toward aroma compounds (2-methyl-butanal, methional, 2-pentanone, 2-heptanone, and nonanal) using solid phase microextraction combined with gas chromatography−mass spectrometry (SPME-GC/MS) analysis. In addition, the interactions between oxidized protein and aroma compounds were further investigated using fluorescence quenching studies to better understand the underlying binding mechanism.

## MATERIALS AND METHODS

**Materials.** Longissimus muscle from three pork carcasses (48 h post-mortem) was purchased from a local commercial abattoir (Zhongshan, China), and the pigs were slaughtered about 6 months of age following standard industrial procedures. Fat was trimmed away and muscle was cut into cubes, minced, vacuum packaged (ca. 100 g), and frozen at −80 °C until use (used within 1 week). The aroma compounds 2-methylbutanal and 3-(methylthio) propanal (methional) were purchased from Sigma−Aldrich (Steinheim, Germany). 2-Pentanone, 2-heptanone, and nonanal were obtained from Aladdin (Shanghai, China). Methanol used was of the highest commercial grade and obtained from Sinopharm Chemical Reagent Co. Ltd. (Shanghai, China). All other chemicals were of analytical reagent grade.

**Preparation of Myofibrillar Proteins.** Raw muscle was thawed at 4 °C and then used for the myofibrillar protein preparation according to the method of Park, Xiong, Alderton, and Ooizumi[22] with slight modifications. The pH of myofibrillar protein suspension at 0.1 M NaCl in the last wash was adjusted to 6.25 before centrifugation. The pellet was finally suspended in 20 mM sodium phosphate buffer (pH 6.0) containing 0.5 M NaCl, and the protein concentration was determined by the Biuret method using BSA as standard.

**Protein Oxidation.** Myofibrillar protein suspension (28 mg/mL containing 0.5 mg/mL $NaN_3$) was incubated at 37 °C for 3 h in 20 mM sodium phosphate buffer (pH 6.0) containing 0.5 M NaCl with a hydroxyl radical-generating system.[22,23] The hydroxyl radicals were produced by a 100 $\mu$M $FeCl_3$/100 $\mu$M ascorbic acid solution with $H_2O_2$ at various concentrations (0−25 mM). The same myofibrillar protein treated without incubation or $H_2O_2$ was chosen as the control. To prevent further oxidation, butylated hydroxyl toluene (BHT) (1 mM final concentration) was then added.

**Evaluation of Oxidative Changes.** *Carbonyls.* The content of carbonyls was determined by the reaction with 2,4 dinitrophenylhydrazine (DNPH) using a Varioskan Flash (Thermo Scientific 3001, Thermo Fisher Scientific Oy, Finland), as described by Oliver et al.[24] with some modifications. Briefly, 200 $\mu$L of 5 mg/mL protein suspension in 20 mM sodium phosphate buffer (pH 6.0) was mixed with 800 $\mu$L of 2 M HCl (control) or 10 mM DNPH in 2 M HCl and incubated at room temperature (25 °C) for 1 h. The DNPH-reacted samples after 10% trichloroacetic acid (TCA) precipitation were recovered by centrifugation at 8000*g* for 10 min and then washed three times with 1 mL of ethanol:ethyl acetate (1:1, v/v) to eliminate free DNPH. The final protein pellets were dissolved in 1.2 mL of 6 M guanidine HCl with 20 mM sodium phosphate buffer (pH 6.0) and were then centrifuged at 8000*g* for 10 min. Protein concentration in the supernatant was calculated at 280 nm in the HCl control using BSA in 6 M guanidine as standard. The carbonyl concentration was calculated using an absorption of 21.0 $mM^{-1}cm^{-1}$ at 370 nm against the HCl control for protein hydrazones.

*Protein Surface Hydrophobicity.* The hydrophobicity was determined using the hydrophobic chromophore bromophenol blue (BPB) method reported by Chelh et al.[25] with slight modifications. The 0.5 mL protein suspension (5 mg/mL in 20 mM sodium phosphate buffer at pH 6.0) was thoroughly mixed with 100 $\mu$L of 1 mg/mL BPB (in distilled water). The resulting samples were continually shaken at room temperature (25 °C) for 10 min and then centrifuged at 4000*g* for 15 min (4 °C). The absorbance of supernatant was measured at 595 nm against a phosphate buffer blank. The sample with the same treatment in the absence of protein was used as the control. The amount of bound BPB was calculated according to the following formula (eq 1) and expressed as an index of hydrophobicity.

$$\text{BPB bound } (\mu\text{g}) = 100\ \mu\text{g} \times (\text{A control} - \text{A sample})/\text{A control} \quad (1)$$

*Mean Particle Size of Oxidized Proteins.* The mean particle size and size distribution of oxidized proteins were measured by a Mastersizer 2000 (Malvern Instruments Co. Ltd., Worcestershire, U.K.) at 25 °C, as described by Sun et al.[18] The refractive index was taken as 1.57, and the absorption index was 0.001. The particle sizes measured are reported as the surface-weighted mean diameter $d_{3,2}$ ($d_{3,2} = \sum n_i d_i^3 / \sum n_i d_i^2$) and volume-weighted mean diameter $d_{4,3}$ ($d_{4,3} = \sum n_i d_i^4 / \sum n_i d_i^3$), where $n_i$ is the number of particles with diameter $d_i$.

*SDS−PAGE Analysis.* SDS−PAGE was performed according to the method of Flores.[26] Briefly, myofibrillar protein suspensions (5 mg/mL in 20 mM phosphate buffer at pH 6.0) were mixed with sample buffer with and without 5% $\beta$-mercaptoethanol ($\beta$ ME) at a ratio of 1:1. The ones with $\beta$ ME were incubated for 5 min at 100 °C before centrifugation (10000*g*, 10 min). Then, 14 $\mu$L of samples were loaded onto the polyacrylamide gel made of 12% running gel and 5% stacking gel and subjected to electrophoresis using a Mini-PROTEAN 3 Cell apparatus (Bio-Rad Laboratories, Hercules, CA).

*Microstructure.* The surface morphology of oxidized proteins were examined using field emission scanning electron microscopy (FE-SEM, model S4800, Hitachi, Japan) at an accelerator voltage of 10 kV. Before imaging, freeze-dried protein samples were mounted on a holder with double-sided adhesive tape and sputter-coated with gold (JEOL JFC-1200 fine coater, Japan).

**Protein−Aroma Binding Measurements.** *Preparation of Aroma Compounds Solution.* A stock solution containing each aroma compound was prepared in methanol. The aroma compounds were then simultaneously added to protein suspension (control or oxidized, 8 mg/mL in 20 mM phosphate buffer containing 0.5 M NaCl at pH 6.0), resulting in a final concentration of 1 ppm for 2-pentanone, 2-heptanone, and nonanal and 2 ppm for 2-methyl-butanal and 5 ppm for methional. Both the control and the oxidized protein samples at different levels were prepared in duplicate. The selection of the five aroma compounds was based on their presence in the headspace and the contribution to the flavor of typical Cantonese sausage as well as other dry-cured meat products.[2,27]

*Solid-Phase Microextraction (SPME) and Gas Chromatography−Mass Spectrometry (GC/MS) Analysis.* Eight milliliters of the mixture was placed in a 20 mL headspace vial and sealed with a PTFE-faced silicone septum (Supelco, Bellefonte, PA). The control vial contained exactly the same buffer just without protein. Control and protein vials were stored overnight (12 h) at 30 °C to allow equilibration.[9] The quantity of aroma compounds in the headspace of protein and control vial was determined using SPME and GC/MS analysis using conditions as described by Gianelli et al.[6] with slight modifications. A 75 $\mu$m carboxen/poly(dimethylsiloxane) (CAR/PDMS) fiber (Supelco, Bellefonte, PA) was exposed to the headspace for sampling the aroma compounds. After 30 min of adsorption, the aroma compounds were desorbed by inserting the fiber into the GC injection port of a gas chromatograph set at 220 °C for 5 min in splitless mode. The split valve was opened for 1 min after injection. The fiber was heated for 5 min in the injection port at 220 °C to avoid analyte carryover between the samples. Analysis of the aromas was performed using Trace GC/MS system equipped with an Ultra GC, a Trisplus automated sampler, and a TR-Wax column (30 m × 0.32 mm × 0.25 $\mu$m, J&W Scientific, Folsom, CA). Helium was used as the carrier gas with a linear velocity of 20.4 cm $s^{-1}$. The fiber was placed in the injector, and the GC oven temperature was started at 38 °C and held for 6 min; next, the temperature was increased to 105 °C at a rate of 6 °C $min^{-1}$, then raised to 220 °C at the rate of 15 °C $min^{-1}$, and held for 5 min. The detector temperature was set at 240 °C. The mass spectrometer was operated in electron impact (EI) mode. The ionization energy, detector voltage, scan range, and scan rate applied for the analysis were 70 eV, 350 V, $m/z$ 35−350, and 3.00 scans/s, respectively. Chromatograms and mass spectra were evaluated using Xcalibur version 2.0 (Thermo Finnigan, San Jose, CA). The results are

dx.doi.org/10.1021/jf502540p | J. Agric. Food Chem. 2014, 62, 9544−9552

expressed as a percentage of the free aroma compound found in the headspace without protein in the solution.

**Fluorescence Spectroscopy Measurements.** Protein intrinsic fluorescence was measured at a constant protein concentration (0.8 mg/mL) with various methional concentrations (0.05−0.5 ppm) in 20 mM phosphate buffer (pH 6.0) using a Varioskan Flash (Thermo Scientific 3001, Thermo Fisher Scientific Oy, Finland). Emission spectra were recorded from 300 to 400 nm at an excitation wavelength of 283 nm. Both the excitation and emission slit widths were set at 5 nm. The fluorescence spectra of the phosphate buffer were subtracted from the respective spectra of the samples. Fluorescence quenching is described according to the Stern−Volmer equation (eq 2):[28]

$$F_0/F = 1 + k_q\tau_0[Q] = 1 + K_{SV}[Q] \quad (2)$$

In this equation $F_0$ and $F$ are the fluorescence intensities in the absence and presence of a quencher, respectively, [Q] is the quencher concentration (mol/L), $K_{SV}$ is the Stern−Volmer quenching constant, $k_q$ is the bimolecular quenching rate constant, and $\tau_0$ is the lifetime of fluorescence in the absence of a quencher ($\sim 10^{-8}$ s). Hence, eq 1 was applied to determine $K_{SV}$ by linear regression of a plot of $F_0/F$ versus [Q].

**Statistical Analysis.** Statistical calculation was investigated using the statistical package SPSS 11.5 (SPSS Inc., Chicago, IL) for one-way ANOVA. Student−Newman−Keuls test was used for comparison of mean values among determinations using a level of significance of 5%. Triplicate preparations of myofibrillar proteins were carried out to confirm the accordance. Data were expressed as means ± standard deviations (SD) of triplicate determinations unless specifically mentioned.

## RESULTS AND DISCUSSION

**Oxidative Modifications of Myofibrillar Proteins.** *Carbonyls.* The carbonyl contents of the control and oxidized myofibrillar proteins are presented in Figure 1A. In this work, carbonyl content of the control protein was 1.66 nmol/mg protein, similar to those reported by Traore et al.[29] on raw *longissimus thoracis* muscle and Morzel et al.[23] on skeletal muscle myofibrillar proteins from pig *longissimus dorsi*. Compared to the control, carbonyl content of the incubated protein sample (0 mM) exhibited no significant difference ($p < 0.05$). Nevertheless, in the presence of oxidant, protein carbonyl content linearly increased ($R^2 = 0.998$) with the increasing $H_2O_2$ concentrations, and a maximum value of 14.03 nmol/mg protein was observed at 25 mM $H_2O_2$. This indicated that the formation carbonyl was weakly affected by the thermal process alone but was markedly exacerbated by the presence of $H_2O_2$, in agreement with previous studies.[19,22] In addition, considering the increase in carbonyl content during storage of meat for 10 days could be reached at approximately 2.5−10 mM oxidizing agent in our experiment,[19] the oxidative system used could be compared to real meat products to some extent.

*Protein Surface Hydrophobicity.* In view of its capacity to monitor subtle changes in chemical and physical states of protein, surface hydrophobicity could be a suitable parameter to estimate protein denaturation.[30] Figure 1B shows the surface hydrophobicity of the control and oxidized myofibrillar proteins. Compared to that of the control (44.74 μg bound BPB), the hydrophobicity of incubated protein sample (0 mM $H_2O_2$) was significantly increased ($p < 0.05$). This indicated that the thermal treatments could markedly increase the protein surface hydrophobicity, which could be related to the unfolding of actomyosin fibers, which begins at 35 °C.[31] For oxidized proteins, as can be seen, relatively low addition of $H_2O_2$ (0.5−1 mM) decreased the hydrophobicity level, while the further ($H_2O_2 \geq 2.5$ mM) significantly ($p < 0.05$) enhanced it. The

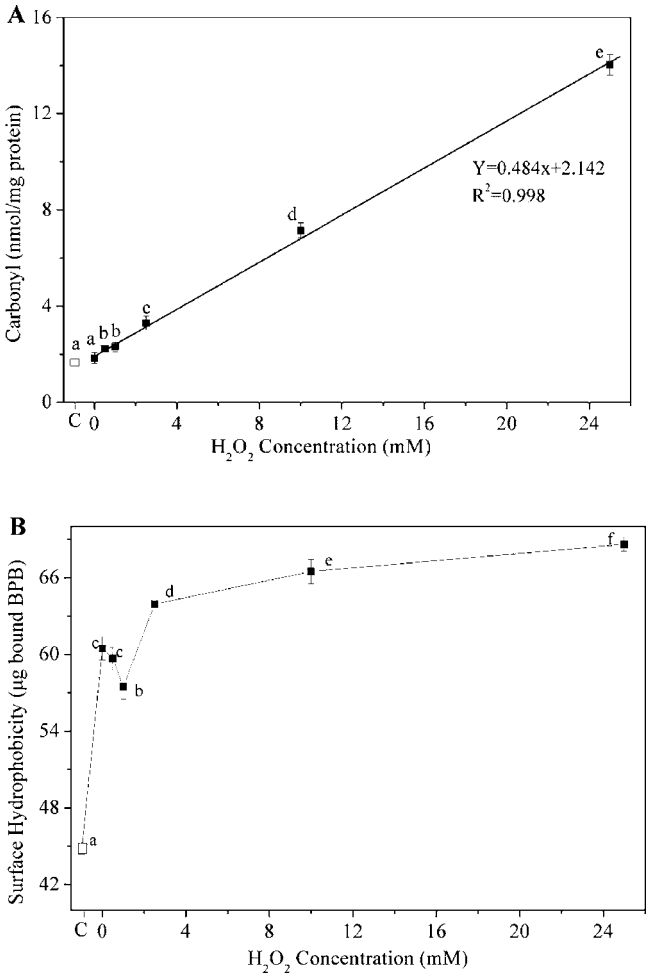

**Figure 1.** Physicochemical changes (A: carbonyl content; B: protein surface hydrophobicity) of the myofibrillar proteins upon oxidation by 100 μM $FeCl_3$/100 μM Ascorbic acid/0−25 mM $H_2O_2$. For the letters a−f, means ($n = 3$) without a common letter differ significantly ($p < 0.05$).

hydrophobicity for protein at 25 mM $H_2O_2$ was 68.61 μg, indicating an obvious increase by about 53% when compared with that of control (44.74 μg). Similar results have also been obtained stating that heating at temperatures close to the physiological temperature under slight oxidative stress might lead to protein refolding,[32,33] which could further lead to the decrease in hydrophobicity. However, with the further increase in $H_2O_2$ concentration (>2.5 mM), the hydrophobic amino acids, which are buried in protein inside, were exposed and thus enhanced protein surface hydrophobicity.[30,34] Moreover, the cleavage of certain peptide under oxidative attack might also contribute to the enhancement of surface hydrophobicity.[13]

*Mean Particle Size and Distribution.* The mean particle size ($d_{3,2}$ and $d_{4,3}$) and size distributions for the oxidized proteins were used to assess the aggregation behavior of protein during oxidation, as shown in Figure 2. It can be clearly seen that, compared to the control, the incubated protein sample (0 mM $H_2O_2$) exhibited a better size distribution, although no significant difference ($p > 0.05$) was observed in the mean particle size values ($d_{3,2}$ and $d_{4,3}$). Upon the presence of $H_2O_2$, it is noted that, compared to the control, the proteins showed markedly higher particle size values ($d_{3,2}$ and $d_{4,3}$) and the particle size distribution was monomodal and narrow. More-

dx.doi.org/10.1021/jf502540p | J. Agric. Food Chem. 2014, 62, 9544−9552

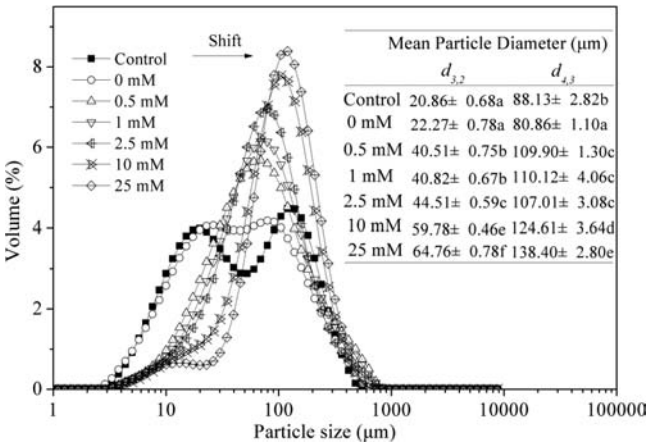

**Figure 2.** Particle size distributions of the myofibrillar proteins upon oxidation. Inset: Mean particle diameter ($d_{3,2}$ and $d_{4,3}$) of the control and oxidized proteins.

over, with the increasing addition of oxidants, an evident shift of the size distribution peak to the right was observed (Figure 2). These results should be attributed to the fact that the $H_2O_2$-induced protein oxidation might promote the intermolecular aggregation behaviors,[15] thus resulting in the change on the size distribution and the increase in particle size values ($d_{3,2}$ and $d_{4,3}$) of proteins. On the basis of the result of protein surface hydrophobicity (Figure 1B), we can thus conclude that the increase in surface hydrophobicity might favor the association between proteins mainly due to hydrophobic interactions and thereby the increase of intermolecular aggregation. In addition, it is interesting to note that, within the $H_2O_2$ concentration range from 0.5 to 2.5 mM, no marked changes on the values of $d_{4,3}$ and $d_{3,2}$ for the oxidized proteins were observed. However, with further increase in $H_2O_2$ concentrations (2.5−25 mM), the $d_{4,3}$ and $d_{3,2}$ values for proteins began to dramatically increase. These results should probably be related to the surface modification of myofibrillar protein under the $H_2O_2$-induced oxidative stresses and were in accordance with the sudden increase in protein surface hydrophobicity when the $H_2O_2$ added reached 2.5 mM (Figure 1B).

*SDS−PAGE.* The aggregation behavior of oxidized proteins was further studied by the SDS−PAGE analysis (Figure 3). As shown in Figure 3, oxidative modification significantly altered the electrophoretic pattern of myofibrillar protein. In the absence of $\beta$ ME, the exposure of myofibrillar protein to •OH caused a gradual disappearance of several subunits in a $H_2O_2$ dose-dependent manner (Figure 3A), among which changes in myosin were most remarkable, similar to those previous reports.[15,35] Herein, both myosin heavy chain (MHC) and heavy meromyosin−myosin heavy chain (HMM-MHC) began to reduce at 0.5 mM of $H_2O_2$ and almost completely vanished since $H_2O_2$ reached 1 mM. A similar, albeit less conspicuous, actin loss was also observed with increasing addition of $H_2O_2$ despite remaining faint even at high $H_2O_2$ concentrations. Simultaneously, upon oxidation, high molecular weight polymers, which barely entered the stacking gel, became accentuated (Figure 3A). These results indicated the occurrence of cross-linking under oxidation, which was consistent with the changes in particle size distributions as aforementioned (Figure 2), and myosin and actin were mainly involved. In addition, changes in troponin T (TnT) and tropomyosin (Tm) were also noticeable for their band intensity both declined upon oxidation and almost disappeared when the oxidant reached 1 mM. Nevertheless, they reappeared with further oxidation. The results implied that TnT and Tm were also involved in the formation of aggregates within the $H_2O_2$, ranging from 0 to1 mM, well explaining the corresponding significant ($p < 0.05$) decrease in protein surface hydrophobicity (Figure 1B). Nevertheless, further oxidation caused the reappearance of TnT and Tm, indicating that they were gradually no longer involved in the aggregates, which might be related with the degradation of protein backbone under •OH attack.[36] In the presence of $\beta$ ME, MHC, actin, TnT, and Tm were mostly recovered (Figure 3B), suggesting that these polymers were formed largely by disulfide bonds (S−S) or mainly through this mechanism. Nevertheless, samples treated with more than 2.5 mM of $H_2O_2$ exhibited rather diffused bands at the top of the resolving gel, and the band intensity increased along with $H_2O_2$ concentration. This suggested the presence of other covalent polymers containing no S−S bonds, such as Tyr−Tyr and active carbonyl−$NH_2$ interaction, as

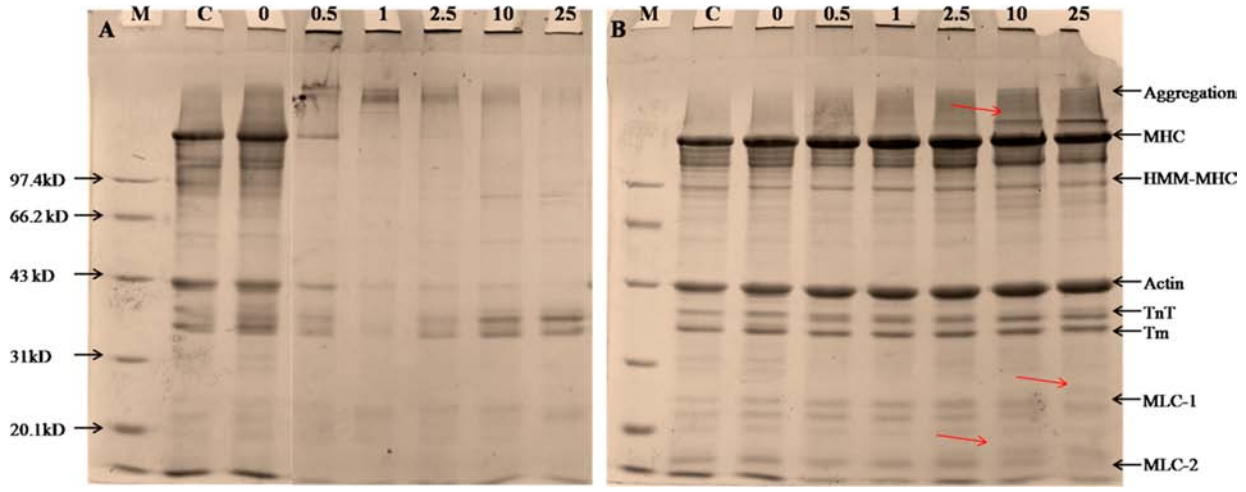

**Figure 3.** Representative SDS−PAGE patterns of the control and myofibrillar proteins oxidized by 100 $\mu$M $FeCl_3$/100 $\mu$M ascorbic acid/0−25 mM $H_2O_2$ (A) without and (B) with 5% $\beta$ ME. MHC, myosin heavy chain; HMM-MHC, heavy meromyosin−myosin heavy chain; TnT, troponin T; Tm, tropomyosin; MLC-1, myosin light chain-1; MLC-2, myosin light chain-2.

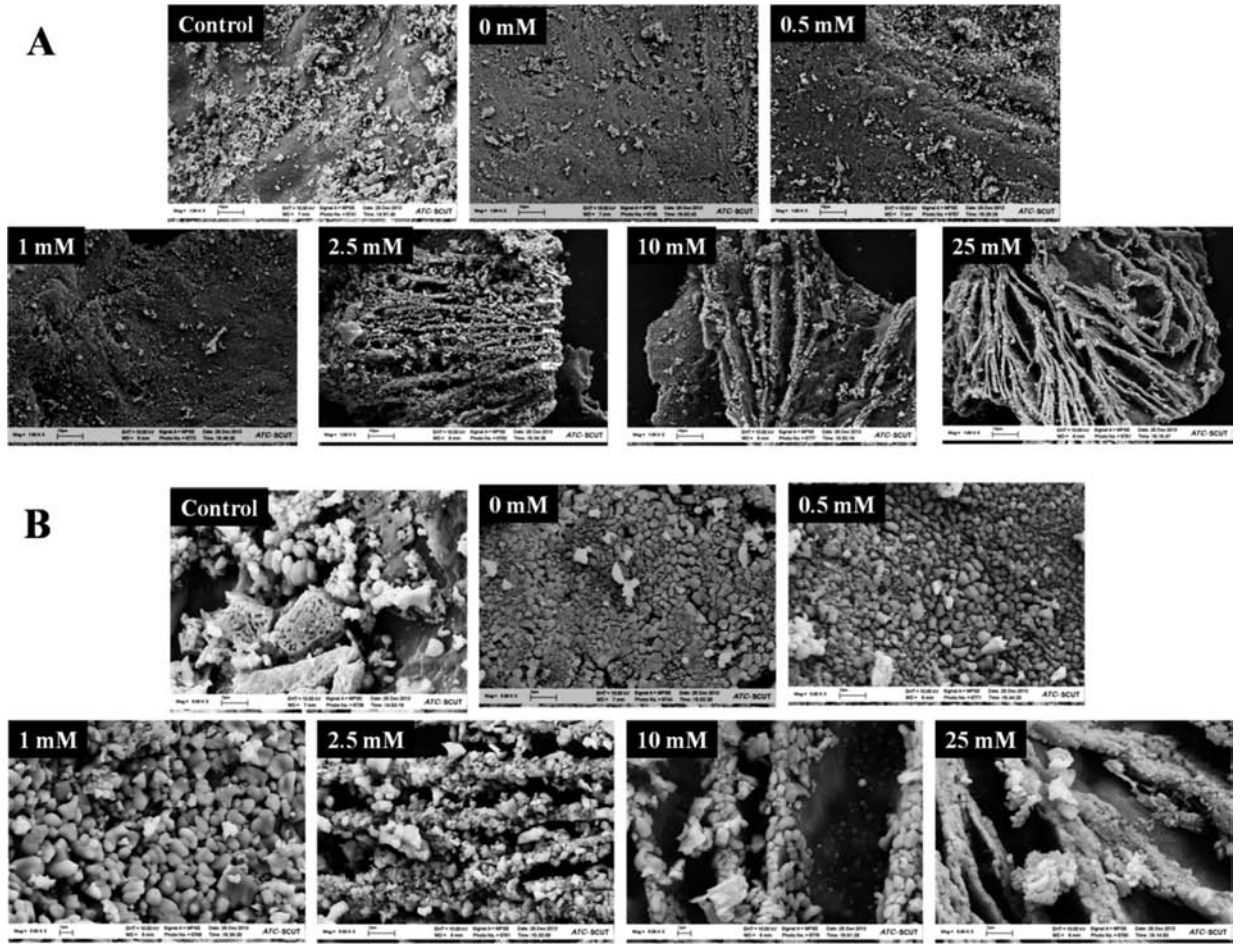

**Figure 4.** Scanning electron microscope micrographs at (A) ×1000 and (B) ×5000 magnification of the control and oxidized (100 $\mu$M $FeCl_3$/100 $\mu$M ascorbic acid/0−25 mM $H_2O_2$) myofibrillar proteins. Scale bars indicate (A) 10 $\mu$m and (B) 2 or 1 $\mu$m.

previously reported.[15,23] These covalent polymers, previously linked together by S−S (therefore too large to enter the stacking gel),[37] were present in those oxidized protein samples. In addition, new but hazy bands with molecular weight similar to MCL-1 and MCL-2 generated in samples treated with more than 2.5 mM of $H_2O_2$, suggesting the fragmentation or degradation of protein backbone under •OH attack, as has been previously reported by Berlett et al.,[36] which could contribute to the increase in protein surface hydrophobicity (Figure 1B).

*Microstructure.* The changes in the physicochemical properties of oxidized myofibrillar proteins were further investigated by the measurements of their morphologic properties. Microstructures of oxidized proteins under different $H_2O_2$ levels, in comparison with the control, are presented in Figure 4. For the control, protein appeared in an intactly dense and firm pattern with the heterogeneous surface (Figure 4, panels A and B). Compared to the control, the incubated protein sample (0 mM $H_2O_2$) showed a more flat surface with few visible pores (Figure 4A), which might be due to the unfolding and slight shrinkage of myofibrillar protein upon incubation.[38] Additionally, evenly distributed granular aggregates, which has been reported by Astruc et al.,[38] were also observed when further magnified (Figure 4B). For proteins with oxidants, at low $H_2O_2$ concentrations (0.5 and 1 mM), the surface microstructures of samples were not appreciably different despite the increasing roughness of overlapped surface (Figure 4A). Moreover, the increase in granular size of the aggregates (Figure 4B) well indicated the accelerated state of aggregation, in agreement with the results of surface hydrophobicity and mean particle size (Figures 1B and 2). When $H_2O_2$ concentrations were increased to higher levels (2.5−25 mM), it was noteworthy that an obvious morphological change was observed and this morphological transition occurred between 1 and 2.5 mM of oxidants. This trend was in accordance with changes in the data of protein surface hydrophobicity, mean particle size, and results revealed by SDS−PAGE (Figures 1B, 2, and 3). It was more likely that samples treated with 2.5 mM of oxidants, which underwent steric modifications, rendered the layered surface with discontinuous aggregates (Figure 4). The enlarged surface area thus resulted in the sudden increase in protein surface hydrophobicity (Figure 1B), which was also consistent with the results revealed by SDS−PAGE (Figure 3). When being further oxidized (10−25 mM $H_2O_2$), myofibrillar protein showed a surface with more wrinkles at a larger size (Figure 4). This suggested that higher levels of oxidation would further modify the protein surface properties and plausibly simultaneously involved protein reaggregation and degradation, as indicated by SDS−PAGE analysis (Figure 3).

**Binding of Aroma Compounds with Oxidized Myofibrillar Proteins.** On the basis of the characterization of oxidized proteins, we attempted to investigate the influence of structural changes of proteins on their binding ability with aroma compounds. Thus, the free percentages of each aroma

dx.doi.org/10.1021/jf502540p | J. Agric. Food Chem. 2014, 62, 9544−9552

compound in the headspace in the presence of myofibrillar protein at different oxidizing levels were determined, as shown in Figure 5. One hundred percent of free aroma compound

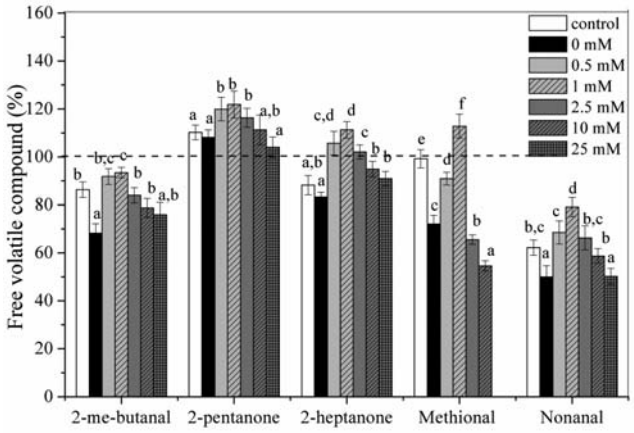

**Figure 5.** Effect of protein oxidation on the binding of aroma compounds. Results are expressed as percentage of free aroma compounds found in the headspace without protein in solution. Bars with different letters are significantly different ($p < 0.05$) among oxidation levels.

corresponds to the headspace concentration present in the control vial that does not contain protein.[10] As can be seen in Figure 5, the presence of the control protein produced a marked reduction of the percentages of free nonanal and a slight decrease of 2-methyl-butanal and 2-heptanone, suggesting that the control protein was able to bind those aroma compounds. In contrast, the increase in 2-pentanone implied its releasing behavior. These results were similar to that reported by Pérez-Juan et al.[2,10] Compared to the control, the incubated protein sample (0 mM $H_2O_2$) exhibited significantly lower percentages of 2-methyl-butanal, nonanal, and methional ($p < 0.05$), suggesting that thermal treatment could enhance the binding ability of protein toward them, which could be mainly attributed to the fact that the unfolding of actomyosin fibers after heating (37 °C) increased the sites available for hydrophobic binding.[10,31] For oxidized proteins, oxidation further affected the protein binding ability in a dose-dependent way. When the $H_2O_2$ added ranged from 0 to 1 mM, the percentages of all aroma compounds increased, indicating the decreased binding ability of protein. However, it was very interesting to note that, with the further increase in $H_2O_2$ concentration (>1 mM $H_2O_2$), an inverse effect on the percentages of aroma compounds was observed. As can be seen with increasing protein oxidation level, the percentages of all the selected aroma compounds decreased, implying the increased binding ability of protein toward them. Specifically, the percentages of free methional dramatically decreased with further oxidation (>1 mM $H_2O_2$) and even could not be detected when the highest concentration of $H_2O_2$ was added (25 mM).

As has been reported, the concentration of free aroma compounds in the gas phase largely depends on their interactions with protein, and changes in the protein conformation affect the interaction between aroma compounds and proteins due to the modification of the available protein binding sites.[3,39] As aforementioned, treatment with 0.5−1 mM of oxidants enhanced protein−protein interactions, mainly leading to the formation of protein aggregates and overlapped/reduced surface, as confirmed by SDS−PAGE and microstructure analysis (Figures 3 and 4). These changes (structural hindrance) impaired the affinity of the aroma compounds for the protein matrix by reducing the number of binding sites for the aroma compound[2] and thus decreased the binding ability of protein with all the selected aroma compounds (Figure 5). However, for protein treated with oxidants more than 2.5 mM, the binding ability of oxidized proteins toward the aroma compounds (especially for methional) increased (Figure 5). This could be explained by the remarkable increase in the protein surface hydrophobicity and modified protein surface properties (wrinkled surfaces) within the oxidant range (Figures 1B and 4), which might contribute to the interaction between protein and these compounds mainly driven by hydrophobic forces, thus enhancing the corresponding binding ability (Figure 5).

**Interactions between Oxidized Proteins and Methional.** Fluorescence spectroscopy is commonly used to study the binding between protein and small molecules, and fluorescence quenching refers to any process that decreases the fluorescence intensity of a sample.[40−42] A variety of mechanisms can cause quenching, such as excited state reaction, molecular rearrangement, energy transfer, ground state complex formation, and collision quenching.[40,43] Since myofibrillar proteins have tryptophan (Trp) residues that possess intrinsic fluorescence, the interaction mechanisms between myofibrillar proteins and aroma compounds could be further studied by the fluorescence quenching method. In the present work, we have demonstrated that oxidation-induced structural changes could markedly influence the protein binding ability with aroma compounds (Figure 5), especially for methional. Thus, methional was first selected as a model aroma compound, and the interaction between oxidized myofibrillar proteins and methional in the aqueous phase was subsequently investigated using fluorescence quenching studies (Figure 6). Figure 6A displays the example of fluorescence emission spectra of oxidized myofibrillar protein (25 mM $H_2O_2$) with various concentrations of methional. The fluorescence spectra of control and other oxidized protein (0−10 mM $H_2O_2$) samples in the presence of methional were also measured (data not shown). Evidently, the oxidized protein alone exhibited a strong fluorescence emission at 330 nm following an excitation at 283 nm. With the increasing of methional, a gradual attenuation of the fluorescence intensity of oxidized protein was observed (Figure 6A). Under the experimental conditions, methional revealed no fluorescence emission in the range of 300−400 nm, which did not affect protein intrinsic fluorescence. Thus, it could be concluded that there was interactions between oxidized myofibrillar protein (25 mM $H_2O_2$) and methional, in agreement with the results of protein binding ability with aroma compounds (Figure 5).

To further discern the influence of protein oxidation on fluorescence quenching mechanism, Stern−Volmer eq 2 was used for data analysis, and the corresponding results fitted from Stern−Volmer plots (Figure 6B) are summarized in Table 1. As shown in Table 1, the Stern−Volmer quenching constant $K_{SV}$ varied among the oxidized protein samples. Compared to the control, the $K_{SV}$ value of the incubated protein sample (0 mM $H_2O_2$) significantly ($p < 0.05$) increased, in agreement with its enhanced binding ability with methional (Figure 5), which might be related to the increased surface hydrophobicity (Figure 1B). For oxidized proteins, with the low addition of

dx.doi.org/10.1021/jf502540p | J. Agric. Food Chem. 2014, 62, 9544−9552

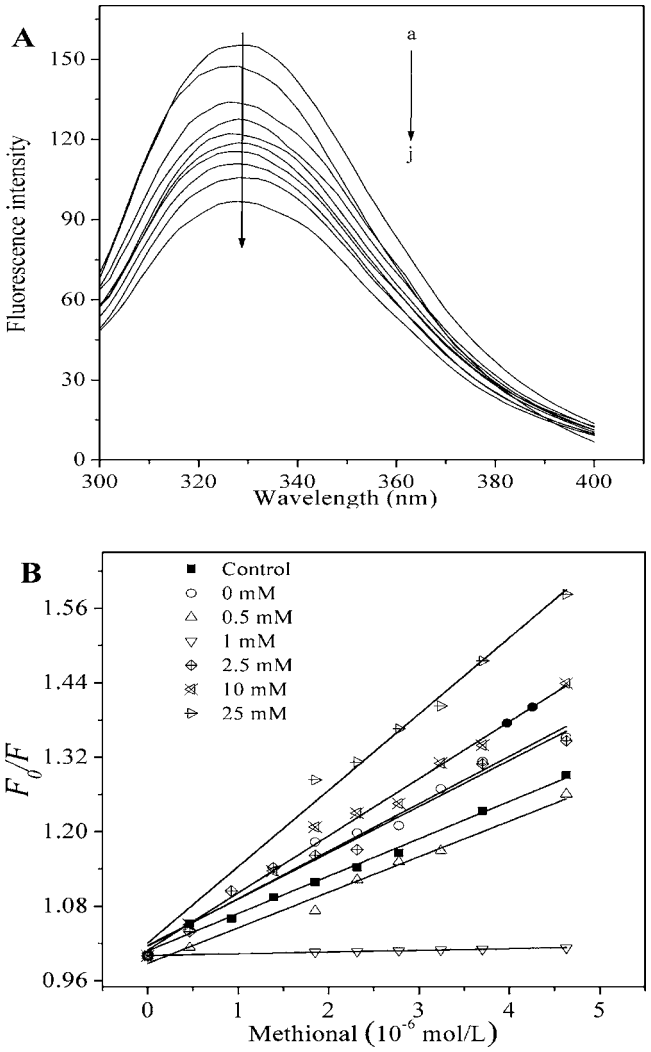

**Figure 6.** (A) Example of fluorescence emission spectra of oxidized myofibrillar protein (25 mM $H_2O_2$) with various amounts of methional in 20 mM phosphate buffer B containing 0.5 M NaCl at pH 6.0: (a) 0.8 mg/mL oxidized protein alone; (b–j) 0.8 mg/mL oxidized protein with 0.05, 0.1, 0.15, 0.2, 0.25, 0.30, 0.35, 0.40, and 0.50 ppm methional, respectively. (B) Stern–Volmer plots describing fluorescence quenching of the control and oxidized proteins at different levels in the presence of methional.

oxidants (0–1 mM $H_2O_2$), the values of $K_{SV}$ dramatically decreased. However, upon the further increase of oxidant concentration (2.5–25 mM $H_2O_2$), an obvious increase in the $K_{SV}$ values was observed when compared to that of the control. This result perfectly matched the general trends seen in the data of surface hydrophobicity (Figure 1B) and protein binding ability with aroma compounds (Figure 5), further implying the interesting influence of protein oxidation on the protein binding reaction with aroma compounds. Furthermore, all the values of $k_q$ calculated (Table 1) were much higher than the maximum value for diffusion-controlled quenching in water ($\sim 10^{10}$ $M^{-1}$ $s^{-1}$), signifying the possible quenching mechanism for control and oxidized protein fluorescence by methional is a static type.[28,40] These results indicated that the methional may bind with hydrophobic sites of protein, forming the protein–aroma compound complex. This is in agreement with previous studies, which have reported that hydrophobic binding of flavor

compounds by food proteins could lead to the formation protein–aroma compound complex.[42]

On the basis of the above analysis, we can conclude that the oxidative system applied could either increase or decrease the binding ability of aroma compounds with myofibrillar proteins, depending on the structural changes, especially the surface modifications of protein under oxidative stress. Specifically, treatment with low oxidant concentration (0.5–1 mM $H_2O_2$) mainly decreased protein surface hydrophobicity due to the formation of aggregates and the subsequent refolding of protein surface structure (Figures 1B, 3, and 4). This led to the reduction of the affinity of the aroma compounds for the protein matrix and thus the decreased binding ability with all aroma compounds selected (Figure 5). However, treatment with oxidant over 2.5 mM further aggregated the protein and at the same time remarkably modified protein surface properties (Figures 3 and 4), which dramatically enhanced protein surface hydrophobicity (Figure 1B). This resulted in the increased binding ability of protein with aroma compounds (especially for methional) (Figure 5) mainly driven by hydrophobic interaction, forming the protein–aroma compound complex, as evidenced by fluorescence quenching (Figure 6). In addition, considering the real meat system, the link between protein structure and flavor binding is not straightforward. However, in view of all these present results, it could be speculated that there is a clear correlation between protein structure modified by hydroxyl radical-induced oxidative system and its aroma binding ability.

In summary, this study clearly showed that the protein binding ability with aroma compounds was correlated with its structural changes, which was found to be strongly influenced by the hydroxyl radical-induced oxidative modifications. Incubation with low oxidant concentration (0.5–1 mM $H_2O_2$) mainly accelerated the aggregation and thus decreased protein surface hydrophobicity, reducing the binding ability with aroma compounds, while the presence of higher oxidant concentrations (>2.5 mM $H_2O_2$) would cause the protein reaggregation and partial degradation, and thus the subsequent modification of protein surface properties. The aggregated protein with wrinkled surfaces largely favored the binding with aroma compounds (especially for methional) mainly driven by hydrophobic interaction, forming the protein–aroma com-

pound complex. These findings provided interesting correlation between protein structure and its aroma binding ability and are critical for the food industry to manufacture meat-flavored foods with myofibrillar protein that underwent oxidative stress.

distributed in cytoplasm when uptaken into Caco-2 cells. The above studies suggest that soy protein nanoparticles have some unique qualities. However, much more studies are needed to find a convenient way to produce stable soy protein nanoparticles, to elucidate the mechanism of particles formation, and to illustrate their inner structure.

In this investigation, we explored the possibility to produce stable soy protein nanogels by heating soy protein dispersion at the critical pH point where it had the lowest polydispersity index. The *z*-average hydrodynamic diameter, polydispersity index, $\zeta$-potential, turbidity, and morphology were evaluated to characterize the nanogels. Their resistance to pH and ionic strength change was also investigated. Influence of heat load (temperature and time) on the stability of soy protein particles would be discussed. A possible mechanism of the nanogels formation was proposed. Soy protein nanogels produced in this study would be useful functional ingredients to modify the optical or rheological properties of food products, or to encapsulate and deliver bioactive ingredients.

## MATERIALS AND METHODS

**Materials.** Defatted soy flakes were purchased from Yuwang Group (Shangdong, China). Soy protein (94.2% protein (Kjeldahl, N × 6.25), 4.5% moisture, and 1.3% ash) was prepared from defatted soy flakes by the method described in this Article. BCA (bicinchoninic acid) protein assay kit and dithiothreitol (DTT) were purchased from Dingguo (Beijing, China). 1-Anilinonaphthalene-8-sulfonic acid (ANS) was purchased from Sigma-Aldrich (St. Louis, MO). Iodoacetamide was purchased from Aladdin Reagent Co., Ltd. (Shanghai, China). All other chemicals were of analytical reagent grade and obtained in China.

**Soy Protein Preparation.** Defatted soy flakes powder was mixed with 15-fold (in weight) deionized water, and the mixture (pH 6.8) was adjusted to pH 7.5 with 2.0 M NaOH. After being stirred for 2 h, the resulting suspension was centrifuged at 8000*g* for 20 min at 4 °C to remove the insoluble material. The pH of the supernatant then was adjusted to pH 4.5 with 2.0 M HCl, and the precipitate was collected by centrifugation at 8000*g* for 10 min at 4 °C. The precipitate was then redissolved with 5-fold (in weight) deionized water, and the pH was adjusted to 7.0 with 2.0 M NaOH. The neutral soy protein solution was dialyzed against deionized water at 4 °C for 48 h and then freeze-dried and stored at 4 °C until use.

**Soy Protein Dispersion Preparation.** The soy protein dispersion was prepared by dispersing soy protein powder in deionized water (1.1%, w/v) and stirring at 25 °C for 2 h. The soy protein dispersion was left for 12 h at 4 °C to allow complete hydration. Afterward, the dispersion was centrifuged at 10 000*g* for 15 min to remove insoluble matter. The protein concentration was analyzed using BCA assay. The protein concentration then was adjusted to 1% (w/v).

**Creation of Soy Protein Nanogels.** The pH of soy protein dispersion was modified to 2.6−7.0 by stepwise addition of 2.0 M HCl. Samples were withdrawn at different pH values for size and polydispersity index analysis. For producing nanogels, soy protein dispersion was adjusted to the pH (5.9) where the dispersion had the lowest polydispersity index and poured into 100 mL glass vials (with a screw-top and solid cap) and heated in a water bath without stirring at 95 °C for 30 min. After the heat treatment, samples were immediately cooled in ice water to 4 °C. Correspondingly, soy protein dispersion (pH 5.9) without heat was used as control. For the study of the effects of holding temperature on the stability of particles, soy protein dispersion (pH 5.9) was heated at 50−95 °C for 30 min (room temperature was 25 °C). For the study of the effects of holding time on stability of particles, soy protein dispersion (pH 5.9) was heated at 95 °C for 0−60 min. Samples were withdrawn at different temperatures and times for further analysis. It should be noted that the reported heating time zero did not take into account the preheating time needed to reach the selected final temperature (it would take a maximum of 6 min to reach 95 °C in this experiment).

**pH Stability of Soy Protein Nanogels.** The effects of pH on the properties of the protein nanogels prepared by heating protein dispersion (pH 5.9) at 95 °C for 30 min were measured by modifying the pH of the dispersions from 2.6 to 7.0. Samples without heat were used as control. For samples withdrawn from different temperatures and times, pH was adjusted to 7.0. Characteristics of particles in different pH were further analyzed.

**Salt Stability of Soy Protein Nanogels.** The effects of salt addition on the stability of the protein nanogels prepared by heating protein dispersion (pH 5.9) at 95 °C for 30 min was measured by adjusting the NaCl concentration of the dispersion from 0−200 mM. Samples without heat were used as control. For the samples withdrawn from different temperatures and times, NaCl concentration of dispersions was adjusted to 150 mM.

**Sedimentation Stability.** The stability of the samples to sedimentation after pH and NaCl concentration adjustment was recorded by taking photographs using a digital camera after they had been stored at 4 °C for 24 h.

**Particle Size, Polydispersity, and Surface Charge Measurements.** Protein dispersion was diluted to 0.1% (w/v) for particle size, polydispersity, and surface charge measurements using a commercial dynamic light scattering and microelectrophoresis device (Nano-ZS, Malvern Instruments, Worcestershire, UK). The particle size was reported as the *z*-average hydrodynamic diameter ($D_h$), polydispersity was reported as polydispersity index (PDI), while the particle surface charge was reported as the $\zeta$-potential. The $D_h$, PDI, and $\zeta$-potential were analyzed by Dispersion Technology Software (DTS) version 4.20 supplied by the manufacturer (Malvern Instruments Ltd.). PDI were calculated by the cumulant analysis method of the autocorrelation function. The autocorrelation function ($G(t)$) was calculated from the fluctuation of the scattered intensity with time: $\ln(G(t)) = a + bt + ct^2$. $t$ is the time (s), and $a$, $b$, and $c$ are terms of polynomial fit calculated. The polydispersity index was calculated from the ratio $2c/b^2$.

**Turbidity Measurement.** The turbidity of soy protein dispersions was determined by measuring the absorbance of the dispersions without dilution at $\lambda$ 500 nm using a UV−vis spectrophotometer (Genesys 10s, Thermo Fisher, America).

**Microscopic Observations.** Transmission electron microscopy (TEM) was used with the negative staining method. Observations were made with JEM-2100F transmission electron microscope operating at 200 kV (JEOL, Japan). A drop of sample was deposited onto a Formvar-carbon-coated copper grid, and excess of product was removed after 5 min using filter paper. The grid was dried at room temperature for 5 min. Phosphotungstic acid (1%) was then added for 5 min, with excess being removed as before. Samples (pH 5.9) with or without heat and the corresponding samples with pH adjusted to pH 2.6 and 7.0 were observed.

**Electrophoresis.** Reducing sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) was performed on a discontinuous buffered system, using 12% separating gel and 5% stacking gel according to our previous method with minor modification.[24] Soy protein dispersion (pH 5.9) after heating at 95 °C for 30 min was adjusted to pH 6.4, 7.0, and 8.0. Then samples with and without pH adjustment were ultracentrifuged at 156 000*g* for 30 min, which was supposed to separate the protein particles and soluble proteins.[25] The supernatant and the sample without ultracentrifugation (pH 5.9 after heat) (250 $\mu$L) were then mixed with 250 $\mu$L of 0.06 M Tris−HCl buffer (pH 6.8), containing 2% (w/v) SDS, 25% (v/v) glycerol, 0.1% (w/v) bromophenol blue, and 5% (v/v) 2-mercaptoethanol (2-ME). Molecular weight marker made from rabbit phosphorglase B (97.4 kDa), bovine serum albumin (66.2 kDa), rabbit actin (43 kDa), bovine carbonic anhydrase (31 kDa), human growth hormone (22 kDa), and hen egg white lysozyme (14.4 kDa) was used as reference.

**Particle Size of Nanogels in Various Solvents.** To unravel the interactive forces involved in the formation and maintenance of the nanogels structure, the *z*-average hydrodynamic diameter of the soy protein nanogels in the presence of 8.0 M urea, 1% SDS, and 30 mM DTT, alone or in combinations, was also determined according to the

method described above. To unravel if the disulfide bonds were accessible, nanogels were first dispersed in 30 mM DTT; second, it was added with iodoacetamide to remove the DTT;[26] and finally SDS was added (final concentration 1%). The corresponding particle size of this nanogel dispersion was then measured. All solvents were prepared with 20 mM pH 8.0 Tris-HCl buffer.

**Sulfhydryl (SH) Group Content.** SH group content before and after heat treatment of soy protein dispersion at pH 5.9 was measured using Ellman's reagent.[27]

**Surface Hydrophobicity Measurement.** Surface hydrophobicity before and after heat treatment of soy protein dispersion was evaluated using ANS as the fluorescent probe according to the method of Alizadeh-Pasdar and Li-Chan.[28] Protein dispersion was diluted with 10 mM pH 7.0 sodium phosphate buffer. Fluorescent intensity was measured via a F7000 fluorescence spectrophotometer (Hitachi Co., Japan).

**Intrinsic Fluorescence of Tryptophan.** Intrinsic fluorescence of the tryptophan before and after heat treatment of soy protein dispersion was measured on a F7000 fluorescence spectrophotometer. Protein concentration was diluted to 0.002% with 10 mM sodium phosphate buffer (pH 7.0). Excitation and emission slits were set at 5 nm. The excitation wavelength was 295 nm to excite tryptophan. The emission spectra were recorded from 300 to 400 nm with a scan speed of 240 nm/min. Each spectrum was the average of two scans and corrected for a protein-free sample.

**Statistical Analysis.** Statistical calculations were performed using the statistical package SPSS 11.5 (SPSS Inc., Chicago, IL) for one-way ANOVA. Least-squares difference was used for comparison of mean values among treatments and to identify significant differences ($p < 0.05$) among treatments.

## RESULTS AND DISCUSSION

**Characteristics of Protein Particles before Heat Treatment.** The initial pH of soy protein dispersion was 7.0. As shown in Figure 1, when the pH decreased, there was no significant increase of particle size above pH 6.2. With the further decreased pH, the surface charge on the protein particle was neutralized, reducing the electrostatic repulsion between particles, which would induce protein aggregation. Therefore, at pH 6.2, particle size significantly increased, indicating the large particle formation. The particle size then increased gradually with a sudden increase at pH 5.7. Correspondingly, the PDI decreased gradually from 0.52, with a sudden decrease at pH 6.2, reaching the lowest at pH 6.0, 5.9, and 5.8, with the value below 0.1. After that, PDI began to increase. Therefore, in the pH range of 5.8−6.0, aggregation would lead to a relatively monodisperse protein particle distribution. The particle size was relatively large and the corresponding dispersion was translucent, but the dispersion was stable and homogeneous, without precipitation. However, protein particles formed at pH 5.8−6.0 were unstable with pH change, taking the particles formed at pH 5.9 as an example. Similar particle size and PDI distribution were observed when pH increased from 5.9 to 7.0, indicating a relatively reversible process. The appearance of the dispersion gradually became transparent (Figure 3A). The soy protein dispersion was unstable in the pH range of 3.5−5.5 as secondary aggregation of protein particles happened and the particles precipitated (Figure 3A). Under pH 3.5, protein precipitates were dissociated and the solution became transparent again (Figure 3A), but PDI was larger than 0.25 (data are no shown), indicating the relative poly dispersiveness of the protein dispersion.

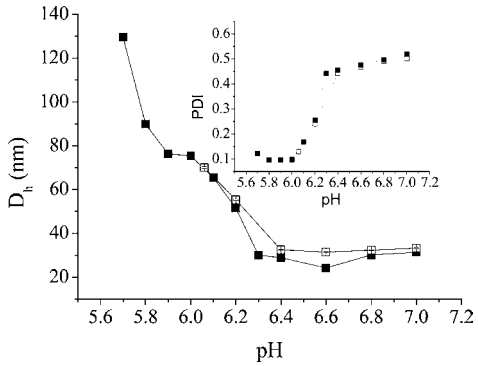

**Figure 1.** Effects of pH on the *z*-average hydrodynamic diameter and polydispersity index of soy protein dispersion before thermal treatment. pH was adjusted from 7.0 to 5.7 (■); from 5.9 to 7.0 (□).

**Characteristics of Protein Nanogels Made by Heat Treatment.** To make protein particles stable, thermal treatment was performed on soy protein dispersion of pH 5.9 under 95 °C for 30 min (the effects of changing the heating protocol are discussed later in this Article). This pH was supposed to make the largest production of stable particles within a narrow range of particle size as it had the lowest PDI. After heat treatment, the pH of the protein dispersion increased from 5.9 to 6.06, which might be the result of self-assembly of protein particle. The increase of pH after thermal treatment was also observed by Donato et al. when they heated dematerialized $\beta$-lactoglobulin solution at 70 and 85 °C under mild acidic pH conditions (pH 5.7−5.9).[8] The behavior of the heated soy protein particles was totally different from that without heat. In the pH range of 6.06−7.0, the particle size increased gradually with the increasing pH (Figure 2A). Surprisingly, the turbidity decreased with the increased particle size, while the PDI value was still very low and remained relatively constantly at about 0.1. This result excluded the possibility that the size changes were caused by the aggregation of the protein particle. Instead, the nanoparticles swelled with the increased pH, containing large amounts of water. It should be pointed out that swelling was the most important characteristic of nanogels.[4,5] Therefore, nanoparticles formed after heating in our study were deemed as nanogels. The appearance of the dispersion was still translucent in pH 7.0 (Figure 3B), indicating the irreversible change of protein particles after heating. In pH 5.9 and 5.8, the particle size, turbidity, and the PDI value increased, which was due to the aggregation of the protein particle. Precipitation of nanogels happened when the protein dispersion pH was in the range of 3.7−5.7 (Figure 3B), but these aggregates were redispersible when the dispersion pH was out of this range. In the pH 2.6−3.2, with the decreased pH, particle size at first decreased and then increased gradually (Figure 2B). The visual appearance of the dispersion was still translucent (Figure 3B). The PDI value decreased to 0.1 at pH 3.0 and remained constantly around 0.1 thereafter. Interestingly, in pH 2.6−3.0, the turbidity decreased with increased particle size. Therefore, nanogels were stable and would also swell in this pH range. The $\zeta$-potential was higher than that before heating when the pH increased from 6.06 to 7.0 (Figure 2C), indicating the redistribution of particle inner structure. The internal and external charge distribution of the aggregated proteins was optimized to promote the structuring of nanogels, resulting in more negatively charged residues exposing. The higher surface charge would contribute to the stability of the protein nanogels as the electrostatic repulsion between them was enhanced. In the pH range 2.6−3.2, the $\zeta$-potential was lower than that without heating. For the salt stability, precipitation occurred, when the ionic strength

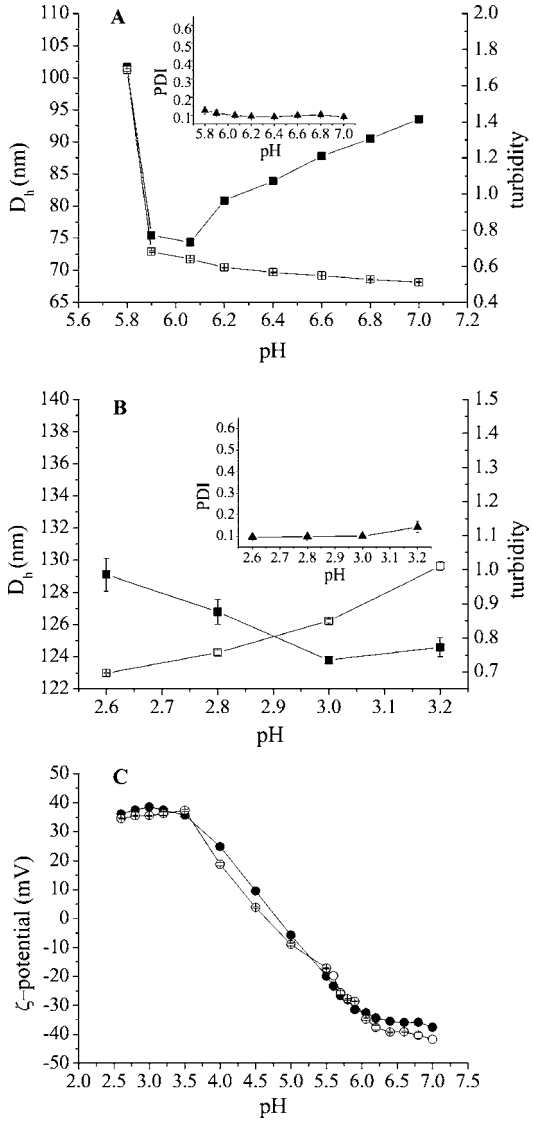

**Figure 2.** Effects of pH on the *z*-average hydrodynamic diameter (■), polydispersity index (▲), and turbidity (□) of soy protein dispersion after thermal treatment (A, pH 5.8−7.0; B, pH 2.6−3.2) and ζ-potential of particles (C) before (●) and after thermal treatment (○).

increased to 50 mM NaCl for protein dispersion (pH 5.9) without heat treatment (Figure 3C). After heat treatment, however, even the NaCl concentration increased to 200 mM, and no precipitation occurred (Figure 3D). When protein concentration increased from 1% to 5%, particle size and PDI would increase, but they still had pH and salt stability as well as swelling characteristics (see the Supporting Information).

To shed more light on the soy protein nanogels, the morphology of the soy protein particles was observed by TEM performed on selected samples. At pH 5.9 without heat, protein particles were mainly characterized by a spherical shape and exhibited a narrow range of apparent lengths (Figure 4B). When pH increased to 7.0 or decreased to 2.6, the number of spherical particles decreased, and some irregular particles were observed. They exhibited a wide range of apparent lengths. At pH 5.9 after heat, protein particles were still mainly characterized by a spherical shape and exhibited a narrow range of apparent lengths (Figure 4E). The spherical particles could still be found when pH increased to 7.0 or decreased to

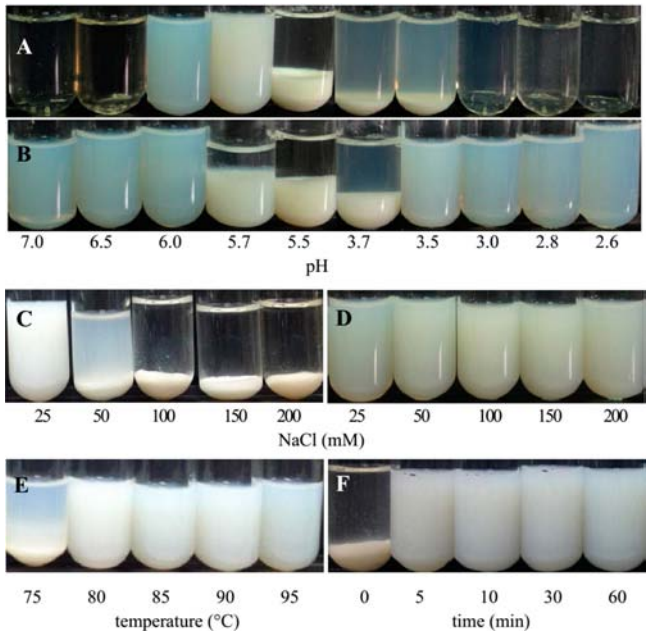

**Figure 3.** Influences of pH and NaCl concentration on the visual appearance of soy protein dispersion (pH 5.9) without (A,C) or with heating (B,D) at 95 °C for 30 min. Influence of holding temperature (for 30 min) on the salt stability (150 mM NaCl) of soy protein dispersion (E). Influence of holding time (under 95 °C) on the salt stability (150 mM NaCl) of soy protein dispersion (F).

2.6 and exhibited a narrow range of apparent lengths. Besides, the apparent lengths of protein particles were larger than that at pH 5.9, which might be the swelling of protein nanogels. These results were in accordance with particle size distribution characteristics at various pH values as described before. The observed particle size by TEM was different from the $D_h$, which might be due to the air-drying process and phosphotungstic acid addition.

All of the above observations led us to conclude that spherical soy protein nanogels with pH and salt stability as well as swelling characteristics were formed by heating soy protein dispersion (pH 5.9) under 95 °C for 30 min. Their stability was closely related to thermal treatment. Therefore, we further did some experiments on the influence of holding temperature and time on the stability of soy protein particles.

**Effect of Holding Temperature on the Protein Particle Stability.** As shown in Figure 5A, before the pH was adjusted to 7.0, there was a very little increase of particle size at 50 °C. Thereafter, particle size decreased gradually from 65 °C, reached the lowest at 80 and 85 °C, and subsequently increased at 90 °C. The turbidity observed almost a similar trend (Figure 5B). Around pH 6.0, the onset denaturation temperature in deionized water is about 85 °C of soy glycinin and 65 °C for β-conglicinin.[21] Therefore, the decrease of particle size was supposed to relate to the denaturation of soy β-conglicinin. The increase of particle size after 85 °C was supposed to relate to the denaturation of glicinin. PDI value was relatively constant around 0.1 (Figure 5C). The ζ-potential increased significantly after 60 °C (Figure 5D). Thus, higher temperature contributed to the exposing of negative charge residues. After the pH of the protein dispersion was adjusted to 7.0, both particle size and turbidity increased with the holding temperature. Before 70 °C, particle size was smaller and PDI value was significantly higher than that before pH adjustment, proving the dissociation of

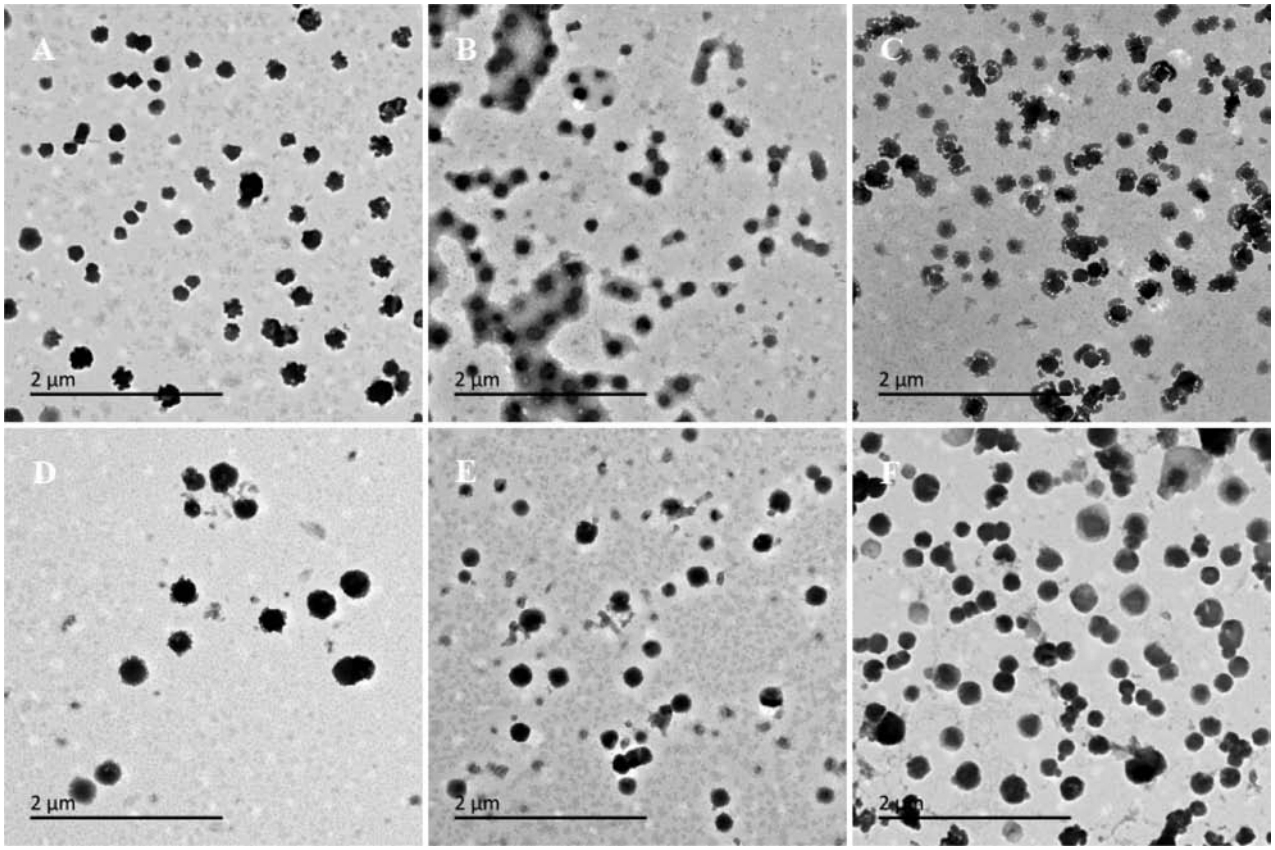

**Figure 4.** TEM negative-staining micrographs of soy protein dispersions (pH 5.9) without heat: pH adjusted to 2.6 (A), not adjusted (pH 5.9) (B), adjusted to 7.0 (C); and the corresponding heat treated dispersion with pH adjusted to pH 2.6 (D), not adjusted (pH 5.9) (E), and adjusted to 7.0 (F). The scale bar represents 2 $\mu$m.

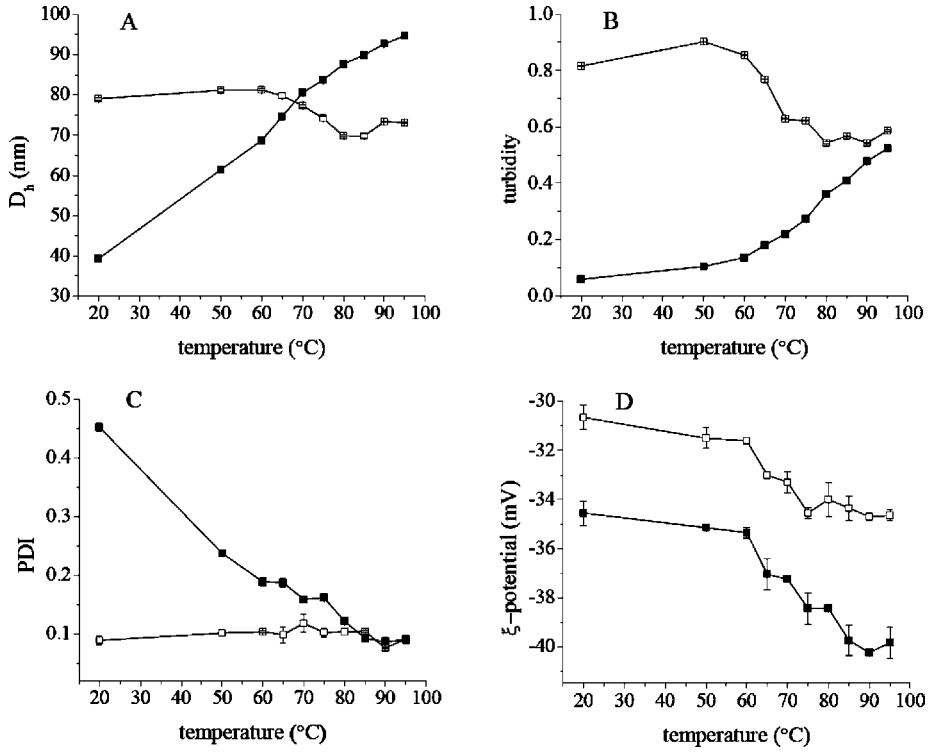

**Figure 5.** Effects of holding temperature (30 min) on the *z*-average hydrodynamic diameter (A), turbidity (B), polydispersity index (C), and $\zeta$-potential (D) of protein particles. Open squares (□) represent the protein dispersion at pH 5.9, while the solid squares (■) represent the protein dispersion with pH adjustment to 7.0.

dx.doi.org/10.1021/jf502572d | *J. Agric. Food Chem.* 2014, 62, 9553−9561

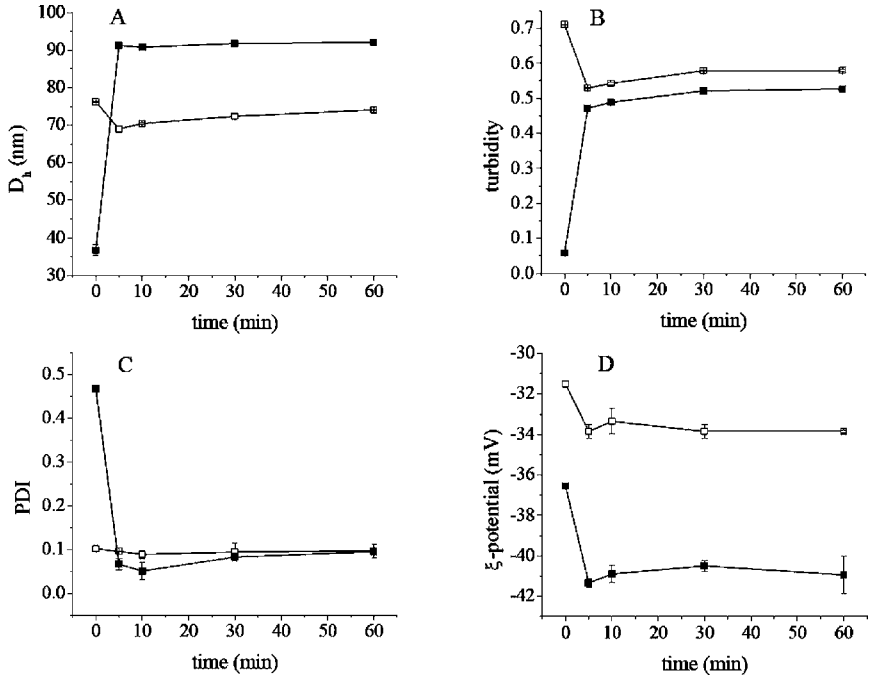

**Figure 6.** Effects of holding time at 95 °C on the *z*-average hydrodynamic diameter (A), turbidity (B), polydispersity index (C), and ζ-potential (D) of protein particles. Open squares (□) represent the protein dispersion at pH 5.9, while the solid squares (■) represent the protein dispersion with pH adjustment to 7.0.

particles. After 70 °C, protein particles gradually swelled as the particle size increased but turbidity decreased. Therefore, the denaturation of β-conglicinin might have induced the swelling of protein particles. Yet before 85 °C, the particle was unstable, as the PDI value increased after pH adjustment. The surface charges of all samples after pH adjustment were larger than those before and increased more noticeably for sample after heating above 80 °C. When the ionic strength of the protein dispersion was adjusted to 150 mM, the above 75 °C treated samples did not precipitate after 24 h (Figure 3E). The above observations indicated that the denaturing of soy glycinin was crucial for the formation of stable soy protein nanogels.

**Effect of Holding Time on the Protein Particle Stability.** As shown in Figure 6A, before the pH was adjusted to 7.0, particle size decreased significantly at 5 min, then increased mildly within the 60 min. It has been proved by many investigations that β-conglycinin could prevent thermal aggregation of glycinin.[29,30] This explained the limited increasing of particle size as the time increased. Correspondingly, turbidity decreased remarkably at 5 min, and then mildly increased as the time increased (Figure 6B). The PDI value was still constantly around 0.1 (Figure 6C). The ζ-potential increased significantly after heating for 5 min, and remained relatively constant thereafter (Figure 6D). When the pH was adjusted to 7.0, the particle size of samples without heat treatment decreased significantly, while that with heat treatment increased remarkably and remained relatively constant as the time increased. The turbidity of the control sample decreased significantly and became transparent, while that of the thermal treated sample decreased mildly. For dispersion without heat treatment, the PDI increased from 0.1 to 0.47 after pH adjustment, proving the dissociation of particles, while that of the thermal treated sample still remained at a constant value around 0.1. The ζ-potential of all samples increased after pH adjustment, while that of samples with heat treatment increased more significantly than the control. This indicated that after heat treatment, more negatively charged residues were exposed. All of the above observations indicated that nanogels began to form after 5 min under 95 °C. Besides, the increase of particle size, surface charge, and the decrease of turbidity after 5 min were relatively constant, indicating that when soy protein nanogels formed, their swelling capacity under a certain pH was constant regardless of heating time. When ionic strength increased to 150 mM NaCl, the protein dispersion without heat treatment precipitated; however, after heat treatment even for 5 min, no precipitation occurred (Figure 3F). The above observation proved that the stable nanogels formed within a very short time at 95 °C. Yet it should be pointed out that with the further increased time to 5 h, the stability of nanogels was disturbed and precipitation occurred.

**Structure Characteristics of Soy Protein Nanogels.** Before ultracentrifugation, reducing SDS-PAGE (Figure 7) observed all of the main subunits of soy protein (lane 5). However, after ultracentrifugation (lane 4), only small amounts of α′, α, acid polypeptides, and some lower molecular fraction were still remaining in the supernatant, indicating that all of the basic poly peptides, β subunits, and most of the α′/α subunits, acid polypeptides took part in the formation of nanogels. When pH increased (lanes 1−3), the content of α′, α, and acid polypeptides in the supernatant increased, indicating that these free α′, α, and acid polypeptides might locate on the surface of the nanogels. They might interact with the nanogels through electrostatic interaction so when the electrostatic repulsion force increased, some of them were "pealed" from the surface. This result was in accordance with Chen et al.[25] Besides, α′/α subunits have an extension region that has been proved to limit the aggregation of soy protein.[31] They located on the surface of the nanogels so that the size of the nanogels was relatively constant despite heating time as indicated formerly (Figure

dx.doi.org/10.1021/jf502572d | J. Agric. Food Chem. 2014, 62, 9553−9561

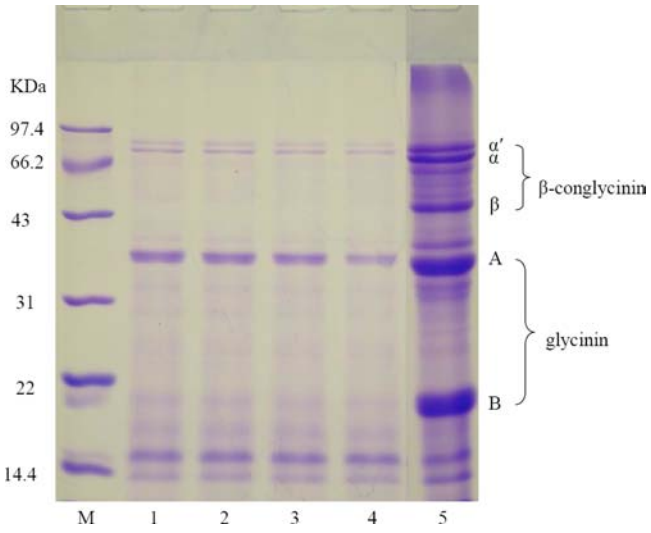

**Figure 7.** Electrophoretic patterns of soy protein nanogels and supernatant protein fraction of different pH nanogels dispersion after ultracentrifugation. Lane M: marker proteins. Lanes 1, 2, and 3 represent supernatant protein fraction in pH 8.0, 7.0, and 6.4 protein dispersions by adjusting the pH of initial nanogels dispersion (pH 6.06). Lane 4 represents the supernatant protein fraction in the initial soy nanogels dispersion. Lane 5 represents the protein electrophoretic pattern of the initial nanogels dispersion. Soy protein constituents: $\alpha'$, $\alpha$, and $\beta$ represent subunits for $\beta$-conglycinin; A and B represent the acidic and basic polypeptides for glycinin.

6A). When heated above 80 °C, both $\beta$-conglicinin and glicinin unfolded and dissociated into monomers (polypeptides).[32] The hydrophobic residues exposed and induced the aggregation. In soy protein, basic polypeptides are highly hydrophobic and would preferentially interact with $\beta$ subunits.[32] On the other hand, basic polypeptides have an isoelectric point around 8.0–8.5,[33] while other subunits ($\alpha'$, $\alpha$, $\beta$, and acid polypeptides) have isoelectric points around 4.0–5.5.[34] Therefore, in the pH range 6.06–7.0, basic polypeptides were positively charged and others were negatively charged. Combined with the increased surface charge after heating, it was reasonable to propose that the positively charged basic polypeptides together with $\beta$ subunits were buried and located in the core of the nanogels, forming the hydrophobic core, while highly negatively charged $\alpha'$, $\alpha$, and acid polypeptides were located on the surface of the nanogels as they were relatively more hydrophilic.[31,35] This kind of core–shell model has also been proposed by Ren et al. when they studied the protein particle formation mechanism in defatted soymilk.[36]

Association of monomers was mainly driven by hydrophobic interaction. After the hydrophobic aggregation, there were still some hydrophobic residues exposed that increased the surface hydrophobicity of nanogels (Table 1). The red shift of $\lambda_{max}$ for tryptophan residues further confirmed the exposure of hydrophobic residues to a more polar environment (Table 1), although it was not significantly different in value. The disulfide bonds between different subunits formed during the heating process as SH decreased significantly (Table 1). To further elucidate the definite inner force stabilizing the nanogels, nanogels were dispersed in various kinds of protein-perturbing solvents, and the particle size was measured. As shown in Figure 8, 30 mM DTT alone could not dissociate

**Table 1. Surface Hydrophobicity ($S_0$), $\lambda_{max}$ of Tryptophan Residues, and Sulfhydryl (SH) Content of Soy Protein (pH 5.9) before and after Heating[a]**

| samples | $S_0 \times 10^3$ | $\lambda_{max}$ (nm) | SH (nmol/mg) |
|---|---|---|---|
| pH 5.9 | 91.13 ± 1.22 a | 337.5 ± 0.14 a | 5.19 ± 0.18 a |
| heat–pH 5.9 | 167.82 ± 11.4 b | 338.7 ± 0.15 a | 3.25 ± 0.07 b |

[a]Values in the same column followed by different letters are of significant difference ($p < 0.05$).

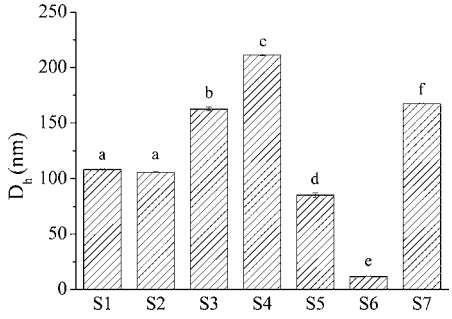

**Figure 8.** Effects of various protein-perturbing solvents on the *z*-average hydrodynamic diameter of nanogels. S1, 20 mM pH 8.0 Tris-HCl buffer; S2, 30 mM DTT; S3, 1% SDS; S4, 8.0 M urea; S5, urea +DTT; S6, SDS+DTT; S7, iodoacetamide was added into nanogels dispersion in S2 to remove the DTT first and then SDS was added. Different letters represent significant difference ($p < 0.05$).

the nanogels. In the 1% SDS and 8 M urea, the particle size increased significantly. This might be that the nanogels were unfolded by SDS and urea, which could disturb the hydrophobic interaction and hydrogen bonds, respectively. Yet they still could not dissociate the nanogels into smaller particles. However, when nanogels were dispersed in SDS and urea solution combined with DTT, the particle size decreased significantly, especially for that of SDS and DTT solution. These results indicated that the inner structure of nanogels had a disulfide bonds cross-linked "skeleton". These disulfide bonds play a crucial role in the stability of nanogels. They were inaccessible without the destroying of hydrophobic interaction as when DTT was removed by iodoacetamide, and addition of SDS could not dissociate the particles. Therefore, hydrophobic interaction was also very important in the formation of nanogels. As compared to hydrophobic interaction and disulfide bonds, hydrogen bonds seemed to play a relatively minor role in the stabilization of the nanogels structure. This kind of structure might be related to the pH and salt stability of the nanogels. According to the above discussion, the proposed model of the soy protein nanogels formation pathway was illustrated in Figure 9.

In conclusion, soy protein nanogels with a hydrophobic core and a hydrophilic shell have been made successfully by a simple

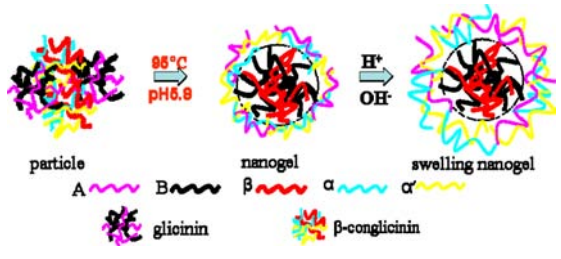

**Figure 9.** Diagrammatic depiction of soy protein nanogels formation.

thermal process under a certain pH value. They are resistant to pH and ionic strength change. They will swell when the electrostatic repulsion force is large enough. Further work will be carried out to explore their inner structure with other technology as well as their functionality.

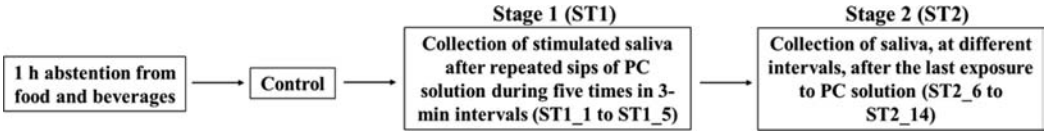

**Figure 1.** Illustration of the experimental approach used to study in vivo interaction between SP and PC.

over effect by a sensory study, evaluating the time−intensity curves for astringency of two red wines.

The central physiological mechanism underlying astringency caused by different foods remains a controversial subject.[30] The aim of this study is to provide new insights on the phenomenon of astringency perception. To evaluate the interaction of the different SP families, a repeated astringency model was developed in which it is possible to understand how the different families of SP interact in an in vivo assay with condensed tannins (procyanidins, PC). In addition, in vitro assays were also performed to investigate which SP families are more susceptible to form insoluble or soluble complexes, and the size of these complexes was evaluated by DLS measurements.

## MATERIALS AND METHODS

**Reagents.** All reagents used were of analytical grade or better. Acetonitrile (ACN) was purchased from Panreac Quimica; trifluoroacetic acid (TFA) and sodium acetate were purchased from Fluka Biochemica; commercial procyanidins (Vitisol) were purchased from Berkem, Plant Extraction; and ethanol was purchased from AGA, Álcool e Géneros Alimentares, SA.

**In Vivo Interaction between Procyanidins and Salivary Proteins.** Human saliva was collected from healthy and nonsmoking volunteers. The experiences were conducted with four subjects aged from 21 to 31 years. Each volunteer contributed to three independent samples ($n$ = 12). All participants were instructed to avoid food and beverages for at least 1 h before the sessions started. The recording procedure was explained in detail to the subjects who provided written consent prior to participation. The study was conducted according to the Declaration of Helsinki and was approved by the Ethics Committee of Medical School of University of Porto (EK84032011).

The PC solution (2.5 g $L^{-1}$) was prepared, and human saliva was collected from different subjects after repeated sips of this solution. The experimental procedure was divided into two stages: Stage 1 (ST1) comprises saliva collected during approximately 15 min with repeated sips of the PC solution at 3 min intervals. It was asked of the subjects to hold 5 mL of this solution in their mouth for 5 s, spit it out, and 3 min later the saliva was collected. This procedure was repeated five times (ST1_1−ST1_5).

On the other hand, stage 2 (ST2) comprises saliva collected at different intervals during 60 min (ST2_6−ST2_14) after the last exposure to PC solution (Figure 1). These intervals (min) and respective designation are indicated in Table 1. ST1_5 was used as reference, so for example ST2_6 refers to saliva collected 5 min after ST1_5, ST2_7 refers to saliva collected 10 min after ST1_5, and so on.

All samples of saliva were mixed with 10% TFA (final concentration 0.1%), centrifuged 5 min at 8000$g$, and the supernatant (acidic saliva, AS) was analyzed by high performance liquid chromatography (HPLC).

**In Vitro Interaction between Salivary Proteins and Procyanidins.** To reduce the variability connected to diurnal variations[31,32] and the influence of circadian rhythms,[33] a pool of saliva collected at 11 am on three different days was prepared. Saliva was collected from the same subjects that participated in the in vivo astringency analysis. The saliva pool was mixed with 10% TFA (final concentration 0.1%), centrifuged (8000$g$ for 5 min), and supernatant (AS) was separated from the precipitate and used for the following experiments.

**Table 1. Time Intervals (min) after the Last Exposure to PC Solution (ST1_5) and Respective Designation in ST2**

| interval (min) | designation |
|---|---|
| 5 | ST2_6 |
| 10 | ST2_7 |
| 20 | ST2_8 |
| 30 | ST2_9 |
| 40 | ST2_10 |
| 45 | ST2_11 |
| 50 | ST2_12 |
| 55 | ST2_13 |
| 60 | ST2_14 |

The AS sample was analyzed by HPLC before and after interaction with PC solution (2.5 g $L^{-1}$). The control condition was a mixture of AS (150 $\mu$L) and 0.1 M acetate buffer (pH 5.0, 12% ethanol) (50 $\mu$L) (final volume 200 $\mu$L).

For the experiments with PC, the necessary volume (50 $\mu$L) of PC solution (2.5 g $L^{-1}$) was added to AS (150 $\mu$L) to obtain the final volume 200 $\mu$L. After shaking, the mixture reacted at room temperature (20 °C) for 2 min and was then centrifuged (8000$g$, 5 min). One-half of the supernatant was directly injected into the HPLC, and the other half was filtered (cellulose acetate 0.22 $\mu$m) and only then injected into the HPLC.

The percentage of insoluble complexes was obtained by subtracting the area of the chromatographic peaks of each family obtained in the HPLC analysis of the nonfiltered solution from the respective area obtained in the control saliva (AS without tannin). The percentage of soluble complexes was calculated in the same way but by subtracting the data obtained in the HPLC analysis of the nonfiltered solution from the respective area obtained in the filtered solution.

**Salivary Flow Rate.** Salivary flow rates were measured at 11 am according to the procedure described by Gaviao et al.[34] During 5 min, subjects spat out the saliva passively accumulating in their mouth into a preweighed plastic container. The salivary flow rate was assessed by three repetitions and was expressed in mL $min^{-1}$.

**Dynamic Light Scattering (DLS) Measurements.** The size of procyanidin/salivary protein aggregates present in solution was measured by DLS, using the Zetasizer Nano ZS Malvern instrument. The same procedure described for protein−tannin interaction in this section was applied herein. Thus, to determine the size of the aggregates, one-half of the supernatant resulting from protein−procyanidins reaction was evaluated by DLS, and the other one-half was filtered (cellulose acetate 0.22 $\mu$m) and then also analyzed by DLS.

This technique measures the time-dependent fluctuations in the intensity of scattered light that occur because particles undergo Brownian motion. The analysis of these intensity fluctuations enables determination of the diffusion coefficients of particles, which are converted into a size distribution. The sample solution was illuminated by a 633 nm laser, and the intensity of light scattered at an angle of 173 was measured by an avalanche photodiode. This analysis provides information concerning particle size (obtained by average size parameter) and polydispersity. In general, $Z$ average size results were considered valid when the polydispersity of solutions was below 0.5. These experiments were performed in triplicate.

**HPLC Analysis.** The method used in the HPLC analysis was adapted from the method described by Soares et al.[11] Ninety microliters of each solution were injected on HPLC Lachrom system (Merck Hitachi, L-7100) equipped with a Vydac C8 column (Grace

dx.doi.org/10.1021/jf502721c | J. Agric. Food Chem. 2014, 62, 9562−9568

Davison Discovery Sciences); the column dimensions are 150 × 2.1 mm, and the particle diameter is 5 μm; detection was carried out at 214 nm, using a UV−vis detector (L-7420). The HPLC solvents were 0.2% aqueous TFA (eluent A) and 0.2% TFA in ACN/water 80/20 (v/v) (eluent B). The gradient applied was linear from 10% to 40% (eluent B) in 75 min, at a flow rate of 0.30 mL $min^{-1}$. After the program, the column was washed with 100% eluent B for 20 min to elute S-type cystatins and other late-eluting proteins. After being washed, the column was stabilized with the initial conditions.[11,35]

**Data and Statistical Analysis.** The mean values of chromatographic peaks and standard error of mean (SEM) were evaluated using analysis of variance (ANOVA), followed by the Bonferroni test. The mean values of salivary flow rates, the percentage of SP involved in the formation of (in)soluble complexes, and standard deviations were evaluated by statistical analysis using *t* test unparametric. Differences were considered to be statistically significant when *P* was at least <0.05, and in each case *P* is indicated in the respective figure. These statistical data were processed using GraphPad Prism version 5.0 for Windows. The correlations between different factors analyzed in this work were assessed by IBM SPSS Statistics version 21 for Windows.

## RESULTS AND DISCUSSION

This work intends to better understand the physiological mechanism underlying the phenomenon of astringency by an in vivo analysis, which could give important informations about the interaction between SP and PC. Factors such as the amount of SP, salivary flow rates, and size of the protein−tannin aggregates could be extremely important in the mechanism responsible for different perceptions of astringency and will hence be analyzed in this study.

**Salivary Proteins and Interaction with Procyanidins.** The initial acidic treatment of saliva with TFA is used to precipitate several high molecular weight SP (such as α-amylases, mucins, carbonic anhydrase, and lactoferrin) and to preserve sample protein composition because TFA partially inhibits intrinsic protease activity.[35] However, peptides and proteins like histatins, bPRPs and aPRPs, statherin, cystatins, and defensins are soluble in AS solution and may be directly analyzed by HPLC, as previously described.[11,35]

The HPLC chromatogram of AS solution detected at 214 nm can be divided into four SP regions: the first region comprises proteins that belong to bPRP and histatin classes (Figure 2). The second region comprises gPRPs, the next region corresponds entirely to aPRPs, and the last region contains phosphorylated and nonphosphorylated forms of statherin.[11]

As it was described in the literature, the intensity of astringency is supposed to increase upon successive sips of red wines.[27] Thus, it became important to investigate how the different families of SP may be affected along this continued astringent stimuli. The experimental approach described herein intends to mimic the phenomenon that occurs in the oral cavity during the ingestion of a product rich in polyphenols, such as the case of red wine. For this, a PC solution (2.5 g $L^{-1}$) was prepared, and it was asked to the subjects to sip this solution five times in 3 min intervals. After this stage, saliva continued to be collected to assess the recovering of the SP families. The HPLC profile of AS solution before and after in vivo interaction with PC solution is shown in Figure 2.

In Figure 2, ST1_1 and ST1_5 were used as examples, and the difference of areas of each peak between control and the other times represents the amount of protein that precipitated with tannins. The difference observed between the peaks of aPRPs and statherin relative to control and different times

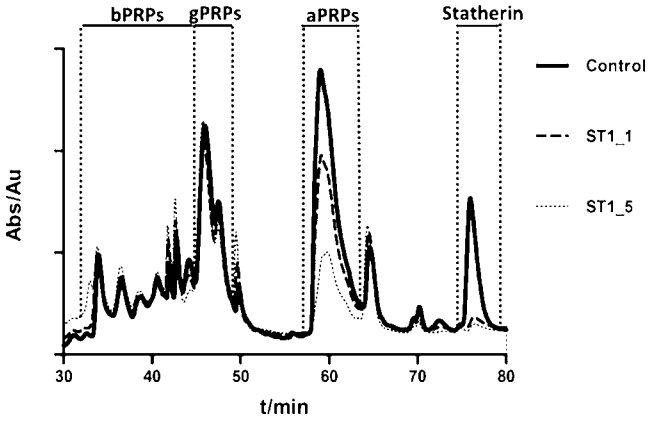

**Figure 2.** HPLC profile detected at 214 nm of the AS solution before (control saliva) and after (ST1_1 and ST1_5) in vivo interaction with PC solution (2.5 g $L^{-1}$). The dotted lines show the different families of SP studied in this work.

tends to be higher with the increase in number of repeated sips of PC solution (data not shown).

The variations in the chromatographic peaks of each SP family during ST1 are presented in Figure 3. The results are

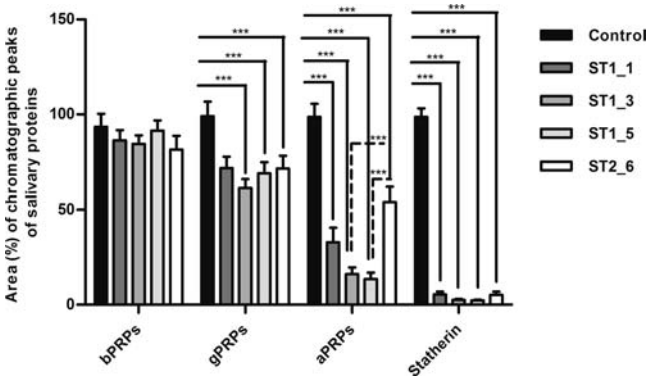

**Figure 3.** Influence of the interaction of SP with the PC solution during ST1, when saliva was collected during repeated sips of this solution (ST1_1−ST1_5). ST2_6 is presented for comparison. The results are expressed as percentage of the area of each protein relative to the control (100%), and each value represents the mean ± SEM ($n$ = 12). Only the significant statistical differences more important to this work are presented (***$p$ < 0.001).

expressed as percentage of the area of these proteins relative to the control saliva (without tannin). To simplify Figure 3, only the times with more relevant changes are presented.

The results displayed in Figure 3 show that the area of each different family of proteins is interestingly affected in a different way by the interaction with a PC solution (2.5 g $L^{-1}$). It was observed that repeated sips of the PC solution practically depleted aPRPs and statherin, and significantly reduced the amount of gPRPs. On the other hand, bPRPs were not significantly affected.

After the last sip of the PC solution, saliva continued to be collected during 60 min to assess the evolution of the SP families (Figure 4). The results are expressed as percentage of the area of these proteins relative to the control saliva (without tannin). To simplify Figure 4, only the times with more relevant changes are presented.

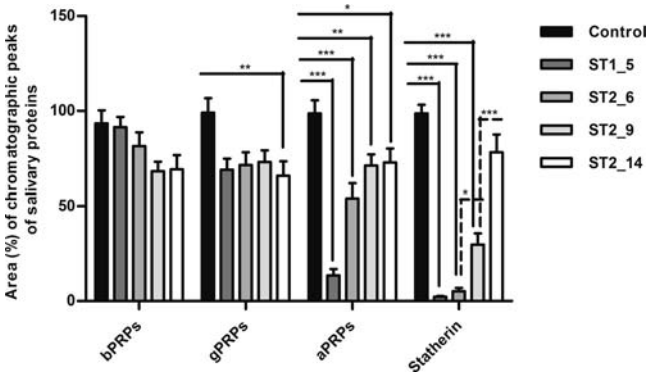

**Figure 4.** Saliva protein composition after the last exposure to PC solution (ST2). ST1_5 is presented for comparison. The results are expressed as percentage of the area of each protein relative to the control (100%), and each value represents the mean ± SEM ($n$ = 12). Only the significant statistical differences more important to this work are presented (*$p$ < 0.05; **$p$ < 0.01; ***$p$ < 0.001).

In the analysis performed at ST2, it was seen a significant recovering of the chromatographic peaks corresponding especially to aPRPs and statherin. On the other hand, the chromatographic peaks of bPRPs and gPRPs seem to slightly decrease or remain practically constant. However, the observed increase of the chromatographic peaks of different SP in ST2 was not sufficient to achieve the control levels during the period studied.

As previously referred, the different families of SP have distinct affinities toward tannins. So, it was expected that these proteins evolved differently over the time after the interaction with PC. Although the area of aPRPs and statherin decreased during astringent stimulus (ST1) and increased significantly during ST2, the same behavior was not observed for the other proteins. The gPRPs family seems to be the least affected, because its percentage remains practically constant during both ST1 and ST2. On the other hand, bPRPs' area seems to be constant during ST1 and to decrease, although nonsignificant, during ST2 (Figure 4). Therefore, the different behaviors of SP during and after the interaction with the PC solution can suggest that several SP families could be involved in different stages of the development of astringency.[36]

The main families affected by the interaction with PC solution were aPRPs and statherin, a common characteristic in all subjects studied. However, it was possible to verify the existence of individual differences, in the percentage of reduction of chromatographic peaks area of these proteins (data not shown).

SPs are stored in secretory granules, and they are released into the mouth gradually in unstimulated conditions. Therefore, saliva collected in these conditions can be considered representative of a basal composition because it results from secretion of preformed vesicles.[37] However, by an appropriate stimulus, such as the case of PC solution, the secretion may be accelerated, depleting statherin. Some works show that de novo synthesis and processing of a protein through the secretory apparatus requires approximately 30 min.[28,38] Considering that ST2_9 corresponds to 30 min after the last sip of PC solution, it is possible to verify a significant recovery of statherin at this time as compared to ST2_6.

Moreover, Castagnola and co-workers[39] verified that statherin was not affected by circadian rhythms, which strongly suggests that its route of secretion is different from that of other proteins, such as the case of histatins.

**In Vitro Reactivity of Salivary Proteins and Procyanidins.** The method for the study of protein−tannin interaction used in these experiments was selected on the basis of the work developed by Soares et al.[20,40] The aim of this part of the work was to verify the in vitro reactivity of PC and SP, respecting the individual characteristics of saliva protein profile. To reduce the variations referred to in the Materials and Methods, saliva pool was made of saliva collected 3 days from each subject. The control condition was prepared with AS and acetate buffer. The volume of 50 $\mu$L of PC solution (2.5 g $L^{-1}$) was added to AS and was allowed to react during 2 min. This reaction time was chosen to be close to what happens in the in vivo astringency analysis. After the reaction, the solution was centrifuged, which results in insoluble complexes. One-half of the supernatant was analyzed by HPLC (nonfiltered solution), and the other half was filtered and then was also analyzed by HPLC (filtered solution).

Figure 5 shows the difference of chromatographic peaks' area of several SP families before (AS without tannin) and after in vitro interaction with the PC solution (nonfiltered and filtered solution). From these results, it is possible to observe that aPRPs and statherin were the proteins that have a higher relative affinity toward PC complexation and precipitation, comparatively to other SP, such as gPRPs that have a medium relative affinity. It is important to note that aPRPs and statherin also formed soluble complexes with PC. On the other hand, these results seem to indicate that bPRPs, when present in a competitive assay, have a lower relative tannin affinity, because they practically did not complex with tannins. It is also possible to observe that filtration induced a decrease of some chromatographic peaks of SP, in particular for aPRPs and statherin, which could be explained by the retention of salivary protein/tannin soluble complexes by the filter.

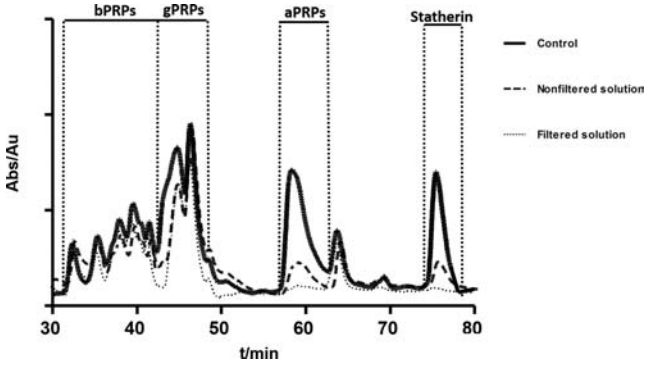

**Figure 5.** HPLC profiles detected at 214 nm of the AS solution before and after the addition of the PC solution (2.5 g $L^{-1}$). The graphics show the difference between chromatographic peaks before (control saliva) and after interaction with PC solution. These solutions were nonfiltered and filtered (0.22 $\mu$m) prior to HPLC analysis.

Differences between saliva protein profiles of subjects can influence the affinity of SP toward tannins and, consequently, the size of (in)soluble complexes formed. The differences between nonfiltered and filtered solutions were also detectable in the experiment size measurements by DLS. Indeed, the average size (nm) of complexes in nonfiltered and filtered solutions was 189.9 ± 9.1 and 83.3 ± 9.2, respectively. The

results indicate the existence of soluble salivary protein−tannin complexes that are retained by the filter (0.22 $\mu$m).

To highlight the differences between nonfiltered and filtered solutions, the percentages of proteins involved in the formation of complexes (soluble and insoluble) are presented in Table 2, considering four subjects ($n$ = 3).

Overall, these results show that the amount of SP involved in the formation of insoluble complexes is in general higher for aPRPs and statherin. On the other hand, bPRPs practically do not complex with PC. However, the behavior for gPRPs is not entirely similar between subjects. It was observed that the percentage of gPRPs involved in the formation of insoluble complexes can be higher than the percentage of the other SP. Interestingly, using the conditions of the present work, there is a little amount of SP involved in the formation of soluble complexes as compared to the amount in the insoluble ones, which can suggest that interaction between SP and tannins results possibly in precipitated aggregates.

Nevertheless, it is important to analyze the quantity of each SP in the control solution. Attending to the control values, the area of aPRPs and statherin together is the highest, and these are the major families responsible for insoluble complexes. In turn, the initial amount of gPRPs (control) is considerably higher, but in some cases, only a small percentage of these proteins is involved in complex formation. These facts are in agreement with the data previously referred to on the higher affinity of aPRPs and statherin to complex and to precipitate with tannins.

Salivary flow rate is also an important factor that should be taken into account in studies dealing with astringency because it can modulate the intensity of astringency induced by phenolic compounds.[29,41] The salivary flow rates of the different subjects are presented in Table 2. Interestingly, results suggest that subjects with higher salivary flow rate have higher amounts of aPRPs and statherin involved in the formation of insoluble complexes. Dinnella and colleagues[28,42] suggested that the subject group with high salivary flow rate perceives astringency at a significantly lower level than the low flow rate group, and the analysis of time−intensity curves showed a longer time of recovering from astringency for the latter group.

Comparing in vitro and in vivo interactions between SP and PC, the descending order of relative affinity is the same: aPRPs and statherin, then gPRPs, and finally bPRPs.

Indeed, aPRPs and statherin have been recently described to interact more strongly with condensed tannins than the other SP families. There are in the literature some recent studies that have used experimental conditions similar to those used in this work and corroborate the results obtained herein. Soares et al.[20] assessed the ability of two different structures of tannins (condensed and hydrolyzable) to precipitate the several SP. For this, saliva was collected from different subjects, a pool of whole saliva was made, and then tannins were added. They found that aPRPs and statherin were the SP more affected by the interaction with tannins.

Besides the central role of the tannin structure, results presented herein point to the importance of the protein structure for the protein−tannin interaction. PRPs are classified into different classes (acidic, basic, and glycosylated) on the basis of small and specific structural differences, in particular, richness in acidic or basic residues and the presence of sugar molecules in their structure.[43−45] The acidic character of aPRPs is confined roughly to the first 30 amino acids, due to the presence of many aspartic and glutamic acid residues. The presence of these acid residues may favor hydrogen-bond interactions, which probably explain the high affinity of aPRPs to tannins. The remaining part is basic and, similarly to bPRPs, shows repeated sequences of proline and glutamine often separated by glycine residues. Regarding the gPRPs, there is little information about the glycosylation pattern of these proteins. Pascal et al.[46] reported that gPRPs are in fact effective in binding tannins; however, these interactions do not necessarily result in precipitation.[47] Possibly, this happens because of the presence of the sugar moiety in their structure.[47] Nayak and Carpenter[48] showed that statherin is precipitated by polyphenols, tea polyphenols. Statherin is rich in tyrosine residues and is phosphorylated at Ser-2 and Ser-3. The presence of protic groups (phosphates) with acidic character may favor the hydrogen-bond interactions, which probably explain statherin's high affinity to tannins.[48]

The results present herein provide important insights concerning the influence of the different families of SP in the development of astringency. In fact, when all of the main families of SP are present in a competitive assay, like in the oral cavity, they demonstrate that tannins interact first with statherin and aPRPs, and then with gPRPs.

In summary, SP families have relative discriminatory functions in rating the perception of astringency depending on the type of astringent stimuli used. Repeated stimulations with PC may affect differently the several families of SP, suggesting that they could be involved in different stages of the development of astringency.

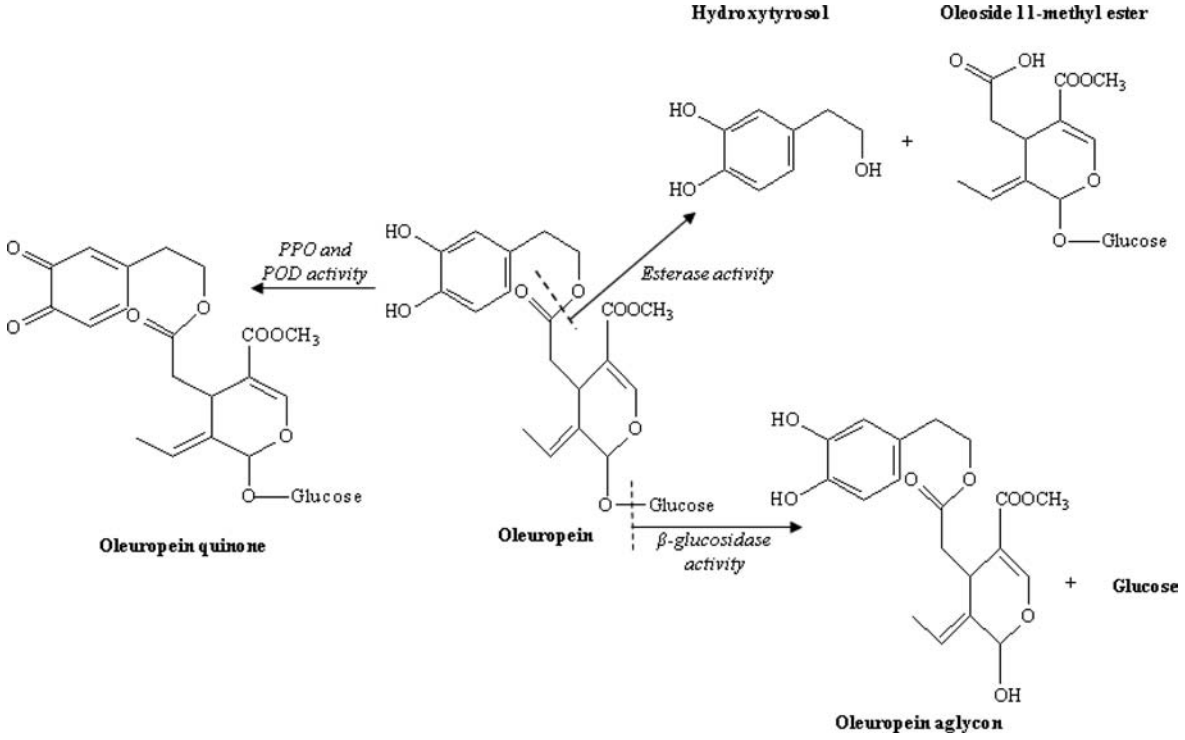

**Figure 1.** Oleuropein and products of its enzymatic transformations.

California-style. Twelve and six samples for each variety during the 2010/2011 and 2011/2012 seasons, respectively, were assessed. The fruits were processed on the same day without any storage period.

**Analysis of Phenolic Compounds.** The extraction of phenolic compounds from the olive pulp was based on the methodology proposed elsewhere.[19] Around 10 g of fresh olive pulp was mixed in an Ultra-Turrax homogenizer with 30 mL of dimethyl sulfoxide (DMSO). After 30 min of resting contact, the mixture was centrifuged at 6000*g* for 5 min (22 °C), and 0.25 mL of the supernatant was diluted with 0.5 mL of DMSO plus 0.25 mL of 0.2 mM syringic acid in DMSO (internal standard). The extraction of phenolic compounds from the fresh olive skin was made similarly to the olive pulp as described above, but this time the mixing ratio was 0.1 g of olive skin and 0.5 mL of DMSO.

Samples were filtered through a 0.22 $\mu$m pore size nylon filter, and an aliquot (20 $\mu$L) was injected into the chromatograph. The chromatographic system consisted of a Waters 717 plus autosampler, a Waters 600 E pump, a Waters column heater module, and a Waters 996 photodiode array detector operated with Empower software (Waters Inc.). A 25 cm × 4.6 mm i.d., 5 $\mu$m, Spherisorb ODS-2 (Waters Inc.) column, at a flow rate of 1 mL/min and a temperature of 35 °C, was used in all experiments. Separation was achieved by gradient elution using (A) water (pH 2.5 adjusted with 0.15% phosphoric acid) and (B) methanol. The initial composition was 90% A and 10% B. The concentration of B was increased to 30% over 10 min and was maintained for 20 min. Subsequently, B was raised to 40% over 10 min, maintained for 5 min, and then increased to 50%. Finally, B was increased to 60, 70, and 100% in 5 min periods. The initial conditions were reached in 10 min. Chromatograms were recorded at 280 nm.[15]

The evaluation of each compound was performed using a regression curve with the corresponding standard. Hydroxytyrosol, oleuropein, verbascoside, luteolin 7-glucoside, luteolin, rutin, and apigenin were purchased from Extrasynthese S.A. (Lyon Nord, Genay, France) and tyrosol, caffeic acid, and *p*-coumaric acid from Sigma Chemical Co. (St. Louis, MO, USA). Hydroxytyrosol-1-glucoside, caffeoyl ester of secologanoside, and comselogoside were quantified using the response factors of hydroxytyrosol, caffeic acid, and *p*-coumaric acid, respectively. Salidroside and ligustroside were quantified using the response factors of tyrosol. Hydroxytyrosol-4-glucoside was obtained using an HPLC preparative system.[20]

**Preparation of Acetone Powder.** Acetone powders were obtained from 50 g of olive pulp or skin homogenized with 100 mL of cold acetone (−30 °C) containing 2.5 g of polyethylene glycol.[6] The mixture was then vacuum-filtered in a Büchner funnel through paper, and the residue was re-extracted three times with 100 mL of cold acetone, obtaining a white solid that was dried overnight at room temperature to remove residual acetone. The acetone powder was stored at −40 °C until use.

**PPO and POD Activity.** A crude enzyme extract was obtained from the above acetone powder as described elsewhere.[11] Half a gram of acetone powder was suspended in 20 mL of 0.1 M sodium phosphate buffer, containing 1 M NaCl, and the pH was adjusted to 6.2 units with NaOH. The suspension was stirred at 4 °C for 30 min and then centrifuged at 15550*g* for 20 min at 4 °C. The pellet was discarded and the supernatant divided into two aliquots; one was used as the active crude enzyme extract, and the other was boiled for 30 min to get the denatured enzyme extract.

The PPO activity was determined spectrophotometrically using a Shimadzu UV−vis 1800 spectrophotometer as described elsewhere.[21] All measurements of PPO activity were carried out with 4-methylcatechol (Sigma Chemical Co.) as substrate by measuring the changes in absorbance at 410 nm at 25 °C for 10 min at intervals of 5 s. The incubation mixture contained 0.5 mL of crude enzyme preparation and 2.5 mL of 0.1 M sodium citrate buffer at pH 5 with 0.02 M substrate. The assay mixture with the denatured enzyme extract served as the control. One unit of enzyme activity was defined as the amount of the enzyme giving a change in absorbance of 0.05 unit (AU) per minute under the above-mentioned conditions. All assays were carried out in duplicate.

The POD activity was determined spectrophotometrically as described elsewhere.[22] All measurements of POD activity were carried out with guaiacol (Sigma Chemical Co.) as substrate by measuring the changes in absorbance at 470 nm at 25 °C for 10 min at intervals of 1 min. The assay mixture with the denatured enzyme extract served as the control. The incubation mixture contained 0.3 mL of crude enzyme extract and 2.7 mL of phosphate buffer at pH 6 containing 0.04 M substrate and 0.026 M hydrogen peroxide. The composition of

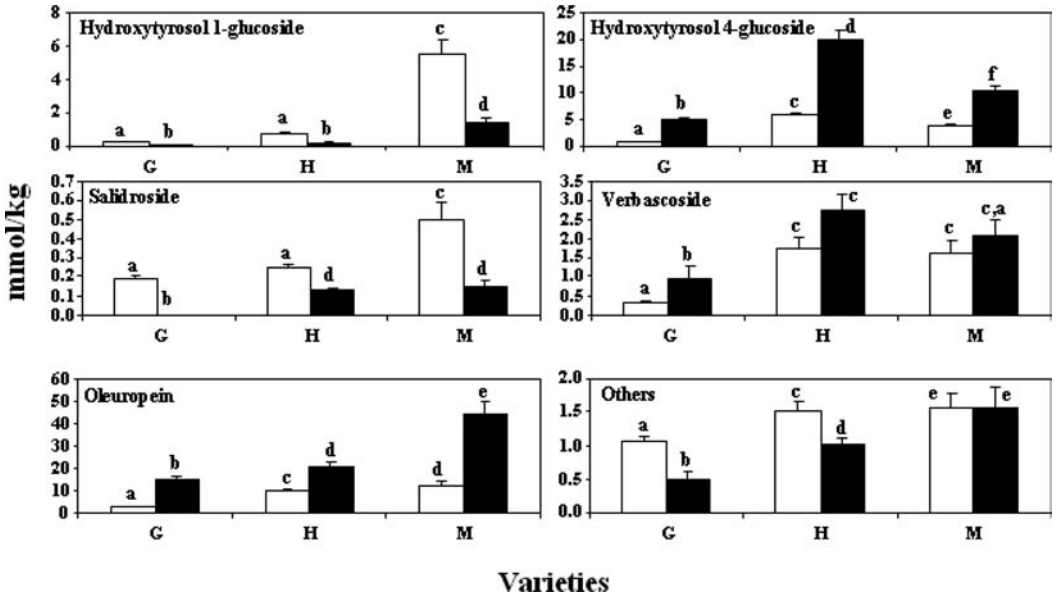

**Figure 2.** Concentration of phenolic composition (mmol/kg) in fruits of Gordal (G), Hojiblanca (H), and Manzanilla (M) varieties. The phenol compounds analyzed were hydroxytyrosol-1-glucoside, hydroxytyrosol-4-glucoside, salidroside, verbascoside, oleuropein, and the sum of tyrosol, luteolin-7-glucoside, rutin, caffeic and *p*-coumaric acid, caffeoyl ester of secologanoside, comselogoside, luteolin, apigenin, and ligustroside ("Others"). Bars indicate the standard error of 12 and 6 samples from the 2010/2011 (white bars) and 2011/2012 (black bars) seasons, respectively. Columns with the same letter are not significantly different by Duncan's multiple-range test at the 5% level for each phenol.

the phosphate buffer was 0.02 M sodium acid phosphate and 0.08 M sodium monobasic phosphate. Initially, the reaction buffer was incubated for 15 min at 30 °C, and the reaction was started by the addition of crude enzyme extract.

One unit of enzyme activity was defined as the amount of enzyme required to increase 0.001 unit (AU) per minute under the above-mentioned conditions. All reactions were carried out in duplicate.

**β-Glucosidase Activity.** A crude enzyme extract was obtained from the above-mentioned acetone powder. Acetone powder (0.14 g) was suspended in 10 mL of a 0.01 M sodium carbonate buffer, containing 0.005 M ethylenediaminotetraacetic acid (EDTA), 0.001 M phenylmethylsulfonyl fluoride (PMSF), and 1% of 2-mercaptoethanol. The pH was adjusted to 9.0 units with NaOH. The suspension was stirred at 4 °C for 1 h and then centrifuged at 15550*g* for 20 min at 4 °C. The pellet was discarded and the supernatant divided into two aliquots; one was used as the active crude enzyme extract, and the other was boiled for 30 min to obtain the denatured enzyme extract.

The β-glucosidase activity analysis was based on the methodology proposed elsewhere.[14] This activity was determined by monitoring the increase in absorbance at 405 nm for 30 min at intervals of 5 min related to the increasing amount of *p*-nitrophenol (p-NP) liberated from the synthetic glucoside *p*-nitrophenyl-β-D-glucopyranoside (p-NPG) (Sigma Chemical Co.). The reaction medium consisted of 100 μL of crude enzyme extract and 100 μL of 0.050 M sodium acetate buffer at pH 5.4 units containing 0.015 M p-NPG as substrate. The mixture was incubated for 30 min at 45 °C. Then, the reaction was stopped by adding 1 mL of 0.5 M sodium carbonate and the spectrophotometrical measurement started at 405 nm. The assay mixture with the denatured enzyme extract served as the control.

The evaluation was performed using a regression curve with p-NP in a range of 0−0.0003 M. One unit of enzyme activity was defined as the amount of enzyme required to produce 1 μmol of p-NP per minute. All reactions were carried out in duplicate.

**Esterase Activity.** A crude enzyme extract was obtained from the above-mentioned acetone powder. Acetone powder (0.25 g) was suspended in 10 mL of a 0.01 M sodium borate buffer, containing 0.005 M EDTA and 0.001 M PMSF. The pH was adjusted to 9.0 units with NaOH. The suspension was stirred at 4 °C for 1 h and then centrifuged at 15550*g* for 20 min at 4 °C. The pellet was discarded, and the supernatant was the enzyme extract.

The esterase activity was analyzed according to the methodology proposed elsewhere.[23] This activity was determined by continuously monitoring the increase in absorbance at 405 nm for 10 min at 40 °C related to the increasing amount of p-NP liberated from the synthetic *p*-nitrophenyl acetate (p-NPA) (Sigma Chemical Co.). The incubation mixture contained 50 μL of crude enzyme extract, 50 μL of 0.15 M p-NPA in ethanol as substrate, and 2.9 mL of a 0.0092 M Tris-HCl buffer at pH 7.5. The reaction was initiated by the addition of the enzyme extract. The assay mixture with 50 μL of extraction buffer served as the control.

The evaluation was performed using a regression curve with p-NP in a range of 0−0.00003 M. One unit of enzyme activity was defined as the amount of enzyme required to produce 1 μmol of p-NP per minute. All reactions were carried out in duplicate.

**Effect of pH.** The enzyme assays at different pH values were performed by measuring the activity of each enzyme using different buffer solutions under standard conditions. In the case of PPO and POD, 0.1 M sodium citrate and a 0.1 M sodium phosphate buffer in the pH range of 4−5 and 6−8 units were used, respectively. The effect of pH on olive β-glucosidase and esterase activity was assessed with a 0.05 M acetic acid−sodium acetate trihidrate solution, 0.05 M sodium phosphate, and a 0.0092 M Tris-HCl buffer in the pH range of 4−5, 6−7, and 7.5−8 units, respectively. In all cases, the pH was finally adjusted with suitable amounts of 1.0 M NaOH and 1.0 M HCl.

**Effect of Temperature.** The optimal temperature for PPO, POD, β-glucosidase, and esterase enzymes was determined by measuring the activity of each enzyme in the temperature range of 10−70 °C under standard conditions.

**Statistical Analysis.** Data were expressed as mean values ± error standard. Statistical software version 7.0 was used for data processing (Statistical for Windows, Tulsa, OK, USA). A comparison among mean variables was made by Duncan's multiple-range tests, and the differences were considered significant when $p < 0.05$.

## RESULTS AND DISCUSSION

**Polyphenolic Compounds.** Hojiblanca, Manzanilla, and Gordal are the main olive varieties employed by the Spanish table olive industry. The concentration of the phenolic composition in the fruit of these varieties for two seasons

dx.doi.org/10.1021/jf5027982 | J. Agric. Food Chem. 2014, 62, 9569−9575

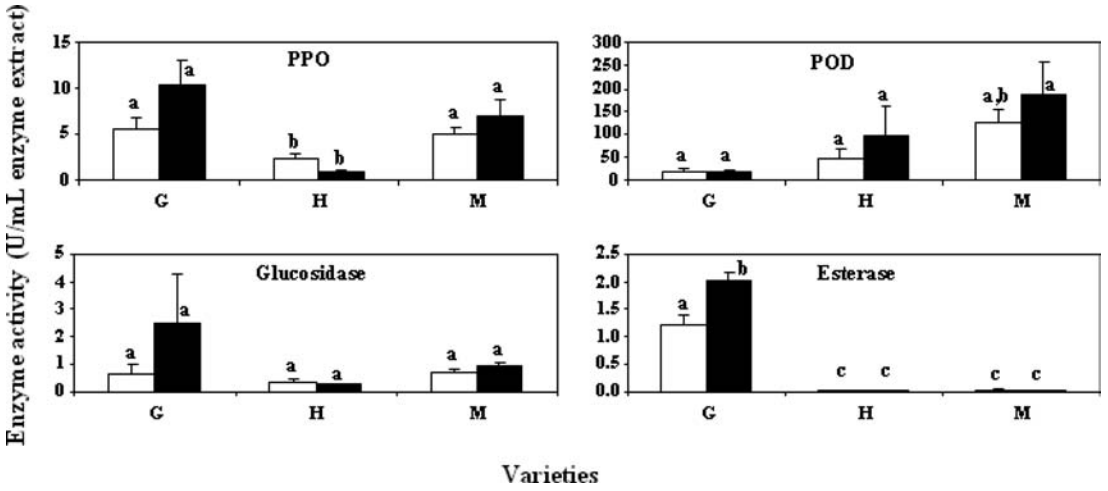

**Figure 3.** Enzymatic activity (U/mL enzyme extract) in fruits of Gordal (G), Hojiblanca (H), and Manzanilla (M) varieties. Bars indicate the standard error of 12 and 6 samples from the 2010/2011 (white bars) and 2011/2012 (black bars) seasons, respectively. Columns with the same letter are not significantly different by Duncan's multiple-range test at the 5% level for each enzyme.

and several orchards is shown in Figure 2. As was expected from previous works,[24−26] the main phenolic compound was oleuropein, followed by hydroxytyrosol 4-glucoside, hydroxytyrosol 1-glucoside, verbascoside, and salidroside, with minor concentrations of tyrosol, luteolin 7-glucoside, caffeic and *p*-coumaric acids, the ester of caffeic acid with secologanoside, comselogoside, luteolin, apigenin, and ligustroside. The hydroxytyrosol 4-glucoside concentration was particularly high in the Hojiblanca variety. This polyphenol increases its concentration in mature olives,[20] but all samples, including those of the Hojiblanca variety, were picked at the same maturity index. Salidroside was not detected in the samples of the Gordal variety as other authors have reported.[27]

In summary, the olives of the Manzanilla variety showed the highest concentration in total polyphenols, 25.4 ± 2.6 and 59.6 ± 6.7 mM, followed by the Hojiblanca variety, 19.7 ± 1.0 and 44.7 ± 1.5 mM, and the Gordal variety, 5.2 ± 0.3 and 21.6 ± 1.4 mM, for the 2010/2011 and 2011/2012 seasons, respectively. These differences among varieties were statistically significant according to Duncan's multiple-range test at the 5% level, and it must also be noted that big differences were found between seasons. A much higher concentration of polyphenols was found in olives from the 2011/2012 season than from the 2010/2011 season, except for hydroxytyrosol 1-glucoside and salidroside. These data are of great importance because of the lack of previous studies and the fact that research was carried out for only one season. In addition, the hydrolysis rate of oleuropein and its residual concentration in edible olives depends on the concentration of this substance in the raw material.

**Enzyme Activity.** Figure 3 shows the PPO activity in fruits of the Gordal, Hojiblanca, and Manzanilla varieties picked with a green-yellow color for two seasons and from several cooperatives.

The first finding that must be noted is the high variability found among the different samples analyzed within the same variety, especially those of the Gordal variety. The standard error of the mean PPO activity of Gordal was 1.28 and 2.61 U/mL enzyme extract for the two seasons studied, whereas these data were recorded as 0.63 and 0.06 U/mL enzyme extract for the Hojiblanca variety. This variability is common in nature, and it has been observed for Italian olive varieties[28] and many other fruits such as peaches.[29]

Regardless of the season, the Gordal variety showed a high PPO activity, followed by Manzanilla and Hojiblanca. In Spain, the Hojiblanca variety destined for table olives is mechanically harvested, whereas the other varieties (Manzanilla and Gordal), which are very prone to bruising, are picked by hand. Indeed, Jiménez-Jiménez et al.[30] found the Hojiblanca variety to have a lower susceptibility to bruising than the others, but no explanation for this phenomenon was reported. Both phenolic compounds and PPO participate in the appearance of bruising after harvesting but from the data reflected in Figures 2 and 3, it seems that the PPO activity could better explain the behavior of the Hojiblanca variety. The low PPO activity in this variety probably contributes to the slow formation of brown spots in harvested olives, whereas the high activity in Manzanilla and Gordal favors their appearance.

The phenolic composition and the PPO activity in both the pulp and the skin of the Manzanilla variety were also characterized (Table 1), which is the variety more prone to bruising. The concentration of the phenolic compounds, except verbascoside, was much higher in the skin than in the pulp but, in contrast, the PPO activity was much lower in the skin than in the pulp. These data are in agreement with those reported by

**Table 1. Enzyme Activity and Polyphenol Compounds in the Skin and Pulp of Manzanilla Olives**

| | skin | pulp |
|---|---|---|
| enzyme activity (U/mL enzyme extract) | | |
| PPO | 4.3 ± 0.1[a] | 19.5 ± 0.4 |
| polyphenol compounds (mmol/kg) | | |
| hydroxytyrosol 1-glucoside | 2.7 ± 0.1 | 0.6 ± 0.2 |
| hydroxytyrosol 4-glucoside | 3.8 ± 0.8 | 2.2 ± 0.7 |
| salidroside | 0.2 ± 0.1 | 0.2 ± 0.1 |
| verbascoside | 0.3 ± 0.1 | 2.4 ± 0.4 |
| oleuropein | 129.4 ± 18.4 | 45.9 ± 8.6 |
| others[b] | 6.8 ± 1.8 | 2.5 ± 0.2 |

[a]Each value is the mean ± standard deviation of three samples. [b]Sum of rutin, caffeoyl ester of secologanoside, comselogoside, and ligustroside.

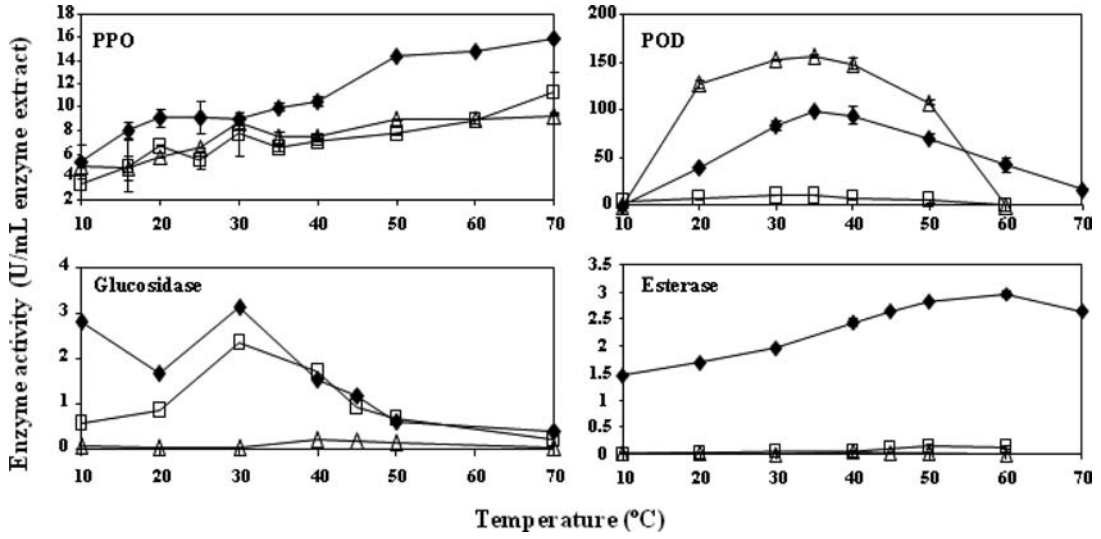

**Figure 5.** Effect of temperature on enzymatic activity (U/mL enzyme extract) in the fruits of Gordal (◆), Hojiblanca (△), and Manzanilla (□) varieties. Bars indicate the standard deviation of two samples.

Chang et al.,[29] who found that in five of nine peach varieties, the PPO activity was higher in the pulp than in the skin.

With regard to the peroxidase activity (Figure 3), the variability of results within a single variety was much higher than that of PPO activity. Particularly, 33% of Hojiblanca samples did not present POD activity for the two seasons studied. In contrast, 50% of Manzanilla samples had a very high POD activity, >170 U/mL enzyme extract, but 15% of the samples had <20 U/mL enzyme extract. The mean values reflect that the Manzanilla variety had the highest POD activity, followed by Hojiblanca and Gordal. The participation of POD in the browning of olives is unknown ,but some researchers have found a much higher concentration of this enzyme in the olive seed than in the rest of the fruit.[31,32] This has been associated with phenolic oxidation of the olive paste during the malaxation step of the olive oil extraction process.

In relation to the $\beta$-glucosidase activity, again a high variability among orchards was found within the same variety for the two seasons (Figure 3). The Gordal variety showed the highest activity, followed by the Manzanilla and Hojiblanca varieties. There are few data about endogenous $\beta$-glucosidase activity in olive varieties, and they were focused mainly on Spanish,[14,17] Tunisian,[18] and Italian[10] olive oil varieties. Furthermore, these studies were carried out with samples from one orchard, one season, and few varieties and did not find the great variability detected in this study.

The cleavage of the ester bond in the oleuropein molecule either chemically with the use of NaOH or enzymatically by esterases gives rise to nonbitter compounds (Figure 1). The activity of this enzyme for the three olive varieties and the two seasons studied is reflected in Figure 3. The two varieties with a high concentration in phenolic compounds and bitterness, Hojiblanca and Manzanilla, had very low esterase activity, whereas the sweet variety Gordal with low concentrations in phenolic compounds showed a very high activity of this enzyme, particularly during the second season. Similar behavior has been reported for the sweet Tunisian variety Dhokar; a low

dx.doi.org/10.1021/jf5027982 | J. Agric. Food Chem. 2014, 62, 9569−9575

concentration in oleuropein was correlated with a high β-glucosidase and esterase activity.[18]

**Influence of External Parameters: pH and Temperature.** The influence of pH on enzyme activity in the fruits of Gordal, Manzanilla, and Hojiblanca varieties is shown in Figure 4. Oxidase enzymes showed a maximum activity in a pH range between 5 and 6 units, which is in agreement with previous data reported for tPPO in Manzanilla olives.[33] However, there are many contradictory findings in the literature on the effect of pH on oxidase activities. Researchers have reported a maximum activity of PPO at pH 4.5[34] and 7.5[35] for the Turkish Domat variety. A maximum POD activity has also been reported at pH 7 and in the range of 4−6 units for Portuguese and Greek olive varieties, respectively.[36,37] These data agree with the result shown in Figure 4, where an optimal pH value of 6 units for POD activity is evident for all varieties.

It must be noted that these oxidase enzymes primarily act in olives during the postharvest period when the pH of the fruit is around 5.

The β-glucosidase activity was at its maximum at pH 5, which is in accordance with data reported by other researchers.[14,38] In contrast, the esterase activity decreased from pH 7 to 4, particularly for the Gordal variety. To our knowledge, there are no data available about the influence of pH on the olive esterase, but our findings mean that the low pH in olives during brining is not favorable for the action of this enzyme.

The effect of temperature on enzyme activity is reflected in Figure 5. It can be observed that the PPO activity increased with increasing temperature up to 70 °C for the three olive varieties studied, which is in contrast to previous data that indicated a maximum activity in the range of 30−50 °C.[34,39] We have no explanation for these results. It could be thought that some nonenzymatic reactions took place during the analyses at high temperature, but the PPO activity was calculated with the difference in absorbance originated from the enzyme extract and the denatured control. It must be noted that PPO stability is high at elevated temperature[35,39] and the analysis was carried out in a few minutes.

The POD presented maximum activity over a temperature range of 30−40 °C, which is in agreement with the range of 30−35 °C reported by other researchers.[36,37]

The β-glucosidase activity in the Gordal variety presented two maximum activity levels at temperatures of 10 and 30 °C, the former temperature was not expected, and the second is similar to previous data found for other olive varieties,[38] even for the Manzanilla variety. Moreover, Hojiblanca showed a maximum activity at 40−45 °C, which agrees with the results found for the Picual variey.[14]

With regard to the esterase activity, the behavior was similar in all varieties, reaching an optimal temperature at around 50−60 °C, particularly for the Gordal variety. This is a very high temperature and not common during the processing of Spanish table olives. Also, there is no information in the literature on the influence of temperature on olive esterase activity.

In conclusion, a great variability in the phenolic content and enzyme activity of olives harvested with the same degree of maturation but from different orchards was found. Variety and season also had a great influence on the contents of polyphenols and enzyme activity in olive fruits. The Manzanilla variety showed the highest concentration in phenolic compounds, followed by Hojiblanca and Gordal with the lowest. With respect to the enzyme activity, it is relevant to say that the lowest PPO activity was found in the Hojiblanca variety, which could explain why this variety is less prone to bruising than the others. Therefore, the results obtained in this study could contribute to the explanation of the great variability found in the quality of processed table olives. Besides, enzyme knowledge can help processors to optimize the elaboration methods of table olives due to the enzymatic transformation of the bitter substance oleuropein instead of the current alkaline hydrolysis.

**Table 1. Juices Used in This Study**

| scientific name | common name | local name | status |
|---|---|---|---|
| | **Mature Flesh** | | |
| *Averrhoa bilimbi* | bilimbi | belimbing buluh | native |
| *Averrhoa carambola* cv. B10 | star fruit | belimbing segi | native |
| *Barringtonia racemosa* | hippo apple | putat | native |
| *Cynometra cauliflora* | nam nam | nam nam, katak puru | native and endemic |
| *Garcinia atroviridis* | Malabar tamarind | gelugor | native |
| *Myristica fragrans* | nutmeg | pala | native |
| *Phyllanthus acidus* | Indian gooseberry | cermai | native |
| *Psidium guajava* cv. GU8 | guava | jambu batu | introduced |
| *Sandoricum koetjape* | santol, kechapi | sentul | native |
| *Spondias pinnata* | wild mango, hog plum | kedondong, amra | native |
| *Syzygium malaccense* | Malay apple | jambu susu, jambu bol | native and endemic |
| *Syzygium samarangense* | wax apple | jambu semarang | native |
| *Zizyphus mauritiana* | Indian jujube | bidara | introduced |
| | **Ripe Flesh** | | |
| *Bouea macrophylla* | gandaria | kundang, remia | native and endemic |
| *Carica papaya* cv. Batu Arang | papaya | betik | introduced |
| *Citrullus lanatus* cv. New Dragon | watermelon | tembikai | introduced |
| *Citrus aurantifolia* | lime | limau nipis | native |
| *Citrus maxima* cv. PO52 | pommelo | limau bali | native |
| *Citrus microcarpa* | calamansi | limau kasturi | native |
| *Cucumis melo* cv. Inodorus | melon | honeydew | introduced |
| *Mangifera indica* cv. Malgoa | mango | mangga | native |
| *Manilkara zapota* cv. CM19 (mega) | sapodilla | ciku | introduced |
| *Musa acuminata* cv. Mas | banana | pisang | native |
| | **Ripe Aril** | | |
| *Annona muricata* | sour sop | durian belanda | introduced |
| *Annona squamosa* | sugar-apple, sweetsop | nona | introduced |
| *Artocarpus heterophyllus* cv. J33 (tekam yellow) | jackfruit | nangka | native |
| *Baccaurea montleyana* | rambai | rambai | native |
| *Baccaurea polyneura* | jentik | jentik | native and endemic |
| *Dimocarpus longan* cv. Edaw | longan | mata kucing | introduced |
| *Garcinia mangostana* | mangosteen | manggis | native |
| *Lansium domesticum* | dokong | dokong | native |
| *Nephelium lappaceum* cv. R191 (Anak sekolah) | rambutan | rambutan | native |
| *Nephelium ramboutan-ake* | pulasan | pulasan | native |
| *Salacca edulis* cv. Z6 (Raja) | snake fruit | salak | native |
| *Sandoricum koetjape* | santol, kechapi | sentul | native |
| | **Young Endosperm** | | |
| *Cocos nucifera* cv. Pandan wangi | coconut | kelapa | introduced |
| | **Ripe Peduncle** | | |
| *Ananas comosus* cv. Moris | pineapple | nenas | introduced |
| | **Stem** | | |
| *Apium graveolens* | celery | saleri | introduced |
| *Saccharum officinarum* | sugar cane | tebu | introduced |
| | **Root** | | |
| *Daucus carota* | carrot | lobak merah | introduced |

Elevation of blood sugar level (hyperglycemia) can be minimized to normal (euglycemia) by inhibiting the carbohydrate-digesting enzymes such as $\alpha$-glucosidase. $\alpha$-Glucosidase is known to catalyze the final step in the digestion of carbohydrate to absorbable monosaccharides. Thus, in this study the juices were also screened for their $\alpha$-glucosidase inhibitory activity to determine their antihyperglycemic effect. Due to the dose-limiting side effects of oral antihyperglycemic drugs, we hypothesized that consumption of the antioxidant-rich juices with $\alpha$-glucosidase inhibitory activity prior to a meal is a safer and appropriate alternative for the treatment of hyperglycemia.

On the basis of the published data from various comparative studies of phenolic-rich extracts from fruits, several tropical fruits were proven to be effective against $\alpha$-glucosidase, such as *Pouteria lucuma* (lucuma), a native Peruvian fruit;[14] *Campomanesia phaea* (cambuci) and *Eugenia dysenterica* (cagaita), which are native to Brazil;[15] *Eugenia uniflora* (pinanga), which is native to tropical America;[16] and *Aristotelia chilensis* (maqui), a Latin-American fruit.[17] However, all of these fruits are not found in Malaysia, and no earlier study on $\alpha$-glucosidase inhibitory activity of tropical juices had been reported.

To the best of our knowledge, there was only one comparative study that had determined the $\alpha$-glucosidase inhibitory activity of five juice samples from fruits and vegetables that are commonly consumed in Korea.[18] However, the highest percentage of inhibition, 30.4% (indicated by the juice from lotus root), was considered very low. Our literature search indicated that, to date, there have only been four reports on the $\alpha$-glucosidase inhibitory activity of 10 fruits selected for this study, which are 99.5% ethanol extracts of dried mature fleshes of *Phyllanthus acidus* (Indian gooseberry), *Spondias pinnata* (hog plum), *Zizyphus mauritiana* (Indian jujube), and *Manilkara zapota* (sapodilla) and *Artocarpus heterophyllus* (jackfruit);[19] 70% methanol extracts of lyophilized ripe fleshes of *Averrhoa carambola* (star fruit) and *Annona muricata* (sour sop);[15] aqueous extracts of fresh ripe fleshes of *Averrhoa carambola, Phyllanthus acidus, Spondias pinnata, Zizyphus mauritiana, Manilkara zapota, Annona squamosa* (sugar-apple), and *Dimocarpus longan* (longan);[20] and 70% methanol extract of lyophilized ripe flesh of *Carica papaya* (papaya).[17] Different extraction solvents and sample matrices were used in these studies.

The aims of the present study were to comparatively analyze the total phenolic contents and vitamin C as well as antioxidant and $\alpha$-glucosidase inhibitory activities of 40 fresh and pure juices from juicy and fleshy fruit parts, stems, and roots that are commonly consumed in Malaysia. The results were correlated with each other, and the unknown phenolic compounds in the juices with higher activities were identified.

## MATERIALS AND METHODS

**Plant Materials.** Table 1 shows a list of 40 juices that were used in this study. For several fruit crops, the information about the cultivars or clones used were also included in Table 1. The juicy parts at their

[a]Values are means ± standard deviations of triplicate analyses. Results from different analyses were analyzed separately. Values per each analysis followed by different letters are significantly different ($p < 0.05$).

commercial maturity stages were harvested by skilled and knowledgeable farmers from various orchards in Penang, Malaysia. This is an important procedure to ensure the identity of the plants and the use of identical maturity stages for each sample. Only top-quality juicy parts (without bruise/injury) were selected for the experimental work. For each of the samples, at least three handpicked fruit parts, stems, or roots from three different trees were combined. To maintain the freshness of the sample, the interval between harvesting and extraction was specified to be <4 h. The skin, peel, husk, or rind and seed were then removed.

**Chemicals.** All chemicals and reagents used in this study were of analytical grade. Folin−Ciocalteu phenol reagent, metaphosphoric acid, 2,6-dichloroindophenol (DCIP), 1,1-diphenyl-2-picrylhydrazyl radical (DPPH), 2,4,6-tri(2-pyridyl)-*s*-triozine (TPTZ), ferric chloride hexahydrate, ferrous chloride hexahydrate, ferrozine, 6-hydroxy-2,5,7,8-tetramethylchroman-2-carboxylic acid (Trolox), myricetin, quercetin, kaempferol, dihydroquercetin, ascorbic, gallic acid, and ellagic acid were obtained from Sigma-Aldrich Chemicals (St. Louis, MO, USA). Sodium carbonate and sodium bicarbonate were purchased from Fluka (Buchs, Switzerland).

**Extraction.** For each sample, the fresh succulent part (200 g fresh weight) was washed with distilled water, and the water remaining at the external surface of the sample was dried out using blotting paper (Whatman 3MM Chr). The sample was later ground for 2 min using a grinder to yield a fine puree (40 mesh or 400 μm of particle size). The puree was equally divided into two groups. The puree from the first group (100 g) was then soaked in 500 mL of distilled water for 15 min at room temperature (27 ± 1 °C). The pure puree from the second group and the diluted puree (from the first group of puree) were then filtered using a clean muslin cloth and centrifuged using a Hittech EBA 20 centrifuge (Japan) at 704*g* for 15 min. The yields of the pure juices (%) were calculated. Concentration of the obtained diluted juice was referred to fresh sample weight resulting in 200 mg/mL (w/v). The pure juices and diluted juices were stored at 4 °C in the dark until further analysis. The interval between extraction process and experimental work was specified to be <1 h. For each sample, the extraction process was carried out in triplicate, using the juicy part from different trees each time.

**Total Soluble Solids (°Brix) and pH.** The total soluble solids and pH values of the pure juices were determined using a hand refractometer (Atago 2340 HSR-500, Japan) and a pH meter (Mettler Toledo 320, Columbus, OH, USA), respectively. Refractive indices were recorded and converted to degrees Brix using a conversion table. All of the measurements were performed at room temperature (27 ± 1 °C) in triplicate.

**Determination of Total Phenolic and Vitamin C Contents.** The total phenolic and vitamin C contents from the diluted juices (200 mg/mL) were quantified as described by Sulaiman and Ooi.[21] Diluted juices were used in both experiments to compare our results with the published data that mostly measured the contents of total phenolic and vitamin C in 1 g of fresh weight or dry weight of sample. The experiments were carried out in triplicate. Standard curves were plotted using gallic acid (0−1 mg/mL) and ascorbic acid (0−2.5 mg/mL). The total phenolic contents were expressed as micrograms of

gallic acid equivalent per gram of fresh weight of sample (μg GAE/g sample), and the contents of vitamin C were expressed as micrograms of ascorbic acid equivalent per gram fresh weight of sample (μg AAE/g sample).

**DPPH Free Radical Scavenging and Ferric Reducing Antioxidant Potential (FRAP) Assays.** The activities of the samples were separately analyzed using DPPH free radical scavenging and ferric reducing antioxidant potential (FRAP) assays according to the methods as described by Sulaiman and Ooi.[21] All tests were run in triplicate. Diluted juices (200 mg/mL) were used in both assays to compare the obtained results with the earlier findings that mostly quantified the contents of antioxidants in 1 g of fresh weight or dry weight of sample. Standard curves were obtained using different concentrations of ascorbic acid (0−0.5 mg/mL) for DPPH assay and Trolox (0−1 mg/mL) for FRAP assay. The absorbance of the diluted juice reaction was compared to that of the standard, and the results from the DPPH assay were expressed as micrograms of vitamin C equivalent antioxidant capacity per gram of fresh weight of sample (μg VCEAC/g sample). The results from the FRAP assay were expressed as micrograms of Trolox equivalent antioxidant capacity per gram of fresh weight of sample (μg TEAC/g sample).

**Metal Chelating Assay.** The metal chelating assay was performed according to the method as described by Sulaiman and Ooi.[21] The metal chelating percentage of pure juices was determined in this study. It was calculated as follows: % metal chelating = [(absorbance of negative control − absorbance of pure juice)/absorbance of negative control] × 100%. All experiments were performed in triplicate.

**α-Glucosidase Inhibitory Assay.** The α-glucosidase inhibitory activity was determined according to the method of Ooi et al.[22] The percentage of α-glucosidase inhibitory activity of pure juices was determined in this study. It was calculated as follows: % α-glucosidase inhibition = [(absorbance of negative control − absorbance of pure juice)/absorbance of negative control] × 100%. All measurements were done in triplicate.

**Ultraperformance Liquid Chromatography (UPLC) Analysis of Phenolic Compounds in *Barringtonia racemosa* and *Phyllanthus acidus*.** The fresh pure juices from *Barringtonia racemosa* and *Phyllanthus acidus* were filtered through a 0.2 μm syringe filter. The phenolic compounds in the juices were separated using an Acquity ultraperformance liquid chromatography (UPLC) system (Waters, Milford, MA, USA) equipped with a reverse-phase Acquity UPLC BEH $C_{18}$ column 1.7 μm (100 mm × 2.1 mm i.d.) and photodiode array detector. Different mobile phases and gradient modes were used to obtain the best separation for each juice. The fresh pure juices (5 mL) were also hydrolyzed according to the method of Harborne[23] with 10 mL of 2 M hydrochloric acid for 40 min in boiling water. Ethyl acetate was used for extracting the aglycones from the hydrolyzed juices. Each extract (5 mg/mL) was filtered through a 0.2 μm syringe filter.

The phenolic compounds in the hydrolyzed juice extracts were quantified using the UPLC system. The mobile phase consisted of solvent A (1% acetic acid) and solvent B (methanol/acetic acid/water, 18:1:1). Each extract was separated using a gradient mode that was initially set at an A/B ratio of 75:25 and then linearly increased to 50:50 at 1.3 min, 25:75 at 3.3 min, and 10:90 at 6 min. The detector was set at 280 nm for quantification of gallic acid and at 350 nm for ellagic acid, myricetin, quercetin, kaempferol, and dihydroquercetin, with a flow rate of 0.20 mL/min and an injection volume of 5.0 μL. Phenolic compounds in the extracts were identified and quantified by comparison of their retention times and UV spectra (detected by photodiode array detector) against the standards. A standard calibration curve of different concentrations (7.81−500 μg/mL) of each standard was plotted. The concentration of phenolic compounds in each extract was calculated using the regression equation of its peak area to peak area of a known concentration of standard from the calibration curve. The results were expressed as milligrams of phenolic compound per 100 g of extract (mg/100 g of extract).

**Statistical Analysis.** Data were analyzed using SPSS 16.0 for Windows (SPSS Inc., Chicago, IL, USA). Values were expressed as means ± standard deviations. Analysis of variance was determined by one-way ANOVA using GraphPadPrism (San Diego, CA, USA). A $p$ value of <0.05 was considered as statistically significant.

## RESULTS AND DISCUSSION

**Total Soluble Solids (°Brix) and pH.** As indicated in Table 2, the pure juice yields varied largely among the samples. *Baccaurea polyneura* achieved the highest yield (74.17 ± 1.44%), and *Musa acuminata* gave the lowest yield (6.33 ± 1.26%). The total soluble solids ranged from 1.01 ± 0.01 °Brix (in *Syzygium malaccense*, *Syzygium samarangense*, and *Spondias pinnata*) to 32.83 ± 0.27 °Brix (in *Baccaurea polyneura*). Meanwhile, the pH values ranged from 1.67 ± 0.67 (in *Averrhoa bilimbi*) to 6.87 ± 0.01 (in *Dimocarpus longan*).

**Total Phenolic Content (TPC).** From 40 juices, juice obtained from *Psidium guajava* exhibited the highest value of TPC (Table 3). Our findings are in agreement with many earlier comparative studies that had reported higher content of TPC in *Psidium guajava* than that of other fruits. However, the value obtained from this study was found to be lower than those quantified from 70% acetone extract,[5] methanol extract,[6] 50% ethanol extract,[7,24] and in acetone/water/acetic acid (70:29.5:0.5).[9] The high reported values of TPCs might be due to the efficiency of the solvent systems in extracting phenolic compounds from the fleshes. The juices of *Barringtonia racemosa*, *Averrhoa carambola*, *Myristica fragrans*, *Garcinia mangostana*, *Sandoricum koetjape* (mature flesh), and *Citrus maxima* ranked next with TPC values >600 μg GAE/g sample.

This is found to be the first TPC quantification for the above-listed fruit juices excluding *A. carambola* and *G. mangostana*. Fu et al.[24] measured lower TPC in the 50% ethanol extracts of these two fruits, whereas >1000 μg GAE/g sample was estimated from the ripe fleshes of *A. carambola*, extracted using 100% methanol,[5] 70% acetone,[6] and 50% ethanol.[7] Higher TPCs were also detected from *Citrus aurantifolia* and *Citrus microcarpa*. These two juices are often freshly consumed and added in various Southeast Asian foods such as tom-yum and curries. The phenolic compounds of *Citrus* are generally dominated by flavanone glycosides.[25] Flavanone glycosides such as hesperidin, neohesperidin, and hesperitin had been isolated from the juice of *Citrus aurantifolia*[26] and might also contribute to increase the content.

**Vitamin C Content.** Vitamin C contents ranged from 51.87 ± 0.74 μg AAE/g sample in *Cocos nucifera* to 590.31 ± 7.44 μg AAE/g sample in *Psidium guajava* (Table 3). Isabelle et al.[9] and Kubola et al.[12] respectively reported 714 and 780 μg AAE/g sample of vitamin C from *Psidium guajava*, whereas other studies mostly found >1000 μg AAE/g sample in this fruit.[5−7] The differences may result from the cultivars and methodologies used to extract and quantify vitamin C from the fresh sample matrices. The juices of *Spondias pinnata* and *Dimocarpus longan* were also found to contain >300 μg AAE/g sample, and the values were respectively higher than that of Kubola et al.[12] (90 μg AAE/g sample) and Mahattanatawee et al.[6] (140 μg AAE/g sample). Moreover, Isabelle et al.[9] reported 633.9 μg AAE/g sample from *Dimocarpus longan* and had identified *Psidium guajava* and *Dimocarpus longan* as fruits with high vitamin C contents. Contents ranging from 200 to 300 μg AAE/g sample were measured from the juices of *Citrus maxima*, *Garcinia atroviridis*, *Carica papaya*, *Citrus aurantifolia*, and *Citrus microcarpa*. Previous studies had reported higher vitamin C contents from the fleshes of *Carica papaya* cv. Exotica,[5] cv. Red Lady,[6] and cv. Solo.[7] Other aforementioned fruits are believed

**Table 3. Total Phenolic Content (TPC) and Vitamin C Content of the Juices[a]**

| scientific name | TPC ($\mu$g GAE/g sample) | vitamin C ($\mu$g AAE/g sample) |

to be native to Southeast Asia, and this study apparently was the first comparative evaluation that revealed higher vitamin C contents of their juices.

**Antioxidant Activities.** The antioxidant activities of the juices were evaluated using DPPH free radical scavenging, ferric reducing power (FRAP), and metal chelating assays. DPPH and FRAP assays were used to measure the direct involvement of an extract as a primary antioxidant. As indicated in Table 4, the juice of *Phyllanthus acidus* was found to exhibit the greatest scavenging and reducing activities. This was followed by the juice of *Barringtonia racemosa*. To date, the phytochemical and antioxidant evaluations of these two species were mainly focused on the leaf extracts.[27,28] Only a pentacyclic triterpenoid, bartogenic acid, was isolated from *Barringtonia racemosa* fruit extract,[29] and 46 volatile compounds were identified from *Phyllanthus acidus* fruit.[30] In Malaysia, *Barringtonia racemosa* fruit is traditionally consumed to treat asthma, sore throat, and stomachache, and *Phyllanthus acidus* fruit is used as a diuretic.[2]

Interestingly, the juice of *Psidium guajava* demonstrated the third highest values of DPPH and FRAP. This fruit juice was found to have the richest in TPC and vitamin C contents (Table 3). The major contents of flavonols such as rutin and flavones such as luteolin in *Psidium guajava*[12] may also be responsible for the activities. Meanwhile, the juice of *Ziziphus mauritiana*, with a low content of vitamin C and moderate TPC, ranked fourth best in DPPH value. The activity might be contributed by *p*-hydroxybenzoic acid that was reported to be the most abundant phenolic compound in the fruit extract.[31] The juices of the ripe aril of *Salacca edulis* and the mature flesh of *Sandoricum koetjape* were found to rank in the top six for both activities. Shui and Leong[32] had identified chlorogenic acid, epicatechin, and proanthocyanidins as the major antioxidants in *Salacca edulis*. The antioxidant activities of *Sandoricum koetjape* could be associated with its high TPC. However, no phenolic compound was previously identified from its flesh. The only phytochemical that was isolated from the flesh is a triterpenoid, bryononic acid.[33]

Other juices that gave DPPH values of >280 $\mu$g VCEAC/g sample and FRAP values of >800 $\mu$g TEAC/g sample were obtained from *Spondias pinnata* and *Citrus maxima*. It is found that the activities of the juices were well-correlated with their TPCs and vitamin C contents (Table 3). The major contents of ferulic and syringic acids in the fruit of *Spondias pinnata*[12] and naringin (a flavanone glycoside) in the juice of *Citrus maxima*[25] might act synergistically or individually to enhance the antioxidant activities of the juices. Furthermore, the FRAP value >750 $\mu$g TEAC/g sample was also measured from the juice of *Manilkara zapota*. This could be due to the presence of several polyphenolics such as methyl 4-*O*-galloylchlorogenate, 4-*O*-galloylchlorogenic acid, methyl chlorogenate, dihydromyricetin, quercitrin, myricitrin, (+)-catechin, (−)-epicatechin, (+)-gallocatechin, and gallic acid in the fruit.[34]

The metal chelating assay assesses the indirect involvement of an extract as a secondary antioxidant by binding the ferrous (Fe(II)) ion that catalyzes oxidation and subsequently prevents the formation of the Fe(II)−ferrozine complex. The highest metal chelating activity was detected from the juice of *Syzygium samarangense*. This was followed by the juices of *Averrhoa bilimbi* and *Averrhoa carambola* with no significant difference. Lim et al.[7] reported lower activity (only 30%) of the 50% ethanol extract of *Averrhoa carambola* at 100 mg/mL. This might be due to higher contents of metal chelating compounds in the juice compared to the extract.

With the exception of the juices of *Averrhoa carambola* and *Barringtonia racemosa*, the juices with >50% of activity were found to contain low TPCs (Table 3). Thus, the results revealed the minor contribution of TPC to the chelating activity. Besides, the activity of polyphenols is related to the presence of an *o*-dihydroxy moiety in their chemical structures

**Table 4. Antioxidant Activities of the Juices[a]**

or those bearing catechol or galloyl groups.[35] Polyphenolics that were previously isolated from *Syzygium samarangense* fruit pulps such as reynoutrin, hyperin, myricitrin, quercitrin, quercetin, guaijaverin, gallic acid, and ellagic acid[36] and from *Averrhoa carambola*, which are chlorogenic, caffeic acids,[24] catechin, epicatechin, and gallic acid,[37] were found having these characteristics.

**α-Glucosidase Inhibitory Activity.** As indicated in Table 4, only 11 juices mostly obtained from the mature fleshes show positive results. The pH values of juices ranged from 1.81 ± 0.01 (in *Garcinia atroviridis*) to 4.37 ± 0.01 (in *Bouea macrophylla*). This indicated no effect of the juice pH on the assay system. The highest α-glucosidase inhibitory percentage (95.37 ± 0.15%) was measured from the juice of *Phyllanthus acidus*. The value was not significantly different from the juices of *Barringtonia racemosa*, *Cynometra cauliflora*, *Myristica fragrans*, *Garcinia mangostana*, *Bouea macrophylla*, *Syzygium samarangense*, and *Citrus microcarpa*. The α-glucosidase inhibitory activity of these fruit parts (excluding *Phyllanthus acidus*) was highlighted for the first time in this study. It is

dx.doi.org/10.1021/jf502912t | J. Agric. Food Chem. 2014, 62, 9576−9585

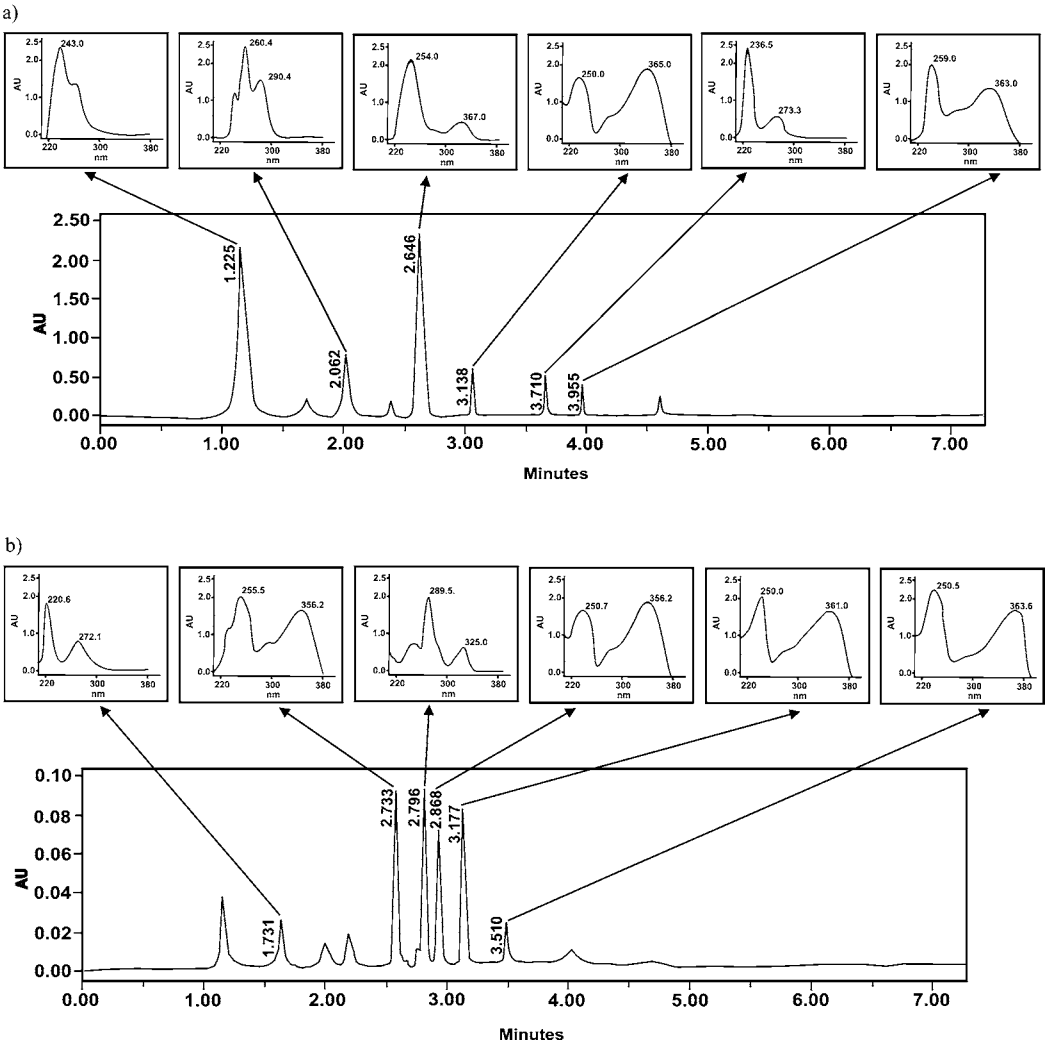

**Figure 1.** UPLC chromatograms (at 350 nm) of the juices of (a) *Barringtonia racemosa* and (b) *Phyllanthus acidus*. The UV spectra of several peaks generated by a photodiode array detector are indicated.

interesting to note that *Cynometra cauliflora* and *Bouea macrophylla* fruits that are endemic and native to Malaysia were also found to have higher activity. To date, no compound was identified from *Cynometra cauliflora* fruit, and only volatile components were identified from *Bouea macrophylla* fruit. The major volatile components of this fruit are (*E*)-*β*-ocimene (68.59%) and *α*-pinene (8.04%).[38] These compounds were also detected in the essential oil of black pepper (*Piper guineense*) seeds, which was reported to inhibit *α*-glucosidase.[39] A very low *α*-glucosidase inhibitory activity was determined from the extracts of *Phyllanthus acidus* in two earlier investigations.[19,20] This might be due to higher contents of *α*-glucosidase inhibitors in the juice compared to the extracts.

The activity of the juices of *Barringtonia racemosa*, *Myristica fragrans*, and *Garcinia mangostana* is in line with their high TPCs (>600 *μ*g GAE/g sample; Table 3). Bartogenic acid, which was also isolated in the fruit[29] and the seed of *Barringtonia racemosa*, was reported to possess *α*-glucosidase inhibitory activity.[40] Caffeic acid and catechin, which were found in the mature flesh of *Myristica fragrans*,[41] were identified as potent *α*-glucosidase inhibitors from the phenolic group.[42] The present study in fact is the first to determine the *α*-glucosidase inhibitory activity of the flesh of *Myristica fragrans* and the aril of *Garcinia mangostana*. Extracts from another two fruit parts of *Myristica fragrans*, which are the methanol extract of the mace (aril)[43] and the water extract of nutmeg (seed),[44] were previously reported to possess a moderate *α*-glucosidase inhibitory activity. Furthermore, three prenylated xanthones (*α*-mangostin, *γ*-mangostin, and gartanin) that were identified as *α*-glucosidase inhibitors were abundantly quantified from the ethanol extract of the seedcase of *Garcinia mangostana*.[45]

The major phenolic compound in the 80% methanol extract of the aril of *Garcinia mangostana* was *p*-hydroxybenzoic acid,[46] and in the juice of *Citrus microcarpa* was *p*-coumaric acid.[47] However, according to Kwon et al.,[42] these compounds have a low capacity to inhibit *α*-glucosidase. Therefore, the low contents of protocatechuic acid and vanillic acid that were also quantified from the extract of *Garcinia mangostana*[46] and caffeic acid in the juice of *Citrus microcarpa*[47] may be responsible for the activity.[42] On the basis of the comparative *α*-glucosidase inhibitory activity of various flavonoids, Tadera et al.[48] had suggested that unsaturated C-ring, hydroxylation on the C-ring at the 3-position, and an increase in the number of hydroxyl group on the B-ring might enhance the inhibitory activity. Therefore, quercetin, four quercetin glycosides (quercitrin, guaijaverin, reynoutrin, and hyperin), and a myricetin glycoside (myricitrin) that were previously isolated from *Syzygium samarangense* fruit pulps could be attributed with the activity.[36]

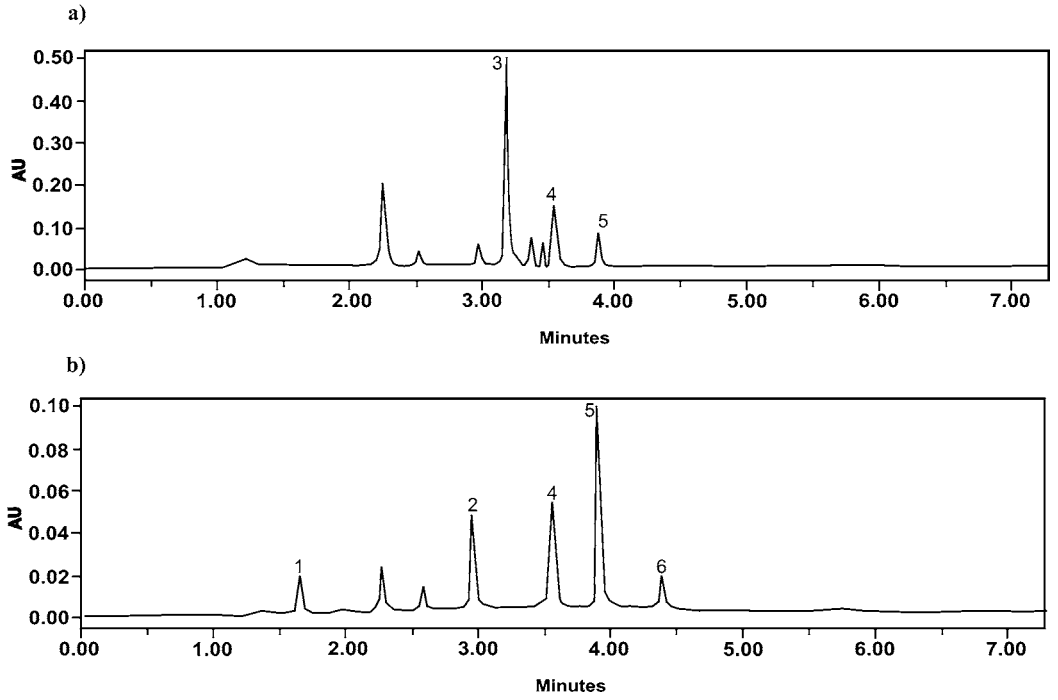

**Figure 2.** UPLC chromatograms (at 350 nm) of the hydrolyzed juice extracts of (a) *Barringtonia racemosa* and (b) *Phyllanthus acidus*. The identified compounds of the labeled peaks are shown in Table 5.

**Table 5. Content of Phenolic Compounds in Hydrolyzed Juice Extracts of *Barringtonia racemosa* and *Phyllanthus acidus* (Milligrams per 100 g of Extract)**

| peak | phenolic | retention time (min) | *B. racemosa* | *P. acidus* |
|---|---|---|---|---|
| 1 | gallic acid | 1.709 | | 230.69 ± 3.31 |
| 2 | dihydroquercetin (taxifolin) | 2.919 | | 103.33 ± 9.31 |
| 3 | ellagic acid | 3.217 | 1269.48 ± 33.82 | |
| 4 | myricetin | 3.661 | 265.57 ± 2.45 | 85.42 ± 6.51 |
| 5 | quercetin | 3.919 | 61.70 ± 1.97 | 142.68 ± 12.49 |
| 6 | kaempferol | 4.407 | | 4.54 ± 0.19 |

**Identification and Quantification of Phenolic Compounds in *Barringtonia racemosa* and *Phyllanthus acidus*.** The fruit juices of *Barringtonia racemosa* and *Phyllanthus acidus* have indicated the highest FRAP, DPPH, and $\alpha$-glucosidase inhibitory activities (Table 4). This is considered the first comparative evaluation to highlight the pronounced activities of these juices. We hypothesized that polyphenolics are the major contributors of the activities. However, no polyphenolics had been previously identified from these two fruits. Thus, polyphenolics were separated from the juices using UPLC, and different chromatograms were obtained when different mobile phases and gradient modes were used. Figure 1 shows one of the UPLC chromatograms that indicated a good separation of polyphenolics of the juices (detected at 350 nm) using solvent A (0.5% acetic acid) and solvent B (acetonitrile) as the mobile phase. The juices were separated using a gradient mode that was initially set at an A/B ratio of 80:20 and then linearly increased to 60:40 at 1 min, to 30:70 at 2 min, and to 10:90 at 4.5 min until 5.5 min. The UV spectrum of each separated peak was detected by the photodiode array detector. Only the peaks of gallic acid in *Phyllanthus acidus* chromatogram and ellagic acid in *Barringtonia racemosa* chromatogram (at retention times of 1.731 and 2.646 min, respectively) were positively identified by comparing the retention times and UV spectra of the peaks with the standards. The UV spectra of myricetin (a flavonol) were detected at the peaks with retention times of 2.868 and 3.138 min, and this indicated the presence of different glycosidic myricetins in *Phyllanthus acidus* and *Barringtonia racemosa* juices, respectively. The presence of three glycosidic quercetins (also a flavonol) was detected by the UV spectra of peaks at retention times of 2.733 and 3.510 min in the chromatogram of *Phyllanthus acidus* and 3.955 min in the *Barringtonia racemosa* chromatogram. The UV spectra of glycosidic dihydroquercetin (a flavanone) and kaempferol (a flavonol) were observed at peaks with retention times of 2.796 and 3.177 min, respectively, in the *Phyllanthus acidus* chromatogram.

Due to the diversity of unknown glycosidic flavonoids and/or bound phenolics found in these two fresh juices, we quantified the polyphenolics as aglycones, after hydrolysis. Moreover, glycosylation of flavonoids was reported to decrease the antioxidant[49] and $\alpha$-glucosidase inhibitory activities.[50] Figure 2 shows the UPLC chromatograms of the hydrolyzed juice extracts of *Barringtonia racemosa* and *Phyllanthus acidus* (at 350 nm) and six labeled peaks that were positively identified by comparison with standards.

The contents of these compounds in the extracts are summarized in Table 5. Ellagic acid (peak 3, Figure 2) was identified as the major compound in the hydrolyzed juice extract of *Barringtonia racemosa*. The hydrolyzed juice extract of

dx.doi.org/10.1021/jf502912t | J. Agric. Food Chem. 2014, 62, 9576−9585

*Phyllanthus acidus* was found to contain the highest content of gallic acid (peak 1, Figure 2). These compounds respectively bear catechol and galloyl groups that might be responsible for enhancing the antioxidant activity of the juices. However, these compounds were reported to possess low $\alpha$-glucosidase inhibitory activity.[42] Two flavonols, myricetin (peak 4, Figure 2) and quercetin (peak 5, Figure 2), were also quantified from these hydrolyzed juice extracts. The contents of these compounds in *Barringtonia racemosa* are respectively more than 3-fold higher and 2-fold lower than *Phyllanthus acidus*. These flavonols with structural configurations of 2−3 double bonds conjugated with the 4-oxo function and hydroxyl groups at the 3-, 5-, 7-, 3′-, and 4′-positions play a major role in enhancing the antioxidant[49] and $\alpha$-glucosidase inhibitory activities.[48]

As indicated in Table 5, a low content of kaempferol (a flavonol) and a moderate content of dihydroquercetin were also detected from the hydrolyzed juice extract of *Phyllanthus acidus*. With the exception of kaempferol, all of the quantified compounds have an *o*-dihydroxy moiety in their chemical structures. This may indicate the major contribution of the compounds to increase the activities of the juices.

Our results indicate that various tropical fruit juices serve as rich sources of antioxidants and $\alpha$-glucosidase inhibitors. The activities can be associated with the combined effect of polyphenolics in the juices or the structure−activity relationships of the major polyphenolics. The results obtained from this study were in line with several earlier comparative antioxidant studies that highlighted higher primary antioxidant activities of *Psidium guajava* fruit compared with other tropical fruits. However, the activities were found lower than those of *Phyllanthus acidus* and *Barringtonia racemosa*. These two medicinal fruits are native to Southeast Asia and were also found to have higher $\alpha$-glucosidase inhibitory activity. The new information obtained by this study would be useful for promoting their consumption and the development of functional foods.

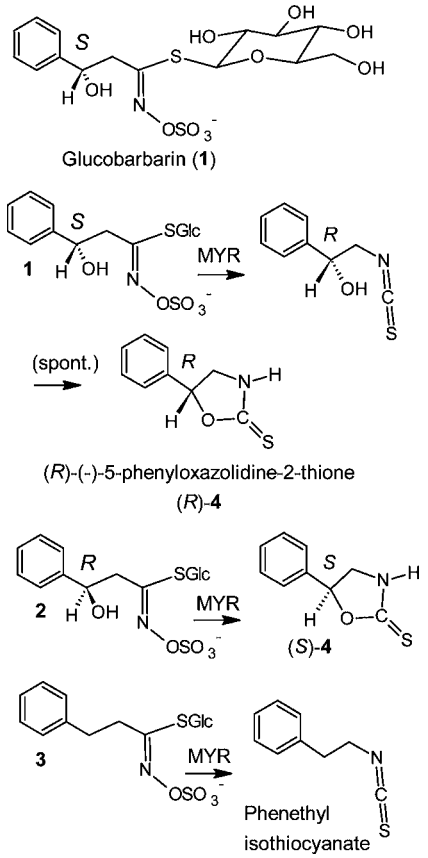

**Figure 1.** Structures of glucobarbarin, epiglucobarbarin, gluconasturtiin, and their natural 5-phenyloxazolidine-2-thione hydrolysis products after hydrolysis catalyzed by myrosinase (MYR), the endogenous glucosinolate-hydrolyzing enzyme in watercress. "Glc" in abbreviated structures indicates the β-D-glucopyranoside part of the structure as detailed in the uppermost full structure of glucobarbarin.

watercress is not only attractive for its taste and culinary value but may also be a health-promoting vegetable.

There are several reports of physiological effects of dietary watercress on markers of human disease.[13−15] Although the physiological effects of watercress may well be due to many phytochemicals, glucosinolates are likely an important class of constituents and are the focus of this paper. We are aware of five reports of the glucosinolate profile of watercress foliage, of which three are considered European material,[14,16,17] one is considered Japanese material,[18] and one is considered U.S. material.[19] In the reports of European material, it was found that **3** was dominant, whereas two indole glucosinolates, two long-chain methylsulfinylalkyl glucosinolates (7-methylsulfinylheptyl and 8-methylsulfinyloctyl glucosinolates), and the corresponding methylthioalkyl glucosinolates were less abundant constituents with some variation in the levels of the aliphatics.[14,16,17]

The reports on North American and Japanese material deviate from the reports on European material. Japanese material was reported to have a profile similar to that reported for European material, except for a quite prominent peak suggested to be **2** and a minor peak suggested to be **1** (common names were interchanged).[18] The reported evidence for **2** and **1** was the exact mass and comparison with published retention times in another laboratory. The calculated and observed $m/z$ values for both **2** and **1** differed by 3 Da.[18] In contrast, U.S. material was reported to contain 4-hydroxybenzylglucosinolate (sinalbin) and 3-butenylglucosinolate (gluconapin) in addition to the dominating **3** and less abundant indoles.[19] Both reports were inconclusive as definitive isomer distinction needs detailed comparison with authentic standards or exhaustive spectroscopic analysis.[1] In the case of **1** and **2**, seven isomers were known by 2014.[1,22,23] Moreover, a number of the isomers were found to exhibit very similar HPLC retention times.[1,23]

The reports of contrasting glucosinolate profiles in non-European watercress were interesting because structural types of glucosinolates and their hydrolysis products have complementary biological effects, such as different inductions of xenobiotic detoxification enzymes.[12] In particular, isothiocyanates with methylsulfinylalkyl and methylthioalkyl side chains exert promising bioactivities.[20] Furthermore, synergistic effects of different classes of hydrolysis products have been demonstrated.[21] In the case of U.K. watercress, the long-chain sulfinyl glucosinolates rather than dominant **3** were concluded to be mainly responsible for a phase II induction effect of the investigated watercress.[17]

The purpose of this work was to investigate glucosinolate profiles of watercress from a wide variety of sources, reflecting material typically used for human consumption around the world, to obtain a better basis for predicting and investigating nutritional and ecological effects of this vegetable. Due to the inconclusive nature of some previous reports of atypical profiles, we aimed at using isomer-specific methods including NMR and MS/MS analysis of HPLC peaks. During the investigation, after the discovery of a 2-hydroxylated glucosinolate and contrasting profiles in some U.S. material, it became relevant to identify the corresponding glucosinolate hydrolysis product and to check deviating material for the possibility of a deviating botanical identity.

## MATERIALS AND METHODS

**Chemicals.** 5-Phenyloxazolidine-2-thione and desulfated derivatives of the glucosinolates **1**, **2**, **3**, **11**, **12**, **13**, sinalbin, gluconapin, *p*-hydroxy-**2**, *p*-hydroxy-**3**, and *p*-methoxybenzylglucosinolate were obtained as previously described,[1,24,25] whereas standards of desulfated **7**, **9**, and **10** (isolated from *Rorippa* species and identified by NMR and MS) were from unpublished work. Sinigrin used as external standard was from Karl Roth, Karlsruhe, Germany.

**HPLC, MS, and NMR Equipment.** HPLC with UV detection was carried out using an LC-10AT pump with an SPD-M10AVP PDA detector (Shimadzu, Kyoto, Japan) at a flow rate of 1 mL/min. Two column stationary phases were used as specified, either "C18" (250 mm × 4.6 mm i.d., 5 μm, Luna C18 (2)) or "phenylhexyl" (250 mm × 4.6 mm i.d., 5 μm, Luna Phenylhexyl) (both Phenomenex, Torrance, CA, USA). The HPLC-MS instrument was an Agilent 1100 series LC (Agilent Technologies, Waldbronn, Germany) coupled to a Bruker HCT-Ultra ion trap mass spectrometer (Bruker Daltonics, Bremen, Germany) fitted with a Zorbax SB-C18 column (Agilent; 1.8 μm, 2.1 × 50 mm). The oven temperature was maintained at 35 °C. The mobile phases were (A) water with 0.1% (v/v) HCOOH and 50 μM NaCl and (B) acetonitrile with 0.1% (v/v) HCOOH. The NMR spectrometer was a Bruker Avance 400 instrument operated at 400.1 MHz, using $D_2O$ as solvent and dioxane ($\delta_H$ = 3.75 ppm) as internal standard.

**Plants.** Fresh commercial watercress for isolation of intact glucosinolates (July and November 2012), glucosinolate analysis (2004, 2005, 2012), and rooting followed by cytological investigation and glucosinolate analysis (November 2013) was obtained from food stores near Boston, Massachusetts (MA), USA. Fresh commercial watercress for rooting, hydroponics growth, glucosinolate analysis, and botanical identification by floral parts morphology was obtained in 2012 from a grocery store in Dayton, Ohio (OH), USA. In all cases of

dx.doi.org/10.1021/jf5032795 | J. Agric. Food Chem. 2014, 62, 9586−9596

commercial Ohio and Massachusetts watercress, the same producer (B&W Quality Growers, FL, USA) was indicated, but material was in no case obtained directly from this producer, so the origin is not absolutely certain. Wild Danish watercress for rooting followed by cytological investigation and glucosinolate analysis was from St. Vejleaa, Taastrup (55°40′ N, 12°19′ E). Fresh watercress for the autolysis experiment, indicated to be from Santa Clara Valley, California (CA), USA, was obtained in a food store (Safeway, Willits) and immediately transported to Denmark by plane, in accordance with relevant Danish legislation. After the autolysis experiment, remains were autoclaved.

Additional watercress was obtained for glucosinolate analysis with the aim of sampling as consumers around the world would typically acquire it: wild-collected, home-grown, or from a food store (fresh or in one case desiccated). Wild watercress was collected in nature in Massachusetts (near Lenox, 42°21′ N; 73°17′ W), Ohio (near Yellow Springs, 39°48′ N; 83°53′ W), and Denmark (Mors, 56° N, 8° E). Watercress seeds were obtained from three different Web-based seed suppliers: Chiltern Seeds (Ulverston, UK), Johnny's Select Seeds (Winslow, ME, USA), and Kitazawa Seed Co. (Oakland, CA, USA). Commercial fresh watercress was obtained in food stores. Chinese desiccated watercress was obtained in a Chinese shop in Copenhagen.

Watercress cultivated from seeds, U.S. food store material from Ohio, and U.S. wild material was grown in a hydroponics system: Tubs for hydroponic growth were filled to 200 L with distilled water. To each tub, 66 mL each of the fertilizer concentrates FloraGro (2−1−6), FloraBloom (0−5−4), and FloraMicro (5−0−1) (General Hydroponics) were added at the start of the planting and not replenished. The growth solution was under continuous aeration by an aquarium pump. Seeds or shoots were placed in glass wool suspended in holes punched in floating Styrofoam blocks, with roots hanging into the nutrient solution. Tubs were placed under fluorescent lights providing ∼75 μmol PAR/($m^2$ s) on a 16:8 light/dark cycle at 22 °C. This light intensity, comparable to reduced natural light intensity in forest streams, promoted abundant growth, flowering, and seed set and did not seem limiting in any way.

**Botanical Identification.** Wild-collected watercress was tentatively identified as *N. officinale* by the collector (either F.S.C, M.Ø. or D.C.) on the basis of general morphology and growth site. For wild U.S. material from 2012, material grown from seeds, commercial watercress obtained on the root in Denmark, and commercial watercress obtained from a grocery store in Ohio, and rooted, the identity was further confirmed by cultivation to flowering and seed set for inspection of key morphological characters. Voucher specimens have been deposited at the Wright State University Herbarium and at CP in the case of Danish material. For cytological analysis, two accessions were rooted in tap water, and numbers of chromocenters in root tip cells were counted as previously described.[26]

**Lyophilization/Drying and Transport to Analysis Laboratory.** Watercress foliage from Denmark (except wild collection), Spain, Portugal, and Massachusetts was lyophilized soon after acquisition (without previous freezing to avoid glucosinolate breakdown during freeze−thaw cycles) until completely crisp. Watercress foliage from Ohio and from growth in our hydroponics system was air-dried at ambient conditions in the laboratory and then placed in plastic bags with silica gel. Watercress foliage from California, Australia, and Argentina and the wild-collected sample from Denmark was dried domestically at ambient indoor conditions until crisp. Dried samples were shipped to the University of Copenhagen analysis laboratory by mail or plane travel. Upon arrival, all material was stored frozen (−20 °C) in closed plastic bags until extraction to prevent reabsorption of moisture. Variable drying conditions were due to lack of availability of freeze-drying at some origins and are discussed under Results and Discussion.

**Intact Glucosinolate Isolation and Identification.** U.S. food store watercress was lyophilized, and two batches (in total 1.42 g) were briefly and repeatedly extracted in boiling 70% aqeuous MeOH in a total of 70 mL. The extracts were filtered (paper), centrifuged (4000*g*), and applied to four 100 mg (dry wt) DEAE Sephadex A-25 anion exchange columns.[1] Each column with bound glucosinolates was washed with 2 mL of 70% aqueous MeOH, 6 mL of AcOH/EtOH/$H_2O$ (1:1:3) to elute weak acids (eluate intensely red), and 2 mL of $H_2O$. Bound glucosinolates were eluted with 10 × 1 mL of aqueous $K_2SO_4$ (saturated, ca. 0.5 M). Most $K_2SO_4$ in fractions was removed by the addition of 2 volumes of 96% EtOH, leaving the mix at −5 °C for 30 min, and centrifugation (4000*g*), discarding the pellet. EtOH was removed by evaporation of two-thirds of the volume under a gentle air stream, and remaining solvent was removed by freezing followed by lyophilization. To remove the remaining the $K_2SO_4$, glucosinolates in the yellowish residue were dissolved in 2 + 2 mL of pure MeOH for each batch, leaving insoluble $K_2SO_4$. The MeOH solution was removed from the insoluble crystals and placed under a gentle air stream for solvent evaporation. The residue was dissolved in a total of 1 mL of $H_2O$ (for the combined batches after testing each separately), and this solution was used for injection to the HPLC, injecting 150 μL six times. We used the analytical HPLC with the phenylhexyl analytical column described above, A = 0.1% aqueous $CF_3COOH$ and B = MeOH: isocratic A for 2 min, 48 min linear gradient to 60% B, 2 min linear gradient to 100% B, isocratic B for 5 min, 3 min linear gradient to 100% A, 7 min isocratic A. Fractions were collected manually (after the waste solvent line had been replaced with a short piece of HPLC tubing after the UV detector), guided by the PDA output followed in real time. To avoid hydrolysis of glucosinolates by $CF_3COOH$, collected fractions were neutralized with 1% (v/v) of a 3 M aqueous potassium acetate solution at the end of the collection day. Neutralized fractions were dried under a gentle air stream and then in vacuo overnight and dissolved in $D_2O$ for NMR analysis and subsequent HPLC-MS carried out as previously reported for intact glucosinolates,[1] except that MS detection was in positive mode (observing $[M - H + 2Na]^+$ adducts) for logistic reasons. Although positive mode detection of glucosinolates is rarely done, both glucosinolates and other anions such as carboxylic acids form positively charged disodium adducts with good ionization efficiency when the eluent is doped with NaCl as here (unpublished observation).

**Autolysis of Fresh Watercress.** The apex of individual branches, with about three small leaves and further primordia, was used. Fresh apex (one large or two small, combined wt 0.4−0.8 g) was either extracted immediately in boiling 70% aqueous MeOH for glucosinolate determination ($n$ = 4) or subjected to autolysis (homogenized in a mortar and incubated as macerated material with 3 mL of $H_2O$ ($n$ = 5) or without any liquid added ($n$ = 5)). After autolysis for 3−4 h, the macerate was either used for glucosinolate determination ($n$ = 2 + 2), using the same extract as for intact material, or subjected to determination of **4** ($n$ = 3 + 3). As a control for the effect of autolysis ($n$ = 2), freshly picked apex was boiled (1 min) before homogenization, then homogenized (including water from the initial boiling), and extracted for **4**. Macerates for determination of **4** were extracted twice with a total of 15 mL of boiling water (2 × 1 min). The extraction volume included any previously added water. Each extract was brought to 15.0 mL; 8.00 mL was taken, mixed with 2.00 mL of MeOH, and allowed to settle at −20 °C overnight. From settled extracts, 1.2 mL was taken and centrifuged at 4000*g*, and the supernatant was transferred to an HPLC vial.

Quantitative analysis for **4** was by HPLC-PDA set at 242 nm, bandwidth 8 nm (phenylhexyl column, injection volume = 100 μL, A = water, B = MeOH: isocratic A for 2 min, 48 min linear gradient to 70% B, 2 min linear gradient to 100% B, isocratic B for 5 min, 3 min linear gradient to 100% A, 7 min isocratic A). Glucosinolates in the studied material were quantitated by the desulfoglucosinolate method (see below). For HPLC-MS analysis of **4**, the gradient program was as follows: 0−0.5 min, isocratic 6% B; 0.5−12.5 min, linear gradient from 6 to 55% B; 12.5−13.1 min, linear gradient from 55 to 95% B; 13.1−15.5 min, isocratic 95% B; 15.6−20 min, isocratic 6% B. The flow rate was 0.2 mL/min but increased to 0.3 mL/min from 15.2 to 17.5 min. For extracted ion chromatograms (combined 202 + 180 + 146 + 120 Da), the width was set to ±0.5 Da.

**Glucosinolate Analysis.** Each accession was extracted at least in duplicate, using around 100 mg of dried foliage (or 0.3−1 g of fresh foliage) per extraction. Extraction, enzymatic desulfation, and HPLC-PDA was carried out as previously reported,[1] except that the C18

column was used. Peak overlap or coelution of either **3** and **13** or **3** and **10** occurred on two other reversed phase columns[1] tested. The elution order in HPLC-PDA, with typical $t_R$ in minutes, was **11** (17.0), **8** (17.7)*, **2** (19.8), **1** (21.5), **9** (23.8), **11** (26.6), **10** (30.3), **3** (31.6), **13** (32.54), **5** (39.7)*, **6** (46.9)*, **7** (53.1). Peaks labeled * were only tentatively identified on the basis of $MS^2$ but not compared with authentic standards. Quantitation was based on UV detection at 229 nm, relative to an external standard of sinigrin desulfated in parallel, using the following response factors: 0.95 for **1**, **2**, and **3**, 1.00 for aliphatic side chain glucosinolates, 0.29 for **11**, 0.28 for **12**, and 0.25 for **13**. Peak identification was based on UV spectra and comparison of $t_R$ with those of authentic desulfoglucosinolate references. HPLC-MS of one sample from each accession was also carried out to support the peak identification. The gradient program was as follows: 0−0.5 min, isocratic 2% B; 0.5−7.5 min, linear gradient from 2 to 40% B; 7.5−8.5 min, linear gradient from 40 to 90% B; 8.5−11.5, isocratic 90% B; 11.60−17 min, isocratic 2% B. The flow rate was 0.2 mL/min but increased to 0.3 mL/min from 11.2 to 13.5 min. The mass spectrometer was run in positive electrospray mode. The elution order was similar in the more condensed HPLC-MS gradient, except that **3** and **13** coeluted. Peak identity inferred from quantitative HPLC with UV detection was confirmed by observation of expected $m/z$ values for sodium adducts in HPLC-MS and inspection of $MS^2$ spectra. $MS^2$ spectra were acquired in automatic mode using SmartFrag with the instrument default settings (isolation width, 4 $m/z$; MS/MS fragmentation amplitude, 1 V; start amplitude, 30%; end amplitude, 200%; acquisition time, 40 ms).

**Statistical Evaluation.** Levels of phytochemicals were log-transformed to ensure variance homogeneity (tested and confirmed by $F$ test) and compared statistically using a two-tailed $t$ test. All procedures were carried out in Excel 2010.

## RESULTS AND DISCUSSION

**Identification of Epiglucobarbarin as a Major U.S. Watercress Glucosinolate by NMR and MS.** To unequivocally identify glucosinolates in watercress obtained in the Massachusetts area, we extracted two independent batches obtained in separate months and separate stores and analyzed the intact glucosinolate fraction by HPLC. As the same eight peaks were detected in both chromatograms, we pooled the fractions and isolated the glucosinolates by preparative HPLC (Figure 2). Three major peaks were identified by NMR and MS: an early-eluting peak was **2**, not previously documented from watercress, whereas the other two peaks proved to be well-established watercress constituents, **3** and 7-methylsulfinylheptylGSL (**9**) (Figure 2). The identification of **2** was unequivocal: not only did the mass, coupling pattern, and chemical shifts agree with the structure of **2**, but the NMR spectrum also closely matched the previously reported spectrum.[24] From this latter comparison it was evident that the *R*-epimer (**2**) was present, as the *S*-epimer (**1**) exhibits slightly different chemical shifts and coupling constants at the 1-, 2-, 1′-, and 6′-positions. The *S*-epimer **1** (Figure 2) was also identified at low levels on the basis of a very weak NMR spectrum[24] and UV and mass spectra, and four minor peaks (Figure 2) were tentatively identified as previously reported[17] watercress constituents by UV and mass spectra (results not shown).

**Formation of 5-Phenyloxazolidine-2-thione during Autolysis of U.S. Watercress.** After crushing fresh watercress from a U.S. food store to allow autolysis catalyzed by endogenous myrosinase, we found the oxazolidine-2-thione type product **4** at similar levels as the combined levels of **1** and **2** in control experiments without autolysis (Table 1). The identification of **4** was by retention time in two different HPLC systems and UV and mass spectra as compared with an

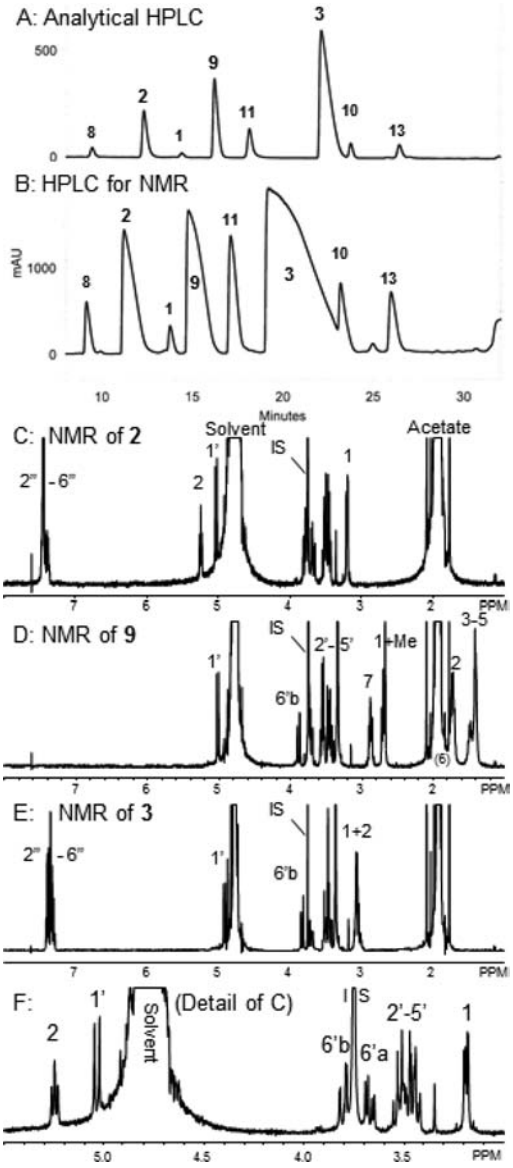

**Figure 2.** Analysis of the total glucosinolate preparation from U.S. food store watercress (Boston, MA) by HPLC followed by $^1$H NMR. HPLC was carried out in (A) analytical scale and (B) preparative scale using the same instrument, conditions, and glucosinolate preparation, but with different injection volumes (10 and 150 $\mu$L, respectively). (C−E) $^1$H NMR spectra of individual peaks after neutralization with acetate and solvent change to $D_2O$. (F) Detail of the NMR spectrum of **2** (=C).

authentic standard (Figures 3 and 4).[1] Four main ions were observed in HPLC-MS from **4**: 202, 180, 146, and 120 (corresponding to $[M + Na]^+$, $[M + H]^+$, $[M - H_2S + H]^+$, and $[M - CSO + H]^+$); this fragmentation and the UV maximum are both characteristic of the oxazolidine-2-thione moiety.[1,23] The products formed from **1** and **2**, (*R*)-**4** and (*S*)-**4**), constitute an enantiomeric pair (Figure 1), but the enantiomers are indistinguishable using achiral HPLC columns and were not distinguished in the analysis. The detected product, probably a mixture of enantiomers dominated by the product of **2**, is for this reason simply termed **4** without specification of enantiomer and compared with the sum of the epimeric precursors. Interestingly, levels of **4** were higher when water was immediately added to the macerated tissue than when the

| autolysis + water | 0.03 | 0.02 | 2 | 3.5 | 1.2 | 3 | **[d] |

[a]Mean levels of other major glucosinolates in the analyzed material (Santa Clara Valley, CA, USA) were as follows: **3**, 6.1; **9**, 3.9; **11**, 0.8; **6**, 0.6. The extent of hydrolysis was in all cases >98%. Statistical significance (signif) relates to levels of **4** and is relative to the control: **, $P < 0.01$; *, $P < 0.05$; ns, $P \geq 0.05$. [b]The number of replicates $n$ generally differs for glucosinolates and hydrolysis products because the values resulted from independent experiments and extractions. [c]Maximum estimate including minor coeluting flavonoid-like matrix component. [d]Level of significance relative to autolysis without water: *, the $F$ test for variance inhomogeneity after log transformation was insignificant but close to significance ($P = 0.10$). However, a $t$ test assuming variance inhomogeneity was still significant (*, $P = 0.010$).

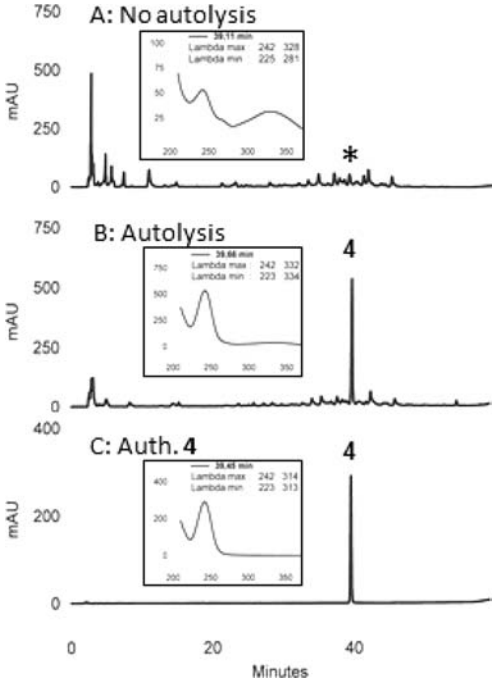

**Figure 3.** Identification and quantitation by HPLC with UV detection at 242 nm of 5-phenyloxazolidine-2-thione (**4**) in U.S. food store watercress either (A) extracted directly or (B) subjected to autolysis. The asterisk indicates a peak containing **4** and an unknown metabolite. (Insets) Photodiode array UV spectra at the peak apex of the **4** peak. (C) Chromatogram of authentic **4** (35 μM) analyzed in parallel.

autolysis happened in macerated tissue alone, even though glucosinolate hydrolysis was essentially complete at both conditions (Table 1).

An unexpected result of the autolysis experiment was the apparent detection of low levels of **4** in fresh watercress believed not to have been subject to autolysis (Table 1). Moderate interference from coeluting matrix components was likely in both HPLC-PDA and HPLC-MS, but the correct $\lambda_{max}$ and diagnostic MS fragments were observed (Figures 3 and 4D). Despite the modest background signals, we suggest that

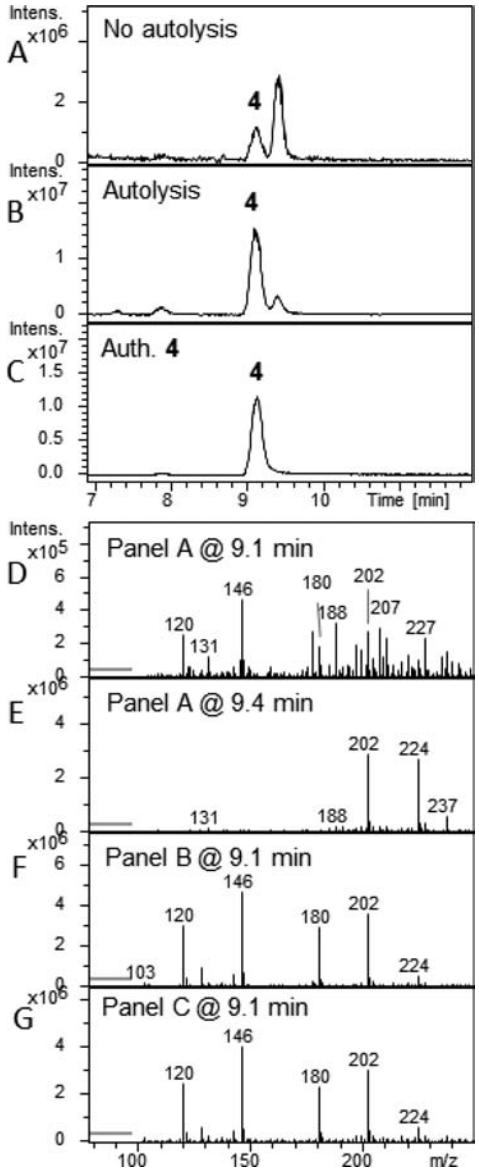

**Figure 4.** Identification by HPLC-MS of 5-phenyloxazolidine-2-thione (**4**) in U.S. food store watercress either (A) extracted directly or (B) subjected to autolysis with water. The trace is the combined extracted ion chromatogram of $m/z$ 202, 180, 146, and 120. (C) Chromatogram of authentic **4** (35 μM) analyzed in parallel. (D−G) Mass spectra of the POAT peak at 9.1 min or an unidentified peak at 9.4 min as indicated.

