**Figure 3.** Anomeric regions of the $^1$H NMR spectra of Bio-Gel P-2 fractions **F1**−**F6**, varying in DP ranges, of the IMMP product derived of Paselli MD10 maltodextrin. The IMMP fractions in the DP8-DP30 range contain a higher percentage of ($\alpha$1 → 6) linkages, compared with the ($\alpha$1 → 4) linkages present.

fractionated by HPAEC on CarboPac PA-1 (Figure 4A/B) to yield fractions containing compounds of a single DP according to MALDI-TOF-MS analysis, that is, for **F3** compounds 1−7 and for **F6** compounds 8−10. The structures of the 10 oligosaccharides were elucidated by one- and two-dimensional NMR spectroscopy, making use of published $^1$H NMR data of a series of GTFB products prepared from short malto-

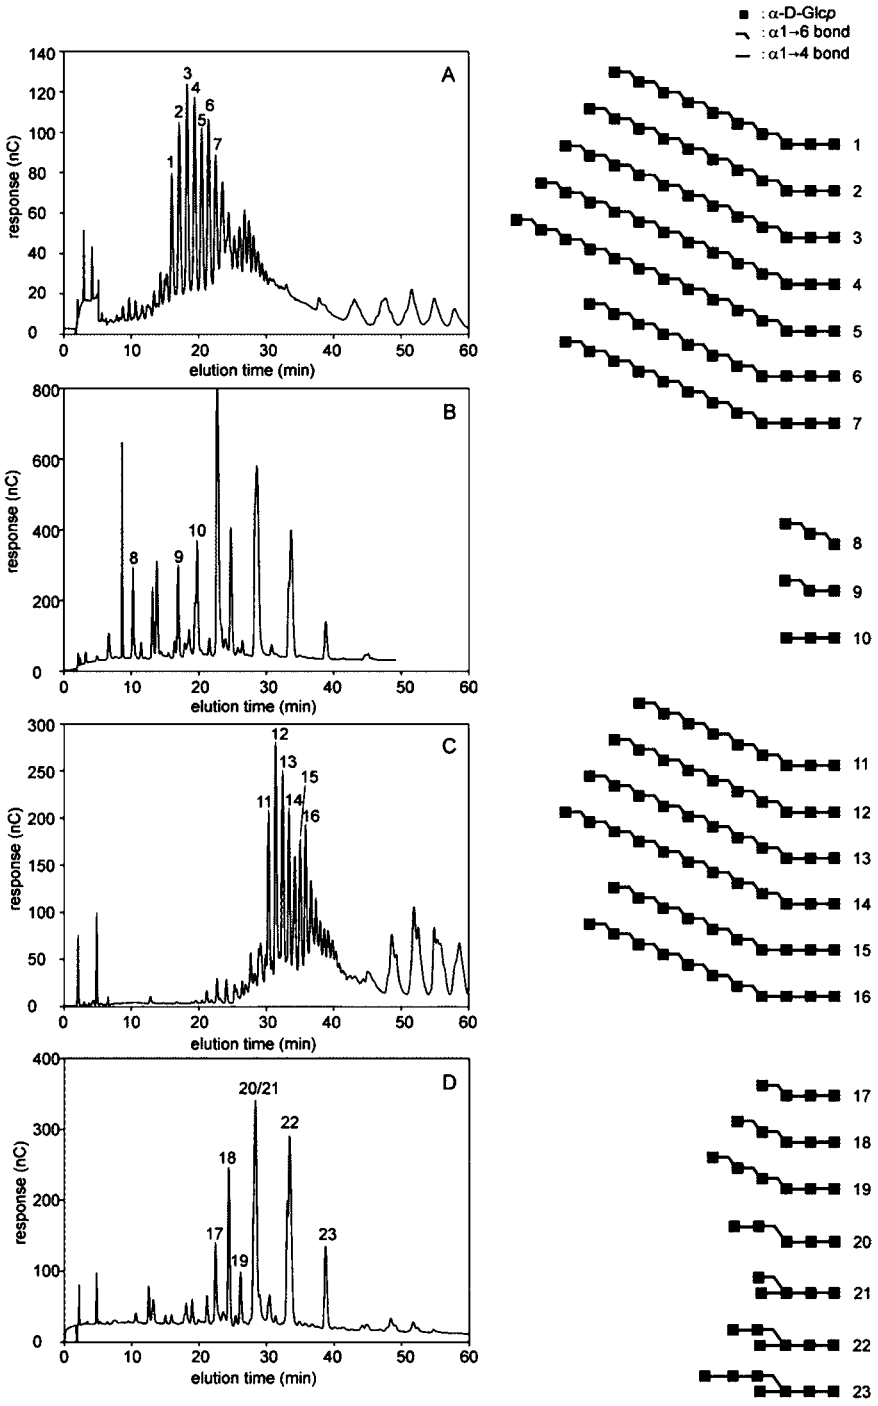

**Figure 4.** HPAEC separations on CarboPac PA-1 of Bio-Gel P-2 fractions, prepared from the IMMP product derived of Paselli MD10 maltodextrin before (A and B) and after (C and D) α-amylase treatment, together with 23 assigned α-glucan structures. (A) Profile of fraction **F3** (elution gradient 15−40% of 600 mM sodium acetate in 100 mM sodium hydroxide in 60 min); (B) Profile of fraction **F6** (elution gradient 5−28.5% in 40 min); (C) Profile of fraction **F′5** (5−50% in 78 min); and (D) Profile of fraction **F′7** (5−40% in 60 min).

oligosaccharides.[25,30] The identified α-glucan structures are depicted in Figure 4A/B, showing for **F3** long isomalto-elongations of maltotriose and maltotetraose and for **F6** maltotriose, panose, and isomaltotriose.

The IMMP product derived of Paselli MD10 was also treated with α-amylase, followed by fractionation on Bio-Gel P-2, yielding nine fractions, denoted **F′1**−**F′9** (data not shown). The α-amylase treatment resulted in a large amount of maltose (**F′9**), but also about 30% oligosaccharides and small polysaccharides. The fraction with the highest molecular masses (**F′1**, DP 17−35; MALDI-TOF-MS analysis) is composed of linear α-glucans (i.e., without branches) and has about 90% (α1 → 6) linkages ($^1$H NMR analysis). This demonstrates that GTFB is able to synthesize product mixtures that contain linear α-glucans with a DP up to 35. Possibly even larger α-glucans are present, but these are much harder to detect with MALDI-TOF-MS. Fractions **F′5** (DP9-DP16) and **F′7** (DP4-DP7) were further fractionated by HPAEC (Figure 4C/D), and the major peaks were isolated to yield for **F′5** compounds 11−16 and for **F′7** compounds 17−23. The

structures of the 13 oligosaccharides were elucidated by one- and two-dimensional NMR spectroscopy, following the same approach as described for **F3** and **F6**, and are depicted in Figure 4C/D. Examples of the 1D $^1$H NMR spectra of isolated compounds (i.e., compounds 11, 15, 16, 20/21, 22, and 23 of Figure 4C/D) are shown in the Supporting Information (Supporting Information Figure S2 and S3). The 1D/2D NMR (HSQC, TOCSY, ROESY) spectra of the branched compound 22 (Figure 4D) is depicted and worked out in the Supporting Information (Figure S4). In total three branched molecules were identified, that is, compounds 21, 22, and 23 in the $\alpha$-amylase-treated IMMP, and these are all typical $\alpha$-amylase degradation products of starch.

Overall, the $\alpha$-glucan structures identified in the IMMP product mixtures, derived of Paselli MD10, convincingly demonstrate that GTFB builds linear ($\alpha$1 → 6)-glucan chains onto the nonreducing end of ($\alpha$1 → 4)-chains when acting on starches and maltodextrins, in analogy to the compounds synthesized from short-chain monodisperse (1 → 4)-$\alpha$-D-gluco-oligosaccharides.[23,25]

**IMMPs are Different from Dextran.** The simple fact that IMMPs have two or more glucose moieties linked via an ($\alpha$1 → 4) linkage at its reducing end makes IMMPs a different kind of $\alpha$-glucan than dextran. However, there are additional differences. Dextrans are much larger polymers, which are synthesized from sucrose by dextransucrase enzymes forming fructose as byproduct.[31,32] GTFB, in contrast, synthesizes IMMPs via disproportionation reactions resulting in a polydisperse mixture of small poly- and oligosaccharide molecules. The size of the dextran molecules can, however, be tuned by either the addition of acceptor molecules during synthesis or by partial acid hydrolysis or dextranase enzymes.[33,34] Even though the size of dextran molecules can be matched to that of IMMPs, dextrans also contain branches which are absent in the IMMPs generated by GTFB. Also dextran dextrinase enzymes act on maltodextrins and produce oligosaccharides rich in ($\alpha$1 → 6)-glycosidic bonds. However, dextran dextrinase products possess branches, involving all three $\alpha$-glycosidic linkage types possible: ($\alpha$1 → 2), ($\alpha$1 → 3), and ($\alpha$1 → 4).[21,35,36] Currently available isomalto-oligosaccharides are produced with transglucosidases (i.e., $\alpha$-glucosidases), however, these compounds are much smaller (DPs in the range of 3 to 6) than the IMMPs made by GTFB. These isomalto-oligosaccharides are so small because the transglucosidase enzymes used (i.e., $\alpha$-glucosidases) are glycoside hydrolases that are relative effective in catalyzing disproportionation reactions at the high substrate concentrations employed in production processes. Thus, the IMMPs described in this paper are a novel class of $\alpha$-glucan structures that can only be obtained with GTFB-like enzymes.

**IMMPs Have a High Dietary Fiber Content.** To evaluate the dietary fiber quality of the IMMPs, they were subjected to a dietary fiber analysis. As the procedure used requires larger amounts of carbohydrate, seven IMMP products derived of Paselli MD10, Paselli MD6, Paselli SA2, Eliane MD6, waxy potato starch, and potato starch were produced at ten gram scale, with the percentage of ($\alpha$1 → 6)-glycosidic bonds ranging from 32 to 92% (Figure 5A). The dietary fiber analysis mimics the passage through the human upper gastrointestinal tract and small intestine, by incubating the IMMPs with representative digestive enzymes, that is, $\alpha$-amylase and amyloglucosidase. As expected this treatment degraded maltodextrins completely, whereas the IMMPs were found to

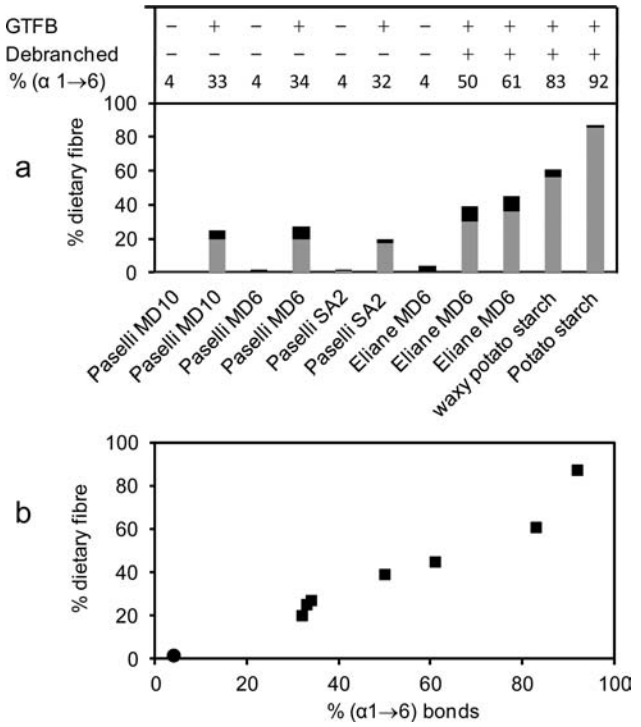

**Figure 5.** Dietary fiber content of seven IMMP products. (a) The percentages of total dietary fibers (height of bar), the high-molecular-weight dietary fiber (HMWDF, gray), and the low-molecular-weight dietary fiber (LMWDF, black) of the IMMP products derived of the indicated substrates. Note that the two Eliane MD6 samples are of incubations that were terminated before completion of the reaction. The numbers and the plus/minus symbols on top indicate the enzymes used in the conversion and the percentage of ($\alpha$1 → 6) linkages in the obtained IMMP product. (b) Increase of the percentage of total dietary fiber with the percentage of ($\alpha$1 → 6)-glycosidic bonds in the IMMP products (black squares). The unmodified maltodextrin Paselli MD6 (filled circle) is included as negative control. The exact numbers are reported in the Supporting Information (Table S2).

have a high dietary fiber fraction, reaching up to 87% (Figure 5A). The dietary fiber material of IMMP is largely composed of high-molecular-weight dietary fiber (HMWDF), which is defined as the fraction that precipitates with 72% ethanol, and a small amount of low-molecular-weight dietary fiber (LMWDF), which is the fraction that is soluble in 72% ethanol and has a DP ≥ 3. The HMWDF fractions obtained of the IMMPs derived of Paselli MD6, MD10 and SA2 maltodextrins were analyzed by $^1$H NMR spectroscopy, revealing that the HMWDF fractions contain about 90% ($\alpha$1 → 6) and 10% ($\alpha$1 → 4) linkages (data not shown). Thus, the dietary fiber analysis protocol specifically degrades the ($\alpha$1 → 4) linkages in the IMMPs products, which is as expected because of the $\alpha$-amylase used in the procedure. The dietary fiber analysis in addition demonstrated that the total dietary fiber fraction increased with the percentage of ($\alpha$1 → 6)-glycosidic bonds (Figure 5B).

Because the above dietary fiber method employs an amyloglucosidase enzyme, which has similar, but not identical, activities than the maltase-glucoamylase and sucrose-isomaltase enzymes of the brush border, two of the IMMP products, with 50 and 92% ($\alpha$1 → 6) linkages (Figure 5A), were also incubated with a rat intestine extract in an effort to closer resemble the digestive power of the small intestinal part of the gastrointestinal tract. The consideration here is that maltase-

glucoamylase and sucrose-isomaltase, which are known to hydrolyze ($\alpha$1 → 6) linkages in the $\alpha$-amylase degradation products of starch, may have a different effectivity toward ($\alpha$1 → 6) linkages in the IMMP products compared to amyloglucosidase. The brush border experiment with Eliane MD6 as example, revealed that as expected, this maltodextrin is rapidly converted into glucose. The 92% ($\alpha$1 → 6) IMMP (derived of potato starch by the combined action of GTFB and pullulanase, Figure 5A) is, in contrast, only very slowly degraded by the rat intestine extract, at the same rate as dextran (Figure 6). After 3 h the maltodextrin is completely converted to glucose, whereas only 9% of the glucose was released of the 92% ($\alpha$1 → 6) IMMP (Figure 6). The 50% ($\alpha$1 → 6) IMMP (derived of Eliane MD6 maltodextrin by the combined action of GTFB and isoamylase, Figure 5A) represents an interesting case. Initially it is degraded like maltodextrin with a rapid release of glucose, after which the further conversion to glucose is slow like that of the 92% ($\alpha$1 → 6) IMMP and dextran. Overall the brush border experiment indicates that the IMMP segments rich in ($\alpha$1 → 6) linkages will largely pass the human small intestine, acting as a soluble dietary fiber, and enter the large intestine were they can serve as carbon and energy source for the large intestine microbiota.

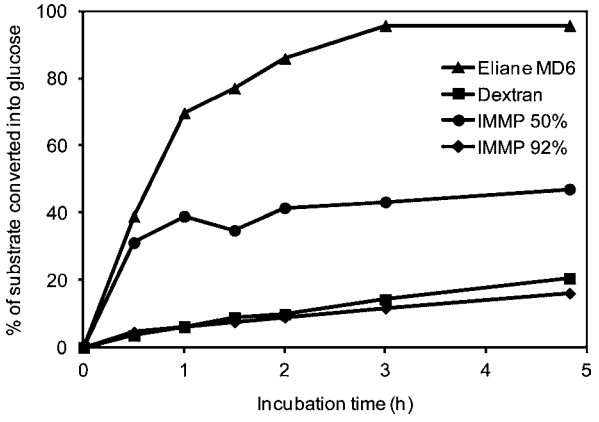

**Figure 6.** Formation of glucose from Eliane MD6 maltodextrin (average DP = 20), dextran (average DP = 37), IMMP derived of Eliane MD6 by the combined action of GTFB and isoamylase debranching enzyme [average DP = 15; 50% ($\alpha$1 → 6) linkages; see Figure 5A] and IMMP derived of potato starch by the combined action of GTFB and pullulanase debranching enzyme [average DP = 50; 92% ($\alpha$1 → 6) linkages; see Figure 5A].

**IMMP Degradation by the Large Intestine Microbiota.** It remained to be studied whether this novel type of dietary fiber is fermented in the large intestine. The human gut microbiota possesses an enormous diversity of carbohydrate degrading enzymes,[37] and short isomalto-oligosaccharides (≪DP10) have been shown to be fermented by the human fecal microbiota in vitro.[38] IMMPs will be partly digested before reaching the large intestine, depending on the percentage of ($\alpha$1 → 6) linkages. The passage through the upper gastrointestinal tract and the small intestine was therefore simulated by subjecting the IMMPs, and the dextran control, first to the dietary fiber analysis method. The HMWDF obtained in this procedure was then used as carbon source in anaerobic fermentations, that were inoculated with a thousand fold diluted fecal sample of one healthy adult human. The IMMP dietary fibers were readily fermented as visualized by a strong increase in the optical density at 600 nm (Figure 7),

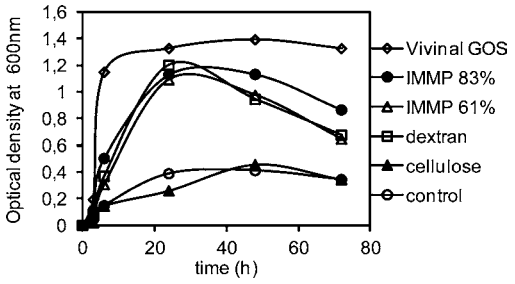

**Figure 7.** Fermentation of IMMP derived of Eliane MD6 by the combined action of GTFB and isoamylase debranching enzyme [61% ($\alpha$1 → 6) linkages; see Figure 5A], IMMP derived of waxy potato starch [83% ($\alpha$1 → 6) linkages; see Figure 5A], Vivinal GOS, dextran, cellulose and no added carbon source (control) by human fecal microbiota. See Materials and Methods for fermentation conditions. The IMMPs and dextran were first subjected to the dietary fiber analysis method, and that 1 g $L^{-1}$ of the obtained HMWDF was added as carbon source, because this is the part of the material that will reach the large intestine. Fermentations were inoculated with a 1,000-fold diluted fecal sample of one healthy adult human, and the optical density was followed in time.

compared to negative control samples with cellulose or without added carbon source. Note that this does not necessarily proof that IMMPs are fermented by the intestinal microbiota of all humans, because individuals significantly differ in their capacity to ferment dietary fibers. The small increase in optical density of these two negative control samples can be explained by the presence of some remaining but still fermentable carbon source in the diluted fecal sample. The faster increase in optical density with the commercially available prebiotic Vivinal GOS (galacto-oligosaccharides), which was included as positive control, is at least partly explained by the presence of glucose in this material. This glucose could not be removed by the dietary fiber method pretreatment, as performed with the IMMPs, simply because no HMWDF fraction is obtained, as the GOS does not precipitate in the dietary fiber analysis method used.

The fermentation experiment with IMMP as added carbon source showed an increased formation of the short fatty acids acetate and propionate compared to the control without added carbon source, after 6, 14, and 48 h. After 48 h, about 150 mg $L^{-1}$ acetate and 80 mg $mL^{-1}$ propionate is formed additional relative to the control. However, because this result is based on a fecal sample of one person only, it is not necessarily true for other individuals as well. Nevertheless, this preliminary result prompts us to further explore IMMPs, which is currently studied in more detail. The key question is whether short chain fatty acids are produced by all individuals of a large group, as these compounds are generally believed to have a positive impact on health.[15,39]

**Conclusions.** In this Article, we report the characterization of IMMP, representing a novel type of soluble dietary fiber, obtained by enzymatic modification of starch and starch-derived maltodextrins using the 4,6-$\alpha$-glucanotransferase GTFB of *Lactobacillus reuteri* 121. This enzyme is unique because it synthesizes completely linear chains of ($\alpha$1 → 6)-glucans onto the nonreducing ends of starch and starch-derived maltodextrin fragments. In the first catalytic cycle an ($\alpha$1 → 4)-glucan chain serves as acceptor substrate. The product displays a non-reducing end glucose moiety linked via an ($\alpha$1 → 6)-glycosidic bond, which apparently represents a better acceptor substrate that is further elongated. This explains the synthesis of products with a high percentage of ($\alpha$1 → 6)-glycosidic linkages.

The percentage of ($\alpha$1 → 6) linkages in the IMMP product can be controlled from 0 to 92% by substrate selection, in- or excluding debranching enzymes, and reaction time or GTFB enzyme concentration. With GTFB only, the highest percentages of ($\alpha$1 → 6) linkages are obtained when utilizing substrates rich in amylose and with a low degree of branching. But basically any starch compound can serve as good substrate, simply by using a debranching enzyme prior or during the incubation of starch with the GTFB enzyme.

Dietary fiber analysis methods, serving as in vitro models for the upper gastrointestinal tract and the small intestine, revealed that the dietary fiber content of the IMMPs is proportional to the fraction of ($\alpha$1 → 6) linkages in IMMP. The dietary fiber material remaining after this procedure, i.e. the material that will enter the large intestine, was used as carbon source by the large intestine microbiota. However, because the microbiota was of one person only it cannot yet been concluded that IMMPs are fermented by the intestinal microbiota of other individuals.

Thus, IMMPs represent a novel type of dietary fiber, and may constitute a new type of prebiotic.[43] Additional research is required to obtain solid evidence for the latter. Focus is on the identification of the groups of bacteria that ferment the IMMP dietary fibers. We still need to show that the IMMP dietary fibers reach the large intestine and promote the growth of beneficial microorganisms by in vivo studies in human subjects.

To conclude, this Article reports on a novel type of soluble dietary fiber, IMMP, which is produced by enzymatic modification of starch and is fermented by the microbiota of the large intestine.

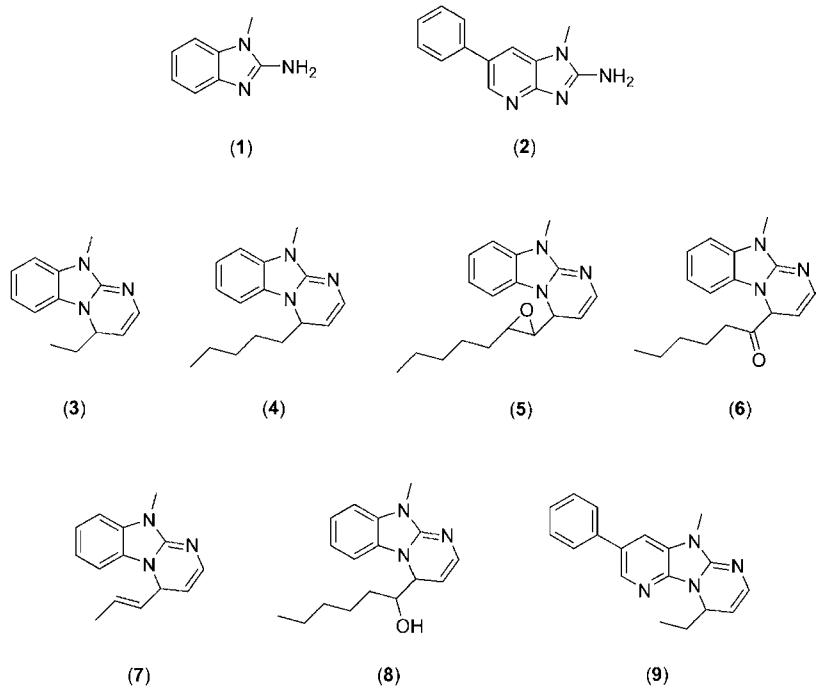

**Figure 1.** Chemical structures of the 2-aminoimidazoles (**1** and **2**) employed in this study and the adducts formed in their reactions with lipid-derived carbonyl compounds.

an Agilent 5973 MSD (mass selective detector, quadrupole type). Liquid chromatography−tandem mass spectrometry (LC−MS/MS) analyses were conducted by using an Agilent liquid chromatography system (1200 Series) consisting of a binary pump (G1312A), a degasser (G1379B), and an autosampler (G1329A), connected to a triple-quadrupole API 2000 mass spectrometer (Applied Biosystems) using an electrospray ionization interface in positive ionization mode ($ESI^+$). High-resolution mass spectra (HRMA) were recorded with a micrOTOF-QII mass spectrometer from Bruker equipped with an electrospray ionization source in positive ionization mode ($ESI^+$). $^1H$ and $^{13}C$ NMR spectra at 300 and 75.4 MHz, respectively, were recorded with a Bruker AC-300P instrument with tetramethylsilane as an internal standard.

Different reactive carbonyls derived from both $\omega$−6 and $\omega$−3 fatty acids were employed in these studies. Alkenals (2-octenal and 2-pentenal) and alkadienals (2,4-decadienal, 2,4-heptadienal, and 2,4-hexadienal) were purchased from Aldrich (Milwaukee, WI). Epoxyalkenals (4,5-epoxy-2-decenal and 4,5-epoxy-2-heptenal) were prepared by epoxidation of alkadienals (2,4-decadienal and 2,4-heptadienal, respectively) with 3-chloroperoxybenzoic acid.[14,15] Oxoalkenals (4-oxo-2-nonenal and 4-oxo-2-hexenal) were synthesized from 2-alkylfurans (2-pentylfuran and 2-ethylfuran, respectively) with *N*-bromosuccinimide.[16,17] 4-Hydroxy-2-nonenal was prepared according to the procedure of Gardner et al.[18]

PhIP was purchased from Toronto Research Chemicals (North York, ON). All other chemicals were purchased from Aldrich, Sigma (St. Louis, MO), Fluka (Buchs, Switzerland), or Merck (Darmstadt, Germany) and were analytical grade.

**Reaction of AMBI with Lipid-Derived Reactive Carbonyls.** A solution of AMBI (5 $\mu$mol in 100 $\mu$L of methanol), the reactive carbonyl (20 $\mu$mol in 170 $\mu$L of methanol), and 230 $\mu$L of 100 mM sodium phosphate buffer (pH 7.4) was heated for 15 h in closed test tubes at 37 °C. At the end of the heating period, samples were cooled and the formed adducts were studied by GC−MS.

In addition to the heating at 37 °C, other samples were also heated for 15 h at 100 °C in sodium citrate buffer (pH 5.0). The obtained results were similar, but reaction yields changed. The most stable adducts were produced with 2-alkenals, and these adducts were formed to a higher extent at high temperatures. When the reactive carbonyls had more functions than the aldehyde group and the carbon−carbon double bond, the produced adduct was more unstable. These adducts were better observed when heating was conducted at 37 °C.

To fully characterize the produced adducts, 2-pentenal was selected as the reactive carbonyl because the corresponding adduct was produced to a higher extent and was fairly stable. Thus, a mixture of AMBI and 2-pentenal heated at 100 °C overnight was fractionated by column chromatography using a diethyl ether/ethanol mixture (1:2) as the eluent. The formed adduct was identified as 2,10-dihydro-2-ethyl-10-methylpyrimido[1,2-*a*]benzimidazole (**3**) by one- and two-dimensional (2D) nuclear magnetic resonance (NMR) spectroscopy and high-resolution mass spectrometry (HRMS). Chemical structures of this and other adducts identified in this study are shown in Figure 1. $^1H$ NMR (300 MHz, $CDCl_3$): $\delta$ 0.88 (t, 3H, $J$ = 7.5 Hz, $C\underline{H}_3CH_2$), 1.25 (m, 2H, $CH_3C\underline{H}_2$), 3.46 (s, 3H, $NC\underline{H}_3$), 4.72 (dd, 1H, $J$ = 3.8 Hz, $J$ = 7.3 Hz, H3), 5.20 (m, 1H, H4), 6.60 (dd, 1H, $J$ = 1.2 Hz, $J$ = 7.3 Hz, H2), 7.05 (m, 4H, H6, H7, H8, H9). $^{13}C$ NMR (75.4 MHz, $CDCl_3$): $\delta$ 7.72 ($\underline{C}H_3CH_2$), 27.40 ($N\underline{C}H_3$), 29.70 ($CH_3\underline{C}H_2$), 54.43 (C4), 99.17 (C3), 106.87 and 107.79 (C6 and C9), 120.88 and 121.63 (C7 and C8), 129.66 and 131.91 (C5a and C9a), 135.88 (C2), 150.52 (C10a). HRMS: $m/z$ 427.259892 ($[2M + H]^+$, error of 1 ppm) and 214.133661 ($[2M + 2H]^{2+}$, error of 1 ppm).

**Study of AMBI/Reactive Carbonyl Adducts by GC−MS.** The formation of adducts between AMBI and lipid-derived reactive carbonyls was studied by GC−MS. Compounds were separated using a fused-silica HP5-MS capillary column (30 m × 0.25 m inside diameter; coating thickness, 0.25 $\mu$m) and injecting 1 $\mu$L of sample in the chromatograph in pulsed splitless mode. Working conditions were as follows: carrier gas, helium (1 mL/min at a constant flow); injector, 250 °C; oven temperature-programmed from 40 °C (1 min) to 240 °C at a rate of 5 °C/min and then to 300 °C at a rate of 10 °C/min; transfer line to MSD, 280 °C; ionization EI, 70 eV; ion source temperature, 230 °C; and mass range, 28−550 amu.

**Reaction of PhIP with 2-Pentenal.** A solution of PhIP (1 $\mu$mol in 150 $\mu$L of methanol), the reactive carbonyl (4 $\mu$mol), and 350 $\mu$L of 300 mM sodium citrate buffer (pH 5.0) was heated overnight in closed test tubes at 100 °C. At the end of the heating period, samples were cooled (5 min at room temperature and 10 min at −20 °C), and the formed adduct was studied by HRMS. HRMS: $m/z$ 581.309905 ($[2M + H]^+$, error of 6 ppm) and 291.159583 ($[2M + 2H]^{2+}$, error of 1 ppm).

**Study of PhIP Disappearance in the Presence of Lipid-Derived Reactive Carbonyls.** A solution of PhIP (1 nmol) and the reactive carbonyl (0−40 μmol) in 500 μL of 0.3 M buffer was heated in closed test tubes for the indicated time (0−1, 6, or 24 h) and temperature (60−200 °C). The buffers employed for controlling the reaction pH were sodium citrate buffer (pH 2.15−6), sodium phosphate buffer (pH 6−8), and sodium borate buffer (pH 8−10).

At the end of the heating period, samples were cooled (5 min at room temperature and 10 min at −20 °C) and analyzed to assess PhIP disappearance.

To study PhIP disappearance, 100 μL of the cooled reaction mixtures was diluted with 50 μL of an internal standard solution (1.29 mg of caffeine in 5 mL of a 30:70 mixture of 0.2% formic acid in acetonitrile and 4 mM ammonium acetate), and 850 μL of a 30:70 mixture of 0.2% formic acid in acetonitrile and 4 mM ammonium acetate, and PhIP was determined by LC−MS/MS.

Samples were separated on a Zorbax Eclipse XDB-C18 (150 mm × 4.6 mm, 5 μm) column from Agilent. As the eluent, a 30:70 mixture of 0.2% formic acid in acetonitrile and 4 mM ammonium acetate was used. The mobile phase was delivered at a rate of 0.5 mL/min in isocratic mode. Mass spectrometric detection was performed by using multiple-reaction monitoring (MRM). The nebulizer gas (synthetic air), the curtain gas (nitrogen), and the heater gas (synthetic air) were set at 45, 25, and 50 (arbitrary units), respectively. The collision gas (nitrogen) was set at 5 (arbitrary units). The heater gas temperature was set at 500 °C and the electrospray capillary voltage at 5.5 kV. The fragment ions in MRM mode were produced by collision-activated dissociation of selected precursor ions in the collision cell of the triple quadrupole, and the selected products were analyzed with the second analyzer of the instrument. Three transitions were acquired for the identification of both PhIP and the IS.

To establish the appropriate MRM conditions for the individual compounds, the mass spectrometric conditions were optimized using infusion with a syringe pump to select the most suitable ion transitions for the target analytes. Precursor and product ions used for confirmation purposes and operating conditions were described previously.[17] The $m/z$ 225.0 → $m/z$ 210.1 and $m/z$ 195.2 → $m/z$ 138.0 transitions for PhIP and caffeine, respectively, were used for quantitation purposes in this study.

Quantitation of PhIP was conducted by preparing five standard curves of this compound in 400 μL of 0.3 M sodium phosphate buffer (pH 8.0) and following the whole procedure described above. For each curve, seven different concentration levels of PhIP (0−2 nmol) were used. The PhIP content was directly proportional to the PhIP:IS area ratio ($r > 0.997$; $p < 0.0001$). The limit of detection (LOD), defined as the lowest sample concentration that could be detected with a signal-to-noise ratio (S/N) of >3,[19] was 0.005 nmol. The limit of quantitation (LOQ), defined as the lowest concentration that could be quantified with a precision of <15%, was 0.01 nmol.

**Statistical Analysis.** All data given are means ± the standard deviation of at least three independent experiments. Statistical comparisons among different groups were made using analysis of variance. When significant $F$ values were obtained, group differences were evaluated by the Tukey test.[20] Statistical comparisons were conducted using Origin version 7.0 (OriginLab Corp., Northampton, MA). The significance level is $p < 0.05$ unless otherwise indicated.

## RESULTS AND DISCUSSION

**Reaction between AMBI and 2-Pentenal.** 2-Pentenal reacted with AMBI producing an adduct that could be isolated and characterized by $^1$H and $^{13}$C NMR, and HRMS. Its $^1$H NMR spectrum was quite simple, and the original chain of 2-pentenal could be easily identified in the spectrum of the adduct by using 2D techniques. Thus, the carbonyl carbon of 2-pentenal was converted into an olefinic carbon in the adduct, and a shift of the carbon−carbon double bond of 2-pentenal was produced. In addition, the formed compound had the methyl group and the four aromatic protons of the original AMBI. The $^{13}$C NMR spectrum showed the positions of the 13 carbons of the adduct. According to these spectra, the adduct was identified as 2,10-dihydro-2-ethyl-10-methylpyrimido[1,2-*a*]benzimidazole (**3**). The structure for this compound is shown in Figure 1. Additional confirmation of the structure was obtained by HRMS. Curiously, compound **3** did not produce the usual $[M + H]^+$ ion, but ions $[2M + H]^+$ and $[2M + 2H]^{2+}$, the second one being the main ion. Compound **3** was fluorescent with excitation and emission maxima at 343 and 458 nm, respectively (Figure S1A of the Supporting Information).

**Reaction between AMBI and Other Lipid-Derived Reactive Carbonyls.** The reaction between AMBI and 2-pentenal described above was general for the different lipid-derived reactive carbonyls assayed, which involved alkenals, alkadienals, oxoalkenals, epoxyalkenals, and hydroxynonenal. All reactions developed fluorescence, and the obtained maxima were similar for all adducts, therefore suggesting a similar structure for all of them. Some the obtained fluorescence spectra are shown in Figure S1A of the Supporting Information.

This similarity among fluorescence spectra of the different adducts was also observed when adducts were studied by GC−MS. Figure S2 of the Supporting Information shows some of the obtained spectra. As one can see, the mass spectrum of adduct **3** produced between AMBI and 2-pentenal showed the molecular ion ($m/z$ 213) and a base ion at $m/z$ 184 that resulted from the loss of the ethyl chain (Figure S2A of the Supporting Information). A similar spectrum was obtained for the adduct **4** produced between AMBI and 2-octenal (Figure S2B of the Supporting Information). Thus, the molecular ion ($m/z$ 255) and the base ion at $m/z$ 184, resulting from the loss of the pentyl chain, were easily observed.

The reaction between AMBI and epoxyalkenals also produced adducts having analogous mass spectra. Thus, the spectrum obtained for adduct **5** resulting from the reaction between AMBI and 4,5-epoxy-2-octenal is shown in Figure S2C of the Supporting Information. This spectrum had the molecular ion at $m/z$ 297 and the base ion at $m/z$ 184 produced by the loss of the chain. An other important ion appeared at $m/z$ 281. This ion was produced by the loss of oxygen, which is in agreement with the presence of the epoxide ring.

The reaction between AMBI and oxoalkenals also produced adducts having similar mass spectra. Figure S2D of the Supporting Information shows the spectrum of adduct **6** produced between AMBI and 4-oxo-2-nonenal. This spectrum was also analogous to the other spectra, and the molecular ion at $m/z$ 283 and the base ion at $m/z$ 184 were the main ions in the spectrum.

The adducts between AMBI and 2,4-alkadienals were produced to an extent much lower than that of the previous adducts. Nevertheless, adduct **7** was produced between AMBI and 2,4-hexadienal. It also exhibited the characteristic molecular ion at $m/z$ 225 and the base ion at $m/z$ 184 (Figure S2E of the Supporting Information).

Finally, an adduct between AMBI and 4-hydroxy-2-nonenal was also produced, and its spectrum is shown in Figure S2F of the Supporting Information. It also exhibited the molecular ion at $m/z$ 285 and a fractionation pattern compatible with the dehydration of the adduct (Figure S2F of the Supporting Information). However, the base ion appeared at $m/z$ 186 and not at $m/z$ 184. For this reason, it is only tentatively assigned as adduct **8**. To obtain an additional confirmation of the structure

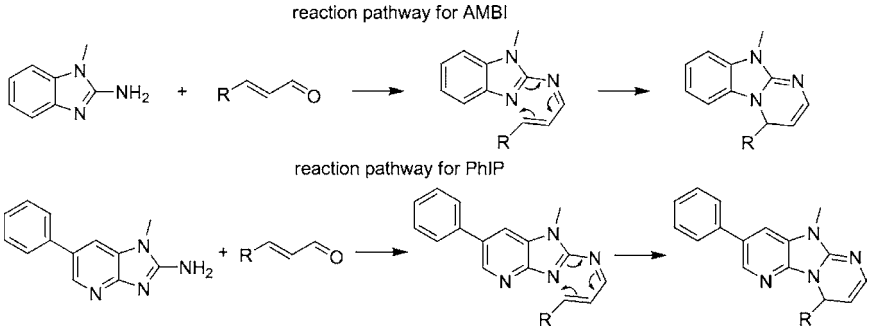

**Figure 2.** Proposed pathways for the formation of adducts between 2-amino-1-methylbenzimidazole (AMBI) or 2-amino-1-methyl-6-phenylimidazo[4,5-*b*]pyridine (PhIP) and lipid-derived reactive carbonyls.

[a]Mixtures of PhIP (1 nmol) and the lipid (40 μmol) in 500 μL of sodium citrate buffer (pH 5) were heated for 6 or 24 h at the indicated temperatures. Values, in nanomoles of PhIP per milliliter of solution, are means ± the standard deviation of at least three different experiments. [b]For the significance of the differences between means, $p < 0.05$ compared to its control. [c]For the significance of the differences between means, $p < 0.01$ compared to its control. [d]For the significance of the differences between means, $p < 0.001$ compared to its control.

of adduct **8**, its HRMS spectrum was obtained. The $[M + H]^+$ ion appeared at $m/z$ 286.191389, which was close to the expected value (error of 5 ppm).

**Formation of the Adduct between PhIP and Lipid-Derived Reactive Carbonyls.** To confirm that the reaction between AMBI and lipid-derived reactive carbonyls was general for 2-aminoimidazoles, the reaction between the heterocyclic aromatic amine PhIP and 2-pentenal was studied by HRMS. This reaction produced a fluorescent adduct **9** that exhibited ions analogous to AMBI−2-pentenal adduct **3**. Thus, ions $[2M + 2H]^{2+}$ (error of 1 ppm) and $[2M + H]^+$ (error of 6 ppm) were observed.

Fluorescence provided a further confirmation that analogous adducts were also produced in the different reactions between lipid-derived reactive carbonyls and either AMBI or PhIP. As observed in Figure S1B of the Supporting Information, all adducts exhibited a similar fluorescence, and this fluorescence was also similar to that exhibited by AMBI−carbonyl adducts.

**Reaction Pathway for Formation of the Adduct between either AMBI or PhIP and Lipid-Derived Reactive Carbonyls.** The reaction between lipid-derived carbonyl compounds and either AMBI or PhIP is likely to take place as indicated in Figure 2. The primary amino group of the 2-aminoimidazole would react with the carbonyl compound producing the corresponding imine, and a later electronic rearrangement of this imine would produce the reaction product. This cyclization reaction, which does not have to be necessarily concerted (arrows are drawn only to indicate a hypothetical flow of electrons), would be favored because of the formation of a stable heterocyclic structure. This mechanism is valid for all α,β-unsaturated aldehydes, although reaction yields are expected to be different depending on the aldehyde structure. Thus, if the β-carbon belongs to a delocalized electronic system, such as in alkadienals, the reaction should be expected to proceed more difficulty, which was experimentally observed (see below). On the contrary, the reaction should be favored if the β-carbon is activated for the reaction, such as in oxoalkenals. In addition, the stability of the adduct will depend on the presence of functional groups in the side chain of the formed adduct. Thus, the adducts produced with alkenals would be the most stable, as observed.

**PhIP Disappearance in the Presence of Lipid-Derived Reactive Carbonyls.** A consequence of PhIP−carbonyl reactions is the disappearance of PhIP. This may be important as an alternative pathway to decrease the amount of heterocyclic aromatic amines in food products. For that reason, the disappearance of PhIP in the presence of lipid-derived reactive carbonyls was studied.

When PhIP was heated alone, PhIP was stable at most of the assayed temperatures (Table 1). Only when it was heated at 200 °C, did PhIP disappear as a function of heating time. Thus, 43% of PhIP disappeared after 6 h at 200 °C, and this level of disappearance was >80% after 24 h at 200 °C. However, the stability observed for PhIP at temperatures below 200 °C disappeared when PhIP was heated in the presence of lipid-derived reactive carbonyls. Furthermore, the ability of lipid-

derived carbonyls to destroy PhIP depended on the type of carbonyl involved and also on the reaction time and temperature (Table 1). Thus, 4-oxo-2-nonenal and 4,5-epoxy-2-decenal turned out to be the most efficient PhIP scavengers. In the presence of 4-oxo-2-nonenal, 49% of PhIP disappeared after 6 h at 60 °C. A similar treatment produced the disappearance of 34% of PhIP in the presence of 4,5-epoxy-2-decenal. On the other hand, alkadienals turned out to be the least reactive carbonyls for this reaction, and a disappearance of 50% of PhIP in the presence of these compounds was observed only after heating at 150 °C for 6 h.

For oxoalkenals and epoxyalkenals, carbonyls derived from $\omega-6$ fatty acids were usually more reactive than the corresponding reactive carbonyls derived from $\omega-3$ fatty acids. Thus, 4,5-epoxy-2-decenal was more reactive than 4,5-epoxy-2-heptenal, and 4-oxo-2-nonenal was more reactive than 4-oxo-2-hexenal. On the other hand, this difference was not so clear for alkenals and alkadienals, which exhibited mostly similar reactivities regardless of the chain length.

In a manner independent of the carbonyl compound involved, PhIP losses increased, in general, with reaction time and temperature. All carbonyl compounds exhibited significantly ($p < 0.05$) decreased PhIP content after being heated for 6 h at 150 °C, and most of them exhibited significantly ($p < 0.05$) decreased PhIP content after being heated for 24 h at 100 °C.

Because the larger PhIP losses were observed in the presence of 4-oxo-2-nonenal, this compound was employed as the lipid-derived reactive carbonyl to study the best reaction conditions that favored PhIP degradation.

**Effect of Reaction Conditions on PhIP Disappearance in the Presence of 4-Oxo-2-nonenal.** PhIP disappearance depended on the reaction conditions, including the pH, the concentration of the lipid-derived reactive carbonyls, the time, and the temperature. Figure 3 shows the effect of pH on the disappearance of PhIP. PhIP disappearance was mostly produced at pH 4–5 using citrate buffer, although PhIP also disappeared to a large extent at pH 3 and 6, when using the same buffer. The PhIP disappearance rate was much lower at pH <3 or >6. In addition, the PhIP disappearance rate was also lower when using sodium phosphate buffer than when using sodium citrate buffer. The study of other reaction conditions to determine PhIP disappearance was conducted at pH 5.

PhIP disappearance also depended on the amount of 4-oxo-2-nonenal added (Figure 4). In fact, the PhIP disappearance rate increased linearly ($r = 0.97$; $p = 0.0001$) within the range of 0–6 $\mu$mol of 4-oxo-2-nonenal and continued to increase at higher concentrations of the carbonyl compound but to a lesser extent.

The PhIP disappearance rate increased linearly ($r > 0.965$; $p < 0.0018$) as a function of time between 60 and 120 °C (Figure 5). In addition, the PhIP disappearance rate increased when the temperature increased. Reaction rates at the different assayed temperatures were calculated by using the equation

$$\text{PhIP disapperance} = kt$$

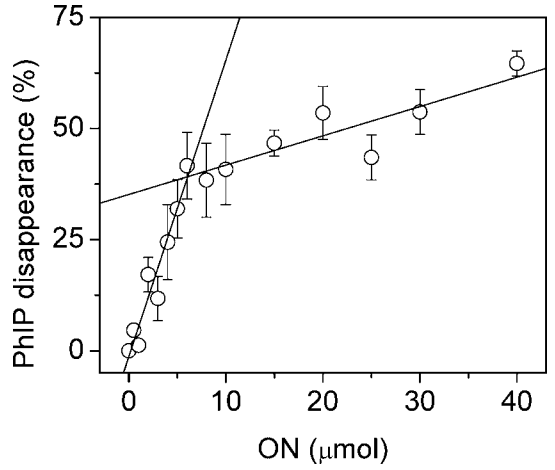

**Figure 4.** Effect of 4-oxo-2-nonenal (ON) concentration on the disappearance of PhIP. Mixtures containing PhIP (1 nmol) and 4-oxo-2-nonenal in 500 $\mu$L of 0.3 M sodium citrate buffer (pH 5) were heated at 100 °C for 24 h.

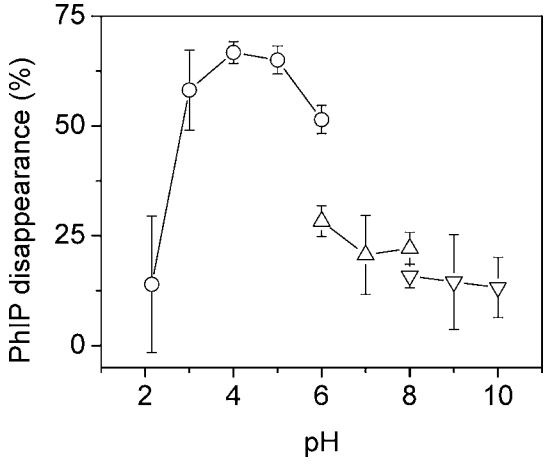

**Figure 3.** Effect of pH on the disappearance of PhIP in the presence of 4-oxo-2-nonenal. Mixtures containing PhIP (1 nmol) and 4-oxo-2-nonenal (40 $\mu$mol) in 500 $\mu$L of 0.3 M buffer were heated at 100 °C for 24 h. The employed buffers were sodium citrate for pH 2.15–6 (○), sodium phosphate for pH 6–8 (△), and sodium borate for pH 8–10 (▽).

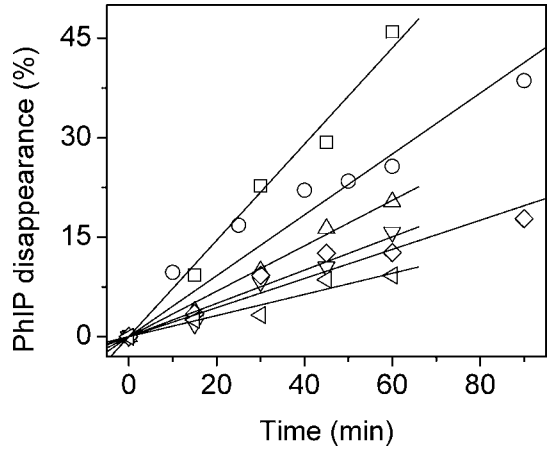

**Figure 5.** Effect of time and temperature on the disappearance of PhIP. Mixtures containing PhIP (1 nmol) and 4-oxo-2-nonenal (40 $\mu$mol) in 500 $\mu$L of 0.3 M sodium citrate buffer (pH 5) were heated at the indicated times and temperatures. The assayed temperatures were 60 (left-pointing triangles), 70 (◇), 80 (▽), 90 (△), 100 (○), and 120 °C (□).

where $k$ is the rate constant and $t$ is the reaction time. These rate constants were used in an Arrhenius plot for the calculation of the activation energy ($E_a$) of PhIP disappearance in the presence of 4-oxo-2-nonenal (Figure S3 of the Supporting Information). The determined $E_a$ was 27.4 kJ/mol.

These results show that 2-aminoimidazoles are able to react with reactive carbonyls, but at the same time, they disappear as a consequence of the produced reactions. Therefore, these reactions might be employed as a strategy for the removal of heterocyclic aromatic amines having this chemical structure, which include all aminoimidazoazarenes.[10]

The formation of the adducts between PhIP and the lipid-derived reactive carbonyl compounds, and therefore the disappearance of PhIP, is produced much more easily than the formation of PhIP in the presence of carbonyl compounds because the $E_a$ of the formation of the cyclic compound (27.4 kJ/mol) is much lower than that obtained for PhIP formation in the reaction among creatinine, phenylalanine, and 4-oxo-2-nonenal (80.9 kJ/mol).[21] Therefore, the results obtained in this study support the previous results of Randel et al.[9] that found losses of PhIP when this last compound was heated in the presence of frying fats. In addition, they also provide an explanation for the reduction of the mutagenic potential observed in parallel to PhIP disappearance.[9] Thus, the formed adduct has lost the primary amino group of the original PhIP, which seems to be the responsible for its metabolic activation.[22]

The results obtained in this study and previous studies[17,21] provide two opposite roles for lipid-derived reactive carbonyls in PhIP formation and disappearance. On one hand, reactive carbonyls promote the conversion of phenylalanine into phenylacetaldehyde, which is needed for PhIP formation.[23] On the other, they are able to react with PhIP after it is produced. Therefore, lipid-derived reactive carbonyls will play one role or another depending on whether PhIP is present. Thus, lipid oxidation in the presence of phenylalanine and creati(ni)ne will contribute to PhIP formation. However, once PhIP is present, lipid oxidation will destroy PhIP over favoring its formation (at least at low temperatures) because the $E_a$ of PhIP destruction in the presence of lipid-derived reactive carbonyls is much lower than the $E_a$ of PhIP formation in the presence of the same carbonyl compounds.[21] For that reason, significant increases in the level of PhIP formation were only observed when phenylalanine and creatinine were heated in the presence of small amounts of the lipid carbonyl compound.[21]

The results obtained in this study and previous studies show the complexity of the reactions involving carbonyl compounds in food because they can react with many food components and consequences for food will be different depending on the reaction that is finally produced to a larger extent. Therefore, identification of the different components that scavenge carbonyl compounds and the study of the competitive ability of carbonyl scavengers are essential for fully understanding many of the changes produced as a consequence of food processing.

## MATERIALS AND METHODS

**Materials.** The sample of FD&C Yellow No. 5 (Y5) used in this study originated from a batch submitted to the FDA for certification. The purified main component of FD&C Yellow No. 5 (MY5) was separated by countercurrent chromatography from a portion of Y5 and was generously provided by Dr. Adrian Weisz of the FDA.[23] Methanol (Fisher Scientific, Fair Lawn, NJ, USA), ammonium acetate ($NH_4OAc$, Fisher), and water were of chromatography grade. The mixed-phase titanium dioxide Deggussa Aeroxide P25 (75% anatase and 25% rutile phase; surface area, 50 ± 15 $m^2/g$) was purchased from Degussa Corporation (Parsippany, NJ). The spin-trap, 5-tert-butoxycarbonyl 5-methyl-1-pyrroline *N*-oxide (BMPO), was purchased from Applied Bioanalytical Laboratories (Sarasota, FL). The 2,2,6,6-tetramethyl-4-piperidone (TEMP) was purchased from Wako Pure Chemical Industry, Ltd. Japan; and 2,2,6,6-tetramethylpiperidine-1-oxyl (TEMPO) was purchased from Alexis, Enzo Life Sciences, Inc. (Farmingdale, NY). The $^{15}N$-labeled 4-oxo-2,2,6,6-tetramethyl-piperidine-d16−1-oxyl ($^{15}N$-PDT) was purchased from Cambridge Isotope Laboratories (Andover, MA). Superoxide dismutase (SOD) and standard buffer solutions were purchased from Sigma Chemical Co. (St. Louis, MO). Before use, each buffer stock solution (pH 3.9 HAc-NaAc, pH 5.0 PBS, pH 7.4 PBS, all at 0.1 M) was treated with Chelex100 molecular biology-grade resin from Bio-Rad Laboratories (Hercules, CA) to remove trace metal ions. Distilled deionized water (18.2 MΩ cm) from a Milli-Q water purification system was used in all experiments.

**Preparation of Au/$TiO_2$ Hybrid Nanostructures.** Au/$TiO_2$ hybrid nanostructures were prepared according to a previously reported photoreduction method with modifications.[24,25] To obtain a 1.00 wt % Au/$TiO_2$ sample, 10 mL of 2.0 mg/mL $TiO_2$ suspension in methanol (50% by volume) was mixed with 0.1 mL of an aqueous solution of $HAuCl_4$ (2 mg/mL Au) in a 50 mL quartz Erlenmeyer flask and sealed. The above mixture was sonicated for 5 min and then irradiated for 30 min under simulated sunlight with magnetic stirring in an ice water bath. The light source was an Oriel Xenon Arc Lamp Solar Simulator. A clearly evident color change from white to greyish pink was observed, which indicated the formation of Au/$TiO_2$ hybrid nanostructures. After centrifugation, UV spectral analysis of the supernatant after each photodeposition revealed that the Au had been almost completely (>99%) deposited as Au on the $TiO_2$ particles. The precipitate was collected, washed three times with double distilled water, and then dried at 45 °C overnight in oven and used for further experiments.

**Characterization of $TiO_2$ NPs and Au/$TiO_2$ Nanostructures.** UV−vis absorption spectra were obtained using a Varian Cary 300 spectrophotometer. Transmission electron microscopy (TEM) and high resolution TEM (HRTEM) images were captured on a JEM 2100 FEG (JEOL) transmission electron microscope (accelerating voltage of 200 kV) located at the NanoCenter, University of Maryland, College Park, MD. Energy-dispersive X-ray spectroscopy analysis (EDS) was conducted using the same microscope. The samples for TEM analysis were prepared by adding drops of the redispersed colloidal solutions onto standard holey carbon-coated copper grids, which were then air-dried at room temperature.

**Dye Degradation.** For examining the degradation of Y5, 10 mL of an aqueous solution containing 25 mg/L MY5 or Y5 and selected concentrations of $TiO_2$ or Au/$TiO_2$ NPs was continuously stirred in the dark for 30 min to establish an adsorption−desorption equilibrium between the NPs and dyes. The $TiO_2$ and Au/$TiO_2$ NPs were dispersed as suspensions for all experiments. Each suspension was transferred to a 50 mL quartz Erlenmeyer flask, sealed, and irradiated using a light source to deliver simulated sunlight. The light resource consisted of a Universal Arc Lamp Power Supply (69920 Universal Supply, Newport, Irvine, CA) and an Oriel Xenon Arc Lamp (880 W) solar simulator. During irradiation, the suspension was continuously stirred and kept in ice water bath. The degradation process was monitored using a Varian Cary 300 spectrophotometer. Before UV−vis analysis, the reaction mixture was centrifuged to remove the $TiO_2$ or Au/$TiO_2$ particles. The photocatalytic degradation of MY5 was observed to follow pseudo-first-order kinetics. When the dye concentration was in the millimolar range, the apparent first-order rate constant, $k_{app}$, was determined from the slope of ln ($C/C_0$) versus irradiation time according to the following relation:

$$-\ln \frac{C}{C_0} = k_{app} t \quad (1)$$

where $t$ is the irradiation time, $C_0$ is the initial concentration of dye, and $C$ is the concentration of dye (mg/L) at time $t$.[26] The concentration was determined by spectrophotometry. The UV−vis spectrum of MY5 consists of two characteristic peaks at 425 and 258 nm. The $\lambda_{max}$ value of the dye (425 nm) was chosen for quantitative degradation studies.

**Electron Spin Resonance.** ESR spin-trap spectroscopy is a powerful tool for evaluating the capability of NPs to generate reactive oxygen species and free radicals.[27] It was employed to detect the generation of ROS and occurrence of electron transfer during irradiation of samples with simulated sunlight. The spin-trap, BMPO, was used to detect the generation of superoxide radicals ($O_2^{-\bullet}$) or hydroxyl radicals (•OH). TEMP was used to investigate the generation of singlet oxygen ($^1O_2$). TEMPO, a stable radical that exhibits an ESR signal with three identical peaks, was used as spin probe to study the electrons generated in the $TiO_2$ aqueous suspension. Oxygen consumption during dye degradation photocatalyzed by $TiO_2$ NPs was monitored by ESR oximetry. A water-soluble spin label, $^{15}$N-PDT, was used to detect the oxygen content in sample solutions. The shape of the $^{15}$N-PDT ESR spectrum is dependent on the amount of $O_2$ that interacts with it, where higher peak-to-peak amplitude ($A$) and narrower peak-to-peak line width ($W$) are found when the levels of $O_2$ in solution are reduced.[28] The $O_2$ concentration was calculated by a calibration standard curve described by

$$[O_2] = 419.72 \times W - 44.12 \quad (2)$$

where $[O_2]$ is the concentration in solution ($\mu$M). The consumption of oxygen was expressed as $[O_{2\text{-time}}]/[O_{2\text{-initial}}]$.

Fifty microliter aliquots of control or sample solutions were put in glass capillary tubes with internal diameters of 1 mm and sealed using Critoseal capillary tube sealant, then placed into the microwave cavity of a Bruker EMX ESR Spectrometer (Billerica, MA) to obtain ESR spectra. All ESR measurements were carried out in situ using the following settings for detection of the spin adducts: 10 mW microwave power for detection of spin adducts using spin-traps and 1 mW microwave power for ESR oximetry using $^{15}$N-PDT, 100 G scan range, and 1 G field modulation. A Schoeffel xenon arc (450 W) solar simulator was used to irradiate samples during ESR measurements. ESR spectra were collected during irradiation at different time intervals. All measurements were performed in replicate at ambient temperature. Control groups, either without catalysts or without irradiation, were also recorded for comparison. The final concentration of each component is described in each figure caption. All experiments were repeated three times. Data are expressed as mean ± standard deviation.

## RESULTS AND DISCUSSION

**Characterization of $TiO_2$ NPs and Au/$TiO_2$ Hybrid Nanostructures.** The morphology of $TiO_2$ NPs and Au/$TiO_2$ hybrid nanostructures was characterized by TEM. Figure 1, panel a shows the original $TiO_2$ P25 agglomerates with the size range of 22−48 nm. Figure 1, panel b shows the Au NPs (dark dots) located on the surface of the individual $TiO_2$ NPs. The size of the photodeposited Au NPs was estimated to be 4−10 nm. After Au was doped onto $TiO_2$ surface, the surface characteristics and size of the $TiO_2$ NPs remained unchanged. EDS analysis was performed to further confirm the formation of Au/$TiO_2$ nanostructure. The EDS spectrum in Figure 1, panel c shows a strong signal for Ti and a weak signal for Au. The mass ratio of Au/$TiO_2$ for the selected area was estimated to be approximately 5% based on this spectrum. Elemental copper and carbon were also detected by EDS, which was associated with the supporting carbon-coated copper grids. The HRTEM image (Figure 1d) taken from the interfacial region of Au and $TiO_2$ shows the lattice image with a lattice spacing of 0.353 nm that corresponds to the {001} facets of anatase phase. Lattice fringes with interplanar distance of 0.202 nm were observed on the dark dots in Figure 1, panel d, which is similar to the planar distance for Au {200} ($d$ = 0.204 nm).

**Degradation of FD&C Yellow No. 5.** *Effect of Initial $TiO_2$ Concentration.* The degradation of Y5 and MY5 in the presence of nano-$TiO_2$ was carried out under simulated sunlight. Figure 2, panel a illustrates the effect of the initial

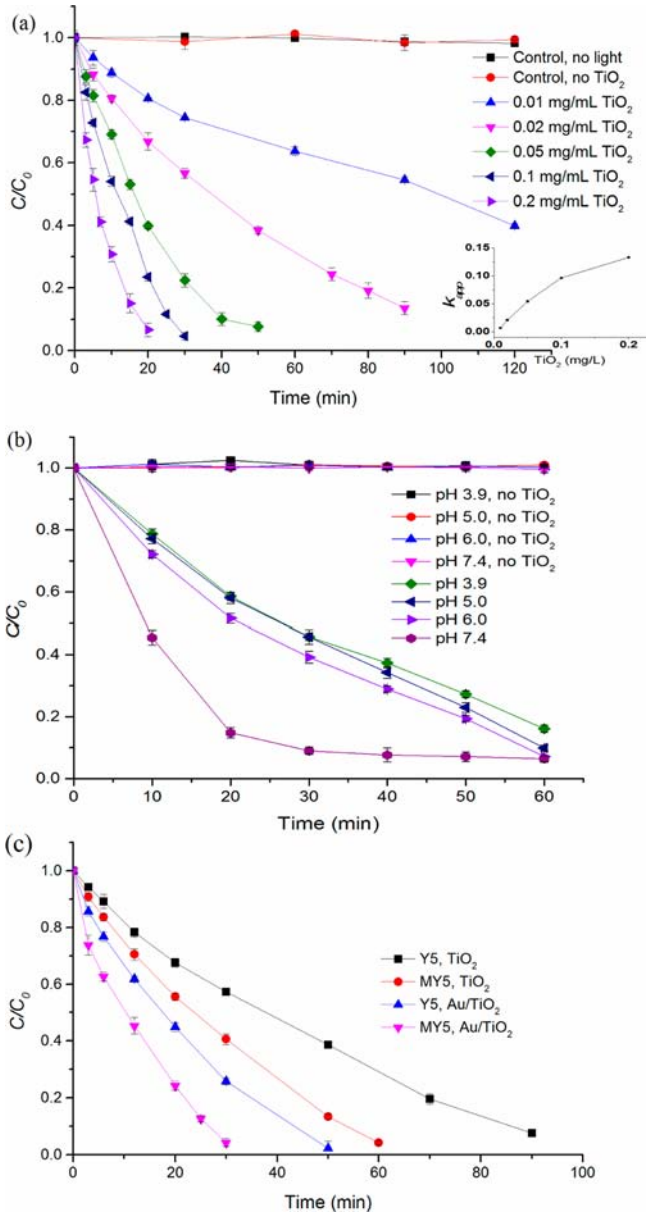

**Figure 2.** Decomposition of purified MY5 under simulated sunlight. $Y$-axis ($C/C_0$) shows the concentration of remaining dye at irradiation time divided by the initial dye concentration. Reactions were carried out in (a) water solutions of MY5 and 0 (control), 0.01, 0.02, 0.05, 0.1, and 0.2 mg/mL $TiO_2$ NPs irradiated by simulated sunlight for different time intervals or without sunlight exposure (control); (b) 10 mM PBS buffer (pH 5.0, 6.0, and 7.4) or 10 mM acetic acid buffer (pH 3.9) solutions containing MY5 and 0.1 mg/mL $TiO_2$ NPs; (c) water solutions of MY5 or batch-certified Y5 containing 0.1 mg/mL $TiO_2$ NPs or Au/$TiO_2$ hybrid nanostructures. The initial dye concentration in all samples was fixed at 25 mg/mL.

$TiO_2$ NPs concentration on degradation kinetics. The initial concentration of MY5 was fixed at 25 mg/L, while the concentration of $TiO_2$ NPs was adjusted to 0.01, 0.02, 0.05, 0.1, and 0.2 mg/mL. Figure 2, panel a demonstrates that MY5 remains unchanged after 120 min for the control groups, either without $TiO_2$ NPs but exposed to simulated sunlight or added with $TiO_2$ NPs but without exposure to simulated sunlight. Dos

dx.doi.org/10.1021/jf5045052 | J. Agric. Food Chem. 2014, 62, 12052−12060

Santos et al. reported a significant reduction of tartrazine in aqueous solution with 15 min of UV irradiation.[21] The difference between this study and our results may be attributed to the different light sources and intensities used. Figure 2, panel a shows that an increase in the concentration of $TiO_2$ resulted in a higher rate of degradation for MY5. At $TiO_2$ NP concentration of 0.1 mg/mL, the dye was not spectrophotometrically detectable after 30 min of exposure to simulated sunlight. The inset of Figure 1, panel a shows the calculated reaction constant, $k_{app}$, at different concentrations of $TiO_2$. The highest rate constant ($k_{app}$ = 0.133 $min^{-1}$) was observed at 0.2 mg/mL $TiO_2$ NPs.

*Effect of pH.* The pH value of the reaction mixture plays multiple roles in the dye degradation process by affecting the ionization state of the $TiO_2$ surface and hydroxyl radical generation in the solution[26] as well as the structure of tartrazine.[23] In this study, we investigated pH values of 3.9, 5.0, 6.0, and 7.4 to mimic the pH range of particular food products. Figure 2, panel b shows that under slightly alkaline conditions (pH = 7.4), the degradation rate was significantly promoted ($k_{app}$ = 0.084 $min^{-1}$), whereas the rate constant $k_{app}$ was calculated to be 0.028, 0.035, and 0.039 $min^{-1}$ for pH values 3.9, 5.0, and 6.0, respectively. The effect of pH value plays multiple roles in dye decomposition, including influences on •OH generation and adsorption as well as the adsorption of dye. Higher pH value could provide higher concentration of hydroxyl ions to react with valence band holes ($h^+$) to form •OH.[29] However, under acidic conditions (pH < 6.8), the $TiO_2$ surface is positively charged, whereas it is negatively charged for pH > 6.8.[30] When $TiO_2$ is negatively charged, Coulombic repulsion takes place, which repels the hydroxyl ion and oxygen molecule from adsorbing on its surface and thus decreases the availability of hydroxyl and superoxide radical for dye degradation.[31] On the other hand, in acidic media, a strong adsorption of the dye onto the $TiO_2$ particle has been observed, which results from the significantly high electrostatic attraction force between the positively-charged $TiO_2$ and the anionic dye molecule, which causes an increase in adsorption and accelerates the degradation process.[32,33] Therefore, with regard to the influence of pH on azo dye degradation, some reported a bell-shaped figure in which the dye degradation reaches its maximum around neutral pH.[34,35] For Y5 (tartrazine) decomposition triggered by $TiO_2$, the rate constant $k_{app}$ was found to increase with pH in the pH range of 2.2−11.[36]

*Effect of Dye Composition.* Y5 is batch certified by the FDA to ensure compliance with specifications in the Code of Federal Regulations (CFR).[23] Among the specifications is a limit of 1% for each of two polysulfonated subsidiary colors: the tetrasodium salt of 4-((4,5-disulfo(1,1-biphenyl)-2-yl) hydrazono)-4,5-dihydro-5-oxo-1-(4-sulfophenyl)-1H-pyrazole-3-carboxylic acid and the trisodium salt of 4,4′-(4,5-dihydro-5-oxo-4-((4-sulfophenyl)hydrazono)-1H-pyrazol-1,3-diyl)bis-(benzenesulfonic acid), which have been assigned the abbreviations Pk5 and Pk7, respectively.[23] To our best knowledge, most of the Y5 samples in previously published studies were obtained from commercially available tartrazine samples that contain around 85% MY5. It is noteworthy that the purity and composition of those samples may lead to different results. Therefore, we studied a certified batch of dye (Y5, ∼86% purity) used for coloring foods, drugs, and cosmetics as well as its purified main component (MY5, ∼99% purity). Under the same treatment conditions, the FDA-certified dye showed a lower degradation rate compared to the purified main component according to data obtained by spectrophotometric analysis. This result points to a higher stability of the batch-certified Y5 compared to MY5, which may be attributable to the more complex mixture of dye components in Y5.

*Effect of Deposition of Au onto $TiO_2$ Surface.* Noble metals have been widely used to enhance the photoactivity of $TiO_2$. Au NPs deposited on $TiO_2$ act as electron traps and enhance the electron−hole separation and the subsequent transfer of the trapped electron to the adsorbed $O_2$ that acts as an electron acceptor. Therefore, to investigate the relationship between dye degradation and electron/hole pair as well as ROS generation, we synthesized Au/$TiO_2$ hybrid nanostructure by depositing Au onto the surface of $TiO_2$. Figure 2, panel c shows that, for both MY5 and Y5, Au/$TiO_2$ exhibited enhanced photoactivity and accelerated color degradation, again with a higher degradation rate for MY5.

**$TiO_2$-Generated Electrons and ROS.** *Detection of Electron Reactivity during Photoexcitation of $TiO_2$ NPs.* ESR was employed to investigate the generation of ROS and occurrence of electron transfer during photoexcitation of $TiO_2$ in aqueous suspension. The reactive electrons generated in 0.1 mg/mL $TiO_2$ NPs were detected using a stable spin probe, TEMPO. TEMPO is a stable radical that has been widely used as a spin label in ESR spectroscopy, and it exhibits a triplet ESR spectrum, whereas its reduced form, hydroxyl amine (TEMPOH), is ESR silent.[37] As shown Figure 3, panel a, the

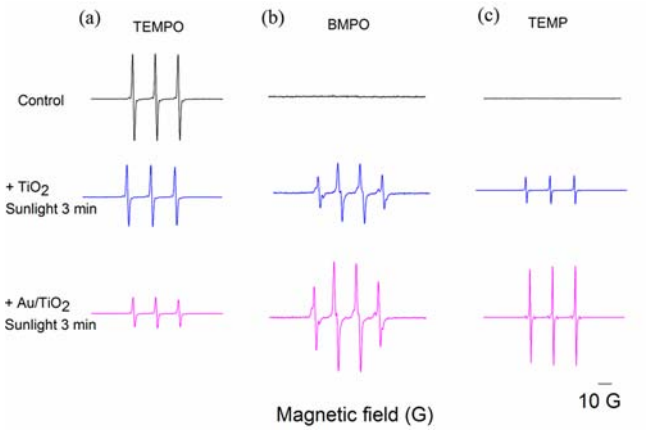

**Figure 3.** Detection of photogenerated electrons and ROS in solutions containing 0.1 mg/mL $TiO_2$ NPs or Au/$TiO_2$ hybrid nanostructures. ESR spectra obtained from samples mixed with different spin probes: (a) 0.02 mM TEMPO; (b) 25 mM BMPO; and (c) 2 mM TEMP. First row of each column presents both of the control groups, which contained the spin probe either without $TiO_2$ NPs or without simulated sunlight irradiation. All the spectra were recorded after 3 min of irradiation with simulated sunlight.

triplet-peak ESR signal of TEMPO remained unchanged for both control groups, either without $TiO_2$ NPs but exposed to simulated sunlight or added with $TiO_2$ $NP_S$ but without exposure to simulated sunlight. When $TiO_2$ NPs were added (0.1 mg/mL) and simulated sunlight irradiation was applied for 3 min, the TEMPO signal intensity was reduced. Further flattening of ESR spectrum was observed for samples containing the same amount of Au/$TiO_2$ NPs, which indicates a higher fraction of TEMPO being reduced to TEMPOH. Since our results indicated that TEMPO does not react with other species in the solution, such as hydroxyl radical or superoxide

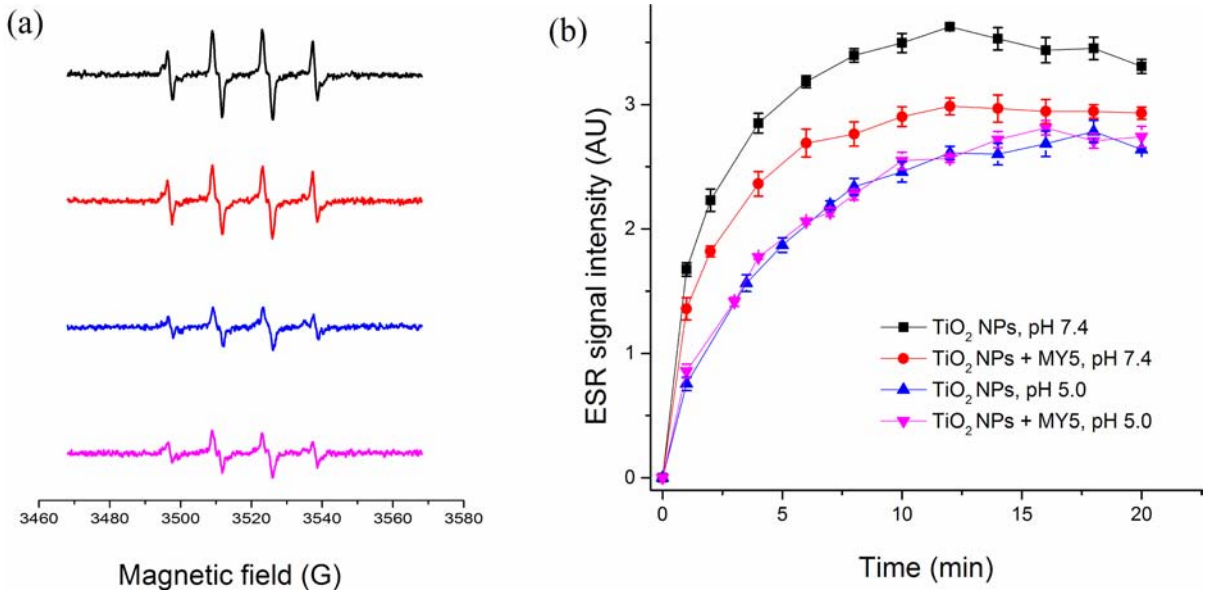

**Figure 4.** ESR detection of •OH during decomposition of dye upon simulated sunlight irradiance: (a) ESR spectra recorded after 1 min of irradiation by simulated sunlight; and (b) time-dependent ESR signal intensity obtained by measuring the peak-to-peak height of the second line of the ESR spectrum of BMPO/•OH. Reactions were conducted in 10 mM pH 5.0 or 7.4 PBS buffer solutions containing 25 mM BMPO spin-trap. All sample solutions contained 0.1 mg/mL $TiO_2$ NPs with (or without) 25 mg/mL MY5.

radical generated by $H_2O_2$ (Figure S1, Supporting Information), the reduction of TEMPO necessarily resulted from the electrons generated during photoexcitation of $TiO_2$ NPs.

*Generation of Hydroxyl and Superoxide Radicals.* The generation of hydroxyl radical by photoexcited $TiO_2$ NPs in aqueous suspension was confirmed using the spin-trap BMPO. Being ESR silent itself, BMPO can trap hydroxyl radical or superoxide radical and become ESR detectable. The spin-adduct BMPO/•OH exhibits a 1:2:2:1 ratio in peak ESR signal intensity, with hyperfine coupling constant $a_N$ = 13.5 G, $a_{H\beta}$ = 15.3 G, and $a_{H\gamma}$ = 0.62 G, while the spin-adduct of BMPO and superoxide radical (BMPO/O2$^{-\bullet}$) has a typical four-line ESR spectrum with hyperfine splitting structure ($a_N$ = 13.4 G, $a_{H\beta}$ = 12.1 G).[38] Figure 3, panel b shows an ESR spectrum identical to the BMPO/•OH spin-adduct signal for $TiO_2$ exposed to simulated sunlight. A similar ESR pattern with higher intensity was observed for Au/$TiO_2$ NPs under the same experimental conditions. Previous studies have reported difficulties when using BMPO as a spin-trap for a system containing both •OH and $O_2^{-\bullet}$ because of possible overlap of BMPO/•OH and BMPO/$O_2^{-\bullet}$ signal.[14] For irradiated $TiO_2$ solutions, the formation of •OH has been widely recognized, while several studies have reported observation of $O_2^{-\bullet}$ detected by ESR spectroscopy.[39] To determine whether superoxide radical is involved in this process, superoxide dismutase (SOD) was employed to scavenge superoxide radicals in order to eliminate any BMPO/$O_2^{-\bullet}$ signal (Figure S2, Supporting Information). With the addition of SOD (0.2 U/ml) to the above $TiO_2$ NP suspension, the 1:2:2:1 peak ESR signal remained the same pattern that is identical to BMPO/•OH spin-adduct. However, the intensity of the above signal was reduced to half. The reduction of this ESR signal suggests that that superoxide radical is involved in ROS generation in photoexcited $TiO_2$ NP suspensions.

*Generation of Singlet Oxygen.* In addition to hydroxyl and superoxide radicals, singlet oxygen is another important ROS that has been implicated in the degradation of dye mixtures.[40] We used the spin probe TEMP to study singlet oxygen ($^1O_2$) generation during irradiation of $TiO_2$ NPs. TEMP is ESR silent. When it reacts with singlet oxygen, the reaction product, a nitroxide radical, 2, 2, 6, 6-tetramethylpiperidine-*N*-oxyl (TEMPONE), is formed and shows a 1:1:1 peak ESR spectrum.[41] No ESR signal was observed for both control groups containing the spin probe TEMP, either without $TiO_2$ NPs but exposed to simulated sunlight or added with $TiO_2$ NP$_S$ but without exposure to simulated sunlight (Figure 3c). ESR spectra with three lines with equal intensities ($a_N$ = 16.0 G), typical of nitroxide radicals, were found for irradiated suspensions containing TEMP and $TiO_2$ (Figure 3c). The hyperfine splitting constant and *g* factor of the observed signal were identical to those of commercial TEMPONE, which indicates the generation of singlet oxygen during irradiation. A similar spectrum with higher intensity was observed for Au/$TiO_2$. Previous studies found evidence that singlet oxygen was formed through the following pathway:[42]

$$O_2^{-\bullet} + h^+_{vb} \rightarrow {}^1O_2 \quad (3)$$

To test this theory, SOD (0.2 U/mL) was added to the above mixture. This resulted in a reduction of this triplet ESR signal (Figure S2, Supporting Information). TEMPO signal significantly reduced upon the addition of SOD. Again, because of the fact that SOD is a specific enzyme that catalyzes the dismutation of superoxide ($O_2^{-\bullet}$), this result confirms that during photoexcitation of $TiO_2$ NP aqueous suspension, superoxide radicals play a role in the formation of singlet oxygen.

**Interaction between ROS and FD&C Yellow No. 5.** *Hydroxyl Radical Consumption.* A time and pH dependence study was carried out to further investigate the role of hydroxyl radical in the decomposition of Y5 (Figure 4). Figure 4, panel a shows the ESR spectra of the BMPO/$^{\bullet}$OH spin-adduct recorded for photoexcited $TiO_2$ NP suspensions with or without MY5 at pH 5.0 or 7.4 after 1 min of simulated sunlight irradiation. The time-dependent ESR signal intensity shown in

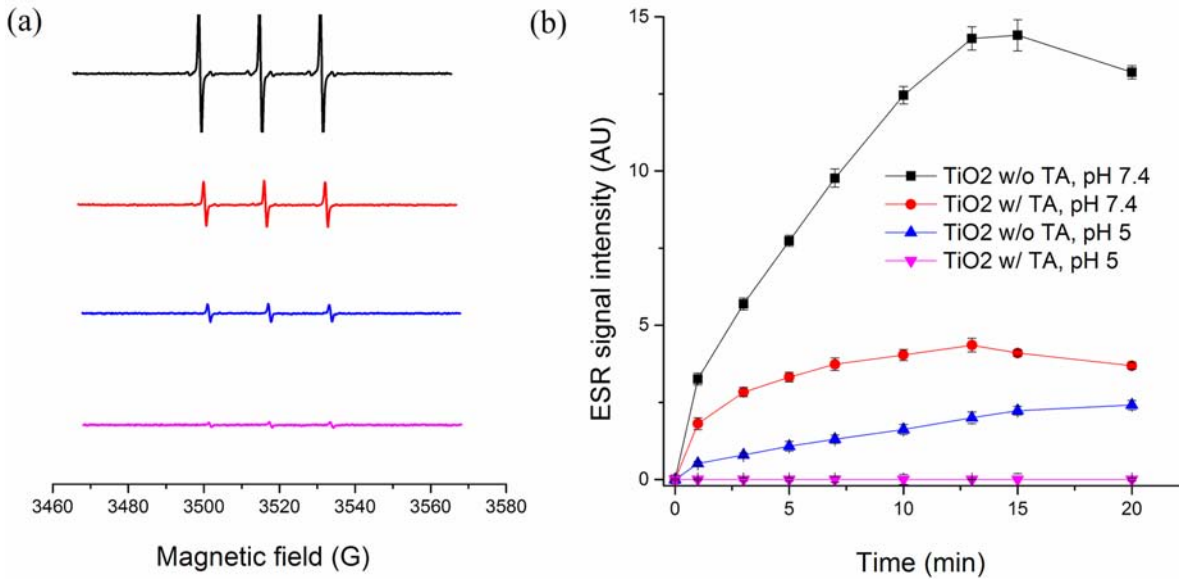

**Figure 5.** ESR detection of $^1O_2$ during decomposition of dye upon simulated sunlight irradiance: (a) ESR spectra recorded after 10 min of irradiation by simulated sunlight; (b) time-dependent ESR signal intensity obtained by measuring the peak-to-peak height of the first line of the ESR spectrum of TEMP/$^1O_2$ adduct. Reactions were conducted in 10 mM pH 5.0 or 7.4 PBS buffer solutions containing 5 mM TEMP spin probe. All sample solutions contained 0.1 mg/mL $TiO_2$ NPs with (or without) 25 mg/mL MY5.

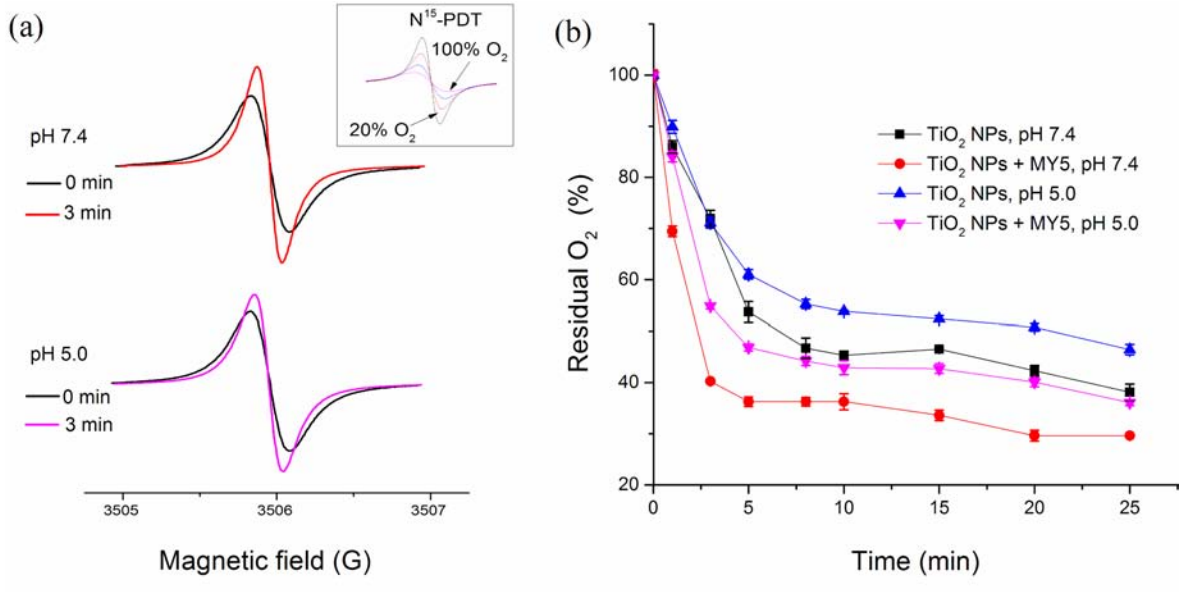

**Figure 6.** $O_2$ consumption detection using ESR oximetry during decomposition of dye upon simulated sunlight irradiation: (a) ESR spectra of spin-probe $^{15}$N-PDT in sample solutions containing 0.1 mg/mL $TiO_2$ and 25 mg/mL MY5 recorded before (0 min) or after 3 min of irradiation by simulated sunlight; and (b) $O_2$ consumption kinetics. $O_2$ concentration was calculated based on the peak-to-peak line width of spin-probe $^{15}$N-PDT using a calibrated standard curve described in the Material and Methods section. Reactions were conducted in 10 mM pH 5.0 or 7.4 PBS buffer solutions containing 0.2 mM $^{15}$N-PDT spin-probe. All sample solutions contained 0.1 mg/mL $TiO_2$ NPs with (or without) 25 mg/mL MY5.

Figure 4, panel b was obtained by measuring the peak-to-peak height of the second line of the ESR spectra. For suspensions containing only $TiO_2$ NPs, the signal intensities of BMPO/•OH adduct tested at pH 5.0 were significantly lower than those of samples tested at pH 7.4. This is most likely due to the lower availability of hydroxide ions in acidic media. It has been stated that in alkaline solution, •OH generation is promoted due to oxidation of more hydroxide ions available on $TiO_2$ surface.[26] At pH 7.4, $TiO_2$ solutions with MY5 show significantly lowered ESR intensity compared to $TiO_2$ NPs only, which indicates that under the simulated sunlight, hydroxyl radicals generated on photoexcited $TiO_2$ NPs were consumed by the azo dye MY5, which results in decomposition. Interestingly, at pH 5.0, the addition of MY5 did not result in a significant change in ESR intensity for •OH spin-adduct, which implies that little or no •OH was used for dye degradation. The results from this ESR time- and pH-dependent study agree with our previous observations shown in Figure 2, panel b, where a lower reaction rate constant was found for acidic solution.

*Singlet Oxygen Consumption.* Figure 5 shows the time dependence of ESR signal for the formation of TEMPONE from TEMP due to the generation of $^1O_2$. Figure 5, panel a exhibits the ESR spectra of TEMPONE observed after 10 min irradiation of $TiO_2$ NP suspensions with or without MY5 at pH 5.0 or 7.4. The time dependence of the ESR signal intensity (Figure 5b) was obtained by measuring the peak-to-peak height of the first line of this ESR spectrum. ESR intensity detected at pH 7.4 was significantly higher compared to that at pH 5. This observation agrees with a previous study by Daimon et al. in which the generation of $^1O_2$ was suppressed when pH < 5 and reaches its maximum between pH 6−11.[15] The decrease in $^1O_2$ at pH 5 compared to pH 7.4 is attributable to the suppression of $O_2^{-\bullet}$ at the $TiO_2$ surface by taking consideration that the $^1O_2$ originated from the oxidation of $O_2^{-\bullet}$ by the valence band holes $h^+$ (eq 1). Unlike hydroxyl radical, the consumption of $^1O_2$ by the azo dye MY5 was found for both acidic and alkaline conditions. At pH 5, the ESR signal for $^1O_2$ was largely reduced when MY5 was added into the reaction mixture; thus, we did not observe any ESR signal for $^1O_2$. However, when BMPO is used in the above solution, a six-peak ESR signal was recorded by ESR spectroscopy (data not shown), which indicates the formation of carbon center radical[28] that was associated the oxidation of dye MY5. The decrease in $^1O_2$ may take place by two mechanisms: one is by direct reaction with the Y5 dye anion, and the other is due to the decrease of available $O_2^{-\bullet}$ that has been consumed by dye oxidation.

*Oxygen Consumption.* It has been well established that the $O_2^{-\bullet}$ in aqueous solutions containing $TiO_2$ NPs results from the reduction of oxygen by conduction band electrons ($e^-_{cb}$):

$$O_2 + e^-_{cb} \rightarrow O_2^{-\bullet} \quad (4)$$

Although $O_2^{-\bullet}$ was indirectly detected by adding SOD to the suspension containing both $TiO_2$ NPs and BMPO spin-trap as discussed above, it was unclear how $O_2^{-\bullet}$ was involved in the decomposition process of MY5. Since difficulties arise when $O_2^{-\bullet}$ is detected by ESR due to the overlap of BMPO/$O_2^{-\bullet}$ and BMPO/•OH spin adducts, a time- and pH-dependent study was conducted for $O_2$ consumption using ESR oximetry. The inset in Figure 6, panel a depicts the ESR spectrum of a commonly used water-soluble spin-label $^{15}$N-PDT. Figure 6, panel a shows that after 3 min of light irradiation, higher peak intensity with broader line width was observed for the sample containing $TiO_2$ and food color, which is associated with the reduction of oxygen in the solution. Figure 6, panel b demonstrates that for suspensions only containing $TiO_2$ NPs, higher $O_2$ consumption was observed at pH 7.4 compared to that at pH 5. The addition of the dye MY5 led to a further decrease in $O_2$ level in both acidic (pH 5) and alkaline (pH 7.4) media, and the degree of this further consumption appeared to be similar for both pHs. On the basis of the observation that upon sunlight irradiation, $O_2$ did not directly react with the azo dye without $TiO_2$ or that the reaction was too slow to be observed and thus negligible (control groups in Figure 2a,b), the main reason for oxygen consumption is very likely to be the reduction of $O_2$ by $e^-$ (eq 4). Therefore, by determination of oxygen consumption, we observed the involvement of $O_2^{-\bullet}$ in the decomposition process. Our findings suggest it is very possible that pH primarily affects the initial rate of $O_2^{-\bullet}$ generation rather than the interaction between the azo dye and $O_2^{-\bullet}$.

Nanosized $TiO_2$ particles may be found in a broad range of consumer products. In conclusion, our results confirmed that when exposed to simulated sunlight, $TiO_2$ NPs at low concentration can trigger decomposition of the azo dye Y5, which is widely used in food, drug, and cosmetic products. By using ESR spin trapping, the only technique that directly monitors the existence of free radicals and identifies them,[43] we demonstrated that dye degradation proceeds via reaction with ROS generated on the surface of photoexcited $TiO_2$, and a higher degradation rate was associated with increased ROS generation. At pH 7.4, a significant reduction in both hydroxyl radical and singlet oxygen was observed after the dye was added into the suspension, while singlet oxygen became the main reactive species at pH 5.0. Our study characterized the decomposition mechanism and directly monitored the involvement of ROS that may occur in food, drugs, cosmetics, and other consumer products that contain both $TiO_2$ and Y5 as ingredients. The findings in this study may provide important insights for the design of new applications or evaluation of the safety of nano-$TiO_2$ in these products. Our results demonstrate that the interaction between nanomaterials and other ingredients should be investigated in addition to studies on the nanomaterials as independent components. Our results were obtained in a simplified chemical system. Further studies are needed to determine the effects of complex food matrices on factors such as aggregation, ROS quenching, and light transmission, which might moderate the photocatalytic activity of $TiO_2$.

clinical diagnosis, bioanalysis, and environmental monitoring.[21−25]

According to our best knowledge, only two publications have been reported for the detection of LIN residues based on immunoassays.[10,11] Compared with these two time-consuming and laborious methods, we adopted FMIA for the detection of LIN based on anti-LIN monoclonal antibody (mAb) for successfully assaying the residues of LIN in milk, honey, beef, and swine urine samples.

## MATERIALS AND METHODS

**Reagents and Materials.** FluoSpheres carboxylate-modified microspheres, 200 nm, red fluorescent (580/605), 2% solids, were obtained from Invitrogen (Carlsbad, CA, USA). Bovine serum albumin (BSA), goat anti-mouse immunoglobulin G (IgG), lincomycin hydrochloride (>98%), 1-ethyl-3-(3-dimethylaminopropyl)-carbodiimide (EDC), and *N*-hydroxysuccinimide (NHS) were purchased from Sigma-Aldrich (St. Louis, MO, USA). 2-(4-Morpholino)ethanesulfonic acid (MES) and polyvinylpyrrolidone (PVP) were purchased from Aladdin Chemistry Co., Ltd. (Shanghai, China). Dextran 4000 and polyethylene glycol (PEG) were purchased from Wako Pure Chemical Industries, Ltd. (Osaka, Japan). A Milli-Q water purification system and nitrocellulose (NC) membrane were provided by Millipore Corp. (Bedford, MA, USA). The whole blood separation membrane (GF-2) and the absorbance pad (H5076) were supplied by Shanghai Jieyi Biotechnology Co., Ltd. (Shanghai, China). Purified anti-LIN monoclonal antibody (mAb) and an ELISA kit for the detection of LIN were purchased from Beijing WDWK Biotechnology Co., Ltd., and stored at 4 °C before use.

**Apparatus.** The ESE-Quant LFR fluorescence reader was supplied by QIAGEN (Dusseldorf, Germany). The NanoDrop ND-1000 spectrophotometer was obtained from Gene Co., Ltd. (Hong Kong, China). A multifunctional microplate reader SpectraMax M5 was purchased from Molecular Devices Co., Ltd. (Sunnyvale, CA, USA). The ZX1000 dispensing platform and the CM4000 Guillotine Cutting Module for the preparation of FMIA strips were provided by Bio Dot Inc. (Irvine, CA, USA). The UV spectrometer was provided by Qiangyun Co., Ltd. (Shanghai, China).

**Preparation of Capture Antigens.** The capture antigens were prepared by conjugating LIN to BSA using the sodium periodate ($NaIO_4$) reduction method as previously described.[11] More details can be found in the Supporting Information (Synthesis of BSA−LIN).

**Preparation of FMIA Strips.** The strip of FMIA consists of three parts: sample pad, NC membrane, and absorbent pad. The sample pad was made of whole blood separation membrane, pretreated with 0.02 M phosphate buffer (pH 6.2) containing 0.04% KCl, 0.2% PVP, and 2% Tween-20 and dried at 37 °C for 2 days. Then, 0.075 mg/mL BSA−LIN (0.7 μL/cm) and 0.9 mg/mL goat anti-mouse IgG (0.7 μL/cm) dissolved in 0.02 M coating buffer (pH 9.4) were sprayed onto the NC membrane as test line (T-line) and control line (C-line), respectively, as shown in Figure 1. Later, the NC membrane was dried at 37 °C for 2 h. Subsequently, different pads were laminated onto the baking part, sample pad, and absorbent pad with an overlap on NC membrane of about 2 mm to promote sample flow. Finally, the whole pad was cut into 3.5 mm wide strips and kept dry at room temperature.

**Conjugation of Fluorescent Microspheres and mAbs.** Thirty microliters of 2% fluorescent microspheres was suspended in 1 mL of 0.05 M MES (pH 6.5) in the dark. To activate the carboxylic groups on the surface of microspheres, 24 μL of 100 mg/mL immediately dissolved EDC solution and 32 μL of a 100 mg/mL NHS solution were dissolved in FM solution for 15 min at room temperature. Subsequently, 10 μL of 0.16 mg/mL mAbs in 0.01 M PBS (pH 7.4) was added for 2 h. One hundred microliters of 0.1 M glycine was added and incubated for another 15 min to terminate the reaction, and then the mixture was centrifuged at 8000 rpm for 10 min at 4 °C. The precipitate was resuspended in 200 μL of 0.05 M PBS (pH 7.4) containing 1% BSA, 2% PEG, and 1% Dextran 4000. Finally, the suspension was dispersed by supersonic vibration for 5 min and stored at 4 °C in the dark before use.

**Procedures of FMIA.** The principle of FMIA is based on the competitive binding of LIN and LIN−BSA conjugate to the anti-LIN mAbs labeled with fluorescent microspheres (FM−mAbs), as shown in Figure 1 (all steps were performed in the dark). Briefly, 2 μL of FM−mAb conjugates were added into one well of the 96-microtiter plate, and then 120 μL of the sample was added and fully mixed for 3 min (Figure 1A). Later the strip was vertically inserted into the corresponding microwell (Figure 1B), standing for another 15 min (Figure 1C). In the blank sample, the free FM−mAbs bound to the BSA−LIN conjugates at the T-line. Meanwhile, the free FM−mAbs were subsequently caught by the specific secondary anti-mouse antibodies at the C-line. All of these together indicated the samples were LIN negative (Figure 1D1). Contrarily, analyte in the sample would bind to FM−mAbs, leading to fewer fluorescent signals at the T-line, suggesting the sample was positive for LIN residues (Figure 1D2). Additionally, the results can be quantitated by an ESE Quant lateral flow reader to provide rich-information answers.

**Standard Curves and Specificity.** On the basis of the optimized conditions mentioned above, the standard curve of LIN was

established for FMIA. A 20 μg/mL LIN standard solution was disposed in dosages of 1, 2, 3, 4, 5, and 6 ng/mL in PBST. Calculations were performed on OrginPro 8.5 software (Origin, Northampton, MA, USA). A four-parameter logistic equation was used to calculate the obtained data.

$$Y = (A - B)/[1 + (X/C)^D] + B$$

$A$ = response value at high asymptote, $B$ = response value at low asymptote, $C$ = concentration corresponding to $IC_{50}$, $D$ = slope, and $X$ = calibration concentration. The $IC_{50}$, dynamic range, and limit of detection (LOD) served as quantitative criteria to evaluate the performance of FMIA. These parameters represent the calibration concentrations obtained at inhibition rates of 50%, between 20 and 80%, and at 90%, respectively.

Antibiotics with structures similar to LIN were studied for the cross-reactivity (CR) to determine the specificity of the FM−mAb conjugates. The corresponding CRs of each antibiotic in respective tests were quantitated from each standard curve on the basis of the following formula:

$$CR\ (\%) = 100 \times (IC_{50}\ \text{of LIN}/IC_{50}\ \text{of related compounds})$$

**Sample Preparations.** Matrix effect, an undesired unspecific obstruction of sample on antigen−antibody, mostly leads to decreased response values.

In this study, we tried three methods for the sample pretreatments: the trichloroacetic acid method (TCA), the dilution method, and the zinc sulfate method (ZSF). For the TCA method,[26] 200 μL of 3% TCA was added into 1 mL of spiked milk and then centrifuged at 8000 rpm for 8 min at room temperature; subsequently, 10 μL of 0.1 M NaOH was added to the supernatant to adjust the pH to 7.0. With regard to the dilution method, different extracting solutions were directly added to samples with series of dilutions. The ZSF method started by the addition of 60 μL of 1.04 M $ZnSO_4$ into 1 mL of spiked milk. After full mixture, the supernatant was obtained by centrifugation at 8000 rpm for 8 min. We also tried TCA and another two extracting solutions (water and 0.01 M PBST) to dilute the honey samples to different multiple factors (4-, 8-, 12-, 16-, and 20-fold). Similarly, we tried four extracting solutions (0.04 M PB, 0.04 M PB plus 0.1% Tween-20, water, and 0.01 M PBST) to deal with the beef samples. One gram of homogenized beef was dissolved into 8 mL of extracting solutions and centrifuged at 4000 rpm for 10 min. The supernatant was extracted for further use. Swine urine was directly diluted in four extracting solutions: 0.04 M PB, 0.04 M PB with 0.1% Tween-20, water, and 0.01 M PBST.

**Recovery Test.** LIN-free skimmed milk, honey, beef, and swine urine confirmed by liquid chromatography−electrospray ionization tandem mass spectrometry (LC-MS/MS) were obtained from the National Reference Laboratory for Veterinary Drug Residues (Beijing, China). The samples were spiked with different volumes of the 20 μg/mL LIN standard solution and treated as described for the sample preparations.

For the recovery test, LIN at final concentration levels of 1, 3, and 5 ng/mL was spiked into the samples. Then the samples were treated according to the methods mentioned above four times before fluorescent reading. Finally, the recoveries were calculated through the correspondence percentages of the fluorescence intensity between spiked and found LIN in the samples.

**Preparation of CGIA.** The principle of CGIA is similar to that of FMIA; they differ from each other by the biomarkers and the methods used to prepare biomarker and antibody conjugates. Unlike the covalent coupling method used for the preparation FM−mAb conjugates, the positively charged antibodies bind to the negatively charged surface of the gold nanoparticles on the basis of electronic interaction.[27] The preparation of CGIA strips has been previously described, as shown in the Supporting Information.[28]

## RESULTS AND DISCUSSION

**Optimization of FMIA.** The characteristics of different diameters (100 and 200 nm) and coloration (red, yellow, and blue) of FMs were first studied. Different sizes had discrepancy of brightness of coloration and sensitivity. Microspheres of 100 nm size showed lighter color and lower sensitivity than did those of 200 nm size. Figure S1 in the Supporting Information shows the coloration of FM−mAbs in the resuspended solution and the strips of negative samples under the UV light at 365 nm for three different FMs. Obviously, the blue light approximates white due to the UV light appearing purple close to blue, and the yellow has a high background value so that it is not easily distinguished. The red fluorescent is bright enough to distinguish. Thus, we chose the red 200 nm FMs to label anti-LIN mAbs. Then, red FMs (580/605) were 100-fold diluted in water and scanned from 300 to 700 nm. The excitation and emission peaks of FMs and FM−mAb conjugates were at 580 and 605 nm, respectively. In the present work, the carboxylic groups on the surface of microspheres were used to bind to the amino groups of the anti-LIN mAbs. Naturally, carboxyl can react with amino groups without the need of additional activator; however, the coupling efficiency was unsatisfactory. Hence, EDC was chosen to be an activator to accelerate the reaction. We have compared the single-step reaction (EDC only) with the two-step reaction (EDC and NHS) and found that the two-step reaction was more stable and showed higher response than the single-step reaction. Also, the dosage of EDC affected activation efficiency; we tried different dosages of EDC (as shown in Table S1 in the

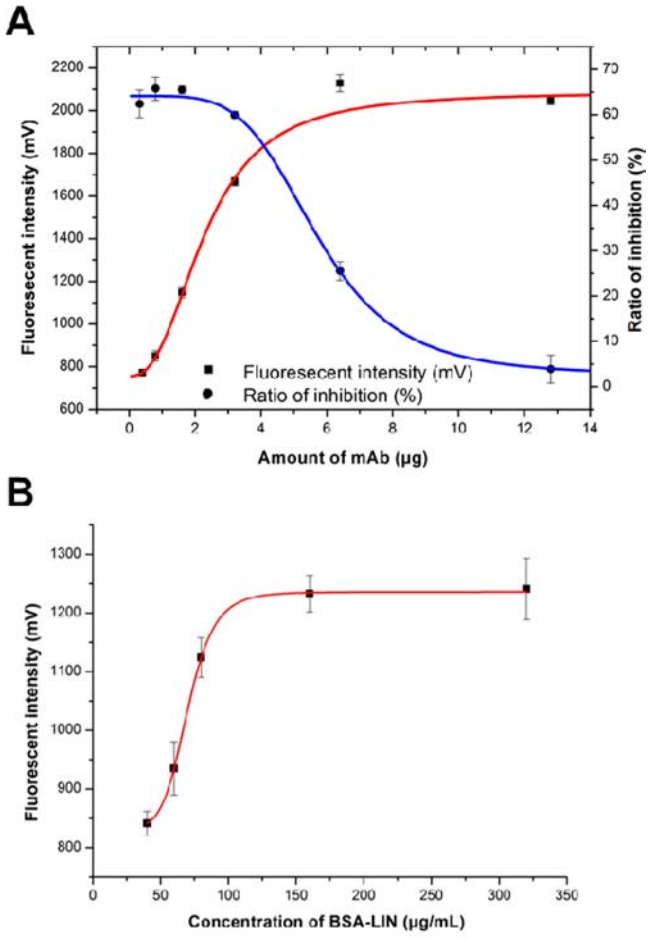

**Figure 2.** (A) Effects of the amount of mAb on the fluorescence intensity and inhibition ratio (at 3 ng/mL LIN). (B) Effect of the concentration of BSA−LIN on the fluorescence intensity.

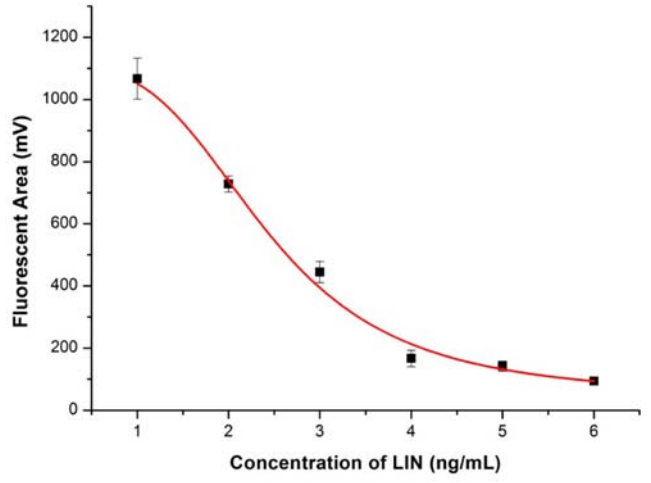

**Figure 4.** Standard curve of LIN in PBST by FMIA.

Supporting Information) to obtain good coloration and stability based on the naked eye and a fluorescence reader. With more EDC, a deeper color was found at the T-line. Meanwhile, the excess activator EDC led to obvious residue on the NC membrane. From Table S1 in the Supporting Information, the ratio of EDC to NHS at 2.4/3.2 showed the highest fluorescent intensity with satisfactory coloration of the T-line.

**Table 1. Recoveries of LIN from Various Biological Matrices Spiked at Different Concentration Levels by FMIA ($n$ = 4)**

| matrix | spiked (ng/mL) | tested (ng/mL) | recovery (%) | variation coefficient (%) |
|---|---|---|---|---|
| milk | 1 | 0.86 ± 0.07 | 86.21 | 8.14 |
| | 3 | 3.34 ± 0.35 | 111.30 | 10.48 |
| | 5 | 4.61 ± 0.80 | 92.27 | 17.35 |
| honey | 1 | 0.78 ± 0.04 | 77.63 | 5.13 |
| | 3 | 2.24 ± 0.16 | 74.74 | 7.14 |
| | 5 | 4.66 ± 0.29 | 93.28 | 6.22 |
| beef | 1 | 0.79 ± 0.09 | 78.50 | 11.39 |
| | 3 | 3.44 ± 0.19 | 114.50 | 5.52 |
| | 5 | 6.03 ± 1.31 | 120.50 | 21.76 |
| urine | 1 | 0.81 ± 0.09 | 80.98 | 11.11 |
| | 3 | 2.22 ± 0.22 | 73.92 | 9.91 |
| | 5 | 5.28 ± 0.18 | 105.50 | 3.41 |

FM−mAbs as the competitive binding targets between LIN of interest and the BSA−LIN conjugates play an important role in the stability and sensitivity of FMIA. The florescent intensity increased in a mAb-dependent manner and reached saturation point at 4 $\mu$g. In contrast, the trend of the inhibition ratio with LIN at 3 ng/mL sharply fell with increased concentration of mAb (Figure 2A). We found insufficient antibody led to the slight presence of the T-line, whereas excess antibody deposited flocks in the coupling process, and the FM−mAbs obviously aggregated on the bottom of the strips during testing for the sample. In addition, the T-line and C-line must be bright enough to distinguish the negative and positive samples. Taken together, 1.6 $\mu$g of mAbs was chosen to functionalize the surface of FMs. Moreover, the dosage of the BSA−LIN conjugates on the NC membrane to bind free FM−mAbs was subsequently optimized. The fluorescent intensity increased sharply in a BSA−LIN-dependent manner and became stable at 100 $\mu$g/mL. Finally, the last point in the linear range of fluorescence intensity (75 $\mu$g/mL) was chosen to achieve better coloration of FMIA (Figure 2B).

**Analytical Performance of the FMIA.** According to the principle described above, the performance of the T-line can represent the concentrations of LIN. As shown in Figure 3A, the coloration of the T-line obviously weakened as the concentration of LIN increased. The T-line disappeared with LIN at 6 ng/mL; thus, 6 ng/mL was the cutoff of this method. The semiquantitation of the corresponding strips is shown in Figure 3B by fluorescent reader. Figure 4 shows the competitive inhibition standard curves for LIN in PBST by FMIA. The dynamic range was from 1.35 to 3.57 ng/mL, with $R^2$ = 0.9825. The LOD and $IC_{50}$ were 0.69 and 2.20 ng/mL, respectively, and the cross-reactivity tests showed there was low cross-reactivity with clindamycin (4.4%) and negligible cross-reactivity (<0.1%) with streptomycin, roxithromycin, kanamycin, kitasamycin, and gentamicin. Therefore, this method showed high specificity to LIN. Furthermore, FMIA was challenged with authentic sample tests, as shown in Table 1. The recoveries ranged from 73.92 to 120.50%, with coefficients of variation under 21.76% in milk, honey, beef, and swine urine samples.

**Comparison of FMIA with CGIA and ELISA.** Compared with CGIA and ELISA methods, FMIA is a novel semi-

[a]Detected by fluorescence reader. [b]Detected by the naked eye under UV light.

quantitative immunoassay. Table 2 presents the main parameters among CGIA, ELISA, and FMIA. On the basis of covalent coupling between mAbs and FMs, FMIA was more stable and consumed fewer mAbs than CGIA. Meanwhile, the sensitivity of FMIA (6 ng/mL) was higher than that of CGIA (10 ng/mL). In addition, the $IC_{50}$ of FMIA was 2.20 ng/mL, lower than that of ELISA, 2.46 ng/mL (Figure S3), with advantages such as easy operation and time savings. Similar to previous papers,[27,29] the FMIA developed in the present work showed satisfactory results compared with the commonly used ELISA and CGIA.

**Sample Analysis.** Similar to the untreated milk samples, the sticky honey sample cannot move on the FMIA strips based on capillarity. Furthermore, the beef and urine samples always have complex matrix effects. To report a positive or negative result of the tested sample, the strip needs a clear background under UV light. In the present work, TCA and ZSF methods showed low response values, which cannot indicate the results. On the contrary, dilution can not only decrease the matrix effects of samples but also enhance the fluorescence response with the additional agents, such as polyvinylpyrrolidone (PVP) and Tween-20. Dilution and extraction of the samples by different solutions play important roles in the sample pretreatment. The best diluting schemes were as follows: milk was diluted 4-fold into 0.01 M PBS (pH 7.4) with 0.5% PVP; honey was diluted 8-fold into 0.01 M PBST; 1 g of homogenized beef was added into 8 mL of 0.04 M PB (pH 7.4) with 0.1% Tween-20, to extract the supernatant for further detection; swine urine was diluted 8-fold with double-distilled water (Table 2). Finally, the cutoff values were 24 ng/mL for raw milk and 48 $\mu$g/mL for honey, urine, and beef.

In conclusion, FMIA was a simple, effective, and semiquantitative method for the detection of LIN residues. A minimum of 0.69 ng/mL LIN was tested in 20 min. FMIA was used to assay the residues of LIN in four different matrices (i.e., milk, honey, beef, and swine urine). Thus, FMs can be widely used to couple antibodies for the detection of various resides of antibiotic or other chemicals in foodstuffs, providing an alternative method for immunoassay.

nucleotides 15−20.[15,16] Because the RNAi mechanism effectively parses sequence mismatches and ambiguities, it has been shown through in vitro studies conducted with transfected small RNAs that small RNAs can cause gene suppression of unintended gene targets.[17] This outcome, commonly referred to as the "off-target" effect, has led to increased scrutiny regarding the specificity of RNAi-based drugs and also been proposed as a putative concern for food crops that are engineered to produce small RNAs. However, this "off-target" effect has been characterized using in vitro systems and is orders of magnitude less potent than "on-target" suppression.[9,11] Such suppression also requires special sequence contexts, thermodynamic criteria, target accessibility, and other conditions.[18,19]

To investigate the level of significance of regularly consumed small RNAs that share sequence homology with human genes, the small RNA profiles of fresh market fruits and vegetables were examined. These were locally purchased tomatoes, watermelons, zucchinis, and onions that were selected because their appearance suggested they were likely to be infected with viral disease(s). Using a next-generation high-throughput sequencing method, between 1.6 and 3.6 million small RNA sequences were obtained from each sample. Although most of the small RNAs found in these vegetables were likely derived from endogenous genome, up to 9.5% were identified as sequences originating from viruses. Many of these small RNAs were found to share sequence similarity with human genes. Small RNA profiles such as these resemble those of plants genetically modified to express fragments of virus sequences for the purposes of conferring virus resistance.[14] The analysis of the small RNAs presented here provides insights into the plant−virus interaction and also evidence of a history of safe consumption for dietary small RNAs. By extension, this research supports the safety of biotechnology-derived crops employing RNA-based gene suppression when consumed by humans or animals.

## MATERIALS AND METHODS

**Plant Materials.** Vegetables suspected of virus diseases based on physical characteristics were selectively purchased at local farmers' markets or supermarkets in the region of Yolo county, California, USA. The tomato fruits displayed lesions with a chlorotic concentric ring pattern typical of those caused by *tomato spotted wilt virus* (TSWV, family Bunyaviridae, genus *Tospovirus*). The onion bulbs with attached green leaves exhibited elongated lesions typical of those caused by the *iris yellow spot virus* (INSV, family Bunyaviridae, genus *Tospovirus*). The squash fruits had mosaic symptoms consistent with those caused by viruses such as the *watermelon mosaic virus* (WMV), *zucchini yellow mosaic virus* (ZYMV), or *papaya ring spot virus* (PRSV) (all viruses in the family Potyviridae, genus *Potyvirus*). The melon fruit was chosen on the basis of mottling symptoms that might be caused by a number of different potyviruses.

**Plant RNA Isolation and Small RNA Sequencing.** Symptomatic portions of the fruits/bulbs were harvested and ground in liquid nitrogen. Total RNA was extracted using TRIzol (Invitrogen, Carlsbad, CA, USA) following the manufacturer's recommended protocol. RNA was quantified by Nanodrop (Thermo scientific, Wilmington, DE, USA), and its integrity was verified by gel electrophoresis. Small RNA library construction and sequencing were performed with Illumina technology (Illumina Inc., San Diego, CA, USA) as described previously.[20] Raw reads (4−6 million) were generated from each library. After the 5′ and 3′ adaptors were identified and removed from the raw reads, reads with sequence length from 18 to 26 nt were parsed out for further analysis (Figure 1). The sequences of these raw reads can be found in NCBI under BioProject accession PRJNA265505.

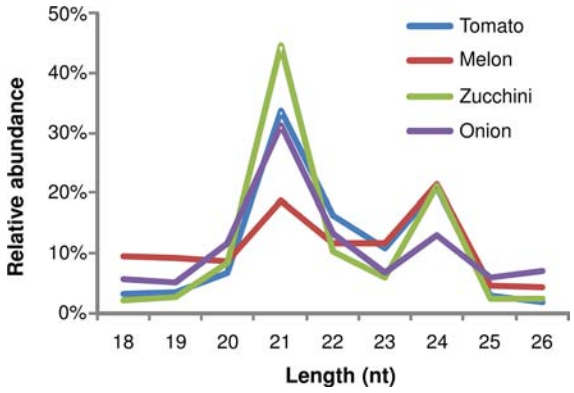

**Figure 1.** Relative abundance of small RNA size classes. The relative abundance of small RNA with lengths ranging from 18 to 26 nt is shown in the graph. All of the samples had the typical plant small RNA size distribution with peaks at 21 and 24 nt. With the exception of the melon sample, the 21 nt class was more abundant than the 24 nt class.

**Small RNA Sequence Analysis.** The parsed small RNAs were mapped to plant virus sequences downloaded from www.dpvweb.net on March 2, 2012. Small RNA matching was performed using "SHRiMP" v2.[21] Only perfectly mapped small RNAs were counted. RNAi plays an important antiviral role in plants. Upon virus infection, small RNAs are generated with the help of host plant Dicer-like protein from viral dsRNAs either as viral replicative intermediates or resulting from host RNA-dependent RNA polymerases on viral templates. The viral siRNAs are from both strands of the dsRNA and predominantly 21 and 22 nt in length. To remove noise from the virus mapping results, such as nonvirus sequence contamination, we applied three filters: (1) A virus is said to have infested the plant if only its sequence has at least 10 perfectly matched and sequence distinct small RNAs; (2) 21 and 22 nt small RNAs account for at least 60% of the small RNAs that mapped to a virus sequence; and (3) the abundance of small RNAs mapping to either strand of a virus sequences reflects a minimum of 5% of overall mapped small RNA abundance to the virus sequence. Virus-mapped small RNAs were then compared to the human reference RNA set downloaded from genome.ucsc.edu on February 7, 2012. For this analysis, up to 2 mismatches in 21 nt small RNAs and 3 mismatches in 22 nt small RNAs were allowed. Similarly, all small RNAs not mapped to virus sequences ("non-virus-mapped"), which were presumably derived from endogenous plant sequences, were also compared to the human reference RNA set. To match this subset of plant small RNAs against human reference genes, human miRNAs, rRNAs, small nucleolar RNAs, and small nuclear RNAs were excluded from the reference RNA set, and up to two mismatches were allowed for each match. Detailed lists of the virus-mapped small RNAs and small RNAs homologous to human genes can be found in the Supporting Information.

## RESULTS

**Deep Sequencing of Vegetable Small RNA Populations.** RNA extracted from tomato (fruit), melon (fruit), zucchini (fruit), and onion (bulb and stem) was sequenced using Illumina technology. Small RNA sequences ranging in length from 18 to 26 nt were parsed out for subsequent analyses (Figure 1 and Table 1). The peaks shown here are typical of plant small RNA distribution, showing major peaks at 21 and 24 nt, consistent with plant dicer-like protein (DCL) cleavage products.[22] The 21 nt class was more predominant than the 24 nt for all samples but melon. The total number of

**Table 1. Total Numbers of Small RNA Reads Obtained from Each Sample Library and the Numbers of Reads That Mapped to the Virus Sequences[a]**

| | | | | parsed reads (18−26 nt) | | virus-mapped reads | |

[a]Only parsed (18−26 nt) reads were used in the mapping.

reads varied from 1,636,524 to 3,609,317, with unique reads well represented in all of the libraries (Table 1).

**Size Class Distribution of Virus-Mapped Small RNAs.** Several filters were applied to map the parsed plant-derived small RNA sequences to the virus genome collections obtained from www.dpvweb.net (see Small RNA Sequence Analysis under Materials and Methods). The 21−22 nt size class siRNAs are significantly more abundant than the 24 nt in all four samples (Figure 2), consistent with the size of small RNA

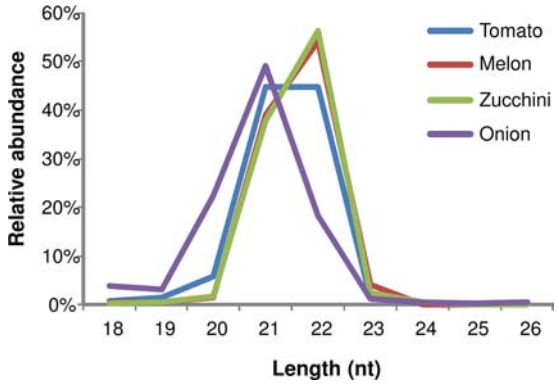

**Figure 2.** Relative abundance of small RNA size classes from small RNAs mapped to the virus sequence database. For all samples, most of the virus-mapped reads belong to the 21 and 22 nt size classes. These small RNAs, usually associated with post-transcriptional gene silencing, are likely generated upon viral infection.

products of post-transcriptional gene silencing usually associated with viral infection. However, the number of reads of the virus-mapped melon small RNA population is >100-fold less than in the other vegetable libraries (Table 1).

**Validation of Virus-Mapped Matches.** The genomic sequences of the top two virus matches (Table 2) generated from mapping the siRNA libraries to the virus sequence collection (except for the melon library where only one matching virus was identified) were plotted against the sequences of their respective small RNA matches to illustrate their distribution (Figure 3). In addition to applying the filters described earlier, the presence of small RNAs across the entire length of the putative virus hit serves as a validation criterion suggesting the legitimate presence of the virus in the sample (Figure 3A−D,F). In the case of the melon sample, although the number of small RNA matches is smaller in number (possibly reflecting low virus titer in the tissue) the virus hit seems to be authentic. Conversely, a sparsely distributed match pattern (Figure 3E,G) is an indication that the matching small RNAs likely originated from sources other than the matched virus. Due to sequence similarities between viruses, some small RNAs match to one virus and also cross-match to another: for

**Table 2. Top Two Virus Matches and the Numbers of Small RNA Reads Matched in Each Sample Library[a]**

| | | | mapped reads | |
|---|---|---|---|---|
| sample | virus species matched | GenBank accession | total reads | unique reads |
| tomato | *tomato spotted wilt virus* (TSWV), segment S | HQ402595 | 100079 | 6211 |
| | *potato virus Y* (PVY) | HQ912865 | 12076 | 4040 |
| melon | *watermelon mosaic virus* (WMV) | FJ623474 | 128 | 122 |
| zucchini | *watermelon mosaic virus* (WMV) | EU660583 | 146333 | 17542 |
| | *soybean mosaic virus* (SMV) | D00507 | 3607 | 419 |
| onion | *iris yellow spot virus* (INSV), segment L | FJ623474 | 108325 | 15979 |
| | *tomato yellow fruit ring virus* (TYFRV), partial L gene | AJ493271 | 802 | 91 |

[a]The melon sample had only one virus match. For viruses that have more than one genome segment, only one segment is shown in the table, although all other segments had similar significant matches.

example, in the zucchini sample, most of the small RNAs mapped to *soybean mosaic virus*, SMV (Figure 3E) were also mapped to WMV (Figure 3D) and in the onion sample, all of the small RNAs mapped to *tomato yellow fruit ring virus*, TYFRV (Figure 3G), also mapped to INSV (Figure 3F).

In the case of the *tomato spotted wilt virus*, segment S matched in the tomato sample (Figure 3A), and the small RNA reads in both the sense and antisense orientations come predominantly from the regions corresponding to the non-structural and nucleocapsid protein coding sequences, and noticeably less from the intergenic region that is not actively transcribed. For PVY (Figure 3B), WMV (Figure 3D), and INSV segment L (Figure 3F), all regions are evenly represented (note the change of scale), consistent with the generation of a single transcript over the genomic segment. The relative abundance of these virus-derived small RNAs across the virus genome and their sequence signatures could also reveal the biochemical properties of plant small RNA processing. For example, using virus-derived small RNA sequences from TSWV infected tomato and *Nicotiana benthamiana*, details of small RNA differential processing were examined previously.[23] Our small RNA sequencing results that include three additional viruses could be applied to such studies in the future.

**Characterization of Tomato Library Reads.** The tomato small RNA library was further investigated and mapped to the Monsanto in-house assembled tomato reference genome. Only sequences with perfect matches to the tomato and/or viral genomes are included in the analysis, and these matches

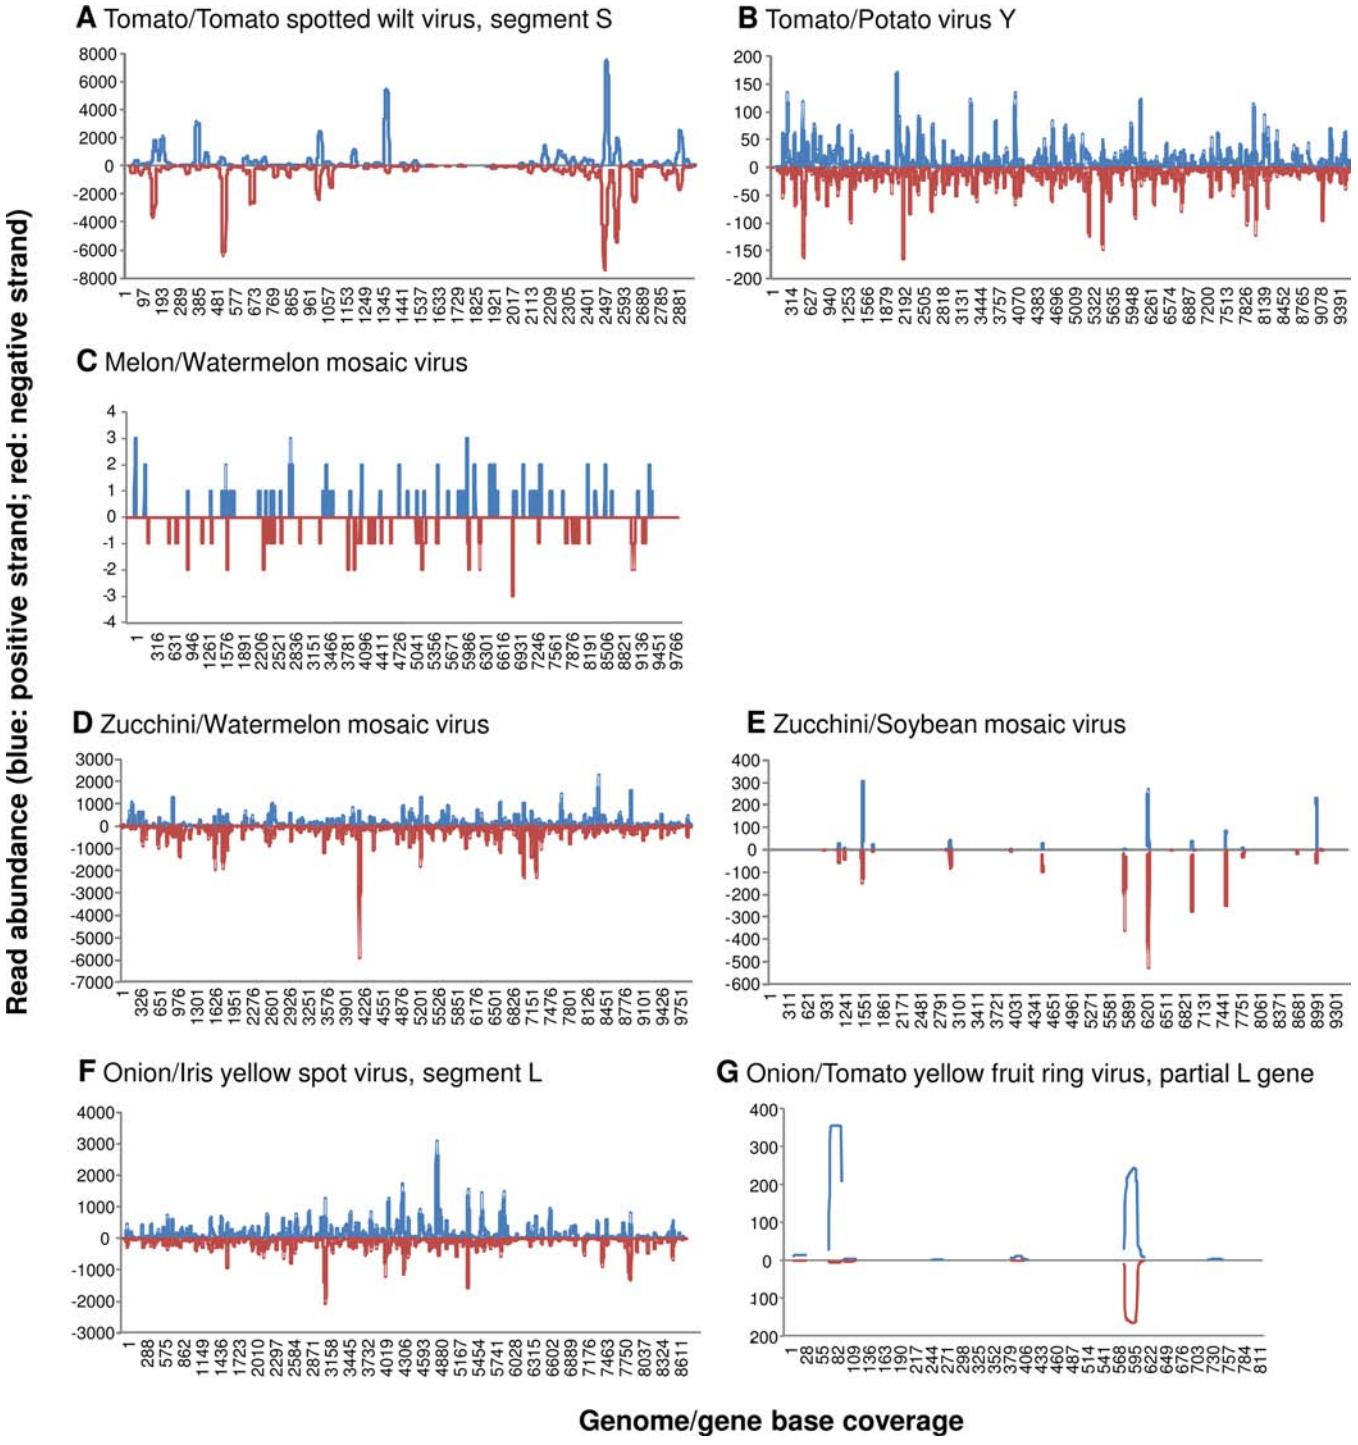

**Figure 3.** Validation of virus-mapped small RNA reads to their respective matching viral sequences. The top two virus matches for each sample were plotted against small RNAs mapped to them. Except for E and G, the small RNAs are mapped across the entire virus sequences. Therefore, there is a high probability that such a virus is present in the samples. On the contrary, only sparse matches were found on E and G, which suggests that these mapped small RNAs were derived from different sources.

**Table 3. Number of Total and Unique Small RNA Reads in Each Category in the Tomato Sample**

| | all reads | | tomato genome-mapped reads | | virus-mapped reads | | overlap reads | |
|---|---|---|---|---|---|---|---|---|
| sample | total reads | unique reads | total reads | unique reads | total reads | unique reads | total reads | unique reads |
| tomato | 3609317 | 120206 | 2596723 | 824996 | 196069 | 23929 | 2374 | 676 |

accounted for 78% of all reads (Table 3). The remaining, nonmatching reads could be mostly sequencing errors and some representing single-nucleotide polymorphisms (SNPs) because the sample is sourced from a tomato variety different

dx.doi.org/10.1021/jf503756v | J. Agric. Food Chem. 2014, 62, 12067−12074

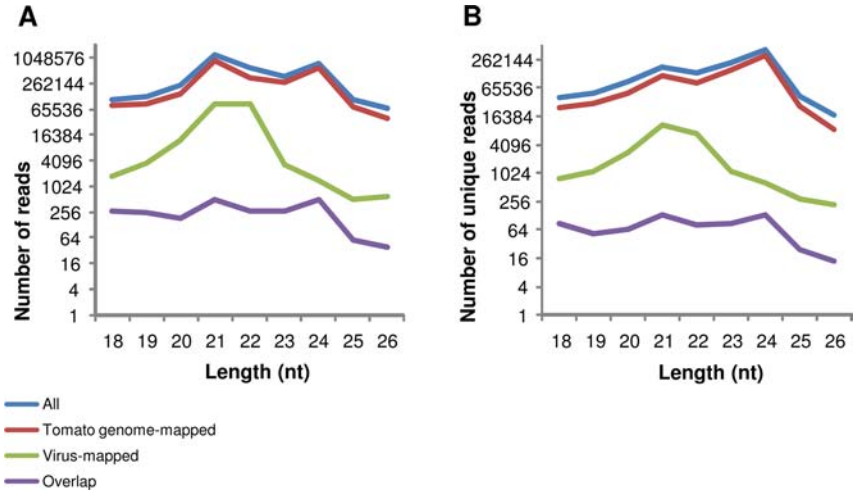

**Figure 4.** Categories of reads and unique reads in small RNA size classes from the tomato sample: the total number of reads (A) and the unique number of reads (B) of tomato small RNAs that matched perfectly to the in-house assembled reference tomato genome (red line), virus genome database (green line), or both (purple line). Together they account for 78% (Table 3) of all reads (blue line).

from the reference sequence. As previously observed, the abundance of 21−22 nt classes appears to have been enhanced by the virus-derived small RNAs (Figure 4A). The 24 nt class small RNAs, mostly derived from the endogenous tomato genome, are both abundant and rich in unique sequences (Figure 4). This is probably due to their roles in genome-wide transcriptional regulation and chromatin modification.[22]

**Comparison of Vegetable Small RNAs to the Human Transcriptome.** To evaluate if small RNAs derived from food have sequence similarity to human genes, we compared our libraries of small RNA sequences to small RNAs using a database of human reference RNAs. A recent study suggested that ingestion of a rice-derived miRNA matching a human gene over its open reading frame could cause transcript suppression in humans,[24] claims that have been strongly challenged in the peer-reviewed literature by several independent research groups collectively.[25−27] Nevertheless, similar matching criteria were used in this evaluation.

We divided the small RNAs in each library into virus-mapped and non-virus-mapped reads, representing exogenous and endogenous sources for the sequences, respectively. To simplify this bioinfomatic evaluation, the positions of the mismatches, which sometimes can have various degrees of impact in target gene suppression efficacy,[15,16] were not given special considerations. The results in Table 4 summarize that, when allowing up to 2 mismatches in the 21 nt size class and 3 mismatches in 22 size class, many human genes are homologous to virally derived small RNAs. Totals of 1580, 43, 884, and 1399 human genes have at least one subregion sharing sequence similarity to virus-mapped small RNAs in the tomato, melon, zucchini, and onion small RNA libraries, respectively (Supporting Information Tables S1−S4). Except for the melon library, where fewer virus-mapped small RNAs were found, virus-derived small RNAs that match to human gene transcripts appear abundant. For example, in the tomato library, 21816 reads or 11.1% of the virus-mapped reads are highly homologous to 1580 human genes (Table 4). In some instances, thousands of virus-derived small RNAs can match a single human gene. The top three human genes matched by the most virus-mapped small RNAs in the tomato, zucchini, and onion are listed in Table 5. However, there is no human gene match shared by the virus-derived small RNAs in all four libraries.

**Table 4. Virus-Mapped Small RNA Reads Sharing Sequence Homology to Human Reference RNA Set[a]**

| sample | no. of human RNAs matched | no. of unique reads | total reads | % of total virus-mapped reads sharing homology with human genes |
|---|---|---|---|---|
| tomato | 1580 | 1786 | 21816 | 11.1 |
| melon | 43 | 22 | 22 | 11.9 |
| zucchini | 884 | 1558 | 16634 | 8.7 |
| onion | 1399 | 1936 | 18005 | 6.0 |

[a]The virus-mapped reads, 21- and 22-nt size classes, in each sample (Figure 2) were matched against the human reference RNA set downloaded from genome.ucsc.edu (Feb 7, 2012), allowing up to two or three mismatches for each 21- and 22-nt small RNA read, respectively.

Beyond the virus-derived small RNAs, the remaining small RNAs in these fruit or vegetable small RNA libraries are probably derived from endogenous plant sequences. These small RNAs can also share sequence homology to human genes. To eliminate trivial and low-complexity matches, the miRNAs, rRNAs, small nucleolar RNAs, and small nuclear RNAs in the human reference RNA set that could be matched from the corresponding fruit or vegetable rRNA sequences were excluded from the sequence search. Up to two mismatches were allowed for each small RNA, and the results are shown in Table 6. These results imply that up to 10.9% of the total small RNAs in regularly consumed vegetables share a high degree of sequence similarity with human genes. Furthermore, 2774 human gene matches are shared by all four libraries (Supporting Information Tables S5−S8). This suggests that some human genes can have frequent matches by small RNAs derived from different fruits and vegetables. Although most of these matched sequences are few in numbers, numbers of endogenous small RNA with high copy numbers appear to have significant sequence similarity with human genes. For example, miRNA159a, which is abundant in all four libraries, can be mapped to a human gene encoding polycystic kidney and hepatic disease 1, PKHD1 protein (Tables S5−S8).

Table 5. Examples of Human RNAs Matching the Sequence of Virus-Mapped Small RNA Reads[a]

| sample | human RNA matched | GenBank ID | region matched | no. of unique reads | total reads |
|---|---|---|---|---|---|
| tomato | multiple EGF-like-domains 8 (MEGF8), mRNA | NM_001410 | 10253−10274 | 20 | 3451 |
| | family with sequence similarity 190, member A (FAM190A), transcript variant 1, mRNA | NM_001145065 | 5152−5170 | 1 | 2419 |
| | rho-associated, coiled-coil containing protein kinase 2 (ROCK2), mRNA | NM_004850 | 4525−4545, 997−1017 | 6 | 2337 |
| zucchini | WD repeat domain 3 (WDR3), mRNA | NM_006784 | 3424−3444 | 6 | 1019 |
| | regulator of G-protein signaling 7 (RGS7), mRNA | NM_002924 | 1273−1295 | 14 | 904 |
| | proline-rich transmembrane protein 2 (PRRT2), transcript variant 1, mRNA | NM_145239 | 1444−1464 | 4 | 462 |
| onion | triosephosphate isomerase 1 pseudogene 3 (TPI1P3), noncoding RNA | NR_027338 | 639−659 | 6 | 1043 |
| | olfactory receptor, family 6, subfamily P, member 1 (OR6P1), mRNA | NM_001160325 | 635−654 | 10 | 941 |
| | DYX1C1-CCPG1 readthrough (nonprotein coding) (DYX1C1-CCPG1), noncoding RNA | NR_037923 | 2962−2983, 3037−3056 | 11 | 689 |

[a]Except for the melon sample, where only a few matches were found, the top three human RNA matches in each sample are listed. The majority of the reads matched a single subregion of the transcript as shown using the base number referenced in GenBank.

Table 6. Non-Virus-Mapped Small RNA Reads Sharing Sequence Homology to Human Reference RNA Set[a]

| sample | no. of human RNAs matched | no. of unique reads | total reads | % of total non-virus-mapped reads sharing homology with human genes |
|---|---|---|---|---|
| tomato | 13683 | 33189 | 337610 | 9.4 |
| melon | 8664 | 14961 | 157019 | 9.6 |
| zucchini | 8286 | 14633 | 144654 | 4.3 |
| onion | 13851 | 34193 | 342541 | 10.9 |

[a]The virus-mapped small RNA reads were removed from each small RNA library. The rest of the small RNA reads, presumably derived from endogenous sequences, were matched against the human reference RNA set downloaded from genome.ucsc.edu. The miRNAs, ribosomal RNAs, small nucleolar RNAs, and small nuclear RNAs were excluded from the human reference RNA set and allowed up to two mismatches for each plant small RNA. The number of human genes matched as well as the numbers of unique and total small RNA reads whose sequences matched these human genes are shown.

## DISCUSSION

A typical plant small RNA size distribution is characterized by abundant 21 and 24 nt size classes; the 24 nt class is commonly present at an abundance similar to, or more than, that of the 21 nt size class.[22] The 24 nt class small RNA is responsible for transcriptional regulation and chromatin modification,[28] whereas the 21 nt class small RNA is mostly involved in post-transcriptional[29] and antiviral defense.[30,31] Except for the melon sample, the small RNA size profiles of all other fruit and vegetable samples displayed a higher abundance of 21 nt sized small RNAs (Figure 1). This is likely due to the presence of viruses in these tissues that induced an antiviral RNA silencing response, resulting in the accumulation of 21 nt small RNAs. Indeed, significant amounts of total small RNA populations are found to have originated from viral sequences, which partially contributed to the greater abundance of the 21 nt class seen in tomato, zucchini, and onion samples (Figure 2). However, directly comparing the small RNA populations between known infected and uninfected plants would be necessary to confirm these results.

Previously, we have shown that it is possible to reassemble significant portions of TSWV genome from overlapping small RNA sequences obtained by small RNA sequencing of tomato infected with the virus.[20] Here we report that several viruses can be easily and precisely detected in fresh market vegetables using small RNA sequencing. Furthermore, except for the WMV in the melon sample where the virus accumulation was likely to be low, the contigs assembled from the small RNA sequences from other samples embody large portions of the virus genomes. For example, as much as 89% of TSWV, 84% of PVY, 76% of WMV, and 96% of INSV total genomic sequences are covered by the small RNAs in their respective samples (data not shown). Therefore, it is possible to use small RNA sequencing to assemble the genome of a novel virus, especially when the endogenous small RNAs of host plant can be identified and excluded. With gradual reduction in cost since its invention, small RNA sequencing has the potential to be used as a one-step diagnostic and discovery tool for plant viruses in the future.

Because RNA-mediated gene suppression in plants and animals operated through fundamentally similar mechanisms and synthetic dsRNA or siRNA/miRNA are known to work in plant or animal cells in vitro in a sequence-specific manner, some have cautioned the use of this RNA-based gene suppression in plant biotechnology. Recently, a study claiming that a miRNA, miR168a, from rice can target a mouse gene for suppression through oral ingestion has intensified the debate.[24] The experimental design and assumptions of this study have been disputed.[11,27,32] This phenomenon of significant miRNA uptake in mice, nonhuman primates, and humans has not been reproduced by others[25−27] and the reported physiological impacts by Zhang and colleagues were not reproduced in a properly controlled feeding study with higher miR168a exposures.[27] In addition, these observations are inconsistent with the weight of the evidence for the safety of ingested nucleic acids, as evidenced by biological barriers to their uptake and/or activity in higher organisms, their extensive history of safe consumption, and the delivery challenges faced by pharmaceutical companies developing oligonucleotide-based therapeutics.[11,33] The human diet is made up of largely eukaryotic sources that contain an abundance of small RNAs. Therefore, it is not surprising that such small RNAs were found, intact, in food through small RNA sequencing.[24−27,34] Studies have also demonstrated that some endogenous long dsRNAs in crop plants share sequence complementarity of at least 21 nucleotides with human genes.[33,34]

In the current study, we have sequenced the small RNAs in fruits and vegetables readily available for purchase and likely to be ingested by consumers in an unprocessed or raw state. Sequences highly homologous to human genes were abundant in these fruits and vegetables, and we found that small RNAs originating within the plant and from infecting viruses can have matches to human genes. However, the consumption of fresh fruits and vegetables like these is not associated with an obvious heath risk; indeed, the opposite is true.[35,36]

It is logical to assume that small RNAs produced by transgenes are fundamentally no different from endogenously derived plant small RNAs. The data presented here provide additional support for the assumption that small RNAs derived from transgenic sources have no more impact on human health than the multitudes of endogenous plant small RNAs present in foods regularly consumed every day. This opinion is shared by the independent statutory agency Food Standards Australia New Zealand (FSANZ), who have noted that "there is no scientific basis for suggesting that small dsRNAs present in some GM foods have different properties or pose a greater risk than those already naturally abundant in conventional foods".[37] Coupled with the long history of safe consumption of these dietary small RNAs, the results described here provide further evidence to suggest that RNA-based gene suppression in biotech crops is unlikely to present a direct safety hazard to humans or animals.

Peach purée at different pH values was divided into 30 mL glass tubes and heated in a water bath at 90 °C for 10 min. The flasks were then cooled to room temperature in ice for 10 min. Tubes were stored in the dark for 90 days at room (ca. 23 °C) and refrigerated (4 °C) temperatures. The headspace gas was equivalent to the mixture existent in the atmospheric air (78 kPa $N_2$ + 21 kPa $O_2$ + 0.03 kPa $CO_2$). Sampling of individual flasks was carried out at 0, 7, 14, 30, 60, and 90 days of storage. This procedure was performed in triplicate.

**Microbiological Analysis.** Total mesophylls were assessed, in duplicate, using plate count agar (PCA, Biokar Diagnostics, Solabia, France) and a spread plate technique. Samples were incubated at 30 °C for 24 h.

Total yeasts and molds were assessed, in duplicate, using potato dextrose agar (PDA, Biokar Diagnostics, Solabia, France) and a spread plate technique. Samples were incubated at 30 °C for 48 h.

In both cases, colonies were enumerated and total viable cells (cfu/g) were determined.

**Color Measurement.** A Petri dish (inner diameter of 50 mm) with a whole in the lid was filled with the purée and placed directly over the Konica-Minolta CR-400 chromameter (Osaka, Japan) equipped with a $D_{65}$ illuminant and 2°. The instrument was calibrated using white ($Y$, 93.9; $x$, 0.3159; $y$, 0.3322) reference tiles. Two measurements from triplicates were performed, and results were averaged. The $L^*$, $a^*$, and $b^*$ CIE color system was used to evaluate the color.

The saturation index ($C^*$; eq 1) and hue angle ($H$; eq 2) were calculated using measured $L^*$, $a^*$, and $b^*$ values as follows and used to describe the color change compared to the control sample:

$$C^* = \sqrt{(a^*)^2 + (b^*)^2} \quad (1)$$

$$H = \tan^{-1}\left(\frac{b^*}{a^*}\right) \quad (2)$$

**Extract Preparation.** Hydrophilic extractions were performed by homogenizing 5 g of peach purée in 50 mL of 80% methanol in water at room temperature. Homogenization (IKA Ultraturrax T18, Wilmington, NC) was performed at 24 000 rpm for 30 s. The slurry was then centrifuged at 4000$g$ and 4 °C for 10 min; the supernatant was filtered through a 0.45 $\mu$m cellulose acetate filter (Orange Scientific, Braine-l'Alleud, Belgium); and the filtrate was used for the assessment of total activities. A 10 mL aliquot of the extract was evaporated to dryness in a RVC 2-18 speed-vacuum evaporator (Christ, Osterode am Harz, Germany) at 30 °C, and the residue was dissolved in 3 mL of methanol. The extract was then analyzed by high-performance liquid chromatography with photodiode array detection (HPLC−DAD) for phenolic compound identification and quantification over time.

Carotenoids were extracted as described by Wright and Kader,[9] where 5 g of peach purée was suspended in 10 mL of cold ethanol and homogenized at 24 000 rpm for 3 min using an IKA T18 Ultraturrax (Wilmington, NC). Hexane (8 mL) was added to the homogenate, and the resulting mixture was homogenized for an additional 2 min before the centrifugation for 10 min at 4000$g$. The hexane layer containing the carotenoids was transferred to a polypropylene tube. A solution of saturated sodium chloride (5 mL) and an additional 8 mL of hexane was added to the purée slurry, and the resulting mixture was homogenized for 1 min. The mixture was centrifuged as described above, and the hexane layer was collected. Both hexane layers were collected in the same polypropylene tube and used for saponification. Saponification was made as described by Kimura et al.,[10] where the resultant hexane fractions were mixed with 10% methanolic KOH and left under agitation overnight at 300 rpm. The mixture then was washed with 10% NaCl, and after three washes with deionized water, the sample was collected and used for spectrophotometric and HPLC−DAD analyses. The saponification procedure was carried out to remove chlorophylls and unwanted lipids and hydrolyzing carotenoid esters.[11]

**Analysis of Total Antioxidant Activity, Total Phenolics, and Total Carotenoids.** The total antioxidant activity was determined by 2,20-azinobis(3-thylbenzothiazoline-6-sulfonic acid) diammonium salt (ABTS) radical scavenging activity as described by Giao et al.[12] Briefly, the $ABTS^+$ radical cation was produced from the reaction of 7 mM ABTS and 2.45 mM potassium persulfate after incubation at room temperature in the dark for 16 h. The $ABTS^+$ solution was diluted with water to an absorbance of 0.70 ± 0.02 at 734 nm. The ascorbic acid concentrations used to give 20−80% inhibition of the blank absorbance for linearity purposes were between 0.02 and 0.50 g/L. The $ABTS^+$ solution was read after 10 $\mu$L of sample extract reacts for 6 min. The antioxidant capacity of the sample was calculated and expressed as milligrams of ascorbic acid equivalent per gram of peach purée.

The total phenolic content was determined spectrophotometrically with an ultraviolet (UV) mini 1240 spectrophotometer (Shimadzu, Tokyo, Japan) by the Folin−Ciocalteu method.[13] Briefly, 50 $\mu$L of methanolic extract, 50 $\mu$L of Folin−Ciocalteau reagent, 1 mL of $Na_2CO_3$ (75 g/L), and 1.4 mL of ultrapure water were mixed. The mixture was vortexed, and the tubes were left for 60 min in the dark at room temperature. The absorbance of the sample was read at 750 nm using gallic acid (0.06−0.5 g/L) as a standard. Results were expressed as milligrams of gallic acid equivalent per gram of peach purée.

Carotenoids were quantified after saponification by measuring the sample absorbance at 454 nm. $\beta$-Carotene was used to prepare the calibration curve in the range of 0.063−4.0 g/L.

**HPLC−DAD Analysis.** Qualitative and quantitative profiles of phenolic compounds and carotenoids present in the extracts were determined by HPLC−DAD (Waters Series 600, Milford, MA). Separation was performed in a reverse-phase Symmetry $C_{18}$ column (250 × 4.6 mm inner diameter, 5 mm particle size, and 125 Å pore size) with a guard column (Symmetry $C_{18}$).

Solvents used in chromatographic separation of phenolic compounds were solvent A, methanol, water, and formic acid (92.5:5:2.5, v/v/v), and solvent B, methanol and water (94:6, v/v). The linear gradient elution starts at 0−10% solvent B in 10 min at 0.5 mL/min, 10−30% in 40 min at 0.65 mL/min, 30−50% in 20 min at 0.75 mL/min, and 50−0% in 10 min at 1 mL/min. The injection volume was 20 $\mu$L.

Carotenoids were eluted using acetonitrile, methanol, dichloromethane, hexane, and ammonium acetate (55:22:11.5:11.5:0.02, v/v/v/v/w) under isocratic conditions at 1.0 mL/min flow rate for 20 min at 25 °C with an injection volume of 40 $\mu$L.

Detection was achieved by a diode array detector (Waters, MA) at wavelengths ranging from 200 to 600 nm in 2 nm intervals, and absorbance was measured at 320 and 454 nm.

The pure standards used were chlorogenic acid, neochlorogenic acid, and $\beta$-carotene (Sigma-Aldrich, Sintra, Portugal) and zeaxanthin and $\beta$-cryptoxanthin (Extrasynthése, Lyon, France), and results were expressed as micrograms per gram of fresh biomass.

**Statistical Analysis.** The changes in antioxidant activity and the contents of total and individual polyphenols and carotenoids were described during storage, where $Y$ represents the ratio between the concentration at time $t$ and the initial concentration at time 0 and $t$ is the storage time (days).

Statistical analysis was performed using GraphPad Prism, version 5.00, for Windows. Normality of data distribution was tested by the Kolmogorov−Smirnov method.

Statistically significant values of the means of groups were made by two-way analysis of variance with Bonferroni post-hoc test for the different pH conditions along time for both storage temperatures. The statistical analyses performed were considered significant when $p < 0.05$.

The case-wise principal component analysis (PCA) scores for the first three principal components were uploaded into the SPSS software package (version 17). PCA was conducted to the data set after normalization (the mean of the values for each variable is subtracted from each variable value, and the result is divided by the standard deviation of the values for each variable). Factor analysis was performed to reduce and explain the variability of the data. The Varimax method was used to produce orthogonal transformations to the reduced factors to better identify the high and low correlations.

## RESULTS AND DISCUSSION

**PCA.** A PCA model containing three principal components (PC1, PC2, and PC3) were calculated, which accounted for 75% of the total variation of the data set (Figure 1).

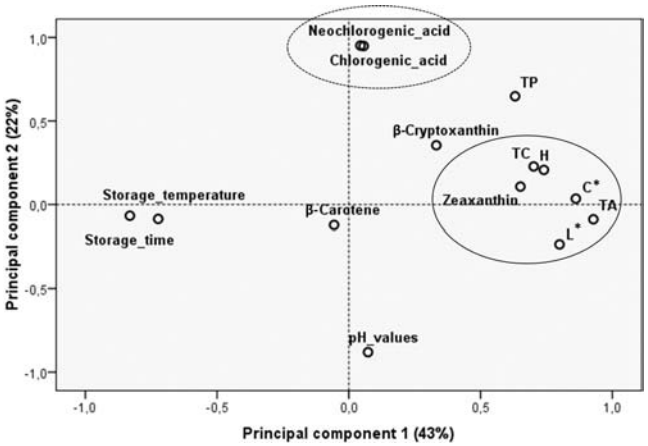

**Figure 1.** PCA of data from peach purée pasteurized and stored for 90 days at 4 and 23 °C for pH 2.5, 3.0, 3.5, 4.0, and 4.5. Total antioxidant activity, total phenolic content, and total carotenoid content are represented as TA, TP, and TC.

The most important component (PC1) explained 43% of the total variance. PC1 is related to purée overall quality, where the increase in storage time and temperature promoted a decrease of total antioxidant activity, total phenolic content, total carotenoid content, zeaxanthin and $\beta$-crytptoxanthin concentration, and color ($C^*$, $H$, and $L^*$). PC2 explained 22% of the total variance and mainly correlates pH variation with neochlorogenic and chlorogenic acids.

Finally, PC3 explained 10% of the variance, and this variation was mostly described by $\beta$-carotene. Variables that appear close together in this plot correlated positively, as seen in Figure 1; there is a close relationship between storage time and temperature, zeaxanthin, $C^*$, and total antioxidant activity.

Negative correlations were observed for storage time and temperature, $C^*$, $H$, $L^*$, total antioxidant activity, total carotenoids, and zeaxanthin.

The content of zeaxanthin was highly correlated with $H^*$ (Figure 1), which is consistent with the fact that an intense yellow color should be indicative of a higher zexanthin content. These results indicated that carotenoids as well as peach purée color were not strongly affected by pH variation, contrary to storage temperature and time, which were the main factors affecting these compounds.

A strong and negative correlation was also observed between pH and individual polyphenols, such as chlorogenic and neochlorogenic acids. Thus, the lower the pH, the greater the chlorogenic and neochlorogenic acid contents.

$\beta$-Carotene was found to be loaded on PC3, and the variables pH, storage time, and temperature seem to not affect the $\beta$-carotene content (Figure 1).

**Effect of pH Changes in Total Antioxidant Activity and Total Phenolic and Total Carotenoid Contents.** The pH value variations (2.5−4.5) on peach purée had no significant effect on antioxidant activity ($p > 0.05$; Figure 2). On the other hand, storage time showed a significant ($p < 0.05$) effect on antioxidant activity decrease, because longer storage periods were associated with lower antioxidant retention. The storage temperature was also a significant ($p < 0.05$) parameter, where, at 4 °C, antioxidant activity decreased 40% and, at 23 °C, antioxidant activity decreased 50% after 90 days (panels A and B of Figure 2).

The total phenolic content presented no significant variations in the range of pH values tested in samples for 90 days of storage at 4 and 23 °C. The total phenolic content decreased between 18 and 30% for 4 °C and between 29 and 40% for 23 °C after 90 days of storage (panels C and D of Figure 2). When açai juice was fortified with ascorbic acid and stored at 4 and 20 °C for 30 and 193 days, a maximum loss of soluble phenolics ranged from 8 to 13%. Authors related losses of total soluble phenolics during storage with polyphenolic oxidation and polymerization reactions that serve to reduce the number of free hydroxyl groups measured by the Folin−Ciocalteu assay.[14] The total phenolic content also decreased in orange juice stored at 18, 28, and 38 °C for 4 months by 7, 11, and 20%, respectively, also reflecting the decrease in antioxidant capacity of those juices.[15]

Total carotenoids were significantly ($p < 0.05$) affected by pH variation. At 4 °C, pH values of 3.0 and 3.5 presented the highest retention in total carotenoids, by decreasing 27 and 29%, respectively. The pH values of 4.0 and 4.5 presented both a similar decrease of ca. 56% (panels E and F of Figure 2). Similarly, at 23 °C and pH 3.0 and 3.5, there was a 40% decrease that was significantly ($p < 0.05$) lower than at pH 4.5 (68%). The percentage of total carotenoid losses was similar for the two storage temperatures, indicating no effect on the total carotenoid content. The present work demonstrates that the pH value of 4.0 and 4.5 induced a higher decrease rate for both storage temperatures and the pH values of 3.0 and 3.5 presented a better condition for a high stability of the carotenoids.

It may be hypothesized that, under acidic conditions, after thermal treatment, carotenoids may be entrapped or encapsulated within aggregates from the cellular components formed after cell wall depolymerization. This can protect the carotenoids from degradation reactions promoted by oxygen.[11] A significant loss of galacturonic acid after long acid hydrolysis times was found to be accompanied by changes in the size and branching of the single polymers and further breakdown of the complexes.[16] Palmero et al.[17] observed a decrease in carotenoid bioaccessibility upon heating carrots because of induced separation of intact cells that encapsulate carotenoids. On the one hand, cell wall components might be physically blocking carotenoid release.[17]

**Effect of pH Changes in Peach Polyphenols and Carotenoids.** In the literature, scarce information is available on the changes in individual phenolic and carotenoid constituents of pasteurized peach during storage at different pH conditions.

The individual phenolic compounds identified were neochlorogenic and chlorogenic acids, and they were stable throughout the storage period. At 4 °C, neochlorogenic acid decreased ($p < 0.001$) 34% after 90 days of storage for the higher pH values (4.0 and 4.5) (Figure 3A). With the increase of the storage temperature to 23 °C, pH variation did not affect the neochlorogenic acid concentration (Figure 3B).

The chlorogenic acid concentration decreased ($p < 0.001$) 32 and 39% for pH 4.0 and 4.5, respectively, for peach purée stored at 4 °C. The lower pH values (2.5, 3.0, and 3.5) presented decreases between 6 and 11% (Figure 3C).

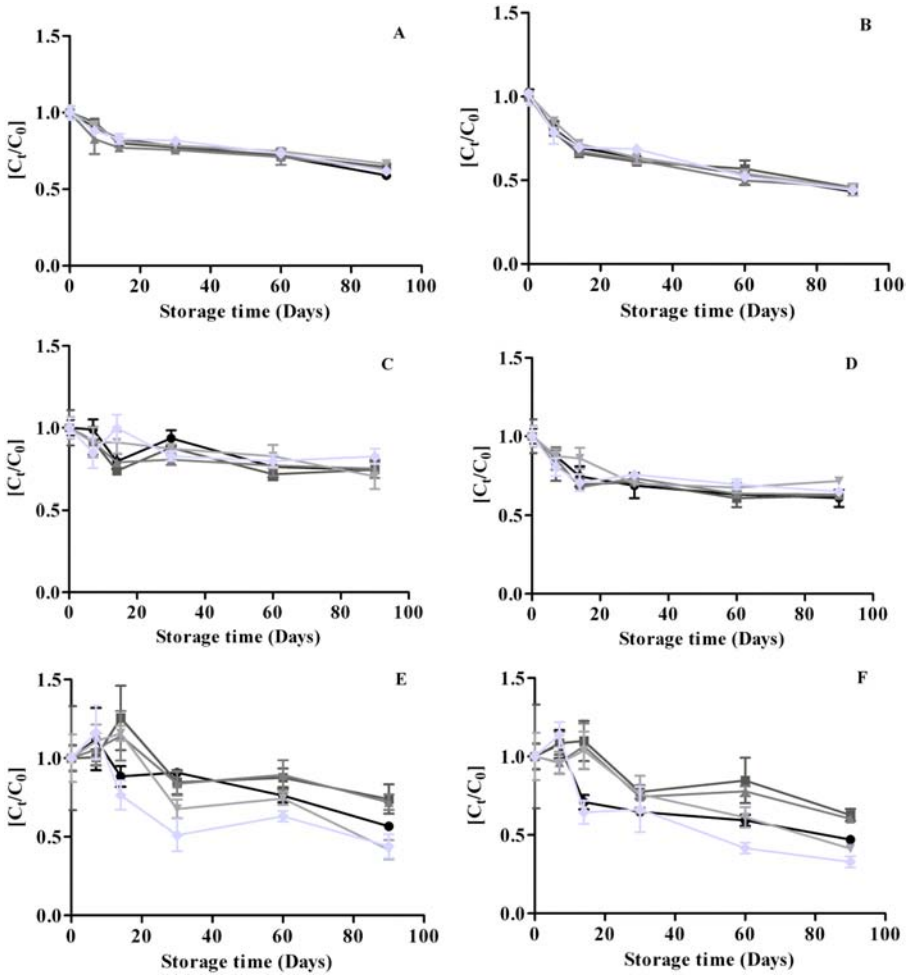

**Figure 2.** Evolution of (A and B) total antioxidant activity, (C and D) total phenolics, and (E and F) total carotenoids measured as the mean ± standard deviation ($n$ = 3) in pasteurized peach purée stored at 4 and 23 °C for 90 days, respectively. The different pH values are represented as (●) 2.5, (■) 3.0, (▲) 3.5, (▼) 4.0, and (◆) 4.5.

Storage at 23 °C led to a decrease of the chlorogenic acid concentration to ($p$ < 0.001) 37% on pH 4.5. The remaining pH values tested (2.5, 3.0, 3.5, and 4.0) presented a decrease of 14% (Figure 3D).

Previous studies revealed that chlorogenic acid was stable when added to apple juice at pH 3 and 4.5 and stored under refrigeration for up to 2 weeks. The susceptibility of phenolic compounds to pH strongly depends upon the structure of the phenol. Chlorogenic and neochlorogenic acids are compounds with OH groups, and their multi-ring aromatic structures are more complex than the mono-ring phenolic compounds. Their ionized and resonance forms are more resistant to acidic degradation than are the monocyclic polyphenolic compounds.[6] van der Sluis et al.[18] predicted by mathematical modeling that chlorogenic acid declined roughly by 40% in apple juice stored for 200 days at 20 °C in the absence of oxygen.

The individual carotenoids identified in peach purée extracts were zeaxanthin, β-cryptoxanthin, and β-carotene. The zeaxanthin concentration decreased ($p$ < 0.01) 11% for pH 3.0 by 90 days of storage at 4 °C. The remaining pH values, 2.5, 3.5, 4.0, and 4.5, decreased 67, 41, 60, and 68%, respectively (Figure 4A). At 23 °C, the zeaxanthin concentration decreased between 56 and 75%, without significant changes between pH conditions (Figure 4B).

The β-cryptoxanthin concentration decreased between 30 and 50% for purées stored under refrigeration, but pH variation did not affect its concentration. Storage under 23 °C caused the β-cryptoxanthin concentration to decrease 36% for pH 3.5, while pH 2.5, 3.0, 4.0, and 4.5 induced a higher significant decrease of 55, 46, 44, and 55%, respectively (panels C and D of Figure 4).

The concentration of β-carotene decreased ($p$ < 0.05) 47 and 52% for pH 2.5 and 4.5, respectively. The intermediate pH conditions resulted in a 24% decrease (Figure 4E) when purée was stored at 4 °C. Chen et al.[19] and Schieber and Carle[20] described that a high concentration of acids resulted in isomerization of β-carotene. At 23 °C, β-carotene decreased 39% at pH 2.5 and 4.5, while at pH 3.0, 3.5, and 4.0, it decreased between 24 and 26% (Figure 4F).

Carotenoids with carbonyl groups (astaxanthin and canthaxanthin) have slower rates of degradation than β-carotene and zeaxanthin, indicating preferential non-degradative protonation of the carbonyl groups.[4,21,22] However, other authors also demonstrated that low pH has a minor effect on β-carotene isomerization.[19,23] Nevertheless, other approaches report that carotenoids can undergo reactions of *cis*−*trans* isomerization containing double bonds through the formation of an intermediate carbocation when exposed to acidic conditions.[24,25] Protonation of carotenoids with a double bond

[a]Different letters in the same line indicate significant differences ($p < 0.05$).

carbon would result in hybridization and the formation of a single bond, leading to free rotation about the new single bond, forming *cis* isomers.[4] Some reports described carotenoids, such as β-carotene, canthaxanthin, and 8′-apo-caroten-8′-al, once dissolved in acetonitrile, benzene, and dichloromethane exposed to strong acid [trifluoroacetic acid (TFA)], revealing *cis* isomerization formed by protonation of carotenoids, and the reaction products are probably carotenoid esters.[4]

However, peach purée antioxidant activity and total phenolics were not affected by pH variation during 90 days of storage. Contrarily, carotenoids revealed a higher degradation for the higher pH values tested of 4.0 and 4.5. The pH values of 3.0 and 3.5, the most similar to the peach pH (3.6), were the optimum conditions for zeaxanthin, β-cryptoxanthin, and β-carotene retention. Chlorogenic and neochlorogenic acids presented a higher content for the lower pH (2.5).

**Color Measurements.** The highest $b^*$ values ($p < 0.05$) were obtained for pH 3.5, and the lowest $b^*$ value ($p < 0.05$) was obtained for pH 4.0 and 4.5; contrarily, the higher $a^*$ value was obtained for pH 4.5 (data not shown). The yellow color decrease had impact on saturation index ($C^*$) values, where the higher decrease was observed for pH 4.0 and 4.5 for both storage temperatures. The hue angle ($H$) values decreased highly for pH 4.0 and 4.5 but at a lower rate (Table 1).

The lowest ($p < 0.05$) lightness ($L^*$) values were obtained for pH 2.5 at 4 °C (Table 1), while for 23 °C, $L^*$ presented no significant differences between the different pH values (Table 1).

Over the 90 day storage period, $L^*$ and $b^*$ parameters decreased, while $a^*$ increased for all pH values. This means that, with the increase of the storage time, the color variation involves a shift from the yellow to red hues among the pH values tested. The decrease in lightness and, consequently, increase in darkening can be indicative of some precipitation along storage. The peach purée treated at 80 °C loses its yellowness and becomes redder, resulting from non-enzymatic browning (Maillard) reactions.[26,27]

This study allowed for the conclusion that pH between 3.0 and 3.5 lead to higher carotenoid content and higher color stability, with time and temperature of storage being more preponderant for peach purée overall quality.

proposed, including milled wood lignin (MWL) and cellulolytic enzyme lignin (CEL),[15] they are not suitable for pummelo fruits due to low yield and contamination.[11,16,17] The organic solvent extraction method is an effective lignin extraction technique that produces less contaminant, does not alter lignin structure,[18−21] and is useful for isolating lignins from pummelo fruits.

Multiple studies assessing lignin have mainly focused on its application in bioenergy[22,23] and pulping;[17,24] however, the effect of lignin on pummelo fruit quality has been rarely studied. Here, we compare the composition and structure linkages of lignin between granulated juice sacs and three other tissues, in three severely granulated cultivars of pummelo. Our findings provide useful information about the main lignin synthesis pathway and specific lignin deposition in juice sacs, which is important for the further investigation of the relationship between lignin metabolism and juice sac granulation. To our knowledge, this is the first report evaluating the composition and structure of specific lignins accumulated in juice sacs of pummelo fruits.

## MATERIALS AND METHODS

**Plant Materials.** Plant materials used in this study included the granulated juice sacs, segment membranes, stems, and leaves. Granulated juice sacs were obtained from three cultivars, 'Hongroumiyou', 'Guanximiyou', and 'Sanhongmiyou', abbreviated HR, GX, and SH, respectively (Figure 1). Segment membranes, stems, and leaves were all from cultivar HR. The main leaf veins were removed before lignin extraction.

**Lignin Isolation.** Soluble substances in samples were washed out according to the modified method of Müse et al.[25] A total of 50 g (segment membranes, stems, and leaves) or 100 g (granulated juice sacs) of plant material was homogenized in 150 mL of homogenization buffer (50 mM Tris-HCl, 5 mL/L Triton X-100, 1 M NaCl; pH 8.3) using a juice extractor. After transfer to an 80 mL Beckman tube with screw cap, the homogenate was thoroughly vortexed and centrifuged (8000*g*, 10 min). The sediments were washed twice with the homogenization buffer, twice with 80% acetone, and twice with pure acetone. The washing procedure was repeated once for stem samples, twice for those from segment membranes and leaves, and three times for granulated juice sac specimens. The sediments from each tissue were combined and lyophilized. After lyophilization, the sediment samples were extracted with toluene/ethanol (2:1, v/v) for >7 h with a Soxhlet extractor and dried. Crude lignin was extracted and purified according to the method of Wu et al.,[19] with the following modifications. Sediment samples (8 g), 4 g/L nitric acid (16 mL), and a mixture of formic acid/acetic acid/$H_2O$ at the ratio of 11:5:4 were placed into a 250 mL three-necked flask. The solid to liquid material ratio was 1:20. After extraction of the crude lignin for 3 h at 110 °C, the liquid part was dried using a rotary evaporator. The sediments were washed with double-distilled water several times and dried by desiccation. The crude lignin was purified according to the method of Wu et al.[19]

**Preliminary Characterization of Lignin by UV.** Lignin was preliminarily characterized by UV−vis spectroscopy after solubilization in dioxane/$H_2O$ (9:1, v/v) according to the method described by Wu et al.[19] with minor modifications. The scanning spectrum was from 200 to 400 nm.

**HSQC NMR Sample Preparation.** Lignin acetylation was performed according to previous studies,[13,26] with minor changes. Purified lignin (20 mg) or segment membrane lignin (8 mg) was dissolved in 2 mL of pyridine/acetic anhydride (1:1, v/v) at room temperature in the dark for 72 h. After the sample had been transferred into an 80 mL Beckman tube, 30 mL of ethyl ether was added and the mixture centrifuged (15000*g*, 7 min). The sediments were washed with ethyl ether until disappearance of the pyridine odor. The sediments were then dissolved in dimethyl-$d_6$ sulfoxide (DMSO-$d_6$, containing 0.03% TMS) and used for HSQC NMR analysis.

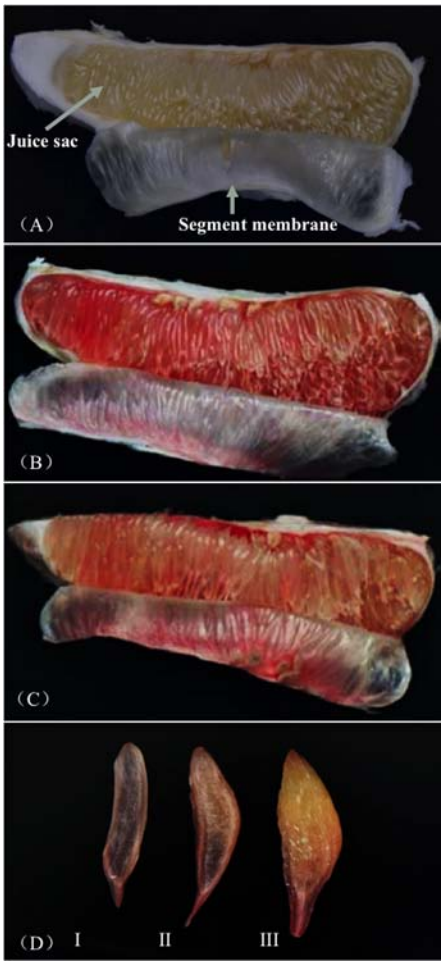

**Figure 1.** Cultivars and juice sacs of pummelo used in this study: (A) GX segment with white juice sacs and segment membranes; (B) HR segment with red juice sacs and segment membranes; (C) SH segment with red juice sacs and segment membranes; (D) comparison of normal juice sacs (I) with the different degrees of juice sac granulation (II and III) in cultivar HR. The granulation was more severe in III than in II.

**HSQC NMR Procedures.** All NMR experiments were conducted on a Bruker AVANCE III 500 instrument equipped with a *z*-gradient BBO probe at a temperature of 298 K. The Larmor frequencies of $^1H$ and $^{13}C$ were 500.0 and 125.7 MHz, respectively. The spectral widths in HSQC experiments were 5000 and 20833 Hz for the $^1H$ and $^{13}C$ dimensions, respectively. The number of complex points collected was 1024 for the $^1H$ dimension; the acquisition time was 0.1 s with a recycle delay of 2 s. The number of transients was 24 (except for the sample of segment membranes for which 96 transients were accumulated to achieve a reasonable signal-to-noise ratio), and 256 time increments were recorded in the $^{13}C$ dimension. The experiments were optimized for the $^1J_{CH}$ of 145 Hz. Prior to Fourier transformation, the data matrices were zero filled to 1024 points in the $^{13}C$ dimension. A squared cosine-bell apodization function was applied in both dimensions. The central solvent (DMSO-$d_6$) peak was used as an internal chemical shift reference point ($\delta_C/\delta_H$ 40.1/2.50).

Semiquantitative analysis of different linkages and basic compositions of lignins was carried out according to previous reports.[15,27] In the aliphatic oxygenated region, the relative abundances of interunit linkages were estimated from $C_\alpha-H_\alpha$ cross-signals. In the aromatic region, $C_2-H_2$ cross-signals from **G′** units were also incorporated into **G** units in the calculation. $C_{2,6}-H_{2,6}$ cross-signals from **S** units and

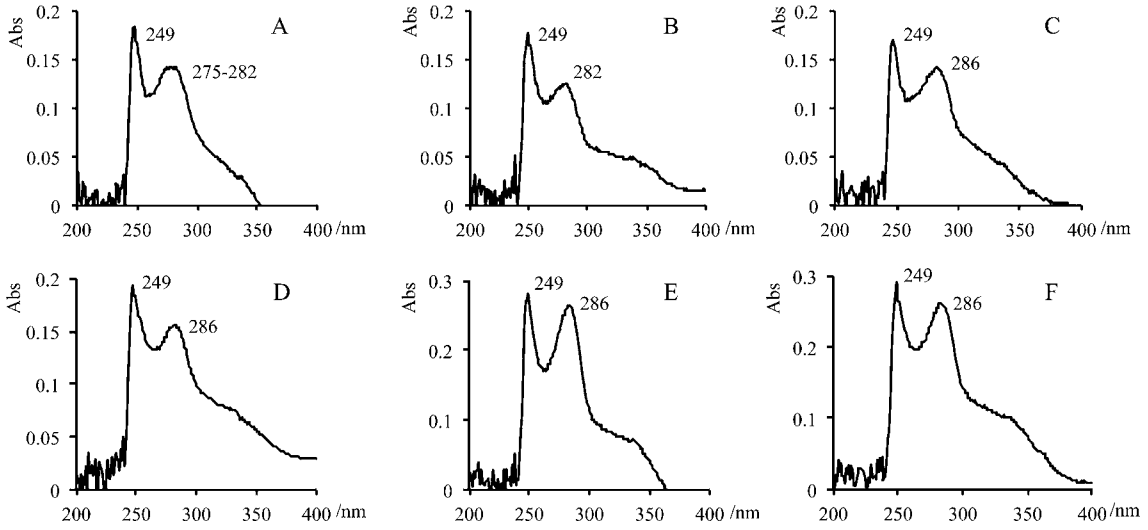

**Figure 2.** UV spectra of lignins isolated from different tissues: (A) lignin from HR leaves; (B) lignin from HR stems; (C) lignin from HR segment membranes; (D) lignin from HR granulated juice sacs; (E) lignin from GX granulated juice sacs; (F) lignin from SH granulated juice sacs.

doubles of $C_2$–$H_2$ cross-signals from **G** and **G′** units were used to estimate the **G**/**S** ratio.

## RESULTS

**Lignin Extraction and Characterization.** Because the lignin contents of the four tissues studied were very low compared with those of woody plants, and no previous work was available, we established a method appropriate to analyze the lignin content and purity of each sample. The organic solvent extraction method was good enough for us to obtain relatively pure lignin suitable for NMR analysis.

The preliminary characteristics of lignins from different tissues are shown in Figure 2. Lignins of all tested tissues displayed a wide absorption peak at 240–300 nm and a characteristic absorption peak at 249 nm. In addition, stem lignin showed a characteristic absorption at 282 nm, whereas that from segment membranes and granulated juice sacs in all three cultivars had an adsorption peak at 286 nm. The lignin from leaves did not have a characteristic peak, but adsorbed between 275 and 282 nm. Because lignins have a specific absorption at 200–300 nm,[28] we concluded that lignin might be present in our samples. These samples were then used for subsequent NMR analysis.

**HSQC NMR Analysis of Isolated Lignin.** The lignin samples from leaves, stems, and segment membranes in HR, and from granulated juice sacs in HR, GX, and SH were analyzed by HSQC NMR. Before measurement, the lignin samples were acetylated to ensure complete solubility in the NMR solvent[29] and acquisition of unique and well-resolved cross-signals.[15] Because the lignin content of segment membranes was low, only 8 mg was used for analysis, but the results were not affected.

The HSQC spectra revealing the key information regarding lignin structures are shown in Figures 3 and 4. Lignin contours in the HSQC spectra were assigned by comparison with data from previous studies.[15,26,30−33] The assignments and relative abundances of main lignin $^{13}C$–$^{1}H$ cross-signals are listed in Tables 1 and 2. The main lignin substructures identified in HSQC spectra are presented in Figure 5.

**Analysis of Lignin Interunit Linkages.** In the side-chain region of HSQC spectra, the main lignin interunit linkages *β*-O-4′, *β*-*β*′, and *β*-5′ were distinctly observed. All spectra showed prominent signals corresponding to the *β*-O-4′ substructures. The $C_\alpha$–$H_\alpha$ cross-signals in *β*-O-4′ substructures (**A** and **A′**) were observed at $\delta_C/\delta_H$ 73.81/5.88 (for *erythro*) and 74.05/5.96 ppm (for *threo*), whereas the $C_\beta$–$H_\beta$ cross-signals were observed at $\delta_C/\delta_H$ 78.96/4.86 and 80.64/4.57 for substructures linked to G and S units, respectively. The $C_\gamma$–$H_\gamma$ cross-signals of substructure **A** were seen at $\delta_C/\delta_H$ 62.37/3.96–4.29, whereas the *γ*-acylated *β*-ether units **A′** were identified at $\delta_C/\delta_H$ 63.60/3.90–4.26, partially overlapping with other signals. Strong signals from *β*-*β*′ substructures (**B**) were observed only in the spectrum of lignin samples from stems, with their $C_\alpha$–$H_\alpha$, $C_\beta$–$H_\beta$, and the two $C_\gamma$–$H_\gamma$ cross-signals at $\delta_C/\delta_H$ 85.35/4.71, 54.19/3.07, and 71.77/3.86 and 4.21, respectively. Phenylcoumaran (*β*-5′) substructures (**C**) were found in lignins of all samples except for leaves; their $C_\alpha$–$H_\alpha$ and $C_\beta$–$H_\beta$ cross-signals were observed at $\delta_C/\delta_H$ 87.29/5.53 and 49.80/3.78, respectively, and the $C_\gamma$–$H_\gamma$ correlation signal overlapped with other signals around $\delta_C/\delta_H$ 64.63/4.38.

The abundance of these three linkages varied among the tested tissues. Leaf lignin only had *β*-O-4′ substructures, whereas stem lignin contained all three linkages with a predominance of *β*-O-4′ units (**A** and **A′**, 76.48% of total side chains) followed by *β*-*β*′ substructures (**B**, 14.88%) and lower amounts of phenylcoumaran (*β*-5′) substructures (**C**, 8.64%). In the lignin of fruits (segment membranes and granulated juice sacs), *β*-O-4′ substructures (**A** and **A′**) were predominant with abundances between 78.76 and 87.65% and certain amounts of *β*-5′ substructures (**B**, 12.35–21.24%) were also observed; however, *β*-*β*′ substructures (**C**) were not detected.

**Analysis of Lignin Units.** The main lignin $^{13}C$–$^{1}H$ cross-signals in the aromatic region of HSQC spectra correspond to the aromatic rings of various lignin units.[11] According to our results, the three main lignin units from the monolignol metabolic pathway were clearly observed. Syringyl (**S**) units showed a prominent signal for $C_{2,6}$–$H_{2,6}$ correlation at $\delta_C/\delta_H$ 103.92/6.68, whereas guaiacyl (**G**) units displayed different cross-signals for $C_2$–$H_2$, $C_5$–$H_5$, and $C_6$–$H_6$ at $\delta_C/\delta_H$ 111.83/6.98, 117.13/7.01, and 120.06/6.93, respectively. In addition, signals corresponding to $C_2$–$H_2$ and $C_6$–$H_6$ cross-signals of $C_\alpha$-oxidized G units (**G′**) at $\delta_C/\delta_H$ 112.11/7.16 and 123.10/

7.06, respectively, were observed. Despite the weak signals of *p*-hydroxyphenyl (**H**) units, we were able to verify the structures using heteronuclear multiple-bond correlation (HMBC) and heteronuclear single-quantum coherence–total correlation spectroscopy (HSQC-TOCSY) NMR (data not shown). Finally, the cross-signals at $\delta_C/\delta_H$ 121.6/6.97 and 130.50/7.24 of $C_{3,5}-H_{3,5}$ and $C_{2,6}-H_{2,6}$ were assigned to **H** units, respectively. The $^{13}C-^{1}H$ cross-signals at $\delta_C/\delta_H$ 126.63/7.16, 128.34/7.22, and 129.54/7.22 could not be clearly identitied. The chemical shifts and HMBC and HSQC-TOCSY data appeared to suggest a phenyl connected to alkyl chains (**X**) as a potential candidate structure. The three cross-signals were assigned to $C_4-H_4$, $C_{2,6}-H_{2,6}$, and $C_{3,5}-H_{3,5}$ of the **X** structure, respectively. The **X** structure was none of the three basic lignin units and was therefore excluded from abundance calculations.

The composition of **S**, **G**, and **H** units presented big differences among tissues. The lignin of leaves was predominantly composed of **H** (55.81%) and **S** (44.19%) units, whereas that of stems contained all three units with a large amount of **S** units (58.57%), followed by a lower amount of **G** units (38.73%) and traces of **H** units (2.7%). The **G** units were predominant in the lignin from segment membranes and granulated juice sacs, with the abundances of 92.45 and 91.13–96.82%, respectively. Of note, **S** and **H** units were not detected

in the lignin from segment membranes and HR, respectively, and barely observed in other tissues. The **G**/**S** ratio was high in the lignin from granulated juice sacs but varied among cultivars: ratios of 30.45, 18.19, and 66.94% were obtained for HR, GX, and SH, respectively.

## DISCUSSION

Because lignin metabolism is closely associated with the juice sac granulation of pummelo fruits, it deserves careful attention and thorough analysis. To our knowledge, no study concerning lignin metabolism in juice sac granulation has been published. Therefore, it is of particular importance to carry out studies that reveal the mechanisms underlying juice sac granulation.

Although MWL is a common method used in lignin extraction, it was not adopted in this research due to its low yield, modifications during milling, and potential "contaminating" compounds such as lignin-linked carbohydrates (LLC).[11,16] The improved organic solvent extraction method used in this work was suitable for the isolation of lignin from pummelo fruits: the resulting products were relatively pure, and yields were high enough for various analyses. According to the NMR results, the signals of LLC linkages and other carbohydrates were not detected, unlike data obtained after MWL extraction, in which lignin signals are often overlapping with those of carbohydrates.[11,15,26,30] Without the overlapping carbohydrate signals, we were able to distinguish the various

types of lignin structures and determine the lignin composition accurately. As numerous lignin isolation methods have focused mainly on plant samples, especially woody plants that contain high levels of lignins,[17,22,24,34−36] the method described here might be useful for studies assessing lignin from plant materials with relatively low lignin levels. In addition, as an aromatic polymer, lignin has a strong ultraviolet absorption; the shape and absorption coefficient of the peak are determined by the type and content of lignin units and its functional groups.[13,28,37] Although different lignin contents were obtained for the tested tissues, the ultraviolet absorption data have provided useful information for the characterization of lignins in various tissues. Indeed, the different absorption peaks among tissues might indicate the distinct lignin types that they contain. However, for a given tissue, the similar lignin absorption peaks for different cultivars might indicate similar lignin composition. These findings were consistent with the HSQC NMR data.

As expected, the $\beta$-O-4′ linkage (**A**) was the most frequent interunit linkage in our samples. This linkage is the easiest to chemically cleave compared with other bonds.[9] According to previous papers,[9,11] the relative abundances of different interunit linkages depend largely on changes in monolignol availability during the polymerization process of lignin. Lignins composed mainly of **G** units contain more $\beta$-5′ linkages (**C**) than those made of **S** units, which show an abundance of $\beta$-$\beta$′ linkages (**B**). This view is in line with our results. As **G** units increased in the lignin samples from leaves, stems, to segment membranes and juice sacs, the $\beta$-5′ linkages (**C**) increased despite the variations observed in juice sac samples from different cultivars. Meanwhile, $\beta$-$\beta$′ linkages (**B**) were detected only in lignin samples from stems, in which the **S** units were more abundant than in other tissues. In addition, the **G**/**S** ratio was found to reflect the degree and nature of polymeric cross-linking. The high **G** content is known to yield more highly cross-linked lignins characterized by a great proportion of biphenyls and other carbon−carbon bonds, whereas **S** units are typically linked by more labile ether bonds. Therefore, **G**-rich lignins depolymerize with more difficulty compared with those rich in **S** units.[38,39] In addition, plant cell walls rich in guaiacyl lignins thicken more rapidly than those rich in syringyl lignins.[40] The high **G**/**S** ratio obtained in the lignin from granulated juice sacs indicated that the specific lignin accumulated may be tightly integrated and not easily degradable; in addition, the cell walls in granulated juice sacs may thicken more quickly. Other linkages and units reported in previous studies[16,31,33,35,41−43] were not detected in our samples; conversely, certain linkages and units found here have not been detected by other groups. This might be due to the insufficient time for NMR procedures and/or their low abundances in the tested tissues.

The cause of lignin formation and accumulation in juice sac granulation is unknown. According to previous studies, lignin deposition not only follows a developmental process but can also be triggered by several biotic and abiotic stresses.[5] As shown above, the lignin deposited in granulated juice sacs was different from that present in other tissues. However, the composition of lignin linkages and interunits did not change significantly among cultivars. This observation suggests a similar mechanism for juice sac granulation among cultivars. The particularly high **G**/**S** ratio of the lignin in SH showed that the lignified juice sacs in this cultivar were stiffer than those in GX and HR; therefore, the juice sac granulation occurring in SH might be more severe. Consequently, cultivar SH could be used as an important material for assessing juice sac granulation. Besides, the **G**/**S** ratio of the lignin in GX was much lower than those obtained for HR and SH, which had darker fruits (Figure 1). This suggests that juice sac granulation might be associated with fruit pigmentation. In addition, the extremely high abundances of **G** units in the lignin of

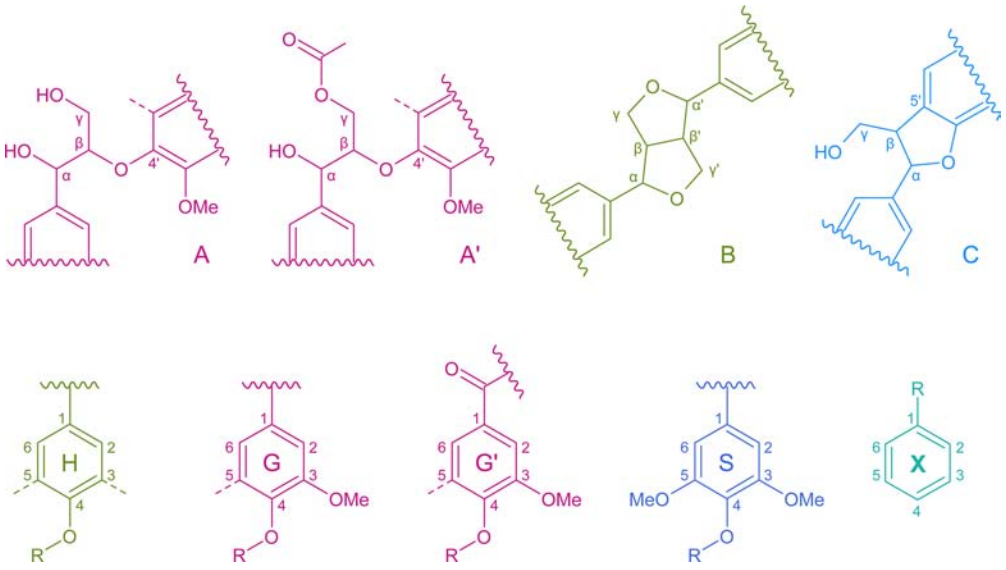

**Figure 5.** Main structures identified in Figures 3 and 4: (**A**) $\beta$-O-4′ linkages; (**A′**) $\gamma$-acetylated $\beta$-O-4′ substructures; (**B**) resinol substructures formed by $\beta$-$\beta'$/$\alpha$-O-$\gamma'$/$\gamma$-O-$\alpha'$ linkages; (**C**) phenylcoumaran substructures formed by $\beta$-5′/$\alpha$-O-4′ linkages; (**H**) *p*-hydroxyphenyl unit; (**G**) guaiacyl unit; (**G′**) $\alpha$-oxidized guaiacyl unit; (**S**) syringyl unit; (**X**) phenyl connected to alkyl chains.

granulated juice sacs indicated that lignins might have polymerized mainly from coniferyl alcohol. No evidence of factors inducing lignin formation was obtained. We propose that regulators or triggers that participate in the synthesis of **G** units might be the key factors for abnormal lignin accumulation in granulated juice sacs. This hypothesis remains to be tested in subsequent studies.

In this study, we established a method to isolate lignins from pummelo fruits. The lignin isolated from leaves, stems, and segment membranes of HR were compared with those from granulated juice sacs of HR, GX, and SH. To our knowledge, this represents the first report describing the specificity of lignins in granulated juice sacs and the possible metabolic pathway for lignin accumulation in pummelo fruits. Our results provide a new insight for further investigations of the mechanism of juice sac granulation in citrus fruits.

humans. The present study investigated effects of natural product EGCG on photodegradation of CTL in aqueous solutions and photodegradation pathways and mechanisms.

## 2. MATERIALS AND METHODS

**2.1. Chemicals and Reagents.** All chemicals and reagents were used as received. Chlorothalonil (99.1%), CTL−OH (99%), EGCG (98%), and *N*,*N*-dimethyl-*p*-nitrosoaniline (PNDA, 98%) were purchased from J&K Chemical Ltd. (Shanghai, China). Acetonitrile (Assay ⩾99.9%, HPLC/Spectro) and methanol (Assay ⩾99.9%, HPLC/Spectro) were purchased from Tedia Co. (Fairfield, USA).

**2.2. Photodegradation Experiments.** CTL standard stock solution was 1.0 g/L (3.76 mmol/L) in acetonitrile. To determine the effect of EGCG on CTL photodegradation in aqueous solution, CTL standard stock solution was transferred into 100 mL flasks followed by addition of EGCG aqueous solution at a mole to mole ratio (CTL: EGCG) of 1:0.6, 1:2.9, 1:5.8, 1:11.6, 1:29.0, and 1:58.1 (CTL is 0.00376 mmol/L). The mixture was then diluted with double-distilled water and subjected to brief ultrasonication. An aliquot of a 10 mL reaction solution of CTL and EGCG was transferred to a quartz cuvette, which was covered with a stopper, and placed under different light sources for photodegradation experiments. The light intensity was 10000−11000 lx for a high-pressure mercury lamp (HPML) (emission line spectrum at 365 nm) and 100000−120000 lx for direct sunlight (N31°52′, E117°17′). The distance between the quartz tube and the HPML was 15 cm. The temperature of the reaction system was maintained at 25 ± 1 °C except for the sunlight treatment which temperatures varied between 25 and 30 °C. A rotary water bath was used to maintain the temperature for the mercury lamp illumination, and the quartz tube was tilted at a 30° angle with the ground to face the sun directly.

Paddy, reservoir, and pond waters were used to determine the effect of EGCG on CTL photodegradation in natural water. The paddy water had turbidity 1.8 FTU, conductivity 0.29 ms/cm, pH 7.42, hardness 264 mg/L, DO 4 mg/L, COD 342 mg/L, $BOD_5$ 2.4 mg/L, TOC 15.08 mg/L, $F^{-1}$ 1.49 mg/L, $Cl^{1-}$ 46.4 mg/L, $NO_2^{-1}$ 0.59 mg/L, $SO_4^{2-}$ 75.98 mg/L. The reservoir water had turbidity 1.4 FTU, conductivity 0.15 ms/cm, pH 7.09, hardness 124 mg/L, DO 15.2 mg/L, COD 8 mg/L, $BOD_5$ 6.4 mg/L, TOC 9.62 mg/L, $F^{-1}$ 0.49 mg/L, $Cl^{1-}$ 14.61 mg/L, $NO_2^{-1}$ 0.53 mg/L, $SO_4^{2-}$ 27.99 mg/L. The pond water had turbidity 2.3 FTU, conductivity 0.32 ms/cm, pH 7.38, hardness 140 mg/L, DO 4.8 mg/L, COD 72 mg/L, $BOD_5$ 2.4 mg/L, TOC 27.82 mg/L, $F^{-1}$ 1.15 mg/L, $Cl^{1-}$ 52.1 mg/L, $NO_2^{-1}$ 0.57 mg/L, $SO_4^{2-}$ 72.54 mg/L. An aliquot of a 10 mL reaction solution of CTL and EGCG (CTL: EGCG of 1:2.9, CTL is 0.00376 mmol/L) was transferred to a quartz cuvette, which was covered with a stopper, and placed under sunlight for photodegradation experiments. The quartz tube was tilted at a 30° angle with the ground to face the sun directly. The light intensity was 82000−88000 lx for direct sunlight (N31°52′, E117°17′), and the temperature of the water solution varied between 40 and 45 °C.

**2.3. Analysis of CTL and Chloride Ion in Photolysis Mixtures.** An appropriate amount of CTL standard stock solution was transferred to a 100 mL volumetric flask, and EGCG was added at a mole to mole ratio of 1:5.8 (CTL is 0.00188 mmol/L). The mixture solution was diluted with double-distilled water and subjected to brief ultrasonication. Controls contained no EGCG. Twenty mL of the mixture was transferred to a quartz tube with a stopper and exposed to HPML. Afterward, samples were taken at different times to measure the concentrations of CTL and chloride ion. A dark control was the flasks completely covered with aluminum foil, while the other conditions remained the same as the treatments. The samples were taken at different time intervals, and each treatment was repeated twice.

**2.4. Detection of Hydroxyl Free Radicals (•OH).** PNDA has a yellow colored sensitive absorption band at 440 nm, and its adsorption decreases when it is reacted with •OH.[15] The reduction of PNDA by •OH thus reflects the amount of •OH it captures. PNDA was used as the •OH scavenger to indicate the changes in the amount of •OH generated by $H_2O_2$ in aqueous solutions under the HPML irradiation. PNDA standard stock solution was transferred to a 100 mL flask, followed by addition of EGCG and $H_2O_2$ at a mole ratio of 1:1.64:1324 and 1:3.28:1324, respectively. The mixture solution was diluted with double-distilled water and subjected to ultrasonic solubilization. A control was prepared without adding EGCG. The reaction solution (10 mL) was transferred to a quartz tube with a stopper and placed under a HPML for the illumination treatment. Samples were taken at different time intervals to measure absorbance at 440 nm using a UV spectrophotometer (UV-1800, Shimadzu Corp.). The results were used to calculate the residual concentration of PNDA at each time interval to reflect •OH changes.

**2.5. Analysis of CTL, CTL−OH, and EGCG.** CTL was analyzed on an Agilent 1200 HPLC system equipped with an Agilent HC-C18 column (4.6 mm × 250 mm, 5 μm) at a detection wavelength of 236 nm (Agilent Technologies, USA). The mobile phase was 80% aqueous acetonitrile at a flow rate of 1.0 mL/min. The column temperature was 30 °C. The injection volume was 10 μL. The limit of detection (LOD) for CTL was 0.01 mg/L.

The HPLC conditions for CTL−OH and EGCG were the same as CTL except the following differences: CTL−OH, detection at 248 nm, acetonitrile/0.5% phosphoric acid mobile phase (60:40 v/v), and injection volume of 20 μL. EGCG, detection at 280 nm, acetonitrile/0.1% citric acid mobile phase (20:80 v/v), and injection volume of 20 μL. The LOD for CTL−OH and EGCG was 0.01 and 0.05 mg/L, respectively.

**2.6. Analysis of Photolytic Products of CTL and Photopolymerization Products of EGCG.** Photolytic products of CTL and photopolymerization products of EGCG were analyzed on an Waters Xevo TQ MS ultra performance liquid chromatograph triple quadrupole tandem mass spectrometer (UPLC-MS/MS; Waters, USA) with an Acquity BEH $C_{18}$ column (1.7 μm × 2.1 mm × 100 mm). The mobile phases were a mixture of water, methanol, and formic acid (98:2:0.1 v/v/v, A) and methanol and formic acid (100:0.1 v/v, B). The gradient elution program was 0−0.25 min 90% A+10% B, 0.25−6 min 0% A+100% B, 6−11 min 0% A+100% B, 11−12 min 90% A+10% B, and 12−15 min 90% A+10% B. The flow rate was 0.35 mL/min. The column temperature was 40 °C. The MS was operated at electrospray ionization (ESI) mode with simultaneous detection of positive and negative ions, cone voltage of 30 V, mass range of 150−1000 ($m/z$), ion source temperature of 150 °C, capillary voltage of 1.5 kV, desolvation gas flow of 800 L/h ($N_2$), and desolvation temperature of 400 °C.

**2.7. Analysis of Chloride Ion ($Cl^-$).** Chloride ion was analyzed on a Dionex ICS 1100 ion chromatograph system equipped with an isocratic pump, an AS-DV automatic injector, a Dionex ASRS-300 suppressor, and a DS6 heated conductivity cell. A mixture of 4.5 mM $Na_2CO_3$ and 0.8 mM $NaHCO_3$ aqueous solution was used as mobile phase at a constant flow rate of 0.5 mL/min. An IonPac AG23 (50 mm × 4 mm) guard column and an IonPac AS23 (250 mm × 4 mm) analytical column (Dionex, Sunnyvale, CA, USA) were employed for separation of target ions. The LOD for $Cl^-$ was 0.2 μg/L.

**2.8. Calculation Methods.** Photodegradation rate was calculated with eq 1

$$\text{photodegradation rate}\ (\%) = [(a - b)/a] \times 100 \quad (1)$$

where $a$ was the residual concentration of CTL in the dark control, and $b$ was the residual concentration of CTL in the light treatment.

Photodegradation half-life ($T_{1/2}$) was calculated with eq 2

$$T_{1/2} = \ln 2/k \quad (2)$$

where $k$ was the photodegradation rate constant and was calculated with eq 3

$$C_t = C_0 \cdot e^{-kt} \quad (3)$$

where $C_0$ and $C_t$ were residual concentrations at time zero and time $t$ after the light treatment, respectively.

Photosensitization efficiency was calculated with eq 4

$$\text{photosensitization efficiency (\%)} = [(k_1 - k_0)/k_0] \times 100 \quad (4)$$

where $k_1$ was the reaction rate constant of CTL with EGCG, and $k_0$ was the reaction rate constant of CTL without EGCG.

## 3. RESULTS AND DISCUSSION

**3.1. Photosensitization Effects of EGCG on Chlorothalonil Degradation in Water.** The photolysis rate constant of CTL without EGCG under HPML illumination (0.0187 $min^{-1}$) was 1.6-fold greater than that (0.0117 $min^{-1}$) under sunlight irradiation (Table 1). The maximum absorption wavelength of CTL was 233 nm. The HPML may contain shortwave light that could be adsorbed by chlorothalonil to facilitate its photodegradation, although the maximum emission spectrum wavelength of HPML was 365 nm.[12] However, sunlight consisted primarily of visible light,[16] consequently, CTL was degraded more slowly than that under HPML illumination. Ferrioxalate is a visible light-responsive photocatalyst. Ferrioxalate/$H_2O_2$ could photosensitize degradation of chlorothalonil in aqueous solution by solar irradiation.[17]

EGCG strongly photosensitized CTL photodegradation under both sunlight and HPML light. The photosensitization efficiency under sunlight was much greater than that under HPML illumination. As the concentrations of EGCG increased, the photosensitization efficiency also increased. The rate constant increased 4-fold under HPML illumination at a molar ratio of CTL to EGCG of 1:11.6, whereas it increased approximately 12-fold under sunlight at a molar ratio of CTL to EGCG of 1:29.0. A maximum rate constant occurred at a ratio of CTL:EGCG 1:11.6 and 1:29.0 under HPML illumination and sunlight irradiation, respectively (Table 1). When the concentration of EGCG further increased, the rate constants decreased. It is noteworthy that EGCG can readily undergo oxidative polymerization and form polymers under irradiation.[13,18] In general, polymers could block light and slowdown

photodegradation. Therefore, polymers formed at high concentrations of EGCG may partially prevent CTL photodegradation.

**3.2. Mechanism of Photosensitization Effects of EGCG on Chlorothalonil Degradation.** To investigate the photosensitization mechanism of EGCG on CTL degradation, EGCG concentrations under the two light sources irradiation were analyzed (Table 2). The residual concentrations of EGCG gradually declined as irradiation time increased (Table 2), which is probably due to oxidative polymerization of EGCG.[13]

Concentrations of $^{\bullet}OH$ in natural waters are approximately $1.5 \times 10^{-18}$–$5 \times 10^{-16}$ mol/L.[19] Hydroxyl free radicals ($^{\bullet}OH$) can degrade organics via free radical reactions. To further confirm the reduction ability of EGCG, PNDA was used as a free radical trapping agent to detect $^{\bullet}OH$. The residual concentrations of PNDA decreased apparently when $H_2O_2$ was added, indicating generation of $^{\bullet}OH$ from $H_2O_2$ (Table 3). However, when EGCG was added into the mixture of PNDA and $H_2O_2$, the residual concentrations of PNDA did not change, suggesting that EGCG quenched $^{\bullet}OH$. The results indicate EGCG photosensitized reductive photolysis of CTL rather than photooxidation by $^{\bullet}OH$ free radicals.

**3.3. Effects of EGCG on CTL Photodegradation Pathways and Minimizing Toxic Metabolite Formation.** Concentrations of both CTL and chloride ion in the reaction mixture were monitored to further confirm the role of EGCG on CTL photodegradation through reductive dechlorination. Upon illumination for 120 min under HPML, 65% of CTL (5

mg/L) was degraded, which was $2.5 \times 10^{-4}$ mmol of CTL (Figure 1), while $5.8 \times 10^{-4}$ mmol of $Cl^-$ ion was detected in this solution. When EGCG was added, 92% of CTL was degraded, which was $3.5 \times 10^{-4}$ mmol of CTL, while $10.3 \times 10^{-4}$ mmol of $Cl^-$ ion was detected, suggesting enhanced dechlorination of CTL after EGCG addition. The apparent increase in $Cl^-$ ion production during CTL photodegradation in the presence of EGCG indicated the photosensitization effect of EGCG on CTL degradation. It is interesting that EGCG promoted the reductive dechlorination of CTL.

The HPLC chromatograms of CTL in the presence of EGCG and without EGCG in the dark and under HPML for 60 min were shown in Figure 2. CTL and CTL−OH were identified by comparison of their retention times and mass spectra with those of their corresponding standards. The other two degradation products shown in Figure 2 were tentatively identified according to their retention times and mass spectra. The one having $m/z$ ($ESI^-$) 195.75, 197.52, and 199.59 with a relative isotope abundance of 9:6:1 may be the molecular ion ($M^+$) of dichloride-1,3-isophthalic nitrile. The peak showing $m/z$ ($ESI^-$) 160.73, 162.77 is possibly $[M-H]^+$ of dichloride-1,3-isophthalic nitrile ($[M-H]^+$, 161.00). CTL−OH ($[M-H]^+$, 245.92) gave $m/z$ ($ESI^-$) 244.82, 246.73, and 248.77 with a relative isotope abundance of 1:1:0.3. The results indicated that CTL mainly underwent step-wide photoreductive dechlorination, and EGCG promoted the dechlorination of CTL.

CTL−OH is one of the main metabolites of CTL photodegradation.[19] Effects of EGCG on the production of CTL−OH were thus studied. The results showed that the concentrations of CTL−OH increased as the illumination time increased to 90 min (Table 4). However, under the same conditions, no CTL−OH was detected in the reaction solution when EGCG was added at a level of 20 mg/L (Figure 2). Chlorinated *m*-dicyanobenzene instead of CTL−OH was produced from CTL photodegradation. EGCG is a polyphenol and a strong antioxidant which can quench free radical reactions[18] in the process of EGCG-catalyzed CTL photodegradation. EGCG not only promoted the reductive photodegradation of CTL but also reduced CTL−OH formation. CTL−OH is greater than 60-fold more toxic than CTL.[20] We concluded that EGCG not only significantly enhances the CTL photodegradation rate but also alters the photodegradation pathways, avoiding the production of the highly toxic CTL−OH. Therefore, EGCG showed a high potential as a natural photosensitizer, which could be of importance in aquatic pollution management.

**3.4. Effects of EGCG on CTL Photodegradation in Nature Water.** Under the sunlight irradiation, EGCG significantly photosensitized CTL photolysis in the three different natural waters. The photodegradation half-lives of CTL in the reservoir, pond, and paddy waters were 19.7, 27.0, and 16.5 min, respectively, while they were 16.2, 15.8, and 13.6 min when EGCG was added (Table 5). We found that EGCG significantly photosensitized CTL degradation in natural waters under sunlight. It indicates that EGCG may be useful in water treatment for cleaning up CTL agricultural pollution via photodegradation. The results warrant further assessments in economic aspects and potential impacts of EGCG on the environment.

plasma.[22,23] The ionization efficiency possibly differs even between the respective time-course plasma samples in which the concentrations of Hyp-containing peptides dramatically vary after the oral ingestion of gelation hydrolysate.

To ensure the quantitative accuracy of MS analysis, many studies have used stable isotope-labeled internal standards for quantification of bioactive peptides in plasma.[24−28] The labeled internal standards are identical to the target analytes in all respects except for the mass and thus can compensate for the matrix effects in MS analysis. In general, stable isotopically heavy internal standard peptides are provided commercially or are synthesized by using labeled amino acids. However, labeled Hyp-containing peptides and even labeled Hyp are not commercially available. We have to custom-synthesize the internal standards of Hyp-containing peptides one by one with labeling on other constituent peptide amino acids.

Recently, we developed a novel tool for highly accurate collagen analyses using LC-MS, including quantification of type-specific collagen, total collagen, and collagen post-translational modifications.[29] We produced a stable isotope-labeled collagen named "SI-collagen" in the culture of human embryonic lung (HEL) fibroblasts, which were metabolically labeled with stable isotopically heavy Pro, Lys, and Arg. By mixing SI-collagen into collagen samples as an internal standard, any errors due to downstream experimental procedures and ionization efficiency changes in MS can be eliminated. Furthermore, we showed that the acid hydrolysate of SI-collagen can be used as internal standards of post-translationally modified amino acids, such as 4-Hyp. In this study, we aimed to expand the applicability of SI-collagen to quantification of the Hyp-containing peptides in blood by preparing internal standards of those analytes. Relatively long peptides (four or more amino acids long) can be generated from collagen/gelatin using a single protease,[30,31] and Gly-X-Y type tripeptides are also available after collagenase digestion.[32] However, it was difficult to comprehensively generate various types of Hyp-containing di- and tripeptides. To achieve this objective, we examined the digestion using trypsin/chymotrypsin and dialyzed plasma by mimicking the protein degradation pathways in the body. The serial digestion allowed efficient generation of all the Hyp-containing peptides identified in blood. Using our method with the digest of SI-collagen (SI-digest) as an internal standard mixture, plasma concentrations of Hyp and 13 Hyp-containing peptides were simultaneously quantified by LC-MS with high accuracy and reproducibility.

## MATERIALS AND METHODS

**Chemicals.** SILAC DMEM, dialyzed FBS, $^{13}C_6$-Lys, and $^{13}C_6{}^{15}N_4$-Arg were purchased from Thermo Scientific (Hudson, NH, USA). Pepsin−agarose, *trans*-4-hydroxy-L-proline, heparin sodium salt, and Dulbecco's phosphate-buffered saline (DPBS) with calcium chloride and magnesium chloride were purchased from Sigma-Aldrich (St. Louis, MO, USA). L-Ascorbic acid phosphate magnesium salt *n*-hydrate and ammonium bicarbonate were purchased from Wako Chemicals (Osaka, Japan), and trypsin and chymotrypsin were purchased from Promega (Madison, WI, USA). $^{13}C_5{}^{15}N_1$-Pro was purchased from Cambridge Isotope Laboratories (Andover, MA, USA), and PicoTag sample tubes were purchased from Waters (Milford, MA, USA). Pro-Hyp, Hyp-Gly, and Gly-Pro-Hyp were purchased from Bachem (Bubendorf, Switzerland), and other synthetic peptides were purchased from Anygen (Kwangju, Korea). All other chemicals were purchased from Sigma-Aldrich. Pepsin-solubilized type I collagen was prepared from bovine skin as described previously.[29]

**Preparation of SI-Collagen.** SI-collagen was prepared from the culture of HEL cells as reported previously.[29] In brief, HEL cells were labeled using SILAC DMEM supplemented with 0.5% dialyzed FBS, 100 mg/L $^{13}C_6$-Lys, 100 mg/L $^{13}C_6{}^{15}N_4$-Arg, 200 mg/L $^{13}C_5{}^{15}N_1$-Pro, and 200 μM L-ascorbic acid phosphate in 100 mm dishes. The culture medium from the first 3 days was discarded, and then collection and changing of the labeling medium were performed every 3 days. The collected culture medium was digested by pepsin−agarose (0.1 mg/mL in 0.1 N HCl) with gentle mixing at 4 °C for 16 h. After removal of the immobilized pepsin by centrifugation, salt precipitation was performed with 1 M NaCl for 3 h on ice. SI-collagen was precipitated by centrifugation at 16000*g* for 10 min at 4 °C and dissolved in 5 mM acetic acid after it had been extensively washed with 1 M NaCl in 0.1 N HCl and 95% ethanol.

**Preparation of Time-Course Plasma Samples after Oral Ingestion of Gelatin Hydrolysate.** The human study was performed according to the Helsinki Declaration under the control of medical doctors. The experimental protocol was approved by the experimental ethical committee of Nippi Research Institute of Biomatrix. A healthy volunteer fasted for 12 h before the experiment and was given 25 g of fish-scale gelatin hydrolysate (FCP; Nippi, Tokyo, Japan), which was prepared by enzymatic hydrolysis and has an average molecular weight of 3000−5000 Da. After oral ingestion of the gelatin hydrolysate, venous blood was collected from the cubital vein before (0 h) and 0.5, 1, 2, 4, and 6 h after the ingestion. Plasma was prepared by centrifugation of the blood at 10000*g* for 10 min at 4 °C and stored at −80 °C until used for analysis.

**Quantification of Free Hyp and Peptide-Form Hyp Using the Acid Hydrolysate of SI-Collagen.** Twenty micrograms of SI-collagen was hydrolyzed by acid to generate $^{13}C_5{}^{15}N_1$-Hyp, which was used as an internal standard of 4-Hyp. After SI-collagen solution in PicoTag sample tubes had been dried with a centrifugal evaporator CVE-3100 (EYELA, Tokyo, Japan), acid hydrolysis was performed with 6 N HCl/1% phenol at 110 °C for 20 h in the gas phase under $N_2$. The acid hydrolysate of SI-collagen was dissolved in 1000 μL of distilled water, and 10 μL of the solution was mixed into 20 μL of the human plasma samples and calibration standards of 4-Hyp. Proteins in the plasma samples were precipitated by adding 3 volumes of ethanol followed by centrifugation at 10000*g* for 10 min at 4 °C. Ten microliters of each ethanol-soluble fraction was diluted 20-fold with 0.1% formic acid/50% acetonitrile, and 5 μL of the solution was directly subjected to quantification of free Hyp. In parallel, 50 μL of the ethanol-soluble fraction was subjected to acid hydrolysis for quantification of total Hyp (sum of free Hyp and peptide-form Hyp). The acid hydrolysate was dissolved in 200 μL of 0.1% formic acid/50% acetonitrile, and 2 μL of the solution was used for the quantification. Analysis was performed on a hybrid triple-quadrupole/linear ion trap 3200 QTRAP mass spectrometer (AB Sciex, Foster City, CA, USA) equipped with an electrospray ionization source. The instrument was coupled to an Agilent 1200 series HPLC system (Agilent Technologies, Palo Alto, CA, USA). The samples were loaded onto a ZIC-HILIC column (5 μm particle size, L × i.d. 150 mm × 2.1 mm; Merck Millipore, Billerica, MA, USA) at a flow rate of 200 μL/min and separated by a binary gradient as follows: 90% solvent B (100% acetonitrile) for 5 min, linear gradient of 10−95% solvent A (0.1% formic acid) for 10 min, 95% solvent A for 5 min, and 90% solvent B for 5 min. Analyst 1.6.2 (AB Sciex) was used to perform data acquisition and analysis, and quantification of Hyp and $^{13}C_5{}^{15}N_1$-Hyp was performed in MRM mode. The MRM transitions are shown in Table S1 in the Supporting Information. Capillary voltage was 3 kV, declustering potential was 26 V, heater gas temperature was 600 °C, curtain gas was 15 psi, nebulizer gas was 80 psi, and heater gas was 80 psi. Quantitation of Hyp was calculated with or without correction using $^{13}C_5{}^{15}N_1$-Hyp. Plasma concentrations of peptide-form Hyp were estimated by subtracting the concentration of free Hyp from total Hyp as described in previous studies.[2,3]

**Preparation of SI-Digest.** Plasma was prepared from male ICR mice (Japan SLC, Shizuoka, Japan). The diet of the mice was replaced with AIN-93 M (Oriental Yeast, Tokyo, Japan) which does not contain collagen, at least a day before the procedure. Whole blood was

collected from the heart with heparin and immediately centrifuged at 10000*g* for 10 min at 4 °C. The obtained plasma was dialyzed against DPBS at 4 °C overnight to completely exclude Hyp and Hyp-containing peptides. The dialysate that contains plasma proteases was used to generate stable isotope-labeled Hyp and Hyp-containing peptides from SI-collagen in the next step.

