**Validation Analysis.** Although the total Mn validation could be conducted using only reference material after microwave acid extraction and ICP-MS analysis, there is no hazelnut-type reference material. Consequently, additional validation was performed by AAS via total manganese determination in our study. The method detection and quantification limits for AAS analysis were 0.64 and 2.13 mg $kg^{-1}$, respectively. Under the optimum conditions, the accuracy was evaluated using recovery studies. Manganese recoveries of 100.0, 94.7, and 102.4% and manganese contents of 74.6 ± 1.0, 85.8 ± 2.8, and 65.5 ± 10.9 mg $kg^{-1}$ were determined by AAS for hazelnut samples 1, 2, and 3, respectively. The total manganese levels in samples 1, 2, and 3 were determined to be 79.9 ± 1.3, 95.5 ± 1.9, and 76.7 ± 9.3 mg $kg^{-1}$, respectively, based on the wet weight basis by ICP-MS, and the moisture

levels for the samples were 2.03, 1.65, and 1.89%, respectively, as shown in Table 1. The instrumental detection and quantification limits for ICP-MS (also for further HPLC-ICP-MS) analysis were calculated as 3 and 10 times the standard deviations of the concentrations derived from the lowest detectable and quantified levels, respectively, near the reagent blanks with reasonable certainty ($k = 3$, a confidence level of 99.86%).[17,36] The sample mass and dilution factors were considered to calculate the method detection and quantification limits. The limits of detection and quantification for manganese by ICP-MS were 0.031 and 0.103 mg kg$^{-1}$, respectively. The calibration equation was $y = 38593x$, with a correlation coefficient ($r^2$) of 0.999960. The intraday precision was 3.3%, whereas the interday precision was 4.5%. The intraday mean value was calculated from the relative standard deviation (%) of six separately prepared samples at the smallest concentration of manganese (0.5 $\mu$g L$^{-1}$) that were analyzed on the same day. Additionally, the interday mean value was calculated from the same smallest concentration of manganese analyzed over a period of a week.[12] Because of the lack of a standard reference material with the same matrix, the accuracy of the ICP-MS method was also evaluated by recovery studies. The recoveries were 100.3, 96.5, and 95.3% for samples 1, 2, and 3, respectively, by ICP-MS. Additionally, two different types of certified reference materials representing the defatted and fatty portions of the hazelnut samples were evaluated. The measured manganese concentration of 12.2 ± 3.4 mg kg$^{-1}$ obtained by ICP-MS after open-wet digestion was in good agreement with the certified value of 9.4 ± 0.9 mg kg$^{-1}$ at the 95% confidence level for wheat flour. In addition, the measured manganese concentration of 11.5 ± 1.7 mg kg$^{-1}$ was in good agreement with the standard value of 10 mg kg$^{-1}$ from the Conostan calibration and verification standard. Because microwave digestion systems are available in many laboratories, the open-wet digestion method was applied as an alternative to the microwave digestion system, and manganese contents of 84.2 ± 11.6, 88.0 ± 1.2, and 74.6 ± 6.1 mg kg$^{-1}$ were determined in the samples by ICP-MS. This method has proven the minimal effect of fat-bound manganese to total manganese levels and might serve as an alternative to microwave digestion. The paired $t$ test was applied to the AAS and ICP-MS results, from which no significant difference between the results at the 95% confidence level was observed.

Open-wet digestion was also applied to the defatted samples remaining after Soxhlet extraction to investigate whether the manganese originated primarily from the protein structures (the most abundant component after oil). The manganese concentrations in the defatted samples were found to be 49.0 ± 4.8, 43.0 ± 8.9, and 65.2 ± 10.2 mg kg$^{-1}$. According to these results, 54−87% of manganese may be associated with the protein components, with a maximum of 67% of the manganese observed to be associated with protein in sample 1, as discussed under HPLC-ICP-MS Analysis.

**In Vitro Bioaccessibility Studies.** The total concentration of metals in foods may not represent the bioavailable amounts for humans. A better approach to assess metal content is to determine the amount of metal released during gastrointestinal digestion.[12] For this purpose, pepsin, pancreatin, or *n*-octanol extraction processes were performed to determine the absorption levels of manganese through the stomach and intestinal pathway. The compatibilities for intestinal absorption of pancreatin and *n*-octanol were thus compared. As stated in our previous studies, *n*-octanol fractions cannot be used to assess the daily intake as an alternative to pancreatic digestion unless an appropriate correction factor is applied.[12,17] To determine this factor, spiked studies were performed, together with *n*-octanol fractionation by Mn(II) standard solutions, at two concentration levels (5 and 10 $\mu$g L$^{-1}$), and recoveries for the three hazelnut samples were 49.07, 34.1, and 39.5%. These values reflect the complexation possibilities of Mn(II) in the *n*-octanol fraction.[17] The recoveries of the samples were used as a correction factor for the *n*-octanol extraction results before comparison with pancreatic digestion. Nevertheless, higher digestible amounts were achieved using pancreatin. Kowalevska et al. determined the metal adsorption on activated carbon from a vegetable oil matrix. As a general approach, activated carbon adsorption represents any bound compounds that can be adsorbed onto the surface.[12,30] Activated carbon adsorption studies were thus performed to assess the presence of bound manganese species that are water- or organic solvent-soluble. Activated carbon can adsorb complexes and aromatic manganese-bound structures,[12] and one of these species may originate from the oily matrix (primarily from fatty acids) of hazelnut. Hazelnut contains a significant amount of fiber, containing approximately 5 and 10% crude and dietary fiber, respectively (Table 1). Previous studies have suggested that the dietary fiber present in many plants is important for metal absorption. Additionally, dietary fiber can facilitate Mn excretion and reduce its accumulation in many tissues.[37] These evaluations suggest that nondigestible or unavailable manganese levels might originate from the dietary fiber or crude fiber contents of nut matrices. The digestible or

absorbable fractions of manganese are shown in Table 4. The manganese levels in the water fractions were found to be 7.3−13.4 mg $kg^{-1}$, varying in the range from 9.6 to 14%. This fraction may represent the free Mn(II) or ionic Mn(II) originating from soluble manganese complexes, hydrolyzable lipids, or sugar compounds.[12] Soluble proteins might also be considered in this context. Because hazelnut predominantly contains oil and proteins, manganese complexes will associate with these structures. None of the organic solvents used in the fractionation analysis were sensitive enough, and validation studies will not be meaningful unless these groups can be precisely identified.[17]

The bioavailability was calculated by dividing the total contents of manganese after in vitro digestion by the contents of manganese in the microwave-assisted acid digests of the samples. The bioavailability of the manganese was found to be 57.6, 32.0, and 62.1% for samples 1, 2, and 3, respectively. The bioavailability of manganese from three hazelnut samples is presented in Table 4. The difference between the total and the gastrointestinal-digested amounts can be attributed to the unavailable manganese originating primarily from the dietary fiber-bound content, as mentioned above, and also to the manganese in particulate form. Importantly, a portion of unavailable manganese could become bioavailable if it can be directly absorbed in the stomach from calcium channels, such as in the form of calcium ions.[38] The pancreatin-digestible and activated carbon-adsorbable values as well as the pepsin- and gastrointestinal-digestible values showed similar tendencies. Because of these similar results, the approaches are interchangeable in assessing bioavailability. Additionally, the similarity of the pepsin and gastrointestinal (pepsin+pancreatin consecutive digestion) bioavailabilities shows that protein structures are the most important food components for manganese bioaccessibility, and the oil-bound structures have a minimal effect. Consequently, it can be concluded that most of the free and/or soluble Mn(II) originated from the water-extractable fractions, which together with the protein-bound manganese are important for hazelnut bioaccessibility. Thus, these fractions were undertaken for a hyphenated technique analysis. As expected, HPLC-ICP-MS provided valuable information regarding the free Mn(II) content and the soluble protein complexes. Only two peaks were extracted as water-soluble manganese fractions, corresponding to well-defined free manganese and most likely charged and complexed Mn(II), which coeluted on the column. As previously mentioned, nuts contain relatively high levels of protein compared to other plant materials,[39] as confirmed by our fractionation studies detailed above. For this reason, it is likely that this fraction is associated with soluble, protein-bound manganese. An elution solvent with an acceptable amount of methanol for ICP-MS analysis was also applied under different gradient elution conditions, and the two peaks were not well separated. This can be attributed to the two charged manganese species. The first peak contained 32.8% of the water-soluble manganese, and the second peak contained 18.2%. There were no significant variations among the samples after qualitative analysis, and for this reason, quantitative online analysis was applied for only one sample (sample 1). The other samples displayed similar chromatograms. The baselines between the extractions were monitored with Chromera software, and the two peaks were well differentiated from the baseline. Because manganese possesses only a single isotope ($^{55}Mn$), possible matrix interferences originating from $^{40}Ar^{14}N^{1}H^{+}$, $^{37}Cl^{18}O^{+}$, $^{40}Ar^{15}N^{+}$, $^{38}Ar^{17}O^{+}$, $^{36}Ar^{18}O^{1}H^{+}$, $^{38}Ar^{16}O^{1}H^{+}$, and $^{37}Cl^{17}O^{1}H^{+}$[40,41] can be reduced by dilution in the online system and by using correction equations from the software. In addition, to eliminate the possibility of interference in the manganese determinations, the peak heights were selected for monitoring instead of the peak areas.

After analysis of the oil contents according to TS 765:1969,[21] the HPLC-ICP-MS chromatograms of the residues (defatted samples) were compared with those of the original samples after the water extraction procedure. As expected from the results of the fractionation studies and as confirmed by the chromatograms obtained by this technique, the defatted hazelnut samples exhibited chromatograms similar to those of the original samples, which were considered sufficient for quantitative analytical purposes. Additionally, there were no significant variations among the samples after fractionation analysis, and for this reason quantitative online analysis was used for only one sample. There is no certified reference material for hazelnut, as mentioned above, and recovery studies with spiked samples are not valuable for speciation studies by HPLC−ICP-MS. For this reason, an external calibration method was applied for free manganese as a Mn(II) standard solution, and peak confirmation was achieved by the standard addition method. Identification was based on the retention times of the samples and the standards. Chromatographic identification was achieved within 5 min with isocratic elution using water. The retention times were 2.5 min for the Mn(II) standard and the first peak of the hazelnut sample. In addition, the second peaks in the chromatograms of the hazelnut samples were detected at $t_R$ = 3.0 min. For HPLC-ICP-MS analysis, the detection limit was 3.6 $\mu g\ L^{-1}$ and the quantification limit was 12 $\mu g\ L^{-1}$. The calibration equation was $y = 1181x - 13609$ with an $r^2$ of 0.975. Additionally, the repeatability calculated from the relative standard deviation (%RSD) was 6.1%. Water-soluble fractions are also important in terms of bioaccessibility, and the amount of manganese in the first and second peaks observed in the HPLC-ICP-MS chromatogram was 51% of the total water-soluble manganese. The bioaccessibility and the water-soluble manganese levels were compatible with one another, and the water-soluble manganese can be attributed to the bioavailable fraction from the hazelnuts. The difference between the total bioavailable fraction and this fraction (11.1%) originates from the bioaccessibility of the lipid and/or the manganese bound to other microconstituents.

In conclusion, a method for the screening and measurement of manganese fractions in hazelnut samples was presented herein. Fractionation, speciation, and matrix characterization can be regarded as three pillars of bioaccessibility assessment. From this perspective, matrix characterization by major constituent analysis and fractionation studies was evaluated in the context of bioaccessibility to increase the accuracy of in vitro methods. This analytical approach can be considered a new method for the evaluation of manganese binding sites in plant-based food matrices together with the fractionation of manganese. Our preliminary results provided good experimental foreknowledge, and future studies are in progress to apply and evaluate this online technique for the speciation of essential elements in hazelnut samples.

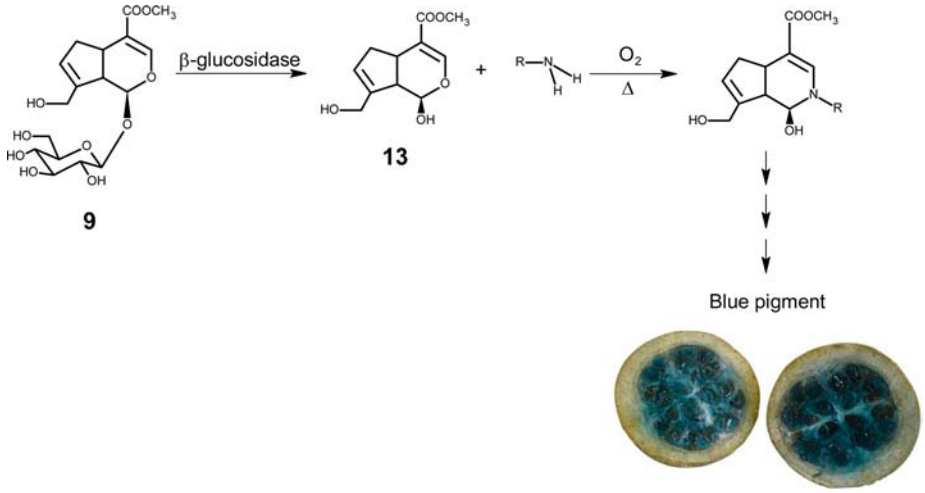

**Figure 2.** Formation reaction for the blue pigment and its appearance in genipap fruit (compounds numbered according to retention time given in Table 2).

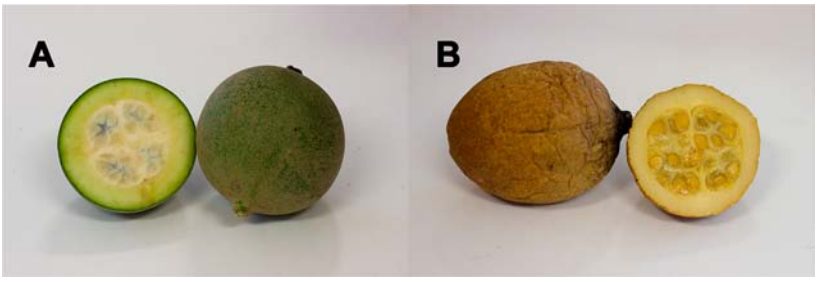

**Figure 3.** Photographs of genipap fruit at two ripening stages: unripe (left) and ripe (right).

from a Milli-Q system (Billerica, MA, USA), and the Folin−Ciocalteu reagent was acquired from Dinâmica (São Paulo, Brazil). The samples and standards were filtered through 0.22 $\mu$m Millipore membranes.

**Materials.** The genipap fruits (Figure 3) were harvested from a tree situated inside the University of Campinas (UNICAMP) campus, located in the city of Campinas (São Paulo State, Brazil), corresponding to the following coordinates: latitude 22°49′88″, longitude 47°04′21″, and altitude of 606 m. The plant material was authenticated by Professor Jorge Yoshio Tamashiro; Department of Plant Biology at the Institute of Biology, UNICAMP, and a voucher specimen was deposited in the UNICAMP Herbarium (UEC 11713).

Three batches of fruits were harvested, with an interval of 10 days between each harvest. All harvests occurred in the months of January and February 2013. The genipap fruits were manually washed and peeled. The portions of mesocarp and endocarp were separated and frozen immediately in liquid nitrogen. Each sample was then freeze-dried (Liobrás, São Paulo, Brazil) and ground in a domestic food processor. The three batches of each sample were mixed together to form a composite sample and vacuum packed in polyethylene bags. The samples were stored in a freezer at −36 °C until analysis.

The moisture of the genipap fruit samples was determined in triplicate according to an AOAC method.[21] The samples exhibited the following moisture contents: unripe endocarp, 85.7 ± 0.1 g/100 g; unripe mesocarp, 80.9 ± 0.1 g/100 g; ripe endocarp, 70.2 ± 0.1 g/100 g; ripe mesocarp, 75.3 ± 0.1 g/100 g.

**Differentiation between Unripe and Ripe Fruits.** The ripeness of the fruits was determined by firmness and peel color analysis. These techniques were chosen for being minimally invasive, because tissue damage can both release the enzyme and expose the interior of the unripe fruits to oxygen, which leads to the formation of the blue pigment. All of the fruits used in this study were submitted to firmness and color analysis.

The firmness was evaluated by determining the maximum force of penetration (MFP) using a TA-XT Plus texturometer (Stable Micro Systems Ltd., Surrey, UK) equipped with a P/2N needle probe. The MFP was determined on two opposite faces in the equatorial region of each fruit. The analysis was performed under the following conditions: pretest speed, 5 mm/s; test speed, 2 mm/s; post-test speed, 10 mm/s; and penetration depth, 10 mm. The results were expressed in newtons (N). Fruits with MFP values >10 N were considered unripe, and fruits with MFP values <2 N were considered ripe. Fruits with intermediate MFP values were discarded. Thus, the samples were composed of 45 ripe and 45 unripe fruits, after preliminary ripeness classification.

The fruit color was determined at four equidistant points around the equatorial region using a Hunter ColorQuest XE (Reston, VA, USA) spectrocolorimeter calibrated in the reflectance mode, with specular excluded, using the illuminant D65 and an observation angle of 10°. The parameters $L^*$, $a^*$, and $b^*$ of the CIELAB color system were determined.

**Determination of the Iridoid and Phenolic Compound Compositions.** The iridoids and phenolic compounds were extracted from the freeze-dried sample (0.4 g) with 20 mL of a methanol/water [8:2 (v/v)] solution in a Teflon tube by vortexing for 5 min at room temperature (22 ± 3 °C), followed by centrifugation (Beckman Coulter, Allegra 64R, Palo Alto, CA, USA) at 22000*g* for 10 min at 4 °C. The supernatant was collected, another aliquot of solvent was added to the tube, and the extraction procedure was repeated until extraction of the sample was complete. The absence of iridoids and phenolic compounds in the residue was confirmed using the Folin−Ciocalteu reagent. In general, five extractions were enough to achieve complete extraction; the supernatants were then combined to form a single extract, which was made up to a final volume of 100 mL using the same extraction solvent.

The extract was analyzed by high-performance liquid chromatography (HPLC) using a Shimadzu chromatograph (Kyoto, Japan) equipped with a quaternary pump (LC-20AD), a degasser (DGU-20A5), and a Rheodyne injection valve with a 20 $\mu$L loop, connected in series to a diode array detector (DAD) (SPD-M20A) and a Amazon

speed ETD mass spectrometer (MS) (Bruker Daltonics, Bremen, Germany), with an electrospray ionization source (ESI) and an ion trap analyzer.

The column used was a 250 × 4.6 mm i.d., 4 μm, $C_{18}$ Synergi Hydro RP80A (Phenomenex, Torrance, CA, USA) at a flow rate of 0.9 mL/min and column temperature set at 29 °C, using as mobile phase water (A) and acetonitrile (B), both containing 0.1% formic acid (v/v), in a linear gradient (v/v) from A/B 99:1 to 50:50 in 50 min, then to 1:99 in 5 min, maintaining this proportion for 5 min, returning to 99:1 in 5 min, and finally maintaining this proportion for 10 min to re-equilibrate the column.[22] The UV−vis spectra were obtained between 200 and 600 nm and the chromatograms were processed at 250 and 320 nm. For the MS analysis, the flow from the DAD was split, allowing the entrance of only 0.15 mL/min onto the ESI source. The MS was configured with the following parameters: negative ionization mode; voltage on the capillary, 2 kV; capillary exit voltage, −110 V; skimmer 1, 10 V; skimmer 2, 5 V; end plate offset, −500 V; drying gas ($N_2$) temperature, 310 °C; flow rate, 5 L/min; and nebulizer, 30 psi.[22] The fragmentation energy to obtain the MS/MS was 1.4 and 1.8 V for the $MS^3$ fragmentation energy. The mass spectra were acquired with a scan range from $m/z$ 100 to 1000.

The iridoids and phenolic compounds were identified through the combined information from the following parameters: elution order and retention time on the $C_{18}$ column, characteristics of the UV−vis and mass spectra as compared to standards analyzed under the same conditions, and information available in the literature.[23−29]

The iridoids were quantitated by HPLC-DAD, using an external analytical curve of genipin (0.5−100 μg/mL), with a detection limit of 0.75 μg/mL and quantification limit of 2.25 μg/mL. The phenolic compounds were quantitated with an external analytical curve of 5-caffeoylquinic acid (0.5−55 μg/mL), with a detection limit of 0.85 μg/mL and quantitation limit of 2.34 μg/mL. The two curves were linear ($r^2$ = 0.99). The limits of detection (LOD) and quantitation (LOQ) were calculated using the parameters of the analytical curves (standard deviation and slope).[30]

**Statistical Analysis of the Results.** The mean and standard deviation results were calculated using the software Origin version 8. The mean values were compared by analysis of variance (ANOVA), complemented by the Tukey test when significant differences were detected, using the software Statistica version 12. A confidence interval of 95% was used.

## RESULTS AND DISCUSSION

**Differences between the Unripe and Ripe Fruits.** Table 1 shows the mean results obtained for the firmness and skin color analyses. After the fruits had been classified, their weights (g) and dimensions (mm) were determined in both ripening stages. The unripe fruits (Figure 3A) were significantly lighter and shorter than ripe fruits (Figure 3B), although the values for the transversal diameter were very similar, independent of the ripening stage. All color parameter values were statistically different between fruit skins from both ripening stages (Table 1). According to these values, the skins of the unripe fruits tended to green color, indicated by negative $a^*$ values, whereas the skins of ripe fruits were yellow-reddish, with positive $a^*$ and high $b^*$ values.

**Table 1. Physical Characteristics, Maximum Force, and CIELAB Parameters for the Unripe and Ripe Genipap Fruits[a]**

| parameter | unripe fruit ($n$ = 45) | ripe fruit ($n$ = 45) |
|---|---|---|
| weight (g) | 96.4 ± 14.9a | 141.4 ± 19.8b |
| longitudinal diameter (mm) | 59.1 ± 3.3a | 78.1 ± 4.7b |
| transversal diameter (mm) | 57.9 ± 3.0a | 59.0 ± 2.9a |
| maximal force of penetration (N) | 13.8 ± 1.7a | 0.6 ± 0.2b |
| $L^*$ | 51.7 ± 0.9a | 47.3 ± 4.9b |
| $a^*$ | −2.8 ± 0.8a | 9.2 ± 1.7b |
| $b^*$ | 20.7 ± 1.3a | 23.4 ± 3.4b |

[a]Results are expressed as the mean ± standard deviation. Means with the lower case letter in the same row show no significant difference between them ($P$ > 0.05). $L^*$, $a^*$, and $b^*$ are CIELAB color system parameters.

**Identification of Iridoids and Phenolic Compounds.** Eighteen compounds (14 iridoids, 3 phenolic compounds, and 1 unidentified compound) were separated by HPLC from the genipap extracts, 14 being from unripe and 13 from ripe fruits (Figure 4). Among the separated compounds, the identities of 2 were confirmed with commercial standards, and 15 were tentatively identified considering their chromatographic and spectroscopic characteristics (Table 2), and 1 was not identified. The proposed structures are presented in Figure 5, and of the 17 identified compounds, 10 had never previously been found in genipap fruits.

Because no access to commercial standards of iridoid glycosides was possible, and the structures of the same iridoids were already determined by nuclear magnetic resonance as containing glucose as their hexose component,[14,15,31−35] in the present study all of the hexoses were identified as glucose.

Peaks 1 and 3 presented the same mass to charge ratio ($m/z$) value for the deprotonated molecule ($[M - H]^-$), and similar maximum absorption wavelengths ($\lambda_{max}$) in the UV spectrum. However, in the MS/MS spectrum of peak 1, the major fragment was an ion at $m/z$ 193, whereas for peak 3 it was at $m/z$ 211. The difference in mass between these fragments (18 Da) was relative to the elimination of one water molecule. When there is an OH at C-8 or the carbon directly bonded to C-8, a hydrogen bond is formed with the oxygen of the glycosidic bond, making it difficult to lose this oxygen during fragmentation, resulting in a neutral loss of 162 Da, as can be seen in the spectrum of peak 3. In the absence of this hydroxyl group, the most common loss is 180 Da, as observed in the MS/MS spectrum of peak 1.[23] The fragment at $m/z$ 149, resulting from the loss of $CO_2$ (44 Da), indicated the presence of a carboxyl group in both molecules. Thus, peaks 1 and 3 were tentatively identified as gardoside and geniposidic acid, respectively, on the basis of the similarities with the same compounds previously found in *Gardenia jasminoides*.[23] This was the first time that gardoside, **1**, was detected in *Genipa americana* L.

Peak 2 presented $[M - H]^-$ at $m/z$ 391 and neutral losses corresponding to a hexose unit (162 Da), $H_2O$ (18 Da), and $CO_2$ (44 Da). Considering the hexose as glucose, this compound was tentatively identified as shanzhiside. The same characteristics were reported by Ren et al.[24] for the standard of this compound.

Peaks 4, 5, and 6 presented in common a formate-adducted ion $[M + HCOO]^-$ at $m/z$ 449 and a deprotonated molecule $[M - H]^-$ at $m/z$ 403 in the MS/MS spectrum. These three peaks showed the same $\lambda_{max}$ in the UV and similar MS/MS fragmentation profiles. However, only peaks 4 and 6 presented the $MS^3$ fragment at $m/z$ 139, formed by the loss of a molecule of methyl 3-oxopropanoate (102 Da). This loss resulted from the cleavage of the basic skeleton of iridoid glycosides of the type 7,8-cyclopentane.[25] Thus, compound **5** was tentatively identified as gardenoside, and compounds **4** and **6** were tentatively identified as deacetylasperulosidic methyl ester (DAME) and scandoside methyl ester (SME). However, DAME and SME are epimers, and the detection methods

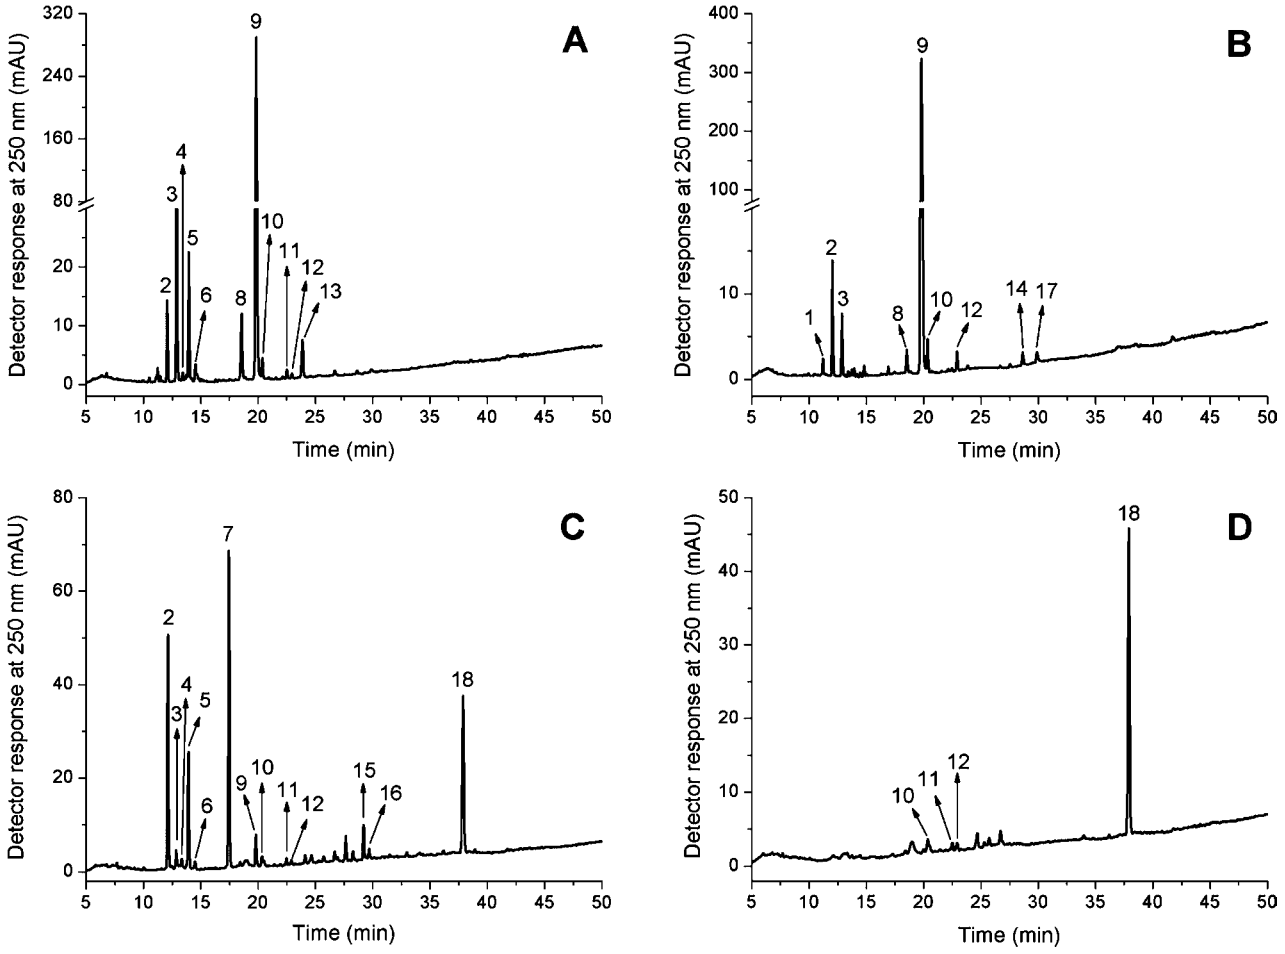

**Figure 4.** HPLC-DAD chromatograms of the iridoids and phenolic compounds of genipap fruits in two ripening stages: (A) unripe endocarp; (B) unripe mesocarp; (C) ripe endocarp; (D) ripe mesocarp. Peak identification is presented in Table 2.

used in this study did not allow the two compounds to be differentiated. Therefore, it was not possible to determine which of the two peaks corresponded to each isomer.

Peaks 7 and 9 also formed adducts with the formate ion ($[M - H + HCOO]^-$). Using MS/MS, the $[M - H]^-$ fragments at $m/z$ 549 and 387 were observed for peaks 7 and 9, respectively. On the $MS^3$ of the deprotonated molecules of both compounds, the major fragment at $m/z$ 225 corresponded to the aglycone genipin after the loss of one (peak 9) or two (peak 7) hexose units. From the fragmentation pattern, peaks 7 and 9 were tentatively identified as genipin-1-$\beta$-D-gentiobioside and geniposide, respectively, on the basis of the similarity of their characteristics with the same compounds found in *Gardenia jasminoides* Ellis.[23] These compounds are the major iridoids in gardenia fruits.[26]

Peak 8 was identified as 5-caffeoylquinic acid on the basis of the same retention time and UV and mass spectra characteristics as an authentic standard of 5-caffeoylquinic acid. The $[M - H]^-$ was detected at $m/z$ 353, and the MS/MS fragments showed 191 and 179 Da due to, respectively, the loss of caffeoyl and quinoyl groups. This is the first study to report the presence of chlorogenic acids in *Genipa americana* L.

Peaks 10 and 11 presented $[M - H]^-$ at $m/z$ 535 and at $m/z$ 519, respectively. Using MS/MS, both compounds presented a common loss of 212 Da. This loss could correspond either to the aglycone of gardoside, **1**, or geniposidic acid, **3**. Considering the same principle used to differentiate compounds **1** and **3**, the loss of the whole aglycone (212 Da) is characteristic of the presence of an OH group linked to C-8, indicating that the aglycone under question was geniposidic acid, **3**.[23] For peak 10, the $MS^3$ from the $m/z$ at 323 resulted in fragments with 179 and 161 Da, which correspond to ionized and dehydrated caffeic acid, respectively. For peak 11, the $MS^3$ from the ion with 307 Da resulted in fragments at $m/z$ 217 and 145, which correspond to the sugar moiety and ionized *p*-coumaric acid, respectively. Thus, compounds **10** and **11** were tentatively identified as caffeoyl geniposidic acid and *p*-coumaroyl geniposidic acid, respectively. Up to now, the presence of iridoid glycosides esterified with acids in genipap fruits has never been reported in the literature.

Peak 12 presented the $[M - H]^-$ at $m/z$ 549 and MS/MS fragments at $m/z$ 355 $[M - H - 194]^-$ and at $m/z$ 337 $[M - H - 194 - 18]^-$, relative to the loss of one dehydrated and one nondehydrated aglycone, respectively. Considering the above discussion, this fragmentation indicates the absence of an OH group on C-8 or on the carbon directly bound to it.[23] Thus, the aglycone present in compound **12** was tentatively identified as that from gardoside, **1**. The $MS^3$ of the ion at $m/z$ 355 produced, in addition to the ion at $m/z$ 337 (loss of $H_2O$), an ion at $m/z$ 193, which corresponded to ionized ferulic acid. Thus, compound **12** was tentatively identified as feruloyl gardoside, which was also found in gardenia fruits.[31]

Peak 13 was identified as genipin, because it showed the same retention time and UV and mass spectra characteristics as

[a]Values of mean ± standard deviation are expressed in mg/g of freeze-dried sample; analyses were carried out in triplicate from the sample pool composed of three batches. [b]Quantitated as genipin equivalents. [c]nd, not identified. [d]Quantitated as 5-caffeoylquinic acid equivalents.

dx.doi.org/10.1021/jf503378k | J. Agric. Food Chem. 2014, 62, 10800−10808

the authentic genipin standard. This compound presented the $[M - H]^-$ at $m/z$ 225 and the following MS/MS fragments: $m/z$ 207 relative to the loss of a water molecule; $m/z$ 123 generated by the loss of a methyl 3-oxopropanoate group (102 Da); and $m/z$ 101, corresponding to the ionized methyl 3-oxopropanoate group.

Peaks 14 and 17 both presented the same $[M - H]^-$ at $m/z$ 515 and a major MS/MS fragment at $m/z$ 353, which is characteristic of dicaffeoylquinic acids. The $MS^3$ fragmentations of the ion at $m/z$ 353 of both compounds were very similar, differing only with respect to the intensity of the major peak. Compound **14** presented a major fragment at $m/z$ 191, resulting from the loss of a caffeoyl group (162 Da), whereas for compound **17** the major fragment was observed at $m/z$ 173, representing a dehydrated quinic acid. The fragmentation pattern of isomers of chlorogenic acids depends on the position of attachment of the caffeoyl group to quinic acid.[28] Thus, peaks 14 and 17 were tentatively identified as 3,5-dicaffeoylquinic acid and 4,5-dicaffeoylquinic acid, respectively. The chlorogenic acids were also found in gardenia fruits.[27]

Peak 15 showed the $[M - H]^-$ at $m/z$ 695 and a major MS/MS fragment at $m/z$ 469, due to the loss of a genipin molecule (226 Da). The $MS^3$ of this ion showed fragments with 367, 307, 265, and 235 Da, characteristic of the fragmentation of two hexose molecules, and also fragments at $m/z$ 163 and 145, which correspond to ionized and dehydrated *p*-coumaric acid, respectively. Taking into account all of the information provided, peak 15 was tentatively identified as *p*-coumaroyl genipin gentiobioside, which was also found in gardenia fruits and in a formulation of a Chinese medicine based on gardenia fruits and fermented soybean.[29,36]

Peak 16 was tentatively identified as feruloyl genipin gentiobioside, considering the same MS fragmentation mechanism and a difference of 30 Da as compared to *p*-coumaroylgenipin gentiobioside, **15**. However, in this case ions at $m/z$ 193 and 175 were obtained on the $MS^3$, representing ionized and dehydrated ferulic acid, respectively. Feruloyl genipin gentiobioside, **16**, has been previously also detected in gardenia fruits.[31,37]

Peak 18 was not identified, because this compound was detected only on the UV spectrum, but was not ionized under the conditions used in this study, neither in the positive nor in the negative mode. Its late elution on the reversed-phase column indicated low polarity in relation to the other compounds. This was the major compound found in the mesocarp of ripe fruits.

**Contents of Iridoids and Phenolic Compounds.** Because genipap (*Genipa americana* L.) and *Gardenia jasminoides* fruits belong to the same family, it is not a surprise that their qualitative compositions of iridoids and chlorogenic acids are very similar.

As in gardenia, geniposide, **9**, was the major iridoid in the unripe genipap fruits (Table 3), corresponding to 72 and 92% of the total iridoids in the endocarp and mesocarp, respectively. Furthermore, the geniposide, **9**, contents in the endocarp and mesocarp of unripe genipap fruits (107.11 and 117.99 mg/g freeze-dried sample, respectively) were higher than those reported for gardenia fruits from different varieties and origins (43.19−95.51 mg/g dry sample).[16,38] In addition, the unripe genipap also presented higher geniposidic acid, **3** (endocarp and mesocarp), and gardenoside, **5** (endocarp), contents than those found in gardenia fruits (0.80 and 1.08 mg/g dry sample, respectively).[26] Genipin-1-$\beta$-D-gentiobioside, **7**, was the major iridoid in the ripe endocarp and was not detected in unripe genipap fruits. This indicates that ripening favors the addition of a second hexoside group to the geniposide, **9**.

According to the biosynthetic pathway of iridoids, geniposidic acid, **3**, is the precursor of geniposide, **9**, that further gives rise to gardenoside, **5**.[7] These three compounds are the major ones found in the unripe genipap endocarp and are among the main compounds of the unripe mesocarp, but their contents indicate that in the unripe genipap fruits, the formation of geniposide, **9**, is the favored route.

Another difference observed between both ripeness stages was the absence of chlorogenic acids in the ripe genipap fruits. In addition, the ripe genipap fruits presented a 90% reduction in the iridoid contents, especially geniposide, **9**, in relation to the green fruits. This behavior was also observed in *Gardenia jasminoides* fruits, in which the geniposide, **9**, contents decreased throughout the fruit-ripening process.[39,40] This fact can be explained by the highest expression levels of the enzyme responsible for iridoid glycosylation in the earlier stages of *Gardenia jasminoides* ripening.[41] This phenomenon was attributed to the fact that the iridoids as well as the phenolic acids act as defense compounds against herbivores, and their synthesis demands precursors of low molecular mass and low enzymatic activity, making their synthesis energetically favorable in the initial developmental stages.[42−44]

**Blue Color and Genipap Ripeness Stage.** Although the endocarp of the unripe fruits showed a low concentration of genipin, **13** (3.40 mg/g of the freeze-dried sample), small lines of blue color were visually observed, most probably due to formation of the blue pigment as the result of a reaction, shown in Figure 2, between amino acids and free genipin, **13**, present in endocarp.

In addition, we verified that extracts from unripe genipap fruit kept at room temperature for a few hours resulted in increased intensity of the genipin, **13**, peak in the endocarp extract or its appearance in the mesocarp extract (data not shown). In addition, reduction of the geniposide, **9**, concentration and formation of a new peak ($t_R$ = 21.1 min, $[M - H]^-$ at $m/z$ 387 and MS/MS fragments at $m/z$ 285 $[M - H - 102]^-$, 207 $[M - H - 162 - 18]^-$, 179 $[M - H - 162 - 18 - 28]^-$, and 179 $[M - H - 162 - 18 - 28 - 18]^-$) were also observed. This new peak may be an intermediate in the reaction shown in Figure 2. These facts indicate the presence of $\beta$-glucosidase in the fruit, which was possibly released by tissue rupture. As shown in Figure 2, the enzyme hydrolyzes the glycosidic bond of geniposide, **9**, furnishing genipin, **13**, that reacts with primary amine sources present in the matrix. The drastic reduction of geniposide, **9**, contents and the absence of genipin, **13**, in the ripe fruit may explain the nonoccurrence and/or formation of the blue pigment in the ripe fruits.

The present study was the first to relate the iridoid and phenolic compound compositions to both ripening stage and part of the fruit (mesocarp and endocarp). Our results show that the stage of ripeness influences both the iridoid and phenolic compound profiles. The unripe genipap fruits were shown to be a very good source of geniposide, **9**, which can be used to produce genipin, **13**, and subsequently the blue pigment for use by the natural dye industry. In addition, the fact that geniposide, **9**, was almost nonexistent in the ripe genipap fruits could explain the nonformation of the blue pigment in this ripeness stage.

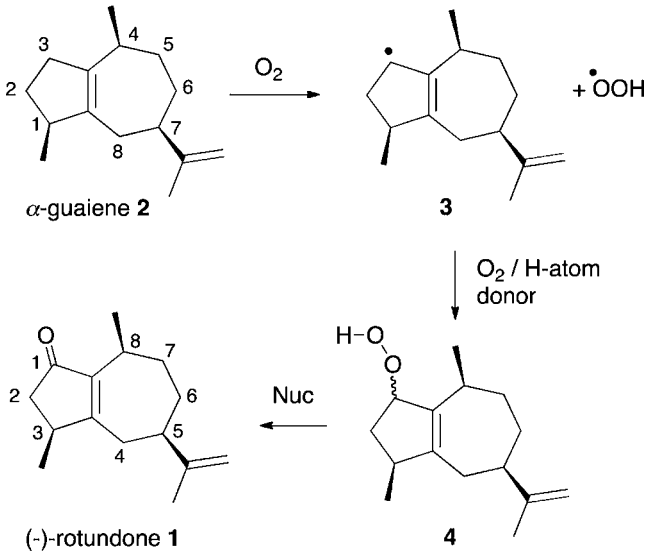

**Figure 1.** Hypothetical aerial oxidation of $\alpha$-guaiene, **2**, to form rotundone, **1**. IUPAC chemical names: (−)-(3*S*,5*R*,8*S*)-3,8-dimethyl-5-(prop-1-en-2-yl)-3,4,5,6,7,8-hexahydroazulene-1(2*H*)-one **1** and (−)-(1*S*,4*S*,7*R*)-1,4-dimethyl-7-(prop-1-en-2-yl)-1,2,3,4,5,6,7,8-octahydroazulene, **2**.

some precursor substrate. Mechanistically, any proposed aerial oxidation of $\alpha$-guaiene, **2**, is likely to begin with a traditional free radical initiation step, namely, hydrogen atom abstraction from $C_3$ to produce the resonance stabilized allylic radical, **3** (Figure 1). This initiation could be caused by dioxygen ($O_2$) itself or by other initiators such as reactive oxygen species (ROS) or the breakdown of $H_2O_2$ produced due to plant−pathogen interactions. Indeed, $H_2O_2$ has recently been identified in distinct cellular compartments of the skins of grapes during grape berry ripening, and as mentioned above, both rotundone and $\alpha$-guaiene have clearly been identified on the skins of grapes.[24] The allylic radical, **3**, could then enter a propagation sequence by first reacting with dioxygen to form an allylic hydroperoxy radical, which in turn abstracts another hydrogen atom from either another guaiene molecule or some other abstractable hydrogen atom source to produce the guaiene hydroperoxide, **4**. Exposure of this hydroperoxide to trace metals (e.g., copper sprays in vineyards) or nucleophiles (e.g., basic amines of plant proteins or pathogens) would allow for decomposition to the ketone rotundone, **1**, via well established chemical mechanisms (Figure 1).[25]

Given this background, the current study has been carried out to evaluate whether $\alpha$-guaiene could be a natural precursor to rotundone via the process of simple aerial oxidation. Autoxidation was carried out both in organic solvents and also on filter paper derived from cellulose to mimic more closely biological matrices of some plant products.