HPLC-PDA is reliable for quantitative determination of **4** *after* autolysis. Whether the minor level observed in control experiments was a natural constituent in intact tissue or due to slight incidental tissue damage is unknown. A baseline-separated peak in HPLC-MS ($t_R = 9.5$ min) shared the $m/z$ 202 ion, but in this case it was interpreted as $[M + H]^+$ (Figure 4E) and appeared to be unrelated to glucosinolate hydrolysis (Figure 4).

**Identification of Desulfated Glucosinolates by HPLC and MS/MS.** Separation of all watercress glucosinolates (Figures 1 and 5) after desulfation was accomplished in HPLC-PDA. To obtain additional certainty, analyses were complemented by HPLC-MS/MS. The initial peak identification was based on retention times, UV spectra, and $m/z$ values of $[M + Na]^+$ adducts in HPLC-MS. In an attempt to

**Indole glucosinolates**

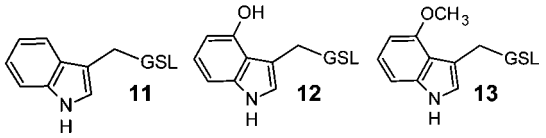

**Figure 5.** Structures, names, and abbreviations of aliphatic and indole glucosinolates detected in watercress. Three of them, **5**, **6**, and **8**, were only tentatively identified on the basis of $MS^2$, whereas the remaining were identified with certainty. "GSL" indicates the constant part of glucosinolates in structures and is an abbreviation of "glucosinolate" in names.

better distinguish isomers, we characterized the known peaks in $MS^2$ of sodium adducts. A universal fragment ion was $[M + Na - 162]^+$ representing an expectable loss of $C_6H_{10}O_5$ (fragment type c) (Figure 6). However, desulfo glucobarbarins and methylthio and methylsulfinylalkyl glucosinolates yielded specific fragmentations that could be rationalized from side-chain structures. Authentic references of both desulfo **1** and **2** showed a fragment at $m/z$ 364 indicating a characteristic loss of water (fragment type f). In addition, a fragment at $m/z$ 276 indicating the loss of benzaldehyde (fragment type e) was observed for both desulfo **1** and **2**. Interestingly, loss of water and benzaldehyde was not observed for available isomers of the desulfoglucobarbarins, desulfated *p*-hydroxy-**3** and *p*-methoxybenzylglucosinolate, whereas loss of water and hydroxybenzaldehyde was observed for desulfo *p*-hydroxy **2**.[23] Hence, loss of water and benzaldehyde provided a useful signature of **1** and **2** specifically reflecting the presence of the 2-hydroxy-2-phenyl substituents. Likewise, the $MS^2$ spectra of $Na^+$ adducts of the two methylsulfinylalkyl desulfoglucosinolates available as authentic references, **9** and **10**, were highly characteristic. Besides apparent loss of $[CH_4SO]$ resulting in $[M + Na - 64]$ fragments (type g), the characteristic feature of this homologous series was the *absence* of the usually observed desulfoGSL fragments at $m/z$ 185 and 219 (corresponding to $Na^+$ adducts of $C_6H_{10}O_5$ and thioglucose, fragment types a and b, respectively) and the *presence* of a major fragment ion corresponding to a $Na^+$ adduct of the aglucone after loss of thioglucose (loss of 196, fragment type h) (Figure 6). On the basis of similar $MS^2$ fragmentation and reasonable retention time and UV spectrum, the lower homologue **8** (not available as authentic desulfo reference) was tentatively identified in a variety of watercress samples. Methylthioalkyl desulfoglucosinolates exhibited a less intense $[M + Na - 196]^+$ fragment ion ($m/z$ 210 in the case of desulfo **6**), whereas the remaining tested desulfoGSLs did not produce this fragment type (type h) (Figure 6). Only one desulfoglucosinolate from this homologous series was available as authentic reference (desulfo **7**), but the two lower homologues (**5** and **6**) were tentatively identified

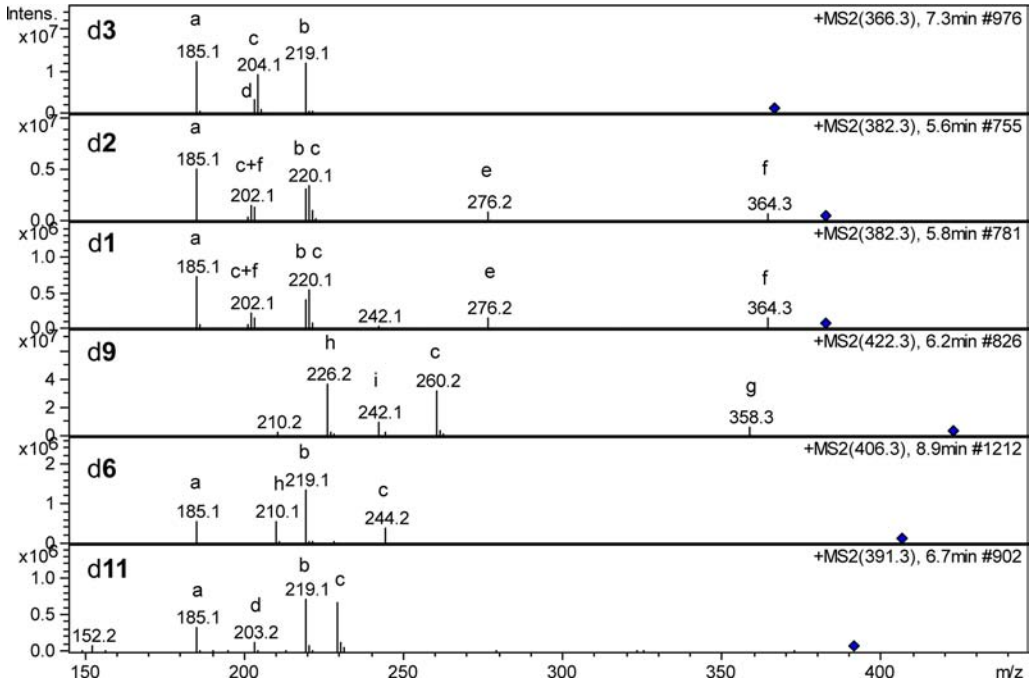

**Figure 6.** Fragments of sodium adducts of desulfated glucosinolates from U.S. food store watercress observed in $MS^2$ after HPLC separation. Types of fragments are indicated with letters as follows: a, $[C_6H_{10}O_5 + Na]^+$; b [thioGlc + Na]$^+$; c, loss of 162 $[M + Na - C_6H_{10}O_5]^+$; d, $[Glc + Na]^+$; e, loss of 106, benzaldehyde $[M + Na - C_7H_6O]^+$; f, loss of 18, water $[M + Na - H_2O]^+$; g, loss of 64, $CH_3(SO)H$ $[M + Na - CH_4SO]^+$; h, loss of 196 $[M + Na -$ thioGlc$]^+$; i, loss of 180 $[M + Na - Glc]^+$.

[a]Levels (in leaves) are shown in bold if they are numerically larger than the average of all freshly obtained leaves for that glucosinolate. Accessions were from 2012 or 2013 unless otherwise indicated. [b]MA, Massachusetts, USA; OH, Ohio, USA; DK, Denmark; CA, California, USA; AR, Argentina; AU, Australia; ES, Spain; PT, Portugal; CN, China. [c]Plants were confirmed as *Nasturtium officinale* by observation of two rows of seeds in siliques. [d]Mean of two similar accessions.

in a variety of watercress samples on the basis of similar $MS^2$ fragmentation, UV, and reasonable retention time.

In general, whether $Na^+$ associates with the glucone or aglucone moiety of desulfoglucosinolates upon fragmentation in the ion trap seems to depend on the nature of the side chain. The highly polar sulfinyl group seems to have higher affinity for $Na^+$ than the thioglucose residue, whereas affinities of the thioether and the thioglucose residue are roughly comparable. A terminal methylsulfinyl group can additionally be recognized by the loss of $[CH_4SO]$. Also, desulfoglucosinolates with a combined 2-hydroxy-2-phenyl substitution seem to be recognizable by the loss of water and a benzaldehyde in a reaction that is somewhat similar to a retro-aldol reaction.

**Diversity of Watercress as Available to Consumers.** We investigated whether consumers would likely obtain watercress containing glucobarbarins (**1** and **2**). Initial inspection of the distribution of high levels revealed an unexpected pattern: **2** was found at relatively high levels in all tested food store accessions from the United States, whereas only very low levels were found in accessions from Europe and in a few tested accessions from other continents (Table 2; Figure 7). The apparent grouping of the accessions was tested statistically in the relevant subset of data: material obtained fresh in food stores. The mean levels of **2** in four U.S. food store samples were significantly higher than the levels in the remaining eight food store samples ($P < 0.001$). Wild material from the United States was variable: watercress from

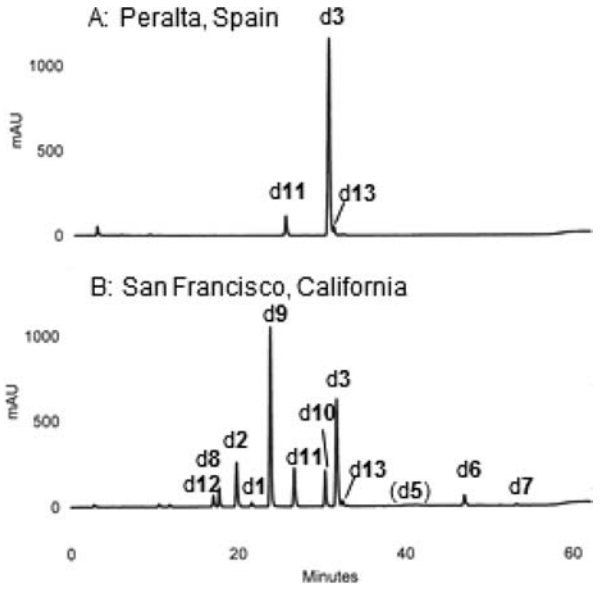

**Figure 7.** Contrasting glucosinolate chromatograms of a typical European accession of watercress from (A) Spain and (B) a typical U.S. food store watercress from California. Glucosinolates were enzymatically desulfated before analysis as indicated by "d" before glucosinolate numbers, and UV detection at 229 nm was employed.

dx.doi.org/10.1021/jf5032795 | J. Agric. Food Chem. 2014, 62, 9586−9596

Massachusetts showed moderate levels of **2**, whereas wild material from Ohio was very low in **2**. Plants grown from commercially obtained seeds were low in glucobarbarins irrespective of the supplier, whereas wild-collected plants grown in parallel retained approximately the same relative levels found in the wild-collected material. We considered whether the apparent trace peaks of **2** in European material and material grown from seeds could be confirmed with certainty by MS/MS. This was the case for seeds of a European type and for material from Denmark (wild), Argentina, and Portugal. Neither sinalbin nor gluconapin[19] was detected.

Interestingly, the four tested U.S. food store accessions were also remarkably high in methylthioalkyl and methylsulfinylalkyl glucosinolates, whereas the remaining eight food store accessions from Europe ($n$ = 5), Argentina ($n$ = 2), and Australia ($n$ = 1) were lower in these kinds of glucosinolates ($P$ < 0.001 for the sum of **5**−**10**). Indeed, 34−55% of the glucosinolate content of U.S. food store samples consisted of these aliphatic glucosinolates (Table 2; Figure 7). Wild material appeared to be more homogeneous for aliphatics, with intermediate levels, whereas material grown from seeds had rather low levels (Table 2). Considering total glucosinolate levels, there was no obvious association of high or low levels with specific origins, except for a tendency for higher total levels in wild-collected watercress compared to watercress grown at our particular artificial light conditions.

To obtain the widest possible temporal and geographical diversity of samples, we had to accept a range of drying methods and storage periods. Spontaneous air-drying was used for some samples, was used in classical qualitative natural product chemistry, and is reliable (N.A., unpublished results) for preparative purposes. However, it cannot be considered optimal for quantitative analysis because of the extended period in which physiological postharvest processes can occur. However, our use of spontaneous air-drying at some remote sampling sites and in the Wright State University laboratory was not a factor in the distinction of two chemotypes of watercress. Indeed, nearly the full range of **1**, **2** and aliphatics (**5**−**10**) was observed in samples from Wright State University, Dayton (Ohio), where spontaneous drying at ambient conditions was used for logistic reasons. This range was comparable with the combined results from Copenhagen, Peralta, and Boston, where lyophilization was used (Table 2). Storage conditions and time were likewise not factors for the distinction of two chemotypes. First, analytical results of our 2004−2005 samples were essentially the same initially and after storage until this investigation (results not shown). Furthermore, the 2012 sample had essentially the same glucosinolate content after storage for a year, although glucosinolate hydrolysis occurred rapidly after the addition of water to the stored sample, so uptake of water during storage was apparently insignificant. Hence, we do not consider even extended frozen storage in closed plastic bags a problem for glucosinolate stability, with the possible exception of the oxidation-sensitive **12**, which was not observed in old samples (Table 2). Indeed, a reliable glucosinolate profile of a 90-year-old herbarium specimen was recently reported with comparison with more recent material,[27] indicating long-term stability.

**Botanical Identity of Watercress Accessions.** Because of the observation of two distinct chemotypes of commercially available watercress, it was relevant to test by conclusive botanical identification whether the chemotypes reflected any of the established watercress taxa mentioned in the Introduction. The key morphological distinction between the two species of watercress discussed here, *N. officinale* and *N. microphyllum*, is based on mature siliques. All tested accessions were fertile and had seeds in two rows in siliques, including watercress foliage from the same grocery store in Dayton (Ohio) as used for glucosinolate analysis, wild-collected material from Ohio, Massachussets, and Denmark, material from a Danish food store, and all accessions grown from seed (Table 2). We concluded that all of these accessions belonged to *N. officinale* as opposed to *N. microphyllum*. The liberal seed set would suggest that the partially sterile hybrid *N.* × *sterile* was not represented.

Because of the unusual glucosinolate profile of the material from U.S. food stores, we also established chromosome numbers based on the number of chromocenters, defined as stainable regions in interphase nuclei that approximately reflect individual chromosomes.[28] The result was striking: whereas the number of chromocenters in Danish material was close to the established chromosome number of *N. officinale*, the U.S. food store material revealed approximately twice as many chromocenters (Figure 8), indicative of chromosome doubling. It was

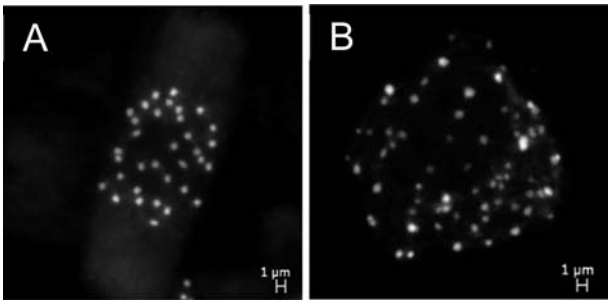

**Figure 8.** Cytological analysis (DAPI-stained interphases) of (A) wild Danish watercress with 34 chromocenters and (B) U.S. food store watercress (Boston, Massachusetts) with ca. 68 chromocenters.

confirmed by glucosinolate analysis that the U.S. food store material with double chromosome number was relatively high in **2** (4.3% of total) and aliphatic glucosinolates (38%), whereas the investigated wild Danish material was low in **2** (0.2%) and had moderate levels of aliphatic glucosinolates (21%).

**Watercress Is Polymorphic for Glucosinolate Profiles and Chromosome Numbers and Is a Dietary Source of 5-Phenyloxazolidine-2-thione.** Combining the morphological, cytological, and chemical evidence, we conclude that watercress, *N. officinale*, as available to consumers is polymorphic for glucosinolate profile and chromosome number. In the cases tested for both characters, they were correlated, but further research will be needed to test for a general association. Specifically, epiglucobarbarin (**2**) was a significant constituent of watercress from U.S. food stores and some wild accessions including chromosome-doubled material, in contrast to the remaining tested accessions mainly from Europe including diploid material. Furthermore, watercress from U.S. food stores exhibited a distinct profile of aliphatic glucosinolates, with considerable levels of long-chain methylsulfinylalkyl and methylthioalkyl glucosinolates in addition to the traditionally recognized glucosinolate in watercress, **3**. These aliphatic glucosinolates were previously known from watercress, with some variation also within European material.[14,16] In the following, we term the complex chemotype obtained in U.S. food stores "the U.S. food store type", whereas

the simpler chemotype dominated by **3** and obtained from a number of European sources is termed "the European type". Altered postharvest glucosinolate biosynthesis induced by storage conditions could in principle explain differences between freshly harvested and shelf-stored produce, but this was not what we observed. Rather, the two chemotypes were observed within both the wild-collected and commercially obtained watercress accessions and in commercial material cultivated and rooted for chromosome counts, suggesting that genetic factors were important for the observed chemical differences.

We have also confirmed the conversion product **4** from U.S. food store watercress. This is the first unequivocal demonstration of **1**, **2**. and **4** in a regular food crop. The formation of **4** suggests that this hydrolysis product will also be formed when watercress is chewed and possibly also by microbial breakdown in the colon.[11,12] The detection method for **4** (achiral HPLC) did not allow distinction of absolute configuration, but from the dominance of **2** in watercress the detected **4** can be inferred to consist mainly of (*S*)-**4** (Figure 1). The common name "barbarin" has been suggested for (*R*)-**4**[29] and may be preferable for daily use. The (*S*)-**4** formed from watercress should preferably be called (*S*)-barbarin in cases when precision is needed.

**Health Benefits and Hypothetical Risks of Watercress Glucosinolates.** There seems to be a consensus regarding phenethyl isothiocyanate (from **3**) and methylsulfinylalkyl and methylthioalkyl isothiocyanates as health-promoting.[12,16,20,21,30,31] Indeed, an increase in the consumption of glucosinolate-containing vegetables seems to be advantageous and is recommended by public health authorities such as the National Cancer Institute.[32−34]

However, the detection of **1** and **2** as well as their product **4** in some watercress needs separate scrutiny because **4** is a different type of hydrolysis product. We are aware of a single investigation of nutritional effects (in rats at quite high levels) of **1** and a hydrolysis product assumed to be (*R*)-**4**.[35] Significant detrimental effects of **1** and/or (*R*)-**4** were observed on the palatability of the feed and on weights of liver, kidney, suprarenal glands, testicles, and thyroid gland. The detrimental effect on thyroid weight is in accordance with the general disturbance of iodine metabolism in the thyroid gland by oxazolidine-2-thiones.[36] Facile conversion of these to mutagenic *N*-nitroso derivatives in the presence of nitrite at "stomach conditions" is also known.[37] A different effect is inhibition of tyrosinase enzymes by (*R*)-**4**.[38] This effect was not suggested to be toxic or antinutritional, but was suggested to be useful in preventing enzymatic browning of fruits and vegetables as well as in cosmetic and medical applications. It is not simple to predict whether the (*S*)-**4** formed in U.S. food store type of watercress would have the same effects as (*R*)-**4** formed from **1**, but it seems relevant to expect physiological effects.

It is relevant to consider the occurrence of a related oxazolidine-2-thione-forming glucosinolates in many cabbages: progoitrin, the precursor of goitrin ((*S*)-5-vinyloxazolidine-2-thione). This glucosinolate causes negative effects of rapeseed meal in animal fodder and also showed antinutritional effects on rats and formed nitrosamides under stomach conditions.[35−37] Nevertheless, we are not aware of any health risk of eating even considerable amounts of, for example, Chinese cabbage containing this glucosinolate at 2−5 μmol/g dry wt,[39] whereas the contribution to bitterness is well established as could also be the case for glucobarbarins.[40,41] This general acceptance of an oxazolidine-2-thione-forming glucosinolate should perhaps be extended to **1** and **2** unless future research shows otherwise.

**Origins, Potentials, and Ecological Risks of U.S. Food Store Watercress.** The difference between European and U.S. food store material suggests a non-European origin of U.S. food store watercress. As watercress is considered introduced in the United States, the ultimate origin must be overseas or by a recent evolutionary event such as hybridization or chromosome number mutation. A simple explanation of the apparent chromosome number difference would be artificial chromosome doubling.[42] However, hybridization or chromosome number mutation is by no means a prerequisite for glucosinolate variation.[23,43,44] The finding of wild material with significant levels of **2** and aliphatic glucosinolates at a natural habitat in United States in both 2005 and 2012 (Table 2) would suggest that the U.S. food store type of watercress occurs in nature to some extent and may have been naturalized for at least a decade. There is some evidence to suggest that the difference in glucosinolate profile between the two types could have ecological effects, and it is possible that variation in glucosinolate profiles may relate to variation in the prevalence of watercress in invaded habitats,[9,10,44−49] including possible conversion of **1**, **2**, **3**, and **4** to phytoalexins.[50,51]

A cultivar of broccoli with increased levels of another methylsulfinylalkyl glucosinolate, glucoraphanin, has been commercialized under the name "superbroccoli".[52] Perhaps a "super watercress" can be created or selected on the basis of the already available material, or the current U.S. material might in itself merit this designation. However, comparison of nutritional effects of watercress with different glucosinolate profiles is needed before one type of watercress can be recommended over another. Although we have discovered a new class of glucosinolates and glucosinolate products in watercress, associated with nutritional problems in animal feed at high doses[35] and possibly in insect resistance in a wild crucifer,[44] there is nothing in our results to suggest that current varieties constitute any nutritional risk at usual human intakes. However, the potentially different invasive properties of the U.S. food store variant with distinct glucosinolate profile and chromosome number should be considered before introduction of this high chromosome number chemotype for cultivation abroad.[9,10]

## ACKNOWLEDGMENTS

We thank four anonymous reviewers for helpful comments and suggestions and the following individuals for contributing watercress samples: Francisco R. Badenes-Peréz (ES, PT), Marta A. Carballo (AR), Deyang Xu (CN), Maya and Marie Louise Mileck (CA), Elizabeth Neilson (AU). We also thank Birgitte Rasmussen and Cecilie Ida Cetti Hansen for skillful

glucosinolate analysis, Samantha Davis for assistance with watercress cultivation, Karen R. Munk for chromosome preparation, and M. S. C. Pedras for sharing a paper in press.

Grain was harvested from three replicated field sites across Chile during the 2006−2007 season. Twelve different conventional maize hybrids were included to provide supplementary data on compositional variability due to field location and water treatment. All field sites utilized a strip-plot design with three replicates per site, with water treatment (well-watered or water-limited) as the whole plot factor and substance type as the subplot factor. Compositional analyses included measurement of proximates, fibers, total amino acids, fatty acids, minerals, vitamins, raffinose, phytic acid, *p*-coumaric acid, and ferulic acid.

## MATERIALS AND METHODS

**Maize Samples for Compositional Analysis.** The drought-tolerant maize MON 87460 (D1) provides a yield benefit when yield is limited by water availability.[1] D1 was produced by stable insertion of the coding sequence of cold shock protein B (CSPB) from *B. subtilis*. Conventional breeding techniques have now developed the combined-trait products D1 × NK603, D1 × MON 89034 × NK603, and D1 × MON 89034 × MON 88017. Each biotechnology-derived trait contributes specific benefits of drought tolerance (D1), herbicide tolerance (NK603), or insect resistance (MON 89034 and MON 88017) to the final product.

Seed of the drought-tolerant combined-trait products and a near-isogenic conventional control were planted in the winter of 2006 at three sites in major maize-producing regions of Chile. Seeds from four different commercial conventional hybrids were also included at each field site (for a total of 12 unique hybrids). Locations of the field sites were as follows: Colina, Region Metropolitana; Calera de Tango, Region Metropolitana; and Lumbreras, Region Metropolitana. All field sites utilized a strip-plot design with three replicates per site, with water treatment (well-watered or water-limited) as the whole plot and substance type as the subplot. The whole-plot factor was arranged as a randomized complete block design. The strip-plot factor consisted of the different maize varieties. The well-watered treatment was managed to provide optimal grain yield. The water-limited treatment was managed to impose a drought stress by withholding water during the late vegetative through early grain fill growth stages (i.e., approximately V10 through R2). The use of a split-plot design allowed comparisons of the drought-tolerant hybrids to the control under two separate irrigation regimens. Tissue was collected from all three blocks for each treatment; tissue from the different commercial references grown at each site was collected from a single block for each treatment. This resulted in a total of 90 test and control samples (5 substances × 3 biological replicates × 3 field sites × 2 water treatments) and 24 commercial reference samples (4 substances × 1 biological replicate × 3 field sites × 2 water treatments).

The genetic purity of the maize plants was maintained by bagging the tassels and ear shoots at anthesis and self-pollinating each plant by hand. Forage was collected at the late dough/early dent stage, and the grain was collected at normal kernel maturity (Supporting Information). After harvest, samples were shipped to Monsanto, St. Louis, MO, USA. The samples were ground to a fine powder in the presence of dry ice and maintained frozen at −20 °C until required for compositional analysis. The identity of forage and grain samples was based on sample handling records and Southern blot or polymerase chain reaction analyses of genomic DNA isolated from grain tissue.

**Compositional Analyses.** Components assessed in grain samples included proximates (protein, fat, ash, and moisture), carbohydrates by calculation, acid detergent fiber (ADF), neutral detergent fiber (NDF), total dietary fiber (TDF), total amino acid composition, fatty acid composition, minerals (calcium, copper, iron, magnesium, manganese, phosphorus, potassium, sodium, zinc), vitamins [vitamin B1 (thiamin), vitamin B2 (riboflavin), vitamin B6 (pyridoxine), vitamin E, niacin, folic acid], furfural, raffinose, phytic acid, *p*-coumaric acid, and ferulic acid. Components assessed in forage samples (Supporting Information) included proximate, carbohydrates by calculation, ADF, NDF, calcium, and phosphorus.

Compositional analyses were performed at Covance Laboratories, Inc. (Madison, WI, USA). Brief descriptions of the methods utilized for the analyses are described in refs 2−5. To control and minimize bias, the samples produced from the three field sites were analyzed in a randomized order.

**Statistical Analysis of Composition Data.** In all, 68 different grain components were measured. The following 16 analytes with >50% of the observations at or below the limits of quantitation (LOQ) of the assay were excluded from statistical analysis: sodium, furfural, caprylic acid, capric acid, lauric acid, myristic acid, myristoleic acid, pentadecanoic acid, pentadecenoic acid, palmitoleic acid, heptadecanoic acid, heptadecenoic acid, γ-linolenic acid, eicosadienoic acid, eicosatrienoic acid, and arachidonic acid. The LOQs for sodium, furfural, and fatty acids were 0.5 ppm, 100 ppm, and 0.004%, respectively. Except for moisture and fatty acids, all component values were converted from a fresh weight to a dry weight basis and into their respective units as presented in Tables 1−6 and Supplementary Table 1 (Supporting Information).

PRESS residuals were used to identify outliers. Extreme data points that were outside the ±6 studentized PRESS residual range were considered for exclusion, as outliers, from the final analyses. This resulted in a single copper value recorded for one of the commercial conventional reference hybrids grown at the Colina site being excluded.

Compositional components were statistically analyzed using a mixed-model analysis of variance from each of the three sites and from the combination of all sites. The combined-site analysis used the model

$$Y_{ijkl} = U + L_i + B(L)_{ij} + T_k + LT_{ik} + TB(L)_{ijk} + S_l + TS_{kl} + LS_{il} + LTS_{ikl} + e_{ijkl}$$

where $Y_{ijkl}$ = unique individual observation, $U$ = overall mean, $L_i$ = random location effect, $B(L)_{ij}$ = random block within location effect, $T_k$ = irrigation treatment effect, $LT_{ik}$ = random location by treatment interaction effect, $TB(L)_{ijk}$ = random treatment by block within location interaction effect, $S_l$ = substance effect, $TS_{kl}$ = treatment by substance interaction effect, $LS_{il}$ = random location by substance interaction effect, $LTS_{ikl}$ = random location by treatment by substance interaction effect, and $e_{ijkl}$ = residual error.

For each component analysis, mean comparison tests of each of the drought-tolerant hybrids to the conventional control within each water treatment were conducted.

SAS software was used to generate all summary statistics and perform all analyses (SAS Institute, 2002−2003). All statistical analyses were conducted by Certus International, Inc. (Chesterfield, MO, USA).

## MULTIVARIATE ANALYSIS

To assess the effect of each factor better, MB-PCA and ASCA were applied to the data. Both models are extensions of the classical PCA model and can separate variances caused by multiple factors and thus provide a better view of the effect of each factor of interest.

For MB-PCA, the original compositional data were repartitioned into a series of *blocks* according to the experiment design (i.e., blocking). Through such blocking, one particular factor would become baseline and no longer have an effect on the data, whereas the other factor(s) would become a *common trend* across all of the blocks and have their influence enhanced, assuming that the samples are properly matched and the effect of the factor(s) of interest is consistent across different blocks. This is clearly a useful approach to analyze a system with multiple and potentially interacting factors. A MB-PCA model comprises three main components, (1) super scores, (2) block scores, and (3) block loadings, where the common trend across all of the blocks is shown in the super scores, the individual patterns of the blocks are shown in the block scores, and the variable contributions to the pattern shown by the MB-PCA model can be found in the block loadings.

ASCA is another recently proposed model aimed at the analysis of data with multiple factors. In ASCA, the data matrix is decomposed into the sum of a series effect matrices and each effect matrix contains the level averages for each factor, which represents the effect of that particular factor. The variations that cannot be explained by the model are put into the residual matrix $\boldsymbol{\varepsilon}$. In this study there are three factors of interest, and thus the ASCA model is written as

$$\boldsymbol{X} = \boldsymbol{1} \times \boldsymbol{m}^{\boldsymbol{T}} + \boldsymbol{X}_{\mathrm{i}} + \boldsymbol{X}_{\mathrm{l}} + \boldsymbol{X}_{\mathrm{s}} + \boldsymbol{X}_{(\mathrm{il})} + \boldsymbol{X}_{(\mathrm{is})} + \boldsymbol{X}_{(\mathrm{ls})} + \boldsymbol{X}_{(\mathrm{ils})} + \boldsymbol{\varepsilon}$$

[a]Percent dry weight of sample, except moisture. [b]Least-square means; upper values are for well-watered, lower values are for water-limited. [c]Range denotes the lowest and highest individual values across all sites. [d]Significantly different ($\alpha$ = 0.05) from control and are highlighted in bold font.

dx.doi.org/10.1021/jf5019609 | J. Agric. Food Chem. 2014, 62, 9597−9608

where $m^T$ is the mean vector of the full matrix; $1$ is a column vector of ones; $X_i$, $X_l$ and $X_s$ are the effect matrices of the three factors, namely, irrigation conditions, locations, and substances, respectively. $X_{(il)}$, $X_{(is)}$, $X_{(ls)}$, and $X_{(ils)}$ are the interaction matrices between these factors, respectively. PCA was performed on each effect matrix, respectively, to calculate loadings, and the score of each effect matrix was obtained by adding the residual matrix $\varepsilon$ back to the effect matrix and projected into the PC space via the corresponding loadings. For example, the score of the effect matrix of the irrigation condition $T_i$ factor is given as

$$X_i = (\Gamma_i) \times P_i^T$$

where $\Gamma_i$ and $P_i$ are the scores and loadings matrix obtained by PCA performed on $X_i$.

$$T_i = (X_i + \varepsilon) \times P_i$$

Unlike MB-PCA, ASCA is essentially a supervised technique; thus, an appropriate validation procedure is needed. In this paper, we employed a permutation test-based validation procedure proposed by Zwanenburg et al.[16] In the validation, the magnitude of the effect of the factor of interest is expressed as the sum of squares (SSQs) of $\Gamma$. A total number of $n$ permutations (in this study $n$ = 1000) are performed, and in each permutation the labels of the samples are randomly permutated, ASCA is performed on the data using the permuted label, and the SSQs of $\Gamma$ are recorded. All of the SSQs of $\Gamma$ form a null distribution, and the SSQ of $\Gamma$ calculated from the ASCA model using the known labels (i.e., the observed SSQ) is then compared with the null distribution. An empirical $p$ value can then derived by counting the number of permutations that obtained equal or higher SSQs than the observed SSQ.

Compositional data were autoscaled so that each variable had zero mean and unit standard deviation before being subjected to MB-PCA and ASCA. All of the multivariate analyses were conducted using in-house scripts written in MATLAB R2012a environment (Mathworks, Natick, MA, USA).

## RESULTS AND DISCUSSION

**Univariate Analysis.** Tables 1−6 show means and ranges of grain components combined across all sites (the combined-site analysis) for all maize hybrids and for both well-watered and water-limited treatments. Forage data are presented in Supplementary Table 1 (Supporting Information). Individual site data for the conventional control are presented in Supplementary Tables 2−8. Overall, the combined-site analysis of the grain data was characterized by extremely few significant differences ($\alpha$ = 0.05) between the drought-tolerant combined-trait products and the conventional control (and in all Tables the statistically relevant differences are highlighted in bold font). From a total of 416 comparisons (comparison of 4 test substances to the control at 2 different water treatments × 52 analytes) only 23 (5.53%) were significant ($\alpha$ = 0.05). These included only 9 comparisons from the well-watered treatments and 14 from the water-limited treatments. Clearly, given the paucity of observed differences, no meaningful trends were observed that would distinguish drought-tolerant hybrids from conventional control. This is described in more detail below.

**Proximate and Fiber Composition.** Levels of proximates and fiber were similar across all of the drought-tolerant hybrids and the conventional control under both water treatments (Table 1). No differences ($\alpha$ = 0.05) between mean values of proximates and fiber of the drought-tolerant hybrids and the conventional control grown under well-watered conditions were observed. Within the water-limited treatment, differences ($\alpha$ = 0.05) from the control ADF and NDF mean values were observed for D1 × NK603 and from control ADF mean values for D1 × MON 89034 × MON 88017. For D1 × NK603, the magnitudes of the differences in mean values for ADF and NDF were 0.72 and 1.13% dwt, respectively. For D1 × MON 89034 × MON 88017, the magnitude of the differences in mean values for ADF was 0.72% dwt. Given the known variability of grain fiber[2−5,7] this was not considered a meaningful difference. Our results, however, did suggest that, for all maize hybrids, the levels of proximate and fibers differed consistently between the two irrigation treatments. Mean values, when combined across all samples, for ash, protein, and fat were ∼5, ∼11, and ∼6% higher, respectively, under water-limited conditions relative to well-watered conditions in the combined-site analyses. Conversely, mean values for ADF (∼6.%), NDF (∼5%), and TDF (∼3%) were lower under water-limited conditions.

**Total Amino Acid Composition.** No differences ($\alpha$ = 0.05) in mean values of amino acids of the drought-tolerant hybrids and the conventional control grown under well-watered conditions were observed (Table 2). Under water-limited conditions, differences were observed for methionine in D1 × NK603 and D1 × MON 89034 × NK603 (see Table 2). The overall lack of differences is clearly related to the lack of differences in protein levels noted above.

**Fatty Acid Composition.** Under well-watered conditions, differences ($\alpha$ = 0.05) between the drought-tolerant combined-trait products were observed for palmitic acid, linoleic acid, and eicosenoic acid in D1 × NK603; for oleic acid and eicosenoic acid in D1 × MON 89034 × NK603; and for palmitic acid in D1 × MON 89034 × MON 88017 (Table 3). Under water-limited conditions, significant differences were observed for eicosenoic acid in D1, palmitic acid in D1 × NK603, and palmitic acid and linolenic acid in D1 × MON 89034 × MON 88017. All differences were characterized by small mean differences, and no trends in differences between the different D1 hybrids and the conventional control were observed. There is little in the scientific literature on the effect of water treatment or drought on fatty acid composition. The data presented in Table 3 also provide some of the first scientific information that fatty acid composition is not greatly affected by water limitation.

**Vitamin Composition.** Overall, levels of vitamins were similar across all of the drought-tolerant hybrids and the conventional control under both water treatments (Table 4). Under well-watered conditions, significant differences ($\alpha$ = 0.05) were observed for vitamin E in D1 × MON 89034 × NK603 and for thiamin (vitamin B1) and pyridoxine (vitamin B6) in D1 × MON 89034 × MON 88017. Under water-limited conditions, differences ($\alpha$ = 0.05) were observed for niacin and riboflavin (vitamin B2) in D1 × NK603; for vitamin E in D1 × MON 89034 × NK603; and for thiamin and vitamin E in D1 × MON 89034 × MON 88017.

To our knowledge, there is little literature on the effect of abiotic stress on grain levels of maize vitamins. In the combined-site analysis, mean values for most vitamins were higher under water-limited conditions relative to well-watered conditions. These included niacin, vitamin B2 (riboflavin), vitamin B1 (thiamin), and vitamin E, which were increased ∼11, ∼14, ∼4, and ∼10%, respectively, upon water restriction. In contrast to the above results, combined-site analysis revealed that mean values for vitamin B6 (pyridoxine) were lower (∼11%) under water-limited conditions relative to well-watered conditions.

**Antinutrient and Secondary Metabolite Composition.** No differences ($\alpha$ = 0.05) between the drought-tolerant combined-trait products and the control for phytic acid, raffinose, ferulic acid, and $p$-coumaric acid were observed (Table 5).

**Mineral Composition.** Overall, levels of minerals were similar across all of the drought-tolerant hybrids and the conventional control under both water treatments (Table 6). No differences

[a]Percent dry weight of sample. [b]Least-square means; upper values are for well-watered, lower values are for water-limited. [c]Range denotes the lowest and highest individual values across all sites. [d]Significantly different ($\alpha$ = 0.05) from control and are highlighted in bold font.

($\alpha$ = 0.05) in mean values of minerals of the drought-tolerant hybrids and the conventional control grown under well-watered conditions were observed (see Table 6). Within the water-limited treatment differences were observed for potassium in D1 × MON 89034 × NK603.

Mean values for all tested minerals, with the exception of K, were higher (~8−15%) under water-limited conditions relative to well-watered conditions in the combined site analyses. There are few reports on the effect of limited water availability on mineral composition in maize grain. A three year study of tropical varieties subjected to preanthesis drought concluded that there was no significant impact of water restriction.[17] Restricting water availability after silking also showed no effect on the levels of measured minerals (P and K) despite a ~33% grain yield reduction.[18] The changes observed imply that water deficit affects mineral composition in grain only modestly, an observation consistent with results from other peer-reviewed studies.[17,18]

**Multivariate Analysis.** The original focus of the study was a comparison of grain composition of the D1 maize hybrids to a near-isogenic conventional comparator. Review of the data presented in Tables 1−6 and in the Supporting Information clearly suggested, however, that water treatment and location contributed more to compositional variation than genetic modification. We were therefore interested in reviewing multivariate options to present meaningful visualization and interpretation of different sources of variation. PCA is one of the most popular tools for exploratory analysis, but it is not always effective when an experiment comprises multiple influential factors such as are present in our study. We initially performed PCA on the full data matrix, and the results appeared to be a complex mixture of the effects of all three factors (substance, location, and water treatment), and no obvious pattern could be observed (data not shown). We therefore attempted to use two different PCA variants, MB-PCA and ASCA, to better discern the effects of each factor.

**MB-PCA.** To better assess the effect of each factor, we created a series of MB-PCA models by repartitioning (i.e. blocking) the data in different ways so that one particular factor became a background and the effect of the factor of interest became a common trend across all blocks. Blocking was performed as follows.

*(1) Three-Locations Blocking, with Each Block Containing Both Irrigation Conditions.* The scores plots from this MB-PCA model are shown in Figure 1. These clearly show that water treatment conditions had a significant influence on the data. On the super scores (Figure 1a), a clear separation between the well-watered condition (wet) and water-limited (dry) condition was seen across the first PC. The block scores (Figure 1b−d) showed similar patterns for all three locations. In addition, the loadings (Figure 2) of the three blocks were highly similar to each other, suggesting that water treatment had a similar impact on grain composition, regardless of location.

Consistent with results from the univariate analysis, no clear separation between the different substances was observed in the scores plots of this model. Two further MB-PCA models were computed, which also blocked according to locations but contained only samples from the same water treatment (either wet or dry, respectively); results of these two models again showed no sign of separation between different substances (data not shown).

*(2) Five-Substances Blocking Where the Data Were Repartitioned into Five Blocks, One for Each Substance.* We first incorporated samples from both water treatments into each block; the super scores plot of the MB-PCA model is given in

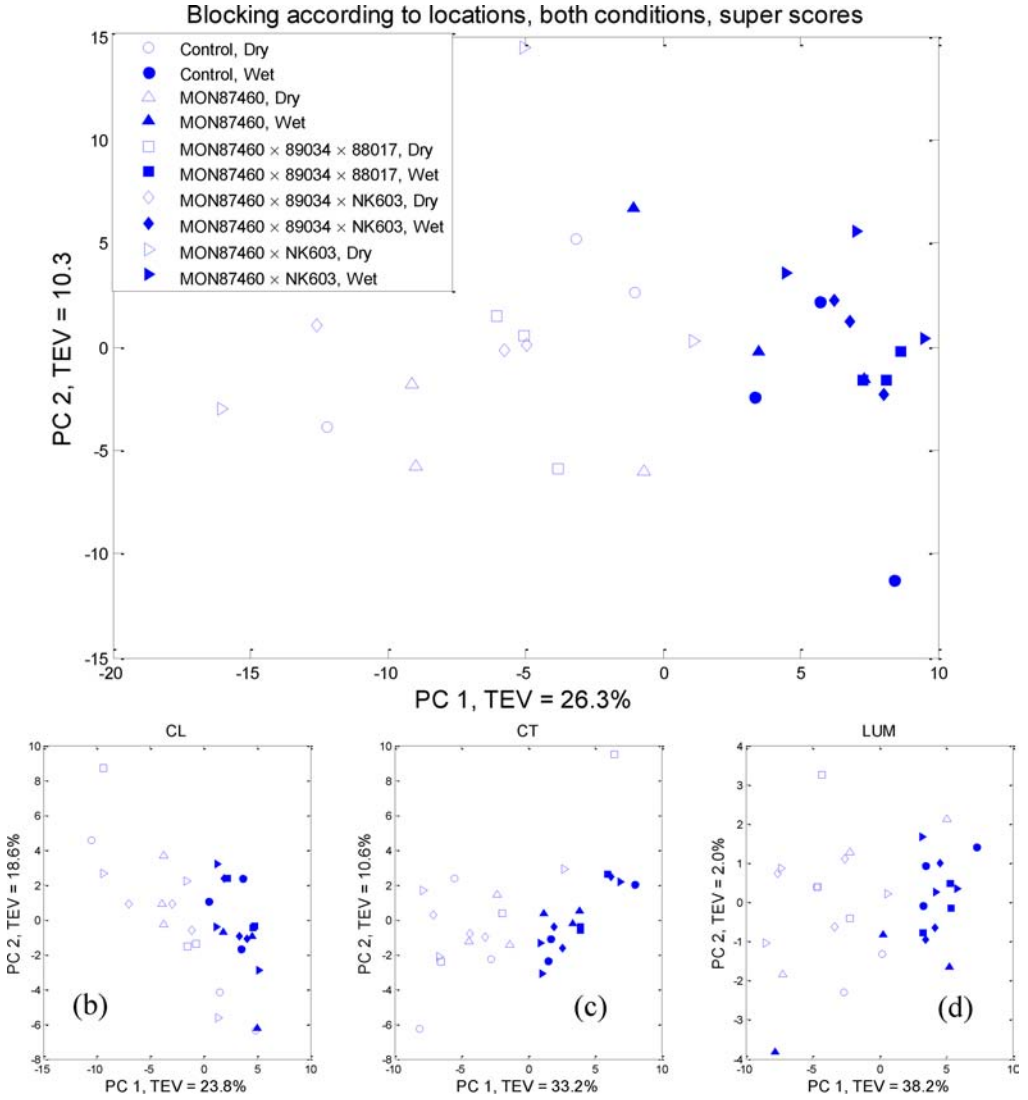

**Figure 1.** MB-PCA performed on the location blocking data set: (a) super scores plot; (b) block scores plot on the site CL block; (c) block scores plot on the site CT block; (d) block scores plot on the site LUM block. TEV, total explained variance.

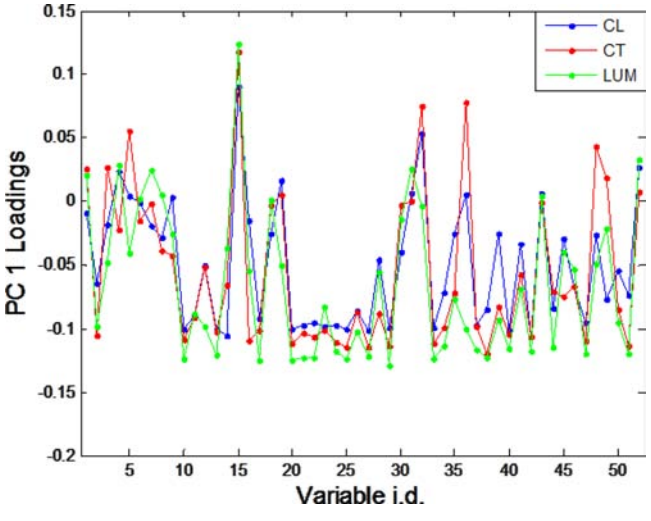

**Figure 2.** Loading plots from MB-PCA. The colors represent the different sites: (blue) site CL; (red), site CT; (green) site LUM. The list of variables (analytical components) is presented in Supporting Information.

Figure 3a. PC 1 clearly separated the two water treatments, and PC 2 separated (albeit with some overlap) the three sites along its axis. This suggested that water treatment had a stronger influence on composition compared to location differences. The super scores plot also showed that separation between the three different locations was better under well-watered conditions than under water-limited conditions. To confirm this, we built another two MB-PCA models using substances blocking, where each block contained only one water treatment, that is, wet or dry only. The super scores of the MB-PCA model based on well-watered samples (Figure 3b) indeed showed a much better separation than the MB-PCA model based on water-limited samples (Figure 3c).

**ASCA.** The MB-PCA models confirmed a lack of substance effect consistent with results from the univariate analysis. On the basis of different blocking strategies, the MB-PCA models further suggested that water treatment had the greatest impact on grain composition. Locations also had an effect, albeit weaker than that of water treatment. These location effects appeared to be greater under well-watered conditions than under water-limited conditions. We tested this observation by employing an ASCA model. The scores plots of the three submatrices of the ASCA model are given in Figure 4. It can be seen that separation

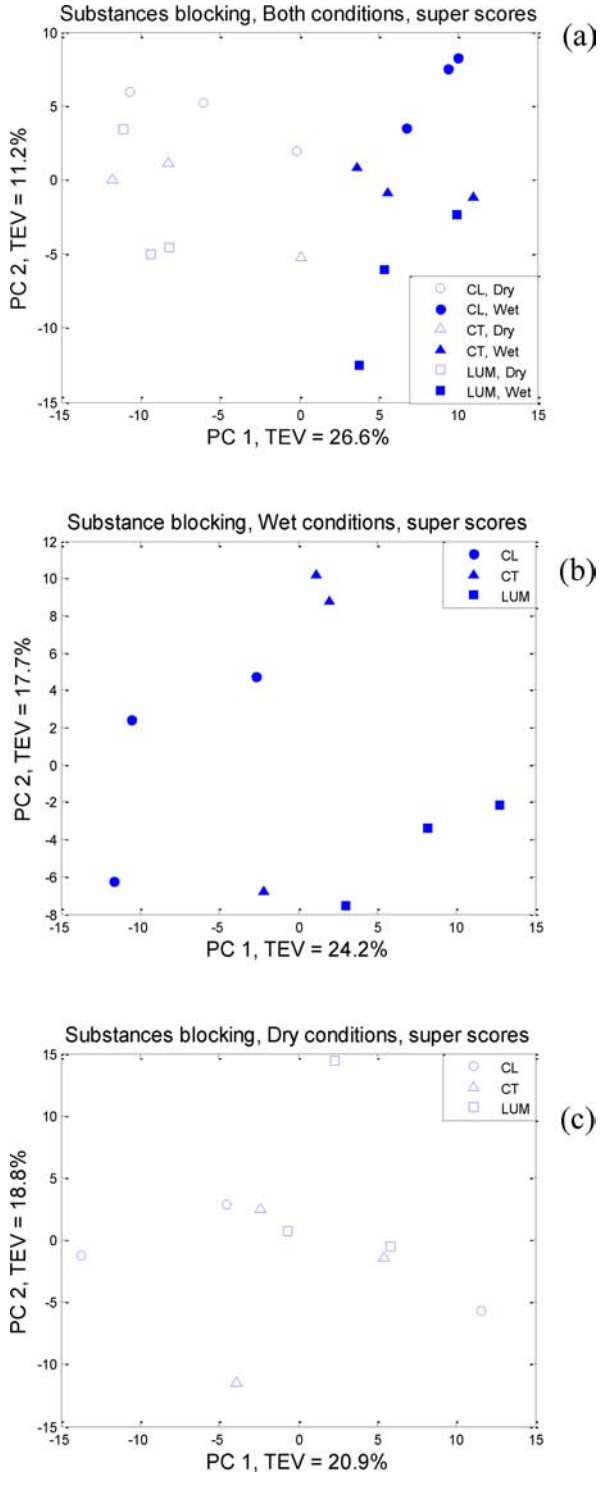

**Figure 3.** Super scores plots of the MB-PCA models based on substances blocking: (a) substances blocking with both conditions; (b) substances blocking with well-watered condition; (c) substances blocking with water-limited condition. TEV, total explained variance.

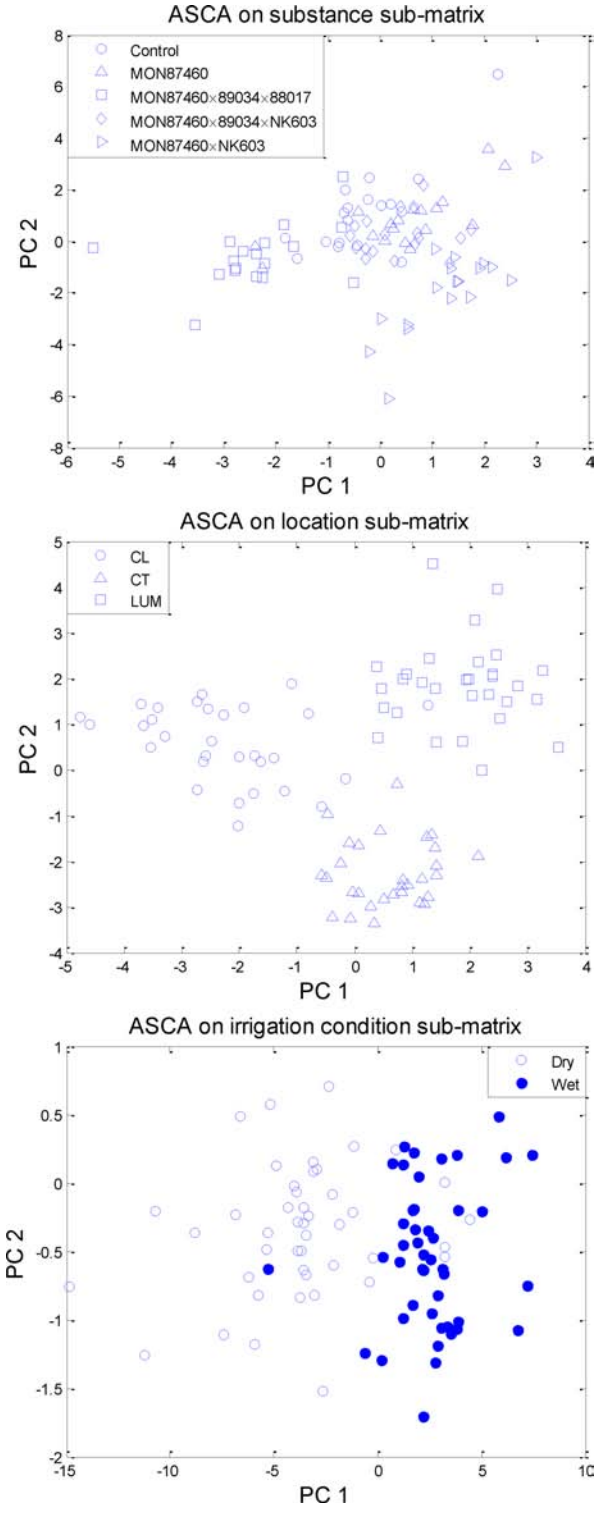

**Figure 4.** Scores plots of the three submatrices of the ASCA model.

between the five different substances was very weak indeed, and a nonsignificant $p$ value of 0.470 was obtained from the corresponding permutation test. By contrast, the scores plots obtained from the location submatrix and the water treatment submatrix showed clear separations between the classes. The $p$ value of the scores of the location submatrix was 0.002, and that of the water treatment matrix was also highly significant at <0.001 (i.e., not a single case of 1000 permutations had obtained higher SSQs than the observed one). The figures of the observed SSQs superimposed on the corresponding null distributions are given in Supplementary Figure S1 (Supporting Information). In summary, ASCA confirmed the results derived through MB-PCA that water treatment was the factor with the most significant impact on grain composition, followed by location, whereas there was significant substance effect.

**Conclusion.** The compositional equivalence of transgenic drought-tolerant maize hybrids to a near-isogenic conventional

dx.doi.org/10.1021/jf5019609 | J. Agric. Food Chem. 2014, 62, 9597−9608

comparator was demonstrated, and additional insights on the effect of drought on maize grain composition were offered. In this study, the effect of genetic modification was contrasted to other experimental factors: water treatment and location. Using the PCA variants MB-PCA and ASAC, it was demonstrated that water treatment had the greatest effect on composition followed by location; moreover, location effects were greater under well-watered conditions than under water-limited conditions. The multivariate options showed no significant differences between the drought-tolerant hybrids and the near-isogenic control, and both options corroborated results from the univariate analysis. This study represents the first application of MB-PCA and ASCA to crop compositional data. Results suggest these multivariate options are of value in unraveling coexisting multiple factors in a complex compositional study and thus present an opportunity to gain better views of each factor of interest whether these be germplasm, environment, management practices, or genetic modification.

fescues, dried, and ground as described below for ergovaline determination.

**Experimental Pastures.** A 0.75 ha plot was sown in September 2009 in Saint-Affrique (Aveyron, France) with an endophyte-infected tall fescue (*L. arundinaceum*, Kentucky 31 E+, infection rate of 94% measured on seedling) provided by RAGT 2n SAS (Rodez, France). Seeds (27 kg seeds/ha) were sown after conventional soil preparation (plowing and harrowing). Plant growth was monitored weekly according to the scale provided by the Biologische Bundesanstalt Bundessortenamt and Chemische Industrie (BBCH scale).[24] The plot was mowed each year at the fully ripe stage (stage 89 on the BBCH scale): June 18, 2010; June 10, 2011; June 19, 2012. In 2011, 120 units of nitrogen per hectare was added in the form of urea on the plot: 70 U/ha on March 9, 2011, and 50 U/ha on April 13, 2011. Rainfall events were recorded with a pluviometer at the Saint-Affrique site, and temperatures were taken daily at the Montlaur meteorological station located 9 km from Saint-Affrique. Effects of temperature were estimated by calculating cumulative degree-d from the beginning of February.[25,26]

**Plant Material.** The concentration of ergovaline in fescue cultivated in the experimental pastures was monitored from April 2010 to June 2012. During the growing season (spring), plants were sampled weekly, whereas outside this period (summer, fall, winter), plants were sampled once or twice a month. At each sampling date, the whole plants were cut just above the ground. From the heading stage (stage 51 on the BBCH scale) to the fully ripe stage (stage 89 on the BBCH scale) three other parts of the plant were collected: inflorescence (after the heading stage), leaves (stem and leaf blade), and base (stem and leaf sheath). On each occasion around 100 g of fresh material was harvested in five different representative areas of each plot. All of the samples were placed in a ventilated ULE 500 oven (Memmert, Schwabach, Germany) for 24 h at 60 °C. One hundred grams of oven-dried sample was then ground to 0.5 mm with a Cyclotech 1093 mill (Foss, Hogande, Sweden) and then stored at room temperature until analysis.

**Chemical Analysis of Ergovaline.** The ergovaline standard was kindly provided by G. E. Rottinghaus (College of Veterinary Medicine, University of Missouri, USA). All reagents and chemicals were of HPLC grade and were purchased from Sigma Chemical Co. (St. Louis, MO, USA). Ergovaline concentrations in the samples were determined by HPLC by fluorescence detection according to the method of Rottinghaus et al.[20] with slight modifications. Five grams of oven-dried milled grass was extracted with 100 mL of chloroform and 5 mL of 0.1 M sodium hydroxide for 2 h on an orbital shaker. Extracts were filtered on 1PS-Whatman phase separators and purified through a homemade column prepared as follows: 1 cm of Ergosil silica gel (Analtech Inc., Newark, DE, USA) was placed in a 5 mL empty SPE cartridge (Silicycle, Quebec, Canada) followed by a biological disk (Silicycle, Quebec, Canada) and 1 cm of sodium sulfate. Columns were preconditioned with 2 mL of dichloromethane, and 10 mL of the extract was then passed through the columns. The extract was eluted with 3 mL of methanol and dried under nitrogen. The dried extract was suspended in 500 $\mu$L of methanol, and 20 $\mu$L was injected in the HPLC system. Separation was achieved with acetonitrile (35%) in aqueous ammonium carbonate (200 mg/L, 65%) through a 150 × 4.6 mm, 5 $\mu$m, 120 Å Prontosil C18 column (Bischoff Chromatography, Leonberg, Germany). Ergovaline was detected by fluorescence with excitation and emission wavelengths of 250 and 420 nm, respectively. The retention time was 9.4 min. The percentage of recovery was 83 ± 4%. The limit of quantitation was 20 $\mu$g ergovaline/kg DM. Samples with ergovaline levels >500 $\mu$g/kg DM were diluted before new analysis.

**Statistical Analysis.** Statistical analysis was performed using R version 2.11.1 (R Foundation for Statistical Computing, Vienna, Austria). Distribution of ergovaline concentration in seeds was assessed by using the Shapiro test. The ergovaline levels in the plant were compared by year using one-way ANOVA. The slopes of ergovaline concentration in whole plant, base, leaves, and inflorescence plotted according to the stage of maturation were compared using ANCOVA. The effects of the year (factor 1) and cumulative temperature or cumulative rainfall (factor 2) on ergovaline concentration were evaluated using two-way ANOVA. The $P$ values obtained at each analysis are reported in results. Results were considered different with a $P$ value below 0.05.

## RESULTS AND DISCUSSION

Since the discovery of ergovaline and its vasoactive properties, most cases of fescue toxicosis have been linked to the presence of this toxin in the plant, and a range of toxic levels has been established. In cattle, threshold levels of approximately 300−400 $\mu$g ergovaline/kg DM have been proposed, higher concentrations of ergovaline in feed and cold temperatures being required to develop necrosis of the extremities.[5,10,27,28] Studies on endophyte-infected fescue in several countries demonstrated the presence of ergovaline at relatively high concentrations, which could explain the cases of toxicity observed in Australia, New Zealand, and the United States.[5,14,19,20] In Europe, although tall fescue is infected with *E. coenophiala*, only a few data are available on the ergovaline concentrations and its factors of variation. Ergovaline (Figure 1) concentrations in seeds and plants were monitored by

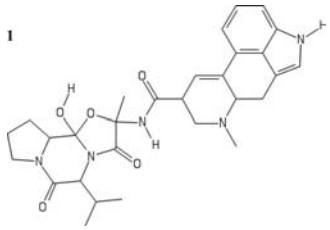

**Figure 1.** Structure of ergovaline.

fluorescence detection after separation by HPLC that permitted a limit of quantitation of 20 $\mu$g ergovaline/kg DM to be reached.[20]

**Ergovaline Concentrations in Wild Tall Fescue Seeds.** Ninety-nine plants of the 166 we collected (60%) were endophyte-infected according to the Phytoscreen immunoblot kit. The level of E+ in the populations collected ranged from 0 to 100%, depending on the point of collection. This rate of infection is consistent with that obtained in a study conducted in central France, where 65% infection was reported.[18] It is within the range of infection reported in Europe, 7% infection being observed in mainland Greece and 100% in Sardinia.[2,17] Figure 2 shows the concentrations of ergovaline in the seeds obtained after 1 year of growth outside without complementary water or fertilizer inputs. All of the endophyte-infected seeds analyzed had ergovaline concentrations higher than the limit of quantitation, the lowest and highest concentrations being 3.1 and 29.3 mg ergovaline/kg DM, respectively. The distribution of ergovaline in the seeds did not follow a normal distribution (Shapiro test, $P = 0.003$). The mean ± SD and the median were 14.8 ± 7.3 and 15.5 mg ergovaline/kg DM, respectively. The ergovaline concentration of the endophyte-infected fescue seeds of Kentucky 31 sown in the experimental pastures was 6.0 mg ergovaline/kg DM. This value is among the highest reported in 25 genotypes of Kentucky 31 tall fescue seeds with high endophyte infection; levels usually range from 1.1−4.8 to 2.0−8.0 mg ergovaline/kg DM, depending on the year of analysis and the country.[8,19] Therefore, 86% of the wild endophyte-infected fescue seeds collected in southern France had higher concentrations of ergovaline than the Kentucky 31 endophyte-infected fescue seeds.

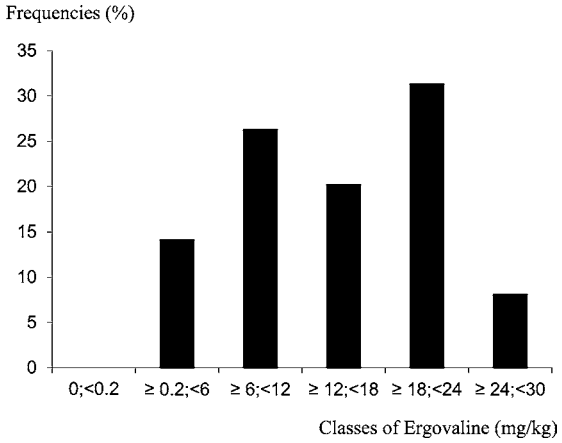

**Figure 2.** Repartition of the concentrations in ergovaline in endophyte-infected tall fescue seeds collected in southern France ($n$ = 99).

**Ergovaline Concentration in Plants.** Because ergovaline production in plants varies with biotic (endophyte strain) and abiotic factors, as well as with the part of the plant analyzed, seeds of endophyte-infected Kentucky 31 were sown in field conditions to monitor the ergovaline concentration in tall fescue under French agricultural conditions. The level of ergovaline in the plant has been reported to vary with the genotype of endophyte-infected tall fescue.[19,29,30] This cultivar was selected because no endophyte-infected tall fescue was commercialized in France and because data on ergovaline levels are available for comparison in other countries. Figure 3 shows the levels of ergovaline in the endophyte-infected tall fescue Kentucky 31 as a function of the sampling period. Each year, the ergovaline concentration increased from the heading stage

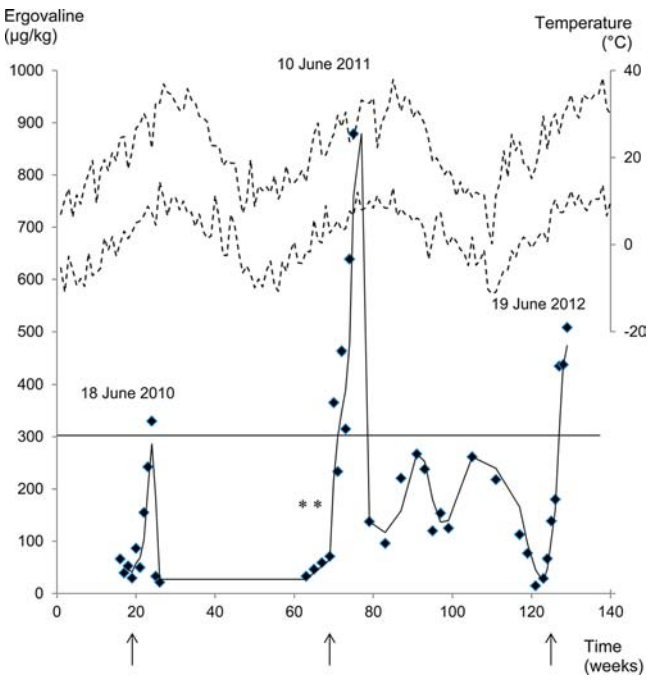

**Figure 3.** Ergovaline concentration in the whole endophyte-infected tall fescue Kentucky 31 plant sown in September 2009 in Saint-Affrique (Aveyron, France): (↑) beginning of heading; (*) fertilization; (—) toxic threshold level; (- - -) minimum and maximum temperatures. Week 1 is the first week in 2010.

(end of April) to reach its maximum level 6 weeks later, at the fully ripe stage. This result agrees with previous data obtained in field conditions and in studies demonstrating that ergovaline accumulates in the seed during its formation.[20,21] Although the maximum levels were always in June (June 18, 2010; June 10, 2011; and June 19, 2012) the concentrations of ergovaline in the plants varied considerably with the year: from 330 $\mu$g ergovaline/kg DM in 2010 to 879 $\mu$g ergovaline/kg DM in 2011. The greatest variations in ergovaline concentrations in the whole plant occurred after the beginning of heading (weeks 20, 70, and 124), when the inflorescences emerged (Figure 3). Before emergence of the inflorescence, mean ergovaline concentrations in the whole plants were 47, 52, and 58 $\mu$g/kg DM for the years 2010, 2011, and 2012, respectively. No significant difference was observed between years (ANOVA), and the mean concentration was 53 $\pm$ 27 $\mu$g ergovaline/kg DM. From emergence of the inflorescence to the fully ripe stage, the concentration of ergovaline in the whole plant was significantly lower in 2010 than in 2011 and 2012 (ANCOVA, $P$ = 0.045 and 0.049, respectively), whereas the difference between the years 2011 and 2012 was not significant. Two other ergovaline peaks were observed, one in September 2011 (weeks 91−93) and another in January 2012 (weeks 105−111). The fall peak corresponded to plant regrowth ("regain"), at the same time as an increase in ergovaline production in planta, and has been previously reported.[21] By contrast, the winter peak is probably linked to the accumulation of ergovaline in the plant that occurs during senescence. High ergovaline has already been reported in leaves in winter.[7] The presence of high levels of ergovaline in the whole plant in winter is of interest because fescue foot disease occurs in winter, even if other factors such as external temperature are involved in the severity of the lesions.[31] Of these three periods, the levels of ergovaline in whole plant were low, in agreement with data obtained in Kentucky 31 tall fescue in Columbia, MO, USA.[20]

Table 1 lists the concentrations of ergovaline measured in the base, leaves, and inflorescence from the heading stage to the fully ripe stage in 2011 and 2012. At the beginning of heading, weeks 69 and 123, the ergovaline concentrations were similar in base, leaves, and inflorescence, but slightly higher in inflorescences in 2011. From 70% of inflorescence emerged to fully ripe, weeks 70−75 and 124−129, the highest level of ergovaline was generally measured in the inflorescence, whereas the concentrations in the base and leaves were lower, except in weeks 70 and 72. Irrespective of the part of the plant analyzed, the ergovaline level obtained at the fully ripe stage did not appear to be correlated with the level at the heading stage. For example, the concentrations of ergovaline in the inflorescences ranged from 57 to 1861 $\mu$g/kg DM in 2012 and from 96 to 1406 $\mu$g/kg DM in 2011.

A comparison of the slope of ergovaline accumulation in the different parts of the plant showed that accumulation in the leaves varied with the year ($P$ = 0.031, ANCOVA), whereas differences in the inflorescence and the bases were not significant. Also, the kinetics of accumulation of ergovaline appeared to vary from year to year. When the inflorescences emerged, weeks 70−71 and 124−125 (Table 1), ergovaline concentrations were markedly higher in bases and leaves in 2011 than in 2012. Later, weeks 72−74 and 126−128, ergovaline concentrations in the bases increased in 2012 to reach values near those measured in 2011, whereas the ergovaline levels in leaves were usually lower in 2012 than in 2011. At the fully ripe stage, weeks 75 and 129 (Table 1), the

[a]B, base; L, leaves; I, inflorescence.

concentration of ergovaline was around 2-fold higher in bases and leaves in 2011 than in 2012, whereas levels in inflorescences were higher in 2012 (1861 and 1406 $\mu$g ergovaline/kg DM in 2012 and 2011, respectively). Finally, these results showed that the speed and the level of accumulation of ergovaline in the bases and in the leaves were higher in 2011 than in 2012, whereas no difference was observed for the inflorescences.

**Factors of Variation.** The relatively wide range of ergovaline concentrations observed in this study depending on the year is in agreement with data obtained in other countries[19,20] and older reports of toxicosis in cattle.[32] The levels obtained at the fully ripe stage agree with the results of studies conducted in 1983 and 1984 in Watskinville, GA, USA, in which maximum mean ergovaline concentrations ranging from 275 to 464 $\mu$g/kg DM were reported depending on the year of analysis and the use of fertilizer.[21] Likewise, ergovaline concentrations measured in head seeds did not differ markedly from those reported in other studies. In the present study, ergovaline concentrations in inflorescences ranged from 1406 to 1861 $\mu$g/kg DM in 2011 and 2012, respectively, whereas they ranged from 1700 to 5000 $\mu$g/kg DM the 1988 and 1987 in a study conducted in Columbia, MO, USA.[20]

Fertilizer was added in 2011. The nitrogen input was within the usual recommendations for this kind of pasture.[33] After fertilization, a rapid increase in ergovaline was observed in the bases and leaves, and concentrations in these parts of the plant were around 2-fold higher in 2011 than in 2012 when no fertilizer was added. Although factors other than nitrogen inputs to the pasture could explain these differences, this result agrees with previous data demonstrating an increase in ergovaline concentrations in fertilized plants.[20] The levels reached in plants are difficult to compare between studies because ergot alkaloid contents vary with the dose and the kind of fertilizer used.[7,20] In the present study, fertilization appears to have had no effect on the level of ergovaline in the inflorescence. No difference in ergovaline content in the whole plant was observed between 2011 and 2012, suggesting that fertilization has only a weak effect on the final level of toxin in the forage, the degree of maturation of the plant being the most important factor in terms of risk of toxicosis. This result is in agreement with data obtained in Watskinville, GA, USA, where different effects of nitrogen fertilization on the level of ergovaline in the whole plant were observed depending on the year of the assay.[21] This result is also in agreement with data showing a lack of correlation between nitrogen and ergovaline concentration in straw.[19]

**Climatic Factors.** Correlations between ergovaline levels in the whole plant and climatic factors were performed to investigate putative risk factors during the three study years. Concentrations of ergovaline in the whole plant were plotted according to the cumulative degree-d observed each year from the beginning of February to the fully ripe stage (Figure 4A). When cumulative degree-d values were below 900 °C, the mean

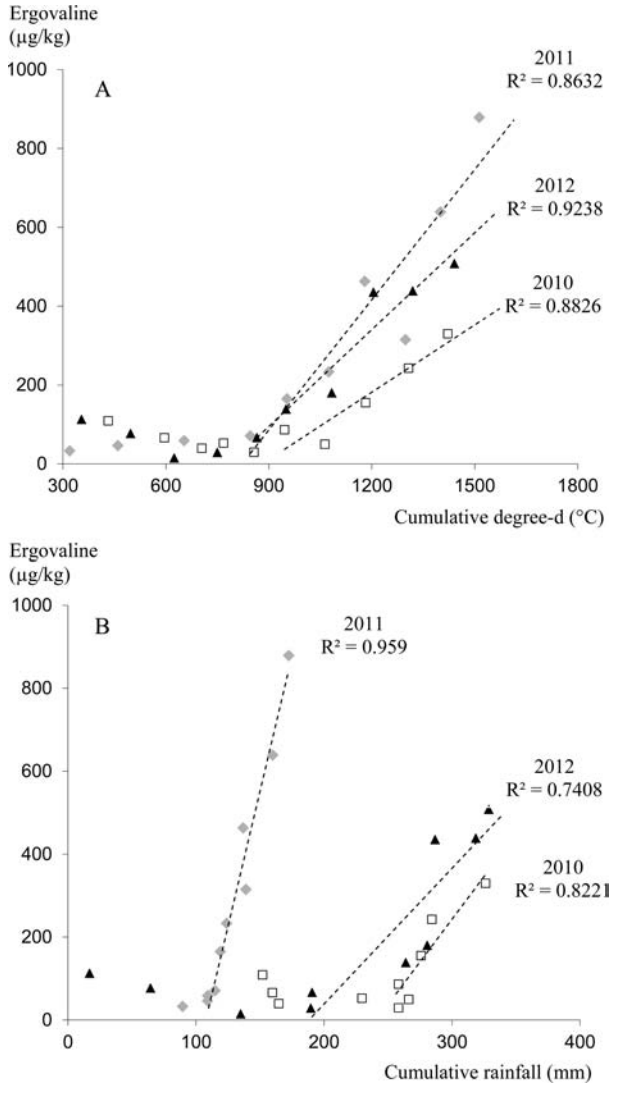

Figure 4. Concentrations of ergovaline in whole endophyte-infected tall fescue Kentucky 31 plants sown in September 2009 in Saint-Affrique (Aveyron, France) plotted according to cumulative degree-d (A) or cumulative rainfall (B) observed each year from the beginning of February to the fully ripe stage.

dx.doi.org/10.1021/jf503015m | J. Agric. Food Chem. 2014, 62, 9609−9614

ergovaline concentration in the whole plant was low and did not differ by year. When cumulative degree-d values were higher than 900 °C, a linear increase of ergovaline in the whole plant was observed, with very high $R^2$ in each study year. Analysis of the effect of year and temperature on the concentration of ergovaline in the whole plant (two-way ANOVA) revealed a strong effect of cumulative temperature ($P < 0.001$), whereas the effect of year was not significant. However, the day for which the cumulative degree-d of 900 °C was reached varied with the year: May 17, 2010; May 3, 2011; and May 19, 2012 (Figure 5). Interestingly, cumulative degree-

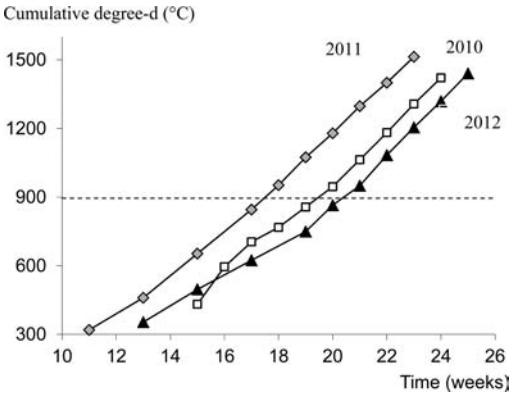

**Figure 5.** Cumulative degree-days according to the week of the year; (---) level required for having an increase of ergovaline concentration in plants.

d values of around 900 °C were required for the development of inflorescence of tall fescue.[25] The fully ripe stage was observed for a cumulative degree-d around 1500 °C (Figure 5). This stage was reached on June 18, 2010; June 10, 2011; and June 19, 2012. Subsequently, ergovaline increased with the increase in cumulative degree-d but with no significant difference between years. This result obtained in the field agrees with data obtained in controlled conditions demonstrating the lack of effect of high temperatures on total ergot contents in tall fescue.[34] Finally, this suggests that, during this assay, the correlation observed between ergovaline content in the whole plant and cumulative degree-d is due to an effect of temperature on plant growth.

Cumulative rainfall from the beginning of February to the fully ripe stage plotted against ergovaline concentrations in the whole plant showed major differences between years (Figure 4B). Concerning plant growth, a linear correlation between the concentration of ergovaline and cumulative rainfall was observed in each year. Comparison of rainfall in 2010 and 2012 revealed no significant difference whatever the period analyzed (from February to June or from the emergence of the inflorescence to the fully ripe stage). By contrast, the year 2011 was drier than either 2010 or 2012. However, analysis of the effect of year and cumulative rainfall on the ergovaline concentration in the whole plant (two-way ANOVA) failed to reveal a significant effect of cumulative rainfall ($P = 0.927$) or of the year of analysis ($P = 0.336$). Finally, the concentration of ergovaline in the whole plant was significantly lower in 2010 than in 2011 or 2012, whereas there was no difference in rainfall between 2010 and 2012, and 2011 was the driest year. Although it has been suggested that a limited supply of water could increase alkaloid production,[23] this result in the field agrees with data obtained under controlled conditions, demonstrating the lack of effect of water availability on total ergot contents in tall fescue.[34]

In conclusion, this study demonstrates for the first time that around 60% of wild tall fescue is infected with *Epichloe* in southern France and that most of the infected plants are able to produce very high ergovaline levels in seeds. Determination of ergovaline contents in Kentucky 31 tall fescue infected with *E. coenophiala* at different growth stages revealed that the levels in plant can be high and do not markedly differ from levels measured in other countries where fescue toxicosis has been reported. Analysis of the factors of variation of ergovaline concentrations revealed that the maturation of the plant is the main factor that needs to be taken into consideration when the risk of toxicity is estimated. Three peaks of concentration were identified: the end of spring, the beginning of fall, and mid-winter. Accurate estimation of the course of maturation of tall fescue is also recommended for better comparison of data between studies. Although fertilization increased the level of ergovaline in bases and leaves, only slight effects were observed in the whole plant. Cumulative temperature appears to affect the level of ergovaline via its effect on plant growth, whereas cumulative rainfall appears to have no effect on the level of ergovaline under the field conditions in the present study.

condensation reaction, where the donor substrate is a monosaccharide, or as (2) kinetically controlled trans-glycosylation, where an activated donor, for example, a disaccharide or a *p*-nitrophenyl (*p*NP) monosaccharide, is employed. In reverse hydrolysis, the maximum yield is determined by the equilibrium, and reaction times are often extended. In contrast, trans-glycosylation makes it possible to "overshoot" the equilibrium to favor the glycosylated acceptor product if the substrate is more reactive than the product, and reaction times are generally shorter than in reverse hydrolysis.[7,17−19] In both cases, the synthetic reaction takes place in competition with hydrolysis of both substrate and product.

As first established by Koshland,[20] glycosidases can catalyze the hydrolysis of substrates or the synthesis of products with either retention or inversion of the anomeric configuration. The glycosidases in focus in this review, that is, $\beta$-galactosidases, belonging to glycosyl hydrolase (GH) families 1, 2, 35, and 42, sialidases, mainly belonging to GH family 33, and $\alpha$-L-fucosidases, mainly belonging to GH family 29, are all retaining glycosidases and employ the classical Koshland double-displacement mechanism. This double-displacement mechanism involves the formation of a covalent glycosyl-enzyme intermediate upon binding of the donor in the active site.[20,21] Figure 1 shows the reactions catalyzed by sialidases, $\beta$-galactosidases, and $\alpha$-L-fucosidases with formation of the glycosyl-enzyme intermediate and concomitant release of the aglycone from the active site, consistent with a ping-pong bibi mechanism, which reduces to an ordered unibi mechanism in the competing hydrolysis.[22] This mechanism has been observed for many glycosidases,[23−26] but evidence of an ordered bibi mechanism with formation of a ternary donor−acceptor−enzyme complex has also been reported for the retaining $\beta$-galactosidase from *Bacillus circulans* (EC 3.2.1.23; GH 42).[1] Recently, a hybrid of the two mechanisms with formation of the ternary complex prior to formation of the sialyl-enzyme intermediate has been suggested for the native trans-sialidase from *Trypanosoma cruzi* (EC 3.2.1.18; GH 33).[27] In the ping-pong bibi mechanism, the glycosyl-enzyme intermediate then undergoes nucleophilic attack, either by water, resulting in hydrolysis, or by another acceptor, resulting in trans-glycosylation (Figure 1). It has been hypothesized that increased stabilization of the covalent glycosyl-enzyme intermediate favors trans-glycosylation over hydrolysis.[28] The trans-glycosylation product is also a substrate for the glycosidase and can thus undergo subsequent hydrolysis (secondary hydrolysis) or function as a donor substrate (Figure 1), the rate being dependent on the regioselectivity in the product formation because not all regioisomers are equally good substrates.[29] The trans-glycosylation yield is therefore the result of a delicate balance between the rates of synthesis, donor hydrolysis, and product hydrolysis (Figure 1). At first glance, the three reactions in Figure 1 appear identical, but all three reactions have been included to emphasize the structural differences in the substrates and products related to each of the three enzyme classes.

The ratio between the trans-glycosylation rate ($r_S$) and the hydrolysis rate ($r_H$) thus describes how efficiently the glycosyl-enzyme intermediate gives the desired trans-glycosylation product (Figure 1). It follows that in order to maximize trans-glycosylation yields, the $r_S/r_H$ ratio must be maximized:[7,18,30]

$$\frac{r_S}{r_H} = S \times \frac{a_{\text{glycosyl acceptor}}}{a_w} = S_c \times \frac{[\text{glycosyl acceptor}]}{[\text{water}]} \quad (1)$$

Thus, the trans-glycosylation yield is influenced both by the activities (or concentrations) of the competing nucleophiles and by the selectivity factor $S$ (or $S_c$), which is dependent on enzyme source and also on choice of donor, acceptor, and reaction conditions.[7,18,30,31] Indeed, the glycosidases most suitable for synthetic reactions are the ones with a high $r_S/r_H$ ratio, especially because product hydrolysis occurs through the same glycosyl-enzyme intermediate.[18] However, much can also be gained from optimizing the reaction conditions, that is, choice of donor, acceptor, acceptor concentration, acceptor/donor ratio, $a_w$, and reaction time as discussed below.

## SELECTIVITY AND SPECIFICITY

The anomeric selectivity of glycosidases is absolute because it is determined by the reaction mechanism.[7] In contrast, glycosidases often show broad selectivity for the donor and particularly for the acceptor molecules as outlined in the following sections. Regioselectivity in the product formation varies from enzyme to enzyme, is dependent on donor and acceptor structures, and may also be adjusted by the use of cosolvents or protein engineering (as discussed below).

**Donor Specificity.** In trans-glycosylation, the glycosyl donor must carry a good anomeric leaving group. Disaccharides such as lactose are sufficiently activated, but nitrophenyl glycosides are also widely used.[32,33] The donor must be fast-reacting to keep reaction times short, thus allowing less time for product hydrolysis. Furthermore, a donor that binds tightly to the catalyst (low $K_m$) also minimizes product hydrolysis.[7] In several cases, aryl donor substrates have given up to 2.5 times higher yields than a di- or trisaccharide donor; this improved yield has been suggested to be due to the aryl aglycone being a better leaving group than the mono- or disaccharides.[14,19,34−36] This is beneficial for synthesis on a smaller scale, but for large-scale synthesis the price of both donors and acceptors becomes an important consideration. For instance, substances such as lactose and casein glycomacropeptide (to be discussed below) are interesting because they are abundantly available in industrial dairy streams. In comparison, nitrophenyl glycosides are expensive substrates and are not suitable for large-scale synthesis unless the resulting product is of extremely high value. Furthermore, the toxicity of the nitrophenol byproduct will be an issue in the approval of this process for use in food applications.

Sialidases (EC 3.2.1.18) specifically catalyze the release of terminal sialic acid (*N*-acetylneuraminic acid) residues $\alpha$-linked to glycoproteins, glycolipids, and polysaccharides, resulting in hydrolysis or trans-sialylation (Figure 1A). Typically, donor substrates such as *p*NP-$\alpha$-sialic acid (Sia-$\alpha$-*p*NP), 2′-(4-methylumbelliferyl)-$\alpha$-D-*N*-acetylneuraminic acid (Sia-$\alpha$-MU), 3′-sialyl-lactose, and dimers and polymers of $\alpha$(2,8)-linked sialic acid, as well as the fetal calf serum glycoprotein fetuin, have been used in trans-sialylation (Tables 1 and 2).[15,35,37−39] Recently, however, a much cheaper source of sialic acid has been introduced in the synthesis of biomimetic compounds, namely, casein glycomacropeptide (CGMP), which is the soluble glycosylated casein residue produced by chymosin action on $\kappa$-casein during cheese manufacture (Tables 1 and 2).[2,4,40−44] CGMP contains 5−11% (w/w) sialic acid depending on the source,[40,45,46] of which approximately half is $\alpha$(2,3)-linked to galactose and the other half is $\alpha$(2,6)-linked to *N*-acetyl-D-galactosamine (GalNAc).[47] The well-studied trans-sialidase from *T. cruzi* is specific for the $\alpha$(2,3)-linked sialyl residues only,[38,48] whereas sialidases from *Clostridium perfringens*, *Arthrobacter*

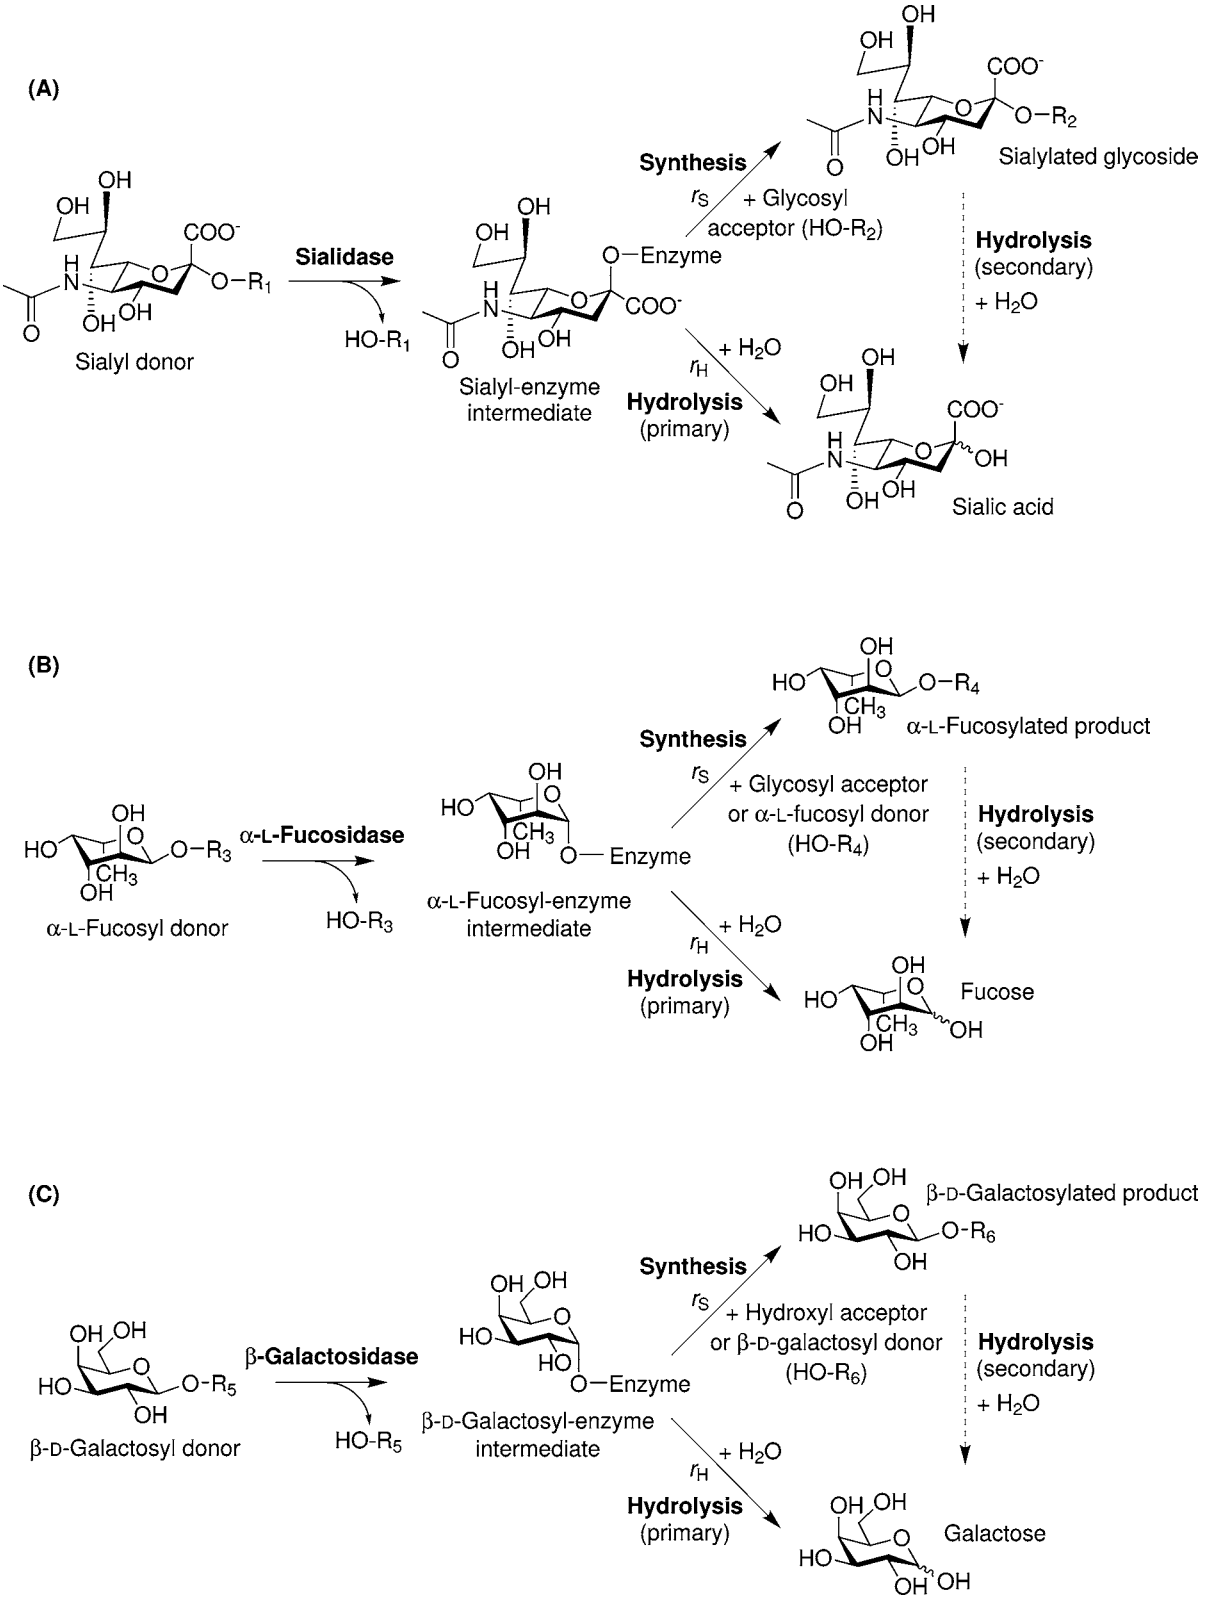

**Figure 1.** Scheme of competing reactions catalyzed by (A) sialidases, (B) α-L-fucosidases, and (C) β-galactosidases. For graphic simplicity, reaction schemes are shown according to the ping-pong bibi mechanism (see text). If the nucleophile attacking the glycosyl-enzyme intermediate is water, hydrolysis occurs. If another nucleophile attacks the intermediate, trans-glycosylation occurs. For β-galactosidases and some α-L-fucosidases, the donor substrate can also function as acceptor, resulting in donor self-condensation (see text). Regioselectivity in the product formation may vary (see text).

*ureafaciens*, *Vibrio cholerae* (all EC 3.2.1.18; GH 33), and Newcastle disease virus (EC 3.2.1.18; GH 83) can also utilize terminal sialyl residues α(2,8)-linked in sialic acid di- and polymers (Table 1).[35] So far, it is unclear whether α(2,6)-linked sialyl moieties on CGMP are utilized. Most sialidases accept aryl sialyl donors (Tables 1 and 2).[14,35]

[a]All of the microbial sialidases belong to GH 33, whereas the sialidase of viral origin (Newcastle disease virus) belongs to GH 83. Abbreviations: Sia, sialic acid (*N*-acetylneuraminic acid); Lac, β-D-lactose; nq, not quantified; Sia-α-*p*NP, *p*-nitrophenyl α-sialic acid (2-*O*-(*p*-nitrophenyl)-α-D-*N*-acetylneuraminic acid); CGMP, casein glycomacropeptide; nd, not determined; LacNAc, *N*-acetyl-D-lactosamine; LNT, lacto-*N*-tetraose; LNnT, lacto-*N*-neotetraose; LNFP V, lacto-*N*-fucopentaose V; LNFP I, lacto-*N*-fucopentaose I; Fuc, L-fucose; GOS, galacto-oligosaccharides; DP, degree of polymerization; IMO, isomalto-oligosaccharides; Gal-β-O-Me, methyl β-D-galactopyranoside; Gal-α-O-Me, methyl α-D-galactopyranoside; Glc-β-O-Me, methyl β-D-glucopyranoside; Lac-β-O-Me, methyl β-D-lactoside; LacNAc-β-O-Me, methyl β-D-*N*-acetyl-D-lactosaminide. [b]The linkage between the transferred sialyl group and the acceptor listed according to prevalence; only single sialylations have been observed. [c]The molar acceptor/donor ratio has been rounded to the nearest integer (for CGMP the A:D is based on the molar sialic acid content in the donor substrate). [d]Total molar trans-sialylation yield on donor (for CGMP the yield is based on the molar sialic acid content in the donor substrate). [e]Complete, no other linkage detected; high, ≥90% of the desired linkage; medium, ≥50% of the desired linkage; low, <50% of the desired linkage; the percentage of the most prevalent linkage (top of 'linkages formed in trans-sialylation' column) is given. [f]Thirty percent acetonitrile added. [g]Sialic acid content in CGMP is given as 4−7%, so an exact number cannot be given. [h]Mass yields estimated from the mass isolation yields and the information that approximately 65% of 3′-sialyl-lactose stayed on the column used for purification. [i]In membrane reactor. [j]Twenty-five percent *tert*-butanol added. [k]The sialyl linkage has not been determined, but this enzyme has been observed to form only α(2,3)-linkages and only single peaks were observed on LC-MS. [l]Note that glucose present in the IMO preparation is also sialylated. [m]Thirty percent DMSO added.

α-L-Fucosidases (EC 3.2.1.51) catalyze the release of terminal fucose residues α-linked to glycans, resulting in hydrolysis or trans-fucosylation (Figure 1B). Fucosidases, which are specific for a given α-linkage, may be classified as α-1,2-fucosidases (EC 3.2.1.63), α-1,3-fucosidases (EC 3.2.1.111), or α-1,6-fucosidases (EC 3.2.1.127). By far, the most trans-fucosylations have used *p*NP-α-L-fucopyranoside (Fuc-α-*p*NP) as fucosyl donor[5,13,29,49−51] (Table 3). In two cases, methyl α-L-fucopyranoside[52] and α-fucosyl fluoride[53] have also been used as donor substrates (Table 3). For large-scale trans-fucosylation there is a need for cheaper substrates.

β-Galactosidases (EC 3.2.1.23) catalyze the release of terminal β-galactosyl residues, resulting in hydrolysis or trans-galactosylation (Figure 1C). However, some β-galactosidases used for trans-galactosylation can also act as β-glucosidases (EC 3.2.1.21) catalyzing trans-glucosylation.[30] Lactose is widely used as a β-galactosyl donor in trans-galactosylation, not least because it is a cheap substrate. Lactose is especially used for production of GOS, where it also functions as acceptor. However, for synthesis of LacNAc or lacto-*N*-biose, *p*NP-β-galactopyranoside (Gal-β-*p*NP) and *o*-nitrophenyl-β-galactopyranoside (Gal-β-*o*NP) are also encountered as a donor substrates,[6,15,35,54,55] even though successful synthesis of these compounds can also be achieved when using lactose as donor, albeit with lower yields (Table 4).[19,36,56,57]

**Acceptor Specificity.** In general, β-galactosidases, sialidases, and α-L-fucosidases show broad acceptor specificity. β-Galactosidases can catalyze trans-galactosylation of various mono-, di-, and oligosaccharides (on terminal moieties as well as nonterminal ones) of both anomeric configurations, *N*-substituted saccharides (*N*-acetyl-D-glucosamine (GlcNAc) and GalNAc), and methyl and aryl glycosides, as well as primary and secondary alcohols and phenols,[31,36,54,58,59] thus emphasizing their widespread potential (Table 4).

The much studied trans-sialidase from *T. cruzi* is known to be specific for terminal β-galactosyl acceptors,[38,48] but can also catalyze sialylation of nonterminal moieties in GOS[42] and galactose dimers[60] (Table 2). Indeed, mainly β-galactosyl acceptors have been used for sialidases,[4,35,38,40,42,44,61] but some sialidases also catalyze sialyl transfer to α-galactosyl residues, α-glucosyl residues, monomers of glucose and fucose, and methyl

**Table 2. Donor, Acceptor, and Acceptor/Donor (A:D) Ratio of Trans-sialylations Catalyzed by the Well-Studied Trans-sialidase from *Trypanosoma cruzi* (GH 33) as well as the Products and Trans-sialylation Yield Obtained[a]**

[a]Trans-sialidase from *T. cruzi* specifically catalyzes the formation of α(2,3)-linkages, but not only at the reducing end.[42,60] The current table serves to emphasize the wide variety of donor and acceptors used. Abbreviations: CGMP, casein glycomacropeptide; Lac, β-D-lactose; Sia, sialic acid (*N*-acetylneuraminic acid); LNT, lacto-*N*-tetraose; GOS, galacto-oligosaccharides; DP, degree of polymerization; LacNAc, *N*-acetyl-D-lactosamine; Lac-BSA, β-D-lactose linked to bovine serum albumin; LNnT, lacto-*N*-neotetraose; allo-LacNAc, Gal-β(1,6)-GlcNAc; LNFP V, lacto-*N*-fucopentaose V; Gal, D-galactose; Man, D-mannose; GalNAc, *N*-acetyl-D-galactosamine; Sia-α-MU, 2′-(4-methylumbelliferyl)-α-D-*N*-acetylneuraminic acid; Sia-α-*p*NP, *p*-nitrophenyl α-sialic acid (2-*O*-(*p*-nitrophenyl)-α-D-*N*-acetylneuraminic acid); Gal-α-O-Me, methyl α-D-galactopyranoside; Gal-β-O-Me, methyl β-D-galactopyranoside; Gal-α(1,6)-Gal-β-O-Me, methyl β-D-galactopyranosyl α(1,6)-D-galactopyranoside; Gal-β(1,6)-Gal-β-O-Me, methyl β-D-galactopyranosyl β(1,6)-D-galactopyranoside. [b]The molar acceptor/donor ratio has been rounded to the nearest integer except when <1 (for CGMP and fetuin the A:D is based on the molar sialic acid content in the donor substrate). [c]Total molar trans-sialylation yield on donor (for CGMP and fetuin the yield is based on the molar sialic acid content in the donor substrate). [d]The sialyl linkage has not been determined, but this enzyme has been observed to form only α(2,3)-linkages. [e]Other acceptors were also tested at these conditions, but no product was observed. [f]An assumption based on the sparse description of the experimental procedure.

galactopyranoses of both anomeric configurations (Table 1).[2,37,39] Some studies have indicated that acceptor size affects the yield, with smaller acceptors being favored.[4,39]

It has been suggested that the presence of aromatic amino acid residues in the +2 acceptor binding site of the α-L-fucosidase from *Thermotoga maritima* (EC 3.2.1.51; GH 29) induces a preference for monosaccharide acceptors or, in particular, *p*NP-monosaccharide acceptors.[51] Indeed, (*N*-substituted) monosaccharides or their methyl, *p*NP, or allyl derivatives are most commonly used as acceptors in trans-fucosylation (Table 3).[5,29,49,50,53,62,63] An example of the use of lactose and LacNAc by α-L-fucosidase from *Alcaligenes* sp. does exist, but even here the presence of a methyl group at the reducing end increased the trans-fucosylation yields (Table 3).[13]

In several cases, the formed products may also function as acceptors for further trans-glycosylation (Tables 2, 3, and 4).[29,42,55,60,64−66] There is a tendency that the most prevalently formed product is also the one used as acceptor in the further trans-glycosylation.[29,65,66]

**Regioselectivity.** Although glycosidase-catalyzed synthesis is more regioselective than chemical synthesis, the regioselectivity varies from enzyme to enzyme, and not all enzymes are equally selective. Whereas some β-galactosidases show complete regioselectivity for *O*-3,[15,54,67] *O*-4,[35] or *O*-6,[19,59,64] others are more promiscuous in the trans-galactosylation (Table 4).[6,55,64] In fact, β-galactosidases from the same organism have shown different regioselectivities: The *B. circulans* ATCC 31382 strain is the source of the much-used commercial β-galactosidase preparation Biolacta, which contains one or more GH 42 β-galactosidases, which mainly catalyze the formation of β(1,4)-linkages and to a lesser extent β(1,6)-linkages.[36,57,65,68,69] In contrast, the GH 35 β-galactosidase purified from the same *B. circulans* strain appears to be primarily specific for β(1,3)-linkages in trans-galactosylation as well as in hydrolysis.[54,68]

**Table 3. Donor, Acceptor, and Acceptor/Donor (A:D) Ratio of α-L-Fucosidase-Catalyzed Reactions as well as the Products, Total Trans-fucosylation Yield, and Regioselectivity Obtained[a]**

[a]The use of co-solvent is indicated where relevant. The α-L-fucosidases used (all GH 29) are mainly of microbial origin, but a few of mammal or mollusk origin have also been used. Abbreviations: *p*NP-α-Fuc, *p*-nitrophenyl α-L-fucopyranosidse; LacNAc, *N*-acetyl-D-lactosamine; Lac, β-D-lactose; LacNAc-β-O-Me, methyl β-D-*N*-acetyl-D-lactosaminide; Lac-β-O-Me, methyl β-D-lactoside; Gal-β(1,3)-Glc-β-O-Me, methyl β-D-galactopyranosyl β(1,3)-D-glucopyranoside; *p*NP-β-LacNAc, *p*-nitrophenyl β-D-*N*-acetyl-D-lactosaminide; *p*NP-β-Lac, *p*-nitrophenyl β-D-lactoside; *p*NP-β-Glc, *p*-nitrophenyl β-D-glucoside; *p*NP-β-GlcNAc, *p*-nitrophenyl β-D-*N*-acetyl-D-glucosaminide; Gal-β-O-Me, methyl β-D-galactopyranoside; DMSO, dimethyl sulfoxide; GlcNAc, *N*-acetyl-D-glucosamine; DMF, dimethylformamide; Glc, D-glucose; Fuc-α-O-Me, methyl α-L-fucopyranoside; Glc-β-O-Me, methyl β-D-glucopyranoside; Gal, D-galactose; GlcNAc-α-O-Me, methyl α-D-*N*-acetyl-D-glucosaminide; GlcNAc-α-O-All, allyl α-D-*N*-acetyl-D-glucosaminide; GlcNAc-β-O-All, allyl β-D-*N*-acetyl-D-glucosaminide; Fuc-α-F, α-L-fucosyl fluoride; MeOH, methanol; *p*NP-β-Gal, *p*-nitrophenyl β-D-galactopyranoside; Gal-β(1,3)-Glc-β-O-Ph, phenyl β-D-galactopyranosyl β(1,3)-D-glucopyranoside; GalNAc, *N*-acetyl-D-galactosamine; nd, not determined; EtOH, ethanol. [b]Listed according to prevalence. [c]The molar acceptor/donor ratio has been rounded to the nearest integer. [d]Total molar trans-fucosylation yield on donor, including donor self-condensation. [e]Complete, no other linkage detected, high, ≥90% of the desired linkage; medium, ≥50% of the desired linkage; low, <50% of the desired linkage; the percentage of the most prevalent linkage (top of "products" column) is given. [f]Similar results were obtained with α-L-fucosidase from *Pecten maximus*, and more acceptors were included for both enzymes, but these are not included here because the yields were not quantified. [g]GlcNAc-β-O-All was also tested as acceptor, but the yield was 0%. [h]Many other mutants gave similar results, but this one has the best combination of high activity, high trans-fucosylation/hydrolysis ratio, and high yield of the desired product.

Most sialidases are specific for either *O*-3[2,4,39,48] or *O*-6[35,39] on the glycosyl acceptor, whereas a few have been reported to show fairly poor regioselectivity (Table 1).[35,37,39] Interestingly, α-L-fucosidases may be specific for *O*-2,[51,62] *O*-3,[5,53,63] or *O*-6,[5,62] but several α-L-fucosidases have shown poor regioselectivity in the trans-fucosylation (Table 3).[29,51,70] Poor regioselectivity may complicate product purification. An alternative method to avoid the presence of isomers in the reaction mixture is to use a promiscuous trans-glycosidase in combination with a glycosidase with specific hydrolytic activity to remove the undesired isomer(s).[57]

The regioselectivity is also dependent on the acceptor structure, that is, substitutions and anomeric configuration, and its interplay with the conformation of the active site. For instance, the anomeric configuration and the presence and/or position of an *N*-acetyl group has been shown to influence regioselectivity of both β-galactosidases and sialidases (Table 1).[35,37,39,59,71] The orientation of the secondary hydroxyl groups is similarly determining for regioselectivity of both β-galactosidases and α-L-fucosidases (Table 3).[29,51,71]

In a few cases, the donor substrate has also been found to influence regioselectivity.[35,36] For sialidases, the effect of each donor substrate on regioselectivity did, however, vary between enzymes (Table 1).[35]

The regioselectivity of β-galactosidases, which are the most studied of the enzyme classes covered by this review, may also be influenced by the acceptor/donor ratio and by the presence of cosolvents, as well as by temperature and pH (see below).

**Donor Self-Condensation.** Another selectivity issue, which may compromise the yield of the desired trans-glycosylation product, is the fact that β-galactosidases can also catalyze donor self-condensation because the galactosyl donor substrate also functions as acceptor (Figure 1C).[6,65,67] This is indeed the goal in GOS production, but not in the selective biocatalytic formation of, for example, LacNAc. Among the relatively few trans-fucosylations reported, only α-L-fucosidase from *T. maritima* has been reported to catalyze donor self-condensation.[51] However, the α-L-fucosidase from *Pecten maximus* and a recombinant canine α-L-fucosidase could easily utilize methyl α-L-fucose as acceptor substrate.[29] Donor self-condensation has not been observed for sialidases, most likely because the sialyl moiety is too unlike the "natural" acceptor substrates (see below), where the ring structure is much less heavily substituted (Figure 1A).

## ■ WATER ACTIVITY ($a_w$)

It follows from eq 1 that a decrease in $a_w$ will favor the desired trans-sialylation over hydrolysis. However, glycosidases require fairly high $a_w$ (≥0.9) for displaying activity compared to, for example, lipases.[72] In a study of β-galactosidase from *B. circulans* (GH 42), trans-galactosylation of GlcNAc in aqueous media with organic cosolvents was maximized at $a_w$ values between 0.92 and 0.99 with a mean of approximately 0.96.[55] The underlying mechanism proposed in several studies is that at low $a_w$ the glycosidase becomes less flexible, thus favoring the smaller water molecule as acceptor even if its activity is low.[30,55,73]

**Table 4. Donor and Acceptor/Donor (A:D) Ratio of Trans-galactosylation Reactions Catalyzed by β-Galactosidases as well as the Products, Total Trans-galactosylation Yield, and Regioselectivity Obtained When Using *N*-Acetyl-D-glucosamine (GlcNAc) as Acceptor[a]**

[a]The use of cosolvent or enzyme immobilization is indicated where relevant. All β-galactosidases used are of microbial origin, but belong to several different GH families as indicated. Abbreviations: Lac, β-D-lactose; OS, oligosaccharide; LacNAc, *N*-acetyl-D-lactosamine; Gal-β-*p*NP, *p*-nitrophenyl β-D-galactopyranoside; [BMIm][$PF_6$], 1-butyl-3-methylimidazolium hexafluorophosphate; Gal-β-*o*NP, *o*-nitrophenyl β-D-galactopyranoside; Gal, D-galactose; GOS, galacto-oligosaccharides; DP, degree of polymerization; [MMIm][$MeSO_4$], 1,3-dimethylimidazolium methyl sulfate; Gal-β-F, β-galactosyl fluoride; DMSO, dimethyl sulfoxide; [OMIm][$PF_6$], 1-octyl-3-methylimidazolium hexafluorophosphate. [b]Listed according to prevalence. [c]The molar acceptor/donor ratio has been rounded to the nearest integer except when <1. [d]Total molar trans-galactosylation yield on donor. [e]Complete, no other linkage detected; high, ≥90% of the desired linkage; medium, ≥50% of the desired linkage; low, <50% of the desired linkage; the percentage of the most prevalent linkage (top of "products" column) is given. [f]Based on yield of identified disaccharides only. [g]Nine other ionic liquids were tested (30% v/v), but this one gave highest yields and no formation of allo-LacNAc, which was observed for the majority of the other ILs. [h]Fourteen other biosolvents were tested (2 M), but this one gave highest yields of the desired compound. [i]More acceptor/donor ratios (1−20) were tested at higher enzyme concentration, where the effect on trans-galactosylation yield was pronounced (1−57%). [j]Five other organic cosolvents (dimethyl sulfoxide, acetonitrile, pyridine, *tert*-butanol, and acetone) were also tested at the same conditions, giving similar results, but the highest yield was obtained with 2-methyl-2-butanol. [k]Only LacNAc yield was determined in this study, and the presence of no other compounds was reported or quantified. [l]More acceptor/donor ratios (0.1−10) were tested, but this one gave the highest yield. [m]Fourteen other organic solvents were tested, of which six (*n*-dibutyl ether, tetracloromethane, 2-butanone, methyl *tert*-butyl ether, ethyl acetate, and toluene) gave higher yields than obtained without cosolvent (but lower than that obtained with cyclohexane), whereas eight (1,4-dioxane, tetrahydrofuran, *n*-hexane, acetonitrile, acetone, *tert*-butanol, trichloromethane, and diglyme) gave lower yields. [n]More acceptor/donor ratios (0.33−2) were tested, but this one gave the highest yields. [o]β-Galactosidse from *Bifidobacterium bifidum* DSM 20456 (also ATCC 29521 and JCM 1255) is not listed in the CAZy database, but in its UniProt entry U2BYL7 GH family 42 is indicated. [p]Other cosolvent concentrations were tested, but yields were generally highest at 20%, and only this concentration is shown here to enable comparison between donors. [q]Three other ionic liquids were tested, but this one gave the highest yield of the desired compound.

Although this review focuses on solute acceptors, not least due to the valuable products they can become, glycosidases can equally well trans-glycosylate primary or secondary alcohol solvents and phenols.[7] Issues and recommendations relating to glycosidase-catalyzed formation of alkyl glycosides were thoroughly reviewed 15 years ago.[7] Major conclusions then included the fact that trans-glycosylation is to be preferred over reverse hydrolysis and that $a_w$ is determining for reaction yields (cf. eq 1). For alkyl glycoside formation where the alcohol is the main solvent, glycosidases that tolerate low $a_w$ conditions are needed, for example, hyperthermostable or immobilized glycosidases.[7,58] For solute acceptors, $a_w$ can only be lowered

according to eq 1 by using very high acceptor concentrations, which is often not favorable for valuable compounds, or by addition of cosolvents (see below).

## COSOLVENTS

It has been shown that the $r_S/r_H$ ratio (eq 1) and consequently the trans-glycosylation yield for glycosidases can be improved by the addition of cosolvents including organic solvents,[41,55,74] ionic liquids (ILs),[31,41,54,56] or glycerol-based biosolvents[75] (Tables 1 and 4). The cosolvents affect the $a_w$ of the reaction mixture[55] as well as the selectivity of the enzyme for the competing nucleophiles, that is, the desired acceptor and water, expressed as the selectivity factor $S$ (or $S_c$)[31] in eq 1. Some controversy exists regarding the mechanism by which the cosolvents alter the enzyme selectivity. Sandoval and co-workers[6,76] hypothesized that the improved trans-galactosylation yields obtained with $\beta$-galactosidase from *Thermus thermophilus* (EC 3.2.1.23; GH 1) when using ILs or biosolvents as cosolvents were linked to alterations in the enzyme's secondary and tertiary structure. It is believed that increased enzyme flexibility makes glycosidases favor the larger acceptor molecules over water.[55,76] In contrast, Lang et al.[31] showed that the effect of an IL cosolvent on enzyme selectivity was acceptor-dependent and hypothesized that the IL removed hydrogen-bonded water from strongly hydrated acceptors, thus improving the selectivity of the enzyme by modification of the acceptor hydration. In a study on $\beta$-galactosidase from *B. circulans* (GH 35) with IL cosolvents,[54] it was found that the addition of [BMIm][$PF_6$] (1-butyl-3-methylimidazolium hexafluorophosphate) to the aqueous medium decreased the distance between the reactive hydroxyl group on the acceptor and the nucleophilic Glu residue in the active site, thus increasing the reactivity with the glycosyl acceptor. In addition, the presence of [BMIm][$PF_6$] increased the binding energy between the enzyme and the substrate, particularly by increasing their electrostatic interaction.[54] Furthermore, the effect on enzyme selectivity, that is, the $r_S/r_H$ ratio, is also dependent on the cosolvent nature.[41,54,55,77,78]

When employing the GH family 42 $\beta$-galactosidase from *B. circulans* for the trans-galactosylation of GlcNAc with *o*NP-$\beta$-Gal, it was seen that total trans-galactosylation yields comparable to those obtained in aqueous medium at an acceptor/donor ratio of 10 could be obtained at an acceptor/donor ratio of 1 by the addition of 10−20% (v/v) organic solvent.[55] This may thus be a useful method to improve reaction yields with expensive acceptors.

For $\beta$-galactosidase-catalyzed reactions, cosolvents have been shown to significantly improve the regioselectivity and/or reduce the extent of donor self-condensation.[6,54,55,76] However, when using aryl saccharide donors, addition of a cosolvent that enhances donor solubility can improve trans-glycosylation yields, but a too high cosolvent concentration may lead to increased donor self-condensation.[78,79] Indeed, the amount of cosolvent must be carefully adjusted, not least to avoid extensive inactivation of the biocatalyst.[19,31,55,78]

The main disadvantage of using cosolvents is the fact that these should be removed from the final product, an issue that is rarely addressed in the studies mentioned above. Whereas some organic solvents can be removed by simple distillation, others form azeotropes with water and cannot be.[41] Sialylated products can be purified by anion exchange chromatography,[4] and it is likely that this can also be used for purification from azeotropic mixtures. Water-immiscible ILs may be removed by centrifugation,[6] whereas water-miscible ones can be removed from saccharide mixtures by a combination of filtration and electrodialysis.[80]

## ACCEPTOR CONCENTRATION AND ACCEPTOR/DONOR RATIO

It follows from eq 1 that an increase in acceptor concentration improves trans-glycosylation. For oligosaccharide synthesis, saccharide concentrations as high as 80% (w/w) have been used to effectively increase reaction yields.[81,82] At these high concentrations, $a_w$ is significantly lowered to as little as 0.6−0.7.[83] Michalak et al.[4] found significant improvement of the trans-sialylation yield from approximately 3% to >50% when increasing the lactose acceptor concentration from 1.3 to 4% (w/w). However, even 4% (w/w) lactose is unlikely to lower the $a_w$ from 1.0. Consequently, this improvement in trans-sialidase activity is more likely linked to the corresponding increase in acceptor/donor ratio from 14 to 25. An increase in acceptor/donor ratio from 1 to 10 also dramatically increased the yield of LacNAc from <1 to 43% in the trans-galactosylation of GlcNAc catalyzed by the GH 42 $\beta$-galactosidase from *B. circulans* when using *o*NP-$\beta$-Gal as donor.[55] Interestingly, another study of the same reaction with the same enzyme reported that whereas an increase in acceptor/donor ratio from 1 to 10 increased the LacNAc yield from 12 to 22%, a decrease to one-third increased the LacNAc yield further to 35%, albeit with a concomitant increase in donor self-condensation.[78] However, by far the majority of the available results supports the correlation between an increase in acceptor/donor ratio and an increase in trans-glycosylation yield for $\beta$-galactosidases, sialidases, and $\alpha$-L-fucosidases, at least to a certain extent (Tables 1, 3, and 4).[4,37,42,51,55,64,67,84] A high acceptor/donor ratio thus increases the probability of a nucleophilic attack from the desired acceptor on the formed glycosyl-enzyme intermediate, thus increasing trans-sialylation yields even if the competing nucleophile, water, is always present in large excess (usually at approximately 55.5 M). An increased acceptor/donor ratio may also improve the regioselectivity and decrease the extent of donor self-condensation.[37,51,55] However, whereas too low substrate concentrations, that is, of both donor and acceptor, promote hydrolysis, too high substrate concentrations may produce lower regioselectivity and promote the formation of higher oligosaccharides.[65,69,78] This is exploited in GOS production, but may compromise the yield of the desired compound in the production of specific human milk oligosaccharides.

In a more recent study with the GH family 42 $\beta$-galactosidase from *B. circulans*,[85] it was found that increasing the concentration of acceptor molecules not functioning as donor substrates had a positive effect on the $V_{max}$ through accelerating the liberation of the transferred $\beta$-galactosyl group from the active site. This acceptor acceleration was not observed with the addition of inert carbohydrates, nor was it caused by a decrease in $a_w$. Furthermore, a decrease in $K_m$ was also observed with increasing concentrations of both inert and acceptor carbohydrates; this increase in enzyme affinity was hypothesized to be caused by molecular crowding, where the enzymatic activity increases if the volume of the enzyme−substrate complex is smaller than the sum of the volume of the enzyme and the volume of the substrate ($V_{E+S} < V_E + V_S$). This molecular crowding effect was, however, much smaller than the effect of acceptor acceleration.[85] In essence, much seems to be gained from ensuring a high acceptor concentration as well as an adequately high acceptor/donor ratio in trans-glycosylation reactions.

## REACTION TIME CONTROL

It follows from Figure 1 that in the kinetically controlled reaction, the maximum trans-glycosylation yield is reached when the rate of trans-glycosylation product formation equals the rate of trans-glycosylation product hydrolysis. From this point, the reaction will no longer be kinetically controlled, and it is important to stop the reaction before thermodynamic control takes over and the trans-glycosylation product undergoes hydrolysis.[18] Indeed, trans-glycosylation product yields often reach a maximum before decreasing due to product hydrolysis.[2,51,56,58] Consequently, it is of major importance to establish the optimal reaction time. Reaction time can be controlled simply by terminating the reaction with a change in pH or temperature or, more elegantly and efficiently, by employing enzyme immobilization/confinement or continuous product removal[40] (see below).

In a few cases, product hydrolysis at extended reaction times has been avoided because the product formed was not a substrate for the glycosidase. For instance, for α-L-fucosidases it has been been reported that α(1,6)-linked fucosyl residues are poor substrates for the hydrolytic activity, resulting in relatively high trans-fucosylation yields (Table 3).[5,29] Recently, a sialyl transferase from *Pasteurella multocida* (EC 2.4.99.1/EC 2.4.99.4; GT 80) was shown to also possess dual trans-sialidase activity, resulting in the formation of both 3′- and 6′-sialyl-lactose from lactose and CGMP.[43] 3′-Sialyl-lactose was formed more rapidly than 6′-sialyl-lactose, but whereas 3′-sialyl-lactose was subject to product hydrolysis during the enzyme catalysis, the 6′-sialyl-lactose was not, eventually resulting in higher yields of 6′-sialyl-lactose at extended reaction times.[43] Other special-case glycosidases have very low hydrolytic activity, for example, a mutant of the α-L-fucosidase from *T. maritima*[51] and the well-studied true trans-sialidase from *T. cruzi*.[38] Even so, also for these reactions the trans-glycosylation yield does reach a plateau, at which point the reaction may be stopped.

## TEMPERATURE AND PH

Generally, trans-glycosylation yields are optimized at low or moderate temperatures (25−40 °C).[4,42,43,65] Indeed, an increase in temperature can compromise reaction yields due to decreased regioselectivity.[57,65,86] For β-galactosidase from *B. circulans* (GH 42) it was found that both pH and temperature influenced the ratio between the LacNAc and allo-LacNAc (Gal-β(1,6)-GlcNAc) produced, favoring LacNAc at low pH and low temperature.[57,86] Similarly, it was found that for the trans-sialidase activity possessed by the sialyl transferase from *Pasteurella multocida*, the optimal pH for production of 3′-sialyl-lactose was different from the optimal pH for producing 6′-sialyl-lactose.[43]

## ENZYME DOSAGE

Data on the optimization of enzyme dosage in trans-glycosylation are scarce. However, it may be an important point to consider as it has been shown that a decrease in concentration of the GH 42 β-galactosidase from *B. circulans* dramatically improved the trans-galactosylation yields.[55] Probably, a high enzyme dosage accelerates primary and secondary hydrolyses, thus compromising trans-glycosylation yields. However, the results obtained may depend on the reaction time (see above), which was not optimized in the aforementioned study.[55] It deserves to be highlighted that an increase in enzyme concentration has also been found to reduce the regioselectivity of the GH 42 β-galactosidase from *B. circulans*.[57,65]

## CONTINUOUS PRODUCT REMOVAL

Another means of avoiding product hydrolysis is to continuously remove the product from the reaction mixture, known as continuous product removal or in situ product removal (ISPR). In β-galactosidase-catalyzed production of GOS from lactose, this has been achieved by adsorption of oligosaccharides to activated carbon, resulting in a yield improvement of 30%.[87] In a model reaction studying β-galactosidase-catalyzed self-condensation of Gal-β-*p*NP, the adsorption of *p*NP-β-galactobioside to a boronate resin gave a yield improvement of 10−15%, the major issue being the discrepancy between the optimal reaction pH and the optimal binding pH.[88] In the sialidase-catalyzed production of 3′-sialyl-lactose from lactose and CGMP, the large size of the limiting substate, that is, CGMP, has been exploited to facilitate continuous product removal in an enzymatic membrane reactor.[40] The use of a membrane reactor also allows for enzyme recycling. Indeed, the biocatalytic productivity of an engineered sialidase from *T. rangeli* was improved by >9-fold in an enzymatic membrane reactor (EMR) compared to the batch process.[40] In this process the acceptor also passed the membrane, but because the acceptor is not limiting (used in 25-fold excess), this did not affect reaction yields negatively. By nanofiltration it was possible to recycle the majority of the unreacted lactose.[89] However, when all substrates are similar in size to, or even smaller than, the product, for example, in the case of GOS production from lactose, the EMR cannot be used because the substrate will not be rejected if the product is not. Nevertheless, EMRs have been used for removal of monosaccharides to avoid β-galactosidase inhibition in GOS production.[90,91]

## ENZYME IMMOBILIZATION

For a mutant sialidase from *T. rangeli* it was observed that the trans-sialylation yield was improved when the enzyme was immobilized, mainly due to a reduction in secondary hydrolysis.[40] Increased trans-glycosylation yields upon immobilization have also been observed for a sialidase from *V. cholerae*[37] and the GH family 42 β-galactosidase from *B. circulans*,[69] but with mixed effects on regioselectivity. It has also been reported that β-galactosidase-catalyzed GOS production is improved by enzyme immobilization, not only due to increased enzyme stability but also as a result of an improved balance between trans-galactosylation and hydrolysis.[87,92] Possible explanations for such an improvement in enzyme selectivity upon immobilization have recently been reviewed.[93]

## PROTEIN ENGINEERING

As outlined above, the rate of hydrolysis is decisive for trans-glycosylation yields. Consequently, several studies have aimed at producing mutant enzymes with lowered hydrolytic activity and unchanged or improved trans-glycosylation activity. The protein engineering approaches include directed evolution of a *T. maritima* α-L-fucosidase[51] and a β-galactosidase from *T. thermophilus*[94] as well as site-directed mutagenesis, or rational design, of a sialidase from *T. rangeli*.[2,95]

For the β-galactosidase from *T. thermophilus* a single mutation (F401S) just in front of the donor binding site caused repositioning of the donor and a better fit of the acceptor, thus favoring an attack by the glycosyl acceptor rather than from water.[94] The trans-galactosylation yield was improved from 8 to 60% when using cellobiose as acceptor. In fact, this mutant gave higher yields than the corresponding glycosynthase (see below) but with cheaper substrates. However, whereas the

trans-galactosylation/hydrolysis ratio was improved 23 times, the trans-galactosylation activity was only approximately 10% that of the wild type.[94] Molecular modeling was subsequently used for another mutant (N282T) that efficiently catalyzed donor self-condensation. This rational approach allowed identification of a mutation (A221W) that prevents donor access to the acceptor binding site without affecting the binding of the preferred donor (GlcNAc-$\beta$-*p*NP).[96] Both N282 and F401 are conserved and located around the donor binding site, and it was recently substantiated that targeting conserved residues in this location might be a general approach for improving trans-glycosylation in enzymes belonging to GH family 1.[97]

For the $\alpha$-L-fucosidase from *T. maritima* the regioselective trans-fucosylation yield increased from 7 to 62% upon introduction of three mutations in the second amino acid shell around the active site via directed evolution.[51] These mutations resulted in a 32-fold increase in the trans-fucosylation/hydrolysis ratio, and the regioselectivity was moreover significantly improved, whereas the mutant maintained 57% of the total activity of the wild type enzyme. On the basis of molecular modeling, the second shell mutations were hypothesized to cause reorientation of amino acids in the active site, resulting in a better docking energy of the product in the binding site.[51]

Due to strong structural and sequence similarity (70% identity) between the *T. cruzi* trans-sialidase and a strict sialidase from the nonpathogenic *T. rangeli*, this was used as a model system to understand the molecular basis for the trans-sialidase activity.[95,98] The pathogenic origin of trans-sialidases may complicate the process of obtaining approval for use in food applications,[4] and this has led to interest in the use of *T. rangeli* sialidase mutants.[2,4] Introduction of five mutations in the *T. rangeli* sialidase ($TrSA_{5mut}$) that affected the acceptor binding site and the sialic acid binding pocket conferred a weak trans-sialidase activity, equivalent to 1% that of *T. cruzi*.[95] Either of two additional mutations increased trans-sialidase activity 10-fold, but also increased $k_{cat}/K_m$ of the hydrolysis of the desired product 3′-sialyl-lactose 1.8-fold.[95] Additional substitution of a seven-amino-acid loop located near the acceptor binding site reduced the hydrolytic activity 4 times without affecting the trans-sialidase activity. The mutation introduced a net charge change of +3 that was hypothesized to result in partial reversal of the water network in the active site, consequently impairing the nucleophilicity of the water.[2] Molecular dynamics and free energy computations have improved the understanding of the mechanism of the *T. cruzi* trans-sialidase.[99,100] A redesign of the *T. rangeli* mutant $TrSA_{5mut}$ by five additional mutations identified by free energy computations was recently suggested but not validated experimentally.[101]

It is clear that alteration of the acceptor binding site and repositioning of the acceptor making its nucleophilic attack more favorable as well as stabilization of the glycosyl-enzyme intermediate are keys to improving trans-glycosylation activity. Toward the development of generic strategies for improving trans-glycosylation in glycosidases, there is a need for improving the understanding of the structure−function relationship to which mutational and structural studies are key. As outlined above, approaches such as molecular modeling and free energy computations have been used in a few cases, but can at present mainly be considered tools for the generation of hypotheses. Thus, improvement of trans-glycosylation by protein engineering requires a significant research effort compared to the other strategies for improving trans-glycosylation yields mentioned above.

**Glycosynthases.** Glycosynthases represent another protein engineering route to avoid contaminating hydrolysis.[102] They are mutant glycosidases, most often retaining ones, where the nucleophilic Asp/Glu residue has been changed to a non-nucleophilic one, for example, Ala, Ser, or Gly. By doing so, the enzyme loses its hydrolytic activity, but also its ability to form a covalent intermediate with the donor substrate (cf. Figure 1). Using an activated donor, most often a glycosyl fluoride, in the configuration opposite to that of the natural substrate they can efficiently catalyze the transfer of the glycosyl group to an appropriate acceptor with high yields.[103,104] Glycosyl azides and aryl glycosides have also been suggested as useful donors, but the field is dominated by glycosyl fluorides, although these are often unstable (especially the $\beta$-glycosyl fluorides used for $\alpha$-glycosynthase catalysis) and hardly commercially available.[105,106] The acceptors mainly include nitrophenyl or methylumbelliferyl derivatives of mono- and disaccharides.[105,107]

An $\alpha$-L-fucosynthase derived from an inverting 1,2-$\alpha$-L-fucosidase from *Bifidobacterium bifidum* (EC 3.2.1.63; GH 95) catalyzed the synthesis of 2′-fucosyl-lactose from $\beta$-fucosyl fluoride and lactose, reaching a 2′-fucosyl-lactose yield of only 6%, mainly due to decomposition of the unstable $\beta$-fucosyl fluoride donor.[108] An $\alpha$-L-fucosynthase based on the retaining $\alpha$-L-fucosidase (EC 3.2.1.51; GH 29) from the hyperthermophilic archaeon *Sulfolobus solfataricus* catalyzed fucosylation using the more stable $\beta$-fucosyl azide as donor. Fucosylation of Gal-$\beta$-*p*NP generated various regioisomers in a total yield of 26%, whereas GlcNAc-$\beta$-*p*NP was selectively fucosylated on *O*-3 with an efficiency of 86%.[109]

Complete regioselectivity was observed for an $\alpha$-L-fucosynthase developed from a retaining 1,3−1,4-$\alpha$-L-fucosidase (EC 3.2.1.111; GH 29) from *B. bifidum*; the enzyme catalyzed the synthesis of valuable biomimetic tri- and tetrasaccharides, including the HMOs 3-fucosyl-lactose (13% yield) and lacto-*N*-fucopentaose II (41% yield) as well as blood group antigens $Lewis^A$ (47% yield) and $Lewis^X$ (55% yield), using $\beta$-fucosyl fluoride as donor.[110] No products were obtained with $\beta$-fucosyl azide as donor.[110]

Sialidases employ a nucleophilic Tyr instead of the more common Asp/Glu. Not being actual glycosynthases, mutations of this nucleophilic Tyr in *Micromonospora viridifaciens* sialidase (EC 3.2.1.18; GH 33) resulted in a number of mutants that retained hydrolytic activity with either retention or inversion of configuration.[111,112] Using phenyl $\beta$-D-sialic acid as a donor, the inverting mutant Y370G catalyzed production of sialyl-lactose with a yield of 13%, with >90% being the $\alpha(2,6)$-isomer and with no subsequent product hydrolysis.[113]

However, it follows that glycosynthase catalysis releases either hydrofluoric acid (HF) or hydrazoic acid ($HN_3$) as its byproduct. Although numerous methods for the removal of fluoride ions from aqueous solution exist,[114] this issue of removal has hardly been addressed by any of the otherwise thorough reviews (see, e.g., refs 103, 105, and 106) of glycosynthases and the use of glycosyl fluorides as substrates. More importantly, the requirement for chemical synthesis to introduce the fluoride or azide groups into the donor substrates significantly increases the cost, thereby lowering the large-scale potential.[106] In conclusion, glycosynthases represent a simple protein engineering route to improved trans-glycosylation, but their use is restricted by the requirement for specialized and, in the case of $\alpha$-glycosidases, unstable substrates.

## CONCLUSIONS

All trans-glycosylation yields given in this paper are molar yields based on the donor. The yields obtained in the literature range from negligible values to as much as 99% of the desired trans-glycosylation product. Generally, the highest yields have been obtained by one or more of the following strategies to improve trans-glycosylation yields: (1) high acceptor/donor ratio; (2) protein engineering; and/or (3) addition of cosolvents, at least for enzymes that tolerate nonconventional solvents (Tables 1−4). When optimizing trans-glycosylation processes, not only the pH−temperature optimum but also the optimal reaction time must be established to avoid undesirable product hydrolysis. Alternatively, continuous product removal can be employed. If combined with enzyme recycling in an EMR, biocatalytic productivity may also be significantly enhanced.

Regioselectivity in the trans-glycosylation is mainly a result of the choice of enzyme, but can also be influenced by acceptor and donor structures, the acceptor/donor ratio, and the presence of cosolvents, as well as by temperature and pH. Thus, all of these factors need to be considered in the design of a trans-glycosylation process, where regioselectivity is important.

For food applications it is important to consider both cost and biocompatibility of substrates and reaction routes. Thus, it is desirable to employ substrates from natural sources such as lactose and CGMP, even if higher yields may be obtained with aryl or fluoride donor substrates.

>0.99. For method validation, intraday ($n$ = 5) and interday ($n$ = 5) accuracy and precision were determined by repeated analysis of three QC samples (10, 200, and 1000 ng/mL), and the resulting accuracy (as a percent difference from nominal values) and precision (as a percent relative standard deviation) did not exceed ±15% for all QC samples tested.

**Assay of β-D-glucosidase, α-L-rhamnosidase, and β-D-galactosidase Activities.** The enzyme activities were measured according to the previously reported method.[18]

**Statistical Analysis.** Data were presented as means ± standard deviation (SD). The statistical significance of the data was analyzed using Student's $t$ test. Differences at $p < 0.05$ were considered statistically significant.

## RESULTS AND DISCUSSION

In this study, we investigated the effects of the gut microbiota on the bioavailability of geniposide, a principal ingredient of *Gardenia* fruits, by using an antibiotics-treated rat model. We optimized the conditions for developing the antibiotics-treated rat model in our preliminary study; we examined the effects of several antibiotics and their combinations on the gut microbiota on the basis of their glycosidase activities (data not shown). Our results showed that an antibiotic mixture consisting of cefadroxil, oxytetracycline, and erythromycin showed the greatest inhibitory effect on metabolism by the gut microorganims and, thus, we used this mixture for treating the rats. Treatment with a mixture of these antibiotics significantly decreased the glycosidase activities of the intestinal microorganisms of the rat, including those of glucosidase, rhamnosidase, and galactosidase, and these effects lasted at least 2 days after the treatment (Figure 1).

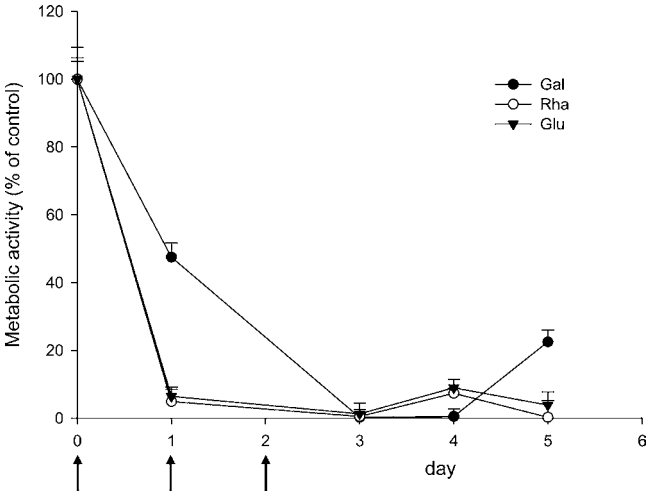

**Figure 1.** β-D-glucosidase (Glu), β-D-galactosidase (Gal), and α-L-rhamnosidase (Rha) activities in fecal samples of antibiotics-treated rats ($n$ = 3). Rats were orally administered cefadroxil (100 mg/kg), oxytetracyclin (300 mg/kg), and erythromycin (300 mg/kg) once per day for 3 days, and the fecal metabolic activities were measured for 5 days. Arrows indicate the administration of the antibiotic mixture. The control value represents the data measured before antibiotic treatment.

On the basis of the results of the intestinal metabolic activity profiles, we performed a pharmacokinetic analysis 2 days after the antibiotics treatment to rule out any possible pharmacokinetic interactions between the antibiotics and geniposide.

We administered GF to the rats to investigate the plasma pharmacokinetics of geniposide. GF is a standardized extract of *Gardenia* fruits, which contains geniposide as a principal ingredient (41.7%) and has trace amounts of genipin (<1.0%). Therefore, any possible effects caused by the biotransformation of GF-originated genipin can be excluded from the interpretation of the results of the pharmacokinetic data of geniposide.

After oral administration of GF to control and antibiotics-treated rats, geniposide level was determined in plasma and feces using LC-MS/MS. Representative LC-MS/MS chromatograms for geniposide are shown in Figure 2. The mean plasma concentration−time profiles of geniposide after oral administration of GF to control and antibiotics-treated rats are shown in Figure 3, and the pharmacokinetic parameters are summarized in Table 1. A marked difference was observed in the time to reach the maximum plasma concentration ($T_{max}$) and area under the curve (AUC) values between the control and antibiotics-treated groups (Table 1); the $T_{max}$ values were 1.69 and 3.13 h and the AUC values were 7.34 and 11.9 μg·h/mL, respectively, in the control and antibiotics-treated groups. A higher AUC value in the antibiotics-treated rats indicated that uptake of geniposide from the gastrointestinal tract increased by suppression of the enzyme activities of the intestinal microorganisms and subsequent increase in the concentration of unmetabolized geniposide.

**Table 1. Pharmacokinetic Parameters of Geniposide after Oral Administration in Control and Antibiotics-Treated Rats ($n$ = 4)**

| parameter | control | antibiotics-treated |
|---|---|---|
| $C_{max}$ | 0.91 ± 0.26 | 1.01 ± 0.04 |
| $T_{max}$ (h) | 1.69 ± 1.72 | 3.13 ± 2.39 |
| $T_{\lambda 1/2}$ (h) | 3.49 ± 1.13 | 3.28 ± 0.22 |
| AUC (μg·h/mL) | 7.34 ± 3.32 | 11.9 ± 2.1*[a] |

[a]*, $p < 0.05$, significant difference compared with control group.

The level of geniposide in the feces was determined to confirm that the biotransformation of geniposide to genipin was attenuated by treatment with antibiotics. The amounts of geniposide in the feces of the control and antibiotics-treated rats were 0.64 ± 0.96 and 15.6 ± 3.2 mg, respectively ($p < 0.01$). The significant increase in the level of fecal geniposide in the antibiotics-treated rats may be because of an increase in unabsorbed geniposide or an increase in the excretion of geniposide via the biliary route. However, in both circumstances, the increase can be attributed to an increase in the level of unmetabolized geniposide. The prolonged $T_{max}$ values in the antibiotics-treated rats could be understood in this context. Thus, the above factors may explain the prolonged $T_{max}$ values as well as the increased AUC values in antibiotics-treated rats.

Functional foods or medicinal plants have several different glycoside compounds as their bioactive ingredients. These glycoside compounds may be transformed to active, nonactive, or toxic metabolites by the intestinal bacterial glycosidase and, then, are absorbed from the gastrointestinal tract.[19] Therefore, alteration or differences in the profile and composition of the intestinal microbiota may lead to different metabolic capabilities of the gut microbiota and, consequently, result in different bioavailabilities of the bioactive ingredients. Thus, individual differences in the gut microbiota may cause different biological effects in individuals after consumption of functional foods. In addition, alterations in the intestinal microbiota induced by medication or pathological conditions may affect the biological activities of functional foods.

The role of gut microbiota in the metabolism of dietary compounds or phytochemicals and the resultant impacts on

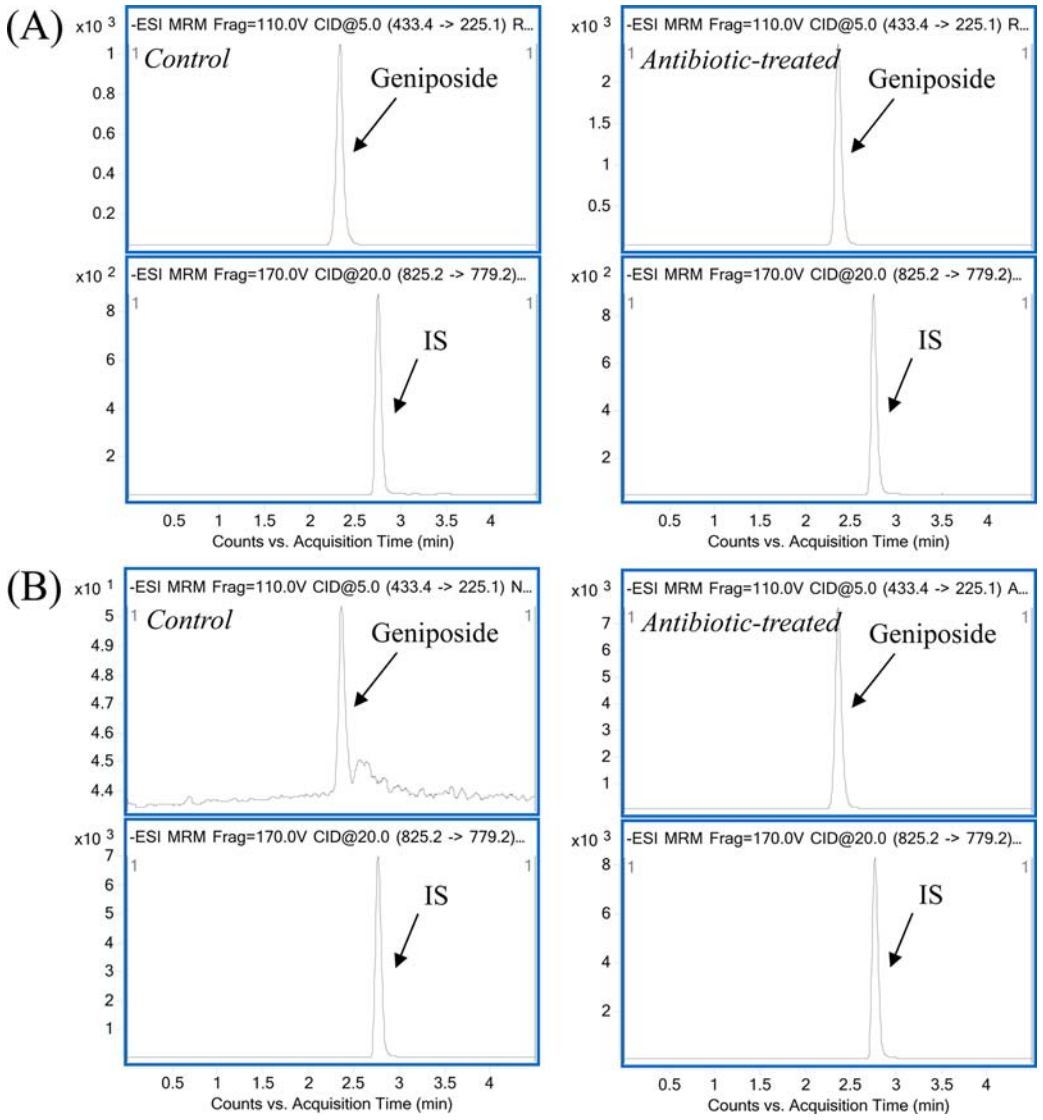

**Figure 2.** Representative LC-MS/MS chromatograms for geniposide in (A) plasma and (B) feces samples from control (left) and antibiotics-treated (right) rats. IS, internal standard (digoxin).

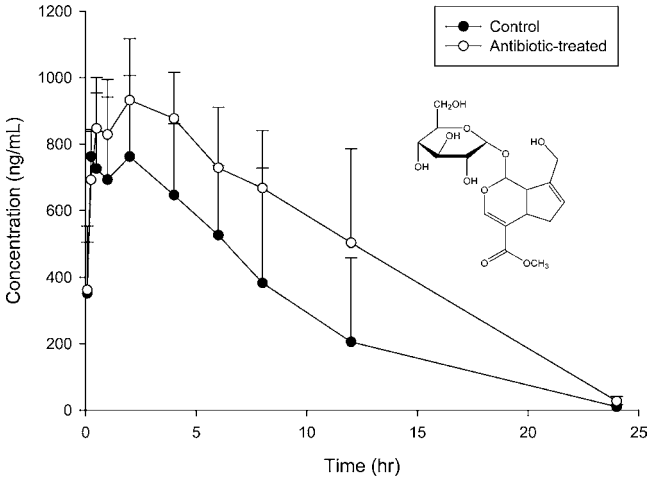

**Figure 3.** Mean plasma concentration−time profile of geniposide after oral administration of GF (equivalent to 250 mg/kg of geniposide) in control and antibiotics-treated rats ($n$ = 4).

bioactivity or toxicity have been extensively investigated.[20−24] Cycasin, a phytotoxin found in cycad trees, is hydrolyzed into the carcinogenic metabolite, methylazoxymethanol, by gut microbial enzymes and directly exerts its toxic effect.[25] Rutin, a citrus flavonoid glycoside found in many plants, also undergoes gut microbiota-mediated hydrolysis to yield its corresponding aglycone (quercetin) and phenolic metabolites, which may cause mutagenic effects.[26] Meanwhile, 2-methoxyestrone is converted to the active steroid form via demethylation, in which gut microbiota are believed to play an important role.[27] Microbial metabolism potentiates the clinical effects of baicalin by hydrolyzing it to generate its corresponding aglycone baicalein, which is readily absorbable and subject to reconjugation into baicalin.[28] Previously, we reported that the pharmacokinetics of hesperidin, a bioactive citrus flavonoid glycoside, was modulated by alteration of the metabolic activities of the intestinal microorganisms.[18]

In conclusion, our study showed that bioavailability of geniposide may depend on its metabolism by the gut microbiota. Thus, alterations in gut microbiota by external factors such as medications, pathological conditions, and food habits

dx.doi.org/10.1021/jf502557f | J. Agric. Food Chem. 2014, 62, 9632−9636

affect the bioavailability of geniposide. Geniposide possesses various biological activities; however, a recent study indicates that it may have toxic effects,[29] and a recent study has shown that human intestinal bacteria may affect the toxicity of geniposide through involvement in the biotransformation to genipin, its toxic metabolite.[30] Therefore, gut microbiota should be considered as a critical factor for understanding the clinical effects of geniposide.

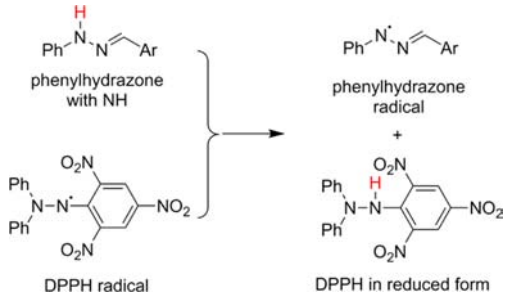

**Figure 1.** Reaction pattern of phenylhydrazones with DPPH radical proposed by predecessors,[28] in which the NH proton is necessary for the radical scavenging activity.

## METHODS

Materials and spectral data are presented in the Supporting Information.

**Synthesis and Purification.** The reaction route is outlined in Scheme 1. The previously reported protocol[29] has been adopted for preparing **2** and **3**. The authors changed "heating" to a milder "sun light at room temperature" condition in the bromination step. In the purification step, because of their similar polarities, single and double brominated substances along with nonbrominated compound **2** were collected together from a column using petroleum ether−EtOAc (2:1). Then, the mixture was oxidized by DMSO to give aldehyde **3** which was later purified by column (petroleum ether−EtOAc = 5:1). The preparations of **5a**−**5z** and **6a**−**6z** were performed according to the methods described by Harden et al.[30] and Belkheiri et al.,[25] respectively. The substituents introduced here include −Me, −OMe, −F, −Cl, −Br, $-NO_2$, $-CF_3$, $-OCF_3$, and −CN. Hydrazone crystals precipitated from methanol in the last step were filtered and washed gently with petroleum ether.

**Crystallographic Study.** The crystal of **6x** was obtained directly from mother methanol liquor without recrystallization. X-ray single-crystal diffraction data for compound **6x** were collected on a Bruker SMART AEPEX CCD diffractometer at 273(2) K using Mo K$\alpha$ radiation ($\lambda$ = 0.71073 Å) by the $\pi$ and $\omega$ scan mode. The program SAINT was used for integration of the diffraction profiles. The structure was solved by direct methods using the SHELXS program of the SHELXTL package and refined by full-matrix least-squares methods with SHELXL.[31] All non-hydrogen atoms of compound **6x** were refined with anisotropic thermal parameters. All hydrogen atoms were placed in geometrically idealized positions and constrained to ride on their parent atoms.

**Antifungal Activity Assay.** The antifungal activity was evaluated as reported protocols.[32,33] Preliminary determination of the inhibitory activity of compounds **6a**−**6z** against four plant-pathogenic fungi (*Rhizoctonia solani*, *Fusarium graminearum*, *Sclerotinia sclerotiorum*, and *Phytophthora capsici*) was conducted *in vitro* by using the mycelial growth test on PDA (Potato Dextrose Agar) medium. The compounds were dissolved in DMSO and then mixed with sterile molten PDA to obtain final concentrations of 10 $\mu g \cdot mL^{-1}$ (containing 4‰ DMSO). PDA with different compounds was poured into 90 mm Petri dishes (15 $mL \cdot dish^{-1}$), on which 5 mm mycelial disks of the four fungi were planted in the center. The disks were obtained from a pure PDA culture plate by punching at the edge of the actively growing mycelia colony. Three replicates were conducted for each treatment. The widely used commercial fungicides validamycin A and

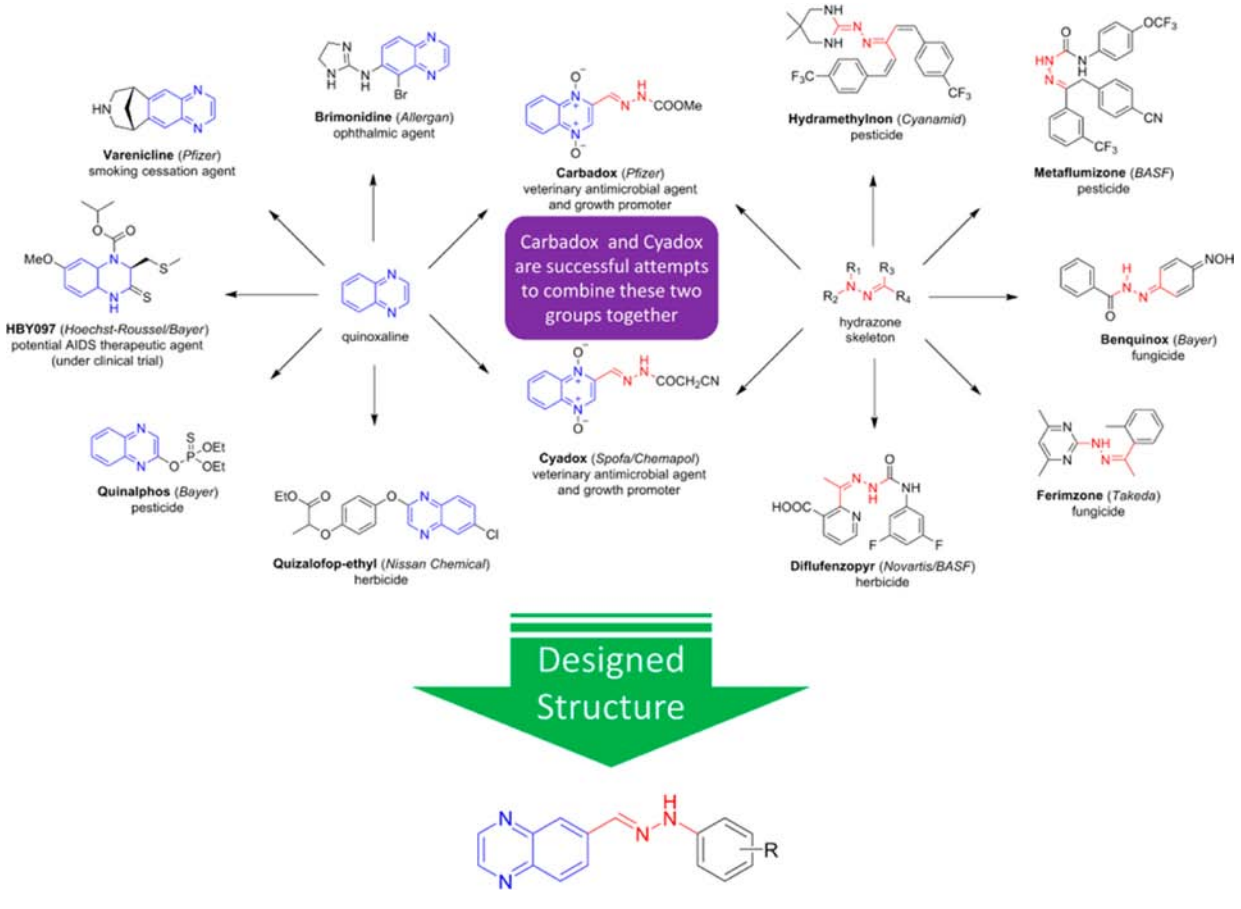

**Figure 2.** Design of the target structure: Above are examples of quinoxaline and hydrazone derivatives commercialized or under clinical trials as agrochemicals or pharmaceuticals. There are earlier successful attempts as Carbadox and Cyadox of combining the two groups together. Herein, we designed the structure below to discover novel biologically active candidates.

carbendazim were co-tested as positive controls while mere DMSO (4‰ contained in PDA) as negative control. After a certain incubation period (1.5 d for *R. solani*, 3 d for *F. graminearum*, 2.5 d for *S. sclerotiorum*, and 4 d for *P. capsici*, according to their different mycelial growth rates) at 25 °C in the dark, mycelial growth diameters were measured. The inhibition percentages were calculated as $(B - A)/(B - 5) \times 100\%$, where $A$ is the mycelial diameter (mm) in Petri dishes with compounds and $B$ is the diameter (mm) of the negative control.

Furthermore, the fungicidal activity of these compounds against *R. solani* was assessed in the same method as above. According to the preliminary test, these compounds were dissolved in DMSO to obtain different final concentration grads. Mycelial growth diameters were measured, and the inhibition percentages relative to the control with 4‰ DMSO were calculated. The $EC_{50}$ values were calculated using linear-regression analysis.

**DPPH Radical Scavenging Assay (RSA).** The scavenging rate of DPPH radical was carried out by the improved protocol of previous literatures.[34,35] Briefly, in 96-well microliter plates, 100 μL of different concentrations (2.5, 5, 10, 20, 40, 80, and 160 μg·mL$^{-1}$ in EtOH) of compounds **6a−6z** were mixed with 100 μL of DPPH solution (0.2 mmol·L$^{-1}$ in EtOH) to be detected as $OD_{6a}$−$OD_{6z}$. 100 μL of different concentrations (as above) of these compounds were mixed with 100 μL of EtOH to be detected as $OD_{6a}'$−$OD_{6z}'$. 100 μL of DPPH was mixed with 100 μL of EtOH to be detected as $OD_{blank}$. 200 μL of EtOH was to be detected as $OD_E$. And 100 μL of different concentrations (as above) of Trolox (positive control) were mixed with 100 μL of DPPH solution to be detected as $OD_T$. The reaction mixtures were shaken vigorously and stored in the dark at 25 °C for 30 min, and the absorbance (OD) was measured at 517 nm using a SpectraMax M5 microplate reader. All of the assays were performed

dx.doi.org/10.1021/jf504359p | J. Agric. Food Chem. 2014, 62, 9637−9643

three times. The radical scavenging rate was measured as a decrease in the OD of DPPH and was calculated using the following equation:

$$\text{scavenging rate } \% = 100 \times [(OD_{blank} - OD_E) - (OD_{6(a-z)} - OD_{6(a-z)}')]/(OD_{blank} - OD_E)$$

The concentration of a certain compound necessary to decrease the initial DPPH concentration by 50% ($EC_{50}$ $\mu g \cdot mL^{-1}$) was determined by linear regression analysis of data obtained by plotting the scavenging rate % against the concentrations of that compound.

**Inhibition of Microsomal LPO.** Mouse liver microsomes used for the LPO studies were prepared adopting the method in the literature.[36] The adult male mice (8−12 weeks old) of Kunming strain (purchased from the Comparative Medicine Center of Yangzhou University) were used for the preparation of liver microsomes. The protein content of microsomes was measured using the method in the literature.[37] Briefly, microsomes (0.67 mg of protein/mL) were incubated at 37 °C for 60 min with test compounds at varying concentrations, 10 mM $FeSO_4$ and 0.1 mM ascorbic acid in 1.0 mL of potassium phosphate buffer solution (0.2 M, pH 7.4). Afterward, the reaction was stopped by 20% (w/v) trichloroacetic acid (1.0 mL) and 0.67% (w/v) 2-thiobarbituric acid (1.5 mL) in succession. Then, the solution was heated to 100 °C for 15 min. After centrifugation of precipitated protein, the absorbance (OD) of the color reaction of malondialdehyde (MDA)−TBA complex was detected at 535 nm by a SpectraMax M5 microplate reader. Trolox was the positive control. In the same way as DPPH-RSA, the inhibition rates and $EC_{50}$ ($\mu g \cdot mL^{-1}$) values were determined.

## RESULTS AND DISCUSSION

**Synthesis.** The synthetic procedure for the title compounds is illustrated in Scheme 1. The condensation of 4-methylbenzene-1,2-diamine (**1**) and oxalaldehyde gave 6-methylquinoxaline (**2**) in high yield (85%). Next, **2** was bromized by *N*-bromosuccinimide. This free radical reaction was initialized by benzoyl peroxide giving single and double brominated substances, which were later oxidized by DMSO under base conditions to give quinoxaline-6-carbaldehyde (**3**). The yield from **2** to **3** is 33%. In order to investigate how substituents on the phenyl ring influence the activities, 26 substituted anilines were treated to give the final products. The anilines **4(a−z)** were diazotized by $NaNO_2$ to give substituted benzenediazoniums, which were then reduced by $SnCl_2$ to give substituted phenylhydrazines **5(a−z)** in 60−80% yield. Finally, **3** and **5(a−z)** were condensed to form the —C═N—NH— bond, giving (*E*)-6-((2-phenylhydrazono)methyl)quinoxaline derivatives **6(a−z)** in 62−84% yield. $^1H$ NMR, $^{13}C$ NMR, and ESI-MS spectra and elemental analysis data of the achieved compounds given in the Supporting Information were in full accordance with their assigned structures.

**The Crystal Structure of Compound 6x.** The crystal data of compound **6x** are presented in Table 1, and Figure 3 gives a perspective view of **6x** with the atomic labeling system.[38] The result demonstrates the —C═N—NH— bond bears an (*E*) rather than (*Z*) conformation.

**Antifungal Activities *in Vitro*.** The preliminary determination of the inhibition rates of compounds **6a−6z** (10 $\mu g \cdot mL^{-1}$) against four plant-pathogenic fungi (*R. solani*, *F. graminearum*, *S. sclerotiorum*, and *P. capsici*) is shown in Table 2. The data suggest that all the compounds show great activities against *R. solani*, with only **6q** lower than 10% and the other 25 compounds higher than 50%. At the tested dose, five compounds inhibited *F. graminearum* with an inhibition rate higher than 50% and four compounds against *S. sclerotiorum*. In contrast, all the compounds inhibited the growth of *P. capsici*

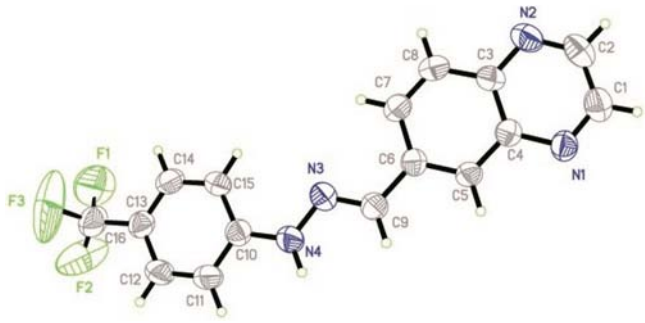

**Figure 3.** ORTEP view showing the atom-labeling scheme with thermal ellipsoids drawn at 30% probability for compound **6x**.

[a]Four plant-pathogenic fungi were employed with the concentration of compounds (**6a−6z**) being 10 $\mu g \cdot mL^{-1}$.

with an inhibition rate lower than 50%. It is obvious that these derivatives are exclusively efficient against *R. solani* mycelial growth *in vitro* but not potent enough against the other three candidates. Thus, *R. solani* was selected as the target for further research.

Afterward, different concentrations of compounds **6a−6z** were treated against *R. solani*. The $EC_{50}$ values were calculated using linear-regression analysis, with validamycin A and carbendazim as positive controls (Table 3). Except for **6q** and **6u**, all the other compounds show great inhibitory activities. Among these 24 compounds, **6a−6c**, **6e**, and **6o** are slightly weaker than validamycin A (5.07 $\mu g \cdot mL^{-1}$), while the other 19 compounds are more potent than validamycin A. Interestingly, 15 compounds are superior to carbendazim (1.42

[a]Values are the mean ± SD of three replicates.

$\mu g \cdot mL^{-1}$). The most promising compound **6p** is 10-fold more potent than the control carbendazim (0.16 vs 1.42 $\mu g \cdot mL^{-1}$). Structure and activity relationship (SAR) analysis indicates two general rules: (i) The electron-withdrawing groups are more favorable than the electron-donating counterparts. The electron-withdrawing compounds (**6f−6z**) as a whole are more potent than **6a** (nonsubstituted) and electron-donating compounds (**6b−6e**). Among the later, except **6d** (1.84) which is slightly stronger than **6a** (4.98), the other three **6b** (6.57), **6c** (4.68), and **6e** (5.98) share the same order of magnitude with **6a**. (ii) *meta* and *para* positions are more beneficial than *ortho* ones. Taking chloro substituents (**6k−6p**) into account, it is obvious that **6m** (*p*-Cl, 0.33) > **6l** (*m*-Cl, 0.73) > **6k** (*o*-Cl, 0.81) (">" means more potent). The di-*ortho* substituent **6o** (2,6-Cl, 5.33) shows the poorest activity, which is even weaker than **6a** (4.98). The 3,4-dichloro substituent **6p** (0.16) shows the strongest activity, which is much more superior than carbendazim (1.42 $\mu g \cdot mL^{-1}$). This rule can also be found in **6b−6d** (−Me), **6f−6i** (−F), **6r−6s** (−Br), and **6w−6x** ($-CF_3$) groups. In conclusion, *meta* and *para* substituents enhance the activity, whereas *ortho* ones debase.

**Antioxidant Activities *in Vitro*.** Two methods were applied to evaluate the antioxidant activities of the 26 compounds. The DPPH method was adopted to assess the radical scavenging activity (RSA), while the LPO method (*in vitro*) was employed to measure the inhibitory activity of microsomal lipid peroxide (LPO). Two series of data are exhibited in Table 4. In RSA, the most potent compound **6e** (7.60) is comparable with the positive control Trolox (5.90), indicating strong radical scavenging activity. As for LPO, besides **6u**, **6q**, and **6t**, the other 23 compounds show greater activities than Trolox (18.23). The most potent compound **6a** (0.96) displays an excellent LPO inhibitory activity with an $EC_{50}$ as low as 1/19 that of Trolox.

SAR analysis reveals some common rules for the two methods referring to antioxidant. The electron-donating groups (**6b−6e**) are generally more beneficial than the electron-withdrawing ones (**6f−6z**). The electron-withdrawing substituents, especially $-NO_2$, $-CF_3$, and −CN, are not favorable in both evaluation systems.

In conclusion, 26 novel phenylhydrazone derivatives linked to the quinoxaline nucleus (**6a−6z**) were synthesized. Antifungal and antioxidant evaluations indicated them to be potential fungicides and/or antioxidants.

Table 4. DPPH Radical Scavenging Activity (RSA) and LPO Assay *in Vitro* Data of Compounds 6a−6z[a]

| | DPPH-RSA | microsome LPO |
|---|---|---|
| compound | $EC_{50}$ ± SD ($\mu g \cdot mL^{-1}$) | $EC_{50}$ ± SD ($\mu g \cdot mL^{-1}$) |

commercial enzymes Olivex, Novoferm 31, Celluclast, and Pectinex AR were kindly provided by Novozymes A/S (Madrid, Spain).

**Plant Material.** White asparagus byproducts were obtained from local producers (Seville, Spain) and were frozen with liquid nitrogen until further use.

**Extraction of Cell Wall Bound PODs.** The residue from the extraction of the soluble POD[9] was re-extracted as described below. The residue (500 g) was homogenized in a Janke & Kunkel Ultraturrax T-25 (IKA-Labortechnik, Staufen, Germany) at top speed for 3 min with 500 mL of 50 mM Tris-HCl buffer, pH 7.0, containing 1 g/L ascorbic acid and 1 M potassium chloride. Afterward, the solid residue was recovered by filtration through nylon. This procedure was repeated twice to maximize the extraction yield. The filtrates were pooled to get the ionic POD extract. The solid residue was washed three times with water prior to the extraction of the covalent peroxidases. Then it was resuspended in a 50 mM sodium acetate buffer, pH 5.0, with 5.0% (v/v) of a commercial enzymatic mixture, Olivex (Novozymes A/S) and subjected to agitation for 12 h at 25 °C followed by centrifugation at 21214*g* for 30 min. The supernatant was saved and aliquoted for further analysis.

**Assay for the POD Activity.** POD activity was determined with ABTS as the reducing substrate in a total volume of 0.2 mL. The assay mixture contained 20 $\mu$L of a 1 M acetate buffer with a pH of 5.0, 20 $\mu$L of 1 mM ABTS, and 20 $\mu$L of 0.3% $H_2O_2$ and variable amounts of $H_2O$ and enzyme preparations to reach the final assay volume. The oxidation of ABTS was followed by monitoring the increase in absorbance at 415 nm and using $\varepsilon_{415\ nm}$ = 31.1 $mM^{-1}$ $cm^{-1}$ for ABTS cation radical formation.[17] One unit of activity (UA) was defined as the amount of enzyme required to oxidize 1 $\mu$mol of ABTS per minute at pH 5.0 and 25 °C. A Bio-Rad iMark microplate reader was used for the spectroscopic measurements.

**Protein Determination.** Protein was quantified on the basis of the dye-binding method of Bradford using bovine serum albumin (BSA) as standard.[18]

**Isoelectric Focusing (IEF).** Preparative IEF was carried out using a Rotofor preparative IEF cell (Bio-Rad). The protein samples were dialyzed against deionized water overnight, supplemented with 2% (v/v) Biolytes (Bio-Rad) of 3.0−10.0 pH range, and then loaded into the Rotofor cell. The IEF, without prerunning, was done according to the manufacturer's instructions. The power supply was set at a constant power of 12 W. Once focusing was complete, the electrofocusing cell was fractionated into 20 aliquots ranging from acidic to basic isoelectric point (p*I*) proteins. POD activity and protein contents were determined for each aliquot.

**Gel Electrophoresis.** SDS-PAGE of the crude extract and purified fraction was performed on a 12% acrylamide minigel in a Bio-Rad protein II electrophoresis cell set at 150 V for 120 min according to the method of Laemmli.[19] Protein band detection was conducted by silver staining as previously described by Rabilloud.[20] Molecular weights of the bands were calculated using Labimage software v2.7.1 (Kapelan Bio-Imaging).

**Purification of Anionic POD.** The different samples were dialyzed against deionized water, centrifuged at 21214*g* for 2 h at 4 °C, and filtered prior to purification. The chromatography purification steps were carried out at room temperature.

**Affinity Chromatography.** The low p*I* fractions from the IEF showing POD activity were combined and loaded into a concanavalin A−Sepharose affinity column (Amersham Pharmacia Biotech, Uppsala, Sweden) pre-equilibrated with 20 mM Tris-HCl buffer at pH 7.0 containing 0.5 M NaCl at a flow rate of 0.3 mL/min. Unbound proteins were removed by repeated washings with concanavalin A loading buffer at 1.0 mL/min. Anionic PODs were eluted from the resin with two successive washes with 5 column volumes of loading buffer containing 0.5 M methyl-$\alpha$-D-glucopyranoside. The resin was left in contact with the buffer for 1 h for the first elution and overnight for the second elution. Afterward, the column was washed with 1.0 M methyl-$\alpha$-D-glucopyranoside to elute the proteins strongly bound to the column. Fractions of 6 mL were collected during all of the chromatography steps, and the POD activity and protein content were measured.

**Effect of pH on POD.** POD activity as a function of pH was established by incubating the purified POD in 1 M sodium acetate buffer (pH 3.0−5.0), 1 M sodium phosphate buffer (pH 5.0−7.0), and 0.05 M Tris-HCl buffer (pH 7.0−9.0). Analysis conditions were the same as those described for the POD activity assay.

**Determination of Optimum Temperature and Thermal Stability.** The optimal temperature and thermal stability of PODs were assayed using a water bath (Precis-Term P-Selecta) with the optimal pH at temperatures ranging from 15 to 80 °C for 10 min prior to substrate addition. After heating, the solutions were rapidly cooled in ice water, and the POD activity was immediately determined. The percent residual activity was plotted against different temperatures. Thermal stability was also tested at various temperatures in the range of 50−85 °C with exposure times ranging from 1 to 30 min.

**Kinetic Constants for ABTS and $H_2O_2$.** Kinetic parameters were calculated from Lineweaver−Burk plots for the two-substrate mechanisms followed by POD[15] using $H_2O_2$ and ABTS concentrations from 0.1 to 10 mM, respectively. Temperature and pH were kept constant in the optimum values determined previously. Taking into account the reciprocal of both sides of the Michaelis−Menten equation leads to the Lineweaver−Burk relationship

$$1/\nu_0 = K_a/A_0V_{max} + K_b/B_0V_{max} + 1/V_{max}$$

where $\nu_0$ is the initial reaction velocity, $V_{max}$ is the maximum reaction velocity, $K_a$ and $K_b$ are $K_m$ values, the Michaelis−Menten constant for substrate A ($H_2O_2$) and B (ABTS), respectively, and $A_0$ and $B_0$ are substrate A and B concentrations. The $\nu_0$ were determined as a function of both substrate concentrations. A plot of $1/\nu_0$ versus $1/B_0$ for varying values of $A_0$ will give a series of parallel lines, each of slope $K_b/V_{max}$. A plot of intercept versus $1/A_0$ will give a line of slope $K_a/V_{max}$ and intercept $1/V_{max}$. Hence, $K_a$, $K_b$, and $V_{max}$ may be determined.

**Removal of Phenolic Compounds.** We evaluated the catalytic activity of the purified PODs using different model compounds such as monoaromatic phenolic type 4-chlorophenol (4-CP), 2,4-dichlorophenol (2,4-DCP) as a model of the disubstituted substrate, and 2-(3,4-dihydroxyphenyl)ethanol [hydroxytyrosol (HT)], a polyphenol present in olive mill wastewater. The assays were performed in a reactor at room temperature. All substances were dissolved in 1 M acetate buffer at pH 4.0. The optimal ratio of AAP and $H_2O_2$ concentration for phenol removal was investigated using $H_2O_2$ concentrations between 1 and 20 mM. To study the influence of AAP, $H_2O_2$, and their combination on the removal of phenols, we followed different incubation conditions: (a) a control solution that consisted of 2 mM phenol, (b) 2 mM phenol and $H_2O_2$, (c) 2 mM phenol and CAP, and (d) 2 mM phenol, $H_2O_2$, and CAP. The course of the reaction was monitored by taking 1 mL of sample, and the concentration of the phenol was analyzed until the value was constant.

**Phenol Quantification.** The removal of each phenol was monitored by high-performance liquid chromatography (HPLC) and an ultraviolet detector. The aliquots were taken from model wastewaters at the indicated times. The reaction was stopped by the addition of 10 $\mu$L of 20% trichloroacetic acid (TCA). After centrifugation, 20 $\mu$L was injected into a MediterraneaSea C18 (Teknokroma), 5 $\mu$m, 25 × 0.6 mm reversed phase HPLC column. The initial mobile phase consisted of 70:30 (v/v) water/acetonitrile with 0.1% formic acid, which was brought to 0:100 (v/v) in a linear gradient lasting for 20 min, held for another 10 min, and then 5 min of 30% acetonitrile. Phenol concentrations were determined from a straight-line standard calibration obtained using known concentrations (standards) of each compound. The results are expressed as removal efficiency, which is defined as the percentage of phenols removed from the solution under the established experimental conditions.

**Statistical Analysis.** The mean ± SD of three replicates was calculated. All data were analyzed using multivariate analysis of variance (MANOVA) followed by the Fisher−LSD multicomparison test. The level of significance was $p < 0.05$.

## RESULTS AND DISCUSSION

**Extraction of Cell Wall Bound PODs.** It is known that a great part of the apoplastic PODs is associated with cell walls either by ionic interactions or by covalent bonds. In this study, we

have developed a sequential method to extract the different forms of peroxidases that were ionically and covalently bound to the cell wall of the asparagus tissues.

The wall-bound POD can partially be released by treatment with a high-molarity solution of NaCl or other salts. In our method, after the extraction of the soluble fraction,[9] the cell walls still contained a considerable amount of POD activity. We performed a washing procedure to determine if POD activities were loosely bound to the cell wall or entrapped inside the intracellular vesicles. The residue obtained after soluble POD extraction was suspended in the same buffer used but with added 1.0 M KCl. Then we followed the extraction procedure for ionic isoenzymes as described under Materials and Methods. The crude extract contained 0.89 UA POD/g fresh material. This value represents a small quantity of the ionically bound PODs (IBPs) compared to soluble PODs (5.31 UA/g fresh material).[9] The highly soluble to IBP ratio has also been reported for other plant foods, such as peaches (5:1),[21] mustard (2:1),[22] and artichoke hearts (6:1).[29]

After extraction with high ionic strength, the cell walls were used as substrate to test the further extractability of POD by the enzymatic method to get the covalently bound PODs (CBPs). Treatment of the cell walls for 12 h with 50 mM acetate buffer, pH 5.0, and various commercial enzymatic preparations with different hydrolytic activities was assayed (Table 1). The POD activity was measured after the enzymatic hydrolysis of the cell walls. As shown in Figure 1, Novoferm 31 extracted the same peroxidase amounts as those detected in the control. After the hydrolysis by Celluclast, the POD activity was higher than that detected in the control sample, but Celluclast did not efficiently extract the CBPs. The treatments of cell wall with Pectinex AR or Olivex resulted in the most efficient extractions. These enzymatic mixtures contain similar polygalacturonase and pectin esterase activities (Table 1), but Olivex possesses higher cellulase activity. To determine if the different efficiencies of these two commercial preparations were due to their different cellulase activities, a mixture of Pectinex AR plus Celluclast was also tested. A similar treatment on oat cell wall led to maximum recovery of CBPs.[23] However, in asparagus byproduct cell walls, the CBP released after the treatment with the combination enzymatic mixture was the same as that obtained with Olivex alone. On the other hand, it is noteworthy that Novoferm 31, despite possessing an enzymatic composition similar to those of Olivex and Pectinex AR, is not effective for the release of peroxidase tightly bound to the cell wall. This fact could be due to the inactivation of the enzymatic mixture or to the presence of some inhibitors. These findings suggest that the concerted action of polygalacturonase, pectin esterase, and cellulase is required to efficiently release CBPs. In fact, with this method we found that the cell walls from the asparagus byproduct possess a high CBP (4.11 UA/g fresh material). This value was similar to the previously reported cytoplasmatic POD (5.31 UA/g).[9] In total, the POD activity in the crude extract of asparagus byproducts was 10.31 UA/g fresh material. This value is higher than values reported for typical sources of peroxidase such as turnip extract (6.5 UA/g)[24] and broccoli (3.5 UA/g).[25] Ionic forms of POD represent <10% of the activity detected (0.89 UA/g); thereby, the CBP is a good source for peroxidase, whereas in other plants this fraction is considered too low to be assayed.[13]

**Table 1. Relation of Enzymatic Commercial Mixtures Used for Covalently Bound to the Cell Wall Peroxidase Extraction and Enzymatic Activity[a]**

| | Celluclast | Pectinex AR | Olivex | Novoferm 31 |
|---|---|---|---|---|
| polygalacturonase | 0.0 | 12.3 | 15.8 | 17.3 |
| pectin esterase | 0.3 | 3.6 | 3.3 | 2.3 |
| cellulase | 8.6 | 0.1 | 1.5 | 3.8 |
| glucosidase | 0.1 | 0 | 0 | 0 |

[a]Values corresponding to activity measured as $\mu$kat mL$^{-1}$.

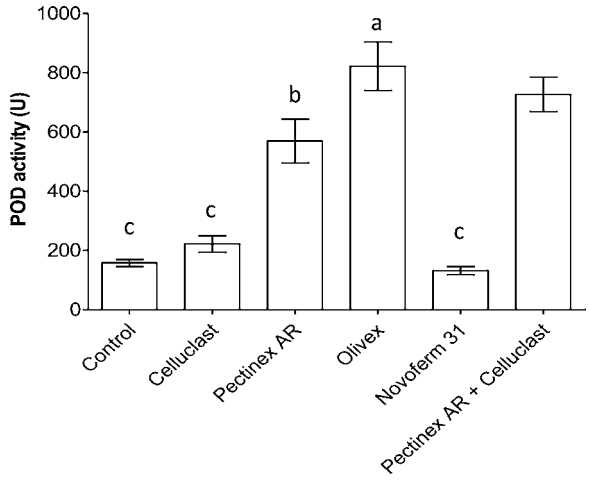

**Figure 1.** Covalently bound peroxidase activity released by different enzymatic mixtures.

**Isoelectric Focusing of Cell Wall Bound POD.** The distinct forms of the peroxidases from the cell walls were characterized by IEF in a pH range of 1−12. Different patterns of activity were obtained for the ionic and covalent fractions (Figure 2). IBP included a broad range of acid (p*I* ca. 4−5), neutral (p*I* ca. 6−7), and basic (p*I* ca. 8−12) isoforms (Figure 2A). A similar IEF profile has been described in flax fibers.[26] However, in green asparagus the IEF profile for ionic POD was similar to that of the soluble POD.[9] These isoenzymes are mainly neutral isoforms, and the activities of the isoenzymes with p*I* between 5 and 7 were weak.[27]

The IEF profiles obtained for CBP showed a group of anionic isoforms (p*I* ca. 5−6), whereas the extreme cationic isoforms present in the soluble and ionic fractions were absent or negligible in the covalent fraction (Figure 2B). A similar IEF pattern has been described for the covalent fraction of proteins from pea root.[28]

Consequently, although CBP is constituted mainly of anionic isoenzymes, the IBP showed a very broad isoenzymatic profile and is a mixture of cationic neutral and anionic isoforms.

**Purification of Anionic POD.** The POD activity in the crude IBP was lower (0.89 UA/g fresh material) than the activity measured in the CBP (4.11 UA/g fresh material), which was similar to the POD activity in the soluble fraction.[9] Previously, we had developed a method for the purification of cationic POD,[9] and here we present a new method to purify the anionic asparagus POD present in the cell wall of asparagus byproducts (AAP). The specific activity and purification factor for the CBP extract are shown in Table 2. The CBP was purified in two consecutives steps: isoelectric focusing and affinity chromatography on concanavalin A. The specific activity of the crude extract was low due to a high content of proteins from the commercial enzymatic mixture and the proteins extracted.

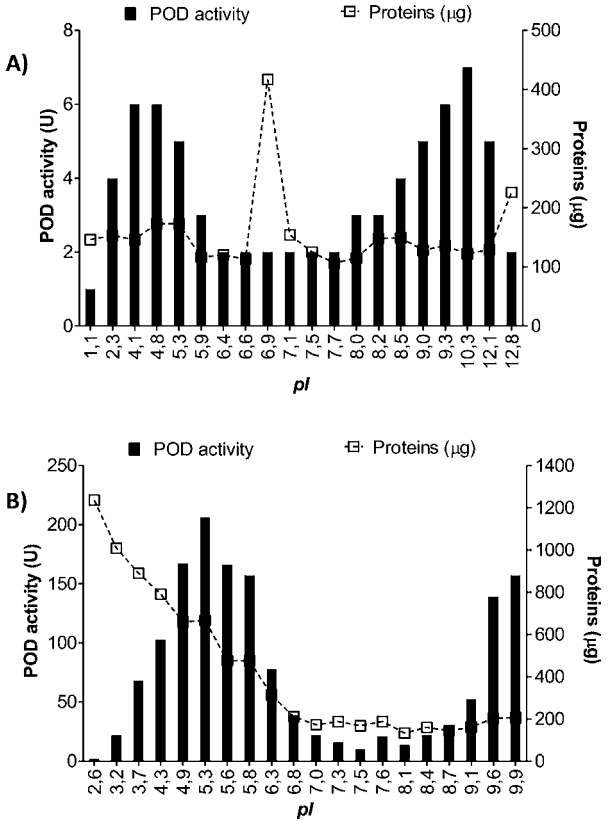

**Figure 2.** Isoelectric profile for ionically bound (A) and covalently bound (B) to cell wall POD from asparagus byproducts.

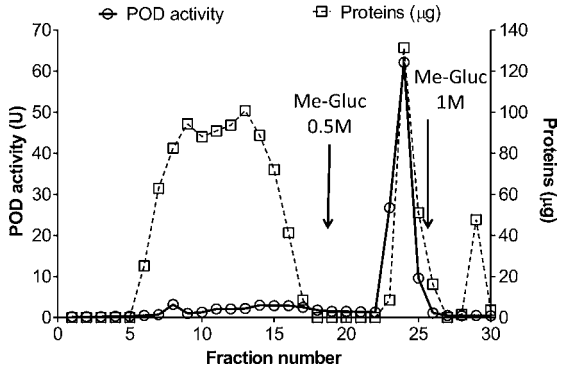

**Figure 3.** Typical elution profile for affinity chromatography of the anionic isoperoxidase fraction.

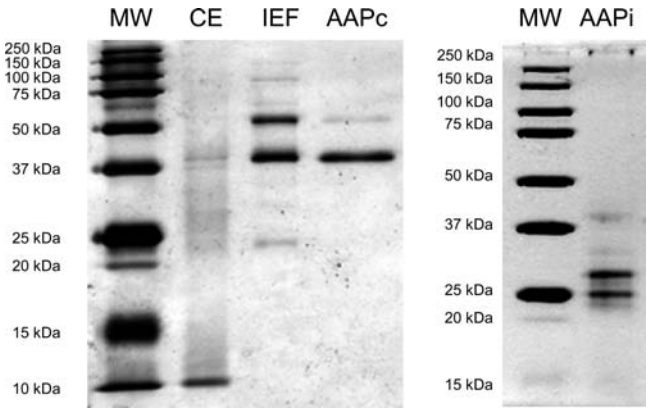

**Figure 4.** SDS-PAGE after 5 min of exposure to the developer ($Na_2CO_3$) of the crude extract, the A1 fraction, and the Con A-purified AAP. Molecular weights (MW) are for 250, 150, 100, 75, 50, 37, 25, 20, 15, and 10 kDa.

The IEF profile of the CBP showed several bands with p*I* values between 4.3 and 5.8 (Figure 2B). These fractions were pooled and separated from the basic isoenzymes, which improved the purity of the enzymes (21-fold, Table 2) and reduced the volume of the crude sample by 32% before the subsequent chromatography step. The pooled acidic fractions, representing 68% of the total activity of the crude extract, were dialyzed and transferred onto the concanavalin A−Sepharose column as described under Materials and Methods. Concanavalin A is a lectin that binds to the carbohydrate molecules containing α-D-mannopyranosyl, α-D-glucopyranosyl, and sterically analogous residues. Figure 3 indicates that POD activity was mainly distributed as a single peak separated from the protein fraction. This purification step allowed us to obtain pure anionic asparagus POD (AAP) with high specific activity from asparagus byproducts (Table 2). Overall, the enzyme was purified about 236 times and showed a high yield for recovery of the activity.

**Partial Characterization of AAP.** SDS electrophoresis was monitored through protein band analysis to determine the molecular weight of the proteins of the isolated fractions (Figure 4). After the IEF purification step, the ionic and covalent proteins showed different protein bands after SDS electrophoresis. The ionic fraction contained two main bands of 25 and 28 kDa and three other faint bands of 23, 32, and 40 kDa. Conversely, the IEF fraction contained two main bands of 40 and 53 kDa and four other faint bands of 20, 65, 90, and 130 kDa. These faint bands were not present after concanavalin A column purification, and the band of 53 kDa was greatly diminished, suggesting that most of the anionic proteins of this molecular weight lack glycosidic residues. Interestingly, small proteins seemed to be ionically bound to the cell walls, whereas medium and large proteins are mainly bound to the cell wall covalently. A previous study on artichokes also found that the molecular weight of POD isoforms in the ionic fraction was smaller than that of covalently bound proteins in the leaf and heart.[29] In pea root, a covalent POD of 70 kDa with nine isoenzymes was described.[28] A relationship between the size, the ionic strength of the POD, and the number of glycosylated residues of amino acids for cell wall anchoring may exist. As we have detailed by IEF, the p*I* of the ionically bound POD is lower than the covalently bound POD. Moreover, basic PODs from asparagus have a p*I* far from 7.0, and their molecular weights have been described to be 23, 27, and 43 kDa.[9]

**Table 2. Summary of the Purification of AAP from Asparagus Byproducts**

| purification step | total activity (UA) | total protein (mg) | specific activity (UA/mg) | recovery activity (%) | purification factor |
|---|---|---|---|---|---|
| crude extract | 491 ± 7 | 923 ± 8 | 0.53 | 100 ± 1 | 1 |
| IEF | 334 ± 9 | 30 ± 4 | 11.08 | 68 ± 4 | 21 |
| dialyzed extract | 323 ± 7 | 27 ± 5 | 11.96 | 66 ± 6 | 22 |
| Con-A | 75 ± 4 | 0.6 ± 0.03 | 125.0 | 25 ± 3 | 236 |

**Optimal pH of AAP.** The optimal activity of AAP was tested against different pH values by using ABTS as substrate. To rule out any buffer effect on the peroxidase activity, we checked that at pH 5 with acetate buffer and with phosphate buffer the POD activity was the same and that this was also true at pH 7 with phosphate buffer and Tris buffer, respectively. AAP displayed a typical bell-shaped pH profile (Figure 5A), which exhibited

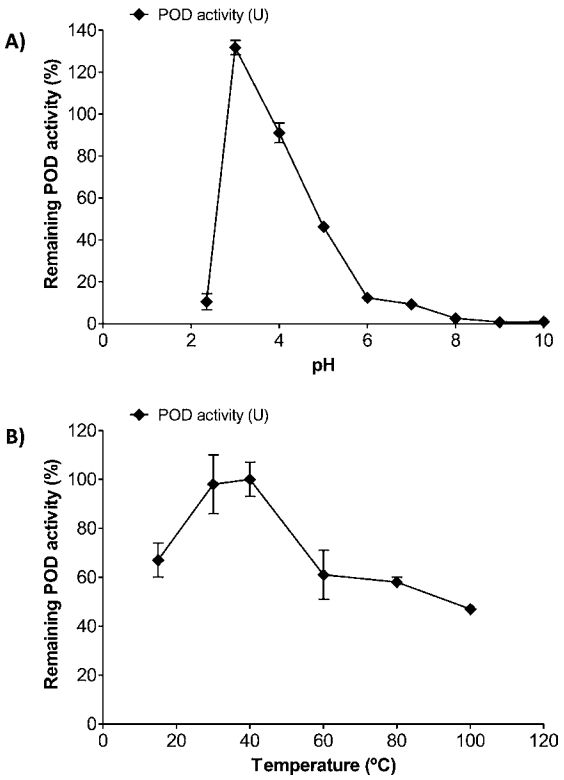

**Figure 5.** Optimal pH (A) and temperature (B) for the enzymatic activity of purified AAP using ABTS as substrate. Values are the means of triplicates ± SD.

stronger activity in a pH range of 3.0−5.0, with an optimal pH of 3.5. At pH 5.0 the AAP activity was around 50% of the maximum activity. In asparagus, the optimal pH for the activity of AAP was lower than those purified from other vegetable sources such as red cabbage (pH 4.0),[12] red algae (pH 5.0),[30] or sweet potato tubers (pH 4.5).[31]

**Thermal Stability of AAP.** The optimal temperature for AAP was between 35 and 40 °C (Figure 5B). These values agree with those obtained for the covalent POD of green asparagus.[27] The $T_m$ value for AAP was around 100 °C, which highlights the thermal stability of the enzyme compared to CAP.[9] To characterize the biocatalytic properties of the AAP, the percent remaining activity was plotted against time (Figure 6). The exposure of the AAP for 30 min at 60 °C did not decrease its activity, whereas the exposure of the AAP at 70 °C for 30 min reduced the POD activity by up to 50%. These results corresponded with the monophasic behavior described for green asparagus extracts treated between 50 and 60 °C.[32] Other authors reported that several POD forms had a higher thermal stability as no reduction in the POD activity was found below 80 °C.[32] From a technological point of view, this is an important outcome as treatment at high temperatures (80−90 °C) provoked a drastic loss in the AAP activity in 5 min. Similar to CAP,[9] Figure 6 shows that the remaining activity gradually

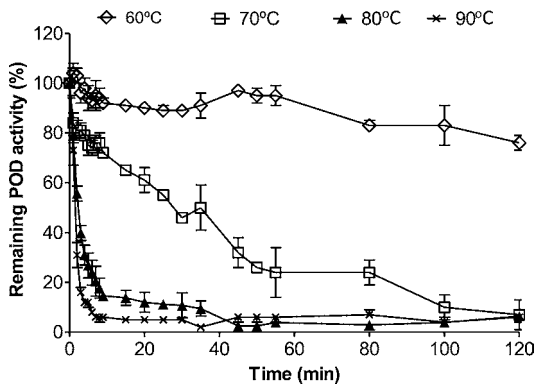

**Figure 6.** Thermal inactivation of purified AAP at 60, 70, 80, and 90 °C. Values are means of triplicates ± SD.

decreased as the temperature increased, yielding nonlinear curves. Our results agreed with those of Ganthavorn et al.,[33] who reported on partially purified raw POD extracts from green asparagus. Their data closely corresponded to a monophasic behavior at 50 and 60 °C and a biphasic behavior at 70 °C.

**Kinetic Constants for ABTS and $H_2O_2$.** The Michaelis−Menten equation is used to distinguish among the ordered, random, and ping-pong mechanisms and to obtain the $K_m$ values for both substrates (ABTS and $H_2O_2$). The purified AAP showed typical Michaelis−Menten kinetics for both ABTS and $H_2O_2$. The substrate saturation curve was obtained by interpolating the substrate concentrations against activity values. Michaelis−Menten constants ($K_m$) were determined from Lineweaver−Burk plots. The double-reciprocal plots of the AAP kinetics are shown in Figure 7A, where the parallel lines indicate that AAP follows a ping-pong mechanism. The calculated *y*-intercepts were plotted against $1/A_0$ and resulted in a straight line (Figure 7B), from which we achieved the $V_{max}$ = 0.695 mM ABTS $min^{-1}$. The $K_m$ value for $H_2O_2$ was found to be 0.53 mM. This value was lower than that reported for turnip POD (0.8 mM).[34] The ABTS $K_m$ value was 0.21 mM, which is 60 times lower than the value reported for red algae POD (13 mM)[30] or turnip POD (0.71 mM).[34] This indicated that AAP may be suitable for applications requiring a high sensitivity for ABTS.

**Phenolic Compound Removal by AAP.** We have previously characterized the activity of cationic POD from asparagus byproducts for removing phenolic compounds such as HT (which is found in olive oil wastewaters at high concentrations), 4-CP, and 2,4-DCP.[9] We now extend this knowledge to the AAP from the same source. The relationship between phenols removed as a function of hydrogen peroxide for 1 h in a stirred batch reaction is shown in Figure 8A. All of the experiments were carried out at the optimal pH and temperature for AAP (as shown in Figure 5). At 2 mM $H_2O_2$, 59% of the total HT was already removed, whereas only 14.6 and 4% were removed for 2,4-CP and 4-C, respectively. The optimal $H_2O_2$ concentration for HT and 2,4-CP removal was 4 mM, whereas for 4-CP 8 mM $H_2O_2$ was needed. Within 1 h, the preferred substrate for AAP was HT > 2,4-DCP > 4-CP. The results clearly show that the optimal relationship of AAP/$H_2O_2$ for the removal of 2,4 DCF and HT was 5 UA AAP $mL^{-1}$ $mmol^{-1}$ $H_2O_2$, whereas for 4-CP it was 10 UA AAP $mL^{-1}$ $mmol^{-1}$ $H_2O_2$. The incubation of AAP with phenolic compounds assayed without $H_2O_2$ did not produce a significant decrease in the concentration of the initial compounds (data not shown), suggesting that phenolic

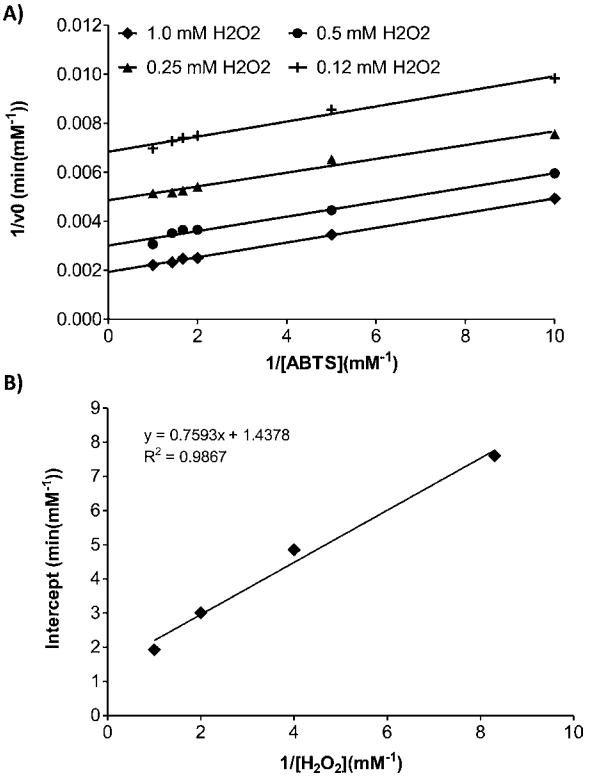

**Figure 7.** Kinetic behavior of the two substrate reactions for purified AAP: (A) plot of 1/[substrate] versus 1/velocity according to the Michaelis−Menten equation; (B) plot of the *y*-intercepts of the lines of panel A versus $1/[H_2O_2]$.

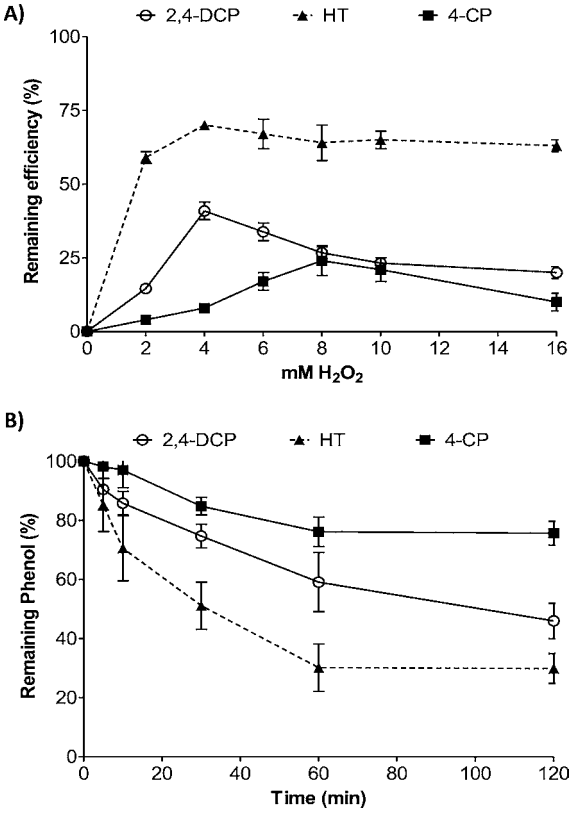

**Figure 8.** Phenols removed as a function of AAP and peroxide concentrations in batch treatment: (A) effect of $H_2O_2$ concentration on phenol reduction (conditions: 2 mM phenol, 20 UA $mL^{-1}$ CAP after 1 h); (B) course of the oxidation with time of 4-chlorophenol, 2,4-dichlorophenol, and hydroxytyrosol (2 mM each) at pH 4.0, 5 UA CAP $mL^{-1}$, and either 4 mM $H_2O_2$ (2,4-DCF and HT) or 8 mM $H_2O_2$ (4-CP).

oxidation is due to POD activity and not to other enzymatic activities that could be present in the extract.

Finally, we studied the time courses of the changes in the phenolic compound concentrations (Figure 8B). The rates of degradation of the three phenols assayed differed. AAP was most active against HT; >70% of the total HT disappeared within the first 1 h compared to 2,4-CP and 4-CP, which were removed at 42 and 25% of the initial concentration, respectively. In the same conditions CAP was able to remove only 25% of the HT.[9] Longer times of exposure of the HT and 4-CP to the AAP did not reduce the amount of phenol concentrations. However, AAP was still active after 2 h in the presence of 2,4-DCP, which was removed by up to 50% for its initial concentration (Figure 8B). Intriguingly, most of the PODs from vegetables are reported to be more active for monophenols such as 4-CP[35] than for orthophenols such as HT. Therefore, the botanical source of PODs plays an important role in the efficiency of bioremediation. Taking into account our previous studies,[9] it can be concluded that in the POD from asparagus byproducts, CAP isoforms have higher efficiency in removing chorophenols, whereas AAPs have higher efficiency in removing orthophenols such as HT. Extensive knowledge about the bioremediation of mono- and dichorophenols exists,[36] whereas little information can be found in relation to the removal of the phenols present in olive oil wastewater.

In conclusion, large differences were found between acidic and basic wall isoperoxidases in relation to their efficacy in the oxidation of the phenolic compounds assayed. Whereas CAP was found to be a good alternative for the removal of chlorinated compounds, the AAP is a better option for the removal of the main phenol present in olive mill wastewaters. Both isoenzymes might exert their activities in an acidic environment, and AAP showed a very high thermostability and resistance to inhibitor action. All of these features make AAP a valuable enzyme for the removal of highly polluted wastewater produced by the agro-food industries.

In this work, we have carried out two sets of experiments involving PMG interaction with metals: (i) surface-enhanced Raman spectroscopy (SERS) experiments after PMG was deposited from an aqueous solution on different metallic surfaces and (ii) attenuated total reflectance Fourier transform infrared (ATR−FTIR) spectra experiments of PMG interacting with metallic ions in aqueous solution. We have used density functional theory (DFT) calculations to identify the vibrational bands, looking for fingerprints of the AMPA and PMG presence. Both experiments show evidence of an abiotic pathway of PMG degradation into AMPA.