Fifty micrograms of SI-collagen was denatured at 60 °C for 30 min and digested by trypsin and chymotrypsin (1:50 enzyme/substrate ratio) in 100 mM ammonium bicarbonate/1 mM $CaCl_2$ at 37 °C for 16 h. After the reaction, the enzymes were deactivated by heating at 100 °C for 5 min. The solution was dried using the centrifugal evaporator, and then digestion by 100 μL of the freshly prepared dialyzed plasma was performed at 37 °C for 24 h. After ethanol precipitation, the supernatant was dried using the centrifugal evaporator and reconstituted in 400 μL of distilled water. A portion of the prepared SI-digest was mixed with a standard mixture of Hyp and Hyp-containing peptides, and the absolute concentrations of respective labeled Hyp and Hyp-containing peptides were calculated from the relative peak areas of labeled analytes compared to nonlabeled ones in MRM analysis described below.

**Quantification of Hyp and Hyp-Containing Peptides Using SI-Digest.** Two microliters of SI-digest was first mixed into 10 μL of the human plasma samples and calibration mixtures of Hyp and Hyp-containing peptides. Then, the plasma samples were subjected to ethanol precipitation and subsequently dried using the centrifugal evaporator. The samples were dissolved in 50 μL of 10 mM ammonium acetate, and 10 μL of the solution was subjected to MRM analysis. The samples were loaded onto an Ascentis Express F5 HPLC column (5 μm particle size, L × i.d. 250 mm × 4.6 mm; Supelco, Bellefonte, PA, USA) at a flow rate of 400 μL/min and separated by a binary gradient as follows: 100% solvent A (10 mM ammonium acetate) for 7.5 min, linear gradient of 0−99% solvent B (100% acetonitrile) for 12.5 min, 99% solvent B for 5 min, and 100% solvent A for 5 min. Capillary voltage was 3 kV, declustering potential was 15 V, heater gas temperature was 700 °C, curtain gas was 15 psi, nebulizer gas was 80 psi, and heater gas was 80 psi. The light and heavy MRM transitions of 16 Hyp-containing peptides are shown in Table S1 in the Supporting Information. Plasma concentrations of Hyp and Hyp-containing peptides were estimated using the external calibration curves with correction using stable isotope-labeled analytes from SI-digest as internal standards. The area under the plasma concentration−time curve ($AUC_{0-6\,h}$) was calculated using the trapezoidal rule.

**Statistical Analysis.** Data are expressed as the mean ± standard deviation (SD), and coefficient of variation (CV) was calculated for $AUC_{0-6\,h}$ of Hyp and Hyp-containing peptides quantified using SI-digest. The mean values of total plasma concentrations of Hyp-containing peptides estimated by two different approaches using SI-collagen were applied for the statistical analysis. Quantitative values of peptide-form Hyp and total of Hyp-containing peptides were compared using Student's *t* test (Microsoft Excel) at each time point.

## RESULTS AND DISCUSSION

**Effect of Plasma on Quantitative Accuracy of LC-MS Analysis.** We first examined the quantitative accuracy of LC-MS analysis of plasma samples with and without an internal standard. The acid hydrolysate of SI-collagen, in which Pro, Lys, Arg, and their post-translational modifications were all labeled with stable isotope, was first mixed into the human plasma samples as an internal standard of 4-Hyp. Free Hyp was directly quantified following ethanol deproteinization of the samples. Peptide-form Hyp, which corresponds to the total of Hyp-containing peptides, was quantified by subtracting the free Hyp from total Hyp analyzed following acid hydrolysis of the deproteinized plasma. As shown in Figure 1, both free and peptide-form Hyp dramatically increased in plasma after oral ingestion of gelatin hydrolysate. The plasma concentrations reached a maximum at 1−2 h and returned to close to the initial level at 6 h after the ingestion as reported previously.[4] Although similar concentration profiles were observed between quantifications with and without the internal standard, the concentrations estimated without the internal standard were significantly lower than those estimated with the internal standard. At 1 h after the ingestion, the plasma concentrations of total Hyp and free Hyp were 150 ± 10 and 131 ± 9 nmol/mL without the internal standard, respectively, and 315 ± 15 and 219 ± 4 nmol/mL with the internal standard, respectively. Furthermore, the concentration values of peptide-form Hyp fell into the minus range at some time points without the internal standard. We confirmed that the presence of plasma critically suppressed the ionization efficiency in LC-MS both during the analysis of free and peptide-form Hyp even after the deproteinization (Figure S1 in the Supporting Information). In addition, it was hard to completely and quantitatively dissolve burnt plasma samples after acid hydrolysis. These factors could account for the underestimated results without the internal standard, especially in the case of the quantification using acid hydrolysis where the minus values of peptide-form Hyp were observed. Taken together, we concluded that the internal standard is indispensable to ensure the quantitative accuracy of LC-MS analysis of plasma samples. To achieve highly accurate quantification of respective Hyp-containing

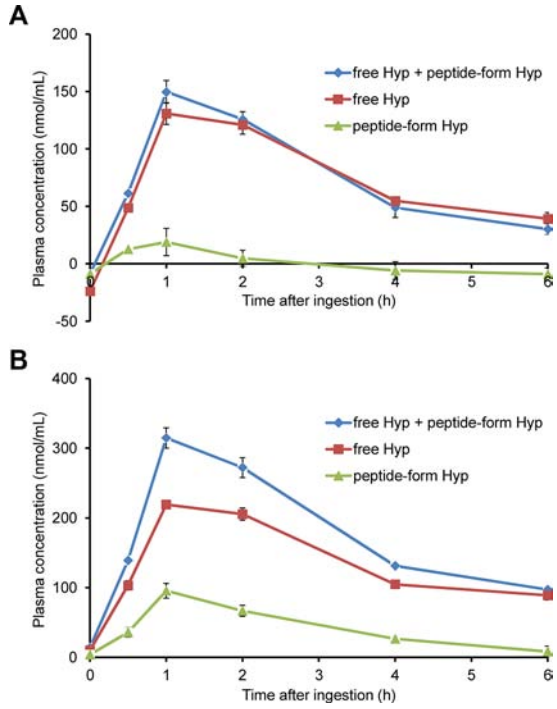

**Figure 1.** Quantification of free Hyp and peptide-form Hyp in human blood after oral ingestion of fish gelatin hydrolysate with or without the acid hydrolysate of SI-collagen. The acid hydrolysate of SI-collagen was first mixed into human plasma samples and calibration standards of 4-Hyp. After ethanol precipitation, part of each ethanol-soluble fraction of the plasma samples was directly analyzed by LC-MS in MRM mode for quantification of free Hyp, and the remaining samples were subjected to acid hydrolysis for quantification of total Hyp (sum of free Hyp and peptide-form Hyp). The plasma concentrations of Hyp were calculated using the calibration curve of 4-Hyp (A) without or (B) with $^{13}C_5{}^{15}N_1$-Hyp from the acid hydrolysate of SI-collagen as an internal standard. The data represent the mean ± SD of three separate measurements on each set of time-course samples from one human subject.

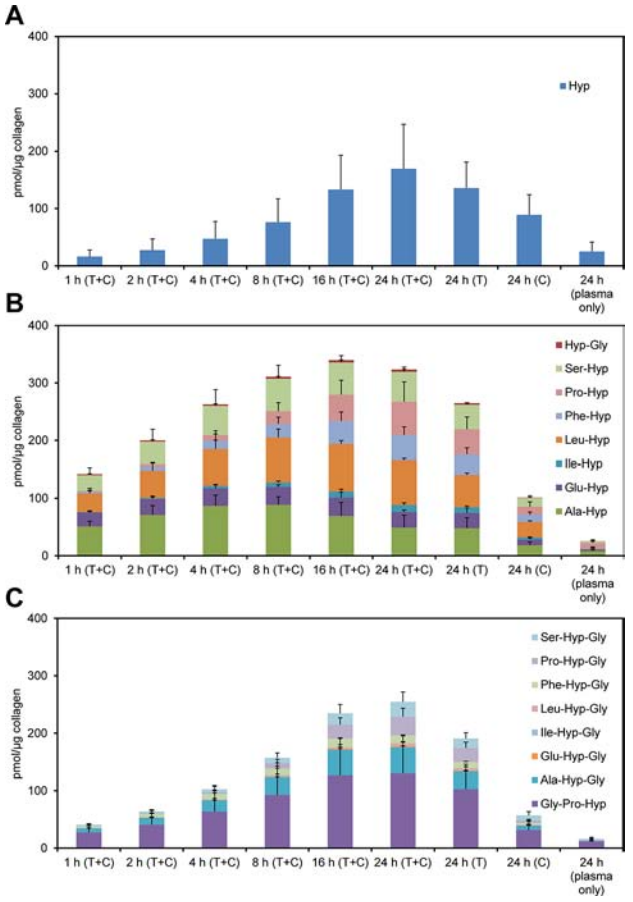

**Figure 2.** Generation of Hyp and Hyp-containing peptides by plasma proteases over various reaction times in combination with trypsin and/or chymotrypsin predigestion. Denatured bovine type I collagen was digested by trypsin and/or chymotrypsin at 37 °C for 16 h. After drying the samples, dialyzed mouse plasma was added to subsequent digestion of the collagen at 37 °C for 1−24 h. The generated (A) Hyp, (B) Hyp-containing dipeptides, and (C) Hyp-containing tripeptides were quantified by MRM analysis. The data represent the mean ± SD of three separate experiments. T indicates trypsin, and C indicates chymotrypsin.

peptides, we prepared internal standards of those peptides from SI-collagen using serial protease digestion as described in the following section.

**Generation of Hyp-Containing Peptides Using Serial Protease Digestion.** Ingested gelatin hydrolysate is first processed through gastrointestinal digestion by trypsin, chymotrypsin, and other proteases. Subsequently, the generated di- and tripeptides are absorbed from the intestine[33,34] and further digested in the blood, which contains many proteases.[35] Herein, we used trypsin/chymotrypsin and plasma proteases to generate various types of Hyp-containing peptides from collagen by mimicking the protein degradation pathways. Plasma prepared from ICR mice was dialyzed to remove non-negligible amounts of Hyp and Hyp-containing peptides, which were detected even after the diet was replaced with a non-collagen-containing one (data not shown). To estimate the generation of Hyp-containing peptides, bovine type I collagen was digested by the dialyzed plasma following trypsin and/or chymotrypsin digestion (Figure 2). Hyp-containing peptides were not detected in heat-denatured collagen, and subsequent digestion using trypsin and/or chymotrypsin did not generate

**Table 1. Content and Labeling Index of Stable Isotopically Labeled Hyp and Hyp-Containing Peptides in SI-Digest[a]**

| | mol wt | content (pmol/μg SI-collagen) | content (ng/μg SI-collagen) | labeling index (%) |
|---|---|---|---|---|

[a]Underscoring indicates a stable isotopically labeled site. Labeling index was estimated as peak areas of the labeled analytes relative to the sum of the peak areas of the labeled and nonlabeled ones from MRM analysis.

the oligopeptides (data not shown). Whereas only trace amounts of Hyp-containing peptides were detected by 24 h of plasma sole digestion, the peptide generation was dramatically enhanced by predigestion with trypsin and/or chymotrypsin, especially by the double digestion (Figure 2B,C). The enhancement of peptide generation was especially significant for Hyp-Gly, which showed relatively lower peptide generation (0.181 pmol/μg by 24 h plasma sole digestion, 0.699 pmol/μg with chymotrypsin, 2.84 pmol/μg with trypsin, and 3.95 pmol/μg with trypsin/chymotrypsin). Concomitantly with the oligopeptide generation, Hyp was also generated as an end-product (Figure 2A). Whereas almost all Hyp-containing peptides increased with increasing plasma digestion time, some peptides showed different profiles. For example, Ala-Hyp increased until 8 h of plasma digestion, and then it decreased. The amount of Ala-Hyp is considered to depend on the balance between degradation from other long peptides and further degradation to Ala and Hyp. The X-Pro (Hyp) bond is generally resistant to proteases,[36,37] and Hyp-containing peptides (Pro-Hyp and Hyp-Gly) have been reported to be highly stable in serum.[3,5] However, excess exposure to plasma proteases led to further degradation at least for some Hyp-containing peptides.

**Preparation of Internal Standards of Hyp and Hyp-Containing Peptides.** On the basis of the above data, we adopted the 24 h plasma digestion with trypsin/chymotrypsin predigestion to prepare internal standards of Hyp and Hyp-containing peptides from SI-collagen. The resultant Hyp-

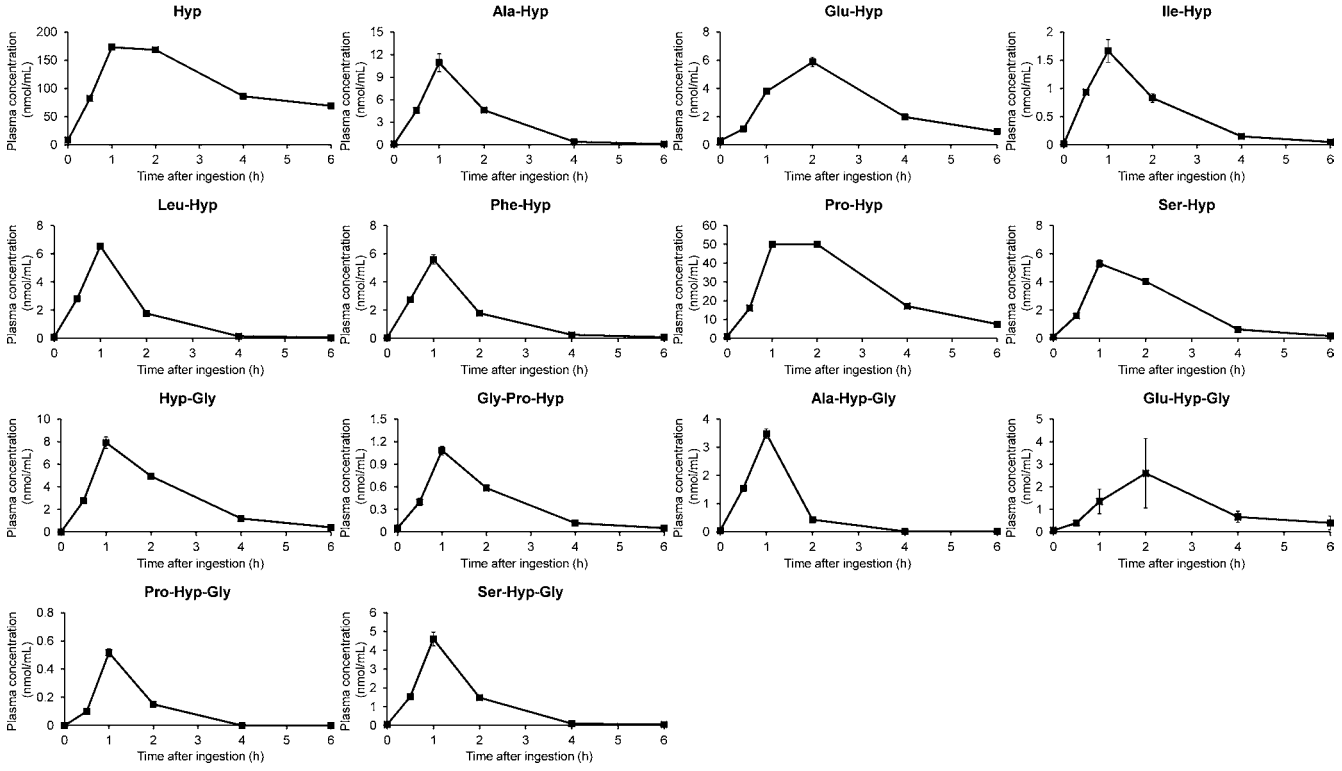

**Figure 3.** Quantification of Hyp and 13 Hyp-containing peptides in human blood after oral ingestion of fish gelatin hydrolysate using SI-digest. SI-digest was first mixed into the human plasma samples and calibration mixtures of 4-Hyp and Hyp-containing peptides. After ethanol precipitation, the supernatants were concentrated using the centrifugal evaporator and subjected to MRM analysis. The plasma concentrations of Hyp and Hyp-containing peptides were calculated using the calibration curves corrected with stable isotope-labeled internal standards of those analytes from SI-digest. The data represent the mean ± SD of three separate measurements on each set of time-course samples from one human subject.

**Table 2. $AUC_{0-6\ h}$ of Hyp and Hyp-Containing Peptides in Human Blood after Oral Ingestion of Fish Gelatin Hydrolysate**

| | $AUC_{0-6\ h}$ (nmol/mL·h) | CV (%) |
|---|---|---|
| Hyp | 668 ± 30 | 4.50 |
| Ala-Hyp | 18.3 ± 0.9 | 5.12 |
| Glu-Hyp | 17.2 ± 0.8 | 4.81 |
| Ile-Hyp | 3.32 ± 0.23 | 6.94 |
| Leu-Hyp | 9.33 ± 0.09 | 1.01 |
| Phe-Hyp | 8.85 ± 0.56 | 6.29 |
| Pro-Hyp | 163 ± 1 | 0.79 |
| Ser-Hyp | 12.3 ± 0.4 | 3.49 |
| Hyp-Gly | 17.5 ± 0.5 | 2.60 |
| Gly-Pro-Hyp | 2.18 ± 0.08 | 3.50 |
| Ala-Hyp-Gly | 4.10 ± 0.22 | 5.29 |
| Glu-Hyp-Gly | 6.86 ± 2.51 | 36.6 |
| Pro-Hyp-Gly | 0.663 ± 0.022 | 3.27 |
| Ser-Hyp-Gly | 6.70 ± 0.37 | 5.46 |

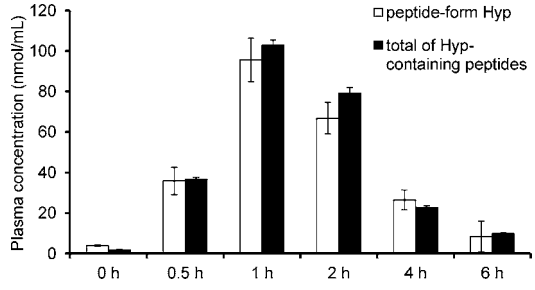

**Figure 4.** Comparison of results obtained with two different approaches using SI-collagen. The data of "peptide-form Hyp" are from Figure 1B, and the data of "total of Hyp-containing peptides" are calculated by integrating the respective values of 13 Hyp-containing peptides from Figure 3. There was no statistically significant difference between "peptide-form Hyp" and "total of Hyp-containing peptides" at each time point, except for 0 h ($p < 0.05$).

containing peptides in the protease digest of SI-collagen (SI-digest) are shown in Table 1. All of the reported Hyp-containing peptides were detected with labeling with stable isotope at Pro and Hyp. The labeling indices were extremely high (>97% for Hyp and all the peptides and >99% for peptides having two labeling sites), which enables highly accurate quantitative analysis. MRM chromatograms of the labeled Hyp and Hyp-containing peptides in the SI-digest are shown in Figure S2 in the Supporting Information. The total of the generated Hyp and Hyp-containing peptides was 10.8% (w/w) of the digested SI-collagen. Considering the Hyp content in collagen (approximately 100 residues/1000 total residues), the digestion procedures appear to efficiently generate the Hyp-containing peptides. Although the abundance of some peptides, such as Hyp-Gly, was relatively low, it was sufficient as an internal standard for LC-MS analysis. We previously confirmed that the linearity and precision of quantification using SI-collagen were excellent, ranging from 1:300 to 30:1 of the internal standard to sample peak area ratio.[29] In the following experiment, SI-digest was mixed into plasma samples appropriately so that all of the heavy to light ratios of respective Hyp-containing peptides fall within the optimum range. SI-digest prepared from SI-collagen from a 3 day culture

dx.doi.org/10.1021/jf5039597 | J. Agric. Food Chem. 2014, 62, 12096−12102

in a 100 mm dish can be used to analyze approximately 100 plasma samples even by conventional LC-MS.

**Quantitative Analysis Using SI-Digest.** To evaluate the usefulness of SI-digest as an internal standard mixture, we reanalyzed the plasma samples measured in Figure 1. The samples were first mixed with SI-digest and subjected to MRM analysis following ethanol deproteinization. As shown in Figure 3, 13 Hyp-containing peptides were detected with a wide range of plasma concentrations after the ingestion of gelatin hydrolysate. The $AUC_{0-6\ h}$ of each Hyp-containing peptide was calculated as ranging from 0.663 ± 0.022 nmol/mL·h for Pro-Hyp-Gly to 163 ± 1 nmol/mL·h for Pro-Hyp (Table 2). The $AUC_{0-6\ h}$ of Pro-Hyp was significantly higher than those of other Hyp-containing peptides, consistent with the previous observations.[3,4,21] To quantify hard-to-detect minor peptides, we concentrated the samples after ethanol precipitation. Although the procedure increases the detection limit of the analytes, it potentially induces increased matrix effects leading to impaired quantitative accuracy. By using SI-digest as the internal standard mixture, we were able to overcome the quantitative limitations and detect previously unreported Hyp-containing peptides (Glu-Hyp, Ser-Hyp, Glu-Hyp-Gly). In addition, high reproducibility of the quantification of respective Hyp-containing peptides was shown by the triplicate measurements with <7% CV (Table 2) except for Glu-Hyp-Gly, the peak intensity of which was near the detection limit.

The estimated values of Hyp-containing peptides were compared between the two different approaches using SI-collagen (Figure 4). The total concentrations of Hyp-containing peptides integrating the respective values from Figure 3 closely matched those of peptide-form Hyp from Figure 1B at each time point, which indicates the high accuracy of the two approaches using the acid hydrolysate or protease digest of SI-collagen. Furthermore, the results can be interpreted as evidence that the 13 di- or tripeptides measured in this study largely account for Hyp-containing peptides appearing in blood after the ingestion of gelation hydrolysate. On the triplicate measurements of peptide-form Hyp, there was a relatively large margin of error. Because the amount of peptide-form Hyp was calculated by subtracting free Hyp from total Hyp, the two-step approach including acid hydrolysis potentially causes quantitative errors. Conversely, the approach using SI-digest showed high reproducibility also for determining the total concentrations of Hyp-containing peptides, probably because of the simple analytical process.

In this study, SI-digest prepared by serial protease digestion of SI-collagen was demonstrated to enable highly accurate and reproducible quantification of Hyp-containing peptides in blood by LC-MS. Thirteen Hyp-containing peptides were able to be simultaneously quantified in human blood after oral ingestion of gelatin hydrolysate using this method. Moreover, we have now additionally detected Leu-Hyp-Gly and Phe-Hyp-Gly in mouse blood (data not shown). Our results in Figure 4 suggested that unidentified major Hyp-containing peptides do not exist at least in the blood analyzed in this study. However, the quantity and structure of Hyp-containing peptides in blood are reported to differ with the animal source of the ingested gelatin hydrolysate.[4] Similarly, we have observed that the quantity and structure also vary with the substrate specificity of the enzyme used to prepare the gelatin hydrolysate (data not shown). Other unidentified Hyp-containing peptides expected to have a beneficial function may still exist in blood and should be suitable targets of our method. In addition, although we have focused on peptides containing Hyp, SI-digest can be also applied to the analysis of other collagen-derived oligopeptides, such as Gly-Pro, which is reported to have an antihypertensive effect.[38]

Over the past decade, many studies have explored functional properties of the oral intake of collagen/gelatin hydrolyzed with enzyme.[39] Tracing the collagen-derived bioactive peptides in the body is important in estimating the effects of the ingestion of gelatin hydrolysate. Our method is useful for quantification of the extent of the absorption and metabolism of orally ingested gelatin hydrolysate and, thus, can facilitate the investigation of biological activity of collagen-derived peptides and the development of functionally characterized gelatin hydrolysate.

There are two types of leaf extracts: full extracts and standardized extracts. The full extracts are usually prepared with alcohol and thus contain all constituents soluble in alcohol. The standardized extracts constitute the major commercial ginkgo products and contain 6% TTLs, 24% flavonol glycosides, and trace amount of ginkgolic acid. Such extracts are prepared in a multistep process, in which some compounds are enriched (TTLs and flavonoids) while others (biflavones and ginkgolic acids) are removed. Because of the significant risk factors of the ginkgolic acids, the content of these undesirable components in standardized extracts of *G. biloba* are currently limited to <5 ppm in the European and U.S. pharmacopoeia.[17,18]

Thus, it is desirable to have a simple, sensitive, validated analytical method for the detection and quantification of each of the alkylphenols in commercial products, such as herbal medicines and dietary supplements. Numerous analytical techniques have previously been proposed for the analysis of GAs including HPLC, GC, HPTLC, ELISA, and NMR. Comprehensive reviews of the chemical analysis (including alkylphenols) of *G. biloba* leaves, extracts, and phytopharmaceuticals by van Beek critiqued the various analytical approaches for GAs up through 2009.[3,19] The major challenges for the analysis of GAs are (i) the low concentrations (<5 ppm) imposed by regulation for standardized extracts, (ii) the complex matrix of *G. biloba* plant samples and dietary supplements, (iii) the difficulties of obtaining pure, authentic standards for identification and quantification purposes, and (iv) the rigorous resolution requirements for the analysis of double bond positional isomers of the alkylphenols. Often only the total concentration of all GAs in a given sample is determined; however, the exact roles of the various isomeric GAs in the pharmacological effects of *G. biloba* have never been determined. Thus, any attempt to correlate a given pharmacological effect with a specific GA isomer will require an analytical method that allows the quantitation of all GA isomers.

Liquid chromatography is currently the analytical method of choice for GAs.[20] The major problem with HPLC techniques is the inadequate resolution of GAs differing by carbon number and unsaturation, such as C13:0 and C15:1 or C15:0 and C17:1, as well as the inability to resolve double bond positional isomers. Lee et al.[21] used column switching (heart cutting) to minimize matrix effects and improve resolution. The method was validated, and the LOD and LOQ for the C15:1 and C17:1 GAs were 10 and 40 ppb with a diode array detector. Negative mode ESI/MS/MS was used for identification of the GAs. Udrescu et al.[22,23] developed an RPLC/UV method that avoided the time-consuming solvent evaporation step involved in most HPLC analysis methods for GAs. The method involved an acidified methanol/water extraction followed by LLE with hexane (20:1) for one standardized extract of *G. biloba*. A large volume (50 $\mu$L) of the hexane was injected into the RPLC column with a very steep gradient. The method was validated, and the LOQ for GAs was 1 ppm. Again, the GAs were confirmed by $MS^2$ methods, and collision-induced fragmentation schemes were presented. Gawron-Gzella et al.[24] used HPLC to analyze several pharmaceuticals and dietary supplements for GAs. The total concentrations of GAs ranged from 2 to 8000 ppm.

Gas−liquid chromatography has been used for GAs analysis; however, these methods suffer from the need for derivatization of the alkylphenols. Wang et al.[25,26] introduced a chemothermolysis with trimethylsulfonium hydroxide or tetramethylammonium hydroxide injection system to avoid the pretreatment schemes required for other chromatographic methods. This method was used to resolve seven GAs and three cardanols including C13:0, C15:0 as well as double bond positional isomers C15:1 Δ8 and Δ10, C17:1 Δ8 and Δ12 along with one GA with two unsaturation sites, viz., C17:2. No C17:0 or C17:1 Δ10 isomers were detected. Possible reaction schemes for the electron impact fragmentation of the methylated GAs were discussed. In earlier work, Schotz[16] developed a GC/MS method for the analysis of the silyl derivatives of a standardized extract EGb 761. Five GAs, viz., C13:0, C15:0, C15:1 (Δ8 and Δ10), and C17:1 (Δ12), were identified.

In 2004, Choi et al.[27] reported an NMR method for the analysis of GAs. This spectroscopic method did not require derivatization of the GAs or calibration standards. The peaks associated with the aromatic protons in GAs were individually integrated to give the total GA concentration rather than individual components. This method, however, was not sufficiently sensitive and suffered interference problems when applied for the analysis of commercial samples.

Very recently, van Beek's group addressed the problem of the lack of pure standards of ginkgolic acids.[28] Magnetic nanoparticles were used to selectively adsorb GAs from petroleum ether extracts of ginkgo leaves. The mixed acids were subsequently desorbed with strong acid or base and isolated by prep-scale LC on a $C_8$ column. Significant quantities of eight GAs were isolated by this novel procedure.

The objectives of the present study were to develop and validate a high-resolution gas chromatographic method for the analysis of the individual isomers of C13, C15, and C17 GAs in ginkgo leaves, extracts, and commercial products. In addition, the double bond position and the concentration of each isomer will be determined. This information may improve our understanding of the GA isomer distribution in various plant parts. The accuracy of the GC method will be assessed by comparison with the accepted HPLC methods. Additionally, the veracity of the extracts in dietary supplements will be established by detection of the marker compounds for *G. biloba,* TTLs and flavonol glycosides, by UHPLC/MS analysis.

## MATERIALS AND METHODS

**Sample Information.** A total of 19 plant samples and reference standards including leaves, seeds, leaf extracts, and sarcotesta, and 21 commercial herbal dietary supplements containing extracts of *G. biloba* leaves were analyzed. The dietary supplement samples were purchased at food supermarkets, local retail pharmacies, or online resources. The detailed information for the plant samples and herbal dietary supplements are given in Tables 1 and 2, respectively. Specimens of all samples are deposited at the botanical repository of the National Center for Natural Products Research (NCNPR), University of Mississippi (documented with NCNPR accession code).

**Reagents and Standards.** Four ginkgolic acid standards, viz., C13:0, C15:0, C15:1, and C17:1, as well as the internal standard anthracene were purchased from Sigma-Aldrich (St. Louis, MO). HPLC grade methanol and methylene chloride were purchased from Fisher Scientific (Pittsburgh, PA). GC grade *n*-hexane, formic acid, and the derivatization reagent trimethylsulfonium hydroxide solution (~0.25 M in methanol, for GC derivatization) were obtained from Sigma-Aldrich.

**Sample Preparation.** The plant materials and the dietary supplements were ground and homogenized to obtain a uniform matrix. The dietary supplements were in the form of capsules or tablets. Ten capsules or tablets were weighed for each sample, and the average was taken for the weight of each capsule or tablet of the sample. About 500 mg of plant sample or equivalent amount for the dietary

supplement sample was sonicated and centrifuged three times with ca. 15 mL of a 1:1 mixture of methanol and 10% formic acid. The combined supernatant layers were extracted three times with *n*-hexane. The *n*-hexane was evaporated to dryness, and the residue was then dissolved in 250 μL of methylene chloride and 150 μL of methanol. Fifty microliters of internal standard (25.64 μg/mL) and 50 μL of trimethylsulfonium hydroxide were added to the solution. Duplicate samples were extracted, and two injections were made for each sample. The content of each ginkgolic acid was reported as a mean value of the test results.

**Chromatography Instruments and Conditions.** *GC/MS Analysis.* Gas chromatographic analysis was performed on an Agilent 7890 GC instrument equipped with an Agilent 7693 autosampler (Santa Clara, CA). A fused silica capillary column (30 m, 0.25 mm i.d.) coated with a 0.20 μm film of cross-linked (88% cyanopropyl) aryl-polysiloxane (J&W HP-88, Santa Clara, CA) was used with helium as the carrier gas at a flow rate of 1 mL/min. In a typical analysis, the oven was held for 2 min at 150 °C, then programmed at 8 °C/min to 220 °C and 3 °C/min to 250 °C, and held for 2 min. The injector temperature was kept at 260 °C. The split ratio was set to 25:1.

Mass spectrometric analysis was carried out with an Agilent 5975C mass specific detector. The instrument was operated to collect scan and selected ion monitor (SIM) data sequentially within a given run. For the scan measurements, the spectra were recorded at 70 eV from $m/z$ 40 to 500. The ions of $m/z$ 161 and $m/z$ 178 were selected in the SIM mode to monitor GAs and internal standard, respectively. Compound identification involved comparison of the spectra with the databases (Wiley and NIST) using a probability-based matching algorithm. Further identification was based on the relative retention indices (RI) compared with literature and the standard references isolated in-house or purchased from commercial sources.

The method was validated in terms of selectivity, linearity, limits of detection and quantitation, as well as intra- and interday precision and accuracy.

**Table 2. Information of Herbal Dietary Supplements Containing Extracts of *Ginkgo biloba* Leaves Provided by the Manufacture Labels**

| accession code | form | extract form | amount of extract/(capsule/tablet, mg) | average content (mg) | daily serving size | preparation in addition to *Ginkgo biloba* leaf extracts |

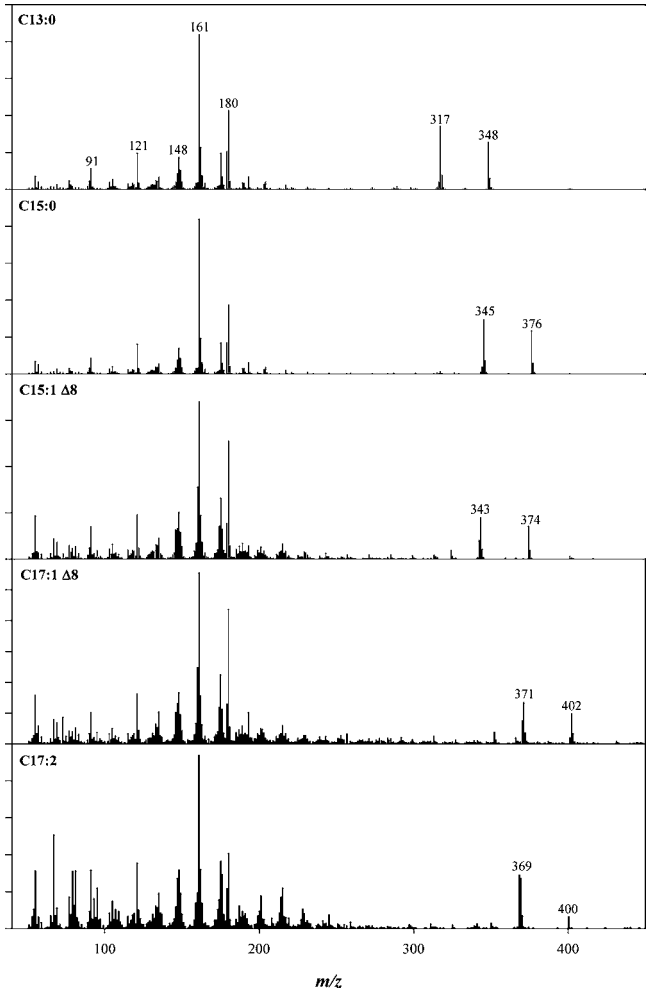

**Figure 3.** EI-MS spectra of the Ginkgolic acids.

*Validation of GC/MS Method with Standard HPLC Technique.* The HPLC system consisted of an Agilent 1290 Infinity series HPLC with a diode array detector, ALS, and thermostated column compartment (Santa Clara, CA). The LC instrument was coupled to an Agilent 6120 quadrupole mass spectrometer with an ESI interface. The column was an Agilent Rapid Resolution Zorbax SB-C8 (2.1 × 100 mm, 1.8 $\mu$m, Santa Clara, CA). The column temperature was 30 °C. The flow rate was 0.4 mL/min. The eluent was 50% acetonitrile (0.1% formic acid) programmed to 100% acetonitrile in 20 min. The ESI was scanned in a mass range from 100 to 500 amu. The fragmentor was set at 120 V; capillary voltage was 3000 V. The SIM was operated to monitor $[M - H]^-$ 319, 347, 345, and 373 for GA C13:0, C15:0, C15:1, and C17:1, respectively. The diode array detector was set to 310 nm.

*UHPLC–MS Analysis of Ginkgo Products.* A published UHPLC-MS method[29] was used for the simultaneous analysis of sesquiterpene lactones and flavonoids from various ginkgo products to confirm the presence of *G. biloba* leaf extracts in the botanical dietary supplements. This method involved the use of $[M + H]^+$ ions of five sesquiterpene lactones and three flavonoids which were observed at $m/z$ 425.2 (ginkgolide J, ginkgolide B), $m/z$ 441.2 (ginkgolide C), $m/z$ 327.3 (bilobalide), $m/z$ 409.2 (ginkgolide A), $m/z$ 303.1 (quercetin), $m/z$ 287.1 (kaempferol), and $m/z$ 317.1 (isorhamnetin). The compound identification was based on retention times and MS in comparison with standard compounds.

**Ozonolysis.** The double bond positions in the C15:1 and C17:1 standards were determined by standard ozonolysis procedures. Each individual C15:1 and C17:1 standard (1.0 mg/mL) was derivatized as described in the sample preparation section. The standard solution was dried. The residue was dissolved in 0.5 mL of methylene chloride. Ozone used for the reaction was generated using a Triozone generator and bubbled through the solution at −78 °C until a blue color was observed indicating ozone saturation. The reaction mixture was stirred for 4 h and then quenched by addition of dimethyl sulfide (200 $\mu$L). The solution allowed to warm to room temperature before analyzed by GC/MS using the method described previously.

## RESULTS AND DISCUSSION

**GC/MS Method Development and Validation.** The selected ion chromatograms (SIC) at $m/z$ 161 for a mixture of four GAs standards (A) and the plant sample 15212 (ginkgo leaves) (B), as well as the total ion chromatogram for the 15212 sample (scan from 40 to 500 amu) (C), are shown in Figure 2. The component pairs that proved difficult to resolve by HPLC, viz., C13:0/C15:1 and C15:0/C17:1, were clearly resolved. The electron impact spectra of eight analyzed GAs are shown in Figure 3. The fragment ions from the salicylic acid moieties ($m/z$ 180, 161, 148, 121, and 91) are identical for all of the ginkgolic acids. The fragment ion at $m/z$ 161 was chosen for selective ion monitoring because it (i) is generally the base peak in the mass spectrum, (ii) is common to all ginkgolic acid components, and (iii) serves as a very sensitive and specific SIM probe ion for all GAs. Possible fragmentation mechanisms different from previous literature[16,26] are given in Figure 4.

A full method validation was performed according to the ICH guidelines[30] by evaluating selectivity, linearity, limits of detection and quantitation, and intra- and interday precision and accuracy.

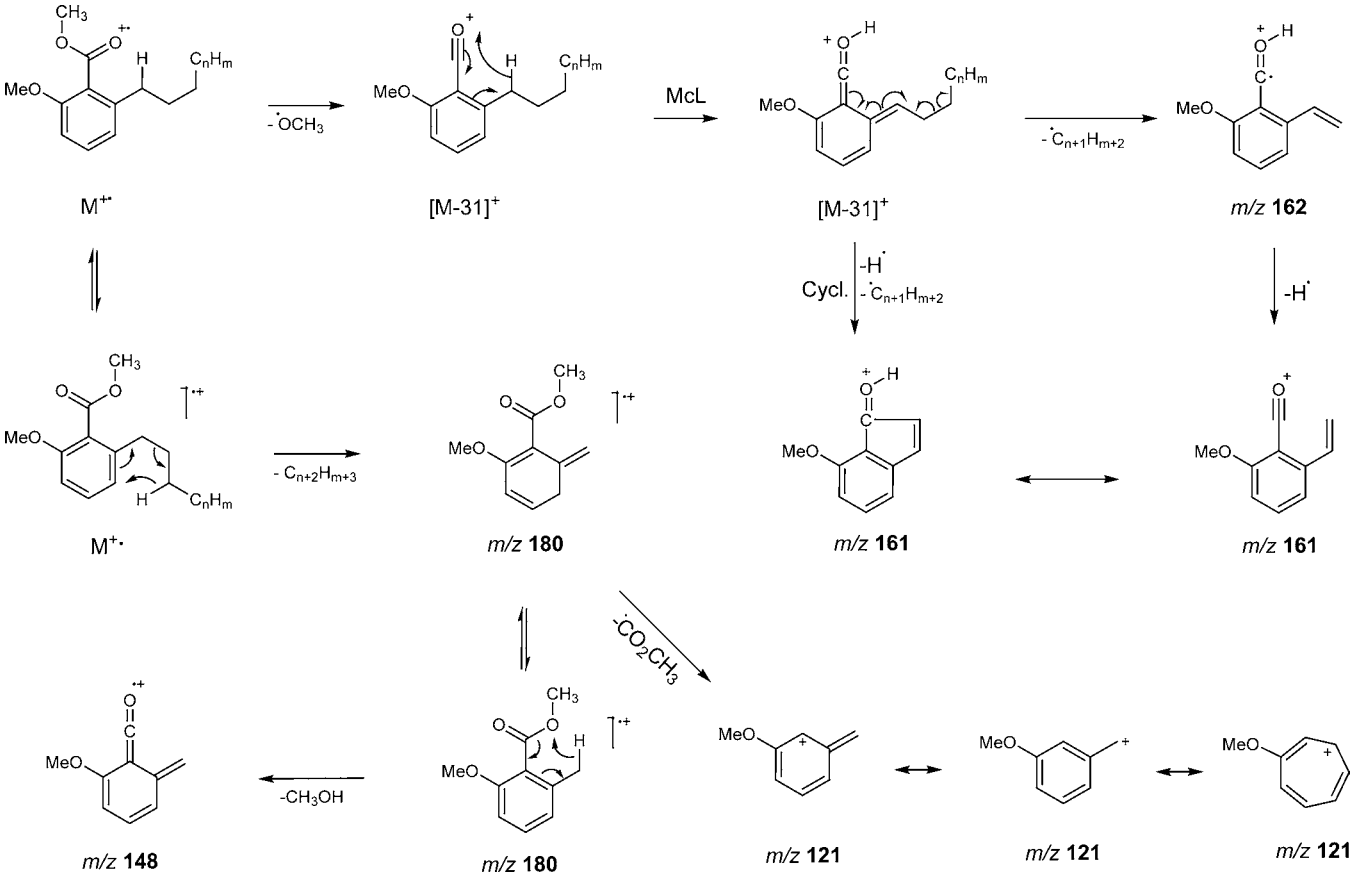

**Figure 4.** Possible EI-MS fragmentation patterns for GAs ($m = 2n + 1$ for C13:0 and C15:1 GAs. $m = 2n$ for C15:1 and C17:1 GAs). McL: McLafferty rearrangement. Cycl: Cyclization.

*Selectivity.* The quantitation analyses were carried out in selected ion monitor mode at $m/z$ 161 for all the GAs. No other components or contaminants were detected at this $m/z$ for the retention time window available for the GAs.

*Accuracy.* The accuracy of the method was determined by spiking ginkgo leaf sample (1095) with a known amount of GA standards. The plant sample was exhaustively extracted six times by following the extraction method described in the experiment section. The sample was dried and then spiked with 40.0 μg/mL C13:0, C15:1, C17:1 and 45.6 μg/mL C15:0 GA standard solutions. The samples were then extracted, derivatized with TMSH, and analyzed under optimized conditions. The percentage recoveries were determined to be 87.7%, 89.5%, 95.4%, and 89.2% for C13:0, C15:0, C15:1, and C17:1, respectively.

*Linearity.* The calibration plots were linear over the range of 5−250 μg/mL with correlation coefficients of >0.99.

*Precision.* The relative standard deviation for triplicate intraday analyses was 1.3−2.1%. The interday variation for nine analyses was 3.8%.

*Limit of Detection (LOD) and Limit of Quantification (LOQ).* The LOD was determined from the signal-to-noise ratio of 3:1 to be 0.5 μg/mL. The LOQ was determined to be 1.5 μg/mL for all of the GAs.

**Localization of the Double Bond in GA Standards.** To date, the exact roles of the various isomeric GAs in the pharmacological effects of *G. biloba* have never been determined. Thus, localization of the double bond position of ginkgolic acids in *G. biloba* is crucial for the determination of biochemical properties, as well as important in structure elucidation of the GA isomers. However, common instrument-based methods cannot elucidate the double bond position and especially clarify the ambiguity of the double bond position for C17:1 GA. To improve our understanding of the GA isomer distribution in various plant parts, ozonolysis of both the C15:1 and C17:1 standards was performed. The reaction products were examined by the same GC/MS method used to analyze the ginkgolic acid samples. All of the reaction products were esters with labile methoxy groups. The electron impact mass spectra of the GAs never contained a molecular ion peak; however, the M-31 peak was prominent in all of the product spectra. Figure 5 illustrates the possible structures of the GAs and the ozonolysis products for the C15:1 and C17:1 standards. The C15:1 standard **3** clearly showed mass peaks corresponding to the loss of methoxy for products **3a**−**c**. The aliphatic ester **3a** resulted from the degradation of the electron-rich aromatic ring of the GAs under the experimental ozonoylsis conditions. Compound **3b** represents a decarboxylated product of **3a**. This confirmed the label claim that the C15:1 standard was Δ8. The results for the C17:1 standard **4**, on the other hand, showed M-31 peaks in the EI spectra for products **4a**−**c**, i.e., the products expected for the C17:1 Δ12 isomer, not the Δ10 positional isomer. The chromatographic results implied that the double bond in C17:1 standard was Δ12 rather than Δ10 as indicated by the CAS number given on the container label.

In addition to the pentanoic acid methyl ester shown in Figure 5, the C17:1 standard also produced heptanoic and nonanoic acid methyl esters as shown in Figure 6. The relative

Ozonolysis of Ginkgolic Acids:

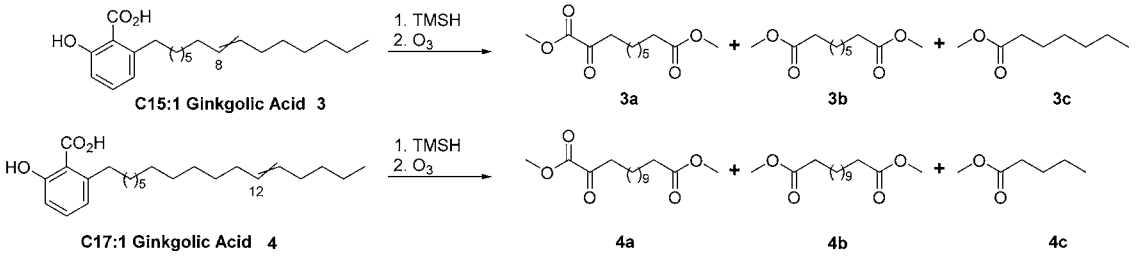

**Figure 5.** Structures of the ginkgolic acids and ozonolysis products for the C15:1 and C17:1 standards.

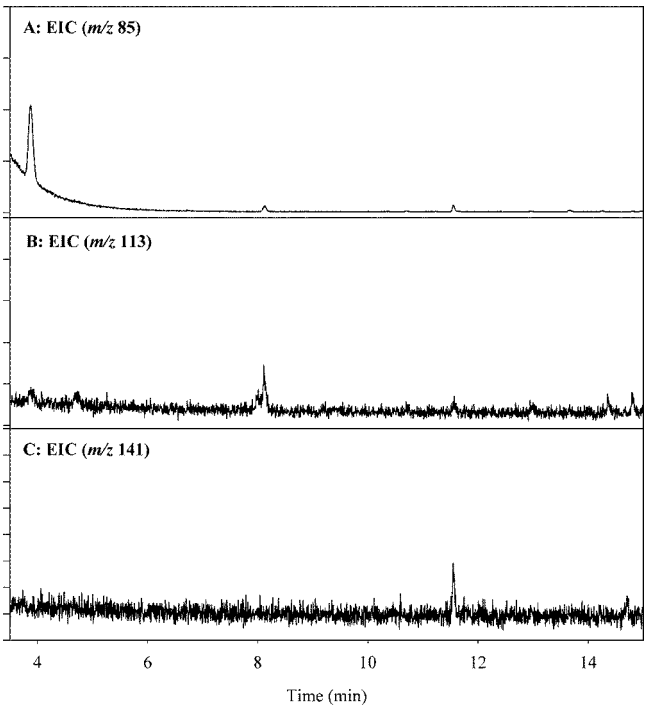

**Figure 6.** Extracted ion chromatograms [M − 31] for the ozonolysis products of the C17:1 standard. A: Pentanoic acid methyl ester. B: Heptanoic acid methyl ester. C: Nonanoic acid methyl ester.

abundance of the three esters agrees with the relative peak areas for the C17:1 isomers circled in Figure 2. Thus, the C17:1 standard was a mixture of isomers with the C17:1 Δ12 isomer accounting for more than 90% of the material. Therefore, in the analyses of plant and dietary supplements, it was assumed that the standard C17:1 contained a double bond at the C12 position (C17:1 Δ12).

**Analysis of Ginkgo Plant Samples.** The plant extracts were complex as shown in Figures 2 B and C. The major peaks with retention times less than 10 min represented methyl esters of saturated fatty acid, viz., palmitic and stearic, as well as unsaturated fatty acids, such as linolenic and linoleic. The compound eluting at ca. 13.8 min was an alkylmethyl ether of unknown structure. Another compound often detected in the plant samples was α-tocopherol with a retention time of 14 min and an $m/z$ of 444 amu. These were the only two contaminants with retention times within the 13−19 min window used for the detection of the GAs. Both contaminants were well resolved from the C13:0 GA, and neither formed an EI fragment at $m/z$ 161.

Nineteen plant samples of *G. biloba* were extracted and analyzed. The samples included seeds, sarcotesta, leaves, and dried alcoholic extracts of leaves. The samples were extracted and injected in duplicate for a total of four analyses. The results for the average analysis are given in Table 3.

The total concentration of GAs in the plant samples varied dramatically. The seed samples contained the lowest concentrations of GAs in the range from 4 to 39 ppm. The sarcotesta sample contained 143 ppm. The dried extracts were in the range of 3−47 ppm. The leaf samples displayed a large range from 42 to 534 ppm with no systematic pattern.

Prior literature results for the analysis of GAs in plant samples are ambiguous. Van Beek[3] cites values of 0.5−4.8% (5000−48 000 ppm) for *G. biloba* leaves and 28 000−53 500 ppm in sarcotesta samples in a 2009 review. Wang et al. reported total GA concentration of 42 000 and 46 000 ppm in sarcotesta samples by GLC and HPLC,[26] 10 000 ppm by GC, and 5000−18 000 ppm by HPLC.[25] On the other hand, Choi et al.[27] used an NMR technique to determine the GA concentration in a single leaf sample to be 16 ppm in agreement with 16 ppm determined by GLC. In 1996, Irie et al.[31] used HPLC methods to determine the concentrations of GAs in ginkgo leaves (17 ppm) and sarcotesta (35 ppm). ELISA techniques were also used to determine the GA concentration in *G. biloba* leaves to be in the range of 12−48 ppm.[32] A sarcotesta sample was found to have a higher concentration of ca. 128 ppm. This large disparity (12−128 000 ppm) for a single species plant is unusual and probably reflects the variations in extraction schemes and analytical techniques (GLC, HPLC, and ELISA) along with collection, production, storage, and environmental variations.

To date, gas chromatography is the only analytical technique for the determination of GAs that is capable of resolving the double bond positional isomers of the GAs. In most of the

[a]DUL: Detected under the limit of quantification. ND: Not detected. [b]Assuming the response factor for Δ10 is equivalent to that for the Δ8 standard. [c]Assuming the response factors for Δ8 and Δ10 are equivalent to that of the Δ12 standard. [d]Assuming the response factors for C17:2 and C17:1 are equivalent.

samples described in Table 3, either C15:1 Δ10 or Δ8 was the major GA component present in every type of plant sample. One interesting observation involves the ratio of the concentrations of these two C15:1 isomers, also given in Table 3. The Δ10/Δ8 ratio for all of the leaf or leaf extract samples was in the range of 1−3. Conversely, the same ratios for the seed and sarcotesta samples were in the range of 0.1−0.5 with the single exception of sample 9604. In other GC analyses, Wang et al.[25,26] found this ratio to be 1.7−1.8 for leaf samples and 0.05 for sarcosta samples. This simple test allows the distinction of samples and products derived from different plant parts. All of the dietary supplements that contained detectable amount of both Δ8 and Δ10 isomers displayed ratios between 1 and 3 indicating that the commercial products were all derived from ginkgo leaves, not seeds or sarcotesta. The C15:1 Δ8 and Δ10 isomers are the only pairs that appear consistently in all of the plant samples. The presence or absence of a single probe component cannot be used to distinguish plant parts because of the wide variation in the GA component concentrations in the ginkgo samples. Gas chromatographic methods are the only technique for the resolution and quantitation of the Δ8 and Δ10 isomers of the C15:1 ginkgolic acid esters.

**GC/MS and LC/MS Analysis and Validity of Ginkgo Dietary Supplement Samples.** Twenty-one dietary supplements in the form of capsules, liquids, or tablets were analyzed

using the developed GC/MS method. In summary, one sample contained no detectable GAs, six samples contained GAs below the limit of quantitation, eight samples contained detectable amounts but less than 5 ppm, and six samples contained >5 ppm GAs ranging from 5 to 56 ppm. The two samples (15913 and 15925) containing the highest concentrations of GAs (56 and 30 ppm, respectively) were both leaf extracts, not standardized extracts. The major active components of *G. biloba* leaf extracts are the flavonoids and sesquiterpenes lactones.[33,34] Standardized commercial extracts usually contain >6% ginkgolides (A, B, C, and J) and bilobalide and 24% flavonoids (quercetin, kaempferol, and isorhamnetin). In order to confirm the presence of *G. biloba* leaf extracts in the botanical dietary supplements, all of the dietary supplements shown in Table 2 were analyzed by a previously published method[29] involving the use of $[M + H]^+$ ions of five sesquiterpene lactones and three flavonoids which were observed at $m/z$ 425.2 (ginkgolide J and ginkgolide B), $m/z$ 441.2 (ginkgolide C), $m/z$ 327.3 (bilobalide), $m/z$ 409.2 (ginkgolide A), $m/z$ 303.1 (quercetin), $m/z$ 287.1 (kaempferol), and $m/z$ 317.1 (isorhamnetin). Based on the retention times and mass spectra in comparison with standard compounds, all commercial ginkgo preparations analyzed were found to contain all eight compounds indicating that all of the analyzed dietary supplements contained ginkgo leaf extracts.

**Confirmation with Standard HPLC Technique.** HPLC with a $C_8$ column, acetonitrile eluent and UV detection at 310 nm is a commonly accepted method for the analysis of GAs without distinction between the double bond positional isomers.[3,20,23,28,35] One leaf sample, 1095, was analyzed in a derivatized form by GC/MS and in the acid form by HPLC. The underivatized 1095 sample was analyzed by LC using three detection schemes, viz., UV at 310 nm, MS scan and MS SIM at $m/z$ 319, 347, 345, and 373 for C13:0, C15:0, C15:1 and C17:1, respectively. The results for the quantitation of GAs in the ginkgo leaf sample (1095) are given in Table 4.

**Table 4. Comparison of HPLC-UV-MS and GC/MS Results for GAs in a Leaf Sample (1095)[a]**

| ginkgolic acid | HPLC SIM | UV 310 nm | average HPLC | GC/MS[b] (from Table 3) |
|---|---|---|---|---|
| C13:0 | 22.3 | 35.1 | 28.7 | 19.0 |
| C15:0 | 8.2 | 8.2 | 8.2 | 2.4 |
| C15:1 | 39.8 | 40.6 | 40.2 | 48.7 |
| C17:1 | 29.8 | 26.9 | 28.4 | 36.9 |
| total | 100.1 | 110.8 | 105.5 | 107.0 |

[a]The concentrations are expressed in ppm. [b]The elution order for a HPLC $C_8$ column is C13:0, C15:1, C15:0, and C17:1. The elution order for a GC-HP88 column is C13:0, C15:0, C15:1, and C17:1.

The GC/MS results agree within experimental error with the standard HPLC analyses. The variation between results obtained with different detection schemes in the HPLC analyses is comparable to the differences between the average GC and HPLC results.

In conclusion, GC/MS methods using selected ion monitoring at $m/z$ 161 can be used to analyze various samples for ginkgolic acid components with detection and quantitation limits of 0.5 and 1.5 ppm, respectively. Gas chromatography allowed the resolution of the double bond positional isomers of the C15:1 and C17:1 ginkgolic acids. This type of resolution could not be achieved with common HPLC techniques. Quantitative analysis results obtained with the GC method were comparable with results achieved by a commonly accepted HPLC method.

The ratios of the concentrations of C15:1 Δ10 to Δ8 observed for leaf samples of ginkgo were in the range of 1−3, whereas the same ratio in the seed samples was always <0.5 with a single exception. This type of test may prove useful in determining the plant parts used to produce ginkgo samples and commercial products. All of the dietary supplements analyzed in this study that contained detectable amounts of GAs displayed a ratio of 1−2.5 indicating that they were probably derived from ginkgo leaves rather than seeds. The seeds and leaves have different functions, metabolic processes, and metabolite distributions resulting in different chemical profiles.

The double bond position in a commercial sample of C17:1 ginkgolic acid was determined to be Δ12 rather than Δ10 by the analysis of the reaction products from an ozonolysis reaction.

A previously developed HPLC method for the analysis of terpene trilactones and flavonol glycosides was used to confirm the presence of *Ginkgo biloba* in all of the commercial dietary supplement samples.

binding phase in the DGT sampler, has been applied to the measurement of dissolved Cr(VI).[33,34] In this paper, A DGT technique with a dialysis membrane as the diffusive phase and a PQAS aqueous solution as the binding phase (PQAS DGT) was investigated for the sampling of DRP in water. The influences of solution pH and ionic strength on the properties of PQAS DGT were studied. The PQAS DGT performance for the sampling of DRP was investigated under laboratory conditions and then deployed in wastewater and natural water. PQAS DGT will be applied for the assessment of P bioavailability in soils, which, in turn, will help effective fertilization tactics and lessen the danger of environmental pollution, owing to excessive fertilization. When PQAS DGT is applied to evaluating bioavailable P in soils, a relation will be established between the plant response to P manure and the concentration of P in soil determined by PQAS DGT, and PQAS DGT can provide a more accurate suggestion of P fertilizer needs. The study of PQAS DGT for the sampling of DRP in water will lay the foundation for the assessment of P bioavailability in soils, and the assessment of P bioavailability in soils by PQAS DGT will be reported later.

## MATERIALS AND METHODS

**Materials.** Cellulose acetate dialysis membrane (CDM, ~14 000 or greater retain) was bought from Shanghai Yuanju Bio-Tech Co., Ltd., Shanghai, China. Cellulose nitrate membrane (0.45 $\mu$m) was bought from Dikma (Tianjin, China). Poly(quaternary ammonium salt) (PQAS; $M_w = 2 \times 10^4$) was obtained from Henan Titaning Chemical Technology Co., Ltd., Zhengzhou, China. Potassium dihydrogen phosphate, antimony potassium tartrate, ammonium molybdate, hydrochloric acid, sodium hydroxide, and sodium nitrate were bought from Sinopharm Chemical Reagent Co., Ltd., Shanghai, China.

**Apparatus.** Ultraviolet−visible (UV−vis) spectroscopy (Beijing Royleigh Analytical Instrument Co., Ltd., China) was used for measurements of the absorbance of PQAS binding solutions containing phosphates at a wavelength of 700 nm by the ammonium molybdate spectrophotometric (AMS) method based on the National Standard of the People's Republic of China (GB 11893-89).[35] A PB-10 digital pH-meter (Sartorius, Germany) equipped with a combined glass electrode was used for the measurements of pH.

**Preprocessing of the Diffusive Phase and the Binding Phase.** Cellulose acetate dialysis membrane has been used as the diffusive phase of the DGT sampler.[17,18] The dialysis membrane was preprocessed according to the procedures suggested by Li et al.[17] The treated diffusive phase was kept in deionized water.

A 50.0 g PQAS solution was put in a dialysis membrane bag prepared as mentioned above, which was immersed in deionized water for 72 h with the water regularly supplemented.[17] This method effectually got rid of all of the low-molecular-weight PQAS that went through the dialysis membrane.

**Capacity of PQAS DGT.** The binding capacity of PQAS DGT was examined by immersing PQAS DGT for 24 h in 10 L $KH_2PO_4$ solutions containing 0.01 M $NaNO_3$. The concentrations of $KH_2PO_4$ were in the range of 0.1−1.2 mg of P $L^{-1}$.

**Measurement of the Diffusion Coefficient.** The diffusion coefficient of $H_2PO_4^-$ in the dialysis membrane in contact with synthetic water containing 0.01 M $NaNO_3$ at pH 7 was measured using a diffusion cell.[17] The cell was made of two perspex chambers linked by a 2.0 cm diameter hole. A 3.0 cm diameter and 85 $\mu$m thickness disc of the new pretreated diffusive phase was put on the opening between the chambers, assuring that the diffusive phase was the only mass transmission medium. A total of 50 mL of 0.01 mol $L^{-1}$ $NaNO_3$ solution containing 30 mg $L^{-1}$ P ($KH_2PO_4$) was put into the source solution chamber, and a total of 50 mL of 0.01 mol $L^{-1}$ $NaNO_3$ solution containing 0.050 mol $L^{-1}$ PQAS, an optimum concentration of PQAS solution, was put into the receptor solution chamber. Both chambers were mixed constantly using a magnetic stirring apparatus. Samples were taken out from both chambers at a 30 min span up to 180 min and measured by the AMS method.

Diffusion coefficients, $D$ ($cm^2$ $s^{-1}$), were calculated from the slope of a linear plot of measured mass of DRP diffused through the diffusive phase versus time, using eq 1, where $A$ is the exposed area of the diffusive phase, $\Delta g$ is the thickness of the dialysis membrane, and $C$ is the concentration of DRP originally existing in the source chamber of the diffusion cell.[36,37]

$$D = \frac{\text{slope}\ \Delta g}{CA} \tag{1}$$

The diffusion coefficients of DRP at different temperatures can be calculated by the Stokes−Einstein equation below (eq 2)

$$\frac{D_1\eta_1}{T_1} = \frac{D_2\eta_2}{T_2} \tag{2}$$

where $D_1$ and $D_2$ are the diffusion coefficients at temperatures $T_1$ and $T_2$ and $\eta_1$ and $\eta_2$ are the viscosities of water at those temperatures.[38]

**Validation of DGT Performance in the Laboratory.** A verification test for the binding phase of DGT was carried out following the programs stated previously.[17] The DGT samplers were installed according to the procedures described by Chen et al.[24] The samplers were immersed in 30 L of 0.01 mol $L^{-1}$ $NaNO_3$ spiked with 50 $\mu$g $L^{-1}$ P ($KH_2PO_4$) at 20 °C; triplicate samplers were taken out at 4, 8, 12, 16, 24, 36, and 48 h. The PQAS solutions in the DGT samplers were removed at each time point and analyzed by the AMS method.

The concentration gradient formed within the diffusive phase allows for the amount of analyte, $M$, that is enriched in the binding phase from a solution, after passing through a diffusive membrane of area ($A$) and thickness ($\Delta g$) with diffusive coefficient ($D$), over a deployment time ($t$), to be related directly to the concentration of analyte in the bulk solution measured by DGT ($C_{DGT}$).[6]

$$M = \frac{DAC_{DGT}t}{\Delta g} \tag{3}$$

PQAS DGT samplers are verified by investigating the relationship between the mass of analyte enriched in the binding phase ($M$) and the deployment time ($t$) with a solution of known concentration. The performance of PQAS DGT is also evaluated by calculating the percentage uptake ($U$%), defined by the following equation:[25]

$$U\% = \frac{C_{DGT}}{C_{bulk}} \times 100\% \tag{4}$$

where $C_{bulk}$ is the total concentration of DRP in the bulk solution directly measured by the AMS method.[37]

**Effect of Solution pH and Ionic Strength on the DGT Performance.** To evaluate the influence of various pH values (2, 3, 4, 5, 6, 7, 8, 9, and 10) and ionic strengths (0.0001, 0.001, 0.01, 0.1, and 1.0 mol $L^{-1}$ as $NaNO_3$) on the PQAS DGT performance, the PQAS DGT samplers were deployed in solutions containing 50 $\mu$g $L^{-1}$ P ($KH_2PO_4$) at various pH values and ionic strengths for the deployment time from 4 to 48 h. The pH values of the bulk solutions were modulated using 2% NaOH or $HNO_3$. The ionic strengths of the solutions were modulated with the proper addition of $NaNO_3$ at pH ~7.

**Field Deployment of the DGT Samplers in Wastewater and Natural Water.** PQAS DGT samplers were deployed in triplicate in a wastewater canal (Jinzhou, China); triplicate samplers were taken out at 24, 48, 72, 96, and 120 h. The PQAS solutions were removed from the PQAS DGT samplers at each time point and measured by the AMS method, and 0.45 $\mu$m filtered grab samples were gathered daily and measured directly by the AMS method.

PQAS DGT samplers were immersed in triplicate in local natural waters (Nuer River, Ling River, and North Lake, Jinzhou, China); triplicate samplers were taken out at 24, 48, 72, 96, and 120 h. The PQAS solutions were removed from the PQAS DGT samplers at each time point and measured by the AMS method, and 0.45 $\mu$m filtered

grab samples were gathered daily and measured directly by the AMS method.

## RESULTS AND DISCUSSION

**Capacity of PQAS DGT.** There is a trend for the binding phase to become saturated because of the high cumulation of the analytes when the sampling is conducted over a long term (weeks or months) or in an environment with high-concentration analytes. The DGT capacity may be a restrictive factor for such applications. The DGT capacity was studied by immersing DGT samplers in stirred solutions with phosphate concentrations in the range of 0.1−1.2 mg of P $L^{-1}$. A linear response ($y = 35.99x + 4.50$; $r^2 = 0.9985$) was gained with the concentration up to 0.8 mg of P $L^{-1}$ (Figure 1). The effective

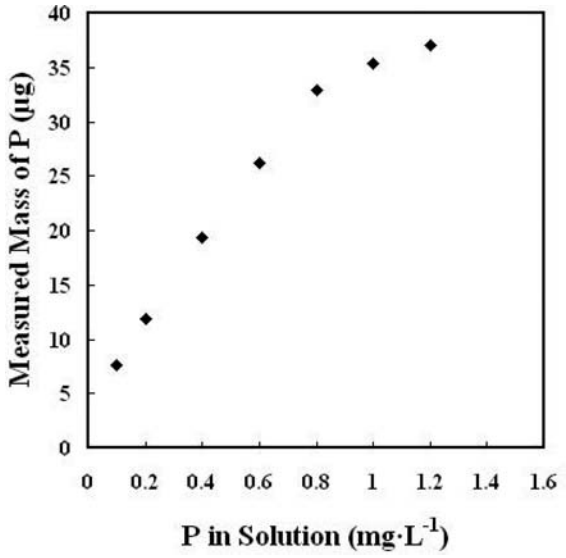

**Figure 1.** Dependence of accumulated mass of phosphorus on the solution concentration for 24 h exposure of a DGT sampler.

binding capacity of PQAS DGT containing 2.0 mL of 0.05 mol $L^{-1}$ PQAS solution was estimated as 9.9 $\mu$g $cm^{-2}$ on the basis of Figure 1 compared to the binding gels used for phosphates reported in the literature, such as ferrous oxide gel (~2 $\mu$g $cm^{-2}$),[26] titanium dioxide gel (~12 $\mu$g $cm^{-2}$),[30] and zirconium oxide gel (~100 $\mu$g $cm^{-2}$).[31] It can be estimated that, if the mean concentration of DRP in a water was 10 $\mu$g $L^{-1}$, DGT could be deployed for up to 54 days. Furthermore, by increasing the volume of the PQAS solution, extended hours of deployment can be expected.

**Diffusion Coefficient of DRP in the Dialysis Membrane.** The diffusion coefficient of DRP through the dialysis membrane in 0.01 mol $L^{-1}$ $NaNO_3$ solutions at 20 °C was $(1.95 \pm 0.17) \times 10^{-6}$ $cm^2$ $s^{-1}$, lower than the value of $D$ in the synthetic polyacrylamide hydrogel ($6.05 \times 10^{-6}$ $cm^2$ $s^{-1}$ at 25 °C). This can be explained by the structure of the dialysis membrane with lower porosity and lower water content.[26,39]

**Validation of the DGT Performance for the Measurement of DRP.** The DGT performance is evaluated in two aspects. First, a linear relationship between the mass of analyte enriched in the binding phase ($M$) and the deployment time ($t$) should be expected, if the DGT sampler works in principle. Second, the percentage uptake of the DGT sampler should be in the range of 90−110%.[40] The uptake of DRP by PQAS in the synthetic solution containing 50 $\mu$g of P $L^{-1}$ increased linearly with time up to 48 h ($r^2 = 0.9993$; $U$% = 98.7%; Figure 2). These results demonstrated that PQAS DGT worked well

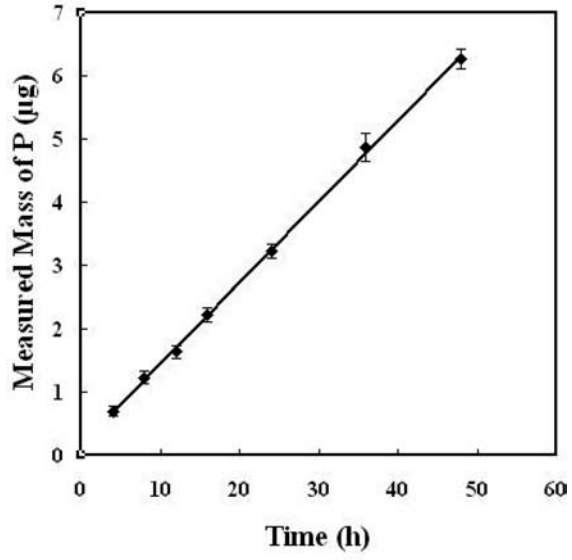

**Figure 2.** Mass of phosphorus accumulated by PQAS DGT in a synthetic solution. Concentration of P ($KH_2PO_4$), 50 $\mu$g $L^{-1}$; ionic strength, 0.01 mol $L^{-1}$ $NaNO_3$; pH, 7; deployment time, from 4 to 48 h; and temperature, 20 °C.

according to the DGT principle and PQAS satisfies the conditions of the DGT binding agent for the sampling of DRP. Therefore, DRP can be measured quantitatively by PQAS DGT.

DRP can be enriched in the PQAS binding phase because of the electrostatic attraction between PQAS and DRP. PQAS is a water-soluble cationic polymer and can interact with anionic substances present in aqueous solutions, whereas DRP exists as various hydrophilic anionic species, such as $H_2PO_4^-$ and $HPO_4^{2-}$, in a water environment and can interact with cationic substances present in aqueous solutions.[32] DRP in water can go through the diffusive phase into the binding phase of the DGT sampler and bind with PQAS quickly; a diffusive gradient of DRP is thereby formed within the dialysis membrane between water and the interface with the binding phase, resulting in an accumulation of DRP in the binding phase.

**Effect of the pH.** The DGT measurements of DRP were not dependent upon solution pH over the pH range of 3−10, which covers most of the pH conditions in natural water (Figure 3), consistent with the earlier findings that DGT measurements of anions were not dependent upon pH.[11,33,41] With the increase of solution pH, more $H_2PO_4^-$ was transferred into $HPO_4^{2-}$ that can be combined by PQAS more strongly because of electrostatic interaction. However, with the increase of solution pH, more competing hydroxide anions must hinder the combination of PQAS and $HPO_4^{2-}$. It was the above two opposite factors that resulted in no significant difference between the bindings of PQAS and anionic species of DRP that existed over the pH range of 3−10. The $U$% values increased significantly at pH 2 probably because PQAS can combine DRP more strongly with the increase of the hydrogen ion concentration.

**Effect of the Ionic Strength.** The binding behavior of PQAS DGT for DRP was investigated in $KH_2PO_4$ aqueous solutions containing various ionic strengths (0.0001, 0.001,

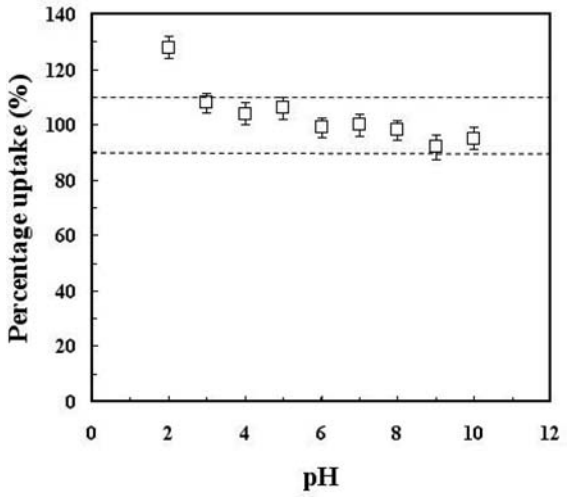

**Figure 3.** Effect of pH on the performance of PQAS DGT by plotting percentage uptake of DRP versus the pH, Concentration of P ($KH_2PO_4$), 50 $\mu$g $L^{-1}$; ionic strength, 0.01 mol $L^{-1}$ $NaNO_3$; deployment time, from 4 to 48 h; and temperature, 20 °C.

0.01, 0.1, and 1.0 mol $L^{-1}$ as $NaNO_3$; Figure 4). The *U*% value of DRP increased with the increase of the ionic strength range

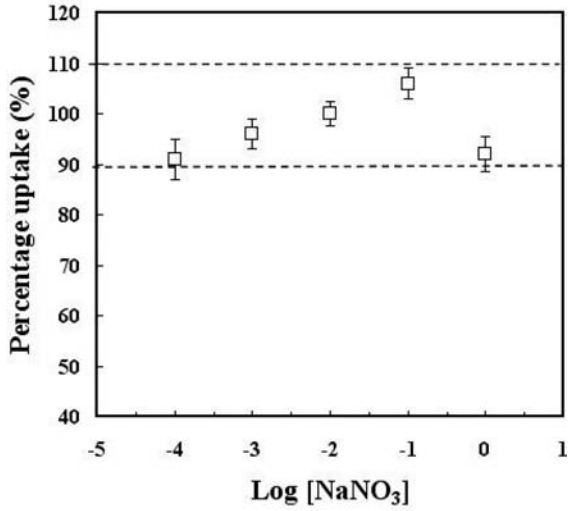

**Figure 4.** Influence of the ionic strength on the performance of PQAS DGT by plotting percentage uptake of DRP versus the $NaNO_3$ concentration. Concentration of P ($KH_2PO_4$), 50 $\mu$g $L^{-1}$; pH, 7; deployment time, from 4 to 48 h; and temperature, 20 °C.

from 0.0001 to 0.1 mol $L^{-1}$, consistent with the experimental results reported by Panther and co-workers and Lucas and co-workers.[42,43] Panther and co-workers found that the diffusion coefficients of As(V) in the negatively charged Nafion membrane increased with the increase of the ionic strength.[42] Lucas and co-workers also found that the diffusion coefficients of Au(III) in a diffusive gel increased with the increase of the ionic strength.[43] The *U*% values decreased at 1.0 mol $L^{-1}$ solution of $NaNO_3$ probably because the competitive diffusion between $NO_3^-$ and DRP in the diffusive phase was strengthened at high ionic strength.[33] However, accumulation was quantitative and consistent in the ionic strength range of 0.001−1.0 mol $L^{-1}$, with *U*% values between 90 and 110%. These results suggest that PQAS DGT can be applied for sampling DRP in the majority of natural fresh and marine waters, although a further study in seawater is essential to guarantee that competing anions other than nitrate do not disturb the measurement of DRP by PQAS DGT.

**Field Deployment.** PQAS DGT samplers were put in a local wastewater canal up to 5 days to investigate the robustness of the technique further. The concentrations of DRP in the wastewater were collected daily and measured directly by the AMS method. The concentration of DRP in the wastewater measured by PQAS DGT was 32.9 ± 0.9 $\mu$g $L^{-1}$, and the $C_{DGT}$ value is in good agreement with the average 0.45 $\mu$m filtered measurement obtained from grab samples ($C_{sol}$), as shown in Table 1. Therefore, DRP in the wastewater can be sampled and measured by PQAS DGT.

**Table 1. Comparison of DRP Measurement by PQAS DGT and Directly by the AMS Method in Wastewater and Natural Waters**

| water sample | $C_{DGT}$[a] ($\mu$g $L^{-1}$) | $C_{sol}$[b] ($\mu$g $L^{-1}$) |
|---|---|---|
| wastewater | 32.9 ± 0.9 | 33.5 ± 1.8 |
| Nuer River | 4.9 ± 0.4 | ND[c] |
| Ling River | 4.6 ± 0.3 | ND |
| North Lake | 6.1 ± 0.5 | ND |

[a]Measured by PQAS DGT. [b]Average value from 0.45 $\mu$m of filtered grab samples. [c]ND = not detected.

PQAS DGT samplers were deployed in natural waters up to 5 days for sampling DRP in the natural water. The concentrations of DRP measured by PQAS DGT in Nuer River, Ling River, and North Lake were 4.9 ± 0.4, 4.6 ± 0.3, and 6.1 ± 0.5 $\mu$g $L^{-1}$, respectively (Table 1). However, the concentrations of DRP in the natural waters cannot be detected directly by the AMS method because they are below the detection limit (Table 1).

This work has demonstrated the feasibility of using PQAS solution as a binding phase for *in situ* sampling and measurement of DRP in water. PQAS is suitable as a liquid binding agent of the DGT technique for sampling DRP. The advantages of PQAS DGT include no requirement of the elution steps and direct concentration measurements of the binding phase. The measurement of DRP in a synthetic solution by PQAS DGT over a 48 h deployment period demonstrated high consistency with the concentration of DRP in the synthetic solution measured directly by the AMS method. A future study should focus on the application of this new technique to the sampling and measurement of DRP in soils and sediments.

al.,[28] and Kane et al.[9] In these publications, the phylogenetic relationship in the genus *Theobroma* is analyzed using isolated DNA from fresh leaf material. The publication by Yang et al.[28] deserves particular mention in this context, because of its similarity to this study. Yang et al. used sequencing to identify SNPs and microsatellites in the plastid genome to identify the origin of Trinitario cultivars.

All cited publications are based on a similar question, and similar DNA-based methods are being used. Although Ecuadorian cocoa types are often objects of publications,[17] the type CCN-51 and the possible mixture of Arriba with the more low-cost CCN-51, in particular, were never mentioned before. The present study combines various approaches of other publications, whereas the sequencing method corresponding to Kane et al. is of particular mention. It was possible to sequence the plastid genome of CCN-51 for the first time. The problem complex of parallel cultivation and, thus, a resulting mixture of the two cocoa types in Ecuador, resulting in interest of the analytical differentiation of Arriba and CCN-51, were also never addressed before.

Other groups who have been involved in work concerning the genome of cocoa are Saski et al.[29] and Argout et al.[1]

## MATERIALS AND METHODS

**CCN-51 and Arriba Samples.** Cocoa bean and leaf samples of CCN-51, Arriba, the parents of CCN-51 (ICS-95, Canelo, and IMC-67), and Criollo were used in this study. A total of 23 leaf samples and 51 bean samples were used. The 8 CCN-51 leaf samples were obtained from the Instituto Nacional de Investicaciones Agropecuarias (INIAP, Guayaquil, Ecuador) and from farms in Naranjal, Ecuador (C1, C2, and C3), from the International Cocoa Germplasm Database (ICGD, University of Reading, England, C4), from the Botanical Garden, Hamburg, Germany (C5 and C6), and from the Centro Agronómico Tropical de Investigación y Enseñanza (CATIE), Cartago, Costa Rica (C7 and C8). The 8 Arriba leaf samples (A1, EET-19; A2, EET-48; A3, EET-62; A4, EET-95; A5, EET-96; A6, EET-103; A7, EET-544; and A8, EET-558) were obtained from the INIAP. The CCN-51 parent samples ICS-95 (E1 and E2) and Canelo (E3 and E4) originated from farms in Naranjal, Ecuador, while the IMC-67 sample (E5) originated from the INIAP. A total of 13 of the 15 CCN-51 bean samples were obtained from the INIAP or were collected on Ecuadorian cocoa farms, and 2 of the 15 CCN-51 bean samples were obtained from the CATIE. All of the 35 Arriba bean samples and 1 of the Criollo bean samples originated from Ecuadorian farms or were contributed by different cocoa producers, such as Lindt & Sprüngli GmbH, Schwartauer Werke GmbH & Co., H.D. Cotterell GmbH & Co. KG, Schlüter & Maack GmbH, Quast & Cons. GmbH & Co. KG, Fassbender & Rausch GmbH, and Alfred Ritter GmbH & Co. KG. The bean samples were obtained fermented, unroasted, and unshelled. The leaf samples were freshly picked, stored, and transported in deep-freeze conditions.

Furthermore, Arriba and bulk chocolate samples were analyzed.

**Chemicals.** In this study, the following chemicals are used: acetonitrile (Merck Millipore, Darmstadt, Germany), agarose (Serva Electrophoresis GmbH, Heidelberg, Germany), bovine serum albumin (BSA) solution (New England Biolabs, Ipswich, MA, USA), bromopenol blue (Merck Millipore, Darmstadt, Germany), cetyl trimethyl ammonium bromide (CTAB) (Sigma-Aldrich GmbH, Seelze, Germany), ethanol (Merck KGaA, Darmstadt, Germany), ethidium bromide (Sigma-Aldrich GmbH, Seelze, Germany), glycerine (Carl Roth GmbH & Co KG, Karlsruhe, Germany), isopropanole (Merck KGaA, Darmstadt, Germany), hydrochloric acid (HCl) (Merck Millipore, Darmstadt, Germany), liquid nitrogen (Linde AG, Hamburg, Germany), sodium acetate (Carl Roth GmbH & Co KG, Karlsruhe, Germany), trichloro-methane (VWR International, Darmstadt, Germany), triethylammonium acetate (Transgenomic, Ltd., Glasgow, UK), tris-(hydroxymethyl)aminomethane (Tris) (Carl Roth GmbH & Co KG, Karlsruhe, Germany), and xylene cyanol (Merck Millipore, Darmstadt, Germany).

**DNA Extraction.** The DNA extraction from beans differs from that of leaves.

*Beans and Chocolate.* A total of 100 mg of crushed beans or chocolate were weighed into a 2 mL Eppendorf tube, and two defatted and autoclaved steel beads ($^1/_8$ in.) were added. The material was processed for 5 min at 30 Hz in a TissueLyser (Qiagen, Hilden, Germany). A total of 1 mL of extraction buffer (55 mM CTAB, 1.4 M NaCl, 0.1 M Tris, and 20 mM $Na_2EDTA$ in double-distilled $H_2O$, adjusted to pH 8.0 with HCl) was added, and the material was processed in the TissueLyser for further 5 min at 30 Hz. After incubation for 30 min at 65 °C in a water bath, 500 μL of chloroform was added. The mixture was vortexed and centrifuged for 5 min at 10000*g*. The supernatant was transferred in a new 2 mL Eppendorf tube. After the addition of 500 μL of isopropanol and vortexing, the mixture was incubated for 30 min at 4 °C. Subsequently, the mixture was centrifuged for 5 min at 10000*g*. The supernatant was decanted and rejected, and isopropanol was removed in the vacuum desiccator for 20 min at 160 mbar. The DNA was solved with 50 μL of double-distilled water and

incubated for 1 h at room temperature. After centrifugation for 5 min at 10000*g*, the solution was transferred to a new 2 mL Eppendorf tube.

*Leaves.* The isolation of DNA from leaves was performed using the DNeasy Plant Mini Kit (Qiagen, Hilden, Germany), including all buffers. The leaves were washed, dried, and pestled using liquid nitrogen. A total of 100 mg of the pulverized material was weighed into a 2 mL Eppendorf tube. Two defatted and autoclaved steel beads were added, and the tube was kept in liquid nitrogen for 30 s. The material was processed for 1 min at 30 Hz in a TissueLyser and kept in liquid nitrogen again for 30 s. The material was processed for a further 1 min at 30 Hz in the TissueLyser, vortexed, and centrifuged for 1 min at 18000*g*. A total of 400 μL of buffer AP1 and 4 μL of RNase A stock solution were added, and the mixture was vortexed. After the mixture was incubated for 10 min at 65 °C in a water bath (meanwhile vortexing 2−3 times), 400 μL of buffer A2 was added and the mixture was vortexed. Incubation on ice for 5 min was followed by centrifugation for 5 min at 16000*g*. The supernatant was transferred into a QIAshredder Mini spin column and centrifuged for 5 min at 18000*g*. The flow through was transferred into a new 2 mL tube without disturbing the pellet, and 1.5 volumes of Buffer AW1 was added. The components were mixed by pipetting. A total of 650 μL of this mixture were transferred into a DNeasy Mini spin column placed in a 2 mL collection tube. The mixture was centrifuged for 1 min at 6000*g*, and the flow through was discarded. This step was repeated with the remaining sample. The spin column was placed into a new 2 mL collection tube; 500 μL of buffer AW2 was added; and the sample was centrifuged for 1 min at 6000*g*. The flow through was discarded. Another 500 μL of buffer AW2 was added, and the sample was centrifuged for 2 min at 16000*g*. The spin column was transferred to a new 2 mL tube, and 100 μL of buffer AE was added for elution. The sample was incubated for 5 min at room temperature and centrifuged for 1 min at 6000*g*. The last step was repeated with 50 μL of buffer AE.

For bigger amounts of leaf material, we used the DNeasy Plant Maxi Kit (Qiagen, Hilden, Germany) in the same way according to the protocol of the manufacturer.

**DNA Purity.** The purity of DNA extracts was measured by the 260/280 nm extinction ratio using the SpectraMax M2 fluorimeter (Molecular Devices, Ismaning, Germany). Quotients between 1.7 and 1.9 are typical for pure DNA.[30]

**DNA Concentration.** The DNA concentration of the DNA extracts was measured fluorimetrically using SYBR Green I (Invitrogen, Eugene, OR) diluted 1:6250 in 1× TAE buffer (40 mM Tris and 2 mM EDTA, adjusted to pH 8.2 with HCl) in 96 fluorescence well plates using a SpextraMax M2 fluorimeter (Molecular Devices, Ismaning, Germany). The chosen excitation wavelength was 495 nm, and the detection wavelength was 535 nm.

For the measurement, 90 μL of the diluted SYBR Green I solution was placed into each well and completed with the sample or the calibration solution to a final volume of 100 μL. The calibration stock solution was a plasmid solution with a concentration of 10 ng/μL. A calibration curve (1, 2, 4, 6, 8, and 10 ng/μL) was obtained by corresponding dilution.

The DNA extracts were adjusted with water to a final concentration of 5 ng/μL for PCR and 20−25 ng/μL for sequencing, respectively.

**Qualitative PCR.** A total of 2 μL of the DNA extracts (final concentration of 5 ng/μL) was used for PCR. The PCR reactions were carried out in a final volume of 40 μL. The PCR reaction mix contained 4 μL of 10× buffer [5 mM Tris, 1 mM $MgCl_2$, 25 mM KCl, and 1% Triton X-100 (m/v), adjusted to pH 8.8 with HCl], 3.2 μL of dNTPs [10/2.5 mM each (Bioline GmbH, Luckenwalde, Germany)], 0.4 μL of forward primer, 0.4 μL of reverse primer [100 μM (Life Technologies, Darmstadt, Germany)], and 0.4 μL of 30 unit *Taq* polymerase (Fermentas GmbH, Sankt Leon-Rot, Germany). The PCR reaction mix for the PCR−RFLP also contained 0.4 μL of BSA solution (10 mg/mL). PCR conditions were 94 °C for 5 min, followed by 35 cycles of 94 °C for 40 s, 55 °C for 40 s, 72 °C for 40 s, 72 °C for 1 min, and holding at 4 °C. The PCR was performed in a T3 thermocycler (Biometra, Göttingen, Germany). The primer sequences are given in Table 1.

**Electrophoresis.** The resulting PCR products were mixed with about 1 μL of loading buffer (40 mM Tris, 2 mM EDTA, 50% glycerine, 0.25% bromophenol blue, and 0.25% xylene cyanol, adjusted to pH 8.2) and separated on 3% agarose gel in TAE buffer (40 mM Tris-acetate and 2 mM EDTA, adjusted to pH 8.2) at 170 V for about 20 min. The separated PCR products were stained using ethidium bromide (0.001%) and visualized under ultraviolet (UV) light with a wavelength of 312 nm.

**Sequence Analysis: Whole Chloroplast Genome.** DNA was isolated from deep-frozen leaf material using the DNeasy Plant Mini or Maxi Kit (Qiagen, Hilden, Germany); see DNA Extraction for Leaves. The DNA extracts were purified by ethanol precipitation: the extract was mixed with 0.1 vol of 3 M sodium acetate solution and 3 vol of absolute ethanol. After incubation for 12−16 h at −20 °C, the mixture was pelletized for 60 min at 15000*g* and 4 °C. The supernatant was discarded. The pellet was washed with cold ethanol (4 °C) and centrifuged for 10 min at 15000*g* and 4 °C. The supernatant was discarded. The pellet was dried for 15 min at 37 °C and solved with water by incubation with gentle agitation for 10 min at 50 °C. The DNA concentration of the isolates was adjusted to 200 ng/μL by diluting or simple concentration at the speed vac. Sequencing was carried out by GATC Biotech AG, Konstanz, Germany. The obtained sequences (FASTA format) were compared using VectorNTI. In addition, we compared the sequences to all cholorplast genome sequences available at the National Center for Biotechnology Information (NCBI).

**Sequence Analysis: $(TAAAG)_n$.** PCR was performed using the primer pair $(TAAAG)_n$ (see Table 1) using the conditions for qualitative PCR, as described above. PCR products were purified using the peqGOLDGel Extraction Kit (PEQLAB Biotechnologie GmbH, Erlangen, Germany) according to the instructions of the manufacturer. The DNA concentrations of the PCR products were adjusted to 20−25 ng/μL using a speed vac. Sanger sequencing was carried out by GATC Biotech AG, Konstanz, Germany.

**Sequence Analysis: IRR.** PCR was performed using the primer pairs described by Dhingra et al.[31] and using the conditions for qualitative PCR, as described above. PCR products were prepared for the sequencing by an enzymatic degeneration of the primer and the dNTPs: 40 μL of the PCR product were mixed with 4 μL of *Exo*I and 8 μL of FastAP. The mixture was incubated for 15 min at 37 °C and then for 15 min at 85 °C. Sequencing was carried out by GATC Biotech AG, Konstanz, Germany. The obtained sequences were compared together and with the sequences of the published chloroplast genomes up to this point in time (accession numbers NC_014676 and HQ336404).

**dHPLC.** For the detection of PCR products by dHPLC (using a Wave Nucleic Acid Fragment Analysis System, Transgenomic, Glasgow, U.K.), 10 μL of the solution was filled into caps and carried over in the chilled rack. The run was performed using the gradient for the running buffers A [0.05% triethylammonium acetate (TEAA) solution] and B (0.05% TEAA and 0.25% acetonitrile solution). Experimental conditions for the buffer composition for the dHPLC analysis are 0.0 min: A, 50.2%; B, 49.8%; 0.7 min: A, 41.8%; B, 58.2%; 3.8 min: A, 41.8%; B, 58.2%; 4.0 min: A, 38.2%; B, 61.8%; 4.1 min: A, 40.8%; B, 59.2%; 4.2 min: A, 41.8%; B, 58.2%; and 4.3 min: A, 55.0%; B, 45.0%.

**CGE.** Detection of PCR products by CGE was carried out with an Experion System (Bio-Rad Laboratories GmbH, Munich, Germany) according to the instructions of the manufacturer using the Experion DNA 1K Analysis Kit (Bio-Rad Laboratories GmbH, Munich, Germany).

**PCR−RFLP.** Primers for the corresponding enzymes are given in Table 1. The PCR was performed as described above (qualitative PCR), and the PCR products were analyzed by AGE (see above). The restriction enzymes *Psi*I, *Eco*RI, *Ase*I, and *Eco*RV were obtained from New England Biolabs GmbH (Frankfurt, Germany) and used along with the supplied buffer. The amounts of restriction enzyme for the digestion of 5 μL of PCR products with 2.5 μL of corresponding NEB buffer are shown in Table 2. The PCR reaction mix was incubated at 37 °C for 3 h in a final reaction volume of 25 μL. The restriction enzyme was then heat-inactivated for 20 min at 65 °C.

Plastid DNA can not only be identified in the cocoa leaves but also in the cocoa beans. That means all DNA-based methods can be carried out not only in fresh plant materials. DNA is that stable, that it can be amplified by PCR also after technological treatments e.g. fermentation and roasting. This fact is highly important for the application of the methods described above for quality control in the food industry.

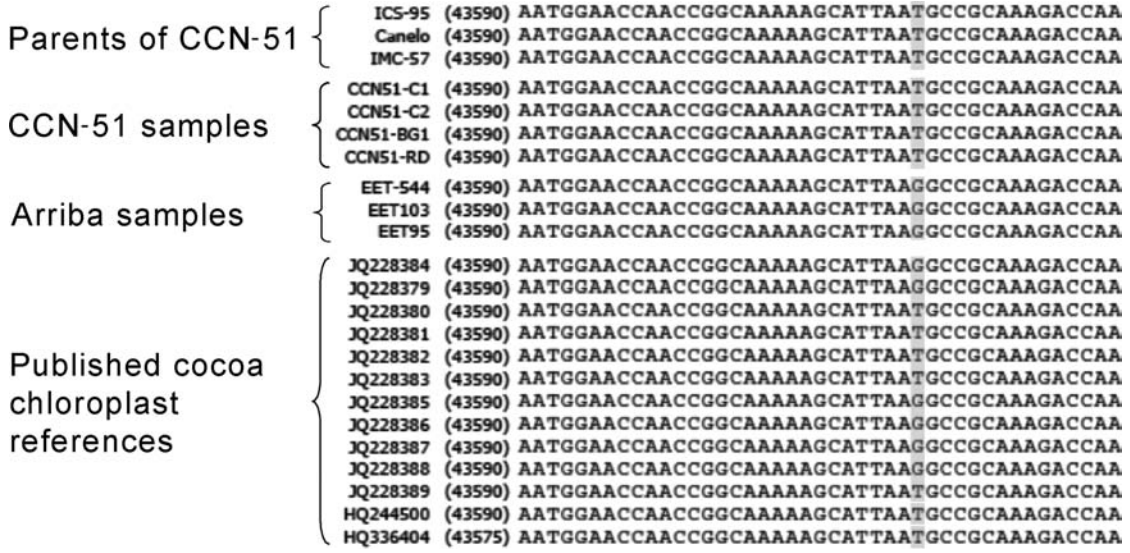

**Figure 1.** Section of the alignment of 10 chloroplast genomes of Arriba, CCN-51, the parents of CCN-51 sequenced in this study, and 13 published cocoa chloroplast genomes: Criollo-22 (JQ228379), Amelonado (JQ228380), ICS-01 (JQ228381), Scavina-6 (JQ228382), ICS-06 (JQ228383), EET-64 (JQ228384), Stahel (JQ228385), Pentagonum (JQ228386), ICS-39 (JQ228387), *T. grandiflorum* (JQ228388), JQ228389, HQ336404, and Scavina-6 (HQ244500).

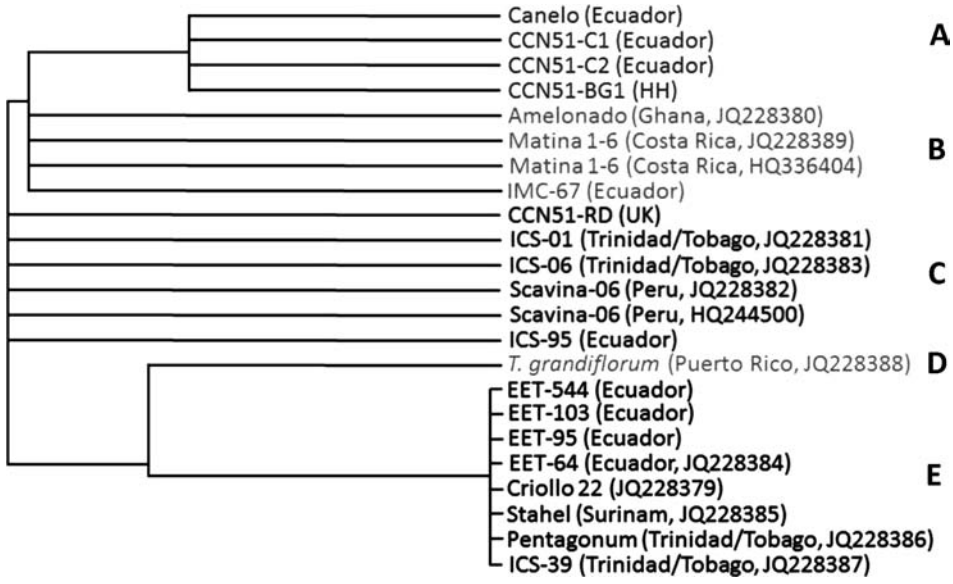

**Figure 2.** Phylogenetic tree of cocoa types based on the alignment of the chloroplast genomes of different cocoa types.

## RESULTS AND DISCUSSION

**Cocoa Samples and DNA Extracts.** The DNA of 23 leaf and 51 bean samples from a number of sources was isolated by two methods: one for leaves and one for beans (see above). Both DNA extraction methods were successful; i.e., it was possible to isolate DNA. The DNA yields of the leaf sample were much higher than those of the bean samples; the purity of both were similar (about $E_{260\ nm}/E_{280\ nm}$ = 1.6). The DNA yield of the extracts varied across a large range (between $c$ = 20 and 900 ng/$\mu$L), which did not influence the PCR.

**Sequencing of 10 Chloroplast Genomes of *T. cacao*.** DNA is a suitable biomarker because of the fact that it is unique for each organism and stable within the time frame relevant for food analysis. As indicated above, besides the nuclear DNA, plant cells contain plastid DNA.[32] In this sort of DNA, a higher genetic variability is assumed,[33] which is an advantage for the discrimination between two very closely related organisms, such as CCN-51 and Arriba cocoa varieties.

To find a difference in the chloroplast genome between CCN-51 and Arriba, the sequence of the genome must be known; therefore, the whole genome must be sequenced. Usually, the plastid DNA must be isolated from the nuclear DNA. Efforts to separate plastid DNA from nuclear DNA using the Chloroplast Isolation Kit (Sigma-Aldrich, Hamburg, Germany) according to the descriptions in other publications were not successful.[34,35] Chloroplasts were isolated from cocoa leaves, and the DNA was extracted from them in correspondence with the DNA extraction of beans. However, the yield of DNA was not sufficient (less than 5 $\mu$g), and nuclear DNA was co-extracted.

Kane et al. described a method for sequencing the whole chloroplast genome by next-generation sequencing, despite the presence of nuclear DNA. It is called "low-coverage whole

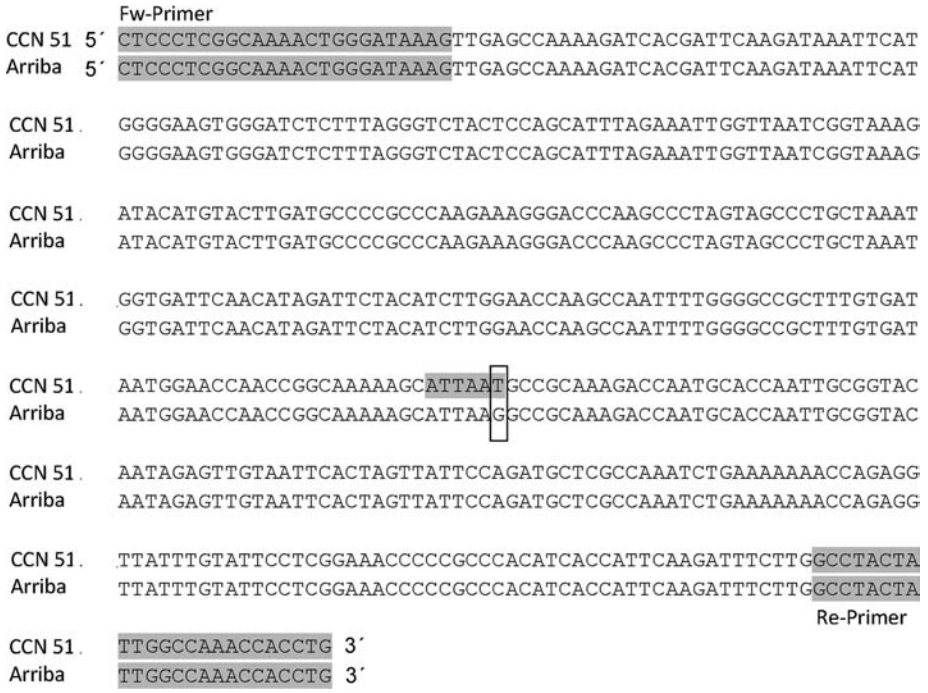

**Figure 3.** Schematic figure of a CCN-51-specific restriction site. This cocoa type includes the recognition sequence for the restriction enzyme *Ase*I. In the cocoa type Arriba, this recognition sequence is disturbed by a SNP. The *Ase*I recognition site is highlighted gray, and the SNP is boxed.

genome shotgun sequencing".[9] In a plant cell, the nuclear genome appears in the cell nucleus in a defined copy number, while the plastid genome occurs in the chloroplasts at a higher copy number. A *T. cacao* cell contains about three to four chloroplasts,[36,37] and each chloroplast disposes of about 70 copies of the plastid genome. At a size of about 160 kbp, the cocoa plastid genome is significantly smaller than the nuclear genome, which has a size of about 330 Mbp.[1] However, as a consequence of low coverage during sequencing, the high copy fraction (the plastid genome) becomes sequenced.

On the basis of this method, the whole chloroplast genome sequences for 10 leaf samples were obtained: 4 CCN-51 samples (2 from Naranjal, Ecuador, 1 from the ICGD, and 1 from the Botanical Garden, Hamburg), 3 Arriba samples (EET-95, EET-103, and EET-544 from the INIAP), and 3 parents of CCN-51 (IMC-67 from the INIAP and ICS-95 and Canelo from Naranjal, Ecuador). The 10 obtained sequences were aligned with 13 already published sequences of the cocoa chloroplast genome. Types of the already published sequences are Criollo-22 (JQ228379), Amelonado (JQ228380), ICS-01 (JQ228381), Scavina-6 (JQ228382), ICS-06 (JQ228383), EET-64 (JQ228384), Stahel (JQ228385), Pentagonum (JQ228386), ICS-39 (JQ228387), and *Theobroma grandiflorum* (JQ228388).

This alignment served as a basis for a search for sequence differences between CCN-51 and Arriba to allow for differentiation between the two types. Figure 1 shows a detail of the obtained data file.

This alignment was also the basis for the development of a phylogenetic tree with which the degree of relationship of the different cocoa types was analyzed. The developed phylogenetic tree is shown in Figure 2. The sequenced Arriba samples form one group with other samples (group E). Similarly, the sequenced CCN-51 samples form a group with one of the parents of CCN-51 Canelo (group A), with the exception of one sample. This CCN-51 sample is located in the group of another parent of CCN-51 (ICS-95). Reasons for this are discussed in the next section.

**SNPs in the Chloroplast Genome.** After analyzing the alignment, we could not find differences between Arriba and CCN-51 that extended over several neighboring base pairs; therefore, the development of a PCR with specific primers was not possible. The only distinctions between the two cocoa types were SNPs. Approximately 30−50 SNPs were determined, corresponding to about 0.03% of the 160 kbp of the chloroplast genome of the cocoa. These SNPs can be used to develop a PCR−RFLP[30,38−40] for differentiation. In this context, it is of vital importance that about five to seven of the 30−50 SNPs are located in the recognition sequences of restriction enzymes. Because of the fact that the method development focused on detecting CCN-51, a SNP that was located in a recognition sequence in the PCR product of CCN-51 was chosen.

We developed five PCR−RFLPs based on five SNPs, which are found in the recognition sequence of a restriction enzyme. Three of these five PCR−RFLP were CCN-51-specific (numbers 8, 21, and 44); one was Arriba-specific (number 43); and one was CCN-51-specific as well as Arriba-specific (number 17). This means that there were two recognition sequences for two restriction enzymes around the SNP and that, depending upon the restriction enzyme used, both CCN-51 (*Psi*I as the applied enzyme) or Arriba (*Eco*RI as the applied enzyme) could be detected. Figure 3 exemplifies one of the CCN-51-specific SNPs, which matches the ATTAAT recognition sequence of the *Ase*I restriction enzyme. Using this enzyme, the PCR product with a size of 436 bp is digested to two smaller fragments of 265 and 171 bp (see Figure 4), whereas the PCR product of Arriba with the size of 436 bp is detected just as before the RFLP (see Figure 4).

The detection limit of the method (carried out with the enzyme *Ase*I) could be determined using well-defined mixtures; even when constituting only 1% in the mixture, CCN-51 was detected.

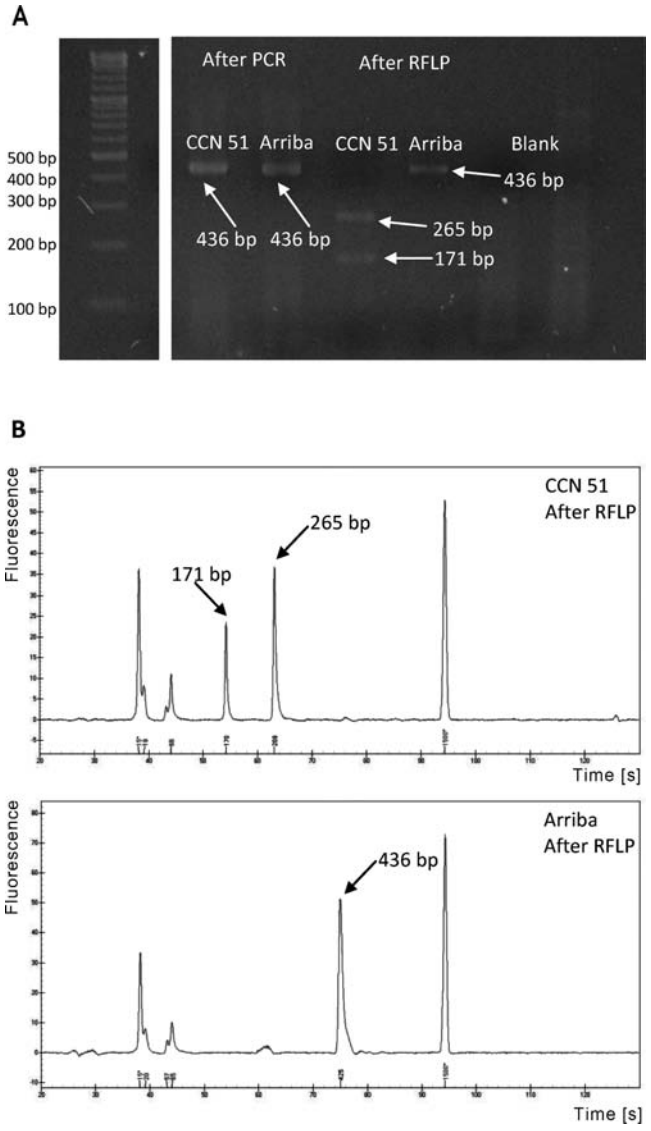

**Figure 4.** Different methods for detecting the amplicons and fragments of Arriba (A) and CCN-51 (C): A, AGE; B, CGE after the PCR–RFLP based on SNPs in the chloroplast genome. PCR product of CCN-51 and Arriba with a size of 436 bp, which includes a SNP, is digested using the restriction enzyme *Ase*I. The CCN-51 DNA fragment includes the correct recognition sequence, leading to two fragments of 265 and 171 bp. The recognition site for *Ase*I is not present in the Arriba sequence, which is why the PCR product is not digested by this enzyme.

The method development was carried out with one Arriba and one CCN-51 leaf sample and was verified using a total of 16 leaf samples and 51 bean samples. Within the leaf samples, 7 of 8 CCN-51 samples showed the expected CCN-51-specific result and 1 CCN-51 sample showed the Arriba-specific result. A total of 6 of 8 Arriba samples showed the expected Arriba-specific result, and 2 Arriba samples showed the CCN-51-specific result. Within the bean samples, 15 of 16 CCN-51 samples showed the expected CCN-51-specific result and 1 CCN-51 sample showed the Arriba-specific result. A total of 16 of 35 Arriba bean samples showed the expected Arriba-specific result and 19 showed the CCN-51-specific result.

In general, the leaf samples showed more homogeneous results than the bean samples, which is assumed to have one main reason: the origin of the leaves can be determined with 100%

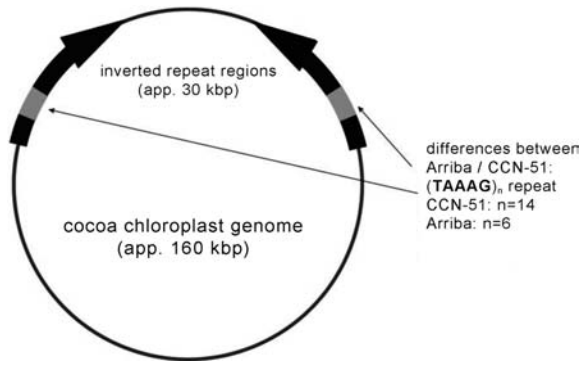

**Figure 5.** Schematic figure of the IRR in the cocoa chloroplast genome, in which the $(TAAAG)_n$ repeat with its different repetitions in CCN-51 ($n$ = 14) and Arriba ($n$ = 6) can be found.

certainty because they were picked by hand from trees that could be classified morphologically as CCN-51 or Arriba. This was different for the bean samples: they were provided to us by cocoa-processing or cocoa-trading companies after several processing steps, such as fermentation and drying. Because of the fact that we did not take the bean samples from the tree, we cannot be sure that they were pure Arriba or pure CCN-51 samples as declared. In fact, our analyses show the relevance of the research field because already the samples seem to be mixtures of both cocoa types or rather Arriba adulterated with CCN-51.

The bean samples from Costa Rica were an exception. Their origin can be considered assured because the raw beans were taken from a fresh fruit whose origin was definitely a CCN-51 tree. Unexpected results within the leaf and the bean samples from Costa Rica must have other reasons. Deviations in Arriba samples may stem from their partially sexual reproduction during which SNPs can develop naturally. This could cause an Arriba sample to behave like a CCN-51 sample. However, this does not apply to CCN-51 samples because this organism is a clone, which is vegetatively reproduced using grafting. Hence, all samples should have an identic genome, and there should not be any differences within the results of CCN-51 samples. It is therefore open to discussion whether the organism CCN-51 really is a pure clone. This question will be verified using the analysis of microsatellites discussed. Microsatellites are short and non-coding sequences that repeat on the same locus present in the chloroplast and in the nuclear genome.[19,41−43]

All five sample of the parents of CCN-51 (ICS-95, Canelo, and IMC-67) showed the CCN-51-specific result for all PCR–RFLP methods, except for one little incident, in which, for only PCR–RFLP number 17, the ICS-95 and IMC-67 samples showed the Arriba-specific result. Because of the accordance of the results of the parents and the CCN-51 samples, it is becoming clear that the SNPs originate from the parents and were not developed during their cultivation in the 1960s. Hence, these SNPs can be valuated as stable traits with a high value as a marker for CCN-51.

**$(TAAAG)_n$ Repeat in the IRR.** Another aberration detected in the sequence of the chloroplast genome between Arriba and CCN-51 is located in the so-called IRR and is represented in Figure 5. The IRR is a sequence that is reverse opposite complementary to another sequence that is located in the same genome. The IRR is typical for chloroplasts and in the cocoa chloroplast genome, and the IRR has a size of about 30 kbp,[31] corresponding to a percentage of about 37%.

**Figure 6.** Alignment of the $(TAAAG)_n$ repeat in the two cocoa types CCN-51 and Arriba. The 5 bp repeat is repeated 14 times in CCN-51 and 6 times in Arriba.

Analyzing the number of repeats using ultra-barcoding at a given target genome is not possible; therefore, we sequenced the IRR separately from the whole chloroplast genome. First, this region was partially sequenced for one CCN-51 and one Arriba sample according to the publication by Dhingra et al., using 27 primer pairs.[31] The obtained two sequences of CCN-51 and Arriba were aligned. We discovered a difference that is shown in the alignment in Figure 6. The IRR includes a sequence 5 bp long, the $(TAAAG)_n$ repeat, which is repeated with varying frequency. In the sequence of the CCN-51 sample, the $(TAAAG)_n$ repeat is repeated 14 times. In that of the Arriba sample, the $(TAAAG)_n$ repeat is repeated 6 times. The obtained result was verified by partial sequencing. A PCR was carried out with the isolates of the CCN-51 and Arriba leaf samples, in which the primer pair flanks the $(TAAAG)_n$ repeat (see Table 1). After sequencing the amplicons, we determined that the $(TAAAG)_n$ repeat appeared 6 times out of 8 Arriba leaf samples. In 6 of 6 CCN-51 leaf samples, the $(TAAAG)_n$ repeat appeared 14 times. This result corresponds to our expectations, because it is congruent with the result of the sequencing of the single CCN-51 and Arriba samples according to the publication by Dhingra et al. (see above and Figure 6). For this reason, the different repetition of the $(TAAAG)_n$ repeat was evaluated as a suitable basis for the development of a method for discrimination between the two cocoa types. PCR products were generated for both cocoa types using a PCR region with a broad margin around the $(TAAAG)_n$ repeat (primer sequences; see Table 1) . In the following step, the obtained PCR products were detected by AGE, CGE, or dHPLC.[13] Dependent upon the cocoa type, one can observe amplicons that differ by 40 bp (CCN-51, 151 bp; Arriba, 111 bp) because the 5 bp long sequence $(TAAAG)_n$ is repeated 14 times in CCN-51 $[(TAAAG)_{14}]$ and 6 times in Arriba $[(TAAAG)_6]$. The three different detection methods AGE, CGE, and dHPLC for the amplicons of CCN-51 and Arriba are shown in Figure 7. The specific bands and peaks for Arriba and CCN-51 appear in the graphic.

The developed method with the three different detection methods for the amplicons was applied to a large volume of sample material. The summarized results are shown in Tables 3 and 4. Within the leaf samples, 5 of 6 CCN-51 samples showed the CCN-51-specific result with an amplicon of 151 bp as expected and 8 of 8 Arriba samples showed the expected result with an amplicon of 111 bp. A total of 3 of the 5 parent samples of CCN-51 showed the Arriba-characteristic result (111 bp), and the other 2 showed the CCN-51-specific result. Therefore, maternal inheritance of plastids[44] could be taken into consideration by the cocoa type Canelo, which shows the CCN-51-specific result. For the Criollo sample, the Arriba-characteristic amplicon was observed. Within the bean samples, 7 of 8 CCN-51 samples showed the CCN-51-specific amplicon of 151 bp and 1 sample showed the Arriba-characteristic result (111 bp). A total of 12 of 13 Arriba bean samples showed the Arriba-specific amplicon (111 bp), and 1 Arriba sample showed the CCN-51-characteristic amplicon (151 bp). For the Criollo sample, the Arriba-characteristic amplicon was observed. For both cocoa types, we detected one exception within the bean samples. The reasons for this are the same as those described for the PCR−RFLP methods based on SNPs in the chloroplast genome. Polymorphisms within the Arriba samples can be explained by sexual reproduction. Polymorphisms should not appear within CCN-51 samples because CCN-51 is defined by the breeders to be a clone. For this organism, all samples should produce the same result. A closer examination of this phenomenon is described in the conclusion.

In a number of PCR experiments and the following detection of the $(TAAAG)_n$ repeat, an additional band/peak with a size of about 100−105 bp was detected. This additional band/peak can be explained by stuttering or slipping of the polymerase during the replication.[45] Nevertheless, the identification of the cocoa types was successful because the CCN-51- or Arriba-specific bands/peaks at 111 and 151 bp were visible, despite the appearance of this more or less broad band/peak.

**Quantitation.** Having established the two methods for qualitative differentiation of the two cocoa types, their ability to quantitate the content of CCN-51 in mixtures of both types was assessed. For this, selected mixtures of both cocoa types with a content of 10, 30, 50, 70, and 90% CCN-51 were analyzed with both methods, on the one hand, with the method based on the $(TAAAG)_n$ repeat in the IRR and, on the other hand, with the PCR−RFLP method based on SNPs in the chloroplast genome.

However, it was not possible to determine the exact content of CCN-51 in the mixture. Only semi-quantitative estimations were possible. The major problem with quantitation using the $(TAAAG)_n$ repeat was the described additional stutter band at about 100−105 bp. This band could not be attributed to either of the two cocoa types and was not consistently intense. Using the PCR−RFLP method, a correct tendency could be established; with an increasing content of CCN-51, the peak area of the two

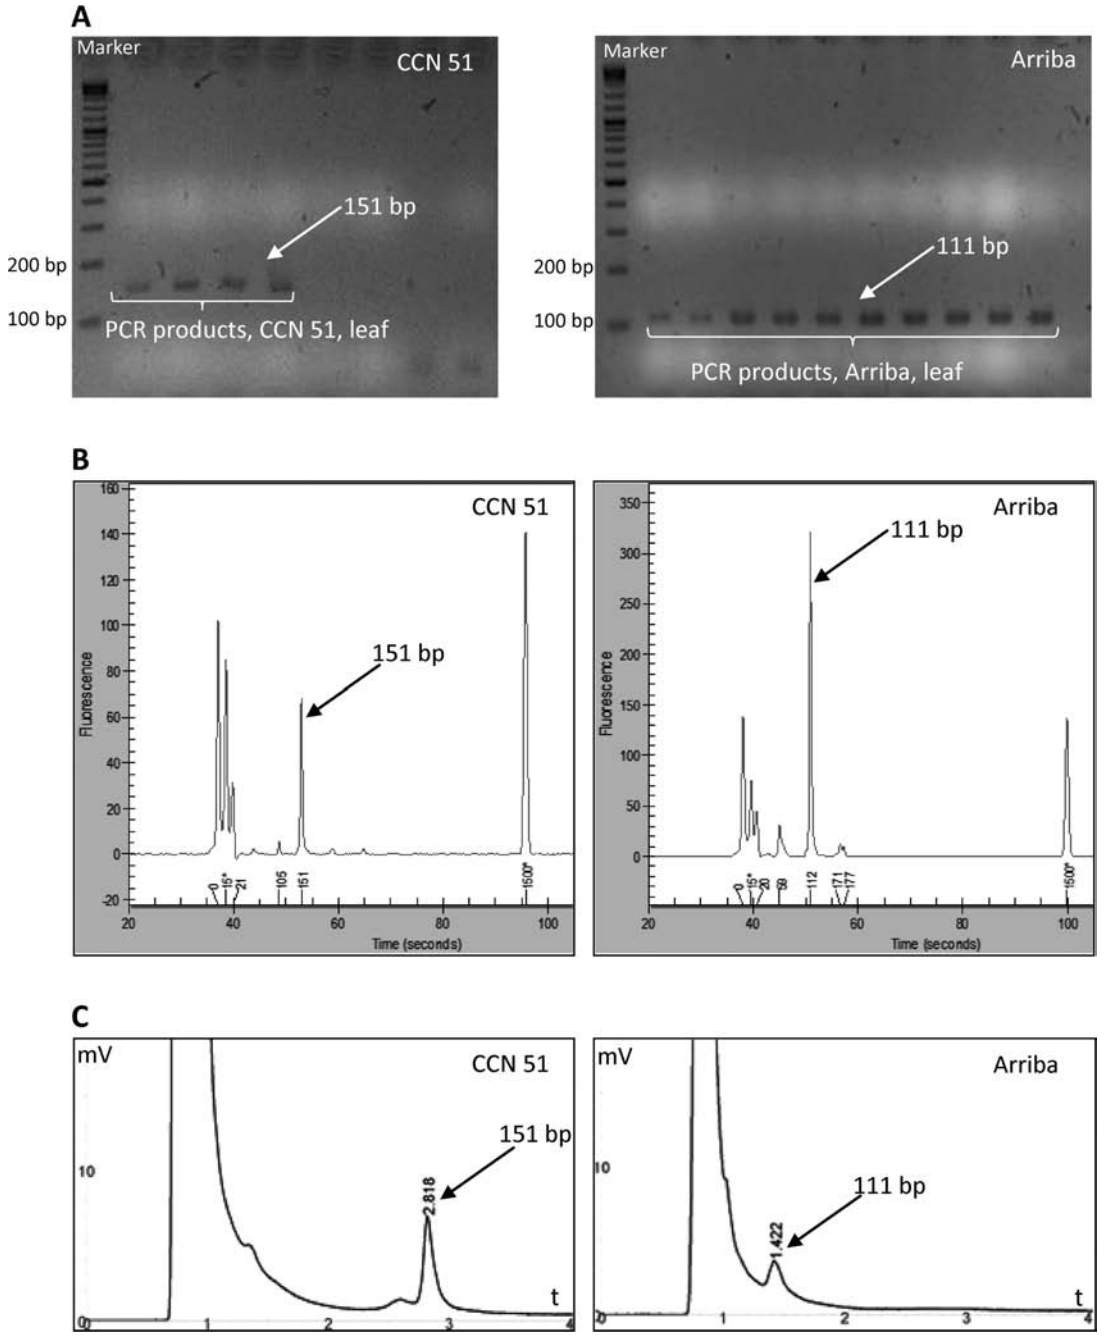

**Figure 7.** Different methods for detecting the amplicons of Arriba and CCN-51: A, AGE; B, CGE; and C, dHPLC. Because of the fact that the $(TAAAG)_n$ is repeated 14 times in CCN-51 and 6 times in Arriba, the size of the amplicons differs by 40 bp: band or peak for CCN-51, 151 bp; band or peak for Arriba, 111 bp.

CCN-51 characteristic fragments rose. However, a quantitation of the exact CCN-51 content was not possible. One reason for this was an inconsistent formation of heteroduplexes,[14] the peak area of which amounted to 15−30%. Another reason why this method is not appropriate for quantitation could be the yield from the isolation of DNA and the grinding of the sample material. It cannot be guaranteed that these two processes are always carried out to an equal extent for CCN-51 and Arriba. This issue is relevant for the cocoa beans and the cocoa liquor made from them, the sample material focused on by the analytics. Neither of the methods can serve as a basis for quantitation of the CCN-51 content in mixtures of both cocoa types. However, a semi-quantitative estimation is possible.

collected and decolorized by adding 30% (v/v) aqueous $H_2O_2$. The solution was concentrated under vacuum and precipitated with 3 volumes of 95% (v/v) aqueous ethanol and then incubated at 4 °C overnight. Polysaccharide precipitates were obtained by centrifugation at 4000 rpm for 10 min and washed sequentially with acetone and ether. The polysaccharide extract was dried using nitrogen gas and stored in a desiccator for further FT-IR analysis.

**Oxygen Radical Absorbance Capacity (ORAC) Assay.** Determination of the oxygen radical absorbance capacity of the polysaccharides was performed as previously reported[16] using an Infinite F200 PRO microplate reader (Tecan, Switzerland). Samples and Trolox standards were prepared in DMSO, and all other reagents were prepared in 75 mM phosphate buffer (pH 7.4). Briefly, each well in a 96-well plate contained 30 μL of sample (or DMSO for the blank control), and 225 μL of 81.63 nM fluorescein. The plate was covered and incubated at 37 °C for 20 min, and 25 μL of 0.36 M 2,2′-azobis(2-amidinopropane) hydrochloride (AAPH) was added to each well to start the reaction, resulting in a final total volume of 280 μL. The fluorescence was recorded every 5 min for 1 h (ex/em, 485/538 nm) at 37 °C. Trolox equivalents were calculated from the relative area under the curve compared to a Trolox standard curve prepared under the same experimental conditions. Reactions were conducted in triplicate, and results are expressed as micromoles of Trolox equivalents per gram of polysaccharides.

**Ferric Reducing Antioxidant Power (FRAP) Assay.** The ferric reducing antioxidant power assay is based on the reduction of $Fe^{3+}$-tripyridyltriazine (TPTZ) to a blue-colored $Fe^{2+}$-TPTZ.[17,18] The FRAP reagent was prepared by mixing 300 mM acetate buffer (pH 3.6), 10 mM TPTZ, and 20 mM ferric chloride in a ratio of 10:1:1 (v/v/v). Then, 3 mL of FRAP reagent was added to 20 μL of sample or Trolox and incubated at 37 °C for 30 min. Absorbance was measured at 590 nm using an Infinite F200 PRO microplate reader (Tecan, Switzerland). Trolox was used as a standard, and the appropriate sample dilutions were determined. Reactions were conducted in triplicate, and results are reported as Trolox equivalents (TE) per gram of polysaccharides.

**Acid Hydrolysis.** Polysaccharides were hydrolyzed using two approaches. For complete acid hydrolysis, polysaccharides (10 mg) were hydrolyzed in 2 mL of 2 M trifluoroacetic acid (TFA) in an ampule sealed under a nitrogen atmosphere and incubated at 110 °C for 5 h. For partial acid hydrolysis, 2 mL of 0.05 M TFA was added and incubated at 110 °C for only 2 h. After cooling to room temperature, reactions were centrifuged at 4000 rpm for 5 min, and supernatants were dried at reduced pressure. Methanol was twice added and evaporated under vacuum to remove residual TFA.

**FT-IR Spectroscopy and Chemometric Analysis.** FT-IR spectra of nonhydrolyzed polysaccharides were obtained using a PerkinElmer Spectrum 100 FT-IR spectrometer. Spectra were recorded in absorbance mode from 4000 to 400 $cm^{-1}$ at a resolution of 4 $cm^{-1}$. Four replicate spectra were collected for each sample. Spectra from each batch of ZJ samples were exported to Excel 2010 to calculate the mean chromatograph. The Pearson correlation coefficient $r$ ($-1 \leq r \geq 1$) was calculated to evaluate the similarity of fingerprints using eq 1.[13]

$$r = \frac{\sum_{i=1}^{n}(x_i - \bar{x})(y_i - \bar{y})}{\sqrt{\sum_{i=1}^{n}(x_i - \bar{x})^2 \sum_{i=1}^{n}(y_i - \bar{y})^2}} \quad (1)$$

$x_i$ and $y_i$ are the $i$th elements of $x$ and $y$ (from two fingerprints), $n$ is the number of variables in the fingerprints, $\bar{x}$ and $\bar{y}$ are means or averages of the ZJ sample set and SC or FJ samples. The calculation was performed using the Pearson function in Excel 2010 (Microsoft).

**Preparation of PMP Derivatives after Complete Acid Hydrolysis.** Monosaccharide standards or hydrolyzed polysaccharide samples were dissolved in 10 mL of dd-water. The standards or hydrolyzed samples (0.2 mL) were mixed with 0.2 mL of a 0.5 M methanol solution of 1-phenyl-3-methyl-5-pyrazolone (PMP) and 0.2 mL of 0.3 M NaOH and stirred at 70 °C for 60 min. Following cooling to room temperature, reactions were neutralized with 0.2 mL of 0.3 M HCl, and 1 mL of chloroform was added and stirred for 30 s before centrifugation at 2000 rpm for 5 min. The chloroform phase was discarded, and the extraction process was repeated a further two times to remove the excess PMP reagent. The aqueous layer was collected, made up to 5 mL with dd-water, and filtered through a 0.45 μm membrane.

**Preparation of PMP Derivatives after Partial Acid Hydrolysis.** Partially hydrolyzed polysaccharides were dissolved in 2 mL of dd-water, and 0.5 mL was mixed with 0.2 mL of a 0.5 M methanol solution of 1-phenyl-3-methyl-5-pyrazolone (PMP) and 0.2 mL of 0.3 M NaOH and stirred. Subsequent steps were as described above for complete acid hydrolysis.

**HPLC Analysis.** Analysis of PMP derivatives was carried out on an Agilent 1260 HPLC system (Agilent Technologies, USA). Separation was achieved using reverse phase elution on a 5 μm Shim-pack VP-ODS column (4.6 mm × 250 mm, 5 μm, Shimadzu, Kyoto, Japan) fitted with a 4.6 mm × 10 mm Shim-pack GVP-ODS guard column (Shimadzu). The chromatographic conditions were as follows: flow rate = 0.8 mL/min; sample injection volume = 20 μL; column temperature = 30 °C. The mobile phase consisted of 82% (v/v) 0.05 M sodium phosphate (pH 6.8) containing 18% (v/v) acetonitrile for isocratic elution. Spectra were collected at a wavelength of 245 nm.

**Data Analysis.** Antioxidant activity data are reported as means ± standard deviation. One-way ANOVA and the LSD test at the level of 0.05 were used to identify differences in means using SPSS for Windows (version rel. 10.05, 1999, SPSS Inc., Chicago, IL, USA). All material pretreatment, extraction, processing, and spectroscopic/chromatographic fingerprinting and data handling were performed as presented on the flowchart (Figure 1). The similarity of FT-IR fingerprints was determined using the Pearson correlation coefficient $r$ calculated using Excel 2010. The similarity of HPLC fingerprints was determined using the Similarity Evaluation System for Chromatographic Fingerprint of Traditional Chinese Medicine version 2004A (Chinese Pharmacopoeia Committee), which was designed specifically for similarity analyses of LC and GC fingerprints and has been recommended by the State Food and Drug Administration of China.[19,20] The correlation coefficients of complete chromatographic profiles of samples were calculated. The chemical fingerprints of polysaccharides from 12 batches of *F. velutipes* fruiting bodies were analyzed by similarity analysis, and principal component analysis (PCA) was performed using SIMCA-P 11.5 (Umetrics AB, Umea, Sweden).

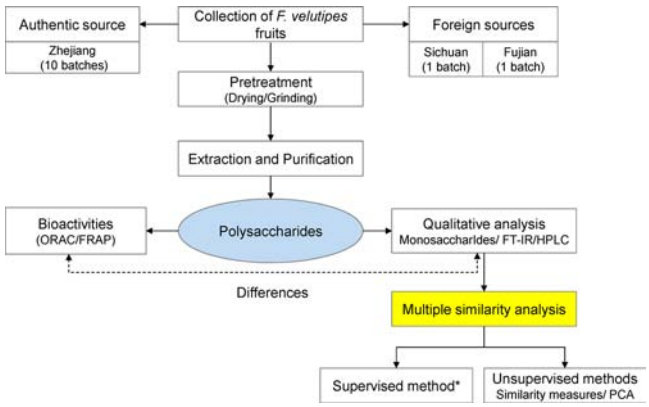

**Figure 1.** Flowchart of material pretreatment, extraction, processing, spectroscopic and chromatographic fingerprinting, and data handling. (*) Similarity Evaluation System for Chromatographic Fingerprint of Traditional Chinese Medicine.

## RESULTS AND DISCUSSION

**Antioxidant Activity of Polysaccharides from *F. velutipes* Fruiting Bodies.** Oxygen radical absorbance capacity (ORAC) and ferric reducing antioxidant power (FRAP) assays were performed to investigate the antioxidant activity of polysaccharide samples and to determine whether

different radical systems influenced the results. Polysaccharides from the authentic source (samples ZJ-1−ZJ-10) and the foreign sources (samples SC and FJ) contributed to the observed ORAC and reducing power in Figure 2. The influence

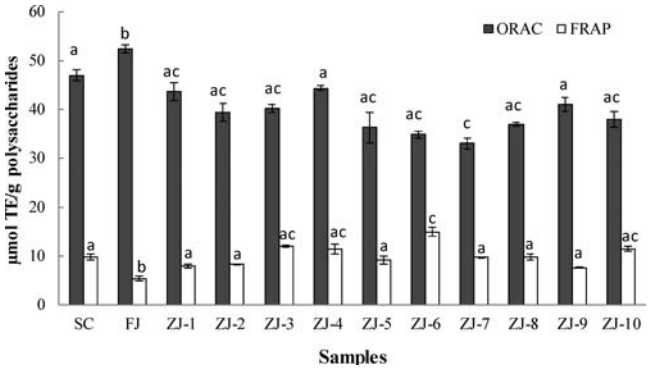

**Figure 2.** ORAC and FRAP values of polysaccharides from *F. velutipes* fruiting bodies. Gray columns indicate ORAC values, and white columns represent FRAP values. ZJ-1−ZJ-10 represent antioxidant values of 10 batches of the authentic source; SC and FJ are the antioxidant values of each of two foreign sources, respectively. Results are expressed as micromoles of Trolox equivalents (TE) per gram of polysaccharides. Tests were conducted in triplicate for each batch, with mean values shown and standard deviations depicted by vertical bars. Shown in the same color, columns marked with different letters are significantly different ($p < 0.05$).

of *F. velutipes* polysaccharides on reactive oxygen species (Figure 2) showed that the antioxidant capacity was highest in fruiting bodies from FJ, and similar in SC and most of the ZJ samples ($p > 0.05$), with ORAC values between 32 and 52 $\mu$mol TE/g polysaccharides. The reducing power serves as a significant indicator of potential antioxidant activity, and this was found to be similar in fruiting bodies from most ZJ samples and SC and to be the lowest in FJ ($p > 0.05$), in the range of 5−11 $\mu$mol TE/g polysaccharides. Variation in antioxidant activities of extracts from different sources of *F. velutipes* fruiting bodies indicated a structural dissimilarity of polysaccharides, which might affect other biological activities of *F. velutipes* fruiting bodies.[9,10]

The quality of polysaccharides in fruiting bodies cannot be determined from mushroom appearance alone, and existing high-throughput methods are unable to differentiate between authentic and foreign sources because distinguishing between complex polysaccharide structures is highly challenging. Therefore, alternative approaches are needed for quality control of *F. velutipes* fruiting bodies.

**FT-IR Fingerprinting: Similarity Analysis and PCA.** The spectroscopic fingerprints of nonhydrolyzed polysaccharide extracts from 10 batches of qualified ZJ samples were analyzed by FT-IR, and the ZJ-7 fingerprint is shown as an example (Figure 3A). The absorption peaks at 3400, 2944, and 1420 $cm^{-1}$ correspond to O−H, C−H, and carboxyl C−O group stretching, whereas the band in the region of 1246 $cm^{-1}$ results from a O−H deformation vibration. Stretching peaks at 934, 885, and 882 $cm^{-1}$ may derive from $\beta$-glycosidic linkages between the sugars, and water molecules bound to the polysaccharides contributed to the absorption band at 1643 $cm^{-1}$. FT-IR chromatograms of SC and FJ samples (Figure 3B,C) were similar to that of ZJ, but key differences in the transmission percent of some peaks were apparent.

The similarity of 12 separate batches of *F. velutipes* fruiting bodies from various sources was evaluated by calculating the correlation coefficient with the original data. All spectra were exported to Excel 2010, and the correlation coefficient $r$ was calculated. The fingerprints of SC and FJ were compared with the standard profiles derived from ZJ samples. A value of 1 indicates a perfect correlation with the standard profile.[13] For 10 batches of ZJ samples, $r$ values varied between 0.973 and 0.996, indicating a high degree of similarity ($r > 0.9$). The $r$ values for SC and FJ samples were 0.788 and 0.828, respectively, indicating significant differences from the ZJ samples.

PCA was applied to confirm the discrimination of sources of *F. velutipes* fruiting bodies based on FT-IR fingerprint data of raw polysaccharide extracts. On the basis of Kaiser's stopping rule, only factors with eigenvalues >1 were considered in the analysis.[21] The 10 characteristic chromatographic peaks (Figure 3) were processed using PCA, and factors 1 and 2 had eigenvalues of 8.60 and 1.07, representing 96.7% of the cumulative variance. Therefore, factors 1 and 2 were used to visualize data inhomogeneity. A two-dimensional PCA plot of IR spectroscopic fingerprints after data pretreatment was constructed in Figure 4. Scattered small triangles representing PCA scores showed that the authentic samples (ZJ-1−ZJ-10) were clustered closely, whereas the SC and FJ samples were more diffuse. This suggests that PCA of IR fingerprint data could be used to discriminate authentic and foreign sources of *F. velutipes* fruiting bodies.

**HPLC Fingerprinting: Similarity Analysis and PCA.** The monosaccharide composition of polysaccharides of *F. velutipes* fruiting bodies was investigated using HPLC following a complete acid hydrolysis and revealed the presence of glucose, mannose, galactose, ribose, and xylose (Figure 5). This profile differed significantly from mycelial tissue, in which glucose was the only monosaccharide identified.[14] Glucose, with a molar ratio of 85.04%, was the predominant monosaccharide, followed by mannose (6.81%), galactose (6.09%), xylose (1.65%), and ribose (0.39%). The fruiting bodies of *F. velutipes* were also previously reported to contain arabinose[22] and fructose.[23]

Similarity analyses were applied to HPLC fingerprints following partial acid hydrolysis because there were too few peaks in the HPLC fingerprints after complete acid hydrolysis. The HPLC profiles of 12 batches of *F. velutipes* fruiting bodies and the mean chromatogram from the 10 ZJ batches (Figure 6A) revealed 17 characteristic peaks suitable for similarity analysis. The correlation coefficients of the 10 ZJ batches were calculated using the Similarity Evaluation System for Chromatographic Fingerprint of Traditional Chinese Medicine software and ranged from 0.930 to 0.998. The $r$ values for SC and FJ samples were 0.955 and 0.982, respectively (Figure 6B,C), suggesting the similarity software was not able to discriminate between the sources.

PCA was applied to the HPLC profiles from precolumn PMP derivatization after partial acid hydrolysis. The relative peak area of 17 characteristic chromatographic peaks (Figure 6) was used for PCA, and three factors had eigenvalues of 7.18, 2.22, and 1.49, representing 90.7% of the cumulative variance. Therefore, a three-dimensional PCA plot of HPLC chromatographic profiles was constructed in Figure 7. Scattered dots representing the PCA scores showed that the qualified samples (ZJ-1−ZJ-10) were clustered closely in geometric space, whereas the SC and FJ samples were more diffuse. This

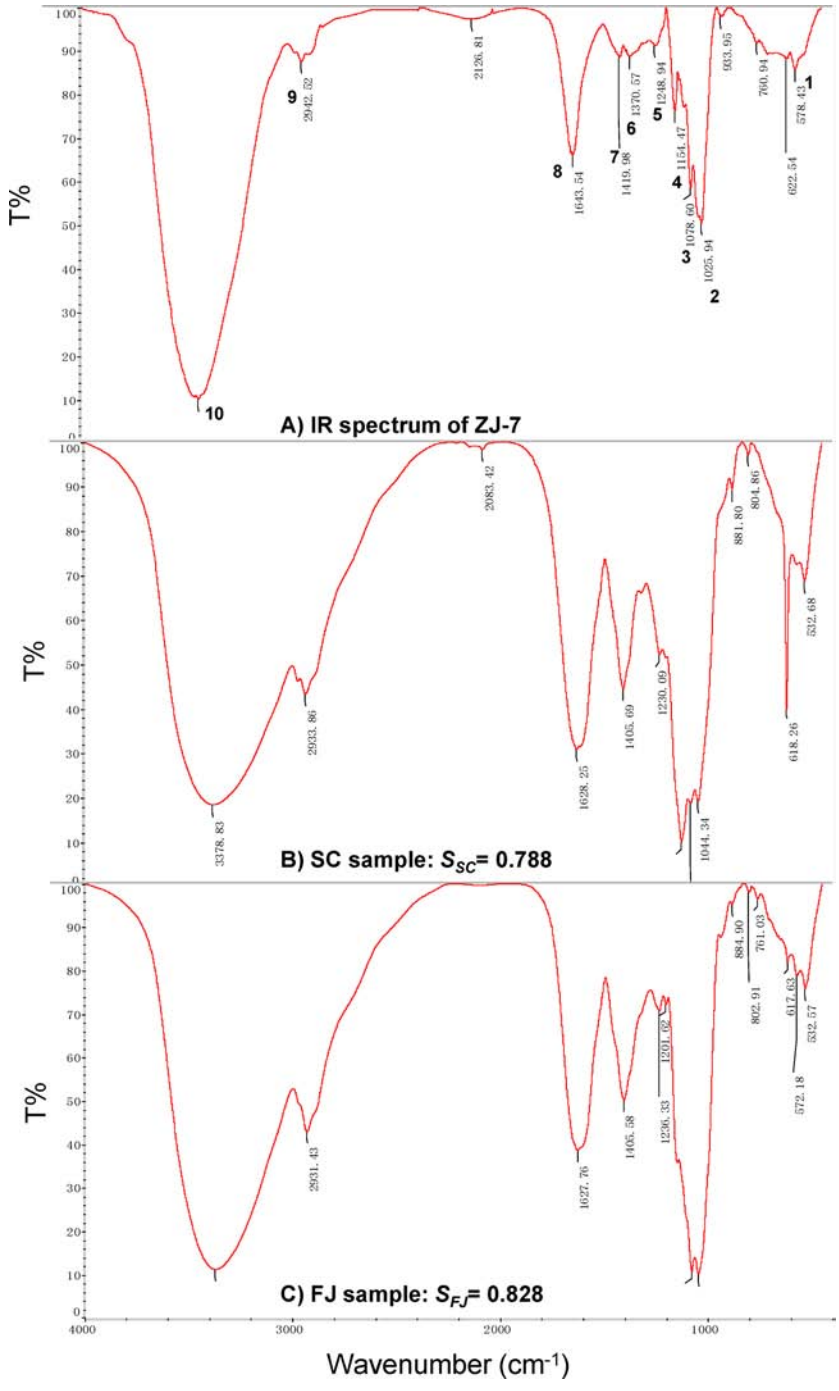

**Figure 3.** Comparison of FT-IR fingerprints of SC and FJ samples (foreign sources) with the mean FT-IR spectra of raw polysaccharide extracts of ZJ samples (authentic source): (A) ZJ-7 sample; (B) SC sample; (C) FJ sample. Peaks 1−10 in (A) were chosen for principal component analysis. $S_{SC}$ and $S_{FJ}$ are similarity values between SC and FJ, respectively, compared with ZJ.

suggests that PCA of partially hydrolyzed PMP derivatives could be used to discriminate between authentic and foreign sources of *F. velutipes* fruiting bodies.

Spectroscopic and chromatographic fingerprints using supervised/unsupervised data analysis techniques including similarity parameters (i.e., correlation coefficient) and PCA have been applied to detect foreign sources of *F. velutipes* fruiting bodies. IR spectroscopic fingerprints using correlation coefficient and PCA proved capable of discriminating sources of *F. velutipes* fruiting bodies. HPLC chromatographic fingerprints using the TCM-supervised method could not discriminate between sources, but PCA of HPLC fingerprints could detect the foreign sources. Generally, IR fingerprinting with unsupervised chemometrics is a reliable identification and qualification method suitable for quality control of *F. velutipes* fruiting bodies. PCA is a widely used mathematical approach for reducing the dimensionality of original data by introducing a small number of underlying factors without losing too much information. In this study, PCA is practicable for analyzing both IR spectroscopic and HPLC fingerprint data to determine the quality of polysaccharides between different sources of *F. velutipes* fruiting bodies. These findings should be taken into

[a]RE: ready-to-eat. CP: classical products. NB: no bands. ×: expected band obtained.

Polymerase chain reaction (PCR), the technique of choice for species identification, is often coupled with sequencing, which is used to determine the precise order of nucleotides in a DNA molecule.[16,18] FINS (Forensically Informative Nucleotide Sequencing) combines DNA sequencing with a phylogenetic analysis.[19] The development of the DNA Barcoding, an evolution of the FINS method, has determined the increase of use of the cytochrome c oxidase I gene (*COI*) as a genetic marker for species identification.[20,21] In a previous work,[12] we showed that a specific pre-DNA extraction treatment, coupled with FINS of a 142 bp *COI* gene fragment, allowed the molecular identification of jellyfish species, also in case of salted products, in which the DNA is heavily degraded.

Considering that FINS is often limited by high costs and long-time of execution, in this work an alternative method to be used with screening purposes was developed to minimize expenses and save time. This new method, a Pentaplex PCR assay, is capable to identify two Asian jellyfish commonly used as food, such as *N. nomurai* and *R. esculentum*, and another three species distributed in the Mediterranean Sea, such as *R. pulmo*, *P. noctiluca*, and *C. tuberculata*, which could represent a novel business for the industry. This is possible by using a common forward primer together with 5 specific reverse primers, capable to amplify five regions with different size of the *COI* gene. This method can be used as rapid test for checking commercial samples, in which the diagnostic morphological characteristics have been lost.

## 2. MATERIALS AND METHODS

**2.1. Jellyfish Reference (RS) and Market Samples (MS) Collection.** Nine samples belonging to the species *Aurelia* sp., *C. tuberculata*, and *P. noctiluca* were kindly provided by the Institute of Sciences of Food Production of the National Research Council of Lecce (Supporting Information Table 1SI).

**2.2. DNA Extraction.** All the jellyfish RS were extracted according to the protocol proposed by Armani et al.[22] The amount of DNA was determined with a NanoDrop ND-1000 spectrophotometer (NanoDrop Technologies, Wilmington, DE, U.S.A.) by measuring the absorbance at 260 nm. DNA samples obtained from 57 RS jellyfish (Supporting Information Table 1SI) and 78 MS (Table 1), all of them molecularly identified in a previous work,[22] were also used to develop and validate the Pentaplex PCR. Finally, three DNA samples of *R. luteum* from the study of Prieto et al.[23] and six DNA samples of *P. benovici* from the study of Piraino et al.[24] were used.

**2.3. Amplification of *COI* and *28SrRNA* Genes.** *2.3.1. COI.* All the DNA reference samples extracted in this study from jellyfish were initially amplified using the primers FFDL and FRDL2[12] to obtain the first 655 bp of the *mtCOI* gene. The samples that failed the amplification were subsequently amplified using internal reverse primers[12] in combination with the same forward primer. The DNA was amplified according to the following PCR protocol: 20 μL of reaction volume containing 2 μL of 10× buffer (5Prime, Gaithersburg, MD, U.S.A.), 200 μM of each dNTP (dNTPmix, Euroclone S.p.A-Life Sciences Division, Pavia, Italy), 300 nM of primers, 25 ng/μL of BSA (Purified BSA 100× , New England BIOLABS Inc., Ipswich, MA, U.S.A.), 1.25 U of PerfectTaq DNA Polymerase (5Prime, Gaithersburg, MD, U.S.A.), 100 ng of DNA and DNase free water (Water Mol. Bio. Grade, DNase−RNase and Protease free, 5Prime GmbH, Hamburg, Germany), with the following cycling program: denaturation at 94 °C for 3 min; 40 cycles at 94 °C for 30 s, 51 °C for 30 s, and 72 °C for 35 s; final extension at 72 °C for 5 min. PCR products (5 μL) were checked by gel electrophoresis on a 2% agarose gel and the presence of fragments of the expected length was assessed by a comparison with the standard marker SharpMass50-DNA ladder (Euroclone, Wetherby, U.K.). Double-stranded PCR products were purified with the Illustra ExoProStar 1-Step Enzimatic PCR and Sequencing Clean-Up (GE Healthcare U.K. Limited, Amersham Place Little Chalfont Buckinghamshire, U.K.) following the manufacturer's instruction and then sequenced by GATC Biotech (Germany). The obtained sequences were analyzed using ClustalW in MEGA 5.0.[25] Fine adjustments were manually made after visual inspection. All the sequences were used to run a BLAST analysis on GenBank (http://blast.ncbi.nlm.nih.gov/Blast.cgi) and analyzed using the Identification System (IDS) on BOLD (Species Level Barcode Records) (http://www.boldsystems.org/index.php/IDS_OpenIdEngine). Finally, the sequences were deposited on GenBank via EBI (Supporting Information Table 1SI).

*2.3.2. 28S rDNA.* The *28SrRNA* gene sequences belonging to the Order Rhizostomeae and Semaestomeae produced in the work of

[a]Boldface, primers finally selected. bp = base pair; MT = melting temperature; AL= amplicon length.

Bayha et al.[26] were downloaded from GenBank and aligned using Clustal W in MEGA 5.0. The overall mean distance was calculated using the Kimura 2-parameter model[27] on a fragment of 1480 bp. Then, a new couple of primers (F28S and R28S) (Table 2) were designed for the amplification of a fragment of ∼1600 bp from the DNA of *N. nomurai* using the same PCR mix described for the *COI* gene, with the following cycling program: denaturation at 94 °C for 3 min; 40 cycles at 94 °C for 30 s, 51 °C for 30 s, and 72 °C for 35 s; final extension at 72 °C for 10 min. The sequences were analyzed as reported in Section 2.3.1. and were deposited on GenBank via EBI (Supporting Information Table 1SI).

**2.4. Primer Design for the Pentaplex PCR Assay.** *2.4.1. Specie-Specific Primers Targeting the COI Gene.* *mtCOI* sequences (666) belonging to 24 species (Table 3) were aligned with Clustal W in MEGA 5.0. Then, two hypothetical common forward primers were designed (FJ1 and FJ2, Table 2) by modifying the primer FFDL designed in a previous work.[12] The reverse primers were designed on highly polymorphic regions for the amplification of fragments of different length in the range 50−200 bp. Primers score were calculated with the software Beacon designer 7.0 (Premier Biosoft International, Palo Alto, CA) and with the software available on the Eurofins MWG Operon (Ebersberg, Germany) Web page (http://www.eurofinsgenomics.eu/). The number of mismatches between the reverse primers and the annealing region of the no-target species (Supporting Information Table 2SI) was also taken into consideration as a criterion to select specie-specific primers. In total, 11 primers, 2 forward and 9 reverse, were synthesized by the Eurofins MWG Operon.

*2.4.2. Control PCR Primers Targeting the 28SrRNA Gene.* With the aim of amplifying in all the species, a control fragment of 55 bp together with the species-specific fragment, two primers (28sfor55 and 28srev55) (Table 2) were designed on highly conserved regions using the software Beacon designer 7.0 after aligning the *28SrRNA* gene sequences (Order Rhizostomeae and Semaestomeae) produced in the work of Bayha et al.[26] with the sequences of *N. nomurai* produced in this study.

**2.5. PCR Reaction Optimization.** The two forward primers were tested on the DNA of all the reference species in single reaction with each of the reverse primers designed (Supporting Information Table 1SI). The primers capable to amplify the target sequence without producing unspecific bands were selected (Table 2).

All the primers were tested in combination in the same PCR reaction mix using different concentrations (from 100 to 400 nM), in the presence of increasing concentration of $MgCl_2$ (1, 2, and 5 mM) and nucleotides (from 200 to 600 μM). We also tested different amount of total DNA (from 1 to 200 ng) and of Taq polymerase (1× and 2×). The optimal annealing temperature was selected after trials in the range of 47 to 51 °C, on a PeqStar 96 Universal Gradient, PEQLAB BiotechnologieGmgH (Euroclone, Wetherby, U.K.). The control PCR primers were initially tested on all the reference DNA samples and then included in the multiplex reaction. The reaction protocol that showed the best amplification performances was tested on 10 samples of not degraded DNA extracted from 5CP and 5RE to verify the output of the Pentaplex method in case of degraded and low quality DNA.

**2.6. Final Pentaplex PCR Protocol and Analysis of Commercial Samples.** The following final protocol: 10 μL of reaction volume containing 1 μL of 10× buffer (Fisher Molecular Biology, Trevose PA, U.S.A.), 400 μM of each dNTP (dNTPmix, Euroclone S.p.A-Life Sciences Division, Pavia, Italy), 300 nM of FJ2, 200 nM of COT2, 200 nM of RHOP1-1, 225 nM of NEMO1, 200 nM of PEL1, 216 and 100 nM of RHIZ1-1 reverse primers, 100 nM of 28sfor55 and 28srev55 control primers, 25 ng/μL of BSA (Purified BSA 100× , New England BIOLABS Inc. Ipswich, MA, U.S.A.), 1 U of SubTherm TAQ Polymerase (Fisher Molecular Biology, Trevose, PA, U.S.A.), 3 mM of $MgCl_2$, 50 ng of DNA and DNase free water with the following cycling conditions: denaturation at 95 °C for 3 min; 40 cycles at 95 °C for 25 s, 49 °C for 5 s, and 72 °C for 5 s; final extension at 72 °C for 5 min. The electrophoresis was performed using a 4% agarose gel. In case of MS DNA, the length of the specific bands obtained with the multiplex PCR was compared to the results of the BLAST analysis performed on the same samples in a previous article[12] (Table 1), with the aim to assess the efficiency and specificity of the assay in case of low quality DNA.

## 3. RESULTS AND DISCUSSION

Seafood species identification has gained increasing importance in the current global market context. In fact, many studies, carried out in different geographical areas, have highlighted that almost one-third of the commercialized seafood is made of a different species with respect to what declared on the label.[20,21] In some cases, the substitution rate can reach alarming levels, as in the case of jellyfish products.[12]

In this light, the diagnostic techniques, particularly those based on DNA analysis, may assist both private companies and official agencies in ensuring a fair commerce in the light of the traceability regulations. Among the available methods, the multiplex PCR has the advantage to allow considerable saving of time and labor. These methods have been successfully used for several different purposes of identification, fish species included.[28,29]

[a]Sequences in bold have been produced in this or previous studies.[22,23]

### 3.1. Selection of the Species and of the DNA Target.

*3.1.1. Species Selection.* *R. esculentum* and *N. nomurai* are the Asian species most exploited for human consumption.[10,12]

Regarding the other species selected as target for the Pentaplex PCR, the *R. pulmo* was chosen due to the fact that it is one of the largest and most abundant jellyfish exclusively distributed in the Mediterranean Sea and adjacent areas.[30] The potential utilization of this Mediterranean jellyfish for food preparation was suggested in the work of Muhammed and Sultana[31] and by the fact that an Italian company has recently started to process *R. pulmo* for exportation to the Japanese market (author's note). Finally, Chinese people use to collect jellyfish that have run aground on beaches and to buy jellyfish from fishermen along the Tyrrhenian coast of Italy.[12] *C. tuberculata* and *P. noctiluca* are also widely distributed in the Mediterranean Sea.[32,33] They may likely be used as food products owing to their anatomical features and wide distribution.[35] In support of this, the molecular analyses carried out in a previous work[12] have identified the presence of the species *P. noctiluca* in some commercial products.

*3.1.2. DNA Target Selection.* The selection of a mitochondrial molecular marker is based on its several advantages with respect to the nuclear markers, such as the higher number of copies and the greater resistance to degradation induced by chemical-physical treatments. Moreover, the higher degree of interspecific variability is particularly useful for discrimination of species very close from a phylogenetic point of view.[16,18] Among the mitochondrial markers most used for seafood authentication (*COI*, *16srDNA*, and *cytb*), in this study, the *COI* gene was chosen due the availability of a higher number of reference sequences (Table 3). In fact, the creation of the Barcode of Life Data Systems database (BOLD) (http://www.

boldsystems.org/) has gained the attention of many researchers worldwide making the first 650 bp of the *COI* region one the most targeted mtDNA region for species identification,[20,21,34]. Furthermore, the *COI* gene was found to be informative enough to allow the identification of edible jellyfish species.[12]

**3.2. Primer Design.** *3.2.1. Specie-Specific Primers Targeting the COI Gene.* One of the main points to take into consideration during primers designing is the nature of the sample to be analyzed. In fact, a net difference exists between fresh and processed products: technological treatments, such as heating, acidification, pressurization, or their combination, may negatively influence the integrity of DNA and hence the PCR outputs.[18] In particular, heat treatments and sharp shifts of pH were identified as the main DNA degrading factors in food.[36]

In a previous work,[12] we found that jellyfish products were characterized by very low pH values: ∼4 and ∼6 in CP and RE, respectively. Despite a certain level of DNA degradation, we were able to amplify bands of about 700 bp in the 75% of the DNA extracted from RE samples and in the 44% of the DNA extracted from CP samples. However, in 100% of the DNA extracted from both kind of products, it was possible to obtain amplicons of ∼200 bp. For this reason, in this work the primers were designed to produce amplicons with a maximum length of 200 bp (Table 2).

With the aim to decrease the probability of template-independent primer interactions during amplification, which is greater in a multiplex PCR than in a uniplex, we decided to design a common forward primer (FJ2). This approach was successfully used to develop other methods based on multiplex PCR.[28,29] Considering the high variability of the *COI* gene, which makes difficult to find a common conserved region among five different species, we decided to design a degenerated primer. This was designed by modifying the forward primers proposed in a previous work,[12] while the reverse primers were designed on a polymorphic region of the *COI* gene. Once tested in single and multiplex reactions, the reverse primers PEL1, NEMO1 showed a high specificity for their target species (*P. noctiluca* and *N. nomurai*), producing the expected amplicon of 165 and 143 bp, respectively. No bands were obtained in case of DNA samples belonging to other jellyfish species of the Rhizostomeae and Semaestomeae order (Supporting Information Table 1SI). Interestingly, the primer PEL1 was able to amplify the DNA of *P. noctiluca* but not the DNA of *P. benovici*, a new *Pelagia* species recently described by Piraino et al.[24] For these reasons the reverse PEL1, NEMO1 were selected without modifications, which, on the contrary, were necessary for RHIZ1, RHOP1, and COT1.

The original RHIZ1 reverse primer gave the expected amplicon of 203 bp on all the species belonging to the genus *Rhizostoma*, which, according to Russell,[30] is composed of *R. pulmo*, *R. octopus*, and *R. luteum*. While a recent study of Prieto et al.,[23] on the basis of morphological and molecular results, confirmed that *R. luteum* is a distinct species with respect to the other two, the status of *R. octopus* is still controversial. In fact, Kramp[37] considered *R. luteum* as a variant of *R. pulmo* and Holst et al.[38] advocated that detailed morphological studies and molecular analyses are needed to better define the relationships among *Rhizostoma* species. For these reason, the pairwise Kimura 2-parameter molecular divergence between *R. pulmo* and *R. octopus COI* sequences (Table 3) was calculated. The low values found (6%) suggest that *R. pulmo* and *R. octopus* cannot be unquestionably considered as distinct species by a molecular point of view, supporting the theory of Kramp.[37] In fact, the literature suggests that 10−20% *COI* sequence divergence may be a suitable benchmark value to define species.[39]

In the light of these considerations, the reverse primer RHIZ1 was improved: two new primers were produced (Table 2) by introducing single (RHIZ1-1) and multiple (RHIZ1-2) base modification at different positions, with the aim to create additional mismatches on the annealing region of *R. luteum COI* sequence. RHIZ1-2 was discarded due to its inability to amplify the DNA of both *Rhizostoma* species, while the reverse RHIZ1-1 was selected for its specificity in uniquely amplifying the DNA of *R. pulmo*.

The primer RHOP1 produced the 101 bp amplicon from the DNA of *P. benovici*, other than of *R. esculentum*, due to the presence of only one difference on the annealing sequence of the two species. For these reason, the primer RHOP1 was modified (RHOP1-1) near to the 3′-end. In fact, mismatch at or near the terminal 3′ base of a primer affects PCR more dramatically than those single mismatches located internally or at 5′ end.[40] The new primer RHOP1-1 gave the expected amplicon only in the presence of DNA of *R. esculentum*. Likely, selectivity of amplification using these primers has been increased by the stringent conditions adopted for the amplification protocol (see section 2.6). In fact, to avoid unspecific amplification we used an annealing time of only 5 s.

Finally, even though specific, the reverse primers COT1 was redesigned (COT2) due to its low amplification performance.

*3.2.2. Control PCR Primers Targeting 28SrRNA Gene.* The extraction of DNA contaminated by inhibitors is one of the main obstacles associated with PCR application in complex matrices, such as food. In fact, the inhibitors can interfere with the reaction, even leading to a complete amplification inhibition.[18] In our previous study,[12] we found that $Al^{3+}$ ions may contribute to the overall DNA amplification failure. In fact, the initial concentration of the aluminum in jellyfish food products is extremely different,[12,41] and even though the pre-extraction procedure can reduce its concentration, it is impossible to predict the residual amount in different DNA samples. Therefore, considering that inhibition may be the cause of false-negative reactions, we decided to introduce a reaction control. This consideration, together with the high degradation level of the DNA extracted from MS, led us to design control primers for the amplification of a short DNA fragment of 55 bp.

Ribosomal genes, such as the *16sRNA* gene, are characterized by a low mutation rate.[42] In this study, the overall mean distance calculated on a fragment of 1480 bp belonging to the *28S rDNA* gene sequences (those produced by Bayha et al.[26] together with the sequence of *N. nomurai* produced in this study) was 2%. In the light of these results and taking into consideration that in a previous study[28] the high degree of conservation has played a decisive role for designing primers to be used for the amplification of many species at once, the *28SrRNA* gene was selected as target for designing the control primers.

**3.3. Pentaplex PCR Assay: Development and Final Protocol.** The optimization of a multiplex PCR can imply several difficulties. In fact, the presence of more than one primer pair in the reaction increases the chance of obtaining spurious amplification products and may increase the possibility to obtain the formation of primer dimers. Increasing the concentration of PCR reagents during the optimization step can increase the likelihood of mispriming, with subsequent

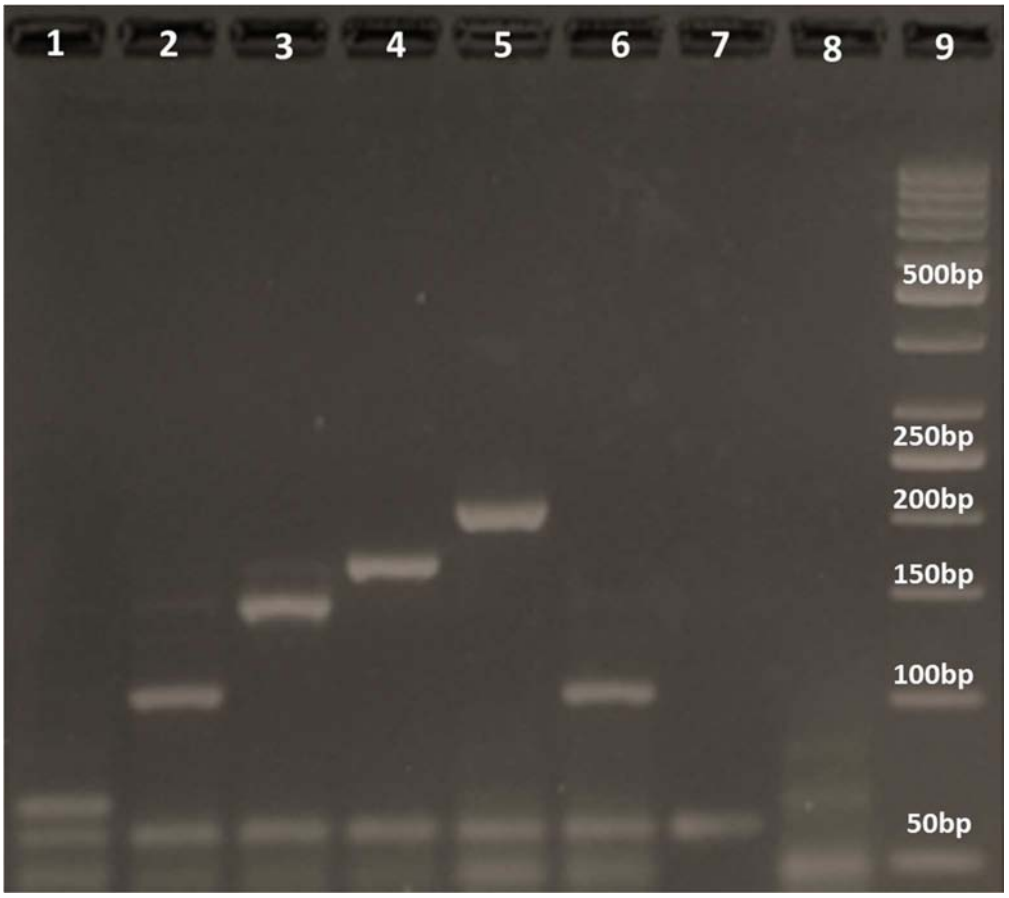

**Figure 1.** Electrophoresis on agarose gel (4%) of the five species of jellyfish selected as target after the Pentaplex PCR. Lane 1, *C. tuberculata* (72 bp); lane 2, *R. esculentum* (101 bp); lane 3, *N. nomurai* (143 bp); lane 4, *P. noctiluca* (165 bp); lane 5, *R. pulmo* (203 bp); lane 6, DNA from RE product; lane 7, DNA from CP product; lane 8, $H_2O$. DNA ladder band size: 1000 bp, 900 bp, 800 bp, 700 bp, 600 bp, 500 bp, 400 bp, 300 bp, 250 bp, 200 bp, 150 bp, 100 bp, 50 bp.

production of nonspecific amplification.[43] However, optimization of these components is usually beneficial. For the aforesaid reasons the final reaction protocol was selected through a process in which different concentration of primers, $MgCl_2$, nucelotides, and Taq polymerase were tested. Meanwhile, the best cycling conditions were selected by testing different temperatures and times.

*3.3.1. Primers and DNA Template Amount.* The primers were used at the same concentration during the first trials (100 nM). Subsequently, the concentrations were modified with the aim to obtain bands of similar intensity. In general, due to the good efficiency of the reverse primers, the concentration was maintained in the range 100−200 nM. Only the degenerated forward primer was used at a higher concentration (300 nM). Overall, primers' concentrations were lower than those at which the formation of considerable amount of primer−dimer (~500 nM) was observed.[43] We found that the introduction of the control primers (28sfor55; 28srev55) reduced the amplification efficiency of some specific primers (PEL1 and NEMO1), even when used at low concentration (50, 100 nM). For this reason, both nucleotides and Taq polymerase concentration were increased (see Section 3.3.3).

Another fundamental step for obtaining of a specific amplification, strictly connected with primers concentration, is the selection of an adequate DNA template concentration. In fact, if the primer-to-template ratio is too low, specific products will not accumulate exponentially while primer dimers may be amplified more efficiently than the desired target.[43,44] In this study, the utilization of total DNA quantities between 50 and 200 ng per reaction did not bring any significant difference regarding bands intensity. On the contrary, DNA quantities over 100 ng negatively affected the background of the gel after electrophoresis, especially in case of DNA extracted from market samples. In fact, when degradation of DNA occurs, small DNA fragments may unspecifically be involved in the reaction, producing spurious amplification products. For this reason, 50 ng were used as working concentration.

*3.3.2. $MgCl_2$, Nucelotides and Taq Polymerase.* To test the influence of $MgCl_2$ different trials were performed keeping the dNTP concentration constant and gradually increasing magnesium chloride from 1 to 5 mM. Using the standard concentration of dNTP (200 $\mu$M), the amplification became more specific and the products acquired comparable intensities at 3 mM: further increases showed a detrimental effect. Then, considering that in a multiplex PCR more amplicons are simultaneously amplified and the pool of enzymes and nucleotides becomes a limiting factor,[45] and in the light of the results obtained after the addition to the reaction mixture of the control primers, we decided to test double concentration of these reagents (400 $\mu$M of dNTP and 1U of TAQ Polymerase). The reaction efficiency was significantly improved and, even though dNTPs directly chelate a proportional number of $Mg^{2+}$ ions, we did not find any advantage using higher concentration of $MgCl_2$.

Table 4. Amplification Rate of DNA Extracted from Market Samples Using the Pentaplex PCR Method

| | sequence length (with primers) | | | | | | | |
|---|---|---|---|---|---|---|---|---|
| | 709 bp | | 256 bp | | 193 bp | | total | |
| | RE | CP | RE | CP | RE | CP | RE | CP |
| tested samples | 20 | 5 | 16 | 9 | 12 | 16 | 48 | 30 |
| positive samples | 19 | 4 | 13 | 5 | 9 | 8 | 41 | 17 |
| percentage of positive samples | 95% | 80% | 81% | 55.5% | 75% | 37.5% | 85.4% | 57% |

*3.3.3. Cycling Condition.* All the primer pairs used in a multiplex PCR should enable similar amplification efficiencies for their respective targets. This may be achieved through the utilization of primers with very similar optimum annealing temperatures. In this work, the average melting temperature of the species-specific reverse primers was 50.5 °C, while the degenerated reverse has a melting temperature of 53.7 °C. Even though our primers produced the expected amplicon in the range of 47−51 °C, an annealing temperature of 49 °C was selected. This temperature facilitate the annealing of the degenerated FJ2 primer and increased the specificity of the reverse primers. This has probably enhanced the specificity of our Pentaplex method allowing to avoid unspecific amplification even in case of close species.

**3.4. Validation of the Pentaplex PCR Assay Using Market Samples DNA.** Once optimized on DNA extracted from RS and from part of the MS (Figure 1), the final Pentaplex PCR protocol was applied to all the DNA samples extracted from MS identified by FINS in a previous work.[12] In particular, 48 RE and 30 CP DNA samples were tested. The results of the amplification are reported in Table 1, while the percentages of successful amplification are summarized in Table 4. Overall, in the case of RE, the Pentaplex PCR was capable to specifically amplify 85.4% of DNA. The higher percentage of amplification (95%) was obtained using those DNA samples from which a sequence of 658 bp (amplicon including primers of 709 bp) was previously amplified, while lower percentages were obtained in case of more degraded DNA samples (Table 4). In case of DNA extracted from CP, the Pentaplex PCR was less effective. Overall, it was able to correctly amplify ∼60% of tested samples. Moreover, the absence of specific amplicons in 3 CP sample that have not been identified at the species level by the phylogenetical analysis (identity value of 86% with *N. nomadica* and 85% with *C. stuhlmanni*) can be considered as a further demonstration of the specificity of the proposed method.

The lower rate of success in case of CP with respect to RE could be attributed to the presence of strongly degraded DNA extracted from products characterized by lower pH values (see Section 3.2.1), rather than to the action of inhibitors, such as aluminum. In fact, in all the DNA from which the specie-specific band was not obtained, the 55 bp control amplicon was always visible (Figure 1). Furthermore, in a previous study,[12] we found that the inhibitory effects affected more the longer than the shorter amplicons.

These results might seem to be in contrast with those obtained in our previous study,[12] in which an amplicon of 145 bp was amplified even from the most degraded DNA from market samples. One possible explanation could be related to the more stringent cycling conditions adopted to increase specificity. In PCR protocols using degenerated primers, the difference between the melting (MT) and the annealing temperature (AT) should be between 10 and 20 °C.[46] In the previous work, in which only degenerated primers were used, AT was 9 °C lower than the mean MT of the primers. In this Pentaplex PCR, the low difference (4.7 °C) between MT and AT of primers could have led to a more difficult annealing. Finally, multiplex PCRs are proven to be less sensitive than single PCR reactions.[47]

**3.5. Jellyfish Labeling: Issues and Outlooks.** All the jellyfish recorded in FAO statistics belong to the order Rhizostomeae and in particular to the genus *Rhopilema*.[48] These statistics are quite questionable considering that at least 11 species in 5 families are known to be exploited worldwide.

Most of the Asian jellyfish are exported to Japan and the remainder are sold to South Korea, Taiwan, Singapore, Hong Kong, U.S.A.,[10,49] and Europe.[11,12] While in eastern Asian countries jellyfish food products are usually categorized in eight types based on the color, form, texture, and size of the semidried products,[49] the Western Countries have tried to regulate the commercialization of these products by establishing a specific labeling.

In U.S.A., the acceptable market name of jellyfish has been associated with all the species belonging to the genus *Rhopilema*.[50] In Italy, the Ministry of Agriculture Food and Forestry Policies (MIPAFF) has adopted the provisional commercial denomination of "Asian jellyfish" for the species *R. esculentum*. At present, to the best of our knowledge, no other EU member Countries has defined a commercial denomination for jellyfish species.

We hypothesize that, due to the impossibility to identify the species in the commodity by a visual inspection, some traceability information, as for example the commercial and scientific denomination, have been deduced at official level from the importation documents. In fact, animal products from third countries outside the EU must be imported via a port or an airport with a Border Inspection Post (BIP), the official office authorized by the Ministry of Health in performing the control according to the European legislation. In fact, the official controls should include at least a systematic documentary check, a random identity check, and, where appropriate, a physical check. However, physical checks, which could include checks on the means of transport, on the packaging, labeling, temperature, the sampling for analysis and laboratory testing, and any other check necessary to verify compliance with the food laws, are performed with a frequency which depends on the risks associated with different foods, the history of compliances with the requirements for the product concerned of the third country, the controls that the food business operator importing the product has carried out, and, finally, the guarantees that the competent authority of the third country of origin has given.[51]

In the U.S., the absence of adequate documentation of fish products entering the market is a serious impediment to establishing the legal origin.[52] Moreover, the incredible rate of adulteration of fish products found in the U.S. market reflected not only the weak collaboration among FDA (Food and Drug Administration), CBP (Customs and Border Protection), and

NMFS (National Marine Fisheries Service) but also the inadequate attention on this issue from FDA.[53] Therefore, new food products coming on the market may be not properly identified.

The hypothesis that, in Italy, the commercial name adopted for Asian jellyfish is not correct seems to be confirmed by one molecular survey previously carried out in our laboratory,[12] which highlighted how most of jellyfish food products sold in Italy were *N. nomurai* instead of *R. esculentum*. Moreover, the identification of other species such as *R. pulmo* and *P. noctiluca* put in evidence the need of a revision of the commercial denomination proposed for these products. For example, the denomination of "Asian jellyfish" should be extended also to the species *N. nomurai* and a new denomination for the Mediterranean species *R. pulmo* should be defined.

It follows that, as specified by the Regulation (EU) No. 1379/2013:[14] "*the available technologies, including DNA-testing, should be used to protect the consumer and in order to deter operators from falsely labeling catches*". In particular, considering the strategic position of the BIPs in the international commerce framework, it could be very important, especially in case of new products (species), to establish a standardized checking procedure to be used during the inspection, to correctly verify the labeling information. This could allow not only to avoid the commercialization of mislabeled products, but to also clearly assess the seafood product characteristics before proposing new official commercial denominations. In fact, in the case of Italy, the number of these denominations has already exceeded nine hundred.[21]

Jellyfish populations appear to be increasing in the majority of the world's coastal ecosystems and seas. Since jellyfish populations can have an important impact on human activities and marine ecosystems but, at the same time, they represent a valuable source of food, it is very important to increase the knowledge regarding the edible species actually exploited worldwide. Although the DNA sequencing appears to be the most commonly applied approach for fish species identification across European laboratories,[17] this procedure needs expensive equipment and long-times of execution. On the countrary, the Multiplex PCR assay developed in this work represents an useful test for the screening of samples and allows to speed up the analysis flow and to reduce costs. Finally, this method represents a useful tool to enforce the law on traceability and to prevent mislabeling in the seafood chain.

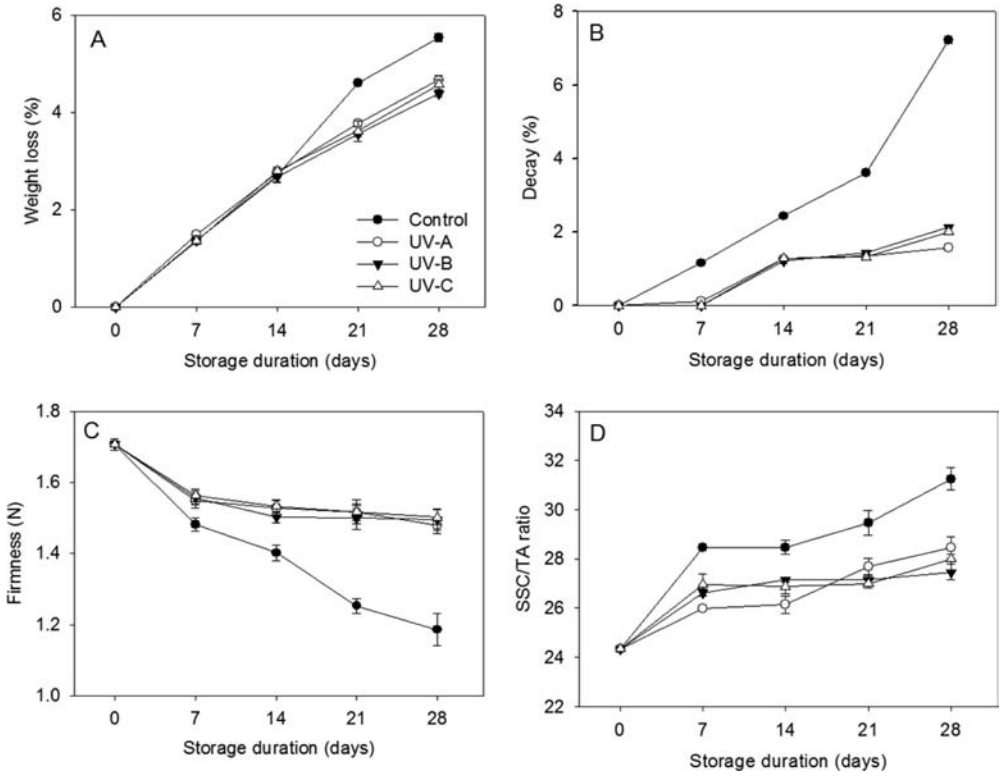

**Figure 1.** Effects of prestorage UV-A, -B, and -C treatments on fruit quality attributes of full-ripe 'Duke' blueberries during subsequent cold storage at 0 °C. Data are the mean ± SE of three replications.

device was equipped with nine 40-W UV lamps and three analog timers.[22] The lamp types of UV-A, -B, and -C were G40TBL ($\lambda_{max}$ = 352 nm), G40T10E ($\lambda_{max}$ = 306 nm), and G40T10 ($\lambda_{max}$ = 254 nm) (Sankyo Denki, Kanagawa, Japan), respectively. The distance of the UV lamp from the fruits was adjusted to obtain the required intensity (10 W/m$^2$) by using a KH-97503 photometer (Cole-Parmer, Vernon Hills, IL, USA). The fruits (about 2 kg) were placed in a mesh bag and radiated for 10 min each on the top and bottom side of the container until the fruits received a radiation dose of 6 kJ/m$^2$. For the control, fruits were not treated with any UV lights. We have selected the 6 kJ/m$^2$ dose from our preliminary study with 1.6, 4.0, and 6.0 kJ/m$^2$, where a dose of 6 kJ/m$^2$ remarkably reduced fruit decay of full-ripe blueberries without surface damage.

**Storage Conditions.** Upon UV treatments, blueberries (200 g) were placed in polyethylene containers (15 × 10 × 10 cm) without covers and stored at 0 °C with 95% relative humidity for 28 days. Experimental fruits were collected at 3 h after UV treatment (AT) and at 7, 14, 21, and 28 days during cold storage. Blueberries from the initial harvest were used as 0 day samples. Three replicates (200 g/container as a replicate) were employed for the experimental analysis.

**Evaluation of Fruit Quality.** Weight loss (%) was determined by the weight changes of samples between the start of the experiment and each sampling date. The values were shown as the percent of weight loss/the initial fruit weight. The decay (%) was calculated by the infected fruit number. The fruit firmness (N) was tested using a texture tester (TA.XT2, Stable Micro Systems, Scarsdale, NY, USA), and a 2 mm flat probe was used. Thirty fruits were randomly selected from each container, and individual fruits were penetrated at a speed of 0.5 mm/s.

Titratable acidity (TA) and soluble solids content (SSC) were determined using fruit juice that was extracted from a 50 g blueberry sample per each container. TA (%) was analyzed using a Fisher Titrimeter (model 35, Pittsburgh, PA, USA) and calculated as percent citric acid. The juice was titrated with sodium hydroxide (0.1 N) until the pH was 8.2. SSC (°Brix) was tested using a Atago PR-32 hand refractometer. The ratio of SSC/TA was expressed by dividing the SSC by the TA values.

**Total Phenolic and Total Anthocyanin Contents.** Blueberries (about 50 g) in bags were blended with 0.5% hydrochloric acid (1:1, w/v) using a home blender. Slurry sample (5 g) was taken and mixied with 30 mL of 80% (v/v) acetone and then centrifuged at 15000*g* for 30 min at 4 °C. The collected supernatants were kept at −80 °C before experiment.

Total phenolics were measured at 765 nm according to the Folin−Ciocalteu method[23] and calculated as milligrams of gallic acid equivalents (GAE) per 100 g of fresh weight. Total anthocyanins were measured using the differences between their absorbance at 515 nm ($A_{515}$) and 700 nm ($A_{700}$) in buffer solution at pH 1.0 and 4.5, where $A = [(A_{515} - A_{700})_{pH\ 1.0} - (A_{515} - A_{700})_{pH\ 4.5}]$.[24] The values were shown as milligrams of cyanidin-3-glucoside chloride equivalents per 100 g of fresh weight.

**2,2-Di-(4-*tert*-octylphenyl)-1-picrylhydrazyl (DPPH) Assay.** The scavenging capacity of the DPPH radicals was determined by a spectrophotometric method[25] with slight modifications. Twenty-four milligrams of DPPH was dissolved in 100 mL of 80% ethanol (v/v), and the solution was kept at −20 °C until the day of the experiment. Ten milliliters of DPPH solution was mixed with 45 mL of 80% ethanol (v/v) to obtain 1.1 ± 0.02 absorbance at 515 nm.

Blueberries were uniformly blended using a home mixer, and fruit slurry was prepared for DPPH and ABTS assays. Five gram samples were homogenized with 25 mL of 80% acetone (v/v), and 150 μL of this homogenate was reacted with the DPPH solution (2.85 mL) for 40 min in total darkness. The absorbance was determined using a Shimadzu UV-2401 spectrophotometer at 515 nm. The standard graph was constructed from 0 to 1.0 μmol of Trolox. The data were calculated as the Trolox equivalent antioxidant capacity (TE) per gram of fresh weight.

**2,2′-Azinobis(3-ethylbenzothiazoline-6-sulfonic acid) (ABTS) Assay.** The ABTS assay was experimented according to the methodof ref 26 with some modifications. A stock of ABTS solution (7.0 mM) was mixed with potassium persulfate (2.45 mM) to make ABTS cation radicals (ABTS$^{\bullet+}$) and was enabled to react for 12 h at 24 °C in total darkness. The ABTS stock solution was diluted with 80% of ethanol (v/v) until the absorbance was 0.7 ± 0.01 at 734 nm. Slurry

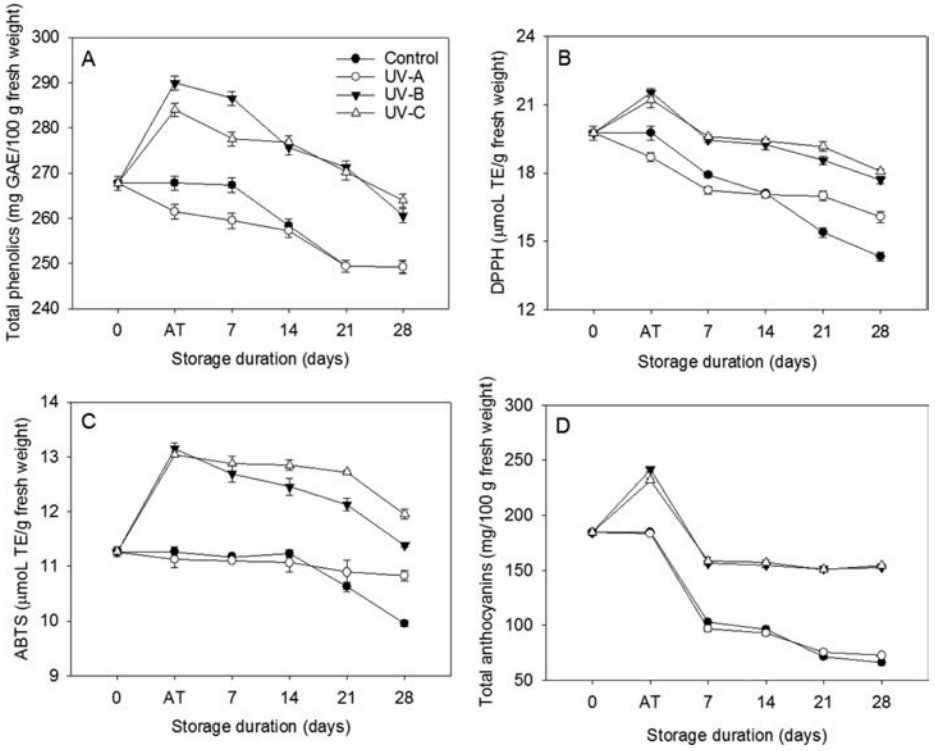

**Figure 2.** Effects of prestorage UV-A, -B, and -C treatments on total phenolics (A), antioxidant activities according to the DPPH (B) and ABTS (C) assays, and total anthocyanins (D) of full-ripe 'Duke' blueberries during subsequent cold storage at 0 °C. AT, measured at 3 h after UV treatments. Data are the mean ± SE of three replications.

samples (5 g) were homogenized with 80% acetone (30 mL). Twenty microliters of fruit extract was combined with $ABTS^{\bullet+}$ solution (3 mL) and kept in total darkness. After 15 min, the absorbance was measured at 734 nm. The Trolox standard curve between 0 and 1.0 μmol was constructed to measure the antioxidant activity, and the activities were shown as TE per gram of fresh weight.

**Extraction and Analysis of Individual Anthocyanins.** Three grams of blueberries was macerated in 20 mL of 80% acetone using a Polytron P-10 tissue homogenizer (Brinkmann, NY, USA). The extracts were filtered and concentrated using a rotary evaporator NN series (EYELA, Tokyo, Japan) in a water bath at 38 °C and then completely dissolved in 3% formic acid in water (v/v). All samples were passed through a $C_{18}$ Sepak cartridge (Waters, Milford, MA, USA). The anthocyanins were then recovered with absolute methanol (2 mL) consisting of 3% formic acid. Ten microliters of sample was separated by high-performance liquid chromatography (HPLC) after passing through a 0.42 μm membrane filter.

Mixed or individual anthocyanin standards were analyzed for the confirmation of anthocyanins extracted from blueberries. Three milligrams of cyanidin-3-glucoside chloride as an external standard was separately dissolved in 2% hydrogen chrolide in methanol (v/v). The individual anthocyanin content was calculated as milligrams of cyanidin-3-glucoside chloride equivalents per gram of fresh weight.

Anthocyanins were analyzed using a YL 9100 HPLC system (YoungLin, Anyang, Korea) consisting of a YL9111 binary pump, a YL9160 diode array detector, and a YL9150 autosampler. An analytical column of Phenomenox Bondclon $C_{18}$ (4.6 × 250 mm, 10 μm) was used. Mobile solvents were 5% formic acid in water (v/v) and acetonitrile (ACN), respectively. The solvent system was programmed from 5% ACN to 20% ACN for 50 min and flushed with 100% ACN for 5 min. The flow rate was 1 mL/min. Ten microliters of sample was injected. Anthocyanins were detected at 520 nm, and spectral data between 200 and 700 nm were collected at a time.

**Identification of Individual Anthocyanins.** Mass identification of anthocyanins was performed on a Surveyor HPLC system (ThermoFinnigan, San Jose, CA, USA). The system was fitted with an LCQ-DECA XP plus quadruple mass spectrometer (ThermoFinnigan). An analytical column of Inno ODS-N-120 (4.6 × 240 mm, 5 μm) was used. As mobile solutions, water and ACN, which both contained 5% formic acid, were eluted. The gradient started at 8% ACN and reached 40% ACN within 50 min. Positive electrospray ionization was performed by applying 5 kV. The temperature of the capillary was held at 275 °C. The Xcalibur 2.0 software package was used to monitor the LC−mass system as well as to process the collected data. Identities were determined by comparison to authentic standards and previous studies.[27,28]

**Statistical Analysis.** The experiment was carried out using a completely randomized design. Measurements and analysis were repeated in triplicate. The means were expressed with standard errors. Descriptive statistics and correlation matrix between studied variables of data from UV-C treatment were analyzed using SAS 9.3 software, and statistically significant levels were considered at $P \leq 0.001$, 0.01, and 0.05, respectively. The figures were generated using Sigma Plot 10.0 (SPSS, Chicago, IL, USA).

## RESULTS AND DISCUSSION

**Quality of Fruits.** The weight loss (%) was comparable for all experimental treatments throughout the storage period, but the control showed ∼1.3% higher rates compared to the UV treatments after 21 days (Figure 1A). A significant reduction in fruit decay was found in the UV treatments, and these differences became greater toward the end of the storage time (Figure 1B). At 28 days, the decay of the control was the highest (7.2%). The decay rate of the UV treatments ranged between 1.3 and 2.1% during storage of 28 days. UV lights effectively inhibited the softening compared with the control; however, differences were not found in fruit firmness between the UV treatments (Figure 1C). The control started to show softening after 7 days. The UV lights delayed further ripening of the fruits as seen by the SSC/TA ratio (Figure 1D) compared with the control. During the storage period, fruits in

the control showed lower acidity and higher sweetness compared with those in the UV treatments. However, there were no differences between UV treatments.

The benefits of low-dose UV lights on fresh fruits have been found in other studies, particularly with UV-C from 0.25 to 8 kJ/m$^2$. Low-dose UV-C promoted the synthesis of phytoalexins[29] or delayed the weight loss and softening of fruits during storage.[30,31] With UV-C treatment between 1 and 4 kJ/m$^2$, the decay in blueberries decreased by 10%.[8] However, a high dose of UV-B treatment from 15 to 30 kJ/m$^2$ induced damage to living organisms, because cellular compounds such as proteins and nucleic acid absorbed the energy-rich radiation.[32] In our experiment, all UV lights of 6 kJ/m$^2$ effectively maintained fruit quality by reducing the weight loss, decay, and ripening of blueberries during subsequent cold storage for 28 days (Figure 1). Therefore, we concluded that the UV treatments regardless of UV light type were beneficial to maintaining fruit qualities of blueberries during cold storage.

**Changes of Total Phenolics.** The total phenolics of blueberries during cold storage were greatly affected by the prior UV treatments. There was a ~17 mg GAE/100 g fresh weight increase in the total phenolics due to the UV-B and -C treatments after 3 h, whereas UV-A showed a slight reduction (Figure 2A). Although the total phenolics gradually declined with storage time, the content in blueberries in the UV-B and -C treatments always remained higher than the control and UV-A treatment. Similarly, the UV-C treatment significantly increased all major individual phenolics as well as the flavonoid compounds in blueberries, but there were no compositional changes of individual anthocyanins.[9] These beneficial effects of UV-C were linked to the PAL activation.[15] In our study, UV-B also showed an effect similar to that of UV-C; however, the total phenolics of blueberries with UV-B and -C decreased quickly with storage time.

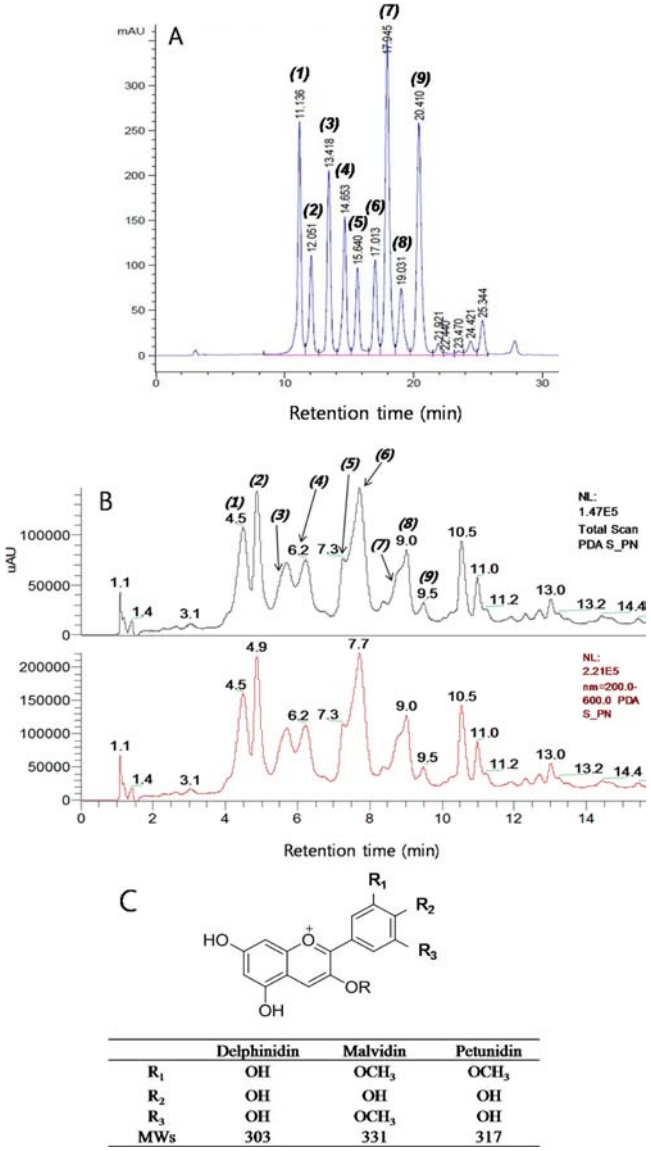
**Changes in Antioxidant Activities.** The antioxidant activity measured by the DPPH assay in UV-B- and -C-treated blueberries immediately increased after UV treatments. Contrary to an increased antioxidant activity in the UV-B and -C treatments, there was a slight reduction in the UV-A treatment at 3 h (Figure 2B). The activities determined by the ABTS assay in the UV-B and -C treatments were also much higher than in both the control and UV-A treatment (Figure 2C). This trend did not change throughout the duration of the cold storage. The control showed the lowest antioxidant levels at 28 days.

**Changes in Total Anthocyanins.** The total anthocyanin changes during storage are shown in Figure 2D. The total anthocyanins remarkably increased by UV-B and -C treatments in 3 h, but sharply decreased at 7 days. After the sharp decrease, the contents of total anthocyanins steadily stabilized. The total anthocyanins in UV-B and -C treatments were still ~88 mg/100 g higher than the control and UV-A treatment at 28 days. We have observed that the anthocyanin contents were rapidly increased by the UV-B and -C treatments, then rapidly decreased in 7 days, and a steady decrease thereafter. The initial differences in the increases were maintained during cold storage.

The total anthocyanin contents increased with the treatments of 2 or 4 kJ/m$^2$ UV-C in 'Bluecrop' blueberries, particularly immediately after treatment.[9] UV-B also showed a rapid increase after treatment, and the contents were nearly identical to those for UV-C treatment during storage. These trends were simmilar to those of the total phenolics and antioxidant activities shown in Figure 2A–C. The UV-A treatment did not show any differences compared with the control and thus was considered not to be as effective in the promotion of anthocyanin synthesis.

The anthocyanin contents were rapidly decreased in the cold storage, regardless of prior treatments, and the initial difference was maintained for 28 days. The control and UV-A treatment, having lower anthocyanin contents, showed higher fruit discoloration (data not shown) and decay rates (Figure 1B), as compared to UV-B and -C treatments. We assume that anthocyanins might be rapidly degraded by an increased activity of the anthocyanase catalyzing the anthocyanin–polyphenol reaction during the storage.[33]

**Analysis of Individual Anthocyanins.** The typical HPLC and LC-MS profiles of anthocyanins in blueberry extracts are presented in Figure 3A,B, and the peak number, retention time, and exact mass of each anthocyanin are listed in Table 1. We have obtained similar anthocyanin profiles by HPLC and LC-



| | Delphinidin | Malvidin | Petunidin |

**Table 1. Peak Retention Time (RT), Identification, and Molecular Mass of Anthocyanins in Full-Ripe 'Duke' Blueberries**

| peak | RT (min) | anthocyanin (abbreviation) | $M^+$ | fragment |
|---|---|---|---|---|
| 1 | 11.1 | delphinidin-3-galactoside (Del-3-Gal) | 465.07 | 303.25 |
| 2 | 12.0 | delphinidin-3-glucoside (Del-3-Glu) | 465.07 | 303.25 |
| 3 | 13.4 | delphinidin-3-arabinoside (Del-3-Ara) | 435.09 | 303.17 |
| 4 | 14.6 | petunidin-3-galactoside (Pet-3-Gal) | 479.07 | 317.22 |
| 5 | 15.6 | petunidin-3-glucoside (Pet-3-Glu) | 479.07 | 317.22 |
| 6 | 17.0 | petunidin-3-arabinoside (Pet-3-Gal) | 449.07 | 317.22 |
| 7 | 17.9 | malvidin-3-galactoside (Mal-3-Gal) | 493.07 | 331.21 |
| 8 | 19.0 | malvidin-3-glucoside (Mal-3-Glu) | 493.07 | 331.03 |
| 9 | 20.4 | malvidin-3-arabinoside (Mal-3-Ara) | 463.05 | 331.25 |

MS analysis and detected nine major anthocyanins in the full-ripe 'Duke' blueberries. Three major anthocyanins of full-ripe blueberries were malvidin-3-galactoside, delphinidin-3-galactoside, and petunidin-3-galactoside (Figure 4A,D,G).

In our samples, delphinidin-, malvidin-, and petunidin-based anthocyanins were detected as major compounds and those based on cyanidin, pelargonidin, and peonidin were not detected or were in very little amounts. In another study, cyanidin-3-galactoside and malvidin-3-galactoside were the main compounds in the same 'Duke' cultivar,[9] but the cyanidin-based anthocyanins were not detected or the minor compounds in our study. In highbush 'Bergitta' cultivar, dephinidin-, malvidin-, and petunidin-based anthocyanins were detected as major compounds and cyanidin-based anthocyanins were minor.[34] The anthocyanin composition in berries could be different according to cultivar,[24] species,[28,35] or fruit development stage.[36] Therefore, the difference from or similarity to other studies seemed to be due to wide variation in the composition of individual anthocyanins or their contents among the cultivars and locations of production.

**Changes in Individual Anthocyanins in Blueberries.** Changes in the individual anthocyanins during cold storage are shown in Figure 4. All of the individual anthocyanins increased significantly within 3 h when treated with UV-B and -C. This increase was especially distinct in the UV-B treatment. These effects diminished as the storage time increased, although there were apparent UV-induced effects in the UV-B and -C treatments. The contents of all individual anthocyanins in the UV-B and -C treatments were higher than those in the control

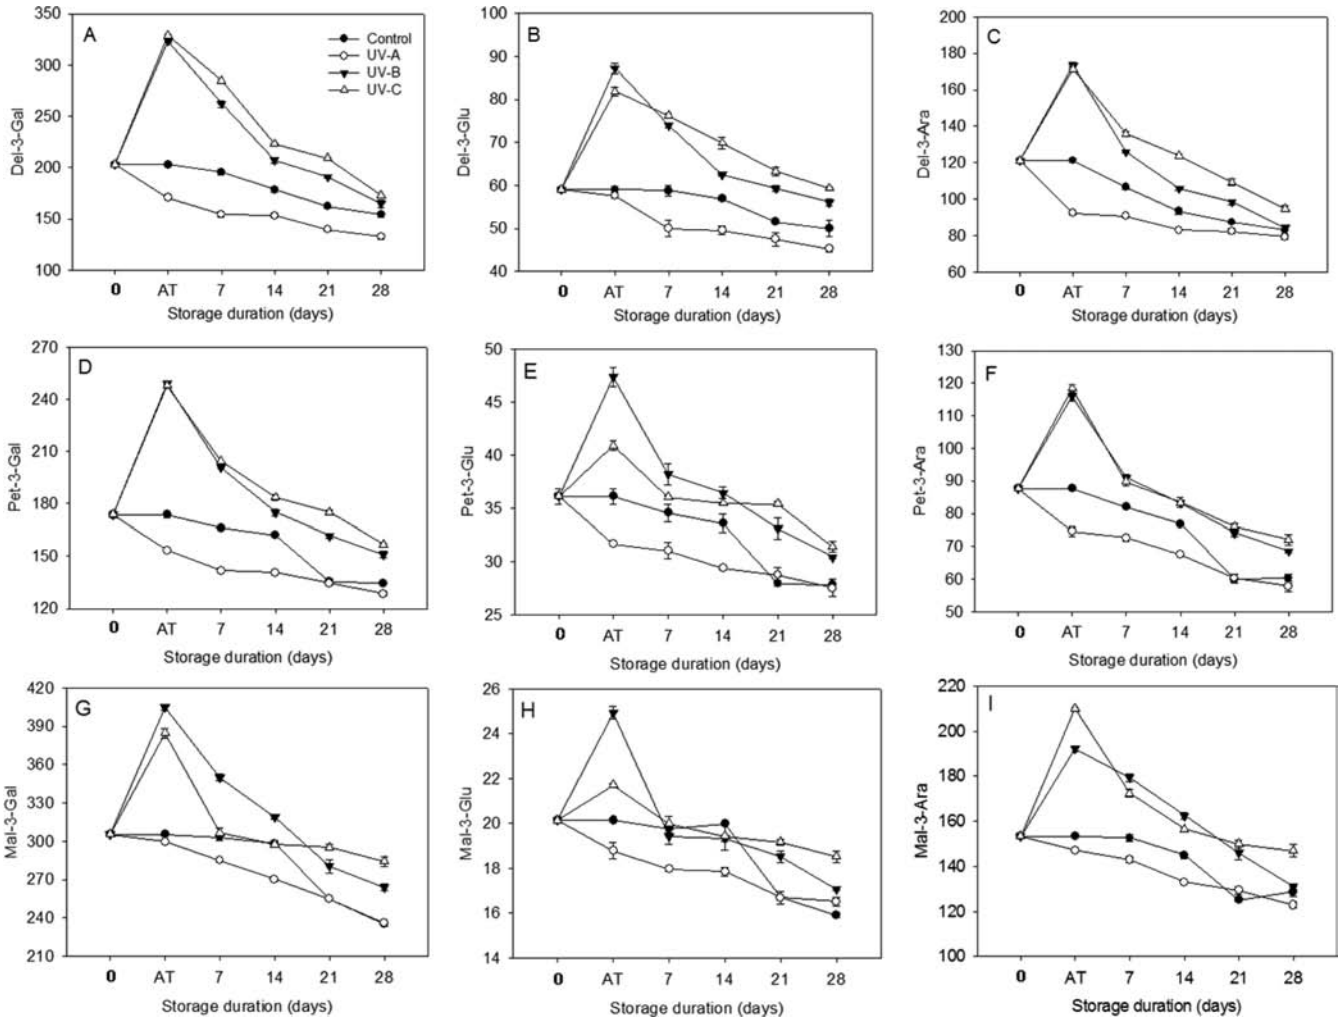

**Figure 4.** Effects of prestorage UV-A, -B, and -C treatments on individual anthocyanin changes ($\mu$g/g fresh weight) of full-ripe 'Duke' blueberries during subsequent cold storage at 0 °C. AT, measured at 3 h after UV treatments. The data are expressed as cyanidin-3-glucoside chloride equivalents. Data are the mean ± SE of three replications.

[a]Abbreviations of anthocyanins are presented in Table 1. Correlations are significant at the (***) 0.001 level, (**) 0.01 level, and (*) 0.05 level or are (ns) nonsignificant. [b]Total phenolic contents. [c]Total anthocyanin contents.

and UV-A during cold storage but not for delphinidin- and malvidin-3-arabinoside at 28 days.

UV-light induced anthocyanin accumulation in plant tissues via the activation of anthocyanin biosynthetic genes.[36,37] In addition to PAL induction, UV radiation also increased the activity of other flavonoid synthesis enzymes, such as chalcon synthase/isomerase or dihydroflavonol-4-reductase.[38] In apples, anthocyanin synthesis was regulated by UV-B.[39] Anthocyanins are one of the most common pigments in plants. However, the effect of UV-A, -B, and -C radiation on anthocyanin biosynthetic genes in harvested blueberries is very little understood. However, we could assume that the nature of UV-induced anthocyanin accumulation in blueberries would be very similar to that of previous reports in other crops.[36,38] In our study, we found that most individual anthocyanins in blueberries were induced by UV-B and -C light and subsequently decreased in the same manner during cold storage.

Our study showed that doses of UV-B and -C at 6 kJ/m$^2$ maintained the postharvest quality of blueberries better than the control, as indicated in Figure 1, and greatly enhanced the total phenolics and antioxidant activities by accumulating phytonutrients in the blueberries (Figure 2). These positive effects of UV-light appeared immediately (in 3 h) after the treatments and gradually diminished during the subsequent cold storage time. The degradation of these compounds in full-ripe blueberries was possibly slowed by the cold temperature, but could not be stopped.

**Correlations between Studied Variables.** The correlation analysis between studied variables is shown in Table 2. Most anthocyanins had a high correlation coefficient with each other, except delphinidin-3-glucoside with petunidin-3-glucoside ($r$ = 0.77), malvidin-3-galactoside ($r$ = 0.77), and malvidin-3-glucoside ($r$ = 0.75). Some pairs had a significant correlation ($r$ = 0.98) at the 0.001 level, such as delphinidin- and petunidin-based anthocyanins, as well as petunidin- and malvidin-based anthocyanins. Total phenolic content also had a significant correlation with most individual anthocyanins, except malvidin-3-galactoside ($r$ = 0.78) and malvidin-3-glucoside ($r$ = 0.79). Although all of the anthocyanins had no significant correlation with the antioxidant activity by the DPPH assay, they had a close correlation in the ABTS assay, except delphinidin-3-glucoside ($r$ = 0.76). The total anthocyanins had a significant correlation with delphinidin-3-galactoside ($r$ = 0.98), petunidin-3-glactoside ($r$ = 0.96), and malvidin-3-galactoside ($r$ = 0.97), which were highly abundant anthocyanins in blueberries. In addition, the antioxidant activity determined by the ABTS analysis had significant correlations with the total phenolics ($r$ = 0.84) and total anthocyanins ($r$ = 0.9) at the 0.05 level, respectively.

The antioxidant capacity, total phenolics, and total anthocyanins in blueberries were highly correlated, from 0.87 to 0.99.[40] Our study also demonstrated that the total phenolic contents were strongly correlated with all individual anthocyanins except malvidin-based anthocyanins. Malvidin-based anthocyanins showed higher antioxidant activities, as measured by the oxygen radical absorbance capacity assay, compared to petunidin- or cyanidin-based anthocyanins.[41] The results from Table 2 showed that all individual anthocyanins except delphinidin-3-glucoside were correlated significantly with total phenolics and antioxidant activity in blueberries, as measured by the ABTS assay. The correlations between delphinidin-based anthocyanins and ABTS assay were relatively low compared to the other anthocyanin compounds. The antioxidant activity in blueberries according to the DPPH assay did not show significant correlations with any of the studied variables. We concluded that the ABTS assay represents the antioxidant activity better than the DPPH assay in individual anthocyanins in blueberry extracts.

The antioxidant activities of anthocyanins are influenced by hydroxylation and glycosylation patterns of their chemical structures.[42,43] The OH group on the positions of both 3′ and 4′ of the B ring contributed to the high antioxidant activity except for delphinidin-based anthocyanins.[42] On the basis of these criteria, anthocyanin compounds with 3′,4′-di-OH substitution in the B ring such as cyanidin- or petunidin-based anthocyanins had high antioxidant capacities compared than the malvidin-based anthocyanins, which show only one OH group in the B ring.[42] In our data, delphinidin-based anthocyanins showed low correlations with ABTS assay compared to the other anthocyanin compounds, but those based on petunidin were correlated significantly with ABTS assay.

There were differences in the response of blueberries to the three types of UV light (A, B, and C). The synthesis of phytonutrient compounds and associated antioxidant activities

were stimulated or maintained by a prestorage UV-B or -C treatment during subsequent cold storage. UV-A had little ability to improve or maintain fruit quality during cold storage. UV-B and -C at 6 kJ/m$^2$ were effective in inhibiting the loss of fruit weight, the development of fruit decay, and the decreases of anthocyanins and antioxidant activities. The UV-B and -C treatments were also effective in the stimulation of individual anthocyanins in 'Duke' blueberries, and the persistence of UV-induced effects was maintained during the cold storage. Our results also showed a strong correlation between these increased individual anthocyanins in blueberries and total phenolics, total anthocyanins, and the antioxidant ability tested by the ABTS assay. Further studies on the dynamics of UV-mediated structural or regulatory gene expression levels involved in anthocyanin biosynthesis in blueberries would elucidate more detailed biosynthesis processes.

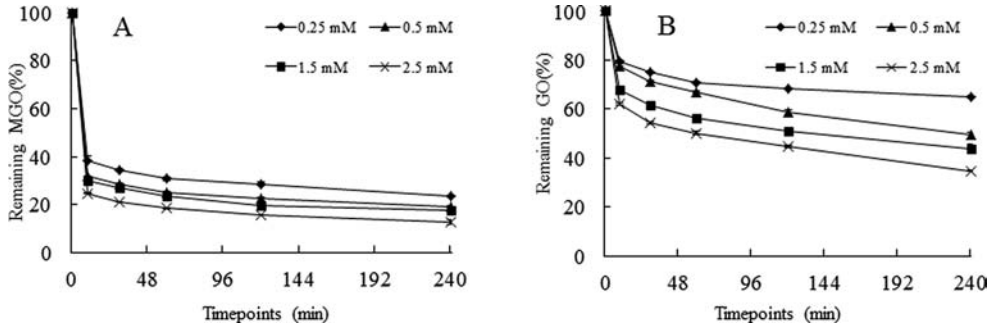

**Figure 1.** Trapping of (A) MGO and (B) GO simultaneously by quercetin under physiological conditions (pH 7.4, 37 °C). MGO (0.5 mM) and GO (0.5 mM) were incubated with quercetin (0.25, 0.5, 1.5, and 2.5 mM) in pH 7.4 phosphate buffer solutions at 37 °C for 10, 30, 60, 120, and 240 min. Data are presented as the means ± SD of three replications.

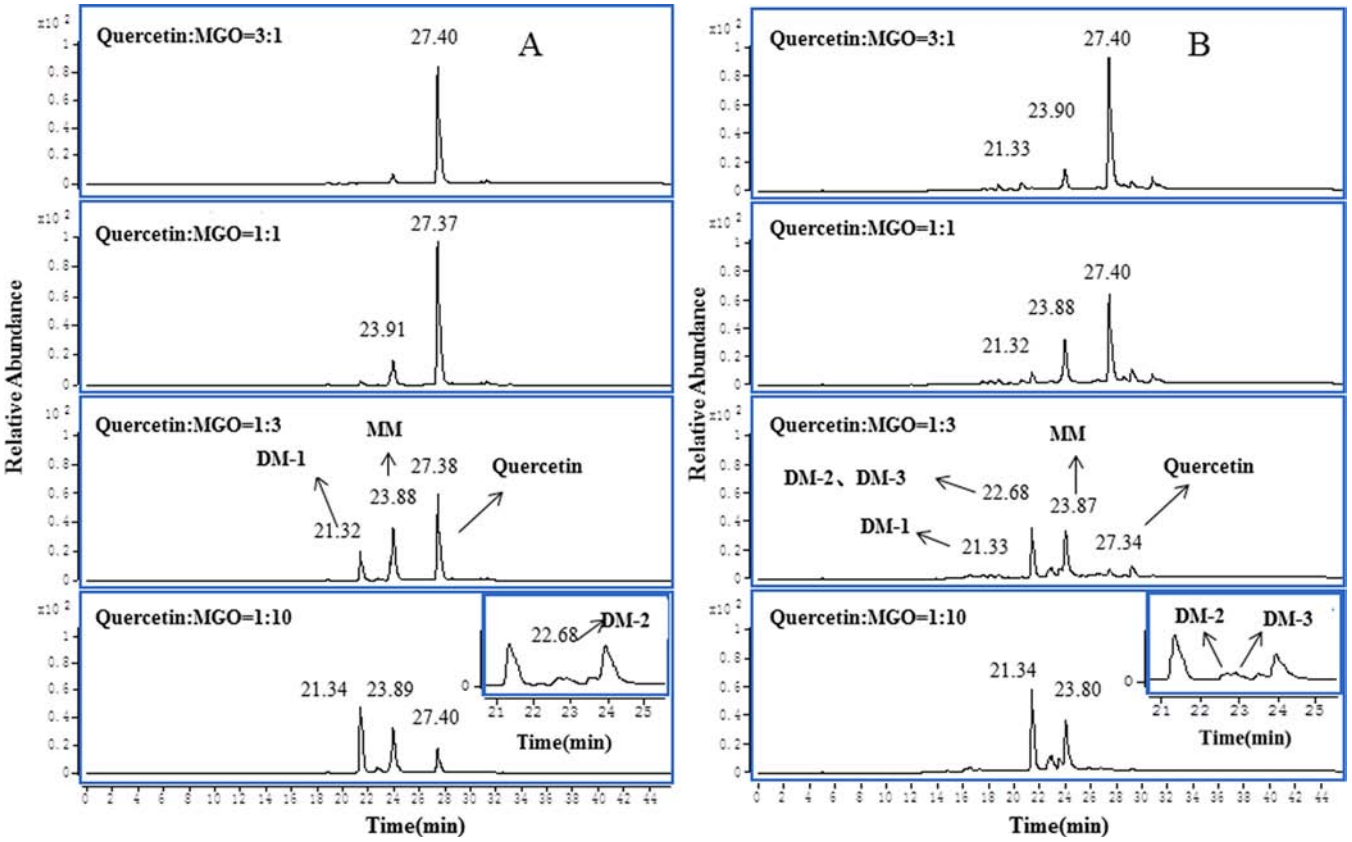

**Figure 2.** LC chromatograms of quercetin after incubation with different ratios of MGO (3:1, 1:1, 1:3, and 1:10) for 4 h (A) and 24 h (B), respectively.

## MATERIALS AND METHODS

**Materials.** Quercetin was obtained from Nanjing Guangrun Biological Products Co., Ltd. (Nanjing, Jiangsu, China). MGO (40% in water), GO (40% in water), 1,2-diaminobenzene (DB), and 2,3-butanedione were purchased from Sigma-Aldrich (St. Louis, MO, USA). Bovine serum albumin (BSA), DMSO, and streptomycin and penicillin mixed solution were purchased from Shanghai Sangon Biological Engineering Technology Co., Ltd. (Shanghai, China). HPLC grade solvents and other reagents were obtained from Shanghai Sinopharm Chemical Reagent Co., Ltd. (Shanghai, China). HPLC grade water was prepared using a Millipore Milli-Q purification system (Bedford, MA, USA).

