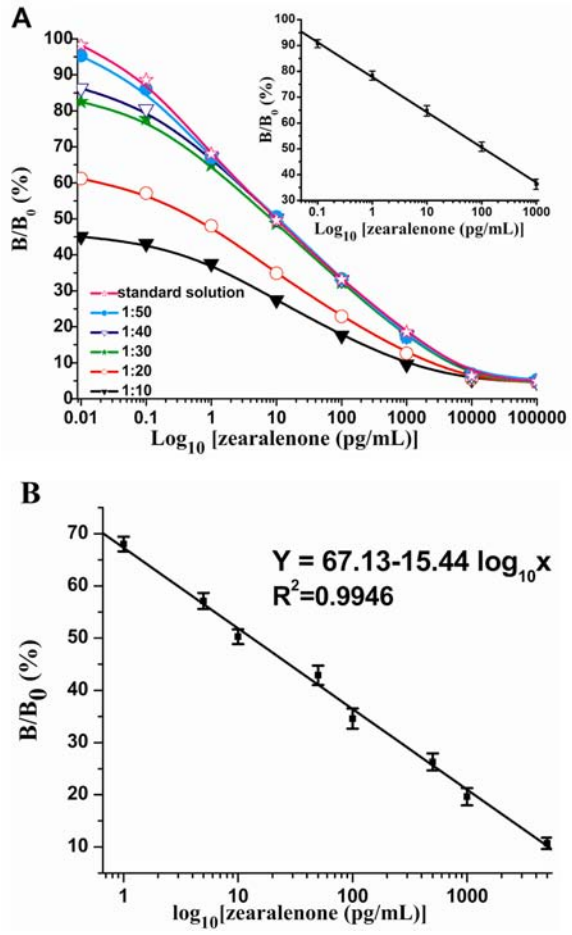

**Figure 5.** (A) Function of centrifugation on the matrix effect in different dilutions of the feed sample and standard curve of the standard solution. The optimal concentration of zearalenone−bovine serum albumin antigen remains at the same level when the sample extract and zearalenone antibodies labeled on the SERS nanoprobes are added together on capture substrates.

Apart from zearalenone−bovine serum albumin antigen, zearalenone antibodies labeled on the SERS nanoprobes are vital and the amount of the antibodies also play an important role in this assay, which demands that the amount is neither too much nor too little. To ensure that the competitive

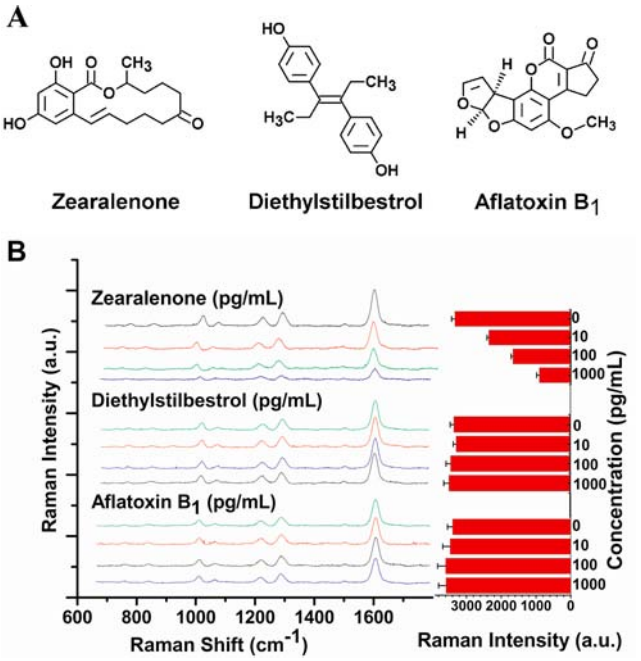

**Figure 6.** Specificity of zearalenone antibody–antigen. (A) The molecular structures of zearalenone, diethylstilbestrol, and aflatoxin $B_1$. (B) Raman spectra of the competitive SERS immunoassay and concentration-dependent SERS intensity of the band at 1612 $cm^{-1}$ of 4,4′-dipyridyl. Error bars indicate the standard deviations of three independent measurements.

immunoassay is established, the amount of antibodies used in the experiment should be comparable to that of zearalenone–bovine serum albumin. In this experiment, 10, 9, 8, 7, 6, 5, 4, and 3 $\mu$L of 0.5 mg/mL zearalenone antibodies were added on the SERS capture substrates with the identical volume 50 $\mu$L of 50 $\mu$g/mL zearalenone antigens, respectively. About 3 h later, we obtained the calibration curve of SERS spectra with different volumes of antibodies. Figure 3B indicates that the Raman intensity reaches the maximum when the volume is 6 $\mu$L. When it is more than 6 $\mu$L, the Raman intensities remain unchanged, which means that the antibodies are excessive. When it is lower than 6 $\mu$L, the Raman intensities increase sharply with the volumes of antibodies increasing. Thus, we determine 5 $\mu$L of 0.5 mg/mL antibodies as the optimal antibodies amount, which indicates that ca. 14 zearalenone antibody molecules are estimated to contact single gold nanoparticle. After we determined the optimal concentrations of the zearalenone–bovine serum albumin antigen and the zearalenone antibody, the free zearalenone concentration was the only variable factor; thus, we could investigate the corresponding relationship between the free zearalenone concentration and the SERS intensity.

**SERS Detection.** In this protocol, a series of zearalenone standard solutions with different concentrations were used to confirm the limit of detection, during which the concentrations of zearalenone standard solutions 1, 10, 100, and 1000 pg/mL, respectively, were used. A control experiment was simultaneously carried out with the solution containing only SERS nanoprobes and phosphate-buffered saline while no zearalenone antigen was added. A blank test was also performed to determine whether nonspecific adsorption existed or not. After SERS nanoprobes and zearalenone standard solutions have been simultaneously incubated on the capture substrate, about 3 h, which has been confirmed as the optimal incubation time, the Raman spectra of the SERS nanoprobes combining with the zearalenone–bovine serum albumin were obtained. In fact, antibody–antigen reaction is very rapid, and in 30 min, most of the reaction has finished.[41,42] We set 3 h as the incubation time to obtain the better sensitivity.

Figure 4A indicates that SERS signal intensities change with the concentrations of zearalenone standard solutions. It clearly shows that the higher the concentrations of zearalenone standard solutions, the weaker the SERS signal intensities. This is because when the concentrations of zearalenone standard solutions get higher, the amount of the SERS nanoprobes conjugated on the capture substrate lessens. This implies that the zearalenone–bovine serum albumin fastened on the capture substrate and the zearalenone antigens in the standard solutions have competitively bound with the zearalenone antibodies labeled on the SERS nanoparticles, which corresponds well with our experimental hypothesis about the detection scheme. To investigate the quantitative relation of SERS signal intensities and zearalenone concentrations in the standard solution, we drew a histogram with the band intensity at 1612 $cm^{-1}$ which is the most intense band. Figure 4B shows that the SERS signal intensity of the control experiment (0 pg/mL free zearalenone) is the highest, ca. 3595 ± 184 a.u., so we set 3227 a.u. (mean of the control intensity minus 2 times standard deviation) as the detection threshold value.[29] Moreover, it is also found that the SERS intensity of 1 pg/mL can be identified from the threshold value with ease and the intensities of any two adjacent concentrations from 1 to 1000 pg/mL can be easily separated. Therefore, ca.1 pg/mL estimated to be the limit of detection for zearalenone in standard solution is acceptable and reasonable. Furthermore, there is an underlying linear relationship between the SERS intensities and their corresponding zearalenone concentrations, implying that quantitative analysis of zearalenone may be feasible in this experiment.

**Feed Sample Analysis.** Whether this method is practical in the detection of zearalenone in feed sample is a question, so experiments were carried out to verify its feasibility. However, for the sake of fulfilling animal requirement of all kinds of nutrition, feed usually contains various ingredients including numerous additives, thus introducing difficulties in zearalenone detection, due to the matrix effect.[43,44] In the present experiment, the matrix is the feed samples diluted with phosphate-buffered saline. Under such circumstances, alleviating the matrix effect is an urgent problem to solve.[45] Only in this way can this method realize its practicability in feed detection. First, we directly detected spiked feed samples. Generally, calibration curves of the pure zearalenone standard solution and feed samples diluted with phosphate-buffered saline (with the final dilutions 1:10, 1:20, 1:30, 1:40, and 1:50) were plotted and the zearalenone concentration range was 0.1–$10^5$ pg/mL, during which $B/B_0$ ($B/B_0$ represents the SERS intensity ratios of different concentrations to 0 pg/mL standard solution) versus the zearalenone concentration is the coordinate axis. However, there is a perfect match only when the zearalenone concentration surpassed 10 pg/mL and the diluted multiples is more than 40. When the zearalenone concentration is lower than 10 pg/mL, none of the dilution curves correspond to the standard solution curve, which suggests that the matrix effect is more obvious in the lower concentration range.

dx.doi.org/10.1021/jf503191e | J. Agric. Food Chem. 2014, 62, 8325–8332

To further alleviate the matrix effect, centrifugal separation has been performed. After the feed sample has been diluted into different concentrations, the solutions were centrifuged for 10 min. Then the supernatant of the feed sample was separated and stored at 4 °C. We set 10 000 rpm as the optimal rotation speed to not only remove the components that are not analyzed but also keep zearalenone undestroyed. Figure 5A shows the function of centrifugation on alleviating the matrix effect and the standard curve of the standard solution which obeys the equation $Y = 77.73-13.59 \log_{10} X$, $R^2 = 0.9992$. After centrifugation, the calibration curves of the 1:30, 1:40, and 1:50 dilute feed samples were similar to that of zearalenone standard solution with the concentration range from 5 to 5000 pg/mL, which indicates that the matrix effect has been effectively diminished. Hence, all experiments were carried out when the feed samples have been diluted 30 times and centrifuged. Figure 5B shows a linear plot which obeys the equation $Y = 67.31-15.44 \log_{10} X$, $R^2 = 0.9969$. On the basis of the calibration curve above, recoveries of 99−105.2% ($n = 3$) and mean relative standard deviation of 8.1% are obtained, which further demonstrates the substantial elimination of the matrix effect compared with the former method. Therefore, this method is appropriate for the quantitative analysis of feed samples.

**Analysis of Zearalenone in Natural Feed Samples.** To validate its availability in natural feed samples, three natural feed samples were analyzed using this method. The feed samples were handled according to the procedure above. However, it was surprising that no SERS signal was obtained. Since matrix effect has been eliminated, the reason may exist in the gold colloid, the buffer pH, or the zearalenone content in the feed sample. The control variable method was used to determine the possible reasons and finally we focused on the zearalenone content, which means the zearalenone content is beyond our detection range. Dilution is a good method to reduce the zearalenone content, so we diluted the samples as 1:30, 1:50, 1:70, and 1:100. When the dilution ratio is 1:50, SERS signal appears, and we calculate the zearalenone content according to the calibration curve. The results are presented in Table 1, with the measured value 111.8 ng/mL ($n = 3$), and relative standard deviation 10.1%. Another two natural feed samples were also analyzed according to the procedure above. From the data in Table 1, we clearly see that the three feed samples are positive. To further confirm the results above, high-performance liquid chromatography (HPLC) was used and the results of the three feed samples have also been listed in Table 1, respectively. The competitive SERS method has a variation in determining zearalenone, which may be due to the difference of sample preparation, laser light intensity, and the instrument. Although HPLC has an excellent accuracy which is even better than ours,[46] the proposed method still has a good enough accuracy with the advantages of high sensitivity, high specificity, and low cost. Moreover, the whole spectrum collection by Raman spectrometry needs only ca. 30 s. It is shorter than that of HPLC, where at least several minutes are needed.[46] Therefore, our method has its characteristic advantages and is suitable to detect zearalenone residuue with very low concentration, especially for the trace detection.

**Investigation of Antibody−Antigen−Mycotoxin Specificity.** The experiments described in this section demonstrate the feasibility of combining SERS and competitive method to detect the presence of specific species in aqueous samples. Zearalenone−bovine serum albumin and free zearalenone competitively binding with antizearalenone monoclonal antibody are used for immunorecognition. Aflatoxin $B_1$, which is a commonly occurring mycotoxin, and diethylstilbestrol, which is another kind of estrogen, are selected to investigate the specificity of antibody−antigen−mycotoxin. Specifically, the competitive immunoassays are carried out as follows: the three reagents with the same concentration in the feed sample were dropped on the capture substrate respectively while SERS nanoprobes were simultaneously added on each capture substrate. After 3 h incubation under room temperature with certain humidity, SERS signals were obtained. Figure 6 shows the chemical structures of the three reagents and their SERS signals, and we also drew the histogram with the SERS band intensity at 1612 $cm^{-1}$ to compare the changes of SERS signal intensity with various concentrations. The SERS signal intensities of aflatoxin $B_1$ and diethylstilbestrol in different concentrations have little changes while that of zearalenone shows a dramatic decline and the histogram shows the changes of the signal intensities along with the concentrations, which indicates that there is a high specificity of zearalenone antibody in recognizing zearalenone antigen. The results of this experiment shown in Figure 6B further establish the viability of our assay concept in natural feed samples detection.

**ABSTRACT:** This study introduces a qualitative method to inspect the compositional authenticity of white nonripened cheeses like Minas Frescal, a typical Brazilian cheese, especially when irregular replacement of milk by whey is suspected. A sodium dodecyl sulfate gel electrophoresis (SDS−PAGE) method, followed by image densitometry, was validated. Cheeses were freeze-dried to electrophoresis, and $\beta$-lactoglobulin ($\beta$-LG) was chosen as the adulteration marker. In gel trypsin digestion followed by matrix assisted laser desorption ionization time-of-flight (MALDI-TOF) mass spectrometry provided its identification. Cheeses with a minimum of 14 mg·g$^{-1}$ of $\beta$-LG are considered to be adulterated. The method shows satisfactory precision with a detection limit of 7 mg·g$^{-1}$. Forty-two commercial samples from inspected establishments were then assessed and subjected to cluster analysis. Compliant and noncompliant groups were set with 24 (57%) authentic samples and 18 (43%) adulterated samples, respectively, showing that proper analytical monitoring is required to inhibit this practice.

**KEYWORDS:** *SDS−PAGE, white cheeses, adulterations, dairy inspection, whey*

## INTRODUCTION

Minas Frescal is a widely consumed cheese in Brazil. It is a white fresh, ready to consume cheese, that usually presents a whitish internal color, a soft consistence, and a close texture with scarce irregular holes. It is a high moisture cheese, whose flavor ranges from mild to slightly acid.[1−3] A national regulation has been established by inspection authority for this product, which shall be obtained from whole or semiskimmed pasteurized milk by enzymatic clotting with rennet and/or other appropriate clotting enzymes, complemented or not by the action of specific lactic bacteria.[4]

In dairy products, modification of composition and adulteration with other dairy or nondairy ingredients may take place for economic reasons.[5,6] In a previous study, unexpected variations were observed in rheological and physicochemical properties of Minas Frescal cheese commercial samples acquired in Brazil. Moreover, based on the electrophoretic profile of those samples, it was suggested that whey was irregularly present in the composition of these products.[7] Considering the large excess and the low price of whey,[8] its fraudulent addition to Minas Frescal cheese production is easily accomplished for financial gain.

Although a reference method is available to detect cow milk in cheeses made from goat, buffalo, and ewe milk in European Union,[9] it seems that adulteration of white cheeses with whey has not been properly assessed, since no analytical method has been validated or is even available with this purpose. Recently, adulterated goat and ewe cheeses were detected in Croatia by isoelectric focusing.[10] Particularly, the addition of whey to several dairy products has been researched for a long time, and depending on the matrix susceptible to adulteration, a different protein marker has to be selected. Proteomic methods have been described with this purpose, such as the classic detection of caseinomacropeptide (CMP) in milk.[11] In Italy, a proteomic approach was performed to assess the adulteration of mozzarella "Fiordilatte" with stored curd and a fragment of the main proteolytic product obtained by rennet digestion of $\alpha_{S1}$-I casein has been patented as a marker protein.[12]

In Brazil, products of animal origin can be inspected by federal, state, or municipal governments. Since 2006, in an attempt to reduce trading restriction in inspected establishments and also to provide technical and sanitary equivalence among those three inspection levels, the Brazilian System of Inspection (SISBI) was created.[13] In that system, an authorized establishment, inspected by a state or municipal inspection service officially recognized as equivalent to the federal inspection service, is allowed to trade its products throughout the whole country. In this growing scenario, where the number of medium and small factories is increasing, the importance of having available analytical methods capable of detecting fraudulent trade practices is evident.

Analytical methodologies that allow the characterization of dairy products can be very useful to support regulative authorities as well as food manufacturers.[14] Polyacrylamide gel electrophoresis (PAGE) is a classic separation method which assisted by advanced scanner and image analysis can result in good separations and high resolutions, leading to accurate and reproducible results.[15] Dodecyl sulfate polyacrylamide gel electrophoresis (SDS−PAGE) has been widely used to identify proteins, and it fits well to dairy products, separating caseins and whey with good resolution.[16−21] This

work aimed to validate an electrophoretic qualitative method to detect Minas Frescal cheese's adulteration by replacement of milk by whey, as a control tool to inspect its authenticity.

## MATERIALS AND METHODS

**Materials.** Whole pasteurized milk (from five different brands), food-grade lactic acid (Purac Sínteses, Campos dos Goytacazes, RJ, Brazil), calcium chloride (Vetec, Duque de Caxias, RJ, Brazil), and commercial rennet (Chr. Hansen A/S, Valinhos, SP, Brazil) were used to prepare cheese reference samples. Commercial Minas Frescal cheeses ($n$ = 42), processed by different state or federally inspected factories (from 7 different states), were purchased at various shops and market stalls in Brazil, within 2−3 weeks after manufacture. Defatted milk powder (Nestlé Brasil Ltda., Araraquara, SP, Brazil) and whole pasteurized milk were purchased at local market. Demineralized whey powder (12.5% net protein content) was obtained from Cooperativa Central Aurora Alimentos (Pinhalzinho, SC, Brazil). Trypsin from porcine pancreas and $\beta$-lactoglobulin (purity ≥90%) from bovine milk were purchased from Sigma-Aldrich (St. Louis, MO). All reagents employed to prepare buffers and solutions were electrophoresis grade and obtained from Bio-Rad Laboratories Inc. (Hercules, CA). All solvents and acids were of analytical grade for HPLC and were purchased from Merck KGaA (Darmstadt, Germany). Standard solution was prepared by diluting $\beta$-lactoglobulin to 1 mg·mL$^{-1}$ with sample buffer before analysis.

**Reference Samples.** Five cheeses were manufactured with commercial pasteurized milk as reference Minas Frescal samples at the laboratory. For the processing of each cheese, milk (4 L) was heated at 37 ± 1 °C, and lactic acid (0.25 mL·L$^{-1}$ of an 85% lactic acid solution), calcium chloride (0.4 mL·L$^{-1}$ of a 40% calcium chloride solution), and commercial rennet (0.9 mL·L$^{-1}$) were added, followed by incubation at 37 ± 1 °C for 40 min. Gel was gently cut into cubes, drained, placed in perforated circular containers (approximately 500 g capacity), and kept overnight under refrigeration for draining. Reference samples were then freeze-dried at a lyophilizer (Liobrás Comércio e Serviço de Liofilizadores, São Carlos, SP, Brazil) and kept at −18 °C.