## MATERIALS AND METHODS

**Raman Experiments.** SERS experiments were made *ex situ* using a Jobin-Yvon T64000 triple spectrometer operating in subtractive mode and equipped with a liquid-$N_2$-cooled charge-coupled device. The excitation was performed using the 647.1 nm line of an Ar−Kr laser. Typical acquisitions employed three integrations of 60 s using laser powers of 20−50 mW, concentrated on a 7 mm long and around 100 mm wide line focus. This was chosen to reduce the photon-induced degradation of the samples. Product formation because of reactions occurring at these excitation wavelengths were further ruled out by checking that the spectra remained constant in time.

Glyphosate and AMPA were purchased from Sigma-Aldrich (analytical standard quality). All other supplies used were of the best analytical grade commercially available.

SERS experiments were performed on sphere segment void (SSV) arrays, fabricated via an hexagonal close packed self-assembly of 600 nm radius polystyrene spheres, followed by an electrochemical Au deposition, as originally described by Bartlett and co-workers.[28,29]

Structured copper surfaces were prepared by underpotential deposition (UPD) on SSV gold arrays from a $5 \times 10^{-4}$ M $CuSO_4$ + 1 M $H_2SO_4$ aqueous solution in a conventional electrochemical cell. A voltammetry sweep from −0.6 to 0 V at 0.25 V $s^{-1}$ was performed with a Pt large area foil as the counter electrode and a Cu wire as the pseudo-reference electrode.

Ag nanoparticles (NPs) were deposited to further increase the Raman signal.[6,30,31] These nanoparticles (spheric, 20 nm mean size) were synthesized according to the Turkevich method.[32] Briefly, 100 mL of 1 mM $AgNO_3$ aqueous solution was stirred and heated until 90 °C and then reduced with 20 mg of sodium citrate. After the color change to yellow, the solution was cooled while stirring until room temperature. Always a fresh stash of Ag NPs was used for each experiment.

PMG and AMPA adsorption on SSV substrates was made following two different methods. (I) Drop casting: a 10 $\mu$L drop of 1 mg/mL PMG or AMPA aqueous solution with Milli-Q water (18.0 MΩ) was deposited on the SSV surface and dried with $N_2$ flux; immediately, the sample was dipped in a Ag nanoparticle solution overnight and then rinsed with Milli-Q water and dried with $N_2$ flux. (II) Dipping: SSV substrate was dipped in 1 mg/mL PMG aqueous solution overnight and then carefully rinsed with Milli-Q water and dried with $N_2$ flux; finally, 10 $\mu$L of Ag nanoparticles were drop-casted on top and dried with $N_2$ flux.

**ATR−FTIR Experiments.** The ATR−FTIR experiments were performed in the 500−4000 $cm^{-1}$ region in a Nicolet 8700 FTIR spectrometer (128 scans, resolution of 4 $cm^{-1}$) equipped with a DTGS detector and a Smart Orbit ATR accessory with a diamond crystal unit with a single reflection. A baseline correction was made for instrumental instabilities, and the background was subtracted. Data were evaluated using OMNIC, version 7.3, Thermo Electron Corporation software.

All chemical reagents were analytical-grade and used without any further purification. Water was purified in a Milli-Q system from Millipore, Inc. Glyphosate was provided by Sigma Co. Copper chloride dehydrated ($CuCl_2 \cdot 2H_2O$) and AMPA (99% pure) were from Aldrich Chemical.

Stock solutions of 1000 mg $L^{-1}$ of each reagent ($Cu^{II}$, AMPA, and PMG) were prepared. The stock solution of $Cu^{II}$ was prepared by dissolving $CuCl_2 \cdot 2H_2O$ in Milli-Q water. The reactant molar ratios of 2.7:1 $Cu^{II}$/PMG and 2.6:1 $Cu^{II}$/AMPA were obtained by adding the required aliquots of $Cu^{II}$ and PMG (or AMPA) stock solutions into a flask, reaching the final volume by the addition of the required volume of Milli-Q water.

The colorless solution of PMG (or AMPA) changed to light blue as soon as the light green solution of $CuCl_2$ was added. The complex solution was frozen and freeze-dried, and a bright green solid was obtained.

**DFT Calculations.** The DFT calculations were carried out within the slab-supercell approach by means of the Vienna *ab initio* simulation program (VASP).[33−35] The electron−ion interactions were described through the projector-augmented plane-wave (PAW) Perdew−Burke−Ernzerhof (PBE) pseudo-potentials. Exchange and correlation (XC) was described within the van der Waals density functional with optB86b as the exchange functional. We used an energy cutoff of 450 eV, and the Brillouin zone integration was performed within the Methfessel−Paxton technique,[36] with an electron smearing of 0.1 eV. The energies and forces were converged to $10^{-4}$ eV and $10^{-1}$ eV/nm. The Cu(111) and Cu(100) surfaces were represented by a $4 \times 4$ unit cell with five-layer slabs. AMPA was adsorbed only on one side of the slab, and during full geometry optimizations, we allowed for relaxation of the three topmost layer metal atoms and all of the atoms of the molecule.

## RESULTS AND DISCUSSION

We started by characterizing the vibration spectra of PMG[17] and AMPA[18] crystals using DFT calculations. Table 1 shows the theoretical frequencies for PMG and AMPA and the vibration mode identification. The crystals have non-equivalent molecules within the unit cell; consequently, the frequencies in Table 1 correspond to averages over sets of modes in similar vibration states.[37]

From the analysis of the DFT results, we identify the mode at 717 $cm^{-1}$ for AMPA and 761 $cm^{-1}$ for PMG (highlighted in blue in Table 1) as a P−C stretching vibration. This mode is separated from neighboring modes by more than 90 $cm^{-1}$, with the only exception of a mode appearing at 783 $cm^{-1}$ in the PMG crystal, which corresponds to a complex vibration [$\nu$(PC) + $\rho(CH_2)$ + $\rho(NH_2)$ + $\nu$(CCOO)]. This feature together with the fact that the AMPA P−C and PMG P−C are separated enough from each other makes these modes easily resolvable in vibrational spectra, therefore providing respective fingerprints for the AMPA and PMG presence.

To study the effect of the molecule surface adsorption on the vibrational spectra, we performed DFT calculations for AMPA on Cu(111) and Cu(100) surfaces (see Tables S2 and S3 of the Supporting Information). The calculated P−C mode frequencies shift down, relative to the crystal, 15 and 7 $cm^{-1}$ for Cu(111) and Cu(100) surfaces, respectively.

The Raman spectra obtained for the AMPA and PMG crystals are shown in panels A and B of Figure 1, respectively. Fits of the P−C peaks are shown in blue for PMG and green for AMPA.

We show in Figure 1C the SERS spectrum of PMG deposited from aqueous solutions on Cu_UPD/Au with Ag nanoparticles, using the drop-casting method. It presents a peak at the frequency previously assigned to the P−C mode of the PMG crystal, but unexpectedly, a second peak is also observed. This second peak is in a region free of PMG vibrations and at the frequency of the AMPA P−C mode, indicating the presence of AMPA in this sample. To the best of our knowledge, this

Table 1. DFT-Calculated Frequencies ($cm^{-1}$) and Vibration Modes for PMG and AMPA Crystals[a]

| PMG crystal | AMPA crystal | Vibration modes |

[a]Mode notation: $\delta$ for bending, $\nu$ for stretching ($\nu_a$ and $\nu_s$ for asymmetric and symmetric stretching), $\omega$ for wagging, $\rho$ for rocking, $\tau$ for twisting, and "skel" for skeleton. In PMG, $CH_2$* refers to the methyl farthest away from the phosphonate group. For further details, see the captions of Tables S2−S3 of the Supporting Information.

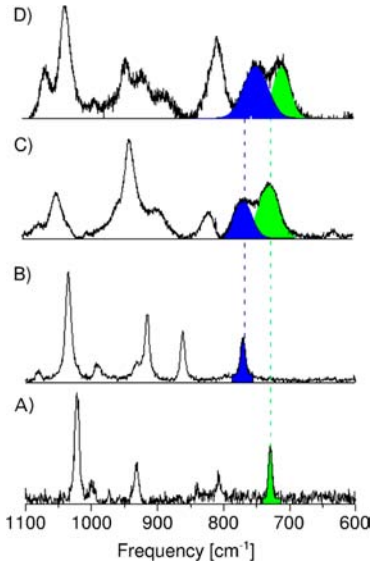

**Figure 1.** SERS spectra for (A) AMPA crystals, (B) PMG crystals, (C) PMG deposited on Cu_UPD/Au with Ag NPs using the drop-casting method, and (D) PMG deposited on Cu_UPD/Au with Ag NPs using the dipping method. The shadowed areas correspond to the P−C mode region for AMPA (green) and PMG (blue).

result provides the first evidence of an abiotic path for PMG degradation into AMPA.

Figure 1D shows the SERS spectrum of a sample prepared with the dipping method. It is noteworthy that, in this preparation, the samples are rinsed before the addition of Ag NPs, and thus, most of the molecules that are not adsorbed on the surface are removed from it.

The P−C peaks of AMPA and PMG are also present in Figure 1D, even though they are shifted to lower frequencies (shifts of 20 $cm^{-1}$ for AMPA and 22 $cm^{-1}$ for PMG). Based on the DFT results for AMPA/Cu, these experimentally observed shifts to lower frequencies indicate that both AMPA and PMG are predominantly adsorbed on the Cu surface.

From the analysis of Figure 1, we conclude that (i) for both sample preparation methods, an abiotic degradation process of PMG into AMPA has taken place, (ii) when the drop-casting method is used, the P−C mode of PMG and AMPA is not shifted relative to the PMG or AMPA crystal mode, indicating that most of the molecules are not bonded to the Cu surface, and (iii) in samples prepared with the dipping method, the resulting PMG and AMPA are mainly adsorbed on the surface.

An estimation of the percentage of PMG degraded into AMPA can be obtained by means of a fitting procedure of the P−C mode frequency region of panels C and D of Figure 1. The approximate amount of degradation is 56% in drop-casted samples and 50% in dipped samples. For a detailed description, see Figure S1 and Table S1 of the Supporting Information.

From further analysis, some additional information regarding the adsorbed molecule configuration can be extracted. By means of DFT calculations for crystals, the most intense peak in Figure 1C is identified with the stretching P−O mode (931 $cm^{-1}$) of both PMG and AMPA (see Table 1). In Figure 1D, this peak decreases, implying that the adsorbed molecules interact with the surface via the phosphonic group.

Complementary SERS spectra for drop-casting experiments of PMG deposited on Ag and Au with Ag NPs show that the degradation of PMG into AMPA is not specific to the

dx.doi.org/10.1021/jf502979d | J. Agric. Food Chem. 2014, 62, 9651−9656

interaction of PMG with a Cu surface but also occurs in the presence of other metallic substrates. The spectra obtained (see Figure S2 of the Supporting Information) are very similar to the spectra in Figure 1C; particularly, the P−C peaks of both molecules appear in all of the samples.

The interaction of PMG with metal atoms in solution is known to result in chelate formation.[20,21,24] This raises the question of whether the surface is itself needed for the degradation process or whether the interaction of PMG with isolated metal atoms can also degrade it into AMPA. To elucidate this point, we prepared a mixture of Cu and PMG in aqueous solution (hereafter referred to as PMG + Cu) using a molar ratio of 2.7:1 Cu/PMG and, after sample lyophilization, characterized it by ATR−FTIR experiments. We also measured the ATR−FTIR spectra for AMPA crystals, PMG crystals, and a 2.6:1 Cu/AMPA mixture in aqueous solution (hereafter AMPA + Cu), to use as references. Figure 2 shows the spectra obtained.

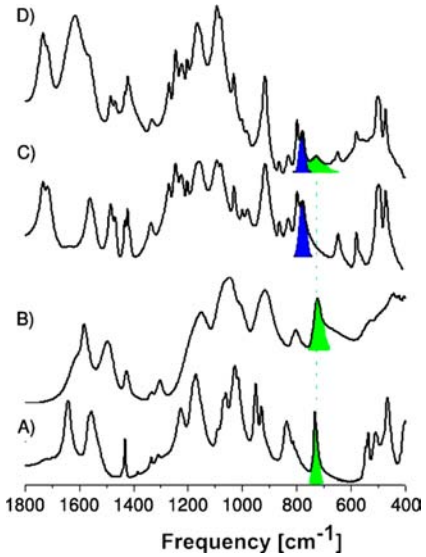

**Figure 2.** IR spectra of (A) pure AMPA crystals, (B) AMPA + Cu with a molar ratio of 2.6:1 Cu/AMPA, (C) pure PMG crystals, and (D) PMG + Cu with a molar ratio of 2.7:1 Cu/PMG. The shadowed areas correspond to the P−C mode region for AMPA (green) and PMG (blue).

The AMPA P−C peak can be clearly observed in the AMPA (Figure 2A) and AMPA + Cu (Figure 2B) spectra, although slightly shifted to lower frequencies in the latter. Likewise, the PMG P−C peak is present in PMG (Figure 2C) and PMG + Cu (Figure 2D) spectra. For both AMPA and PMG, the respective P−C peaks are distinct and appear at frequencies consistent with the Raman measurements. The PMG spectrum shows a wide gap between the P−C (at 777 $cm^{-1}$) and the skeleton (at 643 and 577 $cm^{-1}$) modes. However, in the PMG + Cu spectrum, there is a peak at the frequency of the AMPA P−C mode (729 $cm^{-1}$), indicating the presence of AMPA molecules and/or AMPA−Cu complexes in the sample.

It must be highlighted that the presence of AMPA in the spectra of PMG + Cu samples is also observed for lower Cu/PMG molar ratios. In fact, the AMPA P−C peak can be clearly identified in samples prepared with a 0.7:1 Cu/PMG molar ratio (see Figure S3 of the Supporting Information).

We find further evidence of PMG into AMPA degradation in the 1600−1700 $cm^{-1}$ region. Our calculations show three vibration modes in the AMPA amino group [$\delta(NH_2)$ at 1648 and 1588 $cm^{-1}$, and $\delta(NH_3)$ at 1525 $cm^{-1}$], in agreement with Raman data. Infrared (IR) peaks of AMPA at 1555 and 1641 $cm^{-1}$ correspond to two of these modes. PMG has a single $\delta(NH_2)$ mode at 1567 $cm^{-1}$ (Raman peak at 1568 $cm^{-1}$ and IR peak at 1560 $cm^{-1}$) and a $\nu(C{=}O)$ mode of the carboxylate group at 1705 $cm^{-1}$, associated with Raman and IR structures at 1715−1730 $cm^{-1}$. These two PMG peaks remain in place in the PMG + Cu IR spectrum, but an intense peak in between, at 1616 $cm^{-1}$, is also visible. In IR spectroscopic studies of PMG + metal complexes,[22,23] this peak is usually assigned to a $\nu_a(COO)$ mode and interpreted as the result of the interactions of the carboxylate group with Cu atoms. However, we observe that the $\nu(C{=}O)$ mode at 1715−1730 $cm^{-1}$ is not affected much by the presence of Cu atoms. We hence conclude that the 1616 $cm^{-1}$ peak is a combination of the PMG $\delta(NH_2)$ mode and the $\delta(NH_2)$ and $\delta(NH_3)$ modes coming from AMPA and AMPA + Cu.

Additionally, some information regarding AMPA and PMG reactivity to Cu atoms can be drawn from Figure 2. In the 900−1200 $cm^{-1}$ region, the main contribution to AMPA spectra comes from the phosphonate group.[24] Consequently, the changes observed when comparing the AMPA and AMPA + Cu spectra in that region are consistent with Cu atoms being bonded to this group. Also, the significant frequency shift in the $NH_2{-}NH_3$ region, around 1600 $cm^{-1}$, signals Cu−N interactions. These features are consistent with our AMPA/Cu adsorption analysis, where we find that the most stable configuration involves both Cu−O and Cu−N bonds.

Tables S2 and S3 of the Supporting Information show the calculated DFT frequencies and the complete band assignment of the SERS and IR spectra.

In conclusion, in this work, we have detected the presence of AMPA in SERS spectra of pure PMG deposited on several metal surfaces and in IR spectra after the PMG interaction with metallic ions in aqueous solution. Only an abiotic degradation process of PMG, where metal atoms play a central role, can explain the presence of AMPA in the experiments reported.

Previous experimental studies of glyphosate−metal complexes have not considered the PMG degradation pathway revealed in this work. Reported IR spectra do not include the frequency region around the P−C modes, or when they do, thus exposing the AMPA P−C peak[25] at approximately 730 $cm^{-1}$, the presence of AMPA is not taken into account in the analysis.[6,23,25,26] On the basis of the results presented here, it would be enriching to revisit this literature.

Precision in the dose of application of herbicide products is crucial not only to ensure efficient herbicide treatments but also to reduce the unwanted effects on the environment. Then, it is necessary to study the effectiveness of this abiotic degradation process in agriculture conditions.

Consequently, we expect our results will encourage further research to characterize quantitatively this new PMG into AMPA degradation process.

## MATERIALS AND METHODS

**Materials and Treatments.** The herbicide atrazine was obtained from the Institute of Pesticide Science, Academy of Agricultural Sciences in Nanjing, China, with 99% purity. Alfalfa seeds (*Medicago sativa*, cv. Golden Empress) were surface-sterilized with 5% solution of sodium hypochlorite for 15 min, rinsed with distilled water, and placed on moist filter paper for germination. Germinating seeds were placed on a plastic net floating on distilled water in the dark at 25 °C for 2 d. Then, uniform seedlings were transferred to black polyvinyl chloride pots (1 L) that contained 1/2 strength Hoagland nutrient solution.[26] Culture solutions were renewed every 2 days. When the third true leaf was well developed, seedlings were treated with atrazine at 0, 0.02, 0.04, 0.06, 0.08, and 0.10 mg $L^{-1}$ for 6 d, respectively, in 1/2 strength nutrient solution. Treatment solutions were renewed every 2 d. Each pot contained 30 seedlings, which were grown in a growth chamber under the conditions of 14 h photoperiod, 200 $\mu$mol of photons $m^{-2}$ $s^{-1}$, and 25/20 °C (day/night). Each treatment was repeated thrice.

**Determination of Growth and Chlorophyll Content.** The elongation of shoots and roots of fresh individual plants was measured with a normal ruler. A forced-air oven was used for determination of biomass. Fresh shoots and roots were dried at 105 °C for 20 min, then oven-dried at 80 °C for 48 h, and weighed afterward.[26] Chlorophyll was assayed according to the method of extraction with 80% acetone[27] Fresh leaves (0.1 g) were extracted with 8 mL of 80% acetone (pH 7.8). After extracting solution was centrifuged at 5000$g$ for 10 min, the supernatant was collected, the chlorophyll content was assayed spectrophotometrically, and the content of chlorophyll was expressed as mg $g^{-1}$ fresh weight (FW).

**Analysis of Atrazine.** Alfalfa plants were cultured in 1/2 strength Hoagland nutrient solutions containing 0, 0.02, 0.04, 0.06, 0.08, and 0.10 mg $L^{-1}$ atrazine, respectively. Shoots and roots of plants were separately harvested after atrazine treatment. Fresh shoots or roots (3.0 g) were ground and dissolved in 15 mL of acetone−water (3:1, v:v) and ultrasonicated for 30 min. The homogenate was centrifuged at 4000$g$ for 7 min and filtrated. The above steps were repeated in triplicate. The filtrate was vaporized to remove acetone at 40 °C using a rotary vacuum evaporator. The residual water was partitioned in petroleum ether three times, each time with 10 mL of the solvent. The petroleum ether was concentrated to dryness at 40 °C. The residue was dissolved in 0.5 mL of methanol and diluted with 20 mL of water. The mixture was passed through an LC-18 solid-phase extraction (SPE) column. Eluates were discarded, and the column was washed with 2 mL of methanol−water (80:20, v:v). The washing solution was collected for analysis of high performance liquid chromatography (HPLC, Waters 515; Waters Technologies Co. Ltd., USA) with ultraviolet (UV) detector. The operating conditions of HPLC were as follows: wavelength, 225 nm; room temperature; Hypersil reversed-phase C18 column (Thermo, 250 mm × 4.6 mm i.d.); mobile phase, methanol:water (70:30, v:v); flow rate, 0.6 mL $min^{-1}$; injection volume, 20 $\mu$L. Atrazine in the plant-culture solution was also measured with the LC-$C_{18}$ SPE column as described above. The spiked recovery and determination limit of the above method are shown in Table S1 in the Suppporting Information.

**Assay of Enzyme Activities.** Fresh shoot (1 g) or root tissues (1.5 g) were homogenized in 6 mL of ice-cold sodium phosphate buffer (50 mM, pH 7.8) containing 1 mM EDTA and 1% (w/w) polyvinylpyrrolidone. The homogenate was centrifuged at 12000$g$ at 4 °C for 20 min. Glutathione $S$-transferase (GST, EC 2.5.1.18) activity

dx.doi.org/10.1021/jf503221c | J. Agric. Food Chem. 2014, 62, 9657−9668

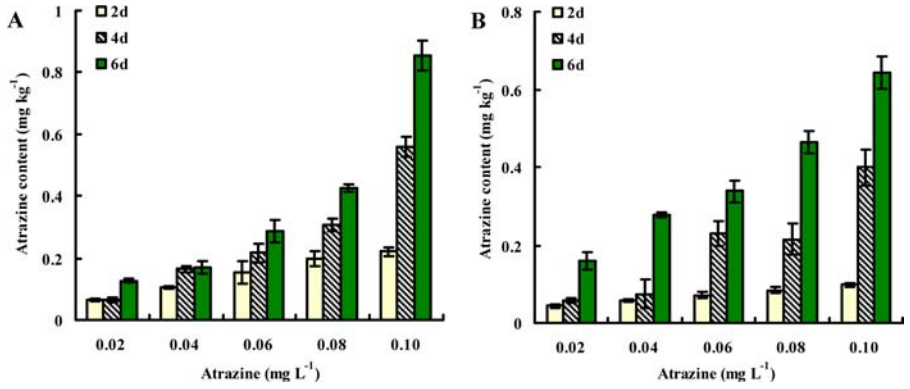

**Figure 2.** Accumulation of atrazine in shoots (A) and roots (B) of *Medicago sativa*. Alfalfa seedlings were cultured in the 1/2 strength Hoagland nutrient solution containing atrazine at 0, 0.02, 0.04, 0.06, 0.08, and 0.10 mg $L^{-1}$ for 2, 4, and 6 d, respectively. Values are the means ± SD ($n$ = 3).

was determined by the method of Song et al.[28] The reaction mixture consisted of 3 mL of 100 mM sodium phosphate buffer (pH 6.5) containing 1 mM GSH, 75 μL of 40 mM 1-chloro-2,4-dinitrobenzene (CDNB), and 100 μL of enzyme extract. The change in absorbance was recorded at 340 nm during 3 min.

Fresh shoots or roots (1 g) were ground and extracted with 1 mM EDTA, 50 mM NaCl, 1% (w/v) polyvinylpolypyrrolidone, and 50 mM Tris−HCl (pH 8.0). The homogenate was centrifuged at 10000*g* at 4 °C for 30 min. The supernatant was collected as crude extract for measurement of UDP-glycosyltransferases (GTs, EC 2.4.*x*.*y*).[9,29] The 250 μL of reaction mixture contained 100 μL of the enzymatic extraction, 0.04 mM *p*-nitrophenol, and 2 mM UDP-glucose. The reaction was carried out at 30 °C for 2 h, terminated by addition of 250 μL of methanol, and chilled to −20 °C for 0.5 h. The reduced rate of the *p*-nitrophenol concentration was assayed by HPLC. One unit of the GT activity was defined as the amount of enzyme activity needed to consume 1 mol of *p*-nitrophenol per minute. The protein concentration in enzyme extract was assayed by the method of dye-binding according to Bradford.[30]

**Analysis of Atrazine Metabolites and Conjugates in Alfalfa.** Fresh shoots or roots (7.0 g) were ground with liquid nitrogen. The process of extraction and purification was run with the same analytical method indicated above except petroleum ether extraction. The washing solution for the LC-18 column was collected for analysis. Metabolites and conjugates of atrazine in alfalfa were analyzed using ultrahigh performance liquid chromatography (UHPLC) (Thermo, USA) coupled to a linear ion trap−Orbitrap hybrid mass spectrometer (LTQ Orbitrap XL) equipped with a heated-electrospray ionization probe. Instrument control was through Tune 2.6.0 and Chromeleon programs. Separations were performed on a Hypersil gold C18 (100 mm × 2.10 mm, 3 μm particle size, Thermo Fisher Scientific). Mobile phase was composed of (A) water + 0.1% formic acid and (B) acetonitrile + 0.1% formic acid. A linear gradient program was performed in 36 min at a flow rate of 0.20 mL/min under the following conditions: 5% B for 1 min, 1−15 min from 5% to 35% B, 15−25 min from 35% to 95% B, 95% B for 5 min, 30−31 min from 95% to 5% B, and 5% B for 5 min. Column oven and autosampler temperature were set at 35 and 10 °C, respectively. The injection volume was 10 μL.

The mass spectrometer was operated in negative mode. HESI-source parameters were as follows: capillary temperature 300 °C, the source voltage 4 kV, and auxiliary gas 25. Accurate mass spectra were recorded from 100 to 800 *m*/*z*. For fragmentation study, a data dependent scan was performed by deploying collision-induced dissociation (CID). The product ions were generated by the LTQ ion trap at normalized collision energy of 35% and *q*-activation of 0.25 using an isolation width of 2 Da. The external mass calibration of the Orbitrap was performed once a week to ensure a working mass accuracy <5 ppm. Data analysis was handled by a computer equipped with Xcalibur software, version 2.1. Atrazine and its metabolism products were identified according to the corresponding spectral characteristics: accurate mass, mass spectra, and characteristic fragmentation.

**Statistical Analysis.** The biological study was performed independently three times. Each experiment was performed in triplicate. Results in figures and tables were the mean of three replicated treatments and expressed as mean ± standard deviation. Statistical analysis between the treatments and control was made by Student's *t* test methods ($p < 0.05$).

## RESULTS

**Effect of Atrazine on Growth.** The elongation and biomass of alfalfa shoots and roots were progressively reduced following the treatment with atrazine at 0−0.10 mg $L^{-1}$ for 6 d (Figure 1). Treatment with 0.10 mg $L^{-1}$ atrazine reduced the elongation of shoots and roots to 39.7% and 33.9% of the controls, respectively (Figure 1A). In comparison with elongation, the biomass appeared more sensitive to atrazine. Under the same condition, the biomass of shoots and roots was reduced to 16.6% and 8.5% of the controls, respectively (Figure 1B). The content of chlorophyll in alfalfa was significantly decreased after exposure to atrazine. At 0.04 mg $L^{-1}$, the chlorophyll content was decreased by 28.9% compared to the control (Figure 1C).

**Accumulation and Translocation of Atrazine in Alfalfa.** Both shoots and roots accumulated atrazine progressively with the concentrations over the time of exposure (Figure 2). A time-dependent change in atrazine accumulation was observed. Accumulation of atrazine in shoots and roots increased significantly for 4 and 6 d compared to 2 d. When plants were treated with atrazine at 0.10 mg $L^{-1}$ for 4 and 6 d, the contents of atrazine in shoots were 0.559 and 0.854 mg $kg^{-1}$, respectively (Figure 2A).

To investigate the uptake and translocation of atrazine in alfalfa, we calculated the bioconcentration factor (BCF), the ratio of atrazine concentration in plant to the nutrient solution, and the translocation factor (TF), the ratio of atrazine concentrations in shoots to roots. As shown in Table 1, BCFs of shoots decreased from 3.71 to 2.19 at 0.02−0.10 mg $L^{-1}$ of atrazine, and under the same condition, BCFs of roots decreased from 2.54 to 0.97. By contrast, the TF values progressively increased from 1.47 to 2.39 when plants were exposured to atrazine at 0.02−0.10 mg $L^{-1}$ (Table 1).

**Analysis of Atrazine Residues and Metabolites in Alfalfa.** The accurate mass data by high resolution MS was used to confirm elemental formula. The isotope (M + 2) was crucial for identifying the chlorine-containing transformation products of atrazine. The structures of metabolites were

[a]Concentrations of atrazine were determined in shoot and root after alfalfa exposure to atrazine 0.02−0.10 mg $L^{-1}$ in nutrient solution for 2 d. Values are the means ± SD ($n$ = 3). The different letters indicate significant difference between treatments ($p$ < 0.05). [b]BCF: fresh weight ratio of atrazine in plant to the nutrient solution. [c]TF: ratio of shoot BCF to root BCF.

determined by analyzing collision-induced dissociation (CID) fragmentation patterns from $MS^2$ and $MS^3$ data. The external mass calibration of the Orbitrap was performed once a week to ensure a working mass accuracy of <5 ppm. The mass spectrometric data of atrazine along with its 10 metabolites of atrazine are summarized in Table 2.

Atrazine (ATZ) peaked at 19.19 min (Figure 3A). The $MS^2$ and $MS^3$ data of atrazine with fragment ions were $m/z$ 188, 174, 146, 138, 132, 104, 96, and 76 (Figure 4A and Table 2). Deisopropylated atrazine (DIA, metabolite #1) was one of the *N*-dealkylation products, peaking at 8.81 min with fragment ion of $m/z$ 146 (Figures 3B and 4B and Table 2). Hydroxyatrazine (HA, metabolite #2), which peaked at 9.20 min, was derived from atrazine by substitution of a hydroxyl group for the chlorine, while the loss of isopropenylacetylene and $H_2O$ resulted in formation of fragment ions of $m/z$ 156 and $m/z$ 180, respectively (Figure 4C and Table 2). Desethylated atrazine (DEA, metabolite #3), which peaked at 11.97 min with fragment ion of $m/z$ 146, was another *N*-dealkylation product (Figures 3B and 4D and Table 2).

Hydroxylation (+O) of atrazine detected at $m/z$ 232 included three isomers, and their retention times were 12.73, 13.28, and 14.22 min, respectively (Figure 3C). The first isomer, hydroxyisopropyl atrazine (HIA, metabolite #4), was confirmed by loss of $H_2O$ and isopropenyl to form $m/z$ 214 and $m/z$ 174, and the oxygenation on isopropyl to form $m/z$ 146 from precursor ion of $m/z$ 174 (Figure 4E and Table 2). The second isomer, which peaked at 13.28 min, was identified as *N*-hydroxy atrazine with the ion of $m/z$ 190 (NHA, metabolite #5), indicating that the oxygen was added to nitrogen atom on *N*-ethyl (Figure 4F and Table 2). The site of oxidation should occur on the ethyl side according to $m/z$ 188 in $MS^2$ (Figure 4G). Because hydroxylation of imine carbon allowed keto−enol type resonance, the loss of $COCH_2$ ($m/z$ 42) resulted in forming the fragment ion of $m/z$ 146 (Figure 4G and Table 2). Therefore, the structure of $m/z$ 230 at 13.73 min was assigned as hydroxy-dehydrogenated atrazine (HDHA, metabolite #6). The third isomer, hydroxyethyl atrazine (HEA, metabolite #7), was identified at 14.22 min ($m/z$ 232), due to the loss of $H_2O$, which resulted in the formation of $m/z$ 214. A further loss of vinyl, forming fragment ion of $m/z$ 188, confirmed that the oxygenation occurring on ethyl and oxygen was added to $\alpha$-carbon on *N*-ethyl of HEA (Figure 4H and Table 2).[31] Demethylated atrazine (DMA, metabolite #8), with a loss of $m/z$ 14, was identified according to the fragment ion of $m/z$ 174 (Figure 4I and Table 2), which occurred on isopropyl but not on ethyl, because the fragment ion of $m/z$ 160 or $m/z$ 188 was not found from $MS^2$ or $MS^3$ data.

For $m/z$ 214, which peaked at 20.28 min, the fragment ion of $m/z$ 172 from the loss of isopropenylacetylene indicated that the double bond occurred on the ethyl group (Figure 3C). The systematic −2 $m/z$ shift for some fragments retaining ethyl showed the double bond that was not on the isopropyl. The structure of metabolite #9 (dehydrogenated atrazine, DHA) did not cause any loss of ethyl moiety such as $m/z$ 146, indicating that imine was formed rather than terminal alkene (Figure 4J and Table 2). Methylated atrazine (MEA, metabolite #10) with a high response was detected with fragment ions of $m/z$ 188 and 146 (Figure 4K and Table 2). Taken together, this study demonstrated that metabolites #4−10 have been reported for the first time in plants.

**Identification of Atrazine Conjugates.** Seven atrazine-homoglutathione metabolites and two glucosylated-atrazine conjugates were identified by analyzing collision-induced dissociation (CID) fragmentation patterns from $MS^2$ and $MS^3$ data (Table 2 and Figure 5A−I). Polarity of nine atrazine conjugates was higher than that of atrazine, resulting in peaking earlier (Figure 3E−H).

Two isomeric glycosylation conjugates of atrazine, hydroxyisopropyl atrazine *O*-glucoside (HIA+Glc-$H_2O$, conjugate #1) and hydroxyethyl atrazine *O*-glucoside (HEA+Glc-$H_2O$, conjugate #2), were distinguished according to $MS^3$ data of $m/z$ 232 from the parent ion of $m/z$ 394. It was obvious that the classical loss of glucose at $m/z$ 162 took place, forming fragment ion of $m/z$ 232. Loss of $H_2O$ on glycosyl for $m/z$ 394 yielded the fragment ion of $m/z$ 376. The $MS^3$ data with fragment ions of $m/z$ 232, $m/z$ 214, and $m/z$ 174 indicated that the receptor was HIA (Figure 5A and Table 2). The parent ion of $m/z$ 394 at 11.64 min was assigned to HIA+Glc-$H_2O$ (conjugate #1), a sugar ring linked to HIA by the *O*-glycosidic bond. The other conjugate was formed by glycosylation and yielded a similar fragment ion. Based on the fragment ions of $m/z$ 232, $m/z$ 174, and $m/z$ 190, HEA was the reasonable receptor (Figure 5B and Table 2). So the parent ion of $m/z$ 394 at 11.75 min should point to HEA+Glc-$H_2O$ (conjugate #2), and a sugar ring was linked with HEA by the *O*-glycosidic bond.

As shown in Figure 5C, the $MS^3$ data with fragment ions of $m/z$ 214, $m/z$ 136, and $m/z$ 94 indicated that the compound was formed by conjugation of DHA and cysteine (Cys). The loss of $H_2O$ from the parent ion of $m/z$ 335 formed the fragment ion of $m/z$ 317. The skeleton rearrangement of hydroxyl formed the fragment ion of $m/z$ 292 after loss of carbonyl and amino, and yielded a fragment ion of $m/z$ 260 by loss of methanol (Figure 5C and Table 2). Thus, the parent ion of $m/z$ 335 at 11.85 min (Figure 3F) was confirmed as a cysteine conjugate for DHA (DHA+Cys, conjugate #3).

A major ATZ conjugate ($m/z$ 301) eluting at 12.02 min with stronger response than other conjugates was detected according to $MS^2$ and $MS^3$ (Figure 3G and Figure 5D). For $m/z$ 301, the loss of $NH_3$ produced the fragment ion of $m/z$ 284 in $MS^2$. The $MS^3$ data with the fragment ions of $m/z$ 214, $m/z$ 172, and $m/z$ 144 showed that a protonated thiol atrazine was generated (Figure 5D and Table 2). This conjugate was clearly identified as a cysteine conjugate by chlorine substitution for atrazine (ATZ-HCl+Cys, conjugate #4). A protonated molecule ($m/z$ was 501, $t_R$ =12.24 min) was created by conjugation (Figure 3H and Figure 5E). The loss of glutamic acid (Glu) for $m/z$ 501

[a]Retention time. [b]Location: Distribution of metabolites of atrazine in plant. [c]$MS^2$ fragments: Base peak of $MS^2$ fragment ions are shown in bold. [d]$MS^3$ fragments: Base peak of $MS^3$ fragment ions are shown in bold. [e]Figure within the brackets: The precursor ions used to produce $MS^2$ and $MS^3$ fragment ions. [f]Compounds that have been reported for the first time.

formed the fragment ion of $m/z$ 372, and the loss of thiol atrazine generated the fragment ion of $m/z$ 288. The $MS^3$ data with $m/z$ 214 and $m/z$ 172 confirmed the existence of protonated thiol atrazine fragment (Figure 5E and Table 2). These data were consistent with the conjugation of ATZ and homoglutathione (hGSH) (ATZ-HCl+hGSH, conjugate #5). A peak ($t_R$ =12.51 min) at $m/z$ 372 was detected (Figure 3H and Figure 5F). The loss of $NH_3$ for $m/z$ 372 formed the fragment ion of $m/z$ 355. The $MS^3$ data contained $m/z$ 214, $m/z$ 172, and $m/z$ 144, indicating that the ATZ conjugate was transformed to protonated thiol atrazine by cracking. Therefore, the conjugate was identified as cysteinyl $\beta$-alanine conjugate by chlorine substitution for atrazine (ATZ-HCl +(Cys-$\beta$-Ala), conjugate #6). The loss of $H_2O$ and DEA from the parent ion of $m/z$ 535 at 12.95 min yielded fragment ions of $m/z$ 517 and $m/z$ 348, respectively (Figure 3E and Figure 5G), indicating that hGSH was not linked to nitrogen. The $m/z$ 322 and $m/z$ 193 were the characteristic ions for hGSH (Table 2). Based on the $MS^2$ spectrum, the structure of the conjugate was confirmed as homoglutathione conjugate for dehydrogenated atrazine (DHA+hGSH, conjugate #7). The conjugates peaking at 13.95 and 14.33 min were detected (Figure 3F). The fragment ion of $m/z$ 386 was the result of the loss of Glu, and the $MS^3$ data with fragment ions of $m/z$ 228, $m/z$ 186, and $m/z$ 144 provided the foundation for fragment-protonated thiol-MEA (Figure 5H and Table 2). Thus, conjugate #8 ($m/z$ 515) was identified as homoglutathione conjugate by chlorine substitution for methylated atrazine (MEA-HCl+hGSH). The loss of $NH_3$ from the parent ion of $m/z$ 315 formed the $m/z$ 298. Similarly, fragment ions of $m/z$ 228, $m/z$ 186, and $m/z$ 144 were evidence for the fragment protonated thiol-MEA (Figure 5I and Table 2). The parent ion of $m/z$ 315 was

identified as cysteine conjugate by chlorine substitution for the methylated atrazine (MEA-HCl+Cys, conjugate #9).

Most of the conjugates could be found in both shoot and root tissues, except HIA+Glc-$H_2O$ and HEA+Glc-$H_2O$, which were only detected in shoots (Table 2). ATZ-HCl+hGSH (conjugate #5) from sorghum was reported previously,[32] whereas HIA+Glc-$H_2O$ (conjugate #1), HEA+Glc-H2O (conjugate #2), ATZ-HCl+Cys (conjugate #4), MEA-HCl +hGSH (conjugate #8), and MEA-HCl+Cys (conjugate #9) have not been documented in plants. Meanwhile, there were few reports about conjugates DHA+Cys (conjugate #3), ATZ-HCl+(Cys-$\beta$-Ala) (conjugate #6), and DHA+hGSH (conjugate #7) transformed from atrazine in plants.

**Effect of Atrazine on Activities of Enzymes.** We further determined the activities of enzymes GST and GTs in plants. The activity of GTs in shoots was highest at 0.06 mg $L^{-1}$ atrazine compared to the control, while in roots the activity of GTs was mildly induced by atrazine from 0.04 to 0.08 mg $L^{-1}$ (Figure 6A). Similarly, the activity of GST was progressively increased in roots with atrazine at 0.02−0.08 mg $L^{-1}$ (Figure 6B). In shoots, the activity of GST was generally unchanged, and only at 0.02 mg $L^{-1}$ atrazine was the activity slightly increased.

## DISCUSSION

Plants (or crops) have developed sophisticated strategies to degrade a broad range of xenobiotics such as pesticides into detoxified products. Chemical modification of these pesticides is the first and most important step leading to the following cellular appartmentation and degradation. Although certain processes are known for the removal of pesticides in plants, the mechanisms underlying the processes remain to be elusive. The present study identified an array of atrazine derivatives including their glucosylated products in alfalfa using multiple analytical and biological approaches. A total of ten atrazine metabolites have been detected. Of these, metabolite #4 (HIA), metabolite #5 (NHA), metabolite #6 (HDHA), metabolite #7 (HEA), metabolite #8 (DMA), metabolite #9 (DHA), and metabolite #10 (MEA) have been characterized for the first time in this study (Table 2). Importantly, two glucosylated products, HIA+Glc-$H_2O$ and HEA+Glc-$H_2O$, along with two other hGSH- and Cys-conjugated products, MEA-HCl+hGSH and MEA-HCl+Cys, are also the new products identified in this study (Table 2). The atrazine degradation in the alfalfa plant may represent a mode in which atrazine is chemically transformed into a variety of other compounds. Also, its derivatives conjugated to thiol-containing amino acids and

glutathione are possibly the major process for atrazine degradation.

It is generally considered that herbicides are detoxified through three phases in plants.[33] Phase I is the most important step, by which a herbicide can be activated through oxidoreduction and hydrolysis reaction; phase II in the process is through the conjugation of the activated herbicide with polar donor molecules, such as glutathione, sugars, and amino acids, and it is anticipated that glycosyltransferases and glutathione *S*-transferase are involved. Following conjugation, the conjugates are either compartmented into the vacuole or released into the apoplast region through phase III.

There were ten metabolites of atrazine through phase I reaction and nine conjugates through phase II reaction (Table 2). Metabolic pathways of atrazine are shown in Figure 7; phase I reaction products are DIA, HA, DEA, HIA, NHA, hydroxy-dehydrogenated atrazine (HDHA), HEA, DMA, dehydrogenated atrazine (DHA), and MEA. Atrazine and four phase I reaction products DHA, MEA, HIA, and HEA were brought in phase II reaction. HIA and HEA were reactants for glycosylation, being generated into HIA+Glc-$H_2O$ and HEA +Glc-$H_2O$ with $\beta$-D-glucose. Moreover, conjugation of DHA and MEA with hGSH or amino acids resulted in production of DHA+hGSH or DHA+Cys, respectively. The $\alpha$-carbon double bond formed on the ethyl group acts as an electrophilic Michael acceptor, which covalently binds to hGSH or cysteine (Cys) and is capable of forming DHA+hGSH or DHA+Cys. As both MEA and atrazine contain chlorine, the substitution reaction favorably occurred with sulfydryl of hGSH, dipeptide, or amino acids generating ATZ-HCl+hGSH, ATZ-HCl+(Cys-$\beta$-Ala), ATZ-HCl+Cys, MEA-HCl+hGSH, and MEA-HCl+Cys. In addition to binding directly with atrazine, DHA+Cys, ATZ-HCl+(Cys-$\beta$-Ala), ATZ-HCl+Cys, and MEA-HCl+Cys might be also formed by losing amino acids from the corresponding parent molecules (Figure 7).

The structure of methylated atrazine (MEA) is identical with another triazine herbicide called propazine. The action mechanism of propazine is similar to that of atrazine. This herbicide is used to control broadleaf weeds and annual grasses during the production of milo grain sorghum, with less toxicological effect on humans.[34] MEA is of low solubility in water due to the additional methyl group. In this study, MEA was detected in alfalfa plants. Nevertheless, it has been identified as conjugates with hGSH and cysteine in the form of MEA-HCl+hGSH and MEA-HCl+Cys, indicating that MEA is easy to interact with a thiol-containing group.

Glycosyltransferase (GT; EC 2.4.*x*.*y*)-dependent detoxification (phase II metabolism) is one of the important mechanisms to cope with absorbed toxic compounds.[35] GTs comprise a large group of enzymes that form glycosidic bonds through the transfer of sugars from activated donor molecules to acceptor molecules. The present study has detected two new glucosylated compounds (HIA+Glc-$H_2O$ and HEA+Glc-$H_2O$) for atrazine in alfalfa (Table 2). HIA+Glc-$H_2O$ and HEA+Glc-$H_2O$ were maximally detected at 11.53 and 11.64 min, which were earlier than other conjugates linked to hGSH or amino acids (Figure 3). This suggests that the polarity of glucosides is stronger than that of other conjugates. The two compounds belong to the *O*-glucosylation type. There were no other types such as *N*-glucosylated and *C*-glucosylated atrazine detected. This could be plant species specific. For example, the persistent pollutant 3,4-dichloroaniline with amino group could interact with *N*-glucosylation in *Arabidopsis thaliana*.[36] Also, Gandia-Herrero et al.[22] found that 2,4,6-trinitrotoluene was shown to undergo *C*-glucosylation on the carbon of benzene ring in *Arabidopsis*. Although both DEA and DIA are equipped with amino group, *N*-glucosylation was not identified in alfalfa. It

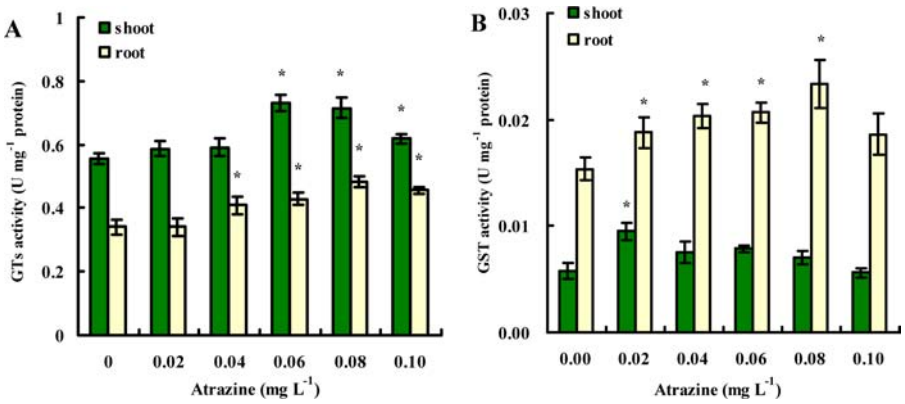

**Figure 6.** Effect of atrazine on the activity of GTs (A) and GST (B) in *Medicago sativa*. Seedlings were cultured in the 1/2 strength Hoagland nutrient solution containing atrazine at 0, 0.02, 0.04, 0.06, 0.08, and 0.10 mg $L^{-1}$ for 6 d. Values are the means ± SD ($n$ = 3). Asterisks indicate significant differences between the treatments and the control ($P < 0.05$).

may be that the concentration of conjugates was too low to be detected. Also, it cannot be ruled out that the alfalfa plants are not able to undergo *C*- or *N*-glucosylation dependent detoxification. Before glucosylation, hydroxyl was added to ethyl and isopropyl of atrazine, forming acceptors HEA and HIA, respectively, which were favorable for *O*-glucosylation. This mechanism is in agreement with the previous reports in which the detoxification of the model benzoxazolinone allelochemical (BOA) in *Arabidopsis* occurred predominantly through *O*-glucosylation of BOA-6-OH.[37] The process most likely requires sequential action of cytochrome P450 and UDP-glucosyltransferase activities. To confirm the involvement of atrazine glucosylation in alfalfa, the activity of GTs was assayed in the plant. The increased activity of GTs with atrazine in alfalfa roots and shoots was observed. The GTs in higher plants are thought to glycosylate many aglycons, and thereby the plant secondary metabolites, hormones, and xenobiotics regulate the development and detoxification of toxic compounds in plants.[10,38] The elevated activity of GTs suggests that the glycosylation-mediated pathway is involved in the detoxification of atrazine.

γGlu-Cys-Gly (glutathione; GSH), a thiol redox tripeptide, is a major water-soluble redox buffer and antioxidant in plants.[39] Its homologous molecule, γGlu-Cys-βAla (homoglutathione; hGSH), exists in legume and has similar functions in plants including transport and storage of sulfur, scavenging of ROS, and defense to toxicants.[40,41] *Medicago sativa* belongs to the Fabaceae family containing both GSH and hGSH.[42] But hGSH is the most abundant thiol compound in alfalfa leaves, stems, and roots.[40] In this study, the conjugates of atrazine with hGSH were detected in the forms of ATZ-HCl+hGSH, DHA+hGSH, and MEA-HCl+hGSH, suggesting that the sufficient generation of hGSH should be beneficial for binding and detoxifying atrazine. By high intensity LC-MS analysis, we also detected the Cys conjugate with a function similar to that of hGSH in alfalfa. According to Leustek et al.,[43] the conjugates with GSH are hydrolyzed to Cys conjugates by action of γ-glutamyl transpeptidases and Cys-Gly dipeptidases in succession. Thus, it is possible that DHA+hGSH, MEA-HCl+hGSH, and ATZ-HCl+hGSH could be hydrolyzed to produce the corresponding Cys conjugates in addition to being transformed by conjugation of Cys and xenobiotics directly (Figure 7).

Classically, GSTs catalyze the transfer of glutathione to a cosubstrate with a reactive electrophilic center to form *S*-glutathionylated product.[44] The function was confirmed in alfalfa with the distinction that atrazine was conjugated with hGSH. The GST enzyme was activated in plants, particularly in the root with atrazine. The result was in accordance with our previous reports with other plant species.[26,45] The GST conjugates are usually processed by phase III pathway, making the conjugates compartmentalize into vacuoles, release into apoplasts, or combine into the insoluble residues within cell wall.[33] Detoxification of atrazine in alfalfa plants is most likely to undergo the same pathways.

In conclusion, the present study demonstrated that alfalfa had a great ability to accumulate atrazine in tissues from its growing environments. As a recognizable symptom, elongation and biomass were reduced and the total chlorophyll accumulation was impaired with treatment of atrazine. The BCF of alfalfa shoots and roots showed a downtrend with the

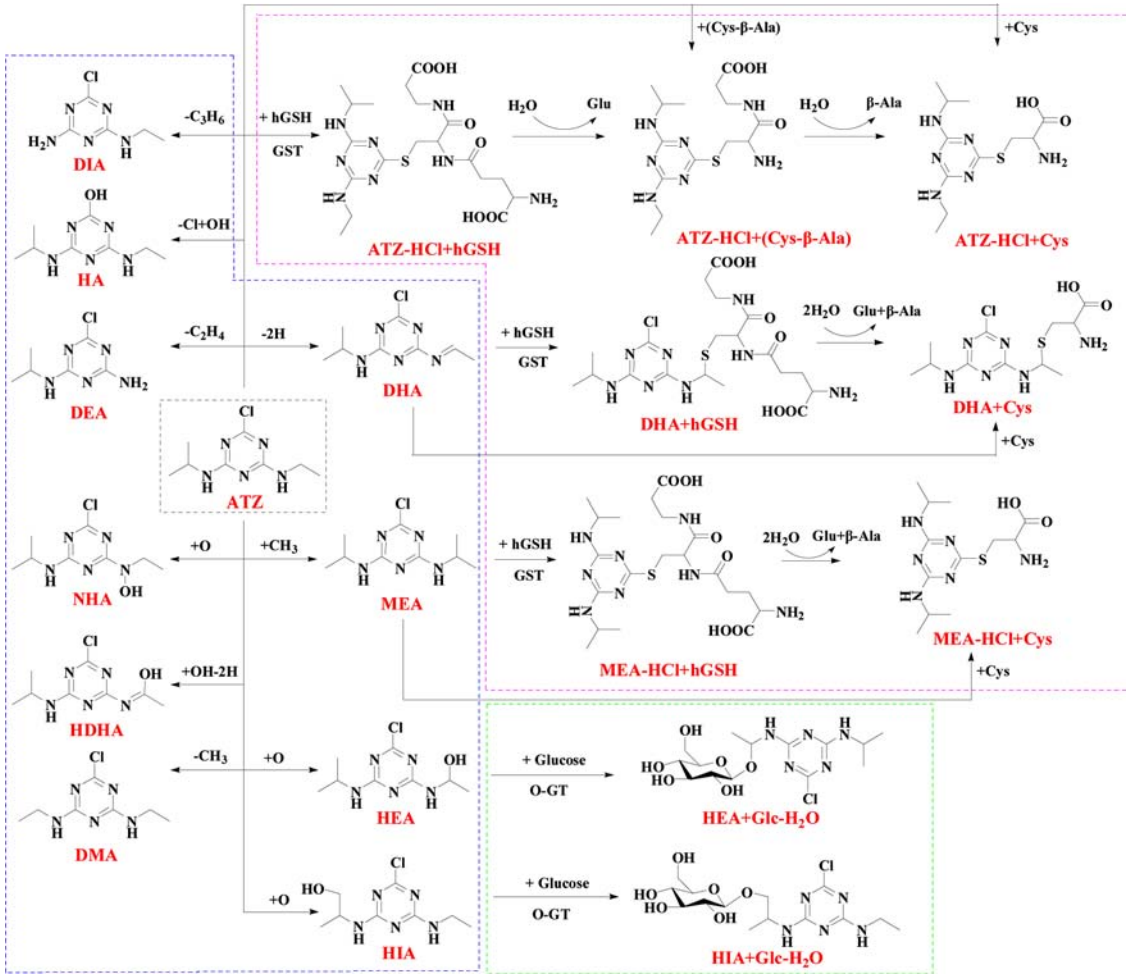

**Figure 7.** Proposed metabolic pathway of atrazine in *Medicago sativa*. The substance in the black dashed-line box is atrazine. The contents in the blue box are from phase I reaction metabolized from atrazine. The substances in the pink box are conjugates from phase II reaction conjugated with hGSH and amino acid of atrazine. The contents in the green box are from phase II reaction, i.e., glycosylation of atrazine.

increasing concentration of atrazine stress, whereas the TF values increased when the concentration of atrazine was elevated, suggesting that a translocation of atrazine occurred from roots to shoots. There were 10 metabolites of atrazine from phase I reaction and 9 conjugates from phase II reaction identified. Furthermore, the activity of GST and GTs was activated. These results indicate that the atrazine toxicity in alfalfa plants could be attenuated by conjugation with polar donor molecules, such as sugars, glutathione, and amino acids. The biochemical responses and metabolism pathway will serve as useful indicators for assessment of the herbicide contamination in agricultural environments.

humidity, light intensity of 340 $\mu$mol·m$^{-2}$·s$^{-1}$) and irrigated three times a week with distilled water (200−300 mL) to maintain saturation. Yoshida nutrient solution[11] was used to fertilize the plant as described in Supporting Information Table S1. Wheat green bug (*Schizaphis graminum*) appeared 65 days after transplanting (DAT), and plants were immediately sprayed with malathion (5 mg/L) (Ortho MAX Malathion). At harvest (94 DAT), spikes, flag leaves, and roots were collected and oven-dried at 80 °C for 5 days. Roots were cleaned thoroughly for 30 min in running tap water and rinsed for 5 min in distilled water. The grains were dehulled and stored at 4 °C until use. Samples for analysis were powdered and passed through mesh no. 40 (W. S. Tyler).

**Evaluation of Agronomic Traits and Yield Components.** Agronomic traits (plant height, chlorophyll content, number of tillers, peduncle length, and number of internodes) were assessed by five measurements from randomly selected plants in each pot. Plant height and chlorophyll content were measured at heading stage (30 DAT). Plant height was determined from soil surface to the flag leaf, while chlorophyll content was measured in the flag leaf by use of a SPAD chlorophyll meter (Spectrum Technologies, Aurora, IL). The number of spikes was counted when the spikes were fully exposed, while physiological maturity was recorded when the spike was completely dry. Shoot biomass from each pot was determined at harvest. For the yield components, the following parameters were measured for five random samples: spike length, number of spikes, number of spikelets/spike, number of grains/spike, gain yield/spike, 100-grain weight, and grain yield/pot. The five measurements from each pot for agronomic and yield components, except grain yield/pot, were averaged and used as one replicate measurement for statistical analyses.

**Cerium and Macro- and Micronutrient Concentrations in Wheat.** A microwave-accelerated reaction system (CEM Mars$_X$, Matthews, NC) was used to digest the samples in a mixture of plasma pure $HNO_3$ and $H_2O_2$ (1:4) and analyzed for elemental composition by inductively coupled plasma optical emission spectroscopy/mass spectrometry (ICP-OES/MS) (PerkinElmer, Waltham, MA) according to the method previously employed by Rico et al.[10] Blank, spikes, and standard reference material (NIST-SRF 1570a) were used to validate the digestion and analytical method.

**Amino Acid Profiling.** Amino acid analysis was performed following the method of Anjum et al.[12] Briefly, the powdered grains (50 mg) were mixed with 10 mL of 6 N HCL in a test tube, which was subsequently evacuated by nitrogen, sealed, and placed in an oven (110 °C) for 24 h. The hydrolysate was filtered and dried under vacuum (60 °C) before dissolving in 1 mL of phosphate buffer (pH 2.2). An aliquot (100 $\mu$L) was diluted 10 times with buffer, filtered in a 45 $\mu$m syringe filter, and analyzed on a Biochrom 20 amino acid analyzer.

**Fatty Acid Analysis.** Fatty acid content was estimated according to Asekova et al.[13] The powdered grains (500 mg) were placed in a 5 mL solution of chloroform/hexane/methanol (8:5:2 v/v/v) overnight. Derivatization was performed by mixing 100-$\mu$L extract with 75 $\mu$L of methylating reagent [0.25 M methanolic sodium methoxide/petroleum ether/ethyl ether (1:5:2 v/v/v)]. After 10 h, the solution was diluted to 1 mL with hexane. Fatty acid content was analyzed on an Agilent (Palo Alto, CA) Series 7890 capillary gas chromatograph fitted with a flame ionization detector with an AT-Silar capillary column (Alltech Associates, Derfield, IL). The temperatures of the oven, injector, and detector were set at 210, 250, and 230 °C, respectively. Standard fatty acid mixtures (Animal and Vegetable Oil Reference Mixture 6, AOACS) were used as calibration reference standards.

**Data Analysis.** The effect of $n$CeO$_2$ treatment on measured parameters was determined by the general linear model procedure in SAS statistical package, version 9.3 (SAS Institute, Cary, NC). Statistical significance between means was tested with Tukey's honestly significant difference test at $p \leq 0.05$.

## RESULTS AND DISCUSSION

**Cerium Accumulation in Wheat Tissues.** The accumulation of ENMs and their component metals in edible portions of plants is becoming a concern. Table 1 presents the Ce concentration in different wheat tissues. In the roots, control and $n$CeO$_2$-L yielded Ce concentration (1974 and 16 828 $\mu$g/kg, respectively) significantly lower than those in $n$CeO$_2$-M and $n$CeO$_2$-H (80 933 and 111 121 $\mu$g/kg, respectively). The Ce accumulations in $n$CeO$_2$-treated leaves and grains were in the range 430−442 and 155−263 $\mu$g/kg, respectively. However, these values did not reach statistical differences compared with values recorded in their respective controls (600 and 248 $\mu$g/kg, respectively). Similarly, the Ce concentration in the hull did not change significantly across treatments (412−450 $\mu$g/kg), strongly suggesting a lack of Ce translocation in wheat grains. Cornelis et al.[3] reported that $n$CeO$_2$ were stable in 16 different types of soil and found a dissolution rate of <3.1% at pH 4. Microscopy techniques have also shown that $n$CeO$_2$ accumulated largely in nanoparticulate form in food crops cultivated in soil and hydroponic suspension.[1] The current findings are in good agreement with previous reports in wheat showing that $n$CeO$_2$ adsorbed on the root surface[7] but are in stark contrast with the remarkable increases in Ce accumulation in rice grains, soybean pods, and tomato and cucumber fruits,[10,14−16] signifying the differences in root storage and above-ground tissues transport of Ce in plants.

**Table 1. Cerium Concentration in Different Tissues of Wheat Cultivated to Grain Production in $n$CeO$_2$-Amended Soil[a]**

| | Ce concn ($\mu$g/kg) | | | |
|---|---|---|---|---|
| soil[b] | root | leaves | hull | grains |
| 0 | 1974 ± 549 c | 600 ± 85 a | 435 ± 20 a | 248 ± 96 a |
| 125 | 16828 ± 332 c | 442 ± 19 a | 412 ± 9 a | 155 ± 45 a |

| 500 | 111121 ± 650 a | 430 ± 64 a | 428 ± 7 a | 263 ± 44 a |

[a]Values are means ± SE ($n$ = 3). Same letters mean no statistical difference between treatments at Tukey's test ($p \leq 0.05$). [b]Control = 0 mg/kg; $n$CeO$_2$-L = 125 mg/kg; $n$CeO$_2$-M = 250 mg/kg; $n$CeO$_2$-H = 500 mg/kg.

**Modifications in Growth Characteristics.** The agronomic characteristics of $n$CeO$_2$-exposed wheat are presented in Table 2 and Figure 1. It is evident from Table 2 that $n$CeO$_2$ had no effect on the exposed peduncle length, number of tillers, number of internodes, and chlorophyll content. $n$CeO$_2$-H improved plant height and shoot biomass by up to 5.32% and 12.71%, respectively, compared to the rest of the treatments. Previous studies found that $n$CeO$_2$ had no impact on growth, gas exchange, and chlorophyll content of cucumber[17] but improved dry stem and leaf biomass in soybean[14] and slightly enhanced plant growth but not chlorophyll content in tomato.[15] On the contrary, $n$ZnO- or $n$TiO$_2$-exposed wheat had reduced biomass production.[6]

In addition, $n$CeO$_2$ treatment caused a 6-day delay in spike formation and physiological maturity in wheat compared to control (Figure 1; Supporting Information Tables S2 and S3). Wang et al.[15] found that $n$CeO$_2$ prolonged by 2 days the fruit ripening in tomato. Although the extended period of time for spike formation and physiological maturity could improve yield in wheat,[8] it may have significant impacts on seeding time since correct planting date is important for growth stages and

phenological development to occur at appropriate environmental conditions.[18]

**Changes in Yield Parameters.** The impact of metal oxide ENMs on the crop yield is not yet well explored. Table 3 displays the influence of $n$CeO$_2$ on yield parameters of wheat. $n$CeO$_2$ altered all yield parameters, except for spike length and 100-grain weight. The number of spikelets per spike was highest (42.5) at $n$CeO$_2$-H and lowest (30.8) in control. However, the number of grains per spike in $n$CeO$_2$-L (25.3) and $n$CeO$_2$-H (26.0) were higher than that of the control (21.9) and $n$CeO$_2$-M (21.6). The grain yield per spike was significantly enhanced at $n$CeO$_2$-H (808.9 mg), but markedly reduced at $n$CeO$_2$-L (663.8 mg). In case of yield, only $n$CeO$_2$-H recorded a significantly higher yield per pot (12.7 g) compared to control (9.3 g). Current literature shows varying effects of $n$CeO$_2$ on the productivity of food crops; $n$CeO$_2$ had no impact on pod yield in soybean,[14] enhanced fruit production in tomato,[15] and reduced yield in cucumber.[17]

Wang et al.[15] found that longer vegetative stage enhanced fruit yield in $n$CeO$_2$-exposed tomato. Similarly, the superior yield at $n$CeO$_2$-H was consistent with the delayed spike formation and maturity as well as improved plant height, shoot biomass, number of grains and spikelets per spike, and grain yield per spike. It is interesting to note that the reduced yield in the control could be due to low number of grains, whereas at $n$CeO$_2$-L, the superior number of grains per spike and low grain weight did not result in improved yield.

**Mineral Accumulation.** Table 4 presents the elemental concentrations in roots, leaves, and grains of wheat. The $n$CeO$_2$ treatments did not modify the Ca, Zn, and Cu concentrations but altered the accumulations of K, P, S, Na, Fe, and Mn in roots; P, Mg, and Fe in leaves; and S and Mn in grains. In roots, K concentration markedly improved at $n$CeO$_2$-H (18 173 mg/kg) compared to the rest of the treatments (8081−12 658 mg/kg) while P accumulation significantly increased at $n$CeO$_2$-M (3686 mg/kg) relative to control and $n$CeO$_2$-L (2417 and 2903 mg/kg, respectively). S concentration was elevated at $n$CeO$_2$-M (2445 mg/kg) and $n$CeO$_2$-H (2772 mg/kg) in the roots but decreased at $n$CeO$_2$-L and $n$CeO$_2$-M (1621 mg/kg) in the grains compared to their respective controls (1667 and 1726 mg/kg, respectively). Mg accumulation in leaves was enhanced at $n$CeO$_2$-M (4559 mg/kg) relative to the control (3944 mg/kg).

The Na concentration in roots increased in all $n$CeO$_2$ treatments (3526−4121 mg/kg) relative to the control (2447 mg/kg), whereas Fe accumulation in all $n$CeO$_2$ treatments in roots (388−426 mg/kg) and $n$CeO$_2$-M and $n$CeO$_2$-H in leaves (97 and 101 mg/kg, respectively) decreased compared to their

| 500 | 18.60 ± 0.07 a | 1.85 ± 0.03 a | 14.67 ± 0.23 a | 59.96 ± 0.08 a | 4.66 ± 0.03 ab |

[a]Values are means ± SE ($n$ = 3). Same letters mean no statistical difference between treatments at Tukey's test ($p \leq 0.05$). [b]Control = 0 mg/kg; $n$CeO$_2$-L = 125 mg/kg; $n$CeO$_2$-M = 250 mg/kg; $n$CeO$_2$-H = 500 mg/kg.

controls (455 and 117 mg/kg, respectively). In contrast, Mn concentration in roots and grains did not differ between $n$CeO$_2$ treatments (56−72 and 48−52 mg/kg, respectively); however, $n$CeO$_2$-H yielded a superior amount of Mn (72 mg/kg) in roots compared to control (49 mg/kg), while $n$CeO$_2$-M had reduced Mn accumulation (48 mg/kg) in grains relative to control (57 mg/kg).

These findings suggest that $n$CeO$_2$ modulated the elemental accumulation in roots and leaves without detrimental impact on the nutritional content of grains. It is possible that the modulation in P storage was due to the association of Ce with $PO_4^{3-}$ as observed in $n$CeO$_2$-exposed soybean and cucumber.[1] The increase in S concentration was opposite to that recorded in $n$CeO$_2$-treated soybean, wherein S accumulation did not change in all tissues analyzed.[19] Likewise, $n$CeO$_2$ altered Na and Fe concentrations in wheat roots and leaves, which was not observed in previous studies in soybean.[19] Unfortunately, there is a lack of understanding in current literature regarding the aggregation, association, and mobility of elements in $n$CeO$_2$-amended soil that could help explain the changes in their accumulation in wheat. In grains, only S concentration at $n$CeO$_2$-L and $n$CeO$_2$-M and Mn concentration at $n$CeO$_2$-M had marked reductions compared to their respective controls. Previous reports also revealed that $n$CeO$_2$ altered S and Mn accumulations in rice grains[10] and cucumber fruit,[16] respectively, but not in soybean pods.[19] At this point it is difficult to determine the cause of the reduced accumulation of S and Mn in grains, but their decrease may have negative implications on food quality.

**Amino Acid Content in Grains.** The effects of $n$CeO$_2$ on amino acid (AA) content of wheat grains was examined and the data are displayed in Table 5. Results showed that $n$CeO$_2$ did not modify the contents of alanine, cysteine, leucine, methionine, proline, and glutamic acid. $n$CeO$_2$-L had generally elevated AA content, but statistical difference relative to the control was achieved only for aspartic acid, glycine, lysine, histidine, and arginine. The control, $n$CeO$_2$-M, and $n$CeO$_2$-H had similar levels of AA except for superior amounts at $n$CeO$_2$-H treatment compared to control and $n$CeO$_2$-M for histidine and phenylalanine, respectively. Among the essential AA, $n$CeO$_2$-L increased lysine and histidine content (15.33 and 13.67 $\mu$g/g, respectively) compared to control (13.24 and 11.76 $\mu$g/g, respectively). The amide-NH$_3$ was highest at $n$CeO$_2$-L and $n$CeO$_2$-M (26.50 and 26.30-$\mu$g/g, respectively) and lowest in the control (24.05 $\mu$g/g), whereas total AA contents did not change between treatments, although it had the tendency to increase at $n$CeO$_2$-L (540.73 $\mu$g/g) compared to the rest of the treatments (494.72−499.08 $\mu$g/g).

These findings revealed that $n$CeO$_2$ interfered with AA synthesis in wheat, with $n$CeO$_2$-L demonstrating the tendency to improve AA content in wheat grains. Currently, there is no other study regarding the effects of ENMs on AA or protein

synthesis in cereal grains, which makes interpretation of the present results difficult. However, studies exhibited that AA metabolism or protein content was modified in ENM-exposed wheat and rice[10,20] while various ENMs (*n*Ag, *n*S, $n$SiO$_2$, $n$TiO$_2$, and *n*ZnO) modified protein levels in different crops.[1]

**Relative Fatty Acid Abundance in Grains.** The influence of $n$CeO$_2$ on the relative fatty acid (FA) abundance in wheat grains was analyzed and presented in Table 6. The analysis revealed that $n$CeO$_2$ treatments did not alter the relative FA abundance of palmitic, oleic, and stearic acids. In contrast, $n$CeO$_2$-L caused a remarkable reduction in the relative FA content of linoleic acid by up to 1.63% relative to the rest of the treatments but afforded a marked increase in the relative FA content of linolenic acid by up to 6.17% relative to the rest of the treatments. These data revealed that $n$CeO$_2$ also disturbed FA synthesis and storage in wheat grains.

Similar to what was observed in the AA analysis, $n$CeO$_2$-L provoked significant changes on FA contents, indicating the impact of this treatment on the nutritional value of wheat grains. Previous studies have shown that $n$CeO$_2$ modified the FA content in rice grains[10] while *n*Au stimulated oil production in mustard seeds (*Brassica juncea*).[21] The modifications in AA and FA contents signify that $n$CeO$_2$ could have serious implications on the nutritional value of wheat grains.

**Pearson's Correlations.** Table 7 displays the correlations between measured parameters and Ce concentration in roots or grains. The data illustrate that, in roots, Ce concentration was positively correlated with K, S, and Na at $p \leq 0.01$ and with P, Mg, and Mn at $p \leq 0.05$. In grains, root Ce concentration was positively correlated with Fe at higher significance level (0.773 08, $p \leq 0.01$) than Na (0.680 55, $p \leq 0.05$). Likewise, root Ce concentration manifested stronger positive correlations ($p \leq 0.01$) with plant height, shoot biomass, number of spikelets, and yield per pot than with spike length ($p \leq 0.10$). Furthermore, the data displayed that root Ce concentration was negatively correlated with threonine, serine, alanine, and valine at greater significance level ($p \leq 0.05$) than in aspartic acid, glycine, and isoleucine ($p \leq 0.10$). Only linoleic acid displayed a positive correlation with root Ce concentration (0.63156, $p \leq 0.05$). The highly significant positive correlations between Ce and growth parameters are in agreement with the fertilizer effect of Ce. However, the improvement in growth and yield was accompanied by detrimental impacts on AA compositions of grains, especially since four essential amino acids were negatively affected. On the other hand, the positive correlation of Ce with P, S, Mg, Mn, and Na concentrations in roots could indicate important implications or associations of these elements with $n$CeO$_2$. Unfortunately, there is limited understanding of this aspect in current literature.

In grains, Ce concentration displayed positive correlation with Ca (0.59941, $p \leq 0.05$) similar to what was observed in $n$CeO$_2$-exposed rice grains[10] and $Ce^{3+}$-treated rice seedlings.[22] On the other hand, the negative correlations between Ce and chlorophyll content, threonine, isoleucine, and lysine suggest that Ce content could have significant impacts on essential amino acids in grains.

In summary, the study revealed that $n$CeO$_2$ improved the plant height, biomass, and grain yield and modified the amino acid and fatty acid contents despite the apparent lack of Ce transport and accumulation in above-ground tissues of wheat. The findings underscore the significance of examining the long-term impacts of ENMs on the productivity and quality of food crops.

nonadienal in fish oil enriched milk.[6] The volatiles (*Z*)-4-heptenal and (*E*,*Z*)-2,6-nonadienal have been associated with fishy off-flavors in oxidized fish oil.[7] One study concluded that the volatile secondary oxidation products (*E*,*Z*)-2,6-nonadienal, 1-penten-3-one, (*Z*)-4-heptenal, and (*E*,*E*)-2,4-heptadienal, while individually not responsible for fishy malodors, were the cause of fishy malodors as a result of a combinatory effect.[1] They did not include 1,5-octadien-3-one in their sensory descriptive experiments even though it had been previously reported as a potent odorant in fish oil because it was not detected in their fish oil enriched milk having a strong fishy off-flavor.

Researchers studying fish oil enriched mayonnaise concluded that the following ketones probably contribute to fishy malodors: 1-penten-3-one, (*E*)-3-penten-2-one, 3-heptanone, (*Z*)-1,5-octadien-3-one, 1-nonen-3-one, 2-nonanone, (*E*,*Z*)-3,5-octadien-2-one, and (*E*,*E*)-3,5-octadien-2-one.[4] Furthermore, they surmise that (*Z*)-1,5-octadien-3-one is probably the most potent fishy odorant due its extremely low threshold value (0.00003 mg/kg in oil) and characteristic geranium-like odor.[2]

While the most potent odorants associated with DHA and EPA oxidation have been identified, demonstration of correlation between their presence and concentration levels with fishy malodor development is lacking. Assuming that the most potent odorants are the cause of fishy malodor could be erroneous. Few if any GC-O supportive studies have investigated odorant synergy effects as the cause of fishy malodors.

GC-O is traditionally used to identify individual odor-active GC fractions. Potential synergy effects cannot be evaluated when single compounds are evaluated over time. Many synergistic effects are known to occur between single compounds in complex food matrices.[8] Combinations of single substances can produce enhancing or masking interactive effects. For example, researchers investigating the aging of beer reported a change in sensory perception of components when evaluated singularly versus when evaluated in combination. Specifically, (*E*)-2-nonenal was evaluated by panelists as cardboard-like and (*E*,*Z*)-2,6-nonadienal was perceived as cucumber-like when the single chemicals were subjected to GC-O. However, the combined effect of the two compounds generated a sweet fruity flavor perception distinctly different from the single substances alone.[8] The researchers concluded that the new sensory perception of the combination appeared to be related to both the absolute and relative concentrations of the two compounds.

Numerous sample preparation analytical techniques prior to GC-O have been applied to the analysis of fishy off-flavors, including dynamic headspace with Tenax GR trapping,[4,9] simultaneous steam-distillation-solvent extraction (SDE using a Likens−Nickerson apparatus),[10] solid-phase microextraction (SPME) using a Carboxen/PDMS fiber,[11] and static headspace.[12] Headspace sorptive extraction (HSSE) with 2 cm PDMS Twisters was used in the present study.[13]

Naude and Rohwer developed a novel GC-O approach to studying odorant synergy effects. In their method, sorptive extraction of aroma volatiles is accomplished using multichannel open tubular silicone (polydimethylsiloxane [PDMS]) rubber traps (MCTs) for fraction collection of aroma compounds.[14] GC peaks from milk samples were collected on MCTs that were fitted into the GC FID (FID and flame gases were turned off) for fraction collection purposes. Selection of peaks to trap was made on a carefully timed basis after preanalyzing samples to determine significant odorants. The captured chemicals on the MCT were transferred to an off-line portable heating device (with a nitrogen flow of 20 mL/min and a temperature of 130 or 160 °C).The aroma of the thermally released compounds could then be evaluated by panelists. As aroma eluted from the MCT, it was sniffed by a team of six evaluators. Using this approach, researchers determined that a synergistic combination of 2-heptanone and 2-nonanone was responsible for a pungent cheese, sour milk-like aroma detected in UHT milk. Interestingly, when smelled individually, 2-heptanone has a fruity-floral-soapy aroma and 2-nonanone has a fruity-sweet aroma.

In the present study, an olfactometry detector was used as a fraction collector to trap various peaks in marine oil chromatograms. The nose cone of the olfactometry detector was replaced with a Gerstel PDMS foam absorption tube at various precise times during GC analysis. Combinations of GC peaks were trapped on PDMS tubes, desorbed in a Gerstel thermal extractor (off-line) at 160 °C, and sniffed by aroma evaluators to determine the combined synergistic perception of mixtures of aroma compounds present in marine oil contaminated with fishy malodors.

This study was conducted to (1) determine which chemicals cause fishy malodors and (2) provide an analytical methodology for studying odor synergy effects.

## MATERIALS AND METHODS

**Experimental Design.** This study was divided into several experiments. Algal oils with varying degrees of fishy malodor were tested by GC-MS. Sample preparation techniques investigated included purge-and-trap, SPME, and HSSE GC-MS. HSSE was selected as the primary analytical technique because it had the highest sensitivity and provided excellent replicate determinations.

In the next step, GC-O experiments were performed on samples with strong fishy malodors. When no single peak was found to contribute fishy malodors, synergy effects between two or more odorants were investigated. First, all sample analytes were trapped on a PDMS foam trap, desorbed simultaneously with the Gerstel Thermal Desorber, and sniffed by panelists. A strong fishy odor was detected by the panel of sniffers, suggesting that odorant synergy effects could be responsible for the fishy malodor. Attempts were made to isolate the odorants responsible for the fishy malodor by trapping odorants in various regions of the chromatogram and then evaluating odor characteristics of the trapped volatiles after simultaneous desorption in the Thermal Desorber. Using this process, only two chemicals—heptanal and (*E*,*Z*)-3,5-octadien-2-one—when present in the trapped volatiles were found essential for generating fishy malodor. To confirm that these two odorants were all that was necessary to generate fishy malodor, only these two chemicals were trapped and subjected to sniffing with the thermal extractor. Omission experiments were also conducted. In omission experiments all volatiles in the chromatogram except heptanal and (*E*,*Z*)-3,5-octadien-2-one were trapped and then desorbed in the Thermal Desorber to see if the fishy odor was present.

Experiments were then conducted to confirm the identity of these two chemicals and to check for the possibility of coelution of contaminating peaks. Identification of (*E*,*Z*)-3,5-octadien-2-one is based on retention index values using a DB-5 column and olfactometry odor characteristics compared to literature results, as well as mass spectra (EI and CI). Accurate mass measurements for the (*E*,*Z*)-3,5-octadien-2-one peak were made using a high resolution time-of-flight mass spectrometer (Leco Pegasus GC-HRT).

**Marine Oil Samples.** Fermentor grown microalgae samples were processed to extract the DHA-rich oil. The finished commercial product is a clear, amber-colored oil rich in DHA. Six algal oil samples were analyzed (two with no fishy malodor and four with fishy malodor). A commercial microencapsulated powder version of the

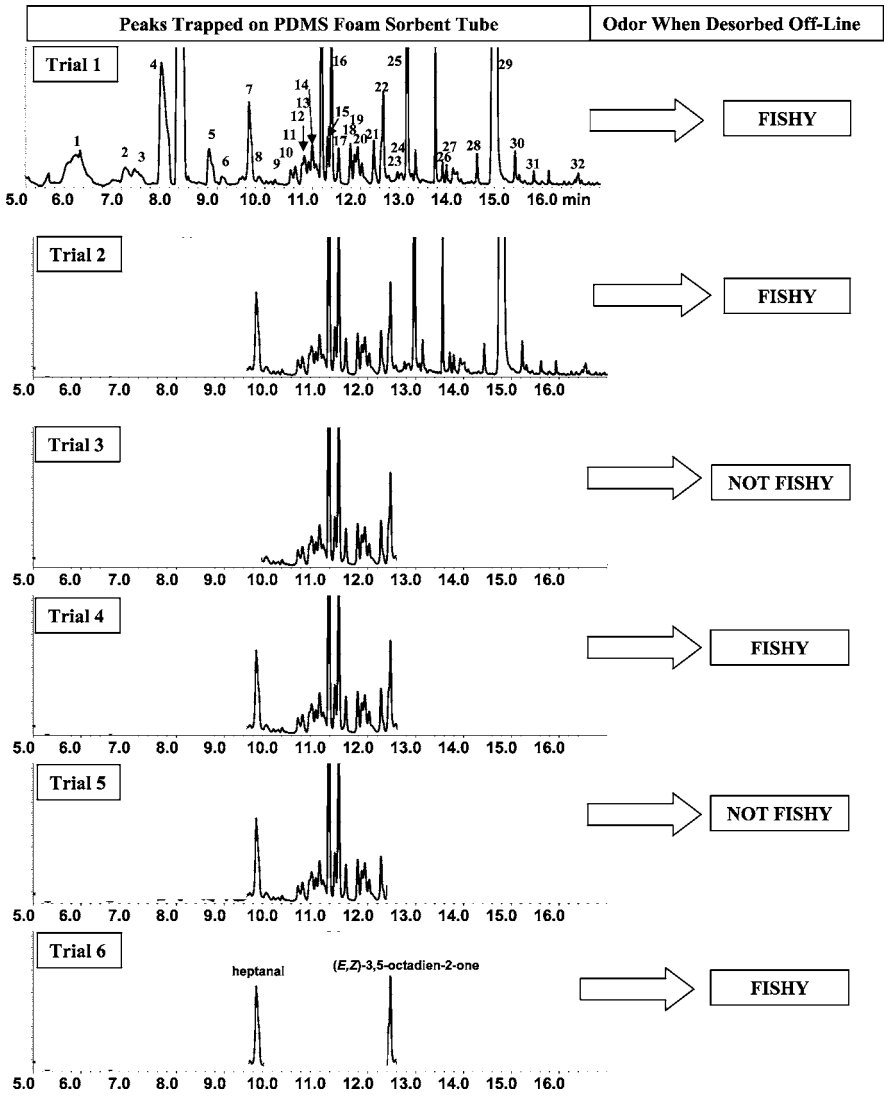

**Figure 1.** 2.00 g of marine oil extracted with 20 mm × df = 0.5 mm (47 $\mu$L) Twister stir bar (PDMS) in headspace for 2 h at 50 °C while stirring with Teflon-coated micro stir bar. The same sample was analyzed six times. Figure shows how peaks contributing to fishy malodor were isolated and identified. Off-line thermal desorption with a Gerstel thermal extractor was used for odor characterization. Peaks that are not numbered are background siloxane impurities in PDMS. Identity of numbered peaks and retention indices [in brackets] are as follows: (1) 1-penten-3-ol [682]; (2) 2-pentenal [750]; (3) 1-pentanol [767]; (4) hexanal [800]; (5) 2-hexenal [854]; (6) 1-hexanol [877]; (7) heptanal [901]; (8) 2,4-hexadienal [912]; (9) methylcyclohexane [933]; (10) 1,1-diethoxy-3-methylbutane [954]; (11) 2-heptenal [958]; (12) benzaldehyde [964] and 1-heptanol [967] coeluting; (13) 1-octen-3-one [970]; (14) 3,5,5,-trimethyl-1-hexene [975]; (15) (*E,Z*)-2,4-heptadienal [996]; (16) octanal [1004]; (17) (*E,E*)-2,4-heptadienal [1013]; (18) 2-ethyl-1-hexanol [1028]; (19) limonene [1030]; (20) eucalyptol [1032]; (21) 2-octenal [1063]; (22) 1-octanol [1074] and (*E,Z*)-3,5-octadien-2-one [1081] coeluting; (23) 2-nonanone [1090]; (24) (*E,E*)-3,5-octadien-2-one [1098]; (25) nonanal [1104]; (26) (*E,Z*)-2,6-nonadienal [1146]; (27) 2-nonenal [1150]; (28) decanal [1207]; (29) 2-ethylhexyl acrylate [1235]; (30) 2-decenal [1253]; (31) 2-undecanone [1291]; (32) 2-dodecenal [1469]. Reprinted with permission from ref 19. Copyright 2014 John Wiley & Sons Ltd.

DHA oil sample with a strong fishy malodor was also analyzed. The samples were sourced from a major supplier of DHA oils.

Algal oil is composed mainly of triglycerides. The composition is approximately 35−45% DHA and other triglycerides, including myristic acid (13−20%), palmitic acid (12−25%), oleic acid (10−25%), lauric acid (2−6%), and capric acid (1%). Heptanal, octanal, nonanal, decanal, 2-decenal, and 2-undecenal are formed from autoxidation of oleic acid, an *n*−9 monounsaturated fatty acid. The (*E,Z*)-3,5-octadien-2-one observed in the samples is derived from DHA oxidation.

**Chemicals.** Standards were obtained to assist in the identification of (*E,Z*)-3,5-octadien-2-one. A standard of (*E,E*)-3,5-octadien-2-one (CAS No. 30086-02-3) was purchased from Penta Manufacturing Company (Fairfield, NJ). A standard consisting of a mixture of (*E,E*)-3,5-octadien-2-one and (*E,Z*)-3,5-octadien-2-one (90% v/v and 10% v/v, respectively) was obtained as a gift from Allard Cossé, Crop Bioprotection Research Unit, USDA−ARS, Nat. Center for Agricultural Utilization Research (NCAUR), Peoria, IL. While this standard assisted in the identification of (*E,Z*)-3,5-octadien-2-one, it was not useful for conducting recombination/model system studies. Recombination studies, which involve spiking odorless control oils with odorant suspects, are frequently used for sensorial confirmation of which odorants are responsible for the odor of a product. Since (*E,Z*)-3,5-octadien-2-one was present in minor amounts compared to the major component of (*E,E*)-3,5-octadien-2-one, which has a strong geranium-like odor, the standard from Allard Cossé could not be used for recombination studies. A pure standard of (*E,Z*)-3,5-octadien-2-one was not commercially available.

**HSSE GC-MS Analysis.** Samples were analyzed by headspace sorptive extraction (HSSE) using the Gerstel Twister, length = 20 mm, df = 0.5 mm, 47 $\mu$L PDMS coating (Part No. 011444-001-00). Two grams of algal oil sample was placed in a 20 mL glass GC vial with a 10

Table 1. Olfactometry Results for Typical Algal Oil with Fishy Malodor[a]

| trial | region of chromatogram trapped (min) | odor characteristic | comment |
|---|---|---|---|
| T1 | 7.62−16.60 | fishy | fishy odorants trapped |
| T2 | 9.30−15.00 | fishy | fishy odorants trapped |
| T3 | 10.30−12.70 | not fishy | at least one contributor to fishy malodor excluded from trapping |
| T4 | 9.30−12.70 | fishy | heptanal suspected as contributor |
| T5 | 9.30−12.30 | not fishy | (*E*,*Z*)-3,5-octadien-2-one suspected as contributor |
| T6 | 9.30−9.75 and 12.35−12.50 | fishy | heptanal and (*E*,*Z*)-3,5-octadien-2-one confirmed contributors |
| T7 | 9.75−12.50 | not fishy | heptanal excluded; confirms heptanal as contributor |
| T8 | 9.30−12.35 | not fishy | (*E*,*Z*)-3,5-octadien-2-one excluded; confirms its contribution to fishy odor |

[a]Odor of combinations of chemicals evaluated off-line after trapping on PDMS foam followed by thermal desorption. Six evaluators used per test; all samples tested in triplicate.

mm Teflon coated micro stir bar. A paperclip was attached to the septum, and the Gerstel Twister was suspended from the paperclip in the headspace of the vial. The sample was heated to 50 °C. Extraction was continued for 2 h at 50 °C while the Teflon micro stir bar was stirred at 350 rpm; the Twister attached to the paperclip remained stationary. The Twister was then removed from the vial and subjected to thermal desorption using the Gerstel TDU. Samples were tested in triplicate.

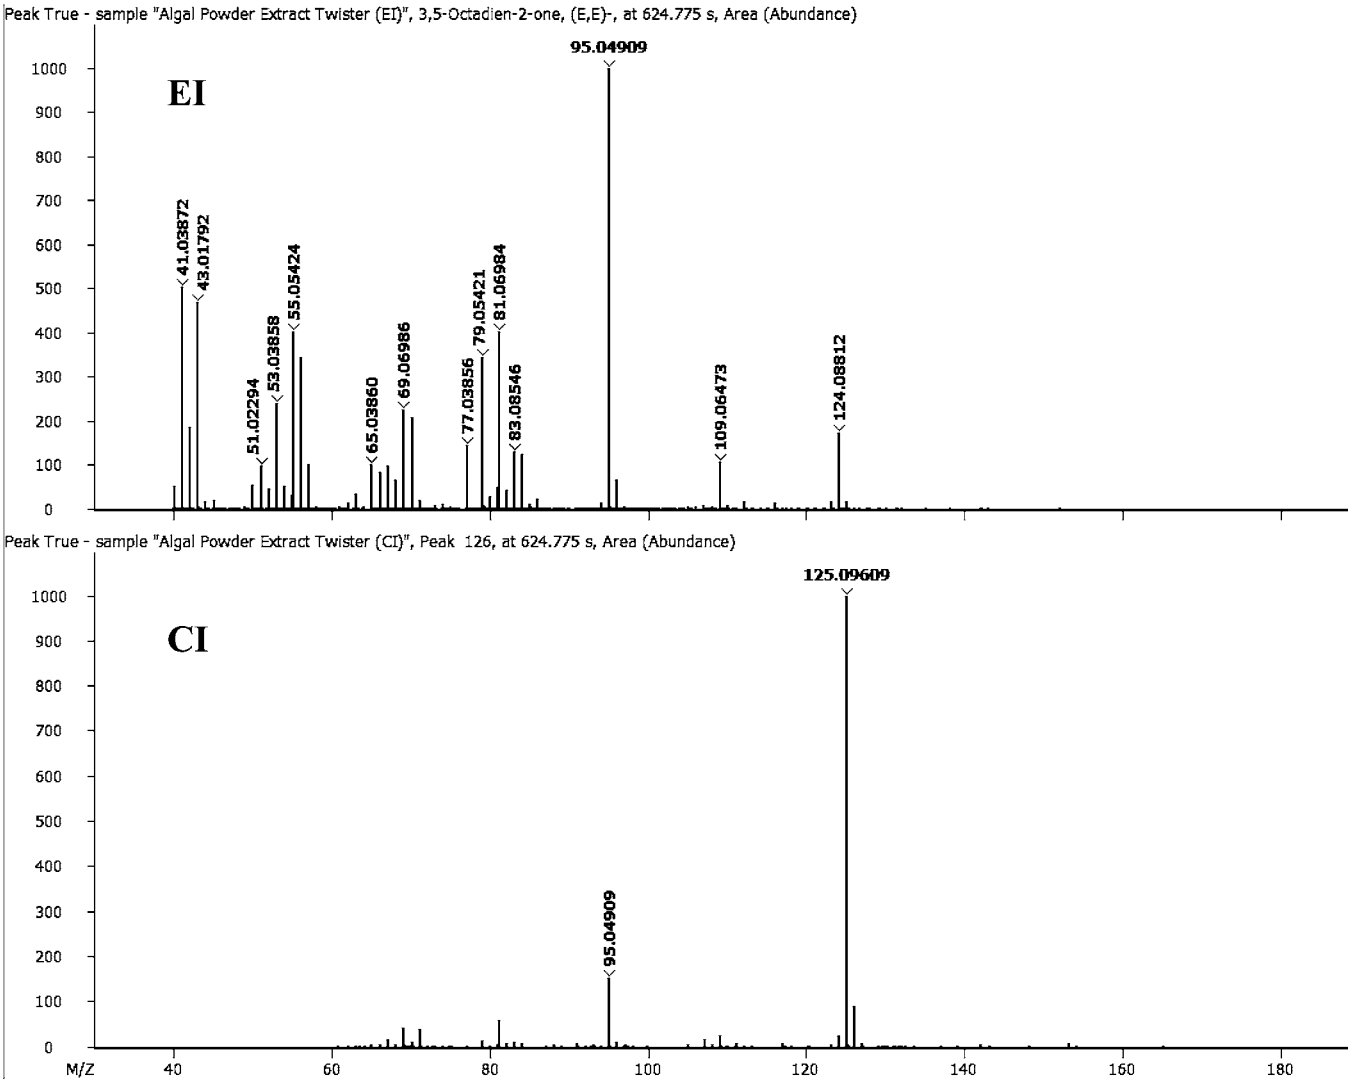
Concentrations of the two oxidation products—heptanal and (*E*,*Z*)-3,5-octadien-2-one—were measured in samples using a method-of-additions HSSE technique. A nonfishy algal oil sample was spiked with varying levels of heptanal and (*E*,*Z*)-3,5-octadien-2-one to develop a standard calibration curve. Since a pure standard of (*E*,*Z*)-3,5-octadien-2-one was not available, the standard containing a mixture of 10% (v/v) (*E*,*Z*)-3,5-octadien-2-one and 90% (v/v) (*E*,*E*)-3,5-octadien-2-one was used for the calibration. Calibration curves were prepared by adding 0, 40, 100, 200, and 500 ppb heptanal ($R^2$ = 0.979) and 0, 4.8, 12, 23.9, and 60 ppb (*E*,*Z*)-3,5-octadien-2-one ($R^2$ = 0.969).

**Thermal Desorption Parameters.** The Gerstel cooled injection system (CIS), a programmed temperature vaporization (PTV) type inlet, was used in the solvent vent mode at 50 mL/min; cryofocusing was at −100 °C followed by heating at 12.0 °C/s to 280 °C and then holding at 280 °C for 3.00 min. The Gerstel cooled injection system (CIS) liner (Gerstel part number 012442-010-00) used was quartz wool. Gerstel TDU parameters were as follows: initial temperature was 30 °C, followed by heating at 60.0 °C/min to 280 °C and holding at 280 °C for 4.00 min.

**GC Parameters.** The column used was DB-5MS, 30 m × 0.25 mm × 0.25 μm (Agilent Technologies, catalog number 122-5532).The initial column temperature was 40 °C for 3 min, followed by heating at 10 °C/min to 270 °C for 3 min. Carrier gas flow was 1.0 mL/min through the column; the inlet was set to splitless mode. The flow was split 1:1 between the MS detector and the olfactometry detector. To check for possible coeluters, samples were reanalyzed on a Leco Pegasus HT GC-TOFMS instrument (sampling rate at 40 spectra/second) using the same method and GC conditions. The peak deconvolution capability of this instrument showed that 1-octanol tended to coelute on the front leading edge of the (*E*,*Z*)-3,5-octadien-2-one peak. Subsequent experiments showed that 1-octanol was not a contributor to the fishy odor. No other coelution of chemicals with heptanal or (*E*,*Z*)-3,5-octadien-2-one peaks was observed.

**Additional Dynamic Headspace Analyses.** Several samples were also analyzed by dynamic headspace GC-MS using either PDMS foam traps (Gerstel catalog number 013758-005-00) or Tenax TA traps (Gerstel catalog number 013741-005-00), both purchased from Gerstel. The PDMS foam traps, which can be heated up to 300 °C, were identical to those used to collect volatiles with the olfactometry detector (see Olfactometry Experiments). Two grams of algal oil and a Teflon stir bar (stirring at 350 rpm) were placed in a desorption tube with the sparging needle just above the surface of the oil. The dynamic headspace glassware was purchased from Scientific Instrument Services (Ringoes, NJ). The sample was heated to 50 °C for 20 min with a nitrogen purge gas flow rate of 50 mL/min. Results were not significantly different from HSSE results and are not reported here. The same TDU program as used for HSSE was used to desorb volatiles from the traps.

**Olfactometry Experiments.** All samples were subjected to GC-O experiments to assess odor quality and intensity of each individual peak. Four trained panelists, three females ages 24−35 years old and one male age 23, were used for GC-O experiments. The Gerstel ODP-3 was used at 160 °C. Panelists sniffed chromatogram effluents for the entire GC run time of the sample (29.0 min). Even though samples had a fishy malodor, none of the individual peaks shown in Figure 1 had a fishy smell. Studying synergistic olfactometry responses from combinations of odorants was more challenging. For example, the strategy used for collecting specific regions of the chromatogram is illustrated in Figure 1 and Table 1 (column titled "region of chromatogram trapped"). Initially (trial 1), all volatiles in the sample were trapped on a polydimethylsiloxane (PDMS) foam sorbent tube and desorbed off-line to characterize the odor of the entire sample. In trial 2, a wide swath of the chromatogram was trapped onto a PDMS tube. The PDMS foam trap is an open porous foam packing used for analyte trapping. PDMS strongly retains nonpolar analytes. The trap is then inserted into a Gerstel thermal extractor (off-line), which is preheated to 160 °C with a nitrogen flow gas at 50 mL/min. Evaluators (four) consecutively sniffed the effluent from the PDMS foam tube for 30 s after tube was placed in the thermal desorber to assess the overall odor impact (fishy or not fishy). If fishy aroma is not detected in the desorbed volatiles mixture but the algal oil sample has a fishy malodor, then the analytical method may not be trapping the analytes responsible for the fishy malodor and alternate sample preparation methods or traps should be considered. However, this was not the case. The "fishy" aroma was noted in all initial trials of complaint samples. The sample was reanalyzed (trial 3), but this time fewer chromatographic peaks were collected. If this sample fraction demonstrated a fishy aroma, then the sample was analyzed again with even fewer peaks collected. In this process, either the front or back end of the chromatogram was sequentially omitted from collection. This process continues until the sample sniffed at the thermal extractor shows no fishy odor, indicating that an important fishy odor contributor has not been captured. Monitoring the MS TIC trace on the computer screen during GC-MS analysis allows for accurate determination of times to attach and detach the PDMS tubes for trapping. To test the accuracy of the trapping technique to collect the desired peaks of interest, one PDMS tube was thermally desorbed after trapping only heptanal and (*E*,*Z*)-3,5-octadien-2-one and analyzed by GC-MS. Its chromatogram showed that the two major contributors to fishy malodor were indeed trapped with no significant background contamination from other peaks. When potential fishy odor causing candidates have been identified, only they are collected on the trap and desorbed off-line for aroma evaluation (trial 6). If the fishy odor is detected, these volatiles are confirmed as the cause of fishy odor development in the oil. Results are then confirmed in omission experiments: by reanalyzing the sample after all peaks are trapped except the ones suspected of causing the fishy odor.



**EI results summary:**

| Name | Similarity | Expected Ion m/z | Observed Ion m/z | Formula | Mass Accuracy (ppm) |
|---|---|---|---|---|---|
| 3,5-Octadien-2-one, (E,E)- | 742 | 124.08827 | 124.08831 | C8H12O | 0.38 |

**CI results summary:**

| Species | Expected Ion m/z | Observed Ion m/z | Mass Accuracy (ppm) | Formula |
|---|---|---|---|---|
| H Gain | 125.09609 | 125.09609 | -0.007 | C8H12O |

**Figure 2.** EI and CI spectra for (*E*,*Z*)-3,5-octadien-2-one on Leco Pegasus GC-HRT.

## RESULTS AND DISCUSSION

A typical HSSE chromatogram of algal oil with a strong fishy aroma is shown in Figure 1 (trial 1). Approximately 32 significant odor-active peaks were detected. None of the chemicals in singularity imparts a fishy malodor to the sample, even though many have high odor activity values (OAVs), the ratio of the chemical concentration in the food to its threshold concentration in that food. No unusual chemicals were detected; most are expected lipid oxidation products that have been previously reported in algal oils. Recent research has shown that OAV measurements for predicting the perceived intensity of odorants and their contribution to their overall aroma are not good indicators of the actual sensory experience.[15]

As indicated in Figure 1 (trial 6) and Table 1, the combination of heptanal and (*E*,*Z*)-3,5-octadien-2-one when smelled together has been shown to cause fishy malodors. The results from olfactometry assessment show that the aromas of the individual oxidation products heptanal and (*E*,*Z*)-3,5-octadien-2-one are distinctly different from the aroma of the two compounds when evaluated in combination. With the off-line sniffing capability of the thermal extractor it is possible to use a team of several aroma evaluators for each sample that is thermally desorbed.

Using PDMS foam as the trapping medium is important because, like the MCTs used by Naude and Rohwer,[14] it has low in-line backpressure and does not cause peak shifting in

dx.doi.org/10.1021/jf502252q | J. Agric. Food Chem. 2014, 62, 9676−9682

chromatograms. Peak retention times when the PDMS trap is attached and when it is not attached are identical.

Identification of heptanal in samples is based on mass spectra (EI), rentention index (compared to pure heptanal standard using DB-5 column), and olfactometry odor characteristics compared to pure standard. Identification of (*E*,*Z*)-3,5-octadien-2-one is based on retention index values using a DB-5 column and olfactometry odor characteristics compared to literature results, as well as mass spectra (EI and CI). Accurate mass measurements for the (*E*,*Z*)-3,5-octadien-2-one peak were made using a high resolution time-of-flight mass spectrometer (Leco Pegasus GC-HRT). The EI spectrum for (*E*,*Z*)-3,5-octadien-2-one indicates the molecular ion at *m*/*z* 124.08831; the formula search indicated $C_8H_{12}O$ with a mass accuracy of 0.38 ppm. The CI spectrum for (*E*,*Z*)-3,5-octadien-2-one shows a strong protonated molecular ion at *m*/*z* 125.09609 that confirmed the molecular weight of the compound. The accurate mass measurement of the CI molecular ion also suggested $C_8H_{12}O$ with a mass accuracy of −0.007 ppm. Figure 2 shows accurate mass results and spectra. Instrument parameters for the Pegasus GC-HRT were as follows: mode, high resolution (*R* = 25,000); mass range, 40−400 *m*/*z* (EI), 60−510 *m*/*z* (CI); acquisition rate, 6 spectra/s; electron energy: −70 eV (EI), −140 eV (CI); and reagent gas for CI, 5% ammonia in methane at 0.8 mL/min.

Table 2 shows that concentrations of both heptanal and (*E*,*Z*)-3,5-octadien-2-one are higher in complaint fishy malodor samples compared to samples lacking the fishy aroma defect and tend to be highest in the most offensive sample (the DHA microencapsulated powder sample).

**Table 2. Concentrations of Heptanal and (*E*,*Z*)-3,5-Octadien-2-one in Algal Oil Samples with and without Fishy Malodor and DHA Powder with Strong Fishy Malodor[a]**

| sample description | heptanal (μg/kg) | (*E*,*Z*)-3,5-octadien-2-one (μg/kg) |
|---|---|---|
| oil #1a: not fishy | 1,715 | 6 |
| oil #2a: not fishy | 1,175 | 9 |
| oil #3a: medium fishy odor | 1,695 | 49 |
| oil #3b: medium fishy odor | 2,025 | 115 |
| oil #4a: medium fishy odor | 5,141 | 58 |
| oil #4b: strong fishy odor | 3,260 | 246 |
| DHA microencapsulated powder: strongest fishy odor | 10,226 | 3,127 |

[a]Samples analyzed by HSSE GC-MS. Method-of-additions calibration used.

Octanol, which tended to coelute on the front end of the (*E*,*Z*)-3,5-octadien-2-one peak with the chromatographic conditions used, was investigated as a potential contributor to fishy malodor; it did not make a significant impact on fishy malodor. (*E*,*E*)-3,5-Octadien-2-one and chemicals other than heptanal and (*E*,*Z*)-3,5-octadien-2-one did not contribute significantly to the fishy malodor.

Future studies will involve synthesizing (*E*,*Z*)-3,5-octadien-2-one in order to use it along with heptanal in recombination/model system studies to assess odor threshold levels required to generate fishy malodors in marine oils. Model system studies have been shown to be highly beneficial for studying combinations of odorants in food products.[16,17]

Synergy effects can impart unexpected and potent aroma changes to foods. For example, synergy can either enhance or diminish a food's perceived aroma. Even more remarkably, it can result in the emergence of a strikingly different sensory perception, completely unrelated to that of the individual compounds alone.

While GC-O experiments have resolved numerous flavor and off-flavor issues in the past, the limitations of methods that only assess odor contribution from individual components need to be reconsidered. Odorant behavior in mixtures demands more studying. Studying synergy effects in olfactometry experiments should be a significant future trend. GC-O experiments are useful for determining which aroma compounds most likely make a contribution to the odor of a food. However, these experiments should be supplemented with sensory work and olfactometric synergy studies.

When traditional GC-O experiments fail to detect the malodor present in the food sample, the researcher should attempt to determine if (1) the analytical sample preparation method is not collecting/trapping the offending odorant; (2) the offending odorant is being trapped efficiently but its concentration level is below the detection threshold of the analytical (MS) detector; (3) the offending odorant is being extracted from the sample but is thermally labile and is decomposing in the injector; or (4) the perceived malodor of the sample is due to odorant synergy effects related to smelling two or more odorants in combination.

An analytical technique for studying odorant synergy effects has been presented as well as an example of how it can be applied. Heptanal and (*E*,*Z*)-3,5-octadien-2-one appear to be significant contributors to fishy malodor in algal oils. It is possible that some additional higher boiling point compounds, not isolated in our methods, could contribute to fishy malodor as has been recently reported.[18] However, according to our present study, these higher molecular weight compounds do not appear to be as significant to fishy off-flavor as heptanal and (*E*,*Z*)-3,5-octadien-2-one, since simple headspace extractions by HSSE and SPME at relatively low temperature (50 °C) were shown to extract strong fishy odors from all samples. This article provides more details of the analytical methods and techniques used to identify odorants in our previous algal oil research.[19] Confirmation of the roles of heptanal and (*E*,*Z*)-3,5-octadien-2-one in causing fishy odors should be conducted using sensory paneling of odorless oil samples spiked with pure standards of these compounds.

relatively expensive. Therefore, the development of effective extraction methods is critical for the quality control of NPTs while minimizing the environmental impact.

With the improvement of living conditions and economic development, the incidence of cardiovascular disease increases dramatically. There is therefore increased emphasis on prevention since the disease is the leading cause of death in many countries. Danshen (DS), also known as *Salvia miltiorrhiza* and derived from the dried root or rhizome of *Salvia miltiorrhiza* Bge, is one of the most popular traditional herbal medicines and has been widely used for the treatment of angina pectoris, myocardial infarction, dysmenorrhea, insomnia, and bacterial infections.[20] Danshen tea (DST), refined from *Salvia miltiorrhiza* and green tea, is a new type of health care product for the prevention and treatment of coronary heart disease and hyperlipidemia. Tanshinone capsules (TC) made from the extracts of *Salvia miltiorrhiza* are one of the most widely used plant preparations and have antibiotic and anti-inflammation functions. These DS products are now experiencing a particularly strong and rapid demand in China, Japan, the United States, and many European countries for treatment and prevention of cardiovascular and cerebrovascular system disorders. Numerous bioactive compounds, mainly including soluble phenolic acids and lipophilic tanshinones, have been isolated from *Salvia miltiorrhiza*. Among them, tanshinones, including dihydrotanshinone I, tanshinone I, cryptotanshinone, and tanshinone IIA, are gaining popularity because of their significant pharmacological activities such as dilating coronary artery, activating blood circulation, and preventing myocardial ischemia.[21−23] Therefore, extraction and quantitative determination of tanshinones are important for physiological and pharmacological studies.

In this study, a novel extraction technique, D-$\mu$-SPE, involving the use of MHM as the sorbent was evaluated for the extraction of semivolatile compounds (dihydrotanshinone I, tanshinone I, cryptotanshinone, and tanshinone IIA). The parameters affecting the extraction, such as mesoporous concentration, extraction time, sample agitation, and desorption solvents, were systematically studied and evaluated. The optimized microextraction methodology combined with ultra-high-performance liquid chromatography coupled with quadrupole time-of-flight tandem mass spectrometry (UHPLC-Q-TOF/MS) was then successfully applied to the determination of tanshinones in complex NPTs.

## MATERIALS AND METHODS

**Reagents and Materials.** HPLC grade hexane, ethanol, acetonitrile, acetone, and methanol were purchased from Sigma-Aldrich (St. Louis, MO). The dihydrotanshinone I, tanshinone I, cryptotanshinone, and tanshinone IIA standards were obtained from Winherb Medical Technology Co., Ltd. (Shanghai, China) (purity higher than 98%). The structures of these compounds are shown in Figure 1. Stock standard solutions for each of the analytes were prepared in methanol at a concentration of 0.5 $\mu$g/mL and were stored at 4 °C. The 0.45 $\mu$m disposable nylon filters were purchased from Anpel Scientific Instrument Co., Ltd. (Shanghai, China). Ultrapure water was produced using a Milli-Q (Millipore, Billerica, MA) water purification system. All tested samples, including DST, DS, and TC, were purchased from a local drugstore (Hangzhou, China). All other chemicals used were of analytical grade (Anpel Scientific Instrument Co., Ltd.) and were used as received without further purification.

**Apparatus.** The UHPLC instrument was an Agilent 1290 Series (Agilent Technologies, Santa Clara, CA), consisting of a binary pump, an autosampler, and a thermostated column compartment. Chromatographic separation was performed at a flow rate of 400 $\mu$L/min using

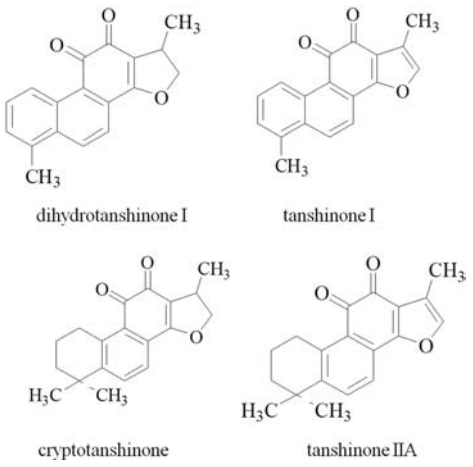

**Figure 1.** Chemical structures of the four tanshinones.

an Agilent Zorbax SB-$C_{18}$ column (1.8 $\mu$m, 2.1 mm i.d. × 50 mm) maintained at 30 °C. Mobile phases A and B were 0.1% formic acid in water and methanol, respectively, and were applied according to the following gradient: 0−1 min, 10−30% B; 1−2 min, 30−50% B; 2−6 min, 50−70% B; and 6−7 min, 70−100% B. The injection volume was 2 $\mu$L for the standards and sample extracts.

The UHPLC system was connected to an accurate mass Q-TOF instrument (Agilent Technologies, Santa Clara, CA) equipped with a Dual ESI ion source. Accurate product ion scan (MS/MS) spectra were acquired in the range of $m/z$ values from 100 to 1000 units, and compounds were ionized in positive ESI by applying a capillary voltage of 3500 V. The other experimental parameters were as follows: drying gas temperature, 350 °C; drying gas flow, 12 L/min; nebulizer, 45 psi; fragmentor, 175 V; skimmer voltage, 65 V; and octapole RFPeak, 750 V. Selective UHPLC−MS and UHPLC−MS/MS chromatograms were extracted with a mass window of 0.01 Da around the $[M + H]^+$ and the most intense product ion of each tanshinone, respectively. The Mass Hunter Workstation software (version B 05.00) was used to control the system and process the obtained data.

**Preparation of Mesoporous Hybrid Materials.** The MHM was obtained by following a previously optimized procedure.[24] Briefly, 1.0 g of [3-(trimethoxysilyl)propyl]-octadecyldimethylammonium chloride was mixed with 28.0 g of deionized water, 4.10 g of tetraethyl orthosilicate, and 0.60 g of 1,3,5-trimethylbenzene under vigorous stirring at room temperature for 15 min. Then, 3.0 g of (2.0 M) NaOH solution was added to the translucent mixture. The mixture was stirred for 2 h at 25 °C, transferred into a hydrothermal bomb, and treated at 110 °C for 24 h. Finally, the obtained precipitate was filtered, washed with 200 mL of ethanol and 50 mL of acetone, and then vacuum-dried at 60 °C overnight to obtain a fine powder.

**Sample Preparation.** A 0.3 g sample of the dried powder (DST, DS, or TC) was accurately weighed and extracted with 50 mL of hot water in an ultrasonic bath for 5 min. After cooling, the solution was centrifuged at 15 000 rpm for 5 min before being subjected to the D-$\mu$-SPE process.

**Extraction Procedures.** An accurately weighed 2 mg aliquot of pristine MHM, added in 10 mL of Milli-Q water, was ultrasonicated (100 W, 40 Hz) for 20 min. Subsequently, the mixture was agitated using a vortex for 2 min to facilitate the dispersion of the material. The experimental setup of the D-$\mu$-SPE extraction is illustrated in Figure 2. Briefly, 10 mL of the aqueous samples containing four tanshinones at a concentration within the quantification linear range was first placed in a 25 mL glass vial. After that, 1 mL of MHM dispersion at a final concentration of 0.02 g/L was quickly added to the vial, and the mixture was agitated at 3200 rpm for 2 min using an orbital shaker. Then, the MHM concentrated with the analytes was recovered by filtration on a 0.45 $\mu$m disposable nylon filter, which was previously cleaned with 3 mL of methanol and 3 mL of ultrapure water to remove any possible contamination. Finally, the analytes were desorbed by

dx.doi.org/10.1021/jf5029625 | J. Agric. Food Chem. 2014, 62, 9683−9689

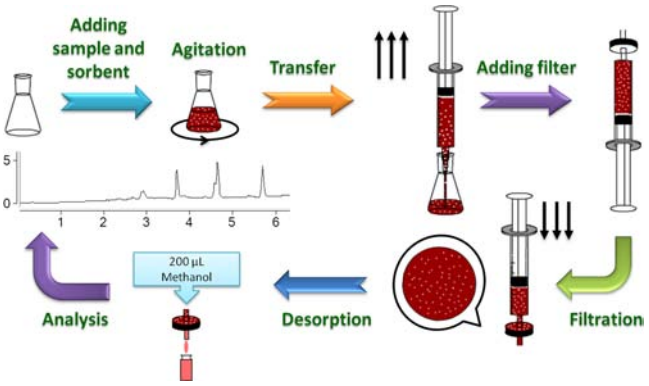

**Figure 2.** Schematic procedure of MHM D-$\mu$-SPE. For details, see text.

passing 200 $\mu$L of methanol through the nylon filter, and 2 $\mu$L was injected into the UHPLC-Q-TOF/MS for identification and quantification of the tanshinones.

**Validation Procedure.** The calibration samples were prepared using the described D-$\mu$-SPE procedure in the range from 0.25 to 100 ng/mL. Five concentrations of the four analytes' solution were extracted in triplicate, and then the calibration curves were constructed by plotting the mean peak areas versus the concentrations of target analytes. Intra- and interday variations, expressed by the relative standard deviations (RSD), were chosen to determine the precision of the proposed method. For intraday precision, the mixed standards solution was analyzed for six replicates on the same day, while, for interday precision, the solution was examined in duplicates for consecutive 3 days. The extraction solution containing 4 reference compounds was diluted to a series of appropriate concentrations, and an aliquot of the diluted solutions was injected into UHPLC-Q-TOF/MS for analysis. The limits of detection (LODs) and quantification (LOQs) under the optimal chromatographic conditions were calculated on the basis of peak areas at a signal-to-noise of 3 and 10, respectively. Recovery test was used to evaluate the accuracy of D-$\mu$-SPE method. The recoveries of four analytes were calculated by the following formula: recovery (%) = 100 × (amount found − original amount)/amount spiked. Table 1 shows the results of four analytes.

## RESULTS AND DISCUSSION

**Optimization of D-$\mu$-SPE Process.** The main parameters affecting the D-$\mu$-SPE process, namely, the mesoporous concentration, extraction time, sample agitation, and desorption solvents, were optimized to obtain optimum performance of the mesoporous D-$\mu$-SPE procedure. A 10 mL water sample containing 25 ng/mL of each tanshinone was used for the optimization experiments.

**Effect of the Mesoporous Concentration.** Previous studies have demonstrated the applicability of nanometric sorbent materials in D-$\mu$-SPE for the isolation and preconcentration of aromatic compounds from water samples, taking into account their higher surface areas.[14] In this study, the usefulness of MHM for the extraction of semivolatile compounds, such as tanshinones, was evaluated. The addition of MHM was expected to enhance the extraction efficiency of D-$\mu$-SPE because the material was different from that of the bulk counterparts due to the higher surface area and pore volume. Hence, the effect of adding MHM in microextraction, ranging from 0.01 to 0.04 (g/L) in the extraction phase, was studied. According to the obtained results (Figure 3), the peak areas of target analytes (25 ng/mL) were highest when 0.02 g/L MHM was used. The presence of MHM in sample solution resulted in an increase in the sensitivity of the analytes. This may be due to the increase in the interaction between the analytes and the sorbent surface following the addition of the appropriate sorbent material, thereby enhancing the mass transfer process. From the results shown in Figure 3, it is clear that the extraction efficiencies gradually decreased as the concentration of MHM increased from 0.02 to 0.04 (g/L). The possible reason for this observation was that the higher concentration of MHM increased the aggregation of the mesoporous material, which effectively reduced the surface available for analytes interaction. Finally, the proposed method permitted the use of a relatively small concentration of adsorbent (0.02 g/L) to ensure complete desorption of analytes from MHM by agitation, compared with other D-$\mu$-SPE (0.2 g/L) in the

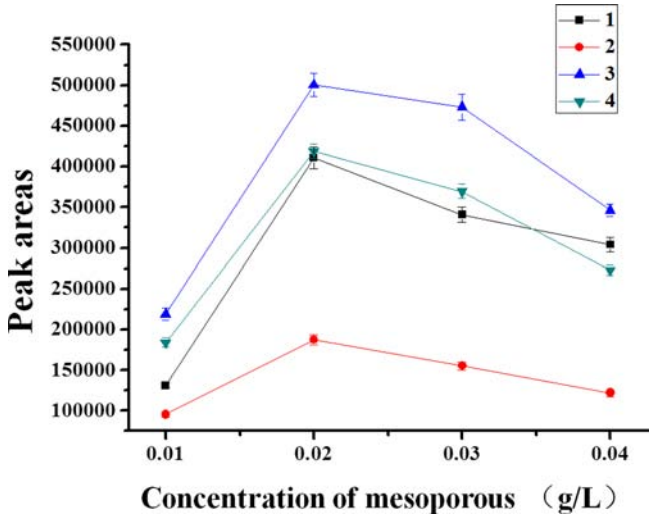

**Figure 3.** Effect of the MHM concentration (0.01−0.04 g/L) on the chromatographic peak areas of the selected tanshinones. Sample concentration: 25 ng/mL. Analytes: (1) dihydrotanshinone I, (2) tanshinone I, (3) cryptotanshinone, and (4) tanshinone IIA.

**Table 1. Linearity, Precision, and Limits of Detection (LODs) and Quantification (LOQs) of the Developed D-$\mu$-SPE Method**

literature.[14,15] Therefore, MHM at a concentration of 0.02 g/L was chosen for the following experiments.

**Effect of the Extraction Time.** Like SPME, D-$\mu$-SPE involves dynamic partitioning of analytes to the sorbent. The extraction efficiency depends on the mass transfer between the MHM and the sample solution. Because mass transfer was a time-dependent process, the effect of the extraction time was investigated in the range 1−32 min. The sample solution was continuously agitated at room temperature with an orbital shaker to facilitate the mass transfer process, and the agitation speed was fixed at 3200 rpm. The results are shown in Figure 4.

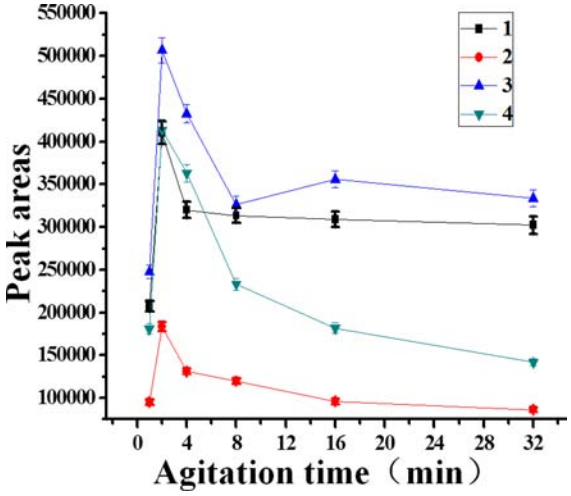

**Figure 4.** Effect of the agitation time (1, 2, 4, 8, 16, and 32 min) on the chromatographic peak areas of the selected tanshinones. Analytes: (1) dihydrotanshinone I, (2) tanshinone I, (3) cryptotanshinone, and (4) tanshinone IIA.

The highest extraction was achieved at 2 min, and after more than 2 min, a considerable decrease in the peak area response was observed for all of the target analytes. The results indicated that, at the given conditions, initial partitioning was rapid, followed by a protracted uptake; eventually, a steady state was reached at 16 min, except for dihydrotanshinone I. For dihydrotanshinone I, when the extraction time was increased from 4 to 32 min, the extraction profile remained flat, implying that the adsorption of the analyte was very efficient. Therefore, in this work, 2 min was chosen as the optimum extraction time.

**Form of Sample Agitation.** Sample agitation played an important role as an assisting factor in the D-$\mu$-SPE process and affected the mass transfer rates of the tested solutes.[15] Three alternatives for sample agitation (magnetic stirring, ultrasound and orbital shaking) were tested in the extraction step. Figure 5 compares the extraction performance of the three modes when samples spiked with 25 ng/mL tanshinones were extracted with 1 mL of mesoporous suspension with an extraction time of 2 min at room temperature (25 °C). The extraction efficiency of magnetic stirring was significantly lower than that of the other two methods, possibly because the MHM was lost as a result of its deposition on the magnetic bar, which reduced the extraction yield of the target analytes. Moreover, for the extraction yields of the four tanshinones, sonication was higher than magnetic stirring but lower than orbital shaking. The obtained results showed that the use of sonication significantly decreased the extraction affinity for the compounds of interest, leading to a low analytical response. Thus, the orbital shaker was chosen for the subsequent experiments because it provided

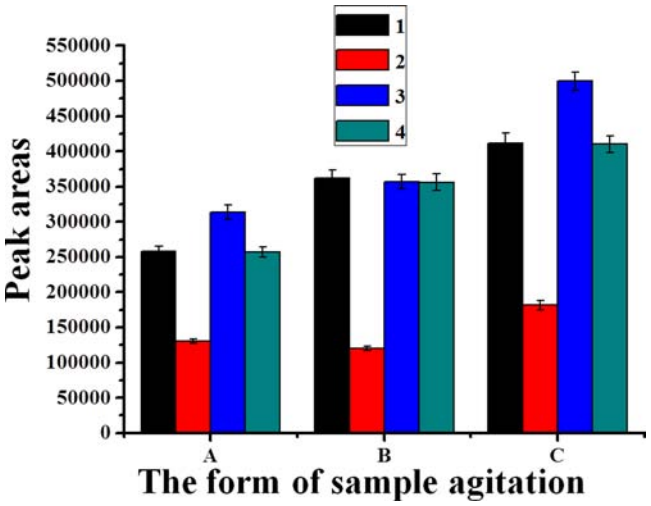

**Figure 5.** Effect of the form of sample agitation on the chromatographic peak areas of the selected tanshinones. (A) magnetic stirring, (B) ultrasound, and (C) orbital shaker. Analytes: (1) dihydrotanshinone I, (2) tanshinone I, (3) cryptotanshinone, and (4) tanshinone IIA.

a vigorous stirring of the analytes and extractant, favoring interactions of the MHM and sample.

**Effect of Desorption Solvents.** The tested tanshinones are relatively hydrophobic and are not easily eluted. Thus, a suitable organic solvent was needed for the desorption process to achieve optimum extraction performance.[25] For this purpose, five solvents, including hexane, ethanol, acetonitrile, acetone, and methanol, were investigated for their suitability as desorption solvents, with the volume fixed at 200 $\mu$L in all instances. Figure 6 shows the influence of the desorption

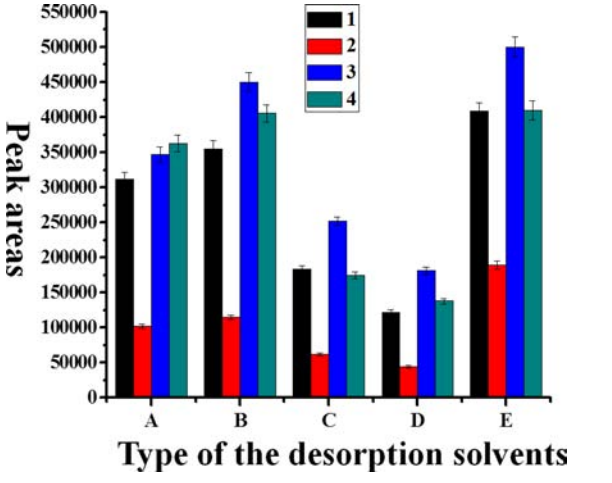

**Figure 6.** Effect of the desorption solvents on the chromatographic peak areas of the selected tanshinones: (A) hexane, (B) ethanol, (C) acetonitrile, (D) acetone, and (E) methanol. Analytes: (1) dihydrotanshinone I, (2) tanshinone I, (3) cryptotanshinone, and (4) tanshinone IIA.

capabilities of these solvents in D-$\mu$-SPE. For all of the tanshinones, methanol offered the highest desorption efficiency, whereas acetone showed the smallest peak areas under the same extraction and elution conditions. The results also indicated that the greater solubility of target compounds in desorption solvents resulted in higher elution performance in

dx.doi.org/10.1021/jf5029625 | J. Agric. Food Chem. 2014, 62, 9683−9689

terms of chromatographic peak areas from the MHM after extraction. Hence, methanol was selected as the optimal desorption solvent.

The suitable volume of methanol used for desorption was also determined to be between 100 and 400 μL. As seen from Figure 7, a small volume (100 μL) of desorption solvent gave

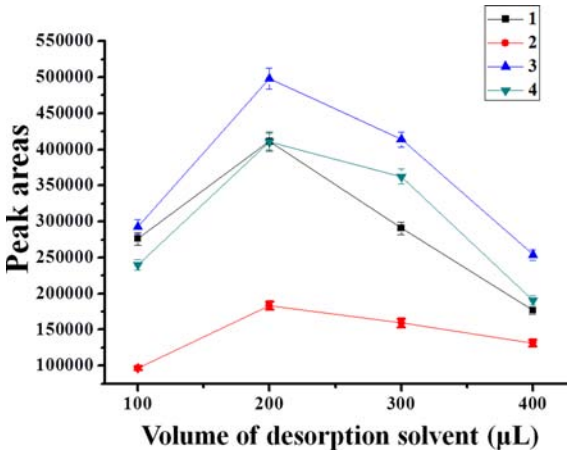

**Figure 7.** Effect of the volume of desorption solvent (100−400 μL) on the chromatographic peak areas of the selected tanshinones. Analytes: (1) dihydrotanshinone I, (2) tanshinone I, (3) cryptotanshinone, and (4) tanshinone IIA.

low peak areas with poor reproducibility. A volume of 200 μL of methanol was found to be sufficient to completely desorb the analytes from the filter containing functionalized mesoporous material. When the volume of methanol was increased from 200 to 400 μL, a considerable decrease in the peak areas for all of the analytes was observed. This phenomenon was due to the dilution of the analytes in the eluent with increasing volume of desorption solvent. To test the carryover effects, the extraction device was further eluted after the first desorption with the above conditions. No analytes remained on the filter in the second desorption using nylon filters with a 0.45 μm pore size. Consequently, 200 μL of methanol was chosen as the optimum volume.

**Analytical Figures of Merit.** The D-μ-SPE method was evaluated by characterizing its analytical performance in terms of linearity, precision, and limits of detection (LODs) at the optimized working conditions determined earlier (i.e., extractant phase, MHM; sample volume, 11 mL; agitation time, 2 min; desorption solvent, methanol). The obtained results are listed in Table 1. The linearity of the method was tested over a range 0.5−50, 1−100, 0.25−25, or 0.4−40 ng/mL, depending on target analytes. The calibration plots of each analyte prepared at five concentration levels were linear, with correlation coefficients ($r^2$) between 0.9980 and 0.9995. The precision of the method was evaluated by calculating the intraday and interday repeatabilities from four individual standards prepared at a concentration of 5 ng/mL. The results obtained are listed in Table 1 as the relative standard deviation (RSD); they ranged from 0.13% to 3.34% ($n$ = 6) for intraday precision and were lower than 6.11% for interday precision in 3 consecutive days. The LODs and LOQs for the tanshinones ranged from 0.012 to 0.046 pg and from 0.040 to 0.153 pg. This resulted in a 334- to 478-fold improvement in the LODs relative to the conventional method, illustrating the better sensitivity achieved by the proposed procedure.

**Application to Real Samples.** Under the indicated extraction and UHPLC-Q-TOF/MS conditions, the proposed D-μ-SPE method was applied to the identification and quantification of four tanshinones in real samples, such as DST, DS, and TC. The results are shown in Table 2. The target components in the samples were identified by matching their retention times and were confirmed by comparing the MS/MS spectra with those of the corresponding standards. Figure 8 shows the MS spectra of tanshinones in the positive ion mode. The accurate protonated molecule $[M + H]^+$ was selected as the precursor ion for CID fragmentation to produce MS/MS product ion spectra. The results showed that all compounds could be detected in all samples (Table 2). However, the contents of these four major compounds varied among three samples. The contents of four active compounds in the DST were much lower than those in the DS and TC. All of the real samples were spiked with the four hydrophobic standard solutions at different concentration levels to evaluate the analyte recovery and matrix effects. The recovery values were 89−102% for DS, 88−96% for TC, and 91−103% for DST, which indicated that the present method was effective for the determination of tanshinones in plant samples. Additionally, the developed D-μ-SPE showed a reduction in extraction time (12 min) when compared to a traditional ultrasonic method (80 min).[21]

In conclusion, an MHM-based D-μ-SPE technique, in conjunction with UHPLC-Q-TOF/MS, was developed in this report. After optimization of the experimental conditions affecting the D-μ-SPE procedure, the sorbent capacity of MHM was tested in plant samples from different sources (DST, DS, TC), yielding satisfactory results for the recovery values and in terms of linearity, precision, and LODs. Most importantly, this newly developed microextraction technique was easy to prepare in-house at a reasonable cost, and it was more precise compared to the conventional method. In general, this study demonstrated that the extraction technique was a fast, simple, and effective method for the preparation of complex samples while preventing coextraction of extraneous materials.

**Table 2. MS/MS Data and Concentrations of Target Analytes**

| analytes | molecular formula | $t_R$ (min) | $[M + H]^+$ | collision energy (V) | MS/MS | concentrations (mg/g) | | |
|---|---|---|---|---|---|---|---|---|

In plants, flavonoids are contained in most compartments of cells, including the cytosol, vacuoles, endoplasmic reticulum (ER), chloroplasts, nucleus, and extracellular space, although the sites of flavonoid biosynthesis, storage, and usage are all separate. This observation indicates the presence of efficient systems that transport flavonoids across endomembranes and plasma membranes in plants.[13] Recent studies have implicated multidrug and toxic compound extrusion transporters (MATEs), which are major proteins involved in the transport of plant secondary metabolites, including flavonoids.[14] MATEs are found on vacuolar membranes in plant cells and mediate flavonoid uptake using electrochemical gradients across membranes, which are generated by proton pumps, including P-type ATPase, vacuolar V-type ATPase, and $H^+$-pyrophosphatase. MATEs have been found in the vacuolar membranes of various plant species, with various substrate specificities. For example, MATE from *Arabidopsis* and *Medicago truncatula* transports epicatechin-3-*O*-glucoside, whereas a grapevine MATE transports cyanidine-3-*O*-glucoside to the inside of the vacuole.[14]

Interestingly, MATE orthologs are also highly expressed in humans, particularly in the kidney, adrenal gland, liver, and skeletal muscle. Human MATE1 has 95% amino acid sequence homology compared to that of *Arabidopsis*. To date, the major role of human MATE1 is thought to be in the transport of various organic cationic drugs, such as tetraethylammonium, 1-methyl-4-phenylpyridinium, and metformin.[15] However, some anionic compounds, including estrone sulfate, acyclovir, and ganciclovir, have also been reported to be MATE1 substrates.[16]

The purpose of this study was to investigate whether MATE1 could take up dietary flavonoids in metabolically active mammalian cells, such as hepatocytes. To assess this, we first demonstrated the cellular localization of MATE1, in both mouse and human liver and intestine, via immunofluorescence microscopy. We then assessed intracellular flavonoid accumulation in cultured hepatocytes and HEK293 cells overexpressing MATE1, using eight representative dietary flavonoids (quercetin, kaempferol, luteolin, apigenin, and their glycosides). Experiments with MATE1 gene knockdown and MATE1 inhibitors were performed to demonstrate MATE1-specific flavonoid transport.

## MATERIALS AND METHODS

**Cell Culture.** HepG2 and HEK293T cells (Korean Cell Line Bank, Seoul, Korea) were grown in Dulbecco's modified Eagle's medium (DMEM) containing 10% heat-inactivated fetal bovine serum and 1% penicillin−streptomycin at 37 °C in 5% $CO_2$. To establish a MATE1-overexpressing stable cell line (hMATE1), human MATE1 plasmid DNA (Origene, Rockville, MD) in a neomycin-resistance vector was transfected into HEK293T cells. Cells that stably expressed MATE1 were selected in medium containing G418 (Sigma-Aldrich, St. Louis, MO) for five rounds of subculture, and the expression of hMATE1 was confirmed with reverse transcription polymerase chain reaction (RT-PCR) (inset of Figure 2F).

**Cellular Flavonoid Accumulation Assay.** Quercetin, kaempferol, luteolin, apigenine, and quercetin-3-*O*-glucoside were purchased from Sigma-Aldrich (St. Louis, MO). Kaempferol-3-*O*-glucoside was purchased from Extrasynthese (Genay, France). Luteolin-7-*O*-glucoside and apigenine-7-*O*-glucoside were purchased from the Indofine Chemical Company (Hillsborough, NJ). HEK293T and hMATE1 cells were seeded in 12-well plates at $5 \times 10^5$ cells/well the day before treatment. Cells were stimulated with flavonoids for 0, 2, 4, 6, 8, and 10 min, and then the cellular flavonoid concentration was quantified using spectrofluorometry as described previously.[17] After washing cells twice with phosphate-buffered saline (PBS), cellular flavonoids were extracted with methanol (1 mL/well) at 65 °C for 1 h, followed by centrifugation at 17 000 rpm for 2 min. The supernatants were concentrated with a SpeedVac concentrator (N-Biotek, Bucheon, Korea) and then dissolved in 200 μL of 4′,6-diamidino-2-phenylindole, which contained dimethyl sulfoxide (DMSO), in a fluoro 96-well plate. The intensity of the fluorescence signal was measured with an excitation/emission of 485/535 nm using a Victor X2 multilabel plate reader (PerkinElmer, Waltham, MA). The flavonoid concentrations were calculated using a standard curve that was generated with known concentrations of the examined flavonoids.

**Effects of MATE1 Gene Knockdown, Overexpression, and Inhibitors on Cellular Quercetin Accumulation.** siRNA of the MATE1 gene was purchased from Santa Cruz Biotechnology, Inc. (Santa Cruz, CA). HEK293T cells were transfected with MATE1 siRNA (20 pmol/$5 \times 10^5$ cells) and incubated for 1 day before experiments. The knockdown of MATE1 gene expression was confirmed by immunoblot analysis. In the assays with transporter inhibitors, phenylmethylsulfonyl fluoride (PMSF, 100 μM), cyclopiazonic (50 μM), pyrimethamine (1 μM), and bafilomycin A1 (100 nM) were incubated for 30 min before quercetin stimulation. Cellular flavonoid quantification was performed according to the method described in the section above.

**Immunofluorescence Assay.** HepG2 and hMATE1 cells were cultured on polylysine-coated glass slides for 24 h and fixed with 4% paraformaldehyde for 20 min. Mouse liver and intestine tissues from C57BL/6J mice were fixed in 4% paraformaldehyde, embedded in optimal cutting temperature (OCT) compounds, and sectioned on a cryotome at −25 °C (10−20 μM thickness, CM3050S, Leica, Wetzlar, Germany). The human tissue sections were purchased from Genetex (San Antonio, TX). For immunofluorescence staining, fixed cells and tissues were incubated with 5% bovine serum albumin (BSA) in PBS for 30 min and immunostained with a rabbit polyclonal MATE1 antibody (Abcam, Cambridge, MA), together with an antibody for a marker protein of intracellular organelles, for 1 h. Antibodies for mouse monoclonal pan-cadherin, goat polyclonal prohibitin, mouse monoclonal lysosome-associated membrane protein-1 (LAMP1), goat polyclonal calnexin, goat polyclonal peroxin, and goat polyclonal catalase were purchased from Santa Cruz Biotechnology, Inc. (Santa Cruz, CA). As a secondary fluorescent antibody, Alexa Fluor 532 goat anti-rabbit was used and incubated for another 1 h with either Alexa Fluor 488 goat anti-mouse or Alexa Fluor 488 donkey anti-goat antibody. The coverslips were embedded in anti-fade mounting medium after staining with 4′,6-diamidino-2-phenylindole. Image analysis was performed using a Zeiss LSM510 META confocal microscope and the Zeiss LSM510 version 3.2 software (Carl Zeiss, Jena, Germany). Co-localized spots were quantified using ImageJ software [version 1.47, National Institutes of Health (NIH), Bethesda, MD] and calculated using [co-localization (%) = yellow spots/total spots × 100].

**Immunoblotting.** Plasma membrane, ER, and peroxisomal fractions were isolated from mouse livers using density gradient centrifugation as described previously.[18,19] The protein concentration was determined using the Bradford reagent, with BSA as a standard. Protein samples (40 μg) in Laemmli sample buffer were boiled for 5 min and separated on 8−10% sodium dodecyl sulfate−polyacrylamide gel electrophoresis (SDS−PAGE) gels. Separated proteins were electrophoretically transferred onto nitrocellulose membranes. Nonspecific binding was blocked with 5% nonfat dry milk in Tris-buffered saline with Tween-20 (TBST) buffer for 1 h at room temperature (RT), and membranes were incubated with primary antibodies. After washing several times with 1% TBST wash buffer, membranes were incubated with the secondary antibody for 1 h at RT. Immunoreactive bands were detected by enhanced chemiluminescence western blot detection reagents and quantified by the ChemiDoc XRS system (Bio-Rad, Hercules, CA) using the Quantity One software (version 4.6.9, Bio-Rad). The enzyme-linked immunosorbent assay (ELISA) assay for MATE1 protein quantification was performed according to the instructions of the manufacturer (Cusabio, Wuhan, China).

**Measurement of Cellular Lipids, Peroxidation, and Glucose Uptake.** Oleic acid was dissolved in ethanol at 100 mM for use as a

stock solution. To make lipid-loading media, the oleic acid stock solution was diluted to 400 $\mu$M in serum-free media, which included 0.5% BSA. Control and hMATE1 cells were seeded in 6-well plates at a concentration of $5 \times 10^5$ cells/well and stimulated with normal media, oleic acid-containing media, or oleic acid- and flavonoid-containing media for 10 min. Cells were washed with PBS, and 2 mL of hexane/isopropanol (2:1) was added and incubated for 30 min. The solvent was then collected and evaporated under vacuum. Extracts were dissolved in 80% ethanol, and total cholesterol and triacylglycerol contents were measured using a Cobas C111 automatic analyzer (Roche, Basel, Switzerland). Lipid peroxidation was measured using a thiobarbituric acid reactive substances (TBARS) assay as described previously.[20] For the glucose uptake assay, a previous study and the instructions of the manufacturer were followed (Cayman, Ann Arbor, MI).[21]

**Statistical Analysis.** The data are expressed as the mean ± standard error of the mean (SEM). Differences were considered statistically significant at $p < 0.05$ or by a one-way analysis of variation (ANOVA) test. Each experiment was performed at least in triplicate.

## RESULTS

**Cellular Localization of MATE1 in the Liver.** The tissue distribution of MATE1 expression in mice revealed substantial

dx.doi.org/10.1021/jf500916d | J. Agric. Food Chem. 2014, 62, 9690–9698

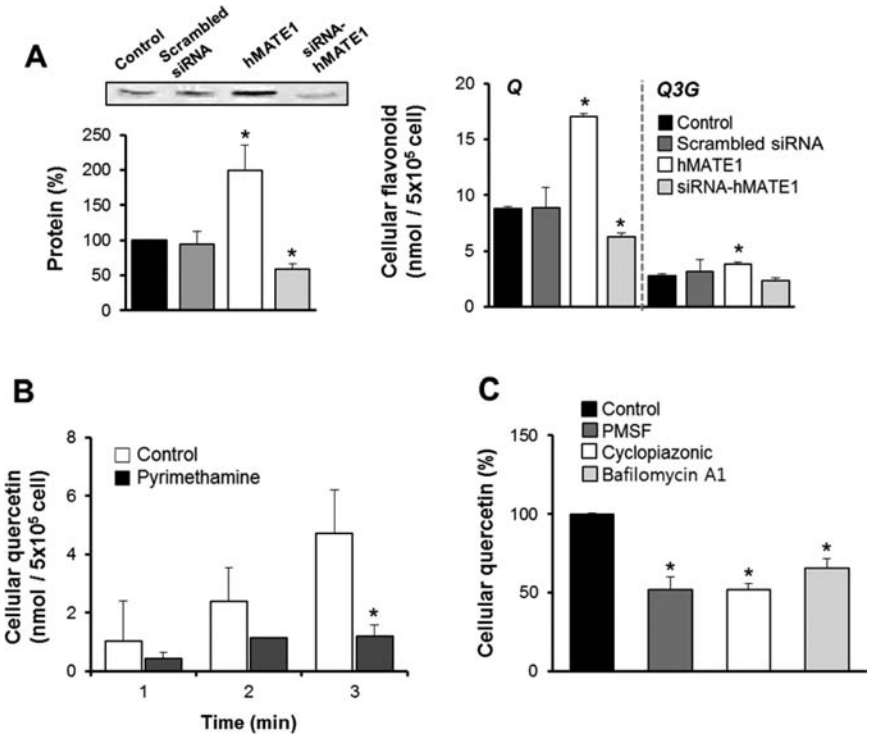

**Figure 3.** Quercetin accumulation in cells with hMATE1 knockdown and MATE inhibitor treatment. (A) HEK293T cells were transfected with the hMATE1 expression vector or MATE1 siRNA, respectively. Then, intracellular quercetin concentrations were measured as described in the Materials and Methods. The knockdown and overexpression efficiencies were assessed with immunoblotting analysis. Quercetin (100 $\mu$M) was incubated for 3 min, and the intracellular accumulation was quantified. (B) Effect of pyrimethamine on cellular flavonoid accumulation. HepG2 cells were incubated with quercetin (100 $\mu$M) for 3 min with or without pyrimethamine (1 $\mu$M). (C) Effects of PMSF, cyclopiazonic, and bafilomycin A1 on flavonoid accumulation in HepG2 cells. Cells were incubated with quercetin (100 $\mu$M) for 5 min with or without the membrane transporter inhibitors. The values are the mean ± SEM. (*) $p < 0.05$ versus the control.

gene expression of MATE1 in the liver and several other tissues, such as the kidney, which suggests that MATE1 may play a role in the cellular accumulation of the flavonoid quercetin in the liver (see Figure S1 of the Supporting Information). Immunofluorescence analysis investigated the subcellular localization of MATE1 in mouse and human liver tissues as well as in cultured cells with antibodies for marker proteins of plasma (pan-cadherin), mitochondrial (prohibitin), lysosomal (LAMP), ER (calnexin), and peroxisomal (peroxin or catalase) membranes (Figure 1). Our results indicate that the MATE1 protein is expressed in liver tissues. The expression levels were similar in both mice and human tissues. Immunofluorescence analysis suggested that MATE1 is primarily expressed in the plasma, ER, and peroxisomal membranes in cultured hepatocytes, hMATE1 cells, and both mouse and human liver tissues (Figure 1A). These results were confirmed with isolated membrane fractions from mouse liver using immunoblotting analysis and ELISA (panels B and C of Figure 1). Analysis with intestinal tissues was confirmed (see Figure S2 of the Supporting Information). To confirm the MATE1 expression on peroxisome, HepG2 cells were transfected with MATE1 siRNA and were analyzed with immunofluorescence analysis (Figure 1D). Result confirmed the reduction of MATE1 expression in cells with MATE1 knockdown (−56% versus MATE1 overexpression; $p < 0.05$). Next, we performed immunofluorescent microscopy to localize the subcellular accumulation of quercetin (Figure 1E). The results suggest that a significant amount of quercetin is accumulated in the peroxisome. The accumulation of quercetin in peroxisomes may be due to uptake by MATE1 in the peroxisomal membrane. A significant amount of quercetin was also found in the nucleus.

**Effect of MATE1 on Flavonoid Transport.** Because MATE1 was highly expressed in the liver tissue, we next investigated cellular flavonoid uptake by MATE in HEK293 cells overexpressing hMATE1. Eight representative flavonoids that are abundant in common dietary plants[22] were examined for cellular accumulation (panels A–D of Figure 2). The flavonoid concentration used in this study was chosen on the basis of preliminary assay results (see Figure S3 of the Supporting Information). Cellular flavonoid uptake occurs rapidly, and of the tested compounds, quercetin exhibited the most efficient uptake by MATE1, which was determined by comparing the uptake in hMATE1 and control cells. The quercetin concentration at 8 min was increased by 110% in hMATE1 cells when compared to the controls (17 versus 8 nmol/5 × $10^5$ cell in hMATE1 and controls, respectively; $p < 0.05$). Kaempferol was transported by MATE1 to a lesser degree than quercetin. The intracellular accumulations of quercetin-3-*O*-glucoside, kaempferol-3-*O*-glucoside, luteolin, luteolin-7-*O*-glucoside, apigenin, and apigenine-7-*O*-glucoside were marginally but significantly altered by hMATE1 overexpression, which suggested that MATE1 might transport diverse flavonoids, including both aglycones and glycosides, with different affinities.

It is difficult to predict the substrate specificity of MATE1, as evidenced by our results. However, four factors appear to determine the efficiency of MATE1-dependent flavonoid uptake: molecular weight, the number of hydrogen bond donors and acceptors, hydrophobicity, and ionization status.

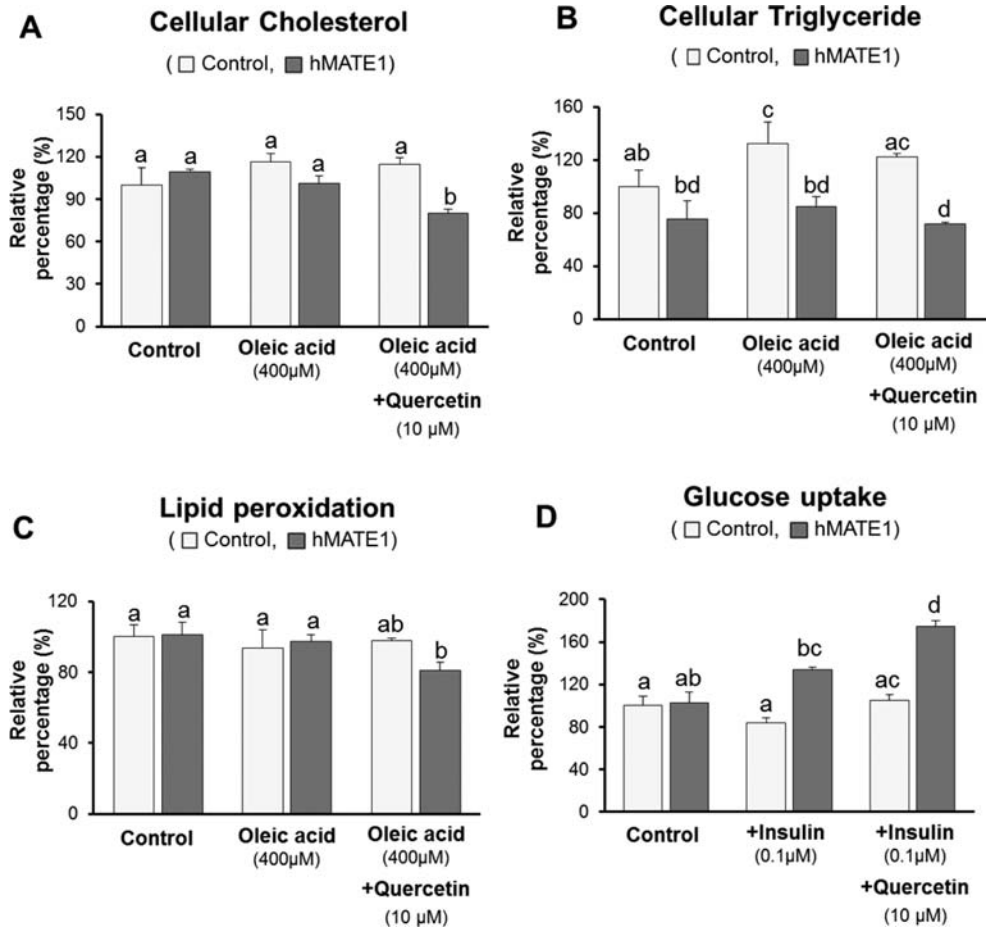

**Figure 4.** Effects of MATE1 overexpression on lipid metabolism. (A and B) Cellular cholesterol and triglyceride concentrations in lipid-loaded cells. (C) Lipid peroxidation levels in lipid-loaded cells with quercetin treatment. Lipid peroxidation was measured using the TBARS assay. (D) Insulin sensitivity test in lipid-loaded cells. Lipid-loaded cells were stimulated with insulin, and then cellular glucose uptake was quantified. The values are the mean ± SEM. Statistical significance was analyzed using a one-way ANOVA.

First, our results demonstrate that aglycones were superior substrates for MATE1 compared to glycosides and exhibited greater cellular uptake. The reason for this is not clear; however, it is possible that flavonoid glycosides may be too large for MATE1, because most known substrates for MATE1 have a molecular weight of less than 300 g/mol. Additionally, aglycones with a greater number of hydrogen bond donors and acceptors and a lower degree of hydrophobicity showed greater cellular uptake. Thus, quercetin showed the highest level of cellular uptake among all of the tested flavonoids because it is a small aglycone and shows the lowest hydrophobicity among tested flavonoid aglycone (see Table S1 of the Supporting Information).

Finally, the ionization of flavonoid aglycones, at a basic pH, hindered cellular uptake. Flavonoids are not ionized at a neutral pH ($pK_a$ = 6.74−7.76), but hydroxyl groups progressively remove protons in accordance with increasing pH.[23] In quercetin, cell viability was reduced slightly at various pH values compared to at pH 7, but the reductions were not statistically significant (Figure 2E). Cellular quercetin uptake was pH-dependent and greatest at pH 6, at which quercetin is not ionized. The quercetin concentration was increased in hMATE1 cells by 105% compared to controls, at this pH value ($p < 0.001$; Figure 2F). In contrast, at pH 9, the cellular quercetin accumulation was markedly reduced in comparison to at pH 6 and was only moderately higher in hMATE1 cells compared to controls. These findings demonstrate that a negative charge on flavonoids may prohibit uptake by MATE1.

**Quercetin Accumulation in Cells with hMATE1 Knockdown in HEK293T Cells and MATE Inhibitor Treatment in HepG2 Cells.** Transfection with hMATE1 siRNA knocked down its protein expression in HEK293T cells by −41% compared to the control (Figure 3A). Cellular flavonoid accumulation was decreased by 29% with statistical significance in siRNA hMATE1 cells compared to the control ($p < 0.05$; Figure 3A). Next, the effects of several inhibitors of membrane transporters were investigated in HepG2 cells. Pyrimethamine is a competitive and specific inhibitor of MATE1.[9] In HepG2 cells that were stimulated with pyrimethamine, quercetin uptake was dramatically reduced by 75% at 3 min when compared to controls ($p < 0.05$ versus the control; Figure 3B). We also quantified quercetin transport in hMATE1 cells that were stimulated with PMSF, cyclopiazonic acid, and bafilomycin A1 (Figure 3C), which are inhibitors for bilitranslocase and P- and V-type ATPases, respectively.[9,24,25] PMSF significantly blocked quercetin accumulation by up to 48%, as reported previously ($p < 0.05$). Cyclopiazonic acid and bafilomycin A1 reduced intracellular quercetin accumulation by 48 and 35%, respectively, when compared to controls ($p < 0.05$). These results suggest that multiple membrane proteins, which include MATE1 and bilitranslocase, mediate intracellular hepatic quercetin transport. Additionally, the data also suggest

dx.doi.org/10.1021/jf500916d | J. Agric. Food Chem. 2014, 62, 9690−9698

that quercetin uptake by MATE1 is mediated by secondary active transport, which requires the activity of both P- and V-type ATPases as well as a proton gradient across the membrane.

**Biological Activity of Quercetin in Lipid-Loaded hMATE1 Cultured Cells.** Quercetin ameliorates symptoms of metabolic syndrome, including dyslipidemia, insulin sensitivity, and obesity. Hepatic lipid accumulation is one of the common symptoms in metabolic syndrome; thus, we investigated the effect of hMATE1 expression on hepatic lipid accumulation. hMATE1 cells that were stimulated with quercetin had intracellular cholesterol and triglyceride concentrations that were significantly reduced by 30 and 41%, respectively, compared to control cells ($p < 0.05$; panels A and B of Figure 4). The antioxidative activity of quercetin (10 $\mu$M) increased in hMATE1 cells when compared to controls; thus, the levels of lipid peroxides were reduced after lipid loading ($p < 0.05$; Figure 4C). In addition, insulin-mediated cellular glucose uptake was improved in lipid-loaded hMATE1 cells when compared to the control (Figure 4D).

## DISCUSSION

Flavonoids are plant-specific; approximately 8000 different types have been isolated from various plants. Quercetin, which is one of the most abundant flavonoids, has been intensively studied for its various biological activities in humans, including its hypolipidemic effects and regulation of metabolic syndrome symptoms.[26,27] However, considering the amount of biological activity studies with flavonoids, including quercetin, their cellular transport mechanism in mammals remains unknown.

The mechanism of flavonoid transport has been investigated intensively in plant tissues, and MATE1 has been reported to carry out the vacuolar transport of anthocyanin in *Arabidopsis*. Interestingly, human MATE1 is expressed at high levels in the kidney, liver, and intestine.[15] Human MATE1 has 95% amino acid sequence homology compared to that expressed in *Arabidopsis*. It has been reported that the major role of human MATE1 is to transport various organic cations; however, some anionic drugs, including estrone sulfate, are also MATE1 substrates.[15,16]

The results of our study demonstrate that MATE1 mediates cellular flavonoid accumulation in cultured cells overexpressing MATE1. Among eight selected flavonoid aglycones and glycosides, quercetin aglycone showed the highest cellular accumulation in cells that overexpressed MATE1, which suggests that MATE1 is a cellular quercetin transporter. Kaempferol, luteolin, and apigenin uptake were moderately enhanced with MATE1 overexpression. Knocking down the expression of MATE1 with siRNA diminished the cellular quercetin accumulation. Additionally, treatment of cells with pyrimethamine, which is a MATE inhibitor, reduced cellular flavonoid accumulation by 75%, demonstrating the critical role of MATE1 in cellular flavonoid accumulation. A reduction of quercetin accumulation in cells that were incubated with V- and P-type ATPase inhibitors also confirmed the secondary active transport of human MATE1. The hypolipidemic, antioxidative, and cellular glucose uptake activities of quercetin in cultured hepatocytes were exaggerated in cells that overexpressed MATE1, which suggests that the increased bioavailability of quercetin enhanced its biological activity. An immunoblotting analysis with isolated subcellular membranous organelles revealed that MATE1 is highly expressed in both the liver and intestine, especially in peroxisomes and the ER as well as in the plasma membrane. Immunohistochemistry with mouse and human liver tissues as well as with cultured hepatocytes demonstrated a similar subcellular localization of MATE1, which was consistent with the immunoblotting analysis. Finally, the fluorescent staining analysis revealed that quercetin was co-localized in peroxisomes and the nucleolus, which suggests the potential accumulation of quercetin in the corresponding organelles, in which peroxisomal accumulation is mediated by MATE1 at least in peroxisome.

In plant tissues, MATE1 has a high affinity for glycoside forms of flavonoids, such as epicatechin-3-*O*-glucoside and cyanidine-3-*O*-glucoside, over the corresponding aglycones. However, the present data demonstrate that aglycones showed higher levels of cellular accumulation than glycosides in cells that overexpressed hMATE1, except for apigenin-7-*O*-glycoside.[13,14] The reasons for the differences in substrate specificity between human and plant MATE1 are unclear at present. Minor differences in amino acid sequence may be associated with differential substrate specificity in human and plant MATE1. It appears that human MATE1 has broad substrate specificity. MATE1 is thought to be involved in the transport of various organic cations, including tetraethylammonium, 1-methyl-4-phenylpyridinium, and metformin,[15] as well as some anionic compounds, including estrone sulfate, acyclovir, and ganciclovir.[16] In this study, we demonstrate that MATE1 also transports flavonoid aglycones with high affinity.

Prediction of the common structural components of MATE1 substrates appears to be highly problematic. However, Wittwer et al. described the major physicochemical parameters of MATE1 substrates in animal cells, including molecular weight, the number of hydrogen bond donors, and degree of hydrophobicity,[28] as being in line with our results pertaining to flavonoid transport. We demonstrated that flavonoid aglycones are superior substrates for MATE1 compared to their glycosides, suggesting that molecular weight may be the key determinant of MATE1 substrate specificity. Among the tested flavonoid aglycones, those with a higher number of hydrogen bond donors and acceptors, together with low hydrophobicity (assessed via the log *P* value), were superior substrates for MATE1. As such, quercetin demonstrated the highest uptake, followed by kaempferol, luteolin, and apigenin. These prerequisites for MATE1 substrate specificity were applied to explain other drug-based substrates for MATE1, such as metformin and 1-methyl-4-phenylpyridinium.[29]

In the MATE1 inhibitor and gene knockdown experiments, the basal level of quercetin uptake was maintained, which indicated that the uptake of quercetin and potentially other flavonoids occurs in a highly complex manner through multiple cellular transporters. With regard to quercetin, we know that MATE1 and bilitranslocase mediate the cellular uptake of quercetin; however, HepG2 cells that were incubated simultaneously with two inhibitors, namely, PMSF and pyrimethamine, revealed slightly increased quercetin accumulation (data not shown), which suggested that there may be an additional low-capacity, high-affinity cellular transporter.

The subcellular localization of MATE1 revealed that MATE1 is also expressed in intracellular organelles, including the ER and peroxisomal membrane as well as the plasma membrane. To our knowledge, this study is the first to confirm the expression of MATE1 in subcellular organelles in animal cells. Previously, Otsuka et al. reported the localization of human MATE1 in the liver, which suggested the expression of MATE1 in the canalicular and apical membranes of bile ducts. The

authors reported that MATE1 may be a polyspecific exporter for various types of organic compounds into the bile canaliculi with multidrug resistant gene-1.[30] Another study also claimed the expression of MATE1 in the brush border membrane of the proximal tubule of the kidney.[31] However, both studies did not report the intracellular localization of MATE1 in humans, which was previously confirmed in plant tissues. The findings of the expression of MATE1 in hepatic subcellular organelles and the accumulation of cellular flavonoids in organelles add a novel function for human MATE1, in addition to the previously reported role of exporting organic cations.

In conclusion, MATE1 is a novel flavonoid transporter in mammalian cells, particularly for quercetin in the liver and intestine. MATE1 is mainly expressed in plasma, ER, and peroxisomal membranes, and increased cellular flavonoid accumulation was observed in hMATE1 cells. Cellular quercetin accumulation in mammalian MATE1 eliminates lipid and glucose disorders. Owing to the limited bioavailability of dietary quercetin, the control of quercetin bioavailability through regulation of MATE1 expression may optimize its health benefits.

[a]Values shown are means of three repetitions. Type of grain: B, black; C, carioca; S, striped; W, white; Bo, bolinha; R, red. Origin: A, Andean; M, Mesoamerican. Isoflavonoids: DA, daidzein, and GE, genistein. Flavonols: KA, kaempferol, M, myricetin, and Q, quercetin. CM, coumestrol. nd, not detected.

was to assess the flavonoid and coumestrol content in germplasm with a broad genetic base of the species, for the purpose of introducing new nutraceutical parameters in the crop breeding program.

## MATERIALS AND METHODS

**Plant Material.** The study was carried out at the Campinas (SP) (22° 54′ 20″ S, 47° 03′ 39″ W) during the rainy season (December–May) with 16 common bean genotypes from the two major gene pools with different seed coats and grain sizes, and one soybean genotype used as a reference (Table 1, Figure 1). Seeds of each cultivar were sown in a 5-m-length row (10 plants/m) for a total area of 105 $m^2$. After 3 months, grains from all genotypes were collected and kept in an air-circulation laboratory oven at 30 °C for drying to constant weight, and afterward ground in a mill and stored with protection against moisture.

**Standards.** Authentic standard daidzein, daidzin, genistein, and genistin (isoflavonoids); quercetin, kaempferol, and myricetin (flavonols); coumestrol (coumestan); and chrysin were purchased from Sigma Chemical Co. (St. Louis, MO). Stock solutions were prepared by dissolving the standards in MeOH–$H_2O$ (1:1) for a final concentration of 10 mg/mL.

**Solvents.** All solvents used were HPLC-grade and were purchased from Sigma Chemical Co. (St. Louis, MO).

**Extraction and Purification of Flavonoids.** Portions (2 g) of dry and ground grains were extracted with 60 mL of 70% ethanol (pH 2.0, adjusted with formic acid) for 24 h at ambient temperature.[21] The extracts were partitioned with 60 mL of hexane, and the aqueous phase was evaporated under reduced pressure to dryness. The residue of each extract was resuspended in MeOH–$H_2O$ (1:1), filtered through a 13 mm PTFE membrane filter of 0.45 μm, and kept at −20 °C up to the time of analysis. Each extract was prepared and analyzed in triplicate.

**Identification and Quantification of Flavonoids.** Quantification of all compounds was conducted from construction of a calibration curve with chrysin as internal standard. Individual identification of the flavonoids (negative mode) was performed on the basis of retention times, spectroscopic data, and mass-to-charge ratio ($m/z$) of each standard by use of 10 points of concentration, 0.005–5 μg/mL, containing the internal standard at a final concentration of 4 μg/mL (Table 2). Results were expressed as milligrams per gram dry weight of seed flour.

Figure 1. Seed coat colors of the 16 genotypes evaluated. (A) Arc1, (B) IAC Diplomata, (C) Raz 55, (D) TU, (E) IPR Uirapuru, (F) IAC Una, (G) IAC Alvorada, (H) IAC Carioca Comum, (I) IAC Formoso, (J) IAC Pérola, (K) IAC Harmonia, (L) IAC Boreal, (M) Brancão Argentino, (N) IAC Jabola, (O) IAC Esperança, and (P) Flor de Mayo.

**Analytical Techniques and Equipment.** The LC-ESI-QTOF-MS MicroTOF-QII Bruker equipped with an autosampler, binary pump, thermostated column compartment, and multiple-wavelength detector was used. Separations of flavonoids were achieved on a 150 × 2.0 mm i.d, 5 μm C18 Luna column (Phenomenex, Torrence, CA) at 30 °C. Injection volume was 20 μL at a flow rate of 0.25 mL/min. Linear gradient elution was performed with solvent A (methanol/formic acid, 95:5 v/v) and solvent B (5% formic acid in water, v/v) at

**Table 2. LC-qMS and Calibration Parameters of Flavonoids**

| compd | $t_R$ (min) | $[M - H]^-$ ($m/z$) | $r^2$ | concn ($\mu$M) |
|---|---|---|---|---|
| daidzein | 13.39 | 253 | 0.976 | 0.02−19.7 |
| genistein | 13.39 | 269 | 0.991 | 0.02−18.5 |
| quercetin | 15.56 | 301 | 0.996 | 0.02−16.5 |
| kaempferol | 17.47 | 285 | 0.995 | 0.02−17.5 |
| myricetin | 13.10 | 317 | 0.999 | 0.01−15.7 |
| coumestrol | 18.19 | 267 | 0.991 | 0.02−18.7 |
| chrysin | 20.25 | 253 | | 0.02−19.7 |

30% A/70% B from 0 to 4 min, 100% A from 4 to 50 min, and 30% A/70% B from 50 to 65 min. Chromatograms were recorded by UV detection at 254, 270, and 330 nm and by ESI-MS in negative-ion scan mode (100−600 $m/z$) with nitrogen as nebulizer gas at 58 psi and 4.5 kV capillary voltage at 350 °C. Identification of flavonoids and coumestan was based on the following ions ($[M - H]^-$, $m/z$) for each analyte: 253 for daidzein, 269 for genistein, 415 for daidzin, 431 for genistin, 301 for quercetin, 285 for kaempferol, 317 for myricetin, 267 for coumestrol, and 253 for chrysin.

**Data Analysis.** Descriptive statistics were used to characterize the data overall and across factors. To identify statistical differences in flavonoid content among factors, ANOVA and canonical analysis methods were employed. Statistical analyses were performed by use of the Genes program.[22]

## RESULTS AND DISCUSSION

**Identification of Bean Flavonoids and Coumestrol.** The maximum and minimum temperatures of the location where the plant material was grown ranged from 17.6 to 27.5 °C (Figure 2) with mean monthly rainfall of 7.14 mm

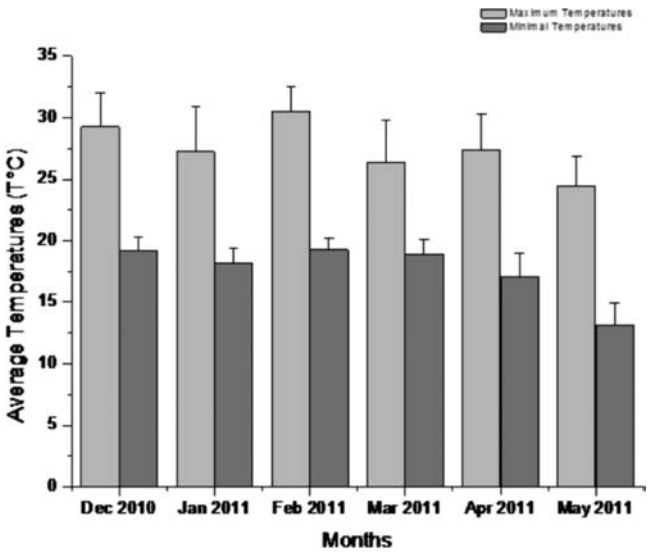

**Figure 2.** Average maximum and minimum temperature during the growth biological assay.

(December 2010−May 2011). Studies on genetic and environmental effects, performed on soybean in locations where mean temperatures ranged from 19 to 27 °C, manifested a strong influence of the environment on isoflavonoid contents.[23,24]

In all 16 genotypes assessed, we found the flavonoids quercetin (Q), myricetin (M), and kaempferol (KA) and the nonglycosylated forms of isoflavonoids daidzein (DA) and genistein (GE), both of greater occurrence among the legumes, as well as coumestrol, all with wide variation of occurrence among the genotypes of the study (Table 1).[25]

With the exceptions of IAC Alvorada (carioca seed coat), IAC Boreal and IAC Harmonia (striped seed coat), and Brancão Argentino (white seed coat), all the genotypes exhibited genistein (GE), ranging from 0.82 (IAC Pérola) to 8.93 (IAC Formoso) $\mu$g/g.

Among the types of grains, the genotypes of black seed coat and Mesoamerican origin stood out: in addition to containing GE, they were the only ones to also exhibit daidzein (DA), as in the case of IAC Una (2.30 ± 0.28 $\mu$g/g), Arc 1 (6.82 ± 0.95 $\mu$g/g), and Raz 55 (8.05 ± 1.83 $\mu$g/g). A similar result was reported by Romani et al.,[26] who observed the presence of these isoflavonoids in a local variety of black bean, and by Díaz-Batalla et al.[25] in assessment of cultivated and wild Mexican common beans. Liggins et al.[10] also reported levels of daidzein and genistein in beans with red seed coat. IAC Una, Arc 1, and Raz 55 were the only ones to show DA and GE at higher levels. IAC Una is considered to be the main Brazilian cultivar for resistance to the anthracnose pathogen (*Colletotrichum lindemuthianum*).[27] In Arc 1 and Raz55, the presence of the protein arcelin was observed, which is considered to be the main source of resistance to *Zabrotes subfasciatus*, one of the main pests of stored grains that occurs in common bean.[28]

With variation from 0.82 to 14.03 $\mu$g/g isoflavonoids for the genotypes assessed, the results obtained were similar to those reported in common bean, where contents from 6 to 14 $\mu$g/g were found for different landraces, from 8.3 to 13.4 $\mu$g/g for striped common beans, and from 7.1 to 11.4 $\mu$g/kg of isoflavonoids (daidzein and genistein) in haricot bean.[26,27,29]

In soybean, a microbial toxic action of the glycosides daidzein and genistein was proposed in resistance to fungus infection of seeds and seedlings.[30] In the genus *Phaseolus*, Adesanya et al.[31] tested isoflavones, isoflavonones, pterocarpans, and coumestan from five species against *Aspergillus niger* and *Cladosporium cucumericum* and observed the importance of at least a phenolic function to activate the fungitoxic activity of these compounds, making assessment of the structure−fungitoxic activity relationships within these groups of isoflavonoids possible.

Corroborating the results found by Beninger et al.,[32] flavonols occurred in all the genotypes assessed, except for the genotype Brancão Argentino (Table 1). The highest occurrence of the flavonol kaempferol (KA) was seen in grains with a light-colored seed coat like those of the bolinha and carioca types. IAC Jabola and IAC Esperança, both with bolinha and carioca seed coat types, such as IAC Carioca Comum, IAC Formoso, and IAC Pérola (all of Mesoamerican origin), exhibited kaempferol contents that ranged from 16.37 to 117.65 $\mu$g/g (Table 1). A similar profile was found by Ranilla et al.[6] in assessment of 25 Brazilian common bean cultivars as a function of color of the seed coat and of the cotyledon. This flavonol modifies a series of cell signaling pathways acting with less toxicity in comparison to standard chemotherapies.[33]

Quercetin (Q) and myricetin (M) occurred preferentially in black grains, ranging from 1.09 to 15.85 $\mu$g/g and from 26.15 to 78.94 $\mu$g/g, respectively. Díaz-Batalla et al.[25] found a similar occurrence of quercetin in black grains and kaempferol in lighter-colored grains. In fact, quercetin and kaempferol are the most abundant flavonols in foods and are antioxidant and chelating compounds with beneficial effects on health.[34] They are also associated with the function of protecting seeds against pathogens and predators.[35] An explanation for the fact of common bean being considered a source of flavonols was the high occurrence of quercetin and kaempferol in the cultivar

dx.doi.org/10.1021/jf5033312 | J. Agric. Food Chem. 2014, 62, 9699−9704

IAC Formoso, exhibiting contents from 9.88 ± 3.04 to 60.07 ± 3.17 μg/g.[11]

Genotypes of Mesoamerican origin with black and carioca seed coats and of Andean origin with bolinha seed coat manifested coumestrol (Table 1). Coumestrol is an important compound which contains high levels of estrogenic activity, 30−100 times greater than that of the isoflavones, and it was identified in all the black grains (Table 1), ranging from 0.75 (TU) to 17.67 (Raz 55) μg/g.[18] Among the grains with carioca seed coat, IAC Formoso presented the greatest content of this coumestan (16.85 ± 0.81 μg/g). Konar[36] assessed common bean and lentils through LC-MS/MS and found this coumestan in common bean (18.5 μg/kg) and a mean value of 16.9 μg/kg in yellow, green, and red lentils. Moreover, by LC-MS/MS and with standards marked with $^{13}C$, Kuhnle et al.[37] found contents ranging from 1 to 10 μg/100 g for common bean, values considered very inferior to ours, even when it is taken into account that the authors expressed their results by fresh weight.

IAC Formoso exhibited the greatest concentration of genistein among all the genotypes assessed (8.93 ± 0.67 μg/g), around 11% of the total presented by the soybean control. Genistein is considered to be the isoflavone with greatest biological activity and is furthermore classified as an inducible phytoalexin.[21] In addition, IAC Formoso exhibited the second greatest concentration of coumestrol (16.85 ± 0.81 μg/g), a compound that has been reported as an estrogen receptor twice as powerful as genistein and, furthermore, a modulator in hormone production of the thymus.[38]

**Grouping Common Bean According to Seed Coat Color.** Canonical variable analysis (CVA) was applied to the values of flavonoid content of the genotypes assessed. This multivariate analysis is similar to principal component analysis, and it is especially used in discriminating analyses with replication of observations because it is based on the variances of these replications.

The first three canonical variables explained 97.5% of the total variance among the 16 genotypes and showed the formation of three groups in accordance with the flavonoid and coumestrol content (Figure 3). A first group gathered the genotypes Arc 1 and Raz 55, both with a black seed coat and of Mesoamerican origin and with the greatest isoflavonoid contents found in the study. A second group was composed of IAC Jabola and IAC Esperança, both with bolinha type grains and the greatest concentrations of the flavonol kaempferol, which occurred preferentially in light-colored grains. All the other genotypes were in a third group.

Canonical variable 1 (VC1), with 78.8% of the total variance, differentiated the genotypes of the study in accordance with daidzein and genistein content. Thus, Arc 1 and Raz 55 were differentiated from IAC Jabola and IAC Esperança, by presenting the highest and lowest contents of daidzein and genistein, respectively (Table 1). Canonical variable 2 (VC2) represents 13.2% of the variation and showed the separation of the genotypes in two groups with contrasting values of concentration of total flavonoids. In VC2, the first group gathered IAC Carioca comum, IAC Jabola, IAC Esperança, IAC Formoso, IAC Una, TU, Arc 1 and Raz 55. A second group was formed by IAC Diplomata, IPR Uirapuru, IAC Alvorada, IAC Pérola, IAC Harmonia, IAC Boreal, Flor de Mayo, and Brancão Argentino.

The variability found for flavonoid content in the grains of 16 genotypes assessed under field conditions may be explained by how these materials arose. Thus, factors such as seed coat type

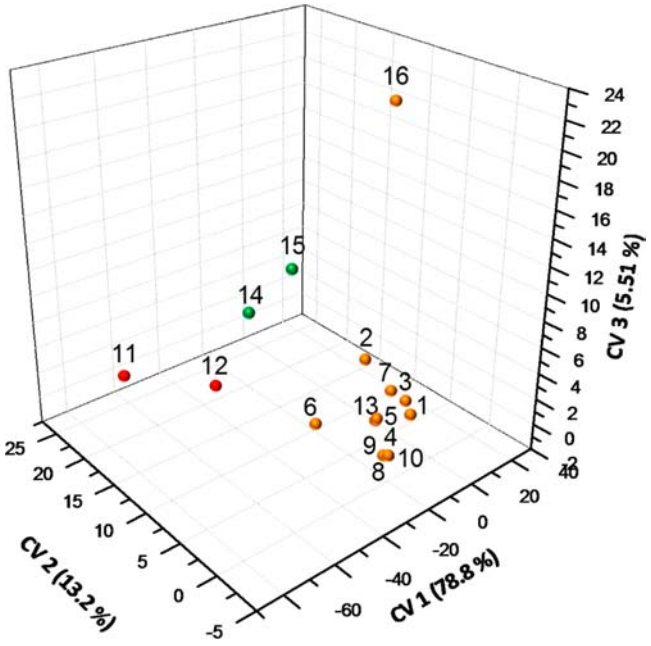

**Figure 3.** Multivariate exploratory analysis for 16 genotypes of common bean. Three groups were formed after canonical analysis: the yellow group contained IAC Diplomata (1), IAC Una (2), IPR Uirapuru (3), IAC Alvorada (4), IAC Pérola (5), IAC Carioca comum (6), TU (7), IAC Harmonia (8), IAC Boreal (9), Brancão Argentino (10), Flor de Mayo (13) and IAC Formoso (16) genotypes; The red group contained IAC Jabola (11) and IAC Esperança (12) genotypes; and the green group contained Arc1 (14) and Raz 55 (15) genotypes.

and selection for tolerance to biotic and abiotic stresses may explain the different concentrations of metabolites found. Related studies reinforce this hypothesis, where differences in the variability of isoflavonoids and flavonoids in accordance with the type of seed coat, genotype, and genotype−environmental interaction were cited by various authors.[23,39,40]

Important levels of flavonoids were observed in the germplasm of common bean grown under the same environmental conditions and high variability between groups with different seed coat colors. Among the beans with carioca-type seed coat, which represents nearly all of the common beans grown, IAC Formoso, a cultivar recently introduced for planting on a commercial scale, showed high values of flavonoids and coumestrol. This result suggests that this cultivar may be used in the genealogy of future genetic materials with a view toward adoption of nutraceutical characteristics in common bean.

of the mechanism and kinetics of a series of oxidation reactions between CAs and different •OX species (•OH, •OOH, •$OCH_3$, and •$OOCH_3$) using the density function theory (DFT) is the ultimate goal of this work.

## COMPUTATIONAL DETAILS

DFT calculations were carried out using the Gaussian09 (rev. C.01) set of programs.[46] The reagent, transition state (TS), and molecular complex (MC) geometries were optimized at the M06-2X level,[47] along with the 6-311+G** basis set. M06-2X is especially recommended for thermodynamic and kinetic calculations.[47,48] An initial conformational analysis was carried out for the reagents to obtain the lowest energy conformation. The nature of the stationary points was assessed by means of the normal vibration frequencies calculated from the analytical second derivatives of the energy. The first-order saddle points, which are related to transition states, must show an imaginary value for the frequency associated with the eigenvector primarily describing the product formation step, whereas the real minima of the potential energy hypersurface, which are related to stable species, have to show positive real values for all of the vibrational frequencies. In addition, intrinsic reaction coordinate (IRC) calculations at the M06-2X/6-311+G** level were carried out to assess each reaction pathway.

The rate constants ($k_{TST}$) were calculated through the thermodynamic formulation of the transition state theory (TST). Gibbs free energy barriers were computed at 298.15 K. The tunneling effect along the reaction coordinate has been accounted for by means of the transmission coefficient $\chi(T)$ given by Wigner's model

$$\chi(T) = 1 + \frac{1}{24}\left(\frac{h|\omega^*|}{k_B T}\right)^2 \quad (5)$$

where $\omega^*$ and $k_B$ are the TS imaginary frequency and the Boltzmann constant, respectively.[49−52] Thus, the final expression for the rate constant ($k_{TST/W}$) becomes

$$k_{TST/W} = \chi(T) k_{TST} \quad (6)$$

## RESULTS AND DISCUSSION

Figure 1S (in the Supporting Information) summarizes the most favored conformers obtained from the initial conformational analysis for the three coumaric acids studied in this work. As discussed above, the oxidation of hydroxycinnamic acid derivatives with reactive oxygen species is expected to be carried out via addition to the double bond or H abstraction. To simplify the study (there are a considerable number of chemically different hydrogen atoms in the studied compounds) and because the most labile hydrogen atoms correspond to the hydroxyl and carboxylic groups, we decided not to consider more H abstraction pathways than those related to these two groups. The transition states corresponding to the addition pathways were computed only on one side of the reagent because coumaric acids show planar structures (see Figure 2) in which both sides are chemically equivalents.

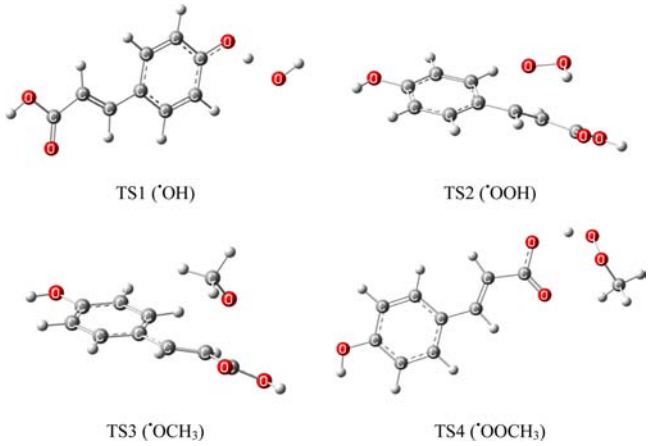

**Figure 2.** Some of the different transitions states found for the reactions of *p*-coumaric acid with reactive oxygen species. Geometries were optimized at the M06-2X/6-311+G** level.

Different transition states were named TS*n*, where *n* indicates the position attacked by the •OX species. Thus, TS1 and TS4 correspond to the transition states in which •OX abstracts the H atom from the −OH and −COOH groups, respectively, whereas the addition mechanism occurs through both TS2 and TS3. Figure 2 shows some examples of the different transitions states found for the reactions of *p*-coumaric acid with •OX. Detailed information on the main geometrical parameters for all of the computed transition states can be found in the Supporting Information. For the H abstraction mechanism, TSs involving •OH radicals show some differences with respect to the rest of TSs. TS1s involving •OH show geometries close to the reagents in which the breaking O···H bond length is within 1.02−1.03 Å, whereas the forming H···O bond is significantly longer (1.40−1.42 Å). For the rest of the TS1s, differences between the lengths of the breaking and forming bonds are significantly smaller, lying within 0.01−0.18 Å. The geometries of TS4s involving •OH are also different from the rest of the TS4s. In the first ones, the difference between the lengths of the breaking and forming bonds are ≤0.09 Å, whereas the other TS4s are within the range of 0.32−0.61 Å. Besides, for TS4s involving •OH and •OOH radicals, the short lengths (≤2.05 Å) between the hydrogen atom from •OX and the carbonyl oxygen from the acid group, compared to the sum of van der Waals radii (2.6 Å),[53] suggest possible stabilizing interactions. This fact may lead to the formation of 5- and 6-membered pseudorings for TS4s involving •OH and •OOH radicals (see Tables 1S−6S in the Supporting Information). No significant differences were observed for TS2 and TS3 with respect to the sort of •OX species chosen. •OX interacts with an unsaturated carbon with a C═C···O angle within 87−110° and with an O···C bond length within 1.88−2.18 Å. Two examples of IRC profiles for H abstraction and addition pathways of the *m*-coumaric acid + •OH reaction can be seen in Figure 3.

dx.doi.org/10.1021/jf5011148 | J. Agric. Food Chem. 2014, 62, 9705−9710

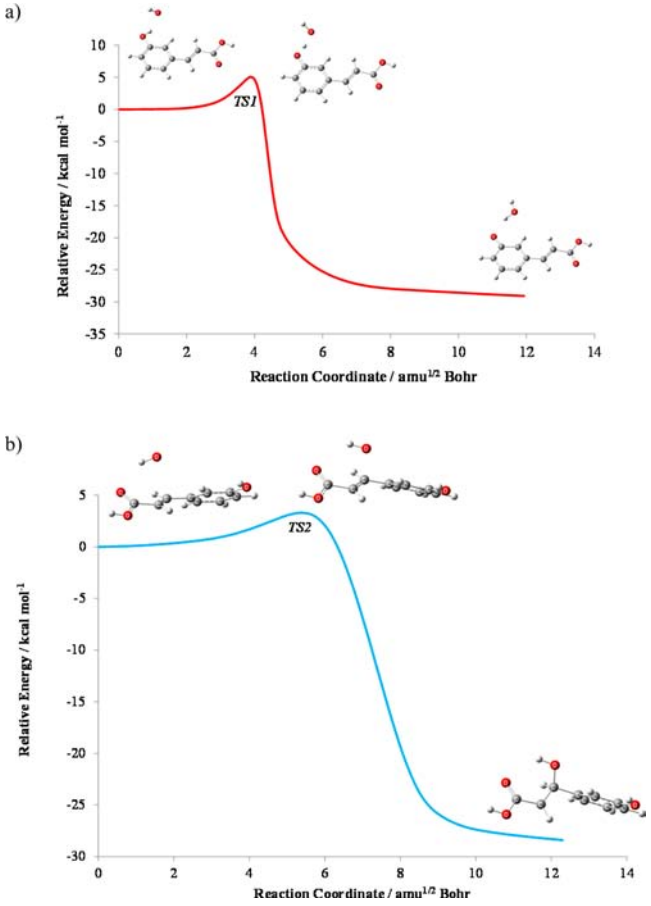

**Figure 3.** IRC calculations for both an H abstraction and an addition channel of the *m*-coumaric acid + •OX reaction computed at the M06-2X/6-311+G** level: (a) pathway through TS1; (b) pathway through TS2.

Table 1 summarizes the activation ($\Delta G^{\ddagger}$) and reaction ($\Delta_r G$) Gibbs free energies calculated for each considered reaction pathway. $\Delta G^{\ddagger}$ increases following the order •OH < $^{\bullet}OCH_3$ < •OOH < $^{\bullet}OOCH_3$, where the most significant rise is observed for the peroxide radicals. The lowest free energy barriers were calculated for TS1 and TS3 in all of the reactions, whereas TS4 shows significantly higher $\Delta G^{\ddagger}$ values than the rest of the pathways. The addition mechanism through TS3 is the pathway with the lowest free energy barriers for the reactions involving •OH. This was expected because the addition of a radical at the 2′-position of C═C via TS3 led to a benzylic radical, which is more stable than that formed after the addition at the 1′-position of the double bond. In a previous DFT study, Leopoldini et al. have also been reported that the addition mechanism is thermodynamically and kinetically favored over the H-abstraction for the reaction of caffeic acid with •OH, being the 2′-position favored over the 1′-position.[41] For the reactions involving $^{\bullet}OCH_3$, •OOH, and $^{\bullet}OOCH_3$, the $\Delta G^{\ddagger}$ values calculated for the TS1 pathways (H abstraction mechanism) are at least 1.7 kcal mol$^{-1}$ lower than the corresponding reaction pathways through TS3 (addition mechanism). In this sense, a DFT study from Galano et al.[32] also reported that the main mechanism for the reaction of •OOH with a related compound, sinapinic acid, should be H abstraction through TS1. In general, H abstraction reactions show a lower free energy barrier for *o*- and *p*-coumaric acids than for *m*-coumaric acid, whereas addition reactions do not show a clear trend. Negative $\Delta_r G$ values were calculated for all pathways considered in coumaric acid reactions with •OH and $^{\bullet}OCH_3$ radicals, in contrast with the positive values computed for reactions involving peroxide radicals.

Kinetic rate constants using the TST were estimated at 298.15 K and are shown in Table 1. In this table, $k_{TST/W}$ values include tunneling coefficient corrections, whereas $k_{TST}$ values do not. Substantial differences in the rate constant values were obtained for reactions involving different •OX species. Those values follow the inverse order of the free energy barrier heights (•OH > $^{\bullet}OCH_3$ > •OOH > $^{\bullet}OOCH_3$). For coumaric acid + •OH reactions, $k_{TST}$ values for the addition mechanism through TS3 are at least 60% higher than the corresponding TS1 H abstraction pathway (for *m*-coumaric acid + •OH reaction, the difference for both $k_{TST}$ values becomes an order of magnitude). However, these differences are reduced or even inverted with the use of tunneling coefficient corrections because the small imaginary frequencies (see Table 2) computed for the different TS1s ($\upsilon < 1600i$ cm$^{-1}$) lead to $\chi(T)$ coefficients from 3 to 4 times larger than those calculated for the addition pathways. Hence, both addition through TS3 and H abstraction through TS1 can be considered pathways with a comparable weight in the global reaction mechanism. Here, it is worth noting that each addition pathway presents two equivalent reaction points because of the planarity of the molecule. For the reactions involving the rest of •OX species studied, H abstraction at the hydroxyl group should be the main reaction mechanism. In these cases, values estimated for $k_{TST/W}$ corresponding to TS1 are ≥2 orders of magnitude higher than $k_{TST/W}$ values estimated for the rest of pathways.

The lowest rate constants were estimated for *m*-coumaric acid reactions with any •OX, which agrees with the experimental observations reported by Nenadis et al.[54] In that work, the highest radical scavenging activity (RSA), using the 2,2-diphenyl-1-picrylhydrazyl (DPPH•) assay, was measured for both *o*-coumaric and *p*-coumaric acid with respect to the *m*-isomer. Nevertheless, the trolox antioxidant activity (TEAC), using the 2,2′-azinobis(3-ethylbenzothiazoline-6-sulfonic acid) ($ABTS^{\bullet+}$) assay, determined for *p*-coumaric acid highlights the rest of the studied compounds (TEAC is about 2 times higher for the *p*-isomer than for the *o*- and *m*-isomers). Comparable TEAC values have been reported for *o*- and *m*-coumaric acids. These differences in the antioxidant activity could not be explained by Nenadis et al.[54] on the basis of bond dissociation energies and ionization energies. Thus, the kind of •OX species seems to play a role in the order of reactivity of coumaric acids, which is consistent with our results. According to our calculations, *p*-coumaric acid may be the most reactive with •OH within the studied compounds, the addition to an unsaturated carbon being the main reaction mechanism. In contrast, *o*-coumaric should be the most reactive with •OOH, $^{\bullet}OCH_3$, and $^{\bullet}OOCH_3$, and in this case, the H abstraction from the hydroxyl group seems to be the main reaction mechanism. As mentioned before, previous theoretical studies on the reactions of related hydroxycinnamic acids with radicals also suggest that the reaction mechanism is controlled by addition for the reactions with •OH and by H abstraction for the reactions with •OOH.[41] Unfortunately, the addition mechanism was not considered in other previous theoretical works on the antioxidant activity of hydroxycinnamic acids such as *p*-coumaric, caffeic, and sinapinic acids.[26,29,40] Mantzavinos et al. determined the reaction intermediates of *p*-coumaric acid

oxidation in different conditions by high-performance liquid chromatography (HPLC). The authors suggested that the oxidation at pH 3.5 starts through two main routes: (i) oxygen attack to the nonaromatic double bond to form glyoxylic acid and *p*-hydroxybenzoic acid (see Figure 1); (ii) decarboxylation reaction leading to *p*-vinylphenol. Under acidic conditions (pH 1) and in the presence of homogeneous catalyst ions such as $Fe^{2+}$, $Cu^{2+}$, $Zn^{2+}$, and $Co^{2+}$, a decarboxylation mechanism is favored.[55,56] Andreozzi et al. also determined the reaction intermediates of *p*-coumaric acid oxidation with ozone by

In a preliminary experiment, FCO seed ethanol extract inhibited NF-κB activation in LPS-stimulated peritoneal macrophages. Therefore, we isolated the primary anti-inflammatory constituent, ursolic acid, from the seed of FCO and investigated its anti-inflammatory effect in LPS- or peptidoglycan-stimulated peritoneal macrophages and 2,4,6-trinitrobenzenesulfonic acid (TNBS)-induced colitis mice.

## MATERIALS AND METHODS

**Chemicals.** RPMI 1640, peptidoglycan purified from *Staphylococcus aureus*, LPS purified from *Escherichia coli* O111:B4, and TNBS were purchased from Sigma-Aldrich (St. Louis, MO). Antibodies for cyclooxygenase (COX)-2, inducible NO synthetase (iNOS), and β-actin were purchased from Santa Cruz Biotechnology (Santa Cruz, CA). Antibodies for IRAK-4, IRAK-1, p-IRAK-1, IκB-α, p-IKK-β, ERK, p-ERK, JNK, p-JNK p38, p-p38, p65, and p-p65 were purchased from Cell Signaling Technology (Danvers, MA). Enzyme-linked immunosorbent assay (ELISA) kits for cytokines and prostaglandin E2 (PGE2) were from R&D Systems (Minneapolis, MN). 3,3′-Diaminobenzidine tetrahydrochloride substrate was purchased from Thermo Scientific (Rockford, IL).

**Isolation of Ursolic Acid.** The dried seed of FCO (500 g) was extracted 3 times with hexane (3 L) at room temperature and 80% ethanol (2.5 L) in boiling water, successively, and evaporated under reduced pressure (35.2 g). The ethanol extract was suspended in distilled water, fractionated with BuOH twice, and evaporated under reduced pressure (21.5 g). The BuOH-soluble fraction was subjected to silica gel column chromatography (40 × 5 cm) with a gradient of $CHCl_3$/MeOH (100:1, 50:1, 25:1, 20:1, 10:1, 5:1, and 0:1, each 1.2 L) to afford seven subfractions. Of them, subfraction E2 (2.5 g) most potently inhibited NF-κB activation in LPS-stimulated peritoneal macrophages. Therefore, it was applied for isolation of the active constituents. Subfraction E2 was subjected to silica gel column chromatography (30 × 5 cm) with a gradient of $CHCl_3$/MeOH (40:1−10:1) to give four subfractions (E2.1−E2.4). Of them, the most potent anti-inflammatory constituent E2.2 (53 mg) was obtained as crystals in MeOH. The isolated compound was identified to be ursolic acid by instrumental analysis [nuclear magnetic resonance (NMR), Varian UNITY INOV-500 spectrophotometer, API-2000 spectrometer] and compared to an authentic standard, as reported in the literature.[14]

*Ursolic Acid (Purity of >95%).* Amorphous white powder. IR $\nu_{max}$ ($cm^{-1}$): 1692, 2928, 3421. Electrospray ionization mass spectrometry (ESI−MS) (*m*/*z*): [$M^+$] 456. $^1H$ NMR ($CDCl_3$, 500 MHz) δ: 5.52 (1H, t, *J* = 3.5 Hz, H-12), 3.48 (1H, dd, *J* = 10.5 and 4.0 Hz, H-3), 2.63 (1H, d, *J* = 3.5 Hz, H-18), 1.27, 1.26, 1.10, 1.08 (each 3H, s H-23, 27, 26, 24), 1.02 (3H, d, *J* = 6.5 Hz, H-30), 0.98 (3H, d, *J* = 6.5 Hz, H-29), 0.89 (3H, s, H-25). $^{13}C$ NMR ($CDCl_3$, 125 MHz) δ: 180.1 (C-28), 139.7 (C-13), 126.1 (C-12), 78.6 (C-3), 56.2 (C-18), 53.8 (C-5), 47.1 (C-17), 42.3 (C-14), 39.6 (C-4), 39.4 (C-1), 37.5 (C-22), 34.6 (C-10), 33.6 (C-7), 29.1 (C-19, C-20), 29.0 (C-15), 26.4 (C-21), 24.2 (C-27), 24.1 (C-11), 24.1 (C-2), 24.0 (C-23, C-30), 23.8 (C-16), 21.7 (C-29), 19.1 (C-6), 16.9 (C-24, C-25), 16.0 (C-26).

**Animals.** All animal experiments were approved by the Committee for the Care and Use of Laboratory Animals in the College of Pharmacy, Kyung Hee University (KHP-2012-11-01-R1) and performed according to the Kyung Hee University guides for Laboratory Animals Care and Usage.

Male C57BL/6J mice (male, 19−23 g, 6 weeks old) and TLR4-deficient C57BL/10ScNJ mice (male, 19−23 g, 6 weeks old) were purchased from Jackson Laboratory (Bar Harbor, ME). All animals were fed standard laboratory chow (Samyang Co., Seoul, South Korea), housed in wire cages at 20−22 °C and 50 ± 10% relative humidity, and allowed water *ad libitum*.

**Isolation and Culture of Peritoneal Macrophages.** The mice were intraperitoneally injected with 4% thioglycolate solution (2 mL) and sacrificed on the fourth day after injection, and their peritoneal cavities were rinsed with RPMI 1640 (10 mL).[15] The peritoneal lavage fluid was centrifuged at 200*g* for 10 min. Collected cells were resuspended with RPMI 1640 and seeded in a 12-well microplate. After incubation for 1 h at 37 °C, the cells were washed 3 times and non-adherent cells were removed by aspiration. Attached cells were used as peritoneal macrophages. The cells ($0.5 \times 10^6$ cells/well) were cultured in 24-well plates at 37 °C for 3 days in RPMI 1640 plus 10% fetal bovine serum (FBS). To count the number of macrophage cells, the adherent macrophages were then scraped with a rubber policeman, suspended into fresh phosphate-buffered saline (PBS), stained with Giemsa, and counted by a hemocytometer. To examine the anti-inflammatory effect of ursolic acid, macrophages were cultured in the absence or presence of ursolic acid (dissolved in 0.1% dimethyl sulfoxide) with 100 ng/mL LPS or peptidoglycan.

**ELISA and Immunoblotting in Peritoneal Macrophages.** For the assay of NF-κB activation-inhibitory activity of FCO ethanol extract, peritoneal macrophages ($0.5 \times 10^6$ cells) were stimulated with LPS (100 ng/mL) for 90 min in the presence or absence of FCO ethanol extract (10 or 20 μg/mL), then lysed, and centrifuged at 2000*g* for 10 min.[15] The macrophages ($0.5 \times 10^6$ cells) were also stimulated with LPS (100 ng/mL) or peptidoglycan (100 ng/mL) for 90 min (for the assay of IRAK-4, IRAK-1, p-IKK-β, IκB-α, p65, p-p65, p38, p-p38, ERK, p-ERK, JNK, p-JNK, and β-actin) or 20 h (for the assay of COX-2, iNOS, and β-actin) in the presence or absence of ursolic acid (10 and 20 μM) (dissolved in 0.1% dimethyl sulfoxide), then lysed, and centrifuged at 2000*g* for 10 min. Cell supernatants were used for immunoblot and ELISA analyses. Cytokine levels were assayed using an ELISA kit. Protein expression was analyzed by immunoblotting. Briefly, the supernatants were separated by 10% sodium dodecyl sulfate−polyacrylamide gel electrophoresis (SDS−PAGE) and transferred onto polyvinylidene difluoride membranes. The membranes were blocked with 5% nonfat dried-milk proteins in phosphate-buffered saline containing 0.05% Tween 20 (PBST, Biosesang, Inc., Seoul, Korea) and then probed with COX-2, iNOS, IRAK-4, IRAK-1, p-IKK-β, IκB-α, p65, p-p65, p38, p-p38, ERK, p-ERK, JNK, p-JNK, or β-actin antibodies. After washing with PBST, proteins were detected by incubating with horseradish peroxidase (HRP)-conjugated secondary antibodies for 50 min. Bands were visualized using an enhanced chemiluminescence reagent (Millipore Cooperation, Billerica, MA).[15]

**Immunofluorescent Confocal Microscopy.** For the assay of LPS/TLR4 complex formation, peritoneal macrophages plated on cover slides were cultured at 37 °C for 20 h. Cells were treated with Alexa Fluor 594-conjugated LPS (100 ng/mL, Invitrogen) for 60 min in the absence or presence of ursolic acid (10 and 20 μM), as previously reported.[16] Cells were fixed with 4% formaldehyde and 3% sucrose for 20 min, then treated with rabbit polyclonal anti-TLR4 antibody (Santa Cruz Biotechnology) for 90 min at 4 °C, and incubated with Alexa Fluor 488-conjugated secondary antibodies (Invitrogen) for 1 h. Stained cells were observed with a confocal microscope.

**Flow Cytometry.** Peritoneal macrophages ($1 \times 10^5$ cells) were incubated with or without Alexa Fluor 448-conjugated LPS (10 μg/mL) in the absence or presence of ursolic acid (5, 10, and 20 μM) for 30 min. Cells were fixed in PBS containing 3% sucrose and 4% paraformaldehyde for 20 min, as previously reported,[16] and then analyzed by flow cytometer (C6 Flow Cytometer System, Ann Arbor, MI).

**Transient Transfection of Small Interfering RNA (siRNA).** Peritoneal macrophages were seeded at $3 \times 10^5$ cells/well in 24-well plates and allowed to rest for 2 days prior to transfection. Cells were transfected with 100 nM siRNA for TLR4 (Dharmacon, Chicago, IL) or MyD88 (Santa Cruz Biotechnology) using Lipofectamine 2000 (Invitrogen, Carlsbad, CA) according to the protocol of the manufacturer. At 48 h after transfection, cells were treated with or without ursolic acid (10 and 20 μM) and/or LPS (100 ng/mL).