## MATERIALS AND METHODS

**General Experimental Procedures.** Acetic anhydride (≥98% ACS reagent grade), pyridinium dichlorochromate, *tert*-butyl hydroperoxide (5−6 M in decane), and *m*-chloroperbenzoic acid (max 77%) were purchased from Sigma-Aldrich (Saint Louis, MO, USA). $d_6$-Benzene was purchased from Cambridge Isotope Laboratories, Inc. (Tewksbury, MA, USA). All reagents were used directly unless otherwise stated. Solvents for synthesis were dried according to known procedures where necessary.[26] Solvents for general chromatography were AR grade except that those used for GC−MS and HRMS analysis were HPLC grade. NMR data were recorded with a Varian-Inova 600 MHz spectrometer (Agilent Technologies, USA). All compounds for NMR analysis were dissolved in $C_6D_6$. All $^1H$ and $^{13}C$ NMR spectra were calibrated with residual deuterated solvent signals set at 7.16 and 128.06 ppm. HRMS (ESI-TOF) analysis was performed with a triple TOF 5600 mass spectrometer from AB Sciex Instruments. Whatman grade 1 cellulose filter paper was used to mimic the oxidation of $\alpha$-guaiene on plant cell wall cellulose.[27] Silica column chromatography was performed using either LC60A 40−63 $\mu$m silica (Grace Davison) or silica gel 60 (0.015−0.040 mm) from Merck. TLC was conducted with TLC silica gel 60 $F_{254}$ plates (Merck KGaA) using standard vanillin stain for visualization. Guaiac wood essential oil (steam-distilled from *Bulnesia sarmientoi,* Paraguay) was purchased from the Australian Botanical Products Company as viscous oil. This oil contains ca. 40% (−)-guaiol as determined by GC−MS analysis.

**Preparation of Standards.** $\alpha$-Guaiene, **2**, was prepared as follows. Recrystallization of guaiac wood essential oil from warm acetonitrile several times afforded (−)-guaiol as white needles in an overall yield of approximately 14% by weight in a similar fashion to that described previously.[1] Treatment with acetic anhydride under reflux conditions afforded the guaiyl acetate in a good yield of 71.9% after workup. Elimination of acetic acid from the guaiyl acetate through pyrolysis was achieved under nitrogen at 210 °C in a similar fashion to that reported previously.[28] Workup and purification by flash chromatography afforded $\alpha$-guaiene, **2**, in a very good yield of 84%. Analysis by GC−MS indicated that the purity of the $\alpha$-guaiene, **2**, was >98% with traces of $\beta$-guaiene and $\delta$-guaiene also present. Rotundone, **1**, was synthesized as follows. Pyridinium dichlorochromate (37.6 g, 0.1 mol) was added to $CH_2Cl_2$ (400 mL) and the resulting mixture cooled in an ice-bath before introduction dropwise of a solution of *tert*-butyl hydroperoxide (5−6 M in decane, 20 mL) in $CH_2Cl_2$ (80 mL) with stirring for 20 min. To this mixture was added dropwise a solution of $\alpha$-guaiene, **2** (20.4 g, 0.1 mol), in $CH_2Cl_2$ (80 mL), and the resulting mixture was stirred at 0 °C under $N_2$ for 4.5 h. The reaction was terminated by filtering through a plug of silica (ca. 80 g). The residue in the flask was further extracted with $CH_2Cl_2$ (2 × 100 mL), which was filtered through the same silica plug. The combined $CH_2Cl_2$ extracts were concentrated under vacuum at 40 °C and the concentrate purified by silica column chromatography (*n*-hexane:$Et_2O$, gradient elution from 100:0 to 85:15) to yield rotundone, **1** (1.39 g, 27% based on 25% conversion), as a pale yellow oil with the recovery of unreacted $\alpha$-guaiene, **2** (15.28 g, 75% recovery). Spectroscopic data of **1** including NMR and MS were in agreement with those reported.[1]

**Aerial Oxidation of $\alpha$-Guaiene, 2, and GC−MS Analysis.** $\alpha$-Guaiene, **2** (1.0 g, 4.9 mmol), was dissolved in $CH_2Cl_2$ (200 mL) at ambient temperature. The mixture was stirred while being purged slowly with a stream of oxygen (ca. 1 mL/min) through a glass frit. Small aliquots (0.2 mL) were removed daily, diluted with $CH_2Cl_2$, and analyzed by GC−MS using an Agilent 6890 gas chromatograph coupled with a 5973N mass spectrometer detector (MSD) and a Gerstel multipurposed autosampler (Gerstel, Germany) and equipped with a HP-wax bonded polyethylene glycol capillary column (DB-Wax 30 m × 250 $\mu$m i.d. × 0.25 $\mu$m film thickness, Agilent Technologies). Samples were prepared in dry dichloromethane and analyzed in split mode with a split ratio of 50.1:1. The inlet and transfer line temperatures were set at 250 °C. Injection volume was 1 $\mu$L. The column flow was set at 1.9 mL/min with a pressure of 15.96 psi. Helium was used as carrier gas. The oven temperature was initially set at 50 °C and held for 0.5 min and ramped up to 240 °C at 10 °C/min and held for a further 6 min. The MSD was operated in full scan mode scanning $m/z$ ions from 50 to 550 amu with EI energy set at 70 eV. MS source and quadrupole temperatures were set at 230 and 150 °C, respectively. The total and selected ion response ratios of $\alpha$-guaiene and its oxidation products were used as indicators for the extent of autoxidation of $\alpha$-guaiene under the different conditions. At the same concentrations and under the same GC−MS conditions, the total ion (TI) response ratio of $\alpha$-guaiene (**2**):epoxy guaienes (**5a**/**b**):rotundone (**1**) was ca. 36:33:31 and the response ratio of $\alpha$-guaiene (204) and rotundone (218) was found to be 1.0:1.11 (Figure 3).

**Preparation of Epoxides 5a/b.** To a stirred solution of $\alpha$-guaiene, **2** (103 mg, 0.50 mmol), in $CH_2Cl_2$ (3 mL) at −78 °C was

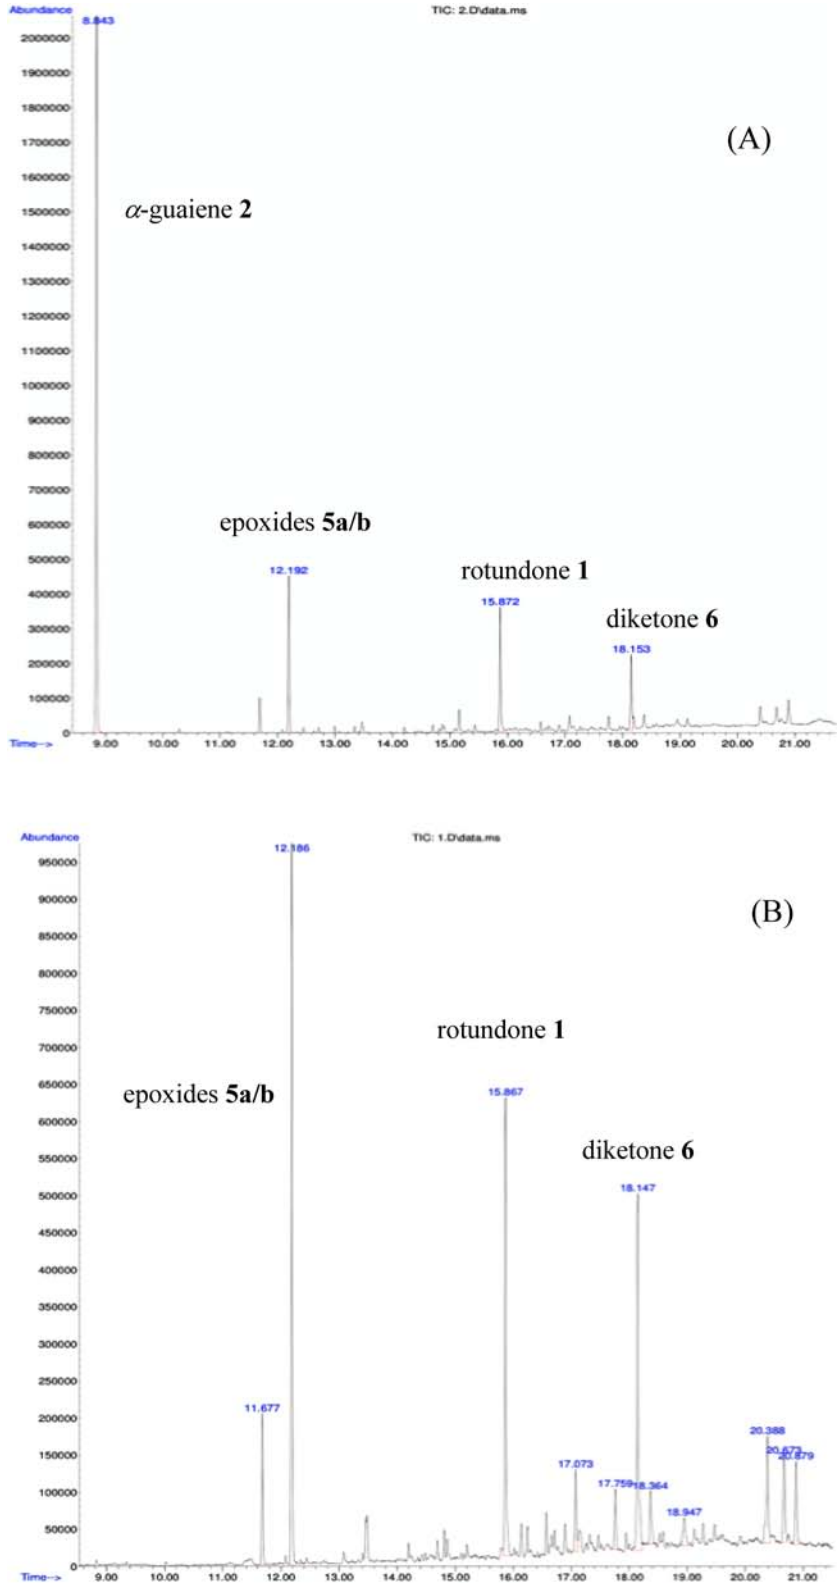

**Figure 2.** GC−MS traces of the aerial oxidation of α-guaiene, **2**, after (A) 4 days and (B) 29 days.

added dropwise a solution of *m*-CPBA (128 mg, 0.57 mmol) in $CH_2Cl_2$ (3 mL). After stirring at −78 °C for 30 min, the reaction was quenched with KI (10 mg), saturated aqueous $Na_2S_2O_3$ (1 mL) and aqueous $NaHCO_3$ (3 mL). The resulting mixture was extracted with $Et_2O$ (3 × 10 mL). The combined ether layers were washed with brine (10 mL), dried over anhydrous $MgSO_4$, and filtered. The filtrate was concentrated in vacuo and purified on neutral alumina to furnish the pair of epoxy diastereomers, **5a**:**5b** (ca. 1:2, 103 mg, 93%), as a colorless oil. **5a**: $^1$H NMR (600 MHz, $C_6D_6$) $\delta$ 4.77 (m, 1H, $H_{12a}$), 4.71 (dq, $J$ = 1.8, 1.5 Hz, 1H, $H_{12b}$), 2.15 (ddd, $J$ = 12.0, 10.8, 6.0 Hz, 1H, $H_7$), 1.94 (br d, $J$ = 14.4 Hz, 1H, $H_{6a}$), 1.88 (dd, $J$ = 13.8, 8.4 Hz, 1H, $H_{3a}$), 1.84−1.78 (m, 2H, $H_{6b\ and\ 10}$), 1.72 (ddq $J$ = 9.6, 7.2, 7.2 Hz, 1H, $H_4$), 1.65 (m, 1H, $H_{9a}$), 1.58 (br s, 3H, $H_{13}$), 1.55 (m, 1H, $H_{8a}$), 1.47 (ddd, $J$ = 14.4, 10.8, 4.8 Hz, 1H, $H_{8b}$), 1.42 (dd, $J$ = 12.6, 8.4 Hz,

**Aerial Oxidation of α-Guaiene, 2, on Filter Paper.** Autoxidation of α-guaiene, **2**, on filter paper was carried out on 50 mg quantities in duplicate at ambient temperature, 40 °C, and 50 °C. Filter paper (10 $cm^2$) was finely cut into approximately 2 $mm^2$ shreds, and these were placed into 20 mL, 75 mm × 25 mm glass vials. Six vials (3 treatments in duplicate) contained approximately 50 filter paper shreds while another six vials contained no filter paper shreds and were used as controls. α-Guaiene, **2** (neat, 50 mg), was added to each of the vials followed by the addition of $CH_2Cl_2$ (0.5 mL), and the mixtures were gently shaken for several minutes. The solvent was then removed under a gentle stream of $N_2$ at 10 °C, which ensured an even coating of guaiene onto the filter paper. The control experiments were identical except for the fact that they did not contain filter paper and were also conducted at ambient temperature, 40 °C, and 50 °C at the same time. The process of autoxidation was monitored by GC−MS by sampling a small fraction of the substrate from each control experiment and by removing one piece of filter paper shred from each filter paper treatment at various time points. A portion of the substrate from the control experiments or the filter paper sheds were placed in dry $CH_2Cl_2$ (1.5 mL) for GC−MS analysis. The selected ion response ratio of rotundone to α-guaiene at their corresponding retention times in the GC chromatogram was used as an indicator for the extent of the aerial oxidation of α-guaiene. The ratio of the areas of rotundone ($m/z$ 218) to those of α-guaiene ($m/z$ 204) under the different autoxidation conditions were plotted against time (Figure 4). Note that the total ion (TI) or other selected ion response ratios of rotundone and α-guaiene can also be used as indicators for the reaction rates of autoxidation of α-guaiene under the different

conditions without altering the trend of the curves shown in Figure 4. At the same concentrations and under the same GC−MS conditions, the total ion (TI) response ratio of α-guaiene (**2**):epoxy guaienes (**5a**/**b**):rotundone (**1**) is ca. 36:33:31 and the response ratio of α-guaiene ($m/z$ 204) and rotundone ($m/z$ 218) was found to be 1.0:1.11. GC−MS analysis was performed on the same instrument (6890 GC-5973N MSD) and with the same capillary column (DB-Wax 30 m × 0.25 mm i.d. × 0.25 μm film thickness, Agilent Technologies). Acquisition parameters were as follows: initial oven temperature set at 100 °C, ramped up to 200 °C at 8 °C/min and then to 240 °C at 20 °C/min and held at 240 °C for 3 min. Injection was in a splitless mode with a purge flow of 6 mL/min in 0.05 min. The inlet temperature was set at 240 °C with a pressure of 12.92 psi. Injection volume was 2 μL and gas flow rate set at 1.2 mL/min. Helium was the carrier gas. MSD was in full scan mode (50−550 Da). Gain factor was 1.0 and EI 70 eV. Transfer line temperature was set at 240 °C, MS source at 230 °C, and MS quadrupole at 150 °C.

## RESULTS AND DISCUSSION

With pure α-guaiene, **2**, in hand we placed 1 g in dichloromethane and bubbled oxygen through the solution over a number of weeks and followed the autoxidation by GC−MS on a daily basis. Figure 2A shows the oxidation at day 4 while Figure 2B displays the progress of oxidation of α-guaiene after 29 days. We indeed found that the aerial oxidation of α-guaiene, **2** ($t_R$ 8.84 min), after 4 days resulted in the formation of rotundone, **1** ($t_R$ 15.87 min), as one of the major products (Figure 2A). Identification was confirmed by comparison with an authentic sample via MS, by symmetrical peak enhancement on coinjection with synthetic rotundone utilizing several column types, and through isolation by column chromatography and comparison by $^1$H NMR.

In addition, two reaction products at retention times of 11.69 and 12.19 min displayed molecular masses of $m/z$ 220 ($C_{15}H_{24}O$) indicating that they had incorporated one oxygen atom when compared to α-guaiene ($m/z$ 204, $C_{15}H_{24}$) itself. These two compounds were identified as the monoepoxides (β-(*cis*)-**5a**, $t_R$ 11.69, and α-(*trans*)-**5b**, $t_R$ 12.19) by comparison with synthetic samples. One other major product at retention time 18.15 min was clearly observable after 4 days of oxidation (Figure 2A). It displayed a molecular mass of $m/z$ 236 indicating that it was likely to be an oxidized product ($C_{15}H_{24}O_2$) with two oxygen atoms incorporated. After careful column chromatography of the autoxidation mixture, this product was isolated and identified as the diketone, **6**, by $^1$H, $^{13}$C, and 2D NMR analysis. This oxidation product presumably results from the oxidative cleavage of the $C_1-C_{8a}$ carbon bond within α-guaiene itself. Indeed, such a cleavage has been proposed for the formation of several related epimers of this diketone isolated from various soft coral extracts in nature.[30]

We followed the aerial oxidation for 29 days, at which point complete consumption of α-guaiene, **2**, was observed (Figure 2B). Again, formation of rotundone, **1**, the two epoxides (**5a** and **5b**), and the diketone, **6**, were clearly visible. In addition, numerous other minor oxidation products were now present, many of which displayed molecular masses of 220 or 236 indicating the incorporation of one or two oxygen atoms when compared to α-guaiene ($m/z$ 204). Conducting the aerial oxidation in a range of other organic solvents (e.g., ether, chloroform or acetonitrile) also resulted in the same four major compounds being formed in very similar time frames.

Table 1 displays the relative GC peak area of the four major products formed at various stages of the autoxidation process (days 0, 4, 7, 9, 17, and 29) as a percentage of the peak area of α-guaiene plus total products observed by GC-MS.

**Table 1. Percentages Determined by GC−MS of Major Products Formed and α-Guaiene Remaining on Aerial Oxidation over Time**

| time (days) | α-guaiene (**2**) | β-*cis*-**5a** | α-*trans*-**5b** | rotundone (**1**) | diketone **6** | total (%) |
|---|---|---|---|---|---|---|
| 0 | 100.0 | 0.0 | 0.0 | 0.0 | 0.0 | 100.0 |
| 4 | 49.9 | 2.5 | 11.3 | 9.5 | 6.0 | 79.2 |
| 7 | 25.0 | 3.9 | 18.6 | 13.6 | 10.0 | 71.2 |
| 9 | 15.8 | 4.5 | 20.2 | 15.1 | 12.2 | 67.8 |
| 17 | 2.4 | 5.2 | 24.6 | 17.3 | 14.9 | 64.3 |
| 29 | 0.2 | 5.0 | 23.6 | 16.7 | 15.1 | 60.6 |

As can be seen from Table 1, the concentration of α-guaiene, **2**, steadily decreased over time, However, the relative proportions of the oxidation products, rotundone, **1**, monoepoxides **5a** and **5b**, and the diketone, **6**, remain approximately constant over the time period, suggesting that they are all being produced from a common intermediate such as the hydroperoxide **4**, as shown in Figure 1, formed first along the reaction coordinate. Removal of the proton α to the peroxide linkage by trace amounts of external nucleophiles would result in the formation of rotundone, **1**, and the loss of $H_2O$.[25] Furthermore, the formation of the monoepoxides (**5a** and **5b**) is highly consistent with the initial formation of hydroperoxide **4**. Once **4** is formed in solution it would be expected to act as an epoxidizing agent, reacting with the more electron rich internally bridged C=C of α-guaiene, **2**, to produce either the *cis* or *trans* epoxides (**5a** and **5b**) in a similar fashion to the action of *m*-CPBA on α-guaiene, **2**, reported herein. The hydroperoxide **4** could act as an epoxidizing agent toward any substrate containing C=C bonds, a situation which may well lead to some of the minor oxidized products seen in the later stages of this autoxidation sequence.

A matrix or scaffold that may well mimic the cellulose biolayers of some processed plant materials is filter paper. Indeed, filter paper disks which are made from compacted cellulose fibers have been used to monitor the disruption of hydrogen bonding between plant cell wall polymers by proteins that induce wall extension and in assays for the measurement of lipid biosynthesis.[27,31] With this scenario in mind, we coated α-guaiene onto cellulose filter paper shreds and allowed it to undergo autoxidation at various temperatures. The selected ion response ratio of rotundone to α-guaiene at their corresponding retention times in the GC chromatogram was used as an indicator for the extent of guaiene degradation (Figure 4). Again the same major products were formed over time, and it was observed that the extent of aerial oxidation of α-guaiene in general rose significantly with increasing temperature. Oxidation of α-guaiene on filter paper was more advanced than that without filter paper at the same temperature. These observations are consistent with the fact that coating α-guaiene onto the surface of filter paper would greatly enlarge the overall contact area between molecular oxygen and the substrate α-guaiene, thus leading to a substantial increase in oxidation rate.

Sesquiterpenes such as α-guaiene are mainly biosynthesized via the mevalonate acid (MVA) pathway in the cytosol of plant cells[32] though the newly discovered plastidial 2-*C*-methyl-D-erythritol-4-phosphate (MEP) pathway also generate sesquiterpenes and takes place in plastids.[33,34] A recent labeling study has suggested that the precursors supplied for the biosynthesis

of sesquiterpenes in the grape berry exocarp are mainly transported from plastids to the cytosol in cells of grape berry skin.[35] Dried grape skins consist of ca. 15% of cell wall materials which are made up of ca. 30−35% of neutral polysaccharides and ca. 20% of acidic pectic substances with 62% moderately methyl-esterified.[36] The only barrier between the cytosol and the plant cell wall is the cell membrane which is permeable to small hydrophobic molecules such as sesquiterpenes according to the well-established solubility−diffusion model (Overton's rule).[37−40] While enzymic oxidation of terpenes by plant or fungal oxidases is well-known,[41] it is possible that hydrophobic sesquiterpenes formed in the cytosol of plant cell matrices such as grapes could also be secreted onto their cell wall matrices and accumulate thereafter, and in the case for $\alpha$-guaiene might be further oxidized into sesquiterpenoids such as rotundone by ROS or atmospheric oxygen.

Overall our studies have shown that simple aerial oxidation of $\alpha$-guaiene, **2**, results in significant formation of the peppery aroma compound rotundone, **1**. Therefore, the mode of formation of rotundone in processed plant products, including dried herbs and spices, may simply be a result of air contact rather than rotundone being a product of enzymatically controlled processes. Furthermore, this autoxidation sequence is enhanced at higher temperatures as indicated by our findings when exploiting cellulose filter paper to mimic nature's biological scaffolds and may have significance when considering the amount of rotundone that may be formed during the cooking, heating, or drying of foodstuffs.

isoelectric point of around pH 5.0 and a single thermal denaturation temperature (around 70 °C).[31,32] However, to our knowledge, the interaction between thermally modified LF and EGCG was not characterized. LF has two lobes, and each one consists of two domains and a single, high affinity metal binding site, which binds, very tightly but reversibly, one ferric ion together with one carbonate as the synergistic anion.[33] When LF is heated, one of the lobes unfolds at around 60 °C, and the other unfolds at around 85 °C,[34−37] leading to a conformational change irreversibly in the LF molecules.[30]

There are some reports available on the heat-induced structural and conformational changes of LF.[6,30,33] None of the papers, however, focused on the interaction between LF and EGCG. Until now, the information for the interaction and structure−affinity relationship of thermally modified LF and polyphenol was not available at different pH values.

In this study, we examined whether protein−EGCG nanoparticles or submicrometer particles could be formed using native and thermally modified LF at different pH values. The effects of LF and EGCG interactions at different pH values on the structure of LF are tested. The binding constant and the number of binding sites of EGCG with native and thermally modified LF were also compared by fluorescence spectroscopy. LF has a much high isoelectric point, and LF−EGCG nanoparticles or submicrometer particles may be positively charged over a wider pH range. These LF−EGCG complexes may be useful functional ingredients in food, cosmetic, and pharmaceutical applications, e.g., to modify the optical or rheological properties of products.

## MATERIALS AND METHODS

**Materials.** Lactoferrin from bovine whey was purchased from New Image International Limited (New Zealand). Its composition was protein (dry basis) 99.41%, of which LF was 92.0% of total proteins, ash 0.31%, and moisture 15.0%. The iron saturation of the LF powder was reported to be 15%. EGCG (purity ≥98%) from green tea was purchased from BSZH Science Company (Beijing, China). All other chemicals used were of analytical grade, unless otherwise stated.

**Solution Preparation.** LF and EGCG aqueous solutions were prepared freshly by dissolving the proper amount of each powder in citrate buffer (pH 3.5, 10 mM), acetate buffer (pH 5.0, 10 mM), and phosphate buffer (pH 6.5, 10 mM) at room temperature and stirring for 2 h. If necessary, pH was adjusted with HCl (10 mM) or NaOH (10 mM). LF was dispersed in buffers to get a final concentration of 200 $\mu$M. The protein solutions were filled in plastic tubes (1 cm diameter). The thermally denatured experiments were conducted in a thermostatic water bath at 70 or 90 °C for 20 min. The two temperatures correspond approximately to the first and second unfolding transition of LF, respectively.[30,34,35,38] After the thermal treatment, the tubes were immediately cooled in ice water to prevent further denaturation. All measurements were performed within 3 min after the heat treatment. The mixtures of Lf and EGCG were prepared by blending the appropriate volume of native LF or thermally modified LF and EGCG solutions in order to achieve the desired final concentrations. All spectroscopic studies were carried out on the heated−cooled protein, implying that only irreversible/permanent structural changes were detected.

The abbreviations $LF_x$ ($x$ = 3.5, 5.0, or 6.5) were used to represent the LF in the buffer solutions at pH 3.5, 5.0, and 6.5, respectively. The abbreviations $LF_{x\text{-}25°C}$ were used to represent the native LF in the corresponding buffer solutions. The abbreviations $LF_{x\text{-}70°C}$ and $LF_{x\text{-}90°C}$ were used to represent the LF heated at 70 and 90 °C for 20 min in the corresponding buffer solutions, respectively.

**ζ-Potential Measurements.** The ζ-potential of the complexes was determined by a particle electrophoresis instrument using a Zetasizer Nano-ZS90 (Malvern Instruments, U.K.). Samples were loaded in the cell and temperature was set at 25 °C without further dilution. The ζ-potential measurements were reported as the average of measurements for three fresh samples, with three readings recorded for each sample.

**Haze and Particle Size Measurements.** LF and EGCG solutions with different concentrations were mixed to obtain final EGCG levels of 0.5, 1.0, 1.5, 2.0, 2.5, 3.0, 3.5, and 4.0 mM with a constant LF concentration of 0.1 mM. Haze formation was monitored by DLS and nephelometry when the mixture was kept at 25 °C for 2 h.[39]

Nephelometry experiments were performed in a HACH 2100N laboratory turbidimeter (Loveland, USA), and the aggregation behavior of LF and EGCG in aqueous solution was evaluated. The optical apparatus was equipped with a tungsten-filament lamp with three detectors: a 90° scattered-light detector, a forward-scatter light detector, and a transmitted light detector. The calibration was performed using a Gelex Secondary Turbidity Standard Kit (HACH, Loveland, USA), which consists of stable suspensions of a metal oxide in a gel.[39] All experiments were performed in triplicate.

Particle size and size distribution of LF−EGCG complexes were determined by dynamic light scattering (DLS) using a Zetasizer Nano-ZS90 (Malvern Instruments, Worcestershire, U.K.). The intensity of light scattered was monitored at a 90° angle. Results were described as cumulants mean diameter (size, nm) for particle size and polydispersity index (PDI) for size distribution. All experiments were performed in triplicate.

**Fourier Transform Infrared (FTIR) Spectroscopy.** The infrared spectra of samples were measured with the potassium bromide (KBr) pellet method using a Spectrum 100 Fourier transform spectrophotometer (PerkinElmer, U.K.) in the 500−4000 $cm^{-1}$ range, with a resolution of 4 $cm^{-1}$. Potassium bromide was used as a reference. For each measurement, 11 scans were taken. The samples analyzed were free LF, free EGCG, and freeze-dried LF−EGCG complexes.

**Circular Dichroism Measurements.** The CD spectra were recorded using a CD spectropolarimeter (Pistar $\pi$-180, Applied Photophysics Ltd., U.K.) at both far-UV (190−250) and near-UV (250−320) regions under a constant nitrogen flush. Path lengths were 0.1 cm for the far-UV region and 1 cm for the near-UV region. Ellipticity was recorded at a speed of 100 nm/min, 0.2 nm resolution, 20 accumulations, and 2.0 nm bandwidth. The collected data were analyzed using Dichroweb: the online Circular Dichroism Web site http://dichroweb.cryst.bbk.ac.uk.[40,41] Each spectrum presented was the average of three consecutive measurements.

**Fluorescence Spectroscopy.** Fluorescence measurements were carried out using a fluorescence spectrophotometer (F-7000, Hitachi, Japan). LF and EGCG solutions with various concentrations were mixed to prepare final EGCG levels of 10, 20, 30, 40, 50, 60, and 70 $\mu$M with a constant LF concentration of 0.1 mM. Spectra were collected when the mixture was kept at 25 °C for 2 h. The interaction between LF and EGCG was investigated using tryptophan fluorescence quenching. Fluorescence emission spectra of LF were recorded with the excitation wavelength at 292 nm. Both excitation and emission slit widths were set at 5 nm.

The fluorescence quenching data were analyzed by fitting to the Stern−Volmer equation (eq 1):

$$\frac{F_0}{F} = 1 + k_q\tau_0[Q] = 1 + K_{sv}[Q] \quad (1)$$

where $F_0$ and $F$ are the fluorescence intensities in the absence and presence of quencher, $k_q$ is the biomolecular quenching constant, $\tau_0$ is the lifetime of fluorescence in the absence of a quencher, [Q] is the concentration of the quencher, and $K_{sv}$ is the Stern−Volmer quenching constant.[33,42]

The binding constant $K_a$ and the number of binding sites $n$ can be calculated according to a double-logarithmic equation (eq 2):

$$\log\frac{F_0 - F}{F} = \log K_a + n\log[Q] \quad (2)$$

The intercept of the double logarithmic Stern−Volmer plot provides the binding constant ($K_a$), and the slope yields the number of binding sites ($n$).

**Statistical Analysis.** The experiments were conducted in duplicate, and all the analyses were done in triplicate. The results were presented as the means ± standard deviation. Data were analyzed by one-way analysis of variance using the SPSS 16.0 package (SPSS Inc., Chicago, IL, USA), and the means were analyzed by Duncan's multiple-range test. The correlations analysis was carried out using the Pearson mode. The concordance between experimental data and calculated values was established by the root mean squared deviation (RMSD).

## RESULTS AND DISCUSSION

**The Turbidity Measurements.** The turbidity of the LF−EGCG solutions was measured to obtain some information about LF−EGCG complexes' aggregation (Figure 1). The order of turbidity of single protein solutions was as follows: pH 6.5 > pH 3.5 > pH 5.0. At pH 6.5, native LF might undergo a pH-induced self-assembly that led to the formation of increasingly larger particles with time extension than those at pH 3.5 and 5.0.[43] This result could be attributed to the fact that the protein particles had a low net charge around pH 6.5 (see Figure 2), therefore, there might be a weak electrostatic repulsion between the particles. Thermally modified LF at pH 3.5 and 5.0 did not display thermal aggregation behavior whereas LF associated into large insoluble aggregates at pH 6.5. Abe et al. and Sreedhara et al. reported that LF was more thermoresistant at acidic pH whereas turbidity and sometimes gelation were observed upon heating at neutral and alkaline pH.[44,45] The thermal aggregation of LF at pH 6.5 probably exposed sites normally buried inside the molecule that increased protein association by noncovalent interactions, with intermolecular thiol/disulfide reactions.[46] There is a simple relationship between turbidity and ζ-potential at different thermal denaturation temperatures and pH values, that is, at pH 3.5, 5.0, and 6.5, the turbidity of free LF solution becomes higher with the increase of ζ-potential as the two lobes of LF unfold successively (see Figure 2).

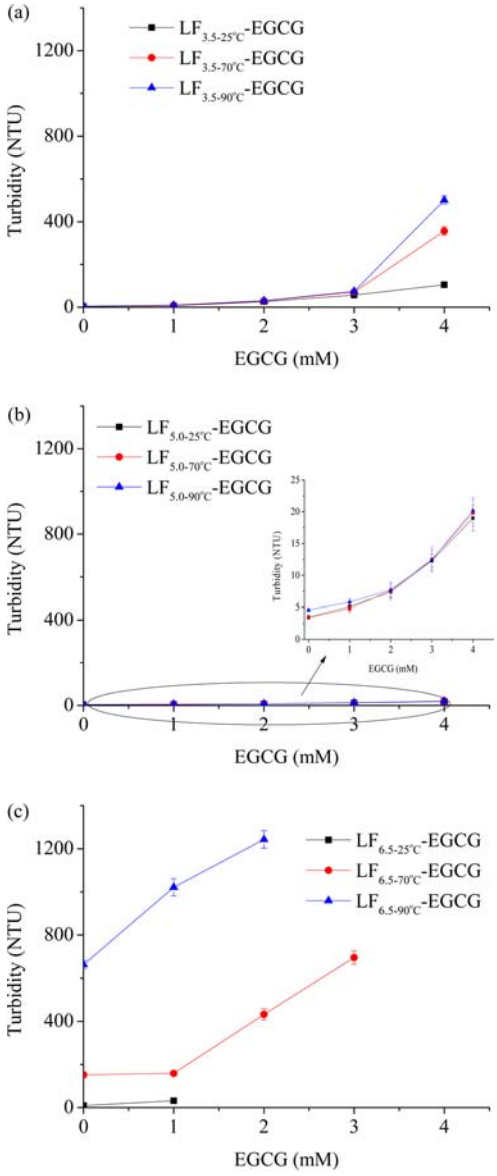

**Figure 1.** Influence of pH and EGCG concentration on the turbidity of LF and LF−EGCG complexes.

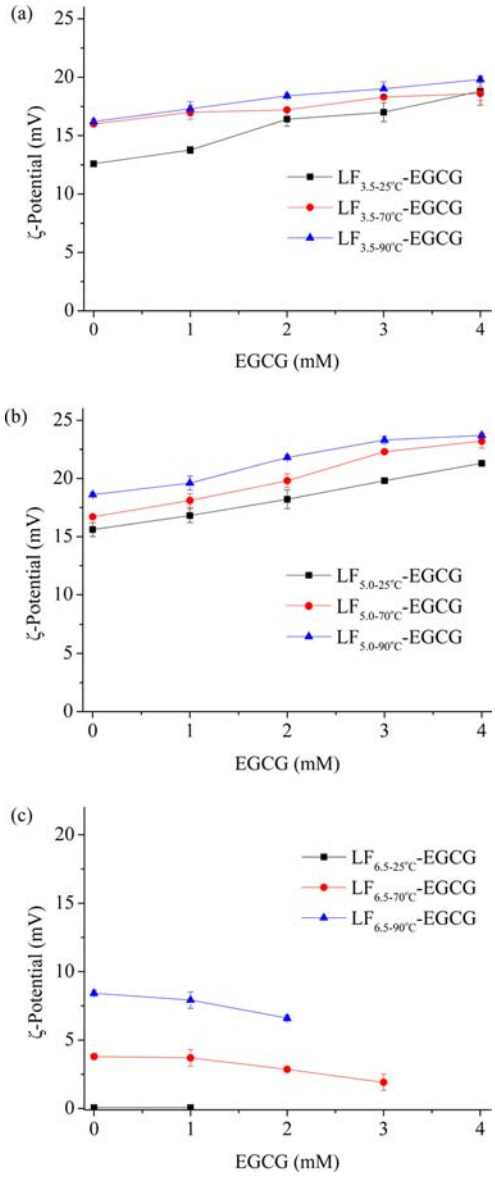

**Figure 2.** Influence of pH and EGCG concentration on the ζ-potential of LF and LF−EGCG complexes.

dx.doi.org/10.1021/jf5038147 | J. Agric. Food Chem. 2014, 62, 10816−10827

In the presence of EGCG, LF−EGCG complexes were formed as indicated by the appearance of increasing turbidity at pH 3.5, 5.0, and 6.5. The precipitations of LF−EGCG complexes resulting from polyphenol−protein interactions were pH sensitive. At pH 3.5 and 5.0, no precipitation was observed for LF−EGCG complexes. This might be ascribed to two reasons: one was the high net surface charge (>13.0 mV) of protein−polyphenol complexes (see Figure 2), which prevented them from coming into close contact and forming large aggregates;[47,48] the other was the small size of complexes formed (see Figure 3). The minimum level of turbidity

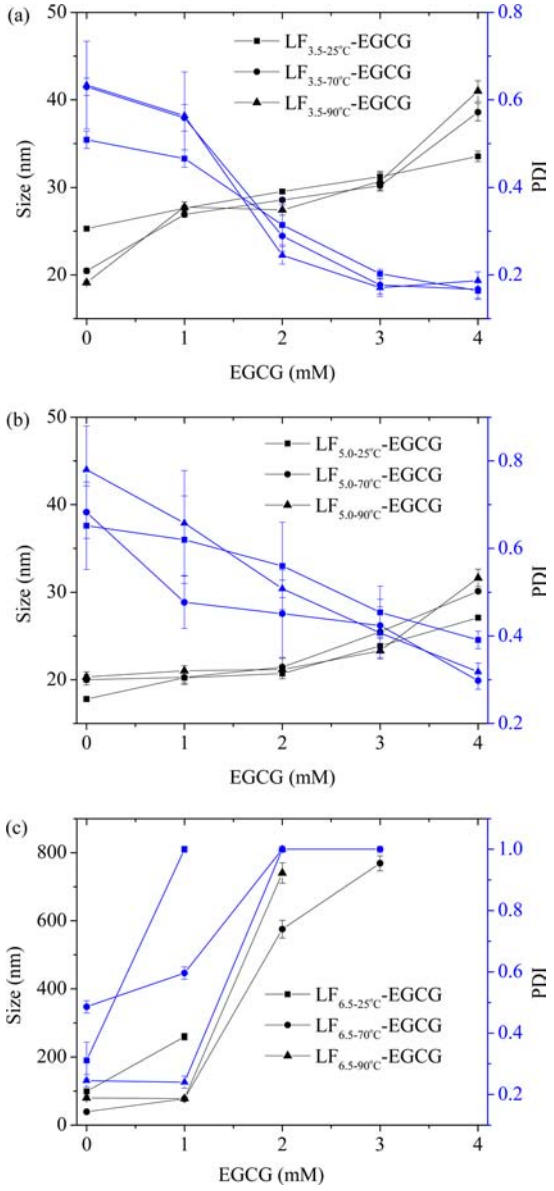

**Figure 3.** Influence of pH and EGCG concentration on the particle size of LF and LF−EGCG complexes.

occurred at pH 5.0 for LF−EGCG complexes; this might be attributed to the higher ζ-potential and smaller size of $LF_{5.0}$−EGCG complex than $LF_{3.5}$−EGCG complex and $LF_{6.5}$−EGCG complex (see Figures 2 and 3), and/or the secondary structure profiles of LF, which presented lower unordered content but higher α-helix content at pH 5.0, while higher unordered content but lower α-helix content at pH 3.5 and 6.5 (see Figure 5 (b)).

It should be noted that the addition of 1.0 mM EGCG resulted in significant sedimentation of $LF_{6.5\text{-}25°C}$−EGCG aggregates. The extensive precipitation could be related to the fact that the ζ-potential of $LF_{6.5\text{-}25°C}$ was very close to neutrality (0.613 ± 0.1 mV for $LF_{6.5\text{-}25°C}$) (see Figure 2) allowing the formation of large aggregates that precipitate.[49] Naczk et al. studied the effect of pH on the formation of crude tannin canola extract and protein (BSA, fetuin, gelatin, and lysozyme) complexes. It was suggested that the lowest solubility of polyphenol−protein complexes occurred at 0.3−3.1 pH units below the isoelectric point of the proteins.[50] Indeed, increased precipitation of protein/polyphenol complex close to the isoelectric point might be attributed to the minimum solubility of the protein at this pH. $LF_{6.5\text{-}70°C}$−EGCG complex and $LF_{6.5\text{-}90°C}$−EGCG complex, having a uniform cloudy appearance, remained relatively stable against particle aggregation until the concentrations of EGCG were more than 2.0 and 3.0 mM, respectively. The low ζ-potential (see Figure 2) explained the low stability of these LF−EGCG complexes at this pH, where particles tended to flocculate and precipitate.