**SDS−PAGE Analysis.** Freeze-dried cheeses were weighed into polypropylene centrifuge tubes and diluted to 4 mg·mL$^{-1}$ in sample buffer [0.1 M Tris−HCl, pH 6.8; 20% (v/v) glycerol, 2% (v/v) SDS, 5% (v/v) $\beta$-mercaptoethanol, and 0.01% bromophenol blue]. Tubes were moderately shaken on a "wrist action" shaker for 30 min and then heated in water (95 °C) for 5 min. SDS−PAGE was carried out as originally proposed by Laemmli (1970)[22] on a 15% (w/v) separating gel, and sample aliquots of 5 $\mu$L were loaded per well at a Mini Protean Tetra Cell cube (Bio-Rad Laboratories Inc., Hercules, CA). Gels were run at constant voltage (200 V) for 45 min. Molecular weight standards (MWS), consisting of a cocktail of proteins of known molecular weights (aprotinin, 6.5 kDa; lysozyme, 14.4 kDa; trypsin inhibitor, 21.5 kDa; carbonic anhydrase, 31 kDa; ovalbumin, 45 kDa; serum albumin, 66.2 kDa; phosphorylase b, 97.4 kDa; $\beta$-galactosidase, 116.25 kDa; myosin, 200 kDa) (Bio-Rad Laboratories Inc., Hercules, CA), were run together with cheese samples. MWS solution was prepared by diluting the standards 1:20 in sample buffer, followed by heating for 5 min at 95 °C. The solution was cooled, and an aliquot of 5 $\mu$L was loaded at the well. After electrophoresis, gels were stained for 16 h in Coomassie blue dye solution [0.3% (w/v) Coomassie blue R-250, 10% (v/v) acetic acid, and 40% (v/v) methanol] and then destained using 10% (v/v) acetic acid and 40% (v/v) methanol solution until the background color was completely removed. Gels were digitalized using a densitometer (Bio-Rad GS800) and the Quantity One 1-D Analysis software (Bio-Rad Laboratories Inc., Hercules, CA). Densitometry analyses were performed using lane-based background subtraction, followed by measurement of the spots by the area under the peaks. The values in optical density (OD) were then used for statistical analysis. Each sample was analyzed on duplicate gels. Proteins were identified by comparison of their relative mobilities with those of molecular weight standards and by comparison of electropherograms from previous reports.[16,17,20,23]

**Selection of a Marker Protein.** In order to identify a marker protein to evaluate the authenticity of Minas Frescal cheeses, the SDS−PAGE profiles of reference samples (processed as described above) were assessed. Milk powder and whey powder samples were also used as references. Milk powder and whey powder were weighed (10 mg), diluted in sample buffer (2.5 mL), and subjected to electrophoresis.

**Establishment of an Action Level.** Aiming to establish the level of the marker protein which can be accepted in authentic Minas Frescal cheeses, we assessed 42 commercial samples and five reference samples with SDS−PAGE. Optical density (OD) values were subjected to clustering using the $k$-means technique ($k$ = 2) and the R software.[24] The two groups formed were classified as compliant or noncompliant. From the compliant group's OD, an action level was then set as follows:

$$\text{action level} = X + 10s \quad (1)$$

where $X$ is the $\beta$-LG OD mean from compliant samples at cluster analysis and from reference samples and $s$ is standard deviation. Mean was obtained from duplicate determinations.

Aiming to obtain the concentration of the marker protein at the established action level, a reference sample was fortified with $\beta$-LG (six levels) and an analytical curve was built from concentrations (mg·g$^{-1}$ cheese) versus OD. Fortification was done by preparing a solution of freeze-dried cheese in sample buffer, to which the standard solution was added (at 0, 3.125, 6.25, 12.5, 25, and 50 mg·g$^{-1}$). The action level was then calculated in mg·g$^{-1}$ of cheese by linear regression from the theoretical concentrations of the fortified blank sample versus the respective OD.

**Performance Characteristics of Method.** Confirmation of identity of the marker protein, selectivity/specificity, limit of detection (LoD), and precision were assessed to evaluate the method's performance, as recommended by Eurachem (1998)[25] for qualitative methods.

**Confirmation of Identity of the Marker Protein and Selectivity/Specificity.** Protein spots corresponding to the selected marker were manually excised from stained gels obtained from whey and the reference sample. Spots were submitted to destaining in 400 $\mu$L of a 25 mM ammonium bicarbonate/acetonitrile solution (1:1, v/v). The solution was replaced by 200 $\mu$L of pure acetonitrile for 5 min and dried under vacuum for 15 min. The samples were incubated for 18 h at 37 °C in the presence of 10 $\mu$L of 0.01 $\mu$g·$\mu$L$^{-1}$ trypsin. The peptides were extracted by washing the gel pieces 3 times with 50% (v/v) acetonitrile and 5% (v/v) trifluoroacetic acid (TFA) solution, and then the supernatant containing digested peptides was transferred into clean tubes. The extract was dried under vacuum and solubilized in 0.1% TFA. Then 0.5 $\mu$L of sample was thoroughly mixed with 0.5 $\mu$L of a saturated matrix solution (10 mg of $\alpha$-cyano-4-hydroxycinnamic acid in 50% v/v acetonitrile, 1% v/v TFA, 49% water). This peptide matrix solution was spotted onto a target plate. The samples were then subjected to matrix assisted laser desorption ionization time-of-flight (MALDI-TOF) on an Autoflex III Smartbean mass spectrometer (Bruker Daltonics, Bremen, Germany) fitted with a 200 Hz Smartbeam pulsed nitrogen laser emitting at 337 nm and operated in reflectron mode. The extraction voltage was 19 kV. Spectral data were collected in the range of 700−3500 Da using positive ionization. Protein identification was performed by searching in the protein sequence database (Swiss-Prot) using the Mascot search engine (http://www.matrixscience.com). The following parameters were used for database search: taxonomy, mammalian; enzyme, trypsin; variable modifications, oxidized methionine; fragment mass tolerance, 0.5 Da; peptide charge, 1 H$^+$; precursor mass tolerance, 100 ppm. The search was initially performed on peptide mass fingerprinting method, and then the MS/MS Ion Search was used.

**Limit of Detection (LoD).** Limit of detection was established as follows:

$$\text{LoD} = X + 3s \quad (2)$$

where $X$ is the $\beta$-LG optical density mean from compliant commercial samples at cluster analysis and from reference samples and $s$ is

dx.doi.org/10.1021/jf502864e | J. Agric. Food Chem. 2014, 62, 8333−8339

standard deviation. LoD was then calculated in $mg \cdot g^{-1}$ of cheese by linear regression from the theoretical concentrations of fortified the blank sample versus the respective OD.

**Precision.** Both blank and fortified blank samples at concentrations below, at, and above the action level were randomly injected in electrophoresis gels. Blind analysis was carried out by two analysts, and then precision was assessed by calculating the rates of false positives/false negatives as follows:

$$\%\ \text{false positives} = \frac{\text{false positives} \times 100}{\text{total known negatives}} \quad (3)$$

$$\%\ \text{false negatives} = \frac{\text{false negatives} \times 100}{\text{total known positives}} \quad (4)$$

## RESULTS AND DISCUSSION

**SDS−PAGE Analysis.** The major proteins of the milk were individually resolved by SDS−PAGE and then visualized by Coomassie blue staining (Figure 1A). Our results show both typical milk and whey electrophoretic profiles and which major proteins could be identified, as caseins (molecular weight ranging from about 19 kDa to 25 kDa) and whey proteins such as $\beta$-LG (molecular weight of about 18.3 kDa) and $\alpha$-lactalbumin (molecular weight about 14 kDa), in accordance with those cited in the literature.[26,27] Moreover, some of milk's minor proteins, such as serum albumin, immunoglobulin G (IgG), and lactoferrin, were also resolved. As expected, the para-$\kappa$-casein peptide was present in all reference samples and in all authentic Minas Frescal cheese samples.

**Selection of a Marker Protein.** The broad objective in assessing food authentication is to identify markers to characterize the authenticity of food or their potential adulterants/contaminants and use them to resolve authenticity issues. The selected marker has to be specific, and its natural variation must be limited and well characterized.[28] Proteins have been widely used as adulteration markers in dairy products, allowing assessment of their animal species or even the irregular replacement of milk by whey.[11,12,29] In Minas Frescal, $\beta$-LG appeared with low optical density (Figure 1B). This behavior is expected, since milk clotting enzyme acts directly on casein, retaining it in the clot, while whey proteins are expelled with the aqueous phase.[30,31] Being the major protein in the composition of whey and in very low concentration in cheese, $\beta$-LG was chosen as the marker to assess the compositional authenticity of Minas Frescal with SDS−PAGE.

**Establishment of an Action Level.** A strong difference among the protein compositions of the samples was seen (Figure 2A). In 43% of samples ($n$ = 18), caseins appeared as moderately or slightly stained spots. This variable concentration is expected among noncompliant samples, suggesting that, when compositional adulteration occurs, milk is used in different combinations with whey. On the other hand, intense spots of $\beta$-LG can be seen. On the contrary, negligible amounts of $\beta$-LG can be seen in reference samples (Figure 2B). Since these commercial samples were declared by the producers as manufactured with milk, it can be assumed that, in white cheeses like Minas Frescal, a high concentration of $\beta$-LG suggests the use of whey as a raw material in its composition, which is inconsistent with the official regulation.[4]

Estimating a "basal value" is important when selecting an authenticity marker, since it can avoid natural errors in milk proteolysis, physiological responses related to feed and climate,

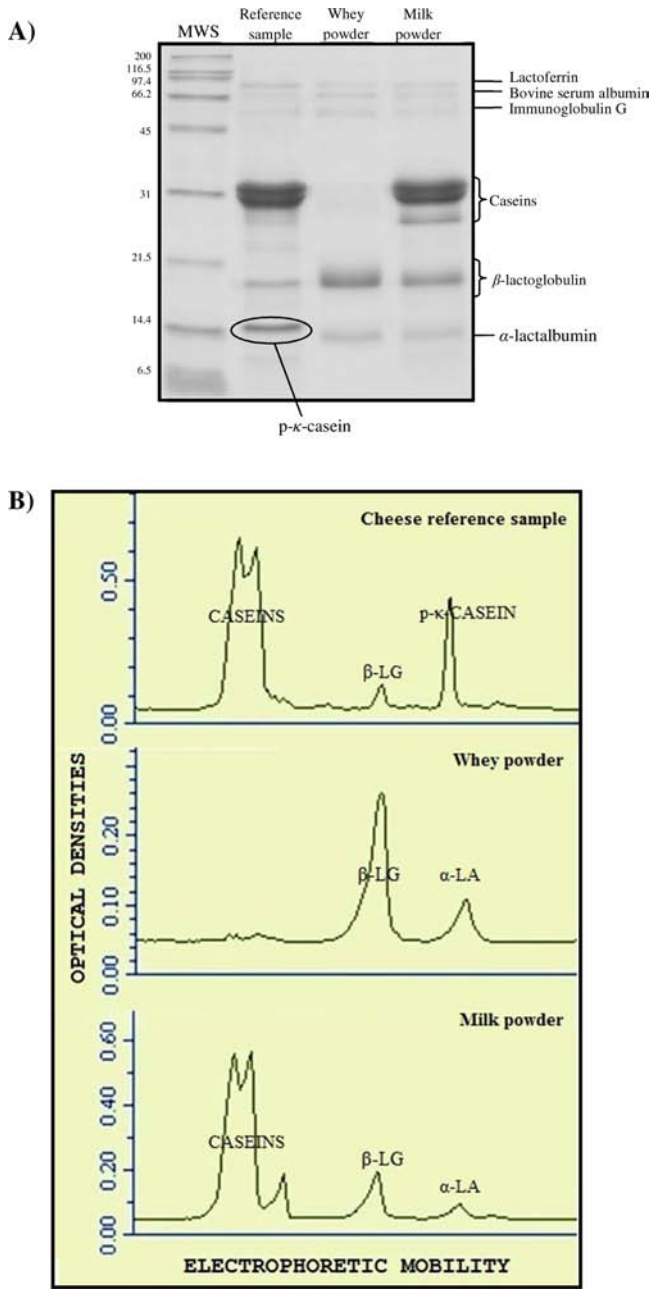

**Figure 1.** SDS−PAGE electrophoretic proteins profile of a Minas Frescal cheese reference sample, demineralized whey powder, and defatted milk powder (A) and respective densitograms (B). $\alpha$-LA: alfa-lactalbumin. $\beta$-LG: $\beta$-lactoglobulin. MWS: molecular weight standards (6.5 to 200 kDa).

and several other factors.[11] The presence/absence of an analyte is not considered to be an absolute measure related to a concentration level of zero but to a specific concentration level.[32] Below this limiting level, analyte concentration is considered insignificant and intrinsic of the sample's composition. In this study, the proposal of an action level aimed to set the maximum OD for the marker protein ($\beta$-LG) in a sample of cheese to be considered compliant (i.e., produced from coagulated milk enzyme). Previously, we tried to establish a casein/$\beta$-LG ratio from the densitometry analysis of cheeses, as a way to distinguish compliant from non-compliant Minas Frescal samples.[7] Although samples could be divided by cluster analysis into two significantly different

dx.doi.org/10.1021/jf502864e | J. Agric. Food Chem. 2014, 62, 8333−8339

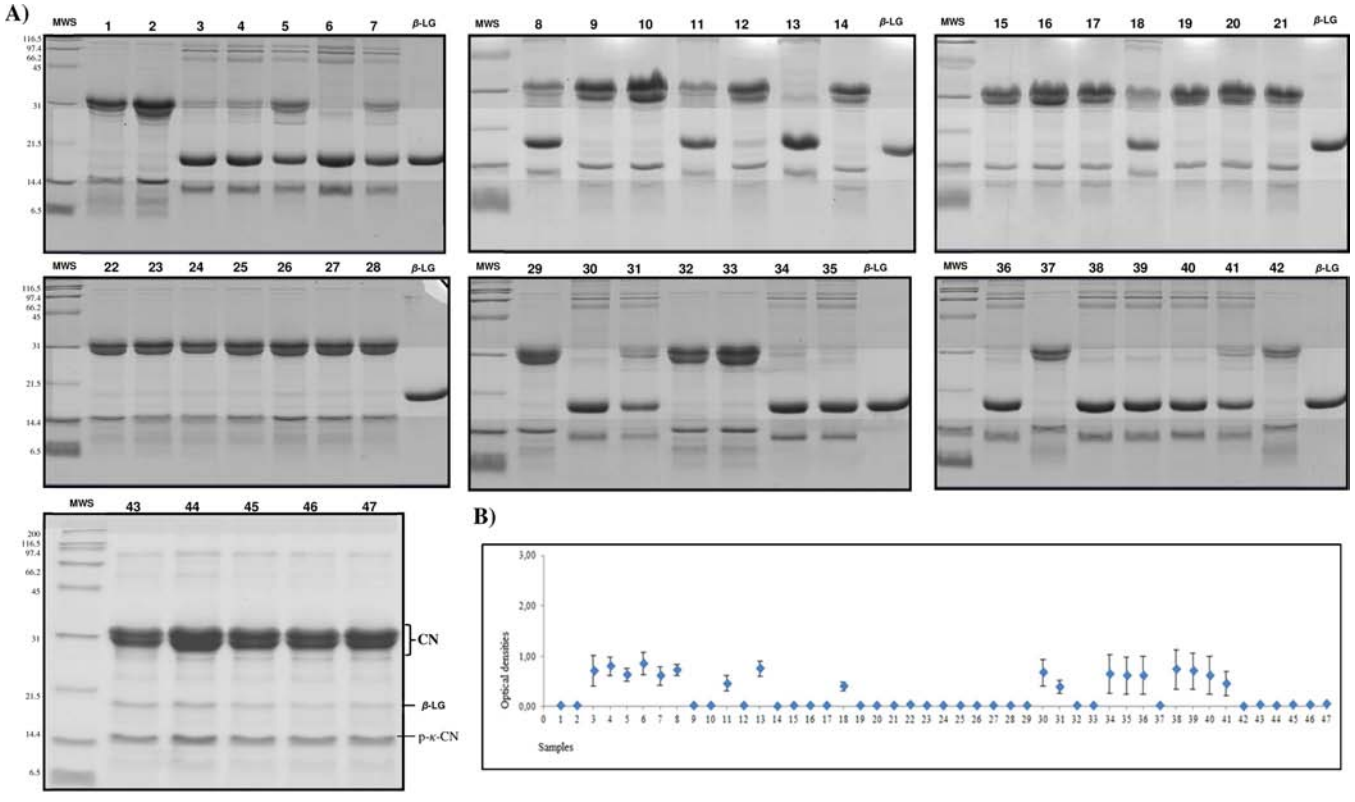

**Figure 2.** SDS−PAGE electrophoretic profiles (A) and mean values ($n$ = 2) of $\beta$-LG optical densities (B) from commercial samples (lanes 1−42) and from reference samples (lanes 43−47) of Minas Frescal cheese. MWS: molecular weight standards (6.5 to 200 kDa). $\beta$-LG: $\beta$-lactoglobulin. CN: caseins. p-$\kappa$-CN: para-kappa-casein.

groups, the wide variation led to set a single adulteration marker instead of calculating a cutoff value for this ratio.

Optical densities for the $\beta$-LG spots from both commercial and reference samples are shown in Figure 2B. Although a wide variation can be observed, cluster analysis revealed two distinct groups: compliant (group A) and noncompliant (group B). As expected, group A consisted of the reference samples and of most commercial cheeses (samples 1, 2, 9, 10, 12, 14−17, 19−29, 32, 33, 37, 42). This cluster showed low OD for the $\beta$-LG spot, ranging from 0.01 to 0.04. On the other hand, group B consisted of the reference samples and most of the commercial samples (samples 3−8, 11, 13, 18, 30, 31, 34−36, 38−41) which showed higher densities for that protein, ranging from 0.39 to 0.85. OD values ranging from 0.04 to 0.39 have not been observed for any sample. Since compliant Minas Frescal cheeses tended to present low OD for $\beta$-LG, an action level, based on the mean value (OD = 0.02) presented by this cluster plus the standard deviation multiplied by 10, could be set. Thus, compliant/noncompliant cheeses can be easily distinguished. Linear regression from the theoretical concentrations of fortified blank samples versus the respective OD resulted in the calculation of the concentration of $\beta$-LG at the action level (14 mg·g$^{-1}$). The results shown in Figure 3 indicated that the intensity of the $\beta$-LG spot was almost linearly related to the concentration of the analyte ($R^2$ = 0.992). A qualitative method must respond to either the presence or absence of the analyte detected either directly or indirectly in a certain amount of sample.[33] The final decision is made by comparing the response of a test sample to the response of a reference sample containing the analyte at the action level. Since the cutoff concentration (action level) has been set, a blank sample fortified with $\beta$-LG must be assessed at the same gel in which unknown samples are being analyzed. If an unknown sample has a higher OD than the fortified sample, it is considered to be positive (noncompliant), and whey must have been used in replacement of milk. On the other hand, if $\beta$-LG OD is lower than fortification, the sample is considered to be negative (compliant), and milk is presumed to have been properly processed.

**Performance Characteristics of Method.** Table 1 shows the results obtained during performance assessment for this qualitative method. By the position of the $\beta$-LG spots in terms of molecular weight and the peptide mass fingerprints obtained by MALDI-TOF mass spectrometry, identification was provided (Figure 4). The use of confirmatory techniques can be useful as a means of verifying the analyte's identity and so to assess the selectivity/specificity of a proposed method.[25] By matching the peptide masses generated following the trypsin digestion with those available in the database, the selected spots were successfully identified as homologous to *Bos taurus* $\beta$-LG, one of bovine milk's major proteins. Significant ($p$ < 0.05) protein scores were obtained (Mascot score = 146). To confirm the identification of $\beta$-LG, the MS/MS spectra of three greater intensity peptides ($m/z$ 837; 1635; 2313) were obtained. A total of 17 peptides matched with 80% of the $\beta$-LG sequence (Table 2). A number of unidentified peaks may represent contaminants from the gel, Coomassie staining, trypsin, or the matrix used. Mass spectrometry provides unequivocal molecular mass identification of peptides. The main advantages of MALDI are rapidity, simplicity, and sensitivity, especially if compared to electrophoretic and chromatographic techniques.[34] Recently, the combination of two-dimensional electro-

phoresis and MALDI-TOF mass spectrometry was also applied to identify an adulteration marker in mozzarella.[12]

The LoD was set to 7 mg·g$^{-1}$, which corresponds to the lowest concentration of the analyte that can be confidently detected by this method. The method presented good precision, since neither false positives nor false negatives have been detected by any analyst below (7 mg·g$^{-1}$), at (14 mg·g$^{-1}$), and above (28 mg·g$^{-1}$) the action level. During the precision assessment, the chosen concentrations for $\beta$-LG fortification were considerably lower than the detected concentrations at the adulterated commercial samples, probably because whey is being deliberately used as a noncompliant raw material (Figure 2). Thus, it must be concluded that, when adulteration with whey is practiced during the manufacturing of Minas Frescal cheese, the concentration for $\beta$-LG is consistently higher than the action level set by the present method. Moreover,

adulteration with whey may be a common, underestimated feature in the processing of white nonripened cheeses. This situation may offer economic profit, since whey is cheaper than milk. As previously reported, when adulterated with whey, Minas Frescal cheeses assume some Ricotta-like properties, presenting a yellowish white color, lower moisture content, and less deformability and tending to be more viscous than elastic.[7] In fact, due to the impossibility of clotting the whey, it can be inferred that heating is employed during the fraud, in a very similar way to Ricotta processing. Adulterated products are then mislabeled, and milk is falsely declared as being used as raw material. Considering the difficulty of identifying this noncompliant practice during factory inspection, laboratory support and availability of a method to detect adulteration of Minas Frescal cheese compositional authenticity is quite convenient.