**Preparation of Experimental Colitis in Mice.** To investigate the curative effect of ursolic acid against colitis in mice, mice were divided into five groups: normal control and TNBS-induced colitis groups treated in the absence or presence of ursolic acid (10 and 20 mg/kg) or mesalazine (10 mg/kg) dissolved in 2% Tween 80.[21] Each group consisted of six mice. TNBS-induced colitis was induced by intrarectal

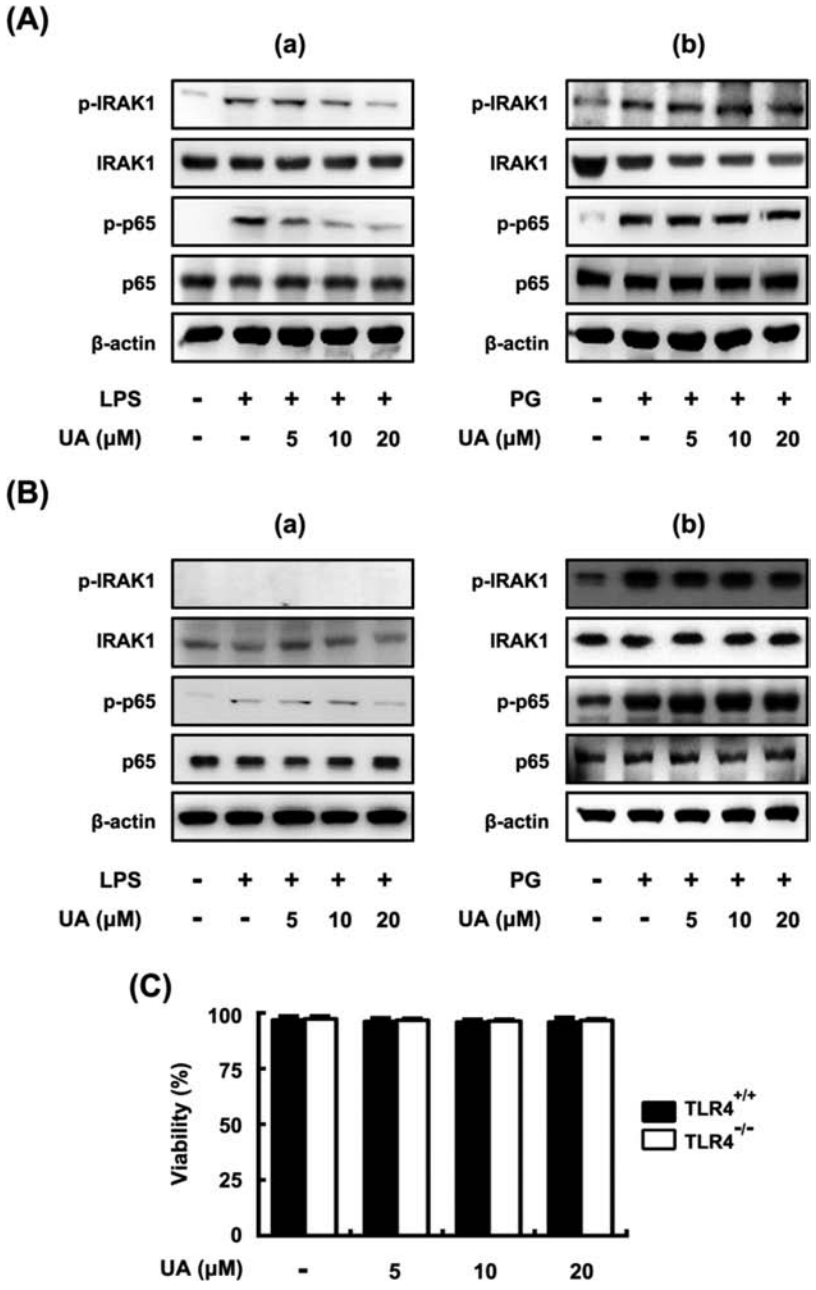

**Figure 1.** Effect of ursolic acid (UA) on IRAK1 phosphorylation and NF-κB activation in normal TLR4$^{+/+}$ and TLR4$^{-/-}$ peritoneal macrophages stimulated with lipopolysaccharide (LPS) or peptidoglycans (PG). (A) Effect in (a) LPS- or (b) PG-stimulated TLR4$^{+/+}$ peritoneal macrophages. (B) Effect in (a) LPS- or (b) PG-stimulated TLR4$^{-/-}$ peritoneal macrophages. Peritoneal macrophages were isolated from TLR4$^{+/+}$ and TLR4$^{-/-}$ mice and then incubated with LPS (100 ng/mL) or PG (100 ng/mL) in the absence or presence of UA (5, 10, or 20 μM) for 60 min. Protein expression of IRAK1, p-IRAK1, p65, p-p65, and β-actin was assayed by immunoblotting. (C) Cell viability of UA for (a) TLR4$^{+/+}$ and (b) TLR4$^{-/-}$ peritoneal macrophages. Cell viability was measured by a tryphan blue staining assay. Ursolic acid was treated for 48 h. All data are expressed as the mean ± SD ($n$ = 4 in a single experiment).

injection of 2.5% (w/v) TNBS solution (100 μL) in 50% ethanol into the colon of lightly anesthetized (with ether) mice via a thin round-tip needle equipped with a 1 mL syringe.[15] The normal control group was treated with vehicle alone instead of TNBS and test agents. A needle was inserted to 3.5−4 cm proximal to anal verge. To distribute agents within the entire colon, the mice were held in a vertical position for 30 s after injection. Using this procedure, >96% of the mice retained the TNBS enema. If an animal quickly excreted the TNBS−ethanol solution, it was excluded. Ursolic acid (10 and 20 mg/kg) or mesalazine (10 mg/kg) was orally administered once a day for 3 days from the first day after TNBS treatment. Mice were sacrificed 18 h after the final administration of test agents. The colon was removed quickly, then opened longitudinally, and gently washed by PBS. Macroscopic assessment of the colitis grade was scored: 0, no ulcer and no inflammation; 1, no ulceration and local hyperemia; 2, ulceration without hyperemia; 3, ulceration and inflammation at one site only; 4, two or more sites of ulceration and inflammation; and 5, ulceration extending more than 2 cm, as previously described.[21] The colon was then stored at −80 °C for immunoblotting and ELISA. For histological exams, the colon was fixed with 4% paraformaldehyde and then stored in 30% sucrose solution.

For histologic exams, colons were fixed in 10% buffered formalin solution, embedded in paraffin, cut into 7 μm sections, stained with hematoxylin−eosin, and then observed under a light microscope.

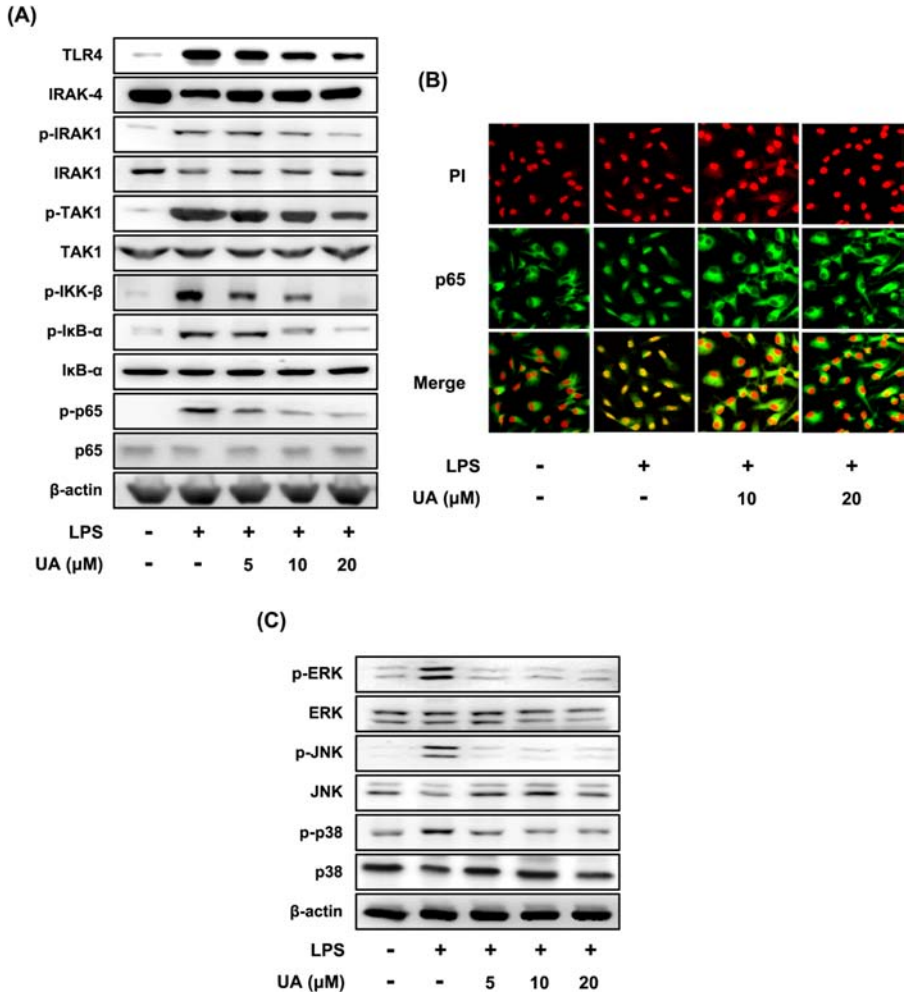

**Figure 2.** Effect of ursolic acid (UA) on the activation of TLR4/NF-κB and MAPKs in lipopolysaccharide (LPS)-stimulated peritoneal macrophages. (A) Effect on TLR4/NF-κB signaling pathway. (B) Effect on translocation of NF-κB into the nuclei. (C) Effect on the activation of MAPKs. Peritoneal macrophages were incubated with LPS (100 ng/mL) in the absence or presence of UA (10 and 20 μM) for 60 min. Protein expressions were assayed by immunoblotting.

**Assay of Myeloperoxidase (MPO) Activity.** Colons were homogenized in 10 mM potassium phosphate buffer (pH 7.0) containing 0.5% hexadecyl trimethylammonium bromide and then centrifuged at 15000*g* and 4 °C for 20 min.[16] The supernatant (50 μL) was added in a reaction mixture preincubated at 37 °C for 5 min, which contained 0.1 mM $H_2O_2$ and 1.6 mM tetramethylbenzidine and scanned at 650 nm at 37 °C for 10 min. MPO activity was defined as the enzyme quantity degrading 1 μmol of hydrogen peroxide/mg of protein. The amount of protein was determined by the Bradford protein assay kit, as previously reported.[16]

**Determination of Cytokines, PGE2, and Nitrite in the Colons of Mice.** Cytokine and PGE2 levels were determined using an ELISA kit. Briefly, colons were homogenized in ice-cold RIPA lysis buffer (1 mL) containing 1% phosphatase inhibitor cocktail and 1% protease inhibitor cocktail. The lysate was centrifuged at 15000*g* and 4 °C for 10 min, and the resulting supernatant was used for immunoblotting and ELISA, as previously described.[16]

Nitrite was measured using Griess reagent.[15] The supernatant (100 μL) was mixed with 100 μL of Griess reagent [the mixture of an equal volume of 1% sulfanilamide in 5% $H_3PO_4$ and 0.1% *N*-(1-naphthyl)ethylenediamine dihydrochloride in $H_2O$] in a 96-well plate, and then the absorbance was spectrophotometrically measured at 550 nm. The concentration of nitrite was determined, using a sodium nitrite, as a standard.

**Statistical Analysis.** Data are presented as the mean ± standard deviation (SD) and were statistically analyzed using one-way analysis of variation (ANOVA) and Turkey's multiple comparison tests (12.0K for Windows, SPSS, Inc., Chicago, IL). *p* values of 0.05 or less were considered statistically significant.

## RESULTS

**Inhibitory Effect of Ursolic Acid on the Expression of Inflammatory Mediators in LPS- or Peptidoglycan-Stimulated Peritoneal Macrophages.** In a preliminary study, FCO seed 80% ethanol extract potently inhibited NF-κB activation in LPS-stimulated peritoneal macrophages (see Supplemental Figure S1 of the Supporting Information). Therefore, we isolated ursolic acid, a potent inhibitor for NF-κB activation, through activity-guided fractionation and investigated the inhibitory effect of ursolic acid on LPS-linked TLR4/NF-κB activation in $TLR4^{+/+}$ or $TLR4^{-/-}$ peritoneal macrophages activated with LPS or peptidoglycan. The stimulation of LPS or peptidoglycan increased IRAK1 phosphorylation and NF-κB activation in $TLR4^{+/+}$ cells (Figure 1A). Treatment with ursolic acid inhibited LPS-induced IRAK1 phosphorylation and NF-κB activation. In contrast, ursolic acid did not inhibit peptidoglycan-induced IRAK1 phosphorylation and NF-κB activation in $TLR4^{+/+}$ cells. However, the stimulation of LPS failed to significantly activate IRAK1 and NF-κB in TLR4-deficient ($TLR^{-/-}$) cells, but the stimulation of

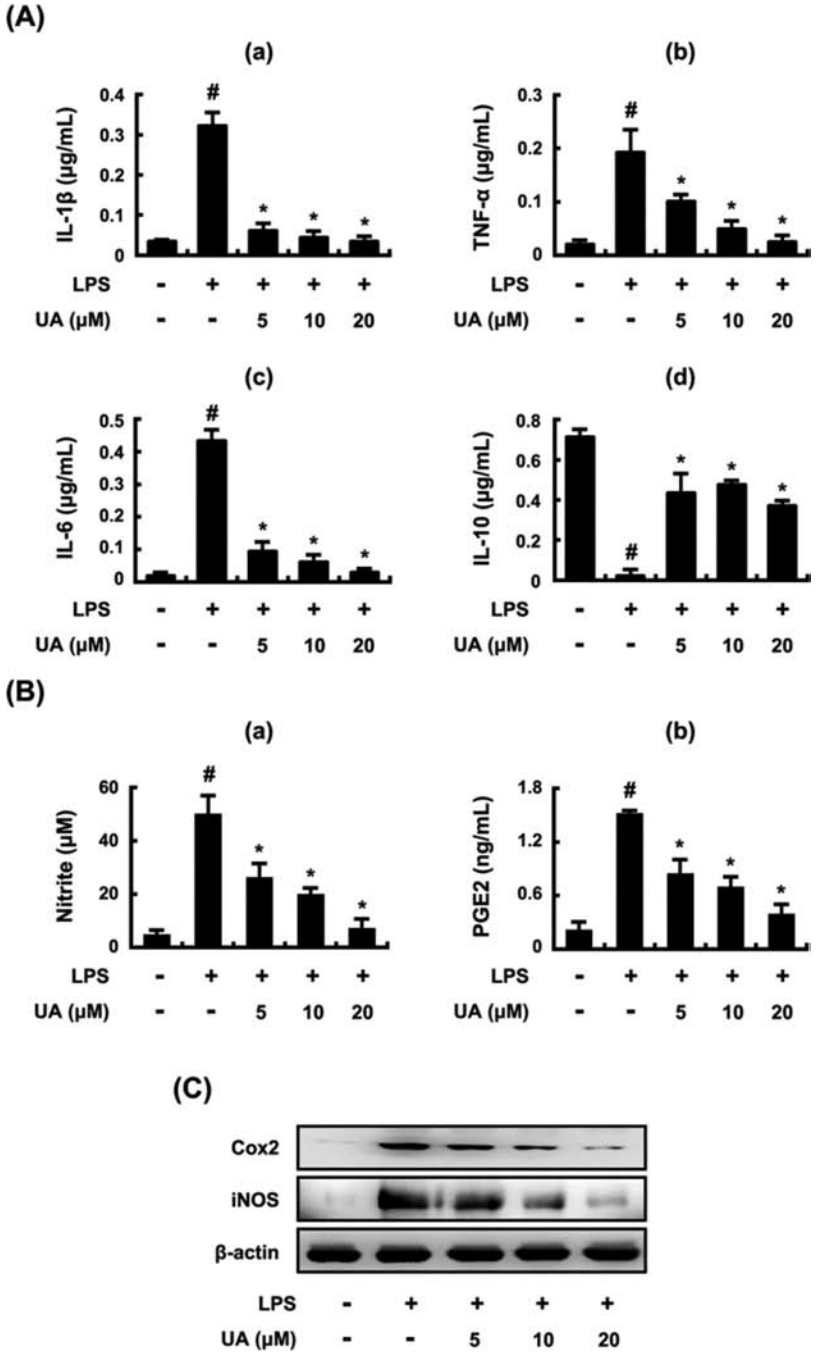

**Figure 3.** Effect of ursolic acid (UA) on the expression of inflammatory markers in peritoneal macrophages stimulated with lipopolysaccharide (LPS). (A) Effect on TNF-$\alpha$, IL-1$\beta$, IL-6, and IL-10. (B) Effect on the production of PGE2 and NO. (C) Effect on the expression of iNOS and COX-2. Peritoneal macrophages were incubated with LPS (100 ng/mL) in the absence or presence of UA (10 or 20 $\mu$M) for 20 h. Cytokines and PGE2 were assayed by ELISA. iNOS and COX-2 were assayed by immunoblotting. NO was assayed, using Griess reagent. All data are the mean ± SD ($n$ = 4). (#) Significantly different versus the normal group ($p < 0.05$). (*) Significantly different versus the control group ($p < 0.05$).

peptidoglycan significantly increased IRAK1 phosphorylation and NF-$\kappa$B activation (Figure 1B). Notably, ursolic acid could not inhibit peptidoglycan-induced IRAK1 and NF-$\kappa$B activation in the TLR4-deficient cells.

To investigate the cytotoxicity of ursolic acid, peritoneal macrophages were treated with ursolic acid (10 and 20 $\mu$M) for 48 h. Cells were then trypsinized, stained with Trypan blue solution, and assessed for viability. No cytotoxic effect of ursolic acid was observed under the experimental conditions (Figure 1C).

Phosphorylation of inhibitor of nuclear factor $\kappa$B kinase subunit $\beta$ (IKK$\beta$) and I$\kappa$B$\alpha$ (through ubiquitination and proteolytic degradation) leads to the translocation of NF-$\kappa$B into the nuclei.[17] Therefore, we measured the effect of ursolic acid on phosphorylation of TAK1, IKK$\beta$, and I$\kappa$B$\alpha$ and degradation of IRAK1 and IRAK4 in LPS-stimulated peritoneal macrophages (Figure 2A). Treatment with LPS significantly induced these processes. Ursolic acid significantly inhibited the phosphorylation of these proteins. To confirm the inhibitory effect of ursolic acid on NF-$\kappa$B activation, we measured its

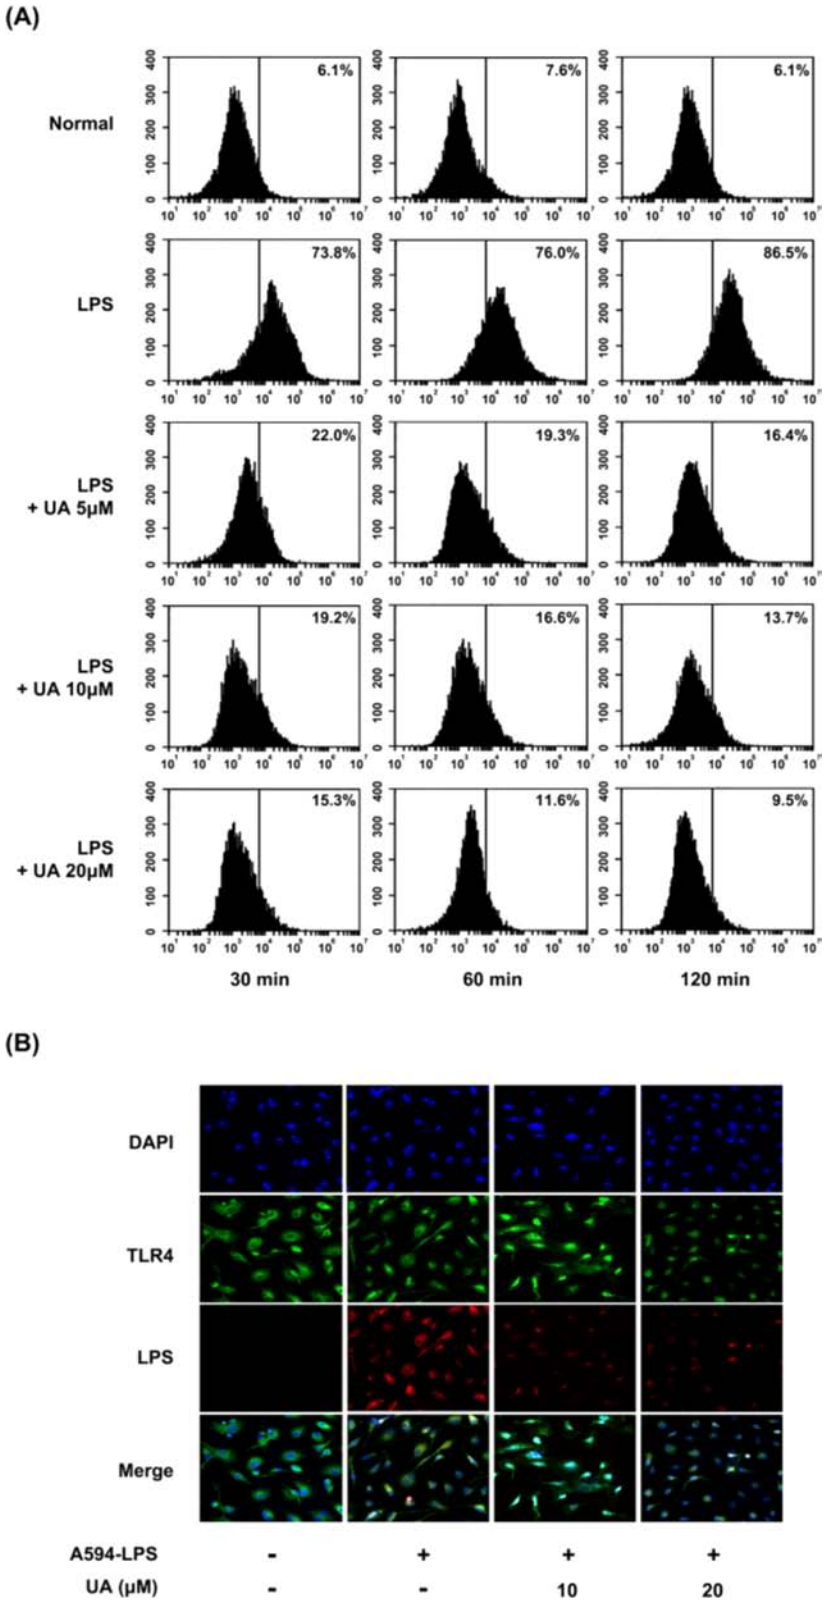

**Figure 4.** Inhibitory effect of ursolic acid (UA) on the binding of LPS to TLR4 in peritoneal macrophages. Peritoneal macrophages isolated from mice were incubated with Alexa Fluor 488-conjugated LPS for 30 min for a flow cytometry or 60 min for a confocal microscopy in the absence or presence of UA (5, 10, and 20 $\mu$M), and the cells were stained with rabbit polyclonal anti-TLR4 antibody for 2 h at 4 °C, incubated with secondary antibodies conjugated with TRITC for 1 h, and then analyzed using a (A) flow cytometer and (B) confocal microscope. The normal group was treated with vehicle alone instead of LPS and UA.

inhibitory effect on the translocation of NF-$\kappa$B into the nuclei in LPS-stimulated peritoneal macrophages (Figure 2B). LPS significantly increased the translocation of NF-$\kappa$B into the nuclei, which was significantly inhibited by ursolic acid. We also

dx.doi.org/10.1021/jf501487v | J. Agric. Food Chem. 2014, 62, 9711−9721

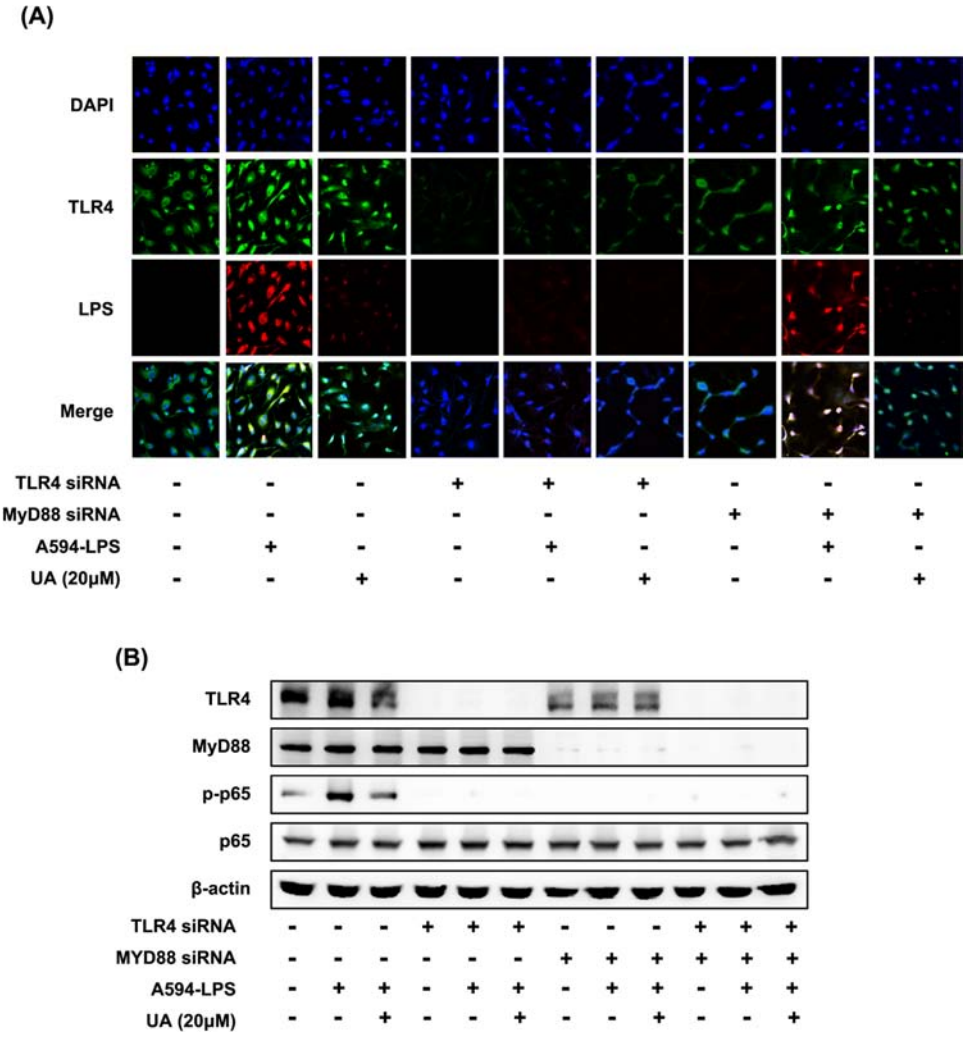

**Figure 5.** Effect of ursolic acid (UA) on the expression of TLR4 and MyD88 and activation of NF-κB in peritoneal macrophages transfected with or without TLR4 siRNA and/or MyD88 siRNA. (A) Peritoneal macrophages isolated from mice were incubated with Alexa Fluor 594-conjugated LPS (100 ng/mL) for 30 min in the absence or presence of UA (10 and 20 μM), and then LPS binding on the surface of TLR4 and/or MyD88 siRNA-transfected peritoneal macrophages was measured using a confocal microscope. (B) Effect on NF-κB activation. TLR4, MyD88, p65, p-p65, and β-actin proteins were assayed by immunoblotting.

investigated the effect of ursolic acid on MAPK activation in LPS-stimulated peritoneal macrophages (Figure 2C). LPS stimulation activated ERK, JNK, and p38. However, ursolic acid significantly suppressed their phosphorylation.

Next, we measured the effect of ursolic acid on the expression of proinflammatory cytokines IL-1β, IL-6, and TNF-α in LPS-stimulated peritoneal macrophages (Figure 3A). LPS significantly increased the expression of these cytokines. Treatment with ursolic acid inhibited TNF-α, IL-1β, and IL-6 expression. Urosolic acid also decreased LPS-induced PGE2 and NO production (Figure 3B). Further, ursolic acid suppressed LPS-induced COX-2 and iNOS expression (Figure 3C).

**Ursolic Acid Inhibits the Binding of LPS to TLR4.** Treatment with ursolic acid (5, 10, and 20 μM) inhibited the phosphorylation of IRAK1, IκBα, and p65 in LPS-stimulated peritoneal macrophages. Therefore, we examined the ability of ursolic acid to inhibit LPS binding to TLR4 on peritoneal macrophages using a flow cytometer (Figure 4A). Treatment of peritoneal macrophages with Alexa Fluor 488-conjugated LPS induced a significant shift. However, treatment with ursolic acid remarkably restored the Alexa Fluor 488-conjugated LPS-mediated shift of macrophages. Next, we examined the ability of ursolic acid to inhibit LPS binding to TLR4 on peritoneal macrophages using a confocal microscope (Figure 4B). Alexa Fluor 488-conjugated TLR4 antibody was found to bind the macrophages, and this binding was unaffected by ursolic acid treatment. Alexa Fluor 594-conjugated LPS was also found to potently bind to macrophages. However, ursolic acid treatment significantly inhibited the binding of Alexa Fluor 594-conjugated LPS to the macrophages.

To further confirm whether ursolic acid inhibits LPS binding to TLR4 on peritoneal macrophages, the macrophages were transiently transfected with TLR4 or MyD88 siRNA for 48 h and then protein expression of TLR4 and MyD88 was detected (Figure 5). Knockdown efficiencies of TLR4 and MyD88 were 93 and 89%, respectively, as determined by immunoblotting. When the cells were treated with Alex 594-conjugated LPS, the LPS did not bind to the macrophages transfected with TLR4 siRNA. Ursolic acid did not influence the binding of LPS to TLR4 or MyD88 siRNA-transfected macrophages (data not shown). However, it was observed that LPS was bound to

dx.doi.org/10.1021/jf501487v | J. Agric. Food Chem. 2014, 62, 9711−9721

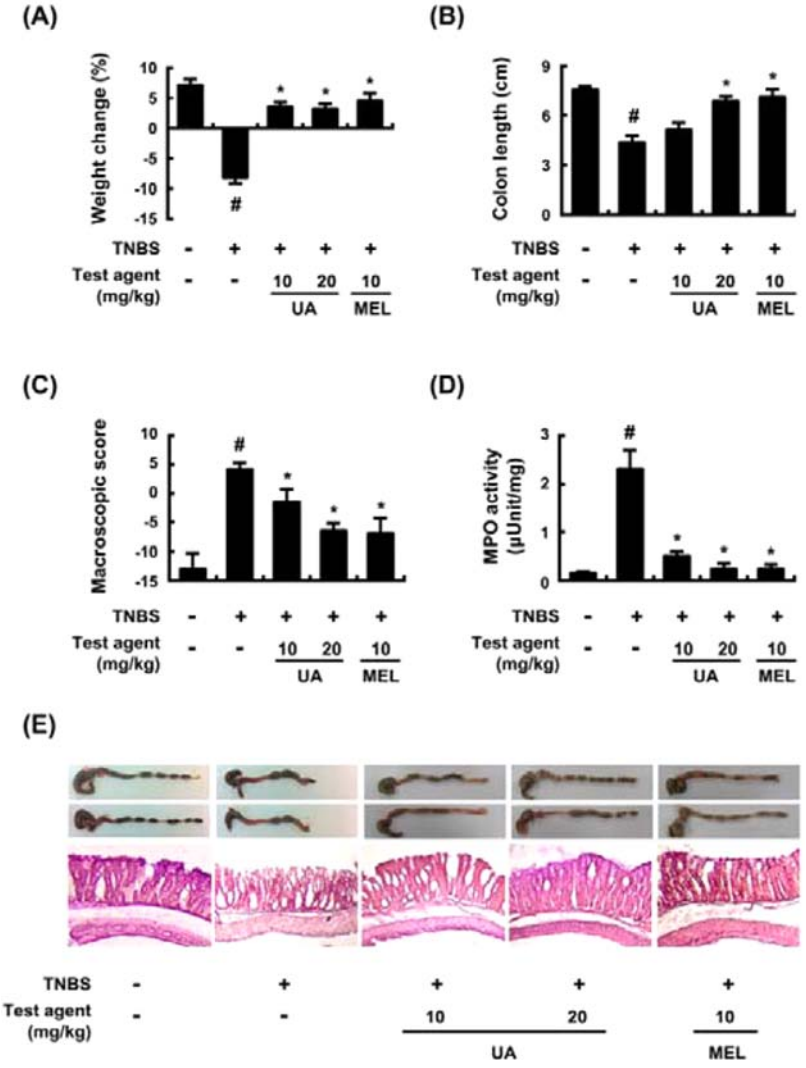

**Figure 6.** Effect of ursolic acid (UA) on (A) body weight, (B) colon length, (C) macroscopic score, (D) peritoneal MPO activity, and (E) histology in the colon tissues of TNBS-induced colitic mice. TNBS (2.5% TNBS in 50% ethanol) was intrarectally administered in mice. Test agents (TNBS, vehicle alone; UA10, 10 mg/kg of UA; UA20, 20 mg/kg of UA; and MEL, 10 mg/kg of mesalazine) were orally administered. The normal group (NOR) was treated with vehicle alone in normal mice. Test agents (dissolved in 2% Tween 80) were orally administered once daily for 3 days after TNBS treatment. Mice were sacrificed 18 h after the final administration of test agents. Colons were stained with hematoxylin−eosin and then assessed by light microscopy. All data are the mean ± SD ($n$ = 6). (#) Significantly different versus the normal group ($p < 0.05$). (*) Significantly different versus the control group ($p < 0.05$).

MyD88 siRNA-transfected cells. Nevertheless, LPS did not activate NF-κB. When ursolic acid (20 μM) was treated prior to stimulation with LPS in MyD88 siRNA-transfected macrophages, ursolic acid potently inhibited the binding of LPS to TLR4 on these cells.

**Ursolic Acid Inhibits the Expression of Proinflammatory Cytokines and Activation of NF-κB in TNBS-Induced Colitic Mice.** We also investigated the inhibitory effect of ursolic acid on TNBS-induced colitis in mice. When TNBS was intrarectally injected in mice, colitis was caused, as observed in previous reports.[15] Oral administration of ursolic acid significantly inhibited TNBS-induced colon shortening and increased the macroscopic score (Figure 6). Ursolic acid (20 mg/kg) inhibited the TNBS-induced MPO activity by 92% compared to normal mice treated with TNBS alone ($p < 0.05$). Histologic examination of the colon in TNBS-induced colitic mice showed edema, dense infiltration of the superficial layers of the mucosa, and epithelial cell disruption by large ulcerations. Orally administered ursolic acid suppressed edema and epithelial cell disruption. We also measured the levels of proinflammatory cytokines, IL-1β, IL-6, and TNF-α, and an anti-inflammatory cytokine, IL-10, in the colons of TNBS-treated mice (Figure 7A). TNBS significantly increased TNF-α, IL-1β, IL-6, and IL-10 expression. Ursolic acid inhibited the expression of pro-inflammatory cytokines TNF-α, IL-1β, and IL-6, although β-actin expression was not affected. Thus, ursolic acid (20 mg/kg) inhibited expression of these cytokines by 93% for IL-1β ($p < 0.05$), 86% for TNF-α ($p < 0.05$), and 85% for IL-6 ($p < 0.05$). However, ursolic acid reversed the TNBS-mediated downregulation of IL-10 expression to 79% of the normal control group ($p < 0.05$). Treatment with TNBS also increased the expression of COX-2 and iNOS, the degradation of IRAK1 and IRAK4, and the activation of IRAK1, IKKβ, and NF-κB (p-p65) (Figure 7B), all of which were blocked by ursolic acid. Further, ursolic acid inhibited the degradation of IRAK1 and IRAK4.

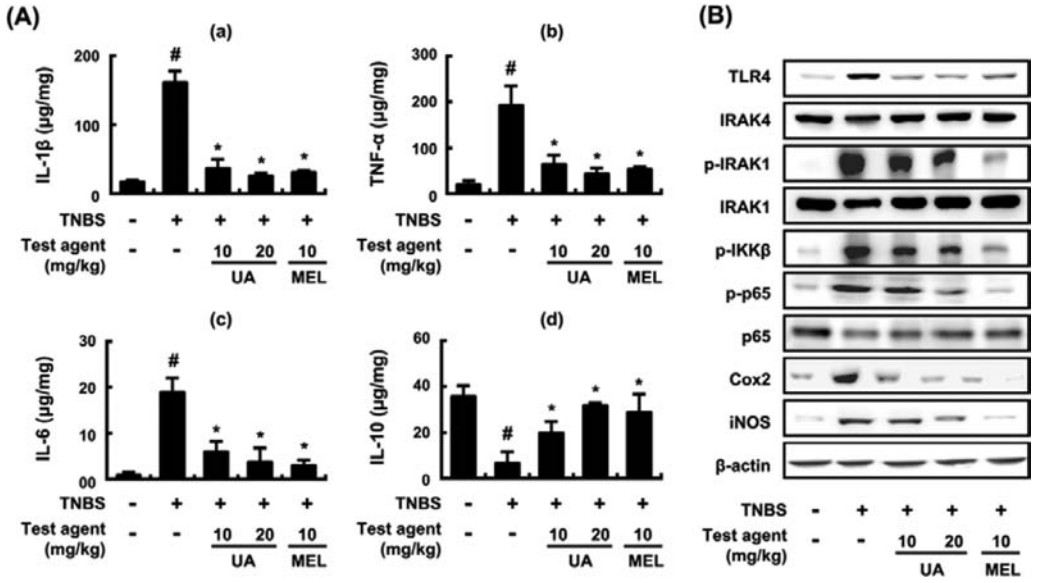

**Figure 7.** Effect of ursolic acid (UA) on the expression of inflammatory cytokines IL-1$\beta$, IL-6, and TNF-$\alpha$, iNOS, and COX-2 and the activation of NF-$\kappa$B in the colon tissues of TNBS-induced colitic mice. TNBS was intrarectally administered in control (2.5% TNBS in 50% ethanol), UA (10 or 20 mg/kg), and mesalazine (MEL, 10 mg/kg) groups; the normal group was treated with vehicle alone. Mice were sacrificed 18 h after the final administration of test agents. (A) Effect on the expression of proinflammatory cytokines. Cytokines were assayed by ELISA. (B) Effect on the expression of TLR4, iNOS, and COX-2 and the activation of NF-$\kappa$B, as determined by immunoblotting. All data values are the mean ± SD ($n$ = 6). (#) Significantly different versus the normal group ($p < 0.05$). (∗) Significantly different versus the control group ($p < 0.05$).

## DISCUSSION

Inflammation is a complex, highly sequential series of events provoked by a variety of stimuli, including pathogens.[18] Inflammation is classified as acute or chronic. Acute inflammation is a normal and beneficial response to injury or infection. However, chronic inflammation is excessive and persistent. This chronically inflammatory response causes progressive injuries to the body, resulting in a variety of severe inflammatory diseases, such as colitis and rheumatoid arthritis.[19,20] The inflammatory process is usually tightly regulated by inflammatory mediators, such as TNF-$\alpha$, IL-1$\beta$, and IL-6, and immune cells, such as neutrophils, monocytes, and lymphocytes.[1] Of these inflammatory mediators, TNF-$\alpha$ and IL-1$\beta$ are activated through NF-$\kappa$B, which consists of five members, including RelA, cRel, RelB, p50, and p52.[3,21] There are canonical and non-canonical NF-$\kappa$B signaling pathways. The canonical NF-$\kappa$B is primarily involved in natural immunity and most inflammation, while non-canonical NF-$\kappa$B plays a role in B-cell maturation and autoimmune diseases. NF-$\kappa$B is an essential transcription factor for immune functions. However, excessive NF-$\kappa$B activation often causes inflammation.[4] Bacterial lipopolysaccharides or peptidoglycans increase blood IL-1$\beta$ and TNF-$\alpha$ levels via canonical and non-canonical TLR-linked NF-$\kappa$B signaling pathways and cause inflammation, although blood IL-1$\beta$ and TNF-$\alpha$ levels are hardly detectable in mice without any stimuli or treatment.[5,22] Therefore, to regulate the expression of proinflammatory cytokines via the canonical NF-kB signaling pathway in macrophages, many constituents isolated from natural products, including saponins and flavonoids, have recently been applied.[23,24]

In a preliminary study, FCO seed 80% ethanol extract potently inhibited NF-$\kappa$B activation in LPS-stimulated peritoneal macrophages. We isolated ursolic acid as a potent inhibitor for NF-$\kappa$B activation from FCO seed. Ursolic acid, which is distributed in vegetables and functional foods as a main constituent, inhibits carrageenan-induced paw edema in rats[25] as well as TPA/croton oil-induced ear edema.[26] Ursolic acid also inhibits LPS-induced cognitive deficits by suppressing p38/NF-$\kappa$B mediated inflammatory pathways,[27] LPS-stimulated lung inflammation via NF-$\kappa$B activation,[28] ovalbumin-induced airway inflammation,[29] and zymosan-induced acute inflammation in mice.[30]

Therefore, we investigated the anti-inflammatory effect on TNBS-stimulated colitis in mice. We found that ursolic acid inhibited the expression of inflammatory enzymes, COX-2 and iNOS, as well as activation of their transcription factor NF-$\kappa$B. Ursolic acid also inhibited the expression of pro-inflammatory cytokines, TNF-$\alpha$ and IL-1$\beta$, but increased the expression of anti-inflammatory cytokine, IL-10, which was reduced by TNBS. These results suggest that ursolic acid may inhibit colitis by inhibiting NF-$\kappa$B activation as well as the activation of Th1 cells, which are activated by pro-inflammatory cytokines TNF-$\alpha$ and IL-1$\beta$,[31] rather than Th2 cells, which are activated by IL-4 and IL-10.[31] This suggestion is supported by previous studies showing that ursolic acid protects $CCl_4$-induced inflammation by inhibiting MAPK, STAT3, and NF-$\kappa$B signaling pathways.[32] Ursolic acid also inhibits Th1 cytokine IL-2 production and induces Th2 cytokine IL-10 production in murine primary splenocytes.[33]

In the present study, we found that ursolic acid inhibited the expression of inflammatory markers COX-2, iNOS, TNF-$\alpha$, and IL-1$\beta$ as well as activation of NF-$\kappa$B and MAPKs in LPS-stimulated peritoneal macrophages, as previously reported in RAW264.7 cells.[34,35]

Ursolic acid inhibits the expression of proinflammaotry cytokines in murine T cells, B cells, and macrophages as well as activation of NF-$\kappa$B in T cells.[36] Ursolic acid also inhibits TPA-induced COX-2 expression and PGE2 synthesis in human mammary epithelial cells via the protein kinase C/MAPK signaling pathway[37] as well as the leucine-stimulated mROC1 signaling pathway in C2C12 myotube cells by suppressing mTOR localization to lysosome.[38]

However, its anti-inflammatory mechanism has not been thoroughly studied.

To understand the anti-inflammatory mechanism of ursolic acid, we investigated its effect on IRAK phosphorylation and binding of LPS to TLR4 in macrophages. Ursolic acid not only inhibited the binding of LPS to TLR4 on peritoneal macrophages transfected with or without MyD88 siRNA but also suppressed the phosphorylation of IRAK1 and IκBα and the degradation of IRAK1 and IRAK4. Further, ursolic acid inhibited the expression of proinflammatory cytokines TNF-α, IL-1β, and IL-6 as well as activation NF-kB and MAPKs. However, ursolic acid did not inhibit IP-10 synthesis in T84 colon carcinoma cells.[39] These results suggest that ursolic acid may suppress NF-κB and MAPK signaling pathways by inhibiting the binding of LPS to TLR4 on immune cells, such as macrophages. Additionally, we investigated the effect of ursolic acid on systemic inflammation and septic death in mice peritoneally injected with LPS (see Supplemental Figure S2 of the Supporting Information). Ursolic acid [10 mg/kg, *per os* (po)] significantly reduced LPS-induced blood proinflammatory cytokines IL-1β and TNF-α levels. Further, Ursolic acid inhibited LPS-induced septic death (systemic inflammation). These results also suggest that ursolic acid may inhibit LPS-stimulated inflammatory responses.

On the basis of these findings, we conclude that ursolic acid may ameliorate inflammatory diseases, such as colitis, by regulating NF-κB and MAPK signaling pathways via the inhibition of LPS binding to TLR4 on immune cells.

capacity has been studied using different assays,[6,9] and high amounts of phenolic compounds and high antioxidant activities were observed. In addition, research on other *Myrica* species has been performed. *Myrica esculenta* (syn. *Myrica nagi*) has also been reported to be rich in antioxidant compounds and to present several medicinal applications and satisfactory antioxidant and anticancer activities.[14−16] However, no studies have been published regarding the chemical composition or antioxidant capacity of *Myrica faya*. Considering the high antioxidant activity reported in previous studies regarding other *Myrica* species, special attention should be paid to the chemical composition of *M. faya* and other underutilized plants.

In this work we present, for the first time, a report on the phytochemical content and antioxidant activity of *Myrica faya*. The methanolic extracts of its fruits and leaves were characterized by HPLC-DAD/ESI-MS$^n$, putting special emphasis on the phenolic composition. In addition, its antioxidant capacity was evaluated using radical scavenging methods (ABTS and DPPH) and analyzing its L-ascorbic acid (L-AA) content. The obtained results were compared to the previous ones reported for other *Myrica* species, the main goal of this work being to find out if the chemical composition of *M. faya* makes it a valuable plant from the health and economic points of view.

## MATERIAL AND METHODS

**Chemicals and Instruments.** All reagents and standards were of analytical reagent (AR) grade. L-Ascorbic acid (L-AA) (purity: 99%), quercetin hydrated (99%), potassium iodate (99%), Folin−Ciocalteu's phenol reagent (FCR), gallic acid (99%), rutin (≥98%), and potassium acetate (>99.5%) were purchased from Panreac (Madrid, Spain). Ellagic acid (≥96%), 6-hydroxy-2,5,7,8-tetramethylchroman-2-carboxylic acid (Trolox) (>99.8%), 2,2′-azinobis(3-ethylbenzthiazoline-6-sulfonic acid) (ABTS) (≥99%), and 2,2-diphenyl-1-picrylhydrazyl (DPPH) (>95%) were obtained from Fluka (Lisbon, Portugal). Apigenin (≥99%) and (+)catechin hydrated (>99%) were purchased from Extrasynthese (Genay, France). Caffeic acid (≥98%), potassium persulfate (99%), sodium carbonate (p.a.), metaphosphoric acid (MPA) (33.5−36.5%), and formic acid (98%) were obtained from Sigma-Aldrich (St. Louis, MO); aluminum chloride hexahydrated (98%) and potassium iodine (98%) were from Riedel-de Haën (Hanover, Germany). Acetic acid (99.8%), ethylenediaminetetraacetic acid disodium salt (EDTA) (98%), and starch (98%) were supplied by Merck (Darmstadt, Germany). Cyanidin-3-glucoside (C3G) chloride (>98%) was obtained from Biopurify phytochemicals LTD (Chengdu, China). The methanol (99.9%) used for the extraction of *M. faya* was purchased from Fisher (Lisbon, Portugal). LC−MS grade acetonitrile ($CH_3CN$) (99%) (LabScan; Dublin, Ireland) and ultrapure water (Milli-Q Waters purification system; Millipore; Milford, MA) were used for analysis.

**Sample Preparation.** Samples of *Myrica faya* were collected in the wild in Machico (Madeira Island) in July 2013 and identified by taxonomist Fátima Rocha. Voucher specimens have been stored at Madeira Botanical Garden Herbarium (Funchal, Madeira) (voucher: MADJ 13165). For analysis, plant material was separated into leaves and berries (fully ripe), destemmed, and washed. Then, samples were lyophilized to dryness (Savant vapor trap RVT400; Thermo Scientific Inc.; Waltham, MA), ground to powder, and stored at −20 °C.

**Extraction of Phenolic Compounds.** Before the samples were subjected to evaluation, an extraction procedure was optimized. Acetone and methanol were tested as extraction solvents. Briefly, 5 g of leaf powder and 100 mL of solvent were submitted to ultrasound sonication (Bandelin Sonorex; Germany) at 35 Hz and 200 W for 60 min (room temperature). Then, extracts were filtered and concentrated to dryness under reduced pressure in a rotary evaporator (Buchi Rotavapor R-114) at 40 °C. The efficiency of the different extraction conditions was determined by means of total phenolic content assay (described below). On the basis of the results, the concentration of solvent in water (%, v/v) and influence of extraction duration were also tested (60, 30, and 15 min). Finally, the optimal conditions found were applied to the target plant material, and the resulting extracts were stored at 4 °C until further analysis.

**Chromatographic Conditions.** The HPLC analysis was performed on a Dionex ultimate 3000 series instrument (Thermo Scientific Inc.) coupled to a binary pump, a diode-array detector (DAD), an autosampler, and a column compartment (kept at 20 °C). Separation was achieved on a Phenomenex Gemini $C_{18}$ column (5 μm, 250 mm × 3.0 mm i.d.) using a mobile phase composed by $CH_3CN$ (A) and water/formic acid (0.1%, v/v) at a flow rate of 0.4 mL min$^{-1}$. The following gradient program was used: 20% A (0 min), 25% A (10 min), 25% A (20 min), 50% A (40 min), 100% A (42−47 min), and 20% A (49−55 min). Spectral data for all peaks were accumulated in the range 190−520 nm. A solution with concentration (w/v) of 5 mg mL$^{-1}$ was prepared by dissolving the dried extract in the initial HPLC mobile phase, filtered through 0.45 μm PTFE membrane filters, and 10 μL was injected. The chromatographic analysis was performed in triplicate ($n$ = 3) for each sample.

For HPLC-DAD/ESI-MS$^n$ analysis, a Bruker Esquire model 6000 ion trap mass spectrometer (Bremen, Germany) with an ESI source was used. MS$^n$ analysis worked in negative and positive mode, and scan range was set at $m/z$ 100−1000 with speed of 13 000 Das$^{-1}$. The conditions of ESI were as follows: drying and nebulizer gas ($N_2$) flow rate and pressure, 10 mL min$^{-1}$ and 50 psi; capillary temperature, 325 °C; capillary voltage, 4.5 keV; collision gas (He) pressure and energy, 1 × 10$^{-5}$ mbar and 40 eV. The acquisition of MS$^n$ data was made in auto MS$^n$ mode, with isolation width of 4.0 $m/z$, and fragmentation amplitude of 1.0 V (MS$^n$ up to MS$^4$). Esquire control software was used for the data acquisition and Data Analysis for processing.

**Quantification of Phenolic Compounds.** For this quantitative analysis, one polyphenol was selected as the standard for each group, and was used to calculate individual concentrations by HPLC-DAD. Caffeic and gallic acids were used for hydroxycinnamic and hydroxybenzoic acids, respectively. Anthocyanins standard was cyanidin 3-*O*-glucoside. Quercetin and apigenin were the standards used for the flavonols and flavones, respectively. (+)-Catechin hydrate and ellagic acid were used as standards for quantification of flavanols and ellagitannins. Stock standard solutions (1000 mg/L) were prepared in methanol, and calibration curves were prepared by diluting the stock solutions with the initial mobile phase. Six concentrations (5−100 mg/L) were used for the calibration, plotting peak area versus concentration, obtaining $R^2 \geq 0.967$ in all cases. Peak area was used as the analytical signal for polyphenol quantification. Total individual phenolic contents (TIPC) was defined as the sum of the quantified phenolic compounds.

**Analysis of L-AA Content and Sugars.** Fresh berries were homogenized in a blender, and the pH was measured directly in the pulp using a Metrohm 7444 pH-meter (calibrated with standard buffer solutions of pH 7 and pH 9, respectively). The total soluble solids (TSS) were determined using an Atago RX-1000 refractometer, and the results were reported as Brix degrees (°Brix).

L-AA determination was carried out using the procedure indicated in our previous work.[17] Briefly, 10 mL of extraction solution (30 g L$^{-1}$ MPA−80 mL L$^{-1}$ acetic acid−1 mmol L$^{-1}$ EDTA) was added to 3 mL of pulp, and the mixture was centrifuged (4000 rpm; 20 min; 4 °C). The resulting extract was immediately analyzed by iodometric titration: 1 mL of 10 g L$^{-1}$ starch solution and 1 mL of 100 g L$^{-1}$ potassium iodide solution were added to fruit extract (diluted 1:10 with deionized water). Then, the samples were titrated with 0.002 mol L$^{-1}$ potassium iodate solution, until the mixture became dark blue and the color persisted for more than 60 s. This procedure was repeated in triplicate.

**TPC, TFC, and Antioxidant Capacities Assays.** *Total Phenolic Content (TPC).* The total phenolic content was determined by the Folin−Ciocalteu method.[18] Briefly, 50 μL aliquots (5 mg mL$^{-1}$ of dried extract dissolved in methanol) were mixed with 1.25 mL of FCR (diluted 1:10) and 1 mL of 7.5% $Na_2CO_3$ solution. After 30 min in darkness and room temperature, the absorbance was measured at 765

dx.doi.org/10.1021/jf503540s | J. Agric. Food Chem. 2014, 62, 9722−9735

nm ($n$ = 3) in a PerkinElmer UV−vis Lambda 2 spectrophotometer. The amounts of total phenolics were expressed as mg gallic acid equivalents (GAE)/100 g of dried extract (DE).

*Total Flavonoid Content (TFC).* The total flavonoid content was evaluated using the aluminum chloride colorimetric method:[18] 0.5 mL of methanolic extract (2.5 mg $mL^{-1}$) was mixed with 1.5 mL of methanol, 2.8 mL of distilled water, 0.1 mL of $CH_3COOK$ (1 mol $L^{-1}$), and 0.1 mL of $AlCl_3{\cdot}6H_2O$. The absorbance was measured at 415 nm after 30 min of reaction. The final results were expressed as mg of rutin equivalent (RUE)/100 g DE.

*ABTS Radical Scavenging Activity.* The $ABTS^{\bullet+}$ assay was performed according to Gouveia et al.[18]For each analysis, 40 $\mu$L of methanolic solution was added to 1.96 mL of $ABTS^{\bullet+}$ solution (diluted in phosphate buffered saline, PBS; absorbance 0.700 ± 0.021). The reduction of absorbance at 734 nm was measured during 10 min, and the results were expressed as $\mu$mol Trolox equivalent (TE)/100 g DE.

*DPPH Radical Scavenging Activity.* The DPPH assay followed a method previously reported:[18] 100 $\mu$L of methanolic solution (5 mg $mL^{-1}$) were added to 3.5 mL of DPPH radical solution (0.06 mol $L^{-1}$). The decrease in absorbance at 516 nm was measured every minute during 30 min. The DPPH results were expressed as $\mu$mol Trolox equivalent (TE)/100 g DE.

**Statistical Analysis.** Analysis of variance (ANOVA) was used to evaluate the results obtained in L-AA, TPC, TFC, and antioxidant assays determinations (IBM SPSS Statistics 20, SPSS, Inc.).

## RESULTS AND DISCUSSION

In this study, we aimed to establish, for the first time, the phenolic profile from different morphological parts of *Myrica faya*. Prior to the phenolic characterization, the influence of different experimental variables on the extraction procedure (solvent type, concentration, and duration of extraction) was investigated to increase the extraction efficiency of phenolics.

The results from the extraction experiments are shown in Figure 1.

A significant difference ($p$ < 0.05) was found between extraction with pure methanol or pure acetone, with a higher extraction yield using pure methanol (Figure 1a). Our results contradict those of Saini et al., who reported that acetone was more efficient than methanol for the extraction of phenolics from *M. esculenta*.[16] On the basis of our data, methanol was chosen for further investigations, and results showed that an increase in the percentage of this solvent influenced positively the extraction efficiency (Figure 1b). Significant differences ($p$ < 0.05) were observed between the different concentrations of methanol, except for 90% and 80%. Moreover, the yields of phenolic content were equal ($p$ > 0.05) when using aqueous methanol (80%) and acetone as the extraction solvents. Taking this fact into account, pure methanol was used to evaluate the influence of extraction time, and the results indicated that increasing the extraction duration had a positive effect on the extraction efficiency ($p$ < 0.05) (Figure 1c). Thus, an extraction time of 60 min with 100% methanol was considered as optimum.

**HPLC-DAD-ESI/$MS^n$ Screening.** Figure 2 shows the chromatogram obtained during the analysis of the methanolic extracts from *Myrica faya* by HPLC-DAD-ESI/$MS^n$. The identification of compounds was carried out by comparison of their UV−vis spectra and mass spectrometric data obtained under negative electrospray ionization ($ESI^-$) conditions with the data available in scientific literature.

The method achieved a good separation, and no relevant variation was observed in the three determinations performed for each sample. In general, in the $MS^1$ spectrum the most

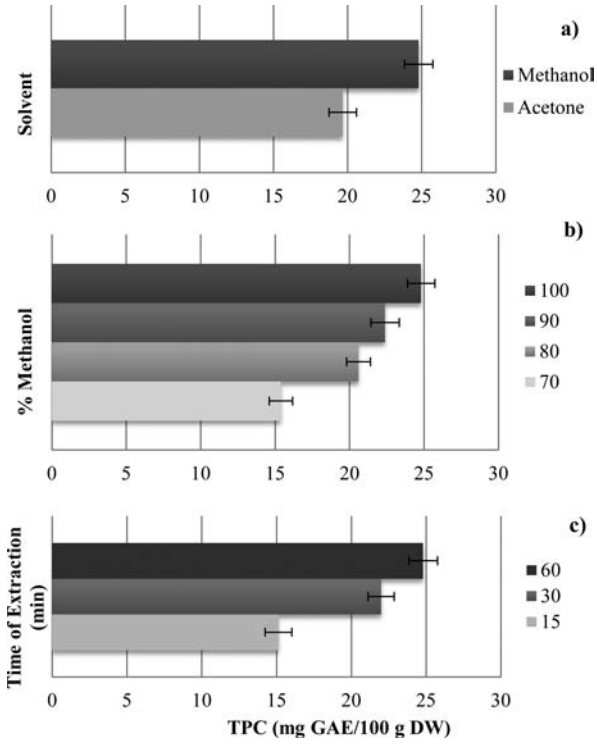

**Figure 1.** Extraction efficiency of different extraction conditions determined by TPC (mg/100 g DW) in *Myrica faya* leaves: (a) effect of solvent (methanol versus acetone); (b) effect of methanol concentration (v/v); (c) effect of extraction time. All extractions procedures were repeated three times ($n$ = 3).

intense peak corresponded to the deprotonated molecular ion $[M - H]^-$. The mass spectra of the conjugated form of the phenolic compounds showed the aglycone ion as a result of the loss of moieties like hexosyl, deoxyhexosyl, pentosyl, rutinosyl, caffeoyl, and glucuronyl (−162, −146, −132, −308, −162, and −176 Da, respectively). The identification of the compounds detected in leaf and berries extracts is presented in Tables 1 and 2, respectively, and their chemical structures are shown in Figure 3.

Compounds were numbered by their elution order, since most of them were not found in both samples (leaves and berries). More than 50 different compounds were detected and classified into two main groups: flavonoids (flavan-3-ols, flavones, isoflavones, and flavonols) and phenolic acids (hydroxybenzoic and hydroxycinnamic acids). Quinic acid and derivatives were also relevant in leaves. Additionally, mass spectra data from the positive ionization mode ($ESI^+$) was used for confirmation of the anthocyanidin compounds, namely cyanidin-3-glucoside and delphinidin-*O*-hexoside, in berries. A characteristic esterification with gallic acid was found in the majority of the compounds, representing the dominant group bound to polyphenols of leaves and berries.

The phenolic profiles obtained by our HPLC-UV/DAD-$MS^n$ analysis were similar to previous reports on *Myrica*.[6−8,10−13,15] In addition, we were still able to identify for the first time in this genus 26 compounds, namely flavones, ellagitannins, lignans, terpenoids, among others. The analysis showed that leaves of *M. faya* were significantly more complex when compared to berries, most of the identified compounds exclusively being detected in the leaf extracts. Nevertheless, some compounds were only detected in berries (**2**, **4**, **6**, **9**, **13**, **16**, **19**, **24**, and **26**).

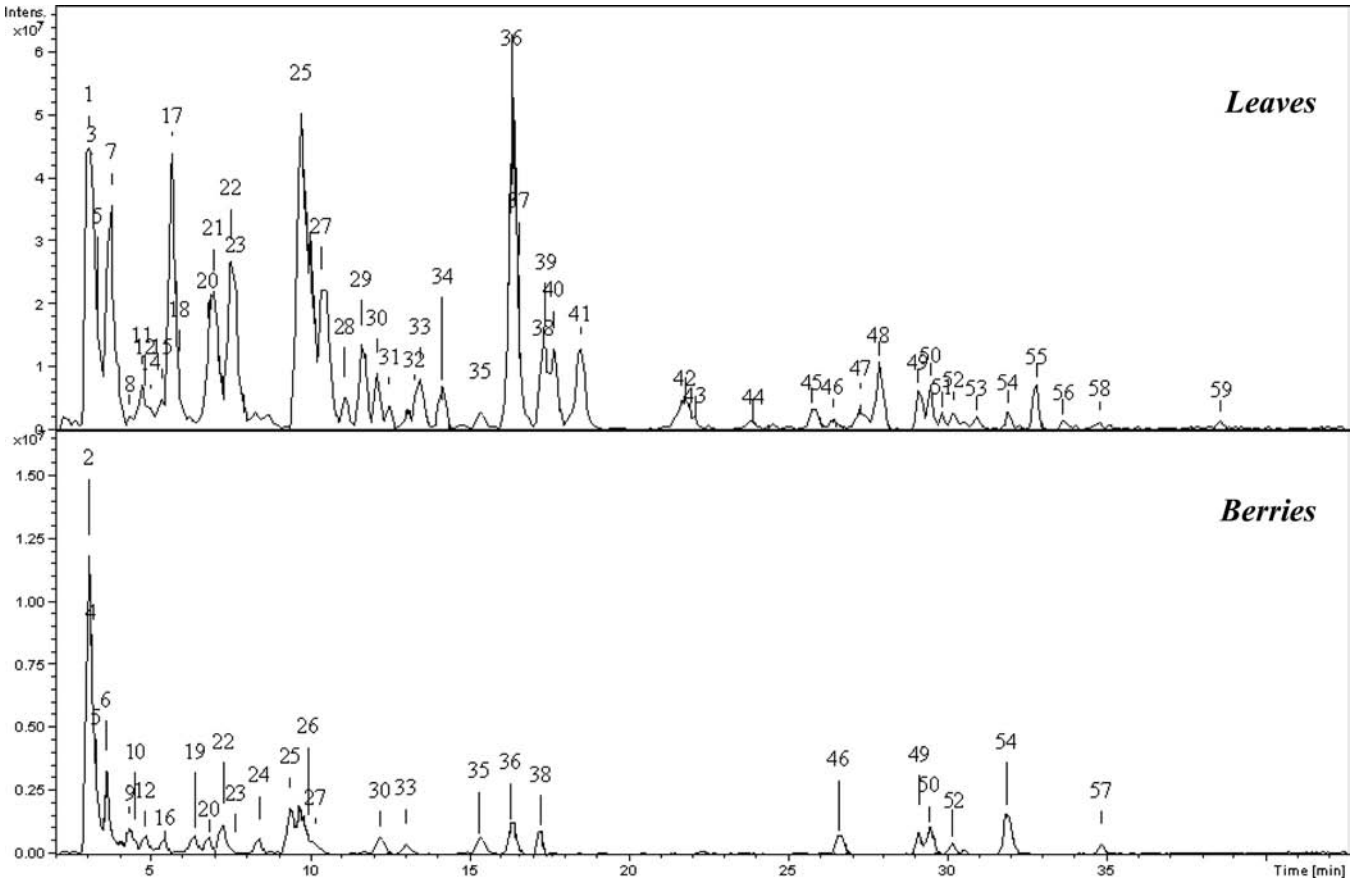

**Figure 2.** HPLC-DAD-ESI/MS$^n$ base peak chromatograms (BPC) of the methanolic extracts from *Myrica faya*: leaves and berries.

*Negative Mode Ionization.* For the analysis of the phenolic composition of *M. faya*, both the positive and negative ionization modes were used. However, the majority of the information was obtained using the negative mode, and the positive mode was mainly used for confirmation purposes.

*Identification of Phenolic Acids.* Compound **4** presented $[M - H]^-$ ion at $m/z$ 341. It suffered the neutral loss of 162 Da (hexoside), producing a fragment ion at $m/z$ 179. This ion suffered further fragmentation, producing fragment ions at $m/z$ 161 and 135, which are typical from caffeic acid, so the compound was identified as caffeic acid *O*-hexoside.[19]

Compound **29** exhibited a $[M - H]^-$ ion at $m/z$ 415 and was characterized as a caffeic acid derivative. Its MS$^n$ spectrum was identical to that described previously in *H. obconicum*[19] by our group. To our best knowledge, the presence of caffeic acid derivatives has not been reported, so far, in *Myrica*.

Compound **17** displayed a $[M - H]^-$ ion at $m/z$ 421, which gave origin to an ion at $m/z$ 385 (by loss of 36 Da). Further fragmentation led to sinapic acid aglycone at $m/z$ 223 (by loss of 162 Da),[10] being characterized as sinapic acid-*O*-hexoside derivative.

Compounds **37** and **39**, showing $[M - H]^-$ ions at $m/z$ 511 and 481, were identified, for the first time in *Myrica*, as derivatives of sinapic acid-*O*-hexoside and ferulic acid-*O*-hexoside, respectively. Both showed identical neutral losses at $MS^2$ (126 + 162 Da), but the presence of sinapic and ferulic acids led to different characterizations. While the 162 Da loss are attributed to hexoside units attached to the aglycones, the 126 Da loss could not be identified.

Compound **6** with $[M - H]^-$ at $m/z$ 331 was plausibly identified as galloyl-*O*-hexoside, according to previous studies in pomegranate.[20,21]

Compound **8** exhibited $[M - H]^-$ ion at $m/z$ 467 and fragmented into ion at $m/z$ 169 [gallic acid $- H]^-$ due to loss of 298 Da. In the absence of more specific data, **8** was assigned as a gallic acid derivative.

Compound **18**, with $[M - H]^-$ at $m/z$ 285, was identified as protocatechuic acid-*O*-pentoside based on bibliographic data.[22] The presence of this hydroxybenzoic acid in *Myrica* species is consistent with previous reports.[13]

*Flavonoids.* In this study, flavonoids (flavones, flavonols, and flavan-3-ols) were detected in their glycosylated form and/or esterified with acyl groups and were the most abundant components identified.

Compound **11** had an $[M - H]^-$ ion at $m/z$ 761 and displayed typical product ions for galloyl-di(epi)gallocatechin at $m/z$ 609 $[M - 152 - H]^-$, 591 $[M - 170 - H]^-$, and 423 $[M - 170 - 168 - H]^-$, which corresponded to losses of galloyl moieties (170 and 152 Da) and retro-Diels–Alder reaction product ion (168 Da), respectively. This fragmentation behavior is congruent with the previously published[11] for this compound in *Myrica rubra*.

Compound **12** was assigned as gallo(epi)catechin with characteristic $[M - H]^-$ ion at $m/z$ 305, based on previous characterization on pomegranate.[21]

Compound **13** displayed $[M - H]^-$ ion at $m/z$ 483 and gave origin to a product ion at $m/z$ 447 (by loss of 36 Da). Sequential loss of a hexoside moiety produced luteolin aglycone

[a]Wavelengths not provided when the UV spectrum was not properly observed due to low intensity. [b]Compound identified for the first time in *Myrica* genus.

($m/z$ 285). Thus, **13** was identified as a luteolin-*O*-hexoside derivative, reported for the first time in *Myrica*.

(epi)Catechin monomer and (epi)catechin-*O*-gallate (compounds **19** and **26**) displayed $[M - H]^-$ ions at $m/z$ 289 and 441, respectively, and were assigned according to previous characterizations[23] in grape pomace. Catechin has been previously detected in *M. esculenta* by an HPLC-PDA method.[15]

Compound **20** exhibited a $[M - H]^-$ ion at $m/z$ 457 and was assigned as gallocatechin-*O*-gallate, on the basis of previous studies in *M. rubra*.[11] Although compound **20** was detected before in leaves of bayberry, we report here for the first time its presence in fruits of this genus. With $[M - H]^-$ ion at $m/z$ 915 and $MS^2$ product ion at $m/z$ 457, compound **21** was plausibly identified as a dimer of gallo(epi)catechin-*O*-gallate.

Conjugates of myricetin (compounds **22**, **23**, **25**, **36**, and **38**), quercetin (compounds **33**, **42**, and **44**), and kaempferol (compounds **28**, **30**, **32**, and **40**) were characterized according to the sugar moieties attached to their aglycones (at $m/z$ 317, 301, and 285, respectively). The characterizations of these compounds in *Myrica faya* were supported by previous reports in *M. rubra*[6−8,11,13] and pomegranate.[20] Myricetin derivatives were reported as the major flavonoids in extracts of *M. rubra*'s leaves and berries. Besides kaempferol-*O*-hexoside (**30**), all

[a]Wavelengths not provided when the UV spectrum was not properly observed due to low intensity. [b]Compound identified for the first time in *Myrica* genus.

other kaempferol conjugates have never been characterized in *Myrica* species.

Compound **27**, with $[M - H]^-$ at $m/z$ 615, was plausibly identified as galloylquercetin-*O*-hexoside after sequential loss of 152 and 162 Da.[24] This compound has been previously characterized in tropical fruits, but not in *Myrica*.

Compound **51** exhibited $[M - H]^-$ at $m/z$ 583, and its $MS^2$ fragmentation revealed kaempferol aglycone at $m/z$ 285 (by loss of 298 Da). However, complete identification of **51** was not achieved, being characterized as a kaempferol derivative.

Compound **53** displayed $[M - H]^-$ at $m/z$ 677 and $MS^2$ base peak at $m/z$ 285, due to the loss of 392 Da. Product ions at $m/z$ 593 and 575 corroborated kaempferol-*O*-rutinoside and dehydrated kaempferol-*O*-rutinoside, with **53** being identified as a kaempferol-*O*-rutinoside derivative.

Compound **43** exhibited a $[M - H]^-$ ion at $m/z$ 565 and a direct loss of 208 Da (46 + 162 Da) that suggested a formate adduct plus hexoside moiety. Further fragmentation showed identical behavior as dichtomitin, an isoflavone, with product ions at $m/z$ 342 $[M - H - CH_3]^-$, 327 $[M - H - CH_3 \times 2]^-$, and 299 $[M - H - CH_3 \times 2 - CO]^-$.[25] Thus, **43** was plausibly classified as dichtomitin-*O*-hexoside, for the first time in *Myrica*.

Compounds **46** and **52** exhibited $[M - H]^-$ ions at $m/z$ 491 and 535 and showed neutral losses of 162 and 208 Da, respectively. The sequential fragmentation allowed for the identification of two losses of 15 Da each in both compounds, due to two methoxyl groups. Their fragmentation behaviors were consistent with those described before in herbs[18] for tricin-*O*-hexoside (dihydroxy-dimethoxy-*O*-hexoside flavones) (**46**) and 5,7-dihydroxy-6,8-dimethoxy-7-*O*-glucuronide flavone (**52**).[26] With longer retention times, compounds **47** ($t_R$ = 27.3 min) and **49** ($t_R$ = 29.1 min) exhibited similar fragmentation pattern as **46**, being also assigned as tricin-*O*-hexoside. On the basis of only $MS^n$ data, the stereochemical structures of the sugar moieties could not be elucidated.

Compound **48** exhibited $[M - H]^-$ ion at $m/z$ 555 and product ion at $m/z$ 269, due to loss of 286 Da. Further fragmentation produced characteristic ions of baicalein: at $m/z$ 251 $[M - H_2O - H]^-$, 241 $[M - CO - H]^-$, and 223 $[M - H_2O - CO - H]$, according to Han et al.[27] Thus, **48** was

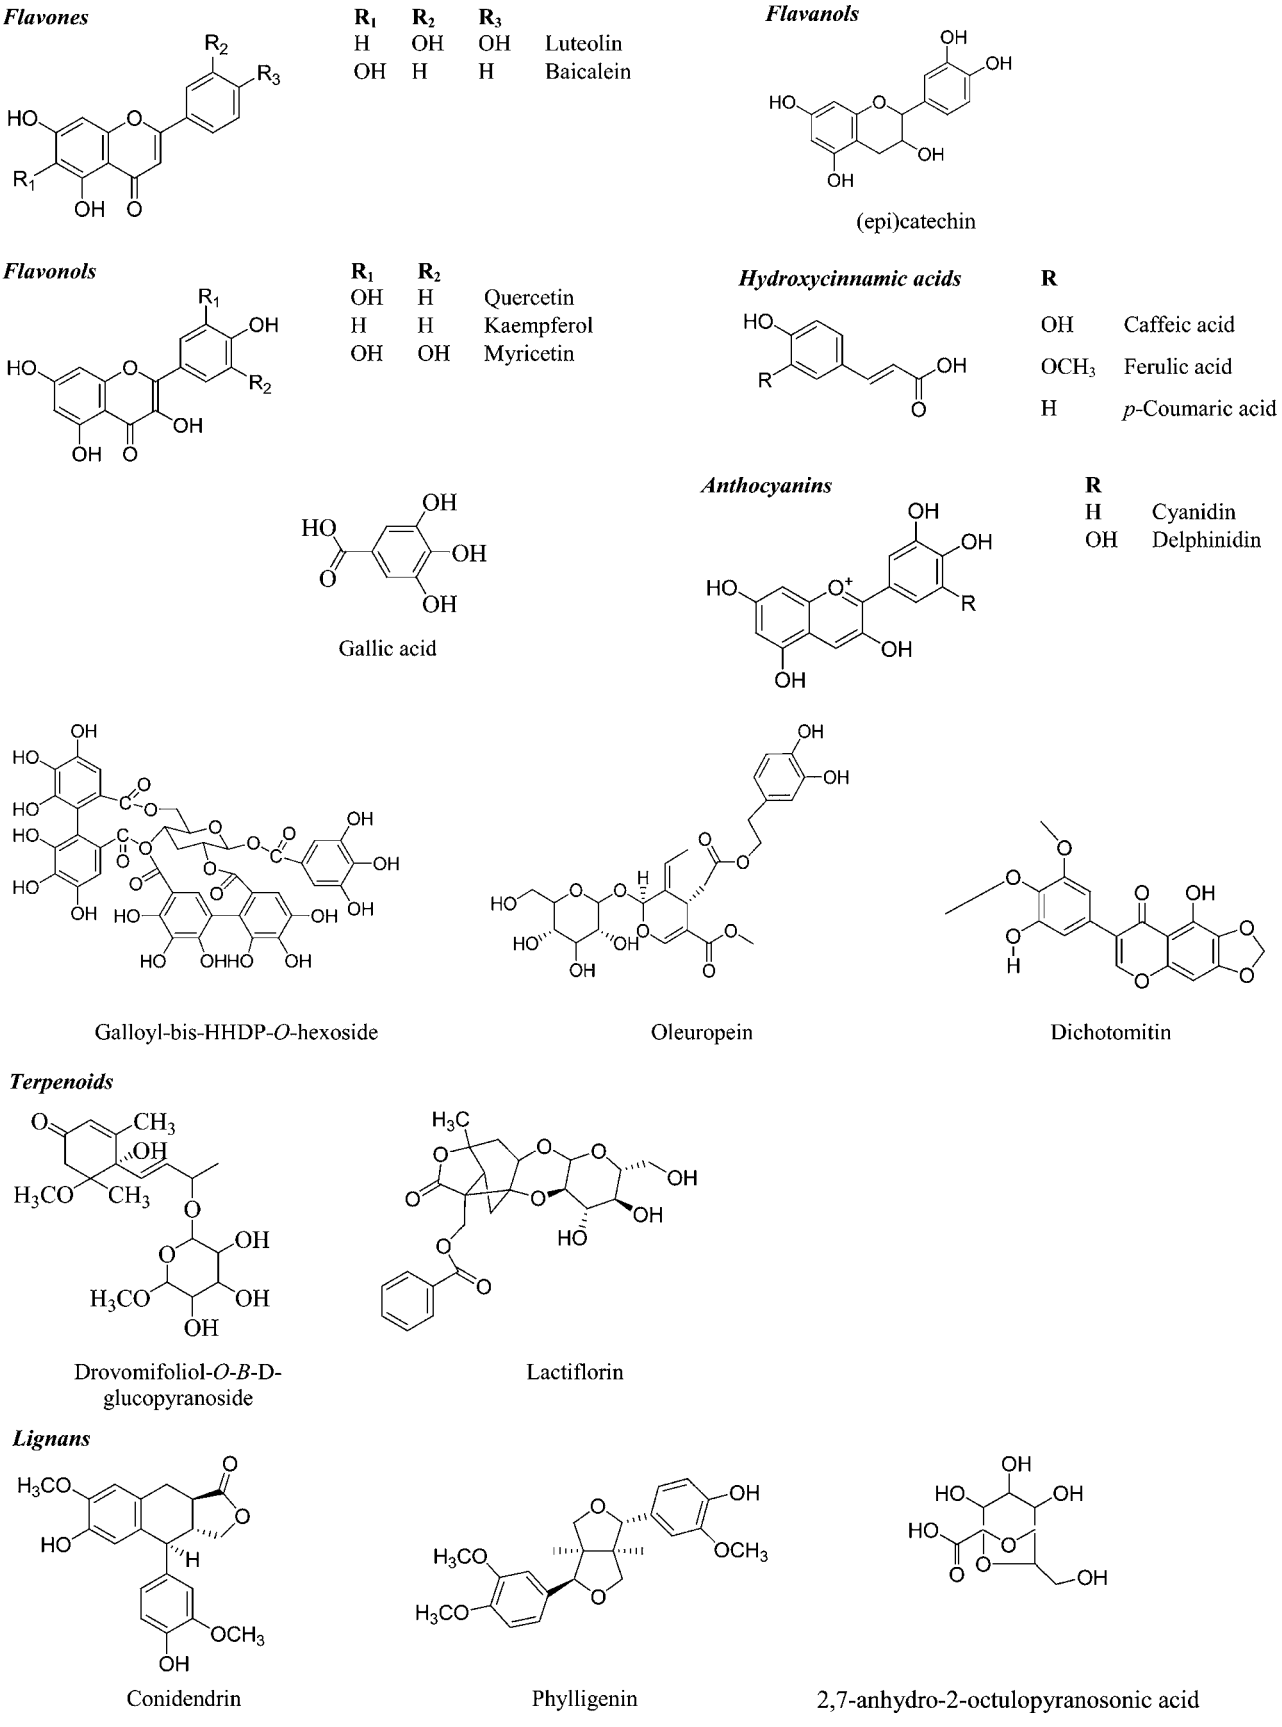

**Figure 3.** Chemical structures of the main phytochemicals detected in the methanolic extracts from *Myrica faya* (leaves and berries).

identified as a baicalein derivative, detected for the first time in *Myrica*.

Compound **59** displayed $[M - H]^-$ ion at $m/z$ 515, and produced kaempferol aglycone at $m/z$ 284 (by loss of 231 Da).

dx.doi.org/10.1021/jf503540s | J. Agric. Food Chem. 2014, 62, 9722−9735

In the absence of more specific data, **59** was characterized as a kaempferol derivative.

*Lignans.* Compounds **31** and **50** displayed $[M - H]^-$ ions at $m/z$ 579 and 563. In $MS^2$ both compounds showed a loss of 208 Da (possibly formic acid plus hexoside moieties). Further $MS^n$ data were in accordance with those previously described in pomegranate for pylligenin and conidendrin.[28] Thus, **31** and **50** were characterized as phylligenin-*O*-hexoside and conidendrin-*O*-hexoside, respectively. To our best knowledge, we report here for the first time the presence of lignans in *Myrica*.

*Other Compounds.* Galloyl-bis-hexahydroxydiphenoyl-(HHDP)-*O*-hexoside (compound **14**) was plausibly identified in leaves according to previous findings.[20] It showed $[M - H]^-$ ion at $m/z$ 935 and main fragment at $m/z$ 633 (HHDP-galloylhexoside) along with other product ions at $m/z$ 615 (dehydrated derivative), 481 (HHDP-hexoside), and 299 (ellagic acid). This finding marks the first report of an ellagitannin in *Myrica* species.

Additionally, some other nonphenolic compounds were detected in this analysis: organic acids, monoterpenes, phenylethanoids, and fatty acids.

Quinic acid showed $[M - H]^-$ at $m/z$ 191 (compound **5**) and was plausibly characterized according to literature data.[19] Quinic acid dimer (compound **7**) with $[M - H]^-$ at $m/z$ 383 showed a direct loss of 191 Da, with further fragmentation behavior identical to compound **5**.

Compound **3**, with $[M - H]^-$ ion at $m/z$ 533, exhibited a fragment ion at $m/z$ 191, which displayed the typical fragmentation pattern of quinic acid. Without further information, it was identified as a quinic acid derivative.

Benzyl alcohol hexose pentose (compound **15**) displayed $[M + HCOO]^-$ ion at $m/z$ 447, and sequential losses of 46 (formate) and 132 (pentose) Da were observed. This fragmentation pattern was similar to that previously described in *Melicoccus bijugatus* Jacq. fruits.[29]

Compound **16** exhibited $[M + HCOO]^-$ ion at $m/z$ 431 and suffered the loss of 46 Da (formate) to produce the ion at $m/z$ 385, which was identified as a roseoside (vomifoliolglucoside). It produced a fragment ion at $m/z$ 223 by loss of a sugar moiety (162 Da), and followed the exact behavior reported by Liet al. to what they called drovomifoliol-*O*-*B*-D-glucopyranoside (a terpenoid).[30] Roseoside has been previously identified in *Myrica*'s barks and leaves, but not in fruits.[14]

Another monoterpene was characterized (compound **45**), with ions at $m/z$ 507 $[M + HCOO]^-$, 461 $[M - H]^-$, 443 $[M - H - H_2O]^-$, and 293 $[M - H - C_7H_6O_2]^-$. It followed the exact same pattern described for lactiflorin,[31] being documented here for the first time in this genus.

Compound **24** displayed an $[M - H]^-$ ion at $m/z$ 597, and its sequential fragmentation led to typical glucaric acid ions (at $m/z$ 209, 191, 147).[32] Thus, with no other information available, **24** was identified as a glucaric acid derivative, reported here for the first time in *Myrica*.

The $MS^n$ spectrum of compound **34** showed an $[M - H]^-$ ion at $m/z$ 539 which produced fragment ions at $m/z$ 377 $[M - 162 - H]^-$ and 307 $[M - 162 - C_4H_6O - H]^-$. Sequential fragmentation was consistent with that reported for oleuropein.[33] This compound is one of the major phenolics (phenylethanoid) present in olive leaves and pulp and to our best knowledge have not been reported, so far, in *Myrica.*

Compound **35** exhibited $[M - H]^-$ at $m/z$ 633 and during $MS^2$ fragmentation lost 163 Da, which could be attributed to a coumaric acid. Further fragmentation gave product ions at $m/z$ 347 and 323, which corroborated the presence of benzoyl and coumaroyl groups (122 and 146 Da, respectively). This behavior was similar to that reported for benzoyl-*p*-coumaryl-2,7-anhydro-3-deoxy-2-octulopyranosonic acid,[34,35] with **35** being identified as this compound. With an extra neutral loss of 146 Da, compound **54** displayed $[M - H]^-$ ion at $m/z$ 779 and was characterized as benzoyl-*p*-tricoumaryl-2,7-anhydro-3-deoxy-2-octulopyranosonic acid. The presence of another coumaryl group instead of a rhamnose unit attached to the molecule was consistent with the longer retention time ($t_R$ = 31.9 min). To our best knowledge, octulosonic acid derivatives were reported here, for the first time, in *Myrica*.

Compound **57** showed $[M - H]^-$ ion at $m/z$ 327. The neutral loss of 98 Da in $MS^2$ corresponded to the loss of an end-group HO—CH═CH$(CH_2)_3CH_3$ from an oxylipin molecule.[36] Compound **57** was thus identified as an oxo-dihydroxyoctadecenoic acid (oxo-DHODE). This compound, together with trihydroxyoctacedenoic acid (THODE), has been found by our group in the leaves of other species from Madeira endemic flora (unpublished results).

Other peaks (compounds **1**, **41**, **55**, **56**, and **58**) were detected, but their UV and $MS^n$ data did not provide any valuable information about their chemical nature. Thus, their structures could not be elucidated.

*Positive Mode Ionization.* *Faya* berries are red or dark in color, attributed mainly to anthocyanins, which are more easily characterized with electrospray ionization operating in the positive mode ($ESI^+$) in combination to the characteristic UV-DAD absorptions.[20,21] The $ESI^+$ analysis was only relevant for the berries extracts.

Compound **2** gave an $[M + H]^+$ ion at $m/z$ 449, and the main $MS^2$ fragment ion was observed at $m/z$ 287, corresponding to the neutral loss of 162 Da. Further fragmentation of the ion at $m/z$ 287 suggested that the aglycone was cyanidin based on literature data.[13] Thus, **2** was characterized as cyanidin-3-glucoside, which has been reported as the dominant anthocyanin (95% of total anthocyanins) present in *Myrica rubra* fruits.

Compound **9** exhibited $[M - H]^-$ ion at $m/z$ 465, forming a fragment ion at $m/z$ 303 (by the loss of 162 Da). $MS^n$ fragment ions at $m/z$ 257 and 229 were consistent with those reported for delphinidin.[37] Therefore, **9** was characterized for the first time in *Myrica* as delphinidin-*O*-hexoside.

**Quantification of Phenolic Compounds.** In the present study, 21 polyphenols were quantified by HPLC-DAD using the corresponding standards for calibration for each group, and the obtained results are shown in Table 3.

The phenolic composition of leaves and berries varied quantitatively. The results indicated that flavonols, flavanols, and phenolic acids were the most abundant compounds in the leaves. Myricetin-*O*-deoxyhexoside presented the highest concentration in leaves, which is in agreement with bibliographic data on *M. rubra*.[11] Leaves were also rich in myricetin-*O*-(*O*-galloyl)deoxyhexoside, gallo(epi)catechin-*O*-gallate dimer, and galloyl-bis-HHDP-*O*-hexoside (casuarin). TIPC of the leaves was comparable to those reported previously in *M. rubra* (1133−2255 mg GAE/100 g of dried leaves).

For berries, anthocyanins, flavonols, and flavones represented the dominant class of polyphenols. C3G was the major compound, followed by myricetin-*O*-hexoside and luteolin-*O*-hexoside derivative. Previous work[7,8,13] on juice and pomace from *M. rubra* also reported C3G as one of the main polyphenols in berries. Flavonoids (in particular flavonols)

**Table 3. Contents of Total and Individual Phenolic Compounds (mg/100 g DW) in Leaves and Berries from *Myrica faya*[a]**

| phenolic compounds | leaves | berries |
|---|---|---|
| Phenolic Acids | | |
| caffeic acid-*O*-hexoside | | 45.73 ± 0.97 |

| cyanidin-*O*-hexoside | | 368.57 ± 5.42 |
| delphinidin-*O*-hexoside | | 16.52 ± 0.36 |
| total | | 385.09 ± 6.61 |
| TIPC | 1540.38 ± 87.76 | 820.11 ± 46.71 |

[a]nd = not detected.

were also present in higher amounts than phenolic acids. (epi)Catechin, myricetin-*O*-(*O*-galloyl)hexoside, and kaempferol-*O*-rhamnoside were not quantified in berries due to their low concentration.

The TIPC of leaves and berries was lower than those determined by the Folin−Ciocalteu method (Table 4). This difference is attributed to the fact that the Folin−Ciocalteu method tends to overestimate the contents of total phenolics, since it gives positive answer to other substances, and also because not all the identified compounds could be quantified.

**Analysis of L-AA Content.** The data regarding L-AA content, pH, and °Brix of *faya* berries are presented in Table 4.

The amounts of L-AA present in *M. faya* berries had not been determined before and were within the range of those reported for bayberries (Table 4). No data were found about vitamin C content in *M. esculenta*. Apart from *Myrica* species, the L-AA contents obtained here were higher than others reported previously in other berry fruits like blackberry, blueberry, chokeberry, raspberry, and redcurrant, but lower than in blackcurrant and strawberry.[17,38] The sugar content, evaluated through the °Brix, was higher than in *M. rubra* and within the range reported for most commercial berries (usually between 10 and 18), and the acidity was low.

**TPC, TFC, and Antioxidant Capacity Tests.** The results obtained for total phenolic and flavonoid contents of *Myrica faya* leaves and berries are presented in Table 3. L-AA is a powerful antioxidant, and its presence in plant extracts produces inaccurate estimations of TPC values because L-AA reduces FCR. One approach to improve the TPC values is the calculation of a corrected TPC value based on the L-AA reducing activity present in the extract.[39,40] The L-AA standard was tested for TPC using the same procedure previously described and it was found to present reducing activity of 0.683 mg GAE/g L-AA. So, for each sample, L-AA contribution was calculated by multiplying the L-AA content by 0.683. The corrected TPC of the samples, calculated by subtracting L-AA contribution, is also shown in Table 4.

Our tests revealed that leaves had a much higher content of total phenolics than berries, which is in agreement with previous literature reports for other subspecies of *Myrica*. TPC values of *Myrica faya* (leaves and berries) are comparable to those reported for other *Myrica* species (with *faya* showing a slightly higher content). Compared with other commonly consumed berries, *faya* presented higher TPC values than blackberry, blueberry, raspberry, and strawberry.[17,38] For TFC assay the same pattern was observed; however, no data regarding flavonoid content of leaves was found in the literature for comparison. Rawat et al. reported TFC values of *M. esculenta* (131−238 mg quercetin equivalent/100 g of dried weight), but those results were expressed in different units, which makes a comparison difficult.[15]

**Table 4. Overview of L-AA, pH, TSS, TPC, TFC, and Antioxidant Capacity Assays (ABTS, DPPH) Determinations in *Myrica faya* (Leaves and Berries)[a]**

| | faya (*Myrica faya*) | | bayberry (*Myrica rubra*) | | box myrtle (*Myrica esculenta*) | |
|---|---|---|---|---|---|---|
| parameters | leaves | berries | leaves | berries | leaves | berries |
| pH | | 4.02 | | | | |
| TSS (°Brix) | | 14.87 | | 11.6−13.4[41] | | |
| L-AA content (mg/100 g FW) | | 48.42 ± 1.93 | | 11−114[41] | 4.16 | |
| TPC (g GAE/100 g DE) | 24.80 ± 0.28 | 5.26 ± 0.13 | 8.14−19.63[11] | 0.07−4.74[6−8,12,13] | 15[15] | 0.18−2.86[15,16] |
| TPC (g GAE/100 g DE)[b] | | 5.23 ± 0.13 | | | | |
| TFC (g RUE/100 g DE) | 12.72 ± 0.16 | 4.21 ± 0.12 | | 0.01−0.12[6,12] | | |
| ABTS (g TE/100 g DE) | 24.10 ± 0.13 | 12.51 ± 0.15 | | 0.33−10.06[6,8,12] | 38.45[15] | |
| DPPH (g TE/100 g DE) | 20.36 ± 0.12 | 9.24 ± 0.11 | | 0.74−9.10[12,13] | | |

[a]All measurements were performed in triplicate (mean ± SD). [b]corrected TPC value (subtracted L-AA contribution).

In this study, both ABTS and DPPH were used to evaluate the antioxidant capacity of *Myrica faya*, and the results are shown in Table 4. *Myrica faya* presented a considerable free-radical scavenging capacity, with leaves showing a stronger reducing power than fruits, which corroborated the measured phenolic and flavonoid contents.

The values obtained for *M. faya* in the ABTS assay were slightly higher than the range of values reported for *M. rubra*, but lower than those from *M. esculenta*. *Faya* berries were much more active than, for instance, strawberries (1455.50 μmol TE) evaluated in the same experimental conditions (data to be published elsewhere). According to Sun et al.,[9] many structure−activity relationship studies have confirmed that the strong antioxidant capacities of *Myrica* species are attributed to the high content of galloyl esters that enhance such properties and confer high radical scavenging activities.[9]

In conclusion, over 50 compounds were characterized, for the first time, in different morphological parts of *Myrica faya* by means of an HPLC-DAD-ESI/MS$^n$ method. *M. faya* shared some characteristics in phenolic profile with other *Myrica* species. Nevertheless, we reported for the first time the presence of some flavonoids, ellagitannins, lignans, phenylethanoids, and other organic compounds in this genus. The levels of L-AA and C3G observed in the berries were high, so they can constitute a good source of these nutrients when compared to other fruits. This study provides scientific evidence that *M. faya* is a rich source of bioactive compounds with great potential as natural antioxidants. *Faya* berries are underutilized, mainly due to the lack of scientific studies about their potential health benefits, and consumption and marketing deserve promotion, representing an opportunity for growers and collectors to reach niche markets to increase their revenues.

stimulates glucose-dependent insulin secretion from pancreatic beta-cells and suppresses glucagon release from alpha-cells, thereby improving glucose control.[10] Recent observations suggested the direct protective role of DPP-4 inhibitor beyond its glucose-lowering potential. DPP-4 inhibition improved albumin excretion and associated renal parameters in streptozotocin (STZ)-induced diabetic animals, while the effects were independent of blood glucose or systolic blood pressure.[11,12] In the clinical trial, DPP-4 inhibitors lower the albuminuria in type 2 diabetic patients, independent of the level of HbA1C.[13] Among the approved DPP-4 inhibitors, the excretion of linagliptin in the urine is particularly low, which may be a beneficial property in diabetic patients suffering from renal impairment.

*Hibiscus sabdariffa*, whose calyces are used as a daily drink in North Africa and Middle and South Asia, was shown to be bioeffective in many ways.[14,15] At least 18 phenolic compounds were found in the polyphenol extracts of *Hibiscus sabdariffa* L. calyx (HPE).[16] Our previous publications have shown the antidiabetic potential of HPE.[16,17] Using the type 2 diabetic rats exhibiting insulin resistance,[18] we demonstrated that HPE has a benefit in diabetic nephropathy by inhibiting albuminuria and hyperfiltration, and reversing the renal fibrosis and associated biomarkers.[19] Recently, we reported that HPE attenuates renal EMT as inhibiting high glucose-induced vimentin and loss of cell junction. HPE recovered the basement membrane surrounding tubular region in diabetic kidneys.[20]

In the present study, using the in vitro and in vivo model, we aim to investigate if insulin resistance signal and DPP-4 could be involved in renal EMT, and further explore the putative role of HPE on this mechanism for preventing diabetic nephropathy.

## MATERIALS AND METHODS

**Preparation of HPE.** *Hibiscus sabdariffa* L. calyx was purchased from Taitung Area Farmer's association. HPE was prepared as previously reported, and its chemical composition was analyzed with liquid chromatography−tandem mass spectrometry. Phenolic compounds including gallic acid, galloyl ester, protocatechuic acid, caffeic acid, caffeoyl quinic acid, chlorogenic acid, and quercetin derivative were found in HPE (shown in the Supporting Information).[16]

**Cell Culture.** HK-2 cells purchased from Food Industry Research and Development Institute were cultured in keratinocyte serum free medium (Gibco BRL) with 5 ng/mL epidermal growth factor and 50 μg/mL bovine pituitary extract. The cells were grown in a humidified incubator at 37 °C in an atmosphere of 5% $CO_2$ and 95% air. HK-2 cells were inoculated into a 6 cm dish at a density of $5 \times 10^5$ cells for 24 h and then treated with 30 mM glucose with or without various concentrations (0.05−5 mg/mL) of HPE for 48 h.

**Cytotoxicity Assay.** HK-2 cells were seeded at a density of $1 \times 10^6$ cells/mL in a 24-well plate and incubated with linagliptin at various concentrations (1−100 μM) for 24 h. Thereafter, the medium was changed and cells were incubated with 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT, 0.5 mg/mL) for 4 h. The viable cell was directly proportional to the production of formazan. Following dissolution in isopropanol, the result was read at 563 nm with a spectrophotometer (Hitachi, U-3210).

**Western Blot Analysis.** Cells were harvested into lysis buffer containing 50 mM Tris-HCl (pH 6.8), 10% glycerol, 2% SDS, and 5% mercaptoethanol and then lysed by sonication. Cell lysate was centrifuged at 9300*g* for 20 min at 4 °C, and the supernatant was collected as the protein sample. After quantifying, equal amounts of protein samples (50 μg) were subjected to 10% SDS−polyacrylamide gel electrophoresis and transferred to nitrocellulosemembranes (Millipore, Bedford, MA). Membranes were blocked with 5% nonfat milk powder with 0.1% Tween-20 in TBS and then incubated with the primary antibody at 4 °C overnight against the following targets. IRS-1: Santa Cruz (1:1000). pIRS-1 (S307): Cell Signaling (1:500). DPP4: Abcam (1:1000). PI3K: Santa Cruz (1:1000). pPI3K (p85, Tyr 458): Cell Singaling (1:500). Antibodies of IRS-1 and PI3K were purchased from Santa Cruz (Santa Cruz, CA), and DPP4 was from Abcam (Cambridge, U.K.). Antibodies of pIRS-1 (S307) and pPI3K were from Cell Singaling, Danvers, MA. Afterward, membranes were washed three times with 0.1% Tween-20 in TBS and incubated with the secondary antibody (1:5000) conjugated to horseradish peroxidase (GE Healthcare, Little Chalfont, Buckinghamshire, U.K.). Band detection was thereafter revealed by enhanced chemiluminescence using ECL Western blotting detection reagents and exposed in FUJFILM Las-3000 (Tokyo, Japan). Protein quantitative was determined by densitometry using FUJFILM-Multi Gauge V2.2 software.

**Assay for DPP-4 Activity.** Cells were seeded on 96-well plate ($1 \times 10^6$/well). After treatment under various conditions, cells of each well were lysed with 100 μL of NP-40 lysis buffer (containing 10 mM HEPES (pH 7.5), 142.5 mM KCl, 5 mM $MgCl_2$, 1 mM EGTA, and 0.2% NP-40) and centrifuged at 9300*g* for 20 min at 4 °C. The supernatants were collected, and the protein concentrations were determined with the Bradford assay. DPP4 activity was measured by DPP4/CD26 Assay Kit for Biological Samples (Enzo Life Sciences). Briefly, H-Gly-Pro-pNA, a chromogenic substrate of DPP-4, is hydrolyzed into the dipeptide Gly-Pro and the product 4-nitroaniline, whose rate of appearance would be measured spectrophotometrically at 405 nm. The activity was normalized with protein concentration, then in proportion to the control. Linagliptin, a gift from Boehringer Ingelheim, was used as DPP4 inhibitor in the experiment.

**siRNA Transfection.** HK-2 cells were seeded at $1 \times 10^5$ cells in each 6 cm Petri dish and incubated for 24 h. Transfection of siRNA (IRS-1 of human) was performed by the Lipofectamine 2000 Reagent Protocol. The final concentration of siRNA (SR302452A: rGrGrArU-rArGrGrArCrArArArUrUrCrArGrUrArArArCrAGG) in transfection medium (keratinocyte serum-free medium without bovine pituitary extract and EGF) was 45 nM; incubation was carried out for 6 h. The transfection medium was subsequently replaced with normal cultured medium and incubated for another 12 h. After that, cells were treated with different conditions. Cell proteins were then extracted and prepared for Western blotting.

**Animal Experiment.** The animal experimental project was approved by the Animal Model Experimental Ethics Committee of Chung-Shan Medical University based on the European Community guidelines (IACUC approval No: 1007). A type 2 diabetic model was carried out according to our previous publication.[16,18] Briefly, male Sprague−Dawley rats (weight 250 ± 20 g) obtained from LuxBiotech Co., Taiwan, were divided into several groups ($n = 8$ for each group), including the control (normal diet), FAT + STZ (high fat diet and streptozotocin injection), FAT + STZ + low HPE (with 100 mg/kg HPE added), and FAT + STZ + high HPE (with 200 mg/kg HPE added). Seven weeks later, when the average body weight attained 425 ± 15 g, the FAT groups were injected with a dose of STZ 35 mg/kgbw. About 2 weeks later, when the hyperglycemic status was confirmed, rats were tube-fed with or without different doses of HPE. The metabolic features, histological findings, and biomolecule expression of this model have been shown in our previous reports.[16,19] Safety evaluation revealed that HPE did no harm to liver, kidney, or cardiovascular tissue. After rats were sacrificed, the kidney chops were added to radioimmunoprecipitation assay (RIPA) buffer and protein inhibitors and homogenized at 4 °C. The tissue homogenates were centrifuged at 9300*g* for 20 min at 4 °C, and the resulting supernatants (whole-tissue extracts) were used for Western blot analysis.

**Immunohistochemistry.** The kidneys were fixed in 4% paraformaldehyde, embedded in paraffin, sectioned into 4 μm, and processed for IHC examination. The primary antibody of pIRS-1 (S307) was from Novus, Littleton, CO. Immunostaining was completed using the UltraSensitive S-P kit (Maxim Co., streptavidin peroxidase method).

**Statistical Analysis.** The statistical software SPSS v.12.0 was used to analyze the data. One-way ANOVA was performed ($p < 0.05$), while Bonferroni's multiple comparison was used for post-test.

## RESULTS

**HPE Inhibits the High Glucose-Induced Expression of Vimentin and Phosphorylation of IRS-1 (S307).** Compared with the control, high glucose increased nearly 3-fold of the vimentin, while HPE inhibited the expression dose-dependently. HPE at 0.5 and 1 mg/mL reduced 45% and 55% of vimentin, respectively (Figure 1A). As well, the phosphorylation of IRS-1 (S307) was increased 2-fold by high glucose. Treatment of HPE inhibited the phosphorylation significantly (Figure 1B). These results implicate that there might be a correlation between EMT and the insulin resistance signals; both are attenuated by HPE. Treatment with HPE has been tested by cytotoxicity assay, and it is nontoxic for HK-2 cells.[20]

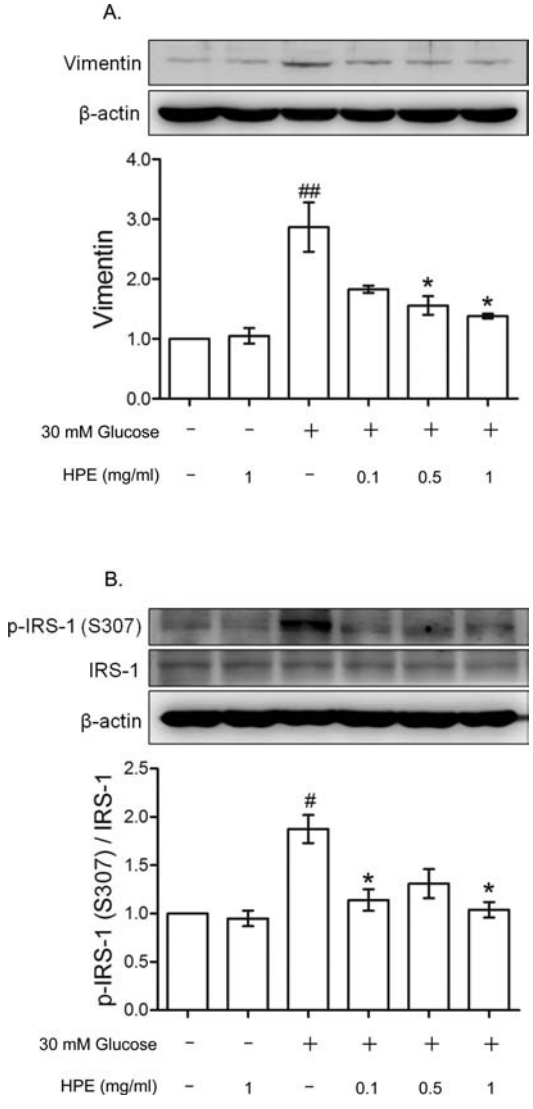

**Figure 1.** Effect of HPE on vimentin and IRS-1 (S307). HK-2 cells were incubated for 48 h under normal or high glucose (30 mM) conditions with or without different concentrations of HPE. Cell proteins were extracted and analyzed with Western blot: (A) vimentin; (B) IRS-1 (S307). Protein levels of vimentin and the ratio of IRS-1 (S307)/IRS-1 were calculated as fold compared with the control. Data are presented as means ± SD ($n = 3$) and analyzed with ANOVA. $^{\#}p < 0.05$, $^{\#\#}p < 0.01$ compared with the control. $^{*}p < 0.05$, compared with the high glucose-treated.

**HPE Inhibits DPP-4 Activity Induced by High Glucose.** Figure 2A showed that neither high glucose nor HPE affect the DPP-4 protein level. However, by measuring DPP-4 activity, the alteration was discovered significantly. High glucose stimulated the activation of DPP-4 about 2.6-fold. Although the dose 0.1 mg/mL could not suppress the activation, 0.5 and 1 mg/mL HPE showed a good inhibitory effect to decrease DPP-4 activity even below that in the control (Figure 2B). Hence DPP-4 could be involved in the high glucose and HPE-regulated signals.

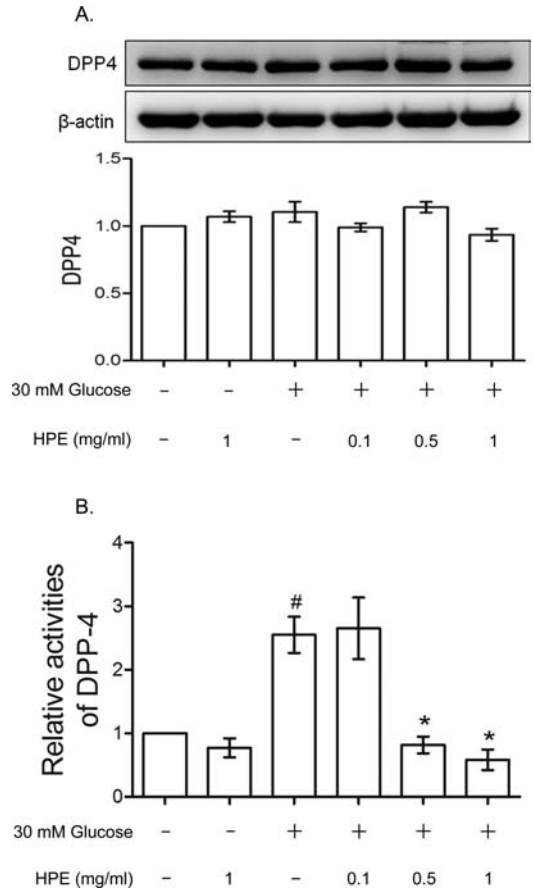

**Figure 2.** Effect of HPE on DPP-4. HK-2 cells were incubated for 48 h under normal or high glucose (30 mM) conditions with or without different concentrations of HPE. (A) DPP-4 proteins were extracted and analyzed with Western blot. (B) DPP-4 activity was analyzed. Protein levels and activity were calculated as fold compared with the control. Data are presented as means ± SD ($n = 3$) and analyzed with ANOVA. $^{\#}p < 0.05$, compared with the control. $^{*}p < 0.05$, compared with the high glucose-treated.

**Linagliptin Was Revealed To Be Nontoxic and Effectively Inhibited DPP-4.** Linagliptin was used as DPP-4 inhibitor to investigate the putative role of DPP-4. The test of cytotoxicity assay revealed that linagliptin is nontoxic under 2 $\mu$M (Figure 3A). In comparison with the control, 1 $\mu$M linagliptin reduced 80% of DPP-4 activity (Figure 3B). Hence it was the dose chosen in the following experiment.

**DPP-4 Mediates the Regulation of Vimentin, IRS-1 (S307), and PI3K.** Figure 4 shows that high glucose-induced vimentin and IRS-1 (S307) phosphorylation were significantly

dx.doi.org/10.1021/jf5024092 | J. Agric. Food Chem. 2014, 62, 9736−9743

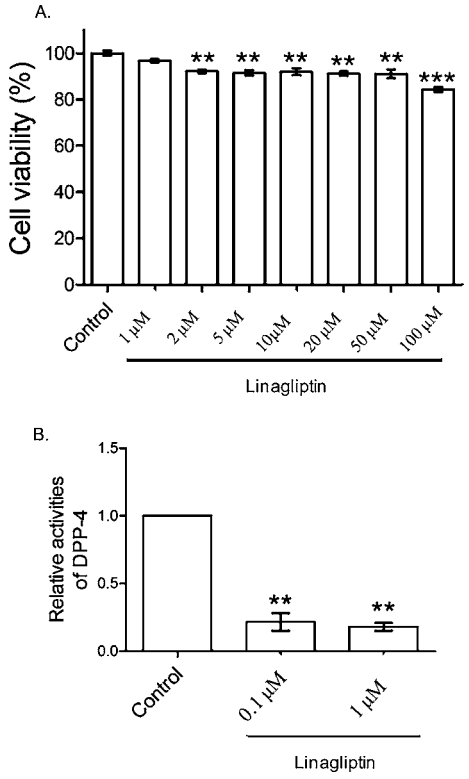

**Figure 3.** Cytotoxicity and DPP-4 inhibitory effect of linagliptin. (A) HK-2 cells were incubated for 48 h with or without different concentrations of linagliptin. Cell viability was calculated as percentage compared with the control group. (B) DPP-4 activity was analyzed. Data are presented as means ± SD ($n$ = 3) and analyzed with ANOVA. $^{**}p < 0.01$, $^{***}p < 0.001$, compared with the control.

reduced by 1 $\mu$M linagliptin or 1 mg/mL HPE. Noticeably, especially IRS-1 (S307) phosphorylation was inhibited by linagliptin or HPE even below that in the control. In contrast, PI3K, a normal response signal transmitting insulin sensitivity, was decreased about 20% by high glucose while recovered by either linagliptin or HPE. These results indicate that DPP-4 activation mediates the downstream resistance and EMT signals, while HPE has potential to improve the pathogenic markers (Figure 4).

**IRS-1 Plays the Pivotal Role To Mediate Downstream Expression of Vimentin.** For illustrating if vimentin elevation could be downstream of IRS-1, si-RNA of IRS-1 was transfected into the high glucose-incubated tubular cells. Figure 5A shows that the knockdown blocked most of the IRS-1 expression and reduced about 75% of the IRS-1 protein. High glucose-induced vimentin was significantly attenuated by the si-RNA (Figure 5B), indicating that IRS-1 and its phosphorylation could be an essential mediator of downstream EMT.

In addition to the resistance marker, we have further tested if glucose uptake could be involved (shown in the Supporting Information). The finding revealed that no matter whether glucose uptake is significantly altered or not, DPP-4/insulin resistance signal is the critical mediator of renal EMT.

**pIRS-1 (S307) and Vimentin Are Coordinately Increased in the Diabetic Kidneys.** Immunochemical staining demonstrated that pIRS-1 (S307) appeared rich in type 2 diabetic rats, especially surrounding the tubular region (Figure 6A–C). As previously indicated,[20] vacuole fusions and lipid accumulation were also found in the diabetic tubular

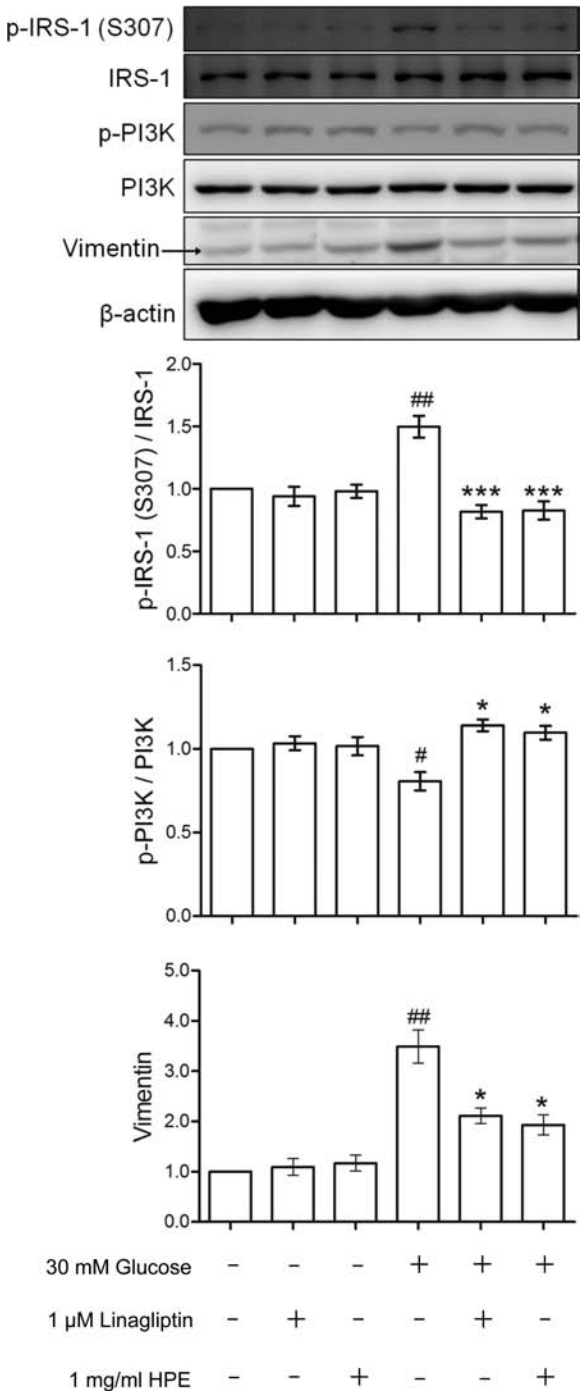

**Figure 4.** Effect of HPE on IRS-1 (S307), p-PI3K, and vimentin. HK-2 cells were incubated for 48 h under normal or high glucose (30 mM) conditions with or without different concentrations of HPE. Cell proteins were extracted and analyzed with Western blot. The ratios of IRS-1 (S307)/IRS-1 and p-PI3K/PI3K and the level of vimentin were calculated as fold compared with the control. Data are presented as means ± SD ($n$ = 3) and analyzed with ANOVA. $^{\#}p < 0.05$, $^{\#\#}p < 0.01$ compared with the control. $^{*}p < 0.05$, $^{***}p < 0.001$, compared with the high glucose-treated.

region, accompanied by the destroyed basement membrane. As well, the protein level of vimentin significantly increased 1.5-fold in diabetic kidneys (Figure 6D). Treatment of HPE, especially at the dose of 200 mg/kg, ameliorated the resistance

dx.doi.org/10.1021/jf5024092 | J. Agric. Food Chem. 2014, 62, 9736–9743

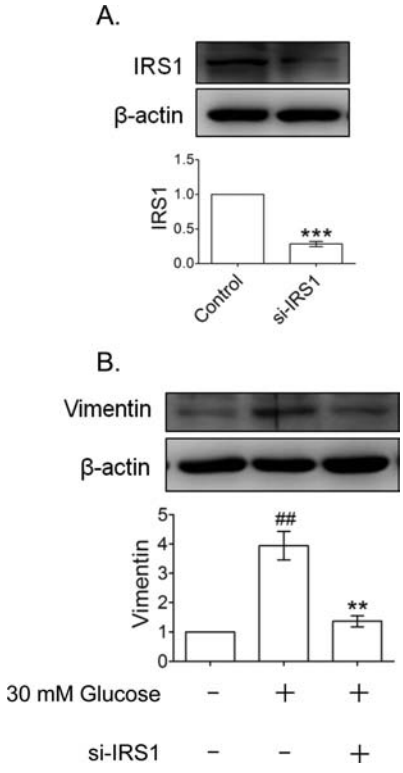

**Figure 5.** Signal cascades of IRS-1 and vimentin. HK-2 cells were transfected with siRNA and then incubated under different conditions. Cell proteins were extracted and analyzed with Western blot: (A) IRS-1; (B) vimentin. Protein levels were calculated as fold compared with the control. Data are presented as means ± SD ($n$ = 3) and analyzed with ANOVA. $^{\#\#}p < 0.01$, compared with the control. $^{**}p < 0.01$, $^{***}p < 0.001$, compared with the high glucose-treated.

signal, and it reduced the EMT marker even below that in the control, thereby improving the histological changes.

## DISCUSSION

We demonstrated the concomitant expression of the pivotal markers of EMT and insulin resistance in renal tubular cells. Treatment of HPE or linagliptin inhibited the high glucose-induced activation of DPP-4, thereby regulating vimentin and phosphorylation of IRS-1(S307), while recovering the signals of PI-3K. Blocking IRS-1 inhibited the elevation of vimentin, suggesting that an essential role of IRS-1 mediates between DPP-4 and the downstream EMT. In the diabetic rat, pIRS-1 (Ser 307) was abundantly expressed especially surround the tubular region, accompanied by increased vimentin in the kidney. Treatment of HPE ameliorated the EMT and resistance and improved the histological change.

EMT is an important process for embryonic development. Moreover, it occurs under pathological conditions, including cancer cell invasion and renal fibrosis.[21−23] EMT involves loss of epithelial cell adhesion, disrupted basement membrane, enhanced cell migration, and invasion.[24] With increasing vimentin, tubular epithelial cells undergo a phenotypic transformation into matrix-producing fibroblasts.[25] Besides measuring the protein markers, we have performed the morphologic observation to identify EMT. Scanning electromicroscopy and immunohistochemical stain proved that high glucose induced typical features of EMT, while HPE attenuated the alteration.[20] In diabetes, transitioned tubular epithelial cells are associated with interstitial fibrosis and renal dysfunction.[26] Our previous report demonstrated the effect of HPE on inhibiting renal fibrosis of type 2 diabetic rats,[19] which should partly be attributed to the improvement of EMT.

IRS-1 (S307), which is phosphorylated via several mechanisms, including insulin-stimulated kinases or stress-activated kinases like JNK1, is a serine residue located near the phosphotyrosine-binding domain of IRS-1. The phosphorylation of Ser307 leading to a conformational change disrupts the interaction between the catalytic domain of the insulin receptor and the phosphotyrosine-binding domain of IRS-1, and thus inhibits insulin signaling and stimulating the phosphatidylinositol 3-kinase and MAPK cascades.[27] IRS-1 (S307) phosphorylation is viewed as a hallmark of insulin resistance in biologically insulin-responsive cells or tissues.[28]

Cellular insulin resistance predominantly affects adipose and muscle cells. However, a spectrum of renal disease is associated with increased markers of insulin resistance, although direct causal mechanisms are not known.[29] Among a variety of kidney cells, podocyte, with kinetics similar to that of muscle cells, was shown to be insulin sensitive with respect to glucose uptake only if nephrin is expressed.[30] Palmitate blocks insulin-stimulated glucose uptake in human podocytes by dysregulating the phosphorylation of the insulin receptor, IRS-1 and PKB, and leads to impaired translocation of GLUT4 to the cell surface.[29] The resistance signals were also found in human embryonic kidney cells.[9] In the present study, high glucose-induced EMT and resistance marker were concomitantly rescued by HPE or linagliptin in renal tubular cells, implying that insulin resistance could get involved in the interstitial fibrosis and diabetic nephropathy. The mediating role was confirmed with IRS knockdown. Moreover, this phenomenon was proved in kidneys of type 2 diabetic rats. Our findings suggest that insulin resistance, attenuated by HPE, should pivotally associate with renal tubular EMT.

Many previous studies showed that DPP-4 inhibitor improved renal function parameters including albuminuria and creatinine clearance, or improved the histological changes of interstitial volume and glomerular basement membrane thickness, while the effects appeared to be independent of blood glucose lowering.[12,13] DPP-4 inhibition on top of angiotensin receptor blocker treatment significantly reduced urinary albumin excretion and oxidative stress in diabetic eNOS knockout mice, and the results were independent of blood glucose or systolic blood pressure.[11] Treatment with DPP-4 inhibitor significantly improved hyperglycemia and insulin resistance in SHR/NDmcr-cp rats, as evidenced by oral glucose tolerance test and homeostasis model assessment for insulin resistance, respectively.[31] In adults with metabolic symdrome, DPP-4 decrease was associated with insulin sensitivity following exercise training and weight loss.[32] There is evidence that DPP-4 inhibitors directly act on collagen metabolism and modulate the fibrosis marker such as transforming growth factor $\beta$.[33,34] We recently showed that HPE inhibit the angiotensin receptor-1/transforming growth factor $\beta$1 mediated EMT.[20] The cascades could be downstream of DPP-4 and even the subsequent resistance signal. Furthermore, the usual dose of linagliptin (MW = 472.54) for type 2 DM is 2.5 mg daily per os, which corresponds to 5.3 $\mu$mol. Taking the serum volume to be approximately 4 L per capita for human, the transient blood concentration could yield 1.325 $\mu$M. In the present study, 1.0 $\mu$M of linagliptin was used as DPP-4 inhibitor of the experiment, which is indeed correct and feasible.

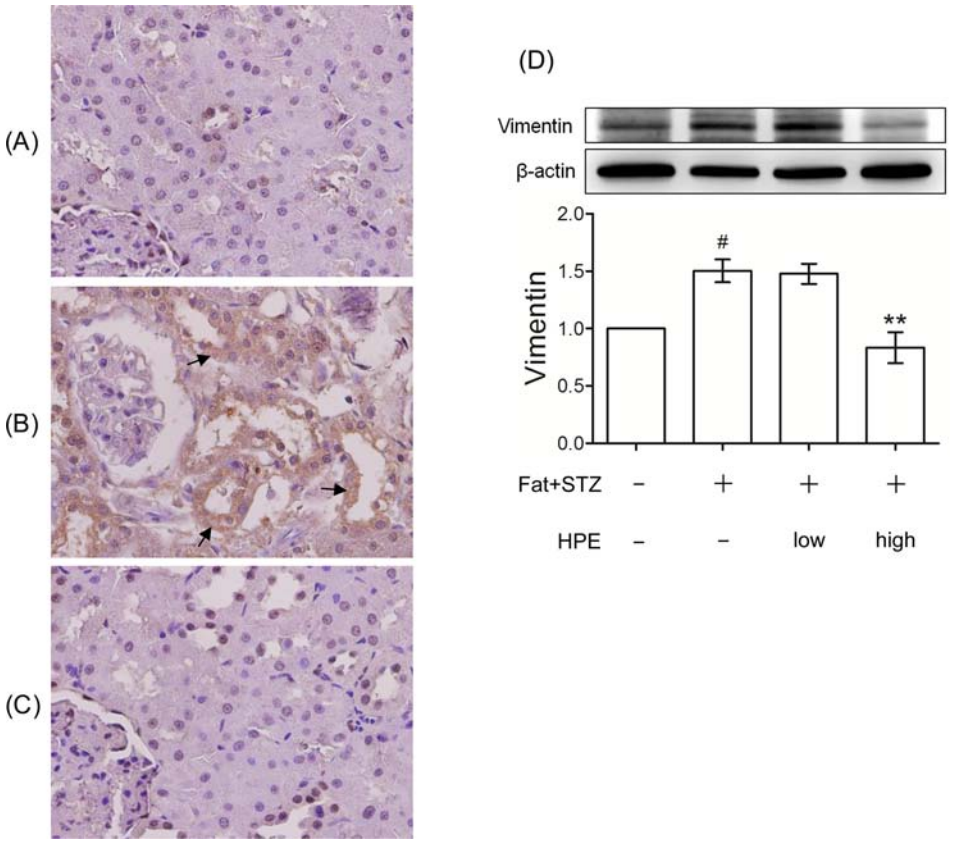

**Figure 6.** Effect of HPE on the diabetic kidneys. Kidneys of normal and type 2 diabetic rats with or without HPE treatment were examined by IHC (200×) and Western blot. (A–C) Histological expressions of IRS-1 Ser (307) (brown staining as arrow-indicated) in normal, diabetic, and 200 mg/kg HPE treated diabetic groups, respectively. (D) Protein levels of vimentin in the diabetic kidneys. $^{\#}p < 0.05$, compared with the control. $^{**}p < 0.01$, compared with the diabetic group.

In the present study, we have tested some of the components of HPE (shown in the Supporting Information). Although caffeic acid, protocatechuic acid, chlorogenic acid, and gallic acid all have the potential to inhibit DPP-4, a low dose of caffeic acid especially inhibits EMT of renal tubular cells. Gallic acid and cholorogenic acid could also exert some effect in triggering DPP-4 and the downstream EMT. The synergistic effects should be considered. In fact, all the tested compounds were reported to be antidiabetic. Caffeic acid promoted glycolysis and glycogen synthesis, but inhibited gluconeogenesis in insulin-resistant hepatocytes.[35] Caffeic acid protected the kidney from diabetic injuries, reducing blood glucose, HbA1c, blood urine nitrogen, urine output, renal advanced glycation end product (AGE), and inflammatory cytokines, while improving clearance of creatinine.[36] Treatment of protocatechuic acid also reduced plasma HbA1c, urinary glycative albumin, renal AGEs, and receptor of AGE.[37] Chlorogenic acid lowered fasting plasma glucose, TBARS, and lipid hydroperoxides in diabetic rats.[38] Gallic acid stimulated insulin secretagogue by regenerating pancreas $\beta$-islets, thus increasing plasma insulin and glucose tolerance.[39] Galloyl ester decreased oxidative stress and AGEs, and improved hepatic and renal function in type 2 diabetic db/db mice.[40]

In conclusion, HPE improves insulin resistance signals and EMT, which is implicated in the pathogenesis of diabetic nephropathy. HPE deserves further investigation and could be an adjuvant to prevent diabetic renal damage.

determination of the bioactivity contribution ratio of certain compounds from a complex extract (7).

Therefore, the present study aimed to figure out the key phenolic compounds accounting for the antioxidant effects of longan seed extract using a combination of Fourier transform ion cyclotron resonance mass spectrometry (FT-ICR−MS), high-performance liquid chromatography electrospray ionization mass spectrometry (HPLC−ESI−MS) analysis, online fishing or knockout, and antioxidant-based screening strategies. Detailed information on the chemical structure−antioxidant activity relationship of longan seed extract will allow us to exploit it as a potentially beneficial phytonutrient.

## MATERIALS AND METHODS

**Plant Materials.** Fresh and fully mature longan fruits (cv. Shixia), which were harvested from south China, were transported to the laboratory for subsequent processing. The longan seeds from non-disease fruits were collected and freeze-dried at −60 °C for 48 h. All of the samples were homogenized to a powder using a stainless-steel grinder and then stored at −20 °C prior to analysis.

**Chemicals.** Analytical or high-performance liquid chromatography (HPLC)-grade solvents and reagents were used. Methanol, acetonitrile, and formic acid were purchased from Fisher Scientific (Waltham, MA). Trolox, fluorescein disodium, and 2,2-diphenylpicrylhydrazyl (DPPH) were obtained from Sigma-Aldrich (St. Louis, MO). 2,2′-Azobis(2-amidinopropane) dihydrochloride (AAPH) was purchased from Wako Chemicals USA (Richmond, VA). D3520 macroporous resin was purchased from Nankai Chemical Plant (Tianjin, China).

**Preparation of Longan Seed Polyphenols (LSPs).** LSPs were extracted according to the modified method by Soong et al.[6] A total of 5 g of dried longan seed powder was refluxed in 100 mL of aqueous ethanol (90%, v/v) at 70 °C for 1.5 h, using a heating mantle to control the temperature and a water-jacketed condenser to return the vapor to the pot. The extract was filtered with a 30 μm Whatman filter paper under vacuum, and the residue was extracted 2 more times. The extract was evaporated under reduced pressure at 35 °C to remove the solvent before lyophilization. The crude polyphenol extract was purified on D3520 macroporous resin.[10] Approximately 10 g of the crude extract was dissolved in 50 mL of 40% ethanol and loaded on a glass column (4.2 × 60 cm) packed with D3520 macroporous resin. Then, 1000 mL of distilled water was used to remove the sugar, and 1000 mL of 40% ethanol was used to elute the phenols at a flow rate of 1.5 mL/min. After elution, the solvent was removed using a rotary evaporator under vacuum, the residue was lyophilized, and LSPs were obtained. Samples were dissolved in methanol to 1 mg/mL prior to HPLC analysis.

**FT-ICR−MS Analysis.** FT-ICR mass spectra were collected on a Bruker Apex-Qe-FT-ICR mass spectrometer equipped with a 9.4 T superconducting magnet (Bruker Co., Chicago, IL). The LSP extract was dissolved in methanol at 0.1 μg/μL. Then, 100 μL of the solution was imported into an electrospray ionization (ESI) technique at a flow rate of 100 μL/h, with the temperature at 180 °C. Mass spectra were obtained in negative-ion mode, and the mass scale ranged from $m/z$ 100 to 2000.

**HPLC−ESI−MS Analysis.** The separation of LSPs by HPLC was performed on an Agilent 1100 liquid chromatograph system (Santa Clara, CA) with a ZORBAX TC-C18 (4.6 × 250 mm, 5 μm, Agilent) column. Separation was accomplished at 30 °C with 0.4% formic acid in water (solvent A) and methanol (solvent B) at 1.0 mL/min using a gradient as follows: 0−10 min, 5−25% B; 10−20 min, 25−55% B; 20−30 min, 55% B; 30−35 min, 55−5% B; and re-equilibration with 5% B for 5 min. Samples were filtered through a 0.45 μm cellulose acetate spin filter before injecting 10 μL, and the eluate was monitored at 280 nm.

Electrospray ionization mass spectroscopy (ESI−MS) analysis was conducted on an Agilent 1100 LC−MS spectrometer (Santa Clara, CA) equipped with a diode array detector and an Agilent 6300 ion trap (Santa Clara, CA) in negative-ion mode. The mobile phase and gradient were the same as HPLC analysis described above. For mass spectroscopy (MS), the heated capillary temperature and spray needle voltage were 350 °C and 4 kV, respectively. The drying gas ($N_2$) flow rate was set at 10 L/min, and mass spectra scale ranged from $m/z$ 100 to 2000.

**Online Knockout.** The strategy included two main steps: (1) screening out the target fractions/peaks in an extract fingerprint and (2) knocking out target fractions/peaks. In this strategy, any component in an extract can be fished or knocked out. On the basis of the method reported by Liu et al.,[7] the online knockout experiments of LSPs were conducted on a SHIMADZU liquid chromatograph system (Shimadzu Co., Kyoto, Japan) with a semi-preparative HPLC column (ZORBAX SB-C18, 9.4 × 250 mm, 5 μm, Agilent). Samples were dissolved in methanol at 50 mg/mL before injecting 20 μL into the system. The mobile phase and gradient were the same as described above for analytical HPLC, except that the flow rate was 4 mL/min. Different ingredients of the extract were separated by the liquid chromatography (LC) column and eluted out from the detector cell. We collected different fractions/peaks manually. To collect accurately, we connected the detector cell with a short PEEK tubing with a narrow inner diameter (Agilent, inner diameter of 0.13 mm). When the elution began, the eluate was collected from the PEEK tube in a brown container to keep away from light. As soon as the target fraction/peak appeared, the target fraction/peak was collected in another flask separately. Once the collection of the target fraction/peak was finished, the residual components were collected in the former container continuously. All of the target fractions or peaks were completely fished from the total extract by repeating this step. Different kinds of samples collected by the online fishing or knockout method were using a rotary evaporator under vacuum to remove solvent and stored at 4 °C for HPLC analysis and antioxidant activity assays.

**Assays for Antioxidant Activity.** *Determination of the Reducing Power.* The ferric-reducing antioxidant power (FRAP) assay was according to the methods by Dudonne et al. and Ozgen et al.,[11,12] with some modification. LSPs were dissolved in methanol to give various concentrations (20, 40, 60, 80, and 100 μg/mL). A total of 1 mL of various LSP solutions was mixed with 0.2 M phosphate buffer (0.2 mL, pH 6.6) and 0.3% potassium ferricyanide (1.5 mL) in a test tube. The mixture was kept in a water bath at 50 °C for 20 min. Then, 10% trichloroacetic acid (1 mL), 0.3% ferric chloride (0.5 mL), and distilled water (3 mL) were added to the mixture before the absorbance was measured at 700 nm.

*Determination of the DPPH-Scavenging Activity.* The DPPH-scavenging activity of LSPs was evaluated according to the methods by Cervato et al.[13] and Goupy et al.[14] A total of 2 mL of sample (10 μg/mL) dissolved in methanol was mixed with 2 mL of 0.2 mM DPPH solution. The mixture was incubated in the dark at 25 °C for 30 min before the absorbance was measured at 517 nm. The reaction mixture without a test sample was used as the control. The scavenging capacity of LSPs was calculated as follows: scavenging rate (%) = (1 − absorbance of sample/absorbance of control) × 100. The activity loss of each sample with target fraction/peak missing was calculated as follows: activity loss (%) = (1 − scavenging rate of sample with one fraction or peak missing/scavenging rate of sample before knockout) × 100.

*Determination of the Oxygen Radical Absorbance Capacity (ORAC).* The measurement of the ORAC assay was based on the method by Huang et al.[15] A total of 25 μL of sample solution (0.1 mg/mL, dissolved in methanol) was transferred to a 96-well polystyrene plate. Then, 150 μL of $8.16 \times 10^{-5}$ mM fluorescein solution diluted in 75 mM phosphate buffer (pH 7.4) was added. The plate was covered with a lid to maintain a constant temperature and preincubated (37 °C) for 10 min. The reaction was initiated by adding 25 μL of 153 mM AAPH. The result was recorded on a fluorescent reader every 5 min for 80 min, with the excitation wavelength at 485 nm and emission wavelength at 530 nm. The standard curve was obtained using Trolox (a water-soluble derivative of vitamin E with antioxidant property) as a standard. The Trolox standard was prepared as follows: 0.250 g of Trolox was dissolved in 50 mL of 75 mM phosphate buffer (pH 7.4)

dx.doi.org/10.1021/jf502995z | J. Agric. Food Chem. 2014, 62, 9744−9750

to give a 0.02 M stock solution. The stock solution was diluted with the same phosphate buffer to 50, 25, 12.5, 6.25, and 3.125 $\mu$M working solutions. The net area under the curve (AUC) of the standard and samples was calculated as

$$\mathrm{AUC} = 0.5 + f_1/f_0 + \ldots + f_i/f_0 + \ldots + f_{15}/f_0 + 0.5(f_{16}/f_0)$$

where $f_0$ is the initial fluorescence reading at 0 min and $f_i$ is the fluorescence reading at time $i$. Final ORAC values were expressed as micromoles of Trolox equivalents per liter of samples.

**Data Analysis.** All of the determinations were performed in triplicate. Data were expressed as the mean ± standard deviation (SD) and evaluated by one-way analysis of variation (ANOVA) of SPSS 19.0 (SPSS, Inc., Chicago, IL) with Duncan's multiple range test. $p$ values of <0.05 were considered as significant.

## RESULTS AND DISCUSSION

We extracted the phenolic compounds from longan seed with 90% ethanol. Polyphenols were enriched by selective treatment with D3520 macroporous resin. HPLC analysis revealed that LSPs were a very complex mixture, with more than 20 peaks being eluted out. Because of the complicated composition of LSPs, we divided it into three fractions, as indicated in Figure 2, and then further analyzed each fraction by the FT-ICR−MS method, which is a powerful tool for characterizing complex compounds.[16,17] FT-ICR−MS spectra of fraction 1 showed two strong signals of $[M - H]^-$ at $m/z$ 169.0106 and 339.0319 (Figure 1a). The former was 0.99 ppm error contrasted to the molecular mass of gallic acid ($C_7H_6O_5$), and the latter was corresponding to $[2M - H]^-$ ion of gallic acid,[18] indicating that gallic acid was the main composition of fraction 1, which was identified in longan seeds by Soong et al. and Sudjaroen et al. previously.[6,18] Similarly, we obtained two strong signals of $[M - H]^-$ at $m/z$ 300.9958 and 602.9996 on the spectra of fraction 3 (Figure 1c). The signal of $[M - H]^-$ at $m/z$ 300.9958 was identified as ellagic acid ($C_{14}H_6O_8$), with the molecular weight error of 1.28 ppm paralleled with the theoretical value, and the signal of $[M - H]^-$ at $m/z$ 602.9996 was corresponding to the $[2M - H]^-$ ion of ellagic acid, suggesting that fraction 3 was mainly composed of ellagic acid.[6]

In comparison to fractions 1 and 3, fraction 2 was more complex (Figure 1b), with three strong signals of $[M - H]^-$ at $m/z$ 387.1631, 469.0584, and 633.0711 and nine weak signals of $[M - H]^-$ at $m/z$ 197.0421, 283.2610, 319.0429, 433.0379, 513.0967, 801.0757, 863.1814, 907.0769, and 951.0717 being observed. Ethyl gallate, 2-*O*-galloyl-$\beta$-D-xylopyranosyl, myricetin, ellagic acid 4-*O*-$\alpha$-l-arabinofuranoside, corilagin, isomallotinic acid, proanthocyanidin trimer (A type), and geraniin (hemiacetal forms) with the $[M - H]^-$ ions of 197, 283, 319, 433, 633, 801, 863, and 951, respectively, were reported in longan seeds and other plant materials.[18−23] Our results provided primary evidence for their probable existence in longan seeds. However, besides these eight known compounds, structures of other signals of fraction 2 as well as their contributions to the antioxidant activity of LSPs were needed to be further elucidated by other means.

The FT-ICR−MS data suggested that LSPs may contain high levels of free and conjugated forms of gallic and ellagic acids. However, the current studies concerning the antioxidant contributions of gallic and ellagic acids to LSPs are inconsistent. For example, Soong et al.[6] suggested that free forms of gallic and ellagic acids had great contribution to the antioxidant activity of LSPs, while Rangkadilok et al.[1] revealed that gallic and ellagic acids might not be the main contributors for the potent antioxidant properties of LSPs. They suggested that the strong antioxidant activity of LSPs may be derived from other unknown phenols. These inconsistent results promoted us to figure out which fraction of LSPs (the gallic-acid-rich fraction 1, the ellagic-acid-rich fraction 3, or the more complex fraction 2) was responsible for the potent antioxidant activity of LSPs. We used the online fishing/knockout technology[7] to screen the bioactive compound group that represented the efficacy of LSPs. According to the online knockout method,[7] three remaining fractions of LSPs (missing fractions 1, 2, and 3) were obtained from HPLC separation. As shown in Figure 2, it was clear that, after the online knockout program, the target fraction in LSPs disappeared completely.

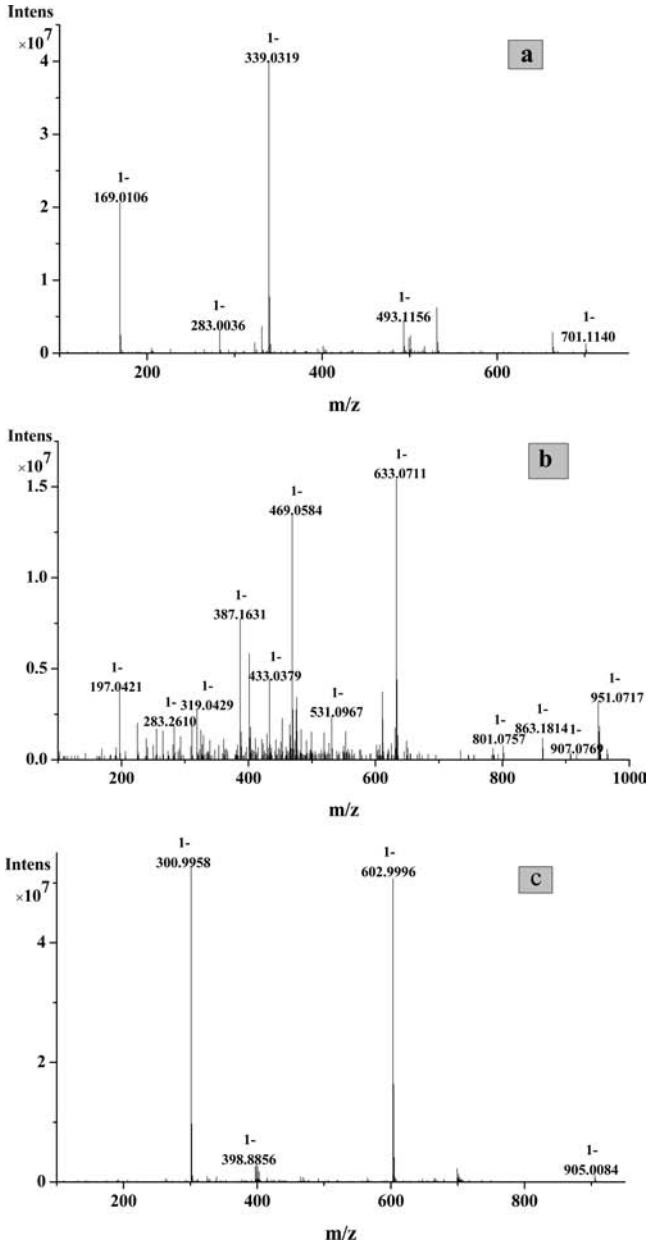

**Figure 1.** FT-ICR mass spectrum of fractions 1, 2, and 3 of LSPs.

The DPPH and FRAP assays were used to evaluate the antioxidant activity of LSPs and their three remaining fractions after knockout. By comparison of the DPPH scavenging rates (Table 1), it was easy to see that the effect of fraction 1 on the DPPH-scavenging activity was little, indicating that fraction 1 had a small contribution to the antioxidant efficiency of LSPs,

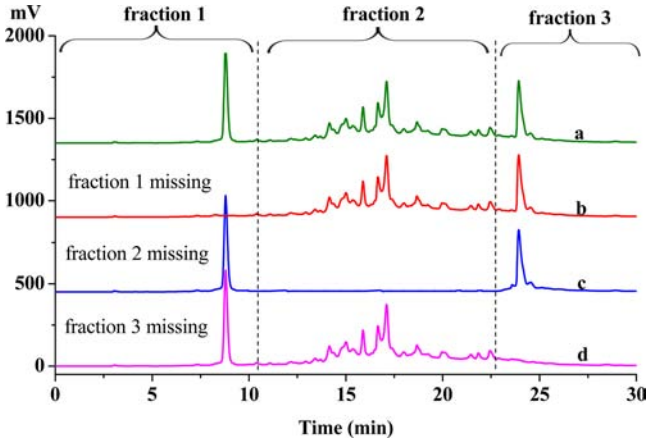

**Figure 2.** Chromatograms of fraction knockout under the same HPLC conditions: (a) chromatogram with total polyphenols of longan seed, (b) chromatogram with fraction 1 knockout, (c) chromatogram with fraction 2 knockout, and (d) chromatogram with fraction 3 knockout.

**Table 1. Scavenging Rate and Activity Loss of the Samples against the DPPH Radical**[a]

| sample by online knockout | scavenging rate (%) | activity loss (%) |
|---|---|---|
| total LSPs | 70.29 ± 0.96 a | |
| sample 1 (fraction 1 missing) | 64.65 ± 1.31 b | 8.03 ± 0.02 b |
| sample 2 (fraction 2 missing) | 56.23 ± 1.44 c | 20.00 ± 0.02 a |
| sample 3 (fraction 3 missing) | 58.42 ± 1.39 c | 16.89 ± 0.02 a |

[a]The data are given as the mean ± SD ($n$ = 3). Mean values in the same column with unlike letters are significantly different ($p$ < 0.05).

while fractions 2 and 3 played important roles in the DPPH-scavenging effect of LSPs. The contribution rate of each fraction to the DPPH-scavenging effect of LSPs was expressed as the activity loss of the correspondent sample before knockout. The contribution order of each fraction to the antioxidant activity of LSPs was fraction 2 > fraction 3 > fraction 1. The same results were also obtained in the FRAP assay (Figure 3). Our results suggested that fraction 1 had very little contribution to the antioxidant activity of LSPs, which was in line with the results by Rangkadilok et al.[1] Therefore, we ignored it in the following study. As described above, fraction 3 was mainly composed of ellagic acid, which was reported to

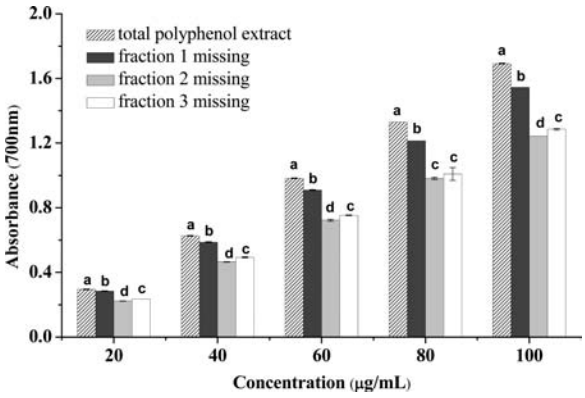

**Figure 3.** Reducing power of total polyphenols, sample 1 (fraction 1 missing), sample 2 (fraction 2 missing), and sample 3 (fraction 3 missing). Bars with different letters at the same concentration differ significantly ($p$ < 0.05).

exert an antioxidant effect *in vitro*,[16] and its prominent effect was due to the special structure unit, catechol hydroxyl, which can produce stable phenoxy radicals by the 1,2-benzoquinone unit after hydrogen abstraction.

According to the results mentioned above, fraction 2 had the highest contribution to the antioxidant properties of LSPs but was a complex mixture. To figure out the main active constituents accounting for the antioxidant properties in fraction 2, we continued to separate it into three fractions by the knockout method. As shown in Figure 4, it was evident that

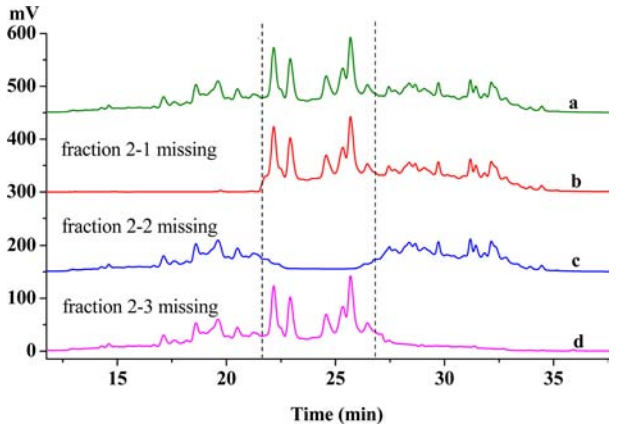

**Figure 4.** Chromatograms of fraction knockout under the same HPLC conditions: (a) chromatogram with fraction 2, (b) chromatogram with fraction 2-1 knockout, (c) chromatogram with fraction 2-2 knockout, and (d) chromatogram with fraction 2-3 knockout.

three fractions (2-1, 2-2, and 2-3) were fishing out successively. Likewise, both the DPPH scavenging and FRAP assays were performed to further evaluate the antioxidant contribution of each missing fraction. Table 2 illustrated that the DPPH

**Table 2. Scavenging Rate and Activity Loss of Fraction 2 and Different Samples against the DPPH Radical**[a]

| sample by online knockout | scavenging rate (%) | activity loss (%) |
|---|---|---|
| fraction 2 | 41.13 ± 0.004 a | |
| sample 4 (fraction 2-1 missing) | 34.89 ± 0.012 b | 15.16 ± 0.028 b |
| sample 5 (fraction 2-2 missing) | 24.68 ± 0.025 c | 40.00 ± 0.06 a |
| sample 6 (fraction 2-3 missing) | 34.11 ± 0.006 b | 17.05 ± 0.016 b |

[a]The data are expressed as the mean ± SD ($n$ = 3). Mean values in the same column with unlike letters are significantly different ($p$ < 0.05).

scavenging effect of each sample with target fraction knockout was in the following order: sample 4 (fraction 2-1 missing) > sample 6 (fraction 2-3 missing) > sample 5 (fraction 2-2 missing), which meant that the order of the contribution of each fraction was fraction 2-2 > fraction 2-3 > fraction 2-1. When fraction 2-2 was knocked out, the scavenging effect of sample 5 (fraction 2-2 missing) reduced significantly, demonstrating that fraction 2-2 had vital contribution to the total radical scavenging activity of fraction 2, while the missing of fractions 2-1 and 2-3 did not affect the scavenging rate notably. The FRAP assay (Figure 5) provided further support for the above conclusion. These findings have led to a conclusion that fraction 2-2 was the target bioactive group in longan seed extract. However, a further online fishing or knockout program was needed to screen the target bioactive compounds.

dx.doi.org/10.1021/jf502995z | J. Agric. Food Chem. 2014, 62, 9744−9750

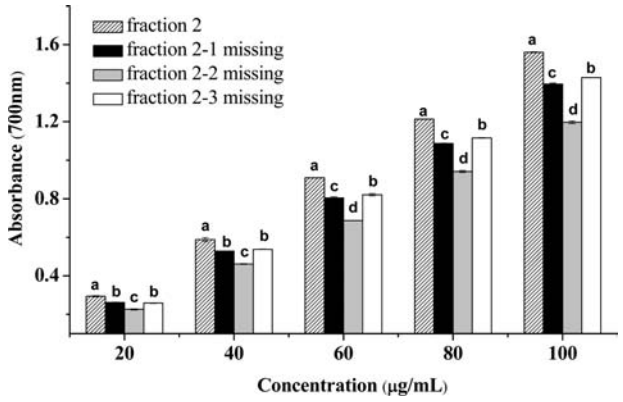

**Figure 5.** Reducing power of fraction 2, sample 4 (fraction 2-1 missing), sample 5 (fraction 2-2 missing), and sample 6 (fraction 2-3 missing). Bars with unlike letters at the same concentration are significantly different ($p < 0.05$).

We obtained good separation of fraction 2-2 by adjusting the HPLC elution program as follows: the mobile phase consisted of 0.4% formic acid mixed with double distilled water (solvent A) and methanol/acetonitrile (50:50, v/v) (solvent B); the gradient program started from 0 min (5% B) to 10 min (25% B) and 20 min (32% B) and then was re-equilibrated for 10 min with 5% B for the next analysis. The HPLC fingerprint of fraction 2-2 was finally obtained with favorable separation.

Likewise, peaks 1−8 in fraction 2-2 were knocked out one by one. By comparison of the obtained chromatograms (Figure 6),

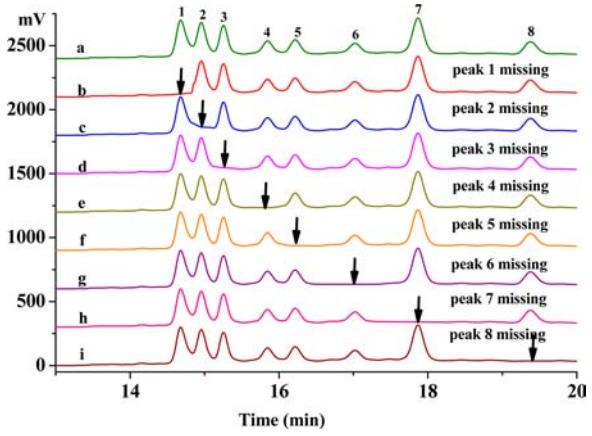

**Figure 6.** Chromatograms of peak knockout under the same HPLC conditions: (a) chromatogram with fraction 2-2, (b) chromatogram with peak 1 knockout, (c) chromatogram with peak 2 knockout, (d) chromatogram with peak 3 knockout, (e) chromatogram with peak 4 knockout, (f) chromatogram with peak 5 knockout, (g) chromatogram with peak 6 knockout, (h) chromatogram with peak 7 knockout, and (i) chromatogram with peak 8 knockout.

it was obvious that the target peaks in fraction 2-2 were knocked out completely. Similarly, DPPH and ORAC assays were used to screen and evaluate the possible target bioactive compounds in fraction 2-2. The scavenging rates of all of the collections with target peaks missing were summarized in Table 3. The DPPH scavenging property of each collection declined as follows: collections 8 (peak 8 missing) > 7 (peak 7 missing) > 2 (peak 2 missing) > 3 (peak 3 missing) > 5 (peak 5 missing) > 6 (peak 6 missing) > 4 (peak 4 missing) > 1 (peak 1 missing), consistent with the results of contribution rates

**Table 3. Scavenging Rate and Activity Loss of Fraction 2-2 and Different Collections against the DPPH Radical[a]**

| collection by online knockout | scavenging rate (%) | activity loss (%) |
|---|---|---|
| fraction 2-2 | 81.54 ± 0.008 a | |
| collection 1 (peak 1 missing) | 28.37 ± 0.007 h | 65.20 ± 0.009 a |
| collection 2 (peak 2 missing) | 54.55 ± 0.008 d | 33.10 ± 0.01 e |
| collection 3 (peak 3 missing) | 41.72 ± 0.007 e | 48.83 ± 0.009 d |
| collection 4 (peak 4 missing) | 34.23 ± 0.008 g | 58.02 ± 0.01 b |
| collection 5 (peak 5 missing) | 40.19 ± 0.005 f | 50.71 ± 0.006 c |
| collection 6 (peak 6 missing) | 35.16 ± 0.011 g | 56.88 ± 0.013 b |
| collection 7 (peak 7 missing) | 57.27 ± 0.008 c | 29.77 ± 0.01 f |
| collection 8 (peak 8 missing) | 69.31 ± 0.007 b | 15.00 ± 0.009 g |

[a]The data are expressed as the mean ± SD ($n = 3$). Mean values in the same column with different letters are significantly different ($p < 0.05$).

(peaks 1 > 4 > 6 > 5 > 3 > 2 > 7 > 8). It was evident that peaks 1, 4, and 6 performed a great contribution to the total antioxidant activity of fraction 2-2. Besides, the contribution rates of peaks 5 and 3 were 50.71 and 48.83%, respectively, which were a little lower than those of peaks 1, 4, and 6. However, very limited decreases on the DPPH-scavenging effects of collections with peaks 2, 7, and 8 knockout were observed, revealing that the three peaks had a small contribution to the bioactivity of fraction 2-2 in comparison to other peaks.

The ORAC assay was used to further confirm the contribution of each peak to the antioxidant activity of fraction 2-2. As illustrated in Figure 7, the ORAC value of each

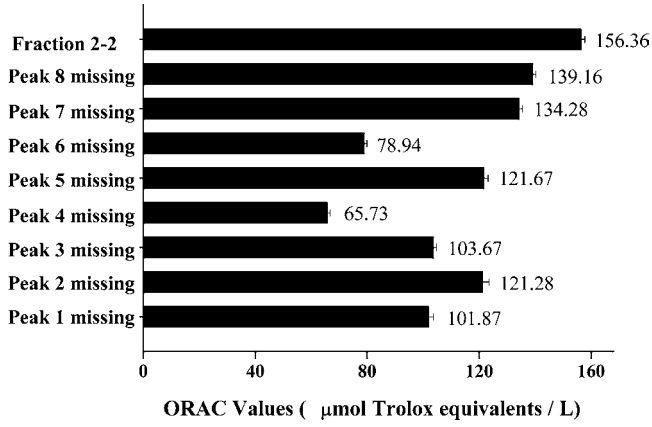

**Figure 7.** ORAC values of fraction 2-2 and different collections with target peak knockout. All of the results are expressed as micromoles of Trolox equivalents per liter.

collection was in the following order: collections 8 (peak 8 missing) > 7 (peak 7 missing) > 5 (peak 5 missing) > 2 (peak 2 missing) > 3 (peak 3 missing) > 1 (peak 1 missing) > 6 (peak 6 missing) > 4 (peak 4 missing), demonstrating that the contribution of each peak to the antioxidant activity of fraction 2-2 declined as follows: peaks 4 > 6 > 1 > 3 > 2 > 5 > 7 > 8. The minor discrepancy between the results of DPPH and ORAC assays may be due to the different systems.[2,24] Taken together, DPPH and ORAC analyses suggested that peaks 1, 4, and 6 could be the main contributors to the total antioxidant activity of fraction 2-2. These specific bioactive compounds may represent the remarkable antioxidant effect of polyphenols in longan seeds.

Table 4. HPLC−ESI−MS Analysis for Individual Phenolic Compounds of Fraction 2-2 of Longan Seed Extract

| peak number | retention time (min) | $[M - H]^-$ ($m/z$) | $MS^2$ ions ($m/z$) | compound |
|---|---|---|---|---|
| 1 | 13.41 | 291 | 247, 205, 161 | unknown |
| 2 | 13.63 | 291 | 247, 205, 161 | unknown |
| 3 | 14.01 | 633 | 463, 301, 275 | corilagin |
| 4 | 14.65 | 387 | 369, 207, 163, 119 | *p*-coumaric acid glycoside |
| 5 | 14.91 | 469 | 425, 301 | (*S*)-flavogallonic acid |
| 6 | 15.77 | 611 | 397, 301, 229 | ellagic acid derivative |
| 7 | 16.61 | 477 | 462, 301, 169 | methyl-ellagic acid glucopyranoside |
| 8 | 17.97 | 197 | 169, 125 | ethyl gallate |

Therefore, we used HPLC−ESI−MS to explore the structures of peaks 1−8 in fraction 2-2. The results are summarized in Table 4.

HPLC−MS analysis in negative-ion mode revealed that peaks 1 and 2 had a common molecular mass and fragmentation pattern, suggesting a pair of isomers. The molecular ion $[M - H]^-$ was observed at $m/z$ 291. Fragment ions were found at $m/z$ 247, 205, and 161 in the $MS^2$ spectrum. The fragment at $m/z$ 247 corresponded to a loss of 44 amu resulting from the elimination of a $CO_2$ molecule from the molecular ion. The fragment ion at $m/z$ 205 was derived from the loss of two ethenone, and the fragment ion at $m/z$ 161 came from the further loss of a $CO_2$ molecule. The ESI−MS fragmentation patterns of peaks 1 and 2 were very similar to that of catechin but with dominant peaks Δ2 amu larger than that of catechin. It was reported to exist in strawberry fruits in a previous study,[25] but the detailed structure was unknown.

Peak 3 showed a distinct molecular ion at $m/z$ 633, and its three characteristic $MS^2$ fragments ions were observed at $m/z$ 463, 301, and 275, indicating that it was galloyl-HHDP-glucopyranose (corilagin).[21] The fragment at $m/z$ 463 was attributed to the loss of a galloyl unit from the parent molecule, and the ion at $m/z$ 301 was defined as ellagic acid.[26] It was also reported to be one of the major polyphenol components of longan seeds by Sudjaroen et al.[18]

The molecular ion of peak 4 was at $m/z$ 387. Four characteristic fragment ions were found at $m/z$ 369, 207, 163, and 119, in the $MS^2$ spectrum of $m/z$ 387. The first fragment ion ($[M - H - 18]^-$) at $m/z$ 369 resulted from the elimination of a water molecule from the parent molecule. The fragment ions at $m/z$ 207 ($[M - H - 18 - 162]^-$) and $m/z$ 163 ($[M - H - 18 - 162 - 44]^-$) corresponded to the further loss of a glucosyl moiety and the continuing loss of a $CO_2$ molecule. The fragment ion at $m/z$ 163, with its typical production ion at $m/z$ 119, was identified as *p*-coumaric acid.[27,28] Thus, it was deduced that peak 4 was probably a *p*-coumaric acid−glucose conjugate linked by a carboxyl group, but further work is needed to verify the structure of this compound.

Peak 5 presented a molecular ion $[M - H]^-$ at $m/z$ 469 with two characteristic $MS^2$ fragment ions at $m/z$ 425 and 301, respectively. The former came from the neutral loss of $CO_2$, and the latter was identified as ellagic acid at $m/z$ 301. On the basis of the mass spectra data,[23] peak 5 was identified as (*S*)-flavogallonic acid.

Peak 6 showed a molecular ion at $m/z$ 611 and two strong fragment ions at $m/z$ 397 and 301. Besides, the fragment ion at $m/z$ 229 was observed, which is indicative of the presence of ellagic acid ($m/z$ 301). Because no more structural information was available, we deduced that this compound could be an ellagic acid derivative.

Peak 7, with a $m/z$ of 477, was identified as methyl-ellagic acid glucopyranoside on the basis of a previous study[29] and the observed mass spectra. The fragment ions at $m/z$ 462 ($[M - H - 15]^-$) and $m/z$ 301 ($[M - H - 15 - 161]^-$) corresponded to the loss of a methyl unit and a glucosyl unit, respectively. Ellagic acid at $m/z$ 301 was also identified.

Peak 8, with a $m/z$ of 197, was determined to be ethyl gallate, which yielded the characteristic fragment ion at $m/z$ 169 (gallic acid) by losing an ethyl unit. The fragment ion at $m/z$ 125 resulted from the continuing loss of $CO_2$, further confirming the proposed structure.[30,31] This compound was previously identified in longan seeds by Zheng et al.[2]

In summary, the combination of FT-ICR−MS analysis, HPLC−ESI−MS analysis, online fishing or knockout, and antioxidant-based screening strategies was used to screen the key phenolic compounds accounting for the potent antioxidant effects of longan seeds for the first time. Ellagic acid and its derivative were proven to have important contribution to the antioxidant activity of LSPs. A new compound, probably *p*-coumaric acid-glycoside, had the greatest contribution to the antioxidant capacity of LSPs, while gallic acid, corilagin, (*S*)-flavogallonic acid, methyl-ellagic acid glucopyranoside, and ethyl gallate did not affect the potent antioxidant activity of LSPs, showing a small contribution to the total bioactivity. Further work on the detailed structures of the newly found phenolic compounds of *p*-coumaric acid-glycoside and ellagic acid derivative with high antioxidant activity and their structure−activity relationships is needed.

However, one of the questions that arise when phenolic compounds are esterified as the polar head of phospholipids would be whether the derived structure would be digested and bioaccesible during gastrointestinal digestion, as the first step before any other physiological action beyond intestinal tissues.

The *in vitro* intestinal models of lipid digestion are an interesting tool for obtaining preliminary and valuable information concerning digestion of lipid species. Due to their utility, the use of *in vitro* digestion models in the study of bioactive compounds has increased, becoming a well-accepted analytical tool.[18] However, as far as we know, all the models of *in vitro* lipid digestion have been developed for the major lipid dietary forms, namely, triglycerides (TG), whereas the *in vitro* digestion models focused on phospholipids have not been extensively investigated. In general, we consider that the development of a model that closely simulates the *in vivo* conditions is especially essential when performing the digestion of novel or unknown lipids under *in vitro* conditions, in order to accurately understand obtained results and to avoid misinterpretations due to the own methodology used. Therefore, a reliable *in vitro* digestion model for phospholipids should be previously developed before the application of the model to the experimental molecule PHT.

Concerning the general digestion process of phospholipids, this is mainly catalyzed by the enzyme phospholipase A2 (PLA2) at the intestinal level, which hydrolyzes fatty acids from the sn-2 location almost completely to release lyso-phospholipids and free fatty acids (FFA).[17] After hydrolysis, a high bioaccessibility has been described for phospholipids, which means that their lipid products are easily solubilized within the micellar phase for absorption.[17] Together with the simulation of these events and results, an *in vitro* model of intestinal digestion of phospholipids should also take into account the coexistence of dietary exogenous phospholipids together with endogenous biliary phospholipids. Furthermore, the simultaneous presence of other dietary fats together with phospholipids should also be considered, in order to mimick a real intake of dietary lipids, where phospholipids are minor compounds compared to TG.

Therefore, the aim of the present research was to perform a simulation of the intestinal digestion of PHT under *in vitro* conditions. First, the *in vitro* intestinal digestion model was optimized for the digestion of phospholipids, in order to be certain that the model reflected physiological intestinal digestion for these compounds, and to reject that any artifact or the own conditions of the digestion method would not interfere with the results obtained for PHT. Furthermore, the bioaccessibility of HT esterified as PHT after digestion was compared with that of free HT, or HT premixed with phospholipids. Finally, the impact of digestion on the antioxidant ability of PHT compared to HT was also assayed.

## MATERIALS AND METHODS

**Reagents and Materials.** HT (purity higher than 90% w/w) was acquired from Seprox Biotech (Madrid, Spain). PHT (86% PHT, 8% HT, and 6% fully hydrogenated phosphatidylcholine) was synthesized by enzymatic transphosphatidilation of HT and phosphatidylcholine (Phospholipon 90H, Lipoid, Switzerland). The detailed procedure of the synthesis of PHT was already described.[15] A commercial olive oil was used as a representative of dietary typical oil.

Trizma, maleic acid, pancreatin from porcine pancreas, bile salts, and ammonium hydroxide solution 30% were from Sigma-Aldrich Chemie GmbH (Steinheim, Germany). Phosphatidylcholine (PC) from egg yolk (98%) was purchased from Lipoid (Ludwigshafen, Germany). Sodium sulfate anhydrous, sodium chloride, calcium chloride, and ethanol absolute were purchased from Panreac (Barcelona, Spain). Ortho-phosphoric acid was purchased from Scharlab (Sentmenat, Barcelona). All solvents used were of HPLC grade from Lab-Scan (Dublin, Ireland).

***In Vitro* Lipid Digestion.** A previously developed model for TG[19] was adapted to simulate the simultaneous presence of dietary TG, dietary phospholipids, and endogenous biliary phospholipids. Briefly, the adapted model consisted of a sample of 0.5 g of olive oil and 0.1 g of phospholipid which were mixed with 16 mL of Trizma−maleate buffer 0.1 M pH 7.5. In the case of control digestions and optimization of the *in vitro* model, the sample was the same phospholipid used for the synthesis of PHT (Phospholipon 90H, PL). In the case of PHT, this was added at the same equivalent weight used for the digestion of PL. The prepared medium was pre-emulsified by homogenization for 2 min at 3500 rpm.

On the other hand, a solution trying to simulate biliary secretion was prepared by mixing 0.1 g of PC, 0.25 g of bile salts, 0.02 g of cholesterol, 0.5 mL of a 325 mM $CaCl_2$ solution, 1.5 mL of a 3.25 mM NaCl solution, and 10 mL of Trizma−maleate buffer, and this mixture was homogenized for 2 min at 3500 rpm. Then, the pre-emulsified sample and the simulated biliary secretion were mixed and homogenized together for 2 min at 3500 rpm. The whole media was placed in a thermostatically controlled vessel at 37 °C and continuously stirred by a magnetic stir bar at 1000 rpm. The simulation of intestinal digestion was started by the addition of fresh pancreatin extract (0.5 g of pancreatine in 3 mL of Trizma−maleate buffer, stirred for 10 min and centrifuged at 1600 × *g* for 15 min). The enrichment with PLA2 was carried out by addition of 5 mg of a food grade PLA2 from *Streptomyces violaceoruber* ($10^3$ U/mg) from Nagase Chemtex Corporation (Fukuchiyama Factory, Kyoto, Japan). After addition of enzymes, reaction was continued for 60 min. In order to study the evolution of lipid products throughout the hydrolytic process, aliquots were taken at 0, 5, 10, 30, and 60 min of reaction.

Additional digestions were performed in order to compare the bioaccessibility of PHT with that of HT, or with that of a premixed HT with a dose of dietary PL (HT+PL). In both cases, HT was added to the media at equivalent weights as those added by PHT. Furthermore, in both cases, the coexistence with olive oil was kept.

*In vitro* digestion of each experiment was performed at least in triplicate.

**Separation of Phases after in Vitro Lipid Digestion.** At the end of digestion, the medium was submitted to centrifugation at 4000 rpm for 40 min at 37 °C (5810R Eppendorf Iberica, Madrid, Spain) according to Soler-Rivas et al.[20] After centrifugation, an upper oily phase (OP), a lower aqueous or micellar phase (MP), and a minor precipitated phase (PP) were obtained. The lipid composition of each phase was analyzed. In the case of the MP, aliquots were collected for quantification of micellar structures by using a light microscope and a Neubauer cell counter chamber (Brand, Germany).[20]

**Lipid Extraction.** The total lipids from samples were extracted twice by a mixture of chloroform/methanol/ortho-phosphoric acid (100:80:4, v/v/v) at a ratio of solvent to sample of 3:1 (v/v). Ortho-phosphoric acid was necessary for a proper recovery of the lyso-PL species. The mixture was vortexed for 1 min and centrifuged for 10 min at 13500 rpm (ScanSpeed mini, Micro Centrifuge). The organic phase containing the separated lipids was collected, and anhydrous sodium sulfate was added before further analysis.

**Analysis of Lipid Products.** *Polar Lipids.* The polar lipid composition was determined on a Luna 5 μm HILIC diol column (250 mm, 4.6 mm, Phenomenex, Torrance, California, USA) coupled to an HPLC Agilent 1200 Series containing a thermostatized column compartment, a quaternary pump, an autosampler, a vacuum degasser, and an evaporative light scattering detector. The used method was based on Casado et al.[15] with brief modifications. The flow rate was 1.5 mL $min^{-1}$. A splitter valve was used after the thermostatized column compartment and part of the mobile phase was directed through the detector (3.5 bar and 55 °C). The column temperature was maintained at 55 °C. The mobile phase utilized consisted of a ternary gradient of (A) hexane/2-propanol/acetic acid/triethylamine (815/

170/15/0.5 v/v/v/v), (B) 2-propanol/Milli-Q $H_2O$/acetic acid/triethylamine (840/140/15/0.5 v/v/v/v), and (C) hexane. The method starts at 50% A and 50% C increasing up to 100% A in 5.1 min, and reaching 12% B and 88% A in 20 min. This percentage is maintained for 15 min, and then is changed up to 40% B and 60% A in 0.5 min. Finally, the gradient returns to initial conditions and is maintained for 20 min.

This methodology was used to analyze phospholipid and lysophospholipid species, HT, and bile salts. Identification and quantification was carried out by using standards for each lipid class. In the case of lyso-PHT, a purification procedure of this standard was previously necessary as described later. In order to minimize error when using HPLC with ELSD, rigorous calibration curves utilizing the appropriated standards were developed for each set of samples injected, since the detector response was nonlinear and specific to each compound.

*Neutral Lipids.* The neutral lipids composition was determined on an Agilent poroshell 120 (2.7 $\mu$m, 100 × 4.6 mm$^2$) coupled to an HPLC Agilent 1200 Series (Avondale, PA) containing a thermostated column compartment (35 °C), a quaternary pump, an autosampler, a vacuum degasser, and an evaporative light scattering detector (ELSD). Conditions of the ELSD were 3.5 bar and 35 °C. A split valve was used after the column, and only 50% of the mobile phase was directed through the detector. The column temperature was maintained at 35 °C. The ternary gradient has already been detailed by Vazquez, Fernandez, Martin, Reglero, and Torres.[21]

This methodology was used to analyze TG, diglycerides (DG), monoglycerides (MG), and FFA. Identification and quantification was carried out by using standards for each lipid class. In order to minimize error when using HPLC with ELSD, rigorous calibration curves utilizing appropriated commercial standards were developed for each set of samples injected, since the detector response was nonlinear and specific to each compound.

**Purification of Lyso-PHT for Analysis of Digestion Products.** For a proper quantification of digestion products from PHT, the major hydrolysis product lyso-PHT was necessary as pure as possible to perform the corresponding standard calibration curves. To obtain this standard, it was necessary to (1) develop a protocol to hydrolyze PHT to lyso-PHT up to enough amounts necessary for the study and (2) develop a protocol for the subsequent purification of the released lyso-PHT.

*Hydrolysis Reaction of PHT to Lyso-PHT.* Taking the digestion model of PL as a reference, diverse modifications were performed in order to reach as complete hydrolysis as possible of PHT up to lyso-PHT. Preliminary assays showed that either other lipids in the medium, as well as other surface active agents, such as bile salts or MG, were necessary for a proper hydrolysis of PL and PHT in general. Therefore, olive oil was kept in the reaction, and MG was used instead of bile salts. This was done because the later separation of bile salts from lyso-PHT and lyso-PL in general during the purification procedure was complicated, contrary to isolation from MG.

Briefly, the hydrolysis medium consisted of 80 mg of PHT mixed with 80 mg of olive oil, 60 mg of MG, 0.4 mL of $CaCl_2$ (325 mM), 1.2 mL of NaCl (3.25 mM), and 20.6 mL of Trizma−maleate buffer pH 7.5. The mixture was homogenized (Ultra-Turrax IKA T18) for 4 min at 3500 rpm. The reaction was started with the addition of fresh pancreatin extract (0.3 g of pancreatin in 1.8 mL of Trizma−maleate buffer pH 7.5, stirred for 10 min and centrifuged at 1600 g for 15 min) and PLA2 solution (0.2 g of PLA2 in 2 mL of Trizma−maleate buffer pH 7.5, vortexed for 1 min). The hydrolysis reaction was performed in a thermostatically controlled shaker (IKA KS 4000 ic control) at 37 °C and 250 rpm for 120 min. Finally, the total lipids from the reaction were extracted by chloroform/methanol (2:1, v/v) for subsequent analysis and purification. Under these conditions, around 95% of PHT was hydrolyzed to lyso-PHT and FFA.

*Purification of Lyso-PHT by SPE.* After the hydrolysis reaction, the obtained mixture of lipid compounds consisted of FFA (45%) and lyso-PHT (35%) as major products, together with minor levels of residual PHT, lyso-PL, and MG. The purification of lyso-PHT was performed by SPE. The method of Mateos et al.[22] to separate phenolic compounds of vegetable oils was combined with the method of Carelli et al.[23] to separate classes of phospholipids of vegetable oils.

Initially, the procedure of Mateos et al.[22] was followed. Briefly, a 500 mg diol-bonded phase cartridge (Isolute, Biotage, UK) was conditioned with 6 mL of methanol and 6 mL of hexane, consecutively. The lipid sample (1 mL, 40 mg/mL in chloroform) was added to the cartridge. Most glycerides (mainly MG, and residual DG and TG in case) were first eluted with 6 mL of hexane. Then, most FFA were eluted with 4 mL of hexane: ethyl acetate (90:10, v/v). The next step of the method of Mateos et al.[22] used methanol for elution of phenolic compounds. However, we modified this step by mixing methanol with ammonium hydroxide (15 mL of methanol/ammonium hydroxide solution 99.5:0.5, v/v) for the proper elution of the polar lipids (lyso-PHT, lyso-PL, and residual PHT), according to the procedure of Carelli et al.[23] This modification was necessary because it was tested that only methanol was not useful to elute lyso-PHT, although it effectively eluted HT. Only the mixture with ammonium hydroxide allowed a proper recuperation of lyso-PHT. Curiously, the complete method of Carelli et al.[23] (without combination with the method of Mateos et al.[22]) was not useful for recovering lyso-PHT, although we tested that it was effective for lyso-PL purification. Finally, we found that the combination of the first steps of the method of Mateos et al.[22] with the last step of Carelli et al.[23] were the most proper conditions to a successful recovery of lyso-PHT. At the end of the procedure, the solvent fraction containing polar lipids was evaporated under $N_2$ at 40 °C and redissolved in chloroform/methanol (2:1 v/v) for subsequent analysis. The purity of the lyso-PHT product obtained by the developed protocol was closer to 80%, together with minor levels of FFA, MG, and lyso-PL.

**Antioxidant Activity of Compounds by DPPH Test.** The antioxidant activity of the intestinal medium containing PHT or HT was measured at 0 and 60 min of digestion by DPPH test. An aliquot (50 $\mu$L) of ethanol solution containing 5−30 $\mu$g/mL of intestinal media was added to 1950 $\mu$L of DPPH in ethanol (23.5 $\mu$g/mL). The reaction was completed after 90 min at room temperature and darkness, and absorbance was measured at 517 nm. The remaining DPPH concentration in the reaction medium was estimated by proper calibration curves of DPPH. The scavenging activities were expressed as 50% of inhibitory concentration (EC50), which denotes the concentration of HT (mM) (expressed as the equivalent concentration of HT in PHT) required for giving a 50% reduction of DPPH concentration relative to that of a DPPH control.

Control experiments of the digestion media in the absence of the tested compounds were also performed, and the lack of change in DPPH concentration was measured.

**Statistical Analysis.** Statistical analyses were performed by means of the general linear model procedure of the SPSS 17.0 statistical package (SPSS Inc., Chicago, IL, USA) by one-way analysis of variance. Differences were considered significant at $p \leq 0.05$. Posthoc Tukey's tests were performed in order to establish significant differences.

## RESULTS AND DISCUSSION

**Development of an *in Vitro* Intestinal Model for Digestion of Phospholipids.** Previous to *in vitro* digestion of PHT, an intestinal digestion model for phospholipids was first developed, in order to be certain that the model reflected the physiological intestinal lipid digestion of these lipids, and to reject that any artifact or the own conditions of the digestion method would not interfere with the results obtained for the PHT hydrolysis.

One of the main problems to optimize a reliable *in vitro* model for phospholipids is the imprecise data in the scientific literature on basic and general parameters such as the typical hydrolysis degree of these lipids, the habitual amount of luminal phospholipids and PLA2, or the exact degree of bioaccessibility. Therefore, as a reference of physiological criteria, we considered the data of Borgström[17] that stated that

phospholipids are absorbed efficiently, that conversion to lysophospholipids is essential for absorption to occur, and that the luminal concentration of PLA2 is high enough for hydrolysis to lysophospholipids.

A previously developed model for TG[19] was adopted as a starting point. Such a model was considered useful because we already demonstrated that it closely reflected the physiological results found in the intraluminal phase in man during fat digestion, namely, TG. However, some modifications would be necessary in order to simulate a proper digestion for phospholipids.

The developed model for intestinal digestion of TG uses the pancreatin as the source of digestive enzymes. Pancreatin is a pancreatic extract that contains most of the digestive enzymes responsible for digestion of major macromolecules at intestinal lumen. In the specific case of lipid digestion, pancreatic lipase is the major enzyme found in pancreatin. Although pancreatic lipase may partially hydrolyze phospholipids, most hydrolysis is catalyzed by PLA2. However, both the presence and the level of PLA2 in pancreatin for proper hydrolysis are not stated in the product specifications.

On the other hand, the developed digestion model for TG was adapted to simulate the simultaneous presence of dietary exogenous phospholipids and TG, as well as endogenous biliary phospholipids. Concerning exogenous dietary phospholipids, those were included at a proper ratio to TG. This is difficult data to establish, because the dietary intake of phospholipids reported in the scientific literature is quite variable, taking into account the variable amount of phospholipids that can be found depending on a meal. Thus, ratios from 1 to 10% of total daily fat intake has been reported.[16,24] A high-phospholipid meal was simulated in the model. Concerning endogenous biliary phospholipids, the included dose was proportional to bile salts and cholesterol, taking into account the gallbladder bile lipid secretion during a fed state.[25]

Furthermore, a separation of the preparation of both fractions of phospholipids at different stages was considered. This is because exogenous phospholipids are found mixed with TG in the aqueous digestion medium, where the phospholipids are found as a surface component of the TG emulsion.[17] On the other hand, the endogenous phospholipids are found as a dispersion in bile salts as lamellar aggregates or mixed micellar aggregates.[17] Therefore, we considered that such different phases should be prepared separately, trying to simulate the pre-emulsion of dietary lipids that would enter later the intestinal lumen to be mixed with the preformed biliary secretion.

Figure 1a shows the *in vitro* digestion initially performed by the use of pancreatin. As shown, the level of pancreatin effectively hydrolyzed TG forms up to the physiologically considered level at duodenal lumen; namely, around 75% was degraded to the main hydrolysis products (FFA and MG). On the contrary, both the hydrolysis of phospholipids and the level of the product lysophospholipids were minor, suggesting that pancreatin does not have enough hydrolytic activity to effectively digest phospholipids. Therefore, the enrichment with PLA2 was considered necessary.

As far as we know, previous information on typical physiological levels of PLA2 has not been clearly reported, so we considered as criteria of PLA2-dose optimization the statement of Borgstrom,[17] who suggested that the luminal concentration of PLA2 is high enough for a complete hydrolysis of phospholipids to lysophospholipids. Therefore, several

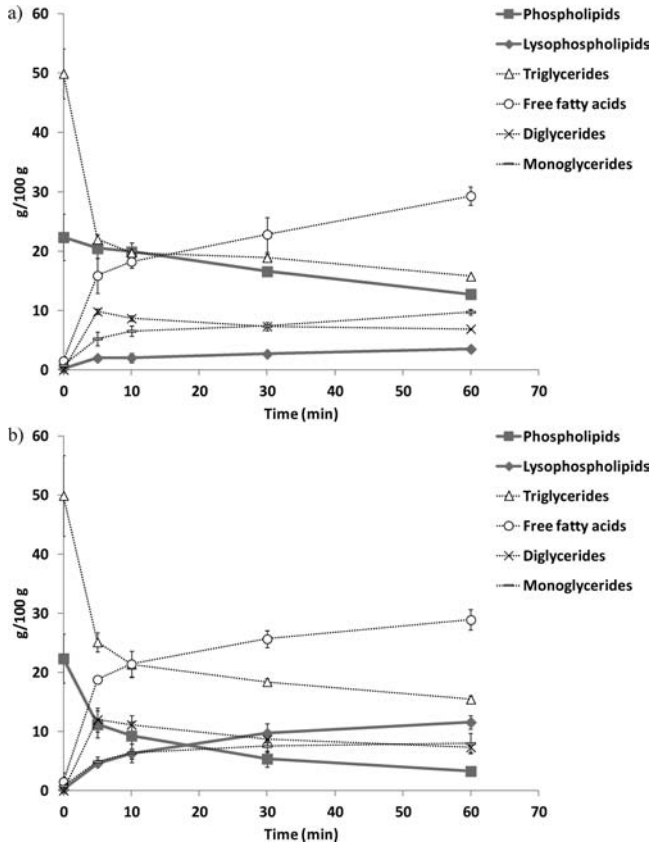

**Figure 1.** Course of *in vitro* intestinal digestion by (a) pancreatin or (b) PLA2-enrichment of pancreatin.

commercial PLA2's added at variable levels were tested (data not shown) up to reaching a quantitative hydrolysis level of phospholipids. As shown in Figure 1b, the final optimized method with a proper dose of PLA2 progressively hydrolyzed phospholipids up to almost complete digestion, releasing lysophospholipid as the major hydrolysis product, together with residual nonhydrolyzed phospholipids. Furthermore, the digestion of the rest of the lipids was not influenced by the presence of PLA2. These results were closer to *in vivo* physiological digestion of phospholipids,[17] so the *in vitro* model that was developed was considered useful to test the intestinal digestion of the experimental molecule PHT. The detailed procedure of the *in vitro* model after performing all the explained modifications was that described in the Materials and Methods section.

***In Vitro* Intestinal Digestion of Phosphatidylhydroxytyrosol.** To perform the digestion of PHT, it was not as easy as replacing total phospholipids of the media by PHT. This is because the fraction of phospholipids from biliary secretion should be kept in order to reproduce a physiological situation. Therefore, the PHT was included in the media as dietary phospholipid, but it coexisted together with the endogenous phospholipid of the medium during the hydrolysis process.

The evolution of *in vitro* intestinal digestion of PHT is shown in Figure 2. It can be observed that PHT was progressively hydrolyzed to lyso-PHT. However, the rate of digestion was slower than the phospholipid control sample (Figure 1b). Thus, at the end of digestion, only around 50% of PHT was hydrolyzed.

To compare the digestion of PHT in the presence and in the absence of endogenous phospholipids, additional experiments

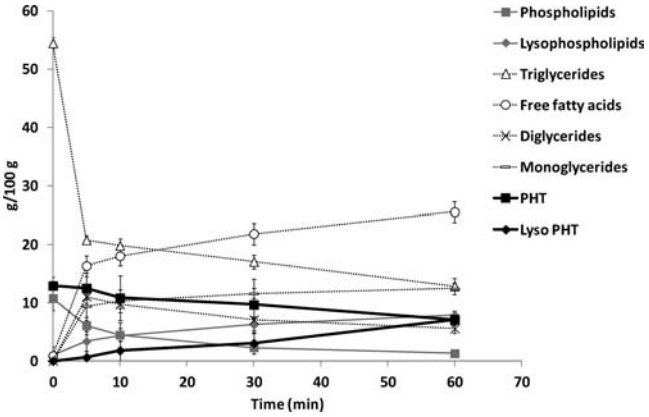

**Figure 2.** Course of *in vitro* intestinal digestion of PHT.

were performed. Thus, PHT as the only form of phospholipid substrate for PLA2 was added to the media, which means that biliary PC was removed and that PHT was added both as dietary and biliary phospholipid. For comparative purposes, the same procedure was performed for PL. The release of lysophospholipid species was considered to compare the rate of hydrolysis. As shown in Figure 3, the rate of digestion of

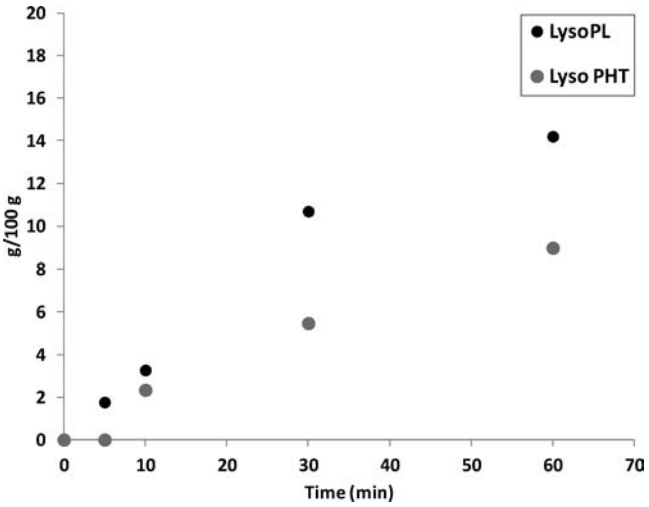

**Figure 3.** Lyso-PL or lyso-PHT releasing during *in vitro* intestinal digestion of PL or PHT, respectively, without coexistence of other phospholipids in the media.

PHT was slower than the hydrolysis of the control PL. Therefore, this experiment showed that the slower digestion of PHT would be related to the own molecule PHT.

The explanation of this result is complex, because previous information on the digestion of phospholipids with a modified polar-head with so atypical structures is scarce. Nevertheless, it has been described that there are different factors that determine the rate and extent of enzymatic hydrolysis of any phospholipid in general. According to scientific literature, the aggregation of the substrate under the form of mixed micelles, lamellar structures, liposomes, or emulsions is necessary, since this appears to facilitate the interaction of the sn-2 fatty acid ester with the catalytic site of the enzyme.[26−28] However, the specific type of aggregation determines the hydrolysis rate. Furthermore, the presence of other lipids which influences the packing of the fatty acid chains and the headgroup are also related to the action of PLA2.[28] Whether PHT determined differences on these factors is unknown but might be considered as potential reasons of the different results on the rate of hydrolysis. According to Scott et al.[27] on the contribution of the sn-3 substituent on the PLA2 binding affinity, these authors stated that the own nature of the phosphatidyl ester affects the physical chemistry of the aggregates, such as surface charge distribution or the state of aggregation. In this respect, it is important to remark that PL and PHT might show a different surface charge distribution, taking into account that the former would be a neutral PL, whereas PHT should be an anionic phospholipid due to the removal of choline. Related to the different state of aggregation, the numbers of micellar structures formed after *in vitro* digestion of PL and PHT were determined. According to Figure 4, a lower number of micellar structures were detected for PHT digestion when compared to PL, which seemed to be in agreement with the lower hydrolysis of PHT.

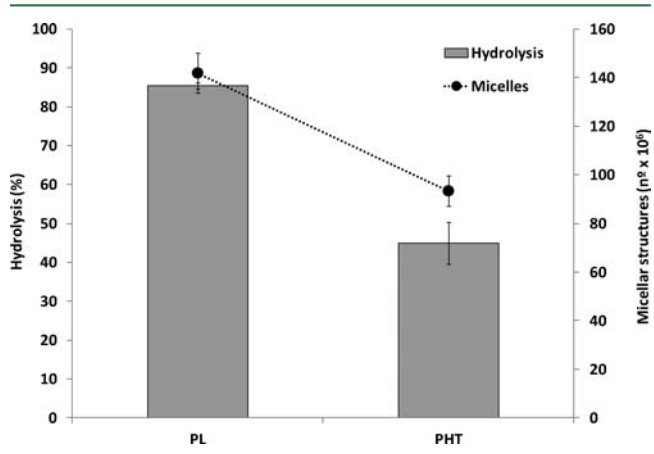

**Figure 4.** Hydrolysis of PL and PHT versus the number of micellar structures.

**Bioaccessibility of Phosphatidylhydroxytyrosol.** During intestinal digestion of dietary fat, it has been shown that the intraluminal content is structured as an oily phase (OP) dispersed in a micellar bile salt solution (MP).[29] This OP mainly contains undigested TG and DG, whereas the MP contains bile salts and the end products of enzymatic hydrolysis, namely, MG, FFA, and lysophospholipids. All of these lipid products are aggregated as mixed micelles, micelles, vesicles, or emulsion droplets.[30,31] Absorption of lipid products takes place supported by this MP, which enhances the transport of lipid products to the enterocytes throughout the unstirred water layer close to the microvillous membrane, where they are absorbed.[32] Furthermore, a minor fraction of insoluble calcium soaps of fatty acids liberated during the pancreatic digestion can be formed, which are not absorbable, tend to precipitate, and are wasted in faeces. The analysis of lipid products of these three phases, MP, OP, and PP, contributes to the study of bioaccessibility, defined as the fraction of a compound that is released from its matrix in the gastrointestinal tract and thus becomes available for intestinal absorption.[33]

According to Figure 5, most hydrolysis products, including neutral and polar lipids, were found distributed within the bioaccessible fraction MP, suggesting a high bioaccessibility. In the case of the control PL samples, a significant OP was isolated (16% of total lipid products), and a minor PP was also detected. The specific distribution of total lipid products within the three phases is detailed in Figure 6. As shown in Figure 6a,

dx.doi.org/10.1021/jf503477h | J. Agric. Food Chem. 2014, 62, 9751−9759

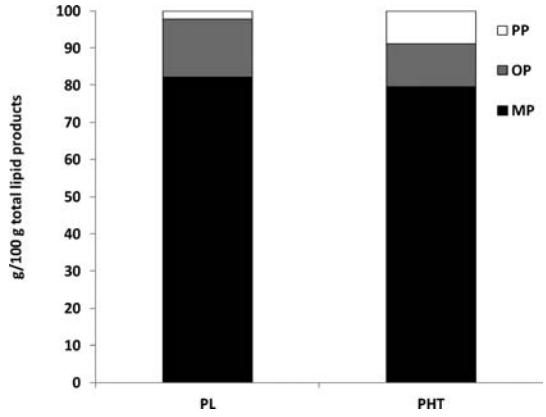

**Figure 5.** Partition of total lipid products between the isolated fractions MP, OP, and PP after 60 min of *in vitro* intestinal digestion.

the polar lipids from hydrolysis of PL (lyso-PL and residual nondigested PL) were totally included in the MP, suggesting a high bioaccessibility of PL. These results were in agreement with the expected physiological data of phospholipids, so these obtained results also validated the *in vitro* model developed on the ability to reproduce *in vivo* physiological results on bioaccessibility of phospholipids, and lipids in general.

Some differences were observed in the case of the sample containing PHT. As shown in Figure 5, the distribution of lipid products within the OP was lower (around 12% of total lipid products), and the PP increased instead (around 9% of total lipid products precipitated) compared to the PL sample. At any case, most lyso-PHT and residual PHT were found within the bioaccessible fraction MP.

As detailed in Figure 6b, the observed increase in the PP fraction was mainly due to an increased precipitation of FFA and a fraction of nondigested PHT. In fact, the bioaccessibility of the FFA changed from 92% in the case of PL samples to 80% in the case of PHT samples. This unexpected a priori result is difficult to explain, attending to the fact that both PL and PHT samples had the same amount and fatty acid profile. In general, any precipitation of FFA during intestinal digestion should be related to a limited solubilization within micellar structures and formation of calcium soaps that cannot be solubilized in the aqueous media. Taking into account that the assays of PHT samples produced a lower amount of micellar structures than PL samples (Figure 4), this might determine the differences on nonmicellated fatty acids between both samples. It was also significant that around 8% of total PHT was precipitated

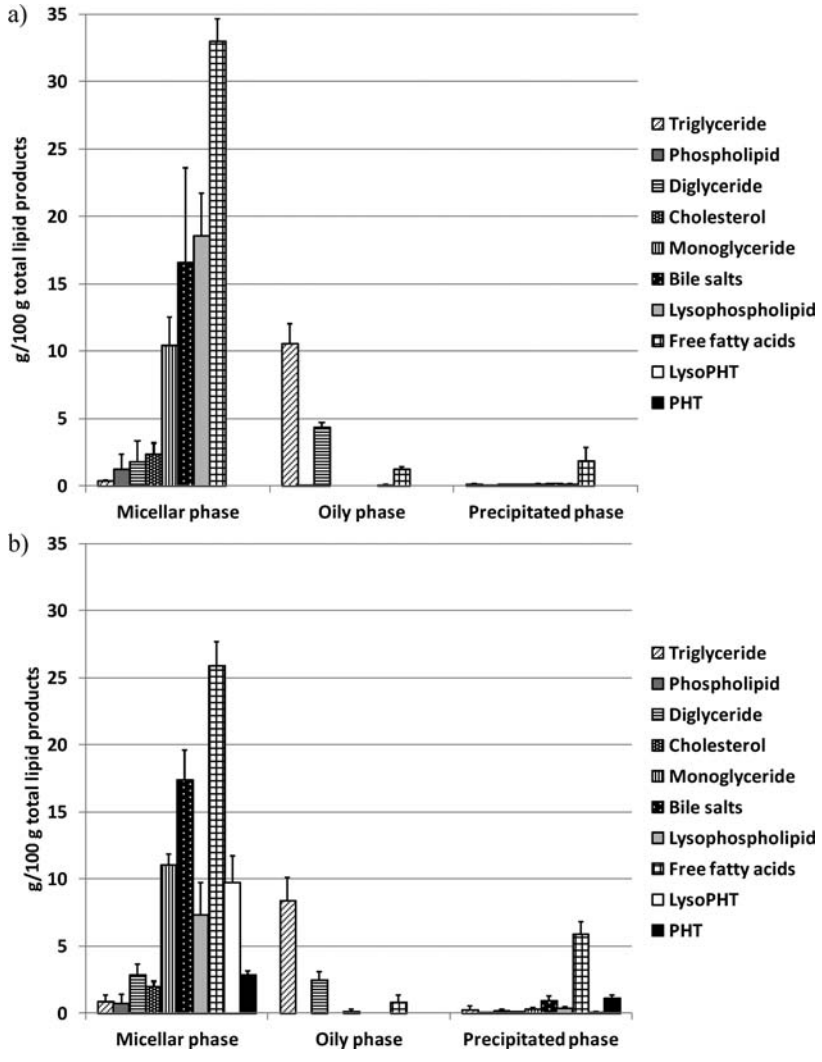

**Figure 6.** Partition of individual lipid products between the isolated fractions MP, OP, and PP after 60 min of *in vitro* intestinal digestion.

dx.doi.org/10.1021/jf503477h | *J. Agric. Food Chem.* 2014, 62, 9751−9759

together with FFA, whereas nondigested PL did not precipitate in the case of PL sample. A minor fraction of precipitated bile salts was also measured for the PHT sample contrary to the PL sample. Therefore, the particular molecule PHT might be related to these results.

In order to evaluate the magnitude of PHT as a carrier of HT, its bioaccessibility as the esterified form was compared to that of HT. Furthermore, a comparative study with a premixture HT+PL was considered of interest in order to compare the bioaccessibility of HT when it coexisted with a dose of dietary PL, with that of HT under the esterified form as PL (PHT). According to Figure 7, most HT was included

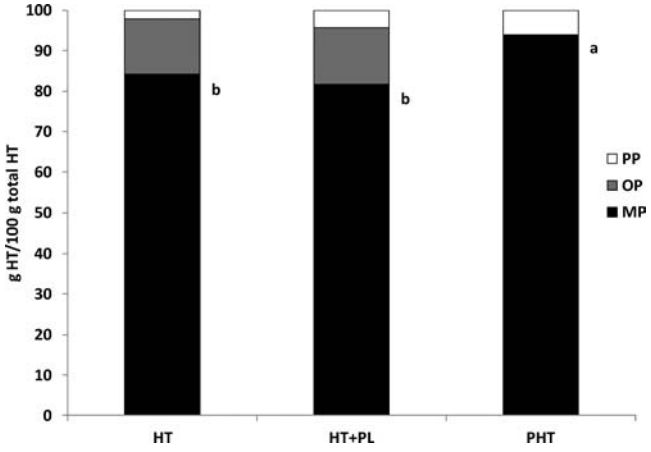

**Figure 7.** Partition of total HT between the isolated fractions MP, OP, and PP after 60 min of *in vitro* intestinal digestion.

within the bioaccessible fraction MP for the three forms of HT addition, suggesting a high bioaccessibility. Nevertheless, the portion of HT within the MP under the form of PHT was slightly superior to the other forms of addition of HT. Such a difference was due to a fraction of HT within the OP that was not detected for the PHT sample. These results would suggest that a portion of HT would not be so easily dispersed in the aqueous media when this phenolic compound was free or premixed with PL, contrary to the esterified forms of HT as PHT. Probably, the amphiphilic properties of PHT as a phospholipid allowed its dispersion in the aqueous media, which in turn indirectly allowed the dispersion of the vehiculated HT. Furthermore, a minor precipitated fraction of HT was found for all samples, which was not significantly different. These results contributed to the study of the potential of PHT as well as to the general behavior of the phenolic HT. Previous detailed information on the fractionation of HT, or combinations HT+PL, between the different phases of the intestinal medium under *in vitro* conditions was not found.

Concerning the bioaccessibility of PHT, it should be noted that Borgström[17] stated that conversion of phospholipids to lysophospholipids is essential for absorption to occur. Therefore, according to the obtained results, despite that most of the digested PHT was found within the bioaccessible MP fraction, PHT would be only partially absorbed as lyso-PHT. However, this fact remains unclear and should be elucidated, since it has also been reported that there is no abnormality in phospholipid absorption in the case of deficiency in PLA2 (nonhydrolyzed phospholipids).[24] Therefore, further studies concerning bioavailability of PHT would be of interest in order to validate whether PHT would be effectively recognized by intestinal mucosa for absorption and subsequent metabolism, and its validation as a potential vehicle of HT.

**Effect of *in Vitro* Digestion on the Antioxidant Activity of Phosphatidylhydroxytyrosol.** In a recent study, we have successfully shown a significant antioxidant activity of PHT in diverse edible oils, which was comparable or even superior to HT.[4] Taking such evidence of antioxidant ability of PHT into account, the antioxidant effect was explored in the current study when it was affected by the intestinal digestion process. This was considered of interest, especially taking into account that PHT was mainly degraded to lyso-PHT after intestinal digestion, and this would be the major bioaccessible molecule. Furthermore, the modification of the antioxidant activity of diverse phenolic compounds after the process and conditions of gastrointestinal digestion has been previously described, including HT;[34] hence, the interest in producing carriers of these compounds that could protect their activity during the gastrointestinal transit.

As shown in Figure 8, either PHT or digested PHT showed a lower antioxidant activity than HT at any moment of digestion.

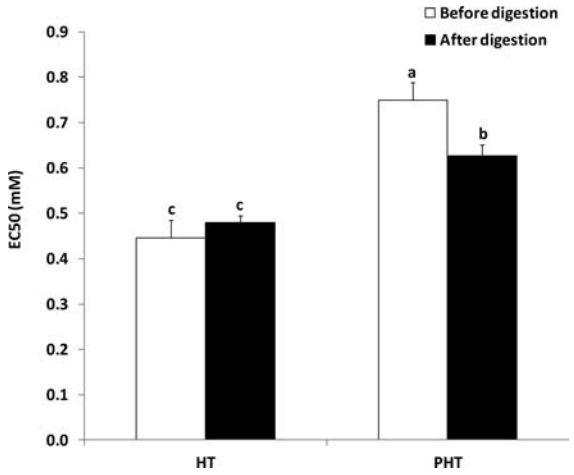

**Figure 8.** Scavenging activity of HT and equivalent concentration of HT under the form of PHT, before and after digestion.