**Determination of the MGO and GO Trapping Capacity of Quercetin by GC.** MGO (0.5 mM) and GO (0.5 mM) were incubated with quercetin (0.25, 0.5, 1.5, and 2.5 mM) in PBS buffer (pH 7.4, 100 mM) at 37 °C for 0, 10, 30, 60, 120, or 240 min. At each time point, the reaction was stopped by adding 10 μL of acetic acid. The samples were then stored at −80 °C for further use.

**Preparation of Samples.** One milliliter of 100 mM DB was added to 1 mL of sample and then mixed with 0.5 mL of 2,3-butanedione (internal standard) at 1 mM. The reaction mixture was kept at 60 °C for 10 min. Then, 1 mL of 1 M acetaldehyde was added and incubated at 60 °C for 15 min to remove the unreacted DB. The mixture was extracted twice with 2 mL of methylene chloride. The organic phase was combined and concentrated to 0.5 mL. One microliter of this sample was injected directly into the GC. The remaining percentage of MGO and GO was calculated using the equation

$$\text{remaining}\,(\%) = \text{amount of MGO (GO) in test compound (as quinoxalines)/amount of MGO (GO) in control (as quinoxalines)} \times 100$$

dx.doi.org/10.1021/jf504132x | J. Agric. Food Chem. 2014, 62, 12152−12158

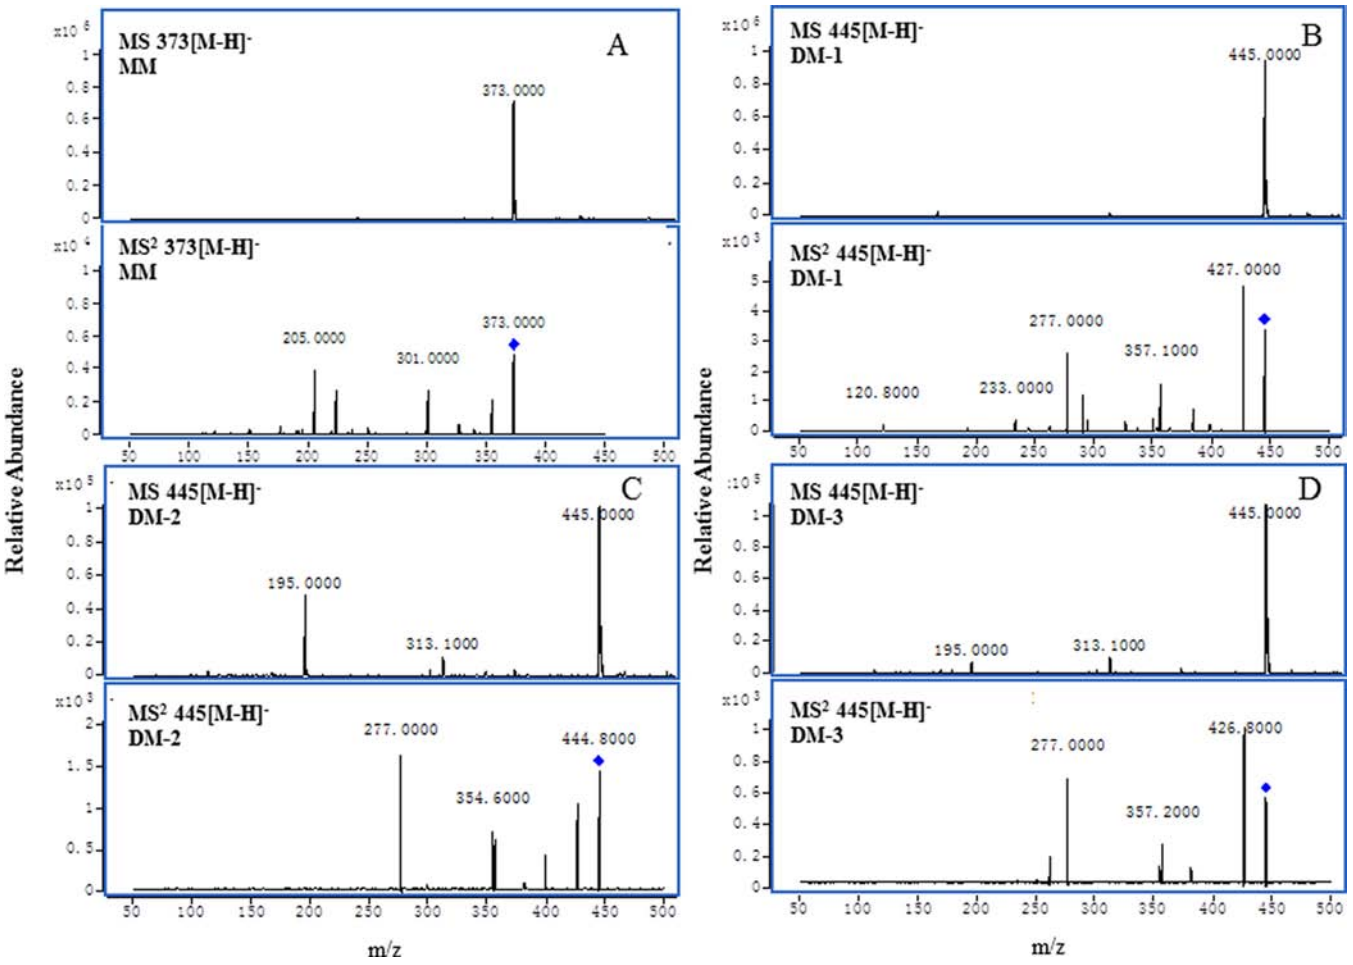

**Figure 3.** Tandem MS/MS spectra of mono-MGO adducts (A) and di-MGO adducts (B–D) of quercetin.

**GC Analysis.** The levels of methylquinoxaline and quinoxaline were analyzed with an Agilent gas chromatograph (7820 series, Agilent Technologies, Palo Alto, CA, USA) equipped with a flame ionization detector (FID). The column was an HP-5 MS (5%-phenyl)-methylpolysiloxane silica capillary (30 m × 0.32 mm i.d., film thickness = 0.25 $\mu$m, Agilent, Wilmington, DE, USA). The injector temperature was 250 °C, and the detector temperature was 280 °C with hydrogen, air, and nitrogen flow rates at 30.0, 300, and 5.0 mL/min, respectively. The injector was in 1:1 split mode. The flow rate of constant carrier gas (nitrogen) was set to be 2.0 mL/min. The GC oven temperature was programmed as follows: the initial oven temperature of 40 °C was held for 1 min, increased to 140 °C at a rate of 5 °C/min, held for 1 min, then increased to 250 °C at a rate of 50 °C/min, and held for 1 min. The total run time was 25.2 min. All of the solvents were filtered with a 0.2 $\mu$m Nylaflo membrane filter. The injection volume was 1 $\mu$L for each sample solution.

**Inhibitory Effects of Quercetin on the Formation of AGEs.** BSA (1.5 mg/mL) was incubated with MGO (500 $\mu$M) or GO (500 $\mu$M) in PBS buffer, pH 7.4, in the presence or absence of quercetin (1.5 mM) at 37 °C. Streptomycin and penicillin (0.3 mL) was added to the solution to prevent bacterial growth. The reaction mixture (500 $\mu$L) was collected and frozen at designated time points (0, 4, 8, 12, 72, 144, 288, 432, and 720 h). The amount of AGEs was determined using fluorescence at an excitation/emission wavelength of 370/440 nm.

**LC-MS Analysis.** LC-MS analysis was performed using an Agilent Masshunter System consisting of a 1290 G4220A BinPump, a 1290 G4226A Wellplate sampler, a G4212A fiode array detector, and a 6460 QQQ mass detector (Agilent, Santa Clara, CA, USA) incorporated with electrospray ionization (ESI) interfaces. A 250 × 4.6 mm i.d., 5 $\mu$m, ZORBAX Eclipse XDB-$C_{18}$ column (Agilent) was used for separation at a flow rate of 0.5 mL/min. The column was eluted with 90% solvent B (water with 0.1% formic acid) for 5 min, followed by linear increases in A (acetonitrile with 0.1% formic acid) to 60% from 5 to 40 min, to 10% from 40 to 41 min, and then with 90% B from 41 to 46 min. The column was then re-equilibrated with 90% B for 5 min. The LC eluent was introduced into the ESI interface. The negative ion polarity mode was set for ESI ion source. The typical operating parameters were as follows: spray needle voltage, 5 kV; nitrogen sheath gas, 45 (arbitrary units); auxiliary gas, 5 (arbitrary units). The structural information on quercetin and the major MGO and GO adducts was obtained by tandem mass spectrometry (MS/MS) through collision-induced dissociation (CID) with a relative collision energy setting of 35%. Data acquisition was performed with Qualitative Analysis of Masshunter (Agilent).

**LC-MS Analysis of MGO or GO Adducts of Quercetin in the BSA–MGO (or GO) System.** The procedure of BSA incubation with MGO/GO and quercetin is the same as the inhibition effect method described above. Samples were collected at designated time points (0, 1, 2, 4, and 8 h) from the quercetin-treated BSA–MGO (or GO) system, and mono- and di-MGO conjugated quercetin was detected using the LC-MS method described above.

## RESULTS

**Trapping of MGO and GO Simultaneously by Quercetin under Physiological Conditions.** The results shown in Figure 1 suggest that quercetin can trap both MGO and GO simultaneously and efficiently under physiological conditions. More than 26.0% of GO and 69.0% of MGO were trapped within 60 min by 0.5 mM quercetin, and the trapping efficiency could be up to 50.5 and 80.1%, respectively, when

Table 1. Percentage[a] of Quercetin−MGO Products for 4 and 24 h at Different Ratios

| | DM-1 | | DM-2 + DM-3 | | MM | | quercetin | |
|---|---|---|---|---|---|---|---|---|
| quercetin/MGO | 4 h | 24 h | 4 h | 24 h | 4 h | 24 h | 4 h | 24 h |
| 3:1 | –[b] | – | – | – | 4.59 | 10.91 | 95.41 | 89.09 |

[a]Percent (%) = peak area of each product at 4 or 24 h at each ratio/total sum of peak areas of products at 4 or 24 h at each ratio. [b]–, not detected.

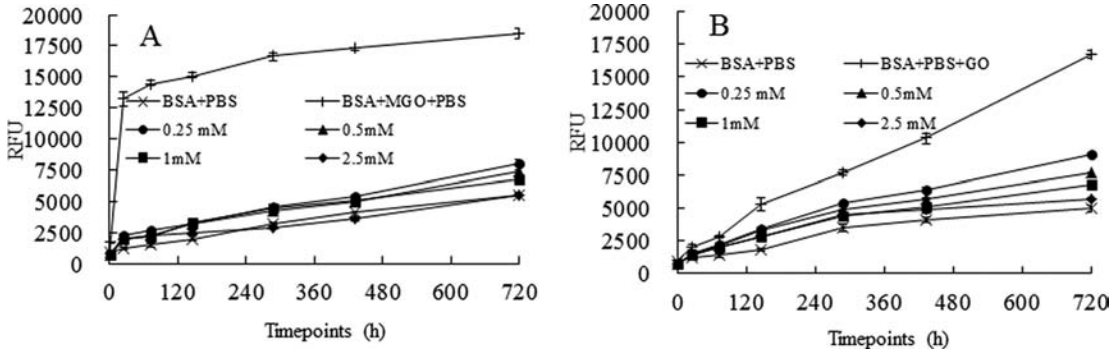

Figure 4. Inhibitory effect of the formation of AGEs by quercetin in the BSA−MGO (or GO) assay: (A) MGO; (B) GO. Data are presented as the means ± SD of three replications.

using 2.5 mM quercetin. Quercetin appeared to trap MGO much more efficiently than GO when both GO and MGO occurred in the same system.

**Analyzing the Formation of MGO or GO Adducts of Quercetin Using LC-MS.** We further identified the quercetin−MGO and quercetin−GO adducts using LC-MS after incubation of quercetin with MGO or GO at four different ratios (3:1, 1:1, 1:3, and 1:10) (Figure 2; Supplemental Figure 1 in the Supporting Information). Under selective ion monitoring (SIM) mode, the structural information on these products was achieved using tandem mass analysis (Figure 3 and Supplemental Figure 2). After 4 h of incubation of quercetin with MGO (ratio = 1:1), one product peak ($t_R$ 23.91 min) appeared in the LC chromatogram as shown in Figure 2A. This peak had the molecular ion $m/z$ 373 $[M - H]^-$ and fragment ion $m/z$ 301 $[M - 72 - H]^-$, indicating the loss of one MGO ($m/z$ 72) molecule, suggesting this product was a mono-MGO conjugated quercetin (MM) (Figure 3A). When quercetin and MGO at a 1:3 ratio were incubated for 4 h, another peak appeared at 21.32 min. This peak had the molecular ion $m/z$ 445 $[M - H]^-$, which was 142 mass units heavier than that of the quercetin, indicating that this peak was a di-MGO adduct of quercetin (DM-1) (Figure 3B). The third new peak appeared at 22.68 min (Figure 2A), with the addition of MGO at the ratio of 1:10 for 4 h, which had the same molecular ion as DM-1, indicating that this peak was also a di-MGO adduct of quercetin (DM-2) (Figure 3C). Under the ratio of 1:3, both mono- and di-MGO adducts were the major products, and the amount of unreacted quercetin dramatically reduced to 12.28% (Table 1), whereas when quercetin and MGO at a 1:10 ratio were incubated for 24 h, di-MGO adducts became the dominant products (Table 1), and one additional peak corresponding to di-MGO adduct (DM-3) was observed (Figure 2B). This peak could not be separated fully from the peak of DM-2 (Figure 2B). When quercetin and GO were incubated at a 1:10 ratio for 24 h, two new peaks were observed at 22.02 and 23.98 min (Supplemental Figure 1). They had the same molecular ion $m/z$ 359 $[M - H]^-$, which was 58 mass units heavier than that of quercetin, indicating both of them are mono-GO adducts of quercetin (Supplemental Figure 2A,B). However, only tiny amounts of mono-GO adducts were detected even when quercetin and GO were incubated at a 1:10 ratio for 24 h, and di-GO adducts were not detectable (Supplemental Figure 1A,B).

**Inhibitory Effects of Quercetin on the Formation of AGEs.** We found that quercetin significantly inhibited the formation of AGEs in the BSA−MGO/GO system (Figure 4). This result is consistent with our observation on the trapping efficacy of MGO/GO by quercetin. When quercetin (0.25 mM) was present in the incubation mixture, the inhibition efficiency could be up to 91.0% at 24 h in the BSA−MGO system (Figure 4A), whereas in the quercetin−BSA−GO system, the inhibitory effect of quercetin on the formation of AGEs seems less than that of the BSA−MGO system, only 76.8% within 30 days (Figure 4B). This may be related to the fact that the formation of AGEs by GO was slow.

**Determining the Adduct Formation of Quercetin in the BSA−MGO or BSA−GO System by LC-MS.** To clarify whether trapping of MGO (or GO) by quercetin is the major mechanism to prevent the formation of AGEs, LC-MS was used to determine the existence of the mono- and di-MGO/GO conjugated quercetin in the samples, which were collected after incubation of quercetin with BSA and MGO or of quercetin with BSA and GO.

As shown in Figure 5, the mono-MGO adduct could be detected after 1 h of incubation, and the di-MGO adduct could be detected after 2 h of incubation. They had retention times and MS/MS spectra identical to those of the mono- and di-MGO adducts in the reaction mixture between quercetin and MGO, but in the BSA−GO system, only mono-GO adducts were detectable at very low levels (Supplemental Figure 3).

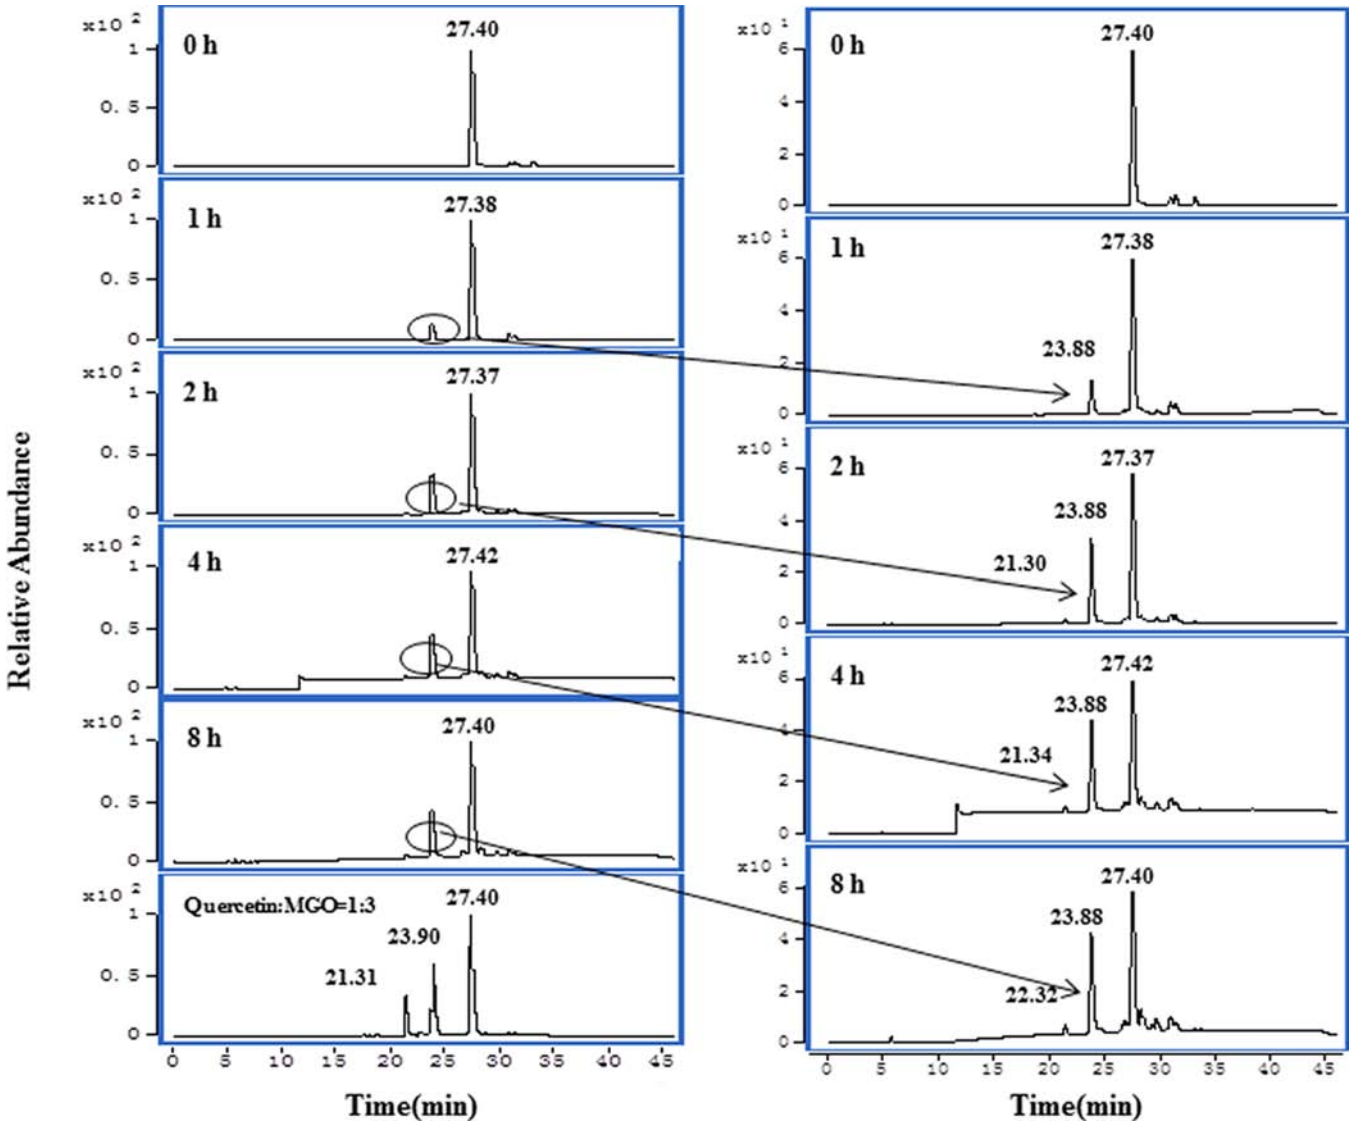

**Figure 5.** LC chromatograms of quercetin and mono- and di-MGO adducts of quercetin after incubation of quercetin in the BSA−MGO assay for 1, 2, 4, and 8 h as well as after the incubation of quercetin with MGO at a 1:3 ratio for 4 h.

## DISCUSSION

Our results revealed that quercetin can rapidly trap MGO and then inhibit the formation of AGEs through forming of mono- and di-MGO adducts under neutral and alkaline conditions in vitro. In this assay, both mono- and di-MGO adducts of quercetin were detected, and the di-MGO adducts became the dominant products during prolonged incubation, whereas only a tiny amount of mono-GO adducts of quercetin was detectable in the reaction mixtures of quercetin and GO.

$\alpha$-Dicarbonyl compounds are known as important precursors of AGEs, which can be generated endogenously through either degradation of glucose or early glycation products. Rising levels of dietary fructose in the Western diet have been associated with an increase of serum MGO and GO.[32] In our study, quercetin efficiently trapped MGO and GO simultaneously under physiological conditions, as MGO and GO appear in the same system. Furthermore, we found that quercetin preferred trapping of MGO to that of GO. The potential reason may be that in aqueous solution GO exists mainly as the hydrated monomer, dimer, or trimer, the conversion of which to free GO is slowed by the trapping reaction between quercetin and GO.[33] Similar results have been reported for EGCG[26] and phloretin;[27] both of them appeared to trap for GO much more slowly than for MGO.

To further study whether quercetin can inhibit the formation of AGEs via trapping MGO/GO, we analyzed the inhibitory effect of quercetin on the formation of AGEs in the BSA−MGO/GO system and then determined the formation of MGO (GO) adducts of quercetin by LC-MS. We demonstrated that quercetin can inhibit the formation of AGEs via trapping MGO and GO. The amount of AGEs rose dramatically with time during incubation with MGO until reaching a plateau. Although no plateau appeared during incubation with GO, the parameter increased progressively with time. Results of this study are consistent with previous reports that MGO rather than GO is the main dicarbonyl compound responsible for albumin glycation.[34] Moreover, the inhibitory activity on the formation of AGEs by quercetin was much higher in the BSA−MGO system than in the BSA−GO system; one of the major causes was that the glycation was dragged down by the conversion among hydrated monomer, dimer, and trimer to free GO.

Flavonoids, consisting of two hydroxy-substituted aromatic rings joined by a three-carbon link (a C6−C3−C6 configuration), can be categorized into flavones, flavanones, isoflavones, chalcones, anthocyanidins, and flavonols according to different C-ring chemical structures. It has been reported that the mechanism of inhibition of AGEs is done via trapping MGO for EGCG[26] (flavanols), genistein[25] (isoflavones), phloretin[27] (chalcones), and proanthocyanidins[35] (oligomers of flavanols). In view of this fact, we investigated quercetin (flavonols) inhibition of the formation of AGEs via trapping MGO and GO. With respect to the structure of these flavonoids, EGCG, genistein, phloretin, and quercetin have the same A ring. The same mechanism for trapping reactive dicarbonyl species and forming mono- and di-MGO adducts at the A ring may be predicted. After quercetin and MGO (1:3) were incubated for 24 h, the MS/MS spectrum of the most abundant daughter ion $m/z$ 373 of the mono-MGO ($t_R$ 27.34 min) adduct had the typical breakdown of the C ring ($m/z$ 150) and a loss of one $H_2O$ to generate the fragment ion 205 $[M - H_2O - 150]^-$ (Figures 3A and 6), which indicates that

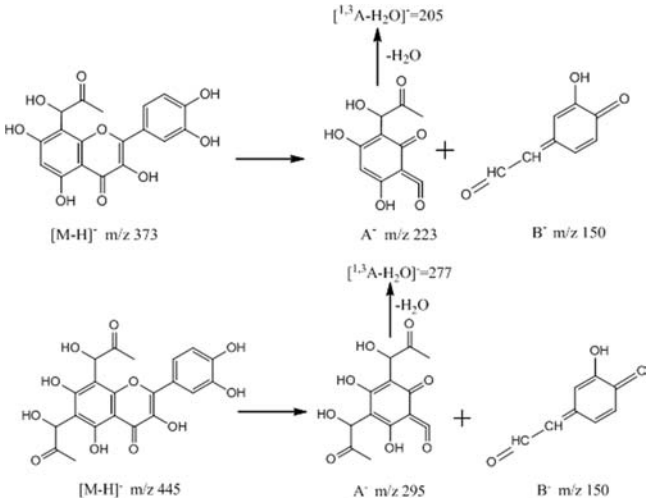

**Figure 6.** Formation pathway of the major fragments of mono- and di-MGO adducts of quercetin.

the MGO conjugates at the A ring of quercetin. Similarly, the MS/MS spectrum of the three di-MGO adducts had the same fragment patent to generate the daughter ion 277 $[M - H_2O - 150]^-$ (Figures 3B−D and 6). Therefore, we could determine that positions 6 and 8 on the A ring of quercetin were the major active sites for trapping MGO (Figure 6), which comprise the essential structural requirement for flavonoids to scavenge methylglyoxal.[36] Quercetin is the major representative of the flavonoid subclass flavonols.[37] It is widely distributed in nature, existing in foods such as apples, onions, tea, berries, red wine, and some herbs. Quercetin is a strong antioxidant,[38] and also possesses antihistamine and anti-inflammatory properties.[39,40] It has been reported that dietary flavonoids including luteolin, rutin, EGCG, and quercetin show effective inhibition on MGO-mediated AGE formation by 82.2, 77.7, 69.1, and 65.3%, respectively.[41] Our results demonstrate the reaction kinetics for quercetin trapping MGO and GO simultaneously, as well as the mechanism of quercetin inhibiting the formation of AGEs in the BSA−MGO/GO system.

In conclusion, using the food-borne flavonoid quercetin intervention to scavenge these dicarbonyl compounds is likely to be an effective strategy to inhibit the formation of AGEs and prevent AGE-mediated processes linked to disease.

fermentations. The primary fermentation may take 1−2 weeks in the presence of grape skins, which are responsible for color development of red wines. Furthermore, the primary fermentation is carried out by yeast cells, and their ability to absorb phenolic compounds may result in a higher or lower phenolic content in the wine and in its byproduct. The secondary step is conducted by bacterial fermentation, in the absence of grape skins, which are removed in the process. Thus, grape skins have no influence in the secondary fermentation.

Reactive oxygen species (ROS) are detrimental to health as they take part in oxidative processes both in vivo and in vitro.[12] ROS are involved in cell damage, cancer development, inflammation, and heart disease. Furthermore, ROS play an important role in aging and the development of Parkinson's disease. ROS are constantly generated via mitochondrial metabolism, which can worsen with unhealthy habits such as smoking. High-lipid foods are also affected by ROS generation, which can be influenced by heating, UV light, and $\gamma$-irradiation, leading to sensory changes, decreasing the shelf life of products and becoming an economic burden.[13] Hydrogen peroxide generates hydroxyl radicals in the presence of ferrous ion or via UV light dissociation. Although generation of the highly reactive short-lived hydroxyl radicals is of much concern as it induces DNA damage and lipid and protein oxidation, the presence of $H_2O_2$ itself causes enzyme inactivation and cell damage. The scavenging activity of phenolics against $H_2O_2$ is attributed to electron donation, but neutralization of $H_2O_2$ to $H_2O$ is also contemplated.[12] Moreover, ferric ion catalyzes the oxidation of proteins and lipids, thus being detrimental to food and biological systems.

The present study focused on the unraveling of the phenolic profile of grape byproducts and the contribution of each fraction to potential bioactivity as well as differences between byproducts generated by the juice- and winemaking industries. Total phenolic content (TPC), proanthocyanidin content (PC), scavenging activities against 2,2-diphenyl-1-picrylhydrazyl (DPPH), 2,2′-azinobis(3-ethylbenzothiazoline-6-sulfonic acid) diammonium salt (ABTS), and $H_2O_2$, and reducing power (RP) were evaluated. The detailed phenolic profile was investigated using HPLC-DAD-ESI-MS$^n$, and the potential health benefits of the extracts were evaluated against copper-induced LDL-cholesterol oxidation and peroxyl radical induced DNA strand breakage.

## MATERIALS AND METHODS

Grape juice (BRS Cora and Isabel) byproducts were donated by Embrapa Semiárido (Petrolina, Pernambuco state, Brazil). Syrah and Tempranillo (winemaking byproducts) were donated by Ouro Verde Farm, Grupo Miolo (Casa Nova, Bahia state, Brazil) and Santa Maria winery (Lagoa Grande, Pernambuco state, Brazil), respectively. Original grapes used in the grape juice- and winemaking processes had 20 and 22 °Brix, respectively. Brazilian grape juice is mainly produced using the Isabel cultivar, due to its large production. BRS Cora, hereafter named Cora, is a Brazilian variety developed by Embrapa through crossing between 'Muscat Belly A' and 'H.65.9.14' varieties. Cora and Isabel grapes were grown in Petrolina, Pernambuco state, Brazil. Syrah grape was grown in Casa Nova, Bahia state, Brazil, and Tempranillo was grown in Lagoa Grande, Pernambuco state, Brazil.

Folin−Ciocalteu's reagent, vanillin, DPPH, ABTS, mono- and dibasic potassium phosphates, hydrogen peroxide, potassium ferricyanide, ferric chloride, copper sulfate, human LDL-cholesterol, ethylenediaminetetraacetic acid trisodium salt ($Na_3EDTA$), tris acetate, 2,2′-azobis(2-methylpropionamidine) dihydrochloride (AAPH), agarose, bromophenol blue, xylene cyanol, glycerol, trolox, caffeic, gallic, protocatechuic, and *p*-coumaric acids, (+)-catechin, and (−)-epicatechin were purchased from Sigma-Aldrich Canada Ltd. (Oakville, ON, Canada). Sodium carbonate, sodium hydroxide, sodium chloride, potassium persulfate, trichloroacetic acid, diethyl ether, ethyl acetate, hexane, acetone, methanol, acetonitrile, formic acid, hydrochloric acid, sodium hydroxide, and pBR 322 from *Escherichia coli* were purchased from Fisher Scientific Ltd. (Ottawa, ON, Canada). SYBR safe gel stain was purchased from Probes (Invitrogen, Eugene, OR, USA).

**Extraction of Phenolic Compounds.** Grape byproducts were freeze-dried at −48 °C and 30 × $10^{-3}$ mbar (Freezone 6, model 77530, Labconco, Co., Kansas City, MO, USA) and ground using a coffee bean grinder (model CBG5 series, Black & Decker, Canada, Inc., Brockville, ON, Canada). The powder so obtained was passed through a mesh 16 (sieve opening 1 mm, Tyler test sieve, Mentor, OH, USA) sieve. Ground samples were defatted three times using hexane (solid/solvent, 1:5, w/v) in a Waring blender (model 33BL73, Waring Products Division Dynamics Co. of America, New Hartford, CT, USA). Defatted samples were then stored at −20 °C until used for the extraction of phenolic compounds within 1 week.

Defatted samples (2.5 g) were extracted with 70% acetone (100 mL) in a gyrotory water bath shaker (model G76, New Brunswick Scientific Co. Inc., New Brunswick, NJ, USA) at 30 °C for 20 min. After centrifugation at 4000*g* (IEC Centra MP4, International Equipment Co., Needham Heights, MA, USA), the upper layer was collected and extraction was repeated twice. The combined supernatants were evaporated to remove the organic solvent, and the residue in water was acidified to pH 2 using 6 M HCl. Free phenolic compounds were extracted five times with diethyl ether and ethyl acetate (1:1, v/v). Combined supernatants were evaporated in vacuo at 40 °C (Buchi, Flawil, Switzerland). The remaining water phase was mixed with 4 M NaOH and hydrolyzed while stirring under nitrogen for 4 h at room temperature (23−25 °C) to release esterified phenolics. This was followed by acidification to pH 2 using 6 M HCl, five extractions with diethyl ether and ethyl acetate (1:1, v/v), and evaporation of combined supernatants in vacuo at 40 °C. Free phenolics and those released from their esterified form were separately reconstituted in HPLC grade methanol and stored at −20 °C until used for further analysis within 3 months.

To the solid residue remaining after the first set of extractions, 4 M NaOH was added and hydrolyzed with stirring under nitrogen for 4 h at room temperature (23−25 °C). The resulting slurry was acidified to pH 2 with 6 M HCl. Phenolics released from their insoluble-bound form were then extracted with diethyl ether and ethyl acetate (1:1, v/v) and reconstituted in HPLC grade methanol, as explained above.

**Total Phenolic Contents.** TPC were determined according to the Folin−Ciocalteu method[14] with slight modifications, as previously described by de Camargo et al.[15] The phenolic extracts were used in concentrations ranging from 3 to 30 mg/mL. First, the extracts with appropriate dilutions (0.5 mL), deionized water (4 mL), and Folin−Ciocalteu's reagent (0.5 mL) were added into flasks and mixed thoroughly. After 3 min, a saturated solution of sodium carbonate (0.5 mL) was added, and the mixture was kept in the dark at room temperature (23−25 °C) for 2 h. Finally, the absorbance was read at 760 nm using an Agilent diode array spectrophotometer (Agilent 8453, Palo Alto, CA, USA). The results were expressed as milligram gallic acid equivalents per gram of dry weight of defatted sample.

**Proanthocyanidin Content.** Total proanthocyanidins (condensed tannins) were determined according to the method of Price et al.[16] as explained by de Camargo et al.[3] Briefly, phenolic extracts were diluted in methanol (10−100 mg/mL), and 1 mL of the extracts so obtained was added to 5 mL of a 0.5% (w/v) vanillin solution prepared in 4% (v/v) HCl in methanol. The mixture was incubated in a gyrotory water bath shaker (model G76, New Brunswick Scientific Co., New Brunswick, NJ, USA) at 30 °C for 20 min. Finally, the absorbance was read at 500 nm using an Agilent diode array spectrophotometer (Agilent 8453). The results were expressed as milligram catechin equivalents per gram of dry weight of defatted sample.

**ABTS Radical Cation Scavenging Activity.** The ABTS assay[17] was performed using a modified version of the method described by de

Camargo et al.[3] The ABTS radical, which was generated by oxidation with potassium persulfate, was prepared in 100 mM phosphate buffer saline solution (PBS) (pH 7.4, 0.15 M sodium chloride). The ABTS stock solution consisted of potassium persulfate (2.45 mM) and ABTS (7.00 mM) in PBS. At the time of analysis, the working solution of ABTS was prepared by diluting its stock solution in PBS to reach an absorbance value of 0.70 (734 nm). Phenolic extracts were diluted in PBS (10−30 mg/mL). Diluted phenolic extracts (20 μL) were added to 2 mL of ABTS radical cation solution, and the absorbance was read at 734 nm after 6 min using an Agilent diode array spectrophotometer (Agilent 8453). ABTS radical scavenging activity was calculated using the equation

$$\text{ABTS radical scavenging activity (\%)} = [(\text{Abs}_{\text{control}} - \text{Abs}_{\text{sample}})/(\text{Abs}_{\text{control}})] \times 100$$

where $\text{Abs}_{\text{control}}$ is the absorbance of ABTS radical + PBS and $\text{Abs}_{\text{sample}}$ is the absorbance of ABTS radical cation + phenolic extract or trolox. The results were expressed as micromoles of trolox equivalents per gram of dry weight of defatted sample.

**DPPH Radical Scavenging Activity (DRSA).** The DPPH assay was carried out using a modified version of the method explained by Chandrasekara and Shahidi.[18] The phenolic extracts were used at different concentrations of 10−50 mg/mL. Two milliliters of a methanolic solution of DPPH (0.5 mM) were added to 500 μL of the extracts diluted in methanol. After 10 min, the mixture was passed through the capillary tubing that guides the sample through the sample cavity of a Bruker e-scan electron paramagnetic resonance (EPR) spectrophotometer (Bruker E-Scan, Bruker Biospin Co., Billercia, MA, USA). The spectrum was recorded using the following parameters: $5.02 \times 10^2$ receiver gain, 1.93 G modulation amplitude, 2.62 s sweep time, 8 scans, 100.000 G sweep width, 3495.258 G center field, 5.12 ms time constant, 9.793220 GHz microwave frequency, and 86.00 kHz modulation frequency. The DPPH scavenging activity of the extracts was calculated using the equation

$$\text{DPPH scavenging activity (\%)} = [(\text{EPR}_{\text{control}} - \text{EPR}_{\text{sample}})/(\text{EPR}_{\text{control}})] \times 100$$

where $\text{EPR}_{\text{control}}$ is the signal intensity of DPPH radical + methanol and $\text{EPR}_{\text{sample}}$ is the signal intensity of DPPH radical + phenolic extract or trolox. The results were expressed as micromoles of trolox equivalents per gram of dry weight of defatted sample.

**Hydrogen Peroxide Scavenging Activity.** The hydrogen peroxide scavenging activity of extracts of grape byproducts was evaluated as explained elsewhere.[12] Phenolic extracts (4−40 mg/mL) and 0.4 mM hydrogen peroxide solution were prepared in 0.1 M phosphate buffer (pH 7.4). The extracts (0.4 mL) were mixed with hydrogen peroxide solution (0.6 mL), and the final volume was made to 2 mL with the same buffer. The samples were kept in a gyrotory water bath shaker (model G76, New Brunswick Scientific Co. Inc.) for 40 min, and the absorbance was read at 230 nm using an Agilent diode array spectrophotometer (Agilent 8453). Blanks devoid of hydrogen peroxide (added by phosphate buffer) were prepared for background corrections. The results were expressed as micromoles of trolox equivalents per gram of dry weight of defatted sample.

The scavenging activity was calculated with the equation

$$\text{H}_2\text{O}_2 \text{ scavenging activity (\%)} = [(\text{Abs}_{\text{control}} - \text{Abs}_{\text{sample}})/(\text{Abs}_{\text{control}})] \times 100$$

where $\text{Abs}_{\text{control}}$ is the absorbance of $H_2O_2$ radical + phosphate buffer and $\text{Abs}_{\text{sample}}$ is the absorbance of $H_2O_2$ + phenolic extract extract or trolox.

**Reducing Power.** The RP assay was conducted according to the method described by Alasalvar et al.[19] The extracts (2−20 mg/mL) were diluted in phosphate buffer (pH 6.6, 0.2 mM). Extracts (1 mL) were then further mixed with phosphate buffer (2.5 mL) and 1% (w/v) potassium ferricyanide solution (2.5 mL), followed by their incubation in a gyrotory water bath shaker (model G76, New Brunswick Scientific Co. Inc.) at 50 °C for 20 min, after which a 10% (w/v) solution of trichloroacetic acid was added (2.5 mL). The mixture was subsequently centrifuged at 1750*g* for 10 min, and the supernatant (2.5 mL) was added to distilled water (2.5 mL) and 0.1% (w/v) ferric chloride solution (0.5 mL). The absorbance was read at 700 nm using an Agilent diode array spectrophotometer (Agilent 8453). A calibration curve was prepared using trolox as a standard, and results were expressed as trolox equivalents per gram of dry weight of defatted sample.

**Copper-Induced Human LDL-Cholesterol Oxidation.** The LDL-cholesterol oxidation method described by Shahidi et al.[4] was slightly modified to evaluate the potential inhibitory effect of phenolic extracts of grape byproducts. The solution of LDL-cholesterol was dialyzed overnight against PBS (10 mM, 0.15 M NaCl, pH 7.4) at 4 °C under a flow of nitrogen. The resulting ethylenediaminetetraacetic acid (EDTA)-free LDL-cholesterol was diluted in PBS to reach a concentration of 0.04 mg/mL. Methanol was removed from grape byproduct extracts under a stream of nitrogen followed by their resuspension in PBS to obtain 100 ppm of total phenolic equivalents in relation to the final volume assay (1 mL). This was calculated on the basis of TPC as evaluated by HPLC-DAD-ESI- $MS^n$ (Figure 1).

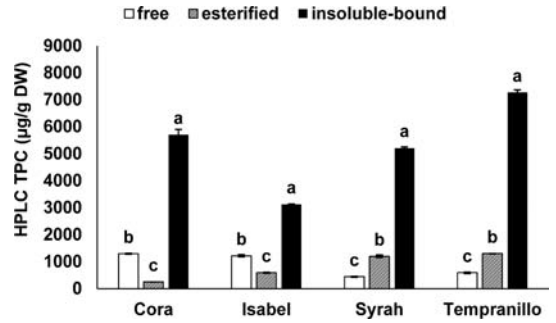

**Figure 1.** HPLC-DAD-ESI-$MS^n$ total phenolic content (HPLC TPC) of different fractions of juice (Cora and Isabel) and winemaking (Syrah and Tempranillo) byproducts. Data represent the mean ± standard deviation of each sample ($n = 3$). Means with different letters indicate significant differences ($p < 0.05$) among fractions within the same grape variety.

Phenolic extracts (100 μL) and LDL-cholesterol (800 μL) were added into Eppendorf tubes and incubated at 37 °C for 15 min, after which the peroxidation was induced by the addition of a 100 μM solution of $CuSO_4$ (100 μL). The reaction was incubated for 24 h at 37 °C, and the conjugated dienes (CD) were assayed at 234 nm using an Agilent diode array spectrophotometer (Agilent 8453). Blanks devoid of LDL-cholesterol and $CuSO_4$ were prepared for background subtraction. A positive control was prepared with catechin (100 ppm), and the results were expressed as percent inhibition according to the equation

$$\text{inhibition of formation of CD (\%)} = [(\text{Abs}_{\text{oxidized}} - \text{Abs}_{\text{sample}})/(\text{Abs}_{\text{oxidized}} - \text{Abs}_{\text{native}})] \times 100$$

where $\text{Abs}_{\text{oxidized}}$ is the absorbance of LDL-cholesterol with $CuSO_4$, $\text{Abs}_{\text{sample}}$ is the absorbance of LDL-cholesterol with extract or catechin and $CuSO_4$, and $\text{Abs}_{\text{native}}$ is the absorbance of LDL-cholesterol without $CuSO_4$.

**Inhibition of Peroxyl Radical Induced Supercoiled Plasmid DNA Strand Breakage.** The supercoiled plasmid DNA strand breakage inhibition was evaluated using a slightly modified version of the method explained by Shahidi et al.[4] Methanol was removed from phenolic extracts under a stream of nitrogen followed by resuspension in water to achieve a concentration of 1−5 mg/mL. An aliquot (2 μL) was pipetted in Eppendorf tubes, and the remaining reagents were added in the following order: 2 μL of PBS (0.5 M, pH 7.4, 0.15 M sodium chloride), 2 μL of supercoiled plasmid DNA pBR 322 from *Escherichia coli* RRI diluted in PBS (50 μL/mL), and 4 μL of a 7 mM

[a]F, E, and B are free, esterified, and insoluble-bound phenolics, respectively. [b]*, compounds identified with authentic standards.

AAPH solution. The mixture was incubated at 37 °C for 1 h in the dark, after which 1 μL of loading dye (0.25% bromophenol blue, 0.25% xylene cyanol, 50% glycerol in distilled water) was added. The samples were loaded onto 0.7 (w/v) agarose gel prepared in Tris−acetic acid−EDTA (TAE) buffer consisting of 40 mM Tris acetate and 1 mM EDTA, pH 8.5. The gel was stained with SYBR safe (100 μL/L). The procedure was conducted at 80 V for 90 min using a submarine gel electrophoresis apparatus (VWR, Radnor, PA, USA). The images were acquired with a Sony digital camera under UV light and analyzed using AlphaEase stand-alone software (Alpha Innotech Co., San Leandro, CA, USA). The inhibition percentage was calculated as follows: inhibition of DNA strand breakage = [(intensity of supercoiled DNA in the presence of oxidant and extract/intensity of supercoiled DNA devoid of oxidant and extract) × 100]. Results were expressed as percentage retention of supercoiled DNA achieved with 1 mg/mL of defatted sample.

**HPLC-DAD-ESI-MS$^n$ Analysis.** Identification of major phenolics in the free, esterified, and insoluble-bound fractions of grape byproducts was carried out using an Agilent 1100 system equipped with a G1311A quaternary pump, a G1379A degasser, a G1329A ALS automatic sampler, a G1130B ALS Therm, a G1316 Colcom column compartment, A G1315B diode array detector (DAD), and a system controller linked to a ChemStation Data handling system (Agilent). Separations were conducted with a SUPERLCOSIL LC-18 column (4.6 × 250 mm × 5 μm, Merck, Darmstadt, Germany). The binary mobile phase consisted of 0.1% formic acid (A) and 0.1% formic acid in acetonitrile (B). The flow rate of mobile phase was 0.5 mL/min, and the elution gradient used was as follows: 0 min, 100% A; 5 min, 90% A; 35 min, 85% A; 45 min, 60% A; held at 60% A from 45 to 50 min. Afterward mobile phase A was increased to 100% at 55 min, followed by column equilibration from 55 to 65 min. The compounds were detected at 280 nm, and the samples were filtered before injection using a 0.45 μm PTFE membrane syringe filter (Thermo Scientific, Rockwood, TN, USA).

HPLC-ESI-MS$^n$ analysis was carried out under the same conditions as described above using an Agilent 1100 series capillary liquid chromatography−mass selective detector (LC-MSD) ion trap system in electrospray ionization (ESI) in the negative mode. The data were acquired and analyzed with Agilent LC-MSD software. The scan range was set from $m/z$ 50 to 1200, using smart parameter setting, drying nitrogen gas at 350 °C, flow of 12 L/min, and nebulizer gas pressure of 70 psi. Phenolic acids, namely, protocatechuic, *p*-coumaric, gallic, ferulic, and ellagic acids, and flavonoids (+)-catechin, (−)-epicatechin, and quercetin were identified by comparing their retention times and ion fragmentation patterns with coded and authentic standards under the same conditions as the samples. Hydroxycaffeic and caftaric acids and monogalloyl glucose as well as isorhamnetin, epicatechin gallate, kaempferol hexoside, quercetin hexoside, quercetin glucuronide, isorhamnetin hexoside, myricetin hexoside, and dimers through tetramers of proanthocyanidins were tentatively identified using tandem mass spectrometry (MS$^n$), UV spectral, and literature data.

**Statistical Analysis.** The experimental design was randomized with three replications, and the results were analyzed using Tukey's test ($p < 0.05$) and SAS software. The correlation analysis ($p < 0.01$ and $p < 0.05$) was carried out using the ASSISTAT 7.6 program.

## RESULTS AND DISCUSSION

**HPLC-DAD-ESI-MS$^n$ Analysis.** In the present study, phenolics from grape juice- and winemaking byproducts were extracted in different fractions (free, esterified, and insoluble-bound) to fill the apparent gap in the existing knowledge and to offer new information on the subject. The MS spectra of free, esterified, and insoluble-bound phenolic fractions of grape

[a]Data represent mean values for each sample ± standard deviations ($n = 3$). Means followed by the same letter within a column are not significantly different ($p > 0.05$). [b]nd, nondetected. [c]tr, trace.

byproducts are shown in Table 1. Compounds **1**−**5**, **7**, and **10**−**12** were identified by comparison of their retention times and ion fragmentation patterns with authentic standards. Compound **6** gave deprotonated ions at $m/z$ 197 and $MS^2$ at $m/z$ 179, due to loss of water $[M - H - 18]^-$, and at $m/z$ 135. This ion fragmentation pattern is typical for caffeic acid, as confirmed using a commercial standard, and thus tentatively identified as hydroxycaffeic acid. In the present study, hydroxycaffeic was found only in the esterified fraction of the Tempranillo variety. Hydroxycaffeic acid, which is found in blackberries and blueberries,[20] has not been reported in grapes, possibly because few varieties may contain it or it may be esterified to other components present.

Compound **8**, which was present in the free fraction of Cora, Isabel, and Tempranillo varieties, showed an $m/z$ at 311 in MS followed by 179 and 135 in $MS^2$ and was tentatively identified as caftaric acid.[21] Monogalloyl glucose (compound **9**) was also tentatively identified due to its $m/z$ of 331 in MS and $m/z$ of 169 and 125 in $MS^2$, both typical of gallic acid.[8] Furthermore, monogalloyl glucose was present in all fractions of all samples tested.

Compound **13** gave deprotonated ion $[M - H]^-$ at $m/z$ 315 and at $m/z$ 271 in $MS^2$, which is compatible with the isorhamnetin dissocitation pattern.[22] Compound **14** was tentatively identified as epicatechin gallate (galloylated flavan-3-ol) due to its deprotonated molecular ion at $m/z$ 441 followed by $m/z$ at 289 and 245 in $MS^2$, showing

decarboxylation of epicatechin $[M - H - 44]^-$, at $m/z$ 169 and 125, the last one from decarboxylated gallic acid.[10]

Compound **15** with a deprotonated ion at $m/z$ 447 gave product ions at $m/z$ 285 (kaempferol) in $MS^2$, showing loss of hexose $[M - H - 162]^-$, thus being tentatively identified as kaempferol hexoside.[8] Compound **16** ($m/z$ 463) also showed loss of hexoside and its typical quercetin dissociation at $m/z$ 179 and 151 in $MS^2$, which was confirmed by quercetin standard, indicating its identity as quercetin hexoside.

Quercetin glucuronide was tentatively identified as compound **17**, which gave a deprotonated ion at $m/z$ 477 and $MS^2$ at 301, 179, and 151.[8] Compound **19** showed $[M - H]^-$ at $m/z$ 477, such as quercetin glucuronide, but its $MS^2$ gave product ions at $m/z$ 315 and 271, enabling its tentative identification as isorhamnetin hexoside.[8] Myricetin hexoside was also tentatively identified according to its deprotonated ion at $m/z$ 479, followed by loss of hexose,[10] which gave signals at $m/z$ 317, 179, and 151, the last ones confirmed by using an authentic standard.

With the exception of galloylated procyanidin dimer,[8] the remaining proanthocyanidins were tentatively identified according to the studies of Sarnoski et al.[23] and de Camargo et al.[24] Procyanidins B1−B8 are currently known;[25] thus, some peaks were identified with the same ionization pattern, which has been common for proanthocyanidins isomers. However, accurate stereoisomer identification requires nuclear magnetic resonance (NMR) analysis; thus, for quantification purposes total value was reported.

The quantification data for the phenolics identified are shown in Table 2. Although anthocyanins have been reported in grape byproducts, the HPLC-DAD acquisition data set at 520 nm, which is typical for anthocyanins, did not show major compounds (data not show); thus, the present study focused on phenolic acids, flavonoids, and proanthocyanidins. Varietal differences in phenolics are well documented in the literature;[1,11,26] thus, statistical treatment was carried out among the free, esterified, and insoluble-bound fractions. With very few exceptions, the insoluble-bound fraction had the highest content of individual phenolics.

The HPLC-DAD-ESI-$MS^n$ evaluation demonstrated that gallic and caffeic acids were the major phenolic acids accounting for up to 20 and 14% of the total, respectively. Gallic acid has previously been reported as being the major phenolic acid in grape seeds.[27] Catechin was the major monomeric flavonoid (up to 17%), and procyanidin dimer B was the main proanthocyanidin, with a content of up to 52%. Several factors such as climatic and stress conditions as well as soil quality play important roles in the content of phenolics; thus, a direct comparison with the literature data is not possible, but some trends may be discernible

The present study reveals similarities with the data reported by Ćurko et al.,[28] in which catechin and procyanidin B were the major monomeric flavonoid and proanthocyanidin, respectively. Interestingly, a high concentration of procyanidin dimer A, which has not been commonly reported for grape and its byproducts, was found in the present study. However, Cheng et al.[1] also reported the presence of procyanidin dimer A in grape byproducts (skins, seeds, and pomace). Furthermore, according to these authors, the highest procyanidin dimer A concentration was found in the seeds.

Total phenolics, as evaluated by HPLC-DAD-ESI-$MS^n$, hereafter named HPLC TPC, are shown in Figures 1 and 2. The HPLC TPC were present in the order insoluble-bound > free > esterified for both juice byproducts and insoluble-bound > esterified > free for both winemaking byproducts, which suggests that the process type influences this distribution. The HPLC TPC were in the decreasing order Tempranillo > Cora > Syrah > Isabel (Figure 2), with insoluble-bound fraction representing up to 12 and 23 times the content of the free and esterified fractions, respectively. This is important because most of the available information is focused only on the soluble phenolics (free plus esterified). Finally, Figure 3 shows the percent contribution of soluble and insoluble-bound phenolics in the samples. Insoluble-bound phenolics accounted for 63−79% of the total, thus demonstrating their dominance as a major source of bioactive compounds in grape byproducts.

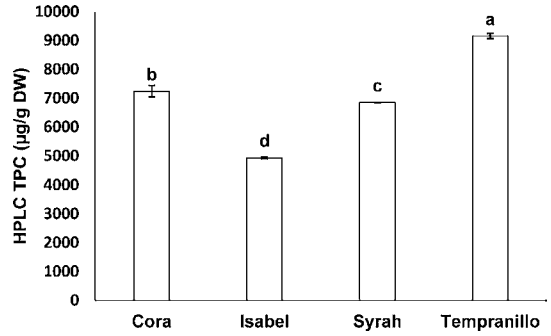

**Figure 2.** HPLC-DAD-ESI-$MS^n$ total phenolic content (HPLC TPC) representing free plus esterified plus insoluble-bound phenolics of juice (Cora and Isabel) and winemaking (Syrah and Tempranillo) byproducts. Data represent the mean ± standard deviation of each sample ($n$ = 3). Means with different letters indicate significant differences ($p < 0.05$).

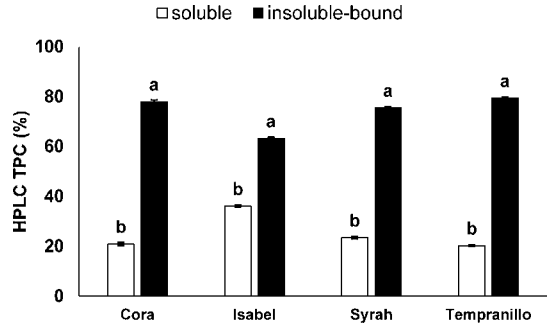

**Figure 3.** HPLC-DAD-ESI-$MS^n$ total phenolic content (HPLC TPC) of soluble and insoluble-bound fractions of juice (Cora and Isabel) and winemaking (Syrah and Tempranillo) byproducts. Means with different letters indicate significant differences ($p < 0.05$) within the same grape variety.

As can be noted by both identification and quantification, a wide range of phenolics was present in the samples. Furthermore, each fraction and grape variety had its own fingerprint; thus, in the following sections, one should bear in mind that this difference may affect each assay to different extents, depending on the operative mechanisms.

**Total Phenolic Contents.** The TPC of grape juice- and winemaking byproducts are given in Table 3. The differences in the TPC, due to different grape varieties, are well documented.[1,11] The TPC of free, esterified, and insoluble-bound fractions were in the ranges of 45.8−124, 48.6−124, and 171−339 mg GAE/g dry weight of fat-free sample, respectively. These data are in accordance with a previous study on soluble

phenolics (free plus esterified) from winemaking byproducts, in which 10 grape varieties were evaluated.[11]

In the present study, byproducts of the juice industry (Cora and Isabel) showed the highest TPC in the free phenolic fraction in comparison with the winery byproducts (Syrah and Tempranillo). The lower TPC in the free fraction of winemaking byproducts in comparison with those of grape juice byproducts may be explained by different grape variety, their maturation, and crop production area; however, the process influence is also possible. Polyphenols have been shown to provide a better affinity to alcoholic solvents; thus, grape skins and seeds of the winemaking process may lose their soluble phenolics to the liquid medium, which mimics a solvent system. Moreover, a clear cluster can be noted in relation to free and soluble esterified phenolics (e.g., grape juice- vs winemaking byproducts). Cora and Isabel, which are grape juice byproducts, had free phenolics in the range of 62−72%, in relation to total soluble phenolics (free plus esterified), whereas Syrah and Tempranillo, which are winery byproducts, had those in the range of 36−41%. The opposite trend was found for the TPC of the fraction containing phenolics released from their esterified form. This can also be noted when the TPC is evaluated by HPLC (Figure 1). TPC of the insoluble-bound fractions did not indicate the same influence of the process as statistical analysis did not allow their grouping into different clusters (e.g., grape juice- or winemaking byproducts), suggesting that the noted differences were due to varietal influences.

The extraction of insoluble-bound phenolics was conducted via hydrolysis using 4 M NaOH for 4 h. Meanwhile, a simple contact with the medium (e.g., grape juice or wine) would hardly be sufficient to release insoluble-bound phenolics during the grape juice- or winemaking manufacture. Only this would enable their loss to the liquid medium. As this is unlikely, it is possible to suggest that the differences found in the fraction containing insoluble-bound phenolics are due to grape variety, their maturation, and crop production area. The distribution of phenolic compounds among all forms (free, esterified, and insoluble-bound) depends not only on the feedstock but also on the variety and field conditions. Although further studies are necessary to confirm this assumption, the present study indicates a possible influence of the process (e.g., grape juice vs wine) in their distribution.

**Proanthocyanidin Content.** Proanthocyanidins, also known as condensed tannins, consist of flavan-3-ol units, ranging from dimers to higher oligomers. Grapes have a high content of proanthocyanidins, especially procyanidin dimer B, which consists exclusively of catechin and epicatechin units; however, prodelphinidins, which have (epi)gallocatechin in their structures, are also found in grapes, as demonstrated before (Table 1). The method for estimating the PC used here showed better correlation with low molecular weight proanthocyanidins (2−4 units);[29] however, the PC showed a significant and positive correlation ($p < 0.01$) with all antioxidant assays carried out in the present study (Table 4), indicating the quality of the results.

The PC is shown in Table 3; the results presented are in good agreement with those reported for soluble phenolics (free plus esterified) of winemaking byproducts.[11] In accordance with TPC in the present study, the highest PC was found in the insoluble-bound fraction, and its content was up to 6-fold higher than that found in the free fraction. Furthermore, winemaking byproducts (Syrah and Tempranillo) had the highest esterified PC in comparison with the juice byproducts (Cora and Isabel), suggesting that the grape juice process influence on PC takes place in the esterified fraction.

The juice process in the present study was carried out at 85 °C and pH 3.5 for 60 min. Meanwhile, no heat was applied during the winemaking process. Acid hydrolysis (95 °C, 45 min) has been used to release phenolics from their glycosidic bonds.[30] Flavanone 3-hydroxylase is the first enzyme in the biosynthesis of proanthocyanidins. Its optimum temperature is 30−40 °C.[31,32] The remaining enzymes also have low optimum temperature (e.g., dihydroflavonol reductase, 30−45 °C; leucoanthocyanidin reductase, 30−37 °C; and anthocyanidin reductase, 45−55 °C).[33−35] High temperature and time used during the juice process may denature all enzymes present. Thus, heating and acidic condition may release phenolics from their esters during juice making. Furthermore, enzyme inactivation probably occurs, which affects further biosynthesis. Thus, both factors lower the content of esterified proanthocyanidins and the remaining phenolics in the juice byproducts as compared to the winemaking ones.

Supporting the findings of the present study, higher contents of soluble proanthocyanidins (free plus esterified) were found in grape skin and seeds produced in winemaking with a longer fermentation process.[36] It is noteworthy that the highest PC in the esterified fraction of winemaking byproducts is supported by the highest procyanidin B content, the major proanthocyanidin present, as evaluated by HPLC-DAD-ESI-MS$^n$ (Table 2). Interestingly, both catechin and epicatechin, which are subunits of procyanidins, were found in higher concentrations in the esterified fraction of the winemaking byproducts in the present study.

**ABTS Radical Cation Scavenging Activity.** In the present study, no difference was found between the ABTS antioxidant activity (Table 3) of the free phenolic extracts from Cora and Isabel (juice byproducts), which had the highest scavenging activities in comparison with those of the winemaking byproducts (Syrah and Tempranillo). On the other hand, the Tempranillo variety showed the highest scavenging activity for esterified and insoluble-bound fractions. Furthermore, the Syrah cultivar exhibited the highest difference between the scavenging activity of the soluble (free plus esterified) and insoluble-bound fractions, the latter contributing up to 6.5-fold higher scavenging activity than the soluble counterpart. Gallic acid is a potent antioxidant, and grapes contain a high amount of gallic acid and polyphenols bearing galloyl groups (Table 2), which may explain the large difference in scavenging activity between soluble and insoluble-bound fractions, despite the relatively low difference found in their TPC, which was not higher than 1.9-fold (Table 3). In accordance with TPC and PC, the highest scavenging activity for all grape byproducts was found for the insoluble-bound fraction.

**DPPH Radical Scavenging Activity Using Electron Paramagnetic Resonance.** The DRSA results (Table 3) showed a trend similar to those for the free phenolic fraction in both ABTS and TPC determinations, for which grape juice byproducts (Cora and Isabel) demonstrated higher values. However, Cora had the highest DRSA, different from that observed in the ABTS assay, which exhibited no significant difference between both juice byproducts. Different results, depending on the method used, may be obtained due to different chemical structures as well as synergistic, additive, or antagonistic interaction effects. Furthermore, pro-oxidant

effects are also possible depending on the reaction mechanism and polyphenol concentration, among other factors,[37,38]

**Hydrogen Peroxide Scavenging Activity.** The scavenging activity of hydrogen peroxide by grape byproducts is shown in Table 3. Similar to other antioxidant assays, the insoluble-bound fraction exhibited a higher efficacy in scavenging hydroxyl radicals. Interestingly, for the first time in the present study, insoluble-bound phenolics from Cora variety exhibited the most antioxidant effectiveness, suggesting the presence of a particular polyphenol or a synergistic effect among some polyphenols that renders a higher protective influence to Cora against ROS. The remaining results for the free fraction followed a similar trend to TPC, rendering a different cluster, grape juice byproducts (Cora and Isabel) being the most effective in the free phenolic fraction. Furthermore, different from other antioxidant assays, the esterified fraction of grape juice byproducts also displayed the highest effect against $H_2O_2$. Grape byproducts have shown scavenging activity against superoxide anion and peroxyl and hydroxyl radicals.[1,8,39]

**Reducing Power.** The RP of grape byproducts is summarized is Table 3, indicating the ability of polyphenols present to reduce the ferric ion to the ferrous ion. The comparison of reducing power within the free fraction showed that Cora and Isabel, which are grape juice byproducts, had the highest efficacy in reducing ferric to ferrous ions, compared to winemaking byproducts (Syrah and Tempranillo). On the other hand, in the esterified fraction, the winemaking byproducts accounted for the highest RP in comparison to grape juice byproducts, which was also found for the insoluble-bound fraction. Finally, the comparison among free, esterified, and insoluble-bound phenolic fractions confirmed the highest potential bioactivity for the insoluble-bound fraction in all grape varieties. Other studies[8,11] provide information supporting the reducing ability of grape byproducts; however, a direct comparison is not possible due to different units used to report the results and the methods employed in these determinations. Most studies have been using ferric reducing antioxidant power assay (FRAP) at pH 3.6, which is different from the pH 6.6 used in this study. The antioxidant/reducing power of phenolic compounds is known to be dependent on the pH of the medium.[40]

**Copper-Induced LDL-Cholesterol Oxidation.** The presence of oxidized LDL-cholesterol at high levels constitutes a risk factor for atherosclerosis. In the present study, copper-induced oxidation of human LDL-cholesterol was inhibited by all phenolic extracts (Figure 4) and the highest effect was rendered by the insoluble-bound fraction. A recent study demonstrated that nonextractable polyphenols are the major contributors to the Spanish diet.[41] Consumption of commodities containing phenolic acids, monomeric flavonoids, and proanthocyanidins has been correlated with a decrease in the level of oxidized cholesterol in high-risk cardiovascular patients.[42] Grapes have a high content of procyanidin B and monomeric flavonoids as well as gallic acid as their major phenolics, the latter being an antioxidatively potent phenol. The presence of this broad range of bioactive compounds may be responsible for the ability of grape products to prevent LDL-cholesterol oxidation and potentially the development of heart disease.

**Inhibition of Peroxyl Radical Induced Supercoiled Plasmid DNA Strand Breakage.** ROS oxidize the native form of DNA, which can be evaluated by its conversion to a nicked circular or linear form via single- or double-strand

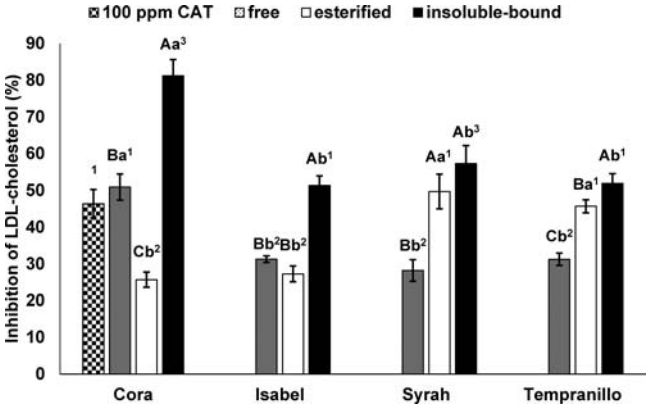

**Figure 4.** Biological activity of free, esterified, and insoluble-bound phenolics of juice (Cora and Isabel) and winemaking (Syrah and Tempranillo) byproducts against LDL-cholesterol induced oxidation. Data represent the mean ± standard deviation of each sample ($n$ = 3). Means with different letters indicate significant differences ($p$ < 0.05) compared to 100 ppm catechin (CAT). Extracts were assayed in concentration of 100 ppm of total phenolic content equivalent (as evaluated by HPLC-DAD-ESI-MS$^n$). Means with different capital letters indicate significant differences ($p$ < 0.05) among fractions within the same grape variety. Means with different lower case letters indicate significant differences ($p$ < 0.05) among grape varieties within the same fraction.

breaks, respectively. Such a process affects DNA replication and transcription, causing mutagenesis and cancer initiation. The present study evaluated the ability of different grape processing byproducts in inhibiting peroxyl radical induced supercoiled plasmid DNA strand breakage (Figures 5−7). Peroxyl radicals

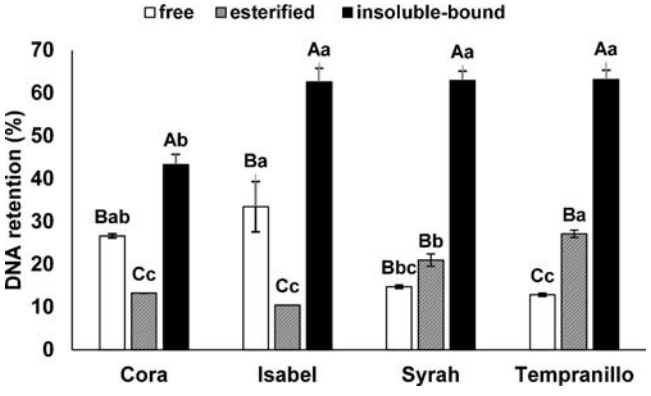

**Figure 5.** Supercoiled plasmid DNA strand breakage inhibition of free, esterified, and insoluble phenolic fractions from juice (Cora and Isabel) and winemaking (Syrah and Tempranillo) byproducts. Data represent the mean ± standard deviation of each sample ($n$ = 3). Means with different capital letters indicate significant differences ($p$ < 0.05) among fractions within the same grape variety. Means with different lower case letters indicate significant differences ($p$ < 0.05) among grape varieties within the same fraction. Results were transformed for concentrations of 1 mg/mL of defatted sample. Representative raw data are given in Figures 3 and 4.

have a relatively long half-life, and therefore their detrimental effects may not only take place at a cellular level but also be extended to biological fluids. All grape extract phenolics rendered a DNA protective effect against peroxyl radicals.

Insoluble-bound phenolics had the highest protective action against peroxyl radical induced supercoiled plasmid DNA

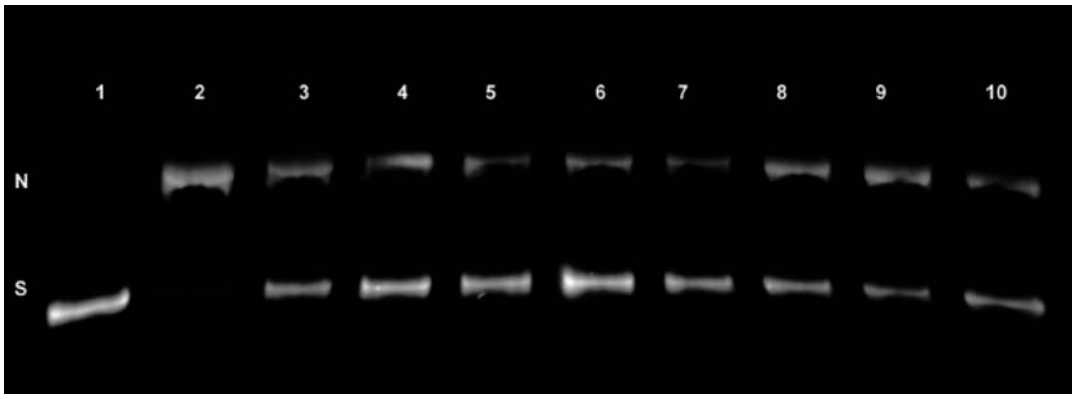

**Figure 6.** Representative raw data of supercoiled plasmid DNA strand breakage inhibition of the free and esterified phenolic fraction of juice (Cora and Isabel) and winemaking (Syrah and Tempranillo) byproducts. Lanes: 1, control (DNA only); 2, DNA + AAPH; 3, free phenolics from Cora (2.5 mg/mL; 53 ± 1% DNA retention); 4, free phenolics from Isabel (2.5 mg/mL; 67 ± 12% DNA retention); 5, free phenolics from Syrah (5.0 mg/mL; 74 ± 2% DNA retention); 6, free phenolics from Tempranillo (5.0 mg/mL; 64 ± 2% DNA retention); 7, esterified phenolics from Cora (5.0 mg/mL; 66 ± 0.3% DNA retention); 8, esterified phenolics from Isabel (5.0 mg/mL; 52 ± 0.2% DNA retention); 9, esterified phenolics from Syrah (2.5 mg/mL; 42 ± 3% DNA retention); 10, esterified phenolics Tempranillo (2.5 mg/mL; 54 ± 2% DNA retention). Data represent the mean ± standard deviation of each sample ($n$ = 3). S and N are supercoiled and nicked plasmid DNA strands, respectively.

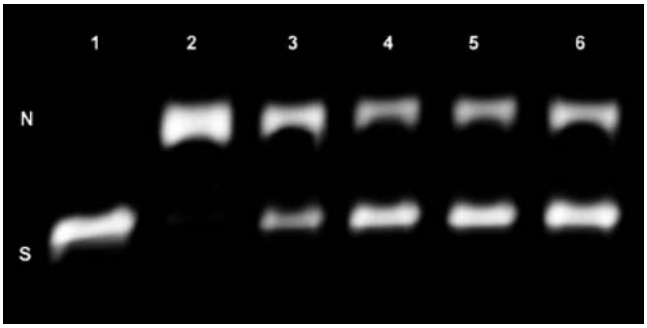

**Figure 7.** Representative raw data of supercoiled plasmid DNA strand breakage inhibition of the insoluble-bound phenolic fraction of juice (Cora and Isabel) and winemaking (Syrah and Tempranillo) byproducts. Insoluble-bound phenolics were assayed in concentration of 1 mg/mL of defatted sample for all varieties. Lanes: 1, control (DNA only); 2, DNA + AAPH; 3, insoluble-bound phenolics from Cora (43 ± 2% DNA retention); 4, insoluble-bound phenolics from Isabel (63 ± 3% DNA retention); 5, insoluble-bound phenolics from Syrah (63 ± 2% DNA retention); 6, insoluble-bound phenolics from Tempranillo (63 ± 2% DNA retention). Data represent the mean ± standard deviation of each sample ($n$ = 3). S and N are supercoiled and nicked plasmid DNA strands, respectively.

strand breakage, showing supercoiled DNA retention of up to 63%. The concentration used for this fraction was equivalent to 1 mg/mL of defatted sample (8 ppm of phenolic compounds as evaluated by HPLC-DAD-ESI-MS$^n$), showing that even a very low concentration of insoluble-bound phenolics of grape byproducts may have health benefits. Minor differences among cultivars were found in the insoluble-bound fraction, thus suggesting little varietal influence on polyphenols liberated from cell walls via hydrolysis. Varietal differences in the free and esterified fractions were in accordance with other antioxidant assays, showing a clear cluster between juice (Cora and Isabel) and winemaking (Syrah and Tempranillo) byproducts, in which, generally, juice byproducts had higher free phenolic content than winemaking byproducts and the opposite was found for their esterified counterparts.

**Correlation of Analyses.** Correlation analyses were carried out between TPC, PC, and the bioactivity evaluations (Table 4). Correlations of individual phenolics quantified were also evaluated to better understand their contribution on each activity. All antioxidant assays were correlated with either TPC and PC, and only the correlation between TPC and inhibition of LDL-cholesterol oxidation demonstrated a lower significance ($p < 0.05$), whereas the remaining results exhibited a higher significance ($p < 0.01$). Most antioxidant assays evaluated (ABTS, DPPH, RP, and supercoiled plasmid DNA strand breakage inhibition) demonstrated a higher correlation with TPC, suggesting that phenolic compounds other than proathocyanidins may play an important role in preventing oxidation-related diseases.

Catechin and epicatechin gallate were the only compounds showing significant correlations with all antioxidant assays. *p*-Coumaric acid, caffeic acid, epicatechin, quercetin, kaempferol hexoside, and procyanidin dimer B had correlations in four of six assays conducted, being positively correlated to 67% of the methods used. In general, epicatechin gallate had higher correlations with the antioxidant assays as compared with epicatechin itself. This suggests that galloyl groups had positive effects on the antioxidant activities of the grape byproducts studied here. Epicatechin has only four hydroxyl groups, whereas epicatechin with a gallic acid attached (epicatechin gallate) has eight. In fact, both the stereochemistry and number of hydroxyl groups may influence the activity of phenolic compounds. *p*-Coumaric acid, gallic acid, caffeic acid, catechin, epicatechin, and epicatechin gallate were positively and significantly correlated with both biological model systems (inhibition of copper-induced human LDL-cholesterol oxidation and peroxyl radical-induced DNA strand breakage), whereas some compounds correlated only with the inhibition of peroxyl-induced DNA strand breakage (quercetin and procyanidin dimer B) or inhibition of copper-induced human LDL-cholesterol oxidation (kaempferol hexoside and procyanidin trimer C). Catechin and epicatechin have also been found to protect against *N*-nitrosodibutylamine- and *N*-nitrosopiperidine-induced DNA damage in human hepatoma cells in vitro.[43] Catechin and caffeic acid also prevented human LDL-cholesterol oxidation.[37]

In summary, the present contribution demonstrated the distribution of free, esterified, and insoluble-bound phenolics in juice- and winemaking byproducts. Although further studies are

necessary for confirmation, it is possible to assume that differences in the distribution of soluble free and esterified phenolics (Figure 1) are due to the process (juice- vs winemaking). Insoluble-bound phenolics must be included in all studies due to their major contribution and efficacy in the byproducts tested. Twenty-five phenolic compounds were positively or tentatively identified by HPLC-DAD-ESI-MS$^n$. Gallic and caffeic acids were the major phenolic acids, catechin was the major monomeric flavonoid, and procyanidin dimer B was the major proanthocyanidin. Procyanidin dimer A was found only in the insoluble-bound fraction, which contained the highest concentration of phenolics, reflecting a higher scavenging activity, reducing power, and inhibition of copper-induced human LDL-cholesterol oxidation and peroxyl-induced DNA strand breakage. Catechin and epicatechin gallate showed significant and positive correlations with all antioxidant assays.

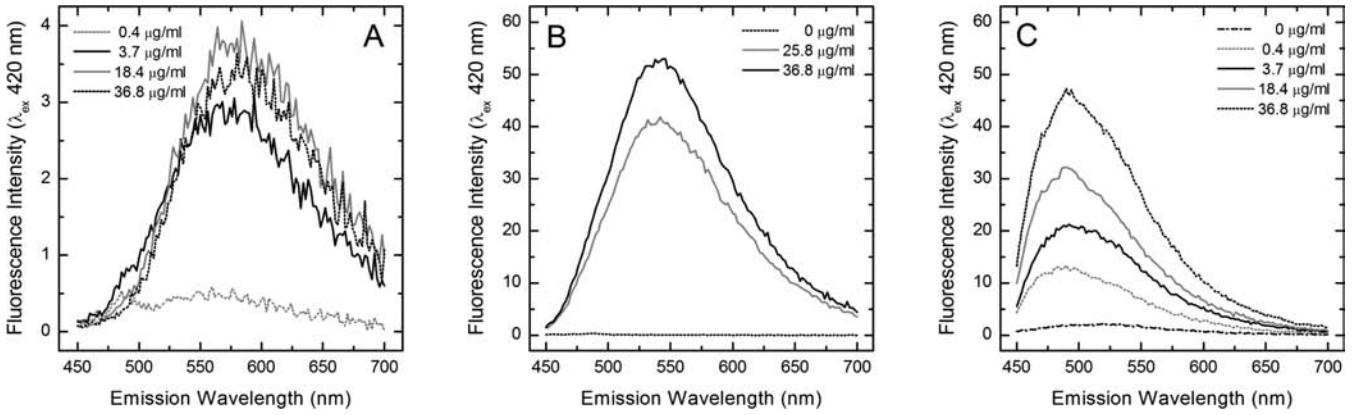

**Figure 1.** Fluorescence spectra of curcuminoids in (A) 2% (v/v) EtOH; (B) a dispersion of $\beta$-glucan (0.28% TS, w/w) in 2% (v/v) EtOH; and (C) a dispersion of oat fiber (1% TS, w/w) in 2% (v/v) EtOH.

dispersions were sonicated in an ultrasonic bath (Unisonic Australia Pty, Brookvale, NSW, Australia) at 20 kHz and 30 °C for 10 min followed by homogenization at 13 500 rpm for 10 min with an Ultra Turax T25 homogenizer (Crown Scientific Pty, Murrarie, QLD, Australia).

**Preparation of Stock Solution and Dispersions for Partitioning and Binding Experiments.** Freshly prepared dispersions (pH 6.8 ± 0.1) of curcuminoids (25.8 $\mu$g/mL) with oat fiber (1% TS, w/w) were used for the partitioning experiments. The curcuminoids were solubilized in 100% EtOH prior to addition to the oat fiber dispersion. The EtOH concentration in the final dispersions was 2% v/v.

To separate the soluble from insoluble fractions of the dispersions, samples were ultracentrifuged (20 400 g, 20 min, 22 °C) to obtain a soluble fraction (supernatant) and an insoluble fraction (precipitate). Each fraction was weighed. The supernatant and precipitate compositions were analyzed separately for total solids, protein, and $\beta$-glucan content. Curcuminoids were also extracted from the supernatant by mixing 5 g of the supernatant with 100% EtOH to obtain an extract in 80% (v/v) EtOH. The dispersion was stirred for 20 min and then centrifuged at 12 100 g at 22 °C for 20 min. A second extraction was carried out, and the supernatants from the first and second extractions were combined and used for fluorescence measurements. For the extraction of curcuminoids in the precipitate, 0.2 g of the precipitated fraction was mixed with 1.6 mL of 80% v/v EtOH. The extraction was repeated twice with 1.6 mL of 80% v/v EtOH. After each extraction, the dispersion was stirred for 45 min and centrifuged at 12 100 g and 22 °C for 20 min, and the supernatant was collected from each extraction and combined for analysis. The concentration of curcuminoids from the extracts was analyzed by fluorescence spectroscopy. The curcuminoid concentration was quantified using a calibration curve of curcuminoids in 80% v/v EtOH at concentrations of 0.4−5.5 $\mu$g/mL. Spiking experiments with a known amount of curcuminoids were also carried out to confirm the recovery of curcuminoids from each fraction. The results showed a recovery of ∼93%.

**Preparation of Curcuminoids−$\beta$-Glucan Dispersion in 2% EtOH.** $\beta$-glucan (84 mg) was dispersed in 29.08 mL of Milli-Q water, and an aliquot of 0.6 mL of the curcuminoid stock solution (1280 $\mu$g/mL) in pure EtOH was added to this dispersion to obtain the final mixtures of curcuminoid (25.8 $\mu$g/mL)−$\beta$-glucan (0.28% TS, w/w) in 2% v/v EtOH. A 0.28% w/w $\beta$-glucan concentration was equivalent to the amount of $\beta$-glucan present in a 1% w/w oat fiber dispersions used to examine the interaction of oat fiber with curcuminoids in this work. The dispersions were sonicated, homogenized, and centrifuged as previously described. The pH value of the mixtures was 7.0. The amount of curcuminoids in the supernatant was analyzed by fluorescence measurements after extraction.

**Fluorescence Measurements.** The fluorescence spectra of curcuminoids, oat fiber dispersion (1% TS w/w), curcuminoid−oat fiber dispersions (1% TS, w/w), and curcuminoid−$\beta$-glucan dispersions (0.28% TS, w/w), all in aqueous EtOH (2% v/v), were measured using a spectrofluorometer (Varioskan Flash microplate reader, Thermo Fisher Scientific Inc., Waltham, MA, USA). Samples (350 $\mu$L) were loaded into a 96-well microplate (OptiPlate-96, PerkinElmer, Santa Clara, CA, USA). The fluorescence emission spectra were recorded from 450−700 nm at a fixed excitation wavelength ($\lambda_{ex}$) of 420 nm.[11,12]

To probe the quenching of the intrinsic fluorescence of proteins in oat fiber dispersions, emission spectra were recorded from 315−600 nm at an excitation wavelength ($\lambda_{ex}$) of 280 nm.[20]

**X-ray Diffraction.** The powdered curcumin (1 g) and the precipitate (1.36 g) obtained after centrifugation of the curcuminoid (25.8 $\mu$g/mL)−oat fiber (1% TS, w/w) dispersions in aqueous EtOH (2% v/v) were analyzed by an X-ray (D8 Advance) diffractometer (Bruker AXS Inc., Madison, WI, USA) with Cu K$\alpha$ radiation. The machine was equipped with backgroundless sample holders. The X-ray diffraction (XRD) scanning was performed at a rate of 0.02 degrees step size and 5 s per step with the scanned angle set from $10° \leq 2\theta \geq 70$. Measurements were performed at a voltage of 40 kV and 30 mA.

**Storage Stability of Curcuminoids.** The storage stability of curcuminoids in the curcuminoids (25.8 $\mu$g/mL)−oat fiber (1% TS, w/w) dispersions in 2% (v/v) EtOH and the supernatant fraction obtained upon centrifugation at 20 400 g (Beckman J2-MC, Ramsey, MN, USA) for 20 min at 22 °C was determined. The curcuminoids content in the precipitated fraction was obtained by difference. Sodium azide was added to all samples (0.02% w/w) to prevent microbial spoilage. Samples (5 g) were placed in glass vials and were stored at 25 °C for 11 days. Samples were taken at intervals for the analysis of curcuminoids. Curcuminoids were extracted using EtOH, and the curcuminoid concentration was estimated using fluorescence spectroscopy as previously outlined.

## RESULTS AND DISCUSSION

**Fluorescence Measurements.** *Fluorescence of Curcuminoids in 2% v/v EtOH.* The florescence intensity of curcuminoid (0−36.8 $\mu$g/mL) in 2% (v/v) EtOH is shown in Figure 1A. The maximum emission wavelength was at 566 nm. The fluorescence intensity of samples containing 3.7, 18.4, and 36.8 $\mu$g/mL were 2.7, 4.0, and 3.6, respectively. One factor that may contribute to the nonlinear increase in fluorescence intensity with increased curcuminoids concentrations from 3.7−18.4 $\mu$g/mL is the supersaturation of curcumin at high concentrations. In addition, with increasing curcuminoid concentration in 2% v/v EtOH, there is likely to be self-quenching of curcuminoids. Self-quenching is particularly prevalent at higher concentrations. Self-quenching of polyphenols compounds has been previously observed.[21]

*Fluorescence of Curcuminoids in the Presence of Pure $\beta$-Glucan in 2% v/v EtOH.* The fluorescence spectra of

curcuminoids in the presence of pure $\beta$-glucan (0.28% TS, w/w) are shown in Figure 1B. There was a blue shift in the position of the maxima when curcuminoids were dispersed in the presence of $\beta$-glucan in 2% v/v EtOH (542 nm) compared to curcuminoids in 2% v/v EtOH alone (566 nm). At an equivalent concentration of added curcuminoid (36.8 $\mu$g/mL), the fluorescent intensity of the curcuminoid−$\beta$-glucan dispersions in 2% v/v EtOH was greater than that in 2% v/v EtOH alone (Figure 1A,B). These observations may be interpreted as an increased solubility of curcuminoids due to binding to the $\beta$-glucan, possibly due to hydrogen bonding and complexation of the phenolic groups of curcumin to $\beta$-glucan.[22]

*Fluorescence of Curcuminoids in the Presence of Oat Fiber in 2% v/v EtOH.* In curcuminoids−oat fiber (1% TS, w/w) dispersions containing 2% v/v EtOH, a blue shift in the wavelength of maximum emission was observed from about 566 nm for curcuminoids in 2% v/v EtOH (Figure 1A) to about 490 nm in oat fiber dispersions with 2% EtOH (Figure 1C). This blue shift in the emission wavelength is consistent with a transfer of the curcuminoids into a less polar microenvironment. At corresponding levels of added curcuminoids (36.8 $\mu$g/mL), the fluorescence intensity of the curcuminoids in the presence of oat fiber in 2% v/v EtOH was approximately 47, whereas it was only approximately 3.6 in 2% v/v EtOH (Figure 1a,c). Blue shifts in the emission spectra of curcuminoids have been observed in mixtures containing casein micelles,[11] hydrophobically modified starch,[14] $\beta$-casein,[23] and $\beta$-lactoglobulin,[24] and for liposomal curcumin preparations,[25] and are consistent with the transfer of curcuminoids into a less polar environment. It was not possible to ascribe the relative binding affinities of the various curcuminoids to components of the oat fiber from the fluorescence spectra obtained in this study.

*Fluorescence of Proteins in Curcuminoids−Oat Fiber Mixtures.* The quenching of the intrinsic fluorescence of proteins within the curcuminoids−oat fiber mixture and the blue shift in the wavelength of maximum emission (Figure 2) are evidence of binding of the curcuminoids to protein. An increase in the curcuminoid concentration from 0−44.2 $\mu$g/mL resulted in a progressive increase in quenching, but there was no further increase when the concentration was raised to 55.3 $\mu$g/mL (Figure 2). Quenching has been observed for binding of curcuminoids to various types of proteins including milk proteins,[12] soy protein,[13] and plasma proteins.[26]

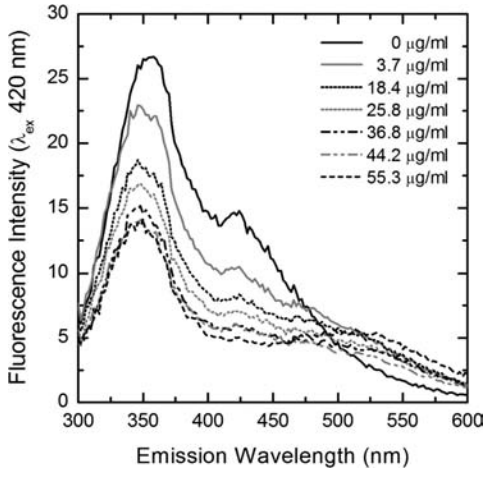

**Figure 2.** Protein fluorescence spectra of curcuminoid−oat fiber (1% TS, w/w) dispersions in 2% (v/v) EtOH at $\lambda_{ex}$ = 280 nm.

**Partitioning of Oat Fiber Components and Curcuminoids between Soluble and Insoluble Fractions upon Centrifugation.** *Partitioning of Oat Fiber Components.* The partitioning of oat fiber components and curcuminoids in the supernatant and precipitated fractions of curcuminoid−oat fiber dispersions was examined to estimate the distribution of curcuminoids in the soluble and insoluble fraction. For these experiments, we used 25.8 $\mu$g/mL curcuminoids in a 1% TS (w/w) oat fiber dispersion in 2% v/v EtOH.

Upon centrifugation of the oat fiber dispersion (1% TS, w/w) in 2% v/v EtOH, a supernatant (soluble) fraction (95.3% w/w, 0.28% TS) and a precipitated (4.7% w/w, 0.73% TS) fraction were obtained (Table 1). Of the total protein in the oat fiber dispersion, 38% partitioned into the supernatant, while 62% partitioned into the precipitate. Most of the $\beta$-glucan (61% of the total $\beta$-glucan) partitioned into the supernatant, with 39% found in the precipitated fraction (Table 1). Both soluble and insoluble proteins and $\beta$-glucans present in unprocessed oats are expected to be present in the oat fiber ingredient used in our experiments. The solubility of the proteins and $\beta$-glucan components and their distribution between the soluble and insoluble phases will depend on the isolation methods used to extract and process the oat fiber ingredient. Oat proteins comprise globulins, albumins, prolamins, and glutenins, and of these, the albumins are the most water-soluble proteins.[27] The insoluble $\beta$-glucans have lower molecular mass than the soluble $\beta$-glucan but remain in the insoluble fiber fraction because of entanglement with arabinoxylan.[28]

*Partitioning of Curcuminoids.* The curcuminoids were approximately equally partitioned between the supernatant and precipitated fractions obtained upon centrifugation of the curcuminoid (25.8 $\mu$g/mL)−oat fiber (1% TS, w/w) dispersion (pH 6.8 ± 0.1) in aqueous 2% v/v EtOH. The supernatant contained 38.6 ± 2.7%, and the precipitated fraction contained 41.1 ± 2.15% of the total added curcuminoids. Thus, the total amount recovered from both the supernatant and precipitated fractions accounted for approximately 79.7% of the total curcuminoids originally added (Table 1). Analysis of the washings from the preparation apparatus (i.e., sample container and the probe used for homogenization) recovered an additional 13.4 ± 0.7% of the total added curcuminoids, which amounts to a total curcuminoids recovery of 93.1%.

**Solubility of Curcuminoids.** *Solubility in 2% v/v EtOH.* Measurement of the supernatant fractions obtained upon centrifugation of 25.8 $\mu$g/mL curcuminoids dispersed in 2% v/v EtOH without oat fiber showed that the highest concentration of curcuminoids in the supernatant was 4.1 $\mu$g/mL. This result showed that the solubility of curcuminoids in aqueous EtOH (2% v/v) exceeds that of the reported solubility of curcumin in aqueous media (11 ng/mL, pH 5).[29]

*Solubility in the Presence of Oat Fiber (1% TS, w/w) in 2% v/v EtOH.* The solubility of the curcuminoids in the oat fiber dispersion was taken as the concentration of curcuminoids in the supernatant. An increase in the concentration of curcuminoids in the oat fiber dispersion from 0 to ∼220 $\mu$g/mL resulted in an increased amount of curcuminoids in the supernatant after centrifugation (Figure 3). However, an increase in the amount of curcuminoids in the dispersion beyond 220 $\mu$g/mL did not result in a further increase of curcuminoids in the supernatant, which indicates a saturation of the sites in the soluble components (i.e., soluble protein and $\beta$-

**Table 1. Composition of Fractions Obtained upon Ultracentrifugation (20 400 g, 20 min, 22 °C) of Curcuminoid (25.8 μg/mL)−Oat Fiber 1% (w/w) Dispersion in 2% EtOH[a]**

| component | supernatant | precipitate | total (supernatant + precipitate) |
|---|---|---|---|
| wt fraction (g) | 95.25 ± 0.13 | 4.74 ± 0.15 | 99.99 |

[a]Data are the mean of three determinations ± standard deviation. [b]An additional 13.4 ± 0.7% of curcuminoids added was recovered from the washings from the beaker and the probe used for homogenization.

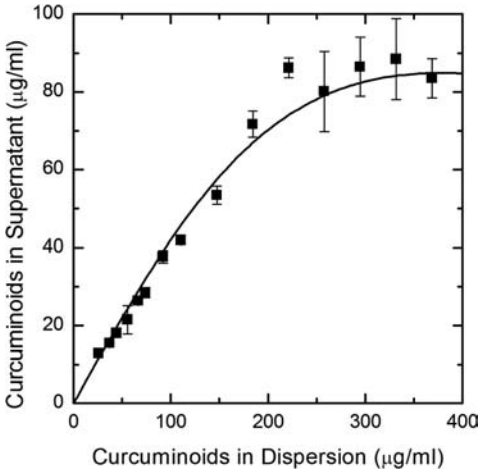

**Figure 3.** Concentration of curcuminoids in supernatant of 1% (w/w) oat fiber dispersion in 2% (v/v) EtOH as a function of total added curcuminoids in initial dispersion.

glucan components) of oat fiber. The highest amount of curcuminoids extracted from the supernatant corresponded to a concentration of ∼88 μg/mL (Figure 3). The solubility of curcuminoids in the soluble supernatant component of the oat fiber dispersion (in 2% v/v EtOH) increased by a factor of 21 over that in 2% v/v EtOH (4.1 μg/mL; this work) without oat fiber. This concentration of curcuminoids in the supernatant is also much higher than that of the reported solubility of curcumin in aqueous media (11 ng/mL, pH 5).[29] This result clearly demonstrated the ability of the soluble oat fiber components to carry curcuminoids in an aqueous system. The combined effects of hydrophobic interactions and hydrogen bonding that govern these reported interactions are likely responsible for the interactions with oat fiber and increased solubility observed.

The increase in curcuminoid solubility in the presence of biopolymers and synthetic polymers has been reported. For example, the addition of curcumin to soy protein (5% (w/v) in water) increased the curcumin solubility by 812-fold because of the formation of a complex, driven by hydrophobic interactions.[13] Micelles of hydrophobically modified starch have also been used to encapsulate curcumin, which resulted in a 1670-fold increase in curcumin solubility.[14] It was suggested that this increase in curcumin solubility was due to the combined effects of the transfer of curcumin into a more hydrophobic environment and hydrogen bonding between curcumin and the starch. Synthesized chemical polymers, including hydroxypropylated derivatives of β (HP-β-CD) and γ (HP-γ-CD) cyclodextrin (CD), also increased the solubility of curcumin to about 1700- and 4700-fold, respectively.[30] The

solubilization of curcumin with various materials appears to be related to the binding of curcumin to hydrophobic regions of molecules. Compared to hydrophobically modified starch and soy protein, oat fiber is less hydrophobic in nature. CDs have a hydrophobic cavity and form inclusion complexes with curcumin.[29] The reduced availability and affinity of hydrophobic sites in oat fiber for curcumin compared to hydrophobically modified starch, soy protein, and CDs possibly explains the lower ability of curcumin to bind to oat fiber and hence its reduced ability to solubilize curcumin.

**Crystallinity of Curcuminoids by X-ray Diffraction.** Wide-angle XRD studies on the precipitated fraction obtained upon centrifugation of the curcuminoid (25.8 $\mu$g/mL)−oat fiber (1% w/w TS) dispersion in aqueous EtOH (2% v/v) were carried out to investigate if crystalline curcuminoid was entrapped in the precipitated fraction.

A powder dispersion of curcuminoid has characteristic peaks between 7 and 30 degrees, which suggest that the powder contains crystalline components (Table 2). The major reflection at ∼17 degrees and relative intensities of reflections are largely consistent with previous reports of curcuminoids in a crystalline form (Table 2). The differences observed are possibly due to the different preparations of curcuminoids used in the various studies.

The XRD spectrum of the precipitate obtained upon centrifugation of the curcuminoids−oat fiber dispersion has an absence of sharp peaks (Figure 4), which suggests that

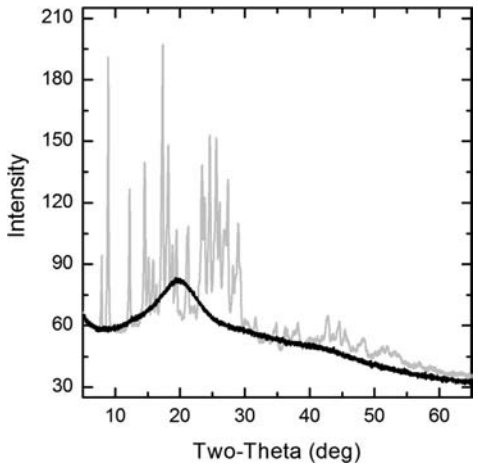

**Figure 4.** XRD spectra of curcuminoids present in the precipitate obtained upon centrifugation of a curcuminoid (25.8 $\mu$g/mL)−oat fiber (1% TS, w/w) dispersion (black) and spectra of the original curcuminoid powder (gray).

curcuminoids in the precipitate were less crystalline in character than the original curcuminoids powder. The broad reflection observed in the precipitated fraction of the curcuminoids−oat fiber dispersions at ∼19 degrees is a typical pattern of a more amorphous substance. The results suggest that the curcumin is in the form of an amorphous solid dispersion. Others have shown that amorphous solid dispersions are formed in a range of cellulose derivative matrices.[31] The curcuminoids in an amorphous form are desirable from a delivery viewpoint as it improves bioavailability.[31]

The position of the reflection ($2\theta$ value) observed for curcuminoids in the presence of oat fiber was at 19.4 deg. The corresponding values for curcumin/curcuminoids encapsulated with various materials were 11−12 and 10−20 deg with sodium caseinate,[32] 19 and 23 deg with soy protein,[33] 8 and 19 deg with zein,[34] and 16 and 22 deg with CD,[35] which show similar trends for the XRD spectrum of encapsulated curcuminoid in different encapsulant materials.

*Storage Stability.* Figure 5 shows the stability of curcuminoids in the presence of the whole curcuminoids−oat

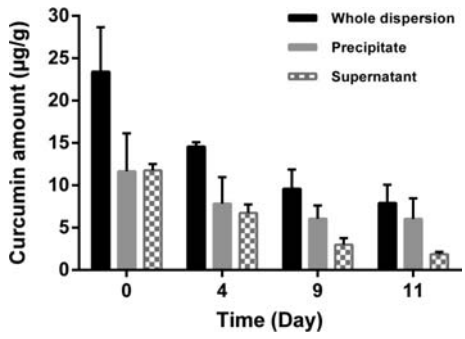

**Figure 5.** Amount of curcuminoids remaining during storage at 25 °C in the dispersion of curcuminoids−oat fiber (1% TS, w/w) and in the supernatant and precipitated fractions obtained upon centrifugation. Values are expressed as the content per g of the original dispersion.

fiber dispersion in 2% (v/v) EtOH and the supernatant and precipitated fractions of this dispersion during 11 days of storage at 25 °C. The concentration of curcuminoids decreased from 23.42 to 8.27 $\mu$g/mL in the whole oat fiber dispersion after 11 days. The degradation of the curcuminoids in the supernatant was faster than that in the precipitate (Figure 5). It is suggested that the difference between the stability of curcuminoid in the precipitate and supernatant is due to the insoluble curcuminoids in the amorphous state in precipitate. Others have shown that curcumin is stabilized against degradation when it is in the amorphous state.[31]

In conclusion, this study showed that both protein and $\beta$-glucan components of oat fiber are able to interact with curcuminoids and increase solubility in an aqueous solution of 2% v/v EtOH. It is possible that curcuminoids also interact with proteins and dietary fibers in the precipitated fraction. These findings illustrate the potential for the curcuminoid carrying capacity of oat fiber to be capitalized upon in the fortification of food with curcuminoids.

Moreover, the egg of SST has been deemed a valuable aquaculture product, and large-scale farming of SST is common in Taiwan due to its high export revenues. Recently, a few reports demonstrated the antihypertensive effect of enzymatic hydrolysate derived from SST;[10,11] however, the active components have not been well characterized.

In our previous study, we isolated a potent ACE-inhibitory (ACEI) peptide generated from a thermolysin digest of soft-shelled turtle egg white (SSTEW), identified as IVRDPNGMGAW (IW-11), which belongs to the protein lysozyme C.[8] According to the simulated gastrointestinal digestion in that study, IW-11 was partly hydrolyzed (approximately 30% of the initial IW-11 was hydrolyzed in 3 h) by trypsin. Interestingly, ACEI activity of the peptide mixture (IW-11 and its hydrolyzed products) increased, and its $IC_{50}$ value improved from 4.39 ± 0.31 $\mu$M (pure form of IW-11) to 2.42 ± 0.09 $\mu$M, which implied that one of the hydrolyzed products shows better ACEI activity than IW-11. IW-11 is expected to be further cut by trypsin to give IVR and DPNGMGAW, and IVR is postulated as the more efficient ACEI component. Because of its excellent ACEI activity and easy digestibility, the aim of this study was to isolate and characterize the ACEI peptide generated by gastrointestinal enzyme hydrolysis of the previously identified IW-11 and also prove its ACEI activity and antihypertensive effect. It is believed that peptides with two and three amino acid residue lengths could be absorbed directly from the digestive tract into the blood circulatory system.[12] In this study, the release of ACE inhibitory peptide from IW-11 and SSTEW by trypsin was demonstrated. The potent ACE-inhibitory tripeptide was subjected to in vivo study on spontaneously hypertensive rats (SHRs), and its binding mechanism was determined through molecular docking simulations. The results of this study may provide valuable information for determining the potential application of SSTEW as a component of antihypertensive functional foods.

## MATERIALS AND METHODS

**Materials and Chemical Reagents.** Unfertilized soft-shelled turtle eggs were obtained from a local farm, Pingtung City, Pingtung County. Chemicals such as acetonitrile (ACN), ammonium bicarbonate (ABC), boric acid, formic acid (FA), sodium chloride (NaCl), and sodium hydroxide (NaOH) were obtained from J. T. Baker (Phillipsburg, NJ); hippuric acid (HA), hippuryl-L-histidyl-L-leucine (HLL), and trifluoroacetic acid (TFA) were purchased from Sigma Chemical Co. (St. Louis, MO). Enzymes such as ACE from rabbit lungs, trypsin (from bovine pancreas), and thermolysin (from *Bacillus thermoproteolyticus rokko*) were purchased from Sigma Chemical Co. All synthetic peptides (IVRDPNGMGAW, DPNGMGAW, and IVR) used in this study were obtained from MDBio, Inc. (Taipei, Taiwan). Water used in this study was produced from a Milli-Q water purification system (Millipore, Billerica, MA). Ultrafiltration membranes (3 kDa molecular weight cutoff (MWCO)) were purchased from Millipore (Bedford, MA). All other chemicals used in this study were of analytical grade.

**One-Stage and Two-Stage Enzymatic Hydrolysis of SSTEW.** For the one-stage strategy, the lyophilized SSTEW was dispersed in ammonium bicarbonate buffer (ABC; 50 mM, pH 8.5) and digested using trypsin with an enzyme to substrate ratio of 1:100. After 24 h of incubation, the tryptic digest was ultracentrifuged using the 3 kDa MWCO membrane; then the resulting filtrate was lyophilized and kept at −20 °C prior to identification and quantification. For the two-stage approach, the first-stage hydrolysis was performed using thermolysin under an optimized condition as previously described by Rawendra et al.[8] Briefly, lyophilized SSTEW was dispersed in 50 mM ABC (pH 8.5) to obtain a 10% (w/v) protein slurry. The SSTEW was digested using thermolysin with an enzyme to substrate ratio of 1:200 at a constant temperature of 60 °C for 3 h. The resulting digest was centrifuged using the 3 kDa MWCO ultrafiltration membrane (14000*g*, 10 min, 4 °C) to give IW-11 as the major product in the filtrate. However, to avoid any loss of the desired peptide, in this study, the crude thermolysin digest was directly subjected to second-stage digestion using trypsin without 3 kDa MWCO ultrafiltration. The trypsin digestion was performed using an enzyme to substrate ratio of 1:50 at a constant temperature of 37 °C for 24 h. The enzyme was inactivated by adding 5% formic acid; then the mixture was lyophilized prior to identification and ACE assay.

**Isolation and Quantification of ACE-Inhibitory Tripeptide IVR.** A freeze-dried trypsin digest of IW-11 dissolved in 5% ACN and 0.2% TFA in deionized water (v/v) was purified using a HYPERSEP Retain-PEP SPE column containing $C_{18}$ resin (Thermo Scientific, United States). After the column was washed with 0.1% TFA (1 mL), the tripeptide IVR was eluted out using 1 mL of 10% ACN in 0.1% TFA. The eluate was collected and freeze-dried to give purified IVR. The abundance of IVR generated from one-stage or two-stage digestion of SSTEW was determined using LC−MS/MS in the selected reaction monitoring (SRM) mode. Standard IVR solutions for the establishment of calibration curves were prepared at concentrations of 0.1, 0.25, 0.5, 1, 5, 10, and 25 ng/$\mu$L. The standard with known concentration was injected into an ODS Hypersil column (Thermo Scientific, 150 mm length, 2.1 mm i.d., 5 $\mu$m particle size) and separated at a flow rate of 350 $\mu$L/min using a mobile phase of 5% acetonitrile containing 0.1% formic acid (solvent A) and 95% acetonitrile containing 0.1% formic acid (solvent B), with a gradient of 0−30% solvent B over 10 min, kept in 30% solvent B from 10 to 15 min, increased to 80% solvent B from 15 to 16 min, kept in 80% solvent B from 16 to 26 min, and then decreased back and equilibrated in 100% solvent A. The MS/MS analysis was performed using an HESI-II ion source and analyzed by a TSQ triple-quadrupole mass analyzer (Quantum Access MAX, Thermo Scientific) in multiple reaction monitoring (MRM) mode. The HESI-II source conditions in the positive ionization mode were as follows: spray voltage, 3.5 kV; tube lens offset, 127 V; skimmer offset, 0 V; capillary temperature, 320 °C; sheath gas pressure (arb), 40; auxiliary gas pressure (arb), 5. The SRM transition for IVR was set as $m/z$ 387.4 > $m/z$ 175.1 under the optimized collision-induced dissociation (CID) energy of 30 V. The hydrolysate was subjected to LC−MS/MS analysis using the same parameters as for the IVR standard. The concentration for IVR was determined on the basis of its calibration curve. Experiments were done in triplicate, and data are expressed as the mean ± standard error (SE).

**Identification of ACE-Inhibitory Tripeptide IVR Using LC−MS/MS.** The peptide identification was carried out according to our previous report.[8] Briefly, freeze-dried peptides dissolved in 5% ACN and 0.1% FA were loaded onto a BioBasic $C_{18}$ column (150 × 2.1 mm, particle size 5 $\mu$m). The peptide mixture was separated using a gradient going from 5% to 70% ACN in 0.1% FA over 90 min at a flow rate of 200 $\mu$L/min. The separated peptides were analyzed online using a mass spectrometer (Thermo LCQ DECA XP MAX system) coupled with an electrospray ionization (ESI) source (Thermo Scientific). The parameters for MS analysis were summarized as follows: flow rate for sheath gas, 50 arb; spray voltage, 4 kV; capillary voltage, 20 V; capillary temperature, 300 °C; MS scan range, from $m/z$ 100 to $m/z$ 1000. The MS/MS raw data were acquired using Thermo-XCalibur (Thermo Scientific) and then converted to MGF files using Mascot Distiller v2.3.2.0 (Matrix Science, London). The database-assisted peptide identification was performed using the Mascot search engine v2.3 (Matrix Science) with the following search parameters: (1) the database option was Testudines (a homemade database established from the combined Fasta files of Testudines); (2) the enzyme option was no enzyme; (3) the mass tolerances for precursor and product ions were 2 and 1 Da, respectively; (4) the significance threshold was $p < 0.05$. In addition to database matching, the peptide sequence was also characterized manually using de novo sequencing based on the peptide's MS/MS spectrum. Finally, the identity of IVR was further confirmed using synthetic IVR.

**ACE-Inhibitory Activity Assay and Determination of $IC_{50}$.** The assay of ACE-inhibitory activity was measured by the method of Cushman et al. with slight modifications.[13] The assay mixture was composed of the following components: 10 $\mu$L of IVR (at different concentrations) was added to 20 $\mu$L of ACE (100 mU/mL) and 30 $\mu$L of HLL (1 mM). The control sample was exactly the same as in the IVR case with only the lack of inhibitor. The reaction mixture was incubated at 37 °C for 30 min without mixing, followed by mixing at the same

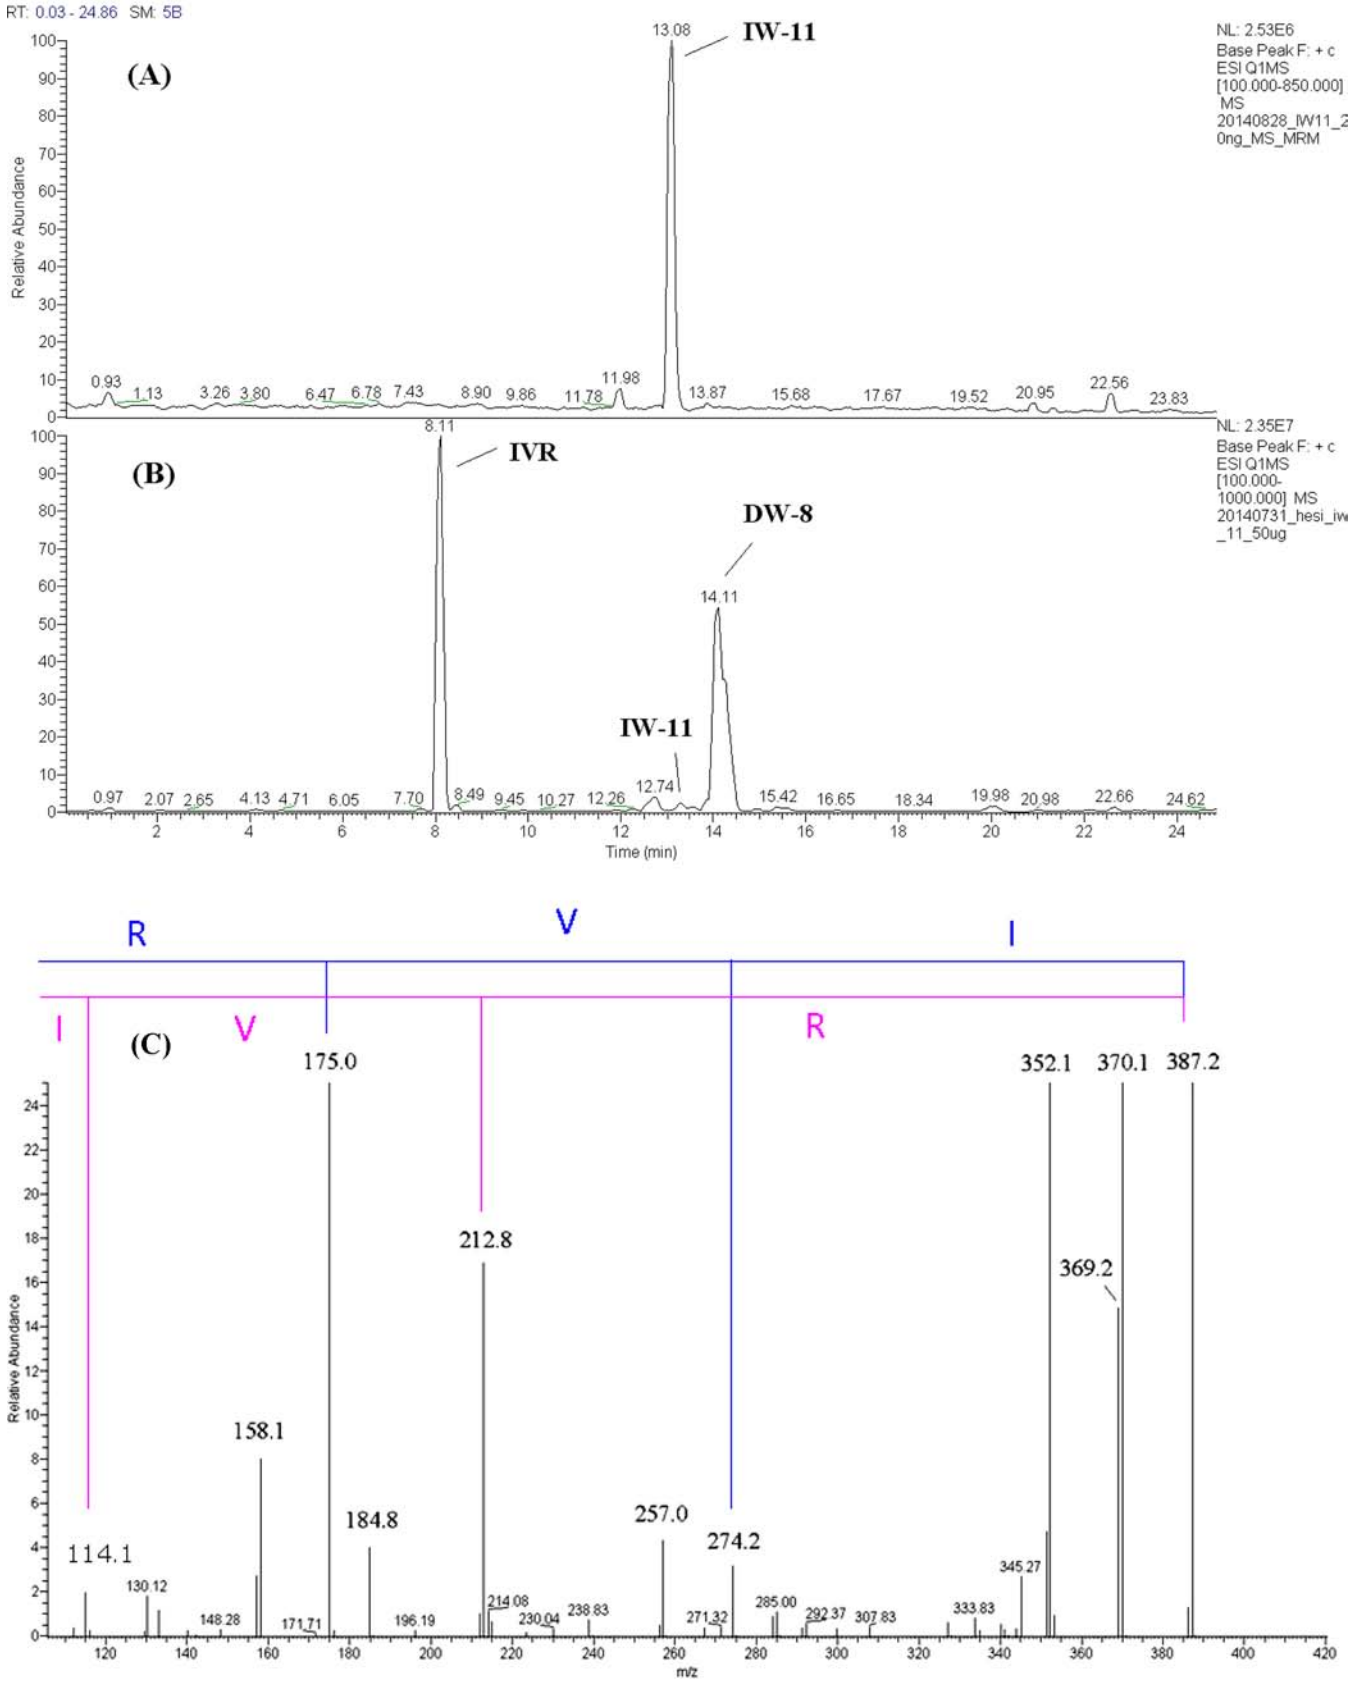

**Figure 1.** (A) LC−MS chromatogram of IW-11. (B) LC−MS chromatogram of the tryptic digest of IW-11 (after 24 h of digestion using trypsin). (C) MS/MS spectrum assignment of IVR. IW-11 represents the peptide IVRDPNGMGAW; DW-8 represents DPNGMGAW.

temperature for the same amount of time in a thermostatically controlled shaker incubator (200 rpm). The reaction was terminated by adding 70 $\mu$L of 1 M HCl, followed by centrifugation at 1500*g* for 5 min. HA and HHL were separated by RP-HPLC in a $C_{18}$ column

dx.doi.org/10.1021/jf504734g | J. Agric. Food Chem. 2014, 62, 12178−12185

(4.6 mm × 250 mm, particle size 5 μm, Thermo Scientific). The mixture was eluted using an isocratic gradient at a flow rate of 1 mL/min with 79% solvent A (5% ACN and 0.1% TFA in deionized water) and 21% solvent B (95% ACN and 0.1% TFA in deionized water) for 15 min. The absorbance was monitored with a UV detector at 228 nm. The degree of ACE-inhibitory activity (%) was calculated according to the following equation:

$$\text{ACE-inhibitory activity (\%)} = [1 - (\Delta A_{\text{sample}}/\Delta A_{\text{blank}})] \times 100$$

where $\Delta A$ is the peak area formed in the sample with or without inhibitor (blank). The definition of $IC_{50}$ is the peptide concentration required to inhibit half or 50% of the ACE activity. The $IC_{50}$ was calculated using linear interpolation of ACE inhibition (%) from five different concentrations of inhibitory peptide.

**Determination of Inhibitory Kinetics.** To characterize the ACE inhibition pattern of IVR, the kinetic study of ACE inhibition was established at different concentrations of substrates according to a previous report.[14] The Lineweaver–Burk plot was used to determine the inhibition type of the peptides, which were competitive, noncompetitive, or uncompetitive. Linear interpolation was plotted at various HHL concentrations (0.5, 1, 2, 3.5, and 6 mM) as the independent variable ($x$-axis) with the production of HA as the dependent variable ($y$-axis). The $x$-axis was proposed in the absence and presence of inhibitor (0.5 and 1 μM). The Lineweaver–Burk plot indicates correlation between $1/V$ and $1/[S]$ with an intercept line between the absence and presence of inhibitor. The slope represents $K_m$, while the $y$-intercept represents $V_{max}$. The dissociation constant ($K_i$) was determined by plotting the slope versus the inhibitor concentration. In the resulting linear regression, the intercept was equal to $K_m/V_{max}$ and the slope was $K_m/(V_{max}K_i)$, and therefore, $K_i$ was equal to the intercept/slope ratio.

**Molecular Docking Simulation.** Docking studies were performed using Molegro Virtual Docker (MVD version 6.0). The conformations of the ACEI peptide were generated using Accelrys Discovery Studio Visualizer version 3.0, and their energies were minimized by the CHARMm program. Crystallographic structures of native human ACE were downloaded from the Protein Data Bank (PDB code 1O8A) and represented the human testicular ACE–lisinopril complex at 2.0 Å resolution.[14,15] The binding site was close to the location of lisinopril, the reference ligand. According to the report by Jimsheena et al., lisinopril can be redocked in this site perfectly using MVD, indicating that this software is feasible to simulate the ACE–ligand docking.[16] Because the binding site and whole C-terminal domain of testicular ACE (tACE) are identical to the catalytic C-terminal domain of the dual-domain human somatic ACE (sACE), the structure of tACE was used to mimic sACE in this study, although sACE is thought to be more important for blood pressure control.[17] Water molecules and lisinopril were removed before the docking simulation. The docking simulation was defined by the presence of cofactors (zinc and chloride ions) using five-cavity detection with a radius of 20 Å with the coordinates $x$ = 37.53, $y$ = 35.24, and $z$ = 45.22.[18] Evaluation of the molecular docking was monitored according to the docking energy, and the best pose of IVR interacted with ACE. Molecular docking was carried out for three runs, and the return data for the 10 best poses obtained in each run were based on the minimum of the affinity energy with a population size of 100 and 10 000 maximum interactions. Hydrogen bonds, $\pi$–$\pi$ interactions, and hydrophobic interactions between peptides and ACE were visualized using Accelrys Discovery Studio Visualizer version 3.0.

**In Vivo Assay of the Antihypertensive Effect.** Male SHRs (10 months old, specific pathogen-free, 250–290 g body weight) with tail systolic blood pressure (SBP) over 200 mmHg were purchased from the National Laboratory Animal Center (Taipei, Taiwan). SHRs were grouped into four groups, and each group consisted of four SHRs. The 16 SHRs resided at room temperature with a 12 h light/dark cycle in clean standard cages. They were fed ad libitum with tap water and a standard diet for rats (LabDiet 5001 rodent diet). Each dose of ACE inhibitors was dissolved in 0.5 mL by following the examined groups: control (saline), positive control (captopril, 2.0 mg/kg), IVR (0.1 mg/kg), IVR (1.0 mg/kg), and IW-11 (1.0 mg/kg). Solutions were given orally by gastric intubation between 10 and 11 a.m. The effect on SBP was measured by the tail-cuff method (NP-NIBP model MK-2000ST, Three Dian Technology Co., Ltd.) 0, 2, 4, 6, 8, and 24 h after administration.

**Statistical Analysis.** In vivo data for SBP were analyzed by one-way analysis of variance (ANOVA) with Dunnett's multiple comparison as postanalysis. Statistical analysis was performed by GraphPad Prism 6.0 software (La Jolla, CA).

## RESULTS AND DISCUSSION

**Isolation and Identification of IVR from the Tryptic Digest of IW-11.** IW-11 (IVRDPNGMGAW) was the first ACEI peptide identified from the enzymatic hydrolysate of SSTEW.[8] Due to the existence of an internal Arg residue, IW-11 is expected to be further cut by trypsin to give IVR and DPNGMGAW during gastrointestinal digestion. In our previous study, the tryptic digest of IW-11 showed an improved ACE inhibition compared to native IW-11. This inspired us to isolate and identify the shorter and better ACEI peptide derived from the IW-11 digest. After 24 h of trypsin digestion at 37 °C, the mixture was analyzed using LC–MS/MS. Two major fragments with $t_R$ = 8.1 and 14.1 min were observed in the LC–MS chromatogram (Figure 1B), and their $m/z$ values were 387 and 847, which matched those of the two predicted fragments IVR (IR-3) and DPNGMGAW (DW-8), respectively. The sequence of IVR was further confirmed by the MS/MS spectrum of the $m/z$ 387 ion, as shown in Figure 1C. To isolate pure forms of IVR and DW-8, the digest was further separated using a C18 SPE column. IVR was isolated in 10% ACN fraction, whereas DW-8 was collected in 50% ACN fraction, without any tedious purification procedure. The ACEI activities of isolated DW-8 and IVR were further examined by ACE-inhibitory assay.

**ACE -Inhibitory Activity and Inhibition Type of IVR.** The ACE inhibitory activities of IW-11, DW-8, and IVR were assessed using the synthetic substrate HHL. IVR showed significantly improved ACE-inhibitory activity, compared to IW-11 (4.39 ± 0.31 μM) and its degradation product DPNGMGAW (14.43 ± 0.21 μM) (data not shown), with an $IC_{50}$ value of 0.81 ± 0.03 μM, as shown in Figure 2. The majority of food protein

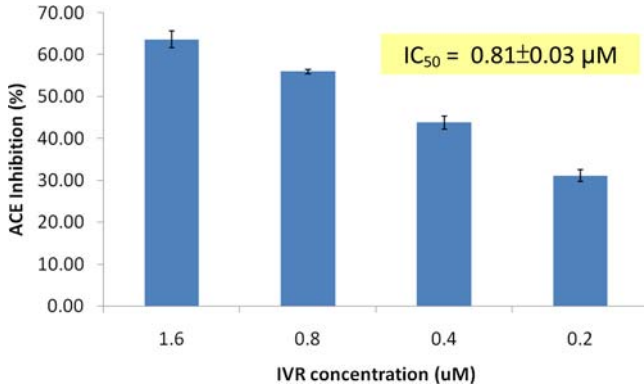

**Figure 2.** Inhibition activities of IVR at various concentrations. Linear regression analysis was used to calculate the $IC_{50}$ value. Data represent the mean ± SD of five independent experiments with three replicates each.

derived ACE-inhibitory peptides typically have moderate inhibitory potencies in the high micromolar range.[19] IVR showed a greater ACE-inhibitory potency compared to other reported peptides derived from milk,[20] eggs,[21] or fish proteins.[22] Tripeptides were reported to have stronger ACE-inhibitory activity compared to longer chain peptides.[23] Notably, the $IC_{50}$ value of IVR (0.81 ± 0.03 μM) is greater than that of lactotripeptide IPP (5 μM)

dx.doi.org/10.1021/jf504734g | J. Agric. Food Chem. 2014, 62, 12178–12185

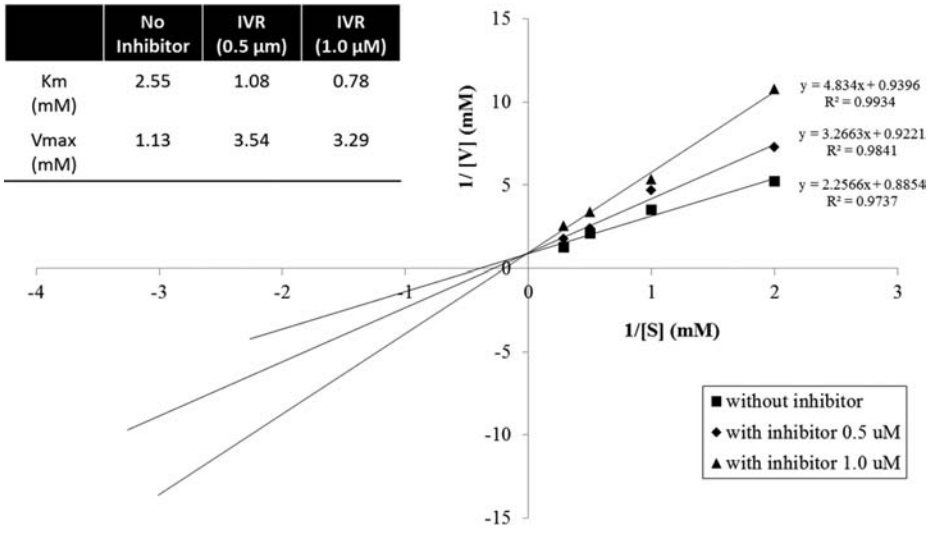

**Figure 3.** Lineweaver–Burk plots of IVR inhibition toward ACE. The ACE-inhibitory activities were measured in the presence or absence of synthetic peptide. $1/[S]$ and $1/V_i$ represent the reciprocal substrate concentration and velocity, respectively. The intersection on the vertical axis indicates that the peptide was a competitive inhibitor.

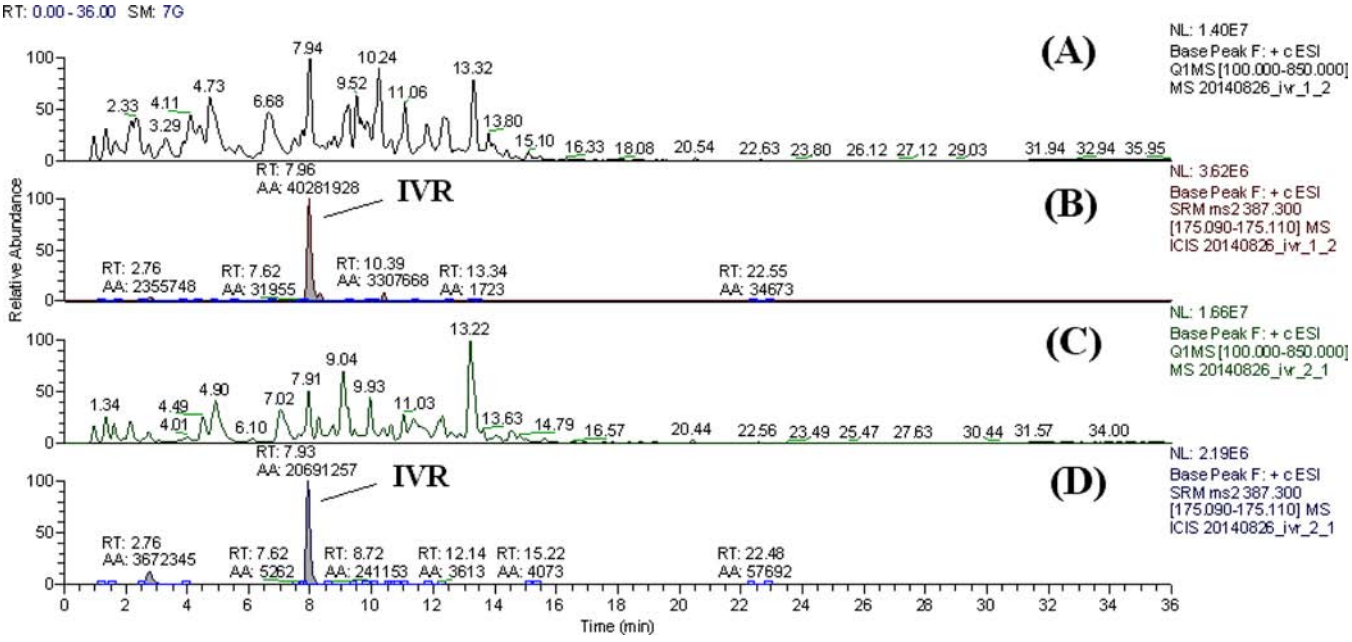

**Figure 4.** Efficacy comparison of IVR production using two-stage and one-stage digestion: (A) LC–MS chromatogram of the crude hydrolysate obtained using thermolysin followed by trypsin digestion. (D) SRM chromatogram of IVR in the crude digest from (C).

and VPP (9 $\mu$M), well-characterized ACE inhibitor peptides found in fermented milk, currently on the market.[24] The amino acid residues at the N-terminal, internal, and C-terminal positions play significant roles in the ACE-inhibitory effects of the tripeptide. An aromatic residue (e.g., phenylalanine, tryptophan, histidine, and tyrosine) at the C-terminal and a hydrophobic amino acid residue (e.g., valine, isoleucine, and leucine) at the N-terminal had been reported to have a strong ACE-inhibitory activity.[23,25] The N-terminal branched aliphatic isoleucine of IVR perfectly matched one of the requirements. However, our result showed that a tripeptide consisting of a basic C-terminal residue (arginine) also has a strong ACE-inhibitory activity. This result is consistent with the structure–activity correlation proposed by Fujita et al., in which the positive charge on the guanidine or $\varepsilon$-amino group of the C-terminal arginine and lysine side chains, respectively, contributes substantially to the inhibitory potency.[26,27] The effect of a central or an internal amino acid residue of tripeptide IVR on ACE-inhibitory activity is also in accordance with the previous reports. Chen et al.,[28] reported that tripeptides with low electronic properties and hydrophilicity and bulky side amino acid residues such as valine, proline, alanine, and methionine have strong ACE inhibition activities. The ACE inhibition pattern of the active peptide was analyzed by the Lineweaver–Burk plot as shown in Figure 3. The Lineweaver–Burk of the peptide converged at the $y$-intercept with that of the reaction containing no inhibitor. In the presence of peptide, the slope changed while the $y$-intercept of $1/V$ remained unchanged. This suggests that IVR serves as a competitive inhibitor by competing for the binding site on ACE, thus preventing substrate

binding. The $K_i$ value of IVR was determined to be 0.84 $\mu$M, as shown in Figure S1 in the Supporting Information. The Lineweaver−Burk plot indicates that IVR competes with HHL for the binding sites of ACE. Competitive ACE inhibitors have been frequently reported; Rao et al. previously reported competitive ACE-inhibitory peptides from hen egg white lysozyme.[14] The competitive inhibitors can bind to the active site to block substrate−enzyme interaction or to alter the enzyme conformation so that the substrate cannot approach the active site.

**Quantitative Determinations of IVR in SSTW Hydrolysates under Different Conditions.** According to the full sequence of SST (*P. sinensis*) lysozyme reported in the NCBI database and our previous result, the ACEI peptide IVR was expected to be generated from lysozyme in SSTEW using direct trypsin digestion or thermolysin followed by trypsin digestion.[8] To examine the efficacies of one-stage and two-stage digestion conditions, the SRM mode of LC−MS/MS was used to quantitatively determine the amounts of IVR in SSTEW hydrolysates. The SRM calibration curve with a linear regression equation ($y = 697909x - 41441$) and coefficient of determination ($R^2 = 0.999$) was established using the synthetic peptide of IVR with a transition of $m/z$ 387.4 > $m/z$ 175.1, as shown in Figure S2 in the Supporting Information. The full MS chromatogram of the crude digest after the digestion using thermolysin followed by trypsin digestion is shown in Figure 4A; the SRM chromatogram of IVR is shown in Figure 4B. The signal of IVR ($t_R$ = 7.96 min) is the base peak in Figure 4A, which indicates IVR is the most abundant peptide in the crude digest derived from two-stage digestion of SSTEW. The full MS chromatogram of SSTEW hydrolysate when the single enzyme trypsin was used is shown in Figure 4C, and the SRM chromatogram of IVR derived from this crude digest is shown in Figure 4D. The SRM experiments indicated that the contents of IVR obtained from 1 g of SSTEW using direct trypsin digestion and thermolysin followed by trypsin digestion were 1.31 ± 0.12 and 3.14 ± 0.17 mg, respectively. The yield of IVR production using two-stage digestion was more than 2 times that obtained using single-stage digestion. This result may be explained by the fact that trypsin-only digestion may leave some missed cleavage sites due to the proteins' incomplete defolding during the hydrolysis process while multiple enzymes (thermolysin followed by trypsin digestion) can provide more complete hydrolysis and hence give a higher yield of IVR.[29]

**Binding Mechanisms of IVR to tACE Rationalized by Molecular Docking.** Molecular docking simulations of the tripeptide IVR with tACE (PDB 1O8A) were carried out to correlate the ACE-inhibitory potential with their three-dimensional interactions. Molegro Dock, a docking algorithm that uses a cavity prediction alogarthm,[18] was used to elucidate the interaction between tACE and IVR and predict its binding affinity. Through such docking simulation, the most favorable binding of IVR to tACE was given by the best pose (pose 00) on the basis of a binding mode in a manner that mimics the binding of lisinopril. Figure 5 presents the best pose for the docking study of IVR with the most favorable affinity energy (−9.61 kJ/mol) at the catalytic site of tACE in the presence of Zn(II). Zn(II) has been included in the docking simulation as it was found in the active site of ACE.[15] The complexation between zinc(II) and the key motif HEXXH on ACE plays an important role in the activity of this dipeptidyl carboxypeptidase. Additionally, this pose was stabilized by H-bonds, $\pi-\pi$ interactions, and hydrophobic interactions with tACE. Table 1 lists the ACE residues which form hydrogen bonds with lisinopril, and if any of those residues form hydrogen bonds with IVR, then the corresponding

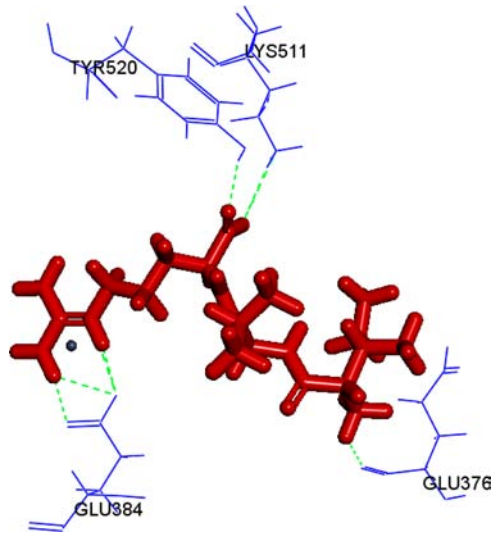

**Figure 5.** Predicted binding mode between ACE and IVR after IVR was docked at the ACE active site. Peptides are shown in a red stick model. ACE residues are shown in blue. Zn(II) and hydrogen bond interactions are represented as a black circle and green dashed lines, respectively. The image was obtained with Accelrys Discover Studio Visualizer.

**Table 1. Hydrogen Bond Contacts of tACE with the IVR Drug Lisinopril and the Best Peptide Pose Obtained from Docking Simulation**[a]

| ACE residue in H-bonding | atom | lisinopril | distance (Å) | IVR (pose 00) | distance (Å) |
|---|---|---|---|---|---|
| Glu 162 | OE2 | √ | 3.4 | X | |
| His 353 | NE2 | √ | 2.8 | X | |
| Ala 354 | O | √ | 2.9 | X | |
| Glu 384 | OE2 | √ | 2.7 | √ | 2.21 |
| Lys 511 | NZ | √ | 2.9 | √ | 3.15 |
| His 513 | NE2 | √ | 3.1 | X | |
| Tyr 520 | OH | √ | 2.6 | √ | 2.02 |
| Tyr 523 | OH | √ | 2.8 | X | |

[a]"√" represents the existence of hydrogen bonding; "X" represents the nonexistence of hydrogen bonding.

hydrogen bond distances are recorded there. Similar to lisinopril, this tripeptide is buried deep inside the active site channel as in the lisinopril−tACE complex. The observed H-bond interactions with Glu384, Lys511, and Tyr520 indicate that IVR is accommodated in the active pocket of a significant and solitary inhibitor registration for the C-terminal carboxylic group of lisinopril,[15] with distances of 2.21, 3.15, and 2.02 Å, respectively. Compared to lisinopril, fewer H-bonds between IVR and the key ACE residues were predicted. However, the H-bonds of IVR with Glu384 (which was located at zinc(II) complexation motif HEXXH) and Tyr520 are shorter than those reported for lisinopril as shown in Figure 5. A shorter distance or closer proximity will greatly favor a stronger interaction between tACE and IVR and obviously contribute as a key factor to the ACE-inhibitory activity of IVR.

**In Vivo ACE-Inhibitory Effects of Peptides in SHR.** The inhibitory potencies of active peptides on ACE activity do not always correlate with their antihypertensive effects.[30] To evaluate IVR's antihypertensive effect, an in vivo experiment using SHRs was further performed in this study. Two doses, 0.1 and 1.0 mg/kg of body weight (BW), were selected to check the dose-dependent antihypertensive effect of IVR. SBP measured by the tail-cuff

dx.doi.org/10.1021/jf504734g | J. Agric. Food Chem. 2014, 62, 12178−12185

method in awake SHRs was 223 ± 3.0 mmHg ($n$ = 16). Oral administration of IVR at 0.1 and 1.0 mg/kg induced significant reductions in SBP, the time courses of which are shown in Figure 6,

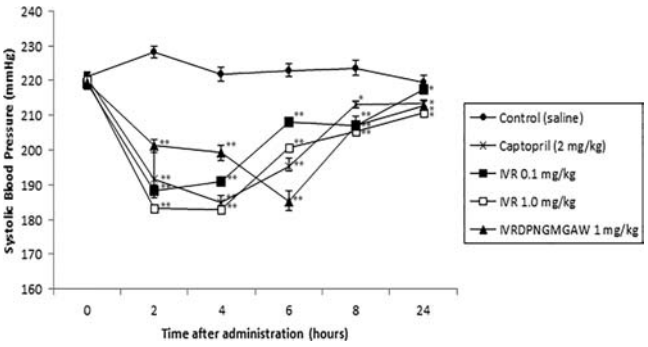

**Figure 6.** Effect of single oral administration of physiological saline alone, captopril (2.0 mg/kg), and IVR (0.1 and 1.0 mg/kg) on systolic blood pressure in SHRs. Blood pressures are expressed in absolute values (mmHg). Data are the mean ± SEM from 12 determinations and were subjected to ANOVA with Dunnett's multiple comparison test as postanalysis. Key: *, significantly different from the control, $P < 0.05$; **, significantly different from the control, $P < 0.01$.

in comparison to the lack of an effect of oral saline and the antihypertensive effect of captopril (2 mg/mL), a common antihypertensive drug, and IW-11 (1 mg/kg), a larger peptide from SST egg white with a higher in vitro $IC_{50}$ value. Maximum antihypertensive activities were shown at 2 h postadministration of 1 mg/kg IVR (183 ± 1.3 mmHg) and 2 h postadministration of 0.1 mg/kg IVR (188 ± 1.79 mmHg), whereas 1.0 mg/kg IW-11 produced its maximum effect at 6 h (185 ± 2.88 mmHg). Notably, IVR at either 0.1 or 1.0 mg/kg reached its maximum effect faster than captopril with a dosage of 2 mg/kg (4 h). The antihypertensive effect remained significant for 0.1 and 1.0 mg/kg IVR up to 8 h postadministration, which is comparable with that of commercially available lactotripeptide VPP/IPP[31] and almost equivalent to that of captopril, a positive control. Interestingly, IW-11 showed its maximum antihypertensive effect in a prolonged period, which implies that the conversion of IW-11 to IVR occurred in the digestive tract of SHRs first and then the resulting more efficient IVR was absorbed and exhibited its ACE inhibition in vivo and therefore decreased the blood pressure. To the best of our knowledge, this is the first report of a potent antihypertensive tripeptide generated from the egg of soft-shelled turtle.

During the past decade, a variety of microbial GADs were expressed and characterized,[34−37] and several crystal structures were determined to investigate the pH dependence of catalytic activity.[12] Consequently, it was found that the N-termini and/or the C-termini of GAD might be responsible for the pH-induced conformational change for the regulation of catalytic activity in the acidic environment. Herein, we overexpressed the *gadB* gene encoding GAD from *Lactobacillus plantarum* in *E. coli* and characterized it. Subsequently, on the basis of the model structure and computational analysis of *L. plantarum* GAD, we attempted to generate C-terminally truncated mutant enzymes and investigated the pH dependence of enzyme activity, underlying the important role of C-terminal region for the GAD activity at low pH values.

## MATERIALS AND METHODS

**Materials.** Restriction enzymes, prime star DNA polymerase, deoxynucleotide triphosphates, and chemicals for PCR were obtained from Takara Biomedicals (Takara Co., Shiga, Japan). The pTOPV2 blunt vector for cloning was obtained from Enzynomics (Daejeon, Korea). The pET-28a expression vector and a His-bind resin kit were obtained from Novagen (Madison, WI, USA). Genomic-tip, gel extraction, PCR purification, and plasmid miniprep kit were obtained from Qiagen (Hilden, Germany). Electrophoresis reagents were obtained from Bio-Rad (Hercules, CA, USA). All chemicals used for enzyme assays and characterization were obtained from Sigma (St. Louis, MO, USA). Oligonucleotides were synthesized by Bioneer (Daejeon, Korea).

**Bacterial Strains and Culture Conditions.** *L. plantarum* ATCC 14917 was obtained from American Type Culture Collection (ATCC). The strain was grown in De Man, Rogosa, and Sharpe (MRS) medium at 30 °C for 72 h. *E. coli* strain DH5$\alpha$ was used as a host for the construction of expression vector. *E. coli* BL21 (DE3) was used as an expression host for GAD from *L. plantarum*. Both *E. coli* strains were grown in Luria−Bertani (LB) medium with kanamycin (50 $\mu$g/mL) in a rotary shaker at 37 and 25 °C, respectively. Plasmid pTOPV2 blunt vector was used as a cloning and sequencing vector, and pET-28a was used for expression.

**Cloning and Expression of *L. plantarum* GAD.** From a search of the microbial genome sequences in GenBank (accession no. CCC80401.1), we found a *gadB*-encoding gene in *L. plantarum*. Genomic DNA was isolated from *L. plantarum* and purified using a genomic DNA extraction kit (Qiagen) according to the manufacturer's instructions. The gene-encoding GAD was amplified by PCR from *L. plantarum* genomic DNA using the forward/reverse primer pair 5′-CATATGGCAATGTTATACGGTAAACAC-3′ and 5′-GAATTCTCAGTGTGTGAATCCGTATTTC-3′. A *Nde*I site was incorporated into the forward primer and an *Eco*RI site into the reverse primer for cloning into pET-28a. PCR was performed in 10× prime star buffer containing 2 mM $MgCl_2$, 20 ng of DNA, 10 pmol of each primer, 200 $\mu$M dNTP mix, and 2.5 U of prime star DNA polymerase in a total volume of 50 $\mu$L. After initial denaturation for 4 min at 94 °C, DNA was amplified over 30 cycles (30 s of denaturation at 94 °C, 30 s of annealing at 57 °C, and 1 min of extension at 72 °C), followed by a final extension step of 5 min at 72 °C. The PCR product was cloned into the pTOPV2-blunt vector and transformed into *E. coli* DH5$\alpha$. Transformants containing the pTOPV2-blunt vector harboring the *L. plantarum gadB* gene were selected on LB medium−ampicillin plates. Plasmid DNA isolated from cells containing the gene was digested with *Nde*I and *Eco*RI. The released *gadB* gene was then ligated into the *Nde*I and *Eco*RI sites of the pET-28a vector, which directs the formation of fusion proteins with N-terminus polyhistidine (6× His) to generate pET-28a-GAD. For expression of the recombinant enzyme, *E. coli* BL21(DE3) cells transformed with pET-28a-GAD were grown in an LB medium (0.5 L) containing 50 $\mu$g of kanamycin per milliliter at 25 °C induced at midexponential phase ($A_{600} \sim 0.6$) with 1 mM IPTG, grown for an additional 12 h, and harvested by centrifugation (10000*g*, 20 min, 4 °C). Bacterial pellets were stored at −70 °C until use.

**Purification of Recombinant *L. plantarum* GAD.** Bacterial pellets were thawed and resuspended in 50 mL of 1× His-binding buffer (0.5 M NaCl, 20 mM Tris, 5 mM imidazole; pH 7.9) and disrupted by sonication. The lysate was centrifuged at 14000*g* for 20 min to remove cell debris, and the supernatant was loaded on a His-bind resin column (5 mL) equilibrated with the 1× His-binding buffer. The column was washed with 10 column volumes of wash buffer (0.5 M NaCl, 20 mM Tris, 60 mM imidazole, pH 7.9), and 250 mM imidazole was applied to elute the recombinant protein. The fractions containing enzyme activity were pooled and dialyzed against 10 mM sodium acetate buffer (pH 7.0). To remove the His-tag from the fusion protein, we added 7 U of thrombin (HTI, USA) to the dialyzed fusion proteins (~10 mg) for 16 h to yield intact GAD without any 6× His tag. For further purification, the reaction mixture was subjected to a HiLoad 16/60 Superdex 200 gel filtration column (GE Healthcare, USA) pre-equilibrated with 50 mM Tris-HCl (pH 7.5, 150 mM NaCl). Protein concentrations were determined by the bicinchoninic acid (BCA) method, with bovine serum albumin as the standard. Enzyme fractions were analyzed by 12% sodium dodecyl sulfate−polyacrylamide gel electrophoresis (SDS-PAGE) and visualized with Coomassie brilliant blue.[38]

**Construction of GAD Truncation Mutants.** GAD truncation mutants were generated by PCR using pET-28a-GAD as a template. Reverse primers containing the mutation were used: 5′-GAATTCTCATCCGTATTTCTTAGGTGC-3′ (for GAD Δ3) and 5′-GAATTCTCAATFATGATAGACAATGTG-3′ (for GAD Δ11). The forward primers were the same as those used to clone the *gadB* gene originally (see above). PCR was performed as described above. The amplified plasmid was digested with *Nde*I and *Eco*RI and transformed into *E. coli* DH5$\alpha$ cells. Clones were sequenced to verify the presence of the mutation. The cloned plasmids were transformed into *E. coli* BL21(DE3) cells and expressed. The truncated mutants (Δ3 and Δ11) expressed in *E. coli* were purified and characterized as described above.

**Enzyme Activity Assay and Statistical Analysis.** Enzyme activity was determined by measuring the amount of GABA produced by GAD through HPLC analysis. The reaction mixture (100 $\mu$L) contained 0.022 mM PLP, 15 mM glutamate, and an appropriate amount of GAD (≈10 $\mu$g) in 100 mM sodium acetate buffer (pH 5.0) or 100 mM piperazine-*N*,*N*′-bis(2-ethanesulfonic acid) (PIPES) buffer (pH 7.0). After a 20 min incubation at 37 °C, the enzyme reaction was stopped by the addition of ice-chilled 100% EtOH (600 $\mu$L) to the reaction mixture. After a centrifugation at 15000*g* for 5 min at 4 °C, the resulting supernatant (120 $\mu$L) was mixed with 380 $\mu$L of *o*-phthalaldehyde (OPA) solutions (pH 9.3) comprising 1.0 mL of methanolic OPA (20 mM OPA in 50% (v/v) methanol), 250 $\mu$L of borate buffer (the 1:1 (v/v) ratio of 0.2 M NaOH and 0.2 M boric acid dissolved in 0.2 M KCl, pH 9.9), and 25 $\mu$L of 2-mercaptoethanol. To detect the amine group, the reaction mixture was further incubated at room temperature for 8 min and then analyzed using the Waters Alliance HPLC system (model 2695; Milford, MA, USA) equipped with a Dual $\lambda$ absorbance detector (model 2487; Waters) with a $C_{18}$ column (SPColumn, 250 × 4.6 mm, 5 $\mu$m particle size). The mobile phase was a 20% (v/v) acetonitrile solution containing 20 mM sodium acetate and 0.02% (v/v) triethylamine. The column temperature was set at 25 °C and eluted at 0.8 mL/min. The reaction products (i.e., GABA) were monitored by measuring the $A_{338\ nm}$, and the amount of GABA was estimated from the integrated peak area based on the HPLC data. One unit of GAD activity is defined as the amount of enzyme that produces 1 $\mu$mol of product per minute under the assay conditions. All experiments were carried out in duplicate.

For kinetic studies, the kinetic parameters of GAD were determined in 100 mM sodium acetate buffer (pH 5.0) or 100 mM PIPES buffer (pH 7.0), by varying the substrate concentration (1−300 mM) for 5 min at 40 °C. Kinetic data were analyzed using Michaelis−Menten equations by fitting data with the Origin 8.0 program.

**Biochemical Characterization of *L. plantarum* GAD.** To determine the effect of temperature on the enzyme activity, the enzyme was incubated in 100 mM sodium acetate (pH 5.0) containing 15 mM glutamate for 20 min at a temperatures from 30 to 60 °C. For a

thermostability test, the enzyme was incubated at various temperatures (40−90 °C) in the presence of 100 mM sodium acetate (pH 5.0) for different periods of time (0−9 h). The residual activity was measured under the same conditions as described above. The pH optimum of the enzyme was determined using the 100 mM sodium acetate buffer and 100 mM PIPES buffer at pH levels from 3.5 to 5.5 and from 5.5 to 6.0, respectively, at 37 °C. To determine pH stability, the enzyme solution was preincubated in each buffer at room temperature for different periods of time (0−96 h), and the residual activity was measured under same conditions as described above. All experiments were performed in triplicate.

**Sequence Alignment and Homology Modeling of GAD Proteins.** In a search of the microbial genome sequences in NCBI, we obtained the amino acid sequence of *L. plantarum* GAD (NCBI protein database accession no. CCC80401.1). The sequence was used to find a suitable template for homology modeling from the Brookhaven Protein Data Bank (PDB) using the software BLAST, revealing that *L. plantarum* GAD had an amino acid sequence identity of 42.6% (similarity of 57.2%) to the crystal structure of *E. coli* GAD (PDB ID 1PMO).[12] On the basis of the *E. coli* GAD structure as a template, homology modeling of *L. plantarum* GAD was performed using the program Modeler[39] in the Homology module of Insight II (Accelrys Inc., San Diego, CA, USA) on a Silicon Graphics R10000 workstation. The dimeric model of *L. plantarum* GAD thus built was subjected to energy minimization by CG using the program DISCOVER (MSI/Accelrys) with the consistent-valence force field (CVFF) until the structure reached the final derivative of 0.001 kcal/mol. To study the interaction between *L. plantarum* GAD and glutamate as the substrate, the crystal structure (PDB code 1PMO) of glutamate bound to GAD was used. The model of glutamate was subjected to energy refinement using the program DISCOVER with CVFF until the structure reached the final derivative of 0.001 kcal/mol. The model of *L. plantarum* GAD was then docked to the glutamate using the Patchdock server.[40] The docked structures that yielded the best score were selected and analyzed visually using the software Insight II. Molecular dynamics (MD) simulations were performed on the docked structures to predict the favorable binding interactions. The docked complexes of *L. plantarum* GAD and glutamate were solvated by a 10 Å water layer by the program SOAK of Insight II. The resulting systems were subsequently energy minimized using Steepest Descent (SD) and DISCOVER. The minimized systems were equilibrated for a period of 210 ps with constant volume and temperature (NVT ensemble, at 298 K) through the velocity verlet integrator.[41] The time step for integration was 1 fs using the RATTLE algorithm, a velocity version of SHAKE.[42] The last 120 ps trajectories were analyzed, saving the coordinates at 0.2 ps intervals. All of the simulations were performed with CVFF force fields; for nonbonded calculations, the cell multipole method along with a dielectric constant of 1 was used. The stereochemical qualities of the final structures were analyzed with PROCHECK. To elucidate the interactions responsible for the dimerization of the protein as well as between the protein and its substrate (i.e., GAD and its substrate glutamate), the What If software package[40] and the Biopolymer module of Insight II were used.

**Thin-Layer Chromatography Analysis.** TLC analysis of monosodium glutamate (Glu) and GABA was performed in *n*-butanol/acetic acid/water (5:3:2 by volume) as a solvent for separation by the ascending technique on 0.2 mm, silica gel-coated, aluminum sheets (type 60; Merck, Deamstadt, Germany). The plate was sprayed with 60% (w/v) ninhydrin and then heated to visualize the spots.[43]

## RESULTS AND DISCUSSION

**Cloning, Expression, and Purification of *L. plantarum* GAD.** The *gadB* gene encoding GAD was amplified by PCR from *L. plantarum* ATCC 14917 genomic DNA and cloned into the pTOPV2 blunt cloning vector. For expression in *E. coli* BL21(DE3) as well as to facilitate subsequent purification, the *gadB* gene was cloned into the pET-28a expression vector, resulting in pET-28a-GAD. The cloned gene was successfully expressed as an N-terminal hexa-histidine-tagged fusion protein

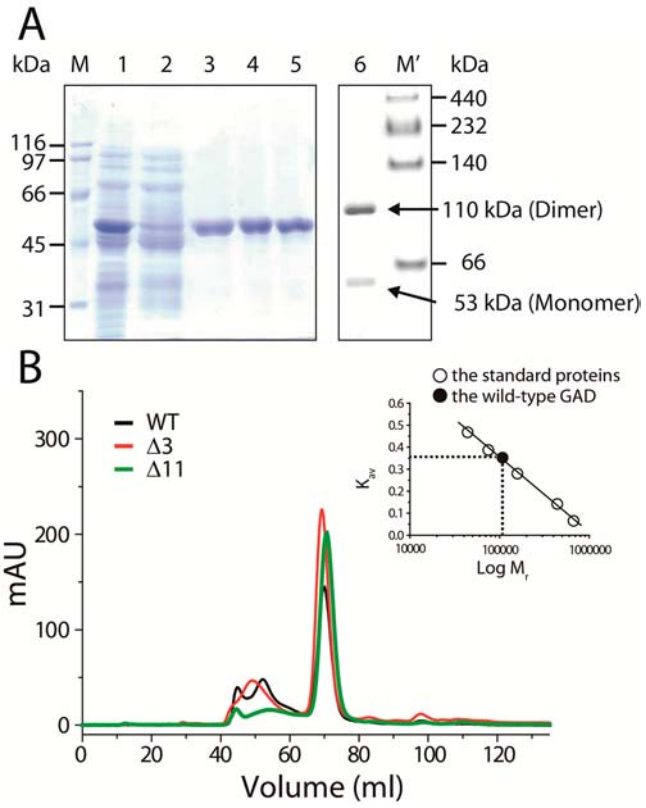

**Figure 1.** Purification of the recombinant *L. plantarum* GADs. Purified wild-type GAD and its truncated mutants were analyzed by SDS-PAGE (left panel) and native-PAGE (right) (A) and by gel filtration chromatography (B). Lanes: M, molecular weight markers (reduced); 1, whole-cell proteins; 2, cytosolic fractions; 3, purified *L. plantarum* GAD; 4, purified *L. plantarum* GAD (Δ3); 5, purified *L. plantarum* GAD (Δ11); 6, purified *L. plantarum* GAD (nonreduced); M′, molecular weight markers (nonreduced). Gel filtration chromatography was performed using a Superdex 200 16/60 column, which was run at a flow rate of 1 mL/min, and the elution profile was monitored at 280 nm. The column was calibrated with blue dextran (2000 kDa), thyroglobulin (669 kDa), ferritin (440 kDa), aldolase (158 kDa), conalbumin (75 kDa), and ovalbumin (44 kDa) as standards.

upon induction with IPTG (Figure 1A). A single $Ni^{2+}$ chelate affinity chromatography step served to purify the expressed *L. plantarum* GAD protein to >95% purity. After removal of the His-tag from the fusion protein by treatment with thrombin, we further purified the intact GAD through gel filtration chromatography (Figure 1B). The apparent $M_r$ of the fusion protein was estimated to be 53 kDa by SDS-PAGE, consistent with the $M_r$ (53 749 Da) calculated from the presumptive amino acid sequence (Figure 1A). However, native-PAGE analysis and gel filtration chromatography on Superdex 200 demonstrated that the purified enzyme was estimated to be about 110 kDa, suggesting a homodimeric structure (Figure 1B). On the basis of the fact that both truncated mutant enzymes were also observed as homodimers, we concluded that truncated mutation did not affect the oligomeric state of both mutant GADs.

**Biochemical Characterization of *L. plantarum* GAD.** The temperature and pH dependences of the recombinant GAD were determined by using HPLC after a 20 min incubation at various temperatures and pH values. Purified GAD had optimal activity at pH 5.0, and its optimum temperature for GAD activity was 40 °C (Figure 2). To investigate the effects of pH on the stability of *L. plantarum* GAD, the purified enzyme

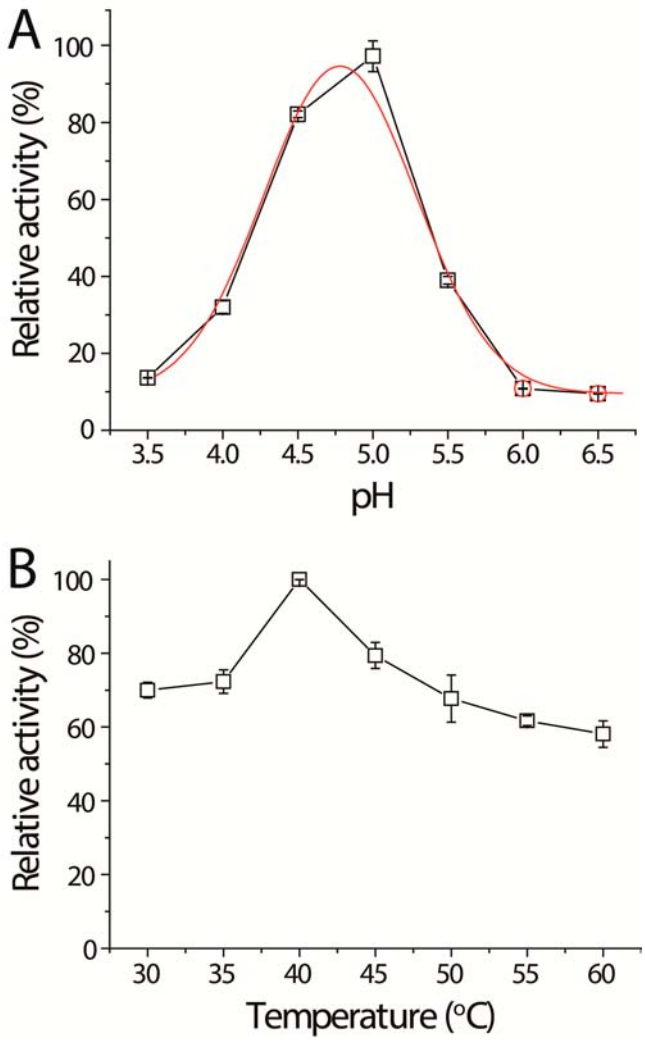

**Figure 2.** Effects of pH (A) and temperature (B) on *L. plantarum* GAD activity. (A) *L. plantarum* GAD activity was measured in 100 mM sodium acetate buffer at pH 3.5−5.5 and 100 mM piperazine-*N*,*N*′-bis(2-ethanesulfonic acid) (PIPES) buffer at pH 6.0−7.0, respectively. (B) *L. plantarum* GAD activity was determined at various temperatures (30−60 °C) in 50 mM sodium acetate buffer at pH 5.0. All experiments were performed in triplicate. Error bars indicate the standard deviation.

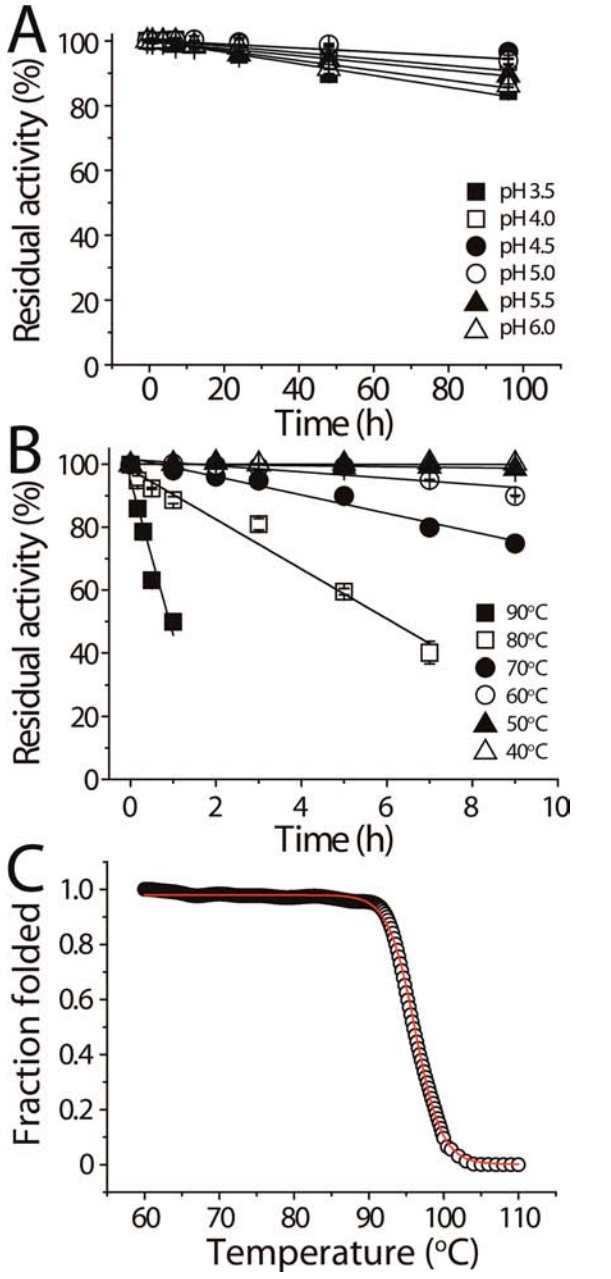

**Figure 3.** Effects of pH (A) and temperature (B, C) on the stability of *L. plantarum* GAD. (A) The purified *L. plantarum* GAD enzyme was preincubated in buffers of various pH values at room temperature for different periods of time (0−96 h) prior to determination of enzyme activity. (B) The purified *L. plantarum* GAD enzyme was incubated at various temperatures (40−90 °C) in 100 mM sodium acetate (pH 5.0) for different periods of time (0−9 h) prior to assessment of the enzyme activity. (C) Irreversible thermal unfolding of *L. plantarum* GAD was monitored by circular dichroism (CD) ellipticity at 222 nm in a 1.0 cm light path quartz glass cuvette at various temperatures ranging from 25 to 110 °C at a heating rate of 1 °C/min. CD measurements were carried out in a Jasco J-810 spectropolarimeter with a Peltier temperature-controlled cuvette holder. Protein concentration was 1 mg/mL in 50 mM sodium acetate buffer. The ratio of denatured and total protein in the transition range, $f_d = (\varepsilon_N - \varepsilon)/(\varepsilon_N - \varepsilon_U)$, was calculated from their CD signal $\varepsilon$ relative to the signal of the native and unfolded baseline $\varepsilon_N$ and $\varepsilon_U$. Melting temperature ($T_m$) is defined as the midpoint transition of unfolding of GAD.

was preincubated at various pH values ranging from pH 3.5 to 6.0 for 96 h at 37 °C, and then their residual activities were measured (Figure 3A). For thermostability, purified enzymes were preincubated at various temperatures ranging from 40 to 90 °C, and the residual activity was also determined under the standard assay conditions (Figure 3B). As expected, incubation of *L. plantarum* GAD at pH values in the range of pH 4.0−5.5 caused no significant loss of GAD activity after a 96 h incubation (>90% of original activity). After a 9 h incubation of *L. plantarum* GAD at various temperatures in the range from 40 to 60 °C, the recombinant enzyme retained >95% of original activity, indicating that *L. plantarum* GAD is thermostable. Indeed, the recombinant enzyme with a thermal half-life of 46 min at 90 °C retained approximately 70% of initial activity even after incubation at 70 °C for 9 h, whereas the enzyme was rapidly inactivated at 100 °C. Therefore, these data indicated that the *gadB* gene from *L. plantarum* encodes a thermostable GAD, the structure of which is quite stable at acidic pH and elevated temperatures.

To further investigate the effect of temperature on the stability of *L. plantarum* GAD in more detail, we performed

**Table 1. Biochemical Properties and Kinetic Parameters of *L. plantarum* and Other Microbial GADs[a]**

| microorganism | $T_{opt}$ (°C) | $pH_{opt}$ | $K_m$ (mM) | $k_{cat}$[b] ($min^{-1}$) | $k_{cat}/K_m$ ($mM^{-1}$ $min^{-1}$) | ref |

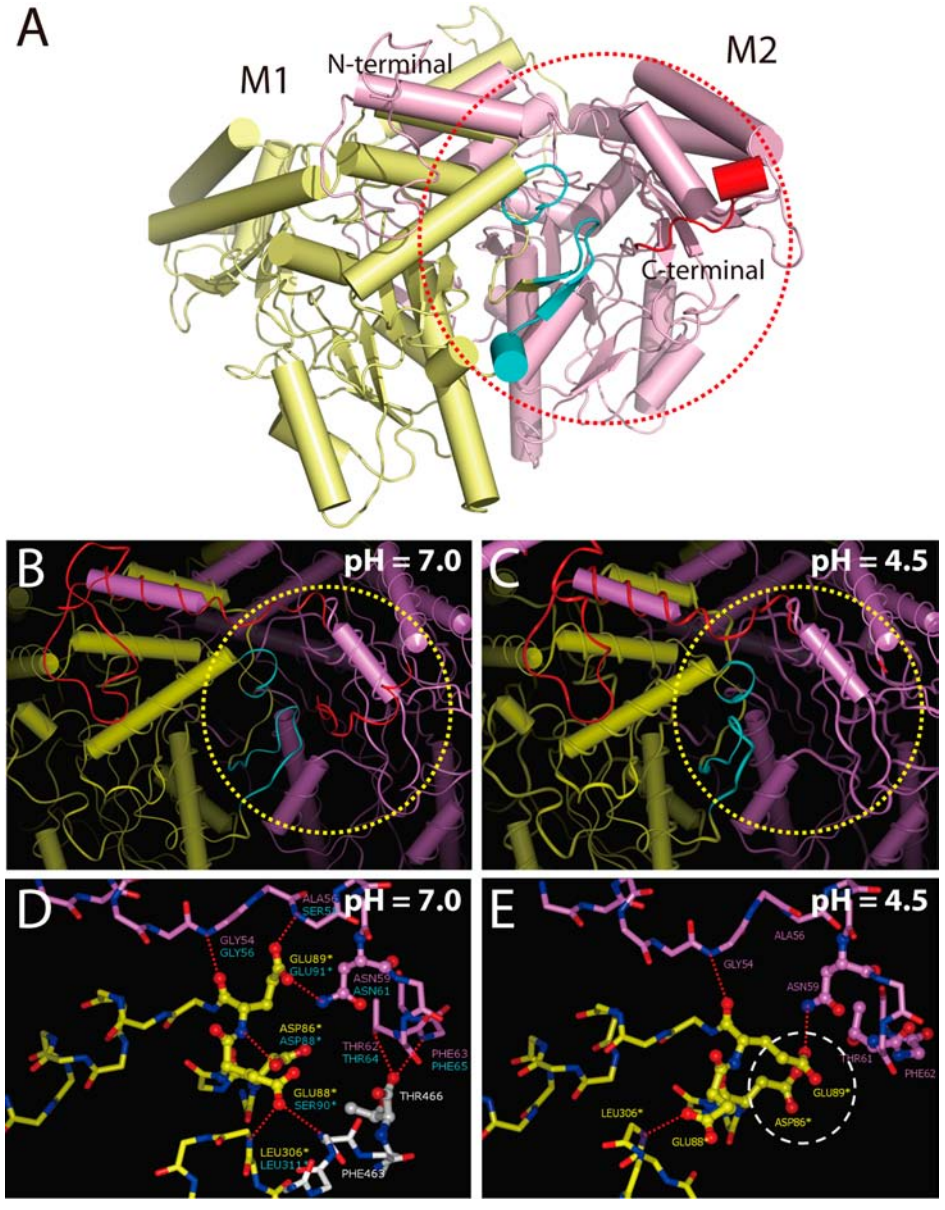

**Figure 4.** Model structure of the dimeric *L. plantarum* GAD and its detailed views. (A) The dimeric *L. plantarum* GAD is shown using cylindrical representations. The modeled structure of *L. plantarum* GAD was generated on the basis of the crystal structure of *E. coli* GAD (PDB code 1PMO) using the SWISS-MODEL program. One monomer (M1, left) is in pale yellow, whereas the other monomer (M2, right) is in pale pink. (B, C) Close-up view of the intersubunit contact regions between the two monomers. N-terminal (1−60 residues, *E. coli* numbering) and C-terminal (Pro452−Thr466, *E. coli* numbering) regions of the monomer (M2) of the *L. plantarum* GAD are in red, and the loop regions (Ile85−Tyr90 and Val300−Phe313, *E. coli* numbering) of the other monomer (M1) are in cyan. (D) The conformation of GAD at normal pH (i.e., pH 7.0) involves C-terminal residues of the protein (colored white) occupying the substrate binding site. Amino acid residues in *L. plantarum* GAD are in blue. (E) At low pH (i.e., pH 4.5), GAD undergoes a conformational change. Red dotted lines indicate hydrogen bonds. Amino acids with asterisks refer to residues specific to the *L. plantarum* GAD sequence.

thermal unfolding experiments using circular dichroism (CD). Thermal unfolding of enzyme was initiated at temperatures beyond the optimal temperature for growth of the corresponding bacterium. Consequently, *L. plantarum* GAD had the apparent melting temperature ($T_m$) of 95 °C (Figure 3C). Together with the thermostability data above, this unfolding experiment clearly demonstrated that *L. plantarum* GAD is not only acidophilic but also thermostable.

To determine the kinetic parameters of *L. plantarum* GAD for glutamate as the substrate, we measured GAD activity after 5 min of incubation at 40 °C as described above. As a result, the $K_m$ for glutamate was 22.8 mM, and the $V_{max}$ was 24.4 U/mg. The catalytic efficiency ($k_{cat}/K_m$) for glutamate was 57.2 $mM^{-1}$ $min^{-1}$ (Table 1). As expected, *L. plantarum* GAD also showed very similar physicochemical properties (i.e., $T_{opt}$ and $pH_{opt}$), in comparison with other microbial GADs including *E. coli* GAD.[44] However, *L. plantarum* GAD had at least a $k_{cat}$ value that is about 3 times higher than for other GADs (Table 1).

**Homology Modeling and Truncation Mutagenesis of *L. plantarum* GAD.** Comparative sequence analysis between *E. coli* and *L. plantarum* GADs was performed by FASTA. *L. plantarum* GAD showed sequence similarity of about 57% with *E. coli* GAD encoded by the *gadB* gene. To provide a structural basis for further investigations of the *L. plantarum* GAD, a homology-based structural modeling was performed as described above (Figure 4). Because the active forms of other microbial GADs derived from *Lactobacillus* strains as well as *E. coli* GadB are known as a dimer and a hexamer, respectively,[12,36] we generated the dimeric model of the *L. plantarum* GAD by superimposing two monomeric models separately into the corresponding monomeric units of *E. coli* GAD and subsequently merging them together by the Biopolymer module of Insight II. To study the interaction between *L. plantarum* GAD and glutamate as the substrate, the crystal structure (PDB code 1PMO) of glutamate bound to GAD was used.

Previously, it has been reported that *E. coli* GAD undergoes a pH-dependent conformational change and exhibits optimal activity at low pH.[12] The GAD enzyme is localized exclusively to the cytoplasm at neutral pH but is recruited to the membrane when pH levels fall. Indeed, our structural modeling by the Insight II program suggested that the Ile85−Tyr90 (*E. coli* numbering) region in M1 adjacent to the other GAD subunit (M2) is where conformational changes occur by mainly Asp86 and Glu89 (*E. coli* numbering) residues in a pH-dependent manner (Figure 4). Intriguingly, such a pH-induced conformational change is accompanied by displacement of the loop region (Val300−Phe313 residues, *E. coli* numbering) away from the entrance site for the substrate at low pH values. Simultaneously, the C-terminal loop region (Pro452−Thr466, *E. coli* numbering) was also pushed away to open the entrance for the substrate binding site at low pH, resulting in the formation of active GAD (Figure 4B,C). On the other hand, both the 300−313 region in M1 and the C-terminal Pro452−Thr466 loop region in M2 occupy the substrate binding site tunnel at neutral pH, resulting in the inactive GAD. These simulation data strongly suggested that the C-terminal loop region may play an important role in the regulation of GAD activity through pH-induced conformational changes. Therefore, we examined whether the C-terminal loop region is mainly involved in the regulation of GAD activity through pH-dependent conformational change. For this, we generated two C-terminally truncated mutants (i.e., GAD Δ3 and GAD Δ11), which contain deletions of 9 and 33 nucleotides, respectively. Notably,

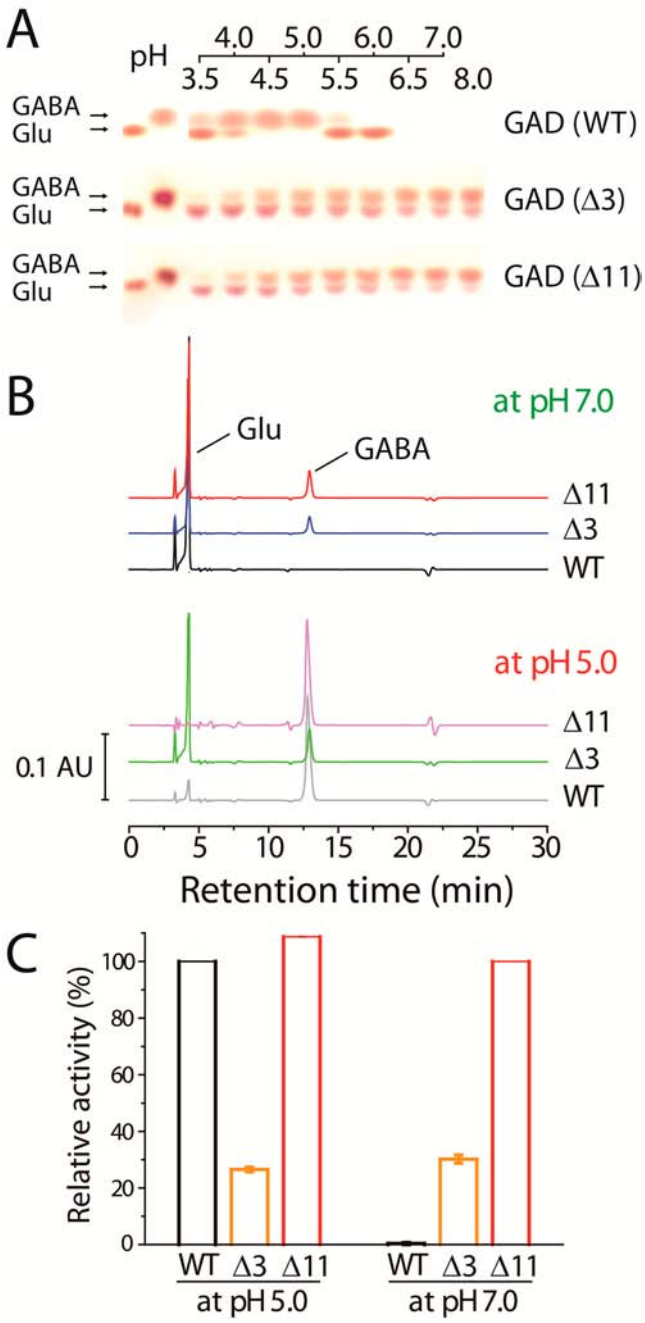

**Figure 5.** pH dependence of catalytic activity for *L. plantarum* GAD and its truncated mutants. After incubation of the wild-type *L. plantarum* GAD and its C-terminally truncated mutants (Δ3 and Δ11) with monosodium glutamate (Glu) as a substrate at different pH values, reaction mixtures were analyzed by (A) TLC and (B) HPLC. (C) Comparison of relative enzyme activities for the wild-type and mutant GADs at pH 5 and 7. The specific activities for the wild-type (8.9 U/mg) and the mutant Δ11 (1.3 U/mg) were set at 100% at pH 5 and 7, respectively.

it was found that the expression level of both truncated mutants in *E. coli* at 25 °C was much higher than that at 37 °C (data not shown). Thus, we purified both mutant enzymes expressed in *E. coli* at 25 °C. After purification of those mutants, their enzymatic activities were then determined on the basis of the production of GABA in a pH range of 3.5−8.0 as judged by thin-layer chromatography. As shown in Figure 5A, the wild-type GAD showed its GABA conversion activity under acidic conditions, indicating that it became an active form at low pH

dx.doi.org/10.1021/jf504656h | J. Agric. Food Chem. 2014, 62, 12186−12193

Table 2. Kinetic Parameters for the Wild-Type GAD and Its Truncated Mutants[a]

| enzyme | pH | $V_{max}$ (U/mg) | $K_m$ (mM) | $k_{cat}$[b] ($min^{-1}$) | $k_{cat}/K_m$ ($mM^{-1}$ $min^{-1}$) |
|---|---|---|---|---|---|
| WT | 5.0 | 24.4 ± 0.4 | 22.8 ± 1.1 | 1304.8 ± 23.3 | 57.2 ± 1.8 |
| | 7.0 | nd[c] | 122.1 ± 3.8 | 0.91 ± 0.01 | nd |
| Δ11 | 5.0 | 45.1 ± 2.9 | 33.8 ± 4.3 | 2415.2 ± 156.5 | 72.1 ± 4.6 |
| | 7.0 | 1.3 ± 0. 1 | 137.1 ± 11.2 | 29.1 ± 0.9 | 0.2 ± 0.1 |

[a]Data are means ± standards deviations. The kinetic parameters were obtained by fitting the experimental data with the Michaelis−Menten equation as follows: $v = V_{max}[S]/K_m + [S]$. [b]$k_{cat}$ is the number of substrate molecules reacted per active site per minute. [c]nd, not determined.

values (pH 3.5−5.0). However, the enzyme did not show any activity at pH 5.5−6.0. On the other hand, both GAD Δ3 and GAD Δ11 exhibited pronounced enzyme activity in the broader pH range of 3.5−8.0. On the basis of these qualitative results, we also performed a HPLC analysis to compare the GAD activities for the wild-type and mutant enzymes (Figure 5B). At pH 5, both truncated enzymes showed lower activities than the wild-type enzyme, as expected. However, although the wild-type enzyme exhibited little activity, both mutants had pronounced GABA peaks at pH 7. Indeed, the amounts of GABA produced by Δ11 and Δ3 mutants were much higher than that of the wild-type enzyme (Figure 5C). These data clearly indicated that deletion of the Ile454−Thr468 region (corresponding to Pro452−Thr466 in *E. coli* GAD) at the C-terminus of *L. plantarum* GAD caused loss of sensitivity to change in pH values. In addition, together with the prediction data, these observations strongly suggested that the C-terminal region might function as a lid for the entrance of glutamate as the substrate, thereby regulating the GAD activity.

**Comparison of the pH Dependence of GAD Activity with Its Truncated Mutants.** To further investigate the pH dependence of the C-terminal domain for GAD activity, we determined the kinetic parameters for the wild-type GAD and its Δ11 mutant at pH 5 and 7. As described in Table 2, the wild-type enzyme showed the $V_{max}$ value of 24.4 at pH 5, whereas its enzyme activity was negligible at pH 7 as expected and described elsewhere.[22] GAD Δ11 showed higher activity than the wild-type at pH 5 (Figure 5C), which is clearly supported by the kinetic values (Table 2). This might be ascribed to the deletion of the C-terminal loop region, where glutamate is more freely accessible to the substrate binding site of GAD. Indeed, even at pH 7 at which there is no activity detected from the wild-type enzyme, the GAD Δ11 mutant showed a prominent level of enzyme activity (0.54 U/mg) with an unusually high $k_{cat}$ value (Table 2), although it had lower levels of activity than those of the wild-type and mutant enzymes at pH 5. To date, it has been noted that the critical feature of microbial GADs is the conformational change of a calmodulin (CaM)-binding domain in the C-terminal region of *Saccharomyces cerevisiae* and the N-termini of *E. coli* GadB for the acidic pH optimum.[12,37] Therefore, our HPLC analysis and kinetic data clearly demonstrated that the C-terminus of *L. plantarum* GAD plays an important role in the regulation of enzyme activity for the pH alteration of environments. These data also provide biochemical evidence for the involvement of protein in functioning as a molecular switch for acid resistance as described in refs 12, 29, 37, and 44.

In this study, we expressed the *gadB* gene-encoding GAD from *L. plantarum* as the generally recognized as safe (GRAS) strain and characterized the recombinant enzyme. Characterization of its physicochemical properties (i.e., the $pH_{opt}$, $temp_{opt}$, thermostability, $V_{max}$, $k_{cat}$, etc.) demonstrated that this *L. plantarum* GAD has properties (i.e., an acidic pH optimum of 5.0 for enzymatic activity) very similar to those of other microbial GADs in terms of the pH dependence of enzyme activity. Its 3D structural model suggested that the C-terminal loop region may be critical for the pH dependence of enzyme activity at low pH. Such a pH-induced GAD activity through conformational changes such as the molecular switch can be a useful engineering target for altering the $pH_{opt}$ of GAD, which allows us to create GAD mutants that are resilient to pH fluctuations. Therefore, this feature might be beneficial for engineering GAD with the broad range of pH optimum for its catalytic activity in the immobilization of the enzyme for the production of GABA.

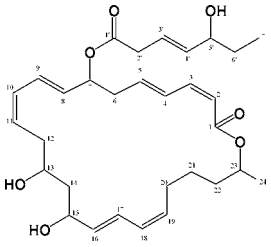
experiments. Standard pulse sequences were used for DEPT, $^1$H−$^1$H COSY, and two-dimensional NOESY, HMQC, and HMBC experiments. Liquid chromatography−mass spectrometry experiments were performed on an Applied Biosystems QTrap 2000 (Applied Biosystems, Darmstadt, Germany) coupled to an Agilent 1100 HPLC system (Agilent, Waldbronn, Germany) using a Luna 5 μm C18 column (100 A, 100 × 4.6 mm, Phenomenex, Aschaffenburg, Germany) or a Luna 3 μm C18 column (100 A, 50 × 1.0 mm, Phenomenex) and a gradient of solvents A (0.1% HCOOH) and B ($CH_3CN$ + 0.1% HCOOH, gradient 0% B to 100% B in 10 min) with a flow rate of 1.5 mL/min or 60 μL/min, respectively. ESI-MS spectra were acquired in the positive and negative modes with a turboionspray voltage, curtain gas, turbo temperature, and nebulizer gas of −4500 V, 30 psi, 500 °C, and 50 psi (flow rate at 1.5 mL/min), respectively. The microbial strains *Vibrio harveyi* MTCC 3438, and *Vibrio vulnificus* MTCC 1146 were procured from the Microbial Type Culture Collection Centre of Institute of Microbial Technology, Chandigarh, India, whereas *Vibrio parahemolyticus* ATCC 17809 was procured from the American Type Culture Collection, Manassas, VA, USA. The solvents used for preparing samples were of analytical grade (E-Merck, Darmstadt, Germany) and were redistilled in an all-glass system. Doubly distilled water was used throughout this work. All of the reagents used in this study were of analytical grade and purchased from E-Merck.

**Isolation of Antagonistic Bacterial Isolates Associated with Seaweeds.** Intertidal seaweeds belonging to Phaeophyceae and Rhodophyceae were collected by scuba diving from the intertidal zone of Mandapam situated at 9° 17′ 0″ N, 79° 7′ 0″ E, Gulf of Mannar region along the southeastern coast of India. The brown seaweeds collected were *Anthophycus longifolius*, *Sargassam myriocystum*, *Padina gymnospora*, *Turbinaria ornata*, and *Dictyota dichomata*, whereas red seaweeds were *Hypnea valentiae* and *Laurentiae pappilosa*. Seaweed samples were processed and the associated bacterial strains were isolated as described earlier.[1] The isolated strains were assayed for antagonistic activity against pathogens including food pathogens *Vibrio parahemolyticus* (ATCC 17802), *Vibrio parahemolyticus* MTCC451, *Vibrio vulnificus* MTCC1145, *Aeromonas hydrophilla*,*Vibrio angullarum*, and *Vibrio alginolyticus*. The inhibitory activity was assayed by a spot over lawn assay as described earlier.[6] Briefly the pathogens were grown to the log phase in nutrient broth with 1% sodium chloride ($10^8$ CFU/mL). They were then swabbed on Mueller−Hinton agar (HiMedia) with 1% NaCl over which the purified isolates were spotted (3 mm diameter) under sterile conditions. The plates were then incubated at 30 °C for 24−72 h, and the zone of inhibition observed around the isolates was recorded. The bacteria showing antibacterial activity were preserved in nutrient agar slants and in 20% glycerol stocks at −80 °C until further use.

**Identification of the Active Isolates.** Bacteria with antagonistic properties were identified using classical biochemical methods followed by 16S rRNA gene sequencing. DNA was extracted from the bacterial isolates showing inhibitory activity against test bacteria. Extraction was conducted from bacterial cultures grown in nutrient broth using the phenol−chloroform extraction method.[10] The DNA samples were examined by gel electrophoresis and concentrations estimated using a Biophotometer (Eppendorf, Germany). PCR was performed in a total volume of 25 μL containing 1× reaction buffer with $MgCl_2$ (Sigma), 0.25 mM of each dNTP (Fermentas), 0.5 mM of each primer (Sigma), 1 ng of DNA, and 0.3 U of Taq DNA polymerase (Sigma). The following cycling conditions were used: initial denaturation at 94 °C for 5 min, followed by 30 cycles of 95 °C for 1 min, 58 °C for 1 min, and 72 °C for 2 min, with a final extension 72 °C for 5 min (Bio-Rad, Hercules, CA, USA). The primers used were AGAGTTTGATCCTGGCTCAG (forward) and ACGGCTACCTTGTTACGACTT (reverse).[11] The molecular sizes of the amplified fragments were estimated by comparison with a 1 kb ladder on a 1.5% (w/v) agarose gel using 1× TAE buffer at 80 V. Fragments with the expected size were gel-purified using a GelElute gel extraction kit (Sigma) following the manufacturer's protocol and sequenced. Sequence data were deposited in GenBank and compared with existing sequences using the blastn search program. Sequences were aligned against reference sequences with CLUSTALW software of the Bioedit program, and the aligned data set was used as input for phylogenetic analysis program. The evolutionary history was inferred using the neighbor-joining method based on the Kimura two-parameter model and bootstrap analysis with 1000 replications.[12,13] Evolutionary analyses were conducted in MEGA6.[14]

**Screening of Metabolite Genes.** Different sets of degenerate primers targeting genes encoding *pks-I* and *nrps* were used to screen the biosynthetic potential of the bacterial isolates to elicit bioactive polyketide compounds and nonribosomal peptides. The primers are listed in Table 1. PCR was performed in a total volume of 25 μL containing 1× reaction buffer with $MgCl_2$ (Sigma), 0.25 mM of each dNTP (Fermentas), 0.5 mM of each primer (Sigma), 1 ng of DNA, and 0.3 U of Taq DNA polymerase (Sigma). The PCR process was set as initial denaturation 5 min at 94 °C followed by 35 cycles of 1 min at 95 °C, 1 min at 45 °C, 1 min at 72 °C, and a final extension of 5 min at 72 °C. All of the amplification products were examined by 1.5% agarose gel electrophoresis, and bands of 700−800 and 1000−1400 bp were classified as products of *pks-I* and *nrps* genes, respectively. Polymerase chain reaction amplicons were separated by agarose gel electrophoresis, and the bands of expected size were gel-purified using electrophoresis; bands of 700−800 bp (*pks-I*) and 1000−1400 bp (*nrps*) were gel-purified using a Gel Elute Gel Extraction Kit (Sigma) and cloned into the pGET-Blunt M13 vector (Fermentas) following the manufacturer's instructions and transformed into chemocompetent *Escherichia coli* cells. The positive recombinants were screened by ampicillin-resistant recombinant selection method assisted with colony PCR with M13 specific primers. Positive clones were used for plasmid isolation using a GenJET Plasmid isolation kit (Fermentas) and sequenced using M13 F and M13 R primers. Forward and reverse sequences of the PKS gene amplified product were assembled using Dna Baser v2.exe, and the vector sequences were removed using Vescreen (NCBI). The sequence data were subjected to GenBank searches with the blastx algorithm. Nucleotide sequences were translated into peptide sequences by EMBOSS Transeq (EMBL-EBI), and blastp searches of deduced amino acid sequences were also

Table 2. NMR Spectroscopic Data of 7-*O*-Methyl-5′-hydroxy-3′-heptenoate−Macrolactin in $CDCl_3$[a]



| carbon | $^{13}$C NMR (DEPT) | H | $\delta^1$H NMR[b] (int, mult, *J* in Hz) | $^1$H−$^1$H COSY | HMBC ($^1$H−$^{13}$C) |

[a]NMR spectra recorded on a Bruker AVANCE III 500 MHz (AV 500) spectrometer (Bruker, Karlsruhe, Germany) in $CDCl_3$ as aprotic solvent at ambient temperature with TMS as the internal standard ($\delta$ 0). [b]Values in ppm, multiplicity and coupling constants (*J*1/4 Hz) are indicated in parentheses. Assignments were made with the aid of the $^1$H−$^1$H COSY, HMQC, and HMBC experiments.

performed. Partial 16S rRNA gene sequences were deposited under accession numbers KC559432−KC559434, KC510279−KC510286, and JX203227−JX203230, and partial PKS sequences were deposited under accession numbers KC589396−KC589400 and KC607821−KC607823.

**Purification and Characterization of 7-*O*-Methyl-5′-hydroxy-3′-heptenoate−Macrolactin from Seaweed-Associated *Bacillus subtilis* MTCC 10403.** The antibiotic-producing bacterium SWI 2 (*Bacillus subtilis* MTCC 10403) was isolated from *Anthophycus longifolius*. The preparation and recovery of secondary metabolites were carried out by a surface culturing method over solid nutrient agar plates. The adsorbed products were subsequently extracted with ethyl acetate by agitation followed by hot extraction at 40 °C. Evaporation of the solvent under reduced pressure yielded the ethyl acetate extract (230 mg) from the total culture volume of 4 L. The pooled ethyl acetate extract (2.3 g) was fractionated by chromatography over silica gel (180−230 mesh) in a flash column chromatograph (Biotage SP, SP1-B1A, Biotage AB, Sweden), with a stepwise gradient of $CH_2Cl_2$/MeOH (0−100% MeOH) using the flash silica gel cartridge (Biotage no. 25+M 0489-1) at a collection UV wavelength at 236 nm to provide 43 fractions (12 mL, F1−23). Fractions F13−17 as eluted by $CH_2Cl_2$/MeOH (3:2 to 1:1, v/v) were pooled together (81.8 mg) and further applied to a silica gel column (80−120 mesh) to yield four subfractions ($F13_1$−$F13_4$). Subfraction $F13_3$ was purified by preparatory TLC ($CH_2Cl_2$/MeOH, 4:1, v/v) to afford 7-*O*-methyl-5′-hydroxy-3′-heptenoate−macrolactin (99% purity, 10.2 mg). Evaporation of solvents from the fractions followed by TLC over precoated silica gel $GF_{254}$ (particle size = 15 mm, E-Merck) using $CH_2Cl_2$/MeOH (99:1, v/v) supported the purity. 7-*O*-Methyl-5′-hydroxy-3′-heptenoate−macrolactin: amorphous solid; UV (MeOH) $\lambda_{max}$ (log $\varepsilon$) 226 nm (3.72) and 248 nm (3.21); TLC (Si gel $GF_{254}$ 15 mm; $CH_2Cl_2$/MeOH 1:99, v/v) $R_f$ 0.70; Rt 6.22 min; IR $\nu_{max}$ (KBr) $cm^{-1}$ 970 (trans C═C oop bending), 1073.71 (unsaturated secondary alcohol C—O str), 1121.80 (C—O—C symmetrical str), 1282.20 (CH—OH in plane bending), 1376.96 (O═C—$CH_2$, C—H bending), 1461.43 (C—H asym-bending), 1640.23 (C═C str), 1753.96 ($\alpha,\beta$-unsaturated C═O str), 2854.74 (−O—$CH_2$ sym C—H str), 2923.22 (alkane C—H str), 3014 (asym alkene C−H str),

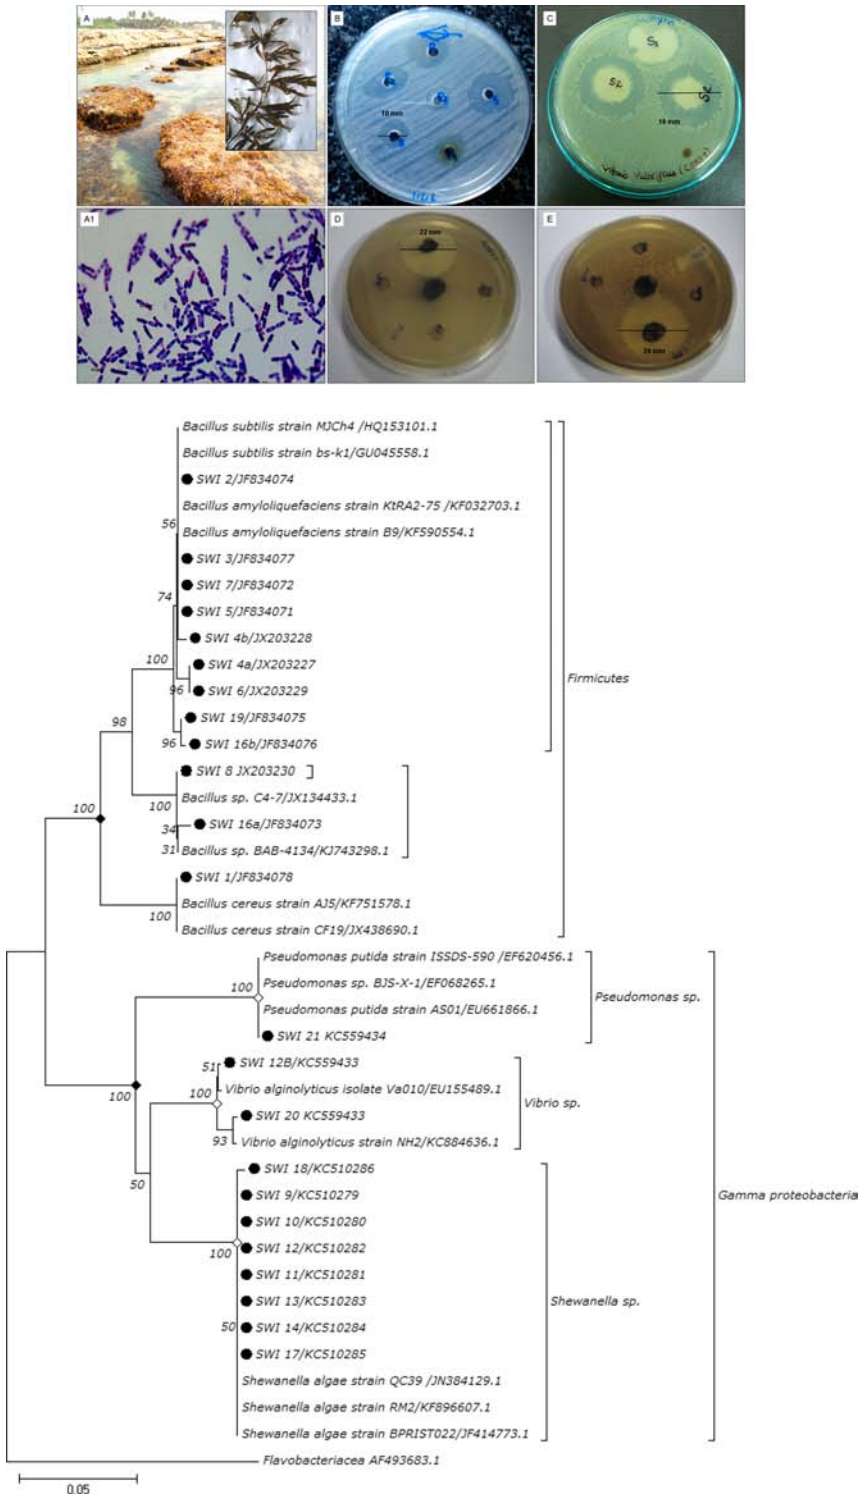

**Figure 1.** (A) Seaweeds at harvest location; (inset) brown seaweed *Anthophycus longifolius* used to isolate (A1) *Bacillus subtilis* MTCC10403 (SWI2). (B) Well diffusion of culture SWI2 supernatant against *V. vulnificus* MTCC 1145; spot over lawn assay of culture SWI2 against (C) *V. vulnificus* MTCC 114, (D) *V. parahemolyticus* ATCC 17802, and (E) *V. parahemolyticus* MTCC 451. The clearance zones realized by the isolates signify the antibacterial activity. Antagonistic activity was recorded as the diameter of inhibition zones determined as a distance of ≥1 mm between the circular area (= lawn of the isolate) and the end of the clear zone bounded by the lawn of the test strain. (Bottom) Phylogenetic tree derived from 16S rRNA gene sequences, showing evolutionary history of the antagonistic bacterial isolates associated with seaweeds. The evolutionary history was inferred using the neighbor-joining method.[12] The analysis involved 40 nucleotide sequences. All positions containing gaps and missing data were eliminated. There were a total of 569 positions in the final data set. Evolutionary analyses were conducted in MEGA6.[14]

3437.24 $cm^{-1}$ (O−H str); $^{1}H$ ($CDCl_3$, 500 MHz, $\delta$) and $^{13}C$ NMR ($CDCl_3$, $\delta$) data, see Table 2; HRMS (ESI) $m/z$ calcd for $C_{31}H_{45}O_7$ 529.6422, found 529.6894 $[M + H]^+$.

**Determination of Antibacterial Activities by Agar Diffusion Method.** Sterile disks (HiMedia, India) containing 10 $\mu$L of crude extract or 10 $\mu$L of purified macrolactin in methanol (the methanol

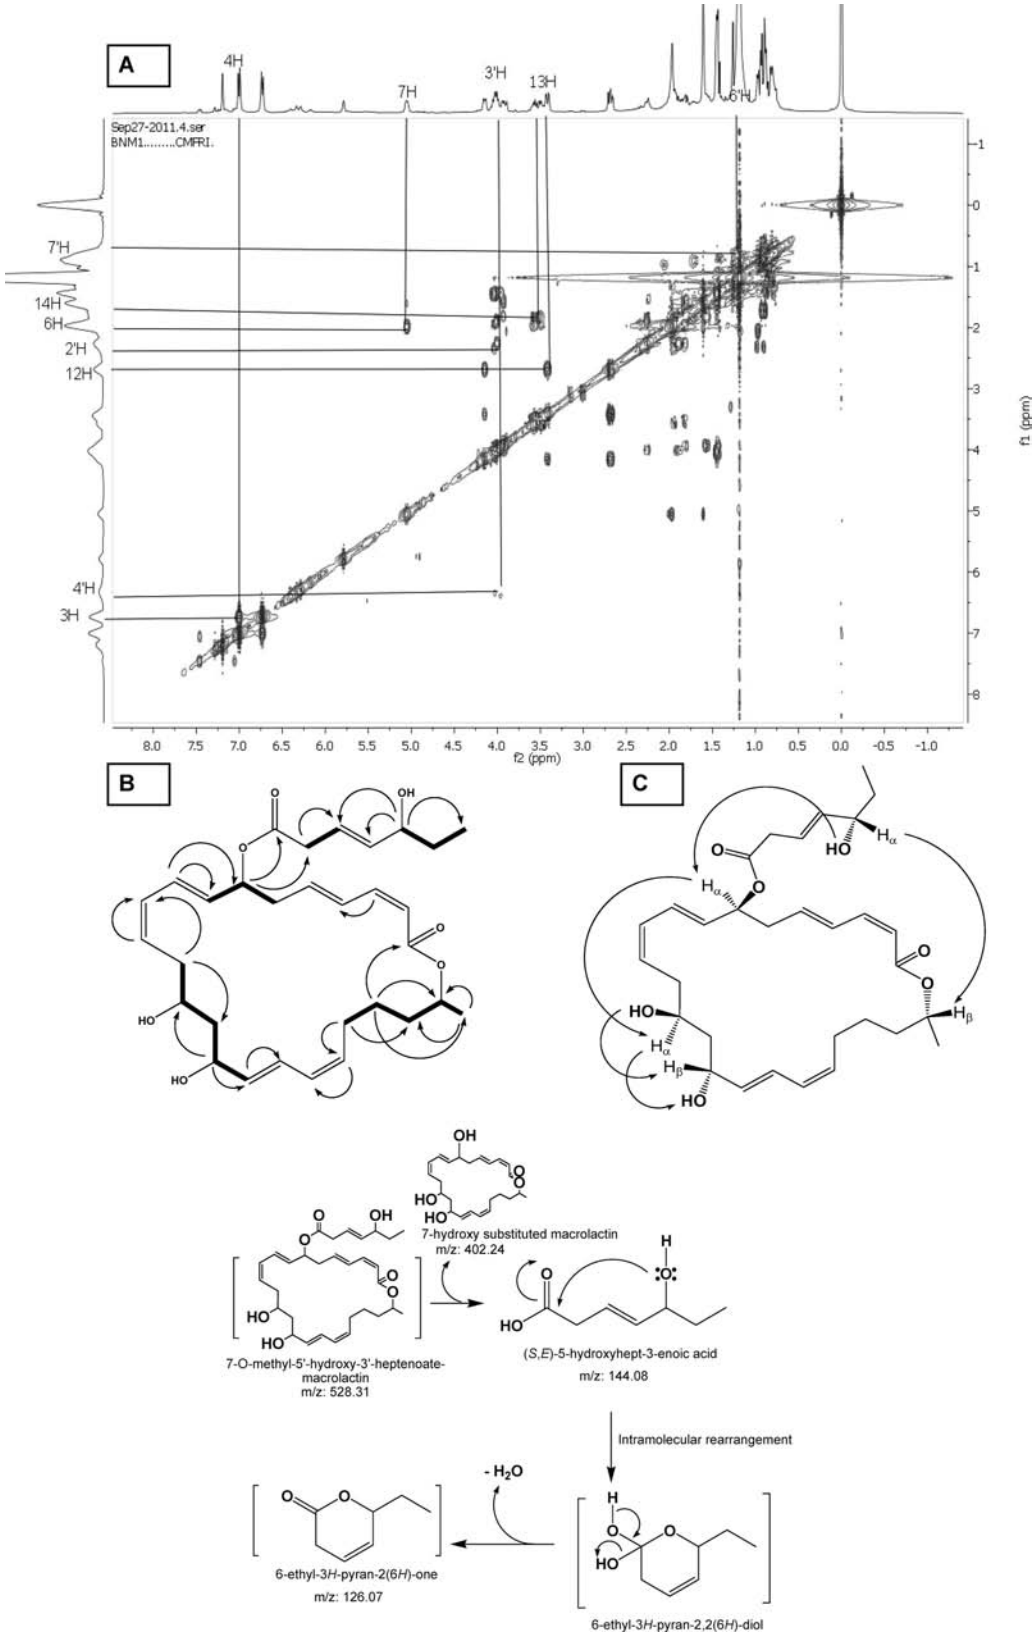

**Figure 2.** 2D NMR correlations in 7-*O*-methyl-5′-hydroxy-3′-heptenoate−macrolactin: (A) key $^{1}$H−$^{1}$H COSY couplings; (B) $^{1}$H−$^{1}$H COSY couplings represented by bold face bonds. The HMBC couplings are indicated as double-barbed arrows; (C) key NOESY correlations. (Bottom) Mass fragmentation pattern of 7-*O*-methyl-5′-hydroxy-3′-heptenoate−macrolactin.

traces were removed by drying in nitrogen, and the final compound concentration on the disk was 100 $\mu$g) were placed on fresh plates of Mueller−Hinton agar (Difco) seeded with suspensions ($10^5$ CFU/mL) of overnight cultures of the test microorganisms. The diameters of the zones of inhibition of growth around the disks were measured after incubation periods of 18 h at 37 °C. Antibiotic disk for Gram-

dx.doi.org/10.1021/jf504845m | *J. Agric. Food Chem.* 2014, 62, 12194−12208

negatives, namely, Octodiscs G-I minus (OD005) (HiMedia, India), was used to compare the results. The antibiotics used were ampicillin (A, 10 μg/disk), ciprofloxacin (Cf, 10 μg/disk), colistin (Cl, 10 μg/disk), cotrimoxazole (Co, 25 μg/disk), gentamicin (G, 10 μg/disk), nitrofurantoin (Nf, 300 μg/disk), streptomycin (S, 10 μg/disk), and tetracycline (T, 30 μg/disk).

## RESULTS

**Isolation and Identification of Bacterial Isolates Associated with Seaweeds.** About 22% of the bacterial isolates showed inhibition against at least one pathogen used in the study, with 9% of these showing broad-spectrum activity against the pathogen screened (Table 3). Figure 1A shows the indicative diagram for activity spectrum of culture isolates from seaweeds. Candidate strains were identified with the aid of biochemical and FAME analyses (data not shown). The bacterial isolates have been submitted to the Microbial Type Culture Collection and Gene Bank (MTCC) of the Institute of Microbial Technology (Chandigarh, India), an International Depository Authority under the Budapest Treaty. The identifications were confirmed through 16S rRNA gene based molecular evolutionary analysis using the neighbor-joining method.[12] The optimal tree with the sum of branch length of 0.80792901 is shown (Figure 1B). The percentage of replicate trees in which the associated taxa clustered together in the bootstrap test (1000 replicates) is shown next to the branches.[15] The evolutionary distances were computed using the Kimura two-parameter method.[13] Evolutionary analyses were conducted in MEGA6.[14] PCR primers used for metabolite gene screening are listed in Table 1. None of the isolates were positive for *nrps* genes, whereas a few *Bacillus* strains could amplify the *pks* gene products (Table 3). Although specific prediction of products of *nrps* and *pks* genes according to the obtained sequences was problematic, because only small gene fragments were amplified, an attempt was made to correlate the structural properties of produced secondary metabolites with the presence of *nrps* and *pks* genes.

**Structural Characterization of Antibacterial Metabolite from *Bacillus subtilis* MTCC 10403.** 7-*O*-Methyl-5′-hydroxy-3′-heptenoate−macrolactin (Figure 2A), a new derivative of the macrolactin, was isolated as an amorphous solid upon chromatography over silica columns. The IR absorption band (in MeOH) at 3014 $cm^{-1}$ was due to −CH stretching vibrations. The −OH group in the skeleton exhibited free −OH stretching vibrations near 3437 $cm^{-1}$. The bending vibration bands near 1753 $cm^{-1}$ denoted the ester carbonyl absorption. The olefinic (C═C), and ether (C—O—C) groups have been symbolized by the absorption bands at 1640 and 1073 $cm^{-1}$. The IR spectrum revealed a broad absorption band at $\nu_{max}$ 3500−3000 $cm^{-1}$, attributed to a hydroxyl functionality and to an olefinic system (1200, 1121 $cm^{-1}$). The ultraviolet absorbances at $\lambda_{max}$ (log e) 226 (3.72) and 248 (3.21) nm were assigned to a chromophore with extended conjugation. Its mass spectrum exhibited a molecular ion peak at $m/z$ 528 (HRESIMS $m/z$ 529.689 $[M + H]^+$; D 0.0 amu), which in combination with its $^1H$ and $^{13}C$ NMR data (Table 2) indicated the elemental composition of $C_{31}H_{44}O_7$ as 7-*O*-methyl-5′-hydroxy-3′-heptenoate−macrolactin with 10 degrees of unsaturation (Figure 2A): 7 degrees of unsturation from double bonds of macrolactin ring, 2 degrees of unsturation from double bonds of the substitution as (*S*,*E*)-methyl 5-hydroxyhept-3-enoate ($C_8H_{14}O_3$), and 1 degree from the ring of macrolacin were demonstrated. The molecular ion peak at $m/z$ 528 appeared to undergo elimination of (5-hydroxyhept-3-enoic acid ($C_7H_{12}O_3$, $m/z$ 144.1708) to yield 7-hydroxy-substituted macrolactin at $m/z$ 402.2450 ($C_{24}H_{34}O_5$), which underwent dehydration ($-H_2O$) to afford a fragment with $m/z$ 386.2580 ($C_{24}H_{34}O_4$). The appearance of the fragment at $m/z$ 126.1507 indicated the presence of a 6-ethyl-3*H*-pyran-2(6*H*)-one moiety ($C_7H_{10}O_2$), resulting from the intramolecular rearrangement and dehydration of 5-hydroxyhept-3-enoic acid via the intermediate 6-ethyl-3*H*-pyran-2,2(6*H*)-dial (Figure 2B).

The $^1H$ NMR in conjugation with $^{13}C$ NMR recorded the presence of two methyl signals at $\delta$ 0.81 and 1.30. The former was assigned to be due to the terminal methyl group at the side-chain 5-hydroxyhept-3-enoate moiety, whereas the methyl group at $\delta$ 1.30 shifted downfield due to the acrylate moiety (−OC(═O)—C═C−) at the $\beta$-position with respect to the deshielded methyl group. The methylene group protons at $\delta$ 2.60 and 2.04 were assigned to be at the 6-carbon position of the macrolactin ring structure, and the downfield shift (about $\delta$ 0.5) was due to the presence of the conjugated butadiene moiety at one side and the side-chain acetate group (−OC(═O)—C) attached to the macrolactin ring at its 7-carbon position. Three methylene groups have been assigned to occupy at the C20−22 positions of the macrolactin ring structure as heptenyl formate moiety. The protons of the $-CH_2-$ group at $\delta$ 1.45 and 1.43 were at C22 and were deshielded due to the presence of the acrylate moiety (−OC(═O)—C═C−) at the $\beta$-position with respect to the deshielded methyl group. The methyl group protons at $\delta$ 2.07 and 1.96 (C-20) also appeared to be deshielded due to the conjugated double-bond structure (butadiene) spanning from position C16 to C19 of the macrolactin ring. The methylene protons at the C21 position appeared at $\delta$ 1.81 and 1.60. The $-CH_2-$ protons appearing at $\delta$ 1.94 and 1.78 were due to the presence of the propanediol group and have been assigned to be present at the C14 position in the macrolactin ring structure. The protons at $\delta$ 2.68 and 2.33 shifted downfield due to the presence of a −C═C− group at its $\alpha$-position and a $\beta$-OH group. The methylene protons at $\delta$ 2.35 and 2.26 have been assigned to be present at the side-chain 5-hydroxyhept-3-enoate moiety, and their downfield shift was due to the ester functionality at the $\alpha$-position of the methylene protons and −C═C− at its $\beta$-position. The other $-CH_2-$ group at $\delta$ 1.21 was a part of the terminal ethyl group of 5-hydroxyhept-3-enoate. The methine protons at $\delta$ 3.42 and 4.84 were assigned to be present at the C13 and C15 positions in the macrolactin ring structure. The downfield shift appeared to be due to the propane-1,3-diol moiety at C13−C15. The methine proton at $\delta$ 4.84 appeared to be deshielded due to the presence of a $\beta$-olefinic group extended by further conjugated structure. The carboxyl ester group at the C1 position of the macrolactin ring resulted in strong deshielding of the −CH− proton at $\delta$ 4.99 and, therefore, has been assigned to be present at the C23 position of the macrolactin ring structure. The methine proton (given a triplet of the doublet) at $\delta$ 5.05 is characteristic of the junction point of the macrolactin ring (C-7) to that of the side-chain 5-hydroxyhept-3-enoate moiety. The $^1H$ NMR spectrum showed three exchangeable hydroxyl protons at $\delta$ 4.23 (1H, bs in $CDCl_3$), $\delta$ 3.79 (1H, bs in $CDCl_3$), and $\delta$ 3.16 (1H, bs in $CDCl_3$), which disappeared upon addition of $D_2O$.