In general, polyphenols normally have a strong binding affinity with proteins, which often leads to precipitation,[51] but some factors, such as pH, temperature, protein type, structure and concentration, and the type and structure of phenolic compounds, basically affect protein−phenolic interactions. The results from aforementioned experiments indicated that the turbidity of LF−EGCG complexes could be manipulated by controlling the pH of solutions, the structure of LF, and the concentration of EGCG.

**ζ-Potential Measurements.** The charge of single LF and LF−EGCG complexes at different pH values is presented in Figure 2. It is interesting to note that the ζ-potential of the $LF_{6.5\text{-}25°C}$ was around 0 mV, despite this pH being below the reported isoelectric point of lactoferrin. The most likely explanation for this result was that the cationic groups on the adsorbed LF bound some anionic phosphate ions present in the buffer.[52]

There were appreciable differences in the influence of pH and thermal treatment on the ζ-potential of LF. As shown in Figure 2, the ζ-potential of LF was increased with the rise of thermal denaturation temperature in different buffer systems. We speculated that the two lobes of the protein are so close that they mask potential interactive sites buried within the interdomains of both lobes of the protein.[46] As the two lobes of LF unfold successively when the protein was heated at 70 and 90 °C, more cationic groups originally located in the hydrophobic interior of LF exposed successively to buffer solutions and/or the thermally modified LF weaken the adsorbed ability of anion present in the buffers, leading to the increased ζ-potential of the thermally modified LF in different buffer solutions.

Some researchers reported that the addition of green tea polyphenols hardly affected the ζ-potential of protein.[47] However, in our study, we interestingly found that the ζ-potential of LF−EGCG complexes was affected by the presence of EGCG. At pH 3.5 and 5.0, the LF had a higher ζ-potential which was further increased by the addition of EGCG. The high net charge of LF−EGCG complexes played an important role in preventing precipitation, which was consistent with the turbidity result that showed a low turbidity at pH 3.5 and 5.0. It should be noted that EGCG bears negative ζ-potential at pH

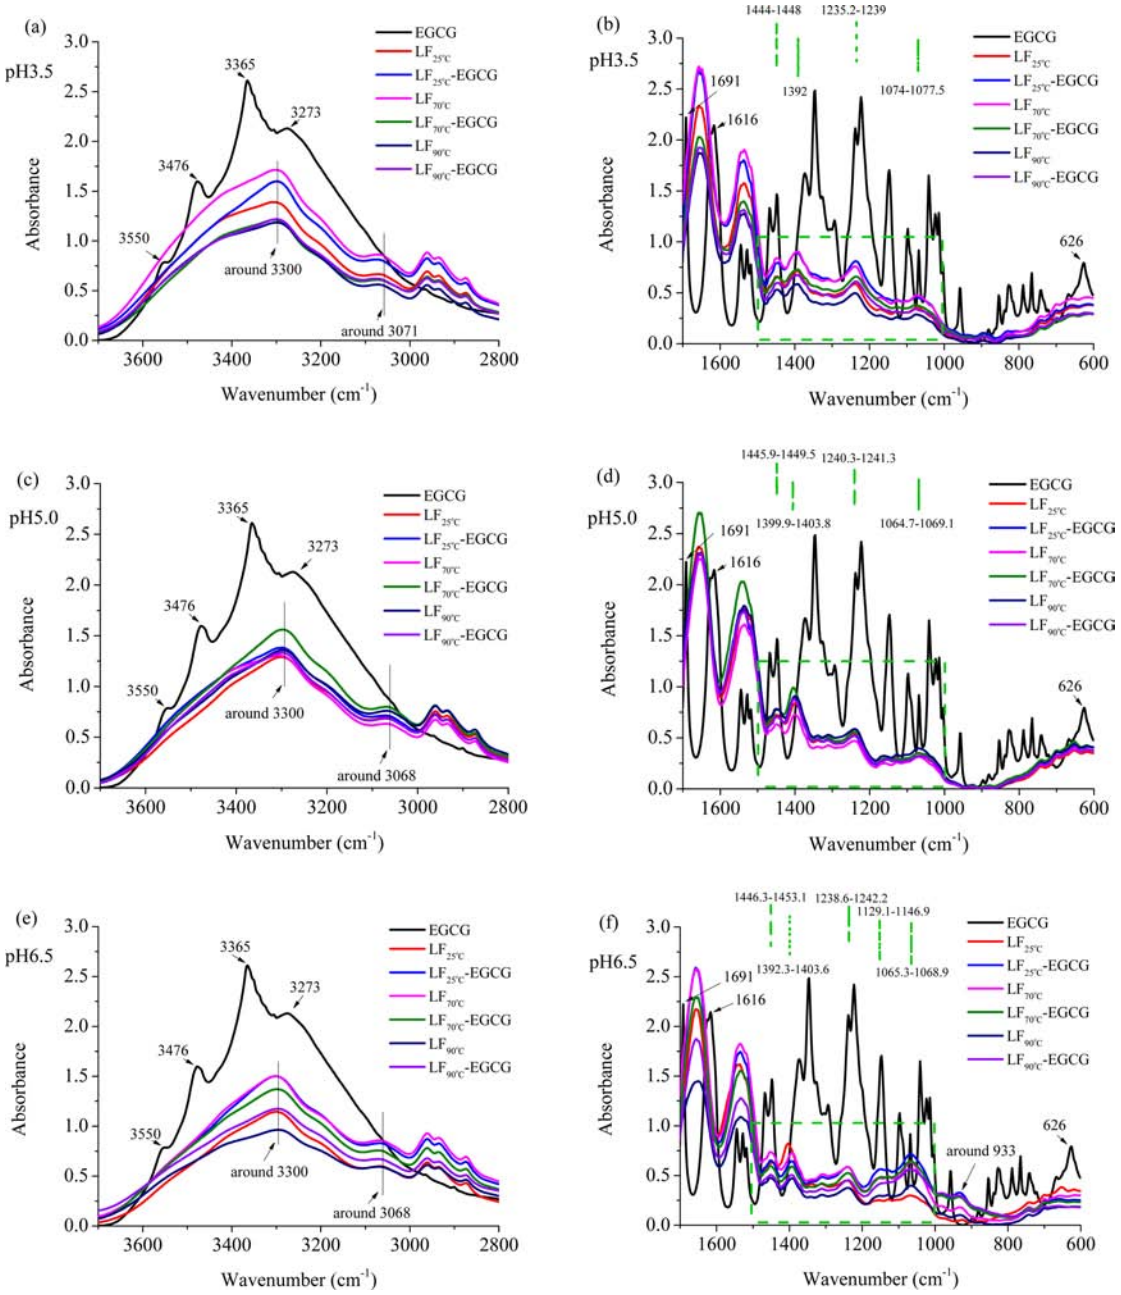

**Figure 4.** FTIR spectra of EGCG, LF, and LF−EGCG complexes (containing 1.0 mM EGCG) at pH 3.5, 5.0, and 6.5.

3.5 and 5.0, opposite to LF. This result revealed that other factors except for the net charge affected the ζ-potential of LF−EGCG complexes, for example, the molecule of EGCG is much smaller than LF, therefore, EGCG might insert into the LF molecule and surround the LF molecule surface, resulting in reorganization of protein secondary and tertiary structures, thereby changing the protein surface charge distribution. At pH 6.5, close to the p$K_a$, the protonated phenolic groups of EGCG could be deprotonated and the generated oxygen center imparts a high negative charge density,[47] which further decreased the ζ-potential value of the complexes, leading to particle aggregation at higher concentration of EGCG.

**The Particle Size Measurements.** Figure 3 shows the particle size and the polydispersity of the LF−EGCG complexes present in buffer solutions. The particle size of thermally modified LF underwent only slight changes compared with native LF at pH 3.5, 5.0, and 6.5. EGCG induced an increase of size of the LF−EGCG complexes at desired pH values, forming larger aggregates that enhanced the scattered light, which was in agreement with the observed increase of nephelometric measurements.

Single LF showed a particle size of 19−25 nm at pH 3.5, and 17.8−20.31 nm at pH 5.0. In the presence of EGCG, this value was increased significantly ($P < 0.05$), but it was always smaller than 41 nm at pH 3.5, and 32 nm at pH 5.0. These nanosized particles were soluble at pH 3.5 and 5.0, in other words, the large-scale aggregation was suppressed in the mixture of LF and EGCG at these two pH values. It is interesting to find that, as the EGCG concentration was increased, the aggregation of LF−EGCG complexes at pH 3.5 and 5.0 was hardly changed, but a narrow range of the particle size distribution was observed (a decreased PDI value, from 0.6 to 0.16 at pH 3.5, and 0.78 to

dx.doi.org/10.1021/jf5038147 | J. Agric. Food Chem. 2014, 62, 10816−10827

0.298 at pH 5.0), indicating a very homogeneous population of these aggregates.

At pH 6.5, the particle size of native LF was larger than 99.35 ± 6.0 nm at the original state because the ζ-potential of LF at pH 6.5 was very close to neutrality (0.613 ± 0.1 mV), and the association was promoted.[53] In the presence of EGCG, this value was increased significantly ($P < 0.05$) and submicrometer particles (0.6−0.8 μm) could be formed. The PDI values, which were different from those at pH 3.5 and 5.0, were enhanced as the size of LF−EGCG complexes increased at pH 6.5, indicating a very heterogeneous population of the aggregates formed. Larger particles remained unstable in solution (see Figure 1) at pH 6.5, which was attributed to the low net charge, with only weak electrostatic repulsion between the particles.

It can be concluded that pH and the structure of LF significantly affected the interaction between LF and EGCG. This interpreted the possibility of monitoring LF−EGCG particle size (nanometer or submicrometer) and morphology with pH and heat treatment as factors. Overall, the sensitivity of the particle size to pH and the structure of LF facilitated the control of the physical properties of LF−EGCG complexes.

**Fourier Transform Infrared (FTIR) Spectroscopy.** EGCG is known to form complexes with proteins leading to changes in the structural, functional, and nutritional properties of both compounds. Figure 4 shows the infrared spectra of LF and LF−EGCG complexes (1.0 mM EGCG). FTIR profiles revealed some pronounced differences between native LF at different pH values, and distinguished LF−EGCG complexes from the native LF.

EGCG has four typical peaks around 3550, 3476, 3365, and 3273 $cm^{-1}$, probably due to the vibration of the O−H linkage of phenolic and hydroxyl groups,[54−56] and two large peaks around 1691 and 1616 $cm^{-1}$, probably due to the carbonyl stretching of the gallic acid,[57] while those peaks were not found in the complexes at all. At the same time, the disappearance of other typical characteristic bands of EGCG, such as peaks in the regions of 1000−1500 and 700−900 $cm^{-1}$, also confirmed the formation of the LF−EGCG complex by noncovalent interaction.

In this study, all complexes showed a broad feature around 3300 $cm^{-1}$, due to intermolecular H-bonded and O−H stretching modes. Slight change of the peak around 3300 $cm^{-1}$ in all LF−EGCG complexes compared to the native LF was an indication of the interaction between LF and EGCG induced by hydrogen bonds.[55] This result was in agreement with previous findings suggesting that polyphenols were bound to the protein partially via H-bonds.[15,58] The absorption bands of LF located at 2936 and 2875 $cm^{-1}$ were attributed to antisymmetric and symmetric $CH_2$ stretching vibrations of proteins.[59] The spectral changes of these vibrations were monitored in order to locate the presence of hydrophobic contact in the LF−EGCG complex. Upon the interaction with EGCG, no shifts of absorption peaks were observed in the LF−EGCG complex compared to native LF (Figure 4), which suggested that the hydrophobic interaction was not the main force when the LF−EGCG complex formed.

Peaks around 1653 and 1535 $cm^{-1}$ in the FTIR spectra of native LF were attributed to C═O stretching vibrations of amide I band[60,61] and N−H bending vibrations and C−N stretching vibrations of amide II band,[62−65] respectively. Both the C═O bonds and the C−N bonds were involved in the hydrogen bonds which took place between the different elements of secondary structure of proteins.[66] LF showed slight or no obvious difference in the amide I band (at 1600−1700 $cm^{-1}$) before and after the addition of EGCG (1.0 mM), but there was some major spectral shifting for LF amide II band at 1535 $cm^{-1}$ upon EGCG interaction. The peak position of amide II blue-shifted from 1535 to 1537 $cm^{-1}$ for $LF_{3.5}$ and $LF_{5.0}$ and red-shifted from 1537.3, 1535.4, and 1533.7 $cm^{-1}$ to 1535.6, 1534.9, and 1533.3 $cm^{-1}$ for $LF_{6.5\text{-}25°C}$, $LF_{6.5\text{-}70°C}$, and $LF_{6.5\text{-}90°C}$, respectively. Peaks around 1448 $cm^{-1}$ for $LF_{3.5}$, 1449 $cm^{-1}$ for $LF_{5.0}$, 1446.3 $cm^{-1}$ for $LF_{6.5\text{-}25°C}$, and 1453 $cm^{-1}$ for $LF_{6.5\text{-}90°C}$ also had obvious red shift (about 1−4 $cm^{-1}$) (Tables 1−3). These results implied that EGCG interacted with the C═O and C−N groups in the protein structural subunits (hydrophilic interaction).

(b) Secondary structure of native and thermally modified LF at pH 3.5, 5.0, and 6.5. (c) Changes in secondary structure of native and thermally modified LF−EGCG complexes (containing 1.0 mM EGCG) at pH 3.5, 5.0, and 6.5.

pH 3.5 and 5.0, and five peaks at pH 6.5 (Figure 4). The shape and intensity of those peaks were varied due to the pH of solutions. The two bands around 1392 and 1446 $cm^{-1}$ associated with the C−O stretching bond of carboxyl groups and the C−H deformation (asymmetrical) vibration in R−$CH_3$,[67,68] respectively; the occurrence of the band at 1238 or 1242 $cm^{-1}$ was assigned to N−H in plane bending of the amide III band;[61] the band observed at 1062 $cm^{-1}$ was attributed to the asymmetrical C−O vibration.[67,69] The characteristic bands of LF in the region of 1500−1000 $cm^{-1}$ were shifted to higher wavelength or lower wavelength, revealing the presence of

specific interactions between LF and EGCG at specific pH values.

It should be noted that the occurrence of a new band at 933 $cm^{-1}$ in thermally modified LF and LF−EGCG complexes at

dx.doi.org/10.1021/jf5038147 | J. Agric. Food Chem. 2014, 62, 10816−10827

pH 6.5 (except $LF_{6.5\text{-}25°C}$) might be associated with the denaturation of LF from thermal treatment or from the interaction with EGCG.[70]

**Analysis of the Secondary Structures of LF and LF−EGCG Complex Using Circular Dichroism (CD).** Far-UV CD was used to obtain information about the changes occurring at the secondary folding level of protein. In this section, the influence of pH on the secondary structure of LF formed by thermal treatment and EGCG-induced conformational transitions of LF (the concentration of EGCG was 1.0 mM) are monitored by far-UV CD spectroscopy (Figure 5).

As shown in Figure 5a, $a_1$−$a_9$, in the 190−260 nm region, the spectra of $LF_{3.5\text{-}25°C}$ were composed of a broad negative band centered at 208−210 nm and a shoulder at 218−220 nm. In the presence of 1.0 mM EGCG, the peak showed a significant decrease in negative ellipticities for all wavelengths of the far-UV CD spectrum, which was a characteristic of $LF_{3.5\text{-}25°C}$ secondary structure conformation change. Similar spectra were obtained for other native and thermally modified LF. The secondary structure content was estimated using the DICHROWEB procedure, which was an online server for protein secondary structure analyses from circular dichroism spectroscopic data.[41] The fractions of $\alpha$-helix, $\beta$-sheet, turn, and unordered coil were estimated by SELCON3 and are shown in Figure 5b.

It should be noted that Sreedhara et al. recently studied the pH-induced change in the structure of bovine lactoferrin, which was similar to our results in this work, finding a structure change for native LF with a relatively low content of $\alpha$-helix structure (18%, 21.4%, and 19.2% for $LF_{3.5\text{-}25°C}$, $LF_{5.0\text{-}25°C}$, and $LF_{6.5\text{-}25°C}$, respectively), but still rich in $\beta$-structure (32%, 33%, and 32.6% for $LF_{3.5\text{-}25°C}$, $LF_{5.0\text{-}25°C}$, and $LF_{6.5\text{-}25°C}$, respectively) (Figure 5b).[45] On the other hand, some researchers reported that LF released iron at pH 3.0−4.0, resulting in a less compact structure.[3,36] Therefore, the structure of LF at pH 3.5 might be less compact than those at pH 5.0 and 6.5. The results in our study were consistent with the reports for LF at pH 3.5 with a relatively higher content (29.1%) of unordered structure than those at pH 5.0 (25.4%) and 6.5 (27.2%).

The protein conformational analysis based on CD data indicated that the thermal process led to changes in the secondary structure of LF. In the presence of 1.0 mM EGCG, the $\alpha$-helical content was increased with a concomitant reduction of $\beta$-sheet and unordered coil contents; whereas the content of $\beta$-turn did not exhibit obvious change (Figure 5c). Therefore, it could be concluded that EGCG induced a progressive increase in the proportion of $\alpha$-helix structure at the cost of $\beta$-sheet and unordered coil structure of LF (both native and thermally modified LF) at pH 3.5, 5.0, and 6.5. In other words, it indicated that EGCG contributed largely to the stability of LF helical conformation and LF became a slightly looser conformation due to the increase of unordered coil fraction.

**Comparison of Binding Constant and Site of EGCG with Native LF and Thermally Modified LF.** In general, heating induces conformational (secondary/tertiary structure) changes of proteins, and exposes previously buried hydrophobic sites, which may influence LF affinity with EGCG. Aromatic residues (Phe, Trp, and Tyr) contribute to hydrophobic interactions that stabilize the core of protein interiors because they have relatively large apolar surface areas.[71] The tryptophan (Trp) residues are often found fully or partially buried in the hydrophobic core of protein interiors, at the interface between two protein domains or subdomains, or at the subunit interface in oligomeric protein systems.[72] There exist 13 Trp residues in the LF structure.[33] By monitoring the emission peak change, some information might be obtained concerning the structural changes and the microenvironment surrounding the fluorophore in the proteins.[73] As shown in Figure 6, the thermal treatment at 70 or 90 °C induced an increase in the fluorescence intensity. The fluorescence intensities of LF solutions exhibited the increases of 6.1% and 16.3% at pH 3.5, 18.7% and 77.4% at pH 5.0, and 26% and 2.4% at pH 6.5 when heated at 70 and 90 °C for 20 min, respectively. This might be attributed to the irreversibly changed conformation of LF as the two lobes successively unfolded and the side chains of LF became more exposed to buffer solutions, leading to the Trp residues gradually exposed to water and the decrease of intramolecular quenching.[33]

The emission of tryptophan may be blue-shifted if the group is buried within a native protein, and its emission may be red-shifted when the protein is unfolded.[74] The fluorescence spectra of LF after the addition of EGCG are shown in Figure 6. It was obvious that the fluorescence intensity of LF was regularly decreased with the rise of EGCG concentration, and this implied that there existed binding behavior between LF and EGCG at pH 3.5, 5.0, and 6.5. There were no obvious shifts of the maximum $\lambda_{em}$ (338 nm) of LF fluorescence at pH 3.5 and 5.0, while the maximum $\lambda_{em}$ of $LF_{6.5\text{-}70°C}$ and $LF_{6.5\text{-}90°C}$ was obviously red-shifted (from 341 to 346 nm for $LF_{6.5\text{-}70°C}$ and from 344 to 355 nm for $LF_{6.5\text{-}90°C}$) in the presence of EGCG (Figure 6h,i). These results revealed that there was a larger change in the immediate environment of the tryptophan residues of thermally modified LF at pH 6.5 than pH 3.5 and 5.0, and then EGCG was situated in close proximity to the tryptophan residues for quenching to occur.

Table 4 summarizes the results correspondingly estimated according to eqs 1 and 2. Figure 6 shows the Stern−Volmer plots for LF fluorescence quenching by EGCG. In the linear range of the Stern−Volmer regression curve, the average quenching constants ($K_{sv}$) of LF were estimated as 6.3, 5.8, and 5.6 × $10^4$ $M^{-1}$ for $LF_{3.5\text{-}25°C}$, $LF_{3.5\text{-}70°C}$, and $LF_{3.5\text{-}90°C}$, respectively; 6.5, 11.4, and 17.6 × $10^4$ $M^{-1}$ for $LF_{5.0\text{-}25°C}$, $LF_{5.0\text{-}25°C}$, and $LF_{5.0\text{-}25°C}$, respectively; 7.6, 9.4, and 10.6 × $10^4$ $M^{-1}$ for $LF_{6.5\text{-}25°C}$, $LF_{6.5\text{-}70°C}$, and $LF_{6.5\text{-}90°C}$, respectively. It is well-known that Trp $\tau_0$ depends on pH and buffer composition. In buffer solutions at pH < 7.0, Trp $\tau_0$ is in the range of 2.33 ± 0.15 ns (at pH 2.55) to 3.16 ± 0.10 ns (at pH 6.8).[75] The lowest $K_{sv}$ value estimated in our study was 5.6 × $10^4$ $M^{-1}$ (for

**Table 4. Stern−Volmer Quenching Constant ($K_{sv}$), the Binding Constant ($K_a$), and the Number of Binding Sites ($n$) for the Interaction of EGCG with Native and Thermally Modified LF at pH 3.5, 5.0, and 6.5**

| 6.5 | $LF_{25°C}$ | 7.61 | 0.980 | 0.24 | 0.86 | 0.954 |
| | $LF_{70°C}$ | 9.43 | 0.965 | 0.18 | 0.82 | 0.948 |
| | $LF_{90°C}$ | 10.60 | 0.927 | 0.03 | 0.61 | 0.987 |

$LF_{3.5\text{-}25°C}$), yielding $k_q$ above $2.4 \times 10^{13}$ $M^{-1}$ $s^{-1}$, at least 3 orders of magnitude higher than $2.0 \times 10^{10}$ $M^{-1}$ $s^{-1}$, the maximum collisional (dynamic) quenching constant for various quenchers interacting with biopolymers.[76,77] These results thus implied that the quenching process was static quenching involving the formation of LF−EGCG complexes.

For the static mechanism of quenching, the double logarithmic Stern−Volmer equation (eq 2) could be used to analyze the quenching data and calculation of the apparent binding constants ($K_a$) of the LF−EGCG complexes formed.

As illustrated in Table 4, the binding constants ($K_a$) and the number of binding sites per LF molecule ($n$) for EGCG with LF were increased with the rise of denaturation temperature at pH 3.5, while they were decreased at pH 5.0 and 6.5. Most of the $K_a$ values were in the range of $10^3$−$10^5$ $M^{-1}$, except $LF_{6.5\text{-}90°C}$, which displayed great thermal aggregation behavior at pH 6.5. The association constants obtained were in agreement with previously published data for other proteins (such as bovine serum albumin, whey protein isolate, sodium caseinate) and EGCG by applying the same methodology ($10^4$−$10^5$ $M^{-1}$).[12,13,31] The $K_a$ values were estimated as $LF_{5.0\text{-}25°C}$ > $LF_{5.0\text{-}70°C}$ > $LF_{3.5\text{-}90°C}$ > $LF_{3.5\text{-}70°C}$ > $LF_{3.5\text{-}25°C}$ > $LF_{5.0\text{-}90°C}$ > $LF_{6.5\text{-}25°C}$ > $LF_{6.5\text{-}70°C}$ > $LF_{6.5\text{-}90°C}$. Based on the aforementioned result, we concluded that if we do not take $LF_{5.0\text{-}90°C}$ into account, the affinity of EGCG toward LF was pH dependent and had the following order: pH 5.0 > pH 3.5 > pH 6.5. Lower pH led to stronger binding because the dissociation of protein had more binding sites at lower pH.[78] Therefore, we hypothesized that when pH changes away from the p$I$ of LF, the electrostatic repulsion between LF molecules increases, which inhibits the self-association of the protein and facilitates the binding of EGCG to LF. The interactions between chlorogenic acid and several proteins such as BSA, lysozyme, and $\alpha$-lactalbumin at pH ≤ 7 resulted from noncovalent bonds and the amount of chlorogenic acid bound by BSA (per molecule) was somewhat higher at lower pH.[79] Some researchers reported that the EGCG-binding capacity of thermally modified $\beta$-lactoglobulin could be enhanced compared to the native protein at pH 7.0,[31] while, with the rise of thermal denaturation temperature, the binding constant decreased at pH 5.0 and 6.5, which implied that EGCG had strong affinity for native LF but weak affinity for thermally modified LF. It seemed that the probably more unfolded structure of $LF_{5.0\text{-}70°C}$ and $LF_{5.0\text{-}90°C}$ decreased the exposure of noncovalent sites normally located on the surface of both lobes of the protein, reducing the binding constant when LF−EGCG complexes formed. Moreover, the thermal aggregation of LF at pH 6.5 probably exposed nonpolar groups normally buried in the LF nonpolar interior, which increased the self-association of the protein through hydrophobic attraction and decreased the binding of EGCG to LF. In contrast, EGCG had weak affinity for native LF but strong affinity for thermally modified LF at pH 3.5. This might be ascribed to the difference of pH in the solution and the secondary structure of the protein at pH 3.5.

In this study, the native and thermally modified LF had potential to form coassembled vehicles for the delivery of EGCG. The changes of pH in the solution and the structure of protein were the crucial factors influencing the noncovalent interaction between LF and EGCG. LF−EGCG nanoparticles have good transparency at pH 3.5 and 5.0, which could be applied in clear beverages and liquid foods. At the same time, LF−EGCG submicrometer particles remained relatively stable to particle aggregation and were formed at pH 6.5, which could be applied in cloudy beverages and liquid foods. Overall, LF−EGCG nano- and submicrometer particles as protective vehicles for EGCG could be obtained by choosing the appropriate reaction parameters, which was beneficial for the development of controlled release of other bioactive materials.

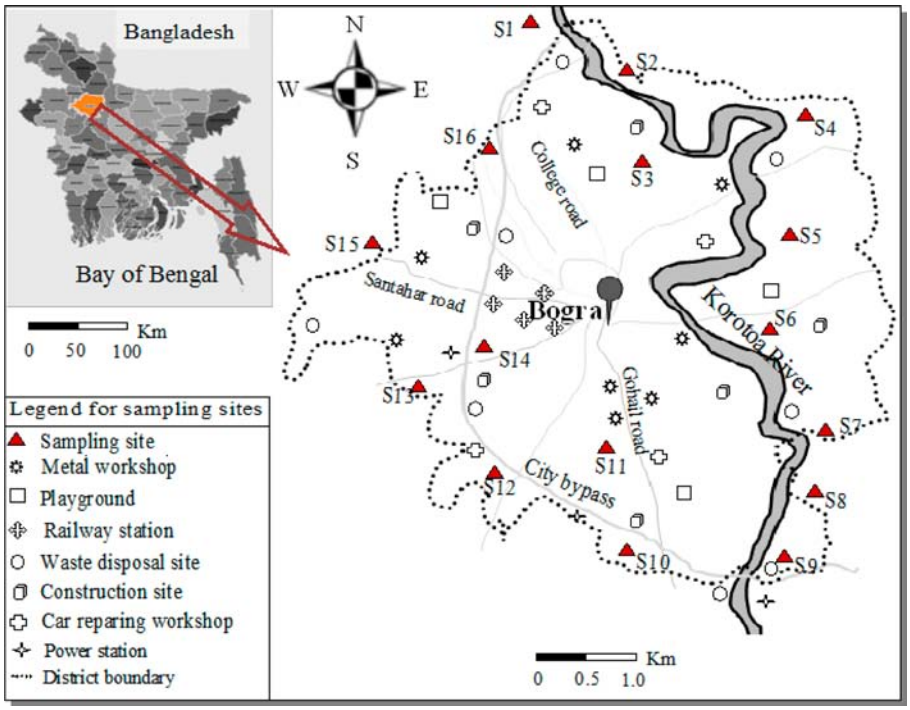

**Figure 1.** Map of the study area of agricultural fields in Bogra district situated at the northern part of Bangladesh.

the middle- and low-income group of the population in Bangladesh, to establish baseline information on the levels of heavy metals (Cr, Ni, Cu, Zn, As, Cd, and Pb) and to estimate their risk to human through dietary intake.

## MATERIALS AND METHODS

**Sample Collection and Preparation.** The per capita per day intake of major food items and intakes of individual food items were used to characterize the food consumption pattern for adults in Bangladesh.[18] The five most consumed types of grains and pulses, i.e., rice (*Oryza sativa*), wheat (*Triticum aestivum*), maize (*Zea mays*), lentil (*Lens culinaris*), and black gram (*Vigna mungo*), were collected from an urban area situated at the northern part in Bangladesh (Figure 1). Wheat, maize, and pulses were collected during February−March 2012, and rice samples were collected during August−September, 2013. In the process of sample transport and storage, we ensured that the samples did not make contact with metal instruments in order to avoid cross-contamination. From each sampling site a composite sample for each food item was prepared and homogenized using a food processor. After collection from the field, about 200 g of fresh food samples were put in the rotary type food processor. The pretreated samples were first mixed and homogenized and then oven-dried at 105 °C for 24 h to remove the moisture content. The dried samples were then stored at −20 °C in the laboratory of the Institute of Nutrition and Food Science (INFS), University of Dhaka, Bangladesh. About 48 composite soil samples were also collected from the same fields of collected food samples. At each sampling station, soil sample (up to 10 cm depth) was collected in the form of subsamples, which were thoroughly mixed to form a composite sample. Soil samples were air-dried at room temperature for 2 weeks, then ground, and homogenized. The dried soil samples were crumbled and pulverized with a porcelain mortar and pestle, sieved through a 2 mm nylon sieve, and stored in an airtight clean zipper bag in freezer conditions until chemical analysis was carried out.

**Measurement of Soil Properties.** The physicochemical parameters of soil such as pH, EC, % C, and texture were measured. The pH of sediments was measured in 1:2.5 soil to water ratio. The soil/deionized water mixture was stirred with a clean glass rod, and the slurry was allowed to equilibrate for 30 min.[19] The pH values were recorded using a Horiba U-23 instrument with the calibration of pH 4.0, pH 7.0, and pH 9.0 standards. For electrical conductivity (EC) determination, 5.0 g of sediment was taken in 50 mL polypropylene tubes. Then, 30 mL of distilled water was added to the tube. The lid was closed properly and was shaken for 5 min. After that, EC was measured using an EC meter (Horiba D-52).[20] Percent organic carbon of soil was measured using an elemental analyzer (model type: Vario EL III, Elenemtar, Germany). The catalytic combustion was carried out at a permanent temperature of up to 1200 °C. The element concentration from the detector signal and the sample weight based on stored calibration curves were measured. Particle size distribution was determined using the hydrometer method.[21] The soils were classified using the United States Department of Agriculture (USDA) classification system (gravel [>2 mm], sand [2−0.05 mm], silt [0.05−0.002 mm], and clay [<0.002 mm]).

**Chemicals and Analytical Methods.** A microwave digestion system (Berghof, Germany) was used in preparation of samples to analyze various metals. The microwave digestion system has been designed to perform chemical digestion procedures under extreme pressure and temperature conditions in chemical laboratories. Digestion reagents that were used included 5 mL of 69% $HNO_3$ acid (Kanto Chemical Co. Japan) and 2 mL of 30% $H_2O_2$ (Wako Chemical Co. Japan). The weighed samples of 0.3 g were then placed into the digestion reagent in a Teflon vessel (DAP-60K type). After digestion, samples were then transferred into a Teflon beaker and total volume was made up to 25 mL with Milli-Q water (Elix UV5 and Milli-Q, Millipore, USA). The digest solution was then filtered (DISMIC 25HP PTFE syringe filter (pore size = 0.45 mm, Toyo Roshi Kaisha, Ltd., Japan) and stored in a screw cap plastic tube (Nalgene, New York).

**Quality Control.** All test batches were evaluated using an internal quality approach and validated if they satisfied the defined internal quality controls (IQCs). For each experiment, a run included blank, certified reference materials (CRM) as internal standard in samples, and samples analyzed in triplicate to eliminate any batch-specific error. Standard stock solutions containing 10 μg/L of each element (Cd, As, Pb, Cr, Ni, Zn, Se, Cu, Mo, Mn, Sb, Ba, V, and Ag) and internal standard solutions containing 1.0 mg/L of indium (In), yttrium (Y), beryllium (Be), telium (Te), cobalt (Co), and titanium (Ti) were purchased from Spex CertiPrep USA. Multielement standard solution

was used to prepare a standard curve. Before starting the sequence, relative standard deviation (RSD < 5%) was checked by using tuning solution purchased from Agilent Company. Metals in samples were analyzed using an inductively coupled plasma mass spectrometer (ICP-MS).

**Transfer Factor of Metals.** The transfer factor (TF) of metals from soil to the edible parts of food was defined as the ratio of the metal concentration in the plant's tissues to the metal concentration in soil. The transfer factor was calculated for each food at each site separately. Transfer factor can be used to evaluate the potential capability of plants to transfer metals from soil to edible tissues. TF was calculated as follows:

$$\mathrm{TF} = \frac{C_{\mathrm{food}}}{C_{\mathrm{soil}}} \quad (1)$$

where $C_{\mathrm{food}}$ and $C_{\mathrm{soil}}$ represent the total metal concentration in the edible part of foods (mg/kg) and total metal concentration in soil (mg/kg) on a dry weight basis.[22]

**Estimated Daily Intakes.** Estimated daily intakes (EDIs) for heavy metals were calculated using the respective average concentration in food samples by the weight of food item consumed by an individual (body weight 60 kg for adult[23] in Bangladesh), which was obtained from the household income and expenditure survey,[18] and calculated by using the following formula:

$$\mathrm{EDI} = \frac{\mathrm{FIR} \times C}{\mathrm{BW}} \quad (2)$$

where FIR is the food ingestion rate (g/person/day), $C$ is the metal concentration in food samples (mg/kg), and BW is the body weight.

**Noncarcinogenic Risk.** The equation used for estimating the target hazard quotient is as follows:[17]

$$\mathrm{THQ} = \frac{\mathrm{EFr} \times \mathrm{ED} \times \mathrm{FIR} \times C}{\mathrm{RfD} \times \mathrm{BW} \times \mathrm{AT}} \times 10^{-3} \quad (3)$$

$$\mathrm{TTHQ\,(individual\,food)} = \mathrm{THQ}_{\mathrm{toxicant1}} + \mathrm{THQ}_{\mathrm{toxicant2}} + \ldots + \mathrm{THQ}_{\mathrm{toxicant}n} \quad (4)$$

In order to assess the overall potential for noncarcinogenic effects from more than one heavy metal, a hazard index (HI) has been formulated based on the Guidelines for Health Risk assessment of Chemical Mixtures of USEPA[12] as follows:

$$\mathrm{HI} = \sum \mathrm{TTHQ} = \mathrm{TTHQ}_{\mathrm{food1}} + \mathrm{TTHQ}_{\mathrm{food2}} + \ldots + \mathrm{TTHQ}_{\mathrm{food}n} \quad (5)$$

where THQ is the target hazard quotient (dimensionless), EFr is the exposure frequency (365 days/year), ED is the exposure duration (70 years), FIR is the food ingestion rate (g/person/day), $C$ is the metal concentration in foods (mg/kg), RfD is the oral reference dose (mg/kg/day), and AT is the averaging time for noncarcinogens (365 days/year × number of exposure years). The oral reference doses were based on 1.5, 0.02, 0.04, 0.3, 0.0003, 0.003, and 0.0035 mg/kg/day for Cr, Ni, Cu, Zn, As, Cd, and Pb.[24] If the THQ is less than 1, the exposed population is unlikely to experience obvious adverse effects. If the THQ is equal to or higher than 1, there is a potential health risk[25] and related interventions and protective measurements should be taken.

**Carcinogenic Risk.** The equation used for estimating the target carcinogenic risk factor (lifetime cancer risk)[12] is as follows:

$$\mathrm{TR} = \frac{\mathrm{EFr} \times \mathrm{ED} \times \mathrm{FIR} \times C \times \mathrm{CSFo}}{\mathrm{BW} \times \mathrm{AT}} \times 10^{-3} \quad (6)$$

where TR represents the target cancer risk or the risk of cancer over a lifetime, AT is the averaging time for carcinogens (365 days/year × ED), and CSFo is the oral carcinogenic slope factor from the Integrated Risk Information System USEPA[24] database, which was 1.5 and 8.5 × $10^{-3}$ (mg/kg/day)$^{-1}$ for As and Pb.

**Statistical Analysis.** Data were statistically analyzed using the statistical package SPSS 16.0 (SPSS, USA). The mean and standard deviation of heavy metals in food samples were calculated. Post hoc Tukey tests were employed to examine the statistical significance ($P$ < 0.05) among mean concentrations of heavy metals among different food groups.

## RESULTS AND DISCUSSION

**Physicochemical Properties and Metals in Soil.** The physicochemical properties of soil are presented in Table 1.

**Table 1. Physicochemical Properties of Soil at Different Sites of Bogra District Urban Area, Bangladesh**

| | | | | (% in <2 mm) | | | |
|---|---|---|---|---|---|---|---|
| land types | pH (1:5 $H_2O$) | EC ($\mu$S/cm) | organic carbon (%) | sand | silt | clay | soil type |
| S1 | 5.6 | 39 | 1.4 | 52 | 25 | 23 | sandy clayey loam |
| S2 | 7.2 | 79 | 2.8 | 51 | 31 | 18 | loam |

| S15 | 6.0 | 26 | 3.1 | 18 | 27 | 55 | clay loam |
| S16 | 5.7 | 38 | 2.9 | 16 | 24 | 60 | clay loam |

[a]According to the United States Department of Agriculture soil classification system.

The studied soils were slightly acidic to neutral except the S4 site, which was alkaline (Table 1) due to the decomposition of organic matter and subsequent formation of carbonic acid.[26] The range of organic carbon (% C) was 0.36 to 3.1, and the highest value was observed in soil collected from the S15 site. According to the United States soil texture classification, the textural analysis revealed that the soil belonged to the sand, sandy loam, sandy clayey loam, loam, loamy sand, and clay loam class (Table 1). The concentrations of heavy metals were measured to estimate the transfer factor in cereals and pulses. Mean concentrations of Cr, Ni, Cu, Zn, As, Cd, and Pb in soil were 41, 45, 42, 75, 10, 4.2, and 44 mg/kg, respectively (Table 2). Metals in soils were compared with the other studies in Bangladesh and other countries. Chromium concentrations of the present study were higher than those of the study conducted in China, Spain, and Turkey and one study in Bangladesh (Table 2), indicating that soils were contaminated

[a]All values are expressed as mg/kg. [b]Data in parentheses indicates range.

by Cr. In Bangladesh, the main sources of Cr in agricultural soils where the farmers grow cereals and pulses are the repeated uses of untreated or poorly treated wastewater from industrial establishments (e.g., textile and tannery sludge) and the application of chemical fertilizers and pesticides.[2,27] Like Cr, other metals were slightly higher than found in the other studies conducted in Bangladesh and other countries. This can be ascribed to the fact that metal processing, battery manufacturing, and smelting industries responsible for severe metal pollution have been reported from many countries.[28] During our sampling campaign, we observed leachates from defused Ni–Cd batteries, Cd plated items, casting lead, and lead product manufacturing at the sampling sites. Used metal fittings, rubber, plastics, tires, paints, etc. are materials emitting Cd to the environment.[29] The mean concentrations of Ni, Cu, and Cd in the present study were above the Dutch soil quality standard[30] (Table 2). The functional properties of these soils such as nutrients and contaminants storage, transformation and biomass production, etc. were seriously hampered or threatened, which could potentially cause an adverse effect on humans, plants, and animals.[30] Therefore, the contaminations of these agricultural fields' soils are a major concern because foods are still being grown on these soils. The Dutch soil quality standard is regarded as the most comprehensive guideline considering all possible exposure pathways for protecting humans, plants, and animals. If any metal concentration in soil is below its respective Dutch Target Value, the soil is considered clean. If the concentration level lies between the target values and intervention values, the soil is regarded to be slightly to moderately contaminated. In contrast, if the value is above the Dutch Intervention Value, the soil is considered detrimental to humans, plants, and animals. According to Table 2, Cd was in the worst situation among the studied metals as the mean concentration of Cd was more than 5 times higher than the Dutch Target value.

**Metals in Cereals and Pulses.** In the present study, concentrations of Cr, Ni, Cu, Zn, As, Cd, and Pb (mg/kg) were determined in the composite samples of most commonly consumed cereals (rice, wheat, and maize) and pulses (lentil and black gram) by the Bangladeshi population and are listed in Table 3. Average concentration of heavy metals among the food groups showed the descending order of maize > black gram > lentil > wheat > rice. The observed variation in metal concentrations for analyzed foodstuffs might be due to variable capabilities of absorption and accumulation of metals by the cereal crops.[31]

An elevated level of Cr was found in black gram (2.4 mg/kg) followed by lentil, maize, rice, and wheat (Table 3). The mean Cr concentration in rice was 1.8 mg/kg (range, 0.26–4.2 mg/kg, $n$ = 32). A previous study by Fu et al.[16] reported mean Cr concentration in Chinese rice of 0.20 mg/kg (range, 0.062–0.42 mg/kg, $n$ = 4), which is lower than in the present study. In the present study, the highest mean concentration of Ni was found in black gram, 1.4 mg/kg (range, 0.047–4.0 mg/kg). In rice, Ni concentration was observed (mean, 1.0; range, 0.03–2.6 mg/kg). However, Ni concentration in all rice samples of the present study was considerably lower than those of Chinese rice (mean, 0.48 mg/kg; range, 0.20–0.82 mg/kg, $n$ = 4)[16] and Indian state of West Bengal (mean, 0.87 mg/kg; range, 0.0002–1.8 mg/kg).[32] Among the studied metals, significant difference of Zn concentration was observed in the studied foods (Table 3), therefore, Zn measured in the current study is more likely to be having a micronutrient effect rather than

[a] $n$ = number of samples analyzed for this study. [b] SD = standard deviation. [c] Different letter (a, b, c) indicates statistical significance ($p < 0.05$).