Furthermore, the antioxidant activity of the control HT did not seem to be affected by the digestion process. An interesting finding was that the EC50 value of digested PHT was significantly inferior to that observed before digestion. This result might suggest that the digestion products, mainly the major lyso-PHT, might show better antioxidant ability than the former PHT. This could be considered reasonable, taking into account the simpler and more hydrophilic molecule of lyso-PHT compared to PHT. Thus, after intestinal digestion, a closer value of EC50 between digested PHT and HT was achieved (0.6 and 0.5 mM, respectively).

As a summary, the present study showed that the synthetic phosphatidyl derivative of HT is recognized by phospholipases during the simulation of intestinal digestion but less efficiently than the analogous PL. At any case, both the major hydrolysis product, namely, lyso-PHT, and most of the nondigested PHT were found within the bioaccessible aqueous fraction; hence, most of the esterified HT was potentially bioaccessible. On the other hand, the digested PHT might be a more superior antioxidant than the nonhydrolyzed PHT. Nevertheless, the evaluation of the potential bioactivity of PHT and its digested

product would be necessary in further studies, in order to validate the carriers of HT under the form of phospholipids.

prepared by dissolving chitosan flakes in HCl to achieve a final pH of 5−6. The solutions of catechol and mediator were prepared in phosphate buffer (0.1 M, pH 7.0).

**Preparation of the Clove−Chitosan Film.** To obtain an insoluble clove fraction, clove (5, 30, or 60 mg/mL) was suspended in water, vortexed, and then, centrifuged (3200*g* for 5 min). After discarding the upper brown solution, the settled clove was suspended in fresh water and again centrifuged. This process was repeated until the upper solution showed no absorbance peaks (300−700 nm) where phenolic antioxidants would be expected (see Figure S1, Supporting Information). The insoluble clove fraction was next suspended in aqueous solutions containing chitosan (0.5%, pH 5.5), and then, small amounts of this suspension (20 $\mu$L) were spread onto a standard gold electrode (area ~ 0.0314 $cm^2$). The film was vacuum-dried at 37 °C for 30 min and then immersed in phosphate buffer (pH 7.0; 30 min). This buffer treatment partially deprotonates the primary amines of chitosan and converts the film into a water-insoluble form. In most experiments, films containing insoluble clove were compared against control chitosan films (lacking clove).

**Electrochemical Instruments.** Electrochemical measurements (cyclic voltammetry and chronocoulometry) were performed using a three-electrode system (CHI Instruments 6273C electrochemical analyzer). The working electrode was the standard gold electrode (with chitosan film, area = 0.03 $cm^2$), the reference electrode was Ag/AgCl, and the counter electrode was a Pt wire. All electrochemical experiments were done in a mixed solution of 50 $\mu$M Fc and 50 $\mu$M $Ru^{3+}$ in phosphate buffer (0.1 M, pH 7.0). Air was excluded by purging $N_2$ during the experiment. For measurement of antioxidant and pro-oxidant activities, the gold-coated silicon wafer was used as a working electrode because its larger surface area (0.9 $cm^2$) increased sensitivities of these measurements.

**Antioxidant Assay.** Antioxidant activity was measured by adapting the standard oxygen radical absorbance capacity (ORAC) method that probes a hydrogen atom transfer mechanism. We used this method to probe if/how antioxidant properties varied depending on whether the clove−chitosan film was poised in an oxidized or reduced state. In this case, the film-coated electrode was electrochemically poised in an oxidized or reduced state (see the text for details) and then incubated in a solution (200 $\mu$L) of fluorescein (10 nM) in 0.1 M phosphate buffer (pH 7.0) followed by the rapid addition of the AAPH solution (20 mM). The mixture was incubated for a fixed time of 30 min at 37 °C, and then, the fluorescence was recorded using a fluorescence plate reader (SpectraMax M2, Molecular Devices, CA).

**Assay for Pro-oxidant Activity.** The film-coated electrodes were electrochemically poised in either oxidized or reduced states, dried with $N_2$, and then, incubated in air-saturated water for 15 min. The $H_2O_2$ generated in this aqueous solution was assayed using Amplex Red reagent (Amplex Red Hydrogen Peroxide/Peroxidase Assay Kit, Invitrogen, OR), and the results were measured using a fluorescence plate reader.

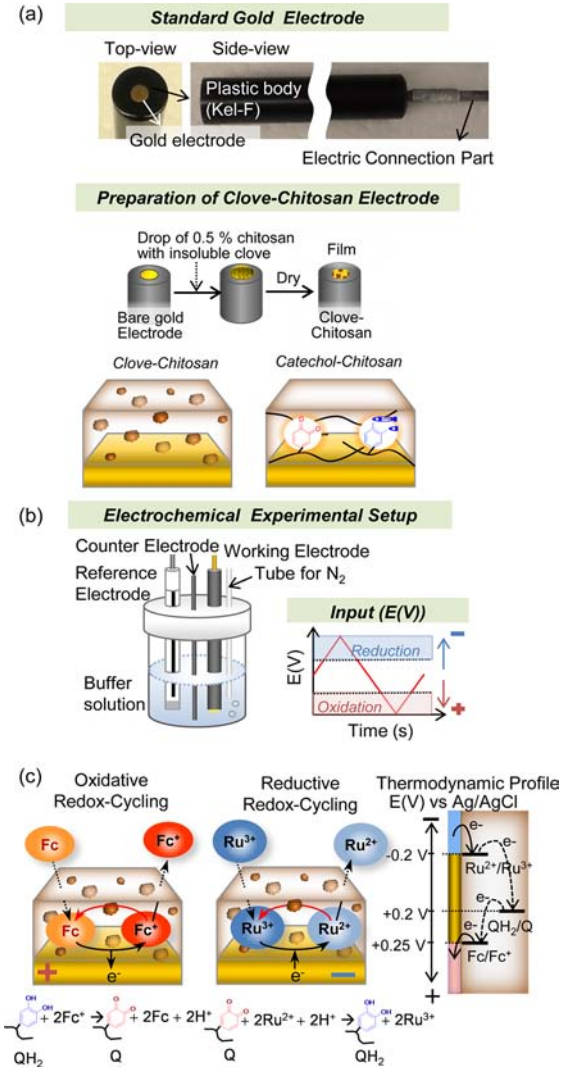
**Statistical Analysis.** All experiments were carried out in triplicate. Statistical analyses were performed using one-way analysis of variance compared with control.

## RESULTS AND DISCUSSION

**Initial Evidence of Redox Activity.** Scheme 1a illustrates the experimental approach for preparing a chitosan film containing insoluble clove. The photograph shows a standard gold electrode while the schematic illustrates that a clove−chitosan film is prepared directly adjacent to this electrode. Scheme 1a also illustrates the structure of this film with the insoluble clove particles entrapped within the chitosan network. Previously, we studied chitosan films containing insoluble melanin particles[36] and chitosan films with grafted catechol moieties.[40] Results from these earlier studies can be used to compare observations with insoluble clove.

Scheme 1b shows the electrochemical system used to probe the redox activities of the clove−chitosan film. This film-coated

**Scheme 1. Experimental Sample, System, and Electrochemical Redox Cycling**[a]



[a](a) Standard gold electrode and preparation of film with insoluble clove entrapped within a chitosan matrix (films with covalently grafted catechol moieties are used for illustrative and comparative purposes). (b) Electrochemical system used for cyclic voltammetry (cyclic input potentials are imposed). (c) Redox cycling of electrochemical mediators (Fc and $Ru^{3+}$) and chemical mechanism proposed for the case of catechol−chitosan films.[40]

"working" electrode is inserted into a buffered solution (0.1 M phosphate; pH 7.0) along with the reference (Ag/AgCl) and counter electrodes. As illustrated, an input potential ($E$; volts) can be imposed to the underlying gold electrode, and the basis of this electrochemical analysis is to infer redox activities from the observed output currents. In initial studies, this clove−chitosan film was probed by cyclic voltammetry such that the potential ($E$) of the electrode was controllably cycled between oxidative values (more positive values of $E$) and reductive values (more negative values of $E$). If a chemical species can access the electrode and undergo redox reactions with the electrode, then oxidation is observed as a negative current while reduction is observed as a positive current. (Note: cyclic voltammetry data is commonly displayed as a plot of current vs potential without explicitly showing time.)

dx.doi.org/10.1021/jf503479d | J. Agric. Food Chem. 2014, 62, 9760−9768

Chemical intuition suggests several expectations for this initial cyclic voltammetry experiment. First, minimal oxidation or reduction currents should be observed if the clove−chitosan film is probed in a buffer solution that lacks diffusible redox-active species. In this case, there are no accessible electrons to exchange with the electrode: chitosan is not redox-active and cannot conduct electrons, and the insoluble clove particles are entrapped too far from the electrode surface for direct electron exchange. The first control in Figure 1a is for a chitosan film prepared with the insoluble fraction of clove and probed in the absence of soluble mediators. As expected, the cyclic voltammograms (CVs) for this control show no oxidation or reduction peaks.

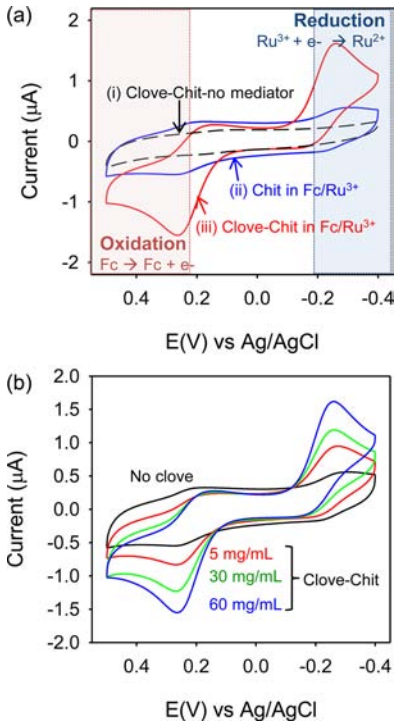


**Figure 1.** CVs provide initial evidence that insoluble clove has redox activity (scan rate = 50 mV/s). (a) CVs for electrodes coated with chitosan films: (i) clove−chitosan control incubated without mediators shows neither chitosan nor clove are conducting (no peak currents are observed); (ii) chitosan control incubated with both Fc and $Ru^{3+}$ mediators (50 $\mu$M each) shows that the chitosan film is permeable to these mediators (the small peak currents correspond to the diffusion of mediators); (iii) clove−chitosan incubated with both mediators shows amplified peak currents consistent with redox cycling. (b) CVs for electrodes coated with chitosan films containing varying clove levels show amplified peak currents increase with increasing clove levels.

In order for oxidation or reduction currents to be observed, a soluble redox mediator must be incorporated in the buffer, and this mediator must be able to diffuse through the film to access the electrode. We incorporate two electrochemical mediators in the buffer: Fc typically exists in its reduced state but can be readily and reversibly oxidized when the potential is cycled near its $E^{\circ}$ (+0.25 V vs Ag/AgCl); and $Ru^{3+}$ typically exists in its oxidized state but can be readily and reversibly reduced near its $E^{\circ}$ (−0.2 V vs Ag/AgCl). A second expectation is that, if these two mediators are added into the buffer, then they should be capable of diffusing through the films to exchange electrons directly with the underlying electrode and thus oxidation and reduction currents should be observed in the CVs. The second control in Figure 1a is for a chitosan film (without clove) that was incubated in the presence of these two mediators. When the potential for this chitosan-coated electrode was cycled to oxidative voltages, a small oxidation peak current was observed near +0.27 V consistent with the expected Fc oxidation. Figure 1a shows that, when the potential for this chitosan-coated electrode was cycled to reductive voltages, a small reduction peak current was observed near −0.27 V consistent with the expected $Ru^{3+}$ reduction.

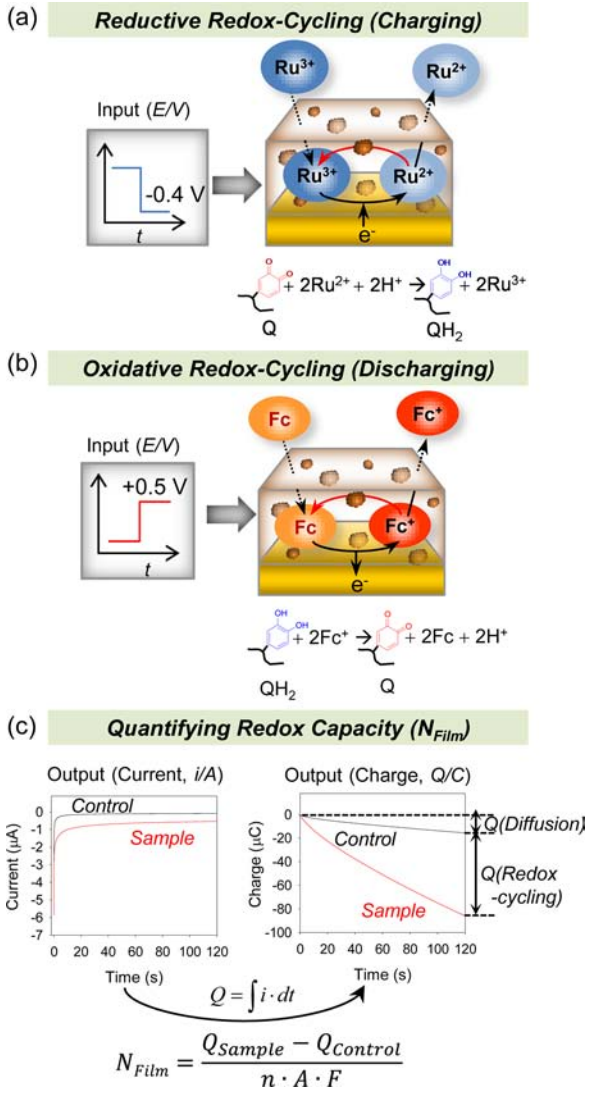
If the insoluble clove particles entrapped in the chitosan film can exchange electrons with the mediators, then a third expectation is that the oxidation and/or reduction currents observed in the CVs should be altered compared to those observed with the chitosan control film. The experimental sample in Figure 1a is the clove−chitosan film incubated in the presence of both Fc and $Ru^{3+}$ mediators. Considerable amplification of the Fc-mediated oxidation currents and the $Ru^{3+}$-mediated reduction currents are observed in Figure 1a. If the observed amplification of mediator currents is due to redox interactions with the entrapped clove particles, then a further expectation is that amplification should vary with the amount of entrapped clove. As expected, the CVs in Figure 1b show that amplification of the Fc-oxidation and $Ru^{3+}$-reduction currents increases with increasing amounts of clove incorporated into the films. These results provide initial evidence that the insoluble components of clove can undergo redox interactions with the soluble Fc and $Ru^{3+}$ mediators.

A possible mechanistic explanation for the above observations is provided in Scheme 1c that was proposed in earlier studies with catechol-modified chitosan films.[41] Specifically, the Fc mediator can diffuse from solution through the film and undergo oxidation at the electrode to generate $Fc^{+}$ species. The oxidized $Fc^{+}$ species can either diffuse out of the film into solution or undergo redox interactions with the insoluble clove incorporated in the film. The observed amplification of the oxidation currents suggests the clove donates electrons to the $Fc^{+}$ to regenerate the Fc species that can undergo oxidative redox cycling with the electrode. Similarly, Scheme 1c illustrates that amplification of the reducing currents is indicative of reductive redox cycling of the $Ru^{3+}$ mediator such that it accepts electrons at the electrode but donates these electrons to the insoluble clove. In previous studies, we proposed that the observed redox cycling involved a switching between the reduced catechols ($QH_2$) and oxidized *o*-quinones (Q) as illustrated by the reactions in Scheme 1c.[41] The thermodynamic plot in Scheme 1c shows that electron transfer occurs from more negative to more positive potentials.

**Switching the Films to Oxidized or Reduced States.** A convenient feature of electrochemical methods is that arbitrarily complex input potentials can be imposed on a sample. As illustrated in Scheme 2, we use step changes in the input potential in the presence of the Fc and $Ru^{3+}$ mediators to switch the redox state of the film. To switch the film to a reduced state, Scheme 2a shows that the potential is stepped to provide reducing conditions (−0.4 V vs Ag/AgCl). As illustrated by the schematic, this step change would drive the $Ru^{3+}$ reductive-redox-cycling reaction to mediate the transfer of electrons from the electrode to the sample (e.g., to quinone moieties). Over time, this reduction (or charging) step should "saturate" the sample with electrons. To switch the film to an oxidized state, Scheme 2b shows that the potential is stepped to an oxidative value (+0.5 V vs Ag/AgCl) to drive the Fc

dx.doi.org/10.1021/jf503479d | J. Agric. Food Chem. 2014, 62, 9760−9768

**Scheme 2. Step Changes in Input Potential Can Be Used to (a) Engage $Ru^{3+}$ Reductive Redox Cycling to Charge the Film with Electrons, (b) Engage Fc Oxidative Redox Cycling to Discharge the Film, and (c) Quantify Redox Capacity by Chronocoulometry (Impose a Constant Potential and Quantify Electron Transfer)**



oxidative-redox-cycling reaction to mediate electron transfer from the sample to the electrode (i.e., to discharge electrons from the sample).

**Quantifying Redox Capacity.** We used such step changes in input potential to quantify the redox capacity of the clove entrapped within the chitosan film. Initially, the film was charged with electrons using a reducing potential step (−0.4 V; 2 min). After charging, the potential was stepped to an oxidative value (+0.5 V; 2 min) to allow Fc to discharge the film. During discharging, the electrode current ($i$) was measured, and the electron transfer ($Q$) was calculated by integration of the measured current as illustrated in Scheme 2c (this method of imposing a constant potential and measuring $Q$ is referred to as chronocoulometry). The redox capacity of the film is determined by comparing an experimental sample (clove−chitosan film) against a control chitosan film. As illustrated in Scheme 2c, the charge transfer observed for the control chitosan film ($Q_{control}$) is attributed to the oxidation of the Fc mediator that diffuses from the bulk solution through the film to the electrode surface. The charge transfer for the clove−chitosan film ($Q_{sample}$) is attributed to both Fc diffusion and Fc redox cycling in the film. The difference between these values is used to calculate the redox capacity ($N_{film}$) of the film as illustrated in Scheme 2c.

Experimental results for samples prepared with differing levels of clove are shown in Figure 2a. As expected, the

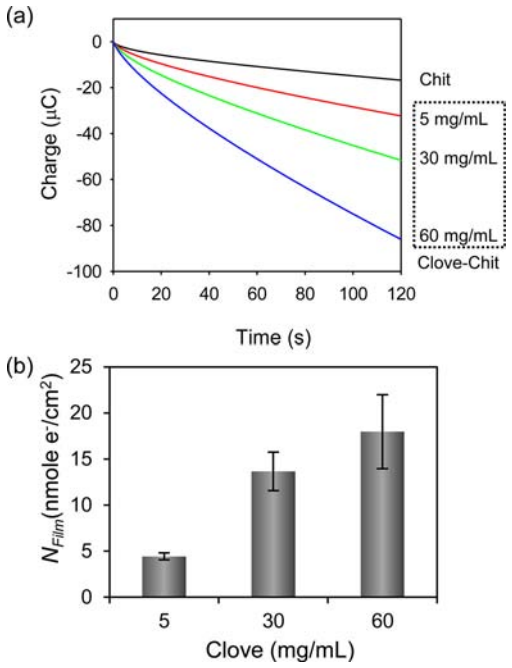


**Figure 2.** Electrochemical method (chronocoulometry) to quantify the redox capacity of the films ($N_{film}$). (a) Experimental results for the Fc-mediated oxidative charge transfer in response to a step input of oxidative potential (from an open circuit potential to +0.5 V vs Ag/AgCl that is maintained constant for 2 min). (b) The redox capacity for clove−chitosan films increases with increasing levels of insoluble clove.

observed charge transfer during this 2 min discharging step was greater when the sample contained more insoluble clove incorporated into the chitosan films. Figure 2b shows the calculated values of redox capacity and demonstrates that the insoluble clove possesses considerable redox capacity. To provide some estimate of the significance of these measured redox capacities, we consider a clove−chitosan film prepared by applying 20 $\mu$L of a 30 mg/mL solution to a working electrode area of 0.03 $cm^2$ to obtain ≈20 mg clove/$cm^2$. If the redox capacity is attributed to a two-electron transfer involving a quinone−catechol couple, then the measured value of 13 nmole $e^-/cm^2$ corresponds to ≈0.7 $\mu g/cm^2$ catechol. Thus, the observed redox capacity could be the result of ≈0.04 $\mu$g/mg catechol equivalence in this insoluble clove sample. It is important to emphasize that, while the above estimate is stoichiometric, redox cycling can act catalytically for transferring electrons from a reductant to an oxidant.[40]

There are two important caveats to the method for calculating $N_{film}$. First, particulate samples (e.g., insoluble clove) can be difficult to completely charge or discharge because of limitations in the abilities of the mediators to diffuse into and access redox-active moieties within the particles.[36] Thus, the measured redox capacities are operational measures

dx.doi.org/10.1021/jf503479d | J. Agric. Food Chem. 2014, 62, 9760−9768

useful for comparison but an underestimation of the true ability of the sample to accept, store, and donate electrons.

Second, our method probes a comparatively small window of redox potentials that is most relevant to the reversible oxidation and reduction of catecholic moieties. We believe this potential region is important given the redox gradients in the gut[42] and the ability of reversible redox cycling in this milieu to provide a means for redox interactions among the microbiota and the epithelium.[43] We do not expect these imposed potentials are sufficiently aggressive to oxidize monophenolics (e.g., eugenol is a major component of clove[39]) that can undergo irreversible reactions important to radical scavenging activities.[44] Again, while this narrow potential region allows us to focus on reversible redox interactions, we are underestimating the true redox capacity of a sample.

**Repeatable Redox Switching.** In addition to using cyclic voltammetry to provide initial evidence for redox activities (Scheme 1 and Figure 1) and chronocoulometry to provide semiquantitative measure of redox capacity (Scheme 2 and Figure 2), we are developing a third electrochemical method to assess the reversibility of these redox interactions. Specifically, we collected CVs for numerous oxidation and reduction cycles to observe the repeatability of redox cycling. In principle, this approach is analogous to approaches used in control theory in which oscillating inputs are used to impose to small perturbations to a system and the resulting oscillating outputs provide information on the response of the system to these inputs. If the response of the system is fully reversible, then the oscillating outputs are expected to be "steady"; the amplitude and frequency should remain constant over time (provided the oscillating input remained the same).

Experimentally, we tested film-coated electrodes (either chitosan or clove−chitosan films) in solutions containing both the Fc and $Ru^{3+}$ mediators with the imposed cyclic input potentials indicated in Figure 3a. Visual inspection of the output currents shows no noticeable changes over the eight cycles of this experiment and provides initial evidence that the output is steady. Steady output currents would indicate that the redox activities being probed by this method are fully reversible (i.e., the oxidation and reduction reactions of clove are reversible). A more subtle implication of steady outputs is that, during each cycle, the Fc-mediated oxidative redox cycling of clove is nearly balanced by the $Ru^{3+}$-mediated reductive redox-cycling reduction of clove.

To more rigorously analyze the results in Figure 3a, we focus on the current versus potential curves (i.e., the CVs) for each cycle as illustrated in Scheme 3. A CV from an individual cycle serves as the "signal" that is divided into four quadrants based on whether the currents are oxidizing or reducing and how the currents are assigned, to the oxidative redox cycler (e.g., Fc) or reductive redox cycler (e.g., $Ru^{3+}$). (We should note that the assignment of each quadrant to activities of a single chemical entity is useful for processing the information although such an assignment is a simplification of the underlying chemistries.) As indicated by the upper equation in Scheme 3b, the charge transfer for each quadrant is calculated by integration of the current for that quadrant ($Q = \int i\, dt$). If the redox reactions being detected by this method are fully reversible, then one expectation is that the charge-transfer values should remain constant over time. Figure 3b shows the calculated Q for the two largest quadrants of Scheme 3a were nearly constant for the eight cycles of the experiment.

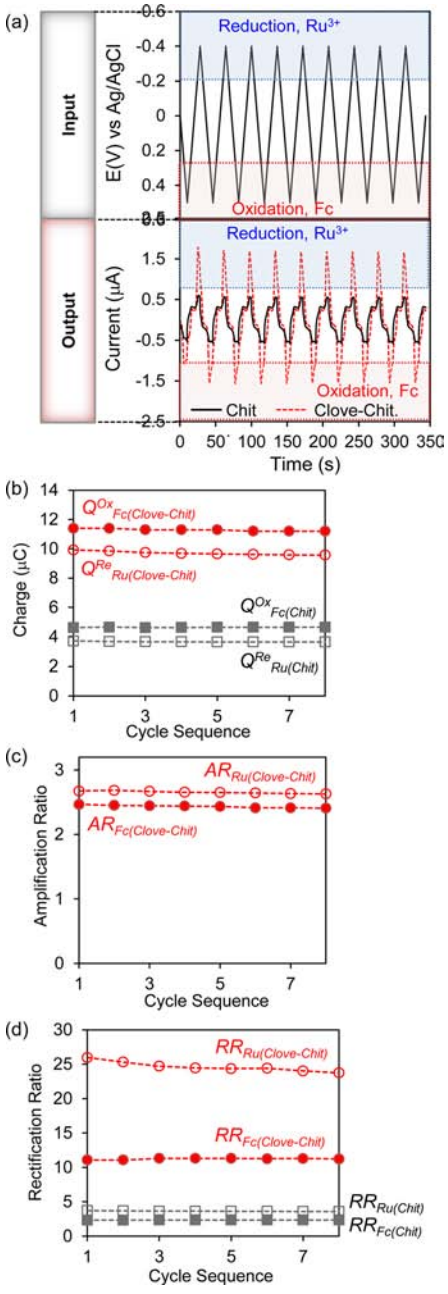

**Figure 3.** Repeatability of the redox cycling of clove with the Fc−$Ru^{3+}$ system (scan rate = 50 mV/s; 60 mg/mL clove). (a) The cyclic potential input allows the Fc and $Ru^{3+}$ mediators (50 $\mu$M each) to sequentially oxidize and reduce the clove (see Scheme 3 for signal analysis). (b) Charge transfer ($Q$) for Fc oxidation and $Ru^{3+}$ reduction with clove−chitosan remains relatively constant over the eight cycles tested. (c) Amplification ratios for Fc oxidation and $Ru^{3+}$ reduction with clove−chitosan exceed 2 and are nearly constant. (d) Rectification ratios for Fc oxidation and $Ru^{3+}$ reduction with clove−chitosan are large (>10) and nearly constant.

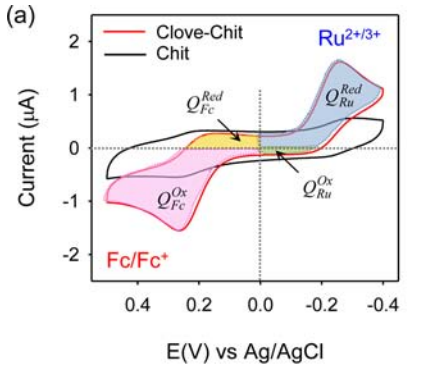
Previous studies have shown characteristic signatures of redox cycling emerge by considering the two sets of ratios indicated in Scheme 3b.[37] The amplification ratios (ARs) compare the charge transfer ($Q$) in a given quadrant for the clove−chitosan film to an equivalent $Q$ for the unmodified chitosan film (control). The AR contains information on redox cycling, since a film that can redox cycle (e.g., clove−chitosan) is expected to have an amplified output current compared to a

dx.doi.org/10.1021/jf503479d | J. Agric. Food Chem. 2014, 62, 9760−9768

**Scheme 3. Signal Analysis of Results from the Individual CV Cycles**[a]



(b)

**Charge Transfer**

$$Q = \int i\,dt = \int \frac{i}{v}\,dE \left( v = \frac{dE}{dt} = Scan\ rate \right)$$

**Amplification Ratio (AR)**

$$AR_{Fc} = \frac{(Q_{Fc}^{Ox})_{Clove-Chitosan}}{(Q_{Fc}^{Ox})_{Chitosan}}$$

$$AR_{Ru} = \frac{(Q_{Ru}^{Red})_{Clove-Chitosan}}{(Q_{Ru}^{Red})_{Chitosan}}$$

**Rectification Ratio (RR)**

$$RR_{Fc} = Q_{Fc}^{Ox} / Q_{Fc}^{Red}$$

$$RR_{Ru} = Q_{Ru}^{Red} / Q_{Ru}^{Ox}$$

[a]Scan rate = 50 mV/s; 60 mg/mL clove. (a) The "signal" for each cycle is analyzed by dividing the CVs into quadrants, calculating the charge transfer ($Q$) for each quadrant, and assigning these values to activities of a single mediator. (b) Calculation procedure for determining charge transfer ($Q$), amplification ratios (ARs), and rectification ratios (RRs).

relevant control film that cannot redox cycle (e.g., unmodified chitosan film). Figure 3c shows a 2−3-fold amplification of both Fc oxidation and $Ru^{3+}$ reduction currents for the clove−chitosan, and these ARs are nearly constant over the course of the eight cycles.

The second ratios in Scheme 3b are the rectification ratios (RRs) that are more subtle and consider how (a) electrode currents in the Fc region are primarily oxidative ($Fc^+$ reduction by redox cycling in the film decreases the amount of $Fc^+$ reduction occurring at the electrode) and (b) electrode currents in the $Ru^{3+}$ region are primarily reductive ($Ru^{2+}$ oxidation by redox cycling in the film decreases the amount of $Ru^{2+}$ oxidation occurring at the electrode). In essence, the RR considers the linkage between Fc-mediated oxidative redox cycling and $Ru^{3+}$-mediated reductive redox cycling; reductive redox cycling charges the sample with electrons that are subsequently removed during the oxidative redox-cycling portion of the cycle. Thus, samples that can sequentially engage these oxidative and reductive redox-cycling reactions would be expected to have large and constant RRs.[37] Figure 3d shows that large RRs are observed for the clove−chitosan film and again these ratios remain nearly constant over the course of the eight cycles.

In summary, the results in Figure 3 demonstrate that the electrochemical mediators Fc and $Ru^{3+}$ can repeatedly oxidize and reduce components in insoluble clove; that is, insoluble clove residue is redox-active and can be repeatedly and reversibly cycled between oxidized and reduced states.

**Antioxidant Behavior.** A method commonly used to examine antioxidant radical scavenging activities is to incubate a sample with the radical generator AAPH ($E^\circ$ = +0.8 V vs Ag/AgCl) and fluorescein. Fluorescein is readily damaged by the resulting free radical while a sample with free radical scavenging activities protects fluorescein. In the next study, we used this method to test whether the radical scavenging antioxidant properties of clove depended on whether it was poised in a reduced or oxidized state. As illustrated in Scheme 2, it is possible to use an electrochemical method to poise the film to either an oxidized or reduced state to investigate this question. In these experiments, we used a gold-coated silicon wafer as our electrode to allow a larger sample area to be probed (0.9 vs 0.03 $cm^2$ for the standard gold electrode of Scheme 1a) and to facilitate comparison with previous studies. To poise the sample in an oxidized or reduced state, the clove-containing film is incubated in the presence of both the Fc and $Ru^{3+}$ mediators. To reduce the sample (i.e., to charge it with electrons), a reducing potential is imposed to the underlying electrode (−0.4 V; 30 min) to allow $Ru^{3+}$ reductive redox cycling to transfer electrons from the electrode to the insoluble clove. To oxidize the sample (i.e., to discharge its electrons), an oxidizing potential was imposed to the underlying electrode (+0.5 V; 30 min) to allow Fc oxidative redox cycling to transfer electrons from the insoluble clove. (Note: we used longer charging and discharging times to facilitate comparison with previous studies[36] and repeated chronocoulometric determinations of $N_{film}$ under these conditions.) These films were then incubated with fluorescein and AAPH for 30 min after which the fluorescence of fluorescein was measured.

The first two entries in Figure 4a are for the negative and positive controls that show no or complete loss of fluorescence of fluorescein. The third entry in Figure 4a shows that chitosan (without insoluble clove) offers little protection from free radical damage. The final two entries in Figure 4a show that insoluble clove offers substantial antioxidant protection and the oxidized and reduced states of insoluble clove offer comparable protection. This result demonstrates the well-known antioxidant properties of clove but further demonstrates that this antioxidant property is not sensitive to whether clove is in an oxidized or reduced state. As mentioned above, the redox window used to poise clove in its oxidized or reduced state is likely too mild to alter the redox state of eugenol that is believed to be a major component of the antioxidant activity of clove.[39] This result suggests that at least some of the moieties that confer radical scavenging antioxidant activities (e.g., eugenol) are not responsible for the reversible redox activities being observed by our electrochemical method.

Figure 4b shows results for samples prepared with differing levels of clove and further indicates that the radical scavenging antioxidant properties are insensitive to redox state. Previous studies with other insoluble phenolic matrices (i.e., melanin) show comparable results: the radical scavenging antioxidant properties are insensitive to the redox state at least for the moieties changed by our electrochemical method.[36]

For comparison with results from studies with other phenolic materials,[36,40] we replot our antioxidant activities in terms of redox capacity as shown in Figure 4c. This normalization

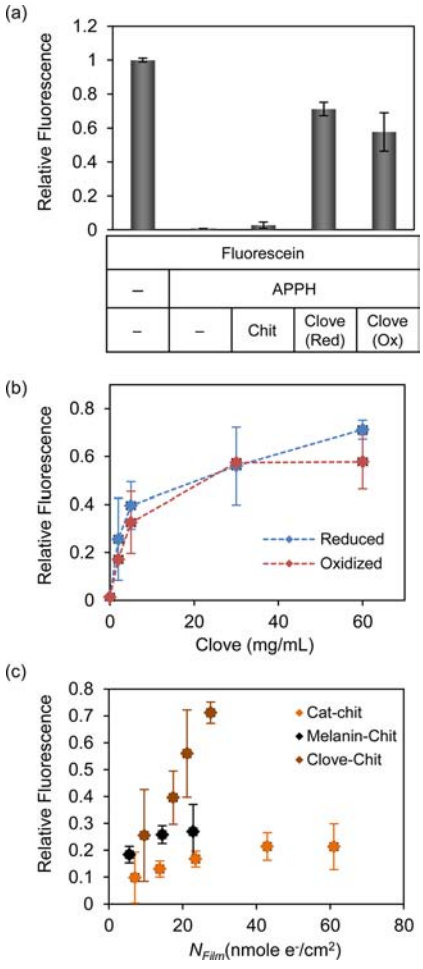


**Figure 4.** Radical scavenging antioxidant activities do not depend on the redox state of insoluble clove. (a) Films (60 mg/mL insoluble clove) poised in either oxidized or reduced states were observed to have similar abilities to protect fluorescein from free radical oxidative damage by APPH. (b) Films prepared with differing contents of insoluble clove have greater free radical scavenging antioxidant activities, and these activities are observed irrelevant to whether the films are poised in an oxidized or reduced state. (c) Comparison of antioxidant activities and redox capacities for chitosan films with either entrapped melanin or clove or chemically modified with catechol (data for melanin- and catechol-modified chitosan are reproduced from prior work).[36]

assesses how the antioxidant activities correlate to redox activities among various materials (note: the comparatively large error bars for the insoluble clove presumably reflects the particulate nature of these samples). While the incorporation of greater amounts of materials (e.g., phenolics) in the film increases both redox and antioxidant activities, the slopes of the curves vary among the different materials. The large slope for the clove–chitosan sample reflects its high antioxidant activities while the low slope for the catechol–chitosan sample indicates that its high redox activity is not accompanied by high radical scavenging antioxidant activities. Presumably, differences in the behavior between clove–chitosan and catechol–chitosan reflect differences in chemical components—that clove has different chemical moieties that confer radical scavenging antioxidant activity. The important observation is that antioxidant and redox activities are not exclusively linked to each other.

**Pro-oxidant Activity: $H_2O_2$ Generation.** In a final experiment, we prepared films on gold-coated silicon wafers (as described in Figure 4), poised the films in either an oxidized or a reduced state, exposed them to air, and examined their abilities to spontaneously generate $H_2O_2$. For these studies, the poised films were exposed to air-saturated water for 15 min, after which the solution was assayed for $H_2O_2$. Figure 5a shows

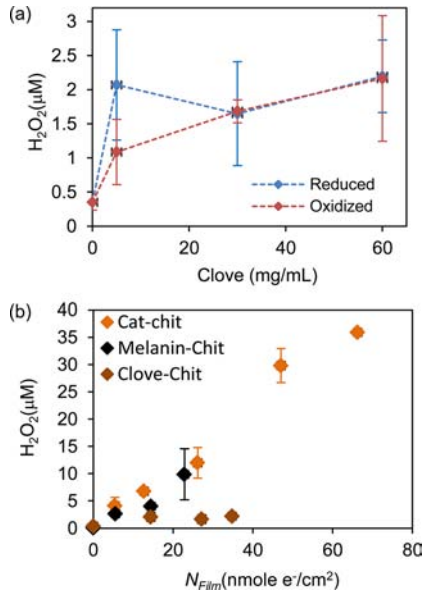

**Figure 5.** Pro-oxidant activities (as measured by $H_2O_2$ generation) for insoluble clove are low and do not depend on the redox state. (a) Clove–chitosan films poised in either an oxidized or a reduced state showed limited ability to generate $H_2O_2$ upon a 15 min exposure to air. (b) Comparison of $H_2O_2$ generation and redox capacities for chitosan films with either entrapped melanin or clove or chemically modified with catechol (data for melanin- and catechol-modified chitosan reproduced from prior work).[36]

relatively low levels of $H_2O_2$ were generated in these experiments and $H_2O_2$ generation was independent of whether samples were in an oxidized or reduced state. This result differs from previous observations with catechol-modified films or melanin-containing films that showed considerable $H_2O_2$-generating abilities but only when the films had been poised in a reduced state.[36,40]

Finally, we compare the $H_2O_2$ generation of clove–chitosan against results previously observed with other phenolic materials.[36,40] In comparison to melanin–chitosan and catechol–chitosan, Figure 5b shows that clove is unusual in that its reversible redox activity is not accompanied by an equivalent ability to generate $H_2O_2$. Presumably, this difference reflects differences in the chemical components in the insoluble clove sample. Possibly the high antioxidant and low pro-oxidant activities of clove may be important in putative health beneficial effects.

In conclusion, electrochemical methods were used to probe the redox activities of a model insoluble dietary antioxidant (i.e., clove), and we report two immediately interesting observations. First, we observed that insoluble clove possesses redox activities and can be rapidly and repeatedly switched between oxidized and reduced states. Recent literature indicates that considerable amounts of dietary antioxidant phenolics pass through the small intestine in an insoluble form and suggest that standard analytical methods may not fully account for their contribution

dx.doi.org/10.1021/jf503479d | J. Agric. Food Chem. 2014, 62, 9760–9768

to health benefits.[45−47] The observation that insoluble clove can undergo redox reactions with soluble mediators (electron shuttles) suggests that dietary antioxidants may participate in redox interactions in the intestine and thus affect redox homeostasis and health even in the absence of solubilization or absorption.[48] Second, we observed that insoluble clove (even when poised in a reduced state) has considerably less ability to generate $H_2O_2$ compared to other catechol-based matrices (e.g., melanin). This observation suggests that insoluble clove may possess little pro-oxidant activities although we should note that (i) we only measured the most stable ROS ($H_2O_2$) while other pro-oxidant species may have been generated; and (ii) we used relatively mild oxidation conditions to focus on reversible redox activities while the literature indicates that, under more aggressive oxidation conditions, eugenol can behave as a pro-oxidant.[49,50] Overall, we suggest that electrochemical methods may provide new and important opportunities to study redox homeostasis and oxidative stress.

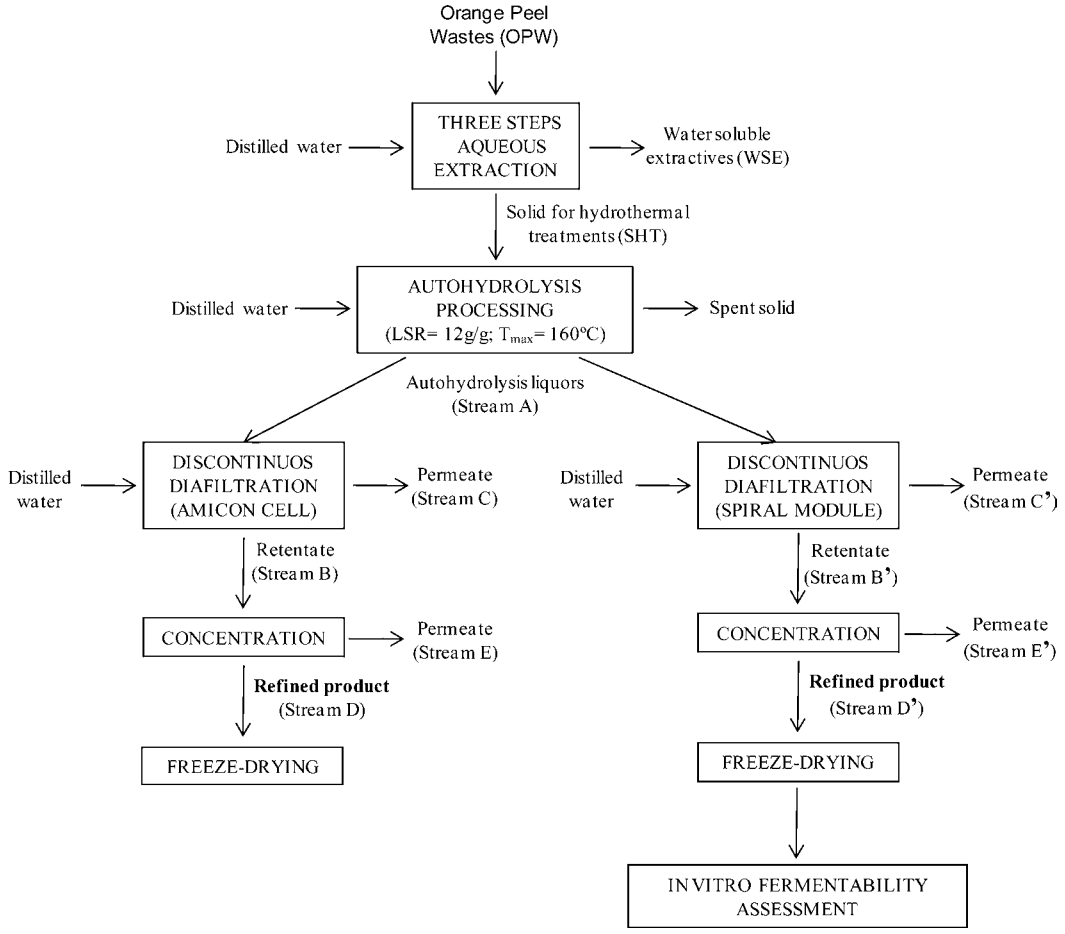

**Figure 1.** Scheme of the process.

and/or concentrating the mixtures of oligosaccharides (OS) generated by hydrothermolysis.[8,12−15]

On the other hand, orange peel wastes (OPW) is also used as raw material for pectin production, which is used in the food industry as an ingredient of drugs used to treat gastrointestinal disorders, diabetes, and high blood pressure or to reduce blood cholesterol.[16−18]

This work deals with (i) the manufacture of POS mixtures obtained from OPW by hydrothermal processing and their refining using membranes; (ii) characterization of the chemical composition and structure of POS; (iii) evaluation of the prebiotic potential of refined POS by in vitro fermentation with human fecal inocula; and (iv) comparison of the POS prebiotic properties with those of orange pectin and commercial FOS. The prebiotic potential of the various substrates was assessed by measuring the dynamics of selected microbial populations using the fluorescent in situ hybridization (FISH) technique, as well as by measuring gas generation, pH, and production of short-chain fatty acids (SCFAs).

## MATERIALS AND METHODS

**Raw Material.** OPW samples were kindly supplied by Indulleida S.A. (Lleida, Spain). To avoid variations in the composition of the raw material, all of the samples were mixed in a single lot, which was stored at −18 °C until use. When necessary, a portion of this lot was defrosted, milled, and used for analytical determinations or processing according to the methods listed below.

**Production and Purification of Pectin-Derived Oligosaccharides.** POS-containing liquors were obtained by OPW hydrothermal treatment under conditions reported as optimal (maximum temperature, 160 °C; severity factor of 288 min)[6] and purified by a two-step membrane process (discontinuous diafiltration and concentration) according to the scheme shown in Figure 1 and following the same method indicated by Gómez et al.[8] previously. The diafiltered solution was subjected to membrane concentration to reach a volume concentration ratio (VCR) of 3.60.

To assess the scaling of membrane purification, samples were purified in an experimental setup made up of the following elements: a spiral wound membrane (regenerated cellulose, 1 kDa, reference TFF6 from Millipore), a 30 L feed-tank with a coil for temperature control, a diaphragm pump (Hydra-cell, Wanner Engineering Inc.), two pressure gauges at the membrane inlet and outlet to measure the transmembrane pressure (TMP), a needle valve located after the membrane to achieve the desired TMP, and a flowmeter to measure the recirculation flow. Operation was performed at TMP = 4 bar. A total volume of 27 L (4.5 L of stream A and 22.5 L of distilled water) was treated in this setup. The refined product (stream D′) was freeze-dried and used as a carbon source for fermentation.

**Pectin Extraction.** OPW samples were extracted with water to reduce the free sugar content,[6] and pectin was obtained from the insoluble fraction by acid extraction as described Hwang et al.[19]

**POS Mixtures Fractionation by Semipreparative Anion Exchange Chromatography.** A freeze-dried sample from stream D was diluted with water (10.2 mL) to a solute content of 5 g/L, and the solution was loaded into a column (30 × 2.6 cm) containing DEAE-Sepharose CL 6B pre-equilibrated with distilled water. The system was eluted sequentially with distilled water, 0.1 M NaCl, 0.2 M NaCl, and 0.3 M NaCl (1 mL/min, 750 min per solution). Fractions of the eluate (9 mL) were collected and assayed for uronic acids. Four pools were prepared by mixing the appropriate fractions. NaCl-containing pools

were desalted and concentrated by nanofiltration through a 300 Da molecular weight cutoff in the Amicon cell before analysis.

**In Vitro Fermentation Assays.** Samples of refined POS (stream D′ in Figure 1) and orange pectin were assayed for in vitro fermentability according the method of Gullón et al.[15] FOS (Sigma) were included as a positive control, and medium without carbon source was used as negative control. Gas generation was measured by inserting a sterile needle into the butyl rubber septum of each tube, and the pressure buildup in the headspace was measured in milliliters. Cells were harvested by centrifugation (10000 rpm), and the supernatants were filtered through 0.20 mm cellulose acetate membranes (Sartorius stedim biotech, Germany) before HPLC analysis and pH measurement. Cell pellets were used for counting the selected bacterial groups by FISH. All additions and inoculations were carried out under anaerobic conditions, in a cabinet flushed with a gas stream containing 5% $H_2$, 10% $CO_2$, and 85% $N_2$.

*Fluorescent in Situ Hybridization.* Changes in bacterial populations were measured by FISH using synthetic oligonucleotide probes targeting specific regions of the 16S rRNA molecule, labeled with the fluorescent dye Cy3 (Sigma). Assays were performed for the following groups: *Bifidobacterium* (Bif164 probe), *Lactobacillus/Enterococcus* (Lab158 probe), *Bacteroides/Prevotella* (Bac303 probe), *Clostridium histolyticum* group clusters I and II (Chis150 probe), *Atopobium* cluster (Ato291 probe), *Clostridium coccoides/Eubacterium rectale* group (*Clostridium* clusters XIVa+b; Erec482 probe), *Faecalibacterium prausnitzii* and relatives (Fpra655 probe), and *Roseburia intestinalis* subcluster (Rint623 probe).[20,21] Total cell counts were performed by staining with 4′,6-diamidino-2-phenylindole (DAPI). At least 15 fields per sample were considered.

*Statistical Analysis.* Differences in bacterial populations and acid concentrations were tested using one-way analysis of variance (ANOVA) and Tukey's post hoc test. Differences were considered significant when $p < 0.05$.

**Enzymatic Degradation of Refined POS and Pectin.** Five milligrams of refined POS (stream D′) was dissolved into 1 mL of sodium acetate buffer (50 mM, pH 5.4) and incubated in shaken flasks at 40 °C sequentially with pectin lyase (PL) from *Aspergillus niger* for 6 h and endopolygalacturonase (PG) from *Kluyveromyces fragilis* for 18 h.[22] The amount of enzymes was selected to produce low-DP GalA oligomers. After incubation, enzymes were inactivated by heating at 100 °C for 5 min, the digest was centrifuged for 10 min at 19500*g*, and the supernatant was analyzed by high-performance anion exchange chromatography (HPAEC).

**Analytical Methods.** *Analysis of Liquors.* As a first approach, samples of streams A, B, D, B′, and D′ were centrifuged, filtered through 0.45 $\mu$m cellulose acetate membranes, and assayed for GalA, glucose, galactose, arabinose, and acetic acid by HPLC. Analyses were performed using a 1260 series Agilent chromatograph fitted with a refractive index detector and a Bio-Rad Aminex HPX- 87H column, which was eluted with 0.003 M $H_2SO_4$ at 50 °C at 0.6 mL/min. Galactose and arabinose peaks can also include traces of xylose and rhamnose, respectively. The content of nonvolatile compounds (NVC), other nonvolatile compounds (ONVC), and oligomers was calculated as described previously.[8]

To get a more complete information, sugar composition of the final POS stream D′ was also quantified by GC as alditol acetates and the uronic acids were determined colorimetrically with 3-phenylphenol using an automated analyzer.[23] The degree of methylesterification (DM) was determined by a colorimetric method[24] after saponification with 1 M NaOH at room temperature, whereas the degree of acetylation (DA) was analyzed using the Megazyme acetic acid kit.[22] Orange pectin samples were subjected to the same analyses.

*High-Performance Anion-Exchange Chromatography with Pulsed Amperometric Detection (HPAEC-PAD).* The neutral sugar constituents of POS pools (from stream D) isolated by column chromatography were determined by HPAEC-PAD after acid posthydrolysis (4 g sulfuric acid/100 g solution at 121 °C for 20 min).[8] Uronic acids were quantitated by using the method mentioned above (see results in Figure 2).

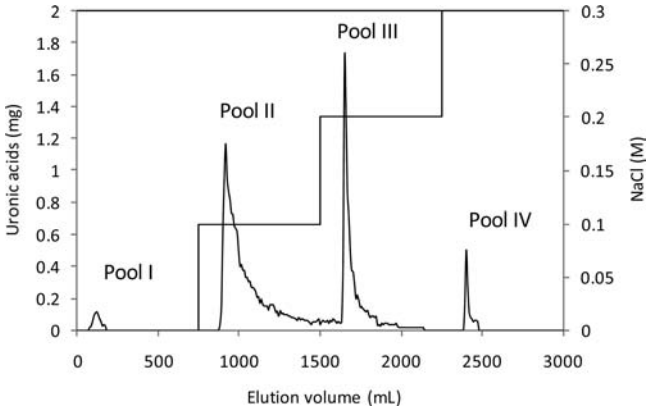

**Figure 2.** Elution profile of GalA (sample from stream D). Pools: eluted with distilled water (pool I), eluted with 0.1 M NaCl (pool II), eluted with 0.2 M NaCl (pool III), and eluted with 0.3 M NaCl (pool IV).

POS in the various process streams were analyzed by HPAEC using an ICS5000 HPAEC instrument (Dionex Corp., Sunnyvale, CA, USA) fitted with pulsed amperometric and diode array detectors (HPAEC-PAD/UV), with a CarboPac PA-1 column (2 mm i.d. × 250 mm) and a CarboPac PA guard column (2 mm i.d. × 25 mm). The flow rate was 0.3 mL/min, and the column temperature was 20 °C. The mobile phases were (A) 0.1 M NaOH and (B) 1 M NaOAc in 0.1 M NaOH. The elution profile was as follows: 0−15 min, 0−5% B; 15−60 min, 5−70% B; 60−65 min, 70−100% B; 65−70 min, 100% B; 70−70.1 min, 100−0% B; and finally column re-equilibration by 0% B from 70.1 to 85 min. Saturated (DP 2−5) and unsaturated (DP 2−6) OGalA and neutral (AraOS and GalOS) standards were used for identification and quantification. The quantification of higher DP OGalA was carried out using the equation

$$\frac{\text{PAD peak area}}{\text{GalA concn}} = k \times \text{DP}^n$$

which relates PAD peak area, GalA concentration, and DP being $k$ = 0.733 and $n$ = −1.06 for saturated OGalA and $k$ = 0.938 and $n$ = −1.42 for unsaturated OGalA.

*High-Performance Size Exclusion Chromatography (HPSEC).* Stream D′ and pectin samples were analyzed by HPSEC using an Ultimate 3000 system (Dionex). A set of four TSK-Gel super AW columns (Tosoh Bioscience, Tokyo, Japan) was used in series: one guard column (6 mm i.d. × 40 mm) and the three separation columns 4000, 3000, and 2500 (6 mm × 150 mm). The column temperature was set at 55 °C, and samples (20 $\mu$L, 2.5 mg/mL) were eluted with filtered 0.2 M $NaNO_3$ at a flow rate of 0.6 mL/min. Elution was monitored using a refractive index detector (Shodex RI 101; Showa Denko K.K., Kawasaki, Japan). Pectin standards were included (82000, 63900, and 51400 Da).

*Hydrophilic Interaction Liquid Chromatography (HILIC).* Pools II and III from stream D were diluted (1:1 v/v) with acetonitrile and analyzed using an Accela UHPLC system (Thermo Scientific, Waltham, MA, USA) coupled to an evaporative light scattering detector (Agilent 1200 series, Gen Tech Scientific Inc., Arcade, NY, USA) and an ESI-IT-MS-detector (LTQ Velos Pro ion trap MS, Thermo Scientific) as described previously by Remoroza et al.[25] Elution was performed at a flow rate of 300 $\mu$L/min and the column temperature was kept at 35 °C. The injection volume was 5 $\mu$L.

The elution profile used was slightly modified: 0−1 min, isocratic 80% B; 1−31 min, linear from 80 to 60% B; followed by column washing, 31−35 min, linear from 60 to 40% B; 35−36 min, 40% B; column re-equilibration; 36−36.1 min, linear from 40 to 80% B; and 36.1−45 min, 80% B.

*Matrix-Assisted Laser Desorption/Ionization-Time of Flight Mass Spectrometry (MALDI-TOF MS).* Pool I was diluted with Millipore water at 1 mg/mL and desalted with AG 50W-X8 resin (Bio-Rad Laboratories, Hercules, CA, USA) (a small amount with a spatula spoon to 50 uL of each sample and desalting was allowed for ∼30 min). After centrifugation for 10 min, 1 $\mu$L of the desalted sample solution was mixed

Table 1. Chemical Composition and Recovery Yields of Process Streams (Expressed as Kilograms per Kilogram NVC)[a]

| | | Amicon cell | | | spiral wound module | | |

on a MALDI plate (Bruker Daltonics, Bremen, Germany) with 1 μL of matrix solution (25 mg/mL 2,5-dihydroxy benzoic acid, Bruker Daltonics) in 50% (v/v) acetonitrile and dried under an air stream. MALDI-TOF MS analysis was performed using an Ultraflex workstation (Bruker Daltonics) equipped with a nitrogen laser of 337 nm, operated in positive mode with a laser power intensity of 60%. After a delayed extraction time of 350 ns, the ions were accelerated to a kinetic energy of 22 kV before detection. The mass spectrometer was calibrated with a mixture of maltodextrins (Avebe, Foxhol, The Netherlands; MD20; mass range $m/z$ 500−2000). The data were processed using the Bruker Daltonics flexAnalysis software.

*Determination of Carbohydrates and Fermentation Products in Cell-Free Supernatants.* Supernatants from the anaerobic culture tubes inoculated with fecal inocula were filtered through 0.2 μm cellulose acetate membranes and analyzed by HPLC for monosaccharides, OS, formate, lactate, succinate, and SCFA (acetic, propionic, and butyric acids) using the method described under (Analysis of Liquors).

## RESULTS AND DISCUSSION

**Production, Purification, and Chemical Characterization of POS.** The hydrothermal processing of OPW led to a POS-containing liquid phase, which was refined by membrane filtration to obtain a purified product with prebiotic potential. Figure 1 shows the general flow of the process, and Table 1 lists compositional and recovery data.

Stream D was enriched in OS (AraOS, 25.3%; OGalA, 53.4%; and GalOS, 16.5%) and presented a low content of nonvolatile, nonsaccharide compounds (1.7 g ONVC/100 g NVC), at high OS recovery yields (91.8−95.4%). In comparison, >90% of ONVC were removed. These results confirmed the suitability of the process considered in this study for manufacturing high-purity POS.

Figure 2 shows the elution profile of OGalA determined for the refined product (stream D). The samples corresponding to the four main peaks were combined in four pools (I−IV), obtained by elution with distilled water and a stepwise NaCl gradient. Table 2 shows the monomer composition of the various samples. Pool I contained 94.6% of neutral oligomers, whereas other pools were characterized by high contents of acidic oligomers (especially pool II, with about 85% GalA present). The presence of oligomer compounds in pools I−III was confirmed by HPSEC analysis (data not shown). Pools II and III accounted for 40.2 and 29.3%, respectively, of the refined product (stream D), whereas pool IV was of minor importance in quantitative terms (5.1%).

Table 2. Yields and Compositions of Pools of the Refined Product in Stream D

| | pool I | pool II | pool III | pool IV | refined product (stream D) |
|---|---|---|---|---|---|
| yield[a] (%) | 26.1 | 40.2 | 29.3 | 5.1 | |
| monomer composition (%) | | | | | |
| rhamnose | 1.36 | 1.30 | 4.27 | 6.89 | 2.4 |
| arabinose | 65.21 | 5.21 | 7.31 | 6.88 | 23.2 |
| galactose | 20.41 | 6.99 | 18.28 | 10.88 | 14.9 |
| glucose | 3.12 | 0.19 | 0.06 | 0.17 | 1.2 |
| xylose | 4.47 | 0.98 | 0.79 | 2.74 | 1.8 |
| acetic acid | 0.00 | 0.43 | 1.10 | 15.89 | 1.3 |
| galacturonic acid | 5.43 | 84.91 | 68.18 | 56.54 | 54.5 |

[a]Yield expressed as mg saccharides/100 mg refined product applied to column.

As expected, arabinose was the major component of pool I (65.2%), followed by galactose (20.4%). Rhamnose accounted for 6.89 wt % of pool IV, in comparison with 1.36 and 1.30 wt % for pools I and II, respectively.

Additional information on the structure and molar mass distribution of pools I, II, and III was obtained by HPAEC-PAD analysis (pool IV was not analyzed because of its low relative abundance). In agreement with the compositional data in Table 2, the elution profiles in Figure 3 confirmed the presence of both AraOS of DP 4−11 (and higher but showing minor response areas) and several types of GalOS (DP > 5) in pool I as identified by available standards. Pools II and III showed rather similar elution profiles (but with different relative responses, being higher in pool II), characterized by the presence of both saturated and unsaturated OGalA of DP 2−12. As reported previously,[8,26] the explanation of finding similar peaks in both chromatograms could be related to the DM; its value affects the order of elution in a DEAE-Sepharose CL 6B column. In fact, the average DM was higher for oligomers in pool II than in pool III (65.4 vs 59.3%). However, other different compounds could be present in both pools; HPSEC profiles (data not shown) demonstrated the presence of higher molecular weight compounds in pool III.

Additional information for pools II and III was obtained by HILIC-ELSD-MS. Figure 4 shows the HILIC chromatograms. The major peaks in pool II corresponded to $GalA_4Me$ ($4^{10}$), $UGalA_7Me_3$ ($U7^{30}$), $GalA_8Me_4$ ($8^{40}$), and $GalA_8Me_3$ ($8^{30}$),

whereas $GalA_2$ ($2^{00}$), $GalA_3Me$ ($3^{10}$), $GalA_4Me_2$ ($4^{20}$), $UGalA_5Me_2$ ($U5^{20}$), $UGalA_7Me_4$ ($U7^{40}$), and $GalA_{12}Me_6$ ($12^{60}$) appeared in minor amounts. Pool III contained some of these components, together with $GalA_3$ ($3^{00}$) and $UGalA_9Me$ ($U9^{10}$).

The components of pool I were characterized by MALDI-TOF MS. Figure 5 illustrates the structure of neutral oligosaccharides. High-intensity signals appeared at intervals of 132 $m/z$ units, corresponding to pentose moieties. On the basis of the compositional data in Table 2, it can be inferred that these oligomers correspond to AraOS with DP in the range of 3−21. In addition, lower signals separated by 162 $m/z$ units (corresponding to hexose units) also appeared, confirming the presence of DP 5−12 oligomers mainly made up of galactose.

The use of an Amicon module has an important drawback: its low capacity to produce sufficient amounts of refined product to carry out extensive in vitro and/or in vivo studies on their biological properties or to commercialize it. Therefore, in both situations, a scaleup is needed and, in this work, a spiral wound module was employed (see details under Production and Purification of Pectin-Derived Oligosaccharides).

The POS obtained with the spiral wound membrane (stream D′) contained 89.4 wt % of oligosaccharides (excluding GlcOS), a value in the range reported for commercial prebiotics and in agreement with reported results.[8] Figure 6A shows the HPSEC response for both pectin and stream D′, which presented a wide DP range. Because of this, a sample of POS was subjected to enzymatic degradation with PL and PG. Figure 6B shows the HPAEC chromatogram determined for the hydrolyzed sample. Using both saturated (DP 2−5) and unsaturated (DP 2−6) OGalA standards and the equation mentioned under HPAEC-PAD, in the sample from the D′ stream just 22.31% of the total GalA could be quantified as oligomers with DP ≤ 12, in comparison with 83.90% in the enzymatically hydrolyzed sample. Therefore, >61% of OGalA showed a DP > 12.

In conclusion, AraOS (DP 3-21), GalOS (DP 5−12), and OGalA (DP 2−12, with variable DM) were identified in POS mixtures, in which long-chain products are also present.

**In Vitro Fermentability of POS from OPW.** To evaluate the prebiotic potential of the refined POS contained in stream D′, a comparative in vitro fermentability study was carried out. FOS (which is accepted as the "gold standard" of a prebiotic ingredient) and orange pectin were also employed as fermentation substrates. The effects of the various substrates on the metabolic activity and on the dynamics of the microbial populations were studied in media inoculated with human fecal samples from three healthy adult volunteers (donors A, B, and C).

Figure 7 shows the concentration profiles determined for the various types of OS, which showed the following relative susceptibility to fermentation: GlcOS > GalOS > AraOS > OGalA. During the first 5 h of fermentation, the concentration of GalOS dropped markedly to reach about 50% of the initial value. Oppositely, OGalA presented an almost flat profile in the first hours of fermentation. GlcOS were almost completely consumed after 10 h, whereas the concentrations of GalOS, AraOS, and OGalA decreased to 12, 16, and 33% of the respective initial amounts. Some variability was observed in the data from individual donors: for example, the media inoculated with samples from donor B presented a lower fermentation rate for all of the considered substrates (data not shown).

GalOS, AraOS, and OGalA were progressively consumed: the concentrations were reduced to 8 and 5% of the initial values after 18 and 24 h, respectively. The observed OS consumption pattern was in agreement with reported results.[15] The slow assimilation kinetics of POS suggests that fermentation of these OS in humans may proceed (at least, in part) in the distal part of the

colon, where protein fermentation results in the production of potentially harmful compounds such as ammonia, phenol, indols, thiols, amines, and sulfides. Increased SCFA production in the distal colon is expected to result in protective effects.[27]

The chemical structure of oligosaccharides (defined by degree of polymerization, sugar composition, type of linkages, or degree of esterification) is influential in the fermentation rate,[28] becausse defined species and strains of microorganisms show predilection

dx.doi.org/10.1021/jf503475b | J. Agric. Food Chem. 2014, 62, 9769−9782

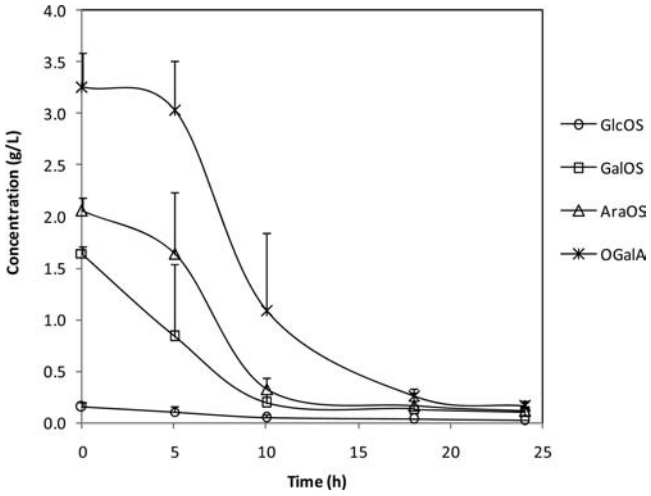

**Figure 7.** Concentration profiles obtained in the in vitro fermentation of the various substrates.

for defined substrates.[29] Fermentation clearly resulted in microbial growth and formation of lactate, gas, SFCA, and other organic acids. Gas production was similar in experiments with POS and FOS (data not shown), with a maximum accumulated production of 22 mL total gas after 48 h. Hernandez-Hernandez et al.[30] and Sarbini et al.[31] also reported on gas generation upon fermentation, which (if excessive) may become an undesirable side effect of prebiotic ingestion.

*Effects on the Microbial Populations.* Table 4 lists the results of bacterial counts corresponding to the various fermentation experiments.

*(a) Total Bacteria (DAPI).* There is strong evidence that the colonic fermentation of prebiotics is influential in the gut function. Fermentation results in increased bacterial mass, increased stool weight (by osmotic water binding), increased stool frequency, and softer stools.[32] The data in Table 4 show that the total cell counts increased markedly with time in media containing suitable carbon sources. In the control experiment, bacterial growth was observed just in the first 5 h of fermentation. In media containing FOS, POS, and pectin, the total cell counts increased by factors of 27−38, with no significant differences among them ($p > 0.05$). This finding is in agreement with data reported for experiments using neutral oligomers and polymers, as well as OGalA and PGalA, as carbon sources.[29]

Lactobacilli, bifidobacteria, and eubacteria are considered to cause health-promoting functions on host health such as inhibition of growth of exogenous and/or harmful bacteria and stimulation of inmune functions and synthesis of vitamins. Clostridia are mainly harmful bacteria, whereas enterococci, bacteroides, and streptococci may cause positive or harmful effects,[33] making individual assessments on the growth pattern of representative bacterial groups necessary.

*(b) Bifidobacterium Genus (Bif164 Probe).* Increased proportions of bifidobacteria and lactobacilli (which are able to convert carbohydrates into acids and generally lack toxicity)[32] are thought to be associated with healthier microbial compositions. The data in Table 4 confirmed a preferential growth of bifidobacteria on the various cultures, (including the control, although statistically significant differences were observed with media containing suitable carbon sources).

In cultures with FOS, orange pectin, and POS, the bifidobacteria counts increased after 24 h by a similar factor (30 on average), confirming the bifidogenic properties of all substrates. This finding is in agreement with the results reported using FOS, apple pectin, and POS derived from apple pectin.[9] The ratio between the counts of bifidobacteria and total cells (expressed as percent) was fairly constant (11.8% at the beginning of the experiment and 11.3% on average during fermentation). The results determined for FOS are in agreement with the data from Onumpai et al.[29] The same authors reported on the inability of acid oligomers to promote bifidobacteria growth, whereas Gullón et al.[15] found that pure bifidobacteria cultures can assimilate neutral OS, but not OGalA. In fact, bifidobacteria can degrade a variety of arabinose and galactose polysaccharides and oligosaccharides.[29] On this basis, the growth of bifidobacteria on POS is preferentially ascribed to utilization of the neutral constituents of oligomers, which account for about 40% of the total. This idea is in agreement with the profiles determined for neutral sugar consumption and relative increase in bifidobaceria counts: both of them took place mainly in the first 5 h or fermentation, a period in which OGalA were scarcely assimilated (see Figure 7). However, other factors (such as structural features of the substrate and individual differences among donors) may also be influential. In a related study, Leijdekkers et al.[34] did not found a clear bifidogenic effect in experiments with POS from sugar beet pulp containing GalOS, AraOS, and mixtures of acidic oligosaccharides (mainly made up of rhamnogalacturonan and homogalacturonan oligosaccharides distinct from the classes of sugar beet POS used previously for in vitro fermentation studies).

*(c) Lactobacillus−Enterococcus Group (Lab158 Probe).* The counts increased upon fermentation of the various substrates, which behave differently. Progressive increases in numbers were observed during fermentations in cultures with pectin and FOS, whereas no significant increases were observed after 5 h in cultures containing POS. This finding is in agreement with the data reported for POS derived from apple.[9] After 24 h of fermentation, the *Lactobacillus−Enterococcus* numbers increased by factors of 76 and 93 in cultures containing FOS and POS, respectively, whereas less marked effects were observed in pectin-containing media (in which the counts increased by a factor of 52). In related studies, Chen et al.[9] reported on the ability of apple-derived POS (sugar composition: GalA, 29.6% w/w; Ara, 18.4%; Gal, 21.1%; Xyl, 8.4%) and FOS for promoting *Lactobacillus* growth, whereas significant effects of inulin and GalOS on *Lactobacillus* growth were also reported.[29] In this latter study, oligorhamnogalacturonides and DP 5 OGalA were found to exert just transient effects. FOS and POS promoted a selective growth of the *Lactobacillus−Enterococcus* group with respect to total cells, increasing its relative proportion from 6.8% at the beginning of fermentations up to 16.2% after 24 h. Considering as a whole the counts of healthy bacteria (*Bifidobacteria* and *Lactobacillus−Enterococcus*), POS and FOS boosted the growth from 18.5 to 27%, whereas the effect of pectin was poorer (accounting for 19.2% of total counts after 24 h).

*(d) Bacteroides−Prevotella Group (Bac303 Probe).* The genus *Bacteroides* is part of the phylum Bacteroidetes, which together with Firmicutes account for about 90% of the human intestinal microbiota. *Bacteroides* may ferment carbohydrates into acetic acid and propionic acid. This latter is considered as a healthy compound that can inhibit the synthesis of cholesterol. However, *Bacteroides* can also produce harmful reactions (for example, amine generation from proteins). From the point of view of this study, this group is important because *Bacteroides* are major carbohydrate-degrading organisms in the gut, which can

[a]Standard error is shown in parentheses ($n$ = 3). Different letters for the same probe and same substrate indicate significant differences (Tukey's test, $p < 0.05$) between different time points (no letter = a). Different numbers in the same row indicate significant differences between different substrates (no number = 1). [b]DAPI, 4′,6-diamidino-2-phenylindole; Bif164, *Bifidobacterium*; Lab158, *Lactobacillus/Enterococcus*; Bac303, *Bacteroides/Prevotella*; Chis150, *Clostridium histolyticum* clusters I and II; Ato291, *Atopobium*; Erec482, *Clostridium coccoides/Eubacterium rectale*; Fpra655, *Faecalibacterium prausnitzii*; Rint623, *Roseburia intestinalis*.

degrade pectins.[29] According to the results in Table 4, the population of *Bacteroides*−*Prevotella* in media containing the considered substrates increased significantly and progressively with time. The highest increase in counts (by a factor of 32) was determined for pectin, even if the differences among substrates were not significant after 24 h. Onumpai et al.[29] reported on the ability of this group to grow on a number of acid substrates (PGalA, methylated pectin, DP 9 OGalA, and methylated OGalA) and compounds with neutral chains (including GalOS, AraOS, the corresponding polymers and inulin). In relative terms, the population accounted for a fairly constant fraction of total counts (15.5% at the beginning of experiments and 14.5% after 24 h).

*(e) Clostridium histolyticum Group Clusters I and II (Chis150 Probe).* The data in Table 4 show that proliferation of this group was significant in cultures with FOS during the first

dx.doi.org/10.1021/jf503475b | J. Agric. Food Chem. 2014, 62, 9769−9782

5 h of fermentation, whereas a progressive evolution was observed in media containing pectin or POS. The data obtained after 10 and 24 h revealed no significant count differences between POS and FOS cultures, whereas pectin led to the highest result. In a related study, Salazar et al.[20] reported increased counts of these clusters after 10 h in media containing inulin, whereas significant increases from PGalA (but not from acidic or neutral oligomers and polymers of neutral sugars) have been reported.[29]

Concerning the ratio between the number of this group of cells and the total counts, scarce effects were observed after 24 h in media containing FOS and POS, whereas a higher value was achieved using pectin as a carbon source. From the point of view of the biological effects, this means that the behavior observed for POS is more favorable than the one determined for pectin; in general, clostridia are considered as harmful bacteria.[33]

*(f) Atopobium Cluster (Ato291 Probe).* The *Atopobium* cluster corresponds to a dominant group of human bacteria, but its role is still undefined.[35] Increased counts of the *Atopobium* cluster upon FOS ingestion were reported.[36] In this work, significant population increases were observed after 5 h. After 10 or 24 h, no significant differences among substrates were found, even if the highest values corresponded to POS cultures. The average factor for population increase after 24 h was 21. In relative terms, the ratio with respect to total counts decreased upon fermentation from 0.105 to 0.062.

The results achieved with the major bacterial groups able to produce butyrate from polysaccharides (or from acetic acid or lactic acid by a cross-feeding mechanism) are listed in the next paragraphs. Many investigations have illustrated the beneficial role of butyrate on gut health.[37−39]

*(g) Clostridium coccoides/Eubacterium rectale Group (Clostridium Clusters XIVa+b, Erec482 Probe).* Bacteria of cluster XIVa are considered beneficial because of their ability to produce butyrate from acetate, lactate, and polysaccharides.[28] The data in Table 4 show significant increases in counts during the first 5 h of fermentation, with no significant differences among the various carbon sources. After 24 h, the number of bacteria belonging to this group increased in media containing FOS, POS, or pectin by an average factor of 26. Their ratio with respect to the total counts increased from 0.138 to 0.175 after 10 h, with a further decrease (0.105 after 24 h). Onumpai et al.[29] reported increases in the counts of this type of bacteria in fermentation using AraOS as substrates.

*(h) Part of Clostridium Cluster IV (Faecalibacterium prausnitzii Group, Fpra655 Probe).* *F. prausnitzii* belongs to the *Clostridium* IV cluster, which includes important butyrogenic bacteria, a deficit of which has been related to the recurrence of imflammatory bowel disease and to ulcerative colitis. Significant increases in counts were observed in the period 0−5 h, with variations of minor importance at longer fermentation times. No significant differences among substrates were observed. On average, the numbers of this group of bacteria increased by a factor of 20 upon fermentation, and their ratio with respect to the total counts decreased from 0.138 at the beginning to 0.105 after 10 h and to 0.083 after 24 h. Literature data indicated increased counts of this group when methylated OGalA was fermented and slight decreases when OGalA with DP 5−9 were grown,[29] whereas important increases of *Faecalibacterium* in experiments using POS from sugar beet as a carbon source have also been reported.[34]

*(i) Roseburia intestinalis (Rint623 Probe).* *R. intestinalis* produces butyric acid (a desired and healthy product as it is the major source of energy of epithelial cells and can contribute to the cell proliferation and differentiation) of which counts increased during the first 5 h in experiments with POS and pectin and in the first 10 h in experiments with FOS. The data in Table 4 confirm that the population increased upon fermentation by a factor of 23 as an average for the three substrates, whereas the count ratio respect to total cells decreased from 0.098 to 0.609 upon fermentation.

Finally, it is worth remarking that the sum of the counts of the individual groups determined in this work accounted for 96.2−98.5% of the total cell counts determined by DAPI.

*Effects of the Substrate on Organic Acid Production and pH.* Table 5 lists data concerning SCFA production (averages and standard errors) during the fermentation of the various types of media. All substrates were utilized, causing pH drops that were more marked in experiments with POS and FOS (1.9 and 2.2 units, respectively) than in assays with pectin (pH drop = 1.5 units). The higher pH decrease observed in FOS cultures is in agreement with literature data[34] and is ascribed to the comparatively high lactic acid concentration (a compound of comparatively low $pK_a$). The fairly constant pH observed in the control is ascribed to the limited SCFA production and to the possible neutralization with ammonia produced from protein.

Scarce production of succinic acid was observed, with maximal concentrations (in the range of 1.25−2.2 mM) that were achieved at short fermentation times.

The lactic acid concentration profile showed differences for individual substrates and donors. Low lactic acid concentrations were achieved in the control and in assays with POS and pectin, whereas progressively growing concentrations (up to 22−24 mM in assays with inocula from donors B and C or 14 mM for inocula from donor A) were achieved in FOS cultures. Dependence of the concentration patterns on the considered donor have been reported using inulin as a substrate.[20] The limited lactate concentrations in cultures containing POS or pectin are in agreement with previous studies,[4,15] and its depletion can be due to utilization by other common intestinal bacteria acting as an intermediary metabolite for the formation of additional acetate, propionate, and/or butyrate.[40,41]

Formic acid is an intermediary product mainly produced by bifidobacteria. The data in Table 5 show scarce formic acid production in the control experiment, but significant concentrations in the case of the cultures with FOS, POS, and pectin. Although the cultures with the three carbon sources led to different formic acid concentrations, the observed variations were not statistically significant. The highest final concentrations were achieved in cultures with FOS and pectin, whereas the concentration profiles depended on the considered donor. In experiments with FOS, the cultures with inocula from the various donors led to profiles of similar shape (a fast increase in formic acid concentration followed by a plateau), but the highest final concentration (28 mM) corresponded to the inocula from donor. In experiments with pectin, the maximum concentrations were achieved after 18 h, but the corresponding values were strongly affected by the donor. The fermentation pattern of POS-containing media was similar in media inoculated with samples from donors A and B (steadily increasing concentrations up to a final value in the range of 8.5−13.8 mM), but different from the media made with samples from donor C (in which the concentration reached a maximum value after 10 h and then dropped markedly).

Figure 8 lists data concerning the production of SCFA (acetate, propionate, and butyrate). For a given substrate, the profiles of the total SCFA concentration (including acetate, propionate, and butyrate) were similar in experiments with

[a]Starting concentrations of the test substrates were 1% (w/v). Standard error is shown in parentheses ($n$ = 3). Different letters indicate significant differences ($P < 0.05$) for the same acid and time (no letter = a). Substrates were compared for seven points of fermentation (0, 5, 10, 18, 24, 32, and 48 h).

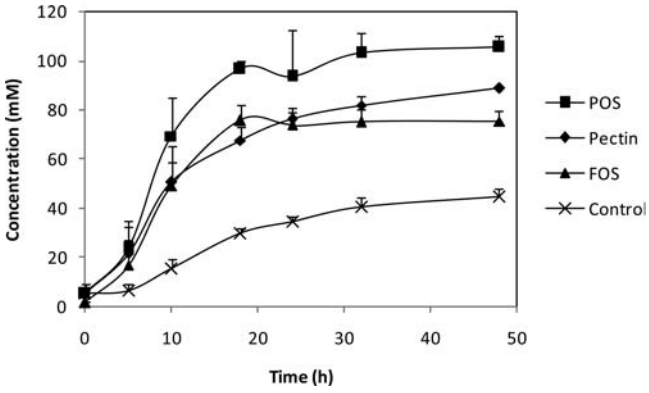

**Figure 8.** Time course of total SCFA production during fermentations.

inocula from the various donors (data not shown). In experiments with FOS, the highest concentration was achieved after 18 h, whereas the assays with pectin and POS showed slower kinetics. The highest SCFA concentration after 48 h (105.3 mM) was obtained using POS, in comparison with 88.6 mM using pectin and 75.1 mM using FOS. Leijdekkers et al.[34] also found higher SCFA concentrations in experiments with POS than with FOS.

Even though the total SCFA concentration profiles presented similar patterns in assays with inocula from the various donors, the product distribution depended on the considered substrate. Acetate was the major individual acid in all cases and was generated mainly in the period 0−18 h, reaching significantly different concentrations in assays with each of the three substrates. The highest concentrations (78.07 mM from POS, 60.72 mM from pectin, and 39.22 mM from FOS) were achieved after 48 h.

A number of studies have confirmed the beneficial effects of butyrate and propionate in gut health. As a consequence, it is important to identify and characterize prebiotics promoting the growth of bacterial groups able to produce butyrate and propionate selectively.

Propionate is mainly produced by *Bacteroides* and other bacteria with the *Clostridium* IX cluster. Propionic acid plays a significant role in lipid metabolism, and the combination of high propionate levels with low acetate/propionate ratios is indicative of hypolipidemic effects.[42] The data in Table 5 show similar propionate concentration profiles in experiments with POS and FOS, whereas the experiments with pectin led to the highest concentration after 48 h, which was statistically different from the ones obtained from POS and FOS. Both the kinetics and the maximum concentrations depended on the considered donor. In general, the media inoculated with samples from donor A exhibited slower kinetics and achieved lower propionate concentrations than in the rest of the cases.

Butyrate, mainly produced by eubacteria and some clostridia, is the major energy source of colonic epithelial cells and may have an impact on growth and cell differentiation. The differences in concentration achieved after 24 h in experiments with the three carbon sources were not significant. The general patterns of the butyrate concentration profiles were similar in experiments with POS, pectin, and FOS, but this latter substrate led to higher a maximum concentration (42 mM) in media inoculated with samples from donor A than in media made with samples from donors B and C (about 19 mM). High butyrate production from POS and FOS has also been reported.[34] In comparative terms, the mass concentration ratio butyrate/SCFA was 0.17 after 24 h, a result significantly higher than the ones reported for assays with POS (concentration ratios below 0.10).[29]

Acetate and butyrate were the major organic acids in POS and FOS fermentation, a finding in agreement with previous studies.[11,13,15] However, when pectin was used as a carbon source, the maximum propionate concentration was higher than the one of butyrate. On the basis of the data listed in Table 4 for the counts of the *Bacteroides*−*Prevotella* group, this finding is ascribed to the metabolic activity of bacteria belonging to the *Bacteroides* group, which are known to be able to produce propionate from carbohydrates[43] and to degrade pectins.[29]

**Conclusions.** POS were manufactured by hydrothermal treatment of orange peel wastes and purified using membranes to yield a refined product containing up to 90% of oligosaccharides. Its prebiotic potential was assessed by in vitro fermentation using human fecal inocula. For comparison, the same type of experimental work was performed using pectin and commercial FOS as carbon sources. The evolution of selected microbial populations was measured during fermentations by FISH. Gas generation, pH, and production of SCFA were also measured.

The various types of carbohydrates making part of the POS concentrates were utilized by microorganisms at different rates, the slowest reaction corresponding to OGalA. All of the tested groups of bacteria increased their populations during fermentation, but their relative proportions with respect to total counts were significantly different. POS boosted particularly the growth of lactobacilli, in a way that the ratio between the joint counts of lactobacilli and bifidobacteria and the total cell number increased from 0.17 to 0.27 upon fermentation. POS fermentation resulted in a remarkable generation of SCFA (maximum concentration = 105 mM after 48 h), with a concentration profile defined by the following sequence: acetate > butyrate > propionate. The same sequence was observed for FOS cultures, whereas pectin fermentation led to propionate concentrations higher than the ones of butyrate.

In general terms, fermentation of POS and FOS resulted in similar SCFA distributions, but the kinetics of acid generation was slower for POS, suggesting that they could be fermented (at least in part) in the distal part of the colon, where the associated healthy effects could be more important.

## ABBREVIATIONS USED

AcO = acetyl substituents in oligomers
AraOS = arabino-oligosaccharides
DAPI = 4′,6-diamidino-2-phenylindole
DA = degree of acetylation
DM = degree of methylation
DP = degree of polymerization

FISH = fluorescent in situ hybridization
FOS = fructo-oligosaccharides
GalA = galacturonic acid
GalOS = galacto-oligosaccharides
GlcOS = gluco-oligosaccharides
HILIC-ELSD MS = hydrophilic interaction liquid chromatography, evaporative light scattering detector mass spectrometry
HPAEC-PAD = high-performance anion exchange chromatography-pulsed amperometric detector
HPLC = high-performance liquid chromatography
HPSEC = high-performance size exclusion chromatography
MALDI-TOF = matrix-assisted laser desorption/ionization-time-of-flight
NVC = nonvolatile compounds
OGalA = oligogalacturonides
ONVC = other nonvolatile compounds
OPW = orange peel wastes
PG = endopolygalacturonase
PGalA = polygalacturonic acid
PL = pectin lyase
POS = pectic oligosaccharides
SCFA = short-chain fatty acids
TMP = transmembrane pressure
VCR = volume concentration ratio

regulate protein translation.[34] Because broiler chicks go through intensive protein synthesis during the growth, it is not only novel but also relevant to determine effects of the dietary microalgal biomass inclusion on their functional expression of signal proteins involved in the mTOR pathway.

Just as broiler chicks, weanling pigs grow at a fast rate with intensive protein metabolism.[35] Likewise, our previous research[13] showed that weanling pigs grew well with diets containing 7.5% DFA to replace corn and soybean meal, but not with 15% DFA replacing corn and soybean meal or 7.5% DFA replacing soybean meal. Subsequently, the same question arose as to whether weanling pigs could tolerate higher inclusion levels of the other apparently "superior" types of defatted microalgal biomass. However, there were different considerations of the pig experiment from those of the broilers. Comparatively, effects of the added microalgal biomass on plasma biochemical measures of nutritional status including tartrate-resistant acid phosphatase (TRAP), alkaline phosphatase (AKP), and alanine aminotransferase (ALT)[8] were less certain than those in the broiler studies. Meanwhile, plasma urea nitrogen (PUN) and amino acid profiles are often used to estimate nutritional values of feed proteins.[36] Apparently, it is more difficult and expensive to sample tissues from pigs than from chicks to study the metabolic regulation of the full production cycle that is likely very different between weanling and finishing pigs.[37,38] Although various sources of NSPases are increasingly added into swine diets containing nonconventional ingredients,[39,40] the general notion remains that these enzymes are more consistently effective[41] in diets for poultry.

Therefore, we conducted two parallel pig and broiler experiments to determine nutritional and metabolic values of a newly acquired defatted green microalgal (DGM, *Desmodesmus* sp., Cellana, Kailua-Kona, HI, USA) biomass from biofuel research that contained 31.2% crude protein. The objective of the pig experiment (I) was to determine impacts of including 10% DGM and (or) 0.06% protease on growth performance and plasma levels of TRAP, AKP, ALT, urea nitrogen, uric acid, and amino acids. The objective of the chick experiment (II) was to determine impacts of including 15% DGM and (or) 0.06% protease or NSP enzymes on growth performance, plasma levels of uric acid and amino acids, and production of signal proteins related to the mTOR pathway in liver and muscle.

## MATERIALS AND METHODS

**Chemicals.** The nutrient composition of the DGM is presented in Table 1. Protease Ronozyme ProAct and NSPase mixture (50% Roxazyme G2, 40% Ronozyme A, and 10% Ronozyme WX) were obtained from DSM Nutritional Products Inc. (Parsippany, NJ, USA). Phthaldehyde complete solution reagent was purchased from Sigma-Aldrich (St. Louis, MO, USA). Kits for determining uric acid, urea nitrogen, and alanine aminotransferase (ALT) were obtained from Thermo Scientific, Inc. (Waltham, MA, USA). Rabbit-anti-$\beta$-actin (4967), rabbit-anti-mTOR (7C10), rabbit-antiphospho-mTOR (S2448), rabbit-anti-S6 (5G10), rabbit-antiphospho-S6 (S235/236), rabbit-anti-S6K1 (49D7), rabbit-antiphospho-S6K1 (T389), rabbit-antiphospho-4E-BP1 (S65), and rabbit-anti-eIF4E (C46H6) monoclonal antibodies were purchased from Cell Signaling Technology, Inc. (Danvers, MA, USA).

**Pig Experiment.** *Experimental Design, Growth Performance, and Blood Sample Collection.* All animal experimental procedures were approved by the Cornell University Institute Animal Care and Use Committee. Weanling Yorkshire × Hampshire × Landrace pigs ($n$ = 32) were allotted into one of four treatment groups in a 2 (DGM: 0 or 10%, on an "as is" basis) × 2 (ProAct: 0 or 0.06%) factorial arrangement ($n$ = 8 pigs per treatment). The experimental diet compositions are presented in Table 2. The inclusion rate of ProAct was based on our previous experiment.[5] All diets were formulated to meet the nutrient requirements of weanling pigs.[42] Pigs were housed in individual pens with a feeder and nipple water drinker. Appropriate feed was weighed out each morning to minimize the amount of spillage. Any spillage was collected and weighed the following morning prior to the addition of fresh feed. Individual pig weights were recorded biweekly for determination of body weight gain and feed conversion efficiency. Blood samples were collected biweekly from the anterior vena cava into heparinized tubes and kept on ice until analyses were completed on the same day.

**Table 1. Nutritional Composition of Defatted Green Marine Microalgal DGM (*Desmodesmus* sp.) Biomass[a]**

| nutrient | % "as is" | amino acid | % "as is" |
|---|---|---|---|
| dry matter | 96.0 | alanine | 2.27 |
| crude protein | 31.2 | arginine | 1.45 |
| crude fat | 1.50 | aspartic acid | 2.69 |
| acid detergent fiber | 15.4 | cysteine | 0.33 |
| neutral detergent fiber | 23.2 | glutamic acid | 2.93 |
| ash | 17.1 | glycine | 1.72 |
| calcium (Ca) | 0.33 | histidine | 0.50 |
| phosphorus (P) | 0.65 | hydroxylysine | 0.37 |
| sodium (Na) | 3.24 | hydroxyproline | 0.07 |
| potassium (K) | 0.89 | isoleucine | 1.10 |
| magnesium (Mg) | 0.63 | leucine | 2.29 |
| | | lysine | 1.61 |
| **mineral** | **mg/kg** | methionine | 0.48 |
| iron (Fe) | 1900 | ornithine | 0.04 |
| copper (Cu) | 16.0 | phenylalanine | 1.34 |
| manganese (Mn) | 154 | proline | 2.73 |
| zinc (Zn) | 34.0 | serine | 1.10 |
| molybdenum (Mo) | 2.4 | taurine | 0.02 |
| selenium (Se) | 0.12 | threonine | 1.26 |
| | | tryptophan | 0.43 |
| | | tyrosine | 1.01 |
| | | valine | 1.59 |

[a]Proximate analysis was carried out by Dairy One Coop Inc. (Ithaca, NY, USA), and amino acids were determined by the Agricultural Experiment Station Chemical Laboratories at the University of Missouri (Columbia, MO, USA).

*Plasma Biochemical Analyses.* Blood samples were centrifuged at 1500$g$ for 20 min to collect plasma. Plasma AKP activity was determined according to the method of Bowers and McComb.[43] Plasma TRAP activity was determined according to the method of Lau et al.[44] with a modification of pH to 5.8. Total plasma amino acid concentration was determined using a modified $o$-phthaldehyde (OPA) derivatization assay. Briefly, phthaldehyde complete reagent was added at equal volume to a plasma aliquot, vortexed, and read within 2 min at 340 nm on a 96-well plate reader (Biotek Instruments, Inc., Winooski, VT, USA). Plasma uric acid, urea nitrogen, and ALT were assayed using the above-described commercial kits.

**Broiler Experiment.** *Experimental Design, Growth Performance, and Sample Collection.* Ross 308 broiler chicks were received at 1 day of age and assigned to one of six treatment groups in a randomized complete block design. A 2 (DGM: 0 or 15%, on an "as is" basis) × 3 (enzyme: none, ProAct, and NSPase) factorial arrangement was used within each block. Each treatment consisted of five battery cages (five birds/cage), and each cage was considered a replicate. The compositions of the control and the DGM-containing diets are shown in Table 3. Both protease and NSPase were incorporated at 0.06% on the basis of our previous experiments.[5] Birds were housed within Petersime battery cages and allowed ad libitum access to feed and water. Birds were fed the starter diet from day 1 to day 21 and the grower diet from day 22 to day 42 (Table 3). All diets were formulated

[a]DGM, defatted green microalgal (*Desmodesmus* sp.) biomass (Cellana, Kailua-Kona, HI, USA) that contained 31.2% crude protein. [b]Vitamin and mineral premix supplied the following amounts (per kilogram of diet): vitamin A, 2200 IU; vitamin $D_3$, 220 IU; vitamin E, 16 IU; vitamin K, 0.5 mg; biotin, 0.05 mg; choline, 0.5 g; folacin, 0.3 mg; niacin, 15 mg; pantothenic acid, 10 mg; riboflavin, 3.5 mg; thiamin, 1 mg; vitamin $B_6$, 1.5 mg; vitamin $B_{12}$, 17.5 μg; Cu, 6 mg; I, 0.14 mg; Mn, 4 mg; Zn 100 mg; Se, 0.3 mg; Mg, 0.4 mg; and Fe, 80 mg. [c]Ronozyme ProAct (DSM Nutritional Products Inc., Parsippany, NJ, USA). Protease activity was measured in PROT units, where 1 unit is defined as the amount of enzyme that releases 1 μmol of *p*-nitroaniline from 1 μM substrate (Suc-Ala-Ala-Pro-Phe-*p*-nitroaniline) per minute at pH 9.0 and 37 °C. [d]Antibiotic additive (Tylan 10) contained tylosin (as tylosin phosphate) at 22 g/kg.

[a]Defatted green microalgal (*Desmodesmus* sp.) biomass (Cellana, Kailua-Kona, HI, USA) that contained 31.2% crude protein. [b]Provided (in mg//kg of diet): $CuSO_4 \cdot 5H_2O$, 31.42; KI, 0.046; $FeSO_4 \cdot 7H_2O$, 224.0; $MnSO_4 \cdot H_2O$, 61.54; $Na_2SeO_3$, 0.13; ZnO, 43.56; $Na_2MoO_4 \cdot 2H_2O$, 1.26. [c]Provided (in IU/kg of diet): vitamin A, 6500; vitamin $D_3$, 3500; vitamin E, 25; and (in mg/kg of diet) riboflavin, 25; D-calcium pantothenate, 25; nicotinic acid, 150; cyanocobalamin, 0.011; choline chloride, 1250; biotin, 1.0; folic acid, 2.5; thiamin hydrochloride, 7.0; pyridoxine hydrochloride, 25.0; menadione sodium bisulfite, 5.0; and ethoxyquin, 66. [d]Each of the four experimental diets contains either starch (control) or protease (Ronozyme ProAct, DSM Nutritional Products Inc., Parsippany, NJ, USA) or NSPase (a mixture of 50% Roxazyme G2, 40% Ronozyme A, and 10% Ronozyme WX (DSM Nutritional Products Inc., Parsippany, NJ, USA). Protease activity was measured in PROT units, where 1 unit is defined as the amount of enzyme that releases 1 μmol of *p*-nitroaniline from 1 μM substrate (Suc-Ala-Ala-Pro-Phe-*p*-nitroaniline) per minute at pH 9.0 and 37 °C. Ronozyme WX activity was measured in FXU units, where the minimum activity of the endo-1,4-β-xylanase is 1000 FXU/g, where an FXU unit is the amount of enzyme that releases 7.8 μmol of reducing sugar (xylose equivalents) from azo-wheat arabinoxylan per minute at pH 6.0 and 50 °C. Roxazyme G2 contains a minimum of 8000 U/g of endo-1,3-β-glucanase, 18000 U/g of endo-1,3(4)-β-glucanase, and 26000 U/g of endo-1,4-β-xylanase, where 1 U is the amount of enzyme that liberates 0.1 μmol of glucose from carboxymethylcellulose, barley β-glucan, or oat spelt xylan per minute at pH 5.0 and 40 °C, for each enzyme, respectively. Ronozyme A (CT) consisted of 200 kilo-Novo α-amylase units and 350 fungal β-glucanase units/g of enzyme concentrate.

to meet the nutrient requirements for both periods[45] except for no supplemental lysine or methionine in the DGM grower diets to test the maximal potential of the microalgal protein. Body weight and feed intake were recorded weekly by cage. Feed spillage was collected and weighed daily. Blood samples (~1−3 mL, not exceeding 10% of blood volume) were collected at days 21 and 42 via right wing vein in heparinized needles. At day 42, one bird per cage was euthanized by $CO_2$ asphyxiation and the liver and right pectoralis muscle were excised and immediately frozen for protein quantitation and Western blot analysis.

*Plasma Biochemical and Western Blot Analyses.* Blood samples were centrifuged at 1500*g* for 20 min to collect plasma. Total plasma amino acid content and uric acid were assayed using the same methods described above under Pig Experiment. Frozen liver and muscle samples were ground in liquid nitrogen. Powdered tissue (10 mg) was then homogenized on ice with ice-cold buffer (80 μL) containing 20 mM 4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid (HEPES), 100 mM KCl, 50 mM NaF, 1 mM dithiothreitol, 0.5 mM sodium orthovanate, 0.2 mM ethylenediaminetetraacetic acid (EDTA), 0.1 mM phenylmethanesulfonyl fluoride (PMSF), and 1 mM benzamidine. Homogenates were centrifuged at 1000*g* for 30 min at 4 °C, and the supernatant was centrifuged at 10000*g* for 10 min at 4 °C. The final supernatants were aliquoted and stored at −80 °C. Tissue lysates (50 μg of protein) were subjected to sodium dodecyl sulfate−polyacrylamide gel electrophoresis (SDS-PAGE) and Western blotting using the appropriate antibody (Supplemental Table 1 in the Supporting Information).

[a]Data are expressed as mean ($n$ = 7−8). Main effects of DGM, protease, and their interaction were analyzed by two-way ANOVA. [b]The significant interactions indicate that the protease exerted negative effects in the control diet but positive effects in the DGM diet. However, Duncan's multiple-range test showed no significant difference among the treatment means.

[a]Data are expressed as mean ($n$ = 7−8). Main effects of DGM, protease, and their interaction were analyzed by two-way ANOVA. Treatment means in the same row without a common letter differ, $P < 0.05$, according to Duncan's multiple-range test. [b]DGM effect, $P < 0.05$: control, 196 vs DGM, 179 U/L, $n$ = 14−16. [c]Protease effect, $P < 0.05$: none, 223 vs protease, 177 U/L, $n$ = 14−16. [d]DGM effect, $P < 0.03$: control, 87 vs DGM, 117 U/L, $n$ = 14−16. [e]Protease effect, $P < 0.02$: none, 13.8 vs protease, 16.8 U/L, $n$ = 14−16. [f]Protease effect, $P < 0.03$: none, 27.7 vs protease, 20.1 μmol/L, $n$ = 14−16. [g]DGM effect, $P < 0.04$: control, 6.60 vs DGM, 5.35 mg/dL, $n$ = 14−16. [h]DGM effect, $P < 0.01$: control, 7.50 vs DGM, 5.40 mg/dL, $n$ = 14−16.

**Statistical Analyses.** Data were analyzed with the GLM procedure of PC-SAS 8.1 (SAS Institute, Cary, NC, USA). The overall main effects of DGM and the enzymes and their interactions were determined using two-way ANOVA (2 × 2 factorial for the pig experiment and 2 × 3 factorial for the chick experiment). Growth parameters were analyzed as time-repeated measurements. Mean comparisons were conducted using Duncan's multiple-range test. If there was an interaction between DGM and the enzyme(s), only conditional (within the same level of the other variable) treatment mean comparisons were considered. Due to the semiquantitative

nature and limited sample size ($n$ = 3) of the Western blot analyses, only selected treatment effects were directly compared with the respective controls using the $t$ test. Data are expressed as means ± SEM, and $P < 0.05$ was considered statistically significant.

## RESULTS

**Pig Experiment.** Neither the 10% DGM nor the 0.06% protease addition alone affected body weight, average daily gain, average daily feed intake, or feed efficiency at any time points of the 28 day experiment (Table 4). However, there was an interaction between DGM and protease on the day 28 body weight ($P$ = 0.03) and overall average body weight gain for the entire 28 day experiment ($P$ = 0.02), showing a beneficial trend of the protease to both measures in the presence of DGM, but an adverse effect in the control diet. The DGM inclusion decreased ($P < 0.05$) the day 14 plasma TRAP activity by 9%, increased ($P < 0.03$) the day 28 plasma AKP activity by 34%, decreased the day 14 plasma uric acid concentrations ($P$ = 0.07) by 32%, and decreased the day 14 and 28 plasma urea nitrogen concentrations ($P < 0.05$) by 23 and 39%, respectively (Table 5). The protease addition decreased ($P$ = 0.05) the day 14 plasma AKP activity by 26%, increased ($P < 0.05$) the day 14 plasma ALT activity by 22%, and decreased ($P < 0.05$) the day 14 plasma uric acid concentrations by 38%, respectively. Plasma amino acid concentrations were not affected by either the DGM or the protease inclusion.

**Broiler Experiment.** There were significant ($P < 0.02$) effects of DGM, enzyme, and their interaction on body weight gains of chicks during the grower period (days 22–42) and (or) the entire period (days 0–42) (Table 6). The gains for both periods were improved ($P < 0.05$) by the protease addition into the control diet, but the gain for the entire period decreased ($P < 0.05$) with NSPase addition to the DGM diet. Chicks fed the DGM diet had 9% lower ($P < 0.05$) feed intake than those fed the control diet during the starter period (days 0–21), but this difference was reversed with an 11% increase during the grower period. Thus, there was no difference in the overall feed intake between these two diets. There were significant interactions of DGM and enzyme ($P < 0.03$) on the gain/feed ratios for all of the assayed periods. During the starter period and the entire period, chicks fed the DGM diet without the enzyme supplementation had 38 and 16% greater ($P < 0.05$) gain/feed efficiency, respectively, than those fed the control diet. Supplementing the NSPase to the DGM diets decreased ($P < 0.05$) the gain/feed efficiencies for all three periods, whereas supplementing the protease to the DGM diets decreased ($P < 0.05$) the gain/feed efficiency for the starter period. The enzyme supplementations in the control diets

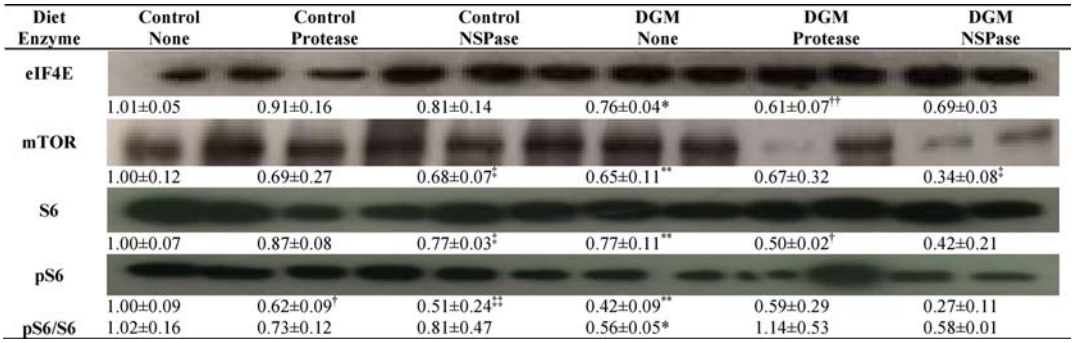

**Figure 1.** Effects of defatted green microalgal biomass (DGM) and hydrolytic enzymes on protein and phosphorylation levels of protein biosynthesis regulators in livers of broilers. Data are expressed as means ± SE ($n$ = 3). Values are expressed as a ratio to $\beta$-actin and then normalized to the control. Blots are representative of three independent replicate gels. (*) Significant effect of DGM versus control ($P$ < 0.05), (**) trending effect of DGM versus control ($P$ < 0.10), (†) significant effect of protease versus treatment control ($P$ < 0.05), (††) trending effect of protease versus treatment control ($P$ < 0.10), (‡) significant effect of NSPase versus treatment control ($P$ < 0.05), (‡‡) trending effect of NSPase versus treatment control ($P$ < 0.10). eIF4E, eukaryotic initiation factor 4E; p70, p70 S6 kinase; S6, S6 ribosomal protein; pS6, phospho-S6 ribosomal protein; mTOR, mammalian target of rapamycin.

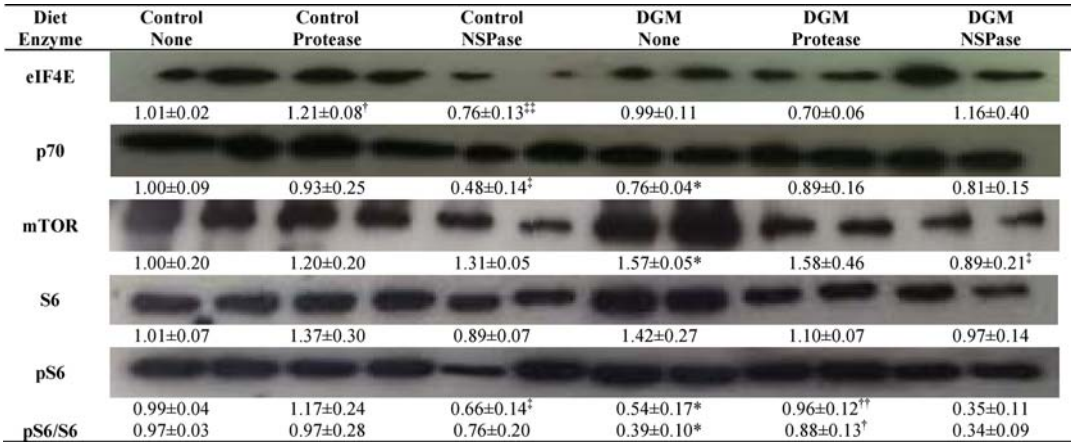

**Figure 2.** Effects of defatted green microalgal biomass (DGM) and hydrolytic enzymes on protein and phosphorylation levels of protein biosynthesis regulators in muscles of broilers. Data are expressed as means ± SE ($n$ = 3). Values are expressed as a ratio to $\beta$-actin and then normalized to the control. Blots are representative of three independent replicate gels. (*) Significant effect of DGM versus control ($P$ < 0.05), (**) trending effect of DGM versus control ($P$ < 0.10), (†) significant effect of protease versus treatment control ($P$ < 0.05), (††) trending effect of protease versus treatment control ($P$ < 0.10), (‡) significant effect of NSPase versus treatment control ($P$ < 0.05), (‡‡) trending effect of NSPase versus treatment control ($P$ < 0.10). eIF4E, eukaryotic initiation factor 4E; p70, p70 S6 kinase; S6, S6 ribosomal protein; pS6, phospho-S6 ribosomal protein; mTOR, mammalian target of rapamycin.

showed no such effects on the gain/feed efficiency. Plasma amino acid concentrations were elevated ($P$ < 0.05) and decreased ($P$ < 0.05) by the addition of the protease into the control diet on days 21 and 42, respectively (Table 7). Plasma uric acid concentrations at day 21 appeared to be decreased by protease, but the only significant difference ($P$ < 0.05) was seen between the two enzyme-supplemented DGM diets.

The inclusion of DGM consistently decreased ($P$ < 0.05−0.1) all four proteins (eIF4E, mTOR, S6, and pS6) and the ratio of pS6/S6 in the liver compared with the control diet without supplemental enzymes (Figure 1). However, the same inclusion exhibited variable effects on the same four proteins, the ratio of pS6/S6, and p70 in the breast muscle (Figure 2). Supplementing NSPase into the control diet decreased hepatic mTOR ($P$ < 0.05), S6 ($P$ < 0.05), and pS6 ($P$ < 0.1) and muscle eIF4E ($P$ < 0.1), p70 ($P$ < 0.05), and pS6 ($P$ < 0.05), respectively. Supplementing NSPase into the DGM diet decreased ($P$ < 0.05) both hepatic and muscle mTOR levels. Supplementing the protease into the control diet decreased ($P$ < 0.05) hepatic pS6 level and elevated ($P$ < 0.05) muscle eIF4E level, whereas supplementing the same enzyme into the DGM diet decreased ($P$ < 0.05) hepatic eIF4E and S6 levels and enhanced muscle pS6 ($P$ < 0.1) and the ratio of pS6/S6 ($P$ < 0.05).

## DISCUSSION

The main finding of the pig experiment was that the 10% inclusion of DGM produced no appreciable adverse effects on growth performance of the pigs except for numerically a 7% decrease in the body weight at day 28 and a 13% decrease in overall daily body weight gain. Interestingly, these decreases were restored by the supplemental protease in the DGM-containing diet. These data are in agreement with past reports that pigs tolerate moderate levels of various species of microalgal inclusion.[6,8,46] As shown in our previous broiler,[5] hen,[12] and pig[13] experiments, feeding weanling pigs with the 10% DGM diet did not alter their plasma ALT activity. Although pigs fed the DGM diet showed elevated plasma AKP activity at day 28 and decreased plasma TRAP activity at day 14, these changes were neither consistent nor sufficient to

suggest altered phosphorus nutrition status.[47] Our previous studies[5] also supported this notion. Apparently, digestibility and bioavailability of phosphorus in this and other sources of microalgal biomass need to be determined directly.

Effects of supplemental DGM and protease on dietary protein digestion and utilization in pigs were assessed by the responses of plasma uric acid, urea nitrogen, and amino acid concentrations. Whereas the DGM diet did not alter plasma amino acid concentration, it lowered substantially plasma uric acid and urea nitrogen concentrations. These favorable decreases seem to indicate that pigs utilized their ingested N more efficiently from the DGM-containing diet than from the control diet. As plasma urea nitrogen is highly correlated with urinary nitrogen excretion rate,[36] its decrease may result in attenuated nitrogen excretion to the environment from the swine production. It is worth mentioning that 1.2% plasma protein was added in the DGM-containing diet to match the protein and amino acid concentrations of the control diet. It is unknown if the superior plasma protein[48,49] helped overcome any possible deficiencies of the DGM-containing diet. Meanwhile, supplementing 0.06% protease in both control and DGM-containing diet also improved plasma uric acid concentration. Along with the above-described positive effect on growth performance of pigs, these improvements suggest an enhanced proteolysis by the extrinsic protease in the DGM-containing diet.

Results of the broiler experiment showed a potential of the inclusion of 15% DGM to improve growth performance of chicks. Gain/feed efficiency of chicks fed the DGM-containing diet was indeed greater than that of chicks fed the control diet during the starter and the entire 42 day period. The decreased feed intake during the starter period followed by an elevated feed intake during the grower period in chicks fed the DGM-containing diet, compared with those fed the control diet, might reflect an adaptation of the animals to the microalgal biomass. Notably, synthetic lysine and methionine were added into the DGM-containing diet only during the starter period. The DGM-containing grower diet was formulated to match only the protein but not the two limiting amino acids of the control diet, which was designed to determine the maximum potential of the DGM protein. Remarkably, chicks fed such grower diet displayed a growth performance similar to that of those fed the control diet. In comparison with the compromised body weight and body weight gain in the weanling pigs fed only 10% DGM, the tolerance of the broiler chicks to the inclusion of 15% DGM without exogenous lysine or methionine implied their better capacity to utilize DGM than shown by the weanling pigs. Nevertheless, thought should be given to possible confounding effects of the rather different lysine and methionine profiles between the control and DGM grower diets and (or) a slight extra methionine supplementation in the DGM starter diets. Along with the positive control diet as used in the present study, an additional negative control diet may be formulated to match the lower levels of lysine and methionine of the DGM grower diet for the future exploration of the full potential and mechanism of DGM in meeting protein and amino acid requirements for chicks and pigs.

Supplementing protease and NSPase to the broiler diets produced mixed or opposite effects on their growth performance. Protease supplementation to the control diets led to an increased weight gain. However, the same supplementation to the DGM-containing diet, as in the case of 7.5% DFA supplementation in our previous research,[5] showed little or no consistent effects. Presumably, the DGM contained a high level of NSPs within the cell wall structure.[50] Because NSPs possess antinutritive activity even at low levels (<50 g/kg) in broiler diets,[51] feeding DGM might alter the intestinal transit time, the intestinal mucosa, and hormonal regulations.[52] Intriguingly, NSPase supplementation to the DGM-containing diet consistently decreased growth performance. The mechanism responsible for this counterintuitive response remains unclear to us. Similar to the results seen at day 14 in the pig experiment, the supplemental protease decreased plasma uric acid concentrations of chicks, suggesting improved dietary nitrogen utilization.[10,11] However, the DGM inclusion, unlike in the case of DFA,[5] did not decrease plasma uric acid concentration of chicks in the present study. The inclusions of DGM and protease exerted a stronger effect on plasma amino acid concentrations at day 21 than at day 42. This time difference may reflect an adaptation of chicks to the microalgal protein and (or) a less dependence on exogenous enzymes to hydrolyze dietary proteins.[41]

The strong impacts of DGM inclusion on the protein production of the five key signal molecules in the pathway of mTOR in both liver and muscle of chicks are novel. Likewise, supplemental protease or NSPase also affected protein levels of these molecules in the two tissues to various extents. Because these proteins are key regulators of cell growth, protein synthesis, and energy metabolism,[51] the inclusions of DGM or enzyme-mediated decreases of these proteins, in particular in liver, were not well correlated with the dietary treatment effects on growth performance or plasma measures unless there was a feedback mechanism at the time-point of our tests. Clearly, these observations should not be used to draw sound conclusions, but regarded as a starting point to stimulate more systematic research. It will be fascinating to determine if any unique composition of protein and amino acids in the DGM and specific hydrolytes produced by the supplemental enzymes mediate the changes of these mTOR pathway-related proteins. It will also be necessary to confirm the tissue and (or) signal protein discrepancies in response to the DGM and enzyme supplementations. Eventually, these molecular regulations should be directly linked to the metabolic outcomes and production traits of animals fed the DGM and enzyme-supplemented diets.

Overall, weanling pigs and broiler chicks performed well with dietary inclusions of 10 and 15% DGM, respectively. The biomass feeding decreased plasma uric acid and urea nitrogen concentrations in pigs and improved feed use efficiency in chicks. Supplemental protease demonstrated moderate benefits on growth performance or certain biochemical indicators in pigs and (or) chicks, whereas supplemental NSPase showed little or somewhat negative effects. Dietary inclusions of DGM or enzymes affected hepatic and muscle protein production of the mTOR pathway, but metabolic implications and molecular mechanisms of the observed effects require future research.

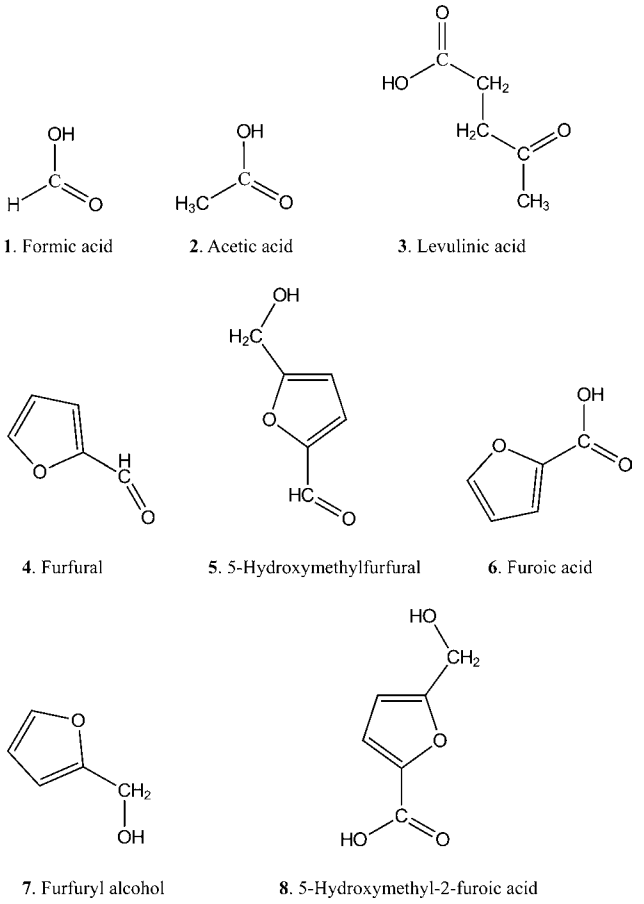

**Figure 1.** Structures of model inhibitors and related conversion compounds: (**1**) formic acid; (**2**) acetic acid; (**3**) levulinic acid; (**4**) furfural; (**5**) 5-hydroxymethylfurfural; (**6**) furoic acid; (**7**) furfuryl alcohol; (**8**) 5-hydroxymethyl-2-furoic acid.

important aliphatic acids and furan aldehydes on cultures of *G. xylinus*.

The influences of formic acid, acetic acid, levulinic acid, furfural, and 5-hydroxymethylfurfural on static cultures of *G. xylinus* were investigated during a period of 7 days when cell proliferation, sugar consumption, the pH of the cultures, and the concentration of the inhibitor were monitored daily by using modern analytical techniques including fluorescence staining, high-performance anion-exchange chromatography (HPAEC), and high-performance liquid chromatography−UV diode array detection (HPLC-UV-DAD). At the end of the cultivation, the yield of BNC was determined, and bioconversion products derived from furan aldehydes were identified and quantitated. This is the first study of the effects of specific lignocellulose-derived aliphatic acids and furan aldehydes on BNC production by *G. xylinus*, and it is also the first demonstration of the ability of *G. xylinus* to convert furan aldehydes. Studies in this area give a better understanding of the properties of *G. xylinus* and can give important information regarding suitable detoxification methods and directions for efficient production of BNC from lignocellulosic feedstocks.

## MATERIALS AND METHODS

**Chemicals and Microorganism.** Reagent grade chemicals purchased from Sigma-Aldrich (St. Louis, MO, USA) were used in the experiments. The substances added to the bacterial cultures were formic acid, **1**, acetic acid, **2**, levulinic acid, **3**, furfural, **4**, and 5-hydroxymethylfurfural, **5** (Figure 1). *G. xylinus* strain ATCC 23770 was obtained from the American Type Culture Collection (Manassas, VA, USA).

**Cultivation of *G. xylinus*.** The liquid seed medium, which was prepared using ultrapure water, contained 3.0 g/L yeast extract, 5.0 g/L tryptone, and 25 g/L glucose. The pH of all media was adjusted to 5.0. The fermentation medium was prepared by dissolving 0.75 g of glucose, 0.15 g of tryptone, and 0.09 g of yeast extract in 23.2 mL of ultrapure water.

Pre-inoculum for all experiments was prepared by transferring a bacterial colony grown on agar seed medium into 100 mL of liquid seed medium. After 24 h of agitated cultivation at 30 °C, 1.8 mL of cell suspension was introduced into a 100 mL Erlenmeyer flask containing 23.2 mL of the fermentation medium. The culture was then incubated at 30 °C with agitation for another 24 h to ensure that the bacterial cells were in the exponential growth phase before the addition of inhibitory substances.

Before the addition of the inhibitors, aqueous stock solutions were prepared and the pH of the stock solutions was adjusted to 5 with $H_2SO_4$ and NaOH. The concentration of the stock solutions of the aliphatic acids was 6 times higher than the concentration in the cultivation medium. For each of the aliphatic acids, 5 mL of the stock solution was added to obtain 25, 100, 175, and 250 mM in the resulting media. Triplicates were performed for each aliphatic acid. Five milliliters of autoclaved ultrapure water was added to reference cultures without inhibitors. The 100 mL Erlenmeyer flasks containing 30 mL of bacterial culture were incubated statically at 30 °C for 7 days. Samples (2 mL) from each flask were taken aseptically every 2 days during this time period. The samples were stored at −20 °C until analyzed.

Distilled furfural was added directly to the culture medium to reach final concentrations of 10, 20, 30, and 40 mM. A stock solution of 5-hydroxymethylfurfural (0.15 g/mL) was prepared in ultrapure water and was then added into the medium to reach the same final concentrations as for furfural. Triplicates were performed for each aliphatic acid.

**Determination of BNC Yield.** Production of BNC was quantitated gravimetrically on the basis of the dry weight of the insoluble BNC obtained at the end of cultivation. The BNC was collected after the incubation and dried to constant weight at 105 °C. After that, the BNC was weighed for calculation of the volumetric yield (g/L) and the yield on consumed sugar (g/g). The yield of BNC on consumed sugar (g/g) was calculated by using the following equation:

$$\text{BNC yield on consumed sugar (g/g)} = \frac{\text{BNC (g)}}{\text{glucose on first day (g)} - \text{residual glucose (g)}}$$

**Analysis of Glucose.** The concentration of glucose during the cultivations was monitored by using an Accu-Chek Aviva glucometer (Roche Diagnostics GmbH, Mannheim, Germany). The consumption rate of the glucose during cultivation was calculated by using the following equation:

$$\text{glucose consumption rate (g/[L·day])} = \frac{\text{glucose on first day (g/L)} - \text{residual glucose (g/L)}}{\text{cultivation time (days)}}$$

**Analysis of Aliphatic Acids.** Quantitation of formic acid, acetic acid, and levulinic acid was done using HPAEC. Before analysis, all samples were filtered through a 0.20 μm Millex-GN syringe-driven filter unit (Millipore, County Cork, Ireland) and diluted with ultrapure water. The HPAEC analysis was performed with a Dionex ICS-3000 system with a conductivity detector. The analytical column used was a 250 mm × 4 mm i.d., 9 μm, IonPac AS15, with a 50 mm × 4 mm i.d., 9 μm, IonPac AG15 guard column (Dionex, Sunnyvale, CA, USA). Isocratic elution with 35 mM sodium hydroxide at a flow rate of 1.2 mL/min was used for separation of the anions. The total run time of the analysis was 16 min. For quantitation of aliphatic acids, standard

dx.doi.org/10.1021/jf502623s | J. Agric. Food Chem. 2014, 62, 9792−9799

curves covering the range from 0.5 to 50 ppm were prepared using reference standards.

**Analysis of Furan Derivatives.** The concentrations of the furan aldehydes **4** and **5** were analyzed using high-performance liquid chromatography (HPLC) with an Agilent series 1200 instrument equipped with a G1315D diode array multiple wavelength detector (Agilent Technologies, Santa Clara, CA, USA). Samples (10 $\mu$L) were diluted 20-fold with ultrapure water and filtered through 0.2 $\mu$m Millex-GN syringe-driven filter units (Millipore). A volume of 2 $\mu$L of each diluted sample was injected into a column. The column used was a 50 mm × 3.0 mm i.d., 1.8 $\mu$m, Zorbax RRHT SB-C18 (Agilent Technologies), and the flow rate was 0.5 mL/min. Elution was performed with a gradient made of a mixture of ultrapure water and acetonitrile, both of which contained 0.1% formic acid. The gradient started with 3% acetonitrile for 3 min, after which the acetonitrile content increased linearly to 10% after 5 min. The column temperature was maintained at 40 °C. For quantitation of furan aldehydes **4** and **5**, standard curves covering the range from 0.5 to 50 ppm were prepared using reference standards. The wavelength used for quantitation of **4** and **5** was 280 nm.

The possible bioconversion of furfural and 5-hydroxymethylfurfural to corresponding acids and alcohols was investigated using HPLC-UV-DAD, and retention times and spectra of reference standards for 2-furoic acid (furan-2-carboxylic acid), **6**, furfuryl alcohol (2-furanmethanol), **7**, and 5-hydroxymethyl-2-furoic acid, **8** (Figure 1). The wavelength for quantitation of **6** and **8** was 254 nm, and the wavelength for quantitation of **7** was 210 nm.

**Analysis of Bacterial Viability.** The bacterial cells were collected by filtration through Durapore membrane filters in a 1225 sampling manifold (Millipore) and were then resuspended in saline. The viability of the bacterial cells was determined by using a BacLight live/dead bacterial viability fluorescence staining kit (Invitrogen, Grand Island, NY, USA) and a Synergy H4 hybrid microplate reader (BioTek Instruments, Winooski, VT, USA). The protocol for microplate assays supplied by the manufacturer was followed. A standard curve for the relative fluorescence value (RFV) and the number of bacterial cells was made before analysis of samples from the bacterial cultures from experimental series with inhibitors.

## RESULTS AND DISCUSSION

**Effects of Aliphatic Acids.** The effects of the three aliphatic acids **1**, **2**, and **3** (Figure 1) were evaluated in the concentration range of 25−250 mM. Figure 2 shows the effects of acid **1** on sugar consumption, cell viability, and the pH of bacterial cultures. When the concentration of acid **1** was 25 mM, *G. xylinus* could consume glucose at a rate of 3.1 g/(L·day), which was similar to the rate observed for cultures grown in the reference medium (Table 1; Figure 2). During the 7 days of cultivation after the addition of acid **1**, the pH of cultures with 25 mM acid **1** decreased from 4.4 to 3.1, which was slightly higher than the 2.7 in the reference medium. The concentration of live bacteria in the culture with 25 mM acid **1** reached the maximal value, 16.8 × $10^6$ cells/mL, at the fourth day, when acid **1** was exhausted. After that, there was a slight decrease in the concentration of live bacteria (Figure 2C). The volumetric yield of BNC in the medium containing 25 mM acid **1** was 3.2 g/L, whereas it was 3.5 g/L in the reference medium (Table 1). The BNC yield on consumed glucose was 0.15 g/g, whereas it was 0.16 g/g in the reference medium (Table 1).

When the initial dosage of acid **1** was increased to 100 mM or higher, the consumption rate of glucose decreased to ≤0.18 g/(L·day) (Table 1) and the pH value did not change much (Figure 2B). Low concentrations of live bacterial cells were observed in the media, and the concentration of acid **1** was constant (Figure 2). There was no synthesis of BNC in the media with 100 mM or higher concentrations of acid **1** (Table 1). Thus, *G. xylinus* could tolerate 25 mM formic acid, but at 100 mM or higher concentrations there was a complete inhibition of both the production of BNC and the growth of the bacterial cells.

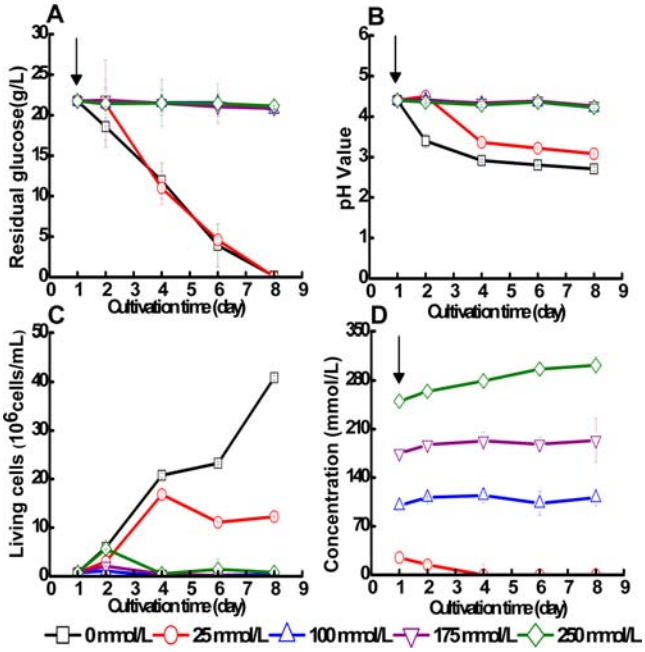

**Figure 2.** Changes in (A) glucose concentration, (B) pH value, (C) cell growth, and (D) formic acid concentration during cultivation of *G. xylinus* in media supplemented with formic acid. The arrows indicate the time for addition of formic acid. Error bars show standard errors of means of three replicates.

Concentrations of acid **2** up to 250 mM did not stop the growth of *G. xylinus* or the production of BNC (Figure 3; Table 1). The glucose was consumed gradually during the cultivation (Figure 3). In the first 3 days after the addition of acid **2**, the consumption rates of glucose for cultures with acid additions of 25, 100, and 175 mM were 4.8, 5.1, and 4.9 g/(L·day), respectively. These were higher than that for the cultures grown in reference medium, which had a glucose consumption rate of 3.3 g/(L·day) after 3 days. At the end of the cultivation, there was little glucose left in the media except for cultures with an initial addition of 250 mM acetic acid, which contained 3.2 g/L (Figure 3A). The average glucose consumption rate during the 7 day cultivation in media with 25−175 mM acetic acid was 3.1 g/(L·day), which was the same as for cultures grown in reference medium (Table 1). For cultures in medium with 250 mM acid **2**, the average glucose consumption rate was 2.6 g/(L·day), which shows a decrease ($p < 0.05$, $t$ test) compared to cultures grown in reference medium. The volumetric yield of BNC in the media with acetic acid did not differ significantly ($p < 0.05$) from the yield of the cultures in reference medium except for cultures with an initial addition of 250 mM acid **2**, for which it decreased to 3.1 g/L. Even though the glucose consumption rate and the volumetric yield of BNC were lower for medium with 250 mM, the BNC yield on consumed glucose (0.17 g/g) was slightly higher than that of the cultures in reference medium (0.16 g/g). It can be concluded that high concentrations of acetic acid tend to inhibit the proliferation of *G. xylinus*, but not its ability to produce BNC. The pH decreased gradually, but the pH in the medium with high concentration of acetic acid did not drop as much as that in the

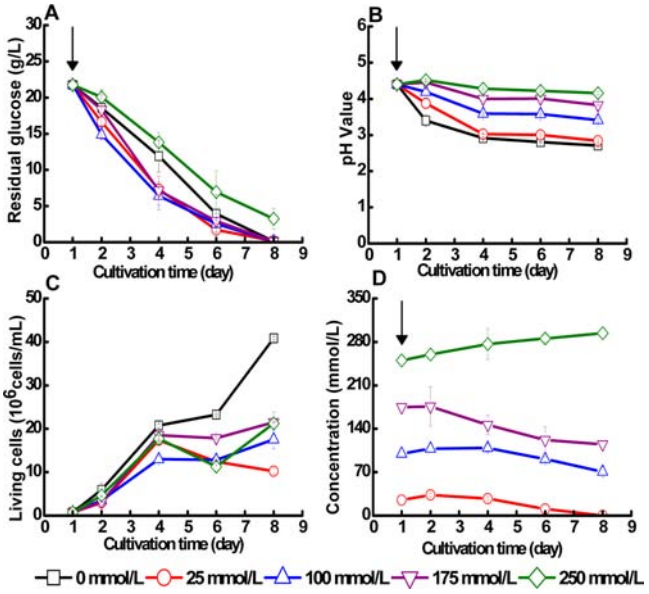

**Figure 3.** Changes in (A) glucose concentration, (B) pH value, (C) cell growth, and (D) acetic acid concentration during cultivation of *G. xylinus* in media supplemented with acetic acid. The arrows indicate the time for addition of acetic acid. Error bars show standard errors of means of three replicates.

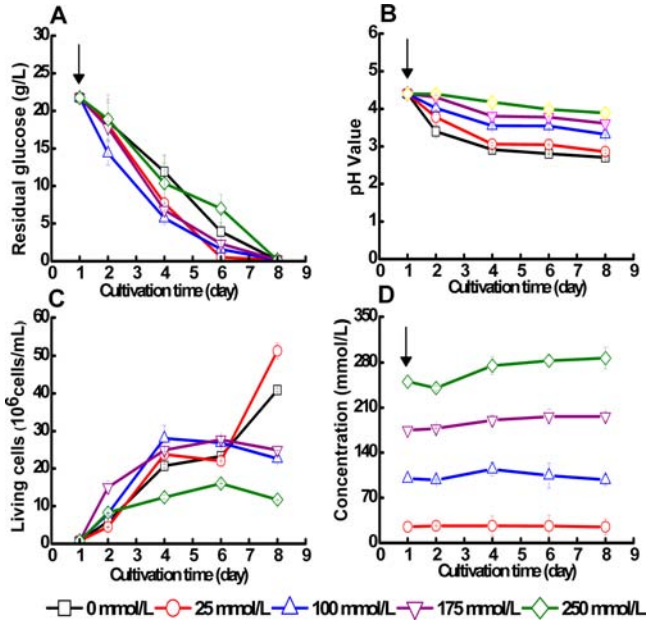

**Figure 4.** Changes in (A) glucose concentration, (B) pH value, (C) cell growth, and (D) levulinic acid concentration during cultivation of *G. xylinus* in media supplemented with levulinic acid. The arrows indicate the time for addition of levulinic acid. Error bars show standard errors of means of three replicates.

medium with low concentration of acetic acid. This can be attributed to the buffering capacity of acetic acid, which has a p$K_a$ of 4.76, close to the initial pH of the cultures. *G. xylinus* consumed acetic acid when the initial concentration was 175 mM or lower (Figure 3D). The concentration of acetic acid increased slightly in cultures with an initial concentration of 250 mM (Figure 3). This may be due to evaporation of water during the cultivation and to the bacterium not being able to convert as much acetic acid as in the other media.

Results obtained with acid **3** are shown in Figure 4 and Table 1. After the addition of acid **3** to the medium, there was a sharp decrease in the concentration of glucose during the first 3 days of cultivation (Figure 4A). The average glucose consumption rate in cultures with 25, 100, 175, and 250 mM levulinic acid during the first 3 days were 4.7, 5.3, 5.0, and 3.8 g/(L·day), respectively. They were higher than that of the reference medium (3.3 g/(L·day)). At the end of the cultivation, there was little glucose left in the media (Figure 4A). The average glucose consumption rate during the 7 days of cultivation with levulinic acid was 3.1 g/(L·day) for all media (Table 1). The pH value in all media decreased gradually, although the decrease of pH in media with higher concentrations of levulinic acid was smaller than that in media with lower concentrations or no levulinic acid. The buffering effect of levulinic acid (Figure 4B) may explain the slightly more rapid initial glucose consumption rates of cultures containing levulinic acid (Figure 4A). The bacterium grew well in media with levulinic acid (Figure 4C), and the maximum concentration of live bacteria ($51.3 \times 10^6$ cells/mL) was observed in the medium with 25 mM levulinic acid. This concentration was even higher than that in the reference medium, which was $40.8 \times 10^6$ cells/mL. The lowest concentration of live cells, $11.7 \times 10^6$ cells/mL, was obtained in the medium with 250 mM levulinic acid. The concentration of levulinic acid did not change during the cultivation (Figure 4D), which indicates that *G. xylinus* was not

dx.doi.org/10.1021/jf502623s | J. Agric. Food Chem. 2014, 62, 9792−9799

able to utilize levulinic acid. The concentration of levulinic acid in cultures with an initial concentration of 250 mM increased slightly at the end of the cultivation, which can be attributed to evaporation of water in combination with the inability of *G. xylinus* to utilize levulinic acid. The volumetric yield of BNC increased significantly ($p < 0.05$) as the concentration of levulinic acid got higher. The maximum yield of BNC, 5.0 g/L, was obtained with an initial concentration of levulinic acid of 100 mM, whereas cultures with reference medium reached only 3.5 g/L (Table 1). Even cultures with an initial concentration of 250 mM gave higher yields than cultures with reference medium (Table 1). There was a similar trend for the BNC yield on consumed glucose (Table 1). The BNC yield on consumed glucose in medium with 100 mM, 0.23 g/g, was the highest value for media with or without aliphatic acids (Table 1).

The results demonstrate that formic acid is more inhibitory to *G. xylinus* than acetic acid, whereas inhibitory concentrations of levulinic acid were not reached in the interval studied. The result is in one way similar to results obtained in experiments with a baker's yeast strain, where formic acid was found to be more inhibitory than levulinic acid or acetic acid.[17] Larsson et al.[17] found that concentrations exceeding around 100 mM tended to decrease the ethanol yield, whereas lower concentrations instead stimulated ethanol production at the expense of biomass synthesis. There are also differences, as levulinic acid was found to be more inhibitory to yeast than acetic acid[18] and the effects of acetic acid and levulinic acid on *G. xylinus* were positive at least up to 175 mM (this work).

Acids may be inhibitory for several reasons. One possibility is that the protonated form of the acid passes across the plasma membrane and releases the proton in the cytoplasm, where the pH is higher than in the surrounding medium.[19,20] To maintain a constant intracellular pH value, protons are pumped out of the cell by a plasma membrane ATPase. This may lead to excessive consumption of ATP and, in the long run, to depletion of the pool of ATP. Another possibility is that they would act as uncouplers, amphiphilic molecules that dissolve in the inner mitochondrial membrane of eukaryotes or in the plasma membrane of prokaryotes and transfer protons across the membrane, which would uncouple the respiratory chain and the oxidative phosphorylation and disturb the regeneration of ATP. However, the anions of formic acid, acetic acid, and levulinic acid are hydrophilic and could not readily traverse the cell membrane.[21] A third possibility could be intracellular anion accumulation. After dissociation, the anionic form of the acid would be captured in the cell.[19] It has been speculated that formic acid would have higher anion toxicity to yeast.[17] It has also been suggested that formic acid would increase the membrane leakage of ethanologenic *Escherichia coli* LY01.[22]

There are several studies of the effect of weak acids on *Acetobacter*, another genus of acetic acid bacteria, which is characterized by a strong ability to oxidize alcohols and sugars to acetic acid and by high resistance to the acid.[23] An efflux pump of *Acetobacter aceti* IFO 3283 has been reported to enable the bacterium to grow in the presence of high concentrations of acetic acid.[24] Addition of acetic acid to cultures of *Acetobacter xylinum* strain DA has been shown to enhance the cellulose yield from glucose.[25] Glucose is catabolized to generate energy for bacterial anabolism and can be used as a building block in the synthesis of bacterial cellulose. If glucose is partly substituted by another carbon source (such as acetic acid), the conversion of glucose to cellulose may be improved.[25] This is a possible explanation for some of our results with *G. xylinus*, where relatively low concentrations of bacteria in media with high concentrations of acetic acid gave similar yields of BNC as obtained with the reference medium (Table 1; Figure 3C).

**Effects of Aldehydes.** As shown in Figure 5, furfural (**4**, Figure 1) had a very clear negative effect on *G. xylinus*. Only 5.6

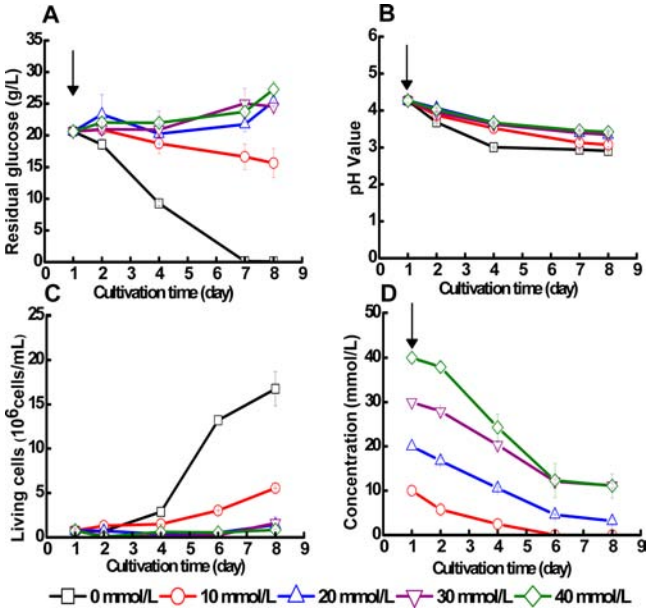

**Figure 5.** Changes in (A) glucose concentration, (B) pH value, (C) cell growth, and (D) furfural concentration during cultivation of *G. xylinus* in media supplemented with furfural. The arrows indicate the time for addition of furfural. Error bars show standard errors of means of three replicates.

$\times 10^6$ live cells/mL were found in cultures with an initial furfural concentration of 10 mM, which can be compared to $16.8 \times 10^6$ live cells/mL in cultures with reference medium. With an addition of 10 mM furfural, the average consumption rate of glucose was 0.71 g/(L·day), only 24% of the rate observed for cultures in reference medium (Table 2). With 10 mM furfural, a BNC yield of 1.1 g/L was achieved, which was 20% of the yield obtained with reference medium. The decreased volumetric yield of BNC in the presence of furfural was mainly due to the reduction of the concentration of live bacteria, although the BNC yield on consumed glucose was also lower (0.22 g/g) than in cultures with reference medium (0.27 g/g). When the concentration of furfural was increased to 20 mM, there was no glucose consumption in the cultures (Figure 5A) and there were hardly any live bacteria in the culture medium (Figure 5C). The slight increase in glucose concentration in cultures with an initial furfural concentration between 20 and 40 mM can be explained by evaporation of water during the incubation (Figure 5A).

Figure 5D indicates that the concentration of furfural decreased as the cultivation continued. This could be due not only to bioconversion of furfural by *G. xylinus* but also to evaporation of furfural. In cultures with furfural, furoic acid was identified as a main product (Table 3). Furoic acid (**6**, Figure 1) was formed in all cultures to which furfural was added, but the highest yield, 88%, was observed in cultures with an initial furfural concentration of 10 mM. No furfuryl alcohol was detected in the culture media. Control experiments with medium with furfural but without bacterial inoculum were

performed. No conversion products from furfural were detected in the medium, which indicates that the furoic acid formed in media with bacteria was a bioconversion product and not a product caused by oxidation by air or by other media components. Apart from bioconversion, the decrease of the concentration of furfural in the culture media (Table 3) can be attributed to evaporation of furfural. Experiments with acid wood hydrolysates have shown that furfural easily evaporates. After evaporation of 10% of the volume, the concentration of furfural was reduced with 37%, whereas the concentration of 5-hydroxymethylfurfural, which is much less volatile than furfural, was unchanged.[18]

The effects of 5-hydroxymethylfurfural (**5**, Figure 1) on the bacterial cultures are shown in Figure 6 and Table 2. When the initial concentration of 5-hydroxymethylfurfural was 10 mM, the growth rate increased rapidly from the fourth day, and the maximum concentration of viable cells, $13.3 \times 10^6$ cells/mL, was obtained on day 7. The average consumption rate of glucose was 2.0 g/(L·day), which was lower than for the culture in control medium (2.9 g/(L·day)). When the initial concentration of 5-hydroxymethylfurfural was increased to 20 mM, the consumption rate of glucose decreased sharply to 0.34 g/(L·day). As the initial concentration of 5-hydroxymethylfurfural was increased further, the growth of the bacteria diminished and the glucose consumption rate was negligible. The pH value decreased gradually during the cultivation. When the initial 5-hydroxymethylfurfural concentrations were 10 and 20 mM, the yields of BNC were 0.31 and 0.22 g/g, respectively (Table 2). As the yield of BNC in the reference medium was 0.27 g/g, low concentrations of 5-hydroxymethylfurfural may have a positive effect on the production of BNC. The data in Table 2 and Figure 6 indicate that 5-hydroxymethylfurfural was less toxic than furfural to *G. xylinus*.

When the initial concentration of 5-hydroxymethylfurfural was 10 mM, all of the 5-hydroxymethylfurfural could be converted by the bacteria (Figure 6D). When the initial concentration of 5-hydroxymethylfurfural was higher, the conversion rate seemed to decline. Analyses of the culture

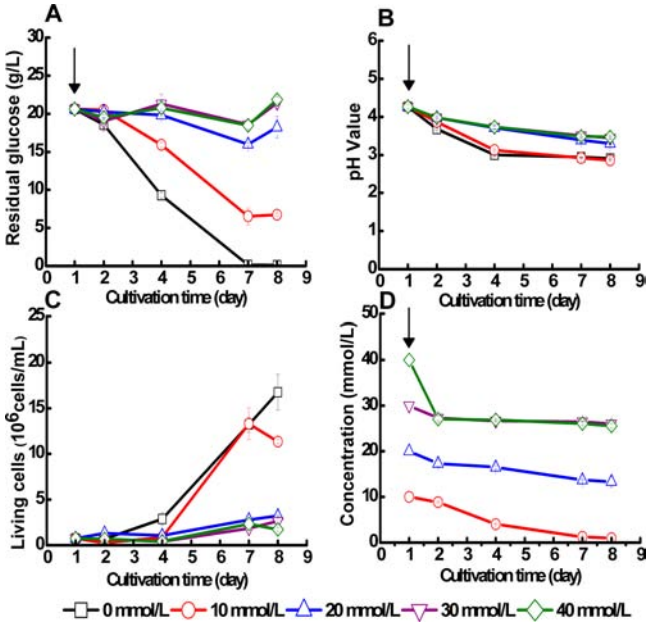

**Figure 6.** Changes in (A) glucose concentration, (B) pH value, (C) cell growth, and (D) 5-hydroxymethylfurfural concentration during cultivation of *G. xylinus* in media supplemented with 5-hydroxymethylfurfural. fluid indicated formation of 5-hydroxymethyl-2-furoic acid (**8**, Figure 1). The yield of 5-hydroxymethyl-2-furoic acid was highest (76%) in cultures with an initial concentration of 5-hydroxymethylfurfural of 10 mM (Table 3), which clearly indicates that it was the predominant bioconversion product. At higher initial concentrations of 5-hydroxymethylfurfural, the yield of 5-hydroxymethyl-2-furoic acid dropped. It is noteworthy that there was formation of 5-hydroxymethyl-2-furoic acid (12% yield) even when the initial concentration of 5-hydroxymethylfurfural was as high as 40 mM, and there were no clear signs of glucose consumption, the concentration of viable cells was low, and there were only minor changes in pH indicating low metabolic activity (Figure 6). Control experiments (without inoculation but with addition of 5-hydroxymethylfurfural) showed no conversion products from 5-hydroxymethylfurfural, which supports the conclusion that 5-hydroxymethyl-2-furoic acid was formed by biocatalytic conversion.

dx.doi.org/10.1021/jf502623s | J. Agric. Food Chem. 2014, 62, 9792−9799

The inhibition by furan aldehydes of ethanologenic microorganisms, such as *S. cerevisiae*, has been studied extensively.[14,15] *S. cerevisiae* would typically be expected to reduce furfural to furfuryl alcohol[26] and 5-hydroxymethylfurfural to 5-hydroxymethylfurfuryl alcohol (2,5-bis-hydroxymethylfuran).[27] However, during respiratory growth *S. cerevisiae* exclusively converted furfural to furoic acid.[28] Under both aerobic and anaerobic conditions, 5-hydroxymethylfurfural was mainly reduced to 5-hydroxymethyl furfuryl alcohol by yeast and only small amounts of 5-hydroxymethyl furoic acid were found.[27] Methanobacteria have been found to convert furfural to furfuryl alcohol,[29] whereas *Clostridium acetobutylicum* was found to reduce both furfural and 5-hydroxymethylfurfural to the corresponding alcohols.[30] Wahlbom and Hahn-Hägerdal[31] studied *S. cerevisiae* TMB 3001 and found that the reduction of furfural was associated with consumption of NADH, whereas the reduction of 5-hydroxymethylfurfural was associated with the consumption of NADPH. NADH plays an important part in many cellular reactions, including respiratory and fermentative catabolism, whereas NADPH is mainly utilized in biosynthetic reactions. NADPH may also function as an essential cofactor for enzymes involved in protection against oxidative stress. Besides intracellular redox balance, stress also affects energy metabolism, as many stress-responsive processes are dependent on ATP availability. The ability of *G. xylinus* to oxidize furan aldehydes has not been reported before. Biotransformation by oxidation is not self-evident, as *G. xylinus* has been found to reduce phenolic aldehydes to the corresponding alcohols.[16]

NAD(P)H- and $NAD(P)^+$-dependent reactions have also been studied in *G. xylinus*.[1] *A. aceti* MIM2000/28 has been reported to have the ability to convert polyconjugated aldehydes to the corresponding acids, an ability that has been used for a number of selective bio-oxidations.[32] The probable reaction behind conversion of furfural by *G. xylinus* would be

$$\text{furfural} + H_2O + NAD(P)^+ \rightarrow \text{furoic acid} + NAD(P)H + H^+$$

Similarly, 5-hydroxymethylfurfural would probably be oxidized to 5-hydroxymethyl-2-furoic acid in a reaction involving the reduction of $NAD(P)^+$. Assuming that these reactions have relatively high priority, as indicated by furan aldehyde bioconversion taking place (Table 3) without concurrent glucose catabolism or BNC production at the higher furan aldehyde concentrations studied (Table 2), the furan aldehydes would be expected to interfere with critical cellular reactions involving oxidized nicotinamide adenine dinucleotides. It is a possibility that the furoic acids are less toxic than the corresponding aldehydes, and in that case the reactions indicated above would represent detoxification reactions, but that possibility needs to be addressed in future investigations.

Kubiak et al.[33] identified a megaplasmid of *G. xylinus* E25 and found some genes connected to oxidoreductases. Megaplasmids may be important for the survival of bacteria under stress. Oxidoreductases would probably be involved in the catalysis of oxidation of furan aldehydes to the corresponding carboxylic acids. The potential effects of *G. xylinus* oxidoreductases on furan aldehydes warrant attention in future studies.

In summary, the effects of presumed inhibitors, three aliphatic carboxylic acids and two furan aldehydes, on cultures of *G. xylinus* have been elucidated. Whereas formic acid, furfural, and 5-hydroxymethylfurfural had an inhibitory effect, appropriately high concentrations of levulinic acid and acetic acid were found to stimulate BNC production. The sensitivity of *G. xylinus* to furan aldehydes differed from that observed for other microorganisms, such as *S. cerevisiae*, which indicates that results obtained with other microorganisms cannot be extrapolated to *G. xylinus*. The main bioconversion products of furfural and 5-hydroxymethylfurfural were found to be the corresponding carboxylic acids. The effects of carboxylic acids need to be further investigated using pH-controlled cultures. Information provided by the current study paves the way for future studies on potential synergistic effects of different inhibitory compounds. A better understanding of inhibitory and stimulatory effects of lignocellulose-derived compounds will facilitate the development of robust processes for the production of BNC from lignocellulosic resources.

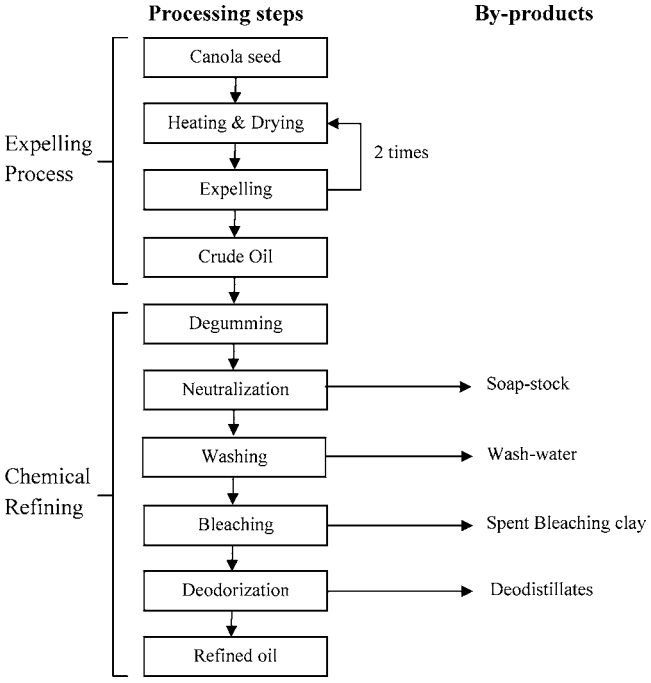

**Figure 2.** Expeller-pressing process for canola oil and the corresponding chemical refining and residual byproducts.

ingredient, raw material for animal feed, and/or a novel source for biodiesel production.[16] The utilization of soap stock to recover other bioactive compounds is an emerging area to add value to the edible oil processing and refining sector. After neutralization, water is commonly added to the oil to reduce the soap content. This soapy water containing the neutralized lipids is a commercial byproduct and is referred to in the present study as wash water. After these refining steps, bleaching and deodorization follow. Spent bleaching clay is generated as a byproduct during bleaching. Finally, edible oil deodorization is conducted to remove off flavors utilizing steam distillation under elevated temperature and vacuum conditions.[17] This results in the production of another byproduct, deodistillates or deodorization distillates, which are a rich source of many bioactive compounds, including tocochromanols, phytosterols, and polyphenols. For instance, a novel canolol dimer, beside sinapic acid and canolol, was detected in significant amounts (3500 mg/kg).[18] Thus, the economic values of the oil refining byproducts can be increased by recovering these valuable bioactive components such as tocopherols and the sinapic acid derivatives.[18,19]

Another implication of the refining processes is that bioactive antioxidants of the edible oils are lost, possibly degraded or even leached during the high-temperature processing of refining.[18,20] The majority of antioxidants found in canola are polyphenols with a hydrophilic nature[21] and, thus, may leach into wash water or soap stock. There are only a few studies associating the antioxidant compositions and their oil refining byproducts.[8,18,19,22] Ortega-García et al.[9] reported many polyphenols in the olive oil refining byproducts (819.9 mg/kg of soap stock and 134.4 mg/kg of wash water samples). The reports that these endogenous antioxidants are being removed by the adsorbent during the bleaching process make the corresponding byproduct, the spent bleaching clay, a candidate for a further recovery study.[22]

These polyphenols and tocopherols have added value by being both abundant and naturally occurring for potential use in cosmetic, food, and pharmaceutical applications.[23−25] Although several studies have been conducted to evaluate the loss of these antioxidants from edible oil refining,[8−13] only a few of these studies explored the possibility of recovering them from the corresponding refining byproducts. Thus, this paper is the first ever attempt to characterize and quantitate the retention and loss of sinapic acid derivatives and tocopherols in the corresponding byproducts associated with the refining processes. In addition, characterization and quantification of antioxidant phenolics of expeller-pressed canola oils at different stages of refining were also studied. Furthermore, the rapid extraction techniques of these bioactive phenolics were also examined to highlight the value-added potential of byproducts of refining.

## MATERIALS AND METHODS

**Industrial Samples and Chemicals.** Canola oils from different refining stages (crude, degummed, neutralized, bleached, and deodorized oils) and corresponding byproducts including soap stock, wash water, spent bleaching clay, and deodistillates were supplied by Vittera Canola Processing Inc. (Winnipeg, Canada). All samples were collected from the same batch of processed oil and stored at −20 °C before analysis. All chemicals used in this study were purchased from Sigma-Aldrich and of analytical grade.

**Extraction of Sinapic Acid Derivatives.** *Canola Oils.* Canola oils were extracted with aqueous methanol (70%) as previously described.[7] Briefly, 2 g of each sample was dissolved in 5 mL of extraction solvent, and the mixture was vortexed for 3 min followed by centrifugation at 5000 for 5 min under refrigerated conditions. The supernatant was collected, and the residue was re-extracted following the same procedure one more time. The supernatants were pooled, and the mixture was then made up to 10 mL using 70% aqueous methanol.

*Refining Byproducts.* Wash water and deodistillates were extracted using the method described above to produce "Extract 1". Additionally, they were also extracted with 50% aqueous methanol to produce "Extracts 2−5" as previously described.[19] Briefly, samples (2 g) were solubilized with 10 mL of hexane (1:5 w/v), followed by extraction using 50% methanol (3 mL) three times. Instead of hexane, other nonpolar solvents such as chloroform, cyclohexane, and toluene were used for solubilization prior to extraction. The methanolic extracts were pooled and made up to 10 mL using 50% methanol.

Spent bleaching clay was defatted using a Soxtec 2050 (Foss-Tecator, Foss North America) and the oil was extracted as described elsewhere. The defatted spent bleaching clay was extracted following the procedure described by Khattab et al.[26] Briefly, spent bleaching clay sample (1 g) was extracted with 9 mL 70% methanol with ultrasound treatment for 1 min twice. The filtrates were pooled and made up to 30 mL.

The soap-stock samples (pH 12) were adjusted to two different pH levels (7 and 2) using 2 M HCl and extracted with 10 mL of ethyl acetate thrice. The extracts were pooled, concentrated in a rotary evaporator at 50 °C to dryness, and then redissolved in 5 mL of 70% methanol.

**Extraction of Tocopherols.** The oils, wash water, or deodistillate samples were extracted directly with absolute methanol and methanol/2-propanol (1:1, v/v) mixture for several times.[27] Briefly, 2 g of oil or byproduct sample were first extracted with 10 mL of absolute methanol for 3 min. The residue was extracted with 10 mL of methanol/2-propanol mixture (1:1, v/v) three times. The supernatants were pooled and made up to 40 mL, filtered using a Whatman No. 1 filter paper, and evaporated to dryness under $N_2$, and the residue was redissolved in 5 mL of the methanol/2-propanol mixture.

**Synthesis of Canolol.** The synthesis of canolol was carried following a previously reported method[28] with slight modifications. Syringaldehyde and malonic acid were mixed and microwave irradiated

for 5 min with piperidine−acetic acid mixture as condensing agent using a domestic microwave oven. The highly viscous reaction mixture was diluted with 70% methanol and filtered using syringe filters (0.45 μm) prior to HPLC quantification. The purity of the obtained canolol was approximately 82%.

**HPLC Analyses of Sinapic Acid Derivatives and Tocopherols.** Sinapic acid derivatives were quantified using a reversed-phase HPLC-DAD (Dionex, Sunnyvale, CA), as described previously,[27] with an 80 mm × 4.0 mm i.d., 4 μm, Synergi Fusion-RP column (Phenomenex, Torrance, Canada). Standards of sinapine, sinapic acid, and synthetic canolol were used to authenticate the retention time and UV absorption spectra. The contents of all sinapic acid derivatives were expressed as sinapic acid equivalents (SAE) in μg/g of sample, wherein sinapine and sinapic acid were detected at 330 nm and canolol was detected at 270 nm. Standard of sinapic acid was prepared in concentrations between 50 and 500 μg/mL.

The chromatographic separation of tocopherols was performed on a 150 mm × 4.6 mm i.d., 5 μm, C18 Prodigy ODS-2 column (Phenomenex, Torrance, Canada) as described previously,[27] with slight modifications. The elution solvents used were (A) 1% acetic acid/water (1:99) and (B) 1% acetic acid/methanol (1:99). An isocratic elution was performed with 1% A and 99% B for 30 min. The column was maintained at 25 °C with a flow rate of 1.0 mL/min. The injection volume was 20 μL. Chromatograms were acquired at 294 nm; identification of tocopherols was achieved by comparing the relative retention times and spectrum with the standards of α-, β-, and γ-tocopherols. Triplicate samples were analyzed with duplicate injections of each sample for statistical validation of results.

**Estimation of Total Phenolic Content.** Total phenolic contents in the extracts of oil and their corresponding refining byproducts were estimated using the Folin−Ciocalteu reagent as described,[21,29] using a DU 800 UV/vis spectrophotometer (Beckman Coulter Inc., Mississauga, Canada). An authentic standard of sinapic acid was used for calibration purposes, and the results of duplicate analyses were expressed as μg SAE/g of sample.

**Estimation of Antioxidant Activity.** The antioxidant activity of the phenolic extract was determined by the free radical scavenging activity using DPPH (2,2-diphenyl-1-picrylhydrazyl) according to the method proposed by Brand-Williams et al.[30] with slight modifications. Briefly, 1 mL of extract was added to 2.9 mL of 0.1 mM DPPH ethanolic solution and reacted for 10 min, and the absorbance was measured at 516 nm. The linear range of the calibration curve of sinapic acid standard was prepared from 10 to 500 μM, and the antioxidant activity was expressed as μM SAE/g of sample.

**Statistical Analyses.** All extractions were carried out in triplicate with duplicate analysis of samples, and results are presented as mean ± SD (Microsoft Excel, Version 2010). One-way analysis of variance (ANOVA) was done using SAS 9.4 software (SAS Institute Inc.). Statistical significance was determined using least significant difference *t*-test. Statistical significance was accepted at $p < 0.05$. Regression analysis was carried out using Microsoft Excel (Version 2010).

## RESULTS AND DISCUSSION

**Effect of Refining on Sinapic Acid Derivatives and Tocopherol Contents of Expeller-Pressed Canola Oil.** The contents of endogenous phenolics of the various canola oils are indicated in Table 1. With respect to sinapic acid derivatives, crude expeller-pressed canola oil retained canolol (697 μg SAE/g), sinapic acid (30.5 μg/g oil), and sinapine (beyond detection limit) in agreement with the levels observed by Koski et al.[7] The amount of canolol in canola oil was slightly decreased during the degumming process, while the concentration of sinapic acid was not significantly affected. Sinapic acid decreased to an undetectable level in the canola oils during neutralization, while the concentration of canolol was slightly increased. In the industrial oil refining practices, neutralization of oil is commonly conducted by converting free fatty acid to soaps by adding caustic soda solutions and the neutralized oil is normally obtained after soap stock separation, oil washing, and drying. The increase of canolol content in neutralized oil might be attributed partially due to the conversion of sinapic acid and other precursors, accelerated by higher temperatures during the drying of washed oil. Thermal decarboxylation and cleavage of sinapic acid have been previous reported for different heat treatments,[2,31] but further studies are required to confirm the cause of this increase. This contradicted the findings of Zacchi and Eggers[14] that polyphenol content was reduced after neutralization; however, the neutralization process in that[14] study was simulated under laboratory conditions, which may be different from industrial practices. Also, different conditions of neutralization, such as the type and concentration of caustic solution, and varieties of oilseeds may have significant influence on the content of polyphenols in oils.[22] A significant amount of canolol was lost during the bleaching process (about >90%), which was further reduced to an undetectable level during deodorization. Substantial reductions in rapeseed oil polyphenols during bleaching and deodorization processes have been previously reported;[14] the authors related this to the high adsorptive activity of the bleaching clay and the elevated temperatures of the deodorization process.

With respect to the total phenolic content, solvent-extracted crude canola oils contain about 125 ppm (as gallic acid equivalents) of total phenolics, and this included sinapine, sinapic acid, and 4-vinyl-2,6-dimethoxyphenol (canolol).[22] In the current study, total phenolic contents of expeller-pressed canola oil extracts were assessed using HPLC-DAD and the Folin−Ciocalteu method. The phenolic contents estimated by these two different methods were compared to determine the correlation. The HPLC-DAD-based total phenolic content was the highest in the crude oil and decreased slightly during

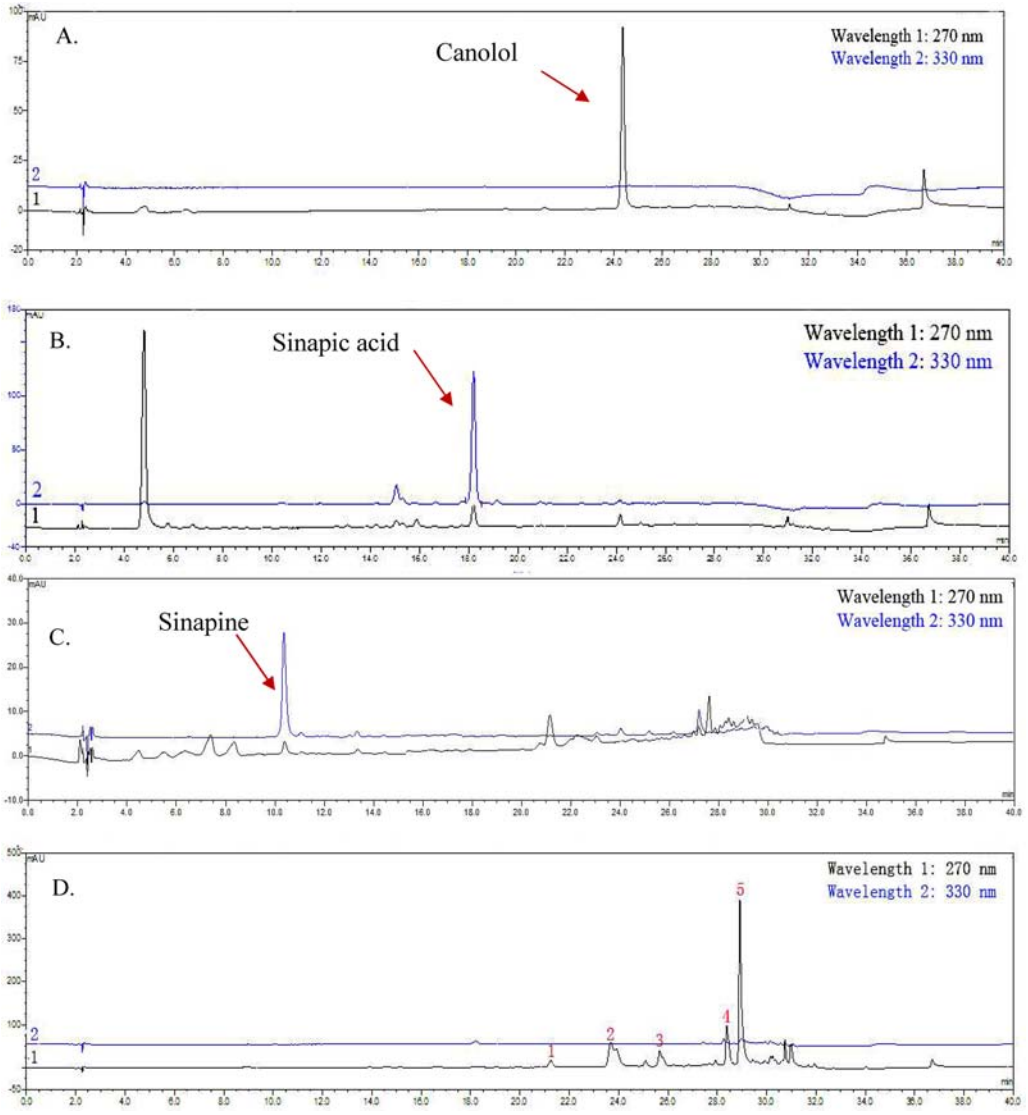

**Figure 3.** HPLC-DAD chromatograms of phenolic extracts obtained from canola oil refining byproducts: (A) wash water, (B) soap stock, (C) spent bleaching clay, and (D) deodistillates.

degumming and neutralization (Table 1). Bleaching and deodorization further reduced the total phenolic content to negligible amounts. The total phenolics quantified by the Folin−Ciocalteu method showed a similar trend, although the values were much lower than the total phenolics detected through the DAD-HPLC method. The Folin−Ciocalteu assay is a well-known method used to determine total phenolic content; however, it is not efficient to measure the decarboxylation products of the hydroxycinnamates.[32] Previous studies were in agreement that the Folin−Ciocalteu method could underestimate canolol.

With respect to tocopherols, another class of antioxidants, the total tocopherol content in crude expeller-pressed canola oil was estimated to be 631 mg/kg with $\alpha$- and $\gamma$-tocopherol in an approximate ratio of 1:3, and $\delta$-tocopherol was absent. Degumming and neutralization had little or no effect on the tocopherols, but bleaching resulted in a slight reduction of $\gamma$-tocopherol in canola oil. This study was consistent with earlier studies on other vegetable oils,[11,33,34] which showed that bleaching resulted in a slight reduction (6%) and deodorization led to the most significant loss (about 37.6%) of total tocopherols.

**Sinapic Acid Derivatives and Tocopherol Profiles in Refining Byproducts.** *Soap Stock.* Sinapic acid was the only phenolic compound detected in the soap stock used in this study (Figure 3B). The amount of sinapic acid in soap stock ranged from 17.1 to 42.9 $\mu$g/g, depending on the extraction pH. Although many studies have noted that high amounts of polyphenols are extractable from soap stocks of some vegetable oils, such as rice bran[35,36] and olive[8] oils, the potential of obtaining sinapic acid from canola oil soap stock was not considered. Our results provide the first data showing the recovery of sinapic acid from canola soap stock. Acid treatment increased the extraction efficiency through solubilization of sinapic acid from soap stocks by 1.8 and 2.5 times at pH values of 7 and 2, when compared to pH 12 (Table 3). The total phenolics obtained with the Folin−Ciocalteu assay (TPC-FC) also supported this trend. These result conformed with previous observations[37] that the acid treatments of phenolic extracts helped to prevent the oxidation of sinapic acid. The TPC-FC values of soap stock extracts were higher than that

determined by HPLC, which may be attributed to the Folin–Cioacalteu-reactive phenolics and other interfering compounds.

Sinapic acid present in the crude and degummed oils was lost during neutralization, perhaps either leached or adsorbed in soap stock. The storage of soap stocks at room temperature is also of special interest, as the alkaline pH might contribute toward unavoidable side reactions, thereby affecting the composition of minor components including antioxidants and their stability.[38] This instability could be partially avoided by neutralization or acidification of samples by facilitating a rapid extraction and recovery of stable antioxidants.

*Wash Water.* A considerable amount of phenolics (365 μg SAE/g) was also observed in the canola oil wash water in the present study (Table 2). Similar results have been reported by many investigators assessing the polyphenol content of wash water from olive oil refining.[9,39] Canolol was the predominant phenolic compound present in the wash water sample (69.8–448 μg SAE/g) with minor variations based on the solvent used for solubilizing it prior to methanolic extraction (Figure 3A and Table 3). For example, solubilization of the wash water sample with hexane and cyclohexane resulted in higher yield of canolol (448 and 419 μg SAE/g, respectively) compared with chloroform (69.8 μg SAE/g) and toluene (167 μg SAE/g). The presence of canolol in wash water is because of the high lipid content (>50%) in the sample, associating more of the fat-soluble antioxidants. The results also indicated that canolol was retained during neutralization.

This study demonstrated a rapid method to extract and identify sinapic acid derivatives in edible oil refining wash water. Results support that the wash water retains canolol. The tocopherol composition of these samples was also assessed, and the result showed that it was similar to that of degummed or neutralized oils. The concentrations of α- and γ-tocopherol in wash water were 169 and 278 mg/kg, respectively (Table 2). The retention of canolol and tocopherols in the wash water could be attributed to the minor amount of neutralized oil that was carried through in the wash water. Neutralized oils retained canolol and tocopherols, as discussed above.

*Spent Bleaching Clay.* Total phenolic content (Folin–Ciocalteu assay) of spent bleaching clay was determined to be 677.9 μg SAE/g, and the tocopherol compositions are summarized in Table 2. A substantial amount of sinapine (199 μg SAE/g) was present in the spent bleaching clay. It might be due to the occurrence of sinapine in neutralized oil which is carried to the bleaching clay. Sinapine might be concentrated in the bleaching clay due to the high adsorptive activities of bleaching clay. Bleaching clay has been primarily used to remove color pigments such as chlorophyll and carotenoids from vegetable oils,[22] and the high polyphenol adsorption efficiency of the clay has been reported previously.[40,41] The absence of sinapine in bleached and deodorized oils also confirmed this result (Table 1). However, phenolics including sinapic acid and canolol were not detected

in the bleaching clay. Low amounts of tocopherols were detected in the spent bleaching clay.

It has been suggested by Loh et al.[42] that the residual oil in spent bleaching clay should ideally be extracted and used for industrial applications in order to reduce the cost of oil processing. Unlike the palm oil refining process, canola oil refining may not generate high residual oil in the bleaching clay, but it could be used as a novel source for recovering sinapine, as demonstrated by our results.

*Deodistillates.* Total phenolic content (Folin−Ciocalteu assay) of deodistillates was 525.7 μg SAE/g, the highest among of all the refining byproducts (Table 2). In the extracts of deodistillates, all peaks were identified at 270 nm and the chromatograms are presented in Figure 3C. There are five unidentified peaks eluting between 21 and 29 min, which have not been previously reported. The UV spectra (maximum absorbance) of these peaks are summarized in Table 4. The highest concentrations of the phenolic compounds were observed for the peaks detected at 28−29 min (peak 4, 349.7 μg SAE/g; peak 5, 1708.6 μg SAE/g). The major peak (peak 5, $t_R$ ∼ 28.9 min) exhibited maximum absorbance at 279 nm and did not correspond to any phenolic compounds present in canola seed or canola oil. The spectrum of peak 4 had two wavelength maxima at 209 and 281 nm. It is likely that these phenolic compounds are derivatives of canolol or other sinapates. A previous study reported canolol dimer as the predominant phenolic compound in commercial rapeseed deodistillates based on the dimerization at high temperature or in acid-catalyzed conditions.[17] The phenolic compounds found in the current study might be oligomers of canolol; however, further studies are required for their structural elucidation and characterization.

**Table 4. Concentration and UV Spectra Data of Phenolic Peaks of Deodistillates Extracts Detected at 270 nm**

| peak number[a] | $t_R$ (min) | UV maximum absorbance wavelength (nm) | concn (μg SAE/g) |
|---|---|---|---|
| 1 | 21.3 | 217, 275 | 52.42 ± 2.67 |
| 2 | 23.6 | 282 | 180.6 ± 3.5 |
| 3 | 25.6 | 206, 273 | 182.3 ± 23.7 |
| 4 | 28.4 | 209, 281 | 349.7 ± 20.0 |
| 5 | 28.9 | 279 | 1708.6 ± 21.6 |

[a]Peak numbers refer to the peaks in Figure 2D.

The polarities of various extraction solvents have a tremendous effect on the solubility and, therefore, extraction efficiency[43] of phenolics. The efficacy of different nonpolar solvents to optimally and rapidly extract deodistillate phenolic compounds was investigated (Table 3). The results were similar to that of phenolic extraction in wash water, where solubilization with hexane and cyclohexane followed by methanolic extraction produced a higher amount of phenolics (2537 and 2065 μg SAE/g) from deodistillates than predissolution with chloroform and toluene. Direct methanol extraction of deodistillates resulted in the highest yield of phenolics compared to presolvent solubilization of deodistillates. However, presolvent solubilization showed advantages in improving extraction yield (37% improvement) for large-scale extractions, as reported in a previous study.[4]

The present study also identified deodistillates as a rich source of tocopherols in addition to other phenolics. Both α- and γ-tocopherols were detected in the deodistillates at 2:1 ratio. The deodistillate extract contained 647 mg of α-tocopherol and 3104 mg of γ-tocopherol per kg of deodistillate, a quantity that is greater than those in any crude vegetable oil. These amounts conformed with the values obtained from rapeseed oil deodistillates.[16]

The study indicated a 2-fold potential of deodistillates. First, deodistillate was the best source for recovery of tocopherols among the oil-refining byproducts investigated. The tocopherol content of canola oil at various processing stages supported that the maximum tocopherol losses occurred during the deodor-

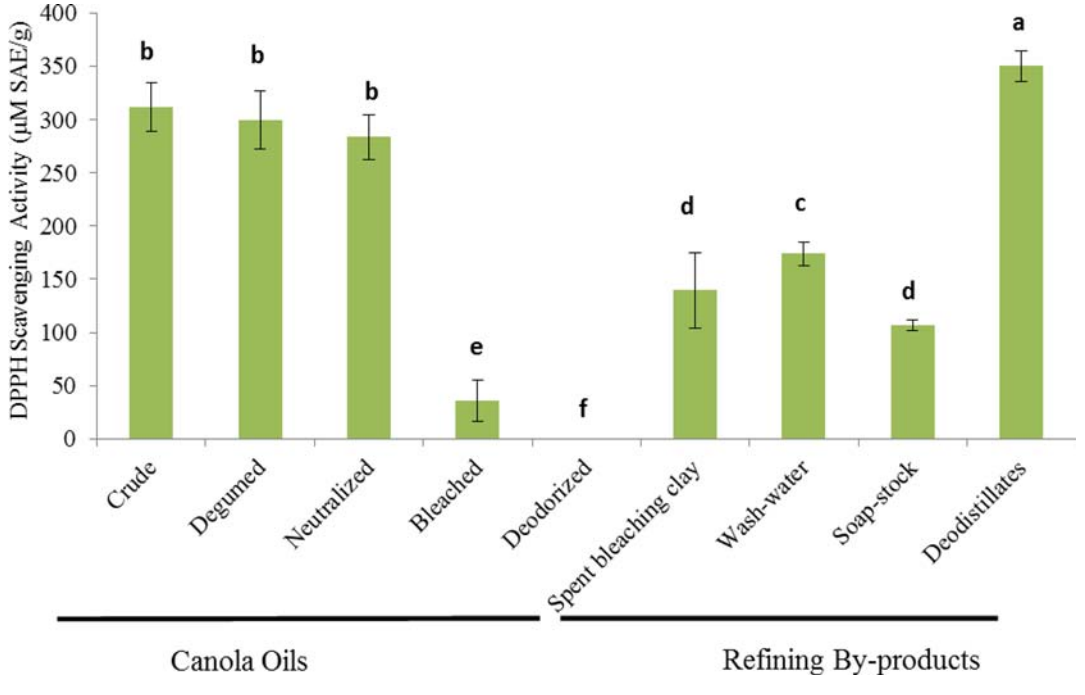

**Figure 4.** DPPH antioxidant activities of expeller canola oils and refining byproducts.

ization process. Second, the extracts of deodistillate showed several phenolic compounds that were not reported until now, requiring further studies for adequate characterization.

**Antioxidant Activity of Phenolic Extracts of Canola Oil and Refining Byproducts.** The antioxidant capacity of expeller-pressed canola oils and refining byproducts were evaluated using the DPPH radical scavenging activities. In the present study, the crude canola oil showed the highest antioxidant activity at a DPPH free radical activity equivalent of 311.9 ± 23.1 $\mu$M SAE/g. These values decreased slightly after degumming and neutralization while reducing rapidly to less than 50 $\mu$M SAE/g after the bleaching step (Figure 4). The decrease was mainly attributed to the loss of endogenous phenolics and tocopherols from expeller-pressed canola oil during refining. Previously, Wakamatsu et al.[2] reported a significant reduction in the anti-ROO• activity of canola oil with each refining stage. The loss of antioxidant activity of oils was translated to a high antioxidant potential of the corresponding refining byproduct in the present study. Among various oil-refining byproducts, deodistillates exhibited the highest radical scavenging activity ($\mu$M SAE/g) of 350.3, followed by wash water (173.5), bleaching clay (139.7), and soap stock (106.7) (Figure 4). This order corroborated with the concentration of the active phenolic compounds contained in the corresponding refining byproducts.

In order to further examine the radical scavenging activity of the phenolic compounds recovered from canola oils and the corresponding refining byproducts, the correlation of the sum of phenolic compounds and antioxidant activity was calculated. There were strong correlations between the total phenolic content and radical scavenging activity in all refining byproducts as well as canola oil ($R^2$ = 0.88−0.99). In addition, the radical scavenging activity of soap stock phenolic extract increased rapidly (slope = 5.670) as the concentration of phenolics (majorly sinapic acid) increased. While this slope of increase was lower in canola oil (0.414) and wash water (0.458) extracts, it was the lowest in deodistillate (0.298) extracts. This result indicated that the DPPH radical scavenging activity of sinapic acid might be more apparent than for sinapine, canolol, and canolol derivatives at the same concentration. A previous study asserted that the 4-vinyl derivatives of hydroxycinnamic acids exhibited lower antioxidant activity than their corresponding phenolic acids.[32] Other studies reported the opposite trend when evaluating the antioxidant potential in different systems such as emulsion[44] and cell culture.[45] Canolol and its polymerized derivatives found in the canola oil refining byproducts could be extracted and potentially used as antioxidants in various food systems.

Renewed interest in utilization of oil-processing byproducts as sources of various high-value coproducts, such as phenolics, phytosterol, protein, and lipids, persists. Processes have been developed to extract phytosterols and tocopherols from refining byproducts of different vegetable oils. The recovery of valuable phenolics with proven bioactivities can improve the economic feasibility of edible oil refining. Given this context, our results provide new knowledge on the byproducts of canola oil subjected to different stages of refining. Sinapic acid (42.9 $\mu$g/g), sinapine (199 $\mu$g/g), and canolol (344 $\mu$g/g) were found in the refining byproducts, namely, soap stock, spent bleaching clay, and wash water, for the first time. Tocopherols (3.75 mg/g) and other nonidentified phenolic compounds (2.7 mg SAE/g) were found in deodistillates. In conclusion, this is the first study showing the retention and recovery of the sinapic acid derivatives and tocopherols using byproducts generated in a commercial expeller-pressed facility. This approach opens up opportunities for utilization of these byproducts as new side streams for commercial utilization in the context of canola and rapeseed oil refining. More studies are recommended to unfold the recovery, extraction, and mechanisms of structural changes of these endogenous biophenols using byproducts of edible oil refining.

17 months) and final live weight (around 665 kg) to avoid weight and age effects on muscle characteristics and beef meat quality.

All bulls were directly transported in a lorry (3 × 2 m) from the experimental farm to the experimental abattoir situated at 1 km from the rearing building, with two bulls of the same home pen per transport to avoid social isolation stress. After unloading, they were slaughtered within 3 min in the slaughterhouse of INRA institute (Saint-Genès-Champanelle, France) in compliance with the current ethical guidelines for animal welfare. Bulls were stunned by captive bolt prior to exsanguination.

Muscle samples from Longissimus thoracis (LT, mixed fast oxido-glycolytic muscle 23% of type I fibers, 36% IIA, and 39% of IIX) and Semitendinosus (ST, mixed fast glycolytic 8% of type I fibers, 24% of IIA, and 64% of IIX) were excised from the carcass of each animal within 15 min after slaughter. Muscle samples were immediately frozen in liquid nitrogen and stored at −80 °C until protein extraction for protein marker quantification. Samples of the two muscles for sensory evaluation and mechanical measurement were cut into steaks 24 h after slaughter and placed in sealed plastic bags under vacuum and kept between 2 and 4 °C for 14 days for aging, then frozen, and stored at −20 °C until analysis.

**Meat Quality Evaluation.** LT and ST samples were grilled on a preheated grill at 310 °C, resulting in an internal cooked temperature of 55 °C. For sensory analysis, a trained sensory panel (12 experienced panelists) evaluated the steak samples of the same muscle. The panel evaluated overall tenderness attribute on a continuous and unstructured scale with scores from 0 to 10 (0 = hard, 10 = tender).[16,17]

Toughness of cooked meat was further evaluated instrumentally by Warner−Bratzler shear force (WBSF) using an Instron 5944 as described by Lepetit and Culioli.[18] Force at rupture during shear compression testing was expressed in N/cm$^2$.

Sensory and mechanical values of tenderness were used to compute a synthetic tenderness index by combining standardized normal sensory and mechanical tenderness/toughness values.[19] This was calculated for each muscle as the difference within each breed between the standardized values of tenderness score minus the standardized value of the WBSF measure. This index was suggested to take into account the very close genetic correlation underlying the moderate phenotypic correlation observed between both traits,[20] suggesting both traits are under the control of common genes.

**Dot-Blot Analysis.** The 21 proteins analyzed are described in Table 1. The conditions for use and specificity of primary antibodies against these 21 proteins in bovine muscle have been determined previously by Guillemin et al.[21] using Western blot techniques (Table 2).

Total protein extractions were performed according to the method of Bouley et al.[22] in a denaturation extraction buffer (8.3 M urea, 2 M thiourea, 1% DTT, 2% CHAPS). The protein concentration was determined using the Bradford protein assay.[23] Protein extractions were stored at −20 °C.

Relative abundances of proteins were evaluated following the dot-blot technique as described by Guillemin et al.[21] Briefly, protein samples were spotted in quadruplicate on a nitrocellulose membrane with the Minifold I dot blot from Schleicher & Schuell Biosciences (Germany) and hybridized with the specific antibody of each protein, with conditions described in Table 2. Secondary fluorescent-conjugated IRDye 800CW antibodies (anti-mouse, anti-sheep, and anti-rabbit) were supplied by LI-COR Biosciences (Lincoln, NE, USA) and used at 1/20000. Subsequently, membranes were scanned by an Odyssey (LI-COR Biosciences) scanner at 800 nm. Protein relative abundance for each sample, given in arbitrary units, was normalized by comparison to a reference sample constituted by mixing all samples from young bulls from this experiment in equal proportions. The technical coefficient of variation of this technique is on average 9%.[21]

**Statistical Analysis.** Analysis of variance was performed using the GLM procedure of SAS for repeated measures (version 9.1, 2002; SAS Institute Inc.). The effects of breed, muscle type (LT vs ST), and breed × muscle type interaction are reported. When significant effects were detected, differences were evaluated by the PDIFF option of SAS.

**Table 1. 21 Protein Biomarkers of Beef Tenderness Investigated in This Study[a]**

| protein name | gene | UniProt ID |
|---|---|---|
| hea shock proteins | | |
| αB-crystallin | CRYAB | P02511 |

| μ-calpain | CAPN1 | P07384 |

[a]Protein biomarkers of beef tenderness established by our group in previous proteomic studies (for reviews see Guillemin et al.,[27] and Picard et al.[6,8,10,11]).

Principal component analyses (PCAs) were performed using the factor procedure of SAS to study the overall relationships between the studied variables (tenderness traits and protein relative abundances).

Multiple regression analyses were carried out using XLStat 2009 software to explain overall tenderness, WBSF, and tenderness index traits for the two muscles separately, presenting the 21 protein biomarkers as potential explanatory variables, as well as breed. The "optimal model" explaining maximal variability option was used with "maximal four variables". The percentage of variability in meat quality parameter explained by proteins is based on the adjusted $r^2$ value of the regression analysis × 100%.

Absence of collinearity was verified for each model. Condition indices and variance proportions were produced using the COLLIN option of SAS, with components identified as collinear if they possessed both a high condition index >10 and a proportion of variation >0.5 for two or more variables.

## RESULTS

**Tenderness Traits.** The values of tenderness evaluated in three ways are presented in Table 3. For the LT muscle, significant breed effects were found for overall tenderness only, AA bulls being more tender than BA and LI bulls (Table 3). In the ST muscle, significant differences between breeds were observed for the WBSF and the tenderness index. A significant muscle × breed interaction was observed for the WBSF and the tenderness index, Limousin ST muscle being tougher than BA, whereas AA had intermediate values (Table 3). Overall tenderness (Table 3) was much higher in the LT. For the WBSF, this was only a tendency.

**Table 2. Suppliers and Conditions for Each Primary Antibody Used in This Study**

| target protein | antibody references | dilution[a] |

| μ-calpain | monoclonal anti-bovine Alexis μ-calpain 9A4H8D3 | 1/1000 |

[a]Dilution of each antibody was defined according to Guillemin et al.[27] [b]MyHC II corresponds to fast MyHC: IIa+IIx+IIb isoforms.

**Protein Relative Abundances.** Significant breed effects were found for at least one of the two muscles for most of the proteins except for Hsp70-1B, MyBP-H, and SOD1 (Table 4). The two muscles of AA bulls presented higher levels of αB-crystallin, Hsp27, Eno3, and PRDX6 and lower levels of MyHC-IIx. Most proteins showed an effect of muscle or a muscle × breed interaction, apart from MyLC-1F, MyBP-H, SOD1, and μ-calpain (Table 4).

**Relationships between Biomarkers and Tenderness Traits.** *Descriptive Analysis.* The PCA illustrating the relationships between relative abundances of protein biomarkers and tenderness traits evaluated by (i) sensory analysis (overall tenderness), (ii) Warner−Bratzler shear force (WBSF), and (iii) tenderness index are presented in Figure 1. In the two muscles, overall tenderness and tenderness index were positively correlated, and both were negatively correlated with the WBSF

*(a) LT Muscle.* As illustrated in Figure 1a, high overall tenderness scores were positively associated with small Hsp proteins (Hsp27, Hsp20, αB-crystallin), Eno3, structural protein CapZ-β, and antioxidants PRDX6 and DJ-1 when considered across breeds. Low tenderness scores were associated with proteins of the Hsp70 family (Hsp70-8, Hsp70-1A/B, and Hsp70/Grp75) or related to fast glycolytic muscle fibers (e.g., LDH-B, MyHC-IIx). The average loadings of the different breeds (Figure 1b) differed on the first axis (BA < LI < AA; $P = 0.0001$), and on the second axis, the AA bulls differed from the other breeds (AA > LI, BA; $P = 0.001$). Compared to LI and BA, LT muscles of AA bulls were characterized by higher abundances of small Hsp (Hsp27, Hsp20, αB-crystallin), Hsp40, Eno3, CapZ-β, PRDX6, and DJ-1 and lower abundances of LDH-B and MyHC-IIx (cf. Table 4).

*(b) ST Muscle.* In the ST muscles, overall tenderness scores were positively associated with LDH-B and MyHC-IIx (Figure 1c) and negatively with small Hsps (Hsp27, Hsp20, αB-crystallin), Hsp40, Eno3, MyHC-I, CapZ-β, PRDX6, and DJ-1. On the first axis (Figure 1d), AA differed significantly ($P < 0.0001$) from the other breeds (LI, BA < AA), and on the second axis all breeds differed significantly (AA < LI < BA; $P < 0.01$). As in the LT, AA were characterized by higher abundances of small Hsp, Hsp40, Eno3, MyHC-I, CapZ-β, PRDX6, and DJ-1 and lower abundances of LDH-B and MyHC-IIx.

*(c) Comparison of the PCAs of the LT and ST Muscles.* The PCA demonstrates inverse relationships between some proteins

and tenderness in the two muscles. MyHC-IIx and LDH-B were positively associated with tenderness in ST muscle and negatively in LT. In contrast, proteins from the small Hsp family, Eno3, Hsp40, CapZ-$\beta$, PRDX6, and DJ-1, were negatively correlated with tenderness in ST and positively in LT muscle. In addition, the graphs show that the Angus breed was associated with high tenderness values in LT muscle and with low tenderness in the ST muscle.

*Regression Analyses.* Multiple regression analyses carried out on the pooled data of the three breeds showed that, for the

LT and ST muscles, the proteins explained only 10−17% of the variability of the three tenderness measurements (Tables 5−7). The models for overall tenderness retained (Table 5) LDH-B, PRDX6, Hsp20, and Hsp70-1A/B for the ST muscle and Hsp20, MyHC-IIx, and Hsp70-1B for the LT muscle. The models for WBSF retained Hsp70-1B for the two muscles and MyHC-IIx for the ST muscle (Table 6). The models of the tenderness index retained MyHC-IIx for the ST and LT muscles. The LT tenderness index was further correlated with α-actin and with Hsp70-1A/B (Table 7).

When breeds were considered separately, the prediction power (adjusted $r^2$) improved, although it varied according to breed and tenderness measurement (Tables 5−7). The models for LI bulls had the most predictive power. The model of overall tenderness of the ST muscle of LI bulls retained (Table 5) fast MyHC, Hsp70/Grp75, and PRDX6, explaining 53% of the variability between animals. MyLC-1F and Hsp70-1A/B explained 35% of variability in overall tenderness of the LT muscle between LI bulls. The model for WSBF explained even 60% of the variability of the LI breed in both muscles (Table 6). Proteins retained in the models were MyHC-IIx and -II for

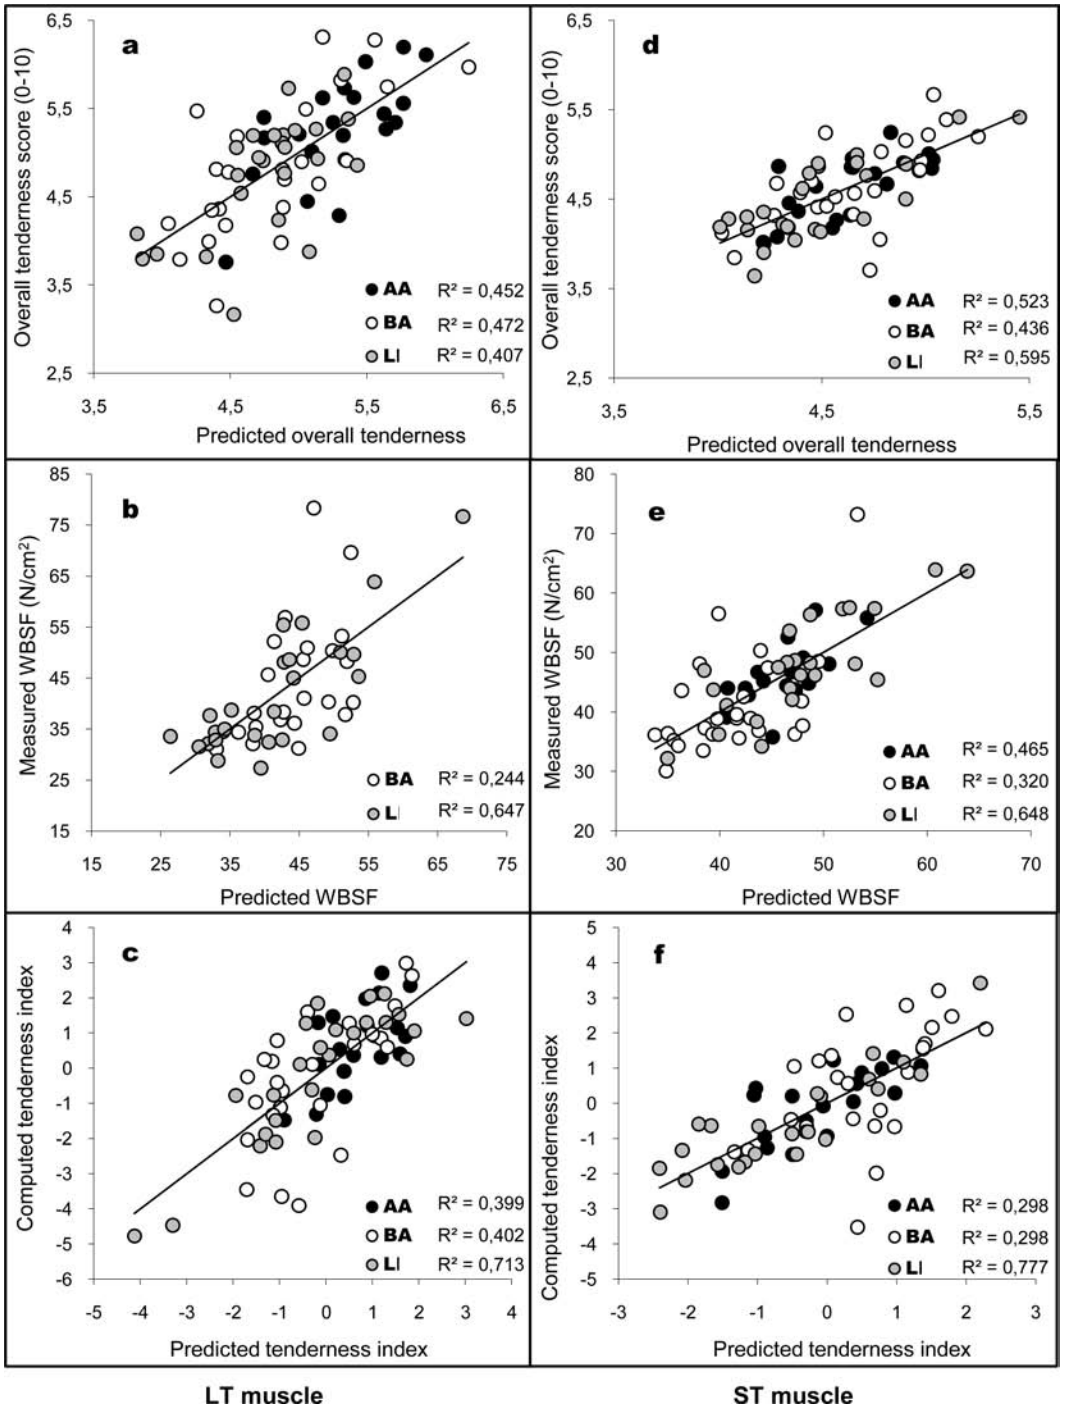

**Figure 2.** Correlations between predicted and measured beef tenderness traits (for tenderness, WBSF, and tenderness index) using best models for the three breeds among LT (a–c) and ST muscles (d–f). Adjusted *r*-squares corresponding to the prediction equations shown in Tables (5–7) for each breed are given. Breed designation: AA, Aberdeen Angus; BA, Blond d'Aquitaine; LI, Limousin.

the ST muscle and LDH-B, Hsp70-1A/B, and MDH1 for the LT muscle (Table 6). The model for the tenderness index for both muscles had high predictive power, explaining 73 and 66% of the variability for the ST and LT, respectively (Table 7).

Correlations between predicted and measured values for each tenderness trait among the two studied muscles are shown (Figure 2).

For the AA bulls, none of the 21 quantified protein biomarkers could predict the WBSF of the LT muscle (Table 6). In the ST muscle, the WBSF was predicted by Eno3 and Hsp70-1A/B (positively) and by αB-crystallin (negatively). Overall tenderness and tenderness index were better predicted in the ST than in the LT muscle.

For the BA bulls, prediction powers were similar in the two muscles with better prediction for overall tenderness by Hsp70-1A/B (negatively) in ST and by DJ-1 (positively) and MyBP-H (negatively) in LT muscle (Table 5). The predictions of WBSF and tenderness index were lower than in the two other breeds (Tables 6 and 7).

dx.doi.org/10.1021/jf501528s | J. Agric. Food Chem. 2014, 62, 9808–9818

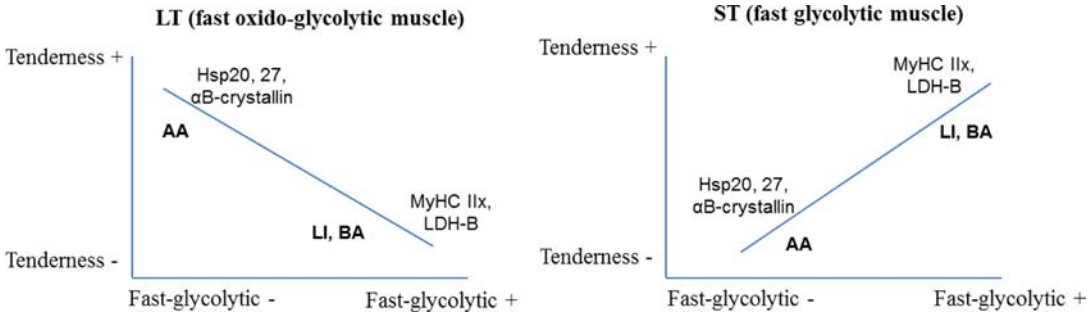

**Figure 3.** Schematic illustration of the relationships between muscle metabolic and contractile properties and tenderness depending on the muscle. (Left) For the Longissimus thoracis (fast oxido-glycolytic muscle), higher degrees of fast glycolytic properties are associated with lower tenderness. (Right) For the Semitendinous (fast glycolytic muscle) higher degrees of fast glycolytic properties are associated with higher tenderness. Consequently, biomarkers associated with contractile and metabolic properties of the muscles such as MyHC IIx and LDH-B are positively or negatively associated with tenderness of the ST and LT muscles, respectively. The opposite is found for other biomarkers such as small Hsps (Hsp20, Hsp27, $\alpha$B-crystallin). ST and LT muscles from Angus breed (AA) have lower levels of fast glycolytic properties than those of Limousin (LI) and Blond d'Aquitaine (BA) breeds. Therefore, their LT and ST muscles are more and less tender, respectively, than those of the LI and BA breeds.

Overall, the results demonstrate that among the 21 quantified proteins, Hsp70-1A/B was often retained in the prediction models of the different breeds and negatively correlated with the different tenderness measurements in both muscles. Proteins representing fast glycolytic fiber types such as MyHC-IIx or LDH-B were correlated with tenderness in the two muscles for the three tenderness traits, but the direction of the correlation depended on the muscle, as also illustrated in the PCA (Figure 1): they were positively correlated with tenderness measurements in the ST and negatively correlated in the LT muscle. The glycolytic Eno3 enzyme was correlated with the three tenderness indicators in the ST muscle of the AA bulls. PRDX6 was correlated with ST overall tenderness and tenderness index but never with WBSF.