The $^{13}C$ NMR spectrum of the purified compound in combination with DEPT experiments indicated the occurrence of 31 carbon atoms in the molecule, including 2 ester carbonyl

carbons at $\delta$ 165.16 and 168.2, 14 methine carbons between $\delta$ 116.1 and 146 assigned to 7 double bonds, 5 oxygenated methine carbons between $\delta$ 67.5and 75.4, and 10 aliphatic carbons between $\delta$ 20.10 and 50.8. The $^{13}$C NMR spectrum displayed two quaternary carbons ($\delta$ 165.16 and 169.54) atoms bearing the carbonyl groups. The low-field quaternary signals ($^{13}$C NMR) were in agreement with that to a quaternary carbon signal carrying the carbonyl groups at C-1 of the macrolactin ring structure and C-1′ of the side chain (5-hydroxyhept-3-enoate) attached to the macrolactin framework at the 7-C position of the ring. This was supported by the relative downfield shift of the H2, 23 signals ($\delta$ 5.60 t and 4.99 ddq, respectively) and methylene signals at C-2′ ($\delta$ 2.26 and 2.35), which referred to a possible oxygenation in its vicinity. The side chain is substituted at C-7 with either an $\alpha$- or a $\beta$-oriented hydroxyl group at the 5′ position.

The position of the hydroxyl group at C-5′ was further confirmed from the $^{1}$H−$^{1}$H COSY, HSQC, NOESY, and HMBC spectra. In the $^{1}$H−$^{1}$H COSY spectrum, the couplings were apparent between H-7/H-6,8; H-13/H-12, 14; H-15/H-14,16; and H-20/H-21/H-22/H-23, which support the presence of a macrolactin skeleton. The point of cyclization of the ester in the macrolactone ring was indicated by the low-field shift of H-23 at $\delta$ 4.99, which has been coupled with the H-24 methyl group at $\delta$ 1.30 (d, $J$ = 6.1 Hz), which also gives clear $^{1}$H−$^{1}$H COSY correlation. Also, the $^{1}$H−$^{1}$H COSY correlations between H′-5/H-6/H-7 supported the presence of the terminal propanol moiety at the 5-hydroxyhept-3-enoate side chain. The proton and carbon connectivity deduced from HSQC and HMBC experiments confirmed the marolactin framework attached to the side-chain 5-hydroxyhept-3-enoate moiety at the seventh position of the macrolactin. The H−H and C−H connectivity apparent in the $^{1}$H−$^{1}$H COSY and HMBC spectra, respectively, indicate that one of the three unsaturations was due to the macrolactin ring framework (Table 2). In the HMBC spectrum, it was observed that H-12/C-10,14; H15/C-13,16; H-20/C-19,22; and H-21/C-1,23,24 were correlated with each other. In addition, a methine proton (H-7) was coupled to the olefinic tertiary carbon (C-9) and methine H-15 with C-16,17. This indicated that these protons (H-7 and H-15) were connected to the olefinic tertiary carbon atoms. The proton at C-21 appeared to demonstrate long-range HMBC correlation with ester carbonyl carbon at $\delta$ 165.16 (C-1). The proton at C-7 realized HMBC correlation at $\delta$ 169.54, which belongs to the second ester carbon. The HMBC analysis revealed that the carbon at $\delta$ 75.4 (C-5′), bearing the hydroxyl group, correlated with a primary methyl proton $\delta$ 0.81 (H′-7).

The HMQC spectrum of the purified compound also revealed connections of the protons (H-2′) to the methylene carbon at $\delta$ 50.8. Placement of the 5-hydroxyhept-3-enoic acid group at C-7 was confirmed by the downfield shift of H-7 ($\delta$ 5.05) in the compound as compared to the baseline value ($\delta$ 4.34) and also by the long-range correlation of H-7 to the carbonyl carbon at $\delta$ 169.54 (C-1′) in the HMBC spectrum.[16] The HMBC spectrum demonstrated long-range correlations of the methine proton (H-5′) to the vinylic carbon at $\delta$ 139.0 (C-3′) and methyl carbon at $\delta$ 14.1 (C-7′). These observed spectral data were indicative of the presence of the hydroxyheptenoic acid half-ester moiety, which was supported by the IR spectral data exhibiting intensely broad hydroxyl absorption from 3500 to 3000 cm$^{-1}$ and ester carbonyl absorption at 1710 cm$^{-1}$. The geometric isomerisms of the olefinic protons have been established by the $^{1}$H coupling constants suitable for the geometries ($Z$ and $E$ forms). The relative stereochemistry of the chiral centers, particularly that of C-13 and -15 carrying the hydroxyl group of the macrolactin framework and that of C′-5, was deduced from the NOESY spectrum of the compound and the $J$ values. NOE couplings were observed between H$\alpha$-13/H$\alpha$-7, thus indicating that these groups must be equatorial and on the $\alpha$-side of the molecule. NOE correlations between H$\beta$-23/H$\beta$-15/H$\beta$-20 and those among H-5′/H-15/H-23 indicated the close proximity of these groups and their $\beta$-disposition. Therefore, the C-1 carboxyl group is equatorial and $\alpha$-oriented. The methine proton at the C′-5 group did not exhibit NOE interactions with H-7 and H-13 and the methylene proton at C-14 ($\delta$ 1.78, m), which is in the $\alpha$-face of the molecule, thereby indicating that H-7 is at the equatorial disposition. An interaction through the space of the hydroxyl protons at C-5′ ($\delta$ 3.16,1H, bs) and C-15 ($\delta$ 3.79, 1H, bs) with H-7 ($\delta$ 5.05, td) and H$\alpha$-14 ($\delta$ 1.94, m in $CDCl_3$) is only possible for the $\alpha$-orientation of the tertiary hydroxyl group on C-5′ and C-15. The stereochemistry at the tertiary alcohol at C-15 position was established by the fact that H-15 has mutual NOE correlations with H-23, which had been shown to be in the $\beta$-face of the molecule (axial configuration) under observation, and the secondary alcohol group that appeared as a broad singlet (at $\delta$ 4.23) has NOE interactions with H-13 and H-7 in the molecule. This is only possible if the C-15 hydroxyl group lies on the $\alpha$-side of the molecule.

**Determination of Antibacterial Activities by Agar Diffusion Method.** The disk diffusion method was used to compare the antimicrobial activities of the crude extract from strain *Bacillus subtilis* MTCC10403, the purified macrolactin, and the clinically important antibiotics against different food pathogenic strains used in the study. The purified macrolactin exhibited a good qualitative inhibitory spectrum to the tested isolates. The crude extract from *Bacillus subtilis* MTCC 10403 was found to possess antibacterial activity against pathogenic *Aeromonas* and *Vibrio* (inhibitory zone diameter >20 mm, 100 $\mu$g on disk). However, 7-*O*-methyl-5′-hydroxy-3′-heptenoate−macrolactin purified from the crude extract showed an inhibitory zone diameter of 18 mm against *Aeromonas hydrophila* and 16 mm against *V. parahemolyticus* ATCC 17802 at a concentration of 100 $\mu$g on disk (Table 4).

## DISCUSSION

Seaweeds are potential sources of bioactive compounds producing bacterial isolates when compared to other marine sources such as seawater and sediments.[17] A greater percentage of active isolates (22%) in this study found good agreement with the literature where the relative proportions of antimicrobial-producing culturable isolates were reported to be >16% from intertidal seaweeds.[3] The pathogens used include reported human pathogens such as *Aeromonas hydrophila*, *Vibrio vulnificus*, and *Vibrio parahemolyticus*. These food pathogens are present in the freshwater and marine environments and were reported to cause gastroenteritis and wound infections in healthy individuals or fatal cases of septicemia in individuals with impaired immune systems or various malignancies.[18] These candidate isolates under study were tested against these food pathogenic bacteria and were found to have a broad-spectrum activity (Table 3).

The taxonomic classifications showed that a higher proportion of the marine isolates belonged to the Firmicutes genera belonging to *Bacillus* sp. Manmadan et al. reported a greater level of epibiotic bacterial isolates belonging to *Bacillus*

with antibiotic activity from the surface of nine species of seaweeds of Japan.[1] *Bacillus* strains were also isolated from the surface of coralline seaweed *Jania rubens* (southern Mediterranean Sea).[8] Recent advances in genome sequencing have highlighted the genus *Bacillus* as a potential source of antibiotic-like compounds such as polyketides, nonribosomal peptide, and bacteriocins as well as other unusual compounds.[19] The remaining isolates in our study belong to γ-proteobacteria.

Polyketides have found application as bioactive leads in pharmaceutical products for use against pathogenic microorganisms and various immunocompromising diseases. Rapamycin, epothilone B, and erythromycin are the common polyketides of industrial importance with immunosuppressant, anticancer, and antibiotic properties, respectively. Lovostatin is the popular anticholesterol drug, which also bears the polyketide backbone. *Bacillus* and *Actinomycetes* have been recognized to contain various PKS gene clusters and bioactive molecules bearing the polyketide backbone. It may be assumed that a genome with a greater number of biosynthetic gene clusters is more likely to result in a positive hit in an *nrps/pks* gene-screening approach. The highly conserved sequences of β-ketoacyl synthase (KS) domains are shared among all *pks*, and therefore the KS domains are useful in the screening for PKS genes in bacteria. Similarly, the most conserved adenylation (A) domain can be used for PCR primer design to survey *nrps* gene diversity. Therefore, positive results in a PCR-based screening for *nrps* and *pks*-II genes not only provide evidence of the production of corresponding metabolites but also may indicate the existence of further metabolic pathways of secondary metabolite synthesis.

Although several studies have investigated the antibacterial activity of seaweed-associated bacteria, the chemical characterization of the isolates for their active metabolites are relatively limited.[1,6−8] In the present study the secondary metabolite of *Bacillus subtilis* MTCC 10403 with potent antibacterial activity against bacterial pathogens was demonstrated to possess the polyketide backbone and was identified as 7-*O*-methyl-5′-hydroxy-3′-heptenoate−macrolactin that represents the scaffold of *pks1* gene-encoded products.

The crude extract from strain *B. subtilis* MTCC10403, the purified macrolactin, and commercial antibiotics (as control) were analyzed against human opportunistic pathogens *V. parahemolyticus*, *V. vulnificus*, and *A. hydrophilla*. 7-*O*-Methyl-5′-hydroxy-3′-heptenoate−macrolactin showed a good qualitative inhibitory spectrum to the tested isolates (Table 4; Figure 3B). It is significant to note that the antibacterial activities of the crude extract against the test pathogens were greater than those exhibited by the pure macrolactin with 5-hydroxyhept-3-enoate moiety at the side chain C-7 position of the macrolactin ring system (Table 4). It is apparent that there might be other bioactive compounds along with the purified macrolactin, which acted synergistically to impart greater antibacterial activities against the test food pathogenic bacteria used in this study.

The macrolactins possess a 24-member lactone ring with three isolated diene elements and have been originally isolated from deep sea bacterium and *Actinomadura* sp.[20,21] A total of 16 macrolactins have been chemically characterized.[20,22] Macrolactin A was found to be the most active compound in this series with potent antiviral properties and was reported to possess antibacterial and anticancerous activities.[16,20] 7-*O*-Succinyl macrolactin F and 7-*O*-succinyl macrolactin A were isolated from the ethyl acetate extract of the marine *Bacillus* sp.

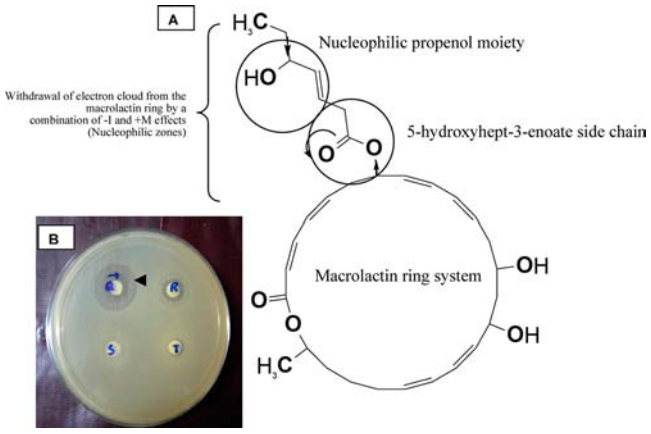

**Figure 3.** (A) Sketch model of 7-O-methyl-5′-hydroxy-3′-heptenoate-macrolactin showing structure−activity correlation. Induction of bioactivity is directly proportional to the inductive (field/polar effect) and resonance effects of the 5-hydroxyhept-3-enoate side chain attached to the macrolactin ring system at C-7. The 5-hydroxyhept-3-enoate moiety with electronegative acetyl group withdraw the electron cloud by a combination of inductive (-I effect) and mesomeric effect (+M-effect) from the substituted macrolactin ring, thus acting as the nucleophilic center of the molecule resulting in a greater level of activity. (B) Antibacterial activity of 7-O-methyl-5′-hydroxy-3′-heptenoate-macrolactin against *V. parahemolyticus* ATCC 17802. The inhibition zone is indicated by an arrow.

SC026 and were reported as antiviral.[16] The antibacterial activities of the macrolactins have been compared by Nagao et al., who reported that the $C_{15}$−OH group is responsible for the target bioactivity of this group of compounds.[21] However, there were no studies regarding the effects of the side chain attached at the $C_7$−OH position of the macrolactin ring system.

The physicochemical parameters of bioactive molecules such as polarizability, steric, and hydrophobic descriptors (lipophilicity, partition coefficients) have a major role in influencing biological activities.[23,24] The ability of any molecule to penetrate biological membranes is a primary factor in controlling the interaction of compounds with biological systems and is dependent on lipophilicity factors as determined by the partition coefficient between 1-octanol and water (log *P*). It is of note that the terminal functional group as the 5-hydroxyhept-3-enoate moiety at the side chain C-7 position of the macrolactin ring system increases lipophilicity. The increased lipophilicity (log *P* 4.43) of 7-*O*-methyl-5′-hydroxy-3′-heptenoate−macrolactin as compared to the parent compound (log *P* 3.28) affords better penetration of the former through the lipoidal membrane barrier to arrive at the receptor site, thereby resulting in greater antibacterial activity of 7-*O*-methyl-5′-hydroxy-3′-heptenoate−macrolactin than the parent compound. The lipophilicity factors of the related compounds have been compared to demonstrate the lesser log *P* value of 7-*O*-methyl-5′-hydroxy-3′-heptenoate−macrolactin than of 7-*O*-succinyl−macrolactin (log *P* 3.24) with a succinate side chain (−C(=O)$CH_2CH_2$COOH) and 7-*O*-malonyl−macrolactin (log *P* 3.18) with a malonyl side chain (−C(=O)$CH_2$COOH) are lesser than 7-*O*-methyl-5′-hydroxy-3′-heptenoate−macrolactin (log *P* 4.43) with a 5-hydroxyhept-3-enoate side chain. 7-*O*-Methyl-5′-hydroxy-3′-heptenoate−macrolactin exhibited significantly greater activity against test pathogens (at a concentration of 20 μg per disk) than the parent macrolactin apparently due to the presence of more polarizable (polarizability 59.91 × $10^{-24}$ $cm^3$) C-7,5-hydroxyhept-3-enoate group as compared to the less polarizable succinate or malonate groups ((52−24) × $10^{-24}$ $cm^3$). It can be inferred that the 5-hydroxyhept-3-enoate moiety with highly electronegative acetyl and olefinic groups withdraws the electron cloud by a combination of inductive (−I effect) and mesomeric effect (+M effect) from the substituted macrolactin ring of 7-*O*-methyl-5′-hydroxy-3′-heptenoate−macrolactin, thus acting as the nucleophilic center of the molecule, resulting in a high level of activity (Figure 3A). This lead demonstrated in the present study will be significant in explaining the pharmacophore-fit in the macromolecular receptor site and exploring the primary site and mode of action of this class of the substituted macrolactone analogues.

The elongation module of type-I PKS harbors the acyl carrier protein (ACP), acyltransferase, (AT) and ketosynthase (KS) domains that synergistically catalyze a series of decarboxylative Claisen condensation involving malonyl units to result in the elongation of the polyketide chain affording the formation of the intermediate biosynthetic product as β-ketoacyl-S-ACP. A series of condensation, dehydration, reduction, and hydrolysis of the intermediate polyketides results in the biosynthesis of 7-*O*-methyl-5′-hydroxy-3′-heptenoate−macrolactin (Figure 4A). It is, however, of note that the ketoreductase (KR), dehydratase (DH), and enoyl reductase (ER) are active in a few steps to reduce the carbonyl group to −OH, olefinic double bond, or a fully reduced end product.

The correlations of metabolite genes such as *pks* with secondary metabolites belonging to polyketides and their putative biosynthesis pathway in related bacteria were reported in earlier studies.[25,26] The *pks* gene has been assigned to the biosynthesis of bacillaene, a polyketide product in the *Bacillus amyloliquefaciens* FZB42 genome. The *pks* gene cluster was identified from *B. amyloliquefaciens* CH12, a genetically engineered strain, and the putitive biosynthetic pathway of bacillane was demonstrated. A bacillaene multienzyme complex of *trans*AT PKSs with *pks*-like chemistry was characterized in an earlier study, where introduction of the β-branch and subsequent incorporation of olefinic bonds into the non-canonical bimodules have been comprehended.[25] The *pksX* polyketide synthase (PKS) genes were also reported in *Bacillus subtilis*.[26] A stepwise aldol addition of acetyl-ACP and Grob fragmentation on the enzymatically loaded acyl carrier proteins were demonstrated to result *pks*-derived antibacterial metabolites bacillaene and curacin.[27,28] Mupirocin H, a novel metabolite resulting from mutation of the HMG-CoA synthase analogue, *mupH* in *Pseudomonas fluorescens*, has been reported.[29] Previous work demonstrated that unlike fatty acid biosynthesis, the biosynthesis of polyketide products does not follow a rigid sequence.[30] Instead, some or none of these steps and reduction reactions occur in different biosynthetic steps to result in various combinations of structural diversity of the PKS products. It is of note that some of the domains remain inactive at one or more steps of macrolactin biosynthesis, thereby leading to the formation of conjugation at three positions (C2−5, C8−11, and C16−19 of the macrolactin ring system) and three hydroxyl groups of the intermediate polyketide product (S-ACP-7,13,15,23-tetrahydroxytetracosa-2,4,8,10,16,18-hexaenethioate). The latter undergoes intramoleculear cyclization by the nucleophilic attack of the terminal hydroxy group on the thioester-activated carbonyl to result in the formation of a −C(=O)—O− linkage in the 24-member macrolactin ring location system with the elimination of ACP-SH.

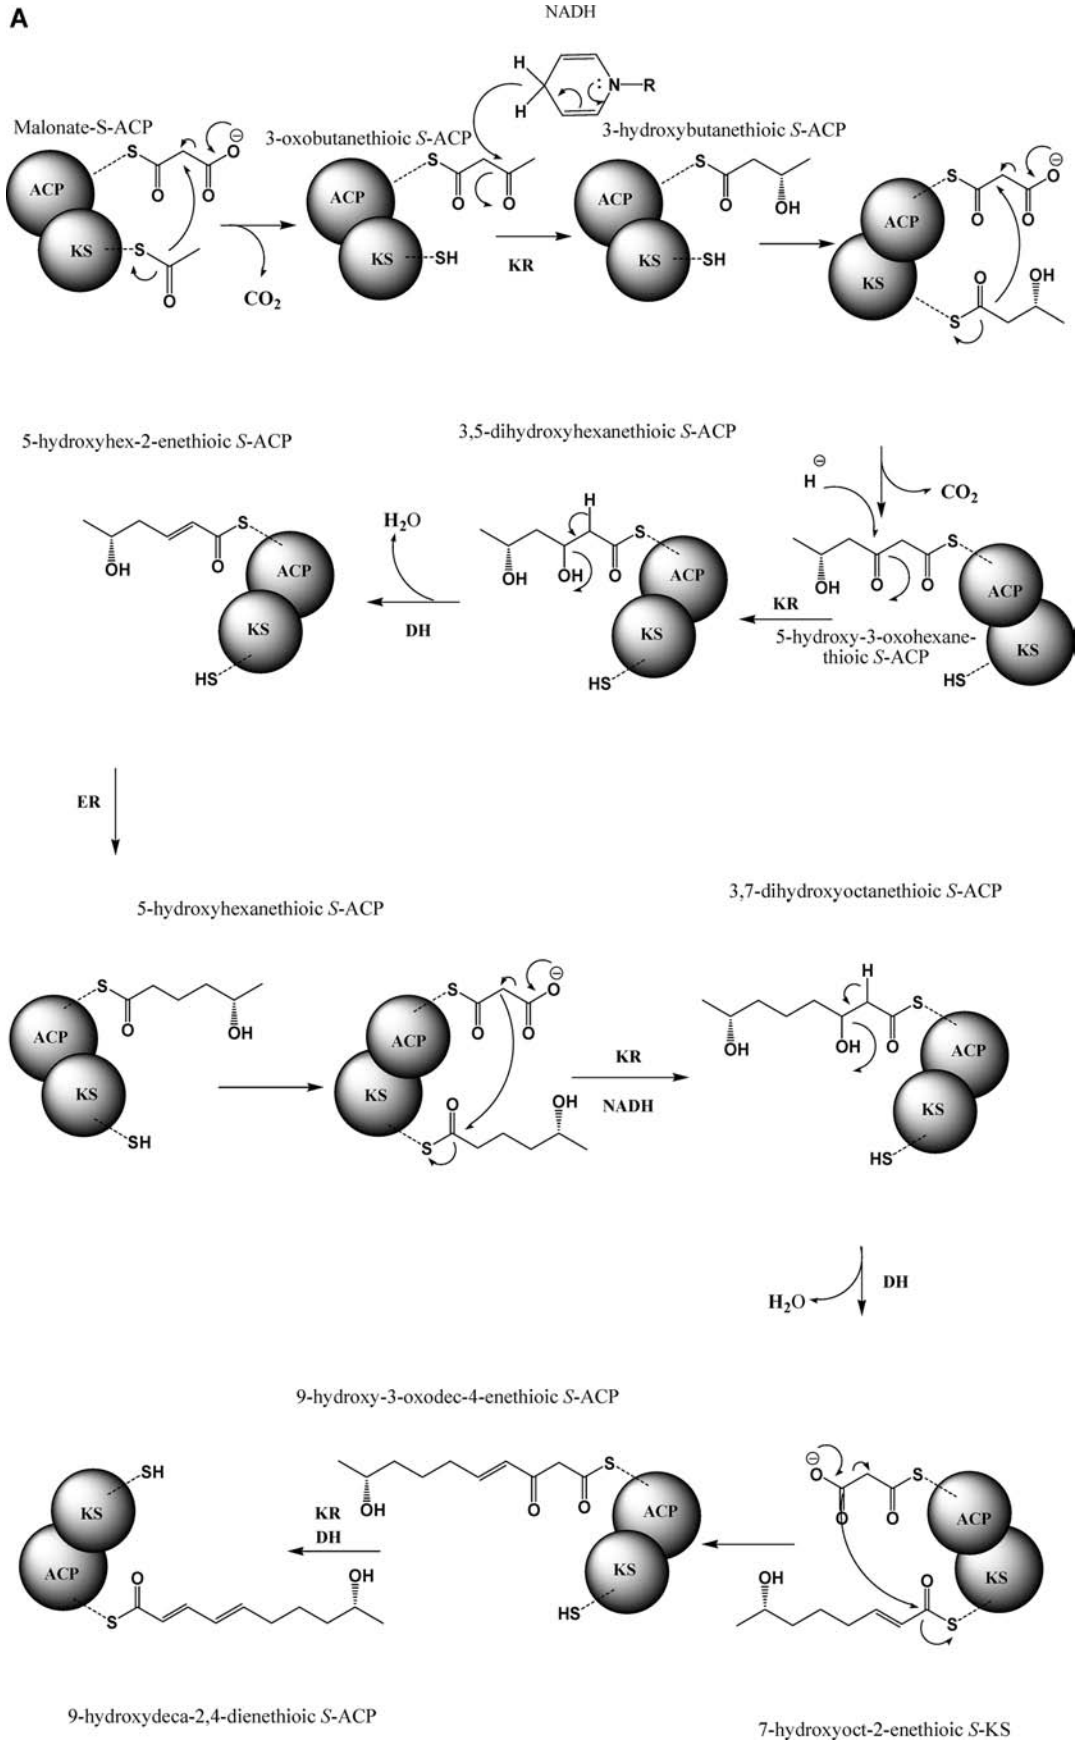

**Figure 4.** continued

dx.doi.org/10.1021/jf504845m | J. Agric. Food Chem. 2014, 62, 12194−12208

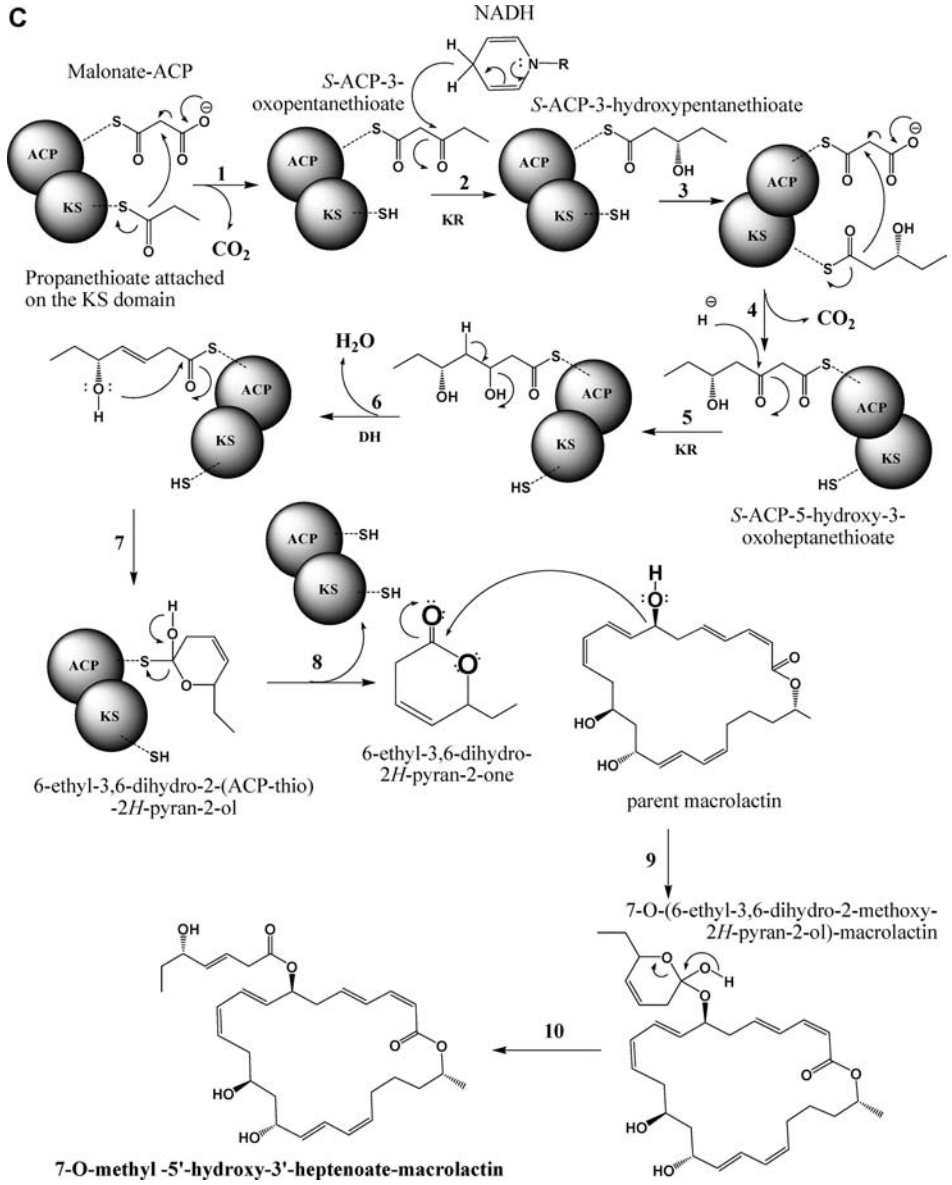

**Figure 4.** (A) Hypothetical biosynthetic pathways of 7-*O*-methyl-5′-hydroxy-3′-heptenoate−macrolactin, showing the loading, decarboxylation, and elongation steps catalyzed by PKS-1. Both enzymes build their products from an acetate starter unit and malonate extender units. The intermediates shown bound to the PKSs are hypothetical, but consistent with experimental results. (B, C) Sequences of events in the biosynthesis of side chain 5-hydroxyhept-3-enoate moiety attached to the macrolactin ring system at C-7, and the final PKS product as 7-*O*-methyl-5′-hydroxy-3′-heptenoate−macrolactin. (1) Chain extension is initiated by decarboxylation of malonyl-ACP to propanoyl-ACP by the KS domain. (2) The propanoate group is then passed from the ACP to the active site cysteine of the KS. (3) The ACP is loaded with another unit of malonate, and then KS-catalyzed condensation takes place, resulting in *S*-5-hydroxy-3-oxohaptanethoate-ACP. (4) The ketoester is then transferred back to the KS, and another cycle of chain extension can begin. The biosynthetic route starts from propanethioate attached on the KS domain and is accomplished by two alternate steps of decarboxylative Claisen condensations and ketoreduction. (5) DH catalyzes the elimination of the water molecule in the intermediate KR product S-ACP-3,5-dihydroxyheptanethioate to afford S-ACP-5-hydroxyhept-3-enethioate. The nucleophilic attack of the terminal hydroxy group (as butanol moiety) on the thioester-activated carbonyl carbon atom of S-ACP-5-hydroxyhept-3-enethioate results in the formation of a cyclic polyketide product as 6-ethyl-3,6-dihydro-2-(ACP-thio)-2*H*-pyran-2-ol in the six-membered pyran ring lactone system. A subsequent elimination of ACP-SH afforded 6-ethyl-3,6-dihydro-2*H*-pyran-2-one. The carbonyl carbon atom of the latter undergoes nucleophilic attack by the 7-OH group in the macrolactin ring system followed by ring opening yielding the final PKS product as 7-*O*-methyl-5′-hydroxy-3′-heptenoate−macrolactin.

The post-biosynthetic modifications of the macrolactin ring at the C7 position of macrolactin has been reported in earlier literature.[16] In general, type I PKSs use malonyl/methylmalonyl/ethylmalonyl derivatives of CoA and hydroxymalonyl/aminomalonyl/methoxymalonyl ACP extender units to biosynthesize diverse natural products bearing the polyketide backbone.[16] It is of note that in the biosynthetic route leading to the formation of the side-chain 5-hydroxyhept-3-enoate moiety is also a polyketide biosynthetic product. A model for biosynthesis of 5-hydroxyhept-3-enoate can be proposed (Figure 4B), which accounts for the fact that propanethioate/malonate as the starting building blocks instead of acetate/malonate in the biosynthesis of this polyketide backbone. Accordingly, the biosynthetic route starts from propanethioate (KS—S—C(=O)$C_2H_5$) attached with the KS domain and is accomplished by two alternate steps of decarboxylative Claisen

condensations and ketoreduction. Finally, DH catalyzes the elimination of the water molecule in the intermediate KR product S-ACP-3, 5-dihydroxyheptanethioate, to afford the S-ACP-5-hydroxyhept-3-enethioate. The nucleophilic attack of the terminal hydroxyl group (as butanol moiety) on the thioester-activated carbonyl carbon atom of S-ACP-5-hydroxyhept-3-enethioate results in the formation of a cyclic polyketide product as 6-ethyl-3,6-dihydro-2-(ACP-thio)-2*H*-pyran-2-oil in the 6-member pyran ring location system. A subsequent elimination of ACP-SH afforded 6-ethyl-3,6-dihydro-2*H*-pyran-2-one. The carbonyl carbon atom of the latter undergoes a nucleophilic attack by the 7-OH group in the macrolactin ring system followed by ring opening, yielding the final PKS product as 7-*O*-methyl-5′-hydroxy-3′-heptenoate−macrolactin (Figure 4C). It is apparent from this study that various combinations of the starter and elongation units used for polyketide biosynthesis lead to the formation of multiple stereocenters and structurally diverse polyketide backbone.

The past decade witnessed the discovery of various polyketide leads from bacterial sources with tremendous importance in food control and from a human health perspective. The newly evolving antibacterials bearing the polyketide backbone will be increasingly important keeping in mind the development of multidrug-resistant bacteria and pathogenic microorganisms against the existing antibiotics and related molecules. In this study, we described a new variant of macrolactin, 7-*O*-methyl-5′-hydroxy-3′-heptenoate−macrolactin. This novel polyketide product holds promise for the development of a new generation of drug candidates for use against the multiresistant microbial pathogens. We have also provided evidence for a biosynthetic route of this compound, and this may lead to the identification of a new target for antimicrobial lead molecule discovery programs. The results of this screening led to the conclusion that these polyene antibiotics are widespread metabolites of seaweed-associated bacterial populace particularly belonging to *Bacillus* species. The present work may have an impact on the exploitation of macrolactins for food, pharmaceutical, and biotechnological applications.

honeys,[15] and flavonoid glycosides containing the aglycone quercetin, kaempferol, or isorhamnetin were reported in *T. carbonaria* honeys from suburban areas of Queensland.[18] Whether these stingless bees collect *Leptospermum* nectars to produce "jellybush-sugarbag" honeys was unknown.

The study of antimicrobial natural products in honeys is important to determine honey varieties with medicinal potential and for clinical applications. Bioactive natural products found in honeys can be derived from plant nectars or other plant materials such as propolis.[19] Propolis is a resinous mixture that the bees produce by mixing their beeswax, salivary secretions, and plant resins. Whether propolis can contribute to the composition of stingless bee honey was yet to be ascertained. Therefore, the natural products, MGO levels, and peroxide content were investigated in this study to assess the contribution of these factors to the antimicrobial effects reported in *T. carbonaria* honeys.[17]

Chemical investigations of Meliponini honeys require an appropriate sample preparation. The complex matrix rich in polar compounds including sugars and proteins can complicate the sample preparation and analysis.[20] Moreover, a high content of flavonoid glycosides that are not hydrolyzed by the bee salivary $\beta$-glucosidases can be expected.[19] Therefore, a combination of methodologies of extraction techniques has proven successful in honey analyses including solid-phase extraction methods and liquid chromatography−mass spectrometry to analyze nonvolatile compounds in extracts.[19,21,22] Other analytical paper have indicated gas chromatography−mass spectrometry to screen the volatiles with a chemotaxonomical relevance in honeys from Australian honeybees foraging on *Leptospermum* spp.[23] A combination of analytical techniques was applied to a dereplication approach for the characterization of natural products in Australian *T. carbonaria* honeys in this study.

The aims were to characterize the natural products, levels of MGO, and peroxide contents in *T. carbonaria* honeys, to determine if these honeys originate from *Leptospermum* nectars using known phytochemical markers, and to assess the in vitro antibacterial activities of their concentrated phenolic fractions and peroxide contents.

## MATERIALS AND METHODS

**Chemicals.** Methanol, acetonitrile, ethanol, and ethyl acetate of analytical grade were purchased from Merck Pty Ltd. (Kilsyth, VIC, Australia). Milli-Q water was obtained from an in-house Milli-Q Ultrapure Water System. Muller−Hinton nutrient broth (MHB) and agar (MHA) media, 3-[4,5-dimethylthiazol-2-yl-]-2,5-diphenyltetrazolium bromide (MTT), hexadecane, phenol standard (>99.5%), *N*,*O*-bis(trimethylsilyl)trifluoroacetamide (BSTFA), *O*-(2,3,4,5,6-pentafluorobenzyl)hydroxylamine−HCl (PFBHA), hydroxyacetone (HA), methylglyoxal (MGO), dihydroxyacetone (DHA), hydroxymethylfurfural (HMF), gallic acid, quercetin hydrate, 3-phenyllactic acid, *o*-dianisidine, horseradish peroxidase type IV, and hydrogen peroxide were purchased from Sigma-Aldrich (Castle Hill, NSW, Australia).

**Beehive Products.** Stingless bee *T. carbonaria* honeys were produced in beehives using wooden compartments (honeysupers) of 25 × 15 cm. Three sites were used for the apiaries ($n$ = 6 beehives each). Two sites contained plants of *L. polygalifolium* and *L. liversidgii* at high density in the coastal area of Tyagarah, NSW (site 1) and heathland of East Beerwah, QLD (site 2). The third and control site was in heathland of West Beerwah, QLD (site 3), and did not contain *Leptospermum* spp. The honeys were produced between September 2012 and April 2013 during *Leptospermum* nectar flow. The honeys from beehives within the same site were pooled to yield one representative batch per each site. The three batches were labeled as honeys 1, 2, and 3 (control).

The honeys were harvested from honeypots and sieved using a metal drainer to remove other hive materials including propolis, bees, and pollen particles. Honey aliquots (200 mL) were centrifuged at 1000 rpm at room temperature for 5 min to recover the supernatants for later analyses. Propolis from the same honeypots of site 2 was extracted by maceration in absolute methanol (5% w/v) for 24 h at room temperature, filtered, and evaporated to dryness under vacuum to yield the propolis extract.

**Liquid−Liquid Extraction for the Phenolics Concentrates.** The raw honeys (ca. 50 g) were extracted in absolute ethanol (20 mL, 40% v/w) at around 60 °C and allowed to cool at 24 °C for 2 h and then at 4 °C for 2 h, followed by storage at −18 °C overnight. The supernatants were decanted, and the sugar precipitates were extracted again following the same protocol. The combined supernatants were evaporated to dryness under reduced pressure. Three cycles of solvent extractions were repeated to precipitate the carbohydrates of the honey matrices and to concentrate the phenolic fractions into ethanolic extracts. The last step of extraction used acetone/ethanol (1:1) followed by evaporation to dryness and freeze-drying to yield three honey phenolic concentrates (2.40, 2.70, and 3.70 mg). Aliquots of the three dry extracts were reconstituted in methanol for the liquid chromatography analyses and in ethanol for the antibacterial assays.

A further extraction involved raw honeys (ca. 50 g) in deionized water/ethyl acetate (2:1) using a modified protocol.[24] The mixture was warmed at 50 °C in a water bath for 5 min and vortexed to homogeneity. The ethyl acetate extracts were transferred into clean test tubes and dried using anhydrous $Na_2SO_4$ (70 mg each) for 5 min. Aliquots of the final solutions were subjected to gas chromatography.

**GC-MS Analyses.** Equipment was a PerkinElmer Clarus580 GC-EI-MS fitted with an Elite-5MS column ($L$ = 30 m, i.d. = 0.25 mm, DF - 0.25 $\mu$m, PerkinElmer) operated at 70 eV ionization. The ethyl acetate extracts (1.0 $\mu$L) were injected at 260 °C into the gas chromatograph, split ratio of 10:1, and the oven temperature was ramped from 50 to 315 °C at 5 °C/min and held for 5 min, for a total run time of 47 min. A solution of *n*-alkane standards ($C_8$−$C_{40}$) was also analyzed for the calculation of retention indices. The mass spectrometer acquisition was set in the range of $m/z$ 50−650.

A further protocol required the analyses of trimethylsilyl (TMS) derivatives after BSTFA derivatization of honey extract. The ethyl extracts were treated with BSTFA (50 $\mu$L) for 2 h at 60 °C and analyzed under the same GC-MS conditions.

**UPLC-UV-ESI-HR-MS Analyses.** Samples of the three honeys and one propolis extract were reconstituted in MeOH (2 mg/mL) and injected onto an Eclipse Plus C18 UPLC column (2.1 × 100 mm, 1.8 $\mu$m particle size). The equipment (Thermo Scientific, New Zealand) included a Dionex Ultimate 3000 UPLC pump linked in series with eluent from the column into the photodiode array detector and then into the qExactive Mass Spectrometer (qEMS). The ESI module was a heated ESI (HESI). The qEMS resolution was set at 140,000, and separate UPLC runs were done for positive and negative ionization modes. Mobile phase A (MPA) consisted of 0.1% acetic acid in water, and mobile phase B (MPB) consisted of 0.1% acetic acid in acetonitrile. The flow rate was 0.4 mL/min. The gradient was 2.5% MPB at $t$ = 0.5 min to 20% MPB at 15 min and 100% MPB at 25 min, held for 2.5 min. A photodiode array detector was coupled to the LC and set at 205, 260, 290, and 340 nm. The spray voltage was set to 3.5 kV with the source temperature at 100 °C.

Quantitation of individual compounds was performed by HPLC-DAD at 205 nm on a HPLC series 200 with a Flexar DAD (PerkinElmer) equipped with an RP-C18 column, 75 $\mu$m, 4.6 × 4 mm (Phenomenex Synergi Fusion), with a flow rate of 1.2 mL/min and the same analytical conditions of mobile phases and gradient method as indicated for the UPLC analyses. Accurate ethanolic solutions of the phenolic extracts were analyzed against a standard calibration curve ($R^2$= 0.9984) of gallic acid (0−0.6 mg/mL), and signals were interpolated to yield gallic acid equivalents (GAE) per 100 mg of phenolic extract. Quantifications were performed at 205 nm, mean values, $n$ = 2.

[a]Quantitative amounts were measured as mg/100 mg of gallic acid equivalents at 205 nm. Mean values, $n = 2$. tr, traces <1%. [b]See structures in Figure 2. [c]nd, not determined. [d]Matched with references. [e]Identified in propolis from the same honeypots of honey 2.

**MGO Protocols.** The calibration of standards MGO, DHA, and HMF was undertaken against the internal standard HA (3.0 mg/mL) according to known protocols.[25,26] The internal standard HA (250 μL) was added to raw honey samples (ca. 0.3 g) and diluted with water (600 μL) before being mixed thoroughly. The solutions were derivatized with 1200 μL of PFBHA (0.02 g/mL in 0.1 M, pH 4, citrate buffer) for 1 h at room temperature, and then acetonitrile was added (2 mL). Solutions were diluted with water (1 mL) and mixed. Aliquots (10 μL) were chromatographed by HPLC-DAD at 263 nm.[25,26] This procedure was repeated in triplicate for batches harvested in 2013.

**Antibacterial Assays.** Two bacterial strains were available at the University of the Sunshine Coast laboratory. Inocula of *Staphylococcus aureus* ATCC 25923 or *Klebsiella pneumoniae* ATCC 13883 were cultured in MHB overnight at 37 °C and used at lag phase as determined by optical density to be 0.500−0.550 OD. Fresh media were inoculated with culture suspensions to the final concentration of $10^5$ CFU/mL in plates. Controls were absolute ethanol and the phenol standard (>99.5% purity) solution in ethanol. The negative control showed no bacterial inhibition. The positive control phenol solution showed mean zones of inhibition of 9.78−28.55 mm used to construct the calibration curves for the concentrations of 0.5−8% (w/v) that were tested against the two bacterial strains. Samples were raw honeys or phenolic concentrates reconstituted in absolute ethanol. Two methodologies were applied for the assays.

In the agar diffusion assay, agar plates of 20 × 20 cm were prepared with MHA inoculated media. Samples were dispensed to wells of 8 mm diameter: aliquots (100 μL) of raw honeys or phenolic solutions (at final weights of 100−800 μg) were delivered to MHA plates. The plates were incubated at 37 °C for 16 h in a humidified incubator. Results of growth inhibition by the samples were reported as the mean zone of inhibition (mm) and calibrated by values of phenol equivalents in the range of 0−8% (w/v).

In the broth dilution assay, 96-well microplates were filled with 170 μL of inoculated MHB. Aliquots (10 μL) of raw honeys or phenolic solutions (at final concentrations up to 3.3 mg/mL) were added to wells of microplates. Absolute ethanol (10 μL) yielded a final concentration of 5.5% v/v. Phenol standard solution ranged between 0.02 and 0.2% (w/v). The microplates were incubated at 37 °C for 16 h in a humidified incubator. The MTT tetrazolium dye was used to visualize the inhibition of bacterial growth, showing a yellow coloration for full inhibition. Minimum inhibitory concentrations (MICs) were replated using cotton swabs on fresh agar plates that were incubated for 24 h at 37 °C. The bactericidal effects were assessed for >99% lack of bacterial growth.

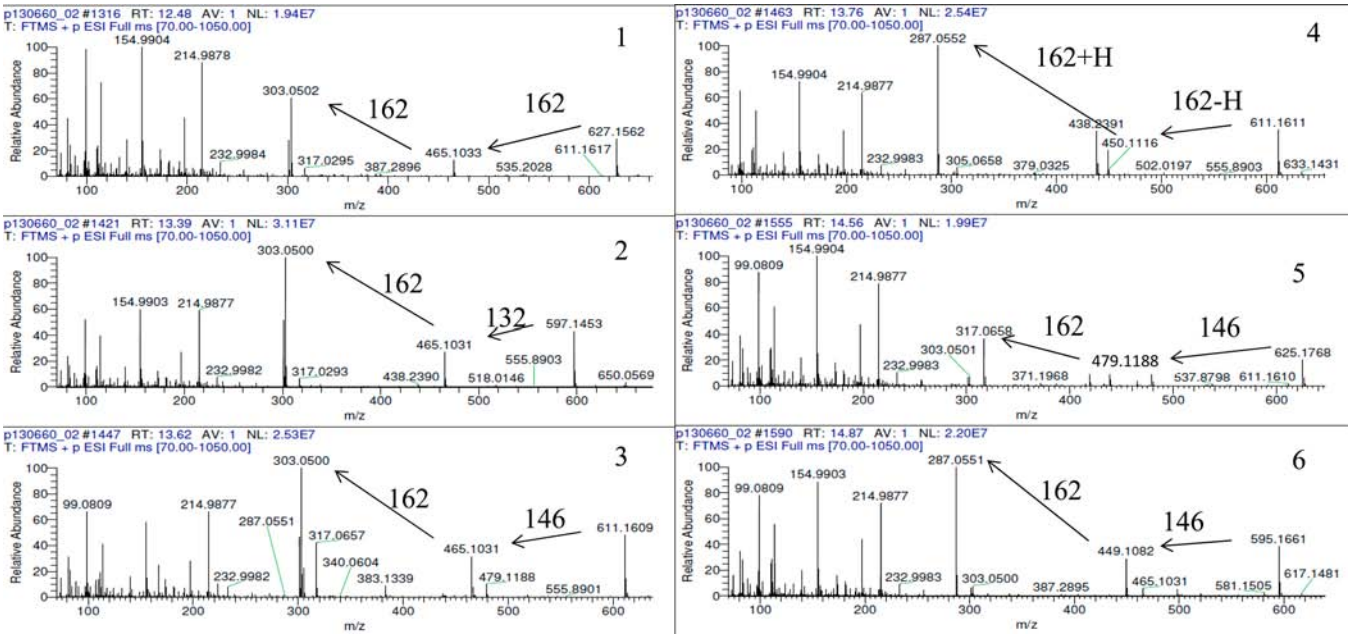

**Figure 1.** Full mass spectra of the glycosylated flavonoids (**1**) quercetin-6,8-di-*O*-glucoside; (**2**) quercetin-3-*O*-glucosyl-*O*-pentose; (**3**) tricetin-3-*O*-rhamnose-*O*-glucoside; (**4**) kaempferol-3-*O*-diglucoside; (**5**) isorhamnetin-3-*O*-rhamnose-*O*-glucoside; and (**6**) luteolin-3-*O*-rhamnose-*O*-glucoside, as identified in honey 2 by UPLC-ESI-(+)-MS. Characteristic fragmentation patterns showed the diagnostic mass losses for hexose moieties of 162 Da for a glucose unit, 146 Da for a rhamnose unit, and 132 Da for the internal cleavage of a *C*-pentosyl unit in **2**.

**Peroxide Quantitation.** Quantitative concentrations of hydrogen peroxide in honey were determined from a modified protocol.[3] Briefly, 135 $\mu$L of a buffer containing 50 $\mu$g/mL of *o*-dianisidine and 20 $\mu$g/mL of horseradish peroxidase type IV (Sigma-Aldrich, Australia) were dispensed to wells of a 96-well microplate. The negative control was deionized water. The positive control was a standard solution of hydrogen peroxide at concentrations of 1 $\mu$M−1 mM used for calibration curves. The assay measured the product formation after horseradish peroxidase catalysis of hydrogen peroxide in the presence of *o*-dianisidine. The absorbance values were read at 540 nm at intervals of 5, 15, 30, and 60 min using a Versa Max Tunable Microplate Reader (Associates of Cape Cod Int. Inc., Liverpool, UK). The enzymatic assays were conducted at 24 °C. Standard and honeys were analyzed in duplicate. Mean values (± standard error) were averaged for the three honeys to show common levels of hydrogen peroxide in undiluted and diluted stingless bee honeys.

Peroxide assays were undertaken using undiluted and diluted honeys to compare the accumulation of hydrogen peroxide. Aliquots (40 $\mu$L) of raw honeys were added to wells containing the reagents for 5 min, and the absorbances were read at the conditions indicated above. A further test employed honeys diluted in water (44%) for 1 h, and aliquots (40 $\mu$L) were transferred to wells containing the reagents for 5 min before the absorbance was monitored at the time intervals aforementioned.

**Data and Statistical Analyses.** GC-MS results were interpreted against NIST library, mass spectra of chemical references, and the literature on norisoprenoids and other volatiles from honeys and nectars including *Leptospermum* sources.[2327,28]

The quantitation of compounds was undertaken by the internal standard method using hexadecane $C_{16}$ (stock 8.89 $\mu$g/100 mL) in the GC-MS analyses. The peak areas were standardized to hexadecane areas to the mass ($\mu$g/g) of individual components in honey. A response factor of 1 was assumed for all constituents.

The HR-MS data were analyzed using Thermo Xcalibur (v. 3.0.63). Accurate mass measurements and elemental compositions were used to generate chemical formula using http://www.chemcalc.org/.[29] Constituents were dereplicated using SciFinder (https://scifinder.cas.org/) against available literature. Known natural products were searched using ESI-MS marker ions in the positive mode at *m/z* 550−700 for glycosyl flavonoids. Other ESI-MS markers were searched at *m/z* 165 for 3-phenyllactic acid and at *m/z* 243 for lumichrome.[30] *Leptospermum* markers of mānuka and jellybush honeys were searched for methyl syringate (MYSR),[7] leptosin,[31] unedone,[10] and MGO.[8] Propolis constituents were identified in honeys from the same honeypots by comparing retention times of individual peaks and their ESI-UV-MS against known data.[32]

MGO, HMF, and DHA were identified by comparison of their retention times and UV spectra against those of commercial standards (Sigma-Aldrich, NSW) showing distinct retention times and UV spectra for DHA ($t_R$, 9.82; $UV_{max}$, 201, 256), HA ($t_R$, 13.27; $UV_{max}$, 199, 259), HMF ($t_R$, 14.45; $UV_{max}$, 276), and MGO ($t_R$, 18.39; $UV_{max}$, 201, 242). Linear regression curves (MGO, $R^2$ = 0.998, $n$ = 3; DHA, $R^2$ = 0.9999, $n$ = 3; HMF, $R^2$ = 0.9996, $n$ = 3) were used for quantitation.

Quantitative amounts of hydrogen peroxide were measured in undiluted (raw) and 44% diluted honeys by interpolating the absorbance readings of samples at 30 min of enzymatic activity against linear regressions of standard peroxide ($R^2$ = 0.9989).

The antibacterial concentration curves from the agar diffusion assay against *S. aureus* were fitted with centered second-order polynomial equations (quadratic curve-fits) using GraphPad Prism 6.0. Phenol equivalents were calculated against calibrated curves of phenol standard solutions tested in the same plate (mean values, $n$ = 3, standard error).

## RESULTS

**Glycosyl Flavonoids and Propolis Phenolics.** The UPLC-UV-HR-ESI-MS(+) analyses of the three phenolic extracts showed the high content of flavonoid glycosides **1**−**7** with MW of 596−626 (Table 1; Figure 1). Their UV maxima were in the ranges of 220−264 nm for flavonoids that could be distinguished at subclass level between flavones for the band I's absorption at 335−350 nm or flavonols at 360−390 nm. The ESI-MS(+) fragmentation patterns of the protonated molecular ions showed diagnostic mass losses of 162 Da for a hexosyl residue and 146 Da for a deoxyhexosyl (most likely rhamnose) residue. Therefore, **1**−**7** were identified to be *O*-glycosylated flavonoids containing two glycosidic residues (Table 1; Figure

1). The ESI-MS(+) fragmentation of **2** showed a mass loss of 132 Da that was indicative of an internal cleavage of a *C*-pentosyl unit. The aglycones were determined from the protonated base peaks with accurate mass measurements at $m/z$ 286 ($C_{15}H_{11}O_6$) for **4** and **6**, at $m/z$ 302 ($C_{15}H_{11}O_7$) for **1**−**3**, and at $m/z$ 317 ($C_{16}H_{13}O_7$) for **5** and **7**: identifications were kaempferol, quercetin, and isorhamnetin, respectively. The base peaks were detected as the deprotonated aglycones of compounds **2**−**4**, **6**, and **7** (Figure 1).

Comparison of UPLC-ESI(−)-MS analyses of the extracts obtained from honey 2 and propolis from the same honeypots showed some common constituents (Figure S1). Trace amounts of flavonoid aglycones pinocembrin and cryptostrobin and of two phloroglucinols were found in the late eluting regions of honey extracts (Table 1). The glycosyl flavonoids were found only in honeys and eluted at 12−17 min by LC. Gallic acid (a phenolic acid) and a catechin (a polar flavonoid aglycone) were found only in propolis by LC.

**Norisoprenoids.** The LC-MS analyses detected three norisoprenoids **9**−**11**, namely, abscisic acid, unedone, and 13-hydroxyabscisic acid, by dereplicating the accurate mass measurements of their deprotonated MS ions (Table 1) for structural identification (Figure 2). The *cis,trans* isomerism of **11** was identified by the diagnostic fragment ion at $m/z$ 151 (Figure S2) as previously reported.[33] The GC-MS analyses of the ethyl acetate extracts of *T. carbonaria* honeys contained 3-oxo-$\alpha$-ionone **13** and related norisoprenoids **14** and **15** that were tentatively identified against entries of the NIST library (Table 2; Figure 2).

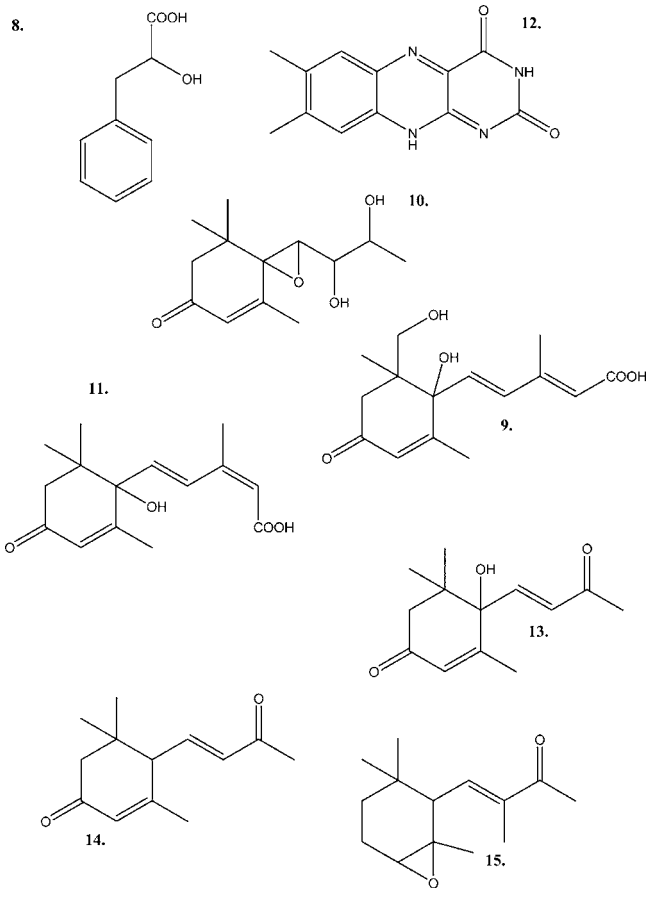

**Figure 2.** Structures of dereplicated honey constitutents: (**8**) 3-phenyllactic acid; (**12**) lumichrome; (**9**) 13-hydroxyabscisic acid; (**11**) abscisic acid; (**13**) 6-hydroxy-3-oxo-$\alpha$-ionone; (**14**) 3-oxo-$\alpha$-ionone; (**15**) oxabicycloheptanyl.

**Lumichrome and Aromatics.** Lumichrome (7,8-dimethylalloxazine, **12**) was identified in trace amounts in honey 1 (Table 1). In the negative mode of ESI-MS, the accurate mass measurement of the deprotonated ion at $m/z$ 241.0733 yielded the elemental composition of $C_{12}H_9N_4O_2$ and $m/z$ 198.0667 ($C_{11}H_8N_3O$) due to the loss of HNCO (Figure S3) and confirmed the interpretations reported previously.[30]

3-Phenyllactic acid (**8**) was found in the three honeys by UPLC-ESI-MS and also by GC-MS (Tables 1 and 2). It showed the same UV spectra with maxima at 224sh and 283 nm of the reference compound (Sigma-Aldrich, NSW). Its deprotonated fragmented ESI-MS ions (Figure S4) were dereplicated against the literature.[30]

In the attempt to determine whether *Leptospermum* nectars contributed to the composition of multifloral sugarbag honeys, samples 1 and 2 were obtained from two sites where these plant species were predominant during *Leptospermum* nectar flow. Results indicated that no MGO or phenolics recommended as *Leptospermum* markers were found within the *T. carbonaria* honeys analyzed in this study.

**Peroxide Content in Honeys and Antibacterial Activity of Standard.** Levels of hydrogen peroxide accumulated to 155.8 ± 10.0 and 91.5 ± 11.3 $\mu$M (mean values, standard error) in undiluted and 44% diluted honeys, respectively. The standard peroxide showed to be bactericidal at 760 $\mu$M in broth dilution, and mean zones of inhibition were up to 43.86 mm against *S. aureus* ATCC 25923 and up to 42.63 against *K. pneumoniae* ATCC 13883 at concentrations of 0−5.5 mM in agar diffusion (Table 3).

**Antimicrobial Effects of Phenolic Concentrates from Honeys.** In agar diffusion, the raw honeys (100 $\mu$L) were active against both bacterial strains (Table 3; Figure S5). However, the phenolic extracts (100 $\mu$g) inhibited only *S. aureus* growth with diameters of inhibition ranging from 10.18 to 19.87 mm with phenol equivalents of 1.0−5.1% (w/v) (Table 3). The phenolic extracts up to 100 $\mu$g did not inhibit *K. pneumoniae* ATCC 13883. The positive control phenol solution showed mean zones of inhibition of 10.00−10.75 mm at the concentration of 1% (w/v) against the two strains (Table 3).

In broth dilution, the raw honeys and phenolic concentrates were active against both strains at the dilution used. The raw honeys in MHB were used at the dilution of 5.5% (v/v) showing bactericidal effects after 16 h of incubation. The phenolic concentrates had bactericidal MIC values ranging from 1.2 to 1.8 mg/mL. The control phenol standard yielded a MIC value of 0.18% (w/v) against both bacterial strains (Table 3).

## DISCUSSION

**Chemotaxonomical Composition and Significance.** The liquid−liquid extraction methodologies applied in this study proved successful in recovering the phytochemicals and concentrating them in phenolic extracts for the chromatographic analyses and the antibacterial assays. The soft ionization of ESI coupled to MS interpretation allowed for the characterization of the aglycone type, the number of sugar units, and the type of *O*-glycosidic flavonoids. The high abundances of the mass-to-charge ions of the aglycone moieties indicated that the glycosidic residues were possibly attached on a single position of the flavonoid core.[19,34] The sugar residues

could be possibly positioned on C-3 or C-7,[18] and previous reports of *T. carbonaria* honeys were identified to be 3-*O*-glycosides.[15,18] For instance, the ESI-MS in positive mode of compounds **2**−**4**, **6**, **7** showed the base peaks of the protonated aglycones after two glycosidic losses, and thus these compounds were identified to be flavonol *O*-diglycosides (Table 1; Figure 1). Compounds **1** and **5** showed low relative abundances of the aglycone ions (Table 1; Figure 1), as previously reported in flavonoid di-*O*-glucosides.[34]

The first-order ESI-MS technique of this study suggested a (1→2) interglycosidic linkage as it was identified on the basis of the high relative abundance (10−35%) of the moieties containing one sugar-*O*-aglycone after the loss of one glucosidic (162 Da) or rhamnosyl (146 Da) unit.[34] Further tandem $MS^n$ studies are warranted to carry out the sequential fragmentation of parent molecular ions and daughter ions to confirm the type of interglycosidic linkage of flavonoids of this study.[19,35] Using ESI-tandem $MS^n$, the interglycosidic linkages on flavonoids were characterized previously.[18,19,35] For instance, the ESI-MS fragmentation in positive mode of a dihexoside flavonol with interglycosidic linkage 1→2 was reported in Argentinean honeybee honeys.[36]

The presence of several *O*-glycosylated flavonoids **1**−**7** and of few flavonoid aglycones was consistent with previous papers describing the honey composition due to Meliponini bees lacking β-glucosidases.[18,19] On the contrary, Australian honeys from honeybees were reported to be low in glycosidic flavonoids and high in flavonoid aglycones,[21] especially myricetin, tricetin, and luteolin that were detected in *Eucalyptus* honeys from Australia and Europe.[37,38] These aglycones were not found in *T. carbonaria* honeys. Aglycones of flavonols **1**−**7** matched previous identifications in sugarbag pot-honeys.[18]

Compounds **3** and **5**−**7** showed a rhamnosyl residue (loss of 146 Da) and were indicative of floral nectars rich in flavonoid rhamnosides that are not hydrolyzed by *T. carbonaria* bees salivary enzymes. Similar observations were reported on flavonoid rhamnosides found in European honeys of honeybees foraging on *Robinia pseudoacacia*.[19] Therefore, sugarbag honeys of *T. carbonaria* bees have a particular profile high in *O*-glycosidic flavonoids including rhamnosides and lower in flavonoid aglycones than that of Australian *A. mellifera* honeybees.[18]

Some flavonoid aglycones and phloroglucinols were found in honey. These natural products are widely distributed in plant materials and are likely to have originated from floral nectars converted into honeys. These compounds were also tracked in propolis extracts from the same honeypots (Figure S4); hence,

it is possible that they were obtained from propolis during honey maturation and harvest.[18] However, a highly polar catechin of propolis was not traced in honey (Figure S4) and was expected to be transferred into the polar matrix of honey from propolis. Therefore, the extent to which propolis can contribute to the phytochemical profiles of honeys remains to be confirmed. Nevertheless, the presence of flavonoids and phloroglucinols in honeys is of interest because these compounds were reported for their in vitro antistaphylococcal activities of stingless bee propolis extracts.[32]

The local flora included several *Eucalyptus* species that were visited by the *T. carbonaria* bees of this study. The monoterpenoid eucalyptol (MW 154) was not found in the ethyl acetate extracts of stingless bee honeys, although it was reported as one abundant compound of honeybee *Eucalyptus* honeys.[39] However, *Eucalyptus* as a source for nectars collected by stingless bees was supported by the presence of norisoprenoids among the volatiles.[23] Norisoprenoids derive from carotenoid degradation.[39] Oxo-$\alpha$-ionone (**14**) together with related norisoprenoids **13** and **15** are chemical markers of honeys from *Eucalyptus*.[39] Other identified norisoprenoids of Australian stingless bee honeys were unedone (**10**), abscisic acid (**12**), and derivative **9** and were previously described in *Apis* honeys originating from Sardinian strawberry-tree (*Arbutus unedo* L., Ericaceae) that was used in medicinal preparations by ancient Greeks and Romans.[33,40] Abscisic acids are plant hormones that help regulate stressful conditions via control of stomatal closure.[33] In the subtropical areas of eastern Australia, water-stress conditions are likely to induce a production of abscisic acid and its derivatives.

Lumichrome was found in trace amounts in *T. carbonaria* honeys. This compound was reported in mānuka honey by German researchers Oelschlägel et al.,[10] as well as in Mediteranean thistle (*Galactites tomentosa* Moench) honeys along with phenyllactic acid.[30] Lumichrome and its carboxyl derivative were indicated as characteristic floral markers of cornflower (*Centaurea cyanus*) honeys from Romania and Germany.[5] Lumichrome is a breakdown product of riboflavin, and it is formed under photochemical-induced conditions, is a plant-growth regulator, and is a constituent of unifloral honeys from Dalmatian sage (*Salvia officinalis* L.).[41] It was not found in previous analyses of *Eucalyptus* monofloral honeys of honeybees, and therefore its botanical origin in Australian stingless bee honeys remains to be determined.

3-Phenyllactic acid is a compound commonly found in honey, including *Leptospermum* mānuka varieties.[10,30] This phenolic is also common in kanuka honey from New Zealand *Kunzea ericoides* (Myrtaceae)[8] and in Australian leatherwood honeys (*Eucryphia lucida*);[27] it was linked to the sensorial notes of thistle honey[30] and found across the three investigated honeys, although being a predominant marker in honey 2.

Investigations of *Leptospermum* varieties of jellybush-sugarbag honeys were attempted using *T. carbonaria* stingless bees in two sites of this study. However, no diagnostic chemical markers of *Leptospermum* nectars were detected in *T. carbonaria* honeys: MGO and DHA levels[26] were nil, and the phenolic markers MYSR,[7] leptosin,[31] and flavonoids pinobanksin, galangin, and chrysin were absent.[9] Traces of unedone were detected in the investigated honeys, but this norisoprenoid is a common phytochemical in honeys from Myrtaceae, that is, *Eucalyptus*, and therefore not specific to *Leptospermum* species.[10] When compared to previous chemical analyses of Australian honeybee jellybush honey,[13] the chemical markers reported for this honey were not found in Australian stingless bee honeys of this study. It was concluded that *T. carbonaria* stingless bees might not collect these nectars for their honey production.

Commercial honeys processed through heating or their improper storage can cause the formation of the undesirable cyclic aldehyde HMF. HMF is mutagenic, and thus a limit of 40 mg/kg is warranted for commercialization to reduce the health hazard to food consumers.[25] In stingless bee honeys of this study, HMF levels were nil; therefore, this bee product can suit future uses for food and medicinal purposes.

**Bioactive Constituents of the Extracts.** *T. carbonaria* raw honeys and their phenolic extracts showed in vitro antibacterial effects (Table 3) that were within the reported ranges of 9.7−23.3 mm and 2.3−8.9% (w/v) of phenol equivalents.[16] However, higher values of 26.3% (w/v) were indicated for other *T. carbonaria* honeys and compared to 18.0% for manuka honeys and 13.4% for other *A. mellifera* honeys.[12] Nevertheless, *T. carbonaria* honey at 5.5% (v/v) inhibited the microbial growth consistently with the reported dilution factor of <10%.[16] As the phenolic fractions contributed to an average of 1.1% phenol equivalents against the Gram-positive *S. aureus*, the identified phytochemicals can be considered as one antimicrobial factor linked to the nonperoxide effects of Australian stingless bee honeys.[12,17]

Different results were observed from the antibacterial testing with the two methods used (Table 3). All raw honeys inhibited the bacterial growth when tested by agar diffusion, but no bactericidal effects were observed in broth dilution at the concentrations used. The broth dilution method indicated that the raw honeys were active via bacteriostatic effects on the bacterial strains tested. This method also seemed more sensitive than the agar diffusion method in detecting the bactericidal activity of the phenolic extracts against *K. pneumoniae*. The phenolic extracts did not stop the bacterial growth in agar testing, possibly due to the limited diffusion of phenolic extracts through the hydrophobic agar media. It is possible that such limited diffusion could be affected by the high molecular weight of the glycosylated flavonoids as well as the reduced hydrophilicity of less polar flavonoid aglycones. When tested in broth dilution, the bactericidal effects of the phenolic extracts were attained possibly from the direct exposure of the compounds to the bacterial cells, because there was no physical limitation to the diffusion as experienced in the agar tests. The phenolic extracts proved to be bactericidal against both strains, therefore indicating that the phenolic fractions contribute to the total antibacterial activities of *T. carbonaria* honeys.

The peroxide content in *T. carbonaria* honeys accumulated up to 155 $\mu$M (Table 3) in undiluted and diluted (44.4% v/v) honeys. However, a minimum concentration of 760 $\mu$M $H_2O_2$ was required for bactericidal effects (Table 3). As a comparison, a higher content of 5.62 mM was reported in medical grade honey of *A. mellifera* bees.[6] Therefore, the total antimicrobial effects of *T. carbonaria* honeys were partly ascribed to the peroxide content, and other factors could be accounted for the nonperoxide activity, including the presence of phytochemicals as previously mentioned.

No MGO was detected in *T. carbonaria* honeys of this study; thus, the nonperoxide antimicrobial activity might be derived from other factors. For instance, one peptide called bee defensin-1, also known as royalisin, was previously linked to the nonperoxide activity of honeys.[6] This cationic peptide with bactericidal properties was reported in medical grade honeys,[42]

but not found in mānuka varieties.[6] It remains to be investigated in Australian stingless bee honeys in future work.

roasted under atmospheric pressure.[24] Approximately 79% of AA in coffee beans is removed by a two-step method, in which the first step involves producing a high amount of AA in coffee beans by pre-roasting and the second step involves decreasing the AA by supercritical $CO_2$ extraction.[25]

The purpose of the present study is to investigate how to decrease the AA content in canned coffee using heat treatment used for sterilization during the manufacturing process of canned coffee. This study might provide us with useful insights for producing healthy and safe coffee drinks.

## MATERIALS AND METHODS

**Materials and Reagents.** L-Cysteine (lot M1P3255), L-alanine (lot M1K9848), glycine (lot M6T9022), L-glutamic acid (lot M1M1635), L-glutamine (lot M1R7813), L-arginine (lot M1M1478), L-asparatic acid (lot M1N2683), L-asparagine (lot M2F9008), L-lysine (lot M1H0151), L-histidine (lot M1R4253), L-serine (lot M1H0189), L-leucine (lot M1T9167), L-isoleucine (lot M2A1588), L-valine (lot M1T1361), L-methionine (lot M4G1363), L-(−)-proline (lot M1N2357), L-threonine (lot M1R4350), L-tryptophan (lot M1H0273), L-tyrosine (lot M1H005), L-phenylalanine (lot M1H2655), dithiothreitol (lot M2A6379), L-(−)-cystine (lot M1R4150), *myo*-inositol (lot M7R9559), L-(+)-ascorbic acid (lot M7T9666), β-cyclodextrin (lot M2P9788), hexane (lot V1K6074), acetone (lot V9P1472), and methanol (lot M2E7208) were purchased from Nacalai Tesque (Kyoto, Japan). Catechin mixture from green tea (lot CDR4267), casein phosphopeptide (lot TSM1329), casein sodium (lot TSH4729), 1 mol/L sodium thiosulfate solution (lot STK4553), 0.05 mol/L bromine solution (lot STH6224), hydrobromic acid (STG0833), potassium bromide (lot HLH7661), AA standard solution (1 mg/mL methanol solution) (lot DCQ3733), and AA (1,2,3-$^{13}C_3$) (1 mg/mL in methanol) (lot SDBF-014) were purchased from Wako Pure Chemicals (Osaka, Japan). D-(+)-Glucose (lot 011W2262) and ethyl acetate (lot 401U1600) were from Kanto Chemical (Tokyo, Japan). Strata-X-C (33 μm, cation mixed-mode polymeric sorbent) and Strata C18-E were from Phenomenex (Torrance, CA). InertSep slim-J active carbon (400 mg) was from GL Science (Tokyo, Japan). Canned coffee and roasted barley tea beverages were purchased at local markets and stored in a refrigerator at 4 °C before use.

**Heat Treatment.** A total of 190 g of the canned coffee and various amounts of the additives were put into a 200 mL flask and mixed at room temperature. The mixture was placed into a new stainless-steel can. A stainless-steel lid was placed on the can containing the mixture and was sealed using a seamer (M-2 semi-automatic seamer, Toyo Seikan, Tokyo, Japan). Next, the can was treated by a retort sterilization apparatus (RCS-40RTGN, Hisaka Works, Osaka, Japan) at 121 °C for 6 min. This process is commonly undertaken in manufacturing canned coffee. The heat-treated cans were immediately cooled in an ice water bath and stored in a refrigerator at 4 °C until further use.

**Preparation of Brominated Samples for the Analysis of AA.** A total of 100 g of the sample was put into a 100 mL flask, followed by the addition of 5 μL of 100 ppm of internal standard solution ($^{13}C_3$-AA prepared in methanol). The combined mixture was applied to a column connected to a Strata C18-E column and an InertSep slim-J active carbon column, and the solution passed through the column was discarded. Only the InertSep slim-J active carbon column was removed from the connected column, and it was dried under reducing pressure at 35 °C for 30 min using an evaporator. The absorption was eluted by the addition of 7 mL of acetone and collected in a 15 mL spitz tube. Subsequently, 300 μL of deionized water was added to the spitz tube and dried under reducing pressure at 35 °C for 5 min using an evaporator to remove the acetone. The solution volume in the spitz tube was adjusted to 1 mL with deionized water. Then, the solution (1 mL) was applied to a Strata-X-C column. Subsequently, 4 mL of deionized water was applied to the column. The first 1 mL of the eluate was discarded, and the subsequent 3 mL was collected in the spitz tube. The collected solution (3 mL) was mixed with 2 mL of a bromination reagent (a mixture of 15 g of KBr, 1.2 mL of HBr, 7.5 mL of $Br_2$ solution, and 30 mL of deionized water) and incubated in the dark for 1 h. The bromination reaction was stopped by adding 100 μL of 1 M sodium thiosulfate solution, and the volume of the reaction mixture was adjusted to 6 mL with deionized water. After 2 mL of hexane was added to the mixture and agitated vigorously, the hexane layer was discarded and the aqueous layer was collected in the spitz tube. A total of 1 g of NaCl was then added to the tube. After 2 mL of ethyl acetate was added to the tube and stirred vigorously, the ethyl acetate layer was collected in another spitz tube. This operation to recover the ethyl acetate layer was performed 3 times with the spitz tube. The spitz tube containing the ethyl acetate layer was placed in a block heater (dry thermo unit DTU-1C, Taitec, Tokyo, Japan), and the volume of the mixture in the tube was reduced with a nitrogen gas purge to less than 0.3 mL and then adjusted to 0.5 mL with acetone.

**Analysis of AA in Brominated Samples.** The AA content was analyzed according to the procedures previously reported,[11,23] with slight modifications. $^{13}C_3$-AA is used as the internal standard. The quantification of AA in the brominated samples was performed using gas chromatography−mass spectrometry (GCMS-QP2010, Shimadzu, Kyoto, Japan) equipped with a split−splitless injector and a Zebron ZB-1 capillary column (30 m × 0.32 mm inner diameter, 1.0 μm film thickness, Phenomenex). A total of 2 μL of the brominated sample was injected into the GC−MS system using the splitless flow control mode and then splitting by a ratio of 1:13.5. The flow of the helium carrier gas was maintained at 55 cm/s using a constant linear velocity mode. The temperatures of the ion source, interface, and vaporization chamber were set at 230, 270, and 270 °C, respectively. The temperature of the column oven was programmed as follows: isothermal at 70 °C for 1 min, increasing from 70 to 120 °C at a rate of 12 °C/min, increasing from 120 to 160 °C at a rate of 5 °C/min, increasing from 160 to 300 °C at a rate of 20 °C/min, and then subjected to isothermal conditions at 300 °C for 5 min. Analysis was performed using the electric impact mode at 70 eV and the single ion monitoring (SIM) mode. The SIM ions selected for identification of 2,3-dibromopropionamide and $^{13}C_3$-dibromopropionamide were $m/z$ 150, 106, and 152 and $m/z$ 155, 110, and 153, respectively. The recovery of AA from canned black coffee was 90.7 ± 2.6% in triplicate experiments. The lowest level of detection (LOD) and the lowest level of quantification (LOQ) for AA were 0.03 and 0.1 ppb, respectively.

## RESULTS AND DISCUSSION

**Effect of the Heat Treatment with the Addition of Additives on the AA in Canned Black Coffee.** The AA content in the commercially available canned black coffee investigated in this study was 6.2 ± 0.2 ppb with three different samples (Figure 1). Previous studies on approximately 30 types of canned coffee in Japan have shown results for the AA content in the range of 5−14 ppb,[22] and our result was in this range. The AA content in major foods is reported to be in the ranges of 170−3700 ppb for potato chips and crisps, 200−12 000 ppb for French fries, and 64−457 ppb for nuts.[26] Commercially available canned coffee contains AA. However, the levels are significantly less than those in other processed foods mentioned above. The AA contents in ground coffee and coffee brews were reported to be in the range of 210−330 and 6−66.7 ppb, respectively.[27,28] It has been reported that AA in coffee beans is extracted approximately 100% by brewing.[29] Therefore, we can conclude that the difference in the AA content in canned coffee and coffee brews might be caused by the dilution by water during the preparation process.

The AA content in canned black coffee after heat treatment at 121 °C for 6 min decreased slightly to be 6.0 ± 0.1 ppb (Figure 1). The heat treatment process used in this experiment is typical of the heat sterilization process used in manufacturing canned coffee. Recently, it has been reported that the AA

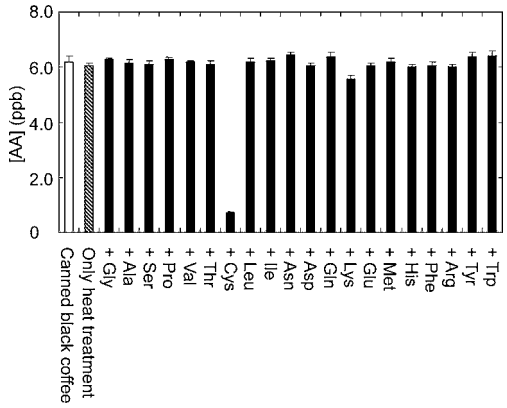

**Figure 1.** AA content in canned black coffee after heat treatment with and without the addition of amino acid at 121 °C for 6 min: (open bar) canned black coffee, (hatched bar) canned black coffee after the heat treatment at 121 °C for 6 min, and (closed bar) 190 g of canned black coffee after heat treatment with 200 mg of each amino acid at 121 °C for 6 min. The AA content in canned black coffee is defined as 100% (control). Each bar represents the mean and standard deviation of triplicate experiments.

content in coffee decreases in the reaction of melanoidins in coffee with AA at 180 °C for 2−12 min.[30] In addition, it has been reported that the residual ratios of AA after heat treatment of 2.8 mM AA aqueous solution for 2 h at 160, 180, and 200 °C are 95, 90, and 80%, respectively.[31] Therefore, it is considered that AA in canned coffee is decreased by heat treatment at 121 °C for 6 min, accompanying with thermal decomposition of AA or conversion to other compounds by combining AA with other components, such as melanoidins.

A total of 200 mg of each amino acid, out of 18 amino acids, except lysine (Lys) and cysteine (Cys), was added to 190 g of canned black coffee. Then, the mixture was treated at 121 °C for 6 min. The relative values of the AA contents contained in the canned coffee after the heat treatment with these amino acids were in the range of 97−104% to that (6.2 ± 0.1 ppb as 100%) in the canned coffee heat treated without amino acids (Figure 1). On the other hand, the relative AA content in the canned coffee after heat treatment with 200 mg of Lys at 121 °C for 6 min decreased to approximately 90% to be 5.6 ± 0.1 ppb (Figure 1). In addition, when 200 mg of Cys was added, the relative AA content decreased remarkably to approximately 10% to be 0.7 ± 0.0 ppb. It was already reported that the AA content was decreased by amino acids, including Cys, Gly, Lys, Arg, Asp, Gln, Glu, Ser, Ala, Tyr, and Val, when 50 mM of each amino acid was added to olive oil juice, followed by heat treatment at 121 °C for 30 min.[32] In this report, the AA-decreasing effect of Cys was the highest. However, the effects of Gly, Gln, and Val are different from our results (Figure 1). The effects of Arg, Asp, Glu, Ser, Ala, and Tyr were not significant, and the residual AA contents for the canned coffee heat treated with these amino acids were almost equivalent to those without amino acids. Of the 20 amino acids examined in this experiment, Cys gives the greatest AA-decreasing effect, followed closely by Lys (Figure 1). The AA-decreasing effects by heat treatment with the addition of Cys and Lys at 121 °C for 6 min were similar to the effects found in the previous study on olive oil juice.[32] It is reported that AA disappears as a result of the nucleophilic attack of a $NH_2$ group of Lys and a SH group of Cys to the C═C double bond of AA.[31,33,34]

The residual AA content in 190 g of canned black coffee after the heat treatment at 121 °C for 6 min with adding 200 mg of dithiothreitol having 2 SH groups was 2.8 ± 0.2 ppb, representing 55 ± 3% of the initial AA content (Figure 2).

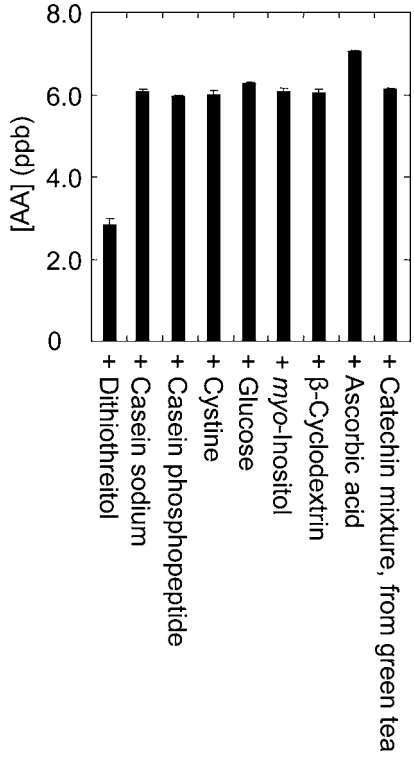

**Figure 2.** AA content in canned black coffee after heat treatment at 121 °C for 6 min with the addition of 200 mg of each compound to 190 g of the canned coffee. Each bar represents the mean and standard deviation of triplicate experiments.

The AA content after the heat treatment with 200 mg of cystine, in which two Cys molecules are combined by a disulfide bond, was substantially the same as that of the coffee that underwent the heat treatment without additives (Figures 1 and 2). From these results, we can conclude that SH groups play an important role in decreasing the AA content in coffee. The content after the heat treatment with 200 mg of ascorbic acid was 7.0 ± 0.1 ppb, being 10% higher than that of the initial value (Figure 2). It has been reported that 14.7 μg of AA is generated when a dried mixture, which was prepared by drying 5 mL of the Asp solution (10 mg/mL) containing ascorbic acid (10 mg/mL) and starch (1 g/mL) as a carrier substance at 110 °C for 30 min, was heated at 170 °C for 1 h in a drying oven.[35] In the same study, it has been also reported that the amount of AA generated by the dried mixture without ascorbic acid is 9.8 μg, being lower than that generated by the mixture prepared with ascorbic acid. In addition, 0.66 μg of AA is generated when a dried mixture, which was prepared by drying 5 mL of an ascorbic acid solution (10 mg/mL) containing ammonium acetate (5 mg/mL) as a source for amino nitrogen and starch (1 g/mL) at 110 °C for 30 min, was heated at 170 °C for 1 h in a drying oven. On the other hand, it has been reported that the AA content decreases by 23.4 and 27.1% by the treatment of a mixture of 2.8 mM AA and 2.8 or 5.8 mM ascorbic acid at 180 °C for 2 h.[31] Future studies are required to clarify the effect of ascorbic acid on the generation of AA examined under different

conditions, investigating the effects of reaction time, temperatures, additives, etc.

**Effects of Cys, Lys, and Arg on Decreasing the AA Content in Canned Coffee.** Figure 3 shows the AA-decreasing effects of heat treatment with the addition of Cys, Lys, and Arg at 121 °C for 6 min in canned coffee. The AA contents in the heat-treated canned coffee decreased with increasing the concentration of these amino acids (Figure 3). The amounts of Cys required to decrease the AA content by 50% was 69.3 ± 1.9 mg. The AA content after the heat treatment with 300 mg of Cys decreased to 0.3 ± 0.1 ppb. Although no countries have placed regulations on the AA content in food and beverages, the maximum safe level of AA in tap water has been set to 0.5 ppb by the WHO. It has been suggested that the AA content in canned black coffee can be decreased to the level below this value by the heat treatment at 121 °C for 6 min with 300 mg of Cys. Similarly, the AA content after the heat treatment with 200 and 300 mg of Lys decreased to 5.6 ± 0.2 and 5.2 ± 0.1 ppb, respectively (Figure 3). The contents after the heat treatment with 200 and 300 mg of Arg were similar as 6.0 ± 0.1 and 5.9 ± 0.1 ppb, respectively (Figure 3). The AA-decreasing effect of Cys is much greater than that of Lys and Arg.

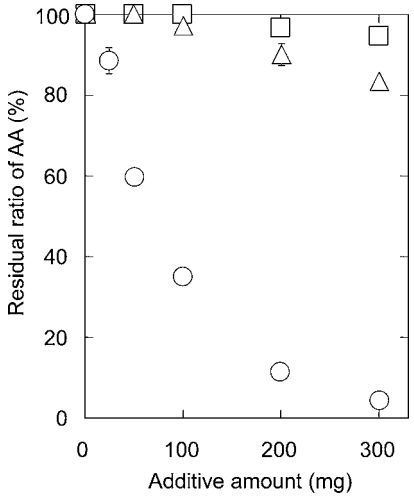

**Figure 3.** Dependence of the concentrations of Cys, Lys, and Arg upon AA decreasing in 190 g of canned black coffee after the heat treatment with the addition of them at 121 °C for 6 min: (○) Cys, (△) Lys, and (□) Arg. Each bar represents the mean and standard deviation of triplicate experiments.

The AA content in medium-roasted coffee beans manufactured under vacuum pressure is approximately 50% less than that in medium-roasted beans manufactured under atmospheric pressure.[24] Approximately 79% of AA in coffee beans can be removed using a two-step method, which consists of the first step producing a high amount of AA in coffee beans by roasting and the second step reducing AA from the coffee beans by supercritical $CO_2$ extraction.[25] The AA content in instant coffee is decreased by 70% with the addition of sucrose and baker's yeast with fermentation at 30 °C for 2 days.[36] These methods are effective but costly and less practical, with special processes being required. These processes are not for the typical manufacturing of canned coffee. Our method can be implemented using normal manufacturing processes and provides an economical benefit to manufacturers. The only cost associated with our method is the raw material cost of Cys, and the heat-treatment time is short. Therefore, we believe that our method is one of the effective means for decreasing AA in canned coffee. However, there are subjects to be investigated further. It is considered that AA might be decreased in the heat treatment with the addition of Cys by converting to cystein-*S*-*β*-propionamide and others, in which Cys and AA are combined by the Michael addition reaction.[31] It has been reported that 0.1, 0.7, and 7.1% (w/w) of AA are generated after heat treatment of cysteine-*S*-*β*-propionamide for 2 h at 60, 120, and 180 °C, respectively.[31] It is necessary to verify about regeneration of AA in the heat-treated canned coffee by our method. In particular, verification of AA regeneration in long-term storage at low temperatures (4−25 °C) is important, because canned coffee is usually drank as refrigerated goods and stored at refrigerated or room temperature. In addition, it is needed to evaluate the toxicity of these products.

**Effect of the Heat Treatment with the Addition of Cys on AA in Canned Milk Coffee and Roasted Barley Tea.** Figure 4 shows the AA-decreasing effects of the heat treatment with the addition of 200 mg of Cys at 121 °C for 6 min to 190 g of commercially available canned milk coffee. The initial AA content was 6.2 ± 0.2 ppb, and the content after the heat treatment with 200 mg of Cys was 0.2 ± 0.0 ppb (Figure 4). It was shown that our method can be applicable to canned milk coffee as well as black coffee. The content in commercially roasted barley tea was 3.9 ± 0.1 ppb and decreased to 0.2 ± 0.0 ppb after the heat treatment with 200 mg of Cys at 121 °C for 6 min (Figure 4). The treatment is also effective for roasted barley tea. It has been reported that approximately 90% of AA can be removed but acrylic acid is generated when roasted green tea containing *Aspergillus oryzae* KBN1010 or *A. oryzae* No. 100 is incubated at 30 °C for 3 days.[37] Our method might be more simple and easier to carry out than the above-mentioned method using *A. oryzae*.

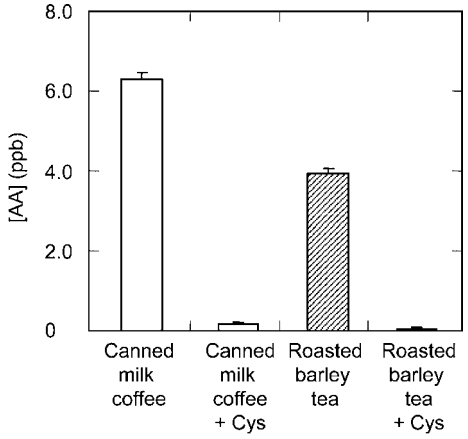

**Figure 4.** AA content in canned milk coffee and roasted barley tea before and after heat treatment with the addition of 200 mg of Cys at 121 °C for 6 min to 190 g of samples: (open bar) 190 g of canned milk coffee before and after heat treatment with the addition of 200 mg of Cys at 121 °C for 6 min and (hatched bar) 190 g of roasted barley tea before and after heat treatment with the addition of 200 mg of Cys at 121 °C for 6 min. Each bar represents the mean and standard deviation of triplicate experiments.

(IR) spectroscopy which is limited by the strong IR absorbance of water. The objective of this study is to use Raman spectroscopy with a range of external and internal standards to identify and quantify the calcium phosphate that forms in response to $CaCl_2$ addition to bovine milk. The study combines the Raman analysis with standard wet chemical analyses to determine the re-distribution of calcium, phosphate, and the major inorganic milk constituents in response to $CaCl_2$ addition to milk and compares this to the solubility product of the calcium phosphate minerals.

## MATERIALS AND METHODS

**Chemicals.** All water used in the experiments was Milli-Q water with a resistivity of 18.2 MΩ·cm. The $CaCl_2$, NaOH, trichloroacetic acid (TCA), and $LaCl_3{\cdot}7H_2O$ were purchased from Sigma-Aldrich. The $NH_4OH$, $(NH_4)_2HPO_4$, $Na_2HPO_4$, $CaCl_2{\cdot}2H_2O$, $H_3PO_4$, and boric acid were purchased from AJAX Finechem while the $NaNO_3$ was from Fluka.

**Milk Samples.** The milk was prepared from a low-heat skim milk powder sample supplied by Westland Co-operative Dairy Co. Ltd., Hokitika, New Zealand, and had a composition of 35.5% protein and 1.25% fat. A stock skim milk was prepared with 20% (w/w) skim milk powder in Milli-Q water and was stirred for 2 h on a magnetic stirrer to ensure complete dispersal of the powder. Calcium fortification between 5 and 50 mM was achieved by adding the appropriate amounts of 0.2 M $CaCl_2$ solution to the milk. After 3 h at room temperature, the pH was adjusted back to 6.7, water was added to take the milk to 11.1% (w/w) solids, and this was left overnight at room temperature. The pH was again adjusted to 6.7 and water added to produce the final milk with 10% (w/w) solids. Changes in pH over time were manually corrected, and the sample was held until there was no further drift in pH. To achieve phase separation between the micellar and serum phases, the milk samples were ultracentrifuged at 20 °C and 38000*g* for 1 h using an Avanti-J-30I instrument with JA-25.50 rotor (Beckman Coulter, Brea, CA, USA). The supernatants were immediately collected by decantation and centrifuged again at 3000 rpm for 30 min in Vivaspin Turbo 15 containing poly(ether sulfone) membranes with molecular weight cutoff inferior to 10 kDa (Sartorius Stedim Biotech GmbH, Goettingen, Germany). These samples are termed the milk sera, and the pellets remaining after ultracentrifugation are the milk pellet samples.

**Preparation of Reference Calcium Phosphate Phases.** Standard methods were used to prepare the reference calcium phosphate phases. Amorphous calcium phosphate was prepared by rapidly adding a calcium solution (46.3 g of $Ca(NO_3)_2{\cdot}4H_2O$ in 550 mL of water containing 40 mL of 28% $NH_4OH$) to a phosphate solution (27.2 g of $(NH_4)_2HPO_4$ in 1,300 mL of water containing 40 mL of 28% $NH_4OH$).[15] The resulting precipitate was immediately filtered, washed, and freeze-dried. Dicalcium phosphate dihydrate (DCPD, $CaHPO_4{\cdot}2H_2O$) was prepared by rapidly adding a calcium solution (4.014 g of $CaCl_2{\cdot}2H_2O$ in 200 mL of water at pH 5.5) to a phosphate solution (0.825 g of $KH_2PO_4$ in 700 mL of water and then addition of 3.01 g of $Na_2HPO_4$, pH 7.4), aging for 80 min, and then filtration and drying at 65 °C.[16] The $\beta$-tricalcium phosphate ($\beta$-TCP, $\beta$-$Ca_3(PO_4)_2$) was prepared by dropwise addition of a calcium solution (71.9 g of $Ca(NO_3)_2{\cdot}4H_2O$ in 250 mL of water at pH 6.30) to a phosphate solution (27.0 g of $(NH_4)_2HPO_4$ in 250 mL of water at pH 8.28) over 150 min while vigorously stirring and maintaining the pH at 8 by manually adding NaOH.[17] The suspension was stirred for 12 h, and solids were filtered, washed, dried at 80 °C, and then calcined at 700 °C for 2 h. Octacalcium phosphate (OCP, $Ca_8H_2(PO_4)_6{\cdot}5H_2O$) was prepared by adding 11.69 g of concentrated $H_3PO_4$ and 13.3 g of $CaCO_3$ to 1 L of water, stirring for 6 h at 60 °C, and followed by filtration and drying at 60 °C.[18] Hydroxylapatite (HAP, $Ca_5OH(PO_4)_3$) was prepared by dropwise addition of a phosphate solution (25.87 g of $(NH_4)_2HPO_4$ in 150 mL of water, pH to 11 with ≈80 mL of $NH_4OH$ and then dilution to 320 mL) to a vigorously stirred calcium solution (43.15 g of $Ca(NO_3)_2{\cdot}4H_2O$ in 90 mL of water, pH to 11 with ≈4 mL of 28% $NH_4OH$ and followed by dilution to 180 mL) over 30−40 min.[19] The resultant suspension was stirred for 24 h and centrifuged at 2000 rpm for 10 min and then the solid washed with water and recentrifuged. The resultant white pellet was vacuum filtered for ≈3 h, and then the filter cake was dried at 90 °C.

**Solid Phase Characterization.** Raman spectra were measured using a Renishaw Raman Imaging Microscope System 1000 equipped with a confocal Leica microscope and CCD detector. Spectra were collected using either the 785 or the 488 nm laser as discussed in Results and Discussion. The instrument was calibrated daily using the 1086 $cm^{-1}$ calcite peak. To allow for quantitative information from the spectra, a range of compounds were assessed for suitability as internal standards. The ideal internal standard should have a strong Raman signal but have no peaks in the 910−1110 $cm^{-1}$ region of the spectrum where the characteristic calcium phosphate phases are observed. The internal standard should not interfere with the chemistry of the system, for example by acting as a ligand toward $Ca^{2+}$. Powder X-ray diffraction (XRD) patterns were measured using a Model D5000 Siemens instrument with a Cu K$\alpha$ source operating at 40 kV and 30 mA. Solid samples were crushed to a fine powder and mounted in an aluminum well. XRD data were collected between 2 and 70° 2$\theta$ with a step size of 0.02° 2$\theta$. The morphology and topography were examined using the environmental scanning electron microscopy (ESEM; FEI Quanta 200F, Hillsboro, OR, USA) with large-field detector (LFD) at 0.58 Torr pressure. Samples were mounted on black carbon tape and sputter coated with platinum (Pt) for 15 min using a Quorum Q150RS at 20 mA current and $1 \times 10^{-1}$ mBar chamber pressure.

**Solution Phase Characterization.** Prior to cation analysis, the milk and milk sera samples were treated using the procedure from Fox et al.[20] Initially 1 mL of 24% TCA was added to 2 mL of a 10-fold diluted sample and the mixture shaken for 30 min. Following this, 1 mL of 5% $LaCl_3{\cdot}7H_2O$ was added as an ionization suppressor for the atomic absorption measurement and the samples were diluted to 50.0 mL with water. All samples were centrifuged at 3500 rpm for 30 min, and the resultant supernatants were collected for measurement. Calcium and magnesium were quantified using atomic absorption spectroscopy (AAS) while atomic emission spectroscopy (AES) was used for sodium and potassium. All measurements were made using an air−acetylene flame and parameters described by de la Fuente and Juarez[21] on a Varian AA-1275 series atomic absorption spectrophotometer (Varian Techron Pty. Ltd., Springvale, Australia). The standards for AAS and AES were prepared from TraceCERT grade 1000 ppm reference standards that were diluted and pretreated using the same method as the samples. Phosphorus in the sera was quantified using a colorimetric method based on that by Allen.[22] Initially protein was precipitated by adding 2.5 mL of 24% TCA to 5 mL of a 10-fold diluted sample and the mixture shaken for 30 min, then diluted to 25 mL, and centrifuged at 3500 rpm for 30 min. Supernatant (18 mL) was removed and to this was added 1.17 mL of 70% $HNO_3$, 2 mL of amidol reagent (2 g of 2,4-diaminophenol dihydrochloride and 40 g of sodium bisulphite in 200 mL water) and 1 mL of an 8.3% (w/v) ammonium molybdate reagent. Samples were mixed for 5 min and left to stand for 15 min, and then absorbance was measured at 695 nm and compared to matrix matched standards.

All milk samples were prepared in duplicate, and the error bars on the figures represent one standard deviation. The milk pellet samples with the internal standard for Raman analysis were prepared in duplicate, and the relationship between Raman band intensity and the amount of phosphate removed from the serum was determined by regression analysis using the Data Analysis Tools facility in EXCEL and a 95% confidence interval.

**Modeling the Serum Chemistry.** The distribution of calcium and $P_i$ in the milk without added $CaCl_2$ was modeled using the framework from Holt.[3] The model input concentrations for fat were 0 g $L^{-1}$, while lactose, total protein, and casein were the measured values of 50.1, 35.5, and 27.3 g $L^{-1}$, respectively, and the total concentration of phosphate centers (PCs) was 1.51 mM based on the distribution of phosphate centers per mole of each casein from Holt.[3] The ratios of $Ca^{2+}$, $P_i$, $Mg^{2+}$, and citrate per PC in the nanoclusters were 13.2, 6.5, 1.0, and 0.637, respectively. The model input total cation

concentrations for $Mg^{2+}$, $Na^{+}$, and $K^{+}$ were the measured values of 4.29, 13.9, and 31.3 mM, respectively, while the total anion concentrations for phosphate, sulfate, citrate, and a generic carboxylate ($ROO^{-}$) were 17.2, 0.12, 4.66, and 3.1 mM, respectively. The calcium and chloride values varied with the added $CaCl_2$, the pH was 6.7, and the partial pressure of $CO_2$ was set at 0. Activity coefficients were calculated using the Davies equation except in the cases of $Ca^{2+}$, $Mg^{2+}$, $H^{+}$, and the −3 charged citrate anion where the ion specific Truesdell−Jones equation was used. The solution phase complexation and protonation constants are from Holt.[3]

## RESULTS AND DISCUSSION

**Serum Chemistry.** *Serum Chemistry without Added $Ca^{2+}$.* The measured total concentrations of calcium and $P_i$ in the milk were 28.0 ± 0.8 mM and 17.2 ± 0.1 mM, respectively. These values are at the low end or slightly below the typical ranges of 26−32 mM and 19−23 mM for total calcium and $P_i$, respectively.[23] In the serum phase the corresponding measured concentrations were 7.0 ± 0.5 mM for calcium and 7.5 ± 0.2 mM for the $P_i$ which represent concentrations inferior to 10 kDa fraction. While some of the nondiffusible calcium will be associated with nonmiscellar proteins, the "great majority of the nondiffusible salts are in the form of colloidal calcium phosphate"[3] indicating that approximately 21 mM calcium and 10 mM $P_i$ were contained within the calcium phosphate nanoclusters. The 2:1 ratio of calcium to $P_i$ in the nanoclusters is typical[3] of milk CPNs but does not reflect the calcium phosphate phase because of the inclusion of the casein based phosphorylated serine residues with the structure. The distribution of calcium and $P_i$ between the serum and the CPN was in good agreement with the ion activity product (IAP) of Holt[3] which is $(Ca^{2+})(HPO_4^{2-})^{0.7}(PO_4^{3-})^{0.2}$ where (X) is the activity of species X and the IAP has a value of $10^{-6.80}$, whereas the value calculated from the measured parameters in this work was $10^{-6.81}$. Based on the PC concentration in the milk (1.51 mM) and the Ca:$P_i$:PC ratio in the CPN (13.2:6.5:1), almost 100% of the PCs are incorporated into the CPNs in the milk without added $CaCl_2$.

It is instructive to consider this system with regard to the individual terms in the equation prior to discussing the systems with added calcium. The 7.5 mM $P_i$ in the serum is predominantly present as either $H_2PO_4^{-}$ (4.3 mM) or as complexes with the group I or II cations present in the milk (1.7 mM). The calculated concentration of $HPO_4^{2-}$ is 1.3 mM and the activity coefficient ($\gamma_2$) = 0.45 so $((HPO_4^{2-})^{0.7})$ = $10^{-2.26}$. Because the pH of the milk (6.7) is much lower than the p$K_a$ of $HPO_4^{2-}$ (12.4), the calculated concentration of $PO_4^{3-}$ is very low at 7.4 nM. The activity coefficient ($\gamma_3$) is 0.15 so $((PO_4^{3-})^{0.2})$ = $10^{-1.8}$. In the case of the 7.0 mM serum calcium approximately 3 mM is complexed by citrate while another 1 mM is complexed by inorganic ligands including $HPO_4^{-}$ and $Cl^{-}$. This leaves 3.5 mM free $Ca^{2+}$ in solution and with a $\gamma_2$ of 0.45 the $(Ca^{2+})$ = $10^{-2.80}$. Therefore, the presence of citrate in the serum approximately doubles the solubility of calcium.

Table SI1 (Supporting Information (SI)) gives the algebraic expressions and values for $K_{SP}$ and the calculated serum IAP for each of the calcium phosphate phases. The milk serum is oversaturated with respect to all of the main crystalline calcium phosphate phases and is most oversaturated with respect to HAP with a ratio of the IAP to the $K_{SP}$ of $10^{10.7}$. This means that, all else being equal, the $(Ca^{2+})$ would have to be 140 times lower, i.e., $(10^{10.7})^{0.2}$, for the solution to be saturated with respect to HAP. The failure of HAP to precipitate from the milk serum contrasts with inorganic ACP in an aqueous suspension for which the transformation to HAP can occur on the time scale of minutes to hours. Table SI1 (SI) also gives the $K_{SP}$ and IAP for two ACP phases from Christoffersen et al.,[24] where mixing $CaCl_2$ and $K_2HPO_4$ solutions initially formed an amorphous phase denoted ACP1 followed after a few minutes by formation of a less soluble amorphous phase termed ACP2. The milk is undersaturated with respect to ACP1 but is oversaturated with respect to ACP2.

*Serum Chemistry in Response to Added Calcium.* The measured concentrations of calcium and $P_i$ in the sera of milk with added $CaCl_2$ are shown in Figure 1a. In response to $CaCl_2$

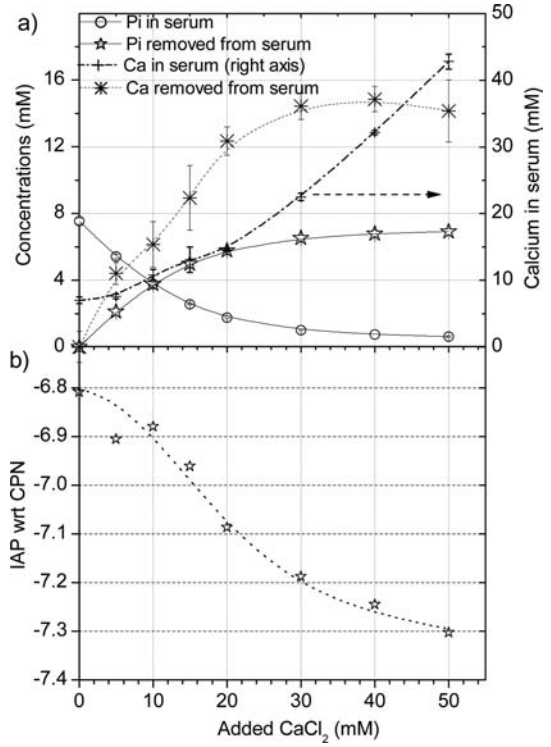

**Figure 1.** Response of milk sera to added $CaCl_2$: (a) measured calcium and Pi in the <10 kDa fraction of the sera and the amount removed from the <10 kDa fraction in response to adding $CaCl_2$ (error bars are 1 standard deviation); (b) calculated ion activity product of the sera with respect to CPN as $CaCl_2$ is added to the milk.

addition to the milk, calcium phosphate is removed from the sera and the $P_i$ concentration in the sera decreases asymptotically toward 0 M. Figure 1a also shows the amount of calcium and $P_i$ that is removed from the sera in response to $CaCl_2$ addition. After 5 mM $CaCl_2$ was added to the milk, 4.4 mM of this added calcium is removed from the sera along with 2.1 mM $P_i$ giving a Ca/$P_i$ ratio removed of 2.1, and this does not change appreciably as more $CaCl_2$ is added. Figure 1b shows the sera IAP with respect to CPN which decreases as $CaCl_2$ is added, falling even after the first 5 mM $CaCl_2$ were added. This presumably reflects the fact that without added $CaCl_2$ essentially all of the PCs were incorporated into the CPNs. Therefore, the addition of just 5 mM $CaCl_2$ results in a change from a CPN system which is thermodynamically stable[12] to the precipitation of metastable calcium phosphate phases. The serum IAP with respect to ACP2 decreases from $10^{-10.8}$ to $10^{-11.1}$ as $CaCl_2$ is added to the milk, and this IAP approaches the ACP2 $K_{SP}$ of $10^{-11.4}$.

**Solid Phase.** *Characterization of the Pure Calcium Phosphate Phases.* The XRD patterns, for the five reference calcium phosphate phases, are shown in Figure SI1 in the Supporting Information. All of the peaks in the XRD patterns correspond to the expected peaks for the synthetic phases with the exception of a small HAP peak present in the XRD pattern for DCPD in addition to a small DCPD peak present in the XRD pattern OCP. As expected for a material with very little long-range order, the ACP has only a very broad weak peak which is present at 30° 2$\theta$ with a very low signal-to-noise ratio. It is clear that XRD will not be useful for detecting the presence of ACP in milk solids. Of the crystalline phases the DCPD had the highest signal-to-noise ratio and the narrowest peaks consistent with the SEM images of the phases (SI Figure SI2) which show that the DCPD had the largest particles with micrometer sized platy crystals. In contrast, the HAP primary particles were not clearly discernible in the SEM and the HAP XRD pattern had the lowest signal-to-noise ratio and the widest peaks. The TCP morphology had sub-micrometer nodules while the OCP had a platy morphology but with smaller plates than the DCPD. The signal-to-noise ratio and the peak widths of the TCP and OCP XRD were, like the particle size, intermediate between those of DCPD and HAP.

The Raman spectra for the five phases (Figure 2) are dominated by the stretching modes of the $PO_4^{3-}$ groups with

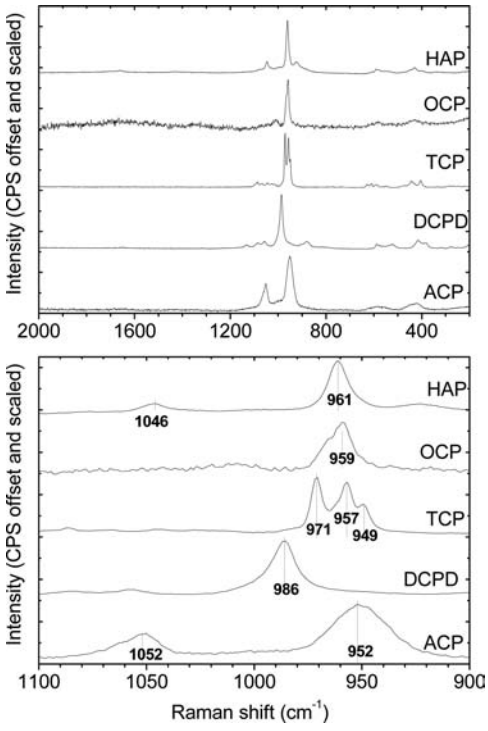

**Figure 2.** Raman spectra measured for the five synthetic calcium phosphate phases using the 488 nm laser. The lower panel has the same spectra with an expanded $x$ axis.

bands between 950 and 1050 $cm^{-1}$. The position and number of bands in the Raman spectra are a reflection of the local environment around the $PO_4^{3-}$ groups in each phase. The Raman spectra of the five phases agree with previously reported spectra,[25−27] and there was little difference in the peak positions or the relative intensities of peaks in spectra measured with a 785 or 488 nm excitation laser. It is clear the ACP Raman spectrum is distinctive, and unlike the XRD patterns, allows for the definitive identification of the phase. With a combination of Raman and XRD, all of the possible phases can be distinguished.

*Characterization of the Calcium Phosphate Phase in Milk.* The XRD patterns of freeze-dried milk pellets obtained from ultracentrifugation of the milk and milk with 40 mM $CaCl_2$ added both have a broad peak at 20° 2$\theta$ as the main feature, and there are no peaks indicative of crystalline calcium phosphate phases. To explore the limits of crystalline phase detection by XRD, samples of freeze-dried pellets were prepared into which known amounts of each synthetic crystalline calcium phosphate standard had been added and homogenized by grinding in a ball mill at −80 °C. The mass of each phase added was the same as the amount of calcium phosphate precipitated in response to $CaCl_2$ addition as calculated from the decrease in $P_i$. For each of the milk pellets with an added crystalline phase there were peaks corresponding with the major peaks of the added standard clearly present in the diffraction patterns. This suggests that crystalline calcium phosphate phases are not formed in response to $CaCl_2$ addition.

The Raman spectra of freeze-dried samples of milk and milk with 40 mM $CaCl_2$ that were measured with the 785 nm laser are shown in Figure 3. The spectra were baseline corrected to

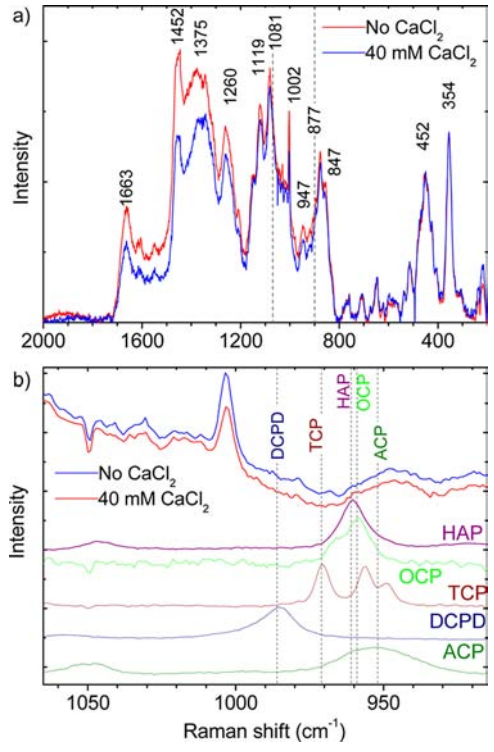

**Figure 3.** Raman spectra measured for the freeze-dried milk and milk with 40 mM of added $CaCl_2$. The main peaks are assigned in SI Table SI2. Panel b shows the $PO_4^{3-}$ stretching region of the spectra with the spectra for five synthetic crystalline calcium phosphate phases.

remove fluorescence, and the intensities of the two spectra were normalized to the lactose band at 354 $cm^{-1}$ because the lactose content in freeze-dried samples will be independent of the added calcium. The main peaks present in the spectra are assigned as previously described, and details are given in Table SI2 (Supporting Information). In the $PO_4^{3-}$ stretching region of both spectra there is a large narrow band at 1002 $cm^{-1}$ which

is due to the phenylanaline ring breathing mode.[28] In addition there is a small broad feature centered at 947 $cm^{-1}$ which is not symmetric and may contain more than one band, one of which could be ACP (Figure 3b). The height of the 947 $cm^{-1}$ feature does not appear to increase with the addition of $CaCl_2$; however, no additional peaks were observed in this region, indicating that no additional phases were detected. Overall, however, the spectra are not particularly convincing regarding the nature of the calcium phosphate removed from the serum in response to $CaCl_2$ addition.

*Raman with an Internal Standard.* The Raman spectra in Figure 3 were of freeze-dried milk which therefore includes the entire content of the serum which precipitates during the drying process. This was done so that the lactose present in milk could serve as an internal reference for the quantification of peaks in the spectra. An internal standard is required because the intensity of peaks in Raman spectra are not directly proportional to the sample composition because of a dependence on factors that affect the scattering phenomena of the sample. However, there are many constituents in the serum that will make the spectra more complex. To avoid the confounding effect of sera contents on the spectra, it is desirable to take spectra of pellets collected by ultracentrifugation. The lactose peaks in these spectra were very small which necessitated the addition of an internal standard. The ideal internal standard needs to meet many criteria such as being water soluble and chemically inert in relation to the $P_i$, calcium, and caseins in the system. The standard needs to have an intense Raman band for referencing peak heights to but also needs to have no bands in the $PO_4^{3-}$ region of the spectra. The compound cannot be volatile or prone to hydrolysis or oxidation. Many small organic molecules were investigated, including D-(+)-galactose, $\beta$-D-fructose, D-glucose, sorbitol, mannitol, and bis tris, HEPES, but these invariably had peaks in the 950−1050 $cm^{-1}$ region of the spectra. Boric acid is a small symmetrical molecule with a simple Raman spectrum which was considered promising with a strong peak at 881 $cm^{-1}$. However, $H_3BO_3$ reacts with the vicinal diols of sugars and therefore could not be used for the milk system.

For these reasons sodium nitrate was used as the internal standard. The $NaNO_3$ Raman spectrum has two strong bands at 1068 and 186 $cm^{-1}$ and weak bands at 726 and 1387 $cm^{-1}$. The nitrate anion is a very weak ligand and does not appreciably coordinate to cations such as $Ca^{2+}$. The only shortcoming of using $NaNO_3$ as an internal standard in this system is that it will raise the ionic strength of the milk and this will affect the solubility of the solid phases by decreasing the activity coefficient of the ions in solution. Therefore, the $NaNO_3$ was added to the milk just before the ultracentrifugation step, and the serum calcium of the systems with added $NaNO_3$ was monitored to determine the effect of the $NaNO_3$ on solubility.

Milk samples having 0, 20, or 40 mM added $CaCl_2$ were prepared with $NaNO_3$ as an internal standard. The Raman spectra of freeze-dried pellets collected by ultracentrifugation of milks with 0.4 M added $NaNO_3$ are shown in Figure 4 with the intensity scale normalized to the height of the $NO_3^-$ peak at 1045 $cm^{-1}$. The spectra are much simpler (i.e., contain less peaks) than the spectra of freeze-dried milk, particularly in the region at <1000 $cm^{-1}$. Because the Raman spectra are collected with a microscope objective, it is important to verify the homogeneity of the internal standard at this spatial resolution. Therefore, spectra were measured at several positions on the sample, and the ratios of the areas of the $NO_3^-$ peak at 1045 $cm^{-1}$ and phenylanaline ring breathing peak at 1002 $cm^{-2}$ were compared. Across the various sample positions the average peak area ratio was 4.1 with a $\sigma$ = 0.2, suggesting a homogeneity within 5% which is adequate for this study.

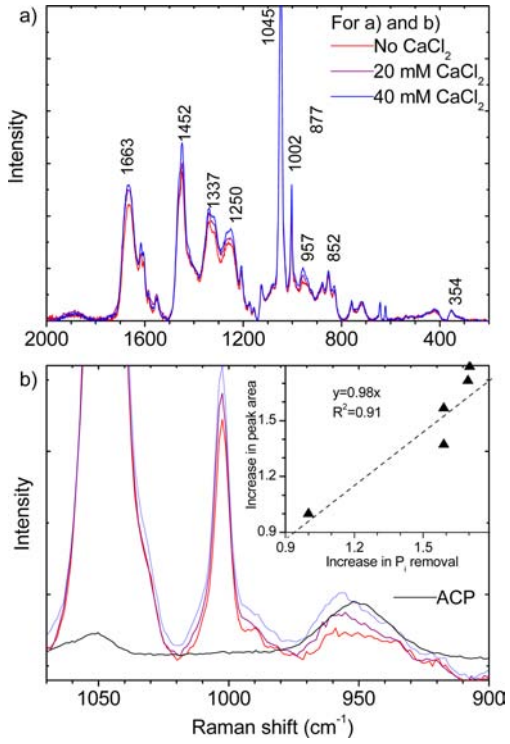

**Figure 4.** Raman spectra measured for the freeze-dried pellets from ultracentrifuged milk with 0, 20, or 40 mM added $CaCl_2$. Panel b shows the $PO_4^{3-}$ stretching region of the spectra with the spectra for the synthetic ACP calcium phosphate phase. Insert: Proportional increase in the area of the $PO_4^{3-}$ stretching band and the amount of $P_i$ removed from solution after 0, 20, or 40 mM $CaCl_2$ addition.

In the lower panel of Figure 4 the $PO_4^{3-}$ stretching region of the spectra is shown, again with the intensity normalized to the $NO_3^-$ band at 1045 $cm^{-1}$. In this view it is clear that the shape and position of the band at 957 $cm^{-1}$ is close to that of the ACP Raman spectrum. In addition as $CaCl_2$ is added to the system and calcium phosphate precipitates, the size of this band increases. In the milk with no added $CaCl_2$ the total concentration of $P_i$ was 17.2 ± 0.1 with 7.5 ± 0.2 $P_i$ in the serum, and adding $CaCl_2$ reduced the serum $P_i$ concentration to almost 0 mM, meaning that there would be 70% more calcium phosphate in the solid phase. If all of the calcium phosphate that precipitated in response to $CaCl_2$ addition is present as ACP, it would be expected that the area of the band centered at 957 $cm^{-1}$ would also increase by 70%. To test this, the areas of the bands were calculated using a baseline from 920 to 975 $cm^{-1}$ and the proportional increase in band area due to added $CaCl_2$ was plotted against the calculated proportional increase in calcium phosphate precipitate. The six data points from replicates with 0, 20, and 40 mM added $CaCl_2$ had a linear relation with a slope of 0.98 ± 0.03 and an $R^2$ = 0.91 and are shown in the insert in Figure 4b. This is reasonably convincing evidence that the calcium phosphate that precipitates in response to $CaCl_2$ addition is in fact an amorphous phase much like the phase that is present in milk with no added $CaCl_2$. Therefore, this work has for the first time demonstrated

the application of Raman spectroscopy using internal and external standards to the qualitative and quantitative determination of the calcium phosphate that forms in response to $Ca^{2+}$ fortification of bovine milk.

Acetonitrile and methanol (chromatographic grade) were purchased from Merck (Darmstadt, FR, Germany).

**Materials.** Ripe Pu-er tea, produced from the crude green tea prepared with leaves of *C. sinensis* var. *assamica*, was provided by Menghai Tea Factory, Yunnan Province, China, in 2007. These materials were identified by Prof. Ying-Jun Zhang, Kunming Institute of Botany, Chinese Academy of Sciences.

**Extraction and Isolation.** Ripe Pu-er tea (1.0 kg) was extracted with hot water (10 L, 100 °C for 30 min) for three times and filtered. The combined filtrate was concentrated to small volume (2 L) and then partitioned with $CHCl_3$, EtOAc, and *n*-BuOH, consecutively. The *n*-BuOH fraction (56.8 g) was applied to a MCI gel CHP20P column chromatography (CC), eluting with water containing increased proportions of MeOH (10% stepwise gradient, each 700 mL) to give six fractions 1−6. Fraction 2 (4.7 g) was chromatographed over MCI gel CHP20P (0−20% MeOH), Toyopearl HW-40F (0−40% MeOH), and Sephadex LH-20 (100% EtOH) columns to afford compound **20** (10.0 mg). Fraction 3 (6.0 g) was chromatographed over MCI gel CHP20P (0−20% MeOH) to yield five subfractions, Fr.3−1 to Fr.3−5. Fr.3−2 was repeatedly subjected to CC over Toyopearl HW-40F (0−20% MeOH) and MCI gel CHP20P (0−20% MeOH) to yield compound **21** (7.0 mg). Fr.3−4 was subjected to CC over Toyopearl HW-40F (0−20% MeOH) and MCI gel CHP20P (0−20% MeOH) to yield compound **18** (7.0 mg). Fr.3−5 was chromatographed over MCI gel CHP20P (30%−100% MeOH) and Toyopearl HW-40F (0−20% MeOH) to yield compound **19** (7.0 mg). Fraction 4 (14.3 g) was chromatographed over Sephadex LH-20 (0−50% MeOH) to yield six subfractions, Fr.4−1 to Fr.4−6.Fr.4−3 was chromatographed repeatedly over MCI gel CHP20P (10%−60% MeOH) and Toyopearl HW-40F (0−20% MeOH) to yield compounds **6** (26.0 mg), **7** (52.0 mg). and **8** (6.0 mg). Fr.4−4, 4−5 and 4−6 were repeatedly subjected to CC over Toyopearl HW-40F (0−30% MeOH), MCI gel CHP 20P (10%−30% MeOH), and semipreparative HPLC (26% MeOH) to yield compounds **1** (5.0 mg), **2** (3.0 mg), **3** (10.0 mg), **4** (60.0 mg), and **5** (9.0 mg). Fraction 5 (14.8 g) was chromatographed over Sephadex LH-20 (30−100% MeOH) to yield four subfractions, Fr.5−1 to Fr.5−4. Fr.5−1 was subjected to CC over Toyopearl HW-40F (40−70% MeOH), MCI gel CHP20P (30−70% MeOH) and silica gel ($CHCl_3$−MeOH−$H_2O$, 8:2:0.2−7.5:2.5:0.2) to yield compounds **9** (18.0 mg), **10** (9.0 mg), and **11** (10.0 mg). Fr.5−2 was repeatedly subjected to CC over Sephadex LH-20 (100% MeOH), MCI gel CHP20P (30−70% MeOH) and silica gel ($CHCl_3$−MeOH−$H_2O$, 8:2:0.2) to yield compounds **12** (24.0 mg), **13** (3.0 mg), and **22** (7.0 mg). Fr.5−4 was subjected to CC over MCI gel CHP20P (30−70% MeOH), and Toyopearl HW-40F (60−100% MeOH) to yield two mixtures of compounds **14** and **15** (24.0 mg), and **16** and **17** (22.0 mg).

**HPLC Analysis for Identification of the Constituents.** The optimal mobile phase for analysis of fractions of *n*-BuOH fraction of Pu-er tea was a binary gradient elution system consisting of solvent A (Aceonitrile) and solvent B (Water containing 0.34% phosphoric acid). The gradient program used started from 4 to 40% of solvent A in solvent B within 40 min at a flow rate of 0.8 mL/min. The injection volume was 10 $\mu$L. The UV detection wavelength was monitored at 210 nm. The peaks were confirmed by the UV absorptions and retention times of authentic samples, which were 6.9 (**22**), 7.5 (gallic acid), 15.0 (**7**), 21.2 (**9**), 21.9 (**10**), 23.0 (**14**), 23.8 (**11**), 24.4 (**12**), 25.5 (**16**), and 26.9 (**13**) min, respectively (Figure 1).

**Insulin Sensitivity Assay.** Insulin sensitivity assays were performed using the method as reported previously.[7−9]

## RESULTS AND DISCUSSION

Repeated column chromatography over MCI gel CHP20P, Sephadex LH-20, Toyopearl HW-40F and semi-preparative

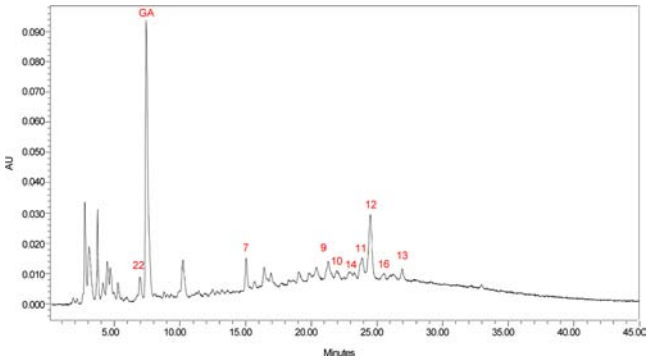

**Figure 1.** HPLC profile of *n*-BuOH-soluble fraction of ripe Pu-er tea (GA: gallic acid).

HPLC led to the isolation of four new flavan-3-ol derivatives **1**−**4** from the thearubigin (*n*-BuOH-soluble) fraction of the commercial ripe Pu-er tea. Moreover, 18 known compounds (**5**−**22**) were identified as three catechin derivatives, 8-carboxyl-(+)-catechin (**5**),[10] (+)-catechin-8-*C*-*β*-D-glucopyranoside (**6**),[11] and (−)-epicatechin-8-*C*-*β*-D-glucopyranoside (**7**),[11] 10 flavonoid glycosides, vicenin-2 (**8**),[12] isoschaftoside (**9**),[13] 2″-*O*-*β*-D-glucopyranosylvitexin (**10**),[14] quercetin 4′-*O*-*α*-L-rhamnopyranosyl-3-*O*-*α*-L-rhamnopyranosyl-(1 → 6)-*β*-D-glucopyranoside (**11**),[15] rutin (**12**),[16] nicotifiorin (**13**),[17] myricetin 3-*O*-*β*-D-glucopyranoside (**14**),[18] myricetin 3-*O*-*β*-D-galactopyranoside (**15**),[19] quercetin 3-*O*-*β*-D-glucopyranoside (**16**),[20] and quercetin 3-*O*-*β*-D-galactopyranoside (**17**),[21] two hydrolyzable tannins, 2-*O*-galloyl-D-glucose (**18**)[22] and 1-*O*-galloyl-*β*-D-glucopyranose (**19**),[23] two quinic acid derivatives, 3-*O*-galloylquinic acid (**20**)[24] and 3-*O*-caffeoylquinic acid (**21**),[25] and one purine alkaloid, 7-methylxanthine (**22**),[26] respectively, by comparing the spectra and physical data with those reported in the literature.

8-Carboxymethyl-(+)-catechin (**1**) was obtained as a white amorphous powder. Its molecular formula $C_{17}H_{16}O_8$ was established on the basis of the HRESIMS at *m*/*z* 347.0768 $[M-H]^-$ (calcd for $C_{17}H_{15}O_8$, 347.0772). The $^1H$ NMR spectrum of **1** showed the presence of three ABX coupled aromatic protons [*δ* 6.87 (d, *J* = 1.9 Hz, H-2′), 6.75 (d, *J* = 8.2 Hz H-5′), and 6.71 (dd, *J* = 8.2, 1.9 Hz, H-6′)], one aromatic singlet proton [*δ* 6.10 (*s*, H-6)], four catechin characteristic aliphatic protons [*δ* 4.61 (d, *J* = 7.5 Hz, H-2), 3.92 (ddd, *J* = 8.0, 7.5, 5.4 Hz, H-3), 2.82 (dd, *J* = 16.0, 5.4 Hz, H-4a), 2.52 (dd, *J* = 16.0, 8.0 Hz, H-4b)], and two mutually coupled aliphatic protons [*δ* 3.51, 3.43 (each 1H, *d*, *J* = 16.7, Hz)]. In $^{13}C$ NMR spectrum, 17 carbon signals were observed, and were further classified as two methylenes ($\delta_C$ 28.5, 29.0), four $sp^2$ methines ($\delta_C$ 95.9, 115.0, 115.7, 119.6), two $sp^3$ methines ($\delta_C$ 68.3, 82.4), one carboxylic carbon ($\delta_C$ 174.8) and other eight $sp^2$ quaternary carbons by HSQC and DEPT experiments. Comparison the $^1H$ and $^{13}C$ NMR data of **1** (Tables 1 and 2) with those of catechin,[27] indicated the presence of an additional carboxymethyl group in **1**, which should be substituted at C-6 or C-8 of the A-ring. The position of substitution was further identified by 2D NMR experiments. In the HMBC spectrum (Figure 2), the correlations from H-2 ($\delta_H$ 4.61) to C-9 ($\delta_C$ 154.5), and from H-4 ($\delta_H$ 2.82, 2.52) to C-5 ($\delta_C$ 155.5) and C-9, clearly assigned the signals of C-5 and C-9. The correlations of the additional methylene protons ($\delta_H$ 3.51, 3.43) with C-7 ($\delta_C$ 155.4), C-8 ($\delta_C$ 101.3), C-9 and the carboxylic carbon ($\delta_C$ 174.8) confirmed that the location of carboxymethyl unit was at

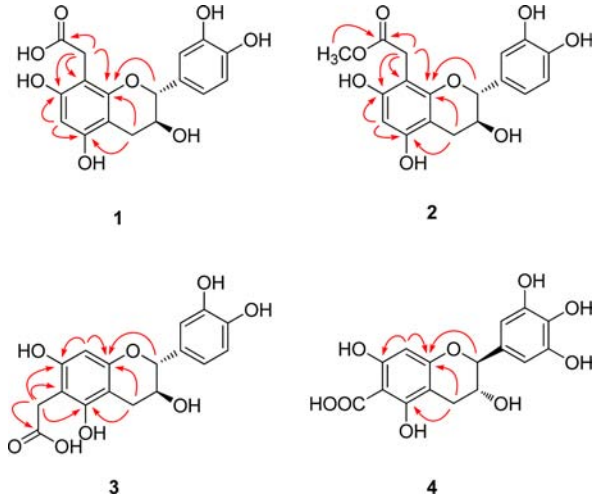

**Figure 2.** Key HMBC correlations (H → C) of **1**−**4**.

C-8. Other 2D NMR experiments further confirmed the planar structure of **1**, as shown in Figure 3. The coupling constant (7.5 Hz) between H-2 and H-3 indicated a 2,3-*trans* configuration. Further comparison the $[\alpha]_D$ of **1** ($[\alpha]_D^{16}$+ 22.0° (*c* 0.18, MeOH)) with (+)-catechin ($[\alpha]_D^{24}$ +15.5°(*c* 1.0, acetone))[27] and (−)-catechin ($[\alpha]_D$ −17.5° (*c* 0.16, MeOH))[28] revealed the 2*R*,3*S* absolute configurations in **1**. This can be confirmed by the CD spectrum, in which compound **1** gave a high-amplitude positive Cotton effect (CE) near 240 nm (Supporting Information Figure S17), corresponding to the $^1L_a$ electronic transition of the flavan-3-ols, consistent with 3*S*-configuration.[29] Based on the above evidence, the structure of **1** was determined to be 8-carboxymethyl-(+)-catechin.

8-Carboxymethyl-(+)-catechin methyl ester (**2**) was obtained as a white amorphous powder, possessing a molecular formula of $C_{18}H_{18}O_8$, as deduced from the HRESIMS measurement at *m*/*z* 361.0925 $[M-H]^-$ (calcd for $C_{18}H_{17}O_8$, 361.0928). The $^1H$ and $^{13}C$ NMR spectra of **2** (Tables 1 and 2) were closely resembled to those of **1**, except for an additional methoxy group ($\delta_H$ 3.48, $\delta_C$ 51.9) in **2**. In the HMBC spectrum of **2**, correlations of H-2 ($\delta_H$ 4.56, d, *J* = 7.5 Hz) with C-9 ($\delta_C$ 154.1), and the methylene protons ($\delta_H$ 3.47, 3.37) with C-7 ($\delta_C$ 154.9), C-8 ($\delta_C$ 100.6), C-9, and the carboxylic carbon ($\delta_C$ 174.3) confirmed that the carboxylmethyl group was attached to C-8. Moreover, the additional methoxy protons ($\delta_H$ 3.48) showed HMBC correlation with the carboxylic carbon ($\delta_C$ 174.3), revealing its linkage to the carboxyl group. Finally, the large coupling constant (7.5 Hz) between H-2 and H-3 in **2**, and the similar $[\alpha]_D$ value ($[\alpha]_D^{16}$ +21.6° (*c* 0.12, MeOH)) with **1**, suggested that **2** possesses the same 2*R*,3*S* configurations to **1**. In the CD spectrum, **2** showed a positive CE near 240 nm supported that **2** has a 2*R*,3*S*-configuration. Accordingly, compound **2** was determined as 8-carboxymethyl-(+)-catechin methyl ester.

6-Carboxymethyl-(+)-catechin (**3**), obtained as a white amorphous powder, has a same molecular formula of $C_{17}H_{16}O_8$ to **1**, as established by the HRESIMS (*m*/*z* 347.0768 $[M-H]^-$). The $^1H$ and $^{13}C$ NMR spectra of compound **3** were also closely resembled to those of **1**. In the HMBC spectrum of **3**, H-2 ($\delta_H$ 4.49) showed correlation with C-9 ($\delta_C$ 154.8), while H-4 ($\delta_H$ 2.84, 2.50) displayed correlations with C-5 ($\delta_C$ 154.5) and C-9 ($\delta_C$ 154.8). These led to the assignments of C-5 ($\delta_C$ 154.5), C-9 ($\delta_C$ 154.8), and C-7

dx.doi.org/10.1021/jf5036959 | J. Agric. Food Chem. 2014, 62, 12229−12234

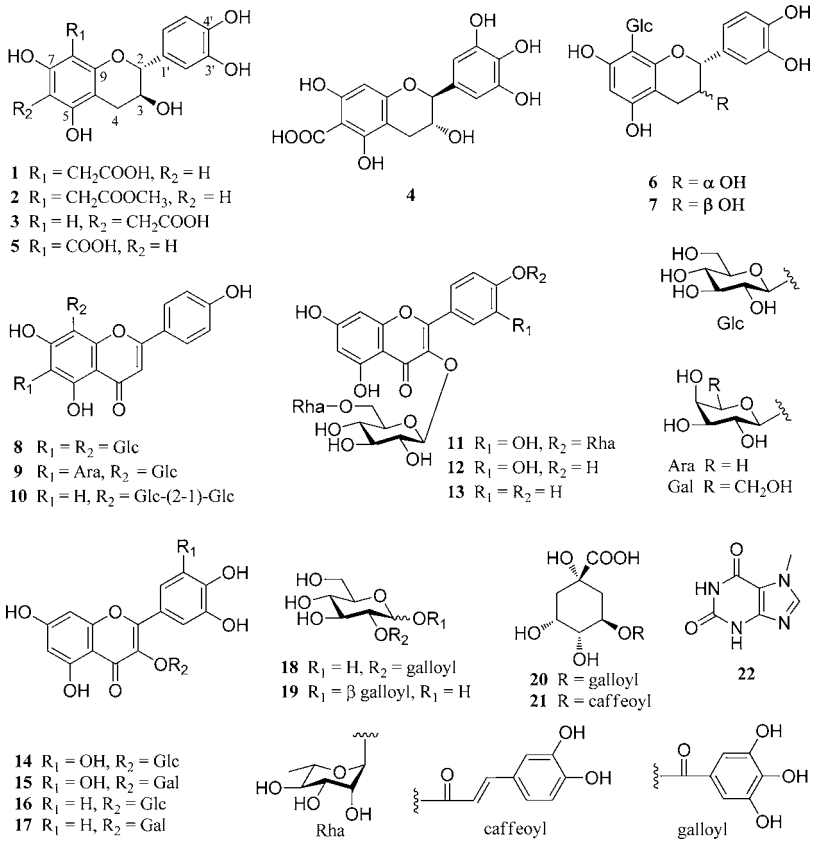

**Figure 3.** Compounds isolated from ripe Pu-er tea.

($\delta_C$ 155.2) clearly. Moreover, the HMBC correlations of the carboxymethyl ($\delta_H$ 3.49) with C-5 ($\delta_C$ 154.5), C-7 ($\delta_C$ 155.2), and the carboxylic carbon ($\delta_C$ 176.3) revealed that the carboxymethyl group in **3** was attached to C-6 (Figure 2). Further analysis of HSQC and HMBC spectra of **3** confirmed its structure as shown in Figure 3. The similar $[\alpha]_D$ of **3** ($[\alpha]_D^{16}$ +7.6° (*c* 0.09, MeOH)) with **1**, together with the positive CE near 240 nm confirmed that **3** has the same 2*R*,3*S* configurations to **1**. Therefore, compound **3** was determined to be 6-carboxymethyl-(+)-catechin, the isomer of compound **1**.

6-Carboxyl-(−)-gallocatechin (**4**), obtained as a white amorphous powder, gave a quasi-molecular ion peak at *m*/*z* 349.0552 $[M-H]^-$ on the HRESIMS, corresponding to a molecular formula of $C_{16}H_{14}O_9$ for **4**. The molecular weight of **4** is 44 mass units larger than that of gallocatechin, corresponding to a carboxyl group. The $^1H$ and $^{13}C$ NMR data of **4** were very similar to those of gallocatechin,[27] except for the disappearance of one aromatic proton and the appearance of an additional carboxyl carbon ($\delta_C$ 177.3) signal. The above data suggested that one of the aromatic protons in gallocatechin was substituted by a carboxyl group in **4**. The position of substitution was identified by HMBC experiment. The HMBC correlations of H-2 ($\delta_H$ 4.42, d, *J* = 8.0 Hz) with the carbon at $\delta_C$ 157.9, and H-4 [$\delta_H$ 2.67 (dd, *J* = 15.6, 4.9 Hz), 2.27 (dd, *J* = 15.6, 8.7 Hz)] with the carbons at $\delta_C$ 160.0 and 157.9 could assign unambiguously these carbon signals as C-5 ($\delta_C$ 160.0) and C-9 ($\delta_C$ 157.9). Thus, an unresolved signal at $\delta_C$ 160.1 must be arisen from C-7. The HMBC correlations of aromatic proton at $\delta_H$ 5.68 with the C-7($\delta_C$ 160.1) and C-9 ($\delta_C$ 157.9) indicated the position of aromatic proton to be H-8. Therefore, the carboxyl group was located on the C-6 position. A $J_{2,3}$ coupling constant of 8.0 Hz confirmed a 2,3-*trans* configuration. Further comparison the $[\alpha]_D$ of **4** ($[\alpha]_D^{16}$ −10.8° (*c* 0.19, MeOH)) with those of (−)-gallocatechin ($[\alpha]_D^{24}$ −11.2° (*c* 1.0, acetone))[27] and (+)-gallocatechin ($[\alpha]_D^{20}$ +150° (*c* 0.1, MeOH))[30] suggested that compound **4** has the same absolute configuration with (−)-gallocatechin, namely, 2*S*,3*R*-configuration. Moreover, **4** gave a high-amplitude negative CE near 240 nm, consistent with 3*R*-configuration. On the basis of the above evidence, the structure of **4** was deduced as 6-carboxyl-(−)-gallocatechin.

Thearubigin, having relative molecular weights between 700−4000 Da, is the main pigments in black tea considered generally as the *n*-BuOH soluble fraction. This fraction is presumed to be the polymers of catechins and/or theaflavins.[31] Inspired by concept of thearubigin in black tea, the *n*-BuOH soluble fraction of ripe Pu-er tea, the relative polar fraction after sequential solvent partitions, was qualitatively analyzed by HPLC analysis. As shown in Figure 1, compounds **7**, **9**−**14**, **16**, **22** and gallic acid (GA) were identified from the *n*-BuOH soluble fraction of ripe Pu-er tea, by comparison the retention time and UV profile with those of authentic samples under the same HPLC condition. The isolates constitute only a small portion of the *n*-BuOH-soluble ripe Pu-er tea pigments, albeit the visible peaks under wavelength of 210 nm in HPLC trace. The large unknown polymer pigments need to be further exploited.

Tea polyphenols from ripe Pu-er tea are reported to be active in antiobesity and antidiabetes,[32] of which, catechins are showing antiobesity and antidiabetes activities.[33] Most of the isolates, **4**, **6**−**17**, and **21**−**22** were tested for their acute activities on insulin sensitivity in differentiated 3T3-L1 adipocytes, but no significant activities were observed in these

dx.doi.org/10.1021/jf5036959 | J. Agric. Food Chem. 2014, 62, 12229−12234

compounds at a concentration of 10 $\mu$M. The above results suggested that the antidiabetes activity of catechins may not undergo the increasing insulin sensitivity.

In conclusion, the isolated phenolic compounds **1**−**21** could be divided into three groups, flavan-3-ol derivatives (**1**−**7**), flavonoid glycosides (**8**−**17**), and simple hydrolyzable tannins (**18**−**21**). Of them, **1**−**3** have additional carboxymethyl group in comparison with catechin. Compounds **4** and **5** are presumed to be formed through enzymatic Kolbe-Schmitt reaction from catechin.[34] Flavonoid glycosides **8**−**11** are reported from tea plants for the first time. Compound **11** have only been reported from *Zizyphus lotus* previously.[15] Simple hydrolyzable tannins (**18** and **19**) and quinic acid derivatives (**20** and **21**) were common constituents reported from green tea. The 7-methylxanthine (**22**) is the precursor of caffeine.[26] The *n*-BuOH-soluble fraction of ripe Pu-er tea was qualitatively analyzed by HPLC, from which nine compounds, **7**, **9**−**14**, **16**, **22** and gallic acid were identified by comparison the retention time and UV profile with those of authentic samples under the same HPLC condition, and gallic acid was found to be the major component. However, the compounds identified in HPLC trace only account for a small portion of *n*-BuOH-soluble fraction of ripe Pu-er tea pigment. The structure and function of the largely unknown polymer pigments are yet to be unveiled.

carbohydrate structure (chain length; pentose/hexose) on the efficiency of these inhibitors have not been studied.

The aim of the present study was to investigate the effects of selected Maillard reaction inhibitors, including aminoguanidine, cysteine, pyridoxamine, and sodium bisulfite, on the production of potato patatin (PTT)−galactose/xylose/galactooligosaccharides (GOS)/xylooligosaccharides (XOS)/galactan/xylan conjugates with specific functionalities. PTT has previously demonstrated numerous biological and functional properties including lipid acyl hydrolase activity,[18] antiproliferative activity on mouse melanoma cells, and antioxidant activity,[19] which makes it an interesting candidate for carbohydrate conjugation. The effectiveness of the investigated inhibitors to control the glycation of PTT was assessed by monitoring the glycation extent and the protein cross-linking along with the formation of dicarbonyl compounds. The PTT−carbohydrate conjugates were produced using the effective inhibitors and their digestibility was assessed.

## MATERIALS AND METHODS

**Materials.** Solanic 206P (≈75% PTT, ≈25% protease inhibitors) was kindly provided by Solanic (Foxhol, Netherlands). Potato galactan (∼280 kDa) and endo-1−4-$\beta$-D-galactanase from *Aspergillus niger* were purchased from Megazyme (Wicklow, Ireland). Furosine standard was purchased from Neosystem Lab (Strasbourg, France). Biogel P2 extra fine, Bradford reagent and broad range SDS-PAGE standards were purchased from Bio-Rad (Philadelphia, PA, U.S.A.). XOS was obtained from Shandong Longlive Biotech (Yucheng, China). Xylan from beechwood (≥90%) and all other chemicals were purchased from Sigma Chemical Co. (St. Louis, MO, U.S.A.).

**Production of Conjugates.** Potato proteins (Solanic 206P) in sodium phosphate buffer (50 mM, pH 7) were ultrafiltered using a stirred ultrafiltration unit (Amicon system, Millipore, Billerica, MA, U.S.A.) fitted with a 30 kDa molecular mass cutoff membrane to remove the protease inhibitors. The protein profile of the purified PTT revealed that the collected retentate was 90% composed of PTT.[20] Galactose, xylose, GOS, XOS, potato galactan, and soluble xylan were investigated as selected carbohydrates for the preparation of conjugates. GOS, with an average molar mass of 1990.9 g/mol, was produced according to Seo et al.[9] Mixtures of enriched PTT and selected carbohydrates at a molar ratio of 1:7 were prepared. The appropriate Maillard reaction inhibitor (aminoguanidine/cysteine/pyridoxamine or sodium bisulfite) was added to the mixtures at a protein to inhibitor ratio of 1:0.2 (w/w). The mixtures were freeze-dried and incubated at 48 °C for 1, 3, 5, and 7 days at $a_w$ of 0.65 (saturated potassium iodide). The collected mixtures were kept at −20 °C.

**Determination of Glycation Extent.** The glycation extent of PTT was determined through the measurement of the furosine amount, formed upon the acid hydrolysis, and of the total amount of available lysine according to the method of Seo et al.[20]

The final percentage of blocked lysine was indirectly estimated from the furosine content, considering that the Amadori compound tagatosyl−lysine formed during the Maillard reaction between lysine residues and galactose moieties generate about 42% furosine upon 8 M hydrochloric acid hydrolysis.[21] Although the amount of furosine formed from xylulosyl−lysine to furosine is unknown, the difference between the amount of furosine formed upon acid hydrolysis from different carbohydrates has been demonstrated to be smaller at stronger acid hydrolysis conditions used in this study.[21] Therefore, the same correction factor for the conversion of tagtosyl−lysine to furosine was used for the estimation of xylulosyl−lysine. The furosine content and the total available lysine content before glycation were used for the estimation of the percentage of blocked lysine that was due to the glycation and not to the protein cross-linking according to the following equation.

$$\%\text{blocked lysine} = (1/0.42 \times \text{furosine}) \times 100/\text{total lysine} \quad (1)$$

Experimental results are presented as averages of triplicates and the standard deviations are ≤5%.

**Determination of the Level of Protein Cross-Linking.** *Advanced Glycation Reaction Index of Glycoforms.* The advanced glycation reaction index was estimated by measuring spectrophotometrically the turbidity/browning of protein−carbohydrate mixtures (10 mg/mL) at 600 nm. All assays were run in triplicates and the presented values are their averages.

*Molecular Weight Distribution of PTT Glycoforms.* The glycated sample mixtures were subjected to size exclusion chromatography on Superdex 200 5/150 (GE Healthcare, Piscataway, NJ, U.S.A.) column on ÄKTA purifier system (GE Healthcare). The isocratic elution was run with potassium phosphate buffer (50 mM, pH 7) containing 0.15 M sodium chloride (3CV) at a flow rate of 0.3 mL/min. The fractions were detected at 280 nm. Selected proteins, including $\beta$-amylase, albumin, chymotrypsinogen A, and lysozyme, were used as standards for calibration. The results are presented as averages of duplicate measurements.

*Particle Size Distribution of PTT Glycoforms.* To estimate the distribution of the protein aggregates, the particle size was estimated through dynamic light scattering (DLS) measurements by Delsa Nano C system (Beckman Coulter) at 25 °C. The means of intensity distributions were obtained from 70 measurements.

**Quantitation of $\alpha$-Dicarbonyls.** The quantitation of $\alpha$-dicarbonyls was carried out according to the method of Marceau and Yaylayan.[22] Glycated samples (20 mg/mL) were suspended in 0.5% (w/v) solution of *o*-phenylenediamine solution and incubated overnight in darkness at 25 °C. After centrifugation (5000*g*, 5 min), the quantitation of $\alpha$-dicarbonyls was performed with a Beckman HPLC system equipped with a programmable solvent module (model 126), a photodiode array detector and 32 Karat software for data collection. The separation was performed on a Zorbax SB-C18 (4.6 × 150 mm, 5 $\mu$m, Agilent Technologies, Palo Alto, CA, U.S.A.) at 25 °C. The elution of the derivatized samples (20 $\mu$L) was carried out with an isocratic mobile phase of methanol/water/formic acid (55:45:0.1, v/v/v) at 0.7 mL/min. The detection was done at 312 nm, and the spectrum was recorded from 200 to 400 nm. The unglycated proteins/carbohydrate mixtures with and without inhibitor were run as controls. To assess the presence of any side derivatization reactions due to the presence of protein, carbohydrate, and/or inhibitors, control reactions were run with each of these glycation components separately. Glyoxal, methylglyoxal, and 2,3-butanedione were used as standards for the identification of the formed dicarbonyls. The derivatization of these standards at selected concentration varying from 8.33 to 300 $\mu$g/mL was carried out as discussed here above. The identification of deoxyosone was done based on the characteristic two absorption maxima of the quinoxaline derivatives (∼250 nm, ∼330 nm) and on the RP-HPLC elution order characterized by Marceau and Yaylayan.[22] Experimental results are presented as averages of triplicates and the standard deviations are ≤5%.

**Simulated Gastric Digestion of PTT and its Glycoforms.** The simulated gastric digestion of PTT and its corresponding glycoforms was performed according to the modified method of Moreno et al.[23] The glycated and nonglycated PTT samples (1 mg/mL) were suspended in 20% (v/v) simulated gastric fluid (0.75 M sodium chloride, pH 2.2). To initiate the enzymatic digestion, porcine pepsin (7 mg/mL, ≥ 2,500 units/mg protein) at a ratio of 1:50 (v/v) was added. After 2 h incubation at 37 °C, the pH of the mixture was raised to 7.5 with ammonium carbonate (0.125 M). The following solutions were added to slightly lower the pH and to simulate a duodenal environment: (1) 10 $\mu$L bile salt mixture consisting of 0.025 M sodium taurocholate, 0.25 M sodium glycodeoxycholic acid, 0.4 M calcium chloride, and 0.5 M Bis-Tris; (2) 6 $\mu$L of porcine trypsin (3 mg/mL, ≥6000 units/mg protein) and 10 $\mu$L of bovine $\alpha$-chymotrypsin (4.77 mg/mL, ≥39 units/mg protein). The sample was then incubated at 37 °C for 1 h. The reaction was stopped by heating the samples in boiling water for 5 min. The control without the incubation steps was prepared as the unhydrolyzed control, and the native PTT was used as hydrolyzed control. All assays were done in triplicate.

**Table 1. Progress of the Maillard Reaction at 48°C at $a_w$ of 0.65**

| | | percent blocked lysine[a,d,e] | | | | | advanced reaction index[b,d,e] | | | | | reaction control ratio[c,d] | | | | |

[a]Percentage of blocked lysine was calculated from furosine content and total free amino groups. [b]Turbidity/browning measurement at 600 nm. [c]Reaction control ratio = percent blocked lysine/advanced reaction index. [d]Mixture containing different Maillard reaction inhibitiors: no inhibitor (N), aminoguanidine (A), cysteine (C), pyridoxamine (P), sodium bisulfite (S). [e]Experimental results are averages of triplicates and the standard deviations are less than 5%.

The analysis of hydrolysates was performed by HPLC using a Beckman HPLC system equipped with a programmable solvent module (model 126), a photodiode array detector, and 32 Karat software for data collection. The separation was performed on a Zorbax SB-C8 (4.6 × 150 mm, 5 $\mu$m) at 25 °C. The hydrolyzed sample (20 $\mu$L) was injected in triplicates. The absorbance was measured at 214 nm. A linear gradient at a flow of 0.5 mL/min was used using water/acetonitrile/formic acid (90:10:0.1, v/v/v) as solvent A and water/acetonitrile/formic acid (10:90:0.07, v/v/v) as solvent B. The elution gradient was as follows: 1−45 min, 50% B; 45−50 min, 100% B; 50−55 min, 58% B; 55−60 min, 0% B, 60−80 min, 0% B. The unhydrolyzed control was used as a standard to quantitate the unhydrolyzed PTT in the samples. Percent hydrolysis was calculated as follows:

$$\text{percent protein digestion} = 100 - (\text{peak area of unhydrolyzed PPT}/\text{peak area of the PPT control}) \times 100 \quad (2)$$

## RESULTS AND DISCUSSION

**Effects of the Inhibitors on the Progress of the Maillard Reaction.** *Changes in the Glycation Level of PTT with Galactose/Xylose in the Presence of Inhibitors.* To investigate the effects of inhibitors on the level of PTT glycation and protein cross-linking, the percent blocked lysine, the advanced reaction index, and their ratio (reaction control index) were estimated (Table 1). The Maillard reaction was conducted at 48 °C to prevent the denaturation of PTT during incubation. The results show a faster glycation reaction rate of PTT with galactose (3 to 5 days) than with xylose (3 to 7 days). Similar findings were reported by Hofmann[24] where the low glycation rate of L-alanine with pentoses was attributed to the higher degradation of pentoses as compared to hexoses, limiting their availability. In addition, higher advanced reaction index values of PTT−xylose conjugates (0.1−9.8) were obtained as compared to those of PTT−galactose conjugates (0.1−4.7). These results may be due to the formation of more reactive dicarbonyls with xylose rather than with galactose.[24] As compared to other inhibitors, the highest percent blocked lysine of PTT−galactose conjugates (21.0%) and the lowest advanced reaction index (0.1) was achieved in the presence of sodium bisulfite, while aminoguanidine inhibitor resulted in the highest percent blocked lysine of PTT−xylose conjugates (16.0%) with the lowest advanced reaction index (0.1). As compared to the reaction without inhibitor (maximum blocked lysine of 97.9%, day 3), the presence of sodium bisulfite limited both the glycation rate and the conjugation level of PTT with galactose achieving maximum percent blocked lysine of 21.0% upon 5 days of incubation. On the other hand, the aminoguanidine lowered the glycation rate of PTT with xylose, without affecting the maximum conjugation level, which was slightly higher as compared to the reaction without inhibitor (maximum blocked lysine of 13.0%, day 5). Such effect of sodium bisulfite may be attributed to its ability to trap the free-radicals and the reactive dicarbonyls formed during the reaction through its sulfite ion.[16] Conflicting results have been reported in the literature regarding the inhibitory effect of aminoguanidine at the early stage of the reaction. Edelstein and Brownlee[12] have shown that, in the presence of excess of carbohydrates, aminoguanidine had no effect on the conjugate

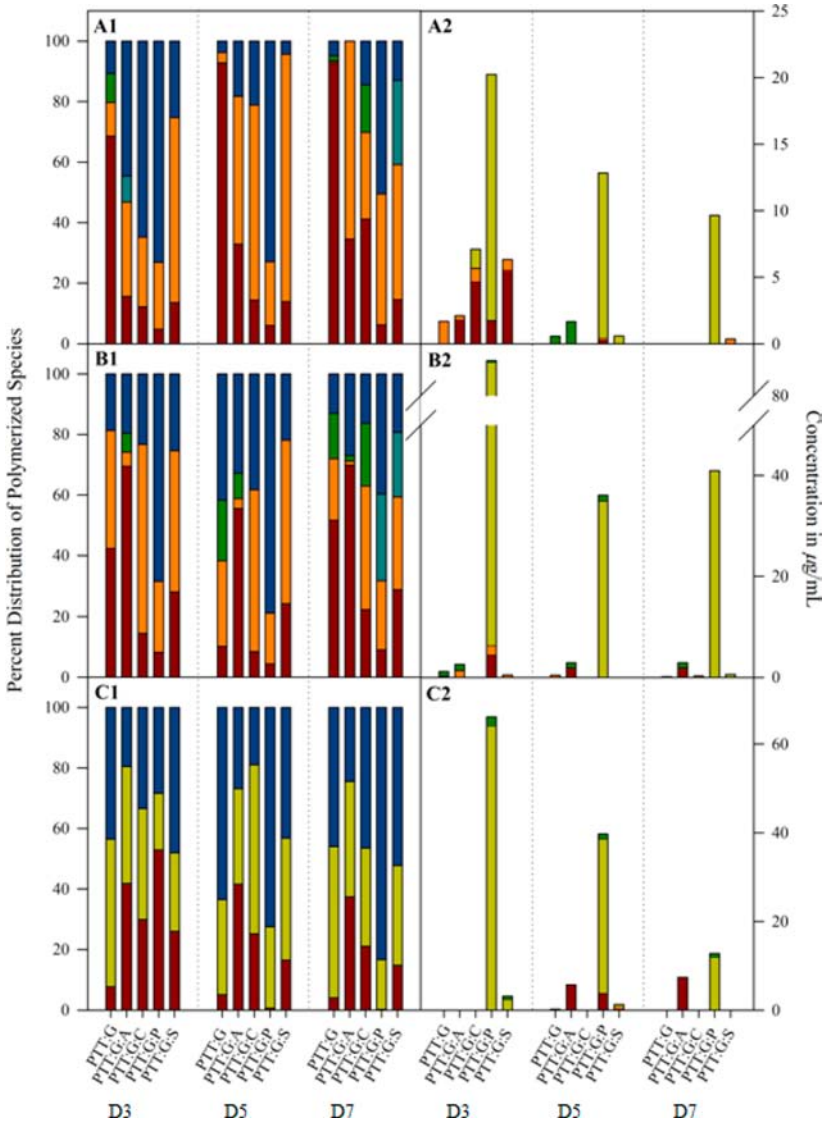

**Figure 1.** Effect of inhibitors on the degree of polymerization of proteins during the reaction between PTT and galactose (A1), GOS (B1), galactan (C1) at days 3, 5, and 7: extensive polymerization (red), degree of polymerization >10 (orange), 8−10 (yellow), 5−7 (green), 3−4 (cyan), <3 (blue). Quantitation of $\alpha$-dicarbonyls present in the incubated mixtures of PTT−galactose (A2), PTT−GOS (B2), PTT−galactan (C2) estimated by measuring quinoxalines derivatized with *o*-phenylenediamine: deoxyosone (red), glyoxal (orange), methylglyoxal (yellow), 2,3-butanedione (green). Inhibitors used: aminoguanidine, A; cysteine, C; pyridoxamine, P; sodium bisulfite, S.

formation and inhibited the Maillard reaction at the advanced stage. On the other hand, Requena et al.[25] have reported that, at concentrations of aminoguanidine similar to the concentration used in this study, the early glycation reaction of albumin with glucose was inhibited. For both PTT−galactose and PTT−xylose conjugates, pyridoxamine did not lead to any improvement in their reaction control ratio (0.0−28.0). These results may be due to the fact that the primary amino group of pyridoxamine competes with protein lysine residues for the carbonyl group of the carbohydrate as demonstrated by the important browning/aggregate formation was found (0.3−2.2, data not shown) in our controls containing only pyridoxamine and galactose/xylose.

*Changes in the Glycation Levels of PTT with XOS/GOS in the Presence of Inhibitors.* XOS (maximum blocked lysine of 11.7%, day 5) exhibited more or less the same reactivity toward the glycation of PTT as its corresponding monosaccharide, xylose (Table 1). However, GOS showed a much slower rate of glycation with the $\varepsilon$-amino groups of PTT lysine residues, reaching a maximum percent blocked lysine of 6.1% after 7 days. The lower reactivity of longer chain carbohydrates has been previously reported.[26] Furthermore, at the early stage of the reaction (1−3 days), the low percentage of blocked lysine of PTT−GOS (0.8−1.3%) and PTT−XOS (0.0−0.4%) conjugates was accompanied by high advanced reaction index (0.5−1.5); these results reveal that the high advanced reaction index values were not significantly due to the degradation of the Amadori products, but to the initial degradation of the oligosaccharides through autoxidation/glycoxidation leading to protein cross-linking.[27] As compared to GOS, the higher maximum glycation level of XOS is probably due to the high release of the degradation products that may have promoted the glycation.[28] As compared to other inhibitors, the highest percent blocked lysine of PTT−GOS conjugates and the lowest advanced reaction index (0.1) were achieved in the presence of cysteine (66.3%, 3 days). These results may be due to the

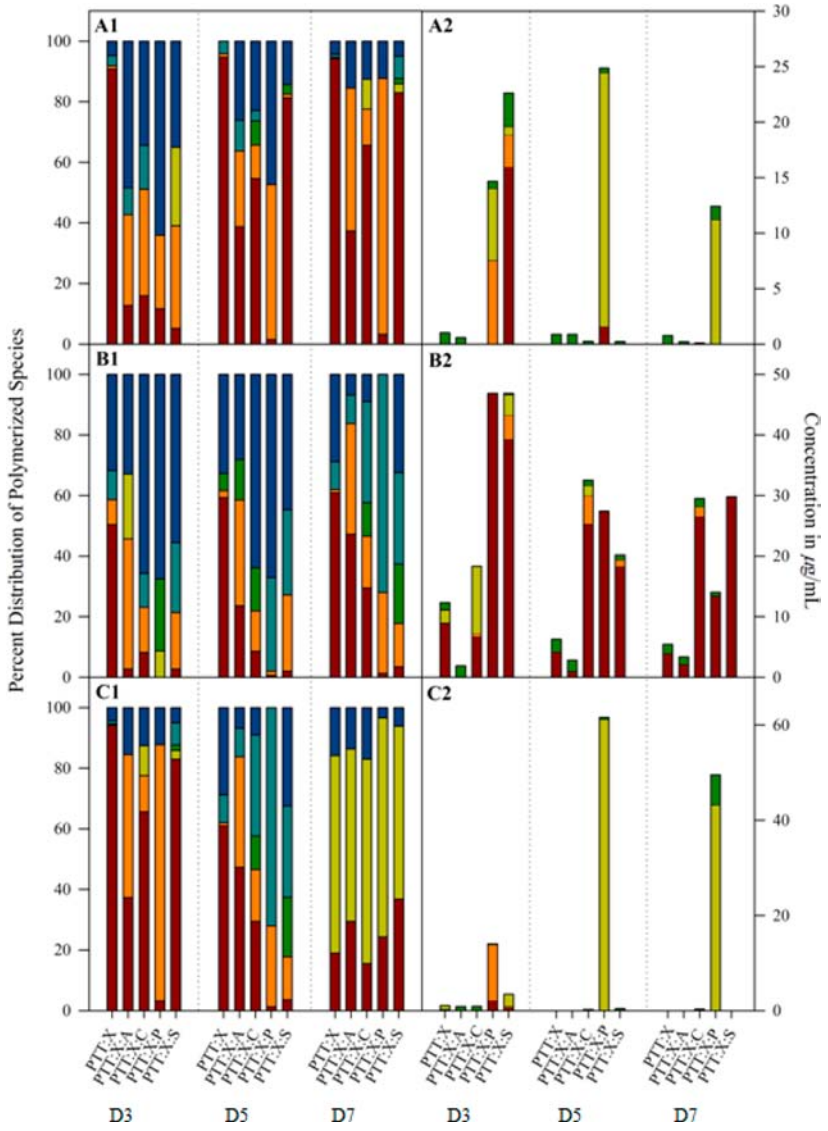

**Figure 2.** Effect of inhibitors on the degree of polymerization of proteins during the reaction between PTT and xylose (A1), XOS (B1), xylan (C1) at days 3, 5, and 7: extensive polymerization (red), degree of polymerization >10 (orange), 8−10 (yellow), 5−7 (green), 3−4 (cyan), <3 (blue). Quantitation of $\alpha$-dicarbonyls present in the incubated mixtures of PTT−xylose (A2), PTT−XOS (B2), PTT−xylan (C2) estimated by measuring quinoxalines derivatized with *o*-phenylenediamine: deoxyosone (red), glyoxal (orange), methylglyoxal (yellow), 2,3-butanedione (green). Inhibitors used: aminoguanidine, A; cysteine, C; pyridoxamine, P; sodium bisulfite, S.

reaction of cysteine with GOS leading to the accumulation of reactive species that increased the affinity of GOS toward PTT glycation binding sites. As compared to PTT−GOS conjugates, cysteine led to lower percent blocked lysine of PTT−XOS conjugates (6.9% at 3 days). This demonstrates the lower reactivity of cysteine toward XOS and its high scavenging of the reactive species generated upon XOS degradation. Aminoguanidine was the most efficient in improving the reaction control ratio of PTT−XOS conjugates (143.0), with a maximum percent blocked lysine of 14.3% at 3 days and an advanced reaction index of 0.1. The accumulation of reactive species produced as precursors at the early stage seems to be important for the initiation of Schiff base formation and hence favoring the glycation of PTT with GOS/XOS.

*Changes in the Glycation Level of PTT with Xylan/Galactan in the Presence of Inhibitors.* Similarly to their oligosaccharides counterpart, xylan (maximum blocked lysine of 16.5%, day 7) resulted in higher percent blocked lysine of PTT as compared to galactan (4.3%, day 5). As compared to PTT−galactan conjugates (0.1−1.7), the higher advanced reaction index values of PTT−xylan conjugates (2.0−6.5) demonstrate the high extent of side autoxidation/glycoxidation reactions of xylan.[24] These results may be due to the presence of arabinose, an intermediate during the autoxidation/glycoxidation of monosaccharides, on the side chains of the soluble xylan.[29−31] Contrary to the reaction with its oligosaccharide counterpart (XOS), the use of Maillard reaction inhibitors with xylan was less effective at inhibiting the formation of protein aggregates and the browning compounds at the intermediate and advanced stages. Nevertheless, the highest reaction control ratio (12.8) of PTT−xylan conjugates was obtained in the presence of sodium bisulfite with a percent blocked lysine of 16.7% (5 days). These results reveal that the use of sodium bisulfite did not inhibit the conjugation of PTT with xylan at the early stages, but slightly prevented the protein cross-linking from occurring. Similarly, Scaman et al.[17] have

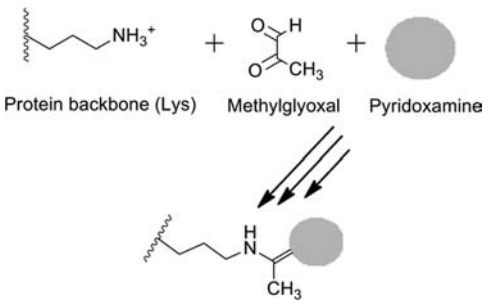
dx.doi.org/10.1021/jf502497r | J. Agric. Food Chem. 2014, 62, 12235−12243

reported that the use of sodium bisulfite did not inhibit the percent glycation of lysozyme with dextran at pH 8.5 at 40 °C but prevented protein cross-linking. Similarly to PTT−GOS conjugates, the highest reaction control ratio (71.0) of PTT−galactan conjugates was achieved in the presence of cysteine after 5 days, where the highest percent blocked lysine of 7.1% and the lowest advanced reaction index of 0.1 were obtained.

**Protein Cross-Linking and Formation of Reactive Carbonyl Species in the Presence of Selected Inhibitors.** Selected reactive carbonyl species, including methylglyoxal, glyoxal, 2,3-butanedione, and deoxyosone, can lead to protein cross-linking at different rates and, as a result, to the formation of aggregates.[32] The reactive dicarbonyl compounds can be formed during the autoxidation/glycoxidation of carbohydrates and/or from the Schiff base, the initial condensation product of a reducing carbohydrate and an amino compound, via the so-called Namiki pathway under oxidative conditions.[33] In addition, the Amadori products, although fairly stable in foods with low water activity, may undergo several degradation reactions leading to the formation of dicarbonyls.[34] Some authors have identified the methylglyoxal as the important intermediate in the formation of protein cross-linking products.[4,7] Others have identified glyoxal, deoxyosone, and methylglyoxal as the key intermediates.[30] To elucidate the protein cross-linking inhibition mechanism in the presence of aminoguanidine, cysteine, pyridoxamine, or sodium bisulfite, the molecular distribution of polymerized species of PTT conjugates and the formation of dicarbonyls' *o*-phenylenediamine derivatives were investigated. The comparison of protein polymerization degree and the quantity of dicarbonyls' *o*-phenylenediamine derivatives can reveal the effectiveness of inhibitors to scavenge the reactive dicarbonyls. Mild protein aggregation of PTT occurred upon incubation at 48 °C forming dimers (59.9%) with some oligomerized species (27.2%) (data not shown). The Maillard reaction between PTT and galactose (Figure 1A1) and xylose (Figure 2A1) led to the formation of a high proportion of extensively polymerized species of 68.5 and 90.8%, respectively, at day 3. At day 3, the presence of inhibitors led to a lower proportion of extensively polymerized species of PTT−galactose/xylose conjugates (4.7−16.0%) and to a higher proportion of its mono/dimer (34.4−73.1%). As compared to other inhibitors, the cross-linking of PTT−galactose/xylose conjugates in the presence of pyridoxamine exhibited the lowest rate, which can be attributed to the low amount of percent blocked lysine. The effectiveness of pyridoxamine as an inhibitor of protein cross-linking occurring during the Maillard reaction has already been demonstrated by Corzo-Martinez et al.,[1] where they have observed lower poly oligomer formation within the reaction between $\beta$-lactoglobulin and galactose/tagatose in the presence of pyridoxamine.

The only $\alpha$-dicarbonyls formed in the reaction with galactose (Figure 1A2) or xylose (Figure 2A2) without inhibitor was glyoxal (1.7 $\mu$g/mL) and butanedione (1.1 $\mu$g/mL), respectively. Glyoxal was found to be formed during the degradation of monosaccharide by retroaldol condensation reactions activated by deprotonation of the 2- or 3-hydroxy groups,[32] which supports the higher amount of glyoxal found in galactose reactions. Butanedione is a well-known sugar fragmentation product, which could arise from xylose fragmentation.[35] The major dicarbonyl formed in the presence of aminoguanidine, cysteine, and sodium bisulfite was deoxyosone for the reactions with galactose, and butanedione and deoxyosone for the reactions with xylose. As compared to methylglyoxal and glyoxal, the lower reactivity of deoxyosone and butanedione[4,7] toward Maillard reaction inhibitors and toward the lysine/arginine residues of the protein may explain the accumulation of these dicarbonyls. The reaction between PTT and galactose/xylose in the presence of pyridoxamine led to more methyglyoxal formation. From our results, it seems possible that pyridoxamine only reacted with one of the two carbonyl groups of methylglyoxal leaving the other carbonyl group available to react with the lysine residues found on the protein preventing its cross-linking. The decrease in lysine residues and pyridoxamine led to the accumulation of unreacted methylglyoxal in the system (Scheme 1, adapted from Miller et al.,[7]). The inhibitors identified previously (Table 1), sodium bisulfite for galactose (day 5) and aminoguanidine for xylose (day 7), which led to the highest reaction control ratios, resulted in the release of low amounts of total unreacted dicarbonyls (0.6 and 0.2 $\mu$g/mL, respectively) and in lower proportions of extensive polymerized species (13.9 and 37.3%, respectively) as compared to the reaction without inhibitor, demonstrating the efficiency of these inhibitors to modulate the reaction progress.

**Scheme 1. Possible Reaction Pathway for Methylglyoxal's Reaction with Lysine Residues on PTT in the Presence of Pyridoxamine**[a]



[a]Adapted with permission from Miller et al.[7] Copyright 2003, Elsevier B.V.

The reaction between PTT and GOS or XOS (Figure 1B1, 2B1) without inhibitor led to higher formation of oligomerized species (18.7 and 41.3%; < 3, 3−4, 5−7) at day 3 as compared to their monosaccharide counterparts (galactose and xylose). In the PTT−GOS/XOS reaction systems, all investigated inhibitors limited the rate of protein cross-linking over 7 days of reaction time, with the exception of aminoguanidine. Similarly to the reaction of PTT with galactose/xylose, the most effective inhibitor for the prevention of protein cross-linking during the reaction of PTT with GOS and XOS was pyridoxamine, leading to only 9.0 and 1.3% of extensively cross-linked polymers, respectively, after 7 days of incubation. The best identified inhibitors, leading to the highest reaction control ratio for PTT−GOS (cysteine, day 3) and PTT−XOS (aminoguanidine, day 5) (Table 1) systems resulted in low amounts of total unreacted dicarbonyls (0.0 and 2.8 $\mu$g/mL) and in lower proportions of extensive polymerized species (14.4 and 23.6%) as compared to the reaction without inhibitor (1.1−6.3 $\mu$g/mL; 42.4−59.3%).

PTT−xylan reaction system without inhibitor (Figure 2C1) exhibited a higher proportion of extensively polymerized species (94.2%) than in the presence of inhibitors (3.2−82.9%) after 3 days of incubation. In contrast, PTT−galactan reaction system (Figure 1C1) showed a lower proportion of

extensively polymerized species (7.7%) than in the presence of inhibitors (26.0−52.9%). However, the decrease in the proportion of extensively polymerized species of PTT−xylan with an increase in incubation time reveals the noncovalent interactions of these species. Indeed, the decrease in the hydrophobicity of PTT upon glycation may have decreased its affinity to interact with xylan and to form large noncovalent complexes (Figure 2C1) through low energy interactions, such as hydrogen bonding and hydrophobic bonding.[36] The lower protein cross-linking observed with galactan may be attributed to its ability to depress the protein polymerization associated with the advanced Maillard reaction.[8] However, as compared to the system without inhibitor, the higher proportion of extensively polymerized species observed at day 3 in the PTT−galactan reaction system containing aminoguanidine (41.8%) or pyridoxamine (52.9%) could be due to the higher reactivity of galactan toward these inhibitors. Methylglyoxal (34.9−41.0 μg/mL) was identified as the main unreacted dicarbonyl with galactan/xylan (Figures 1C2 and 2C2) in the presence of pyridoxamine as with their monosaccharide counterparts (Figures 1A2 and 2A2), except for the reaction with xylan at day 3 of incubation. The best identified inhibitors, leading to the highest reaction control ratio, for PTT−galactan (cysteine, day 5) and PTT−xylan (sodium bisulfite, day 5) (Table 1) systems resulted in lower amounts of total unreacted dicarbonyls (0.0 μg/mL) for the galactan reaction system and in lower proportions of extensive polymerized species (3.5%) for the xylan reaction system as compared to the reaction without inhibitor (0.0−0.2 μg/mL; 5.1−60.9%).

**Particle Size and Digestibility of the Conjugates Produced Using Selected Inhibitors.** Cysteine and aminoguanidine were identified as the best inhibitors for galactose-type or xylose-type PTT conjugates, respectively, favoring high glycation levels and limiting protein cross-linking to a certain extent during the advanced stages of the Maillard reaction. Although pyridoxamine was the most efficient in inhibiting protein cross-linking, it exhibited an inhibition effect on the PTT conjugation by limiting or delaying the formation of Amadori product (Table 1). PTT conjugates were produced using the identified inhibitors and their particle size distribution and digestibility were investigated (Figure 3). These conjugates produced with or without inhibitor were compared to the native PTT on the basis of their relative percent digestibility and their increase in average particle size per 5.0% blocked lysine to normalize the effect of the different levels of glycation on these parameters. The average particle size and the total digestibility of the incubated PTT controls were 321.3−347.2 nm and 59.6−60.2%, respectively (data not shown). PTT−galactose conjugates showed more or less similar increase in the particle size of their aggregates, per 5.0% blocked lysine, in the presence (44.0 nm) or in the absence (45.9 nm) of cysteine inhibitor. In contrast, a significantly smaller increase in the particle size distribution of PTT−xylose conjugates, per 5.0% blocked lysine, was obtained in the presence of aminoguanidine (16.3 nm) as compared to without inhibitor (2640.6 nm). Due to the higher cross-linking level of PTT−xylose conjugates produced without inhibitor, their relative digestibility (43.1%) was lower than that of PTT−galactose (94.8%). However, the use of cysteine and aminoguanidine as inhibitors resulted in an increase in the relative digestibility of PTT−galactose and PTT−xylose conjugates by 0.4 and 8.2%, respectively, as compared to without inhibitor. The relative digestibility of PTT−xylose conjugates was nonconcomitantly increased, upon

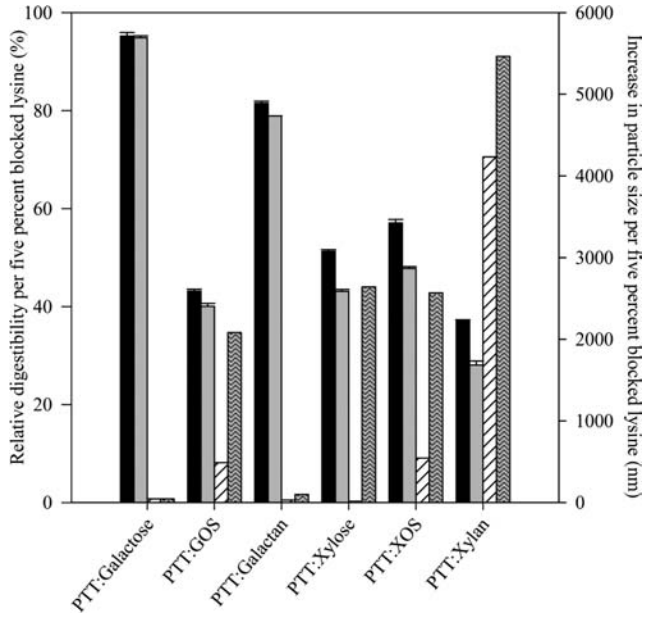


**Figure 3.** Relative digestibility and the increase in particle size, per 5% blocked lysine, of the PTT−galactose/GOS/galactan:cysteine incubated mixtures and of the PTT−xylose/XOS/xylan:aminoguanidine incubated mixtures compared to the reaction mixture without inhibitors: digestibility with (black) and without inhibitors (gray), and the particle size with (white diagonal stripes) and without inhibitors (gray zigzag stripes). The error bars represent the standard deviations of triplicate measurements. The particle size is an average of 70 measurements and the polydispersity index of each sample was ≤0.5.

the use of aminoguanidine, as compared to the large decrease of their particle size demonstrating that the large particle size of PTT−xylose conjugates produced without inhibitor was largely due to their noncovalent aggregation. The results also show the high increase of the average particle size, per 5.0% blocked lysine, of PTT−GOS conjugates (2080.8 nm) produced without inhibitor. As expected, the use of cysteine dropped the increase in the average particle size of PTT−GOS conjugates to 487.3 nm. The increase in average particle size of PTT−XOS conjugates, per 5.0% blocked lysine, produced with and without aminoguanidine was 544.0 and 2567.3 nm, respectively. As a result of the lower level of protein cross-linking, PTT−GOS and PTT−XOS conjugates produced in the presence of the inhibitors showed 3.1 and 9.3% increases in their percent digestion, respectively. The experimental findings also show that PTT−galactan conjugates produced in the presence of cysteine (29.9 nm) had a smaller increase in the average particle size of its aggregates, per 5.0% blocked lysine, than without cysteine (100.2 nm). Contrary to PTT−galactan conjugates, the average particle size of PTT−xylan conjugate aggregates increased significantly (5,463.4 nm) per 5.0% blocked lysine, and the use of aminoguanidine as inhibitor limited slightly this increase to 4,231.6 nm. The use of cysteine or aminoguanidine as inhibitors for the production of PTT−xylan or PTT−galactan conjugates led to 2.6 and 9.0% increase in the percent digestion. These increases are in good agreement with the decrease in the particle size of the conjugate aggregates. To the best of our knowledge, this is the first study where the effect of Maillard reaction inhibitors on the improvement of digestibility of protein−carbohydrate conjugates has been investigated.

**Conclusion.** The effect of selected Maillard reaction inhibitors on the production of PTT−carbohydrate conjugates was investigated. Sodium bisulfite (galactose, xylan), aminoguanidine (xylose, xylooligosaccharides), and cysteine (GOS, galactan) were the inhibitors that led to the highest glycation level of the conjugates. These glycation levels were mostly similar or even higher than those of the conjugates produced without inhibitors. The use of these inhibitors led to lower proportions of extensive polymerized species or to lower amounts of total unreacted dicarbonyls. By using cysteine for the production of PTT−galactose/GOS/galactan conjugates, and by using aminoguanidine for the production of PTT−xylose/XOS/xylan conjugates, the particle size distribution of the conjugates was lowered and the digestibility of the conjugates was improved. The use of the Maillard reaction inhibitors to limit the protein cross-linking, associated with the intermediate and advanced stages, will allow the production of protein−carbohydrate conjugates with improved properties as potential functional ingredients.

Chemicals were purchased from Merck (Darmstadt, Germany) or Sigma-Aldrich (St. Louis, MO, USA), unless otherwise specified. Fruit bodies of *G. tsugae* were washed, wiped by a paper towel, and then cut into small piece. Deionized water was added (500 mL per 7.5 g of dry solid). The mixture was crumbled for 5 min by a Waring blender (Blender 7012S, Waring Commercial, Stamford, CT, USA) and then was pulverized by using a high-speed blender (Polytron PT 3000, Kinematica AG, Switzerland) at 12000 rpm for 5 min. The resulting material was designated the blended suspension.

**Proximate Composition.** Small pieces of *G. tsugae* were used for composition analysis. The contents of moisture, ash, crude fat, and crude protein were determined, according to the methods of the Association of Official Analytical Chemists (AOAC).[21] Moisture and dry matter were presented on the basis of wet weight; others were reported on a dry weight basis.

**Hot-Water Extraction.** The blended suspension was placed in a hot water bath at 99 °C for extraction of 3 h. Then, the suspension was cooled and filtered through Whatman no. 1 filter paper. The filtrate was collected and designated the hot-water extract. Micro-organisms were removed by filtration using a 0.45 μm membrane for cell cultures. The filtrate was designated the S-extract.

**Media Milling.** A two-step milling was employed to prepare nano/submicrometer *G. tsugae* suspension using a media mill (MiniPur, NETZCH-Feinmahltechnik GmbH, Germany) with a driving motor of 0.94 kW. Media (yttria-stabilized tetragonal zirconia, YTZ) of 0.8 or 0.3 mm were loaded in the milling chamber (200 mL) at 70% v/v filling ratio. The blended suspension was placed into a jacket-cooling tank and then fed at a flow rate of 220 mL/min into the milling chamber by a circulation pump. During milling, particles smaller than the gap of the media separator were brought out into the stirred tank for cooling by the circulation system. The temperature of the suspension was thus maintained below 35 °C during milling. The milling was conducted with 0.8 mm media for 1 h with an agitation speed of 2700 rpm, and then 0.3 mm media were employed for 2 h with an agitation speed of 3000 rpm. Total milling time was 3 h. Samples, designated the milled suspension, were taken at 0, 1, 2, and 3 h for particle size distribution measurement and SEM observation.

Large particles and aggregated clusters in 3 h milled suspension were removed by centrifuge (4 °C, 10000*g*, 10 min) (Rotina 35R Hettich Zentrifugen, Tuttlingen, Germany). The supernatant, designated the nano/submicrometer *G. tsugae*, was collected for determining particle size distribution and further studies. The nano/submicrometer *G. tsugae* was filtered through a 0.45 μm membrane for removing micro-organisms. The filtrate was designated the S-supernatant.

**Particle Size Analysis.** The particle size distributions were determined by using a static laser diffraction particle size analyzer (LS230, Beckman Coulter, Brea, CA, USA) with a detection range of 0.04−2000 μm. The instrument was calibrated with deionized water. All samples were pretreated by violently shaking (1 min in a Vortex-Genie 2, Scientific Industries, Inc., Bohemia, NY, USA) and degassed by ultrasound. Average diameters of particles were obtained using the equations

$$\text{by volume,}\quad D_V = \sum_i \frac{n_i d_i^4}{n_i d_i^3}$$

$$\text{by number,}\quad D_N = \sum_i \frac{n_i d_i}{n_i}$$

where $n_i$ is the number of $i$ particles with diameter of $d_i$. All of the measurements were done in triplicate, and the average data were reported.

**Morphology.** The morphology of suspended particles in *G. tsugae* samples was examined by scanning electron microscope (SEM) (Hitachi S-800, Hitachi Co. Ltd., Tokyo, Japan). Critical-point drying was employed to prepare samples for SEM. Sample (3 mL) was mixed with 27 mL of 75% ethanol and evaporated to 3 mL at 60 mmHg. Two more replacement processes were conducted by using 95% ethanol. After a final replacement using 99% ethanol, solids were suspended in 3 mL of 99% ethanol. The suspensions were further dried using liquid $CO_2$ in a critical-point drying apparatus (Hitachi HCP-2, Hitachi Co. Ltd., Tokyo, Japan) at 31.1 °C and 73.9 bar. After being dried, the sample was attached on an SEM stub using double-backed cellophane tape. The stub and sample were coated with gold−palladium and then were examined and photographed at 10 kV.

**Total Carbohydrate Content.** The method of phenol−sulfuric acid reaction[22] was used to determine the total carbohydrate content. Sample (0.2 mL) was mixed with 0.2 mL of 5% phenol in a test tube. Subsequently, 1 mL of concentrated sulfuric acid was added rapidly to the mixture. After allowing the test tubes to stand for 10 min, they were vortexed for 30 s and placed for 20 min in a water bath at 25 °C for color development. Then, optical density at 490 nm was recorded on a spectrophotometer. The content of glucose was determined against a standard curve. Glucose solutions with concentrations from 0 to 100 μg/mL were employed as the standard.

**Protein Content.** The protein content was determined by following the method of Bradford.[23] A protein assay kit was purchased from Bio-Rad (Hercules, CA, USA). The protein solution (20 μL), containing 0.05−0.5 mg protein, was pipetted into each well of 96-well plates. The reagent (dye) was diluted by deionized water at 5 times of volume. The diluted dye (200 μL) was pipetted into each sample well, mixed, and reacted at 25 °C for 5 min. The optical density at 595 nm was determined by an ELISA reader (iMark microplate and Microplate Manager 6 software, Bio-Rad). The standard curve was established by using bovine serum albumin (BSA) solutions at different concentrations.

**Content of (1→3)-β-D-Glucan.** Aniline blue assay[24] was employed to determine the content of (1→3)-β-D-glucan. Sample was mixed with 1 N NaOH (1:1 by volume) and stirred at 25 °C for at least 30 min for complete dissolution of polysaccharides The pH of the mixture was adjusted to 11.5 ± 0.1 by adding 1 N HCl, and the volume was then made up to 10 mL by using $Na_2HPO_4$−NaOH buffer (pH 11.5 and containing 0.5 M NaCl). Sample aliquot (2 mL) was reacted with 0.2 mL of 0.1% (w/v) aniline blue (Ferak, Berlin, Germany) for 2 h at 25 °C. The fluorescence intensity was read by a fluorescence spectrophotometer (Hitachi F4500, Tokyo, Japan). The excitation and emission wavelengths of the fluorescence spectrophotometer were set at 395 and 495 nm, respectively. A standard curve was established by using laminarin at concentrations from 0 to 50 μg/mL. The branching of 1→3-β-D-glucan was not determined in this study.

**Mutagenicity Assay.** By following the method of Mortelmans and Zeiger[18] with slight modification, the Ames test was conducted with five *Salmonella* Typhimurium tester strains of TA98, TA100, TA102, TA1535, and TA1537, with or without S9 mix. For each tester strain, a specific positive control was always used to test. Without S9 mix, 4NQO was used as a positive control for TA98, SA was used for TA100 and TA1537, MMC was used for TA102, and 9AA was used for TA1537; benzo[*a*]pyrene (B[a]p) (for TA98) and 2-aminoanthracene (2AA) (for others) were used as positive controls with metabolic activation.

We added 500 μL of S9 mix (or 500 μL of phosphate buffer), 100 μL of test solution at designated concentration, and 100 μL of cell suspension from an overnight culture together. The mixtures were incubated at 37 °C for 20 min with shaking at 100 rpm. The admixtures were diluted using 2 mL of molten top agar and then poured on minimum salts agar. Plates were incubated at 37 °C for 48 h, and the revertant bacterial colonies on each plate were counted. Positive controls and negative controls (distilled water) were maintained concurrently. Three independent assays were performed for statistical analysis. A positive response for mutagenicity was defined as a reproducible 2-fold increase in revertant number with dose−response relationship.[25,26]

**Primary Cell Viability.** Male BALB/c mice were purchased from the National Laboratory Animal Center of Ministry of Science and Technology (Taipei, Taiwan) and domesticated in an air-conditioned room at 23 ± 2 °C with a relative humidity of 40−60% and a 12 h interval light/dark cycle. The organ tissues, including stomach, intestines, colon, liver, and kidney of mice, were collected after

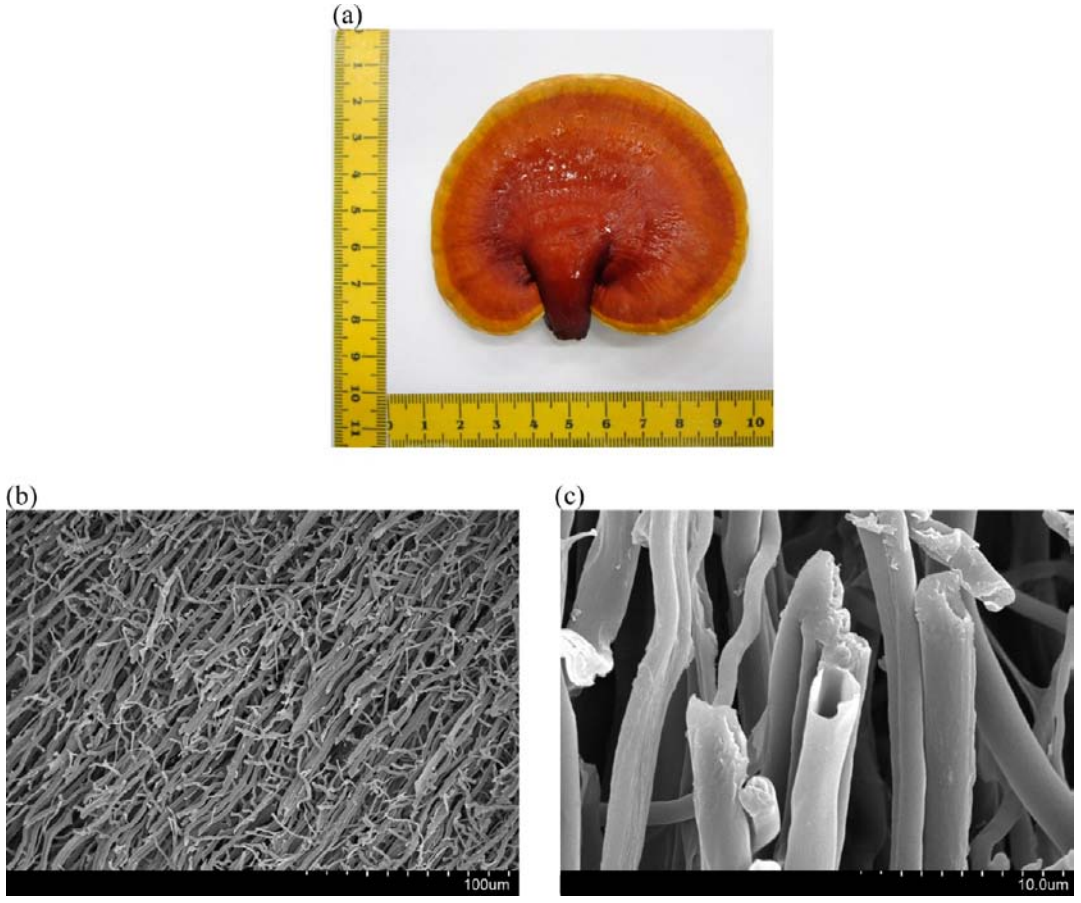

**Figure 1.** (a) Fruit body, (b) hyphae, and (c) enlargement of hyphae of *G. tsugae*.

euthanization. Cell suspensions were prepared according to the method of Park et al.[27] with slight modification. Organ tissues were moistened with RPMI 1640 medium (BI, Biological Industries, Kibbutz Beit Haemek, Israel) containing 10% fetal bovine serum (FBS, BI) and were smashed through a 70 $\mu$m screen filter (BD) in RPMI 1640 medium. Cells were collected, and red blood cells were removed by treatment with a hypotonic solution (8.29 g of $NH_4Cl$, 37.2 mg of $Na_2EDTA$, and 1.0 g of $KHCO_3$). After being washed twice in RPMI 1640 medium, the cells were resuspended in RPMI 1640 with 10% heat-inactivated FBS. Cell suspension was added into the trypan blue on plate to count cell numbers by microscope, and then the cell suspension was adjusted to contain $4 \times 10^5$ cells/mL for MTT assay.

An MTT colorimetric assay[28] with slight modification was employed to determine cell viability. The cell suspensions ($2 \times 10^4$ cells/well) in RPMI 1640 medium supplemented with 10% FBS were treated with *G. tsugae* samples (S-extract or S-supernatant at 0−500 $\mu$g/mL) in a 96-well plate. The control group was treated with an equivalent volume of sterilized deionized water. The 96-well plates were then placed in an incubator (5% $CO_2$, 37 °C) for 24, 48, and 72 h. Then, 25 $\mu$L of 3-[4,5-dimethylthiazol-2-yl]-2,5-diphenyltetrazolium bromide (MTT) (2 mg/mL) was added to each well and incubated for 3 h. After incubation, 50 $\mu$L of DMSO was added to each well, and the optical density at 570 nm was measured by an ELISA reader.

**Statistical Analysis.** Data were reported as the mean of measurements in triplicate. One-way analysis of variance (ANOVA) was used to determine the significance of treatment using the Statistical Analysis System (SAS version 9.1; SAS Institute Inc., Cary, NC, USA), followed by a Duncan's new multiple-range test. Differences were considered as statistically significant when the $P$ value was <0.05.

## RESULTS AND DISCUSSION

**Morphology and Particle Size Distribution.** The appearance of the fresh fruit body of *G. tsugae* is illustrated in Figure 1a, which was similar to the report of Wang et al.[29] Both the contents of ash and crude fat were lower than 2% (dry basis). Crude protein (14.5%) and carbohydrate (81.8%) were two major components. It was woody and rigid even with a water content of 73.9% due to the compounded structure of hyphae (Figure 1b), which appeared to be a hollow tube (Figure 1c). Cao and Yuan[30] have observed hyphae similar to a tube by using a light microscope. This confirmed the microstructure of hyphae by using SEM. Most hyphae had a diameter of about 3 $\mu$m with a few smaller than 0.9 $\mu$m, which could be recognized as natural nanotubes.

Particle size distributions of samples after the treatments are illustrated in Figure 2. The size (in volume) of blended *G. tsugae* ranged from 1.75 to 905 $\mu$m with a volume-mean diameter of 248.50 ± 2.12 $\mu$m (Figure 2a and Table 1). The size distribution was quite wide with multiple peaks. Nevertheless, the size distribution became monomodal in terms of number (Figure 2b) with a range of 1.45−23.8 $\mu$m and a number-mean diameter of 3.38 ± 0.03 $\mu$m (Table 1). The data showed that all of the particles were in micrometer scale. After 3 h of media milling, the largest particle was reduced from 905 to 23.8 $\mu$m (in volume) (Figure 2c). In addition, there existed about 22% of particles smaller than 1 $\mu$m. When counted by number, all of the particles were smaller than 1 $\mu$m with a number-mean diameter of 0.11 $\mu$m (Figure 2d and Table 1). There were about 62% of particles smaller than 0.1 $\mu$m. The

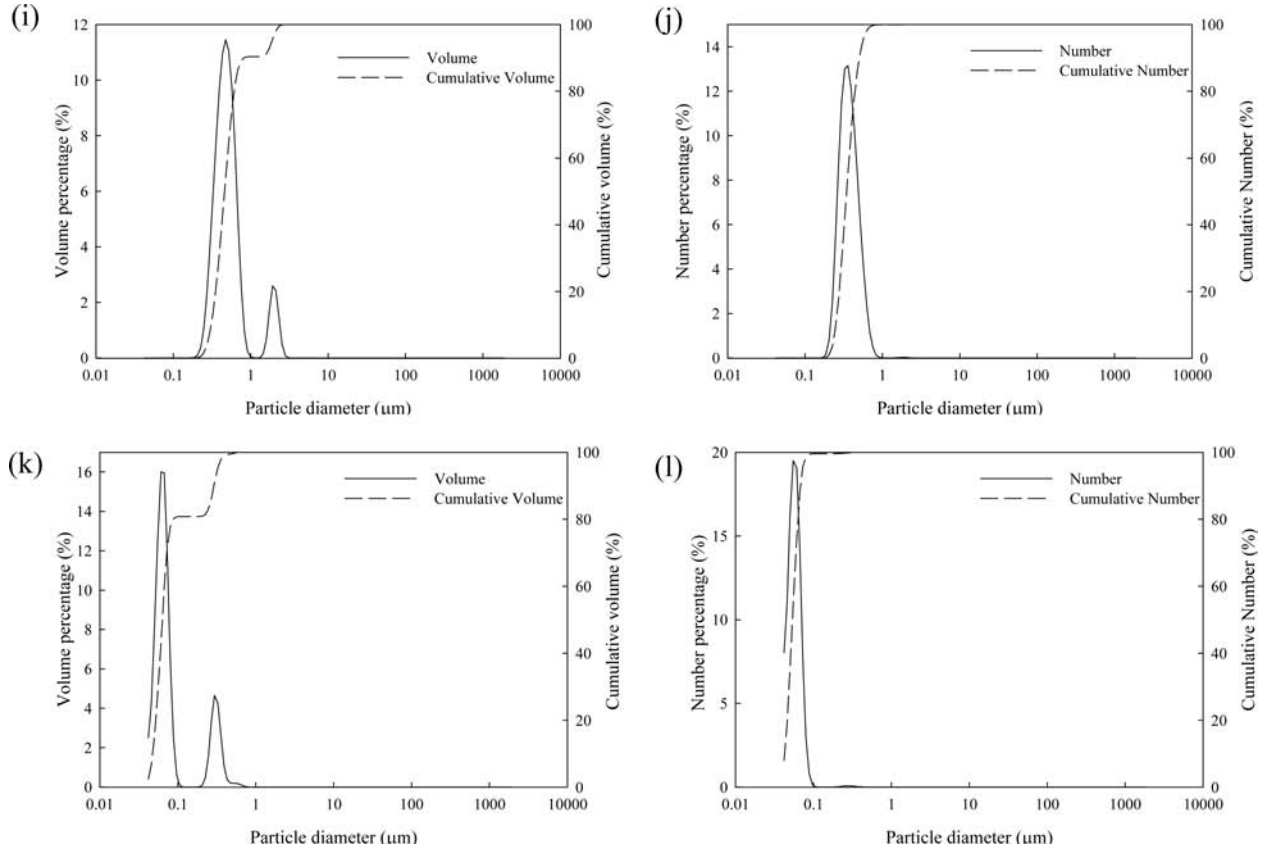

**Figure 2.** Particle size distribution of blended *G. tsugae* in (a) volume and (b) number, 3 h media-milled *G. tsugae* in (c) volume and (d) number, supernatant of centrifuged media-milled (nano/submicrometer) *G. tsugae* in (e) volume and (f) number, filtered media-milled *G. tsugae* (S-supernatant) in (g) volume and (h) number; *G. tsugae* hot-water extract in (i) volume and (j) number, filtered *G. tsugae* hot-water extract (S-extract) in (k) volume and (l) number.

**Table 1. Mean Diameters ($D_v$, $D_n$)[a] of *G. tsugae* Samples with Different Treatments[b]**

| sample | $D_v$ ($\mu$m) | $D_n$ ($\mu$m) |
|---|---|---|
| blended | 248.50 ± 2.12a | 3.38 ± 0.03a |
| media milled 1 h | 10.26 ± 0.47b | 0.10 ± 0.00c |
| media milled 2 h | 6.40 ± 0.75c | 0.10 ± 0.00c |
| media milled 3 h | 3.70 ± 0.23d | 0.11 ± 0.00d |
| supernatant | 0.14 ± 0.02e | 0.08 ± 0.00cd |
| S-supernatant | 0.14 ± 0.00e | 0.07 ± 0.01d |
| hot-water extract | 0.62 ± 0.02e | 0.38 ± 0.01b |
| S-extract | 0.11 ± 0.01e | 0.06 ± 0.00d |

[a] $D_v$, volume mean diameter; $D_n$, number mean diameter. [b] Mean ± standard deviation ($n$ = 3). Values in the same column with different lower case letters (a–e) are significantly different by Duncan's new multiple-range test ($P$ < 0.05).

data indicated that 3 h of media milling resulted in most of the particles being smaller than 1 $\mu$m with a few particles greater than 1 $\mu$m.

After centrifugation (10000 *g*, 10 min), particles in the supernatant (nano/submicrometer *G. tsugae*) ranged from 0.042 to 0.393 $\mu$m with a mean diameter of 0.14 $\mu$m (in volume) (Figure 2e and Table 1). There were 21% of particles smaller than 0.1 $\mu$m. The size distribution of particles was shifted to smaller ones in terms of number (Figure 2f). The percentages of particles smaller than 0.1 $\mu$m were increased to 82%. The centrifugation resulted in a more uniform size distribution by removing large particles. Filtration resulted in bimodal size distribution (Figure 2g,h). The ranges of particle size in volume and number were similar. There were about 84% of particles smaller than 0.1 $\mu$m in terms of number. All of the particles in nano/submicrometer *G. tsugae* and S-supernatant fell in the nano/submicrometer scale. As illustrated in Figure 2i, particles in the hot-water extract ranged from 0.17 to 3.06 $\mu$m with a volume-mean diameter of 0.624 ± 0.019 $\mu$m (Table 1). When counted by number, the size distribution (Figure 2j) was similar to that counted by volume, but no particles were greater than 1 $\mu$m. The data indicated that there existed a more uniform size distribution for the hot-water extract than for media-milled samples. After filtration, all of the particles were smaller than 1 $\mu$m in terms of both volume and number (Figure 2k,l). There were about 99.5% (in number) of particles smaller than 0.1 $\mu$m. The size of both the hot-water extract and the S-extract fell in the nano/submicrometer scale.

After blending, fibrous structure was observed as shown in Figure 3a. An enlargement (Figure 3b) of the image indicated that blending only tore off the fibrous structure of hyphae. This confirmed that there were no nanoparticles in the blended sample. One hour of media milling generated abrasion on the surface of the fibrillar structure and resulted in the reduction of the diameter of filamentous materials (Figure 3c) and the presence of nanoparticles (Figure 3d). There existed few fine particles on the surface of fibrillar structure. From the size measurement, the volume-mean diameter was counted as 10.26 ± 0.47 $\mu$m (Table 1) with a number-mean diameter of 0.1 $\mu$m. Continuous milling (2 h) reduced the volume-mean diameter to 6.40 ± 0.75 $\mu$m (Table 1) with no significant change in

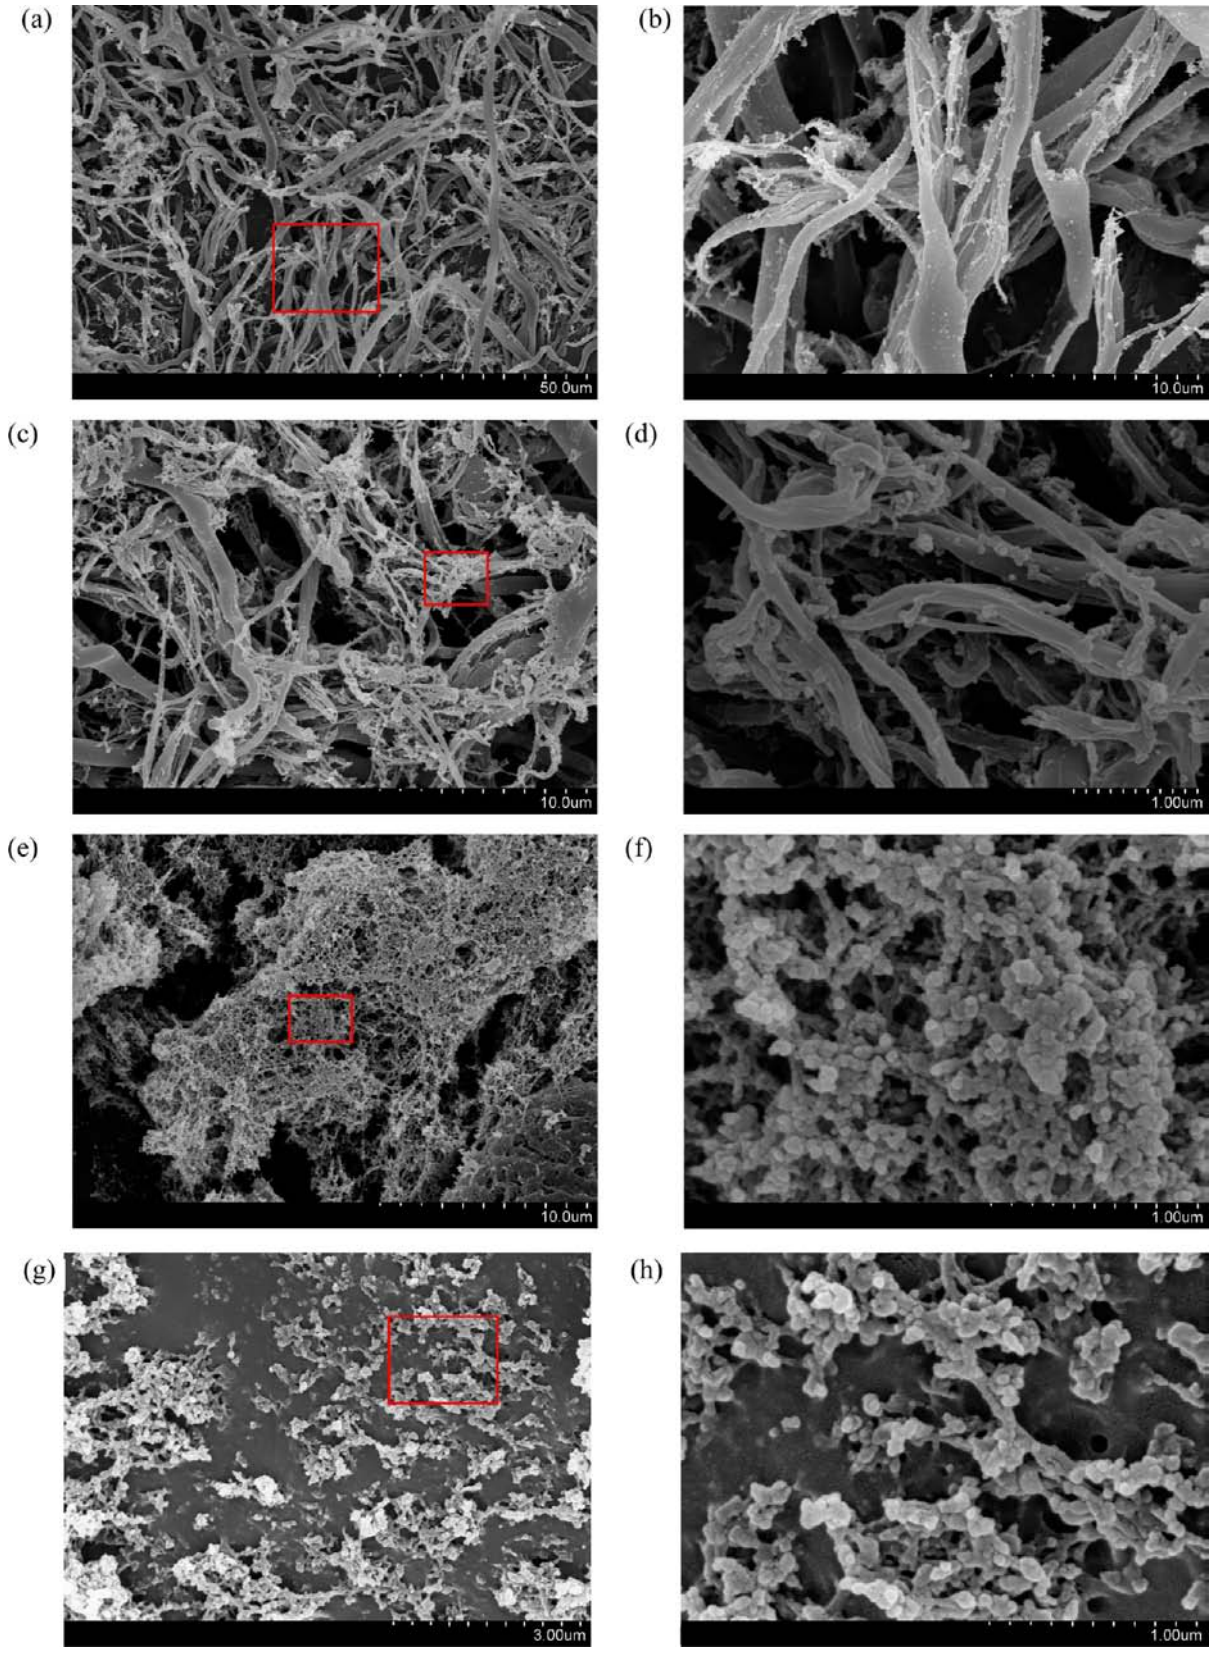

**Figure 3.** continued

dx.doi.org/10.1021/jf503898y | *J. Agric. Food Chem.* 2014, 62, 12244−12255

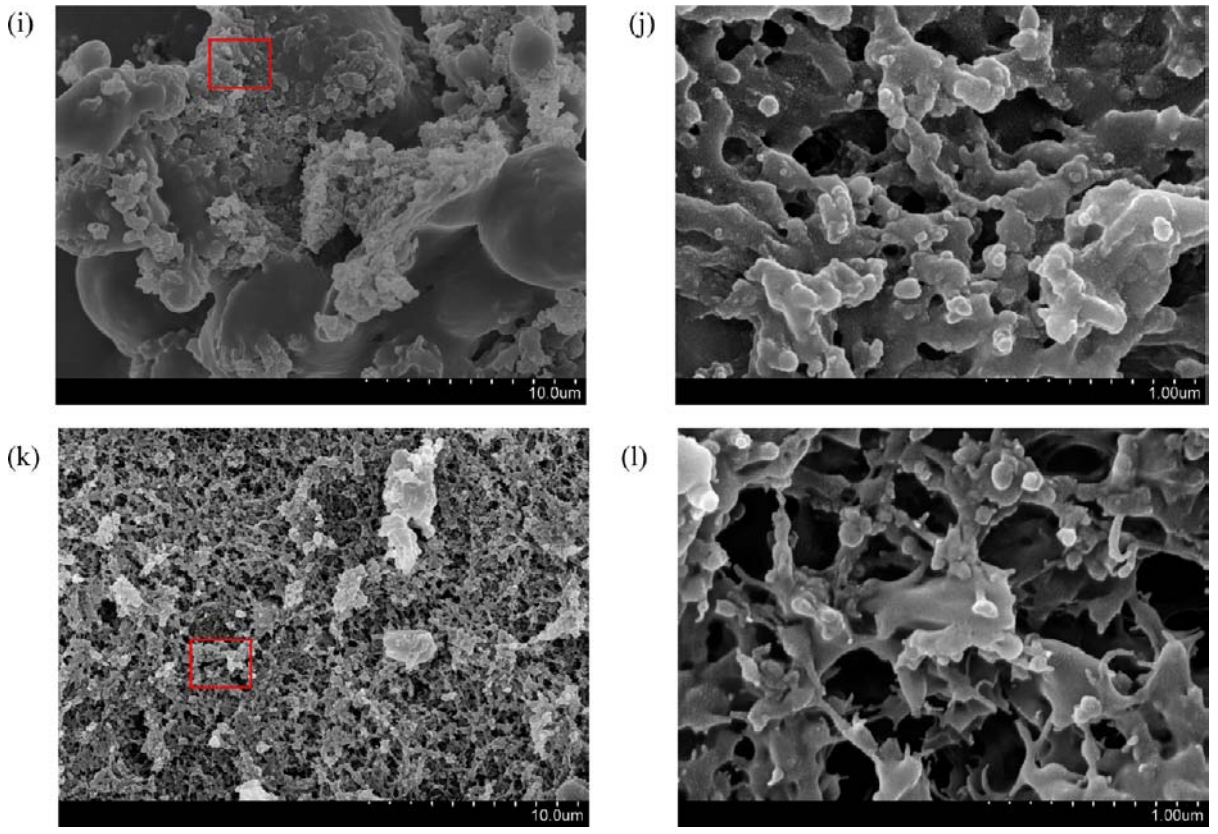

**Figure 3.** SEM of (a, b) blended, (c, d) 1-h media milled, (e, f) 3-h media-milled, and (g, h) filtered media-milled (S-supernatant) *G. tsugae* and (i, j) hot-water extract and (k, l) filtered hot-water extract (S-extract) of *G. tsugae*.

number-mean diameter. The volume-mean diameter was slightly reduced to 3.70 ± 0.23 μm (Table 1) with extended milling (3 h). No fibrillar structures were observed (Figure 3e), and most of the particles were in nano scale (Figure 3f). The observation concurred with the size measurement. Nevertheless, particles aggregated due to lack of dispensers, which would result in the presence of large particles during size measurement.

Filtration removed large particles (Figure 3g) and resulted in finer particles (Figure 3h) with a volume-mean diameter of 0.14 μm and a number-mean diameter of 0.07 μm (Table 1). There existed a few large particles (mostly smaller than 10 μm) in the hot-water extract (Figure 3i). Most of the particles were smaller than 1 μm (Figure 3j) and aggregated similarly to media-milled sample. It was not surprising to see large particles being removed by filtration (Figure 3k), which resulted in a volume-mean diameter of 0.11 μm and a number-mean diameter of 0.06 μm (Table 1). Again, an enlargement of the image illustrated the presence of nanoparticles (Figure 3l). The SEM confirmed that both 3 h media-milled samples and *G. tsugae* hot-water extract consisted of nanoparticles.