The proposed method in the present work has been successfully applied in our laboratory and constitutes a simple control tool to inspect Minas Frescal cheese compositional authenticity, being helpful to official dairy inspection. The main advantages of this method rely on the low cost and reasonable simplicity of SDS−PAGE, and the possibility of simultaneous analyzing of several samples. Noncompliant products (43%) were detected, enlightening the need for proper analytical monitoring in order to inhibit this practice.

[‡]Departamento de Química, Universidade Federal de Santa Maria, Santa Maria, Rio Grande do Sul 97105-900, Brazil

**ABSTRACT:** This work reports the development of a method for Fe extraction in white and red wines using dispersive liquid–liquid microextraction (DLLME) and determination by ultraviolet–visible spectrophotometry. For optimization of the DLLME method, the following parameters were evaluated: type and volume of dispersive (1300 $\mu$L of acetonitrile) and extraction (80 $\mu$L of $C_2Cl_4$) solvents, pH (3.0), concentration of ammonium pyrrolidinedithiocarbamate (APDC, 500 $\mu$L of 1% m/v APDC solution), NaCl concentration (not added), and extraction time. The calibration curve was performed using the analyte addition method, and the limit of detection and relative standard deviation were 0.2 mg $L^{-1}$ and below 7%, respectively. The accuracy was evaluated by comparison of results obtained after Fe determination by graphite furnace atomic absorption spectrometry, with agreement ranging from 94 to 105%. The proposed method was applied for Fe determination in white and red wines with concentrations ranging from 1.3 to 4.7 mg $L^{-1}$.

**KEYWORDS:** *dispersive liquid–liquid microextraction, iron, wine, UV–vis spectrophotometry, food analysis, sample preparation, GFAAS*

## INTRODUCTION

Wine is defined as a beverage obtained exclusively by alcoholic fermentation of grapes.[1] With regard to its chemical composition, wine has a great concern considering nutritional and toxicological aspects, because it is a worldwide consumed beverage.[2] Among the main components present in wine, some of them can be cited as volatile organic compounds (ethanol), non-volatile organic compounds (superior alcohols, sugars, organic acids/salts, and others) and major and trace elements.[3] The presence of metals in wine can be originated from natural and/or anthropogenic sources.[2] The range and level of inorganic compounds in wine depends upon several factors, such as the type of grape, soil characteristics, environmental conditions, and contamination during the manufacturing process.[4]

Iron is an essential element, which plays an important role in biological systems, participating in the maintenance of cellular homeostasis and several metabolic and fermentation processes, such as enzymatic activator, stabilizer, or as a functional component of proteins. Iron deficiency leads manly to anemia, causing changes in muscle metabolism and dysfunctions in the immunological system.[5] Otherwise, excess of Fe cause hemochromatosis, characterized by pigmentation in the skin, pancreatic injury, such as diabetes, cirrhosis, and others.[6] The presence of iron (ferric salts) in wine may cause cloudiness and precipitation, which modify organoleptic characteristics.[7]

In general, detection techniques, such as flame atomic absorption spectrometry (FAAS),[7] graphite furnace atomic absorption spectrometry (GFAAS),[8] and inductively coupled plasma–optical emission spectrometry (ICP–OES),[9] have been applied for Fe determination in wine samples. Although there are a few works reporting ultraviolet–visible (UV–vis) spectrophotometry for the determination of Fe in wine, it is a useful technique and stands out mainly by its availability, simplicity, and relatively low cost when compared to other spectrometric techniques already cited.[10] However, the direct element determination at low concentrations by UV–vis is often difficult because of its insufficient sensitivity and selectivity. Besides, some wines (especially the red wines) show an intense color, which causes several interferences for UV–vis detection.[11] Therefore, a prior extraction and preconcentration step is convenient, especially for matrix removal. Thus, many sample preparation methods, such as solid-phase extraction (SPE),[7] cloud point extraction (CPE),[12,13] and liquid–liquid extraction (LLE),[14,15] have been evaluated for subsequent element determination in wine. However, some of these methods demand excessive solvent consumption, high waste generation, and long extraction times.

Recently, dispersive liquid–liquid microextraction (DLLME) was developed[16] as an alternative for conventional LLE. This method shows some advantages, such as simplicity, quickness, low waste generation, and good enrichment factors.[17] Initially, DLLME was employed for the extraction of organic analytes from aqueous samples.[16] However, it has recently been applied for element extraction[18] and selected chemical species.[19] It is important to mention that, when DLLME is applied for

extraction of elements (or their species), it is necessary to perform a chemical modification (addition of a complexant agent), which results in a complex with affinity by extraction solvent, which can be easily extracted.[20]

In this sense, the aim of this work was to develop a method for Fe extraction in white and red wine samples using DLLME to allow for the determination by UV−vis. Some parameters, such as type and volume of dispersive and extraction solvents, pH, complexant agent [ammonium pyrrolidinedithiocarbamate (APDC)] concentration, NaCl concentration, and extraction time, were exhaustively investigated. The optimized method was applied for Fe determination in commercial white and red wine samples. For accuracy evaluation, Fe was also determined by GFAAS in all samples after sample digestion.

## 2. EXPERIMENTAL SECTION

**2.1. Instrumentation.** Iron determination was performed in a Shimadzu UV−vis spectrophotometer (model UV-2550, Japan) with 1.0 cm quartz microcells. Iron was determined [as a complex of $Fe(APDC)_3$] at 587 nm using peak height.[18]

For results comparison, a graphite furnace atomic absorption spectrometer (model AAnalyst 800, PerkinElmer, Waltham, MA) equipped with a Zeeman-effect background correction system and an auto sampler (model AS 800, PerkinElmer) were used for the analysis of wine samples previously digested with nitric acid. Transversely heated pyrolytically coated graphite tubes using standard platforms were used throughout. A Fe hollow cathode lamp (Hamamatsu Photonics, Japan) was (248.3 nm). The spectral bandpass was set at 0.2 nm. The main conditions of the heating program were optimized, and the follow temperatures were chosen: drying 1, ramp of 15 °C $s^{-1}$ up to 90 °C and hold for 15 s; drying 2, ramp of 5 °C $s^{-1}$ up to 130 °C and hold for 10 s; pyrolysis, ramp of 15 °C $s^{-1}$ up to 1300 °C and hold for 20 s; atomization, ramp of 2000 °C $s^{-1}$ up to 2400 °C and hold for 6 s; and clean out, ramp of 500 °C $s^{-1}$ up to 2500 °C and hold for 3 s. Results were obtained using integrated absorbance (peak area), with 20 $\mu$L of reference solutions or sample extract and 5 $\mu$L of 1000 mg $L^{-1}$ Pd solution (Merck, Germany), which were injected into the graphite tube. Argon (99.999%, White Martins, Brazil) was used as the purge gas. Wine samples were digested in a heating block with open vessels. About 2 mL of sample were transferred to the vessels and submitted to a step for alcohol removal (80 °C for 2 h). After cooling, 4 mL of concentrated $HNO_3$ was added, followed by heating at 80 °C for 1 h and 120 °C for 1 h. After cooling, the digests were diluted with ultrapure water up to 50 mL for further Fe determination by GFAAS.

A centrifuge (model 80-2B, Centribio, Brazil) with 15 mL calibrated centrifuge tubes was used for separation of phases after the DLLME procedure. The pH was adjusted using HCl or NaOH solutions with a Hanna pH meter (model pH21, Brazil).

**2.2. Reagents.** All reagents used in this work were of analytical grade. Ultrapure water was purified by a Direct-Q UV3 purification system (resistivity of 18.2 MΩ cm, Millipore, Billerica, MA). Stock reference solutions of 100 mg $L^{-1}$ Fe were prepared by dissolving an appropriate amount of $FeNH_4(SO_4)_2{\cdot}12H_2O$ (Vetec, Brazil) in 1.0 mol $L^{-1}$ HCl (Merck). Other reference solutions were prepared daily by serial dilution of stock solution in ultrapure water. The complexant agent (APDC, purity of 99%, Sigma-Aldrich, St. Louis, MO) was prepared by dissolving an appropriate amount of this reagent in ultrapure water. Dichlorobenzene ($C_6H_4Cl_2$, $d$ = 1.30 g $mL^{-1}$), carbon tetrachloride ($CCl_4$, $d$ = 1.59 g $mL^{-1}$), monochlorobenzene ($C_6H_5Cl$, $d$ = 1.11 g $mL^{-1}$), and tetrachloroethylene ($C_2Cl_4$, $d$ = 1.62 g $mL^{-1}$) were evaluated as extraction solvents and purchased from Vetec. Acetone, acetonitrile, ethanol, methanol, and tetrahydrofuran (THF) were evaluated as dispersive solvents and obtained from J.T.Baker (Center Valley, PA). Solutions of 0.1 mol $L^{-1}$ HCl and 0.1 mol $L^{-1}$ NaOH (both Merck) were used to adjust the pH of wine samples. All materials used in this work were previously cleaned by immersion in 20% (v/v) $HNO_3$ (Merck) solution for 24 h and washed with ultrapure water.

**2.3. Samples.** Samples used in this work (two samples of white wine and five samples of red wine) were produced and purchased in Rio Grande do Sul State (Brazil). All samples were stored in glass bottles in the dark at room temperature and were named as WW1 and WW2 (white wine) and RW1, RW2, RW3, RW4, and RW5 (red wine). The alcohol content of samples ranged from 10 to 13.4%. Sample WW1 (1 mL of sample, pH adjustment and dilution up to 5 mL with water) was used for method optimization.

**2.4. DLLME Optimization.** Initially, experiments were performed to evaluate the wavelength with a maximum absorbance signal and less susceptible to interferences on Fe determination by UV−vis. The formation of the sedimented phase using all possible combinations between extraction and dispersive solvents was evaluated. Some parameters of DLLME, such as type of dispersive solvent (acetone, acetonitrile, ethanol, methanol, and THF), volume of dispersive solvent (100−1500 $\mu$L), type of extraction solvent ($C_6H_4Cl_2$, $CCl_4$, $C_6H_5Cl$, and $C_2Cl_4$), volume of extraction solvent (20−160 $\mu$L), pH (2−4), APDC concentration (0.1−3%, m/v), extraction time (0.5−5 min), and NaCl concentration (0−0.5 mol $L^{-1}$), were evaluated. For these experiments, samples were spiked with a Fe(III) solution up to a final Fe concentration of 2 mg $L^{-1}$, and results were shown as Fe recovery (%). Even considering the natural Fe concentration, samples were spiked to ensure the detectability of analyte and to allow for a suitable comparison of extraction conditions.

**2.5. DLLME Procedure.** Aliquots of 1 mL of wine and 500 $\mu$L of APDC solution were placed in a 15 mL glass tube with a conic bottom and diluted up to 5 mL with ultrapure water. The pH was adjusted with HCl or NaOH solutions. A mixture containing the dispersive and extraction solvent was quickly injected into the sample solution with aid of a 2.5 mL microsyringe. After injection, a cloudy solution was formed, which was centrifuged at 3000 rpm for 3 min, and small droplets of extraction solvent containing the complexed analyte [$Fe(APDC)_3$] were deposited at the bottom of the glass tube. To reduce some interference during the measurements, the sedimented phase (extract) was washed with ultrapure water (3 mL and centrifugation at 3000 rpm for 3 min). The aqueous phase was removed, and extract was further diluted up to 3 mL with acetonitrile for subsequent Fe determination by UV−vis.

All statistical calculations were performed using GraphPad InStat software (GraphPad InStat Software, Inc., version 3.06). A significance level of 95% was adopted for all comparisons.

## 3. RESULTS AND DISCUSSION

Initially, experiments were performed to find the spectral region with maximum absorbance for the $Fe(APDC)_3$ complex. In a previous study of our group,[18] APDC was used for complexation of Fe(II) and Fe(III) species. It was observed that Fe(III) is instantaneously complexed by APDC, while Fe(II) is complexed by APDC and quickly oxidized to Fe(III), making it difficult to perform Fe speciation analysis.[18] It was observed [using an aqueous solution containing Fe(III) and APDC] that $Fe(APDC)_3$ complex shows one absorption band in UV region (wavelength of maximum absorbance at 354.0 nm) and two absorption bands in visible region (wavelengths of maximum absorbance at 499.0 and 587.0 nm). Although the most intense absorption band was in the UV region (data not shown), it was highly influenced by the absorption band of APDC, making the use of this wavelength difficult for analytical purposes. Thus, to minimize possible interferences, the wavelength of 587.0 nm was selected for Fe determination by UV−vis.

**3.1. Effect of the Type of Extraction and Dispersive Solvents.** The choice of dispersive and extraction solvents is essential to obtain suitable analyte recoveries using DLLME. The extraction solvent should have the ability to extract the analytes and present low solubility in water.[21] Initially, several combinations between extraction and dispersive solvents were qualitatively evaluated (results not showed) for red and white

wines. The main parameters to choose the solvents that were used for subsequent experiments were taken into account, with the minimum amount of solids around the drop and the minimum undesirable effects (e.g., changes in baseline) during measurements by UV−vis. In this case, solvents with higher density than water, such as dichlorobenzene, carbon tetrachloride, monochlorobenzene, and tetrachloroethylene, were evaluated as the extraction solvent. These solvents were investigated using 50 $\mu$L of extraction solvent combined with 500 $\mu$L of acetonitrile as the dispersive solvent. As showed in Figure 1, the higher recovery (48%) was found using

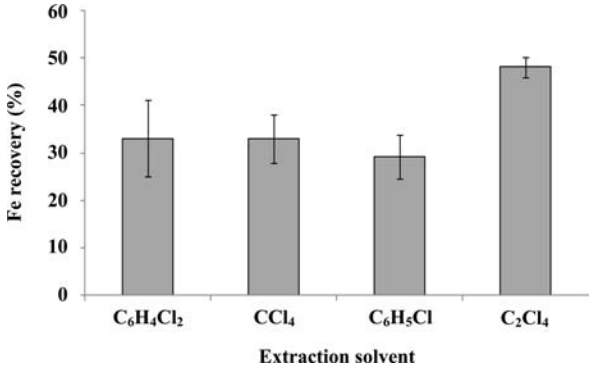

**Figure 1.** Effect of the type of extraction solvent on Fe recovery. Conditions: 5 mL of white wine sample (5 times diluted), addition of 240 $\mu$L of 25 mg $L^{-1}$ Fe(III) solution, 500 $\mu$L of 1% APDC, 50 $\mu$L of extraction solvent, 500 $\mu$L of dispersive solvent (acetonitrile), and pH 3.3. The error bars represent the standard deviation ($n$ = 5).

tetrachloroethylene, whereas the recoveries for other solvents were lower than 33%. Additionally, tetrachloroethylene presented the lowest relative standard deviation (RSD, about 3%), which was also considered for choosing this solvent for further experiments.

For the selection of the dispersive solvent, the key factor is the miscibility of dispersive solvent into the extraction solvent and aqueous sample.[22] The effect of dispersive solvent (acetone, acetonitrile, ethanol, methanol, and THF) on Fe extraction was evaluated using 500 $\mu$L of each solvent and 50 $\mu$L of tetrachloroethylene (as the extraction solvent). As can be seen in Figure 2, the highest recovery (about 48%) was obtained using acetonitrile, with RSD below 2%. Thus, acetonitrile was used as the dispersive solvent for subsequent experiments.

**3.2. Effect of Volumes of Dispersive and Extraction Solvents.** The volume of the dispersive solvent is an important parameter in DLLME because, at small volumes, the dispersion of the extraction solvent does not occur and the cloudy solution is not formed. On the other hand, the use of large volumes increases the solubility of the extraction solvent (and analyte) in the aqueous phase, decreasing the extraction efficiency.[23] After dispersive (acetonitrile) and extraction (tetrachloroethylene) solvents have been chosen, experiments were performed to evaluate the volume of these solvents. The volume of acetonitrile ranged from 200 to 1500 $\mu$L in combination with 50 $\mu$L of $C_2Cl_4$ and 500 $\mu$L of 1% (m/v) APDC at pH 3.3. As can be seen in Figure 3, Fe recovery increased according to the increase of acetonitrile volume up to 1300 $\mu$L. A significant difference (Tukey−Kramer test) between 1300 and 1500 $\mu$L of acetonitrile was not observed,

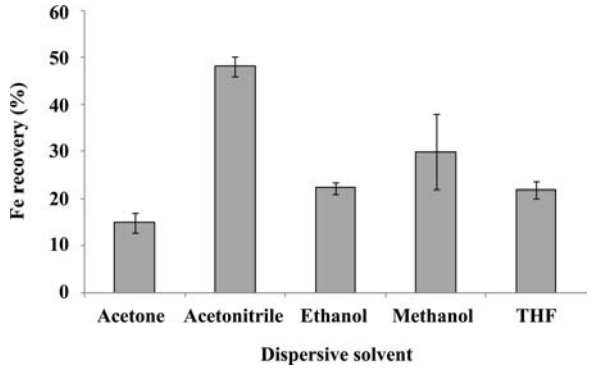

**Figure 2.** Effect of the type of dispersive solvent on Fe recovery. Conditions: 5 mL of white wine sample (5 times diluted), addition of 240 $\mu$L of 25 mg $L^{-1}$ Fe(III) solution, 500 $\mu$L of 1% APDC, 500 $\mu$L of dispersive solvent, 80 $\mu$L of extraction solvent ($C_2Cl_4$), and pH 3.3. The error bars represent the standard deviation ($n$ = 5).

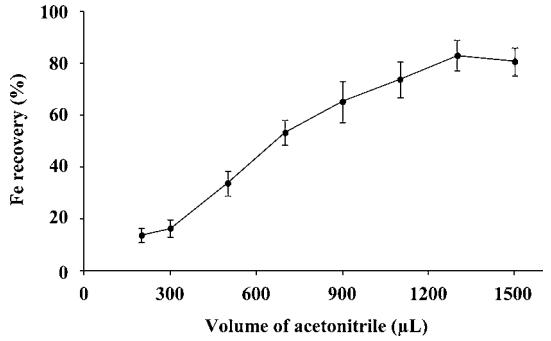

**Figure 3.** Effect of the dispersive solvent volume (acetonitrile) on Fe recovery. Conditions: 5 mL of white wine sample (5 times diluted), addition of 240 $\mu$L of 25 mg $L^{-1}$ Fe(III) solution, 500 $\mu$L of 1% APDC, 80 $\mu$L of extraction solvent ($C_2Cl_4$), and pH 3.3. The error bars represent the standard deviation ($n$ = 5).

and the condition using 1300 $\mu$L was selected for further experiments.