## ■ DISCUSSION

The first objective of this study was to determine in two different muscles of young Aberdeen Angus, Limousin, and Blond d'Aquitaine bulls the relationships between tenderness indicators and several protein biomarkers previously identified as good predictors of meat tenderness.[6] The second objective was to propose prediction equations of tenderness based on the abundances of the biomarkers. Among the quantified proteins, Hsp70-1A/B was the only protein associated with the different tenderness indicators in the two muscles and the three breeds. Other proteins including LDH-B, MyHC-IIx, and various small Hsps were associated with tenderness, but oppositely in the ST compared to the LT muscle. These data suggest that different mechanisms underlie tenderness, some which are common between both muscles, whereas others differ. The underlying mechanisms appear to be related to the contractile and metabolic properties of the muscle, and they differ in the sense that the direction of the correlation with tenderness depends on the muscle.

**Muscle- and Breed-Specific Biomarkers of Tenderness.** Our findings show that MyHC-IIx and LDH-B are positively and negatively correlated with tenderness of the ST muscle (fast glycolytic) and LT muscle (fast oxido-glycolytic, respectively. These opposite correlations are in agreement with earlier studies. For example, Chaze et al.[19] showed in young bulls from three main French beef breeds that in the LT muscle several proteins representing fast glycolytic properties were negatively correlated with tenderness and several proteins corresponding to slow oxidative properties were positively correlated with tenderness. Studying the same muscle in young Blond d'Aquitaine, Morzel et al.[24] found succinate dehydrogenase, an oxidative enzyme, to be a good marker of tenderness. In Charolais young bulls, fast proteins such as Troponin T fast isoforms, phosphoglucomutase, fast MyHC, and glycogen phosphorylase were found to be potential biomarkers of toughness, and slow MyHC, ATP synthase $\beta$, and ApoBEC were associated with increased tenderness.[12] Other studies based on fiber types and enzyme activities showed positive relationships between slow oxidative fiber types and tenderness in the LT and a negative relationships in the ST muscle.[2] This was further confirmed in a meta-analysis combining more than 332,000 data on fiber types and enzyme activities of these two muscles in several types of cattle.[4] The present results indicate also that in the case of a fast glycolytic muscle such as ST, muscles containing a greater proportion of fast glycolytic fibers will produce more tender meat and, in the case of a more oxidative muscle such as LT, muscles containing a greater proportion of slow oxidative fibers will produce more tender meat. In the present study, LT meat of AA bulls was more tender and ST meat was less tender compared to the LI and BA breeds. This is coherent with the opposite correlations described above. Irrespective of breed, for the LT muscle, the more glycolytic it is, the less tender it is, and for the ST muscle, the more glycolytic it is, the more it is tender. The LT of AA was less glycolytic compared to the other breeds and, consequently, more tender. The ST of AA was less glycolytic compared to the other breeds and, consequently, less tender. Other factors, such as lipid content, may of course also play a significant role.

The positive correlation between MyHC-IIx and tenderness observed in the LT muscle of the AA bulls may seem to contrast with the above idea. Other authors found similarly positive relationships between fast glycolytic type and tenderness in LT muscle from animals with muscles with oxidative characteristics. For example, D'Allessandro et al.[25] in Longissimus dorsi from Chianina beef cattle observed that the tender meat group on the basis of WBSF was characterized by higher levels of glycolytic enzymes.

Overall, existing results demonstrate that the contractile and metabolic properties of muscle play a major role in the elaboration of tenderness.

The present study found other opposite associations between proteins and tenderness according to the muscle or breed. Thus, proteins from the small Hsp family (Hsp20, Hsp27, and αB-crystallin) were inversely associated with tenderness depending on the two muscles. These proteins were negatively associated with tenderness in the ST muscle and positively in the LT muscle. These data are in agreement with the results of Guillemin et al.,[26] who demonstrated that in the ST muscle, Hsp from both the Hsp70 family and small sHsp family were inversely correlated with tenderness as observed in the present study. Nevertheless, these Hsps were not correlated with tenderness of the LT muscle. In a previous experiment with Blond d'Aquitaine young bulls, we found inverse relationships between sHsp abundances and tenderness in ST and LT muscles.[10] This could demonstrate that the functions of sHsp depend on the contractile and metabolic properties of the muscle. Guillemin et al.[27] showed that slow oxidative fibers have the highest abundance of αB-crystallin. This is in accordance with our data showing higher abundances in LT than in ST muscle and earlier data reported by Guillemin et al.[26] showing higher abundances in Charolais young bulls and AA than in LI and BA.

Overall, these results allow understanding why the correlations between one biomarker and tenderness could be reversed as described in the literature. Our results give explanations as described in Figure 3. These relationships according to muscle and breed types need to be confirmed in other muscles and animal types.

In the present study, PRDX6, an antioxidant enzyme, was associated with tenderness mainly of the ST muscle, but in opposite directions, depending on the breed. This is in accordance with earlier results. Guillemin et al.[27] found that PRDX6 is a biomarker of low tenderness of the ST muscle in young Charolais bulls, whereas Jia et al.[28] reported an overexpression of PRDX6 in tender meat in young Norwegian Red bulls. The antioxidant action of PRDX6 is based on the hydrolysis of hydrogen peroxides and facilitation of the repair of damaged cell membranes via reduction of peroxidized phospholipids.[7,29] Antioxidant enzymes such as PRDX6 and also SOD1 are involved in the protection of the cell against oxidative stress, which is causal of free radicals of oxygen, resulting in the formation of protein aggregates.[30] These aggregates may hamper the tenderization process of the meat. In agreement with this finding, D'Alessandro et al.[25] proposed that oxidative stress promotes meat tenderness and elicits heat shock protein responses. Ouali and co-workers[7,31] proposed that the first step of the conversion of muscle into meat is the onset of apoptosis. This death process is energy dependent and involves a large number of proteins including Hsp families. D'Alessandro et al.[25] discusses the possible causes of opposite relationships between abundances of oxidative enzymes and tenderness. The authors speculate that post-mortem metabolism in tender and tough meat is subtly modulated via higher levels of specific enzymes and amino acidic residue phosphorylation in a breed-specific fashion. Results of the present study showing that PRDX6 is positively associated with overall tenderness in AA and negatively in LI young bulls are in accordance with this suggestion. Guillemin et al.[27] showed that the relationship between antioxidant enzymes such as PRDX6 and also SOD1 was more significant in Charolais steers than in young bulls, suggesting that gender may also play a role. They showed that SOD1 was correlated with tenderness only in steers, which may explain the absence of an association between tenderness and SOD1 in the present study.

Overall, these data demonstrate that the contractile and metabolic properties of muscles play a major role in the elaboration of tenderness. It is likely that mechanisms underlying the determinism of tenderness involve several biological processes such as apoptosis, oxidative stress, and proteolysis, which depend probably on these muscle properties.

**Hsp70-1A/B Is a Good Candidate Biomarker of Meat Tenderness in the Three Breeds.** Proteins from the Hsp70 family (Hsp70-1A/B, Hsp70-8, GRP 75) were recently found to be related to tenderness.[8] In the present study, among Hsp70s, only Hsp70-1A/B (gene HSPA1B), also called Hsp70-2 depending on species, was negatively associated with overall tenderness and tenderness index and positively with WBSF in the two muscles across the three breeds.

The members of the Hsp70 family serve a variety of roles: (i) they act as molecular chaperones facilitating the assembly of multiprotein complexes, (ii) they participate in the translocation of polypeptides across cell membranes and to the nucleus, and (iii) they help in the proper folding of nascent polypeptide chains.[32] In the Diaphragma muscle from Holstein−Friesian cattle, Sugimoto et al.[33] showed that misfolding of energy-related proteins due to Hsp70 deficiency might lead to protein aggregation and muscle fiber degeneration. This is in coherence with the negative association with tenderness observed in the present study. Moreover, the study of Crawford and Horowits[34] showed that, in particular, scaffolding proteins and chaperone proteins such as Hsp90 and Hsp70 are required for individual steps in the assembly of myofibril. The study of Miyabara et al.[35] showed that Hsp70 improves structural and functional recovery of skeletal muscle after disuse atrophy. This is in agreement with several studies showing that Hsp70 is one of the most important heat shock proteins for maintenance of cell integrity during normal cellular growth as well as under pathophysiological conditions.[36,37] These data suggest that Hsp70 is important for maintaining structural, ultrastructural, and functional properties of skeletal muscle. Possibly, Hsp70-1A/B plays also an important role in structural modifications during post-mortem aging. Hsp70-1A/B has further an antiapoptotic role in skeletal muscle. Gao et al.[36] reported a function of Hsp70-1A/B in regulating TNF-α-induced cell apoptosis. By forming the complex Hsp70/CHIP/ASK1, Hsp70 promotes ASK1 proteasomal degradation and prevents TNF-α-induced cell apoptosis. Hsp70 proteins are also known to sequester pro-apoptotic factors such as BCL-2.[38] These data are in agreement with the important role of apoptosis in meat aging.[7,39]

The present study found that in contrast to Hsp70-1A/B, the association between the relative abundance of the other Hsp70s and tenderness traits differed according to breed and muscle. This may be explained by different regulation of the expression of these Hsp70s in the muscle. In the present study, Hsp70/Grp75 and Hsp70-8 were less abundant in AA than in BA, particularly in the LT muscle. However, Hsp70-1A/B abundance did not differ between breeds in the two muscles. These data are in agreement with the results of Guillemin et al.,[27] who showed no effect of gender on Hsp70-1A/B abundance between steers and young bulls. This would explain the association between Hsp70-1A/B and tenderness across muscles and breeds observed in the present study. The lack of consistent associations between tenderness and Hsp70/Grp75 may be explained by the fact that it is exclusively expressed in

the mitochondrial matrix and that it is involved in the translocation and folding of nascent polypeptide chains of both nuclear and mitochondrial origin.[40]

These findings suggest that Hsp70-1A/B could be a relatively general biomarker of tenderness in different muscles and breeds compared to proteins discussed earlier, which appear to be quite strongly muscle- or breed-specific.

In conclusion, this study shows that some biomarkers of tenderness such as MyHC IIx, LDH-B, and small Hsp are dependent on the contractile and metabolic properties of the muscle (cf. Figure 3), explaining their opposite relationships with tenderness in the ST compared to the LT muscle and in AA compared to LI and BA bulls. It further shows that Hsp70-1A/B is a biomarker of low beef tenderness across the breeds and muscles studied. All of these biomarkers need further testing in various muscles from cattle of different genders and breeds before they can be used as biomarkers in routine immunological testing.

proteins, sorghum protein bodies are more highly cross-linked, leading to increased levels of covalent bonding and protein polymerization in the matrix.[8,9] This increased level of cross-linking reduces overall protein digestibility, which compounds nutritional deficiencies of sorghum, such as low inherent levels of lysine and threonine, and often needs to be supplemented in food and feed.[13]

Identification and characterization of endosperm proteins and the elements regulating their synthesis, localization, and degradation facilitates enhancement of amino acid content and starch accessibility for improved grain nutritional value.[14] This study involves the evaluation of grain protein composition in sorghum lines with allelic variation in kafirin storage proteins using a range of proteomic tools, including reversed-phase HPLC (RP-HPLC), lab on a chip (LOC), SDS-PAGE, and liquid chromatography−tandem mass spectrometry (LC−MS/MS). The focus of the work is to identify candidate proteins, which may impact on quality traits, particularly those which are differentially expressed across the genotypes.

## MATERIALS AND METHODS

**Plant Material.** Twenty-eight inbred sorghum lines, with previously determined allelic variation in the $\beta$-, $\gamma$-, and $\delta$-kafirin storage proteins, were included in the study.[15] The primary focus of the analysis was on comparisons between the $\beta$-kafirin null line QL12 and 296B, an important food line of Indian origin. Plants were cultivated under field conditions at the University of Queensland, Gatton campus, QLD, Australia, over the 2008/2009 and 2011/2012 summer growing seasons.

**Protein Extractions.** *Albumin/Globulin (A/G).* Wholegrain flour (100 mg) prepared from kernels ground in liquid nitrogen using a mortar and pestle was mixed in 1 mL of extraction solvent (50 mM Tris·HCl pH 7.8, 100 mM KCl, and 5 mM EDTA). The sample was vortexed and centrifuged, and a 500 $\mu$L aliquot of supernatant was removed to a new tube.[16] The process was repeated by adding an additional 1 mL of extraction solvent to the pellet, repeating the extraction process and removing an additional 500 $\mu$L of supernatant to the same tube.

*Prolamin.* The A/G pellet from the above extraction procedure was retained and washed with 1 mL of distilled water ($dH_2O$), and 1 mL of solvent was added (60% *tert*-butyl alcohol, 0.5% sodium acetate w/v, and 2% $\beta$-mercaptoethanol ($\beta$-ME) v/v). The pellet was then vortexed and centrifuged, and 500 $\mu$L of supernatant was transferred to a new tube. The procedure was repeated once, and a further 500 $\mu$L of supernatant was removed to the same tube.

*Glutelin/Residual Proteins.* The pellet from the prolamin extraction was washed with 1 mL of $dH_2O$ and 1 mL of sodium borate buffer (125 mM pH 10.0 containing 1% SDS w/v and 1% $\beta$-ME v/v) was added to the pellet. The suspension was vortexed and centrifuged, and 500 $\mu$L of supernatant was transferred to a new tube. The procedure was repeated once, and a further 500 $\mu$L of supernatant was removed to the same tube.

**Reversed-Phase HPLC (RP-HPLC).** Protein samples were analyzed using an Agilent 1100 HPLC system (Agilent, Foster City, CA), fitted with a Poroshell column of varying stationary phases (as indicated below for the various protein fractions). The system employed a binary gradient with a constant flow rate of 0.7 mL/min, and a column temperature was maintained at 55 °C. Solvents for RP-HPLC included water containing 0.1% trifluoroacetic acid (TFA) w/v (A), and acetonitrile (ACN) containing 0.07% TFA w/v (B), with gradient flow specifications as follows: 0−18 min, 45%−60% B; 18−19 min, decreased to 45% B; followed by a 7 min post run. Absorbance was measured with a UV detector at 214 nm.

*Albumin/Globulins.* After extraction, 250 $\mu$L A/G aliquots were freeze-dried in a SpeedVac overnight. Prior to RP-HPLC analysis, the aliquots were resuspended in 100 $\mu$L of 50% ethylene glycol to stabilize proteins.[17] Samples (5 $\mu$L) were analyzed using a 2.1 × 75 mm Poroshell 300 SB C3 column.

*Prolamins.* After extraction, protein samples (1 mL) were alkylated by adding 33 $\mu$L of 4-vinylpyridine and vortexed for 10 min. Samples (5 $\mu$L) were then injected directly for RP-HPLC analysis using 2.1 × 75 mm Poroshell 300 SB C18 column.[16] Proteins were detected by UV at 214 nm.

**Lab on a Chip (LOC).** The lab-on-a-chip procedure was carried out on an Agilent 2100 Bioanalyser using the Protein 80 assay kit (Agilent Technologies, Palo Alto, CA). A 1:1 mixture of protein to denaturing buffer was used.

**Sodium Dodecyl Sulfate Polyacrylamide Gel Electrophoresis (SDS-PAGE).** *Protein Sample Cleanup.* Samples were cleaned and concentrated with a 2-D Clean-Up Kit (GE Healthcare Ltd.). Concentrations were measured using a 2-D Quant Kit (GE Healthcare Ltd.) according to the manufacturer's instructions.

*One-Dimensional (1D) SDS-PAGE.* A 10 $\mu$L sample was resuspended in 5 $\mu$L of 3X loading buffer (100 mM Tris, 1% SDS (w/v), 0.01% bromophenol blue, 15% glycerol, 0.05% $\beta$-ME), and heated to 95 °C, and then chilled on ice and loaded onto a small format precast anyKd (10−250 kDa range) gradient gel (Bio-Rad, Hercules, CA), with 15 $\mu$L of ColorPlus prestained marker (broad range 7−175 kDa) added to the first and last wells. Gels were run in SDS buffer (25 mM Tris, 200 mM glycine, 0.1% SDS w/v) at 200 V for 40 min until the loading dye front reached the bottom of the gel. Gels were fixed in 50% MeOH, 7% acetic acid for 1 h with shaking, and then stained in ∼50 mL of Coomassie stain overnight. Gels were destained in 1% acetic acid for 30 min, and then rinsed with $dH_2O$ and scanned.

*Two-Dimensional (2D) Isoelectric focusing.* A rehydration solution containing 100 $\mu$g of protein was prepared to a total volume of 125 $\mu$L (20 $\mu$L of protein [concentration 5 $\mu$g/$\mu$L], 100 $\mu$L of rehydration buffer [7 M urea, 2 M thiourea, 2% CHAPS, 0.5% (v/v) IPG buffer, 0.0002% bromophenol blue], 4 $\mu$L of fresh 1 M dithiothreitol (DTT), 1.25 $\mu$L of carrier ampholytes [pH 3−11]). The sample mixture was loaded onto 7 cm IPG strip (3−11 nonlinear gradient (NL) small strips), placed in a carrier coffin, and 0.8 mL of dry strip cover fluid was applied to minimize evaporation and urea crystallization. IEF was run for a total of ∼16 000 V h at 20 °C on the IPGphor with the following program settings: 30 V for 14 h (rehydration), 100 V for 2 h (Step-n-hold), 500 V for 1.5 h (Step-n-hold), 1000 V for 1.5 h (Step-n-hold), 5000 V for 1 h (gradient), 5000 V for 2 h (Step-n-hold), and 50 V (hold). It was ensured that the voltage reached at least 5000 V to achieve a standard protein gradient. Strips were removed from the coffin and either used immediately for 2D SDS-PAGE gel analysis or stored at −20 °C until required.

*Two-Dimensional SDS-PAGE.* IPG strips were saturated with MES running buffer [50 mM 2-morpholinoethanesulfonate (MES), 50 mM Tris base, 0.01% SDS w/v, 1 mM EDTA], 6 M urea, 30% glycerol, 2% SDS w/v, and 0.001% bromophenol blue by first equilibrating in MES buffer plus 50 mg/mL (DTT) for 15 min with shaking to reduce disulfide bonds, and then soaking strips in MES buffer plus 125 mg/mL iodoacetamide (IAA) for 15 min with shaking to alkylate the free cysteine residues. IPG strips were fitted into Bis/Tris small format precast gels (15%) (Invitrogen, Carlsbad, CA). The loading well was then sealed with ∼0.8 mL agarose sealing solution (0.5% agarose, 0.001% bromophenol blue). The gel was run in 1X MES running buffer at low voltage (25−50 V) for 30 min, and then the voltage was increased to 125 V and run until the loading dye front disappeared off the bottom of the gel (approximately 1.5−2 h). Gels were fixed in 50% MeOH, 7% acetic acid for 1 h with shaking, and then transferred to a Sypro Ruby silver stain solution overnight with shaking and destained for 30 min (10% MeOH, 7% acetic acid) prior to scanning using a Typhoon 9400 (GE Healthcare). The gel was then stained in Coomassie overnight with shaking to visualize spots for excision from gel and subsequent mass spectrometric analysis. Coomassie stained gels were destained in 1% acetic acid and scanned with Odyssey at 700 nm.

**Mass Fingerprinting (LC−MS/MS).** *Reduction/Alkylation of Gel Pieces.* Protein spots were manually excised from gels and destained in 50 mM ammonium bicarbonate (ABC)/50% acetonitrile (ACN), 2 × 200 $\mu$L, with shaking for 3−4 h or overnight. For 1D gel pieces, buffer/destain was removed from gel pieces with pipetting and the sample was soaked in 40 $\mu$L of 10 mM DTT to reduce cysteine residues. Gel pieces were incubated at 60 °C for 30 min, DTT solution was removed, and 40 $\mu$L of 55 mM fresh IAA was added. Samples were then incubated at room temperature for 30 min in the dark. IAA was discarded and (for 1D

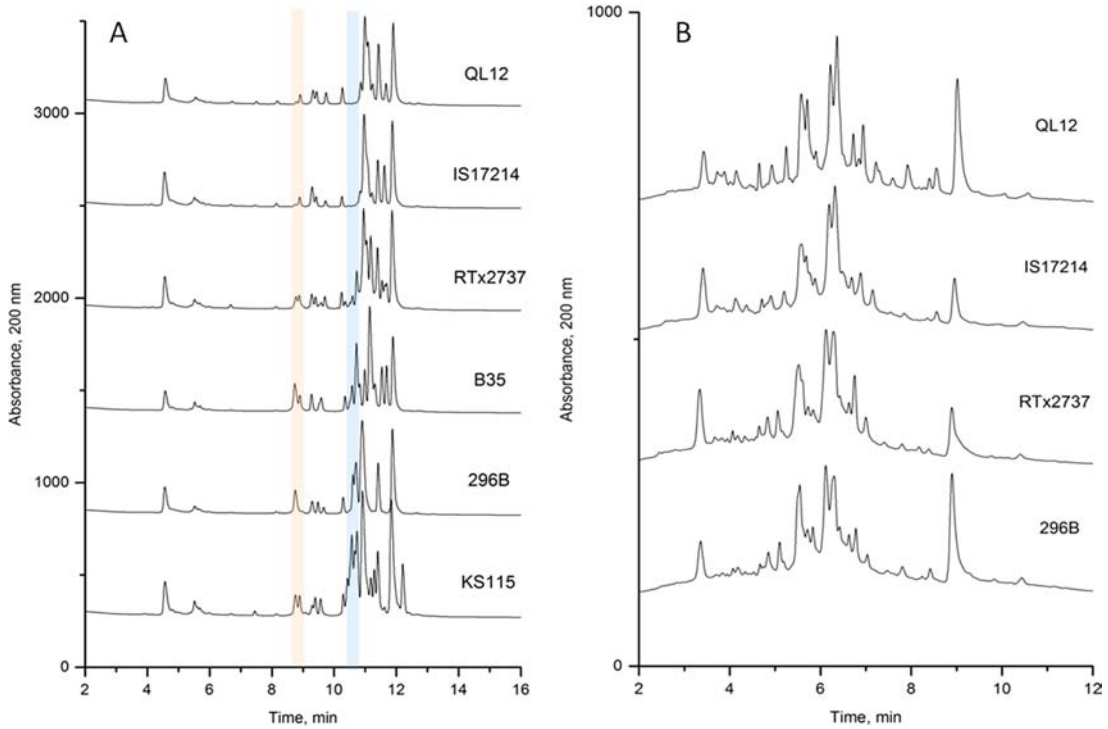

**Figure 1.** RP-HPLC profiles for the (A) alcohol-soluble (prolamin) fraction and (B) water/salt-soluble (albumin/globulin) fraction across $\beta$-kafirin null allelic variants QL12, 1517214, and RTx2737, and lines with normal $\beta$-kafirin content, including B35, 296B, and KS115. In the prolamin fraction $\beta$-kafirin null lines showed a reduction in the size of a peak eluted at 9 min (outlined in orange). Peak distribution profiles at 10−11 min elution times were similar across lines with normal $\beta$-kafirin content, while a significant proportion of protein in this area of the chromatogram was missing in the $\beta$-kafirin null mutants (outlined in blue).

and 2D gel pieces), 100 $\mu$L of 50 mM ammonium bicarbonate (ABC) was added, with vortexing/shaking for 1−2 min, removal of solution, and repeated washing. Gel pieces were then dehydrated in 50 $\mu$L of 100% ACN for 5 min, with vortexing.

*Enzymatic Digestion and Peptide Extraction.* Gel pieces were rehydrated in a 50 mM ABC solution containing 8 $\mu$L of trypsin (10 ng/$\mu$L) (sequencing-grade modified trypsin, Promega, Madison, WI) for 10−20 min at 4 °C. An additional volume (6−16 $\mu$L) of 50 mM ABC buffer was then added, depending on the size of the gel piece, and samples were incubated overnight at 37 °C. Then, 50 $\mu$L of 50% ACN/0.1% TFA was added to of gel pieces and samples were sonicated in a water bath for 10 min, and centrifuged briefly, and supernatant was transferred to a new tube. An additional 50 $\mu$L aliquot of 50% ACN/0.1% TFA was added, sonication was repeated, and supernatant was combined with the first extract. Supernatant was lyophilized in a SpeedVac at 45 °C, and peptides were resuspended in 10 $\mu$L of 5% ACN/0.1% TFA. A Ziptip cleanup was carried out according to the manufacturer's instructions (Millipore) for removal of acrylamide contamination prior to MS analysis.

*LC−MS/MS.* Digested peptides were run on LC−MS/MS using an ESI-QTOF instrument. MS parameters were similar to those in Kappler and Nouwens,[18] with the following modifications: Samples were desalted for 5 min on an Agilent C18 trap (0.3 × 5 mm, 5 $\mu$m), followed by separation on a Vydac Everest C18 column (300 A, 5 $\mu$m, 150 mm × 150 $\mu$m) at a flow rate of 1 $\mu$L/min, using a gradient of 10−60% buffer B over 30 min, where buffer A = 1% ACN/0.1% formic acid and buffer B = 80% ACN/0.1% formic acid. Eluted peptides were directly analyzed on a TripleTof 5600 mass spectrometer (ABSciex) using a Nanospray III interface. Gas and voltage were set as required. MS TOF scan across $m/z$ 350−1800 was performed for 0.5 s, followed by data-dependent acquisition of 20 peptides with intensity above 100 counts across $m/z$ 40−1800 (0.05 s per spectrum) with rolling collision energy. MS data were converted to Mascot generic format and submitted to Mascot.

*MS Data Analysis.* The automated Mascot search engine (Matrix Science, London, U.K.) was used to identify best matched protein sequences to the peptides detected by MS. Trypsin was specified as the proteolytic enzyme, and carbamidomethyl (C) of cysteine and oxidation (M) of methionine residues were taken into account. Charged states of 2+, 3+, and 4+ were considered for parent ions. Using a Ludwig-based search of plant species, a profile of best matched protein(s) was generated employing an algorithm to rank the proteins identified based on their peptide mass fingerprints. Individual ion scores were calculated as $-10 \times 10g(P)$, where $P$ is the probability that the observed match is a random event. Peptides identified with an ion score of >40 were considered to indicate identity or extensive similarity. Each of the peptide identifications was manually inspected and verified to ensure that the spectra were composed of a wide series of intense fragments, which could be designated as major fragments (b or y) of the proposed peptide. Each protein match also generated a protein score in the MS/MS search report, which is the sum of the highest ions scores for each distinct sequence. The exponentially Modified Protein Abundance Index (emPAI) provided an approximate, relative quantification of the proteins present in the sample. Functionally characterized homologues to putative uncharacterized sorghum proteins identified with MS were identified through BLAST searches based on FASTA sequences derived through queries to the Uniprot database.

**Statistical Analysis.** Absorbance values from RP-HPLC of alcohol-soluble proteins were interpolated by a spline method, and absorbance area values were calculated to 0.01 min intervals using MATLAB (release 2012a, The MathWorks, Natick, MA). Linear correlation coefficients were calculated between an individual absorbance area and digestibility and shown as a continuous spectrum over RP-HPLC retention time.

## RESULTS AND DISCUSSION

**RP-HPLC Profiling of Seed Proteins.** Profiling of alcohol-soluble prolamin (Figure 1A and Supporting Information, Figure S1) and water/salt-soluble albumin/globulin (A/G) (Figure 1B

dx.doi.org/10.1021/jf5022847 | J. Agric. Food Chem. 2014, 62, 9819−9831

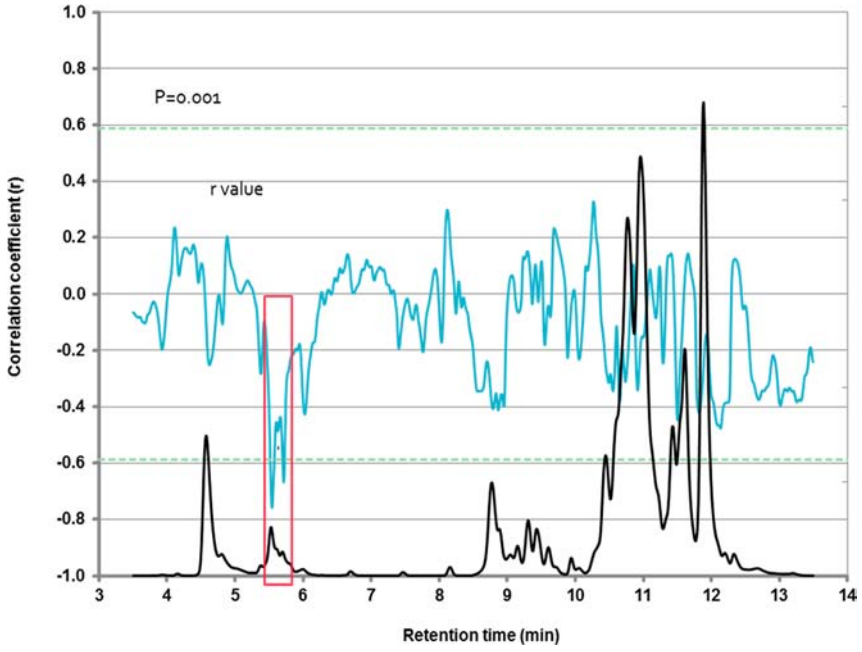

**Figure 2.** RP-HPLC analysis showing a significant negative correlation between protein digestibility (%) and an alcohol-soluble kafirin protein peak eluting at 5.5−6 min on the chromatogram (outlined in red). Analysis was carried out across 26 diverse sorghum lines (listed in Table 1), including the genotypes evaluated for ethanol conversion by Cremer et al.[20]

and Supporting Information, Figure S2) protein fractions across 28 sorghum lines using RP-HPLC revealed a range of diversity, particularly in the alcohol-soluble kafirin-containing fraction. Variation observed across wild-type and mutant lines could

dx.doi.org/10.1021/jf5022847 | J. Agric. Food Chem. 2014, 62, 9819−9831

contribute to phenotypic differences, such as increased flour viscosity and fermentation efficiency.[19,20] Among the β-kafirin null lines QL12, IS17214, and RTx2737, a high degree of similarity was observed in the alcohol-soluble peak distributions compared to lines with functional β-kafirin alleles. An approximately 50% reduction in the height of a peak eluting at 9 min was observed in β-kafirin null lines compared to wild type (Figure 1A, highlighted in orange), indicating a likely elution profile for β-kafirin (under the analysis conditions described here) and presenting a potential marker for the protein. Alternately, the β-kafirin peak could have been masked by a series of larger peaks eluting from the column at 10−11 min, which were absent in null lines (Figure 1A, highlighted in blue). Further work to positively identify the β-kafirin in RP-HPLC separations under these exact conditions is needed. RP-HPLC analysis of the water/salt-soluble fraction showed less similarity among peak profiles for the β-kafirin null mutants relative to other lines. However, substantial quantitative differences in peak heights were observed among the genotypes and there was a high level of variability across the sample set in a peak eluting at 9 min, which was unrelated to fluctuations in total sample protein concentration.

Interestingly, a statistically significant negative correlation was identified between a set of protein peaks eluted in the kafirin fraction and protein digestibility across sorghum grain lines, providing evidence for links between seed protein composition and end-use traits (Figure 2). Further research is needed to identify the protein(s) present in this peak; however, given the sequential extraction procedure utilized in this work, it is likely that this is a member of the kafirin family.

**Lab-on-a-Chip (LOC) Analysis of Seed Proteins.** LOC analysis, employing microfluidic chip−capillary electrophoresis, generated size-separated protein profiles for alcohol-soluble (prolamin) (Figure 3) and water/salt-soluble (A/G) fractions (Supporting Information, Figure S3). The prolamin fraction showed a large set of peaks present in the 22−26 kDa size range, representing the previously characterized α- and γ-kafirins. Small peaks were also visible at 11 and 19 kDa, with the 19 kDa peak representing the β-kafirins and the 11 kDa peak potentially representing the δ-kafirins. The β-kafirin peak was diminished in size in β-kafirin nulls, but, interestingly, a peak or set of peaks was visible at 19−20 kDa across all lines. This indicates that an additional protein of a similar size to β-kafirin may be present in the peak. This protein could represent a different protein, such as peptidyl-prolyl cis/trans isomerase (PPIase), identified in the same band/spot as β-kafirin through SDS-PAGE and LC−MS/MS, as outlined in the section SDS-PAGE and LC−MS/MS Protein Profiling. Chip profiles indicate that several cultivars in addition to the β-kafirin null mutants contain relatively low levels of β-kafirin, including 296B, a highly digestible line.[20] LOC analysis also revealed the presence of a small peak visible at 46 kDa in alcohol-soluble samples, which could represent a high molecular weight kafirin or kafirin dimer. In subsequent analysis, a protein spot extracted from the corresponding size range on 2D gels was identified through LC−MS/MS as a ∼36 kDa γ-prolamin homologue (Supporting Information, Figure S4 and Supplementary Table 1), thus providing sequence information for this kafirin entity at the protein level. As observed with RP-HPLC, the LOC profiling of the water/salt-soluble fraction shows that QL12 contains a relatively high content and diversity of A/G's compared to other genotypes (Supporting Information, Figure S3). High-lysine sorghum varieties, such as P721, exhibit an elevated A/G content, with increased nutritional value.[21] This indicates that QL12, among other lines, may contain increased levels of lysine and other essential amino acids due to a high A/G content.

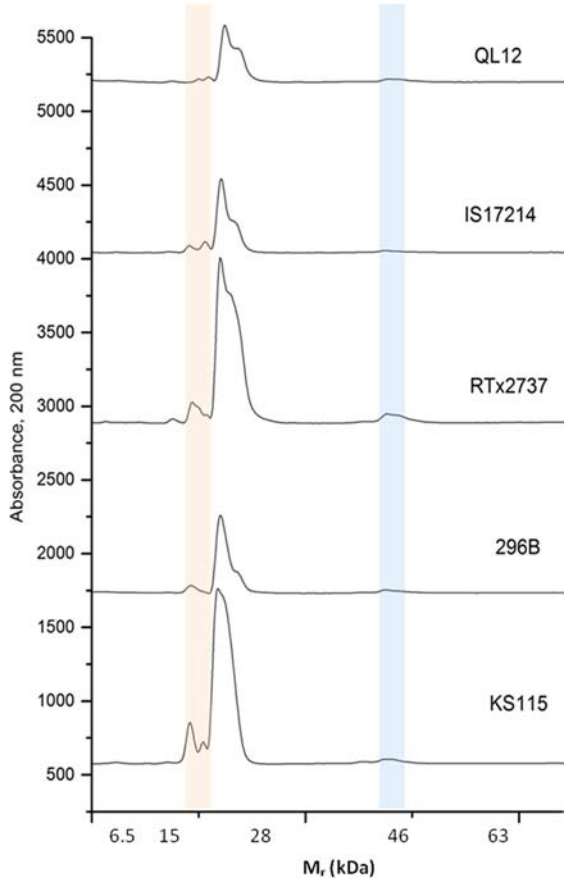

**Figure 3.** Alcohol-soluble proteins visualized on lab on a chip (LOC) across β-kafirin null lines QL12, 1517214, and RTx2737, and normal β-kafirin lines 296B and M35. A 19 kDa β-kafirin peak (highlighted in orange) precedes a set of large 22−25 kDa α- and γ-kafirin peaks, and a HMW prolamin is visible across the genotypes as a small peak at ∼50 kDa (highlighted in blue).

**SDS-PAGE and LC−MS/MS Protein Profiling.** Profiling of water/salt-soluble (A/G), alcohol-soluble (prolamin), and alkali-soluble (glutelin) protein fractions across the β-kafirin null mutant QL12 and wild-type line 296B using SDS-PAGE gel separation methods, coupled with mass spectrometry (LC−MS/MS) (Figure 4 and Supporting Information, Figure S4 and Supplementary Table 1), identified a range of proteins involved in storage protein biochemistry and starch metabolism. One-dimensional gel separation of each of the protein fractions by size (Figure 4) showed that the A/G fraction contains a highly concentrated, complex array of proteins present across a broad size range, similar to profiles generated in previous studies.[22] The prolamin fraction was less complex and more concentrated within the 23−26 kDa size range, which contains the more abundant α-kafirin storage proteins. The alkali-soluble glutelin fraction exhibited some similarities to the prolamin fraction, likely due to incomplete extraction of the prolamin fraction, but contained a wider diversity of protein bands visible across a greater size range, which was also verified on 2D gels, and has been reported in previous studies.[23,24] It is hypothesized that the glutelin proteins are more diverse because they both play a role in connecting the protein:starch matrix and provide a source of

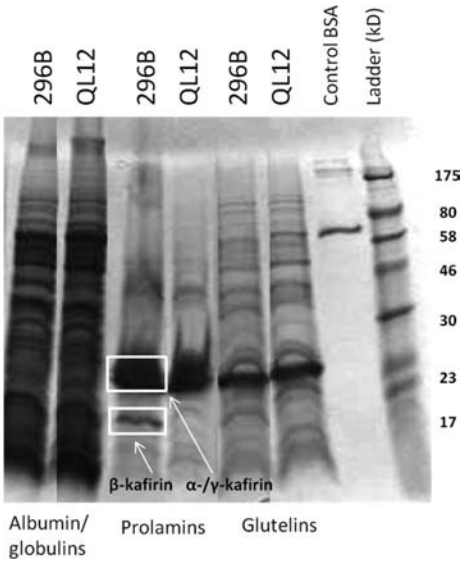

**Figure 4.** One-dimensional SDS-PAGE separation of water/salt-soluble (albumin/globulins), alcohol-soluble (prolamins), and alkali-soluble (glutelins) from normal $\beta$-kafirin allelic variant 296B, and $\beta$-kafirin null QL12. Excised protein bands (outlined in white) were digested with trypsin and analyzed using LC−MS/MS (results listed in Supporting Information, Supplementary Table 1). Ladder: P7709V ColorPlus Prestained Protein Marker, Broad Range (7−175 kDa) Mw ladder.

hydrolytic enzymes for the breakdown of starch and protein during germination.[25]

**Characterization of Kafirin Subclasses and the $\beta$-Kafirin Null Mutation.** Each kafirin subclass in the alcohol-soluble fraction was isolated using SDS-PAGE and identified through LC−MS/MS. $\alpha$- and $\gamma$-kafirins were visualized within the 22−25 kDa size range on the 1D SDS-PAGE gel (Figure 4, outlined in white). Using 2D SDS-PAGE separation of proteins by both size and charge, the $\delta$-kafirin protein was isolated in the prolamin fraction for genotype 296B (spot 11) (Supporting Information, Figure S4 and Supplementary Table 1). Matches to $\alpha$- and $\gamma$-kafirins were also generated on 2D gels in prolamin gel spots 8 and 11 for genotype QL12, and with spot 9 returning $\alpha$-kafirin as a top hit. Differential expression of the $\beta$-kafirin protein was detected in the alcohol-soluble fraction across mutant and wild-type germplasm. This provided a positive control for the MS technique and allowed for further characterization of the mutant at the protein level. One-dimensional separation of the prolamin fraction revealed altered expression of $\beta$-kafirin in a 19 kDa protein band, present in 296B and absent in QL12 (Figure 4, outlined in white), as predicted based on previous molecular characterization.[15] On 2D gels differential expression of $\beta$-kafirin was identified in 296B prolamin spot 11 and glutelin spot 4 (Supporting Information, Figure S4 and Supplementary Table 1). Identification of $\beta$-kafirin in the glutelin fraction (296B spot 4) may reflect the incomplete sequential extraction of alcohol-soluble proteins in the previous step.[26] $\beta$-Kafirin was completely absent in QL12, with the exception of a weak hit in the 2D prolamin spot 1, which had a low Mascot score achieved across two peptide matches and was discarded due to poor-quality spectral data. This match may represent a truncated form of the protein, as it was identified in a smaller size range on the gel. Although protein expression was generally similar across the genotypes within the range of spots analyzed on 2D gels, differential expression of a low molecular weight thioredoxin (Trx) enzyme was identified in the water/salt-soluble fraction, where spot 4 was present in 296B and absent in QL12. This was the only Trx identified across the protein fractions analyzed in the study, with the finding replicated in triplicate (Figure 5 and Supporting Information , Supplementary Table 1). Trx catalyzed the conversion of seed proteins from the oxidized to the reduced state during germination, with significant impacts on protein digestibility and grain nutrition.

**Sorghum Homologue to 50 kDa $\gamma$-Prolamin.** High molecular weight (HMW) $\gamma$-prolamins (~50 kDa) have been identified and characterized across a range of plant species,

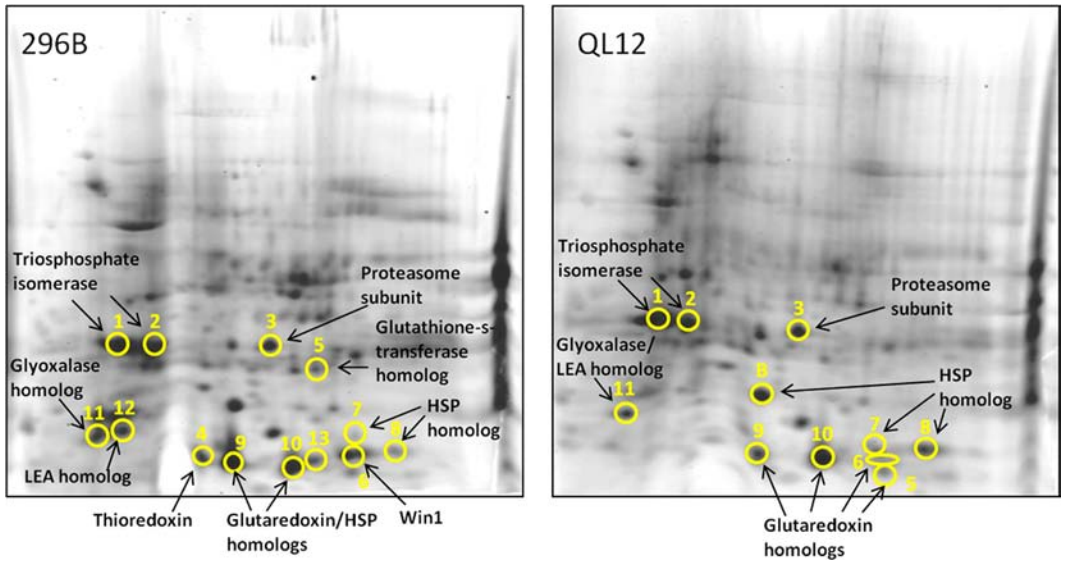

**Figure 5.** Two-dimensional SDS-PAGE analysis of the water/salt-soluble protein fraction in $\beta$-kafirin null allelic variant compared with wild-type 296B. Protein samples were loaded onto 7 cm IPG strips (3−11 NL) and run on IPGphor machine for isoelectric focusing. SDS-PAGE gels (4−12% Bis/Tris small format precast) were utilized for separation of proteins by size (Mw). Protein spots (circled in yellow) were excised across a range of size and pI, digested with trypsin, and identified with LC−MS/MS. Spot 4 was identified as a differentially expressed thioredoxin, present in 296B and absent in QL12.

dx.doi.org/10.1021/jf5022847 | J. Agric. Food Chem. 2014, 62, 9819−9831

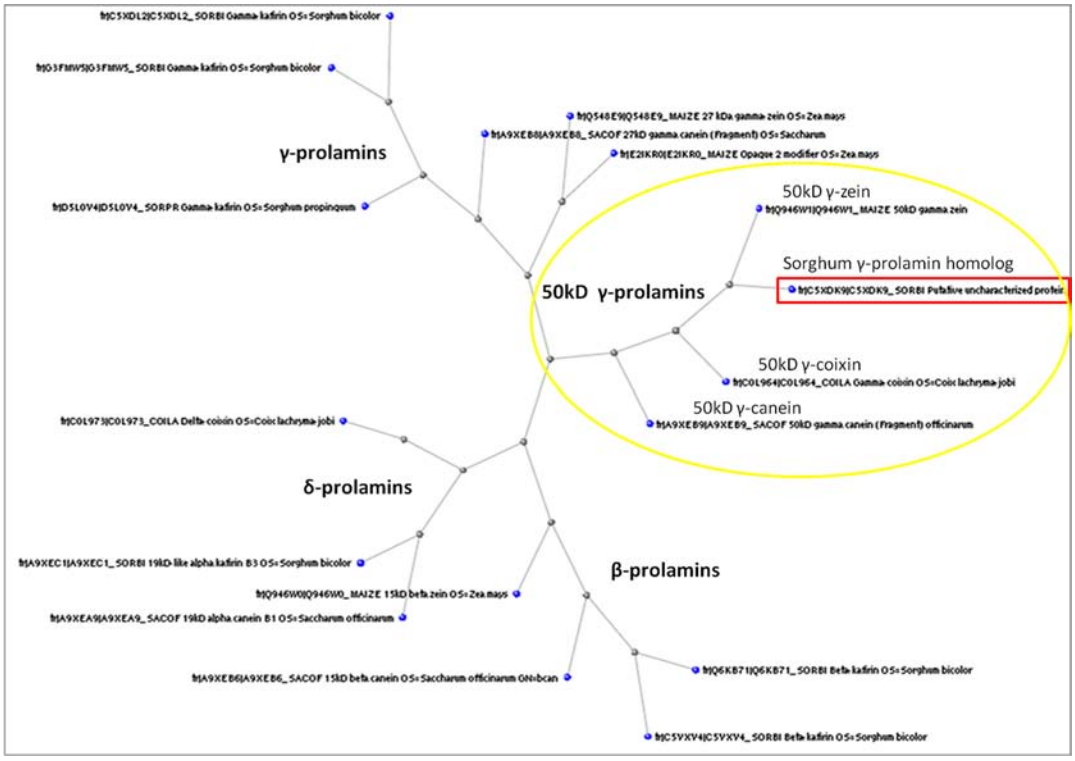

**Figure 6.** Phylogenetic neighbor joining tree view of the alignment of protein sequences representing prolamin subclasses across grass species using the Grishin protein method. Uncharacterized sorghum γ-prolamin homologue groups with 50 kDa γ-zein and γ-canein of maize and sugarcane, and groups away from the LMW γ-prolamins.

including maize and wheat.[27,28] Previous studies on sorghum have identified a protein band at ∼45 kDa in the alcohol-soluble fraction using 1D SDS-PAGE. However, this protein has not yet been characterized at the genetic level.[15] The HMW protein band was previously reported as a kafirin dimer because it diminishes in intensity upon treatment with increasing concentrations of reducing agent, indicating that it can be broken down into smaller peptides.[8,29] However, because the original 45 kDa band is still intact on reduced gels, it has also been suggested that the protein may be linked by bonds that are not broken by reducing agents.[30] In the present study, this HMW protein was visible in reduced alcohol-soluble protein samples from both genotypes QL12 and 296B, on 1D and 2D gels. LC−MS/MS data indicate that this protein represents a homologue to HMW γ-prolamin identified in closely related species (Supporting Information, Figure S4 and Supplementary Table 1). Across both genotypes, 2D prolamin spot 4 returned a match for a putative uncharacterized sorghum protein (accession number C5XDK9), exhibiting homology to 50 kDa γ-zein, γ-canein, and γ-coixin (Figure 6). The sorghum γ-prolamin homologue is larger than any previously characterized kafirin, with a calculated Mw 36 615 Da. LOC analysis of the prolamin fraction revealed the presence of two small peaks at ∼44 and 46 kDa across the majority of the sample collection (Figure 3, highlighted in blue), which may correspond to two genetic variants of the HMW γ-prolamin.[8,27] In a previous study using LOC, similar peak profiles were also observed for the HMW prolamin peak in reduced alcohol-soluble protein samples extracted from three grain genotypes (QL12, QL41, and 296B) from the kafirin allelic variant sample set, which had been harvested in a previous growing season.[31] Across our data set, quantitative peak area values were attained through LOC for the peaks in the 44−46 kDa size range and these data were aligned with readings for grain quality parameters. The general structure and distribution of prolamins in the protein bodies has been shown to be uniform across maize and sorghum. In maize, 50 kDa γ-zeins localize to the periphery of the protein bodies, similar to other γ-zeins.[27] Immunocytochemistry shows that γ-kafirins also localize to the periphery of protein bodies, and may prevent proteolysis of internally positioned α-kafirins.[32] Sorghum lines with increased digestibility exhibit a change in the protein body structure from spherical to invaginated, with the γ-kafirins located from the periphery to the folds of the structure, resulting in an increased exposure of the α-kafirins to proteolytic breakdown.[33] In maize, a clear physical distribution of zein classes is observed within the seed. Protein bodies in the subaleurone layer are smaller and contain mainly β- and γ-zeins, while those encapsulating starch in the inner endosperm are larger and contain continuous central regions of α-zeins with β- and γ-zeins located on the periphery.[34] Construction of mutant γ-zein proteins has pinpointed the proline-rich N-terminal domain as being critical in wild-type protein body development.[35] Furthermore, deletion of a cysteine-rich γ-zein domain results in abnormally structured protein bodies. The different kafirin classes exhibit variable solubilities according to their degree of polymerization and cross-linking.[29] Interactions between β- and γ-kafirins on the periphery of protein bodies may limit enzyme accessibility to α-kafirin, impeding digestion of protein and starch encased in the matrix. This study presents evidence for the seed-specific expression of a high molecular weight γ-prolamin homologue in sorghum. Characterization of this protein in sorghum could enhance efforts to further distinguish the roles of the different classes of kafirins in maintaining endosperm connectivity and access to starch.

**Identification of Proteins with Potential Impacts on Grain Quality.** Profiling of water/salt-, alcohol-, and alkali-soluble proteins across the sample population of kafirin allelic

variants using mass spectrometry identified proteins with potential various impacts on the structure of the protein−starch matrix, such as enzymes functioning in protein cross-linking and the mobilization of starch during germination[36,37] (Table 2, Figure 5−7, and Supporting Information, Figure S4 and Supplementary Table 1). Identification and localization of these proteins in the mature grain indicates they may have an impact on endosperm development and/or germination. Deciphering the precise activities of these proteins in sorghum will involve additional analysis of the transcriptome and proteome throughout grain development.

*Thioredoxins (Trx) and Glutaredoxins (Grx).* Thioredoxins are small proteins containing a site with a redox-active disulfide, which functions in the reversible oxidation of protein SH groups to a disulfide bridge[38] (Table 2). Differential expression of a sorghum Trx protein, C5XB72, homologous to maize Trx B6SX54, was observed in the A/G fraction, with 2D protein spot 4 present in 296B and absent in QL12 (Figure 5). Matches to sorghum Trx had a high emPAI protein quantification score, pI 5.79, and Mw 13 061 Da. Trx labeling studies have shown in vitro and in vivo that the enzyme catalyzes the reduction of seed proteins during germination.[39] Therefore, Trx has been linked to enhanced grain digestibility in wheat and sorghum.[40,41] Alternate expression of Trx in this study may be associated with the *β*-kafirin null mutation and could have potential downstream impacts on digestibility, in addition to effects of the mutation.

The sorghum homologue to a maize glutaredoxin Grx_C2.2−glutaredoxin subgroup 1 was identified in the A/G fraction in 296B spots 9 and 10, and in QL12 spots 5 and 6, which localized to the same size range (Mw ∼13 kDa) (Figure 5). Grx, including the maize Grx_C2.2 identified in this study, catalyze the enzymatic reaction where proteins with reduced sulfide groups are converted to those with oxidized disulfide bonds (Table 2). Grx have been implicated in the oxidative stress response through regeneration of enzymes involved in peroxide and methionine sulfoxide reduction.[42] These proteins therefore have dual roles in protein aggregation and stress responses, creating opportunities for the development of streamlined grain improvement strategies affecting multiple traits.

*Protein Disulfide Isomerases (PDIs).* PDIs function as molecular chaperones in disulfide-mediated protein folding. They contain two Trx domains with a redox site.[43] Matches to HMW PDI from maize (C0PLF0 and A5A5E7) were generated in glutelin spot 2 across both genotypes (Supporting Information, Figure S5 and Supplementary Table 2). These proteins appear to migrate to the same location on A/G and prolamin gels, but the spots were not analyzed in this fraction using LC−MS/MS. However, it is possible that they share the same identity as the PDIs identified in the glutelin fraction because their distribution on the gel is similar. Again, the presence of these spots across multiple fractions may be a result of incomplete sequential extraction of the proteins.

Previous studies indicate that PDI mutations can result in irregular starch granule formation and chalky grain phenotypes.[44] The rice mutant *esp2* lacks protein disulfide isomerase-like (PDIL) 1:1, but shows enhanced expression of the thiol disulfide oxidoreductase OsEro1.[45] The grain exhibits altered seed storage protein compartmentalization through inhibition of disulfide bond formation. It has been proposed that the formation of native disulfide bonds in proglutelins also depends on an electron transfer pathway involving the OsEro1 and the PDI-like OsPDIL.[46] In the *floury2* mutant, PDIL is up-regulated, where a mutation in a signaling peptide results in the abnormal

**Table 2. Protein Candidates Identified in Sorghum Grain with Reported Effects on Protein−Starch Matrix Structure, Grain Quality, and Stress Responses**

| accession no. | protein | 296B spot | QL12 spot | protein fraction | homologues | function |
|---|---|---|---|---|---|---|
| C5XB72/C5YGL1 (sorghum) | thioredoxin | 4 | absent | A/G | B6SX54_maize | converts seed proteins from the oxidized to the reduced state during germination |
| C5YBX1 (sorghum) | glutaredoxin Grx_C2.2−glutaredoxin subgroup 1 | 9 and 10 | 5 and 6 | A/G | B6THA1_maize | converts proteins with reduced sulfide groups to those with oxidized disulfide bonds |
| F2DDK1 (barley) | peroxiredoxin | 5 | 5 | prolamin | HB6T2Y1_maize and PR2E1_ORYSJ (rice) | interacts with glutaredoxins, thioredoxins, and cyclophilin as both reductants and non-dithio−disulfide exchange proteins |
| C5XT06, B3GQV9, and C5Z9C6 (sorghum) | peptidyl-prolyl cis/trans isomerase (PPIase) | 9, 10, and 11 | 9 and 10 | prolamin/glutelin | maize B4FZZ2 and B4FY3T, wheat AZLM55, sugarcane C7E3V7 | facilitates protein folding through slow isomerization of peptide bonds in oligopeptides and through the amino acid proline in cellular proteins |
| A5A5E7 (maize) | protein disulfide isomerase (PDI) | 2 | 2 | glutelin | maize C0PLF0 and A5A5E7 | promotes the correct disulfide pairing in proteins |
| P81368 (sorghum) | α-amylase inhibitor | 1, 2, 8, and 11 | 1 and 2 | prolamin | IAA5_SORI (sorghum) | slows the conversion of starch to sugars (and ethanol) |

dx.doi.org/10.1021/jf5022847 | J. Agric. Food Chem. 2014, 62, 9819−9831

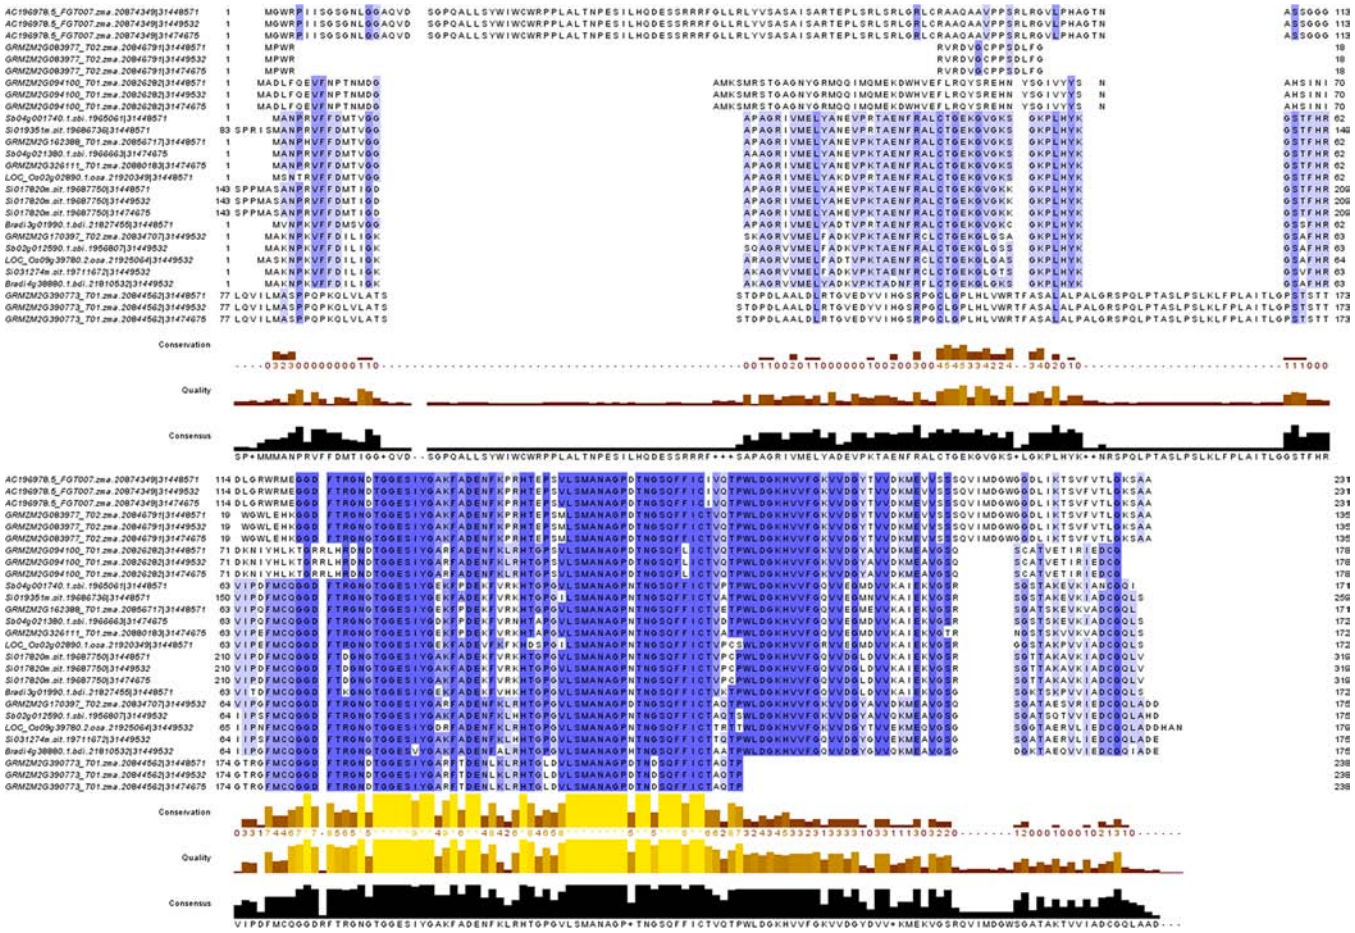

**Figure 7.** ClustalW alignment of peptidyl-prolyl cis/trans isomerase (PPIase) peptide sequences across major grass species, illustrating a high level of sequence homology. PPIases identified in sorghum grain prolamin and glutelin protein fractions (Supporting Information, Figure S4 and Supplementary Table 1) are included. Dark purple indicates exact homology; light purple indicates highly conserved homology.

processing and accumulation of small precursor $\alpha$-zeins and high levels of luminal binding protein (BiP) in irregularly shaped protein bodies.[47] Mutations in sorghum protein isomerases, such as PDI, may have a similar effect on protein body formation.

*Peptidyl-prolyl cis/trans Isomerases (PPIases).* PPIases catalyze protein folding through isomerization of peptide bonds in oligopeptides and on proline residues in cellular proteins.[43,48,49] PPIases were identified in the 19 kDa band colocalized with $\beta$-kafirin on the 296B 1D prolamin gel, as well as in the 26 kDa band, colocalized with $\alpha$-kafirin (Figure 4). On 2D gels, PPIases were detected in the 296B prolamin fraction gel spots 9, 10 and 11, and in QL12 gel spots 9 and 10, as well as in the QL12 glutelin fraction spot 4 (Supporting Information, Figure S4 and Supplementary Table 1). Sorghum PPIases identified in the study (accession numbers C5XT06, C5Z9C6, and B3GQV9), consistently localized to the same size region (~18 kDa) on 1D and 2D PAGE gels, and within the same pI range pH 8–9. PPIases colocalized with $\beta$- and $\delta$-kafirins in the 296B 2D prolamin gel spot 11 and with $\alpha$-kafirin in QL12 spot, as well as in the prolamin fraction on the 1D SDS-PAGE gel, indicating that they are hydrophobic enzymes, which may interact with the kafirins.

The PPIase family is encoded by multiple genes, exhibiting some redundancy in plants.[50] An alignment of the sorghum PPIases identified in this study, with orthologues from closely related species, reveals a high level of sequence homology at the protein level (Figure 7). The sorghum PPIases exhibited close homology to their counterparts in *Zea mays* (B4FZZ2 and B4FY3T), *Triticum aestivum* (AZLM55), *Saccharum officinarum* (C7E3V7), *Citrus sinensis* (D0ELH5) and *Gerbera* (A8CYN7). PIN1-type PPIases are encoded by multiple genes and are present in a wide variety of plant species. A four amino acid insertion site is situated next to the phosphor-specific recognition site of the active site, regulating the activity of the enzyme.[51] The PPIase activity of cyclophilins is regulated by thioredoxin,[52] also identified in this study and discussed above. PIN1At in *Arabidopsis* encodes a PPIase, which regulates flowering time through phosphorylation-dependent prolyl cis/trans isomerization of key regulatory pathway specific transcription factors.[53] Alterations to protein folding status catalyzed by PPIases with the cis/trans isomerization of proline imidic peptide bonds could also affect protein body composition in sorghum and other grain crops.[54]

*Heat Shock Protein (HSP)/Luminal Binding Protein (BiP).* HSP/BiP chaperones are key regulators of protein body biogenesis, with significant impacts on grain quality traits and composition[55] (Table 2). HSPs/BiPs were isolated predominantly from the water/salt-soluble (A/G) and alkali-soluble (glutelin) protein fractions across both genotypes (Figure 5 and Supporting Information, Figure S5 and Supplementary Table 2). A/G spot 2 produced a strong match to sorghum protein (accession number C5XY25), which exhibits homology to the *Oryza sativa* 19 kDa class II HSP. The protein has a calculated Mw 19 982 Da and pI 5.71, appropriate to its position on the gel.

dx.doi.org/10.1021/jf5022847 | J. Agric. Food Chem. 2014, 62, 9819–9831

A sorghum homologue to a maize 16.9 kDa class I heat shock protein was also identified (C5XQR9) in a lower molecular weight region of the gel within a more basic pI range, relative to spot 2 discussed above. The HSP homologue C5XQR9 localized to an appropriate position on the gel, corresponding to Mw 17 121 Da and pI 6.18. Matches to C5XQR9 were observed in 296B spots B, 7, 8, 9, and 10, and in QL12 spots B and 7. QL12 spot 8 contained an additional sorghum homologue (accession number C5XML7) to a maize 17.5 kDa class II HSP.

In addition, several HMW (50−75 kDa) putative uncharacterized proteins with homology to HSP chaperones or luminal binding proteins (BiPs) were identified in the alkali-soluble glutelin fraction across both 296B and QL12 genotypes (accession numbers C5YU58, C5WNX8, and C5XPN2). Sorghum HSP C5YU58 has also been identified in grain proteomic analyses carried out by other researchers.[56] In maize, elevated HSP/BiP levels during development are linked to mutations in $\alpha$- and $\gamma$-zeins resulting in an opaque or floury phenotype.[55,57,58] BiP has been found to associate with the surface of rice protein bodies, assisting in prolamin deposition through disulfide bonding at specific cysteine residues.[59] In wheat, these chaperones are localized to the interior, rather than on the surface of protein bodies, indicating diverse roles for HSP/BiP in protein body aggregation across different plant species.[60]

*α-Amylase Inhibitors.* Sorghum $\alpha$-amylase inhibitors were isolated from the prolamin fraction in both genotypes (Figure 5, Table 2). The enzyme was isolated from a low molecular weight (10−15 kDa) size range, within pI 7−8. The inhibitor was identified in 296B gel spots 1, 2, 8, and 11, and in QL12 spots 1 and 2, which was observed across duplicate gels. The activity of $\alpha$-amylase inhibitors in the grain affects starch digestion into glucose, slowing the conversion of starch to ethanol during the fermentation process.[61] Lines expressing low levels of $\alpha$-amylase inhibitor may be appropriate candidates for the biofuels industry. $\alpha$-Amylase inhibitors also play a role in plant defense, where they deter crop destruction by snails and birds in tannin-containing sorghum and have been shown to enhance insect resistance in wheat.[62−64]

**Non-Prolamin Proteins in the Protein−Starch Matrix.** Non-prolamin proteins, such as albumins and globulins, are rich in essential amino acids, including lysine and tryptophan, and provide the embryo with additional readily accessible nitrogen reserves during germination. Sorghum homologues to the major nonkafirin storage proteins were identified across all protein solubilities (Supporting Information, Figure S4 and Supplementary Table 1). In the water/salt-soluble fractions sorghum homologues to globulin and cupin-like proteins in *Zea mays* were abundant, including accession numbers C5WY16 and C5WQD2.

Globulins are saline-soluble secondary storage proteins, with many belonging to the cupin superfamily. For example, 7S globulins function exclusively as storage proteins, but are not required for normal seed function.[65] Globulin S-1 (63 kDa) and globulin S-2 (45 kDa) collectively represent ∼20% of seed protein content in maize and share amino acid sequence similarity with the 7S seed proteins of wheat and legumes.[66] These proteins have significant impacts on the nutritional quality of the grain.

Proteins identified in the alkali-soluble glutelin fraction included a range of vicilin- and legumin-like storage proteins. The sorghum homologue to uncleaved maize legumin, accession number C5YY38, and the globulin/vicilin-like sorghum homologue C5WUN6, were identified in this fraction. Immuno-localization studies in *Medicago trunculata* using antivicilin antibodies show preferential targeting of vicilins to the periphery of the protein bodies.[67] Sorghum glutelins have not yet been extensively characterized, but it is hypothesized that they may form complex highly linked protein networks encasing protein bodies and providing additional structure to the protein−starch matrix.[68,69] Protein members of the legumin superfamily are most abundant in legumes, oats, and rice. Wheat legumin-like protein, or triticin, accumulates in globulin inclusion bodies at the periphery of prolamin bodies. Overexpression of pea legumin in wheat forms crystalline patterns contributing to the altered structure of the protein−starch matrix.[70,71]

A range of proteins were identified in the glutelin fraction in addition to legumin and vicillin, which included HSPs/BiPs, cell division cycle proteins, homologues to maize caleosin, glutathione *S*-transferases, RuBisCo large subunit binding protein, and wheat MOTHER OF FT AND TFL1 (MFT), which regulates seed dormancy and the onset of germination.[72] Significant amounts of $\alpha$-, $\beta$-, and $\delta$-kafirins were also identified in this fraction, although quantification scores indicate that their concentrations were considerably less than in the prolamin fraction, and their presence may be due to incomplete sequential extraction of the alcohol-soluble fraction as previously noted.

Across the study, protein spots excised from HMW areas of 2D gels generally produced matches specifically to HMW proteins, while spots excised from LMW areas tended to produce matches to both high and low molecular weight proteins. This indicates that spots in LMW areas of the gel may contain a mix of intact proteins and protein subunits, or cleaved products of larger proteins. For example, sorghum homologues to HMW globulin S-1 and S-2 (C5WY16 and C5WQD2), cupin family proteins (C5WUN and C5X0T3), and uncleaved legumin (C5YY38) were isolated from every protein fraction, from both high and low molecular weight areas of the gel, whereas LMW proteins (∼13 kDa), such as thioredoxin, glutaredoxin, and $\alpha$-amylase inhibitors, were isolated exclusively from the lower molecular weight area of the gel. Highly abundant sorghum homologues to glyceraldehyde-3-phosphate dehydrogenase as well as various HSPs were detected in the glutelin fraction. These proteins were generally found in the area of their calculated pI values, but localized across a broader size range. Because the presence of these proteins was so widespread, the matches were not listed in results tables (Supporting Information, Supplementary Table 1), unless they represented the only quality match returned for a protein spot.

**Sorghum Proteomics.** Our proteomic analysis compiles sequence and biochemical information describing a range of proteins affecting sorghum endosperm structure and composition. The derived data set will further augment annotation of the sorghum proteome and facilitate identification of potential targets for improved grain quality. Furthermore, the data provide a basis for comparative analysis with other major grain crops. Possible avenues for utilizing protein sequence data include the development of high-lysine varieties with increased A/G content for enhanced nutritional quality, as well as the modification of enzyme-regulated protein aggregation in the endosperm for increased starch availability.

Differential regulation of thioredoxin in the $\beta$-kafirin null mutant QL12 indicates that expression of the enzyme may be either directly or indirectly linked to the $\beta$-kafirin mutation. Evaluation of Trx expression at the RNA/protein level across additional $\beta$-kafirin mutants and at varying stages of development

could provide further insights into this relationship. Future research on previously uncharacterized proteins identified in this study may reveal elements related to grain quality parameters, such as digestibility and flour pasting properties. In particular, the HMW $\gamma$-prolamin homologue identified provides an interesting candidate for further functional analysis as it has been shown to localize to the periphery of the protein bodies in maize, possibly limiting enzymatic access to internally located $\alpha$-zeins and starch. Identification of proteins with desirable amino acid content and enhanced digestibility will also benefit future research initiatives to improve sorghum grain nutritional value and palatability.

The commercial success of grain crops with altered protein composition, such as high lysine and increased digestibility lines, can be limited by negative pleiotropic effects accompanying changes in the amino acid profile. For example, maize endosperm protein mutants, *o2* (*opaque2*) and *fl2* (*floury2*) have an improved amino acid content, but exhibit a number of undesirable traits such as reduced grain yield and increased susceptibility to diseases and pests. This work supports the development of high throughput screening methods for biomarkers associated with grain quality and endeavors for the genetic improvement and biofortification of sorghum through molecular breeding and transformation. The identification and characterization of proteins impacting on various grain quality parameters in sorghum, such as nutritional quality, grain hardness, and stress resistance, will assist breeders in their introgression of genetic factors associated with these traits into established breeding lines. The rapid introgression and selection of desirable grain quality traits will require the linking of the proteome with the genome. Next generation genome resequencing[73] and genotyping by selection[74] tools are now publically available and are being incorporated into sorghum prebreeding for other grain quality traits such as digestibility.[75] This will ultimately lead to more cost-effective and efficient plant breeding for improved sorghum varieties tailored to specific end uses.

Extensive support in proteomic techniques was kindly provided by Dr. Amanda Nouwens at the SCMB protein facility (The University of Queensland). Identification of proteins with LC−MS/MS was facilitated through open access queries to the Mascot server.

## ■ ABREVIATIONS USED

A/G, albumin/globulins; BiP, luminal binding proteins; Grx, glutaredoxins; HPLC, high performance liquid chromatography; IEF, isoelectric focusing; HSP, heat shock proteins; HMW, high molecular weight; kDa, kilodalton; LMW, low molecular weight; LC−MS/MS, liquid chromatography−tandem mass spectrometry; LOC, lab on a chip; MS, mass spectrometry; Mw, molecular weight; PDI, protein disulfide isomerase; PPIase, peptidyl-prolyl cis/trans isomerase; SDS-PAGE, sodium dodecyl sulfate polyacrylamide gel electrophoresis; Trx, thioredoxin

Table 1. PPO Purification from Manila Mango Fruit (*Mangifera indica* cv. Manila)[a]

| purification step | volume (mL) | activity (units/mL) | total activity (units) | protein content (mg/mL) | specific activity (units/mg protein) | purification (fold) | yield (%) |
|---|---|---|---|---|---|---|---|
| crude extract | 920 | 779 | 717048 | 19.10 | 41 | 1 | 100 |
| $(NH_4)_2SO_4$ precipitation 30−85% | 800 | 804 | 643200 | 4.95 | 162 | 4 | 90 |
| phenyl-Sepharose | 20 | 4366 | 87320 | 1.03 | 4205 | 103 | 12 |
| ion exchange | 16 | 1399 | 22384 | 0.15 | 8839 | 216 | 3 |

[a]These values were obtained in a typical purification.

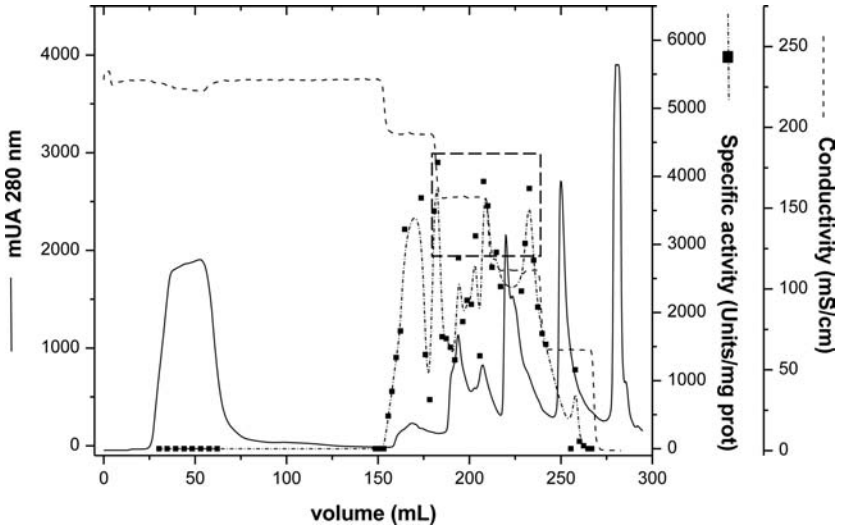

**Figure 1.** Elution profile by hydrophobic interaction. The column used was a phenyl-Sepharose 4-fast flow. Polyphenol oxidase activity was determined in collected fractions. Absorbance at 280 nm (mAU) (solid lines), specific activity (■), and conductivity (mS/cm) (dashed lines) are shown. Fractions with the highest specific activity are framed with dashed lines.

York, NY, USA). All other reagents were from Sigma-Aldrich (St. Louis, MO, USA).

**Extraction Procedure.** PPO crude extract was obtained from 350 g of Manila mango pulp mixed with 700 mL of 0.2 M sodium phosphate buffer, pH 7.0, 1% w/v poly(vinylpolypyrolidone) (PVPP), 1% v/v Triton X-100, and protease inhibitors (0.33 mg/100 mL aprotinin and 0.1 mM phenylmethanesulfonyl fluoride (PMSF)). PPO crude extract was left to rest overnight and centrifuged at 10650*g* for 30 min. The supernatant obtained was filtered and aprotinin (0.33 mg/100 mL) was added. All extraction procedures were carried out at 4 °C.

**PPO Activity Assay.** PPO activity assay was performed in (1 mL) 0.2 M sodium phosphate buffer, pH 7.0, containing 50 mM catechol or pyrogallol as substrate; 33 μL of the enzyme solution was added to initiate the reaction. PPO assay was performed at 25 °C using an Agilent 8453 UV−vis (New York, NY, USA) diode array spectrophotometer. $\Delta Abs_{420\ nm}$ was recorded every 5 s during 5 min. One unit of PPO activity was defined as the change in absorbance of 0.001 $min^{-1}$ $mL^{-1}$ of enzyme.[15]

**Purification Procedure.** PPO was purified as described by[10] briefly, filtered crude extract was subjected to $(NH_4)_2SO_4$ precipitation (30−85% saturation) at 4 °C, then centrifuged at 10650*g*, 30 min. The precipitate was resuspended in a small volume of phosphate buffer (50 mM sodium phosphate, pH 7.0), 1.2 M ammonium sulfate, and 0.6 M potassium chloride and dialyzed overnight against three changes of the same buffer. The dialyzed solution was centrifuged at 34500*g* for 30 min and the supernatant collected. Aprotinin (0.33 mg/100 mL) was added to the supernatant. Protein concentration was determined by UV absorbance at 280 nm.

Chromatography was carried out at room temperature using a Fast Protein Liquid Chromatography (FPLC) system from GE. The supernatant was loaded onto an XK 16/20 column packed with phenyl-Sepharose 4-fast flow previously equilibrated with buffer used in dialysis (equilibrium buffer). Then, the column was washed with equilibrium buffer (70 mL) to remove unbound proteins. The equilibrium buffer was displaced stepwise from 100 to 0% with distilled water, and the bound proteins were eluted. Flow rate was 1.0 mL/min, and fractions (2.5 mL) were collected. PPO activity and protein concentration were determined, obtaining the elution profile. Fractions showing high specific activity were pooled and then dialyzed overnight against three changes of buffer A (20 mM Tris-HCl, pH 7.0) at 4 °C. Aprotinin (0.33 mg/100 mL) was added to the dialyzed enzyme.

After that, the suspension was loaded onto anion exchange column Mono Q HR 10/10, previously equilibrated by washing with low ionic buffer A (40 mL) followed by high ionic buffer B (80 mL 20 mM Tris-HCl pH 7.0, containing 1.0 M KCl) and finally with low ionic buffer A (80 mL). The flow rate was 2 mL/min,and fractions (2 mL) were collected. Protein was eluted by linearly increasing the ionic strength; four linear gradients were used in the elution process: (a) from 0 to 16% in 34 mL, (b) from 16 to 19% in 10 mL, (c) from 19 at 25% in 40 mL, and (d) from 25 to 100% in 40 mL. Then the column was washed with 100% elution buffer by using a volume of 24 mL. PPO activity and protein concentration were determined in each fraction, and the elution profile was obtained.

**PPO Molecular Weight (MW) Determination.** Column chromatography was used for MW determination of the native enzyme and carried out at room temperature using an FPLC system. Briefly, a Superdex 200 10/300 GL column was washed with distilled water (50 mL) and then with elution buffer (50 mL of 50 mM phosphate, pH 7.0, and 0.15 M KCl) at a flow rate of 0.5 mL/min. After that, 350 μL of purified PPO was loaded onto the column and eluted with elution buffer (30 mL); fractions (1 mL) were collected, and for each fraction activity was determined. PPO molecular weight was determined by extrapolation of the PPO elution time in a calibration curve generated using a set of proteins with different molecular weights.

dx.doi.org/10.1021/jf5029784 | J. Agric. Food Chem. 2014, 62, 9832−9840

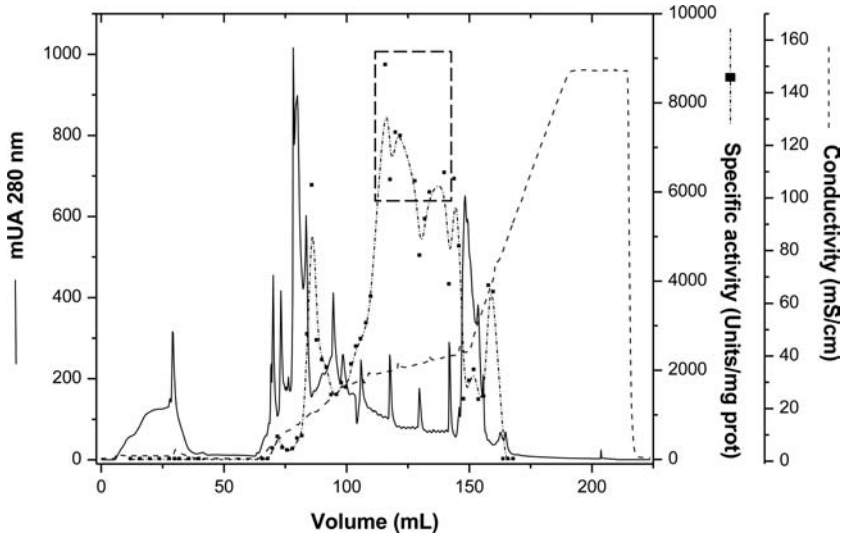

**Figure 2.** Elution profile by ion exchange chromatography. The column used was a Mono Q HR. Polyphenol oxidase activity was determined in collected fractions. Absorbance at 280 nm (mAU) (solid lines), specific activity (■), and conductivity (mS/cm) (dashed lines) are shown. Fractions with the highest specific activity are framed with dashed lines.

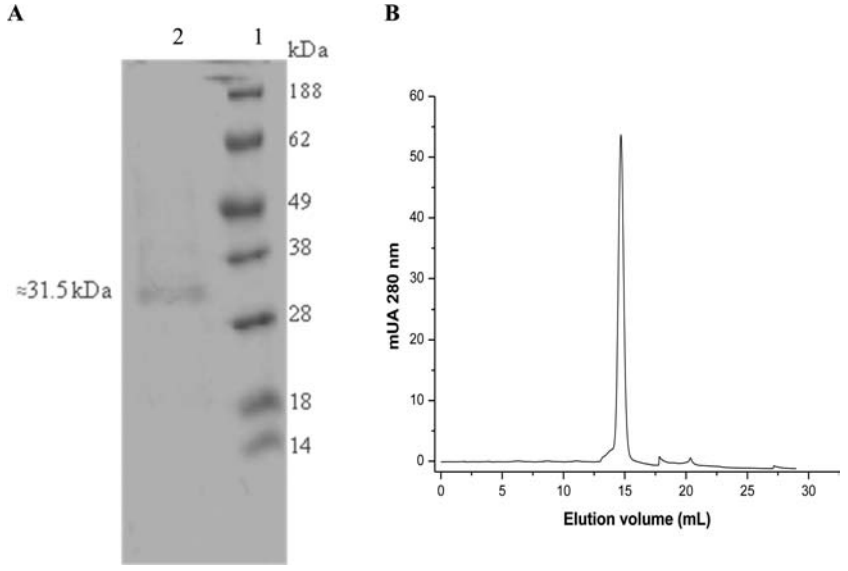

**Figure 3.** (A) SDS-PAGE of PPO purified from Manila mango: lane 1, molecular weight markers; lane 2, purified enzyme. (B) Elution profile by gel filtration from mango PPO.

**Gel Electrophoresis (SDS-PAGE).** Enzyme purity was determined at different purification steps using SDS-PAGE.[16] The concentration of the separating gel was 12%, and that of the stacking gel was 4%. Protein standard molecular weight markers were used.

**pH Dependence of PPO Activity.** The effect of pH on PPO activity was measured in 1 mL of 50 mM catechol in 0.1 M citric acid−0.2 M sodium phosphate buffer and in 2.5−8.0 M borate buffer, pH range 8.5−12.0 at 25 °C. Reaction was started by the addition of 33 $\mu$L of the isolated PPO. PPO specific activity (U/mg protein) was determined as described above.

**Optimum Temperature.** PPO activity was assayed in 1 mL, by incubating 33 $\mu$L of the enzyme in 0.1 M citric acid−0.2 M sodium phosphate buffer, pH 6.0, containing 50 mM catechol or pyrogallol for 30 min at different temperatures (20−80 °C). PPO activity was determined as described above.

**Determination of PPO Kinetic Parameters.** PPO velocity ($v$) at different substrate concentrations was measured in 0.2 M sodium phosphate buffer, pH 7.0, and various concentrations of substrates catechol, pyrogallol, and 4-methylcatecol (1−150 mM). The Michaelis−Menten constant ($K_m$) and maximum catalytic velocity ($V_{max}$) for each substrate were determined by Lineweaver−Burk and nonlinear regression.

**PPO Substrate Specificity.** PPO substrate specificity was determined using eight different substrates. PPO activity was monitored as the change in substrate absorbance (ΔAbs) at a given wavelength ($\lambda$) as follows: catechol, pyrogallol, 4-methylcatecol, epicatechin, caffeic acid, ferulic acid, and phenol at $\lambda$ = 420 nm; L-3,4-dihydroxyphenylalanine (DL-dopa) at $\lambda$ = 480 nm. PPO activity assay solution was prepared in 0.2 M sodium phosphate buffer, pH 7.0, and variable concentrations of the given substrate (1, 2.5, and 10 mM).[9,10] PPO specific activity (U/mg protein) was determined as described above.

**Effect of Inhibitors on PPO Activity.** PPO activity was measured with 50 mM catechol (substrate) in 0.2 M sodium phosphate buffer, pH 7.0, in the presence of different concentrations of inhibitor (0.1, 1, and 10 mM): tropolone, kojic acid, ascorbic acid, sodium chloride, sodium metabisulfite, citric acid, EDTA disodium salt, succinic acid,

dx.doi.org/10.1021/jf5029784 | J. Agric. Food Chem. 2014, 62, 9832−9840

benzoic acid, and potassium sorbate. The effect of inhibitors on PPO specific activity (U/mg protein) was determined as described above.

**Effect of Metal Ions on PPO Activity.** PPO activity was measured with 50 mM catechol in 0.2 M sodium phosphate buffer, pH 7.0, and the presence of different concentrations (0.1, 1, and 10 mM) of the following salts: KCl, $CaCl_2$, $Na_2SO_4$, $MgSO_4$, $MgCl_2$, $ZnSO_4$, and $MnSO_4$. For $CuSO_4$ the concentrations used were 0.5, 2.5, 5, and 10 mM. PPO specific activity (U/mg protein) in the presence of ions was determined as described above.

## RESULTS AND DISCUSSION

**PPO Extraction from Manila Mango.** In plants, PPO is a plastid enzyme; in contrast, their phenolic substrates are located in vacuoles. The extraction of PPO from Manila mango was performed by using Triton X-100, a nonionic detergent. Triton X-100 is widely used in the recovery of membrane constituents as it provides a mild nondenaturing condition for proteins. In addition, PVPP was included in the PPO extraction buffer to minimize *o*-quinone formation and prevent phenol–protein interactions.[17] Increased recovery in PPO activity has been observed by the addition of protease inhibitors to the extraction buffer, usually aprotinin (trasylol), PMSF, and/or benzamide.[18] Therefore, it was decided also to include aprotinin and PMSF in the PPO extraction buffer. After extraction was performed, the determined specific activity for Manila mango PPO (crude extract) was 41 U/mg protein, in contrast to those reported for PPOs from other fruits and vegetables such as Badami mango peel (1.34 U/mg protein),[13] Kensington mango (1.8 U/g fresh weight),[19] Haden mango (0.1 U/min·mL),[11] mamey (22 U/mg protein),[10] persimmon (8.8 U/mg protein),[20] and banana (20.7 U/mg protein).[8]

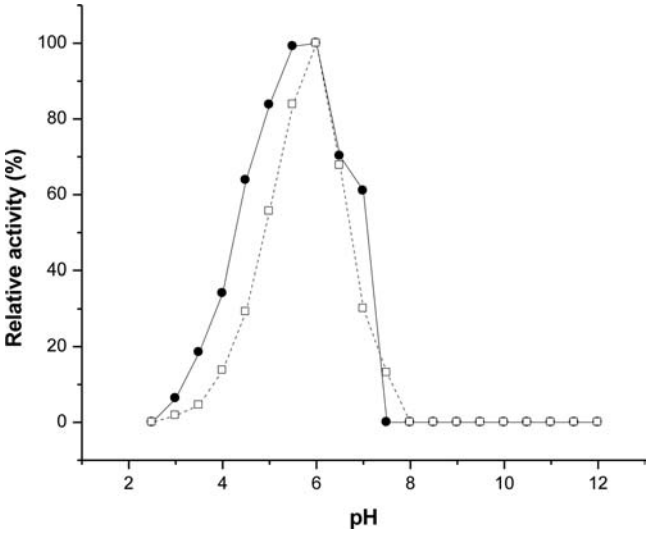

**Figure 4.** PPO activity from Manila mango dependence on pH. Catechol (□) and pyrogallol (●) were used as substrate in 0.1 M acid citric–0.2 M disodium phosphate buffer (pH 2.5–8.0) and 0.2 M borate (pH 8.5–12). Activity was expressed as relative activity (%) compared with high activity determined. Lines are drawn to aid visualization. Values are means from three replicates. Standard deviations were <5%.

**PPO Purification.** Ammonium sulfate precipitation (30–85%) resulted in a 4-fold increase in PPO purity (Table 1). Then, hydrophobic interaction chromatography was performed using phenyl-Sepharose 4-fast flow; this technique has been used previously in the purification of PPOs from different vegetables and fruits, that is, in apple,[9] mamey,[10] d'Anjou pear,[21] and peach,[22] but has not been used in mango PPO.

Figure 1 shows the elution profile of PPO. Unbound proteins were eluted at initial fractions, between 25 and 75 mL as monitored by absorbance at 280 nm. Then, the bound proteins began to be eluted at ≈195 mS/cm (fractions above 150 mL) (Figure 1). PPO activity was determined in collected fractions, and the highest activity was observed in fractions eluting at ≈160 mS/cm (182–232 mL). At this purification step, PPO showed a 103-fold increase in purity (Table 1). Fractions showing the highest specific activity were pooled and dialyzed against 20 mM Tris-HCl buffer, pH 7.0. Then, the dialyzed enzyme was loaded onto a Mono Q HR 10/10 anion exchange column and eluted; the above procedure has been useful in the purification of PPO from different sources including mamey,[10] Goldnugget loquat,[23] apple,[9] banana pulp,[8] Badami mango peel,[13] and Raspuri mango sap (latex) (DEAE-Sephacel).[24] On the other hand, in Kensington mango PPO sap and skin have been partially purified by Sephadex G-25.[19]

The elution profile (absorbance at 280 nm) showed a protein peak that elutes before the salt concentration increases (Figure 2). However, highly absorbing (280 nm) peaks were observed during elution with salt gradient; PPO activity was determined in collected fractions, and the highest PPO activities were located in fractions eluting between 32 and 42 mS/cm (108–150 mL) (Figure 2). At this purification step, PPO was purified 216-fold (Table 1).

**Electrophoresis and PPO MW Determination.** PPO purity was determined by sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS-PAGE) and protein stained with Coomassie brilliant blue. The Manila mango PPO was essentially pure as observed in SDS-PAGE and showed a MW of ≈31.5 kDa; however, a MW of 65 kDa was determined by gel filtration (GF) (Figure 3). Therefore, the Manila mango PPO seems to be a dimer in its native state. After GF elution, PPO was collected and enzyme activity assayed and, importantly, the eluted enzyme showed a specific activity similar to that previously loaded. PPO MW determination by combining both SDS-PAGE and GF has been used before in other PPOs from different plant sources with confident results: (a) MW for PPO from mamey was ≈18 kDa by SDS-PAGE and 16.1 kDa by GF, a monomer;[10] (b) MW for PPO from loquat fruit was 58 kDa by SDS-PAGE and 55 kDa by GF, a monomer;[25] (c) MW for PPO from pineapple was ≈25 kDa by SDS-PAGE and ≈104 kDa by GF, a tetramer;[26] and (d) MW for PPO from Raspuri mango sap was ≈105 kDa by SDS-PAGE and ≈100 kDa by GF, a monomer.[24] In this regard, most PPOs from plants are monomers, but it has been found that some fungi PPOs are mainly oligomers (tetramers with small subunits).[27]

**Effect of pH on PPO Activity.** The activity of purified PPO was determined at different pH values using catechol and pyrogallol as substrates. PPO activity was observed in the pH range between 3.0 and 7.0 with both substrates. The maximum PPO activity was observed at pH 6.0 with 100% activity. Therefore, it may be considered that the optimum pH for PPO activity is 6.0 (Figure 4). At pH >7.5, PPO activity decreased drastically. Interestingly, PPO from Manila mango showed the highest activity at pH 6.0 with both substrates. As shown in Table 2, usually PPOs from fruits are more active at neutral or slightly acid pH.[26] For example, in PPO in flesh from varieties Tainong and Haden mango, the optimum pH values were shown at 7.0 and 6.0,[11,12] respectively; on the other hand, for

[a]ND, not determined.

PPO in peel from varieties Chokanan and Badami mango, the optimum pH values were presented at 5.5 and 5.4, respectively,[13,14] using catechol as substrate in all cases. However, for PPO in the sap and skin from Kensington mango, the optimum pH values were 5.3 and 5.8, respectively, using 4-methylcatechol.[19] In this regard, it has been observed that the optimum pH for PPO activity seems to be dependent on the type of substrate, enzyme localization into the cell, plant source, and extraction method.

**Optimum Temperature.** The optimum temperature for PPO activity was analyzed by assaying the enzyme at temperatures ranging from 20 to 80 °C for catechol and pyrogallol using 0.1 M citric acid−0.2 M sodium phosphate buffer, pH 6.0, because at this pH was obtained the highest activity. PPO activity was maintained within the temperature range of 20−70 °C with catechol as substrate. On the other hand, maximum PPO activity with pyrogallol was in the range of 60−70 °C, with the highest activity observed at 65 °C for both substrates. PPO activity decreased when the temperature was increased above 70 °C. However, at 80 °C PPO activity was zero due to thermal inactivation (Figure 5). High temperatures disrupted the three-dimensional structure of the enzyme, leading to its denaturation.[17] Activity dependence on temperature has been studied in PPOs from different plant sources (Table 2). In the case of mango, PPO in flesh from Tainong mango showed highest activity at 30 °C using catechol as substrate,[12] but in Badami and Chokanan mango peel the highest activities were observed at 50 and 55 °C, respectively,[13,14] using the same substrate. In PPO from Kensington mango sap (latex) the highest activity was presented at 70−80 °C and in skin at 30 °C, using 4-methylcatechol.[19] The optimum temperature for PPO activity usually depends on the environmental condition where the fruit grows, plant species, and/or variety. However, it may be affected also by the type of substrate used in the activity assay.[17]

**PPO Kinetic Parameters.** The dependence of PPO velocity on substrate concentration was studied. Three different substrates were chosen: catechol, pyrogallol, and 4-methylcatechol.The lowest $K_m$ (highest affinity) was observed for pyrogallol (2.77 mM), followed by 4-methylcatechol (3.14 mM) and catechol (15.14 mM). The $K_m$ for pyrogallol was similar to that observed for PPO from mamey,[10] but very low when compared to that for Tainong mango ($K_m$ = 47.81 mM);[12] for PPO from Badami mango peel it was observed that epicatechin presented the highest affinity ($K_m$ = 2.0 mM),[13] followed by catechol, dopamine, and caffeic acid. Kinetic parameters have not been studied for varieties Haden, Chokanan, and Kensington mango.[11,14,19] Catechol seems to be the least preferred substrate for PPOs from most fruits and vegetables except Medlar ($K_m$ = 5.7 mM) (Table 2). In this

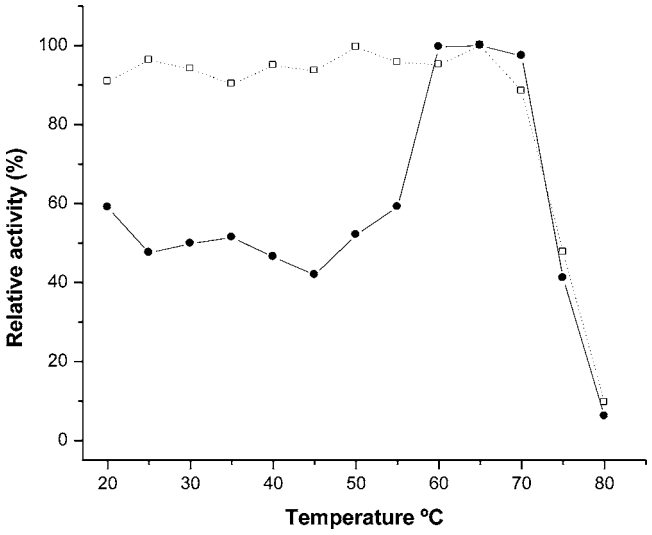

**Figure 5.** Optimum temperature of PPO from Manila mango. Catechol (□) and pyrogallol (●) were used in 0.1 M acid citric−0.2 M disodium phosphate buffer, pH 6.0. Pyrogallol also was probed. The results are very similar (data not shown). Activity was expressed as relative activity (%) compared with high activity determined. Lines are drawn to aid visualization. Values are means from three replicates. Standard deviations were <5%.

**Table 3. Substrate Specificity from Manila Mango PPO[a]**

[a]Values are means from three replicates. Standard deviations were <5%. [b]Activities are expressed as relative activity (%) compared with activity determined with 50 mM catechol. The compounds were prepared with 0.2 M disodium phosphate buffer 7.0 in catechol 50 mM.

regard, PPOs from plants and fruits have different affinities toward diverse substrates. The active site of the enzyme seems to interact in different ways with substrates where the proper −R group structure and position provide the advantage for efficient binding and catalysis. However, the main criterion for choosing the best substrate is by the highest catalytic efficiency ($V_{max}/K_m$). In this regard, the $V_{max}/K_m$ (U $mM^{-1}$ $min^{-1}$) ratio for pyrogallol was 1926 followed by 1162 for 4-methylcatechol and 376 for catechol. Therefore, in this study pyrogallol seems to be the most effective substrate for Manila mango PPO.

**Substrate Specificity.** Substrate specificity for Manila mango PPO was studied using eight different substrates (Table 3). Relative activities were compared with activity observed in the presence of catechol (100%). The highest activity was found using pyrogallol (a trihydroxyphenol), followed by catechol, 4-methylcatechol, and DL-dopa (dihydroxyphenols) (Table 3). In contrast, no activity was detected for dihydroxyphenols epicatechin and caffeic acid or for monohydroxyphenols ferulic acid and phenol. Some authors suggest that the most common substrates for PPOs are catechol, 4-methylcatechol, chlorogenic acid, and catechins.[17,28] In this regard, it has been observed that pyrogallol is the best substrate for PPO from mamey,[10] whereas 4-methylcatechol has been shown to be the best substrate for PPO from atemoya[29] and Bramley's Seedling apple.[9] In contrast, catechol has been observed to be the best substrate for PPO from Izmir grape[30] and Tainong mango.[12] These differences maybe due to

[a]Values are means from three replicates. Standard deviations were <5%. [b]Activities are expressed as relative activity (%) compared with activity determined with 50 mM catechol. The compounds were prepared with 0.2 M disodium phosphate buffer 7.0 in catechol 50 mM. ND, not determined.

either plant species (and cultivars), the substrate, or the chemical structure of the side chain, number of hydroxyl groups, and position in the benzene ring.[17]

Natural phenols have been found in mango fruit; some of these are (a) cinnamic acid derivatives such as chlorogenic acid and ferulic acid; (b) flavonol derivates such as xanthone-*C*-glycosides, epicatechin gallate, and flavonol glycosides; (c) gallic acid derivatives such as gallotannins; (d) hydroxybenzoic acid derivates such as gallic acid, protocatechuic acid, and vanillic acid; and (e) xanthones such as mangiferin and mangostin, benzophenones, and ellagic acid.[31] In this regard, the observed relative abundance of phenolic compounds in fruits is as follows: cinnamic acid derivatives > catechins ≈ leucoanthocyanidins (flavan-3,4-diols) > flavonols. Many phenolic compounds are excellent as browning substrates and antioxidants. However, as antioxidants they are usually present at relative low concentrations such that at high concentration they are susceptible to autoxidation; however, they are found in fruits and vegetables in all structural parts. The presence of phenolic compounds in foods is considered beneficial for human health. In biological systems, they appear to react with oxygen species, whereas PPO causes most of the oxidative damage in foods when phenolic compounds act as substrates.[32]

**PPO Inhibition Profile.** PPO activity inhibition was determined in the presence of the following molecules: tropolone, kojic acid, ascorbic acid, sodium chloride, sodium metabisulfite, citric acid, ethylenediaminetetraacetic acid (EDTA) disodium salt, succinic acid, benzoic acid, and potassium sorbate. Complete inhibition was observed with tropolone, ascorbic acid, and sodium metabisulfite at 0.1 mM. Kojic acid also inhibited completely PPO activity but at 10 mM, whereas sodium chloride, benzoic acid, citric acid, succinic acid, potassium sorbate, and EDTA inhibited PPO but to a lower degree (Table 4).

PPO inhibitors are classified on the basis of the inhibition mechanism as follows: (a) reducing agents, (b) chelating agents, (c) complexing agents, (d) acidulants, (e) enzyme inhibitors, and (f) enzyme modifiers. All of them inhibit the formation of melanin by preventing the accumulation of *o*-quinones or by forming stable colorless products.[17]

Ascorbic acid inhibits PPO by reacting specifically with histidine residues, but it is commonly used also as an antibrowning agent.[17] Manila mango PPO exhibited 100% inhibition by ascorbic acid, and the same inhibition degree has been observed for PPOs from mamey[10] and Tainong mango.[12] The most effective inhibitor of enzymatic browning is known to be sodium metabisulfite. In agreement with the above, in the present study PPO showed 100% inhibition by metabisulfite. A similar result has been observed in PPOs from mamey,[10] atemoya,[29] Bramley's Seedling apple,[9] and medlar fruit,[33] with potassium metabisulfite. Sulfites act by reducing molecular oxygen present in the food system, thus making it unavailable for oxidative reactions. In addition, sulfites react with *o*-quinones and intermediate molecules in the browning reaction, preventing thus the formation of colored complexes. The use of this preservative has several disadvantages such as negative effects on texture, development of unpleasant flavors, and possible corrosion of containers.[34] Many inhibitors of PPO are known, but only a few have been considered as potential alternatives to sulfites. Kojic acid is a chelator of transition metal ions as well as a free radical scavenger. Kojic acid inhibits PPO from several *Aspergillus* species, mushrooms, and some plants and crustaceans and also inhibits effectively the formation rate of pigments and oxygen uptake.[35] Tropolone is structurally analogous to *o*-diphenol substrates and also acts as an effective copper chelator; that is, tropolone behaves as a potent competitive inhibitor in enzymes such as dopamine-$\beta$-hydroxylase and PPO from mushroom.[36] In this regard, PPO from Manila mango was 100% inhibited by tropolone (0.1 mM) and kojic acid (10 mM). In contrast, in PPO from Dominga grape, tropolone and kojic acid (1 mM) showed 85 and 12% activity inhibition, respectively;[37] in PPO from banana, tropolone and kojic acid (1 mM) inhibited the enzyme 80 and 10%, respectively;[38] in PPO from persimmon, tropolone (1 mM) inhibited completely the enzyme;[20] and in PPO from mamey, tropolone and kojic acid (10 mM) showed 100% activity inhibition.[10]

Sodium chloride, benzoic acid, citric acid, succinic acid, potassium sorbate, and EDTA were found to be the less effective inhibitors in Manila mango PPO. Similar results were observed in PPOs from mamey[10] and Bramley's Seedling apple.[9] EDTA is well-known as a metal ion chelator but displays low specificity for copper; however, in some cases it may inhibit PPO, whereas high salt (NaCl) concentration

enhances hydrophobic interactions, causing enzyme aggregation and consequently a loss in activity.[39] Some isolated PPOs seem to be relatively unaffected by inhibitors.[28]

PPOs from various sources have been studied in the presence of nonclassical inhibitors; that is, Tainong mango,[12] Haden mango,[11] Izmir grape,[30] and atemoya[29] were tested with β-mercaptoethanol, L-cysteine, glycine, diethyldithiocarbamate, sodium azide, thiourea, erythorbic acid, and resorcylic acid. In this regard, β-mercaptoethanol and L-cysteine exhibit high inhibition efficiency. However, β-mercaptoethanol may not be used in the food industry because of its toxicity concerns. L-Cysteine acts by readily forming complexes with quinones, thus inhibiting PPOs through formation of side products with *o*-quinone and 4-methylcatechol.[40]

**Effect of Metal Ions on PPO Activity.** The effect of metal ions on PPO activity is shown in Table 5. The presence of salts resulted in the increase (almost twice in some cases) of PPO activity; KCl has little effect on the PPO activity. The exceptions were $MgCl_2$ and $CuSO_4$, which caused inhibitory effects of ≈10 and >50%, respectively. A similar result was observed for $Mg^{2+}$ in PPO from atemoya, where both $MgCl_2$ and $MgSO_4$ caused inhibition of 20%.[29] In the presence of $MgCl_2$ Chokanan mango peel decreased 18% its PPO activity.[14] In contrast, $CuSO_4$, $FeSO_4$, and $MnCl_2$ have no measurable effect on PPO activity.[29] $BaCl_2$, $ZnSO_4$, $MnCl_2$, and $CuSO_4$ have no effect on enzyme activity as it just decreases ≈3% in PPO from banana.[8] Some of these metal ions probably combine with substrate and/or PPO, thus favoring the binding to active site and enhancing enzyme catalysis and resulting in increased activity.[39]

$$\frac{\partial C(x, t)}{\partial t} = D_e \frac{\partial^2 C(x, t)}{\partial x^2} \quad (1)$$

To solve eq 1, the following boundary conditions were set: $x = \pm a$, $C = C_o$ and $-a < x < a$, $C = f(t)$, with sample thickness $2a$.

The geometry of apple slices can be reduced to a slab, i.e., a "thin film with negligible edge effects". This means that diffusional mass transport through the edges of the film is negligible compared to that through the main surface of the film[18] (Figure 1). The solution proposed by Crank[19] for slab geometry is

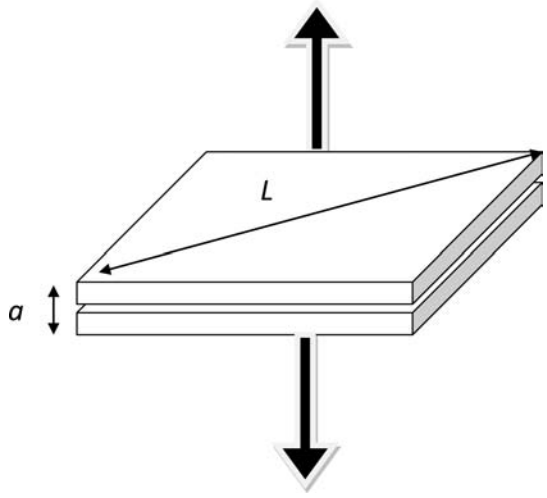

**Figure 1.** Scheme of diffusion from slab ($4a < L$) (→, solute leaching direction).

$$\frac{C(t) - C_\infty}{C_o - C_\infty} = \frac{8}{\pi^2} \sum_{n=1}^{n\to\infty} \frac{1}{(2n+1)^2} \exp\left(-\frac{D_e(2n+1)^2}{2a^2}\pi^2 t\right) \quad (2)$$

$$\frac{C(t) - C_\infty}{C_o - C_\infty} = \frac{8}{\pi^2} \exp\left(-\frac{D_e}{2a^2}\pi^2 t\right) \quad (3)$$

where $C$ is the average solute concentration at time $t$ of sampling, $C_o$ is the initial uniform concentration, and $C_\infty$ is the solute concentration after time $t$.

It is generally assumed that, for a Fourier number ($-D_e/4a^2\pi^2$) greater than 0.1,[20] only the first term in the series becomes significant. When this condition is attained, the effective diffusivity can be calculated by plotting $\ln(Y)$ against time ($t$). $Y$ is the dimensionless concentration (eq 5).

Linear behavior must be observed in accordance with

$$\ln Y = \ln \frac{8}{\pi^2} - \frac{D_e}{2a^2}\pi^2 t \quad (4)$$

with

$$Y = \frac{C(t) - C_\infty}{C_o - C_\infty} \quad (5)$$

For each set of conditions, the adjustable parameters of each model for decreases in sugar and polyphenols were determined.

## MATERIALS AND METHODS

**Plant Materials.** Two varieties of dessert apple (Golden Delicious and Granny Smith), purchased in a local supermarket (Auchan, Avignon, France), were used for the experiments. Tissue from the parenchyma zone of the apple was chosen after manually removing the peel and core. Planar pieces 20 mm high were cut from the parenchyma tissue; four slices were obtained per fruit. To prevent any polyphenol oxidation, the apple slices were sprayed with a solution of 40 g/L sodium fluoride (NaF). A total of 10 fruits per cultivar were used for each leaching run, with different batches of 10 fruits replicated 3 times in leaching experiments.

**Determination of the Isotonic Point.** Cylindrical samples of diameter 1 cm were cut with a core borer from the flesh side of the section, trimmed to a length of 4.70 cm using a double-bladed razor, and then soaked overnight in a mannitol solution (from 0 to 0.8 M). For each mannitol concentration, six apple cylinders coming from six different apples were used. To minimize cellular degradation of tissue strength during the experiment because of pH variation and following the method described by Lin and Pitt,[21] the mannitol solutions were buffered at pH 7 with $K_2HPO_4$ (0.02 M) and $KH_2PO_4$ (0.02 M).

Samples represented approximately 30% of solution volume. Before and after the soaking, weight and dimensions (diameter and height) of the samples were determined using an analytical balance (±0.01 g, CP124S, Sartorius, Germany) and digital calliper (Absolute Digimatic, Mitutoyo, U.K.). The apple tissue cylinders were carefully blotted with tissue paper to remove excess water before the measurements. The isotonic point was calculated by interpolation to zero weight gain or volume change from the weight gain or loss of tissue as a function of the mannitol concentration. The water potential ($\Psi$) in the cell after soaking was estimated from the molarity of the solution using the ideal gas law

$$\Psi = -MRT \quad (6)$$

where $M$ is the molarity, $T$ is the temperature (K), and $R = 0.008\,314$ kJ mol$^{-1}$ K$^{-1}$.

To estimate the osmotic pressure ($\Psi_{op}$) of the cell contents in any solution, the osmotic pressure at incipient plasmolysis ($\Psi_{op}{}^0$) was first determined. $V^0$ is the sample volume at incipient plasmolysis, and $V$ is the sample volume in the given solution. The turgor pressure ($P_c$) in a given solution was obtained from

$$\Psi_{op} = \Psi_{op}{}^0 (V^0/V) \quad (7)$$

$$P_c = \Psi - \Psi_{op}{}^0 \quad (8)$$

**Mass-Transfer Experiment.** Mannitol was used as the osmotic agent. A solid/liquid ratio of 1:20 was used under magnetic stirring. Experiments were run at a constant temperature (20 °C) in stainless-steel vessels, each containing a different concentration of osmotic solution, namely, 0.2, 0.4, and 0.6 M. An additional vessel of distilled water was used as a control. Apple pieces were retrieved for biochemical analysis after 1, 2, 4, and 6 h.

Matrix mass changes were monitored to determine water gain, after each immersion time during soaking experiments. The measurements were repeated 3 times, with a different batch of apple each time.

Water gain percentage ($W_g$)

$$W_g\,(\%) = \frac{M(t) - M_o}{M_o} \times 100 \quad (9)$$

where $M_o$ is the matrix weight (g) before the experiment and $M(t)$ is the matrix weight (g) during the experiment at a time $t$.

**Biochemical Analyses.** Biochemical analyses were performed on powdered product after freeze-drying. All of the samples were freeze-dried in a USIFROID SMH 15 freeze-dryer (Usifroid, France) for 48–72 h.

*Solvents and Chemicals.* Methanol, acetonitrile, and acetone of chromatographic quality were provided by Fisher Scientific (Fair Lawn, NJ), and toluene-α-thiol was provided by Sigma-Aldrich (Deisenhofen, Germany). Deionized water was obtained with a

dx.doi.org/10.1021/jf503100d | J. Agric. Food Chem. 2014, 62, 9841–9847

Milli-Q water system (Millipore, Bedford, MA). (+)-Catechin, (−)-epicatechin, caffeoylquinic acid, mannitol, glucose, and fructose were also provided by Sigma-Aldrich. Phloretin and *p*-coumaric acid were from Extrasynthese (Lyon, France). Phloridzin was from Fluka (Buchs, Switzerland).

*Quantification of Sugar.* Fruit parenchyma freeze-dried powder (5 g) was added to 20 mL of distilled water and homogenized with a polytron homogenizer for 1 min. The homogenates were centrifuged at 9000*g* for 10 min at 4 °C. The supernatant was collected to analyze sugars by a colorimetric enzymatic method as described by Bureau et al.[12]

*Quantification of Polyphenols by High-Performance Liquid Chromatography (HPLC) after Thioacidolysis.* Polyphenols were quantified by HPLC after thioacidolysis as described by Bureau et al.[12] The average degree of polymerization ($DP_n$) was measured by calculating the molar ratio of all of the flavan-3-ol units (thioether adducts plus terminal units) to (−)-epicatechin and (+)-catechin corresponding to terminal units. A HPLC system equipped with a diode array detector (SPD-M20A, Schimadzu, Inc., Kyoto, Japan) and a Lichro 250 × 4 mm column, Lichrospher 100 RP-18.5 $\mu$m (25 cm × 4.6 mm), were used. Quantification was performed by the external standard method. Results were expressed in milligrams per kilogram of fresh weight (FW). Losses of phenolic compounds (MC) were calculated, using eq 10 and expressed as percentage (w/w) of the initial concentration

$$\mathrm{MC}\ (\%) = \frac{\mathrm{DM}(0)C(0) - \mathrm{DM}(t)C(t)}{\mathrm{DM}(0)C(0)} \times 100 \qquad (10)$$

where $C(0)$ is the initial phenolic compound concentration in the sample (mg/kg of dry weight), $C(t)$ is the phenolic compound concentration in the sample at time $t$ (mg/kg of dry weight), DM(0) is the initial dry matter of the sample (g/100 g of FW), and DM($t$) is the dry matter of the sample at time $t$ (g/100 g of FW)

**Statistical Analysis.** Data underwent statistical analysis using the analysis of variance (ANOVA) test with SPSS (version 7.0, IBM, Chicago IL) Windows 7 software. Means were compared using Duncan's multiple range tests. Pooled standard deviations (SDs) were also estimated.[22] Pooled SDs were calculated using the sum of individual variances weighted by the individual degrees of freedom of each series of replicates.[23] A multiple regression analysis module was also used to determine raw material characteristics on the response to osmotic variation. To obtain the model parameters, the R (version 3.0.1, free license) nonlinear regression tool was used.

## RESULTS AND DISCUSSION

**Determination of the Isotonic Point.** Figure 2 presents matrix length changes as a function of the mannitol concentration. Turgor and osmotic pressure values in soaking solution were calculated. Osmotic pressure increased and turgor pressure decreased as the mannitol concentration increased. A relationship between the solution osmotic pressure and cell turgor pressure was observed. The isotonic points of Granny Smith and Golden Delicious were determined by plotting the sample volume variation against the mannitol concentration. The point of equilibrium of Granny Smith was 0.43 M, and the point of equilibrium of Golden Delicious was 0.61 M. Therefore, the value of the isotonic point for Granny Smith was −1.15 MPa, and the value of the isotonic point for Golden Delicious was −1.49 MPa. Similar results were found by Lin and Pitt[21] and Alamar et al.[24] on apple slices in various mannitol solution concentrations. We can assume that variety and composition effects explain differences in isotonic point values.

**Effects on Dry Matter (DM) Changes.** During the leaching process, the DM content at different immersion durations was experimentally obtained over a range of concentrations (0, 0.2, 0.4, and 0.6 M). In Figure 3, for both

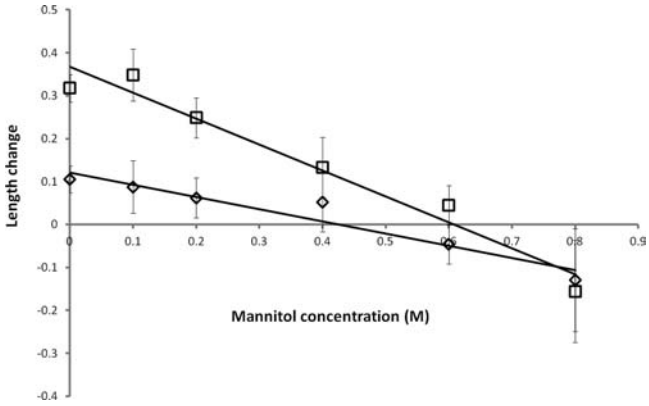

**Figure 2.** Parenchyma tissue length changes in various mannitol solutions (three biological replicates). Two apple varieties were used (□, Golden Delicious; ◇, Granny Smith). Isotonic points were determined by linear regression. Pooled SD values were 0.026 for Golden Delicious and 0.039 for Granny Smith, respectively.

apples, DM data means are plotted against time. The rates of matter loss were determined from the graph. Water entry into the sample was also monitored, as presented in Figure 3. Water gain resulted in a weight increase from 12 to 16% in apple matrix in 0 M mannitol solution (pure water). No data are available for other mannitol solutions. Similar results were reported by Linn and Pitt[21] in hypotonic solution. Two simultaneous phenomena, DM loss and water entrance, took place during the leaching process. Their combined effect could explain DM losses according to immersion time. Apparent diffusivity and equilibrium matter content ($C_\infty/C_o$) were therefore determined.

For Golden Delicious, DM decreased at 0 and 0.2 M mannitol contents. No changes were observed for higher mannitol concentrations. For Granny Smith, a DM decrease was observed only at 0 M. The losses of DM were probably due to diffusion mostly of sugars in soaking solution. According to the isotonic point of each apple variety, the leaching occurred only for a difference of at least 0.4 M between cells and external solution. DM losses were closely linked to differences in osmotic pressure between fruit and external solution.

Apparent diffusivity values were estimated from analytical solutions by Crank[19] by fitting DM. Apparent diffusivity was then determined. Table 1 presents diffusivity values as a function of the mannitol concentration. DM losses occurred only from 0 to 0.2 M for Golden Delicious and 0 M for Granny Smith. The apparent diffusivity values were therefore determined. DM losses decreased with increasing the mannitol concentration. The decrease in turgor pressure between cells and aqueous solution seemed to limit DM losses.

**Effect on the Total Sugar Content.** The majority of the DM in ripe apple is made up of simple sugars. Figure 4 shows the plots of the sugar concentration versus immersion time. For both apples, total sugar losses decreased as mannitol in the solution increased from 0 to 0.6 M. The total sugar retained in the matrix then went from 5.3 to 7.7 g/100 g of FW for Golden Delicious and from 6.7 to 9.5 g/100 g of FW for Granny Smith. The losses depended upon the mannitol concentration in the medium. As in previous results, sugar leaching in solution could also be due to an osmotic pressure difference. The experimental data were then fitted to estimate apparent diffusivity from eq 2, with only the first term of the series being retained. The results presented in Table 1 show that the decrease in apparent

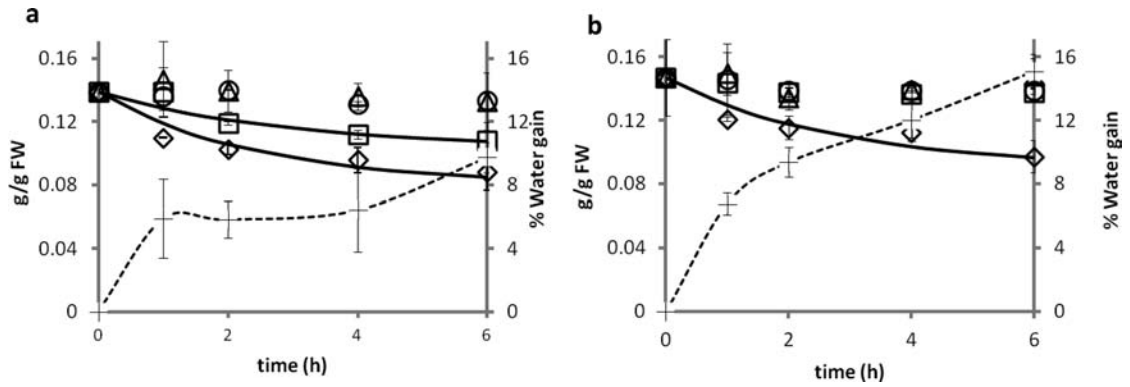

**Figure 3.** DM changes in different osmotic solutions (◇, 0 M; □, 0.2 M; △, 0.4 M; and ○, 0.6 M) against time for two apple varieties: (a) Golden Delicious and (b) Granny Smith. Water gain (+) percentage against time in different osmotic solutions.

**Table 2. Concentration of Phenolic Compounds (mg/kg of FW) in Parenchyma Tissue of the Apple Cultivar Samples[a]**

| apple variety | CAT | EPI | PCA | $DP_n$ | CQA | *p*CQ | XPL | PLZ | PT |
|---|---|---|---|---|---|---|---|---|---|
| Golden Delicious | 26 ± 25 | 70 ± 37 | 580 ± 280 | 7.17 ± 0.01 | 87 ± 13 | 1.5 ± 0.8 | 11 ± 4 | 12 ± 3 | 780 ± 30 |
| Granny Smith | 20 ± 17 | 58 ± 25 | 760 ± 50 | 6.52 ± 2.26 | 56 ± 9 | 10 ± 0.7 | 7 ± 1 | 9 ± 2 | 910 ± 100 |

[a]Data are expressed as the mean ± SD for three biological replicates. CAT, (+)-catechin; EPI, (−)-epicatechin; PRO, procyanidins; $DP_n$, average degree of polymerization of procyanidins; CQA, cafeoylquinic acid; *p*CQ, *para*-coumarylquinic acid; XPL, phloretin xyloglucoside; PLZ, phloridzin; and PT, total polyphenols.

diffusivity was from 1.8 to 0.3 × $10^{-9}$ $m^2$ $s^{-1}$ for Golden Delicious and only 2.5 × $10^{-9}$ $m^2$ $s^{-1}$ for Granny Smith. No apparent diffusivity value was determined for the sugar content, which did not decrease significantly. The model did not apply. The values of $D_e$ were found to depend upon the mannitol solution concentration, with no effect of the apple variety. Total sugars were decreased during the leaching process. However, the increase of the solution concentration by an osmotic agent, such as mannitol, could preserve total sugar losses.

This conclusion agrees with results obtained for the extraction of total sugar in similar conditions for apple in different concentrations of osmotic solution.[25,26]

The different behaviors of total sugar may reflect the mechanism of transport in the cell.[25] As reported by Lin and Pitt[21] in distilled water, cell rupture because of high turgor pressure caused cytolysis. According to the apple variety, an increase in the mannitol concentration in aqueous solution decreased total sugar losses. This may be linked to the extent of cytolysis or the slope of the concentration gradient.

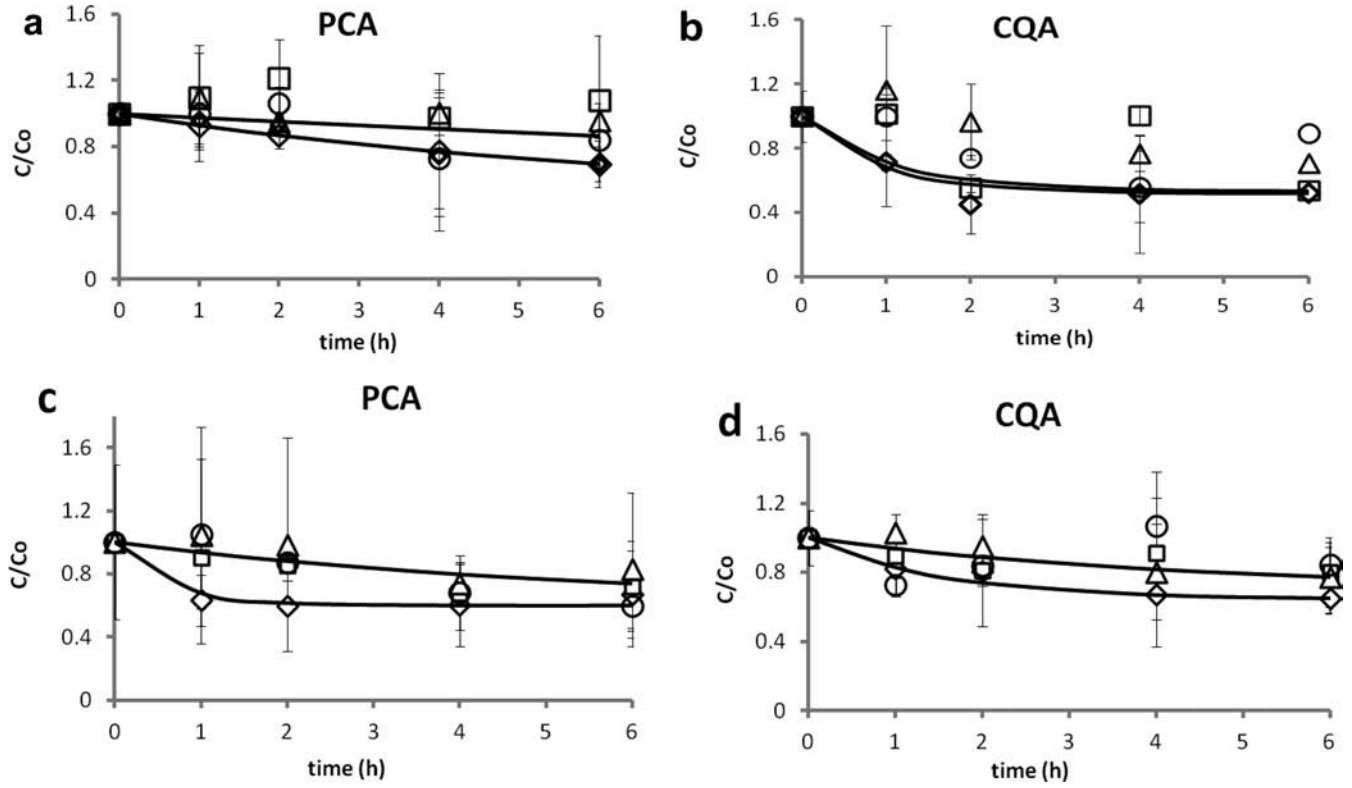

**Figure 5.** Changes in phenolic compounds in different osmotic solutions (◇, 0 M; □, 0.2 M; △, 0.4 M; and ○, 0.6 M) according to time for two apple varieties: (a and b) Granny Smith and (c and d) Golden Delicious (three biological replicates). Models of diffusion are represented by full lines. PCA, procyanidins; CQA, caffeoylquinic acids.

**Characterization of the Polyphenol Composition in Fresh Fruit.** The two dessert apple varieties were selected for their different phenolic contents and concentrations; the initial measurements are presented in Table 2. The main antioxidants in Golden Delicious and Granny Smith are polyphenols. Marked differences in total polyphenol content were found as a function of cultivar. Granny Smith contained more polyphenols than Golden Delicious. Our results were similar to those of previous studies.[14]

HPLC individual identification found polyphenols from three subclasses in the flesh of both apples: (1) flavan-3-ols (monomeric catechins and procyanidins), (2) hydroxycinnamic acids (chlorogenic acid and *para*-coumaroylquinic acid), and (3) dihydrochalcones (phloretin xyloglucoside and phloridzin).

In agreement with previous studies,[14] procyanidins were the main phenolic compounds, representing 74 and 84% of total polyphenols in Granny Smith and Golden Delicious, respectively. Their degree of polymerization ($DP_n$) of 7.2 and 6.6 for Golden Delicious and Granny Smith, respectively, were also close to those reported earlier.[14] Monomeric flavan-3-ols, accounted for 12 and 8% of total polyphenol in Golden Delicious and Granny Smith parenchyma, respectively. Caffeoylquinic acid, the main hydroxycinnamic acid, represented 11 and 6% of total polyphenols in Golden Delicious and Granny Smith parenchyma, respectively. Finally, dihydrochalcones represented less than 3% of the phenolic compounds in both apple varieties.

**Effects of Osmotic Solutions on Polyphenol Leaching.** Because slices were pretreated by NaF, a potent inhibitor of polyphenol oxidase, no oxidation was expected to occur, and within the time scale of the experiment, auto-oxidation was not significant. Losses of phenolic compounds from apple tissues in this experiment were therefore solely due to leaching.

Osmolarity of mannitol solutions affected polyphenol leaching. Figure 5 presents the evolution of concentrations (relative to FW) of procyanidins and caffeoylquinic acid. Losses of phenolic compounds were estimated by the difference in their concentrations relative to FW of slices before and after leaching.

*Flavan-3-ol Subclass.* For the Granny Smith variety, (+)-catechin decreased during the first 4 h of the treatment in distilled water and fell to 15% of the initial content. However, no (+)-catechin losses could be quantified in mannitol solutions, regardless of the mannitol concentrations. Losses of (−)-epicatechin were 47% in distilled water, with again no losses in the different mannitol solutions. Similar results were also found with losses of 31% procyanidins in distilled water and no losses in different mannitol solutions.

In Golden Delicious, (+)-catechin decreased by 47% in distilled water but only very slightly in mannitol solutions. Similar results were obtained for (−)-epicatechin and procyanidins.

*Hydroxycinnamic Acid Subclass.* In the Granny Smith variety, caffeoylquinic acid losses decreased with increasing the mannitol concentration. For *p*-coumaroylquinic acids, the opposite behavior was observed.

For the Golden Delicious variety, caffeoylquinic acid losses were also observed. However, no losses of *p*-coumaroylquinic acids were observed. The results present few different trends as a function of apple cultivar.

*Dihydrochalcones.* In the Golden Delicious variety, phloridzin losses were 30 and 35% in 0 and 0.2 M mannitol solutions, respectively. No losses were observed at higher

[a]CAT, (+)-catechin; EPI, (−)-epicatechin; CQA, caffeoylquinic acid; PT, total polyphenols; GD, Golden Delicious; GS, Granny Smith; and $C/C_o$, equilibrium polyphenol content. [b]Standard error. [c]Not determined.

mannitol solutions. Phloretin xyloglucoside decreased by 15% in pure water, while no changes appeared in mannitol solutions. For the Granny Smith variety, phloridzin losses were 50% in pure water. No losses were observed in mannitol solutions. Phloretin xyloglucoside losses were 30% in 0 and 0.2 M mannitol solution, but in 0.4 and 0.6 M, losses fell to 20%.

Monomeric catechins, hydroxycinnamic acids, and dihydrochalcones were either preserved or had limited losses in mannitol solution. The same trends were found for procyanidins.

The decreases in the leaching of phenolic compounds in the presence of mannitol were due to physiological barriers in cells. Cell structural integrity thus affected polyphenol diffusion. Difference in osmotic pressure caused changes in cell structure integrity.

The losses found here were considerably lower than those observed by Renard,[27] who studied diffusion to water of thermally treated pear slices. Devic et al.,[5] after 3 h in an optical density (OD) system, i.e., with very high sugar contents in the external solution, observed very limited diffusion of polyphenols. The differences between monomeric phenols (catechins, hydroxycinnamic acids, or dihydrochalcones) and procyanidins could be explained by their affinity with cell walls, as stated by Renard et al.[28] and Le Bourvellec et al.[29] A further indication for the involvement of this mechanism is an increase in the degree of polymerization for the retained procyanidins (up to 7.2 in Golden Delicious and 7.4 in Granny Smith after 6 h). Le Bourvellec et al.[30] found that procyanidins were mainly bound to pectins. Watrelot et al.[31] also found that stronger association was obtained with longer procyanidin molecules interacting with highly methylated pectins.

*Estimation of Apparent Diffusivity of Polyphenols.* The experimental data were also fitted, and results are presented in Table 3. Apparent diffusivity values were determmined when changes in polyphenol content were significant.

Apparent diffusivity values decreased with increasing the mannitol solution concentration. Total phenolic values varied from 0.1 to 0.2 × $10^{-9}$ $m^2$ $s^{-1}$ for Golden Delicious and from 0.2 to 0.3 × $10^{-9}$ $m^2$ $s^{-1}$ for Granny Smith. Total phenolic compound apparent diffusivities depended upon the osmotic solution concentration and were lower than those observed for total sugars. Sugars present in cells seem to leach faster than polyphenols, possibly owing to their lower molecular weight but also their physiological role in the plant.

Phenols must thus overcome the physiological barriers, mainly cell membranes, which provide dominant resistance for phenol release and influence mass transfer.[32] Different cell states in osmotic solution as reported[21,26] also seemed to affect polyphenol migration out of the matrix. Procyanidins presented lowest diffusivities, possibly owing to their high molecular weight[33] and non-covalent interaction with cell wall materials.[34]

Sugar and polyphenol concentrations decreased during the immersion of apple slices in mannitol solution depending upon a certain level of the mannitol concentration. The changes were probably due to leaching into the soaking solution. The application of Fick's second law allowed for the determination of apparent diffusivity. The link found between the decrease in solute loss and increase in the mannitol concentration could be associated with integrity of the cell structure. In all cases, the concentration of phenolic compounds changed according to the difference in osmotic pressure of the soaking solution. In raw fruit, leaching occurs if cell integrity is lost. Some of the difference in phenolic compound leaching was found to be a function of apple variety.

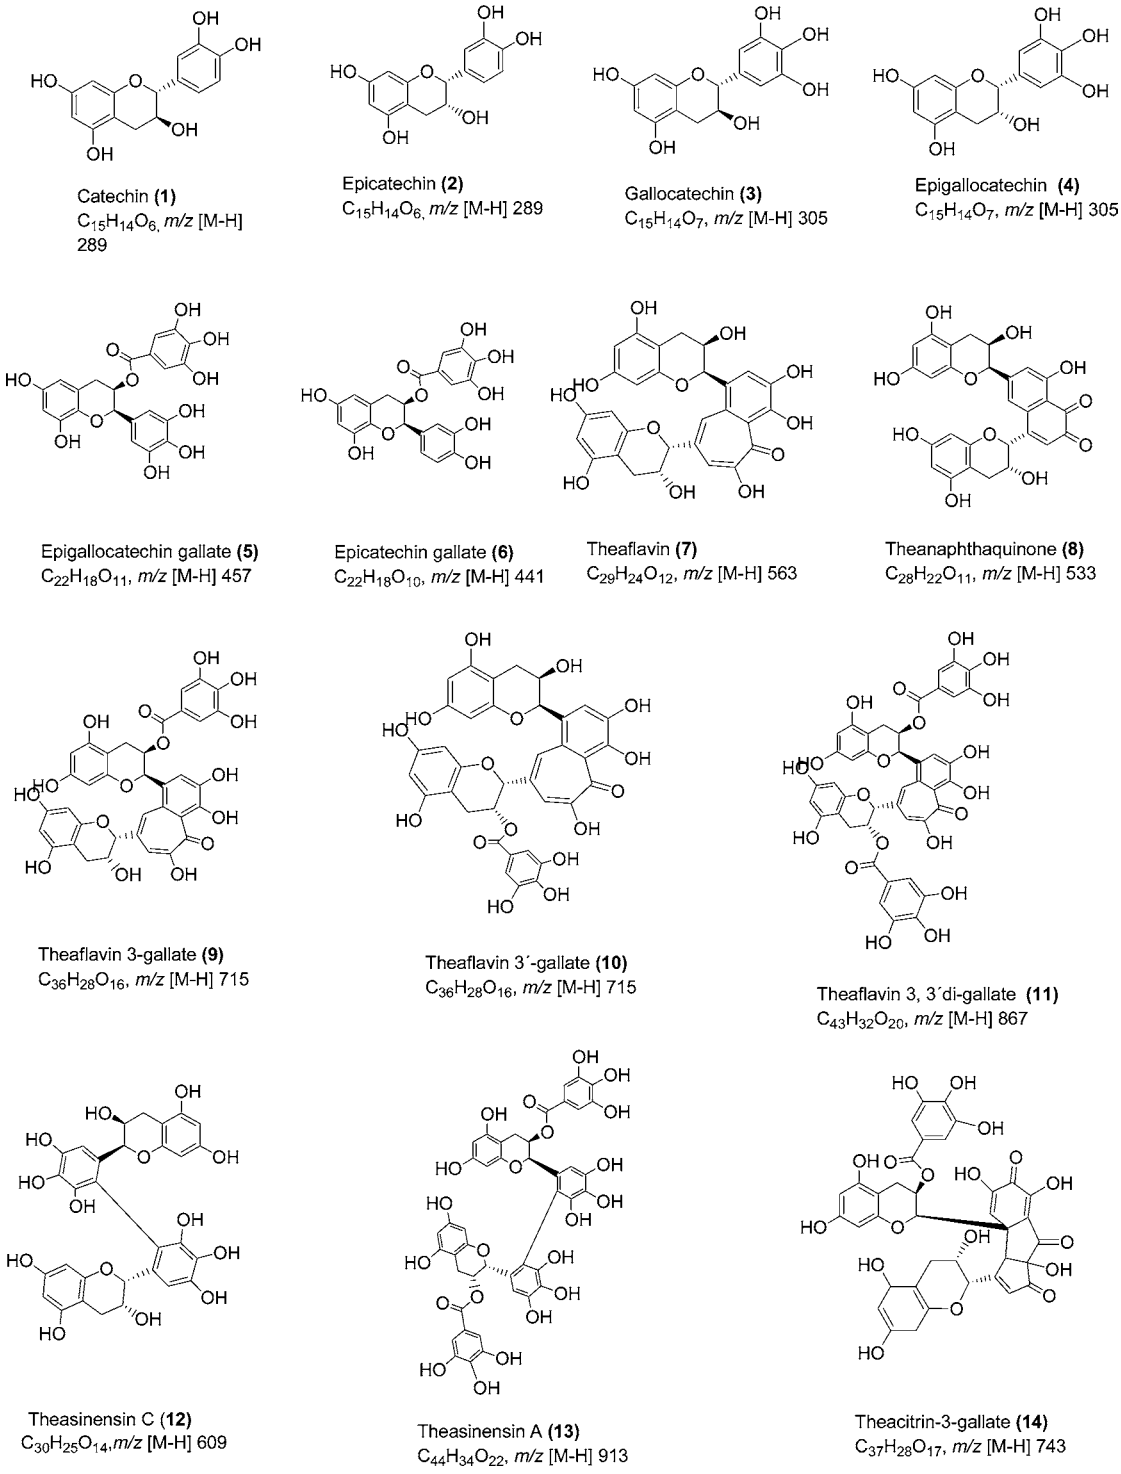

**Figure 1.** Structures of catechins and their formal dimers previously identified in black tea.

(O), hydrogen ($H_2$), gallates ($C_7H_5O_4$), and catechins in various oxygenation degrees acting as main building blocks in black tea chemistry. According to the data generated, oxygen insertion was observed as mass increment in the largest number.[16] However, the type and nature of the compounds were still unknown. Later, on the basis of initial ESI-FTICR-MS data[17,18] from targeted tandem LC-MS experiments, the data revealed that a significant fraction of thearubigins consists of polyhydroxylated derivatives of catechin dimers (a stepwise increase of oxygen increments within the dimeric structures), the so-called "homologous series".[9] On the basis of the experimental data, the oxidative cascade hypothesis was proposed. This hypothesis proposes the formation of the *o*-quinones of different dimeric and oligomeric structures in the oxidation process, where these could be followed by nucleophilic addition of water in the fermentation process, leading to polyhydroxylated structures, and this continues until all aromatic hydrogens are replaced by OH functionalities, thus increasing the number of the components within the thearubigin fractions. Previous investigations carried out on

dx.doi.org/10.1021/jf502220c | J. Agric. Food Chem. 2014, 62, 9848−9859

the oxidative cascade hypothesis revealed the presence of homologous series of theaflavins (TFs), their gallate esters theaflavin mono- and digallates, and theacitrin (TC) structures.[16,17] Kuhnert et al. additionally showed that a significant portion of these compounds are in redox equilibrium with their quinone counterparts.[17] MALDI-MS experiments on TRs[18] and detailed tandem MS investigations by Yassin et al. additionally showed that trimers and teramers of flavan-3-ols are major products of oxidative tea fermentation.[18]

The aim of this study is to further confirm the second level of the oxidative cascade hypothesis and to structurally elucidate the novel thearubigin components. For this investigation electrospray ionization tandem mass spectrometry (ESI-LC-ion trap-MS) was employed for characterizing thearubigins in homologous series reaching $m/z$ 1000. A particular emphasis was put on derivatives of theasinensins (TSs, also referred to as bisflavanones) and theanaphthaquinones (TNQs), the two dimeric catechin derivatives so far not investigated. The experimental strategy used was based on generating extracted ion chromatograms EIC at the mass of the parent ion and their corresponding hydroxylated derivatives, where the signals are strong enough to obtain $MS^2$ and $MS^3$ spectra. In this approach, the different $m/z$ signals of the parent ion of theanaphthaquinone and theasinensin C dimeric structures and their hydroxylated components were obtained in the homologous series, where several regioisomers were detected at distinct retention times, increasing the structural variety of the newly identified thearubigin compounds.

Furthermore, interestingly a new series of compounds could be also identified for the first time revealing the presence of $H_2O_2$ as a contributor in the fermentation process.[19] Previous studies done by Sinkar et al. confirmed the presence of $H_2O_2$ and its important role in the oxidation process leading to the formation of thearubigins in the presence of peroxidase enzyme.[20] In this investigation, by focusing on the ESI-LC-tandem mass $MS^n$ measurements, the homologous series of dimeric structures theasinensin C and theanaphthaquinone are obtained, and a new series containing epoxide derivatives of theasinensin A that has not been previously investigated are reported.

## MATERIALS AND METHODS

**Chemicals and Reagents.** All chemicals and reagents were purchased from Sigma-Aldrich. Black tea samples of Ceylon, Assam, and Indian tea varieties were purchased from a local supermarket and provided from the Unilever Excellence Center.

**Preparation of Thearubigins.** Freshly ground black tea leaves (8 g) were added to 150 mL of freshly boiled water and kept for 10 min in a Thermos flask, which was inverted every 30 s. The flask contents were filtered through a Whatman no. 4 filter paper to remove the leaves, and the remaining brew was allowed to cool to room temperature. Caffeine sufficient to achieve 20 mM was added to the brew, stirred to ensure dissolution, allowed to stand at 4 °C for 2 h, and centrifuged at 23300*g* for 20 min. The resulting precipitate was recovered and suspended in boiling water and partitioned against aliquots of ethyl acetate (40 mL) until no further color was extracted (usually five times).

The ethyl acetate supernatant was removed and evaporated to dryness under nitrogen below 35 °C, and the residue (TF fraction) was recovered in 10 mL of distilled water. The aqueous phase was partitioned at 80 °C against 2 volumes of chloroform, and the decaffeinated liquid was stored overnight at −80 °C and freeze-dried. The freeze-dried material (TR fraction) was stored at −20 °C until required and reconstituted as required for the analysis. The yield of thearubigins in this method was mainly 10% and obtained as orange to light brown fluffy powders.

**LC-$MS^n$ Method.** The extracted thearubigin solutions were reconstituted to a 0.5 mg/mL concentration in 1:1 methanol/water, filtered through a 0.45 $\mu$m HPLC filter, and analyzed by LC-MS method using Aligent 1100 series LC equipment and a DAD detector with a light pipe flow cell (recording at 400 and 245 nm and scanning from 200 to 600 nm). This was coupled to an ion trap mass spectrometer fitted with an ESI source (Bruker Daltonics HCT Ultra) operating in the negative ion Auto $MS^n$ mode to obtain fragment ion $m/z$. Separations were achieved on a Polaris 5-C18-A column (length, 250 mm; diameter, 3 mm; particle size, 5 $\mu$m) with a step gradient elution employing acetonitrile (MeCN) and water containing 0.005% formic acid, as follows: 8% MeCN from 0 to 50 min, then changing to 31% MeCN for 10 min, then changing to 25% MeCN for a further 5 min. The column eluent was first directed to the UV detector and then to the ESI interface operating with a capillary voltage of 1 V, and fragmentation amplitude was set starting at 30% and ending at 200%. The capillary temperature was also set at 300 °C. Nitrogen gas was used here as nebulizing and drying gas at a flow rate of 10 L/min and a pressure of 10 psi, respectively.

**High-Resolution LC-MS.** High-resolution LC-MS in the negative ion mode was carried out using the same HPLC equipped with a MicrOTOF Focus mass spectrometer (Bruker Daltonics) fitted with an ESI source, and internal calibration was achieved with 10 mL of 0.1 M sodium formate solution injected through a six-port valve prior to each chromatographic run. Calibration was carried out using the enhanced quadratic calibration mode. It should be noted that in TOF calibration the intensities of the measured peaks have a significant influence on the magnitude of the mass error with high-intensity peaks, resulting in detector saturation displaying larger mass errors. Where necessary, this was avoided by using a more dilute sample. All MS measurements were carried out in the negative ion mode.

**HPLC Analysis.** The extracted thearubigins were analyzed by HPLC using an Agilent 1200 HPLC pump with a 5 $\mu$L loop, coupled to an Agilent 1100 autosampler and an Agilent 1100 DAD-UV−vis detector. Black tea extracts and thearubigin extracts were reconstituted at 5 mg/mL in 1:1 MeOH/$H_2O$ and filtered through a 0.45 $\mu$m HPLC filter prior to injection of a volume of 3 $\mu$L. HPLC analysis used a Polaris 5-C18-A column (length, 250 mm; diameter, 3 mm; particle size, 5 $\mu$m) with a step gradient elution employing acetonitrile (MeCN) and water containing 0.005% formic acid, as follows: 8% MeCN from 0 to 50 min, then changing to 31% MeCN for 10 min, then changing to 25% MeCN for a further 5 min.

**Data Analysis.** Data were analyzed using Bruker Data Analysis 4.0 software. Micro TOF data were analyzed (TICs, EICs) after external enhanced quadratic calibration. Ion trap data were analyzed in terms of EICs, TICs, and neutral loss chromatograms (NLCs) using the implemented software routines.

## RESULTS AND DISCUSSION

For further investigating the hydroxylation process of the dimeric components and confirming their presence within the oxidative cascade hypothesis in thearubigin fractions, ESI-LC-$MS^n$ experiments were carried out on the homologous series of theasinensin C (**12**) and its gallate ester theasinensin A (**13**) (Figure1). These structures are formed via dimerization of two catechin derivatives. Additionally, a homologous series of theanaphthaquinones (**8**) (Figure 1) were investigated, which is formed via further oxidation of theaflavin. Both dimeric structures are likely implicated in the thearubigin formation.

LC−tandem MS experiments were performed on the selected $m/z$ parent ions expected for these compounds, which are potentially the first member of the anticipated homologous series. Extracted ion chromatograms (EICs) were created from the $m/z$ values of hypothetical members of the homologous series, and in case strong signals were observed at the corresponding $m/z$ values, targeted fragmentation experi-

[a]$MS^2$ fragment ions highlighted in bold are subjected for further fragmentation for $MS^3$ fragment ions. [b]RT, retention time (min). [c]$\delta$M(S1 − S2), mass loss (Da).

ments were carried out corresponding to $MS^2$ and $MS^3$ spectra. The presence of fragment ions with their neutral losses was located; therefore, the fragmentation pattern and its mechanism have been determined for the parent structure forming the first member of each homologous series. Later, oxygen mass increments were introduced, and different signals at $m/z$ values corresponding to the majority of predicted hydroxylated derivatives were established. The interpretation here was based on the fragment ions and the neutral losses for the parent ions observed, where the mechanism of fragmentation has been previously established either from investigation of authentic reference compounds or from literature precedents.[16] The assumption for identifying the homologous series of different hydroxylated parent ions was based on their $m/z$ values and their $MS^2$ fragment spectra observed. An identical fragmentation mechanism has to be obtained for the whole homologous series. For example, theaflavins (**7** shown in Figure 1) undergo fragmentation with a neutral loss of an enone of $m/z$ 137 ($C_7H_6O_3$), which can be rationalized in terms of retro Diels-Alder fragmentation (RDA) at one of the benzopyran moieties.[21] It has been confirmed that the whole homologous series of this compound underwent the same fragmentation.[16] On the other hand, its gallate esters, for example, theaflavin mono/digallates (**9**, **10**, and **11** in Figure 1) underwent losses of 152 and 170 Da, indicating the loss of galloyl moieties. The whole series underwent oxygen insertions within the sites of the fragment ions obtained or within the available sites of the galloyl neutral losses having the same fragmentation mechanism. Hence, it was suggested that it is reasonable to expect that a similar fragmentation mechanism will apply to all members of the homologous series investigated. There is ample evidence in the literature for many classes of compounds, where minor structural changes do not alter the basic fragmentation pathways.[22,23] Therefore, the hydroxylated derivative will fragment by the same mechanism as the parent compound. It was anticipated that generally retention time on reversed phase packings would decrease relative to the parent compound as hydroxylation increased unless internal hydrogen bonding significantly increased the hydrophobicity.[16]

**Theanaphthaquinone and Its Homologous Series.** Theanaphthaquinone (**8**) showed an MS spectrum at $m/z$ 533 characterized by its $MS^2$ fragment ions: at $m/z$ 514 as a base peak revealing the loss of $H_2O$; at $m/z$ 464 having a neutral loss of 69 Da, which is rationalized by the loss of $C_3HO_2$ from the quinone part of this compound; a fragment ion of a very weak intensity at $m/z$ 396 showing a neutral loss of 137 Da indicating a RDA fragmentation occurring on one of the catechin moieties of this molecule. The EIC of theanaphthaquinone and its fragment spectra are shown in Figure 1 in the Supporting Information. Theanaphthaquinones have different sites available to hydroxylation, and to evaluate the assignment of these peaks as hydroxy-theanaphthaquinone, EICs were prepared to their corresponding predicted masses and the data are exhibited in Table 1. Furthermore, by using constant neutral loss analysis of the tandem mass, the presence of particular fragment ions and their neutral losses corresponding to their chromatographic peaks could be located and tentative structures assigned.

EICs were created for the predicted polyhydroxylated compounds of theanaphthaquinone (**8** + $O_x$). These showed the presence of $m/z$ values corresponding to the components with two oxygen insertions at $m/z$ 565.1 ($C_{28}H_{21}O_{13}$), three oxygen insertions at $m/z$ 581.2 ($C_{28}H_{21}O_{14}$), four oxygen insertions at $m/z$ 597 ($C_{28}H_{21}O_{15}$), and five oxygen insertions at $m/z$ 613.1 ($C_{28}H_{21}O_{16}$). However, these were of low intensity when compared to other signals corresponding to members of homologous series of TFs and TCs previously reported.[17] The high-resolution masses of all TNQ derivatives were in line with data from previous FT-ICR-MS data and confirmed the elemental composition of these ions.[9]

Only a single chromatographic peak was detected for $m/z$ 565.4 corresponding to **8** + $O_2$ for the predicted dihydroxylated derivative at a retention time of 50.1 min. Tandem mass experiment of this compound gave $MS^2$ fragment ions at $m/z$ 544.9, revealing a loss of $H_2O$ molecule, and a characteristic fragment ion at $m/z$ 494.5, revealing a loss of $C_3HO_2$. The same fragmentation was previously observed in the parent ion, thus showing that this compound belongs to the homologous series of theanaphthaquinone with two oxygen insertions. This peak was tentatively assigned as a dihydroxylated derivateive of TNQ (**8** + $O_2$).

Four chromatographic peaks were detected in the EIC at the $m/z$ 581.2 (**8** + $O_3$) at different retention times of 53.5, 43, 34.7, and 30.9 min, as expected for the trihydroxylated theanaphthaquinone. All exhibited an $MS^2$ fragment ion at $m/z$ 512.5 as a base peak revealing a loss of 69 Da, thus

corresponding to the loss of $C_3HO_2$ and revealing three oxygen insertions within the compound. Minor fragment ions with different intensities at *m/z* 444.5 were also observed revealing RDA fragmentation as previously identified in the parent ion. These four peaks were tentatively assigned as tetrahydroxylated derivatives of TNQ (**8** + $O_4$).

One chromatographic peak was detected for the *m/z* 597 at a retention time of 48.4 min corresponding to **8** + $O_4$. Tandem mass experiments showed a transition of this precursor ion to a fragment $MS^2$ ion at *m/z* 528.5 as a base peak characterized by a neutral loss of 69 Da of $C_3HO_2$ and revealing four oxygen insertions within this compound.

Two chromatographic peaks were detected for the *m/z* 613 at retention times of 39 and 28.1 min as expected for the pentahydroxylated theanaphthaquinone. Tandem mass fragmentation experiments showed a main fragment ion $MS^2$ at *m/*

$z$ 544.5 having a neutral loss of 69 Da of $C_3HO_2$, thus indicating all of the oxygens are inserted in the fragment ion, which corresponds to **8** + $O_5$.

The main neutral losses of all the chromatographic peaks identified revealing losses of $H_2O$, loss of $C_3HO_2$, and weak RDA fragmentation are shown in Figures 2 and 3, thus confirming the assignment made. Therefore, theanaphthaquinone undergoes nucleophilic addition of $H_2O$ in the fermentation process for TR formation, where successive oxygen insertion takes place, giving its polyhydroxylated derivatives. These are exhibited in Figure 3, showing the hydroxylation process. Again, it should be noted that in the absence of authentic reference compounds, assignments of detailed structures are tentative and information on the regiochemistry of oxygen insertion is speculative with structures shown corresponding to positions of random oxygen insertion. Therefore, a new homologous series of theanaphthaquinone was observed within the oxidative cascade hypothesis extending the members of the thearubigin family.[16,17]

**Theasinensin C and Its Homologous Series.** Another systematic search for homologous series was carried out on theasinensin C ($C_{30}H_{25}O_{14}$) (**12**) shown in Figure 1 as a parent compound. Signals corresponding to $m/z$ values of polyhydroxylated theasinensins were previously identified in FT-ICR-MS and MALDI-MS data of TR extracts.[16,24] EICs were also generated for the mass of parent ions expected for this homologous series. Theasinensin C (**12**) is characterized by it mass spectrum with $[M - H]$ ion at $m/z$ 609, revealing the presence of two isomers at different retention times of 34.6 and 48.1 min, with the major chromatographic peak of this compound detected at 34.6 min as shown in Figure 2 in the Supporting Information. Performing tandem MS experiments with the precursor ion at $m/z$ 609 gave a $MS^2$ fragment spectra characterized by a base peak at $m/z$ 538.6 exhibiting a neutral loss of 70 Da, thus indicating a loss of $C_3H_2O_2$. Further $MS^3$

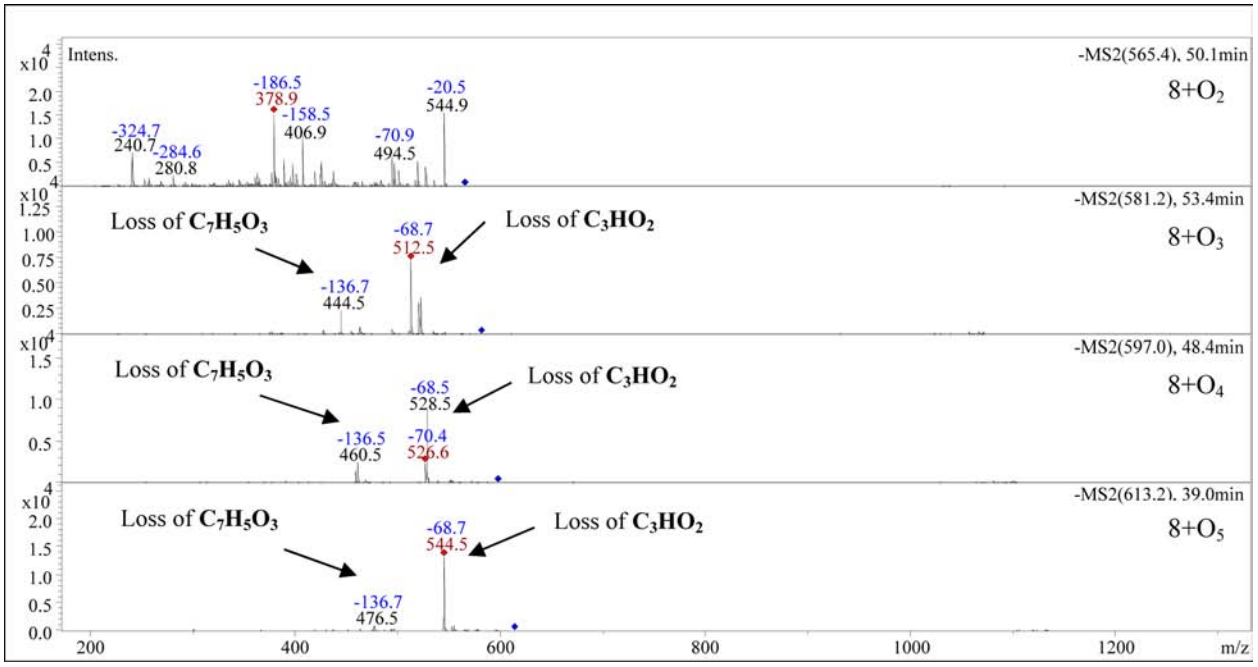

**Figure 5.** Constant neutral losses for the hydroxylated components of theanaphthaquinones (**8** + $O_x$): *m*/*z* 565.4, 581.2, 597.2, and 613.2 exhibiting losses of $H_2O$, $C_3HO_2$, and retro-Diels–Alder fragmentation.

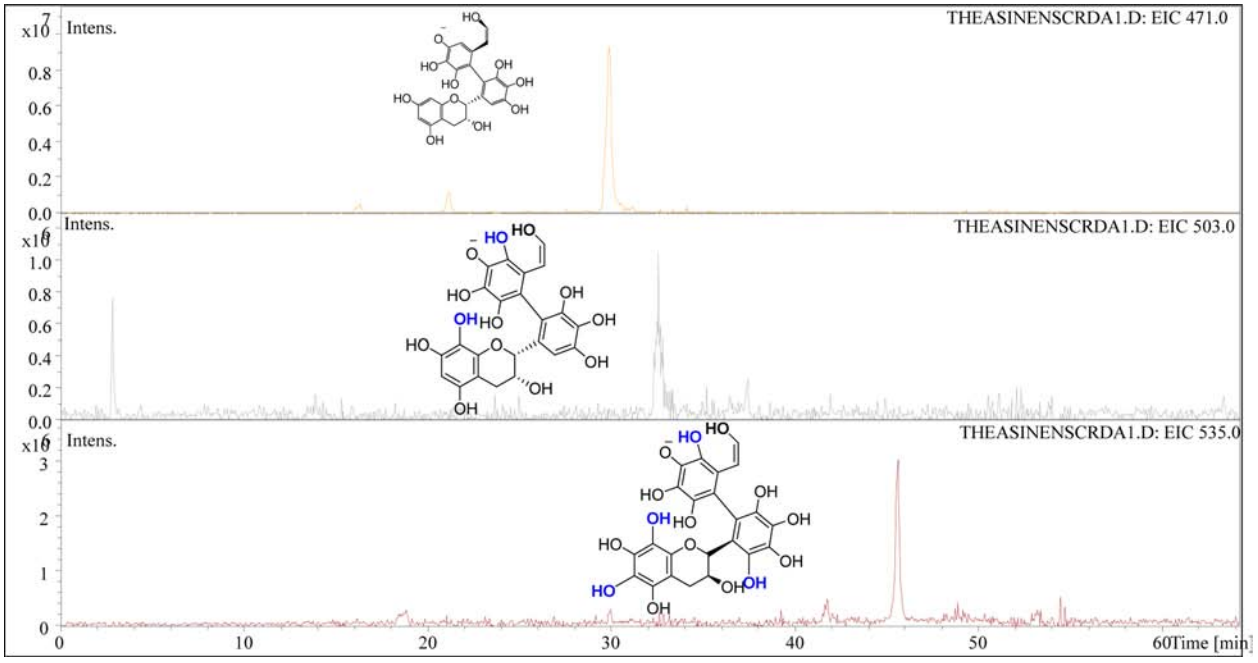

**Figure 6.** Extracted ion chromatograms EICs showing the retro-Diels–Alder (RDA) fragment ions in the homologous series of theasinensin C (**12**); (a, top) EIC at *m*/*z* 471; (b, middle) EIC at *m*/*z* 503; (c, bottom) EIC at *m*/*z* 535. (The sites of deprotonation in $[M - H]^-$ and regioisomers are selected randomly.)

tandem mass experiments with a precursor ion at *m*/*z* 538.6 gave the characteristic $MS^3$ fragment ion at *m*/*z* 470.5 corresponding to a loss of 138 amu, and this indicates that the molecule underwent first a loss of $C_3H_2O_2$, with fragmentation on one of the two benzopyran A-ring moieties followed by a RDA fragmentation with the loss of an enone fragment. The fragmentation mechanism is shown in Figure 4.

It is worth noting that while theasinensins have a biphenyl connection on the catechol B-rings, proanthocyanidins (another dimeric catechin structure) are connected from the resorcinol A-ring to the C-ring as indicated in Figure 5 in the Supporting Information. Both classes of compounds are constitutional isomers of one another with proanthocyanidins as well reported previously in tea chemistry. Both can be identified and differentiated by their different $MS^2$ fragment ions obtained in LC tandem MS. Proanthocyanidins show different $MS^2$ fragment spectra characterized by retro Diels–Alder fragmentation R.D.A. with a neutral loss of 168 Da giving *m*/*z* 441, Quinide Methide fission Q.M. giving *m*/*z* 305, and heterolytic ring fission H.R.F. giving an *m*/*z* 483 with a neutral

loss of 126 Da. Further details for differentiating between these two isomeric structures are shown in the fragmentation mechanism of the proanthocyanidin isomeric structure in Figure 6 in the Supporting Information.

To evaluate the assignment of the hydroxylated components within the homologous series of theasinensin C (**12**), EICs were prepared for their corresponding expected *m/z* values. Whereas theasinensin C (**12**) $C_{30}H_{25}O_{14}$ was detected at *m/z* 609, the EICs of its hydroxylated components were detected at *m/z* 641 for $C_{30}H_{25}O_{16}$, at *m/z* 673.1 for $C_{30}H_{25}O_{18}$, and at *m/z* 705.6 for $C_{30}H_{25}O_{20}$. The identity of the molecular formulas was previously established by FT-ICR-MS.[9] A detailed study for the hydroxylated derivatives of this compound and their $MS^2$ and $MS^3$ fragment ions is exhibited in Table 2.

One chromatographic peak was identified for *m/z* 641 $C_{30}H_{25}O_{16}$, corresponding to theasinensin C with two oxygen insertions (**15** + $O_2$), eluting at a retention time of 33.2 min. This compound gave a fragment ion at *m/z* 604.8 as a major peak exhibiting a neutral loss of 36 amu, corresponding to a loss of two $H_2O$ molecules from this ion, and another characteristic $MS^2$ ion at *m/z* 570.5 revealing the loss of $C_3H_2O_2$. Further fragmentation gave $MS^3$ as base peak at *m/z* 504.5 revealing the further RDA fragmentation occurring in this compound. Hence, the fragmentation pattern observed match fragment ions expected for a dihydroxylated theasinensin derivative.

Three isomers in the EIC with *m/z* 673 were detected at different retention times of 20.1, 40.1, and 40.9 min, corresponding to the predicted tetrahydroxylated theasinensin **12** + $O_4$ ($C_{30}H_{25}O_{18}$). One of them eluting at 20.1 min showed a transition from *m/z* 673.1 to a fragment ion at *m/z* 602.5 as a base peak, indicating the loss of $C_3H_2O_2$ and the oxygen insertions within the dimeric ring. The second isomer of the *m/z* 673 eluting at 40.1 min showed a transition from *m/z* 673 to 604.5 and 535.5, exhibiting a major loss of $C_3H_2O_2$ on the benzopyran ring and a minor loss of 136.6 amu due to RDA fragmentation occurring, whereas all of the hydroxyl groups are inserted within the fragment ion of the theasinensin C ring. The third isomer of the *m/z* 673 was eluting at 40.9 min showing a transition from *m/z* 673 to 655 exhibiting a neutral loss of 18 amu, which is the loss of water, and indicating three hydroxyl insertions within this compound. A further $MS^3$ fragmentation for this compound gave a transition of the $MS^2$ fragment ion at *m/z* 655 to $MS^3$ at *m/z* 503, which indicates that two hydroxyl groups are inserted within the theasinensin fragment ion and one hydroxyl insertion was occurring within the eliminated benzopyran moiety, whereas this molecule was undergoing a loss of water at the same time. This is briefly illustrated in Figure 7. Hence the fragmentation pattern observed matches the fragment ions expected for the tetrahydroxylated theasinensin derivative. In a part of fragmentation pattern of these compounds a loss of water was observed, which has not been observed in the parent compound. An additional set of EICs were created in the all $MS^n$ mode searching for fragment ions that would be characteristic for hydroxylated theasinensins. Representative data are shown in Figure 6. Here fragment ions originating from RDA fragmentations at *m/z* 471, 503, and 535 were observed corresponding to bisflavanol-like compounds with two or four oxygens inserted, respectively. These observed fragment ions point toward the presence of hydroxylated theasinensins. It should as well be noted that the fragment spectra obtained showing frequently loss of two water molecules from the precursor ion might as well correspond to hydroxylated theasinensin derivatives, in which, due to a

change of the aromatic substitution pattern, the fragmentation pathway is altered.

Only one isomer of $C_{30}H_{25}O_{20}$ corresponding to **15** + $O_6$ was observed at $m/z$ 705.6, giving a transition to $m/z$ 636.4 as a major peak intensity, which reveals a loss of $C_3H_2O_2$ from the A-ring and indicating all of the hydroxyl groups are inserted within the theasinensin fragment.

All of the above-mentioned results are exhibited in Table 2, confirming the presence of a new homologous series for theasinensin C present in thearubigin fraction. Tetntative

structures of the homologous series of theasinensin C are shown in Figure 8.

**Theasinensin A and Its Homologous Series.** Theasinensin A (**13**) as indicated in Figure 1 is characterized by its mass spectrum with a pseudomolecular ion at $m/z$ 913.2 [M − H] in the negative ion mode, exhibiting different characteristic fragment ions. In the EIC of $m/z$ 913 as shown in Figure 8 in the Supporting Information, three signals are observed at different retention times of 1.7, 16.3, and 22.5 min. The first fragment ion was observed at $m/z$ 761.2 with a neutral loss of 152 amu, and a second fragment ion was also observed at $m/z$ 743.2 with a neutral loss of 170 amu, both revealing the loss of one of the galloyl moieties of this compound. A third fragment ion was observed at $m/z$ 609.1, exhibiting a loss of 304 amu, which can be rationalized due to a loss of two galloyl moieties from both parts of theasinensin A. A base peak fragment ion was exhibited in the MS$^2$ spectra at $m/z$ 591.2, indicating the loss of one galloyl group from one part of the molecule and another gallate ester from the second part. The fragmentation of this compound and its mechanism are shown briefly in Figure 9.

To evaluate the assignment of the hydroxylated components within the homologous series of theasinensin A (**13**), EICs were prepared for their corresponding expected $m/z$ values. Whereas theasinensin A (**13**) was detected at $m/z$ 913.2 ($C_{44}H_{33}O_{22}$), EICs for its predicted hydroxylated components were prepared at $m/z$ 929 ($C_{44}H_{33}O_{23}$), at $m/z$ 945 ($C_{44}H_{33}O_{24}$), at $m/z$ 961 ($C_{44}H_{33}O_{25}$), at $m/z$ 977.1 ($C_{44}H_{33}O_{26}$), and at $m/z$ 993.3 ($C_{44}H_{33}O_{27}$). These results are shown in Table 3. Targeted tandem MS experiments of the hypothetical hydroxylated components of theasinensin A (**13**) were carried out for evaluating the presence of oxygen insertions within these compounds, to confirm whether a homologous series of theasinensin A is present.

As shown in Table 3, the EIC at $m/z$ 929 showed a single peak at a retention time of 32.6 min corresponding to a theasinensin A with one oxygen inserted (**13** + $O_1$). The precursor ion at $m/z$ 929.1 displayed a MS$^2$ fragment ion at $m/z$ 913.3 as a base peak having a neutral loss of only 16 amu. However, such MS$^2$ fragmentation did not show a similar fragmentation as the parent ion of theasinensin A, undergoing the neutral losses of the galloyl moieties, which is its characteristic fragmentation mechanism. Hence, this could not be in agreement with the hypothesis of the homologous series as previously described by which the whole series undergoes similar if not identical fragmentation as described for the parent ion. Neutral loss of 16 amu is characteristic for either peroxide functionalities or epoxide functionalities, so that the compound observed was tentatively assigned to a peroxo or epoxy derivative of a bisflavanol.

Two chromatographic peaks corresponding to the predicted dihydroxylated component of theasinensin A (**13** + $O_2$) were detected in the EIC at $m/z$ 945.0. The first peak was observed at a retention time of 52.3 min, where its MS$^2$ spectrum exhibited fragment ions at $m/z$ 926.6 showing a loss of $H_2O$, a base peak at $m/z$ 909.1 with a neutral loss of 36 amu, thus indicating a further loss of $H_2O$ molecule, and a characteristic fragment ion with a very weak intensity at $m/z$ 657.2, revealing a loss of two galloyl moieties from this compound undergoing a loss of oxygen ($2C_7H_5O_4 - O$) and three oxygen insertions within the fragment ion, which is in agreement as the fragmentation pathway of the parent ion theasinensin A. A second isomer of $m/z$ 945 was detected at a retention time of 47.8 min; the MS$^2$ spectrum of this compound gave a fragment ion with a medium intensity at $m/z$ 909.2 revealing a loss of two molecules of $H_2O$.

Only one chromatographic peak in the EIC at $m/$ 961 corresponding to three oxygen insertions (**13** + $O_3$) was observed at 64.0 min. Its MS$^2$ spectrum showed a characteristic base peak at $m/z$ 916.9 suffering a neutral loss of 44 Da (loss of $CO_2$), and further fragment ions were observed, one of which was detected coeluting with a low intensity at $m/z$ 657 exhibiting a neutral loss of 304 Da, which indicates the loss of the two galloyl groups from this compound as in the parent ion and three oxygen insertions within the fragment ion. The latter fragment ion is in agreement with a trihydroxylated theasinensin structure.

Two chromatographic signals in the EIC at $m/z$ 977.1 for the predicted tetrahydroxylated derivatives of theasinensin A (**13** + $O_4$) were detected. The first one was observed at a retention time of 51.2 min, exhibiting MS$^2$ fragment spectra characterized by a weak fragment ion at $m/z$ 959.4 having a neutral loss of 17.5, which corresponds to a loss of one hydroxyl group, and another characteristic MS$^2$ ion with high intense peak was identified at $m/z$ 920.6 having a neutral loss of 56 Da ($-C_3H_4O$) characteristic for flavanol C-ring cleavage. The second isomer at $m/z$ 977.3 was observed eluting at 32.8 min, and the latter showed no characteristic fragmentation of

dx.doi.org/10.1021/jf502220c | J. Agric. Food Chem. 2014, 62, 9848−9859

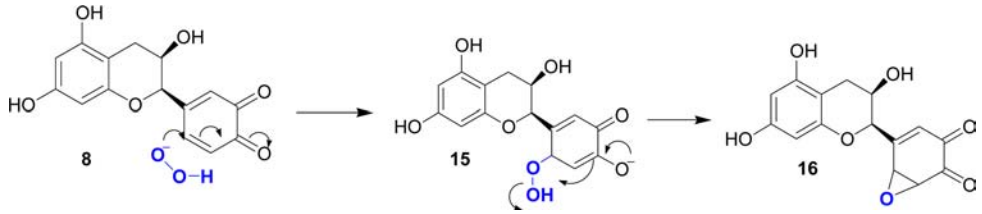

**Figure 10.** Proposed mechanism undergoing oxygen insertion by nucleophilic addition of $H_2O_2$.

theasinensin A. Thus, these two mentioned isomeric compounds could not be considered as a part of the homologous series of theasinensin A, so no tetrahydroxylated components of this series are present.

A single chromatographic peak was observed in the EIC at $m/z$ 993.3, a value predicted for a pentahydroxylated derivative of theasinensin A (**13** + $O_5$). The $MS^2$ spectrum of this component exhibited a characteristic fragment ion at $m/z$ 961.2 showing a neutral loss of 32 amu, which indicates the loss of two oxygens, whereas only three oxygens were inserted within the fragment ions of this compound. As in the previously identified compounds, this new component did not undergo the same fragmentation as the parent compound, theasinensin A, thus indicating that this compound does not belong to the homologous series suggested.

Accordingly, this observation can be rationalized by suggesting that a new series of oxidation products in thearubigin formation may exist. These new compounds undergo mainly oxygen losses (−32 Da, $-O_2$) during $MS^2$ is a characteristic for peroxides or epoxides. It is proposed that these compounds can be formed in the presence of $H_2O_2$ in black tea thearubigin fractions, with hydrogen peroxide acting as a nucleophile adding to *o*-quinone moieties. It should be noted that due to the $\alpha$-effect hydrogen peroxide is around 1000 times more nucleophilic if compared to water, the conventional nucleophile involved in thearubigin chemistry. The existence of $H_2O_2$ in black tea has been previously discussed and confirmed by Sinkar et al. in an attempt to investigate the biochemistry and chemistry of thearubigins using polyphenol oxidase and peroxidase enzymes.[20] In his work, Sinkar demonstrated that TPPO, while oxidizing catechins, generates $H_2O_2$ in concentrations of 290−390 $\mu$M, which may play a role in the oxidation process in the thearubigin formation. In this part of research, we were able to identify a further oxygenation process taking place but here by nucleophilic addition of $H_2O_2$ as the second suggested mechanism in the oxidation process for the formation of new peroxide intermediate (**15**) or epoxide structures (**16**) by nucleophilic attack of the enolate moiety in peroxo intermediate (**15**). The new suggested mechanism is shown in Figure 10.

**Alternative Graphical Representation in Modified Kendrick Plot of Homologous Series.** In our study new thearubigin components were clearly characterized by employing tandem LC-$MS^n$ experiments. The data generated in the homologous series of theanaphthoquinone and theasinensin C were consistent with the hypothesis previously formulated, in which polyhydroxylated dimers of catechins are formed by nucleophilic addition of water to the quinone oxidized counterparts of catechins. On the other hand, new compounds containing oxygen insertions in the series of theasinensin A were identified, where the latter were rationalized according to the nucleophilic addition of hydrogen peroxide, thus forming thearubigin components of a different structural class. Data on the homologous series of theasinensin A were inconclusive, with MS data not allowing tentative structure suggestions. In summary, this study has complemented previous knowledge on thearubigin chemistry and added evidence for the presence of homologous series of formal oxygen insertion for the two previously not studied dimers of catechins, theasinensins and theanaphthaquinone. Most TR components identified so far must be considered as belonging to the class of flavonoids originating from flavonoid precursors all possessing at least one characteristic C6−C3−C6 moisty.

In previous work we have used conventional Kendrick diagrams using Kendrick masses plotted against Kendrick mass deficits as visual display tools.[9,16] However, this type of representation seems inadequate for black tea chemistry or in general any other processed food. Therefore, we introduce at this stage a modified graphical representation of homologous series reminiscent of a mass deficit diagram in Figure 11. In the

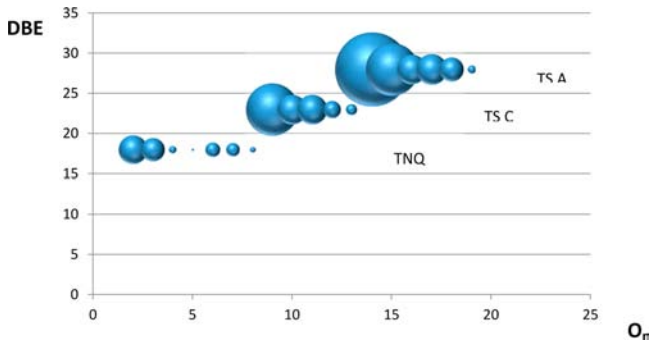

**Figure 11.** Modified Kendrick diagram with numbers of oxygens $O_n$ plotted against double-bond equivalents (DBE) displaying homologous series of theanaphthoquinone (TNQ) and theasinensins A and C (TS A and TS C) with bubble size corresponding to absolute intensities from direct infusion mass spectral data in the negative ion mode (see ref 16).

case of TR components homologous series differ in number of oxygen atoms, which are plotted on the *x*-axis. On the *y*-axis a compound class-specific parameter needs to be chosen. We suggest using double-bond equivalents (DBEs) as such a parameter. In certain cases, for example, if comparing TFs with TSs, the number of DBE (18 in this case) is identical, so for such situations we suggest using as a compound class-specific parameter, the number of carbon atoms $C_n$ divided by DBEs. As an additional third parameter in Figure 11 the intensity of the mass spectral peak corresponding to the member of the homologous series is shown in a bubble plot with intensity corresponding to the diameter of the bubble.

Such a modified Kendrick diagram with numbers of oxygens $O_n$ plotted against DBE displaying homologous series of theanaphthoquinone (TNQ) and theasinensins A and C (TS A

antibodies were obtained from Novus (Littleton, CO). Anti-ERK, anti-pERK, anti-acetyl-CoA carboxylase (ACC), and C/EBP$\beta$ were purchased from Cell Signaling (Danvers, MA). Anti-perilipin A and anti-PPAR$\gamma$ were obtained from Chemicon International (Billerica, MA) and Cayman (Ann Arbor, MI), respectively. Goat anti-rabbit peroxidase-conjugated antibody was purchased from Jackson ImmunoResearch (West Grove, PA).

**Cell Culture.** 3T3-L1 preadipocytes (BCRC 60159) purchased from Bioresource Collection and Research Center (BCRC) of Food Industry Research and Development Institute (Hsinchu, Taiwan) were cultured in DMEM supplemented with 10% CBS at 37 °C in a humidified atmosphere containing 5% $CO_2$. At 2 days after confluence, cells were cultured in FBS-containing DMEM (10%, v/v) with the addition of insulin (0.862 $\mu$M), DEX (1 $\mu$M), and IBMX (0.5 mM) to induce differentiation (day 0). On day 2, the medium was substituted by DMEM with 10% FBS and insulin (0.862 $\mu$M) for another 2 days. On day 4, the medium was changed to DMEM with 10% FBS only, and the same medium was provided again on day 6. 2,4,5-TMBA dissolved in DMSO was added in the medium (final concentration of 0.5 mM) at specific time periods. Control samples were prepared by the addition of isovolumetric dimethyl sulfoxide (DMSO) to the medium.

**Oil Red O Staining of Adipocytes and Quantification of Triglyceride Accumulation.** The formation of lipid droplets in adipocytes was observed by Oil Red O staining. Cells were washed twice with phosphate-buffered saline (PBS) before the addition of 10% formaldehyde at room temperature. After 10 min, formaldehyde was removed. Cells were then fixed with fresh 10% formaldehyde for 1 h, followed by the washes with water twice and with 60% isopropanol for 5 min. The cells were completely dry at room temperature before they were stained with Oil Red O (three parts of 0.35% Oil Red O dye in isopropanol and two parts of water) for 15 min at room temperature with shaking and then washed 4 times with water before photographed under a microscope. For the measurement of lipid accumulated in adipocytes, the isopropanol-washed and completely dried cells were shaken with 100% isopropanol for 10 min. The dissolved lipid was quantified by measuring the absorbance at 500 nm. The results were expressed as the lipid accumulation relative to that of the control group.

**Measurement of PPAR$\gamma$ Activation.** Activation of PPAR$\gamma$ in cells harvested at the second and eighth days of adipogenesis was measured by an enzyme-linked immunosorbent assay (ELISA) kit (Signosis, Sunnyvale, CA). Briefly, the nuclear extracts prepared from culture cells by an extraction kit (Signosis, Sunnyvale, CA) were added to the 96-well plate, which was pre-immobilized with PPAR$\gamma$ consensus sequencing oligo. The activated PPAR$\gamma$ was detected with the specific antibody against the PPAR$\gamma$ subunit and a horseradish peroxidase (HRP)-conjugated secondary antibody. The colorimetric detection was measured by a spectrophotometer at 450 nm.

**Western Blotting.** Cells were washed with cold phosphate-buffered saline (PBS) twice, harvested, and centrifuged at 936$g$ for 5 min. The pellets were resuspended in lysis buffer containing 150 mM sodium chloride, 1% Nonidet P 40, and 50 mM Tris-HCl at pH 7.5. The cell suspension was centrifuged at 16805$g$ at 4 °C for 30 min. After centrifugation, the supernatant was collected for analysis and its protein content was determined by a DC Protein Assay Kit (Bio-Rad, Hercules, CA). Equal amounts of proteins from each sample were denatured and separated by gel electrophoresis before being transferred to polyvinylidene fluoride (PVDF) membranes (PerkinElmer, Waltham, MA). The membranes were blocked with 5% nonfat dry milk in Tris-buffered saline containing Tween (TBST) (137 mM NaCl, 0.1% Tween-20, and 20 mM Tris-HCl at pH 8.3) for 1 h before sequentially incubated with primary antibody overnight in a cold room and HRP-conjugated secondary antibody for 1 h at room temperature. Immunoreactive proteins were detected using an enhanced chemiluminescence kit (ECL, PerkinElmer, Waltham, MA), and the film was analyzed using ImageQuant software (Molecular Dynamics, Sunnyvale, CA) to obtain densitometric values. For stripping and reprobing, the membrane was incubated with stripping buffer [0.2 M glycine, 3.5 mM sodium dodecyl sulfate (SDS), and 0.1% Tween-20 at pH 2.2] at room temperature for 10 min. After the buffer was discarded, the membrane was incubated with fresh stripping buffer for another 10 min, followed by two 10 min washes by PBS buffer and two 5 min washes by TBST buffer. After striping, the blocking and probing were performed as mentioned above. The relative expression of each protein was calculated as the "densitometric value of protein/densitometric value of $\beta$-actin collocated". The ratio of phosphorylated proteins to total proteins was calculated by the comparison of relative expression.

**Statistical Analysis.** Statistical analysis was carried out using Statistical Analysis System (SAS Institute, Cary, NC). Analysis of variance (ANOVA) and Student−Newmann−Keuls multiple range test were performed to evaluate the differences among groups ($\alpha$ = 0.05).

## RESULTS

**Effect of the Incubation Period of 2,4,5-TMBA on Adipogenesis.** To figure out the time period critically affected by 2,4,5-TMBA during adipogenesis, preadipocytes were cultured with 2,4,5-TMBA specifically at post-induction days 0−2, 2−4, 4−6, or 6−8 only (Figure 1A). At day 8, photos were taken for each group under a microscope and the relative accumulation of lipids was estimated. As shown in panels B and C of Figure 1, preadiopcytes were poorly differentiated without the presence of adipogenic factors ("−IDI") but well-differentiated with the presence of adiogenic factors ("+IDI"). When preadipocytes were treated with 2,4,5-TMBA at different time periods in the presence of adipogenic factors, relative lipid accumulation was decreased by 67.93, 34.65, 49.56, and 34.32% for days 0−2, 2−4, 4−6, and 6−8 groups, respectively (Figure 1D). The most significant inhibitory effect was observed when 2,4,5-TMBA was present in the medium at days 0−2. Withdrawal of 2,4,5-TMBA from the medium did not restore adipogenesis.

**Effect of 2,4,5-TMBA on the Expression of MEK and ERK during Adipogenesis.** Different from the study design for Figure 1 (Figure 1A), the study design for Figures 2−4 (Figure 2A) was to investigate the expression of signaling molecules and transcription factors at different stages when 2,4,5-TMBA was co-cultured with preadipocytes during the differentiation process. The cells were harvested at post-induction days 2, 4, 6, and 8 (Figure 2A).

Phosphorylation of the MEK/ERK signaling pathway is crucial for the differentiation of preadipocytes. To study how MEK/ERK is affected during adipogenesis, preadipocytes cultured with 2,4,5-TMBA were harvested at post-induction days 2, 4, 6, and 8 (Figure 2A). 2,4,5-TMBA decreased the level of phosphorylated MEK at the early stage but increased the level at the late stage (Figure 2B). ERK1 but not ERK2 is specifically required for the differentiation of 3T3-L1. During adipogenesis, ERK1 has to be turned on by phosphorylation at the initial stage but shut off later on.[7] Because activation of MEK leads to the phosphorylation of ERK1, the effect of 2,4,5-TMBA on ERK1 phosphorylation was in accordance with the result of MEK phosphorylaiton; the expression of phosphorylated ERK1 was suppressed initially but enhanced at the terminal period (Figure 2C), which is opposite to the conditions required for adipogenesis.

**Effect of 2,4,5-TMBA on the Expression of C/EBP$\alpha$, $\beta$, and $\delta$ and PPAR$\gamma$ during Adipogenesis.** Activation of ERK is followed by the expression of C/EBP$\beta$ and C/EBP$\delta$, which further induces the expression of PPAR$\gamma$ and C/EBP$\alpha$.[5,6] As the study design shown in Figure 2A, the expression of C/EBP$\alpha$, $\beta$, and $\delta$ and PPAR$\gamma$ was determined when 2,4,5-TMBA-

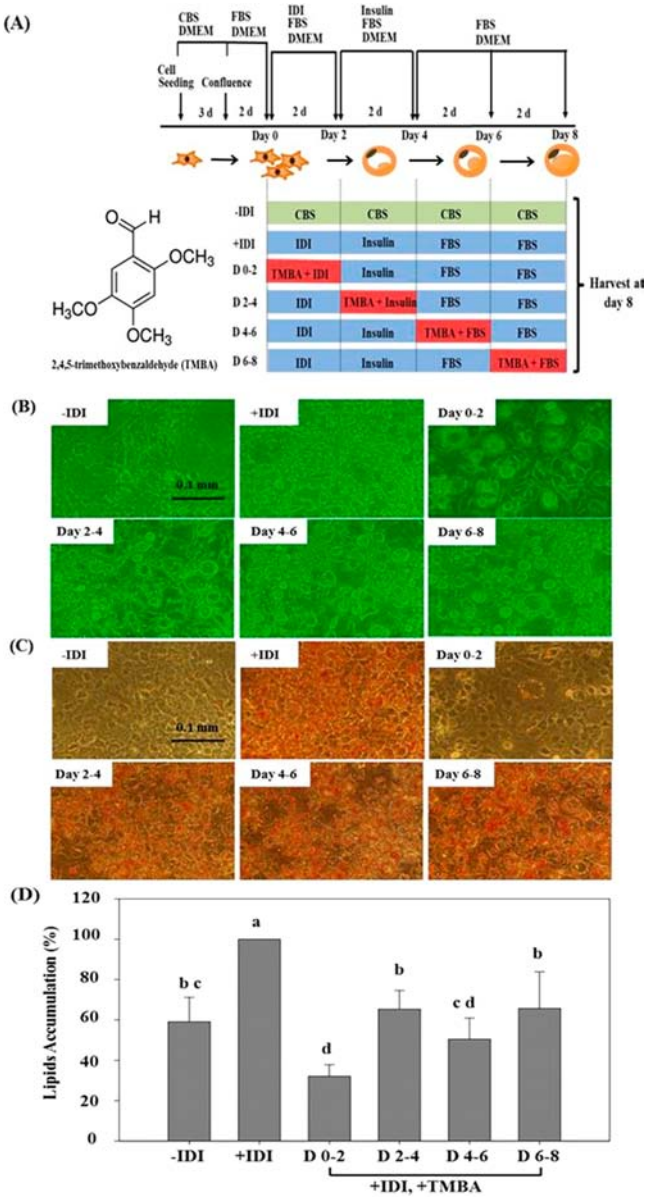

**Figure 1.** Effect of the incubation period of 2,4,5-TMBA on adipogenesis. (A) Study design. "−IDI" refers to the absence of adipogenic factors (insulin, dexamethasone, and isobutylmethylxanthine) in DMEM. "+IDI" refers to the presence of adipogenic factors in culture medium. "D 0−2" to "D 6−8" groups refer to the specific post-induction period for the addition of 2,4,5-TMBA (0.5 mM) to medium containing adiopgenic factors. CBS, calf bovine serum; FBS, fetal bovine serum. (B) Photos taken under a microscope at day 8 (200×). (C) Photos taken under a microscope after Oil Red O staining at day 8 (200×). (D) Relative lipid accumulation at day 8. Values are means of three replicated cultures. Groups with the same letter are not significantly different ($\alpha$ = 0.05).

treated preadipocytes were harvested at post-induction days 2, 4, 6, and 8. When preadipocytes were cultured without the presence of 2,4,5-TMBA, the levels of C/EBP$\beta$ and C/EBP$\delta$ gradually increased throughout the intermediate to terminal differentiation periods. However, the treatment of 2,4,5-TMBA downregulated the overall expression of both proteins (panels A and B of Figure 3).

PPAR$\gamma$2 but not PPAR$\gamma$1 is required for the activation of adipogenesis.[12] Phosphorylation of PPAR$\gamma$2 by ERK at the late stage of adipogenesis decreases the transcription activity of PPAR$\gamma$2 and suppresses differentiation of preadipocytes.[13,14] Without the treatment of 2,4,5-TMBA, the ratio of PPAR$\gamma$2 being phosphorylated was lower at the late stage than that at the early stage; however, culture with 2,4,5-TMBA increased the level of phosphorylated PPAR$\gamma$2 at the late stage (Figure 3C), which decreased the transcription activity of PPAR$\gamma$2, as shown in Figure 3D. The pattern of C/EBP$\alpha$ expression was similar to that of C/EBP$\beta$ and C/EBP$\delta$. The level of C/EBP$\alpha$ gradually increased during adipogenesis, but the expression was suppressed in the presence of 2,4,5-TMBA (Figure 3E).

**Effect of 2,4,5-TMBA on the Expression of ACC, FAS, and Perilipin A.** ACC is the rate-limiting enzyme in fatty acid *de novo* synthesis, providing malonyl-CoA substrate for the biosynthesis of fatty acids.[15] FAS is a multifunctional protein with the function of catalyzing the synthesis of long-chain saturated fatty acids from acetyl-CoA and malonyl-CoA.[16] As the study design shown in Figure 2A, the expression of ACC, FAS, and perilipin A was determined when 2,4,5-TMBA-treated preadipocytes were harvested at post-induction days 2, 4, 6, and 8, respectively. Without the presence of 2,4,5-TMBA, expression of ACC and FAS in preadipocytes was elevated along the process of adipogenesis. However, when preadipocytes were cultured with 2,4,5-TMBA, expression of ACC and FAS was suppressed at the terminal stage of adipogenesis, an important stage for lipid accumulation (panels A and B of Figure 4).

At the late stage of lipid droplet formation and maturation, perilipin replaces the other droplet-coating proteins and becomes the only coating protein to reside on the large lipid droplets. Perilipin A is the predominant isoform of perilipin proteins found in mature adipocytes.[17,18] Without the treatment of 2,4,5-TMBA, expression of perilipin A gradually increased during adipogenesis, reaching the maximum when the cells were fully differentiated (Figure 4C). Although a similar pattern was observed in 2,4,5-TMBA-treated cells, the overall expression of perilipin A was attenuated.

## DISCUSSION

Previously, we showed that 2,4,5-TMBA suppresses the differentiation of preadipocytes.[11] In this study, preadipocytes were co-cultured with 2,4,5-TMBA specifically at post-induction days 0−2, 2−4, 4−6, or 6−8 only to further figure out the stages that are critically affected by 2,4,5-TMBA during adipogenesis. Moreover, preadipocytes were co-cultured with 2,4,5-TMBA during the differentiation process and harvested at days 2, 4, 6, and 8 to study the expression of signaling molecules and transcription factors at different stages of adipogenesis (Figure 5).

Although several signal transduction pathways are involved in adipogenesis, transient activation of the MEK/MAPKs signaling pathway is required for the differentiation of preadipocytes.[19] Activation of MEK by adipogenic stimuli leads to the phosphorylation of MAPKs: ERK, c-Jun amino-terminal kinase (JNK), and p38 MAPK. ERK1 and ERK2 isoforms have distinct biological functions. ERK1 has been clearly linked to the regulation of preadipocyte differentiation and adiposity. Using *ERK1*$^{-/-}$ mice, Bost et al. demonstrated that *ERK1*$^{-/-}$ mice have fewer adipocytes and decreased adiposity than those of wild-type animals. In addition, *ERK1*$^{-/-}$ mice challenged with a high-fat diet are protected from obesity and insulin resistance.[20] Bost et al. also showed that preadiocytes isolated from *ERK1*$^{-/-}$ mice exhibit impaired differentiation.[7]

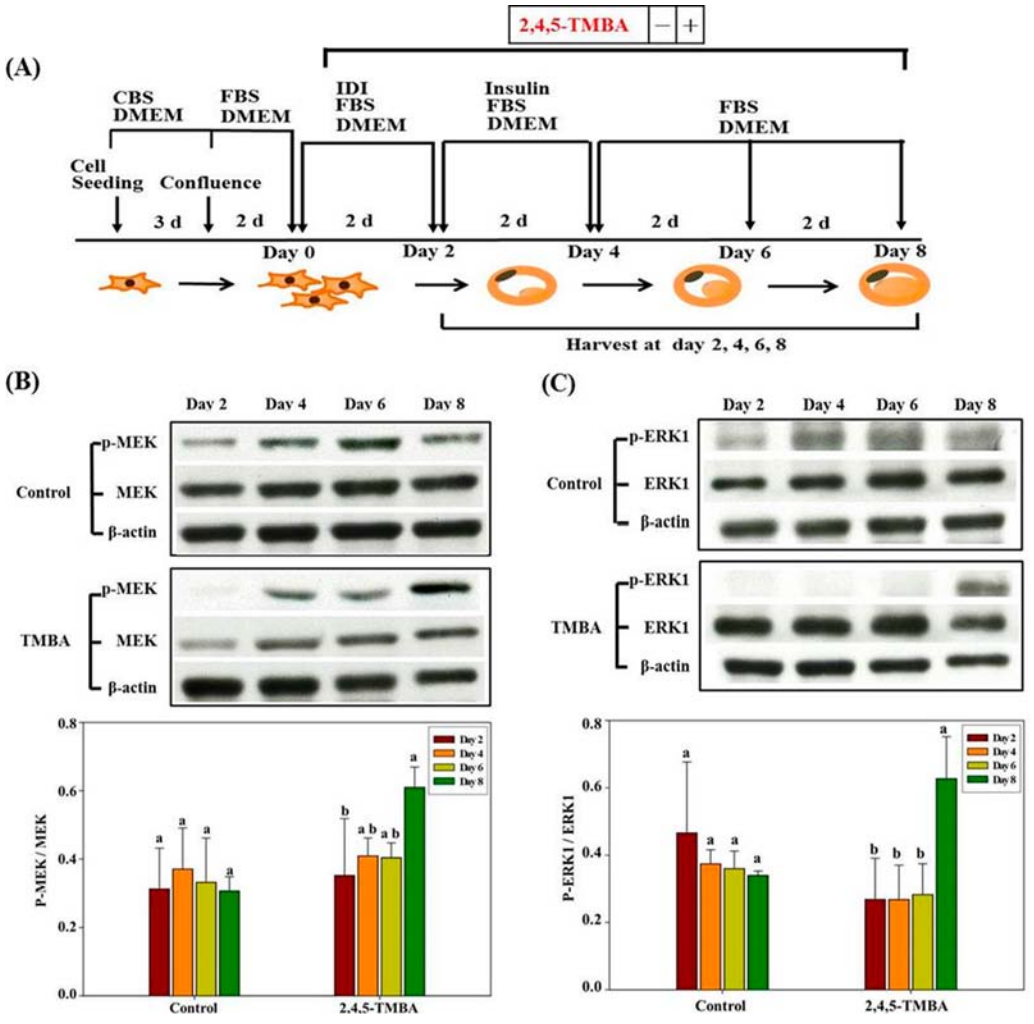

**Figure 2.** Effects of 2,4,5-TMBA on the expression of MEK and ERK during adipogenesis. (A) Study design. 2,4,5-TMBA (0.5 mM) was supplemented to culture medium during the adipogenic process. The cells were harvested at days 2, 4, 6, and 8. (B) Protein expression of phosphorylated MEK (pMEK) and MEK. (C) Protein expression of phosphorylated ERK (pERK) and ERK. Relative expression of proteins was calculated according to the reference band of $\beta$-actin. The ratio of phosphorylated proteins to total proteins was calculated by the comparison of relative expression. Values are means of three replicated cultures. Groups with the same letter are not significantly different ($\alpha = 0.05$). MEK, MAP kinase kinase; ERK, extracellular signal-regulated kinase.

Phosphorylation at specific threonine and tyrosine residues by MEK leads to the activation of ERK1, and the activation needs to be timely regulated during adipogenesis.[7,21] ERK1 has to be turned on at the early stage for a proliferative process but to be shut off later on to prevent the phosphorylation of PPAR$\gamma$.[7,20] PPAR$\gamma$ is a substrate of ERK, and its phosphorylation by ERK decreases its transcription activity.[14,22] Prusty et al. observed a rapid induction of ERK1 phosphorylation following the exposure of preadipocyte to adipogenic stimuli, but the level of phosphorylation gradually declines during adipogenesis.[23] Lii et al. showed that diallyl trisulfide, the second most abundant organosulfide in garlic oil, suppresses the differentiation of 3T3-L1 preadipocytes through prolonging ERK phosphorylation along adipogenesis.[24] Turpin et al. reported carbamazepine, a dibenzazepine, strongly inhibited adipogenesis through activation of the ERK pathway.[25] Moreover, both evodiamine (a major alkaloidal compound extracted from the fruit of *Evodia fructus*) and EGCG [(−)-epigallocatechin gallate] suppress preadipocyte differentiation through the ERK pathway.[26,27] In this current study, treatment of 2,4,5-TMBA attenuated ERK phosphorylation at the early stage but elevated the phosphorylation during terminal differentiation, which is opposite to the conditions required for adipogenesis.

The cytotoxic effect of 2,4,5-TMBA was estimated in our previous study.[11] When preadiopcytes were co-cultured with 0.5 mM 2,4,5-TMBA during differentiation, the cell viability was decreased by 25.82% at the end of the 8 day differentiation period. On the basis of the results, the inhibition on adipogenesis observed in this study mostly resulted from the action of 2,4,5-TMBA instead of cytotoxicity. When the rats were orally administered with 100 mg/kg 2,4,5-TMBA, the serum concentration of 2,4,5-TMBA reached 5.44, 8.39, 9.09, and 5.64 $\mu$g/mL at 30, 60, 120, and 240 min, respectively (data not shown). Because rats did not show toxicity when gavaged with 2,4,5-TMBA at a dose of 2000 mg/kg,[28] a serum concentration close to 0.5 mM (100 $\mu$g/mL) might be reached *in vivo* by administering a higher dose of 2,4,5-TMBA.