Figure 4 summarizes the morphological change in *G. tsugae* during the milling process. Before treatments, native hyphae had a diameter of about 3 μm with few less than 0.9 μm (Figure 4a). Once physical forces were imparted by blending, the surface of hyphae was threaded off and few small particles (smaller than 0.1 μm) were generated (Figure 4b). It appeared that hyphae were torn off by further milling, which resulted in more fine particles (Figure 4c). A mixture of threads and ultrafine particles (Figure 4d) was formed after extended milling. Most of the particles aggregated to form tiny threads, probably due to van der Waals forces and no emulsifiers.

**Composition and Solid Content.** Total carbohydrate, protein, and 1→3-β-D-glucan are three important components in *G. tsugae*. As discussed previously, filtration removed large particles. Nevertheless, filtration did not result in significant difference in the content of total carbohydrate, 1→3-β-D-glucan, and solid for both media-milled samples and hot-water extract (Table 2). The contents of solid and 1→3-β-D-glucan were similar to the report of Lin et al.,[31] who used three different sizes of media. The data indicated that the percentages (in terms of weight) of large particles were small. Thus, the removal of large particles did not significantly affect the solid content. The solid content in S-supernatant was 61% more than in S-extract. The contents of total carbohydrate, protein, and 1→3-β-D-glucan in S-supernatant were >3 times those in S-extract. For example, the content of 1→3-β-D-glucan in S-supernatant was about 3.5-fold that in S-extract. The data indicated that media milling exerted abrasive forces, which was helpful for releasing bioactive compounds from *G. tsugae*. Media milling would be an attractive method for replacing extraction.

**Mutagenicity.** In both non-S9 and S9 conditions, the mutagen in positive control induced the mutation of *Salmonella* Typhimurium strains with high readings of revertant colonies (Tables 3 and 4). Without S9, the $His^+$ revertants of six different concentrations of S-supernatant and S-extract were not significantly different from those of the spontaneous revertants among five tester strains (Table 3). With S9, the $His^+$ revertants of six different concentrations of S-supernatant and S-extract were not significantly greater than those for the

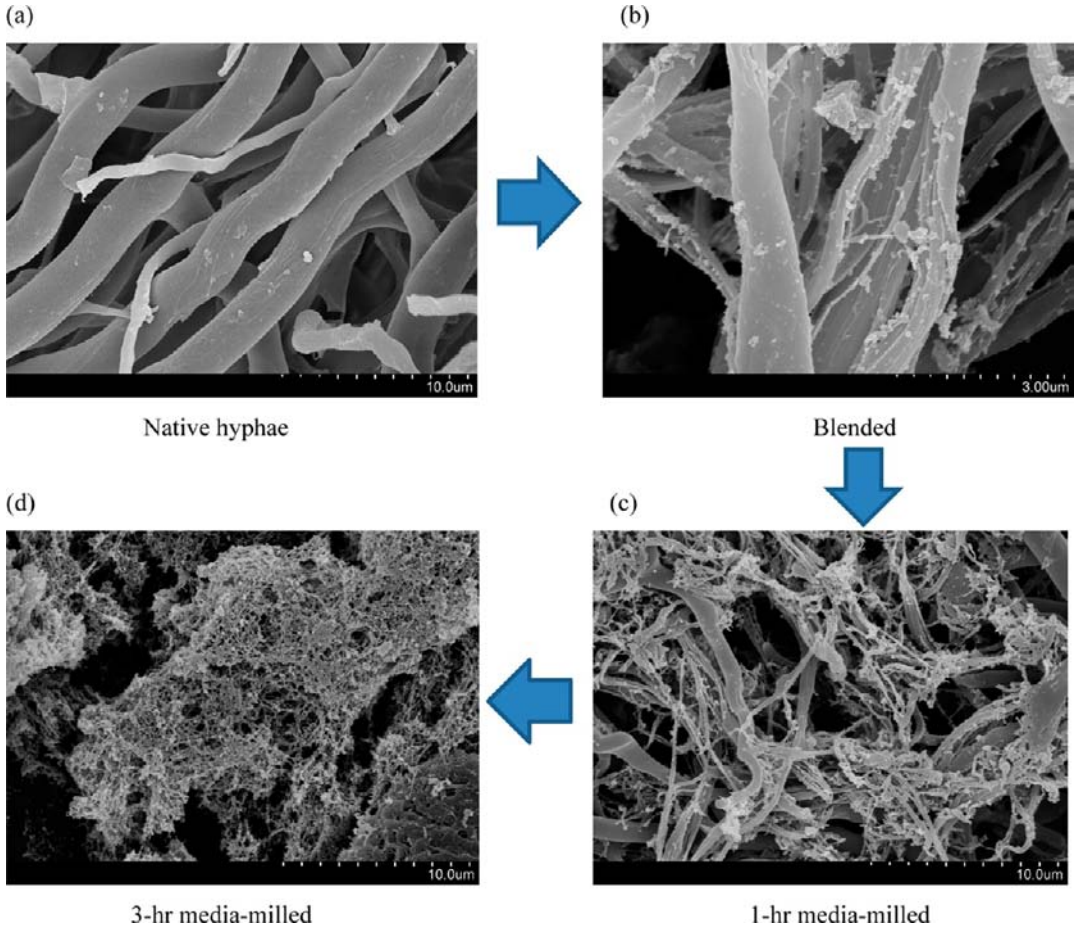

**Figure 4.** Structural change of hyphae from (a) native to (b) blended, (c) 1 h media-milled, and (d) 3 h media-milled.

**Table 2. Total Carbohydrate,[a] Protein, and 1→3-β-D-Blucan Contents of Nano/Submicromemter *G. tsugae*, S-Supernatant,[b] *G. tsugae* Hot-Water Extract, and S-Extract[c]**

| sample | total carbohydrate (μg/mL) | protein (μg/mL) | 1→3-β-D-glucans (μg/mL) | solid content (mg/mL) |
|---|---|---|---|---|
| nano/submicrometer *G. tsugae* | 1528.3 ± 139.4a | 155.5 ± 24.4a | 62.6 ± 8.8a | 3.8 ± 0.4a |
| S-supernatant | 1444.2 ± 150.8a | 132.5 ± 21.0b | 59.8 ± 8.5a | 3.7 ± 0.4a |
| *G. tsugae* hot-water extract | 394.9 ± 38.7b | 22.0 ± 4.7c | 17.9 ± 5.5b | 2.4 ± 0.1b |
| S-extract | 383.1 ± 32.0b | 17.2 ± 4.7c | 17.3 ± 5.b8 | 2.3 ± 0.2b |

[a]Mean ± standard deviation ($n$ = 3).Values in the same column with different lower case letters (a−c) are significantly different by Duncan's new multiple-range test ($p < 0.05$). [b]S-supernatant: nano/submicrometer *G. tsugae* solution filtered by 0.45 μm membrane. [c]S-extract: hot-water extract solution filtered by 0.45 μm membrane.

spontaneous revertants among four strains of TA98, TA102, TA1535, and TA1537. For S-extract, $His^+$ revertants were significant greater than the spontaneous revertants on TA100 strain at three concentrations (25, 100, and 200 μg/mL), but not dose dependent. As pointed out in the literature,[27,28] a compound exhibited mutagenic potencies when $His^+$ revertants were more than doubled the control group with dose dependency. Thus, S-extract did not exhibit mutagenic potencies. The toxicity test against *Salmonella* Typhimurium strains showed the maximum concentrations of S-supernatant and S-extract (300 and 240 μg/mL, respectively) were not toxic at non-S9 and S9 conditions (Tables 3 and 4). Mutation in *Salmonella* (SAL) has been recognized as the most predictive for carcinogenicity among in vitro genetic toxicity in short-term tests. When chemicals exhibit mutagenicity to SAL, 89% of those chemicals have been found to be carcinogenic in rodents.[32] The data indicated that neither S-supernatant nor S-extract exhibited mutagenic potencies.

**Viability of Primary Cells.** S-supernatant did not exhibit any inhibition on the viability of primary cells from the mouse alimentary canal (Figure 5a−c). Once the concentrations of S-supernatant were no less than 250 μg/mL, the viability of primary cells (stomach, intestines, and colon) was significantly greater than the control. The data indicated that S-supernatant was good for the growth of primary cells. Similar results were obtained for S-extract. For intestine cells, there existed a decrease in cell viability when S-extract was employed at 5−100 μg/mL. Nevertheless, the viability remained greater than 100% when the addition levels were no less than 250 μg/mL (Figure 5b-2). Both S-supernatant and S-extract were not toxic to the primary cells from mouse alimentary canal. Both S-supernatant and S-extract exhibited similar effects on the growth of primary cells from liver and kidney (Figure 5d,e) and thus did not

restrain the cells. These might be due to some nutrients present in samples, which resulted in more cell proliferation. In the control group, sterilized deionized water was added to the medium (RPMI 1640, 10% FBS) and resulted in dilution of nutrients. The addition of S-supernatant or S-extract might bring nutrients into the culture. Thus, the enhancement on cell proliferation was concentration dependent. To check this concept, a positive control (not shown in this study) was conducted by adding medium (RPMI 1640, 10% FBS) instead of sterilized deionized water or samples. In other words, there were no concentration changes in culture. There was about a 150−250% increase in cell viability compared with the control group. It appeared that the nutrient concentration in the control group was the least one. In addition, polysaccharides have been found to stimulate cell proliferation via the *c-myc* gene.[33] Nevertheless, the mechanism of the increase in cell proliferation needs further studies. Some nanoparticles have been found to exhibit cytotoxic and genotoxic potential, such as copper oxide nanoparticles[34] and methyl parathion and parathion.[35] Unlike metallic material and insecticide, both S-supernatant and S-extract (containing nano/submicrometer-scaled particles) originated from the edible resource of *G. tsugae*

chain length, $M_w$ of $\beta$-glucan, and addition of acyl imidazole were investigated. On the basis of the structural features and aqueous self-assembly behavior of the products characterized by FT-IR, $^1$H NMR, and TEM, the structure–curcumin loading capacity (CLC) relationship of FAOGEs was investigated.

## MATERIALS AND METHODS

**Materials.** A commercial soluble $\beta$-glucan (80 wt % $\beta$-glucan content) extracted from oats was bought from Zhangjiakou Yikang Biological Technology Co., Ltd. (Zhangjiakou, China). Methyl decanoate, methyl octanoate, methyl hexanoate, *N*,*N*′-carbonyl-di-imidazole (CDI), and curcumin (98%) were purchased from Adamas Reagent Co. (Shanghai, China). Hexanoic acid, octanoic acid, decanoic acid, isopropanol, dimethyl sulfoxide (DMSO), acetonitrile, and formic acid were bought from KeLong Reagent Co,. Ltd. (Chengdu, China). Potassium bromide (KBr) of infrared spectroscopy grade was obtained from GuangFu Reagent Chemical Co., Ltd. (Tianjin, China). All chemical reagents were commercially available and used as received.

**Preparation of Oat $\beta$-Glucan Hydrolysates.** Two hydrolysates of oat $\beta$-glucan (denoted OG1 and OG2) were prepared according to a previously described method with slight modifications.[19] In detail, oat $\beta$-glucan (2.0 g) was dispersed in 1 L of distilled water and heated at 80 °C with magnetic stirring for 2 h. The resulting solution was cooled to room temperature and then centrifuged at 3000*g* for 10 min to obtain oat $\beta$-glucan solution. One milliliter (OG1) or 3 mL (OG2) of hydrochloric acid (6 M) was mixed with 500 mL of the above-prepared oat $\beta$-glucan solution. Then, the mixture was incubated at 50 °C for 10 min to allow the intended hydrolysis. After hydrolysis completed, the hydrolysates were rapidly cooled to room temperature and neutralized (pH 6–7) with 2 M NaOH. The mother $\beta$-glucan solution and its hydrolysates were precipitated by respectively mixing them with 2 volumes of ethanol and lyophilized. The $M_w$ values of oat $\beta$-glucan, OG1, and OG2 were determined as $16.8 \times 10^4$, $12.1 \times 10^4$, and $7.4 \times 10^4$ g/mol, respectively, on a high-performance size-exclusion (HPSEC) system.[20]

**FAOGE Synthesis.** To synthesize FAOGE, a two-step reaction was carried out according to the method reported in the literature (Figure 1).[21] For the first step, fatty acid (0.031 mol) and CDI (5.02 g, 0.031 mol) were dissolved in 50 mL of DMSO. The resultant solution was kept at 60 °C for 16 h to realize the activation of fatty acid in the form of acyl imidazole. In the next step, oat $\beta$-glucan (1 g) was dissolved in DMSO (20 mL) at 70 °C with continuous stirring for 30 min. Then the non-isolated acyl imidazole was added dropwise into the oat $\beta$-glucan solution, and the resultant solution was kept at 70 °C under continuous agitation for 4 h to produce FAOGE. The DS of the products was monitored by the addition of acyl imidazole. The product was precipitated from reacting solution by mixing with 2 volumes of isopropanol. It was recovered by vacuum filtration through an 80 mm diameter Buchner funnel and washed five times with

isopropanol (300 mL) to completely eliminate the unreacted regents. The precipitate was dissolved in distilled water and successively dialyzed against tap water (24 h) and distilled water (24 h) in a dialysis bag (MD44-14, Union Carbide Co., Seadrift, TX, USA) with a size exclusion of 14000 g/mol for globular molecules.[22,23] Finally, the dialysate was lyophilized to obtain FAOGE. The effects of synthesis parameters on the reaction efficiency, in terms of DS, were investigated using a response surface methodology (RSM). The observed parameters included $A$, acyl chain lengths; $B$, $M_w$ of $\beta$-glucan; and $C$, addition of acyl imidazole. The independent factors, levels, and experimental design in terms of coded and uncoded values are shown in Table 1.

**Determination of Degree of Substitution.** The DS of FAOGEs was determined according to a previously described method with slight modifications.[24] The sample (30 mg) dissolved in 0.5 mL of DMSO was mixed with 1 mL of 0.07 M sodium methoxide in methanol. The mixture was then hermetically heated to 80 °C and kept for 60 min. After the mixture was completely cooled, 1 mL of deionized water and 1 mL of $n$-heptane were added. The mixture was shaken for 1 min and left to settle. The top organic phase could be subjected to GC analysis with methyl laurate as an internal standard.[25] A gas chromatography (GC) system (GC-2010, Shimadzu, Kyoto, Japan) equipped with a DB-WAX capillary column (30 m × 0.25 mm i.d.; SGE Inc., Austin, TX, USA) and a flame ionization detector (FID) was applied. Nitrogen was supplied as carrier gas, and the column oven temperature was equilibrated at 100 °C for 3 min, ramped at 10 °C/min to 220 °C, and maintained at 220 °C for 3 min. The DS of the fatty acid ester was calculated using the equation previously reported by Singh et al.[5]

**FAOGE Characterization.** The esterification of oat $\beta$-glucan with fatty acids were evidenced with the aid of $^1$H NMR and Fourier transform infrared spectroscopy (FT-IR). $^1$H NMR spectra of the samples in DMSO-$d_6$ were recorded on a Bruker AV 600 MHz (Bruker Corp., Fallanden, Switzerland). Chemical shifts were given in parts per million (ppm) from tetramethylsilane. FT-IR spectra were acquired on a PerkinElmer Spectrum 2000 Fourier transform IR spectrometer (Shelton, CT, USA) using KBr disks prepared from powdered samples mixed with dry KBr in a weight ratio of 1:30. The morphology of nanoparticles of FAOGE in aqueous solution was observed at 200 kV using a JEOL JEM-2100 instrument (JEOL, Japan) equipped with a Gatan 94 Ultrascan 1k charge-coupled device camera.[15,26] The behavior of the aqueous solution of FAOGE was characterized by fluorescence spectroscopy.[27] Meanwhile, the size of

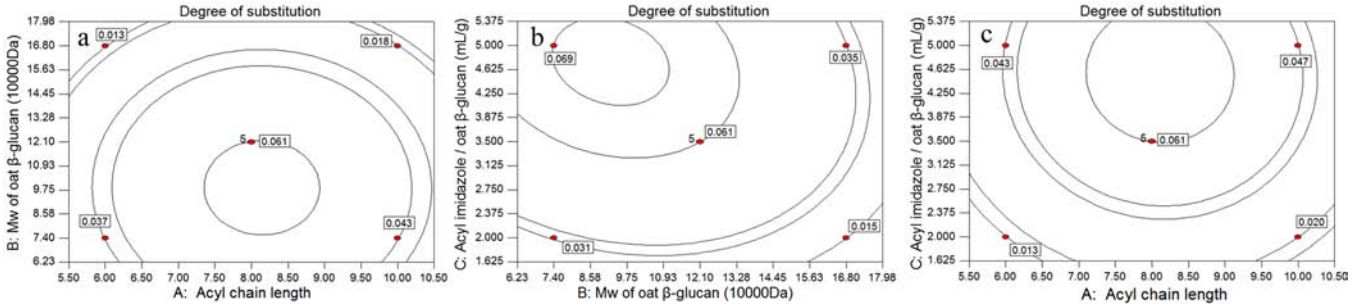

**Figure 2.** Response surface plots showing the interactive effects of acyl chain length ($A$), $M_w$ of oat $\beta$-glucan ($B$), and addition of acyl imidazole ($C$) on the degree of substitution of fatty acid oat $\beta$-glucan esters (FAOGEs).

the self-aggregates formed by FAOGE was determined by dynamic light scattering (DLS) with a Malvern Zetasizer, Nano ZS90 (Malvern Instruments Limited, Malvern, Worcestershire, UK).[28] Finally, the solubilizing or loading capacity of FAOGE for curcumin, a representive of hydrophobic phytochemicals, was determined according to a previously reported method.[16] With the aid of RSM, the structure−CLC of FAOGEs was explored by using CLC as dependent and $M_w$ of $\beta$-glucan, acyl chain length, and DS as variables. The experimental design in terms of coded and uncoded values is shown in Table 3.

**Statistical Analysis.** All results were expressed as means with standard deviations of at least three measurements. Statistical significance of difference between groups was tested by one-way analysis of variance (ANOVA) using SPSS 19.0 (SPSS Inc., Chicago, IL, USA). In all statistical analyses, $P < 0.05$ was considered significant.

## RESULTS AND DISCUSSION

**FAOGE Synthesis.** The design of RSM and the determined and predicted results of 17 designed experimental runs are depicted in Table 1. ANOVA (Table 2) was used to attest the effects of the acyl chain length ($A$), $M_w$ of $\beta$-glucan ($B$), addition of acyl imidazole ($C$), and their quadratic terms ($A^2$, $B^2$, $C^2$) and interactive terms ($AB$, $AC$, $BC$) on the DS of FAOGE. The results indicated that $M_w$ of $\beta$-glucan ($B$), addition of acyl imidazole ($C$), and all three quadratic terms ($A^2$, $B^2$, $C^2$) generated significant effects on DS, whereas the DS values of FAOGEs were independent of acyl chain length ($A$) and all three interactive terms ($AB$, $AC$, $BC$). Together, these results indicate that the three selected factors are vital to FAOGE synthesis. Comparatively, $M_w$ of $\beta$-glucan ($B$) and the addition of acyl imidazole ($C$) are of more importance than the acyl chain length ($A$) in terms of their effects on DS.

To reflect the effect tendencies of selected factors on DS, the isoresponse curves are plotted as a function of two factors, whereas the third is maintained at its central level (0) (Figure 2). Panels a and b of Figure 2 reveal that the DS of FAOGEs with the same acyl significantly decreased with the $M_w$ of $\beta$-glucan. With regard to the plausible reason for the effects of $M_w$ on DS of modified $\beta$-glucan, the increase in the number of hydroxyl groups resulting from acid hydrolysis was first considered. However, on the basis of the number-average molecular weights of native $\beta$-glucan ($13.95 \times 10^4$), OSG1 ($3.93 \times 10^4$), and OSG2 ($2.71 \times 10^4$), the number of hydroxyl groups per mole of OSG1 and OSG2 increased by approximately 0.27 and 0.40% in contrast to that of native $\beta$-glucan, whereas the DS of their modified products with octanoic acid substantially increased by 154.6 and 168.2%. Therefore, the increased number of hydroxyl groups is not the sole explanation for the increased DS of modified $\beta$-glucan with lowered $M_w$. To make the truth clearer, differences in the average reactivity, steric hindrance, and solution viscosity of $\beta$-glucans with varied $M_w$ should be addressed. In acid hydrolysis of $\beta$-glucan, the cleavage of a 1,3- or 1,4-glycosidic bond generated a new $C_1$−OH and a $C_3$− or $C_4$−OH. Commonly, the reactivity of hydroxyl groups decreased in a position sequence of $C_4 < C_3 < C_2 < C_6 < C_1$.[29−31] In this context, the newly derived hydroxyl groups by acid hydrolysis possessed a higher reactivity than those in native $\beta$-glucan. Obviously, hydrolyzed $\beta$-glucans were certainly smaller than native $\beta$-glucan and possessed more flexible chains,[32] which substantially decreased the steric hindrance of backbone chains[30] and consequently increased the regent accessibility.[33] In addition, decreased solution viscosity of $\beta$-glucans was always accompanied by the decrease in their molecular weight.[34] The decreased viscosity denoted more vivid Brownian movements of substrates and, as a result, an increase in their contact frequency was obtained, which finally facilitated the expected etherification.[35]

Panels a and c of Figure 2 reveal that the DS of FAOGEs first increased and then decreased with the acyl chain length within an insignificant level. Similarly, according to the research of Aburto et al., under the same reaction conditions, the DS of fatty acid starch esters prepared with octanoyl and decanoyl were equivalent.[36] Fang et al. also reported that no obvious differences were observed on the DS of fatty acid starch esters when gelatinized potato starch was reacted under the same conditions with butyryl chloride, capryloyl chloride, and lauroyl chloride.[37] Consequently, the present results implied the hexanoyl imidazole, octanoyl imidazole, and decanoyl imidazole presented analogous reactivity with oat $\beta$-glucan.

Panels b and c of Figure 2 illustrate that the DS of FAOGEs sharply increased with the addition of acyl imidazole. This was obviously due to the fact that the increase in acyl imidazole concentration brought about a higher contact frequency between acyl imidazole and $\beta$-glucan. The enhanced contact frequency improved the reaction efficiency of esterification.[38]

According to the results of RSM, the dependence of DS on the acyl chain length ($A$), $M_w$ of $\beta$-glucan ($B$), and addition of acyl imidazole ($C$) could be described by the following equation:

$$DS = 0.061 + 0.0028A - 0.013B + 0.014C - 0.02A^2 - 0.013B^2 - 0.01C^2 - 0.00025AB - 0.00075AC - 0.0043BC$$

This equation could be used as a model to provide a solid support in synthesizing water-soluble FAOGEs with required DS by modulating the addition of acyl imidazole in the reaction system. The good performance of this model is attested by Table 2 in terms of the significance of the model ($P$ value), the coefficient of determination ($R^2$), "lack of fit", and the coefficient of variation (CV). The present $P$ value (<0.0001)

and "lack of fit" ($P$ value = 0.12) indicated the equation was accurate enough to represent the actual relationship between DS and the addition of acyl imidazole. A high value of $R^2$ (0.98) implied a heavy dependence of DS on the addition of acyl imidazole. In other words, when specific oat $\beta$-glucan (with known $M_w$) and fatty acid (with known chain length) were used as substrates, 98% of the variability in DS could be explained by the variation in the addition of acyl imidazole.[39] Furthermore, a small value in CV (9.24%), not higher than 10%, indicated a good reproducibility of this model in controlling FAOGE synthesis.[40] To validate this model, a FAOGE with an expected DS of 0.030 was synthesized in triplicate in our laboratory with native oat $\beta$-glucan ($M_w$ = 16.8 × $10^4$ g/mol) and octanoic acid. The obtained results (0.028, 0.030, 0.029) gave an average DS of 0.029, which was comparative to the expected value.

**FAOGE Characterization.** The structural characteristic changes of oat $\beta$-glucan induced by the esterification with fatty acids were evidenced by FT-IR and $^1$H NMR analysis. The native oat $\beta$-glucan and its octoates with varied DS were compared as representatives. Figure 3 compares the FT-IR

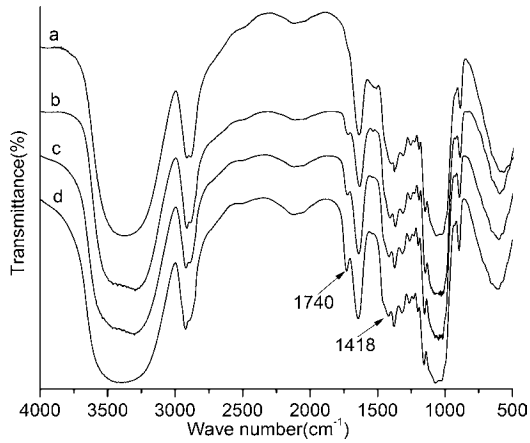

**Figure 3.** FT-IR spectra of native $\beta$-glucan (a) and $\beta$-glucan octoates with degrees of substitution of 0.011 (b), 0.021 (c), and 0.034 (d).

spectra of $\beta$-glucan octoates with that of native $\beta$-glucan. Obviously, the differences between FT-IR spectra of $\beta$-glucan octoates and native $\beta$-glucan were mainly related to the presence of a peak at 1740 $cm^{-1}$ and the peak intensity at 1418 $cm^{-1}$. With regard to peak at 1740 $cm^{-1}$, it was unlimitedly observed for $\beta$-glucan octoates but absent from the FT-IR spectrum of native $\beta$-glucan. Moreover, the intensity of this peak increased with the DS of $\beta$-glucan octoates. On the basis of the related references, this peak could be assigned to C═O stretching vibration of octanoyl groups and evidenced the successful synthesis of FAOGE.[18,41] With regard to the peak at 1418 $cm^{-1}$ attributed to the C—H scissoring vibration of $CH_2$ groups,[42] $\beta$-glucan octoates presented stronger intensity than native $\beta$-glucan. Therefore, the increased number of $CH_2$ groups by the introduction of acyl groups revealed the truth.

The $^1$H NMR spectra of native oat $\beta$-glucan (Figure 4a), oat $\beta$-glucan octoates with DS of 0.011 (Figure 4b), 0.021 (Figure 4c), and 0.034 (Figure 4d) are depicted in Figure 4. Obviously, the $^1$H NMR spectra of oat $\beta$-glucan octoates showed significant differences from that of native oat $\beta$-glucan. The most relevant changes were observed in the scope of 0.80−2.30 ppm. The important signals in the $^1$H NMR spectra were assigned according to previously reported data in the literature. The prominent peaks at 3.33 and 2.49 ppm resulted from the solvents, that is, $H_2O$ and DMSO, respectively.[43] Peaks around 5.39, 5.26, and 4.65 ppm were assigned to chemical shifts of 3-OH, 2-OH, and 6-OH, respectively.[8] Compared to native $\beta$-glucan, $^1$H NMR signals at 2.31, 1.49, 1.24, and 0.85 ppm arose in the $^1$H NMR spectra of $\beta$-glucan octoates as protons of octanoyl groups suggested that the oat $\beta$-glucan were substituted by octanoyl groups during the esterification process. The triplet peak (peak 5 in Figure 4), centered at 0.85 ppm, was assigned to the three protons in the terminal methyl group of the octanoyl chain.[41] Another triplet peak (peak 4 in Figure 4) located around 1.24 ppm was associated with the four methylene groups adjacent to the terminal methyl group.[18] The weak peak (peak 3 in Figure 4) at 1.49 ppm was related to the second methylene group in the octanoyl chain. Finally, the proton resonance at 2.31 ppm (peak 2 in Figure 4) was linked to the methylene group directly attached to the carbonyl group.[44]

When the intensity of peaks at 1.49, 1.24, and 0.85 ppm was correlated to the DS of oat $\beta$-glucan octoates, high correlation coefficients of 0.9781, 0.9866, and 0.9739 were obtained, respectively. This confirmed that $^1$H NMR spectroscopy is a reliable method for determining the DS of fatty acid polysaccharide esters.[45]

As is well-known, water-soluble amphiphilic molecules can spontaneously self-assemble in aqueous solution and form self-aggregates, such as micelles and vesicles.[3] The solution behavior of FAOGEs was investigated with a soluble oat $\beta$-glucan octoate (DS = 0.021) as the substrate. The present study evidenced the self-aggregate formation of oat $\beta$-glucan octoate with the aid of TEM (Figure 5a). This figure also depicted that the self-aggregates were spherical with diameters ranging from 100 to 400 nm. To obtain more information on the formation of the self-aggregate, the behavior of $\beta$-glucan octoate in aqueous solution was investigated by fluorometry and its CAC was determined. As shown in Figure 5b, the $I_{373}/I_{384}$ ratio was approximately 1.80 at low concentration of oat $\beta$-glucan octoate (0.0003−0.03 mg/mL). However, it was gradually decreased with further increase in oat $\beta$-glucan octoate concentration, suggesting the onset of $\beta$-glucan octoate micellization.[46] Accordingly, the CAC of oat $\beta$-glucan octoate (DS = 0.021) was determined as 0.144 mg/mL, which was comparative to the previous results obtained for octenylsuccinated oat $\beta$-glucan in our laboratory.[15] Furthermore, the size distribution of the self-aggregate was characterized by DLS. The obtained DLS curves gave two peaks, that is, a smaller peak located around 100 nm and a bigger one centered at a larger size (300−600 nm). The smaller peak was related to polymeric micelles, and the bigger one was ascribed to the larger self-aggregates.[47] By comparing two curves in Figure 5c, it was concluded that the average size of the self-aggregate increased with the concentration of $\beta$-glucan octoate. This was possibly due to the increased viscosity of the $\beta$-glucan octoate solution resulting from high concentration.[15]

**Structure−CLC Relationship of FAOGE.** The self-aggregate of an amphiphilic polymer in aqueous media possessed a hydrophobic inner core surrounded by a hydrophilic outer shell.[3] The former guaranteed its ability to capture the hydrophobic agents, and the latter was responsible for its solubility in water. Therefore, the self-aggregates of amphiphilic polymers could be used as a tool to increase the solubility, stability, and bioavailability of small hydrophobic

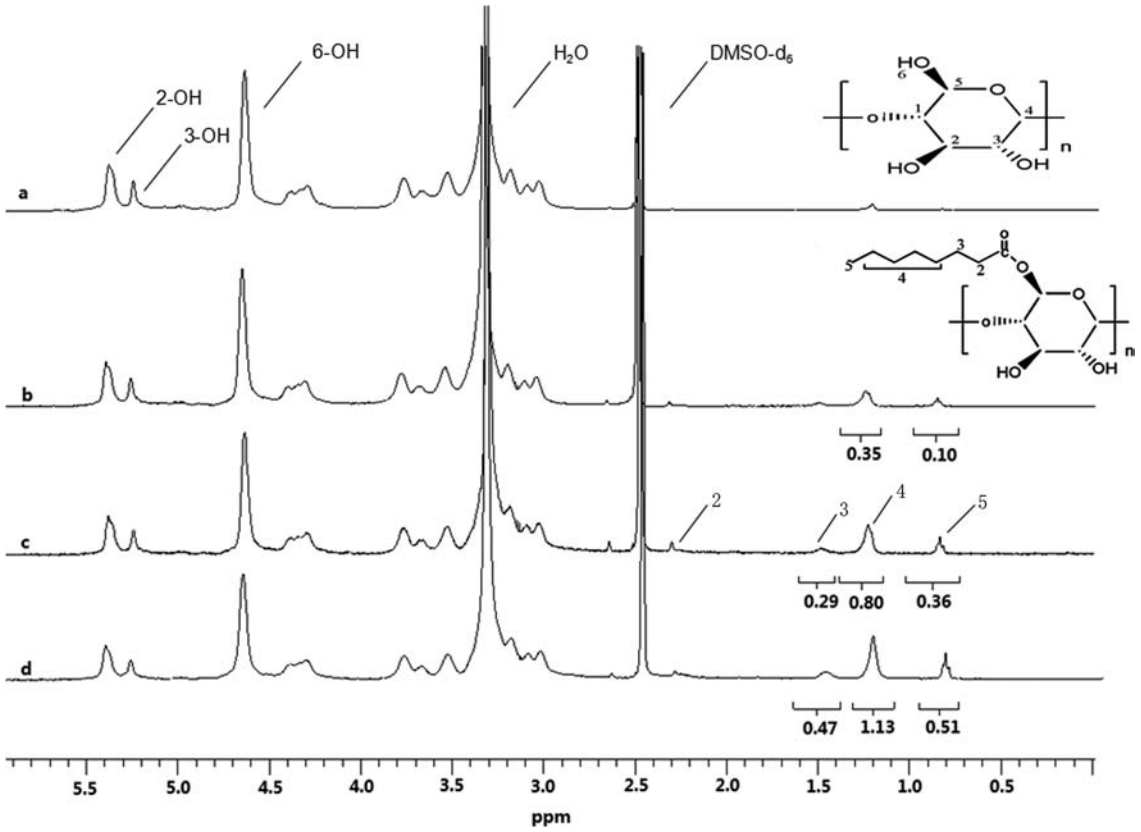

**Figure 4.** [1]H NMR spectra of native $\beta$-glucan (a) and $\beta$-glucan octoates with degrees of substitution of 0.011 (b), 0.021 (c), and 0.034 (d). The data located beneath a peak correspond to its intensity.

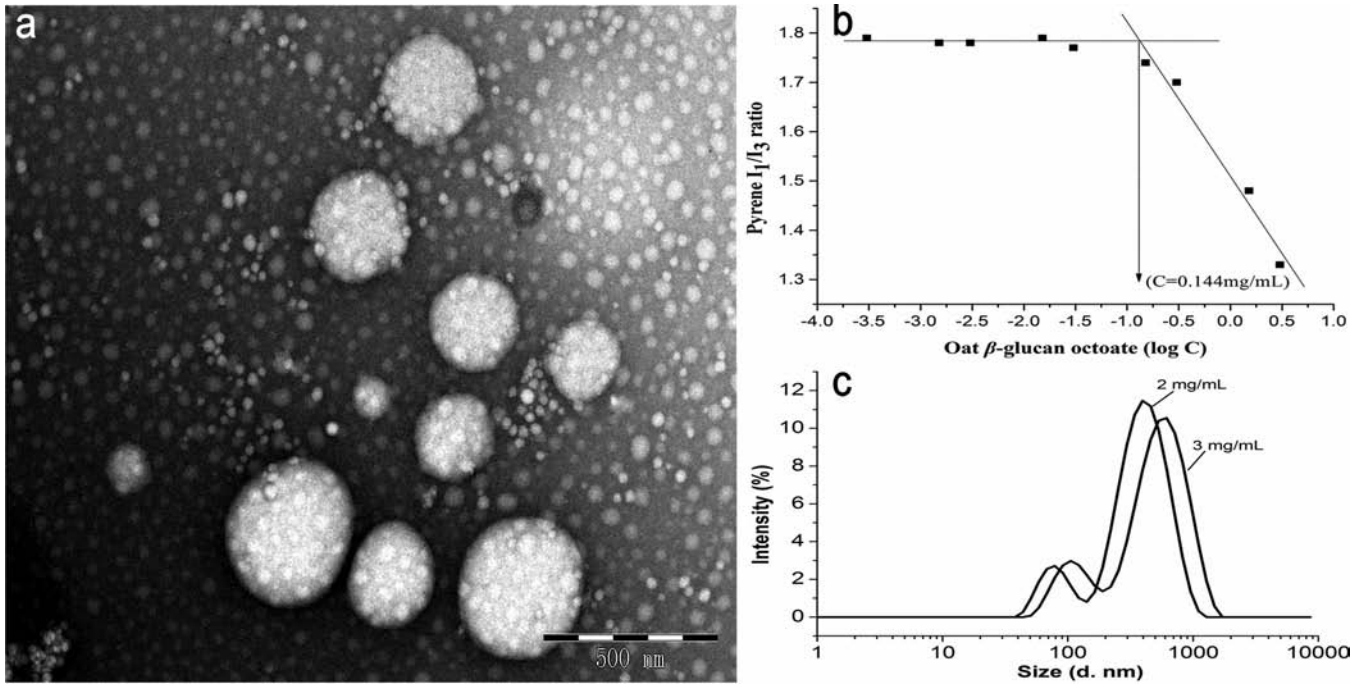

**Figure 5.** Morphology (a), critical aggregation concentration (b), and size distribution (c) of self-aggregates of oat $\beta$-glucan octoate (DS = 0.021) determined or recorded by transmission electron micrograph, fluorescence spectroscopy, and dynamic light scattering, respectively.

compounds.[4] Basically, the solubilizing or loading capacity of a specific hydrophobic agent by micelles formed with an amphiphilic polymer was heavily dependent on its structure parameters.[48] Accordingly, the effects of key structural parameters of FAOGEs, namely $M_w$ of $\beta$-glucan, DS, and acyl chain length, on hydrophobic agent loading capacity by its micelle were explored. This investigation was performed with RSM by using curcumin as an example hydrophobic agent and

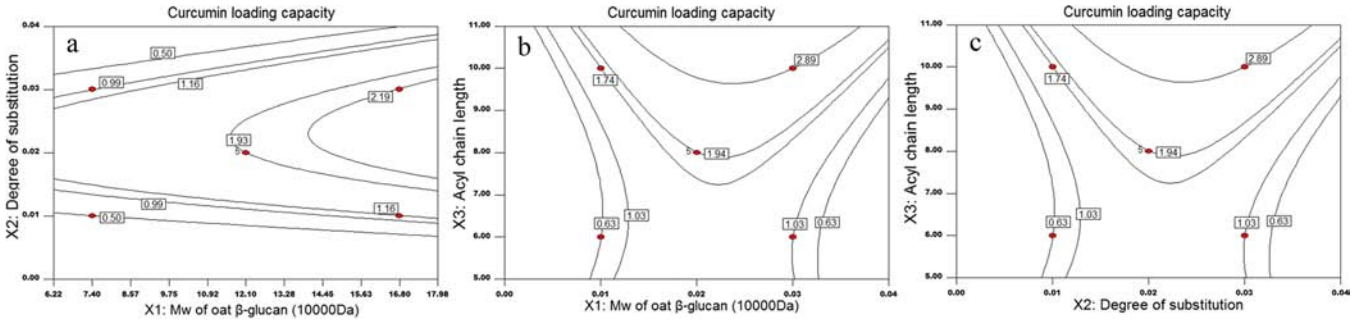

**Figure 6.** Response surface plots showing the interactive effects of $M_w$ of $\beta$-glucan ($X_1$), degree of substitution ($X_2$), and acyl chain length ($X_3$) on the curcumin loading capacity of fatty acid oat $\beta$-glucan ester (FAOGE) micelles.

the above-mentioned structural parameters as variables. The design of RSM and the determined and predicted loading capacities of 17 designed experimental runs are depicted in Table 3. The 17 subjects required for the experiment of structure−capacity relationship (with known $M_w$ of $\beta$-glucan, specific acyl chain length) were synthesized by modulating the addition of acyl imidazole using the above-obtained model. The subjects were validated by judging whether their DS located in the scope of uncoded value ±0.002. The structure−CLC relationship was obtained by multiple regression analysis. The effects of $M_w$ of $\beta$-glucan ($X_1$), DS ($X_2$), and acyl chain length ($X_3$) on the dependent variable CLC ($Y$) could be described by the following model:

$$Y = 1.93 + 0.47X_1 + 0.39X_2 + 0.74X_3 + 0.14X_1X_2 + 0.31X_1X_3 + 0.19X_2X_3 + 0.019X_1^2 - 0.74X_2^2 + 0.39X_3^2$$

The ANOVA (Table 4) results showed that the quadratic polynomial model was statistically significant ($P < 0.0001$) together with an $R^2$ value of 0.98. This indicated that the obtained regression model is effective in explaining the effects of three selected structural parameters on CLC and could be used as a tool to quantitatively predict the resulting changes in CLC when any of the considered parameters had been changed. The "lack of fit $P$ value" of 0.0946 implied the "lack of fit" was not significant relative to the pure error. The small value of CV (9.74%) indicated the considerable precision and reliability of the obtained model. From Table 4, it was also observed that $M_w$ of $\beta$-glucan ($X_1$), DS ($X_2$), acyl chain length ($X_3$), the quadratic terms ($X_2^2$, $X_3^2$), and the interactive terms ($X_1X_3$) had significant effects on the CLC of FAOGE micelles ($P < 0.05$), whereas the quadratic term of $M_w$ of $\beta$-glucan ($X_1^2$), the interactive term of $M_w$ of $\beta$-glucan and DS ($X_1X_2$), and the interactive term of DS and acyl chain length ($X_2X_3$) presented little effect on the CLC of FAOGE micelles ($P > 0.05$).

The effect tendencies of selected factors on CLC were studied by plotting the isoresponse curves (Figure 6) as a function of two factors, whereas the third is fixed at zero level. Panels a and b of Figure 6 reveal that the CLC of FAOGE micelles increased with the $M_w$ of $\beta$-glucan. The similar tendencies were observed in loading curcumin in octenylsuccinate oat $\beta$-glucan,[16] pluronic block copolymer,[49] and poly(ethylene oxide)-*b*-poly($\varepsilon$-caprolactone).[50]

For the effects of DS on CLC of FAOGE micelles, a typical parabola pattern was observed (Figure 6a,c). In other words, CLC values maximized at a medium DS. In lower DS scope (0.01−0.024), CLC increased with DS. This could be ascribed to the following reasons: (1) the increase in DS improved the self-aggregating ability of FAOGEs and resulted in a significant increase in the number of micelles for cucurmin solubilization; (2) the increase in DS enhanced the molecular interaction between cucurmin and FAOGE and facilitated the cucurmin solubilization. Oppositely, in higher DS scope (0.024−0.03), CLC decreased with DS. This could be explained as the (1) further increase in DS decreasing the micelle size significantly, leading to less accommodation for curcumin loading;[15] or (2)

the presence of too much acyl group in the hydrophobic core of the formed micelles impeding the loading of curcumin. The similar tendencies in the effects of DS on loading capacity were observed for complexing steroids by sulfoalkyl ether β-cyclodextrins[51] and loading curcumin in octenylsuccinate oat β-glucan micelles.[16]

With regard to acyl chain length, its increase was always accompanied by an increase in CLC (Figure 6b,c). With the similar DS, the FAOGE with a longer acyl chain length was more hydrophobic than the counterpart with a shorter acyl chain length.[52] As reported previously, hydrophobic interaction is the driving force for the FAOGE micelle to encapsulate curcumin.[16] Thus, the longer the acyl chain length, the more curcumin entrapped in the micelles.

Theoretically, according to the obtained model, a maximum CLC (4.01 μg/mg) could be achieved when a FAOGE with structural parameters of $M_w$ = 16.8 × $10^4$ g/mol, acyl chain length = 10, and DS = 0.0243 was applied. At a FAOGE concentration of 2 mg/mL and solubilizing procedure duration of 24 h, the maximum CLC was validated as 4.05 ± 0.26 μg/mg (Supporting Information).

In summary, with an aim to prepare a novel amphiphilic polymer, FAOGEs were first synthesized in the present study by reacting oat β-glucan with CDI-activated fatty acids in DMSO. RSM was used to analyze the effects of three key reaction parameters (acyl chain length, $M_w$ of β-glucan, addition of acyl imidazole) on the synthesis efficiency, that is, DS. The results indicated that the DS of product increased with the addition of acyl imidazole but decreased with $M_w$ of β-glucan. Meanwhile, the acyl chain length was not significantly related to DS. As a result, with known $M_w$ of β-glucan and fatty acid, a precise model was obtained to control the DS of product by modulating the addition of acyl imidazole in the reaction system. In view of the chemical structure, the FT-IR and $^1$H NMR spectra evidenced the successful synthesis of FAOGE. Finally, the effects of structural parameters of FAOGE ($M_w$ of β-glucan, acyl chain length, and DS) on CLC were investigated by using RSM. As a result, a quadratic polynomial model was obtained to quantitatively describe the structure−CLC relationship of FAOGEs. However, this study is only the first small step toward exploring the application possibility of FAOGEs in solubilizing hydrophobic compounds. Further works on the toxicology, stability, and bioavailability of cucurmin-loaded FAOGE micelles should be addressed.

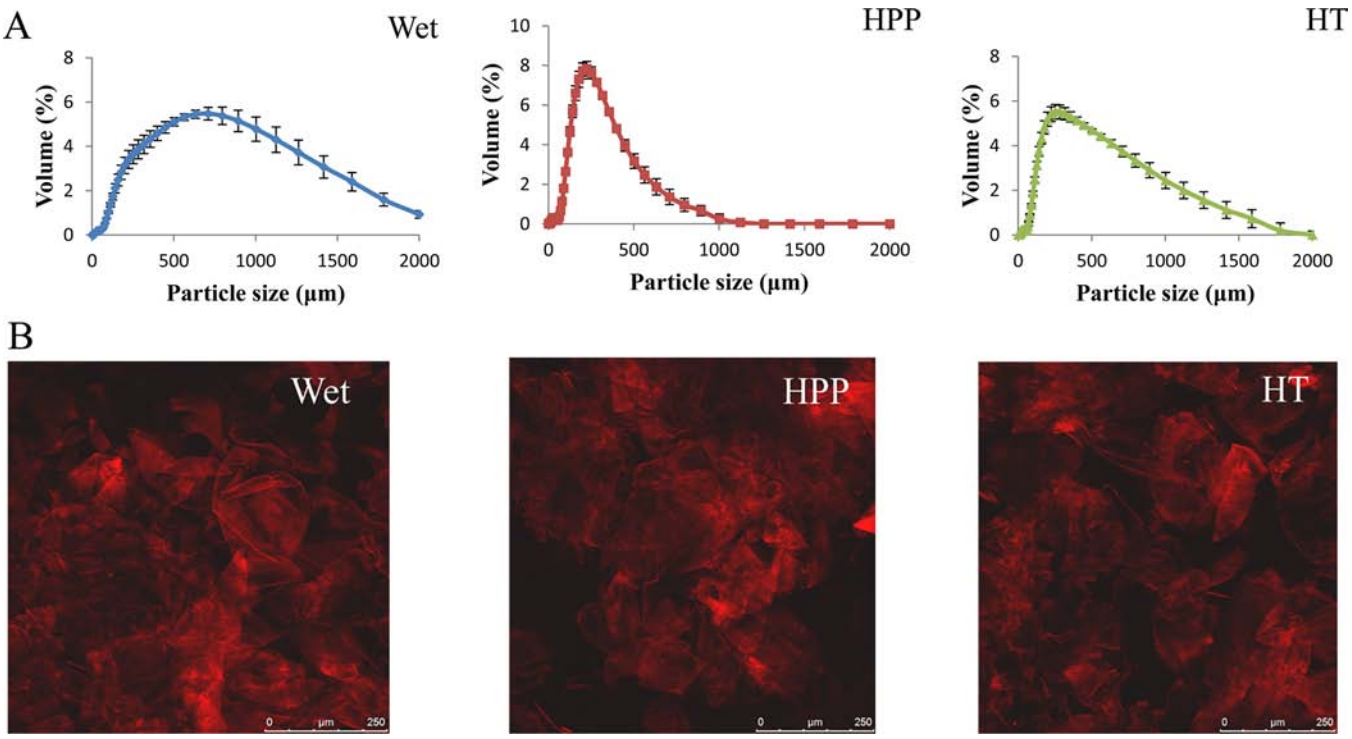

**Figure 1.** (A) Particle size distribution and (B) confocal laser images of wet, HPP, and HT apple pomace.

121 °C for 5 min using an autoclave (Centenary Series, Atherton Company, Victoria, Australia). The processed pomace was stored at 4 °C and used within 1 week of preparation. The moisture contents of the wet, HPP, and HT apple pomace, as determined using the MA-30 moisture meter (Sartorius, GER), were 76.8 ± 0.4, 76.6 ± 0.8, and 76.4 ± 0.5% (w/w), respectively. The pH of the apple pomace after HPP and HT was 4.2 ± 0.2. Unless otherwise stated, EGCG, porcine pancreatin, pepsin, and other chemicals were purchased from Sigma-Aldrich Chemical Co. (St. Louis, MO). High-performance liquid chromatography (HPLC)-grade acetonitrile was from Fisher Scientific Company (Waltham, MA).

**Particle Size Distribution.** The particle size distribution of the apple pomace was measured using a laser diffraction analyzer (Mastersizer 2000, Malvern Instruments, Ltd., U.K.). The apple pomace samples were diluted with water until an obscuration reading ranging from 13 to 17%. A general purpose model (on the basis of Mie and Fraunhofer scattering) was used to fit the particle size data, using a refractive index of 1.533 in the calculation. Analyses were carried out in triplicate on the diluted samples in distilled water.

**Confocal Laser Microscopy.** The fresh frozen wet, HPP, and HT apple pomace were assessed using a Leica SP5 confocal laser scanning microscope (Leica Microsystems, Wetzlar, Germany). The sample was stained with a drop of fluorescent Congo red dye (0.2%, w/v) to stain polysaccharides. Observation was conducted at room temperature (~22 °C) using a HC PL APO 20× objective, and excitation was achieved with the use of a 488 nm argon laser.

**Adsorption Kinetic Studies.** Samples of pomace (0.50 g equivalent dry weight; pH 4.2 ± 0.2) were added to 100 mL of EGCG solution (200 mg of EGCG $L^{-1}$) in separate conical flasks. The conical flasks were sealed by parafilm (Pechiney Plastic Packaging, Inc., Chicago, IL) and placed in a shaking water bath at 120 rpm at 25 °C. Aliquots (1.0 mL) were taken at specific time intervals (5, 15, 30, 60, 120, 180, 300, and 480 min) and subjected to HPLC analysis. The amount of EGCG adsorbed at time $t$, $q_t$ (mg $g^{-1}$), was calculated using the following equation:

$$q_t = \frac{(C_0 - C_t)V}{W}$$

where $C_0$ and $C_t$ (mg $L^{-1}$) are the EGCG concentrations of the liquid phase initially and at time $t$, $V$ (L) is the volume of the solution, and $W$ (g) is the dry mass of adsorbent used. The experiment was carried out in duplicate.

***In Vitro* Digestion Simulation.** A total of 10 mL of EGCG aqueous solution (10 g $L^{-1}$) was mixed with 40 g of apple pomace, and the mixture was blended with a mixer (BSB-380, Breville Pty Ltd., Botany, New South Wales, Australia) for 1 h. Then 1 g of mixture was taken for *in vitro* digestion simulation. For the control, 1 mL of 2 g $L^{-1}$ EGCG solution was used. *In vitro* digestions were carried out in simulated gastric fluids with or without added enzymes according to a published method.[19]

*Preparation of Simulated Gastric Fluid (SGF) and Simulated Intestinal Fluid (SIF).* For the preparation of SGF, 2.0 g of sodium chloride was dissolved in 500 mL of deionized water. To this solution was added 7 mL of 36% (w/v) hydrochloric acid and 3.2 g of pepsin (800−2500 units/mg of protein), and the mixture was made up to a volume of 1000 mL using deionized water. The pH was adjusted to1.2 using 1.0 M hydrochloric acid.

For the preparation of SIF, 13.6 g of potassium dihydrogen phosphate was dissolved in 800 mL of deionized water. To this solution was added 154 mL of 0.2 M sodium hydroxide and 2.5 g of 8× USP pancreatin. The mixture was made up to a volume of 1000 mL using deionized water and stirred at 4 °C overnight. The final pH was adjusted to 6.8 using a few drops of 1.0 M sodium hydroxide.

*Sequential Gastric and Intestinal Digestion in Vitro.* For each treatment, 22 digestion tubes were prepared and subjected to *in vitro* digestion. For each tube, apple pomace (1.0 g) was mixed with 10 mL of SGF, vortexed, placed into a glass tube, and held at 37 °C in a shaking water bath (120 rpm for 2 h). Following gastric digestion, the pH was adjusted from pH 1.2 to 6.8 and 10 mL of SIF was added. The tube was then placed in a shaking water bath (120 rpm for 3 h) at 37 °C. Samples were removed at 30 min intervals during the digestion for analysis of remaining EGCG. For each time point, two samples were removed for analysis.

**Extraction and Preparation of Samples for HPLC Analysis.** For samples containing apple pomace, the contents of the whole tubes containing EGCG−apple pomace sample were used for extraction of EGCG. For EGCG−apple pomace samples exposed to simulated

gastric fluid, the whole sample was mixed with 10 mL of ethanol and stirred for 3 h prior to centrifugation. Extraction of samples at time $t$ = 0 min showed that the amount extracted was the same as that originally added into the sample, showing that the extraction protocol was adequate. For EGCG−apple pomace samples exposed to sequential gastric and simulated intestinal fluids, the whole sample was mixed with 20 mL of ethanol, the pH was then adjusted to ∼3.5 to stabilize the EGCG against degradation, and the mixture was stirred for 3 h prior to centrifugation. All ethanol extracts were centrifuged at 10 000 rpm and 4 °C for 10 min, and the supernatant was used for HPLC analysis. For the control, where only EGCG solutions were added into gastrointestinal fluids (without apple pomace), samples were centrifuged at 10 000 rpm and 4 °C for 10 min and then the supernatant was used for HPLC analysis. The amount recovered at $t$ = 0 min was also the same as that originally added.

**HPLC Analysis.** The concentration of EGCG in the supernatants was determined following the method that we previously used.[15] The HPLC [Surveyor system with photodiode array (PDA) detector and mass spectrometry (MS) pump, Thermo Finningan, NJ] conditions were as follows: injection volume, 10 μL; VYDAC $C_{18}$ monomeric 238EV52 column (250 × 2.1 mm inner diameter × 5 μm particle size); column temperature, 28 °C; mobile phase A, acetonitrile + 0.08% trifluoroacetic acid; mobile phase B, water + 0.1% trifluoroacetic acid; and linear gradient elution, from 2% A/98% B to 24% A/76% B within 45 min and then change to 2% A/98% B until 50 min, with a flow rate of 200 μL/min. The ultraviolet−visible (UV−vis) detector wavelength was set at 280 nm. For quantification of EGCG, peak areas were compared to an external standard solution of EGCG. When an extract from apple pomace alone was analysed, there was no EGCG peak detected at the expected retention time for EGCG, confirming the absence of EGCG in the original apple pomace used.

**Data Analysis.** All experiments were carried out at least in duplicate, and the data were analyzed using Origin 8.0 (Origin Lab, Inc., Northampton, MA) for a one-way analysis of variation (ANOVA). Duncan's multiple range test was used to determine whether significant difference ($p < 0.05$) existed between mean values.

## RESULTS AND DISCUSSION

**Effect of Processing Treatments on the Particle Size and Structure.** The particle size distributions of the wet, HPP, and HT apple pomace are given in Figure 1A, and the confocal images of the corresponding samples are shown in Figure 1B.

The characteristics of the size distribution were different for the three samples, with the high-pressure-treated apple pomace having the narrowest size distribution (Figure 1A). The particle size distribution of the wet apple pomace was wider, and particles were larger compared to those of high-pressure-treated or heat-treated pomace. The $d(0.5)$ for high-pressure-treated pomace was 227 ± 3 μm, while those for the heat-treated and original wet apple pomace were 329 ± 2 and 563 ± 12 μm, respectively. There was a broad distribution of particles in fresh frozen wet apple pomace, with a peak observed at approximately 800 μm (Figure 1A) and particles larger than 800 μm, which may be particles comprising clusters of undissociated cells and also smaller particles existing, which may be ascribed to fragments of broken cells. As for HPP apple pomace, there was a narrow size distribution with a peak at ∼200 μm (Figure 1A), which may be individual cells because of the separation of cell clusters as a consequence of HPP. In heated apple pomace, the distribution centered around 300 μm, indicating that the parenchyma may have been disrupted and separated into small pieces of clusters during heat processing. The fact that processing treatments including thermal processing separate cell clusters and disrupt the apple cell wall into fragments has been previously observed.[20,21] The confocal laser images of the wet, HPP, and HT pomace are shown in Figure 1B. Although there were differences in the particle size distribution obtained using particle sizing data from light scattering (Figure 1A), the differences between the treatments of the apple pomace were not that obvious (Figure 1B).

**Adsorption of EGCG onto Apple Pomace.** The adsorption capacity of EGCG onto wet apple pomace was significantly higher than that for HPP or HT ($p < 0.05$) processed apple pomace at 25 °C (Figure 2). In the initial stages, there were sufficient available adsorption sites on the surface of apple pomace, resulting in rapid adsorption of EGCG onto the pomace. There was subsequent plateauing with increasing time because of the saturation of available adsorption sites.

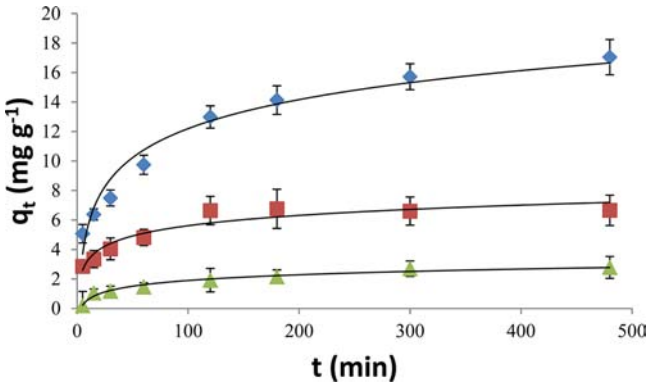

**Figure 2.** Adsorption of EGCG onto wet (blue diamonds), HPP (red squares), and HT (green triangles) apple pomace in sequential contact time at 25 °C. Initial [EGCG] = 200 mg L$^{-1}$.

The apple pomace consists of insoluble fiber, such as lignin and cellulose. Hence, there are a large number of hydroxyl groups in these polymers that could potentially associate with EGCG through hydrogen bonding. Various processing treatments, such as heating and HPP, may cause multiple structural changes at the molecular, microstructural, and macroscopic levels and change the characteristics of the dispersed phase of the processed material.[22] All of these changes are likely to impact on the adsorption capacity of small molecules, such as bioactive molecules, and the kinetics of the adsorption.

**Gastric and Intestinal Digestion *in Vitro*.** The total EGCG in EGCG−apple pomace samples and EGCG alone exposed to gastrointestinal fluids is shown in Table 1 and Figure 3.

*Digestion in the Presence of Enzymes.* As there is no EGCG in apple pomace, any EGCG detected in the system will be due to EGCG carried by the apple pomace. Upon exposure to SGF, there was minimal degradation of EGCG (<10% degradation), irrespective of whether EGCG was delivered in combination with apple pomace or on its own. However, there was a marked decrease in the amount of EGCG in all systems in SIF, with only 16−35% EGCG remaining at the end of SGF−SIF exposure. These results are similar to other studies which showed that the major degradation of tea polyphenols occurs in intestinal fluids.[13,23] The pH-dependent stability of EGCG observed in this study is consistent with the reported EGCG degradation at near neutral or alkaline pH.[11,13]

At the end of the digestion process, only 16% EGCG was recovered in the control sample without apple pomace in our study (Table 1), which is of a similar order to the recovery of

**Table 1. Measured EGCG Contents in the Sample before and after Exposure to SGF and Sequential Exposure to SGF + SIF *in Vitro*[a]**

| system | initial EGCG (mg) | after exposure to SGF (2 h) | | after sequential exposure to SGF (2 h) + SIF (3 h) | |
|---|---|---|---|---|---|
| | | amount of EGCG (mg) | percentage of initial EGCG (%) | amount of EGCG (mg) | percentage of initial EGCG (%) |
| EGCG alone | 2.01 ± 0.02 a | 1.84 ± 0.06 a | 92 | 0.33 ± 0.19 b | 16 |
| EGCG−wet apple pomace | 1.99 ± 0.10 a | 1.82 ± 0.03 a | 91 | 0.40 ± 0.06 b | 20 |
| EGCG−HPP apple pomace | 2.04 ± 0.08 a | 1.94 ± 0.05 a | 95 | 0.71 ± 0.02 a | 35 |
| EGCG−HT apple pomace | 2.05 ± 0.10 a | 1.90 ± 0.02 a | 93 | 0.56 ± 0.13 a | 27 |

[a]The data are the average ± standard deviation (SD) of the measured values. The same amount of EGCG (2 mg) was used initially in all samples. Different letters between treatments in the same column denote that there are significant differences ($p < 0.05$).

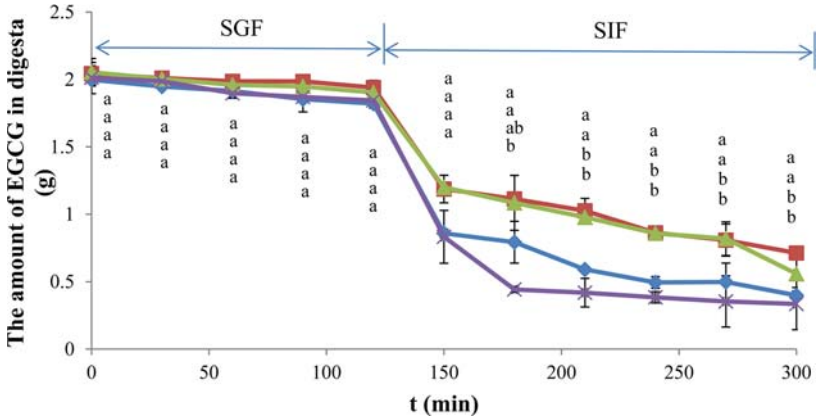

**Figure 3.** Amount of EGCG that remained in wet (blue diamonds), HPP (red squares), and HT (green triangles) apple pomace and EGCG solution alone (purple crosses) exposed to SGF and SIF *in vitro* in the presence of enzymes. The letters in the same column represent the significant difference ($p < 0.05$) at the same time point between HPP apple pomace, HT apple pomace, wet apple pomace, and EGCG alone (from top to bottom).

EGCG obtained in other studies.[24,25] The protection to EGCG provided by the apple pomace follows the order: HPP = HT > wet apple pomace. The recovery of EGCG in EGCG−HPP and EGCG−HT apple pomace mixtures was significantly higher ($p < 0.05$) than that of control and that for EGCG−wet apple pomace at the end of intestinal digestion. This demonstrates the ability of apple pomace to protect EGCG against degradation at ∼ neutral pH.

Although the measured adsorption of EGCG to apple pomace follows the order of wet > HPP > HT apple pomace under equilibrium conditions when apple pomace is mixed with EGCG (Figure 2), it is possible for the binding affinity to change with pH of the gastrointestinal fluids. This was not measured in our study. However, the observation that apple pomace protects EGCG against degradation in SIF suggests that the protection afforded to EGCG may in part be due to the binding of EGCG to the pomace. It is also likely that the differences in the microstructure of the pomace may also have had an influence on degradation of bound EGCG. It is conceivable that a physical barrier to contact with the external environment provided by the apple pomace may contribute to the stabilization of EGCG. Other studies have suggested that processing treatments on plant tissue (e.g., tomato and potato) that alter structure affect the bioaccessibility of bioactives.[26]

*Effect of the Enzyme.* To determine if intestinal enzymes contributed to the rate of degradation of EGCG in simulated gastrointestinal conditions, the EGCG degradation in the absence and presence of enzymes (pepsin and pancreatin) was compared. Figure 4 shows the comparison of the digestion system with or without enzyme. The effect of the enzyme was significantly different ($p < 0.05$) when only EGCG was delivered as an aqueous solution during intestinal digestion (Figure 4A). In contrast, the presence of enzyme did not have a marked effect on the EGCG−pomace mixtures during gastrointestinal digestion (panels B−D of Figure 4). In the presence of apple pomace, there already exists an interaction between EGCG and the pomace. It is not understood why there was a significant effect of the enzyme in EGCG only solutions (Figure 4 A) but not when EGCG was delivered in the presence of pomace (panels B−D of Figure 4). However, the effect of the enzyme, although significant, is small in comparison to the effect of pH on EGCG solutions (Figure 4A). Overall, the results suggest that pH had the overriding effect on the rate of EGCG degradation.

In the *in vitro* system examined, the EGCG−pomace mixture markedly decreased the extent of degradation of EGCG during intestinal digestion. The enzyme had an effect on the digestion of EGCG solution, but the main factor influencing the degradation of EGCG was the pH. The observations that apple pomace protects EGCG against degradation implies that apple pomace could be considered as a suitable carrier for EGCG and polyphenols, with the potential to enhance the stability and bioavailability of polyphenolic compounds. The use of apple pomace as a carrier for EGCG is an alternative to use of encapsulation of EGCG in liposomes or biopolymeric nanopartricles for protecting EGCG against degradation in the gastrointestinal tract. Comparative studies between the efficacy of apple pomace as a carrier for EGCG compared to the use of encapsulation systems would be of interest. Experiments *in vivo* with humans are needed to validate the effects of apple pomace

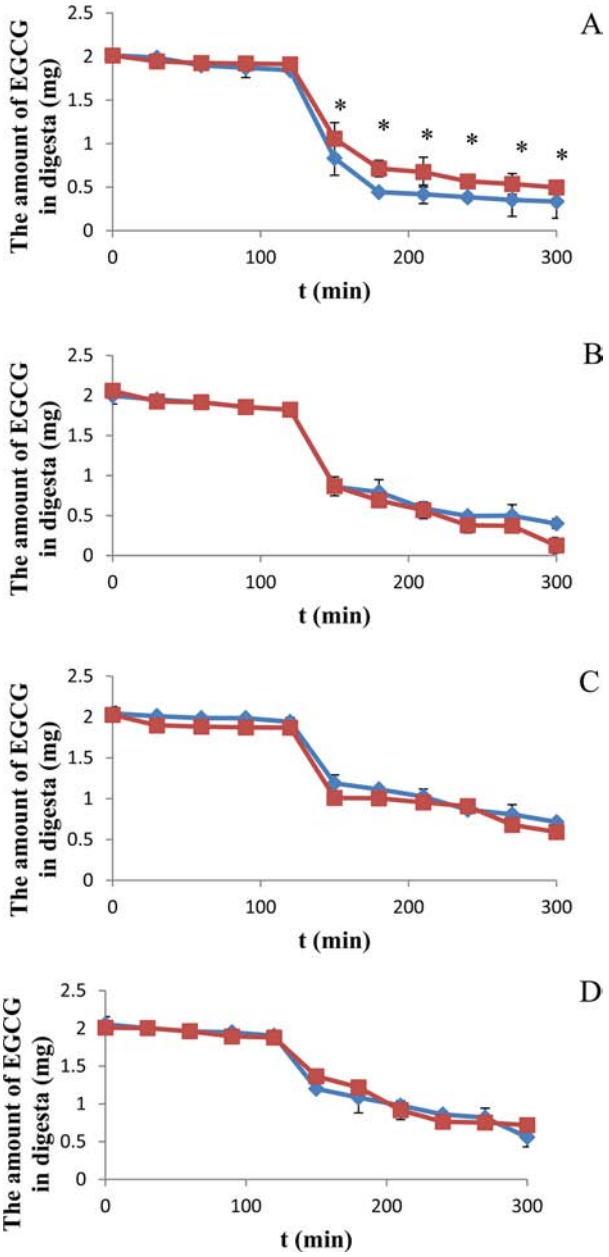

**Figure 4.** Amount of EGCG digested with (blue diamonds) or without (red squares) enzyme during the gastrointestinal digestion simulation, with the asterisks indicating that there is a significant difference ($p < 0.05$) at the same time point: (A) EGCG alone, (B) EGCG–wet apple pomace, (C) EGCG–HPP apple pomace, (D) EGCG–HT apple pomace.

on the bioavailability of polyphenols and to determine whether this can be translated to the achievement of desirable physiological properties.

[a]Key: Δ = control (room temperature); ∫ = −15 °C; ≈ = −15 °C to room temperature; control samples were monitored on days 2, 7, and 14. [b]Retention indices relative to *n*-alkanes on DB-Wax column for compound identification including comparison of retention times and mass fragmentation to authentic samples. [c]Volatiles detected at day 0 in all treatments. [d]Tentatively identified.

performed in five replicates. Collected volatiles were analyzed using a method identical to previously published protocols[9] on a DB-Wax column, 60 m × 0.32 mm i.d. × 0.25 μm (J&W Scientific, Folsom, CA, USA) installed on a 6890 gas chromatograph coupled to an HP-5973 mass selective detector (Agilent, Palo Alto, CA, USA). Retention index (RI) values were calculated using a homologous series of *n*-alkanes on the DB-Wax column. The identities of the reported volatiles were determined by comparison of fragmentation patterns to NIST and Wiley databases, as well as verified by injection of authentic samples and comparison of retention times and fragmentation patterns. Sources of compounds for GC-MS authentication were identical to those in a recent publication.[16] Compounds not verified by authentication are listed as tentative in Table 1.

**Statistical Analysis.** Volatiles were only considered for analysis if they were detected within three of the five replicates at any time point. Relative peak areas were log transformed. Principal component analyses (PCA) were performed on the data using BioNumerics 4.6 (Applied Maths, Austin, TX, USA) where the three treatments (five replicates per treatment, $n = 15$) were compared at each of the three time points.

## RESULTS AND DISCUSSION

The volatiles α-pinene, α-fenchene, camphene, and *p*-cymene were detected from the cactus tissue samples in all treatments at day 0 (Table 1). The compounds α-pinene, β-pinene, and *p*-cymene have been reported from the headspace of intact *Opuntia stricta*;[17] however, the previously reported cymene was the meta-isomer, whereas we detected and report the para-isomer. Additionally, we report the monoterpene camphene as a component of *O. humifusa* plugs, whereas camphene was not detected in the previous study of *O. stricta*. In an additional note regarding volatiles from cacti, Flath et al.[18] report numerous compounds of various classes from their hydrodistillation of prickly pear fruit. However, the differences of method extraction and tissue studied[18] do not allow for comparison to either the present study or the headspace analysis performed by Pophof et al.[17]

PCA showed three distinct clusters representing the three treatments (control, cold, and shock) at days 3 and 8, respectively (Figure 2A,B), thus supporting the overall difference in volatile emissions from the tissues as shown in Table 1. From the PCA for day 3, the volatiles α-pinene, hexanal, β-pinene, and limonene in the cold treatment and 3-octanone, 3-hepten-1-yl acetate, and 1-octen-3-ol in the shock treatment were most responsible for the distinct clustering of the shock (red ellipse) and cold (blue ellipse) treatments (Figure 2A).

The volatiles 3-octanone and 1-octen-3-ol on day 3 from the shock tissue are characteristic of fungal metabolism of fatty acids,[9,19] as well as the volatiles 3-hepten-1-yl acetate and 2-ethyl-1-hexanol. Both of these latter volatiles have reported plant origins,[20,21] but the compound 2-ethyl-1-hexanol is also thought to be a contaminant.[22] Whereas we found no reported semiochemical activity of either 3-hepten-1-yl acetate or 2-ethyl-1-hexanol, it should be noted that 3-octanone and 1-octen-3-ol elicited high electrophysiological responses from both male and female *Amyelois transitella* (Lepidoptera: Pyralidae) moth antennae.[16]

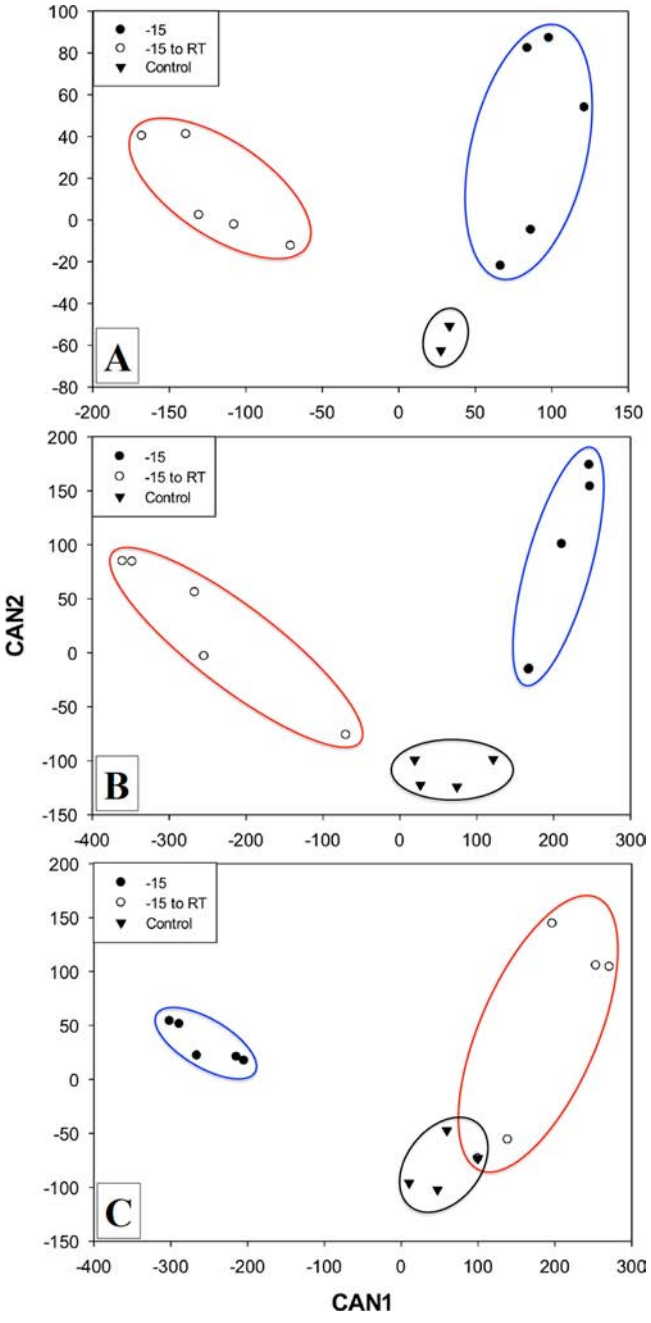

**Figure 2.** Principal component analysis of data from the five replicates of all treatments at (A) day 3, (B) day 8, and (C) day 15. Control treatments are shown in black ellipses, cold treatments in blue ellipses, and shock treatments in red ellipses.

The shock and cold treatments at day 8 produced a number of new compounds not found in the control samples (Figure 2B and Table 1). The volatile composition of the cold treatment cactus tissue (blue ellipse) is suggestive of tissue stress with detection of hexanal, a fatty acid breakdown product,[5,23] as well as a sudden increase in monoterpenes, such as $\beta$-pinene, limonene, and *p*-cymene, which are not seen in the control or shock treatments. This latter phenomenon may contribute to the plants' production of certain terpenoids as a defense mechanism against oxidation,[4] as well as to the inhibition of fungal germination.[24] An interesting finding was the detection of benzaldehyde (days 8 and 15) and nonanal (day 15) in the later days of cold treatment. These aldehydes, among other compounds, have been reported as fungistatics produced by plant bacteria,[25] although the reason for their presence in this tissue and this particular treatment is presently unknown. Therefore, the increase in volatiles with these notable activities in the cold treatment at day 8 warrants further investigation regarding the role of extended cold on plant tissue volatile emissions.

The shock tissue at day 8 produced a diverse range of compounds (Table 1) not detected in the control and cold tissue treatment and resulted in the separation of the shock treatment (red ellipse) relative to the other treatments as seen in the PCA (Figure 2B). The most striking and a primary reason for this paper was the production of a number of compounds that have elicited noteworthy electrophysiological and behavioral responses in other lepidopteran[11,16] and coleopteran[13,14] insects. Most notable among these were the spiroketals conophthorin (**1**) and chalcogran (**2**), the origin of which has been directly associated with developing fungal spores.[9]

Aside from guaiacol, the volatiles from the day 8 shock treatment have associations with fungi and damaged tissue,[9,26] semiochemical activity in Coleoptera,[27] and elicition of electrophysiological responses from navel orangeworm moth antennae.[16] In particular, the volatile 2-phenylethanol elicited a very strong response from male navel orangeworm antennae (Lepidoptera).[16] Additionally, 2-phenylethanol has been reported as a yeast-produced volatile that inhibited aflatoxin-producing genes in the fungus *Aspergillus flavus*,[28] thus raising a possible secondary role for signaling among fungi. Furthermore, a recent report[29] described the semiochemical activity of conophthorin for the ambrosia beetle (Coleoptera) and the emission of conophthorin from stressed and weakened deciduous tree hosts. Given our findings[9,10] concerning the apparent spirogenesis from fungal spores, it would be of interest to determine if the condition of the tree and the beetle's attraction to it are a result of fungal emissions.

Conspicuously absent from the day 8 and 15 shock treatment volatiles were the monoterpenes, which have been implicated in antifungal activity.[24,25] The differences in volatile profiles of the shock and cold treatments raise numerous questions regarding the effect of cold on ex situ plant tissue, either as a preservation and defensive mechanism (sustained cold) or as brief instance (tissue shock). These differences also suggest a subsequent effect on the microbial community within the plant tissue and a consequential effect toward possible insect−microbe mutualisms.

The results described in this paper address a number of important issues in several ongoing investigations: (1) the identification of potential semiochemicals from *O. humifusa* of the insect pest cactus moth (*Cactoblastis cactorum*), a highly invasive pest that has spread across the southeastern portions of the United States, threatening native *Opuntia* species that are important agricultural, ecological, and ornamental plants;[30] (2) the role of abiotic stress on plant tissue, its resident microbes, and the resultant volatiles in either insect−microbe or microbe−microbe interactions; and (3) the expanding role of the spiroketals conophthorin and chalcogran in the possible mutualism between certain insects and fungal spores. The results also highlight several important new findings and include a unique tissue source of the spiroketals; the implication of abiotic cold-shock stress as a trigger for spiroketal production; and, given our previous findings of spirogenesis,[9,10] the possibility of spore involvement as a

biosynthetic origin of the spiroketals. Likewise, these findings have important implications regarding fungal volatile emissions when plants may be vulnerable to insect pests.

| Zearalanone |  | 5975780 | 320.4 | 4.10 | 2.5 |

[a]Aqueous solubilities were estimated via the U.S. EPA EPISuite using WSKOW (v. 1.41).[36] [b]Experimentally measured in this study. [c]Value reported by Card et al.[9]

oxides,[17] via mechanisms including electrostatic interactions and surface complexation. Alternatively, they may represent reactive substrates able to promote transformation reactions. For example, MGA and the zeranol family have hydrolyzable functionalities, whereas the 4,9,11-triene structure of trenbolone includes several electron-deficient carbon centers possibly susceptible to nucleophilic attack. Although hydrolysis is reportedly slow at near-neutral pH values for SGPMs,[18−20] metal oxides common to soil can catalyze hydrolysis, and presumably nucleophilic addition, via the formation of surface complexes that leave carbon centers more favorable to attack by $H_2O$ or $OH^-$ than the freely dissolved molecule.[21] Furthermore, manganese oxides and some iron oxides can oxidize species structurally analogous to SGPMs[22,23] including estrone and 17$\beta$-estradiol. Although such mineral-promoted transformation pathways remain uncharacterized, we suspect some SGPMs are highly reactive toward inorganic phases routinely encountered in soil.

Here, we explore the abiotic pathways influencing SGPM fate in soils. The rate and extent of SGPM sorption were considered in sterilized (with azide) systems using a model, organic-rich soil (Pahokee Peat, 43% organic carbon) and several commercially available model soils exhibiting a range of soil organic carbon (1.0−5.9% OC). Sorption kinetics and isotherms were used to examine trends both within (e.g., 17$\alpha$-TBOH, 17$\beta$-TBOH, and TBO) and across SGPM families (e.g., comparing TBA metabolites, MGA and melengestrol, and metabolites), explore the nature of chemical interactions (e.g., specific or hydrophobic) contributing to uptake, and establish the extent to which SGPM sorption is reversible. We emphasize that in all model soil systems, solvent (i.e., methanol) extraction of equilibrated soils was used to recover the mass of sorbed SGPM, and loss of mass over time in our experimental systems was interpreted as evidence for abiotic transformation processes (i.e., reaction with inorganic mineral phases). To further explore the potential for such abiotic transformations, experiments also monitored the stability of select SGPMs (17$\beta$-TBOH, MGA, and zeranol) in suspensions of metal oxides (e.g., manganese, iron, and silica oxides) representative of those naturally occurring in soil. Results from this study will help to characterize more fully the environmental fate and mobility of SGPMs in subsurface environments, thereby improving our ability to predict the risk posed to ecosystems by this emerging pollutant class.

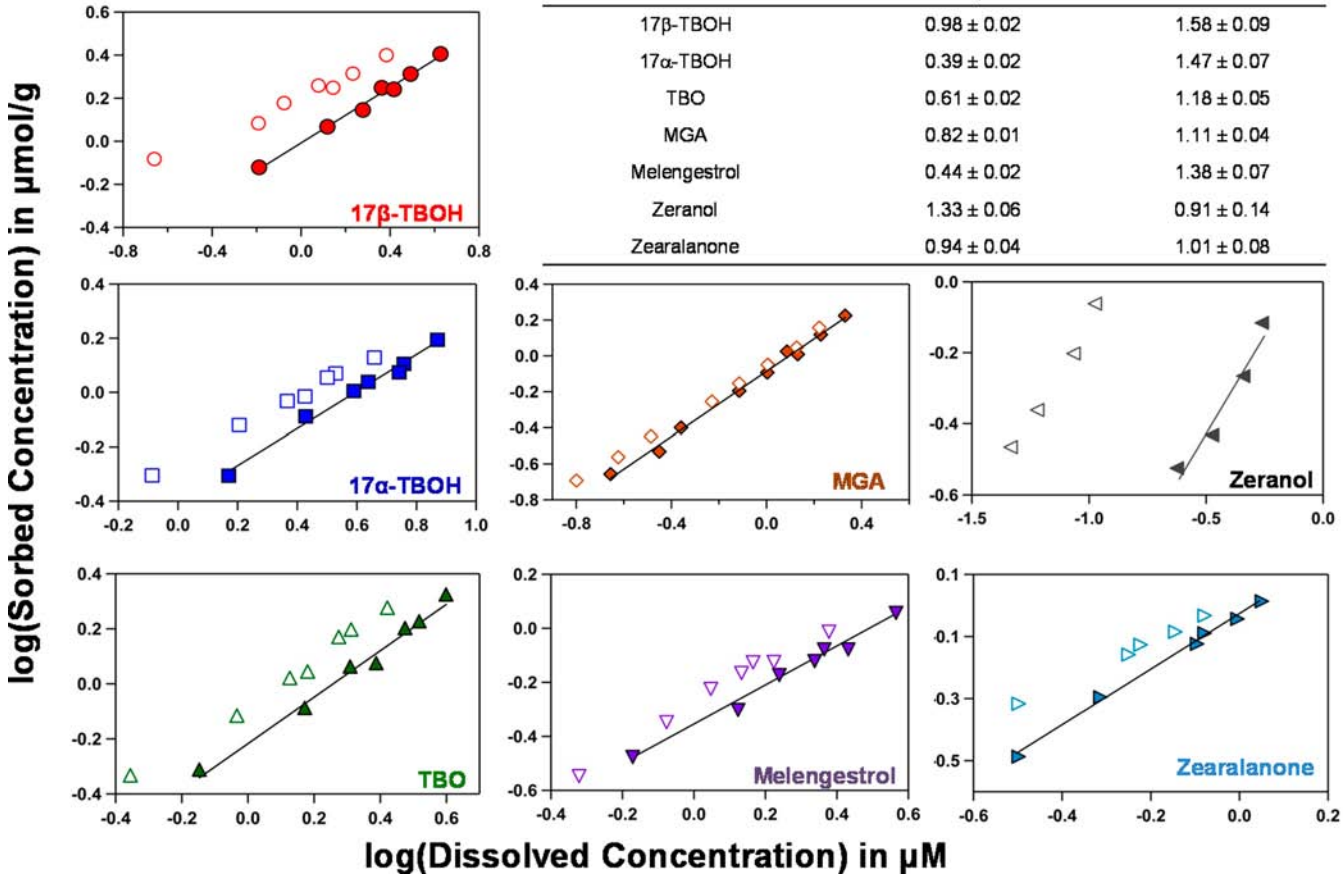
## MATERIALS AND METHODS

**Reagents.** A complete reagent list is provided in the Supporting Information (SI).

**Measurement of $K_{ow}$ Values for Select SGPMs.** Octanol−water partitioning coefficients ($K_{ow}$ values) were measured for SGPMs without published values available in the literature. These were trenbolone acetate, melengestrol, zearalanone, and $\beta$-zeralanol. Details of our method, which was adapted from that of Khan et al.,[8] are provided in the SI. To assess the accuracy of our approach, we also measured the $K_{ow}$ value for 17$\beta$-trenbolone so that our experimental value could be compared to a reference value available in the literature.

**Model Soils and Mineral Oxides.** Seven commercial, model soils exhibiting a range of soil OC content were used in sorption studies. Pahokee Peat (43% OC) was purchased from the International Humic Substances Society (IHSS), whereas other soils with various textures and OC contents were acquired from AGVISE Laboratories (Benson, MN, USA). These include two sandy loams (referred to as PVPF and LBLS with OC contents of 5 and 3%, respectively), two loams (PVLPF and EL-7 with OC contents of 5.9 and 2.8%, respectively), a clay loam (DUL; 3.3% OC content), and a loamy sand (RMN; 1% OC content). The OC content of Pahokee Peat was determined by Test America via the Lloyd Kahn method,[24] whereas the OC values of all other soils were provided by AGVISE Laboratories and quantified by loss-on-ignition methods.[25] Also explored were several mineral phases representative of naturally occurring metal oxides including a commercially available silica dioxide ($SiO_2$; Sigma-Aldrich, 99%), ferrihydrite synthesized via the method of Burleson and Penn,[26] and an amorphous manganese dioxide ($MnO_2$) synthesized according to the method of Murray.[27] Synthesis details are provided in the SI.

**Sorption Experiments.** Soils were first sterilized by adding sodium azide ($NaN_3$) as described by Wolf et al.,[28] with the exception that the dose was increased to 30.8 mmol $NaN_3$/kg soil.[29] Additional details and our rationale for sterilizing with azide as opposed to other methods are provided in the SI. Batch sorption experiments were then conducted at pH 7.0 in a 5 mM phosphate buffer. The rate of SGPM sorption was explored using initial concentrations between 2 and 5 $\mu$M and a soil loading between 2 and 10 g/L. Sorption isotherms were collected over a range of initial concentrations (1−10 $\mu$M) using a constant sorbent (i.e., soil sample or metal oxide) loading of 2 g/L at room temperature. Although these initial concentrations are higher than environmental relevance, they were necessary to facilitate SGPM analysis via high-pressure liquid chromatography with diode array detection (HPLC-DAD), which was the preferred method for processing the large number of samples generated experimentally. In



| SGPM | $K_f$ | $n$ |
|---|---|---|
| 17β-TBOH | 0.98 ± 0.02 | 1.58 ± 0.09 |
| 17α-TBOH | 0.39 ± 0.02 | 1.47 ± 0.07 |
| TBO | 0.61 ± 0.02 | 1.18 ± 0.05 |
| MGA | 0.82 ± 0.01 | 1.11 ± 0.04 |
| Melengestrol | 0.44 ± 0.02 | 1.38 ± 0.07 |
| Zeranol | 1.33 ± 0.06 | 0.91 ± 0.14 |
| Zearalanone | 0.94 ± 0.04 | 1.01 ± 0.08 |

**Figure 1.** Linearized Freundlich isotherms for SGPMs on Pahokee Peat (please note the difference in the *x*- and *y*-axes scales for each species). Solid symbols indicate measured concentrations after 3 days (sufficient to achieve sorption equilibrium), whereas open symbols correspond to data collected to test the reversibility of sorption according to the protocol described in the text. Linear regression and resulting best-fit parameters for values of $K_f$ (in $\mu$mol$^{(1-(1/n))}$ $L^{(1/n)}$ g$^{-1}$) and $n$ (unitless) are provided, along with 95% confidence intervals associated with the regression analysis. Experimental details are provided in the text.

all cases, the highest initial concentration used for each SGPM was below aqueous solubility (based upon reported values of 1330, 2.6, and 15 $\mu$M for 17$\alpha$-trenbolone, MGA, and zeranol, respectively;[18−20] estimated aqueous solubilities are provided for all SGPMs in Table 1). Nevertheless, control experiments were conducted in the absence of soil to ensure the aqueous phase stability of the SGPMs at these concentrations.

To initiate sorption experiments, a small volume (2−18 $\mu$L) of SGPM methanolic stock solution was added to a suspension of sterilized soil via syringe to achieve the desired initial concentration. In all cases, this approach resulted in no more than 0.1% of methanol by volume in our reactors, below the threshold likely to induce cosolute effects.[30] To avoid sorption losses to vial septa (which was observed for some species in preliminary experiments), all experiments were conducted in 20 mL glass beakers, and the contents were well-mixed via a glass-coated, magnetic stir bar and electronic stir plate. We note that initial experiments using Teflon-coated stir bars revealed losses of some SGPMs in controls, presumably due to sorption on the stir bar. Over the duration of the experiments, reactors were sealed with Parafilm to slow evaporation and covered in Al foil to prevent photoreactions.

Sorption rate studies were typically conducted over 1 week, with sample collection at predetermined time intervals to monitor the change in SGPM solution concentration over time. For sorption isotherms, equilibrium was typically established after 3 days, at which time samples were collected to monitor the mass of SGPM remaining in solution. The extent to which sorption was reversible was considered as follows. After 3 days, the entire equilibrated suspension (18 mL) was centrifuged (3000 rpm for 5 min), and a fixed volume (typically 8 mL) of supernatant was replaced by fresh buffer to perturb the sorption equilibrium. The altered suspension was then allowed to re-equilibrate for another 3 days, at which time the aqueous phase SGPM concentration was once again measured.

Reactor samples were centrifuged, and the supernatant was analyzed immediately on HPLC-DAD to quantify dissolved phase concentrations. Centrifugation was chosen for solid removal rather than filtration because most commercially available filters (PTFE or nylon) resulted in some loss of SGPMs during application. Using this approach, the amount of SGPM sorbed to the soil was quantified via mass balance from the difference in the initial SGPM concentration in the reactor and the aqueous phase concentration of SGPM present in solution at equilibrium.

At the conclusion of sorption experiments, the mass of SGPM sorbed on the soil sample was quantified via extraction with organic solvent.[8] The entire suspension was centrifuged, the supernatant was removed, and 3 mL of methanol was added to the soil. The resulting suspension was sonicated for 5 min, which was found to be sufficient for recovery of the sorbed mass. After sonication, the suspension was centrifuged once again to separate the methanol from the solid, and the solvent phase was analyzed by HPLC-DAD.

**SGPM Reactivity toward Metal Oxides.** Reactions with metal oxides $SiO_2$ and ferrihydrite were conducted at pH 7.0 in 5 mM phosphate buffer at room temperature. For $MnO_2$, we observed reactivity inhibition in phosphate buffer; thus, experiments were conducted in 5 mM $NaClO_4$ at either pH 6 or 7. Experiments with metal oxides were conducted over a range of solid loadings (1−10 g/

L) and SGPM initial concentrations (1−5 μM). The oxide suspensions were allowed to equilibrate with the buffer/electrolyte solution for 20 min, after which the pH of the system was adjusted (if necessary) back to the desired initial value using 1 M HCl or NaOH. Once the pH was stabilized, a small volume of methanolic stock solution delivered the SGPM to the suspension. The suspension was well-mixed using a glass-coated magnetic stir bar and stir plate, and reactors were covered by Al foil to prevent photoreaction. Over time, 1 mL aliquots of suspension were collected and centrifuged to separate the metal oxide from the aqueous phase, and the supernatant then was transferred to an amber autosampler vial for immediate HPLC-DAD analysis.

**Analytical Methods.** Aqueous samples were analyzed on a 1200 series Agilent HPLC-DAD equipped with an Eclipse XBD-C18 column (4.6 × 150 mm, 5 μm particle size) according to the methods presented in our earlier work[31] and also detailed in the SI. All soils and metal oxides were characterized via powder X-ray diffraction using a Rigaku MiniFlex II with a Co Kα source.

## RESULTS AND DISCUSSION

**SGPM Sorption Isotherms on Organic-Rich Pahokee Peat.** Sorption rate experiments suggested that most SGPMs, with the exception of β-zearalanol (see SI), achieved steady state (i.e., no further decrease in solution phase concentration over time) in Pahokee Peat suspensions within 3 days (at 2 g/L Pahokee Peat and ∼5 μM initial SGPM; Figure S1). Accordingly, sorption isotherms collected after 3 days are shown in Figure 1, in which data are presented on a log−log scale. Also shown are fits in which sorption is assumed to follow the Freundlich isotherm model (eqs 1 and 2).

$$C_s = K_f C_w^{1/n} \quad (1)$$

$$\log C_s = \log K_f + 1/n \log C_w \quad (2)$$

In eqs 1 and 2, $C_s$ is the sorbed SGPM concentration and $C_w$ is the aqueous phase concentration at equilibrium (after 3 days). The Freundlich adsorption capacity parameter, $K_f$, and the Freundlich adsorption intensity parameter, $1/n$, were obtained from linear regression analysis of experimental data (according to eq 2), as summarized in Figure 1 for each SGPM.

These model fit parameters were used to explore trends in SGPM sorption on Pahokee Peat. For example, $K_f$ values indicate the magnitude of sorption,[32] and correlations between $K_f$ values and metrics of sorbate hydrophobicity (e.g., $K_{ow}$ values) have occasionally been suggested as evidence for hydrophobic interactions driving sorption.[33] Here, the largest $K_f$ values (with units of $\mu mol^{(1-(1/n))}\ L^{(1/n)}\ g^{-1}$) were measured for zeranol (1.33 ± 0.06) and its metabolite zearalanone (0.94 ± 0.04), 17β-TBOH (0.98 ± 0.02), and MGA (0.82 ± 0.01). However, across families of growth promoters, octanol−water partitioning coefficients ($K_{ow}$ values) were a weak predictor for sorption on Pahokee Peat (Figure S2a). Moreover, we failed even to observe clear trends in $K_f$ values within SGPM families; trendione exhibited greater sorption than 17α-TBOH despite its lower $K_{ow}$ value.

A notable and important distinction across SGPMs in Pahokee Peat systems was that some isotherms were essentially linear. The greatest degrees of nonlinearity, based on model fit values of $n$, were observed for 17β-TBOH, 17α-TBOH, and melengestrol, whereas the slopes of isotherms for zeranol and zearalanone were statistically equivalent to unity (i.e., their isotherms were linear). Linear isotherms are most often observed when hydrophobic interactions drive uptake and an excess of such hydrophobic sorption sites exists.[30] In contrast, nonlinear isotherms are typically observed for more polar compounds, for which specific interactions will also contribute to sorption.[30] SGPM sorption appears consistent with these scenarios, with linear isotherms most frequently observed for more hydrophobic SGPMs (based on reported or measured $K_{ow}$ values; Figure S2b). Thus, the linear isotherms for zeranol and zearalanone suggest an excess of hydrophobic sites on Pahokee Peat suitable for partitioning, behavior likely linked to the aromatic functionalities of zeranol and it metabolites. In contrast, nonlinear isotherms for 17β-TBOH, 17α-TBOH, and melengestrol are evidence that more limited, specific sites on Pahokee Peat also contribute to sorption.

We also interpret trends in $n$ values within a family of compounds as evidence of the functional groups involved in such specific interactions. Specifically, isotherms for 17β-TBOH and 17α-TBOH exhibited greater nonlinearity than TBO, whereas the isotherm for melengestrol exhibited greater nonlinearity than that of MGA. In each of these cases, therefore, the presence of an −OH group at the C17 position increased the degree of specific interactions. We attribute this observation to the ability of this hydroxyl group to promote sorption via hydrogen bonding with functionalities of Pahokee Peat.

**Reversibility of SGPM Sorption on Organic-Rich Pahokee Peat.** A final consideration for SGPM sorption in Pahokee Peat systems is the extent to which the process is reversible. Data pertaining to sorption reversibility are also presented in Figure 1. Open symbols represent data collected after system equilibrium was first disrupted after 3 days and then once again allowed to achieve steady state over an additional 3 days. In Figure 1, therefore, overlap between open and solid symbols indicates a sorption process that is entirely reversible.

MGA was the only SGPM to sorb onto Pahokee Peat reversibly (see overlap in Figure 1 of open and solid symbols), whereas sorption of 17α-TBOH, TBO, melengestrol, and zearalanone was partially reversible. Sorption of zeranol and 17β-TBOH was essentially irreversible, as evidenced by the nearly identical concentration of adsorbed species after system equilibrium was perturbed (i.e., open symbols are horizontally, but not vertically, offset from their solid counterparts). Notably, we were able to recover completely all of the sorbed mass via extraction with methanol. Measured percent recoveries in Pahokee Peat systems were 110 (±8), 99 (±7), 165 (±10), 125 (±0.12), 105 (±9), and 124 (±11) for 17β-TBOH, 17α-TBOH, MGA, melengestrol, zeranol, and zearalanone, respectively. Values represent the mean and standard deviation for at least $n$ = 3 extractions (we note that only one instance of trendione extraction was completed, resulting in 115% recovery). Thus, concentration changes in Pahokee Peat systems occur via sorption and not from processes such as abiotic transformation reactions or biodegradation.

Several trends in the reversibility of SGPM sorption are noteworthy, if not surprising. MGA and zeranol have comparable log$K_{ow}$ values, and both produced linear isotherms, collectively suggesting that hydrophobic interactions govern their sorption. However, the nature of these hydrophobic interactions must be fundamentally different because MGA uptake was entirely reversible, whereas zeranol sorption was essentially irreversible. Likewise, 17β-TBOH is among the more polar of SGPMs considered herein, and the presumed specific interactions (e.g., hydrogen bonding) associated with its sorption are typically considered relatively weak. Nevertheless, the irreversible nature of 17β-TBOH sorption implies rather

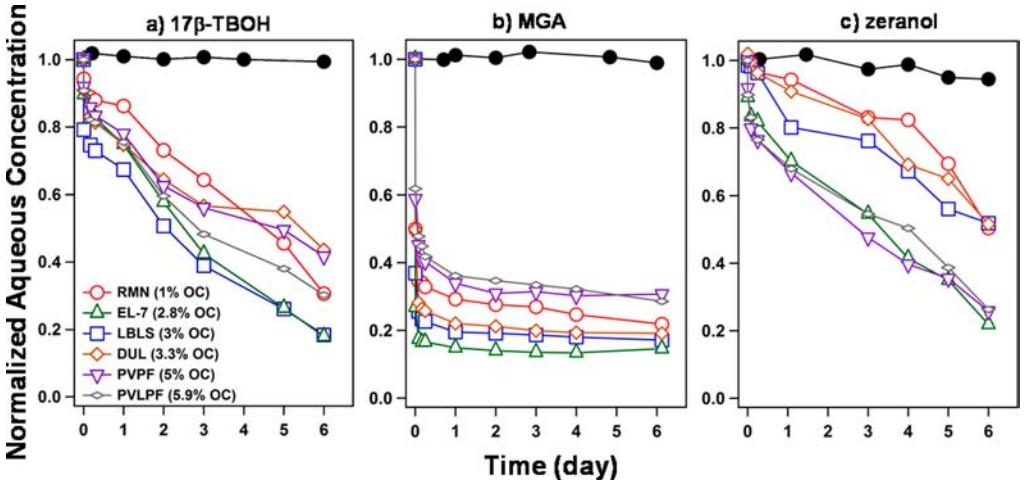


**Figure 2.** Change in aqueous phase concentration over time for (a) 17$\beta$-TBOH, (b) MGA, and (c) zeranol in 4 g/L suspensions of azide-treated model soils. Results from soil-free controls are shown as solid black symbols. All experiments were conducted in 5 mM phosphate buffer at pH 7. The initial concentrations were 4, 2, and 2 $\mu$M for 17$\beta$-TBOH, MGA, and zeranol, respectively.

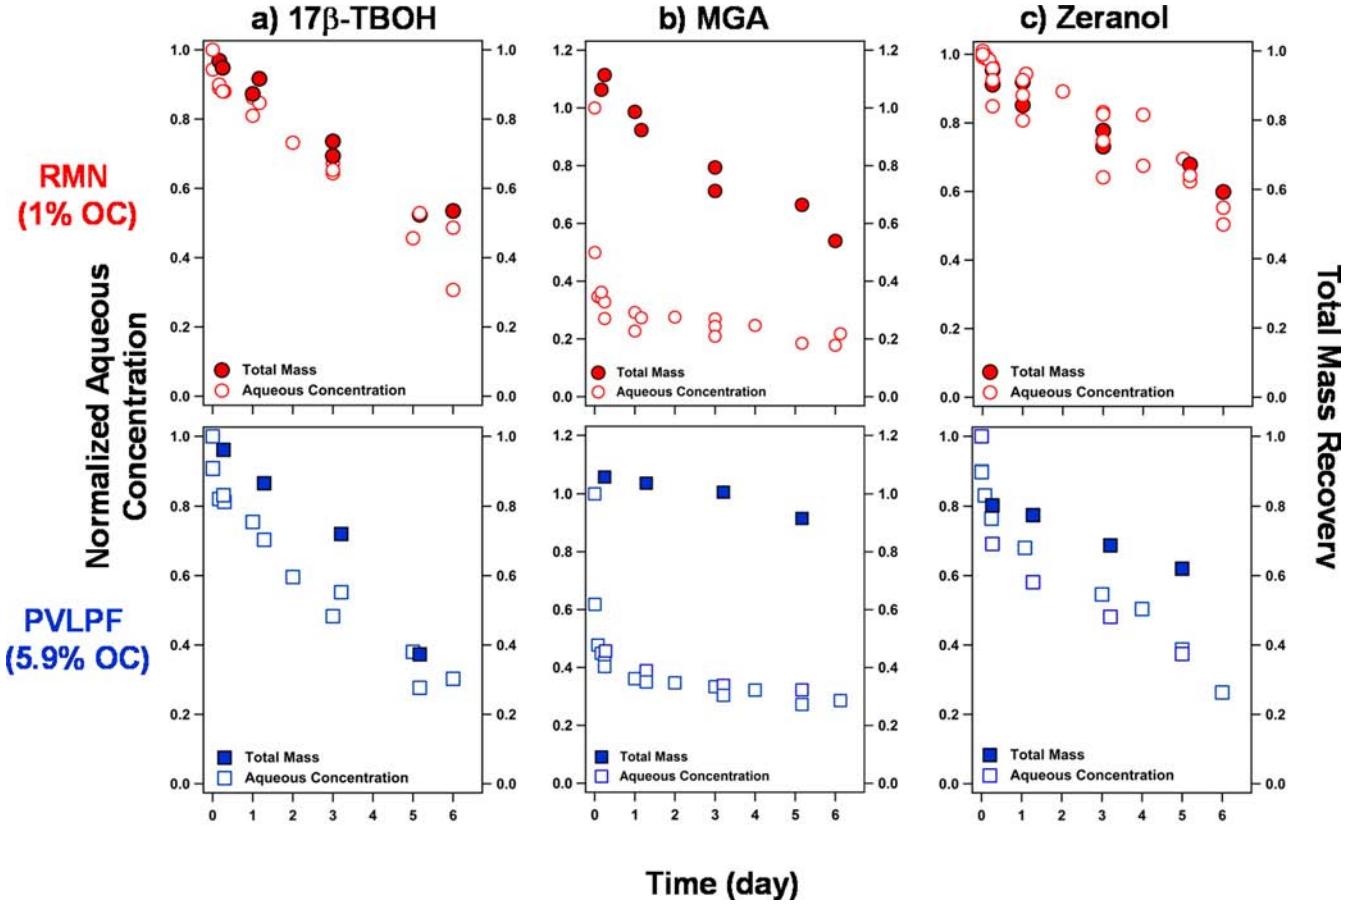

**Figure 3.** Aqueous phase concentration change over time for (a) 17$\beta$-TBOH, (b) MGA, and (c) zeranol in suspensions (4 g/L at pH 7) of two model soils, RMN (red; top) and PVLPF (blue; bottom), which represent those with the lowest (1%) and highest (5.9%) organic carbon content. Also presented (solid symbols) are data pertaining to the total mass of each species in the systems over time, which also includes the mass that was recoverable from extraction of solids with methanol.

strong binding with Pahokee Peat, perhaps suggesting multiple sorption mechanisms occurring in parallel (e.g., hydrogen bonding in combination with electron donor−acceptor interactions) to strengthen the overall degree of interaction. Ultimately, these findings complicate prediction of SGPM mobility in soils and the subsurface; not only do log$K_{ow}$ values fail to reasonably predict the extent of sorption onto soil organic matter either within or across SGPM families, but they also appear to have little correlation with the extent to which sorption is reversible.

**SGPM Sorption on Model Soils.** Initial experiments with 17$\beta$-TBOH, MGA, and zeranol explored the time scales

dx.doi.org/10.1021/jf5035527 | J. Agric. Food Chem. 2014, 62, 12277−12286

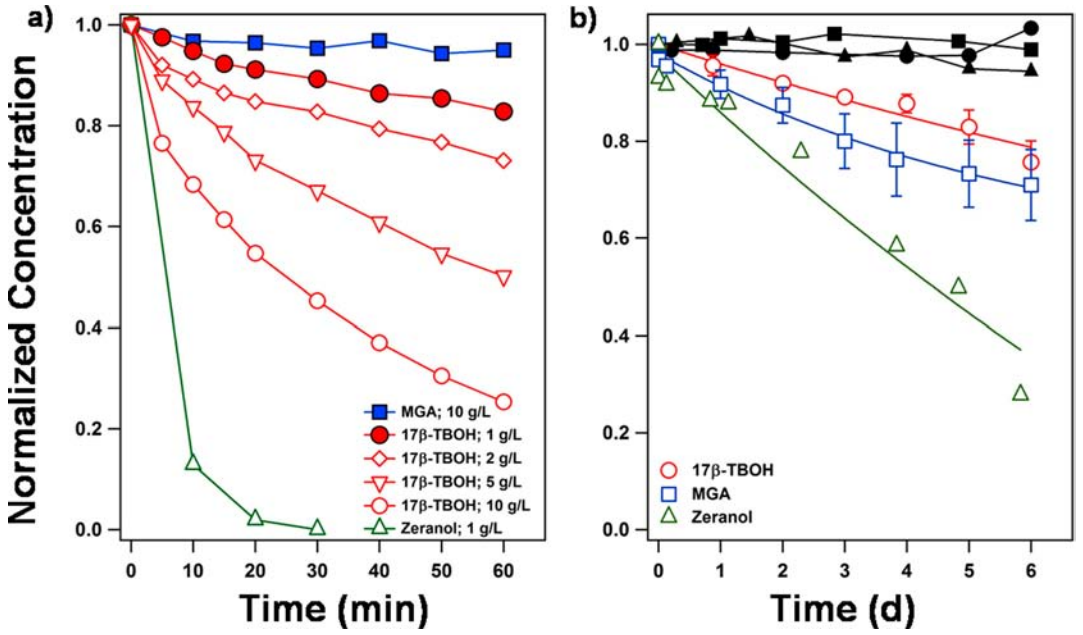

**Figure 4.** (a) Aqueous phase concentration change over time of MGA, 17$\beta$-TBOH, and zeranol in suspensions of $MnO_2$. For 17$\beta$-TBOH, data are shown for several $MnO_2$ solid loadings. All experiments were conducted in 5 mM $NaClO_4$ at pH 6. The initial concentrations of 17$\beta$-TBOH, MGA, and zeranol were 10, 2, and 2 $\mu$M, respectively. All SGPMs were stable in $MnO_2$-free controls (data not shown). (b) Aqueous phase concentration change of 17$\beta$-TBOH, MGA, and zeranol in ferrihydrite suspensions (5 g/L). Reactions were conducted in 5 mM phosphate buffer at pH 7. Lines are exponential decay model fits from which half-lives were estimated. Data are also presented from control systems conducted in the absence of solid (shown as corresponding solid black symbols).

necessary to achieve sorption equilibrium in suspensions of azide-sterilized model soils (Figure 2). Over 6 days, the MGA appeared to reach steady state; after an initially sharp, nearly immediate drop, aqueous phase MGA concentration was essentially stable over the remainder of the 6 day period for all soils. However, the amount of MGA lost from solution did not scale with soil organic carbon content. Rather, if anything, we observed an approximately inverse relationship, in which soils with the highest OC content (PVPF with 5.0% and PVLPF with 5.9%) tended to produce the smallest amount of MGA loss from solution.

Unlike MGA, the solution phase concentrations of 17$\beta$-TBOH and zeranol failed to achieve steady state, even after 6 days of mixing with soils (whereas soil-free controls were stable over the same time scale). For 17$\beta$-TBOH, there was no apparent relationship between the rate of disappearance and soil OC content, whereas zeranol loosely exhibited behavior expected if hydrophobic interactions were driving sorption in these suspensions (i.e., rates and extent of loss were generally greatest in higher OC soils). However, zeranol's inability to achieve sorption equilibrium in these model soil suspensions was notable; whereas equilibrium was readily achieved with high OC Pahokee Peat, the lack of equilibrium in lower OC content soils implies that other, nonconservative, processes may be contributing to the loss of solution phase zeranol.

Additional experiments with select model soils suggest that sorption occurs concurrently with abiotic chemical transformation of SGPMs. Figure 3 shows dissolved concentration versus time plots for 17$\beta$-TBOH, MGA, and zeranol for low (RMN; 1% OC) and high (PVLPF; 5.9% OC) OC content soils, which are identical to the data previously shown in Figure 2 for these soils. However, also provided for comparison are data corresponding to the total mass in these systems over time (i.e., dissolved + sorbed concentration), in which sorbed concentration was determined via methanol extraction of soils at each sampling point (recall that this extraction technique successfully recovered all sorbed mass from Pahokee Peat during our isotherm experiments).

In nearly all systems, we observed loss in total SGPM mass, and the extent of this loss generally increased over time. For 17$\beta$-TBOH and zeranol, there was little, if any, difference in the measured aqueous concentration and the total recoverable mass, and equivalent behavior was observed for both soil systems considered. The agreement in aqueous concentration and total mass profiles is consistent with all 17$\beta$-TBOH and zeranol loss in these soil systems being attributable to some nonconservative process (e.g., reaction) rather than sorption. Because systems were sterilized, we propose that this loss is due to mineral-promoted surface reactions such as hydrolysis or oxidation occurring on underlying inorganic phases in these soils. We note, however, that no products were detected using LC-DAD methods, suggesting that such products either are too polar to be separated on C-18 columns with our existing analytical method or are no longer chromophoric.

Results with MGA may elucidate factors controlling the rate at which SGPMs are degraded in soil systems via such nonconservative processes (i.e., transformation reactions). For both soils in Figure 3, the aqueous phase concentration of MGA showed nearly identical profiles; about 60−70% of the solution concentration disappeared within the first day, after which it remained relatively constant over the experiment's 6 day duration. In contrast, the total mass profiles were distinct for each soil system. For high OC PVLPF, the total mass of MGA in suspension was relatively stable and ∼90% remained after 5 days, consistent with most if not all of the MGA loss from solution being due to sorption. In contrast, total MGA mass decreased steadily over time in the low OC soil RMN, with only 50% remaining after 6 days. However, the rapid,

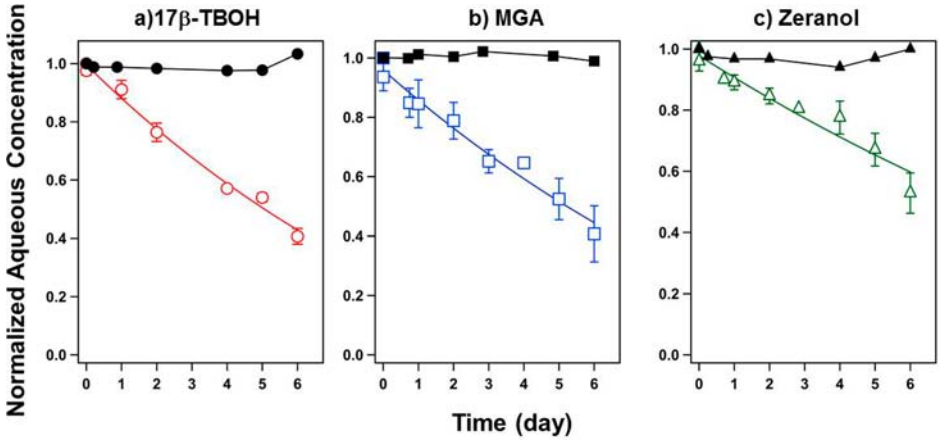

**Figure 5.** Reaction of 17$\beta$-TBOH, MGA, and zeranol with 10 g/L $SiO_2$ at pH 7. Lines represent exponential decay model fits from which half-lives were estimated. Experiments were conducted in 5 mM phosphate buffer at pH 7 and used initial concentrations of 4, 2, and 2 $\mu$M for 17$\beta$-TBOH, MGA, and zeranol, respectively.

initial MGA loss from solution appears to result entirely from sorption, as the total mass recovery for the RMN system was nearly 100% over the short time scales associated with this initial, steep decrease in aqueous concentration. Then, although there was relatively little change in the solution phase concentration of MGA between days 2 and 6, the total MGA mass in the system decreased by ~50%. This suggests that transformation processes in RMN suspensions involve the initially sorbed MGA mass.

One potential explanation for our MGA results is a two-step process for its mineral-promoted transformation in low-to-moderate OC-containing soils. The MGA first sorbs to the organic layer coating the particle, through which it must then diffuse to react at the surface of the underlying inorganic phase, which we assume is the same reactive mineral in both RMN and PVLPF systems. Because MGA has a relatively high $K_{ow}$ value and its isotherm with Pahokee Peat is consistent with hydrophobic partitioning, it is not surprising that the extent of its mass loss from reaction is highly dependent upon soil OC content. Specifically, for high OC content PVLPF (5.9%) MGA is more tightly and/or frequently bound to the organic phase, ultimately making it less available for transformation at the underlying mineral interface. In contrast, the smaller reservoir for hydrophobic partitioning on lower OC RMN (1%) allows MGA to more readily access reactive sites on the surface of the inorganic phase.

When this scenario is extended to 17$\beta$-TBOH and zeranol, their relative rates of organic partitioning (sorption) versus surface transformation (reaction) must be considered. Notably, instances when losses in total mass and solution phase concentration are equivalent (e.g., as we observed for 17$\beta$-TBOH and zeranol) imply that the rate of surface reaction is much faster than that of organic partitioning, thereby limiting the amount of sorbed mass that can accumulate in the system. Unfortunately, without greater understanding of the differences in OC composition and/or the nature of the reacting species in these two soil systems, it is difficult to more fully explain why 17$\beta$-TBOH and zeranol behave so distinctly from MGA.

**Reactivity of SGPMs toward Inorganic Mineral Phases.** The preceding discussion is predicated on the reactivity of SGPMs toward naturally occurring mineral phases. To assess the potential for such mineral-promoted transformations, additional experiments were conducted with several metal oxides representative of those naturally occurring in soil. Figure 4a shows the reactivity of amorphous manganese oxide (hereafter $MnO_2$), a known oxidant of certain steroids,[22] toward 17$\beta$-TBOH, MGA, and zeranol at pH 6. Zeranol was most reactive, undergoing nearly complete transformation over the course of 0.5 h at a relatively low $MnO_2$ loading (1 g/L). Although not as reactive as zeranol, the rate of 17$\beta$-TBOH decay increased with $MnO_2$ solid loading (from 1 to 10 g/L), behavior that is consistent with loss via surface reaction. Also, HPLC-DAD analysis of samples from these 17$\beta$-TBOH suspensions provided evidence of product formation. We note that these products, although not yet structurally identified, are considerably more polar than the monohydroxylated photoproducts of 17$\beta$-TBOH we have elucidated,[31,34,35] which is consistent with highly oxidized products resulting from 17$\beta$-TBOH oxidation by $MnO_2$. Interestingly, MGA is essentially unreactive toward $MnO_2$, exhibiting stability in 10 g/L at pH 6. In fact, we observed evidence of only limited MGA transformation under far more extreme suspension conditions (20 g/L at pH 4).

Iron oxides such as amorphous ferrihydrite are weaker oxidants than $MnO_2$ but may also promote other processes including hydrolysis[21] or, similarly, nucleophilic (e.g., $H_2O$ or $OH^-$) addition. Indeed, a modest amount of 17$\beta$-TBOH and MGA loss (~25%) was observed over approximately 1 week in ferrihydrite suspensions (5 g/L, pH 7) (Figure 4b), whereas zeranol was most reactive. These losses in ferrihydrite suspensions correspond to half-lives of 5 days for zeranol and roughly 15 days for 17$\beta$-TBOH and MGA. Furthermore, attempts to recover any SGPM mass sorbed to the ferrihydrite surface via methanol extraction were unsuccessful, consistent with a nonconservative process being responsible for SGPM loss. However, the relative reactivity of MGA and17$\beta$-TBOH is far different from the trend observed for $MnO_2$, which is reasonably assumed as an oxidant. Thus, we believe the data from ferrihydrite suspensions are evidence of a nonredox, surface-promoted reaction for SGPMs, although reaction products were not detected. This is particularly noteworthy for MGA, as melengestrol, a plausible hydrolysis product easily detected via our analytical methods, was not observed.

Finally, the stability of 17$\beta$-TBOH, MGA, and zeranol was examined in suspensions (10 g/L, pH 7) of $SiO_2$ (Figure 5). $SiO_2$ is not a viable oxidant, so it would be expected to promote

only nonredox pathways (e.g., hydrolysis or nucleophilic addition). Solution phase concentrations of 17$\beta$-TBOH, MGA, and zeranol decreased over time in these suspensions, and once again we were unable to recover any of this lost mass via methanol extraction of the $SiO_2$ at the conclusion of the experiment. Similar to observations with ferrihydrite, 17$\beta$-TBOH and MGA exhibited comparable rates of decay in $SiO_2$ (half-lives of 4.9 and 5.3 days, respectively), seemingly supporting a shared transformation pathway between iron and silica oxide systems. In fact, because 17$\beta$-TBOH and MGA share identical structures in the steroid A ring, we propose these similar time scales indicate A-ring susceptibility to hydroxylation via surface-promoted nucleophilic addition rather than hydrolysis. Zeranol, which has a hydrolyzable ester group, decays at a slightly slower rate compared to the other SGPMs ($t_{1/2}$ of ~8 days).

Although work is ongoing to better characterize SGPM reactivity and fate in these metal oxide systems, these data clearly support the surface-promoted transformation of SGPMs in model soils. Oxidation by manganese oxide appears viable for the TBA and zeranol families, whereas all SGPMs are susceptible to hydrolysis or nucleophilic addition on iron and silica oxides. As for the primary reactive inorganic phase in our model soil systems, our data appear to implicate $SiO_2$. Assuming exponential decay in our model $SiO_2$ systems, the relative rate of transformation for 17$\beta$-TBOH, MGA, and zeranol is 1:1.1:1.6. Notably, if we apply a similar exponential decay model to the total SGPM mass data obtained in our low OC model soil (i.e., RMN; see Figure 3), we find an equivalent trend in relative reactivity for 17$\beta$-TBOH, MGA, and zeranol (1:1.1:1.5). Consistent with these identical trends in relative reactivity, silica was the only mineral phase detected during X-ray diffraction analysis of model soils, although we cannot rule out that iron and manganese oxides were present at levels below the limit of analytical detection. We note that reactivity differences observed in the high OC content soil (PVLPF; 5.9% OC) may indicate a combination of reactive oxides (e.g., $SiO_2$ and $MnO_2$) at play or simply reflect an influence of the organic matter coating on transformation rates by concentrating the SGPMs at the interface of the reactive mineral phase.

**Environmental Implications.** Consistent with initial expectations, our results indicate that the fate of SGPMs in soil is likely far more complex than currently appreciated. Although sorption and biodegradation have long been thought to dominate SGPM fate in soil, we provide converging lines of evidence that abiotic transformation reactions promoted by naturally abundant mineral surfaces, including quartz (i.e., $SiO_2$), can occur over time scales comparable to those previously reported for biotransformation.[7] These transformation pathways likely will influence the persistence of SGPMs in soil while also producing novel, yet uncharacterized, transformation products.

Collectively, our findings highlight the challenges in accurately predicting SGPM fate in soil as a result of their many competing fate pathways (e.g., sorption, biotransformation, mineral-promoted transformation). Generally, we can conclude that SGPM sorption will dominate only in soil systems with very high OC content. For example, the Pahokee Peat systems used herein may indeed be a reasonable approximation of organic-rich agricultural topsoil or land-applied manure, both of which would then be expected to effectively retain SGPMs. However, the extent and reversibility of SGPM uptake do not appear easily predictable from traditional metrics of compound hydrophobicity (e.g., $K_{ow}$ values), which are typically used as a starting point to assess soil partitioning. In particular, more polar species (i.e., those with functionalities capable of specific binding interactions such as hydrogen bonding) will be most difficult to model, as their interactions with organic-rich soil will be influenced heavily by soil organic carbon properties responsible for such specific binding interactions.

A clear need arising from this work is a closer examination of mineral-promoted transformation pathways of SGPMs. This includes identifying the key properties and constituents of soils most likely to promote such reactions, especially because prior studies with these compound classes in model soils (e.g., Card et al.[9]) have failed to observe similar evidence of transformation. Another priority is the structural identification of products generated via mineral-promoted reactions. Whereas the structure of some products may be inferred on the basis of the presence of reactive moieties in the parent structure (e.g., the hydrolyzable ester functionality in zeranol), such mechanistic details remain less obvious in other cases. For example, there are several electron-deficient carbon centers within the trienone structure of trenbolone that could be prone to surface-promoted hydroxylation, although our initial assessment suggests this reaction may proceed through the A ring.

We contend that identification of trenbolone transformation products is a particular priority on the basis of our prior findings regarding trenbolone photolysis. Recently, we reported[35] on the formation of metastable photoproducts of trenbolone, C5 and C12 hydroxylated species, that unexpectedly decompose, or revert, into the parent metabolite from which they were generated. Mineral-promoted nucleophilic addition, as we have proposed, will also likely yield hydroxylated products. We believe that if such hydroxlyation occurs within or adjacent to trenbolone's unique trienone moiety, such products may also be prone to similar transformations to yield novel steroidal byproducts with unknown implications for ecosystem health. We reiterate, however, that all evidence to date suggests that products of mineral-promoted reactions with trenbolone are different from those generated photolytically. Furthermore, changes in solution conditions that promote product-to-parent reversion in photoproduct mixtures (e.g., lowering solution pH to promote acid-catalyzed reversion) have thus far failed to regenerate parent trenbolone metabolites in reacted mineral suspensions.

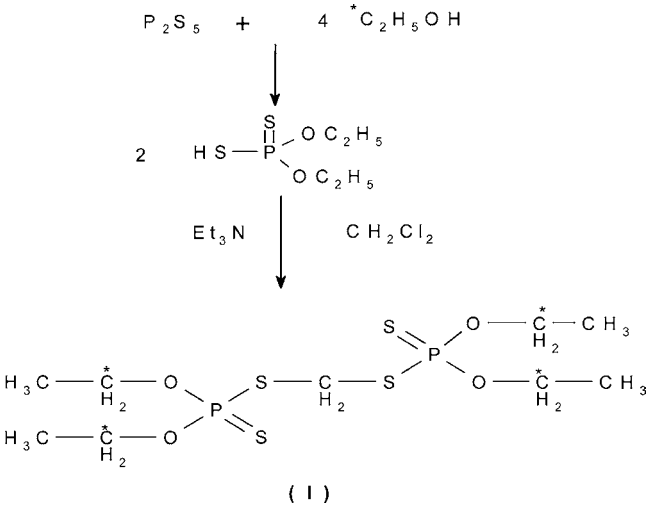

**Figure 1.** Pathway of $^{14}$C-ethion synthesis.

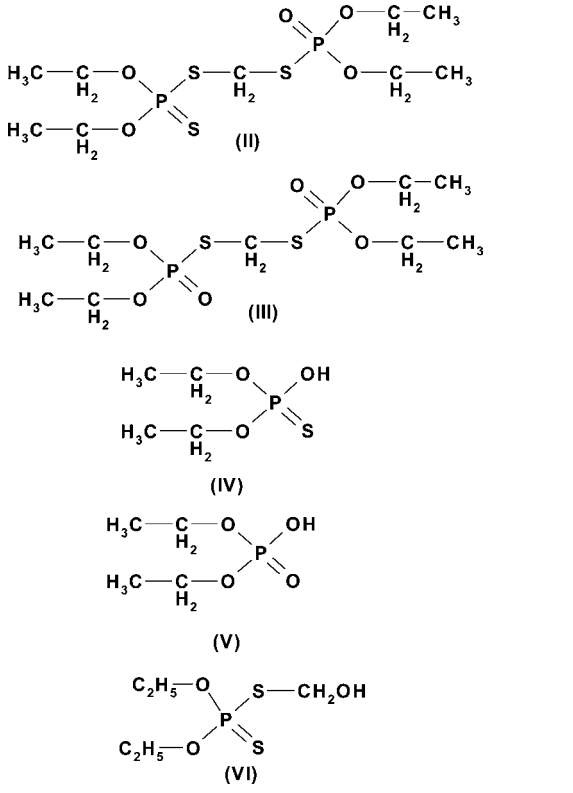

**Figure 2.** Main degradation products of ethion insecticide.

**Field Experiments.** *Treatment of Plants with Pesticides.* Pesticide-free *G. hirsutum* L. seeds (var. Giza 86) were obtained from the Agricultural Research Centre, Cairo. The seeds were cleaned from any dockage and impurities before cultivation. Sound whole seeds of cotton were cultivated under normal field conditions in a controlled, isolated field area. Irrigation, fertilization, and hand weeding were performed, and soil management was conducted as usually practiced in the field. A control field plot of similar soil characteristics to the experimental plot was cultivated as in the experimental plot and kept untreated with pesticides. Shortly at flowering stage, leaves of plants were treated twice, 21 days apart, with $^{14}$C-ethion alone (8 mg/plant) and in the presence of deltamethrin (3.6 mg/plant) and dimilin (1.6 mg/plant) pesticides. Samples of cotton plant were collected manually at harvest time. The cotton seed samples were air-dried and delinted to get cotton seed for preparation of oil and cake and determination of radioactivity.

*Extraction of Cotton Seeds.* The analysis procedures for $^{14}$C-residues in cotton seeds are shown in Figure 3. Dry cotton seeds were crushed and extracted with *n*-hexane for 12 h using a Soxhlet apparatus. After evaporation of hexane under reduced pressure, radioactivity in the cotton oil was measured. The residue remaining after extraction (cake A) was further extracted with ethanol (Figure 3). Aliquots of the hexane extract (oil) and the ethanol extract were determined for radioactivity.

The remaining cake (cake B) was air-dried and digested by adding 1 mL of Solusol (tissue and gel solubilizer); samples were digested at 40−50 °C until the tissue dissolved and then decolorized with 30% $H_2O_2$ (1 mL). Seventy microliters of glacial acetic was added to eliminate chemiluminescence.[12] The radioactivity was determined using a liquid scintillation counter.

*Removal of Pesticide Residues from Oils.* Oil processing was conducted in four steps, namely, alkali refining, bleaching, winterization, and deodorization, as previously reported.[5]

*Neutralization (Alkali Refining).* Samples of the crude cotton oil (17.5 g) were heated at 85 °C with continuous stirring for 30 min and then neutralized by adding 2 N NaOH ,and stirring was continued for another 30 min. The mixture was then centrifuged at 3000 rpm for 10 min. After the oil had been separated from the soap stock, i was washed with 100 mL of hot distilled water several times using a separating funnel until the washings were neutral. This process removed free fatty acids and other acidic material from the oil. The $^{14}$C-activity of the oil was determined.

*Bleaching.* Bleaching clay performs not only color removal but also the removal of trace metals and the adsorption of phospholipids, soap, and decomposition of oxidation products such as peroxides. Neutralized oil was heated to 60 °C and fuller earth (Tonsil, 0.15 g) was added. The mixture was then heated to 100−110 °C on an oil bath for 30 min with continuous stirring. The oil was centrifuged at 3000 rpm for 10 min, and $^{14}$C-residue levels were determined.

*Winterization.* The clear dry oil was winterized (cooled) at 5 °C for 3 days, and the high saturated glycosides that separated were removed by filtration or centrifuged at 3000 rpm for 10 min; $^{14}$C-residue levels were determined.

*Deodorization.* Deodorization is the last major processing step in the refining of edible oil and is responsible for removing undesirable ingredients. The winterized oil was heated at 200−220 °C on an oil bath while superheated steam passed. The deodorization was continued for 3 h. The oil was then separated, and $^{14}$C-residue levels were determined.

*Bioavailability of Bound Residues in Rats.* Three-month-old, sexually mature white male rats (derived from Sprague−Dawlay strain) weighing 150 ± 10 g were purchased from animal house colony, Dokki, Giza Egypt. The animals were individually housed in glass metabolism cages that allowed separate collection of feces, urine, and expired air. The rats were conditioned for 2 days to a daily diet consisting of standard feed mixed with extracted untreated cotton seeds for acclimatization under the laboratory conditions (29 ± 3 °C). The animals were kept without food for 24 h and then fed the diet containing bound $^{14}$C-ethion residues for 3 days. To make the feed palatable, the extracted seeds were mixed thoroughly with an equal amount of white cheese, and the paste was left to dry.

The respiratory carbon dioxide was trapped in a 10% NaOH solution. Urine, feces, and $^{14}CO_2$ were collected separately for 3 days and assayed for radioactivity. After the end of 3 days, each rat was lightly anaesthetized with ether and blood removed from the pumping heart. The animal was then killed with an overdose of ether, and samples from liver, kidney, fat, blood, lung, and brain were collected and kept frozen until analysis of radioactivity by digestion and LSC.

*Isolation and Characterization of $^{14}$C-Residues.* Analysis of radioactive compounds was achieved by thin layer chromatography (TLC). Samples of crude oil at harvest time and after each refining process were partitioned between acetonitrile and hexane to remove the oil. The radioactive residues were almost completely retained in

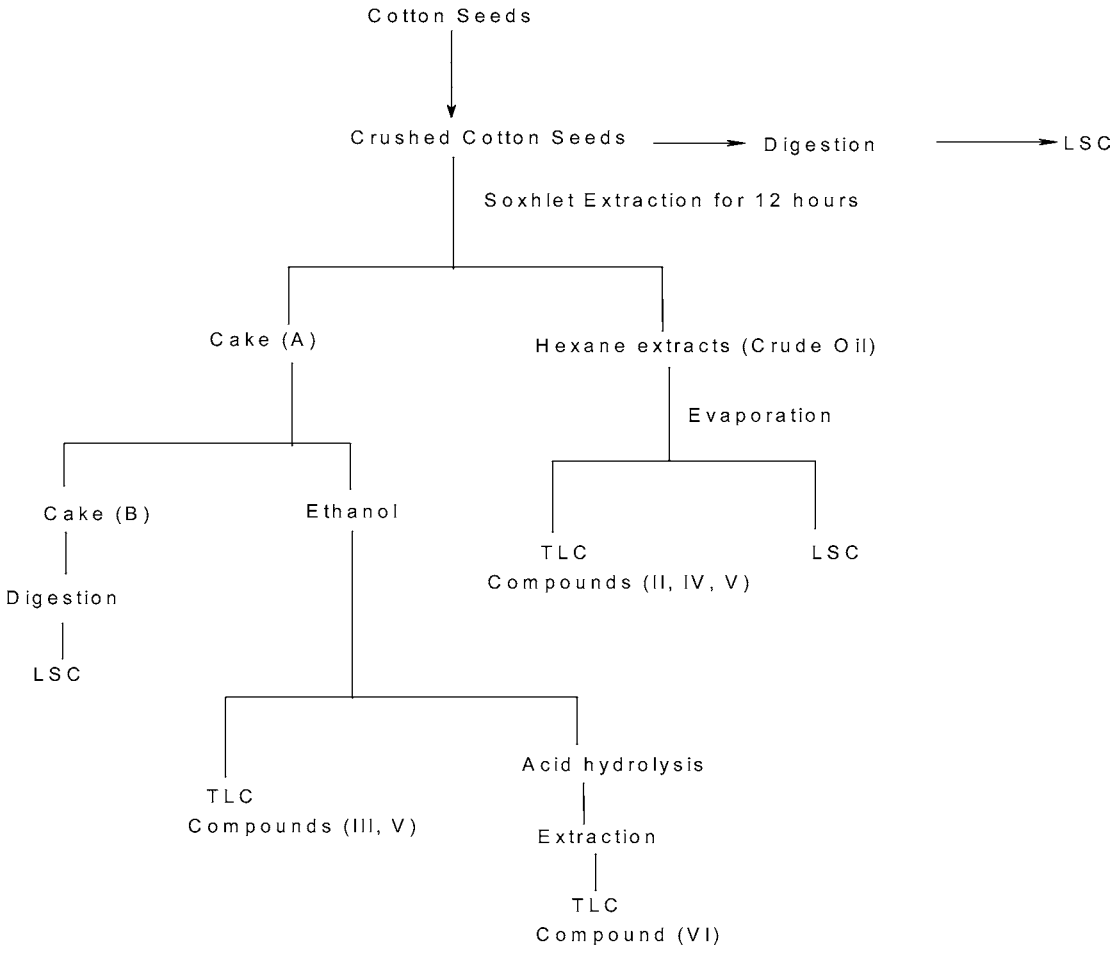

**Figure 3.** Analysis procedures for $^{14}$C-residues in cotton seeds and oils.

the acetonitrile layer. Analysis of crude and refined oil extracts were achieved by TLC.

Urine was extracted with chloroform (chloroform 1), and the aqueous layer was then acidified with 2 N HCl and heated for 2 h at 100 °C on a water bath and reextracted with chloroform three times. The combined chloroform was dried over anhydrous sodium sulfate, filtered off, and evaporated under vacuum (chloroform 2) to obtain the conjugated metabolites. Aliquots from both chloroform 1 and 2 and ethanol layers (after hexane extraction) were analyzed by TLC on silica gel plates using suitable solvents.

Residues were characterized by TLC on silica gel plates (20 × 20 cm; 0.25 mm thickness) with fluorescent indicator (Kiesel gel 60 $F_{254}$, Merck, Darmstadt, Germany) using these solvent systems: system 1, toluene/xylene 50:50 (v/v); system 2, dioxane/xylene/petrolum ether 20:40:40 (v/v/v); system 3, *n*-hexane/ethyl acetate 98:2 (v/v).

Authentic samples were run alongside as references, and spots were viewed under UV light at 254 nm and by spraying the plates with a freshly prepared Hans–Isherwood reagent,[13] or after preliminary spraying with $PdCl_2$ solution, the plates were subjected to $I_2$ vapor to detect the compound by color.[14,15]

*Radioactivity Measurements.* Radioactivity in oil (acetonitrile extracts), ethanol extracts, urine, and other liquid samples was measured directly by LSC using a Packard Tri-Carb liquid scintillation spectrometer (model 2300, PerkinElmer Life Science, Boston, MA, USA) in vials using a dioxane-based scintillation cocktail composed of dioxane (1 L), naphthalene (100 g), 2,5-diphenyloxazole (PPO; 10 g), and 1,4-di[2-(5-phenyloxazolyl)]benzene (POPOP; 0.25 g).

Cake, feces, ground cotton, and animal tissues (100 mg) were assayed for radioactivity by digestion using [1 mL of Solusol (tissue and gel solubilizer), 1 mL of 30% $H_2O_2$, and 70 μL of glacial acetic at 40–50 °C]. The radioactivity was determined using a LSC. The internal standard technique was used for quench correction. Thin layer plates were divided in 1 cm increments, scraped into vials, eluted with methanol, covered with scintillator, and counted.

## RESULTS AND DISCUSSION

**$^{14}$C-Residues in Seeds, Oil, and Cake.** The $^{14}$C-residues in dry cotton seeds obtained from $^{14}$C-ethion-treated plants amounted to 0.11% of the applied dose at harvest time. The percentage of residues decreases to 0.08 and 0.05% in the presence of deltamethrin and dimilin pesticides, respectively (Table 1). The insecticide was absorbed and translocated very slowly from the treated leaves to the seeds of investigated plant due to enzyme metabolic activity.[5,16] Following foliar application of soybean plants with $^{14}$C-pirimiphos-methyl,[17] and cotton plants with $^{14}$C-malathion,[18] the aged insecticide

| sample[a] | oil hexane[b] (ppm) | ethanol[b] (ppm) | cake[b] (ppm) | % recovery |
|---|---|---|---|---|
| ethion | 0.280 ± 0.025 | 0.063 ± 0.005 | 0.220 ± 0.015 | 95.4 |
| ethion and deltamethrin | 0.280 ± 0.018 | 0.098 ± 0.003 | 0.038 ± 0.002 | 88.5 |
| ethion and dimilin | 0.140 ± 0.004 | 0.083 ± 0.002 | 0.028 ± 0.001 | 92.9 |

[a]After the second application. [b]Results are expressed as the mean ± SD for three determinations of ethion residue level for each sample.

residues in seeds amounted to 0.37 and 0.11% of the applied dose, respectively. The data obtained are in agreement with those reported by Singh et al.[19] in their studies on the persistence of ethion residues on cucumber. Although persistent insecticides are beneficial for controlling pests for extended periods, their residues in consumable parts of the crops may be harmful to the consumers when they exceed the maximum residue limit (MRL) values.[20]

About 47.5% of $^{14}$C-activity in dry seeds was found to be associated with oil (hexane extract). The ethanol-soluble $^{14}$C-residues accounted for 10.6% of the total seed residues, whereas the cake contained about 37.3% of the total residues as nonextractable or bound residues in the case of ethion only. The percentage of bound residues decreases when deltamethrin or dimilin pesticide was used in combination with ethion and amounted to 8.1 and 10.4%, respectively. The recovery percent of the applied radioactivity ranged from 88.5 to 95.4% as shown in Table 2. When two compounds are mixed, there are basically four types of interactions that change the efficacy of pesticide combinations; they can either be additive effects or synergistic responses (potentiating) or antagonism or enhancement in an insect species. If a mixture is potentiating, it is a useful tool in enhancing control efficacy and combating insecticide resistance. If a mixture is antagonistic, it should not be used, because it will reduce the efficiency of pest control and aggravate the resistance problem.[1,21] It is worth mentioning that Zayed et al.[22] found that repeated applications of pesticides might enhance the release of $^{14}$C-bound residues in their study on the impact of repeated pesticide applications on the binding and release of methyl $^{14}$C-monocrotophos and U-ring-labeled $^{14}$C-carbaryl to soil matrices under field conditions.

**Effect of Refining Processes.** Simulated commercial processing procedures resulted in a gradual decrease in the total amount of $^{14}$C-residues in oils with aged residues (Table 3). This decrease could be attributed to alkali hydrolysis, effect of adsorption, effect of heat, or evolution of $^{14}CO_2$ gas. The deodorization processes proved to be the most effective step in reducing $^{14}$C-ethion residues, as they eliminated 95% of the residues originally present in crude oil. On the other hand, the alkali treatment, bleaching, and winterization eliminated 30, 75, and 82% of the originally present radioactivity in oil, respectively. These results agree with Miyahara and Saito,[23] who found that in some organophosphorus insecticides, such as malathion, dichlorvos, and chlorpyrifos, the deodorizing process was effective in removing pesticide residues due to decomposition and volatilization. This also agreed with the findings of Ruiz Méndez et al.,[24] who reported that pesticide residues (simazine) were highly eliminated in olive oil during the deodorizing step. Zayed et al.[17,25] showed that the amounts of both $^{14}$C-carbofuran and $^{14}$C-pirimiphos-methyl residues in soybean oil decreased to 16 and 25%, respectively, through the refining processes. Hegazi et al.[26] found that the sunflower oil obtained from treated sunflower plants lost about 64% of the total $^{14}$C-zineb residues in crude oil through refining processes. Abdel-Gawad and Hegazi[5] noted that the refined oil from canola seeds treated with prothiofos lost about 69% of the total $^{14}$C-residues in crude oil through the processing procedures. Also, Abdel-Gawad et al.[6,7] reported that the refined oil from maize and soybean seeds treated with ethion lost about 70 and 62.5% of the total $^{14}$C-residues in crude oil, respectively, through refining processes.

Table 3. Effect of Refining Processes on $^{14}$C-Ethion Residues in Cottonseed Oil

| sample | $^{14}$C-residues[a] (ppm) | % reduction[b] |
|---|---|---|
| crude oil | 0.280 ± 0.025 | 0.0 |
| neutralized oil | 0.196 ± 0.017 | 30 |
| bleached oil | 0.070 ± 0.004 | 75 |
| winterized oil | 0.050 ± 0.003 | 82 |
| deodorized oil | 0.014 ± 0.001 | 95 |

[a]Results are expressed as the mean ± SD for three determinations of ethion residue level for each sample. [b]Percent reduction = [(crude oil − each step)/crude oil] × 100.

**Identification and Characterization of Radioactive Degradation Products in Oil.** The $R_f$ values and the average concentration of $^{14}$C-ethion and its metabolites in cotton oil extract at harvest time are shown in Table 4. Chromatographic analysis of cotton oil extracts (acetonitrile layer) revealed the presence of ethion monooxon (**II**), *O*,*O*-diethyl phosphorothioate (**IV**), and *O*,*O*-diethyl phosphoric acid (**V**) in addition to one unknown compound in the case of ethion alone and ethion and dimilin. The same degradation products are found in the case of ethion and deltamethrin besides ethion dioxon (**III**).

The ethanol-extractable residues contain the hydrophilic compounds ethion dioxon (**III**) and *O*,*O*-diethyl phosphoric acid (**V**) as free metabolites, in addition to an unknown compound. Acid hydrolysis of the ethanol extract with 2 N HCl at 100 °C followed by extraction with chloroform yielded *O*,*O*-diethyl *S*-hydroxymethyl phosphorodithioate (**VI**).

The residues in refined cottonseed oil were identified as ethion monooxon (**II**), *O*,*O*-diethyl phosphorothioate (**IV**), and *O*,*O*-diethyl phosphoric acid (**V**) in addition to one unknown compound. Their amounts decreased during the refining steps (Table 5). Abdel-Gawad et al.[11] studied the distribution and elimination of $^{14}$C-ethion in chamomile flowers and found the presence of the parent compound together with four metabolites, which were identified as ethion monooxon, ethion dioxon, *O*,*O*-diethyl phosphorothioate, and *O*-ethyl phosphorothioate.

The suggested metabolic fate of ethion labeled with $^{14}$C-ethyl groups in cotton seeds and oil after double application to leaves in the presence of deltamethrin and dimilin pesticides at harvest time is shown in Figure 4. Three pathways are suggested for the degradation of $^{14}$C-ethion in cotton seeds. The first is oxidation of P═S to P═O, yielding ethion monooxon (**II**) and ethion

**Table 4. $^{14}$C-Ethion and Its Degradation Products in the Presence of Deltamethrin and Dimilin Pesticides in Extracts of Cottonseed Oil (Crude Oil) at Harvest Time**

| *O,O*-diethyl phosphoric acid (**V**) | 0.61 | 0.71 | 0.82 | 0.071 | 0.060 | 0.003 |
| unknown | 0.10 | 0.15 | 0.00 | 0.095 | 0.091 | 0.003 |

[a]System 1, toluene/xylene 50:50 (v/v); system 2, dioxane/xylene/petrolum ether 20:40:40 (v/v/v); system 3, *n*-hexane/ethyl acetate 98:2 (v/v). [b]A, neutralization; D, deodorization.

dioxon (**III**). The second is cleavage of the P−S−alkyl to yield *O,O*-diethyl phosphorothioate (**IV**) and *O,O*-diethyl phosphoric acid (**V**). The third is hydrolysis to yield *O,O*-diethyl *S*-hydroxymethyl phosphorodithioate (**VI**). Katagi and Mikami[27] noted that the metabolism of organophosphorus pesticides in plants has revealed cleavage of the P−O−aryl linkage and *O*-dealkylation to be among the most predominant metabolic pathways. Ethion is converted via desulfuration in the liver by cytochrome P-450 enzymes to its active oxygen analogue, ethion monooxon.[28]

**Bioavailability in Rats.** Elimination and distribution of $^{14}$C-ethion residues following the feeding of rats with the extracted cotton seeds (cake containing 13.2 $\mu$g equiv per rat) are shown in Table 6. Most of the radioactivity was eliminated via urine (60%), whereas residues in feces and expired air were 9 and 10% of the ingested $^{14}$C-activity, respectively. Appreciable amounts of $^{14}$C-residues (11%) were also detected in the liver, kidney, blood, lung, brain, and fat. Bound $^{14}$C-ethion in cotton

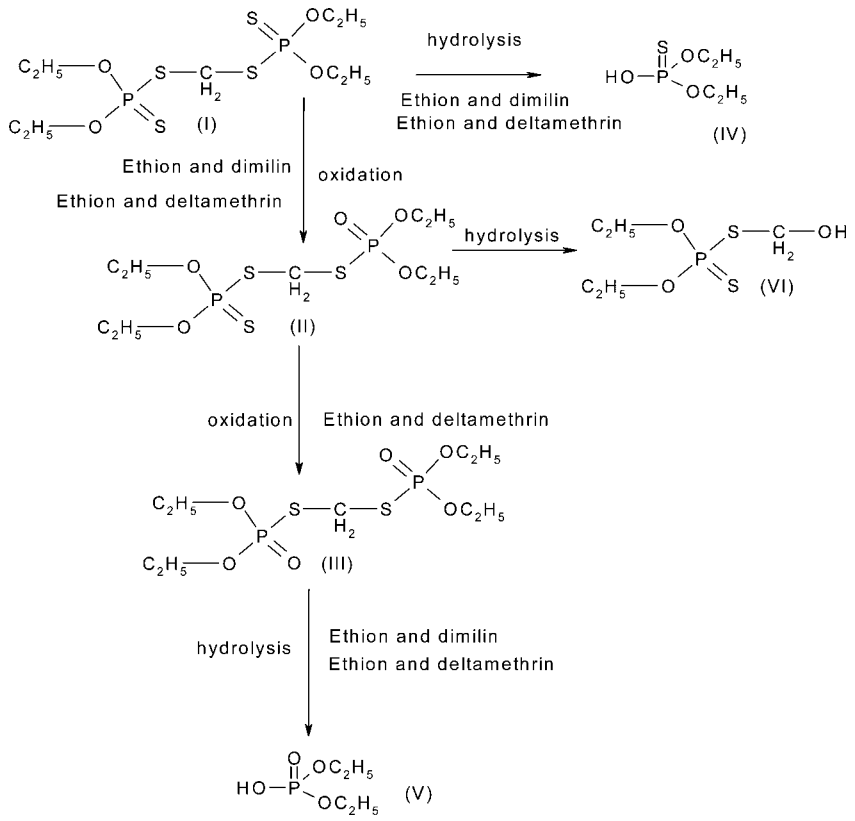

**Figure 4.** Metabolic pathway of $^{14}$C-ethion in cottonseed oil and in the presence of deltamethrin and dimilin.

seeds proved to be highly bioavailable to rats. Similar observations were reported from studies on the bioavailability of soybean-bound residues of dichlorovos[29] and fenitrothion.[30] Also, the data obtained are in line with many other studies that indicate a moderate to high bioavailability of grain-bound $^{14}$C-pesticide residues in experimental animals.[5,31,32]

Chromatographic analysis of urine extracts (chloroform layer) revealed the presence of three metabolites, which were identified as ethion dioxon (**III**), *O*,*O*-diethyl phosphorothioate (**IV**), and *O*,*O*-diethyl phosphoric acid (**V**) as free metabolites in addition to one uknown substance. Compound *O*,*O*-diethyl *S*-hydroxymethyl phosphorodithioate (**VI**) was detected as a conjugated metabolite, and its concentration was 0.004 ppm (Table 7). This result agrees with some previous studies,[5,33,34]

which noted that in adult rats, prothiofos gave prothiofos oxon, *O*-ethyl phosphoric acid, and 2,4-dichlorophenole. Fenitrothion insecticide was converted to phosphorothioate and dimethyl-phosphate. Malathion insecticide was converted to malathion monocarboxylic acid and malathion dicarboxylic acid. Carbofuran, on the other hand, gave carbofuran phenol and 3-hydroxycarbofuran. Ethion is converted via desulfuration in the liver by cytochrome P-450 enzymes to its active oxygen analogue, ethion monooxon.[28]

**Conclusion.** The joint action of deltamethrin and dimilin in combination with the organophosphate ethion was studied on cotton plants by using radiolabeled insecticide. Ethion produced a good potentiation with deltamethrin and dimilin, respectively. The residues of ethion in cotton oil included both free and conjugated metabolites. The $^{14}$C-ethion residues decrease in the presence of deltamethrin and dimilin pesticides. The number of degradation products increases in the presence of deltamethrin more than with dimilin. The bound residues decrease in the presence of deltamethrin and dimilin pesticides as compared with ethion alone. The major part of the insecticide residues (about 95%) could be eliminated during processing of the oil. Refining processes led to progressive degradation of the parent insecticide. The deodorization was found to be an efficient step for reduction of the insecticide residues. Alkali treatment, bleaching, and winterization led to significant losses of the pesticide residues in oil as well. The removal efficiency during the refining processes seems to depend upon the nature of the residue present. The data obtained emphasize the importance of studying the effect of oil refinement on reduction or elimination of aged pesticide residues in edible oils. The present results obtained indicate that cotton-bound $^{14}$C-ethion residues are highly bioavailable to rats. It should be stressed that the presence of bound pesticide residues can no longer be ignored in the evaluation of toxicological hazards.

commercial-grade and obtained from Sinopharm Chemical Reagent Co., Ltd. (Shanghai, China).

All used reagents were analytical-grade, and all dilutions and samples were prepared using deionized water. Fermented and deep-colored soy sauce samples were analyzed because they are the most popular types in China. These samples represented different fermentation processes and geographic regions.

**Isolation of Volatile Aroma Compounds.** Divinylbenzene/carboxen/polydimethylsiloxane (DVB/CAR/PDMS) 50/30 $\mu$m fiber from Supelco Company (Bellefonte, PA) was used to extract volatile components. The fiber was preconditioned as recommended by the manufacturer. Soy sauce (10 g) was pipetted into a conical screw-cap test tube by a polytetrafluoroethylene (PTFE)/silicone septum. The headspace in the vial was stabilized by equilibration for 15 min at 60 °C before extraction. The extraction efficiency is a function of both the temperature and extraction time to obtain the maximum extraction yield. DVB/CAR/PDMS was exposed at 30 °C for 60 min with magnetic stirring (200 rpm).

**Gas Chromatography with Mass Spectrometric Detection.** A HP 5890 II gas chromatograph with a HP 5971A mass selective detector was used for GC−MS. After the extraction, injections provided the fiber thermal desorption into GC. Sample injection was performed in splitless mode. A fused silica HP-5MS capillary column (30 m × 0.32 mm × 0.25 $\mu$m) was employed with the following temperature program: 35 °C (0.5 min), 4 °C/min, and 220 °C. Helium was used as the carrier gas (linear velocity of 25 cm/s), and the ionization energy was 70 eV. The selected compounds were identified by comparing the spectral pattern to the NIST08 MS spectral database or using reference materials and published retention indices. Further instrumental details are described in the literature.[12]

A total of 28 volatile aroma compounds were detected in all soy sauce samples. These volatile aroma compounds represented the flavor compounds of soy sauces in China. In total, 78 soy sauce samples were included in the data set (three geographic regions and two fermentations) for analysis. Hence, the data tables should be 78 × 28 (row × column). A complete data table is needed; however, only 28 variables involving the concentrations of volatile aroma compounds in the table columns were used and surveyed in Table 1. These volatile aroma compounds include alcohols, acids, furans, aldehydes, phenols, esters, ketone, sulfocompound, and pyrrole.

**Identification and Quantification.** Identification was based on the retention indices and mass spectra of reference standards matching in the standard National Institute of Standards and Technology (NIST) 08 library. Positive identifications were achieved by matching linear retention indices and mass spectra to those of standard reference compounds analyzed under the same experimental conditions. When reference standards were not available, tentative identification was conducted in accordance with the mass spectra and retention indices matched in the NIST 08 Standard Reference Database and Wiley library. Retention indices were calculated by using a $C_6$−$C_{33}$ *n*-alkane series (Supelco) under the same chromatographic conditions.

A series of concentrations of standard compounds with 2-octanol (1 mg/L compound solutions) as an internal standard was prepared. For key volatile compound quantification, a five-point calibration curve was developed for each of the identified key volatile compounds. The calibration curve was drawn by plotting the concentration ratio of a standard compound to the internal standard against the corresponding peak area of the standard compound to that of the internal standard. The concentration of each compound was calculated on the basis of the standard curve derived from the area ratio and the concentration ratio of each compound.

**ANNs.** ANNs are computational models inspired by the central nervous systems of animals that are capable of machine learning and pattern recognition. A back-propagation (BP) neural network was used for neural network training on the basis of the data set of varying input−output pairs with input, output, and hidden layers. In accordance with the previous layer, the processing of each layer data, multiplied by the corresponding weight, obtaining the sum value, adopting nonlinear or linear activation function ($f$), and adding the bias, can be mathematically expressed as

$$y_j = \sum_{i=1}^{n} f(w_{ij}x_i) + b_j \quad (1)$$

where $x$ and $y$ are the input and output of the neuron, respectively, and are the number of inputs to the neurons, which is the weight of the connection between neurons $i$ and $j$, and $b$ is the bias associated with jet neuron.

$$E = \sum_{i=1}^{t} E_i = \sum_{i=1}^{t} (y_i - d_i)^2 \quad (2)$$

The aim of the neural network training is to minimize the error $E$ by changing the weights and offsets, where $r$ is the number of input−output vector pairs in the training set, $d_i$ is the respective component of the required output vector, and $y_i$ is the response to the adequate component $x_i$ of the input vector. The error $E$ is usually minimized by the steepest descent method or another gradient method.

**Genetic Algorithm (GA).** The GA was employed in accordance with the fitness function and was operated by selection, crossover, and mutation. Superiority of winner beings is due to their individual characteristics that normally depend upon their genes. Individuals were screened; superior individuals were reserved, and inferior individuals were eliminated. The optimal fitness individuals were identified through selection, crossover, and mutation. The selection operation is the first to choose the best individuals according to the roulette wheel and fitness function. On the basis of mutation probability, the mutation operation randomly alters the element of the individual. Mutation improves the GA ability by random search and global mutation, which allows the GA to avoid learning into local

[a]The $p$ value expresses the probability that the variable is insignificant for the classification by fermentation and geographic region.

optima. These three operations are repeated until the optimal or near-optimal convergence of the solutions is achieved.[13] The ANN modeling and GA optimization in the present study were set in a NeuroSolution (version number 5.07) environment.

**Feature Selection or Detection of the Best Variables for Sensitive Analysis.** The importance of an individual variable and the concentration of a selected volatile compound differ and depend upon the classification criteria, namely, fermentation and geographic region. Therefore, new chemical information on the classified samples is obtained by detecting the most useful variables for soy sauce classification. The process is generally called feature selection, which aims to eliminate redundant variables and, thus, avoids problems with overfitting in the ANN application.

Feature selection can be implemented in ANN in several ways: (1) sensitivity analysis, (2) forward feature selection, and (3) backward feature selection. We have used the first way, which is frequently used in multivariate data analysis, discriminant analysis, or logistic regression. A sensitivity analysis was conducted to select features that exert the largest contribution to the network. The elimination of irrelevant inputs reduces the data collection cost and can sometimes improve the performance of a network. Furthermore, sensitivity analysis will provide insights into the underlying relationships between volatile compounds and the classification by fermentation and geographic region.

**Building Neural Networks.** A total of 78 samples of three geographic regions and two fermentation processes were used in this study. Of the 78 samples, 28 were accepted as final variables for the training process. The soy sauce samples were classified through the ANN technique by fermentation (two classes: HLFSS and LSFSS) and geographic region (three classes: southern, northern, and eastern).

The numbers of input and output neurons were set by the numbers of variables and classes (two for fermentation and three for geographic region), respectively. The training of the BP networks was terminated after a maximum of 1000 iterations or until no increase in mean square error (MSE) was observed. For each cross-validation, the network with the minimum MSE from the cross-validations was calculated to identify the best network. The learning rule in which weights and biases were adjusted was BP through the network. In this work, the hyperbolic tangent function of S type was used in the hidden layer, whereas a linear function was applied in the output layer. The Levenberg−Marquardt algorithm served as a training algorithm.

For convergence and avoidance of overlearning of the ANN, the available training data (78 samples) were split into two subsets: training (62 samples) and testing (15 samples) data. The Kennard−Stone algorithm is well-known in the field of sample selection and has already found many applications. For ANN modeling, 15 samples were selected from the 78 samples using the Kennard−Stone algorithm. The training data set was used to train the network, and the testing data set was used to evaluate the performance of the network on new data that did not appear during the training.

**Classification by Linear Discriminant Analysis (LDA) and ANN.** Two discrimination methods, namely, LDA and non-parametric K-nearest neighbor (KNN) methods, were used and compared to ANN. The KNN algorithm simply works on the basis of the minimum distance from the query instance to the training samples to determine the KNN. This algorithm classifies a new object on the basis of attributes and training samples. Under the test, the nearest neighbor was a set of five with the best performance. LDA was used in pattern recognition to find a linear combination of features, which characterizes or separates two or more classes of objects or events. It uses high-dimensional projection mode samples to the best vector space to extract classified information and the effect of the compression feature space dimension. It guarantees mode samples after projections in the new subspace of minimum and maximum distances between clusters

Table 3. Summary of Optimized Network Architecture Using the Genetic Algorithm

| | hidden layer | | | output layer | |
|---|---|---|---|---|---|
| | number of neurons | learning rate | momentum | learning rate | momentum |
| network information (fermentation) | 7 | 0.645 | 0.896 | 0.457 | 0.343 |
| network information (geographic region) | 6 | 0.431 | 0.565 | 0.125 | 0.835 |

from within a class. That is, the model separability in that space is the best. The leave-one-out validation technique was used to improve the performance of LDA and KNN. A total of 78 samples were created, of which 77 were used in the modeling set and the remaining sample was used to establish a test set; hence, each soy sauce sample was used only once as the test set.

**Optimizing the Parameters of ANNs through the GA.** Rules for determining the parameters of ANNs are inadequate; thus, the GA is used to develop the parameters of the BP network. These parameters include learning rate, momentum, and hidden layer number. To apply the GA to the ANN, the parameter values of chromosomes were translated into the predefined ANN, and the network was trained with the training data set. Learning rate and momentum influenced the prediction accuracy and convergence rate of the ANN. Using a very small value causes a long training time, and applying a very large learning rate may result in a non-convergent training. The range of neuron numbers in hidden layers, step size, and momentum was set to 3−21, 0−1, and 0−1, respectively, to determine the neural network with the best performance by trial and error. The generation number was set to 100 on the basis of the termination criterion. The set of crossover and mutation parameters was reported.[14] The resulting values were based on computational experiences and a literature review. Uniform crossover and mutation operators with a mixing ratio of 0.5 were used, and the probabilities of crossover and mutation operators were adjusted at 0.9 and 0.01, respectively. Increasing the population size positively influenced model fitness but prolonged the training time. Thus, the best generation number was determined to be 50.[15] Therefore, the termination criterion of 40 was chosen.

## RESULTS AND DISCUSSION

**Contribution Assessment of Volatile Compounds by Sensitivity Analysis.** Table 2 shows the contribution of each of the 28 selected volatile compounds in China soy sauce classification. The calculation by sensitivity analysis only considered the volatile compounds and disregarded other volatile compounds.

Furans represented the variables with the greatest contribution in classifying soy sauce samples by fermentation. However, furans are not among the influential variables for China soy sauce classification by geographic region. Ketones and alcohols also played important roles for soy sauce classification by fermentation, whereas phenols and alcohols represented the variables with the greatest contribution in classifying soy sauce samples by geographic region.

The most important compounds for soy sauce class differentiation were as follows: (1) 2-furylmethanol for the classification by geographic region of eastern and southern, (2) 4-ethyl-2-methoxyphenol for the classification by geographic region of northern, (3) 2-methyl 3-octanone for the classification by fermentation of LSFSS, and (4) ethyl phenylacetate for the classification by fermentation of HLFSS.

**Classification of Soy Sauce Using GA−ANN.** On the basis of a successfully performed feature selection, which agreed with the sensitivity analysis results, we used the volatile compounds for ANN training. Calculations for the factors of fermentation and geographic region, followed by sensitivity analysis, were performed in a similar way as described above. The optimum network architecture was 22−6−3 and 15−7−2, as determined on the basis of the MSE by the GA. BP networks were trained with one hidden layer and different neuron numbers. The best network with the lowest MSE was selected after training with different hidden layers, neuron numbers, momentums, and step sizes by trial and error. Table 3 summarizes the different parameters of the developed network using the GA for fermentation and geographic region. The optimum network architecture was selected using all soy sauce samples after GA optimization. As shown in Table 4, the success rate of the classification by fermentation and geographic region was 100% for the 15 test samples. The best fitness, in which the MSE is the lowest across all of the networks within the corresponding generation, is decreased crosswise generations until it becomes relatively constant after 10 generations.

Table 4. Selection of Soy Sauce Samples That Create the Test Data Set and Classification Performance by GA−ANN for Two Classification Criteria

| network | performance (%) | eliminated variables |
|---|---|---|
| fermentation classification | 100.0 | v2, v3, v5, v6, v7, v11, v12, v13, v14, v17, v18, v25, and v27 |
| 15 × 7 × 2 | | |
| geographic region classification | 100.0 | v1, v7, v10, v11, v17, and v22 |
| 22 × 6 × 3 | | |

After variable selection based on the Kennard−Stone algorithm, 15 samples were also used to estimate the performance of LDA and ANN. Under the described leave-one-out technique, the 15 test data were classified using LDA and KNN, and the results are shown in Table 5. LDA and KNN yield good classification results; however, the results of GA−ANN are better than those of LDA and KNN.

Table 5. Classification Performance by KNN and LDA Using Testing Data Set

| classification criterion | KNN | LDA |
|---|---|---|
| fermentation test data | 86.7 | 73.3 |
| geographic region test data | 80.0 | 86.7 |

It has been demonstrated that ANN can be a very useful tool for China soy sauce classification. An ANN with single hidden layer architecture of feed forward type was designed and trained using the BP algorithm to classify soy sauce by fermentation and geographic region. The optimal variable selection was performed by sensitivity analysis. The results of the sensitivity analysis are independent of volatile compound correlations and, thus, can be used complementarily with the ANN results. Therefore, GA−ANN proved to be a dependable software tool for identifying the characteristic volatile compounds of soy sauce. The results of this study can be further used to establish a database of the flavors of soy sauce from different fermentation processes and geographic regions.

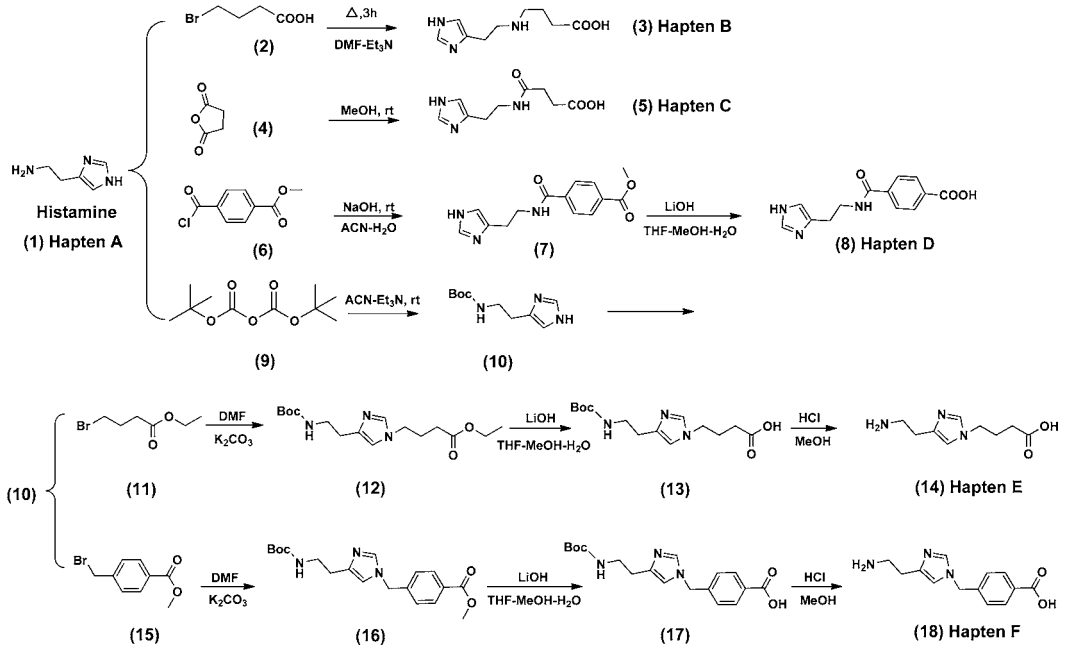

**Figure 1.** Synthetic route for haptens.

chemical residues. However, the development of a high affinity antibody against HA is not easy, and has puzzled immunochemists for some time due to the simple structure of HA (MW, 111 Da).[25] In general, all reported antibody methods used for immunoassay determination of HA in foods can be classified into three categories. (1) An antibody that specifically recognized the *p*-benzoquinone−histamine conjugate was initially reported in 1986.[26] Based on this conjugate, ELISAs were proposed for HA detection in foodstuffs, using a preanalysis HA derivatization step with *p*-benzoquinone.[27,28] But drawbacks did exist for this strategy. The derivatization reaction between HA and *p*-benzoquinone was complicated due to side reactions, and the product was unstable. (2) A second antibody was developed against a modified HA by coupling succinylated HA to BSA grafted with a glycyl residue.[29] The obtained antibody also showed no binding affinity for free histamine, but it had high binding affinity for modified HA which was formed through the reaction between HA and *N*-hydroxysuccinimide ester−succinyl-glycinamide (NHS-SGA). However, the synthesis of the derivatization reagent, NHS-SGA, was laborious with multisteps, making this reagent costly. (3) The only antibody developed that was able to recognize intact HA was developed by coupling HA to KLH via glutaraldehyde, and then the conjugate was used as an immunogen to immunize New Zealand white rabbits.[30] However, the repeatability of this strategy is poor, and four attempts using this strategy to produce an antihistamine antibody have failed in our group.

This study aimed at finding a reliable strategy for producing an antihistamine antibody, as well as the development of a competitive indirect enzyme-linked immunosorbent assay (ciELISA) for HA determination in foods based on the obtained antibody. For this purpose, several haptens were synthesized in attempts to obtain an antibody with specific histamine affinity or derivatized histamine affinity. Although, the development of an antibody against free HA failed, a highly specific polyclonal antibody produced against *p*-nitrobenzoylated HA (NPHA) was used to develop a ciELISA for derivatized HA in foods. Because HA can be efficiently and quantitatively converted to NPHA by PNBA-OSu under mild basic conditions at room temperature, a ciELISA was developed here for the analysis of HA in food samples via a preanalysis HA derivatization step. This work also fully optimized the assay conditions. In addition, the immunoassay results were validated by comparison with LC−MS/MS results.

## MATERIALS AND METHODS

**Animals and Reagents.** Histamine dihydrochloride, L-histidine, L-tryptophan, tryptamine hydrochloride, tyramine hydrochloride, phenethylamine hydrochloride, and cadaverine hydrochloride were obtained from Heowns Biochem Technologies Co. Ltd. (Tianjin, China). Methyl 4-(chlorocarbonyl)benzoate, *p*-nitrobenzoic acid, *N*-hydrosuccinimide, dicyclohexylcarbodiimide (DCC), and triethylamine were obtained from Aladdin Chemical Technology Co., Ltd. (Shanghai, China). Histamine, 3,3′,5,5′-tetramethylbenzidine (TMB), glutaraldehyde (50%, v/v), complete and incomplete Freund's adjuvants, keyhole limpet hemocyanin (KLH), bovine serum albumin (BSA), ovalbumin (OVA), horseradish peroxidase, and peroxidase-labeled goat anti-rabbit IgG (secondary antibody) were obtained from Sigma-Aldrich (St. Louis, MO, USA). *N*,*N*-Dimethylformamide (DMF), acetonitrile (ACN), Tween-20, ethanol, methanol (MeOH), ethyl acetate (EtOAc), tetrahydrofuran (THF), and chloroform ($CHCl_3$) were obtained from Damao Chemical Reagent Co., Ltd. (Tianjin, China). New Zealand white rabbits were raised at the Guangdong Medical Experimental Animal Centre. 96-Well polystyrene microplates were obtained from Shenzhen Jinchanhua Industrial Co. Ltd. (Shenzhen, China). All other reagents were of analytical reagent grade or higher purity.

**Instruments.** ELISA plates were washed in a Multiskan MK2 microplate washer (Thermo Scientific, Hudson, NH, USA). Absorbance was measured at a wavelength of 450 nm using a Multiskan MK3 microplate reader (Thermo Scientific). Ultraviolet spectrometry (UV) was recorded on a UV-3010 spectrophotometer (Hitachi, Tokyo, Japan). LC−MS/MS analysis was carried out by using the 1200 series LC system (Agilent Technologies) equipped with the Agilent 6410 Triple Quad LC−MS system (Agilent Technologies). Nuclear magnetic resonance (NMR) spectra were achieved with either a DRX-400 or DRX-600 NMR spectrometer (Bruker, Rheinstetten, Germany).

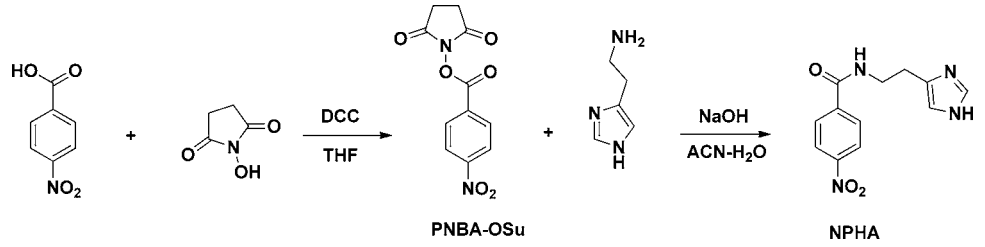

**Figure 2.** Synthetic route for the derivatizing reagents, PNBA-OSu and NPHA.

**Buffers and Solutions.** The following were the buffers and solutions used in this study: (1) Borate buffer (0.2 mol/L, pH 9.0) was used for histamine chemical derivatization; (2) 50 mmol/L carbonate buffer (pH 9.6) was used for coating antibody on plates; (3) $PBST_1$ (10 mmol/L phosphate-buffered saline (PBS) with Tween-20 (0.05%), pH 7.4) was used for washing plates and secondary antibody dilution and was the working buffer used in the nonoptimized ciELISA; (4) $PBST_2$ (20 mmol/L PBS, Tween 20 (0.05%), pH 7.4) was used for the working buffer in the optimized ciELISA; (5) 0.1 mol/L sodium acetate (pH 5.5) was used for the substrate buffer; (6) 2 mol/L $H_2SO_4$ was used for the stop reagent; and (7) HA stock standard solution (1 mg/mL HA in distilled water (d.w.)).

**Synthesis and Verification of Histamine Derivatives.** Five histamine derivatives (haptens B–F) were synthesized by introduction of different spacer arms containing a carboxyl group at histamine's primary amine or by substitution of H on the ring NH group (Figure 1). Figure 2 shows the synthetic route to produce the derivatization reagents PNBA-OSu and NPHA. The following is a detailed description of the synthetic procedure and characterization of these compounds.

*Hapten A, HA (**1**).* Hapten A is intact HA. Histamine was conjugated to the carrier protein via glutaraldehyde according to previous work.[30]

*Hapten B, 4-((2-(1H-Imidazol-4-yl)ethyl)amino)butanoic Acid (**3**).* Histamine dihydrochloride (1.84 g, 10 mmol) and triethylamine (6 mL) were added to DMF (20 mL) containing 4-bromobutanoic acid (**2**, 1.65 g, 10 mmol). The mixture was stirred at room temperature for 1 h and then refluxed at 80 °C for 3 h, after which time the solvent was evaporated under vacuum, leaving a gummy residue. The residue was purified on a silica gel column, using $CHCl_3$/MeOH/$NH_4OH$ (10:5:1) as the eluent, and then crystallized from ethanol (10 mL) to afford hapten B (**3**, 832 mg, 4.2 mmol): ESI analysis (positive ion) $m/z$ 198 $[M + H]^+$; $^1H$ NMR (600 MHz, $D_2O$) $\delta$ 8.84 (s, 1H), 7.57 (s, 1H), 3.11 (t, $J$ = 5.2 Hz, 2H), 2.94 (t, $J$ = 5.2 Hz, 2H), 2.62 (t, $J$ = 7.7 Hz, 2H), 2.34 (t, $J$ = 8.2 Hz, 2H), 1.86 (t, $J$ = 7.9 Hz, 2H).

*Hapten C, 4-((2-(1H-Imidazol-4-yl)ethyl)amino)-4-oxobutanoic Acid (**5**).* Succinic anhydride (**4**, 500 mg, 5 mmol) was added to a solution of histamine dihydrochloride (920 mg, 5 mmol) in methanol (15 mL) and stirred at room temperature for 4 h, and the solvent was removed by evaporation. The residue was redissolved in ethanol (20 mL) and kept at 4 °C overnight, and then hapten C (**5**, 650 mg, 3.1 mmol) was crystallized: ESI analysis (negative ion) $m/z$ 210 $[M - H]^-$; $^1H$ NMR (600 MHz, $D_2O$) $\delta$ 8.54 (s, 1H), 7.26 (s, 1H), 3.45 (t, $J$ = 6.3 Hz, 2H), 2.89 (t, $J$ = 6.4 Hz, 2H), 2.44–2.35 (m, 4H).

*Hapten D, 4-((2-(1H-Imidazol-4-yl)ethyl)carbamoyl)benzoic Acid (**8**).* A solution of methyl 4-(chlorocarbonyl)benzoate **6** (198 mg, 1 mmol) in 5 mL of ACN was added dropwise to a solution of histamine dihydrochloride (184 mg, 1 mmol) in 1 M NaOH (5 mL). The mixture was stirred at room temperature for 3 h, and then the ACN was removed by rotoevaporation under vacuum. A yellow precipitate was filtered and washed three times with 0.1 M HCl and dried to yield intermediate **7** (232 mg, 0.84 mmol). A solution of intermediate **7** (232 mg, 0.84 mmol) in a mixture of THF/MeOH/$H_2O$ (1:1:1, 15 mL) was treated with LiOH·$H_2O$ (84 mg, 2.0 mmol) and refluxed at 40 °C overnight. The organic solvent was evaporated under vacuum, and the aqueous layer was acidified with 1 M HCl until a white precipitate formed. The precipitate was filtered off and washed with 0.1 M HCl, and dried to yield hapten D (**8**, 196 mg, 0.75 mmol): ESI analysis (negative ion) $m/z$ 258 $[M - H]^-$; $^1H$ NMR (400 MHz, methanol-$d_4$) $\delta$ 8.54 (d, $J$ = 1.4 Hz, 1H), 8.12–8.05 (m, 2H), 7.90–7.82 (m, 2H), 7.27 (d, $J$ = 1.3 Hz, 1H), 3.72 (t, $J$ = 6.8 Hz, 2H), 3.04 (t, $J$ = 6.8 Hz, 2H).

*Hapten E, 4-(4-(2-Aminoethyl)-1H-imidazol-1-yl)butanoic Acid (**14**).* Histamine dihydrochloride (3.68 g, 20 mmol) and triethylamine (56 mL, 40 mmol) were mixed in acetontrile (150 mL), then di-*tert*-butyl dicarbonate (**9**, 4.36 g, 20 mmol) was added. The mixture was stirred at room temperature overnight and then filtered. The filtrate was evaporated under vacuum, and the residue was washed with petroleum ether (100 mL). The undissolved substance was treated with d.w. (100 mL), and the mixture was filtered. The aqueous solution was saturated with NaCl and extracted with ethyl acetate. The organic layer was dried over anhydrous $Na_2SO_4$ and evaporated under vacuum, leaving an oil. The residue was crystallized from ether/petroleum ether to afford the intermediate **10** (2.3 g, 10.8 mmol). Ethyl 4-bromobutanoate (**11**, 386 mg, 2 mmol), the intermediate (**10**, 422 mg, 2 mmol), and DMF (20 mL) were mixed, and then $K_2CO_3$ (500 mg, 3.6 mmol) and tetrabutyl ammonium bromide (5 mg, 0.016 mmol) were added. The mixture was stirred under reflux at 80 °C overnight and then was concentrated by rotoevaporation under vacuum. The crude product was purified on a silica gel column, using EtOAc/MeOH (20:1) as eluent to afford **12** (334 mg, 1.02 mmol). Compound **13** was synthesized from **12** by subjection of **12** to the same hydrolysis step as previously used to convert **7** to **8**. The resulting mixture was concentrated by rotoevaporation under vacuum and purified on a silica gel column using EtOAc/MeOH (4:1) as eluent to give **13** (280 mg, 0.94 mmol). Compound **13** was dissolved in methanol (20 mL), and concentrated hydrochloric acid (5 mL) was added. The mixture was stirred on an ice bath for 1 h and then concentrated by rotoevaporation under vacuum to give hapten E (**14**, 262 mg, 0.78 mmol, in its hydrochloride form): ESI analysis (negative ion) $m/z$ 196 $[M - H]^-$; $^1H$ NMR (600 MHz, methanol-$d_4$) $\delta$ 8.97 (s, 1H), 7.61 (s, 1H), 4.30–4.26 (m, 2H), 3.30–3.28 (m, 1H), 3.14 (t, $J$ = 7.5 Hz, 2H), 2.45 (t, $J$ = 7.2 Hz, 2H), 2.21–2.18 (m, 2H).

*Hapten F, 4-((4-(2-Aminoethyl)-1H-imidazol-1-yl)methyl)benzoic Acid (**18**).* The synthetic route of hapten F (**18**) was similar to hapten E (**14**), except the initial ester, ethyl 4-bromobutanoate (**11**), was replaced with 4-((4-(2-aminoethyl)-1*H*-imidazol-1-yl)methyl)benzoic acid (**15**) (see Figure 1): ESI analysis (positive ion) $m/z$ 246 $[M + H]^+$; $^1H$ NMR (600 MHz, methanol-$d_4$) $\delta$ = 9.05 (s, 1H), 8.03 (t, $J$ = 5.3, 2H), 7.54 (s, 1H), 7.50 (t, $J$ = 6.6, 2H), 5.47 (s, 2H), 3.24 (t, $J$ = 7.6, 2H), 3.07 (t, $J$ = 7.5, 2H).

*Derivatization Reagent (PNBA-OSu) and N-(2-(1H-Imidazol-4-yl)ethyl)-4-nitrobenzamide (NPHA).* PNBA-OSu was synthesized as previously described:[31] ESI analysis (positive ion) $m/z$ 306 $[M + ACN]^+$; $^1H$ NMR (600 MHz, $CDCl_3$) $\delta$ 8.37 (d, $J$ = 9.0 Hz, 2H), 8.33 (d, $J$ = 9.0 Hz, 2H), 2.94 (s, 4H). A solution of PNBA-OSu (700 mg, 2.65 mmol) in ACN (20 mL) was added dropwise (with stirring) to a solution of histamine dihydrochloride (460 mg, 2.5 mmol) in 1 M NaOH (10 mL). The resulting mixture was stirred at room temperature for 2 h, and then the organic solvent was removed by evaporation under vacuum. The yellow precipitate that formed was filtered off and washed with 0.1 M NaOH and dried to give NPHA (588 mg, 2.25 mmol): ESI analysis (positive ion) $m/z$ 261 $[M + H]^+$; $^1H$ NMR (400 MHz, methanol-$d_4$) $\delta$ 8.54 (d, $J$ = 1.1 Hz, 1H), 8.09 (d, $J$ = 8.5 Hz, 2H), 7.86 (d, $J$ = 8.5 Hz, 2H), 7.27 (s, 1H), 3.72 (t, $J$ = 6.8 Hz, 2H), 3.04 (t, $J$ = 6.8 Hz, 2H).

**Synthesis of Immunogen and Coating Antigen.** Histamine (hapten A) was coupled to KLH via glutaraldehyde for the immunogen and to OVA for the coating antigen.[30] Haptens B−F were conjugated to BSA with 1-ethyl-3-(3-dimethylaminopropyl)-carbodiimide hydrochloride (EDC) and used as the immunogen, and they were conjugated to OVA and used for the coating antigen according to previous work, with modifications.[32] Briefly, a hapten (0.1 mmol) and carrier protein (10 mg) were dissolved in the conjugation buffer (PBS, pH 6.0, 5 mL). The resulting solution was cooled on an ice bath, and EDC (32 mg) was added with stirring. The mixture was held at 0 °C overnight with stirring, and then the conjugation mixture was dialyzed against 10 mM PBS (4 × 5 L) at 4 °C for 72 h, and finally stored at −20 °C until used. UV−vis spectral data was used to confirm the structures of final conjugates, and the hapten density was estimated by the TNBS method.[33]

**Immunization and Polyclonal Antibody Production.** Twelve New Zealand white rabbits were housed and maintained at the Guangdong Medical Laboratory Animal Center. All animal experiments were performed in compliance with the protective and administrative laws for laboratory animals of China and conducted with the approval of the Institutional Authority for Laboratory Animal Care, South China Agricultural University, Guangzhou, China. The rabbits (10-wk-old, 1.5−2.0 kg) were equally divided into six groups for the six immunogens, and each was intradermally and intramuscularly immunized with 1 mL of an emulsion (1:1) containing 0.5 mg/mL of an immunogen in PBS and complete Freund's adjuvant. Four booster immunizations using the same amount of immunogen emulsified in incomplete Freund's adjuvant were given monthly. Ten days after the fourth booster injection, the rabbits were exsanguinated and their blood was collected. The obtained antiserum was stored at −20 °C until purified by saturated ammonium sulfate precipitation.[34] Serum was collected from the marginal ear vein from each rabbit prior to the first immunization and used as the negative controls.

**Antibody Screening and Characterization.** A ciELISA was used to evaluate the antiserums for binding ability to the analytes (histamine or its derivatives). Briefly, the coating antigens (1 mg/L, 100 μL/well) in carbonate buffer were added to 96-well polystyrene ELISA plates and incubated at 4 °C overnight, and then the wells were washed twice with $PBST_1$ solution prior to adding 5% skimmed milk in $PBST_1$ (100 μL/well) to block the uncoated sites for 3 h at 37 °C and dried at 37 °C for 1 h. Histamine standards or other competitors in PBS (50 μL) and the diluted antiserum (50 μL) in $PBST_1$ were added to each well and incubated at 37 °C for 40 min, and then the wells were washed five times with $PBST_1$. The secondary antibody diluted 1:10000 in $PBST_1$ (100 μL/well) was then added to the wells and incubated for 40 min at 37 °C. The wells were washed again five times with $PBST_1$ before the TMB solution was added to the wells (100 μL/well) and incubated for 10 min. Finally, 50 μL of 2 M $H_2SO_4$ was added to quench the reaction and the optical density was measured at 450 nm. The percent inhibition of antibody binding used to characterized the binding ability of antibodies was expressed as follow: inhibition (%) = $[1 - (B/B_0)] \times 100$; $B_0$ was the mean absorbance of the wells in the absence of a competitor; $B$ was the mean absorbance of wells in the presence of a competitor.

**Optimization of ELISA Conditions.** To improve performance of the ELISA, heterology in the chemical structure of the coating hapten was used, and optimization was performed of the physicochemical parameters considered to have significant effects on immunoassay performance,[35] such as antibody dilution/coating concentration, and working buffer (concentration of Tween 20, ionic strength, and pH). For each condition, NPHA was used as the competitor analyte to construct inhibition curves ($n$ = 3). The maximum value of the inhibition curve (Amax) and competitor analyte concentration leading to a 50% decrease in Amax ($IC_{50}$) were calculated from these curves. The optimal conditions were confirmed by evaluating the ratio of Amax to $IC_{50}$. Higher value of Amax/$IC_{50}$ equates to better assay performance under such conditions.

**Preparation of Food Samples.** Fish, red wine, and yoghurt samples were purchased from a local supermarket in Guangzhou, China. For fish, an equivalent weight of d.w. was added to the muscles and homogenized, and then d.w. (8 mL) and the homogenate (2 g) were mixed and shaken vigorously for 1 min. The mixture was centrifuged at 3000$g$ for 10 min, and the supernatant was then diluted 20-fold in d.w. and subjected to the derivatization procedure as follows: 200 μL of diluted supernatant, 400 μL of borate buffer (pH 9.0), and 400 μL of PNBA-OSu solution (2 mg/mL in ACN) were successively added to a 1.5 mL conical tube and vortexed for 10 s. The reaction mixture was kept at room temperature (25 °C) for 20 min, and 100 mg of NaCl was added to separate the organic layer (ACN) from the aqueous layer. The organic layer was diluted (10-fold) in $PBST_2$ (optimized working buffer) for ciELISA analysis, and in a mixture of MeOH/$H_2O$ (v/v, 10:90) for analysis by LC−MS/MS. For red wine and yoghourt, d.w. (9 mL) was added to the samples (1 mL or 1 g) and shaken for 1 min, and then centrifuged at 3000$g$ for 10 min. The supernatant was directly subjected to the same derivatization process as were the fish samples above, and then analyzed by ciELISA and LC−MS/MS. All prepared samples were filtered through a 0.22 μm membrane before LC−MS/MS analysis.

**Histamine Assay.** Each prepared sample was split and subjected to histamine analysis by both ciELISA and LC−MS/MS methods.

*ciELISA.* A calibration curve was constructed as follows: 200 μL serial dilutions of HA from the HA stock solution were subjected to the derivatization procedure as described above, 50 μL of the resulting solution was used as competitor in the ciELISA, and then the calibration curve was obtained by plotting the percent binding of antibodies in the wells ($B/B_0 \times 100$) against the logarithm of the HA concentration. For sample analysis, 50 μL of the prepared samples, as described above, were used as competitor in the ciELISA, and the determined $B/B_0 \times 100$ was used to calculate the HA concentration from the calibration curve.

*LC−MS/MS.* The results from the ciELISA were confirmed by the LC−MS/MS method (completed by the Zhongshan Quality Supervision & Inspection Institute of Agricultural Products of Guangdong Province, Zhongshan, China). A 5 μL portion of the prepared samples was injected into the LC system (Agilent 1200-6410) equipped with an Agilent ZORBAX SB-C18 column (2.1 mm × 150 mm, 3.5 μm) and separated at a 0.4 mL/min flow rate (mobile phase A, 0.1% acetic acid; mobile phase B, ACN) in the following gradient profile: 0−3 min, 8%−15% B; 3−5 min, 15%−30% B; 5−5.01 min, 30%−90% B; 5.01−8 min, 90% B. Analytes were determined by an Agilent 6410 Triple Quad mass spectrometer (Agilent Technologies, Lexington, MA, USA) using ESI-MS/MS in the positive ion mode. The MS parameters were as follows: capillary voltage at 4.0 kV; desolvation temperature at 350 °C; desolvation gas ($N_2$), flow rate at 10 L/min; ion spray voltage at 4000 V. The analytes were identified by parent/daughter ions as well as peak retention times in comparison to the standards. The $[M + H]^+$ at $m/z$ 261.0 was the parent ion of NPHA. The daughter ion at $m/z$ 95.1 was used for quantitation, and the daughter ion at $m/z$ 68.1 was selected as a qualitative ion (see Figure S1 in the Supporting Information).

A calibration curve for HA analysis by LC−MS/MS was constructed as follows: Serial concentrations (10−1000 ng/mL) of HA standard solutions in d.w. were prepared from the HA stock solution, and were subjected to the derivatization and treatment steps as described above. The treated solutions (5 μL) were injected into the instrument and analyzed. The responses of the mass spectrometer were plotted against the concentration of HA, which resulted in the calibration curve.

## RESULTS AND DISSCUSSION

**Hapten Synthesis and Antibody Production.** It cannot be underestimated how big a key role the proper hapten design plays in antibody production and immunoassay development, especially for a compound like HA having an extremely simple structure. As can be seen from the structure of HA (Figure 1), the structure consists of two parts, an imidazole ring and a side chain (amino ethyl) containing a primary amino group. The only previously reported antibody that could specifically recognize free HA was produced by conjugating HA to KLH

[a]Titer is defined as dilution factor of antiserum with the abosorbance at 450 nm being situated at about 1.0 at coating concentration of 1.0 mg/L. [b]Percentage inhibition was expressed as follow: inhibition (%) = $[1 - (B/B_0)] \times 100$. $B_0$ was mean absorbance of the wells in the absence of competitor; $B$ was mean absorbance of the wells in the presence of certain concentration of competitor (50 mg/L histamine). [c]Not calculated.

via the primary amino group using the glutaraldehyde method.[30] Initially, our laboratory attempted the same strategy using intact HA as hapten (hapten A). Meanwhile, two carboxyl groups containing spacer arms were also introduced via the primary amino group, forming hapten B and hapten C. To maintain functionality around the primary amino group, a carboxyl group containing a 4-carbon length spacer arm (hapten E) and a carboxyl group containing a benzene ring in the spacer arm (hapten F) were introduced in the ring at N-1. These haptens were conjugated to KLH (hapten A) or BSA (haptens B, C, E, and F) and used to immunize rabbits, while no antisera against these haptens were found to contain antibodies specific against free HA (Table 1). The failure in production of an antibody that possessed the desired affinity and specificity for HA using the above immunogens probably resulted from the extreme simplicity of HA's structure and lack of a sufficient epitope to be identified by the T helper or naive (virgin) B cells. This result revealed the necessity for chemical derivatization of HA for immunoanalysis of HA, which was similar to most of the past studies on immunoanalysis of histamine.[26−29] However, derivatization of histamine by *p*-benzoquinone did not meet the requirements necessary for immunoanalysis due to the reaction's complexity with side reactions and instability of the target analyte.[26,27] In work by Morel et al.,[29] synthesis of the derivatization reagent, NHS-SGA, was laborious, requiring multiple steps, making this reagent quite costly. However, the use of the *N*-hydroxysuccinimide ester, PNBA-OSu, in our work can preferentially and efficiently acylate primary amino groups under mild conditions.[36] HA can smoothly and rapidly convert to NPHA by the interaction with PNBA-OSu under mild conditions (Figure 2). It can be seen from the structure of NPHA (Figure 2) that the structure of benzoylated histamine exhibits more than a 100% increase in mass compared to histamine and contains a benzene ring. Thus, NPHA should substantially improve the rate of successful generation of specific antibody. Therefore, hapten D, benzoylated histamine, with a carboxyl group para to the amido bond was synthesized according to the synthetic route shown in Figure 1, and then coupled to BSA to form an immunogen. As expected, the corresponding antiserum showed high binding affinity to NPHA, and no binding affinity to free histamine (Table 2). Thus, a ciELISA based on antiserum D could be used to quantitate histamine by introducing a quick preanalysis derivatization of the samples.

**Table 2. Evaluation of Antiserum D against NPHA[a] under Heterologous and Homologous Coating Formats**

| coating antigen | antiserum D | |
|---|---|---|
| | titer ($\times 10^3$) | inhibn (%) |
| hapten A-OVA (hetero-)[b] | <1 | –[c] |
| hapten B-OVA (hetero-) | <1 | – |

| hapten D-OVA (homo-) | 512 | 72.4 |
| hapten E-OVA (hetero-) | <1 | – |
| hapten F-OVA (hetero-) | <1 | – |

[a]Analyte, 0.5 mg/L NPHA. [b]The coating antigen format is indicated as being heterologous or homologous. [c]Not calculated.

**Optimization of the ciELISA.** The effect from the degree of heterology in the chemical structure of the coating antigen on ELISA performance was investigated. As shown in Table 2, the obtained antibody exhibited a much lower affinity for the heterologous coating antigen (hapten C-OVA, titer 1:16000) than for the homologous coating (hapten D-OVA, titer 1:512000), and no affinity for coating antigens with a high degree of heterology (haptens A, B, E, and F, titer >1:1000). However, there was about 20 times improvement in assay sensitivity when using hapten C-OVA ($IC_{50}$ = 9.1 ng/mL) as the coating antigen compared to using hapten D-OVA ($IC_{50}$ = 174.6 ng/mL) based on the $IC_{50}$ obtained from the inhibition curves (Figure 3). Hapten C possesses the *N*-acetylated HA moiety, which has a partial structure of the target analyte NPHA. The result of this work is consistent with conclusions obtained in our previous studies:[37,38] that using a partial structure of the target molecule as the coating hapten may be a good strategy to improve assay sensitivity. Therefore, coating antigen hapten C-OVA was chosen for further experimentation.

Effects of the physicochemical parameters on ELISA performance are summarized in Table S1 (see Supporting Information). To determine the coating concentration and antibody dilution, a preliminary checkerboard titration was employed to screen several combinations of coating concentration and antibody dilution, while keeping the Amax value at about 1.0. The highest sensitivity was achieved when the coating concentration and antibody dilution were at 125 ng/mL and 1:2000, respectively. For the working buffer, PBS with different $PO_4^{3-}$ concentrations (10−100 mmol/L), Tween-20 concentrations (0−0.2%), and pH values (6.6−8.5) was

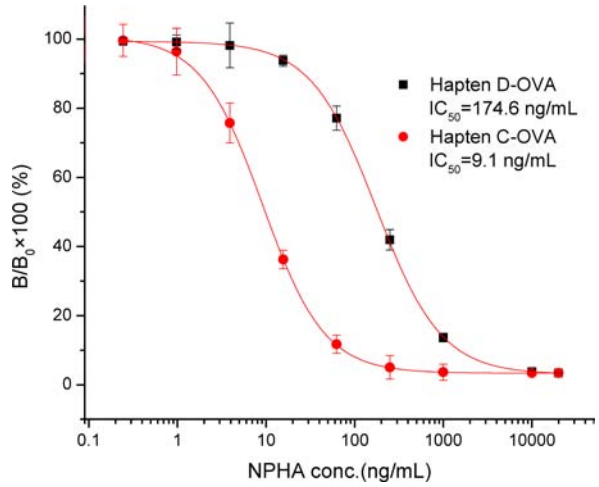

**Figure 3.** Dose-dependent competitive indirect ELISA curves for NPHA with heterologous coating (hapten C-OVA) and homologous coating (hapten D-OVA) ($n$ = 3).

evaluated. The results indicated that a $PO_4^{3-}$ concentration of 20 mmol/L, a Tween-20 concentration of 0.05%, and a pH value of 7.4 were the most suitable for improving assay sensitivity.

**Optimization of Derivatization Conditions.** The chemical structure of PNBA-OSu and its reaction with HA are depicted in Figure 2. In order to achieve the maximum derivatization yield, factors influencing the efficiency of derivatization were optimized, including pH of the buffer, reaction time, and concentration of derivatization reagent. Since this is a nucleophilic substitution reaction, alkaline conditions are important. LC−MS/MS was used to monitor the process of the reaction with borate buffer over the pH range of 7.4−9.6. Figure 4 shows that the reaction proceeds more quickly with a

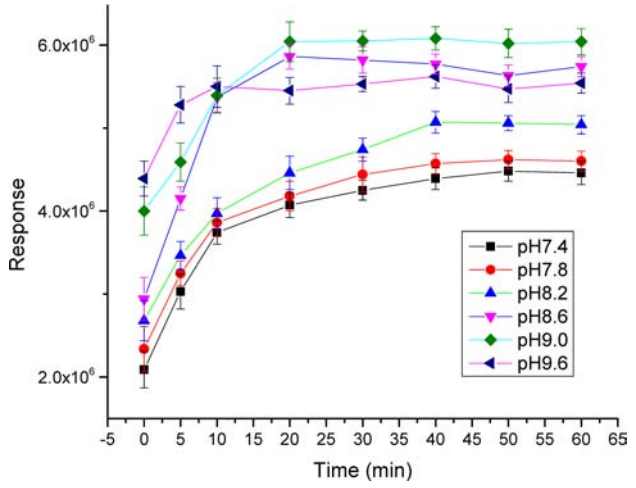

**Figure 4.** Effect of pH on the reaction process of histamine conversion to NPHA ($n$ = 3).

borate buffer of higher pH values, and a maximum yield was observed at 20 min when the pH of the buffer solution was at 9.0. Thus, the HA derivatization conditions with the borate buffer at pH 9.0 and 20 min reaction time were selected. The concentration effect of the derivatization reagent on assay performance was investigated by comparing the inhibition curves obtained by using different concentrations (1−16 mg/mL) of PNBA-OSu. High concentrations of PNBA-OSu (exceeding 2 mg/mL) were detrimental to assay sensitivity (Figure 5). But to guarantee that the HA in high level HA

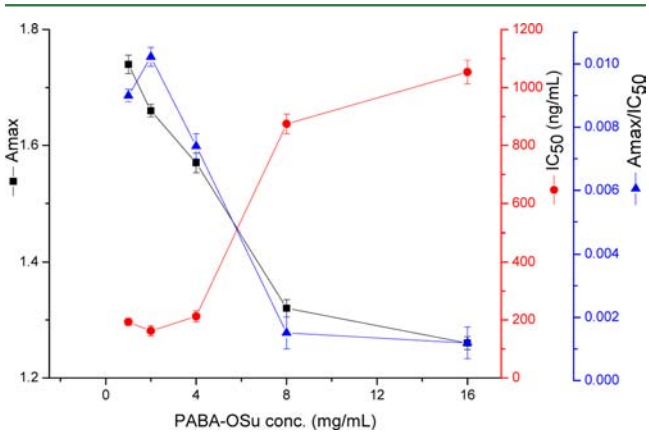

**Figure 5.** Concentration effect of PNBA-OSu on ciELISA performance.

samples was completely derivatized, 2 mg/L of PNBA-OSu was selected. Since the reaction can efficiently proceed at room temperature (25 °C), room temperature was chosen for the reaction temperature without further optimization.

**Sensitivity and Specificity of the ciELISA.** The calibration curve for histamine constructed under the optimal conditions is shown in Figure 6. The assay demonstrated an $IC_{50}$ of 153.2 ng/mL and a limit of detection (LOD) of 9.4 ng/mL (the HA concentration which inhibits 10% of the binding of the antibody, $IC_{10}$) for histamine, whereas the quantification linear range was 12.7−1853.1 ng/mL ($y$ = 126.37 − 34.09$x$). The assay specificity, cross-reactivity (CR) of related compounds including some biogenic amines and amino acids commonly found in foods, was examined, and the results are summarized in Table 3. Since L-histidine has a high degree of similarity to HA and may be contained in foods at high concentration levels, a small CR may interfere with the analysis of HA and would be unacceptable. However, no CR was observed to all the related compounds tested, including L-histidine. This result demonstrated the excellent specificity of the developed ciELISA to HA, which probably results from the high specificity of the antibody to NPHA.

**Detection of Histamine in Spiked Foods.** Sample preparation is the process of sample cleanup and matrix effect elimination and plays a significant part in development of the analytical procedure. To study the matrix effect, a matrix-matched inhibition curve for HA was constructed by diluting the stock solution of HA with blank sample extracts. Since HA is a compound commonly occurring in meat and fermented foods and is spontaneously formed, it is impossible to find blank samples containing no HA for fish, red wine, and yoghurt. Therefore, fresh fish and yoghurt containing HA at a level below the LOD of LC−MS/MS was considered a blank sample. The matrix effect was assessed by comparing the matrix-matched inhibition curves with standard inhibitory curves. It was found that the yoghurt matrix-matched inhibition curve was similar to the solvent inhibition curve, indicating the effectiveness of the yoghurt sample preparation method; while a 20-fold dilution of fish extracts was required to minimize the matrix effect. Therefore, blank fish samples were fortified with relatively higher levels of HA (5.0, 10.0, and 50.0 mg/L) than

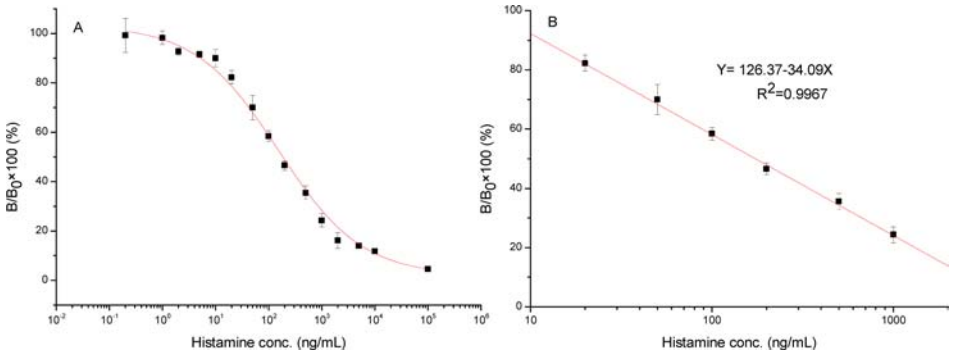

**Figure 6.** (A) Calibration curve and (B) ciELISA calibration curve in the linear range for histamine.

**Table 3. Cross-Reactivity of Related Compounds in ciELISA (under Optimized Conditions)**

| Compound | Structure | CR[a](%) |
|---|---|---|
| Histamine |  | 100 |
| L-Histidine |  | <0.01% |
| L-Tryptophan |  | <0.01% |
| Trytamine |  | <0.01% |
| Tryamine |  | <0.01% |
| Phenethylamine |  | <0.01% |
| Cadaverine |  | <0.01% |

[a]CR, cross-reactivity. The percentage of CR was calculated by the following equation: CR (%) = [$IC_{50}$ (histamine, mmol/L)/$IC_{50}$ (cross-reactant, mmol/L)] × 100.

the blank yoghurt samples (0.5, 2.0, and 5.0 mg/L). For red wine, a blank sample was not found. The HA level in red wine samples was initially analyzed by LC−MS/MS, and then the sample was spiked in the linear range of the ciELISA at three levels (0.5, 2.0, 5.0 mg/L). Average recoveries were observed from 80.9% to 110.1% with the coefficient of variance (CV) ranging from 8.4% to 16.3% after all the spiked samples were analyzed by ciELISA (Table 4), which indicated that the matrix effect of these three types of samples was negligible using the sample preparation method. The LOD of the developed ciELISA in fish, red wine, and yoghurt was estimated as the LOD of the calibration curve multiplied by the dilution factor required during sample preparation, which was 1.8 mg/kg, 93.6 μg/L, and 93.6 μg/kg, respectively. Taking the maximum residue limits (MRLs) set for HA in fish (50−300 mg/L) and recommended upper limits for HA in wine (2−10 mg/L)[39] into consideration, the ciELISA was sensitive enough for HA analysis in these food samples.

To confirm the reliability of the developed ciELISA, spiked food samples were subjected to HA analysis by LC−MS/MS which had a LOD of 2.9 ng/mL (LOD is defined as the lowest concentration level that produces a signal-to-noise ratio of 3, S/N = 3) and good linearity over the HA range of 10−1000 ng/mL, with a correlation coefficient of 0.996 (see Figure S2 in Supporting Information). Average recoveries obtained by LC−MS/MS ranged from 92.0% to 105.4% with CVs between 5.2% and 10.7% (Table 4). The results of the ciELISA were in good agreement with those of LC−MS/MS with a correlation coefficient ($R^2$) of 0.978 (Figure 7), revealing good reliability and accuracy for this ciELISA.

**Analysis of Blind Samples.** The developed ciELISA was then applied to detect HA in blind samples to assess its effectiveness. Four fish samples having different degrees of

[a]ND, not detected. Data were below the LOD of the assay in the corresponding samples.

freshness, four red wine samples, and four yoghurt samples were randomly collected from a local supermarket and analyzed by the ciELISA and LC−MS/MS. As shown in Table 5, a good correlation was observed between the results of the ciELISA and those of the LC−MS/MS, demonstrating the effectiveness and applicability of the developed ciELISA for HA analysis in these foods.

In summary, a ciELISA for the determination of HA in foods was developed based on a highly specific antibody against the NPHA derivative. All attempts to generate a specific antibody for free HA with enough affinity for the required HA analysis failed. Thus, a preanalysis chemical derivatization of HA was used in a similar manner as in the previously reported immunoanalysis of HA. However, the novel HA chemical derivatization involved in this assay was ideally suited for the requirements of a rapid immunoassay for HA, for rapidity, simplicity, and low cost. Rapidity: Conversion of HA to the NPHA derivative was efficient (completed in 20 min) under mild conditions (room temperature in borate buffer). Simplicity: Owing to the high hydrophobicity of NPHA, it can easily be extracted by organic solvent (ACN) from aqueous solutions containing high ionic strength and separated from most interfering substances, and then directly analyzed by dilution with working buffer ($PBST_2$). Low cost: Compared with the derivatization reagent SGA-NHS, which was used for derivatization of HA in a previous report,[29] PNBA-OSu is easily accessible by a one-step synthesis between $p$-nitrobenzoic acid and $N$-hydroxysuccinimide, which are cheap and easily available. The developed ciELISA exhibited the required sensitivity for detection of HA with LOD values of 1.8 mg/kg, 93.6 μg/L, and 93.6 μg/kg for fish, red wine, and yoghurt samples, respectively. Excellent recoveries (ranging from 80.9% to 110.1%) from HA-spiked food samples and a satisfactory correlation ($R^2$ = 0.978) between the results of ciELISA analysis and those of LC−MS/MS analysis were observed. Overall, the ciELISA described in this study was ideally suited as a screening tool for routine HA monitoring in large numbers of food samples.

quantification and limits of detection of Robusta that may be too high. Also, a DNA-based food authenticity assay was recently proposed[16] that is able to detect 5% Robusta in Arabica coffee.

The content of 16-OMC remains a valuable option for detection of Robusta additions to Arabica blends, but a fast, reliable, and sensitive method is needed. The aim of the present work is to report an analytical method based on nuclear magnetic resonance (NMR) spectroscopy that could be used as an alternative to the DIN standard and that could guarantee the authenticity of 100% Arabica blends by detecting possible commercial frauds in a rapid and dependable way. NMR spectra can be acquired in a very short time; the technique is inherently reproducible and provides quantitative and structural information. These features combined with the minimal sample preparation required and the absence of any derivatization step make NMR a promising choice for our purposes.

## MATERIALS AND METHODS

**Chemicals and Materials.** Deuterated chloroform ($CDCl_3$, 99.96% D, stabilized with silver, Sigma-Aldrich), deuterated water (≥99.96% D, Eurisotop), *N*,*N*-dimethylformamide [DMF, ≥99.99% (GC), Fluka-Sigma-Aldrich], 16-OMC (phyproof References Substances, PhytoLab), 5 mm precision glass NMR tubes (535-pp, Wilmad), and coaxial insert (wgs-5bl, Wilmad) were used.

**Coffee Samples.** *C. canephora* from Ivory Coast, India, and Uganda, hereafter named R1, R2, and R3, respectively, were roasted to a medium roasting degree in a lab roaster (Probat). The *C. arabica* sample came from Brazil. Several commercial roasted coffee samples (in whole beans) were purchased in local markets. These samples were named CB0, ..., CB*n*.

**Sample Treatment.** Coffee powder was obtained by grinding the roasted coffee beans in liquid nitrogen. Extraction of ca. 0.45 g of powder (accurately weighed) was carried out by vortexing for 15 min with 1.5 mL of $CDCl_3$. Samples were then quickly filtered through a cotton wool filter directly into the NMR tube. All of the operations were conducted at about 4 °C to minimize solvent evaporation. A $^1$H NMR spectrum was acquired immediately after filtration.

**Preparation of the External Standard Solution.** To quantify absolute concentrations, a coaxial insert filled with a DMF solution in $D_2O$ was placed inside the NMR tube. This standard was chosen because of its long-term stability that allows for a large set of samples to be measured and quantified with respect to the same reference solution. The solution was prepared by accurately weighing DMF and the $D_2O$ solvent for a final concentration of the standard in the capillary tube of 5.99 mM to provide a S/N ratio comparable to that of the test substance.

**NMR Spectroscopy.** The assignment of $^1$H and $^{13}$C of the standard 16-OMC was achieved using one-dimensional (1D) and two-dimensional (2D) spectra. The complete assignment of the esterified form of 16-OMC was also achieved using 2D NMR experiments performed directly on the extracts and by comparison to the NMR data of the standard 16-OMC. A Bruker (Rheinstetten, Germany) Avance DMX600 spectrometer operating at 599.90 MHz for $^1$H and equipped with a 5 mm TXI xyz-triple gradient probe was used. The 1D spectra were acquired in deuterated chloroform using a common one-pulse sequence with a spectral width of 6000 Hz, with 32 768 data points; the receiver gain ranged from 64 to 128; and scans varied from 32 to 64 depending upon the 16-OMC concentration.

Two-dimensional total correlation spectroscopy (TOCSY), heteronuclear multiple-quantum coherence (HMQC), heteronuclear multiple-bond coherence (HMBC), and nuclear Overhauser effect spectroscopy (NOESY) spectra were recorded at 298 K using standard Bruker pulse programs. Chemical shifts are reported in $\delta$ values using the residual signal of $CHCl_3$ set to 7.27 and 77.00 ppm as reference for $^1$H and $^{13}$C, respectively.

The ACD software (ACD labs 12.0) was used to process the spectra. Fourier transformation was performed after exponential line broadenings of 0.2−0.4 Hz. Integrations were manually obtained after careful manual phase and baseline correction.

**Quantification.** To determine the total concentration of the 16-OMC esters, a scale factor of 0.108 was used, corresponding to the ratio between the volume of the coaxial insert ($V_c$) and the volume occupied by the sample in the outer part of the NMR tube ($V_t$), calculated as reported by Rastrelli et al.[17] The absolute concentration of 16-OMC esters ($C_a$) was determined by comparing the integral value of the area of the methyl protons at position 21 ($I_a$) and that of the methyl protons of DMF at 3.02 ppm ($I_s$), using the relationship

$$C_a\ (\mathrm{mol/L}) = (I_a/I_s)(V_c/V_t)C_s$$

where $C_s$ is the concentration of the external standard. These methyl protons fall in a free region in all of the analyzed samples.

The following formula gives the concentration of the free 16-OMC in mg/kg:

$$C_{16\text{-OMC}}\ (\mathrm{mg/kg}) = C_a \mathrm{MW}_{16\text{-OMC}} V_{extr}\ (\mathrm{mL})/m_{coffee}\ (\mathrm{kg})$$

where $\mathrm{MW}_{16\text{-OMC}}$ is the molecular weight of 16-OMC, $V_{extr}$ is the $CDCl_3$ volume used in the extraction, and $m_{coffee}$ is the weight of the coffee powder.

The longitudinal relaxation time $T_1$ of all signals of interest was determined in the matrices, in the standard solutions, and in chloroform using the inversion−recovery sequence. To produce quantitative data, the relaxation delay was at least 5 times the longest measured $T_1$, corresponding to one of the methyl signals of DMF in $D_2O$, which determined a relaxation delay of 43 s.

**Method Validation.** To verify the linearity of the proposed method with respect to the concentration of 16-OMC, 12 coffee blends with increasing content of Robusta were prepared. For each mixture, the $CDCl_3$ extraction was performed in triplicate and a $^1$H NMR spectrum of each sample was acquired using identical experimental conditions. The integrals of the non-overlapping signals of esterified 16-OMC (i.e., protons 17 and 21) were plotted versus the nominal concentration of 16-OMC.

To calculate the limit of detection (LoD) and limit of quantification (LoQ), a signal-to-noise ratio of 3 and 10 was used, respectively. These limits were determined by plotting the S/N value versus the 16-OMC amount using a concentration range of 0−450 mg/kg. The coffee powder/solvent ratio chosen was 0.3 g/mL (see the Method Development section), and the spectra were acquired with 64 scans for a total acquisition time of about 48 min.

**Extraction Efficiency.** To assess the extraction efficiency of the proposed method, three different samples were extracted twice. Specifically, after the first extraction, the residual solvent remaining on the ground beans was evaporated and the solid residue was subjected to a second extraction procedure. The amount of esterified 16-OMC recovered in the second extraction was calculated taking into account the amount of esterified 16-OMC present in the solvent that was not recovered during the first filtration. The following equations were used:

$$n^1_{16\text{-OMC}} = V_1^{add} C^1_{16\text{-OMC}}$$

$$n^2_{16\text{-OMC}} = V_2^{add} C^2_{16\text{-OMC}} - (V_1^{add} - V_1^{rec}) C^1_{16\text{-OMC}}$$

where $n^1_{16\text{-OMC}}$ and $n^2_{16\text{-OMC}}$ are the moles of 16-OMC recovered in the first and second extraction, respectively, $V_1^{add}$ and $V_2^{add}$ are the volumes of $CDCl_3$ used in the first and second extraction, respectively, $C^1_{16\text{-OMC}}$ and $C^2_{16\text{-OMC}}$ are the concentrations of 16-OMC determined in the first and second extraction, respectively, and $V_1^{rec}$ is the volume recovered in the first extraction. The value of $n^2_{16\text{-OMC}}$ is taken as a measure of the efficiency of the first extraction.