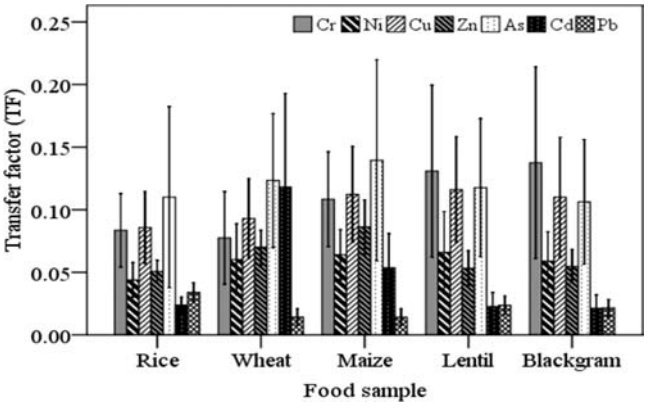

**Figure 2.** Transfer factor of metals from soil to cereals and pulses collected from agricultural fields of Bogra district, Bangladesh (bars represent standard error at 95% CI).

posing a significant risk of toxicity. However, the highest Zn concentration was found in maize (mean, 3.6 mg/kg; range, 1.5−7.3 mg/kg, $n$ = 32) (Table 3). The mean concentration of As in rice was 0.47 mg/kg, which was higher than in the previous study conducted by Williams et al.,[33] where As concentration in Bangladeshi rice was 0.13 mg/kg. The elevated As concentration in rice was attributed to the higher accumulation of As from soil to grain in the anaerobic paddy soil systems for rice production and uncontrolled application of As enriched fertilizers and pesticides.[34] Cadmium is a metallic element that occurs naturally at low levels in the environment. Food, rather than air or water, represents the major source of cadmium exposure.[35] The highest Cd concentration was observed in wheat (mean, 0.16; range, 0.001−0.66 mg/kg).

**Transfer Factor of Metals.** The accumulation of metals in the edible parts of cereals and pulses could have a direct impact on human health through the food chain. Metals with high TF are more easily transferred from soil to the edible parts of

[a]The total metals THQs (TTHQ, sum of individual metal THQs). [b]Carcinogenic risk for As was calculated based on 90% inorganic As in cereals and pulses. [c]HI: the sum of THQ values of heavy metals due to consuming the diet.

plants than the ones with low TF. As seen from Figure 2, large variations in TFs were observed among different samples and metals. The average TF of metals in all crops was in the following order: As > Cr > Cu > Zn > Ni > Cd > Pb. In rice, average values of TF were 0.084, 0.044, 0.086, 0.051, 0.11, 0.024, and 0.034, in wheat, average values of TF were 0.078, 0.060, 0.093, 0.070, 0.12, 0.12, and 0.014, and in maize, average values of TF were 0.11, 0.064, 0.11, 0.086, 0.14, 0.054, and 0.014 for Cr, Ni, Cu, Zn, As, Cd, and Pb, respectively. The TF of Cd in wheat was higher than those of any other metals examined. It was noticeable that Cd was considered as a very dangerous substance for human health by the long-term effects.[36] Therefore, the risks of Cd for health should be highlighted by its high toxicity and mobility from soil to wheat grain. In lentil, average values of TF were 0.13, 0.066, 0.12, 0.053, 0.12, 0.023, and 0.024, and in black gram, average values of TF were 0.14, 0.059, 0.11, 0.055, 0.11, 0.021, and 0.022 for Cr, Ni, Cu, Zn, As, Cd, and Pb, respectively. The major pathway for Pb to enter the above-ground tissues of plants is through atmospheric deposition.[37] Therefore, the factual TF of Pb should be lower than the calculated value. In this study, the soil-to-plant TF for various metals and for most common cereals and pulses consumed by local residents were calculated (Figure 2), and our data showed that TF values slightly varied among metals within the same crop. The difference in TFs between metals and species might be related to soil properties, nutrient management, crop genetic features, and physicochemical properties of pollutants.[22] For instance, soils from S2, S3, S15, and S16 were generally higher in organic matter and clay content might be responsible for higher metal transfer from soil to plants.

**Estimated Daily Intakes (EDIs).** The EDIs of seven metals (Cr, Ni, Cu, Zn, As, Cd, and Pb) were evaluated according to the average concentration of each metal in each food crop from each site and the respective consumption rates. The EDI and maximum tolerable daily intake (MTDI) of studied metals from consumption of grain crops are shown in Table 4. Total daily intake of Cr, Ni, Cu, Zn, As, Cd, and Pb were 0.95, 0.57, 0.95, 1.2, 0.26, 0.28, and 0.35 mg/day, respectively (Table 4). The maximum contribution of daily intake of studied metals came from rice; this is due to the highest consumption rate of rice (445 g/person/day).[38] The total EDIs of Cr, Ni, As, Cd, and Pb from all examined food items were higher than the MTDI values recommended by the international regulatory bodies (Table 4), indicating that these foods might pose health risks to consumers.

**Noncarcinogenic Risk.** Risk assessment is the process that evaluates the potential health effects from doses to humans of one contaminant received through one or more exposure pathways. The health risks from consumption of cereals and pulses by adult populations were assessed based on the target hazard quotients (THQs). The THQ is a ratio of determined dose of a pollutant to a reference dose level. If the ratio is greater than 1, the exposed population is likely to experience obvious adverse effects.[25] The methodology for estimation of THQs does not provide a quantitative estimate on the probability of an exposed population experiencing a reverse health effect, but it offers an indication of the risk level due to contaminant exposure. The estimated THQs of studied metals are shown in Table 5, indicating that THQ values of As and Pb were above 1 through consumption of rice, suggesting that people would experience significant health risks if they only ingest these two metals from rice. The consumption of rice per

capita in Bangladesh is 445 g/day.[38] Therefore, consuming rice containing high As and Pb might put pregnant women at a higher risk. Among all the metals studied, the TTHQ through consuming rice was 14, suggesting that Bangladeshi people might have significant noncarcinogenic health risk through only consuming rice. However, the total target hazard quotient (TTHQ) values through consuming other cereals and pulses were equal to or less than 1, indicating that there were no potential significant health risks in terms of these food items. The hazard index (HI) value expresses the combined noncarcinogenic effects of multiple elements. In Table 5, the HI value through selected food consumption was 17, indicating that consumers of the studied foodstuffs may experience adverse health effects.

**Carcinogenic Risk of As and Pb.** Concerning the carcinogenic risk, the CR values of As were $4.7 \times 10^{-3}$, $3.4 \times 10^{-4}$, $3.8 \times 10^{-4}$, $2.1 \times 10^{-4}$, and $2.0 \times 10^{-4}$ (assuming 90% of inorganic As[39]) and of Pb were $4.5 \times 10^{-5}$, $1.1 \times 10^{-6}$, $1.1 \times 10^{-6}$, $1.2 \times 10^{-6}$, and $1.1 \times 10^{-6}$ for rice, wheat, maize, lentil, and black gram, respectively, which were clearly higher than the USEPA threshold level ($10^{-6}$) or residual level ($10^{-4}$) for causing cancer,[24] indicating carcinogenic risks for all adults of the study area.

The concentrations of heavy metals widely varied among the samples. Among cereals and pulses, rice contributes the highest intake of the studied metals. Considering the transfer factor of metals from soil to cereals and pulses, As showed higher TF values than the other metals. Total intake of Cr, Ni, As, Cd, and Pb for the exposed people was slightly higher than that recommended as the MTDI (for a person weighing 60 kg), indicating that people would experience significant risks. From the human health point of view, the THQ values for As and Pb were higher than 1, suggesting that people would experience significant health risks if they ingest these two vital metals through consuming the studied foodstuffs. However, consumption of all foodstuffs could lead to a potential health risk to the consumers since HI value was higher than 1. Concerning the carcinogenic risk, the total CR values of As and Pb were clearly higher than the USEPA threshold level ($1 \times 10^{-6}$). However, health risks associated with food consumption are not negligible and the sources of metal pollution should be controlled to achieve safe foodstuffs. The present study is of great interest in terms of toxicology and food safety for the Bogra district urban population, given the absence of previous studies to determine dietary intake of heavy metals, not only for the district urban population but also at the national level.

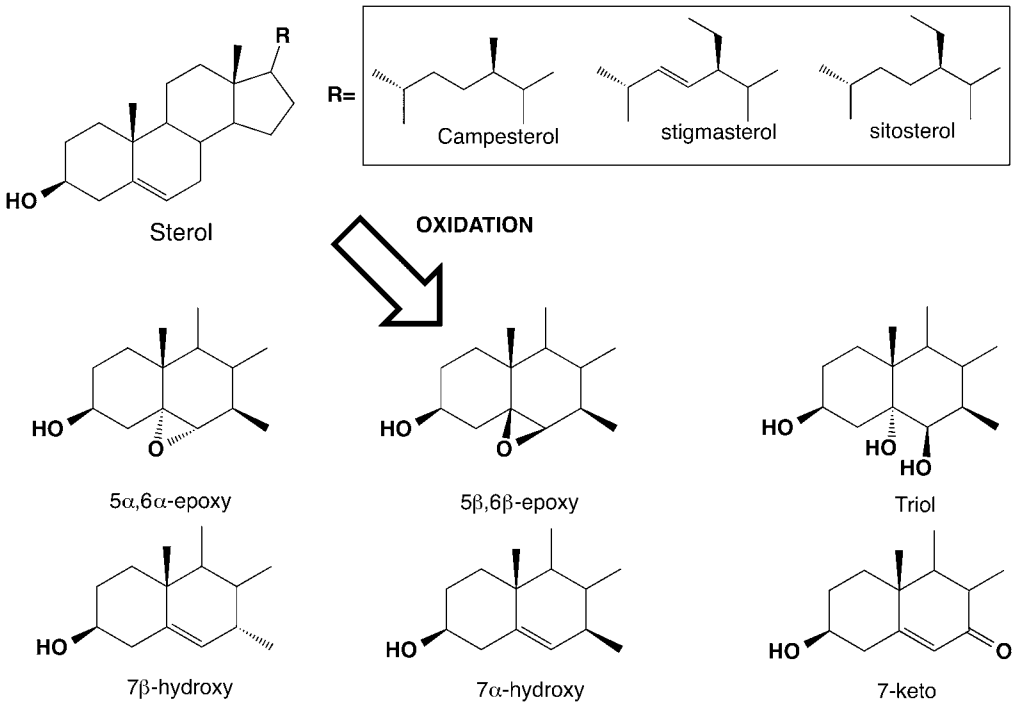

**Figure 1.** Structures of campesterol, stigmasterol, sitosterol, and their main oxidation products (POPs).

storage; in fact, the presence of OTA in green coffee was reported for the first time in 1974,[22] and thereafter, many authors have determined the OTA content in green and roasted coffee or in coffee beverages.[5,21,23−25] Contradictory results about the effect of roasting on the reduction of OTA in coffee beans have been reported. However, it seems that roasting can diminish OTA content, as reported by Napolitano et al.[5] and Romani et al.,[23] who observed an OTA reduction >90% in green coffee after roasting. Although the latter could be an effective process for reducing OTA content in coffee, it should be pointed out that roasting conditions (time/temperature) could differently impact OTA destruction. On the other hand, several studies mention physical removal of OTA by elimination of coffee silverskin before and during the roasting process;[5] in fact, since CS covers and protects the coffee bean, it is possible that a high amount of OTA is concentrated in CS. Nevertheless, only a few papers reported the presence (<4 μg/kg) of OTA in CS.[4,15]

Also, the lipid fraction of CS could be potentially a source of bioactive molecules, such as phytosterols (PS) (Figure 1), which are known to reduce the low-density lipoproteins (LDL) cholesterol concentration and are thus often incorporated into functional foods.[26] However, PS are prone to oxidation, like cholesterol,[27] leading to a wide range of oxidation products[26] (POPs; Figure 1). While the toxicological aspects of cholesterol oxidation products are well-documented,[28] the information about the biological impact of POPs is limited.[26] Recently, O'Callaghan et al.[29] reported the role of POPs in many different biological mechanisms (cholesterol uptake and metabolism, atherosclerosis, inflammation, cytotoxicity, oxidative stress, etc.), while Adcox et al.[30] demonstrated that β-sitosterol and campesterol oxides display a similar toxicity to that of COPs in a culture-derived macrophage cell line (C57BL6). To the best of our knowledge, no data about the content of PS and/or POPs in CS have been reported in the literature. However, in order to propose some reuse of CS, it is of outmost importance to define the potential safety risks.

The aim of this paper was to evaluate the CS suitability as possible source of bioactive compounds, as well as the presence of potentially hazardous compounds, in usual storage conditions employed for this waste product. A full characterization study focused on both lipophilic and hydrophilic components of CS was carried out. OTA and POPs were determined, together with the fiber content, the total phenolic compounds, the carbohydrate composition, and the caffeine amount. Different methods for extracting the lipid fraction were tested, and its total fatty acid composition and total PS content were investigated.

## 2. MATERIALS AND METHODS

**2.1. Samples.** CS was obtained from a mix of Arabica and Robusta coffee, supplied by a local coffee-roasting enterprise (Bologna, Italy). CS was removed during roasting through a cyclone and then stored in closed containers kept in a separate locale at uncontrolled room temperature and relative humidity. Two-kilogram CS samples were weekly collected in triplicate for a total of 5 weeks ($n$ = 15). For OTA determination, the CS sampling was extended to 10 weeks ($n$ = 30).

**2.2. Reagents and Solvents.** All chemicals and solvents were of analytical grade. HPLC-grade methanol (≥99.9%) and water (≥99.8%) were purchased from Merck (Darmstadt, Germany), while bidistilled water (100%) was supplied by Panreac (Castellar del Vallès, Spain).

Caffeine (assay ≥99%) and magnesium oxide (MgO) were purchased from Caelo (Hilden, Germany) and Riedel-de-Haen (Seelze, Germany), respectively. A fiber kit was provided by Megazyme International Ireland Ltd. (Wicklow, Ireland). The standard mixture of fatty acid methyl esters (GLC 463) was purchased from Nu-Chek (Elysian, MN). 19-Hydroxycholesterol (19-HC) were supplied by Steraloids (Newport, RI). Triolein (≥99.0%), tripalmitin (≥99.0%), tristearin (≥99.0%), 1,3-diolein (≥99.0%), 1,2(3)-dipalmitin (≥99.0%), cholesteryl palmitate (≥97%), 1-oleoyl-*rac*-glycerol (≥99.0%), tridecanoic acid (≥99.0%), methyl tridecanoate (≥99.5%), gallic acid (≥98%, GA), D-dulcitol (≥99%), D-mannitol (≥98%), D-

sucrose (≥99.5%), D-glucose (≥99.5%), D-inositol (≥99.5%), (±)-α-tocopherol (≥96%), rac-β-tocopherol (≥96%), (+)-δ-tocopherol (≥96%), (+)-γ-tocopherol (≥96%), Folin−Ciocalteu phenol reagent, 5α-cholestan-3β-ol (dihydrocholesterol, ≥95%), stigmasterol (≥95%), β-sitosterol (≥95%), betulinol (≥98%), and tetramethylbenzidine (TMB) were purchased from Sigma (St. Louis, MO). The purity of sterols was controlled by GC−FID. No. 1 filters (70 mm diameter) were used (Whatmann, Maidstone, England). Aminopropyl solid-phase extraction (SPE-$NH_2$) cartridges (Strata $NH_2$-55 mm, 500 mg/3 mL) from Phenomenex (Torrence, CA), were utilized for sterol oxide purification. The silylation mixture was prepared with dried pyridine, hexamethyldisilazane, and trimethylchlorosilane at a ratio of 5:2:1 by volume. Silylating agents and large silica TLC plates (20 cm × 20 cm × 0.25 mm film thickness) were supplied by Merck (Darmstadt, Germany).

**2.3. Extraction and Determination of Caffeine from CS.** CS was pulverized and subjected to caffeine extraction as reported by the ISO 20481:2008 method.[31] Briefly, 1 g of CS was placed in a flask and extracted with 250 mL of bidistilled water in the presence of 5 g of magnesium oxide for 20 min, under continuous stirring in a water bath at 90 °C. The supernatant was filtered through a nylon filter (0.45 μm) and diluted at 50% with methanol, and 10 μL of the extract was injected into a high-performance liquid chromatography (HPLC) system (HP1050 series; Hewlett-Packard, Palo Alto, CA). The latter was equipped with a quaternary pump, an autosampler Series 1100 (Agilent, Santa Clara, CA), an UV−vis photodiode, and a Poroshell 120 EC-C18 (Phenomenex, Torrance, CA) analytical column (50 × 3.0 mm, 2.7 μm particle size). An isocratic elution with HPLC-water:methanol (76:24, v/v) at a flow rate of 0.4 mL/min was carried out at room temperature. Data were acquired with Chemstation for LC3D software (Agilent Technologies, Palo Alto, CA). The caffeine determination and quantification was performed at the wavelength of maximum absorbance ($\lambda$ = 272 nm).

Caffeine was quantified by using an external standard calibration curve with a concentration range of 8.08−40.40 μg/mL. The linear regression equation and correlation coefficient were calculated for caffeine ($y = 71.933x + 11.127$; $R^2 = 0.999$). Limit of detection and limit of quantitation were calculated as 3- and 10-fold the signal-to-noise ratio. Caffeine content of CS samples is expressed as grams per 100 g of CS (g/100 g CS), and each determination was performed in triplicate.

**2.4. Determination of Moisture.** The moisture content of CS was determined as reported by AOAC.[32] Samples were kept under vacuum (2 mbar) at 70 °C for 16 h. The moisture and dry weight were gravimetrically determined in triplicate.

**2.5. Determination of Insoluble, Soluble, and Total Dietary Fiber.** The insoluble (IDF), soluble (SDF), and total (TDF) dietary fiber contents were determined by using the total dietary fiber assay kit, according to the enzymatic−gravimetric method suggested by Borrelli et al.[15]

One gram of CS was suspended in 40 mL of Tris-Mes buffer (0.05 mM) and added with 50 μL of α-amylase. The mixture was heated at 95 °C for 35 min. Then the solution was cooled down at 60 °C, 10 μL of the protease was added, and the mixture incubated at 60 °C for 30 min. In order to stop the reaction, 5 mL of HCl (0.56 M) was added and pH was adjusted to a value between 4.1 and 4.8, by using NaOH (0.5 M) and HCl (0.5 M). Finally, 200 μL of amyloglucosidase was added and the solution was incubated at 60 °C for 30 min (A).

For the IDF determination, the enzymatically digested solution (A) was filtered on the crucible and the insoluble material (which contains the IDF) was washed with 10 mL of warm bidistilled water (60 °C). Two identical aliquots of insoluble matter were prepared. Both aliquots were placed at 103 °C overnight and then weighed. Afterward, one of them was placed in a muffle furnace at 525 °C for 5 h and then weighed to quantify the ashes; the other one was used to quantify the protein amount ($p$) by the Kjeldahl method.[33] The digestion was performed with $H_2SO_4$ (96%) at 420 °C for 2 h.

The protein amount was subtracted from IDF by applying the following formula:

$$\text{IDF}\ (\%) = [[R - (p + (\text{As}/100))R] - B]/100m$$

where $R$ is the total solids from $m$, $m$ is the sample weight (g), $p$ is the protein weight (g), As is the ashes weight (g) from $R$, and $B$ is the weight of blank (g) (enzymes + solvents without sample). $B$ was calculated as follows:

$$B = \text{total solid weight} - (\text{protein weight} + \text{ashes of solid weight})$$

For SDF determination, 300 mL of ethanol (95%) at 60 °C was added to filtered fractions collected from IDF separation, in order to precipitate the fiber fraction; after 1 h, SDF was recovered by filtration on the crucible. The insoluble matter was washed with 10 mL of ethanol (78%), followed by 10 mL of ethanol (90%). The following steps were performed as above-described for the IDF determination. The percentage of SDF was calculated using the same formula for IDF evaluation.

For TDF determination, 300 mL of ethanol (95%) at 60 °C was added to the enzymatically digested solution (A), and after 1 h, this solution was filtered. The TDF was obtained by filtering the ethanol solution through a crucible with a Celite filter (1 g). Subsequently, insoluble material was repeatedly washed with 15 mL of ethanol (78%), followed by 10 mL of ethanol (90%) and 10 mL of acetone. The following steps were performed as aforementioned for IDF determination. The percentage of TDF was calculated from the same formula used for IDF evaluation.

The results are expressed as a percentage (%).

**2.6. Extraction and Determination of Soluble Carbohydrates.** The soluble carbohydrates were extracted from 10 g of CS using 250 mL of bidistilled water at 50 °C and ultrasound (Branson 2510, Thermo Fischer Scientific, Waltham, MA) for 30 min. After cooling, the supernatant was filtered through a nylon filter (0.45 μm) and injected into HPLC system by autosampler. The soluble carbohydrate amount and composition were determined using an HPLC equipped with a LC-10 A (JASCO, Tokyo, Japan) quaternary pump, a Rezex RPM-Monosaccharides $Pb^{2+}$ column (300 mm × 7.8 mm × 8.0 μm) at 75 °C, and a refractive index (RI) detector. HPLC-grade water was used as mobile phase at flow rate of 0.7 mL/min. The identification of soluble carbohydrates was carried out by injecting a standard mixture containing D-dulcitol, D-inositol, D-mannitol, D-sucrose, D-glucose, and D-fructose. Soluble carbohydrates were quantified by using an external standard calibration curve of glucose. Soluble carbohydrate content of CS samples are expressed as a percentage of glucose equivalent. The determination was performed in triplicate.

**2.7. Determination of Total Phenolic Compounds.** Phenolic compounds were extracted from CS by solid−liquid extraction, according to a modified version of the method suggested by Pirisi et al.[34] Ten milliliters of $CH_3OH$:$H_2O$ solution (60:40, v/v) were added to 1 g of CS, and total phenols were extracted at 45 °C for 15 min. The sample was then centrifuged for 20 min at 1000$g$ and the supernatant was collected; other two extractions were performed using the same conditions. The supernatant fraction was collected, and after solvent evaporation by rotary evaporator, the phenolic fraction was dissolved in 8 mL of $CH_3OH$:$H_2O$ solution (50:50, v/v).

Folin−Ciocalteu reactive solution (0.5 mL) was added to 100 μL of the extracted phenolic fraction and incubated in the presence of $Na_2CO_3$ (15%, p/v) for 2 h at room temperature. The absorbance was measured at 750 nm, using a double-beam UV−visible spectrophotometer (JASCO model V-550, JASCO International, Tokyo, Japan). For the quantification of total phenolic compounds, a calibration curve of gallic acid (GA) was used with a concentration range of 2.01−10.1 μg/mL ($y = 128.65x + 0.0492$; $R^2 = 0.996$). The results are expressed as milligrams of GA equivalents per 100 g of CS (mg GA equiv/100 g CA).

**2.8. Determination of Lipid Content.** Different extraction methods were tested and compared: a modified version of the method proposed by Folch et al.[35] (A), the Soxhlet method[36] performed with $n$-hexane (B) and petroleum ether (40−60 °C) (C), and a direct solid−liquid extraction with $n$-hexane:CS (1:100, v/w) (D). In the latter case, 1 g of CS was added to the solvent,

homogenized by Ultra-Turrax for 3 min, and then subjected to ultrasound for 20 min. The organic layer (containing the lipid matter) was separated by centrifugation (1620*g* for 20 min); this procedure was carried out in triplicate. The lipid fraction was collected and dried with a rotary evaporator; the fat amount was determined gravimetrically.

Each method for lipid extraction was performed in triplicate ($n = 3$).

**2.9. Chromatographic Lipid Profile.** Twenty milligrams of the lipid extract was dissolved in 1 mL of *n*-hexane, and 1 μL was injected in the GC−FID. A fused silica capillary column (Restek RTX-5, 10 m × 0.25 mm i.d. × 0.1 μm film thickness; Bellefonte, PA), coated with 95% dimethyl- and 5% diphenylpolysiloxane, was used. The temperature was programmed from 100 to 350 °C at 6 °C/min. The injector and FID temperatures were set at 350 °C. The injection was performed in the split mode (1:50), and helium at a flow of 1 mL/min was used as the carrier gas. The different lipid classes (free fatty acids, free and esterified sterols, monoacylglycerols, diacylglycerols, triacylglycerols) were identified using diverse commercial standards. The data are expressed as area percentage.

**2.10. Determination of Total Fatty Acids Methyl Esters.** About 20 mg of lipid extract were methylated with 200 μL of diazomethane;[37] 1.01 mg of tridecanoic acid methyl ester was added (as internal standard), and the mixture was transmethylated with 40 μL of 2 N KOH in methanol.[38] The composition of total fatty acid methyl esters was determined by injecting 1 μL of the supernatant of transmethylated solution into a GC−FID, as reported by Cardenia et al.[39] The data are expressed as a percentage of CS and total fatty acids.

**2.11. Determination of Sterols in CS.** A 150 mg subfraction of the lipid extract was added with known amounts of the internal standard solution (1.6 mg of dihydrocholesterol and 0.125 mg of 19-HC for the determination of total sterols and POPs, respectively). Subsequently, the sample was dried under nitrogen stream and treated with 10 mL of 1 N KOH solution in methanol to perform a cold saponification at room temperature for 18 h, as reported by Sander et al.[40]

One-tenth of the unsaponifiable matter was used for the determination of total sterols, whereas the remaining part was utilized for POP analysis.

Two milligrams of unsaponifiable matter was dissolved in chloroform and loaded on a 20 × 20 cm silica TLC plate, which had been previously immersed in a 0.2 N KOH solution in ethanol. The mobile phase was a mixture of *n*-hexane:diethyl ether (65:35, v/v). The TLC bands of the unsaponifiable components were visualized by spraying with a 0.2% ethanolic solution of 2′,7′-dichlorofluorescein sodium salt, under UV light (254 nm). The bands were separately scraped off, transferred in tubes, and extracted three times with 3 mL of chloroform each time. The fractions were collected, dried under nitrogen flow at room temperature, silylated,[41] and analyzed by Fast GC/MS.

Fast GC/MS analysis was performed using a GC Shimadzu QP 2010 Plus (Kyoto, Japan) equipped with a split−splitless injector and coupled to an electron impact (EI) mass spectrometric detector. A Restek RTX-5 fused silica capillary column (10 m × 0.1 mm i.d. × 0.1 μm film thickness; Bellefonte, PA), coated with 95% dimethyl- and 5% diphenylpolysiloxane, was used. A nonsilanized standard split liner (95 mm × 5 mm o.d. × 3.4 mm i.d.) was utilized. The temperature was programmed from 220 to 325 °C at 5 °C/min. The injector and the ion source temperatures were set at 325 and 200 °C, respectively. The injection was performed in the split mode (1:50), and helium at a linear velocity of 47.7 cm/s was used as the carrier gas. The electron energy was 70 eV. A mass range from 50 to 650 *m*/*z* was scanned at a rate of 2500 amu/s, which corresponded to 0.3 event time. The acquisition and integration modes were full scan (TIC) and single ion monitoring (SIM), respectively. PS were recognized and quantified by their corresponding characteristic ions, as reported by Inchingolo et al.:[42] 215 *m*/*z*, dihydrocholesterol (internal standard); 382 *m*/*z*, campesterol; 83 *m*/*z*, stigmasterol; 396 *m*/*z*, β-sitosterol; 488 *m*/*z*, sitostanol; and 459 *m*/*z*, campestanol. The data are expressed as percentage of CS and lipid matter.

**2.12. Determination of Phytosterol Oxidation Products (POPs).** The $^{9}/_{10}$ of the unsaponifiable matter was purified by silica solid-phase extraction (SPE-SI), as reported by Guardiola et al.[43] TMSE derivatives of POPs were analyzed by Fast GC−MS, as suggested by Cardenia et al.[45] with minor modifications. A Shimadzu GC-MS QP 2010 Plus (Kyoto, Japan) was fitted with an RTX-5 Restek capillary column (10 m × 0.1 mm i.d. × 0.1 μm film thickness; Supelco, Bellefonte, PA), and helium was used as carrier gas (0.5 mL/min). The oven temperature was programmed from 220 to 325 °C at the rate of 5 °C/min. The injector and transfer line temperatures were set at 325 and 320 °C, respectively. Manual injection of 1 μL of the solution containing POPs and the solutions obtained from samples was performed in the split mode at a 1:50 ratio. The filament emission current was 70 eV. A mass range from 40 to 650 *m*/*z* was scanned at a rate of 1500 amu/s. The acquisition and integration modes were full scan (TIC) and single ion monitoring (SIM), respectively.

Identification of POPs was performed by comparing their retention times and mass spectra with an internal laboratory library, as well as with those reported in the literature. POPs were recognized and quantified by their corresponding characteristic ions, which show a high abundance in SIM mode: 353 *m*/*z*, 19-hydroxycholesterol (19-HC, internal standard); 470 *m*/*z*, 7α/β-hydroxycampesterol (7α/β-HCA); 482 *m*/*z*, 7α/β-hydroxystigmasterol (7α/β-HST); 484 *m*/*z*, 7α/β-hydroxysitosterol (7α/β-HSI); 488 *m*/*z* α/β-epoxycampesterols (α/β-ECA); 500 *m*/*z*, α/β-epoxystigmasterols (α/β-EST); 412 *m*/*z*, α/β-epoxysitosterols (α/β-ESI); 417 *m*/*z*, campestanetriol (CATr); 429 *m*/*z*, stigmastentriol (STTr); 431 *m*/*z*, sitostanetriol (SITr); 486 *m*/*z*, 7-ketocampesterol (7-KCA); 498 *m*/*z*, 7-ketostigmasterol (7-KST); 500 *m*/*z*, 7-ketositosterol (7-KSI). The full MS fragmentation of POPs is reported in Figures S.1−S.18 and Table S.1 in the Supporting Information. Considering that POP standards are not commercially available and that POP fragmentation is similar to that of cholesterol oxidation products (COPs), POPs quantification was performed by using the calibration curves obtained for cholesterol oxides in SIM mode.[44] The data are expressed as milligrams per 100 g of CS (mg/100 g CS).

**2.13. Determination of Ochratoxin A (OTA).** A Helica Ochratoxin A Assay Kit (Helica Biosystem Inc., Santa Ana, CA), which is a solid-phase direct enzyme immunoassay, was used for the determination of OTA in CS. OTA was extracted from 25 g of CS with 125 mL of methanol (70%) and the extracted fluid was filtered by Whatman filter (No. 1; Whatman International Ltd., Maidstone, England). The latter (100 μL) was allowed to react with 200 μL of horseradish peroxidase (HRP), put in polystyrene microwells coated by antibody with high affinity for OTA, and incubated for 5 min. Thereafter, the wells were washed with water and TMB, and substrate was added, which develops a blue color in the presence of the enzyme that is inversely proportional to the content of OTA. The reaction was stopped by adding 100 μL of diluted $H_2SO_4$, and the blue color of the solution became yellow. The absorbance was determined at 450 nm, by using an ELISA reader. OTA was quantified by using a calibration curve of OTA with a concentration range of 0.4−8.0 ng/mL, which corresponded to 20.0−40.0 μg/kg OTA. The results are expressed as micrograms per kilogram of CS (μg/mg CS).

**2.14. Statistical Analysis.** For all analytical determinations, the data are reported as median values and the standard deviation of 15 independent replicates ($n = 15$), except for OTA, where 30 independent replicates ($n = 30$) were analyzed. Statistical analysis of the data was performed by R 3.0.2 (R Foundation for Statistical Computing, 2013).

## 3. RESULTS AND DISCUSSION

**3.1. Caffeine Content.** A noticeable amount of caffeine in CS samples was found. In general, the average caffeine content (0.8−1.0%) was in agreement with those reported by Napolitano et al.[5] (0.83−1.37%). However, other authors found higher caffeine levels (1.7−4.1 and 8.9−11.1%).[1,16,45] Such differences could be attributed to the diverse methods used for caffeine extraction from CS.

Table 1. Chemical Composition of CS [moisture (g/100 g CS), dietary fiber (g/100 g CS), caffeine (g/100 g CS), carbohydrates (g/100 g CS), and polyphenols (g GA/100 g CS)] and Its Comparison with Literature Data[a]

| | Present work | Ref 15 | Ref 17 | Ref 3 | Ref 16 | Ref 1 |

| TG | 9.2 ± 0.1 c | 47.6 ± 0.9 a | 48.9 ± 1.0 a | 18.9 ± 2.6 b | *** |

[a]The results are expressed as mean ± standard deviation ($n$ = 15). Different letters in each row denote statistically different means (Tukey's test; $P \leq 0.05$). Abbreviations: method A, Folch et al.'s method;[35] method B, Soxhlet[36] performed with $n$-hexane; method C, Soxhlet[36] performed with petroleum ether (40−60 °C); method D, direct solid−liquid extraction with $n$-hexane:CS (1:100, v/w); stat signif, statistical significance. [b]The asterisks denote the level of significance: *significant at $P \leq 0.05$; **significant at $P \leq 0.01$; ***significant at $P \leq 0.001$.

**3.2. Moisture Content.** Since microbial growth is greatly affected by humidity,[46] the moisture content of CS was determined during storage. After CS removal during the roasting process, it was collected and pressed in the presence of water; however, a noncontrolled hydration system was used, and this could have affected the moisture content of the CS samples (Table 1). In fact, high data dispersion was observed (average values 2.6−8.2%), with the highest and lowest moisture levels found in the first and the fourth weeks, respectively. Nevertheless, the present data are in agreement with those reported in the literature.[4,15]

**3.3. Content of Dietary Fibers.** TDF, IDF, and SDF were determined (Table 1). Average TDF (70−79%) was composed of about 85% IDF and 15% SDF, which are in agreement with the results reported by Murthy et al.;[47] however, the present data were higher than those found by Borrelli et al.,[15] which might be due to the different extraction conditions used. The high content of fibers confirms that CS could be utilized in the food industry, to develop functional food and beverages for the control of human body weight, for prevention of pathologies related to carbohydrates metabolism (such as obesity, diabetes, etc.),[8] or as an alternative source of dietary fiber for bread making.[17]

**3.4. Soluble Carbohydrate Content.** As shown in Table 1, the average total amount of soluble carbohydrates ranged from 0.87 to 1.39% and were mainly composed of fructose (0.34−0.58% CS), sucrose (0.09−0.25% CS), mannitol (0.11−0.23% CS), glucose (0.08−0.21% CS), and inositol (0.08−0.19% CS). It must be pointed out that CS is mainly constituted by two polysaccharides, cellulose and hemicellulose, which contain glucose, xylose, galactose, mannose, and arabinose; however, Mussatto et al.[7] found that glucose was the main carbohydrate in CS, which is in contrast with data found here. Furthermore, other authors found a wide range of total sugar content (1.6−12%) in CS.[16] These differences might be related to the extraction procedures used, as they might have led to a diverse hydrolysis degree of the native polysaccharides, thus being reflected in a different final content of the single mono- and disaccharides.

**3.5. Content of Phenolic Compounds.** Phenolic compounds are well-known for their antioxidant activity and their defense role, so many authors have studied their presence in CS.[1,3,15,16,48] The total phenolic compounds were determined by the Folin−Ciocalteau method, and their average content ranged from 0.46 to 0.71 g/100 g CS; these levels agree with those found by Murthy and Naidu[3] and Bresciani et al.,[1] but they were lower than those reported by Narita and Inouye,[16] who used subcritical water. It might be possible that, during coffee roasting, phenols were degraded due the high processing temperature and that melanoidins were formed, thus affecting the Folin−Ciocalteau method, probably due to a chemical redox-based principle as described by Bresciani et al.,[1] who reported that the phenolic matter of CS was mostly

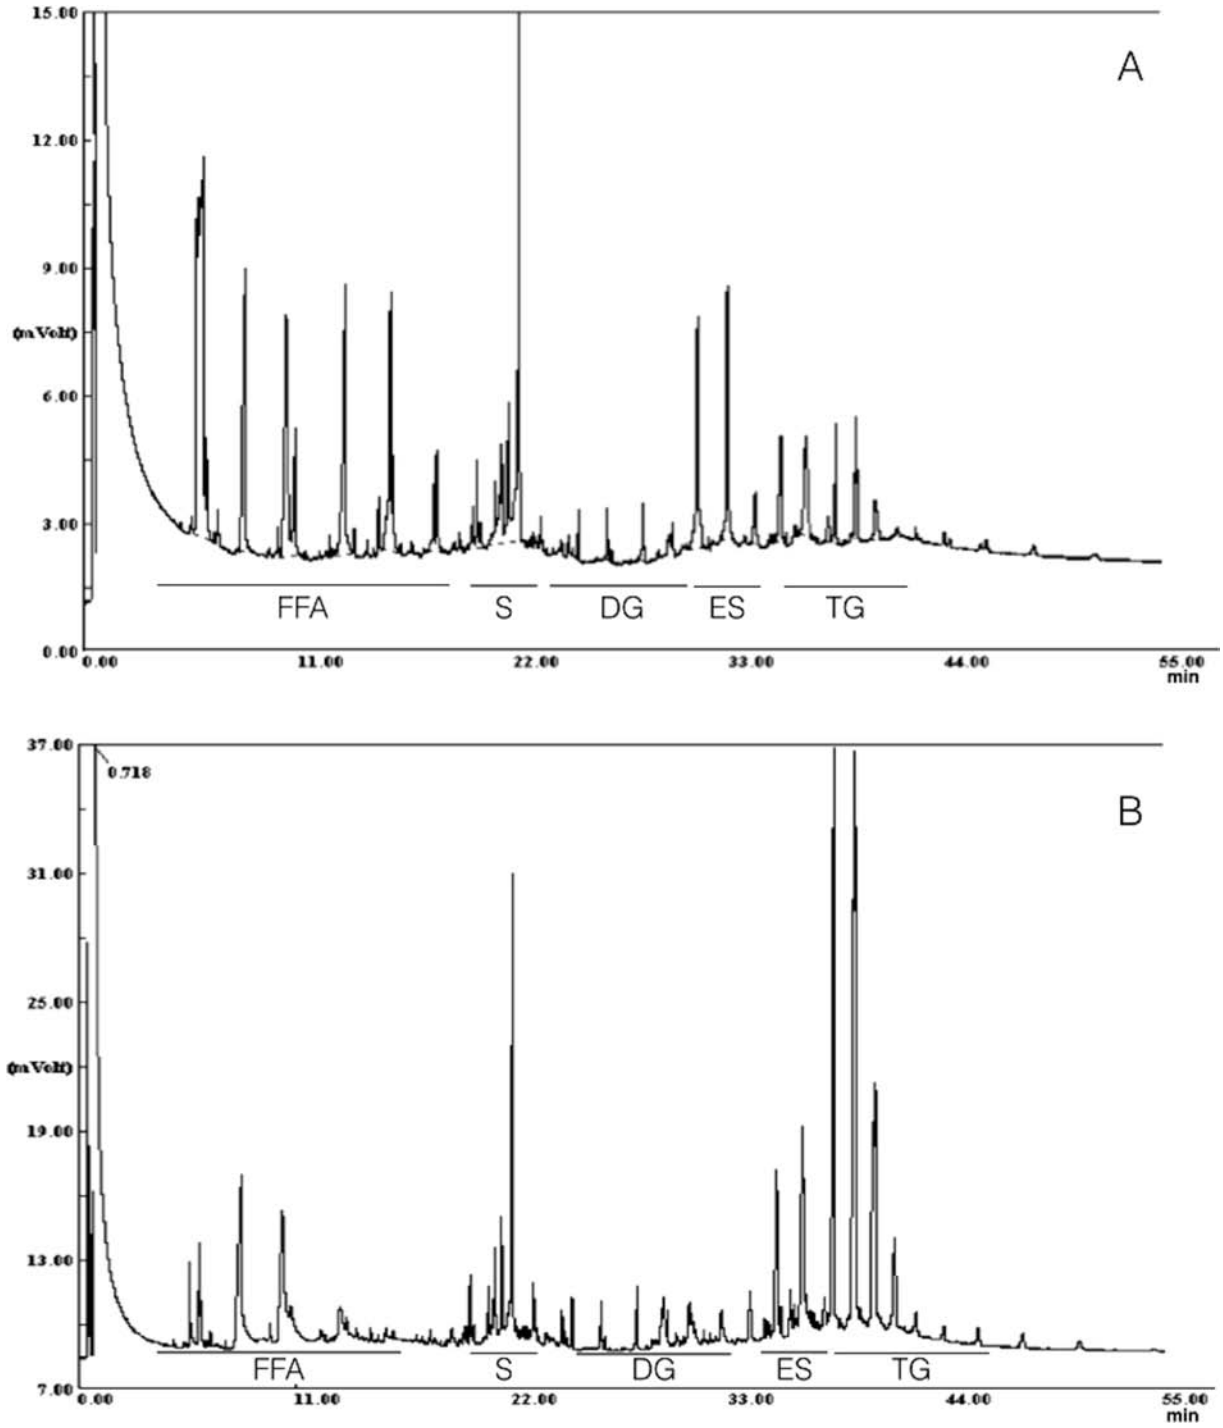

**Figure 2.** Chromatographic lipid profile of CS, obtained after extraction with two different methods (A and B). Abbreviations: FFA, free fatty acids; S, free sterols; DG, diacylglycerols; ES, esterified sterols; TG, triacylglycerols.

constituted by chlorogenic acids (coumaroylquinic, feruloylquinic, and caffeoylquinic acids).