Activation of MEK/MAPKs in preadipocyte is rapidly followed by the expression of C/EBP$\beta$ and C/EBP$\delta$, which further induces the expression of PPAR$\gamma$ and C/EBP$\alpha$, the two transcription factors that oversee the terminal differentiation

dx.doi.org/10.1021/jf503344v | J. Agric. Food Chem. 2014, 62, 9860−9867

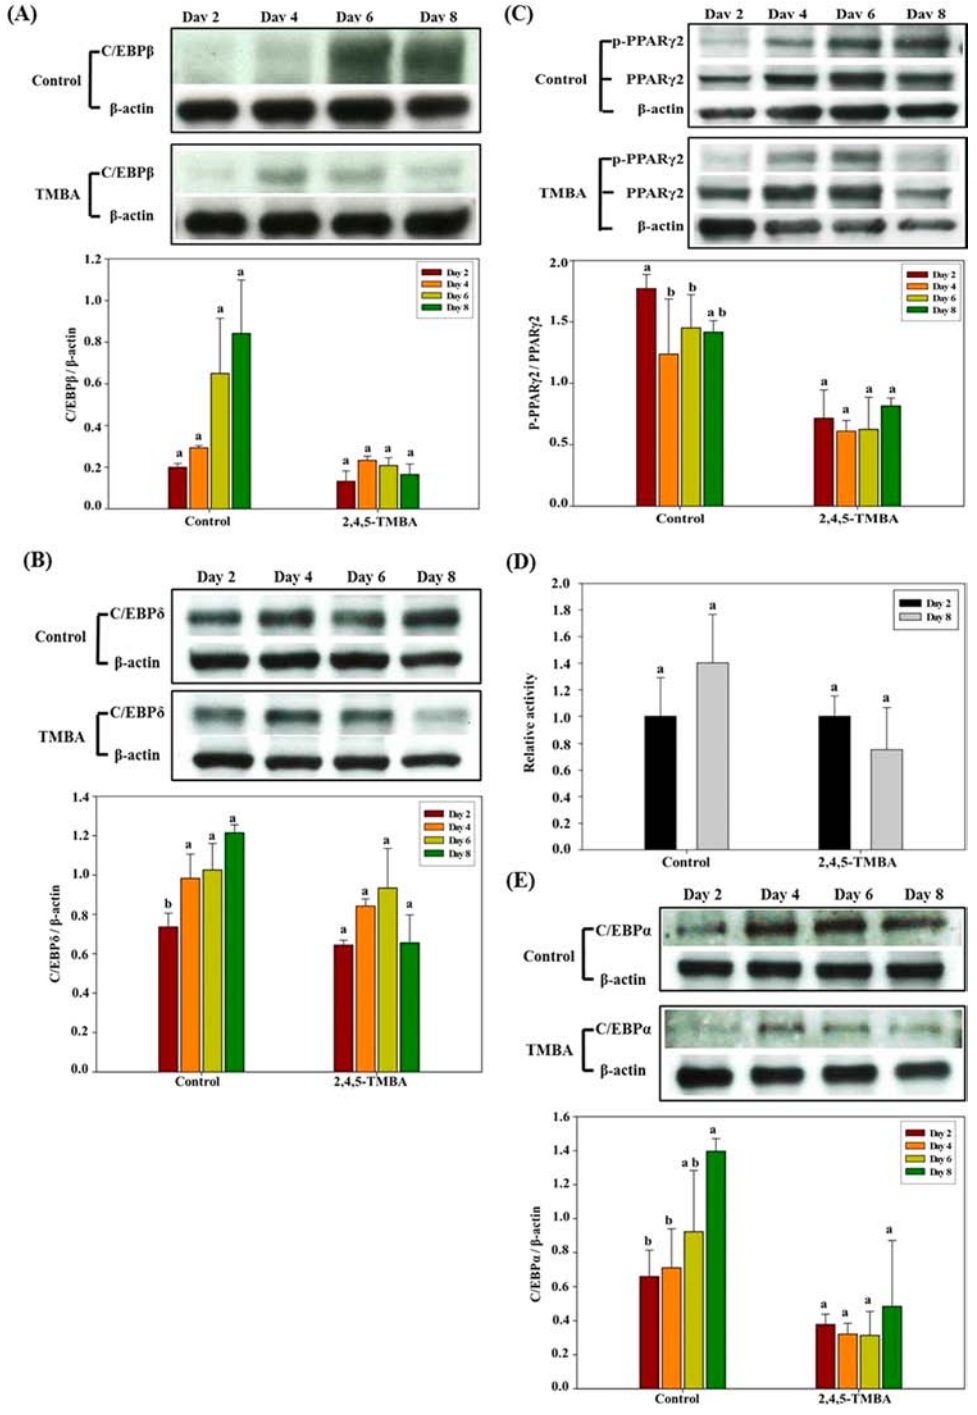

**Figure 3.** Effects of 2,4,5-TMBA on the expression of transcription factors. The cells were cultured with 2,4,5-TMBA (0.5 mM) and harvested at days 2, 4, 6, and 8. Expression of (A) C/EBP$\beta$, (B) C/EBP$\delta$, (C) PPAR$\gamma$2, and (E) C/EBP$\alpha$. (D) Result of PPAR$\gamma$ activation. Relative expression of proteins was calculated according to the reference band of $\beta$-actin. process.[29] C/EBP$\beta$ and C/EBP$\delta$ play a synergistic role in preadipocyte differentiation. Embryonic fibroblasts derived from mice lacking either C/EBP$\beta$ or C/EBP$\delta$ do not differentiate into mature adipocytes.[30] PPAR$\gamma$ is the master regulator of adipogenesis.[31] Activated PPAR$\gamma$ enhances the expression of C/EBP$\alpha$, and then both factors synergistically induce the genes responsible for the maturation of adipocytes. PPAR$\gamma$ can promote adipogenesis in C/EBP$\alpha$-deficient cells, but C/EBP$\alpha$ has no ability to promote adipogenesis in the absence of PPAR$\gamma$.[32] PPAR$\gamma$2 but not PPAR$\gamma$1 is required for the activation of adipogenesis.[12] *PPAR$\gamma$2*$^{-/-}$ mouse embryonic fibroblasts showed a dramatically reduced capacity for adipogenesis compared to wild-type mouse embryonic fibroblasts.[33] Phosphorylation of PPAR$\gamma$2 by ERK decreases its transcription activity.[14] In this study, co-culture with 2,4,5-TMBA down-regulated the overall expression of C/EBPs and PPAR$\gamma$2 but elevated the ratio of PPAR$\gamma$2 being phosphorylated at the terminal stage (panels A–C and E of Figure 3), which results in

dx.doi.org/10.1021/jf503344v | J. Agric. Food Chem. 2014, 62, 9860–9867

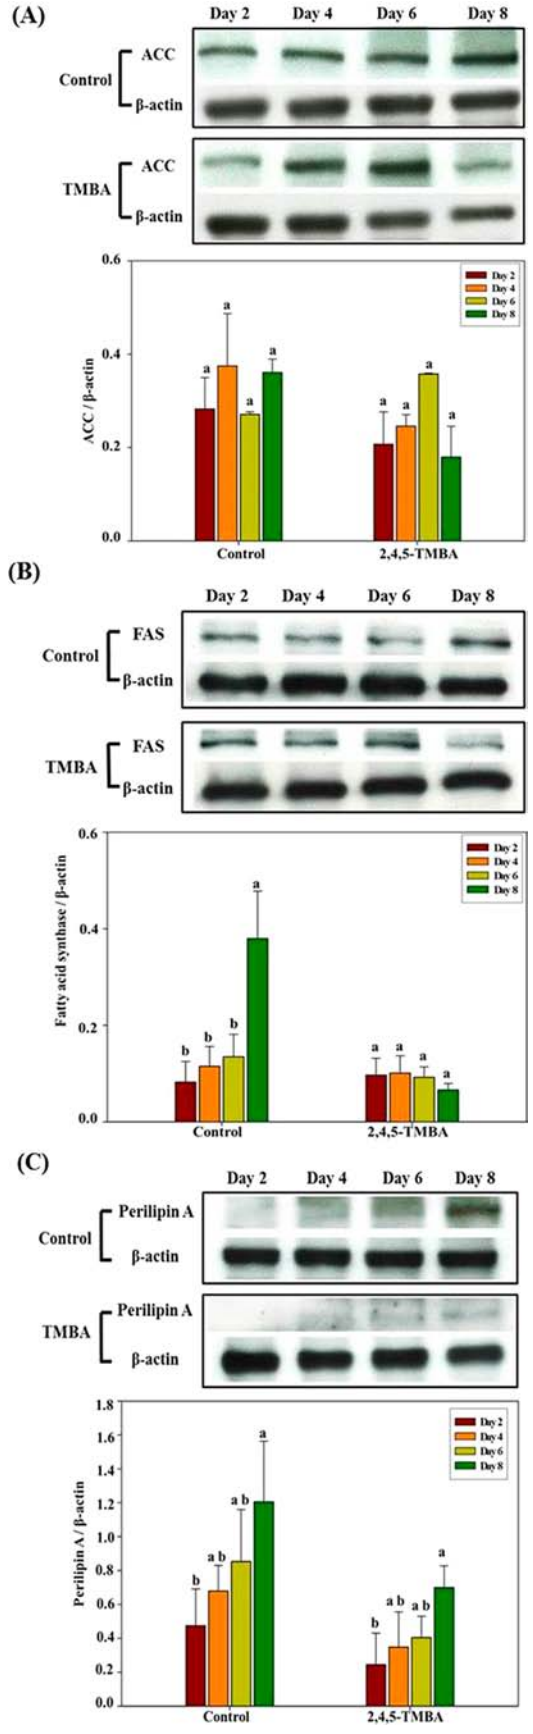

**Figure 4.** Effects of 2,4,5-TMBA on the expression of lipogenic enzymes and lipid droplet-coating protein. The cells were cultured with 2,4,5-TMBA (0.5 mM) and harvested at days 2, 4, 6, and 8. Expression of (A) ACC, (B) FAS, and (C) perilipin A. Relative expression of proteins was calculated according to the reference band of $\beta$-actin. Values are means of three replicated cultures. a decreased transcription activity of PPAR$\gamma$2 (Figure 3D), leading to the attenuation of adipogenesis. This increased phosphorylation of PPAR$\gamma$2 resulted from enhanced ERK1 phosphorylation by 2,4,5-TMBA at the terminal stage.

The increase in size of adipocytes arises in part from progressive lipid accumulation during adipogenesis. Both ACC and FAS play crucial roles in *de novo* lipogenesis in mammals.[15,16] The study by Wu et al. showed that husk extract, punicalagin, and ellagic acid exhibit FAS inhibitory activity. When 3T3-L1 adiocytes were incubated with these extracts and compounds, adipogenesis was inhibited.[34] Lower levels of ACC and FAS were also observed in carbamazepine-treated preadipocytes, which showed impaired lipid accumulation.[25] Loftus et al. have demonstrated that animals with lowered ACC and FAS activities showed significantly reduced adiposity.[35] In a previous study, we showed that incubation with 2,4,5-TMBA decreased the amount of lipid accumulated in adipocytes.[11] Results of this current study show that the inhibitory effect of 2,4,5-TMBA on the expression of ACC and FAS is mainly observed at the late period of adipogenesis, an important stage for lipid accumulation.

One characteristic of mature adipocytes is the formation and enlargement of intracellular lipid droplets. The proteins that coat lipid droplets change during droplet biogenesis and play critical roles in the maintenance of the lipid droplet structure and regulation of lipid metabolism. At the late stage of lipid droplet formation and maturation, perilipins become the only coating protein and perilipin A is the predominant isoform found in mature adipocytes.[18] In obese subjects, expression of perilipin A in adipose tissue is elevated.[36] However, lipid accumulation in adipocytes is significantly decreased in *perilipin* null mice.[37] In this study, we observed an inhibition on the expression of perilipin A when preadipocytes were cultured with 2,4,5-TMBA. Suppression of perilipin A could impair the formation of lipid droplets and maturation, leading to a decreased lipid accumulation as observed in 2,4,5-TMBA-treated cells.

Taken together, our results showed that 2,4,5-TMBA may suppress adipogenesis through the regulation of ERK1 phosphorylation. 2,4,5-TMBA inhibited the phosphorylaton of ERK1 at the early stage of the adipogenic process but enhanced it at the late stage, which is opposite the conditions required for adipogenesis. Although all of the effects observed might be coincidental and not yet mechanistically interdependent, the opposite effects of 2,4,5-TMBA on ERK at the early and late stages of the 8 day adipogenic process may be mediated by the modulation of scaffolding protein AEBP-1 and phosphatases MKP-1 and MKP-3. AEBP-1 protects the ERK from specific phosphatase and is downregulated at the late stage of adipogenesis. Conversely, expression of MKP-1 and MKP-3 is upregulated in mature adipocytes.[38−40] Prospectively, the interaction of 2,4,5-TMBA with AEBP-1, MKP-1, and MPL-3 will be worth studying. Moreover, application of microarray technology to monitor global changes in gene expression

dx.doi.org/10.1021/jf503344v | J. Agric. Food Chem. 2014, 62, 9860−9867

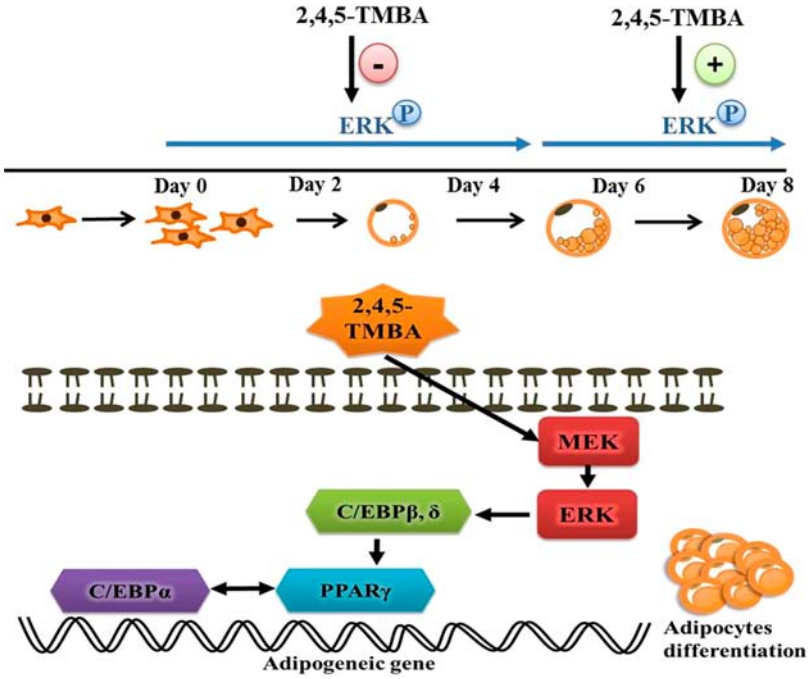

**Figure 5.** Proposed mechanism for the suppression of adipogenesis by 2,4,5-TMBA.

profiles during 3T3-L1 differentiation will help to elucidate the mode of regulation by 2,4,5-TMBA.

Obesity results from the hypertropy of adipocytes and the recruitment of new adipocytes from preadipocytes. Both processes are significantly dependent upon the regulation of adipogenesis. Although results from *in vitro* studies cannot be directly extrapolated into clinical effects, our study will help to elucidate the anti-adipogenic potential of 2,4,5-TMBA.

reduced browning tendency of treated wines after a maderization test, which they assumed to be due to the removal of up to 30% procyanidins and cinnamates.

More recently, a winemaking process with a modified chitosan-based biofilm was patented,[30] claimed to protect wine from oxidation thanks to the presence of phenolic compounds grafted onto the chitosan film, with this latter inserted in the bottle just before bottling.

However, taking into consideration all of the reported activities for unmodified chitosan, in particular those linked to the antiradical and antioxidant properties, it would be interesting to test the effect of this polysaccharide on phenol oxidative kinetics in wine-like conditions, in view to hypothesize its use in musts and wines with reduced levels of sulfur dioxide and at different vinification stages.

The aim of this work was, hence, to compare the efficacy of chitosan and sulfur dioxide in controlling the browning of air-saturated white wine model solutions containing (+)-catechin, metal ions, and tartaric acid. The color of the solutions and the generation of brownish xanthylium cations and intermediate phenolic species were monitored by means of high-performance liquid chromatography with diode array detection and mass spectrometry (HPLC−DAD/MS). In addition, the protecting capacity of the two additives toward the chemical oxidation of three varietal thiols was further evaluated by gas chromatography/mass spectrometry (GC/MS).

## MATERIALS AND METHODS

**Chemicals.** HPLC-grade acetonitrile and acetic acid were obtained from Merck (Darmstadt, Germany). Water was of Milli-Q quality. (+)-Catechin, (+)-tartaric acid, $Fe^{II}$ sulfate heptahydrate, $Cu^{II}$ sulfate pentahydrate, potassium metabisulfite, low-molecular-weight 75−85% deacylated chitosan (product 448869), 5,5′-dithiobis(2-nitrobenzoic acid), and 3-mercapto-3-methylbutan-1-ol (3MMB) were obtained from Sigma-Aldrich (Milan, Italy). 3-Mercaptohexan-1-ol (3MH) and 3-mercaptohexyl acetate (3MHA) were purchased from Interchim (Montluçon, France). 4-Methoxy-2-methylbutane-2-thiol (4MMB) was provided by Oxford Chemical (Hartlepool, U.K.). High-purity nitric acid (Suprapur, Merck, Germany) was used for the inductively coupled plasma−optical emission spectroscopy (ICP−OES) analysis.

**Model Wine Solutions.** A total of 4 L of a solution containing 5 g/L (+)-tartaric acid and 12% (v/v) ethanol was prepared. The pH was adjusted to 3.6 with 2 M NaOH before bringing to the mark progressively by adding water.

The solution was stirred at room temperature in open air until saturated with $O_2$ (1 h),[31] before (+)-catechin addition at 100 mg/L. To this solution, 5 nM/L 3MH, 3MHA, and 3MMB were further added (from bulk standard solutions, according to Ellmann's method[32]).

Trials were arranged by transferring aliquots (80 mL) of the above-cited solution in 125 mL inert glass bottles (Supelco, Bellefonte, PA), leaving air in the headspace with the aim to accelerate the oxidation phenomena. A total of 80 μL of an aqueous solution containing $Fe^{II}$ sulfate heptahydrate (5 g/L) and $Cu^{II}$ sulfate pentahydrate (300 mg/L) was added to each bottle to give a final concentration of 5 mg/L Fe and 0.30 mg/L Cu. When appropriate, 80 mg/L sulfur dioxide (as potassium metabisulfite) and 1 g/L chitosan were separately added, to constitute the following solutions: MS (model solution), $SO_2$ (model solution + sulfur dioxide), and Kt (model solution + chitosan). The bottles, closed with a silicone septum (Supelco, Bellefonte, PA) and crimped with airtight aluminum caps (Supelco, Bellefonte, PA), were stored at room temperature (22 °C), in the dark.

Because of chitosan insolubility, once closed, Kt samples were mechanically shook (Roller 6, IKA, Germany) for 5 min to permit a homogeneous distribution of the polisaccharides. A total of 5 min of shaking was also performed, on Kt samples, each 2 days all along the experiment.

With the aim to deepen both the adsorption efficacy of chitosan on oxidized phenols and the chelating capacity on metals, at day 21, a portion of each MS solution was transferred to a 25 mL inert glass bottle, added with 1g/L chitosan, ermetically closed with aluminum caps and mechanically shook for 30 h (samples Kt 30 h). These solutions were analyzed for their browning level and phenolic and metal content using the methods outlined below.

**Browning and $SO_2$ Measurement.** The experimentation lasted 21 days, during which three bottles, prepared identically for each trial (MS, $SO_2$, and Kt), were taken at time points 0, 3, 7, 14, and 21 days, for the analytical determinations to be carried out in triplicate. The browning development of the samples was followed measuring the increase in absorbance at 440 nm (1 cm optical path) using a Jasco 810 spectrophotometer (Tokyo, Japan), after filtration (0.45 μm, cellulose filters). Total $SO_2$ concentrations were determined in accordance with the official International Organization of Vine and Wine (OIV) method.[33]

**Reversed-Phase (RP)-HPLC/Electrospray Ionization (ESI)−MS Analysis of (+)-Catechin and Other Phenols Generated during Its Oxidation.** HPLC separation and identification of (+)-catechin and phenolic compounds generated during its oxidation were performed on a Agilent LC-MSD 1100 series single quadrupole (Agilent Technologies, Palo Alto, CA), equipped with an autosampler and a diode array UV−vis detector, according to a previous method.[31] The column was a Poroshell 120 SB C18, 2.7 μm, 150 × 4.6 mm inner diameter, operating at 30 °C with a flow of 0.9 mL/min. Elution solvents were 2% acetic acid in HPLC-grade water (eluent A) and 2% acetic acid in HPLC-grade acetonitrile (eluent B). Gradient elution was as follow: from 98 to 95% A in 9 min, from 95 to 90% A in 6 min, from 90 to 82% A in 4 min, from 82 to 80% A in 3 min, from 80 to 70% A in 3 min, from 70 to 50% A in 3 min, from 50 to 0% A in 2 min, and from 0 to 98% A in 3 min. A post-run time of 5 min was further applied. Mass detection was carried out using an ESI interface operating in positive mode, scanning from $m/z$ 100 to 1000 and using the following conditions: drying gas flow, 9.0 L/min; nebulizer pressure, 50 psi; gas drying temperature, 350 °C; capillary voltage, 4000 V; and fragmentor voltage, 15 V. Identification of (+)-catechin was accomplished by comparison of the UV spectrum and retention time of the standard compound. Phenolic compounds generated by (+)-catechin oxidative decay, which lacked of available standards, were identified on the basis of the UV and MS spectrum already reported in other studies.[31,34] Quantification of residual (+)-catechin in the samples was performed at 280 nm using an external calibration curve built by injecting solutions of known concentrations. Other phenols were monitored according to their maximum absorption wavelength (280 nm for carboxymethine-linked dimers and xantene and 440 nm for xanthylium ions and their esters) and quantified in a semi-quantitative fashion as peak area. Before injection, synthetic wines were filtered at 0.45 μm with a cellulose filter. All analysis were performed in duplicate.

**Extraction of Volatile Thiols.** Thiols were quantified after solid-phase extraction (SPE) separation as proposed by Fedrizzi et al.,[35] with little modifications. A 50 mL sample volume containing 0.1 mL of internal standard (4MMB at 50 μM/L in 50% hydroalcoholic solution) was percolated through an Isolute ENV+ cartridges (1 g/6 mL) (IST, Ltd., Mid Glamorgan, U.K.) previously conditioned with methanol (15 mL) and 12% hydroalcolic solution (20 mL) in that order. Analytes were recovered by passing 30 mL of $CH_2Cl_2$. The extract was added with 60 mL of *n*-pentane, dried with $Na_2SO_4$, and distilled to about 100 μL with a small vigreux column.

**GC/MS Analysis of Thiols.** A total of 2 μL of the extract were injected in the splitless mode (splitless time of 1 min) into a Thermo Scientific Trace GC ultra gas chromatograph (Waltham, MA), equipped with a Thermo Scientific Trace DSQ selective mass detector and a fused silica capillary Stabilwax DA column (Restek, Bellefonte, PA) (30 m, 0.25 mm inner diameter, and 0.25 μm film thickness), under the following working conditions: GC-grade helium as the carrier gas at a flow rate (constant flow, vacuum compensation) of 1.0 mL/min; column temperature program, 40 °C heated at 1 °C/min to 45 °C, then at 3 °C/min to 100 °C, and finally heated at 5 °C/min to

dx.doi.org/10.1021/jf5025664 | J. Agric. Food Chem. 2014, 62, 9868−9875

240 °C. The injection temperature was 250 °C. Detection was carried out by electron ionization (EI) mode, using an ionization energy of 70 eV. The transfer line was heated at 220 °C, and the ionization source was heated at 250 °C. 3MH, 3MHA, 3MMB, and the internal standard (4MMB) were detected in single ion monitoring (SIM) mode by monitoring the following ions: $m/z$ 134 and 100 for 3MH and 4MMB (internal standard), $m/z$ 120, 86, and 75 for 3MMB, and $m/z$ 116, 101, and 88 for 3MHA. The quantification ions were $m/z$ 134 for both 3MH and the internal standard, $m/z$ 86 for 3MMB, and $m/z$ 116 for 3MHA. The content of each single thiol in the solutions has been expressed as the relative chromatographic area with respect to the area of the internal standard.

**Metal Content.** ICP−OES analysis of Fe and Cu was carried out on a Spectro Archos apparatus (Kleve, Germany) equipped with a 1.8 mm torch and a side on plasma interface (SPI). Radio frequency (RF) power was 1350 W; plasma flow was 12.5 L/min; auxiliary flow was kept at 0.5 L/min; nebulizer flow was 0.8 L/min; and the pump rate was kept at 1.5 mL/min. Total iron and copper were monitored at wavelengths of 324.754 and 238.204 nm, respectively, and plasma view was in radial mode. Because of the relatively simple composition of the samples, the analysis was performed by directly aspirating the filtered solutions (0.22 $\mu$m, cellulose filters), without prior digestion.

Standard calibration curves were prepared from 1000 $\mu$g/mL single-element solutions (Alfa Aesar, Germany) in 1% $HNO_3$ (v/v).

**Statistical Analysis.** One-way analysis of variation (ANOVA) was performed using Statistica 6 (StatSoft Italia srl, Italy) software package. In the case of significant differences, the Tukey honest significant difference (HSD) test at $p < 0.05$ was used to evaluate differences between means of each treatment.

## RESULTS AND DISCUSSION

**Browning of White Wine Model Solutions.** The color development of the solutions all along the entire duration of the trial was spectrophotometrically monitored at 440 nm (Figure 1), that is, at the maximum absorption wavelength of brown pigments generated by the oxidative decay of (+)-catechin.[10] All of the solutions remained virtually colorless for the first 7 days, after which a steady increase in browning was observed for the MS solutions. At our conditions, hence, this could be thought of as the time necessary to generate the xanthylium cations in "not protected" model wines (as was the case of MS samples).

$SO_2$ and Kt samples shared a common evolution in color development until day 14, with a moderate increase in browning [<0.040 absorbance (ABS) units] with respect to days 3 and 7. However, at day 21, $SO_2$ solutions were significantly more oxidized than the Kt solutions. This likely is the consequence of the almost complete consumption of sulfites in the former solutions, which, at the 14th and 21st days, were found to contain 12.8 and <0.6 mg/L of total $SO_2$, respectively (data not shown). For experimental conditions similar to the conditions that we used in this work, the fast browning of model wine solutions once sulfites had been completely oxidized has already been reported.[31]

In the same Figure 1, it is possible to appreciate the changes in absorbance at 280 nm of the model wines. The contribution to this absorbance mainly comes from (+)-catechin, but other colorless intermediates (carboxymethine-linked dimers and xanthenes, both coming from (+)-catechin oxidation) may significantly contribute, depending upon their amounts in solutions. The figure clearly shows that, at day 3, chitosan provoqued a relevant reduction in absorbance, which remained substantially unchanged after the 7th day of conservation onward. This trend of absorbancies could well be due to the initial adsorption of (+)-catechin and phenolic intermediates on the chitosan chain and/or the lack in generation of the latter.

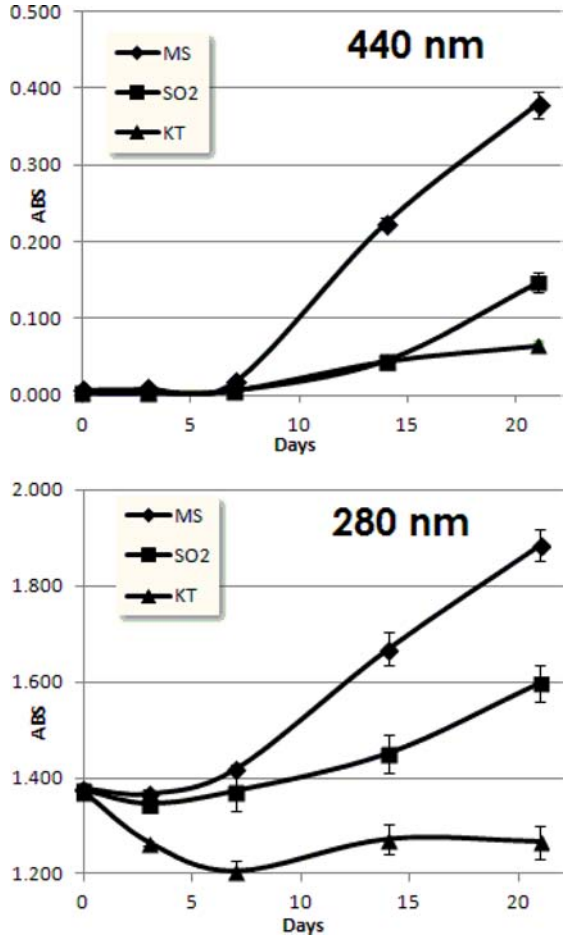

**Figure 1.** Changes in absorbance at 440 and 280 nm of MS, $SO_2$, and Kt solutions during 21 days of oxidation. MS, model solution; $SO_2$, sulfur dioxide; and Kt, chitosan.

On the contrary, $SO_2$ solutions and to a significantly greater extent MS, increased their absorbance at 280 nm likely because of the progressive generation of oxidized dimers. Further comments on these data will be given in the continuing of the discussion.

Overall, Figure 1 shows that, when individually present in solutions, 1g/L chitosan and 80 mg/L free $SO_2$ exerted an apparently comparable antibrowning ability. As previously mentioned, two other works,[28,29] aimed to evaluate the effects of different fining agents on white wine oxidation, outlined the reduced tendency to browning of white wines added with up to 4 g/L chitosan. In those papers, the treated wines were filtered and submitted to an accelerated oxidation (2−5 days at 50 °C) at the end of which chitosan performed comparably (or marginally worse) to polyvinylpolypyrrolidone (PVPP) or potassium caseinate. Even though the authors only linked this results to the ability of chitosan to adsorb phenols (preferentially hydroxycinnamic acids), other concomitant antibrowning mechanisms could not be excluded.

In addition, specific information on the effect of chitosan on the generation of intermediate oxidized compounds in environments pertinent to wine is totally lacking in the literature.

To deepen this latter subject, the presence of phenolic compounds [e.g., (+)-catechin and dimers generated from its

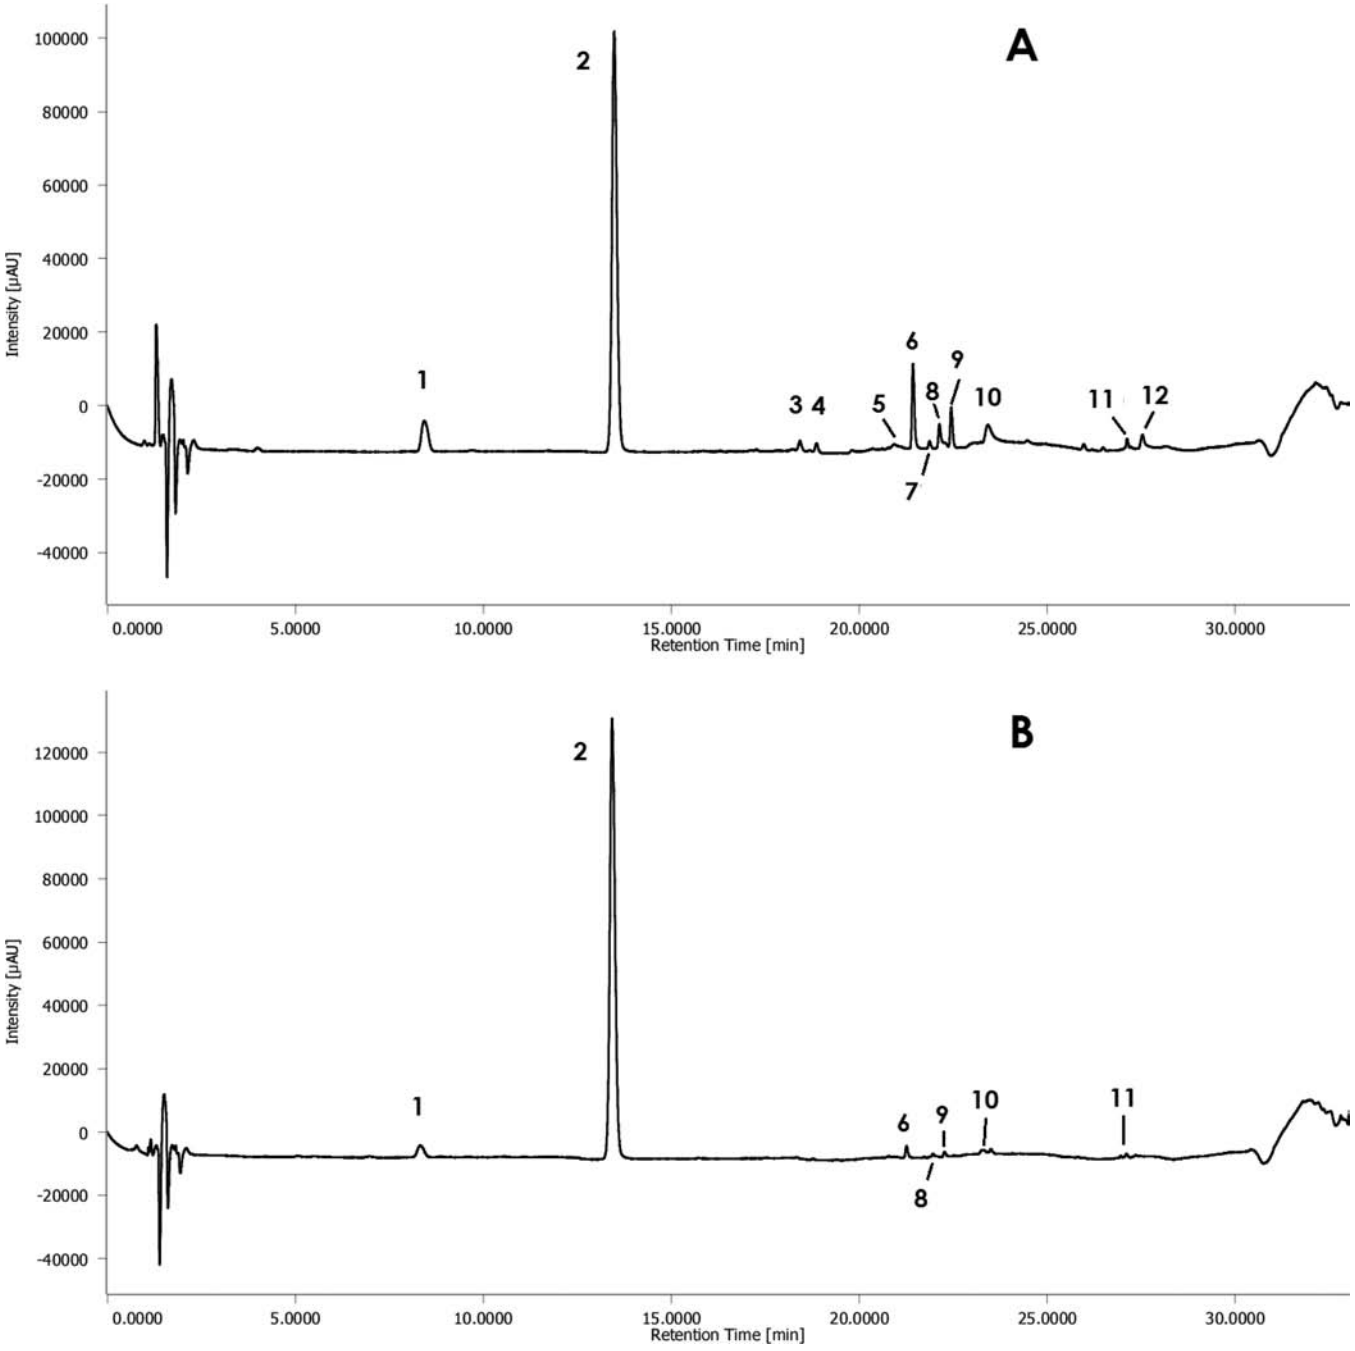

**Figure 2.** HPLC traces at 280 nm of phenolic compounds present in model white wines after 21 days of oxidation: (A) MS sample (model solution) and (B) Kt sample (chitosan). Peak identification: 1, 3, 4, and 7, carboxymethine-linked (+)-catechin dimers; 2, (+)-catechin; 5, 6, 8, and 9, xanthylium cation isomers; 10, xanthenes; and 11 and 12, xanthylium cation ethyl esters.

oxidation] in the solutions was monitored by means of HPLC–DAD/MS, all along the trial.

In Figure 2, two representative chromatograms of MS and Kt solutions (panels A and B, respectively) at day 21 are depicted. A total of 12 compounds were identified according to previous works,[31,34] including 4 carboxymethine-linked isomers, 4 xanthylium cation isomers, 2 xanthylium cation ethyl esters, and 1 peak corresponding to xanthene. This pattern of compounds could give a full representation of the kinetics underlying the browning development of model wines, because it is now accepted that glyoxylic-mediated oxidation of (+)-catechin ensues the following steps: (1) tartaric acid oxidation to give glyoxylic acid, (2) generation of glyoxylic-acid-bridged (+)-catechin dimers, (3) dehydration of dimers to generate xanthene derivatives, and (4) oxidation of xanthene giving rise to xanthylium cations.[10]

As shown in Figure 3A and independent from the sample considered, no dimers where formed before day 3. A very fast generation in MS samples followed, bringing those solutions to accumulate the maximum amount of pigment precursors at day 7, just in coincidence with the beginning of the browning (Figure 1), even if to a much lesser extent, also Kt samples showed the formation of carboxymethine-linked dimers, indicating the occurrence of the first step of the oxidative

dx.doi.org/10.1021/jf5025664 | J. Agric. Food Chem. 2014, 62, 9868–9875

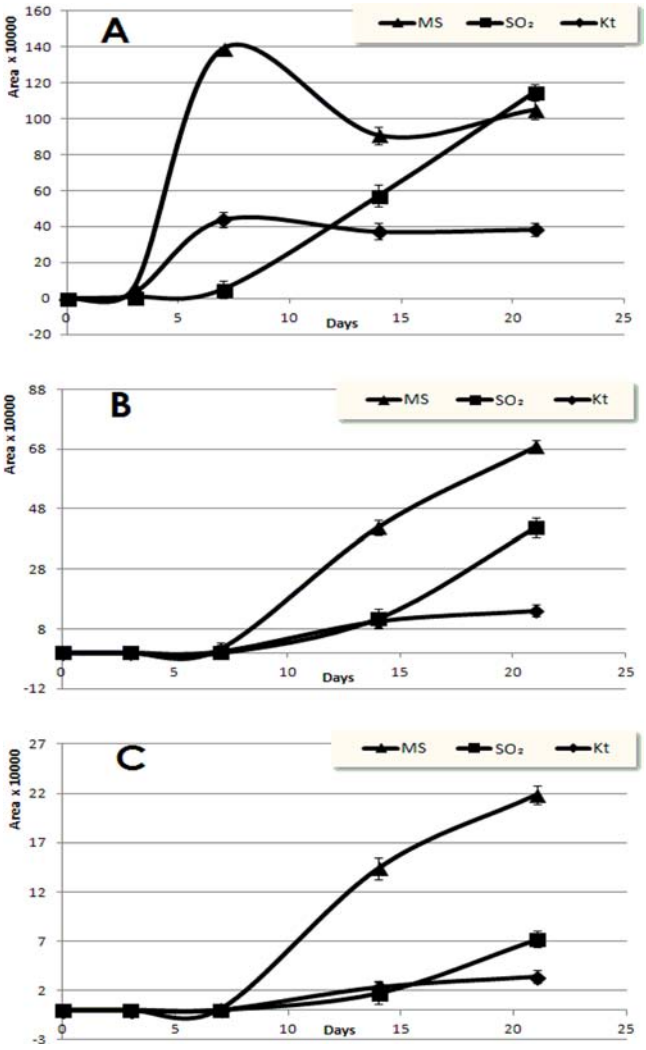

**Figure 3.** Change in the peak area of (a) carboxymethine-linked (+)-catechin dimers (sum of peaks 1, 3, 4, and 7 from Figure 2), (b) xanthene (peak 10 from Figure 2), and (c) xanthylium cations (sum of peaks 5, 6, 8, 9, 11, and 12 from Figure 2) during the experiment. All peaks were detected at 280 nm, except xanthylium cations and corresponding esters (440 nm).

ladder. Interestingly, in these solutions, the amounts of dimers remained unchanged until the end of the trial. For what concern $SO_2$, it effectively inhibited the formation of dimers up to day 7. This capacity could be attributed to both the trapping of glyoxylic acid[36] and the scavenging of RSO generated by the metal redox cycle and hydrogen peroxide.[8] However, at day 14, the content of carboxymethine-bridged dimers in the samples containing sulfites significantly increased, exceeding the amount found in Kt solutions. This imply that, even in the presence of sulfites, radical-mediated tartaric acid oxidation occurred, which is in accordance with Elias and Waterhouse,[37] who found that, to completely inhibit the Fenton reaction, more than 64 mg/L free $SO_2$ was needed, although 32 mg/L did inhibit the production of radical adducts by 87% compared to the control. At the end of the observed period (day 21), because of the complete oxidation of sulfites, the carboxymethine-bridged dimer amount in $SO_2$ samples further increased, equalizing the content of MS solutions.

Panels B and C of Figure 3 depict the generation of xanthenes and xanthylium cations, respectively. It is shown that these compounds followed a common kinetic, being produced apparently simultaneously after day 7 and increasing with time according to the amount of carboxymethine-linked dimers present in each solution (Figure 3A). It seems, hence, that, while, for the production of xanthenes from its precursors, a 4 day period is needed (compare panels A and B of Figure 3), the next oxidative step, driving to yellow pigments, is considerably faster. It is also apparent that, for each sample, the xanthylium cation concentration is perfectly reflected in the browning level, as shown in Figure 1.

Table 1 reports the data relative to the residual amount of (+)-catechin in the solutions.

**Table 1. Residual (+)-Catechin Content (mg/L) in Model Wine Solutions During the Trial**[a]

| | days | | | |
|---|---|---|---|---|
| | 3 | 7 | 14 | 21 |
| MS | 94.7 ± 2.6 a | 82.0 ± 3.1 a | 69.4 ± 2.6 a | 58.9 ± 1.3 a |
| $SO_2$ | 97.5 ± 3.0 b | 93.0 ± 2.7 b | 80.2 ± 2.1 b | 64.4 ± 1.8 b |
| Kt | 92.7 ± 2.8 a | 79.8 ± 2.2 a | 77.3 ± 2.4 b | 73.6 ± 1.4 c |

[a]In each column, significant differences ($p < 0.05$) are identified with different letters. MS, model solution; $SO_2$, sulfur dioxide; and Kt, chitosan.

Sulfited solutions consistently had the highest amount of residual (+)-catechin (at least up to day 14, i.e., when suitable amounts of additive were still detected), confirming the ability of this additive to protect flavanols from oxidation.[13] In accordance with UV absorbancies at 280 nm of Kt samples (Figure 1), chitosan initially provoqued a decline in (+)-catechin content (Table 1) likely because of the interaction of this latter with the polysaccharide chain. However, at day 14, those solutions had the same (+)-catechin content as the $SO_2$ samples, suggesting that chitosan may have reduced the (+)-catechin oxidative decay in those solutions.

**Interaction of Chitosan with Metals, (+)-Catechin, and Products of Its Oxidation.** Stimulated by the intriguing results, a further experiment was carried out to estimate both the extent of the adsorption of oxidized phenolic compounds on chitosan and the chelating aptitude of this additive (e.g., two mechanisms that could have contributed to the reduced browning of Kt solutions). To do this, the oxidized MS solutions withdrawn at day 21 were added to 1 g/L chitosan and continuously stirred for 30 h. On these samples, the analysis of phenols and metals was performed and reported in Figure 4 and Table 2, respectively.

According to the results from phenol analysis (Figure 4), chitosan appeared to have a relevant interaction with xanthylium cations, carboxymethine dimers, and (+)-catechin, whose amounts in solutions were reduced by 70, 45, and 15%, respectively, while no interaction was found with xanthene and ethyl esters of xanthylium cations. These interactions entailed a reduction in absorbance at 280 and 440 nm as high as 33 and 72%, respectively (data not shown), and suggest that at least a portion of the observed antibrowning capacity of chitosan could be due to the removal of intermediate compounds and xanthylium pigments eventually formed through the oxidative ladder.

The different behaviors of chitosan with respect to phenolic compounds are the consequence of several interaction mechanisms described for it. In fact, it contains functional groups, such as amino, acetamido, and hydroxy, that are prone

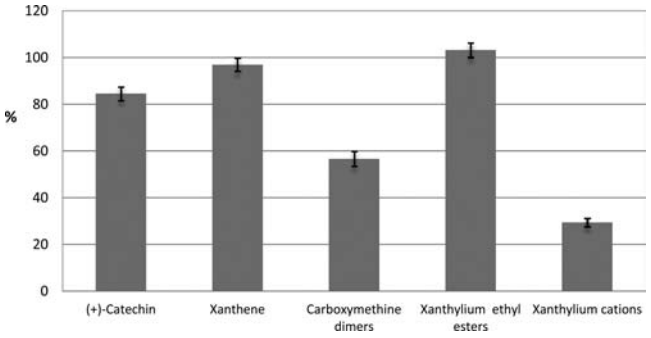

**Figure 4.** Percentage of residual phenolic compounds in MS samples (sampled at day 21) after the addition of 1 g/L chitosan and stirring for 30 h.

**Table 2. Metal Concentration (mg/L) in Model Wines at Day 21**[a]

| | Cu | Fe | percentage of residual Cu (%) | percentage of residual Fe (%) |
|---|---|---|---|---|
| MS | 0.318 ± 0.005 | 5.090 ± 0.068 | 101 | 100 |
| $SO_2$ | 0.320 ± 0.002 | 5.130 ± 0.058 | 101 | 101 |
| Kt | 0.227 ± 0.005 | 1.480 ± 0.021 | 71 | 29 |
| Kt (30 h)[b] | 0.162 ± 0.001 | 0.865 ± 0.013 | 51 | 17 |

[a]In the third and fourth columns, residual percentages are given with respect to the same sample at day 0. MS, model solution; $SO_2$, sulfur dioxide; and Kt, chitosan. [b]Sample Kt (30 h) identifies MS solutions (sampled at day 21) after the addition of 1 g/L chitosan and 30 h of stirring.

to link molecules by ion exchanges, van der Waals interactions, and hydrogen bonds, also as a function of pH.[38] It was found that the lower the pH, the higher the phenol adsorption efficiency, because of the electrostatic interaction exerted by ammonium groups on phenolate anions.[38] In addition, Spagna et al. proposed the "cooperative" nature of the phenomena involving chitosan and hydroxycinnamic acids, where adsorption is favored by the presence of compounds already adsorbed on the polysaccharide surface.[28] As a matter of fact, on the basis of the results shown in Figure 4 and considering that the compounds that did not interact with chitosan eluted later in RP-HPLC conditions (Figure 2), it is possible to hypothize that hydrophilicity may play a further role.

The chelating activity of chitosan was also evaluated, and the results are shown in Table 2. In this table, the residual metal content of MS, $SO_2$, and Kt samples after 21 days of conservation have been compared to that of the same MS samples added with 1 g/L chitosan and stirred for 30 h.

It could be highlighted that, at day 21, Kt samples had about 30 and 70% residual amounts of Fe and Cu, respectively, if compared to the initial concentration. Even more significant results were obtained in the solutions stirred for 30 h, where the reduction in metals was of 83 and 49% for Fe and Cu, respectively. Our results indicate the higher affinity of chitosan for Fe, with respect to Cu, and confirm the findings by Bornet and collegues,[26] who reported chelation activities up to 90% for Fe and 65% for Cu after the addition of 2 g/L chitosan in both white and red wines. On the basis of these results, hence, a further explanation for chitosan antibrowning efficacy could be the trapping of transition metals and the consequent suppression of Fenton chemistry.

**Decay of Varietal Thiols in White Wine Model Solutions.** Apart from phenols, oxidation may involve other reactive molecules constitutive of wines. Thiols, in particular, are highly sensitive to oxidation and may concurrently undergo either nucleophilic addition with (+)-catechin *o*-quinones or autoxidation, catalized by metals and hydroxyl radicals, which gives disulfides.[39] In both of these reactions, the presence of radical species generated by the transition metal redox cycle plays a primary role.[8] Accordingly, to compare the efficacy of sulfites and chitosan in protecting thiols from oxidation, the bulk model wine solution had been added 3MH, 3MHA, and 3MMB, three varietal thiols already identified as aromatic markers in Sauvignon Blanc.[40]

Figure 5 shows the residual amounts (as a percentage of the chromatographic area with respect to day 0) of each thiol in

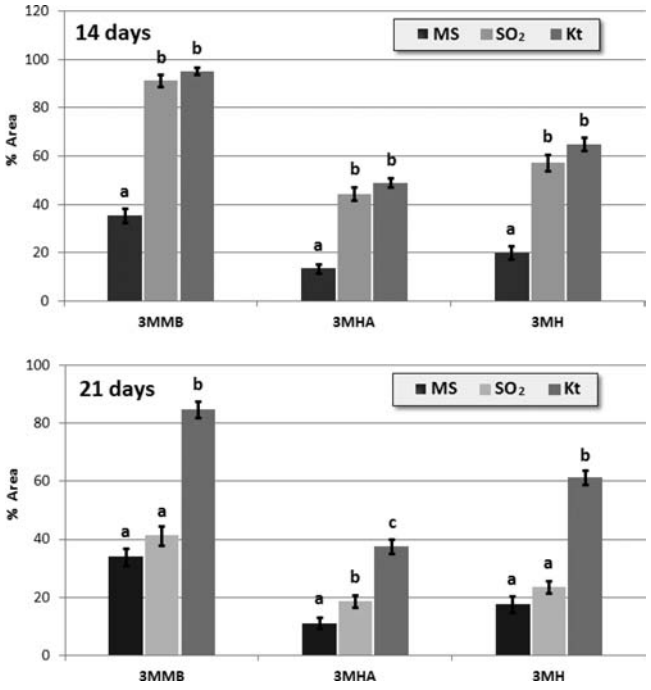

**Figure 5.** Percentage of the residual amount of 3MMB, 3MHA, and 3MH in sample solutions after 14 and 21 days of oxidation. Relative peak areas (with respect to internal standard 4MMB) are diagramed. For each cluster, significant differences ($p < 0.05$) are identified with different letters.

samples after 14 and 21 days of conservation. As a general consideration and independent from the sample, 3MMB, probably because of the weak nucleophilic character of its tertiary SH group,[39] demonstrated to be the least oxidizable thiol, being reduced by about 6, 9, and 64% after 14 days in Kt, $SO_2$, and SM solutions, respectively. On the contrary, the 3MHA amount decreased to the highest extent. For this ester, in fact, acid-catalyzed hydrolysis as a loss mechanism should be considered together with oxidation of the thiol moiety.[7] From Figure 5, it is evident that the highest protective effect is exerted by sulfite up to 14 days, as the consequence of its ability to both reduce back or quench *o*-quinones,[8] and reacts with oxygen radicals.[14] In another study on aerated model wines, 50 mg/L $SO_2$ protected 3MH for a 7 day period, after which a quick oxidation took place, making those samples not dissimilar to the samples not containing $SO_2$.[39] At our experimental conditions, this happened after 21 days of conservation (sample

dx.doi.org/10.1021/jf5025664 | J. Agric. Food Chem. 2014, 62, 9868−9875

$SO_2$ in Figure 5), because of the complete disappearence of sulfites in solutions. For what concern Kt model wines, at day 14, they had the same thiol amount of the $SO_2$ samples. In addition, the prolonged presence of chitosan in the sample permitted the highest protection of these volatiles even after 21 days of conservation (Figure 5). It is possible to hypothesize that these findings are, at least in part, due to the antiradical activity of chitosan, which can lower the amount of reactive species in the medium, in this way reducing the generation of *o*-quinones and/or the direct oxidation of thiols. It is worth mentioning that a significant radical scavenging activity of chitosan toward superoxide ($O_2^{\bullet}$) and hydroxyl ($OH^{-\bullet}$) radicals and hydrogen peroxide has already been reported.[23,41]

Overall, the results obtained in this work demonstrate the efficacy of chitosan in controlling the oxidative decay of (+)-catechin in model white wines submitted to air exposure. The antibrowning capacity of 1 g/L of this polysaccharide has been found to be comparable to that of 80 mg/L free $SO_2$ for at least 14 days, i.e., until the additives were present in the solutions. Afterward, following the complete oxidation of sulfites, those samples added to $SO_2$ became significantly darker than the samples containing chitosan. The chitosan antibrowning activity is proposed to be the result of a series of concurrent mechanisms, including phenolic adsorption, metal chelation, and radical scavenging, which cooperate in lowering the oxidative strength of the solution, with respect to (+)-catechin. In addition, chitosan effectively protected thiols from oxidation and did not appear to interact with them. To our knowledge, this is the first investigation on the mechanisms subtended to the antioxidant activity of chitosan in a model environment pertinent to wine.

Our results suggest that chitosan could be a potential candidate in view to find technological alternatives to sulfite in winemaking. Trials on real wines are now needed to verify its efficacy as, for example, a stabilizing treatment before bottling or during conservation in tanks. Its use in $SO_2$-free fermenting grape musts and/or in specific steps of the winemaking process is currently under investigation by our group.

amine, $N^{\alpha}$-*t*-BOC-lysine, $N^{\varepsilon}$-formyl-L-lysine, *N*-formyl-L-proline, *o*-phenylenediamine (OPD), quinoxaline (Q), 2-quinoxalinol, sodium cyanoborohydride, $D_2O$, methanol (HPLC gr., VWR Chemicals, Darmstadt, Germany), TLC plates, dipotassium hydrogen phosphate trihydrate, potassium dihydrogen phosphate, dimethyl sulfoxide, diethylenetriaminepentaacetic acid (Merck, Darmstadt, Germany), heptafluorobutyric acid (ACROS Organics, Geel, Belgium), formic acid (Grüssing GmbH, Filsum, Germany), $CDCl_3$ (ARMAR Chemicals, Leipzig/Döttingen, Germany), and hydroxymethylfurfural (Alfa Aeser, Karlsruhe, Germany). $N^{\varepsilon}$-Carboxymethyl-L-lysine was synthesized according to the literature.[14] Quinoxaline reference standards (maltosone-Q, threosone-Q, 1-deoxypentosone-Q, 3-deoxymaltosone-Q, 3,4-dideoxypentosone-Q, 4-deoxyglucosone-Q, 1,4-dideoxyglucosone-Q, 1,5-dideoxymaltosone-4-ene-Q, 3-deoxygalactosone-Q, 5,6-dihydroxy-2,3-dioxohexanal-Q, 1-deoxymaltosone-Q, 3-deoxyglucosone-Q, glucosone-Q, 1-deoxyglucosone-Q, 3-deoxypentosone-Q, 1-deoxytheosone-Q, 3-deoxythreosone-Q) were isolated and characterized in previous work.[9,15]

**Beer Samples.** For the present study 11 commercially available Pilsner type beer samples were obtained. Analyses of the fresh beer samples were carried out in duplicate. Aging was conducted for one beer sample under aerated and deaerated conditions at 50 °C for 2 weeks. Aeration was achieved by opening the bottles, flushing the headspace shortly with air, and capping it again. Samples from the aging experiment were analyzed in triplicate. Aliquots were taken directly after cooling down. Samples were degassed by filtration for further processing.

***N*-(Furan-2-ylmethyl)naphthalene-1-amine (Furfural-N).** One millimole of furfural was dissolved in 50 mL of water. A mixture of 2 mmol of 1-naphthylamine in 25 mL of 15% acetic acid and dimethyl sulfoxide (50:50, v/v) and a solution of 5 mmol of sodium cyanoborohydride in 25 mL of water were added. The reaction mixture was stirred overnight at 40 °C. The reaction mixture was extracted twice with 100 mL of hexane, and the organic phase was concentrated under vacuum. The crude product was further purified by column chromatography (silica gel 60, hexane−acetone 8:1). Fractions containing furfural-N (TLC (silica gel): $R_f$ 0.4, hexane−acetone (8:1), UV detection) were concentrated under vacuum to obtain the compound as a brownish oil. (0.9 mmol, 87%). $^1$H NMR (500 MHz, $CDCl_3$): $\delta$ [ppm] = 4.51 (s, 2H), 6.34 (dd, $^3J$ = 3.2, $^4J$ = 0.8 Hz, 1H), 6.38 (dd, $^3J$ = 3.2, $^3J$ = 1.8 Hz, 1H), 6.73 (d, $^3$ =7.5 Hz, 1H), 7.31 (d, $^3J$ = 8,5 Hz 1H), 7.38 (pt, $^3J$ = 7.5 Hz, $^3J$ = 8.5 Hz, 1H), 7.44 (dd, $^3J$ = 1.8 Hz, $^4J$ = 0.8 Hz, 1H), 7.50−7.45 (m, 2H), 7.86−7.81 (m, 2H). $^{13}$C NMR (125 MHz, $CDCl_3$): $\delta$ [ppm] = 41.9, 105.1, 107.4, 110.6, 118.3, 120.1, 123.7, 124.9, 125.9, 126.6, 128.8, 134.4, 142.2, 142.9, 152.6. HR-MS: *m*/*z* 224.1070 (found); *m*/*z* 224.1070 (calculated for $C_{15}H_{14}NO$ $[M + H]^+$).

**5-(Naphthalene-1-aminomethyl)-2-furanmethanol (HMF-N).** The synthesis of HMF-N was carried out as described above. One millimole of hydroxymethylfurfural was used as the educt. The crude product was extracted with 100 mL of $CHCl_3$, concentrated under vacuum, and purified by column chromatography (silica gel 60 using hexane−acetone 5:2). Fractions HMF-N (TLC (silica gel): $R_f$ 0.26, hexane−acetone (5:2), UV detection) were concentrated under vacuum to obtain the compound as white crystals (0.7 mmol, 70%). $^1$H NMR (500 MHz, $CDCl_3$): $\delta$ [ppm] = 4.46 (s, 2H), 4.57 (s, 2H), 6.23 (d, $^3J$ = 3.2 Hz, 1H), 6.25 (d, $^3J$ = 3.2 Hz, 1H), 6.70 (dd, $^3J$ = 7.5, $^4J$ = 0.8 Hz, 1H), 7.29 (d, $^3J$ = 8.5, 1H), 7.35 (pt, $^3J$ = 8.5, $^3J$ = 7.5 Hz 1H), 7.44−7.41 (m, 1H), 7.48−7.45 (m, 1H), 7.81−7.79 (m, 1H), 7.85−7.82 (m, 1H). $^{13}$C NMR (125 MHz, $CDCl_3$): $\delta$ [ppm] = 41.9, 57.5, 105.2, 108.3, 108.8, 118.4, 120.1, 123.8, 125.0, 125.9, 126.5, 128.8, 134.4, 142.8, 152.5, 153.8. HR-MS: *m*/*z* 254.1176 (found); *m*/*z* 254.1176 (calculated for $C_{16}H_{16}NO_2$ $[M + H]^+$).

***N*-Carboxymethyl-L-proline (CMP).** CMP was synthesized according to the literature with some modifications.[16] Twenty millimoles of chloroacetic acid was cooled to −18 °C and stirred under argon atmosphere. To this was added dropwise 2.5 g of potassium hydroxide dissolved in 10 mL of water. Twenty millimoles of L-proline and 1.2 g of potassium hydroxide were dissolved in 5 mL of water and added dropwise to the reaction mixture. The solution was then heated to 80 °C, and the temperature was held for 4 h. Within this time 0.28 g of potassium hydroxide in 5 mL of water was added dropwise. The reaction mixture was cooled down and neutralized with 6 M hydrochloric acid. CMP was extracted from the reaction mixture with a strong anion exchanger (Amberlite IRA-410, Sigma-Aldrich, Munich/Steinheim, Germany). After elution with 1 M hydrochloric acid, the solution was dried and the crude product was further purified by column chromatography (cellulose, *n*-butanol−acetic acid−water 20:3:5). The fractions containing CMP (TLC (cellulose), $R_f$ 0.28, same solvent, detection with bromcresol green) were concentrated under vacuum, redissolved in water, and lyophilized to give CMP as a white powder (5.9 mmol, 30%). $^1$H NMR (500 MHz, $D_2O$): $\delta$ [ppm] = 1.84 (m, H), 1.97 (m, 2H), 2.30 (m, 1H), 3.12 (m, 1H), 3.53 (m, 1H), 3.88 (d, 1H, $^2J$ = 16.7 Hz), 4.08 (d, 1H, $^2J$ = 16.7 Hz), 4.16 (dd, 1H, $^3J$ = 6.1 Hz; $^3J$ = 6.3 Hz). $^{13}$C NMR (500 MHz, $D_2O$): $\delta$ [ppm] = 22.7, 28.2, 54.5, 54.7, 65.8, 168.7, 171.1. HR-MS: *m*/*z* 172.0613 (found); *m*/*z* 172.0615 (calculated for $C_7H_{10}NO_4$ $[M - H]^-$).

**Incubation of Carbohydrates.** In general, incubations were conducted in 0.1 M phosphate buffer at two different pH levels (pH 5 and pH 7) and 50 °C for up to 7 days. Maltose, maltotetraose, maltopentaose, maltohexaose, and maltoheptaose (42 mM) were incubated individually with either $N^{\alpha}$-*t*-BOC-lysine (42 mM) or L-proline (42 mM). Incubations were performed under aerated and deaerated conditions. Deaeration was achieved by degassing of the buffer with helium, addition of 1 mM diethylenetriaminepentaacetic acid, and using minimum headspace volume during incubation. Samples of maltotetraose were prepared in triplicate and incubated up to 7 days, the rest in duplicate for 7 days, respectively. Data for all target analytes showed coefficients of variation <5%.

**Enzymatic Assay of Formic Acid.** For the quantitation of formic acid in maltotetraose incubations an enzyme test kit obtained from R-Biopharm AG (Darmstadt, Germany) was used.

**Analytical HPLC-FLD (Fluorescence Detection) for Carbohydrates.** Derivatization of carbohydrates was carried out following the method of Rakete and Glomb.[3] The derivatized samples were diluted with eluent B to concentrations appropriate for detection. Eluents were water (A) and a mixture of methanol and demineralized water (7:3, v/v; B). Heptafluorobutyric acid (0.6 mL/L) was added to both eluents as ion pair reagent. Analyses were carried out on a Waters HPLC system consisting of a Waters 600-MS pump, a Waters 470 fluorescence detector, and a Waters 712 WISP autosampler (Waters Corp., Milford, MA, USA). Chromatographic separations were performed on a stainless steel column (Knauer, Eurospher 100-5 C18, 250 × 4.6 mm, 5 $\mu$m, Berlin, Germany) using a flow rate of 1 mL min$^{-1}$ at 20 °C (Jetstream 2 column oven, Jasco, Groß-Umstadt, Germany). The wavelengths of excitation and emission were adjusted to 318 and 440 nm, respectively. The separation started at 65:35 (A:B). After 75 min, B was raised to 100% in 5 min to flush the column for 15 min. Within 5 min the composition of the eluents was changed to starting conditions and equilibrated for 15 min prior to injection of the next analysis.

**Analytical HPLC-MS$^2$.** A Jasco PU-2080 Plus quaternary gradient pump with degasser and a Jasco AS-2057 Plus autosampler (Jasco, Gross-Umstadt, Germany) were used. Chromatographic separations were performed on a stainless steel column (KNAUER, Eurospher 100-5 C18, 250 × 4.6 mm, 5 $\mu$m, Berlin, Germany) using a flow rate of 1 mL min$^{-1}$. The mass analyses were performed using an Applied Biosystems API 4000 quadrupole instrument (Applied Biosystems, Foster City, CA, USA) equipped with an API source using an electrospray ionization (ESI) interface in the positive mode. The LC system was connected directly to the probe of the mass spectrometer. Nitrogen was used as sheath and auxiliary gas. All compounds were analyzed by scheduled multiple reaction monitoring (sMRM). Quantitation was based on the standard addition method. More precisely, increasing concentrations of authentic reference compounds were added to aliquots of the sample (50:50, v/v). A regression of response versus concentration was used to determine the concentration of the analyte in the sample. Calibration with this method resolves potential matrix interferences.

Table 1. Mass Spectrometric Parameters for AGEs and Derivatized Furfural (Furfural-N) and Hydroxymethylfurfural (HMF-N)[a]

| | mass (amu) | | | | | |
|---|---|---|---|---|---|---|
| | Q1 | Q3 | retention time (min) | DP (V) | CE (eV) | CXP (V) |

*α-Dicarbonyl Compounds.* Sample aliquots were reincubated with *o*-phenylenediamine (OPD, 5 mM) for 5 h at 25 °C. OPD was added at the time of sampling to avoid artifacts. The derivatized samples were diluted with water to concentrations appropriate for detection. The mobile phase used consisted of water (solvent A) and methanol/water (7:3 (v/v), solvent B). To both solvents (A and B) was added 0.6 mL/L heptafluorobutyric acid (HFBA). Chromatographic parameters were according to Henning et al.[17] Elution of quinoxalines (1-deoxymaltosone-Q at 8.3 min, maltosone-Q at 8.7 min, glucosone-Q at 9.8 min, 1-deoxyglucosone-Q at 12.0 min, 3-deoxymaltosone-Q at 11.1 min, threosone-Q at 14.5 min, 1,5-dideoxymaltoson-4-ene-Q at 11.4 min, 4-deoxyglucosone-Q at 13.6 min, 3-deoxyglucosone-Q at 13.9 min, glyoxylic acid-Q at 17.1 min, 1-deoxypentosone-Q at 17.3 min, 3-deoxypentosone-Q at 16.7 min, 3-deoxygalactosone at 14.4 min, 5,6-dihydroxy-2,3-dioxohexanal-Q (1) at 17.4 min, 5,6-dihydroxy-2,3-dioxohexanal-Q (2) at 18.3 min, 1,4-dideoxyglucosone-Q at 18,4 min, 3-deoxythreosone-Q at 18,8 min, 1-deoxythreosone-Q at 19.3 min, glyoxal-Q at 20.6 min, 3,4-dideoxypentosone-Q at 20.0 min, methylglyoxal-Q at 22.1 min, and diacetyl-Q at 23.4 min) was monitored by mass spectrometry. The optimized parameters for mass spectrometry as well as limits of detection and quantitation for all compounds monitored were according to previous work.[9]

*AGEs.* Prior to injection into the HPLC-$MS^2$ system, solutions were diluted to appropriate concentrations with water. For deprotection of the $N^{\alpha}$-BOC protection group an equal volume of 6 M hydrochloric acid was added to the sample and kept at room temperature for 30 min. The mobile phase used consisted of water (solvent A) and methanol/water (7:3 (v/v), solvent B). To both solvents (A and B) was added 1.2 mL/L HFBA. Samples were injected at 1% B, and gradient was then changed to 20% B within 15 min and to 100% B after 2 min (held 8 min). Then gradient was changed to 1% B within 2 min and held for 7 min. The optimized parameters for mass spectrometry and retention times are shown in Table 1.

*Furfural and Hydroxymethylfurfural.* Derivatization of furfural and hydroxymethylfurfural was carried out analogously to carbohydrate derivatization.[3] However, samples were reincubated for only 1 h at 20 °C and diluted to appropriate concentrations with methanol prior to injection into the HPLC-$MS^2$ system. The mobile phase used consisted of water (solvent A) and methanol/water (7:3 (v/v), solvent B). To both solvents (A and B), 0.8 mL/L formic acid was added. Samples were injected at 90% B, and gradient was then changed to 100% B within 10 min and held for 15 min. Then the mobile phase was changed to 90% B within 1 min and equilibrated for 7 min prior to injection of the next analysis. The optimized parameters for mass spectrometry and retention times are shown in Table 1.

**Identification of *N*-Formylproline (FP) and *N*-Carboxymethylproline (CMP) in Beer.** Filtrated beer was subjected to several analytical HPLC runs as mentioned above. Fractions containing FP and CMP were combined and dried in a vacuum concentrator (Savant Speed-Vac Plus SC 110 A combined with a Vapor Trap RVT 400, Thermo Fisher Scientific GmbH, Dreieich, Germany). The residue was dissolved in water and injected into the HPLC-$MS^2$ system performing a CID experiment. The fragmentation spectra of the authentic references were obtained with the same parameters (declustering potential (DP), collision cell exit potential (CXP)) as in Table 1. Parameters for collision energy (CE) were as follows: FP, 19 eV; CMP, 21 eV).

**Nuclear Magnetic Resonance Spectroscopy (NMR).** $^{1}H$ and $^{13}C$ NMR spectra were recorded on a Varian Unity Inova 500 instrument operating at 500 MHz for $^{1}H$ and 125 MHz for $^{13}C$. $SiMe_4$ was used as a reference for calibrating the chemical shift.

**High Resolution Mass Determination (HR-MS).** The positive and negative ion high resolution ESI mass spectra were obtained from an Orbitrap Elite mass spectrometer (Thermofisher Scientific, Bremen, Germany) equipped with an HESI electrospray ion source (spray voltage 4 kV; capillary temperature 275 °C, source heater temperature 40 °C; FTMS resolution >30.000). Nitrogen was used as sheath and auxiliary gas. The sample solutions were introduced continuously via a 500 μL Hamilton syringe pump with a flow rate of 5 μL $min^{-1}$. The data were evaluated by the Xcalibur software 2.7 SP1.

## RESULTS AND DISCUSSION

Since dextrins represent the predominant carbohydrates and proline is the most relevant free amino acid in beer, they are the major source for Maillard induced carbohydrate degradation. The formation of α-dicarbonyl compounds, furfural, and hydroxymethylfurfural (HMF) has been previously studied in beer and numerous model incubations. Nevertheless, this is the first time mechanistic investigations of amine induced degradation of dextrins up to maltoheptaose were performed and compared directly to changes during beer aging. Maltotetraose as the major carbohydrate in beer was investigated in more detail. The formation of Maillard reaction products derived from maltose and dextrins in the presence of proline and lysine was followed in a defined aqueous model system under aerated and deaerated conditions at pH 7 and pH 5. To compare results to previous findings of Smuda et al., especially the formation of α-dicarbonyls, incubations were also performed in the presence of $N^{\alpha}$-*t*-BOC-lysine, later referred to as lysine.[9] All parameters were also monitored in 11 fresh and commercially available Pilsner type beers as well as in two artificially aged beers, of which one was additionally exposed to oxidative stress. Though beer normally is not exposed to temperatures above 30 °C, the aging experiment conducted at 50 °C delivered conclusive results and was comparable to other aging procedures found in the literature. However, reaction kinetics may differ in comparison to lower temperatures.

**Changes in the Carbohydrate Profile.** The breakdown of dextrins was studied in model incubations. As shown in Table 2, formation of glucose, maltose (Mal), and maltotriose (M3) during incubation of maltotetraose (M4) with proline at pH 7 and pH 5 revealed significantly higher amounts of M3 vs Mal and glucose. Levels of glucose, Mal, and M3 were throughout higher under aerated than deaerated conditions. The degradation of higher molecular dextrins maltopentaose (M5), maltohexaose (M6), and maltoheptaose (M7) showed

**Table 2. Formation of Glucose, Maltose, and Maltotriose during Degradation of Maltotetraose (M4) with Proline in mmol/mol M4 after 7 d under Aerated (a) and Deaerated (d) Conditions**

| | glucose | | maltose | | maltotriose | |
|---|---|---|---|---|---|---|
| pH | a | d | a | d | a | d |
| 7 | 0.19 | 0.09 | 0.25 | 0.08 | 0.71 | 0.42 |
| 5 | 0.18 | 0.09 | 0.25 | 0.08 | 0.68 | 0.27 |

a similar depolymerization down to glucose (data not shown). The results for lysine were quite similar (Supporting Information). The change in the carbohydrate profile during aging of beer is given in Table 3. Unfortunately, M3 could not be separated from isomaltose and, thus, was not quantitated in beer. Levels of M4 to M7 slightly decreased during aging but showed no significant change between fresh and aged beer. In agreement with the model incubations, much higher amounts for glucose and Mal were found in aged samples. The ratio of glucose to Mal was two to one detected in fresh samples. Mal increased 9-fold during aging, glucose only 2-fold. In contrast to the model incubations the impact of aeration on the degradation and formation of carbohydrates was negligible in beer samples.

**Table 3. Changes in the Carbohydrate Profile of Beer during Forced Aging (mmol/L)**

| | fresh | deaerated | aerated |
|---|---|---|---|
| maltoheptaose | 0.77 | 0.78 | 0.78 |
| maltohexaose | 1.04 | 1.01 | 0.98 |
| maltopentaose | 1.67 | 1.61 | 1.59 |
| maltotetraose | 7.1 | 7.0 | 6.9 |
| maltose | 0.03 | 0.33 | 0.31 |
| glucose | 0.07 | 0.14 | 0.14 |

**Formation of α-Dicarbonyl Compounds.** The α-dicarbonyls were trapped postincubation with *o*-phenylenediamine as their corresponding quinoxalines following an established method.[9] The concentrations of the α-dicarbonyls formed during the degradation of all used carbohydrates in the presence of proline at pH 7 are summarized in Table 4. In general, formation of α-dicarbonyl compounds monitored during model incubations of maltotetraose to maltoheptaose was in good agreement with the results found for maltose.[9] However, in contrast to Smuda and Glomb, only ten α-dicarbonyls were identified in oligosaccharide incubations. Levels of 1-deoxyglucosone, threosone, and 1-deoxypentosone were under the limit of quantitation or detection, respectively. These α-dicarbonyls are formed by glucose degradation in maltose incubations, which only has a minor impact in oligosaccharide incubations. As expected, the maltose derived α-dicarbonyls 1-deoxymaltosone, 3-deoxymaltosone, 1,5-dideoxymaltoson-4-ene, and maltosone were only quantitated in maltose incubations and, thus, are not listed. For higher oligosaccharides reference compounds with the complete carbon backbone are not available.

Formation of α-dicarbonyls in the presence of lysine at pH 7 was up to ten times higher compared to proline incubations, showing the same response to oxidative conditions. Obviously, lysine represents a better nucleophile than proline. Moreover, the degradation of the Amadori product of proline may require more activation energy.[18] As proline represents the most abundant free amino acid in beer, data of lysine incubations are given in the Supporting Information. When the experiments were conducted at pH 5, some α-dicarbonyls could not be quantitated. However, most α-dicarbonyls showed a similar response to oxidative conditions but at much lower concentrations (factor 3 to 10). The effect of pH value has been shown to have significant impact on reaction rates and mechanistic pathways of the Maillard reaction.[19] Due to protonation of amino functions the reaction rate decreases with decreasing pH. Nevertheless, at the approximate pH of beer (4 to 5), α-dicarbonyls are still formed and degraded during aging at 50 °C while their absolute concentrations remain relatively low. Thus, we decided to only show the results for pH 7, with one exception. Interestingly, 3-deoxyglucosone and 3-deoxygalactosone showed higher amounts at pH 5. 3-Deoxygalactosone had its maximum even after 3 days and decreased afterward (Table 5). Moreover, 3-deoxyglucosone was formed at approximately equal concentrations in incubations containing either lysine or proline, strongly suggesting an acid−base catalyzed formation pathway involving dextrins in addition to the amine induced degradation of glucose. 3-Deoxyglucosone along with 3-deoxygalactosone were also the predominant α-dicarbonyls detected in beer. Formation of 3-deoxygalactosone by epimerization of 3-deoxyglucosone was previously described in the literature.[20,21]

**Table 4. Formation of α-Dicarbonyls (mmol/mol Carbohydrate) during Degradation of Maltose (Mal), Maltotetraose (M4), Maltopentaose (M5), Maltohexaose (M6), and Maltoheptaose (M7) with Proline under Aeration (a) and Deaeration (d) (pH 7, 7 d)**

Analogously, 3-deoxyglucosone and 3-deoxygalactosone may also be formed from 3-deoxyosones derived from carbohydrate degradation of dextrins. This should be the subject of future investigations since 3-deoxyglucosone and 3-deoxygalactosone represent the direct precursors of HMF. At either pH, some α-dicarbonyls also showed a strong influence of the degree of polymerization, in particular glyoxal and glyoxylic acid. Most other α-dicarbonyls also increased, but to a much lesser extent. This must be caused by the quality of the leaving group, which obviously improves with increasing degree of polymerization. Alternatively, continuous depolymerization of dextrins down to glucose may also generate new sources for α-dicarbonyls, but has to be estimated to be only of minor importance.

In general, the results of model incubations at pH 7 were in support of the changes observed during beer aging. The α-dicarbonyls determined in beer are given in Table 6. Contrary to the model incubations, 21 α-dicarbonyls were found in beer. It is noteworthy that, based on preparation of mash and wort, glucose and maltose derived α-dicarbonyls are indeed present in fresh beer. Especially, α-dicarbonyls generated in the presence of oxygen, e.g., maltosone, glucosone, 3-deoxypentosone, and 3-deoxythreosone, were in good agreement. About half of the α-dicarbonyls measured in fresh samples decreased during aging. Especially 3-deoxyglucosone and 3-deoxygalactosone as well as 3-deoxypentosone and 1-deoxyglucosone showed considerably lower amounts after thermal processing. Others occurred at larger quantities compared to their concentrations measured in fresh beer. Vanderhaegen et al. reported an impact on the formation of Maillard reaction products in the presence of oxygen.[6] However, due to the respective beer matrix it is rather difficult to predict the behavior of highly reactive intermediates such as α-dicarbonyls. Bravo et al. demonstrated the extent of α-dicarbonyl formation and their effect on flavor deterioration during extended shelf life.[4] In particular, they depicted that a variety of these compounds are already preformed during preparation of beer and therefore found in the final product while both formation and degradation still continue during shelf life. Levels detected for 3-deoxypentosone, 3-deoxyglucosone, 1-deoxypentosone, 1-deoxyglucosone, methylglyoxal, and diacetyl in fresh beer were in good agreement with their results.

Formation of α-dicarbonyls was studied in detail in incubations of M4 with proline at pH 7. Levels of methylglyoxal were almost identical under aerated and deaerated conditions (0.041 vs 0.038 mmol/mol M4, Figure 1). Methylglyoxal also increased slightly during beer aging, revealing a negligible effect of aeration. Glyoxal showed an 18-fold higher concentration

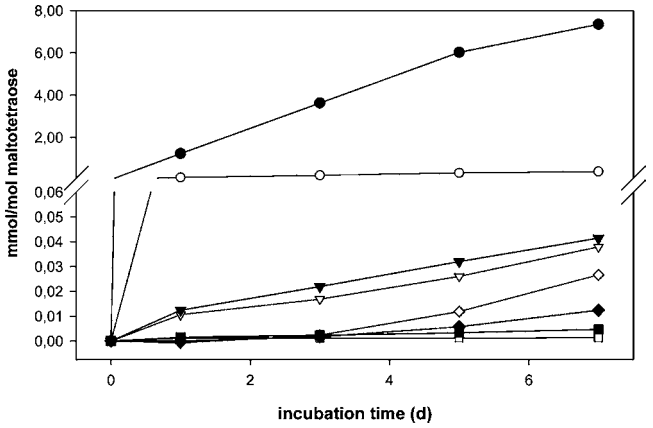

**Figure 1.** Formation of $C_2$−$C_4$ $\alpha$-dicarbonyl compounds in maltotetraose/proline incubations at pH 7 under aerated (closed symbols) and deaerated (open symbols) conditions: methylglyoxal (▼), glyoxal (●), glyoxylic acid (■), diacetyl (◆).

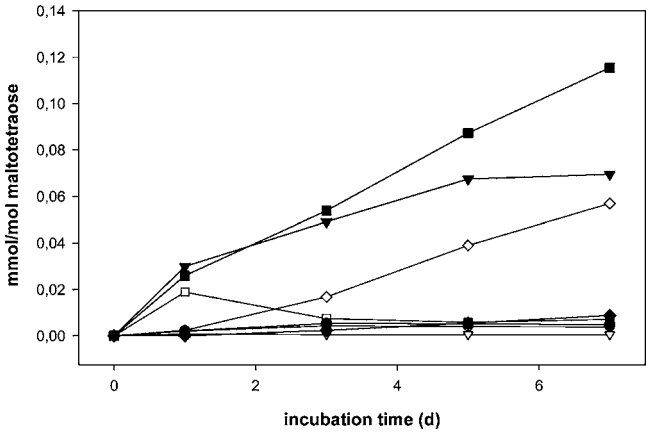

**Figure 2.** Formation of $C_4$−$C_5$ $\alpha$-dicarbonyl compounds in maltotetraose/proline incubations at pH 7 under aerated (closed symbols) and deaerated (open symbols) conditions: 1-deoxythreosone (●), 3-deoxythreosone (▼), 3-deoxypentosone (■), 3,4-dideoxypentosone (◆).

under aeration (7.3 vs 0.38 mmol/mol M4) in model incubations and increased from maltose to maltoheptaose. During beer aging glyoxal levels decreased, but significantly responded to aeration. Glyoxylic acid was found only in small quantities under aeration (0.005 mmol/mol M4) and considerably increased with increasing degree of polymerization. In contrast to the findings of Smuda et al. for maltose degradation, glyoxylic acid revealed significantly higher amounts under aeration from dextrins. This supports the findings of Velisek et al., who described glyoxylic acid as an oxidation product of glyoxal.[22] This hypothesis is further facilitated by the fact that concentrations of glyoxylic acid increased with levels of glyoxal at approximately the same rate from maltose to maltoheptaose. Glyoxylic acid was not quantitated in fresh beer or during aging. However, this may be explained by reaction of glyoxylic acid with other compounds in beer and also by its extremely low levels of formation as shown in model incubations. Levels of diacetyl doubled under nonoxidative conditions (0.012 vs 0.027 mmol/mol M4) in model incubations. In contrast, diacetyl levels in beer behaved differently and revealed higher amounts under aeration during aging. This suggests other chemical pathways like the oxidation of 2,3-butanediole or acetoin to be of major importance. Threosone, which was not detectable in dextrin incubations, was identified in beer and responded to aeration.

Investigations on $\alpha$-dicarbonyls with a backbone consisting of four and five carbon atoms are shown in Figure 2. Only small amounts of 1-deoxythreosone were found in model incubations, and they showed only minor differences between aeration and deaeration. Levels also hardly changed during beer aging. 3-Deoxythreosone revealed a strong response to aeration (0.070 mmol/mol M4). Under deaeration levels measured were at the limit of quantitation. A similar picture was found for the beer aging experiment, where 3-deoxythreosone levels increased especially under aeration. Levels of 3-deoxypentosone, the precursor of furfural, responded considerably to aerated conditions (0.116 vs 0.007 mmol/mol M4). Though 3-deoxypentosone decreased during beer aging, levels in aerated beer were significantly higher. 3,4-Dideoxypentosone increased under deaerated conditions (0.056 mmol/mol M4), whereas amounts formed under aeration remained low (0.009 mmol/mol M4). In contrast, 3,4-dideoxypentosone was only found in traces in beer. This may be explained by the high reactivity of the structure itself or, more likely, of its unknown precursor. Mavric et al. are so far the only authors proposing a possible mechanism considering 4-deoxyglucosone as the educt.[23] 1-Deoxypentosone represents a specific fragmentation product of glucose, hence, we were able to detect small amounts in fresh beer and only traces after thermally induced stress.[15]

Formation of $\alpha$-dicarbonyl compounds with a backbone consisting of six carbon atoms is shown in Figure 3. 5,6-Dihydroxy-2,3-dioxohexanal, 4-deoxyglucosone, and 1,4-dideoxyglucosone were already mentioned as specific degradation products of oligosaccharides with 1,4-glycosidic linkage.[23−25] 5,6-Dihydroxy-2,3-dioxohexanal was found to be lower under aeration than deaeration. Based on its structure, 5,6-dihydroxy-2,3-dioxohexanal is prone to further fragmentation, explaining the low amounts detected in beer. Levels of 4-deoxyglucosone were slightly higher under deaerated conditions in model incubations (0.4 vs 0.5 mmol/mol M4). During beer aging, 4-deoxyglucosone decreased and displayed a lower concentration in aerated samples, which is rather contrary to model incubations and must be explained by oxidative degradation. In incubations formation of 1,4-dideoxyglucosone responded

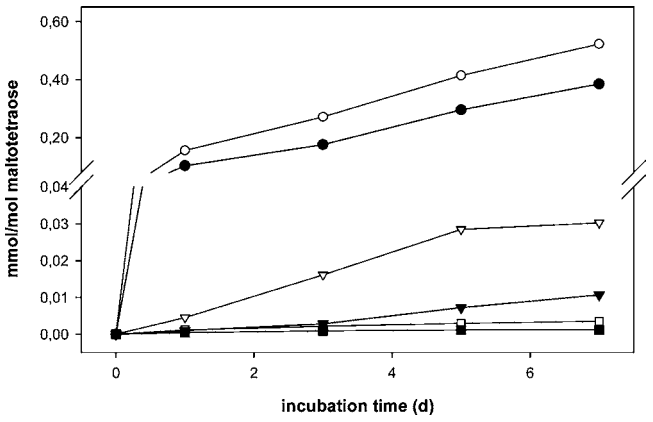

**Figure 3.** Formation of $C_6$ $\alpha$-dicarbonyl compounds in maltotetraose/proline incubations at pH 7 under aerated (closed symbols) and deaerated (open symbols) conditions: 5,6-dihydroxy-2,3-dioxohexanal (■), 4-deoxyglucosone (●), 1,4-dideoxyglucosone (▼).

dx.doi.org/10.1021/jf503038c | J. Agric. Food Chem. 2014, 62, 9876−9884

considerably to nonoxidative conditions and was found to be low under aeration (0.011 vs 0.030 mmol/mol M4). Contrary to the findings of Bravo et al., only small amounts of 1,4-dideoxyglucosone were found in beer, and they slightly decreased during beer aging. Glucosone responded strongly to the aeration of beer and increased during aging while levels were found to be lower in normal aged beer.

For the first time maltosone, 1-deoxymaltosone, 3-deoxymaltosone, and 1,5-dideoxymaltoson-4-ene were quantitated as specific Mal derived degradation products in beer. As their concentrations remained below the limit of detection during incubation of maltotetraose and higher molecular weight dextrins, they refer solely to the Maillard chemistry of Mal.[9] 1,5-Dideoxymaltoson-4-ene, among other $\alpha$-dicarbonyls, was previously identified by Bravo et al. in beer.[4] It is again important to note that these degradation products of maltose are already formed during mash preparation and wort boiling, reflecting the high concentrations of Mal in mash and wort. During aging, Mal was formed in relatively high amounts by depolymerization of oligomeric dextrins, suggesting a net increase in the formation of $\alpha$-dicarbonyls mentioned above. This is supported by the accumulation of 3-deoxymaltosone as a relatively stable intermediate. On the other hand, concentrations of maltosone and 1,5-dideoxymaltoson-4-ene remained almost unchanged during beer aging, and 1-deoxymaltosone was even degraded significantly. These results must be explained by the high reactivity of these compounds as their degradation exceeds their formation.

**Formation of Furfural and Other Follow-Up Products.** Besides the formation of $\alpha$-dicarbonyls a range of other Maillard reaction products was analyzed in model incubations (Table 7) and beer (Table 6). Formation of furfural with 3-deoxypentosone as the immediate precursor is well described for pentose and hexose degradation in the literature.[26,27] Furthermore, 3-deoxypentosone has been described as a predominating $\alpha$-dicarbonyl derived from the degradation of oligosaccharides.[28] However, more recent studies strongly suggest the formation of 3-deoxypentosone via hydrolytic $\beta$-dicarbonyl cleavage of oxyosones.[9,15] Furthermore, amine induced cleavage leading to amides may also be of importance.[25] Consequently 3-deoxypentosone and therefore furfural should also be formed by oxidative degradation of dextrins as shown in Figure 4. The oxidation of dextrins leads to oxyosones. The nucleophilic cleavage of the 1,3-tautomer at the C1 position leads to formation of formic acid as well as of *N*-formylproline (FP). The emerging 1,2-enediol will immediately cleave off substituents at position 3 to give 3-deoxypentosone and subsequently, after cyclization and dehydration, furfural. As described above, the preferred formation of 3-deoxypentosone and depolymerization of dextrins under aerated conditions supported the given mechanism. In further accordance with this mechanism furfural was found in much higher concentrations in aerated M4 incubations (1.04 $\mu$mol/mol vs 0.25 $\mu$mol/mol M4). The results for M4/lysine incubations were quite similar (Supporting Information). Levels of furfural detected in fresh beer were in accordance with the literature.[29] Furfural increased up to 20-fold (0.26 $\pm$ 0.01 $\mu$M, fresh, vs 4.2 $\pm$ 0.2 $\mu$M, deaerated, vs 5.5 $\pm$ 0.2 $\mu$M, aerated) after thermal processing of beer, exceeding the degradation of 3-deoxypentosone (decreased by 20 to 40%) and therefore suggesting a simultaneous net increase of 3-deoxpentosone. Again in line with the mechanism shown in Figure 4, concentrations of furfural were significantly higher under aeration than deaeration and strongly suggested a major participation of Maillard mechanisms in the formation of furfural during beer aging. As counterparts of the hydrolytic $\beta$-dicarbonyl cleavage shown in Figure 4, formic acid and FP must be found in the aerated model incubations, too. Indeed, both structures were formed in higher yields under aerated conditions (4.1 vs 3.0 mmol/mol M4 and 0.89 vs 0.64 mmol/mol M4, respectively), showing almost the same ratio between deaerated and aerated conditions (Table 7). This supports the proposed parallel mechanism of formation by hydrolytic $\beta$-dicarbonyl cleavage. Interestingly, formation also occurred under deaeration, which must be explained by fragmentation of other reactive intermediates. Levels of formic acid were significantly higher than those of FP because the hydroxide ion represents a better nucleophile compared to proline. Unfortunately, the sensitivity of the formic acid enzyme assay was not sufficient for the determination in incubations at pH 5. FP levels at pH 5 were about 20 times lower compared to pH 7, nevertheless, showing the same ratio between aeration and deaeration. Formation of FP increased from Mal to M7 and displayed an increasing deviation between aerated and deaerated conditions (data not shown). Levels of FP in beer (2.98 $\pm$ 0.01 $\mu$M, fresh, vs 3.04 $\pm$ 0.04 $\mu$M, deaerated, vs 3.08 $\pm$ 0.06 $\mu$M, aerated) showed no noticeable changes during aging. Thus, FP must be primarily generated during beer production before bottling. FP was also confirmed in beer by $MS^2$ spectra (Supporting Information). The lysine analogue $N^{\varepsilon}$-formyllysine (FL) was also determined in model incubations displaying an almost similar behavior compared to FP (Supporting Information). As lysine levels in beer are very low, FL was not detectable in beer samples.[30]

**Table 7. Levels of Furfural ($\mu$mol/mol Maltotetraose), *N*-Formylproline (FP), *N*-Carboxymethylproline (CMP), and Formic Acid Concentrations (Each mmol/mol Maltotetraose) in Incubation Mixtures of Maltotetraose (M4) with Proline at pH 7 and pH 5 (7 d)**

| | pH 7 | | pH 5 | |
|---|---|---|---|---|

| CMP | 0.560 | 0.059 | 0.170 | 0.049 |

[a]na: not analyzed.

HMF was already found in relatively high amounts in nonincubated solutions of M4 and decreased during incubation. This is most likely caused by impurities of the used carbohydrates, where HMF could be generated during the preparation of the carbohydrates and then degraded during incubation. Levels of HMF detected in fresh beer were in accordance with the literature.[29] During aging, levels of HMF increased 10-fold (2.2 $\pm$ 0.1 $\mu$M, fresh, vs 19.3 $\pm$ 0.3 $\mu$M, deaerated, vs 21 $\pm$ 2 $\mu$M, aerated). As implied above, epimerization of 3-deoxyglucosone to 3-deoxygalactosone may impair the formation of HMF. Instead, the strong increase of HMF supports a high formation and degradation rate from both 3-deoxyglucosone and 3-deoxygalactosone, regardless of the presence of oxygen during thermal processing of beer.

$N^{\varepsilon}$-Carboxymethyllysine (CML) is one of the most commonly identified AGEs in foodstuffs.[31] However, analogously to FP, *N*-carboxymethylproline (CMP) must be

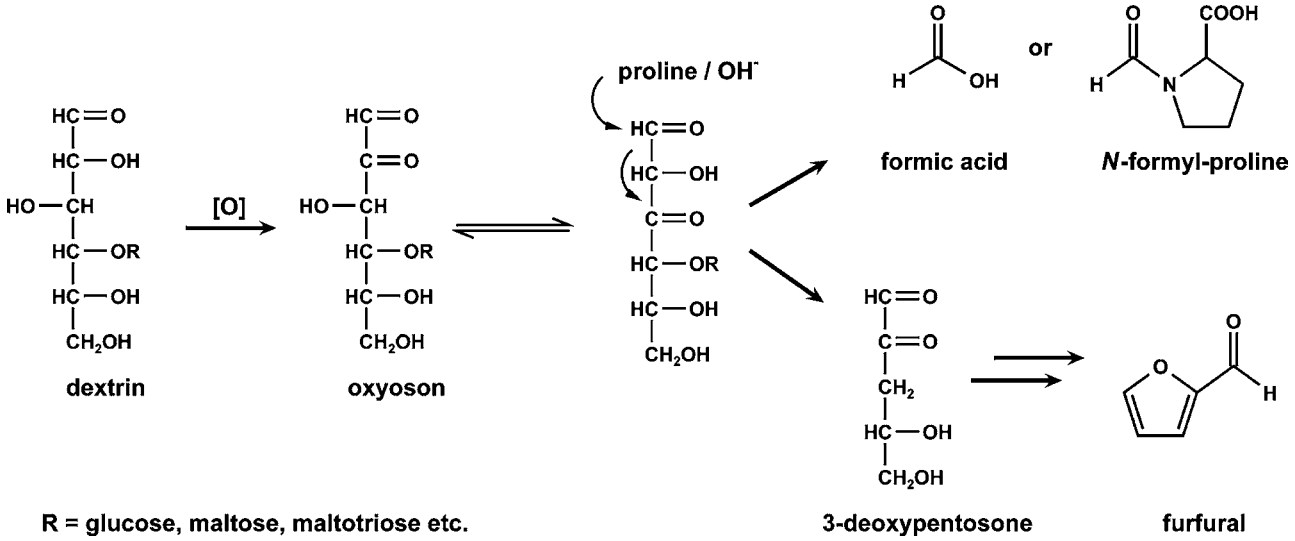

**Figure 4.** Oxidation of oligosaccharides leads to the formation of formic acid, *N*-formylproline, and 3-deoxypentosone by hydrolytic $\beta$-dicarbonyl cleavage of the oxyosone. 3-Deoxypentosone gives furfural after cyclization and dehydration.

regarded as more important in the context of beer. Similar to the formation of CML, CMP can be formed by oxidative fragmentation of the proline Amadori compound or by reaction with glyoxal and glycolaldehyde.[14,32] This was confirmed as CMP was almost exclusively generated under oxidative conditions in model incubations (0.560 vs 0.059 mmol/mol M4). At pH 5 relatively high levels of CMP were still found (0.170 vs 0.049 mmol/mol M4). In contrast to FP, the accumulation of CMP responded considerably to aging of beer and the impact of oxidative stress. CMP was also confirmed in beer by $MS^2$ spectra (Supporting Information). The results of incubations of M4 with lysine showed a very similar behavior of CML to CMP (Supporting Information). However, CML was not detectable in beer samples, reflecting again the low lysine concentrations in beer.[30]

In conclusion, we were able to identify significant changes in the formation of Maillard specific compounds involving oxygen dependent mechanisms. Dextrins were shown to be the major source for $\alpha$-dicarbonyl formation in bottled beer. As shown by the rapid formation of furfural and HMF during forced beer aging, $\alpha$-dicarbonyls are still formed at high rates at low pH values. In contrast to HMF, formation of furfural was unequivocally enhanced under oxidative conditions from dextrin degradation. The underlying mechanism of hydrolytic $\beta$-dicarbonyl cleavage also entailed the established formation of formic acid and FP. On the other hand, the formation of CMP must be attributed to the oxidative fragmentation of the proline Amadori product. In a first attempt to assess the importance of the novel proline AGEs CMP and FP, solely CMP must be recommended as a marker for oxidative stress in beer. Thus, these results will now allow a better evaluation of the chemical processes during processing and aging of beer.

| 40 | 57.60 ± 0.10a | 2.40 ± 0.10a | 7.10 ± 0.10a | 71.30 ± 1.10a |

[a]Data are expressed as means ± SD, $n = 3$, $p < 0.05$.

It was found that the C-terminus of the allene oxide synthase (AOS)−LOX fusion gene from *Anabaena* sp. PCC 7120 belonged to the LOX family.[16] Previously, we successfully cloned, expressed, and secreted an ana-rLOX from *Anabaena* sp. PCC 7120 in *Bacillus subtilis*.[17] The recombined ana-rLOX exhibited ability as a flour improver to form peroxidation radical in the presence of polyunsaturated fatty acid[12] and improve the quality of wheat flour.[10] However, the mechanism of improving the quality of wheat flour by adding ana-rLOX was not clear. Therefore, the protein component and dough properties of wheat flour were investigated by measuring their farinograph and extensograph parameters and analyzed by HPLC-MS/MS in this study.

## MATERIALS AND METHODS

**Raw Materials.** Wan 44 wheat used in this study was a medium-gluten variety bred in Anhui province of China, and it was suitable for noodle-making (protein content, 11.7%; wet gluten, 36.5%; gluten index, 75.7). Measurement methods are described in detailed in the next paragraph. These cultivars were milled into flour by using a Brabender Laboratory Mill (Brabender, Duisburg, Germany) according to the AACC-approved method 26-21A (AACC 2000).[18] The flours were stored at 4 °C until further use. Purified ana-rLOX was used in the work, and the enzyme activity was 30000 U/mg.

**Measurement of Dough Property.** The farinograph parameters of flour were measured by using a Brabender Farinograph (mixer bowl, 300 g; Brabender), according to the standard method. Ana-rLOX was added into 300 g of wheat flour (Wan 44), reaching final enzyme activities of 10, 20, 30, and 40 U/g flour, respectively. Then, these flours were mixed in the farinograph bowl at 63 rpm and 30 °C for 20 min. The parameters of water absorption and stability time were automatically exported from the farinograph device.

The extensograph parameters of flour were measured by using a Brabender extensograph. A piece of dough (150 g) was cut into a standard cylindrical shape by using the extensograph. The test piece was allowed to rest for 45 min in the extensograph rest cabinet at 30 °C. After that, the dough was stretched by the extensograph hook until rupture occurred. The characteristics were described as proposed by the extensograph, according to the standard method (AACC, 2000). Resistance to extension ($R$, mm), dough extensibility ($E$, mm), and $R/E$ values at 45, 90, and 135 min were indicated.

**Protein Extraction and Concentration Measurements.** Protein was extracted from wheat flour on the basis of its solubility using a modified Osborne procedure.[19] The protein extracts were further purified through dialysis and lyophilization and stored at 4 °C until use. Protein content was assayed by the colorimetric Bradford method using bovine serum albumin (BSA) as standard. Analyses were carried out at wavelength $\lambda$= 595 nm (UV−vis spectrophotometer (Shimadzu, UV-2450, Japan). To determine protein concentration, the standard curve based on BSA was made ($y = 0.492x$; $R^2 = 0.9966$).

**FT-IR Measurements.** An FT-IR spectrum of glutenin was collected between 4000 and 500 $cm^{-1}$(mid-infrared region) on a PerkinElmer Spectrum 100 FTIR spectrometer (Thermo Nicolet Corp., Avatar 360, USA) with 256 scans at a resolution of 4 $cm^{-1}$. The sample was ground with spectroscopic grade potassium bromide (KBr) powder and then pressed into 1 mm pellets (2 mg of sample per 200 mg dry KBr). A blank KBr disk was used as background. The FT-IR spectrum was smoothed and the baseline was corrected automatically by using the built-in software of the spectrophotometer.

**Detection of Total Proteins in the Dough by HPLC.** The total protein from 100 mg of dough was extracted stepwise three times with 1.5 mL of Tris-HCl (pH 8.5), vortexed for 2 min at room temperature, and incubated for 60 min at 40 °C with shaking. Samples were centrifuged at 10000$g$ for 3 min. Supernatants were collected, mixed all together, and filtered through a 0.45 $\mu$m nylon filter. The protein extracts were analyzed on a Waters chromatography system (600S controller, 616 pumps, and 717 autosampler) (Waters Corp., New Castle, DE, USA), controlled with Millennium software by using a procedure similar to that of Marchylo et al. Twenty microliters of the filtered extract was injected into a 300SB-$C_8$ reverse phase analytical column (4.6 × 250 mm, 5 $\mu$m particle size, 300 Å pore size; Agilent Technologies), and separation was carried out at 60 °C by using a linear gradient of aqueous acetonitrile containing 0.1% TFA at a flow rate of 1 mL/min. The acetonitrile concentration was increased from 24 to 50% over 80 min and held constant thereafter. Absorbance was monitored at 210 nm. To determine protein concentration, the standard curve based on BSA was made ($y = 0.492x$; $R^2 = 0.9966$).

**Determination of Protein Component in the Dough by MS/MS.** One hundred microliters from the HPLC fraction was vacuum concentrated (Speed Vac) to complete dryness and redissolved in 5 $\mu$L of 50% acetonitrile containing 0.1% TFA. Then, 5 $\mu$L of 100 mM ammonium hydrogen carbonate was added into the solution to optimize conditions for tryptic digestion. The proteins were reduced by adding 1.1 $\mu$L of 100 mM dithiothreitol (DTT), followed by incubation in a water bath at 60 °C for 45 min with intermittent vortex every 10 min. The reduced proteins were alkylated by adding 11.1 $\mu$L of 100 mM iodoacetamide and keeping the solution in the dark for 30 min with intermittent vortex every 10 min. The reduced and alkylated proteins were incubated with 1.5 $\mu$L of trypsin (100 ng/ul) at 37 °C for 20 h. Tryptic digests (1 $\mu$L) were deposited on a metal surface sample plate, and 160 mg/mL 2,5-dihydroxybenzoic acid (DHB) (1 $\mu$L) was added on the top with air-drying.[20] Samples were then analyzed in positive ion mode by using a MALDI with hybrid quadruple time-of-flight tandem mass spectrometry (QqToF-MS) prototype instrument constructed in collaboration with MDS SCIEX (model PBS-II, Ciphergen Biosystems Inc., Fremont, CA, USA). Peptide spectra were obtained using 600−1200 shots, whereas MS/MS spectra were obtained using 4000−6000 shots.

**Statistical Analysis.** Data were reported as means ± standard deviations (SD) for triplicate treatments. One-way analysis of variance (ANOVA) was performed using SPSS for Windows (version 10.0.5; SPSS Inc., Chicago, IL, USA).

## RESULTS AND DISCUSSION

**Effects of Ana-rLOX on the Index of a Flour's Quality Property.** The dough rheological properties are considered to predict the processing behavior and control the quality of food products. The farinograph is used to estimate the water absorption of flour, the formation time, the stability time, and the degree of softening of dough during mixing. These parameters are often used as indices to evaluate flour quality. The improvement effects of ana-rLOX on flour quality were

Table 2. Ana-rLOX Effect on Extensogram Characteristics of Wheat Dough[a]

[a]Data are expressed as means ± SD, $n$ = 3. BU, Brabender unit; ratio $R/E$, resistance/extensibility.

investigated by using the farinograph, and the results are shown in Table 1.

The water absorption of the dough was significantly increased after the addition of 30 U/g of ana-rLOX to wheat flour, reaching the maximum of 65.2%. However, the water absorption decreased when 40 U/g ana-rLOX was added to the flour. Flour water absorption is the percent of weight gain after the flour soaked in water under 30 °C. Higher water absorption reflected higher production rate. The increase of water absorption in wheat food could soften the core of the food and prolong the shelf life.[21]

The dough development time (DDT) reached the longest at 10 U/g enzyme, and then it decreased by 13% with increasing ana-rLOX to 40 U/g. For pure wheat flour, DDT reflects the total energy amount that is needed to develop the gluten network.[22] The increase in the DDT showed that the dough became a more compact gluten network. However, DDT has an effect on the productivity; therefore, longer DDT for the dough should be avoided to improve output.[23]

The dough stability time was an indicator of the strength of flour. A higher value represents a stronger dough property. The dough stability time increased from 7 to 9.5 min when ana-rLOX was added to wheat flours from 0 to 30 U/g. This showed that the addition of ana-rLOX increased the stability time of the dough. In addition, the softening degree, also called mixing tolerance index, was applied to determine the degree to which dough would soften over a period of mixing. In this study, the softening degree of dough increased with the addition of ana-rLOX and reached the maximum of 97 at 30 U/g, an increase of 31.1% compared to that without ana-rLOX. The result suggested that the gluten network was strengthened with the addition of ana-rLOX, which led to cross-linking of inter/intra-proteins of the rough. From the above result, it was found that the indices of the quality property of flour were improved and so the strength of the dough increased when a certain range of ana-rLOX was added to the flour. However, an overdose of ana-rLOX would shorten the development time and stability time and yield a poor-quality dough because overadding ana-rLOX could cause excessive cross-linking of the wheat protein and prevent the flour from absorbing water.

**Effects of Ana-rLOX on Extensograph Parameters of Flour Dough.** The extensograph measures the extensibility and resistance of dough to stretch. A higher resistance to extension indicates that the dough requires a larger force to stretch. Table 2 presents the ana-rLOX effect on the extensograph parameters of the dough at 45, 90, and 135 min of fermentation time. The extension area and maximum resistance of the dough with addition of ana-rLOX were larger than those without enzyme. The maximum resistance reached 749.0 ± 6.7 BU at 135 min, which was a 34.73% improvement as compared to no enzyme. However, the extensibility of the dough with ana-rLOX was lower than that without enzyme.

$R/E$ of the dough with ana-rLOX was larger than that without enzyme and approached around 7.0 at 135 min, which indicated that the strength of the dough was significantly improved. It is generally known that the strength of dough and its three-dimensional network depends on the arrangement and number of disulfide bonds and sulfhydryl groups of the proteins, and most of the changes in dough-mixing properties are caused by thiol−disulfide interchange reactions.[24] It has been reported that LOX reacted with the molecular oxygen and polyunsaturated fatty acids and formed the peroxides and hydroperoxides, which could oxidize the thiol groups of the proteins to form inter- and intramolecular disulfide bonds.[12] Thus, the improvement of stretching ability of the dough could be because of cross-linking between the flour proteins by ana-rLOX in the work.

**Ana-rLOX Effect on Protein Component in the Dough.** Various kinds of proteins in dough were extracted to investigate the change of quality properties of the flour by adding ana-rLOX. As shown in Figure 1, it was found that the glutenin in

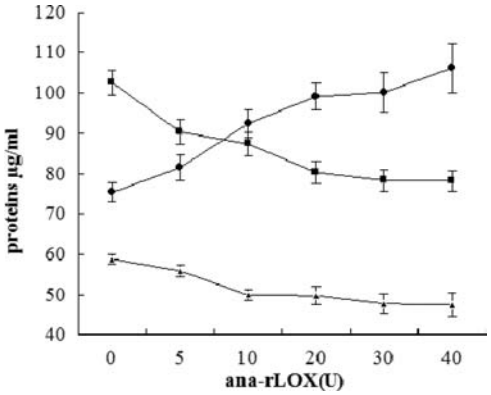

**Figure 1.** Effect of ana-rLOX on the protein component of the dough: (▲) albumin globulin; (■) gliadin; (●) gluten.

the dough was increased, whereas the levels of gliadin, albumin, and globulin were decreased, with the increase of ana-rLOX activity from 5 to 40 U/g, indicating that the protein component was changed after the addition of ana-rLOX. Part of albumin and globulin was combined with glutenin turned into glutenin copolymers; therefore, the resistance of dough was improved. The protein component of wheat flour influenced mixing and baking properties. Gliadins and glutenins were the two primary storage proteins in wheat. Glutenin shows elastic property and enhanced cohesive strength of flour dough, and gliadin exhibits a viscous property and increases the extensibility of the gluten phase.[25] This could also demonstrate that ana-rLOX could improve the rheological properties of wheat flour dough.

**Ana-rLOX Effect on FT-IR Spectroscopy of Glutenin.** FT-IR spectra of the glutenin have several bands due to

different vibrations of the peptide moiety. Amide I and amide III bands are the most frequently used to assign secondary structures of proteins. Amide I originates from C═O stretching vibration of the amide group, whereas amide III comes from C—N stretching and N—H bending.[26] In this work, the effect of ana-rLOX on the glutenin structure was evaluated through the two bands around 1660 and 1231 $cm^{-1}$ and assigned to amides I and III, respectively.

Figure2 shows that the amide I band at around 1660 $cm^{-1}$ correlated to the $\alpha$-helix conformation shifted to 1653 $cm^{-1}$,[27]

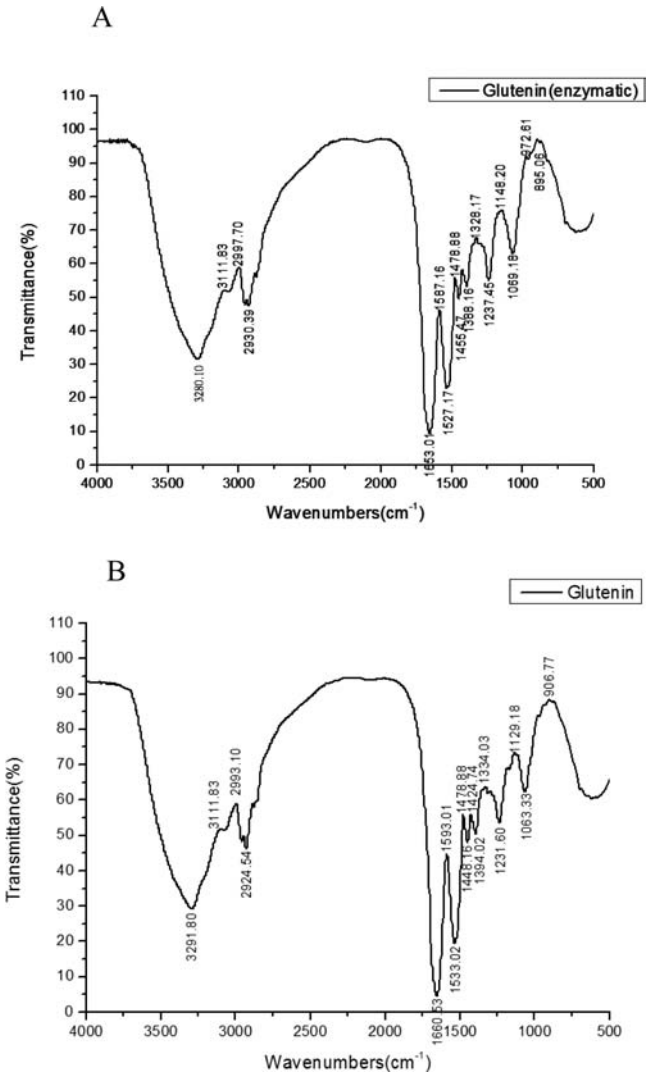

**Figure 2.** FT-IR spectra of glutenin from wheat dough before and after the addition of ana-rLOX: (A) glutenin with ana-rLOX; (B) glutenin without ana-rLOX.

indicating that the $\alpha$-helix conformation in the glutenin of the dough with ana-rLOX was decreased as compared to that without ana-rLOX. However, the amide III band (1200−1300 $cm^{-1}$) at around 1231 $cm^{-1}$ correlating to the $\beta$-sheet conformation was shifted to 1237 $cm^{-1}$,[28] which indicated that the $\beta$-sheet conformation in the dough glutenin modified by ana-rLOX tended to increase. The $\alpha$-helix conformation of the protein has a more compact and stable structure, whereas the structure of the $\beta$-sheet conformation of protein is less compact and stable.[27] Belton et al. reported that $\beta$-sheet was related to high chain mobility produced by an increase of hydration glutenin.[26] The observed result could explain the enhancement of the water absorption in wheat flour modified with ana-rLOX as being due to the increased flexibility of the glutenin molecule by the shift of amide I and III bands. A similar effect of NaCl on $\beta$-sheet conformations was observed by FT-IR in glutenin proteins.[29]

**Analysis of Protein Component of Dough Modified with Ana-rLOX by HPLC and MS/MS.** HPLC coupled with mass spectrometry is a very powerful analytical technique due to its high sensitivity and accuracy. In HPLC, the proteins are eluted according to different surface hydrophobicities. Total protein in wheat dough before and after the addition of ana-rLOX was extracted and determined by HPLC to understand the change of the protein components. Figure 3 shows that

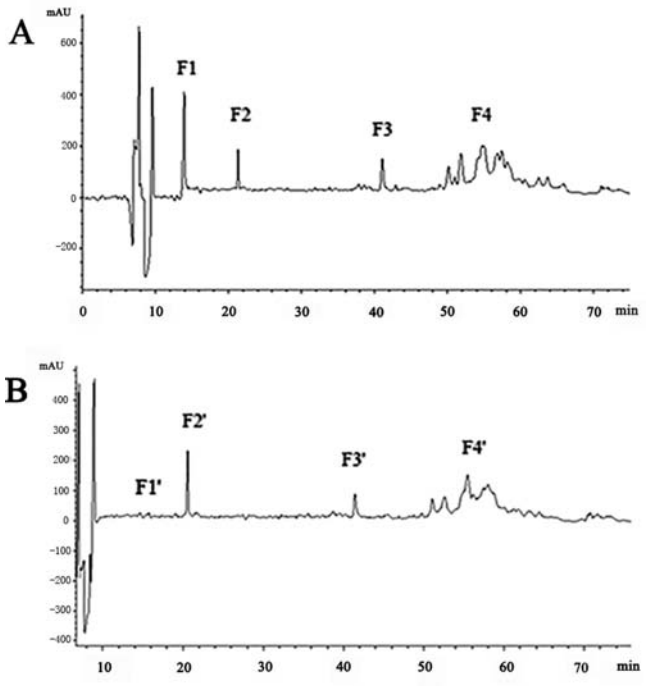

**Figure 3.** HPLC chromatograms of the protein extracts from wheat dough before and after the addition of ana-rLOX: (A) non-ana-rLOX; (B) 30 U/g ana-rLOX.

there were four protein peak regions in the dough without the addition of ana-rLOX. However, the F1 peak at 14 min was not shown in the dough with ana-rLOX, indicating that the protein component could be altered with the addition of ana-rLOX. Generally, as the elution time increased, the polarity of the substances eluted out gradually decreased in gradient elution. Thus, the protein at 14 min could be considered as a polar and hydrophilic substance, such as albumins or globins with better water solubility.

Then, each fraction was analyzed by MS/MS to determine the protein component to investigate why the protein at F1 peak did not show in the dough with ana-rLOX. The protein kinds, their molecular weights, and the characteristics of these fractions are summarized in Tables 3 and 4.

The fractions at 14 min (F1), 20 min (F2), and 55 min (F4) peaks were analyzed by MS/MS. Seventeen peptide adductions $[M + H]^+$ ($m/z$ 1189.6, 1189.6, 1064.6, 2426.1, 1360.7, 1906.0, 1822.9, 1189.6, 1012.4, 991.5, 1280.6, 1028.6, 3164.4, 1813.9, 1522.8, 1311.6, 1362.5, and 1346.5) for fraction F1 were

[a]Italic and bold indicate the occurrence in wheat proteins before and after the addition of ana-rLOX. [b]GenBank accession number. [c]Rrank of preliminary score.

Twelve peaks at $m/z$ 1966.9, 1950.9, 2652.2, 2636.2, 2652.2, 3217.5, 2651.2, 2635.2, 1425.7, 1425.7, 1320.6, and 2083.0 were assigned to the peptide adduction $[M + H]^+$ in fraction F2 at the 20 min peak. The compounds of the fraction F2 were identified as three major proteins, namely, γ-gliadin and two gliadin/avenin-like seed proteins (Table 3). However, the protein component was changed in the protein fraction F2′ by adding ana-rLOX (Table 4), and the new protein moleculed such as globulin 3A, globulin 1, and grain softness protein besides γ-gliadin and two gliadin/avenin-like seed proteins were found in fraction F2′. This observation indicated that the hydrophilic globulin could be integrated into the gliadin owing to the peroxidation radicals initialized by ana-rLOX.

In the protein fraction F4 at the 55 min peak, six of the peptides adductions ($m/z$ 1717.9, 2691.2, 2076.0, 2676.0, 2060.0, and 2060.0) were found and were identified as low-molecular-weight glutenin and GLTA-wheat glutenin from *T. aestivum*. In fraction F4′, new protein molecules, such as S48186 grain softness protein 1a, grain softness protein 1B2, and globulin 3A, were also observed. This result demonstrated that the hydrophilic protein component in wheat flour was combined into glutenin by enzymatic reaction after the addition of ana-rLOX.

The oxidative polymerization of the proteins to HMW fractions was an important prerequisite to obtain strong gluten. In our previous study, we had already observed that the flour treated with ana-rLOX improved the dough quality in terms of higher strength and tenacity, which have shown an increase of disulfide bond content because of the oxidation of free −SH groups.[17] Moreover, these results provided clear evidence that ana-rLOX from *Anabaena* sp. PCC 7120 could make globulin cross-link with gliadin and LMW glutenin, which improved the rheologcal properties of the dough. Some studies have shown that LOX affected the flour quality by inducing S−S bond formation of glutenin,[30] but this study demonstrated that ana-rLOX could make glutenin cross-link with other kinds of proteins, such as globulin-3A, globulin 1, and S48186 grain softness protein 1a, and 15K, forming HMW glutenin. These results not only provided clear evidence that ana-rLOX influenced the protein component of wheat flour but also explained the mechanism of its improving effect on the farinograph and extensograph parameters of wheat flour.

temperature (RT) with 10 times their weight of distilled water. Using a kitchen mixer, the soybean seeds were homogenized at low speed for 1 min. Soybean milk was obtained from the resulting slurry by the removal of an insoluble residue (soy pulp fiber) by filtration (FILTER-LAB qualitative filter paper, pore size 43−48 $\mu$m). The soybean milk was heated in boiling water for 15 min and then cooled to RT.

**Protein Extraction.** The three protocols used to prepare the protein extracts, one for soybean seed samples and two for the soybean milk samples, are outlined in Figure 1.

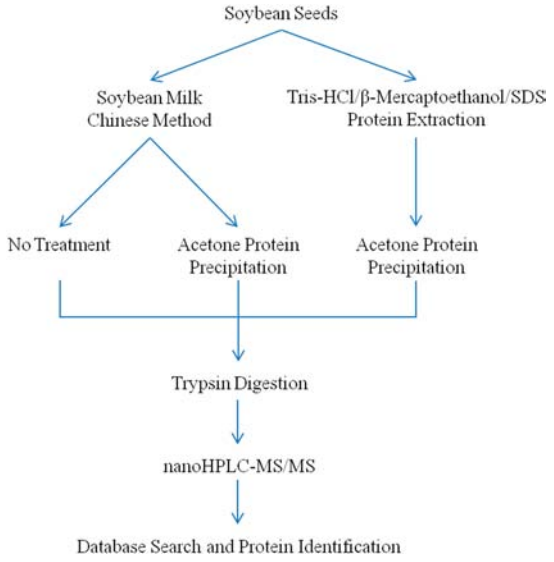

**Figure 1.** Workflow diagram for the experimental procedure.

*Extraction of Proteins from Soybean Seeds.* Soybean seeds were shortly sterilized with 70% ethanol for 10 s and then washed with distilled water three times. Dry seeds (ca. 1 g) were frozen in liquid nitrogen and ground to a fine powder in a precooled mortar with pestle. The powder (0.1 g) was defatted three times with 1 mL of petroleum ether, shaking gently and thoroughly for 15 min. Then, the proteins were extracted with 1 mL of a solution containing 50 mmol $L^{-1}$ Tris-HCl pH 8.8, 1.5 mmol $L^{-1}$ KCl, 0.07% $\beta$-mercaptoethanol, 1% protease inhibitor cocktail, and 1% (w/v) sodium dodecyl sulfate (SDS). The samples were incubated on ice for 1 h with intermittent mixing with vortex (1 min) every 15 min, and insoluble materials were removed by centrifugation at 4 °C for 15 min at 11 000*g*. The supernatant was transferred to a new centrifuge tube, four volumes of cold acetone with 0.07% (*v*/*v*) $\beta$-mercaptoethanol were added, and then the sample was mixed thoroughly and incubated at −20 °C overnight. The precipitate was collected by centrifugation (18 400*g* for 15 min at 4 °C), washed three times with acetone containing 0.07% (v/v) $\beta$-mercaptoethanol, air-dried, and solubilized in urea buffer pH 8.5 (8 mol $L^{-1}$ urea in 50 mmol $L^{-1}$ $NH_4HCO_3$). The proteins were quantified by Bradford assay using BSA standard[17] and stored at −80 °C until the trypsin digestion. Three experimental replicates were performed.

*Proteins from Soybean Milk without Any Treatment.* From a 10 mL aliquot of soybean milk, prepared as described above, the proteins were directly quantified by Bradford assay using BSA standard[17] and stored at −80 °C until further processing.

*Acetone Precipitation of Proteins from Soybean Milk.* The soybean milk (10 mL) was placed in acetone-compatible tube, and four volumes of cold (−20 °C) acetone with 0.07% (v/v) $\beta$-mercaptoethanol were added. The tube was vortex-mixed and incubated overnight at −20 °C. The precipitated proteins from soybean milk were collected by centrifugation (18 400*g* for 15 min at 4 °C), washed three times with acetone containing 0.07% (v/v) $\beta$-mercaptoethanol, air-dried, and solubilized in urea buffer pH 8.5 (8 mol $L^{-1}$ urea in 50 mmol $L^{-1}$ $NH_4HCO_3$). The protein content was quantified by Bradford assay using BSA standard[17] and stored at −80 °C until the trypsin digestion. Three experimental replicates were performed.

**Enzymatic Digestion and Off-Line Desalting.** Aliquots from soybean seed samples, soybean milk samples, and precipitated proteins from soybean milk samples were reduced, alkylated, and digested with trypsin. For the digestion of the proteins from soybean milk without any treatment, we added urea to the soybean milk to reach a 8 mol $L^{-1}$ concentration in order to denature the proteins. Reduction of disulfide bonds was performed with dithiothreitol (DTT, 200 mmol $L^{-1}$) in incubation at 37 °C for 1 h, under slight agitation. Carbamidomethylation of thiol groups was performed by addition of iodoacetamide (IAA, 200 mmol $L^{-1}$) and incubation for 1 h in the dark at RT. To consume any leftover alkylating agent and to avoid trypsin alkylation, DTT (200 mmol $L^{-1}$) was added, and samples were incubated at 37 °C for 1 h, under slight agitation. The samples were then diluted with $NH_4HCO_3$, pH 8.5 (50 mmol $L^{-1}$) to obtain a final 1 mol $L^{-1}$ urea concentration. Sequencing-grade modified tryspin was added (1:20, w/w, enzyme to protein ratio), and the samples were incubated overnight at 37 °C. Enzymatic digestion was quenched with trifluoroacetic acid (TFA). Digested samples were desalted using SPE C18 cartridges conditioned with ACN and rinsed with 0.1% TFA aqueous solution. Peptides were eluted from the SPE column with ACN/dd$H_2O$ (50/50, v/v) containing 0.05% TFA, and were dried in a Speed-Vac SC 250 Express (Thermo S 164 avant, Holbrook, NY, U.S.A.). Each sample was reconstituted with 0.1% HCOOH aqueous solution and stored at −80 °C until analysis.

**NanoHPLC-MS/MS Analysis.** Nano high-performance liquid chromatography (nanoHPLC) coupled to tandem mass spectrometry (MS/MS) analysis was performed on a hybrid linear ion trap-Orbitrap mass spectrometer (model Orbitrap Elite, Thermo Scientific, Bremen, Germany) equipped with a nanoelectrospray ion source. Peptide mixtures were separated by reversed-phase (RP) chromatography using the Dionex Ultimate 3000 (Dionex Corporation Sunnyvale, CA, U.S.A.). The LC system was connected to a manufactured 25 cm fused-silica nanocolumn, 75 $\mu$m i.d., packed in-house with Acclaim-C18 2.2 $\mu$m silica microparticles, with outlet frit prepared using Kasil. Peptide mixtures were enriched on a 300 $\mu$m i.d. × 5 mm Acclaim PepMap 100 C18 (5 $\mu$m particle size, 100 Å pore size) precolumn (Dionex), employing a premixed mobile phase $H_2O$/ACN 98:2 (v/v) (from loading pump) containing 0.1% (v/v) HCOOH at a flow-rate of 10 $\mu$L $min^{-1}$. LC gradient was optimized to detect the largest set of peptides, using $H_2O$/HCOOH (99.9:0.1, v/v) as mobile phase A and ACN/HCOOH (99.9:0.1, v/v) as mobile phase B. After an isocratic step at 1% B for 5 min, B was linearly increased to 11% within 2 min and then to 31% within 120 min; afterward, phase B was maintained at 31% within 10 min, and increased to 80% within the following 10 min. Then, phase B was maintained at 80% for 10 min to rinse the column. Finally, B was lowered to 1% over 1 min and the column re-equilibrated for 22 min (180 min total

run time). MS spectra of tryptic digests were collected over an $m/z$ range of 380−2000, using a resolution setting of 60 000 (full width at half-maximum, fwhm, at $m/z$ 400), operating in the data-dependent mode to automatically switch between Orbitrap-MS and linear ion trap-MS/MS acquisition. MS/MS spectra were collected for the 20 most abundant ions in each MS scan. Rejection of +1, and unassigned charge states was enabled. All MS/MS spectra were collected using normalized collision energy of 30%, and an isolation window of 2 $m/z$. Ion trap and Orbitrap maximum ion injection times were set to 100 and 200 ms, respectively. Automatic gain control (AGC) was used to prevent overfilling of the ion traps and was set to $1 \times 10^6$ for full FTMS scan, and $1 \times 10^4$ ions in $MS^n$ mode for the linear ion trap. To minimize redundant spectral acquisitions, dynamic exclusion was enabled with a repeat count of 1 and a repeat duration of 30 s with exclusion duration of 70 s. In order to increase the number of identified peptides/proteins, we performed three technical replicates (nanoHPLC-MS/MS runs) for each of the three experimental replicates.

**Database Searching and Protein Identification.** Raw MS/MS data files from Xcalibur software (version 2.2 SP1.48, Thermo Fisher Scientific) were submitted to Proteome Discoverer software (version 1.3, Thermo Scientific) with the Mascot (v.2.3.2, Matrix Science) search engine for peptide/protein identification. The searches were performed against Swiss-Prot database (Release 01-2014, 541 954 sequences). The search was limited to proteins from species of the *Other Green Plants* (18 092 sequences) taxonomy entries and performed using the built-in decoy search option of Mascot. Enzymatic digestion with trypsin was selected, together with maximum of 2 missed cleavages, peptide charges from +2 to +5, a precursor mass tolerance of 10 ppm and a fragment mass tolerance of 0.8 Da; acetylation (N-term), oxidation (M), and deamidation (N, Q) were used as dynamic modifications, whereas carbamidomethylation (C) was used as static modification.

**Scaffold Analysis.** Scaffold software (version Scaffold 3.4.3, Proteome Software Inc., Portland, OR, U.S.A.)[18] was used to validate MS/MS based peptide and protein identification. The additional X! Tandem search engine (The GPM, Cyclone version 2010.12.01.1) was also used, keeping the same parameters previously used for Mascot. According to the Peptide and Protein Prophet algorithms[19,20] implemented into Scaffold, identifications were accepted if they could be established at a probability greater than 95% and 99% for proteins and peptides, respectively, and if proteins contained at least 2 unique peptides, resulting in a false discovery rate of 0.02% for peptides and 2.1% for proteins. Proteins that contained similar peptides and could not be differentiated on the basis of MS/MS analysis alone were grouped to satisfy the principles of parsimony.

## RESULTS AND DISCUSSION

**Design of the Experiment and Proteomic Approach.** The objective of this study was to characterize the protein profile of mature seeds of soybean and soybean milk obtained from the seeds themselves using the Chinese method. Furthermore, precipitation with acetone was also evaluated in order to assess whether the protein precipitation of soybean milk could improve the subsequent nanoHPLC-MS/MS analysis and the identification of proteins. Therefore, a shotgun proteomic approach was employed. The proteins extracted from the mature soybean seeds, the proteins of the soybean milk and those obtained from soybean milk by precipitation with acetone were digested with trypsin, and the resulting peptides were characterized using nanoHPLC-MS/MS analysis and database search. Figure 1 shows a workflow diagram for the experimental procedures.

**Proteins Identified in Mature Soybean Seeds and Soybean Milk.** This is the first study reporting the comparison of protein profiles of mature soybean seed and soybean milk by a shotgun proteomic approach. The analysis of the protein profile of the three systems under investigation led to the identification of 209 proteins in seeds, 200 in milk, and 183 in precipitated soybean milk. Figure 2 shows a Venn diagram in which the protein profiles of the three systems investigated are compared. From a first analysis, the protein profiles of the three systems apparently showed some differences. The Venn diagram shows 19 unique proteins for the seeds, 15 unique proteins for the soybean milk, and 13 unique proteins for the precipitated soybean milk. These differences are, however, misleading. The milk samples, and in particular the precipitated milk samples, cannot present unique proteins, because they derive from the same seeds, the proteome of which was also characterized (see Supporting Information file). Thus, the unique proteins identified for the milk and the precipitated milk samples are to be ascribed to the three different approaches for obtaining the protein samples and to the statistical variability of the LC-MS/MS experiments.

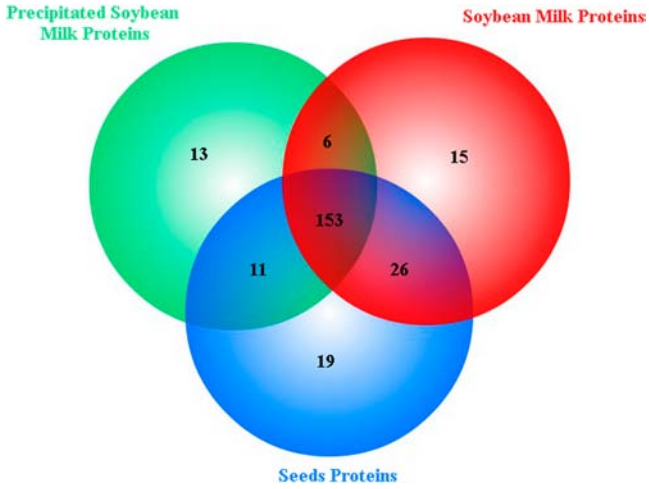

**Figure 2.** Venn diagram of the differentially identified proteins in soybean seeds, soybean milk, and precipitated soybean milk.

Proteins extracted from the mature soybean seeds were obtained with a standard extraction procedure, which requires the use of specific reagents (Tris-HCl, KCl, $\beta$-mercaptoethanol, protease inhibitor cocktail, and SDS) and a precipitation step with acetone (Figure 1); on the contrary, the soybean milk proteins were obtained with a simple but effective extraction from the aqueous phase at RT (Figure 1). In our opinion, the two protein extraction methods provide comparable results; the few differences exhibited by protein profiles (unique proteins) are due to the statistical variability of the experiments. Indeed, small changes in the signal intensity of a peptide (especially if present at low concentration) affect its selection for MS/MS spectrum acquisition, which can therefore be different between different LC-MS experiments. The quality of the MS/MS experiments can also vary, leading to successful identification in some cases but not in others.[21] Therefore, this shotgun

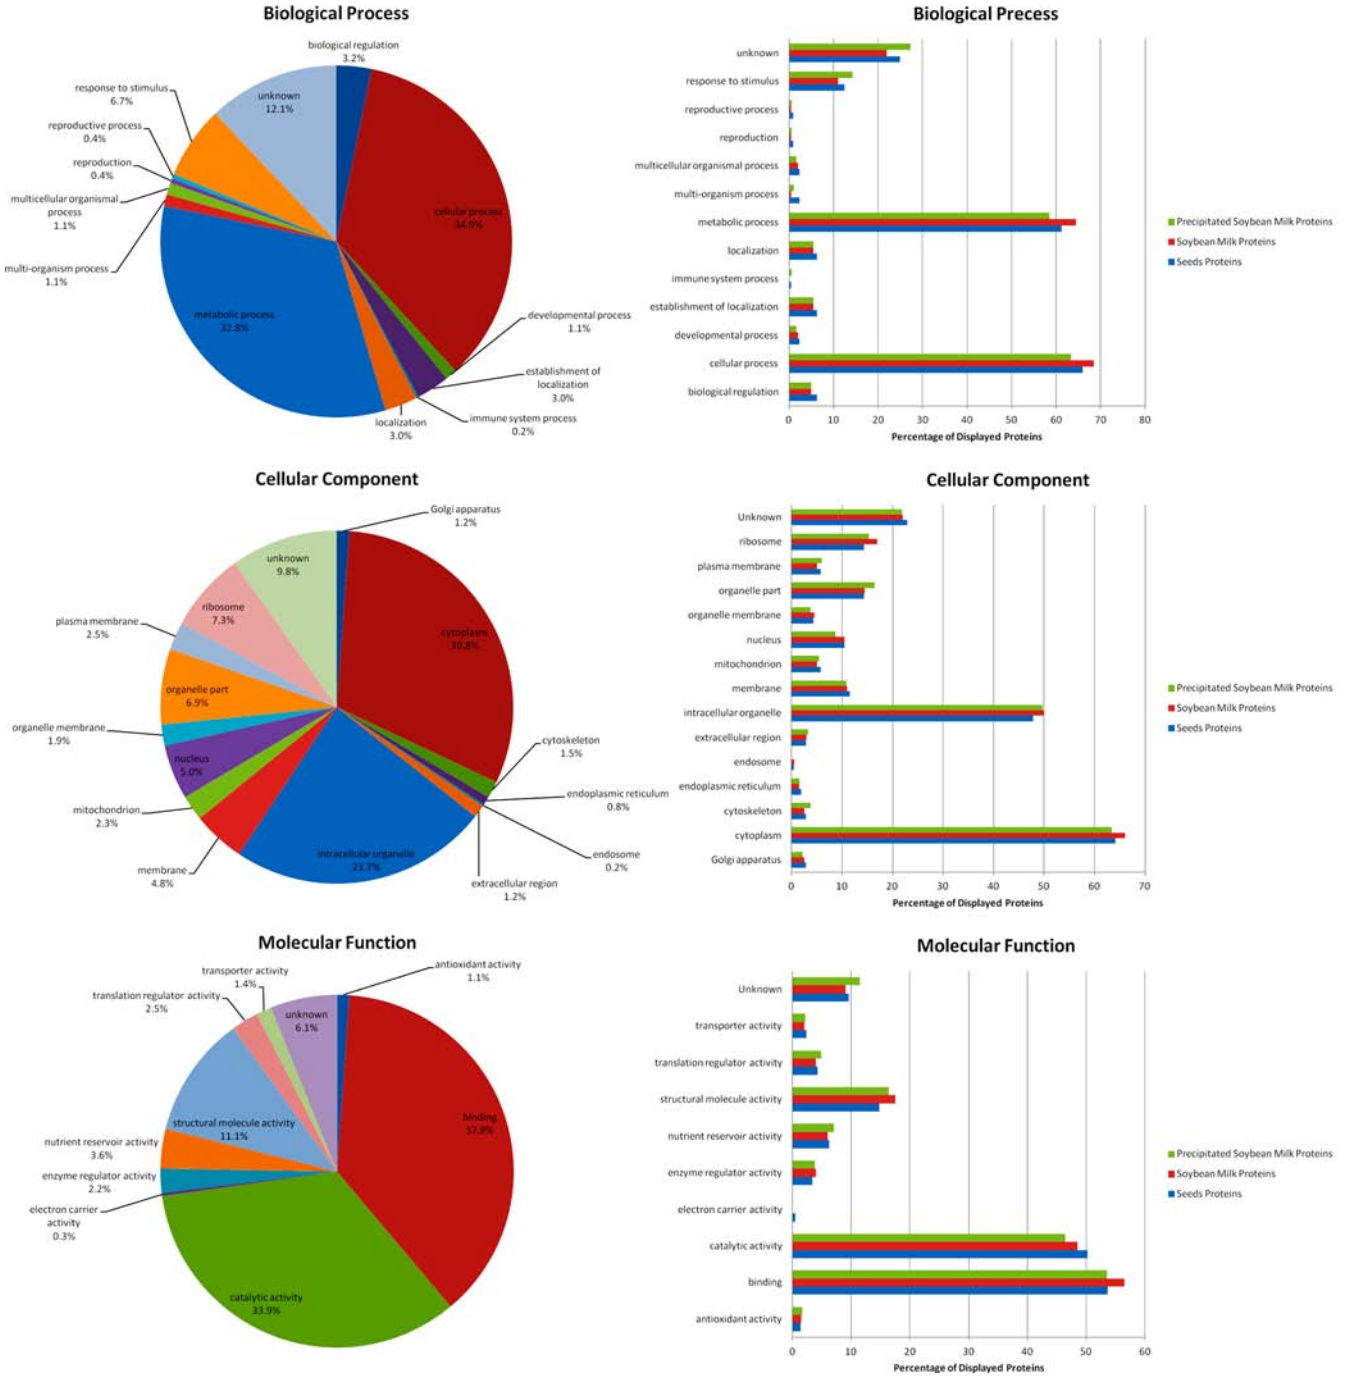

**Figure 3.** Gene Ontology annotation according to biological process, cellular component, and molecular function of the 243 nonredundant identified proteins and relative distribution of the seed proteins, soybean proteins, and precipitated soybean milk proteins.

proteomics analysis showed substantial equivalence of the soluble protein composition in mature soybean seeds and prepared soybean milk.

The largest differences presented by the third system (precipitated soybean milk) compared to the other two (Figure 2) are mainly due to the different procedure by which the proteins were obtained (i.e., the precipitation from soybean milk with acetone).

Precipitation is frequently used to concentrate proteins and to remove interfering compounds which could be responsible for irreproducible results. This is the case, for example, of most agriculturally interesting species, where the precipitation step is necessary to remove secondary metabolite compounds, which are present in large amounts. The precipitation with acetone or, even more significantly, the precipitation with acetone/TCA definitely improve the results obtained by two-dimensional polyacrylamide gel electrophoresis (2D-PAGE) analysis because it allows a better resolution.[14] However, in the shotgun proteomics approach, the precipitation leads to a loss of information, i.e. a smaller number of identified proteins (Figure 2). Our study showed that the prepared soybean milk, which contains sugars, lipids, and secondary metabolic compounds over proteins, can be analyzed by the shotgun proteomics approach directly, without any precipitation step with acetone.

dx.doi.org/10.1021/jf5034152 | J. Agric. Food Chem. 2014, 62, 9893−9899

The protein profile of the mature soybean seeds provided in this study is the most comprehensive one to the authors' best knowledge. Ten years ago, two studies based on 2D-PAGE, which is an extremely time-consuming technique, were published on the proteomic analysis of mature soybean seeds; Herman et al.[11] identified 111 protein spots, and Mooney et al.[13] identified 44 protein spots. A more recent study, based on nanoUPLC-MS$^E$ technique,[22] identified 113 proteins; Gomes et al.[15] identified 117 proteins with one-dimensional gel electrophoresis followed by MS and MS/MS analysis. Our results far exceed the low number of proteins identified in these previous works and provide additional identifications for the proteins present at low amounts in addition to those particularly abundant, such as the seed storage proteins. However, recently, Miernyck et al.[23] reported the identification of proteins in different stages of maturation only in the testa from developing soybean seeds. In almost every maturation stage Miernyck et al.[23] identified a larger number of proteins then the one obtained from the proteomic analysis of the whole mature soybean seed. This difference can be explained by several reasons: (i) In the mature whole seeds, 70−80% of the protein content is made up of storage proteins, which are highly abundant and thus hinder the detection of the lower abundance proteins, (ii) although in this work, a specific database for *Glycine max* was not employed; SwissProt was used, instead, because it is a high quality, curated, annotated, and non-redundant protein sequence database. Despite this, our results (243 identified proteins) are not excessively lower than the ones reported by Miernyck et al.[23] for the last stages of development of the testa (193 identified proteins in S8 and 272 identified proteins in S9).

This study demonstrated that a shotgun proteomics approach with in solution digestion is not sensitive to the presence of lipids, saccharides, and secondary metabolites that are in the soybean milk. Vice versa, a 2D-PAGE analysis would have been sensitive to the presence of contaminants of any nature and therefore requires a precipitation step that improves the resolution and reproducibility of the gels but leads to loss of information, with fewer identified proteins.

**Protein Classification.** In the present study, a total of 243 nonredundant proteins was identified (Figure 2). However, 161 proteins were annotated with a taxonomy other than *Glycine max*, like *Nicotiana tabacum*, *Pisum sativum*, or *Zea mays*. This could be ascribed to the fact that soybean is a newly sequenced species and several proteins are still not annotated in SwissProt. Consequently, we blasted all the proteins in the entire UniProtKB database, filtering the results by *Glycine max* only. All the blast searches gave good results (the majority with more than 85% of identity and maximal E-values of $10^{-18}$) with proteins of soybean present only in TrEMBL section (see Supporting Information, Tab: BLAST).

The identified proteins were classified by the Gene Ontology (GO) terms in three broader domains: biological process, cellular component, and molecular function, and according to the Scaffold's system, each protein displayed in the samples may have one or many GO terms (Figure 3). With regard to the molecular function domain, the two most represented categories are binding and catalytic activity, with a large number of proteins belonging to both categories. This finding is in agreement with the classification based on the biological process, where the two most represented categories are cellular process and metabolic process, and also in this case many proteins belong to both categories. These proteins are often referred to as "housekeeping" proteins, which are essential for the maintenance of normal cell metabolism and involved in seed development, and some of these proteins are enzymes or enzyme inhibitors. The housekeeping protein fraction is made up of relatively small amounts of numerous protein species.

The other important category of proteins in molecular function domain is nutrient reservoir activity (Figure 3), better known as storage proteins. The two major seed storage proteins from soybean are multimeric with Svedberg coefficients of 7S and 11S. The 7S globulins are composed of $\beta$-conglycinin subunits, whereas 11S globulins are composed of glycinin proteins.[24−26] The storage proteins account for the major part of the seed proteins, 70−83% of the total proteins in terms of abundance, and are represented by relatively few different species of proteins. The main characteristics of seed storage proteins are that (i) they accumulate in seeds in large quantities, (ii) they are tissue-specific and occur only in the seed, (iii) they are synthesized during seed development, (iv) they are often sequestered in membrane-bound organelles (protein bodies), and (v) they are hydrolyzed to release their constituent amino acids during germination.

There are several housekeeping proteins, but they are present in a small amount; vice versa, the storage proteins comprise only few proteins, but they are present in a large amount, as confirmed by MS/MS data (Supporting Information). Indeed, the storage proteins showed high values of spectral counts, whereas the housekeeping proteins showed low values of spectral counts.

Liu et al.[27] demonstrated a linear relationship between the spectral count and the relative protein abundance over a dynamic range of 2 orders of magnitude. The spectral counting method relies on the simple concept that an increase in protein abundance can increase the number of its detectable proteolytic peptides (i.e., the total number of MS/MS spectra that are acquired for that peptide).

With regard to domain cellular component, the two most represented categories are cytoplasm and intracellular organelle. This result confirms that most of the seed proteins are storage proteins. Storage proteins primarily accumulate in the protein storage vacuoles of terminally differentiated cells of the embryo and endosperm and as protein bodies (PBs) directly assembled within the endoplasmic reticulum.

PBs form as a consequence of developmentally regulated events that induce storage protein synthesis in specialized cells and promote storage protein accumulation in specific organelles. Storage proteins may remain in the endoplasmic reticulum or be transported through the endomembrane system to distal sites. The major seed vacuolar storage proteins, (i.e., 7S and 11S globulins) form dimers, trimers, and tetramers in the endoplasmic reticulum lumen shortly after synthesis.

Figure 3 shows that the relative distribution of the seed proteins, soybean proteins and precipitated soybean milk proteins, on the basis of GO classification, is substantially equivalent.

**Identified Allergens in Soybean.** The soybean, a legume of high nutritional value, is also known to be one of the major allergenic foods. Identification and characterization of specific protein components linked to soybean allergy has been the focus of several studies. The results of these investigations have shown that a heterogeneous group of proteins are IgE-binding and are potential allergens. In the present study, some of the proteins already described as allergens were found (Table 1).

**Table 1. Identified Allergens in Soybean**

| no. | identified proteins | entry name |
|---|---|---|
| 1 | hydrophobic seed protein | HPSE_SOYBN |
| 2 | profilin 1[a] | PROF1_SOYBN |
| 3 | profilin 2[a] | PROF2_SOYBN |
| 4 | stress-induced protein SAM22 | SAM22_SOYBN |
| 5 | beta-conglycinin, alpha chain | GLCA_SOYBN |
| 6 | 34 kDa maturing seed protein | P34_SOYBN |
| 7 | glycinin | GLYG5_SOYBN |
| 8 | 2S albumin | 2SS_SOYBN |
| 9 | lectin (agglutinin) | LEC_SOYBN |
| 10 | trypsin inhibitor A | ITRA_SOYBN |

[a]Profilin was found with only one unique peptide and thus is not reported in the Supporting Information file.

The hydrophobic seed proteins are a group of proteins with low molecular weight which belong to the lipid transfer proteins (LTP) family,[28] the role of which is to transport the phospholipids from liposomes to mitochondria. It has been observed that these proteins are responsible for soybean epidemic asthma,[29] but they are not responsible for asthma that affects the workers of intermediate products of the soybean, which is instead due to proteins at higher molecular weight.[30]

Profilin 1 and profilin 2 are proteins involved in the growth process of actin microfilaments and belong to a group of structural and metabolic proteins. The sequences that are capable of binding to IgE are maintained in all the proteins belonging to the family of profilin. They are the main cause of the allergic response to pollen. Rihs et al.[31] have shown that the ability of profilin to bind IgE depends on the structural and conformational integrity.

Stress-induced protein SAM22 belongs to the BetVI family. It is involved in defense response of the plant. This protein is the leading cause of allergy to soybean in patients with birch pollinosis. Mittag et al.,[32] through a clinical investigation, revealed that 96% of patients reacting to *Bet v* 1 have also *Glym* 4-specific IgE and that 64% of them recognized other soybean proteins.

Beta-conglycinin is a seed storage glycoprotein which is accumulated during the seed growth and stored in order to be later hydrolyzed and used as a source of carbon and nitrogen atoms for the plant. The alpha-subunit of beta-conglycinin is responsible for the allergic response.[33]

The 34 kDa maturing seed protein, also known as P34, is considered a major allergenic protein of soybean seeds.[34] It belongs to the peptidase C1 family and is involved in the hydrolysis of peptide bonds by a mechanism in which the sulfide group of an amino acid residue of the protein behaves as a nucleophile.

Glycinin is the most widespread storage protein in soybean, as well as one of the major allergens. The glycinin belongs to the globulins family, and as the Beta-conglycinin, each subunit is composed of an acidic and a basic chain. Pedersen et al.[35] reported IgE-binding to all of the native acidic subunits of glycinin but little or none to the basic subunits.

2S albumin is also a storage protein, but it belongs to the 2S seed storage albumins family and is formed by two chains linked by a disulfide bridge. As LTP, it is classified in the prolamin superfamily having a similar structure of alpha helices. The allergenicity of this protein also depends on this similarity.

Lectin is a protein found in the seeds of plants, mainly of leguminous plants. It is formed by four subunits, 30 kDa each, and it is able to bind sugars. It is involved in carbohydrate recognition by a virus membrane and plays an important role in the immune system of plants. Barnett et al.[36] have investigated the possible role of lectin binding of IgE in RAST of legume and wheat extracts. They reported that there was significant immune binding of some of the lectins by specific IgE, and they concluded that these lectins may be important in expression of IgE-mediated allergic responses.

Trypsin inhibitor A belongs to the protease inhibitor I3 (leguminous Kunitz-type inhibitor) family, and it has endopeptidase and protease inhibitor activity. This protein is part of the defense system of the plant. Hypersensitivity to trypsin inhibitor is also documented by inhalation and was reported for the first time on soybean mill workers. Quirce et al.[37] have shown a relationship between a skin and a bronchial response to purified soybean KTI and work-related asthma in two bakers who were occupationally exposed to soybean flour.

Despite their well-documented allergenicity, soybean derivatives continue to be increasingly used in a variety of food products due to their well-documented health benefits. In this context, the knowledge of the protein profile of the soybean milk becomes important for a conscious consumption. We believe that proteomics should be considered a powerful tool in the functional characterization of the proteome as well as in the assessment of food safety. Indeed proteomic analysis could help to define specific allergenic proteins present in complex matrices, such as soybean seeds or soybean milk.

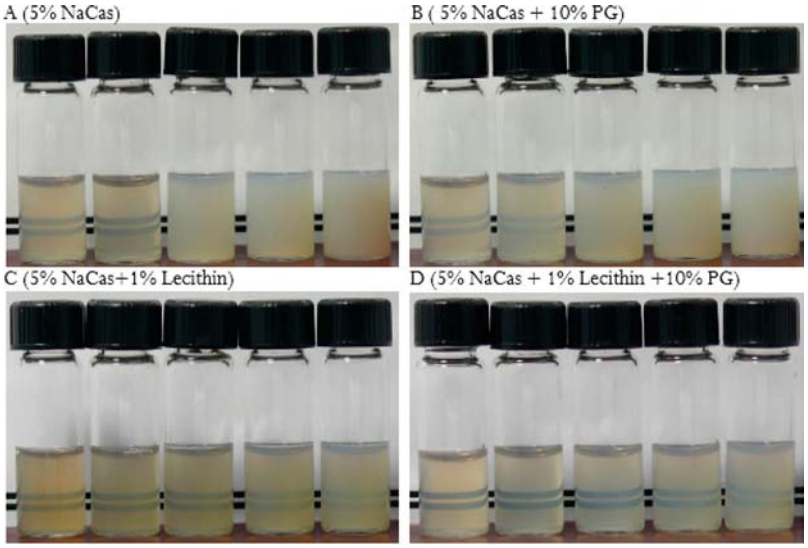

**Figure 1.** Appearance of thyme oil nanoemulsions prepared with various combinations of 5% w/v NaCas, 10% v/v PG, and 1% w/v lecithin. Thyme oil concentration in each image is 0.5, 1.0, 1.5, 2.0, and 2.5% w/v from left to right.

**Preparation of Emulsions.** NaCas was hydrated at 5% w/v in deionized water overnight at room temperature (21 °C). Four sets of thyme oil emulsions were prepared. In the first set, different amounts of thyme oil (0.5, 1.0, 1.5, 2.0, and 2.5% w/v) were directly emulsified in 10 mL of NaCas solution (9 mL of 5% NaCas and 1 mL of deionized water) at 15,000 rpm for 3 min using a model Cyclone I.Q.$^2$ microprocessor homogenizer (The VirTis Company, Inc., Gardiner, NY). In the second set, same amounts of thyme oil were dissolved in 1 mL of PG, which was then mixed with 9 mL of the 5% w/v NaCas solution and emulsified as above. In the third set, 0.1 g of lecithin was added into 9 mL of the 5% w/v NaCas solution, vortexed for 30 min, and then mixed with thyme oil and homogenized as in the first set. In the fourth set, lecithin was mixed with the NaCas solution as in the third set, and thyme oil predissolved in PG was homogenized as in the second set. Emulsions as prepared in the fourth set were also studied for NaCas (2.5% and 5% w/v) and lecithin (0, 0.5, and 1.0% w/v) concentrations in the aqueous phase.

**Turbidity.** The absorbance of thyme oil emulsions was measured at 600 nm ($Abs_{600}$) as an indicator of turbidity using a UV−vis spectrophotometer (model Biomate 5, Thermo Electron Corp., Woburn, MA).

**Particle Size and Zeta Potential Measurements.** The dynamic light scattering experiments were conducted using a Delas Nano-Zeta Potential and submicron particle size analyzer (Beckman Coulter, Inc., Brea, CA). The emulsion samples were diluted 20 times in 0.01 M phosphate-buffered saline (PBS, pH 7) at ambient temperature prior to analysis. The zeta potentials of thyme oil emulsions were measured using the same instrument for samples diluted 100 times in deionized water and adjusted to pH 7.0. Two emulsion replicates were tested three times each.

**Atomic Force Microscopy (AFM).** The morphology of thyme oil emulsions was characterized using a Multimode VIII microscope (Bruker Corp., Santa Barbara, CA). Emulsions containing 1% thyme oil prepared with NaCas and lecithin were diluted $10^5$ times using 0.01 M PBS at pH 7. Four microliters of each sample was spread evenly onto a freshly cleaved mica sheet that was mounted on a sample disk (Bruker Corp., Santa Barbara, CA) and air-dried for >2 h. The samples were scanned using a rectangular cantilever probe (Bruker Nanoprobe, Camarillo, CA) with aluminum reflective coating on the back side and a quoted force constant of 2.80 N/m. The topography images were collected at the tapping mode.

**Quantification of Protein Surface Load.** The amount of NaCas on thyme oil droplet surface was quantified to investigate the effect of lecithin on surface adsorption of NaCas. To facilitate the separation of oil droplets, an excess amount (10% w/v) of thyme oil was directly emulsified in the aqueous phase with various combinations of NaCas (0, 2.5, and 5% w/v) and lecithin (0, 0.5, and 1.0% w/v). Particle sizes were measured right after homogenization and after storage at room temperature (21 °C) for 15 days. Emulsions before and after storage were centrifuged at 12550*g* for 60 min using an Eppendorf MiniSpin plus centrifuge (Hamburg, Germany). The bottom aqueous phase was filtrated through a 0.22 $\mu$m polyvinyl difluoride membrane filter. To minimize the interference of thyme oil compounds such as thymol on protein assay, 50 $\mu$L of the permeate was mixed with 500 $\mu$L of an acetone−hexane (1:1, v:v) mixture[29] to extract thyme oil and precipitate protein. After vigorous mixing and centrifugation at 6700*g* for 10 min, the supernatant (organic phase) was discarded, and the bottom protein precipitate was redissolved in 600 $\mu$L of 100 mM NaOH and was quantified using the bicinchoninic acid (BCA) method (Thermo Fisher Scientific Inc., Morris Plains, NJ). NaCas was used as a reference protein in the BCA assay. The surface load ($\Gamma_s$, mg/m$^2$) of protein and the volume−area ($d_{3,2}$) mean diameters were calculated using eq 1 and 2, respectively.

$$\Gamma_s = \frac{M_s d_{3,2}}{6V_{oil}} \quad (1)$$

where $M_s$ is the mass of NaCas adsorbed on oil droplets, and $V_{oil}$ is the volume of thyme oil. The thymol oil density used in calculation was 0.932 g/mL.[30]

$$d_{3,2} = \frac{\sum_{i=1} n_i d_i^3}{\sum_{i=1} n_i d_i^2} \quad (2)$$

where $d_i$ is the diameter of the $i$th group of droplets and $n_i$ is the corresponding number of droplets.

**Statistical Analysis.** Two independent emulsion replicates were studied throughout. Analysis of variance (ANOVA) testing was conducted using the SPSS 16.0 statistical analysis system (SPSS Inc., Chicago, IL). The least significant difference (LSD) test was used to determine the significant difference of mean values at a $P$ level of 0.05.

## RESULTS AND DISCUSSION

**Turbidity of Emulsions.** Photographs of thyme oil emulsions prepared with various combinations of 5% w/v NaCas, 1% w/v lecithin, and 10% v/v PG are shown in Figure 1. The treatments with 5% w/v NaCas alone and its combination with 10% v/v PG were only capable of emulsifying 1.0% w/v thyme oil as transparent or translucent dispersions. In comparison, after addition of 1% w/v lecithin, emulsions with

dx.doi.org/10.1021/jf5034366 | J. Agric. Food Chem. 2014, 62, 9900−9907

up to 2.5% w/v thyme oil were translucent when prepared with 5% w/v NaCas, and the clarity further improved with 10% v/v PG. The appearance generally agreed with the $Abs_{600}$ (Figure 2). Since PG is fully miscible with water, predissolving thyme

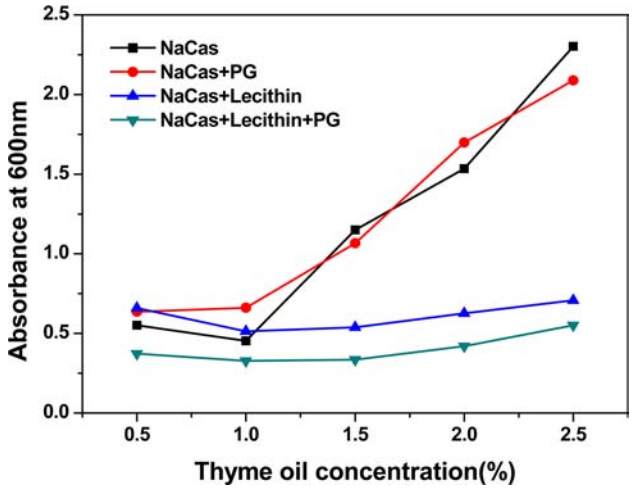

**Figure 2.** Absorbance at 600 nm of nanoemulsions with 0.5−2.5% w/v thyme oil prepared with various combinations of 5% w/v NaCas, 10% v/v PG, and 1% w/v lecithin.

oil in PG before emulsification likely reduces the oil/water interfacial tension, which is a main mechanism of cosurfactants facilitating the formation of nanoemulsions.[31] Furthermore, PG had no significant impact on emulsion formation by NaCas but facilitated emulsion formation for the NaCas−lecithin blend. This is likely due to the impacts on solubility of surfactants: NaCas is water-soluble, while lecithin (phosphatidylcholines) is not.

Subsequently, two concentrations (1.0 and 2.0% w/v) of thyme oil were emulsified using various combinations of NaCas (2.5% w/v) and lecithin (0.5 or 1% w/v) concentrations. Photographs are shown in Figure 3, while the $Abs_{600}$ is

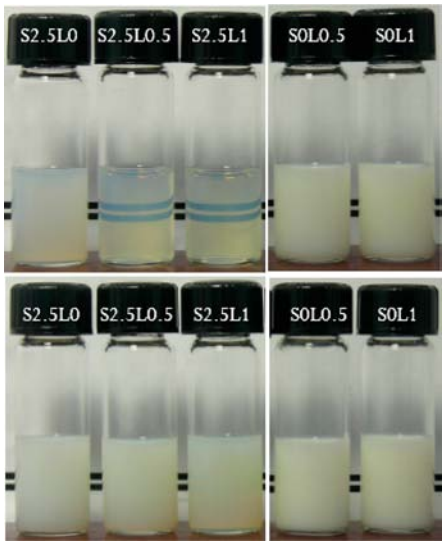

**Figure 3.** Appearance of nanoemulsions with 1.0% w/v (top) or 2.0% w/v (bottom) thyme oil emulsified by 2.5% w/v NaCas, 0.5 or 1% w/v lecithin, or both. All samples contained 10% v/v PG. Labels on vial caps: S, NaCas; L, lecithin; numbers, surfactant concentrations.

compiled in Table 1. With 1.0% w/v thyme oil, emulsions prepared with combinations of NaCas and lecithin were all

**Table 1. Absorbance at 600 nm of 1 or 2% w/v Thyme Oil Emulsified by 2.5% w/v NaCas and 0−1.0% w/v Lecithin[a]**

| thyme oil (% w/v) | lecithin (% w/v) | $Abs_{600}$ |

| 2.0 | 0.5 | 2.21 ± 0.16 b |
| 2.0 | 1.0 | 1.35 ± 0.01 c |

[a]All samples contained 10% v/v PG. Numbers are mean ± standard deviation from duplicates. Different letters represent significant differences in the mean.

transparent, while those with 2.5% NaCas or (0.5 or 1.0% w/v) lecithin alone were turbid. As thyme oil concentration increased to 2.0% w/v, all samples were turbid. The $Abs_{600}$ of thyme oil emulsions in Table 1 showed that addition of lecithin significantly decreased the turbidity of thyme oil emulsions prepared with NaCas ($P < 0.05$).

**Hydrodynamic Diameters of Emulsions.** Mean hydrodynamic diameters of thyme oil emulsions are compiled in Table 2. Emulsions prepared with NaCas−lecithin blend had significantly smaller particles than those prepared with NaCas or lecithin alone ($P < 0.05$). For example, compared to treatments with 1.0% w/v thyme oil emulsified by 1.0% w/v lecithin (mean diameter = 179.7 nm) or 5.0% w/v NaCas alone (mean diameter = 105.5 nm), the corresponding nanoemulsion prepared with the NaCas−lecithin blend had much smaller droplets with a mean diameter of 66.6 nm ($P < 0.05$). These results were consistent with the visual appearance (Figure 3) and $Abs_{600}$ (Table 1). Similar results have been reported for emulsions made with blends of NaCas and sucrose esters (with lipids being mono-, di-, and tristearate or palmitate).[35] Small molecular weight surfactants may coadsorb with NaCas or displace NaCas on droplet surfaces and therefore alter the composition and properties of interfaces, and the reduction of interfacial tension may facilitate the formation of smaller droplets.[32]

**Emulsion Structures Studied by AFM.** Emulsions containing 1.0% w/v thyme oil prepared with 2.5% w/v NaCas, 0.5% w/v lecithin, or both were imaged using AFM (Figure 4). Relatively bigger particles were observed for the emulsions prepared with NaCas or lecithin alone (Figures 4A and 4B) when compared to the treatment prepared with the surfactant blend (Figure 4C). The average particle dimension estimated in AFM was 134.3, 147.3, and 76.9 nm for emulsions prepared with NaCas only, lecithin only, and both, respectively. These results were generally in agreement with those obtained using dynamic light scattering (Table 2).

**Zeta-Potential of Emulsions.** Zeta-potentials of emulsions prepared with 1.0% w/v thyme oil emulsified by NaCas alone, lecithin alone, and their blend were measured at pH 7 (Table 3). The emulsion prepared with 1% w/v lecithin only had a highly negative zeta-potential (−58.2 ± 1.2 mV), which is attributed to the phosphate group of lecithin.[33] In comparison, the zeta-potential of the emulsion prepared with 2.5% w/v NaCas only had a significantly smaller magnitude (−25.8 ± 6.8 mV) than that with lecithin only ($P < 0.05$). When 5% w/v NaCas was used in homogenization, the zeta-potential

**Table 3. Zeta-Potential (mV) of Thyme Oil (1.0% w/v) Nanoemulsions Prepared with NaCas with and without Lecithin at pH 7.0[a]**

| | zeta-potential (mV) | | |
|---|---|---|---|
| lecithin (% w/v) | 0% NaCas | 2.5% w/v NaCas | 5.0% w/v NaCas |
| 0 | | −25.8 ± 6.8 c | −39.7 ± 1.2 b |
| 1.0 | −58.2 ± 1.2[a] | −44.6 ± 2.6 b | −41.7 ± 2.4 b |

[a]All emulsions contained 10% v/v PG. Numbers are mean ± standard deviation from duplicates. Different letters represent significant differences in the mean.

magnitude (−39.7 ± 1.2 mV) was higher than that prepared with 2.5% NaCas and was close to the zeta-potential of NaCas solution,[34] which may suggest a significant amount of free NaCas in the aqueous phase. For the nanoemulsion prepared with 2.5% w/v NaCas and 1% w/v lecithin, the magnitude of zeta-potential (−44.6 ± 2.6 mV) was between those prepared with lecithin and NaCas alone. Since free NaCas was not removed, the zeta-potential data in Table 3 did not provide straightforward information about interfacial structures. It however should be noted that the electrostatic attraction between negatively charged phosphate group of lecithin and positively charged amine groups of NaCas is still possible at neutral acidity despite that both are overall negatively charged, as previously demonstrated for pectin and NaCas.[14]

**Effect of Lecithin on Surface Adsorption of NaCas.** The protein content on unit surface area of emulsion droplets ($\Gamma_s$, mg/m$^2$) is commonly determined to study the surface activity of proteins and the impacts by competing or coadsorbing surfactants. For 10% thyme oil emulsified by 2.5% w/v NaCas and 0−1% w/v lecithin, an increase in lecithin content decreased the droplet dimension but not the amount of adsorbed NaCas ($P > 0.05$), resulting in the reduced $\Gamma_s$ (Table 4). Because a larger surface area (smaller droplets) requires the coverage by a greater amount of surfactants, the data suggest the coadsorption of NaCas and lecithin. The $\Gamma_s$ did not change significantly after 15-day storage at 21 °C, suggesting that there was no detachment of NaCas. With the gradual increase in lecithin content, the droplet dimension decreased to near those prepared with lecithin only. Therefore, lecithin is more surface-active than NaCas in emulsifying thyme oil. For emulsions prepared with 5% w/v NaCas, the droplet size ($P < 0.05$) and the percentage of adsorbed NaCas ($P > 0.05$) were smaller than those for emulsions prepared with 2.5% NaCas, corresponding to similar $\Gamma_s$ ($P > 0.05$). The $\Gamma_s$ of treatments prepared with 5% w/v NaCas and 0 and 0.5% lecithin decreased ($P < 0.05$) after storage for 15 days. Because the droplet dimension of these two emulsions did not change after storage, the results indicated the detachment of NaCas. Conversely, the treatment prepared with 5% NaCas and 1% lecithin showed insignificant changes in both droplet dimension and $\Gamma_s$ ($P > 0.05$).

The competitive surface adsorption and possible displacement of NaCas by more surface-active lecithin are dependent on their overall concentrations and molar ratios.[22,35,36] In a study coemulsifying 20% w/w soybean oil by 0.2−2% w/w NaCas and lecithin at lecithin:casein molar ratios of 0.7:1−49:1,[22] the gradual reduction of $\Gamma_s$ of NaCas with increases in lecithin concentration was similar to the findings of the present study (Table 4), but their $\Gamma_s$ increased with increases in NaCas concentration and were all below 3.5 mg/m$^2$. The $\Gamma_s$ in the present study was much higher than that in ref 22 and was not significantly different at two (2.5 and 5% w/v) NaCas

concentrations (Table 4) although the lecithin:casein molar ratios (2.8−11.4:1) in this work were within their range. The differences in their and the present studies can result from differences in the droplet dimension (300−800 nm in ref 22), emulsification conditions, polarity of oil, and overall NaCas and lecithin concentrations. As for the interfacial structure, Fang and Dalgleish[22] proposed that the thickness of the adsorbed casein layer could increase when lecithin concentration increases gradually and, when there is a sufficient amount of lecithin, the oil droplets are directly covered mostly by lecithin that can be adsorbed by caseins protruding to the continuous aqueous phase. At their studied conditions, Fang and Dalgleish[22] did not observe surface displacement of NaCas by lecithin, which is mostly in agreement with the present study (Table 4). However, in our case, $\Gamma_s$ decreased for nanoemulsions prepared with 5% w/v NaCas and 0 and 0.5% w/v lecithin that also showed a decrease in droplet dimension after storage (Table 4). Since the thickness of the NaCas layer increases with its bulk concentration,[22] the observations from these two emulsions can result from the detachment of caseins rather than the displacement by lecithin. The speculation however requires experimental verifications.

**Emulsion Stability.** One common concern about essential oil nanoemulsions is their stability against Ostwald ripening because of the water solubility of essential oil components being higher than that of lipids composed of medium- or long-chain fatty acids.[31] Physically, compounds in smaller particles have a higher solubility, which results in the continuous dissolving and eventual disappearance of smaller particles, and the dissolved compounds join bigger particles that grow during storage.[37] Nonpolar substances such as corn oil[38] can be blended with essential oils in emulsion preparation to serve as inhibitors of Ostwald ripening.[31] Ripening inhibitors however lower the loading level and antimicrobial activity of essential oils.

Emulsions with 1 and 2% thyme oil were studied for storage stability at 21 °C for 120 days. Creaming was observed for emulsions prepared with NaCas alone after 2- or 3-day storage at room temperature and became more significant after longer storage. Creaming can be contributed by increases in overall particle dimension due to depletion flocculation (by unadsorbed NaCas) or particle growth due to coalescence and/or Ostwald ripening.[4] In contrast, nanoemulsions prepared with 1 and 2% thyme oil and NaCas−lecithin blend appeared transparent or translucent throughout storage.

When particle size distributions of emulsions prepared with lecithin only or NaCas−lecithin blend were compared before and after 4-month storage at room temperature (Figure 5), several trends were observed. Emulsions prepared with NaCas−lecithin blend exhibited smaller particles with narrower distributions than that prepared with lecithin only, indicating the better emulsifying activity of the blend. For these emulsions, the interfacial layer next to thyme oil is likely composed of both lecithin and NaCas, different from the model of sequential layers of lecithin and NaCas as proposed by Fang and Dalgleish[22] that would otherwise result in bigger droplets for emulsions prepared with both surfactants. The growth of particle size was observed for all emulsions, and the growth was much smaller for emulsions prepared with the blend than those with lecithin alone, suggesting the better stabilizing ability of the blend. The growth of average hydrodynamic diameter (Table 2) however was overall not statistically significant ($P > 0.05$).

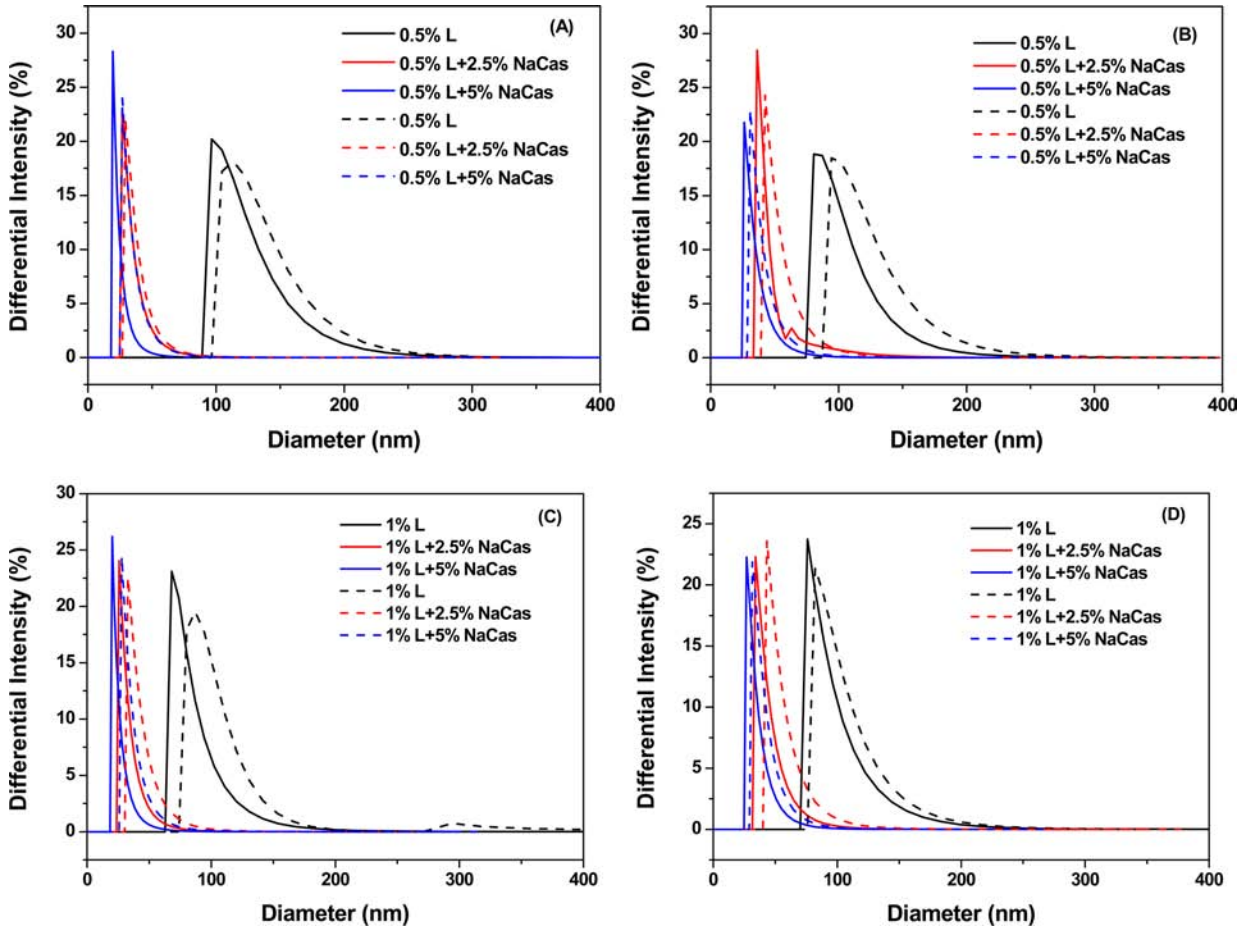

**Figure 5.** Particle size distributions of nanoemulsions with 1.0% w/v (A and C) or 2% w/v (B and D) thyme oil emulsified by lecithin and NaCas–lecithin blend before (solid curves) and after (dashed curves) storage at room temperature (21 °C) for 4 months.

In addition to Ostwald ripening discussed above, coalescence can also cause the growth of particles during storage, particularly for small molecular surfactants such as lecithin with a small headgroup.[39] Coalescence is initiated by the aggregation of two oil droplets controlled by colloidal interactions. In the present study, emulsions prepared with lecithin only had a higher magnitude of zeta-potential (Table 3) than those with the NaCas–lecithin blend. Since emulsions prepared with lecithin only and the NaCas–lecithin blend had insignificant increase in mean particle diameter (Table 2), it may suggest that the electrostatic repulsion is effective in preventing particle aggregation. The protrusion of NaCas in the continuous phase of emulsions prepared with the surfactant blend may have provided additional steric repulsion that resulted in smaller net growth of droplets after storage than emulsions prepared with lecithin only (Table 2). Similar phenomena were reported for orange oil emulsions prepared with lysolecithin and sucrose monopalmitate.[29] Therefore, it is likely that Ostwald ripening is the major mechanism responsible for particle growth of emulsions in the present study, and the narrower particle size distribution and thicker interface of emulsions prepared with the NaCas–lecithin blend both resulted in less significant particle size changes than those prepared with NaCas or lecithin only.

The stability of emulsions prepared with a mixture of proteins and small molecular surfactants has been widely studied. In some cases, the interaction or displacement between emulsifiers resulted in the significantly decreased stability. For example, combinations of caseinate and Tween 20 at certain ratios led to severe flocculation and creaming, which was attributed to the depletion flocculation by unabsorbed protein.[40] Combinations of lecithin with other small molecular surfactants also have been shown to improve the stability of emulsions. Lecithin added in emulsions stabilized by sucrose monopalmitate strengthened the electrostatic repulsion at acid conditions and resulted in the excellent stability of emulsions against Ostwald ripening, flocculation, and coalescence.[41] Emulsifying soybean oil by combinations of lecithin and nonionic steric surfactants such as polyethylene glycol hexadecyl ether (Brij) increased the stability of emulsions at increased ionic strengths when compared to those prepared with lecithin only.[42] This is because, although the surfactant blend reduced the zeta-potential magnitude of droplets when compared to those stabilized by lecithin, Brij provided steric repulsion to stabilize emulsions.[42]

In summary, technological advancement has been shown in the present work for stable and transparent thyme oil nanoemulsions prepared using combinations of GRAS emulsifiers NaCas and lecithin. These transparent nanoemulsions had mean diameters smaller than ~100 nm at neutral pH. The clearer and smaller droplets of nanoemulsions prepared with the NaCas–lecithin blend than those with individual surfactants suggested that NaCas and lecithin synergistically emulsified thyme oil rather than the preferential adsorption and displacement of NaCas by more surface-active lecithin. The interface composed of both NaCas and lecithin

dx.doi.org/10.1021/jf5034366 | J. Agric. Food Chem. 2014, 62, 9900–9907

provided repulsive electrostatic and also likely steric interactions against destabilization mechanisms of creaming, flocculation, and coalescence and, together with narrow particle size distributions, minimized Ostwald ripening. These transparent nanoemulsions prepared from GRAS ingredients have great potential to incorporate lipophilic antimicrobials such as thyme oil in transparent beverages to enhance the microbiological safety.

used to make a patty using a Petri dish (6 cm × 1.5 cm) to ensure uniformity. Neither fat nor oil was used for roasting. A RATIONAL SCC 61E Self-cooking Center (Landsberg, Munich, Germany) was used to roast (only dry heat) the beef patties. The hot plate was preheated for 5 min to 230 °C. The patties were put into the preheated oven, and roasted for 10 min on each side. The internal temperature was measured by inserting an accessary digital contact thermometer into the geometric center of each ground beef patty. The core temperature of the patties immediately after cooking was 85 °C. After completing the cooking processes, the beef patties were cooled at room temperature and the cooked meat samples were cut into small pieces, freeze-dried, and stored at −20 °C until used.

**Extraction of HAs.** The HAs were extracted using a modified method originally developed by Gross and Grueter.[20] Three grams of minced, freeze-dried meat was dissolved in 3 mL of 1 mol/L NaOH and homogenized for 1 min. The alkaline solution was mixed with 13 g of diatomaceous earth. Then, 50 mL of ethyl acetate was added and ultrasonic extracted twice for 30 min. The ethyl acetate extracts of the HAs were added into a Waters Oasis MCX cartridge, which was preconditioned with 6 mL of methanol, 6 mL of distilled water, and 6 mL of 0.1 mol/L HCl. The cartridge was sequentially rinsed with 6 mL of 0.1 mol/L HCl and 6 mL of methanol. The retained analytes were eluted with 6 mL of a methanol−ammonia (19:1, v/v) mixture. The eluted mixtures were evaporated to dryness under nitrogen, and the final extracts were dissolved in 250 $\mu$L of methanol just before measurement.

**Identification and Quantification of HAs.** The HAs were identified and quantified using an UPLC equipped with a triple quadripole mass spectrometer (Waters, Milford, MA, USA) using positive electrospray ionization. HA chromatography of HAs was performed on an ACQUITY UPLC BEH $C_{18}$ reversed-phase column (1.7 $\mu$m particle size, 2.1 mm × 50 mm) at 35 °C. The A solvent was 10 mM ammonium acetate (pH 6.8), and the B solvent was acetonitrile. The solvent composition was 0−0.1 min, 90% A; 0.1−18 min, 10−30% B; 18−20 min, 30−100% B; 20−20.1 min, 100−10% B. The flow rate was 0.3 $\mu$L/min, and the injection volume was 1 $\mu$L. The mass spectrometric detection was conducted in the multireaction monitoring (MRM) scan mode. The mass spectrometry operating conditions were capillary voltage 3.5 kV, ion source temperature 120 °C, and desolvation temperature 350 °C. The HAs were quantified with calibration curves of each kind of HA at eight calibrant levels, ranging from 0.2 to 30.0 ng/mL.

**Statistics.** Three independent repeated experiments were used for standard calibration. The averages from duplicate beef patties were calculated for each HA. Student's *t*-tests were performed in SPSS (SPSS Inc., Chicago, IL) to detect significant differences between the quantities of HA in the spiced and control beef patties. PCA was performed for visualizing the effects of spices on HA profiles. For PCA analysis, the contents of HAs that could be detected and quantified in all beef patties were employed to generate a data matrix, in which the rows and columns represent the observations (samples of beef patties with spices) and the variables (contents of HAs in the same

[a]Recoveries were performed by adding 70, 120, and 180 $\mu$L of 30 ng/mL mixed standard solutions to control samples. Recoveries were represented as means ± standard deviations ($n$ = 3). [b]Eight levels ($n$ = 3) of each kind of HAs were employed for calculating the calibration curve. $y$ is the peak area of HA, and $x$ is the corresponding concentration (ng/mL).

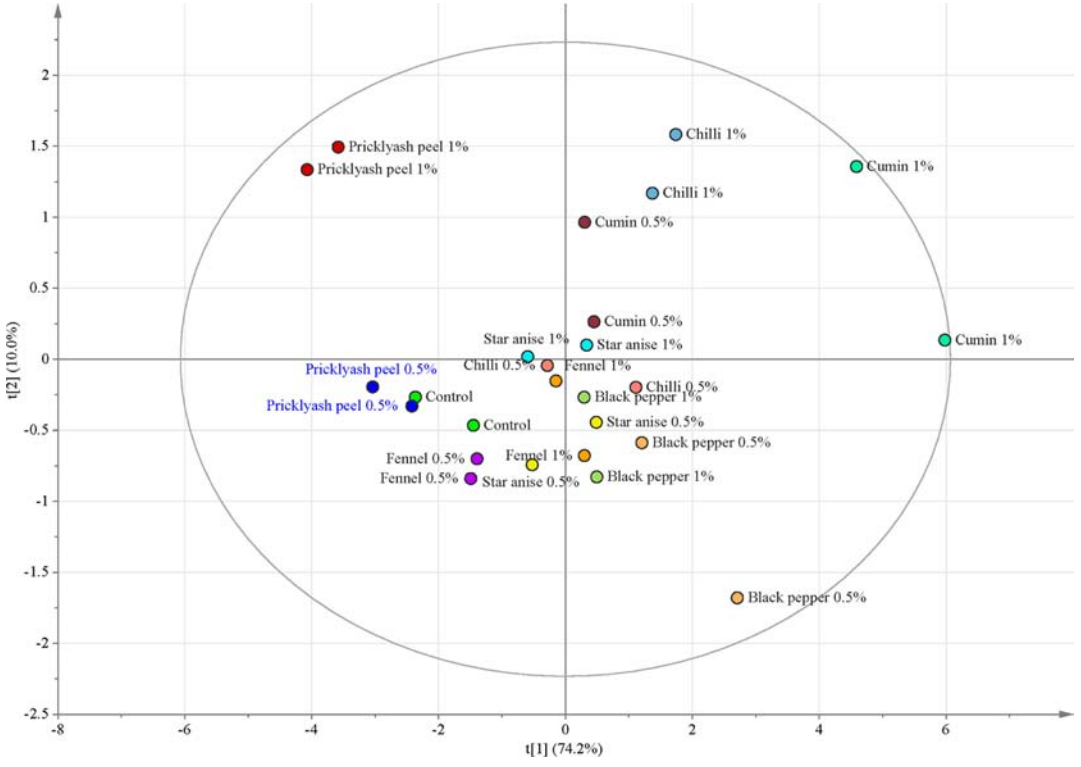

**Figure 2.** PCA score plot (PC1 versus PC2) of the HA profiles of the imidazopyridines (PhIP, DMIP, and 1,5,6-TMIP), imidazoquinoxalines (MeIQx and 4,8-DiMeIQx), and $\beta$-carbolines (harman and norharman).

chromatograms of a single beef patty). The resulting data matrix was then imported into SIMCA-P+13 (UMETRICS, Umea, Sweden) for PCA analysis. Two principal components were used for calculating the PCA models, and the normal distribution of the variables was checked first to ensure that the data were suitable for conducting a PCA.

## RESULTS AND DISCUSSION

**Quantification of the HA Profiles by UPLC-MS/MS.** The profiles of seven HA categories, the $\alpha$-carbolines (A$\alpha$C and MeA$\alpha$C), $\beta$-carbolines (harman and norharman), $\delta$-carbolines (Glu-P-1), imidazopyridines (PhIP, DMIP, and 1,5,6-TMIP), imidazoquinolines (IQ, MeIQ, and IQ[4,5-$b$]), imidazoquinoxalines (IQx, MeIQx, 4,8-DiMeIQx, 7,8-DiMexIQx, and 4,7,8-TriMeIQx), and phenylpyridines (Phe-P-1), were inves-

dx.doi.org/10.1021/jf503682j | J. Agric. Food Chem. 2014, 62, 9908−9915

tigated to assess the effects of six spices commonly used in China, pricklyash peel, star anise, fennel, cumin, chilli, and black pepper, on HA formation in roast beef patties. The patties were either made with no spice, or 0.5 or 1% of one of these spices.

HAs in each patty were extracted and quantified by UPLC-MS/MS. The imidazopyridines (PhIP, DMIP, and 1,5,6-TMIP), imidazoquinoxalines (MeIQx and 4,8-DiMeIQx), and $\beta$-carbolines (harman and norharman) were detected in all of the samples. The $\alpha$-carbolines (A$\alpha$C and MeA$\alpha$C), $\delta$-carbolines (Glu-P-1), imidazoquinolines (MeIQ), and imidazoquinoxalines (7,8-DiMeIQx) were not detected in any of the samples. The signal-to-noise ratios of the phenylpyridines (Phe-P-1), imidazoquinolines (IQ, IQ[4,5-*b*]), and imidazoquinoxalines (IQx and 4,7,8-TriMeIQx) were too low to allow detection in the control samples; however, for these HAs, quantifiable amounts were found after addition of spices.

Figure 1 shows the UPLC-MS/MS chromatograms of a standard solution and a beef patty spiked with a standard solution containing 17 HAs from all seven categories. The HA recoveries were between 54.2 and 108.4%, except for DMIP, which was 36.9%. The HA recoveries were higher than those reported by Gross and Grueter (33−85%).[20] Although the harman and norharman recoveries were larger than 100%, the values were reasonable considering the variances caused by the heterogenicity and complexity of the beef matrix, and the very low levels of HAs,[21] and are in agreement with previously reported values.[22,23]

The precision for all 17 HAs upon repeated samples showed good repeatability, as illustrated in Table 1. Most of the coefficients of the HA standard curves were above 0.999, indicating good linearity of the levels of each HA under certain peak areas. The results showed that the developed method was suitable for assessing the effects of spices on the HA profiles of roast beef patties. The rest of the analysis focused on seven HAs from the imidazopyridine, imidazoquinoxaline, and $\beta$-carboline categories, which were found in all of the samples.

**Effects of Chinese Spices on the HA Profiles.** PCA was used to examine the differences between the control and spiced samples' HA profiles. The first and second principal components (PCs) explained 74.2 and 10.0% of the systematic variation, respectively. The score plot of PC1 versus PC2 is displayed in Figure 2. As shown in the figure, most of the samples scatter into each other, which may indicate that the HA profiles of those samples were similar. The samples with 1% pricklyash peel, chilli, or cumin are located far away from the other samples in the figure, including the controls. These spices may therefore have had large effects on the HA profiles.

Table 2 shows the total HA levels. The total HA mean value of the 1% pricklyash peel samples was significantly ($p < 0.05$) lower than that of the control samples, representing an inhibition of 35%. In contrast, the total HA mean values of the 1% cumin and chilli samples were significantly ($p < 0.05$) higher than the control samples, representing a promotion of 175 and 88%.

Many studies have reported that spices can inhibit HA formation to a certain extent. For example, 20% ethanolic extracts of rosemary in beef patties were reported to inhibit PhIP by 85.3% and MeIQx by 91.7%.[24] The Asian spices turmeric, fingerroot, and galangal were shown to significantly decrease HA formation by 39.2, 33.5, and 18.4%, respectively.[17] Black pepper was also found to have an inhibitory effect on the total HA amount of between 12 and 100%.[15] However, the results for the effects of spices on HA formation have not

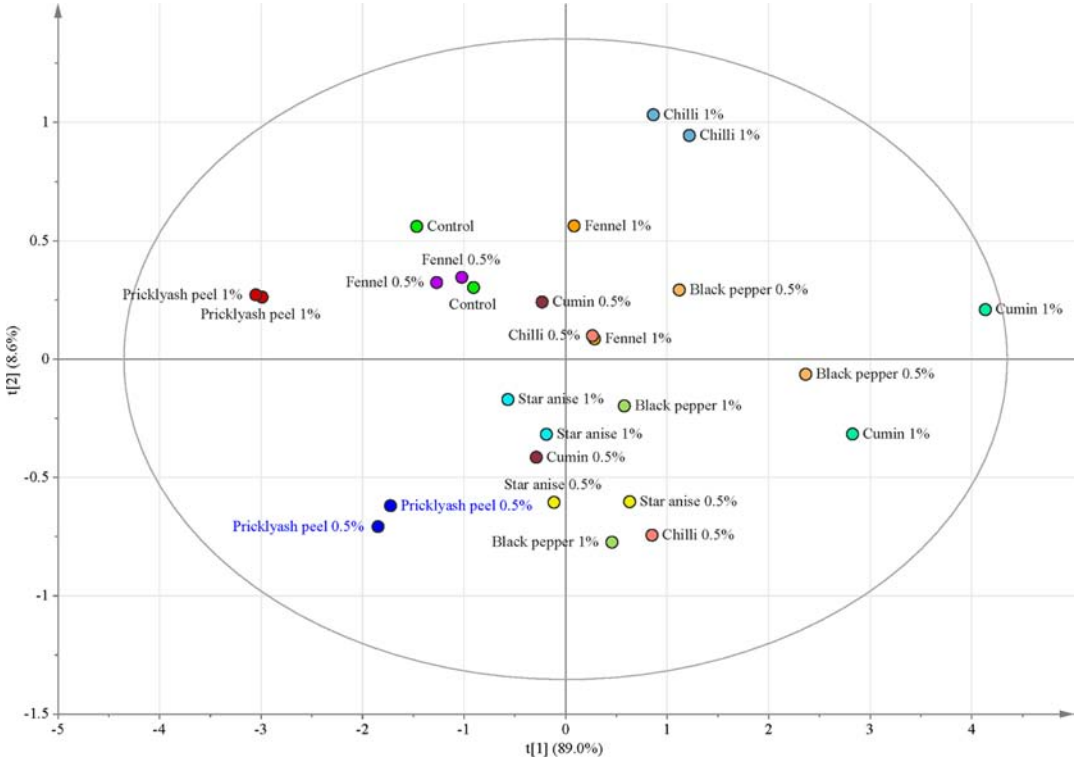

**Figure 3.** PCA score plot (PC1 versus PC2) of the imidazopyridine profiles (PhIP, DMIP, and 1,5,6-TMIP).

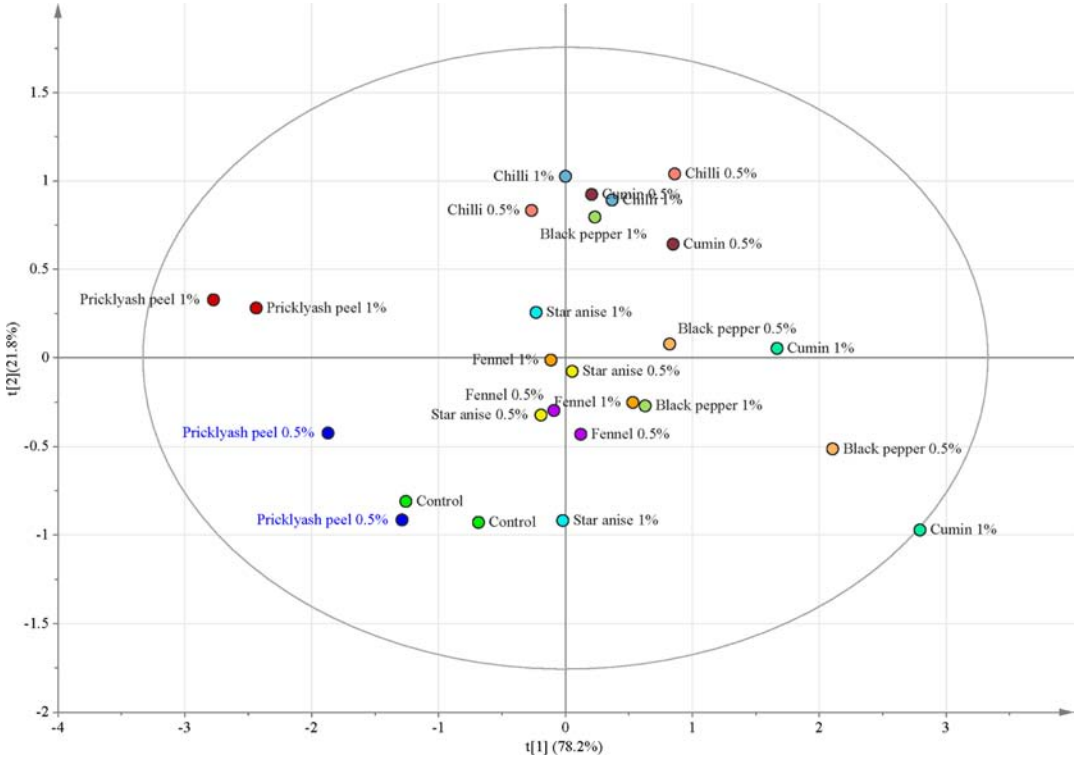

**Figure 4.** PCA score plot (PC1 versus PC2) of the imidazoquinoxaline profiles (MeIQx and 4,8-DiMeIQx).

always agreed. For instance, oregano and basil extracts were reported to increase PhIP.[21]

In contrast to most previous findings, most of the spices studied here promoted rather than inhibited the formation of HAs. The results may be attributed to the specificity of the interactions between individual HAs and the recipe of added spices. Many antioxidants that act protectively in low amounts may act as pro-oxidants in higher concentrations.[25] Furthermore, HAs have stability problems at high temperatures and start to degrade.[26]

The formation of HAs is dependent on the heating temperature and time. However, the main purpose of this

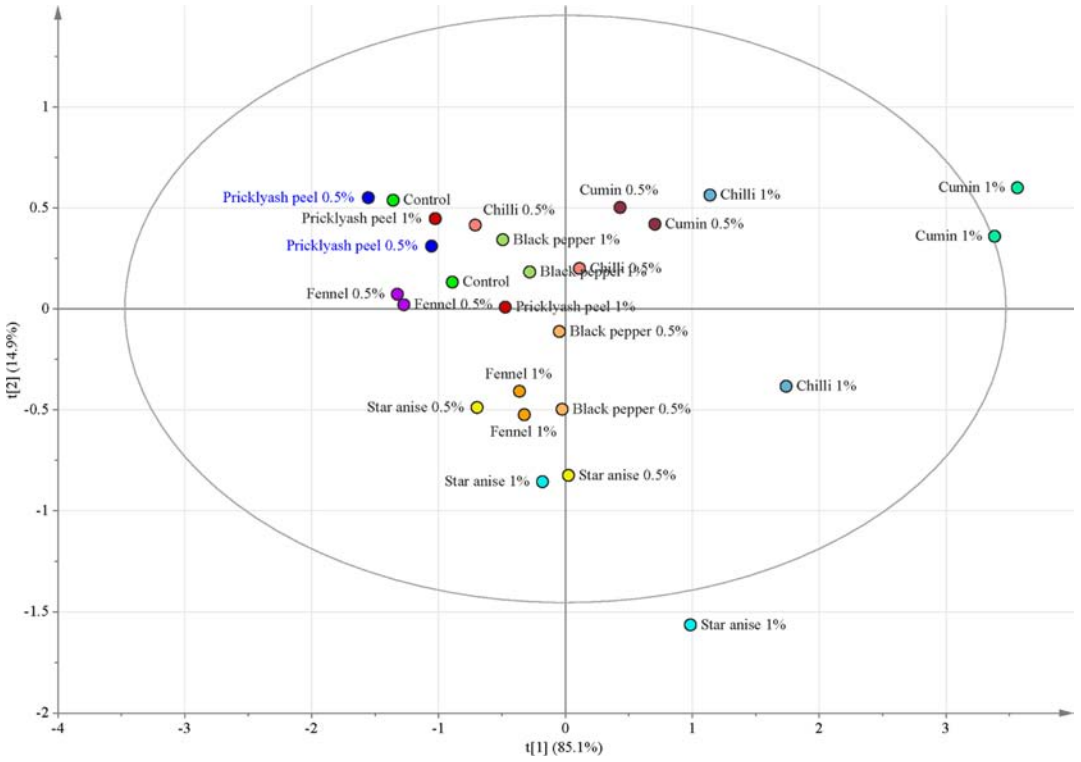

**Figure 5.** PCA score plot (PC1 versus PC2) of the $\beta$-carboline profiles (harman and norharman).

study is to evaluate the effects of commonly used Chinese spices on HA profiles. In future studies, we will examine how the cooking parameters, such as temperature and time, moderate the effects of Chinese spices on HA profiles. The changes in HA precursors after the roasting of control and spiced patties will also be examined.

**Effects of Chinese Spices on the Imidazopyridine Profiles.** The imidazopyridines PhIP, DMIP, and 1,5,6-TMIP were detected in all of the samples. PCA was used to evaluate the effects of adding spices on the imidazopyridine profiles. Figure 3 shows the score plot (PC1 versus PC2) of the control and spiced samples. The first two PCs explained 97.6% of the systematic variation. In Figure 3, the data points corresponding to the 1% pricklyash peel, chilli, and cumin samples are located far away from the other samples' data points, as in the score plot of all of the HA profiles in Figure 2. We can conclude that these spices greatly affected the imidazopyridine profiles. Table 2 shows that 1% pricklyash peel significantly inhibited the total imidazopyridine levels ($p < 0.05$) by 58%, whereas 1% chilli and 1% cumin significantly ($p < 0.05$) promoted the total imidazopyridine levels by 61 and 117%, respectively.

In the literature, PhIP is usually quantified to assess the effects of spices; however, limited studies have mentioned DMIP and 1,5,6-TMIP. For example, Puangsombat demonstrated that the addition of 0.2% cumin slightly decreased PhIP formation.[17] However, we found that 0.5 and 1% cumin both promoted the formation of PhIP, although the increase was only significant for 1% cumin. Previous research has suggested that the antioxidant effect may depend on the concentration of the antioxidant and the heating time.[24] We used larger amounts of spices (0.5 and 1% versus 0.2%) and longer roasting times (10 min/side versus 5 min/side), which may have resulted in the different effects on PhIP formation.

**Effects of Chinese Spices on the Imidazoquinoxaline Profiles.** Figure 4 shows the PCA score plot (PC1 versus PC2) of the imidazoquinoxaline profiles, including the MeIQx and 4,8-DiMeIQx. The first two PCs explained 78.2 and 21.8% of the systematic variation, respectively. Figure 4 shows that the samples containing 1% pricklyash peel and 1% cumin are situated relatively far away from the other samples. These spices may therefore have had a great effect on the imidazoquinoxaline profiles. The mean of the total imidazoquinoxaline levels on the addition of 1% pricklyash peel was significantly ($p < 0.05$) lower than in the control samples, indicating inhibition of 51%. The mean value on addition of 1% cumin was remarkably ($p < 0.05$) higher than in the control samples, indicating promotion of 103%.

Imidazoquinoxalines such as MeIQx and 4,8-DiMeIQx have been widely detected in beef.[14,27,28] Black pepper (at 1% level) has been reported to inhibit 4,8-DiMeIQx completely in high-fat meatball at 225 °C,[15] whereas the addition of 0.2% cumin had little effect on MeIQx and total HAs at 204 °C in beef patties.[17] However, our results showed that cumin and black pepper promoted both MeIQx and 4,8-DiMeIQx formation, except for 0.5% cumin. The differences may be due to different cooking temperatures and times.

**Effects of Chinese Spices on the $\beta$-Carboline Profiles.** The PCA scores plot (PC1 versus PC2) of the $\beta$-carboline (harman and norharman) profiles is shown in Figure 5. The first two PCs explained 85.1 and 14.9% of the systematic variation. In Figure 5, most of the samples are dispersed, but the samples containing 1% cumin lie far away from the rest of the samples. It is therefore likely that 1% cumin had a great effect on the $\beta$-carboline profiles in the roast beef patties. The mean of the total $\beta$-carboline values in samples with 1% cumin was significantly ($p < 0.05$) larger than in the control samples, a promotion of 322%. Although the two $\beta$-carbolines harman and

dx.doi.org/10.1021/jf503682j | J. Agric. Food Chem. 2014, 62, 9908−9915

norharman have been detected in beef,[22] little is known about the effects of spices on their formation.

In conclusion, pricklyash peel primarily inhibits the formation of all of the HA categories, whereas other spices primarily promote HA formation. Furthermore, the total HA and imidazopyridine profiles are significantly affected by 1% pricklyash peel, chilli, and cumin; the imidazoquinoxaline profiles are significantly influenced by 1% pricklyash peel and cumin; and the $\beta$-carboline profiles are only significantly affected by 1% cumin. These results shed light on the selection of spices for use in meat processing.

comprehensive approach to evaluating the biological context of statistically significant differences.