## RESULTS AND DISCUSSION

**Analysis of Spectra.** The $CDCl_3$ extraction of coffee powder provides a mixture of the main components of coffee

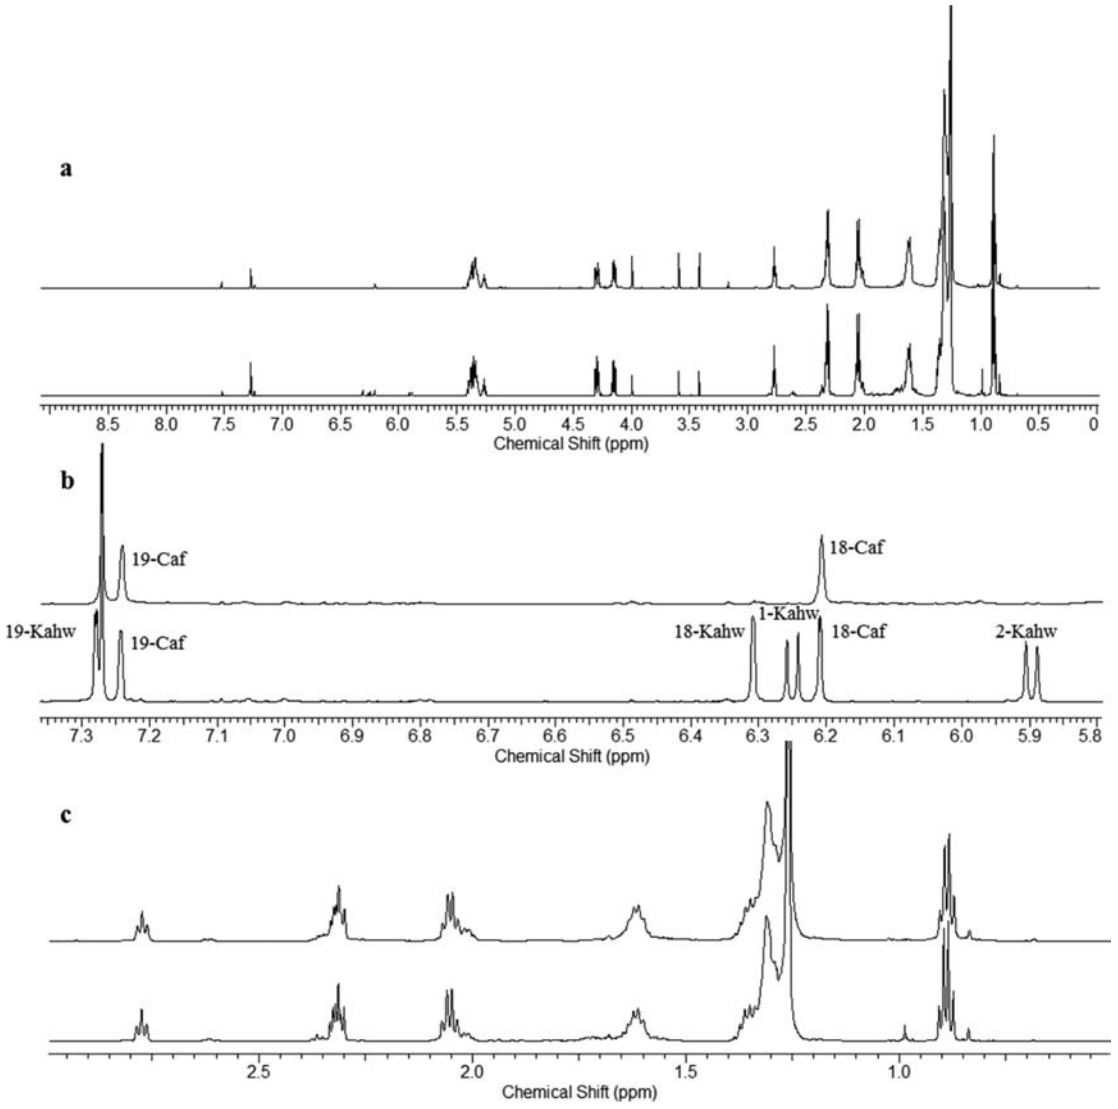

**Figure 1.** (a) $^{1}$H NMR of samples extracted from 100% Arabica (bottom) and 100% Robusta (top) roasted coffee powder. (b) Expanded region containing the olefinic proton resonances of cafestol and kaweol. The olefinic protons of 16-OMC and those of cafestol are overlapped. (c) NMR profile of the fatty acid proton region.

oil, i.e., fatty acids, caffeine, diterpenes (principally present as esters of fatty acids[18]), and other less concentrated species (see Figure 1). Identification of the $^{1}$H and $^{13}$C signals of the marker (i.e., esterified 16-OMC) was carried out using the assignment of free 16-OMC, which was compared to that reported in the literature[19] as an aid, and it is reported in Table 1. The chemical structures of esterified 16-OMC, cafestol, and kahweol are shown in Figure 2.

In Figure 3a, the diagnostic region (protons 17 and 21) of 16-OMC in a Robusta extract is shown. Protons 21 in esterified 16-OMC resonate as a singlet at 3.17 ppm, slightly shifted with respect to the free form (3.18 ppm; see Figure 3c). Protons 17 form a second-order system at 3.78 ppm in the free form, while, in the ester, two doublets are obtained at 4.28 and 4.45 ppm, respectively, with a scalar coupling constant $J_{AM}$ = 12.8 Hz. Only the doublet at 4.45 ppm is well-resolved in the spectrum, while the other doublet is partially overlapping the signals of the glycerol moiety of triglycerides. The same region in a $^{1}$H spectrum of Arabica is shown in Figure 3b. As expected, the signals of protons 17 and 21 from the 16-OMC unit are absent.

The free form of 16-OMC is generally present in trace amounts, visible in some samples, as shown in the inset of Figure 3.

As a first consideration, a visual inspection of the spectrum allows for an immediate distinction of a 100% Arabica coffee from a mixture with Robusta. Specifically, the protons 21 of esterified 16-OMC immediately reveal the presence of Robusta, while the signals attributed to kahweol (18, 19, 1, and 2 of Figure 1b) that almost disappear in the Robusta sample reveal the presence of Arabica.

**Method Development.** We optimized a very fast and simple procedure that requires only a few steps using a deuterated solvent directly. The selection of $CDCl_3$ as the solvent for extraction was based on the observation that the diterpenes are very soluble in this solvent and that it is not expensive. Also, the residual signal of the protonated form does not overlap with important peaks to integrate. The coffee powder/solvent ratio was optimized to obtain an easily filterable solution and a well-resolved spectrum. The best solid/liquid ratio was found to be $\leq$0.3 g/mL.

**Table 1. $^{1}H$ and $^{13}C$ Resonances of Esterified 16-OMC in the Chloroform Extract of Robusta Roasted Coffee Beans[a]**

| | esterified 16-OMC (esterified cafestol) | |
|---|---|---|
| | $\delta^{1}H^{b}$ | $\delta\ ^{13}C^{b}$ |
| 1 | 1.25, 2.07 | 33.8 |
| 2 | 2.63 | 21.4 |
| 3 | | 149 |
| 4 | | 120.1 |
| 5 | 2.29 | 43.1 |
| 6 | 1.81, 1.85 | 22.7 |
| 7 | 1.57−1.67 | 41 |
| 8 | - | |
| 9 | 1.19 | 53.1 |
| 10 | - | 38.5 |
| 11 | 1.57−1.67 | 19.8 |
| 12 | 1.57−1.67 | 22.9 |
| 13 | 2.26 (2.10) | 45.6 (46.8) |
| 14 | 1.48, 2.00 | 38.34 |
| 15 | 1.57, 1.67 (1.54, 1.58) | 55.3 (53.0) |
| 16 | - | 84.58 (79.9) |
| 17 | 4.24, 4.44 (4.27−4.29) | 62.72 (68.37) |

| 19 | 7.24 | 140.52 |
| 20 | 0.83 | 14.16 |
| 21 | 3.17 (-) | 49.84 (-) |
| CO fatty acid | | 173.72 |

[a]Only the cafestol assignments that differ from those of 16-OMC are reported in parentheses. [b]$\delta$ is in parts per million. NMR solvent was $CDCl_3$.

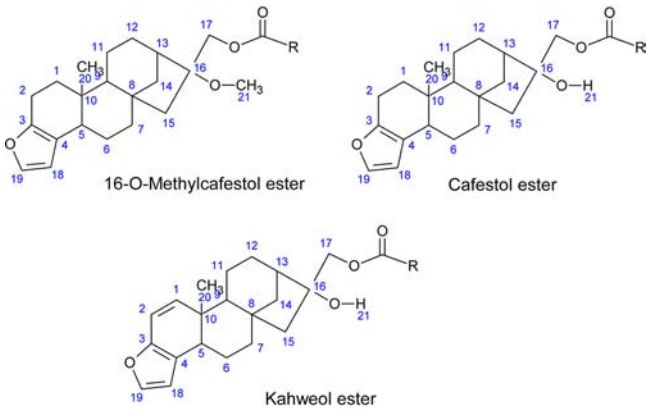

**Figure 2.** Chemical structure and atom numbering of esterified diterpenes: 16-OMC, cafestol, and kahweol.

**Quantification of 16-OMC.** 16-OMC was quantified by integrating the resolved peaks at 3.17 ppm (protons 21) and the signal of one of the protons in position 17 (4.45 ppm) of the analyte compared to the integral of the methyl signal of DMF at 3.02 ppm, which did not present any overlap in any of the samples studied. The proximity of the methyl 21 peaks of the free and esterified forms allowed us to integrate them together; therefore, the value of 16-OMC that is obtained is always referring to the total amount.

**Linearity, Precision, and Sensitivity of the Analytical Procedure.** Good linearity was achieved for both signals, as indicated by the equation shown in Figure 4 for concentrations ranging from 5 to at least 1500 mg/kg, with a satisfactory determination coefficient $R^2$. Because a higher $R^2$ value was obtained for the methyl singlet at 3.17 ppm, this signal was used for quantification of 16-OMC. The values of the relative standard deviation (RSD) ranged from 2 to 5% and confirm the suitability of the proposed method.

By plotting the S/N versus nominal concentration ($R^2$ = 0.9906, data not shown), the sensitivity of the method was assessed in terms of LoD and LoQ, which were 5 and 20 mg/kg, respectively. These LoD and LoQ values are satisfactory; by considering the reported range of the 16-OMC content found in Robusta green beans (0.8−2.5 g/kg of dry weight, with both the median and mean values equal to approximately 1.7 g/kg of dry weight[3]), this method allows for the detection of the presence of Robusta at percentages lower than 0.9% and down to 0.2%. This level is lower than that reported by the DIN method (about 2%).

**Extraction Efficiency.** For all three of the samples investigated, the corrected amount of marker ($n^{2}_{16\text{-OMC}}$) recovered from the second extraction was lower than 2% with respect to the first extraction. This indicates that the first extraction is practically quantitative. Interestingly, by grinding at room temperature with a coffee mill, according to the DIN recommendations, a lower extraction efficiency was obtained for all examined samples (73−82%, data not shown). Therefore, grinding at a low temperature seems to be crucial.

**Comparison to the DIN Method.** The method presented here is able to detect and to quantify 16-OMC in roasted coffee samples without complex sample manipulation and in a few minutes. Exploiting the power of NMR to determine the presence and amount of a substance in a complex mixture, this method avoids long Soxhlet extractions, a saponification step, and chromatographic procedures to isolate and separate the analyte of interest. In addition to easy detection, the method that we propose permits the quantification of 16-OMC and, in principle, determines the content of Robusta ingredients in roasted coffee blends.

To evaluate the accuracy of the proposed method, the entire procedure was repeated twice on the same sample and the quantities of 16-OMC found were compared to that determined by the DIN method. In Table 2, a comparison between the 16-OMC content determined by the two methods is reported. The agreement between the two different determinations is satisfactory, although the values obtained by the DIN method are often lower than those determined by NMR. An underestimation of the 16-OMC content by the DIN method is possibly related to the complex manipulation necessary to perform the analysis, while the much simpler sample preparation of our procedure avoids the danger of loss of analyte. Therefore, the small amounts of sample required, the rapidity, precision, and accuracy, and the low detection limit of the analysis make the NMR method promising for screening purposes.

The wide range of the 16-OMC concentration in different Robusta samples poses a serious obstacle for the quantification of Robusta percentage in roasted coffee blends. This problem is common to every method that exploits 16-OMC and makes the determination of this molecular marker more appropriate for authentication of 100% Arabica blends. This point, however, could be the subject of further investigation. In this regard, a large database might help in better defining the real range of the 16-OMC concentration in different Robusta samples and in a possible correlation with geographical origin and agronomical practices.

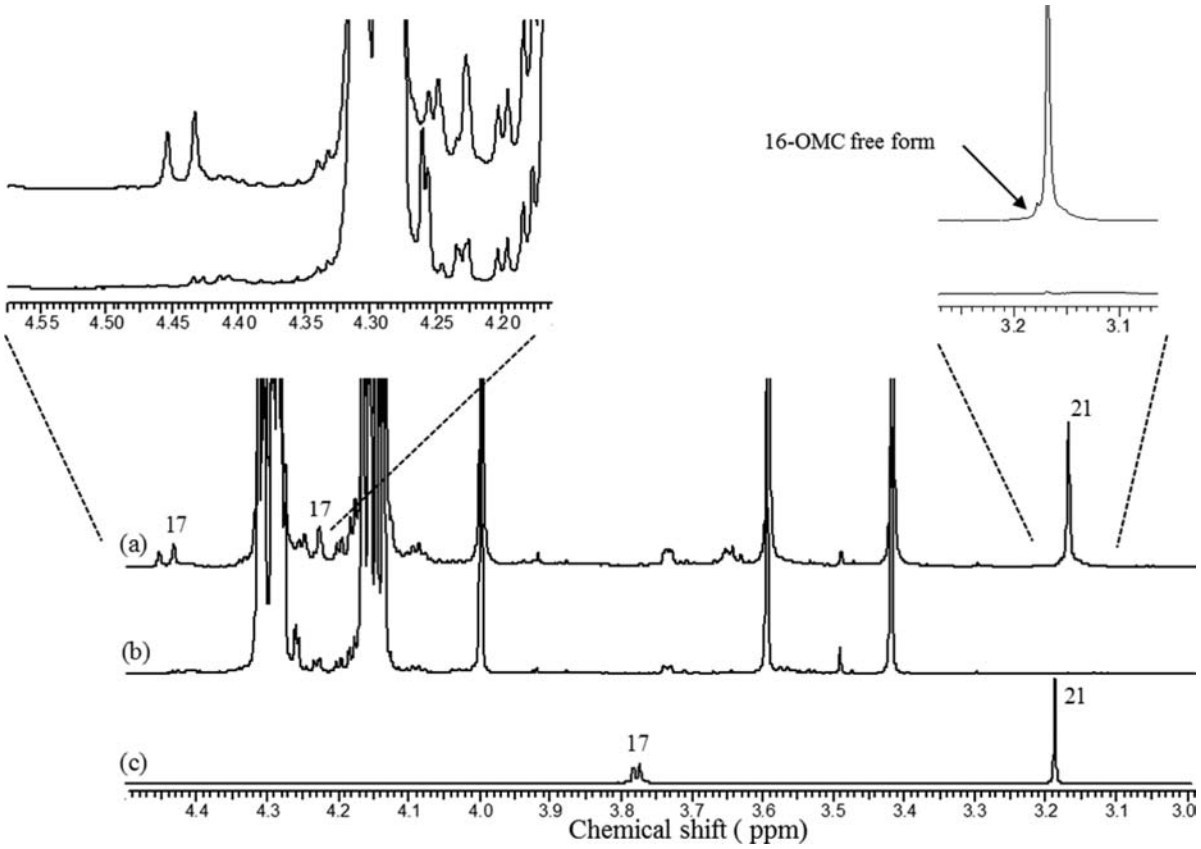

**Figure 3.** Expanded region of the $^{1}$H NMR spectrum showing the diagnostic resonances of protons 17 and 21: (a) 100% Robusta sample, (b) 100% Arabica sample, and (c) 16-OMC standard. In the insets on the top of the figure, the signals of 17 and 21 protons of 16-OMC ester are enlarged. They are clearly visible in the Robusta sample (top), but they are absent from the Arabica sample. The arrow shows the weak methyl signals in position 21 of 16-OMC in its free form.

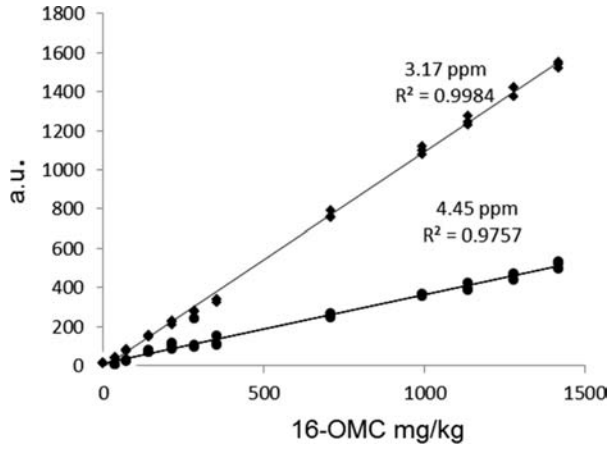

**Figure 4.** Plot of the integrals of non-overlapping signals of esterified 16-OMC (i.e., protons 17 and 21) versus nominal 16-OMC content of 12 coffee blends with increasing content of Robusta. For each mixture, the $CDCl_3$ extraction was performed in triplicate.

**Table 2. 16-OMC Content in Commercial Roasted Coffee Samples**

| | | 16-OMC (mg/kg) | |
|---|---|---|---|
| | blend | NMR[a] | DIN[a] |
| R1[b] | 100% R | 1841 (36) | 1980 (100) |
| R2[b] | 100% R | 1770 (43) | 1630 (240) |
| R3[b] | 100% R | 1490 (40) | 1008 (200) |
| CB0 | 100% R | 1442 (44) | 1428 (18) |
| CB1 | 100% R | 1739 (14) | 1450 (18) |
| CB2 | A/R | 1160 (24) | 1193 (51) |

| CB8 | nd | 1348 (61) | 1305 (80) |
| CB9 | nd | 32 (2) | <50 |
| CB10 | nd | 591(11) | 388 (45) |

[a]Values are averages of duplicate analysis ± standard error. [b]Samples are from a single geographical origin. [c]nd = not declared.

An aspect that we have not pursued in this work but that is naturally present in the NMR analysis is the possibility to detect and to quantify also kahweol in Robusta samples. This feature may provide the opportunity to trace, on a very large number of samples, the content of kahweol in Robusta. Beside those typical of 16-OMC and kahweol, other resonances may be useful to discriminate Arabica from Robusta samples and could be used to detect the percentage of the latter in 100% Arabica commercial blends in a more precise way. Indeed, caffeine, chlorogenic acids, and other markers were used in multivariate approaches for the botanical and geographical characterization of green or exotic coffee.[20−22] Our extraction method could be applied to a large database in an untargeted metabolomics investigation.

The validation of the quantitative NMR method in conformity with the Eurachem guidelines[23] and the NMR characterization of other coffee diterpenes will constitute the grounds for further studies.

proteasomal degradation of the modified protein, whereas the K63 polyubiquitin chain or linear polyubiquitination can promote the protein−protein interactions and signal transduction.[7] On the other hand, the ubiquitination process can be reversed by DUB enzyme, which, through cleaving the ubiquitin chains from their substrates, leads to the termination of NF-κB signaling.[8]

Among the known DUBs, TNF-α-induced protein 3 (TNFAIP3), also known as A20, has been recognized as a potent modulator of NF-κB signaling. TNFAIP3 has typical deubiquitinating activity with its ovarian tumor (OTU) domain at its amino terminus. Also, a carboxy-terminal zinc finger (ZnF) domain endows it with E3 ubiquitin ligase activity.[9] In most cell types, TNFAIP3 serves as a negative feedback regulator of the NF-κB-driven response, either by directly removing ubiquitin moieties from the signaling molecule of TRAF6 or through binding to TRAF6 to prevent its interactions with Ubc13, an E2-conjugating enzyme.[10,11] Consequently, TNFAIP3-null cells appear to be highly activated and secrete excessive pro-inflammatory cytokines. TNFAIP3-deficient mice die prematurely from multiorgan inflammation. Moreover, the clinical relevance of TNFAIP3 is underscored by the fact that a loss-of-function mutation within the TNFAIP3 gene is closely associated with certain inflammatory and autoimmune diseases, such as rheumatoid arthritis (RA), systemic lupus erythematosus (SLE), inflammatory bowel disease (IBD), psoriasis, and type I diabetes.[12,13]

In the respiratory system, maintaining TNFAIP3 levels is essential for tissue homeostasis. TNFAIP3 acts as a checkpoint to prevent the production of the pro-inflammatory cytokine interleukin-8 (IL-8) and down-regulate TLR2- and TLR4-induced inflammation in healthy human bronchial airway epithelial cells.[14] Loss of TNFAIP3 resulted in the amplification of pro-inflammatory responses and exaggerated lung inflammation and injury, and its levels showed to be negatively associated with the number of inflammatory cells infiltrated and the levels of pro-inflammtory cytokines.[15] Recently, a study showed that TNFAIP3 levels were substantially lower in patients with cystic fibrosis (CF), a type of lung disease with intrinsically dysregulated inflammation, and that TNFAIP3 levels were proportional to forced expiratory volume in 1s (FEV1), indicative of lung function. Additionally, a nonfunctional form of TNFAIP3 has been found in inflamed airway epithelial cells, which was unable to colocalize with TRAF6 and failed to prevent or diminish NF-κB activation.[16] Consistent with these findings, the clinic data critically implicated aberrant expression or dysfunction of TNFAIP3 in the pathogenesis of inflammatory lung disorders such as asthma, CF, and chronic obstructive pulmonary disease (COPD).[17] Thus, TNFAIP3 is emerging as a potent diagnostic marker as well as therapeutic target in these diseases, and the endeavor to search for novel TNFAIP3-targed treatment is currently under way.

Daphnetin is a natural product extracted from plants of the genus *Daphne* and belongs to the coumarin family. It has been shown to possess a variety of biological properties, including anti-inflammation, antihypoxia, antimicrobial, and anticancer properties.[18,19] The traditional Chinese medicine Zushima, primarily composed of daphnetin, has been used to treat inflammatory diseases in clinic. It can alleviate collagen-induced arthritis as revealed by suppressed synovial hyperplasia, joint destruction, and chondrocyte degeneration, and accompanying this, the infiltration of inflammatory cells and production of interleurin 1β (IL-1β), tumor necrosis factor α (TNF-α), and macrophage migration inhibitory factor (MIF) were significantly repressed by daphnetin treatment.[20] In addition, daphnetin exhibited the ability to blunt the differentiation of inflammatory Th17 and Th1 cells and promote the development of regulatory T (Treg) cells, thus alleviating T cell-mediated immunopathology in the inflammatory autoimmune disorders.[21] It is noted that daphnetin has been used to treat inflammatory airway diseases such as bronchitis and demonstrated to be a promising alternative for these disorders with little side effect.[18] However, the protective efficacy of daphnetin in inflammatory pulmonary disorders has not yet been fully explored and, particularly, the ability of daphnetin to antagonize the inflammatory signaling and the molecular mechanism underlying its action remain to be determined.

In the present study, we, for the first time, reveal the significant protective effect of daphnetin against lung inflammation and injury. By impairing the key signaling events involved in NF-κB activity, daphnetin negatively regulated the TLR-triggered inflammatory response. Moreover, TNFAIP3 was identified as a target of daphnetin to modulate the K63-linked ubiquitination of TRAF6 and thereby NF-κB-driven pro-inflammatory signaling. This finding provides an insight into the action mode of daphnetin in the inflammatory context and has profound implications for its use as a protective or even therapeutic agent in ALI and related compliance.

## MATERIALS AND METHODS

**Reagents.** Daphnetin (7,8-dihydroxycoumarin), with a purity >99.4%, was obtained from Tauto Biotech Co., Ltd. (Shanghai, China). Dimethyl sulfoxide (DMSO), LPS (055:B5), 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT), Griess reagent, and 4′,6-diamidino-2-phenylindole (DAPI) were purchased from Sigma-Aldrich Co. (St. Louis, MO, USA). All antibodies, unless otherwise indicated, were obtained from Cell Signaling. Antibodies against β-actin were obtained from Sigma-Aldrich, and the pRL-TK plasmids were purchased from Promega. All cell culture reagents and media were obtained from Life Technologies.

**Cell Lines and Generation of Peritoneal Macrophages.** The A549 and RAW264.7 cell lines were obtained from the American Type Culture Collection and grown in RPMI 1640 medium containing 10% (v/v) heat-inactivated fetal bovine serum. To prepare murine peritoneal macrophages, 8−10-week-old mice were injected intraperitoneally (ip) with 3% thioglycolate broth. After 72 h, the peritoneal cells were harvested, and macrophages were enriched by quick adhesion. All cells were grown at 37 °C in a humidified atmosphere in the presence of 5% $CO_2$.

**Cell Viability Assay.** Cell viability was determined using an MTT reduction assay. In brief, RAW264.7 cells were treated with various concentrations of daphnetin or vehicle for 24 or 48 h. Then the culture supernatants were replaced with MTT (0.5 mg/mL) and the resulting dark blue crystals were dissolved with DMSO. The absorbance values were read at 550 nm and obtained by replication in at least three independent experiments.

**RNA Isolation and Quantitative RT-PCR.** Total RNA was isolated using TRIzol reagent (Takara) following the manufacturer's protocol. SYBR Green PCR Master Mix (Bio-Rad) was used to detect mRNA levels, and relative expression levels were determined by applying the ΔΔCt method using β-actin as the endogenous control. The following primers were used: TNF-α, forward 5′-AAGGCCGGGGTGTCCTGGAG-3′ and reverse 5′-AGGCCAGGTGGGGACAGCTC-3′; IL-6, forward 5′-CCACTTCACAAGTCGGAGGCTTA-3′ and reverse 5′-AGTGCATCATCGTTGTTCATAC-3′; IL-1β, forward 5′-AACCTCACCTACAGGGCGGACTTCA-3′ and reverse 5′-TGTAATGAAAGACGGCACACC-3′; and inducible nitric oxide synthase (iNOS), forward 5′-CCCTTCCGAAGTTTCTGGCAGCAGCG-3′ and reverse 5′-GGCTGTCAGAGCCTCGTGGCTTTGG-3′.

**Bronchoalveolar Lavage, Differential Cell Counts, and Histological Analysis.** Briefly, the trachea was exposed through a midline incision and cannulated with a sterile 22-gauge needle. Bronchoalveolar lavage fluid (BALF) was obtained by flushing three times with 1 mL of 0.5 mM EDTA/PBS. After centrifugation, the supernatants were stored at −80 °C until use. The total cell numbers in the BALF were counted with a hemocytometer, and differential cell counts were determined on cytospin preparations with Diff-Quick staining (IMEB). Alternatively, neutrophils and macrophages in the BALF were assessed through immunostaining and subsequent flow cytometry. For histological analyses, mouse lung samples were washed thoroughly in PBS, fixed in 4% (wt/vol) formalin, and embedded in paraffin; 5 $\mu$M sections were then stained with hematoxylin and eosin (H&E) using standard procedures.[22]

**Plasmid Transfection and Luciferase Reporter Assays.** To investigate NF-$\kappa$B reporter activity, the mouse PGL3-NF-$\kappa$B reporter plasmid was transfected into peritoneal macrophages or RAW264.7 cells using Jet-ENDO transfection reagents (Polyplus). After 24 h, the cells were treated with DMSO or daphnetin at different concentrations (20, 40, 60, 80, and 100 $\mu$M, respectively) followed by stimulation with LPS (100 ng/mL) for 6 h. The cells were then collected and lysed for dual luciferase assays (Promega).

**RNA Interference.** Small interference RNA (siRNA) targeting TNFAIP3 and scramble siRNA were synthesized by GIMA Co. (Shanghai, China). siRNA duplexes were transfected into macrophages using INTERFERin-HTS according to standard protocols (Polyplus). For the in vivo knockdown of TNFAIP3, 60 $\mu$g of siRNA per mouse was administered intratracheally.[23] The knockdown efficacy was determined through RT-PCR or Western blotting.

**Animal Experiments.** All procedures were conducted in accordance with university guidelines and approved by the ethical committee for Animal Care and the Use of Laboratory Animals, Hangzhou Normal University. The mice were anesthetized ip with ketamine hydrochloride (100 mg/kg) and xylazine (10 mg/kg). Daphnetin was injected at 5 mg/kg (ip) for a total of 100 $\mu$L into each mouse, and 1 h later, a total volume of 50 $\mu$L of PBS or LPS (1 mg/kg) was instilled intratracheally.[24] For mortality studies, C57BL/6 mice were injected with daphnetin (5 or 10 mg/kg, ip) or DMSO 1 h before LPS injection (25 mg/kg, ip). Survival was monitored twice daily for up to 6 days.

**Determination of Cytokines and MPO Levels.** The levels of TNF-$\alpha$, IL-6, and IL-1$\beta$ were measured in the culture supernatants or BALF by ELISA (R&D Systems). Lung myeloperoxidase (MPO) levels were determined using mouse MPO ELISA (Hycult Biotech) following the manufacturer's instructions.[25]

**Immunofluorescence Staining and Confocal Microscopy.** RAW264.7 cells, seeded on slides at 30% confluence, were pretreated with daphnetin (160 $\mu$M) or DMSO 30 min prior to LPS stimulation. After the indicated time, the cells were collected, fixed with 100% methanol, washed, and permeabilized in 0.2% saponin. Upon blocking with 5% bovine serum, the cells were stained with primary rabbit anti-p65 overnight at 4 °C and then stained with goat anti-rabbit IgG conjugated to Texas Red (Invitrogen). The nuclei were labeled with DAPI (Invitrogen). The cells were finally mounted in Vectashield and detected through fluorescence confocal microscopy (LSM confocal microscope, Carl Zeiss, Inc.).[26]

**Immunoprecipitation and Immunoblotting.** Briefly, cell lysates were prepared, and the protein concentrations were determined using a bicinchoninic acid (BCA) protein assay (Thermo Fisher Scientific). For the immunoprecipitation of polyubiquitinated proteins with linkage-specific Abs, the cells were lysed at room temperature in buffer containing 1% Triton-X-100, 6 M urea, and 2 mM *N*-ethylmaleimide (NEM). Cell lysates were precleared and then incubated overnight with a specific primary antibody, followed by the incubation of protein A/G plus agarose beads. After extensive washing, the bead-bound complexes and cell lysates were resolved on 10% SDS-PAGE gels and finally immunoblotted with the appropriate monoclonal antibodies.[27] Targeted proteins were visualized using an ECL Western blotting kit (Millipore).

**Statistical Analyses.** The data are presented as the mean ± SD of independent experiments. The statistical significance between two groups was analyzed using Student's *t* test. Survival data were analyzed with the Kaplan−Meier method and the log-rank test. Differences with a *p* value of ≤0.05 were considered significant.

## RESULTS

**Daphnetin Confers Protection against LPS-Induced Lung Inflammation and Injury.** Daphnetin is a natural plant-derived product with the chemical structure of 7,8-dihydroxycoumarin, which was shown to have no notable effect on cell survival as revealed in our study (Figure 1). It has long been used in the treatment of inflammatory disorders and is therefore considered to have the potential to regulate the immune response. To further understand the biological activity of daphnetin, we used a prototypical model of LPS-induced lung inflammation and injury, which has been widely used to investigate the mechanisms of ALI.[28,29] Histopathological examination revealed that, compared with the control mice, the animals pretreated with daphnetin exhibited lessened alveolar damage and inflammation, characterized by reduced interstitial edema and debris deposit, less inflammatory cell recovery, and decreased MPO activity in lung tissues (Figure 2A−C). Moreover, protein leakage into the BALF and production of pro-inflammatory cytokines including IL-6, TNF-$\alpha$, and IL-1$\beta$ were repressed by daphnetin (Figure 2D,E). On the basis of these results, daphnetin appeared to protect against endotoxin-induced lung inflammation and injury.

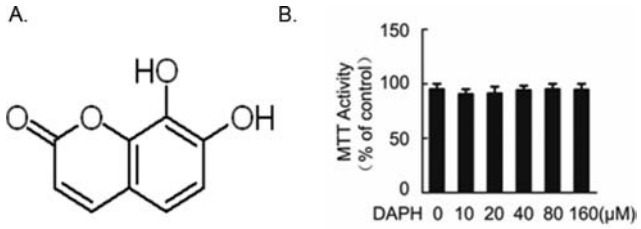

**Figure 1.** Chemical structure and effect of daphnetin on macrophage survival: (A) chemical structure of daphnetin; (B) viability of RAW264.7 cells that were treated with daphnetin (DAPH) at the dose indicated for 48 h, analyzed by the MTT assay. Data represent the mean ± SD of three independent experiments.

To further understand its protective role in the inflammatory setting, we evaluated the effect of daphnetin in sepsis-induced mortality. The mice were preinstilled with daphnetin (5 or 10 mg/kg, ip) or vehicle and then challenged with lethal doses of LPS. Animal survival was monitored for up to 6 days. As shown in Figure 2F, the mice treated with daphnetin exhibited significantly prolonged survival compared with the animals pretreated with the vehicle, and greater protection was conveyed by daphnetin at the higher dose relative to the lower dose.

**Daphnetin Negatively Regulates the Inflammatory Response.** Given the importance of macrophages in the pathogenesis of lung inflammation and injury, we then assessed the effect of daphnetin in the LPS-stimulated macrophage response. As expected, LPS stimulation in macrophages caused a remarkable production of pro-inflammatory cytokines, including IL-6, TNF-$\alpha$, and IL-1$\beta$, at the mRNA and protein levels, which nevertheless was significantly repressed by

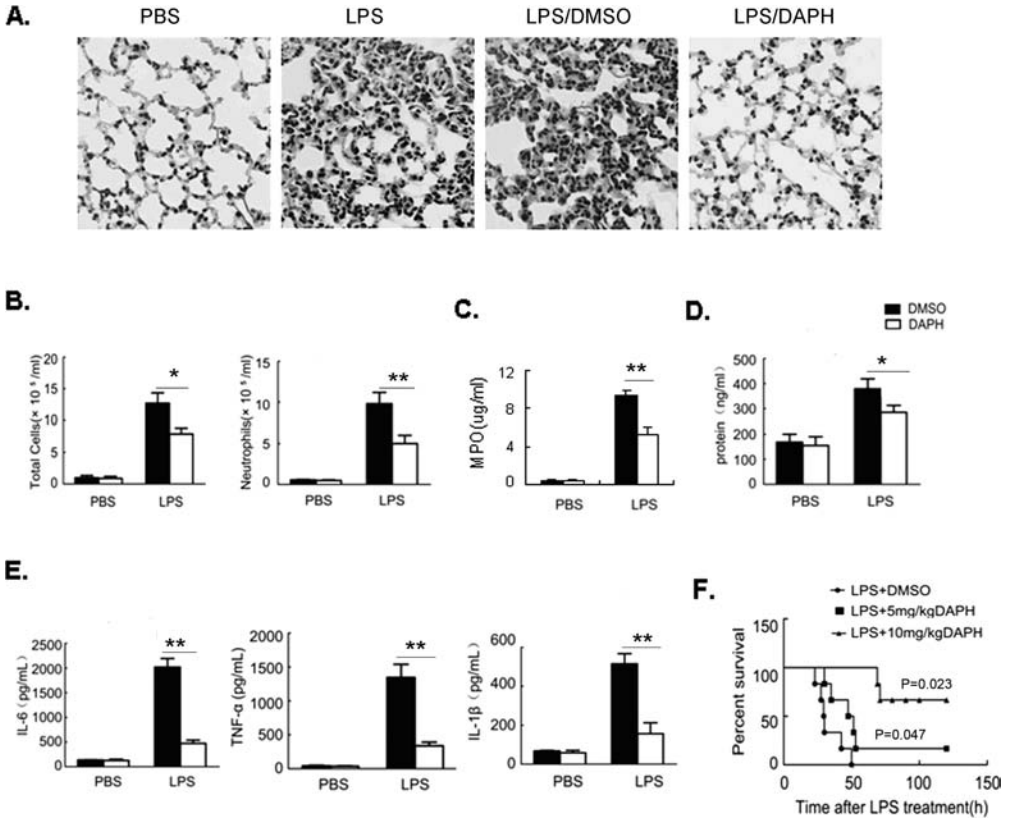

**Figure 2.** Daphnetin renders the mice resistant to LPS-induced inflammation and acute lung injury. (A–E) Age- and sex-matched C57BL/6 mice (5 mice/group) were pretreated with DAPH (5 mg/kg, ip) or DMSO as a vehicle and then intratracheally challenged with LPS (1 mg/kg) or PBS. Twelve hours later the animals were sacrificed for the analysis: (A) representative H&E staining of lung tissues; (B) BAL fluid cell recovery; (C) MPO activity of lung tissues; (D) protein and (E) cytokine levels in BAL fluid. Original magnification, ×200. All results are expressed as the mean ± SD: (∗)$p < 0.05$ and (∗∗)$p < 0.01$ by Student's $t$ test. (F) Mice were injected with DAPH (5 or 10 mg/kg, ip) or DMSO 1 h before LPS administration (25 mg/kg, ip). Kaplan–Meier survival plots are depicted, and comparisons were made with the log-rank statistic ($n$ = 10 per group).

daphnetin in a dose- and time-dependent manner (Figure 3A,B). Because nitric oxide (NO) is a well-known mediator in ALI pathogenesis, we examined the expression of inducible nitric-oxide synthase (iNOS), the enzyme required for NO production. The results showed a profound reduction in iNOS expression in daphnetin-treated macrophages (Figure 3C), suggesting a general effect of daphnetin on the production of the inflammatory mediators. Unexpectedly, expression of IL-10, an anti-inflammatory cytokine, was also found to be repressed (Figure 3D). Furthermore, we extended the study to A549 cells, human alveolar epithelial cells critically involved in lung inflammation. The results showed that LPS-induced expression of IL-6 and TNF-$\alpha$ in A549 cells was also markedly suppressed by daphnetin (Figure 2E). Together, the data defined a crucial role for daphnetin in the negative regulation of TLR-triggered innate and inflammatory responses.

**Daphnetin Modulates NF-κB and MAPK Signaling.** It is known that NF-κB and MAPK signaling are essential for the expression of pro-inflammatory genes in response to TLR stimulation. To investigate the molecular mechanism through which daphnetin controls inflammatory cytokine production, we analyzed the key signaling events involved. As shown in Figure 4A, phosphorylation of MAPKs, including p38, ERK, and JNK kinases, was down-regulated by daphnetin. In addition, daphnetin suppressed LPS-stimulated NF-κB activation, and the critical signaling events including phosphorylation of RelA/NF-κB, phosphorylation and degradation of IκBα, and activation of the upstream kinase IKK were substantially impaired by daphnetin treatment in murine macrophages (Figure 4B–D). Consistent with these results, NF-κB-driven transcriptional activity in RAW264.7 and A549 cells was also repressed by daphnetin in a dose-dependent manner (Figure 4E). Additionally, considering that derepression of Rel/NF-κB from the restraint of IκBα and the translocation of RelA into the nuclear constitutes the key step for the pro-inflammatory gene transcription, we thus detected the impact of daphnetin on LPS-initiated nuclear translocation of RelA. The result clearly showed that a robust nuclear translocation of RelA induced by LPS was remarkably affected in daphnetin-treated macrophages, particularly at the early stage of activation (Figure 5A,B). Together, daphnetin profoundly modulated the key signals required for the expression of pro-inflammatory genes, which might contribute to its anti-inflammatory property and protective effect in ALI.

**TNFAIP3 Is Targeted by Daphnetin during the Inflammatory Response.** Next, we sought to obtain further insights into the mechanism used by daphnetin to regulate NF-κB and MAPK signaling. TAK1, a member of the MAP3 kinase family, is presumed to be a key intermediate that transmits signals to the downstream IKK and MAPKs.[30] Our present study showed that TAK1 phosphorylation was remarkably attenuated in daphnetin-treated macrophages as compared with that in the control cells (Figure 6A). We then questioned whether TRAF6, which is known to associate with TAK1 and has the potential to regulate its activity, was affected by daphnetin in LPS-stimulated macrophages. TRAF6 is a RING

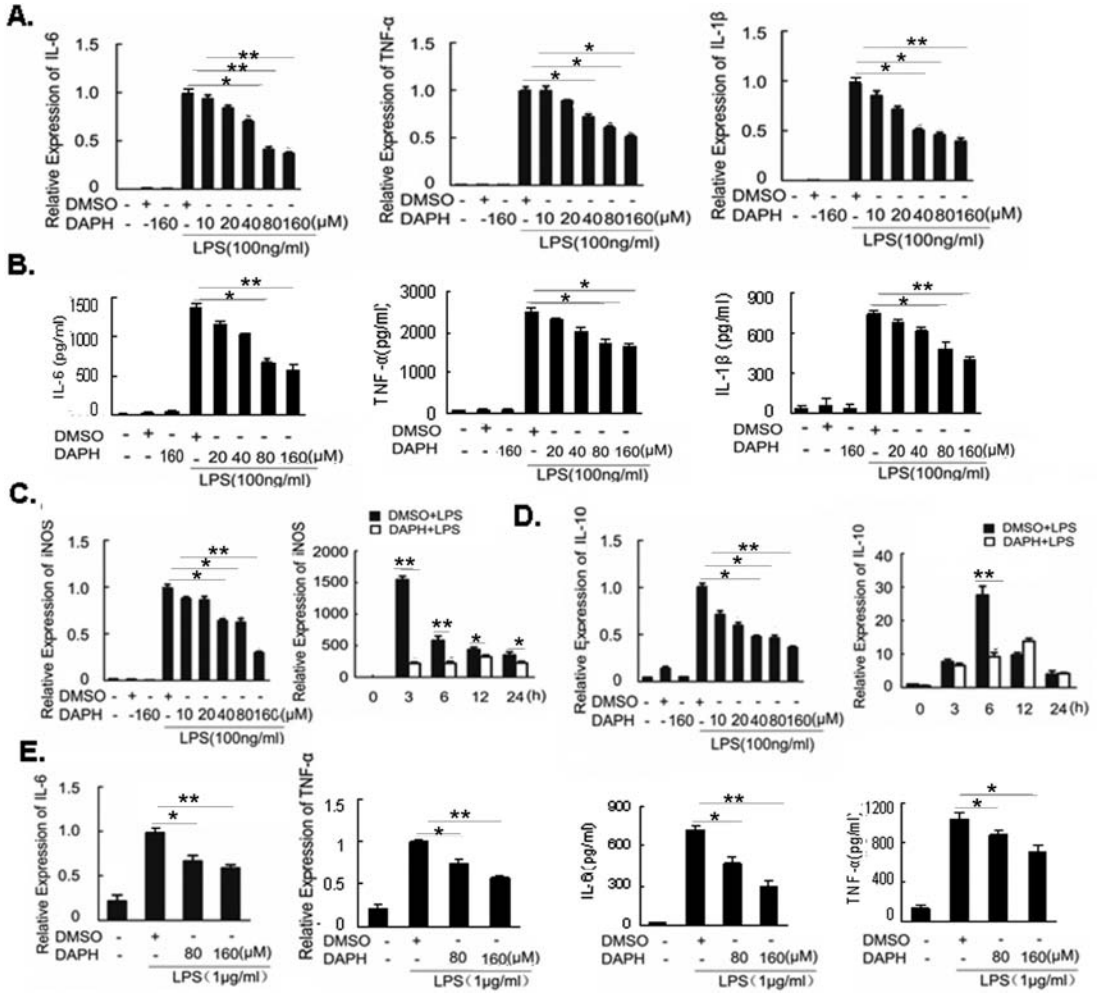

**Figure 3.** Daphnetin inhibits LPS-triggered production of pro-inflammatory cytokines. (A–D) RAW264.7 cells were pretreated with DMSO or DAPH for 30 min at the dose indicated and followed by LPS (100 ng/mL) stimulation for 6 h (for the mRNA) or 24 h (for the protein). Expression of IL-6, TNF-$\alpha$, and IL-1$\beta$, at the mRNA level (A) and protein level (B) was assessed by quantitative real-time PCR and ELISA, respectively. (C, D) iNOS and IL-10 expression was time- and dose-dependently inhibited by daphnetin. (E) Production of IL-6 and TNF-$\alpha$ in A549 cells was induced by LPS with pretreatment of DAPH (160 $\mu$M) or DMSO. Data are the mean ± SD of three independent experiments: (*) $p < 0.05$ and (**) $p < 0.01$ by Student's $t$ test.

domain ubiquitin ligase that mediates the assembly of K63-linked poly-Ub chains required for TAK1 and the subsequent IKK activation. As depicted in Figure 6B, our data showed that TRAF6 level was not altered upon daphnetin treatment. However, K63-linked ubiquitination of TRAF6 triggered by LPS was substantially suppressed in daphnetin- but not vehicle-treated cells. We next wondered what drove the daphnetin-induced modulation of TRAF6 ubiquitination. As protein ubiquitination is a dynamic process tightly regulated by ubiquitinating and deubiquitinating enzymes, our attention was focused on the impact of daphnetin on TNFAIP3, a ubiquitin-editing enzyme with the ability to cleave K63-linked polyubiquitination of TRAF6 and thereby counteract NF-$\kappa$B signaling. Indeed, in a dose- and time-dependent manner, treating macrophages with daphnetin caused a significant increase in TNFAIP3 expression, at either mRNA or protein levels (Figure 6C,D). Also, the mice pretreated with daphnetin exhibited enhanced expression of TNFAIP3 in lung tissues following LPS challenge when compared with the control animals (Figure 6E,F). The data thus implicated TNFAIP3 activity in daphnetin-mediated regulation on the inflammation and lung injury.

**TNFAIP3 Is Required for Daphnetin-Mediated Anti-inflammatory Activity.** To further relate TNFAIP3 to the action mode of daphnetin, we knocked down TNFAIP3 in macrophages using specific siRNA. As expected, TNFAIP3 deficiency in macrophages led to enhanced I$\kappa$B$\alpha$ phosphorylation and degradation (Figure 7A), indicative of augmented activation of NF-$\kappa$B activity. NF-$\kappa$B transcriptional activity in response to LPS was consistently strengthened upon TNFAIP3 loss. Strikingly, specific interference of TNFAIP3 in daphnetin-treated cells elevated NF-$\kappa$B transcriptional activity to a level comparable to that in DMSO-treated cells, indicating that daphnetin-driven down-regulation of NF-$\kappa$B activity was largely abrogated by TNFAIP3 deletion (Figure 7B). Consistent with these data, defective production of IL-6, TNF-$\alpha$, and IL-1$\beta$ upon daphnetin administration was, to varying degrees, restored by TNFAIP3 knockdown (Figure 7C,D). The data thus established the importance of TNFAIP3 in the anti-inflammatory activity of daphnetin in macrophages. Furthermore, TNFAIP3 protein in murine lungs was knocked down through the intratracheal delivery of the specific siRNA prior to daphnetin treatment, and the response of the mice to the endotoxin was evaluated.[23] As shown in Figure 8A, there

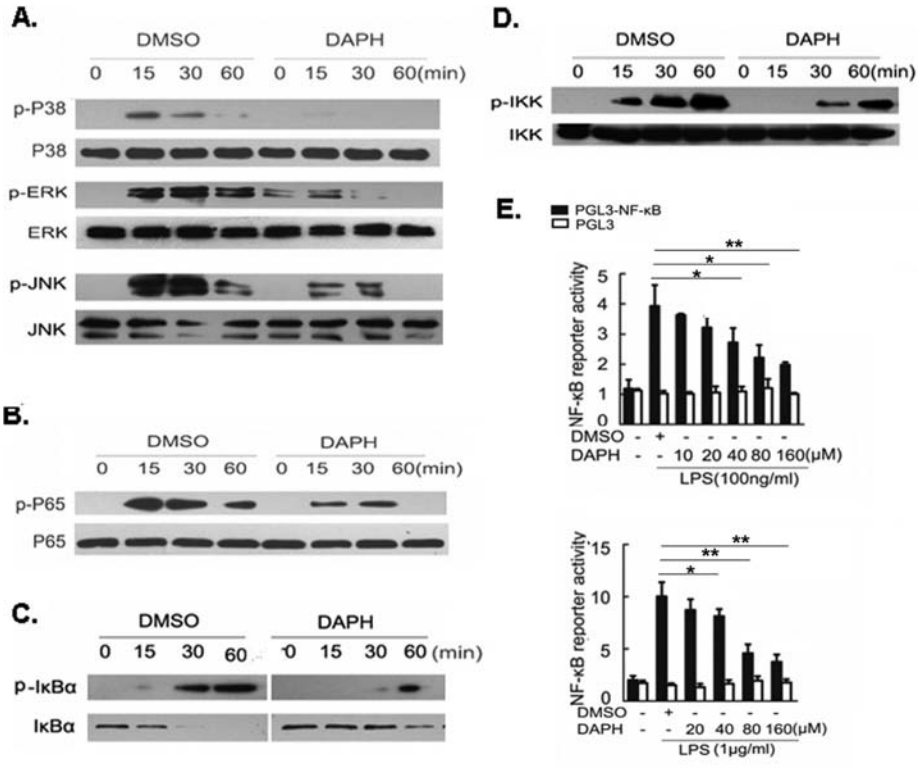

**Figure 4.** Daphnetin suppresses NF-κB-dependent signaling. Peritoneal macrophages were pretreated with either DMSO or DAPH (80 μM) 30 min prior to LPS stimulation. Levels of total and phosphorylated p38, ERK, and JNK (A), p65 (B), IκBα(C), and IKK (D) were measured by immunoblotting. Results are representative of three individual experiments. (E) NF-κB-driven promoter activity in response to LPS was analyzed in RAW264.7 cells (upper) or A549 cells (lower). Cells were transfected with pGL3-NF-kB or the control pGL3 plasmid. After 24 h of transfection, cells were pretreated with DMSO or DAPH (80 μM) and then subjected to LPS stimulation. Six hours later, cells were collected for luciferase activity analysis. Data are the mean ± SD of three independent experiments: (∗)$p < 0.05$ and (∗∗) $p < 0.01$ by Student's $t$ test.

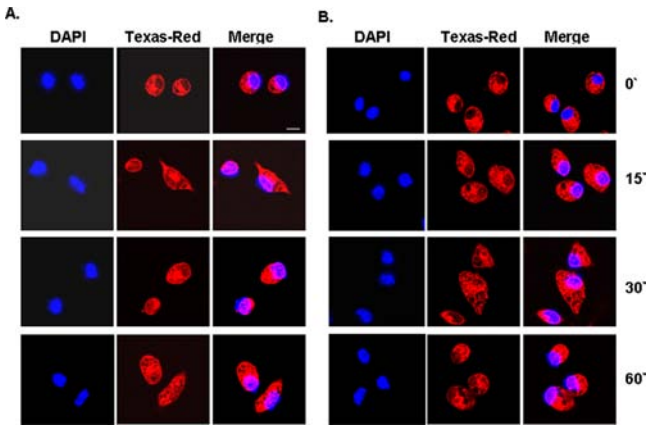

**Figure 5.** Daphnetin blocks LPS-triggered RelA/NF-κB nuclear translocation. RAW264.7 cells were pretreated with either DMSO (A) or 80 μM DAPH (B) 30 min prior to LPS stimulation. Nuclear translocation of RelA was analyzed by confocal fluorescence microscopy. Immunoreactivity of RelA is shown in red, and the nuclei are stained with DAPI (blue). Scale bar = 10 μm. Representative results from three independent experiments are depicted.

occurred about 80% less TNFAIP3 protein in the mice given TNFAIP3-specific siRNA relative to control siRNA at 48 h post delivery. The symptoms of lung inflammation and injury induced by LPS in TNFAIP3 siRNA-treated mice were significantly greater than those of their counterparts instilled with nonspecific siRNA (Figure 8B). Also, the repressed activation of p65/NF-κB by daphnetin was elevated by TNFAIP3 siRNA treatment, and production of inflammatory cytokines, protein leakage, and MPO activity showed to be exaggerated by TNFAIP3 silence in daphnetin-treated mice, as compared with the animals receiving nonspecific siRNA (Figure 8C−F). The data thus suggested that TNFAIP3-mediated negative regulation of pro-inflammatory signaling contributed substantially to the anti-inflammatory activity and protective effect of daphnetin in ALI.

## DISCUSSION

Unrestrained activation of leukocytes and persistent lung inflammation are presumed to be the major reasons for excessive lung injury or acute respiratory distress (ARDS). Despite pharmacological developments over the past several decades, inflammation-associated pulmonary diseases still result in high morbidity and mortality rates. Exploring effective treatments is therefore of critical importance. Using a prototypical model of LPS-induced inflammation and lung injury, we for the first time have established the protective effect of daphnetin in inflammatory airway disorders and suggest a novel promising therapy for these conditions. In particular, we demonstrated that daphnetin alleviated the symptoms of lung injury, blocked the infiltration of inflammatory cells, and dampened the expression of pro-inflammatory cytokines such as IL-6, TNF-α, and IL-1β, which are highly expressed in patients with severe pulmonary inflammatory diseases.[31] In addition, animals treated with daphnetin displayed a remarkable survival advantage in endotoxin shock, highlighting its beneficial effect in the inflammation-associated disorders. More impor-

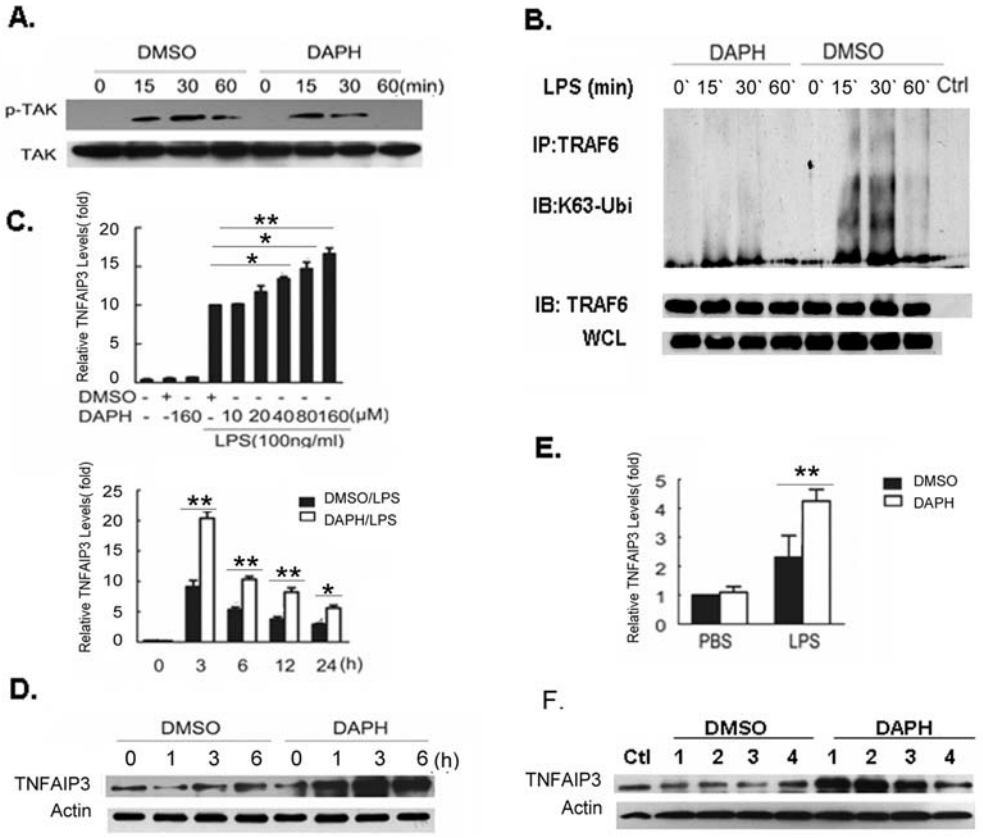

**Figure 6.** TNFAIP3 is involved in daphnetin-mediated negative regulation of NF-κB signaling. RAW264.7 cells were pretreated with DMSO or DAPH (80 μM) 30 min prior to LPS (100 ng/mL) stimulation. (A) Levels of total and phosphorylated TAK1 were measured by immunoblotting. (B) Immunoprecipitation (IP) of TRAF6 by immunoblotting (IB) for K63-linkage ubiquitin in the cells. IP with immunoglobulin (IgG) serves as an IP control (Ctrl), and IB of TRAF6 in whole cell lysates (WCL) serves as a loading control. Data were confirmed in at least three biological replicates. (C) Time- and dose-dependent induction of TNFAIP3 production by daphnetin was tested in murine peritoneal macrophages. Cells were pretreated with DMSO or DAPH at the concentration indicated (or 160 μM in the lower lane) and then stimulated with LPS. (D) TNFAIP3 protein levels upon DMSO or DAPH (160 μM) treatment were analyzed by Western blot in LPS-treated macrophages. (E) Real-time PCR and (F) Western blot analysis illustrate TNFAIP3 levels in lung tissues from LPS-challenged mice that were pretreated with DAPH or DMSO. Ctl, no treatment prior to LPS instillation. Representative results are depicted. All data are the mean ± SD of three independent experiments: (*) $p < 0.05$ and (**) $p < 0.01$ by Student's $t$ test.

tantly, we demonstrate that daphnetin targeted the DUB TNFAIP3 and selectively reversed TRAF6 ubiquitination to limit the NF-κB-driven pro-inflammatory signaling. The study thus revealed the action mode of daphnetin in counteracting inflammatory response, providing insights into the biological properties and protective applications of this naturally occurring coumarin compound.

The NF-κB signaling pathway is essential in the transcription of most pro-inflammatory cytokines and other effector molecules, thereby contributing to an excessive inflammatory response and tissue injury when uncontrollably activated. Enhanced and prolonged NF-κB activation has been described in chronic inflammatory lung diseases.[32,33] In keeping with its therapeutic effect in LPS-induced pulmonary inflammation and injury, daphnetin exhibited the ability to potentially modulate NF-κB signaling mostly by disturbance of the major events in this cascade. We have shown that daphnetin reduced the phosphorylation and degradation of IκBα, retarding the release of NF-κB and the subsequent nuclear translocation, the presumed determinant for the initiation of transcription of pro-inflammaotry genes. In addition, we revealed a role for daphnetin in modulating the TAK1/IKK axis upon LPS stimulation. TAK1 is a master kinase that mediates the activation of IKK and MAPKs.[28−30] Upon stimulation, TAK1 forms ternary complexes with its adaptor molecule TAK1-binding proteins (TABs), conveying the signaling to IKK and promoting phosphorylation and proteasome-mediated degradation of IκBα.[34] TAK1 thus becomes a key point in TLR-triggered inflammatory signaling and is vulnerable to multiple layers of modulation, particularly to the post-translational mechanism. For example, it has been revealed that phosphorylation of Thr-184/187 in the activation loop of TAK1 correlates with its kinase activity.[35] Our data showed that daphnetin significantly repressed TAK1 phosphorylation at Thr-184/187, which might account for the down-regulation of IKK and MAPKs by daphnetin. Additionally, TAK1 was previously reported to be regulated by ubiquitination, methylation, or O-GlcNAcylation.[36] The DUB cylindromatosis (CYLD) proved to physically interact with TAK1 and inhibit its ubiquitination and the resultant catalytic activity.[37] In our present study, we demonstrated that modulation of TAK1 by daphnetin in LPS-stimulated macrophages was most likely through down-regulation of TRAF6 activity. Despite the previous proposal that TAK1 exerted an effect on the activity JNK and p38 MAPKs downstream of MKK6 signaling, a recent investigation indicated that TAK1 also modulated ERK activity

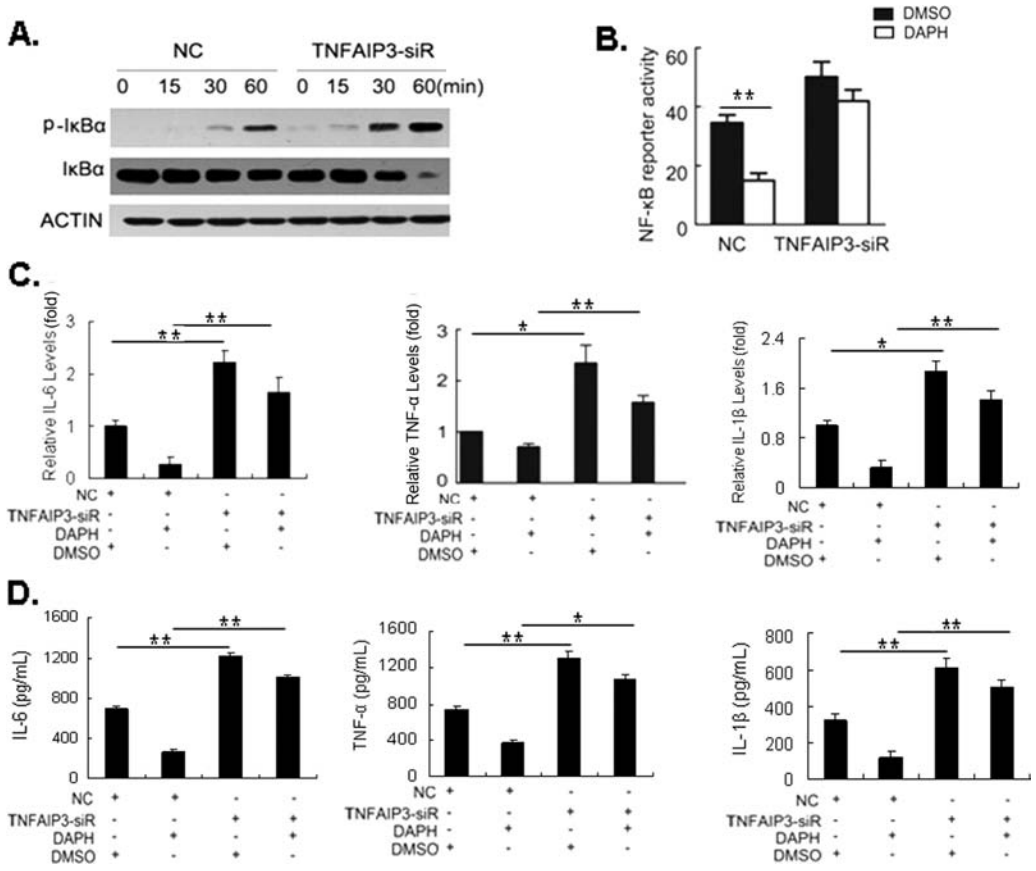

**Figure 7.** TNFAIP3 is required for anti-inflammatory action of daphnetin. (A) Macrophages were transfected with TNFAIP3 siRNA or scramble siRNA for 24 h and then subjected to LPS stimulation. Levels of total and phosphorylated IκBα were measured by immunoblotting. Results are representative of three individual experiments. (B) NF-κB-driven promoter activity in response to LPS was analyzed in DAPH- or DMSO-treated macrophages. RAW264.7 cells were transfected with pGL3-NF-κB or pGL3 for 24 h and were transfected with TNFAIP3 siRNA or scramble siRNA (NC). Twelve hours later, cells were administered DMSO or DAPH followed by LPS stimulation. (C, D) RAW264.7 cells were transfected with TNFAIP3 siRNA or scramble siRNA for 24 h and then treated with DMSO or DAPH followed by LPS stimulation. Levels of IL-6, TNF-α, and IL-1β were analyzed 12 h after the exposure. Data are the mean ± SD: (∗) $p < 0.05$ and (∗∗) $p < 0.01$ by Student's $t$ test.

via regulation of IKK-β activity.[38] This agrees with our finding that, along with the defective TAK1 activity in daphnetin-treated macrophage, LPS-induced MAPK activation was also profoundly affected. Together, our data indicated that daphnetin might act on TAK1 or the upstream kinase to disrupt IKK and MAPKs for termination of the inflammatory signaling.

Protein ubiquitination is a process that has been suggested to play important roles in a variety of cellular events, including DNA repair, signal transduction, and receptor endocytosis.[39] Modification of TRAF6 by the addition of K-63-linked polyubiquitin (polyUb) chains is essential for the TLR-induced inflammatory response. The RING type E3 ligase TRAF6 can promote K63-linked ubiquitination within the kinase domain, facilitating TAK1 phosphorylation and hence IKK-NF-κB activation and transcription of pro-inflammatory cytokine gene expression.[40] We herein revealed that daphnetin impaired K63-linked ubiquitination of TRAF6 in LPS-stimulated macrophages without altering TRAF6 protein level, thereby implicating the modulation of the nondegradative polyubiquitination of TRAF6 in the anti-inflammatory action of daphnetin. Given the key role for TRAF6 in NF-κB-driven signaling, it can be expected that aberrant expression or dysfunction of TRAF6 might cause the inflammation-associated disorders,[41] and understanding of the mechanism responsible for TRAF modulation should be helpful in the search for novel treatments. One important finding in the present study is the identification of TNFAIP3 as a target by daphnetin in regulating the inflammatory response. TNFAIP3 has been recognized as a key regulator that dampens NF-κB signaling mostly by removing K63-linked polyubiquitin chains from TRAF6.[13,42] Our study revealed that daphnetin enhanced TNFAIP3 expression in macrophages as well as in lung tissues following LPS challenge. Using TNFAIP3-specific siRNA, we showed that TNFAIP3 deletion in macrophages overcame the daphnetin-elicited suppression of IκBα degradation and, hence, NF-κB transcriptional activity. Thus, the reduced expression of IL-6 and TNF-α caused by daphnetin was almost abolished. Most strikingly, when TNFAIP3 was knocked down in the airway prior to endotoxin challenge, the protective effect of daphnetin appeared to be, at least partially, abrogated. These results thereby establish a critical role for TNFAIP3 in the protective effect of daphnetin and suggest a promising treatment for inflammatory lung disorders. Indeed, the beneficial effect of TNFAIP3 in counteracting airway inflammation has been documented. It has been found that TNFAIP3 expression in bronchial airway epithelial cells or other innate immune cells is required for the restricted NF-κB activation upon engagement of TLRs, IL-1R, IL-33R, and even high-affinity IgE receptor (FcεRI).[43,44] In addition, TNFAIP3

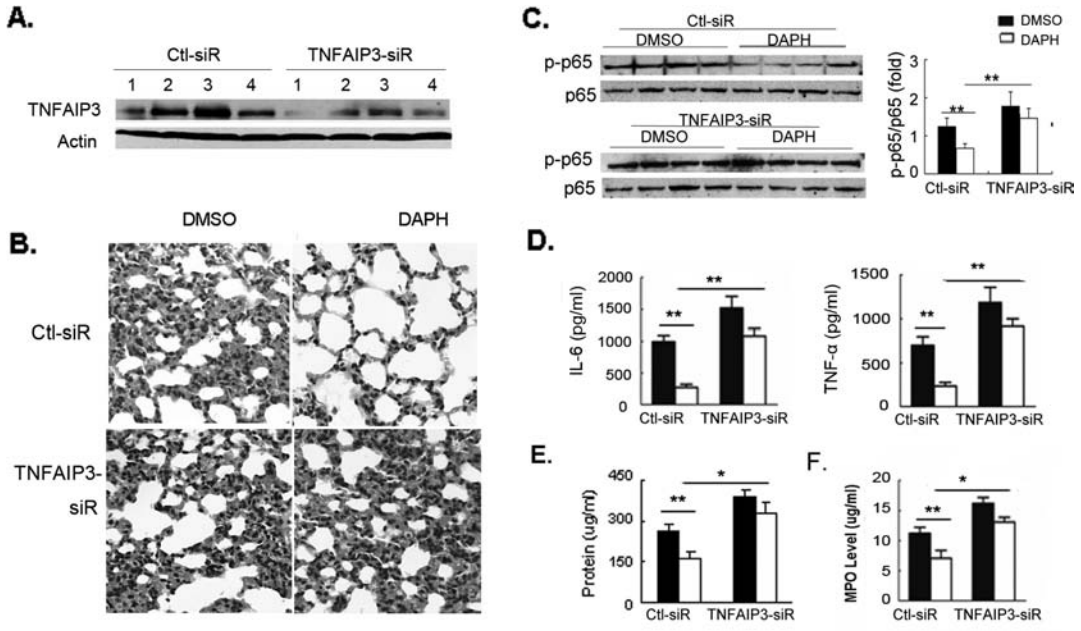

**Figure 8.** Loss of TNFAIP3 abrogates the protective effect of daphnetin in endotoxin-induced lung injury and inflammation. C57BL/6 mice were instilled with TNFAIP3 siRNA or scramble siRNA (60 $\mu$g/mice, i.t.) for 12 h and then administered DMSO or DAPH (5 mg/kg, ip) followed by intratracheal inoculation of LPS (1 mg/kg). Twelve hours later mice were sacrificed: (A) immunoblot analysis of TNFAIP3 in lungs from the mice ($n$ = 4 per group) injected with TNFAIP3 siRNA or control siRNA (Ctl-siR); (B) representative H&E staining performed on the lung sections (original magnification, ×200); (C) immunoblot analysis of phosphorylated and total p65 in lungs from the mice (relative density was obtained by densitometry of the corresponding band); (D) cytokine secretion and (E) protein lavage in BAL fluid and (F) MPO activity in lung tissues. Data are the mean ± SD: (∗) $p < 0.05$ and (∗∗) $p < 0.01$ by Student's $t$ test.

contributed substantially to the relief of lung immunopathology caused by infection of *Pseudomonas aeruginosa* or influenza virus.[45,46] Recently, a trial on TNFAIP3-targeted gene therapy was conducted in allergic asthma mice via the adenoviral transfer method, which showed that, compared with controls, the animals with enforced TNFAIP3 expression can decrease the production of mucin and inflammatory cytokines and attenuate the airway hyper-responsiveness.[47] These findings highlight the potential of TNFAIP3-targeted treatment in inflammatory lung disorders that are largely associated with exaggerated NF-$\kappa$B activity. However, the strategy by gene transfer of functional TNFAIP3 into the airway may be limited by ethical issues. Pharmaceutical induction of TNFAIP3 or members of the TNFAIP3 ubiquitin-editing complex has yet to be developed and will require a significant financial and time investment. In view of the established low toxicity, relatively low cost, and availability in herbal plants, the natural compound daphnetin and other similar plant derivatives might have implications in treating inflammatory respiratory diseases.[48,49] However, we should note that daphnetin pretreatment, in the absence of TNFAIP3, did not fully abolish its protection of the mice from LPS-induced lung injury and inflammation, suggesting that daphnetin might also act via other anti-inflammatory mechanisms.

In conclusion, we provide the first evidence to establish a beneficial effect of daphnetin in LPS-induced inflammation and pulmonary injury and elucidate a molecular mechanism through which daphnetin dampens NF-$\kappa$B-dependent inflammatory signaling. Our results might serve as a basis for the development of new approaches to lessen the severity of inflammation through use of the naturally occurring coumarin derivative.

examined the histological changes of this organ related to toxicity of nitrite. Nitrite is an intermediate compound in bacterial nitrification and denitrification processes; therefore, an imbalance in these processes can lead to a built up of nitrite in aquatic habitats.[19]

Red shrimp *P. muelleri* has a large distribution area in southwest Atlantic waters from 20° S, Espíritu Santo, Brazil, to 50° S, Santa Cruz, Argentina. This shrimp has acquired great interest on account of its potential use in culture in temperate areas; therefore, it is important to determine the optimal culture conditions to have healthy individuals.

The aim of this research was to investigate the interaction between the astaxanthin concentration in the feed and antioxidant response to exposure to nitrite in postlarvae of *P. muelleri*. For this purpose, the effects of these compounds on growth, survival, free radical scavenging, and functional morphology of the midgut gland were evaluated.

## MATERIALS AND METHODS

**Chemicals.** The DPPH standard was obtained from Aldrich. Astaxanthin (98%) was obtained from Sigma and stored in the dark at 253 K. Sodium nitrite ($NaNO_2$) and all other reagents were analytical-grade. The solvents were from Merck, and they were carefully purified following the literature method to have them free of alkenes and carbonyl compounds. All solvents used were dried conveniently.

**Experimental Animals.** Specimens of *P. muelleri* were reared from hatchery-raised postlarvae (15 ± 0.004 mg initial weight) at Nágera Station, Marine Science Department, Mar del Plata National University, Mar del Plata, Argentina. Feeds were tested in three replicate groups of 90 individuals each for 30 days. Shrimps were stocked at a density of 10 per 0.1 $m^2$ in aquaria with continuous aeration, and filtered seawater (to 5 $\mu$m) was exchanged at a rate of 50% per day. The experimental conditions were as follows: photoperiod, 12 h light/12 h dark; temperature, 20 ± 0.8 °C; salinity, 33 g $L^{-1}$; and pH, 7.

The treatments consisted of three feeds (37% protein and 7.5% lipids) supplemented with astaxanthin at concentrations of 0 mg of astaxanthin $kg^{-1}$ of diet ($C_0$), 100 mg of astaxanthin $kg^{-1}$ of diet ($C_{100}$), and 300 mg of astaxanthin $kg^{-1}$ of diet ($C_{300}$). Feeds were freshly prepared every 2 weeks to avoid carotenoid decomposition during storage (at −20 °C). Measurements confirmed the stability of the carotenoids within this period of time by scanning the spectrum between 200 and 750 nm using an ultraviolet−visible (UV−vis) spectrophotometer. Formulations of feed were made according to the chemical composition results of the byproduct meal to obtain isoproteic and isolipidic feeds.[20] All ingredients, from a local feed manufacturer, were mixed and cold-pelleted (<50 °C) by extrusion[21] and were oven-dried for 24 h at 50 °C (Table 1).

All groups of animals were fed *ad libitum* once a day. Upon completion of the feeding trial, surviving postlarvae from each treatment were weighed and transferred to glass jars with four postlarvae of each in triplicate for the static test of acute toxicity nitrite ($NO_2Na$). Nitrite test solutions were prepared with seawater at concentrations of 0, 10, 20, 40, 80, 100, 120, 160, and 200 mg $L^{-1}$. Animals were not fed during experimental trial. Shrimp behavior and death were monitored at 24 h intervals up to 96 h.

At the end of the static test, some postlarvae from each treatment and control individuals were fixed in Davidson fluid for 24 h and processed using routine techniques for light microscopy.[22] The fixed tissues were dehydrated in ascending concentrations of ethyl alcohol and embedded in paraffin. The tissue sections were cut to ∼5 $\mu$m and stained with hematoxylin and eosin (H&E).

**EPR Sample Preparation.** About 25 mg of lyophilized tissue of postlarvae from each treatment and control individuals was mixed with 1 mL of chloroform under an argon atmosphere. Each reaction mixture contained 50 $\mu$L of the tissue solution and 50 $\mu$L of DPPH ($2.8 \times 10^{-5}$ M) solution. Control or blank preparations, containing 50 $\mu$L of DPPH in chloroform solvent, remained unaltered after a long period of time. Samples for EPR measurements were prepared in quartz tubes with an internal diameter of 4 mm to achieve an adequate tuning at a constant room temperature of 293 K and were analyzed at fixed time intervals for 60 min. DPPH proved to be a very stable free radical;[9] the intensity of the signal decays with time and represents the radical−tissue reaction.

**Table 1. Percent Composition of the Control Feed**

| ingredients (g 100 $g^{-1}$) | $C_0$ |
|---|---|
| fish meal (65% crude protein)[a] | 48.0 |
| soybean meal (42% crude protein)[b] | 17.0 |
| corn starch | 20.0 |
| squid protein concentrate | 1.0 |
| wheat bran | 8.5 |
| fish oil | 2.0 |
| fish soluble | 2.0 |
| soybean lecithin | 0.5 |
| cholesterol | 0.5 |
| vitamin supplement[c] | 0.5 |

[a]Agustinier S.A., Mar del Plata, Argentina. [b]Melrico S.A., Buenos Aires, Argentina. [c]Cholecalciferol, 1.8 g/kg; thiamin, 8.2 g/kg; riboflavin, 7.8 g/kg; pyridoxine, 10.7 g/kg; calcium panthothenate, 12.5 g/kg; biotin, 12.5 g/kg; niacin, 25.0 g/kg; folic acid, 1.3 g/kg; $B_{12}$ HCl, 1.0 g/kg; ascorbic acid (Rovimix Stay C), 39.1 g/kg; menadione, 1.7 g/kg; inositol, 0.3 g/kg; choline chloride, 0.2 g/kg; $\alpha$-tocopherol acetate, 75 g/kg; and vitamin A acetate, 5.0 g/kg.

**EPR Measurements.** Potential antioxidant activity of postlarvae extracts was determined on the basis of the scavenging activity of the stable free radical DPPH using EPR with a Bruker ELEXSYS E 500 T spectrometer, operating at X-band. Amplitude signals were transformed in radical concentrations by comparing the area under the EPR absorption spectrum of the sample to that of a chloroform solution of the concentration standard, DPPH. All data were recorded at the same acquisition parameters: microwave power, 12.93 mW; microwave frequency, 9.71 GHz; modulation frequency, 100 kHz; attenuation, 12 dB; modulation amplitude, 100 mT; magnetic field center, 346.5 mT; sweep width, 10 mT; and sweep time, 60 s for three scans.[25] Measurements were repeated at least 3 times to minimize random errors. The standard plotting program Origin Pro was used to fit all sets of points whenever necessary.

**Statistical Analysis.** The analysis of variance and least significant difference tests were conducted to identify differences among means. Data were reported as the mean ± standard deviation. The concentration of nitrite lethal to 50% of the test organisms in a specified time period ($LC_{50}$) values were derived from regression of Probit-transformed mortalities against the log concentration[23] with the computer software XLSTAT 2010. The estimated Probit line and the results of a $\chi^2$ test for goodness of fit were computed. In all cases, significance was set as $p < 0.05$.[24]

## RESULTS AND DISCUSSION

After 30 days of rearing trial with feeds $C_0$, $C_{100}$, and $C_{300}$, percent weight gain ranged from 172 to 190%, with no significant differences between treatments. In most cases, there is no positive effect observed on growth of crustacean penaeoids fed with carotenoid-supplemented feeds.[26,27] Some studies showed that dietary astaxanthin has a positive effect on shrimp survival. In the study by Niu et al.,[28] growth performance and survival in *Litopenaeus vannamei* were significantly higher when fed diets with supplemental astaxanthin (100−400 mg $kg^{-1}$) related to shrimp fed with the control diet and there were no significant differences among the three dietary treatments supplemented with astaxanthin. However, in *Marsupenaeus japonicus*, similar survival between shrimp fed at different concentrations of pigmented feeds was

observed, indicating that carotenoid supplemented at 100 mg $kg^{-1}$ had no extra benefit on the survival of shrimp when compared to 50 mg $kg^{-1}$.[27]

In *P. muelleri*, survival was between 71 and 82%, with no significant differences among them, even with feeds supplemented with astaxanthin; the use of carotenoids as a nutritional additive would not be necessary for this species if they are fed diets containing animal meals, such as fish or squid, or vitamin A as a supplement.

The $LC_{50}$ values of nitrite N (mg $L^{-1}$) at 96 h estimated for shrimps by the Probit statistical method were 76.3, 89.7, and 157 mg $L^{-1}$ fed with $C_0$, $C_{100}$, and $C_{300}$, respectively (Table 2).

**Table 2. $LC_{50}$ of Nitrite to *P. muelleri* Fed with Experimental Feeds after 96 h of Exposure**

| | | confidence intervals (95%) | | |
|---|---|---|---|---|
| feed | $LC_{50}$ (mg $L^{-1}$) | low limit | upper limit | $\chi^2$ |
| $C_0$ | 76.3 | 51.1 | 61.5 | 0.28 |
| $C_{100}$ | 89.7 | 13.1 | 55.4 | 0.46 |
| $C_{300}$ | 157 | 9.4 | 57.8 | 0.51 |

Research in fish and other aquatic animals have disclosed that nitrite is a disrupter of multiple physiological functions, including ion balance, respiratory, cardiovascular, endocrine, and excretory processes.[19] Enhancement of resistance to environmental stress in penaeoid shrimp postlarvae was associated with an increase in dietary and body astaxanthin.[8] Present results showed that astaxanthin improves shrimp health in terms of resistance against nitrite stress; the median lethal concentration of nitrite increases with higher astaxanthin dietary concentrations. In the trial testing nitrite N tolerance, it was determined that the 96 h $LC_{50}$ values for shrimps fed with $C_0$, $C_{100}$, and $C_{300}$ were significantly lower than the results reported by Lin and Chen[29] for *L. vannamei* juveniles (322 mg $L^{-1}$) but higher than those found for freshwater prawn *Macrobrachium rosenbergii*, with values between 8.8 and 12.9 mg $L^{-1}$. When the toxicological effects of nitrite in aquatic ecosystems are checked, it can be concluded that seawater animals are more tolerant to nitrite toxicity than freshwater animals, probably because of the improving effect of chloride ions on the tolerance of aquatic animals.[30]

Figure 1 shows the histology of the midgut gland of *P. muelleri*. Control treatment (no addition of nitrite) shows normal morphology of the midgut gland, composed of many tubules lined by a simple epithelium with clearly differentiated cells, namely, embryonic (E), fibrillar (F), absortive (R), and blister-like (B). Individuals of all nitrite treatments showed tissular alterations compared to the initial histological conditions. The main histopathological alteration was the retraction of the epithelium within the layer of laminar connective tissue that surrounds each tubule. Some tubules had a reduction in the number and size of store lipid vacuoles, while other tubules were completely devoid of epithelial cells and with tubular lumen dilated. Both types of tubules contained sloughed epithelial cells and cellular debris. Histological structure analysis of shrimps from treatment groups with elevated nitrite levels displayed varying degrees of tissue pathology in the midgut gland. It was observed in the sample of animals fed with astaxanthin and submitted at the highest concentration of nitrite that the general structure of the organ studied was less affected than the sample of those fed $C_0$. This allows for the inference that the addition of astaxanthin in feed

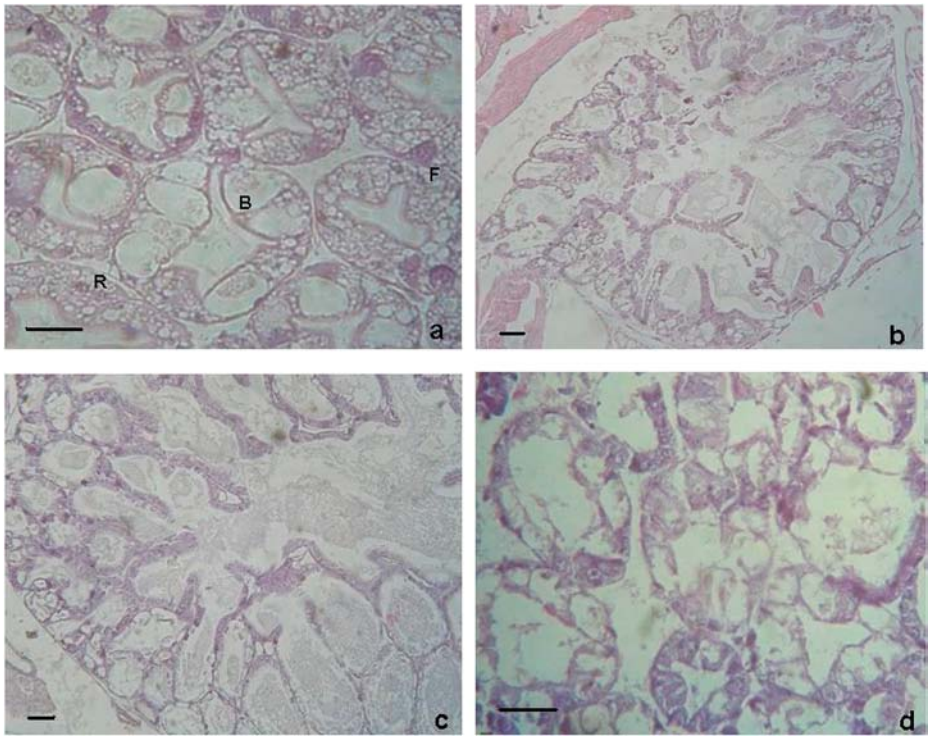

**Figure 1.** Transverse section through the midgut gland from postlarvae *P. muelleri* stained with H&E: (a) control treatment (no addition of nitrites) showing normal tubules, with B, B cell; F, F cell; and R, R cell, with a scale bar of 50 $\mu$m; (b) treatment with $C_{300}$ and 80 mg/L nitrite, with a scale bar of 200 $\mu$m; (c) treatment $C_0$ with 10 mg/L nitrite, with a scale bar of 100 $\mu$m; and (d) treatment $C_0$ with 80 mg/L nitrite, with a scale bar of 50 $\mu$m.

avoids the damage in the animals subjected to concentrations of 80 mg $L^{-1}$ nitrite. All of these changes suggest that elevated nitrite levels negatively affect the health of the shrimp even if outward signs are no evident, such as growth and survival. According to Vogt,[31] the process of desquamation in the midgut gland of *P. monodon* starts with the cell lysis, particularly R cells, and the neighboring cells protrude in small basolateral extensions, pushing the damaged cells into the tubular lumen, generating ulcerations. In the present work, degenerative desquamation of the tubular epithelium in the midgut gland of *P. muelleri* was a pathological feature observed with all nitrite concentrations tested. This alteration was also observed in marine crustaceans acclimatized to low salinities, such as *Artemesia longinaris*[32] and *P. muelleri*,[33] and freshwater prawn *Palaemonetes argentinus* under hypersaline conditions.[34] The increased desquamation produced by different stressors resulted in a high rate of cell loss that does not make possible the restitution of the damage tissue. The midgut gland plays an important role in lipid metabolism; alterations observed in R cells suggest that the shrimp not metabolizing feeds normally might be due to the enhanced energy demand in response to stress by high concentrations of nitrite.[35]

In Figure 2, the kinetics of the DPPH reaction of tissue homogenates of shrimp fed with $C_0$ and $C_{300}$ exposed at different sublethal concentrations of nitrite (0, 20, 40, and 80 mg $L^{-1}$) can be observed. Figure 2a ($C_0$) shows that free radical scavenging activity was detected at all tested nitrite concentrations; the signal decayed between 34 and 52% at 30 min. Similar kinetic curves were observed for control and 20 mg $L^{-1}$ nitrite, and the lowest activity was at 80 mg $L^{-1}$ nitrite. Higher contents of carotenoids in the feed (300 mg $kg^{-1}$) promoted production of protective substances, thereby increasing the quenching free radical in the system (Figure 2b). There exist some mechanistic explanations for the radical scavenging reactions of carotenoids *in vitro*,[36] but it is difficult to be certain which antioxidant role that carotenoids play in biological systems and the possible interference of toxic stressors, such as nitrite. The extracts of individuals exposed at 80 mg $L^{-1}$ nitrite concentration for all feed treatments showed DPPH scavenging capacity, although some differences were noted among shrimp fed with $C_0$ (43%) and those fed with $C_{100}$ and $C_{300}$, which had the greatest activity to quench DPPH (62 and 59%, respectively) (Figure 3).

Carotenoids have been reported to be the most efficient quenchers of singlet oxygen ($^1O_2$). Astaxanthin as a member of the carotenoid family reduces the oxidation rate;[37] for this reason, it plays an important role in animal health as an antioxidant through inactivation of the free radical produced from normal cellular activity and various stressors.[38] A previous work on *P. muelleri* demonstrated that the postlarval stages (with higher carotenoid concentrations) promoted a greater percentage of decay of DPPH over time, because radicals are consumed in the tissue at a speed that depends upon the amount of protective substances.[25] The long-standing controversy of function of carotenoids as antioxidants may be related to extrapolation of properties determined in homogeneous solution to more complex biological systems, where other factors, such as spatial organization and interaction between antioxidants, become important.[39] Nitrite exerts part of its toxicity through the formation of reactive oxygen intermediates (ROIs) that are able to attack almost all biomolecules present in their vicinity, causing protein modification, lipid peroxidation, and DNA damage. Activities

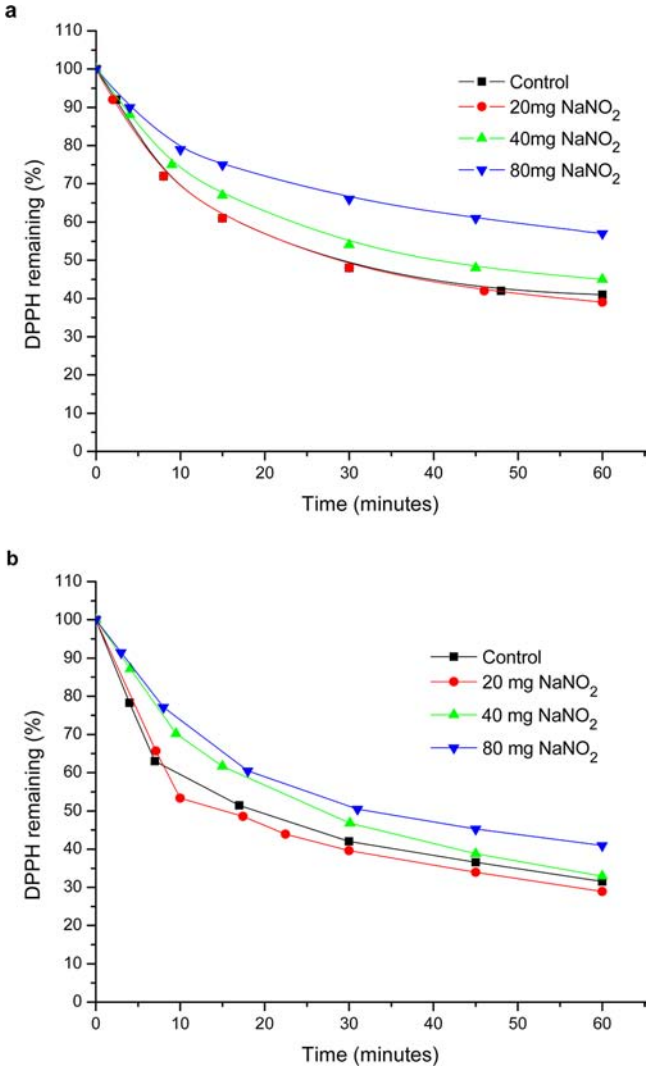

**Figure 2.** Reaction kinetics of tissue with the DPPH radical. Tissue extracts were tested for a pool of animals exposed at different concentrations of nitrite, by mixing 0.025 g of tissue with 50 $\mu$L of DPPH solution ($2.8 \times 10^{-5}$ M). All tests were conducted in triplicate, and the means are used: (a) animals fed with $C_0$ (without astaxanthin) and (b) animals fed with $C_{300}$.

of the three major antioxidant enzymes (glutathione peroxidase, superoxide dismutase, and catalase) responsible for combating the effects of ROIs diminished significantly in response to levels of ambient nitrite in *L. vannamei*.[40] Polar carotenoids, such as astaxanthin, are localized perpendicularly in the plasma membrane, consequently, allowing for the protection of the unsaturated lipids from the adverse effects of the oxidants.[41]

Results of the present work show a relationship between the carotenoid feed supplementation and the protective capacity of the homogenate against the nitrite concentration. Chien et al.[8] suggest that astaxanthin is a "semi-essential" nutrient for *P. monodon*, mainly when the animal is under physiological stress. Because an enhancement of antioxidant capacity by dietary astaxanthin in *P. muelleri* was observed. One of the most important aspects of this study is to optimize culture techniques for this species. The use of bioactive substances, such as nutritional additives, to improve performance in shrimp farming is receiving increasing attention, and efforts are being made to define the role of astaxanthin as a dietary supplement. The

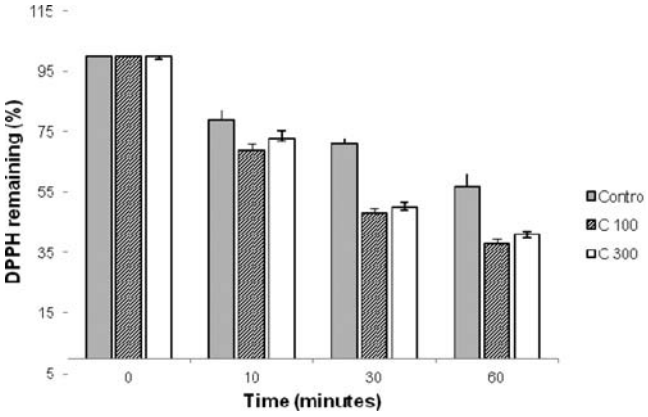

**Figure 3.** DPPH scavenging effect followed up to 60 min. Midgut gland extracts for a pool of animals exposed at 80 mg of nitrite and fed with different diets were tested by mixing 0.025 g of tissue with 100 $\mu$L of DPPH solution ($2.8 \times 10^{-5}$ M). Vertical bars represent the standard deviation of each data point ($n$ = 3).

addition of carotenoid pigments as bioactive additives, which affect physiological and molecular processes under controlled conditions, is more evident as a result of not be synthesized *de novo*. It can be concluded that these compounds act as protectors of ambient nitrite under culture conditions. Further studies are necessary to identify the free radicals that contribute to total antioxidant activities of carotenoids under different physiological conditions and to determine the relationship between their radical scavenging properties and their biological effects.

Table 1. Name, Origin, and Total Polyphenols of Sour Cherry Cultivars Used in This Study

| cultivars | origin | | | TP (mg/100 g dm) |
|---|---|---|---|---|
| | parents | country | date of harvest | |
| Agat | Łutówka x Nefris | Poland | June 30 | 2278.92 |
| Ametyst | Łutówka x Nefris | Poland | July 14 | 2270.15 |
| Cesarzowa Eugenia | unknown | France | July 14 | 2261.91 |
| Dradem | Łutówka x Northstar | Poland | July 14 | 2748.75 |
| Erdi Botermo | Pandy Meggy 38 x Nagy Angol | Hungary | June 30 | 2244.24 |
| Erdi Nagygyümöscu | unknown | Hungary | June 22 | 1539.43 |
| Fanal | selected from local cherry, origin unknown | Germany | July 7 | 2366.25 |
| Fortuna | unknown | Germany | June 22 | 1687.22 |
| Groniasta z Ujfehertoi | unknown | Hungary | July 7 | 1672.68 |
| Karneol | Kerezer x Schattenmorelle | Germany | July 14 | 1894.68 |
| Kelleris 14 | Ostheimska x Marchijska | Denmark | July 14 | 2292.73 |
| Książęca | unknown | unknown | June 22 | 2193.17 |
| Lucyna | Łutówka x Shirpotreb | Poland | July 7 | 1880.89 |
| Łutówka | unknown | France or Holand | July 21 | 2286.99 |
| Meteor Korai | unknown | Hungary | June 22 | 2679.22 |
| Morina | Kerezer x Reinharts Ostheimer | Germany | July 7 | 2733.46 |
| Nana | Crisina x Morello Neagra | Rumunia | July 14 | 2251.07 |
| Northstar | English Morello x Serbian pie | USA | July 7 | 2427.49 |
| Pandy 103 | clone cv Pondy | Hungary | July 7 | 2349.43 |
| Sabina | Łutówka x Shirpotreb | Poland | June 30 | 2449.25 |
| Safir | Schattenmorelle x Fanal | Germany | July 7 | 2842.41 |
| Stevensbaer | clone *P. ceraus* | Denmark | July 14 | 2572.28 |
| Topas | Fanal x Kelleris 16 | Germany | July 7 | 2651.91 |
| Turgieniewka | seedling cv Żukowskaja | Rosja | July 7 | 2608.20 |
| Wanda | Neferis x Wołyńska | Poland | June 30 | 2160.74 |
| Wiblek | selected from local cherries, origin unknown | Poland | July 14 | 2112.77 |
| Wider (syn. Skierka) | selected from local cherries, origin unknown | Poland | June 30 | 2543.59 |
| Wifor | selected from local cherries, origin unknown | Poland | July 21 | 1709.04 |
| Wilena | selected from local cherries, origin unknown | Poland | July 7 | 2046.32 |
| Wilga | selected from local cherries, origin unknown | Poland | July 14 | 1685.01 |
| Winer | selected from local cherries, origin unknown | Poland | July 21 | 2485.18 |
| Wisok | selected from local cherries, origin unknown | Poland | July 21 | 2982.51 |
| Wołyńska (syn. Morelka) | selected from local cherries, origin unknown | Poland | July 14 | 2288.72 |

## MATERIALS AND METHODS

**Chemicals.** 2,2′-azinobis(3-ethylbenzothiazoline-6-sulfonic acid) (ABTS), 6-hydroxy-2,5,7,8-tetramethylchroman-2-carboxylic acid (Trolox), 2,4,6-tri(2-pyridyl)striazine (TPTZ), 2,2′-azobis (2-amidino-propane) dihydrochloride (AAPH), fluorescein disodium (FL), potassium persulfate, acetic acid, phloroglucinol, and methanol were purchased from Sigma-Aldrich (Steinheim, Germany). (−)-Epicatechin, (+)-catechin, procyanidins B1, *p*-coumaric acid, quercetin and kaempferol-3-*O*-glucoside, cyanidin-3-*O*-sophoroside, cyanidin-3-*O*-glucoside, cyanidin-3-*O*-rutinoside, peonidin-3-*O*-rutinoside, and pelargonidin-3-*O*-glucoside were purchased from Extrasynthese (Lyon, France). Chlorogenic acid, neochlorogenic acid, cryptochlorogenic acid, and 3,5-dicaffeoylquinic acid were purchased from TRANS MIT GmbH (Giessen, Germany). Acetonitrile for ultra-phase liquid chromatography (UPLC; Gradien grade) and ascorbic acid were from Merck (Darmstadt, Germany). UPLC grade water, prepared by HLP SMART 1000s system (Hydrolab, Gdańsk, Poland), was additionally filtrated through a 0.22 $\mu$m membrane filter immediately before use.

**Plant Materials.** Thirty-three sour cherries cultivars ('Agat', 'Ametyst', 'Cesarzowa Eugenia', 'Dradem', 'Erdi botermo', 'Erdi Nagygyümöscu', 'Fanal', 'Fortuna', 'Groniasta', 'Karneol', 'Kelleris 14', 'Książęca', 'Lucyna', 'Łutówka', 'Meteor korai', 'Morina', 'Nana', 'Northstar', 'Pandy 103', 'Sabina', 'Safir', 'Skierka', 'Stevensbaer', 'Topas', 'Turgieniewka', 'Wanda', 'Wiblek', 'Wifor', 'Wilena', 'Wilga', 'Winer', 'Wisok', and 'Wołyńska', Table 1) were used in this research; all of them were appropriate for food manufacturing and widely grown in Poland. The fruits were harvested at the Research Station for Cultivar Testing in Zybiszów near Wrocław (51° 3′ 51.11″ N, 16° 54′ 43.56″ E). The sour cherries were collected at "ready-to-eat" ripening stage, evaluated by means of change in ground color from green to red. Since sour cherries quality shows variablility within tree, fruit sampling under the following conditions: middle vigor trees, south exposure, external part of the tree. In the course of the measurements, five replications (each 100 g randomly chosen fruits) from three trees, i.e., 15 replications per cultivar, were established.

The fruit mass, dry matter, soluble solids, pH and titratable acidity, sugars, and ascorbic acid content were measured on fresh berries soon after harvest. For polyphenolic compounds and antioxidant activity analyses, the whole fruits were cut directly to liquid nitrogen and crushed by laboratory mill for homogeneous powder in liquid nitrogen (IKA 11A; Staufen, Germany) and freeze-dried (24 h; Alpha 14 LSC; Martin Christ GmbH, Osterode am Harz, Germany). The samples were stored in a freezer (−70 °C; Frilabo; Lyon, France) until analysis, no longer than 2 weeks.

**Physicochemical Analyses.** Fruit weight was evaluated in triplicate from a 10 whole fruit sample (fruit and seed). The sour cherry seeds were manually removed. Titratable acidity (TA) was determined by titration aliquots of homogenate of fresh fruits by 0.1 N NaOH to an end point of pH 8.1 using an automatic pH titration system (pH-metr typ IQ 150; Warsav, Polska) and expressed as g of malic acid. The pH was measured with the same equipment used for TA, while the soluble solids content (SSC) was determined in fresh juices with a refractometer (Atago Rx 5000, Atago Co. Ltd., Japan) and expressed as °Brix. Total and directly reducing sugars was determined by the Lane−Eynon method (PN-90/A-75101/07).

**Identification of Polyphenols by the LC-PDA-MS Method.** The extract of polyphenols for analysis was prepared as described previously by Wojdyło et al.[13] Identification and quantification of polyphenols of sour cherry extracts was carried out using an Acquity ultraperformance LC system equipped with a photodiode detector (PDA; UPLC) with binary solvent manager (Waters Corp., Milford, MA, USA) series with a mass detector G2 QTof Micro mass spectrometer (Waters, Manchester, UK) equipped with an electrospray ionization (ESI) source operating in negative and positive modes. Separations of polyphenols were carried out using a UPLC BEH C18 column (1.7 $\mu$m, 2.1 × 100 mm; Waters Corp., Milford, MA, USA) at 30 °C. Samples (5 $\mu$L) were injected, and elution was completed within 15 min using a sequence of elution modes: linear gradients and isocratic. The flow rate was 0.45 mL/min. The mobile phase was composed of solvent A (4.5% formic acid) and solvent B (100% of acetonitrile). The program began with isocratic elution with 99% A (0−1 min), and then a linear gradient was used until 12 min, lowering A to 0%; from 12.5 to 13.5 min, returned to the initial composition (99% A), and then held constant to re-equilibrate the column. Analysis was carried out using full scan, datadependent MS scanning from $m/z$ 100 to 1000. The mass tolerance was 0.001 Da, and the resolution was 5.000. Leucine enkephalin was used as the mass reference compound at a concentration of 500 pg/$\mu$L at a flow rate of 2 $\mu$L/min, and the $[M - H]^-$ ion at 554.2615 Da was detected over 15 min of analysis during ESIMS accurate mass experiments, which was permanently introduced via the LockSpray channel using a Hamilton pump. The lock mass correction was ±1.000 for Mass Window. The mass spectrometer was operated in a negative ion mode, set to the base peak intensity (BPI) chromatograms, and scaled to 12 400 counts per second (= 100%). The optimized MS conditions were as follows: capillary voltage of 2500 V, cone voltage of 30 V, source temperature of 100 °C, desolvation temperature of 300 °C, and desolvation gas (nitrogen) flow rate of 300 L/h. Collision-induced fragmentation experiments were performed using argon as collision gas, with voltage ramping cycles from 0.3 to 2 V. The characterization of the single components was carried out via the retention time and the accurate molecular masses. Hydroxycinnamic acids, flavan-3-ols, and flavonols were optimized to its estimated molecular mass $[M - H]^-$ in the negative mode before and after fragmentation and for anthocyanidin compounds optimized to its estimated molecular mass $[M + H]^+$ in the positive mode. The data obtained from LCMS were subsequently entered into MassLynx 4.0 ChromaLynx Application Manager software. On the basis of these data, the software is able to scan different samples for the characterized substances.

**Determination of Polyphenols by UPLC Coupled to PDA and FL Detector.** The analysis of polyphenolic compounds was carried out on a UPLC system Acquity (Waters Corp., Milford, MA, USA) consisting of a binary solvent manager, sample manager, PDA (model $\lambda$e), and fluorescence detector (FL). Empower 3 software was used for chromatographic data collection and integration of chromatograms. The UPLC analyses were performed on a BEH Shield C18 analytical column (2.1 mm × 50 mm; 1.7 $\mu$m). The flow rate was 0.45 mL/min. A partial loop injection mode with a needle overfill was set up, enabling 5 $\mu$L injection volumes when a 10 $\mu$L injection loop was used. Acetonitrile (100%) was used as a strong wash solvent and acetonitrile−water (10%) as a weak wash solvent.

**Analysis of Polyphenol Compounds.** Five milliliters of the resultant extract were centrifuged for 10 min at 15000$g$ at 4 °C. The analytical column was kept at 30 °C by column oven, whereas the samples were kept at 4 °C. The mobile phase was composed of solvent A (4.5% formic acid) and solvent B (acetonitrile). Elution was as follows: 0−5 min, linear gradient from 1 to 25% B; 5.0−6.5 min, linear gradient from 25 to 100%; 6.5−7.5 min, column washing; and reconditioning for 0.5 min. PDA spectra were measured over the wavelength range of 200−600 nm in steps of 2 nm. The runs were monitored at the following wavelengths: flavan-3-ols at 280 nm, hydroxycinnamates at 320 nm, flavonol glycosides at 360 nm, and anthocyanins at 520 nm. Retention times and spectra were compared with those of pure standards. Calibration curves at concentrations ranging from 0.05 to 5 mg/mL ($r^2 \leq 0.9998$) were made from (−)-epicatechin, (+)-catechin, chlorogenic acid, neochlorogenic acid, 3,5-dicaffeoylquinic acid, quercetin-3-$O$-glucoside, quercetin-3-$O$-rutinoside, kaempferol-3-$O$-rutinoside, cyanidin-3,5-$O$-diglucoside, cyanidin-3-$O$-glucoside, cyanidin-3-$O$-rutinoside, peonidin-3-$O$-rutinoside, and pelargonidin-3-$O$-rutinoside as standards. 3-$p$-Coumarylquinic acid was expressed as $p$-coumaric acid, and quercetin derivatives was expressed as quercetin-3-$O$-glucoside, kaempferol derivatives was expressed as kaempferol-3-$O$-rutinoside, and derivatives of apigenin were expressed as quercetin-3-$O$-glucoside. All determination were done in triplicate. Results were expressed as milligrams per 100 g of dry matter (dm).

**Analysis of Proanthocyanidins by the Phloroglucinolysis Method.** Direct phloroglucinolysis of freeze dried sour cherry varieties was performed as described previously by Wojdyło et al.[13] Portions (0.05 g) of powder were precisely measured into 2 mL Eppendorf vials, then 0.8 mL of the methanolic solution of phloroglucinol (75 g/L) and ascorbic acid (15 g/L) was added. After the addition of 0.4 mL of methanolic HCl (0.3 mol/L), the vials were closed and incubated for 30 min at 50 °C with continuous vortexing using a thermo shaker (TS100; BIOSAN, Lithuania). The reaction was stopped by placing the vials in an ice bath; 0.5 mL of the reaction medium was drawn out and diluted with 0.5 mL of 0.2 mol/L sodium acetate buffer. Next the vials were cooled in ice water and centrifuged immediately at 20000$g$ for 10 min at 4 °C. The analytical column was kept at 15 °C by column oven, whereas the samples were kept at 4 °C. The mobile phase was composed of solvent A (2.5% acetic acid) and solvent B (acetonitrile). Elution was as follows: 0−0.6 min, isocratic 2% B; 0.6−2.17 min, linear gradient from 2 to 3% B; 2.17−3.22 min, linear gradient from 3 to 10% B; 3.22−5.00 min, linear gradient from 10 to 15% B; 5.00−6.00 min, column washing; and reconditioning for 1.50 min. The fluorescence detection was recorded at an excitation wavelength of 278 nm and an emission wavelength of 360 nm. The calibration curves, which were based on peak area, were established using (+)-catechin, (−)-epicatechin, and procyanidin B1 after phloroglucinol reaction as (+)-catechin and (−)-epicatechin−phloroglucinol adduct standards. The average degree of polymerization was calculated as the molar ratio of all the flavan-3-ol units (phloroglucinol adducts + terminal units) to (−)-epicatechin and (+)-catechin, which correspond to terminal units. All determinations were done in triplicate. Results were expressed as milligrams per 100 g dm.

**L-Ascorbic Acid Analysis.** L-Ascorbic acid was analyzed according to the method described previously by Oszmiański et al.[15] Fresh fruits (3−4 g) were mixed with 50 mL of 0.1 M phosphoric acid and centrifuged at 20000$g$ for 10 min. The estimation of ascorbic acid was carried out using a Waters liquid chromatograph with a tunable absorbance detector (Waters 486) and a quaternary pump with a Waters 600 Controller apparatus (Waters Associates). A 20 $\mu$L sample was injected into a Chromolith Performance RP18e column (100 × 4.6 mm) (Merck, Darmstadt, Germany). The elution was carried out using 0.1 M phosphoric acid at the flow rate of 1.0 mL/min. The absorbance was monitored at 254 nm. Ascorbic acid was identified by comparison with the standard. The calibration curve was prepared by plotting different concentrations of the standard versus the area measurements in HPLC. All determination were done in triplicate. Results were expressed as milligrams per 100 g dm.

**Analysis of Antioxidant Activity.** The solvent for analysis of polyphenols was prepared as described previously by Wojdyło et al.[14] The ORAC, ABTS$^{\circ+}$, and FRAP assay were determined as previously described by Ou et al.,[16] Re et al.,[17] and Benzie et al.,[18] respectively. All antioxidant activity were expressed as millimoles of Trolox per 100 g of dry matter (dm). ORAC assay was performed using a RF5301 PC spectrofluorometer (Shimadzu, Kyoto, Japan). Determinations by ABTS and FRAP methods were performed using a UV2401 PC spectrophotometer (Shimadzu, Kyoto, Japan).

**Statistical Analysis.** Results are given as the mean of three independent determinations. Principal Components Analysis (PCA) was carried out using the Statistica version 10 software (StatSoft, Krakow, Poland).

[a] $[M + H]^+$ ($m/z$) for anthocyanins were obtained in the positive ion mode. [b] The $m/z$ values of the predominant ions are given in bold type.

## RESULTS AND DISCUSSION

**Identification and Quantification of Phenolic Compounds in the Sour Cherry Fruits.** *Total Polyphenol (TP).* Table 2 shows the data after LC/MS QTOF analysis. The LC/MS analysis of different sour cherry cultivars allowed for a characterization of 41 compounds. These can be classified into four groups of phenolic compounds: anthocyanins, hydroxycinnamic acids, flavonols and flavons, and flavan-3-ols (monomer, dimers, and polymeric procyanidins).

The concentration range of total phenolics (TP) determined for different sour cherry cultivars is presented in Table 1. The TP contents ranged from 2982.51 to 1539.43 mg/100 g dm for the 'Wisok' and 'Erdi Nagygyümöscu' cultivars, respectively (Table 1). The average TP content of 33 sour cherry cultivars analyzed was 2278.69 mg/100 g dm and depended significantly on the cultivar. High TP levels (>2500 mg/100 g dm) were found in 'Meteor Korali', 'Skierka', 'Turgieniewka', 'Morina', 'Topas', 'Safir', 'Dradem', and 'Stevensbaer', but 'Wifor', 'Wilga', 'Lucyna', 'Groniasta', 'Groniasta z Ujfehertoi', 'Fortuna', and 'Karneol' revealed <1900 mg/100 g dm of polyphenols.

Considerably variable amounts of TP were reported previously.[19,20] It is difficult to compare them with our results, because different methods of extraction and determination were used, but the proportions of individual phenolics seem to be

similar. The highest polyphenol content was measured in a Polish cultivar, 'Wisok', but many other cultivars contained significantly less polyphenols. Variability in the content of phenolic compounds in fruits depends on many factors, such as degree of maturity at harvest, environmental conditions during fruit development, etc.[21] However, the production of fruit with high content of nutritional components and extensive antioxidant properties depends to a much greater degree on their genetic background than on the climatic conditions and agricultural practices. Additionally, the total content of polyphenolic compounds in red-colored fruits increases at the last ripening stage, due to maximal accumulation of anthocyanins and flavonols.[22]

*Flavan-3-ols.* Based on the LC/MS technique, 12 additional compounds belonging to flavan-3-ols were detected and identified in the sour cherry fruits (Table 2). These compounds included three procyanidin dimers with $m/z$ 577, one of which was identified compared to standards as procyanidin B1, seven procyanidin trimers with $[M - H]^-$ at $m/z$ 865, and two procyanidin tetramers with $[M - H]^-$ at $m/z$ = 1153. All the detected procyanidins had the characteristic fragmentation pattern of a negatively charged molecular ion $[M - H]^-$ at $m/z$ = 577 and/or 289.

The difference between the content of (−)-epicatechin and (+)-catechin was significant. Concentrations of (−)-epicatechin ranged from 18.12 to 282.87 mg/100 g dm and of (+)-catechin from 4.27 to 115.72 mg/100 g dm. The highest monomer levels were found in 'Dradem', 'Meteor Koral', and 'Winer' fruits, while the lowest were found in 'Wanda', 'Lucyna', and 'Wifor' fruits (Table 3).

Previous studies by Serra et al.,[23] Toydemir et al.,[24] and Diaz-Garcia et al.,[25] concerning flavan-3-ols profiles of sour and sweet cherry, suggested that the major compounds in this group were (−)-epicatechin and (+)-catechin. However, Kołodziejczyk et al.[26] suggested, based on HPLC/MS analysis, that the sour cherry pomace extract contained different polymeric procyanidins, up to pentamers. Similarly, Tomas-Barberan et al.[27] reported the presence of (−)-epicatechin and procyanidin dimers and trimers in plums, peaches, and nectarines that belong to the same plant family.

Individual concentration of polymeric procyanidins in the sour cherry fruits was difficult to estimate, and to this end the phloroglucinol method was employed to determine their quantity in different cultivars. Phloroglucinol degradation of sour cherry procyanidins released (+)-catechin and (−)-epicatechin as the only free flavan-3-ols and (−)-epicatechin phloroglucinol as the main flavan-3-ol adduct, suggesting that these procyanidins essentially consisted of (−)-epicatechin units with (+)-catechin present only in a very low proportion as a terminal unit.

Regarding the polymeric procyanidin levels, the investigated cultivars can be classified into three groups: the first group with levels ranging >1000 mg/100 g dm ('Agat', 'Skierka', Fanal', 'Wilena', 'Karneol', 'Stevensbaer', and 'Łutówka' cvs), the second group with intermediate levels between 700 and 1000 mg/100 g dm ('Lucyna', 'Morina', 'Pandy', 'Groniasta', 'Nordstar', 'Topas', 'Safir', 'Nana', 'Wilbek', 'Dradem', 'Keleris 14', 'Ametyst', 'Wilga', 'Wołyńska', 'Wifor', 'Winer', and 'Wisok' cvs), and the third group with much lower levels below 700 mg/100 g dm ('Książęca', 'Erdi Nagygyümöscu', 'Fortuna', 'Meteor Korai', 'Sabina', 'Wanda', 'Erdi botermo', 'Turgieniewka', and 'Cesarzowa Eugenia' cvs). An analysis of the polymeric procyanidins content in sour cherry fruit revealed significant differences between Polish cultivars.

A degree of polymerization (DP; number of flavan-3-ol units) modulates the physicochemical properties of procyanidins. The DP of the sour cherry polymeric fraction ranged from 2.6 to 6.6. The highest DP was found in 'Groniasta' cultivar, and the other cultivars were characterized by lower DP values of about 3.2−4.4. According to the literature data, the DP was similar for blue honeysuckle berries (2.5−6.1),[13] but lower than for chokeberry fruits (23),[28] lowbush blueberry (∼15),[29] and quince fruits (8.3−11.2).[14] Lower DP value means that the sour cherry fruits are characterized by lower astringency than other fruits. Bitterness and astringency in fruits and fruit-based products depend on the flavonol content, DP, and residual pectin.[30]

*Anthocyanins.* Red color of the sour cherry is mainly due to anthocyanins. A total of 11 anthocyanins were detected across all the investigated fruits, including 8 cyanidins, 1 pelargonidin, and 2 peonidins (Table 2). However, the profile was not the same for all the cultivars. Five main anthocyanins, i.e., cyanidin-3-*O*-sophoroside, cyanidin-3-*O*(2′-glucosyl)rutinoside, cyanidin-3-*O*-glucoside, cyanidin-3-*O*-rutinoside, and peonidin-3-*O*-rutinoside, detected in the studied sour cherry cultivars, were the same as those identified in different cultivars by other authors.[8,12,31,32]

This is the first time that acylated anthocyanins such as *p*-coumaric acid (peonidin-3-(6′-*p*-coumaroylglucoside)glucoside with $[M + H]^+$ at $m/z$ = 771 and cyanidin-3-(6′-*p*-coumaroyl)glucoside with $[M + H]^+$at $m/z$ = 595) have been identified. The rest of the anthocyanins were non-acylated compounds; however, there were mono- and diglucosides (cyanidin-3-*O*-diglucoside-5-glucoside with $[M + H]^+$ at $m/z$ = 773; cyanidin-3,5-pentoside-hexoside with $m/z$ = 581; cyanidin-3-*O*-(xylosyl)-rutinoside with $[M + H]^+$ at $m/z$ = 727; pelargonidin-3-*O*-(2′-glucosyl)-rutinoside) with $[M + H]^+$ at $m/z$ = 741, and peonidin-3-*O*-rutinoside with $[M + H]^+$ at $m/z$ = 609). The main sour cherry anthocyanins were glycosides of cyanidin ($[M + H]^+$ at $m/z$ = 287), and among 8 various cyanidin derivatives, cyanidin-3-*O*-(2′-glucosyl)-rutinoside and cyanidin-3-*O*-rutinoside were the most abundant.

Total anthocyanin levels ranged from 994.00 mg/100 g dm in 'Sabina' cultivar to 844.77 mg/100 g dm in 'Wisok' cultivar. 'Safir', 'Książęca', 'Fortuna', 'Erdi botermo', and 'Nana' cultivars also showed high content of anthocyanins, but it was low in 'Karneol' (91.40 mg/100 g dm), 'Wilena' (199.71 mg/100 g dm), 'Pandy' (292.05 mg/100 g dm), and 'Groniasta' (238.01 mg/100 g dm) (Table 3). The fruits of 'Karneol' cultivar were typically the lightest in color, and therefore their anthocyanin content was lower than in the other examined cultivars.

Total anthocyanin levels in our study were comparable to those reported for other fruits and berries. The total anthocyanin content of sweet cherry cultivars was 7.56−94.20 mg/100 g of fresh weight (fw),[20] in red grape it was 316−1911 mg/100 g fw,[33] in black currant 1044−1568 mg/100 g dm,[34] in blackberry 126−152 mg/100 g fw,[35] and in blueberries 650−2290 mg/100 g fw.[36] Some of our results were comparable with these outcomes, and it can be concluded that the sour cherry cultivars were found to be a good source of anthocyanins among fruit species. The anthocyanin content and their composition in fruits depend on environmental factors, as

**Table 3. Concentrations of Anthocyanins, Flavan-3-ols, Hydroxycinnamic Acids, and Flavonols and Flavons (in mg/100 g dm) in the Fruit of Sour Cherry Cultivars, Estimated by UPLC[a]**

well as on postharvest processing conditions and analytical methods.[37]

Concerning anthocyanin distribution, there were significant differences ($p < 0.05$) in the content of individual anthocyanins among the examined cultivars (Table 3). In general, cyanidin-3-*O*-(2′-glucosyl)-rutynoside was a predominant compound in the sour cherry fruits, with a mean range of 57% of the total anthocyanins. The next most abundant was cyanidin-3-*O*-spohoroside with a mean range of 20%, and finally cyanidin-3-*O*-rutinoside, with a mean range of 19%. The other anthocyanins were of minor importance. Cyanidin-3-*O*-xylosyl-rutinoside was detected and quantified only in some Polish cultivars, i.e., 'Wifor', 'Winer', and 'Wisok'. These anthocyanins are typically present in red currant berries.[35,38]

*Hydroxycinnamic Acids.* Hydroxycinnamic acids were the next major group of sour cherry polyphenols. The identification of hydroxycinnamic acid derivatives and their conjugates is presented in Table 2. Tentative identifications were made according to the UV/vis spectra, MS and MS/MS spectra, and molecular ions $[M - H]^-$. Retention times compared with standards were identified for four derivatives of caffeoylquinic acid: noechlorogenic acid, chlorogenic acid, 4-*O*-caffeoylquinic acid with $[M - H]^-$ at $m/z = 353$, and 3,5-dicaffeoylquinic acid with $[M - H]^-$ at $m/z = 515$ (Table 2). The presence of 4-*O*-caffeoylquinic acid and 3,5-dicaffeoylquinic acids has not been reported in sour cherry fruits until now. In addition, one ion was identified $[M - H]^-$ at $m/z = 337$ as corresponding to *p*-coumarylquinic acid derivatives, one of which was classified as 3-*p*-coumarylquinic acid. Similar configuration of these compounds was described in plum fruits,[39] belonging to the same family.

Contrary to anthocyanidins, the same hydroxycinnamic acid compounds were present in each cultivar, but there were differences in their relative levels. In almost all cultivars, neochlorogenic acid (~47%) was the major hydroxycinnamic acid derivative, followed by chlorogenic acid (~30%) and *p*-coumaroylquinic acid (~19%). The highest concentration of hydroxycinnamic acids was found in 'Morina' and 'Dradem' cultivars (1200.90 and 1108.29 mg/100 g dm, respectively), and the lowest in 'Agat' and 'Fortuna' cultivars (258.86 and 286.26 mg/100 g dm, respectively).

In some sour cherry cultivars, such as 'Sabina', 'Fanal', 'Safir', 'Wilena', 'Nana', 'Dradem', 'Cesarzowa Eugenia', 'Wilga', 'Stevensbaer', 'Łutówka', and 'Winer', the levels of chlorogenic acid were found to be higher than those of neochlorogenic acid. Additionally, in the cultivars such as 'Agat', 'Erdi botermo', 'Skierka', Nana', 'Dradem', 'Stevensbaer', 'Winer', and 'Wisok', the levels of 3-*p*-coumarylquinic acid were found to be higher than those of neochlorogenic acid. However, for many other cultivars the content of this acid was lower than 50 mg/100 g dm. The content of 3,5-dicaffeoylquinic acid was very stable (except in 'Groniasta' cv), and in all the analyzed cultivars it ranged between 7.28 and 50.02 mg/100 g dm (Table 3). Mozetic et al.[40] demonstrated that the levels of hydroxycinnamic derivatives changed during ripening. A change in the ratio of neochlorogenic acid and *p*-coumaroylquinic acid could also be due to the hydroxylation of *p*-coumarylquinic acid to neochlorogenic acid during biosynthesis pathways.

In the present study, the concentrations of hydroxycinnamic acid derivatives were higher than in sweet cherry[20,41−43] blue honeysuckle[13] or plums,[39] lower than in quince fruits,[14] and comparable to black currant fruits.[35,38] The concentration of phenolic acids, especially of chlorogenic acid, is very important, because these compounds are the precursors of flavor.[44]

*Flavonols and Flavon.* Three types of flavonol derivatives with a fragment at $m/z$ 301, 285, and 315, characteristic for quercetin, kaempferol, and rhamnetin derivatives, respectively, were found in the sour cherry fruits (Table 2).

In this study, four quercetins, i.e., 3-*O*-rutinoside-glucoside ($[M - H]^-$ at $m/z = 771$), 3-*O*-glucosidedirhamoside ($[M - H]^-$ at $m/z = 755$), 3-*O*-rutinoside ($[M - H]^-$ at $m/z = 609$), and 3-*O*-galactoside ($[M - H]^-$at $m/z = 463$) were found, at a wavelength characteristic for these compounds $\lambda_{max} = 350$ nm. Similar results were obtained for kaempferol derivatives, which were identified as trihexose with $[M - H]^-$ at $m/z = 773$; dihydrokaempferol-dihexoside, and dihydrokaempferol-glucoside with $[M - H]^-$ at $m/z = 611$ and 449, respectively, and kaempferol-3-*O*-rutinoside with $[M - H]^-$at $m/z = 593$ at $\lambda_{max} = 340$ nm. Additionally, two derivatives of isorhamnetin, i.e., -3-rutinoside-7-rhamnoside and -3-*O*-rutinoside, were identified with $[M - H]^-$at $m/z = 769$ and 623, respectively. Some of these compounds were previously reported in sour cherry pomace by Kolodziejczyk et al.[26] However, neither naringenin nor genistin was found by these authors.

Additionally, one flavon was identified as apigenin derivative, according to its UV spectrum and MS fragmentation. This compound was apigenin aglycone $[M - H]^-$ at $m/z = 269$, in a negative mode at 7.26 min, with $[M - H]^-$ at $m/z = 431$, and characteristic $\lambda_{max} = 241$ and 340 nm of apigenin-7-*O*-glucoside. Chaovanalikit et al.[31] suggested the presence of this flavon compound in the sour cherry. This is the first time the identification and quantification of so many flavonol and flavon derivatives were performed in the sour cherry fruit. Previous work by Serra et al.[23] indicated the presence of quercetin-3-*O*-rutinoside and quercetin-3-*O*-glucoside. Kirakosyan et al.[32] claimed quercetin, kaempferol, and isorhamnetin rutinoside to be the main flavonol compounds in the tart cherry. Quercetin derivatives even than rarely the major polyphenolic compounds of fruits, they are very important for human health.[45] Flavonols are also effective antioxidants. Their high antioxidant potential is due to 3′,4′-dihydroxy substitution in B-ring and conjugation between A and B rings. In general, flavones have higher antioxidant activity as compared with anthocyanins with the same hydroxylation patterns measured with ORAC assay.[46]

Among the five groups of phenolic compounds identified is the sour cherry fruits, flavonols and flavon were found to be the least abundant. Major compounds in this group were quercetin-3-*O*-rutinoside (8−52% of total flavonol+flavon) > kaempferol-3-*O*rutinoside (18−64%) > isorhamnetin-3-*O*-rutinoside (0−57%); less abundant compounds included quercetin-3-glucoside-dirhamnoside (2−10%) and isorhamnetin-3-rutinoside-7-rhamnoside (0−11%), but the other compounds were present in trace amounts and not in all cultivars (Table 3). Total content of flavonols in the sour cherry samples ranged from 82.07 to 374.17 mg/100 g dm. The cultivars showing the highest content of flavonols were 'Erdi botermo', 'Norstar', 'Wołyńska', 'Meteor Korali', and 'Safir', whereas 'Wifor' and 'Lucyna' cultivars were characterized by the lowest flavonoid content. Kirakosyan et al.[32] reported comparable amounts of flavonols in the sour cherry cultivars to those presented in this study. The concentration of apigenin-7-*O*-glucoside amounted to 11.98 mg/100 g dm for the 'Nordstar', but it was detected in only 17 other cultivars.

**Antioxidant Activity in Sour Cherry Fruits.** Three in vitro assays, based on the scavenging activity of the stable oxygen radical absorbance capacity (ORAC) assay, ABTS radical scavenging capacity assay, and ferric reducing antioxidant potential (FRAP) assay, were used as complementary methods to evaluate the potential antioxidant activity of sour cherry fruits (Table 4). Significant differences were observed among the cultivars with reference to these three assays, but all the cultivars revealed the same trend. Antioxidant activity of the sour cherry evaluated using the ORAC assay was 8.13−38.11 mmol TE/100 g dm; for ABTS assay it was 3.72−18.40 mmol TE/100 g dm, and for FRAP assay it amounted to 1.93−12.95 mmol TE/100 g dm. 'Książęca', 'Erdi Nagygyümöscu', and 'Groniasta' cultivars showed the lowest antioxidant potential, and 'Łutówka', 'Fanal', 'Topaz', and 'Wołyńska' were characterized by the highest antioxidant activity among all the investigated cultivars across all the assays.

**Table 4. Antioxidant Activity of Sour Cherry Cultivars Measured by ABTS, FRAP, and ORAC Methods, Expressed as mmol Trolox/100 g dm[a]**

| cultivar | ABTS | FRAP | ORAC |

[a]Values are means of three repetitions.

Literature data[16,24,35,47,48] indicate that not only the total content of polyphenolic compounds played a very important role in antioxidant activity, but also the type of phenolic compounds, i.e. anthocyanins, was essential. Our results suggest that antioxidant activity of the sour cherry is not related to the presence of anthocyanins, but may be ascribed to polymeric procyanidins. Significant positive correlations were found only between the results of total antioxidant assays and polymeric procyanidins (Pearson correlation = 0.742, 0.692, and 0.482 for ORAC, ABTS, and FRAP, respectively). Our results indicated that these compounds markedly contributed to the total antioxidant capacity in the investigated fruits.

Rice-Evans et al.[47] discussed the relationship between the antioxidant potential of polyphenols and their chemical structure and claimed that hydroxylation of B ring and glycosylation had a strong influence on the antioxidant potential of phenolic compounds. Bandoniene et al.[48] tested kinetic behaviors of different antioxidants present in apple and apple extract with the HPLC/DPPH method and showed that the antioxidant activity was to the greatest extent influenced by polyphenolic compounds from the group of flavan-3-ols, such as (+)-catechin and (−)-epicatechin, as well as their oligomers, i.e., procyanidin dimer and trimer (B1, B2, and C1). Khoo et al.[6] pointed out that the sour cherry biologically active antioxidants involved not only anthocyanins, but colorless phenolics also exerted an important antioxidant impact by affecting the plant biological performance. Usenik et al.[42] reported that the relationship between antioxidant activity and total anthocyanin content varied between cultivars from $r^2$ = 0.01 to 0.99. According to these authors, antioxidant activity depended on different chemical attributes and was cultivar-specific. Their study showed that some cultivars of sweet cherry ('Ferrador' cv) contained low levels of phenolic compounds and anthocyanins, but exhibited very high antioxidant activity. Comparable results was observed in our study for 'Książęca' cultivar. Goncalves et al.[49] found that the antioxidant activity of sour cherries correlated with the content of *p*-coumaroylquinic acid and also tended to correlate with catechin monomer concentration.

**L-Ascorbic Acid in Sour Cherry Fruits.** Fruits are generally a good source of ascorbic acid (vitamin C). The content of ascorbic acid in individual sour cherry cultivars differed greatly, ranging from 5.45 to 22.11 mg/100 g fw (Table 5). The highest ascorbic acid content (up to 18 mg) was detected in 'Morina', 'Meteor Korai', 'Erdi botermo', 'Wilena', and 'Stevensbaer' cultivars. Ascorbic acid content in most of the analyzed variations was lower than 10 mg, as was the case in e.g. 'Książęca', Erdi Nagygyümöscu', 'Fortuna', 'Sabina', 'Skierka', 'Nordstar', 'Turgieniewka', 'Safir', 'Nana', 'Karneol', 'Keleris 14', Ametyst', 'Łutówka', and 'Wifor' cultivars. In addition, ascorbic acid concentration in these cultivars was lower than in other fruits, well known for their high ascorbic acid content, such as kiwi (29−80 mg/100 g fw)[50] or cornelian cherries (31−112 mg/100 g fw).[51] However, the content of ascorbic acid found in this study was comparable with quinces (6−26 mg/100 g fw),[14] nectarines (4.8−13.2 mg/100 g fw),[52] peaches (3.6−12.6 mg/100 g fw),[52] plums (2.5−10.2 mg/100 g fw),[52] and blue honeysuckle (4.86−20.69 mg/100 g fw).[53] Additionally, we found no significant correlation between the results of total antioxidant activity assays and vitamin C content.

**Fruit Weight, Dry Matter, Soluble Solids, pH, Total Acidity, and Total and Reducing Sugar in Sour Cherries Fruits.** The main physicochemical characteristics of 33 sour

[a]Values are means of three repetitions. Abbreviations and units: FW, fruits weight (g); dm, dry matter (%); SSC, total soluble solids content (°Brix); TA, total titratable acidity (g malic acid/100 g); TS, total sugars (mg/100 g); RS, reducing sugars (mg/100 g); MI, maturity index (−); A, ash (%); P, pectins (%); AA, ascorbic acid (mg/100 g).

cherry cultivars were evaluated in this study. Some of these cultivars ('Agat', 'Ametyst', 'Dradem', 'Lucyna', 'Sabina', 'Wanda', 'Wible', 'Wifor', 'Wilena', 'Wilga', 'Winer', 'Wisok') were new Polish cultivars, investigated for the first time (Tables 1 and 5).

Fruit size is a varietal characteristic that may fluctuate depending on climatic and agricultural conditions. Fruit weight depends on fruit load, agricultural conditions, and fruit maturity stage.[53] Average fruit weight in our study ranged from 2.10 g ('Stevensbaer') to 6.10 g ('Ksiażęca') (Table 5). Many of the investigated cultivars had larger fruits than the mean value of 4.15 g. Especially interesting were 'Keleris 14', 'Pandy', 'Fanal', 'Sabina', 'Erdi botermo', 'Safir', 'Karneol', 'Erdi Nagygyümöscu', and 'Topas' cultivars, characterized by the largest fruits (Table 5). In contrast, new Polish cultivars, such as 'Wilbek', 'Wołyńska', 'Wisok', and 'Wilena', were characterized by rather small fruits, lighter than 3.00 g. The above-mentioned variability of weight parameter of sour cherry fruits is important for industrial processing effectiveness and for efficient depitting procedure, especially in the case of products where the shape of the fruit should be retained after processing. Additionally, the weight and size of berries play important roles in the evaluation of fruit quality and clearly affect consumers' acceptance.

Differences were found among the analyzed sour cherry cultivars in dry matter, total soluble solids (SSC), pH, total titratable acidity (TA), reducing sugars, and maturity index (MI) (Table 5).

The lowest dry matter and SSC values were determined for 'Fortuna' (13.71% and 12.9°Brix, respectively), 'Erdi Nagygyümöscu' (14.37% and 13.3°Brix, respectively), and 'Książęca' cultivars (14.71% and 13.5°Brix, respectively). The highest dry matter and SSC content were observed in 'Morina' (21.89% and 20.3°Brix, respectively), 'Wilena' (21.33% and 20.6°Brix, respectively), 'Stevensbaer' (25.96% and 25.2°Brix, respectively), and 'Wołyńska' cultivars (20.88% and 19.8°Brix, respectively). Compared to other fruits, SSC content in sour cherry was similar to that in pomegranate (10.0−16.5°Brix)[54,55] and cornelian cherry (14.4%),[51] but higher than in raspberry (7.1−8.8°Brix).[58]

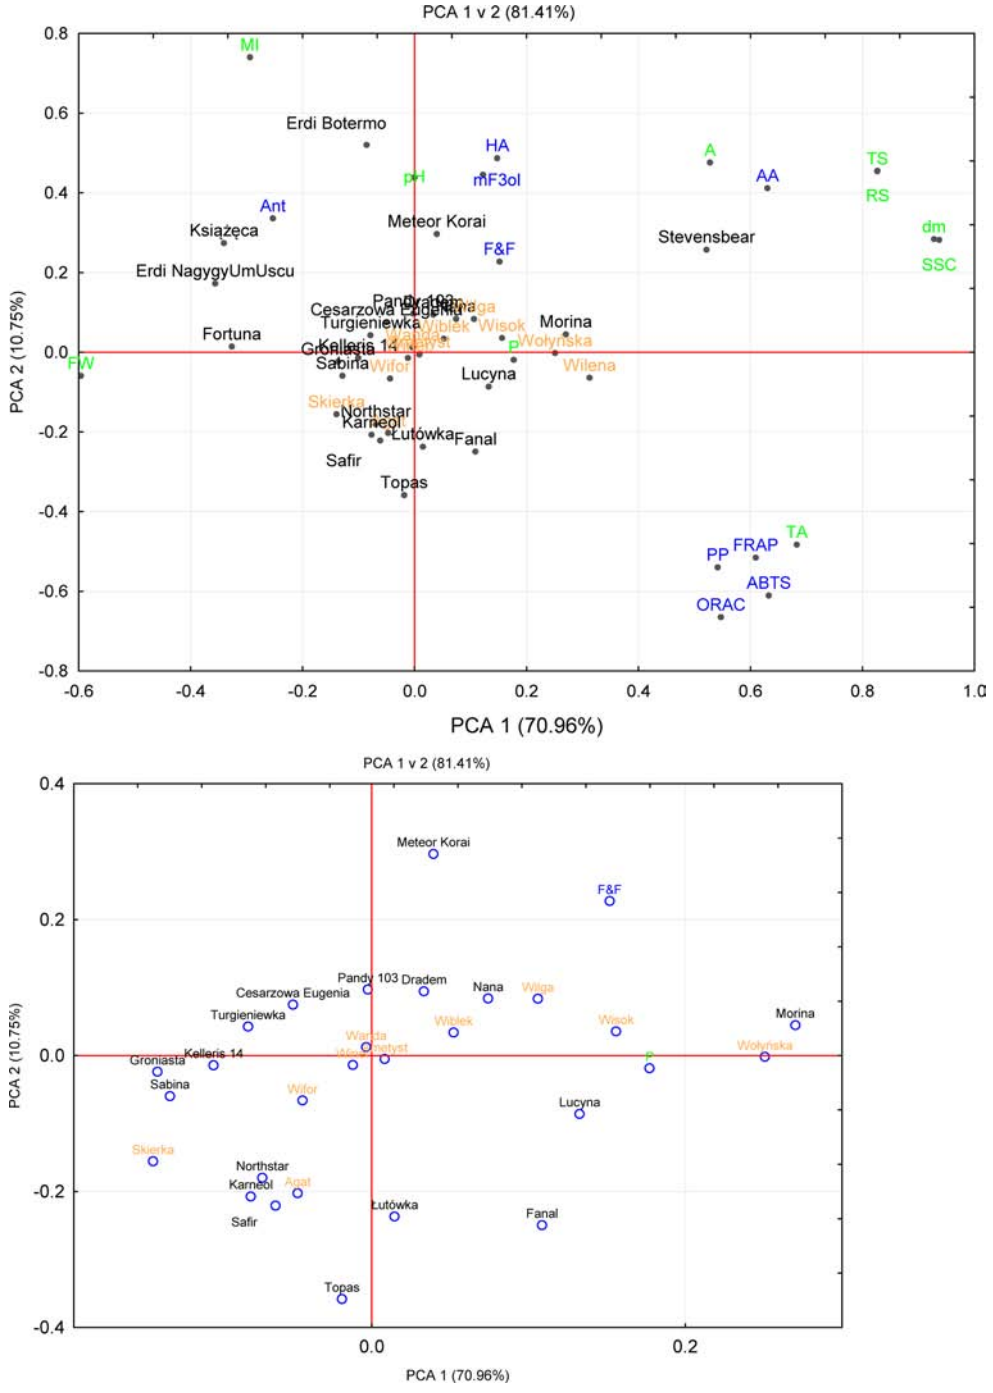

**Figure 1.** PCA map (top, and bottom, zoom) showing the relationship among phytochemical profile and health-related compounds of sour cherry fruits.

pH values of the sour cherry ranged from 3.04 in 'Topas' and the highest pH of 3.55 was recorded in both 'Keleris 14' and 'Cesarzowa Eugenia' cultivars. 'Książęca', 'Erdi Nagygyümöscu', and 'Fortuna' cultivars were the least acidic, with TA value of 0.90, 0.97, and 0.96 g of malic acid/100 g fw, while the fruits of 'Topas', 'Wilga', 'Stevensbaer', and 'Wisok' cultivars were the most acidic, with TA value of 2.67, 2.21, 2.11, and 2.23 g of malic acid/100 g fw, respectively. These pH and TA values were lower than reported for the sweet cherry.[20] However, these results were in agreement with other data reported in the literature for blue honeysuckle,[13] pomegranate,[55] or cornelian cherry.[51] In general, sour cherry fruits are rich in organic acids, and this characteristic confers a distinct sour taste of these fruits.

Maturity index (MI = SSC/TA) appears to be a key factor responsible for the taste and flavor of fruits and the factor influencing consumers' preference and acceptance. Some authors[13,21,55] used the maturity index to classify fruit cultivars as sour, sour-sweet, and sweet. MI in the analyzed sour cherry cultivars varied considerably from 5.7 in 'Topas' to 15.3 in 'Erdi botermo' and 'Książęca'. According to a classification established for the analyzed fruits, most of the cultivars were soursweet rather than only sour or only sweet.

dx.doi.org/10.1021/jf504023z | J. Agric. Food Chem. 2014, 62, 12332−12345

Total sugar content in the sour cherry cultivars varied between 9.09 and 16.33%, and reducing sugar between 8.33 and 14.41%. The lowest level of total and reducing sugars was detected in 'Fortuna' (9.09% and 8.33%), 'Skierka' (9.20% and 8.42%), 'Topas' (9.61% and 8.82%), and 'Karnelo' (9.89% and 8.85%), and the highest in 'Nana' (12.97% and 12.01%), 'Wilena' (13.27 % and 12.10%), 'Morina' (13.25% and 12.25%), and 'Stevensbaer' cultivars (16.33% and 14.41%) (Table 5). The content of total sugars in sour cherry fruit was lower than in apples,[56] but higher than in cornelian cherry.[51]

The investigated sour cherry cultivars differed in their ash composition. Mineral composition of fruits depends not only on the species or cultivars, but also on the growing conditions, such as soil and climate-related factors.[57] Only in 'Stevensbaer' and 'Wołyńska' cultivars was the content of ash higher than in the other analyzed fruits. The rest of analyzed cultivars were characterized low ash content, especially 'Topas', 'Groniasta', 'Sabina', 'Wanda', 'Łutówka', 'Lucyna', 'Turgieniewka', 'Safir', and 'Winer' (< 0.50% ash content).

Fruits are essential dietary components and a good source of pectins. The highest pectin level was found in 'Wilena' cultivar (0.72%), while extremely low content was detected in 'Northstar', 'Karneol' (0.14%), and 'Dradem' cultivars (0.19 %). Some cultivars of raspberry[58] and blue honeysuckle berries[13] contained more pectins than sour cherry fruits.

Many of the discussed factors depend on the cultivar, but also on a number of environmental conditions.[57,59]

**Principal Component Analysis (PCA).** To better understand the trends and relationships among the 43 different sour cherry cultivars, principal component analysis (PCA) was applied (see Figure 1). When considering the first two dimensions of the biplot (PCA1 and PCA2), quality parameters and contents of bioactive compounds explained 81.41% of the variation. The results obtained from PCA, using the linkage method among groups, indicated the presence of four clusters:

(1) 'Fanal', 'Wołyńska', 'Ametyst', 'Lucyna', 'Wilena', and 'Łutówka' cultivars, characterized by high content of polymeric procyanidins (PP) and high total antioxidant activity (e.g., ABTS, FRAP, and ORAC). Additionally, high levels of total acid (TA) and pectins (P) were detected in these cultivars.

(2) 'Stevensbaer', 'Meteor Korai', 'Morina', 'Wołyńska', 'Wisok', 'Wilga', 'Nana', 'Wibek', 'Dradem' cultivars, characterized by high content of polyphenols (hydroxycinnamic acid (HA), stotal amount of (+)-catechin, and (−)-epicatechin (mF3ol), flavonols and flavon (F&F), and L-ascorbic acid (AA). Fruits in these cultivars were scored high in such parameters as dry matter (dm), total soluble solids (SSC), total and reducing sugars (TS and RS), and ash (A).

(3) 'Erdi Botermo', 'Książęca', 'Erdi Nagygyumuscu', 'Fortuna', 'Cesarzowa Eugenia', 'Pandy 103', 'Turgieniewka', 'Keleris 14' and 'Wanda' cultivars, characterized by high content of anthocyanins (Ant). Fruits located in this cluster high correlated with maturity index (MI).

(4) 'Groniasta', 'Keleris 14', 'Winer', 'Skierka', 'Sabina', 'Northstar', 'Karneol', 'Agat', 'Safir', and 'Topas' cultivars, with typically high fruits weight but additionally positive correlation with antioxidant activity (ABTS, FRAP, ORAC) and content of polymeric procyanidins (PP) but negative correlations with other phenolic compounds such as HA, mF3ol, and F&F.

In this study, fruit quality parameters and chemical properties of 33 sour cherry cultivars grown in Poland were evaluated. The results confirm the correlation between a cultivar and the content of bioactive compounds and antioxidant activity of sour cherry fruits, which possibly affect dietary choices. Therefore, the sour cherry cultivars used as progenitors in a breeding program are vital for generating new cultivars with high content of bioactive compounds. On the other hand, a high number of evaluated cultivars, from different genetic origins and with large phenotypic variability, constitutes a considerable contribution on sour cherry species, especially for breeding purposes. New Polish cultivars, particularly 'Wider', 'Winer', 'Wilena', 'Wisok', and 'Ametyst', are promising, but they should be constantly improved through breeding programs to refine their functional properties.

## MATERIALS AND METHODS

**Animals and Samples Preparation.** Forty, 47 week-old Single Comb Hy-Line Brown Leghorn hens, purchased from Sangol Egg Farm (Sancheong, Korea), were housed in individual cages in a room with a light regimen of 15 h light and 9 h dark (lights on at 6:00 AM) and an ambient temperature of 20 ± 2 °C during the entire experimental period. A commercial layer diet and tap water were provided *ad libitum*. This study was approved by the Institutional Animal Use and Care Committee of Gyeongsang National University (GAR-101020-X0007).

After adaptation to the experimental environment for the first 14 days, hens were divided into two groups, each of which was provided for the next 14 days with either ethanol (Control) or corticosterone (Stress)-containing diet at 30 mg/kg.[3,14] A commercial layer diet (Nonghyup Feed Co., Ltd., Seoul, Korea), which was used as a basal diet for the adaptation, was mixed for 30 min in a mixer with ethanol (95%) with or without corticosterone (92%, Sigma) at 2.61 mg/mL to produce either Stress or Control diet, respectively. Therefore, ethanol in the diet (12.5 mL/kg) was completely evaporated at the end of the 30 min mixture.

For each hen, feed intake, egg production and egg weight were monitored daily in the morning and body weight measured weekly throughout the experimental period. Eggs, laid by the same laying hens on 0 and 5 days (days 0 vs 5) after the initiation of providing hens with the experimental diets, were selected for the ongoing proteomic analysis as egg production started to decrease around day 5 by 30% (Figure 1). Immediately after being manually separated from the egg

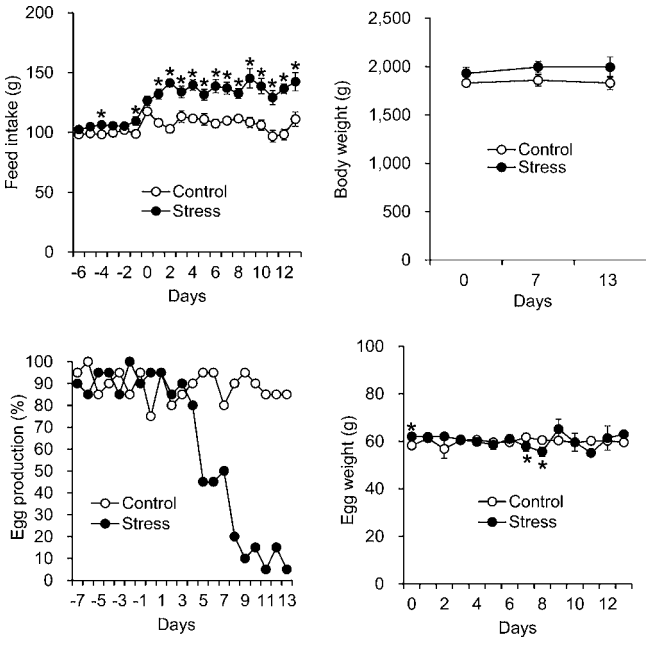

**Figure 1.** Feed intake (g), body weight (g), egg production (%), and egg weight (g) in laying hens. Hens were acclimatized to the experimental environment for the first 2 weeks (days −14 to 0) and then were divided into two groups to receive either ethanol- (Control) or corticosterone- (Stress) containing diet at 30 mg/kg for the next 2 weeks (days 0−14), respectively. Data are means ± SEM ($n$ = 20 per group). *$P \leq 0.05$ vs Control.

yolk, the egg white was freeze-dried using a lyophilization freeze-dryer (#PVTFD50A, Ilshin Bio Base, Dongduchen, Korea) and then stored at −80 °C. Hens, which had a mean egg production of higher than 90% and their egg weights of being higher than 60 g during the adaptation period (63.4 ± 0.46 g in average), were selected for the study.

At the end of the entire experimental period (day 14), hens were killed using a guillotine and blood was collected from the trunk into 10 mL tubes treated with sodium heparin (BD, Franklin Lakes, NJ, USA) followed by centrifugation at 2 000*g*, 4 °C for 10 min. Plasma obtained was stored at −80 °C for further analysis. Organs including the oviduct were sectioned off, frozen in liquid nitrogen, and stored at −80 °C for later analysis. The magnum was cut into three parts of similar length before being stored at −80 °C, and the middle one was used for subsequent analysis.

**Corticosterone Assay.** Corticosterone concentrations in plasma were determined in duplicates each sample by ELISA using a kit (#ADI-901−097, Enzo Life Sciences, Farmingdale, NY, USA), according to the manufacture's instruction. Optical density was measured at 405 nm using a Multiskan FC Microplate Photometer (#51119000, Thermo Scientific, Waltham, MA, USA). Inter- and intra-assay coefficients of variations of this assay were 8.2% and 8.4%, respectively.

**Reagents and Apparatus.** Sodium dodecyl sulfate (SDS), phenyl methanesulfonyl fluoride (PMSF), tris(hydroxymethyl)aminomethane (Tris), urea, thiourea, 3-[(3-cholamidopropyl)dimethylammonio]-1-propanesulfonate hydrate (CHAPS), dithiothreitol (DTT), glycerol, bromophenol blue, isopropanol, silver nitrate, sodium thiosulfate pentahydrate and iodoacetamide were purchased from Amresco (Cochran, GA, USA); protease inhibitor cocktail from Roche (Indianapolis, IN, USA); agarose from GeorgiaChem (Suwanee, GA, USA); trypsin from Promega (Fitchburg, WI, USA); potassium ferricyanide, ammonium bicarbonate (ABC), ∂-cyano-4-hydroxycinnamic acid (CHCA), trifluoroacetic acid (TFA), formaldehyde and ethidium bromide (EtBr) from Sigma (St. Louis, MO, USA); 2-D Quant kit and immobilized pH gradient (IPG) buffer from GE Healthcare Life Sciences (Little Chalfont, UK); PrimeScript first strand cDNA synthesis kit from Takara (Ootsu, Japan); SYBR Green PCR Master Mix and Sequazyme Peptide Mass Standard Kit (Calibration 1) from Applied Biosystems (ABI, Foster City, CA, USA); IPG strip (pH 4−10 Nonlinear (NL), 180 × 3 × 0.5 mm) from Genomine (Pohang, Korea); Gradi-Gel II gradient PAGE analysis kit from Elpis (Daejeon, Korea); methanol, acetic acid and acetonitrile (ACN) from DaeJung (Siheumg, Korea); and Easy-spin total RNA extraction kit from Intron (Sungnam, Korea).

**Extraction of Solubilized Proteins from Egg White for Proteomics.** Lysis buffer A consisted of 1% SDS, 1 mM PMSF, protease inhibitor cocktail, and 100 mM Tris-HCl (pH 6.8), and lysis buffer B of 7 M urea, 2 M thiourea, 4% CHAPS, 0.1 M DTT, and 40 mM Tris-HCl (pH 6.8). One gram of dried egg white was ground into fine powder using a mortar and a pestle. Twenty mg of powdered egg white was dissolved in 25-fold volume lysis buffer A of the weight of egg white (v/w) and then dissolved in the same volume of lysis buffer B as lysis buffer A. The solution was shaken gently at room-temperature (RT) for 1 h, followed by sonication with a 2 s-on and 9 s-off cycle for five times. After incubation at RT for 1 h, this solution was centrifuged at 15 000*g*, 4 °C for 20 min to remove debris. The supernatant was incubated at 4 °C for 1 h and then the process was repeated twice to remove debris. The solubilized protein extracts were quantified using a 2-D Quant kit (#80-6483-56, GE).

**SDS-PAGE.** Egg white protein (10 μg) was diluted in a buffer (2% SDS, 10% glycerol, and 125 mM Tris-HCl (pH 6.8)), which was loaded on 4−20% premade SDS polyacrylamide gels (#84713, Thermo Scientific) at 20 mA, RT for 3 h until the bromophenol blue dye, containing a standard protein marker (#161-0374, Bio-Rad, Hercules, CA, USA) of 10−250 kDa, disappeared from the bottom of the gel.

**Two-Dimensional Electrophoresis (2DE).** Egg white protein (200 μg) was mixed in rehydration buffer (7 M urea, 2 M thiourea, 4% CHAPS, 2.5% DTT, 10% isopropanol, 5% glycerol, and 2% IPG buffer) to a total volume of 450 μL. The sample was loaded onto a swelling tray in which IPG strips (pH 4−10 NL) were allowed to be rehydrated overnight. The first dimensional isoelectric focusing (IEF) was then performed using an IEF unit (#28926930, Ettan IPGphor 3, GE) at 20 °C, 50 V for 30 min, 100 V for 30 min, 250 V for 1 h, 8 000 V gradient for 9 h and 8 000 V for 6 h. The IPG strips were placed for 15 min in an equilibration solution (6 M urea, 30% glycerol, and 2% SDS, and 50 mM Tris-HCl (pH 8.8)) containing 1% DTT, and then

treated with the same equilibration solution containing 2.5% iodoacetamide for 15 min. The second dimensional separation was performed on 7.5% SDS polyacrylamide gels using a Gradi-Gel II gradient PAGE analysis kit (#EBA-1056, Elpis). The gels were placed into a Protean II XL for 2DE (#165−3188, Bio-Rad) at 20 mA, RT for 18 h until the bromophenol blue dye, with the standard protein marker of 10−250 kDa (Bio-Rad), disappeared from the bottom of the gel. After the electrophoresis, the gels were fixed in a fixation solution (38% water, 50% methanol, and 12% acetic acid) overnight and stained in a silver nitrate solution as previously described.[15] Gel images were scanned using an imaging densitometer (#GS-800, Bio-Rad), and the intensity of protein spots from 3 gel images each group was processed using an image master (#28−9380−55, Image Master 2D Plantinum, v.7.0, GE), followed by the determination of molecular weights of the spots.

**Matrix-Assisted Laser Desorption−Ionization Time-of-Flight/Time-of-Flight Mass Spectrometry/Mass Spectrometry (MALDI-TOF/TOF MS/MS).** Selected spots were excised out from 2DE gels and subjected to in-gel digestion with trypsin as previously described.[15] Shortly, each of the spots predetermined by the image analysis was repeatedly picked up using a pipet tip into a 1.5 mL tube, and a destaining process was performed to remove the silver dye. Individual protein spots, 50 μL of 30 mM potassium ferricyanide, and 50 μL of 0.1 M sodium thiosulfate pentahydrate were vortexed for 1 min and spun down to remove the supernatant. To break the disulfide bonds, the samples were incubated in 0.1 mL of 10 mM DTT in 0.1 M ABC at 56 °C for 45 min and then the supernatant was removed after centrifugation. For alkylation, they were incubated again in 0.1 mL of 55 mM iodoacetamide in 0.1 M ABC at RT for 30 min, and then spun down to remove the supernatant. Individual precipitates were incubated with 5 μL of 50 ng trypsin in order to cleave peptide chain mainly at the carboxyl side of the amino acids lysine or arginine in 25 mM ABC at 37 °C overnight for in-gel digestion and spun down to collect the supernatant. The digested products were then dried using a vacuum concentrator (Ecospin 3180C, Hanil Science Industrial, Incheon, Korea) and stored at −20 °C. The peptides, dissolved in 1 μL of matrix solution (0.05 g CHCA in 0.1% TFA/50% ACN), were eluted onto a MALDI plate (#1016629, ABI), and was air-dried in a clean bench. MS and MS/MS analyses were performed on an ABI 4800 Plus TOF-TOF Mass spectrometer (ABI) using a mass standard kit (calibration mixture 1, ABI), according to the method described by Kwon et al.[15] The spectrometer used a 200 Hz ND:YAG laser operating at 355 nm and air as a collision gas. At least, ten most intensive ionized peptides per MALDI spot, with signal/noise ratios >25, were selected for subsequent MS/MS analysis in 1 kV mode and 1 000−1 500 consecutive laser shots. MS/MS spectrum data were searched against the UniProt Knowledgebase (UniProtKB) by ProteinPilot (v.3.0) in combination with MASCOT as the database search engine and with peptide and fragment ion mass tolerance of 50 ppm. Both carbamidomethylation of cysteine and oxidation of methionine were taken into account during the search of the peptides. High confidence identifications had statistically significant search scores which were equivalent to the expected values on the MASCOT at $P \leq 0.05$ and were consistent with the pI and MW of the individual proteins, which accounted for the majority of ions present in the mass spectra.

**mRNA and Protein Expression Analysis of the Magnum.** Total RNA was isolated from homogenized magnum tissue using an Easy-spin total RNA extraction kit (#17221, Intron), according to the manufacturer's protocol. One hundred mg of frozen magnum tissue was homogenized in 1 mL of lysis buffer (Intron). Each of the homogenized samples was mixed with 200 μL of chloroform and then centrifuged at 13 000 rpm, 4 °C for 10 min to harvest the supernatant. Four hundred μL of the supernatant was mixed with 400 μL of a binding buffer (Intron) by inverting and spun down, which was incubated at RT for 1 min and loaded into a spin column (Intron). The spin column was centrifuged at 13 000 rpm, RT for 30 s, and the eluted buffer was discarded. Seven hundred μL of washing buffer (Intron) was loaded into each column and centrifuged again in the same way as before. After washing, the column membrane was dried by centrifugation at 13 000 rpm, RT for 1 min, soaked with 50 μL of the elution buffer (Intron) and then centrifuged at 13 000 rpm to extract RNA. The total amount of RNA was determined by measuring optical density at 260 nm using a Nanodrop2000C spectrophotometer (Thermo Scientific). RNA quality was assessed by loading 2.5 μg of each RNA sample on a 1% agarose gel with formaldehyde and EtBr to visualize the bands of 28S and 18S rRNA.

For magnum tissues, proteomics was performed based on the methods similar to those for egg white with some modification: magnum tissues (100−200 mg) were homogenized in lysis buffers A and B of 10-fold magnum volume, followed by incubation, sonication and centrifugation to obtain solubilized protein. Protein (150 ug) was loaded onto IPG strip (pH 4−7 L) and 12% SDS polyacrylamide gels, followed by MALDI-TOF/TOF MS/MS analysis.

**Reverse Transcription (RT) and Real-Time Quantitative PCR (qPCR).** Relative expressions of each gene encoding the proteins differentially expressed in the egg white were determined in the magnum of the oviduct. Primer sequences, shown in Table 1, were designed with software (Primer Express, v. 3.0.1, ABI), in which glyceraldehyde-3-phosphate dehydrogenase (GAPDH) served as a housekeeping gene. Two μg of RNA was reverse-transcripted using a PrimeScript first strand cDNA synthesis kit (#6110A, Takara) in a final volume of 20 μL according to the manufacturer's protocol. qPCR was then performed using a Step One Plus Real-Time PCR System (ABI) with Power SYBR Green PCR Master Mix (#4368702, ABI). Thermal cycling had 3 stages which were 1) activation of DNA polymerase at 95 °C for 10 min, 2) fluorescent detection of amplification by 40 cycles at 95 °C for 15 s and at 60 °C for 1 min, and 3) fluorescent

detection of melting curve at 95 °C for 15 s, 60 °C for 1 min, with a heating rate of 0.5 °C/s between 60 °C ~ 95 °C, and 95 °C for 15 s.

**Statistical Analysis.** All experimental data were represented as mean ± SEM. Student's *t*-test was performed using Microsoft Excel program to assess differences between Control and Stress at $P \leq 0.05$. Feed intake, body weight and egg production were measured in 20 hens each group to estimate mean values of each parameter. For corticosterone concentrations, mean values were calculated from 8 hens each group. For 2DE analysis, mean values of each spot were calculated from triplicated data in egg white samples and magnum tissues. Protein spots, which were differentially expressed at least 1.2 fold between days 0 and 5 in each group, were selected from 2DE gels, and statistically analyzed by a *t*-test ($P \leq 0.05$). Relative mRNA expression in magnum samples collected from 8 hens each group was measured in duplicates based on the $2^{-\Delta\Delta CT}$ method, and differences between both groups were analyzed by *t*-test.

## RESULTS

**Animal Study.** No hens were found dead from any of the dietary treatments during the whole period of the experiment. During the adaption period (days −7−0), feed intake, egg production, and egg weight were relatively constant. Stress resulted in significant increase in mean-daily feed intake compared with Control (days 1−7: 109 ± 1 g for Control vs 136 ± 2 g for Stress, $P \leq 0.0001$; days 8−13: 105 ± 2 g for Control vs 137 ± 2 g for Stress, $P \leq 0.0001$). No differences were, however, detected in body weight between the two groups although it was slightly higher in the Stress group throughout the entire experimental period (Figure 1). Egg production was drastically decreased to approximately 30% in Stress on day 5 while Control had about 90% (days 1−7: 89 ± 3% for Control vs 70 ± 8% for Stress, $P \leq 0.05$; days 8−13: 88 ± 2% for Control vs 12 ± 2% for Stress, $P \leq 0.0001$). Dietary corticosterone resulted in a significant decrease in the number of follicles equal to or greater than 10 mm in diameter and in increased corticosterone concentrations in plasma ($P \leq 0.05$) (Figure 2).

**Differential Protein Abundance in Egg White of Treated and Untreated Hens (Day 5 after Treatment).** Because egg production was sharply reduced around 4 days (45%) after hens started to consume dietary corticosterone while no changes were detected between the two groups during the adaptation period (Control: 89 ± 3% vs Stress: 92 ± 2%, $P \leq 0.47$, for the second week of the adaptation period), eggs produced on day 5 were used for subsequent proteomic analysis. Protein profiles of the egg white were significantly changed in the eggs laid between days 0 and 5 in Stress whereas they remained unchanged in Control (Figures 3−5). SDS-PAGE analysis showed a drastic reduction in protein bands between 37 and 50 kDa and between 50 and 75 kDa on day 5 compared with day 0 in Stress, whereas such changes were not seen in Control (Figure 5). These findings were confirmed using 2DE analysis (Figure 4).

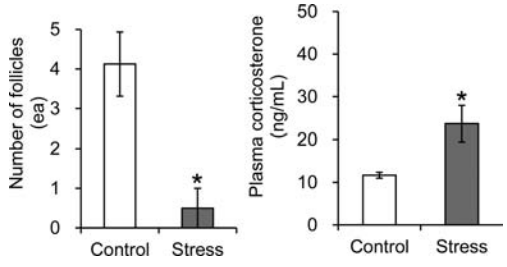

**Figure 2.** Number of follicles (≥10 mm in diameter) and plasma concentrations of corticosterone (ng/mL) in laying hens. Laying hens were acclimatized to the experimental environment for the first 2 weeks (days −14 to 0) and then were divided into two groups to receive either ethanol- (Control) or corticosterone- (Stress) containing diet at 30 mg/kg for the next 2 weeks (days 0−14), respectively. The number of follicles equal to or greater than 10 mm in diameter was counted at the end of the experiment ($n$ = 8 per group), and blood obtained from the trunk of the hens was determined for plasma corticosterone concentrations by ELISA ($n$ = 8 per group). Data are means ± SEM. *$P \leq 0.05$ vs Control.

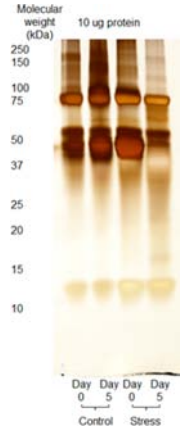

**Figure 3.** SDS-PAGE analysis of egg white proteins of hens. Laying hens were acclimatized to the experimental environment for the first 2 weeks (days −14 to 0) and then were divided into two groups to receive either ethanol- (Control) or corticosterone- (Stress) containing diet at 30 mg/kg for the next 2 weeks (days 0−14), respectively. Eggs laid by the same hens on days 0 and 5 in each group were used for proteomic study. Egg white protein samples (10 μg) were loaded on 4−20% SDS polyacrylamide premade gel and stained with silver nitrate staining.

Thirty-four protein spots in Stress were up- or down-expressed at least 1.2-fold compared with Control (Figure 4). Eight protein spots (#6−12 and 18) were significantly up-expressed on day 5 ($P \leq 0.05$) but six (#2, 15, 22, 27, 28, and 29) were down-expressed ($P \leq 0.05$) in Stress. By contrast, such change was detected in the only one protein spot (#19) from Control, which was up-expressed on day 5 compared with day 0 ($P \leq 0.05$).

From 34 protein spots, 9 proteins were identified through MALDI-TOF/TOF MS/MS analysis and the data mining based on subsequent bioinformatics: ovoinhibitor, ovalbumin-related protein X (OVAX), transiently expressed in neural precursors (TENP), hemopexin (HPX), ovotransferrin, IgY-Fc$\upsilon$3-4, extracellular fatty acid-binding protein (Ex-FABP), ovalbumin-related protein Y (OVAY), and ovalbumin. Of nine spots (#3−11) that were estimated as ovoinhibitor, 6 spots (#4−8 and 11) were determined as ovoinhibitor. While expression of this protein was significantly increased over 5 days in egg white in Stress ($P \leq 0.05$), no such significant changes were detected in Control (Tables 2 and 3). Three spots (#12, 18, and 24) were determined as OVAX, and corticosterone-treatment resulted in significant increase in 2 spots ($P \leq 0.05$) whereas no significant changes were detected in Control. Eight spots were considered to be TENP: among them, 4 spots (#17, 18, 27, and 28) were confirmed as TENP. Corticosterone treatment up-regulated 1 spot (#18) and down-regulated the other three spots (#17, 27, and 28) but no

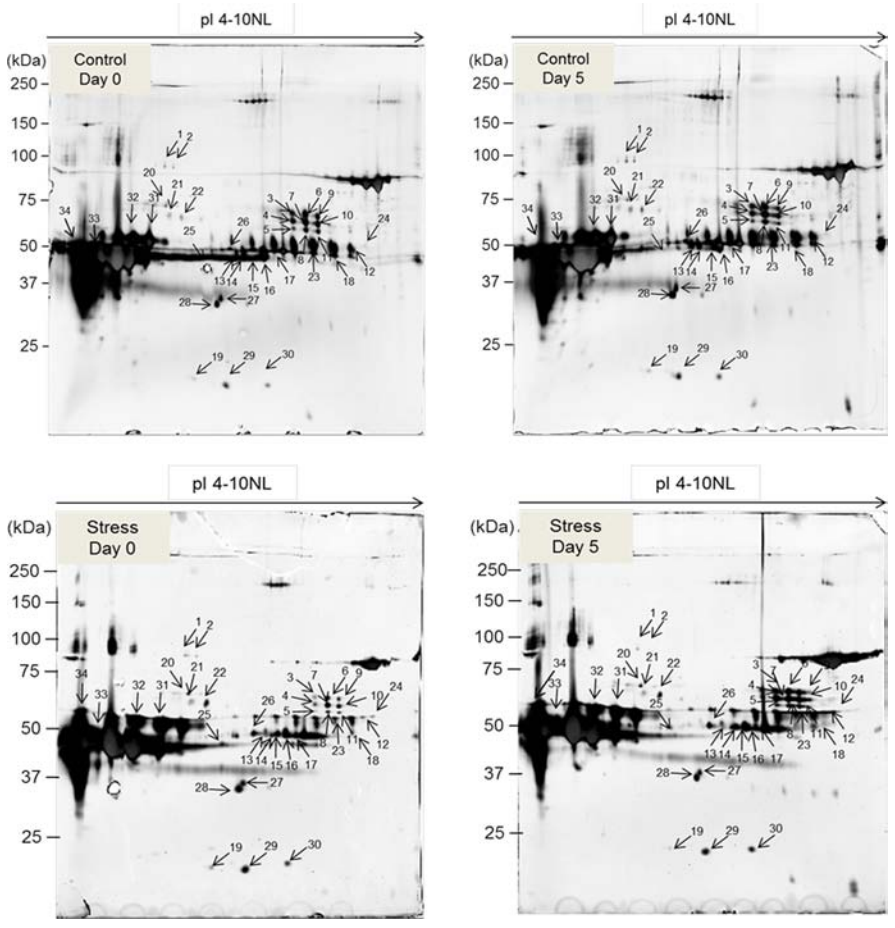

**Figure 4.** Representative two-dimensional electrophoresis (2DE) of hen's egg white proteins. Laying hens were acclimatized to the experimental environment for the first 2 weeks (days −14 to 0) and then were divided into two groups to receive either ethanol- (Control) or corticosterone- (Stress) containing diet at 30 mg/kg for the next 2 weeks (days 0−14), respectively. Eggs laid by the same hens on days 0 and 5 in each group were used for proteomic study. The 2DE gel images of egg white were obtained from eggs laid on days 0 and 5 by the same laying hens treated with Control or Stress. Egg white protein samples (200 $\mu$g) were loaded on 7.5% SDS polyacrylamide gels using a Gradi-Gel II gradient PAGE analysis kit and stained with silver nitrate staining. Protein spots determined are ovoinhibitor (#4−8 and 11), OVAX, ovalbumin-related protein X (#12, 18, and 24), TENP, transiently expressed in neural precursors (#17, 18, 27, and 28), HPX, hemopexin (#21 and 22), ovotransferrin (#24), IgY-Fc$\upsilon$3-4 (#27), Ex-FABP, extracellular fatty acid-binding protein (#29), OVAY, ovalbumin related protein Y (#31 and 32) and ovalbumin (#33 and 34), whereas spots are estimated for ovoinhibitor (#3, 9, and 10), TENP (#13, 14, 15, and 16), OVAY (#23 and 26), CAL, chondrogenesis-associated lipocalin (#19 and 30), and HPX (#20) based on recent publications. However, estimation for proteins was not possible for spots #1, 2, and 25, due to either lack of reference data or ambiguity of reference.

significant change was found in Control. Of three spots estimated as HPX, 2 spots (#21 and 22) were confirmed. HPX expression was significantly reduced by Stress on days 5 over 0 ($P \leq 0.05$), but no such changes were seen in Control. One spot (#27) was identified as IgY-Fc$\upsilon$3-4, expression of which was significantly reduced in Stress ($P \leq 0.05$) but not in Control. Similarly, another spot (#29) corresponding with Ex-FABP was significantly down-expressed by corticosterone-treatment ($P \leq 0.05$) but not by control. Among 4 spots which were estimated as OVAY, two spots (#31 and 32) were verified as OVAY, and one (#32) spot was significantly increased in Control ($P = 0.06$), but not in Stress. Although 2 spots (#33 and 34) were identified to be ovalbumin protein, no significant changes were found in both groups over 5 days. Two spots (#19 and 30), which were estimated to be chondrogenesis-associated lipocalin (CAL), were significantly increased in Control ($P \leq 0.05$) but not in Stress. One spot (#24), which was determined as ovotransfferin, was detected in Stress but not in Control.

Proteins "determined" were identified based on proteomic analysis in the present study (Table 3) whereas proteins "estimated" were found to have similar molecular weight (MW) and pH in the 2DE gels to those reported in recent papers.[16,17] Spots #18, #24, and #27 were determined to contain each of two different proteins (OVAX and TENP; OVAX and ovotransferrin; and TENP and IgY-Fc$\upsilon$3-4, respectively) (Tables 2 and 3).

Some of the proteins show differences between the theoretical (MWt) and observed (MWo) molecular weights (Table 2). The latter was based on the analysis of 2D gels using an image analyzer. The MWo values for some proteins were nearly the same as (#4, 5, 7, 8, 11, 17, 18, and 29), much smaller than (#24, 27, 28, and 34), or much larger than (#6, 12, 18, 21, 22, 24, 27, 31, 32, and 33) those of MWt.

**Differential Protein Abundance in Magnum of Treated and Untreated Hens (Day 14).** Of the proteins differentially abundant in the egg white on day 5 there were 6 proteins (ovalbumin, ovoinhibitor, ovotransferrin, hemopexin, IgY-Fc$\upsilon$3-4, and OVAY) which were also differently abundant

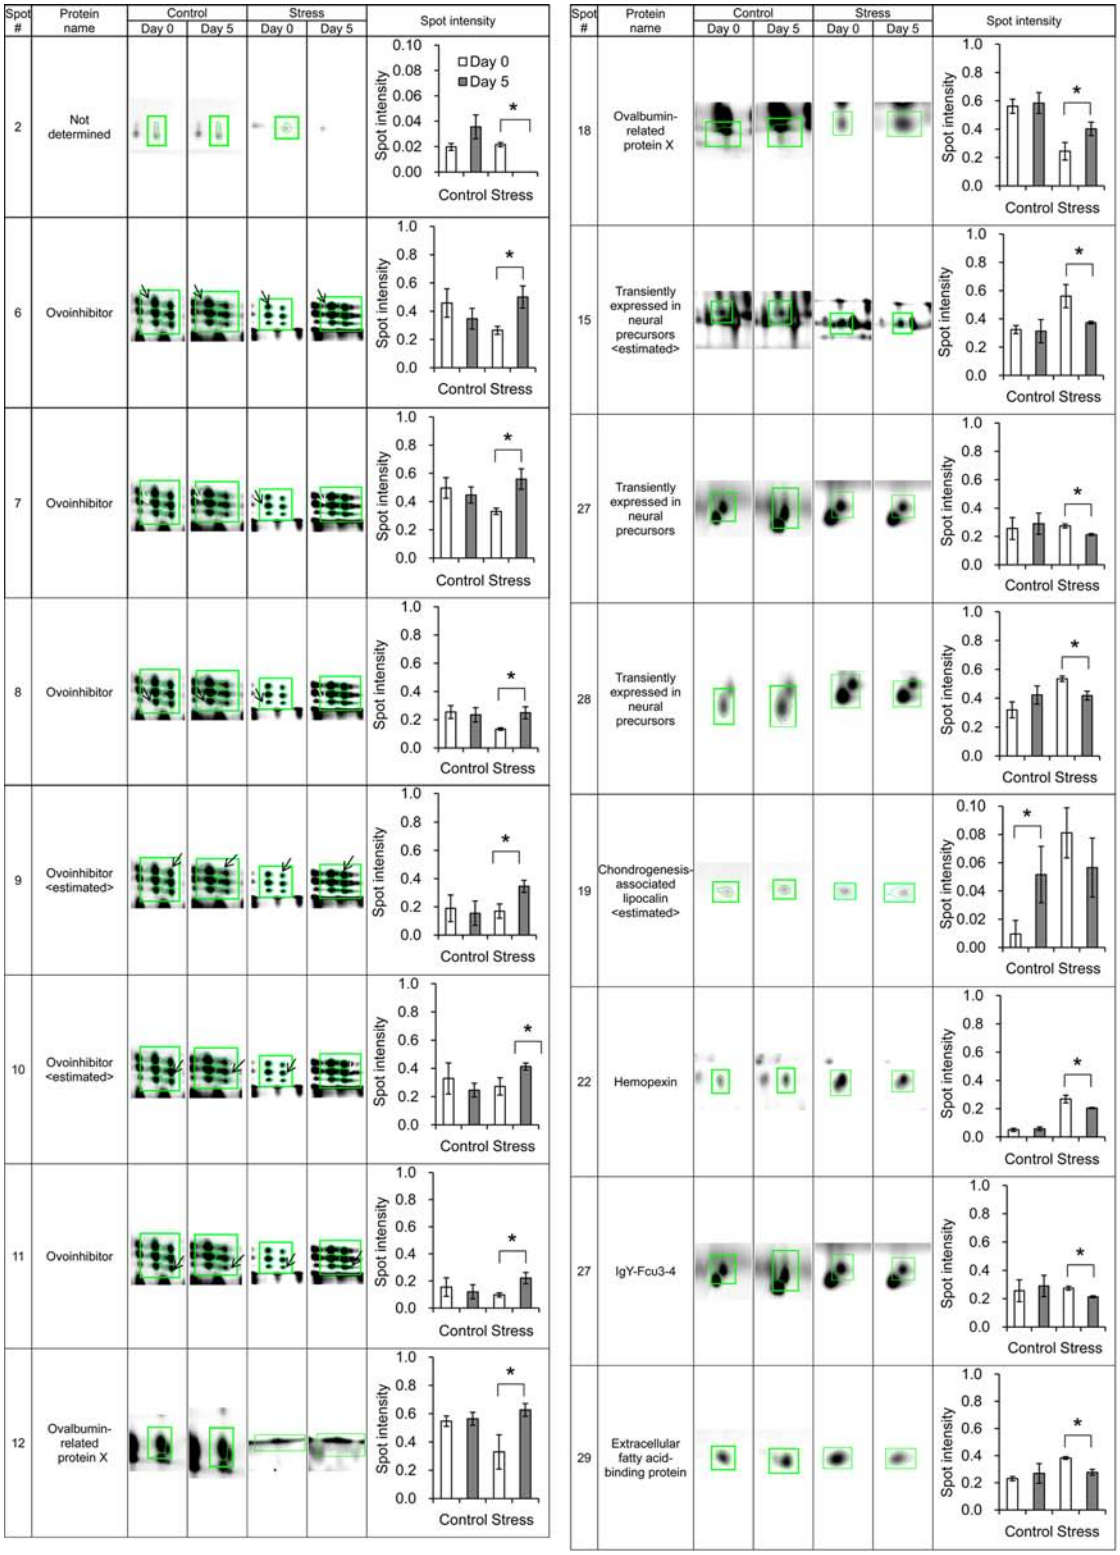

**Figure 5.** Differential expression of egg white proteins in spots derived from two-dimensional electrophoresis (2DE). Laying hens were acclimatized to the experimental environment for the first 2 weeks (days −14 to 0) and then were divided into two groups to receive either ethanol- (Control) or corticosterone- (Stress) containing diet at 30 mg/kg for the next 2 weeks (days 0−14), respectively. Eggs laid by the same hens on days 0 and 5 in each group were used for proteomic study. The 2DE gel images of egg white were obtained from eggs laid on days 0 and 5 by the same laying hens treated with Control or Stress. Individual spots on the gels were matched between the 2 days and between two treatments, and their intensities equal to or greater than 1.2-fold in expression were compared between days 0 and 5 in each treatment and were shown in graphs. The spot numbers are the same as those specified in Figure 4. Data are means ± SEM ($n$ = 3 per day per group). *All spots identified show statistically significant differences at $P \leq 0.05$ by $t$-test.

Table 2. continued

[a]Spot numbers correspond to the labels in Figure 4. Spots #1, 2, 3, 9, 10, 13, 14, 15, 16, 19, 20, 23, 25, 26, and 30 were not determined due to the limit of either database availability or instrumental detection. [b]Abbreviations: OVAX, ovalbumin-related protein X; TENP, transiently expressed in neural precursors; HPX, hemopexin; Ex-FABP, extracellular fatty acid-binding protein; and OVAY, ovalbumin related protein Y. [c]Accession numbers are from the UniProt Knowledgebase (UniProtKB) databases. [d]Molecular weights in theory. [e]Calculated molecular weights from 2D gels using by ImageMaster 2D Platinum 7.0. [f]Score (MOWSE), used in MASCOT PMF (peptide mass fingerprint), represents MS data from the UniProtKB database. Scores greater than 84 are significant ($P \leq 0.05$). [g]Sequence coverage. [h]The number of both ionized and nonionized peptides identified using MALDI-TOF/TOF MS/MS were matched with the whole peptides. [i]The sequences of peptides identified using MALDI-TOF/TOF MS/MS were matched with the whole sequences.

in the magnum of Stress ($P \leq 0.05$) on day 14, whereas no significant changes were detected for Ex-FABP and TENP (Figure 6). Ovoinhibitor, ovalbumin, and IgY-Fc$\upsilon$3-4 had at least two different spots which were significantly increased or decreased in the magnum whereas the expression of ovotransferrin and hemopexin was up-regulated. OVAY was decreased ($P \leq 0.05$), and no significant changes of both Ex-FABP and TENP were detected (Figure 6).

**Differential Gene Expression in Magnum of Treated and Untreated Hens (Day 14).** The genes, whose proteins were significantly up- or down-expressed in the egg white proteomic study ($P \leq 0.05$), were analyzed using qPCR in protein extracts of the magnum of the oviduct on day 14 (Figure 7). The seven genes encoding the proteins ovalbumin, OVAY, ovotransferrin, Ex-FABP, TENP, ovoinhibitor, and HPX were significantly down-expressed ($P \leq 0.0001$) in the magnum of laying hens treated with corticosterone compared with Control. One twenty-ninths for ovalbumin, 1/46 for OVAY, 1/12 for ovotransferrin, 1/23 for Ex-FABP, 1/33 for TENP, 1/16 for ovoinhibitor, and 1/49 for HPX genes were down-expressed in Stress against Control. The expressions of both the genes and proteins for HPX, TENP, Ex-FABP, OVAY, and ovalbumin were equally decreased. The gene for ovoinhibitor was down-regulated but its protein up-regulated.

## DISCUSSION

**Corticosterone Decreases Egg Production.** Corticosterone, the primary stress hormone in avian species including chickens, stimulates gluconeogenesis for survival to provide the body with energy when chickens are under stress.[2,4] Stress can affect performance in quantitative and qualitative manners as well as health by causing endocrine, metabolic, physiological, and behavioral changes in chickens.[5,7] The results of the present study show that although laying hens treated with corticosterone consumed more feed and had higher plasma corticosterone concentrations than did control hens, body weight was not significantly different from Control ($P = 0.11$). In a sharp contrast to the current results, corticosterone treatments show different effects in laying hens: corticosterone injected subcutaneously at 2 mg/kg body weight twice a day caused significant reduction in feed intake and body weight,[18] whereas dietary corticosterone at 1.5 mg/bird/day enhanced feed intake while reducing body weight gain.[19] Administration of corticosterone via drinking water at 20 mg/L for 1 week at 7, 11, and 15 weeks of age resulted in reduced body weight in laying hens.[3] ACTH, which stimulates the secretion of corticosterone from the adrenal and was delivered via osmotic pumps, increased feed intake and body weight in laying hens.[5] The controversy among these results may have resulted from different methods such as age of birds and delivery and dosage of corticosterone.

In the present study Stress caused significant reduction in egg production with relatively constant egg weight while increasing plasma corticosterone concentrations. The reduced egg production can be accounted for in part by decreased numbers of ovarian follicles (≥10 mm in diameter) in this study and by increased numbers of atretic follicles and reduced weights of the oviduct and ovary.[3,5] A strong negative relationship has been reported between elevated corticosterone concentrations and reduced egg production in studies in which hens were treated with ACTH via osmotic pumps,[5] subcutaneous corticosterone injections,[18] or corticosterone administration by way of either feed[19] or drinking water.[3] Indeed, stressful

[a]Abbreviations: OVAX, ovalbumin-related protein X; TENP, transiently expressed in neural precursors; HPX, hemopexin; Ex-FABP, extracellular fatty acid-binding protein; OVAY, ovalbumin related protein Y; and CAL, chondrogenesis-associated lipocalin. [b]Proteins "Determined" were those identified based on MALDI TOF/TOF MS/MS analysis followed by bioinformatics in the present study. In contrast, proteins "Estimated" have not been identified due to the detection limit of the mass spectrometry. Proteins of these spots were estimated based on both those reported in recent papers[16,17] and the observational molecular weight (MWo) from the 2D gels of the current study using an image master. Ovoinhibitor (#3, 9, and 10): 64, 61, and 56 kDa; TENP (#13−16): 51 kDa; HPX (#20): 66 kDa; OVAY (#23 and 26): 52 and 51 kDa; CAL (#19 and 24): 24 and 25 kDa, respectively. [c]Relative changes of proteins show the spot intensity of any given protein on day 5 against those on day 0 under the same treatment. [d]Spots #18 (OVAX and TENP), #24 (OVAX and ovotransferrin,) and #27 (TENP and IgY-Fcu3-4) were determined as two different proteins.

environment caused reduced plasma concentrations of testosterone, progesterone, and estrogen,[1] which resulted in decrease ovarian function[1] and low-quality offspring.[2] This proclivity suggests that various environmental stimuli enhancing the release of corticosterone in plasma can contribute to decreased egg production and quality.

**Corticosterone Modulates Egg White Protein.** The present study is the first to present evidence suggesting that dietary corticosterone can not only contribute to decreased egg production and quality but also modify the expression of proteins in the egg white. We found several proteins that differentially expressed in the egg white in response to dietary corticosterone: ovoinhibitor and OVAX were significantly increased while TENP, Ex-FABP, HPX, and IgY-Fc$\upsilon$3-4 were decreased. With the exception of OVAY, however, such changes were not seen in Control, suggesting that the changes are treatment-specific.

The present results of proteomic analysis show that some spots were identified as two or more different proteins. There is one spot (#18) that was identified as both OVAX and TENP. As shown in Table 3, expression of the spots that were determined as OVAX protein was consistently increased in the egg white associated with stress. With the exception of spot #18, which was positively expressed, those that were determined as TENP protein were consistently negatively regulated. Therefore, it is plausible to consider, based on these data and the literature,[16] that spot #18 is OVAX protein rather than TENP. However, the spot (#24), which was determined as both OVAX and ovotransferrin, was positively expressed in the egg white by Stress whereas the spot (#27), which was

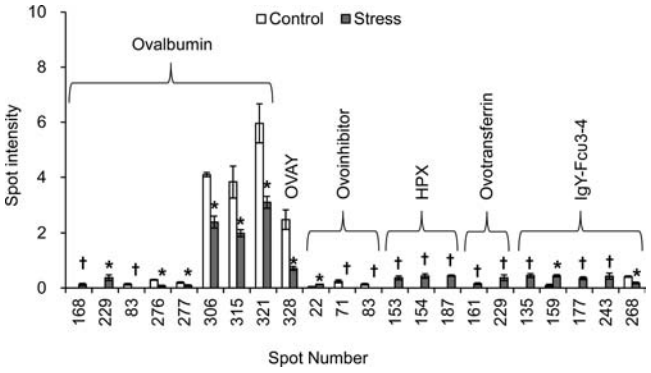

**Figure 6.** Differential expression of proteins in the magnum of the oviduct in hens. Laying hens were acclimatized to the experimental environment for the first 2 weeks (days −14 to 0) and then were divided into two groups to receive either ethanol- (Control) or corticosterone- (Stress) containing diet at 30 mg/kg for the next 2 weeks (days 0−14), respectively. The magnum obtained on day 14 was used for proteomic analysis. After individual protein spots on the gels derived from two-dimensional electrophoresis (2DE) were matched between two groups, their intensity was quantified and compared to identify protein spots that expressed equal to or greater than 1.2-fold, and is shown in graphs. Data are means ± SEM ($n$ = 3 per group). Spots identified by ∗ show significant differences at $P \leq 0.05$ by $t$-test, and those identified by † were detected in only one group. Abbreviations: OVAY, ovalbumin related protein Y; and HPX, hemopexin.

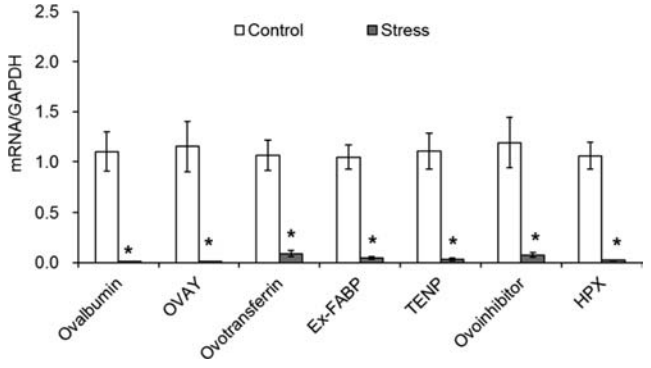

**Figure 7.** mRNA expression of ovalbumin, OVAY, ovotransferrin, Ex-FABP, TENP, ovoinhibitor, and HPX genes in the magnum of the oviduct in laying hens. Laying hens were acclimatized to the experimental environment for the first 2 weeks (days −14 to 0) and then were divided into two groups ($n$ = 20 each) to receive either ethanol- (Control) or corticosterone- (Stress) containing diet at 30 mg/kg for the next 2 weeks (days 0−14), respectively. Hens were killed using a guillotine, and the magnum was cut off at the end of the entire experimental period. Relative mRNA expression of individual genes against GAPDH was determined in duplicate using qPCR. Data are means ± SEM ($n$ = 8 birds each group). *$P \leq 0.0001$ vs Control. Abbreviations: OVAY, ovalbumin related protein Y; Ex-FABP, extracellular fatty acid-binding protein; and HPX, hemopexin.

determined as both TENP and IgY-Fc$\upsilon$3-4, was negatively expressed. Due to the limit of data available, whether or not each of these spots has a single protein or includes two different proteins remains to be determined.

In the present study, MWo values for some spots were similar to, lower than, or higher than those for MWt, suggesting their possible degradation or polymerization during the preparation of proteins for the 2DE analysis, which is consistent with those reported by Guerin-Dubiard et al.[16] and Wang et al.[17]

**Corticosterone Modulates Protein and Gene Expression in Magnum.** Several differential proteins, with the exception of Ex-FABP, TENP, and OVAX, were common between the egg white and oviductal magnum of hens administered with dietary corticosterone. Furthermore, we also found that mRNA expression of the genes encoding these proteins was significantly modified in the magnum.

There are different patterns of expression among proteins in the egg white and genes and proteins in the magnum in the current study. This could be attributable to the differences in collection time between eggs and the oviduct: eggs laid on days 0 and 5 were used for proteomic analysis whereas mRNA and protein expression was determined using the oviduct obtained at the conclusion of the whole experiment (day 14), thus being highly likely to reflect different physiological and cellular events from those on day 5. The oviduct was visually regressed in these hens treated with dietary corticosterone for 14 days in this study, and differential expression of genes[9,10] and proteins[20] has been reported in the oviduct of hens subject to molting. Another explanation is that the time and process of transcription may be different among individual genes, after which translation for protein biosynthesis would occur.[21]

**Ovoinhibitor.** Ovoinhibitor is one of the 4 proteinase inhibitors found in the egg white that are ovostatin, ovomucoid, ovoinhibitor, and cystatin.[11] Distinct expression of ovoinhibitor mRNA was detected in the liver, magnum, and uterus of chickens, and the protein was up-regulated in the liver of prelaying hens (14−16 weeks of age) compared with laying hens (41 weeks).[22] Ovoinhibitor has MW of 48.6−49 kDa,[11] consists of 1.5% of total egg white protein,[11] and inhibits serine proteinase such as trypsin, chymotrypsin, and elastase.[23] Synthesis and secretion of ovoinhibitor are controlled by estrogen and progesterone,[11] as seen in other enzymes in the oviduct and ovary.[11]

In the current study, ovoinhibitor was significantly up-expressed ($P \leq 0.05$) in the egg white produced from hens treated with corticosterone, but its gene expression was down-regulated in the magnum by Stress ($P \leq 0.001$). Significant changes of this protein were also seen in the oviduct. Estrogen increases the transcription rate of ovoinhibitor in the liver,[11] although concentrations of estrogen were not measured in this study. A recent study shows that expression of 6 ovoinhibitor precursor spots was strongly increased in fertilized egg white on 7 days after hatching.[24] Discrepancy in expression patterns between the gene and protein of ovoinhibitor remains to be solved.

**Ovalbumin, Ovalbumin-Related Protein X (OVAX), and Ovalbumin-Related Y (OVAY).** Ovalbumin is the major protein in the egg white, consisting of 54% egg white protein.[25] Ovalbumin, OVAX, and OVAY proteins are encoded by three distinct genes, the ovalbumin, ovalbumin X, and ovalbumin Y genes, respectively, belonging to the ovalbumin gene family located within a 40 kDa region.[26] Ovalbumin is composed of 386 amino acids, alternatively named as allergen Gal d II, egg albumin, plakalbumin, or allergen=Gal d 2 (UniProtKB ID: P01012); OVAX of 232 amino acids, alternatively named as gene X protein (UniProtKB ID: P01013); and OVAY of 388 amino acids, alternatively named as gene Y protein (UniProtKB ID: P01014). According to the nomenclature guidelines of serpin, ovalbumin, gene X, and gene Y are named as serpinb14, serpinb14c, and serpinb14b, respectively.[26] OVAX has been

shown to be similar to OVAY in the amino acid sequence and structure.[8,27] OVAY is present in the yolk,[28] and OVAX is approximately 2.4 mg/mL in average in egg white and seems to show antimicrobial activity.[29]

Glucocorticoids (e.g., cortisol and corticosterone) increase the expression of ovalbumin mRNA and protein in the chicken oviductal magnum.[30,31] Study showed that ovalbumin gene expression and protein synthesis in the magnum were increased in chicks administered with glucocorticoid at 2 mg/chick every 6 h, but decreased in those treated with 10 mg of glucocorticoid.[31] Synthesis and secretion of ovalbumin are also controlled by estrogen.[32] Corticosterone treatment reduces plasma concentrations of estrogen[1] and expression of its gene and protein.[30,31] Stress such as molting can also decrease plasma concentrations of estrogen[33] and reduce ovalbumin protein expression in egg shell.[34]

In the present study, OVAX protein abundance was significantly increased in the egg white of hens treated with dietary corticosterone at 30 mg/kg diet but not in Control. Expression of ovalbumin and OVAY proteins remained unchanged in both groups. On the other hand, gene expression of ovalbumin and OVAY was significantly decreased in the magnum of Stress. Together, these findings suggest that expression of these genes and proteins is differentially regulated by glucocorticoids depending on hormone concentrations and severity of stress.

**Transiently Expressed In Neural Precursors (TENP).** Protein TENP is a member of BPIFB subfamilies which belong to the bactericidal permeability-increasing protein (BPI) fold-containing (BPIF) superfamily,[35] and it consists of 440 amino acids.[36] The full name of the gene encoding this protein, known as TENP, is BPI fold containing family B, member 7, the official symbol of which is BPIFB7 (NCBI gene ID: 395882). As indicated in its name "transiently expressed in neural precursors", TENP was originally reported to be temporarily expressed only in the retina and brain of embryonic chicks being hatched but not in the other organs such as the heart, liver, and kidney.[36] mRNA expression diminished over time in the brain and retina of the chicken embryo but up-regulated in adult birds.[37] TENP has been now well-known to be present in the extraneural organs/tissues such as the oviductal magnum and appears to be avian specific, expressing almost exclusively in the magnum of adult birds.[37] In fact, protein TENP has been shown to be detected in the egg: the egg white[16,27] and yolk[28] of unfertilized chicken eggs and in emu egg white,[38] suggesting that expression of this protein is independent of fertilization and avian species.

Protein TENP consists of 0.1−0.5% of dried egg white protein[27] with MW of 47−50 kDa.[16] In the present study, TENP in the egg white was down-regulated by Stress while no such changes were seen in Control, and we even failed to detect TENP expression in the magnum. A recent study has shown that TENP mRNA was largely increased in the magnum of the oviduct in laying hens compared with nonlaying hens and in juvenile chicks administrated with either estrogen or progesterone, and was site-specifically expressed in the magnum of adult chickens and ducks,[37] suggesting gonadal regulation of TENP expression. The roles of TENP are not clear in chickens but appear to be associated with natural defense of avian eggs and embryonic development.[36]

**Hemopexin (HPX).** HPX is a plasma glycoprotein which is mainly expressed in the liver and less abundantly in the central and peripheral nervous systems, and it has a high binding affinity to heme in an equimolar ratio to protect the body from oxidative damage.[39] HPX increases the resistance of proteolytic digestion when it binds to heme.[40] HPX belongs to the acute phase protein and is increased by inflammation and stress.[39] Avian serum HPX is a 52 kDa $\alpha_1$-glycoprotein and can be detected from a few days before the egg hatches.[40] HPX concentrations in 4-day-old chicks were half those of adults (3.5 months old), and its concentrations in plasma were gradually increased after hatching.[41] HPX protein concentrations in plasma are significantly increased by immune challenge such as injection of lipopolysaccharide.[42] Both full length (IgY) and truncated isoforms (Fc) of IgY were isolated from ducks vaccinated against *Escherichia coli* (*E. coli*) and used to make *E. coli*-Ig immune complexes. When IgY and IgY (Fc) were injected intravenously into naive Mallard ducks, plasma HPX concentrations were higher in ducks given either 0:100 ratio or 100:0 ratio than in those given 50:50 or *E. coli* alone.[43] HPX has been recently shown in a variety of eggs produced from different raising conditions in nutrients or hens' strains, which suggests that its abundance can be affected by hens' strain, nutrients, or housing conditions.[17]

In the present study we found that HPX protein in the egg white and its gene in the magnum were significantly down-expressed in laying hens treated with corticosterone whereas HPX protein was increased in the magnum. Considering the findings that HPX concentrations are increased by acute stress such as inflammation,[39] it is notable in the current study that both HPX protein and gene expressions were different depending on what was investigated, which is worthy of further study.

**IgY-Fc$\upsilon$3-4.** Yolk proteins occupy approximately 16% of the total weight of egg yolk in fresh eggs.[23] Livetin fraction is a type of egg yolk proteins including $\alpha$-, $\beta$-, and $\gamma$-livetin. Both yolk $\alpha$-livetin and chicken serum albumin are the same protein.[23] $\beta$-Livetin is a D-2-glycoprotein with a MW of 45 kDa. A third protein, $\gamma$-livetin, is IgY with a MW of approximately 167 kDa.[23] Avian IgY is closely related to the ancestors of mammalian IgG and IgE.[44] The predominant serum immunoglobulin (Ig) in chickens has been proposed to be called IgY rather than IgG.[45] IgY consists of two heavy and two light chains,[46] and IgY-Fc$\upsilon$3-4 is an IgY-Fc fragment containing heavy chain constant domains 3 (C$\upsilon$3) and 4 (C$\upsilon$4).[44,46]

As IgY in the egg has passive immunity granted from the mother, it is transported into the yolk by receptors from blood, and its amount in the yolk is related to plasma IgY concentrations.[47] IgY was detected in 3.26−6.02 mg per 1 mL of hen's plasma and in 1.15−2.26 mg per 1 mL of the egg yolk.[47] Human (h) IgG was increased to maximum in the yolk on 5 days after laying hens were administered with hIgG.[48] Although hIgA, but not hIgG, was detected from egg albumen,[48] the current results, showing the presence of IgY-Fc$\upsilon$3-4 in the egg white of hens treated with corticosterone, suggest the presence of IgY in the egg white. Indeed, IgY has been shown to be detected in the egg white (3.57−9.58 $\mu$g/mL), at a much lower concentration than that in the yolk (1.15−2.26 mg/mL).[47] When some of the hens were infected with pathogen, IgY concentrations were increased in the circulation, which in turn resulted in an elevation of IgY in the egg.[49] In the present study, the abundance of IgY-Fc$\upsilon$3-4 was rather decreased in the egg white, which cannot be accounted for by possible infection of the hens. Furthermore, these hens had an increased feed intake during the entire treatment period (Figure 1). Thus, down-expression of IgY-Fc$\upsilon$3-4 in the egg

white means that the eggs of hens treated with corticosterone or raised under stressful environment are highly likely to have less amount of antibody than those in normal environment. In other words, if breeder hens are being raised under stress, their offspring produced are likely to be susceptible to diseases.[7] Concentrations of IgY in egg yolk and white were not determined in this study.

**Extracellular Fatty Acid-Binding Protein (Ex-FABP).** Fatty acids are present in complex with binding proteins rather than free form in order to be dissolved and transported in biological fluids for metabolism because fatty acid is hydrophobic. Ex-FABP is identified for the first time from the bone and cartilage of the developing chicken embryo[50] and then was also detected in muscle fibers and blood granulocytes in chickens.[50] It is also called protein Ch21, quiescence-specific protein, p20K (UniProtKB ID: P21760), or chondrogenesis-associated lipocalin, and it belongs to the chondrogenesis-associated lipocalin superfamily.[50] Ex-FABP is transported in the extracellular fluid and serum following binding to long-chain unsaturated fatty acids.[50] Ex-FABP is involved in heart development, fatty acid transport, and lipid metabolism, and it supposedly acts as a cell survival protein that protects cells from toxic lipid accumulation of fat.[51] Expression of Ex-FABP is enhanced in the liver of embryonic chickens by inflammatory agents such as lipopolysaccharide,[52] and it plays a role as an acute phase protein that is reduced by treatment with anti-inflammatory agents.[52,53] Ex-FABP gene expression is significantly increased in the lung, liver, and spleen of 3-week-old White Leghorn chicks infected with *E. coli*.[52,53] Growth inhibition of *E. coli* was observed in the presence of Ex-FABP,[54] suggesting that this protein possesses an antibacterial activity. On the other hand, suppressing gene expression of Ex-FABP resulted in increased apoptosis, decreased differentiation, and proliferation of cells.[52]

The results of the present study show that both Ex-FABP in the egg white and its gene in the magnum were significantly down-regulated in hens treated with dietary corticosterone. We failed however to detect Ex-FABP expression in the magnum using 2DE plus MALDI-TOF/TOF MS/MS. Although the relationship between Ex-FABP expression in the egg white and gene expression of Ex-FABP in the lung or liver has not been investigated in the present study, the present findings in the egg and magnum show an inverse relationship with protein and gene expressions in other organs (e.g., embryo, lung, liver, and spleen) of chickens infected.[52−54] Together, these results suggest that the reduced expression of Ex-FABP in the egg white may have resulted from the reduced expression of its gene, specifically in the magnum, but not the lung, liver, or spleen. From this perspective, a recent proteomic study,[55] which shows that the amount of an Ex-FABP precursor was gradually decreased in the egg white as the storage temperature of eggs was increased, implies that Ex-FABP can be used as an indicator for the evaluation of egg quality.

**Ovotransferrin.** Ovotransferrin is a 78 kDa, disulfide-rich (15 disulfide bonds) single-chain glycoprotein consisting of 686 amino acids and accounts for 13% of total egg white proteins.[25] Ovotransferrin is a member of the transferrin family that has high ability to bind two $Fe^{3+}$ ions (iron-binding capacity) and can be transferred into the egg white through the oviduct of hens.[56] Ovotransferrin and its hydrolysates have been shown to exert antimicrobial, antiviral, and antioxidant activities and to play as markers for stress and metabolic diseases in chickens infected with various pathogens.[56] Concentrations of ovotransferrin are increased in serum of chickens infected with pathogens or treated with inflammatory agents.[56] As ovotransferrin is regulated by inflammatory or microbial stress,[56] its concentrations in blood could be used as a diagnostic marker of chickens subject to infection or inflammation. Glucocorticoids (e.g., cortisol and corticosterone) stimulate enhanced synthesis of ovotransferrin mRNA and protein in the chicken magnum in vivo.[31] We found in the current study that ovotransferrin was slightly but not significantly up-regulated in the egg white by corticosterone and was significantly increased in the magnum while its gene expression was significantly reduced in the magnum. Others showed that gene and protein expression was increased in the magnum of chicks administrated with glucocorticoid at 2 mg/chick in every 6 h but decreased in chicks at 10 mg,[31] suggesting that their expression depends upon its concentrations used.

In summary, the results of the present study show that dietary corticosterone modulates the expression of proteins in the egg white. Similar findings were observed in the expression of proteins and genes of the magnum. Recent studies have shown, by proteomics, that expression of egg white proteins are affected by egg storage conditions, time, or fertilization.[55,57] In other words, the quantity of individual proteins consisting of the egg white can be changed in response to environmental conditions, which can have a direct impact on the quality of eggs. Egg quality can be affected by various factors, such as nutrients, ambient temperature, housing conditions, and stressful conditions, under which hens are raised,[58−60] and by the age and strain of hens.[58−60] Thus, egg quality has been evaluated based on external and internal aspects of the egg as well as on a food safety perspective that has long been a subject of public concern, having been linked to hens' welfare. Therefore, egg white proteins could be used as markers which help estimate the state of animal welfare or housing environment at the time of laying the egg. In conclusion, the findings from the current study provide evidence for the first time that dietary corticosterone modulates protein abundance in the egg white in laying hens, and suggest that environmental stress can differentially modify expression of egg white proteins in laying hens.

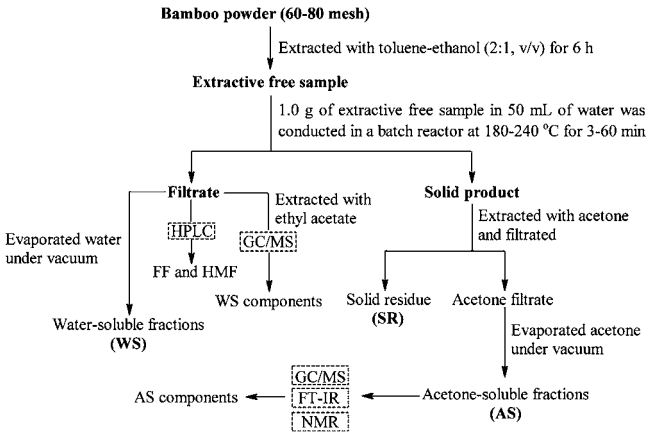
## MATERIALS AND METHODS

**Materials.** Bamboo (*Dendrocalamus membranaceus* Munro) was kindly provided by a pulp and papermaking factory (Yunnan, China). Bamboo was first ground into powder, and the powder between 60 and 80 mesh was collected for subsequent experimentation. The bamboo powder was dewaxed by refluxing in a Soxhlet apparatus with toluene-ethanol (2:1, v/v) for 6 h to remove extractives. The extractive-free bamboo powder was consisted of cellulose (36.6%), acid insoluble lignin (30.4%), hemicelluloses (19.7%) and ash (5.5%) according to the method of NREL.[14] All chemicals used were of analytical grade and purchased from Aladdin-Reagent.

**Methods.** Schematic illustration of the experimental procedure is shown in Scheme 1. In this study, all experiments were conducted in a batch reactor equipped with heating module (SLM 50, Beijing Century Senlong experimental apparatus Co., Ltd., Beijing, China), which was made of 316L stainless steel (50 mL nominal capacity, internal diameter = 35 mm; height = 80 mm). The hydrothermal processes were carried out using 1.0 g of extractive-free bamboo powder dispersed in 50 mL of distilled water. Magnetic stirring was used and the agitation was set at 500 rpm. The reactor was purged five times with nitrogen to remove the inside air, and finally the pressure was released to normal pressure. Then the mixture was heated up to designed temperature (180−240 °C) and maintained at this temperature for 3−60 min. The pressure in the reactor was equal to the saturated vapor pressure of water at the operating temperature. Upon completion of the reaction, the reactor was cooled down first by fan and then immersed into cold water. The reaction mixture was separated by filtration. The filtrates were collected in plastic bottles for further analysis. The solid residues were extracted with acetone to collect the acetone-soluble samples (setting the volume to 50 mL). Then, the solid residues (SR) were dried in a vacuum oven at 60 °C overnight. The water in the filtrate was evaporated under vacuum to recover the water-soluble (WS) fractions. The acetone extractives were also evaporated under vacuum to obtain the acetone-soluble (AS) fractions. WS, AS, and SR fractions were weighed, and each product yield was calculated according to the equations below based on the initial weight of bamboo. The gaseous products and loss (GL) was calculated by determining the weight change between the initial weights of bamboo and recovered weights of solids (SR, WS, and AS). SR, WS, and AS samples were collected for further analysis.

**Scheme 1. Illustration of the Experimental Procedure**



$$SR + WS + AS + GL = \frac{m_r}{m_b} + \frac{m_{w-s}}{m_b} + \frac{m_{a-s}}{m_b} + GL = 1 \quad (1)$$

where $m_b$ is the initial weight of dried bamboo, $m_r$ is the weight of hydrothermal solid residue after acetone extracting, $m_{w\text{-}s}$ is the weight of the water-soluble fractions, and $m_{a\text{-}s}$ is the weight of the acetone-soluble fractions.

**Characterizations of Hydrothermal Solid Residues, WS, and AS Fractions.** The major compositions of these hydrothermally treated bamboo samples were determined according to the method of NREL.[14] These compositions, acid-insoluble fractions (AIF), cellulose (Cel), and hemicelluloses (Hem) were all calculated based on the initial weight of bamboo.

As illustrated in Scheme 1, the ethyl acetate extractives (WS fractions) and acetone extractives (AS fractions) were treated with anhydrous $MgSO_4$ to remove the residual water. Equal volumes of WS filtrates and acetone extractives were employed and treated exactly the same to guarantee their comparability. These samples were determined on an Agilent 7890/5975 GC/MS (Agilent Technologies, U.S.A.) with a DB-5 ms column (30 m × 250 μm, J&W Scientific). The injector temperature was kept at 250 °C. For WS, the oven temperature was programmed from 40 °C (2 min) to 280 °C (5 min) with a heating rate of 5 °C/min. For AS fractions, the oven temperature was programmed from 40 °C (10 min) to 280 °C (10 min) with a heating rate of 5 °C/min. Helium (99.999%) was used as the carrier gas with a constant column flow rate of 1 mL/min and a split ratio of 1:10. The mass spectra were obtained from $m/z$ 30 to 500. The chromatographic peaks were identified by comparison with the NIST05 library.

FT-IR spectra of AS samples were recorded on a Bruker spectrophotometer (Bruker Tensor 27, Germany) in the range of 4000−400 $cm^{-1}$ with a resolution of 4 $cm^{-1}$. KBr disc containing 1% finely ground sample was used for measurement. $^1H$ NMR spectra of AS fractions were carried on a Bruker DRX-400 spectrometer (Bruker, Germany) in acetone-$d_6$ solution operating at 400.12 MHz at 25 °C.

Furfural (FF) and 5-hydroxymethyl furfural (HMF) contents in the filtrates were quantified by an Agilent 1100 series HPLC (Agilent Technologies, U.S.A.) with a Platisil ODS C18 column (250 × 4.6 $mm^2$, 5 μm) and a UV/vis detector at 277 and 285 nm, respectively. The sample loop had a volume of 50 μL, and the column temperature was maintained at 30 °C. Methanol and water (30/70, v/v) were used as the eluents at a flow rate of 1.0 mL/min.

## RESULTS AND DISCUSSION

**Product Distributions.** HTC is considered as a simple, convenient, inexpensive, and environmentally friendly method to upgrade lignocellulose into various valuable products. During the hydrothermal progress, lignocellulose can be transformed into solid, liquid, or gaseous products. Some loss is inevitable in the following separation and recovery of these products. Since lignocellulose hydrolysis and formation of gases were slow under subcritical water conditions (below 374 °C),[15] the major loss was likely caused by the substance attached on the surface of the reactor and the weight losses of WS and AS fractions during drying process. Therefore, gaseous products and loss (GL) were integrated to determine the product loss during the hydrothermal process. Figure 1 shows the hydrothermal product distributions of bamboo and the product loss under different hydrothermal conditions. The hydrothermal products were mainly composed of 37.11−89.98% of SR, 4.51−20.41% of WS, and 4.23−16.17% of AS. Obviously, a decrease of SR content indicated that more lignocellulosic components were decomposed and transferred into WS, AS, and GL fractions with the elevation of temperature and the elongation of time. The WS fraction ranged from 4.51% to 20.41%, and the maximum value was obtained at 200 °C for 3 min. The proportion of WS increased with the elongation of time at 180 °C, while as the temperature rose to 200 °C, the WS value started to decrease with the elongation of time. As the temperature further increased to 220−240 °C, the WS values were relatively stable. Additionally, considerable amounts of AS fractions (4.23−16.17%) were extracted from the hydrothermal residues of bamboo. The AS content gradually increased with

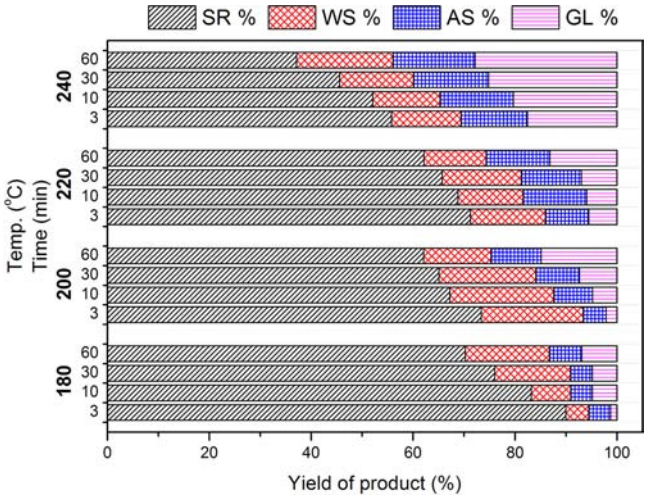


**Figure 1.** Hydrothermal products distributions of bamboo and the product loss under different hydrothermal conditions.

the increase of temperature and time. It was assumed that partial WS fractions were likely converted into AS fractions during the HTC process. In addition to the decomposition of bamboo into WS fractions, a lot of AS fractions were produced and attached to the hydrothermal solid residue, which might finally lead to the formation of hydrochar via dehydration, aromatization, condensation, etc. Additionally, 1.25−27.82% of GL were observed and the GL also gradually increased with the increase of temperature and time.