**3.6. Lipid and Fatty Acid Composition.** Many authors have suggested the potential reuse of CS, mainly due to its content of antioxidant compounds, fiber, and caffeine. However, there are few data available about the lipid composition; in fact, only three studies report the lipid content of CS, which varies from 2.0 to 7.0%.[6,15,17]

In the present paper, different extraction methods were tested to obtain the lipid fraction; in particular, the method suggested by Folch et al.[35] (A) was compared with the Soxhlet one[36] using *n*-hexane (B) and petroleum ether (40−60 °C) (C), and a liquid extraction with *n*-hexane (D). The method A led to the highest amount of extracted lipids (5.2%), but no significant differences were found with respect to methods B and C (3.4% and 3.61%, respectively); method D, instead, resulted in the significantly ($P \leq 0.05$) lowest amount of extracted lipids (about 1.9%) (Table 2). The different extraction procedures greatly impacted the lipid composition, as shown in Figure 2. When method A was used, the lipid fraction was mainly composed of free fatty acids (FFA; 58%), free sterols (S; 17%), diacylglycerols (DG; 12%), triacylglycer-

Table 3. Total Fatty Acid Composition of CS, Expressed in Matrix (g/100 g CS) and Lipid Basis (% of total fatty acids)[a]

| ∑UFA/∑SFA | 1.271−1.714 | (1.48; 0.15) | 1.27−1.73 | (1.54; 0.15) |

[a]The results are expressed as min−max (median; standard deviation, $n$ = 45). Abbreviations: CLA, conjugated linoleic acid *cis*-9,*trans*-11-isomer; ∑SFA total saturated fatty acids; ∑UFA, total unsaturated fatty acids.

ols (TG; 9%), and esterified sterols (ES; 3.7%), whereas the lipid matter obtained with method B was essentially constituted by TG (48%), followed by FFA (21%), S (13%), ES (15%), and DG (4%) (Table 2). A slightly polar solvent (method A) increased the extraction of FFA in spite of TG, whereas when apolar solvent was used (e.g., method B), TG became the most abundant lipid class and the polar fraction (e.g., FFA) decreased. No significant differences ($P \geq 0.05$) were found on lipids extracted by method C with respect to method B (except for ES content), while method D led to a higher amount of FFA and a lower content of TG than B and D methods (Table 2). Comparing the different methods for the quantitavely extraction of lipids, method B was the most sustainable choice, and thus, all lipid analytical determinations (FAMEs, unsaponifiable composition, and POPs content) were carried out on the lipid extract obtained with method B.

Table 3 reports the total FA composition of CS. In general, the mean FA composition of the lipid fraction was principally constituted by saturated fatty acids (SFA) (0.9% CS, which corresponded to 60.6% lipid matter); in particular, palmitic acid (PA; C16:0) (0.39% CS; 27.5% lipid) was the main SFA, followed by behenic acid (BA; C22:0) (0.17% CS; 11.5% lipid), arachidic acid (AA; C20:0) (0.16% CS; 10.8% lipid), and stearic acid (SA; C18:0) (0.10% CS; 6.7% lipid). The unsaturated fraction (UFA) (0.6% CS; 39.4% lipid matter) was mainly composed of the essential fatty acids (EFAs) linoleic acid (LA; C18:2 *n*-6) (0.42% CS; 29.2% lipid) and oleic acid (OA; C18:1 *n*-9) (0.10% CS; 6.9% lipid), whereas only traces of the EFA α-linolenic acid (ALA; C18:3 *n*-3) (0.02% CS; 1.3% lipid) and conjugated linoleic acid *cis*-9,*trans*-11-isomer (CLA) (0.01% CS; 0.35% lipid) were found. No data about the FA composition of CS are available in literature, but it seems to be similar to that of crude coffee beans[49] and roasted coffee.[50] The average UFA/SFA ratio was about 1.5, which could be used as a potential tool to understand the oxidative stability of CS as related to storage. In fact, a higher presence of SFA, together with a considerable content of phenolic compounds, could limit CS degradation due to lipid oxidation. It should be noted that a negative relationship between the LA intake and LDL-cholesterol concentrations has been found, while a positive effect on HDL cholesterol concentrations and a consequent reduction of cardiovascular events have been reported.[51] Nevertheless, to the best of our knowledge, this is the first report of the fatty acid composition of CS, and according to the data here obtained, CS could also represent a possible source of EFAs.

**3.7. Sterol Composition.** Before investigating the sterol composition of CS, a qualitative analysis of the unsaponifiable matter was carried out by TLC. As shown in Figure 3, five

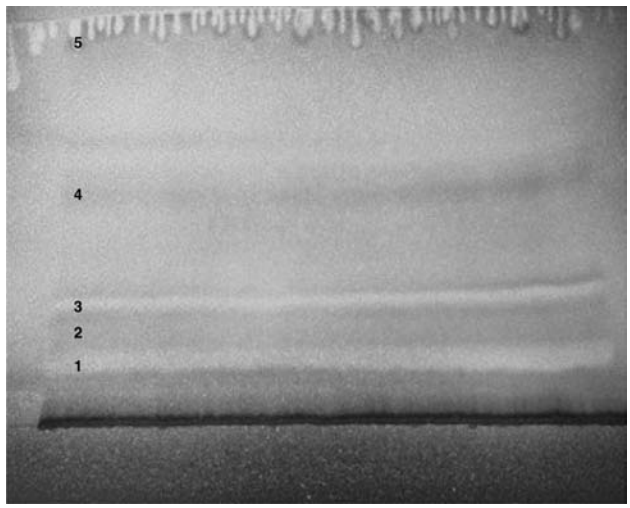

**Figure 3.** TLC fractionation of the unsaponifiable matter of CS. Identification of the TLC bands: (1) sterols, (2) 4-methylsterols, (3) 4,4′-dimethylsterols, (4) tocopherols, and (5) hydrocarbons.

different bands were well-separated, which corresponded (from the bottom to the top of the TLC elution direction) to sterols, 4-methylsterols, 4,4′-dimethylsterols, triterpenes, tocopherols, and hydrocarbons, respectively. Qualitative determination of the extracted TLC bands by GC/MS confirmed the presence of citrostadienol, α-amirine, β-amirine, cycloartenol, 24-methyl-

enecycloartenol, α-tocopherol, β-tocopherol, campesterol, stigmasterol, β-sitosterol, and 5-avenasterol.

The average total amount of sterols ranged from 7.0 to 12.1% of lipid, which corresponded to 0.21−0.36% of CS and was mainly composed of β-sitosterol (71.1%), campesterol (14.0%), stigmasterol (10.5%), and 5-avenasterol (4.4%). Comparing the data found here with those described for green coffee,[49,52] it is possible to observe that CS contains a lower amount of sterols; however, it should be considered that, during roasting, sterols could have been involved in a different degradation process (dehydration, oxidation, etc.), which could have led to their reduction[53]

**3.8. Composition of Phytosterol Oxidation Products (POPs).** Table 4 reports the amount of POPs in CS. The average total POPs was about 114.11 mg/100 g CS, the most abundant being those arising from β-sitosterol (93.26 mg/100 g CS, which corresponded to 2.98% lipid matter); in fact, 7α-hydroxysitosterol (1.70% lipids) was the main oxyphytosterol, followed by 7-ketositosterol (0.62% lipids), 7β-hydroxysitosterol (0.42% lipids), β-epoxysitosterol (0.09% lipids), α-epoxysitosterol (0.07% lipids), and triolsitosterol (0.07% lipids). Lower average amounts of POPs deriving from oxidation of campesterol (11.24 mg/100 g CS) and stigmasterol (9.60 mg/100 g CS) were found, 7α-hydroxyl and 7-keto derivatives being the main ones (Table 4). Epoxy isomers of these minor phytosterols and 5-avenasterol oxidation products were not found, probably due to the low amount of such sterols present in CS. The average phytosterol oxidation rate was determined (% POPs/PS; OR) and varied from 27.6 to 48.1%, which indicated that a high amount of PS was oxidized, probably due to the extensive heating during coffee roasting. It should be pointed out that while the toxicological aspects of cholesterol oxidation products are well-documented, the information about the biological impact of POPs is still limited. Some authors[26,29] have reported the role of POPs in many different biological mechanisms (cholesterol uptake and metabolism, atherosclerosis, inflammation, cytotoxicity, oxidative stress, etc.); Adcox et al.[30] have demonstrated that β-sitosterol and campesterol oxides have a similar toxicity in culture-derived macrophage cell (line C57BL6) as compared to COPs. In addition, according the threshold of toxicological concern (TTC) for unclassified compounds (0.15 μg per person/day[54]), the level of POPs found in CS could represent a risk for human health. Therefore, before suggesting the reuse of CS in foodstuffs, a deeper investigation on the presence of POPs and the prevention of their formation is indispensable.

**Table 4. Total Phytosterol Oxidation Products (POPs, expressed as mg/100 g CS) and Phytosterol Oxidation Ratio (OR, %) in CS[a]**

| | Derivative | POPs | OR |
|---|---|---|---|
| Campesterol | 7α-H | 6.88 ± 2.01 | 2.28 ± 0.67 |
| | 7β-H | 1.62 ± 0.37 | 0.54 ± 0.12 |
| | β-E | nd | nd |
| | α-E | nd | nd |
| | triol | 0.27 ± 0.22 | 0.09 ± 0.07 |
| | 7-K | 2.47 ± 1.10 | 0.82 ± 0.36 |
| Stigmasterol | 7α-H | 6.58 ± 1.49 | 2.18 ± 0.49 |
| | 7β-H | 1.62 ± 0.51 | 0.54 ± 0.17 |
| | β-E | nd | nd |
| | α-E | nd | nd |
| | triol | 0.16 ± 0.05 | 0.05 ± 0.02 |
| | 7-K | 1.24 ± 0.53 | 0.41 ± 0.18 |
| Sitosterol | 7α-H | 53.28 ± 19.89 | 17.66 ± 6.59 |
| | 7β-H | 13.26 ± 4.89 | 4.40 ± 1.64 |
| | β-E | 2.90 ± 1.48 | 0.96 ± 0.49 |
| | α-E | 2.25 ± 0.05 | 0.74 ± 0.02 |
| | triol | 2.10 ± 1.05 | 0.70 ± 0.35 |
| | 7-K | 19.48 ± 10.05 | 6.46 ± 3.33 |
| ∑POPs | | 114.11 ± 43.74 | 37.83 ± 14.50 |

[a]The results are expressed as mean ± standard deviation ($n$ = 15). Abbreviations: 7α-H, 7α-hydroxy derivatives; 7β-H, 7β-hydroxy derivatives; β-E, 5,6β-epoxy derivatives; α-E, 5,6α-epoxy derivatives; triol, triol derivatives; 7-K, 7-keto derivatives; nd, not detected.

**3.9. Ochratoxin A (OTA) Content.** In addition to the presence of a high level of POPs in CS, the occurrence of OTA could represent a further safety problem. The level of OTA in CS was controlled for 10 weeks. The content of OTA ranged from 17.8 to 36.1 μg/kg CS, being 5−9 times higher than those reported by Borrelli et al.[15] Since CS is considered a waste, there is no specific OTA regulation limit and there are very little OTA data in the literature. Considering the OTA limit fixed for coffee, the European Commission regulation[55] states that the maximum level of OTA in roasted coffee and soluble coffee should be 5 and 10 μg/kg, respectively, which is more than 3 times lower than the data found in the present study. Moreover, some authors[21,23] reported that the temperature used during roasting leads to an OTA reduction in coffee; however, it is important to consider that CS was removed during roasting and stored, so it is reasonable that the isolated CS showed a higher level of such mycotoxin. It is well-known that the presence of OTA is correlated to human nephropathy and urothelial urinary tract tumors, while in mice it increases the incidence of hepatocellular tumors, renal-cell adenomas, and carcinomas.[20] Therefore, a possible solution for the removal or dilution of OTA from CS should be studied, if CS is intended for human or livestock consumption.

In conclusion, data obtained in the present work suggest that CS could be used as a source of cellulose for paper production, as well as a source of bioactive compounds (such as fiber and polyphenols) to be employed as ingredients in pharmaceutical/cosmetic industries or for development of functional foods. However, the noticeable amounts of POPs and OTA found in CS might represent a risk for human safety if intended for human or livestock use; therefore, it is very important to set up a rigorous quality control and to develop a suitable procedure for the reduction of the aforementioned contaminants.

model server and processed using SwissPDB viewer.[18] Conversion of receptor and ligand from.pdb to.pdbqt format, also grid map and other docking parameters were set using AutoDock 4.2 software.[19] Virtual screening was carried out using AutoDock Vina software and the Lamarckian genetic algorithm as a searching procedure.[20] Binding energy obtained for each complex was represented in heat map format using MeV software packages (http://www.tm4.org/mev/). The gradient ruler is an indicator of interaction strength. Represented molecules showing strong binding against all the selected targets, represented by lower free energy, were selected for further in vitro and simulation study.

**Methodology of Chemical Derivatization of Caffeic Acid.** Four derivatives (1a−d) were procured from Sigma Chemical Co., and other derivatives (1e−j) were synthesized in laboratory. A detailed methodology is given in the Supporting Information (SI).

**Inhibition Kinetics Study.** Concentration-dependent reduction in trypsin activity by CA was also estimated through a BA*p*NA assay using chromogenic substrate Benzoyl-L-arginyl *p*-nitroanilide (BA*p*NA; Purity: >99%; Sigma Chemical Co., St. Louis, MO, U.S.A.). BA*p*NA assays were performed as previously described.[21] A minimum three replicates of each experiment were performed. Michaelis−Menten constant (Km) for trypsin was calculated by using various concentrations of BA*p*NA substrate (1 to 5 mM), and then plotting the double reciprocal curve with 1/(v) and 1/[S]. The kinetic properties of CA were analyzed over a range of concentration of inhibitors (1 $\mu$M to 1 mM). $IC_{50}$ values for each inhibitor were calculated from the sigmoid curve, indicating the best fit for the percentage inhibition data obtained. The values of $K_i$ values for each inhibitor were calculated directly from $IC_{50}$ values using Cheng-Prusoff's classical equation.[21]

$$K_i = \frac{IC_{50}}{\left(1 + \frac{[S]}{Km}\right)}$$

**Feeding Assay and Nutritional Indexing.** Bioassays were conducted by feeding *H. armigera* larvae on artificial diet containing 5 to 200 ppm/g of CA. Three independent sets ($n$ = 30 insects larvae of first instar) were used for feeding on control and CA containing AD. Detailed method is as previously described.[22] The insect growth, development, and survival of insect fed on control and CA containing diet were analyzed on each alternate day for 10 days.

**Semiquantitative Gene Expression Analysis.** Total RNA was extracted from whole larval body using Trizol reagent (Invitrogen, CA, U.S.A.), followed by RQ1 DNase treatment (Promega, U.S.A.). cDNA was synthesized from 2 $\mu$g of the DNA-free RNA samples by reverse transcription using oligo dT primers and reverse transcriptase (Promega, U.S.A.) following the manufacturer's recommendations. Primers pairs were designed for Acetylcholinesterase, Amylase, Chymotrypsin, CYP450, GSTs and Trypsin genes of *H. armigera*. cDNA was diluted (1:10) before use in a PCR. Semiquantitative RT-PCR performed under the following conditions: initial denaturation at 95 °C for 2 min; 30 cycles at 95 °C for 30 s; 60 °C for 30 s; 72 °C for 30 s and a final extension at 72 °C for 5 min.[23]

**Fluorescence Quenching Assay.** Fluorometric experiments were carried out on a fluorescence spectrometer from Thermo Scientific (Waltham, MA, U.S.A.). Stock solutions of CA (1 mM) in ethanol and Bovine Trypsin (1 mM) in 100 mM TrisHCl (pH 7.8) was prepared at room temperature. The final concentration of CA was from 0.2 to 30.0 $\mu$M with a constant bovine trypsin content of 1 $\mu$M. The fluorescence spectra were recorded at $\lambda_{exc}$ = 280 nm and $\lambda_{em}$ from 300 to 500 nm.[24−27]

**MALDI-TOF Analysis.** Different molar concentration of CA and trypsin were mixed and incubated for 20 min at 37 °C. The mass spectral analysis of the reaction mix was done on Q-TOF-MALDI-TOF-MS with a standard instrumental protocol (High Definition Mass spectrometer, ABSCIX, MA, U.S.A.). Sample preparation, spectral acquisition, and processing were done as described earlier.[28]

**Isothermal Titration Calorimetry.** ITC was performed using Microcal Auto-iTC instrument (GE Healthcare, Buckinghamshire, U.K.). Nineteen injections of 2 $\mu$L bovine trypsin (Stock = 2.0 mM) was titrated against 0.1 mM solution of CA. Experiments were carried out at 37 °C in a Tris buffer, pH 7.8. Reference titration was carried out by injecting the same concentration of trypsin into buffer. Reference titration was subtracted from experimental titration. Origin 6.0 software was used to derive affinity constants ($K_d$), the molar reaction enthalpy (CH), and the stoichiometry of binding (N), by fitting the integrated titration peaks.[29]

**Circular Dichroism Spectroscopy.** A Jasco J-810 spectropolarimeter (Jasco, Easton, MD, U.S.A.) running the software Jasco J815CD was used to collect spectra at wavelengths 190−240 nm (far-UV) and 240−300 nm (near-UV). Quartz cuvettes of path lengths 5 mm was used for spectral scan. The scanning speed was 20 nm/min, the response was 4 s, and the bandwidth was 1 nm. Trypsin (10 $\mu$M) was incubated with CA in 1:2, 1:1, and 2:1 ratio for 4 h at room temperature, a similar process was done for chymotrypsin. Baseline corrections were performed by subtracting the spectra of the buffer and phenolic compounds from the sample spectra. The data are reported as mean residue ellipticity ([Θ]) in $deg^3cm^2$ $3dmol^{-1}$. Each spectrum is the result of three accumulations. The CD spectra were analyzed using the DicroWeb server and applying the CONTIN/LL program with a reference database, SP175, containing 70 proteins with complex structures including trypsin.[28]

**Molecular Dynamic Simulation.** The structures with 27 CA molecules (aggregation study) and bovine trypsin-CA complex were relaxed using all-atom MD simulation in explicit water with GROMACS software package using the AMBER99SB force field[21] and the simple point charge (SPC) water model.[30] The time step used in the simulation was 0.002 ps while list of neighbors was updated every 0.01 ps with the grid method and a cut off radius of 14 Å. The coordinates of all atoms in the simulation were saved every 2 ps. The initial velocities were chosen randomly. NPT ensemble was used with the user-defined box dimension. The temperature and pressure were kept at the desired value using the Berendsen method and an isotropic coupling for the pressure ($T$ = 300 K, $\zeta T$ = 0.1 ps, $P_0$ = 1 bar, coupling time = $\zeta T$ = 1 ps). The electrostatic term was calculated using the Particle Mesh Ewald (PME) algorithm with the radius of 16 Å with Fast Fourier Transform (FTT) optimization (with an order of 4 for the cubic interpolation). The cut off algorithm was applied for the noncoulomb potential with a radius of 9 Å. Initial minimization was done for a total of 50 000 steps, followed by volume and pressure equilibration each for 1 ns. The production MD run for the complexes were then carried out.

Both of these systems were then simulated using the simulation parameters mentioned in the previous section. The parameters for CA were retrieved from the SWISSPARAM server (http://www.swissparam.ch/).[30,31] Both of these simulations were performed and analyzed using the supercomputing facility provided by BRAF cluster using GROMACS.[32]

**Enzymatic Assays.** Five hundred milligrams of whole insect tissue of *H. armigera* were ground to a fine powder and extracted in 500 mL of 200 mM Glycine-NaOH buffer (pH 10) for 2 h at 4 °C. The extract was then centrifuged at 12 000*g* (4 °C; 10 min) and the clear supernatant was used as a source of enzyme for all solution assays. Control and CA fed insects protein lysate (50 $\mu$g) was used to carry out the following functional assays: (a) total proteaseactivity;[21] (b) Trypsin-like activity;[22] (c) Chymotrypsin like activity;[22] (d) Amylase activity;[23] (e) Lipase activity;[32] (f) Acetylcholinesterase activity;[33] (g) GSTs activity;[34] and (h) CYP450 activity.[34] The detailed methodology is described in corresponding references.

**Statistical Analysis.** All the experiments were performed three times independently. Student's $t$ test was used for statistical analysis. Data were expressed as mean ± SD. A $p$-value< 0.05 was considered as statistically significant.

## RESULTS AND DISCUSSION

**Protease Inhibition Potential of Hydroxycinnamic Acid Derivatives.** Comparison of binding energies of various HCA derivatives against bovine and *H. armigera* proteases displayed variability in binding affinity (Figure 1A). Caffeic,

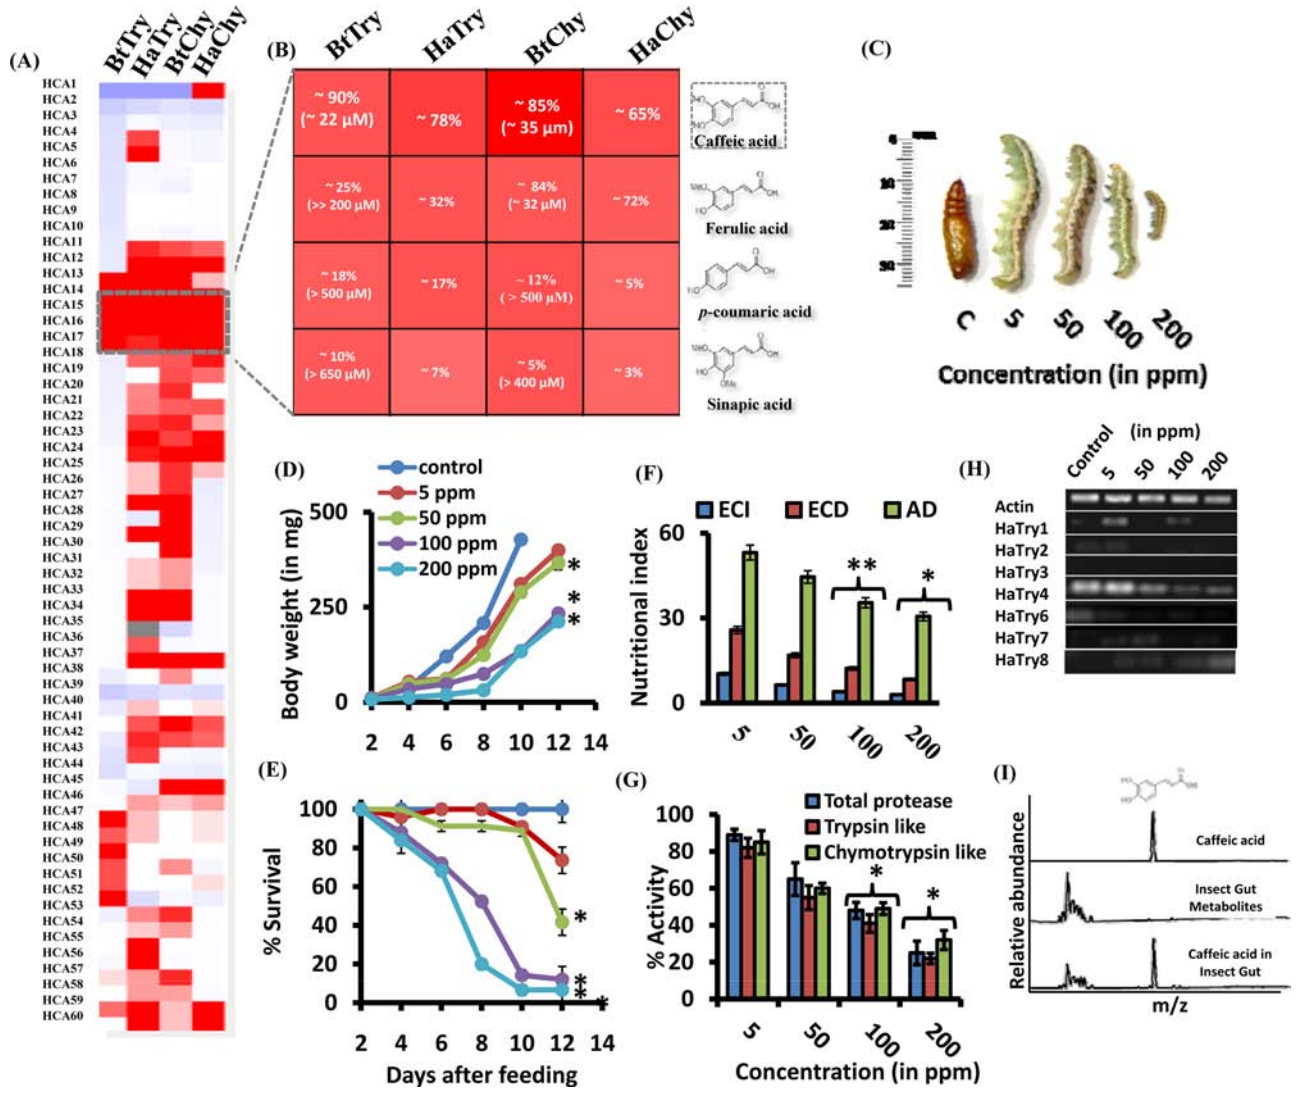

**Figure 1.** (A) Interaction energy of binding of various hydroxycinnamic acid derivatives with bovine and *H. armigera* proteases is compared by using Heatmap analysis. Relative free binding energy (obtained from docking study) normalized by mean values of cumulative free energy was obtained from *Bos taurus* (Bovine) trypsins, bovine chymotrypsin, *H. armigera* trypsin, and chymotrypsin binding with different derivatives. The gradient ruler is an indicator of interaction strength, where the blue color indicates weak binding and red indicates strong binding. Values in parentheses indicate $K_i$. (B) Derivatives with strong binding affinities are marked with dash board. *H. armigera* larvae were raised on artificial diets containing 5 to 200 ppm/g of CA. (C) Average size of larvae recorded on day 10. (D) Insect growth and (E) survival rate normalized with control (F) nutritional parameters ECI, ECD, and Ad and (G) In vivo proteolytic activity of insect fed on control and CA containing dietwere assessed. Bars represent means (±) SE from three independent experiments at *$p$_0.05 (H) Protease gene expression analysis at the transcript level by performing semiquantitative RT-PCR using total RNA isolated from control and CA fed larvae. All samples were analyzed on 2% agarose gels containing gel red. This analysis showed differential expression of protease gene in CA fed larvae. (I) HRMS analysis of insect gut metabolites indicated the fate of CA in insect gut environment. Results are representative of three independent experiments.

ferulic, sinapic, and *p*-coumaric acid emerged as strong inhibitors of candidate proteases (Figure 1B). It was observed that caffeic acid (CA) showed strong competitive inhibition of bovine (*Bos tarus*) trypsin ($K_i \approx 22\ \mu M$) and bovine chymotrypsin ($K_i \approx 32\ \mu M$), while ferulic acid (FA) showed exclusive inhibition of bovine chymotrypsin with $K_i \approx 32\ \mu M$. CA and FA showed significant inhibition of *H. armigera* trypsin and chymotrypsin activity (Figure 1B). Molecular docking analysis and binding energy comparison indicated that natural phenols have affinity toward insect proteases. Moreover, the interaction between phenols and the proteases from different insects is conserved. (Polyphagous: *H. armigera and Ptullae xylostella*; Monophagous: *Menduca sexta*) (SI Figure S1). Analysis of 130 docked complexes revealed that CA had strong interaction (low binding energy) with various insect serine proteases, especially with trypsin like proteases. This observation might support the fact that elevated concentration of CA and other similar natural phenols in plant tissues upon insect infestation might have direct role in inhibition of digestive function of the insects.[12−16]

**Molecular Response of *H. armigera* to CA Ingestion.** Delayed pupation indicates the retardation of development in larvae fed on CA (Figure 1C). CA appeared to have significant and concentration-dependent negative impact on growth and survival of *H. armigera*. Larvae fed on diet containing 50 to 200 ppm of CA showed ∼20 to 50% less body mass (in g) as compared to control (Figure 1D). Furthermore, CA fed leave had ∼50 to 80% reductions in survival rate (Figure 1E).

dx.doi.org/10.1021/jf503437r | J. Agric. Food Chem. 2014, 62, 10847−10854

Evaluation of nutritional parameters like Efficiency of Conversion of Ingested Food (ECI), Efficiency of Conversion of Digested Food (ECD) and Approximate Digestibility (AD) revealed that the ingestion of CA had deleterious effect on growth and rudimentary metabolism of the insect (Figure 1F). Insects fed on CA exhibited a substantial reduction in trypsin-like (~20 to 60%) and thus total protease (~15 to 50%) activity (Figure 1G). Inhibition of digestive proteases by CA probably causes starvation in insects. It might lead to nutritional scarcity, less pool of free amino acids, and also energy required for metabolism, thus causing the growth retardation followed by insect death.[12,15]

Candidate protease gene expression analysis indicated that ingestion of CA also led to a differential response. Several of the *H. armigera* trypsin's and chymotrypsin's (HaTry1 to 8; HaChy1 to 4) were down-regulated, except HaTry4 (Figure 1H). Overexpression of HaTry4 and HaChy4 in CA fed insects might have been resulted in response to compensate for reduced the protease activity. HaTry4 and HaChy4 might be inhibitor resistant/insensitive proteases, and thus overexpression of these proteases might be help in rescuing the insect from growth retardation, which could further predominate and hijack the insect digestive system to fulfill the insect's growth requirement.[35−37]

**The Fate of CA in the Insect Gut Environment.** Stability of CA in insect gut environment and probability of formation of subsequent metabolites were investigated by LC-ESI (−)-HRMS analysis (Figure 1I). Chromatograms of gut metabolite extract of CA fed larvae in 1:1 acetonitrile and methanol showed the presence of intact CA molecule and no additional peaks in comparison to control. Thus, it excluded the possibility of the formation of degraded products of CA in digestive tract of insect. Stability of CA in insect gut leads to maximum availability and hence causes it to be constitutively active as protease inhibitor. In vivo stability of CA made it a lucrative molecule to be used as an insecticidal agent.[38]

**Structure−Activity Relationship of CA as Protease Inhibitor.** Functional group-activity relationships provide a detailed insight into the essentiality of individual functional groups to maintain the inhibitory potency (Table 1). Semisynthesized derivatives were structurally characterized by mass spectrometric and NMR data (SI) which were well in agreement with the previous reports.[39−44] Masking of 3-hydroxyl group as methoxy on the phenolic ring (FA, **1b**) resulted in the considerable reduction in gut protease inhibition (40 to 60%). Even the addition of another methoxy group at 5-position (**1c**, sinapic acid) on the phenolic ring led to further reduction in inhibitory potencies (20 to 30%). Removal of the 3-hydroxyl group (**1d**, cinnamic acid) from the CA structure resulted in drastic reduction in the inhibitory activity (15 to 25%). Masking of the terminal carboxylic acid as a methyl (**1e**) ester also caused a significant lowering in inhibitory activities (35 to 50%). Further increment in the chain length as an ethyl ester (**1f**) showed far more reduction in inhibitory potency (25 to 30%). Hydrogenation (reduction) of the double bond in the side chain of CA (**1g**) reduced the activity extensively (12 to 20%). A similar effect was observed when methyl ester of CA was subjected to hydrogenation (**1h**) (inhibition 25 to 50%). Protection of both the hydroxyl groups on the phenolic ring by acetylation (**1i** and **1j**) drastically attenuated its inhibitory potential (10 to 20%). In brief, modification in any of the functional groups (phenolic hydroxyl, carboxylic acid, and double bond) on CA structure led to reduction in the inhibitory activity against proteases with variable extent and all of them were found to be essentially responsible for the activity. Therefore, the parent natural product (**1a**) found to be most potent among all the derivatives screened.

**Table 1. IC50 ($\mu$M) Values of Bovine Trypsin and Chymotrypsin and % Inhibition of HGP for Derivatives of CA**

| | Compound | Inhibition | | |
|---|---|---|---|---|
| | | Trypsin (~ $IC_{50}$ in μM) | Chymotrypsin (~ $IC_{50}$ in μM) | % Inhibition (~) of HGP activity |
| 1a |  | 22 | 35 | 70-80 |
| 1b |  | 120 | 32 | 40-60 |
| 1c |  | 650 | 460 | 20-30 |
| 1d |  | 780 | 525 | 15-25 |
| 1e |  | 80 | 125 | 35-50 |
| 1f |  | 165 | 205 | 25-30 |
| 1g |  | 225 | 320 | 12-20 |
| 1h |  | 109 | 165 | 25-50 |
| 1i |  | 380 | 520 | 10-20 |
| 1j |  | 350 | 451 | 10-20 |

**Binding of CA Causes Structural and Conformational Change in Target Protein.** Bovine trypsin showed reduction in tryptophan fluorescence in response to titration with CA, suggesting the change of the molecular environment of tryptophan (Figure 2A). A red shift is observed in this case, indicating the conformational change in protease on ligand binding. Furthermore, it was found that multiple CA molecules were interacting noncovalently with proteases. It was validated

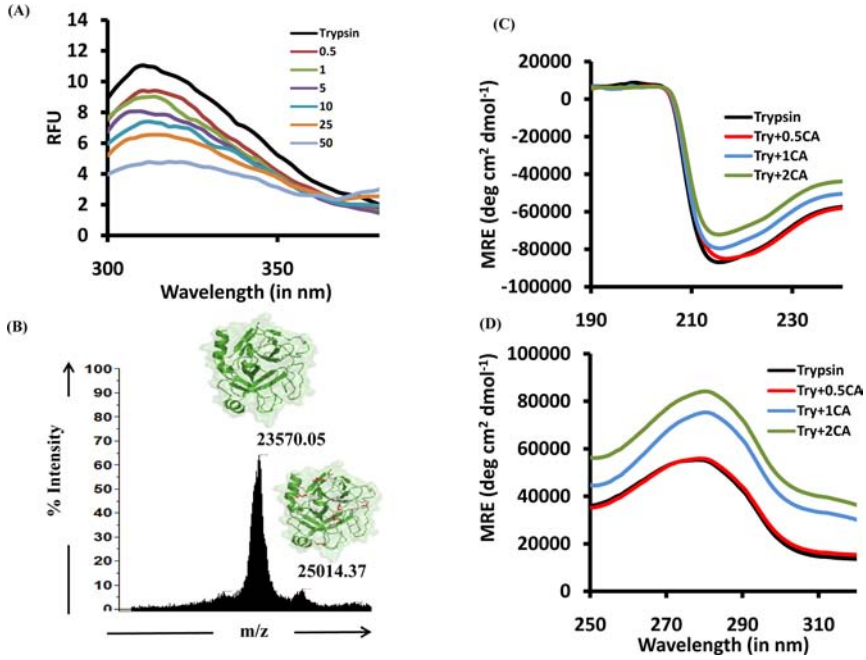

**Figure 2.** Biophysical characterization of CA and protease interaction: (A) Fluorescence emission of bovine trypsin in the presence of various concentration of CA and (B) binding of multiple CA to protease molecule was analyzed by MALDI TOF analysis. Structural change in protease on CA binding was examined at secondary level by (C) near UV CD spectra and at tertiary level by (D) far UV CD spectra.

by mass spectrometric analysis, where shift in mass ($m/z$) was observed in comparison to native enzymes due to binding of multiple CA molecules to the proteases (Figure 2B). Circular dichroism (CD) spectroscopy of proteins in near and far UV regions suggested the secondary and tertiary structure alteration in the protease respectively, on CA binding (Figure 2C,D). Fluorescence quenching and CD spectroscopy analysis together indicated that binding of CA caused environmental alteration around the tryptophan residue, resulting in structural and conformational changes in the protease, which might further be attributed to the reduced enzyme activity.[23−26]

**CA Showed Sequential Binding to Protease and Exhibit Heterogonous Mode of Inhibition.** In the set of simulation systems to study the impact of CA binding on the structure of protease, the system containing *H. armigera* trypsin 4 (HaTry4, predominant trypsin from *H. armigera* gut) with multiple CA in the vicinity was simulated for1 $\mu$S, and the trajectory was analyzed. The CA molecules in this simulation were initially restrained at discrete positions on the protease molecule, and the restrain was released, until 10 ns of the simulation. Out of these 5 CA molecules, one was found to remain in the active site for the rest of the simulation, interacting with Ser200 of HaTry4 (Figure 3A). Hydroxyl groups of CA can form multiple transient interactions with the protease active site, however, the H-bond between the OH group of CA and Tyr45 and Ser200 was found to be stable throughout the simulation time (Figure 3B). Further, after around 208 and 300 ns of the simulation, two more CA molecules were found to be located near the mouth of the active site (Figure 3C). These three CA clubbed near active site to form stacked triad via $\pi-\pi$ interactions and maintains its position through another set of $\pi-\pi$ interaction with lining residues of active site mouth, i.e., Tyr45, Trp144, and Tyr154 (Figure 3D). In this way, CA binding to *H. armigera* trypsin might cause heterogeneous type of inhibition by (i) competitively binding to the active site residue i.e. Ser200 (ii) blocking the mouth of the active site, leads to inaccessibility to the substrate. This suggests that CA might be having some crucial interactions with the active site residues and longer time-scale simulation might be required to explore major structural changes in the protein.

Thermodynamic studies of trypsin-CA interaction was carried out using isothermal titration calorimetry (ITC) as it is one of the most widely used quantitative technique for direct measurement of the enthalpy change when two species interact, allowing the determination of heat of association, stoichiometry, and binding affinity from a single experiment. The raw data and corresponding thermogram of the binding experiment is depicted in Figure 3E. Binding was strongly exothermic and showed 1:3 stoichiometry for trypsin and CA. The spontaneity of the process was evidenced by a negative change in the enthalpy, CH, and a positive change in the entropy, CS. Binding of first CA molecule showed lower $\Delta G$ as compared to the second and third molecule binding. This thermodynamic pattern of binding indicates that binding of first CA molecule was strong as compared to the second and third CA molecule.

To investigate the aggregation propensity of CA in solution and its effect on protein binding, 27 CA molecules (aggregation study) were relaxed using all-atom MD simulation in explicit water with GROMACS software package using the AMBER99SB force field and the simple point charge (SPC) water model.[29] The 50 ns trajectory of this system was analyzed to see how individual CA molecules display the phenomenon of aggregation. At around 1 to 2 ns of simulation, formation of aggregates were initiated (Figure 2F). These aggregates were observed in different clusters with varying number of CA molecules in individual clusters. Initially after 2 ns of the simulation, two major clusters were observed having 12 CA molecules each and remaining 3 CA in none of them. Likewise, a big cluster of 21 CA molecules was observed after 6.5 ns and just after 30 ns of the simulation, a cluster of 27 CA molecules was also observed. Some of these aggregated CA molecules also

dx.doi.org/10.1021/jf503437r | J. Agric. Food Chem. 2014, 62, 10847−10854

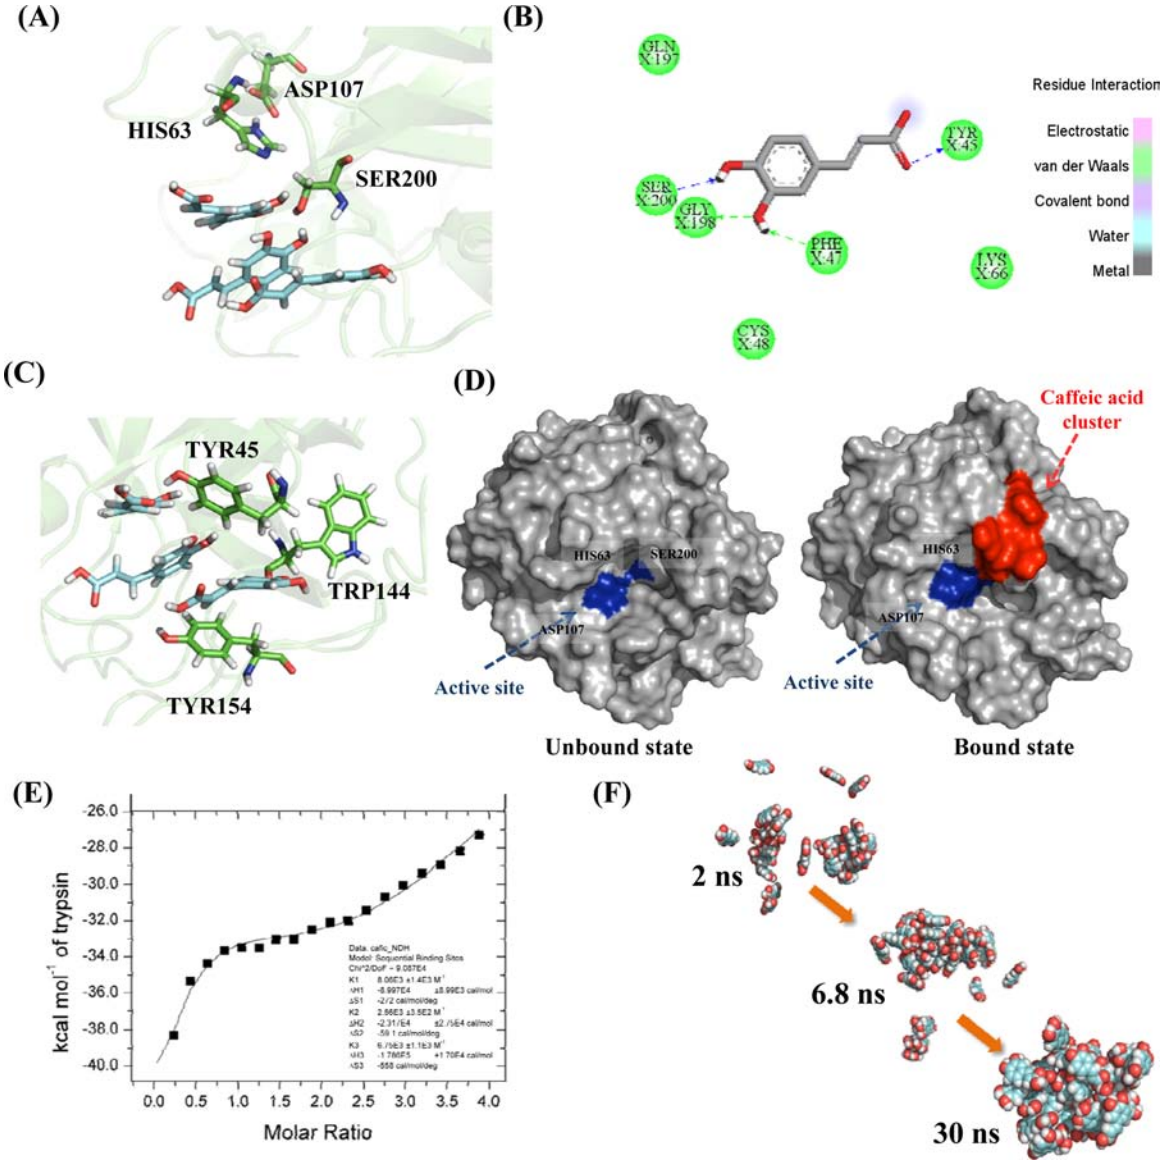

**Figure 3.** Simulation of bovine trypsin and CA in one system illustrates (A) binding of single CA molecule at the active site residue SER200. (B) 2D interaction map showed establishment of multiple interactions of CA with trypsin binding pocket. Strong binding of CA at active site leads to (C) formation of nucleation center for aggregation of other two CA molecules in the active site. (D) Aggregate formation in binding pocket further blocks complete access to the active site, which is shown in the surface model. (E) Simulation of only CA in the solvation box showed that CA has intrinsic propensity to form aggregate and this might enhance its chances to interact with the proteases.