After optimization of the volume of acetonitrile (1300 $\mu$L), the volume of tetrachloroethylene was evaluated from 20 and 160 $\mu$L. Results are shown in Figure 4, and a significant difference (Tukey−Kramer test) was not observed among 40 and 160 $\mu$L of $CCl_4$. Considering the use of lower volumes of

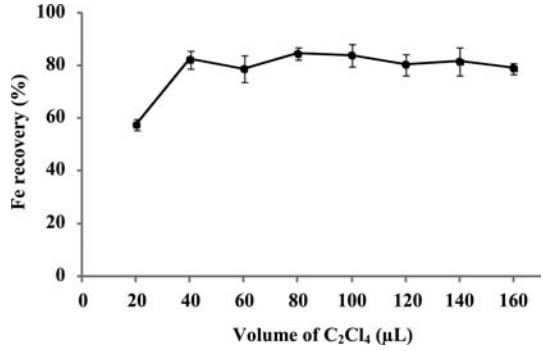

**Figure 4.** Effect of the extraction solvent volume ($C_2Cl_4$) on Fe recovery. Conditions: 5 mL of white wine sample (5 times diluted), addition of 240 $\mu$L of 25 mg $L^{-1}$ Fe(III) solution, 500 $\mu$L of 1% APDC, 1300 $\mu$L of dispersive solvent (acetonitrile), and pH 3.3. The error bars represent the standard deviation ($n$ = 5).

dx.doi.org/10.1021/jf5019774 | J. Agric. Food Chem. 2014, 62, 8340−8345

tetrachloroethylene (from 20 to 60 $\mu$L), it was difficult to handle the extract because of the low volume of solvent. Thus, 80 $\mu$L was chosen for the subsequent experiments, which presented the lowest RSD values (about 2%) and also assured a suitable amount of extraction solvent.

**3.3. Effect of pH.** The effect of pH for element extraction using DLLME has an important role on the formation of the complex and its subsequent extraction. The influence of pH in the Fe recovery was evaluated from 2 to 4. Results are shown in Figure 5. Using pH 3, Fe recovery of about 80% was obtained

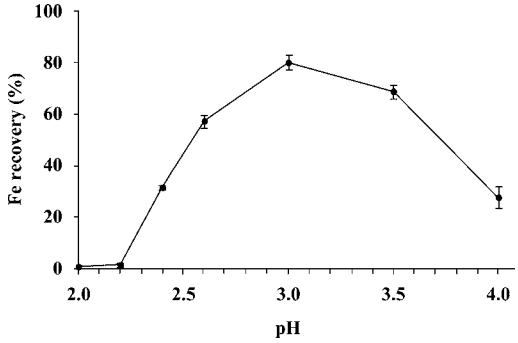

**Figure 5.** Effect of pH on Fe recovery. Conditions: 5 mL of white wine sample (5 times diluted), addition of 240 $\mu$L of 25 mg $L^{-1}$ Fe(III) solution, 500 $\mu$L of 1% APDC, 80 $\mu$L of extraction solvent ($C_2Cl_4$), and 1300 $\mu$L of dispersive solvent (acetonitrile). The error bars represent the standard deviation ($n$ = 5).

(RSD of 3%). For pH values below 3, low recovery values could be attributed to the protonation of APDC (complexant agent). Similarly, low recoveries were obtained at pH values higher than 3, which can be attributed to the formation of Fe–hydroxyl complexes. It can directly affect the transference of analyte to the extraction solvent because the formation of the Fe(APDC) complex is avoided.[24] Therefore, pH 3 was selected for further experiments. This pH (3) was in agreement with those found for Fe extraction using APDC as the complexant agent.[25]

**3.4. Effect of the APDC Concentration.** The effect of the APDC concentration was investigated using 500 $\mu$L of solution ranging from 0.1 to 3% (m/v). The maximum recoveries (about 80%) were found using 1% APDC solution, which remained constant up to 3%. Once significant differences ($p$ > 0.05) among the values ranging from 1 to 3% were not observed, 1% APDC solution was selected for further studies. For the APDC concentration below of 1%, the lower recoveries can be explained because of the low APDC concentration, which was not enough for complete complexation of the analyte, especially because of the presence of other ions that could compete with the analyte by complexation with APDC.

**3.5. Effect of the NaCl Addition.** Generally, the addition of salt in the DLLME procedure increases the extraction efficiency because of the salting out effect that promotes the transfer of analyte to the organic phase by decreasing its solubility in the aqueous phase.[26] To investigate the influence of ionic strength, experiments were performed by adding variable amounts of NaCl (from 0 to 25 g $L^{-1}$). Other experimental conditions were kept constant, but at this range of the NaCl concentration, no statistical difference (Tukey–Kramer test) on Fe recovery was observed. Thereby, for further studies, NaCl was not added.

**3.6. Effect of the Extraction Time.** In general, the extraction time for DLLME is defined as the time between the injection of the mixture of dispersive and extraction solvents before the centrifugation.[27] The extraction time was evaluated from 0.5 to 5 min, but results (not shown) did not presented significant influence (Tukey–Kramer test) on Fe recovery. Because of the large surface area between the extraction solvent and aqueous phase after the formation of a cloudy solution, the complex quickly diffuses into the extraction solvent.[28] Therefore, the DLLME procedure was considered time-independent, which is an important advantage of the proposed method.

**3.7. Analytical Performance.** The optimized DLLME method was evaluated considering some parameters, such as linearity, limit of detection (LOD), limit of quantification (LOQ), accuracy, and precision. A complementary study for evaluating the matrix effect on Fe determination by UV–vis was also performed comparing the slopes of calibration curves, through the DLLME method, in aqueous reference solution and wine samples. When these slopes were compared, suppression in the analytical curve of about 16 and 26% was found for white and red wines, respectively. This suppression was also observed during method optimization, once recoveries were not better than 84%. Thus, to minimize this effect, the instrument calibration was carried out using a calibration curve with analyte addition. It is important to point out that the behavior (slope) for the same type of wine (white or red) was similar for all samples. In this sense, for Fe determination in white wine, sample WW1 was used for instrument calibration. Similarly, for red wine, sample RW1 was used for instrument calibration for further Fe determination. The calibration range was linear from 0.75 to 2.5 mg $L^{-1}$ Fe(III) with coefficients of determination ($R^2$) of 0.9985 and 0.9988, for white and red wines, respectively. It is important to mention that the effect of coexisting ions was also investigated. As expected, it was observed that transition metals, such as $Cd^{2+}$, $Cr^{3+}$, $Mn^{2+}$, $Ni^{2+}$, $Pb^{2+}$, $Sn^{2+}$, and $Zn^{2+}$, with concentration below 1 mg $L^{-1}$, did not affect Fe extraction/determination by UV–vis spectrophotometry. For major elements, such as $Ca^{2+}$, $K^{+}$, $Mg^{2+}$, and $Na^{+}$, the concentration limit is about 5000 mg $L^{-1}$. It is important to mention that $Co^{2+}$ and $Cu^{2+}$ have a strong influence on Fe extraction/determination (concentration limit of about 0.4 mg $L^{-1}$).

The LOD and LOQ were estimated using a calibration curve with analyte addition, defined as 3 and 10 times the standard deviation of 10 measurements of blanks divided by the slope of the calibration curve.[29] The LOD and LOQ were 0.2 and 0.8 mg $L^{-1}$, which are significantly lower than the maximum Fe concentration established by Brazilian legislation. Considering that the proposed DLLME method is relatively fast and low cost, it can be an important alternative for Fe monitoring in a wine sample easily applied in routine analysis.

Because of the lack of a certified reference material presenting certified values for Fe in wine samples, accuracy was evaluated by comparison to Fe determination by GFAAS. It is important to mention that Fe determination by GFAAS was performed using samples decomposed in a heating block with open vessels. Results are summarized in Table 1. By comparison to results obtained by GFAAS, the proposed method showed an agreement ranging from 93 to 105% for all samples, with RSD lower than 7%. The proposed method was also applied for Fe determination in commercial white and red wine samples (Table 1), and the concentration ranged from 1.3 to 4.7 mg $L^{-1}$ and from 2.5 to 4.2 mg $L^{-1}$, respectively. It is

**Table 1. Iron Determination in White and Red Wines by UV−vis and GFAAS (Results in mg $L^{-1}$ ± Standard Deviation; $n$ = 5)**

| sample | UV−vis | GFAAS |
|---|---|---|
| white wine 1 | 1.3 ± 0.1 | 1.4 ± 0.1 |
| white wine 2 | 4.7 ± 0.1 | 5.0 ± 0.2 |
| red wine 1 | 4.2 ± 0.2 | 4.4 ± 0.2 |
| red wine 2 | 3.3 ± 0.1 | 3.2 ± 0.1 |
| red wine 3 | 3.9 ± 0.2 | 4.1 ± 0.3 |
| red wine 4 | 2.5 ± 0.1 | 2.5 ± 0.1 |
| red wine 5 | 3.0 ± 0.2 | 3.0 ± 0.2 |

worth highlighting that results are below the maximum limit of Fe in Brazilian legislation (maximum value of Fe in wine is 15 mg $L^{-1}$), making the proposed extraction procedure appropriate for Fe control in wines.

In summary, the proposed DLLME method combined with UV−vis spectrophotometry was successfully developed for total Fe determination in wine samples. This method was considered as environmentally friendly because it uses low volumes of organic solvents and showed the same suitable features, such as simplicity, quickness, and relatively low cost, when compared to AAS- or ICP-based techniques. In addition, the proposed method showed good results in terms of linearity, accuracy, and precision, providing evidence of the feasibility of UV−vis spectrophotometry as an alternative to routine quality control for Fe concentration in white and red wines.

**ABSTRACT:** Intestinal inflammation is a natural process crucial for the maintenance of gut functioning. However, abnormal or prolonged inflammatory responses may lead to the onset of chronic degenerative diseases, typically treated by means of pharmacological interventions. Dietary strategies for the prevention of inflammation are a safer alternative to pharmacotherapy. Anthocyanins and other polyphenols have been documented to display anti-inflammatory activity. In the present study, three bioactive fractions (anthocyanin, phenolic, and water-soluble fractions) were extracted from a wild blueberry powder. The Caco-2 intestinal model was used to test the immunomodulatory effect of the above fractions. Only the anthocyanin-rich fraction reduced the activation of NF-κB, induced by IL-1β in intestinal epithelial Caco-2 cells. Specifically, concentrations of 50 and 100 μg mL$^{-1}$ decreased NF-κB activation by 68.9 and 85.2%, respectively ($p \leq 0.05$). These preliminary results provide further support for the role of food bioactives as potential dietary anti-inflammatory agents.

**KEYWORDS:** *wild blueberry, anthocyanins, Caco-2 cells, NF-κB, luciferase reporter system*

## INTRODUCTION

Inflammation is a nonspecific immune response consisting of complex reactions as the body defends itself against injuries that are encountered daily by host cells such as the mucosal surface of the gastrointestinal tract. The orchestration of these responses guarantees both effective protection against harmful agents and maintenance of homeostasis. The nuclear factor κB (NF-κB) pathway is an immunological route through which inflammation processes are triggered and regulated. The NF-κB transcription factor exists in an inactive state in the cytosol of cells; upon its activation and translocation into the nucleus, the induction of genes involved in immune and pro-inflammatory responses is induced, leading to the expression of cytokines and chemokines, adhesion molecules, and inflammatory enzymes.[1]

In some individuals, or in particular conditions, the above system fails to suppress the inflammatory processes once activated, leading to exacerbated responses and to the onset of pathological consequences such as inflammatory bowel diseases (IBD). Usually, effective therapies are mainly based on pharmacological interventions, which are often connected with adverse side effects. Therefore, the potential of utilizing dietary strategies to prevent and/or reduce the inflammatory state may represent a safer and affordable tool.

Polyphenols are a class of phytochemicals that have been shown to modulate inflammatory processes.[2] In vitro and in vivo studies report that pure polyphenolic molecules, but also plant extracts, can interfere with immunological pathways and the production of inflammatory mediators.[3]

The anti-inflammatory abilities of polyphenols have been partially attributed to a direct action on the host immune system. It is reported that these bioactives could affect different intracellular pathways in the intestinal mucosa by triggering specific immune responses.[4] In fact, diverse phenolic compounds (e.g., kaempferol, quercitin, genistein, luteolin) have been documented to exert their effects through the attenuation of pro-inflammatory cytokines.[5,6] Consequently, it has been proposed that such compounds may decrease the risk of individuals to develop chronic inflammation.[4] Specifically, previous investigations (both in in vitro and in mouse models) documented that polyphenols can exert modulatory effects in the presence of different inflammatory stimuli.[2]

Anthocyanins (ACNs) are pigments of the polyphenol class that confer red to blue color to several common fruits and vegetables, which have been shown to exert different health-promoting properties as documented in both in vitro and in vivo studies.[7−12] Apart from their antioxidant activity,[13] ACNs play a key role in promoting host health through diverse mechanisms: from improvement of lipid profiles, vasomotor tone, and blood pressure to the modulation of detoxifying enzymes[7−10] and inflammation.[11,12,14]

ACNs are poorly absorbed,[15] even if new evidence suggests higher bioavailability than previously reported.[16] Consequently, most of them reach the colon, where their concentrations, as well as that of other polyphenols, can reach high concentrations, justifying a beneficial effect against IBD.[17]

Thus, the present study aims to investigate the effect of different bioactive fractions, obtained from an ACN-rich wild

blueberry (WB, *Vaccinium angustifolium*) powder, on immune responses in CaCo-2 cells following exposure to a pro-inflammatory stimulus.

## MATERIALS AND METHODS

**Chemicals and Materials.** Standards of cyanidin (Cy)-, delphinidin (Dp)-, petunidin (Pt)-, peonidin (Pe)-, and malvidin (Mv)-3-*O*-glucoside (glc), Cy- and Pt-3-*O*-arabinoside (ara), Cy-3-*O*-galactoside (gal), Dp, Cy, and Mv were purchased from Polyphenols Laboratory (Sandes, Norway). Eagle's minimum essential medium (EMEM), trypsin, fetal calf serum (FCS), D-luciferin, adenosine triphosphate (ATP), phosphate buffer saline (PBS), penicillin, streptomycin, nonessential amino acids, L-glutamine, HEPES, Tris-HCl buffer, interleukin 1$\beta$, and standards of chlorogenic, caffeic, ferulic, glucose, fructose, malic, and citric acid were obtained from Sigma-Aldrich. Hydrochloric acid, methanol, acetonitrile, triethylamine, phosphoric acid, trifluoroacetic acid (TFA), and ethyl acetate were from Merck (Darmstadt, Germany). Water was obtained from a Milli-Q apparatus (Millipore, Bedford, MA, USA). Zeocin and plasmid pNiFty2-Luc were purchased from Invivogen (Labogen, Rho, Italy). Freeze-dried WB powder, standardized at 1.5% total ACNs, was provided by Future-Ceuticals Co. (Momence, IL, USA).

**Separation and Chemical Characterization of WB Fractions.** *Extraction of Bioactives from the WB Powder.* The freeze-dried WB powder was used to extract three different fractions providing the main WB bioactives: the water-soluble fraction (containing mainly sugars and organic acids, WS fraction), the ethyl acetate-soluble fraction (containing mainly chlorogenic acid, Phe fraction), and the methanol-soluble fraction (containing mainly anthocyanins, ACN fraction).

Extraction was performed following the method described by Wrolstad[18] with a few modifications. Briefly, the WB powder was suspended in water, sonicated for 10 min, and centrifuged at 3000*g* for 10 min. Fraction separation from the supernatant was obtained through a solid-phase extraction (SPE) cartridge (Strata-X 300 mg/3 mL, Phenomenex, Torrence, CA, USA). Three milliliters of supernatant was loaded, and the elution of WS, Phe, and ACN fractions was carried out respectively with 0.01 N HCl (5 mL), ethyl acetate (10 mL), and methanol (5 mL) containing 0.1% HCl. The fractions were dried under vacuum with a rotavapor (RC Jouan 10, Jouan, Winchester, VA, USA) at 20 °C for ACN, at 40 °C for Phe, and at up to 60 °C for the WS fraction. The residues were dissolved in methanol acidified with HCl (0.05 mM) for the ACNs, methanol for the Phe, and water for the WS fractions. The solutions were analyzed for the content of ACNs, Phe, sugars, and organic acids and stored at −20 °C until use.

*Analysis of ACN and Phe-Rich Fractions.* Analysis was performed with a liquid chromatographic system, which consisted of an Alliance model 2695 (Water, Milford, MA, USA) equipped with a model 2998 photodiode array detector (Waters). The separation was carried out through a $C_{18}$ Kinetex column (150 × 4.6 mm, 2.6 $\mu$m, Phenomenex) at 45 °C with a 1.7 mL min$^{-1}$ flow rate. The eluents were (A) 1% $H_3PO_4$ and (B) acetonitrile/water (35:65, v/v). The elution gradient was linear as indicated: 0−15 min, 14% B; 15−25 min, from 14 to 20% B; 25−35 min, from 20 to 32% B; 35−45 min, from 32 to 50% B; 45−48 min, from 50 to 90% B; 90% for 3 min. Chromatographic data were acquired from 200 to 700 nm and integrated at 520 nm (ACNs) and 320 nm (Phe). Calibration curves ranging from 2 to 50 $\mu$g mL$^{-1}$ were obtained for Cy-, Dp-, Pt-, Pe-, and Mv-3-*O*-glc, Cy- and Pt-3-*O*-gal, and Pt-3-*O*-ara and chlorogenic acid. For the ACNs, the working solution was diluted from the stock solution with methanol acidified with 0.1% TFA. Each analysis was carried out in duplicate. The identification of single ACNs was confirmed by LC coupled to electrospray ionization−mass spectrometry (ESI-MS) as already described by Del Bo' et al.[9] Briefly, the mass spectrometer operated in positive full-scan mode in the range of 200−800 Da. The capillary voltage was set to 3.5 kV, the cone voltage to 20 V, the source temperature to 130 °C, and the desolvating temperature to 350 °C. Data were acquired by Masslinx 4.0 software (Micromass, Beverly, MA, USA).

*Analysis of Sugars.* Glucose and fructose were quantified in WB fractions by UPLC (Acquity, Waters) coupled with a triple-quadrupole mass spectrometer model Quattro micro (Micromass).

The separation was carried out on an ethylene-bridged hybrid (BEH) amide column (150 × 2.1 mm, 1.7 $\mu$m, Waters) at 35 °C. Solvents were (A) 0.2% triethylamine and (B) 0.2% triethylamine in acetonitrile. The flow rate was 0.40 mL min$^{-1}$. The calibration curve was obtained from 1 to 50 $\mu$g mL$^{-1}$ for both sugars. The mass spectrometer operated in ESI negative mode monitoring the ions with $m/z$ 179 (glucose, fructose). The capillary voltage was set to 3.0 kV, the cone voltage to 20 V, the source temperature to 120 °C, and the desolvating temperature to 250 °C.

*Analysis of Organic Acids.* Malic and citric acids were analyzed by UPLC (Acquity, Waters) coupled to a triple-quadrupole mass spectrometer model Quattro micro (Micromass). The separation was performed on a $C_{18}$ Atlantis T3 column (150 × 2.1 mm, 1.7 $\mu$m, Waters) at 45 °C, and the flow rate was 0.5 mL min$^{-1}$. The eluent was 0.05% formic acid. The calibration curves were obtained over the concentration range from 2 to 25 $\mu$g mL$^{-1}$ for both malic and citric acid. The capillary voltage was set to 3.5 kV, and the cone voltage and the collision energy were specific for each compound. The source temperature was 120 °C, the desolvating temperature was 300 °C, and argon was used at 1.3 × 10$^{-3}$ mbar to improve fragmentation in the collision cell. Masslinx 4.0 acquired data with Quan-Optimize option for fragmentation study. The fragmentation transitions for the multiple reaction monitoring (MRM) were $(m/z)^-$ 133 → 115 and 133 → 71 for malic and $(m/z)^-$ 191 → 111 and 191 → 87 for citric acid, with a dwell time of 0.2 s per transition.