**Composition of SR from Different Hydrothermal Conditions.** To clearly illustrate the composition variation of bamboo under different hydrothermal conditions, the yield and chemical composition of the hydrothermally treated bamboo are shown in Table 1. It should be noted that the contents of acid-insoluble fractions (AIF), cellulose (Cel), and hemicelluloses (Hem) were all calculated based on the initial weight of bamboo instead of SR. As can be seen, all of these three compositions showed a declined tendency with the increase of the hydrothermal severity, suggesting that the degradations of lignin, cellulose, and hemicelluloses were more severe under high temperatures or extended periods. Among these three major compositions, the decompositions of hemicelluloses were much easier than those of cellulose and lignin. Only 5.9% of hemicelluloses could be detected at 180 °C for 60 min as compared with the initial 19.7%. When the bamboo was hydrothermally treated at 220 °C for 10 min or treated under more severe conditions, only less than 1.0% of hemicelluloses were retained. For cellulose, it was relatively stable at 180−220 °C and only a small quantity of cellulose was degraded as the reaction time increased. However, as the temperature further increased to 240 °C, the degradation of cellulose became obvious. It was in line with the results found by Sasaki et al.,[16] who reported that hemicelluloses and lignin could be mainly converted into a water-soluble fraction at 200−230 °C, while cellulose was hydrolyzed at hydrothermal temperatures higher than 230 °C. In this study, only 15.5% of cellulose was retained at 240 °C for 60 min, as compared with 36.6% of cellulose in the initial bamboo material. Most hemicelluloses and cellulose would be initially decomposed into their corresponding oligosaccharides and monomers, and then further degraded into small molecular compounds, especially FF and HMF.[17] For AIF, the content of AIF decreased gradually with the increase of reaction temperature and time, and about half of AIF was retained at 240 °C for 30 min. Due to the high stability of aromatic structures, most products derived from lignin are phenolic compounds, such as 2-methoxy-phenol, 4-methyl-phenol, benzenediol, etc.[18] The degradation products of these compositions were analyzed to further investigate the degradation pathway of lignocellulose.

**Table 1. Yield and Chemical Composition of the Hydrothermally Treated Bamboo**

| temp. (°C) | $t$ (min) | yield[a] (%) | AIF (%)[b] | Cel (%)[b] | Hem (%)[b] |
|---|---|---|---|---|---|
| | | | 30.4 | 36.6 | 19.7 |
| 180 | 3 | 90.0 | 29.5 | 34.3 | 18.3 |
| | 10 | 83.2 | 27.4 | 34.3 | 15.6 |
| | 30 | 76.0 | 24.5 | 34.1 | 11.5 |
| | 60 | 70.3 | 24.5 | 32.5 | 5.9 |
| 200 | 3 | 73.4 | 24.7 | 32.7 | 9.4 |

**GC/MS Analysis of WS Fractions.** To identify the degradation products in WS fractions, the WS solutions extracted with ethyl acetate were further analyzed using GC/MS (Supporting Information, SI, Figure S1). The compositions in the WS solutions were checked against NIST mass spectral library and their structures are shown in SI Figure S2. The absolute areas of these identified compositions are illustrated in SI Table S1. Among these identified compounds, high concentrations of FF and HMF were always detected in the hydrothermal liquid of hemicelluloses and cellulose, respectively.[19,20] Generally, FF and HMF were considered as typical degradation products derived from the dehydration of pentose and hexose, especially xylose and glucose. In consideration of the especial phenyl-propane structures of lignin, these phenolic compounds in the hydrothermal liquid are likely originated from the degradation of lignin. Previous literature also reported that lots kinds of phenolic compounds were observed in the hydrothermal liquid of lignin.[21] Therefore, according to their origins, these identified chemicals were further classified into hemicelluloses derivatives (Hem-D), cellulose derivatives (Cel-D), and lignin derivatives (Lig-D).

The integral area of hydrothermal products derived from hemicelluloses, cellulose, and lignin in water-soluble fractions are shown in Figure 2. The integral area of Hem-D increased rapidly as a function of time at 180 and 200 °C. However, as the temperature further increased to 220 °C, the increase of Hem-D started to slow down, which was observed obviously as the reaction time increased from 30 to 60 min. According to data in Table 1, it was likely that the formation rate of Hem-D decreased dramatically with the exhaustion of hemicelluloses. As the temperature further increased to 240 °C, the area of

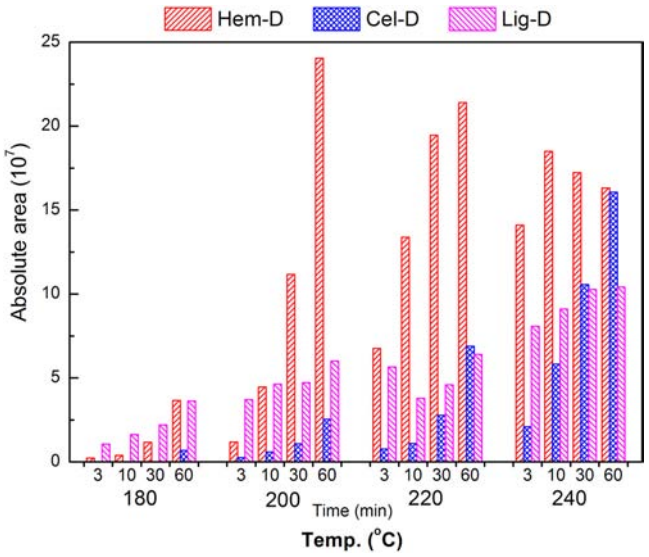

**Figure 2.** Integral area of hydrothermal products derived from hemicelluloses, cellulose, and lignin in water-soluble fractions.

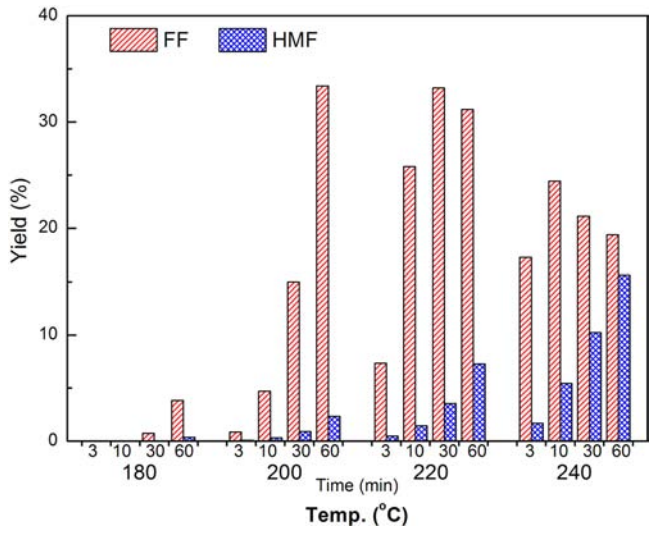

**Figure 3.** Yields of FF and HMF in water-soluble fractions.

Hem-D showed a trend to decrease with the extension of time, suggesting the server decomposition or condensation of FF at such high temperature.[21] For Cel-D, the area of Cel-D increased steadily with the temperature and time in this study. Since lignin is a heterogeneous, cross-linked three-dimensional phenylpropane polymer, the formation of most phenolic compounds originates from the decomposition of lignin. As can be seen in SI Table S1, many phenols with different substitution groups were detected in the WS fractions. Furthermore, the area of Lig-D was higher than that of Cel-D in most cases. Since chromatographic peak area of compound is considered linear with its quantity,[22] it was assumed that the hydrothermal stabilities of the three major components in the bamboo material were likely in the order of cellulose > lignin > hemicelluloses over the temperature range of this study, which was in line with the data in Table 1.

**HPLC Analysis of FF and HMF in WS Fractions.** As we know, FF and HMF are the characteristic degradation products of xylan and cellulose, respectively. To quantitatively study the degradation products of hemicelluloses and cellulose in bamboo material during the HTC process, the yields of FF and HMF as functions of hydrothermal temperature and time are illustrated in Figure 3. The HPLC chromatograms of partial WS fractions are shown in SI Figure S3. As can be seen, the yield variations of FF and HMF showed very similar trends to the area changes of Hem-D and Cel-D measured by GC/MS. FF and HMF were first observed at 180 °C for 30 and 60 min, respectively. It suggested that both hemicelluloses and cellulose could be converted into FF and HMF at 180 °C, but the formation rate of HMF was much lower than that of FF. As the hydrothermal temperature rose to 200 °C, the yield of FF increased dramatically from 0.9% to 33.4% as the reaction time increased from 3 to 60 min, while the corresponding yield of HMF increased gradually from 0.1% to 2.3%, which was much lower than that of FF. At 220 °C, the yield of FF displayed a rapid upward trend as the reaction time extended from 3 to 10 min, which increased dramatically from 7.3% to 25.8% within 7 min. The highest yield of FF at 220 °C was 33.2% for 30 min, which was very close to that obtained at 200 °C for 60 min (33.4%). As the reaction time further increased to 60 min, the yield of FF began to decline. When the hydrothermal temperature increased to 240 °C, 17.2% of FF could be obtained for 3 min, which was much higher than that at 220 °C (7.3%). The highest yield of FF at 240 °C could be obtained at 10 min (24.4%), and then it started to decrease gradually. The yield of HMF gradually increased with the elevation of temperature and the elongation of time, and the highest yield of HMF (15.6%) could be obtained at 240 °C for 60 min. Furthermore, no visible yield decrease of HMF was observed from Figure 3 over the temperature and time range. Previous studies reported that the decomposition rates of xylose and glucose were significantly higher than those of FF and HMF under the same condition.[21,23] However, as the content of xylose or glucose decreased and the degradation of FF or HMF increase, the yield of FF or HMF would start to decline with increasing time. Therefore, there was always an initial increase and then decrease in the yield for FF and HMF during the HTC process. The optimum temperature to produce FF without catalysts was mainly located at 200−220 °C, while the highest yield of HMF was observed at 240 °C.

**GC/MS, FT-IR, and $^1$H NMR Analyses of AS Fractions.** In order to identify the degradation products in AS fractions, the AS solutions were also analyzed by using GC/MS and their total ion chromatograms (TIC) are shown in SI Figure S4. A broad and strong peak at around 9.7 min was found in all the chromatograms, which originated from 4-hydroxy-4-methyl-2-pentanone. It was reported that 4-hydroxy-4-methyl-2-pentanone could exist in the AS fractions as the major product.[24,25] Furthermore, 4-hydroxy-4-methyl-2-pentanone was also observed in the bio-oils from fast pyrolysis of some energy crops.[23] Previous studies showed that phenolic compounds, such as 2-methoxyphenol and 4-methylphenol, likely existed in the AS fractions.[18,27] However, phenolic compounds, like 2-methoxyphenol or 4-methylphenol, were hardly found in the AS fractions in our study. The signals appearing after 48 min were mostly unrecognizable compounds with high boiling points. Two relatively strong signals at 54.7 and 56.4 min are assigned to a complex aromatic compound with two benzene rings and column packing material, respectively. In addition to these peaks, almost no peak with large area was found in these chromatograms. Therefore, FT-IR

and $^1$H NMR were used to further investigate the components in AS fractions.

The FT-IR spectra of these AS samples were recorded and illustrated in SI Figure S5. Very similar spectra were observed among these samples, indicating that these AS fractions obtained at different hydrothermal conditions had similar composition. Peak at around 1701 $cm^{-1}$ is assigned to the carbonyl group in 4-hydroxy-4-methyl-2-pentanone. Four sharp peaks observed at 1603, 1514, 1462, and 1427 $cm^{-1}$ are characteristic absorption peaks of substituted benzene. The strong signals at 3423 and 1271 (1217) $cm^{-1}$ are assigned to the O—H stretching and O—H and C—O combination band of phenolic compounds, respectively. Furthermore, signals at 1121 (1032) and 833 $cm^{-1}$ are originated from the C—H in-plane and out-of-plane bending of 1,2- or 1,4-disubstituted benzene. Obviously, the major aromatic compounds in AS fractions are originated from the decomposition of lignin.[18,24,27]

Additionally, $^1$H NMR of AS sample in acetone-*d*6 was also recorded and shown in SI Figure S6. These sharp peaks appearing at around 1.06 (s), 1.96 (t), and 2.47 (s) ppm are assigned to 4-hydroxy-4-methyl-2-pentanone, while the broad peaks observed at around 3.68 and 6.66 ppm originate from methoxy groups on the benzene ring and aromatic hydrogens, respectively. The broad signals of methoxy groups and aromatic hydrogens indicated that the aromatic products in the AS fractions consisted of many similar phenolic compounds. Therefore, according to the results from GC/MS, FT-IR, and $^1$H NMR, it was assumed that 4-hydroxy-4-methyl-2-pentanone and complex aromatic compounds with multibenzene rings were likely the major components of the AS fractions.

In this study, the major products of bamboo hydrothermally treated at 180−240 °C for 3−60 min, and their distributions were comparatively studied. More lignocellulose components were transformed into hydrothermal products with the increase of hydrothermal severity. Besides 4.51−20.41% of lignocellulose was converted into water-soluble fractions, considerable amounts of acetone-soluble fractions (4.23−16.17%) were extracted from the hydrothermally treated solid residue. The products in WS fractions mainly consisted of furfural (FF), 5-hydroxymethylfurfural (HMF), and phenolic compounds, while the products in AS fractions were mainly 4-hydroxy-4-methyl-2-pentanone and complex aromatic compounds with multibenzene rings. Additionally, various kinds of hydrothermal products with relatively low yields were observed in the noncatalytic HTC process. The utilization of appropriate catalyst may be helpful to convert lignocellulose into valuable products with high energy efficiency and atom economy.

transcription of the corresponding genes immediately.[18] Extensive studies showed that abundant anthocyanin accumulation in certain tissues of some purple fruits and vegetables arises from the spatiotemporal transcriptional activation of R2R3MYB or bHLH transcription factors.[8,19−23] On the other hand, light, which acts as an essential environmental stimulus, also modulates the intensity of the pigment through the regulation of anthocyanin structural genes.[24] It is known that a basic leucine zipper (bZIP) type of transcription factor LONG HYPOCOTYL 5 (HY5) plays a central role in the biological process of the coordination of light signals and the adjustment of appropriate gene expression. Furthermore, HY5 has also been demonstrated to positively regulate anthocyanin biosynthesis by directly binding to the promoters of *CHS* and *F3H* in *Arabidopsis*.[25,26]

As a variant cultivar of the turnip, bok choy (*Brassica rapa* var. *chinensis*) was originally cultivated in China and distinct from another leafy vegetable, Chinese cabbage, which usually forms a compact head in winter. Being winter-hardy, bok choy is widely

cultivated and consumed in China and northeastern Asia and is increasingly grown in northern Europe and North America. Furthermore, the purple bok choy receives more attention from the public than green cultivars for high levels of anthocyanin accumulation in mature leaves besides the well-known health benefits of cruciferous vegetables.[27,28] However, being an economically important crop, the composition of anthocyanins and molecular mechanisms of anthocyanin biosynthesis in purple bok choy remain unknown. In this paper, we characterize the components of anthocyanin production in the purple cultivar (Zi He) with high-performance liquid chromatography–electrospray ionization tandem mass spectrometry (HPLC-ESI-MS/MS). For the purpose of investigating the molecular mechanisms underlying anthocyanin accumulation in the purple edible leaves, the expression level of anthocyanin biosynthetic and regulatory genes was analyzed by quantitative real-time polymerase chain reaction (qRT-PCR) in corresponding tissues of the purple and green cultivars. Because the production of anthocyanins in seedlings of Zi He is strictly dependent on lightness, the expression profiles of anthocyanin biosynthesis associated genes were further analyzed in seedlings of different developmental stages under light and dark conditions. These results certainly expanded our understanding about the mechanisms of anthocyanin accumulation in purple bok choy at both the metabolic and transcriptional levels.

## MATERIALS AND METHODS

**Chemicals and Solvents.** Anthocyanin (cyanidin 3,5-diglucoside) for external standards was purchased from Phytolab (Germany). High-performance liquid chromatography (HPLC) grade formic acid and methanol (MeOH) were bought from Sigma. All other solvents were provided from Aldrich (St. Louis, MO, USA).

**Plant Materials and Culture Conditions.** Bok choy (*B. rapa* var. *chinensis*) seeds of green cultivar (Su Zhouqing) and purple cultivar (Zi He) were obtained from the Chongqing Academy of Agriculture Sciences. The samples used for HPLC-ESI-MS/MS and qRT-PCR analysis were collected from edible leaves of green and purple cultivars that were grown in a greenhouse with a 16 h photoperiod at 25 °C. The samples used for total anthocyanin and qRT-PCR analysis were collected from seedlings of green and purple cultivars that were generated by follow procedures. Bok choy seeds were surface-sterilized with 70% ethanol for 30 s and with a 4% (v/v) bleach solution for 15 min and then rinsed several times in sterile water. These seeds were then placed on half-strength sterilized Murashige–Skoog medium (1/2 MS) solidified with 0.8% agar. The two cultivars were germinated in a growth chamber under light/dark (16/8 h) or dark conditions at 25 °C and approximately 60% humidity. Samples were harvested after 3, 6, 9, and 12 days, measured for their length and fresh weight, frozen in liquid nitrogen, and stored at −80 °C until other analysis.

**RNA Extraction and qRT-PCR Analysis.** The samples of the two bok choy cultivars were ground into powder in liquid nitrogen. Total RNA was isolated from various tissues for three biological repeats using RNAiso reagent according to the manufacturer's instruction

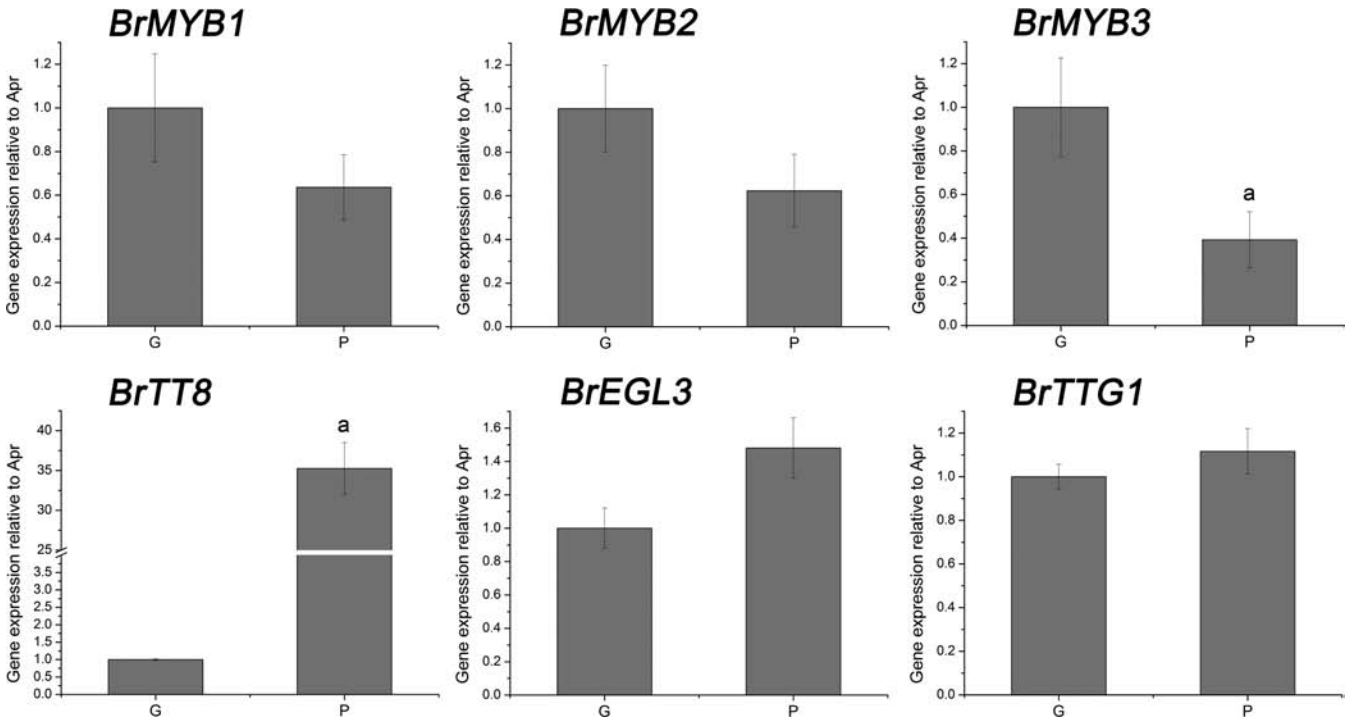

**Figure 3.** Expression analysis of anthocyanin biosynthesis regulatory genes in edible leaves of the two bok choy cultivars. P and G represent purple edible leaves and green edible leaves separately. Error bars represent the standard error of the mean ($n = 3$). Statistical significance of the differences between samples was calculated with ANOVA by paired-group comparisons. Different letters indicate significance at $P < 0.05$.

(Takara, Dalian, China). RNA samples (1 $\mu$g) were reverse transcripted into complementary DNA (cDNA) with an oligo(dT)20 primer and M-MLV reverse transcriptase (Promega, Madison, WI, USA) following the manufacturer's protocol. The synthesized cDNAs were diluted five times in $H_2O$ for qRT-PCR analysis.

qRT-PCR was carried out using the CFX96 Real-Time System (C1000 thermal cycler). All reactions were performed using the GoTaq qPCR Master Mix according to the manufacturer's instructions. Reactions were performed in triplicate using 5 $\mu$L of Master Mix, 0.25 $\mu$M of each primer, 1 $\mu$L of diluted cDNA, and DNase-free water to a final volume of 10 $\mu$L. The PCR amplification was as follows: 1 cycle of 3 min at 95 °C, 40 cycles of denaturation for 15 s at 95 °C, annealing for 30 s at 60 °C, and elongation for 15 s at 72 °C. Amplification was followed by a melting curve analysis with continual fluorescence data acquisition during the 60−95 °C melt. Melt curve analysis of qPCR samples revealed that there was only one product for each gene primer reaction. The primers used for qPCR analysis of bok choy were designed by Primer Premier 5 and are listed in Supplementary Table 1 (Supporting Information). In addition, primers used for qPCR analysis for regeneration shoots of tomato are listed in Supplementary Table 2 (Supporting Information). The PCR products were sequenced to confirm the specific amplifications. The gene expression was normalized to *BrApr* and *SlCAC* as a reference gene for bok choy and tomato, respectively.[29,30] Values reported here were calculated from three biological repeats for each sample.

**Anthocyanin Extraction and HPLC-ESI-MS/MS Analysis.** Anthocyanin extraction of bok choy was carried out in the same way as for radish.[31] The extract was filtered through a 0.2 $\mu$m PTFE syringe filter. The samples were then analyzed by an Agilent Technologies 1200 series HPLC (Agilent Technologies, Palo Alto, CA, USA), equipped with an Agilent 1200 HPLC variable-wavelength detector. The results were analyzed by Agilent 1200 HPLC ChemStation software. The chromatographic separation was performed on a Zorbax Stablebond Analytical SB-C18 column (4.6 mm × 250 mm, 5 $\mu$m, Agilent Technologies, Rising Sun, MD, USA). The injection sling was 5 $\mu$L. Elution was performed using mobile phase A (aqueous 2% formic acid solution) and mobile phase B (methanol). The detection was at 520 nm, and the column oven temperature was set at 40 °C. The flow rate was 0.6 mL/min. The gradient program is described as follows: 0−2 min, 10−20% B; 2−40 min, 20−55% B; 40−41 min, 55−80% B; 41−45 min, 80% B; 45−50 min, 80−10% B; 50−55 min, 10% B. Quantification of the different anthocyanins was based on peak areas and calculated as equivalents of the standard compounds. All contents were expressed as milligrams per gram dry weight. Low-resolution electrospray mass spectrometry was performed with a solariX ion trap mass spectrometer (Bruker Daltoniks, Billerica, MA, USA). The experimental conditions were as follows: ESI interface, nebulizer, 50 psi; dry gas, 15.0 psi; dry temperature, 320 °C; MS/MS, scan from $m/z$ 200 to 1500; ion trap, scan from $m/z$ 200 to 1500; source accumulation, 50 ms; ion accumulation time, 300 ms; flight time to acquisition cell, 1 ms; smart parameter setting (SPS), compound stability, 50%; trap drive level, 60%.

**Total Anthocyanin Analysis.** Spectrophotometric differential pH method was used for the total anthocyanin measurement of bok choy following the procedure of Yuan et al.[15]

**Gene Cloning and Sequence Analyses.** The primers used for BrMYB1, BrMYB2, BrMYB3, and BrTT8 were designed from the sequences of known orthologous sequences (Supplementary Table S3 in the Supporting Information). Then, the PCR products were cloned into a T-Blunt vector (Takara) and sequenced. Sequence similarities were calculated with DNAMAN version 5.2.2. The phylogenetic and molecular evolutionary analysis was used with MEGA (Molecular Evolutionary Genetics Analysis) version 3.1.

**Statistical Analyses.** SPSS, version 17.0 (SPSS Inc., Chicago, IL, USA), was used for the data analysis. One-way analysis of variance (ANOVA) followed by pairwise comparisons was performed with post hoc Tukey's honestly significant different (HSD) test, with significance set at $P < 0.05$.

**Vector Construction and Transformation of Tomato.** The complement DNA was synthesized with total RNA with M-MLV (Promega) as the recommendation of manufacturer. The full-length coding sequence of *BrTT8* was cloned into pBI121 for the replacement of GUS to obtain the construct pBI121-BrTT8. Primers used for amplification of *BrTT8* were *BrTT8*-con-F, TCTAGATACAGGTTT-TCATCTCGGG, and *BrTT8*-con-R, GAGCTCCATTAAGGTTAG-AATCTCGGAA. The binary vector pBI121-*BrTT8* containing the *BrTT8* cDNA driven by the 35S promoter was transferred into

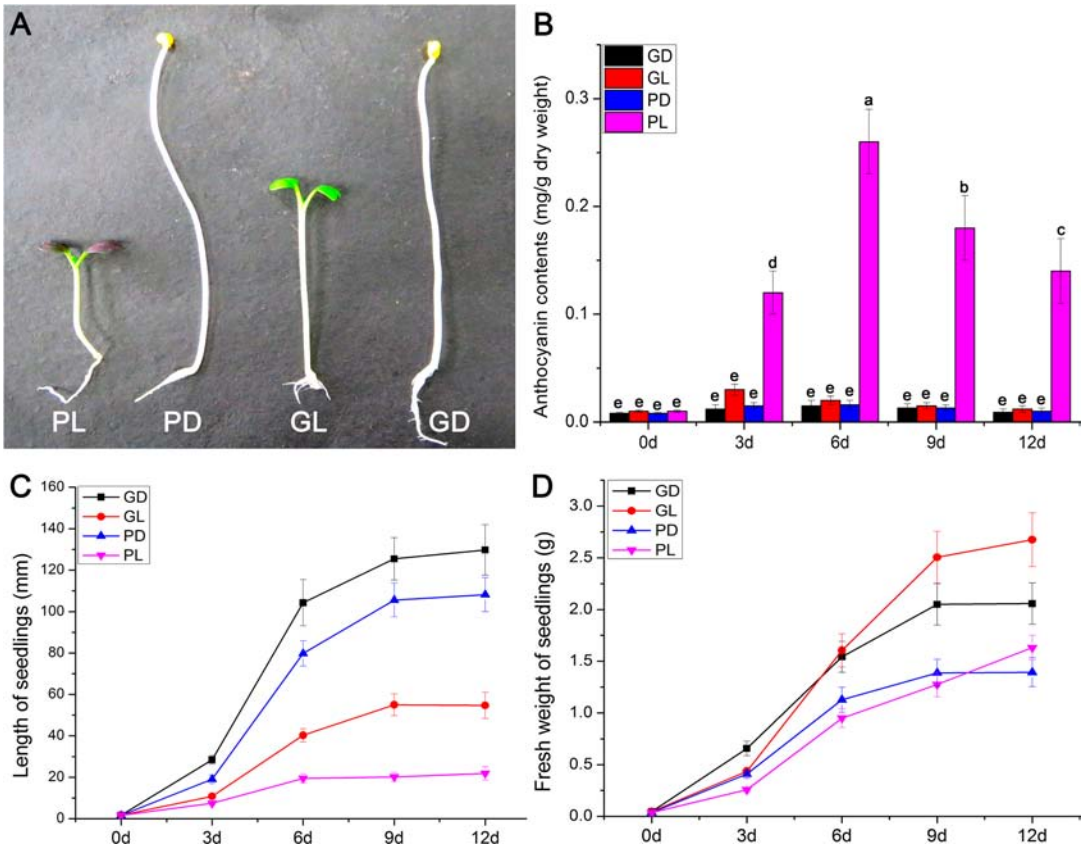

**Figure 4.** Phenotype of bok choy seedlings grown under dark and light conditions: (A) photographs of the two bok choy cultivars 6 days after sowing under dark and light conditions; (B) anthocyanin contents (mg/g dry weight) during the development of bok choy seedlings under dark and light conditions; (C) average length of seedlings of bok choy from 0 to 12 days after sowing ($n$ = 30 per treatment); (D) average fresh weight of seedlings of bok choy from 0 to 12 days after sowing ($n$ = 30 per treatment). PL, purple light; PD, purple dark; GL, green light; GD, green dark. Error bars represent the standard error of the mean ($n$ = 3). Statistical significance of the differences between samples was calculated with ANOVA by paired-group comparisons. Different letters indicate significance at $P < 0.05$.

*Agrobacterium tumefaciens* strain LBA4404 by the freeze−thaw method. Tomato (*Solanum lycopersicum* Mill. cv. Ailsa Craig) was used for the generation of transgenic shoots by *Agrobacterium*-mediated transformation, using the protocol previously reported.[32]

## RESULTS AND DISCUSSION

**Identification and Quantitative Analyses of Anthocyanins.** By analyzing the extracts from edible leaves of Zi He (purple cultivar) and Su Zhouqing (green cultivar) with the method of HPLC-ESI-MS/MS, a total of 15 anthocyanins were separated and characterized (Figure 1A,B). To verify the identity of anthocyanins in the purple cultivar, fragmentation patterns of MS/MS ($m/z$) were used to compare with those radical groups emerged in a previous study.[33] As the results show in Table 1, some new anthocyanins such as cyanidin 3-(sinapoyl) diglucoside-5-(malonyl) glucoside never reported in plants were identified in purple bok choy. Moreover, cyanidin was characterized as the major anthocyanidin in the purple bok choy with the absence of pelargonidin (Table 1). Obviously, acylated cyanidin of anthocyanidins is the most common modification of anthocyanins except for cyanidin 3,5-diglucoside. Broadly, the composition of anthocyanins identified in purple bok choy is similar to those of the other cruciferous vegetables except radish reported so far.[15,31,34]

Total anthocyanin content was found to be 3.13 mg/g dry weight for edible leaves from Zi He (Table 2). However, there were no obvious anthocyanins detected in mature leaves of Su Zhouqing. Furthermore, the anthocyanins showing the highest levels were cyanidin 3-(sinapoyl) diglucoside-5-(malonyl) glucoside and cyanidin 3-caffeoyl (sinapoyl) rutinoside-5-glucoside at 0.91 and 0.69 mg/g dry weight, respectively (Figure 1C,D; Table2). Nevertheless, a trace amount of petunidin 3,5-diglucoside was detected in HPLC profiles of anthocyanins in Zi He. This kind of anthocyanin has not been reported in the species of *Brassica* up to now. Previously published papers showed that accumulation of petunidin needs further hydroxylation at the 3′- and 5′-positions in the B-ring of naringenin;[35] that is to say, isoenzymes which share the same catalytic activity with F3′5′H probably exist in bok choy.

**Expression Analysis of Anthocyanin Biosynthesis Associated Genes in Edible Leaves of Different Cultivars.** To investigate the molecular mechanisms underlying the pigment accumulation in purple leaves of Zi He, the transcripts of anthocyanin biosynthetic and regulatory genes were examined by qRT-PCR. The expression levels of *BrPAL*, *BrC4H*, *BrCHS*, *BrCHI*, *BrF3H*, *BrF3′H*, *BrANS*, *BrDFR*, and *BrUFGT* are shown in Figure 2. In the edible leaves, all of the genes in the anthocyanin biosynthetic pathway were significantly up-regulated in the purple bok choy. Compared with the green cultivar, the expression levels of *BrDFR* and *BrANS* were especially up-regulated to at least 500-fold in the purple leaves. As the early studies reported, trace amounts of transcripts of all the anthocyanin biosynthetic genes were always observed despite the absence of visible pigment accumulation in the corresponding

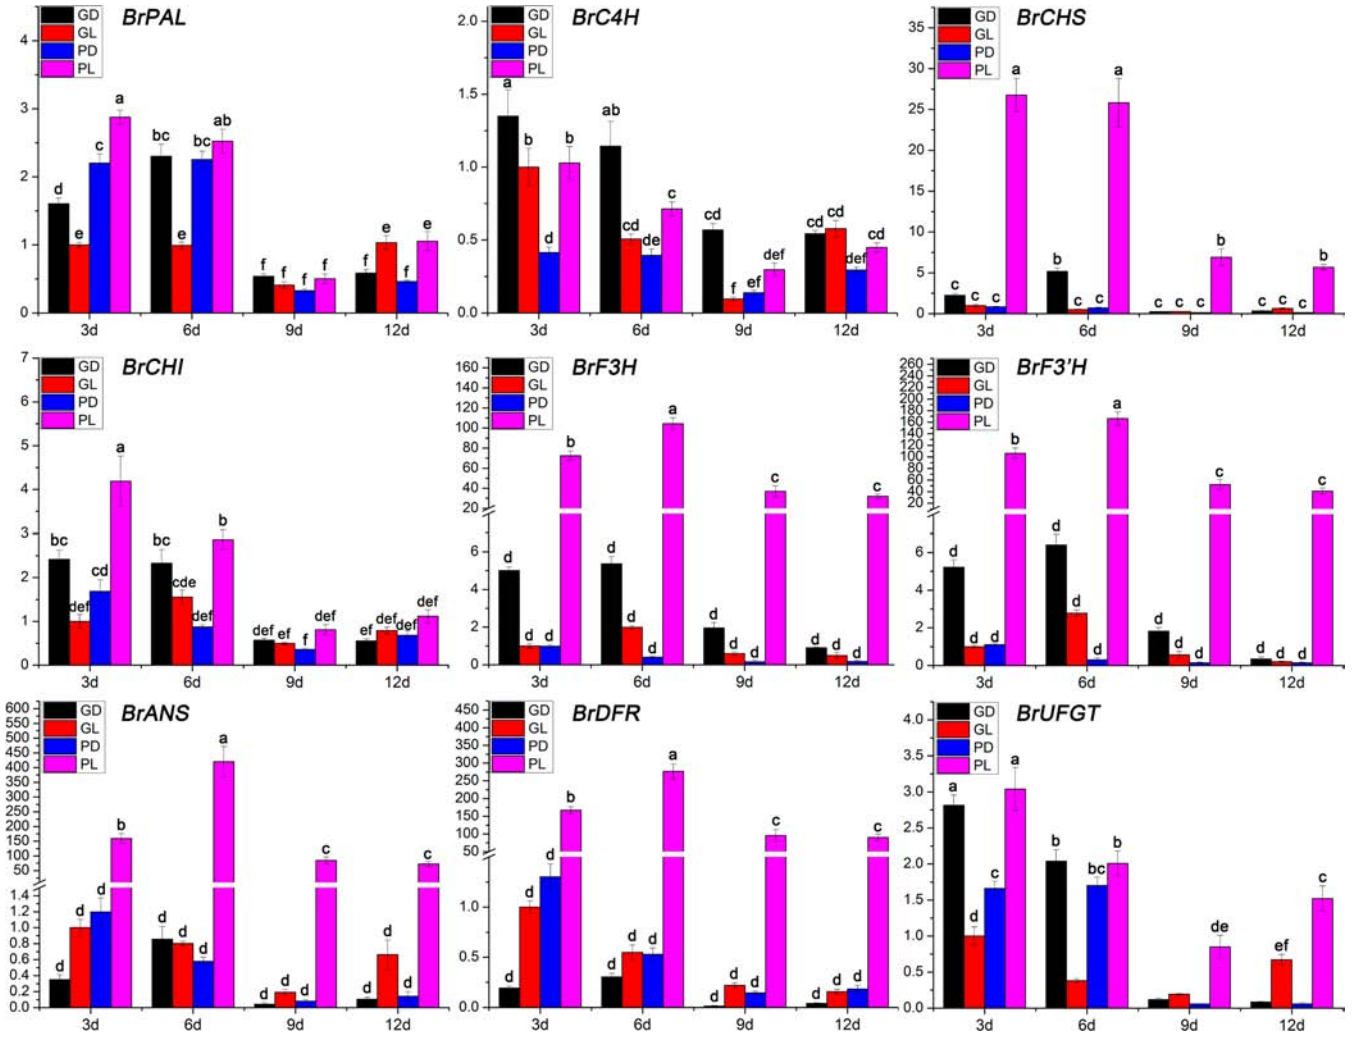

**Figure 5.** Expression analysis of anthocyanin biosynthetic genes during the development of bok choy seedlings under dark and light conditions. GD, green dark; GL, green light; PD purple dark; PL, purple light. The longitudinal axis indicates the expression levels of genes relative to the level of *BrApr*. Error bars represent the standard error of the mean ($n = 3$). Statistical significance of the differences between samples was calculated with ANOVA by paired-group comparisons. Different letters indicate significance at $P < 0.05$.

tissues.[15] These results indicate that adequate transcripts of some vital structural genes are essential for a large sum of anthocyanin biosynthesis. It is worth mentioning that the drastic increment of F3′H should make a complete conversion of DHK to dihydroquercetin because of the absence of pelargonidin-based anthocyanins.

To investigate the mechanisms about transcriptional regulation of structural genes that are responsible for pigmentation production, the transcripts of some anthocyanin biosynthesis regulatory orthologous genes of *Arabidopsis*, *BrMYB1*, *BrMYB2*, *BrMYB3*, *BrTT8*, *BrEGL3*, and *BrTTG1* were examined by qRT-PCR. It is worth mentioning that the three MYB genes (*BrMYB1*, *BrMYB2*, and *BrMYB3*) share high similarity with *AtPAP1* and *AtPAP2*, which regulate anthocyanin biosynthesis by activating the transcription of structural genes directly in a bHLH- and TTG1-dependent manner.[18,36] However, the up-regulation of bHLH transcription factors accounts for visible pigment accumulation in certain tissues of some species.[23,37,38] As the data show in Figure 3, *BrTT8* was the only transcription factor that is found to be significantly up-regulated in the leaves of the purple cultivar. The deduced amino acid sequences of BrTT8 were aligned with other bHLH transcription factors, which were known to regulate the anthocyanin biosynthesis in diverse species. BrTT8 exhibited highest sequence similarities with other bHLH proteins within the bHLH domain and the N-terminal MYB interaction domain (Supplementary Figure 1). Phylogenetic analysis divided bHLH regulators into two different clades. BrTT8 was placed in the same cluster with TT8 from *Arabidopsis*, NtAn1a and NtAn1b from tobacco, MdbHLH3 from apple, and PhAn1 from petunia (Supplementary Figure 2). Ectopic expression of *NtAN1a*, *NtAN1b*, and *MdbHLH3* activated the transcription of anthocyanin biosynthetic genes efficiently, whereas ectopic expression of *PhAN1* failed to activate the expression of DFR.[23,39,40] As the mechanism of anthocyanin biosynthesis pathway genes regulated by the MBW complex directly is widely found in many species, the different background expression levels of R2R3MYB transcription factors in respective species might explain the discrepancy observed above. These results suggest that the dramatically increased expression of BrTT8 might account for the anthocyanin accumulation in edible leaves of Zi He by activating the transcription of structural genes upon the formation of MBW complex with sufficient amounts of R2R3MYB and WD40 proteins.

**Growth of Bok Choy Seedlings under Light and Dark Conditions.** To evaluate the effects of light on seedling development

dx.doi.org/10.1021/jf503453e | J. Agric. Food Chem. 2014, 62, 12366−12376

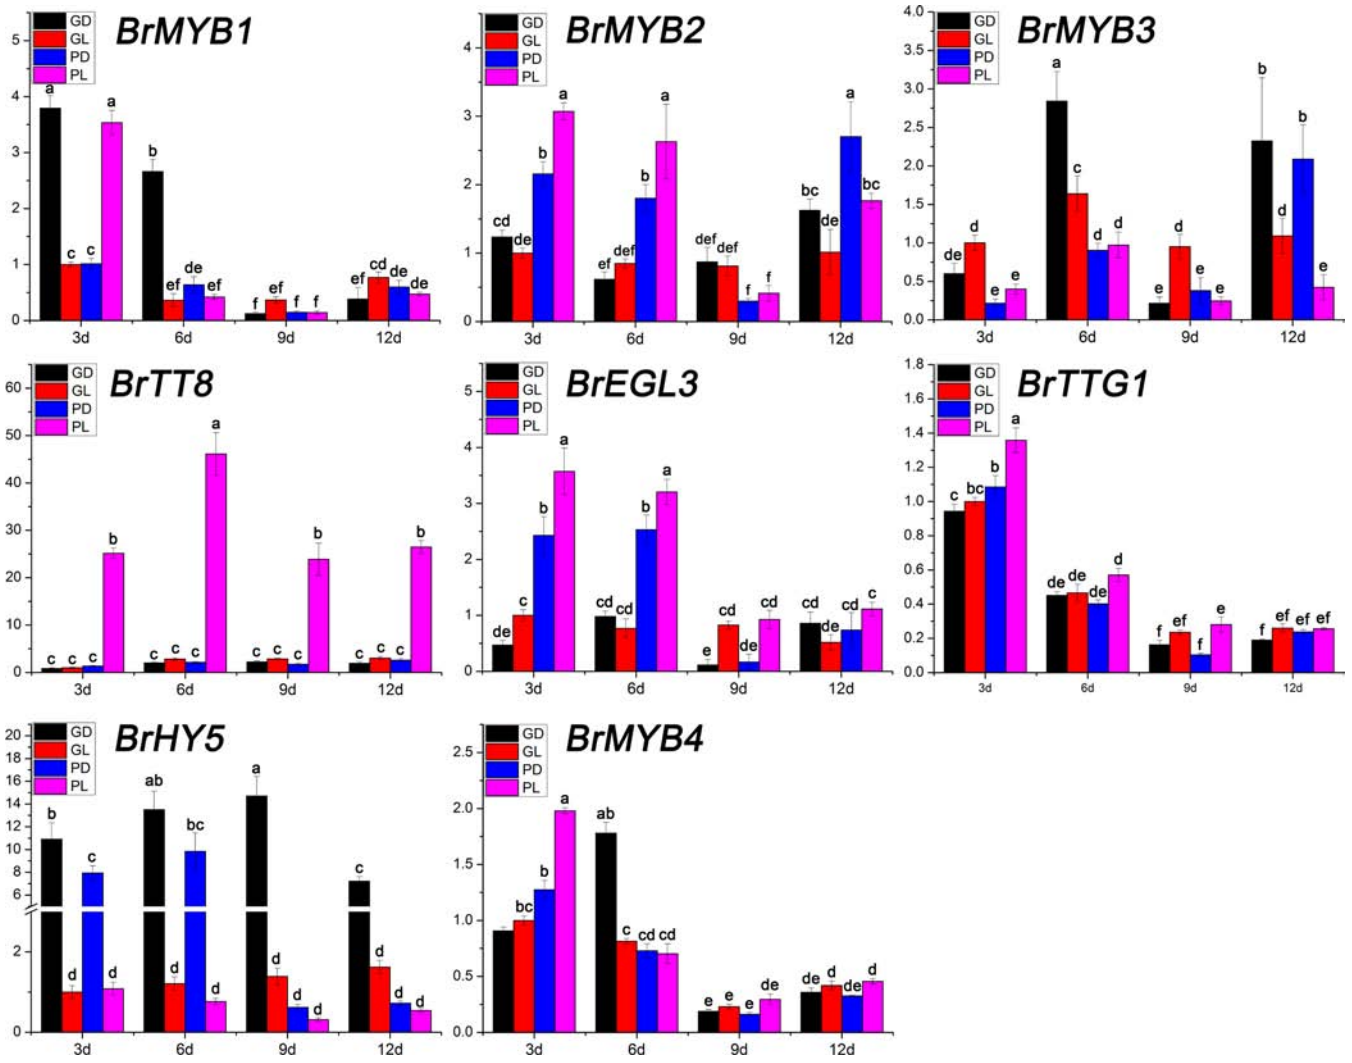

**Figure 6.** Expression analysis of anthocyanin biosynthesis regulatory genes during the development of bok choy seedlings under dark and light conditions. The longitudinal axis indicates the expression levels of genes relative to the level of *Apr*. Error bars represent the standard error of the mean ($n = 3$). Statistical significance of the differences between samples was calculated with ANOVA by paired-group comparisons. Different letters indicate significance at $P < 0.05$.

and anthocyanin accumulation, the length, fresh weight, and total pigment content of seedlings of both cultivars under light and dark conditions were examined every 3 days until 12 days after sowing (DAS) (Figure 4). Compared with the seedlings grown under light, the seedlings of both cultivars grown in darkness were all long and yellow (Figure 4A,C). The fresh weights of seedlings grown in dark conditions of both Zi He and Su Zhouqing were all obviously higher than those of the cultivars grown under light initially. However, the fresh weight of seedlings of both cultivars grown under light exceeded that of the seedlings grown in dark conditions gradually. Interestingly, the seedlings of Zi He grown in light took about 10 days to exceed the seedlings grown in darkness at the level of fresh weight, whereas the seedlings of Su Zhouqing took only 6 days to exceed the seedlings grown in darkness (Figure 4D). The growth rate of seedlings of the purple cultivar under light seems apparently lower than that of green cultivars. One reasonable explanation for this phenomenon is that the pigments synthesized in the cotyledon of Zi He reduced the efficiency of photosynthesis by inhibiting the light capture of chlorophyll.[24] Moreover, a large amount of anthocyanin production might consume a certain amount of energy and nutrients of plant cell and interfere with the normal metabolic activities in the plant itself. Although extensive studies showed that an adequate amount of anthocyanin production provides photoprotective function against excess visible light during the early development of young leaves and facilitates nutrient recovery in autumn by shielding leaves from potentially damaging light levels,[41−43] the results displayed above strongly suggest that constant anthocyanin accumulation in leaves might be a burden during the process of development, especially in seedlings.

**Expression Profiles of Anthocyanin Biosynthetic and Regulatory Genes in Seedlings of Different Cultivars under Light and Dark Conditions.** The expression profiles of anthocyanin pathway genes in the four groups of materials collected at different DAS were examined by qRT-PCR. As the results show in Figure 5, the transcript levels of *BrCHS*, *BrF3H*, *BrANS*, and *BrDFR* were greatly up-regulated in light-grown seedlings of Zi He, in contrast to the other three materials. In addition, the expression levels of these structural genes reached the maximum at 6 DAS in purple light-grown seedlings of different stages. The expression profiles of these structural genes

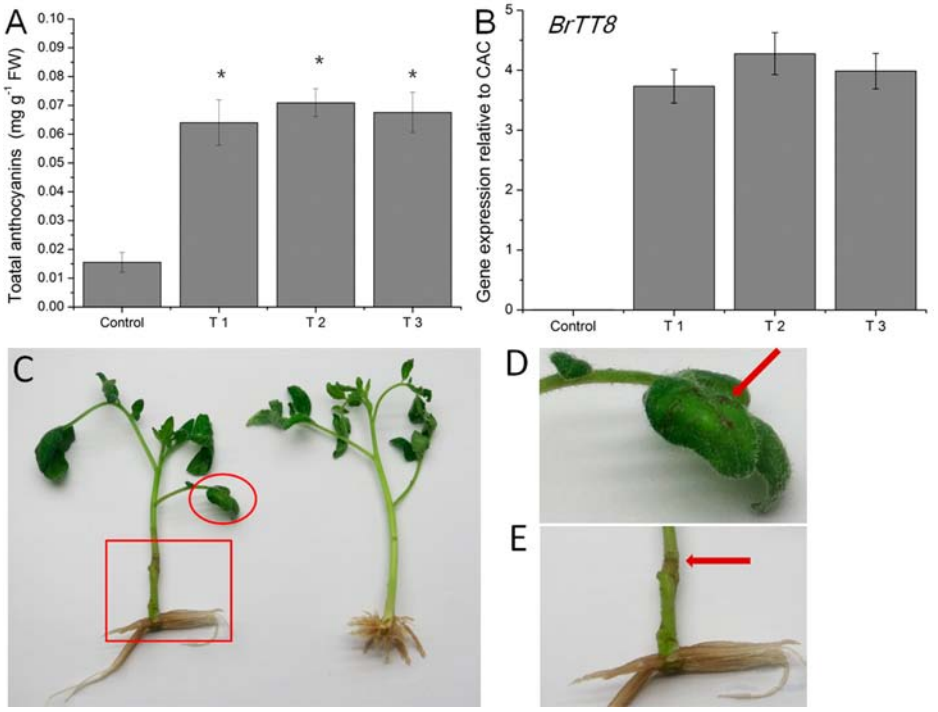

**Figure 7.** Heterologous expression of *BrTT8* in regenerating shoots of tomato promotes the biosynthesis of anthocyanins: (A) anthocyanin content in different lines of shoots; (B) transcriptional analysis of *BrTT8* in different regeneration shoots; (C) transformants (the T0 generation) of tomato transformed by pBI121-BrTT8 (left) and empty vector (right), respectively; (D) anthocyanins accumulated as small purple spots in leaves of transgenic seedlings; (E) anthocyanins accumulated visibly in the lower part in stems of transgenic seedlings. T1, T2, and T3 indicate independent regenerating shoot lines transformed with pBI121-BrTT8, whereas control indicates regenerating shoots transformed with empty vector. Asterisks above each column indicate a significant difference ($P < 0.05$) between control and transgenic lines.

were highly in accordance with the patterns of anthocyanin accumulation in seedlings of bok choy (Figure 4B). That is, it was the significantly increased expression of *BrCHS*, *BrF3H*, *BrANS*, and *BrDFR* that activates visible pigmentation production in seedlings of Zi He under light.

As we have speculated above, a bHLH transcription factor, *BrTT8*, probably regulates the anthocyanin biosynthesis by activating the transcription of structural genes in purple edible leaves with MYB and WD40 proteins. To investigate the molecular mechanisms of light-dependent anthocyanin accumulation in purple seedlings of bok choy, the transcripts of related regulatory genes were examined in the four serials of materials referred above. As Figure 6 shows, only the expression profile of *BrTT8* agreed well with those of *BrCHS*, *BrF3H*, *BrANS*, and *BrDFR*. Therefore, it is reasonable to speculate that the light-induced expression of *BrTT8* plays an important role in the anthocyanin biosynthesis activation in seedlings of Zi He under light. As the results show, *BrHY5* is greatly up-regulated in the seedlings of Zi He and Su Zhouqing under dark conditions. The high-level expression of *BrHY5* should be important for the inhibition of excessive elongation of hypocotyls of bok choy seedlings grown in darkness.[25,44] Besides, the increased expression of *BrHY5* might account for the slight up-regulation of *BrCHS* and *BrF3H* in early stages of Su Zhouqing despite no visible pigment accumulation in corresponding tissues. Nevertheless, the functions *BrHY5* plays during light-induced anthocyanin accumulation in seedlings of Zi He need further studies. In addition, *BrMYB4*, which is a potential transcriptional repressor of *BrC4H*, shows no significant changes at the mRNA level under visible light, in contrast with the seedlings grown in darkness.[45]

**Heterologous Expression of *BrTT8* in Transgenic Tomato Promotes the Expression of Partial Anthocyanin Biosynthetic Genes.** Phylogenetic and sequence analysis shows that BrTT8 lays in the same cluster with the anthocyanin synthesis activators *AmDEL*, *MdbHLH1*, *NtAN1a*, and *NtAN1b* (Supplementary Figures 1 and 2). To further study the function of the *BrTT8* gene, the full-length coding sequence of *BrTT8* driven by 35S promoter was expressed in the callus of tomato. Compared with the seedlings (the T0 generation) of tomato transformed by empty vector, the transgenic seedlings, which show high expression levels of the *BrTT8* gene, display visible anthocyanin accumulation as small purple spots in leaves and the lower part in stems (Figure 7). Furthermore, the expression level of anthocyanin biosynthetic genes in regeneration shoots was confirmed by qRT-PCR. The heterologous expression of *BrTT8* was in accordance with a coordinated increase in transcript levels of *SlPAL*, *SlCHS2*, *SlF3H*, and *Sl3GT* (Figure 8). In addition, SlCHS2 and SlF3H were significantly up-regulated in regeneration shoots. which showed visible accumulation of anthocyanins. These results suggest that the up-regulation of some vital structural genes is able to enhance the anthocyanin biosynthesis in shoots of transgenic tomato. As indicated before, the overexpression of NtAN1a and NtAN1b was able to enhance the accumulation of anthocyanin in petals of transgenic tobacco.[39] Furthermore, the purple spots in transgenic leaves resembled the phenotype observed in leaves of transgenic tomato that showed high expression of a heterologous gene *AmDEL* from snapdragon.[37] These results prove that heterologous expression of *BrTT8* in tomato is able to promote anthocyanin biosynthesis by activating the transcription of some vital anthocyanin structural genes.

dx.doi.org/10.1021/jf503453e | J. Agric. Food Chem. 2014, 62, 12366−12376

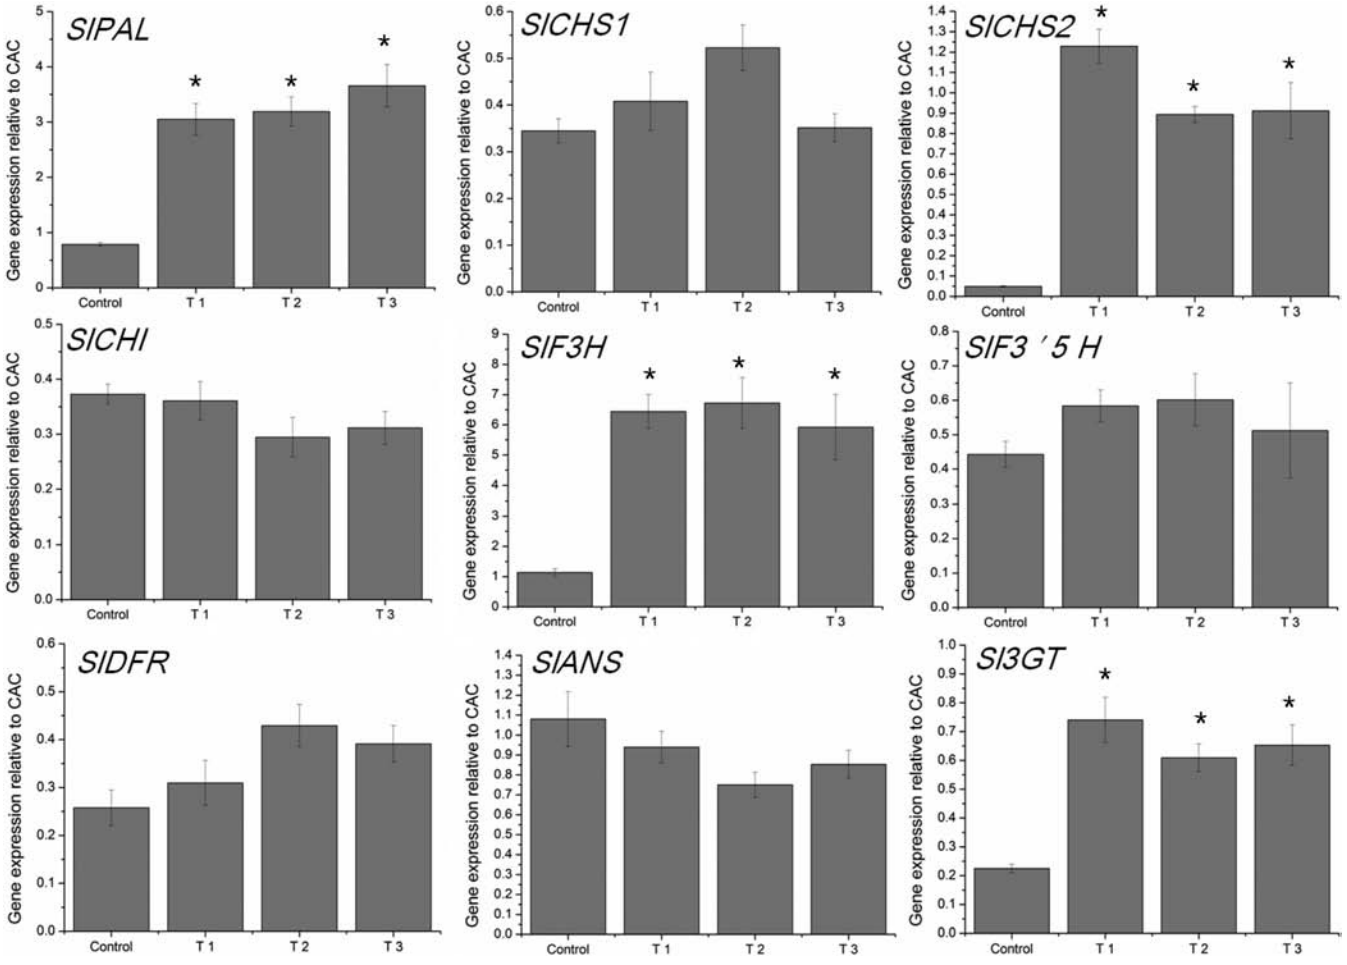

**Figure 8.** Expression analysis of structural genes of anthocynanin pathway in regeneration shoots of transgenic tomato. The longitudinal axis indicates the expression levels of genes relative to the level of *SlCAC*. Asterisks above each column indicate a significant difference ($P < 0.05$) from the control.

In this paper, the mechanisms of anthocyanin accumulation in bok choys were analyzed at both molecular and metabolic levels using the methods of HPLC-ESI-MS/MS and qRT-PCR. Cyanidin 3-(hydroxyferuloyl) diglucoside-5-(malonyl) glucoside and cyanidin 3-caffeoyl (sinapoyl) rutinoside-5-glucoside were identified as the major anthocyanins in edible leaves of Zi He. Moreover, the solely up-regulated transcription factors *BrTT8* in both edible leaves and seedlings under light probably contribute to the onset of anthocyanin biosynthesis by activating the transcription of structural genes in purple bok choy. Similarity and phylogenetic analysis of BrTT8 with other bHLH proteins from different species suggests that *BrTT8* may probably be a functional anthocyanin biosynthesis activator in purple bok choy. Furthermore, the anthocyanins detected in the regeneration shoots of tomato transformed by pBI121-BrTT8 confirmed the hypothesis we speculated above. As we have mentioned before, the large amount of anthocyanin accumulation in leaves inevitably counts against the growth of purple cultivars. This explanation agrees well with the facts that the growth rates of plants with excessive purple pigment accumulation are always significantly lower than those of the green cultivars.[24,41] However, a large amount of anthocyanin production is an important contributor to nutrition and consumer preference for bok choy. One possible solution for this conflict is the breeding of new cultivars with anthocyanin accumulation activators spatiotemporal specific expressed in edible parts during harvesting time like the strategy used in transgenic tomato.[5] Thence, the elucidation of the primary transcriptional control of anthocyanin accumulation in bok choy provides an important basis for the breeding of new purple cultivars of bok choy with more excellent agronomic characteristics.

extracted with ethanol (100 mL) after soaking at room temperature for 24 h. The ethanol solution was filtered through filter paper, and then the filtrate was then evaporated under reduced pressure at 40 °C. The purple residue after vacuum desiccation resulted in a gummy product (237 mg, 4.7%). 5,7-DMF and 5,7,4′-TMF were isolated according to the published method.[11] Flavonoids used for the reactivity study were purchased from Indofine Chemical Company (Hillsborough, NJ). Gifu anaerobic medium (GAM) from Nissui Pharmaceutical Co. (Tokyo, Japan) was used for isolation and growth media. GAM broth was prepared according to the instructions of the manufacturer, and GAM plates were prepared by the addition of 1.5% agar to the GAM broth.

**PMF Biotransformation with Fecal Samples.** The experiment was performed in compliance with the Bioethics and Safety Act enforced by the Korean government and the policies of the Chung-Ang University Institutional Research Board (CAU-IRB). Fresh fecal samples from a healthy 34-year-old female were collected directly once in deoxygenated GAM broth (4 mL), covered with sterilized mineral oil, and placed immediately in an anaerobic chamber (5% $CO_2$, 10% $H_2$, and 85% $N_2$) at 37 °C. The inoculated medium was stabilized for 2 h after filtration through sterilized gauze, and a portion of the medium was stored in liquid $N_2$ for further investigation. For the biotransformation of PMFs, 100 μL of the medium was inoculated in GAM broth (2 mL) and grown for 17 h at 37 °C. PMFs obtained from the ethanol extraction of krachaidum were dissolved in DMF at the concentration of 3 mg/mL, and then 2 μL was added to the 200 μL of bacterial culture and reacted for 3 days at 37 °C. After 3 days, ethyl acetate (1 mL) was added to each tube to stop the reaction and the mixture was vortexed for 20 s. After centrifugation at 10770*g* for 10 min, 800 μL of the organic supernatant was taken and the solvent was evaporated with a centrifugal evaporator (Micro-Cenvac NB-503CIR, N-Biotek, Gyeonggi, Korea). The residue was redissolved in 10 μL of methanol for further analysis. For thin-layer chromatography (TLC) analysis, 1 μL each of the methanol extract and the PMFs were applied on a silica gel TLC plate (Merck silica gel 60 F254). The TLC plate was developed in a mixture of hexanes/acetone (1:1, vol/vol). For HPLC analysis, the Finnigan Surveyor Plus high-performance liquid chromatography (HPLC) system (Thermo Scientific, Waltham, MA) equipped with a photodiode array detector (PDA Plus) and a $C_{18}$ reverse-phase column (Hypersil GOLD 5 μm, 4.6 × 100 mm, Thermo Scientific, Waltham, MA) was employed. The mobile phase was composed of 0.1% acetic acid in water (A) and 0.1% acetic acid in methanol (B). The solvent gradient profile started with 45% solvent B for 1 min and then increased from 45 to 55% solvent B over 14 min, from 55 to 60% solvent B over 9 min, and from 60 to 65% solvent B over 8 min, after which it decreased to 60% solvent B for 5 min at the flow rate of 1.0 mL/min.

**Isolation of PMF-Metabolizing Bacterium and Culture Conditions.** Strain MRG-PMF1 was isolated from the fecal samples, which showed PMF bioconversion activity. The mixed cell culture (360 μL) prepared from fecal samples was diluted to $10^{-4}$ with GAM broth after the addition of 3.6 μL of the PMF solution (3.0 mg/mL in DMF). The diluted solution was spread on GAM agar plates for isolation. After incubation for 2 days at 37 °C, single colonies were picked from the plates, transferred into 500 μL of GAM broth, and incubated overnight. The PMF-metabolizing activity was checked by TLC and HPLC, as described above. Subcultures and activity checks were repeated until a pure bacterium was obtained.

**16S rRNA Gene Sequencing and Phylogeny Analysis.** 16S rRNA gene sequence analysis of the isolated bacterium was performed for identification of the bacterial strain. The bacterium was streaked on GAM agar plates in an anaerobic chamber and grown for 2 days at 37 °C. The 16S rRNA gene was amplified by PCR with universal bacteria primers 27F (5′-AGAGTTTGATCMTGGCTCAG-3′) and 1492R (5′-GGYTACCTTGTTACGACTT-3′), and sequencing was performed via the sequencing service at Solgent, Inc. (Daejeon, Korea). The 16S rDNA sequences were analyzed using the BLASTN tool of the National Center for Biotechnology Information (NCBI) to identify bacterial strains with sequence similarity.[12] Phylogenetic trees were constructed by the neighbor-joining method using the MEGA 6 program.[13]

**Bacterial Growth and pH Changes.** The bacterial culture stored in liquid nitrogen was thawed in an anaerobic chamber, and 100 μL was then transferred to 2 mL of GAM broth. When the optical density at 600 nm ($OD_{600}$) reached 0.7, 400 μL of the cell culture was transferred to 20 mL of fresh GAM broth. Bacterial growth was monitored by measuring $OD_{600}$ with the ultraviolet−visible (UV−vis) spectrophotometer S-3100 (Scinco, Seoul, Korea), and the pH of the medium was also measured by the Laqua pH meter F-74BW (Horiba Scientific, Kyoto, Japan) every 30 min.

**Biotransformation of 5,7-DMF and 5,7,4′-TMF.** 5,7-DMF and 5,7,4′-TMF were used for the study of biotransformation kinetics in an anaerobic chamber and the identification of the intermediates. When the growth of the bacteria in GAM broth reached $OD_{600}$ of 0.8, each substrate was added to the reaction media (1.5 mL, 100 μM) to initiate biotransformation. Aliquots of the reaction mixtures (100 μL) were taken and allocated into Eppendorf tubes every 3 h. The allocated media were extracted with 1 mL of ethyl acetate, and the supernatant (800 μL), collected after vortexing and centrifugation (10770*g* for 10 min), was dried under vacuum. The residue was dissolved in 100 μL of methanol and analyzed by HPLC. The solvent gradient profile for 5,7-DMF biotransformation started with 53% solvent B for 1 min and then increased from 53 to 55% solvent B over 14 min and from 55 to 70% solvent B over 3 min. The solvent gradient profile for 5,7,4′-TMF biotransformation started with 45% solvent B for 1 min and then increased from 45 to 55% solvent B over 9 min, from 55 to 61% solvent B over 3 min, and finally from 61 to 70% over 2 min.

**Structural Analyses of 5,7-DMF and 5,7,4′-TMF Metabolites.** 5,7-DMF and 5,7,4′-TMF metabolites were analyzed by a Dionex Ultimate 3000 HPLC system (Thermo Scientific, Waltham, MA) equipped with a $C_{18}$ reversed-phase column (Kinetex, 100 × 2.1 mm, 1.7 μm, Phenomenex, Torrance, CA) and a diode array detector (DAD). A Thermo Fisher Scientific LCQ fleet instrument (Thermo Scientific, Waltham, MA) was coupled to the HPLC system for electrospray ionization mass spectrometry (ESI−MS) analysis. The mobile phase was a gradient of water with 0.1% formic acid (A) and acetonitrile with 0.1% formic acid (B). The initial composition of the mobile phase was 33% solvent B for 1 min. In linear gradients, the composition changed to 45% solvent B over 2 min and then 50% solvent B over 8 min, where it stayed for 10 min at the flow rate of 0.2 mL/min. ESI−MS analyses were performed in positive-ion mode within the $m/z$ range of 50−500 and processed with Xcalibur software (Thermo Scientific, Waltham, MA). ESI conditions: spray voltage, 5.4 kV; sheath gas, 15 arbitrary units; auxiliary gas, 5 arbitrary units; heated capillary temperature, 275 °C; capillary voltage, 27 V; and tube lens, 100 V.

For the isolation of intermediate A produced during the biotransformation of 5,7-DMF, 1 mL of GAM medium containing MRG-PMF1 ($OD_{600}$ of 0.6) was added to 200 mL of GAM medium. When the $OD_{600}$ of the GAM medium reached 0.8, 5,7-DMF (10 mg, 5 mL of 5 mM DMF) was added to the reaction medium and reacted in an anaerobic chamber. The conversion of 5,7-DMF was monitored by TLC analysis of the medium. After 58 h, the reaction medium was centrifuged (10770*g* for 20 min) and the supernatant was extracted with EtOAc (100 mL × 3). The combined organic layer was dried with anhydrous $MgSO_4$, and the organic solvent was removed under reduced pressure by a rotatory evaporator. After vacuum desiccation of the residue, the fraction containing intermediate A (2 mg) was isolated by vacuum liquid chromatography.[14] Intermediate A was further purified by preparative TLC (0.5 mg, isolation yield of 2.4%), and the proton nuclear magnetic resonance ($^1$H NMR) spectrum was recorded in MeOH-$d_4$ on a Varian VNS (600 MHz, Palo Alto, CA). Chemical shift ($\delta$) was reported in parts per million (ppm). Intermediate A (5-methylchrysin): UV ($\lambda_{max}$, nm), 264, 314; $^1$H NMR (600 MHz, $CD_3OD$) $\delta$, 7.92 (*m*, 2H, H-2′, H-6′), 7.52 (*m*, 2H, H-3′, H-5′), 7.51 (*m*, H, H-4′), 6.64 (*s*, 1H, H-3), 6.56 (*d*, 1H, $J$ = 2.2 Hz, H-6), 6.41 (*d*, 1H, $J$ = 2.2 Hz, H-8), 3.96 (*s*, 3H, −$OCH_3$).

**Reactivity Study of PMF-Metabolizing Bacterium.** To study the substrate specificity of flavonoid biotransformation, the isolated bacterium was reacted with 100 μM of various substrates. In detail,

bacteria were grown to $OD_{600}$ of 0.7 in 495 μL of GAM broth in an anaerobic chamber at 37 °C, after which 5 μL of each substrate (10 mM in DMF) was added. After incubation for 15 min and 1, 2, 3, and 7 days, 100 μL of reaction media was taken from each culture and 1 mL of ethyl acetate was added to stop the biotransformation. The mixture was then vortexed for 20 s and centrifuged (10770*g* for 10 min). The supernatant (800 μL) was taken and dried under reduced pressure. The residue was dissolved in 100 μL of methanol, and a 10 μL aliquot was injected for HPLC. The solvent gradient profile started with 20% solvent B for 1 min and then increased from 20 to 50% solvent B over 9 min and from 50 to 70% solvent B over 5 min at the flow rate of 1.0 mL/min. The reaction products were detected and identified from comparison to the expected standard flavonoids.

## RESULTS

**PMF Biotransformation by Human Fecal Sample and the Isolation of Strain MRG-PMF1.** The PMF mixture obtained by ethanol extraction of krachaidum was completely metabolized by the fecal sample obtained from a healthy 34-year-old female (see Figure S1 of the Supporting Information). From the diluted fecal samples showing PMF-metabolizing activity, 75 single colonies were isolated and further tested for activity. An obligatory anaerobic Gram-positive coccobacilli, which can metabolize PMFs was isolated under anaerobic conditions (see Figure S1 of the Supporting Information) and successfully subcultured on GAM plates without losing the PMF-metabolizing activity. The 16S rRNA gene of the isolate was sequenced for identification and deposited in GenBank under accession number KJ078647. The partial 16S rRNA gene sequence (1361 bp) was most closely related with *Blautia producta* ATCC 27340T (X94966), showing 99.85% similarity. Other strains in the family Lachnospiraceae and genus *Blautia*, particularly *Blautia coccoides* ATCC 29236T (M59090, 99.70% similarity), *Blautia stercoris* GAM6-1T (HM626177, 95.39% similarity), *Blautia hansenii* DSM 20583T (ABYU01000028, 95.37% similarity), *Blautia stercoris* SJTU C 02 47 (EF403927, 95.30% similarity), *Blautia schinkii* BT (X94965, 95.13% similarity), *Blautia faecis* M25T (HM626178, 95.00% similarity), and *Blautia glucerasea* HFTH-1T (AB439724, 94.77% similarity), also showed high sequence similarity to the isolated bacterium (Figure 1). Therefore, the isolated PMF-metabolizing anaerobic bacterium was identified as *Blautia* sp. MRG-PMF1.

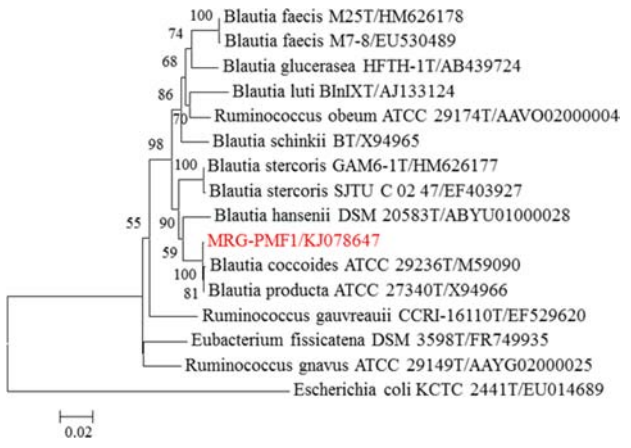

**Figure 1.** Molecular phylogenetic tree analysis of *Blautia* sp. MRG-PMF1. Numbers at the branching points indicate bootstrap values greater than 50% based on 1000 samplings. *Escherichia coli* was used as an out group. Bar, 0.02 nucleotide substitutions per position.

The PMF biotransformation by strain MRG-PMF1 was studied by HPLC analysis. The ethanol extract of krachaidum is known to contain 11 PMFs, for which TLC and HPLC analyses of the compositional changes were reported before.[11] The mixture of PMFs used herein for the reaction with fecal samples contained 5,7-DMF (10%), 5,7,4′-TMF (12%), and 3,5,7,3′,4′-pentamethoxyflavone (3,5,7,3′,4′-PMF, 20%) as the major compounds. Along with these three compounds, 3,5,7,4′-tetramethoxyflavone (3,5,7,4′-TMF, 6%) and 5-hydroxy-3,7,4′-trimethoxyflavone (5-OH-3,7,4′-TMF, 6%) were also abundant.[9] After the 3 day reaction with MRG-PMF1, biotransformation products of the PMFs were analyzed by HPLC (Figure 2). Chrysin (5,7-dihydroxyflavone) and apigenin (5,7,4′-trihydroxyflavone) were identified by comparing their retention times and UV spectra to the standard compounds. The other metabolites 3-*O*-methylquercetin and 3-*O*-methylkaempferol were assigned on the basis of the HPLC retention times and published UV spectra.[15] From analysis of the biotransformation of PMFs by MRG-PMF1 (Figure 3), it was found that the methyl group at the C-3 position of flavone was not hydrolyzed even after 3 days of incubation.

A growth curve of the isolated bacteria in GAM medium under anaerobic conditions was obtained by monitoring the changes in $OD_{600}$. *Blautia* sp. MRG-PMF1 reached the stationary phase in 9 h after a lag phase of 3.5 h at 37 °C (see Figure S2 of the Supporting Information). After the stationary phase, a decrease in $OD_{600}$ was observed. The growth of MRG-PMF1 showed good correlation with the pH changes of the media. The initial pH of the medium was pH 6.9, and a decrease to pH 5.4 was observed during exponential cell growth of the strain.

**Biotransformation of 5,7-DMF and 5,7,4′-TMF and Kinetics Study.** Biotransformation of 5,7-DMF and 5,7,4′-TMF by *Blautia* sp. MRG-PMF1 produced chrysin and apigenin, respectively, through the hydrolysis of methyl aryl ether functional groups of the substrates (Figure 2). In the time-dependent study, *Blautia* sp. MRG-PMF1 was found to metabolize completely 0.1 mM 5,7-DMF and 5,7,4′-TMF within 30 h (see Figure S3 of the Supporting Information). Furthermore, biotransformation intermediates were observed for both PMFs via TLC (see Figure S4 of the Supporting Information) and HPLC (Figure 4) analyses. During the biotransformation of 5,7-DMF, an intermediate A was identified on the HPLC chromatogram. The HPLC retention time and UV spectrum of intermediate A were different from 7-methoxychrysin, another PMF found in krachaidum extract.[11] The UV absorption at 264 and 314 nm was the same as the reported data for 5-methoxychrysin.[16] The molecular ion $[M + H]^+$ peak of intermediate A was found at $m/z$ 269.23 from the ESI−MS spectrum, which was smaller than that of 5,7-DMF ($m/z$ 283.24) by 14 Da and larger than that of chrysin by 14 Da (see Figure S5 of the Supporting Information). Between two possible demethylation intermediates of 5,7-DMF, intermediate A was assigned as 5-methoxychrysin by comparison of the HPLC retention times and electronic spectra. The molecular structure of intermediate A was confirmed by $^1$H NMR spectroscopy. Two methoxy groups of 5,7-DMF are found at $\delta$ 3.96 ppm (5-$OCH_3$) and $\delta$ 3.92 ppm (7-$OCH_3$),[11] but the peak corresponding to the 7-methoxy group disappeared from the $^1$H NMR spectrum of intermediate A. Two metabolic intermediates B and C were observed during the biotransformation of 5,7,4′-TMF, which were assigned as 7-OH-5,4′-DMF and thevetiaflavone, respectively (Figure 5).

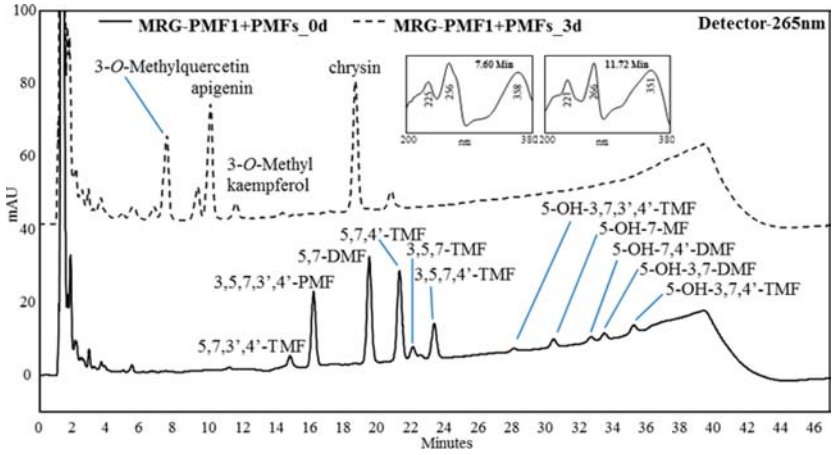

**Figure 2.** HPLC analysis of PMF metabolism by fecal sample. The solid and dotted lines represent PMFs before and after 3 days of reaction, respectively. (Inset) PDA UV spectra and the retention times of metabolites from the 3 day reaction data were used for the identification of 3-*O*-methylquercetin and 3-*O*-methylkaempferol. Abbreviations: 5,7,3′,4′-TMF, 5,7,3′,4′-tetramethoxyflavone; 3,5,7,3′,4′-PMF, 3,5,7,3′,4′-pentamethoxyflavone; 3,5,7-TMF, 3,5,7-trimethoxyflavone; 3,5,7,4′-TMF, 3,5,7,4′-tetramethoxyflavone; 5-OH-3,7,3′,4′-TMF, 5-hydroxy-3,7,3′,4′-tetramethoxyflavone; 5-OH-7-MF, 5-hydroxy-7-methoxyflavone; 5-OH-7,4′-DMF, 5-hydroxy-7,4′-dimethoxyflavone; 5-OH-3,7-DMF, 5-hydroxy-3,7-dimethoxyflavone; and 5-OH-3,7,4′-TMF, 5-hydroxy-3,7,4′-trimethoxyflavone.

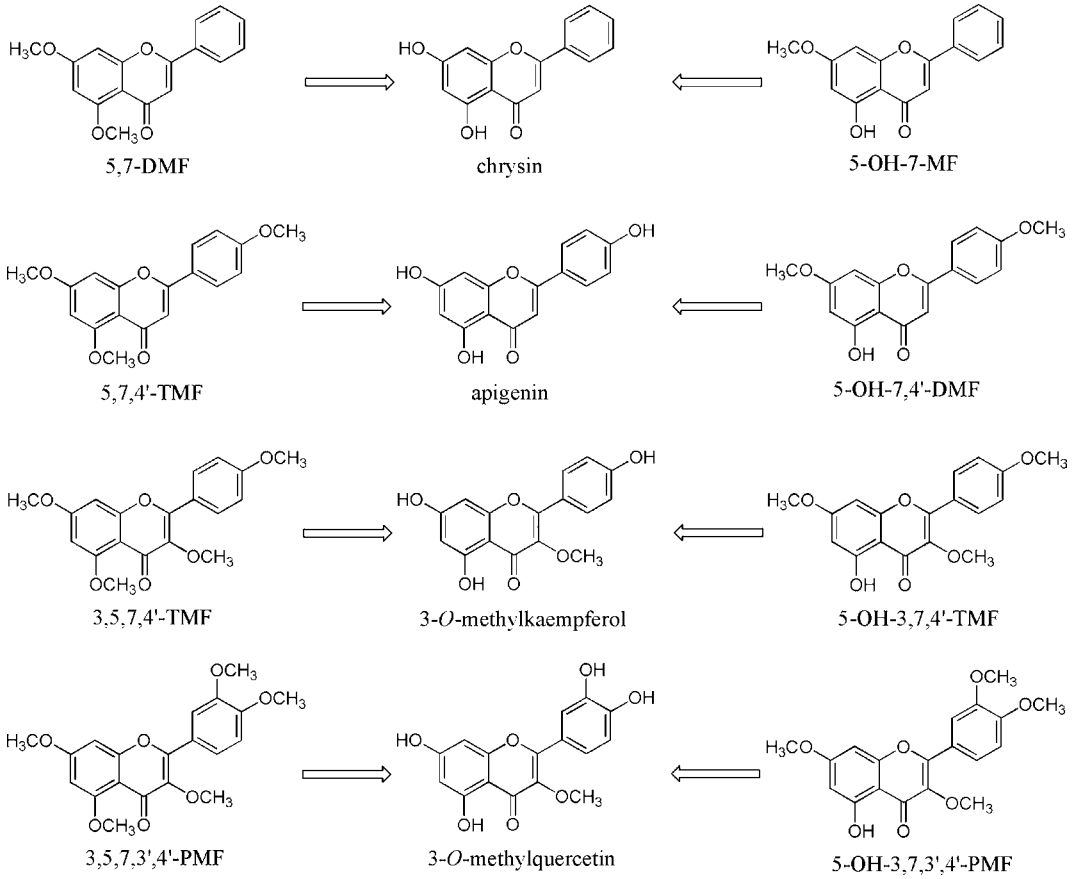

**Figure 3.** Bioconversion of the PMF mixture by *Blautia* sp. MRG-PMF1.

**Biotransformation of Other Flavonoids by *Blautia* sp. MRG-PMF1.** *Blautia* sp. MRG-PMF1 was tested for the ability to metabolize other flavonoids (Table 1). The metabolites, except for eriodictyol (5,7,3′,4′-tetrahydroxyflavanone), were identified by comparison to the retention times and UV spectra of the standard compounds by HPLC. The other two metabolites were confirmed by comparing the UV spectrum to the published data.[17] Along with PMF-metabolizing activity, *Blautia* sp. MRG-PMF1 also showed flavone *O*-glucose and flavone *O*-rutinose hydrolysis activities. Apigetrin and rutin were converted to apigenin and quercetin, respectively. Various isoflavones, except for puerarin, were also metabolized by *Blautia* sp. MRG-PMF1. For example, daidzin, genistin, glycitin, ononin, and sissotrin were converted to their aglycones, daidzein, genistein, glycitein, formononetin, and biochanin A, respectively, because of the *O*-glucose and *O*-methyl hydrolysis

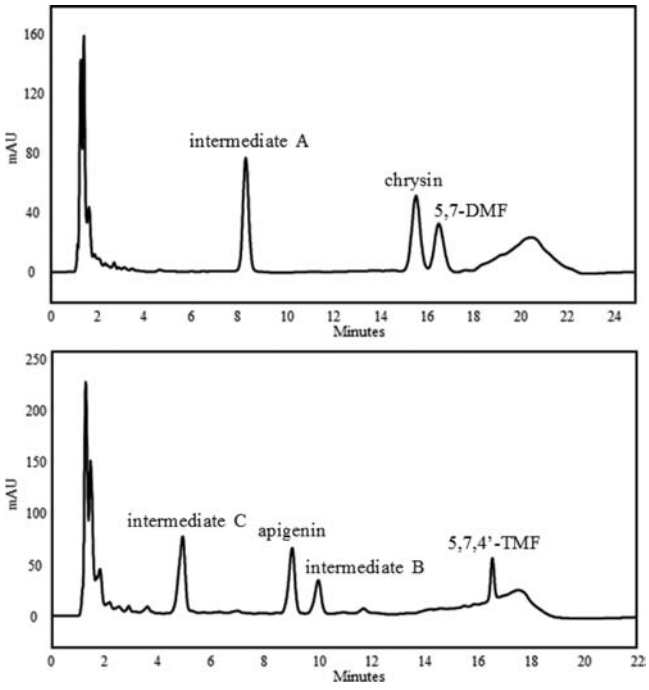

**Figure 4.** HPLC chromatograms (265 nm) of *Blautia* sp. MRG-PMF1 biotransformation products obtained from 5,7-DMF (18 h, above) and 5,7,4′-TMF (21 h, below).

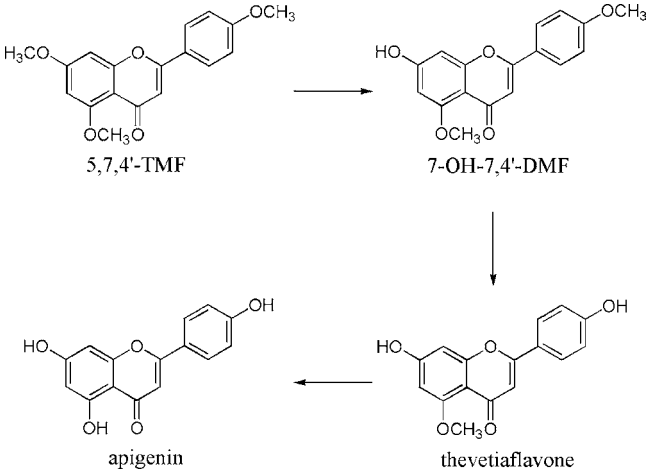

**Figure 5.** Metabolic pathway of 5,7,4′-TMF biotransformation.

activities. Glycitein biotransformation by human fecal flora was reported to produce the metabolite 6,7,4′-trihydroxyisoflavone.[18] However, strain MRG-PMF1 did not show *C*-glucoside-hydrolyzing activity.[19] Flavone and isoflavone *C*-glucosides, such as puerarin and vitexin, were not metabolized by *Blautia* sp. MRG-PMF1. Flavanones with methoxy groups, hesperidin and hesperetin, were metabolized, but naringin was not.

## DISCUSSION

Although dietary polyphenols, including flavonoids, are known to exhibit various biological activities, there is accumulating evidence that it is their metabolites, produced by human intestinal bacteria, which contribute more significantly to human health.[20,21] PMFs are a group of bioactive flavonoids that exhibit a broad spectrum of biological activities, including anticancer and anti-inflammatory properties. To investigate PMF metabolism in the human intestine, PMFs were reacted with human fecal samples herein for the first time. Demethylated metabolites of the PMFs from the fecal samples of rats to which krachaidum extract was orally administered were reported previously.[8] Although PMFs were considered to be stable bioactive compounds because of the chemical stability of the methyl aryl ether functional group, the robust biotransformation of PMFs was observed by a human fecal sample at room temperature under anaerobic conditions. The chemical cleavage of ether bonds usually requires high temperatures in the presence of strong acid or base.[22] As shown in Figure 2, the PMF biotransformation by MRG-PMF1 produced chrysin, apigenin, 3-methylkeampferol, and 3-methylquercetin. It is interesting to note that these compounds are reported to be present in propolis.[23] Therefore, different flavonoids were produced by demethylation of the PMFs, and new biological effects of these metabolites are expected to be observed in humans. In the case of nobiletin, the metabolites 3′-demethylnobiletin, 4′-demethylnobiletin, and 3′,4′-bisdemethylnobiletin, were reported to exhibit stronger anti-inflammatory and anticarcinogenic properties.[24]

From the time-dependent biotransformation of 5,7-DMF and 5,7,4′-TMF, the metabolic pathways of 5,7-DMF → 5-methylchrysin → chrysin and 5,7,4′-TMF → 5,4′-dimethoxy-7-hydroxyflavone → thevetiaflavone → apigenin were elucidated, respectively. Demethylation was faster for the 7-methoxy group and slower for the 5-methoxy group. From biotransformation of the mixture of PMF, *Blautia* sp. MRG-PMF1 was found not to be able to hydrolyze the 3-methoxy group of flavone. There are surprisingly few reports on the biotransformation intermediates identified herein, such as 5-methylchrysin, 5,4′-dimethoxy-7-hydroxyflavone, and thevetiaflavone. Most PMF metabolites and their intermediates were reported from bee products.[23] In addition to the PMFs, various flavonoids were also observed to be biotransformed by *Blautia* sp. MRG-PMF1 (Table 1). Through the tested substrates, it was found that MRG-PMF1 exhibited hydrolysis activity for methyl ether, *O*-glucose, and *O*-rutinose functional groups of flavone, isoflavone, and flavanone. The only exception of this finding was naringin, but it was not clear whether or not naringin metabolites have antibacterial activity against MRG-PMF1.

Although bioinformatic approaches using high-throughput sequencing contribute significantly to the areas of food and clinical microbiology, it is evident from our previous work that the biotransformation of bioactive flavonoids by human intestinal bacteria can produce new bioactive compounds that may not exist in the human diet and that cannot be biosynthesized in the body.[25] For example, the new metabolic intermediates, *R*-DHD,[26] (3*S*,4*R*)-THD,[27] and *R*-*O*-DMA[28] were discovered from the biosynthetic study of *S*-equol.

Besides, the isolation of new intestinal bacteria and characterization of metabolites are of great significance to the discovery of novel enzymes and leading bioactive compounds. Identification of bioactive metabolites produced by specific intestinal bacteria is also important and is a prerequisite to investigating microbiota−host interactions at the molecular level. Furthermore, the structural characterization of various metabolites formed from dietary flavonoids can provide valuable data for the metabolomic study in human microbiome research.[29] The unprecedented PMF demethylation activity of *Blautia* sp. MRG-PMF1 will expand our understanding of

**Table 1. Flavonoid Metabolism by *Blautia* sp. MRG-PMF1**

| substrate | product | activity | time |
|---|---|---|---|
| | Flavone | | |
| apigetrin | apigenin | *O*-glucose hydrolysis | <24 h |
| rutin | quercetin | *O*-rutinose hydrolysis | <3 days |

termed Elovl4 were cloned and functionally characterized. The preference for n−6 PUFA substrates of these enzymes implied an advanced adaptation of noble scallop to the marine environment. The results increased our knowledge of the relationship between LC-PUFA biosynthesis pathways and the habitat and feeding habit of mollusk species.

## MATERIALS AND METHODS

**Cloning of a Putative Desaturase cDNA.** The noble scallops maintained at Nan'ao Island of Guangdong Province, China, were sacrificed. Female gonad was sampled to extract total RNA using TRIzol reagent (Invitrogen, Grand Island, NY). The first fragment of scallop Fads2 and Elovl4 was obtained by BLASTX searching against noble scallop transcriptome data set (Accession: SRX253988). 3′ and 5′ RACE PCRs were carried out using the SMART RACE cDNA amplification kit (Clontech, USA) according to the instructions. The preparation methods of cDNA and amplification conditions of RACE PCRs were both conducted as suggested by the manufacturers. Positive fragments were obtained by two-round PCR based on the known partial sequences using RACE PCR primers, then cloned into pMD18-T vector (TaKaRa, Guangzhou, China), and sequenced (Sangon Biotech, Shanghai, China). Full lengths of the two genes were obtained by aligning the 3′-end fragment with 5′-end fragment.

**Sequence and Phylogenetic Analyses.** The multiple sequence alignment was performed using ClustalX 2.1, and phylogenetic trees were made using the neighbor-joining method in the MEGA 4.1 package on the basis of putative protein sequence of desaturase or elongase from the scallop and other organisms. Confidence in the resulting phylogenetic tree branch topology was measured by bootstrapping through 1,000 iterations.

**Heterologous Expression of Desaturase ORFs in Yeast and Fatty Acid Analysis by GC.** The open reading frames (ORFs) encoding Fads2 or Elovl4 were amplified from scallop gonad cDNA using the high-fidelity *Pfu* DNA polymerase (Tiangen, Beijng, China). D8EF1 and D8ER1 were used to perform the first round PCR, and D8EF2 and D8ER2 were used to perform the second PCR to get Fads2 ORF. Similarly, a two-round PCR approach was used to amplify Elovl4 ORF, with the first round performed with primers E4EF1 and E4ER1, and second with primers E4EF2 and E4ER1 (Table 1). All PCR amplifications involved an initial denaturation step at 95 °C for 2 min, followed by 30 cycles of denaturation at 95 °C for 30 s, annealing at 57 °C for 30 s, and extension at 72 °C for 90 s. After PCR, the DNA fragments were purified, digested with restrictive enzyme, and ligated into similarly digested yeast expression vector pYES2.0 (Invitrogen). The recombinant plasmids with right sequence were transformed into yeast accordingly to the method of Liu et al.[25] Recombinant yeast was cultivated in minimal medium minus uracil (SCMM−uracil) broth using galactose for induction of gene expression as described previously.[27] Cultures with Fads2 were supplemented with one of the following PUFA substrates: 18:2n−6, 18:3n−3, 20:2n−6, 20:3n−3, 20:3n−6, 20:4n−3, 22:5n−3, and 22:4n−6. Cultures with Elovl4 were supplemented with 20:4n−6 or 20:5n−3. Total lipids of yeast cells were extracted by homogenization in chloroform/methanol (2:1, vol/vol), containing 0.01% butylated hydroxytoluene (Sigma-Aldrich) as the antioxidant. Fatty acid methyl esters (FAMEs) were prepared, extracted, and purified by TLC on a 20 cm × 20 cm × 0.25 mm silica gel 60 plate (Merck, Germany), accordingly to the method of Liu et al.[25] FAMEs were analyzed using gas chromatography (GC-17A, Shimadzu, Kyoto, Japan) equipped with a hydrogen flame ionization detector and a capillary column (30 m × 0.25 mm × 0.25 μm, VF-23ms, Varian, USA). When analyzing FAMEs from cultures with Fads2, the column was temperature-programmed from 50 to 170 °C at 40 °C/min and 170 to 230 °C at 3 °C/min. When analyzing FAMEs from cultures with Elovl4, the column was temperature-programmed from 50 to 170 °C at 40 °C/min and 170 to 230 °C at 10 °C/min. Hydrogen was used as carrier gas at flow rate of 1.1 mL/min. Both detector and injection port were set at 250 °C. Individual methyl ester was identified by comparison to authentic standards (Sigma-Aldrich). The proportion of substrate fatty acid converted to desaturation product or elongation product was calculated from the gas chromatograms as 100 × [product area/(product area + substrate area)].

**Fatty Acids Composition of Tissues in Scallop.** Scallops at 14 months old were cultured in a 500 L plastic bucket and fed daily using about 15−20 cells/mL of *Platymonas subcordiformis*. The temperature was 19.0 ± 0.5 °C, and the salinity was 31 ± 0.5 ppt. Four weeks later, viscera, adductor, mantle, and gonad from 10 scallops were sampled after 12 h starvation. The scallop tissues and *P. subcordiformis* cells were dried in a vacuum freeze-drying machine and ground to fine powder in mortars. Lipid extraction and preparation of FAMEs were as described above. The column was temperature-programmed from 50 to 170 °C at 40 °C/min and 170 to 230 °C at 3 °C/min for analysis of FAMEs. Individual fatty acids were identified by comparison against commercial standards (Sigma-Aldrich), and the results are presented as area percent FAME composition (%).

## RESULTS

**Identification and Characterization of Scallop Fad and Elovl4.** BLASTX analysis of scallop transcriptome revealed a transcript whose putative amino acid sequence was different from previously cloned Δ5 Fad, but highly homologous to Δ6 Fads2 of vertebrate origin. Another transcript was also identified whose putative amino acid sequence was highly homologous to that of vertebrate Elovl4.

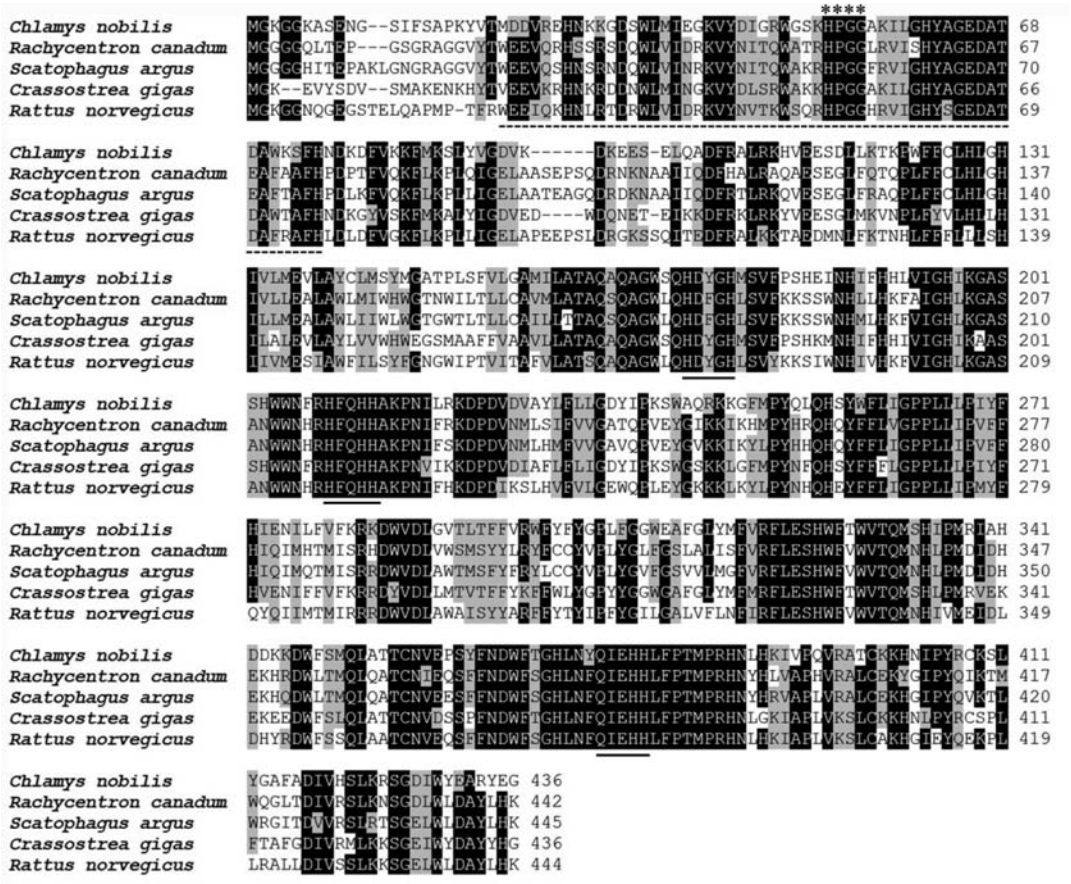

**Figure 1.** ClustalW2 alignment of the deduced amino acid sequence of noble scallop Fads2 with *Rachycentron canadum* (ACJ65149), *Scatophagus argus* (AHA62794), *Crassostrea gigas* (EKC33620), and *Rattus norvegicus* (NP_112634) Fad. Identical residues are shaded black and similar residues are shaded gray based on the BLOSUM62 matrix, and the cutoff for shading was 75%. The dotted line indicates the cytochrome b5 domain, with asterisks above to indicate the heme-binding motif. The solid underlines indicates the three histidine boxes (HXXXH, HXXHH, and QXXHH).

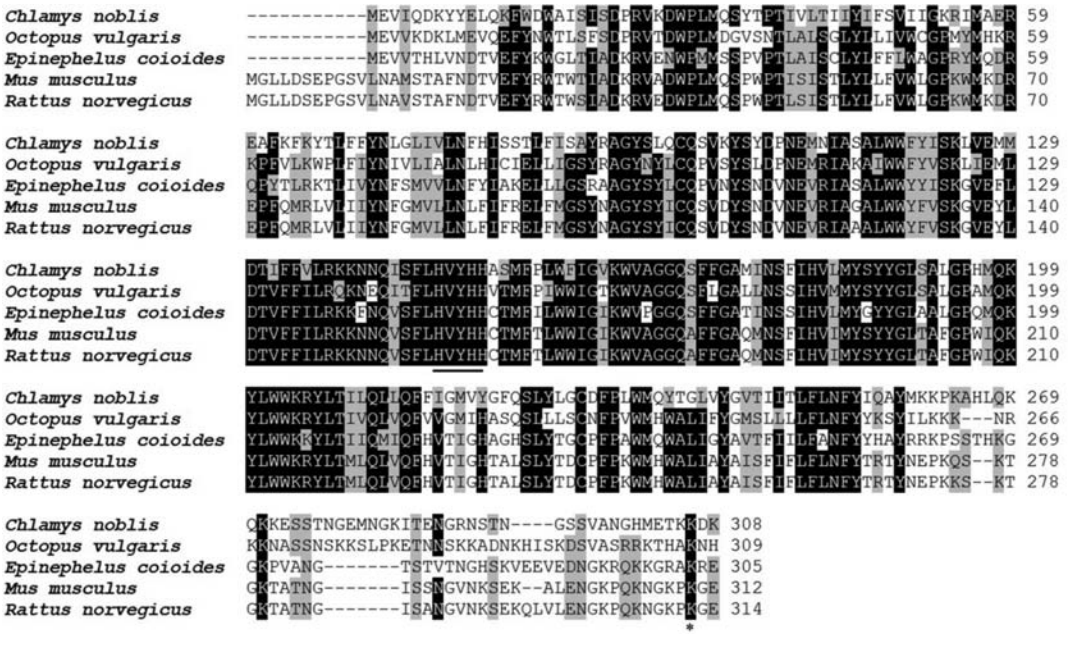

**Figure 2.** ClustalW2 alignment of the deduced amino acid sequences of noble scallop Elovl4 with *Octopus vulgaris* (AIA58679), *Epinephelus coioides* (AHI17192), *Mus musculus* (NP_683743), and *Rattus norvegicus* (NP_001178725) Elovl4. Identical residues are shaded black and similar residues are shaded gray based on the BLOSUM62 matrix, and the cutoff for shading was 75%. The solid underline is the conserved histidine box motif. An asterisk indicates the lysine or arginine residuals proposed to function as ER retrieval signals.

Full lengths of the two genes were obtained by using RACE PCR based on partial fragments.

Thus, the putative Fad, designated as CnFads2, containing an ORF of 436 amino acid, shared 52% identity with functionally characterized Δ6 Fad from *Rachycentron canadum* (ACJ65149), *Scatophagus argus* (AHA62794), and *Rattus norvegicus* (NP_112634). It was also 68% similar to a putative protein of the Pacific oyster *C. gigas* (EKC33620) which was not functionally characterized. The newly cloned scallop Fads2 possessed three diagnostic histidine boxes, a cytochrome b5-like domain, and a heme-binding motif that are characteristic of PUFA desaturase (Figure 1). Phylogenetic analysis showed that CnFads2 was not grouped with mollusk Fad, but instead clustered with vertebrate Fad (Figure 3).

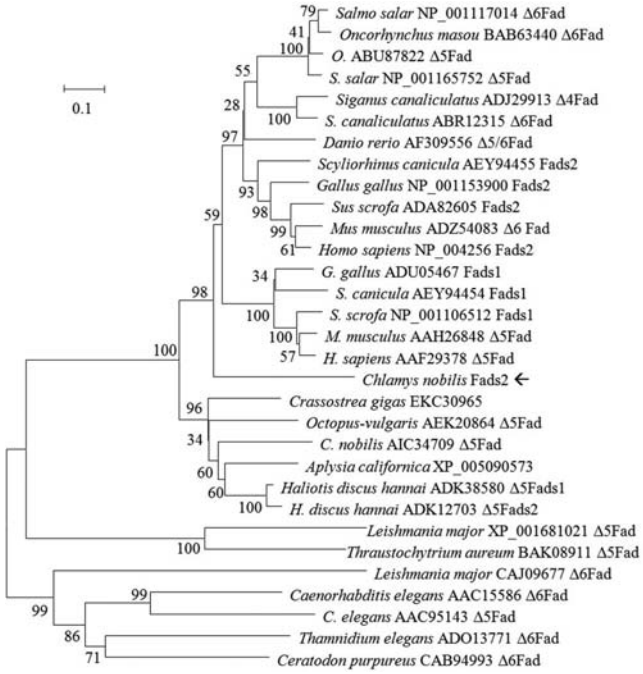

**Figure 3.** Phylogenetic tree comparing the deduced aa sequences of *C. nobilis* Fads2 with Fad proteins from mollusk and other organisms. The alignment was generated by the Clustal W program, and the tree was constructed using the neighbor joining method with MEGA4 software. The horizontal branch length is proportional to aa substitution rate per site. The numbers represent the frequencies with which the tree topology presented was replicated after 1,000 iterations.

The putative scallop Elovl4 contained an ORF of 308 amino acid which was 56% similar to Elovl4 of mollusk octopus (AIA58679), while sharing 49−51% identify with functionally characterized Elovl4 from teleosts such as *Epinephelus coioides* (AHI17192), *R. canadum* (ADG59898), *Siganus canaliculatus* (ADZ73580), and *S. argus* (AHX22600), and mammals such as *Mus musculus* (NP_683743) and *R. norvegicus* (NP_001178725). Scallop Elovl4 was characterized for containing a histidine box of HXXHH motif (Figure 2), which was conserved in all elongases.[28] Phylogenetic analysis comparing a variety of elongase from Elovl1 to Elovl7 showed that scallop Elovl4 could be clustered first to vertebrate Elovl4, and then grouped with Elovl2/5 (Figure 4).

**Functional Characterization.** The putative scallop Fads2 and Elovl4 were functionally characterized by determining the FA profiles of yeast *Saccharomyces cerevisiae* transformed with

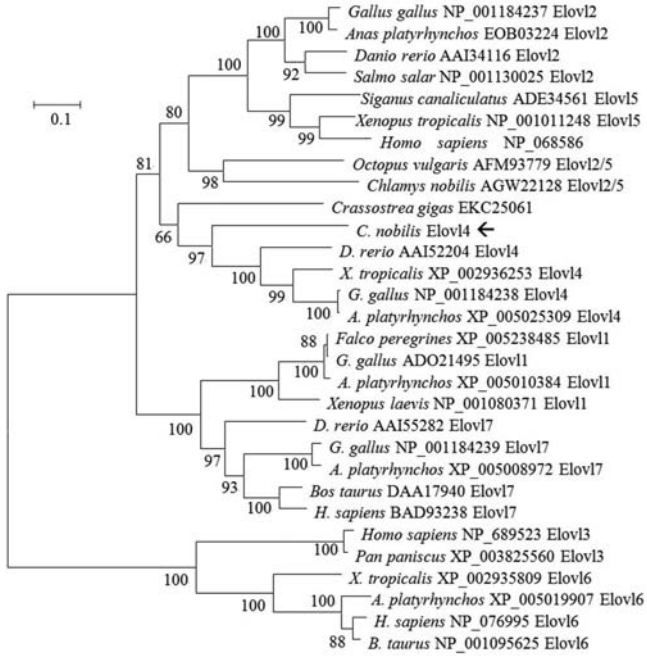

**Figure 4.** Phylogenetic tree comparing the deduced aa sequences of *C. nobilis* Elovl4 with Elovl proteins from mollusk and other organisms. pYES2 vector alone or containing Fads2 and Elovl4 cDNA ORF. The FA composition in yeast with empty plasmid was characterized of essentially only C16:0, C16:1n−7, C18:0, and C18:1n−9 (peaks 1−4).[27] Yeast transformed with pYES2-Fads2 recombinant plasmid was grown in the presence of Δ6-(18:3n−3 and 18:2n−6), Δ5- (20:4n−3), Δ4- (22:5n−3 and 22:4n−6), and Δ8-desaturation (20:3n−3 and 20:2n−6) substrates. Thus, only exogenously added 20:2n−6 (peak 7; Figure 5D) and 20:3n−3 (peak 9; Figure 5D) were converted into 20:3n−6 (peak 8; Figure 5D) and 20:4n−3 (peak 10; Figure 5E) respectively, indicating that the noble scallop Fads2 possessed Δ8-desaturation activity. 29% of 20:2n−6 and 13% of 20:3n−3 were desaturated to 20:3n−6 and 20:4n−3 respectively (Table 2), indicating that Fads2 desaturated n−6 PUFA substrates more efficiently than n−3 substrates. No additional desaturated products were detected when Δ6 (18:3n−3 and 18:2n−6), Δ5 (20:3n−6), or Δ4 (22:5n−3 and 22:4n−6) were used as the substrates, indicating that the new cloned Fads2 possessed no Δ6-, Δ5-, or Δ4-desaturation activity.

In order to assess the role of scallop Elovl4 in PUFA biosynthesis, yeast transformed with Elovl4 ORF was incubated with ALA, LA, EPA, and AA substrates. Thus, 41% of exogenously added AA (peak 13; Figure 5I) was elongated to 22:4n−6 (peak 11; Figure 5I) and 24:4n−6 (peak 14; Figure 5I); while 23% of exogenously added EPA (peak 15; Figure 5J) was elongated to 22:5n−3 (peak 12; Figure 5J) and 24:5n−3 (peak 16; Figure 5J). In addition, 9% of 22:4n−6 and 5% of 22:5n−3 were elongated to 24:4n−6 and 24:5n−3 respectively. The elongase elongated n−6 PUFA substrates more actively than their homologous n−3 substrates. No FA with C26 or

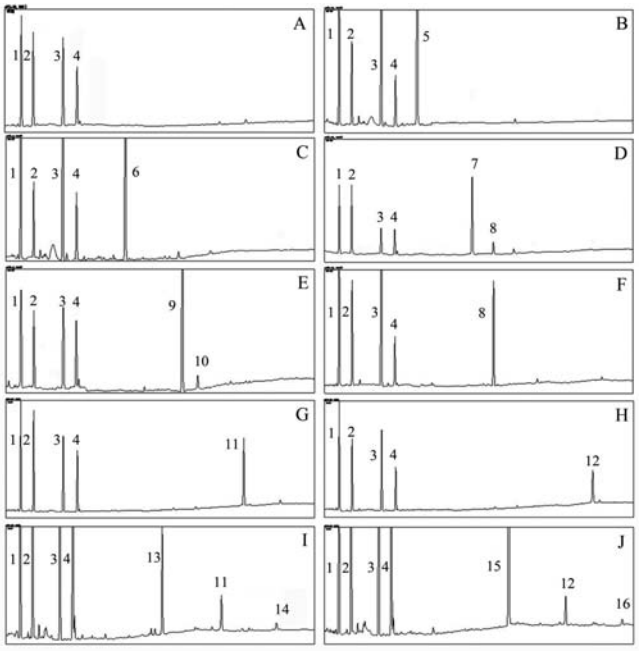

**Figure 5.** Functional characterization of the *C. nobilis* putative Fads2 and Elovl4 in transgenic yeast (*S. cerevisiae*). FAMEs were extracted from yeast transformed with pYES2 vector alone (A) or pYES2-Fads2 (B–H) and pYES2-Elovl4 (I, J), and grown in the presence of FA substrates (peak number) 18:2n−6 (5), 18:3n−3 (6), 20:2n−6 (7), 20:3n−6 (8), 20:3n−3 (9), 22:4n−6 (11), 22:5n−3 (12), 20:4n−6 (13), and 20:5n−3 (15). Peaks 1–4 represent main endogenous FAs of *S. cerevisiae*, namely, 16:0, 16:1, 18:0, and 18:1n−9, respectively. Based on retention times, PUFA productions were identified as 20:3n−6 (D, 8), 20:4n−3 (E, peak 10), 22:4n−6 (I, peak 11), 22:5n−3 (J, peak 12), 24:4n−6 (I, peak 14) and 24:5n−3 (J, peak 16). Vertical axis: FID response. Horizontal axis: retention time.

| | | total | 23 ± 3 B | |

[a]Conversion rates represent the proportion of substrate fatty acid converted to desaturated fatty acid product, calculated from gas chromatograms as 100 × [product area/(product area + substrate area)]. Uppercase letter indicates comparison of conversion rate exhibited by the same enzyme, and different letter means significant difference by one-way ANOVA test.

more carbon was detected. No elongation production was detected in the presence of ALA and LA.

**Fatty Acid Profile of Scallop Tissues.** Some fatty acids are important intermediates which could give some clues on how PUFA was biosynthesized. For example, 18:4n−3 and 20:4n−3 were usually the intermediates of major route pathway, while 20:2n−6 and 20:3n−3 might indicate a "Δ8 pathway".

Fatty acid profile in microalgae *P. subcordiformis* and scallop tissues including the viscera, adductor, mantle, and gonad were determined (Table 3). Microalga *P. subcordiformis* was

characterized of relatively high percent of intermediate fatty acid 18:4n−3 with predominant fatty acid of 16:0, 18:1n−9, and 18:3n−3. EPA accounts for 3.22% while no DHA was detected. Scallop viscera was characterized of high percent of 20:5n−3, and the interesting point was that DHA was occupied 10.52%, which was absent in diet microalgae. In addition, 20:4n−3 and 22:5n−3 were also detected, implying biosynthesis activity of DHA through major route pathway in viscera.

The adductor and mantle were characterized as having a high degree of unsaturated FAs encompassing high percentages of n−3 PUFA (22:6n−3 and 20:5n−3), while the gonad displayed high percent of saturated FAs. In these three tissues, 16:0 was the most abundant among the six saturated FAs, followed by 18:0 and 14:0. Further, four MUFAs including 16:1n−7, 18:1n−7, 18:1n−9, and 20:1n−9 were detected. As for PUFAs, EPA and DHA followed by AA were among the most

represented. 20:2n−6 and 20:3n−6, which were absent or quite lacking in diet microalgae and viscera, suggested a possible "Δ8 pathway" in noble scallop.

## DISCUSSION

The ability of PUFA biosynthesis in mollusks has also been investigated in some marine species by using $^{14}$C-labeled radioactive FAs,[16,29−32] resulting in the functional characterization of several genes/enzymes involved in the PUFA biosynthesis pathway. The Δ5 desaturase reported in common octopus represents the first molecular proof of the existence of enzyme that is involved in PUFA biosynthesis in mollusk species.[21] Subsequently, an elongase from common octopus[22] and two Δ5 Fad in abalone *Haliotis discus hannai*[23] have been successively characterized. However, whether mollusk could de novo synthesize important LC-PUFAs such as AA, EPA, and DHA is still ambiguous due to the lack of desaturase with Δ6 or Δ8 activity. In noble scallop *C. nobilis*, an elongase has been found to elongate 18:2n−6 and 18:3n−3 to 20:2n−6 and 20:3n−3 respectively, providing Δ8 FA substrates.[26] Further, a desaturase with Δ5 activity has been recently reported to desaturate 20:3n−6 and 20:4n−3 to AA and EPA.[25] In this study, a second Fad (Fads2) was cloned and functionally characterized to display Δ8 activity, providing the first compelling evidence that marine mollusks could at least de novo biosynthesize EPA and AA via the alternative "Δ8 pathway" of elongation−Δ8-desaturation−Δ5-desaturation. Consistent with the PUFA biosynthesis pathway observed in vitro, the FA profiles of scallop tissues indicated the existence of the alternative pathway accounting for the production of intermediates FAs 20:2n−6 and 20:3n−3 (Table 3).

The alternative pathway using Δ8-desaturase has been mainly reported in unicellular organisms,[33−35] and some mammalian Δ6-desaturases also show a Δ8 activity.[11] Using yeast expression system, Óscar et al. have demonstrated that Δ8 desaturase activity is a common feature of vertebrate Δ6 Fad from a range of freshwater, diadromous, and marine teleost fish, and marine species display far higher Δ8 activity than mammal.[36] Different from vertebrate Δ6 Fad with bifunctional activity, scallop Fads2 reported in this study displayed only a Δ8 activity. Based on our results, we speculated that the alternative "Δ8-pathway" was actually the major route of PUFA biosynthesis in some marine bivalves.

Oyster *C. gigas* has been reported to be able to elongate and desaturate n−3 FAs to produce EPA and DHA,[16] whereas clam *Mesodes mamactroides* displays no ability to produce 20:5n−3,[30] indicating that the ability to de novo biosynthesize PUFAs varies among bivalves. Different from oyster or clam, noble scallop could biosynthesize EPA but had quite limited ability to synthesize DHA from EPA due to the lack of desaturase with Δ4 or Δ6 activity. It seems impossible for noble scallop to synthesize DHA through the alternative "Δ8 pathway" by elongating EPA to 26:5n−3, then desaturating to 26:6n−3 with Δ8 Fad, followed by two steps of $\beta$-oxidation, because the newly cloned Elovl4 had quite limited efficiency to elongate 20:5n−3 to 24:5n−3, and no production of 26:5n−3 was detected. Additionally, two elongases and two desaturases, which had been isolated from this species, might represent the complete set of enzymes necessary for the synthesis of LC-PUFA from precursors, because no more PUFA elongase or desaturase could be found in the scallop transcriptome database. Therefore, noble scallop possibly had quite limited ability to de novo synthesize DHA, and heavily relied on dietary supplied DHA to optimize health.

PUFA biosynthesis genes/enzymes have been functionally characterized in many species, most of which show more activity toward n−3 PUFA substrates in vertebrates.[4−9] Contrarily, study on conversion rate of four scallop PUFA biosynthesis genes/enzymes reveals that scallop Elovl2/5,[26] Elovl4, and Fads2 tended to be more active toward n−6 substrates than n−3 substrates (Figure 5D,E,I,J); only Δ5 Fad1 shows similar activity toward n−3 and n−6 substrates.[25] Similar results have also been reported in the common octopus, whose elongase has more activity toward n−6 FA substrates,[22] while Δ5 Fad shows equal activity toward n−3 and n−6 FA substrates.[21] The marine ecosystem is characterized by high levels of n−3 LC-PUFA, particularly EPA and DHA,[37] produced by marine microalgae, which then are passed on to high trophic mollusks through the food chain. Compared to abundant n−3 PUFAs, n−6 PUFAs are relatively insufficient in the marine ecosystem. Higher conversion of n−6 FA substrates than n−3 FA substrates displayed by noble scallop PUFA biosynthesis genes/enzymes indicates a greater efficacy to de novo biosynthesize n−6 PUFAs, which could compensate shortage of n−6 PUFAs in the natural diet. Meanwhile, the low conversion rate of 20:3n−3 to 20:4n−3 exhibited by Fads2 and 20:4n−3 to 20:5n−3 by Fads1 indicated that noble scallop had low efficiency to de novo biosynthesize EPA. Furthermore, noble scallop had limited capability to produce DHA due to lack of enzymes with Δ6 or Δ4 activity, implying that noble scallop would heavily rely on dietary DHA to optimize its health. These results indicate that noble scallop is highly adapted to the marine environment.

In summary, our result provided compelling evidence that noble scallop had the capability to endogenously produce EPA and AA from PUFA precursors, but limited ability to synthesis DHA from EPA. Preference of PUFA biosynthesis enzymes indicated that noble scallop relied on diet supplied n−3 PUFA and showed an advanced adaptation to the marine environment.

| PUCr | AGCGGATAACAATTTCACACAGGAA | N/A |
| TF | CATGGCCAAGTTGACCAGTGC | N/A |
| TR | CAATCTAGAGGTACCAGACATGATAAGATACATTG | *Xba*I |
| V3F | TTGAAGGAGCATGGCGTTAC | N/A |
| V3R | GCGTACAAATCTGCTTCCACT | N/A |

[a]Underlined positions indicate the inserted restriction site.

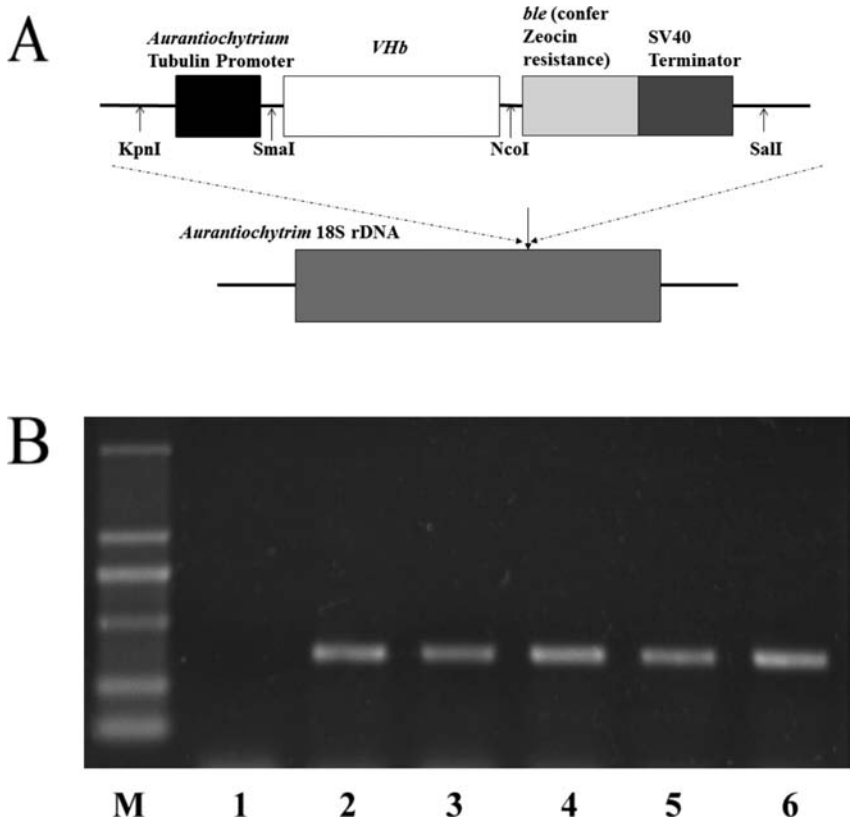

**Figure 1.** Expression construct and PCR detection of transformants: (A) schematic diagram of pUC18-SK4 tubulin promotor−*VHb*−*ble*−SV40 teminator; (B) genomic PCR detection of VHb in transformants resistance to zeocin generated by transformation with the above construct. The PCR product corresponding to VHb is 370 bp. Lanes: M, 250 bp marker; 1, MP4; 2, TMP4−VHb1; 3, TMP4−VHb10; 4, TMP4−VHb24; 5, TSK4−VHb2; 6, positive control (with plasmid containing VHb as a template).

*V. stercoraria* ATCC 15218 was cultured in tryptic soy broth (15 g/L tryptone, 5 g/L soytone, 5 g/L sodium chloride, pH 7.3) at 26 °C.

*Aurantiochytrium* sp. MP4 and SK4 were maintained in glucose−yeast extract agar plates (1 g/L glucose, 15‰ artificial seawater (v/v), 1 g/L yeast extract, 1 g/L peptone, and 15 g/L bacto agar, pH 5.5). The innoculum of each *Aurantiochytrium* sp. strain was prepared by culturing the cells in a 250 mL Erlenmeyer flask, which contained 50 mL of 15‰ artificial seawater (v/v) with 10 g/L glucose and 1 g/L yeast extract at pH 5.5. The flasks were incubated in an orbital shaker set at 200 rpm at 25 °C in the dark.

**Genomic DNA Isolation from *V. stercoraria* and *Aurantiochytrium* sp. SK4.** The standard phenol/chloroform method was used to extract genomic DNA from *V. stercoraria* ATCC 15218 and *Aurantiochytrium* sp. SK4, respectively, at the late exponential phase.[23]

**Cloning of the VHb Gene.** The primers used in the study are listed in Table 1. VHb gene was amplified from the genomic DNA of *V. stercoraria* ATCC 15218 with the standard polymerase chain reaction (PCR), using the primers V1F and V1R. The amplified fragment was ligated to the correponding restriction sites on the pTZ57R plasmid for cloning in *Escherichia coli*.

The expression cassette shown in Figure 1 was constructed. It was then cloned into the *Xba*I and *Sal*I restiction sites of an *Aurantiochytrium* 18S rDNA fragment cloned in a pUC18 vector. This was for the homologous recombination of the expression cassette into the genome of *Aurantiochytrium* sp. MP4 and SK4.

The tubulin promoter was amplified from the genomic DNA of *Aurantiochytrium* sp. SK4 with PCR with the primers PF and PR. VHb gene was amplified from the plasmid pTZ57R−VHb cloned in the previously transformed *E. coli*, using the primers V2F and PUCr. Moreover, the fragment with the *ble* gene and the SV40 terminator was amplified from the plasmid pcDNA3.1/zeo(−) (Invitrogen, Carlsbad, CA, USA), with the primers TF and TR. The VHb, tubulin promoter, and *ble*−SV40 terminator fragments were cloned sequen-

dx.doi.org/10.1021/jf5048578 | J. Agric. Food Chem. 2014, 62, 12392−12398

tially into the pUC18-18s rDNA vector through the ligation at the complementary restriction sites. Restriction enzyme cutting and sequencing were used to confirm the correct construct for transformation into *Aurantiochytrium* sp. MP4 and SK4.

**Transformation of *Aurantiochytrium* sp.** *Aurantiochytrium* sp. was transformed with the construct described under Cloning of the VHb Gene by electroporation using the Micropulser Electroporator (Bio-Rad, Hercules, CA, USA). The parameters of electroporation were set as 1.8 kV, 300 Ω, and 50 μF. Cells of each electroporated strain were resuspended in 15 mL of 15‰ artificial seawater (v/v) with 10 g/L glucose and 1 g/L yeast extract. The cells were allowed to recover for 24 h in an orbital shaker at 150 rpm at 25 °C in the dark. Then they were selected on glucose−yeast extract agar plates with 50 μg/mL zeocin. The colonies resistant to zeocin were isolated and cultured for subsequent analysis. The presence of the VHb gene and its expression were varified by PCR with primers V3F and V3R and the carbon monoxide (CO) difference spectra.[24]

**Growth of VHb-Expressing *Aurantiochytrium* sp. in Flask Cultures.** The innocula of the VHb-expressing MP4 and SK4 and their corresponding wild types were prepared. Five percent of each exponentially growing inoculum was used to inoculate 100 mL of glucose−yeast extract (GYE) medium (20 g/L glucose, 15‰ artificial seawater (v/v), 10 g/L yeast extract, pH 5.5) in 250 mL Erlenmeyer flasks. The culture of each strain was separated into two batches, each in triplicates: the flask opening was covered with a filter in one batch to allow free air diffusion, whereas it was covered with a rubber plug in the other batch to block air diffusion. The condition was aerobic when free air diffusion was allowed, as the DO level was above 2% saturation (data not shown). In constrast, it was defined as microaerobic when free air diffusion was blocked, as the DO level was below 0.5% saturation (data not shown). All flasks were incubated in an orbital shaker set at 200 rpm at 25 °C in the dark. Growth of the VHb-expressing MP4 and SK4 and their correponding wild type controls was measured by the optical density (OD) at 660 nm.

**GC Analysis on the Fatty Acid Content.** Freeze-dried samples of VHb-expressing MP4 and SK4 and their wild type controls (from aerobic flask cultures) were collected at day 3 (for TMP4−VHb24 and MP4) or day 7 (for TSK4−VHb2 and SK4) of growth in GYE medium. They were treated by direct transmethylation with sulfuric acid in methanol to convert the fatty acids in the samples to fatty acid methyl esters (FAMEs). Briefly, 20 mg of each freeze-dried sample was weighed and incubated with 2 mL of 1% sulfuric acid in methanol (v/v) and 0.8 mL of the internal standard, nonadecanoic acid (C19:0) (1 mg/mL hexane), in 1 mL of toluene at 50 °C for 12 h. The upper hexane layer with FAMEs was washed with 5% sodium chloride solution (w/v) and 2% potassium hydrogen carbonate solution (w/v) sequentially and then dried by passing nitrogen gas. The FAMEs extracted were then redissolved in 1 mL of hexane and analyzed by a Hewlett-Packard (HP) 6890 capillary gas chromatography (GC) system with a flame ionization detector (FID) and a HP-INNOwax capillary column (30 m × 0.32 mm) (Agilent Technologies, Santa Clara, CA, USA). The carrier gas was nitrogen, and the column temperature was programmed to rise from 170 to 230 °C at 1 °C/min. Two microliters of sample was injected under the splitless mode through the injector, which was kept at 250 °C while the FID was kept at 270 °C. Individual FAMEs were identified by comparsion to the retention time of the peak with that of each pure standard, and they were quantified by the peak area of the internal standard C19:0 fatty acid, which was injected in a known amount. The analysis was done in triplicates for each strain.

**HPLC Analysis on the Carotenoid Contents.** VHb-expressing SK4 and its wild type control were collected at day 9 of growth (from aerobic and microaerobic cultures prepared as under Growth of VHb-Expressing Aurantiochytrium sp. in Flask Cultures) in a modified By+ medium (30 g/L glucose, 1 g/L yeast extract, 1 g/L peptone, and 15‰ artificial seawater (v/v)). Samples were freeze-dried for the extraction of the carotenoid pigments from the biomass. Twenty milligrams of each sample was ground in liquid nitrogen, and the carotenoids released were dissolved in acetone, which were blown to dryness with nitrogen gas and then redissolved in 200 μL of acetone for analysis.

The extracted pigments were then analyzed by a high-performance liquid chromatography (HPLC) system of Waters 2695 separation module (Waters, Milford, MA, USA). They were separated through a Waters Spherisorb ODS2 analytical column (5 μm, 4.6 × 250 mm). Two solvents were used as the mobile phase: solvent A (acetonitrile/methanol/0.1 M Tris-HCl (pH 8.0), 84:2:14, v/v/v) and solvent B (methanol/ethyl acetate, 68:32, v/v). The extracted pigments were eluted through the column with a linear gradient from 100% solvent A to 100% solvent B at a flow rate of 1.2 mL/min over 15 min and then 10 min of 100% solvent B at the same flow rate. The absorption spectra between 250 and 700 nm were recorded with a Waters 2996 photodiode array detector. The carotenoids were qualified and quantified by the comparing the retention times and peak areas of the individual absorption spectra with those of pure carotenoid standards. The analysis was done in duplicates for each strain.

**Statistical Analysis.** Statistical analyses were performed with the SPSS statistical package. Paired-samples *t* test was applied. The experimental results were considered statistically significant when $p < 0.05$.

## RESULTS AND DISCUSSION

**Transformation of *Aurantiochytrium* sp. by VHb-ble.** A linear DNA fragment of VHb-ble (Figure 1A) was introduced

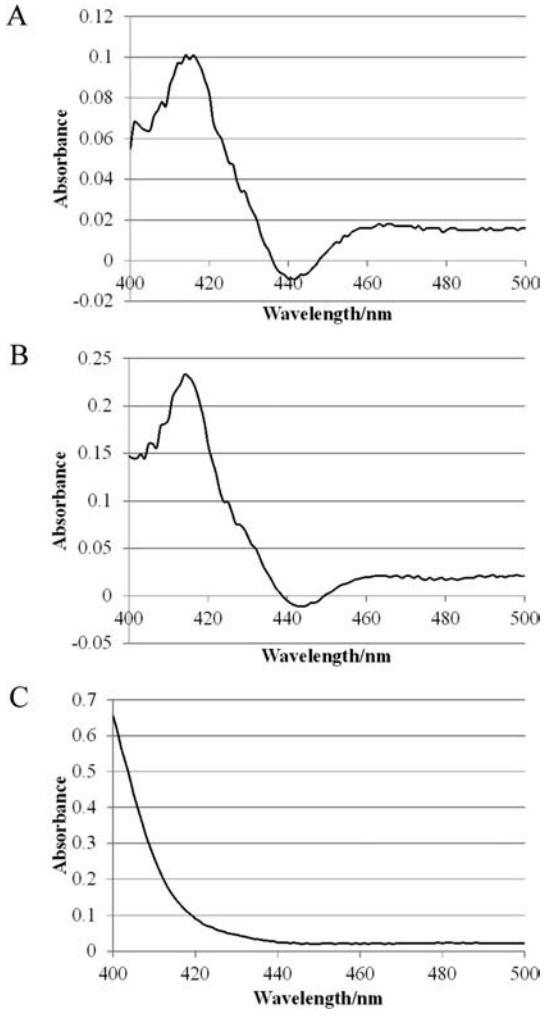

**Figure 2.** CO difference spectrum of wild type and VHb-expressing *Aurantiochytrium* sp.: (A) TMP4−VHb24; (B) *Aurantiochytrium* sp. TSK4−VHb2; (C) MP4.

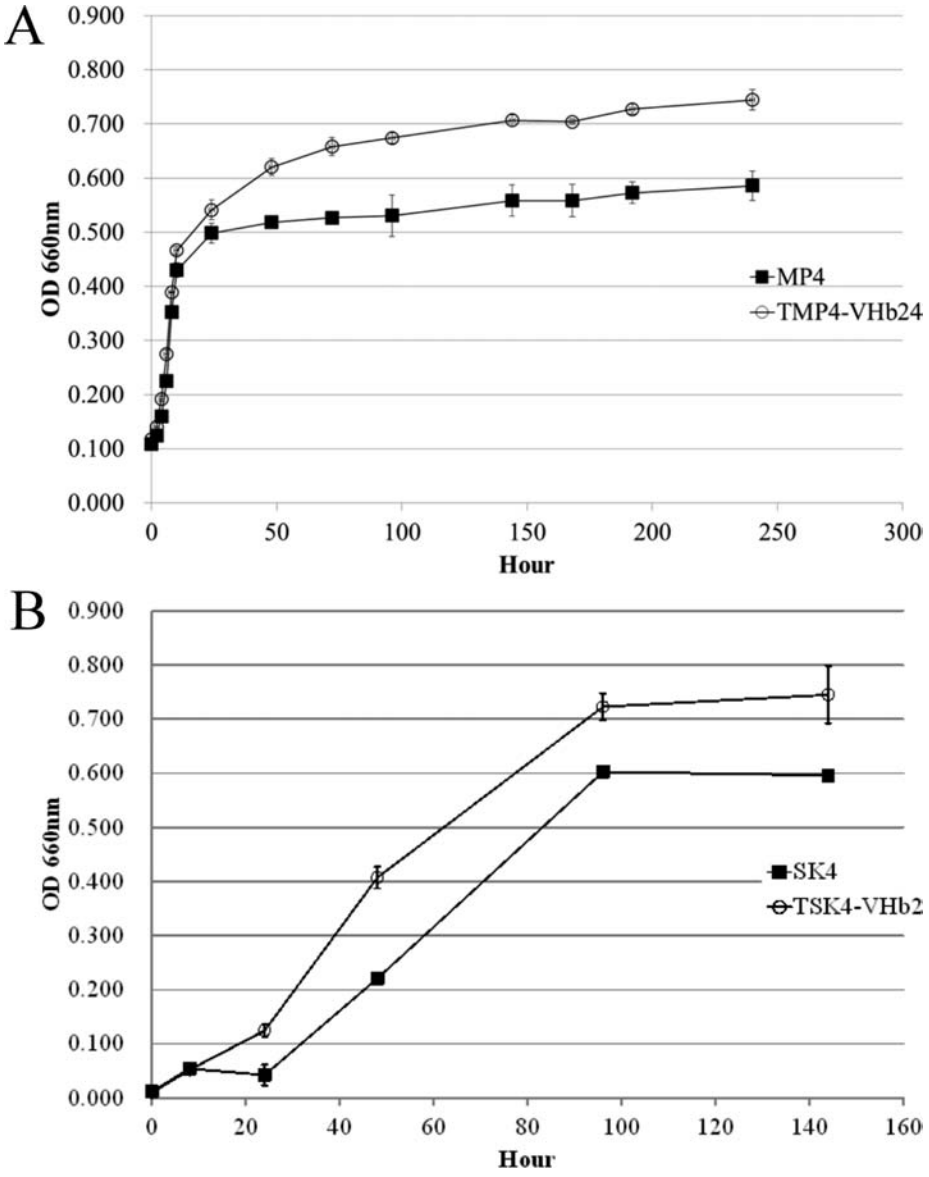

**Figure 3.** Growth curve of *Aurantiochytrium* sp. cultured in microaerobic conditions, measured in terms of OD at 660 nm: (A) MP4 and TMP4−VHb24; (B) SK4 and TSK4−VHb2. Data are expressed as the mean ± standard deviation of triplicates.

into *Aurantiochytrium* sp. MP4 and SK4 by electroporation. The *Ble* gene conferring zeocin resistance was used as a selective marker to screen positive transformants of *Aurantiochytrium* sp. Generally 50−100 zeocin-resistant colonies were obtained on a 9 cm Petri dish, suggesting the feasibility of the electroporation approach for the introduction of foreign genes into *Aurantiochytrium*. The presence of VHb was verified by genomic PCR amplification (Figure 1B). Three MP4 transformants (namely, TMP4−VHb1, TMP4−VHb10, and TMP4−VHb24) and one SK4 transformant (namely, TSK4−VHb2) were selected for further investigation. To verify the expression of VHb, the carbon monoxide (CO) difference spectra of both transformants and wild types were measured, and the results are shown in Figure 2. The VHb-specific CO difference spectrum, a maximal absorbance peak at about 419 nm, was observed in the CO-treated crude extracts of TMP4−VHb24 (Figure 2A) and TSK4−VHb2 (Figure 2B) but not in the control (Figure 2C). These results clearly show that biologically active VHb was produced in the PCR-verified transformants.

**Growth of VHb-Expressing *Aurantiochytrium* sp.** The effect of VHb expression on the growth of *Aurantiochytrium* sp. was studied in both microaerobic and aerobic conditions. Significant improvement of cell growth was observed in TMP4−VHb24 (Figure 3A) and TSK4−VHb2 (Figure 3B) in microaerobic conditions. The effects of VHb led to 27 and 24% higher maximum OD values achieved in TMP4−VHb24 and TSK4−VHb2, respectively, when compared with the corresponding wild type controls. In contrast, the effects of VHb on cell growth in aerobic conditions were not significant, possibly due to the sufficient supply of oxygen in both transgenic cells and control cells as well as a relatively low cell density achieved (data not shown). Dissolved oxygen concentrations decline as cell density increases in fed-batch processes. Our results support the feasibility of VHb to economically solve the common problem of limited DO occurring in high-cell density fermentation.

Table 2. Fatty Acid Composition and Content of *Aurantiochytrium* sp. MP4, TMP4−VHb24, SK4, and TSK4−VHb24, Respectively[a]

| | % total fatty acids | | | |
|---|---|---|---|---|

[a]Data are expressed as the mean ± standard deviation of triplicates; data indicated by * in the same fatty acid category are significantly different from each other ($p < 0.05$), same case for data indicated by **. AA, arachidonic acid; EPA, eicosapentaenoic acid; DPA, docosapentaenoic acid; DHA, docosahexaenoic acid. [b]SFA, saturated fatty acids. [c]MUFA, monounsaturated fatty acids. [d]PUFA, polyunsaturated fatty acids. [e]TFA, total fatty acids.

**Fatty Acid Biosynthesis of VHb-Expressing *Aurantiochytrium* sp.** DO levels are a critical factor not only for cell growth but also for fatty acid productivity in *Aurantiochytrium*.[12] To determine the effect of VHb expression on fatty acid biosynthesis, TMP4−VHb24 and TSK4−VHb2 were surveyed on the fatty acid composition and content under normal culture conditions (see GC Analysis on the Fatty Acid Content). In aerobic conditions, the total cellular fatty acid content in TMP4−VHb24 was 500.72 mg/g, which is 10% higher than the value of 454.86 mg/g in nontransformed control (Table 2). *Aurantiochytrium* sp. SK4 accumulated much less total fatty acids than strain MP4[21](Table 2). However, the expression of VHb in this strain resulted in a greater increase of total fatty acids by 44% from the value of 86.30 mg/g in SK4 to 124.57 mg/g in TSK4−VHb2 (Table 2). In addition, the expression of VHb also induced significant changes in the fatty acid composition, especially to the ratio of saturated and polyunsaturated fatty acids (Table 2). Generally the effect of VHb led to increases of saturated fatty acids (SFAs) and decreases of polyunsaturated fatty acids (PUFAs) with a lower effect on strain SK4.

**Carotenoid Biosynthesis of VHb-Expressing *Aurantiochytrium* sp.** In addition to accumulating significant amounts of fatty acids, *Aurantiochytrium* sp. SK4 also synthesizes carotenoids, with $\beta$-carotene being the prominent pigment, and echeninon, canthaxanthin, adonirubin, and astaxanthin the minor ones[21] (Figure 4A). The effect of VHb led to great changes of carotenoid profiles, making astaxanthin the major pigment and all of its precursors, including $\beta$-carotene, the minor ones (Figure 4B.) The carotenoid compositions and contents of TSK4−VHb2 and SK4 grown in aerobic conditions were measured, and the results are shown in Figure 4C. The cellular astaxanthin content of TSK4−VHb2 was 131.09 $\mu$g/g, which is about 10-fold that in SK4 (14.47 $\mu$g/g), suggesting that the conversion of $\beta$-carotene to astaxanthin was greatly promoted in the transformant. Such a promotion might result from the increased DO levels due to the effect of VHb expression because the biosynthesis of astaxanthin strongly depends on oxygen accessibility. Similar results were achieved in an astaxanthin-producing bacterium that simultaneously expressed a hemoglobin gene.[25] The authors suggested that possibly the heterologous hemoglobin improved the activity of the oxygen-requiring enzymes involved in astaxanthin biosynthesis. Wang et al.[26] suggested that VHb improved the oxygen-required metabolism and antioxidant biosynthesis through up-regulating the mRNA levels of $\beta$-carotene hydroxylase, which converts $\beta$-carotene to zeaxanthin and canthaxanthin to astaxanthin.

Previously, the biosynthetic pathway of astaxanthin in thraustochytrids was proposed to be ketolating $\beta$-carotene first to form canthaxanthin via echinenone followed by hydroxylation reactions.[8] This study demonstrated that a similar pathway existed in *Aurantiochytrium* sp. SK4 according to the existence of the intermediates and changes of carotenoid profiles between TSK4−VHb2 and SK4. In addition, *Aurantiochytrium* sp. SK4 and its transformant accumulate astaxanthin in free form rather than esterified form as in some green algae, such as *Haematococcus pluvialis* and *Chlorella zofingiensis*. *Aurantiochytrium* sp. SK4 accumulates much less astaxanthin than the green algae, which may result from its failure to store astaxanthin in esterified form.

The effect of VHb not only significantly improved the growth of *Aurantiochytrium* sp. under microaerobic conditions (Figure 2) but also enhanced the biosynthesis of both fatty acid (Table 2) and astaxanthin (Figure 4) under aerobic conditions. Therefore, VHb expression may serve as an approach to solve the problem of limited DO occurring in high-cell density fermentation with controlled air pumping and agitation rate to provide DO > 2%, which is the range of DO levels in the aerobic flask cultures in this study. This is not a relatively high

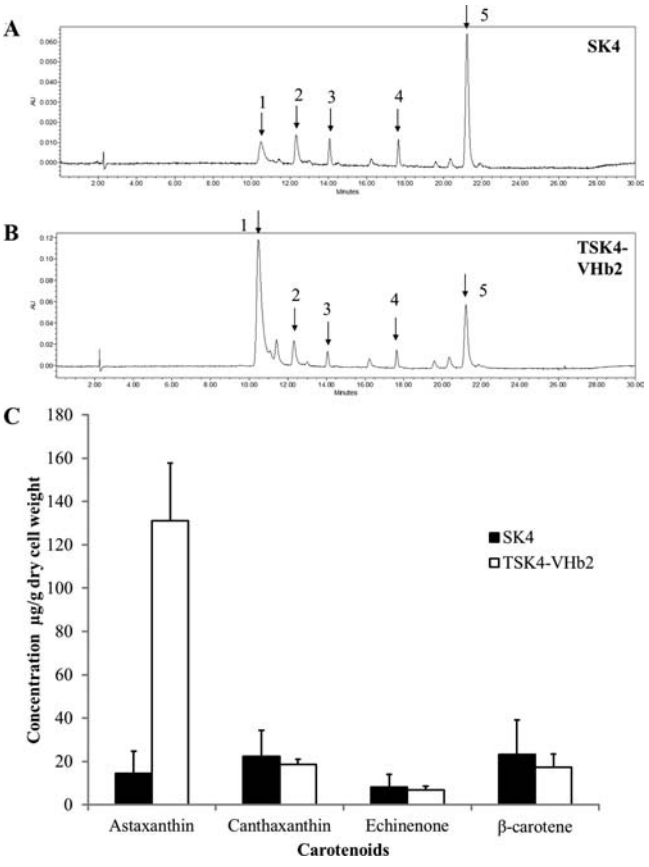

**Figure 4.** Analysis of carotenoids from wild type and VHb-expressing *Aurantiochytrium* sp. SK4: HPLC chromatogram of the carotenoid from *Aurantiochytrium* sp. SK4 (A) and TSK4−VHb2 (B) in flask cultures with free air diffusion. Peaks: 1, astaxanthin; 2, adonirubin (phoenicoxanthin); 3, canthaxanthin; 4, echineone; 5, $\beta$-carotene. (C) Composition and content of carotenoids in *Aurantiochytrium* sp. SK4 and TSK4−VHb2 in flask cultures with free air diffusion. Data are expressed as the mean ± standard deviation of duplicates.

DO level to achieve in a fermenter, and therefore the energy consumption to maintain it will not be too high. In this condition, the action of VHb can relieve the limitation of low oxygen availability to cell growth at high density, whereas the fatty acid or astaxanthin production can also be improved.

In conclusion, the effect of VHb expression in *Aurantiochytrium* sp. was studied. VHb expression led to improved growth under microaerobic conditions and enhanced productions of total fatty acids and astaxanthin in the thraustochytrid cells under aerobic conditions. This study highlights the potential of VHb to enhance cell growth and the production of value-added metabolites by large-scale high-cell density fermentation.

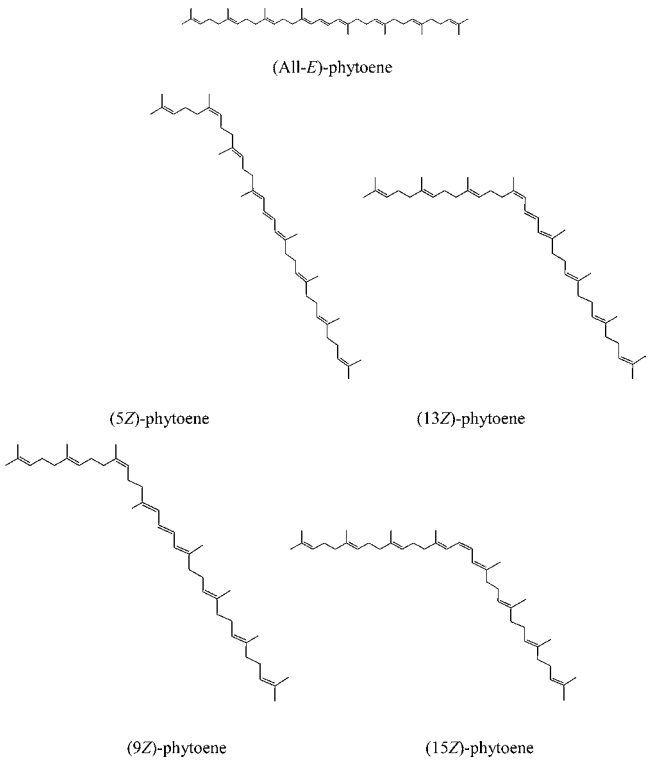

**Figure 1.** Representation of the chemical structures of geometrical isomers of phytoene.

standpoints. In this study, lycopene, phytoene, and phytofluene from a natural extract of lycopene-rich tomatoes have been stereomutated following two different methodologies. We have compared the different isomeric sets at the equilibrium and obtain information about kinetically and thermodynamically favored compounds. Furthermore, we carried out *in silico* studies on the relative stability of different lycopene, phytoene, and phytofluene isomers. This information is useful to gain further insight into the meaning of the existence of certain (*Z*)-lycopene isomers in foods, plasma, tissues, and other matrices. More importantly, it led us to hypothesize the isomeric mixtures of phytoene and phytofluene (two largely understudied carotenoids) that can be expected in certain foods, plasma, and tissues.

## MATERIALS AND METHODS

**Isolation of Carotenoid Standards.** The carotene standards (phytoene, phytofluene, and lycopene) were isolated by open column chromatography according to standard procedures[15] from a natural extract of lycopene-rich tomatoes (Lycomato). This was kindly provided by LycoRed Ltd. (Beer Sheva, Israel). Briefly, the Lycomato material was dissolved in hexane and gently poured into the column, which was packed with MgO:HyfloSupercel (1:1). Phytoene, phytofluene, and lycopene were eluted with hexane, 2% diethyl ether in hexane, and acetone, respectively. Fractions containing mixtures of phytoene and phytofluene were further purified by HPLC by collecting the fractions of the corresponding peaks.

**Stereomutation Conditions.** *Thermal Isomerization.* The fractions of pure carotenoids obtained were evaporated at room temperature by flushing nitrogen. Solutions of carotenoids in toluene (0.1 mg/mL, 5 mL) were heated in a thermoblock at 75 °C. Aliquots were taken at times 0, 15, 30, 60, 90, 120, 240, 480, and 1440 min, evaporated to dryness by flushing nitrogen, redissolved in ethyl acetate, and injected on the HPLC system. After every sampling, the tube was flushed gently with nitrogen. The experiments were carried out in duplicate on two consecutive days (one experiment each day).

*Iodine-Catalyzed Isomerization.* A 10 μL portion of a 1 mg/mL iodine solution in toluene was added to 0.1 mg/mL solutions of carotenoids in toluene placed in transparent glass tubes. These were exposed to illumination (conventional fluorescent bulbs) for 24 h at a distance of 50 cm. Aliquots were taken at times 0, 15, 30, 60, 90, 120, 240, 480, and 1440 min, evaporated to dryness, redissolved in ethyl acetate, and injected on the HPLC system. After every sampling, the tube was flushed gently with nitrogen. The experiments were carried out at room temperature in duplicate on two consecutive days (one experiment each day).

**HPLC Analysis and Identification of Isomers.** The HPLC conditions and criteria for the identification of geometrical isomers are explained in detail.[16] Briefly, the separations were carried out on an YMC C30 column, (3 μm, 4.6 mm × 150 mm, YMC America, Inc., Allentown, PA) kept at 25 °C. Methanol (MeOH, containing 0.1% of ammonium acetate) and methyl-*tert*-butyl ether (MTBE) were used for the separations according to the following gradient.

| time (min) | % MeOH | % MTBE | curve |
|---|---|---|---|
| 0 | 100 | 0 | |
| 45 | 85 | 15 | lineal |
| 55 | 40 | 60 | lineal |
| 60 | 30 | 70 | lineal |
| 65 | 30 | 70 | lineal |
| 70 | 100 | 0 | lineal |

The tentative identification of the lycopene isomers was carried out by comparing the spectroscopic data with those reported in previous studies.[17,18]

*In Silico Study.* The MOE suite 2010.11 software version (Molecular Operating Environment (MOE 2007.09), Chemical Computing Group, Inc. Montreal, Quebec, Canada) was used for the analyses. The three-dimensional (3D) structures of the (all-*E*)-isomers of lycopene, phytofluene, and phytoene (Figure 2), as well as of their mono- (*Z*)-isomers,

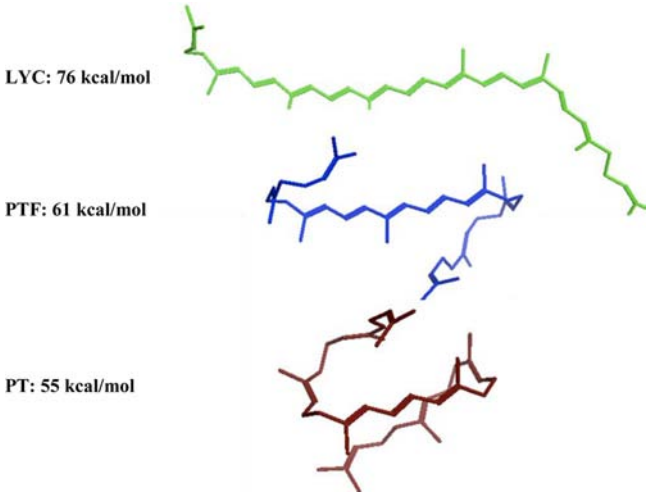

**Figure 2.** Energy-minimized three-dimensional representations of lycopene (LYC), phytofluene (PTF), and phytoene (PT) in the all-*E* configuration.

were built. Their energies were subsequently evaluated and minimized using the MMF94x force field method. In this, the potential energy of a molecular system is a function of the atomic coordinates:

$$E(\chi) = E_{str} + E_{ang} + E_{oop} + E_{tor} + E_{vdw} + E_{ele} + E_{sol} + E_{res}$$

Each of the energy terms is itself a sum involving particular kinds of atomic interactions like stretching (str), angle bending (ang), out of plane (oop), torsional (tor), van der Waals (vdw), electrostatic (ele), solvation (sol), or restriction (res).

dx.doi.org/10.1021/jf5041965 | J. Agric. Food Chem. 2014, 62, 12399−12406

In a second step, all the structures were energy minimized. Energy minimization consists of finding a set of atomic coordinates that correspond to a local minimum of the molecular energy function (such as the potential energy model). This is done by applying large-scale nonlinear optimization techniques. The goal is to calculate a conformation close to the starting geometry for which the forces on the atoms are zero. Nonlinear optimization algorithms typically have a sequence of four steps: a test for convergence, the compute to stablish the search direction $p_k$, the evaluation of the step size, and the advance.

As a third step, all putative conformations were systematically searched for each energy-minimized model. The systematic search method generates molecular conformations by rotating nonring bonds in a molecule by discrete dihedral increments. All possible combinations of the dihedral increments are produced. Each dihedral angle combination is subjected to dihedral angle energy minimization to relieve gross strain due to atom overlap, followed by an all-atom energy minimization. As we aimed to find all putative conformations of the geometrical isomers, a restriction to maintain the corresponding (*Z*)- and (all-*E*)-conformations was added. We obtained conformational databases of the above 50 conformations for each geometrical isomer, with a total of 1200 conformations (data not shown).

As a fourth step, the MMFF94x potential energy was minimized again for all the conformations of all the geometrical isomers and the lowest energy conformation of each was selected. A new database of isomers was finally obtained and ranked by their torsional potential energies (Figure 3).

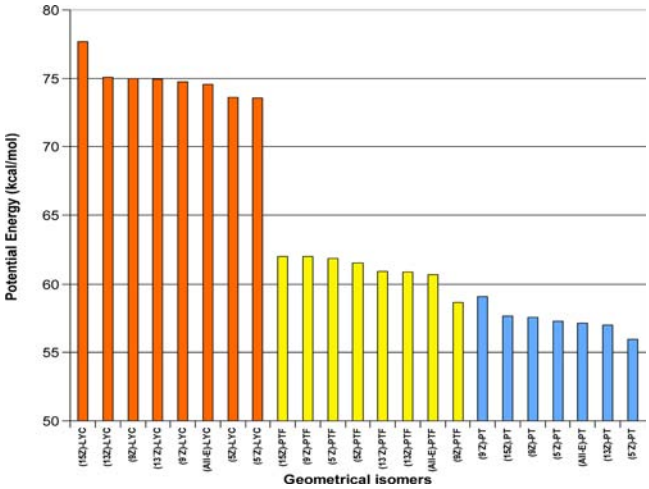

**Figure 3.** Torsional potential energies (kcal/mol) of different geometrical isomers of lycopene (LYC), phytofluene (PTF), and phytoene (PT).

**Statistical Analyses.** The results of the isomerization reactions were expressed as the mean and standard deviation of the two independent determinations.

## RESULTS AND DISCUSSION

**Isomerization Reactions.** An isomerization reaction for carotenoids can be kinetically or thermodynamically controlled. In the first case, the composition of the set of all the geometrical isomers formed (stereoisomeric set) is determined by the relative rate of formation for each one. Kinetically controlled isomerizations of carotenoids can be easily achieved by gentle heating. In the case of thermodynamically controlled reactions, the composition of the stereoisomeric set at the equilibrium is dependent on the relative stability of each isomer. These reactions have been traditionally carried out by using iodine as catalyst.[19]

Chromatograms corresponding to the stereochemical sets of lycopene, phytofluene, and phytoene at the thermodynamic equilibrium are shown in Figure 4. Chromatographic and UV−vis spectroscopic data are summarized in Supporting Information Table 1.

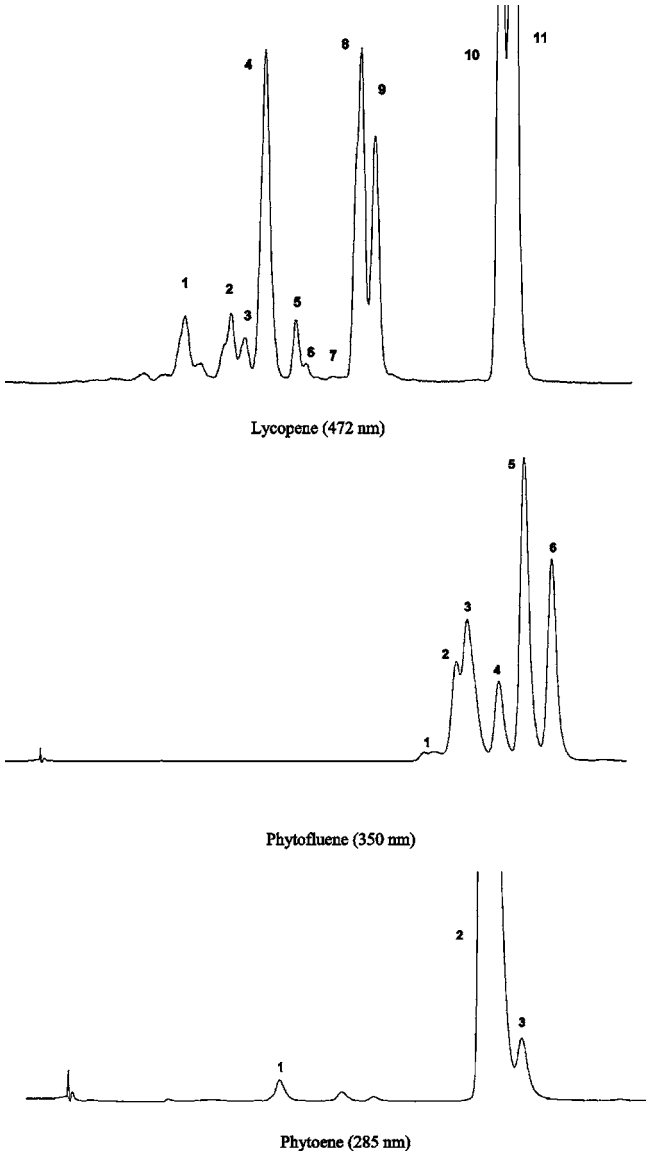

**Figure 4.** Chromatograms corresponding to the stereochemical sets of lycopene, phytofluene, and phytoene at the thermodynamic equilibrium. Chromatographic and UV−vis spectroscopic details are summarized in Supporting Information Table 1.

The time-course changes in the proportions (calculated as a function of chromatographic peak area) of their different geometrical isomers as a function of the stereomutation method used are represented in Figure 5.

The results indicated that the equilibrium in the thermal isomerization of lycopene was already achieved at time (*t*) = 60 min, as the relative proportions of the isomers remained almost constant from this time point. At 60 min the relative proportions of the major compounds were as follows: (5*Z*)-lycopene (approximately 33%), (all-*E*)-lycopene (approximately 22%), lycopene isomers 8 (tentatively identified as (9*Z*)-lycopene) (approximately 13%), lycopene isomer 4 (tentatively identified as (15*Z*)-lycopene) (approximately 13%), and lycopene isomer 9 (tentatively identified as (5*Z*,9*Z*)-lycopene) (approximately 8.5%). In a recent study the thermal isomerization at 50 °C

dx.doi.org/10.1021/jf5041965 | J. Agric. Food Chem. 2014, 62, 12399−12406

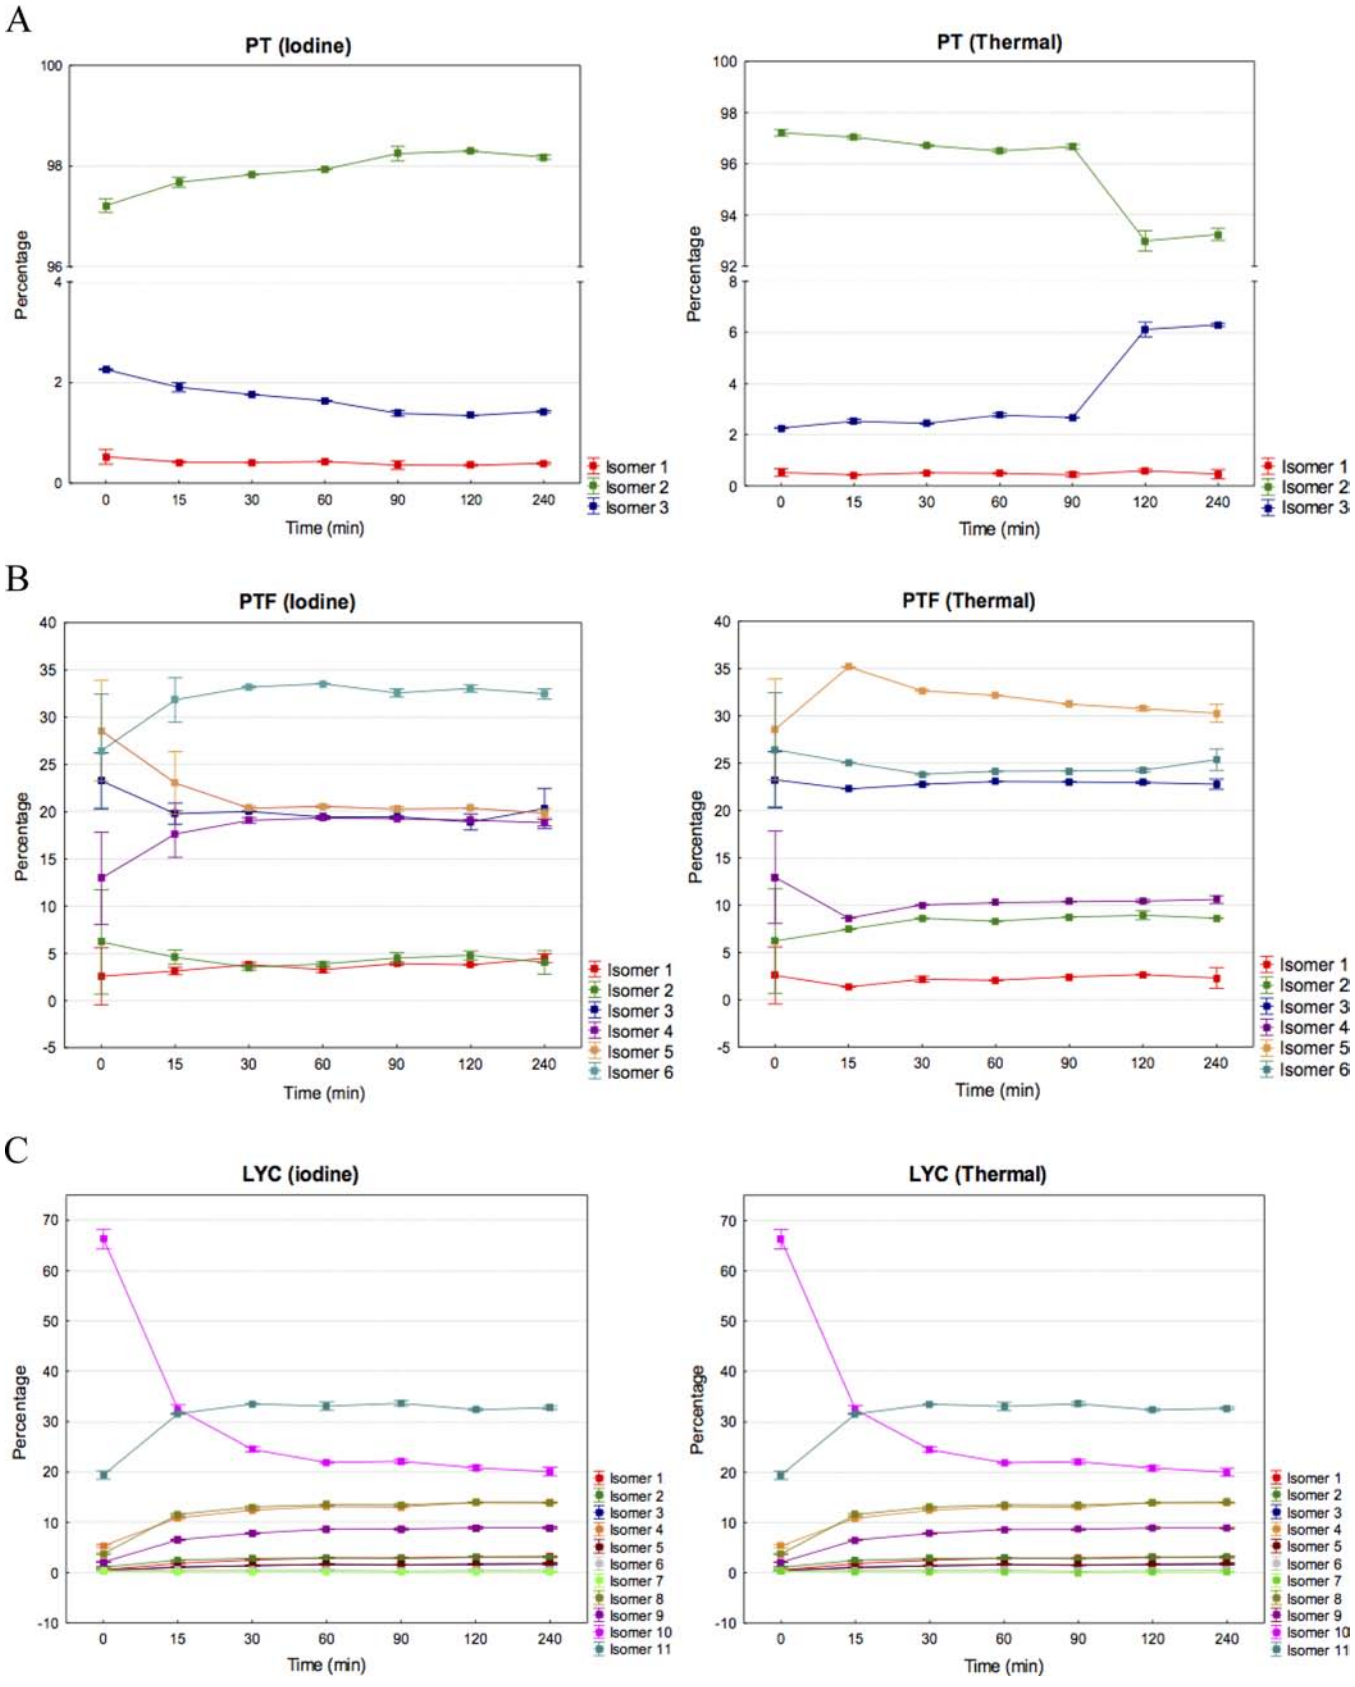

**Figure 5.** Time-course changes in the proportions of the different geometrical isomers of phytoene (PT, part A), phytofluene (PTF, part B), and lycopene (LYC, part C) as a function of the stereomutation method used.

of lycopene in both hexane and benzene was evaluated. In the case of the reaction in hexane, the levels of (5*Z*)-lycopene were the highest from 96 h up to the end of the test period (192 h). In the case of the reaction in benzene, its levels increased steadily

dx.doi.org/10.1021/jf5041965 | *J. Agric. Food Chem.* 2014, 62, 12399−12406

from time 0 until the end of the test period, which was only 96 h in this case. (13*Z*)-Lycopene was identified as the first (*Z*)-isomer to be formed as a result of the heating of (all-*E*)-lycopene[20]

Considering the iodine-catalyzed isomerization, the equilibrium was also achieved at $t$ = 60 min. At that time the major compounds were the same as those observed in the thermal stereomutation. Interestingly, their relative proportions were also almost the same (Figure 5).

Concerning phytofluene, the equilibrium of the thermal stereomutation was already achieved at $t$ = 30 min. The major isomers at that point were the isomer tentatively identified (please see Supporting Information Table 1 and Figure 4) as (all-*E*)-phytofluene (approximately 33%, peak 5), phytofluene isomer 6 (approximately 24%, peak 6), and phytofluene isomer 3 (approximately 23%, peak 3). The isomeric set at the equilibrium achieved with the iodine catalyzed isomerization ($t$ = 30 min) was different in quantitative terms. The relative proportions of the major isomers were the following: isomer 6 (approximately 33%, peak 6), isomer 5 (approximately 20%, peak 5), isomer 3 (approximately 20%, peak 3), and isomer 4 (approximately 19%, peak 4).

The changes in the relative proportions of geometrical isomers of phytoene as a result of the isomerization reactions were less noticeable. As a result of the thermal treatment the equilibrium was already achieved at $t$ = 120 min. The relative proportion of (15*Z*)-phytoene was approximately 93% and that of (all-*E*)-phytoene approximately 6%. The photoisomerization catalyzed by iodine led to a different isomeric set at the equilibrium ($t$ = 90 min). Specifically, the relative proportions of (15*Z*)-phytoene and (all-*E*)-phytoene were approximately 98% and 1.5%, respectively.

Altogether, the experiments indicated that, regardless of the compound and the stereomutation procedure, the levels of (*Z*)-isomers clearly predominated over their all-*E* counterparts at the equilibrium. Except in the case of lycopene, noticeable differences were observed in the isomeric sets at the equilibrium as a function of the stereomutation method followed. Considering that the photochemical isomerization catalyzed by iodine leads to a thermodynamic equilibrium, it appears that both (5*Z*)-lycopene and (15*Z*)-phytoene are more stable than their (all-*E*)-isomer. In addition, the compound identified as phytofluene isomer 6 seems to be more stable than the isomer tentatively identified as (all-*E*)-phytofluene.

On the other hand, heating leads to a kinetic equilibrium. In the light of our results it seems that such equilibrium favors (5*Z*)-lycopene and (15*Z*)-phytoene over their (all-*E*)-counterparts. Likewise, the equilibrium favors (all-*E*)-phytofluene over phytofluene isomer 6.

**In Silico Study of the Relative Stability of Isomers.** To gain further insight into the relative thermodynamic stability of geometrical isomers, *in silico* studies were performed. As a first step, the (all-*E*)-isomers of the three carotenoids were modeled and their minimal energies calculated. As it can be readily observed in Figure 2, the shapes of the three (all-*E*)-isomers are markedly different. In the case of lycopene, the longh chromophore of 11 conjugated double bonds (cdb) prevents the molecule from folding to a great extent. Phytoene and phytoene (with 5 and 3 cdb, respectively) can fold more freely and adopt less rigid shapes. Consequently, the torsional potential energies (kcal/mol) increased in the following order: phytoene < phytofluene < lycopene. The same trend was observed after the conformational analysis once the (*Z*)-isomers were included, the phytoene isomers being the least energetic due to their increased flexibility (Figure 3).

In the case of lycopene it was observed that the energy of the (5*Z*)-isomer (73.6 kcal/mol) was lower than that of (all-*E*)-lycopene (74.6 kcal/mol). This agrees with a previous study on the relative stability of several lycopene isomers.[21]

Concerning phytofluene, the energy of the modeled (9*Z*)-isomer was lower (58.7 kcal/mol) than that of (all-*E*)-phytofluene (60.7 kcal/mol). Regarding phytoene, the modeled (5*Z*)- and (13*Z*)-isomers were found to be less energetic (55.9 and 57.0 kcal/mol) than (all-*E*)-phytoene (57.1 kcal/mol). This finding is in disagreement with the observation that (15*Z*)-phytoene is the major isomer in the equilibria achieved by the stereomutation methods used in this study and in carotenogenic organisms in general. Altogether the results of the *in silico* studies indicate that, in the case of the major tomato carotenes, all of which are linear (i.e., they do not contain rings), the (all-*E*)-isomers are not the most stable thermodynamically. However, it should be noted that the energy differences between isomers were very low in some cases.

Interestingly the calculated energy of apparently symmetrical isomers (for example (5*Z*)- and (5′*Z*)-lycopene) was slightly different (Figure 3).

**Technological Implications.** *Presence of (Z)-Carotene Isomers in Tomato Fruits and Products.* Lycopene is largely in the (all-*E*) configuration in most red tomato genotypes whereas phytoene occurs largely as the (15*Z*)-isomer.[22] Information on the main configuration of phytofluene in tomatoes is not as conclusive. Different geometrical isomers of phytofluene in tomato were separated by HPLC on a calcium hydroxide column[23] and from the tomato source used in the present study (Figure 6). Some of these phytofluene isomers have also been observed in other studies,[16] although their conclusive annotation remains obscure.

(*Z*)-Lycopene isomers proportions ranging from 8% to 21% of total lycopene have been reported in processed tomato products, with (5*Z*)-lycopene being the predominant (*Z*)-isomer.[24] The mean proportions of (*Z*)-lycopene isomers in tomato and tomato products reported in that study were very similar (13% and 14%, respectively), and agreed well with data reported by Schierle et al.[25] This proportion is lower than that found in the thermodynamic or kinetic equilibria, indicating that the conditions of the industrial processing and the food matrix play an important role in the isomerization. These results further support that lycopene from tomato is relatively stable to isomerization during industrial processing. In contrast to lycopene, the occurrence of different isomers of phytoene and phytofluene in commercial tomato products has not been specifically studied previously.

*Effect of Thermal Treatments on the Isomerization of Tomato Carotenes.* Industrial thermal treatments are not expected to result in an extensive isomerization of (all-*E*)-lycopene to (*Z*)-isomers.[26−29] Some studies indicate that long times and very high temperatures are required to markedly increase lycopene (*Z*)-isomers. Colle et al. (2010)[30] concluded that 140 °C for 30 min was needed to cause noticeable increases in (*Z*)-isomers. The impact of thermal processing in the levels of tomato phytoene and phytofluene has not been studied in detail.

*Isomerization of Tomato Lycopene, Phytoene, and Phytofluene: Technological Implications.* Considering the large proportions of lycopene (*Z*)-isomers achieved in our experiments (approximately 80%), it appears that they (particularly the (5*Z*)-isomer) are favored both thermodinamically

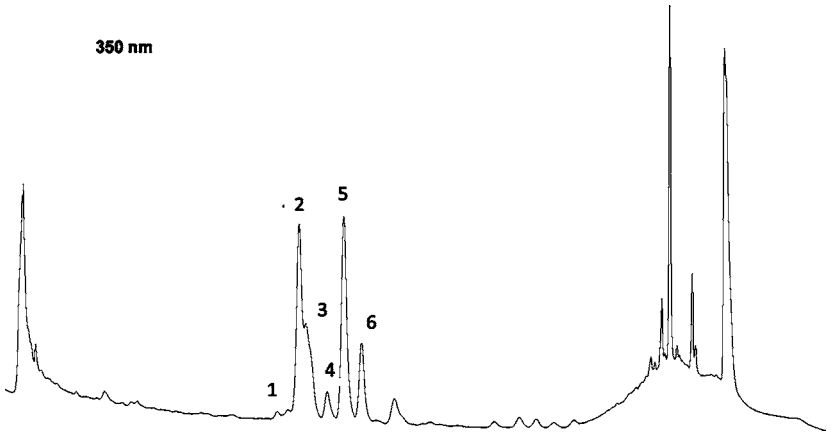

**Figure 6.** Chromatogram at 350 nm of the tomato extract used for the isolation of pure carotenoids. Major phytofluene isomers detected are indicated (peaks 1−6).

and kinetically in the equilibria. The fact that such a proportion does not match those observed in processed tomato products is striking. However, it is well-known that (all-*E*)-lycopene aggregates into crystalline structures in tomato chromoplasts,[9] and lycopene molecules in crystalline structures are not expected to participate in isomerization reactions.[31] There is evidence that the addition of oil results in an increase of the levels of (*Z*)-lycopene isomers,[29,32] attributable to the solubilization of the crystals. Thus, van het Hof et al. (1998)[33] reported a proportion of (*Z*)-isomers approximately 55% when a tomato product was thermally treated in the presence of 10% maize oil, such proportion being lower (approximately 35%) with 5% oil addition and in the absence of oil (approximately 5%).

Phytoene occurs mainly (typically >95%) as the (15*Z*)-isomer in tomatoes.[22] The data obtained in the present study indicated that (15*Z*)-isomer is (>94%) the predominant isomer in the equilibria. (*Z*)-Isomers are thought to show less tendency to form crystals. In fact, phytoene crystals in tomato have not been described. Consequently, it is unlikely to expect high levels of other phytoene isomers as a result of the thermal treatment and/or addition of oil to tomato products. In the untreated phytofluene extract for the stereomutation experiments, up to 6 isomers were detected, with proportions ranging from approximately 2.5% to approximately 28% ($t$ = 0, Figure 5). Consequently, it can be deduced that the (all-*E*)-isomer was in a lower proportion that the sum of the (*Z*)-isomers independent of the procedure followed. The aggregation of tomato phytofluene into crystals has not been described, and the presence of 3−4 predominant geometrical isomers of phytofluene as a result of tomato processing can be expected. Presently the impact of oil addition on the isomerization of both phytoene and phytofluene is sparsely studied.

**Nutritional Implications.** Stahl and Sies (1992)[34] hypothesized that lycopene (*Z*)-isomers may be better absorbed than the (all-*E*)-isomer and that there may be *in vivo* isomerization mechanisms. Several studies reported that lycopene (*Z*)-isomers predominate in human samples[25,35] and that the absorption of those isomers was possibly favored.[36,37] Other investigators concluded that (all-*E*)-lycopene remains largely in that isomeric form during digestion and that the intestinal cells may be a key location for its isomerization.[38] Unlu et al. (2007)[37] concluded that the hypothesis of the preferential absorption of lycopene (*Z*)-isomers could not explain their increased proportion in human samples suggesting that additional *in vivo* isomerization may take place. Richelle et al. (2010)[38] observed that in their *in vitro* and *in vivo* models the lycopene isomeric profiles were comparable, suggesting that the ability of "low" and "high" lycopene absorbers for the isomerization of lycopene is very similar. The formation of lycopene isomers may therefore depend to a great extent on factors like their relative thermodynamic stability or formation rate. Evidence for this hypothesis was obtained in a study[39] where meals containing high proportions (approximately 70%) of different lycopene (*Z*)-isomers were provided to humans and high proportions of the (5*Z*)- and (all-*E*)-isomers were found in the triglyceride-rich lipoproteins. These observations agreed well with the data reported in the present study indicating that the thermodynamic stability and formation rates of (5*Z*)- and (all-*E*)-lycopene are higher in comparison to other geometrical isomers. Interestingly, Clinton et al. (1996)[40] reported proportions of lycopene (*Z*)-isomers in human serum and prostate sample tissues resembling those found at the equilibrium (approximately 80%) in the present study.

Although there are studies that report the presence of both phytoene and phytofluene in the plasma and tissues of mammals (including humans),[5,41,42] data on their isomeric profile are very scarce. In a recent study, the presence of large amounts of (15*Z*)-phytoene and several isomers of phytofluene in samples from mammals has been reported.[16]

In conclusion, the results of the stereomutations and the *in silico* studies performed in this study indicate that certain (*Z*)-isomers of lycopene, phytoene, and phytofluene are favored thermodynamically and kinetically. Although these observations cannot be extrapolated to biological systems directly, they can aid in understanding the findings of some nutritional studies, where high levels of lycopene (*Z*)-isomers are consistently found in human plasma and tissues. The results also enlighten why the concentration of lycopene (*Z*)-isomers can increase when oil is added to tomato products. The data on the proportions of different isomers of the colorless carotenes, phytoene, and phytofluene in the equilibria is useful to forecast their expected isomeric mixtures in foods and human tissues and biological fluids. According to the results of this study, phytoene could be expected to occur largely as the (15*Z*)-isomer in humans and phytofluene as a mixture of several geometrical isomers. Finally, on the basis of our results, the use of geometrical isomers of lycopene and phytofluene on their own or as mixtures are recommended in the *in vitro*, *ex vivo*, and *in vivo* future studies aimed at assessing their possible biological activities. Likewise, it is recommended to use (15*Z*)-phytoene in such studies.

are also explored in relation with their concentrations to evalute their contribution to the antioxidant capacity of calafate. This research is a contribution to promote, from a scientific perspective, the potential of this underexploited fruit, complementing previous work about anthocyanins and hydroxycinnamic acids now with flavonol and alkaloid levels and antioxidant capacity.

## MATERIALS AND METHODS

**Reagents, Standards, and Extraction Materials.** Commercial standards of quercetin-3-rutinoside (<94%), quercetin-3-galactoside (>97%), quercetin-3-glucoside (>90%), quercetin-3-rhamnoside (85%), quercetin-3-*O*-(6″malonyl)-D-*β*-glucoside (85%), berbamine dihydrochloride, and berberine hydrochloride (<90%) were obtained from Sigma (Steinheim, Germany). Quercetin-3-glucoside (99%), jatrorrhizine hydrochloride (99.71%), palmatine hydrochloride (96.98%), and canadine (99.99%) were provided by Phytolab (Vestenbergsreuth, Germany), and oxyacanthine was from Extrasynthese (Genay, France). Formic acid, ammonia (25%), dichloromethane, hydrochloric acid, and HPLC grade solvents (acetonitrile, methanol, and water) were provided by Merck (Darmstadt, Germany). Flavonol cleanup was accomplished using a 150 mg Oasis MCX 6 $cm^3$ mixed phase SPE cartridges from Waters (Milford, MA, USA) and alkaloid recovery by using organic extracts from Extrelut NT 20 columns from Merck.

**Plant Material.** Flavonols and alkaloids were studied in 65 mature calafate samples and in 16 mature samples of other endemic *Berberis* species including *B. empetrifolia*, *B. darwinii*, *Berberis ilicifolia*, *Berberis montana*, and the introduced *Berberis vulgaris*. All of the fruits were collected from Chilean Patagonia, between the Araucanía and Magallanes regions (37−54° S and 74−69° W) in 2010 and 2011, with the exception of *B. vulgaris*, which was obtained in the Bio Bio region (36° 49′ S; 73° 02′ W). Other samples of roots, leaves, branches, and fruits were obtained from six different *Berberis* plants (*B. microphylla* G. Forst, *B. ilicifolia*, and *B. vulgaris*) to study the distribution of alkaloids in the plants. Additionally, calafate berry samples collected with three different phenological stages from one plant from sector Barranco Amarillo, Magallanes (53° 05′ S; 70° 52′ W) were included to study their influence on flavonol and alkaloid profiles and concentrations. The study of flavonol profile and concentrations in skin, pulp, and seed obtained from two composed calafate samples, one from Magallanes and other from Aysen, was also accomplished. All samples were kept frozen (−20 °C) before their analyses, and all their classifications were made by a taxonomy expert compared with specimens from the University of Concepcion Herbarium.

**Instruments.** An analytical balance of Denver Instrument Co. (New York, USA), an ultrasonic bar homogenizer Cole Palmer Series 4710 (Chicago, IL, USA), a mechanical shaker Stuart S01 Bibby Sterilin LTD (Stanford, UK), a centrifuge Sigma 3-16p Christ, (Osterode, Germany), and a rotavapor complemented with a vacuum pump V-700 and controller system V-850, Büchi (Flawil, Switzerland) were used for sample preparation. A microplate reader (Epoch, Biotek Instruments, Winooski, VT, USA) was used for antioxidant assays.

The HPLC-DAD-ESI-MS/MS analyses for flavonol and alkaloid identification were carried out by using a Shimadzu Nexera UHPLC/HPLC system (Kyoto, Japan) equipped with a quaternary LC-30AD pump, a DGU-20A5R degasser unit, a Prominence CTO-20 AC oven, an SIL-30AC autosampler, and an SPD-M20A UV−vis photodiode array spectrophotometer detector coupled in tandem with a LC-MS/MS detector QTrap 3200 MDS Sciex (USA). Instrument control and the data collection system were carried out using CLASS-VP DAD Shimadzu Chromatography Data System (Kyoto, Japan) and Analyst software version 1.5.2 for MS/MS analysis AB Sciex (Framingham, MA, USA).

Quantitative analyses of alkaloids were carried out using a HPLC with fluorescence detector composed of a LaChrom Elite L-2130 pump, an L-2200 autosampler, and an L-7485 detector from Hitachi High Technologies Co, (Tokyo, Japan), with a CTO-10AVP oven Shimadzu (Kyoto, Japan). The data collection was done using an interactive software graphics version 6.2 Varian Inc. (Palo Alto, CA, USA).

**Sample Pretreatments.** *Flavonols.* Whole extract preparation and cleanup were carried out on the basis of the methods described by Ruiz et al. and Castillo-Muñoz et al.[2,11] with minor modifications. Five grams of whole fruit was ground in a stainless steel mixer with 10 mL of methanol/water (93:7% v/v); the extract was treated for 45 s with the ultrasonic bar, followed by 16 h of mechanical shaking under darkness. After centrifugation, the separated supernatant was transferred, and the residual solid was washed three times with 5 mL of the same solvent by mechanical shaking for 15 min. Cleanup of the combined extracts (25 mL) was made by using Oasis MCX cartridges, to eliminate the interfering anthocyanins. One milliliter of crude extract was dried in a rotary evaporator and reconstituted in 1.0 mL of 0.1 N hydrochloric acid. This solution was loaded on a MCX cartridge previously conditioned with 5.0 mL of methanol and 5.0 mL of water. A washing step, using 5.0 mL of 0.1 N hydrochloric acid and 5.0 mL of water, was necessary to remove sugars. The flavonol fraction was eluted with 3 × 5.0 mL of methanol and, finally, the solvent was distilled off by vacuum evaporation and the residue was redissolved in 1 mL of the mobile phase (0.1% formic acid in water/acetonitrile 85:15%v/v) for its chromatographic analysis. This fraction also contained the hydroxycinnamic acids.

In the study of flavonol distribution in different parts of the fruits (seeds, pulp, and skin), frozen berries were peeled, the pulp was separated from the seed, and all were carefully dried with paper toweling. Each was separately ground before the same extraction procedure as described above was applied.

*Alkaloids.* The method was adapted from a procedure described for alkaloid extraction of lupine seeds and plants,[9] which was based on the method proposed by Wink,[10] with modifications: 1 g of calafate sample (fruit, seeds, leaves, branches, or roots) was extracted with 8 mL of 0.1 N HCl with the assistance of an ultrasonic bar for 45 s and mechanical shaking for 10 min. After centrifugation, the supernatant was transferred to a 25 mL volumetric flask, and the solid residues were washed three times with 5 mL of the same solvent (in the case of fruits, seeds, and leaves) and 8 mL (in the case of roots and branches). The whole extract was neutralized using $NH_4OH$ and completed to 25 mL. Twenty milliliters of extract was transferred to an Extrelut NT-20 column, to carry out the liquid−liquid extraction, using dichloromethane as the elution solvent (4 × 25 mL). After that, the solvent was evaporated at reduced pressure (30 °C) and finally redissolved in 1 mL of mobile phase (0.1% of formic acid in water/acetonitrile 20:80% v/v) and filtered before its chromatographic analysis.

**Flavonol Analyses.** *HPLC-DAD.* Three $C_{18}$ columns were evaluated for flavonol HPLC separation: (A) $C_{18}$ column (Kromasil $C_{18}$ 100 A, 5 $\mu$m, 250 × 4.6 mm) with a $C_{18}$ precolumn (Nova-Pak Waters, 4 $\mu$m, 22 × 3.9 mm); (B) $C_{18}$ core−shell column (Kinetex $C_{18}$ 100 A, 2.6 $\mu$m, 150 × 4.6 mm) with a $C_{18}$ precolumn for UHPLC columns (Phenomenex AJ0-9000, 2.2 $\mu$m, 22 × 3.9 mm); (C) $C_{18}$ UHPLC column (Shim-pack XR-ODS III, 2.2 $\mu$m, 150 × 2.0 mm) without a precolumn. The chromatographic separation conditions were optimized for each column and were carried out at 30 °C using 0.1% of formic acid in water (A) and acetonitrile (B) as mobile phase. The optimized separation using column A was carried out at a flow rate of 1 mL/min, with a gradient starting with 80% A for 6.5 min, from 80 to 76% in 6 min, from 76 to 60% in 2.5 min, and from 60 to 0% in 0.5 min, maintaining the proportion for 6.5 min, and a final stabilization step of 10 min at 80% A. The injection volume was 10 $\mu$L.

The separation using column B was carried out also at 1 mL/min with a gradient starting with 85% A for 0.1 min, from 85 to 80% in 5 min, from 80 to 70% in 2.5 min, from 70 to 0% in 0.5 min, maintaining the proportion for 2 min, and with a final stabilization step of 5 min at 85% A. The injection volume was 5 $\mu$L.

Finally, the separation in column C was carried out at a flow rate of 0.5 mL/min, with a gradient starting with 85% A for 12 min, from 85 to 60% in 3 min, from 60 to 0% in 0.5 min, maintaining the proportion for 5 min, and with a final stabilization step of 7 min at 85% A. The injection volume in this case was also 5 $\mu$L.

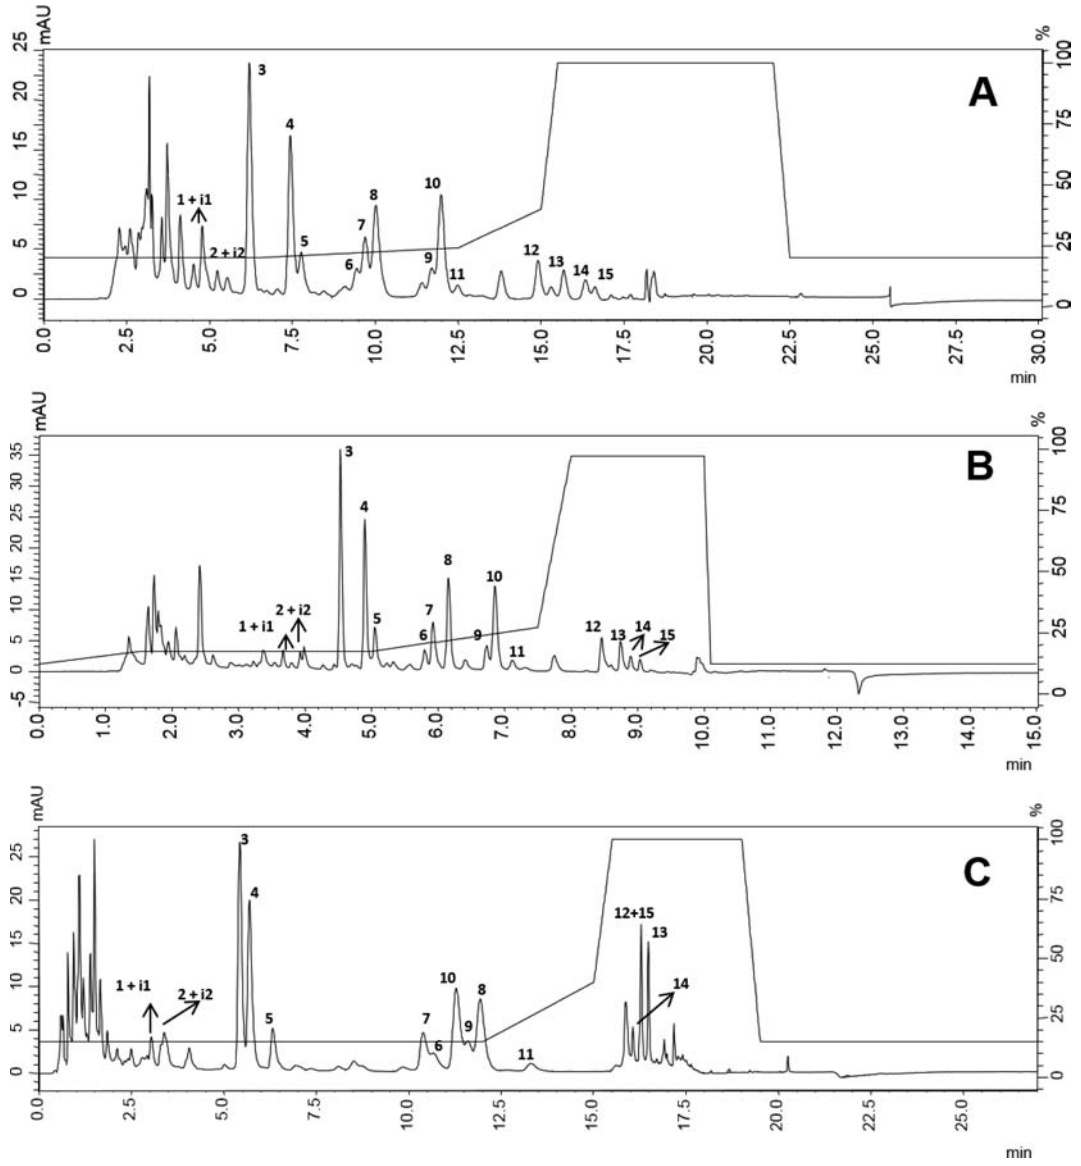

**Figure 1.** Chromatograms of flavonols extract of *B. microphylla* G. Forst fruit (from Reserva Forestal Magallanes) using different columns: (A) classical column; (B) core−shell column; (C) UHPLC column. Chromatographic conditions are described in the text.

Flavonol quantitation was performed through a DAD chromatogram extracted at 360 nm by external calibration using quercetin-3-rhamnoside, quercetin-3-rutinoside, quercetin-3-galactoside, and quercetin-3-glucoside. Because of the lack of pure standards, 3-rutinoside derivatives were quantitated using the quercetin-3-rutinoside calibration curve. The other detected flavonols were quantitated using the quercetin-3-glucoside curve, based on the similitude between their molar absorptivities.[12] Results were expressed as micromoles per gram FW to compare values obtained using different standards.

*HPLC-DAD-ESI-MS/MS.* The identification by MS/MS was carried out using the same chromatographic condition for core−shell columns (B) with 0.5 mL/min as mobile phase flow. Negative ionization mode was as follows: −20 V declustering potential, −5 V collision energy, −4000 V ionization voltage, capillary temperature at 450 °C, and $N_2$ nebulizer at 15 psi. The identity assignation of analytes was carried out by comparison of their retention time ($t_R$) with those of their respective commercial standards and also by comparison of characteristic spectral data (MS/MS and UV).

In the context of the study of antioxidant capacity, hydroxycinnamic acid derivatives and total phenolics were quantitated by HPLC-DAD according to methods described by Ruiz in 2013 and 2010, respectively.[2,3] Total phenolics were determined as the sum of flavonols, hydroxycinnamic acid derivatives, and anthocyanins present in the whole extracts.

**Alkaloid Analyses.** *Separation and Quantitation.* A $C_{18}$ column (Kromasil C18 XDB, 5 $\mu$m, 250 × 4.6 mm) with a $C_{18}$ precolumn (Nova-Pak Waters, 4 $\mu$m, 22 × 3.9 mm) was used. The separation was carried out at 30 °C at a flow rate of 1 mL/min, by using a mobile phase constituted by 0.1% of formic acid in water (A) and acetonitrile (B), with a gradient starting with 80% A for 1 min, from 80 to 50% for 11 min, from 50 to 0% for 1 min, maintaining the proportion for 5 min, and with a final stabilization step of 10 min at 80% A. The injection volume was 25 $\mu$L, and the detection by fluorescence used 350 and 530 nm as excitation and emission wavelengths, respectively. The quantitative analysis was carried out by external calibration with berberine standard.

*Identification.* Using the same separation conditions described in the preceding paragraph, identification was carried out using the following MS/MS conditions: positive ionization mode, 60 V declustering potential, 10 V collision energy, 5000 V ionization voltage, capillary temperature at 500 °C, and $N_2$ nebulizer at 30 psi. Analyte identity was by comparison of their $t_R$ with those of reference compounds and by comparison of MS/MS and UV spectra.

Table 1. Identity Assignment of Flavonols in *B. microphylla* G. Forst Extracts by HPLC-DAD-ESI-MS/MS

| flavonol | peak identification | $t_R$ (min) | $\lambda_{max}$ (nm) | $[M - H]^-$ | product ion |
|---|---|---|---|---|---|

**$TEAC_{CUPRAC}$ and $TEAC_{ABTS}$ Assays.** $TEAC_{CUPRAC}$ assays were conducted in 96-well microplates. To each well was added with 50 $\mu$L of solution constituted by 10 mM copper(II) solution, neocuproine solution (7.5 mM), and buffer (1 M, pH 7). Microplates were incubated at 37 °C for 15 min before 100 $\mu$L of TROLOX solution or sample was added, and then the plates were incubated at 37 °C for 30 min, after which absorbance was determined at 450 nm using a microplate reader. To evaluate intrinsic absorbance of samples, copper(II) solution and neocuproine solution were replaced by 100 $\mu$L of Milli-Q water. ABTS assay was performed as explained by Ruiz et al.[2] Antioxidant capacity of whole calafate extracts was compared with the SPE fractions (containing flavonols/hydroxycinnamic acids), obtained as previously described.

## RESULTS AND DISCUSSION

**HPLC of Flavonols.** Flavonol separation in the calafate extract is a complex task due to the high diversity of flavonols and other compounds, such as phenolic acids, which coelute on reversed phase columns. As described under Materials and Methods, three reversed phase C-18 columns were evaluated to obtain a better separation of this complex sample. The first column (A) was a classic HPLC column (250 × 4.6 mm, 5 $\mu$m), which allows a higher sample load; the second was a core−shell column (B), with the same internal diameter but a shorter length (150 mm) and smaller particle size 2.6 $\mu$m; and the last one was an UHPLC column (C) with the same length (150 mm) but smaller internal diameter (2 mm) and particle size 2.2 $\mu$m, allowing reduction of solvent consumption.[13] The respective chromatograms obtained for each under optimal conditions are presented in Figure 1.

The best separation was reached using the core−shell column (B). This is a sub-3-$\mu$m particle size column, with higher permeability due to the external layer of porous silica bonded to the stationary phase. This type of stationary phase has diminished eddy diffusion coefficients in the van Deemter equation, a decreased axial diffusion by diminution of intraparticle porosity, and a reduced mass transference by decreasing diffusion into the particles of stationary phase.[14] This improved the chromatographic efficiency, with the advantage of working at a much lower pressure and obtaining a more acceptable resolution. All subsequent flavonol analyses were carried out by using the core−shell column (B).

**Flavonol Identification in Calafate Extract.** A great diversity of flavonols was found in calafate samples, with 16 flavonol derivatives being detected in the methanolic calafate extract. The results are summarized in Table 1 and are in accordance with those previously described for a reduced number of samples.[2] However, some exceptions were found. Traces of isorhamnetin malonyl-hexoside, quercetin and kaempferol derivatives, and kaempferol aglycone were observed, with the last one being detected at 20 min by only the MS/MS detector. The low intensity of these signals may have hindered their identification in the previous study by Ruiz et al.[2] On the other hand, 3-rutinoside-7-galactosides of myricetin, quercetin, and isorhamnetin, which have been previously described as present in trace amounts in calafate,[2] were not detected in any of the current samples. Additionally, the higher hydrophilic characteristic of these flavonols, under the separation condition used in this method, could have resulted in the coelution with other interfering compounds in the first part of the chromatogram, mainly hydroxycinnamic acids (see Figure 1B).

The identities of quercetin-3-galactoside (peak 4) and quercetin-3-glucoside (peak 5) were assigned by comparison with retention time of standards. Their identity was confirmed on the basis of their fragmentation pattern, where both compounds showed a quasi-molecular ion of $m/z$ 463, with a product ion of $m/z$ 300. In the case of 3-galactoside and 3-glucoside derivatives of isorhamnetin (peaks 9 and 11), their identities were assigned according to data on flavonol glycosides from the literature.[15]

Signals 6 and 7 showed the same fragmentation pattern, with a quasi-molecular ion of $m/z$ 505 and a product ion of $m/z$ 300, which may be the acetyl hexoside of quercetin. However, the presence of a minor signal of $m/z$ 549 suggested the presence of a malonyl derivate instead. Retention time and mass spectra were compared against a commercial standard of quercetin-3-*O*-(6″-malonyl)-D-$\beta$-glucoside, confirming the identity of this compound. In Figure 2 are presented the mass spectra of the standard and signal 7, showing the same fragmentation patterns. According to the elution order described by Cho et al.,[15] where galactoside showed a shorter retention time in reversed phase chromatography than glucoside derivatives because of their higher polarity, signal 6 was assigned as the

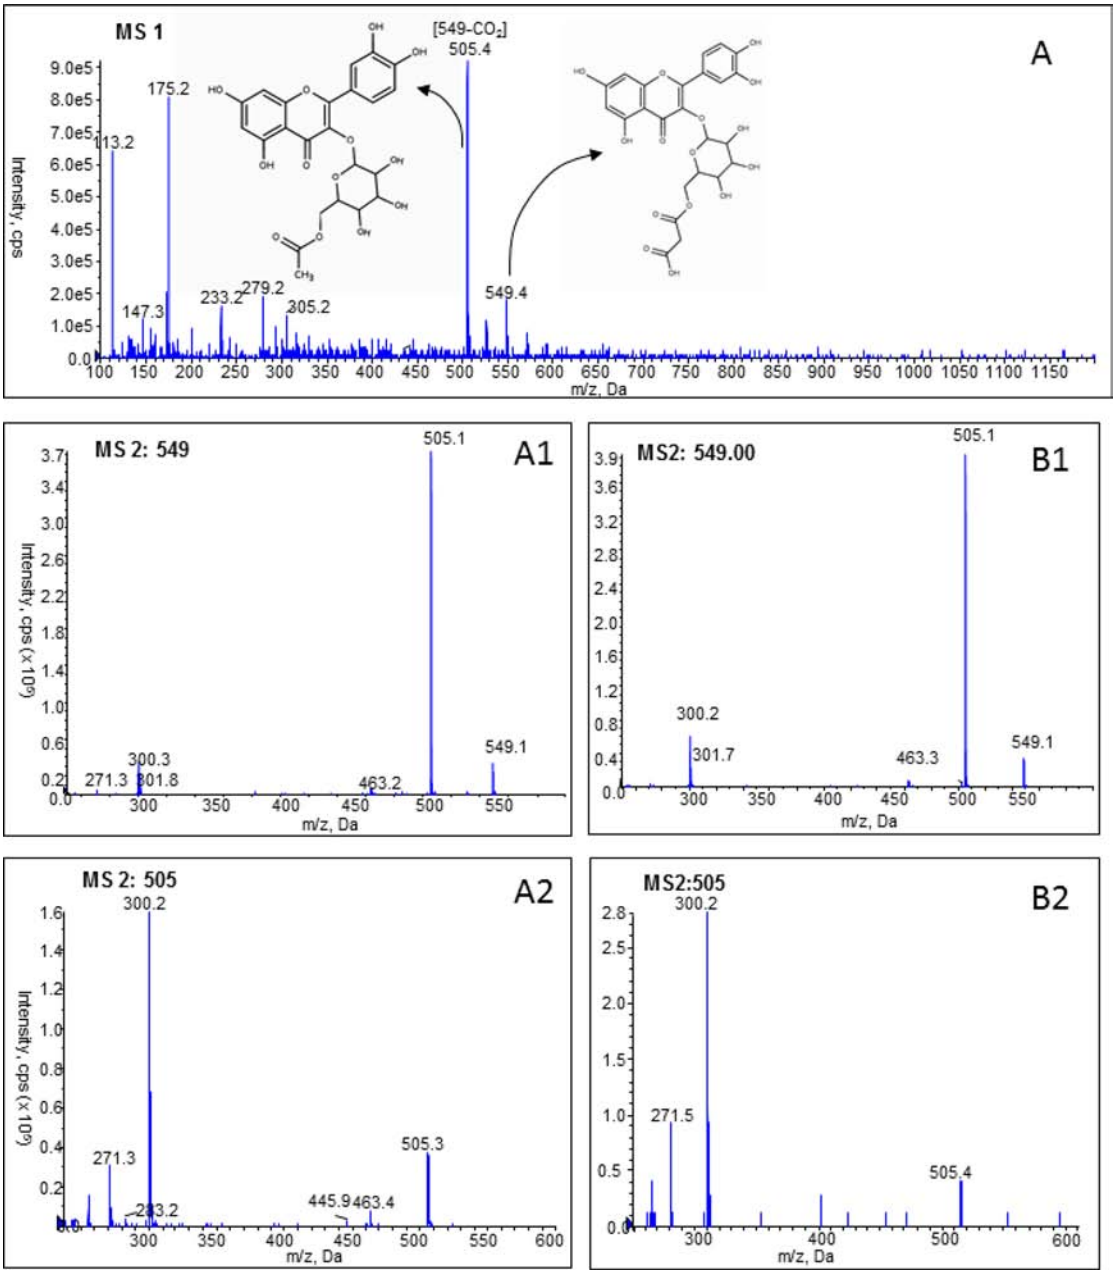

**Figure 2.** (A) Mass spectra of quercetin-3-malonyl glucoside standard; (A1, A2) $MS^2$ of $m/z$ 549 and 505, respectively, of the standard (peak 7); (B1, B2) $MS^2$ of $m/z$ 549 and $m/z$ 505, respectively, of calafate sample (peak 7).

galactoside derivate of this compound. Similar mass spectra were observed for signals 12 and 13 showing a quasi-molecular ion of $m/z$ 519 and a product ion of $m/z$ 314 corresponding to an isorhamnetin. The same criterion was used to assign the malonylgalactoside and malonylglucoside derivatives, respectively, being in this case tentatively identified because no commercial standards were available.

The deoxyhexoside derivatives of quercetin and kaempferol (peaks 10 and 15) were assigned on the basis of their MS/MS spectra. In both cases, a neutral loss of 146, consistent with a rhamnose, was detected.[15] Peak 10 was confirmed as quercetin-3-rhamnoside by comparison with their respective standard.

Another quercetin derivative, with a quasi-molecular ion of $m/z$ 563 and two product ions of $m/z$ 463 and 300, was detected. This compound was assigned as a quercetin-glucoside derivative according to the fragmentation pattern. Finally, peaks 1 and 2 coeluted with interfering signals (i1 and i2, respectively). Their MS/MS identification, as well as that of peaks 3 and 10, was consistent with the previous study.[2]

**Quantitative Analytical Parameters for Flavonol Analyses.** The quantitative method validation included the efficiency of the flavonol extraction, which was evaluated using a calafate sample subjected to seven successive extraction steps, to ensure exhaustive extraction. The quantitative results were obtained for each of them. After seven steps, no further increase in flavonol concentration was detected, and the total concentration of the seven steps was considered to be 100% extraction. The results showed that by applying four extraction steps, >95% of the flavonols were extracted, which is a good compromise between extraction efficiency and extraction time. The internal precision of flavonol determination in calafate samples, considering the whole method including liquid−solid

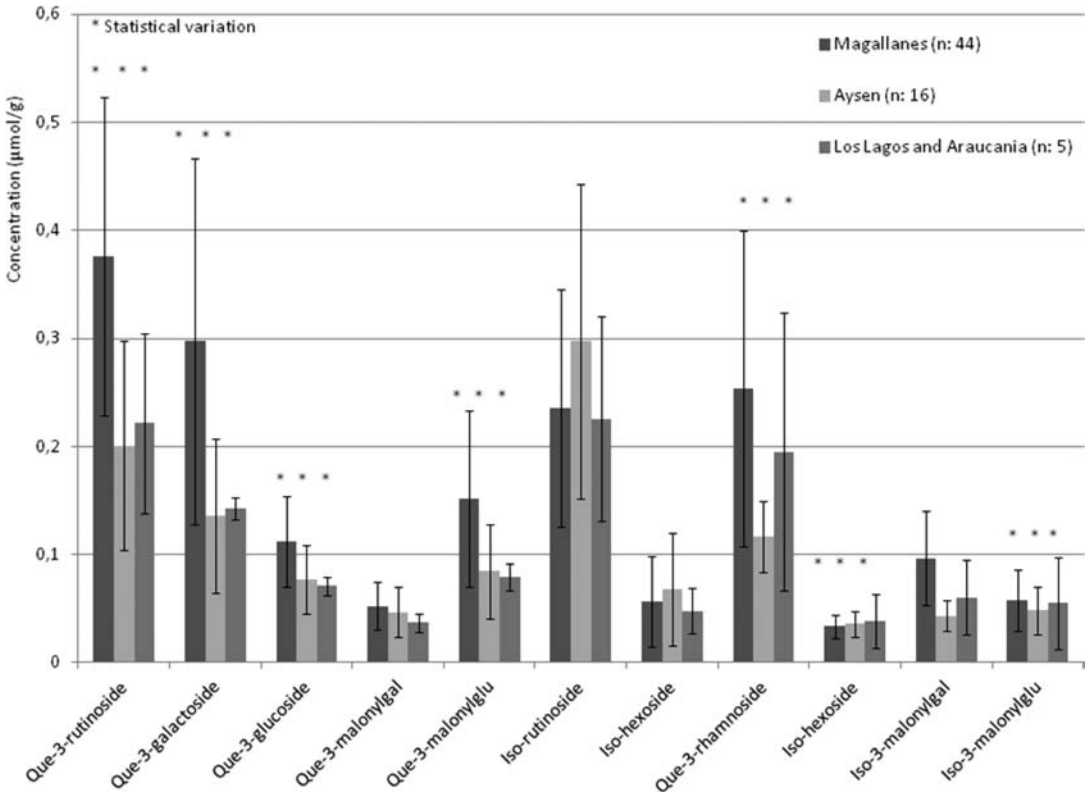

**Figure 3.** Individual flavonol concentrations in 65 samples of *B. microphylla* G. Forst obtained in Magallanes, Aysen, and Los Lagos and Araucania.

extraction, SPE cleanup steps, and chromatographic separation, was 7.9%, and the extracts were stable for 7 months at −20 °C. The analytical response and other analytical parameters for the main flavonols are summarized in the Supporting Information. Total flavonols were determined by the sum of individual flavonols detected over the limit of quantitation of the method.

**Flavonol Quantitation in Calafate and Other *Berberis* Berries.** Sixty-five samples of calafate berries obtained at different latitudes in Patagonia were analyzed. In all of them, 16 flavonol derivates were detected. The most abundant was quercetin-3-rutinoside, showing a mean concentration of 0.32 ± 0.15 μmol/g FW, with a range from traces to 0.74 μmol/g FW. Quercetin-3-galactoside, quercetin-3-rhamnoside, and isorhamnetin-3-rutinoside also showed interesting concentrations of 0.24 ± 0.16, 0.25 ± 0.12, and 0.24 ± 0.14 μmol/g FW, respectively. For the other quercetin and isorhamnetin derivates, their mean concentrations were <0.10 μmol/g FW. The myricetin and kaempferol derivatives were detected only at trace levels. In Figure 3 are summarized and compared the quantitative results for each quantifiable flavonol in relation to its origins. By ANOVA (Tukey−Kramer test), statistical variations in concentrations of flavonols in calafate from different regions were evaluated. The most significant differences were observed in quercetin derivatives (quercetin-3-rutinoside, quercetin-3-galactoside, and quecetin-3-rhamnoside), the most abundant flavonols in calafate, whereas no significant differences were observed for isorhamnetin derivatives, except isorhamnetin-3-malonylglucoside, which presented lower concentrations in samples from the Aysen region.

For all quantifiable flavonols, the total concentration, expressed as a mean of all studied samples ($n$ = 65), was 1.33 ± 0.54 μmol/g FW, with a range between 0.27 ± 0.01 and 2.89 ± 0.05 μmol/g FW; no significant difference was observed between samples obtained in 2011 and 2012 (1.34 ± 0.55 and 1.32 ± 0.49 μmol/g FW, respectively). Samples from more southerly latitudes (Magallanes 51−54° S) showed higher concentrations than those from the northern ones (Aysen 43−47° S) and Chiloe Main Island (42° S). This trend is similar to that observed for hydroxycinnamic acid derivates,[3] in which a decrease in their concentrations was observed from south to north. However, in the flavonol study, an exception was observed for four samples obtained further north, in Gorbea (39° 06′ S; 72° 40′ W in the Araucanía region), which showed similar mean concentrations to the Magallanes samples. The quantitative results by region are summarized in Table 2.

The profile and concentration of flavonols in mature samples of calafate (*B. microphylla*) were compared with those for mature berry samples of other endemic *Berberis* species obtained in the same study zone (between Bio-Bio and Magallanes regions). The respective flavonol chromatograms for the *Berberis* species are presented in Figure 4.

The results showed different profiles for the species, especially for *B. empetrifolia*, *B. ilicifolia*, and *B. darwinii*, in comparison with *B. microphylla*. In the first one, only three flavonols (rutinoside, galactoside, and glucoside derivatives of quercetin) predominated, only traces of other flavonols being observed (isorhamnetin-3-rutinoside, isorhamnetin-3-galactoside, and isorhamnetin-3 malonylglucoside). In *B. ilicifolia*, isorhamnetin-3-rutinoside predominated, whereas quercetin-3-rhamnoside, quercetin-malonyl derivatives, and the other isorhamnetin malonyl derivatives were absent. In *B. darwinii*, the absence of isorhamnetin-3-rutinoside and isorhamnetin-3-galactoside was noted, with a similar proportion of the other flavonols to *B. microphylla*. *B. montana* and *B. vulgaris* presented flavonol profiles similar to that of calafate, with similar proportions of them. This observation is interesting because

*B. montana* and *B. microphylla* are taxonomically similar,[1] which could explain their similar profiles. However, *B. vulgaris* is an introduced species, which is used as an ornamental plant in gardens and is very different from *B. microphylla*.