A statistical tolerance interval is derived from a sample distribution to estimate the population range (Figure 1). The

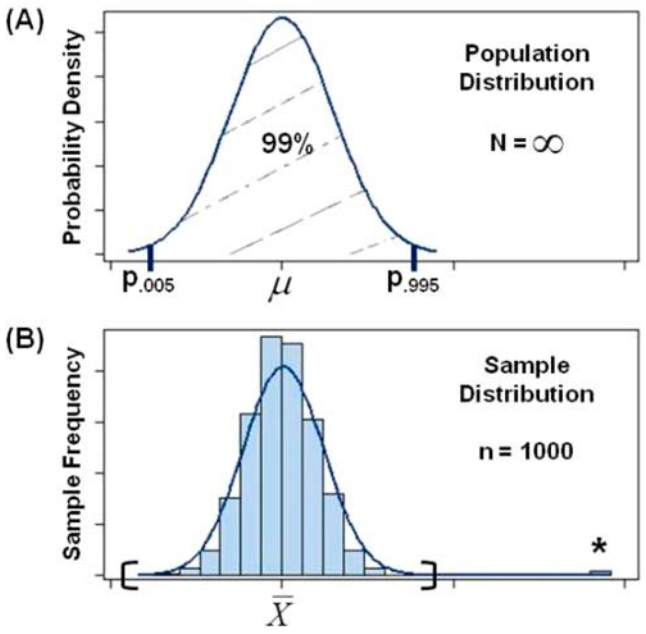

**Figure 1.** Conceptual illustration of a 99%-content, 95%-confidence tolerance interval. (A) Theoretical population distribution where $p_{.005}$ and $p_{.995}$ represent the 0.5th and 99.5th percentile points, respectively. Between $p_{.005}$ and $p_{.995}$ lie 99% of the population values. The population distribution is based on an infinite number of population values (i.e., $N = \infty$), where $\mu$ represents the center of the distribution or the population mean. (B) Sample distribution is based on a finite number of sample values (e.g., $n = 1000$), where $\bar{X}$ represents the center of the distribution or the sample mean. The 99%-content, 95%-confidence tolerance interval, denoted by the brackets on the $x$-axis, is generated on the basis of the sample distribution to infer the range between the 0.5th and 99.5th percentile points of the population distribution. In practice, there can be extreme sample values, also known as outliers. The asterisk (*) denotes an example of an extreme value, which is not included in the tolerance interval.

better the sampling of natural variability associated with a crop population, the better the true population can be modeled using a tolerance interval. For the compositional equivalence evaluation, a statistical tolerance interval for each analyte can be computed from the cumulative historical data to infer the natural range of analyte values from the crop population with a history of safe use. A tolerance interval is a statistically constructed interval that is expected to contain at least a specified proportion (i.e., percent content) of the population, with a specified confidence level.[15,16] For example, a 99%-content tolerance interval with 95% confidence for a specific analyte is intended to contain at least 99% of the population values for this analyte, with a confidence level of 95%. Figure 1 illustrates the concept of a 99%-content, 95%-confidence tolerance interval. The tolerance interval is generated using the sample data distribution to infer the range between the 0.5th and 99.5th percentiles of the population distribution.

There are varied approaches to the computation of tolerance intervals. Both the classical parametric approach[17,18] and the nonparametric approach[19] have been used to compute tolerance intervals for composition data. These two approaches assume data values are identically and independently distributed (*iid*).[15,16] However, data values from multisite field studies are not independent from each other and tend to be highly correlated. Additionally, data sets from multisite field studies are typically unbalanced due to unequal allocation of genotypes to environments. These tolerance interval approaches failed to consider the data structure when applied to composition data.

In this paper, we describe a model-based parametric approach to derive a statistical tolerance interval from cumulative historical data. A linear mixed model, which has been widely used to statistically analyze data from agricultural experiments involving multisite studies,[20] is applied to estimate parameter values that are subsequently needed for the tolerance interval computation. The theoretical basis underlying this tolerance interval approach is presented and compared to other currently employed approaches used to represent natural variation observed in conventional crop composition. An example of the use of this tolerance interval approach is demonstrated using maize grain cumulative historical data, both as an overall composition data set and in the context of two specific analytes.

## MATERIALS AND METHODS

**Maize Grain Samples from Multisite Field Studies for Compositional Analyses.** Maize grain samples were collected from 61 unique Pioneer brand non-GM commercial hybrid maize lines, which ranged in comparative relative maturity (Pioneer CRM) rating from 75 to 119 (Figure 2). Commercial launch of these hybrid

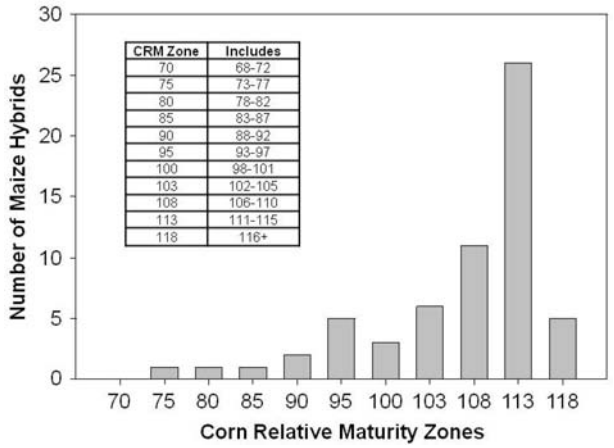

**Figure 2.** Distribution of corn relative maturity zones of the 61 Pioneer brand non-genetically modified commercial maize hybrids used to generate tolerance intervals. Comparative relative maturity (CRM) ratings of individual maize lines are grouped into zones as shown.

lines occurred between 1989 and 2011 (Figure 3). The maize grain samples were collected from eight multisite field studies between 2003 and 2011. These field sites consisted of 47 unique environments representative of commercial maize-growing regions of the United States, Canada, Chile, and Argentina (Table 1). Each field site, season, and planting date combination represents one unique environment. The experimental design utilized at each field site was a randomized complete block design with either three or four blocks.

Maize production at each field site was conducted using standard agronomic practices in accordance with local practices and recommendations. A summary of monthly temperature, precipitation, and irrigation data from each location is provided in Supporting Information (Supplementary Tables 1−5). Grain samples were

collected after reaching physiological maturity (R6 growth stage),[21] where five previously self-pollinated ears per plot (one ear per plant) were husked, shelled, and pooled to make one grain sample per plot. Grain samples were shipped frozen to EPL Bio Analytical Services (EPL BAS, Niantic, IL, USA). Samples were stored frozen prior to and after grinding.

**Compositional Analyses of Maize Grain Samples.** Compositional analyses of processed samples were conducted in accordance with guidance from the Organisation for Economic Co-operation and Development (OECD) maize composition consensus document[22] and included an assessment of proximate, fiber, fatty acid, amino acid, mineral, vitamin, secondary metabolite, and antinutrient analyte concentrations. For an in-depth illustration of substantial equivalence assessment of composition data, discussion herein is limited to the two individual analytes tryptophan and oleic acid.

Compositional analyses of the processed samples were conducted by EPL BAS using validated methods. For tryptophan analysis, samples were hydrolyzed with lithium hydroxide and quantified using reverse phase high-performance liquid chromatography (HPLC) with ultraviolet (UV) detection (HPLC-UV).[23] The HPLC-UV instrument was calibrated using external standards. For oleic acid analysis, ether extraction and base hydrolysis were conducted on the samples, followed by conversion of free fatty acids to fatty acid methyl esters (FAME). FAME concentrations were quantified using gas chromatography with flame ionization detection (GC-FID). The GC-FID instrument was calibrated using external standards.[24−26] A molecular weight conversion was performed to convert the FAME concentration value to a fatty acid concentration value.

**Construction of Statistical Tolerance Intervals for Composition Data Derived from Multisite Field Studies.** For a given composition analyte, the response value $y_{ijk}$ from the $i$th environment, $j$th genotype, and $k$th block was modeled as

dx.doi.org/10.1021/jf502158q | J. Agric. Food Chem. 2014, 62, 9916−9926

$$y_{ijk} = \mu + \text{environment}_i + \text{genotype}_j + (\text{genotype} \times \text{environment})_{ji} + \text{block(environment)}_{ki} + \varepsilon_{ijk}$$

where $\mu$ represents the grand mean; random effect environment$_i$ is identically and independently distributed (*iid*) $N(0,\sigma_E^2)$; random effect genotype$_j$ is *iid* $N(0,\sigma_G^2)$; interaction effect (genotype × environment)$_{ji}$ is *iid* $N(0,\sigma_{G\times E}^2)$; random effect block(environment)$_{ki}$ is *iid* $N(0,\sigma_B^2)$; and the plot error term $\varepsilon_{ijk}$ is *iid* $N(0,\sigma_\varepsilon^2)$. Other than the grand mean being a fixed effect, all other terms in the model are random effects. This linear mixed model (LMM) is also known as a random effects model. On the basis of the LMM configuration described above, the variance of $y_{ijk}$ is the sum of variance components from all identified sources in the model, denoted as

$$Var(y_{ijk}) = \sigma_E^2 + \sigma_G^2 + \sigma_{G\times E}^2 + \sigma_B^2 + \sigma_\varepsilon^2 \equiv \sigma_{total}^2$$

A two-sided 99%-content tolerance interval was constructed with 95% confidence for the distribution of $N(\mu,\sigma_{total}^2)$. With $\hat{\mu}$, $\hat{\sigma}_E^2$, $\hat{\sigma}_G^2$, $\hat{\sigma}_{G\times E}^2$, $\hat{\sigma}_B^2$, and $\hat{\sigma}_\varepsilon^2$ denoted as the restricted maximum likelihood estimates of the grand mean and the variance components of the LMM, the estimate of total variance $\hat{\sigma}_{total}^2$ was computed as

$$\hat{\sigma}_{total}^2 = \hat{\sigma}_E^2 + \hat{\sigma}_G^2 + \hat{\sigma}_{G\times E}^2 + \hat{\sigma}_B^2 + \hat{\sigma}_\varepsilon^2$$

Let $R_0$ represent the ratio of $\sigma_{total}^2$ over the variance of $\hat{\mu}$ and assume that $R_0$ is known. It follows from sections 2.3.1 and 4.5.1 of Krishnamoorthy and Mathew[27] that the lower and upper tolerance limits (*LTL* and *UTL*, respectively) for the two-sided 100(1-$\gamma$)%-content, 100(1-$\alpha$)%-confidence tolerance interval are

$$LTL = \hat{\mu} - \hat{\sigma}_{total}\sqrt{\frac{m\cdot\chi_{1;1-\gamma}^2(1/R_0)}{\chi_{m;\alpha}^2(0)}} \qquad (1.0)$$

$$UTL = \hat{\mu} + \hat{\sigma}_{total}\sqrt{\frac{m\cdot\chi_{1;1-\gamma}^2(1/R_0)}{\chi_{m;\alpha}^2(0)}}$$

where

$$m = 2\frac{(\hat{\sigma}_{total}^2)^2}{\mathbf{J}\hat{\Delta}\mathbf{J}'}$$

Here $\chi_{1;1-\gamma}^2(1/R_0)$ represents the 100(1 − $\gamma$)th percentile of a noncentral chi-square distribution with the degree of freedom being 1 and the noncentrality parameter being $1/R_0$; $\chi_{m;\alpha}^2(0)$ represents the 100$\alpha$th percentile of a central chi-square distribution with $m$ degrees of freedom; $m$ originates from the Satterthwaite approximation[28] to the degrees of freedom of $\hat{\sigma}_{total}^2$; $\hat{\Delta}$ is the estimated variance−covariance matrix of ($\hat{\sigma}_E^2$, $\hat{\sigma}_G^2$, $\hat{\sigma}_{E\times G}^2$, $\hat{\sigma}_B^2$, $\hat{\sigma}_\varepsilon^2$); $\mathbf{J}$ is a row vector of 1; and $\mathbf{J}'$ is a column vector of 1.

Following the approach taken by Bagui, Bhaumick, and Parnes,[29] here the unknown parameter $R_0$ (the ratio of the variance of the population over the variance of the grand mean estimator $\mu$) was approximated by its point estimate $\hat{R}_0 = \hat{\sigma}_{total}^2/\hat{V}ar(\hat{\mu})$, with $\hat{V}ar(\hat{\mu})$ being the estimated variance of the grand mean. This results in a two-sided tolerance interval that is narrower than the true two-sided 100(1-$\gamma$)%-content, 100(1-$\alpha$)%-confidence tolerance interval.

The SAS (SAS Institute Inc., Cary, NC, USA) code for constructing the tolerance interval is provided in the Supporting Information (Supplementary Method).

## RESULTS AND DISCUSSION

**Justification for Model-Based Tolerance Interval Approach.** The parametric tolerance interval approach, which incorporates the linear mixed model described here, is superior to a classical parametric or nonparametric approach for unbalanced data generated from multisite field studies. Both the classical parametric and nonparametric approaches assume data values are identically and independently distributed (*iid*). However, data values from multisite field studies are not *iid* and tend to be highly correlated. Data from multisite field studies are correlated on several levels: data values collected from the same genotype at the same field site are apt to be highly correlated, data values collected from different genotypes at the same field site are more likely correlated than those grown at different field sites, and data values collected from the same genotype at different field sites are likely correlated as well. Data from multisite field studies conducted over multiple seasons (referred to as cumulative historical data) are unbalanced in structure due to an unequal allocation of genotypes to environments. Our linear mixed model, which is a random effects model, considers and accommodates the correlated and unbalanced data structure resulting from multisite field studies conducted over multiple seasons. The linear mixed model incorporated into this parametric tolerance interval approach has been widely used to statistically analyze data from agricultural experiments involving multisite field studies.[20]

The conventional formula for the classical parametric tolerance interval was developed assuming responses are *iid* following a normal distribution,[15] and our model-based parametric tolerance interval approach degenerates into the classical parametric solution under those conditions. When the data values are *iid* normal with sample size $n$, then $m$ equals $n - 1$ and $R_0$ equals $n$, and formula 1.0 is simplified into the conventional formula for the two-sided tolerance interval.[27]

When employing random effects models for unbalanced data, construction of the tolerance interval becomes substantially more complicated, but our approach is computationally feasible and straightforward to execute via SAS (see Supplementary Method in the Supporting Information) or other appropriate statistical software. Compared to simple cases such as those with normally distributed *iid* data, analytical formulas for the tolerance limits are not available for unbalanced and correlated data, and numerical methods or approximations become necessary.[27] For a one-way random effect model with balanced data, the unknown $R_0$ is approximated by its lower confidence limit to achieve the desired content with the nominal confidence level.[30] However, "no guidelines are given regarding the choice of the confidence level" for unbalanced data.[27] Alternatively, with a one-way random effect model, the tolerance interval has been successfully developed using generalized pivotal quantity machinery.[31,32] This approach involves statistical resampling and heavy computation, which is difficult for most practitioners to implement. To our knowledge, an extension from the one-way random effect model to a two-way random effects model is not available with a generalized pivotal quantity approach.[27] Our random effects model is multiway, as it involves more than two random effects and our data sets are unbalanced; therefore, instead of solving for an unbiased solution using heavy computation, the unknown $R_0$ is simply replaced with its point estimate. As a result, our tolerance interval is expected to be narrower than a true 99%-content, 95%-confidence tolerance interval, and as such is conservative in the context of a GM crop safety assessment.

A simulation study was conducted to demonstrate that the actual coverage of our tolerance interval is indeed narrower than the nominal coverage level. The tolerance interval coverage was evaluated according to the approach of Liao.[33] In this exercise, 5000 data sets were simulated following an experimental design similar to the cumulative historical data set

and a given set of variance component values. For each of the simulated data sets (data not shown), the actual content of the computed tolerance interval was recorded and compared to the nominal content level (i.e., 99%). Of the 5000 sets of tolerance intervals, 94.24% of the sets had an actual content of at least 99%. With the size of the simulation ($n$ = 5000), the standard error associated with 94.24% is 0.3295%. This result, which is less than the nominal confidence level of 95%, demonstrates that our tolerance interval is indeed narrower than a true 99%-content, 95%-confidence tolerance interval.

**Sample Size.** In the context of a cumulative historical data set with a correlated data structure, a recommended minimum sample size in terms of total number of data points is impractical because our tolerance interval solution is a complex function of various factors. Using the tolerance interval formula 1.0, the width of a tolerance interval (represented by the minimum and maximum calculated limits) is a function of three factors: $\hat{\sigma}^2_{\text{total}}$ (the estimated total variance), $m$ (the Satterthwaite degrees of freedom), and $\hat{R}_0$ (the estimated ratio of $\hat{\sigma}^2_{\text{total}}$ over the variance of the estimated grand mean $\hat{\mu}$). As the natural variation of the population ($\hat{\sigma}^2_{\text{total}}$) increases, so does the width of the tolerance interval. Parameter $R_0$ can be considered the effective sample size of the population, as it is the ratio of the variance of the population ($\hat{\sigma}^2_{\text{total}}$) over the variance of the grand mean estimator $\mu$ (formula 1.0). As $R_0$ is dependent on each of the individual variance factors that make up the total variance of the population, $R_0$ would be different for each analyte of an individual data set. Therefore, it is not straightforward to determine a universal minimum sample size $n$ that could be applied to all analytes. In contrast, we recommend minimum values for the two parameters $m$ and $R_0$ associated with our tolerance interval approach.

Minimum $m$ and $R_0$ values were determined by plotting the functional relationship for critical components of the tolerance interval formula versus $m$ and $R_0$, with recommended minimum values corresponding to when the respective plot converges. For data collected under multisite field studies over multiple seasons with unbalanced allocations of genotypes to environments, both $m$ and $R_0$ are increasing functions with respect to the number of unique environments, number of genotypes at each environment, and number of blocks within environments. Due to the unbalanced nature of cumulative historical data, it is cumbersome to provide an explicit formula for $m$ and $R_0$ as functions of the number of unique environments and genotypes. As a result, it is impractical to provide a recommendation for the minimally required number of genotypes or environments. Additionally, $m$ and $R_0$ are determined by the estimated variance components as well as the variance−covariance matrix of the estimated variance. Instead, it is more feasible to investigate the empirical behavior of the tolerance limits using functional curves that examine the relationship between $m/\chi^2_{m;\alpha}(0)$ and $m$ and the relationship between $\chi^2_{1;1-\gamma}(1/R_0)$ and $R_0$ (Figure 4). As both $m$ and $R_0$ approach infinity, the calculated tolerance interval stabilizes and the tolerance limits approach the true percentiles of the population.

As illustrated in Figure 4, $m/\chi^2_{m;\alpha}(0)$ starts to stabilize when $m$ approaches 60, and $\chi^2_{1;1-\gamma}(1/R_0)$ starts to stabilize when $R_0$ approaches 50; therefore, we recommend a minimum $m$ of 60 for the Satterthwaite degrees of freedom and a minimum $R_0$ of 50 for the effective sample size when tolerance intervals are constructed from data derived from multisite field studies. In the context of composition data, $m$ and $R_0$ are estimated

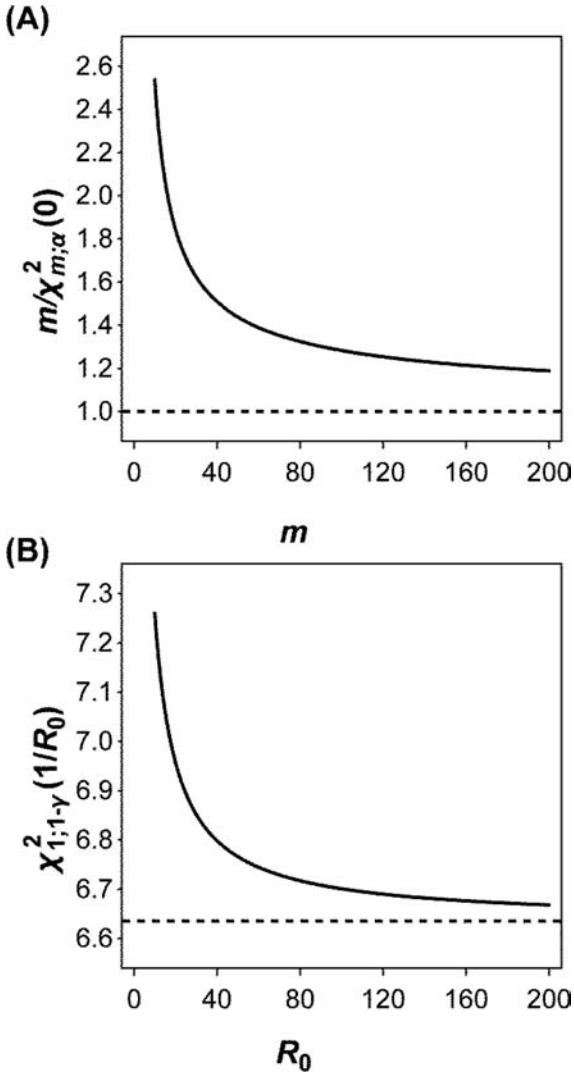

**Figure 4.** (A) Plot of $m/\chi^2_{m;\alpha}(0)$ versus $m$. Solid line corresponds to $m/\chi^2_{m;\alpha}(0)$. Dashed line corresponds to the limit of $m/\chi^2_{m;\alpha}(0)$ as $m$ approaches infinity. (B) Plot of $\chi^2_{1;1-\gamma}(1/R_0)$ versus $R_0$. Solid line corresponds to $\chi^2_{1;1-\gamma}(1/R_0)$. Dashed line corresponds to the limit of $\chi^2_{1;1-\gamma}(1/R_0)$ as $R_0$ approaches infinity. $m$ is the Satterthwaite degrees of freedom, and $R_0$ is the estimated ratio of the total variance over the variance of the grand mean. $m/\chi^2_{m;\alpha}(0)$ and $\chi^2_{1;1-\gamma}(1/R_0)$ are two critical components of the tolerance interval equation that determine the width of a tolerance interval (represented by the minimum and maximum calculated limits).

individually for each analyte, and then estimated $m$ and $R_0$ values are examined across analytes to evaluate the adequacy of the data set for the purpose of generating tolerance intervals. For example, $m$ and $R_0$ were estimated for each individual analyte in a data set composed of cumulative maize grain data from 2003 to 2011 (referred to here as the 2003−2011 maize grain cumulative historical data set; data not shown). The minimum estimated $m$ value for a given analyte in this cumulative historical data set was 76, which exceeded the recommended minimum of 60. The estimated $R_0$ values for 2 of 55 analytes in the 2003−2011 maize grain cumulative historical data set were below the recommended minimum of 50, and the lower of the two $R_0$ values was 47. Therefore, this cumulative historical data set was deemed adequate for generating tolerance intervals for maize grain analytes.

**Tolerance Interval Construction and Results.** Tolerance intervals are constructed by estimating parameters (grand mean and variance components) using linear mixed model analysis and subsequently using these parameter values in formula 1.0. Within the 2003−2011 maize grain cumulative historical data set, two analytes (tryptophan and oleic acid) are used as examples to illustrate how tolerance intervals are constructed. For each individual variance component that contributed to the total variance of tryptophan and oleic acid, the estimated values are provided in Table 2, along with the corresponding

**Table 2. Variance Components**

| | tryptophan | | oleic acid | |
|---|---|---|---|---|
| source of variation | variation | % total variation | variation[a] | % total variation |
| genotype | $6.70 \times 10^{-6}$ | 6.7 | 0.0131 | 55.6 |
| environment | $7.11 \times 10^{-5}$ | 71.6 | 0.00387 | 16.4 |
| genotype × environment | $3.51 \times 10^{-6}$ | 3.5 | 0.00206 | 8.7 |
| block (environment) | 0 | 0.0 | 0 | 0.0 |
| residual | $1.80 \times 10^{-5}$ | 18.1 | 0.00456 | 19.3 |

[a]Variance component estimates were obtained on the log-transformed scale.

percentages of the total variance. Environmental variance was the largest contributor to the total variation of tryptophan values (71.6% of the total variance), whereas genotypic variation was the largest contributor to the total variation of oleic acid values (55.6% of the total variance). Any given composition analyte has a natural variation that is influenced by various individual contributors (e.g., genotypic factors, environmental factors). However, it is important to recognize that the natural variation is the sum of these variation sources and the key objective here is to capture and estimate the total variation, not to characterize or quantify the individual factors that make up the total variation.

Tolerance intervals (99%-content, 95%-confidence) were constructed on the basis of the grand mean and the total variance estimated from the linear mixed model analysis. Tolerance interval results for tryptophan and oleic acid are presented in Table 3 along with the corresponding range of

**Table 3. Tolerance Interval Results**

| analyte | tolerance interval | data range |
|---|---|---|
| tryptophan[a] | 0.0344−0.0940 | 0.0348−0.0927 |
| oleic acid[b] | 18.1−44.0 | 17.0−42.8 |

[a]Percent dry weight. [b]Percent total fatty acids.

individual data values for each analyte. To illustrate the reasonableness of the tolerance interval coverage, the tryptophan and oleic acid tolerance interval results were compared to the individual data points for each multisite field study included in the cumulative historical data set using dot plots (Figure 5). Of the 1038 samples included in the cumulative historical data set, all of the tryptophan sample values were within the respective tolerance interval, and all but three of the oleic acid sample values were within the respective tolerance interval. It is expected that 1% of all data values from a population would fall outside a 99%-content tolerance interval. However, a sample set such as the 2003−2011 maize grain cumulative historical data set is unlikely to cover all

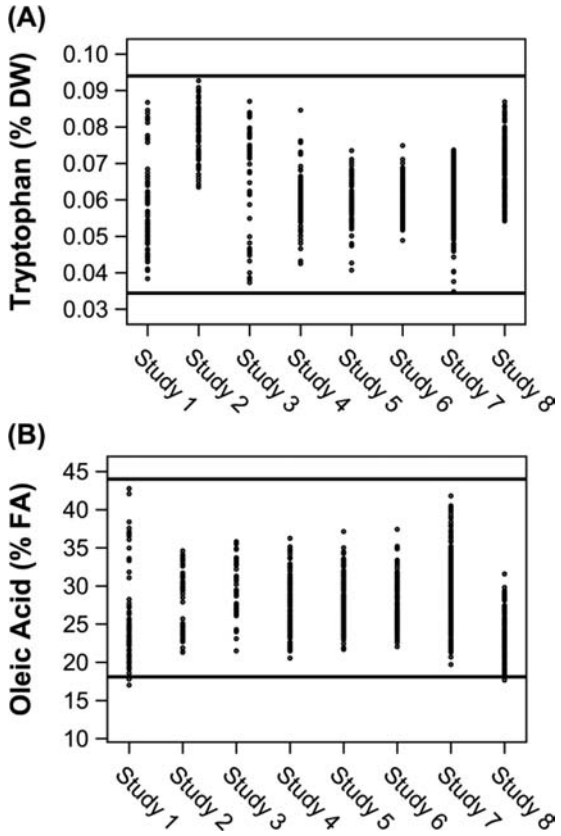

**Figure 5.** Dot plots for (A) tryptophan (% dry weight) and (B) oleic acid (% total fatty acids). The horizontal lines are tolerance interval limits constructed from the 2003−2011 maize grain cumulative historical data set for (A) tryptophan (0.0344, 0.0940) and (B) oleic acid (18.1, 44.0).

extremes of the population and may have <1% of data values outside the calculated tolerance interval for a given analyte. The same sample set may also have >1% of data values outside the calculated tolerance interval for a different analyte due to the random nature of sampling. As shown in Figure 5, this tolerance interval approach appropriately reflects the natural variation observed in this cumulative historical data set without over-extrapolation.

**Tolerance Interval Application.** During a substantial equivalence assessment, tolerance intervals can be used to interpret statistical differences within the biological context of natural variation. A statistically significant difference between the GM crop and the non-GM comparator in the compositional assessment may not be biologically relevant. Like any statistical test, the statistical power (i.e., the power of detecting a difference) is driven by the size of the study and the variation in the study data,[34] and detection of a statistical difference does not address whether the difference is biologically relevant. Composition data may vary more or less for some analytes compared to other analytes. Therefore, individual analytes end up having different statistical powers, and some analytes may be statistically overpowered due to smaller data variation. For any statistical comparison, there is a possibility of identifying a statistically significant difference by chance (known as type I error or false-positive error). In other words, across all composition analytes for which statistical comparisons are conducted between a GM crop and a non-GM comparator at the significance level of 0.05, statistically significant differences

dx.doi.org/10.1021/jf502158q | J. Agric. Food Chem. 2014, 62, 9916−9926

are expected to be identified for 5% of the analytes due to false-positive error. Additionally, even if a statistically significant difference could be attributed to the genetic modification, the magnitude of the difference is usually negligible when compared to the influence from genetics and environments as demonstrated previously in compositional equivalence evaluations of GM crops.[35−37] Consequently, it is critical to place any statistical difference within biological context. Tolerance intervals derived from cumulative historical data are a powerful tool to examine biological relevance of significant differences because the data are collected from the population with a history of safe use. Our tolerance interval approach makes statistical inference to the natural range of population values for a given analyte. This inferred natural range then becomes the basis of biological context for compositional equivalence evaluation.

To provide an example of how a tolerance interval is utilized to assist with the substantial equivalence assessment of GM crop composition data, one multisite field study is presented here. This study (identified as study 4 in Figure 5) was conducted in North America during the 2010 growing season at nine field sites. The study contained four GM maize hybrids and one non-GM near-isogenic control maize hybrid (referred to as control maize hybrid). All GM maize hybrids and the control maize hybrid were from the same genetic background. The study also contained six non-GM commercial maize hybrids (referred to as reference maize hybrids). At each site, three of the six reference maize hybrids were randomized together with all four GM maize hybrids and the control maize hybrid in a randomized complete block design according to European Food Safety Authority (EFSA) guidance.[38] The resulting grain composition data were statistically analyzed to compare the across-site means of each of the four GM maize hybrids to the across-site mean of the control maize hybrid.

Tryptophan and oleic acid concentrations are summarized in side-by-side box plots for each GM and control maize hybrid, as well as for the pooled data from the six reference maize hybrids (Figure 6). The tryptophan and oleic acid tolerance intervals constructed from the 2003−2011 maize grain cumulative historical data set are also provided in Figure 6. For tryptophan, a statistically significant difference (at the significance level of 0.05) was identified between one GM maize hybrid and the control maize hybrid (identified as GM2 and COMP91, respectively, in Figure 6A). When the mean values designated by the diamond within each box plot are compared, the statistical difference between the GM2 and control means for tryptophan is not visually obvious, with a magnitude of <4% (GM2 mean = 0.0610% dry weight, control mean = 0.0632% dry weight). For oleic acid, a statistically significance difference was identified for three of the GM maize hybrids (identified as GM2, GM3, and GM4 in Figure 6B) compared to the control maize hybrid (COMP91). The statistical difference between each GM mean compared to the control mean for oleic acid was <20% (GM2 mean = 31.0% total fatty acid, GM3 mean = 31.4% total fatty acid, GM4 mean = 32.7% total fatty acid, control mean = 27.3% total fatty acid); this magnitude of difference is more visually obvious when the mean values designated by the diamond within each box plot are compared.

The next step in the substantial equivalence assessment was to compare any relevant GM maize line data ranges to the corresponding tolerance interval for each identified statistically significant difference, to examine the statistical difference in the context of the crop population with an established history of safe use. For both analytes, all box plots fell within the respective tolerance interval (constructed from the 2003−2011 maize grain cumulative historical data set). Because the tryptophan and oleic acid data ranges of the corresponding GM maize hybrids fell within the respective range of natural variation for the analyte, it can be concluded that the statistical differences are not biologically relevant.

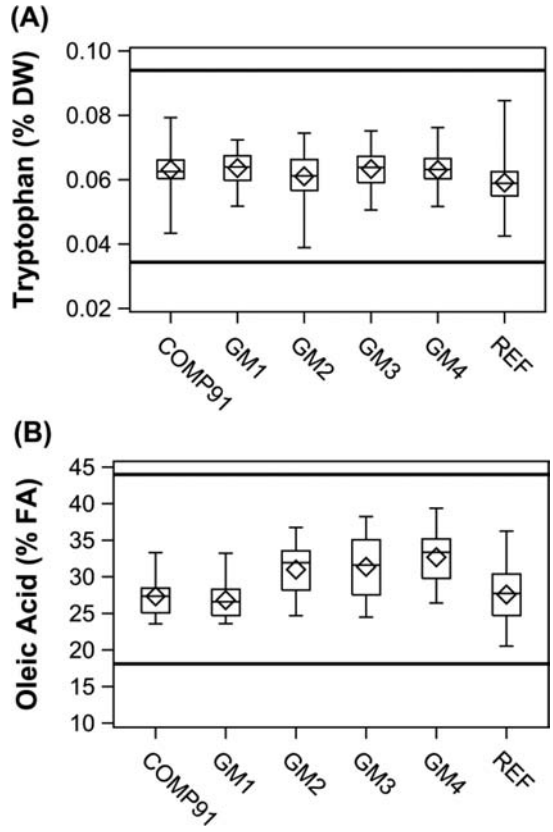

**Figure 6.** Box plots by genotype for (A) tryptophan (% dry weight) and (B) oleic acid (% total fatty acids) in a single study (study 4 in Figure 5). Data were plotted for the near-isogenic control maize hybrid (coded COMP91), the four genetically modfied maize hybrids (coded GM1, GM2, GM3, and GM4), and combined data from the six reference maize hybrids (coded REF). The diamond within each box plot represents the mean value. The whiskers were drawn from the first quartile and third quartile to the minimum and maximum data points, respectively. The horizontal lines are tolerance interval limits constructed from the 2003−2011 maize grain cumulative historical data set for (A) tryptophan (0.0344, 0.0940) and (B) oleic acid (18.1, 44.0).

Additionally, Figure 6 illustrates a limitation of sampling commercial reference data in a single study, in that the interquartile ranges for the pooled data from the reference maize hybrids are not noticeably larger than those of the individual GM or control maize hybrids. The limited number of environments and genotypes represented in one multisite field study conducted in a single year results in reference data that do not adequately represent the population. This reference data may even be a biased sample set due to extreme environmental conditions experienced in that particular year. As illustrated in Table 4, $m$ and $R_0$ values derived from the single-study reference hybrids are well below the recommended minimums of 60 and 50, respectively. The best way to ensure that individual $m$ and $R_0$ values for a given data set are above the recommended minimums is to include more extensive sampling

**Table 4. Comparison of Key Parameters for Sample Size Adequacy**

| | cumulative historical data[a] | | single study data | |
|---|---|---|---|---|
| analyte | $m$[b] | $R_0$[c] | $m$ | $R_0$ |
| tryptophan | 81 | 57 | 23 | 12 |
| oleic acid | 140 | 66 | 22 | 12 |

[a]The 2003−2011 maize grain cumulative historical data set. [b]$m$ is the Satterthwaite degrees of freedom. [c]$R_0$ is the estimated ratio of the total variance over the variance of the grand mean.

from a large number of genotypes and representative environments, which may require multiple years of data accumulation.

**Importance of Cumulative Historical Data.** A cumulative historical data set provides a greater number of environments (i.e., field sites) and a greater diversity of environmental and other site-specific factors including soil characteristics (e.g., soil type, pH, organic matter), environmental conditions (e.g., temperatures, precipitation, solar radiation, humidity, wind), management practices (e.g., crop history, tillage practices, pesticide applications, fertilizer applications, irrigation), and biotic factors (e.g., insects, pathogens, weeds). For example, the environmental diversity of the North American sites used in the 2003−2011 maize grain cumulative historical data set is illustrated in Figure 7. An environmental classification system that defines long-term abiotic macroenvironment types for maize production[39] was used to construct Figure 7. Cumulative historical data also incorporate increased genotypic diversity compared to a single-year multisite field study because of the availability and inclusion of more genotypes over time. Tolerance intervals generated from cumulative historical data are more robust than reference data from a single study due to sample size adequacy and increased environmental and genotypic diversity and are, therefore, more representative of the actual corresponding range of values for the population.

Over the past few years, some interest has been expressed in the application of an equivalence testing approach to the substantial equivalence assessment of GM crops. One approach is to grow non-GM commercial reference lines in the same study at the same field sites as the corresponding GM and non-GM near-isogenic control lines and to utilize the resulting non-GM commercial reference composition data to generate an equivalence interval for each analyte.[38] The purpose of the equivalence test is to assess whether the mean of the GM crop (i.e., 90% confidence interval of the mean) for each given analyte falls within the corresponding equivalence interval at a given level of statistical confidence (i.e., 95%). This approach is conceptually appealing but has a number of limitations.

As discussed previously, the limited number of environments and genotypes contained in a single multisite field study results in an inadequate representation of the population. This particular equivalence interval approach relies heavily on the estimated value of genotypic variance (i.e., parameter $\sigma_G^2$ is the key component of the equivalence interval), but without extensive testing of the genotypes under their relevant environments, it is impossible to obtain an accurate estimate of the genotypic variance. In the previously described single multisite field study, the non-GM near-isogenic control maize, although considered as safe as the non-GM commercial reference lines, has a tryptophan mean confidence interval (0.0607% dry weight, 0.0649% dry weight) that does not entirely fall within the equivalence interval (0.0530% dry weight, 0.0646% dry weight) established by the non-GM commercial reference lines within the study. It is therefore

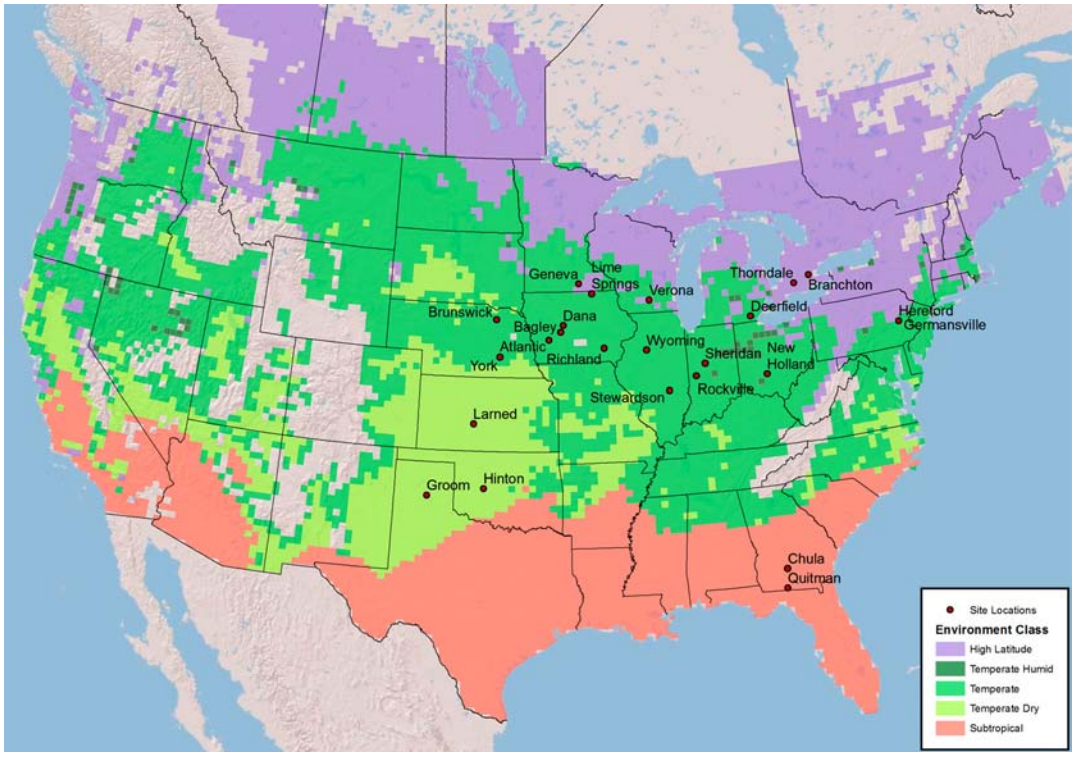

**Figure 7.** Environmental classification of long-term abiotic macroenvironment types for maize production in North America using the classification system described by Löffler et al.[39] and 30 year (1982−2012) weather data.

dx.doi.org/10.1021/jf502158q | J. Agric. Food Chem. 2014, 62, 9916−9926

noted that the equivalence test, as well as any statistical test, cannot be relied on as the sole tool to evaluate the compositional equivalence of a GM crop. In fact, because the equivalence limits are estimated values that depend on which reference lines are included in a given study, this particular equivalence testing approach is not a legitimate statistical equivalence test. A classical equivalence test requires the equivalence limits to be fixed a priori.[40] Tolerance intervals generated from cumulative historical data are more robust and provide a more adequate inference to the natural ranges of the population values compared to equivalence intervals generated from a single multisite field study.

**Advantages of Tolerance Interval Approach.** Environmental and genotypic variances are generally large contributors to the overall total variation of composition data values.[9−11,13] Appropriate and adequate sampling of both environments and genotypes is critical to accurately estimating the total variance of the population and the resulting tolerance intervals. Our model-based parametric tolerance interval approach has many advantages over other approaches for use in substantial equivalence assessment of a given GM crop. This approach considers the correlated and unbalanced data structure of multisite field studies over multiple seasons, as opposed to nonparametric and classical parametric approaches, which assume the data are *iid*. The approach can be executed using SAS or other appropriate statistical software and is more computationally feasible than some other alternatives that require statistical resampling and heavy computation. The approach is conservative in that it provides a tolerance interval narrower than a true 99%-content, 95%-confidence tolerance interval. The conservative nature of this approach is acceptable in the context of GM crop safety assessment because it is less likely to incorrectly conclude that a statistical difference is not biologically relevant. The two parameters associated with this tolerance interval approach, $m$ and $R_0$, can be used to evaluate the adequacy of a data set in the context of the correlated and unbalanced data structure. The use of $m$ and $R_0$ for data set evaluation is of greater practical value compared to a universal minimum sample size $n$ applied to all composition analytes regardless of data structure. Tolerance intervals generated from cumulative historical data are more robust than reference data ranges or equivalence intervals derived from a single study, because cumulative historical data provide a more adequate sample size as well as greater environmental and genotypic diversity. It is appropriate to use these tolerance intervals as reference ranges to evaluate biological relevance of statistical differences identified during substantial equivalence assessment of a GM crop.

The use of literature ranges in a substantial equivalence assessment is a complementary way to evaluate the biological context of statistical differences. In the case of the 2003−2011 maize grain cumulative historical data set, some tolerance intervals were narrower than the corresponding literature ranges, and some were wider (data not shown). The width of a given literature range may be influenced by the number of maize genotypes represented (which may be larger or smaller than the number of genotypes represented by Pioneer brand non-GM commercial maize lines in the corresponding tolerance interval derived from the 2003−2011 maize grain cumulative historical data set). The width of the literature range may also be restricted by the infrequent updates of existing data sources, such as the International Life Sciences Institute (ILSI) Crop Composition Database (which is a compilation of non-GM crop composition data from a number of companies engaged in the agricultural biotechnology industry),[41,42] or by the lack of recent publications to add to the literature ranges. Because access to a diverse range of non-GM commercial lines can be restricted due to proprietary concerns, and given the premise that all non-GM commercial lines have a history of safe use, it is therefore worthwhile to consider establishing a common set of tolerance intervals and/or equivalence intervals across the agricultural biotechnology industry. Currently, the necessary information for model-based tolerance interval construction is not available from the ILSI Crop Composition Database[42] (e.g., distinguishing between different lines and different locations). There might be future opportunity to expand the existing ILSI Crop Composition Database with this additional information or to establish a different database that is suitable for this purpose.

In conclusion, under the substantial equivalence framework for crop composition assessment, it is important to acknowledge the value of cumulative historical data. One way to utilize cumulative historical data is to generate a set of tolerance intervals using an approach that appropriately considers the correlated data structure. Our tolerance interval approach has a solid theoretical basis, provides an ease of implementation, and offers a practical solution to the representation of natural variation derived from crop populations with an established history of safe use for practitioners in the field of GM crop safety assessment.

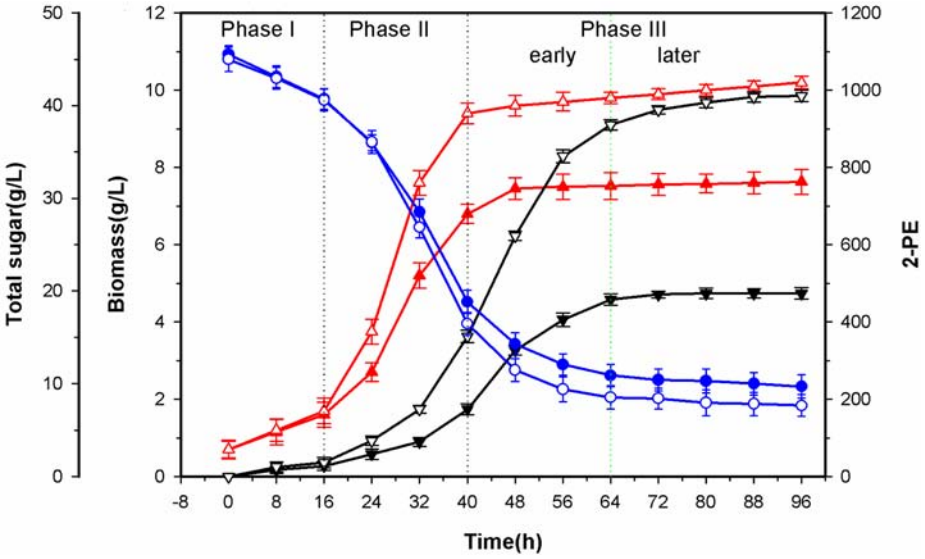

**Figure 1.** Time course profiles of key fermentation parameters (dry cell weight, total sugar, and 2-PE concentration) with 2 L airlift loop reactors. Red triangles represent dry cell weight, black inverted triangles represent 2-PE production, and blue circles represent total sugar. Solid and open symbols represent C1 and C2 conditions, respectively. Values shown represent the means of five independent experiments, and error bars represent standard deviations of five values.

understanding of the influences of intracellular metabolites on 2-PE production, as well as revealing the mechanism of MMC high-producing 2-PE at a systematic level, becomes increasingly important.

Here, the MMC utilizing CMW were employed to produce 2-PE under different conditions. Differences in 2-PE production and cell growth are presented, and comparative metabolomics was applied to analyze the differences for overall intracellular metabolites of microbes. Feeding experiments were further carried out to verify the analysis results, and the metabolic mechanism hypothesis of the MMC high-producing 2-PE was proposed eventually.

## MATERIALS AND METHODS

**Wastewater.** Cane molasses wastewater (CMW), discharged in the pretreatment of cane molasses and alcohol fermentation process, was obtained from a cane sugar refinery in Nanning, Guangxi Province, China. CMW was centrifuged at 10000*g* for 10 min, the insoluble impurities were removed, and then an appropriate concentration of ammonium sulfate and sodium dihydrogen phosphate at the ratio chemical oxygen demand (COD):N:P = 100:2:1, as well as 6 g/L Phe, were added into the supernatant.

**Chemicals.** Succinic acid was purchased from Fluka (Buchs, Switzerland). Spectroscopic-grade methanol, acetonitrile, and trichloroacetic acid were purchased from Concord (Tianjin, China). *N*-Methyl-*N*-(trimethylsilyl)trifluoroacetamide (MSTFA) was purchased from J&K Scientific. Pyridine, methoxyamine hydrochloride, glucose 6-phosphate, ribulose 5-phosphate, ribose 5-phosphate, and fructose 6-phosphate were obtained from Sigma–Aldrich (St. Louis, MO). Distilled water was purified by use of the Milli-Q20 system (Millipore, Billerica, MA).

**Microbes and Culture Conditions.** The strains used in this study were derived from Mu et al.[18] in our previous work. They were identified as *Bacillus* sp., *Pseudomonas* sp., *Candida tropicalis*, *A. niger*, *S. cerevisiae*, *Kluyveromyces hubeiensis*, *Rhodotorula glutinis*, and *Issatchenkia orientalis*. All the fungi in this study were proposed as main 2-PE producers.[2,6] The eight strains could tolerate high concentrations of 2-PE, and mutual cooperation between the strains could well decolorize the wastewater and achieve resource ultilization.[18]According to the Kyoto Encyclopedia of Genes and Genomes (KEGG) database, each of the microbes contains six basic metabolic pathways: Embden–Meyerhof–Parnas (EMP) pathway, tricarboxylic acid (TCA) cycle, pentose phosphate pathway (PPP), shikimate pathway, amino acid metabolism, and fatty acid metabolism.

Airlift loop reactors with 2 L volume were used in the experiments, and 1.2 L of fermentation broth was transferred into each reactor. The initial operating conditions (C1) were set as temperature 30 °C, pH 5.0 ± 0.1, and air flow rate 0.4 vvm. The optimized operating conditions (C2) were kept as the temperature 35 °C, pH 7.0 ± 0.1, and air flow 0.8 vvm.

**Analysis Method.** The reactor operated for 96 h in batch cultivation mode. Five parallel cultures were sampled with 10 mL aliquots regularly. Biomass, calculated by dry cell weight, was measured by filtering through a preweighed 45 μm pore size filter, washing with 0.9% NaCl (w/w), and then drying to a constant weight at 80 °C.[19] Total sugar concentration in the fermentation broth was determined by anthrone colorimetry.[20] 2-PE was quantified by gas chromatography (GC, Agilent 6890N); conditions were set as PEG-20 M capillary column (30 m, 0.32 mm internal diameter, 0.25 μm film thickness, China) at 210 °C with a nitrogen carrier gas flow rate of 90 mL/min. A flame ionization detector was employed with hydrogen flow rate of 500 mL/min and air flow rate of 50 mL/min. The detection and sample temperatures were 210 and 240 °C, respectively.

**Sampling, Quenching, and Extraction of Intracellular Metabolites.** Samples (10 mL) for metabolic profiling were harvested at 24, 40, 64, and 80 h from the initial inoculation. The mixed cells were quenched and extracted as in previous reports[16,21] with slight modifications. For metabolite extraction, 1 mL of cold methanol–water solution (50% v/v, −40 °C) was added into cells, which were then frozen in liquid nitrogen for 1 min. The freeze–thaw cycle was repeated three times. After centrifugation at 5000*g* for 3 min, the supernatant was collected. Another 2.5 mL of cold methanol–water solution (60% v/v, −40 °C) was added into the precipitate for further extraction. After mixing and centrifugation at 10000*g* for 3 min, the extract was pooled with the former one, and the combined sample was centrifuged at 10000*g* for 5 min again. Finally, 100 μL extracts, mixed with 10 μL of succinic acid-$d_4$ (0.1 mg/mL) as internal standard, were lyophilized (D307 Christ, Germany) at −40 °C for 3–4 h and stored at −80 °C for further processing.

**Determination of Intracellular Metabolites.** Intracellular metabolites were determined by gas chromatography–mass spectrometry (GC-MS) and liquid chromatography–tandem mass spectrometry (LC-MS/MS). The apparatus, specific process, and parameter selection were performed according to Xia et al.[19] with slight changes

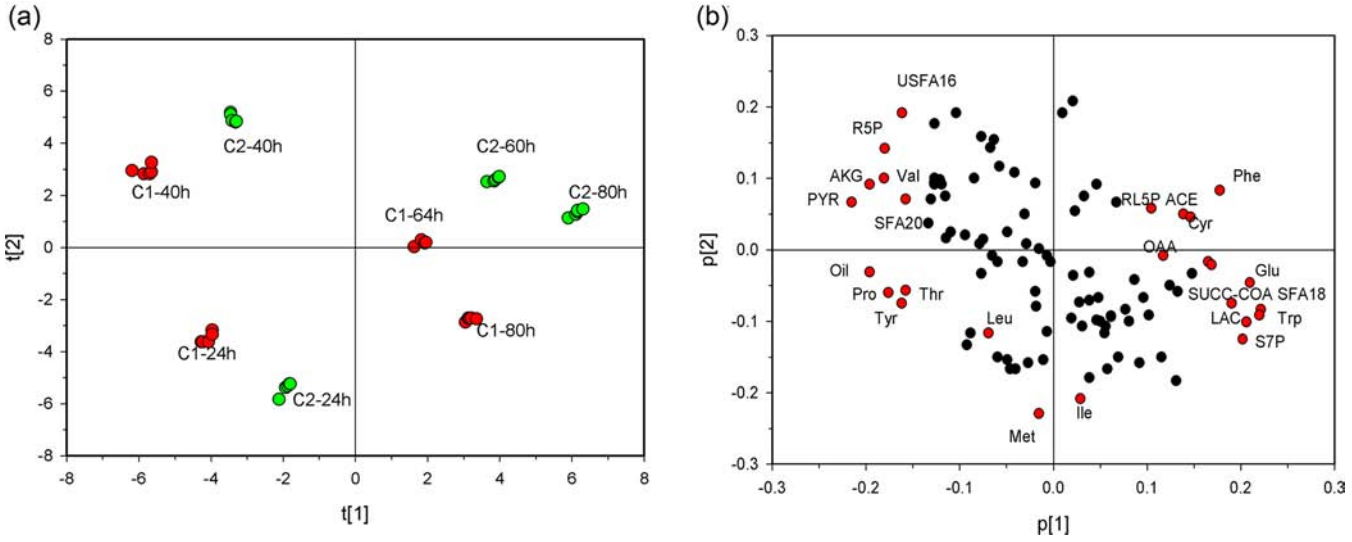

**Figure 2.** (a) PCA score and (b) loading plots.

in parameter settings. Derivatized sample (1 $\mu$L) was injected with a split ratio of 1:10, and scan range was set as 50−800 $m/z$ to acquire mass spectra in GC-MS.

High-performance liquid chromatography−electrospray ionization tandem mass spectrometry (HPLC-ESI-MS/MS) analysis was performed to quantify CoA esters. Extraction and analysis of intracellular CoA esters was carried out according to the method described by Park et al.[22] Parameters of selective ion scan of ester coenzyme A ($m/z$ parent > $m/z$ daughter) were monitored as a series of chromatograms: acetyl-CoA for 810/303, succinyl-CoA for 868/361. The area of each metabolite peak was normalized with the internal standard and cell biomass on the same chromatograph.

The generated normalized peak areas (variables) were imported into SIMCA-P v 11.0 (Umetrics, Umea, Sweden) for multivariate statistical analysis. Principal component analysis (PCA) and partial least-squares (PLS) discriminant analysis were carried out to investigate intracellular metabolite profiles. PCA, an unsupervised method, can gain insight into the nature of multivariate data. The PCA score plot was used to judge the similarities and differences among the samples by similar scores clustering together and different scores scattering. In the loading plot, each data point represented a unique metabolite, which was important to discriminate metabolic differences.[19] PLS analysis, a supervised method, was subsequently applied to evaluate the relationship between metabolites and products.[23] The variable importance in the projection (VIP) index was introduced to estimate the contribution of each metabolite variable to the pattern recognition quantitatively. Generally, a metabolite with VIP value greater than 1 illustrates a significant contribution to the separation of sample groups within the PLS model, and the higher the VIP value of a metabolite, the greater contribution it has.[19]

**Statistical Analysis.** Two-tailed $t$-tests were performed on specific metabolites by Microsoft Excel. At least a $P$ value < 0.01 was considered statistically different. Five replicates were used to perform multivariate analysis for each sample. Data were shown as the mean ± standard deviations for each analyzed sample.

## RESULTS AND DISCUSSION

**Performance of MMC Fermentation under C1 and C2 Conditions.** Fermentation performance under C1 and C2 conditions is shown in Figure 1. According to the change of biomass, the entire fermentation process could be divided into lag phase (phase I, 0−16 h), logarithmic phase (phase II, 16−40 h), and stationary phase (phase III, 40−96 h).

In lag phase, the mixed microbes were adapting themselves to the substrates, and the utilization of corresponding substrates and synthesis of some enzymes were being activated.[24] The biomass and total sugar consumption under the two conditions showed no significant difference. The biomass increased to 0.18 (C1) and 0.19 (C2) g/L. Little 2-PE was detected (Figure 1). In logarithmic phase, the highest biomass was achieved, up to 6.8 and 9.4 g/L under C1 and C2 conditions, respectively. The total sugar concentration decreased from 45 to 18.8 (C1) and 16.5 (C2) g/L. The production of 2-PE accumulated up to 175 (C1) and 361 (C2) mg/L, beginning to present significant differences. But it was not the main phase of 2-PE biosynthesis (Figure 1). During this period, some preferable nitrogen source ammonium sulfate existing in wastewater was first absorbed to facilitate the rapid growth of MMC but contributed little to 2-PE biosynthesis. When ammonium sulfate was depleted, the uptake of Phe was begun to synthesize 2-PE.[9] In stationary phase (phase III), cell growth stopped. As the main nitrogen source, Phe was utilized for 2-PE synthesis. During 40−64 h, the productivity of 2-PE was 0.01 (C1) and 0.02 (C2) $g{\cdot}L^{-1}{\cdot}h^{-1}$. The 2-PE concentration reached 459 (C1) and 910 (C2) mg/L, 2.62- and 2.52-fold higher compared to phase II, respectively. However, during 64−96 h, the production of 2-PE remained invariable with extremely low substrate consumption. The final concentration of 2-PE under C2 conditions (987 mg/L) was 2.07-fold higher than that under C1 conditions (477 mg/L). Therefore, based on the variation of 2-PE biosynthesis, phase III was divided into early stationary phase (40−64 h) and later stationary phase (64−96 h) for discussion below. Results indicated that the biosynthesis of 2-PE under two conditions mainly occurred in early stationary phase, and the MMC presented a perfect performance in production of 2-PE under C2 conditions.

Taken together, the MMC exhibited different fermentation behaviors under C1 and C2 conditions. To explore the reason why microbes had higher production under C2 conditions, it is necessary to study the intracellular metabolite profile of the mixed microbes. Hence, the changing of MMC intracellular metabolites would be profiled, and the metabolic mechanism hypothesis of MMC high-producing 2-PE could be proposed eventually.

**Identification of Key Metabolites and Metabolic Pathways Closely Associated with 2-PE Biosynthesis.** In total, 102 intracellular metabolites were identified by GC-

MS, LC-MS/MS, and HPLC-ESI-MS/MS, including sugars, organic acids, alcohols, amino acids, fatty acids, amines, and other compounds (see Table S1 in Supporting Information). The intracellular metabolic differences under C1 and C2 conditions were analyzed by multivariate statistical analysis. Initially, PCA ($R^2$ = 0.91, $Q^2$ = 0.94) was performed. A tight clustering of five parallels for individual time points and a clear separation between the different conditions revealed quite clear discrimination between samples under different culture conditions and fermentation times (Figure 2a). The result

dx.doi.org/10.1021/jf502239d | J. Agric. Food Chem. 2014, 62, 9927−9935

indicated that metabolomics was suitable to monitor culture processes and metabolic characteristics under different conditions.[25] In the loading plot (Figure 2b), each data point represented a unique metabolite and reflected the contribution of a specific component to the loading value. It demonstrated that the intermediate metabolites (represented by red circles in Figure 2b) from the EMP pathway, TCA cycle, PPP, shikimate pathway, amino acid metabolism, and fatty acid metabolism contributed most to the separate clustering.

In addition, PLS was applied to further verify the differences and identify the metabolites mainly responsible for discrimination between the two conditions. Owing to relatively high 2-PE production under C2 conditions, the samples were located in the upper right quadrant at 64 and 80 h, while the other samples were located in the lower left quadrant of the plot (Figure 3a). The significant discrimination on the PLS score plot profiling reflected the MMC metabolic differences under different conditions and stages. The contribution of each intracellular metabolite to 2-PE was shown by VIP score. Metabolites correlated to the first component (VIP score >1) were selected for further investigation. A total of 17 identified metabolites including lactate (LAC), pyruvate (PYR), acetate (ACE), oxaloacetate (OAA), succinyl-CoA (SUCC−COA), α-ketoglutarate (AKG), sedoheptulose-7-phosphate (S7P), erythrose 4-phosphate (E4P), L-tyrosine (Tyr), L-tryptophan (Trp), L-phenylalanine (Phe), L-glutamate (Glu), L-proline (Pro), L-leucine (Leu), L-threonine (Thr), stearic acid (SFA18), and oleic acid (USFA18) were found to be the key metabolites that were responsible for differentiation between the two conditions (Figure 3b). Those metabolites were involved in six basic metabolic pathways stated above (Figure 4) and will be discussed below in detail.

**Analysis of Six Basic Metabolic Pathways.** *Embden−Meyerhof−Parnas Pathway.* As illustrated in Figure 5, EMP

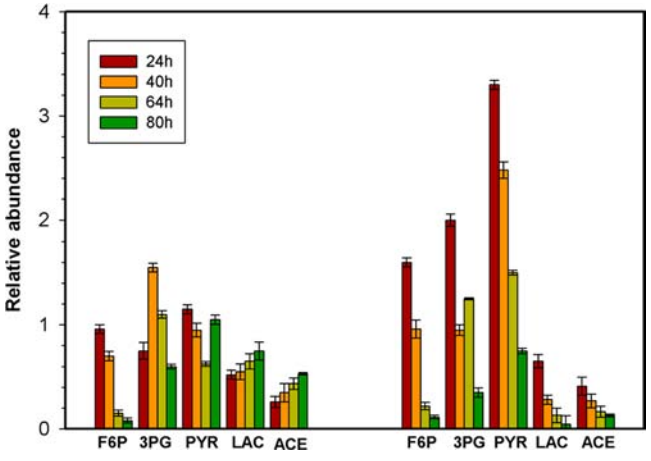

**Figure 5.** Relative abundance of intracellular metabolites in EMP pathway under (left) C1 and (right) C2 conditions. F6P, fructose 6-phosphate; 3PG, 3-phosphoglyceric acid; PYR, pyruvate; LAC, lactate; ACE, acetate.

metabolite levels under C2 conditions were higher than those under C1 conditions at 24 and 40 h. However, few differences could be seen in the EMP pathway at 40 and 80 h. In the whole fermentation process, 3-phosphoglyceric acid (3PG) presented different trends between C1 and C2. The relative abundance of 3PG under C1 conditions rose from 0.75 (24 h) to 1.55 (40 h) and then decreased to 0.6 (80 h). But under C2 conditions, it declined from 2 (24 h) to 0.95 (40 h), then rose slightly up to 1.25 (64 h), and eventually fell to 0.35 (80 h). The change of 3PG was closely related to levels of its derivatives such as serine, glycine, and cysteine (Figure 4). During 24−40 h, with 3PG being consumed rapidly, amino acids were quickly synthesized under C2 conditions. During stationary phase, synthetic rates of amino acids slowed down with the accumulation of 3PG; afterward 3PG was consumed for maintaining the survival of microbes. The relative abundance of pyruvate under C2 conditions was obviously higher than that under C1 conditions at 24 and 40 h. Then it dropped sharply in the entire fermentation process, falling from 3.3 to 0.75. But no significant change was found for C1. However, lactate and acetic acid under C1 conditions were accumulated, and the relative abundance reached 0.75 and 0.53, respectively, at 80 h. Conversely, the relative abundance of lactate and acetate under C2 conditions was extremely low at 80 h: 0.043 and 0.13, respectively. According to the carbon metabolic network of microorganisms, pyruvate flux could be toward lactate, acetate, amino acids, or acetyl-CoA. These metabolic branches competed with each other for carbon flux, and the flux distribution determined the metabolic state of MMC.[26] Results indicated that some pyruvate metabolic flows under C1 conditions distributed to lactate and acetate, resulting in accumulation of lactate and acetate during stationary phase. However, under C2 conditions, pyruvate was mainly expended in anabolism or converted to acetyl-CoA, and intracellular lactate and acetate were utilized. The high VIP from PLS suggested that lactate (VIP = 2.3), acetate (VIP = 2.5), and pyruvate (VIP = 4.37) were significant relevant to 2-PE biosynthesis. Therefore, feeding experiments were carried out to prove the analysis above, under the premise that carbon flux distribution to acetyl-CoA under C2 conditions was still insufficient. Pyruvate (5 g/L), lactate (2 g/L), and acetate (0.5 g/L) were added at 16 h under C2 conditions, since their high concentration would make the pH drop and cause microorganism overload.[27] It was found that 2-PE production was increased to 1077, 1204, and 1180 mg/L, respectively, suggesting that an improvement of carbon flux distribution to acetyl-CoA would benefit the accumulation of 2-PE.

*Tricarboxylic Acid Cycle.* TCA cycle metabolite levels under C2 conditions were apparently higher than those under C1 conditions at 24 and 40 h (Figure 6). It demonstrated that the intracellular metabolites NADH and ATP under C2 conditions were higher at 24 and 40 h, providing more material, reduction−oxidation, and energy to maintain microbe energetics and keep the 2-PE synthesis system highly efficient.[28] The levels of OAA, AKG, SUCC−COA, and FUM dropped at 64 and 80 h compared to those at 24 h. Furthermore, the relative abundance of intracellular OAA under C2 conditions was lower than that under C1 at 64 and 80 h, reflecting the weak TCA cycle under C2 conditions during stationary phase. No obvious differences were found for FUM and CIT between C1 and C2. However, AKG and SUCC−COA under C2 conditions were much higher than under C1 conditions. Since AKG and SUCC−COA were correlated with TCA cycle as well as amino acid (Glu and Pro) metabolism (Figure 4), higher AKG and SUCC−COA level as well as lower citric acid level indirectly reflected the higher catabolism of Glu and Pro. Furthermore, not only could AKG provide NADH for microbes when AKG converted to SUCC−COA, but it could also be regarded as the ammonia receptor in the deamination process of Phe. Therefore, a higher intracellular AKG level under C2

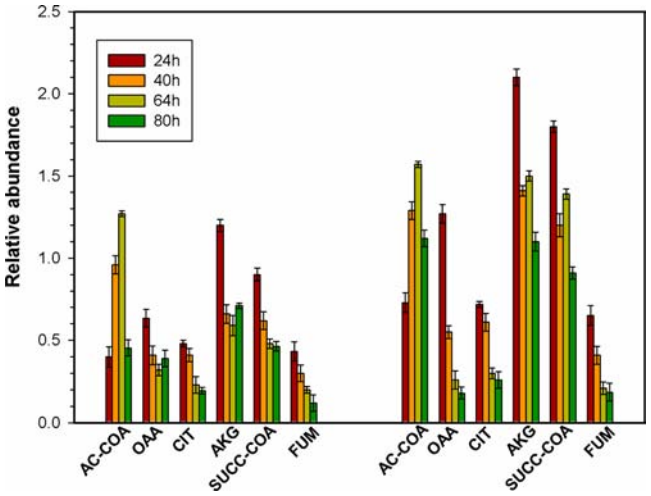

**Figure 6.** Relative abundance of TCA cycle intracellular metabolites under (left) C1 and (right) C2 conditions. AC−COA, acetyl-CoA; OAA, oxaloacetate; CIT, citrate; AKG, $\alpha$-ketoglutarate; SUCC−COA, succinyl-CoA; FUM, fumarate.

conditions during stationary phase contributed to 2-PE biosynthesis.

*Pentose Phosphate Pathway.* PPP metabolites under C2 conditions were at higher levels than under C1 conditions at 24 h (Figure 7). However, the relative abundance of 6-

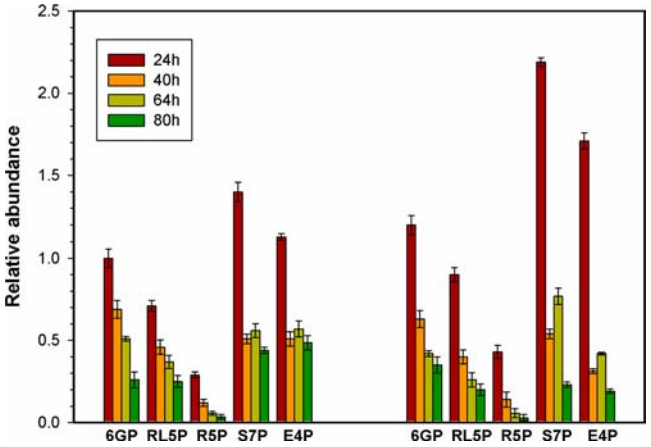

**Figure 7.** Relative abundance of intracellular metabolites in PPP under (left) C1 and (right) C2 conditions. 6PG, glucose 6-phosphate; RL5P, ribulose 5-phosphate; R5P, ribose 5-phosphate; S7P, sedoheptulose 7-phosphate; E4P, erythrose 4-phosphate.

phosphogluconic acid (6PG), ribulose 5-phosphate (RL5P), and ribose 5-phosphate (R5P) under both conditions declined in the entire metabolic process. As precursors of nucleotide synthesis, 6PG, RL5P, and R5P were rapidly consumed in nucleotide synthesis. The level of sedoheptulose 7-phosphate (S7P) and erythrose 4-phosphate (E4P) under C2 conditions declined at 40 h and then slightly increased at 64 h. E4P is a precursor of aromatic amino acid biosynthesis. The level change of S7P and E4P was opposite to that of intracellular aromatic amino acids. This phenomenon might be related to the process where anabolism of aromatic amino acids was repressed and turned into catabolism.[29] It was accompanied by rapid catabolism of Phe and biosynthesis of 2-PE. Therefore, S7P and E4P declined during logarithmic phase, with a slight accumulation during early stationary phase. It could be concluded that S7P and E4P influenced 2-PE biosynthesis by influencing the metabolism of the shikimate pathway indirectly.

*Shikimate Pathway.* The relative abundance of shikimic acid presented similar variation under both conditions. It first increased from 0.45 (24 h) to 0.82 (40 h) and then gradually decreased to 0.35 (80 h) under C2 conditions, and it increased from 0.23 (24 h) to 0.41 (40 h) and then decreased to 0.33 (80 h) under C1 conditions (Figure 8). It can be seen that shikimic

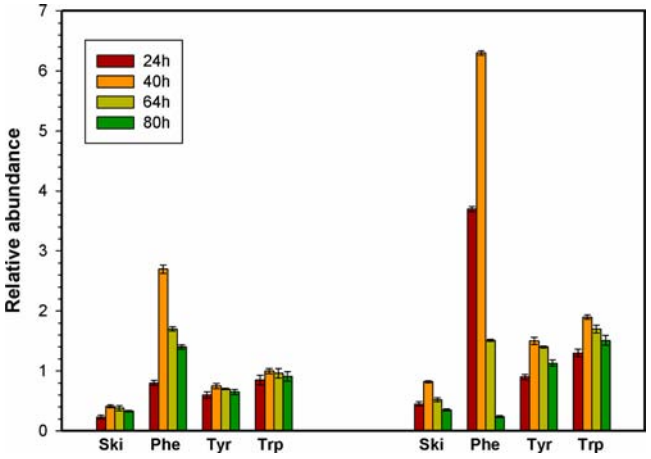

**Figure 8.** Relative abundance of intracellular metabolites in shikimate pathway under (left) C1 and (right) C2 conditions. Ski, shikimic acid; Phe, L-phenylalanine; Tyr, L-tyrosine; Trp, L-tryptophan.

acid was rapidly synthesized during logarithmic phase, which was confirmed by the simultaneous increment of intracellular aromatic amino acids. During stationary phase, the anabolic rate of shikimic acid declined, which could be seen from the decline of intracellular shikimic acid concentration. Meanwhile, the relative abundance of aromatic amino acids Tyr and Trp slowly decreased under both C1 and C2 conditions. It might be that accumulation of excessive aromatic amino acids at 40 h generated feedback inhibition on the activity of key enzymes in the shikimic acid anabolic pathway.[29] As a result, shikimic acid synthesis was repressed and the metabolism of aromatic amino acids was shifted from anabolism to catabolism, promoting 2-PE biosynthesis. The relative abundance of Phe under C2 conditions declined notably from 6.3 at 40 h to 0.14 at 80 h. Phe under C1 conditions also declined in some degree, from 2.7 to 1.4. It was thought that the Ehrlich pathway was activated, leading to rapid decline of Phe as well as biosynthesis of 2-PE during the process.[30] At 40 h, the intracellular Phe level under C2 was higher than that under C1. It may be because metabolism of MMC under C2 conditions was more active, and more nitrogen (Phe) uptake from the environment was needed.[9,31] Subsequently, intracellular Phe was consumed to biosynthesize 2-PE and thus declined sharply.[32]

To prove the analysis above, feeding experiments were performed, with the assumption that the uptake of amino acids from the environment by cells did not saturate. Phe (12 g/L), Tyr (1 g/L), and Trp (1 g/L) were supplied at 32 h under C2 conditions, since a high concentration of Tyr and Trp could compete with Phe for catabolism, which would reduce 2-PE production.[33] The results showed that 2-PE production was increased to 1341, 1200, and 1169 mg/L, for enhancement of 36%, 21.6%, and 18.4%, respectively. This suggested that the appropriate accumulation of intracellular Tyr and Trp could

dx.doi.org/10.1021/jf502239d | J. Agric. Food Chem. 2014, 62, 9927−9935

facilitate the shift of aromatic amino acids from anabolism to catabolism, and high Phe concentration could promote 2-PE biosynthesis through the Ehrlich pathway at the end of logarithmic phase.

*Amino Acid Metabolism.* For amino acid metabolism, changes of various amino acids are shown in Figure 9. These

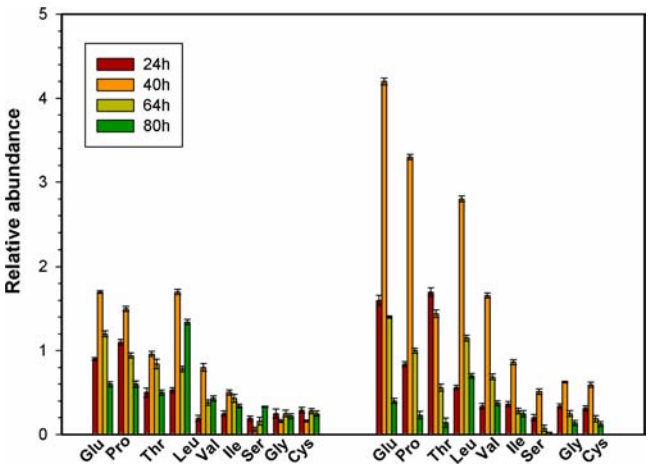

**Figure 9.** Relative abundance of intracellular metabolites in amino acid metabolic pathway under (left) C1 and (right) C2 conditions. Glu, L-glutamate; Pro, L-proline; Thr, L-threonine; Leu, L-leucine; Val, L-valine; Ile, L-isoleucine; Ser, L-serine; Gly, L-glycine; Cys, L-cysteine.

detected amino acids required biosynthetic precursors involved in central carbon metabolism (EMP pathway, TCA cycle, and PPP) and were linked to the synthesis of new cellular components or energy sources needed in fermentation at the expense of the amino acid pool. For example, Gly, Ser, Cys, Leu, and Ile could derive from the EMP pathway. Glu, Pro, and Val could flow to TCA, and Thr could flow to the EMP pathway. PLS analysis demonstrated that Glu, Pro, Thr, and Leu, with VIP values greater than 1, were correlated with 2-PE biosynthesis.

Glu and Pro are important carbon skeletons for AKG by catabolism (Figure 4).[34] The relative abundance of Glu and Pro under C2 conditions was 4.2 and 3.3 at 40 h and then significantly fell to 0.4 and 0.23, respectively. However, the maximum relative abundance of Glu and Pro under C1 conditions was just 1.7 and 1.5 and subsequently declined to 0.6 and 0.6, respectively. It could be inferred that intracellular Glu and Pro under C2 conditions were consumed rapidly during the 2-PE biosynthesis period. Apart from supporting protein synthesis and cell growth, Glu and Pro are also catabolized for AKG regeneration, which is consistent with the analysis result of TCA. Thr is an important amino acid for pyruvate synthesis. The alteration of Thr level directly reflected its metabolic flux state toward the EMP pathway.[35] Under C1 conditions, relative abundance of Thr remained below 1, without obvious fluctuation. On the contrary, under C2 conditions, the abundance of Thr changed dramatically from 1.7 at 24 h to 0.2 at 80 h, indicating that Thr was consumed to provide some metabolites related to the EMP pathway and maintain cells' normal metabolism during stationary phase. The sharp decline of Thr under C2 conditions reflected the urgent need of microbes for catabolism, and indirectly influenced 2-PE biosynthesis. Leu could be derived from pyruvate and degraded to acetyl-CoA, which was closely associated with fatty acid synthesis (Figure 4).[36] The abundance of Leu may reflect the level of EMP pathway and metabolic flux to fatty acid pathway. At 40 h, the relative abundance of Leu was up to 2.8 under C2 and 1.7 under C1, demonstrating that intracellular metabolic flux of EMP pathway was higher under C2 during logarithmic phase. However, the relative abundance of Leu under C2 decreased to 1.6 at 80 h. The sharp decline of Leu under C2 conditions might correlate with the precursor supplement of fatty acid synthesis and promote the synthesis of membrane lipid composition to tolerate 2-PE toxicity.[37]

Therefore, feeding those amino acids in the early stage could provide precursors for metabolism. However, as the adding time was delayed, those amino acids, regarded as nitrogen, could compete with Phe for nitrogen utilization,[32] which would result in the drop of 2-PE production. Complex amino acids (2 g/L Glu, Pro, Thr, and Leu, mixed in equal proportion) were added to wastewater at 16 h under C2 conditions. The 2-PE production was increased to 1133 mg/L, demonstrating that Glu, Pro, Thr, and Leu would affect 2-PE biosynthesis.

*Fatty Acid Metabolism.* In fatty acid metabolism, the levels of metabolites such as eicosanoic acid (SFA20), stearic acid (SFA18), heptadecanoic acid (SFA17), and palmitic acid (SFA16) under C2 conditions were significantly lower than under C1 conditions (Figure 10). However, the levels of

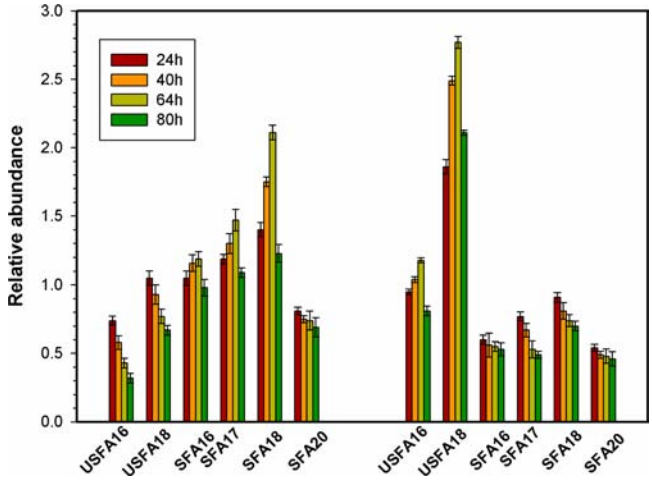

**Figure 10.** Relative abundance of intracellular metabolites in fatty acid metabolic pathway under (left) C1 and (right) C2 conditions. USFA16, palmitoleic acid; USFA18, oleic acid; SFA16, palmitic acid; SFA17, heptadecanoic acid; SFA18, stearic acid; SFA20, eicosanoic acid.

palmitoleic acid (USFA16) and oleic acid (USFA18) were higher than under C1 conditions. During the whole fermentation process, the average relative abundance of SFA18 under C2 conditions was only 0.49-fold of that under C1, and USFA18 was 2.7-fold of that under C1 conditions. The ratio of unsaturated fatty acids (USFA) to saturated fatty acids (SFA) under C2 conditions was obviously higher than that under C1 conditions. A high USFA/SFA ratio is conducive to the cell membrane gaining a strong capacity to resist the tough outside environment.[38] It is the main mechanism for microbes to adapt to environmental stress. 2-PE was toxic to microbes. One of the toxicity mechanisms is that aromatic alcohol could change the liquidity of the membrane, leading to easy permeability. Then the transport systems of sugars and amino acids in cytoplasmic membrane are affected, the passive diffusion of ions and small metabolites through the membrane

dx.doi.org/10.1021/jf502239d | J. Agric. Food Chem. 2014, 62, 9927−9935

is accelerated, and the gradient of transmembrane protons is disturbed, thus leading to leakage of intracellular ions and reduced intake of amino acids and sugars.[1] It was reported that oleic acid could prevent alcohol poisoning of cells by regulating the liquidity of the cell membrane.[39] Thus, unsaturated fatty acid played a significant role in improving the capacity of cell membrane to resist the toxicity of 2-PE. However, it also had been reported that a high concentration of oleic acid could inhibit the growth of microorganisms.[40] During early growth phase, oleic acid existing in the medium would be toxic to microbes.[41] Therefore, 15% (v/v) oleic acid was added to the CMW at 40 h under C2 conditions. Finally, 2-PE production was elevated to 1378 mg/L, increased by 39.6% compared to the control group without oleic acid supplement. The results suggested that cell membranes of 2-PE high-producers had a strong capacity to resist outside toxicity by increasing the ratio between intracellular unsaturated and saturated fatty acid concentrations.

**Metabolic Mechanism Hypothesis for High 2-PE Production by MMC Utilizing CMW.** From the analysis above, it was found that EMP pathway, TCA cycle, PPP, shikimate pathway, and amino acid pathway presented high metabolic levels during logarithmic phase, which was beneficial for absorbing nutrition for cell growth and promoting Phe uptake from the wastewater. During stationary phase, the metabolic levels of EMP and TCA cycle weakened. To maintain basic metabolism, the catabolism of intracellular amino acids was accelerated and the intracellular Phe was predominantly used to transaminate and synthesize 2-PE through the Ehrlich pathway.

On the basis of metabolic profiling analysis, during logarithmic phase, the metabolic flux of intracellular pyruvate, lactate, and acetate for high-producing MMC was converted to acetyl-CoA, improving the metabolic flux related to acetyl-CoA, which facilitated the uptake of Phe by cells for 2-PE biosynthesis. In the shikimate pathway, an appropriate accumulation of intracellular Tyr and Trp as well as an increase of intracellular Phe for microbes at the end of logarithmic phase could inhibit de novo synthesis of 2-PE, leading to 2-PE biosynthesized in quantity through the Ehrlich pathway. In amino acid metabolism, Glu, Pro, Thr, and Leu, associated with central carbon metabolism and fatty acid metabolism, indirectly reflected the cell metabolic state. In fatty acid metabolism, the resistance of cell membrane to 2-PE toxicity could be strengthened by increasing USFA/SFA. Those findings provided theoretical guidance for species domestication and selection as well as medium optimization when MMC utilized CMW to produce 2-PE.

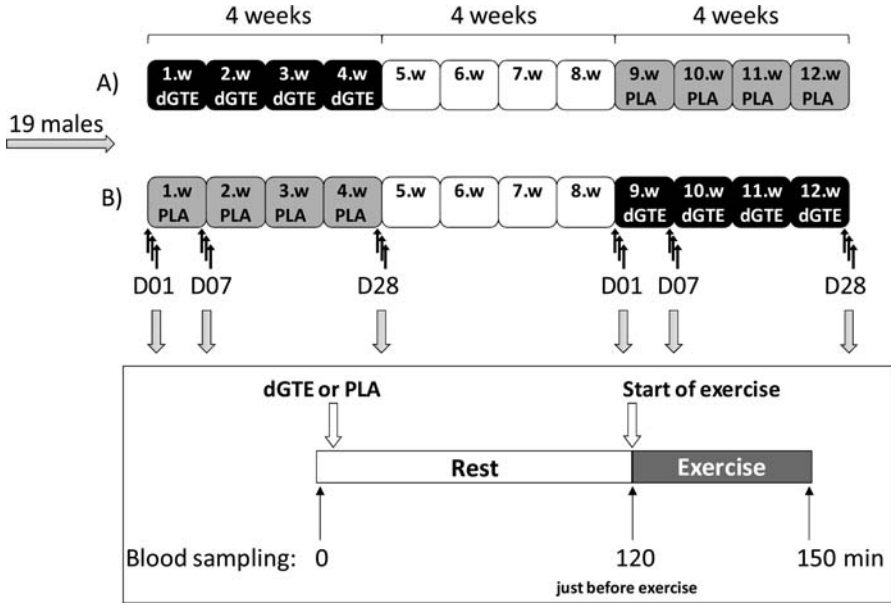

**Figure 1.** Study design: (A, B) study arms. PLA, placebo; dGTE, decaffeinated green tea extract; w, week; D01, D07, D28, day 1, 7, or 28 of the respective supplementation period.

useful in capturing the multifactorial and subtle influences of complex dietary ingredients on overall metabolism.

Therefore, in the present study, we applied GC-MS- and LC-MS-based untargeted four-phase metabolite profiling and targeted profiling of catecholamines to human plasma to compare the metabolic effects (i) between cGTE and dGTE supplementation and (ii) between 1, 7, and 28 days of dGTE ingestion at rest and during exercise.

## MATERIALS AND METHODS

**Study Design.** The study was designed as a double-blind, crossover, counterbalanced study (Figure 1) and has been described previously.[26] In brief, 20 healthy, physically active, habitual caffeine-consuming, male participants [mean ± SD age, 21 ± 2 years; weight, 75.0 ± 7.0 kg; body mass index (BMI), 23.2 ± 2.2 kg/m$^2$; maximal oxygen consumption ($\dot{V}O_{2max}$), 55.4 ± 4.6 mL·mL·kg$^{-1}$·min$^{-1}$] completed two 28 day supplementation periods of dGTE and PLA ingestion, separated by a 28 day wash-out period. One subject dropped out of the study. Each supplementation period included three experimental days, namely, on the first day (dGTE_D01 or PLA_D01), after 7 days (dGTE_D07 or PLA_D07), and after 28 days (dGTE_D28 or PLA_D28) of supplementation. Before each experimental day, the subjects followed a 24 h controlled diet (consisting of three meals each containing ∼50% carbohydrate, ∼35% fat, and ∼15% protein, total energy intake = 2700 kcal) and were asked to refrain from any physical activity and not consume alcohol- or caffeine-based beverages. On each experimental day, a resting blood sample (5 mL) was taken at baseline ($t$ = 0 min) after a 12 h overnight fast. Then the participants consumed two capsules of dGTE or PLA with 200 mL of water, rested for 2 h in a seated position and subsequently completed a 30 min cycle exercise bout at 50% $W_{max}$ (55 $\dot{V}O_{2max}$). Blood samples were taken before the exercise bout commenced ($t$ = 120 min) and at 30 min during the exercise bout. Participants ingested four capsules per day containing dGTE or PLA for a total of 28 days, respectively. Two capsules were consumed an hour before lunch (or 2 h before the exercise bout on the experimental days), and two additional capsules were consumed an hour before dinner. The dGTE was Sunphenon 90 DCF-T (lot 003191) obtained from Taiyo Europe (Fiderstadt, Germany). Each dGTE capsule contained 156 ± 3 mg of EGCG, 284 ± 6 mg of total catechins, and ∼3 mg of caffeine. (The catechin composition has been reported in ref 28.) The total catechin ingestion was 1136 ± 24 mg per day. The PLA capsule contained 273 ± 25 mg of cellulose.

All participants gave written informed consent to participate in the study. The study was approved by the Life and Sciences Ethical Review Committee at the University of Birmingham.

All blood samples were collected in EDTA-containing tubes and stored on ice for no longer than 35 min. Subsequently, plasma was separated by centrifugation (3500 rpm, 15 min, 4 °C), aliquoted in 1 mL samples, and stored at −80 °C.

**Data Acquisition.** *Plasma Analysis of Polyphenols.* Polyphenol concentrations in plasma from 19 subjects were analyzed at $t$ = 0 min and $t$ = 120 min on all six experimental days. In total, 225 samples (3 samples were missing) were measured by high-performance liquid chromatography multiple-reaction monitoring mass spectrometry (HPLC-MRM-MS) with prior enzymatic deconjugation of glucuronides and sulfates, as described previously.[23] In total, 9 phenolic compounds were quantified by means of 10-point calibration curves using external standards. They included (−)-catechin (C), (−)-epicatechin (EC), (−)-gallocatechin (GC), (−)-epigallocatechin (EGC), (−)-epicatechin gallate (ECG), (−)-epigallocatechin gallate (EGCG), 3/4-*O*-methylgallic acid (3/4-OMGA), 5-(3′,4′-dihydroxyphenyl)-γ-valerolactone (3,4-diOH-VL), and 5-(3′-methoxy-4′-hydroxyphenyl)-γ-valerolactone (3-MeO-4-OH-VL). The concentrations of 3-*O*-methylgallic acid (3-OMGA) and 4-*O*-methylgallic acid (4-OMGA) were combined to 3/4-OMGA because they could not be fully separated. Similarly, combined ECG values were reported for ECG and CG.

*Metabolite Profiling.* Plasma metabolite profiles from 19 subjects were acquired from samples collected at $t$ = 0, 120, and 150 min on four experimental days (dGTE_D01, dGTE7_D07, dGTE_D28, PLA_D28), respectively.

Four-phase metabolite profiling and quantification of catecholamines were performed on human plasma samples at Metanomics Health GmbH, Berlin, Germany. Three types of mass spectrometry analyses were applied. GC-MS (gas chromatography−mass spectrometry; Agilent 6890 GC coupled to an Agilent 5973 MS-System, Agilent, Waldbronn, Germany) and LC-MS/MS (liquid chromatography-MS/MS; Agilent 1100 HPLC-System (Agilent) coupled to an Applied Biosystems API4000 MS/MS-System (Applied Biosystems, Darmstadt, Germany)) were used for broad profiling, as described by van Ravenzwaay et al.[29] SPE-LC-MS/MS (solid phase extraction-LC-MS/MS; Symbiosis Pharma (Spark, Emmen, The Netherlands) coupled to an Applied Biosystems API4000 MS/MS-System (Applied Biosystems, Darmstadt, Germany) was used for the determination of catecholamine concentrations. Two hundred and one metabolites fulfilled the quality criteria for relative quantification, and absolute quantification was

performed for additional 10 metabolites. From a total of 211 metabolites, 184 were known metabolites and 27 were not chemically identified with sufficient certainty (i.e., thus considered in the present study to be unknown analytes). The known metabolites belonged to different metabolite (ontology) classes: 22 amino acids; 17 metabolites related to amino acids; 12 carbohydrates and related metabolites; 84 complex lipids, fatty acids, and related metabolites; 16 metabolites related to energy metabolism; 13 hormones, signal substances, and related metabolites; 4 nucleobases and related metabolites; 7 vitamin, cofactors, and related metabolites; and 9 miscellaneous metabolites.

Technical reference samples were measured in parallel with the study samples to allow the relative quantification of metabolites in the study samples. These technical reference samples were generated by pooling aliquots of plasma from all study samples. Relative quantification for each metabolite was obtained by normalizing peak intensity in the study samples to the median peak intensity of the corresponding metabolite in the technical reference samples measured in the same batch.

For the metabolite profiling by GC-MS and LC-MS/MS, proteins were removed from plasma samples (60 $\mu$L) by precipitation. Subsequently, polar and nonpolar plasma fractions were separated for both GC-MS and LC-MS/MS analysis by adding water and a mixture of ethanol and dichloromethane. For GC-MS analyses, the nonpolar fraction was treated with methanol under acidic conditions to yield the fatty acid methyl esters derived from both free fatty acids and hydrolyzed complex lipids. The polar and nonpolar fractions were further derivatized with *O*-methyl-hydroxyamine hydrochloride (20 mg/mL in pyridine, 50 $\mu$L) to convert oxo groups to *O*-methyloximes and subsequently with a silylating agent (MSTFA, 50 $\mu$L) before GC-MS analysis.[30] For LC-MS/MS analyses, both fractions were reconstituted in appropriate solvent mixtures. High-performance LC (HPLC) was performed by gradient elution using methanol/water/formic acid on reversed phase separation columns. Mass spectrometric detection technology was applied as described in U.S. patent 7196323, which allows targeted and high-sensitivity "multiple reaction monitoring" profiling in parallel to a full screen analysis.

For the lipid phase, the broad profiling technology determines, for example, fatty acid concentrations after acid/methanol treatment, which is essential for derivatization preceding GC-MS analysis. As a consequence, complex lipids are hydrolyzed to components of the lipid backbone (i.e., glycerol) and fatty acids. Hence, the concentration of a fatty acid determined by this procedure represents the sum of its occurrence in free and in lipid-bound form. Components of the backbone can be recognized by the term ("lipid fraction") added to the metabolite name. As an example "glycerol, lipid fraction" represents glycerol liberated from complex lipids; in contrast, "glycerol, polar fraction" represents glycerol that had been present originally in the biological sample. The use of "additional" (add) indicates that quantification can be affected by the co-occurrence of metabolites exhibiting identical characteristics in the analytical methods. Literature data and/or comparison with alternative methods (e.g., LC-MS/MS, GC-MS) suggest that such metabolites are present at minor concentrations only.

Catecholamines and their related metabolites were measured by online SPE-LC-MS/MS, as described by Yamada et al.[31] Quantification was performed using stable isotope-labeled standards.

**Data Analysis of Metabolite Profiles.** The data set included 215 metabolite profiles. (One subject was excluded because of protocol violation. Another sample was missing.) Analysis of the four-phase metabolite profiles and the catecholamines were based on pool-normalized ratios and on absolute concentrations in nanograms per milliliter, respectively. For the multivariate and univariate statistical analysis, the data were log-transformed to better match normal distribution.

Principal component analysis (PCA) was performed using SIMCA P + version 12 software (Umetrics, Umea, Sweden). Data were centered and scaled to unit variance to introduce a common scale for all metabolites independent of their absolute variance. The explorative unsupervised multivariate analysis method PCA was used for the detection of trends, patterns, and groupings among samples and variables. PCA revealed outliers that belonged to samples from one subject and thus were excluded from further analysis.

Single-metabolite analysis of variance (ANOVA) analysis was performed using the R-software package nlme.[32,33] For this analysis, additional six samples were excluded, because their plasma catechin concentrations significantly deviated from average concentrations. The analysis was performed for in total 211 metabolites including all SQ metabolites from four-phase metabolite profiling and all catecholamines quantified by targeted profiling. A mixed-effects ANOVA model was built using the factors *treatment* (PLA_D28, dGTE_D01, dGTE_D07, dGTE_D28), *time* (0, 120, 150), *study arm* (A, B) and *subject*. All possible secondary and tertiary interactions between fixed factors were evaluated in the model refinement process. Model diagnostics was performed to ensure adequacy of the model structure. To this end, residuals were inspected visually by scatter plots of standardized residuals versus fitted values. Additionally, factors or interactions resulting in a number of significantly changed metabolites beneath the expected false-positive rate were excluded. Inclusion of all other factors and interactions ensured that residuals did not correlate with fitted values and showed homogeneous variance. No interaction between the factors *time* and *study arm* was considered. Thus, the following model was used (R annotation):

$$\text{fixed: } \sim(\text{treatment} + \text{time})^2 + \text{study arm}$$

$$\text{random: } \sim 1|\text{subject}$$

The *t* statistics results of the ANOVA models comprised estimates, standard deviations, *t* values, and *p* values and *q* values corrected according to the methods of Benjamini-Hochberg (*q* value) or Bonferroni (qval.Bonf). The resulting numbers of significantly changed metabolites were evaluated by binomial test to account for false positives due to multiple hypotheses testing.

## RESULTS

**Effect of dGTE on Exogenous Metabolites.** To check the compliance, the concentrations of several catechins were measured in plasma after deconjugation of glucuronides and sulfates at baseline ($t$ = 0 min) and 2 h after the ingestion of two capsules of dGTE or PLA ($t$ = 120 min) on D01, D07, and D28, respectively. Six individual samples were identified as outliers, and thus removed, because they did not confirm dGTE exposure in the dGTE condition or indicated dGTE exposure in the PLA condition.

The concentrations of the remaining 219 samples are shown as box plots in Figure 2. As expected, the concentrations of EGCG, EGC, EC, and ECG/CG significantly increased 2 h after dGTE ingestion. These catechins accumulated in plasma following 7 days of dGTE ingestion, as shown by the increased baseline levels at D07 when compared to D01. However, there was no further accumulation, because the baseline levels after 7 and 28 days dGTE intake were similar. The plasma concentrations of GC, C, and GCG were <10 ng/mL and did not show significant effects of dGTE (data not shown).

Besides the catechins, slight increases in 3/4-OMGA and salicylic acid (detected by the four-phase metabolite profiling) were found 2 h after dGTE ingestion. These metabolites appeared early in plasma, because 3/4-OMGA can be formed by methylation of gallic acid in the liver and salicylic acid may be present in dGTE, as it has been earlier identified in green tea infusion.[34] In contrast, the gut microbial metabolites 3,4-diOH-VL, pyrogallol, and hippuric acid (detected by the four-phase metabolite profiling) did not increase 2 h after dGTE ingestion, because they enter into the circulation at a later time. However, 3,4-diOH-VL and pyrogallol were increased at baseline after 7 and 28 days of dGTE ingestion, showing that these metabolites circulate in a steady state in plasma. The baseline concentrations of 3/4-OMGA, salicylic acid, pyrogallol, and hippurate after PLA

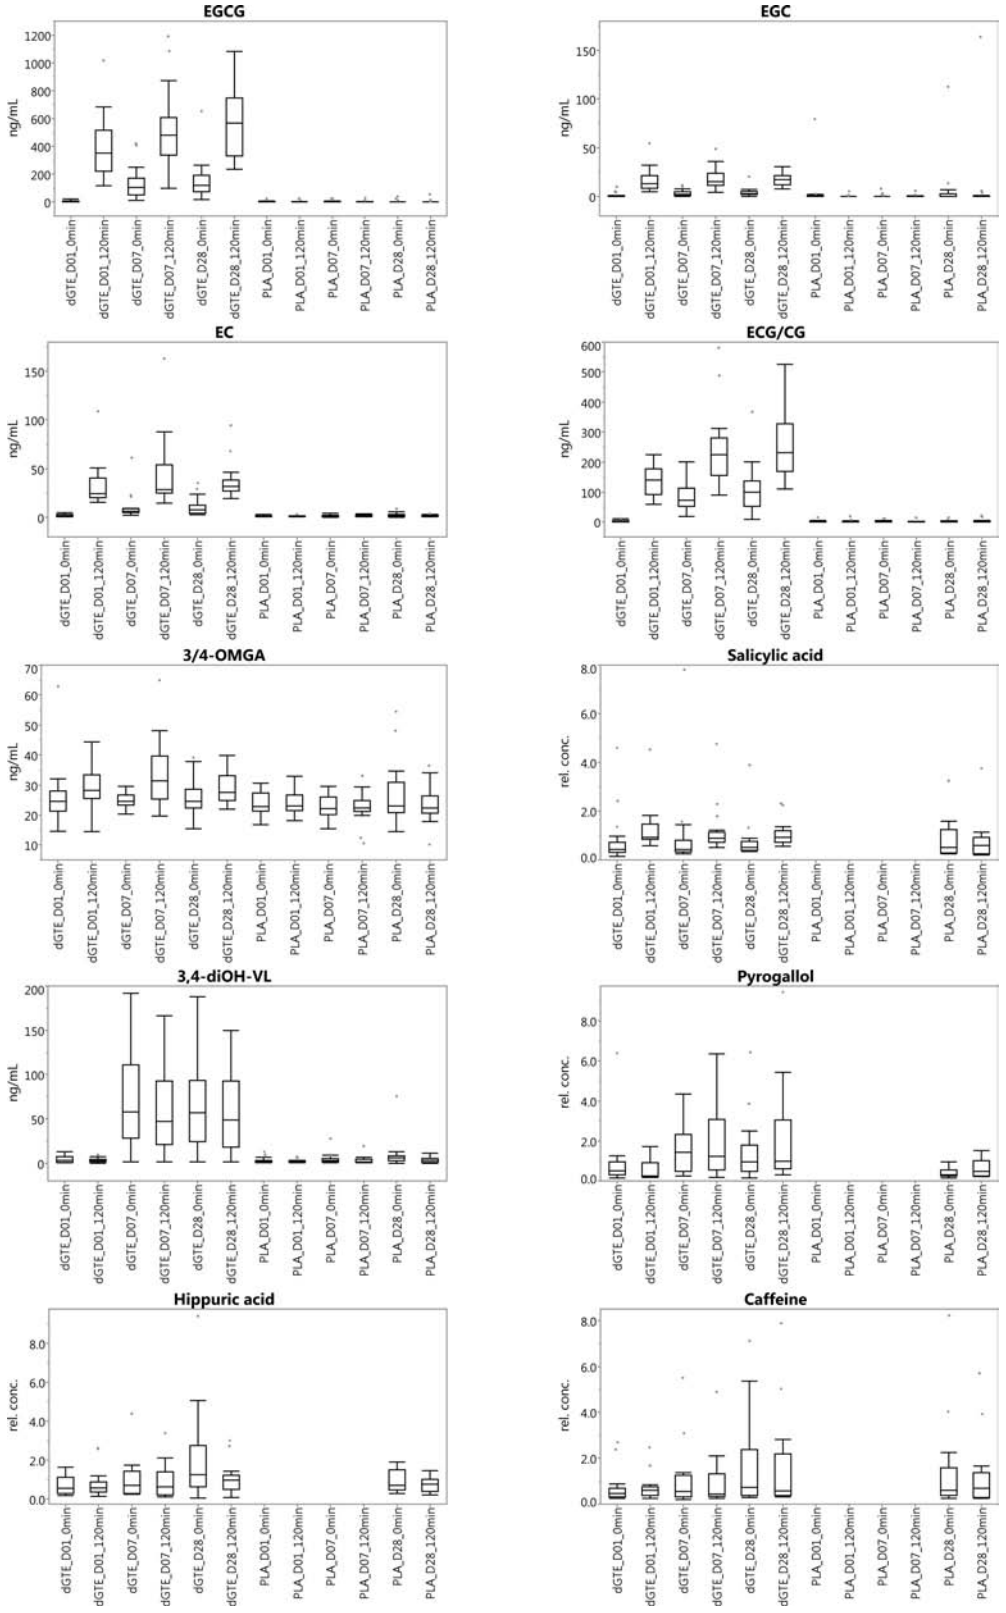

**Figure 2.** Concentrations of exogenous metabolites in plasma after deconjugation of glucuronides and sulfates at baseline ($t$ = 0 min) and 2 h after intake of two capsules of dGTE or PLA ($t$ = 120 min) on D01, D07, or D08, respectively. (−)-Epicatechin (EC), (−)-epigallocatechin (EGC), (−)-epi/catechin gallate (ECG/GC), (−)-epigallocatechin gallate (EGCG), 3/4-*O*-methylgallic acid (3,4-OMGA), and 5-(3′,4′-dihydroxyphenyl)-$\gamma$-valerolactone (3/4-diOH-VL) were measured in absolute concentrations. Salicylic acid, pyrogallol, hippurate, and caffeine were measured in relative concentrations and not on D01 and D07 after PLA ingestion.

ingestion can be explained by the intake of other polyphenol-containing food sources.

In addition to the catechin metabolites, caffeine was relatively quantified from the four-phase metabolite profiles. The caffeine

Font coding: black & bold: ( ratio < 0.5 ) or ( ratio >2 )
black & normal: ( 0.5 ≤ ratio < 0.9 ) or ( 1.1 < ratio ≤ 2 )
grey & normal: 0.9 ≤ ratio ≤ 1.1.

concentrations in plasma were indeed lower after dGTE ingestion when compared to our previous study performed with cGTE,[13] as demonstrated by the different ratios of 120 to 0 min upon dGTE and cGTE ingestion (dGTE_D07, 1.0; vs cGTE, 2.47). Moreover, no significant differences in caffeine concentrations were observed between the PLA and dGTE ingestion, also confirming that the caffeine concentrations in the dGTE capsules were negligible. Yet, a slight increase of caffeine was observed at baseline after 28 days of dGTE ingestion when compared to D01, which may be explained by a lower compliance to refrain from caffeinated products on the day before the experimental trials.

**Effect of dGTE on Endogenous Metabolites at Baseline under Resting Conditions ($t$ = 0 min).** A total of 211 metabolites including 184 known and 27 unknown (not chemically identified) metabolites from different ontology classes were measured in plasma of 18 healthy males after 1 day (D01), 7 days (D07), and 28 days (D28) of dGTE ingestion and 28 days of PLA ingestion using four-phase metabolite profiling and quantitative targeted analysis of catecholamines. (Samples from one subject were excluded because they were identified as outliers in PCA.)

Initially, the effects of 7 and 28 day dGTE ingestion were compared at baseline ($t$ = 0 min) under fasting and resting conditions to both the 28 day PLA ingestion (PLA) and the first day of dGTE ingestion (dGTE_D01). Both samples can be used as references, because two capsules of dGTE or PLA were consumed only after the collection of the baseline sample on D01. The comparison between dGTE_D01 and PLA thus served as control. Table 1 shows only those significant effects that were consistently observed for both comparisons (reference to PLA and to dGTE_D01) to avoid overinterpretation of the data. The table including all significant effects is given in the Supporting Information (Table S1). After both 7 and 28 days of dGTE ingestion, increases in 3-hydroxybutyrate and pyrogallol, and a reduction in coenzyme Q9 were observed. Moreover, some effects were different between 7 and 28 days of dGTE ingestion: After 7 days of dGTE ingestion, reductions in arginine, citrulline, and coenzyme Q10 as well as increases in 3-hydroxyisobutyrate, cresol sulfate, homovanillic acid, and pseudouridine were observed. After 28 days of dGTE ingestion, reductions in alanine, cholesta-2,4,6-triene, triacylglycerides (TAG C16:0, C16:1; TAG C18:2, C18:3), *myo*-inositol liberated from complex lipids and phosphatidylchloline (C16:1, C18:2) as well as increases in glucose-1-phosphate, phosphatidylchloline (C16:0, C18:2), and dodecanoylcarnitine were found.

**Acute and Acute-on-Chronic Effects of dGTE on Endogenous Metabolites at Rest ($t$ = 120 min).** The acute and acute-on-chronic effects were assessed 2 h after the ingestion of two capsules of dGTE on D01 (acute), D07 (acute-on-chronic), and D28 (acute-on-chronic) or PLA on day 28 ($t$ = 120 min) under resting conditions. The changes occurring within these 2 h on D01, D07, and D28 after dGTE ingestion were compared with those after PLA ingestion. In addition, the effects of dGTE ingestions on D01, D07, and D28 were compared to PLA at $t$ = 120 min. All significant metabolite changes are summarized in the Supporting Information (Table S2). In addition, plots of mean concentrations versus time are depicted for the most relevant metabolites in Figure S1. The 2 h resting period induced significant effects on the metabolism: When comparing the effects at $t$ = 120 min to $t$ = 0 min after PLA ingestion, reductions in many metabolites were observed, including, for example, some amino acids and related metabolites (glutamate, phenylalanine, tyrosine, isoleucine, valine, sytine, taurine, keutoleucine, citrulline, ornithine), catecholamines (2,3-dihydroxyphenylacetatate (DOPAC), 5-hydroxy-3-methoxymandelic acid, normetanephrine, homovanillic acid), cortisol, 3-hydroxybutyrate, lactate, succinate, and some lysophosphatidylcholines. Moreover, 2-hydroxybutyrate, pyruvate, citrate, and glucose liberated from complex lipids were significantly increased. Similar changes were observed on D01, D07, and D28 after dGTE ingestion, indicating that dGTE did not significantly affect these metabolites. There were only a few consistent effects that could be attributed to the dGTE ingestion. Apart from the significant increase in salicylic acid, which is most likely an exogenous metabolite, as already mentioned above, only phosphate and glucose liberated from complex lipids were reduced at $t$ = 120 min on D01, D07, and D28 after dGTE ingestion when compared to PLA because their concentrations were increased 2 h after the PLA ingestion. Moreover, a slightly stronger increase in 4-hydroxy-3-methoxyphenylglycol (HMPG) and a slightly stronger reduction in *myo*-inositol were observed after the 2 h of both acute and acute-on-chronic (7 and 28 days) dGTE ingestion when compared to their changes after PLA ingestion. However, these changes resulted only in marginally at 120 min on one of the dGTE treatment days when compared to PLA (D01 for HMPG and D28 for *myo*-inositol). In addition, the reductions of some carnitines (dodecanoylcarnitine, oleoylcarnitine, tetradecanoylcarnitine) were stronger after 2 h of dGTE ingestion, in particular on D28 due to their higher baseline values. Furthermore, the increases in cholesterol esters may potentially be attributed to the acute dGTE ingestion. Cholesterol ester C18:1 levels were significantly increased at $t$ = 120 min on D01, D07, and D28 after dGTE ingestion when compared to PLA and their baseline values. However, such changes were not consistently found for all cholesterol esters or on all dGTE treatment days. Likewise, several other metabolite changes such as for 4-hydroxyphenylpyruvate, cysteine, pyruvate, DOPAC, pyrogallol, some fatty acids, and sphingomyelins were observed only on specific treatment days but not consistently on D01, D07, and

dx.doi.org/10.1021/jf502764r | J. Agric. Food Chem. 2014, 62, 9936−9943

D28. Other statistically significant differences between dGTE and PLA treatment at $t$ = 120 min such as those found for phosphatidylcholine (C16:1, C18:2), *trans*-4-hydroxproline, asparagine, glucose-1-phosphate, and homovanillic acid can mainly be attributed to differences in baseline values rather than significant changes induced within 2 h after dGTE or PLA ingestion. All together, the endogenous metabolic effects observed upon acute and acute-on-chronic (D07 and D2) dGTE ingestion were either inconsistent or could be attributed to baseline effects or did not allow for a clear biological interpretation.

**Acute and Acute-on-Chronic Effects of dGTE on Endogenous Metabolites during Exercise ($t$ = 150 min).** The acute and acute-on-chronic effects of dGTE during exercise were assessed by comparing the metabolite changes after 30 min of moderate intensity exercise ($t$ = 150 min) to those observed just prior to exercise under resting conditions at $t$ = 120 min. This comparison was carried out on D01 (acute), D07 (acute-on-chronic), and D28 (acute-on-chronic) following dGTE ingestion and on D28 following PLA ingestion. In addition, the effects of dGTE ingestions on D01, D07, and D28 were compared to PLA at $t$ = 150 min. All significant metabolite changes are summarized in the Supporting Information (Table S2). In addition, plots of mean concentrations versus time are depicted for the most relevant metabolites in Figure S1. The comparison following PLA ingestion reflected the effects of moderate intensity exercise alone on the metabolism. Many metabolites were up-regulated, in particular, those that were related to adrenergic stimulation and energy metabolism.

Resting and exercise had opposite effects on several metabolites. For example, glutamate, taurine, glycerol, and cortisol were reduced under resting conditions, but increased during exercise. In contrast, 2-hydrxobutyrate was increased at rest and decreased during exercise. The effects of exercise were similar on D01, D07, and D28 following dGTE ingestion, indicating that exercise was the dominating effect and that the exercise test was reproducible.

When the effects of dGTE on D01, D07, and D28 were compared to PLA during exercise, dGTE did not induce consistent changes in metabolites related to energy metabolism such as markers of lipolysis and glycolysis, catecholamines, and tricarboxylic acid (TCA) cycle metabolites. Most metabolite changes during exercise were scattered, meaning that they were observed either on D01, D07, or D28 (i.e., glucose-1-phosphate, lactate, allantoin, 2-hydroxybutyrate, 3-indoxylsulfate, sphingomyelin (C18:1, C24:0)) or not substantiated by other metabolites from the same pathway. Therefore, it is questionable whether these changes can unambiguously be attributed to dGTE ingestion. Only a stronger increase in uridine was consistently observed during 30 min of exercise after acute and acute-on-chronic (7 and 28 days) dGTE ingestion, when compared to the change after PLA ingestion. Other differences between dGTE and PLA ingestion at $t$ = 150 min such as those for cholesterol esters, 3-hydroxybutyrate, and some fatty acids were due to differences in concentrations at $t$ = 120 min rather than differences in slopes during exercise. No statistically significant effects of dGTE were found when the data were normalized to $t$ = 120 min, except for the scattered results of 3-indoxylsufate and sphingomyelin (C18:1, C24:0).

## DISCUSSION

The present results suggest that sustained dGTE ingestion increases metabolic markers of fat oxidation under resting conditions but not during exercise. Together with our previous study,[16,27] we have now shown that 7 days of ingestion of dGTE and cGTE both increase 3-hydroxybutyrate at baseline under fasting and resting conditions. The production of this ketone body is indicative of augmented fat oxidation. However, in contrast to our previous results with cGTE, no increases in glycerol[27] and nonesterfied fatty acids[26] were observed after 7 days of dGTE ingestion, indicating that dGTE did not enhance lipolysis. Furthermore, like cGTE, dGTE also did not increase markers of fat oxidation during exercise.

After 28 days of dGTE ingestion, 3-hydroxybutyrate was still increased at baseline. In addition, an increase in dodecanoylcarnitine was found, indicating enhanced mitochondrial fatty acid oxidation. An increase in fat oxidation may also be related to the reductions in certain TAGs observed after 28 days of ingestion of dGTE. In agreement with this, reduced TAG levels at baseline have been found in our previous study using cGTE[27] and in another study in which overweight and obese adults consumed a beverage containing GT catechins or a caffeine-matched, catechin-free beverage for 12 weeks.[35] However, there is still limited and inconsistent evidence on the effect of GTE on lipid metabolism from in vivo studies, although many in vitro and animal models have already proposed several modes of actions such as decreased adipocyte differentiation and lipogenesis, increased $\beta$-oxidation, and decreased lipid absorption.[17,36]

Interestingly, the concentrations of coenzyme Q9 were reduced at baseline after 7 and 28 days of dGTE ingestion. In addition, reductions in coenzyme Q10 were observed after 7 days of dGTE ingestion. Coenzymes Q function as electron carrier for the production of cellular energy[37] and as endogenous antioxidants in protecting lipoproteins against peroxidation.[38] They are considered as early markers of oxidative damage. Thus, the reductions in coenzymes Q may provide indirect evidence of the pro/antioxidant activity of green tea catechins.[39] This activity seems to be stronger after 7 days of dGTE ingestion than after 28 days not only because of the reduction in coenzyme Q10 but also because of the slight reductions in arginine and citrillune, which are also known to be involved in radical scavenging.[40]

In this study, we could not confirm the acute metabolic effects observed in our previous study using cGTE.[23] Two hours after the ingestion of a single dose of dGTE or PLA, no consistent changes in taurine, 3,4-dihydroxyphenylethylene-glycol, serotonin, some cholesteryl esters, fatty acids, triglycerides, sphingosines, and any other metabolites were found in plasma, which may be explained not only by the absence of caffeine but also by different catechin concentrations in the plasma. Despite the same dose of total catechins administered in both studies, average concentrations at $t$ = 120 min for ECGC and (E)CG were, respectively, 2.1- and 1.5-fold higher and for EGC and EC, 0.17- and 0.42-fold lower, in this study when compared to our previous study. Differences in the food format (previous study: drink; this study: capsules) and in the composition of the GTE (e.g. 312 mg of EGCG in two capsules, 207 mg of EGCG in 330 mL of drink) may have led to differences in the bioavailability of the catechins and to different effects on the endogenous metabolism.

Further to the effects observed at rest, dGTE did not elicit significant and consistent changes on the endogenous metabolites in plasma during exercise, neither after acute nor for acute-on-chronic (7 and 28 days) ingestion of dGTE. This result is in line with our findings on whole body fat oxidation rates,[26] yet differ from our earlier metabolomics results showing that cGTE induced subtle changes on metabolites related to energy metabolism during exercise (increase in pyruvate, lactate and alanine, and reduction in 3-hydyroxybutyrate).

Taken together, there is evidence from two studies that both dGTE and cGTE ingestion induced increases in 3-hydroxybutyrate, a marker of fat oxidation. suggesting that catechins, and not caffeine, are the main actives driving this effect. The absence of caffeine in dGTE, however, also abolished some other significant metabolic effects related to energy metabolism under resting and exercise conditions that were previously seen with cGTE. For example, using dGTE no metabolic changes related to lipolysis were observed at rest. Considering that ketone body homeostasis in humans is determined by lipolysis, intrahepatic ketogenesis, and peripheral ketone body utilization, the results from our studies with dGTE and cGTE may suggest that caffeine alters the free fatty acid supply liberated from adipose tissue or that GT catechins promote hepatic ketone body production. These processes are regulated by hormones such as insulin, catecholamines, and thyroid hormones. Yet, changes in insulin (data not shown) and catecholamines were not observed at baseline after 7 days of ingestion of either dGTE or cGTE. Thus, neither study supports the hypothesis that catechins enhance fat oxidation through the inhibition of catechol-*O*-methyl-transferase (which degrades norepinephrine, thereby prolonging the action of sympathetically released norepinephrine[36]).

Our metabolomics approach clearly provided comprehensive insights into the sensitive regulation of the plasma metabolome. The metabolic effects induced by resting and moderate-intensity exercise clearly dominated over those induced by dGTE. Various metabolites related to glycolysis (pyruvate, lactate), fatty acid oxidation (carnitines, glycerol, 3-hydroxybutyrate), TCA cycle (succinate, malate), stress (catecholamines, cortisol), amino acid catabolism (alamine, glutamate, taurine, ketoleucine), inflammation (sphingosines) were involved in regulating the metabolism during moderate-intensity exercise. Many of these metabolites have already been discussed in relation to exercise in other studies.[41−46] Most metabolite changes were consistently observed on all four experimental days, showing that the effects of exercise and resting were reproducible. On the other hand, several effects were statistically significant yet inconsistent, indicating either that the plasma metabolome is sensitive to unknown factors that were not controlled in the study or that dGTE itself induced irregular effects. The fact that the daily ingestion of high doses of dGTE was able to elicit only subtle effects on the endogenous metabolism hampers a clear distinction between effects induced by dGTE or other factors. The findings of our studies suggest that consistent metabolic effects of GTE may be reliably captured and compared only from well-controlled studies. Moreover, there is a clear need to further assess whether the GTE-induced increase in the metabolic marker of fat oxidation is relevant for whole body fat oxidation rates under sedentary conditions.

differences,[19] metabolic effect to dietary intervention,[20] and information about gut health status.[21−23] Thus, assessment of metabolic changes in feces using metabolomics may be a unique approach to disect gut microbe interactions in the complex gut system and identify metabolic changes induced by the intake of fibers and prebiotics.

The aim of the present study is to extend a previous investigation evaluating the impact of PDX on fecal microbiota in humans by Costabile et al.[24] In this previous study, PDX consumption was shown to significantly increase butyrate-producing *Ruminoccus intestinalis* and *Clostridium Cluster* I, II, and IV. In addition, PDX fermentation was shown to reduce the genotoxicity of fecal water and affect the bowel habits of human subjects. Consequently, the findings from the previous study encouraged us to learn more about the effects of PDX intake on the gut metabolome. For this purpose, high-resolution nuclear magnetic resonance (NMR) spectroscopy-based metabolomics was performed on feces from the study by Costabile et al.[24] In addition, the relationship between the fecal metabolome and gut microbial profiles was investigated to elucidate the potential of NMR-based metabolomics to decipher the specific metabolic activity of the gut microbiota.

## MATERIALS AND METHODS

**Sampling and Sample Material.** Samples from an intervention with a double-blind, randomized, placebo-controlled crossover design were used.[24] A total of 31 volunteers from the area of Reading, United Kingdom (U.K.) were involved in the original study; however, because of sample scarcity, we could only include samples from 12 healthy volunteers (4 males and 8 females) aged 18 to 50 years. For anthropometric measures, see Table 1. During each intervention period, subjects were not allowed to intake prebiotics, probiotics, antibiotics, or drugs active on gastrointestinal motility, such as laxatives. All subjects consumed PDX powder (Litesse Ultra, 8 g/day; Danisco UK, Redhill, U.K.) or an equivalent placebo (maltodextrin powder, 8 g/day, Syral, Marckolsheim, France) for 3 weeks followed by a 3-week washout period, and then crossover occurred. Fecal samples were collected from each volunteer at five different time points, before PDX intake at baseline, following PDX treatment, following washout 1, following maltodextrin intake, and following washout 2 (Figure 1). The study protocol was approved by the Ethics and Research Committee of the University of Reading and conducted according to the guidelines in the Declaration of Helsinki.

**Table 1. Anthropometric Characteristics of the Subjects[a]**

| characteristics | |
|---|---|
| age (years) | 33.9 ± 8.3 |
| BMI (kg/m$^2$) | 23.8 ± 2.4 |
| waist (cm) | 80.66 ± 9.3 |

[a]Values are means ± standard deviation.

**Preparation of Fecal Water Samples.** The extraction was performed and described previously by Costabile et al.[24] Fecal water was extracted 1:1 (w/v) in 1 M-ice-cold phosphate buffer saline (PBS, pH 7.4). The samples were homogenized in a stomacher bag for 2 min, and the aliquots were ultracentrifuged at 64000 *g* for 2 h at 4 °C (Beckman Optima L90K Ultracentrifuge; Beckman Limited, High Wycombe, U.K.). The supernatants were carefully removed and stored in a 1.5 mL Eppendorf tube at −70 °C until analysis.

**$^1$H NMR Spectroscopic Analyses.** Fecal water samples extracted in 1:1 (w/v) PBS were thawed and diluted with an equal amount of PBS. Further dilution was performed due to the limited amount of samples available for NMR analysis. The diluted mixture was vortexed (10 s) and centrifuged at 10000*g* for 15 min at 4 °C. A volume of 500 μL of clear supernatant was transferred to a 5 mM NMR tube and 100 μL of deuterium oxide ($D_2O$) containing 0.025 mg/mL of 3-(Trimethylsilyl) propionicacid-$d_4$ sodium salt (TSP) was added as a lock solvent. One dimensional NMR experiments were conducted using a Bruker Advance DRX 600 MHz spectrometer equipped with a 5 mm triple resonance (TXI) probe at a temperature of 298 K. The Noespr1d (90°-d1−90°-$d_{mix}$-90°-FID, Bruker, Rheinstetten, Germany) sequence was performed to suppress signals from water molecules where d1 is a 4 μs delay time and $d_{mix}$ is the mixing time. The spectra was acquired with 64 scans, a spectral width of 7288 Hz collected into 32K data points, an acquisition time of 2.24 s, and a relaxation delay of 5 s. The obtained free induction decay (FID) was multiplied by 0.3 Hz of line broadening before Fourier transformation. The spectra were referenced to TSP (chemical shift 0 ppm), phased, and baseline corrected in the Topspin 3.0 software (Bruker). Relative quantification of selected $^1$H resonance was performed by integration of peak areas using Topspin 3.0 (Bruker). The integrals were normalized to the concentration of TSP added as an external reference. Assignments of $^1$H NMR signals were carried out using Chenomx NMR Suite 7.7 (Chenomx, Canada) and according to the Human Metabolome Database[25] and the literature.[20] In addition, the heteronuclear single quantum correlation (HSQC) 2D NMR technique was applied to confirm the identity of the given metabolites. The 2D experiment was acquired with a spectral width of 6127 Hz in the $^1$H dimension and 27164 Hz in the $^{13}$C dimension, a matrix with size of 4096 × 1024, 512 transients per increment and a relaxation delay of 2 s.

**Data Analysis.** NMR spectra were imported to MATLABR2010b (The Mathworks, Inc.), and the misalignments of the spectra were corrected using the algorithm icoshift based on the correlational shifting of spectral intervals.[26] The spectrum with the highest correlation to the rest of the spectra in the matrix was used as a reference. The algorithm for icoshift is open-source and available at

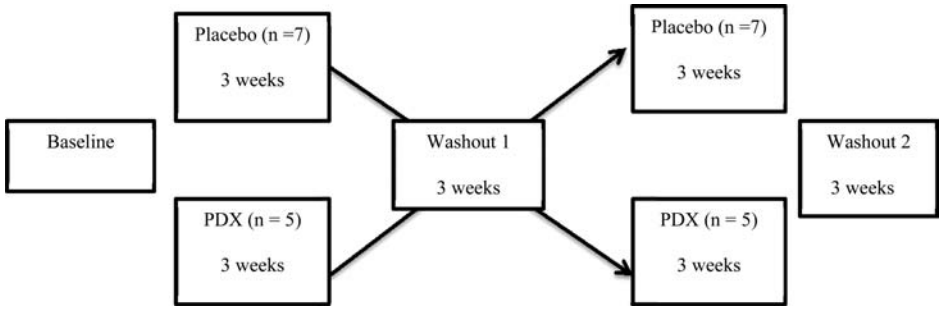

**Figure 1.** Schematic of the crossover intervention design. Each box represents a group of human subjects in the crossover design. The first group consumed PDX powder for 3 weeks, and then after a 3-week washout period, they consumed the equivalent placebo for 3 weeks. The second group received first the placebo (maltodextrin) for 3 weeks, and then after a 3-week washout period, PDX powder for another 3-week treatment period. The fecal samples were collected at five time points from each subject; before PDX intake at baseline, following PDX treatment, following washout 1, following placebo, and following washout 2.[24]

dx.doi.org/10.1021/jf5031218 | J. Agric. Food Chem. 2014, 62, 9944−9951

www.model.life.ku.dk/icoshift. Both the unwanted region (12 to 9 ppm, 0.5 to −1.2 ppm) and the region containing the water resonance (5 to 4.7 ppm) were removed from the aligned spectra. The spectra were normalized to unit area and pareto-scaled. Multivariate data analysis was performed to explore whether the PDX intervention led to systematic metabolic changes and to identify which metabolites were the most differentiating biomarkers between the PDX treated and placebo samples.

Initially, principal component analysis (PCA) of the preprocessed NMR spectra ($n$ = 60) was performed to visualize general grouping, trend, and outliers in the data. Subsequently, supervised partial least-squares discriminant analysis (PLS-DA) was performed to discriminate between the treated and placebo samples ($n$ = 24). In addition, PLS regressions between NMR spectra from the PDX and placebo-treated subjects ($X$ variable) and the bacterial cell count ($\log_{10}$, $Y$ variable) were used to elucidate the relationship between the NMR metabolic profile and bacterial cell count. PLS-DA and PLS models were performed on unit-normalized NMR spectra using full cross validation. Enumeration of bacterial cells was performed and previously described by Costabile et al.[24] PCA, PLSDA, and PLS-regression were conducted using the PLS Toolbox (eigenvector Research) in MATLAB2009b. Furthermore, statistical total correlation spectroscopy (STOCSY) analysis was performed in multiple samples from PDX treated spectra ($n$ = 12) in MATLABR2010b. Kirill Veselkov, Imperial College 2009, wrote the script for STOCSY.[27]

## RESULTS

**NMR Metabolite Profiles of Fecal Samples.** The $^1$H NMR spectra of fresh fecal samples revealed a wide range of metabolites. Figure 2 shows a representative spectrum of a fecal sample extracted in PBS buffer. The use of buffer during extraction allowed us to reduce the chemical shift inconsistency between the samples. The obtained $^1$H NMR spectra contained resonances from SCFA (predominantly acetate, propionate, and butyrate), branched chain fatty acids, biogenic amines, bile acids, organic acids, carbohydrate, and amino acids (Table 2). A pronounced effect of PDX intake was observed on the NMR profile. Visual inspection of spectra showed that samples collected after PDX intervention had a markedly different fecal metabolite profile than baseline, placebo, and washout samples. The difference can be ascribed to the presence of undigested PDX material (3.5−4.5 ppm) and compounds in the spectral region of 5.0−5.5 ppm (Figure 3), which are assigned to oligomers of glucose (alpha anomeric protons) and other unidentified carbohydrates, appearing as a result of cleavage of PDX. This assignment was confirmed from $^1$H NMR spectra obtained on a pure standard of PDX (10 mg/L) (data shown in Supporting Information Figure S1).

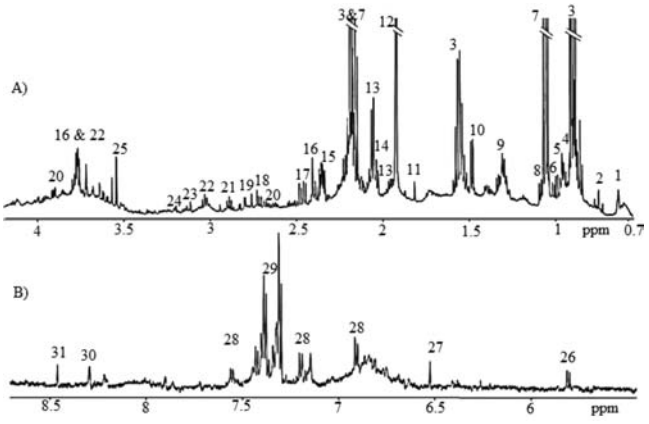

**Figure 2.** Representative $^1$HNMR spectrum of a human fecal sample extracted in PBS buffer: (A) 0.8−4.2 ppm and (B) 5.5−8.6 ppm. The aromatic region in the spectrum (5.5−8.6 ppm) has been magnified three times compared to the aliphatic region. Keys to the figure are given in Table 2.

[a]Tentative assignment with best matched signals.

**Multivariate Data Analysis.** To determine and characterize the global metabolic effect of PDX on the human gut metabolome, multivariate data analysis was applied on the NMR spectra. In total, 60 NMR spectra from 12 subjects were included in the data analysis. PCA was performed on the pareto-scaled normalized $^1$H NMR spectra to explore the metabolic difference between baselines, PDX treated, wash out 1, placebo, and wash out 2 samples. The score plot shows that the PDX treated samples have distinct clustering along PC1 explaining 30.46% of the total variation (Figure 4A), and the corresponding loading reveals that the clustering could mainly be ascribed to the presence of undigested residuals PDX in the region 3.5 to 4.5 ppm of the spectra (Figure 4B). It is also apparent from the loading plot that propionate, butyrate, and acetate varied between the samples; however, these metabolites were not indicative to any distinct clusters but represented a sample-to-sample variation.

To minimize the sample-to-sample variation, PCA was also performed including only the $^1$H NMR spectra from the PDX and placebo samples. The score plot depicts two distinct

dx.doi.org/10.1021/jf5031218 | J. Agric. Food Chem. 2014, 62, 9944−9951

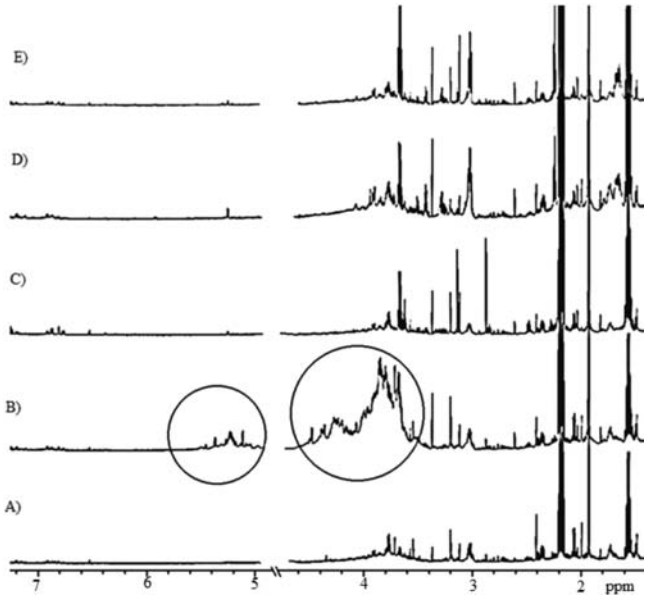

**Figure 3.** Typical 600 MHz $^1$HNMR spectra of fecal samples extracted in PBS buffer. Each spectrum represents fecal samples collected from the same human subject at five different time points: (A) baseline, (B) PDX treated, (C) washout 1, (D) placebo, and (E) washout 2. The large circle region (Figure 3B, 3.5−4.5 ppm) in the spectra represents the broad signals from PDX + other unidentified carbohydrates and a smaller circled region (Figure 3B, 5−5.5 ppm) represents alpha anomeric protons of PDX + other unidentified carbohydrates.

clusters along PC1 (Figure 4C). From the corresponding loading, the metabolites contributing to this clustering included succinate, lysine, phenylacetate, acetate, propionate, and butyrate, which were all decreased while signals from residual PDX and oligomers of glucose (alpha anomeric protons) and other unidentified carbohydrates were increased for the PDX-treated samples (Figure 4D). In addition, PLS-DA was performed on the $^1$H NMR spectra excluding the 3.5−5.5 ppm region in the spectra in order to discover potential metabolic differences between the PDX-treated and placebo samples. However, the model had more than 50% of classification error, indicating that the generated models were not sufficiently robust (data not shown).

**Targeted Analyses of Metabolite Concentrations.** The relative concentrations of fecal SCFA (acetate, butyrate, and propionate), branched chain fatty acids (iso-valerate), biogenic amine (dimethyl amine), organic acid (succinate), and amino acid (phenylacetate) were quantified from the $^1$H NMR spectra (Table 3). No significant changes in any of the fecal metabolites were observed after PDX or placebo treatment. This finding is in agreement with the previous study by Costabile et al.[24] and is supported by the correlation between the NMR and GC MS derived content for acetate, butyrate, and propionate (data shown in the Supporting Information Table S1).

**Correlation Analysis.** To identify intervariable correlations, STOCSY analysis was performed on $^1$H NMR spectra of multiple PDX-treated samples ($n$ = 12). The STOCSY approach enables the detection of highly correlated peaks whose concentrations are interdependent or under some common regulatory mechanism.[27] In one-dimensional STOCSY analysis, variables are correlated to a given chemical shift value (for instance $\delta$ = 5.25 ppm). The positive and negative values between the covariance of variables indicate the association to the 5.25 ppm variable that represents the particular signal from a molecule in the spectrum. The covariance pattern is indicated in a color code which represents the strength of statistical associations (red high and blue low). The STCOSY analysis shows (Figure 5) that the oligomers of glucose (alpha anomeric protons) and other unidentified carbohydrates in the 5 to 5.5 ppm region (covariance $\delta$ = 5.25 ppm) of the PDX treated spectra were positively correlated with the broad signal at 3.5 to 4.5 ppm from PDX, propionate, and acetate signals. The highest statistical associations (significance level of $p < 0.05$) were observed for the 3.5 to 4.5 ppm PDX signal and propionate. Thus, STOCSY enables us to identify associations between PDX and other fecal metabolites.

Furthermore, PLS regressions were performed to elucidate the relationship between the NMR metabolite profile (placebo and PDX treated, $n$ = 24) and bacterial cell count ($\log_{10}$) for bacteria in the fecal extract. From PLS regressions between the NMR metabolite profile and fecal bacterial count, the highest level of correlation could be established with *Bifidobacterium* ($R^2$ = 0.66) (Table 4). Intriguingly, the regression coefficient plot (Figure 6A) shows that succinate, acetate, and propionate were negatively correlated with the amount of *bifidobacteria* while butyrate and malonate content are positively correlated with *bifidobacteria* in feces. The variable importance for projection (VIP) plot was used to rank the importance of the variables. The VIP plot showed acetate and succinate to be the most influential variable. In addition to *Bifidobacterium*, regression analysis also showed positive correlation of *Bacteroides* ($R^2$ = 0.45) with acetate content in the feces (Figure 6B). Similar results were obtained when correlations between bacterial cell count and the data from previous gas chromatography-mass spectrometry (GC-MS) analyses were performed (described in Supporting Information). This finding substantiates that changes in the *Bifidobacterium* and *Bacteroides* populations in the colon could be correlated to succinate and acetate concentrations in feces.

## DISCUSSION

Previous studies have shown a prebiotic potential of PDX;[8,10,11,24,28] however, little is known about the global metabolic impact of PDX in the human gut. $^1$H NMR-based metabolite profiling enabled identification of a wide range of metabolites such as SCFA (acetate, butyrate, and propionate), organic acids (succinate, fumarate), branched chain fatty acids (iso-butyrate, iso-valerate), biogenic amines (trimethylamine, dimethyl amine), carbohydrates, and amino acids (phenyl-acetate, tyrosine) in feces. Thus, a broad view of the diet-induced metabolite changes could be explored using the approach conducted here compared to the gas chromatography analysis performed earlier.[24]

PCA (Figure 4A) showed a distinct clustering of PDX-treated samples when compared with the corresponding metabolite profile from the baseline, placebo, and washout samples. The clustering could mainly be ascribed to residual PDX and unknown oligosaccharides in the feces. Thus, the present study reveals a very strong effect of PDX intake on the NMR metabolome due to the presence of residual PDX and partly degraded PDX products. Previous studies have also shown that during gastrointestinal transit, a proportion of undigested PDX is excreted in the feces.[24,28,11] Our data provide additional and strong evidence of undigested PDX as we could visually identify the presence of residual PDX in the

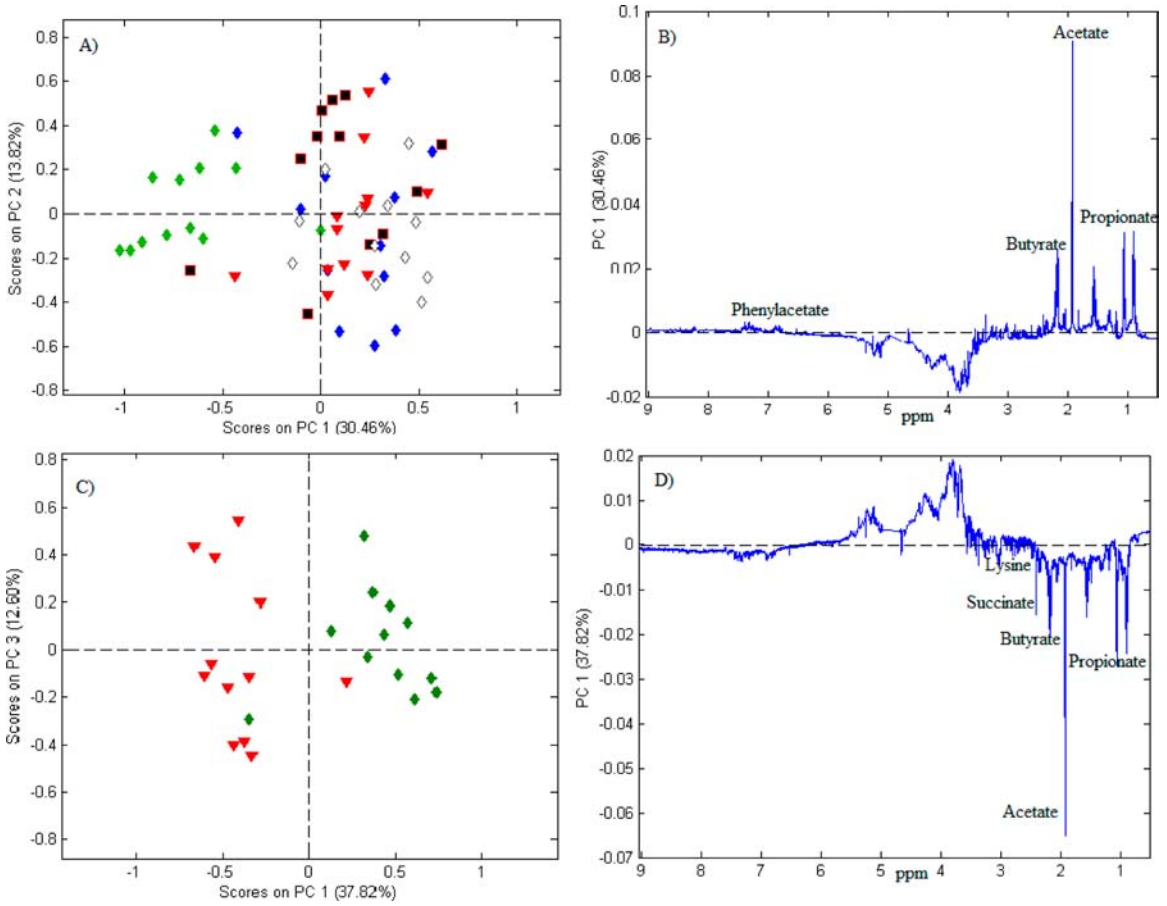

**Figure 4.** PCA score plots and loadings: (A) score plot of the first and second principal component (PC) from 60 fecal samples (black quare with red outline) baseline samples, (green diamond) PDX treated samples, (blue diamond) wash out 1 sample, (downward pointing red triangle) placebo treated, and (white diamond) washout 2 samples. (B) Loading profile of first principal component from 60 fecal samples. (C) Score plot illustrating (downward pointing red triangle) placebo and (green diamond) PDX treated samples. (D) Loading profile of first PC.

**Table 3. Relative Quantification of Fecal Metabolites**[a]

| metabolite | control mean (±) SE | PDX treated mean (±) SE | *P*-value |
|---|---|---|---|
| phenylacetate | 0.10 ± 0.01 | 0.05 ± 0.05 | 0.12 |
| succinate | 0.19 ± 0.01 | 0.52 ± 0.01 | 0.21 |
| acetate | 6.46 ± 0.22 | 5.71 ± 0.22 | 0.29 |
| butyrate | 2.29 ± 0.01 | 1.90 ± 0.07 | 0.42 |
| alanine | 0.46 ± 0.02 | 0.45 ± 0.29 | 0.82 |
| propionate | 2.97 ± 0.12 | 2.78 ± 0.11 | 0.35 |
| isovalerate[b] | 0.52 ± 0.02 | 0.51 ± 0.01 | 0.23 |
| dimethylamine[b] | 0.52 ± 0.02 | 0.03 ± 0.01 | 0.90 |
| malonate[b] | 0.13 ± 0.01 | 0.20 ± 0.01 | 0.52 |

[a]The values are integrals relative to the TSP signal in the spectra. [b]Resonance signals below detection limit are not included.

NMR spectra of the feces (Figure 3). The results imply that NMR could be a very useful method to determine whether the subject consumed PDX. Thus, compliance of PDX consumption by a subject during intervention studies can be confirmed by NMR analysis, which commonly is a challenge for dietary intervention studies. In this context, NMR spectroscopy is simple, rapid, reproducible, and less labor intensive than many other analytical techniques.[29,30]

The results from this study demonstrate that depolymerized products of PDX were present in the feces of PDX-treated subjects. This finding provides evidence that the fermentation of PDX is continued until the distal part of the colon. Saccharolytic activity in the distal colon has been associated with a specific health benefit due to a reduction of proteolytic activities, which are linked to production of genotoxin and carcinogenic effects.[31] Costabile et al. also showed that the genotoxicity of the fecal water was significantly reduced due to PDX fermentation.[24]

PDX intake has been found to increase the production of SCFA in studies on rats,[11,32] dogs,[9] in vitro models,[32,10] and humans.[8] In particular, levels of butyrate and acetate have been highly elevated in the previous studies due to PDX fermentation; however, such changes were not observed in this study. Nevertheless, the STOCSY analysis performed on multiple $^1$H NMR spectra obtained after PDX consumption showed that residual PDX could be correlated with acetate and propionate and that the correlation was significant ($p < 0.05$). This correlation suggests that the concentration of acetate and propionate might be interdependent or under some regulative mechanism with bacterial degradation of PDX. Thus, it is likely that high inter- and intrasample variation in the subjects might have masked any additional effects of PDX consumption. Additionally, the diet, genotype of the individuals, lifestyle, environmental factors, or gut microbial variation might have had a higher impact on the metabolic outcome than the PDX treatment. To overcome the masking effect, we believe further, controlled studies with a larger number of individuals are

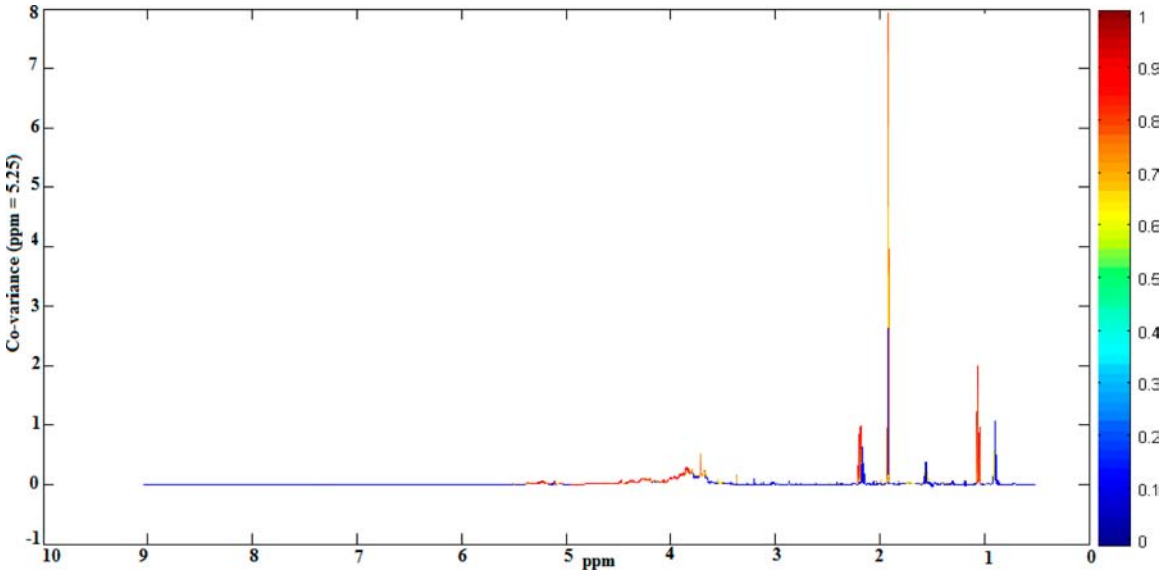

**Figure 5.** One-dimensional STOCSY analysis to identify intensity variables correlated to the chemical shift, $\delta$ = 5.25 ppm. The positive and negative values between the covariance of variables indicate the association to the 5.25 ppm variable that represents PDX. The color code of covariance patterns indicates the strength of statistical associations.

**Table 4. Correlation of Bacterial Cell Count ($\log_{10}$) and NMR Data Obtained from PLS Regression**

| S/N | species | $R^2$ | $\log_{10}$ max | $\log_{10}$ min |
|---|---|---|---|---|
| 1 | *Atopobium* group | 0.13 | 10.22 | 8.45 |
| 2 | *Bacteroides* genus | 0.46 | 10.45 | 9.23 |
| 3 | *Bifidobacterium* genus | 0.66 | 10.14 | 7.09 |
| 4 | *Eubacterium rectale* group | 0.01 | 10.58 | 9.61 |
| 5 | *Lactobacillus/Enterococcus* genera | 0.14 | 10.12 | 8.23 |

needed to establish the link between metabolic response and PDX consumption.

There is an increasing interest in understanding how fibers and prebiotics affect specific gut bacteria and the gut fermentation pattern.[33−36] PLS regression analyses between NMR fecal metabolite profiles and the bacterial cell count of individual bacteria showed a strong correlation between the fecal metabolite profile and the amount of *bifidobacteria* present in feces. Intriguingly, the VIP loading revealed a negative correlation between the content of *bifidobacteria* and levels of succinate and acetate. In parallel, the *Bacteroides* content had a positive correlation with acetate in the feces (Figure 6). This finding is consistent with the fact that acetate and succinate are associated with carbohydrate metabolism and major metabolites of *Bacteroides*.[37] The result indicates that carbohydrate metabolism in the colon is affected by varying numbers of *bifidobacteria* and *Bacteroides* populations in the gut. Recently, production of succinate by *Bifidobacterium* has also been demonstrated, but their ability to produce succinate was found to be dependent on energy source and the presence of different *bifidobacterial* species.[38] On the basis of our results, we suggest the negative correlation between *bifidobacteria* and the level of succinate might be due to alterations in the *bifidobacteria* species in the colon. Thus, the potential to correlate the fecal metabolome and microbial groups demonstrated in the present study suggests great promise for NMR based metabolomics to explore correlations between the microbial community and their activity expressed as the metabolites that are present.

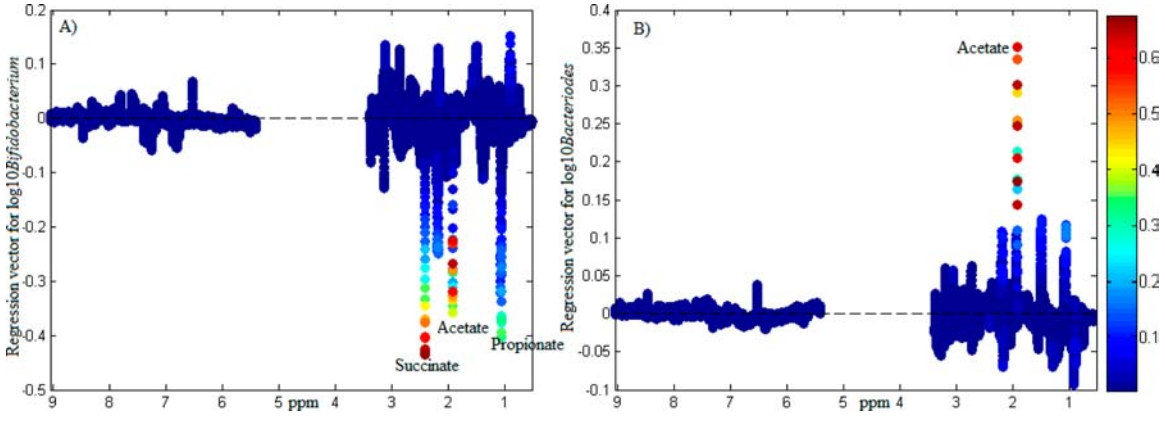

**Figure 6.** Results from PLS regression analysis. (A) Regression coefficients from PLS regression analysis show that succinate, acetate, and propionate contents were negatively correlated with the *Bifidobacterium* content while butyrate and malonate were positively correlated with *Bifidobacterium* content. (B) Regression coefficients from PLS regression analysis show that acetate content is positively correlated with the *Bacteroides* content in feces.

dx.doi.org/10.1021/jf5031218 | J. Agric. Food Chem. 2014, 62, 9944−9951

While a correlation could be established between the fecal metabolome and bacterial cell counts of *Bifidobacterium* and *Bacteroides*, correlations could not be established for other bacterial groups (Table 4). This result could be due to low variations in the content of these bacteria between the subjects and that they were not influenced by the intervention with PDX,[24] or for a bacterial genus such as *Lactobacillus*. The lack of correlations for other bacterial groups may be because other bacteria do not produce any of the metabolites that may also be because it is not producing any of the metabolites that vary in the $^1$H NMR spectra.

In conclusion, the present study demonstrated that NMR-based metabolomics is a useful and efficient technique for metabolite profiling of feces and to test compliance to a dietary intervention with PDX. It is anticipated that the approach could be applied to other dietary fibers. In addition, through the application of STOCSY, novel associations between PDX and the metabolites acetate and propionate could be identified, demonstrating the potential of metabolomics to unravel intermolecular interactions and small metabolite alterations that may not appear as significant treatment effects. Finally, the establishment of a correlation between the fecal metabolome and the levels of *Bifidobacterium* and *Bacteroides* demonstrates the potential of NMR-based metabolomics to elucidate metabolic activity of specific bacteria in the gut.

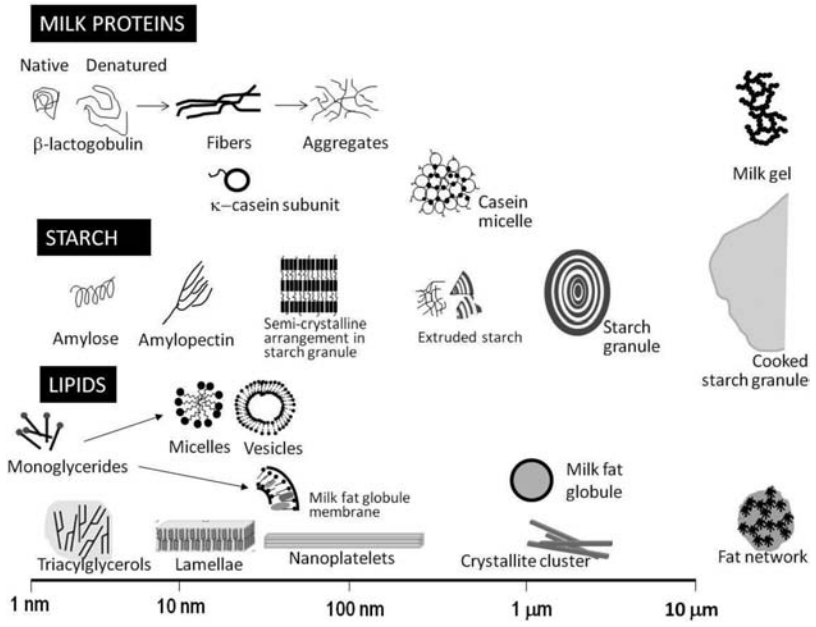

**Figure 1.** Proteins, starches, and lipids undergo major transformations at several length scales during processing and cooking. Casein micelles and fat globules in milk enter the kitchen already as micrometer or submicrometer structures to later give rise to a myriad of dairy products. Starch granules must be cooked so that amylose and amylopectin are released from their natural semicrystalline arrangement of nanosize dimensions. Lipid molecules may form nanostructures (monoglycerides) or become hierarchically assembled into fat crystal networks (triacylglycerols). (Approximate scales.)

pH (Figure 2a).[7] Denatured globular proteins in milk form coaggregates with casein, resulting in stiff gels (e.g., yogurt).

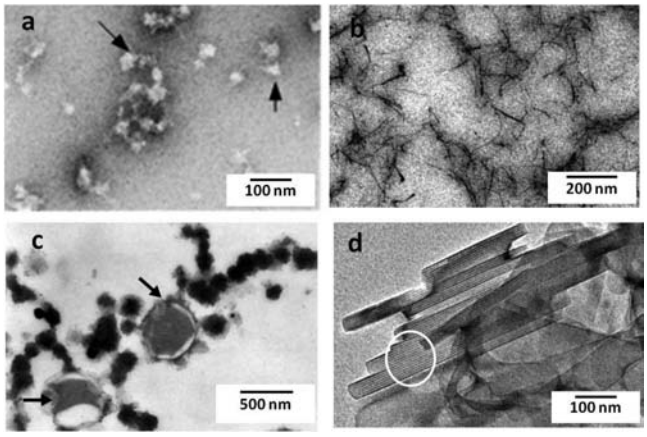

**Figure 2.** Images of some food structures at the nanoscale: (a) protein aggregates (arrows) produced by heating native $\beta$-lactoglobulin at 80 °C and pH 6.0[7] (these types of aggregates may also be formed when milk is heated); (b) TEM image of a 1% $\kappa$-carrageenan gel;[10] (c) yogurt-type gel showing two milk fat globules (arrows) and casein micelles arranged as a string of beads[2] (note anchoring of the strands to the globules' surface); (d) cross section of nanoplatelets (circle) in a fat crystal network.[13] All images were acquired by transmission electron microscopy.

Incidentally, $\alpha$-lactalbumin has the ability to form nanotubules, but their presence in dairy products has not been reported.[8] Wheat flour has two unique proteins: the macropolymer glutenin (approximate length of 50 nm and diameter of 1.8 nm) and the monomeric units of gliadin. During kneading the long glutenin chains associate via physical entanglements into a large network and further interact with space-filling gliadins to form the thin films that give the unique viscoelastic properties and gas-holding capacity to wheat dough.[9] Polysaccharide gels trap abundant water inside a polymer or colloidal network, turning liquid foods into a semisolid material. Electron micrographs show that some polysaccharide gels, such as those of $\kappa$-carrageenan that may be present in flans and puddings, have fine and long filaments a few nanometers in diameter (Figure 2b).[10] Conversely, casein gels, the basic structures in cheeses and yogurts, have thick strands formed by casein micelles attached as a string of beads (Figure 2c).

All starches in cereals and legumes (and roots as well) are present in the form of densely packed granules 5−50 $\mu$m in size. Inside the granule, the branched polysaccharide amylopectin is ordered as neat semicrystalline layers 10 nm in thickness holding amylose molecules in inner spaces (Figure 1). Cooking in the presence of abundant water hydrates and swells the starch granules, obliterating their native structure and releasing both polymers. Thus, a cake mix may now set in the oven into a firm matrix formed by gluten proteins interspersed with swollen starch granules, fat, and sugar that harbors many gas cells. However, most cereal foods are metastable amorphous materials, and the released starch biopolymers may recrystallize on cooling into domains 10−20 nm in size, as those found in stale bakery products or cooled potatoes.[11] Con-Conversely, expanded snacks are produced by heating and shearing a low-moisture starchy flour inside an extruder-cooker, physically fragmenting the granules to submicrometer sizes and breaking down amylose and amylopectin into dextrins. Upon exiting the extruder's die, the melt is blown up by the released steam, resulting in a spongy and soft material characteristic of extruded snacks.[12]

Lipids in oilseeds are stored in discrete subcellular organelles called lipid bodies, <1 $\mu$m in size, surrounded by proteins that act as natural emulsifiers. Most lipids that we consume are triacylglycerol molecules (triglycerides) that may crystallize

dx.doi.org/10.1021/jf5016939 | J. Agric. Food Chem. 2014, 62, 9953−9956

from the molten state as nanoplatelets 30−40 nm thick and extending for around 370 nm (Figure 2d).[13] In turn, stacks of nanoplatelets form crystallites that cluster together into aggregates, eventually developing a fat network that occludes portions of liquid fat resulting in a plastic structure typical of butter and margarine (Figure 1). Monoglycerides and phospholipids are used as emulsifiers due to their amphiphilic nature. In an aqueous phase they may self-associate into a multitude of nanosized structures, for example, micelles and vesicles, which may be found in emulsions such as salad dressings (Figure 1).[14]

Two-phase systems in foods such as emulsions and liquid foams owe their existence to interfacial liquid films stabilized by amphiphilic lipids and/or proteins. Adsorption at oil/water (O/W) interfaces in protein-stabilized food emulsions occurs at dimensions of 10 nm.[15] The stability of beer foam (head) depends on the interaction of proteins and polypeptides extracted from malt and iso-$\alpha$-acids from hops to form an elastic film around 10 nm thick at the liquid/air interface. Although the channels separating adjacent bubbles (lamellae) may have initially an average thickness of around 1 $\mu$m, liquid continuously drains from them until thinning leads to the eventual collapse of the foam.[16]

Solid particles and droplets produced by mechanical size reduction are present in several foods and ingredients. From a sensorial viewpoint soft foods containing solid particles >40 $\mu$m are described as having a "sandy texture", thus the need for fine milling. Grinding and homogenization involve a kinetics of size reduction that yields a particle or droplet size distribution usually characterized by a mean value that in O/W emulsions (e.g., dressings and mayonnaise) produced by high-pressure homogenization may be around 300 nm.[17] Most particles in a commercial chocolate enrobing mass, for instance, are between 8 and 40 $\mu$m, but ca. 0.5% have sizes <1 $\mu$m.[18] This may seem a low volume fraction, but it represents a large number of particles due to their tiny size. The shelves in our kitchens store food powders that tend to agglomerate, so amorphous silica particles are a permitted additive to avoid caking. Some commercial samples of food-grade $SiO_2$ contain aggregates in the range of 50−200 nm with a mode of 70−120 nm.[19] Titanium dioxide nanoparticles, used to enhance the whiteness of a wide variety of foods (e.g., candy and chewing gum), are <300 nm in at least one dimension and 30% of them are <100 nm.[20] They are eliminated in the urine and feces. However, some inorganic nanoparticles have been demonstrated to have biological activity at the cellular and subcellular levels when they are neither soluble in water or oil nor degraded in the gastrointestinal tract nor readily excreted.

Several food components crystallize during processing or storage. The size of crystals increases continuously with time after nucleation, whereas the reverse occurs as they become dissolved in saliva or in the gastrointestinal fluids. Heat and mass transfer limitations during crystallization result in a distribution of sizes whose tail representing small crystals may well intrude into the nanorange. A domestic ice cream machine produces ice crystals 30−40 $\mu$m in size that may be perceived as sandiness on the tongue. However, pouring liquid nitrogen (−196 °C) directly into the cream mix under vigorous agitation causes the formation of tiny ice crystals <1 $\mu$m, giving ice cream a smooth texture that fascinates modern chefs.[21] On the contrary, it has been known for more than a century that the grittiness we appreciate in some cheeses corresponds to crystals of different amino acids that develop during aging (e.g., Roquefort cheese and tyrosine crystals).[22] Crystals (mainly of calcium oxalate) have also been found in many edible plants, but they are probably dissolved during cooking or digestion.[23]

Nanoprocessing of foods does not end in the kitchen but continues inside our bodies. Different from most other materials of our daily life, the "utility" of food structures lies in the rate and extent to which they are broken down and disintegrated. It is quite likely that as nutrients become liberated from the food matrix during digestion they will participate in interactions among them and with other molecules, thus forming new nanosized particles,[24] complex aggregates,[25] and self-assembled colloidal nanostructures,[26] a phenomenon that we are just starting to understand.

Nanoparticles may unintentionally find their way into our foods, for example, after being released from food packaging, coatings of processing equipment, or products of plant or animal origin. Some nanoparticles, particularly those of inorganic sources, have been shown to transverse the gastrointestinal mucosa, getting into some organs and reaching the cellular level.[27] In vivo studies on the cytotoxicity or genotoxicity of these nanomaterials, generally conducted in mice and rats, are scarce, and most of them fail at adequately characterizing the materials utilized; thus, no generalizations could be made of their biological activity.[28] Despite efforts from food regulatory agencies and institutions (e.g., FAO/WHO), gaps continue to exist as to the methodologies to be used in evaluating the safety of these nanomaterials and the relevance of the data generated.[29]

## ■ CONCLUSIONS

There are many identifiable nanostructures in the foods we eat. These edible nanostructures are assembled by nature, created during processing or cooking, intentionally added as ingredients, and perhaps incorporated inadvertently from the surroundings (e.g., nanoparticles in the air beaten into food foams). So far, they have proven to be either soluble, degradable in the gut, or eliminated from our bodies and nontoxic, conditions expected to be satisfied also by fabricated nanostructures added to foods. Increasing knowledge of the nanostructures present in our foods may provide a basis for the rational design of structures at the nanoscale to impart desired taste/texture attributes, thus replacing the trial-and-error approaches presently used. Conceivably, food scientists may be inspired by how these "natural" nanostructures come into being to develop novel and functional products from the "bottom-up". Meanwhile, the toolbox provided by the nanosciences is assisting not only in our understanding of the nanoscale phenomena of the materials we eat and digest but also in our assessment of the potential implications of new food nanotechnologies.[30]

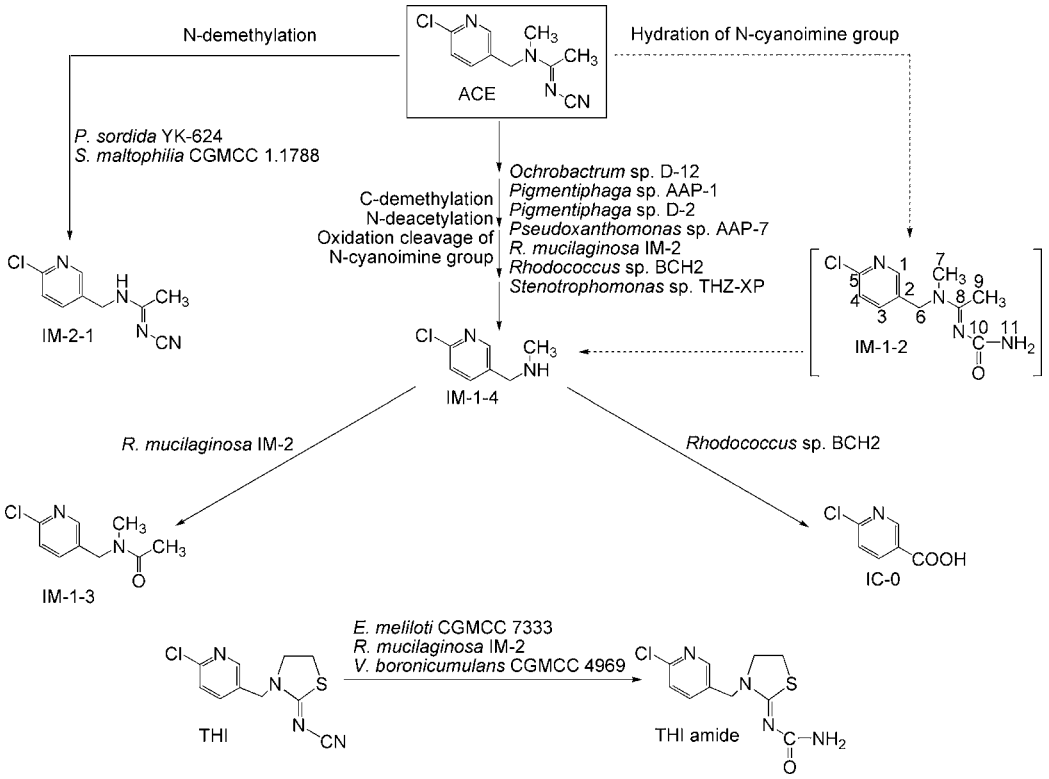

**Figure 1.** Molecular structures of ACE and its metabolites and the pathway in microbial metabolism.

*Phanerochaete sordida* YK-624 metabolize ACE via N-demethylation to IM-2-1.[17,18] The bacteria *Ochrobactrum* sp. D-12, *Pigmentiphaga* sp. AAP-1, D-2, *Pseudoxanthomonas* sp. AAP-7, *Rhodococcus* sp. BCH2, and *Stenotrophomonas* sp. THZ-XP and the yeast *Rhodotorula mucilaginosa* IM-2 metabolize ACE via the proposed N-deacetylation, C-demethylation, or oxidative cleavage of the *N*-cyanoimine group to IM-1-4, which is further metabolized by *Rhodococcus* sp. BCH2 to IC-0 or by *R. mucilaginosa* IM-2 to IM-1-3.[10,19−23] Notably, the formation pathway of the *N*-carbamoylimine metabolite IM-1-2 in plants, animals, and soils was not detected in the microbial ACE degradation pathways listed above. Nevertheless, although the metabolism of ACE in plants, animals, and soil has been clearly described, as have a few cases of microbial degradation, the corresponding enzymatic mechanism of ACE degradation by potentially useful environmental microorganisms has not yet been explored.

The seven major commercial neonicotinoid insecticides contain three structural components: an *N*-heterocyclyl-methyl moiety (A), a heterocyclic or acyclic spacer (B), and an *N*-nitroimine, nitromethylene, or *N*-cyanoimine pharmacophore (C).[14] It is interesting that the same structural components in related chemical compounds are metabolized by the same microbes; for example, *S. maltophilia* CGMCC 1.1788 hydroxylates the same site of component B, that is, the imidazolidine ring in IMI and imidaclothiz and also the thiazolidine ring of THI.[24] *Pseudomonas* sp. 1G transforms IMI and TMX at the component C *N*-nitroimine group via a nitro reduction pathway.[25] THI has the same *N*-cyanoimine group as ACE, and we isolated four THI-degrading bacteria, *Variovorax boronicumulans* CGMCC 4969, *Ensifer meliloti* CGMCC 7333, *Ensifer adhaerens* 6315, and *Ensifer* sp. SCL3-19, with the ability to hydrate THI by converting an *N*-cyanoimine group to an amide metabolite.[26,27] Therefore, we examined these four strains for their ability to degrade ACE and identified the metabolic pathway of ACE transformation used by these ACE-degrading bacteria. Metabolites were then tested for bioefficacy against the horse bean aphid, and the corresponding enzymatic conversion of ACE was further studied. The present study will help to elucidate the environmental fate of ACE, the toxicity of its metabolites, and the mechanism of enzymatic ACE degradation.

## MATERIALS AND METHODS

**Chemicals.** ACE was provided by Professor Jueping Ni of the Jiangsu Pesticide Research Institute, Nanjing, China (98% purity). HPLC grade acetonitrile (part no. AB1124-134) and methanol (part no. MS1922-001) were purchased from TEDIA (Fairfield, OH, USA). All other reagents were of analytical grade and purchased from Sinopharm Chemical Reagent Co., Ltd. (Shanghai, China).

**Strains and Media.** The wild bacteria *E. meliloti* CGMCC 7333,[27] *Ensifer* sp. SCL3-19,[27] *E. adhaerens* CGMCC 6315,[28] and *V. boronicumulans* CGMCC 4969[26] were isolated from soil and identified by 16S rRNA gene analysis. *Ensifer* sp. SCL3-19 was stored in our laboratory, and the other strains were deposited in the China General Microbiological Culture Collection Center (CGMCC) (Beijing, China). *Escherichia coli* Rosetta (DE3), the host for nitrile hydratase (NHase) gene expression, was maintained in our laboratory. Luria−Bertani (LB) medium (pH 7.2) for cell cultivation contained 10.0 g of peptone, 5.0 g of yeast extract, and 10.0 g of NaCl in 1.0 L of deionized water.

**Biodegradation of ACE by the Four THI-Degrading Bacteria, Resting *E. coli* Rosetta (DE3) Cells Overexpressing the NHase Gene from CGMCC 7333, and Purified NHase.** To evaluate the ability of resting bacterial cells to biotransform ACE, a single bacterial colony grown on an LB agar plate was inoculated into a 100 mL flask containing 10 mL of LB broth. The broth was incubated in a rotary shaker at 220 rpm and 30 °C for 24 h. Then, 1 mL of this culture was inoculated into a 500 mL flask containing 100 mL of LB broth and 0.1 mmol/L $CoCl_2$ and incubated using the same culture conditions for 12 h. Subsequently, 5 mL of cultivated broth was sampled, and cells were

dx.doi.org/10.1021/jf503557t | J. Agric. Food Chem. 2014, 62, 9957−9964

harvested with centrifugation at 6000*g* for 10 min. The cell pellet was washed with 0.2 mol/L sodium phosphate buffer (pH 7.5) and resuspended in a 50 mL plastic centrifuge tube containing 5 mL of the same buffer with 500 mg/L ACE. These cell suspensions were used for resting-cell ACE transformation. Meanwhile, phosphate buffer inoculated with either bacteria or dissolved ACE alone was used as control.

The NHase gene cluster from CGMCC 7333 was 1671 bp in length and contained $\alpha$- and $\beta$-subunits of 642 and 660 bp in length, respectively, and an accessory protein gene of 387 bp in length.[27] The GenBank accession numbers for the NHase $\alpha$-subunit, $\beta$-subunit, and accessory protein-coding genes from *E. meliloti* CGMCC 7333 are KF601242, KF601243, and KF601244. Overexpression of recombinant NHase in *E. coli* Rosetta (DE3) and purification of the NHase protein with His-tag affinity chromatography were performed according to the manufacturer's (Takara Bio Co., Dalian, China) protocols. The ACE biotransformation protocol was identical for the THI-degrading bacteria. To test the transformation of ACE by NHase, 10 $\mu$L of NHase was sampled and added to 1 mL of 0.2 mol/L phosphate buffer (pH 7.5) with 500 mg/L of ACE added in a 1.5 mL plastic centrifuge tube and covered.

Transformations were conducted under the above cultivation conditions for the indicated times. The samples were centrifuged at 10000*g* for 10 min to remove residual cells. The supernatant was collected, subjected to filtration with a 0.22 $\mu$m pore-size membrane, and diluted 10-fold for HPLC analysis of substrates and metabolites.

**Preparation of Metabolites.** ACE biotransformation by resting *E. coli* Rostta (DE3) cells overexpressing the NHase from *E. meliloti* CGMCC 7333 was scaled to a 1 L flask containing 300 mL of transformation broth and cultivated in a rotary shaker at 220 rpm and 30 °C until the ACE substrate was completely converted as determined by HPLC analysis. Cell residue was removed by centrifuging the mixture at 10000*g* for 20 min. The supernatant was extracted three times with equal volumes of ethyl acetate. The organic fraction was dehydrated with anhydrous sodium sulfate, after which the organic phase was filtered using a 0.22 $\mu$m pore-size organic membrane. Samples were then concentrated in a rotary vacuum evaporator at a temperature of 40 °C and crystallized in a vacuum dryer. The metabolite crystals were checked for purity using HPLC.

**HPLC, Liquid Chromatography–Mass Spectrometry (LC-MS), and Nuclear Magnetic Resonance (NMR) Analyses.** An Agilent 1260 HPLC system (Agilent Technologies, Santa Clara, CA, USA) equipped with a reverse-phase HC-C18 guard column (4.6 × 12.5 mm, 5 $\mu$m particle size, part no. 520518-904, Agilent Technologies, Wilmington, DE, USA) and an HC-C18 column (4.6 × 250 mm, 5 $\mu$m particle size, part no. 588905-902, Agilent Technologies, Wilmington, DE, USA) was used to analyze the transformation of ACE and its metabolites. Elution was conducted at a flow rate of 1 mL/min in a mobile phase that contained water, acetonitrile, and 0.01% acetic acid (water/acetonitrile, 65:35). The signal was monitored at a wavelength of 235 nm using an Agilent G1314A UV detector. LC-MS was conducted using an Agilent 1290 infinity LC with a G1315B diode array detector and an Agilent 6460 triple-quadrupole LC-MS system equipped with an electrospray ion (ESI) source (Agilent Technologies, Wilmington, DE, USA) that was operated in the positive ion mode. The column, mobile phase, and its proportion were similar to those mentioned for HPLC. The flow rate of elution was set to 0.6 mL/min, and the monitored wavelength of the metabolites formed in the biotransformation of ACE and IM-1-2 was set to 270 and 250 nm, respectively. $^{13}$C and $^{1}$H NMR spectra for the metabolite were obtained in DMSO-$d_6$ using a Bruker AV-400 NMR spectrometer (Bruker, Faellanden, Switzerland) operating at 100 and 400 MHz, respectively. Chemical shifts were referenced against internal tetramethylsilane. Several NMR techniques were used to assign proton and carbon atom chemical shifts ($\delta$), including distortionless enhancement by polarization transfer (DEPT), heteronuclear multiple bond correlation (HMBC), and heteronuclear single-quantum correlation spectroscopy (HSQC).

**Half-Life of ACE Degradation.** Half-life values for the degradation of ACE and its metabolites were determined by plotting $\ln(I/I_0)$ against time using the equation $\ln(I/I_0) = -kt$, where $I_0$ and $I$ represent the initial and residual concentrations. The half-life was calculated as

$$t_{1/2} = (\ln 2)/k$$

where $t_{1/2}$ is the half-life and $k$ is the apparent elimination constant. In all cases, the first-order equation provided a satisfactory fit for the data ($r > 0.9$) and thus provided the basis for the half-life calculation.[21]

**Bioefficacy of ACE Metabolites.** Bioefficacy assays were conducted at the National Pesticide Research and Development South Centre, Nanjing, China, during October 2013. Horse bean plants and the aphid *Aphis craccivora* Koch were used for bioefficacy tests. Oral ingestion and contact bioassays were performed using methods described by Buchholz and Nauen.[29]

## RESULTS

### Biodegradation of ACE by Resting *V. boronicumulans* CGMCC 4969, *E. meliloti* CGMCC 7333, *E. adhaerens*

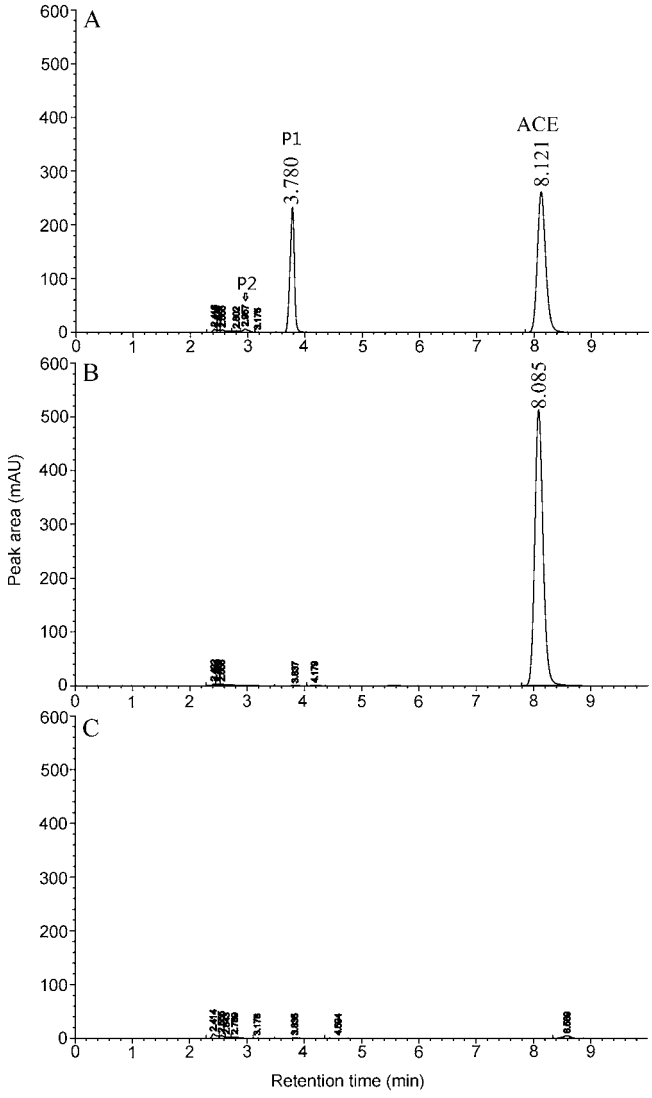

**Figure 2.** HPLC spectra of ACE biodegradation by resting *E. meliloti* CGMCC 7333 cells: (A) phosphate buffer containing 500 mg/L ACE and CGMCC 7333; (B) phosphate buffer containing 500 mg/L ACE; (C) phosphate buffer containing CGMCC 7333. Elution rate of the mobile phase was 1 mL/min, and the detection wavelength was 235 nm; the $OD_{600}$ value of the resting cell suspensions was 5; and the sampled time was 96 h.

**CGMCC 6315, and *Ensifer* sp. SCL3-19 Cells.** The four THI-hydrating bacterial strains *V. boronicumulans* CGMCC 4969,[26] *E. adhaerens* CGMCC 6315,[28] *E. meliloti* CGMCC 7333, and *Ensifer* sp. SCL3-19[27] were tested for ACE degradation. After transformation for 60 h, *V. boronicumulans* CGMCC 4969, *E. meliloti* CGMCC 7333, and *E. adhaerens* 6315 degraded 23 ± 2, 45 ± 5, and 8 ± 1% of ACE, respectively, whereas *Ensifer* sp. SCL3-19 did not degrade ACE. *E. meliloti* CGMCC 7333, which degraded THI at the highest level,[27] also degraded ACE the most efficiently of the tested bacteria. Therefore, this bacterium was used for further studies.

**Identification of Metabolites Formed during ACE Biotransformation.** ACE biotransformation by resting *E. meliloti* CGMCC 7333 cells resulted in the formation of an apparent new peak (P1) with an HPLC retention time of 3.78 min (Figure 2A). This peak could be detected in 12, 24, 36, 48, and 60 h, and no comparable peak was observed upon analysis of controls containing ACE (Figure 2B) or inoculated bacterium alone (Figure 2C). After transformation for 48 h, another new small peak (P2) with a retention time of 2.96 min was observed in the transformation broth. Peaks P1 and P2 with retention times of 4.30 and 5.33 min, respectively, were observed in LC-MS analysis of the biotransformation of ACE in 96 h (Figure 3A). As shown in Figure 3B, metabolite P2 displayed a protonated parent ion (M + H) at $m/z$ 157 and a major fragment ion (M − $CH_4N$) at $m/z$ 126. Thus, P2 could be assigned to IM-1-4 (Figure 1), a major metabolite that appears in soil, plant, and microbial metabolism of ACE.[10,20,23,30] Metabolite P1 (Figure 3C) displayed a protonated parent ion (M + H) at $m/z$ 241, a sodiated adduct (M + Na) at $m/z$ 263, a fragment ion (M − O) at $m/z$ 224, an unknown fragment ion at $m/z$ 198, and a fragment ion (M − $C_4H_8N_3O$) at $m/z$ 126. The unknown fragment ion at $m/z$ 198 also appeared in the spectrum of the gas chromatography−mass spectrometry (GC-MS) analysis of IM-1-2 reported by Yeter and Aydin.[31] The mass of metabolite P1 was enhanced by the addition of a water molecule to the substrate ACE (M + H) at $m/z$ 223 (Figure 3D) and was identical to the mass data reported for IM-1-2 by Yeter and Aydin[31] and Kamel et al.[32] Resting *E. coli* Rosetta cells overexpressing CGMCC 7333 NHase also hydrolyzed ACE to a metabolite with the same HPLC retention time as metabolite P1, and this metabolite showed the same mass as P1 in LC-MS analysis (data not shown). This *E. coli* strain transformed ACE completely in 2 h and was thus used for preparation of metabolite P1. The purified P1 was then used for NMR analysis. As is shown in Table 1, there are 10 carbon atoms in the $^{13}$C NMR spectrum, which was identical to the parent ACE. Therefore, the previously reported metabolites IM-2-1 (nine carbon atoms), IM-1-4 (seven carbon atoms), and IM-1-3 (nine carbon atoms) could be excluded.[17,20,23] There were 13 protons in the $^{1}$H NMR spectrum of the ACE metabolite P1, which was an

dx.doi.org/10.1021/jf503557t | J. Agric. Food Chem. 2014, 62, 9957−9964

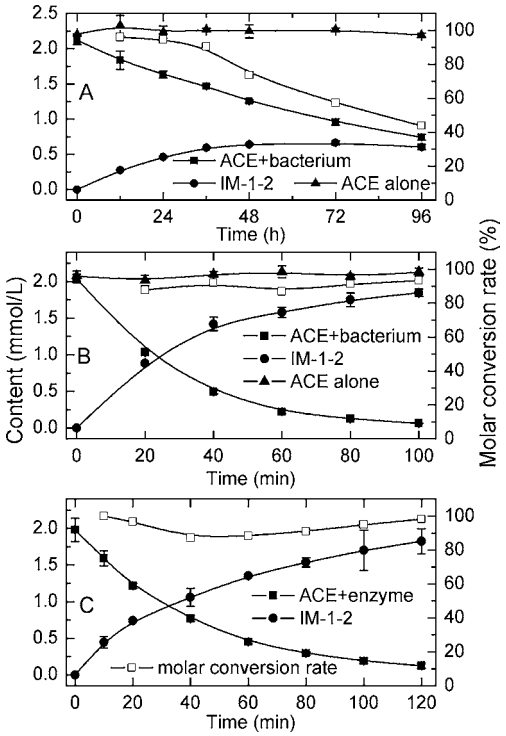

**Figure 4.** Time course of ACE degradation by *E. meliloti* CGMCC 7333 (A), *E. coli* Rosetta overexpressing NHase (B), and pure NHase (C). Preparation of resting *E. meliloti* CGMCC 7333 and *E. coli* Rosetta (DE3) cells is described under Materials and Methods. The $OD_{600}$ value of resting cell suspensions was 5. The NHase concentration was 67.9 μg/mL in 0.2 mol/L phosphate buffer (pH 7.5) with the addition of 0.1 mmol/L $CoCl_2$, and the reaction conditions were the same as for the resting-cell transformation of ACE. Average values and standard deviations were calculated from three parallel cultures tested three times ($n$ = 9).

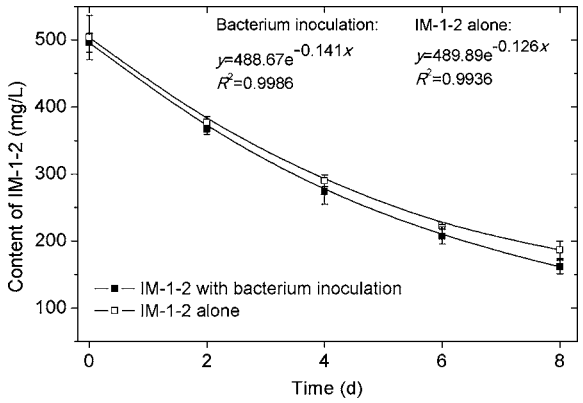

**Figure 5.** Degradation of IM-1-2 by *E. meliloti* CGMCC 7333. IM-1-2 was used as a substrate for transformation. The transformation conditions were the same as for ACE. The control was not inoculated with bacteria, and therefore any IM-1-2 degradation was spontaneous.

increase of 2 protons relative to the ACE substrate. The 2 new protons had chemical shifts of $\delta$ 6.13 and 6.28, respectively. These two protons had no correlation with the carbon atom in HSQC analysis. Therefore, they were assigned to the protons of the amide moiety. Meanwhile, a chemical shift was not observed for the C10 carbon atom of ACE in the $^{13}C$ NMR spectrum, and a new chemical shift ($\delta$ 165.4) appeared in metabolite P1 that could be assigned to the carbon atom of the amide moiety. On the basis of MS and NMR data, ACE metabolite P1 was the *N*-carbamoylimine derivate previously called IM-1-2.[15]

**Kinetics of ACE Transformation by Resting *E. meliloti* CGMCC 7333 Cells, the *E. coli* Rosetta (DE3) Strain Overexpressing the NHase Gene from *E. meliloti* CGMCC 7333, and Purified NHase.** Time course analyses of ACE hydration by resting *E. meliloti* CGMCC 7333 cells (Figure 4A) indicated that the quantity of ACE declined from 2.12 to 0.74 mmol/L in 96 h with an ACE degradation ratio of 65.1%. ACE degradation fitted first-order dissipation kinetics ($R$ = 0.99) with a half-life of 63.0 h. For ACE biodegradation, the molar conversion rates (the amount of IM-1-2 formed divided by the amount of ACE lost) at 12, 24, 36, 48, 72, and 96 h were 96.0, 94.6, 90.5, 73.7, 57.2, and 43.8%, respectively. In the initial 36 h, the molar conversion rate was >90%, which indicated that ACE hydration was the primary pathway of ACE degradation.

As is shown in Figure 4B, the quantity of ACE in the NHase overexpressing *E. coli* Rosetta (DE3) reaction declined from 2.04 to 0.06 mmol/L in 100 min with a degradation ratio of 97.1%. The half-life of ACE degradation was calculated to be 19.7 min ($R$ = 0.99). The molar conversion rates of ACE degradation by NHase overexpressing *E. coli* Rosetta cells at 20, 40, 60, 80, and 100 min were 87.7, 92.1, 86.8, 91.3, and 93.3%, respectively.

The quantity of ACE in the pure NHase reaction (Figure 4C) declined from 1.98 to 0.12 mmol/L in 120 min with a degradation ratio of 93.9%. The half-life of ACE degradation was calculated to be 30.1 min ($R$ = 0.99). The molar conversion rates of ACE degradation by NHase at 10, 20, 40, 60, 80, 100, and 120 min were 98.1, 96.8, 87.2, 88.3, 91.0, 94.9, and 98.2%, respectively. These results indicated that the NHase from *E. meliloti* CGMCC 7333 was responsible for the conversion of ACE to IM-1-2.

**Degradation of IM-1-2.** We previously reported that *E. meliloti* CGMCC 7333 hydrolyzed THI to THI amide with a molar conversion rate of >90% at every sampled time.[27] Interestingly, the molar conversion rate of ACE degradation declined significantly after transformation for 36 h. This result indicated that the IM-1-2 formed by hydration of ACE by *E. meliloti* CGMCC 7333 may have been further degraded. Therefore, IM-1-2 was used as a substrate for transformation by *E. meliloti* CGMCC 7333 to explore whether further IM-1-2 degradation was mediated by the bacterium. As shown in Figure 5, both the experimental group with bacterial inoculation and the control without CGMCC 7333 inoculation showed apparent IM-1-2 degradation. After incubation for 8 days, the amount of IM-1-2 was reduced by 1.40 and 1.32 mmol/L with bacterial inoculation and with IM-1-2 alone, respectively, and the corresponding degradation rates were 67.5 and 62.9%, respectively. The half-lives for IM-1-2 degradation for the experimental and control groups were fitted into first-order dissipation kinetics ($R^2$ = 0.9986 and 0.9936, respectively) and were calculated to be 4.9 and 5.5 days, respectively. There was no significant difference ($P$ > 0.05) in IM-1-2 degradation between the experimental and control groups at any sampled time. These results indicate that IM-1-2 degradation did not result from bacterial transformation and instead resulted from spontaneous chemical degradation.

As shown in Figure 6A, three new peaks with retention times of 4.26, 4.53, and 6.84 min, respectively, were observed in the LC-MS analysis of the control group sample without bacterial inoculation after incubation for 8 days. It can be observed that

dx.doi.org/10.1021/jf503557t | J. Agric. Food Chem. 2014, 62, 9957−9964

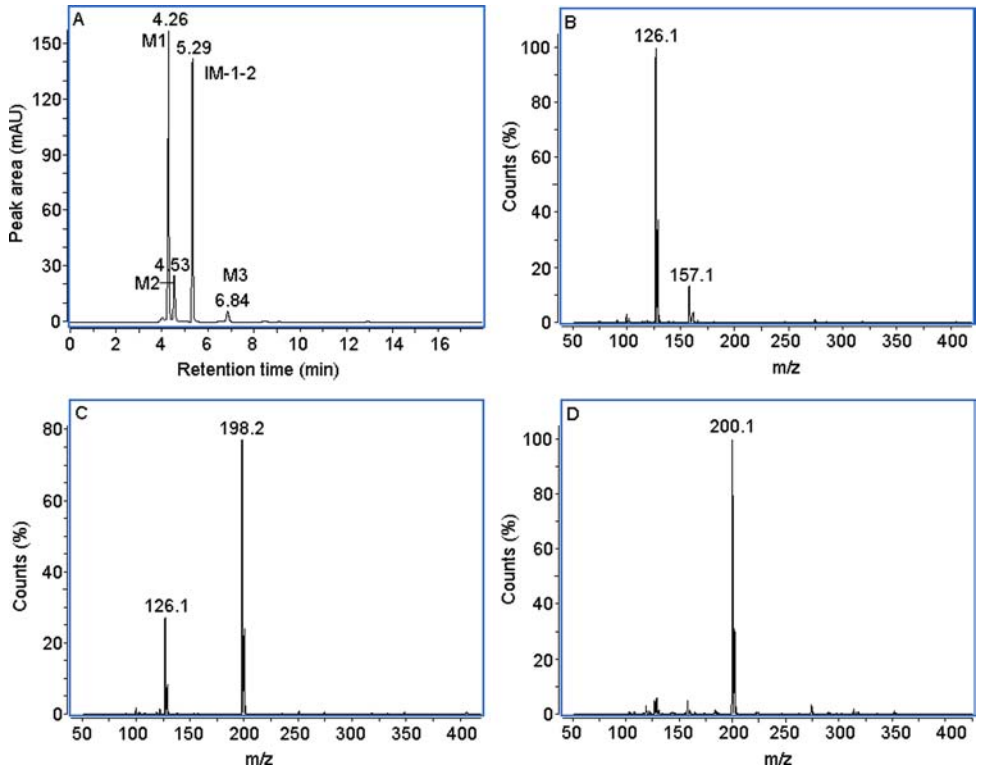

**Figure 6.** LC-MS data for the degradation of IM-1-2 in phosphate buffer without CGMCC 7333 inoculation: (A) HPLC spectrum of IM-1-2 degradation for 8 days without bacterial inoculation (substrate IM-1-2 peaked at a retention time of 5.29 min); (B, C, D) mass data of the metabolite peaks M1, M2, and M3 at retention times of 4.26, 4.53, and 6.84 min, respectively. The elution rate of the mobile phase was 0.6 mL/min, and the detection wavelength was 270 nm.

**Table 2. Bioefficacy of IM-1-2 against the Horse Bean Aphid *A. craccivora***

| compound | content (mg/L) | total insects tested | mortality[a] (%) |
|---|---|---|---|
| IM-1-2 | 1.0000 | 59 | 13.56 ± 5.85 |
| | 0.2500 | 50 | 12.00 ± 1.24 |
| | 0.0625 | 65 | 7.69 ± 0.85 |
| | 0.0156 | 73 | 8.22 ± 4.22 |
| ACE | 0.2500 | 51 | 100.00 ± 0.00 |
| | 0.0625 | 67 | 100.00 ± 0.00 |
| | 0.0156 | 70 | 87.14 ± 4.57 |
| control | 0 | 71 | 5.63 ± 0.94 |

[a]Mortality is expressed using the mean ± standard error from three parallel tests. Mortality was examined at 72 h after application of ACE or IM-1-2.

M1 (Figure 6B) has a protonated parent ion (M + H) at $m/z$ 157 and a major fragment ion (M − $CH_4N$) at $m/z$ 126. These mass data were identical to product P2 (Figure 3B), which was thus assigned to IM-1-4. M2 has a protonated parent ion (M + H) at $m/z$ 198 and could be attributed to the metabolite resulting from cleavage of the *N*-carbamoylimine group in IM-1-2. This metabolite has been detected in mice and plant metabolism of ACE and was named ACE-NH.[33] M3 had a parent ion (M + H) at $m/z$ 200 and could be attributed to the metabolite resulting from the reduction of the C═NH group in ACE-NH to form a C—$NH_2$ group. M3 was not reported previously[33] and was named ACE-$NH_2$. Metabolites M1, M2, and M3 will be purified and subjected to NMR analyses in future studies.

**Laboratory Bioassays of IM-1-2 against the Horse Bean Aphid *A. craccivora*.** The insecticidal activities of metabolites produced by microbial transformation contribute to the bioefficacy persistence of neonicotinoid insecticides.[8] ACE is recommended as a plant foliar spray, and IM-1-2 is one of its plant metabolites.[33] Therefore, we examined the bioefficacy of IM-1-2 against the horse bean aphid *A. craccivora*. As is shown in Table 2, ACE showed perfect and acute insecticidal activity in both the contact and oral ingestion bioassays. At applied concentrations of 0.2500, 0.0625, and 0.0156 ppm, aphid mortalities were 100, 100, and 87.14%, respectively. At the same tested concentrations, the mortality rates of IM-1-2 were only 12.00, 7.69, and 8.22%, respectively. Even when the concentration of IM-1-2 was increased to 1 ppm, the mortality level was only 13.56%. Laboratory bioassays indicated that IM-1-2 had dramatically reduced activity against the aphid *A. craccivora*. Similar results were observed for the bioassay of the THI amide, which reduced insecticidal activity by at least 1 order of magnitude when compared with the THI parent.[19] The above data indicated that the replacement of the crucial pharmacophore cyano group in ACE and THI with an amide group results in a significant reduction in insecticidal activity.

## DISCUSSION

ACE is stable in buffered solutions at pH 5.0−8.0 and in sunlight. It is degraded slowly at pH 9 and 45 °C.[34] However, ACE was degraded rapidly by aerobic soil metabolism, with a half-life ranging from 1 to 8.2 days in studies of various U.S., European, and Chinese soils and varied from 16 to 17 days under field conditions in Indian soils.[17,32] In our present study, ACE was readily degraded by *E. meliloti* CGMCC 7333, the

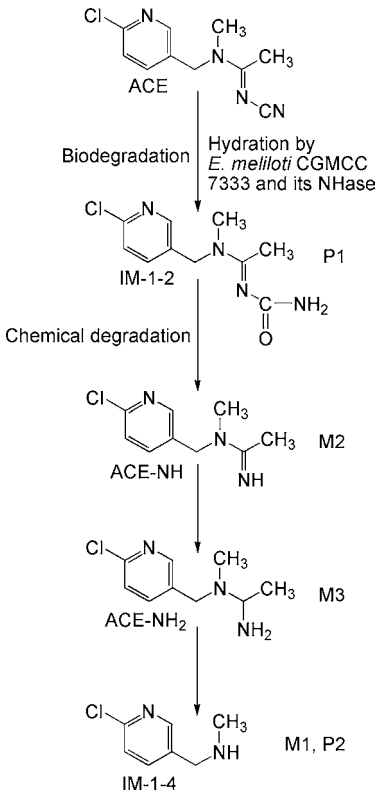

**Figure 7.** Proposed metabolic degradation pathways for ACE by *E. meliloti* CGMCC 7333 and further degradation of IM-1-2.

CGMCC 7333 NHase overexpressing *E. coli*, and the purified CGMCC 7333 NHase with half-lives of 63.0 h, 19.7 min, and 30.1 min, respectively. LC-MS and NMR analyses indicated that CGMCC 7333 NHase mediated the hydration of ACE to metabolite IM-1-2. IM-1-2 is unstable in phosphate-buffered solutions with a half-life of 5.5 days, and this chemical degradation resulted in cleavage of the *N*-carbamoylimine group to an ACE-NH derivate. ACE-NH was then converted to ACE-$NH_2$, which was subsequently cleaved to IM-1-4. The proposed pathway of ACE metabolism by *E. meliloti* CGMCC 7333 and chemical degradation of IM-1-2 are presented in Figure 7. Apparently, ACE degradation via the IM-1-2 pathway mediated by NHase and the chemical degradation of IM-1-2 resulted in the rapid degradation fo ACE in soil.

Metabolites of neonicotinoid insecticides have been shown to contribute to the toxicity of these insecticides.[7] For example, olefin metabolite of IMI was noted to be >10 times more toxic than the parent IMI,[35,36] whereas ACE metabolites, including IM-2-1, IC-0, IM-O (6-chloro-3- pyridiylmethanol), IM-1-4, and IM-1-3, were found to exhibit lower toxicity than ACE.[17,19,37] In our present study, we further proved that one of the major metabolites of ACE degradation, IM-1-2, also showed a dramatic reduction in toxicity (Table 2). Therefore, the rapid biotransformation and detoxification of the metabolites leading to the cyano-group-containing ACE is less toxic than the nitro-group-containing IMI against certain insects.[37] However, the selectivity of neonicotinoids to insect nAChR could be attributed to the pharmacophore group nitroimine (=N—$NO_2$) and cyanoimine (=N—CN), because they have a much higher affinity for insects, when compared with vertebrate nAChRs, and the loss of a nitro or cyano group to the imine metabolite (=NH) can completely reverse the selective toxicity of neonicotinoid insecticides to insects over vertebrates.[38] As shown in Figure 7, IM-1-2 can be spontaneously converted to the imine group containing metabolite ACE-NH and, therefore, ACE degradation via IM-1-2 pathway to form ACE-NH may increase the risk of ACE toxicity to vertebrates. Our present results may help to explore the mechanism of the adverse effect of ACE and IMI on human health.[11]

The molecular structures of ACE and THI have 6-chloro-3-pyridinylmethyl and *N*-cyanoamidine groups in common, but differ in their cyclic thiazolidine and acyclic methyl moieties (Figure 1). *E. meliloti* CGMCC 7333 hydrolyzes ACE and THI to the corresponding *N*-carbamoylimine derivatives despite the molecular differences between these two molecules. *Ensifer* sp. SCL3-19 hydrolyzes only the cyclic THI, not the acyclic ACE. We speculate that this difference in substrate selectivity between *E. meliloti* CGMCC 7333 and *Ensifer* sp. SCL3-19 may be attributed to differences in NHase structure between the two *Ensifer* species. The full NHase gene from *Ensifer* sp. SCL3-19 is being cloned and expressed, and site-specific mutation of various NHase genes will be conducted in the future to explore NHase function and the specific hydrolysis of the neonicotinoid insecticides ACE and THI.

Among ACE-degrading bacteria, *Rhodococcus* sp. BCH2 has been reported to degrade ACE, and three metabolites were observed in HPLC spectra. Two of these metabolites were determined to be IM-1-4 and IC-0 by GC-MS analysis. The authors assumed that ACE was degraded via IM-1-2 because they found an *N*-carbamoylimine group in the extraction of the mixed metabolites by Fourier transform infrared spectrum analysis, although they did not identify IM-1-2 itself by LC-MS or NMR analysis.[10] The present findings suggest that IM-1-2 cannot be directly detected as a product of ACE metabolism by *Rhodococcus* sp. BCH2, perhaps because IM-1-2 is hydrolyzed in this preparation process. In addition, it is known that the NHase of *Rhodococcus* catalyzes the conversion of the nitrile compound acrylonitrile to acrylamide in industrial processes,[39] and therefore it has been suggested that ACE degradation by *Rhodococcus* sp. BCH2 requires further study.

In conclusion, our present study first found that the nitrogen-fixing bacterium *E. meliloti* CGMCC 7333 and its NHase specifically transform the neonicotinoid insecticide ACE to IM-1-2. IM-1-2 is unstable due to chemical hydrolysis and produces the metabolites ACE-NH, ACE-$NH_2$, and IM-1-4. The present findings will improve our understanding of the environmental fate of ACE and the corresponding enzymatic mechanisms.