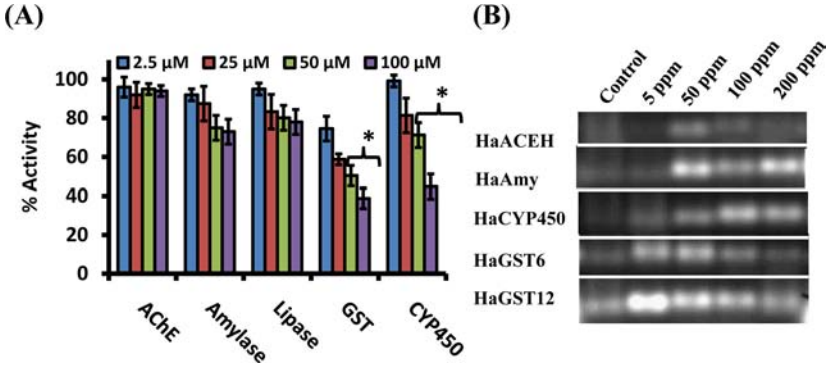

**Figure 4.** Enzymatic activities of (A)AChE, Amylase, lipase, GST, and CYP450 were analyzed for control and CA treated insects using protocols described in corresponding references. In CAfed insects, significant and concentration dependent reduction in GST and CYP450 activity was observed. Bars represent means (±) SE from three independent experiments at *$p$_0.05 (B) Gene expression analysis of AChE, Amylase, lipase, GST, and CYP450 genes at the transcript level by performing semiquantitative RT-PCR using total RNA isolated from control and CA fed larvae.

dx.doi.org/10.1021/jf503437r | J. Agric. Food Chem. 2014, 62, 10847−10854

formed stacked orientation with one another during the simulation. This suggested that the CA had an intrinsic property of displaying stacking interactions as well as self-aggregation. Formation of aggregates might enhance the probability of CA to interact with proteases. Kinetic, simulation, and ITC data demonstrated the binding of single molecule of CA to the active site of trypsin initiates the sequential binding of CA molecules at the active site.

**CA Inhibits the Insect Detoxification Machinery.** Estimation of different enzyme activities and semiquantitative gene expression analysis indicated that other than protease inhibition activity, CA also had adverse effects on various enzymes primarily involved in detoxification mechanism. It was observed that activity of Glutathion S-tranferase (GST) and Cytochrome P450 (CYP450) reduced drastically in insects fed with CA containing diet (Figure 4A), and insect attempted to compensate this activity reduction by overexpression of these genes at transcript level (Figure 4B). Reduction in these enzyme activities was concentration dependent and almost 60% GST and CYP450 enzyme activity was reduced at 200 ppm concentration. Other than these enzymes, various other digestive enzymes activities like amylase, lipase was found to be maintained in the presence of CA even at concentration of 200 ppm. Amylase, proteases, and lipases are three major enzymes contributing to the insect digestive system. Proteases are more crucial for insect development, growth, metamorphosis, and immunity, and thus their inhibition is found to be significantly detrimental as compared to amylase and lipase inhibition. Inhibition of detoxification enzymes by natural phenols might intensify the detrimental effect on insect growth and development.

In conclusion, CA has been found and validated as a potential insecticidal molecule. All the functional groups contributed to its protease inhibitor property, and it also remains stable in the insect gut environment. Ingestion of CA causes differential molecular responses at transcriptional and translational level. Structural investigation showed that CA showed sequential binding at the active site of major insect protease, thus inhibiting its activity. Although overexpression of proteases was observed in CA fed larvae, the strong inhibition potential of CA overcomes the effect of the enhanced expression of insect proteases. All these finding suggests that exploration of natural phenols could be an effective approach to develop a "Dietary pesticide" against *H. armigera* infestation.

soil and the surface chemistry of fresh and aged biochar was characterized. Knowledge gained on the mechanisms of mineral incorporation with biochar would be useful to reveal the interactions and aggregation of biochar and soil materials and how this affects the fate and behavior of herbicides.

## MATERIALS AND METHODS

**Chemicals.** Pure analytical (>99%) standards and radiochemicals of indaziflam (*N*-[(1*R*,2*S*)-2,3-dihydro-2,6-dimethyl-1*H*-inden-1-yl]-6-[(1*R*)-1-fluoroethyl]-1,3,5-triazine-2,4-diamine) (3.96 MBq $mg^{-1}$, 97.9% radiochemical purity) and fluoroethyldiaminotriazine (6-[(1*R*)-1-fluoroethyl]-1,3,5-triazine-2,4-diamine) (3.79 MBq $mg^{-1}$, 90% radiochemical purity) were graciously supplied by Bayer Crop Science (Wuppertal, Germany). Nicosulfuron (2-[[[[(4,6-dimethoxy-2-pyrimidinyl)amino]carbonyl]amino]sulfonyl]-*N*,*N*-dimethyl-3-pyridinecarboxamide) (2.33 MBq $mg^{-1}$, >98% radiochemical purity) was provided by DuPont Crop Protection. Unlabeled MCPA (4-chloro-2-methylphenoxyacetic acid) (purity = 98.9%) and terbuthylazine (6-chloro-*N*-ethyl-*N*′-(2-methyl-2-propanyl)-1,3,5-triazine-2,4-diamine) (purity = 99.6%) were purchased by Dr. Ehrenstorfer Lab. Chemical structures of the pesticides are shown in Figure 1 and physicochemical characteristics in Table 1 (data from www.eu-footprint.org[17] and www.chemaxon.com[18]).

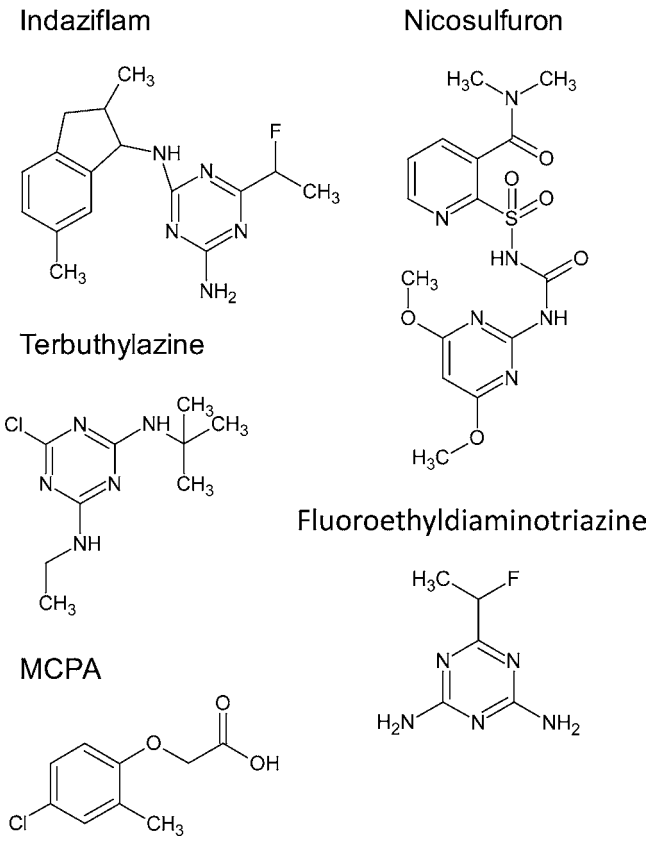

**Figure 1.** Chemical structures of indaziflam, nicosulfuron, terbuthylazine, fluoroethyldiaminotriazine, and MCPA.

**Biochar.** Three macadamia nut shell biochars, ranging in soil equilibration time (zero, one, and two years), were used as pesticide sorbents (Table 2). The biochar was aged in a Waukegan silt loam containing approximately 22% sand, 55% silt, and 23% clay with a pH (1:1 $H_2O$) of 6.3−6.6, and 2.6% organic carbon (OC). Average annual temperature is 6.85 °C with 887 mm of annual precipitation (102 cm snowfall).[19]

The specific surface area of the biochars was measured by nitrogen surface sorption, using a Micromeritics ASAP 2420 and the Brunauer, Emmett, and Teller (BET) method on a previously degassed 0.2 g sample at 8 °C during a 24 h period. The pH was determined in a 1:5 biochar:deionized water slurry. Dissolved organic carbon (DOC) was extracted from biochar by shaking 5 g of the sorbent with 20 mL of 0.01 M $CaCl_2$ for 15 min. The suspension was centrifuged at 8000 rpm for 15 min and filtered through a 0.45 $\mu$m pore nylon filter. The solution was diluted (1:5) in 0.01 M $CaCl_2$ and analyzed using a total carbon analyzer (Shimadzu TOC-V). The absorbance of the extracted DOC was measured with a VWR UV-3100 PC at 254 nm. The estimated aromaticity, $SUVA_{254}$ (L $mg^{-1}$ $m^{-1}$), was calculated using the equation

$$SUVA_{254} = a_{254}/DOC$$

where $a_{254}$ is the absorbance coefficient measured at 254 nm ($m^{-1}$) and was defined as $a_\lambda = 2.303A_\lambda/l_L$; $A_\lambda$ is the absorbance, and $l_L$ is the path length of the optical cell in meters (here $l_L$ = 0.01 m). DOC is the dissolved organic carbon expressed in (mg $L^{-1}$). $SUVA_{254}$ has previously been found to be a useful parameter for estimating the dissolved aromatic carbon content.[20]

The surface morphology of the sample was studied using a JEOL 6500 scanning electron microscope. The functional groups of the biochars were determined using a Nicolet Series II Magna-IR System 750 FTIR spectrometer, recording the spectral region from 4000 to 400 $cm^{-1}$ with a resolution of 2 $cm^{-1}$ (University of Minnesota CharFac facility).

**Sorption Experiments.** Sorption experiments were conducted using the batch equilibrium technique according to OECD guideline 106.[21] Duplicate 0.1 g biochar samples were equilibrated with 8 mL of 0.01 M $CaCl_2$ solution containing initial concentrations of 1 mg $L^{-1}$ terbuthylazine and MCPA, 0.3 mg $L^{-1}$ fluoroethyldiaminotriazine and indaziflam, and 0.2 mg $L^{-1}$ nicosulfuron. Radiolabeled chemicals were added to nonradioactive solutions to give a final solution concentration of ∼174 Bq $mL^{-1}$ for fluoroethyldiaminotriazine, indaziflam, and nicosulfuron. The 0.01 M $CaCl_2$ solution was used as the background electrolyte to maintain constant ionic strength of sorption and desorption equilibration solutions and to facilitate flocculation of the soil. Suspensions were shaken mechanically at 21 ± 2 °C for 24 h and centrifuged at 370*g* for 30 min, and the supernatant was removed for analysis of the equilibrium concentration.

For fluoroethyldiaminotriazine, indaziflam, and nicosulfuron, 1 mL aliquots of the clear supernatant were mixed with 5 mL of scintillation cocktail (Ecolite, ICN Biomedicals, Costa Mesa, CA) and the amount of radioactivity was determined by liquid scintillation counting for 1 min in a liquid scintillation analyzer (1500 TRI-CARB, Packard Instruments, Downers Grove, IL). The amount of the chemicals in solution was calculated by considering the specific activity of each chemical. The equilibrium concentrations ($C_e$) of terbuthylazine and

| BC-2yr | 6.7 | 5.79 | | | |

[a]Absorbance.

MCPA were determined by HPLC with a Waters 600E chromatograph coupled to a Waters 996 diode array detector, under the following conditions: Nova-Pak C18 column (150 mm length × 3.9 mm i.d.); flow rate, 1 mL $min^{-1}$, 25 $\mu$L injection; eluent system for terbuthylazine 50:50 (v/v) water/acetonitrile mixture and UV detection at 220 nm; eluent system for MCPA 60:40 (v/v) methanol/diluted $H_3PO_4$ (pH 2) mixture and UV detection at 230 nm. Differences between the initial ($C_i$) and equilibrium ($C_e$) solution concentration were assumed to be sorbed ($C_s$). The sorption coefficient ($K_d$) was calculated as $C_s/C_e$.

## RESULTS AND DISCUSSION

**Biochar.** Fourier transform infrared spectra (FTIR) of the fresh biochar (BC-fr) and biochars aged 1 (BC-1yr) or 2 (BC-2yr) years are displayed in Figure 2. The appearance of new peaks in the infrared spectra of the aged biochars compared to those present in the spectra of the fresh biochar provides evidence for chemical alteration of the surface moieties due to the interactions between the soil and biochar. Additional bands at 3695 and 1003 $cm^{-1}$ for BC-1yr and BC-2yr, corresponding to the O−H stretching and Si−O vibrations of clay minerals, could be due to soil mineral incorporation onto the surface of the biochars (see Figure 3c−e). The band at ∼2660 $cm^{-1}$ can be assigned to O−H stretching vibration of carboxylic groups from fatty acids that coat the surface of the fresh biochar. The band close to 1700 $cm^{-1}$ corresponds to C═O stretching vibration mode, and the group of bands between 1030 and 1090 $cm^{-1}$ can be assigned to C−O stretching vibrations corresponding to the carboxylic acid group. The decrease of the intensity of the band at about 1700 $cm^{-1}$ and the increase of the band at 1400 $cm^{-1}$ correspond to the C−H bending and the carboxylate anion stretching[22] for the aged biochars and, in comparison with the BC-fr, reveal a partial elimination of the unsaturated fatty acid with the aging process and a partial interaction of the carboxylate anion.

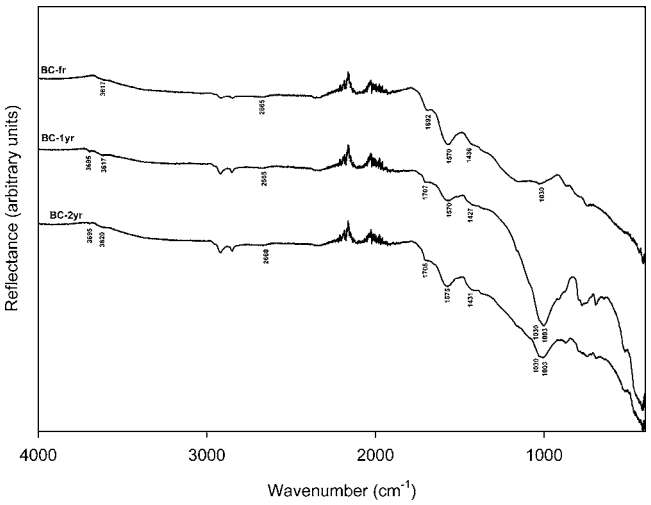

**Figure 2.** Attenuated total reflectance (ATR) infrared spectra of fresh biochar (BC-fr) and biochars aged 1 (BC-1yr) and 2 years (BC-2yr).

Figure 3 shows the SEM images of the fresh biochar (BC-fr) (Figure 3a,b), the biochar aged 1 year and a biochar aged 4 years in soil (Figure 3c−f). SEMs of fresh biochar show a macropore (Figure 3a) with an organic layer coating the micropores and remaining surface structures (Figure 3b). In contrast, the surface of the BC-1yr shows a highly porous surface, with only some of the pores having a range of organic and mineral matter (Figure 3c,d). The SEM image of the biochar aged 2 years show that most of the pores were filled after longer exposure in the soil (Figure 3e,f). Lin et al.[23] observed that clay and mineral particles were adhered to the biochar surface, the mineral attachment occurred preferentially around the biochar external surface, and most of the pores inside the biochar were free of mineral phases. This agrees with our observations.

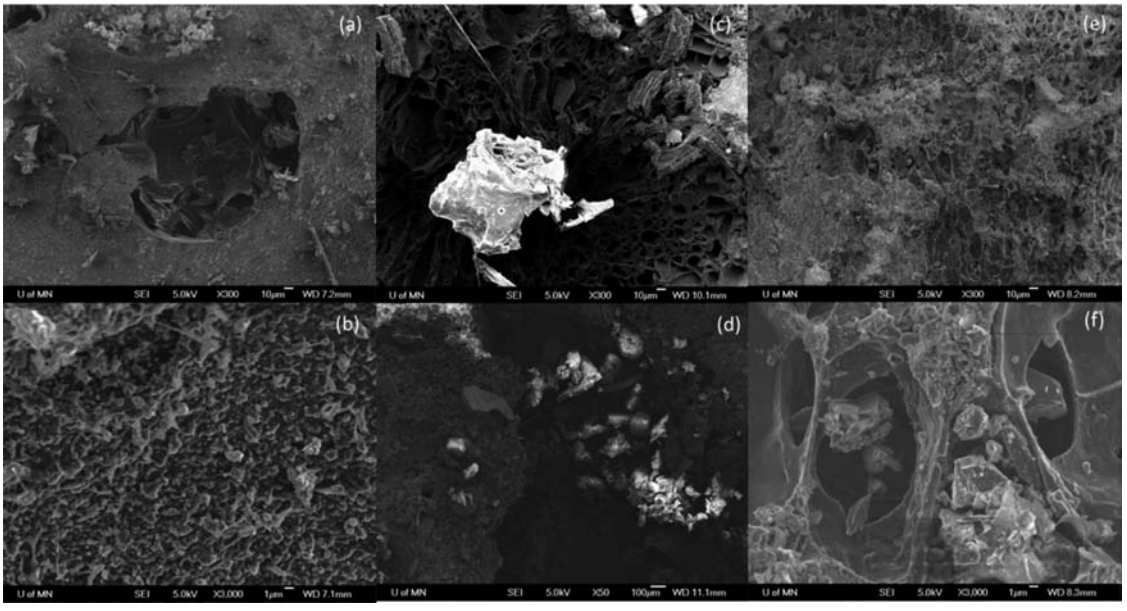

**Figure 3.** (a) SEM image showing a macropore on the fresh biochar (×300 magnification). (b) Fatty lipid surface (organic layer) on the fresh biochar (×3000). (c) Soil particles on the porous surface of BC-1yr (×300). (d) Soil particles on the porous surface of BC-1yr (×50). (e) Surface and pores covered with soil particles for biochar aged 4 years (×300). (f) Surface and pores covered with soil particles on the porous surface of BC-4yr (×3000). Note the significant difference in the appearance of the BC surface in panels b and f, which are at the same magnification (×3000).

Table 3. Sorption Coefficients ($K_d$) for the Pesticides in the Biochars

| | $K_d$ (L kg$^{-1}$) | | | | |
|---|---|---|---|---|---|
| biochar | terbuthylazine | indaziflam | MCPA | fluoroethyldiaminotriazine | nicosulfuron |
| BC-fr | 595 ± 9 | 162 ± 20 | 7.49 ± 2.00 | 0.26 ± 0.15 | 0.00 ± 0.00 |
| BC-1yr | 312 ± 27 | 156 ± 18 | 2.23 ± 0.00 | 1.18 ± 0.75 | 0.00 ± 0.00 |
| BC-2yr | 221 ± 4 | 237 ± 25 | 2.48 ± 0.00 | 2.95 ± 0.92 | 0.03 ± 0.02 |

The specific surface area (SSA) of the biochars (Table 1) increased with time after soil application, from 0.095 m$^2$ g$^{-1}$ for the fresh biochar (BC-fr) to 69.774 m$^2$ g$^{-1}$ for biochar aged 1 year. The increase in SSA is assumed to be due to the elimination of the organic film from the BC-fr surface exposing the underlying micropores. The SSA was still higher than the initial biochar after 2 years (5.786 m$^2$ g$^{-1}$), even though some pores were filled with organic and mineral matter (Figure 3e,f).

Complex reactions take place on biochar surfaces, especially for those biochars that have high mineral content. Due to the high-temperature pyrolysis (850 °C) of the biochar, a high mineral-ash biochar with characteristics of a highly aromatic composition and recalcitrant microbial decomposition are expected.[3] Several mechanisms for interactions between biochar and minerals or biochar and organic matter have been hypothesized:

(i) The interactions at mineral surfaces could be cation−$\pi$ interactions between mineral surface cations and with the negative electrostatic surface of the aromatic ring,[24] hydrogen−$\pi$ interactions between the face of electron-rich $\pi$-system of the aromatic ring of the biochar and the H silanol groups of the minerals, or n−$\pi$ electron donor−acceptor interactions (n = nonbonding electrons at siloxane surface) between a nitroaromatic compound ($\pi$-acceptor) and a basal siloxane surface.

(ii) $\pi$−$\pi$ interactions could happen between the $\pi$-donor or $\pi$-acceptor system of the biochar with the natural organic matter (NOM) or polar−$\pi$ interactions between aromatic systems with positively polarized or charged organic moieties. It has been shown that NOM can suppress sorption of organic contaminants on environmental black carbon by blocking micropores.[25]

The decline in DOC of BC-1yr (31.6 mg L$^{-1}$) in comparison to BC-fr (80.4 mg L$^{-1}$) (Table 2) could be a result of the natural elimination in soil of the organic covering on the fresh biochars and also for the degradation of the more labile fraction of DOC, which would enhance the proportion of recalcitrant aromatics,[26] increasing the aromaticity ($SUVA_{254}$) (6.12 L mg$^{-1}$ m$^{-1}$ for BC-1yr and 3.70 L mg$^{-1}$ m$^{-1}$ for BC-fr). Cox et al.[27] found that the humification index (HIX) of DOC from a solid organic amended with a high amount of aromatic molecules after two months of soil incubation shows just a small increase with residence time. This can be attributed to the sorption of organic matter that must be more humified and have higher adsorption capacities. Lin et al.[23] noticed that the hydrophobic DOC fraction decreased in a biochar mineral complex indicating that hydrophobic DOC could be immobilized in the complex because of a strong affinity toward clays.[28]

**Sorption Experiments.** The greatest sorption for the fresh and two aged biochars was for indaziflam and terbuthylazine, both weak bases (Table 3). At the pH of the solutions (6.5−6.7) while >99% of both chemicals would be molecular species, cationic species may significantly contribute to the net sorption through (1) an interaction of a positively charged ion with the negative electrostatic potential surface of the aromatic ring of the biochars,[23] (2) carboxylic groups of the organic surface covering of the fresh biochar, and (3) partially being sorbed in the pores of the aged biochar. As the cation is sorbed, a portion of the molecular species is protonated to reestablish the solution equilibrium. The greatest sorption of terbuthylazine is due to a high number of cationic species at the same pH as compare to indaziflam. In addition, dispersive and hydrophobic forces are thought to act in support of this type of association.[29] For pesticides with low water solubility, organic matter provides important sorbent surfaces in soil because phase partitioning is driven by hydrophobic interactions.[30] Cox et al.[31] found a high sorption of simazine in a soil amended with humified organic matter. Sorption values ($K_d$) of indaziflam and terbuthylazine found in different soil were 27.44−4.86 (Alonso et al., 2011)[32] and 3.7−0.4 (Alister et al., 2011),[33]respectively. These values are around 10 and 300 times higher than the adsorption observed for biochars for indaziflam and terbuthylazine.

The $K_d$ values for the aged biochars (BC-1yr and BC-2yr) decreased for terbuthylazine ∼52% for BC-1yr and ∼63% for BC-2yr with respect to BC-fr because of a decrease of the number of the cationic molecules with the increase of the pH and due to a decrease of the carboxylic groups of the surface of the aged biochars for a natural elimination or a sorption of the unsaturated acid in soil. Conversely, for indaziflam the BC-2yr $K_d$ value increased ∼43% in comparison with BC-fr and BC-1yr. Indaziflam sorption could be more affected for the hydrophobic interactions than terbuthylazine due to its lower solubility, so the increase of the number of available pores from removal of the organic layer aids sorption. As we mentioned above, aging may have altered the qualitative DOC character affecting its chemical affinity.

Nicosulfuron and MCPA are weak acids and at the pH of the solutions (6.7−6.5) >98% of the molecules are anionic. This negatively charged species could create a repulsion to negative groups on the biochar surface, and only the molecular species are sorbed. Cabrera et al.[34] evaluated several biochars made from different feedstocks under different pyrolysis conditions and observed a correlation between MCPA sorption and the biochar surface area, where BC2 biochar with the same characteristic of BC-fr had the smaller SSA value (3.3 m$^2$/g) and showed the lower $K_d$ value. No sorption of nicosulfuron was observed on the biochars, which may be due to higher repulsion of anionic molecules (>99%). Unlike other sulfonylureas for which adsorption is usually controlled by organic C content, different results show that clay mineralogy plays an important role in nicosulfuron adsorption.[35−37] For MCPA, an increase of anionic molecules is expected at more alkaline conditions, which decreases the sorption of the molecular species and enhances the charge repulsion interaction for BC-1yr and BC-2yr. Oliveira et al. (2001)[38] found $K_d$ values for nicosulfuron of 0.14−1.38 in six Brazilian soils, and Reginato and Koskinen (2008)[39] determined in three American soils and two Brazilian soils values in the range of 0.14−1.81. Lopez Piñeiro (2013)[40] established $K_d$ values of

MCPA in different soils of 0.29−0.43. The increase on MCPA sorption in biochar was 18 times even for this herbicide where biochar surface repulsion happened and only the molecular species are sorbed. Nicosulfuron $K_d$ values are higher in soils than in biochars.

According to the $K_d$ values of biochar in the four herbicides mentioned above, it appears that the sorption depends on the p$K_a$ and hydrophobicity of the chemical. This indicates that the metabolite of indaziflam (fluoroethyldiaminotriazine) would be more polar than the parent compound, which explains the lower values of $K_d$ (0.26−2.95) than the parent and its dependency on the biochar pH explaining the sorption increase in BC-1yr and BC-2yr. Using a theoretical p$K_a$ value for fluoroethyldiaminotriazine of 4.10 (www.chemaxon.com),[18] a higher percentage of cationic molecules and sorption than indaziflam is predicted, so the difference in the observed sorption could be due to the differences in the hydrophobic biochar interactions.

These results indicate that, for a biochar made under high pyrolysis conditions, the sorption of pesticides depends highly on the hydrophobicity of the chemicals. The aging process of the biochars modified the pH of the solution and correspondingly affected the sorption behavior of the herbicides. Even so, the aged biochars are highly effective in adsorbing terbuthylazine and indaziflam, due to its high initial adsorptivity.

Our results indicate that biochar and soil components interaction happened in the surface of the aged biochars and the specific surface area (SSA) increased with this process. For this biochar the major facet of the aging process was loss of the sorbed organic films present on the fresh biochar particle. The adsorption of pesticides is highly dependent not only on biochar characteristics but also on the physicochemical characteristics of the pesticides. For the biochar examined here, aged biochars in soils still remain highly effective at adsorbing pesticides, due to the high initial adsorptivity. Due to the variable nature of biochars, individual characterization of the biochar used as soil amendment is recommended prior to field applications. However, these results do indicate the potential for increased sorption behavior to exist 2 years after the initial biochar application, despite the observed clogging of biochar pore space with soil particles. In addition, it is important to match the target chemical characteristics with the correct biochar properties to optimize the sorption potential of biochar in a particular application.

varietal dependents, so such composition can be associated with the so-called "terroir character" of their vineyards and their wines.

There are a number of solid−liquid extraction (SLE) techniques used for the extraction of phenolic compounds from different vegetable waste materials, most of them using organic solvents (mainly ethanol), high temperatures (up to 240 °C), and long extraction times (up to 1 h) to exhaust the materials.[20−22] However, such long extraction times can cause the generation of artifact compounds, and the use of organic solvents limits the search for new applications, due to their negative environmental impact and other human health issues. SLE procedures may be assisted by other parameters such as as ultrasound (UAE),[23] pressure (PSE),[13,24] or the use of supercritical fluids[25] among others.

Nowadays there is a trend that encourages the use of free environmental techniques to enhance sustainability; it is the so-called "green chemistry". Such techniques are developed to reduce and/or eliminate the use of organic solvents, and the use of water as extractant should be preferred. As well, the resulting aqueous extracts will have the advantage of being exempt from certification based on their vegetal origin,[26] although the compounds' concentration in such extracts may be lower than when other techniques are used as the exhaustion of the vegetable material does not take place. Other SLE techniques that may be in agreement with this new green postulated may be based on the Naviglio principle[27,28] or on microwave extraction (ME).[29,30] Whereas the Naviglio solid−liquid extraction technique is carried out at room temperature and compression/decompression times are modified, ME uses higher temperatures but shorter extraction times.

Extraction techniques to get aromatic plant extracts are very limited, except for essential oil production.[31] Delgado de la Torre et al.[15] have only refereed vine-shoot aroma description where ethanolic water mixtures at 220 °C for 60 min were the selected extraction conditions. Volatile phenols and furanic derivates were described in the previous work as the main components in vine-shoots, the same compounds found in oak aqueous extracts with biostimulant properties.[18]

Consequently, the aim of this work was to compare Airén vine-shoot waste aqueous extracts produced by four solid−liquid extraction techniques (conventional solid−liquid extraction (CSLE), solid−liquid dynamic extraction (SLDE-Naviglio), solvent free microwave extraction (ME), and pressurized solvent extraction (PSE) and to study their chemical composition in terms of phenolic, volatile, and mineral valuable compounds as they may have agricultural applications such as plant biostimulants or foliar fertilizers.

## MATERIALS AND METHODS

**Vine-Shoot Samples.** One hundred kilograms of Airén white *V. vinifera* vine-shoot wastes was sampled in D.O. Mancha, located in the Castilla-La Mancha Spanish region, 4 months after the harvest of 2013, by randomized selection. Samples were dried for 72 h at room temperature until a final humidity of 6.5% ($g_{water}$/100 g $_{of\ sample}$). Dry vine-shoot wastes were ground by using a hammer miller (LARUS Impianti, Skid Sinte 1000, Zamora, Spain) to get a homogeneous 40 mesh sieve sampling. Samples were kept under vacuum until their use at room temperature (25−27 °C).

**Vine-Shoot Extraction Procedures.** All vine-shoot waste aqueous extracts were submitted twice for each extraction technique and condition tested.

*CSLE.* Fifty grams of ground Airén vine-shoot waste samples was extracted with 250 mL of boiling water, and then the solution was kept at 100 °C. The extraction time was set at 15, 30, and 60 min (CSLE-15, CSLE-30, and CSLE-60, respectively).

*SLDE-Naviglio.* A dynamic solid−liquid extraction was carried out using a Naviglio Extractor (FT 110, Armfield, UK) following the Naviglio methodology.[27] The Naviglio extraction is based on a suction effect generated by a compression of water, used as extracting solvent, on solids at room temperature (25−27 °C) and a pressure of 8 bar, followed by immediate decompression at atmospheric pressure. Two hundred grams of ground vine-shoot wastes was placed inside the extraction chamber, and 1.1 L of water was added as a solvent. The conditions tested for compound extraction were as follows: 20 extractive cycles of 6.5 min (5 min in the static phase and 1.5 min in the dynamic phase; SLDE-Naviglio-6.5), 8 min (5 min in the static phase and 3 min in the dynamic phase; SLDE-Naviglio-8), and 12 min (9 min in the static phase and 3 min in the dynamic phase; SLDE-Naviglio-12) each.

*ME.* Microwave extraction was carried out with a NEOS apparatus (Milestone, Italy). Fifty grams of ground vine-shoot waste samples was placed into the reactor with 250 mL of water at 100 °C. The extraction program was set at 600 W (held for 5, 10, and 15 min; ME-5, ME-10, ME-15, respectively). A rotating microwave diffuser ensured homogeneous microwave distribution throughout the plasma-coated PTFE cavity. The temperature was monitored by an external IR sensor.

*PSE.* Twenty grams of ground vine-shoot wastes was placed into each cell (four cells) with 100 mL of water and extracted using a pressurized extractor (Speed Extractor BUCHI E-914, Barcelona, Spain). The extractor parameters were set at temperature of 30 °C ($T_1$) and 100 °C ($T_2$), pressure of 50 bar ($P_1$) and 100 bar ($P_2$), three cycles (heat up, 1 min; hold (10, 15, 30 min), and discharge (9 min) named PSE-time, pressure, temperature (PSE-10$P_1T_1$, PSE-10$P_1T_2$, PSE-10$P_2T_1$, PSE-10$P_2T_2$, PSE-15$P_1T_1$, PSE-15$P_1T_2$, PSE-15$P_2T_1$, PSE-15$P_2T_2$, PSE-30$P_1T_1$, PSE-30$P_1T_2$, PSE-30$P_2T_1$, PSE-30$P_2T_2$). After the discharge of the last cycle, the extraction cells were flushed with water for 3 min and with $N_2$ gas for 5 min.

All extracts were filtered through a PVDF Durapore filter of 0.45 μm (Millipore, Bedford, MA, USA).

**Extract Analysis.** Extracts general parameters such as °Brix, pH, and total phenol index (TPI, measured at 280 nm by means of an UV−vis spectrophotometer Lambda 25 (PerkinElmer, Norwalk, CT, USA) were determined.

*Determination of Phenolic Compounds by HPLC-DAD-MS.* This method was based on Pardo-García et al.'s[19] work, but the gradient condition was slightly modified to improve the resolution of new standards. The HPLC grade solvents used were water/formic acid/acetonitrile (97.5:1.5:1 v/v/v) as solvent A and acetonitrile/formic acid/solvent A (78.5:1.5:20 v/v/v) as solvent B. The elution gradient was set up for solvent B as 0 min, 5%; 2 min, 10%; 4 min, 14%; 9 min, 14%; 37 min, 18.5%; 35 min, 20%; 50 min, 25%; 55 min, 50%; 60 min, 5%; and 65 min, 5%. The loop volume was 20 μL.

Phenolic acid, stilbene, and flavanol detections were carried out with the DAD by comparison with the corresponding UV−vis spectra and retention time of their pure standards in the chromatogram. Acids *trans*-caftaric and *trans*-*p*-coutaric were not available, so they were identified with the molecular ion and the spectral parameters, which were very close to their analogous *trans*-caffeic and *trans*-*p*-coumaric acids. Compounds were quantified and identified at different wavelengths: (+)-catechin, (−)-epicatechin, gallic acid, protocatechuic acid, pyrogallol, and syringic acid at 280 nm; ellagic, ferulic, and vanillic acids at 256 nm; *trans*-caffeic acid, *trans*-caftaric acid, and sinapaldehyde at 324 nm; *trans*-resveratrol, piceid (*t*-resveratrol-3-glucoside), *trans*-*p*-coumaric acid, and *trans*-*p*-coutaric acid at 308 nm.

Quantification was based on calibration curves of the respective standards (Sigma-Aldrich, Steinheim, Germany) at five different concentrations (0.70−175 mg/L) ($R^2$ > 0.97). All analyses were made in duplicate.

*Determination of Volatile Compounds by HS-SBSE-GC-MS.* Volatiles were extracted by means of headspace stir bar sorptive extraction (HS-SBSE) according to Pardo-Garcia et al.'s[32] method. The volatile analysis was performed using an automated thermal

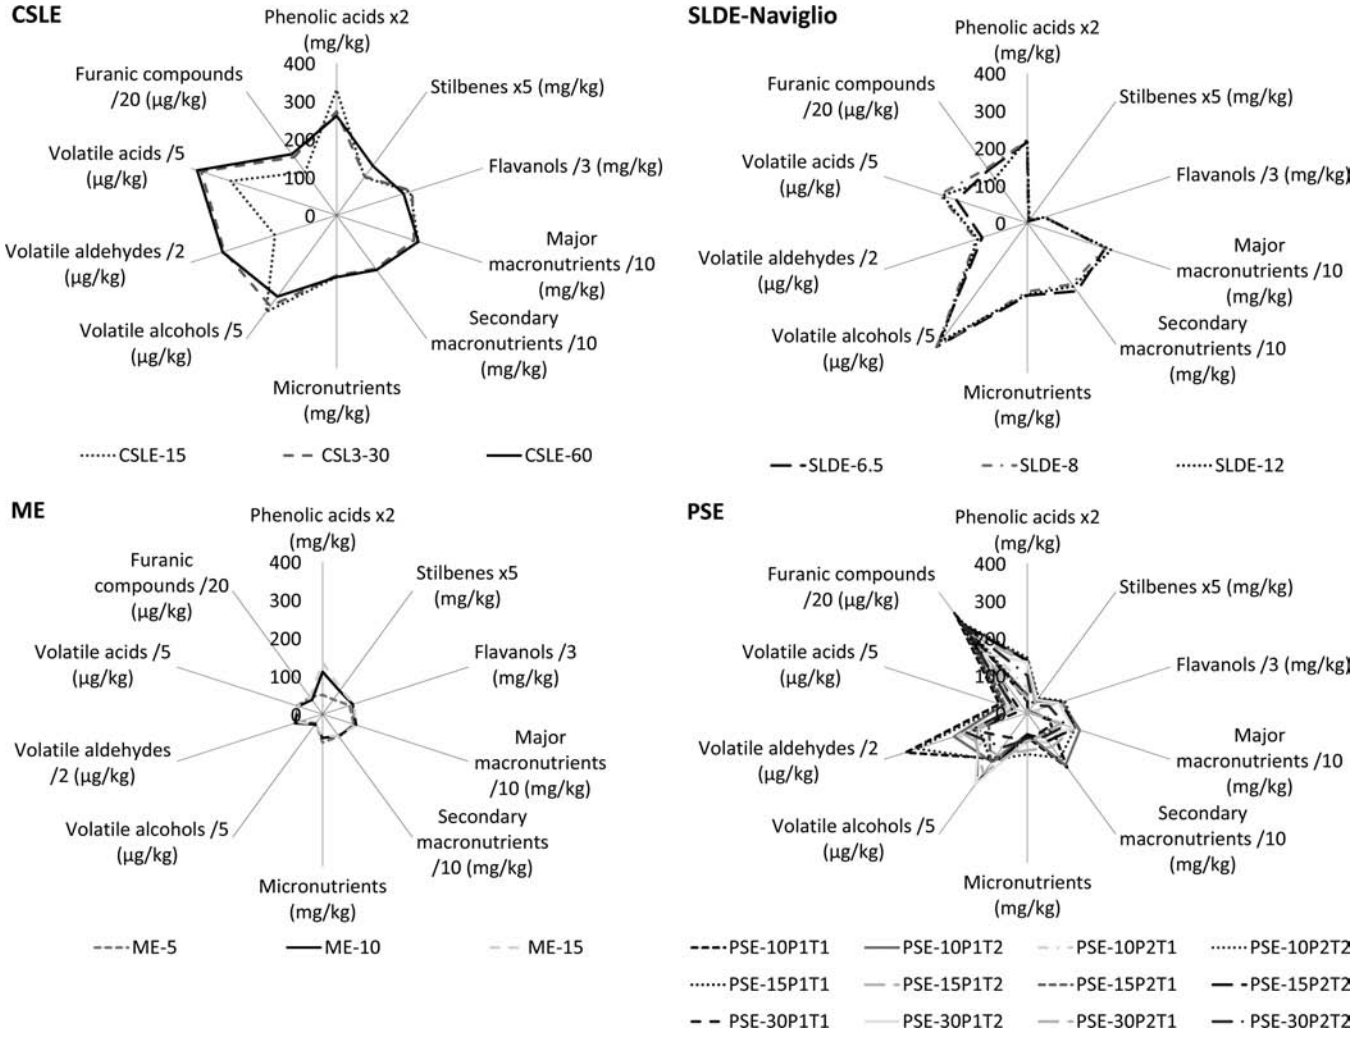

**Figure 1.** Total composition, in terms of the main chemical families, for the aqueous vine-shoot waste extracts obtained under different extraction systems and conditions. ME, solvent-free microwave extraction (ME-5, 5 min; ME-10, 10 min; ME-15, 15 min); CSLE, conventional solid−liquid extraction (CSLE-15, 15 min; CSLE-30, 30 min; CSLE-60, 60 min); SLDE-Naviglio, solid−liquid dynamic extraction (SLDE-Naviglio-6.5, 5 min in the static phase and 1.5 min in the dynamic phase; SLDE-Naviglio-8, 5 min in the static phase and 3 min in the dynamic phase; SLDE-Naviglio-12, 9 min in the static phase and 3 min in the dynamic phase); PSE, pressurized solvent extraction (extraction temperature, 30 °C ($T_1$) and 100 °C ($T_2$); pressure, 50 ($P_1$) and 100 bar ($P_2$); cycles, 3 (heat up, 1 min, hold (10, 15, 30 min), and discharge (9 min) named PSE-time, pressure, temperature (PSE-10$P_1T_1$, PSE-10$P_1T_2$, PSE-10$P_2T_1$, PSE-10$P_2T_2$, PSE-15$P_1T_1$, PSE-15$P_1T_2$, PSE-15$P_2T_1$, PSE-15$P_2T_2$, PSE-30$P_1T_1$, PSE-30$P_1T_2$, PSE-30$P_2T_1$, PSE-30$P_2T_2$).

desorption unit (TDU, Gerstel, Mülheim and der Ruhr, Germany) mounted on an Agilent 7890A gas chromatograph system (GC) coupled to a quadrupole Agilent 5975C electron ionization mass spectrometric detector (Agilent Technologies, Palo Alto, CA, USA) equipped with a fused silica capillary column (BP21 stationary phase, 30-m length, 0.25 mm i.d., and 0.25 μm film thickness) (SGE, Ringwood, Australia). The carrier gas was helium with a constant column pressure of 20.75 psi.