The quantitative results of the 16 samples of other *Berberis* species were compared with the results for calafate samples summarized in Table 2. The total flavonol concentration of *B. microphylla* was less than that observed for *B. montana* samples ($n$ = 4), showing 1.33 ± 0.54 and 1.61 ± 0.64 μmol/g FW, respectively, and for *B. empetrifolia* (2.01 μmol/g FW, $n$ = 1), but was higher than that observed for *B. ilicifolia* (0.71 ± 0.18 μmol/g FW, $n$ = 1), *B. darwinii* (1.04 ± 0.31 μmol/g FW, $n$ = 6), and the only available sample of *B. vulgaris* (0.72 μmol/g FW), which was obtained from University of Concepción gardens.

The flavonol concentration in different parts of the calafate fruit (skin, pulp, and seeds) was determined in two composed samples, one of them from Magallanes and the other from the Aysen region. The results were similar for samples from both regions. Flavonol concentrations were lower in the seeds than in the pulp and skin. Quercetin-3-rutinoside and quercetin-3-galactoside were the predominant flavonols in skin and pulp, followed by isorhamnetin-3-rutinoside. Quercetin-3-rhamnoside was detected only in seeds, being the main flavonol found in this structure (>60% of the total flavonols in seed). It is important to note that this flavonol is one of the predominant flavonols in calafate. This distribution within the different structures of the fruit is very interesting and must be explained by the calafate plant metabolism; however, this has not been studied until now.

The profile and concentrations of flavonols in different phenological stages was evaluated using berry samples obtained from the same plant in the stages of fruit setting, green fruit, and full-colored fruit. The samples were taken on December 15, 2011; January 15, 2012; and February 15, 2012, respectively. Results showed that the flavonol profile changed in this process. Quercetin-3-malonylglucoside decreased, whereas quercetin-3-rhamnoside increased, and the overall flavonol concentration decreased to 75% of the initial level. These results are presented in Figure 5. These observations are similar to those previously obtained for hydroxycinnamic acid derivatives in calafate[3] and are correlated with those observed by Arena et al.[16] for total polyphenol and flavonoid contents in calafate. The phenolic content decrease has also been observed for other berries, including different cultivars of the blueberry,[17] in which a change in the pool of total phenolics toward anthocyanin synthesis, with an overall decline in the content of other phenolic components, is observed during ripening.

These findings about flavonols in calafate are very relevant because of the enhancement of calafate and other *Berberis* from a nutraceutical point of view. They also contributed to finding the optimal growing time and conditions.

**Reducing Capacity of Whole and SPE Fractions Calafate Extracts.** Four previously quantitated fractions obtained by SPE were subjected to in vitro antioxidant capacity assays ($TEAC_{CUPRAC}$ and $TEAC_{ABTS}$). This was carried out to evaluate the contribution of these anthocyanin free fractions on the antioxidant capacity of calafate. These fractions contained mainly flavonols and hydroxycinnamic acids. Two of these samples (C1 and C2) had low concentrations of these compounds, whereas the other two were included due to its high concentrations (C3 and C4). In Table 3 are summarized these results. High $TEAC_{CUPRAC}$ and $TEAC_{ABTS}$ values were observed for whole extracts with high total phenolics (C1 and C4). This is explained mainly due to the high anthocyanin concentrations present in these extracts. Also, it is possible to observe a trend of higher $TEAC_{CUPRAC}$ and $TEAC_{ABTS}$ values for SPE fractions with high flavonol−hydroxycinnamic acid concentrations (C3 and C4), compared with the fraction with minor concentrations of this compounds (C1 and C2); however, this trend is less clear than those observed for whole extracts. The antioxidant capacities obtained for flavonol plus hydroxycinnamic acid fractions represent 15 ± 5 and 5 ± 4% of $TEAC_{CUPRAC}$ and $TEAC_{ABTS}$ values, respectively, in comparison with the values obtained for the whole extracts. This shows that flavonols and hydroxycinnamic acids have a notable incidence in the antioxidant capacity of calafate, despite its lower concentration in comparison with anthocyanins.

**Alkaloid Identification and Quantitation in Calafate and Other *Berberis* Berries.** Alkaloid determination was done with the objective of guaranteeing the innocuousness of *Berberis*. The identification of alkaloids in calafate and other

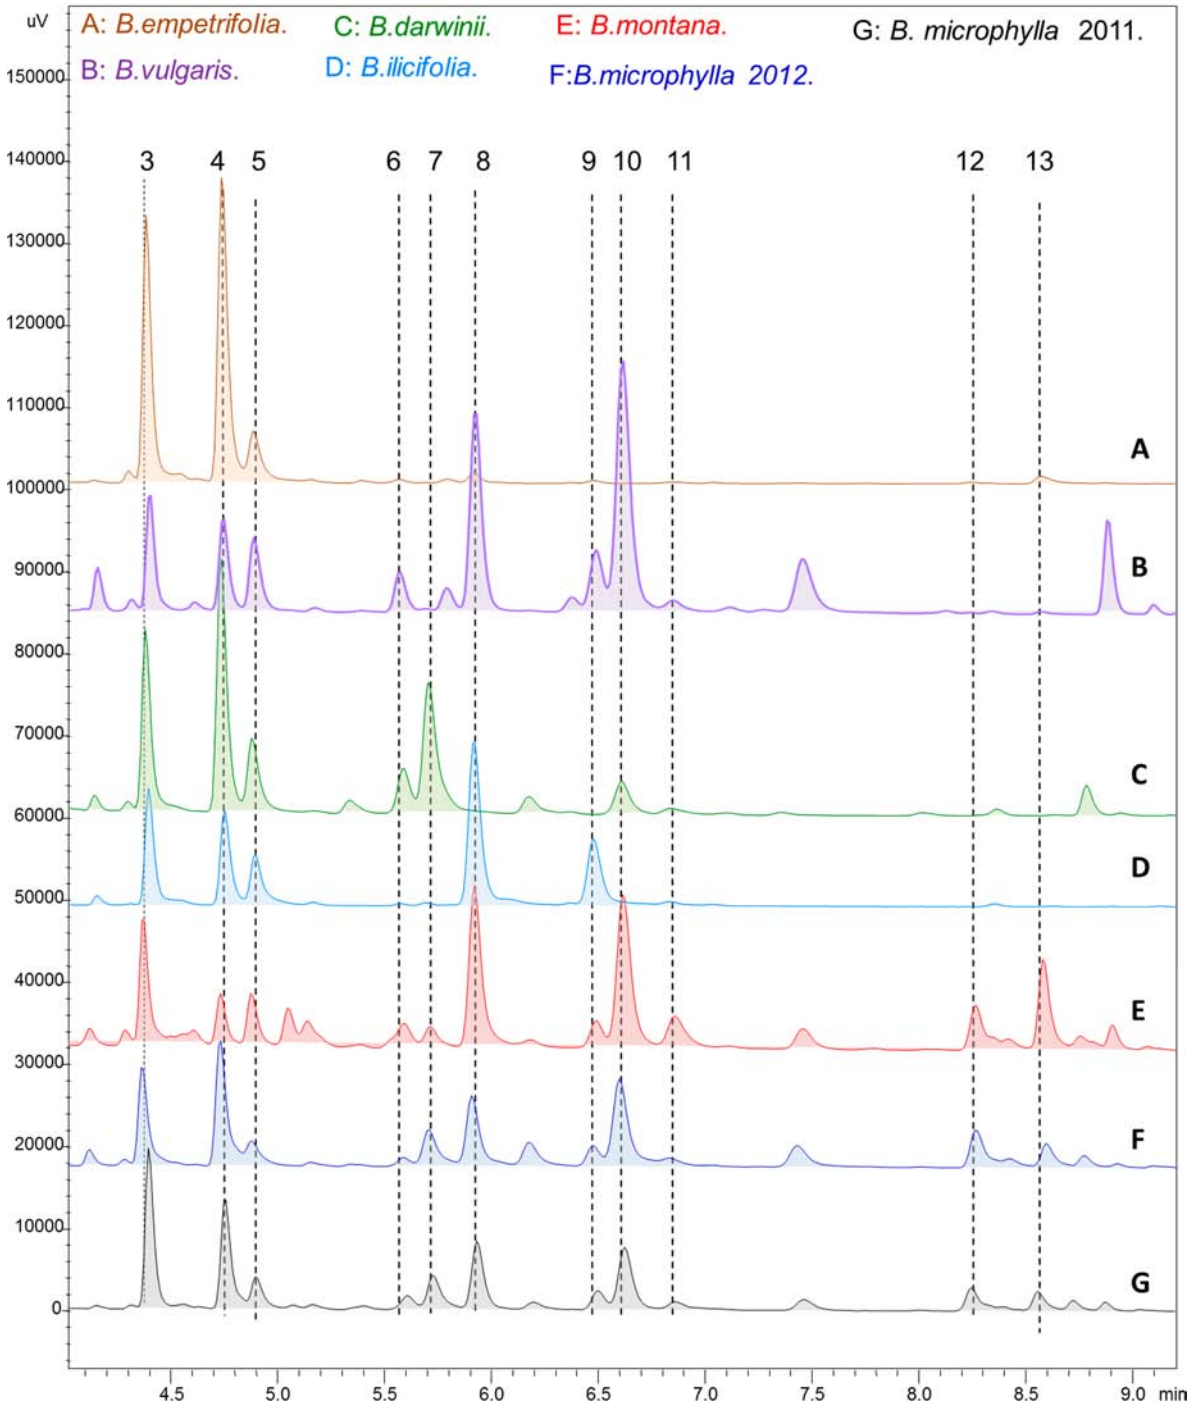

**Figure 4.** Chromatographic profiles of flavonols extract of different *Berberis* species, by HPLC-DAD using core−shell column: (A) *B. empetrifolia* (sample from Parque Pinguino Rey, Provenir, Tierra del Fuego); (B) *B. vulgaris* (sample from gardens of University of Concepción, Concepción); (C) *B. darwinii* (sample from Gorbea, Temuco); (D) *B. ilicifolia* (sample from Lago Deseado, Porvenir, Magallanes); (E) *B. montana* (sample from Valle Las Trancas, Chillan); ( (F) *B. microphylla* 2012 (sample from Lago Fagnano, Magallanes); (G) *B. microphylla* 2011 (sample from Seno Otway, Magallanes).

*Berberis* species was done by comparison of $t_R$ with commercial standards. The identity confirmation was based on their MS/MS and UV−vis spectra. Table 4 presents spectroscopic characteristics of alkaloids detected in different *Berberis* structures. In all calafate fruits analyzed in this part of the research ($n$ = 62), only berberine was detected. However, jatrorrhizine and palmatine were detected at trace levels in calafate leaves. The alkaloid coridaline was assigned to a signal found in fruits of *B. ilicifolia* based on the MS/MS spectra, in accordance with Wang et al.[18]

Quantitative analysis of berberine was carried out by HPLC with fluorescence detection using an external calibration curve, which was performed by triplicate injection at six levels of berberine standard concentration. The calibration curve showed a low level of dispersion, with a regression coefficient of 0.9993 and an equation of ($y$ = 560704.27$x$ − 80514.59). Fluorescence detection showed a high sensitivity and low

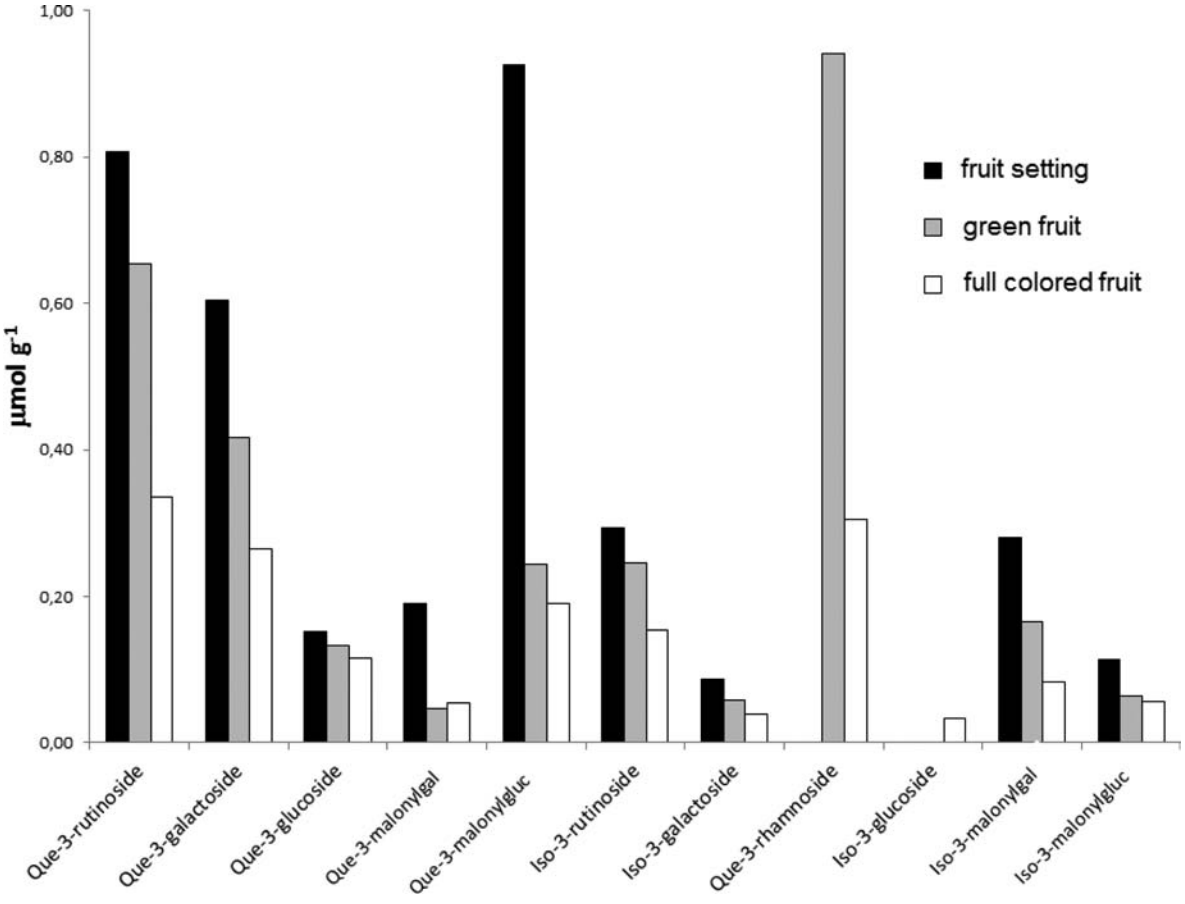

**Figure 5.** Flavonols profile and concentration during the maturation process of *B. microphylla* G. Forst (sample from Sector Barranco Amarillo, Magallanes).

[a]The identifications of each sample are, respectively, calafate 1, Puerto tranquilo, Aysen; calafate 2, Gorbea, Temuco; calafate 3, Rio San Luis, Magallanes; calafate 4, Camino Provenir. Km 25, Magallanes. HCADs, hydroxycinnamic acids.

detection and quantitation limits (0.6 and 1.5 nmol/g, respectively). Repeatability and intermediate precision were also evaluated, giving RSD values of 8.9 and 10.9%, respectively. The quantitative method validation included the efficiency of the extraction, and it was evaluated in the same manner as that of flavonols. The results showed that with three extractions, a recovery of >90% of berberine was obtained, reaching 94.3% when four steps were carried out. Three extractions were considered optimal as a good compromise between accuracy and time/cost of analysis.

Berberine levels were evaluated in fruits of different *Berberis* species, showing low concentrations; however, some variations between the different samples were observed. The highest concentration of berberine was detected in *B. ilicifolia* ($n$ = 3) with 160.0 nmol/g FW. In calafate fruits (*B. microphylla*) collected in the year 2011 ($n$ = 45) levels of berberine were between 1.8 and 126.9 nmol/g FW, whereas in samples collected in 2012 ($n$ = 18) concentrations between 3.3 and 152.8 nmol/g FW were determined. Higher contents of berberine were found in *B. ilicifolia* (55.9−160.5 nmol/g FW)

Table 4. Spectroscopic Characteristic of Alkaloidd Found in *Berberis* Genera from Patagony by HPLC-DAD-MS/MS

| | $t_R$ (min) | $\lambda_{max}$ (nm) | $[M + H]^+$ | product ions | detected in |
|---|---|---|---|---|---|
| berbamine[a] | 6.7 | 274 | 609 | 566, 305, 535, 552 | |
| coridaline | 11.99 | 345 | 370 | 322, 192, 307 | *B. ilicifolia* (fruits) |
| berberine | 12.88 | 347 | 337 | 321, 292, 278, 306 | *B. microphylla* (fruits, leaves, seeds, branches, and roots), *B. montana*, *B. ilicifolia*, *B. empetrifolia*, *B. vulgaris* |
| jatrorrhizine | 11.96 | 344 | 338 | 323, 294 | *B. microphylla* (only in leaves) |
| palmatine | 12.66 | 344 | 352 | 337, 308 | *B. microphylla* (only in leaves) |

[a]Not detected in the *Berberis* samples studied. Data were obtained for a standard solution.

and *B. darwinii* (57.7−156.1 nmol/g FW), whereas the upper concentrations are in berries of *B. microphylla*. In two samples of *B. vulgaris* collected from the University of Concepcion gardens, lower levels of berberine (1.8−3.3 nmol/g FW) were observed. The only *B. montana* analyzed contained 8.3 nmol/g FW berberine. The observed variations could be explained by different factors that can contribute to the biosynthesis of alkaloids in plants, such as the *Berberis* species, the place of collection, climate conditions, and number of seeds per fruit, as well as insect and disease attack.[19]

The distribution of berberine in calafate plants and fruit was evaluated using four samples. The results showed that berberine levels decreased with the distance of the analyzed structure from the roots. The highest levels were detected in the roots (4655.7 ± 1067.3 nmol/g FW), followed by the branches (1343.8 ± 981.1 nmol/g FW), and much lower levels in their fruits (32.7 ± 11.9 nmol/g FW) and leaves (35.7 ± 8.9 nmol/g FW). On the other hand, in two of these fruit samples, it was possible to analyze the berberine distribution, showing a higher level in the seeds (between 55.0 and 121.3 nmol/g FW) than in a sample of pulp mixed with the skin (between 3.6 and 6.2 nmol/g FW). Seeds are principally responsible of berberine content in the edible part of calafate fruits. This implies that in calafate products such as juices or jams, which are produced without seeds, berberine levels will be even lower than in whole fresh berries.

Berberine levels were also studied in fruits with different phenological stages, using the same methods as in the flavonol study. A low concentration of berberine in the first stage (fruit setting) was observed (6.8 nmol/g FW), which increased toward maturation, reaching concentrations of 47.0 and 41.9 nmol/g FW in green berry and colored berry, respectively. This is consistent with the maturation process, if one of the functions of the seeds is to provide chemical protection to the plant during germination.

$LD_{50}$ of berberine has been previously reported in mice.[20] According to these data and assuming a 7 times lower metabolic rate in humans,[8,21] a consumption of 139 kg of calafate fruits, assuming the highest level of berberine detected in calafate berries in the present study, is necessary to reach the $LD_{50}$ in humans. The berberine concentrations in calafate fruits suggest that they are innocuous for human consumption. On the other hand, considering the beneficial biological effect attributed by several authors to this molecule,[22,6] its low presence in calafate fruit would not be relevant from a nutraceutical point of view; however, calafate roots and branches constitute an interesting source of this compound. It mediates the chemical defense of plants against viruses, bacteria, fungi, other plants, insects, and vertebrates,[23] protecting the vegetative part of the plant and the seeds, but not the edible part of the berry, facilitating the dissemination of the species, that is, by birds.

Finally, the distribution of these phytochemicals in the calafate berries, the effect of the maturity process, the different growing latitudes, and the antioxidant capacity of the extract have influence on the nutraceutical potential of this wild and underexploited fruit.

turonase.[15,16] We have previously found that the general pattern and extent of uronic acid solubilization and depolymerization showed high similarity in firm and soft cherries.[9] However, soft cherries had lower total cell wall content (alcohol-insoluble residue, AIR) and higher branching of tightly bound pectins than firm fruit. Unfortunately, almost all studies looking at cherry genotypes with contrasting firmness have compared a single firm cultivar to a soft genotype, making it difficult to determine whether or not the changes observed are valid in broader contexts. In order to explore further this, we have extended the chemical study by analyzing the changes in cell wall polysaccharides on five cherry cultivars ('Sunburst', 'Regina', 'Chelan', 'Sumele', and 'Brooks') at two developmental stages (immature and ripe). Pectin evaluations were complemented by their analysis by ultraviolet matrix-assisted laser desorption/ionization time-of-flight (UV-MALDI-TOF) mass spectrometry.

## MATERIALS AND METHODS

**Plant Material.** Cherry fruit cultivars 'Chelan', 'Brooks', 'Sumele', 'Sunburst', and 'Regina' were randomly picked from trees located in the Río Negro Upper Valley, Argentina (39° 01′ 32′′ S, 67° 44′ 22′′ W, 242 m above sea level). Samples of about 1.5 kg of each genotype were collected in 2009 at two different developmental stages, namely immature (I) ('Sumele', 45 days after anthesis (DAA); 'Regina' and 'Chelan', 47 DAA; 'Brooks' and 'Sunburst', 49 DAA) and ripe (R) ('Sumele', 73 DAA; 'Brooks' and 'Chelan', 75 DAA; 'Sunburst', 84 DAA; 'Regina', 90 DAA).

**Firmness, Soluble Solids Content, Titratable Acidity, Surface Color, Dry Matter, and Cracking Index.** Firmness was measured at 20 °C for each cultivar on 20 randomly selected fruits, by measuring the force required to compress the fruit over the equatorial zone (distance, 0.5 mm; speed, 50 mm/s) using a Durofel texture analyzer (Güss FTA, Strand, South Africa). Given the average diameter of the fruit (25−27 mm), this test yielded only a small compression (ca. 2%) For soluble solids measurements, juice samples obtained by squeezing ten cherries were evaluated with a hand-held temperature-compensated refractometer (Atago Co., Tokyo, Japan). Measurements were done in triplicate. Titratable acidity (TA) was determined by titrating a 10 mL juice sample (out of 20 cherries) with 0.1 mol/L NaOH to an end point of pH 8.2, and expressed as g malic acid/100 g juice (% w/w). Three replicates per condition were evaluated. Fruit surface color measurements were taken with a CR-300 chroma meter (Minolta, Osaka, Japan) using D65 illuminant lighting conditions, in 20 cherries per cultivar. Dry matter was determined on ten cherries by drying in an oven at 45−55 °C until constant weight (ca. 7 d). The cracking index (CI) was determined after leaving 50 cherries per condition in deionized water at 20 °C. After 2, 4, and 6 h, the fruit was checked for wounds or exocarp/skin leaks, and those unaffected were submerged again. The index was calculated as

$$\mathrm{CI} = \frac{5n_{2h} + 3n_{4h} + n_{6h}}{250} \times 100$$

where $n_{xh}$ is the number of affected fruit after $x$ hours.[17]

**Alcohol Insoluble Residue (AIR).** After removal of the core and peduncle, the pulp was treated as described by Ponce et al.[18] in order to obtain the AIR. Briefly, about 100 g of pulp were put in cool 80% ethanol (4 mL/g fruit) and blended in an Omni Mixer homogenizer (Omni International, Kennesaw, GA). The homogenate was boiled for 30 min, cooled, and filtered through glass filter paper (Whatman GF/C). The retentate was thoroughly washed with 95% (v/v) ethanol. The solids were then resuspended in a mixture of chloroform:methanol (1:1, 3 mL/g fruit), stirred for 15 min, and filtered. The retentate was washed with the same solvent mixture. The insoluble material was washed with acetone, yielding the crude cell wall extract (AIR). The AIR was air-dried in a hood and in a vacuum desiccator overnight and weighed.

**Cell Wall Fractionation.** AIR fractionation was performed as previously described[18] with minor modifications. Briefly, 1 g of AIR was stirred for 4 h at room temperature with 100 mL of 0.02% (w/v) thimerosal aqueous solution and filtered. The suspension was filtered, and the filtrate was saved and designated as water-soluble fraction (WSF). Sequential extraction of the pellet with 0.05 mol/L *trans*-1,2-diaminocyclohexane-*N*,*N*,*N*′,*N*′-tetraacetic acid (CDTA) in 0.05 M NaOAc/HOAc buffer, pH 6, containing 0.02% (w/v) thimerosal (24 h), 0.1 mol/L $Na_2CO_3$ containing 0.02 mol/L $NaBH_4$ (24 h), 1 mol/L KOH containing 0.02 mol/L $NaBH_4$ (24 h), and 4 mol/L KOH containing 0.02 mol/L $NaBH_4$ (24 h), yielded the CDTA-soluble fraction (CSF), $Na_2CO_3$-soluble fraction (NSF), and 1 and 4 mol/L KOH-soluble fractions (1KSF and 4KSF), respectively. The supernatants were recovered after centrifugation at 13100*g* at 6 °C for 40 min. In the case of the KOH-soluble fractions, pH was adjusted to 5 with glacial acetic acid. All fractions were dialyzed (molecular weight (MW) cutoff 6000−8000 Da) against tap water for 2 days and against distilled water for 1 day at 4 °C. The fractions were freeze-dried and stored until analysis.

**Uronic Acids, Total Carbohydrate, and Neutral Sugar Measurements.** Uronic acids (UAs) were quantitated with the *m*-hydroxybiphenyl method[19] using galacturonic acid as standard, and expressed as anhydro units. Total carbohydrates were determined by the phenol−$H_2SO_4$ method[20] using glucose as standard. The proportion of neutral sugars (NSs) was determined after subtracting the UA content from that of total carbohydrates. For this purpose, the phenol−$H_2SO_4$ reaction was also carried out with a galacturonic acid standard, which showed an absorbance ratio of 0.28 against the same glucose weight.[18]

**Size-Exclusion Chromatography (SEC).** To examine the size distributions of polymers in CSF and NSF, ca. 3 mg of lyophilized samples from each fraction were dissolved in 0.8 mL of 0.4 mg/mL imidazole, to which 0.2 mL of 1 mol/L ammonium acetate (pH 5) was added. The samples were centrifuged, and the supernatants were chromatographed on a low-pressure SEC by employing a 300 mm × 9 mm i.d. Sepharose CL-2B column (Sigma Chemical Co., St. Louis, MO). Samples were eluted at room temperature with 0.2 mol/L ammonium acetate, pH 5. Fractions were collected, and aliquots were assayed for total carbohydrates.[20] Samples from the WSF, 1KSF, and 4KSF were dissolved in 0.1 mol/L NaOH, cleaned up by centrifugation, and chromatographed on a 300 mm × 9 mm i.d. Sepharose CL-6B column (Sigma Chemical Co., St. Louis, MO) eluted at room temperature with 0.1 mol/L NaOH. Fractions were collected, and aliquots were assayed for total carbohydrates.[20]

**Neutral Sugar Composition.** Each fraction (ca. 3 mg) was hydrolyzed with 1 mL of 2 mol/L trifluoroacetic acid (TFA) for 90 min at 120 °C in closed-cap vials. The TFA was eliminated by evaporation, and the resulting monosaccharides were reduced to alditols using $NaBH_4$, converted to alditol acetates, and subsequently analyzed using a Hewlett-Packard 5890 gas chromatograph (Agilent Technologies Inc., Santa Clara, CA) fitted with a capillary column (30 m × 0.25 mm i.d. × 0.20 μm, SP-2330, Supelco Inc., Bellefonte, PA) and equipped with a flame ionization detector (FID) operated at 240 °C. The injector temperature was 240 °C, and the oven temperature was kept isothermally at 220 °C. Nitrogen was used as the carrier gas at a head pressure of 1.05 bar. Samples were injected with a split ratio of 80:1. *Myo*-inositol was used as the internal standard, and the different alditol acetates were identified by comparison with authentical standards. The percentage of the different monosaccharides was calculated by considering that the integrated FID responses are proportional to the MW of the alditol acetates.

**UV-MALDI-TOF Mass Spectrometry.** Solutions of pectin samples (1 mg/mL) were prepared in Milli-Q water with the aid of sonication at 20 kHz (3 × 20 min). Two different matrices were used: nor-harmane (9-*H*-pyrido-[3,4*b*]indole) and gentisic acid (2,5-dihydroxybenzoic acid). The stock solutions of the matrices were prepared by dissolving 2 mg of the selected compound in 1 mL of methanol (HPLC-grade)/water (75:25, v/v). In order to prepare the analyte−matrix sample the thin-film layer method (sandwich method[21]) was used. Typically 0.5 μL of the matrix solution was

Table 1. Soluble Solids Content (SSC), Acidity, Weight, Lightness (L*), Firmness, and Cracking Index of Ripe 'Sunburst', 'Brooks', 'Chelan', 'Sumele', and 'Regina' Cherries[a]

| cultivar | SSC (% w/w) | acidity (% w/w) | weight (g) | $L^*$ | firmness (g/mm) | cracking index |
|---|---|---|---|---|---|---|
| Sunburst | 22 ± 3 a | 1.29 ± 0.03 a | 7.8 ± 0.9 c | 24.3 ± 0.04 e | 415 ± 2 e | 68 ± 2 b |

[a]Different letters within a column indicate differences based on a Tukey test at a level of significance of $P < 0.05$.Values are expressed as means ± SD ($n$ = 50 for cracking index, 30 for weight, 20 for firmness and lightness, 3 for SSC and acidity).

placed on the sample probe tip and air-dried at room temperature. Subsequently, 0.5 μL of the analyte solution were placed on the sample probe tip, covering the matrix and partially dissolving it, and air-dried. Then, two additional portions (0.5 μL) of matrix solution were deposited on the same sample probe tip, producing a partial dissolution of the previously deposited thin-film, and air-dried. The matrix-to-analyte ratio was 3:1 (v/v), and the matrix and analyte solution loading sequence was (i) matrix, (ii) analyte, (iii) matrix, and (iv) matrix. Comparative experiments were also conducted preparing the analyte−matrix sample by the mixture method. The pre-prepared mixture was done mixing the matrix and analyte solutions in 3:1 (v/v) and 1:1 (v/v) ratios. Three portions (0.5 μL) of the mixture were successively loaded on the probe, and air-dried as described above. Similar results were obtained with both sample preparation methods. Spectra were recorded on a BrukerUltraflex II TOF/TOF, controlled by the FlexControl 3.0 software (BrukerDaltonics, Bremen, Germany). Desorption/ionization was performed using a frequency-tripled Nd:YAG laser emitting at 355 nm with a 100 Hz shot frequency. All mass spectra were taken in the positive linear and reflectron modes. Experiments were performed first using the full range setting for laser firing position in order to select the optimal position for data collection, and second fixing the laser firing position in the sample sweet spots. The laser power was adjusted to obtain high signal-to-noise ratio while ensuring minimal fragmentation of the parent ions, and each mass spectrum was generated by averaging 500 laser pulses per spot. Spectra were obtained and analyzed with the programs FlexControl and FlexAnalysis, respectively. MTP plate steel with 384 circular spots, 3.5 mm diameter, was used (Bruker, Bremen, Germany).

**Statistical Analysis.** Statistical significance was determined by one-way ANOVA with the Stratgraphic software package (Manugistics Inc., Rockville, MD). The model assumptions of homogeneity of variance and normality were probed by means of Levene's and Shapiro-Wilk's tests, respectively. When these assumptions were not satisfied, data were transformed into ranks for further analysis. When a significant $F$-value was found, treatment means were compared using the Tukey's studentized range test ($P < 0.05$).

## RESULTS AND DISCUSSION

**Fruit Size, Soluble Solids Content, Acidity, Color, Firmness, Dry Matter, and Cracking Susceptibility.** Quality attributes of ripe fruit of the five varieties are shown in Table 1. 'Brooks', 'Sumele', 'Chelan', and 'Regina' showed similar levels of soluble solids (19−20% w/w) and acidity (0.92−1.01% w/w) upon ripening. 'Sunburst' presented slightly higher SSC (22% w/w) and titratable acidity (1.29% w/w). 'Regina' and 'Brooks' yielded fruit having higher weight (Table 1) and size (ca. 27 mm), whereas the remaining three cultivars produced the lighter and smaller cherries (ca. 25 mm). Fruit lightness ($L^*$) was highest in 'Brooks', with minimum values in 'Sunburst'. The dry matter content varied between 21 and 23% with no association to the cultivar firmness.

Firmness showed a large inter-cultivar variation. 'Regina' cherries were the firmest followed by 'Sumele', 'Chelan', and 'Brooks'. Soft cherries were produced by 'Sunburst'. The genotypes with the extreme firmness values were studied previously, on another batch.[10] Although prior work on strawberry showed that for a given cultivar, larger fruit tended to be softer,[22] in the current study no correlation was found between fruit size and firmness. This indicates that fruit size is not a major factor contributing to the genotypic differences in cherry texture. The cultivars also showed large differences in their cracking susceptibility. 'Chelan' fruit manifested relatively low cracking incidence, as opposed to 'Brooks' which was highly susceptible. Firmness as measured in compression tests was not related to the susceptibility of the fruit to cracking. The variations in cracking incidence and severity may be more highly associated with differences in cuticle thickness and composition.[23] Variations in the cell wall composition yielding changes in tissue physical properties under tension may be also important.

**Cell Wall Yield and Fractionation.** To further characterize the wall composition of the cultivars with contrasting firmness, the cell walls (AIR) were obtained after treatment of the fruit tissue with ethanol and chloroform/methanol, and further dehydration with acetone. The AIR was later fractionated into five different fractions, corresponding to pectins which are loosely bound (WSF), ionically bound (CSF), covalently bound (NSF), and loosely bound (1KSF) and strongly bound (4KSF) cross-linking glycans (hemicelluloses). Their yields for the five cultivars and two ripening stages are shown in Figure 1. The overall yield of non-cellulosic biopolymers from AIR was above 50% for immature cherries, and usually much less (<40%, with the exception of 'Sumele') for ripe cherries. The yields of the cell wall preparations dropped during ripening in all cultivars (Figure 1). No association between the accumulated yield of the different cell wall fractions and cultivar firmness was found at the immature or ripe stages, differing from previous reports.[9]

Growth and ripening change the architecture of fruit cell wall.[24] Although soluble polysaccharides usually accumulate during ripening[8] and some studies have associated softening of cherry with high levels of water-soluble polysaccharides, this does not seem to be a general feature, but rather a cultivar-dependent response. In fact, in the present study the yield of WSF increased with ripeness in 'Sunburst' and 'Regina', whereas no marked variation was detected in 'Brooks' and 'Sumele'. Moreover, a decrease in the WSF yield was found in 'Chelan'. It is also worth noting that the fraction of loosely bound polysaccharides represented for all cultivars (even at the ripe stage) less than 5% of the total wall non-cellulosic polysaccharides.

Tightly bound pectins (NSF) comprised the most abundant cell wall fraction in the five cultivars regardless of the ripening stage. The drop in polysaccharide yield accompanying ripening was in all cases due to the decrease of the NSF (Figure 1). A

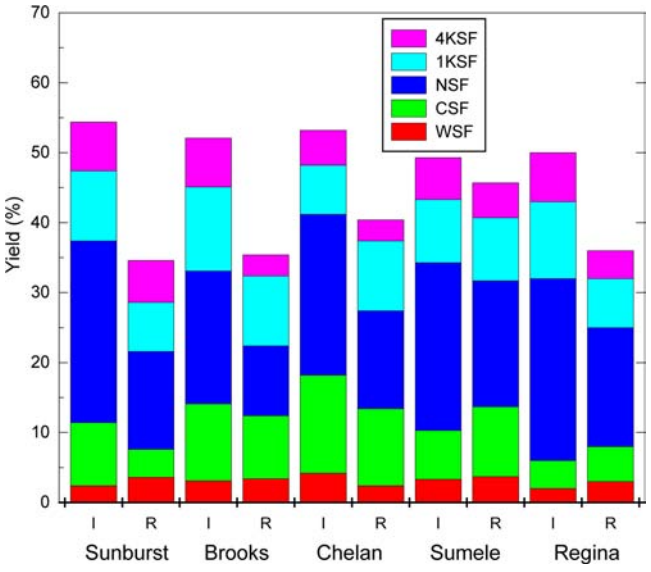

**Figure 1.** Accumulated yields of the water-, CDTA-, $Na_2CO_3$-, 1 M KOH-, and 4 M KOH-soluble fractions (WSF, CSF, NSF, 1KSF, 4KSF) of immature (I) and ripe (R) 'Brooks', 'Chelan', 'Sumele', 'Sunburst', and 'Regina' cherry fruit. Data represent an average of two independent weight measurements.

similar trend was previously observed on cherries,[8,9] grapes,[25] raspberries,[26] among other fruit species.[27]

**Depolymerization of Pectins and Cross-linking Glycans.** The MW distribution of all the isolated samples was determined by SEC, using Sepharose CL-6B for fractions WSF, 1KSF, and 4KSF, and Sepharose CL-2B for CSF and NSF. The WSF of immature cherries showed a wide profile of MWs in most cultivars. Depolymerization of pectins with ripening is highly variable among fruit species. Pectin downshifts were very limited in strawberry[28] and apple,[29] moderate in tomato[30] and peach,[31] but extensive in avocado.[32] Even within a single species, large variations have been reported depending on the cultivar.[33] In the present work a clear shift of the WSF profile toward lower MWs was observed as ripening proceeded. Firm 'Regina' cherries showed little or no depolymerization. In contrast, a downshift trend was observed in the WSF of the remaining cultivars. No association between firmness and pectin size was observed in these four genotypes indicating that the extent of fruit softening is not directly dependent on the degree of polymerization of loosely bound polyuronides.

The CSF showed a broad distribution of pectin MWs from early development, with no major changes occurring during ripening. A slight loss of high-MW polysaccharides was evident in soft 'Sunburst' fruit. The highly abundant NSF showed some unexpected features considering the traditional direct association that has been made between depolymerization and softening in several fruits. Indeed, the firmest genotype showed a lower degree of polymerization than soft 'Sunburst' cherries. Thus, the intermolecular interactions between polymers or their preferential distribution within the cell wall may be more relevant than their individual polymerization degree. No marked depolymerization was observed in this fraction as ripening progressed with the exception of relatively firm 'Sumele' fruit.

As occurs in blueberry,[34] and in contrast to raspberry[26] depolymerization of matrix glycans was related to ripening. For both loosely and tightly bound cross-linking glycans, soft 'Sunburst' cherries showed a greater reduction in polymer size than firm 'Regina' fruit. However, it is important to note that the firmest cultivar ('Regina') presented unripe cross-linking glycans with a relatively low MW. The 1KSF profile was characterized by a second, sharper peak with relatively high MW upon ripening, already observed for prunes and in previous work on cherries.[9,18] Overall, results from low-pressure SEC of pectin and hemicelluloses suggest that cherries show some depolymerization of WSF and 1KSF. However, with a few exceptions, the degree of polymerization of non-cellulosic

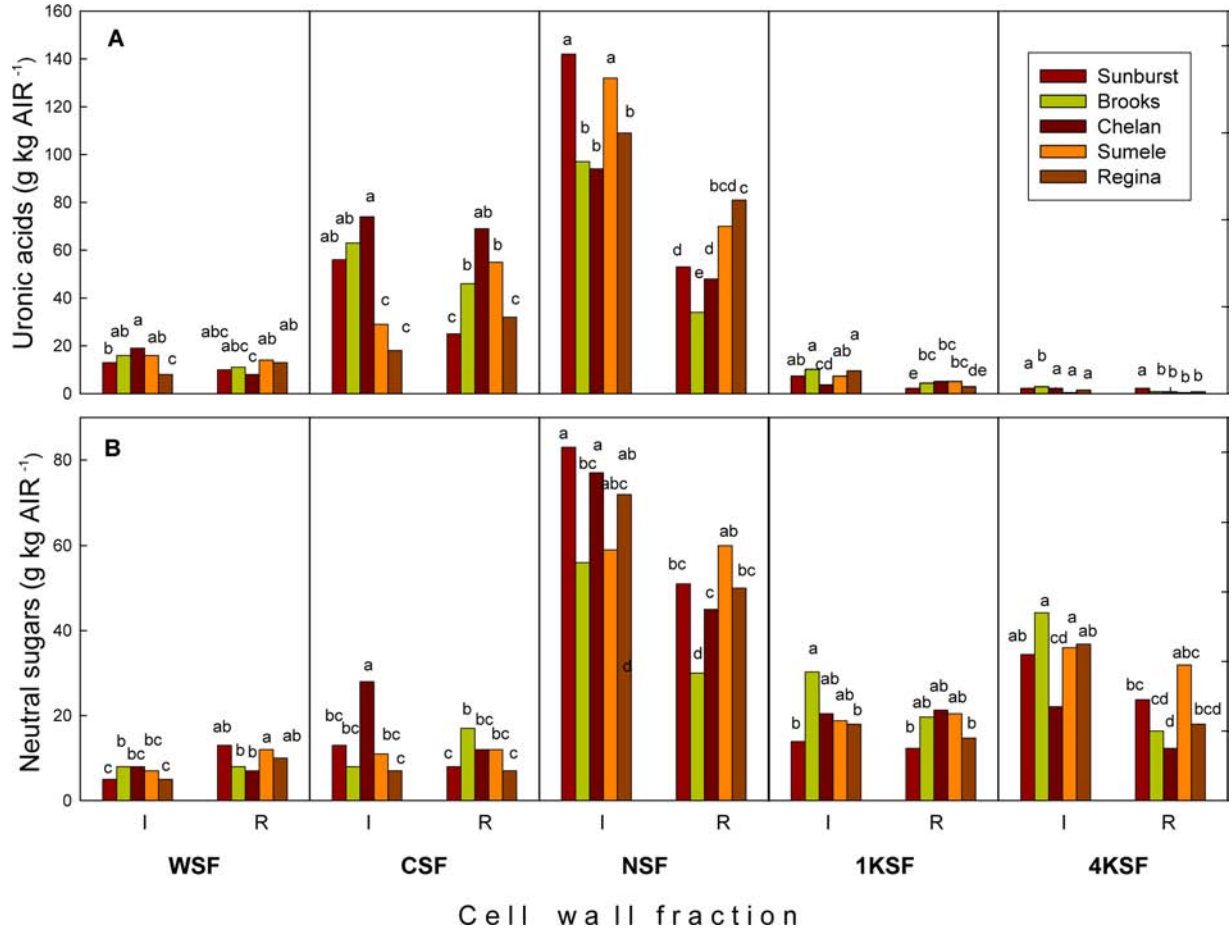

**Figure 2.** Uronic acids (A) and neutral sugars (B) in the water- (WSF), CDTA- (CSF), $Na_2CO_3$- (NSF), 1 M KOH- (1KSF), and 4 M KOH-soluble fractions (4KSF) of immature (I) or ripe (R) 'Brooks', 'Chelan', 'Sumele', 'Sunburst', and 'Regina' cherries during development. Different letters indicate significant differences between cultivars and stages based on a Tukey test at a level of significance of $P \leq 0.05$.

polysaccharides at immature stages and its variation during ripening do not correlate with genotype firmness.

**Polysaccharide Neutral Sugar Composition.** The NS compositions of the different cultivars were surprisingly similar. Arabinose was the most abundant monosaccharide in all pectic fractions and cultivars (Table 2). Arabinose represented 31% of total NSs in the WSF. Its level increased to ca. 60% in the CSF and 65–76% in the NSF. In pear, arabinose was rather lost,[35] but in cherries this sugar increases its proportion with ripening. Galactose and rhamnose were also present in substantial amounts, indicating the presence of RG-I in all three pectic fractions and cultivars. Xylose, glucose, and mannose only appeared in considerable levels in the WSF, whereas the most abundant pectic NSF fraction only showed low proportions of

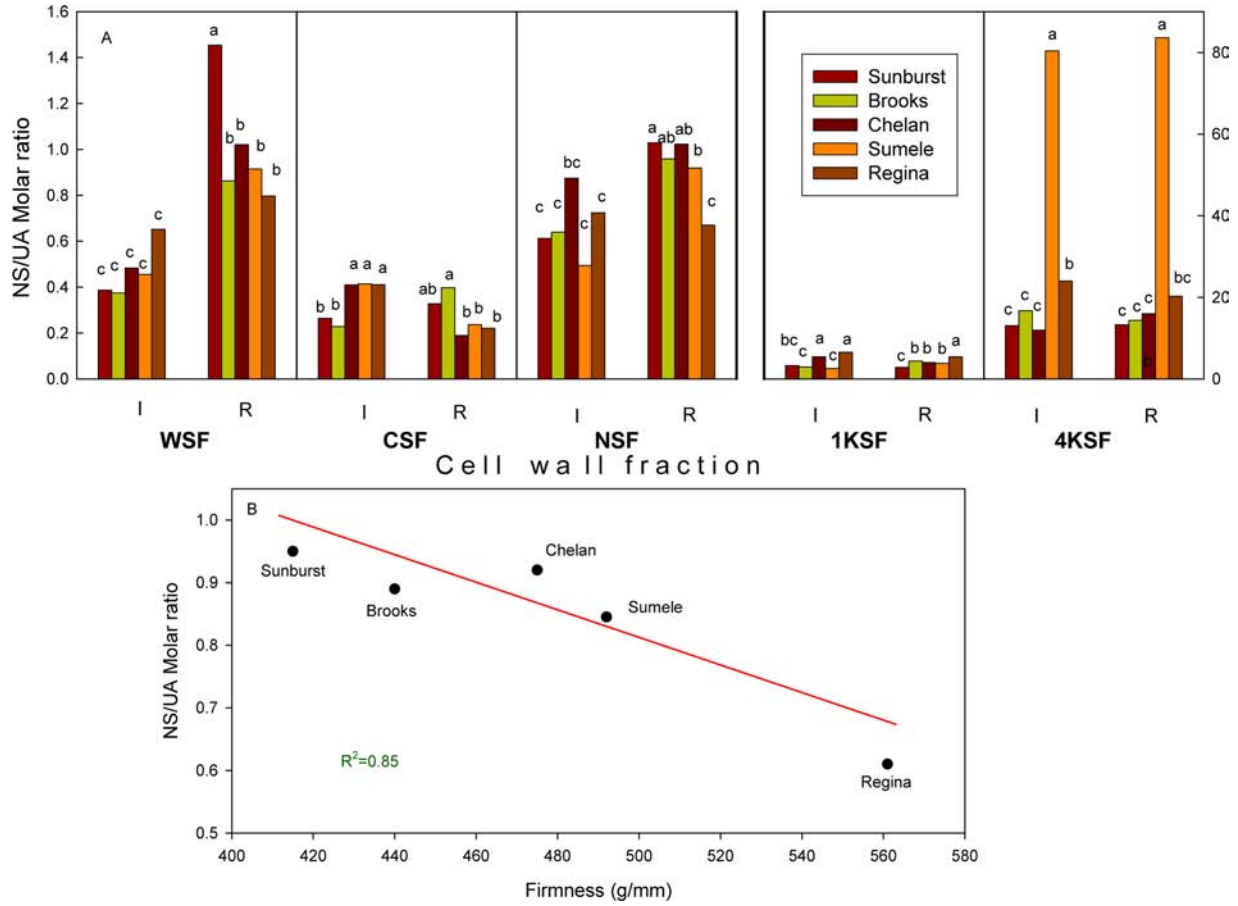

**Figure 3.** (A) Neutral sugars-to-uronic acids molar ratios calculated for the water- (WSF), CDTA- (CSF), $Na_2CO_3$- (NSF), 1 M KOH- (1KSF), and 4 M KOH-soluble fractions (4KSF) of immature (I) and ripe (R) 'Brooks', 'Chelan', 'Sumele', 'Sunburst', and 'Regina' cherry fruit during development. Different letters indicate differences based on a Tukey test at a level of significance of $P \leq 0.05$. Note the different scale for the two last figures. (B) Association between the NS/UA ratio and firmness from the NSF of ripe 'Brooks', 'Chelan', 'Sumele', 'Sunburst', and 'Regina' cherries.

these residues (Table 2). The proportion of arabinose in the WSF varied with ripening in a different fashion depending on the cultivar. This fraction also showed some increase in glucose proportion at the ripe stage.

No marked enrichment or drop of a specific NS was observed during ripening in the ionically bound pectins (CSF), regardless of the cultivar. The UA/rhamnose ratio may be indicative of the relative proportion of RG-I to homogalacturonan (HG) in the pectic fractions, with higher values being expected in fractions enriched in HG. The NSF showed lower UA/rhamnose ratios (10−20) than the other pectic fractions, suggesting a higher prevalence of RG-I. The proportion of arabinose in this fraction increased in all the cultivars during ripening, with a corresponding reduction in galactose. This points out to a preferential cleavage of galactan side chains from RG-I, or from an arabinose enrichment originated in material associated with cross-linking glycans or cellulose. Loss of galactose is important in some species but not in others.[35−38]

Although hemicelluloses are usually considered to be predominant in the KOH-soluble fractions, arabinose still represented 50% of total NS in the 1KSF. The residual pectins present in the cross-linking glycan fraction 1KSF show considerably lower ratios (UA/rhamnose = 4−12) than those of the pectin-richer fractions. The ratio is even lower (<2) for the 4KSF, suggesting that these residual pectins are RG-I-rich and that tight association through side-chain interactions exists between hemicelluloses and RG-I regardless of the cultivar[39,40] (Table 3). Xylose was the second most abundant sugar, but its proportion (ca. 20%) dropped upon ripening. The presence of xylose in levels exceeding those of glucose, suggests that besides some xyloglucan, xylans may be present. This may also contribute to the relatively high arabinose levels which could be, at least in part, in the form of arabinoxylans.

Arabinose proportion was, as expected, lower in the 4KSF, but, differently from other fruit species, it still represented the most abundant NS, closely followed by xylose and glucose. As for the 1KSF, the level of xylose tended to decrease with ripening. Noteworthy, the presence of small but constant levels of rhamnose and UA suggests that some RG-I still remains in this fraction, possibly entangled to the cellulose-xyloglucan/arabinoxylan network.

**Pectin and Hemicellulose Solubilization.** At the immature stage UAs were ca. 2- and 7-fold higher in the NSF than in the CSF and WSF (Figure 2A). The UA of the tightly bound pectin showed a marked decrease during ripening. This has also been observed in other fruits.[27] The drop of UA in the NSF did not occur with a concomitant accumulation in the water or CDTA-soluble fractions, suggesting that it was caused by the action of exo-acting galacturonate hydrolases yielding free galacturonic acid, which may be possibly lost in the ethanol washings of the AIR. At the ripe stage, firmer 'Regina' cherries maintained higher levels of tightly bound UA (Figure 2A). However, the absolute level of $Na_2CO_3$-soluble polyuronides showed no high association with

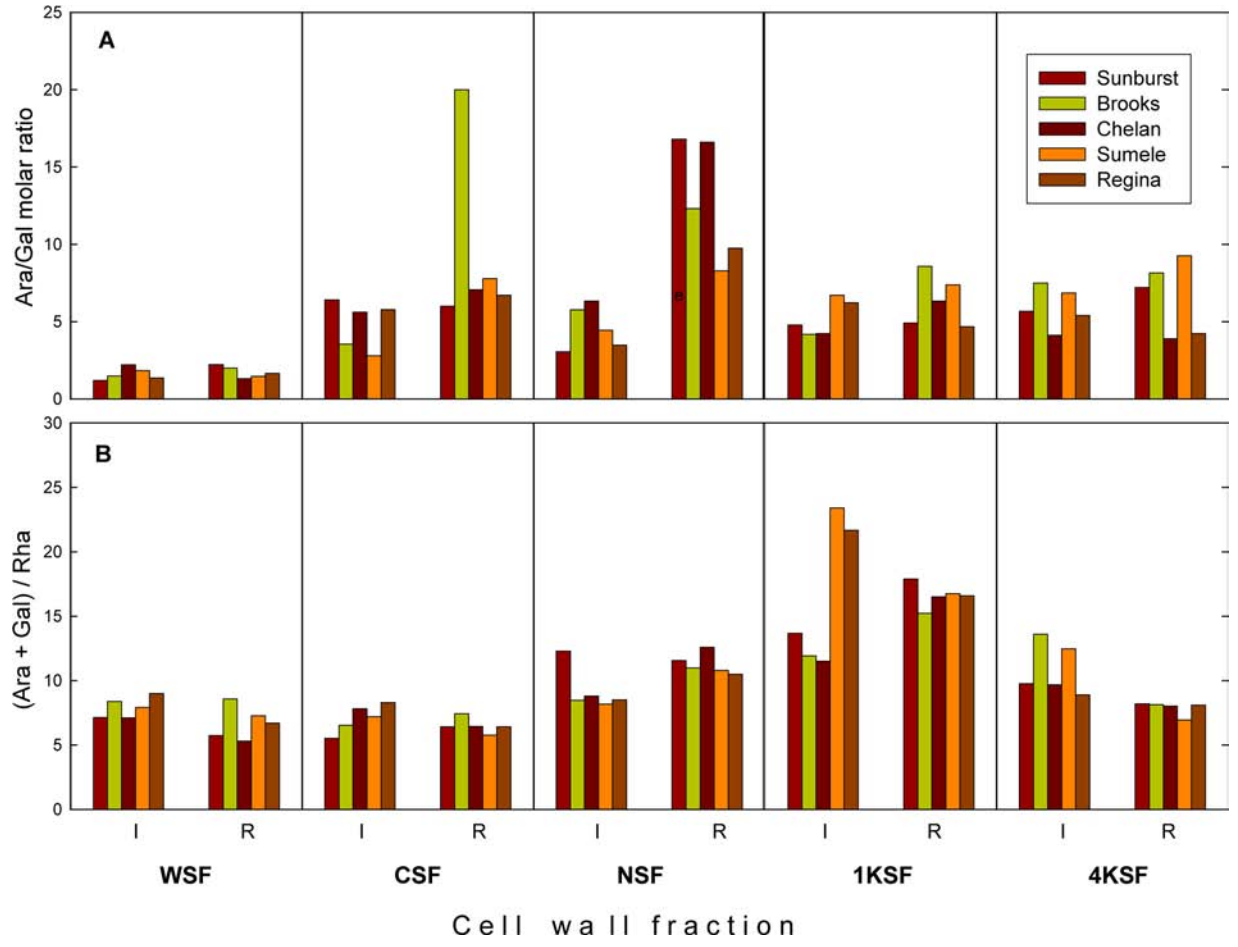

**Figure 4.** (A) Ara/Gal and (B) (Ara+Gal)/Rha molar ratios calculated for the water- (WSF), CDTA- (CSF), $Na_2CO_3$- (NSF), 1 M KOH- (1KSF), and 4 M KOH-soluble fractions (4KSF) of immature (I) and ripe (R) 'Brooks', 'Chelan', 'Sumele', 'Sunburst', and 'Regina' cherry fruit during development. Different letters indicate differences based on a Tukey test at a level of significance of $P \leq 0.05$.

cultivar firmness. For the CSF, a more erratic behavior of the UA content changes with ripening was observed; they increased with ripening in 'Sumele' and diminished in 'Sunburst'. The strong interaction between pectic and hemicellulosic matrices by covalent linkages[39,40] was also evident in cherry by the fact that alkali-soluble fractions still contained considerable amounts of UA. These polyuronides showed a progressive loss between early ripening stages and commercial maturity.

Analysis of the fate of the NSs on ripening (Figure 2B) showed small quantitative variations for WSF, an erratic behavior for CSF, but a decreasing tendency in the remaining fractions. The sum of NSs diminished clearly on ripening for all cultivars excluding 'Sumele', where it remained unchanged. The decrease ranged from 28% in 'Regina' and 'Sunburst' to 37% in 'Chelan' and 'Brooks'.

**Relationship between Cell-Wall Polysaccharides.** By considering the neutral sugars-to-uronic acids molar ratio (NS/UA) (Figure 3A), an outline of the proportion of branching on RG-I can be assessed on pectic fractions, as well as the hemicellulose/pectin ratios on cross-linking glycan fractions. Pectin fractions WSF, CSF, and NSF were enriched in UAs, and thus gave relatively low NS/UA ratios (0.2−1.4). The glycan fractions 4KSF gave high values (12−84), whereas intermediate levels were observed in the 1KSF (3−6). No major variations in the NS/UA molar ratio with ripening were observed for the cross-linking glycan fractions 1KSF and 4KSF. However, some inter-cultivar differences could be depicted (Figure 3A). For WSF, a significant increase in the NS/UA ratio with ripening was observed (Figure 3A) in all varieties. A lower but still significant increase was also found in the NSF fraction of three varieties. On the other hand, the CSF fractions showed the lowest ratio among the pectic fractions (Figure 3A), suggesting that they are HG-rich. Only a small variation with ripening was observed in this fraction. For the most abundant NSF, a high negative correlation ($R^2$ = −0.85) was found between the NS/UA ratio and cultivar firmness (Figure 3B). Firm cherries presented pectic polymers with lower NS/UA ratio, suggesting that the branching of polyuronides or the proportion of branched RG-I to HG may contribute to the differences in firmness between cultivars.

The Ara/Gal molar ratio allows an estimate of the relative importance of these monosaccharides in RG-I side chains. These ratios (Figure 4A) were always well above 1. The lowest ratios were found in the WSF (i.e., the most galactose-rich RG-I). For the CSF, the arabinose/galactose ratios for immature fruit were at or below 5, but they increased for ripe fruit, especially in 'Brooks'. The NSF showed a clear increase in this ratio upon ripening for all cultivars. This suggests that during ripening, higher loss of galactan or arabinogalactan chains occurs as compared to those of arabinans, regardless of the cultivar. However, since cherries show overlap between growth and ripening, *de novo* deposition of polysaccharides may occur

providing more complexity to the interpretation of the results. The Ara/Gal ratios in the cross-linking glycan fractions (Figure 4A) showed a more or less constant value, close to 5, regardless of the ripening stage, and changes were more dependent upon the variety.

As these Ara and Gal moieties are mostly part of the side chains of RG-I, their ratios relative to Rha estimate the degree of branching on RG-I. These results are shown in Figure 4B. A small decrease of these ratios upon ripening was observed in WSF and CSF, but for NSF these ratios became larger and increased further at the ripe stage. Ripe fruit showed (Ara +Gal)/Rha ratios in these fractions close to 11−12, regardless of the cultivar. This suggests that the variation in NS/UA ratio of the tightly bound pectin was more likely due to different proportions of HG and RG-I. The independent presence of HG and RG has been questioned by some authors. Vincken et al.[41] proposed a molecular brush model in which HG, (arabino) galactan, and arabinan occur as side chains of RG-I. Considering this model and the results found herein, firm cherry fruit would have a brush structure richer in HG side chains than soft cultivars. Overall, our results suggest that branching of polyuronide occurs early in development, and that the proportion of branched RG-I to HG may contribute to the differences in firmness between cherry cultivars. Studies evaluating differences in the levels of enzymes involved in pectin biosynthesis (e.g., rhamnosyl, galactosyl and arabinosyl transferases) could be of great interest for further work.

Few studies have analyzed changes in turgor pressure during fruit ripening, but early reports suggested that turgor pressure may be also an important contributor to fruit texture.[42] Recent work[43] has shown that turgor pressure drops during cherry fruit development. Thus, the potential role of differences in turgor pressure on cultivar texture could not be ruled out.

**UV-MALDI-TOF Mass Spectrometry of Pectins.** Determination of changes in polymer composition attracts the interest of researchers in the field of plant cell wall carbohydrates synthesis and degradation. Even with only a limited number of monosaccharides used as building blocks, variations in sequence, linkage, branching, side-chain distribution, and functional group modifications result in a wide structural diversity. No single analytical method alone is capable of resolving carbohydrate structures, especially when present in complex mixtures. Mass spectrometry is a selective and powerful technique to identify and obtain structural information and quick profiles on compounds present in complex mixtures.[44,45] Since it requires only small amounts of sample, it is an excellent tool for researchers interested in detecting changes in composition of complex plant carbohydrates. Nevertheless, detection of native non-derivatized polysaccharides by UV-MALDI MS is still a challenge due to the shortage of adequate matrices.[44−49] So far, there have been only a few studies reported for detection of native polysaccharides with MW > 40 000 Da[44,45,49−51] In the current work, our challenge was to observe if the association of this pattern of depolymerization with firmness and development among cultivars can be foreseen in a different fashion using UV-MALDI-MS than that found by traditional size exclusion chromatography.

In the current work, we have found that 2,5-dihydroxybenzoic acid[46] and 9*H*-pyrido[3,4*b*]indole (nor-harmane)[48] are good matrices for MALDI-MS analysis of native polysaccharides with high MWs and broad mass ranges ($m/z$ 40 000−160 000).

In order to further characterize the cell wall changes occurring on development and to identify putative factors associated with firmness variation in cherry fruit genotypes, we performed a detailed evaluation of the UV-MALDI-TOF mass spectra of the different pectin fractions WSF, CSF, and NSF for the five cultivars. Experiments were conducted with two different matrices, nor-harmane and gentisic acid, in order to get complementary information, and in five independent experiments. In this analysis, the intensity of the signals, the signal-to-noise ratio (S/N), and the number of signals with intensities higher than a given threshold (S/N > 2) in all the $m/z$ region analyzed were taken into account. Although each mass spectrum appears as a bidimensional image (intensity vs $m/z$), the number of "true" signals in each $m/z$ region yields additional data. These three variables (intensity, number of signals, and $m/z$) were taken into account for the comparative analysis of all the extracts studied. In the range $m/z$ 80 000−200 000, a large number of pectin signals originated in the WSF fractions from immature fruit were very conspicuous by this technique, showing clear spectra. The CSF gave much poorer spectra with very low S/N, whereas for the NSF almost no signals were observed in this $m/z$ range. As an example, the results obtained for cv. Regina using nor-harmane as matrix are shown in Figure 5. From ripe cherries, WSF showed poor

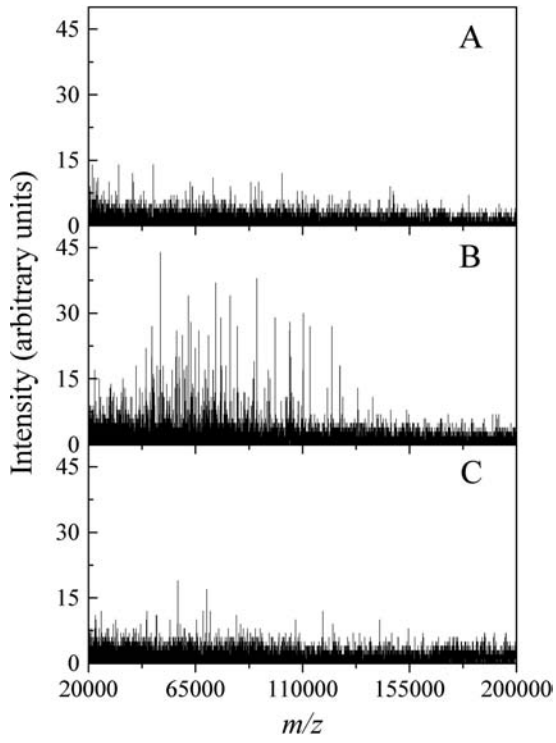

**Figure 5.** UV-MALDI-MS analysis of 'Regina' fractions in positive ion mode using nor-harmane as matrix. Characteristic profiles obtained for WSF from ripe fruit (A), WSF from immature fruit (B), and CSF from immature fruit (C).

spectra in the range $m/z$ 20 000−150 000 (no signals with intensity >15 arbitrary units and S/N > 2 (Figure 5A). In contrast, WSF of immature cherries showed clear profiles with abundant high-intensity ion signals (Figure 5B) in the same $m/z$ range. Poor spectra with very few signals at the $m/z$ range 40 000−80 000 with the stated intensity and S/N were obtained when the corresponding CSF was analyzed (Figure

5C). The differences observed in the spectra agree with the facts that complex mixtures of polysaccharides were analyzed and with the possibility that ion source decomposition occurs.[44,45] Similar characteristic profiles were obtained for immature WSF from the other four varieties studied.

In this work, we have focused on the evaluation of the changes in cell wall polysaccharides of five cherry cultivars ('Chelan', 'Sumele', 'Brooks', 'Sunburst', and 'Regina') with contrasting firmness at two developmental stages, showing that, contrary to what is usually shown in most fruits, cherry softening could occur is some cultivars without marked increases in water-soluble pectin. The degree of pectin or hemicellulose depolymerization or the solubilization of polyuronides is not directly associated with fruit firmness. The tightly bound polyuronides represented the most abundant cell wall fraction in all cultivars. A high negative correlation was found between the NS-to-UA ratio in this fraction and tissue texture, causing firm cultivars to exhibit lower NS/UA than soft cherries. The similar molar ratio of arabinose and galactose relative to rhamnose [(Ara+Gal)/Rha] suggests that the cultivars differed in their relative proportion of homogalacturonan and rhamnogalacturonan I rather than in the size of RG side chains, with greater proportions of HG in firmer cherries. Finally, we showed that UV-MALDI-TOF mass spectrometry may be a powerful analytical approach to complement traditional methods used to study polysaccharides contributing to improve our understanding of cell wall catabolism, as the mass spectra allowed immature to be distinguished from ripe fruits. WSF of immature cherries showed clear profiles with abundant ion signals in the range $m/z$ 20 000−150 000, but poor spectra with very few signals in the range $m/z$ 40 000−80 000 were obtained when CSF was analyzed. On the contrary, from ripe cherries WSF showed poor spectra with either matrix at the former $m/z$ region.

based studies have been complemented with electron spin resonance (ESR) spectroscopy for detection of radical-related reactions, and oxygen consumption for monitoring the overall extent of lipid oxidation in emulsions.

## MATERIALS AND METHODS

**Materials.** Medium-chain triglyceride (MCT) oil was obtained from Cognis GmbH, Ludwigshafen, Germany, and used as received. Linseed oil (LSO) and sunflower oil (SFO) were purchased from a local supermarket and purified of peroxyl radicals, trace metals, and tocopherols by alumina column chromatography according to Yoshida et al.[7] with few changes: the oil was mixed with hexane 1:1 and extracted from hexane by rotaty evaporation (Büchi Rotavapor R-144, Labortechnik AG, Flawil, Switzerland). The probe (*E*,*E*)-3,5-bis(4-phenyl-1,3-butadienyl)-4,4-difluoro-4-bora-3a,4a-diaza-*s*-indacene (BODIPY$^{665/676}$, B-3932) was purchased from Life Technologies Corp. N-*tert*-Butyl-α-phenylnitrone (PBN), methyl linoleate, methyl oleate, and Tween-20 were purchased from Sigma−Aldrich Inc., St. Louis, MO. Di-*tert*-butyl peroxide (DTBP) was purchased from Merck Schuchardt OHG, Hohenbrunn, Germany, and 2,2′-azobis(2,4-dimethyl)valeronitrile (AMVN) was purchased from Santa Cruz Biotechnology Inc., Dallas, TX.

**Radical-Initiated Fluorometric Studies.** *UV-Irradiation-Induced Radical Reactions.* Fluorometric measurements of UV-irradiation-induced radical reactions were performed with a 1 cm path length quartz cuvette on a spectrofluorometer (PerkinElmer Instruments, LS55 luminescence spectrometer, Seer Green, U.K.). UV irradiation was conducted with a Rayonet miniphotochemical reactor (model RMR-500, The Southern New England Ultraviolet Co., Hamden, CT) using four 300 nm UV lamps as described earlier.[6] Briefly, a sample in a quartz cuvette was placed in the middle of the minireactor, and UV light was exposed from four sides, making the irradiation uniform throughout the whole sample. The irradiation procedure was carried out on a control (oil with 1 μM BODIPY$^{665/676}$) and a sample (oil with 1 μM BODIPY$^{665/676}$ and 5.7 μM DTBP) for specific periods of time. Subsequently, the fluorescence spectra at excitation wavelengths ($\lambda_{ex}$) 675 and 580 nm were measured. Samples included MCT oil and linseed oil (LSO). In the case of LSO, handling of the oil was carried out under a nitrogen atmosphere. The extent of oxidation was quantified as a relative decrease of the fluorescence intensity measured at $\lambda_{ex}$ 675 nm, and a relative increase of the fluorescence intensity at $\lambda_{ex}$ 580 nm in the samples compared to the nonirradiated controls. The measurements were conducted in triplicate.

*Fluorescence Studies of Radical Reactions in Oils.* Fluorometric measurements of heat-induced radical reactions were performed with a 1 cm path length quartz cuvette on a luminescence spectrometer (Aminco-Bowman Series 2, Thermo Fisher Scientific, Waltham, MA). Heating in a thermo chamber at 37 °C was carried out on the control (oil with 1 μM BODIPY$^{665/676}$) and on the sample (oil with 1 μM BODIPY$^{665/676}$ and 13 mM AMVN) for 3 h. Fluorescence spectra were recorded at 1 min intervals at $\lambda_{ex}$ 580 nm. Samples included MCT oil, sunflower oil (SFO), mixtures of MCT oil and SFO in various ratios, MCT oil mixed with methyl linoleate (10 wt %), and MCT oil mixed with methyl oleate (10 wt %). The samples containing unsaturated fatty acids were handled under a nitrogen atmosphere. The extent of oxidation was quantified as percentage of increase of the fluorescence at $\lambda_{ex}$ 580 nm in irradiated samples compared to the nonirradiated controls. The measurements were conducted in triplicate.

**Electron Spin Resonance Spectroscopic Studies.** The rate of radical formation in oils containing radical initiator AMVN (6 mM) and spin trap PBN (20 mM) were determined by electron spin resonance (ESR). The oil phase was kept on ice while AMVN was dissolved, and subsequently PBN was added. The intensity of the generated spin adducts was recorded with an ESR spectrometer (Miniscope MS200, Magnettech, Berlin, Germany). The samples in the ESR measuring cavity were heated at 37 °C by using a temperature controller (temperature controller M01, Magnettech, Berlin, Germany). The oil samples included MCT oil, sunflower oil (SFO), and blends of MCT oil and SFO in various ratios. The samples containing unsaturated fatty acids were handled under a nitrogen atmosphere. The settings in all ESR measurements were as follows: sweep width 99.63 G, sweep time 30 s, modulation 1000 mG, and microwave attenuation 10 dB. The peak-to-peak amplitudes of the center doublet peaks of the ESR spectra were used to quantify the amount of spin adducts, and all results were expressed as an initial rate of radical formation calculated from the slopes of the initial linear parts of plots of spin adduct ESR intensities as a function of heating time. However, in the case of MCT oil mixed with 10 wt % methyl linoleate, MCT oil, and MCT oil blended with SFO in the ratios of 7:3 and 9:1, the plots were fitted to exponential curves from which the initial rates of spin adduct formation were calculated. The measurements were conducted at least in duplicate.

**Oil-in-Water Tween-20-Stabilized Emulsions.** Oil-in-water emulsions stabilized by Tween-20 were made according to Berton et al.[8] Emulsions consisted of 30 wt % MCT oil or sunflower oil (SFO), 0.5 wt % Tween-20, and 69.5 wt % sodium acetate−acetic acid buffer (pH = 4.65). Homogenization was done with Ultra Turrax T25 (IKA Works GmbH & Co. KG, Staufen, Germany) at 8000 rpm and with a dispersion element of 8 mm in diameter. The fluorescent probe BODIPY$^{665/676}$ and the radical initiator AMVN were added to the oil phases prior to homogenization. In the case of added AMVN, the emulsion preparation and homogenization were done on ice. When SFO was used, the whole mixing process was additionally carried out under a nitrogen atmosphere.

**Confocal Laser Scanning Microscopic Studies of Radical Reactions in Oil-in-Water Emulsions.** A series of emulsions were made as described above containing oil (MCT or SFO), radical initiator (with AMVN or without) and a fluorescent probe (with BODIPY$^{665/676}$ and without). Mixtures of two different emulsions were made such that each combination contained AMVN (6 mM) and BODIPY$^{665/676}$ (1 μM), although not necessarily present in the same lipid droplet of the original emulsions (Table 1). The controls were single emulsions and consisted only of oil, emulsifier, and aqueous phase. Radicals were generated by unimolecular decomposition of AMVN upon heating samples in a water bath at 37 °C during specific periods of time. The measurements were conducted with a confocal Leica TCS SP5-X MP microscope. The objective was an oil immersion 40× HCX PL APO CS, NA 1.30, pinhole 1 AU, and image resolution 1024 × 1024. The samples were scanned with a supercontinuum white light laser either at $\lambda_{ex}$ 580 nm, with signal detection by a hybrid detector at the emission band of 585−620 nm, or at $\lambda_{ex}$ 670 nm, with signal detection at the emission band of 675−785 nm. Droplets loaded with BODIPY$^{665/676}$ were selected to study the changes in fluorescence emission intensities at $\lambda_{ex}$ 580 and 670 nm, and droplets without BODIPY$^{665/676}$ were selected to establish background intensities. Droplets with BODIPY$^{665/676}$ and droplets without BODIPY$^{665/676}$ were discernible at both excitation wavelengths, $\lambda_{ex}$ 580 and 670 nm, due to emitted fluorescence of BODIPY$^{665/676}$-loaded droplets and simultaneous use of transmitted light mode. For each combination of

[a]MCT, medium-chain triglyceride; SFO, sunflower oil; BODIPY$^{665/676}$, (*E*,*E*)-3,5-bis(4-phenyl-1,3-butadienyl)-4,4-difluoro-4-bora-3a,4a-diaza-*s*-indacene; AMVN, 2,2′-azobis(2,4-dimethyl)valeronitrile.

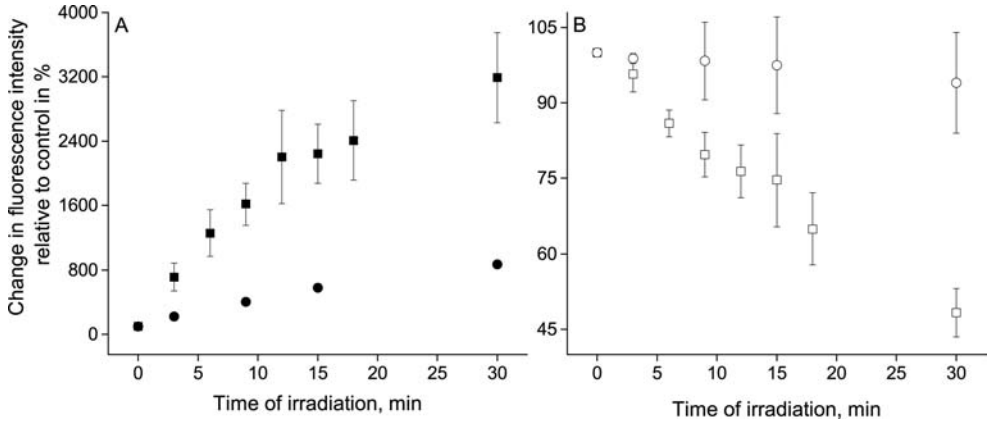

**Figure 1.** Fluorescence intensity changes of BODIPY$^{665/676}$ in (□, ■) MCT oil and (○, ●) LSO. The oils contained DTBP (5.7 $\mu$M) and BODIPY$^{665/676}$ (1 $\mu$M) and were irradiated with 300 nm UV lamps. The fluorescence intensity was measured (A) at $\lambda_{ex}$ 580 nm (closed symbols) and (B) at $\lambda_{ex}$ 670 nm (open symbols). The fluorescence changes are reported relative to the nonirradiated control.

emulsions, five droplets loaded with BODIPY$^{665/676}$ and five droplets without BODIPY$^{665/676}$ were quantified. For that purpose, a region of interest (ROI) for about $^4/_5$ the diameter of the droplet, excluding the border regions, was drawn; average intensity of the ROI was acquired; and changes in the fluorescence intensities were expressed relative to the unexposed controls.

**Oxygen Consumption Measurements of Emulsions.** A Clark-type oxygen electrode (Radiometer, Copenhagen, Denmark) was used to determine the oxygen concentration in emulsions. The data were recorded by use of a Unisense picoammeter (Unisense PA2000, Aarhus, Denmark) by a method described earlier.[2] Briefly, a sample was transferred into a 2.7 mL glass vessel with a ground glass stopper, a capillary-size hole through the center, and a magnetic stirring bar and was then placed in a water bath at 37 °C. Oxygen concentrations were recorded every 30 s. The rates of oxygen consumption were calculated as slopes of the linear part of plots of percent oxygen concentration as a function of time in minutes. The samples studied included (1) MCT oil emulsion, (2) SFO emulsion, (3) SFO emulsion containing BODIPY$^{665/676}$, and (4) blended oil emulsions with MCT oil and SFO blended in weight ratios 3:7 or 7:3. Various concentrations of AMVN (0, 1.8, 4.2, or 6 mM) were added to oils prior to mixing of the emulsions. In addition, MCT oil and SFO emulsions mixed in ratios 3:7 and 7:3 were studied, where only one of the two original emulsions contained AMVN.

**Statistical Analysis.** All data shown are presented as the mean value and standard deviation of at least three measurements. Box and whisker diagrams (Figure 5) illustrate mean values, ranges of scores between 25% and 75%, and outliers.

## RESULTS

**BODIPY$^{665/676}$ as Radical Probe in Bulk Triglyceride Oils.** The effect of radicals on the fluorescence of BODIPY$^{665/676}$ was tested in purified unsaturated linseed oil (LSO), where lipid oxidation after initial formation of radicals can be maintained through radical chain reactions. The probe has been demonstrated to be able to detect radicals in saturated medium-chain triglyceride (MCT) oil.[6] The bulk LSO samples contained di-*tert*-butyl peroxide (DTBP), which upon irradiation with 300 nm UV light generates alkoxyl radicals that can initiate lipid autoxidation. The relatively low concentration of added DTBP (5.7 $\mu$M) was chosen on the basis of previous experiments to provide an adequate radical flux, to ensure propagation of radical-induced processes, and reduce the effect of terminating bimolecular radical reactions.[6] The UV irradiation was carried out in 3 min intervals during the initial 18 min of irradiation, and a final measurement was carried out after a total of 30 min of irradiation. The fluorescence of BODIPY$^{665/676}$ was measured at $\lambda_{ex}$ 675 and 580 nm (Figure 1). Control experiments with saturated MCT oil showed that the fluorescence intensity at $\lambda_{ex}$ 580 nm increased initially linearly with irradiation time, but after the first 12 min of irradiation, the increase in the fluorescence intensity began to level off. For MCT oil the total $\lambda_{ex}$ 580 nm fluorescence intensity increased around 3000% relative to a nonirradiated control sample, whereas the $\lambda_{ex}$ 675 nm fluorescence intensity decreased around 50% in comparison with the unexposed control (Figure 1B). Accordingly, the change in fluorescence intensity measured at $\lambda_{ex}$ 675 nm was not as pronounced as in the case of $\lambda_{ex}$ 580 nm. The experiments with bulk LSO gave a linear increase in the fluorescence intensity of BODIPY$^{665/676}$ at $\lambda_{ex}$ 580 nm with irradiation time (Figure 1A). However, the maximum intensity reached only 900% relative to the unexposed control, and the variations between the repetitions were smaller with LSO than with MCT oil. Also, with LSO the fluorescence measured at $\lambda_{ex}$ 675 nm was constant, in contrast to MCT oil, where it decreased during irradiation (Figure 1B).

The fluorescence changes of BODIPY$^{665/676}$ in the two oils were not in agreement with the expected levels of oxidation, because highly unsaturated LSO should be oxidatively unstable and be able to sustain pronounced radical-chain lipid oxidation. The response of BODIPY$^{665/676}$ toward lipid oxidation was therefore tested in an alternative set of experiments based on the temperature-dependent lipid-soluble radical initiator AMVN in blends of oxidatively stable MCT oil and purified unsaturated sunflower oil (SFO). Oil samples containing BODIPY$^{665/676}$ were heated at 37 °C, and the rate of fluorescence change was measured as the initial change of fluorescence intensity with heating time (Figure 2). The blends of oils with high levels of SFO gave low rates of fluorescence changes in comparison with the pure MCT oil, where the rates were substantially higher. In addition, blends of MCT oil with 10 wt % methyl oleate and MCT oil with 10 wt % methyl linoleate were included in the experiment, and these blends gave similar high rates of changes in fluorescence intensity as the pure MCT oil.

The two sets of experiments with different unsaturated oils and different modes of radical generation both indicated that BODIPY$^{665/676}$ was most sensitive toward radicals in pure saturated MCT oil, while the response in unsaturated LSO and SFO was low. To further understand the underlying mechanism of radical reactions and differences in radical sensitivity of the

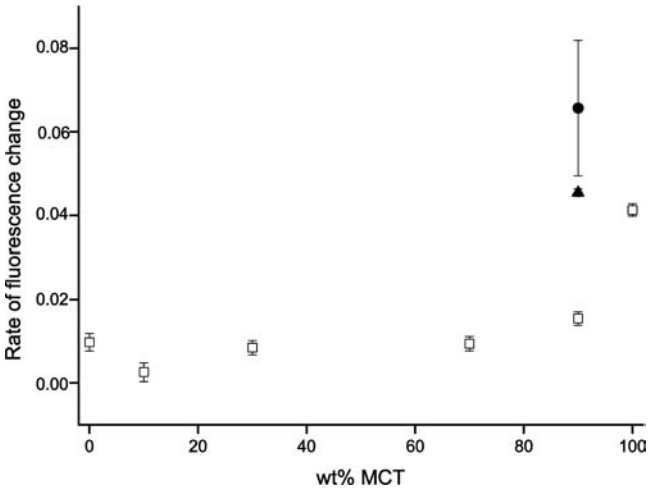

**Figure 2.** Rate of fluorescence change of BODIPY$^{665/676}$ in blends of MCT oil and sunflower oil (SFO) measured at $\lambda_{ex}$ 580 nm. The samples of oil blends contained AMVN (13 mM) and were subjected to heating at 37 °C for 3 h. The rate of fluorescence intensity change is presented as a function of weight percent MCT oil in the oil blend. (□) Various blends of MCT oil and SFO, (●) blend of 90 wt % MCT oil and 10 wt % methyl linoleate, (▲) blend of 90 wt % MCT and 10 wt % methyl oleate.

probe, electron spin resonance (ESR) spectroscopy was used to evaluate the level of radical reactions initiated by AMVN in the oils and their blends (Figure 3). The detection of radicals was

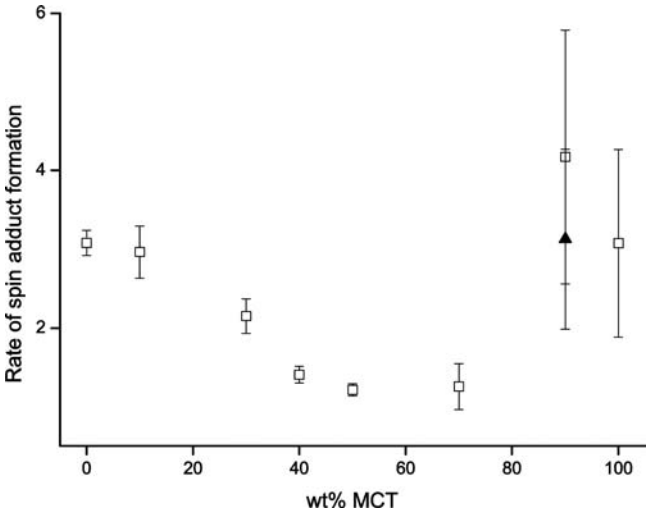

**Figure 3.** Rate of spin adduct formation in blends of MCT oil and SFO. The samples of oil blends contained the spin trap PBN (20 mM) and radical initiator AMVN (6 mM) and were subjected to heating at 37 °C. The rate of spin adduct formation is calculated as an increase of the spin adduct signal detected by ESR as a function of heating time and is reported as a function of weight percent MCT oil in the oil blend. (□) Blends of MCT oil and SFO in various concentrations; (▲) blend of 90 wt % MCT oil and 10 wt % methyl linoleate.

based on the formation of long-lived spin adducts with the spin trap PBN, which traps radicals generated directly from AMVN as well as radicals formed during radical-chain lipid oxidation reactions. The ESR experiments demonstrated that rates of spin adduct formation in the oil blends decreased with increasing concentration of MCT oil up to 70 wt %. However, at MCT oil concentrations above 70 wt %, rates of spin adduct formation increased to levels similar to that of pure SFO. The high rate of spin adduct formation in SFO was expected, since the high degree of unsaturation should give a high level of oxidative chain reactions, thus sustaining a high steady-state concentration of radicals.[9,10] At the same time, the high rate of spin adduct formation in MCT oil was surprising. A blend of MCT oil with 10 wt % methyl linoleate gave the same high rate of spin adduct formation as the MCT oil blend with 10 wt % SFO.

**Oxidation in Emulsions.** Confocal laser scanning microscopy (CLSM) together with BODIPY$^{665/676}$ was used to study the progression of oxidation in emulsion systems on the scale of single oil droplets. The fluorescent probe BODIPY$^{665/676}$ has been shown not to diffuse between oil droplets, and remaining localized in the droplets where it has been initially dissolved during preparation of the emulsion.[6] In order to study the transfer of radicals between oil droplets, a series of experiments were carried out where two Tween-20-stabilized emulsions made from different oils were mixed in a way so that the temperature-dependent radical initiator AMVN was present in some oil droplets and the fluorescent probe BODIPY$^{665/676}$ was present in the same droplets, or in the droplets without AMVN, or no AMVN was present at all (Table 1). When the respective combinations were investigated under a confocal microscope, the images showed that droplets loaded with BODIPY$^{665/676}$ were easily recognizable by their fluorescence at $\lambda_{ex}$ 670 nm, while droplets without BODIPY$^{665/676}$ could be detected and located in the transmitted light mode. In the case when no radicals were released (samples not heated), no fluorescence was seen at $\lambda_{ex}$ 580 nm. Therefore, no differentiation based on fluorescence between the two emulsions could be made, and the droplets were visible and could be defined only in transmitted light. Upon heating of the AMVN-containing mixtures of emulsions, an increase in the fluorescence at $\lambda_{ex}$ 580 nm could be noticed in the BODIPY$^{665/676}$-loaded oil droplets, indicating the presence of radicals. During the heating of the samples and consequent constant generation of radicals for up to 60 min, it was seen that the fluorescence intensities were rising independent of the location of the radical initiator AMVN and the probe BODIPY$^{665/676}$ (Figure 4). Extended heating for more than 60 min resulted in a drop in the fluorescence intensity of the mixtures of emulsions, where SFO droplets contained the probe, while in the combination where MCT oil droplets were loaded with BODIPY$^{665/676}$ a further increase was measured up to 120 min. Regardless of the oil medium of the droplets carrying the probe, the oil droplets without the probe showed no increase in fluorescence during the experiments (Figure 4).

The combination of SFO emulsion containing AMVN and BODIPY$^{665/676}$ mixed with MCT oil emulsion had a high level of fluorescence (~100 fluorescence units, FU) already before heating. This resulted in a stable initial fluorescence, which did not change during the heating (data not shown). No change in the fluorescence intensity was seen in the two emulsion combinations that did not contain AMVN, serving as internal controls. Similarly, MCT oil emulsion with BODIPY$^{665/676}$ and control experiments on emulsions without BODIPY$^{665/676}$ did not show any changes in the fluorescence intensities upon heating (data not shown). The presence of radicals also influenced the fluorescence intensities at $\lambda_{ex}$ 670 nm. At this wavelength, a weaker contrast between the BODIPY$^{665/676}$-loaded droplets and their counterparts was seen. The fluorescence decrease in oil droplets observed at $\lambda_{ex}$ 670 nm

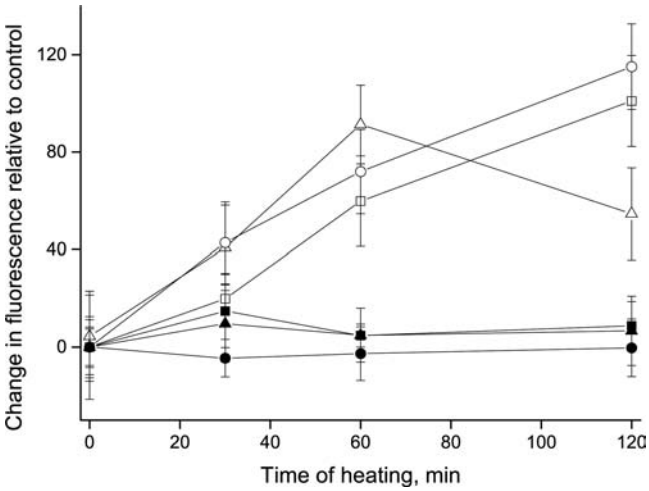

**Figure 4.** Changes in fluorescence intensity at $\lambda_{ex}$ 580 nm of single oil droplets in mixtures of emulsions observed with CLSM. The following systems were studied: (○, ●) MCT oil emulsion containing AMVN (6 mM) and BODIPY$^{665/676}$ (1 $\mu$M) mixed with SFO emulsion; (□, ■) MCT oil emulsion containing BODIPY$^{665/676}$ (1 $\mu$M) mixed with SFO emulsion containing AMVN (6 mM); and (Δ, ▲) SFO emulsion containing BODIPY$^{665/676}$ (1 $\mu$M) mixed with MCT emulsion containing AMVN (6 mM). The combinations were heated at 37 °C. Open symbols depict the fluorescence intensities of droplets in the combinations of emulsions containing BODIPY$^{665/676}$, and closed symbols show the fluorescence intensities of droplets where BODIPY$^{665/676}$ was absent. The fluorescence intensities are reported relative to unexposed control samples.

correlated with the increases of fluorescence observed at $\lambda_{ex}$ 580 nm for all the studied emulsions (data not shown).

The effect of location of the radical initiator AMVN in the mixtures of emulsions on lipid oxidation was also studied on a macroscopic scale by measuring rates of oxygen consumption (Figure 5). The rates of oxygen consumption in MCT oil emulsions both with and without added AMVN were very low (Figure 5A). Mixing MCT emulsion containing AMVN with SFO emulsion gave rates of oxygen consumption even higher than the rates of oxygen consumption in a pure SFO emulsion without AMVN (Figure 5A,B). The level of oxidation in these combinations increased with the amount of SFO from 30 to 70 wt %, although the total concentration of AMVN decreased, from 4.2 to 1.8 mM at the same time. These results demonstrate that oxidation was accelerated in the mixed emulsions.

SFO emulsions with different concentrations of AMVN gave rates of oxygen consumption very similar when 6 mM or 4.2 mM AMVN was used, whereas in the case of 1.8 mM AMVN the rate of oxygen consumption was significantly lower (Figure 5B). Moreover, the presence of BODIPY$^{665/676}$ with AMVN in the SFO emulsion slightly increased the oxidation rate indicating that BODIPY$^{665/676}$ did not inhibit the progression of lipid oxidation as it has been reported earlier.[11,12]

Experiments were also carried out where the total concentration of AMVN in the mixed emulsions was kept constant at either 4.2 or 1.8 mM but the localization of AMVN within the oil droplets, either in MCT oil or SFO, was different (Figure 5C). The rates of oxygen consumption in the samples, which contained a combination of two SFO emulsions, were similar when AMVN was located with a higher local concentration in either 70 or 30 wt % of the droplets as compared to being present in all droplets (Figure 5C). The mixture of SFO emulsion containing AMVN with MCT emulsion gave a lower rate of oxygen consumption in the case of a total concentration of 4.2 mM AMVN. However, the combinations, where MCT oil and SFO emulsions with added AMVN were mixed in a ratio of 7:3 (corresponding to a total concentration of 1.8 mM AMVN) seemed to have a critical combination of components, and despite several repeated measurements, a rather large variation of the oxygen consumption rates was observed.

Oxygen consumption was also measured in emulsions made with blended MCT and SFO oils (Figure 6). Emulsions based on blended oils with 70 wt % MCT oil gave very low rates of oxygen consumption independent of the concentration of AMVN, whereas the emulsions made with 30 wt % MCT oil gave high rates of oxygen consumption, and the emulsion with 4.2 mM AMVN gave the highest rate. These results correspond to the evaluation of radical formation in bulk oil blends by ESR, where higher level of radicals were observed in the 30 wt % MCT oil blend than in the 70 wt % MCT oil blend (Figure 3).

## ■ DISCUSSION

The lipophilic fluorescent probe BODIPY$^{665/676}$ has previously been shown to be suitable for oxidation studies in single droplets of oil-in-water emulsions made with saturated MCT oil, since it does not diffuse between droplets and its fluorescence changes in the presence of radicals.[6] In the present work, it was found that the fluorescence of BODIPY$^{665/676}$ changed more in oxidatively stable saturated MCT oil than in oxidation-sensitive unsaturated linseed oil (LSO) and sunflower oil (SFO). The fluorescence changes were low in oil blends with high levels of SFO, and only at high levels of MCT did the rate of fluorescence intensity change increase. These experiments were based on the radical initiator AMVN, which produces radicals at a constant rate. The amounts of radicals generated in the different oil blends can therefore be assumed to be similar. The experiments with BODIPY$^{665/676}$ in the various blends of MCT oil and SFO, taken together with the concentration of radicals evaluated by ESR, suggest that BODIPY$^{665/676}$ was most sensitive to the initial radicals generated from AMVN and less sensitive to bulky lipid autoxidation-derived radicals. It has been reported that probes belonging to the C11 class, including BODIPY$^{665/676}$ and BODIPY$^{581/591}$ C-11, overestimate the oxidation of lipids due to their own high susceptibility to oxidation.[11,13] Moreover, Yoshida et al.[12] reported that the rates of reaction between unsaturated fatty acids and peroxyl radicals were half the reaction rates between BODIPY$^{581/591}$ C-11 and peroxyl radicals, which suggests that BODIPY$^{665/676}$ will react with radicals even more readily since it is more sensitive toward peroxyl radicals than BODIPY$^{581/591}$ C-11.[14] In the experiments based on the radical initiator DTBP, radicals in MCT oil interacted directly with the probe, mainly because the probe was the only available substance prone to oxidation. In LSO, on the other hand, probably due to the competition between BODIPY$^{665/676}$ and the unsaturated lipids, fewer radicals attacked the radical-sensitive fluorescent probe. Fluorometric experiments with fatty acid methyl esters in MCT oil gave higher rates of fluorescence intensity changes than in LSO, indicating that the reaction between the lipid-derived radicals and BODIPY$^{665/676}$ was affected by steric effects and thus mitigated the response to oxidation reported by the probe.

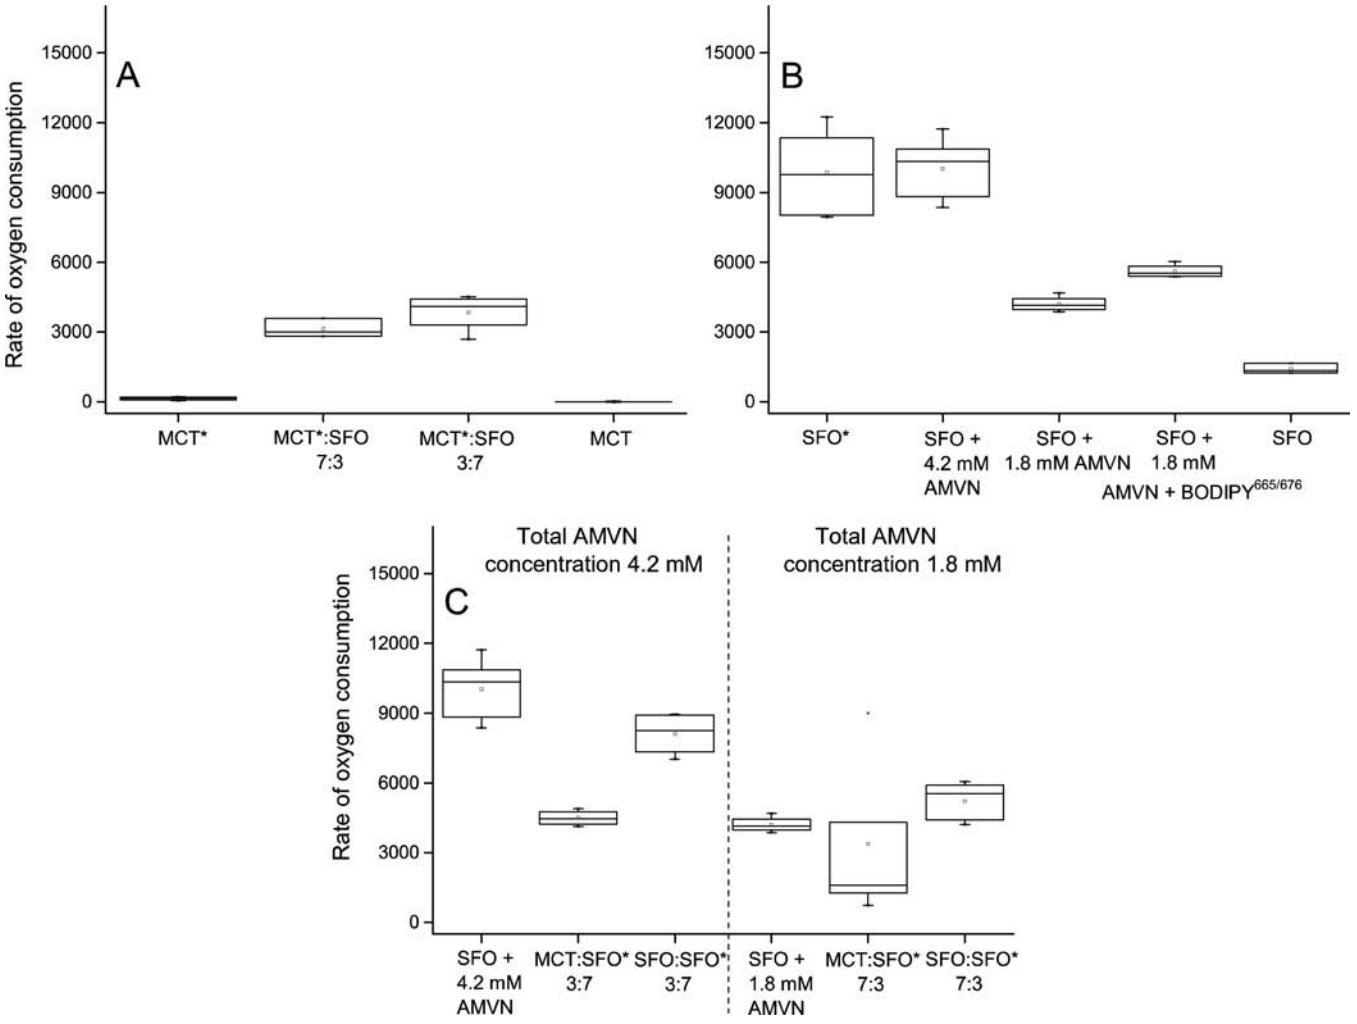

**Figure 5.** Rate of oxygen consumption in Tween-20-stabilized emulsions and mixtures of emulsions measured at 37 °C, and presented as percent of oxygen consumption per minute. (A) Experiments with MCT oil emulsion containing AMVN (6 mM) and MCT oil emulsion mixed with SFO emulsion. MCT emulsion without AMVN was included as a control. (B) Experiments with SFO emulsions with different concentrations of AMVN and SFO emulsion with AMVN (1.8. mM) and BODIPY$^{665/676}$ (1 $\mu$M). (C) Experiments with SFO emulsions containing AMVN and combinations of MCT oil emulsion and SFO emulsions. An asterisk indicates the original emulsion that contained 6 mM AMVN.

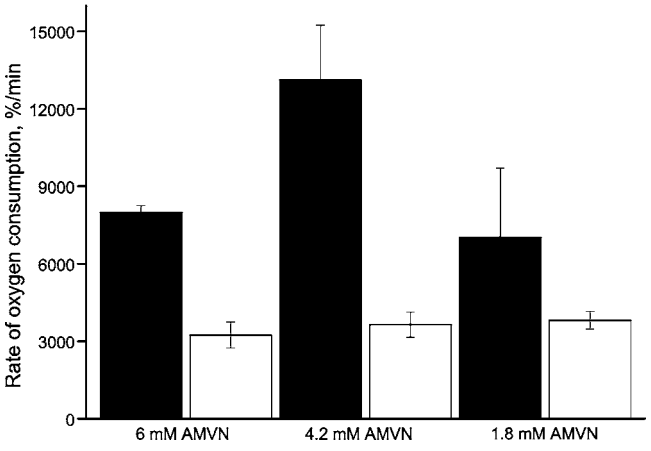

**Figure 6.** Rate of oxygen consumption in Tween-20-stabilized emulsions made with blended oils and with various concentrations of added AMVN measured at 37 °C, presented as percent of oxygen consumption per minute. Solid bars: blends of 30 wt % MCT oil and 70 wt % SFO. Open bars: blends of 70 wt % MCT and 30 wt % SFO.

The spin trap PBN also gave varying levels of detectable spin adducts in different oil blends. The decrease of spin adduct formation when the level of MCT oil was increased up to 50 wt % in oil blends could be due to dilution of the unsaturated SFO, which is in agreement with the notion that the level of oxidation decreases with decreasing level of unsaturation. In these oil blends, trapping of lipid oxidation-derived radicals is dominant.[15] Under the present experimental conditions at 37 °C, the PBN spin adducts with peroxyl radicals are very unstable, and thus PBN formed detectable stable adducts probably with alkoxyl and alkyl radicals.[16−19] The high levels of spin adduct formation at high concentrations of MCT in oil blends were surprising and suggest PBN was more efficiently reacting with the initial radicals generated from AMVN when the extent of competing reactions between AMVN-derived radicals and unsaturated fatty acids were low, due to low levels of unsaturation.

Experiments with oil blends illustrate that the fluorescence intensity changes of BODIPY$^{665/676}$ can be used for detecting reactive radicals in triglyceride systems; however, the structure of the radicals can significantly affect the level of intensity changes: bulky triglyceride-derived radicals apparently give

smaller changes due to steric effects. The degree of unsaturation should therefore always be taken into consideration when spectral changes of BODIPY$^{665/676}$ are compared between different triglyceride blends. In addition, a low level of intensity changes in highly unsaturated oil cannot be directly interpreted as indicative of a low level of lipid oxidation.

In confocal microscopy studies of two mixed Tween-20-stabilized emulsions with different compositions of oil phase, the probe BODIPY$^{665/676}$ gave a clear indication of transfer of radicals between oil droplets. Having BODIPY$^{665/676}$ and the radical initiator AMVN localized within the same droplets led, as expected, to changes of fluorescence spectra measured at $\lambda_{ex}$ 580 and 670 nm. However, more interestingly, when BODIPY$^{665/676}$ and AMVN were located in separate droplets, the fluorescence intensity of the probe also changed, showing that radicals could be detected in droplets neighboring the AMVN-loaded droplets. The concentration of Tween-20 was higher than the critical micelle concentration, and the emulsifier micelles could potentially solubilize smaller compounds, including AMVN and AMVN-derived radicals, providing transporter mechanism for radical reactions.[20,21] The escape of AMVN-derived radicals from lipid-containing particles has been observed in the case of LDL particles, where it was found that they could initiate lipid oxidation in neighboring particles.[22,23] Krainev and Bigelow[24] found that negligible amounts of AMVN-derived radicals were able to leave the lipophilic environment of rabbit skeletal sarcoplasmic reticulum membranes and egg phosphatidylcholine liposomes.

The hypothesis that radicals are able to move between the oil droplets, either by transporter mechanisms or by diffusion, was supported by determining the rates of oxygen consumption in the mixtures of emulsions. Oxygen consumption was expected to reflect the overall extent of lipid oxidation, and accordingly the rates of oxygen consumption were very low in MCT emulsions, even in the presence of AMVN, whereas the rates were very high in SFO emulsions. Experiments with combinations of emulsions showed that AMVN located in MCT oil droplets led to increased oxidation when mixed with SFO droplets, indicative of the transfer of radicals between droplets. A mixture of SFO emulsion containing 6 mM AMVN and MCT oil emulsion in the ratio 7:3 decreased the rate of oxygen consumption compared to SFO emulsion with added 4.2 mM AMVN. Furthermore, a combination of SFO emulsion containing 6 mM AMVN and SFO emulsion in the ratio 7:3 gave rates of oxygen consumption comparable to those of SFO emulsion with added 4.2 mM AMVN. Since the total concentration of AMVN in all these mixed systems was the same and identical amounts of radicals were generated, the presence of MCT oil must have had an effect on the level of oxidation, as has previously been observed with mixed mayonnaises.[2] This suggests the transfer of radicals from radical-loaded SFO droplets to saturated MCT oil droplets may inhibit the efficiency of radical transfer to other SFO droplets, and therefore may lead to reduction of the overall rate of oxidation in the mixture of emulsions, since MCT oil droplets are not expected to be able to sustain the transfer of radicals.

In conclusion, BODIPY$^{665/676}$ is a useful lipophilic fluorescent probe for detecting and studying radical reactions in bulk oils and oil-in-water emulsions. However, the structure of radicals can significantly affect the level of fluorescence intensity changes, and a low level of BODIPY$^{665/676}$ intensity change cannot be directly interpreted as indicative of a low level of lipid oxidation. Studies of mixed emulsions by confocal laser scanning microscopy with BODIPY$^{665/676}$ as a fluorescent probe, supplemented by oxygen consumption studies, demonstrated that radicals can be transferred between oil droplets and lipid autoxidation can spread between neighboring oil droplets.

The possibility of radical transfer between oil droplets will have to be taken into account when discussing the mechanisms of lipid autoxidation in oil-in-water emulsions. Radical-driven lipid autoxidation is not taking place as an isolated event in individual droplets but can spread between emulsion droplets. Although it is expected that radicals mainly are generated by metal-catalyzed mechanisms in the aqueous phase, the present results suggest that radicals generated in the interior of oil droplets can contribute to the initiation of autoxidation in neighboring droplets. Such transfer of radicals between droplets could be the main mechanism of initiating and spreading lipid autoxidation at higher temperatures, where generation of radicals by cleavage of preformed lipid hydroperoxides inside oil droplets may begin to play a significant role. The design of emulsion protection schemes based on surface-active antioxidants would accordingly have to consider that radicals may be able to both enter and exit droplets.

## MATERIALS AND METHODS

**Chemicals.** 1,1-Diphenyl-2-picrylhydrazyl (DPPH), Folin-Ciocalteu's reagent, gallic acid, protocatechuic acid, caffeic acid, vanillic acid, chlorogenic acid, syringic acid, ferulic acid, rutin, myricetin, rosmarinic acid, *trans*-cinnamic acid, naringenin, luteolin, kaempferol, apigenin, phytic acid dodecasodium salt, (+)-catechin, vanillin, BAPA (*N*-benzoyl-DL-arginine *p*-nitroanilide hydrochloride), trypsin, sinigrin hydrate, ecteola cellulose, Supelco 37 component fatty acid methyl ester mix, 2,2′-bipyridine, palladium(II) chloride, ammonium iron(III) sulfate dodecahydrate, and tris(hydroxymethyl) aminomethane were purchased from Sigma−Aldrich GmbH (Sternheim, Germany). Methanol (HPLC, gradient-grade), quercetin, formic acid (HPLC-grade), *n*-heptane (GC-grade), and 50% boron(III) fluoride in methanol were purchased from Merck (Darmstadt, Germany). Anhydrous methanol and sodium chloride were obtained from Avantor Materials (Gliwice, Poland). Thioglycolic acid was purchased from Kemika (Zagreb, Croatia). Calcium chloride dehydrate, dimethyl sulfoxide, methanol, and other chemicals used for proximate composition were of p.a. (pro analysis) quality and obtained from Lach-Ner (Neratovice, Czech Republic). Water used throughout the experiments was purified on a Millipore Elix UV and simplicity water purification system (Milford, MA).

**Materials.** Hemp meal, a byproduct remaining after cold mechanical pressing of hemp seeds, was supplied by the company Svet Konoplje (Kisač, Serbia). Cannabinoid-free hemp variety Helena, bred by the Institute of Field and Vegetable Crops, Novi Sad, Serbia, was grown in 2013 in the South Bačka district in the northern part of Serbia. Hemp flour was obtained by grinding hemp meal in a laboratory mill, Foss Knifetec 1095 (Foss, Hillerød, Denmark), fitted with tubing to allow circulation of water to cool the sample during milling. Ground hemp meal was separated into four fractions of different particle size by use of a universal laboratory sifter (Bühler AG, Uzwil, Switzerland) equipped with a stack of sieves of decreasing mesh size (>350 $\mu$m, >250 $\mu$m, >180 $\mu$m, and <180 $\mu$m). Along with the individual fractions, the whole ground hemp meal was analyzed.

The hemp meal extracts were prepared for subsequent determination of DPPH$^{\bullet}$ free radical scavenging activity and phenolic compounds by an HPLC method as follows: hemp meal was extracted with methanol/water mixture (80:20 v/v), with the ratio of raw materials to methanol solution 1:80. After treatment in an ultrasonic bath at room temperature for 10 min, the extracts were macerated for 2 h, filtered through a filter paper (Whatman, grade 4 Chr), and dried by vacuum evaporation at 40 °C. The dried extracts were redissolved in methanol (HPLC-grade) and stored at −4 °C until further use.

**Color Measurements.** Color measurements were carried out in five replicates on a Minolta Chroma Meter CR 400 colorimeter equipped with accessories for granular materials attachment CR-A50 (glass light-protection tube with plate 40 mm CR-A33b; Konica Minolta Sensing Inc., Japan). The instrument was calibrated against a standard light white reference tile, and the measurements were conducted under standard illuminant D65. The results were recorded according to the CIELab color system, where the determined parameters were expressed as $L^*$ describing lightness ($L^* = 0$ for black, $L^* = 100$ for white), $a^*$ describing intensity in greenness/redness ($a^* < 0$ for green, $a^* > 0$ for red), and $b^*$ describing intensity in blueness/yellowness ($b^* < 0$ for blue, $b^* > 0$ for yellow). Moreover, the total color difference ($\Delta E$) between whole hemp meal and separated hemp meal fractions was expressed as

$$\Delta E = \sqrt{\Delta L^2 + \Delta a^2 + \Delta b^2}$$

where $\Delta L$ is the lightness difference, $\Delta a$ is the redness/greenness difference, and $\Delta b$ is the yellowness/blueness difference. For $\Delta E < 1$, color differences were not considered obvious to the human eye; for $1 < \Delta E < 3$, color differences were not considered appreciated by the human eye; and for $\Delta E > 3$, color differences were considered obvious to the human eye.[13]

**Chemical Composition.** The moisture content of hemp meal fractions was determined by oven-drying to a constant mass at 105 °C. Crude protein, crude lipid, crude fiber, ash, and total sugars content were determined according to AOAC standard methods.[14]

**DPPH$^{\bullet}$ Free Radical Scavenging Activity.** Free radical scavenging activity against the stable DPPH$^{\bullet}$ (1,1-diphenyl-2-picrylhydrazyl) radical was determined spectrophotometrically following the procedure of Espin et al.[15] The $IC_{50}$ value (milligrams per milliliter), defined as the mass concentration of an antioxidant extract that was required to quench 50% of the initial DPPH$^{\bullet}$ under the given experimental conditions, was obtained by interpolation from linear regression analysis.

**Separation and Determination of Phenolic Compounds.** Determination of phenolic compounds was performed by a single rapid resolution reverse phase HPLC method as previously described by Mišan et al.[16]

**Fatty Acid Determination.** Fatty acid composition of the samples was expressed as fatty acid methyl esters (FAMEs). Lipids were

extracted with chloroform/methanol (2:1 v/v) mixture following the Folch extraction procedure,[17] and the obtained extracts were dried by vacuum evaporation at 40 °C. Methyl esters were prepared from the extracted lipids by transesterification with 14% boron(III) fluoride in methanol.[18] The obtained samples were analyzed by a GC Agilent 7890A system with flame-ionization detector (FID), autoinjection module for liquid samples, equipped with fused silica capillary column (DB-WAX 30 m, 0.25 mm, 0.50 μm). Helium was used as a carrier gas (purity >99.9997 vol %, flow rate = 1.26 mL/min). The fatty acids peaks were identified by comparison of retention times with retention times of standards from Supelco 37 component fatty acid methyl ester mix (Sigma–Aldrich) and with data from an internal data library based on previous experiments. Results were expressed as the mass of fatty acid or fatty acid group (grams) in 100 g of fatty acids.

**Antinutritional Factors.** Phytic acid was extracted from defatted flour with 0.2 M HCl and determined according to Haug and Lantzsch.[19] Tannins were extracted from defatted material with 70% acetone, evaporated to dryness, and then resuspended in methanol. Condensed tannins were determined by the vanillin method (absorbance at 500 nm) with catechin as a standard.[20] Trypsin inhibitors were extracted from defatted flour with 0.01 M NaOH (pH adjusted to 8.4–10.0). Trypsin inhibitor activity was measured according to Hamerstrand et al.[21] with *N*-benzoyl-DL-arginine *p*-nitroanilide hydrochloride (BAPA) as a substrate for trypsin. One unit of trypsin inhibitor was defined as 0.01 decrease in absorbance at 410 nm under the assay conditions compared with the control (without inhibitor).The glucosinolates content was determined according to MSZ-08-1908.[22] The assay is based on measurement of absorbance of Pd–glucosinolate complex at 425 nm. A standard curve was constructed with synigrine as a standard.

**Statistical Analysis.** The results were analyzed by one-way analysis of variance with Fisher's least significant difference (LSD), which was performed by Statistica 12.0 (Statsoft, Tulsa, OK). The significance of differences among the mean values is indicated at the 95% confidence level.

## RESULTS AND DISCUSSION

**Physical Characteristics of Hemp Meal Fractions.** Hemp seed oil is a niche market product, mainly produced in small-scale artisan-type plants by mechanical pressing with a screw press. Although this type of oil production does not involve any refining procedures, the oil is purified by simple sedimentation to remove contaminants, such as fine pulp, resins, and water. Although this type of processing appears to be rather simple, the disposal of waste generated throughout the processing can pose a number of problems to the processors having not enough resources to cope with it.

Figure 1 shows the simplified processing flow diagram of mechanical hemp oil pressing. During the cold oil processing, different byproducts could be distinguished: sludge or sediment and press cake or meal. The sludge represents a complex mixture comprising small pieces of pressed seed and hull as well as phospholipids, oil, waxes, and minor amounts of other constituents like phytosterols, tocopherols, pigments, and fatty acids. Hemp seed press cake or meal is a byproduct obtained after the seeds are pressed to extract the oil.

The obtained hemp meal was milled with simultaneous sample cooling to avoid the decomposition of thermolabile components. Subsequently, it was fractionated by sieving, which enabled the separation on the basis of the differences in particle size. Generally, two groups of fractions were identified: coarse fractions of particle sizes >350 and >250 μm, containing hull particles, and fine fractions of particle sizes >180 and <180 μm, containing predominantly cotyledon particles. The yield of these fractions was determined relative to the amount of starting material (Figure 1). The fraction with the highest yield (39.4%) was that with particle size in the range 180–250 μm, which, according to the appearance and structure was predominantly composed of ground cotyledon particles, while sieving yielded 33.0% coarse fraction consisting of hulls. Different particle size distribution was due to different grinding behavior of cotyledons and hulls, which were of higher elasticity due to higher content of structural carbohydrates. which made them more resistant to the grinding.[23] The obtained fractions were clearly separated according to their color, which was quantified by total color difference (Table 1).

The obtained results indicated the existence of a significant difference in lightness ($L^*$), ranging from 28.74 for the coarsest fraction (>350 μm) to 53.46 for the finest fraction (<180 μm). The difference in lightness can be attributed to the difference in scattering effect by the particles of various sizes. Thus the finest fraction, with the smallest particles and increased surface area, scattered more light and appeared to be lighter, unlike the

fractions with larger particle size.[24] The redness of the separated fractions increased with increasing the particle size and varied between 1.15 for the finest fraction (<180 $\mu$m) and 3.92 for the medium coarse fraction (>250 $\mu$m). Conversely, the yellowness of the fractions increased with decreasing particle size, being highest for the finest fraction (<180 $\mu$m). Significant differences in redness ($a^*$) and yellowness ($b^*$) were observed between coarse and fine fractions. The increase in greenness with decreasing particle size could be associated with the presence of chlorophyll pigments, which were found to be abundant in hemp oil.[25] Namely, fractions with smaller particle size (>180 $\mu$m and <180 $\mu$m) had significantly higher oil content in comparison to other meal fractions (Table 2), which resulted in increased chlorophyll content and thus led to pronounced green color of these fractions. Consequently, the increase in yellowness of the fractions rich in oil (lipid; Table 2) could be related to high content of $\gamma$-tocopherol present in hemp oil.[25] In order to quantify the difference in the appearance between separated fractions, the total color difference was calculated relative to the whole hemp meal. Since the total color difference was greater than 3 between all the fractions and the whole hemp meal, an indication of the perception of a color difference by human eye was confirmed.

**Proximate Composition of Hemp Meal Fractions.** The proximate composition of hemp meal is primarily determined by the quality of starting raw material, itself dependent on variety, locality, applied agrotechnical measures, weather conditions, and processing parameters. The proximate composition of hemp meal fractions is shown in Table 2. The moisture content of hemp meal fractions varied between 6.98% and 7.88%, being significantly the lowest ($p < 0.05$) for hull-containing fractions. When it is considered that the cotyledons are the main reserve of proteins, carbohydrates, and oils, cotyledon fractions (of particle size <250 $\mu$m) appeared to be of the richest nutritive composition. More specifically, protein content of hemp meal fractions varied between 10.62% for the coarsest fraction and 44.36% for the finest cotyledon fraction. The same trend was observed for oil and total sugar content, ranging between 8.26% and 18.60% and between 0.00% and 4.96%, respectively. Differentiation of hemp meal fractions in relation to protein, fat, total sugar, ash, and crude fiber content was achieved by sieving as previously indicated by Maaroufi et al.[23] for pea flour and Sreerama et al.[26] for chickpea and horse gram flours.

The protein content in the whole meal was lower than that reported by Callaway[4] and Tang et al.[27] in hemp meal, but it progressively increased in cotyledon-containing fractions. The protein content in whole meal was also lower than that determined in defatted soy flour, as reported by Sudha et al.[28] as well as in rapeseed and soybean meal.[29] The results of crude fiber content (which comprise only insoluble fibers) and ash content in hemp meal were in accordance with the results obtained for hemp seed residue after oil extraction reported by Anwar et al.[30] Crude fiber content varied from 4.96% to 29.54% between the hemp meal fractions. Large quantities of crude fibers were found in coarse meal fractions and consequently were significantly lower in cotyledon fractions. Oil content in the whole meal was consistent with the results reported by Callaway.[4]

**Antioxidant Compounds and Activities of Hemp Meal Fractions.** The radical-scavenging capacities ($IC_{50}$ values) of fraction extracts are presented in Figure 2. $IC_{50}$ values significantly differed ($p < 0.05$) between hemp meal fractions,

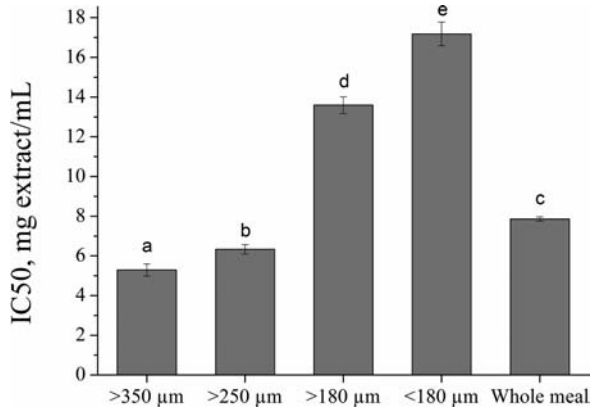

**Figure 2.** Radical scavenging capacities ($IC_{50}$ values) of fraction extract.

the lowest being the coarsest fraction (>350 $\mu$m), indicating the strongest radical-scavenging activity (5.29 mg/mL), unlike that of the finest cotyledon fraction (<180 $\mu$m), which appeared to have the weakest radical-scavenging activity (17.18 mg/mL). Although reported for selected pulses, the same distribution of the radical-scavenging capacity was observed by Duenas et al.[31] and Sreerama et al.[32] Moreover, fractions originating from the peripheral parts of soybean seed manifested higher antioxidant capacity than those originating from cotyledons.[33]

The antioxidant potential of hemp oil has been recently reported, as it has been recognized as one of the nontraditional vegetable oils not so long ago introduced to the market.[34] Literature data on phenolic profile of hemp products other than hemp oil are very limited, except that published by Chen et al.,[35] who reported only phenolic compounds with major significance. Phenolic compounds of hemp meal fractions are presented in Table 3. Apart from *N-trans*-caffeoyltyramine and cannabisin B, identification of phenolic compounds in crude extracts was performed by comparing the retention times and spectra of phenolic compounds of extracts with those of the corresponding external standards. *N-trans*-caffeoyltyramine (UV $\lambda_{max}$ in MeOH 220, 294, 318 nm) and cannabisin B (UV $\lambda_{max}$ in MeOH 220, 245, 283, 335 nm) were identified on the basis of their spectral characteristics, as they were previously isolated and identified as phenolic compounds with predominant radical-scavenging activity in hemp seed.[35] The identification of *N-trans*-caffeoyltyramine and cannabisin B within the present research, solely based on UV spectral characteristics, has been only tentative. However, the presence of previously known and new lignanamides and cannabisins was recently reported by Lesma et al.,[6] who performed a thorough investigation of the metabolic content of hemp seeds in various cultivars, making an important contribution to their NMR spectroscopic characterization. Quantification of phenolic compounds was based on external standards calibration except for *N-trans*-caffeoyltyramine and cannabisin B, which were expressed in *trans*-cinnamic acid equivalents due to the lack of corresponding external standards. The determination of distribution of *N-trans*-caffeoyltyramine and cannabisin B between our hemp meal fractions revealed that they were abundantly present in the hull-containing fractions, in accordance with the results of Chen et al.[35] Apart from those, important phenolic compounds detected in defatted hemp meal were catechin and *p*-hydroxybenzoic acid in the cotyledon fractions, and ferulic and sinapic acid in the hull

| PUFA/SFA ratio | 6.94 | 7.14 | 6.02 | 6.24 | 6.88 |

[a]Values are means ± SD and are given as grams per 100 g total fatty acids. Means in the same row followed by different letters are significantly different ($P < 0.05$). [b]SFA, saturated fatty acids; MUFA, monounsaturated fatty acids; PUFA, polyunsaturated fatty acids; UFA, unsaturated fatty acids.

fractions. The content of gallic acid, protocatechuic acid, *p*-hydroxybenzoic acid, vanillic acid, and catehin increased from hull fraction to cotyledon fraction, thus disproving the fact that hull is necessarily the main source of natural antioxidants (Table 3). Conversely, the content of ferulic and sinapic acids in the hull fractions was significantly higher than that of cotyledon fractions. However, the content of ferulic and gallic acid was lower than those determined in defatted flaxseed.[36] The content of *p*-hydroxybenzoic acid in all hemp meal fractions was higher than that of coconut, cottonseed, sesame, flax, and peanut flours as reported by Dabrowski and Sosulski.[37] Furthermore, whole hemp meal and cotyledon fractions contained higher content of *p*-hydroxybenzoic acid than that of rapeseed and sunflower flours and a similar level as soybean flour. The content of all determined phenolic compounds was higher than that determined for cold-pressed hemp oil, wherein protocatechuic acid was not detected in hemp oil.[34] The content of sinapic acid was lower than that determined in canola meal.[38]

**Fatty Acid Composition of Hemp Meal Fractions.** Fatty acid compositions of different hemp meal fractions are provided in Table 4. According to obtained data, fatty acid distribution was mainly uniform across different fractions. The main fatty acids were linoleic (54.09−55.42%), linolenic (17.31−18.42%), and oleic (12.96−13.93%) acids, followed by palmitic (6.48−7.90%), stearic (3.18−3.86%), and γ-linolenic (2.61−2.76%) acids. Similar results were obtained for hemp seed oil according to Teh and Birch[25] and Da Porto et al.[7] Moreover, high content of polyunsaturated acids, especially of linoleic (18:2 n6c) as well as ω-3 linolenic acid in the ratio of approximately 3:1, indicated a positive nutritional profile of all hemp meal fractions. Similar results were reported for fatty acid composition of hemp seed oil.[7]

Results presented in Table 5 show relatively high content of polyunsaturated fatty acids (PUFA) in all fractions. Hemp meal fraction with coarse particles (>250 μm) was characterized by higher content of polyunsaturated fatty acids and consequently lower level of monounsaturated fatty acids (MUFA) in comparison to other hemp meal fractions. Moreover, slightly

Table 6. Distribution of Major Antinutrients in Different Fractions of Hemp Meal[a]

| | hemp meal fractions | | | | |
|---|---|---|---|---|---|
| antinutrient | >350 μm | >250 μm | >180 μm | <180 μm | whole meal |
| trypsin inhibitor (TIU/mg of protein) | 1.39 ± 0.00 a | 1.96 ± 0.04 b | 3.70 ± 0.02 d | 3.90 ± 0.07 e | 2.88 ± 0.09 c |
| phytic acid (mg/g) | 4.36 ± 0.05 a | 18.35 ± 0.57 b | 21.2 ± 0.11 c | 21.4 ± 0.11 c | 22.5 ± 0.07 d |

| condensed tannins (mg/g) | 0.19 ± 0.04 a | 0.33 ± 0.05 b | 0.25 ± 0.00 a | 0.26 ± 0.00 ab | 0.23 ± 0.01 a |

[a]Values are means ± SD. Means in the same row followed by different letters are significantly different ($P < 0.05$).

higher content of saturated fatty acids was found in fine hemp meal fractions (>180 μm and <180 μm). Saturated fatty acids (SFA) have been labeled as a possible cause of cancer and coronary heart diseases when present in excessive amounts in human diet. The mean ratio of PUFA/SFA recommended by the British Department of Health is more than 0.45, and WHO/FAO experts have reported guidelines for a "balanced diet" in which the suggested ratio of PUFA/SFA is above 0.40.[39,40] In this respect, all investigated meal fractions exhibited a favorable PUFA/SFA ratio (from 6.02 to 7.14).

**Antinutritive Factors in Hemp Meal Fractions.** The concentrations of antinutrients in different hemp meal fractions are shown in Table 6. Considerable variability in trypsin inhibitor activity between hemp meal fractions was evident, the lowest being in the fraction containing mainly husk (>350 μm) and the highest for cotyledon fraction. These results were higher than those obtained for watermelon, pumpkin, and paprika seed flour reported by El-Adawy and Taha.[41] Considerable variability in phytic acid content between hemp meal fractions was observed, being the highest in the fine fractions (Table 6). The coarsest fraction (>350 μm) appeared to have the lowest phytic acid content. The phytic acid content was lower than that of canola meal reported by Bell[42] and those determined in hemp seed meal of Italian and French varieties.[43] The presence of certain antinutrients (condensed tannins, polyphenols, trypsin, chymotrypsin, α-amylase inhibitors, oligosaccharides, trypsin inhibitors, phytic acid, tannins, glucosinolates, and saponins) may limit their conversion into edible-grade products and utilization in human nutrition as they influence protein digestibility, organoleptic properties, and bioavailability of macro- and microelements. However, in recent decades an increasing trend of reutilization of plant byproducts in food, cosmetic, and pharmaceutical industries has been observed.[2,29] Apart from the well-known harmful effects of antinutrients, certain health-promoting and disease-preventing properties also have been attributed to them. A preventive impact of phytic acid, phenolics, saponins, protease inhibitors, phytoestrogens, and lignans on diabetes, cardiovascular diseases, and cancer has been demonstrated.[44,45]

Finally, it can be concluded that fractionation by sieving can be used as a processing operation in order to preserve and concentrate target valuable compounds from hemp meal, a byproduct of hemp oil processing. While certain fractions might be used as food functional ingredients, the other fractions, due to increased antinutritive factors, could be used as a substrate for recovery of valuable compounds or in cosmetic and pharmaceutical industries.

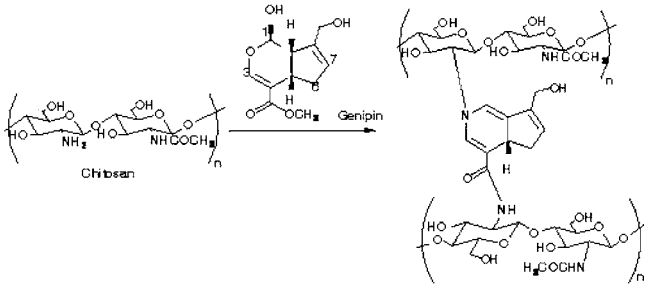
**Scheme 1. Genipin Reacted with Amino Groups in CS and Peptide To Yield Two Main Cross-Linking Reactions (Taking CS, for Example)**



synthetic chemicals as cross-linking agents, such as glutaraldehyde, ethylene glycol, diglycidyl ether, and diisocyanate.[20]

Herein, the CPP−CS (NPs) were cross-linked with genipin, and the critical centrifuge parameters for purification of the biopolymer nanoparticles were optimized. The morphology, particle size, and surface charge of the nanoparticles before and after the centrifugal purification were characterized using TEM, DLS, and electrophoretic mobility ($\zeta$-potential) measurements. The cross-linking reaction was confirmed and characterized by FT-IR. The structure behaviors of the nanoparticles, including morphology, particle size, and surface charge, as well as the controlled release profile of EGCG, from the nanoparticles under different digestion pH and enzyme conditions were investigated systematically. EGCG is the most abundant and bioactive polyphenol in green tea. However, the bioavailability of EGCG is very low.[21] The anticancer activities of the EGCG-loaded CPP−CS nanoparticles cross-linked with genipin were investigated by in vitro cell assays.

## MATERIALS AND METHODS

**Materials.** CS of molecular weight 100 kDa with a 90% deacetylation degree, derived from crab shell, was obtained from Golden-Shell Biochemical Co. Ltd. (Hangzhou, China). CPPs were prepared and identified with HPLC-MS-MS as described in our previous study.[22] EGCG (purity > 98%) and trypan blue were purchased from Sigma-Aldrich Co. (St. Louis, MO, USA). Genipin (purity > 98%) was purchased from Linchuan Zhixin Biotechnology Co., Ltd. (Jiangxi, China). High-purity grade pepsin with activity of 3000−3.5 NF U/mg and trypsin with activity of >250 NF U/mg were purchased from Beijing Solarbio Science and Technology Co., Ltd. (Beijing, China). Dimethyl sulfoxide (DMSO) and acetic acid were obtained from Sinopharm Chemical Reagent Co., Ltd. (Shanghai, China). Human gastric BGC823 and liver HepG2 cancer cells were obtained from the Cell Bank of Shanghai Institute of Cell Biology (Shanghai, China). Dulbecco's modified Eagle's medium (DMEM) and fetal bovine serum were purchased from Wisent Biotechnology (Wisent Inc., Quebec, Canada). All other chemicals were of analytical grade.

**General Procedure for Preparation of CPP−CS NPs and EGCG-Loaded CPP−CS NPs.** CPP−CS NPs were prepared according to our previously reported procedure.[22] Briefly, CS was dissolved in 1% (w/v) acetic acid solution with sonication until the solution was transparent. The aqueous solution of CPP was obtained at a suitable concentration. Both CS and CPP solutions were adjusted to pH 6.2 with 1.0 N HCl or NaOH solution. Subsequently, CS solution was added to CPP solution under stirring at room temperature. For the preparation of EGCG-loaded CPP−CS NPs, an aqueous solution of EGCG was added to a CPP solution before the addition of CS solution. The formation of CPP−CS NPs started spontaneously via the CPP-initiated ionic gelation mechanism.

**Cross-Linking of CPP−CS NPs and EGCG-Loaded CPP−CS NPs with Genipin.** For the preparation of genipin-cross-linked CPP−CS NPs, different amounts of genipin were added to the CPP−CS nanoparticle suspension, forming different final genipin concentrations of 0, 0.031, 0.063, 0.125, 0.250, 0.500, 1.000, and 2.000 mg/mL. The reaction mixture was incubated at 37 °C for different times of 3, 6, 12, and 24 h. The cross-linking reaction of the CPP−CS NPs was terminated by separating the nanoparticles from the residual free genipin in the reaction system using a centrifugal purification method that was optimized in following section. The genipin-cross-linked nanoparticles were washed three times using deionized water, precipitated, and collected. Cross-linking of the EGCG-loaded CPP−CS NPs with genipin was operated using the same procedure as described above.

**Purification of CPP−CS NPs and Genipin-Cross-Linked CPP−CS NPs.** The CPP−CS NPs and the genipin-cross-linked CPP−CS NPs were purified from their parental reaction suspension by centrifugation using an Avanti J-25 high-speed centrifuge (Beckman Coulter, Inc., Brea, CA, USA), with different centrifugal forces (25000, 10000, 7500, 5000, and 2500$g$) and various duration times (15, 30, 45, and 60 min) to optimize the critical centrifuge parameters, under which the nanoparticles could be just precipitated and then recovered to nanoparticle suspension after redispersion. The redispersion property of the nanoparticle precipitate was preliminarily observed by checking whether there were visible particles in the redispersed colloid solution. The nanoparticles were washed three times using deionized water and redispersed to the same volume as that before centrifugation. The size distribution, surface charge, and surface morphology of the purified nanoparticle suspension and their parental ones were characterized by DLS, zeta-potential measurement, and TEM.

**Nanoparticle Stability and Structure Behavior in Simulated GI pH and Enzyme Environments.** Equal amounts of the precipitates of the CPP−CS NPs and the genipin-cross-linked CPP−CS NPs were first redispersed in pH 1.2 (0.1 N HCl), pH 6.2, and pH 7.4 (10 mM PBS) solutions for 2 h, respectively, simulating the pH environments of the GI tract. The size distribution, surface charge, and morphology of the nanoparticles at these distinct pH conditions were characterized by DLS, zeta-potential measurement, and TEM. The nanoparticles that withstood the GI pH environments were further dispersed in 50 mL of 0.1 N HCl (pH 1.2) containing 0.1% pepsin as the simulated gastric fluid (SGF) and 50 mL of 10 mM PBS (pH 7.4) with 1.0% trypsin as the simulated intestinal fluid (SIF) for 2 h, respectively. The samples after gastric and intestinal digestion were isolated from the SGF and SIF, washed, and redispersed in deionized water for the determinations of size distribution, surface charge, and morphology.

**Cytotoxicity of the EGCG-Loaded CPP−CS NPs Cross-Linked with Genipin against Cancer Cells.** Cytotoxicity was measured using the trypan blue dye exclusion test. Human liver HepG2 cells or human gastric BGC823 cells (100,000) were seeded in 6-well plates, in 2.5 mL of medium per well. After 24 h, supernatants were discarded and replaced by fresh EGCG, CPP−CS NPs cross-linked with genipin, or the EGCG-loaded CPP−CS NPs cross-linked with genipin dilutions in cell culture medium in a range of concentrations from 12.5 to 200 $\mu$g/mL (0.0273−0.437 mmol/L) for EGCG and from 12.5 to 200 $\mu$g/mL (0.0273−0.437 mmol/L) for the nanoparticles. After 24 h of exposure, supernatants were discarded and cells rinsed twice with PBS. Cells exposed to EGCG, CPP−CS NPs cross-linked with genipin, or the EGCG-loaded CPP−CS NPs cross-linked with genipin were harvested with 1× trypsin. Cells were mixed with an aqueous solution of trypan blue 0.4% in PBS (pH 7.0) according to a method previously described.[23] Cell counting was performed using Kova counting chambers (Kova Glasstic Slide, Hycor Biomedical) by microscopy. The cell viability was calculated as the ratio between uncolored cells and total cells. All measurements were performed in triplicate.

**Statistical Analysis.** Data were expressed as the mean ± standard deviation (SD) of at least triplicates. The least significant difference (LSD) test and one-way analysis of variance (ANOVA) were used for multiple comparisons by SPSS 16.0. Difference was considered to be statistically significant at $p < 0.05$.

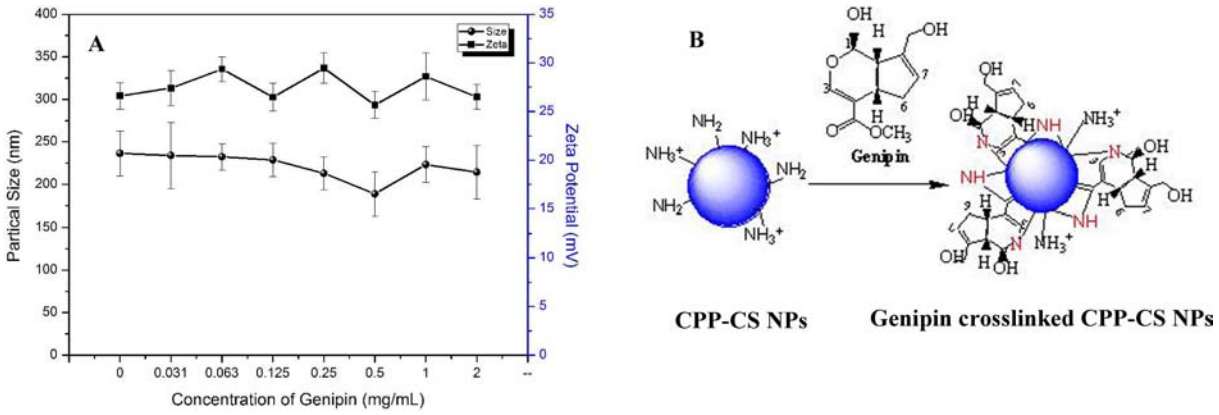


**Figure 1.** (A) Particle size and surface charge of the genipin cross-linked CPP−CS nanoparticles (NPs) with different concentrations of genipin; (B) schematic plot of the intra-cross-linkage of the CPP−CS NPs.

## RESULTS AND DISCUSSION

**Cross-Linking the CPP−CS NPs with Genipin.** Covalent cross-linking of the CPP−CS NPs with genipin took place spontaneously when genipin was added to the parental suspension. The appearance of blue coloration in the reaction mixture was traditionally considered as rapid evidence that the cross-linking reaction was taking place.[17] The cross-linking reaction occurred by means of a complex mechanism.[24] When the CPP−CS NPs were submitted to cross-linking with genipin, a nucleophilic attack by the amino groups of CS (peptide) on the olefinic carbon atom at C-3 in genipin occurred, followed by opening the dihydropyran ring and attack by the secondary amino group on the newly formed aldehydo group (Scheme 1). Genipin could form multiple cross-linkings among CS and CPP. In the product, short chains of condensed genipin acted as cross-linking bridges. The cross-linking reaction of the CPP−CS NPs with genipin could be further characterized by FT-IR, which will be presented and discussed later.

Theoretically, genipin might cause intra- and inter-cross-linkage of the CPP−CS NPs, leading to changes in particle size and surface charge. Therefore, the effect of different genipin concentrations on the physicochemical properties of the CPP−CS NPs was first investigated. Figure 1A shows the particle size and surface charge of the CPP−CS NPs and the covalently cross-linked CPP−CS NPs with different genipin concentrations. The particle size of CPP−CS NPs before cross-linking was 236.5 ± 26.3 nm ($n$ = 3) with a polydispersity index (PDI) of 0.152 ± 0.032 ($n$ = 3), which indicated a homogeneous dispersion of nanoparticles. Zeta-potential analysis revealed a surface charge of 26.6 ± 1.4 mV ($n$ = 3). After cross-linking with different genipin concentrations at 37 °C for 24 h, no significant change in particle size and surface charge of the nanoparticles could be observed. It could be found that the particle size decreased slightly with the increase of genipin concentrations, which might be related to the tighter cross-linking of the nanoparticles at higher concentration of genipin. The PDIs of the genipin cross-linked CPP−CS NPs were in the range of 0.108−0.204, which also indicated a homogeneous dispersion of nanoparticles. Therefore, it could be concluded that genipin mainly produced intra-cross-linkage of the CPP−CS NPs (Figure 1B), leading to little influence on their physicochemical properties.

**Purification of Nanoparticles.** CS-based polyelectrolyte nanoparticles are some of the most widely utilized engineered nanocarriers in bioimaging and biomedical therapeutics.[10,25] However, scarce data on purification of the CS-based nanoparticles from the reaction systems have been reported. Excess free CS, the corresponding negative polyelectrolytes, and the unloaded free cargoes are expected to remain in the product solution and should be removed before use, which otherwise could cause misleading results, such as in fluorescence labeling experiments. Furthermore, purification of the polymer nanoparticles is essential for further modification of nanoparticle surface properties, such as conjugating with functional groups, layer by layer coating with multilayers, and tests of the polymer nanoparticles' effects on biological tissues. In the present study, separation of the covalently cross-linked CPP−CS NPs from the free genipin, CS, and CPP remaining in the reaction system was of primary importance to terminate the spontaneous cross-linking reaction and to characterize the physicochemical and biological properties of the nanoparticles.

Centrifugation is most commonly used to separate nanoparticles, probably because of the easy availability of the instrument.[26] This purification method also offers more flexibility to vary the final volume of the treated nanoparticle suspension.[27] However, during centrifugation, the polymer nanoparticles are prone to cluster and mesh, leading to precipitation, even a polymer film that can never be redispersed as nanoparticle suspension. Therefore, a critical centrifuge parameter has to be optimized, under which the nanoparticles could just be precipitated and could also be recovered to nanoparticle suspension with similar physicochemical properties as the original ones. We summarized the centrifuge speed and duration employed in various studies to purify the CS-based nanoparticles (Supporting Information, Table S1) and found that the use of different parameters (e.g., rpm vs $g$-force) in the papers challenged attempts to cross-compare the studies. Even if a similar unit expression was adopted, the centrifuge forces and durations were seemingly selected arbitrarily (Supporting Information, Table S1).

To address the above-mentioned issues, in the present study, the critical centrifuge parameters for purification of the CPP−CS NPs and the genipin-cross-linked CPP−CS NPs were optimized with different centrifuge forces (25000, 10000, 7500, 5000, and 2500$g$) and various centrifugal times (15, 30, 45, and 60 min). The $g$-force ($g$) can be widely used and cross-compared, independent of different types of centrifuge equipment. As different genipin concentrations had little impact on the physicochemical properties of the nanoparticles,

we first took the cross-linked CPP−CS NPs with a genipin concentration of 0.125 mg/mL as the test sample. The redispersion properties of the nanoparticle precipitate were preliminarily checked whether there were visible particles in the redispersed colloid solution. Eventually, it was found that, under a centrifuge force of 2500*g* for 45 min, the nanoparticles could be just fully precipitated (Figure 2A) and then redispersed without visible particles (Figure 2B). The purified nanoparticles were washed and centrifuged three times before further characterization.

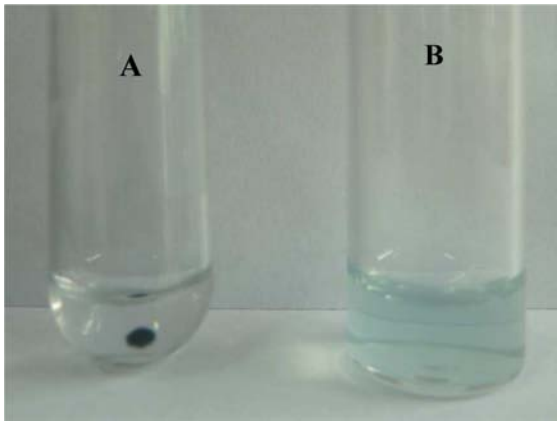

**Figure 2.** Centrifugation and redispersion of the genipin cross-linked CPP−CS NPs operating at a centrifuge force of 2500*g* and duration of 45 min (genipin concentration = 0.125 mg/mL).

Figure 3 shows the structure and morphology of the CPP−CS nanoparticle and the genipin-cross-linked CPP−CS nanoparticle samples before and after centrifugal purification at 2500*g* for 45 min, which were characterized using TEM. It can be seen that the parental CPP−CS NPs (Figure 3A) and genipin cross-linked CPP−CS NPs (Figure 3C) were regularly spherical in shape, dispersed homogeneously, and surrounded with free polymers. According to our previous study, it was mainly the excess free CS that was around the nanoparticles, allowing adsorption of free CS onto the surface of the nanoparticles and desorption of CS from the nanoparticles to reach equilibrium.[22] In addition, CS aggregates including certain crystal structures (marked with red arrows) could be observed in the background of the TEM images of the nanoparticle sample before centrifugation (Figure 3A,C). Comparatively, after centrifugal purification, in the TEM images of both the CPP−CS NPs (Figure 3B) and the genipin-cross-linked CPP−CS NPs (Figure 3D), the free CS surrounding the nanoparticles and the CS aggregates in the background disappeared, and the background of the images became clear. This phenomenon indicated that the CPP−CS NPs and genipin-cross-linked CPP−CS NPs had been successfully separated from the reaction system by the centrifugal purification method. The purified nanoparticles were regular spheres as well and dispersed homogeneously without aggregations (Figure 3B,D). No significant variations in the nanoparticle structure and morphology can be found by comparing the CPP−CS NPs with the genipin-cross-linked CPP−CS NPs themselves.

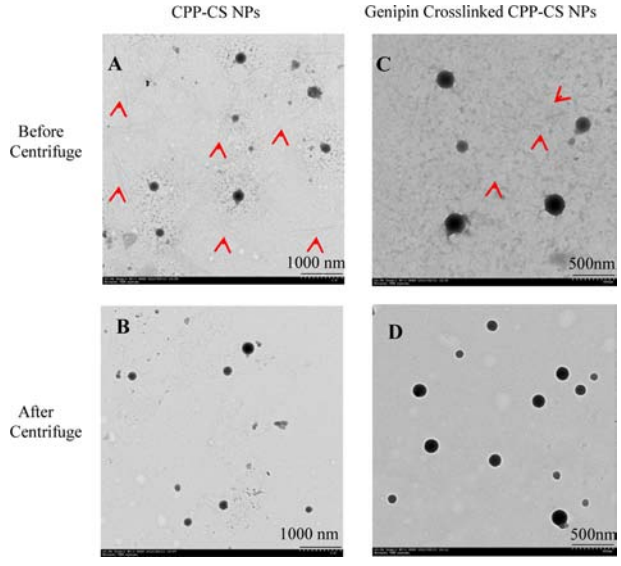

**Figure 3.** TEM images of CPP−CS NPs (A, B) and genipin-cross-linked CPP−CS NPs (C, D) before (A, C) and after (B, D) purification with centrifugation at a centrifuge force of 2500*g* and duration of 45 min (genipin concentration = 0.125 mg/mL).

The particle size and surface charge of the CPP−CS nanoparticle and genipin-cross-linked CPP-CS nanoparticle samples before and after centrifugal purification were further determined by DLS and zeta-potential measurement, which are shown in Figure 4. The mean particle size of the parental CPP−CS NPs and genipin-cross-linked CPP−CS NPs before centrifugation were 269.2 ± 19.6 nm (Figure 4A) and 246.2 ± 17.0 nm (Figure 4C), with PDIs of 0.165 and 0.142, respectively, indicating that the nanoparticles dispersed homogeneously. After centrifugation and redispersion, the particles size of the purified CPP−CS NPs (279.4 ± 21.1 nm) and genipin-cross-linked nanoparticles (245.3 ± 18.3 nm) were almost the same as that of their parental nanoparticles before centrifugation. This result was in accordance with the TEM result (Figure 3). After centrifugation, the surface charge of both the CPP−CS NPs and the genipin-cross-linked CPP−CS NPs increased from 20.3 ± 1.5 to 25.9 ± 3.8 mV and from 24.3 ± 3.5 to 32.4 ± 6.1 mV, respectively. This phenomenon might be related to the removal of the shielding effect caused by the excess free CS around the nanoparticles (Figure 3).

Therefore, operation at 2500*g* for 45 min was the critical centrifuge parameter for purification of the CPP−CS NPs and the genipin-cross-linked CPP−CS NPs for terminating the cross-linking reaction and for further separating the nanoparticles from the simulated GI fluids. The nanoparticles themselves maintained their structure and physicochemical properties after centrifugal purification. The CPP−CS NPs and the genipin-cross-linked CPP−CS NPs with different genipin concentrations (0.063, 0.125, and 0.250 mg/mL) and various reaction times (3, 6, 12, and 24 h) were purified by the centrifuge method and lyophilized for further FT-IR analysis.

**FT-IR Analysis.** To characterize the cross-linking reaction, we acquired the FT-IR spectra of the purified CPP−CS NPs and genipin-cross-linked nanoparticles with different genipin concentrations and reaction times (Figure 5). In Figure 5A, the covalently cross-linked CPP−CS NPs were obtained after cross-linking reaction for 3 h with different genipin concentrations of 0.063, 0.125, and 0.250 mg/mL. In Figure 5B, the genipin cross-linked nanoparticles with a fixed genipin concentration of 0.125 mg/mL were purified at different reaction times of 3, 6, 12, and 24 h. The main characteristic

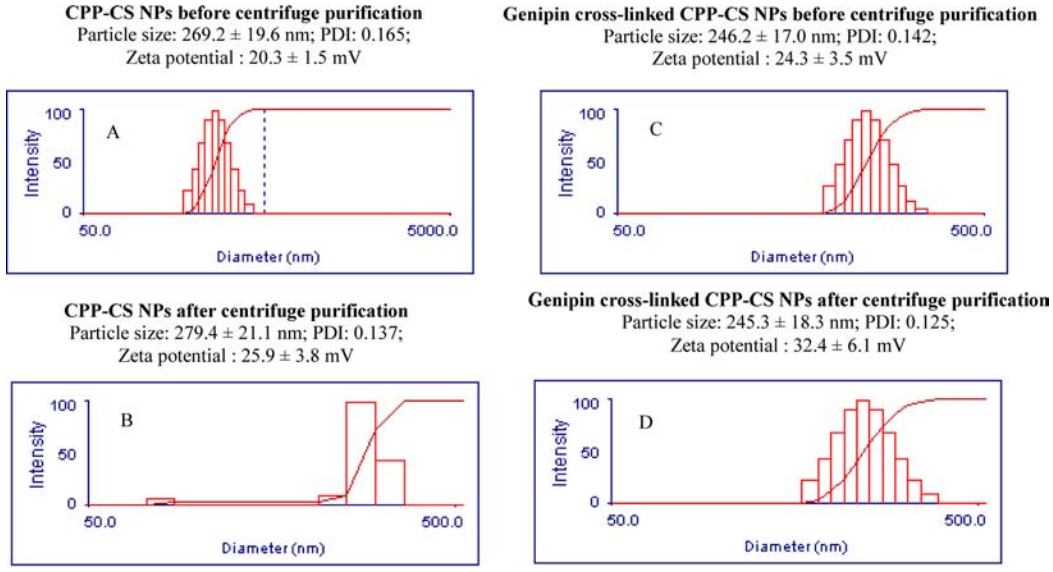

**Figure 4.** Particle size distribution of the CPP−CS NPs (A, B) and the genipin cross-linked CPP−CS NPs (C, D) before and after centrifugal purification at a centrifuge force of 2500*g* and duration of 45 min (genipin concentration = 0.125 mg/mL).

absorption bands of the CPP−CS NPs appeared at 1625, 1518, and 1150−1040 $cm^{-1}$, which corresponded to amide I and amide II groups and glycosidic linkage (C—O—C), respectively.[28] The amide I bands originated from C═O stretching vibrations coupled to N—H bending vibration. The amide II bands arise from the N—H bending vibrations coupled to C—N stretching vibrations. After cross-linking with genipin, the characteristic absorption band of amide I at 1625.15 $cm^{-1}$ shifted to 1636.80 $cm^{-1}$ with the increase of genipin concentration from 0.063 to 0.250 mg/mL, indicating the formation of secondary amides as a result of the reaction between the ester groups on genipin and the amino groups on CS.[29] A similar phenomenon also appeared in Figure 5B; the absorption band of amide I at 1624.72 $cm^{-1}$ shifted to 1634.92 $cm^{-1}$ with the increase of reaction time from 3 to 24 h. Furthermore, in both panels A and B of Figure 5, two new very weak absorptions at 1719 and 1700 $cm^{-1}$ appeared after cross-linking with genipin, and the intensity of these two absorptions increased with the elevation of the genipin concentration and prolonged reaction time.

The appearance and increased absorption of the peak at 1719 $cm^{-1}$ corresponded to the formation of aldehydo that was the reaction product between the carboxymethyl group of genipin and the amino groups on the surface of CPP−CS NPs[30] (insets of Figure 5). The absorption at lower wavenumber (1700 $cm^{-1}$) represented the aldehydo that formed intermolecular hydrogen bonding with other groups. After cross-linking with genipin, there were still many amino groups available on the surface of the CPP−CS NPs, which could be used as reaction sites for further surface modification.

**Stability of Nanoparticles under Simulated GI pH Conditions.** To study the stability of nanoparticles under simulated GI pH conditions, equal amounts of the purified CPP−CS nanoparticle and genipin-cross-linked CPP−CS nanoparticle precipitates were redispersed in pH 1.2 (0.1 N HCl), pH 6.2, and pH 7.4 buffers (PBS), respectively, for 2 h. Then, the samples in different pH conditions were submitted to characterization of particle size and morphology using DLS and TEM. The particle size and PDI of the CPP−CS NPs and the genipin-cross-linked CPP−CS NPs in different pH conditions are summarized in Table 1. It can be seen that, under pH 6.2, the CPP−CS NPs and the genipin-cross-linked CPP−CS NPs (reaction for 3 or 24 h) had similar particle sizes with PDI ranging from 0.095 to 0.189. After dispersion in 0.1 N HCl for 2 h, stimulating the pH environment in the stomach, the average count rate (ACR) of the CPP−CS nanoparticle suspension under laser decreased sharply from 342.8 kcps (pH 6.2) to 3.6 kcps (pH 1.2), indicating the disappearance of the nanoparticles under pH 1.2. ACR is a parameter that is influenced by the number and size of the particles in a suspension. In the experimental condition used in the present study, the detected particle size values were legal and reasonable only when the ACR value was in the range of 100−500 kcps. Therefore, under an ACR of 3.6 kcps, the detected particle size was illegal, which was recorded as "nd" in Table 1. Dispersed in pH 7.4 PBS buffer for 2 h, the particle size of the CPP−CS NPs was 310.6 ± 24.9 nm, which was larger than that under pH 6.2. Comparatively, after cross-linking with genipin (reaction for both 3 and 24 h), the CPP−CS NPs became very stable with just slight changes in particles size and PDI values under different simulating GI fluid pH values (pH 1.2, 6.2, and 7.4). The morphology and structure of the samples under different pH conditions were further investigated by TEM.

Figure 6 shows the structure and morphology of the CPP−CS NPs and the corresponding genipin cross-linked CPP−CS NPs (reaction for 3 h) after they were dispersed in pH 1.2, 6.2, and 7.4 buffers for 2 h, respectivley. Both the CPP−CS NPs (Figure 6B) and the genipin-cross-linked nanoparticles (Figure 6B′) were regular spheres and dispersed well under pH 6.2. Under pH 1.2 (Figure 6A), it can be seen that the CPP−CS NPs were dissoved with cloudy morphology and the release of the inner composition peptides (black dots marked with arrows), which was consistent with the DLS result of the sharp decrease of ACR value. This phenomenon was caused by the strong repusion among the highly protonated amino groups in CS under strong acidic condition, leading to the burst of the CPP−CS NPs. On the other hand, under pH 7.4, the CS capping on the surface of the nanoparticles seemed to precipitate in the insoluble state, which could be seen clearly

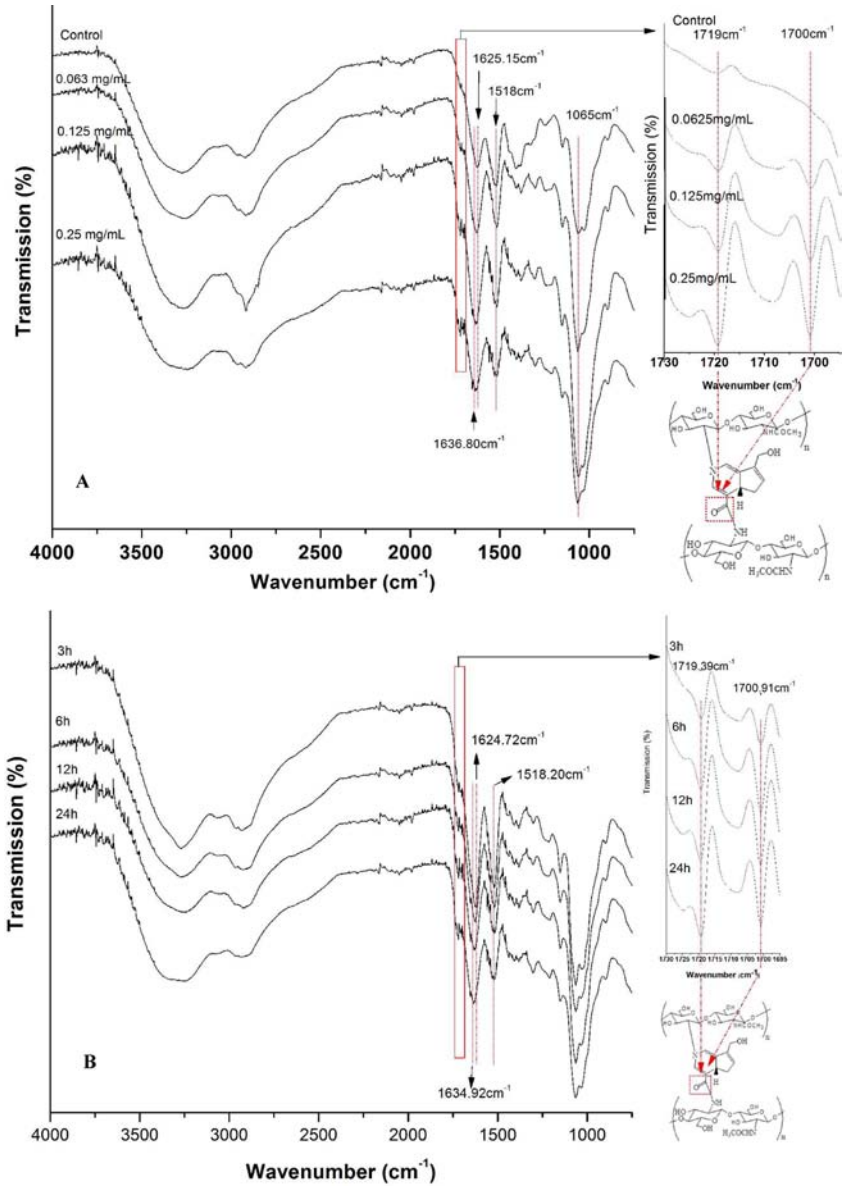

**Figure 5.** FT-IR spectra of the purified genipin cross-linked nanoparticles with different genipin concentrations (A) and reaction times (B).

**Table 1. Effects of pH on Particle Size and Polydispersity Index (PDI) Values of the CPP−CS NPs and the Genipin-Cross-Linked CPP−CS NPs[a]**

| | CPP−CS NPs | | G-CPP−CS NPs for 3 h[b] | | G-CPP−CS NPs for 24 h[c] | |
|---|---|---|---|---|---|---|
| pH value | particle size (nm) | PDI | particle size (nm) | PDI | particle size (nm) | PDI |
| 1.2 | nd | nd | 289.4 ± 18.2 | 0.099 | 276.1 ± 8.5 | 0.141 |
| 6.2 | 269.4 ± 15.2 | 0.095 | 266.4 ± 13.3 | 0.189 | 268.1 ± 18.9 | 0.143 |
| 7.4 | 310.6 ± 24.9 | 0.174 | 269.4 ± 16.6 | 0.143 | 266.9 ± 16.9 | 0.129 |

[a]Genipin concentration was 0.125 mg/mL. Values are expressed as the mean ± standard deviation ($n$ = 3). [b]The parental CPP−CS nanoparticle suspension was incubated with genipin for 3 h. Then, the cross-linked NPs were purified by the centrifugal purification method. [c]The parental CPP−CS nanoparticle suspension was incubated with genipin for 24 h. Then, the cross-linked NPs were purified by the centrifugal purification method.

in the inset image of Figure 6C. A similar result was also reported by Tang et al.[31] As the p$K_a$ value of the amine groups on CS is approximately pH 6.5, CS precipitates at neutral pH due to deprotonation of amine groups. This property of CS suggests that the CS NPs can be effective as a mucoadhesive agent and an absorption enhancer only in a limited area of the intestinal lumen where the pH values are below or close to its p$K_a$. In contrast, after cross-linking with genipin, no significant changes on structure and morphology of the CPP−CS NPs could be observed after they were dispersed in pH 1.2, 6.2, and 7.4 buffers for 2 h, respectively (Figure 6A′,B′,C′), which was consistent with the DLS results in Table 2. This meant that cross-linking with genipin, a simple and green method, could significantly enhance the stability of the CPP−CS NPs and successfully extend their effective scope in GI fluid, which was

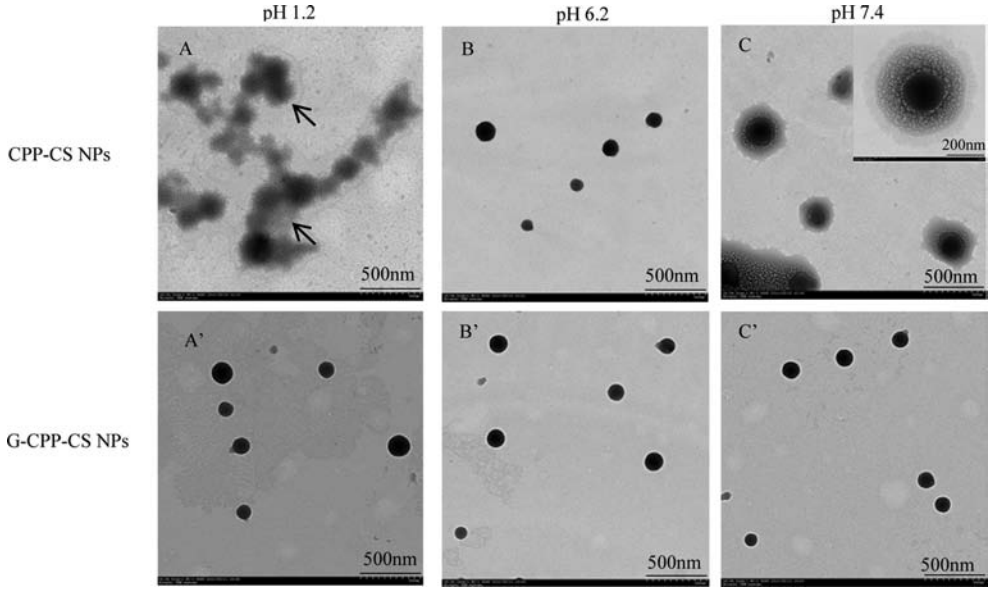

**Figure 6.** TEM images of the CPP−CS NPs (A, B, C) and genipin cross-linked CPP−CS NPs (A′, B′, C′) under different simulated GI pH environments.

**Table 2. Effects of Digestion Enzymes on Particle Size, Polydispersity index (PDI) Value, and Surface Charge (Zeta Potential) of the Genipin Cross-Linked CPP−CS NPs (G-CPP−CS NPs)[a]**

| sample | mean particle size (nm) | PDI | zeta potential (mV) |
|---|---|---|---|
| G-CPP−CS NPs | 245.3 ± 18.3 | 0.125 | 32.4 ± 6.1 |
| G-CPP−CS NPs incubated with SGF for 30 min | 262.7 ± 25.1 | 0.097 | 29.6 ± 11.5 |
| G-CPP−CS NPs incubated with SGF for 120 min | 251.8 ± 31.3 | 0.176 | 32.6 ± 7.5 |
| G-CPP−CS NPs incubated with SIF for 30 min | 523.8 ± 62.9 | 0.104 | 34.4 ± 5.6 |
| G-CPP−CS NPs incubated with SIF for 120 min | 1388.9 ± 152.1 | 0.285 | 32.1 ± 5.3 |

the prerequirement for intestinal mucosal delivery of therapeutics.

**Structure of Nanoparticles under Simulated GI Enzyme Conditions.** Despite the genipin-cross-linked CPP−CS NPs were able to maintain their stability under the GI pH environments, the presence of digestion enzymes was another big challege for them. To investigate the effects of digestion enzymes on the physicochemical properties of the polymer nanoparticles, equal amounts of the purified genipin-cross-linked CPP−CS NPs were incubated in SGF and SIF for 2 h, respectively. After incubation for 30 and 120 min, the nanoparticle samples were isolated from the SGF and SIF according to the centrifugal purification method as mentioned above. Their structure were characterized by TEM, DLS, and zeta-potential measurement. After incubation with SGF for either 30 or 120 min, no significant changes could be observed in the particle size, PDI value, and zeta potential of the genipin-cross-linked CPP−CS NPs compared with those of the original ones (Table 2).

It can be seen from Figure 7A,B that the nanoparticles remained stable and dispersed well after incubation with the SGF for either 30 and 120 min, which was consistent with the DLS results. In fact, the stability of nanocarriers in gastic fluid has attracted a lot of attention in the rational design of oral delivery nanodevices. It was found that the negatively charged nanodevices, such as poly(lactic acid) (PLA) nanoparticle and [32] $\beta$-lactoglobulin ($\beta$-lg)-stabilized emulsions,[33,34] underwent aggregation or flocculation in gastric conditions, which were mainly caused by neutralization of their surface charge. Comparatively, in the present study, the genipin-cross-linked CPP−CS NPs were stable and well dispersed in SGF, which

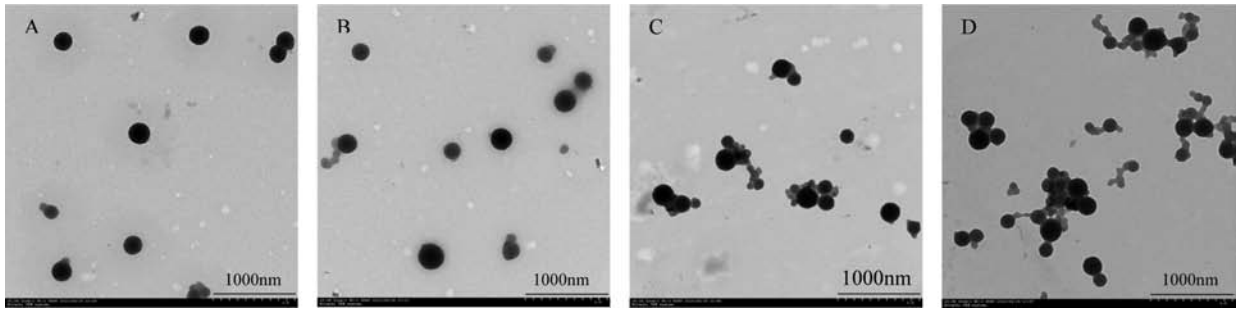

**Figure 7.** TEM images of the genipin-cross-linked CPP−CS NPs under simulated gastric fluid for 30 min (A) and 120 min (B) and under simulated intestinal fluid for 30 min (C) and 120 min (D).

dx.doi.org/10.1021/jf5046766 | J. Agric. Food Chem. 2014, 62, 12443−12452

should be mainly attributed to their highly positive surface charge. It could be concluded that pepsin in the stomach had little impact on the colloid structure and physicochemical properties of the genipin-cross-linked CPP−CS NPs.

After incubation with the SIF for 30 min, the particle size increased from 245.3 ± 18.3 to 523.8 ± 62.9 nm and further sharply to 1388.9 ± 152.1 nm when the incubation time was prolonged to 120 min (Table 2). Meanwhile, the PDI of the nanoparticle suspension increased to 0.285 (Table 2) with the incubation time of 120 min, which indicated the increased heterogeneity of the nanoparticle suspension. Observed with TEM (Figure 7C), it could be seen that aggregations of the genipin-cross-linked CPP−CS NPs appeared after the nanoparticles were incubated with SIF for 30 min. The degree of aggregation increased with prolonged incubation time. When the nanoparticles were incubated with SIF for 120 min, much bigger clusters of the nanoparticles could be seen (Figure 7D), compared with those with an incubation time of 30 min (Figure 7C). The nanoparticles inside the aggregations/clusters were still integral and compact. Therefore, it could be concluded that the increase of particle size was mainly caused by the aggregation of the nanopaticles, rather than the swelling of the nanoparticles. Similar results were also reported by Tobío et al., that PLA nanoparticles interacted with the digestive enzymes, thus leading to their agglomeration in the incubation medium.[35]

**In Vitro Release Profile of EGCG from the CPP−CS NPs and the Genipin-Cross-Linked CPP−CS NPs in Simulated GI Environments.** The encapsulation efficiencies of EGCG in the CPP−CS NPs and genipin-cross-linked CPP−CS NPs were around 71% in the present stduy, which was consistent with our previous result.[21] The in vitro release of EGCG from the CPP−CS NPs and the genipin-cross-linked CPP−CS NPs in simulated gastric and intestinal environments is shown in Figure 8. Compared with the non-cross-linked nanoparticles, cross-linking the CPP−CS NPs with genipin significantly ($p < 0.05$) reduced the burst release or leakage of EGCG from the CPP−CS NPs either in simulated gastric or in intestinal environments. It should be related to the significantly enhanced structure stability of the nanoparticles in simulated gastric and intestinal environments after cross-linking with genipin (Figure 6). Furthermore, for the genipin-cross-linked CPP−CS NPs, the release of EGCG from the nanoparticles slowed significantly ($p < 0.05$) to a much more controllable manner with the increase of the cross-linking degree. This meant that the controlled release profile of the EGCG from the nanoparticles could be modulated effectively through changing the genipin cross-linking degree. For the genipin-cross-linked nanoparticles, the release rate of EGCG in the simulated intestinal environment was higher than that in the gastric environment, which should be caused by the instability and aggregation of the nanoparticles under intestinal conditions (Figure 7). This release profile was especially desirable for oral delivery systems. In Figure 8B, the decrease of the measured release rate after 120 min was mainly caused by the instability and degradation of the EGCG under neutral and alkaline environments,[36,37] which also indicated it was necessary to encapsulate EGCG in polymer nanoparticles. Preventing the burst release of loading drugs, especially small molecular and hydrophilic drugs, from the delivery systems in the GI tract is important. The results in the present study indicated that the release profile of the payloads from the genipin-cross-linked CPP−CS NPs could be adjusted through changing the genipin cross-linking degree, which would favor the controlled release of the payloads at the sites of their action.

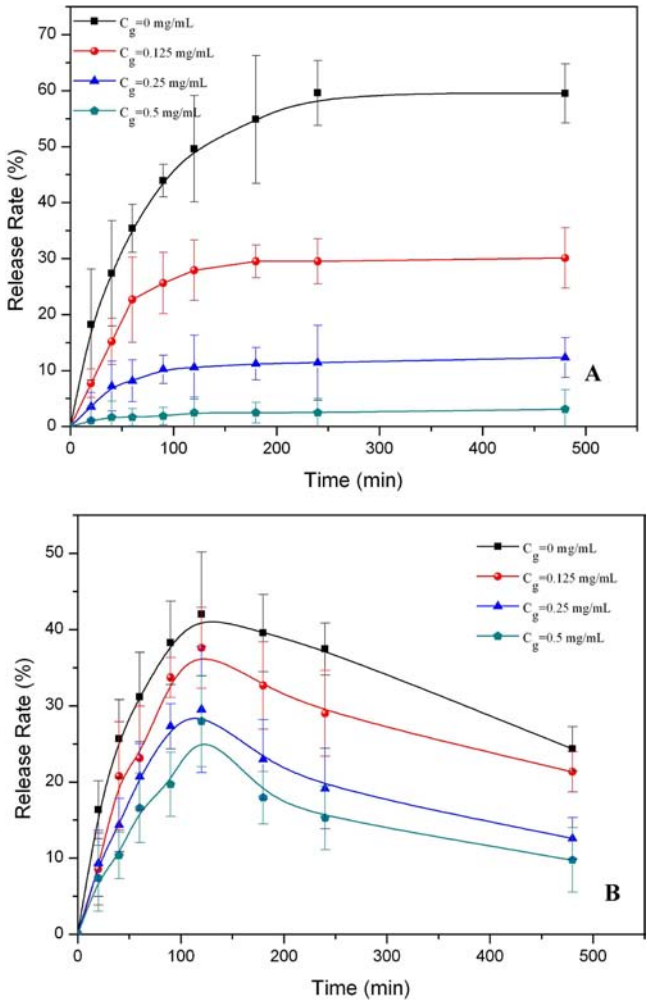

**Figure 8.** Release profile of EGCG from the CPP−CS NPs and the genipin-cross-linked CPP−CS NPs in simulated gastric (A) and intestinal (B) environments.

**Anticancer Activities of the EGCG-Loaded CPP−CS NPs Cross-Linked with Genipin.** The cytotoxicity of the EGCG-loaded CPP−CS NPs cross-linked with genipin against gastrointestinal cancer cells (human gastric BGC823 cells) and human liver HepG2 cells was investigated. In our previous studies, it had been found that the CPP−CS NPs could significantly enhance the intestinal absorption of EGCG in an in vitro cell assay, and the uptake of the nanoparticles played an important role in this process.[12] Generally, the oral drugs and delivery systems would first transport to the liver. To evaluate the anticancer potential of the EGCG-loaded CPP−CS NPs cross-linked with genipin, we conducted a trypan blue assay to determine gastric cell and live cell density. The viable cells could exclude the trypan blue dye, which could not be stained. The trypan blue assay showed that the EGCG-loaded CPP−CS NPs cross-linked with genipin exhibited cell growth inhibition similar to that of EGCG (Figure 9). The naked CPP−CS NPs cross-linked with genipin did not show cytotoxicity against the cells. In BGC823 cancer cells, the $IC_{50}$ values of the EGCG-loaded CPP−CS NPs cross-linked with genipin and free EGCG were 0.107 and 0.123 mmol/L (calculated in terms of EGCG concentration), respectively, which in HepG2 cells were 0.208

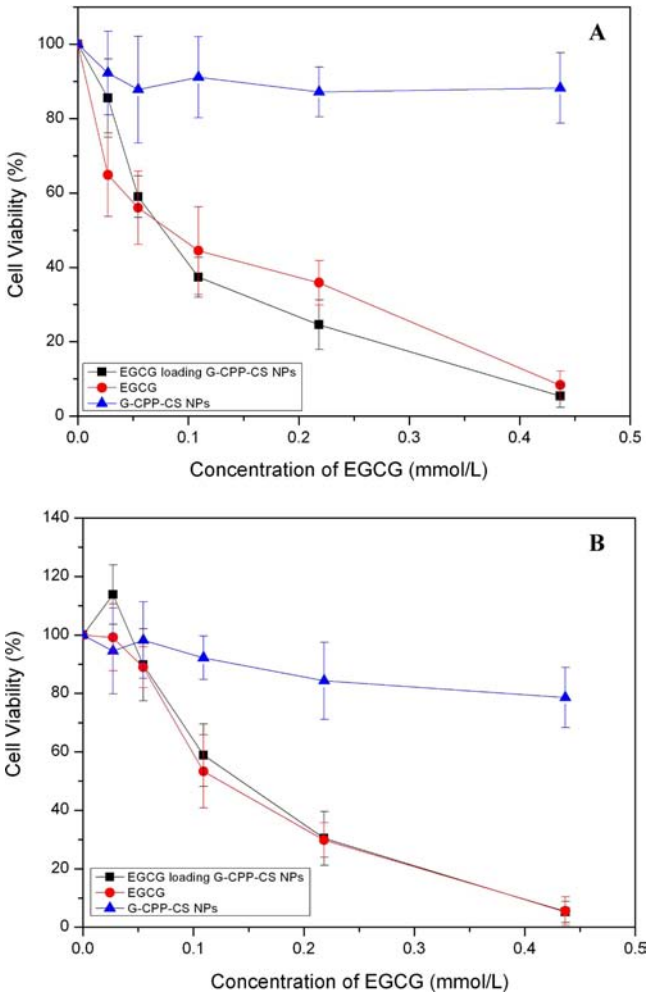

**Figure 9.** Cell viability of the human gastric BGC24 (A) and liver HepG2 (B) cancer cells incubated with the CPP−CS NPs cross-linked with genipin (G-CPP−CS NPs), EGCG, and EGCG-loaded CPP−CS NPs cross-linked with genipin (EGCG loading G-CPP−CS NPs).

and 0.193 mmol/L, respectively. This meant that encapsulation of EGCG in the nanoparticles maintained its anticancer activities. Similar results in the cytotoxicity of the polyphenol-loaded nanoparticles against cancer cells were also reported in previous studies. Majumdar et al. found that nano-luteolin encapsulated in PLA−polyethylene glycol ether (PEG) nanoparticles showed anticancer activities similar to those of the free luteolin.[38] Shutava et al. reported that encapsulation of EGCG in the gelatin-based nanoparticles with a surrounding layer-by-layer shell retained its biological activity as potently as free EGCG.[39] The animal studies about the in vivo bioavailability and cancer prevention functions of the EGCG-loaded CPP−CS NPs cross-linked with genipin will be further investigated in our following studies.

In conclusion, novel biopolymer nanoparticles with significantly improved stability and adjustable release profile in simulated GI environments were successfully developed through cross-linking the CPP−CS NPs with genipin at different cross-linking degrees. Genipin cross-linking represented an efficient, simple, and green method to enhance the stability of the amine-group-containing biopolymer nanoparticles and to adjust their release profile under harsh GI environments, which favors the controlled release of the payloads at the sites of their action. The structure behaviors of the biopolymer nanoparticles under simulated GI conditions were thoroughly characterized, providing basic information for the rational design of oral delivery nanoparticles. In addition, the established centrifugal purification method will provide technical reference for further purification of other polymer nanoparticles. The EGCG-loaded CPP−CS NPs cross-linked with genipin demonstrated significant anticancer activities, similar to that of free EGCG. Therefore, the novel polymer nanoparticles showed promise as an efficient oral delivery vehicle of polyphenols.

acid biosynthesis and fat partitioning. Recently, our research group described the effect of RPD in combination with *n*-3/*n*-6 PUFA-containing plant oils, linseed oil (lipids high in *n*-3 PUFA), and sunflower seed oil (lipids high in *n*-6 PUFA) on carcass traits, meat quality, and fatty acid profile in porcine muscle of Landrace pigs.[23] We hypothesize that RPD in combination with *n*-3/*n*-6 PUFA-containing plant oil supplementation led to an increase of IMF contents including higher accumulation of precursor and de novo synthesized long-chain PUFA in muscle associated with minor effect on back fat tissue of pigs. The focus of the present study was to investigate protein expression levels of transcription factors and lipogenic enzymes related to the contents of fatty acid products in muscle, back fat, and liver of pigs fed RPD/high protein diet (HPD) supplemented with plant oils (linseed oil/sunflower seed oil).

## MATERIALS AND METHODS

**Experiment.** In total 40 male Landrace pigs (castrates) were used in the diet experiment. The animals were individually housed and allocated into five feeding groups (each $n$ = 8) at a live weight of approximately 60 kg (Table 1). The pigs were fed ad libitum from 60 to 100 kg live weight and restricted to 2.8 kg/day until 120 kg. The animals in the experimental groups (1−4, Table 1) were fed with two different levels of protein and two different types of vegetable oil. The animals in the control group were fed with a normal pig diet without plant oil supplementation. The chemical and fatty acid composition of the diet of the five groups (HPD-SO, HPD-LO, RPD-SO, RPD-LO, and CON) are presented in Table 1 (Hohburg Mineralfutter, Lossatal, Germany). The diet experiment was previously described in detail.[23] Briefly, the HPD was formulated to contain 19.6% crude protein, and the RPD was formulated to contain 15.5% crude protein. Sunflower oil was used in the diet groups HPD-SO and RPD-SO and linseed oil in diet groups HPD-LO and RPD-LO as fat sources. The diets contained the same level of metabolizable energy (ME) of approximately 13.6 MJ/kg. The feed intake acquisition data was performed for each single animal. The pigs were weighed during the diet experiment once a week. The pig experiment was carried out at the facilities of University of Rostock (Germany), Faculty of Agricultural and Environmental Sciences. All experiments were conducted simultaneously to avoid seasonal effects between the different feeding groups. All animals were slaughtered at an average live weight of 120 kg in the abattoir of the Leibniz Institute for Farm Animal Biology in Dummerstorf (Germany). The slaughter and dressing procedures were in accordance with EU specifications. Immediately after slaughtering, tissue samples were collected from the right side of the carcass. *Longissimus* muscles and back fat, directly located over the muscle, were taken from the 13th/14th rib, snap-frozen, and stored at −80 °C until analysis. The liver samples were taken from the top of the Spigelian lobe, snap-frozen, and stored at −80 °C until analysis.

**Protein Expression Analysis via Western Blotting.** Proteins were extracted by homogenizing muscle, liver, and back fat samples in ice-cold lysis buffer (1 g/L Triton X-100, 50 mmol/L HEPES/Tris, 4 mmol/L EGTA, 10 mmol/L EDTA, 100 mmol/L $\beta$-glycerophosphate, 15 mmol/L tetrasodium pyrophosphate, 5 mmol/L sodium orthovanadate, 2.5 mmol/L sodium fluoride with protease and phosphatase inhibitors, pH 7.4) using TissueRuptor (Quiagen, Hilden, Germany). After centrifugation (1000*g*, 10 min, 4 °C), clear protein supernatant aliquots (10 $\mu$g) were collected, analyzed for protein concentration (Bio-Rad protein assay cat. no. 500-0006, Munich, Germany) by using microtiter plates and a plate reader (SynergyMx, Biotek, Germany), and stored at −20 °C until further analysis. Post a denaturing protein sample pretreatment [thawing of protein samples, adding blue loading buffer (Cell Signaling Technology, Boston, USA), at 94 °C 4 min], proteins (10 $\mu$g/lane) were separated by using self-prepared SDS−PAGE Maxi Gels (Maxi gel casting module; Roth, Karlsruhe, Germany) (7.5% Tris-HCl, 1.0 mm, 43 well) in a Maxi Buffer tank with gel running buffer (cat. no. 3060.1; Roth, Karlsruhe, Germany) with electrophoresis constant power supply (Consort, Turnhout, Belgium). Subsequently, proteins were transferred (90 min, 1.0 mA/cm$^2$) to a PVDF membrane (Roth, Karlsruhe, Germany) with a semidry blotting unit (Hoefer, San Francisco, CA, USA). Nonspecific binding sites were blocked with skim milk powder in TBST (w/v = 5%). For the recognition of pSREBP-1c (125 kDa) the PVDF

membrane was incubated with specific primary antibody (sc-367, Santa Cruz Biotechnology, Santa Cruz, CA, USA), and for mSREBP-1c (68 kDa) the specific primary antibody (sc-366, Santa Cruz Biotechnology, Santa Cruz, CA, USA) was used, overnight at 6 °C. After washing, the PVDF membrane was probed with the secondary antibody goat anti-rabbit IgG-HRP (Santa Cruz Biotechnology, Santa Cruz, CA, USA) during 90 min incubation at room temperature, followed by washing three times with TBST and water. For visualization, membranes were developed with SuperSignal West FEMTO chemiluminescent agent (ThermoScientific, Schwerte, Germany). Membranes were scanned with a Chemiluminescence Imager (Intas Science Imaging Instruments, Goettingen, Germany) and band intensities were densitometrically evaluated using LabImage 1D L340 Electrophoresis Software (Kapelan Bio-Imaging, Leipzig, Germany). For recognition of ACC, the primary antibody (ab72046, abcam, Cambridge, U.K.) for FAS (SC-20140, Santa Cruz Biotechnology, Santa Cruz, CA, USA) and for SCD-1 (PAB9094, Abnova, Taipei, Taiwan) was used. For each protein, the same procedure with the same secondary antibody (Rabbit TrueBlot anti-Rabbit IgG HRP, 18-8816, eBioscience, San Diego, CA, USA) was performed as for the SREBP-1c. Western blot analyses were performed in triplicate, applying all 40 individual protein samples per tissue of all five diet groups per gel. To exclude chemiluminescent protein signal intensity differences between the three repeated blots as factors influencing protein expression data, individual protein expression values were normalized to tubulin intensity for all investigated protein expression values per blot. Statistical evaluation was performed as described in the statistical analysis section.

**Lipid Extraction and Fatty Acid Analysis.** Samples of muscle (approximately 2.0 g), liver (approximately 2.0 g), and back fat (approximately 0.5 g) were thawed at 4 °C. The detailed sample preparation procedure has been previously described by Nuernberg et al.[3] Briefly, after homogenization (Ultra Turrax, IKA, Staufen, Germany; T25, 3 × 15 s, 12,000 rpm) and the addition of the fatty acid C19:0 as an internal standard, the total lipids were extracted in duplicate using chloroform/methanol (2:1, v/v) at room temperature. All of the solvents contained 0.005% (w/v) of *tert*-butylhydroxytoluene (BHT) to prevent the oxidation of PUFAs. The extraction mixture was stored at 5 °C for 18 h in the dark and subsequently washed with 0.02% aqueous $CaCl_2$. The organic phase was dried with $Na_2SO_4$ and $K_2CO_3$ (10:1, w/w), and the solvent was subsequently removed under nitrogen at room temperature. The lipid extracts were redissolved in 300 μL of toluene, and a 25 mg aliquot was used for methyl ester preparation. Next, 2 mL of 0.5 M sodium methoxide in methanol was added to the samples, which were shaken in a 60 °C water bath for 10 min. Subsequently, 1 mL of 14% boron trifluoride ($BF_3$) in methanol was added to the mixture, which was then shaken for an additional 10 min at 60 °C. Saturated $NaHCO_3$ (2 mL) was added, and the fatty acid methyl esters (FAMEs) were extracted three times in 2 mL of *n*-hexane. The solvent containing the FAMEs was reduced to dryness under an oxygen-free nitrogen stream, and the FAMEs were resuspended in 100 μL of *n*-hexane and stored at −18 °C until used for gas chromatography (GC) analysis. The FAMEs were evaporated under an oxygen-free nitrogen stream and dissolved in *n*-heptane for GC analysis. The fatty acid analysis of the muscle lipids was performed using capillary GC with a CP-Sil 88 CB column (100 m × 0.25 mm, Chrompack-Varian, Lake Forest, CA, United States) that was installed in a PerkinElmer gas chromatograph Autosys XL with a flame ionization detector and split injection (PerkinElmer Instruments, Shelton, CT, United States). The detailed GC conditions were recently described by Shen et al.[24] Briefly, the initial oven temperature was 150 °C, which was held for 5 min; subsequently, the temperature was increased to 175 °C and then to 200 °C at a rate of 2 °C $min^{-1}$ and held for 10 min. Finally, the temperature was increased to 225 °C at a rate of 1.5 °C $min^{-1}$ and held for 25 min. Hydrogen was used as the carrier gas at a flow rate of 1 mL $min^{-1}$. The split ratio was 1:20, and the injector and detector were set at 260 and 280 °C, respectively.

**Statistics.** The effects of the RPD in combination with vegetable oils on protein expression and fatty acid concentrations were estimated by one-way analysis of variance with fixed factor group (groups 1 to 5) using the GLM procedure of the SAS software system (SAS Systems, Release 9.2, SAS Institute Inc., Cary, NC). The least-squares means (LSMs) and the standard errors (SEM) of the LSMs are given in the tables. All post hoc tests were performed at a significance level of $p \leq 0.05$ using the Tukey−Kramer correction for multiple tests.

## RESULTS

**Protein Expression.** Protein expression of the transcription factor SREBP-1c precursor (pSREBP-1c) in muscle of the present study was not affected by diet; however the active nuclear form of SREBP-1c (mSREBP-1c) was significantly increased in muscle of HPD-SO-fed pigs compared to the pigs of the other diet groups (Figure 1). For SCD-1, the protein expression in *longissimus* muscle of pigs was not affected by different dietary protein level or linseed/sunflower seed oil supplementation. The expression of the cytosolic enzymes in pig muscle, ACC and FAS, was low, and no abundances were detected in the total muscle extract. In back fat, the expression

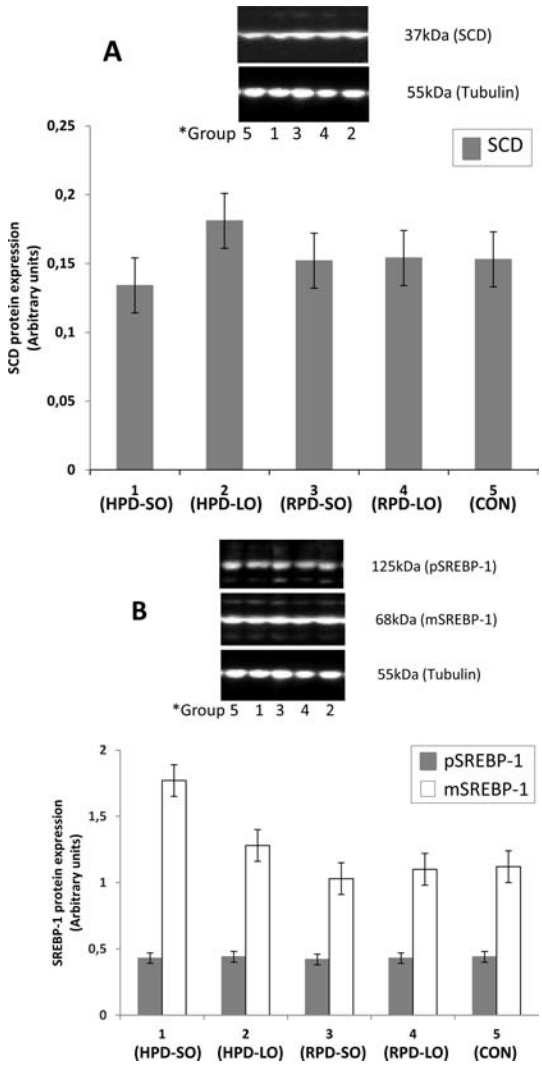

**Figure 1.** Protein expression of SCD (A) and pSREBP-1 and mSREBP-1 (B) in *longissimus* muscle of pigs fed different diets (normalized to tubulin); a, b: significant effect of diet, <0.05, *one selected sample per diet group. HPD-SO: High protein diet with sunflower oil. HPD-LO: High protein diet with linseed oil. RPD-SO: Reduced protein diet with sunflower oil. RPD-LO: Reduced protein diet with linseed oil. CON: Control.

of SREBP-1c precursor (pSREBP-1c) was not affected by different diets. RPD supplemented with linseed/sunflower seed oil significantly increased the mSREBP-1c expression in back fat compared with the control group, and showed a higher level compared with HPD groups; however the values did reach statistical significance (Figure 2). For ACC, FAS, and SCD-1, the protein expression in back fat of Landrace pigs was not affected by different dietary protein level or linseed/sunflower seed oil supplementation. In liver, the expression of transcription factors pSREBP-1c and mSREBP-1c and expression of the lipogenic enzyme SCD-1 were not affected by different dietary protein level or linseed/sunflower seed oil supplementation. Both ACC and FAS expression in liver of pigs in the control group was significantly higher compared with protein expression of RPD/HPD groups in combination with linseed oil or sunflower oil (Figure 3).

**Fatty Acid Concentrations.** The fatty acid concentrations of *longissimus* muscle, back fat, and liver in Landrace pigs fed diets with RPD/HPD supplemented with vegetables oils (sunflower seed oil/linseed oil) are shown in Tables 2, 3, and 4, respectively. In *longissimus* muscle, the sum concentration of all fatty acids (IMF) was not affected by diet and ranged between 1.29 and 1.52 g/100 g (Table 2). RPD in combination with linseed oil (RPD-LO) did not affect single and sum concentrations of MUFA and *n*-3 or *n*-6 PUFA in muscle of pigs compared with HPD in combination with linseed oil (HPD-LO). Furthermore, RPD in combination with sunflower oil (RPD-SO) did not affect single and sum fatty acids in muscle compared with HPD in combination with sunflower oil (HPD-SO). However, different plant oil supplementations resulted in significant changes in single and sum *n*-3 or *n*-6 PUFA concentrations in muscle as well as in RPD and HPD groups (Table 2). Linseed oil supplementation caused significantly higher single (18:3*n*-3, 20:5*n*-3, 22:5*n*-3) and sum *n*-3 fatty acid concentrations up to 113 mg/100 g in porcine muscle of RPD and HPD groups compared to sunflower oil supplemented RPD and HPD groups, except 22:6*n*-3. In muscle, diet did not affect the concentration of single SFA (14:0, 16:0, and 18:0). In back fat, the sum concentration of all fatty acids (fat content) was not affected by diet and ranged between 71.9 and 76.1 g/100 g (Table 3). As was shown for muscle, RPD in combination with linseed oil or sunflower seed oil (RPD-LO, RPD-SO) did not affect single and sum concentrations of SFA, MUFA, and *n*-3 or *n*-6 fatty acids in back fat of pigs compared to HPD in combination with linseed oil or sunflower seed oil (HPD-LO/HPD-SO). Different vegetable oil supplementations resulted in significant changes in single and sum MUFA, PUFA, and *n*-3 or *n*-6 fatty acid concentrations in back fat as well as in RPD and HPD groups (Table 3), expect for 22:6*n*-3. Linseed oil supplementation significantly decreased the *n*-6/*n*-3 PUFA ratio in back fat of RPD and HPD group compared to sunflower oil supplemented RPD and HPD groups from 6.4 to 7.2 to 1.3, respectively. As was shown in muscle and back fat, the sum concentrations of all fatty acids (fat content) in pig liver were not affected by diet and ranged between 3.04 and 3.30 g/100 g, and RPD in combination with linseed oil or sunflower oil (RPD-LO, RPD-SO) did not affect single and sum concentrations of SFA, MUFA, and *n*-3 or *n*-6 fatty acids in liver of pigs compared to high protein diet in combination with linseed oil (HPD-LO) (Table 4). Linseed oil supplementation caused significantly higher single (18:3*n*-3, 20:5*n*-3, 22:5*n*-3) and sum *n*-3 fatty acid concentrations up to 743 mg/100 g in porcine

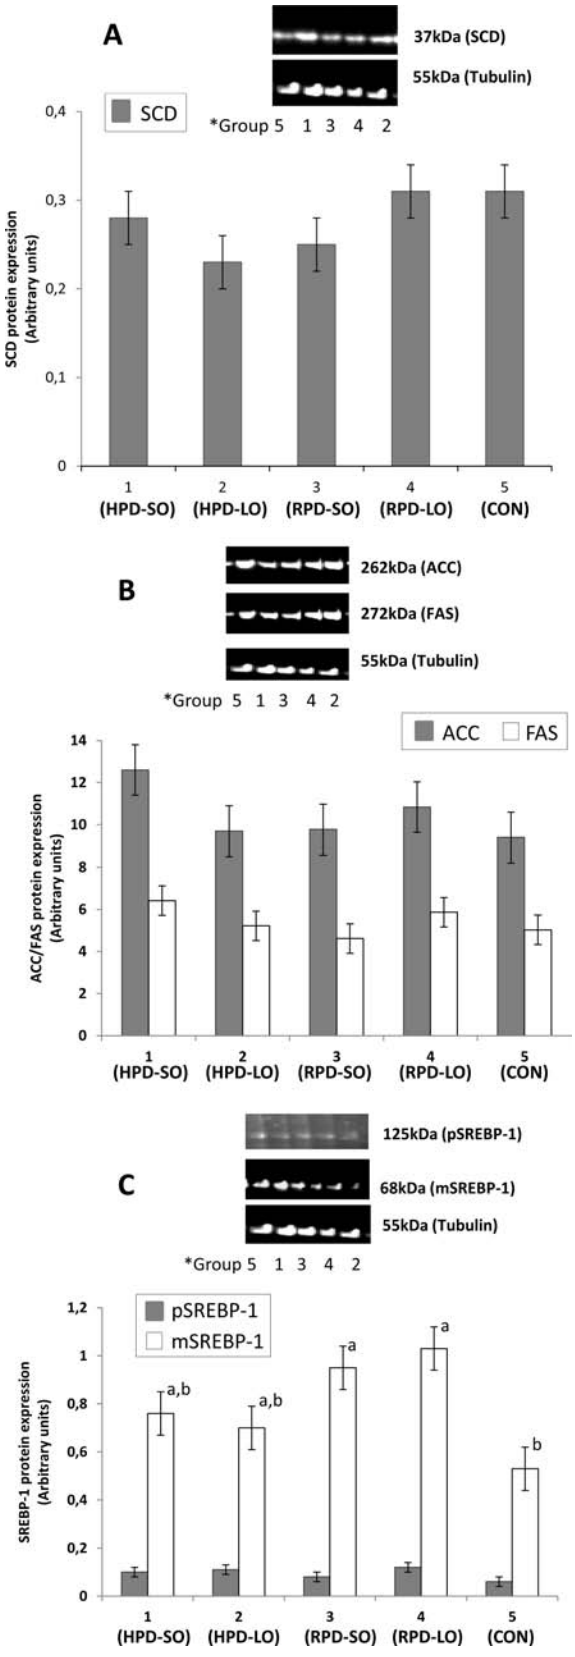

**Figure 2.** Protein expression of SCD (A), FAS and ACC (B), and pSREBP-1 and mSREBP-1 (C) in back fat of pigs fed different diets (normalized to tubulin); a, b: significant effect of diet, <0.05, *one selected sample per diet group. HPD-SO: High protein diet with sunflower oil. HPD-LO: High protein diet with linseed oil. RPD-SO: Reduced protein diet with sunflower oil. RPD-LO: Reduced protein diet with linseed oil. CON: Control.

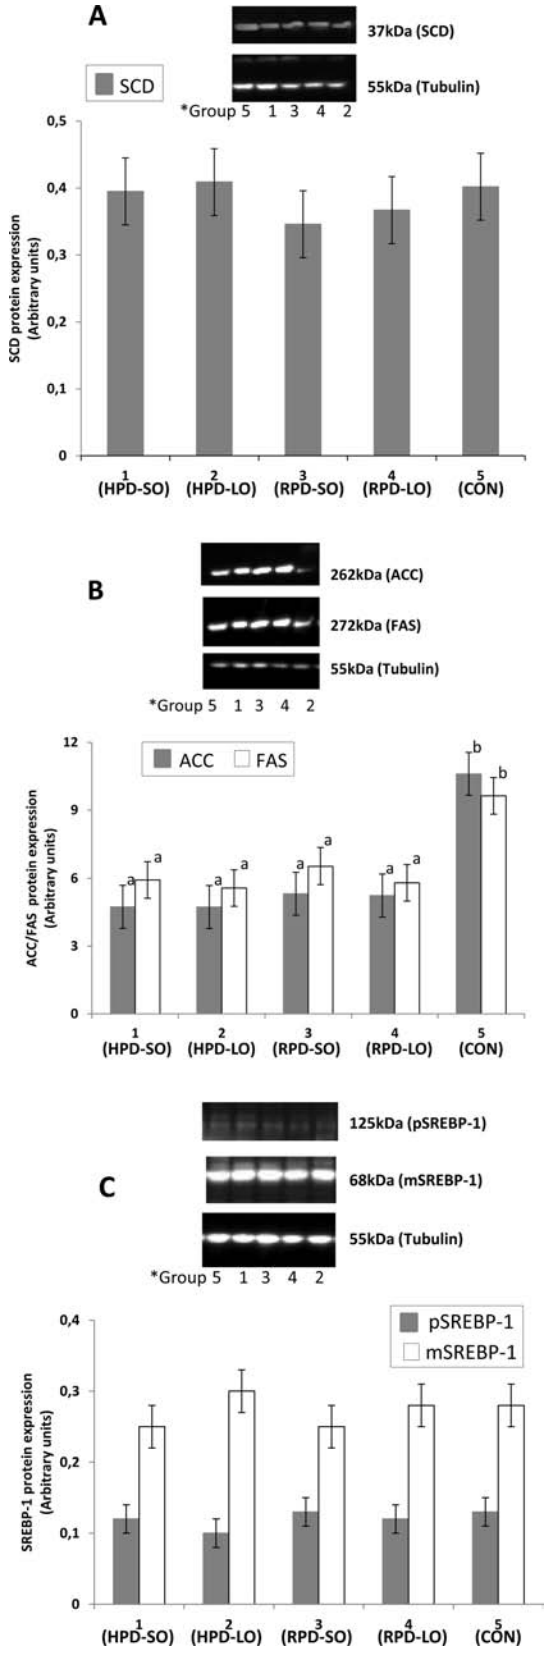

**Figure 3.** Protein expression of SCD (A), FAS and ACC (B), and pSREBP-1 and mSREBP-1 (C) in liver of pigs fed different diets (normalized to tubulin); a, b: significant effect of diet, <0.05, *one selected sample per diet group. HPD-SO: High protein diet with sunflower oil. HPD-LO: High protein diet with linseed oil. RPD-SO: Reduced protein diet with sunflower oil. RPD-LO: Reduced protein diet with linseed oil. CON: Control.

liver of RPD and HPD groups compared to sunflower oil supplemented RPD and HPD groups, except 22:6*n*-3.

## DISCUSSION

A number of studies have revealed that IMF and adipose tissue (back fat) contents in pigs might be affected independently by dietary means. Previous studies indicated that RPD intervention increased the IMF contents with much smaller/no effects on back fat content in pigs.[20,25−27] However, the mechanisms regulating de novo fatty acid synthesis and fat partitioning in different tissues in pigs are not completely understood.[17,18,20] Inadequate dietary protein and/or lysine limit protein synthesis and increase the amount of energy available for fat deposition, resulting in higher IMF. In addition, the IMF content varies in different pig breeds, fatty and lean pigs, fed RPD diet compared with control diets.[16,17,28] One explanation for higher IMF contents fed RPD in pigs might be the tissue-specific activation of expression of lipogenic enzymes which may lead to the increase of synthesis of de novo fatty acids in the muscle tissues. It is generally known that one of the key factors regulating the de novo synthesis of fatty acids and fat deposition is expression of lipogenic enzymes. The key enzyme involved in MUFA biosynthesis is stearoyl-CoA-desaturase (SCD-1).[20] SCD-1 is under control of transcription factors like SREBP-1c. It has been previously demonstrated that the increase of IMF content under RPD conditions was accompanied by increased SCD-1 expression levels in crossbred pigs.[18,20,25] In contrast to crossbreds, recent published results showed that the IMF content of Alentejana purebred (fatty) pigs did not respond to any dietary treatment.[17] Furthermore, different dietary amino acid levels (reduced lysine and/or high arginine and leucine contents) were reported to increase the IMF contents in pigs mediated via the upregulation of SCD-1 gene expression.[17,18,29] Madeira et al.[18] observed that dietary arginine supplementation did not affect the IMF content in male crossbred pigs (Duroc × Pietrain × Large White × Landrace) but increased amount of subcutaneous fat. In the same RPD study, with/without leucine supplementation elevated IMF contents were observed possibly caused by increased FAS and SCD-1 gene expression levels.[18] The hypothesis of the present study was that RPD in combination with *n*-3/*n*-6 PUFA containing plant oils (linseed oil/sunflower seed oil) could lead to an increase of IMF contents accompanied by a higher accumulation of de novo synthesized long-chain *n*-3/*n*-6 PUFA in pig muscle. This hypothesis rested on recent findings, which suggest that RPD results in elevated IMF deposition in pigs based on activated expression of lipogenic enzymes.[16,17,25] However, the results of the present study did not confirm the starting hypothesis and showed that the IMF contents in the lean Landrace pigs fed RPD/HPD (approximately 15.3% vs 19.5% of CP) combined with *n*-3/*n*-6 PUFA-containing plant oil supplementation were not affected by diet. Indeed, the muscle fatty acid concentrations of the present study appeared to be significantly affected by the diet, resulting in significantly higher single and sum *n*-3 PUFA concentrations (sum *n*-3 PUFA up to 113 mg/100 g muscle) in linseed oil-containing RPD/HPD groups compared to sunflower seed oil diet fed groups. However, this effect seems to be only caused by the use of different plant oil (linseed oil vs sunflower seed oil) and was not depending on RPD vs HPD intervention. As a result, the single and sum *n*-3/*n*-6 PUFA concentrations in muscle of RPD-LO/RPD-SO fed pigs showed no significant differences compared with the

corresponding concentrations of HPD-LO/HPD-SO fed animals. The results of the present study are not in line with those of Teye et al.,[30] who reported that PRD in combination with palm kernel, palm, or soybean oil supplementation led to significantly decreased single *n*-3/*n*-6 PUFA and sum PUFA contents in muscle of crossbreds (Duroc × Large White × Landrace). RPD intervention per se resulted in increased single *n*-3 PUFA and sum PUFA contents in muscle of Wujin pigs,[31] but in significantly lower contents of single *n*-3/*n*-6 PUFA and sum PUFA in muscle of crossbred pigs (Landrace × Large White).[8,18] It has been previously demonstrated that the expression/activity of lipogenic enzymes have decisive control on IMF deposition in pigs. SREBP-1c, a key transcription factor, regulates the expression of lipogenic enzymes including

ACC, FAS, and SCD-1.[18,20] The protein expression of the SREBP-1c precursor (pSREBP-1c) in muscle of the present study was not affected by RPD compared with HPD and control diet, except increased expression level of SREBP-1c (mSREBP-1c) in muscle of HPD-SO-fed pigs compared to the other diet groups. Based on the regulatory function of SREBP-1c for expression of lipogenic enzymes, also the protein expression levels of SCD-1 in muscle of the present study highlighted no significant differences between RPD and HPD intervention. It has been shown that $n$-3 PUFA can inhibit transcription of lipogenic genes by suppressing SREBP-1c gene expression or inhibiting the proteolytic release of nuclear SREBP-1c in bovine muscle and adipose tissues.[32] It is generally known that $n$-3 and $n$-6 PUFA as ligands/modulators for nuclear receptors suppress de novo fatty acid synthesis; $n$-3 PUFA seems to be more potent than $n$-6 PUFA.[33] Based on present results, we assume that the unaffected SCD-1 expression in muscle of Landrace pigs fed RPD in combination with $n$-3/$n$-6 PUFA-containing plant oils may be explained by the mentioned opposite effects of RPD and $n$-3/$n$-6 PUFA supplementation with respect to protein expression levels. This can potentially result in their canceling out the effects of each other. This is reflected in SCD-1 expression levels and single and sum MUFA muscle concentrations of the present study resulting in both unchanged SCD-1 expression levels and unchanged MUFA concentrations within the RPD and HPD groups. Intervention studies using RPD intervention without $n$-3/$n$-6 PUFA-containing plant oil supplementation revealed increased single and sum MUFA contents in pig muscle caused by enhanced SCD expression levels, the key enzyme involved in MUFA biosynthesis, compared with control diets.[18,30,31] Furthermore, the protein expression of the lipogenic enzymes ACC and FAS, key rate limiting enzymes in the de novo pathway of fatty acid synthesis in pig muscle of the present study, seems to be on a quite low level and no abundances were detected in the total muscle extract. The corresponding concentrations of single SFA, e.g., 14:0, 16:0, and 18:0, and sum SFA were not affected by either the protein content or the type of oil supplementation. Madeira et al.[17] showed that RPD intervention per se resulted in significantly higher SFA contents relative to control diet in pig muscle of Alentejana and commercial crossbred (Large White × Landrace × Pietrain), despite no significant effect of RPD on relative mRNA level of key genes controlling fatty acid deposition, such as ACC and FAS and also fatty acid-binding protein 4 (FABP4), lipoprotein lipase (LPL), PPAR alpha (PPARa), and PPARg. In addition, Doran et al.[20] fed RPD in combination with palm kernel, palm, or soybean oil supplementation to crossbred pigs and reported elevated muscle concentrations of 14:0, 16:0, and total SFAs caused by increased ACC and FAS protein expression level in RPD compared with control intervention.

It has been previously demonstrated that increases in the de novo biosynthesis of fatty acids caused by RPD are accompanied by rather low effects on back fat tissue in pigs. This seems to be due to tissue-specific activation of expression of lipogenic enzymes based on RPD.[17,18,20] These findings are consistent with results of the present study, that RPD intervention led to an increase of protein expression of the active nuclear form of SREBP-1c (mSREBP-1c) in back fat of pigs, but not in muscle compared to the control diet. This is in agreement with results of Zhao et al.,[22] who investigated the impact of dietary protein on lipid metabolism in back fat of different old Wujin pigs. Both the relative mRNA level and protein expression of SREBP-1c in 60 and 100 kg pigs were increased by RPD (14% CP) diet compared with HPD (18% CP). In contrast, Madeira et al.[17,18] reported in two studies investigating the effect of RPD on lipid metabolism in back fat of Alentejana purebred and/or Large White × Landrace × Pietrain crossbred pigs that dietary protein level did not significantly affect the relative mRNA level of SREBP-1c and other genes controlling the fatty acid metabolism, e.g., ACC, FAS, LPL, PPARa, FABP4. Even lower dietary protein level (6% CP in dry matter) compared to before discussed RPD studies induced only modest variations in the adipose tissue proteome of newborn Landrace piglets.[34] Also in the present study, besides SREBP-1c, the protein expression of the

lipogenic enzymes of SCD-1, ACC, and FAS was not affected by dietary protein level or type of *n*-3/*n*-6 PUFA-containing plant oil in back fat of Landrace pigs. Consequently, the concentrations of single and sum SFA in back fat of pigs were not affected by RPD or HPD compared with the control group. Furthermore, based on unchanged SCD-1 expression levels, the single and sum MUFA concentrations in back fat of Landrace pigs were not diet affected, with the exception of increased sum MUFA concentrations in the back fat of the control group compared with the RPD/HPD groups. In contrast, Zhao et al.[22] reported that the relative mRNA abundances for ACC and FAS in back fat of 60 and 100 kg Wujin pigs were significantly increased by RPD compared with HPD intervention. This also suggests differences in response of different dietary protein levels on lipid metabolism in adipose tissues between lean pigs (Landrace) and fatty pigs (Wujin) and also crossbred pigs. The tissue-specific response of RPD vs HPD of the present study is also reflected by the protein expression of SCD-1, FAS, ACC, pSREBP-1c, and mSREBP-1c in liver of pigs. In contrast to muscle and back fat, both dietary protein level and type of *n*-3/*n*-6 PUFA-containing plant oil revealed no significant differences in protein expression of SCD-1, FAS, ACC, pSREBP-1c, and mSREBP-1c in the liver of pigs. In addition, independent of dietary interventions the overall expression levels of SCD-1, FAS, ACC, pSREBP-1c, and mSREBP-1c in muscle, back fat, and liver tissues of the present study were different and tissue-specific. The highest pSREBP-1c and mSREBP-1c expression levels (based on arbitrary units) were detected in muscle and the lowest ones in liver. In back fat, there were found the highest ACC expression levels (based on arbitrary units), and the highest SCD-1 expression levels (based on arbitrary units) were measured in liver tissue compared to muscle of pigs.

Our hypothesis that RPD in combination with *n*-3/*n*-6 PUFA-containing plant oils would lead to an increase of IMF contents including higher accumulation of de novo synthesized *n*-3/*n*-6 PUFA in muscle was not confirmed in Landrace pigs. The protein expression level of lipogenic enzymes in muscle was not increased as expected. One explanation of unchanged IMF contents in pigs could be based on mutual effects of RPD intervention and *n*-3/*n*-6 PUFA-containing plant oil supplementation on de novo fatty acid synthesis and IMF deposition. Further studies should clarify if (i) an RPD-based diet intervention increases expression of lipogenic enzymes and (ii) an *n*-6/*n*-3 PUFA supplementation suppresses the lipogenic enzyme expressions, and subsequently if the effects cancel each other out using a combination of RPD and *n*-6/*n*-3 PUFA supplementation in Landrace pigs. In the literature there exists a discrepancy of results feeding RPD with respect to lipid metabolism in muscle and adipose tissues in pigs. This might be also explained by different genetic backgrounds which are expressed also in different results in studies of purebred vs crossbred pigs and should be further investigated.

**Figure 1.** Structure of BEA and ENs. ENA, enniatin A; $ENA_1$, enniatin $A_1$; ENB, enniatin B; $ENB_1$, enniatin $B_1$; BEA, beauvericin.

Because of the susceptibility to mycotoxin contamination in mixed feeds and the presence of these mycotoxins in animal tissues, the aim of this work was to develop a new rapid, sensitive, and reproducible analytical strategy for the determination of ENs and BEA in feeds for farmed fish and fish tissues by LC-MS/MS-LIT.

## MATERIALS AND METHODS

**Chemical and Reagents.** All solvents (acetonitrile and methanol) were purchased from Merck (Darmstadt, Germany). Deionized water (<18 MΩ cm resistivity) was obtained from a Milli-Q water purification system (Millipore Corp., Bedford, MA, USA). Ammonium formate ($HCO_2NH_4$, 97%) was supplied by Sigma-Aldrich (St. Louis, MO, USA). All solvents were passed through a 0.22 μm cellulose filter from Membrane Solutions (Dallas, TX, USA).

The stock standard of BEA was purchased from Sigma-Aldrich. EN toxin solutions were provided by Biopure (Tulln, Austria). Individual stock solutions of BEA, ENA, $ENA_1$, ENB, and $ENB_1$ with concentrations of 1000 mg/L were prepared in methanol. They were stored in glass-stoppered bottles and darkness in security conditions at −20 °C. These stock solutions were then diluted with pure methanol to obtain the appropriate working solutions (ranging from 0.01 to 100 μg/kg) and were stored in darkness at 4 °C.