**Immunomodulatory Activity of ACN-Rich Fraction Evaluated on Caco-2 Cell Line.** *In Vitro Cultivation.* Caco-2 cells (human epithelial colorectal adenocarcinoma cell line; ATCC HTB-37) are a well-established and validated model of the human intestinal barrier.[19] They were routinely grown in EMEM supplemented with 10% (v/v) heat-inactivated (30 min at 56 °C) FCS, 100 U mL$^{-1}$ penicillin, 100 $\mu$g mL$^{-1}$ streptomycin, 0.1 mM nonessential amino acids (NEAA), and 2 mM L-glutamine and were incubated at 37 °C in a water-jacketed incubator in an atmosphere of 95% air and 5% carbon dioxide.

*Study of NF-κB Activation.* Stable recombinant Caco-2 cell line was generated by transfecting cells with the plasmid pNiFty2-Luc as described by Guglielmetti et al.[20] This plasmid contains a promoter with five NF-κB-binding sites followed by the firefly luciferase reporter gene *luc*. Stimuli that activate NF-κB promote its binding to the vector promoter, resulting in the expression of the luciferase gene. Briefly, Caco-2 cells were transfected by means of the StoS transfection kit (GeneSpin, Milan, Italy), in accordance with the manufacturer's protocol. Afterward, cells were resuspended in fresh EMEM, seeded in 24-well plates, and incubated for 48 h to obtain the expression of the antibiotic resistance. Finally, stable recombinant clones were selected by adding into the culture medium 50 $\mu$g mL$^{-1}$ zeocin.

*Stimulation Protocol and NF-κB-Luciferase Assay.* After growth in the presence of 50 $\mu$g mL$^{-1}$ zeocin, differentiated cell monolayers (approximately 3 × 10$^5$ cells well$^{-1}$) were carefully washed with 0.1 M Tris-HCl buffer (pH 8.0). Subsequently, fresh EMEM containing 100 mM HEPES (pH 7.4) was added to Caco-2 cells. The WS-, Phe-, and ACN-rich fractions obtained by WB powder have been tested. Concentrations used were 25, 50, and 100 $\mu$g mL$^{-1}$ for the WS fraction (calculated considering the sugars and organic acid concentration) and 5, 25, 50, and 100 $\mu$g mL$^{-1}$ for the Phe-rich fraction (calculated considering the chlorogenic acid concentration) and the ACN-rich fraction (calculated considering the total ACN concentration). Only minor changes of pH were registered (pH 7.6 ± 0.1) when cells were supplemented with extract doses corresponding to the highest concentration. Recombinant Caco-2 cells were simultaneously stimulated with interleukin-1$\beta$ (IL-1$\beta$, 2 ng mL$^{-1}$), used as pro-inflammatory stimulus. After incubation at 37 °C for 4 h, 24-well plates were put on ice for 15 min; recombinant Caco-2 cells were detached mechanically from the bottom of a well, and samples were transferred into an eppendorf tube and subjected to sonication at maximum power for 5 s using a Bandelin SONOPLUS ultrasonic

homogenizer (Bandelin Electronic GmbH & Co., Berlin, Germany). Insoluble particles were removed by centrifugation, and the supernatants were transferred into a new tube. One hundred microliters of supernatants was aliquoted in duplicate into the wells of a 96-well white microtiter plate (PerkinElmer, Monza, Italy) by means of an epMotion Automated Pipetting System (Eppendorf, Milan, Italy). Then 12.5 $\mu$L of a 10 mM ATP solution (i.e., up to the final concentration of 1 mM) and 12.5 $\mu$L of 0.1 mM D-luciferin solution were added, and the emitted bioluminescence was immediately measured every 120 s with a VICTOR3 1420 multilabel counter (PerkinElmer). The maximum of light production curve was considered for comparison of results. All conditions were analyzed in duplicate in eight independent experiments.

*Cell Viability Assay.* The methosulfate (MTS) test is a spectrophotometric method used to evaluate the vitality and number of living cells.[21] The test was performed on cells treated with ACN-rich fraction (5, 25, 50, and 100 $\mu$g mL$^{-1}$), with media (control 1), and with media with added MetOH + 0.05 mM HCl (control 2). After incubation at 37 °C for 4 h, the medium was removed from Caco-2 cells, and the cells were carefully washed with 500 $\mu$L of PBS. Trypsin (0.25% trypsin, 2.5 g porcine trypsin + 0.2 g EDTA) was added to lyse cells. EMEM, containing 100 mM HEPES (pH 7.4), was added, and 100 $\mu$L of supernatant was aliquoted into a 96-well microtiter plate (PerkinElmer, Monza, Italy) by means of an epMotion automated pipetting system and then 10 $\mu$L of MTS was added. The plate was incubated at 37 °C for 90 min, and the absorbance of MTS at 490 nm was measured by a spectrophotometer (Biorad, UK).

**Statistical Analysis.** Statistical analysis was performed by means of STATISTICA software (Statsoft Inc., Tulsa, OK, USA). Analysis of variance (ANOVA), with type of treatment as the dependent factor, was used to evaluate the immunomodulatory activity of the different WB fractions on Caco-2 cells. The same analysis was performed to ensure cell viability following the ACN-rich fraction supplementation. Post hoc analysis of differences between treatments was assessed by the least significant difference (LSD) test with $p \leq 0.05$ as the level of statistical significance.

## RESULTS

**Characterization of WB Fractions.** The three fractions obtained from the WB powder were analyzed to evaluate the content of sugars and organic acids, phenols, and ACNs. The water-soluble fraction (WS) contained 4.12 $\mu$g mL$^{-1}$ sugars, corresponding to 2.28 ± 0.12 and 1.84 ± 0.13 $\mu$g mL$^{-1}$ of glucose and fructose, respectively. The contents of malic acid and citric acid were 19.9 ± 2.10 and 47.2 ± 4.23 $\mu$g mL$^{-1}$, respectively. Conversely, the contents of ACNs and phenols were negligible. Sugars and organic acids were detected only in the WS fraction.

In the Phe-rich fraction, throughout chlorogenic acid was the main phenolic compound (719.2 ± 21.4 $\mu$g mL$^{-1}$), with traces of caffeic and ferulic acids. No ACNs, sugars, or organic acids were detected.

The ACN-rich fraction composition is reported in Table 1. The total ACN content was 1563 ± 102 $\mu$g mL$^{-1}$. Fourteen different ACNs were detected in the fraction; the dominant compounds were Mv glycosides (about 540 $\mu$g mL$^{-1}$; 35% of the total ACN amount) and Dp glycosides (about 492 $\mu$g mL$^{-1}$; 31%) followed by Cy glycosides (about 293 $\mu$g mL$^{-1}$; 19%), whereas Pt and Pe glycosides represented about 11 and 4.2% of the total ACNs, respectively. The rank order for conjugated sugars was glucoside > galactoside > arabinoside from the most to the least representative (Table 1). No phenolic compounds, sugars, and organic acids were detected.

**Modulation of NF-κB Activation by WS, Phe, and ACN-Rich Fractions in Caco-2 Cells.** To identify the class of potential bioactive molecules provided by our WB powder, we tested the effects of the three different fractions isolated from WB (i.e., WS, Phe, ACN-rich) on NF-κB pathway activation. Experiments on Caco-2 cells were performed in the presence of the pro-inflammatory stimulus IL-1$\beta$. No significant differences in light emission levels were observed following Phe and WS exposure, and none of the Phe or the WS concentrations used (up to 100 $\mu$g mL$^{-1}$) resulted in a significant reduction in the NF-κB induction level compared to control. On the contrary, the ACN-rich fraction was able to reduce significantly NF-κB activation (Figure 1). In particular, the bioluminescence, and therefore NF-κB activation, was reduced by 68.9 and 85.2% at concentrations of 50 and 100 $\mu$g mL$^{-1}$, respectively ($p \leq 0.05$).

**Cell Viability.** No significant difference in cell viability was observed following Caco-2 cell supplementation. Thus, the reduction of NF-κB activation observed was not ascribable to a

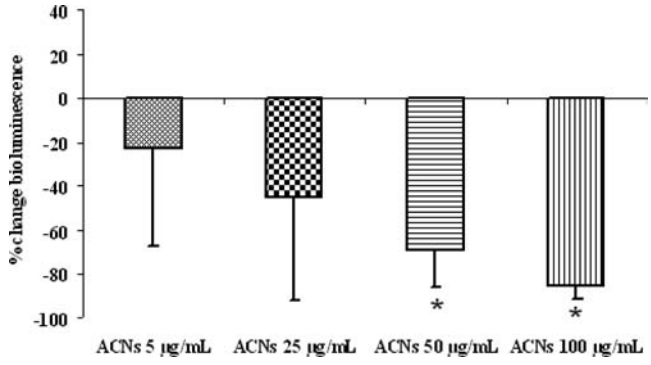

**Figure 1.** Modulation of light emission expressed by Caco-2 cells transfected with a NF-κB/luciferase reporter vector and incubated in the presence of interleukin-1$\beta$ with the ACN-rich fraction. Data are reported as percent variation of light emission, referred to the control. Control, Caco-2 cell layers incubated only with media supplemented with MetOH + 0.05 mM HCl. ACNs, anthocyanin-rich fraction. ACN concentrations (5, 25, 50, 100) are referred to $\mu$g mL$^{-1}$. The values are the means (± standard deviations) for eight independent experiments conducted in duplicate. Asterisks indicate statistically significant differences compared to results for the control (*, $p < 0.05$).

cytotoxic effect of high concentrations of the ACN-rich fraction (Table 2).

**Table 2. MTS Viability Test**[a]

| cell viability | % |
|---|---|
| control 1 | 100 |
| control 2 | 74.5 ± 18.3 |
| ACNs 5 $\mu$g mL$^{-1}$ | 77.4 ± 14.9 |
| ACNs 10 $\mu$g mL$^{-1}$ | 73.3 ± 18.9 |
| ACNs 50 $\mu$g mL$^{-1}$ | 65.7 ± 25.1 |
| ACNs 100 $\mu$g mL$^{-1}$ | 90.1 ± 10.2 |

[a]Data are reported as a measure of absorbance at 490 nm. Caco-2 cell layers incubated with ACN-rich fraction (5, 25, 50, 100 $\mu$g mL$^{-1}$) only with media (control 1) and media with MetOH + 0.05 mM HCl (control 2). ACNs, anthocyanin-rich fraction. Values are expressed as percentage mean (± standard deviations) for two independent experiments.

## DISCUSSION

Prolonged inflammation mediated by NF-κB activation may contribute to the pathogenesis of chronic diseases such as inflammatory bowel disease, diabetes, neurodegenerative diseases, cancer, and cardiovascular diseases.[3,22,23] In particular, the regulation of NF-κB activation at the epithelial interfaces, such as at gut level, is of particular importance for the maintenance of mucosal integrity, barrier function, and homeostasis. Excessive activation of NF-κB at the gut level has been associated with IBD.[24]

NF-κB is the main target in several anti-inflammatory therapies (e.g., nonsteroidal anti-inflammatory drugs)[25,26] that are not specific for NF-κB inhibition and are required in relatively high concentrations, leading to problems of adverse side effects and toxicity.[26]

The use of natural bioactive molecules, such as polyphenols, which possess the ability to attenuate NF-κB activation, might represent a safer and effective strategy in repressing inflammatory processes. Several studies suggest that blueberry polyphenols display anti-inflammatory effects that are not specifically related to their antioxidant properties.[27] ACNs, flavonols, and phenolic acids could be the phytochemicals mainly responsible for this activity. Thus, in our study, we extracted and characterized three fractions (WS, Phe, and ACN-rich fraction) from the freeze-dried WB powder to investigate the potential anti-inflammatory ability exerted by the different bioactive-rich fractions. The ACN profile of the WB used in the current research differs from that of previous studies in both qualitative and quantitative composition.[28,29] Generally, Mv-, Dp-, Cy-, Pt-, and Pe-glycosides are the most abundant ACNs found in wild blueberry.[9,30,31] In the ACN-rich fraction prepared for this study that originated from wild blueberry (*Vaccinium angustifolium*), the dominant compounds were Mv-glycosides (35% of the total ACN amount), Dp-glycosides (31%), and Cy-glycosides (19%). On the contrary, Yi et al.,[28] using three different blueberry cultivars (Briteblue, Tifblue, and Powderblue), reported higher levels of Pt- and Pe-glycosides in the ACN fraction, whereas Triebel et al.[29] detected higher levels of Dp-glycosides and Cy-glycosides from bilberry (*Vaccinium myrtillus* L.). These differences may be explained considering that the ACN profile of blueberry can vary between different cultivars and growing conditions;[32] finally, the extraction procedures may affect molecule recovery. However, it is noteworthy that the absorption of ACNs and their antiproliferative effects were demonstrated to be comparable in Caco-2 cell monolayers supplemented with different ACN fractions obtained from several blueberry cultivars.[31] Moreover, the authors reported that ACN absorption and average transport efficiency in the Caco-2 cell model were comparable to those evidenced in in vivo studies (i.e., about 3−4%).[33]

With regard to the Phe-rich fraction, chlorogenic acid was the main compound detected. Traces of hydroxycinnamic acids, such as caffeic and ferulic acids, were also found. These results disagree with findings by Yi et al.[28] in which gallic, caffeic, *p*-coumaric, and ferulic acids were identified in three different cultivars. The differences may be due to the blueberry cultivar investigated as well as to the freeze-drying process, which may contribute to the decrease in phenols.

Finally, the immunomodulatory effect of the WS fraction was investigated to ascertain the potential contribution of sugars (i.e., glucose and fructose) and organic acids (i.e., malic acid and citric acid), not included in the ACN- and Phe-rich fractions.

The WS fraction did not show any immunomodulatory potential, even though some studies suggest an induction of the NF-κB pathway following supplementation with sugars.[34] Similarly, no significant effect was observed following Phe-rich fraction exposure. These results are in contrast with other studies that documented an anti-inflammatory and inhibitory activity of phenolic compounds on NF-κB.[5,6,35] In particular, Rodriguez-Ramiro et al.[36] documented that a cocoa polyphenolic extract (10 $\mu$g mL$^{-1}$) decreased the nuclear levels of NF-κB and the expression of several cytokines in the colon of rats. Additionally, the authors confirmed in Caco-2 cells that the cocoa polyphenol-rich extract down-regulated the levels of inflammatory markers by inhibiting NF-κB activation. The capacity of polyphenols to down-regulate the NF-κB signaling pathway was also observed by Romier et al.[37] in a Caco-2 intestinal model upon supplementation with different polyphenols (50 $\mu$mol L$^{-1}$). Moreover, Kim et al.[38] reported that the flavonoid luteolin (50 $\mu$mol L$^{-1}$) prevented lipopolysaccharide (LPS)-induced NF-κB signaling and gene expression by blocking IκB kinase activity in intestinal epithelial cells. These conflicting results could be attributed to the different type and amount of polyphenols used and the specific role played by each phenolic compound.

In the present study, only the ACN-rich fraction tested revealed an immunomodulatory potential on transfected human intestinal epithelial Caco-2 cells. In particular, a significant decrease of NF-κB activation was observed at ACN-rich fraction concentrations of 50 and 100 $\mu$g mL$^{-1}$.

Our results are in agreement with others demonstrating the ability of ACNs in the modulation of NF-κB and downstream signaling in vitro in different cell models.[3,39−41] For example, supplementation with ACN-rich extract (100 $\mu$g mL$^{-1}$) isolated from bilberries and black currants modulated in vitro LPS-induced activation of NF-κB in monocytes.[3] Kim et al.[42] showed that the administration of a soybean seed coat extract (providing from 1 to 100 $\mu$g mL$^{-1}$ ACNs) significantly inhibited NF-κB activation in endothelial cells.

Beneficial effects were also observed in vivo with ACN-rich foods. For example, the use of a WB-enriched diet in Zucker rats was able to down-regulate the expression of NF-κB, both in the liver and in the abdominal adipose tissue, and to reduce several circulating inflammatory markers such as CRP, IL-6, and TNF-α.[14] Moreover, interestingly, in a parallel-design con-

trolled clinical trial, the supplementation of healthy subjects with ACNs from blueberry (Medox, 300 mg day$^{-1}$ for 3 weeks) reduced the levels of circulating NF-κB-dependent inflammatory mediators such as IL-8 and IFN-α.[3]

In the present in vitro study, the use of extracts instead of single ACNs is limited because it does not reveal the effect of single bioactive compounds on the NF-κB pathway. In this regard, the ACN-rich fraction was further characterized for the content of vitamins A and E,[43] ascorbic acid,[44] carotenoids,[43] fatty acids,[45] fiber,[46] and minerals eventually recovered during the extract preparation. None of the compounds were detectable apart from traces of fatty acids (palmitic, stearic, oleic, and linoleic acids). With regard to minerals, only traces of magnesium, phosphorus, and manganese were present, whereas calcium, sodium, and zinc were the main compounds found. However, Caco-2 cell supplementation with the ACN-rich fraction provided <1.1 μg mL$^{-1}$ of the above minerals. In addition, we cannot exclude that other bioactive compounds not identified in the ACN-rich fraction could have contributed to the anti-inflammatory effect observed. In fact, some of them might interact synergistically or additively with ACNs or other bioactives. In this regard, the contribution of ACN metabolites such as protocatechuic acid, the in vivo concentration of which is reported to be much higher than that of the parent compound,[47,48] cannot be ruled out. The extensive activity of the gut microbiota in the colon may also be another contributory factor.[49] Additionally, it is known from cell culture studies that under simulated physiological conditions (pH and temperature) a significant rate of degradation of ACNs occurs with formation of isoforms (e.g., chalcone, hemiketal) and phenolic acids that can contribute to the effects observed.[50,51] Finally, a possible limitation of cell culture studies in which food extracts are used is the omission of the step simulating gastrointestinal digestive processes as happens in vivo.

In conclusion, our preliminary results show that the ACN-rich fraction extracted from the WB powder displayed anti-inflammatory properties by decreasing the activation of NF-κB in the presence of the pro-inflammatory stimulus IL-1β. This ability might be particularly useful in the prevention/control of several inflammatory disorders, such as IBD, as already observed in a mouse model.[49]

Further investigations are necessary to identify the individual components and/or metabolites of the ACN-rich fraction responsible for this immunomodulatory ability. Future research should target the identification of potential functional components that could aid in the development of innovative strategies preventing chronic inflammatory diseases without the side effects of pharmacotherapy.

# Potential of a Renin Inhibitory Peptide from the Red Seaweed *Palmaria palmata* as a Functional Food Ingredient Following Confirmation and Characterization of a Hypotensive Effect in Spontaneously Hypertensive Rats

Ciaran Fitzgerald,*[,†] Rotimi E. Aluko,[‡] Mohammad Hossain,[†] Dilip K. Rai,[†] and Maria Hayes[†]

[†]Food Biosciences Department, Teagasc Food Research Centre, Ashtown, Dublin 15, Ireland

[‡]Department of Human Nutritional Sciences, University of Manitoba, Winnipeg R3T 2N2, Canada

**ABSTRACT:** This work examined the resistance of the renin inhibitory, tridecapeptide IRLIIVLMPILMA derived previously from a *Palmaria palmata* papain hydrolysate, during gastrointestinal (GI) transit. Following simulated GI digestion, breakdown products were identified using mass spectrometry analysis and the known renin and angiotensin I converting enzyme inhibitory dipeptide IR was identified. In vivo animal studies using spontaneously hypertensive rats (SHRs) were used to confirm the antihypertensive effects of both the tridecapeptide IRLIIVLMPILMA and the seaweed protein hydrolysate from which this peptide was isolated. After 24 h, the SHR group fed the *P. palmata* protein hydrolysate recorded a drop of 34 mm Hg in systolic blood pressure (SBP) from 187 (±0.25) to 153 (± 0.64) mm Hg SBP, while the group fed the tridecapeptide IRLIIVLMPLIMA presented a drop of 33 mm Hg in blood pressure from 187 (±0.95) to 154 (±0.94) mm Hg SBP compared to the SBP recorded at time zero. The results of this study indicate that the seaweed protein derived hydrolysate has potential for use as antihypertensive agents and that the tridecapeptide is cleaved and activated to the dipeptide IR when it travels through the GI tract. Both the hydrolysate and peptide reduced SHR blood pressure when administered orally over a 24 h period.