The stir bars were thermally desorbed in a stream of helium carrier gas at a flow rate of 75 mL/min with the TDU programmed from 40 to 295 °C (held 5 min) at a rate of 60 °C/min. The analytes were focused in a programmed temperature vaporizing injector (PTV) (CIS-4, Gerstel), containing a packed liner (20 mg tenax TA), held at 25 °C with Peltier cooling prior to injection. After desorption and focusing, the CIS-4 was programmed from 25 to 260 °C (held for 5 min) at 12 °C/s to transfer the trapped volatiles onto the analytical column. The TDU was operated in the splitless desorption mode, whereas the CIS-4 was operated in the PTV solvent vent mode (purge flow to split vent of 80 mL/min, vent 75 mL/min, and pressure 20.85 psi). The GC oven temperature was programmed to 40 °C (held for 2 min), raised to 80 °C (5 °C/min, held for 2 min), raised to 130 °C (10 °C/min, held for 5 min), raised to 150 °C (5 °C/min, held for 5 min), and then raised to 230 °C (10 °C/min, held for 5 min). The MS was operated in scan acquisition (27−300 u) with an ionization energy of 70 eV. The temperature of the MS transfer line was maintained at 230 °C. The identification of the compounds was performed using the NIST library and confirmed by comparison with the mass spectra and retention time of chromatographic standards. To avoid matrix interferences, the MS quantification was performed in the single ion-monitoring mode using characteristic $m/z$ values. The standards employed to identify and quantify volatiles (GC-MS) were purchased from Sigma-Aldrich (Steinheim, Germany) (the numbers in parentheses indicate the $m/z$ used for quantification): D-limonene ($m/z$ 69), 1-hexanol ($m/z$ 56), 3-hexen-1-ol (*Z*) ($m/z$ 67), nonanal ($m/z$ 57), 1-octen-3-ol ($m/z$ 57), furfural ($m/z$ 96), benzaldehyde ($m/z$ 106), linalool ($m/z$ 71), linalyl acetate ($m/z$ 93), 5-methylfurfural ($m/z$ 110), 1-nonanol ($m/z$ 56), α-terpineol ($m/z$ 59), hexanoic acid ($m/z$ 60), geranyl acetone ($m/z$ 43), guaiacol ($m/z$ 109), benzyl alcohol ($m/z$ 108), *trans*/*cis*-whiskey lactones ($m/z$ 99), 2-phenylethanol ($m/z$ 91), β-ionone ($m/z$ 177), octanoic acid ($m/z$ 60), decanoic acid ($m/z$ 60), and vanillin ($m/z$ 151), together with the internal standards 3-methyl-1-pentanol and γ-hexalactone. **Figure 2.** (a) Canonical discriminant analysis of the 21 vine-shoot waste aqueous extracts obtained by four extraction systems. (b) Standarized canonical coefficients of the main discriminant variables in functions 1 and 2 obtained for phenolic compounds, volatile compounds, and mineral composition data. ME, solvent-free microwave extraction (ME-5, 5 min; ME-10, 10 min; ME-15, 15 min); CSLE, conventional solid–liquid extraction (CSLE-15, 15 min; CSLE-30, 30 min; CSLE-60, 60 min); SLDE-Naviglio, solid–liquid dynamic extraction (SLDE-Naviglio-6.5, 5 min in the static phase and 1.5 min in the dynamic phase; SLDE-Naviglio-8, 5 min in the static phase and 3 min in the dynamic phase; SLDE-Naviglio-12, 9 min in the static phase and 3 min in the dynamic phase); PSE, pressurized solvent extraction (extraction temperature, 30 °C ($T_1$) and 100 °C ($T_2$); pressure, 50 ($P_1$) and 100 bar ($P_2$); cycles, 3 (heat up, 1 min, hold (10, 15, 30 min), and discharge (9 min) named PSE-time, pressure, temperature (PSE-10$P_1T_1$, PSE-10$P_1T_2$, PSE-10$P_2T_1$, PSE-10$P_2T_2$, PSE-15$P_1T_1$, PSE-15$P_1T_2$, PSE-15$P_2T_1$, PSE-15$P_2T_2$, PSE-30$P_1T_1$, PSE-30$P_1T_2$, PSE-30$P_2T_1$, PSE-30$P_2T_2$).

tion was based on calibration curves of the respective standards at five different concentrations (2 μg/L–15 mg/L) ($R^2$ > 0.97). All analyses were made in triplicate.

*Mineral Composition.* Al, As, B, Be, Bi, Ca, Cd, Co, Cr, Cu, Fe, K, Li, Mg, Mn, Mo, Na, Ni, P, Pb, S, Sb, Se, Sr, Ti, Tl, V, and Zn were quantified in vine-shoot waste aqueous extracts by inductively coupled plasma–optical emission spectrometry (ICP-OES) using an ICP spectrometer (Thermo Scientific ICAP 6500 Duo, Madrid, Spain). Anion quantifications such as P, S, Cl, F, N (as $NO_3^-$ and $NO_2^-$) were determined by ion chromatography (850 Professional IC Anion, Suppressor Module MSM, Metrohm, Herisau, Switzerland) coupled with a conductivity detector (model 819, Metrohm). Aliquots of 20 μL were injected after filtering through a 0.45 μm PTFE filter in a Metrosep A Supp 7 analytical column (4.0 mm i.d. × 250 mm, 5 μm particle size, Metrohm) at 50 °C. An isocratic elution was performed with 3.6 mM $Na_2CO_3$ at a flow of 0.8 mL/min.

Quantification was based on calibration curves of the respective standards (Sigma-Aldrich, Steinheim, Germany) at five different concentrations (0.01–25.00 mg/L) ($R^2$ > 0.99). All analyses were made in duplicate.

**Statistical Analysis.** The statistical elaboration of the data was performed using SPSS version 19.0 statistical package for Windows (SPSS, Chicago, IL, USA). Phenolic, volatile, and mineral compound data were processed using the variance analysis (ANOVA). Differences between means were compared using the least significant difference (LSD) test at a 99.95% probability level.

## ■ RESULTS AND DISCUSSION

The first approach of this paper was to produce aqueous extracts from vine-shoot wastes of Airén white *V. vinifera*. Four extraction systems (CSLE, SLDE-Naviglio, ME, and PSE) were assayed with the same vine-shoot sample/water ratio, combining, according to the system selected, parameters such as time, temperature, and pressure, resulting in 21 different aqueous vine-shoot waste extracts for their study. Different extraction yields were obtained, so all data have been homogenized and expressed as milligrams per kilogram or micrograms per kilogram of dry vine-shoot matter. Extracts were characterized in terms of phenolic, volatile, and mineral compounds. All extracts had a pH value ranging from 5.93 (ME) to 6.62 (PSE).

Due to the large quantity of compositional data, some chemical associations were carried out to have a general look at each extraction system and their respective conditions (Figure 1). The most concentrated family of compounds, independent of the extraction technique used, were macronutrients (major and secondary), followed by flavanols and phenolic acids, all of

[a]CSLE, conventional solid−liquid extraction (CSLE-15, 15 min; CSLE-30, 30 min; CSLE-60, 60 min); SLDE-Naviglio, solid−liquid dynamic extraction (SLDE-Naviglio-6.5, 5 min in the static phase and 1.5 min in the dynamic phase; SLDE-Naviglio-8, 5 min in the static phase and 3 min in the dynamic phase; SLDE-Naviglio-12, 9 min in the static phase and 3 min in the dynamic phase). Different letters in the same row indicate significant differences among extraction conditions according to the LSD test ($\alpha < 0.05$). The mean values ($n = 4$) are shown with their standard deviation. [b]nd, not detected.

them expressed in milligrams per kilogram. The volatile content was the lowest, expressed in micrograms per kilogram, the most abundant being furanic compounds. CSLE and SLDE-Naviglio techniques produced the most concentrated extracts in relation to the groups of compounds previously discussed. Both extraction techniques are very different from one another, equating a conventional solid−liquid extraction technique with a novel technique based on a suction effect generated by a compression/decompression cycle (SLDE-Naviglio). The other two innovative extraction systems tested, ME and PSE, showed lower compositional data in comparison with CSLE and SLDE-Naviglio, and, more importantly, they did not show significant differences between any of the conditions test.

It has to be pointed out that all SLE systems extracted the same number of compounds, except for vanillic acid and ferulic acid (not found in PSE system) and sinapaldehyde, D-limonene, and linalyl acetate (not found in SLDE-Naviglio).

To differentiate extracts according to the different extraction conditions, a discriminant analysis was performed (Figure 2a). Three main groups can be distinguished, which were clearly separated by two canonic discriminating functions, explaining 47.7% of the total variance with the first function and 87.3% together with the second function. One of the groups encompasses the ME and PSE systems, whereas the other two groups account for CSLE and SLDE-Naviglio systems. The compounds that contributed most to the differentiation (Figure 2b) are phenolic compounds, especially gallic acid, ellagic acid, (−)-epicatechin, and *trans*-caftaric acid. In terms of minerals, calcium, iron, and boron showed the highest weight on the canonic coefficients. However, no volatile compound contributed to this differentiation. It is surprising that general parameters such as total phenolic index (TPI) or °Brix values were not selected for these differentiations. TPI and °Brix higher values were found in ME (61.60 and 3.55, respectively) and CSLE (45.8 and 2.88, respectively) techniques, followed by SLDE-Naviglio (13.90 and 2.0, respectively) and PSE (11.13 and 0.9, respectively).

The objective of the present research is to get aqueous extracts for agricultural purposes to be applied as a mix. For this reason, the composition discussion will focus on the CSLE and SLDE-Naviglio extraction systems as they are the ones with the highest concentration of valuable compounds (phenolic and volatile compounds, minerals), although they may be in detriment of a specific compound extracted by the other tested techniques.

Furthermore, it is interesting to point out that both systems are not of remarkable energy requirements with respect to other extractive processes. For example, CSLE is the process traditionally more used in industries.

**Phenolic Composition by HPLC-DAD-MS.** Table 1 lists the concentration of the phenolic compounds identified within the Airén vine-shoot waste aqueous extracts obtained by CSLE and SLDE-Naviglio. Significant differences were found among both extraction systems, as CSLE extracts were more concentrated that SLDE-Naviglio ones, independent of the extraction conditions tested, except for the group named "others".

(+)-Catechin and (−)-epicatechin were the only flavanol compounds detected in all extracts. By CSLE it was possible to extract 4 times more flavanols than with SLDE-Naviglio (Table 1), suggesting that higher temperature (100 °C) favored their release in comparison with room temperature conditions (25−27 °C). (+)-Catechin represented 60% of the CSLE total flavanol fraction, whereas in SLDE-Naviglio it was approximately 80% of the total content. When Airén vine-shoots were extracted by ethanol superheated liquid extraction (SHLE), (+)-catechin, pyrogallol, and syringic acid were the most abundant compounds.[13]

Among phenolic acids, *trans*-caffeic acid was the only compound for which the concentration was higher when the SLDE-Naviglio extraction system was used. *trans*-Caffeic acid concentration (Table 1) was higher in the present extracts than the one found (19 μg/kg) in other vine canes of which extracts were obtained by CSLE with an ethanol aqueous solution.[14] This compound was not detected when SHLE was used as extraction system.[13] *trans*-*p*-Coumaric and ferulic acids were highly extracted in terms of temperature, due to the high concentrations found in CSLE extracts. The presence of the hydroxycinnamoyltartaric acids (*trans*-*p*-coutaric and *trans*-caftaric) has not been previously reported in the literature in any type of wood. Such compounds are identified as oxidation substrates and browning precursors in white wines.[33] *trans*-Caftaric acid was the third compound in abundance within the phenolic pool (Table 1), especially when CSLE-15 was used. The content of *trans*-*p*-coutaric acid was significantly higher for CSLE-15 and CSLE-30 than for the other conditions tested.

The presence of low molecular weight compounds such as gallic and ellagic acids indicated that vine-shoots contain as well hydrolyzable tannins, although other authors[13] did not found ellagic acid in Airén vine-shoots. The concentration of gallic acid was higher than that of ellagic acid, favored by the CSLE system that produced a 50% more concentrated extract than SLDE-Naviglio, independent of the conditions tested on each system (Table 1). Protocatechuic acid, related to gallic acid by dealcoholization, was extracted by CSLE rather than by SLDE-Naviglio. An opposite behavior was found by pyrogallol, included in the "others" chemical group (Table 1) and which is related to gallic acid by decarboxylation. This latest compound, together with *trans*-caffeic acid, was highly extracted at room temperature (25−27 °C) (SLDE-Naviglio) rather than at 100 °C (CSLE), but no significant differences were observed when the different compression/decompression times were tested (Table 1).

Syringic acid was highly extracted by the CSLE system, showing the same behavior as most phenolic compounds. Vanillic acid behavior was different between the assayed extracts, as the higher concentration was quantified in CSLE-15, which indicated that higher extraction temperature but shorter times favored its extraction. This observation may be also justified by the fact that 3 mg/kg of this compound was quantified when SHLE was used.[13]

An important group of phenolic compounds is the stilbenes, which are best represented by *trans*-resveratrol, and it is identified in a wide variety of plant spices, especially in grapevines.[34−36] *trans*-Resveratrol has attracted research interest because of its demonstrated therapeutic effects, anti-inflammatory or even anticancer ones.[34] The glycosylated form of resveratrol, piceid, may also be found in the same or lower proportion depending on grape variety. The higher concentration of *trans*-resveratrol has been reported by some authors, between 1100 and 5000 mg/kg, in different vine-shoot cultivars, especially high in Pinot noir,[12] whereas in Turkish cultivars the concentration was around 2.5 μg/kg.[14] Although Delgado de la Torre et al.[13] did not find *trans*-resveratrol in Airén vine-shoots, it was found in the present aqueous extracts. Especially interesting is the CSLE concentration, which was approximately 20 times more concentrated than by SLDE-Naviglio (Table 1). The differences found between both systems indicate that the extraction temperature is an important parameter to enhance the extraction of this compound, but no significant differences were found in terms of time when the CSLE conditions were tested. Several factors could produce the differences found with other authors' references, not only by the grape variety, but the health of the grape vine and grape canes, together with the differences on the extraction system used.[11,35] The other identified stilbene, piceid, was not detected by any other authors, and it had the same behavior as its nonglycosylated derivate when CSLE was compared with the SLDE-Naviglio. The concentration of the piceid was 7 times lower than that of *trans*-resveratrol. Other stilbenes (*trans*-piceatannol, *trans*-ε-viniferin, or vitisinol among others) have been also characterized in other vine-shoot cultivars,[11,12] but those compounds could not be detected in the present aqueous extracts.

It is surprising that sinapaldehyde was not found in SLDE-Naviglio extracts in comparison with CSLE extracts, but it was quantified in those extracts previously reported.[13] Compounds such as acetovanillone, pyrocatechol, 4-hydroxybenzoic acid, and coniferaldehyde referred to in the Delgado de la Torre et al.[13] study were looked for but not found in our extracts.

**Volatile Composition by HS-SBSE-GC-MS.** Table 2 summarizes the results of volatile compounds identified, classified into different families according to their chemical structure, within the Airén vine-shoot waste aqueous extracts obtained by CSLE and SLDE-Naviglio. It is the first time that vine-shoot waste aqueous extract volatile composition is quantified, as only a qualitative profile was carried out by Delgado de la Torre et al.[15] Because the vine-shoots are subjected to a degradation process while extracting, cellulose and lignin may release such important aroma compounds. In all extracts, the furanic compounds were the most abundant followed by alcohols and acids. For both extraction systems, furanics showed around 48% of the total content; however, alcohols and acids presented some differences. If in SLDE-Naviglio alcohols reached around 30% of the total content, in the CSLE extraction system they were about 20%. With regard to acids, the higher proportion within the total content was observed by CSLE, 24 versus the 16% reached by the SLDE-Naviglio system.

Significant differences were found among the extraction systems used, depending on the extraction conditions tested; both extraction systems did not extract the same number of compounds. For example, D-limonene and linalyl acetate were not found in SLDE-Naviglio extraction system.

[a]SLE, conventional solid−liquid extraction (CSLE-15, 15 min; CSLE-30, 30 min; CSLE-60, 60 min); SLDE-Naviglio, solid−liquid dynamic extraction (SLDE-Naviglio-6.5, 5 min in the static phase and 1.5 min in the dynamic phase; SLDE-Naviglio-8, 5 min in the static phase and 3 min in the dynamic phase; SLDE-Naviglio-12, 9 min in the static phase and 3 min in the dynamic phase). Different letters in the same row indicate significant differences among extraction conditions according to the LSD test ($\alpha < 0.05$). The mean values ($n = 6$) are shown with their standard deviation. [b]nd, not detected. [c]Identification only tentative and expresed as μg/kg of furfural. [d]Expresed as μg/kg of 3-methyl-1-pentanol.

The obtained extracts were rich in acids, especially in hexanoic. No significant differences in total acids were observed among the extraction systems used, except for CSLE-30 and CSLE-60, with the highest concentrations due to the hexanoic acid; thus, longer times favor its extraction. In other woods, such as seasoned oak wood chips of American origin, these acid compounds were also found.[37,38]

Total alcohols showed significant differences regarding the extraction system, as SLDE-Naviglio produced the highest content, independent of the extraction conditions tested. A clear behavior for each compound was not observed under SLDE-Naviglio conditions, such as the case of the 1-hexanol, the most abundant alcohol. The presence of 1-hexanol was expected, because it is derived from the unsaturated fatty acids, which are present in all plants.[39] On the other hand, 3-hexen-1-ol (*Z*) content was affected significantly by SLDE-Naviglio-12 conditions; guaiacol content was significantly higher in SLDE-Naviglio-6.5, being quantified as 4% of the total alcohols fraction, whereas in SLDE-Naviglio-8 and SLDE-Naviglio-12 conditions it was only about 2%. α-Terpineol concentration was significantly lower under SLDE-Naviglio-6.5 conditions. The compounds more influenced by SLDE-Naviglio were linalool and 2-phenylethyl alcohol, the first quantified only in SLDE-Naviglio-12 and the second increasing when the compression/decompression times were longer.

About the influence of CSLE conditions, 1-hexanol content decreased significantly with extraction time, going from 71% of the total alcohols fraction by CSLE-15 to 40% with CSLE-60. With regard to linalool, although no statistical differences were observed, it is worth mentioning that it is an important odorant terpene present in grapes, especially in Muscat varieties, which gives them their characteristic aroma.[40] Benzyl alcohol and guaiacol contents were highest in CSLE-60 conditions, reaching 42.5 and 6.7%, respectively, of the total alcohols. Guaiacol is a volatile phenol common in other types of woods, such as oak, chestnut, ash, acacia, or cherry, because their source is lignin,[41,42] and it is one of the most abundant compounds in commercial aqueous oak extracts (0.21 mg/L).[19] These oak extracts, when applied to vineyard by a foliar treatment, increased the concentration of glycosidically bound aroma precursors of guaiacol in grapes and the concentration of this compound in their respective wines.[18] In the same way, recent works have also shown that the application of an aqueous solution of guaiacol stimulated the varietal aroma composition of grapes, showing an important influence in the aroma of wines.[19]

Total aldehydes showed significant differences with regard to the extraction system, as CSLE-30 and CSLE-60 had the highest content with around twice those of the CSLE-15 and SLDE-Naviglio systems. Vanillin was the major aldehyde, having a big influence in the total aldehydes content, its concentration ranging from 76% for SLDE-Naviglio-12 to 95% for CSLE-15. Vanillin is one of the most important odorant compounds present in commercial aqueous oak extracts used within grapevines,[19] providing them a vanilla aroma. In wines from such grapevines, a significant increase in vanillin content and woody aroma was observed.[18] The reported levels of these compounds were similar to those found in some varieties of oak chips.[41,42] Besides, Delgado de la Torre et al.[15] suggested the possibility of using vine-shoots in wines as flavoring agents, after observing similar chromatographic peak areas of a comparative study with oak chips. As vanillin, the highest benzaldehyde content was at CSLE-30 and CSLE-60, around

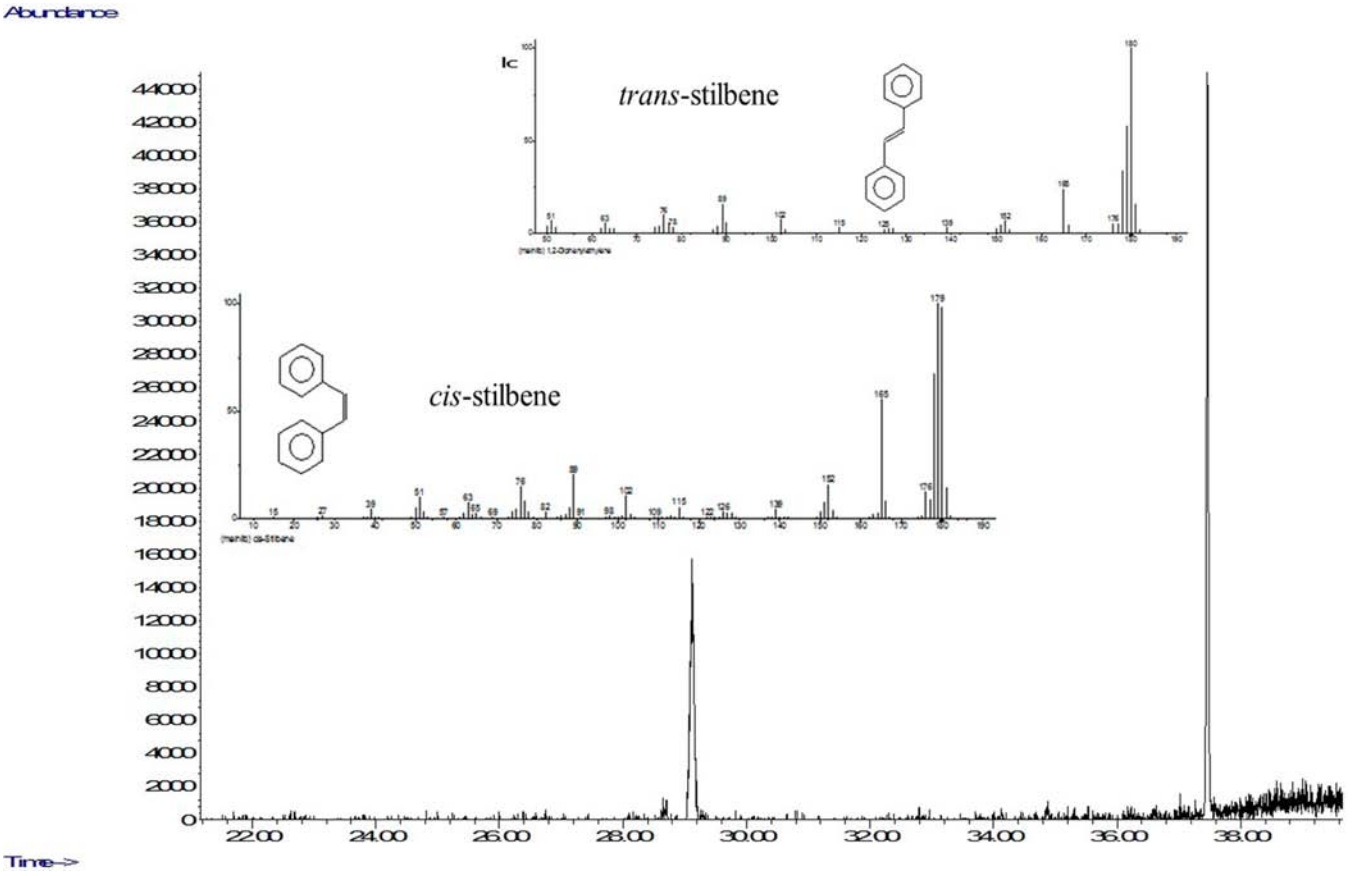

**Figure 3.** Chromatographic peaks corresponding to volatile *cis*- and *trans*-stilbenes at SIM mode, with characteristic $m/z$ at 179 and 180, respectively, identified for the first time in vine-shoots.

15% of total aldehydes, followed by SLDE-Naviglio-12, where its percentage was the highest, 22% of total aldehydes.

As expected, furanic compounds were the most abundant volatile compounds found in the vine-shoot aqueous extracts, because they are carbohydrate derivatives appearing in other woods such as oak, chestnut, cherry, or ash.[42] Their total content was not dependent on the extraction system used, as no significant differences were observed between them. Furfural and 5-hydroxymethylfurfural were the most abundant furanic compounds (53 and 43%, respectively), as it was observed in the aqueous oak extracts used as plant biostimulants.[19] Compounds such as 5-methylfurfural and methyl furoate were not influenced by the extraction system and conditions used. Most furanic compounds were also found in previous vine-shoot aroma research.[15]

It is important to emphasize the presence of whiskey lactone compounds, which are characteristic mainly in oak woods, but they were not previously detected in other vine-shoot wastes;[15] however, these lactones come from the degradation of lipids, and they are abundant in oak green wood.[43] They were influenced by the extraction system, especially *cis*-whiskey lactone, which reached the highest concentration when SLD-Naviglio-6.5 was used. Both whiskey lactones are compounds present in aqueous oak extract,[19] and recently it has been observed that when a solution of whiskey lactones was used in grapevines, wines from such grapes had enhanced varietal aroma after the malolactic fermentation.[44] Because it has been shown that some of these compounds presented in both vine-shoots and oak aqueous extracts, then the same applications carried out with the latest could be performed.

With regard to the compounds grouped as "others", no significant differences were found between the extraction systems used, except for D-limonene and linalyl acetate, which were not present in SLDE-Naviglio extracts. The latest behavior suggests that the extraction of such compounds was temperature dependent (CSLE vs SLDE-Naviglio). Geranyl acetone, which appears in all extracts, did not show a clear behavior.

*β*-Ionone is a norisoprenoid compound known as an important varietal aroma in grapes and wines, but it was not affected by the extraction system and conditions used.

Although the stilbenes fraction has been widely studied in different vine canes,[11,12] until now no reference about the two volatile stilbenes found in the present extracts has been mentioned in other woods. However, such compounds were detected during the lignin pyrolysis produced in pulping of corn.[45] Figure 3 illustrates the chromatographic profiles of such compounds, with $m/z$ 179 and 180. Neither stilbene showed significant differences among SLDE-Naviglio and CSLE extraction systems and their respective conditions, but according to previous authors,[45] stilbene structures are stable even at pyrolysis temperature.

**Mineral Composition by ICP-OES.** The mineral composition of the different vine-shoot extracts is listed in Table 3, excluding the ones with a concentration <0.03 mg/kg. All minerals shown are essential nutrients for plant growth, so they are used in fertilization. Regardless of the extraction system used, the higher concentration (>1 g/kg) corresponded to potassium and sulfur nutrients, followed by calcium, magnesium, and phosphorus with concentrations around 0.3 g/kg. Among the other nutrients, the most abundant was chlorine (approximately 0.2 g/kg), followed by nitrogen as nitrate or nitrite depending on the extraction system used. As cation micronutrients, the most abundant was manganese and the lowest was iron.

The mineral contents quantified in Airén vine-shoot aqueous extracts were lower than the ones referred for other cultivars,[10,14] although it was dependent on the grape variety and the soil composition. Anyway, the mineral content found in Airén aqueous vine-shoot extracts could be sufficient to support the plant nutrition whether they are directly applied on the leaves or suitably diluted, as other byproducts.[46]

From a long time ago, foliar fertilization based on micronutrients has been used, because it reduces the need for soil-applied fertilizer and the leaching of nutrients, decreasing the impact on the environment of fertilizers' salts. It does not totally replace soil-applied fertilizer, but it does increase the uptake and hence the efficiency of the nutrients applied to the soil.[46] In such a way, the presence of small quantities of major nutrients such as N, P, and K, in the vine-shoot aqueous extracts, may leave the opportunity to be applied at any time depending on the needs of the crop. In the case of grapevines it is known that N is the major nutrient affecting vigor and must quality; for this reason it is used in great quantities, but it results as well in poorer wine quality.[47] In the case of K, it is widely used in viticulture as it can increase grape yield, as a result of increased cluster number and weight.[48] Phosphorus is also an essential nutrient for vines as it favors root development,[49] although their quantity requirements are lower than those for N and K.

The extraction technique used did not modify the potassium content in all extracts, but it increased significantly the content of nitrogen as nitrite and phosphorus when SLDE-Naviglio was used, whereas nitrogen, in the form of nitrate, which is the preferable form to be taken up by plants, was significantly higher when CSLE-15 or CSLE-60 was used. Such nutrients (N, P, K) are the main nutritive sources for plants, so foliar fertilization can be one of their possible uses, because they are already dissolved in water, which is the main requisite to be assimilated by the plants. In should be pointed out that when nutrients are applied to the soil in forms available to the plants, important losses are produced because they can react with soil components, giving insoluble forms.

Secondary macronutrient and micronutrient contents were higher in extracts from the SLDE-Naviglio system than in the CSLE one, independent of the extraction conditions tested. It is worth mentioning that the highest boron content is by CSLE-60 and that of iron by CSLE-30. The SLDE-Naviglio extraction technique did not show a clear behavior related to micronutrients.

In conclusion, it has been observed that vine-shoot waste aqueous extracts from *V. vinifera* Airén variety obtained by CSLE and SLDE-Naviglio were the highest concentrated extracts in phenolic, volatile, and mineral valuable compounds. Such compositions suggest that these wastes may have a new potential uses as bioestimulants or foliar fertilizers in the vineyard. It could be implemented in the "Sustainable Viticulture" concept, where the cycle of the vine could be closed, as such vine-shoot extracts may modulate the grape quality, returning to the grapevines what they took from the soil, and even enhancing the terroir effect. Moreover, these extracts may be produced in the owner wineries, using the facilities available once the winemaking process ends.

of the volatile fraction, DDG was milled to particles less than 500 μm using an Ultra Centrifugal Mill ZM200 from Retsch (Haan, Germany) by 5000−6000 rpm.

**Chemicals.** Chemicals were obtained from the following sources: diethyl ether (≥99.5%) and anhydrous sodium sulfate (≥99.0%) from Sigma−Aldrich (Taufkirchen, Germany), sodium carbonate (≥99.5%) from Merck (Darmstadt, Germany), sodium chloride from Avantor Performance Materials (Deventer, Netherlands), and hydrochloric acid (37%) from Roth (Karlsruhe, Germany). Reference standards of aroma compounds were purchased from commercial sources: Alfa Aesar, Karlsruhe, Germany; Merck, Darmstadt, Germany; Sigma−Aldrich, Taufkirchen, Germany; others were kindly provided from flavor companies (Firmenich, Switzerland; Symrise, Holzminden, Germany).

**Sample Preparation for HS-SPME.** A 3.0 g amount of DDG was weighed in a 20 mL headspace vial and sealed with flanged caps. The septum was pierced with the SPME needle, and subsequently, the fiber was manually exposed to the sample for a normal adsorption time of 1 h and a prolonged adsorption time of 6 h for a better enrichment of medium and low volatile compounds. The adsorption process was performed in a tempered water bath at 30 and 70 °C. SPME fiber material was 50/30 μm divinylbenzol/carboxen/PDMS (Supelco Inc., Bellefonte, PA, USA). Fibers were conditioned in a GC injector at 270 °C for 1 h. After adsorption, the fiber was directly transferred to the injection port of the gas chromatograph. Volatiles then were desorbed at 250 °C for 30 s. Before the next analysis, the fiber was reconditioned at 250 °C for 15 min in the GC injector to avoid carry-over of compounds from previous samples.

**Sample Preparation for SDE.** SDE was performed in a Likens−Nickerson apparatus, as modified by Schultz et al.[8] using 100 g of DDG suspended in 500 mL of water. The sample−water mixture and 100 mL of diethyl ether were boiled for 2 h. After cooling down to room temperature, diethyl ether was dried over sodium sulfate and concentrated to 1 mL using a Vigreux column (30 cm × 1 cm i.d.).

**Sample Preparation for SAFE.** A 150 g amount of DDG was mixed with diethyl ether (2 × 100 mL) and extracted for 2 h. For quantitation, 500 μL of methyl decanoate ($c$ = 0.81 mg/L) as the internal standard was added to the DDG−diethyl ether mixture. After filtration, the volatile fraction of the diethyl ether extract was isolated by means of the SAFE technique,[9] dried over sodium sulfate, and subsequently, concentrated to 1 mL using a Vigreux column.

**Separation into Neutral-Basic and Acidic Fraction.** The distillate obtained by SAFE was fractionated into a neutral-basic fraction (NBF) and an acidic fraction (AF) by treatment with 0.5 M sodium carbonate solution (2 × 50 mL, pH 10.0). After drying over anhydrous sodium sulfate, the NBF was concentrated to 1 mL using a Vigreux column. The AF was treated with a solution of 100 mL of saturated sodium chloride, and the pH was adjusted to pH 1.0 with hydrochloric acid. After treatment with diethyl ether, the organic phase was dried over anhydrous sodium sulfate and concentrated to 1 mL as described above.

**GC-Olfactometry and GC/MS.** Identification of aroma compounds was carried out on a SiChromat II gas chromatograph (Siemens, München, Germany) directly coupled to a Finnigan MAT 8222 magnetic sector mass spectrometer. At the end of the capillary column, the effluent was split into two equal parts using a Life-T effluent splitter to the mass spectrometer and a sniffing port.[10] The sniffing port was heated to 250 °C and rinsed with humidified air, to avoid dehydration of nasal membranes of assessors. Samples were separated using a silica capillary column SPB5 (Supelco) (30 m × 0.53 mm i.d., 1.5 μm film thickness). The column carrier gas was helium at a constant flow of 3 mL/min. A 2 μL amount of samples was applied with a split ratio of 1:10. The injector temperature was 250 °C, and the transfer line temperature was 200 °C. The oven program started with an initial temperature of 100 °C and subsequently was raised to finally 250 °C at a rate of 5 °C/min. MS detection was performed with an electron impact (EI) energy of 70 eV. The analyzed mass range was 35−350 amu in EI mode. For quantitation, an internal standard was added (500 μL of methyl decanoate with $c$ = 0.81 mg/L) at the beginning of the sample preparation step. Calculated concentrations are semiquantitative, since no response factors were determined.

**Aroma Compound Identification.** Identification of aroma compounds was based on the following criteria: odor description, linear retention indices (RIs), comparison with reference substances, and mass spectrometric data from the literature and the NIST library. In the case that MS data were too weak for unequivocal identification, aroma compounds were tentatively identified based on the remaining criteria. Linear RIs were determined after van Den Dool et al.[11] using a mixture of linear alkanes $C_6$−$C_{20}$ under the same chromatographic conditions described above.

**Sensory Analysis.** The sensory analysis of DDG was performed twice by a group of at least 10 panelists from the Institute of Brewing and Beverage Technology on different days. The analysis took place in a room for sensory analysis at room temperature. Panelists were trained weekly after DIN 10961 in general odor and taste perception and especially on cereal-based food products. In a preliminary session, panelists were asked to define attributes, which describe the odor of DDG. Subsequently, in the following sessions, panelists evaluated the intensity of the prior defined attributes on a scale of 0 (not present) to 5 (very intensive).

## RESULTS AND DISCUSSION

**Sensory Analysis of DDG from Wheat.** The incorporation of DDG in food products was a topic for many studies during the late 1980s, but unfortunately, the investigated products did not have a sufficient odor for being a popular food product.[1] Since no research has been done on the systematic study of flavor volatiles of DDG, a sensory analysis of the aroma profile was performed first.

For the development of an aroma profile, panelists were asked to list and evaluate perceptible odor impressions and the overall odor impression. In the following sessions, panelists rated these impressions in their intensity on a scale from 0 (not present) to 5 (very intensive). The three impressions caramellike, roasty, and brothlike were rated as most frequently mentioned impressions. The evaluation of the intensity during the following sessions emphasizes these results as it is shown in Figure 1 with seasoninglike and roasty, breadlike as the most

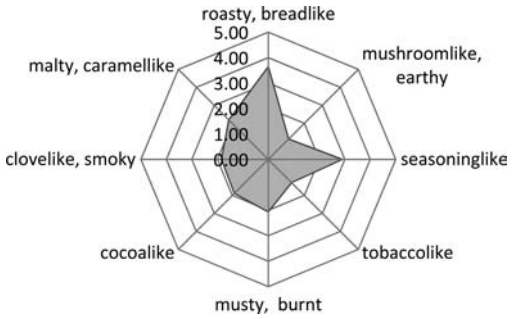

**Figure 1.** Flavor profile of DDG from wheat after sensory analysis; intensities of descriptors on a scale from 0 (not present) to 5 (very intensive), $n \geq 20$, results where averaged.

intensive odor impressions in DDG from wheat. High intensities could be determined for malty, caramellike and musty, burnt as well. During the production of DDG, fermentation, distillation and drying steps play an important role. In the distillation process, highly volatile compounds can be distilled together with ethanol, and new components can be formed during the drying process. Thus, odor-active compounds from Maillard reaction, byproducts of yeast fermentation, or thermal reaction compounds of the drying process are expected to contribute to the odor of DDG. The results of

sensory analysis indicate the presence of volatiles from thermal processing such as pyrazines (roasty and breadlike, burnt) or sugar degradation products (caramellike, seasoninglike). The analysis of odor-active volatiles was carried out in the next step to substantiate the results of the sensory evaluation.

**Analysis of Odor-Active Volatiles in DDG.** Sample preparation and isolation procedures applied before the analysis can determine the composition of aroma extracts. Since there is no knowledge concerning odor-active compounds in DDG, the sample preparation step is performed with multiple techniques to avoid misinterpretations and to work out a representative classification of odor-active volatiles. For this purpose, one headspace technique (HS-SPME) and two solvent-extraction techniques (SDE, SAFE) were carried out.

With the three applied methods, 42 odor-active compounds could be found in total in DDG from wheat. Nineteen of the 42 compounds were identified in accordance with the application of every specific method (upper part, Table 1). Twenty-three compounds (lower part, Table 1) could only be identified with one respectively two specific techniques and confirms the dependence of traceability and the sample preparation step. Classification of identified aroma compounds reveals four

[a]RIs on a DB-5 column. [b]Values show peak areas × $10^8$.

furanones (3(2*H*)- and 2(5*H*)-furanones), four pyrazines (2,5-dimethylpyrazine, 2-ethyl-5-methylpyrazine, 2-ethyl-3,6-dimethyl-, and 2-ethyl-3,5-dimethylpyrazine), and six acids (acetic and butanoic acids, 2-methylpropanoic acid, 3- and 2-methylbutanoic acids, and 2-phenylacetic acid). Moreover, four phenolic compounds (2-methoxyphenol, 2-methoxy-4-vinylphenol, 4-vinylphenol, and 4-hydroxy-3-methoxybenzaldehyd), two sulfur-containing compounds (dimethyl trisulfide and 3-methylthiopropanal), and a number of aldehydes and ketones (2,3-butanedione, 3-methylbutanal, 2,3-pentanedione, hexanal, 1-octen-3-one, 1,5-octadien-3-one, 2-phenylacetaldehyde, (*E*)- and (*Z*)-2-nonenal, (*E*,*Z*)-(2,6)-nonadienal, (*E*,*E*)- and (*E*,*Z*)-2,4-decadienal, and $\beta$-damascenone) were determined. Besides 2-phenylethanol and 2-phenylethyl acetate, no alcohols and esters were determined. 3-Methylindole was determined as single N-heterocyclic compound.

Unequivocal MS data could not be obtained for 10 compounds ((*Z*)-2-nonenal, (*E*,*Z*)-2,6-nonadienal, 5-ethyl-3-hydroxy-4-methyl-2(5*H*)-furanone, 4-vinylphenol, 3-hydroxy-4,5-dimethyl-2(5*H*)-furanone, 1-octen-3-one, 1,5-octadien-3-one, 3-methylindole, 4-hydroxy-5-methyl-3(2*H*)-furanone, and 4-hydroxy-2,5-dimethyl-3(2*H*)-furanone), so the identification was based on the remaining criteria. Further, six odor-active regions in the GC chromatogram could not be identified by any of the applied methods, because of low concentrations and insufficient MS data.

**Identification of Odor-Active Compounds in DDG from Wheat via SPME.** To get a first impression of volatile compounds in a matrix, HS-SPME is a reasonable technique for a qualitative overview. Moreover, HS-SPME is a proven method for the analysis of volatiles in food and wheat products such as partially baked bread.[12,13] The application of SPME on DDG from wheat revealed 33 odor active regions in the gas chromatogram, of which 29 could be identified. The four compounds acetic acid, 2,3-butanedione, 3-methylbutanal, and 2,3-pentanedione could only be determined by HS-SPME, due to the coelution and overlay with diethyl ether used as the solvent in the distillation methods. Odor-active compounds eluting before or simultaneously with the solvent cannot be determined. Therefore, a headspace method complements information caused by solvent delay.