**KEYWORDS:** *in vitro simulated gastrointestinal digestion, spontaneously hypertensive rats, renin inhibitory peptides, red macroalga*

## INTRODUCTION

Therapeutic peptides of natural origin are used widely in the pharmaceutical industry.[1] Peptide therapies range from anticancer and antimicrobial applications to peptide use in the treatment of the symptoms of Alzheimer's disease.[1] Cardiovascular disease (CVD) is the biggest natural cause of death in Western society, and there is a focus by pharmaceutical and functional food manufacturers on the prevention of its onset.[2] High blood pressure or hypertension is the main contributory factor to CVD.[2] To fight hypertension, different components of the renin angiotensin aldosterone system (RAAS) can be positively affected. High blood pressure is ordinarily treated with the use of drugs such as captopril and enalopril that are proven and effective antihypertensive agents.[3] These drugs work by inhibiting angiotensin converting enzyme (ACE-I), the second rate-limiting enzyme of the renin angiotensin system (RAS) that forms part of the RAAS.[3] However, inhibition of this enzyme can lead to side effects such as development of a dry cough and angioneurotic edema due to the disruption of kinin metabolism.[4] The enzyme renin is the initial rate-limiting enzyme in the RAAS, and even though its importance within this system is known since 1898[5] and its substrate specificity described since 1957, commercialization of viable renin inhibitory drugs is a relatively recent occurrence.[6] Inhibition of renin has advantages over ACE-I inhibition as it is not associated with the negative side effects previously mentioned.[4] Peptides that inhibit ACE-I were discovered from a range of natural sources including soy,[7] cereal,[8] fish,[9] and macroalgae.[10] Similar to the trend observed with synthetic renin inhibitors, naturally occurring renin inhibitors have only recently been reported from sources such as peas[11] and hemp seed.[12]

Previous work carried out by this group isolated a renin inhibitory tridecapeptide with the amino acid sequence IRLIIVLMPILMA from a protein hydrolysate generated using the food-grade enzyme papain from the red seaweed *Palmaria palmata*.[13] This peptide, IRLIIVLMPILMA, had a renin inhibitory $IC_{50}$ value of 3.34 mM compared to the positive control used.

The aim of this work was to assess if the tridecapeptide IRLIIVLMPILMA could survive gastrointestinal (GI) digestion and therefore could be used as a viable functional food ingredient that positively affects hypertension. In silico cleavage analysis coupled with a simulated GI digestion method were used to assess the resistance of this peptide in vivo using spontaneously hypertensive rats (SHRs). The peptide hydrolysate from which the tridecapeptide IRLIIVLMPILMA was isolated along with the chemically synthesized peptide was administered separately via oral gavage to SHRs. The effect on the blood pressure of the animals was observed over 24 h.

## MATERIALS AND METHODS

**Chemicals.** The tridecapeptide IRLIIVLMPILMA was synthesized by GL Biochem Ltd. (Shanghai, China). All enzymes used for the simulated gastric digestion of the tridecapeptide including pepsin from

porcine gastric mucosa, amylase, pancreatin, and porcine bile extract were obtained from Sigma–Aldrich (Dublin, Ireland). All reagents used in the formation of the gastric fluids including potassium chloride, monobasic potassium phosphate, sodium bicarbonate, sodium chloride, and magnesium chloride hexahydrate were also sourced from Sigma–Aldrich (Germany).

**In Silico Analysis of the Renin Inhibitory Peptide IRLIIVLMPILMA.** The program Expasy Peptide Cutter (http://web.expasy.org/peptide_cutter/) was used to predict where the main proteases of the GI tract could cleave the renin inhibitory peptide IRLIIVLMPILMA.

The online tool ToxinPred (http://crdd.osdd.net/raghava/toxinpred/index.html) was used to predict the toxicity of the peptide and its fragments after hydrolysis.[14]

**Simulated Gastric Digestion of the Peptide IRLIIVLMPILMA.** The simulated gastric digestion method was carried out according to the method described by the European Cooperation in Science and Technology (COST) funded group INFOGEST (http://www.cost-infogest.eu/). This method was devised under COST action FA1005 in an attempt to promote harmonization of currently used digestion models. Simulation of the gastric process was carried out in three phases as shown in Figure 1. Initially, an oral phase containing 1 g of

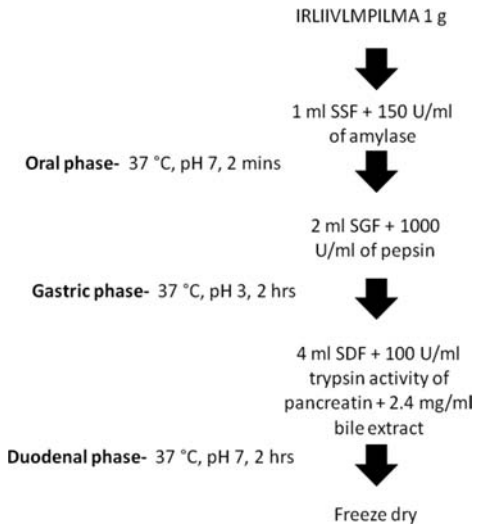

**Figure 1.** Schematic representation of the simulated, in vitro gastric digestion protocol used. The simulated digestion was carried out in three stages: (1) oral stage; (2) gastric stage; (3) duodenal stage.

the synthesized peptide was mixed with 1 mL of simulated salivary fluid (SSF) (Table 1) and 150 U/mL amylase. This mixture was left to stir in a water bath (Stuart shaking water bath, Staffordshire, UK) at 37 °C for 2 min. The second phase of the simulation was the gastric phase. The oral phase was mixed with 2 mL of the prepared simulated gastric fluid (SGF) (Table 1) along with pepsin at a concentration of 1000 U/mL SGF. The pH was adjusted to pH 3 using 1 M hydrochloric acid (HCl) and left to stir in a water bath (Stuart shaking water bath) at 37 °C for 2 h. The final stage of the digestion was the duodenal phase. For this phase, 4 mL of the simulated duodenal fluid (SDF) (Table 1) was added to the SGF along with pancreatin at a concentration of 100 U/mL trypsin activity. Porcine bile extract was also added at a concentration of 2.4 mg/mL of the total volume. The mixture was adjusted to pH 7 using 1 M NaOH and left to stir in a water bath at 37 °C for 2 h before being deactivated using heating at 90 °C for 20 min and subsequently freeze-dried.

**Removal of Polyethylene Glycols from *P. palmata* Protein Digested Samples Using a Titanium Dioxide Cleanup Procedure.** Digested samples were cleaned-up for further analysis using Pierce graphite spin columns available as part of the Pierce titanium dioxide phosphopeptide enrichment and cleanup kit (Thermo Fischer Scientific, Waltham, MA, USA). The graphite spin columns were used according to the manufacturer's instructions. Briefly, the column was prepared by placing it in a 1.5 mL Eppendorf tube followed by centrifugation at 2000*g* for 1 min to remove storage buffer. The column was then rinsed twice with 100 $\mu$L of $NH_4OH$ and subsequently centrifuged at 2000*g*. The graphite was activated by adding 100 $\mu$L of acetonitrile followed by centrifugation at 2000*g* for 1 min before adding 100 $\mu$L of 1% trifluoroacetic acid (TFA) in water (1:99 v/v) followed again by centrifugation of the column at 2000*g* for 1 min. After column preparation, 50 mg of the hydrolysate was added and allowed to bind to the column for 10 min with periodical vortexing. The column was then centrifuged at 1000*g* for 3 min, and the flow through was discarded. The column was subsequently placed in a new tube and washed with 200 $\mu$L of 1% TFA followed by centrifugation at 2000*g* for 1 min. The column was then placed in a new tube and spun at 2000*g* for 1 min following addition of 100 $\mu$L of 0.1% formic acid (FA) in a 50:50 acetonitrile/water v/v ratio. This step was repeated three times, and the resulting elution was freeze-dried.

**Tandem Mass Spectrometry Analysis of the Hydrolysate.** The enriched digested fraction was further analyzed using an electrospray ionization quadrupole time-of-flight (ESI-Q-TOF) mass spectrometer coupled to a nanoultra performance liquid chromatography (nano-UPLC) system (Waters Corporation, Milford, MA, USA) used in positive ionization mode. The sample was dissolved in water/acetonitrile (80:20, v/v). The redissolved hydrolysate was injected onto a nano-UPLC Acquity column BEH130 $C_{18}$ (100 $\mu$m × 100 mm, 1.7 $\mu$m particle size) preceded by a Symmetry $C_{18}$ (180 $\mu$m × 200 mm, 5 $\mu$m particle size) trapping column. Mobile phases consisted of solvent A, which contained 0.1% FA in water, and solvent B, which contained 0.1% FA in acetonitrile. Trapping of the peptide/peptide fragments was achieved using a loading time of 3 min at a flow rate of 5 $\mu$L/min with 98% solvent A and 2% solvent B and then elution onto the analytical column at 300 nL/min. Chromatographic conditions consisted of 95% solvent A and 5% solvent B isocratically for 2 min, followed by a linear gradient from 85% to 20% solvent A over 63 min.

Mass spectrometry (MS) data were acquired in $MS^e$ mode with collision energy for a full mass scan of 6 eV and a collision energy ramp of 15–35 eV for a mass range $m/z$ 155 to $m/z$ 1600. The Q-TOF was calibrated externally using MS/MS fragment ions of Glu-fibrinopeptide (Glu-fib).

**In Vivo Determination of the Antihypertensive Effect of the *P. palmata* Protein Hydrolysate and the Tridecapeptide IRLIIVLMPILMA in Spontaneously Hypertensive Rats.** All rat experiments were performed according to protocols approved by the University of Manitoba Animal Care Protocol and Management

Review Committee in accordance to the Canadian Council on Animal Care regulations. Adult (20 week old) SHRs weighing between 360 and 400 g were kept under a 12 h day/night cycle at 21 °C and fed a standard chow diet and water ad libutum. The SHRs were split into four groups of four rats each and administered the following treatment: (a) *P. palmata* hydrolysate dissolved in phosphate buffer saline (PBS, pH 7.2) at 50 mg/kg body weight, (b) the synthesized tridecapeptide IRLIIVLMPILMA dissolved in PBS at 50 mg/kg body weight, (c) the positive control captopril dissolved in PBS at 10 mg/kg body weight, and (d) PBS only. Each group received a 1 mL dose of each treatment via oral gavage. Before blood pressure was determined, rats were first anesthetized in a chamber at 40 °C with 4% isofluorane for 4 min to avoid stress-related blood pressure effects. The systolic blood pressure (SBP) of the SHRs was measured at 0, 2, 4, 6, 8, and 24 h by the tail cuff method while the rats were in an unconscious state using the Mouse Rat Tail Cuff Blood Pressure System (IITC Life Sciences, Woodland Hills, CA, USA). The change in SBP mm Hg (ΔSBP) was determined by subtracting the SBP at time $n$ (where $n$ is equal to 2, 4, 6, 8, or 24 h) from the SBP at time 0.

**Statistical Analysis.** The student's $t$ test was performed using GraphPad Prism version 5.04 for Windows, GraphPad Software (La Jolla, CA, USA) and was considered significantly different if $P < 0.05$.

## RESULTS AND DISCUSSION

The feasibility of functional food or pharmaceutical application of bioactive peptides depends on overcoming several challenges including lack of oral bioavailability. In addition, bioactive peptide action is often hampered by proteolytic attack. In this work, the resistance of a renin inhibitory tridecapeptide with the amino acid sequence IRLIIVLMPILMA was assessed using a combination of in silico analysis followed by a simulated GI digestion procedure and in vivo administration to SHRs. Table 2 shows the resultant peptide fragments obtained from the tridecapeptide IRLIIVLMPILMA following in silico analysis using the online tool Expasy Peptide Cutter. It shows that the peptide is cleaved at position 3, 6, and 11 by pepsin at both pH 1.3 and pH > 2. More importantly, however, in terms of renin inhibitory activity, the enzyme trypsin cleaves the peptide at position 2 at the carboxy end of the amino acid arginine releasing the dipeptide, amino acid sequence IR. Previous work showed that this dipeptide inhibited renin, and ACE-I activities at concentrations of 1 mg/mL previously when isolated from a pea peptide hydrolysate.[11]

To confirm the results obtained using in silico analysis, the tridecapeptide was subjected to the in vitro simulated gastric digestion outlined in Figure 1. In addition, the sample was analyzed using UPLC-MS in order to identify the breakdown products and the dipeptide IR. Figures 2 and 3 show the UPLC chromatograms obtained following MS analysis of the tridecapeptide following in vitro simulated GI digestion according to the INFOGEST procedure and the corresponding nano-ESI-MS spectra data. The base peak intensity chromato-

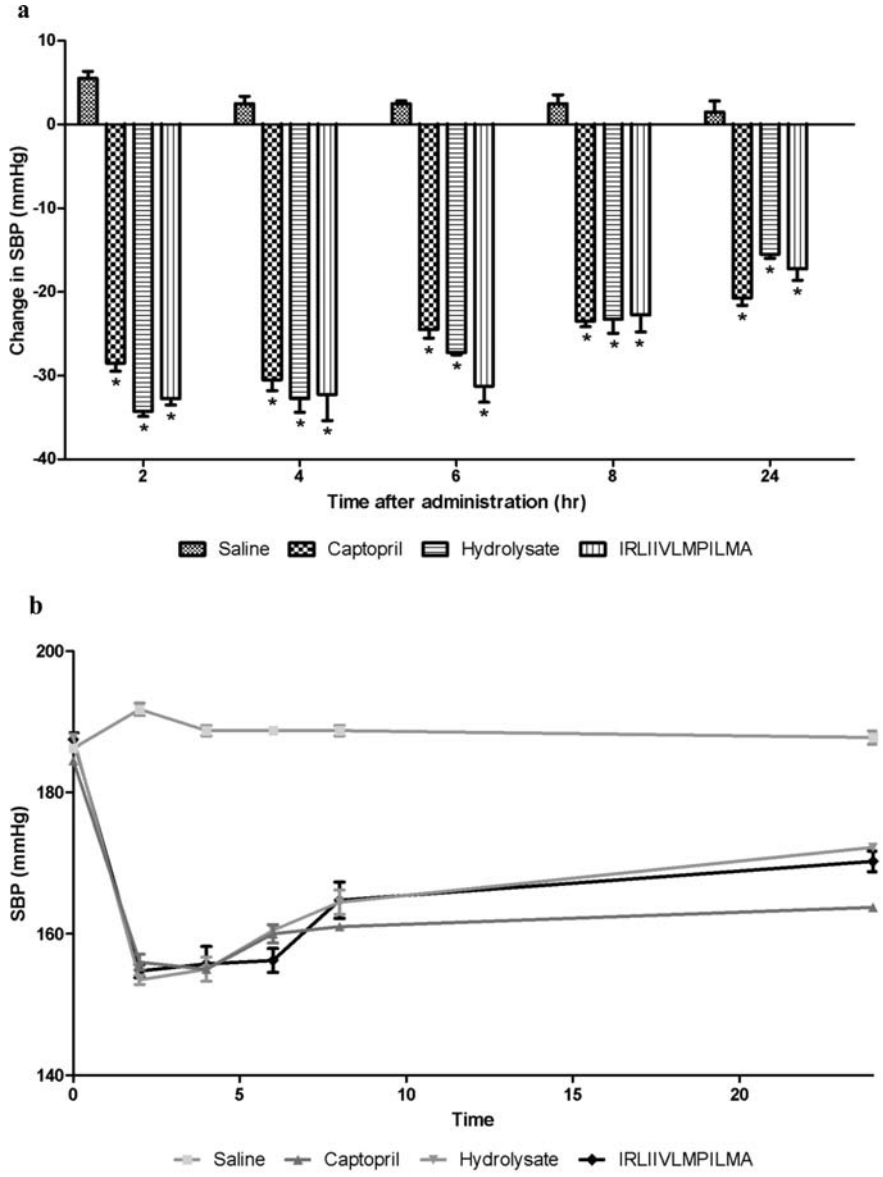

**Figure 4.** (a) Short-term (24 h) changes in systolic blood pressure (SBP) of spontaneously hypertensive rats (SHRs) after oral administration of saline, captopril, *P. palmata* protein hydrolysate, and the synthesized peptide IRLIIVLMPILMA. (b) SBP of SHR rats over 24 h after oral administration of saline, captopril, P. palmata protein hydrolysate, and the synthesized peptide IRLIIVLMPILMA. Values are mean ± SEM ($n$ = 3). *$P$ < 0.05 compared to the control (saline).

gram (Figure 2a) displays the peaks of all hydrolyzed analytes. The extracted chromatogram in Figure 2b displays doubly charged $[M + 2H]^{2+}$ ions at $m/z$ 748 representing the whole, uncleaved tridecapeptide IRLIIVLMPILMA (theoretical mass = 1494). The corresponding nano-ESI-MS spectra data in Figure 3a shows both the protonated molecular ions for IRLIIVLMP-ILMA at $m/z$ 1495 and the doubly protonated at $m/z$ 748. Figure 2c displays the extracted chromatogram highlighting the peaks corresponding to the $[M + H]^{+}$ ions at $m/z$ 1226 representing the cleaved fragment LIIVLMPILMA (theoretical mass = 1225). Figure 3b displays the resultant nano-ESI-MS spectra data hydrolyzed peptide fragment LIIVLMPILMA at $m/z$ 1226. Figure 2d shows the extracted ion chromatogram displaying $[M + H]^{+}$ ions at $m/z$ 288 the expected observed mass of the peptide IR (theoretical mass = 287) now cleaved from the parent peptide. The consequential nano-ESI-MS spectral data in Figure 3c shows the dipeptide IR at $m/z$ 288. The MS data obtained confirms the in silico cleavage analysis results that predicted that the renin inhibitory dipeptide IR remains intact during normal digestive processes. Previous studies examined the ACE-I inhibitory activity in pea and whey protein digests using in vitro digestion but chose to analyze the resulting hydrolysates with SDS-PAGE and HPLC.[15] In this study, ESI-Q-TOF mass spectrometry was used in tandem with UPLC due to the high sensitivity of peptide detection that ESI-Q-TOF offers along with the rapid and high degree of separation offered by UPLC.[16]

The results shown in Figure 4 present the short-term changes in SBP observed over a 24 h period of SHRs fed a diet of the seaweed protein papain hydrolysate, the synthesized tridecapeptide, a positive control (captopril), and a saline solution (negative control). Figure 4a displays changes in SBP over a 24 h period whereas Figure 4b shows the actual SBP over the same time period following administration of the

control (saline), the known blood pressure lowering drug captopril (3 mg/kg bw) as a positive control, the *P. palmata* protein hydrolysate (50 mg/kg bw), and the synthesized peptide IRLIIVLMPILMA (3 mg/kg bw). Interestingly, both the hydrolysate and the tridecapeptide IRLIIVLMPILMA displayed very similar trends in lowering the SBP of the rats over a 24 h period. After 2 h, the group that was fed with captopril recorded a 29 mm Hg drop in SBP from 184 (±0.28) mm Hg to 156 (±1.08) mm Hg . Likewise, the group fed the *P. palmata* protein hydrolysate recorded a drop of 34 mm Hg in SBP from 187 (±0.25) to 153 (±0.64) mm Hg SBP, while the group fed the tridecapeptide IRLIIVLMPLIMA presented a drop of 33 mm Hg in blood pressure from 187 (±0.95) to 155 (±0.94) mm Hg SBP. After 24 h, the effect of all blood pressure lowering agents was drops of 21, 16, and 17 mmHg SBP, respectively, compared to the SBP recorded at 0 h. Previous papers examined the blood pressure lowering effects of a pea peptide hydrolysate in SHRs.[17] Blood pressure was measured using the tail cuff plethysmography method to avoid stress-related blood pressure effects. However, the pea protein hydrolysates were administered at a concentration of 200 mg/kg, and this dose resulted in a 19 mm Hg drop in SBP of SHRs. Likewise, SHRs treated with an antihypertensive buckwheat hydrolysate recorded an initial decrease in SBP of 27 ± 7.6 mm Hg after 2 h but only when treated with 100 mg/kg body weight,[18] twice the concentration of the *P. palmata* protein hydrolysate and the tridecapeptide IRLIIVLMPLIMA used in this study. In silico analysis of the peptide using the online tool ToxinPred also showed that the peptide was nontoxic, which indicates that it is suitable for use in functional foods and pharmaceutical agents. In addition, an earlier study carried out by this group found that the *P. palmata* hydrolysate was nontoxic to zebrafish when administered at a concentration between 1 and 5 mg/mL.[19]

This study demonstrates that the tridecapeptide IRLIIVLMPLIMA is a renin inhibitory peptide with the ability to impart an antihypertensive effect in vivo confirmed by monitoring changes in SBP in SHRs over a 24 h period. Both the peptide and the *P. palmata* protein papain hydrolysate may have potential for use as functional ingredients in the growing nutraceutical market to prevent hypertension.

**ABSTRACT:** Varying amounts of epigallocatechin-3-gallate (EGCG) were encapsulated in β-lactoglobulin (β-Lg) nanoparticles, either native or processed, denoted as heated or desolvated protein. The stability, physical properties, and bioactivity of the β-Lg−EGCG complexes were tested. Native β-Lg−EGCG complexes showed comparable stability and binding efficacy (EGCG/β-Lg molar ratio of 1:1) to heated β-Lg nanoparticles (1% and 5% protein w/w). The sizes of heated and desolvated β-Lg nanoparticles were comparable, but the latter showed the highest binding affinity for EGCG. The presence of EGCG complexed with β-Lg did not affect the interfacial tension of the protein when tested at the soy oil−water interface but caused a decrease in dilational elasticity. All β-Lg complexes (native, heated, or desolvated) showed a decrease in cellular proliferation similar to that of free ECGC. In summary, protein−EGCG complexes did not alter the bioefficacy of EGCG and contributed to increased stability with storage, demonstrating the potential benefits of nanoencapsulation.

**KEYWORDS:** *β-lactoglobulin, EGCG, nanoencapsulation, fluorescence spectroscopy, interfacial tensiometry, bioefficacy, Caco-2 cells*

## 1. INTRODUCTION

Tea (*Camellia sinensis*) has been consumed for thousands of years and is the most common beverage after water.[1] Green tea extracts have shown antibacterial and antiviral activity[2] and also have been associated with a decreased risk of cancer or cardiovascular disease.[3] These activities are mainly attributed to the presence of polyphenolic compounds in tea leaves (i.e., flavonoids). Flavonoids contribute to color and taste of foods[3] and are widely found at high concentrations in plant-derived materials.[4]

In green tea, flavonoids are a large and heterogeneous group of molecules. Catechins account for 80% of total green tea flavonoids and include the majority of bioactive molecules in tea.[4] Epigallocatechin-3-gallate (EGCG) is the most prevalent (approximately 50%) and bioactive tea catechin[5] and is a highly water-soluble compound. As an anticarcinogen, EGCG inhibits the growth of cancer cells, such as human cervical cancer cells or colon cancer cells, and although its mechanisms of action are not fully understood, it has been shown to induce apoptosis and regulate gene expression in such cells.[6] However, recent in vivo studies on prostate cancer have led to the conclusion that green tea may not be considered yet as a chemopreventive agent.[7]

As an antioxidant, EGCG was demonstrated to act up to 10 times as effectively as L-ascorbate or β-carotene,[8] as assessed by the survival of *Escherichia coli* incubated with alkyl peroxyl radical (pH 7.3, 37 °C, 35 min). EGCG can be easily oxidized in aqueous environments, rendering it highly unstable in aqueous solutions, especially at neutral and basic pH.[9,10] The aqueous stability of EGCG can be improved by the addition of metal ion scavengers (such as ethylenediaminetetraacetic acid, EDTA) or other antioxidants (such as vitamin C) in the medium.[11] It is important to note that the bioavailability of EGCG depends not only on its stability but also on its complexed state in the food matrix, the extent of its intestinal absorption, and the extent of its bioconversion.[3]

In addition to their nutritional value, proteins are utilized for a variety of functional properties in foods, such as gelation, emulsification, or foam formation. They have the ability to bind with small hydrophilic and hydrophobic molecules, making them potential carriers of bioactive molecules in the human body[12] and in the creation of functional foods.[13−15] β-Lactoglobulin (β-Lg) is the major whey protein with an approximate concentration of 1 g·L$^{-1}$ in milk and a molecular mass of 18 400 Da.[16] Its ability to act as a nanocarrier system has been shown with model compounds such as bixin,[17] vanillin,[18] resveratrol,[19] and tea polyphenol extracts.[20]

The structure and functionality of β-Lg is highly dependent on environmental conditions such as pH and temperature. Previous studies showed that the EGCG-binding characteristics of β-Lg can be enhanced up to 3.5 times after thermal denaturation of the whey proteins.[9] The binding of polyphenols to proteins occurs mainly through hydrophobic interactions,[16] hydrogen bonding,[21] and, in some instances, electrostatic forces.[22] These interactions depend on the size and structure of the polyphenol molecules. EGCG has the highest binding affinity to whey proteins among tea catechins,[16] because of its esterification with gallic acid, which creates a galloyl functional group with multiple peptide binding sites, able to form hydrophobic interactions and hydrogen bonds with the proteins.[23]

The utilization of β-Lg as a delivery system for EGCG could potentially improve the stability of the polyphenol in a wider pH range, limit its gastric degradation, and enhance its

intestinal uptake. A well-designed β-Lg−EGCG system should not negatively affect the digestibility of the protein and the health-promoting properties of EGCG. The effect of tea polyphenols on digestive enzymes remains controversial, as shown by Shpigelman et al.[24] According to their results, complexation of β-Lg with EGCG did not significantly affect in vitro gastric digestion of the protein. Similar conclusions were drawn for casein−EGCG complexes: the presence of EGCG did not affect casein hydrolysis, in two different in vitro models.[25] In the literature, the role of β-Lg−EGCG interactions in the prevention of EGCG degradation in aqueous medium remains controversial regarding the extent to which EGCG is protected. It was demonstrated that the binding of EGCG to heat-denatured (85 °C, 20 min) β-Lg can effectively reduce the extent of oxidative degradation (up to 33 times) in 30 mM phosphate-buffered saline (PBS, pH 6.9), especially over the first 8 days.[24] However, it was also reported that degradation of EGCG over time is not significantly limited by binding with native or heated β-Lg.[4]

In vitro assays have been conducted to measure EGCG antioxidant activity as well as that of β-Lg−EGCG complexes.[26] To the best of our knowledge, the antioxidant activity of β-Lg−EGCG complexes has not been studied in cell culture experiments.

In this study, the interactions between β-Lg and EGCG as influenced by processing conditions were investigated. Thermal processing and desolvation were utilized in order to manufacture protein−EGCG complexes along with the unprocessed protein. The physicochemical characteristics of such complexes including encapsulation efficiency, particle size, and charge were studied by a variety of analytical techniques. It has been repeatedly shown in the literature that utilization of cell culture models in the testing of bioefficacy of medicinal drugs or bioactive compounds is a valuable approach prior to animal or human trials as an efficient and cost-effective strategy.[27,28] The bioefficacy of these complexes was studied in Caco-2 cells. This cell line was chosen as representative of epithelial tissues; it is one of the most commonly utilized cell culture models in current pharmacological studies. The effect of free EGCG, or EGCG associated with native protein, as well as protein nanoparticles, was tested by measuring their ability to inhibit cellular proliferation.

## 2. MATERIALS AND METHODS

**2.1. Sample Preparation.** Highly pure β-Lg (>99%) used in the experiments was purified from whey protein isolate (New Zealand Dairy Products, NZMP, Palmerston North, New Zealand) by preparative ion chromatography on Q-Sepharose (GE Healthcare) as previously reported.[29] β-Lg stock solution (2−5% w/w) was prepared in a buffer medium (see below) and kept refrigerated overnight (4 °C) to ensure complete hydration. The stock solution was then filtered through a 0.45 μm filter (Millipore, Millex HV, Billerica, MA). EGCG (min. 94%) was a gift of DSM Nutritional Products (Teavigo, Ayr, Ontario, Canada) and its stock solutions (0.1−5 mg·mL$^{-1}$) were freshly prepared and filtered as described for β-Lg solutions. Unless otherwise stated, all solutions were prepared in sodium phosphate buffer (20 mM, pH 7.0) that contained sodium azide as bacteriostat (0.02%). β-Lg stock solution was equilibrated at room temperature (30 min) before it was mixed with varying volumes of EGCG solutions to obtain different EGCG/β-Lg molar ratios (0−10). Each sample was immediately vortexed for 5 s.

**2.2. Fluorescence Spectroscopy.** β-Lg−EGCG complexes were prepared by mixing 10.9 μM β-Lg solution with equal volumes of diluted EGCG stock solutions ranging from 0 to 135.9 μM. Eleven different samples with EGCG/β-Lg molar concentration ratios of 0−10 were prepared, and 200 μL aliquots of each sample were transferred to a 96 well fluorescence plate (Fisher Scientific). The protein intrinsic fluorescence spectra (300−450 nm) were directly recorded with a Synergy H4Microplate Reader (Biotek, Winooski, VT) utilizing an excitation wavelength of 280 nm and slit width of 5 nm. The Stern−Volmer equation was used to determine the quenching mechanism that takes place due to EGCG binding to β-Lg molecules:

$$\frac{F_0}{F} = 1 + K_{SV}[\mathrm{EGCG}] \quad (1)$$

where $F_0$ is the initial fluorescence intensity of 0.02% (w/w) β-Lg solution, $F$ is the fluorescence intensity of the sample at the peak (325 nm emission), and $K_{SV}$ is the Stern−Volmer constant.[30] The binding constant and stoichiometry were calculated as follows:

$$\log\left(\frac{F_0 - F}{F}\right) = \log(K_s) + n\log[\mathrm{EGCG}] \quad (2)$$

where $K_s$ is the static binding constant and $n$ is the binding number.[20] All measurements were carried out at least in duplicate.

**2.3. Preparation of EGCG-Bearing β-Lactoglobulin Nanoparticles.** *2.3.1. Thermal Processing.* Thermal processing of β-Lg solutions was carried out at 85 °C (20 min, 400 rpm) with a thermomixer (Eppendorf 5436, Brinkmann Instruments, Mississauga, ON, Canada). The samples were immediately transferred to an ice bath and were mixed with EGCG solutions at room temperature at a molar ratio ranging from 0:1 to 3:1 (EGCG/β-Lg). The final β-lactoglobulin concentrations in the mixture were 1% or 5% (w/w) in all cases.

*2.3.2. Desolvation Procedure.* Whey protein nanoparticles were prepared by an established procedure.[14] To maximize electrostatic repulsion between protein molecules, pH of the native β-Lg solutions was adjusted to pH 9 with concentrated sodium hydroxide solution (2 M). Pure ethanol was then added to 2 mL of β-Lg solution at a rate of 1 mL·min$^{-1}$. The final volume of ethanol added was 5 times the volume of β-lactoglobulin solution (i.e., 10 mL). Immediately after desolvation, the mixture was diluted 20 times in 20 mM sodium citrate buffer (pH 3) to stabilize the desolvated particles. In this case, as heating was not applied, EGCG was dissolved in the dilution buffer prior to mixing (0−190.7 μM). Due to the high extent of dilution in the desolvation protocol (i.e., 120 times), all desolvation experiments were conducted at an initial protein concentration of 5% (w/w).

**2.4. Interfacial Tensiometry.** To further probe the formation of complexes and possible changes in the protein functionality, interfacial tensiometry was applied to determine changes in protein adsorption at the interface. This technique is based on analysis of the size and shape of a dispersed phase droplet (i.e., soy oil) suspended in a continuous phase (i.e., aqueous suspension of β-Lg−EGCG complexes). Interfacial tension was measured for at least 2 h to ensure that equilibrium was established. Immediately afterward, the oil droplet was sinusoidally oscillated around its initial volume (±10%) to measure the elastic modulus. A dilational amplitude range of 0−40% was within the linear viscoelastic range (data not shown).

The interfacial activity of EGCG-bearing β-Lg nanoparticles was determined by drop shape tensiometry at the aqueous dispersion−soybean oil interface (25 °C) (Tracker, IT Concept, Longessaigne, France). The oil phase was purified prior to the experiments by mixing it with Florisil (Sigma−Aldrich, catalog no. 46385, particle size 149−250 μm)[31] at a ratio of 10:1, shaking for 2 h (60 rpm) on a shaking plate, and then removal of Florisil by filtering (Whatman cellulose filter #52, 7 μm). The purification process was repeated three times prior to all measurements. A soy oil droplet (approximately 6 μL) was automatically formed at the tip of a syringe, which was immersed in a cuvette containing the aqueous dispersion of protein−EGCG complexes or protein only. The assembly of the cuvette and syringe was monitored by a charge-coupled device (CCD) camera for acquisition of high-quality images, and the shape of the oil droplet was automatically analyzed in order to calculate the time dependence of the interfacial tension up to a drop age of 10 000 s. Since the calculation of dynamic interfacial tension was based on the Young−

Laplace equation, the shape of the drop was periodically monitored to ensure a Laplacian shape and the absence of partial detachment of the drop throughout the run. All the measurements were carried out in duplicate. The focus, verticality of the syringe tip, and measured image volume were reset or recalibrated daily.[32]

Dilational elasticity gives an indication of the ability of the adsorbed moieties to stabilize the interface during droplet volume changes. The method utilized here is based on the automatically controlled, sinusoidal compression−expansion of the aqueous droplet at a defined oscillatory frequency and amplitude of dilation.[33] The interfacial modulus of dilational elasticity was calculated from the change in interfacial tension ($d\gamma$) relative to the change in droplet surface area ($dA$):

$$\varepsilon = \frac{d\gamma}{d \ln A} \quad (3)$$

Heated and desolvated $\beta$-Lg particles were prepared and EGCG was added to prepare complexes of these particles and along with native protein, as detailed above. The interfacial activity of the complexes was measured. A molar ratio range of 0:1 to 3:1 (EGCG/$\beta$-Lg) was utilized throughout the experiment. All measurements were carried out at least in duplicate.

**2.5. Determination of Apparent Particle Diameter and $\zeta$-Potential by Dynamic Light Scattering.** The particle size distribution and $\zeta$-potential of EGCG-bearing $\beta$-Lg nanoparticles was determined by dynamic light scattering (DLS) on a Zetasizer Nano (Malvern Instruments, Worcestershire, U.K.). No further dilution was carried out prior to DLS measurements due to the low extent of scattering of the protein dispersions. All particle size distributions reported here were determined on the basis of volume frequency, and the apparent mean diameter was measured.

**2.6. Separation of Uncomplexed Polyphenols.** To determine the amount of encapsulated EGCG, free EGCG was separated from bound EGCG on a desalting column (HiTrap desalting column, product no. 17-408-01, GE Healthcare, Uppsala, Sweden). The extent of EGCG encapsulation was then quantified on the basis of absorbance measurements (at a wavelength of 280 nm). The complexes were eluted with 20 mM sodium phosphate buffer (pH 7) that contained 50 mM NaCl. Free EGCG was removed from the column with 20% ethanol, and the absorbance measurements were carried out in ethanolic solution on a UV−visible spectrophotometer (RF-5301PC, Shimadzu, Japan). A range of EGCG controls (0−0.2 mg/mL) was also studied along with the samples.

**2.7. Cellular Proliferation Assays.** Caco-2 cells were provided form CRIFS culture collection (Canadian Research Institute for Food Safety) and were maintained in Dulbecco's modified Eagle medium (DMEM; Sigma−Aldrich Corp., Oakville, ON, Canada) supplemented with 10% (v/v) heat-inactivated fetal bovine serum (FBS) (Invitrogen Canada Inc., Burlington, ON, Canada), 2 mM L-glutamine, 1% (v/v) penicillin−streptomycin, and 1% (v/v) essential amino acids as well as 0.25% (v/v) *N*-(2-hydroxyethyl)piperazine-*N*′-ethanesulfonic acid (HEPES) buffer. Cells were passaged weekly (80−90% confluence) with 0.25% trypsin−EDTA (Invitrogen) and medium was changed every other day. Cells were kept daily at 37 °C in humidified atmosphere in 5% $CO_2$. Cells at passage 29−38 were used for the proliferation tests.

Freshly prepared EGCG−$\beta$-Lg and respective aged samples (24 h at 4 °C) were administered to the Caco-2 cell culture. Sulforhodamine B (SRB) assay was used to evaluate the influence of the samples on the proliferation rate of Caco-2 cancer cells.[34] Briefly, Caco-2 cells at a concentration of $6 \times 10^3$ cells/well were seeded on clear bottom 96 well plates (Fisher Scientific, Mississauga, ON, Canada) and allowed to adhere for 24 h. Afterward, fresh samples were added to the cells at a dilution rate of 1:5.6 in the medium (sample/medium v/v) and incubated for 24 h. Loading on the cells was calculated on the basis of the amount of EGCG originally present in the sample. The amount of protein $\beta$-Lg in final dilution in the well was 1.8 $\mu$g/mL for native and heated samples, while for desolvated samples it was 0.08 $\mu$g/mL. EGCG concentrations were 0.05 and 0.13 $\mu$g/mL for EGCG/$\beta$-Lg molar ratios of 1 and 3, respectively, when complexed with native or heated $\beta$-Lg. On the other hand, the EGCG concentration was 0.006 $\mu$g/mL when complexed with desolvated $\beta$-Lg to maintain a EGCG/$\beta$-Lg molar ratio of 3. Control samples (cells with medium only) along with blank samples (medium only) were also tested. The optical density of plates was measured on an automated 96-well plate reader (Synergy H4Microplate Reader, Biotek, Winooski, VT) at 570 nm. Results were expressed as percentage proliferation with respect to control wells grown with no sample treatments.

**2.8. Statistical Analyses.** Unless otherwise stated, all the experiments were carried out in triplicates and the results are expressed as means ± standard deviation (SD). Statistical differences were evaluated by analysis of variance (ANOVA) (XL Stats [7.5.2], Addinsoft, Paris, France). The differences were considered to be significant at $p < 0.05$.

## 3. RESULTS AND DISCUSSION

**3.1. Fluorescence Spectroscopy.** Figure 1 shows the changes in intrinsic fluorescence in native $\beta$-Lg solutions

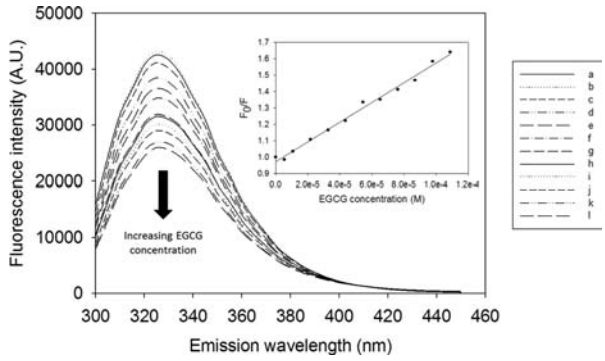

**Figure 1.** Fluorescence spectra of 0.02% (w/w) $\beta$-lactoglobulin and the influence of EGCG concentration (millimolar) on intrinsic fluorescence of the protein. The molar ratio range tested was 0−10. Curves a−l respectively correspond to EGCG/$\beta$-Lg molar ratios 0, 0.5, 1, 2, 3, 4, 5, 6, 7, 8, 9, and 10. Excitation was carried out at 280 nm. Representative runs are shown. (Inset) Stern−Volmer plot (eq 1) derived from fluorescence intensity data.

(0.02% w/w) as a function of EGCG concentration (0−0.05 mg·mL$^{-1}$, corresponding to EGCG/$\beta$-Lg molar ratios 0−10). For EGCG/$\beta$-Lg ratios that are lower than 4:1 (0.02 mg/mL EGCG), the absorbance values recorded for the mixture were lower than 0.1 (data not shown), thus rendering the measurements valid in this concentration range. In all cases, the intensity of the intrinsic fluorescence intensity of the protein decreased with EGCG addition. The linearity of the Stern−Volmer plot (Figure 1, inset) suggested that all fluorophores in the protein were equally accessible to the EGCG molecules.[30] The quenching was attributed to binding of EGCG to $\beta$-Lg.

Figure 2 illustrates the linearity of the double logarithmic plot (eq 2), employed to determine the binding constant ($K_s$) and number of EGCG binding sites per $\beta$-Lg molecule ($n$). These values were $4.3 \times 10^4$ M$^{-1}$ and 1.2, respectively. These figures were found to be comparable with those reported in previous studies where a similar fluorescence method was used: $1.25 \times 10^4$ M$^{-1}$ and 0.94[4] and $1.3 \times 10^4$ M$^{-1}$ and 1.3,[16] respectively, for binding constant and number of binding sites. On the basis of these findings, each native $\beta$-Lg molecule can be expected to bind approximately one EGCG molecule (i.e., 1:1 on a molar concentration basis).

Previous authors reported an increase in the EGCG binding capabilities of $\beta$-Lg with heating.[9] In the present work, the

dx.doi.org/10.1021/jf5029834 | J. Agric. Food Chem. 2014, 62, 8357−8364

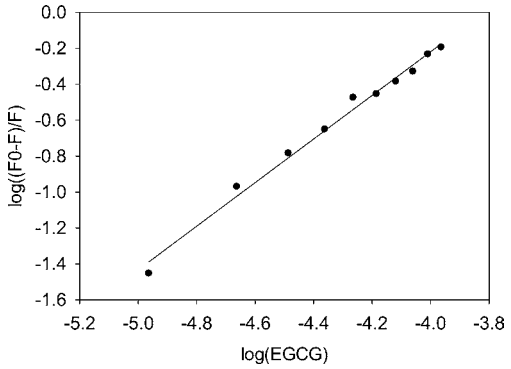

**Figure 2.** Double logarithmic plot of changes in fluorescence intensity as a function of EGCG concentration (10.9−108.8 $\mu$M). The binding constant and number of binding sites of $\beta$-Lg for EGCG binding can be inferred from the intercept and slope, respectively (eq 2).

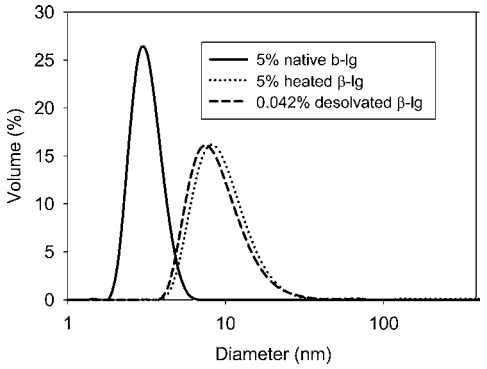

**Figure 3.** Particle size distribution of native (—), heated (85 °C, 20 min) (···), or desolvated (5× ethanol) (− − −) $\beta$-lactoglobulin solutions mixed with EGCG solutions at molar concentration ratio (EGCG/ $\beta$-Lg) of 3 as determined by dynamic light scattering (DLS). The protein concentration was 5% for native and heated protein, whereas it corresponded to 0.042% due to extensive dilution requirement for desolvated samples. Representative runs are shown.

association of EGCG with $\beta$-Lg was studied after preparation of protein nanoparticles by either thermal processing or desolvation techniques. We hypothesized that $\beta$-Lg−EGCG complexes could be obtained and that, in the complexed form, EGCG could maintain its bioefficacy in a cell culture model for intestinal cells (i.e., Caco-2 culture).

**3.2. Physicochemical Characteristics of EGCG-Bearing $\beta$-Lactoglobulin Particles.** The average apparent diameter for nanoparticles is summarized in Table 1, and Figure 3 shows the particle size distribution of EGCG-bearing $\beta$-Lg nanoparticles (heated or desolvated, 1:3 molar ratio of protein/EGCG) or native $\beta$-Lg, as measured by dynamic light scattering. Both heating and desolvation resulted in significantly larger protein complexes but <100 nm in average apparent diameter. The experiments were conducted at 10 and 50 $\mu$g·mL$^{-1}$ protein in the case of solutions heated at 85 °C for 20 min and at 50 $\mu$g·mL$^{-1}$ for desolvated nanoparticles (due to the high dilution in pH 3 buffer; see Materials and Methods). Native $\beta$-Lg solutions showed an average apparent diameter between 11 and 14 nm, and heating significantly increased the size to about 30 nm for 10 $\mu$g·mL$^{-1}$ and 40 nm for 50 $\mu$g·mL$^{-1}$ protein. The presence of EGCG did not affect the particle size significantly at the protein concentration levels studied (Table 1). This finding might be attributed to the molecular mass of EGCG (458 Da), which is considerably smaller compared to that of $\beta$-Lg (18.4 kDa) and the low extent of EGCG binding on a molar basis as shown by fluorescence measurements (i.e., $n$ = 1.2). Furthermore, EGCG interactions with the protein did not cause aggregation of the particles.

Desolvated $\beta$-Lg particles (with a starting solution of 50 $\mu$g·mL$^{-1}$) showed a significantly higher apparent diameter than both heated and native particles, with a larger standard deviation between experiments ($p$ < 0.05). This was due to a small fraction (1.2% of the volume) of larger particle (>1000 nm) in some of the replicate runs (data not shown). These results are in agreement with the observation of desolvated $\beta$-Lg samples by cryo-transmission electron microscopy (cryo-

TEM) showing small spherical particles and some larger particles.[14]

The thermal denaturation point of β-Lg is ∼76 °C.[35] Previous studies[35,36] showed that the first steps of denaturation lead to formation of surface-exposed hydrophobic clusters that increase protein−protein interactions. At temperatures higher than 60 °C, β-Lg monomers are partially unfolded, exposing the thiol group.[37] The free sulfhydryl group of β-Lg becomes reactive and causes thiol/disulfide interchanges with the other β-Lg monomers.[37,38] Heating caused aggregation of β-Lg, and the size of the aggregates significantly increased with protein concentration from 10 to 50 $\mu g \cdot mL^{-1}$ ($p < 0.05$). This observation was previously attributed to an acceleration of the polymerization reaction with increasing protein concentration.[38] Although the tertiary structure of β-Lg is affected by heating, as shown by Fourier transform infrared (FTIR) measurements, a reversible change in secondary structure will take place once β-Lg is cooled down quickly after heating.[26] Furthermore, it was reported that binding of EGCG did not affect the secondary structure of the protein, which is composed primarily of β-strands (55%).[26] This was in contrast with the findings of Shpigelman et al.[24] who suggested, using attenuated total reflectance (ATR)-FTIR, that binding of EGCG on heated β-Lg changed the protein secondary structure toward a higher extent of random coils. In the case of desolvated nanoparticles, however, the addition of ethanol to a β-Lg solution triggers a change in solvent polarity that affects the protein secondary structure and its ability to bind with other molecules. It has been shown that, in the presence of ethanol, β-Lg increases its α-helix content, and the structural changes lead to aggregation of the monomers.[39]

The ζ-potential of native β-Lg and heated β-Lg nanoparticles was found to be negative at pH 7, for example, −17 mV for 1% native and heated protein alone. When measured at a higher protein concentration, the values for native β-Lg particles were significantly lower; this may indicate the presence of residual ions in the purified protein fractions, which increases the overall ionic strength in the medium with protein concentration. In all cases, the presence of EGCG significantly increased the magnitude of ζ-potential of native β-Lg, as well as for the heated β-Lg nanoparticles (Table 1). This is consistent with results reported by Thongkaew et al.[40] when adding catechins to whey protein isolate. At 50 $\mu g \cdot mL^{-1}$, the heated nanoparticles were significantly more negatively charged than the native proteins, and the ζ-potential was also found to significantly increase in magnitude with EGCG concentration (Table 1). These results were consistent with a previous study[24] showing that the stability of EGCG-bearing heated β-Lg complexes was greater than that of heated β-Lg alone, which demonstrated that EGCG tends to stabilize β-Lg particles. It can be explained by the fact that, at pH 7, EGCG phenolic groups are deprotonated, generating an oxygen center of negative charges that will prevent further aggregation of β-Lg−EGCG complexes.[37] A recent work also pointed out a change in the structure of the protein upon polyphenol addition, namely, an increase in α-helix and β-sheet secondary structures and a decrease in random coil.[16] This could also stabilize the β-Lg−EGCG complexes. However, at high polyphenol concentration (1% w/v), precipitation of whey protein isolate has been reported and attributed to the aggregation of soluble complexes forming insoluble flocs.[37] In the case of desolvated particles (Table 1), since pH 3 is below the isoelectric point of β-Lg, their ζ-potential was positive, as previously demonstrated.[14] The value did not significantly vary with the presence of EGGC. In all cases, the particles showed a charge of about +26 mV, which indicates stability of the particles.

**3.3. Encapsulation Efficiency of EGCG-Bearing β-Lg Nanoparticles.** The amount of EGCG associated with the protein was determined after separation of the protein fraction from the unbound EGCG by a gel-filtration method. The values of EGCG recovery and encapsulation efficiency are summarized in Table 1 for 10 and 50 $\mu g \cdot mL^{-1}$ protein. The amount of EGCG recovered with β-Lg in 10 $\mu g \cdot mL^{-1}$ solutions was not significantly different between native and heated β-Lg (Table 1). At a molar ratio of 1:1 (EGCG/β-Lg), most of the EGCG was found associated with the protein, which was consistent with the fluorescence data reported in Figures 1 and 2. Since the fluorescence measurements indicated a molar binding ratio of approximately 1.2, the two sets of measurements are coherent. However, at the same β-Lg concentration, upon further addition of EGCG to the system (EGCG/β-Lg molar ratio increasing from 1:1 to 3:1), the encapsulation efficiency (percent) significantly decreased to about 60%, which implied the saturation of complexes. On a weight basis, the extent of binding increased from about 20 to 50 $\mu g \cdot (\text{mg of protein})^{-1}$ when the EGCG/β-Lg molar ratio increased from 1:1 to 3:1.

Table 1 also summarizes the association behavior of EGCG at 50 $\mu g \cdot mL^{-1}$ β-Lg. At this concentration, again, as for the 10 $\mu g \cdot mL^{-1}$ samples, there was no significant difference between heated and unheated β-Lg particles, and in all cases, the percent encapsulated was about 80% for EGCG/β-Lg molar ratio 1:1. These results are in contrast with earlier reports showing that EGCG binding of β-Lg increases after thermal denaturation of the protein.[9] At the higher molar ratio, the amount of encapsulated EGCG significantly decreased to about 25%, and the amount of loading was consistent at approximately 20 μg of EGCG/mg of protein. When 1% native dispersion and heated β-Lg particles complexed with EGCG were compared, at a molar concentration ratio of 1, almost complete encapsulation of EGCG took place, whereas at higher EGCG/β-Lg ratios, part of the EGCG remained free in solution. These findings are in full agreement with the fluorescence data shown in Figures 1 and 2 (i.e., $n = 1.2$). The findings can be attributed to increased extent of protein−protein interactions upon thermal denaturation, which could limit protein−polyphenol interactions.

Desolvated β-Lg particles showed very different encapsulation behavior. Due to their high extent of dilution (to a final protein concentration of 0.42 $\mu g \cdot mL^{-1}$), the percentage encapsulated was tested only for a molar ratio of 3:1 (EGCG/β-Lg). The encapsulation efficiency for these samples was approximately 90%, which was significantly higher than the other methods. It has been previously demonstrated that desolvated whey protein particles show high encapsulation efficiency.[15] The data shown in Table 1 clearly demonstrate that most of the EGCG added was found associated with the desolvated protein particles. The amount of EGCG bound was 68 μg of EGCG/mg of β-Lg, which was significantly higher than the values obtained with heated β-Lg particles. Compared to native β-Lg, which can bind approximately 1 EGCG molecule/β-Lg protein molecule (as shown in Figures 1 and 2), desolvated particles can bind approximately 2.7 EGCG molecules/β-Lg protein molecule. The different pH value (pH 3) could clearly affect the structural attributes of the protein, including surface charge and secondary structure.[41] However, the high dilution ratio utilized here may limit the applicability in

food systems. Although the ethanolic desolvation procedure enhanced the molar encapsulation ratio and the encapsulation efficiency on a weight basis (mg/mg), the stabilization of desolvated proteins and the reduction in ethanol content require extensive dilution, which in turn limits the total amount of EGCG that can be encapsulated. However, this approach could extend the EGCG encapsulation characteristics of β-Lg to acidic pH values and relevant food products.[10]

**3.4. Interfacial Characteristics of EGCG-Bearing β-Lactoglobulin Nanoparticles.** β-Lactoglobulin is known for its interfacial properties, and it is commonly found as an ingredient in emulsion systems, due to its ability to adsorb at interfaces and stabilize oil droplets or air bubbles. The interfacial characteristics of β-Lg were studied to determine whether the interfacial characteristics of the protein could be modified by formation of a complex with EGCG. The interfacial characteristics of the samples (at EGCG/β-Lg molar ratios of 0:1 and 3:1) were studied at the soy oil−dispersion interface by drop shape tensiometry. It has been previously reported that EGCG in isolation does not demonstrate interfacial activity.[42]

In all experiments, β-Lg reduced the interfacial tension of the oil−water interface, initially measured at 30.7 $mN{\cdot}m^{-1}$,[32] regardless of presence or absence of EGCG (Table 2). The interfacial tension data show that there were no significant differences in equilibrium interfacial tension values between native, heated, or desolvated protein particles. In the absence of EGCG, interfacial tension values for the oil−water interface were approximately 16 $mN{\cdot}m^{-1}$. This was consistent with previous findings on desolvated whey protein particles.[14] The presence of EGCG did not significantly affect the equilibrium interfacial tension for any of the samples, which implied that EGCG binding does not limit the extent of protein adsorption at the oil−dispersion interface.

Dilational elasticity was also tested for native β-Lg dispersions, β-Lg nanoparticles, and their corresponding EGCG complexes, as shown in Table 2. The method of sample manufacture did not significantly alter the dilational elasticity characteristics of the interface. The presence of EGCG significantly decreased the dilational modulus in all cases. In the absence of EGCG, the elasticity modulus was approximately 33 $mN{\cdot}m^{-1}$, while at a molar ratio of 3:1 (EGCG/β-Lg), dilational elasticity decreased to 21, 23, and 29 $mN{\cdot}m^{-1}$ (Table 2), for native dispersion and heat-induced and desolvated particle systems, respectively. It was concluded that the association of EGCG with β-Lg may decrease the ability of the protein to interact with other protein molecules at the interface and therefore hinder the creation of a rigid interface. These results are in contrast with the study of Rossetti et al.,[42] who have shown that EGCG increases elasticity when complexed with other proteins (saliva proteins from whole human saliva). This may be due to the differences in proteins and environments. We can infer from the current findings that the presence of EGCG did not significantly affect interfacial tension but decreased the extent of protein−protein interactions at the interface. These results demonstrated that EGCG binding only slightly affected the functional, and possibly nutritional, properties of the protein.

**Table 2. Interfacial Tension and Dilational Elasticity Characteristics of EGCG-Bearing β-Lg Dispersions at the Soy Oil−Dispersion Interface as a Function of Composition and Processing Conditions[a]**

| EGCG/β-Lg molar ratio | interfacial tension ($mN{\cdot}m^{-1}$) | dilational elasticity ($mN{\cdot}m^{-1}$) |
|---|---|---|
| | Native | |
| 0 | 17.5 ± 2.1 | 32.8 ± 12.9 |
| 3 | 16.3 ± 2.4 | 21.2 ± 4.3 |
| | Heated | |
| 0 | 15.8 ± 1.2 | 33.3 ± 6.3 |
| 3 | 16.0 ± 1.6 | 23.7 ± 7.6 |

| 0 | 14.7 ± 0.5 | 34.8 ± 11.7 |
| 3 | 17.4 ± 0.0 | 29.3 ± 1.4 |

[a]Native and heated samples contained 1% protein, whereas due to extensive dilution, desolvated samples had a β-Lg concentration of 0.042%. Dilational elasticity was measured at a dilational frequency of 10 mHz, and the extent of dilation was 10% in all cases.

**3.5. Bioefficacy of β-Lactoglobulin−EGCG Complexes.** Proliferation tests were conducted on confluent Caco-2 cells after 24 h of growth. The viability (percent) of Caco-2 cells that were administered freshly prepared or aged samples (24 h, 4 °C) after incubation for 24 h is shown in Table 3. Since EGCG is known for its anticancer properties on the vast majority of cancer cell lines,[6,43,44] in this study, its antiproliferative capacity was investigated in isolation or complexed with native β-Lg or desolvated or heated β-Lg nanoparticles. In the case of

[a]Final β-Lg and EGCG concentrations in the medium were calculated respectively on the basis of the amount loaded initially for 1 and 3 protein/EGCG molar ratios after final dilution in the medium (1:5.6 v/v). A high dilution ratio (120×) was applied on desolvated protein−EGCG complex. Controls of respective buffers and EGCG solution pH 3 and 7 were also tested.

unheated $\beta$-Lg and heated $\beta$-Lg nanoparticles, 1.8 $\mu g \cdot mL^{-1}$ solutions were tested at EGCG/$\beta$-Lg ratios of 1 and 3. On the other hand, for the desolvated nanoparticles, due to dilution effects, final dilutions brought the $\beta$-Lg concentration to 0.08 $\mu g \cdot mL^{-1}$, and a molar ratio of 3 was employed. In all cases, about 90% of the EGCG was encapsulated (see Table 1). Control samples containing buffer at pH 7 or citrate buffer at pH 3 (with or without traces of ethanol) were tested, and they did not affect Caco-2 viability. Free EGCG showed a significant decrease in cell proliferation in fresh samples ($p < 0.05$); however, in all cases, both at pH 7 and 3, the decrease in efficacy after storage of the EGCG solution at 4 °C was noticed. When EGCG was associated with native $\beta$-Lg, there was a clear decrease in cell proliferation. The values were comparable to those obtained with free EGCG. Similarly, heated $\beta$-Lg−EGCG complexes showed a statistically significant decrease in cell proliferation ($p < 0.05$). All the samples of EGCG complexed with proteins showed bioefficacy also after 24 h at the incubation temperature. In the desolvated $\beta$-Lg samples, due to the extensive dilution requirements in buffer at pH 3, a smaller amount of EGCG was added to the cell culture wells (see Table 3). The bioefficacy of EGGC in the desolvated $\beta$-Lg nanoparticles was fully maintained, with results not significantly different in fresh and aged samples. In both cases, the cell viability decreased up to 35%. Encapsulation of EGCG in nanostructures such as liposomes or casein micelles also has been shown to maintain its antiproliferative capacity on colon carcinoma cells.[45,46]

In this work we demonstrated that $\beta$-Lg, both native and after heat or desolvation treatment,can be an effective, protective carrier for EGCG. The bioactivity of $\beta$-Lg−EGCG complexes tested on Caco-2 cell monolayers did not alter its antiproliferative activity, and in all cases this activity was maintained. Furthermore, the results of this study confirm previous suggestions by Shpigelman et al.[9] that $\beta$-Lg−EGCG complexes provide considerable protection against oxidative degradation of EGCG. As shown in Table 3, such complexes were able to preserve the bioactivity of EGCG after 24 h storage of the solutions, compared to free EGCG solutions. Further studies should be conducted to investigate whether such processing conditions are able to protect EGCG activity after prolonged storage, if such complexes were to be considered in beverage formulations.