Furthermore, the isolation of flavor compounds by SPME reveals strong dependence of adsorption behavior on the SPME fiber from adsorption time and temperature as it is shown in Table 2. Low-temperature adsorption (30 °C) and prolonging of adsorption time from 1 to 6 h results in lower peak areas for highly volatile compounds (e.g., dimethyl trisulfide) and increased peak areas for medium and low volatile compounds (e.g., 4-hydroxy-3-methoxybenzaldehyde). The prolonging of adsorption time shifts the spectrum of volatiles to medium and low volatile compounds. High-temperature adsorption (70 °C) and prolonging of adsorption time leads to a reduction of peak areas of high volatile compounds (e.g., 2-phenylethyl acetate, 2-phenylethanol, and acetic acid). The odor perception of 4-hydroxy-5-methyl-3-(2*H*)-furanone, 3-methylindole, and an unknown compound with green, metallic odor at the sniffing port ($RI_{DB5}$ = 1197) is enabled only at a longer adsorption time and a higher temperature (6 h and 70 °C). Moreover, prolonging of adsorption time to 6 h made the odor perception of 1,5-octadien-3-one, 2-phenylacetaldehyde, (*Z*)-2-nonenal, 2-phenylacetic acid, and two unknown compounds ($RI_{DB5}$ = 1083, sweet, caramellike; $RI_{DB5}$ = 1283, roasty, nutty) possible. Basically, an enhanced intensity of odor perception could be obtained by higher temperature and prolonging of adsorption time (70 °C and 6 h); nevertheless, artifact formation at these conditions cannot be excluded.

**Identification of Odor-Active Compounds in DDG from Wheat via SDE.** SDE, as developed by Likens and Nickersson[14] and modified by Schultz et al.,[8] is a method for continuous and concurrent vapor distillation and solvent extraction. For the isolation of volatiles from a food matrix, SDE still represents a standard procedure.[15−17] In the case of DDG from wheat, 32 odor-active areas could be located in total in the GC chromatogram obtained by an aroma extract derived by means of SDE, of which 29 could be identified. The isolation of volatile compounds with SDE revealed an extract with intensive roasty and breadlike aroma. Besides 2-ethyl-3,6-dimethyl- and 2-ethyl-3,5-dimethylpyrazine, two additional pyrazines (2-ethyl-5-methylpyrazine and 2,5-dimethylpyrazine) were determined. Since it is well known that pyrazines contribute to the roasty odor of processed food, the increased

number of pyrazines in the SDE extract might contribute to the intensified roasty odor.

Further, the aldehydes hexanal (green), (*E*,*Z*)- and (*E*,*E*)-2,4-decadienal (fatty, rancid) were detected in the SDE extract. Since these aldehydes were not detectable or perceptible with SPME or SAFE, the artifact formation during the distillation process cannot be excluded. Moreover, lipid oxidation products are enriched due to the temperature treatment during extraction. After isolation with SDE and in accordance to SPME, 3-(methylthio)-propanal, 3-methylindole, and two additional unidentified compounds ($RI_{DB5}$ = 883, caramellike; $RI_{DB5}$ = 1283, roasty) could be determined. In accordance to SAFE, SDE was able to determine (*Z*)-4-heptenal and 2-phenylethylacetat. In addition, an unidentified compound ($RI_{DB5}$ = 920) was determined. Because of the musty and burnt odor quality, it might be an artifact. SDE was not able to isolate 2-phenylacetic acid, as well as the two furanones 4-hydroxy-5-methyl-3(2*H*)-furanone and 4-hydroxy-2,5-dimethyl-3(2*H*)-furanone. The good solubility in water leads to poor extractability and retention in the water matrix, which was already reported by Siegmund et al.[18] Since highly hydrophilic compounds are prevented from extraction out of the water suspension and thus remain in the extraction residue during SDE, an important part for a responsible aroma profile is missing. For this reason, SAFE was applied as an additional extraction procedure on DDG from wheat.

**Identification of Odor-Active Compounds in DDG from Wheat via SAFE.** SAFE as developed in 1999 by Engel et al.[9] was chosen as the second solvent-extraction method, since SAFE is known as a gentle isolation process preserving the native profile of odor-active compounds in a food product. An extract derived with SAFE generally neither contains or enriches oxidation products and thermal reaction compounds nor supports the formation of artifacts. The isolation of volatile compounds of DDG from wheat with SAFE revealed an extract with strong seasoninglike, breadlike, and spicy odor impression. By contrast to SDE, the aroma of the extract was less roasty and breadlike but showed a strong seasoninglike odor impression. Twenty-four odor-active areas were located in the gas chromatogram after injection of an extract derived via SAFE. Present results confirm that SAFE represents a gentle isolation process of volatile compounds, because Strecker aldehydes (e.g., 3-methylthiopropanal) and possible artifacts isolated via SPME and SDE could not be confirmed with SAFE under moderate conditions. Because of the native odor profile, the SAFE extract was chosen for further analysis.

In the last step of aroma analysis, the extract derived via SAFE was fractionated into an AF and NBF, to determine coelutions and improve the separation behavior on the capillary column. The fractionation revealed five additional odor-active areas in the GC chromatogram. One could be identified as 3-hydroxy-2-methylpyran-4-one ($RI_{DB5}$ = 1123, caramellike), already identified as an odor-active volatile in the crust of wheat and rye bread.[19] Because of the coelution with 2-phenylethanol ($RI_{DB5}$ = 1124) and the similar odor impression, 3-hydroxy-2-methylpyran-4-one could not be determined without fractionation. Four of the five additional compounds could not be identified due to unequivocal MS data.

**Key Aroma Compounds in DDG from Wheat.** To investigate key odorants in DDG from wheat, the distillate obtained by SAFE was analyzed by means of AEDA. Therefore, the gas chromatogram was compared to the flavor dilution (FD) chromatogram (Figure 2), and eight compounds with a

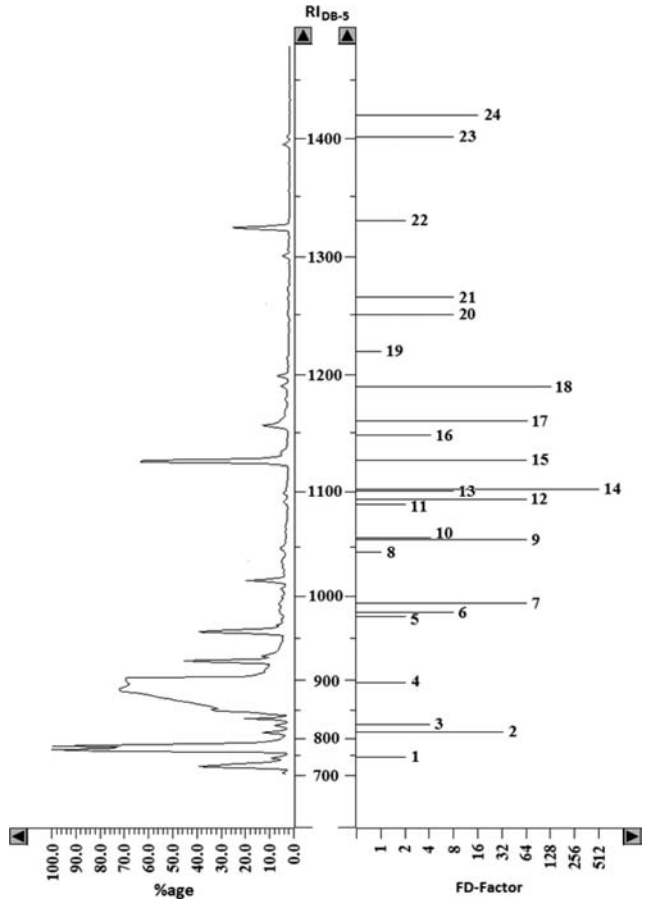

**Figure 2.** FD chromatogram compared to the gas chromatogram of a SAFE distillate from DDG from wheat; numbers indicate flavor-active compounds as identified in Table 3.

FD factor ≥ 32 could be determined. The highest FD factor of 512 was determined for 3-hydroxy-4,5-dimethyl-2(5*H*)-furanone (sotolon) with seasoninglike odor and a slightly lower FD factor of 128 for the ethyl-homologue 5-ethyl-3-hydroxy-4-methyl-2(5*H*)-furanone (brothlike, spicy). These furanones were revealed as the most influential odor-active volatiles in DDG from wheat, which is in accordance with the results of the sensory evaluation shown in Figure 1. 3-Hydroxy-4,5-dimethyl-2(5*H*)-furanone is the character impact compound of fenugreek and has also been identified in white and whole wheat flour and Bavarian wheat beer as an important odor-active volatile with high FD factors of 256 for the formers and 512 for the latter.[20−22] Blank et al.[20] proposed that, in the case of fenugreek, 3-hydroxy-4,5-dimethyl-2(5*H*)-furanone originates from thermally induced oxidative deamination of 4-hydroxyisoleucine and its lactone 3-amino-4,5-dimethyl-3,4-dihydro-2(5*H*)-furanone as shown in Figure 4. Moreover, it was revealed that the yield is improved by boiling several hours at acidic conditions. Regarding the thermal conditions of the drying process and the acidic pH of 3.8 of DDG, it can be concluded that the formation of 3-hydroxy-4,5-dimethyl-2(5*H*)-furanone can be enhanced.

Further, a high FD factor of 64 could be determined for 4-hydroxy-2,5-dimethyl-3(2*H*)-furanone (Furaneol) with caramellike odor. 3(2*H*)-Furanones are an important group of hydroxyl furanones, usually responsible for the sweet and caramellike odor impression of processed food. 4-Hydroxy-2,5-dimethyl-3(2*H*)-furanone could already be identified in wheat

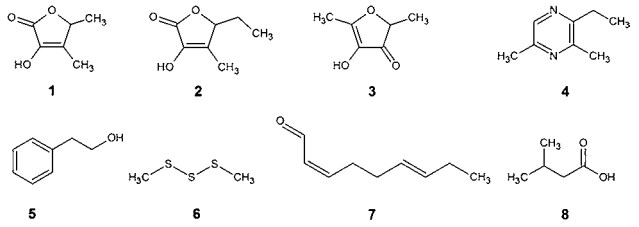

**Figure 3.** Chemical structures of key aroma compounds in DDG obtained by AEDA with FD factor ≥ 32: 3-hydroxy-4,5-dimethyl-2(5*H*)-furanone (**1**), 3-hydroxy-4-methyl-5-ethyl-2(5*H*)-furanone (**2**), 4-hydroxy-2,5-dimethyl-3(2*H*)-furanone (**3**), 2-ethyl-3,5-dimethylpyrazine (**4**), 2-phenylethanol (**5**), dimethyl trisulfide (**6**), (*E*,*Z*)-2,6-nonadienal (**7**), and 3-methylbutanoic acid (**8**).

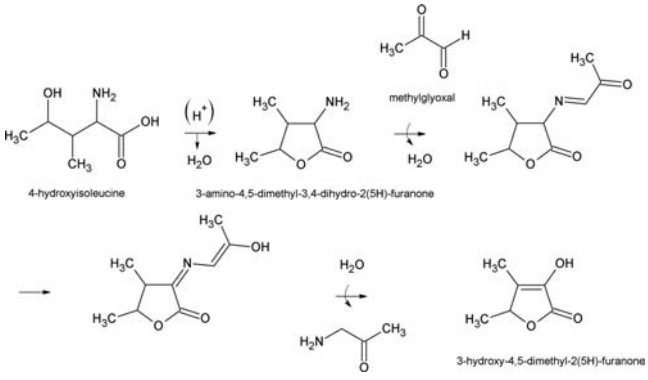

**Figure 4.** Formation pathway leading to 3-hydroxy-4,5-dimethyl-2(5*H*)-furanone from 4-hydroxyisoleucine, modified according to Blank et al.[20]

beer and wheat bread crumb.[19,22] The formation pathway of 4-hydroxy-2,5-dimethyl-3(2*H*)-furanone in wheat bread crust is known to descend from yeast as the most important source, with fructose-1,6-diphosphate as the predominant precursor.[23] The roasty and breadlike odor impression revealed during sensory analysis can be attributed to 2-ethyl-3,5-dimethylpyrazine with a FD factor of 64. Besides the seasoning and caramellike odor impression, the roasty character represents a central odor impression of DDG. It is well known that a number of volatile pyrazines contribute to the flavor of thermal processed foods originating from nonenzymatic browning of food products. Schieberle and Grosch identified 2-ethyl-3,5-dimethylpyrazine as an odor-active compound in wheat bread crust[19] and rye bread crust,[24] with FD factors of 16 and 64, respectively. Moreover, 2-ethyl-3,6-dimethylpyrazine with a FD factor of 4 and the identification of 2,5-dimethylpyrazine and 2-ethyl-5-methylpyrazine substantiate the contribution of pyrazines to the roasty odor impression of DDG from wheat. With a FD factor of 32, dimethyl trisulfide, the cabbagelike odor typically arising in plants of the genera *Brassica* and *Allium,* plays an important role in DDG odor as well. In processed wheat products, dimethyl trisulfide has not been found as a relevant key odorant by now. Nevertheless, Lee at al. showed that the analysis of volatiles from a wheat gluten hydrolysate thermally processed with glucose or fructose revealed dimethyl trisulfide as a product from Maillard reaction.[25] Because of the high FD factor and very low odor threshold of 0.01 μg/L in $H_2O$, dimethyl trisulfide could be a possible source for the off flavor in DG from wheat described previously.[26] The differences in DDG flavor to the flavor of wheat products might occur especially due to the presence of dimethyl trisulfide, which is not known as a key odorant of processed

**Table 3. Odor-Active Volatiles and Corresponding FD Factors Obtained by AEDA in DDG from Wheat**

| no.[a] | odor-active compound | odor quality[b] | RI (DB-5)[c] | FD factor[d] |

wheat products by now. 2-Phenylethanol with a FD factor of 64 is also one of the eight most important odor-active volatiles in DDG and consequently contributing to its sweet and floral odor. It is formed as byproduct in the fermentation of yeasts by enzymatic reactions via Ehrlich pathway.[27,28] The presence of 2-phenylethanol in processed wheat products is already known, since it was revealed as an important odor-active volatile in wheat bread crumb.[29] Likewise, 3-methylbutanoic acid with a FD factor of 32 was enlightened as an important odor-active volatile in DDG from wheat. Together with 2-methylbutanoic acid, the two methyl-substituted butanoic acids are responsible for the rancid off flavor in wheat bread.[30] (*E*,*Z*)-2,6-Nonadienal, a degradation product of linolenic acid, is another of the most important odorants of DDG from wheat with a FD factor of 64. It is already identified in wheat bread crust and white wheat flour.[19,21] A number of other unsaturated aldehydes such as (*E*)-/(*Z*)-2-nonenal and (*E*,*Z*)-/(*E*,*E*)-2,4-decadienal were also identified in DDG from wheat. These unsaturated aldehydes are well known to contribute to the fatty and rancid odor impression.

In summary, 42 odor-active compounds could be identified in total in DDG from wheat. Ranges of concentrations and odor activity values of selected important odor-active volatiles can be seen in Tables 4 and 5. Eight compounds were determined as key aroma compounds with a FD factor ≥ 32 as shown in Figure 3. These eight key odorants of DDG from wheat point out that the overall aroma of DDG is based on reaction compounds and precursors from thermal food processing, in particular Maillard reaction and Strecker degradation. This is also supported by a view on the production process of DDG. Regarding the further processing of the yeast fermented grain matrix, the mash is distilled for separation of ethanol at 78 °C. After a temporary storage (75−80 °C, 2−8 h), the thickening process of the thin stillage to syrup (55−65 °C, 2−4 h) follows. Subsequently, the main drying process takes place, where the stillage is dried at 100−105 °C for 1−3 h. These conditions markedly favor the formation of oxidation products and the continuation of Maillard and Strecker reactions. Aroma volatiles and key aroma compounds in DDG from wheat show high compliance to wheat processed products such as white wheat bread. DDG represents a thermal processed wheat product, which is supported by its composition of flavor volatiles.

in 1988.[8] However, appreciable amounts of coumarin have been found in various foods, such as bakery products, breakfast cereals, confectionary, and so on.[9,10] Vanilla extracts adulterated with coumarin as a fragrance enhancer[11] are other potential paths for baby's coumarin exposure.

Recently, China's authorities and the media have reported the illegal use of flavorings in some infant formulas. Meanwhile, considering the low limits of the usage and the complex matrix of formula samples, a reliable analytical method must be established for their simultaneous identification and quantification. Several methods have been developed for analyzing the four above-mentioned flavorings in various samples. High-performance liquid chromatography (HPLC),[12] liquid chromatography−tandem mass spectrometry (LC-MS/MS),[13] and gas chromatography−mass spectrometry (GC-MS)[14] have been used for the simultaneous analysis of vanillin, ethylvanillin, and coumarin in vanilla extracts. Meanwhile, more attention has been focused on the simultaneous analysis of vanillin and ethylvanillin both in vanilla extracts and in foods, and various methods were investigated including gas chromatography (GC),[15] HPLC,[16,17] capillary electrophoresis (CE),[18,19] chemiluminometry,[20] atmospheric pressure solids analysis probe,[21] and so on. However, there have only HPLC methods been reported for the analysis of methylvanillin in industrial waste waters[22] and food.[23] To the best of the authors' knowledge, there is no paper focused on the simultaneous determination of these four flavorings in any samples.

Recently, we proposed a sufficient LC-MS/MS method for the simultaneous determination of vanillin, ethylvanillin, and coumarin in infant formula samples,[24] but methylvanillin was unnoticed. Except for LC-MS/MS, gas chromatography−tandem mass spectrometry (GC-MS/MS) has become one of the most widely used methods for the identification and quantification of residues in food because of its higher selectivity, sensitivity, and necessity for confirmation.[25−27] Therefore, in this study we developed a GC-MS/MS method for the simultaneous determination of vanillin, methylvanillin, ethylvanillin, and coumarin in infant formula samples, and this is the first trial performed for this objective.

## MATERIALS AND METHODS

**Chemicals.** Certified standards of vanillin (CAS Registry No. 121-33-5, 99.9% purity) and ethylvanillin (CAS Registry No. 121-32-4, 97.3% purity) were purchased from Chroma Dex (Irvine, CA, USA). Coumarin (CAS Registry No. 91-64-5, 98% purity) was purchased from Dr. Ehrenstorfer GmbH (Augsburg, Germany). Methylvanillin (CAS Registry No. 120-14-9, 98.0% purity), methylvanillin-$^{13}C$ (CAS Registry No. 1173022-44-0, 98.0% purity), vanillin-$^{13}C_6$ (CAS Registry No. 201595-58-6, 98%), and coumarin-$D_4$ (CAS Registry No. 185056-83-1, 98%) were purchased from Toronto Research Chemicals Inc. (North York, Canada). The structures of these standards are shown in Figure 1. The water used was purified with a Milli-Q water purification system from Millipore (Bedford, MA, USA). HPLC grade methanol was obtained from Merck (Darmstadt, Germany).

**Preparation of Standard Solutions.** Individual standard stock solutions were prepared at a concentration of 500 mg $L^{-1}$ in methanol and stored at 4 °C in the dark. A multistandard mixture working solution, containing 5 mg $L^{-1}$ of each standard compound, was prepared by diluting each above stock solution with methanol and was then used for spiking blank infant formula samples and for preparation of matrix-matched calibration solutions. Matrix-matched calibration standards with six final concentration levels of 0.001, 0.002, 0.005, 0.01, 0.02, and 0.05 mg $L^{-1}$ were prepared by adding to infant formula blank extracts appropriate volumes of the standard working solutions.

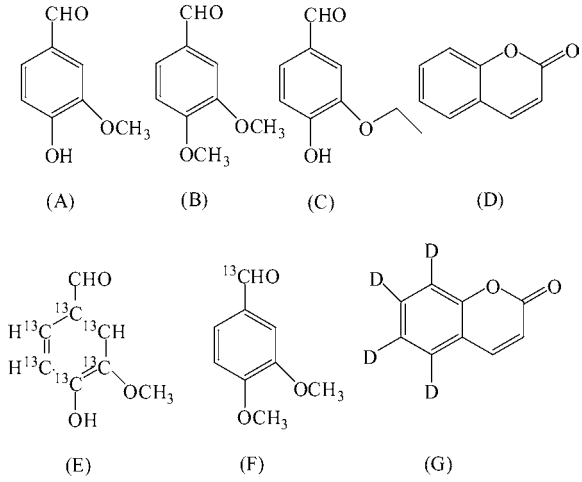

**Figure 1.** Chemical structures of vanillin (A), methylvanillin (B), ethylvanillin (C), coumarin (D), vanillin-$^{13}C_6$ (E), methylvanillin-$^{13}C$ (F), and coumarin-$D_4$ (G).

Vanillin-$^{13}C_6$, methylvanillin-$^{13}C$, and coumarin-$D_4$ were used as internal standards, and the final concentration was 0.01 mg $L^{-1}$.

**Sample Preparation.** Twenty infant formula samples for 0−12-, 6−12-, and 6−18-month-old babies were randomly purchased from local supermarkets, and the brands covered both Chinese domestic brands and foreign brands. Sample preparation was based on a previously reported process developed by our group[24] with few adaptations. A 1.00 g infant formula sample was weighed into a 50 mL polypropylene centrifuge tube. Before the addition of 25 mL of methanol/water (v/v, 1:1) for extraction, 500 μL of vanillin-$^{13}C_6$, methylvanillin-$^{13}C$, and coumarin-$D_4$ mixed internal standards solution (0.4 mg $L^{-1}$) was first added. The sample was vortexed for 1 min, and then an ultrasonic extraction was performed for 30 min at 30 °C. After extraction, the suspension was centrifuged at 8875*g* for 15 min, and then the supernatant layer was transferred into a 50 mL volumetric flask and diluted with water. This extract was then forwarded to the next cleanup procedure.

**Solid-Phase Extraction.** The cleanup procedure based on a solid-phase extraction was also referenced to our previous paper.[24] An Oasis HLB solid phase extraction (SPE) cartridge (60 mg, 3 mL, Waters, Milford, MA, USA) was used and conditioned with 5 mL of methanol and then 5 mL of water before use. Five milliliters of sample extracting solution was then introduced to the conditioned cartridge and allowed to elute by gravity. The cartridge was washed with 5 mL of pure water, followed by 5 mL of a methanol/water (v/v, 1:9) mixture, and then dried under vacuum for 1 min. Finally, the cartridge was eluted with 6 mL of methanol into a glass culture tube, and the eluate was evaporated to dryness under vacuum at 45 °C. The dried extract was reconstituted in 2.0 mL of methanol, vortex mixed for 60 s, and then filtered through a 0.22 μm nylon membrane into a glass GC vial ready for analysis.

Blank infant formula samples were prepared in the same way as mentioned above without the addition of the internal standard solution. The matrix-matched standard solutions were prepared from the blank extracts as mentioned earlier.

**GC-MS/MS Analysis.** A Thermo Fisher Trace 1300 GC coupled with a Thermo Fisher TSQ 8000 triple-quadrupole mass spectrometer and a Triplus RSH autosampler (Thermo Fisher Scientific, Waltham, MA, USA) was used in the GC-MS/MS system. The separation of analytes was performed on a Thermo Scientific TG-SQC 15 m × 0.25 mm × 0.25 μm capillary column. Splitless injection mode was used, and the injection volume was 1.0 μL. The GC oven temperature program was as follows: initial at 80 °C, held for 1 min, increased to 200 °C at a rate of 30 °C $min^{-1}$, then increased to 280 °C at a rate of 15 °C $min^{-1}$, and held for 5 min. The injector temperature was set at 250 °C. Helium (99.9999% purity) was used as carrier gas at a constant flow rate of 1.0 mL $min^{-1}$ and Argon (99.999% purity) was

[a]The MS/MS transition was used for quantitation.

used as collision gas in the ion trap chamber of the MS/MS system. The mass spectrometer was operated in electron ionization (EI) mode. The ion source and transfer line temperatures were set at 250 and 280 °C, respectively. Retention times of the four flavorings were detected in full scan mode by recording the mass range between $m/z$ 50 and 300. For the determination of target analytes, MS/MS mode was selected and performed in selected reaction monitoring (SRM) mode.

## RESULTS AND DISCUSSION

**Optimization of MS/MS Conditions.** For the unambiguous identification and accurate quantification of vanillin, methylvanillin, ethylvanillin, and coumarin in real infant formula samples at trace levels, MS/MS conditions were optimized. First, individual flavoring and isotope-labeled standards were performed in full scan mode separately in the $m/z$ 50−300 scan range to identify the optimal precursor ions. Molecular ions present in all seven target substances appeared and were selected as the parent ions beyond doubt. High masses were preferred as the precursor ions because it could avoid interferences from isobaric masses resulting from common molecule fragments.[28] Once the precursor ions were chosen, the MS/MS conditions were further optimized to obtain maximum resolution and sensitivity. The collision energies with different values between 10 and 30 eV were applied to find the two most abundant fragments for further qualitative and quantitative intentions. The dwell time was 200 ms for each compound, and the optimal collision energies for each transition are listed in Table 1. Moreover, one precursor ion and two daughter ions were applied, which well fitted the European Union (EU) criteria.[29] Although the precursor ions of methylvanillin and ethylvanillin were the same due to their completely same molecular formula, their daughter ions were different due to their different chemical structures. This permitted their separate recognition even if insufficient GC separation was encountered.

A complete SRM chromatogram of a real blank infant formula sample spiked with 10 $\mu g\ kg^{-1}$ of four flavorings and three isotopic labels is shown in Figure 2. It was observed that vanillin, methylvanillin, and ethylvanillin were well separated, whereas methylvanillin and coumarin had almost the same retention time from 6.5 to 6.6 min. However, in SRM mode, they could be unambiguously identified without any question. In the MS/MS analysis mode, the target was initially identified by the retention time and typical SRM transitions and then further confirmed by the relative ion abundance ratio between the qualitative ion and the quantitative ion (shown in Table 1). Meanwhile, a clean background was obtained in spiked sample analysis as shown in Figure 2, which indicated that no chromatographic interference occurred from the sample matrix.

The GC-MS/MS product scan spectra of the investigated compounds were obtained and are shown in Figure 3. Moreover, on the basis of the fragment information given by Figure 3, plausible interpretation of the MS/MS fragmentation was proposed and is presented in Figure 4. Note that we have interpreted the MS/MS fragmentation of vanillin, vanillin-$^{13}C_6$, ethylvanillin, coumarin, and coumarin-$D_4$ obtained in HPLC-MS/MS using a positive electrospray ionization (ESI) mode in our earlier study.[24] The obviously different cracking behavior was noted for all compounds, and this might be attributed to the different ionization mode. At this point, there is no related reported work as reference.

**Method Validation.** To investigate the applicability of the developed method for routine real analysis, general analytical merits including linearity, limits of quantification (LOQ), specificity, precision, and accuracy (recovery) were detected.

Matrix effects, expressed as suppression or enhancement of instrument signals, have been generally recognized as an important and serious error source in the quantitative analysis of trace-level compounds in food samples by using either the GC-MS/MS or LC-MS/MS method.[30−32] In our previous trial on analysis flavorings in infant formula by LC-MS/MS,[24] the matrix effects were discussed and verified by contrastive experiments. To correct matrix effects, a combination of isotope-labeled internal standards and matrix-matched calibration solutions was performed, and satisfactory results were obtained.

Quantification was performed on the basis of calibration plots using the peak area of the most intense MS/MS transition of the analyte, which was defined as the quantitative ion shown in Table 1. The calibration curves with $1/x$ weighting were plotted for each individual target compound, and the response data were adjusted according to the relative ratios of responses to the stable isotope internal standards in the standards. Good linearity was achieved, and the correlation coefficients were in the range from 0.9991 to 0.9995. The LOQ was calculated as 10 times the standard deviation, and it was 10.0 $\mu g\ kg^{-1}$ for vanillin, methylvanillin, ethylvanillin, and coumarin. For vanillin

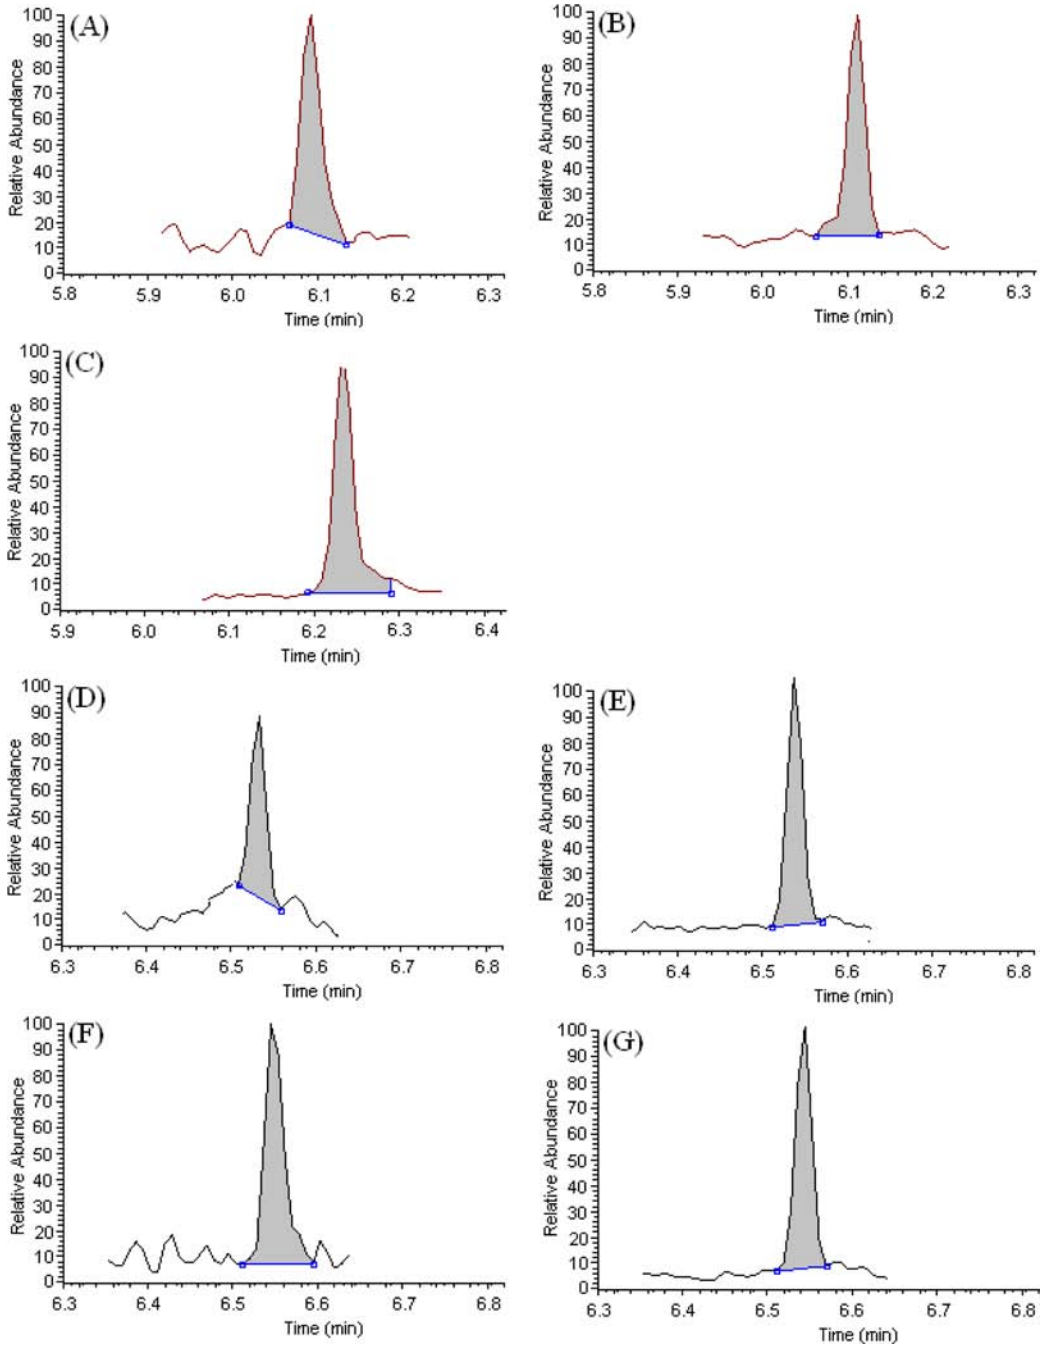

**Figure 2.** GC-MS/MS SRM chromatograms of a blank infant formula sample spiked at 10 $\mu$g kg$^{-1}$ with four flavorings: vanillin (A); vanillin-$^{13}C_6$ (B); ethylvanillin (C); methylvanillin (D); methylvanillin-$^{13}C$ (E); coumarin (F); coumarin-$D_4$ (G).

and ethylvanillin, which are permitted to be added to follow-up formula (for >6-month-old infants and children) in China with maximum usage amount of 5 mg/100 mL, the LOQ is available without any doubt. According to the general average use instructions of infant formula, there are approximatly 13−17 g of milk powder contained in 100 mL of ready-to-use liquid nutrition for babies; thus, a vanillin or ethylvanillin content of 294−385 mg kg$^{-1}$ in powder samples (average 333 mg kg$^{-1}$) complies with the regulations of China's usage limit. For coumarin, the LOQ of 10.0 $\mu$g kg$^{-1}$ is also far below the limit of 2 mg kg$^{-1}$ set by Codex Alimentarius and the EU. This indicated that this method is suitable for analysis of these flavoring agents in infant formula samples.

To evaluate the specificity of the developed method, 10 different blank infant formula samples were investigated. No interfering peaks from endogenous compounds of sample extracts were observed at or near the retention times of all target analytes, indicative of the specificity of the method.

To evaluate the precision of this method, both intraday and interday repeatabilities were examined by determination of a fortified sample at three different concentrations (low, medium, and high) at 10, 50, and 100 $\mu$g kg$^{-1}$. Good stability and satisfactory repeatability were achieved, and the relative standard deviation (RSDs) values were <3.62%.

The method accuracy was evaluated by analyzing series of fortified spiking samples using the developed method. The

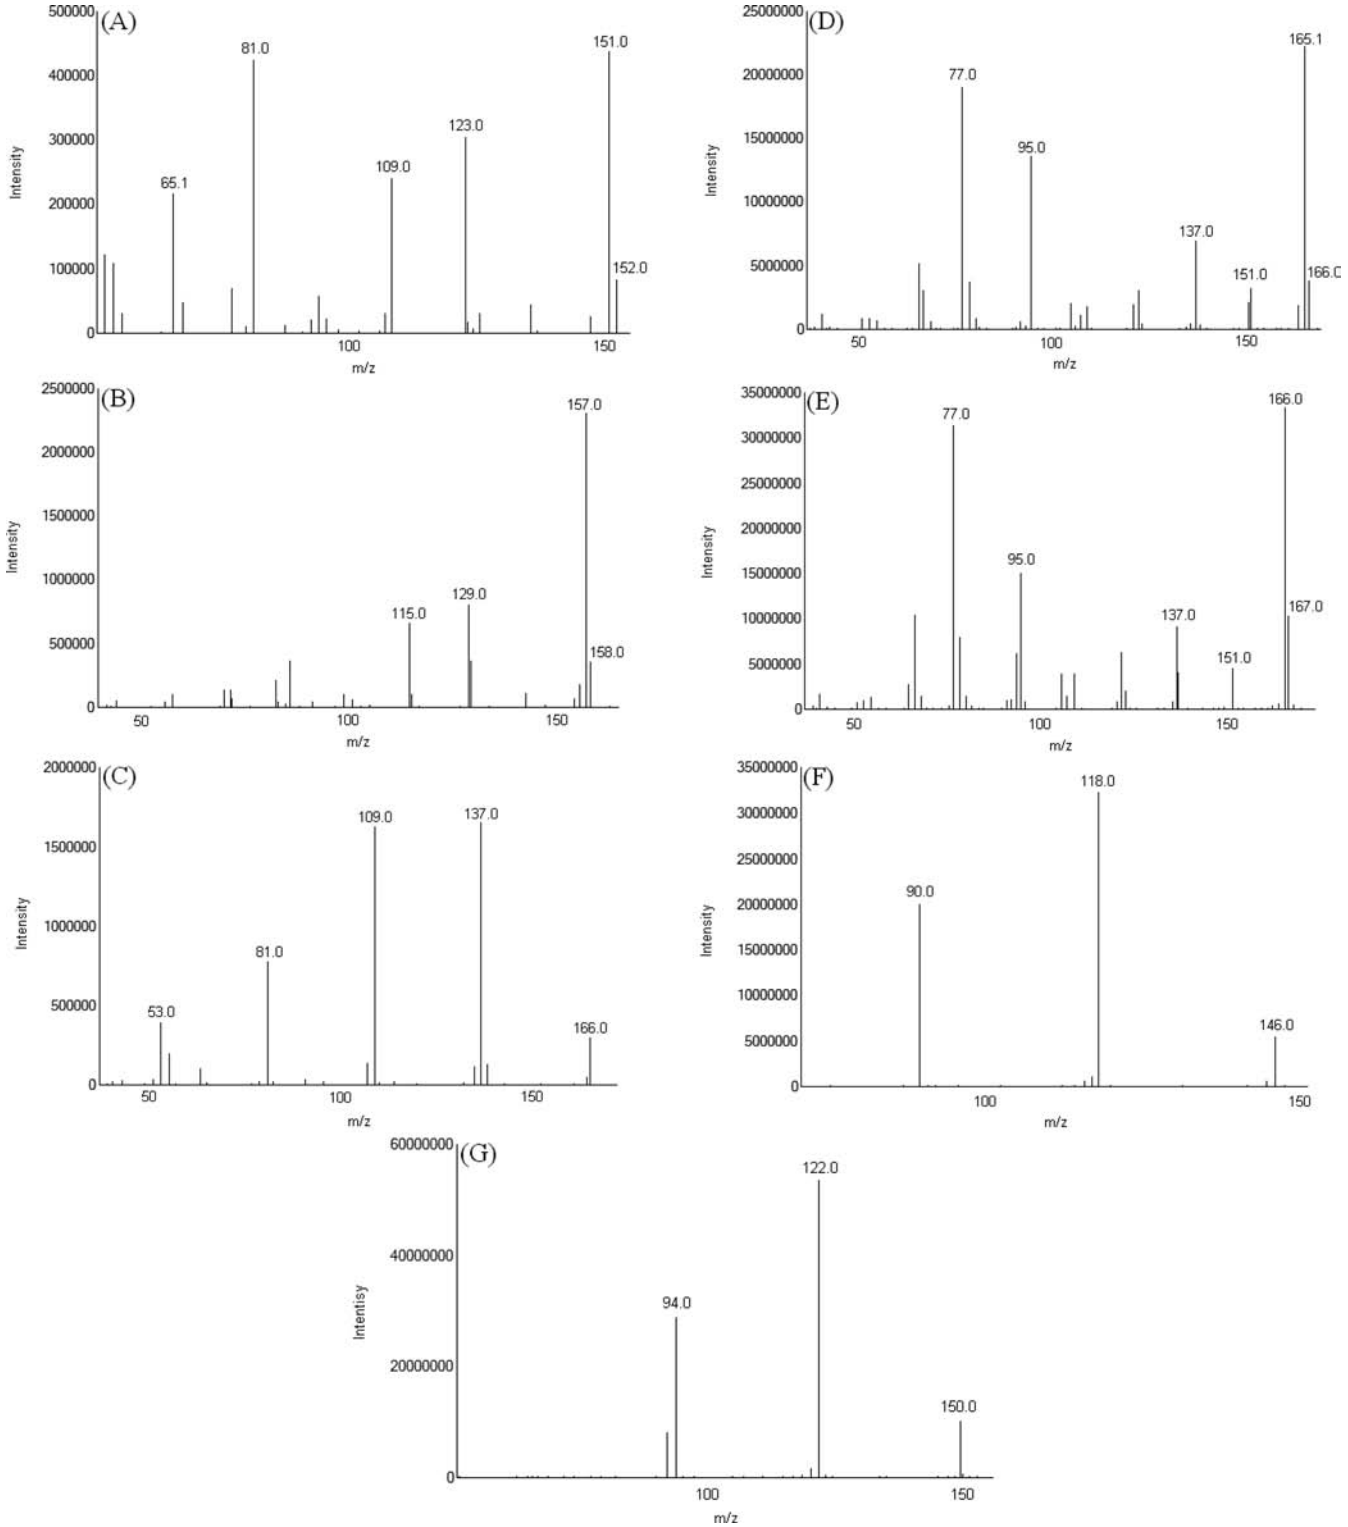

**Figure 3.** GC-MS/MS product scan spectrum of vanillin (A), vanillin-$^{13}C_6$ (B), ethylvanillin (C), methylvanillin (D), methylvanillin-$^{13}C$ (E), coumarin (F), and coumarin-$D_4$ (G). Collision energy (eV): A, 20; B, 20; C, 15; D, 15; E, 15; F, 10; G, 10.

appropriate amounts of the standard target compounds were spiked into the "blank" infant formula samples and given at three final concentration levels of 10, 50, and 100 $\mu g\ kg^{-1}$. The spiked samples were treated following the same procedure as mentioned and determination by GC-MS/MS. Average recoveries ranging within 82.8−107.5% (Table 2) were achieved, and RSDs were <8.9%, indicative of the good recovery and precision of the method.

**Application to Real Samples.** Twenty infant formula samples were purchased from local supermarkets and analyzed following the proposed method, and the blanks were periodically run during the sample analysis sequence to confirm the absence of contamination. Neither ethylvanillin nor

coumarin was detected in any sample, whereas vanillin was detected at concentration levels ranging from 2.4 to 706.8 mg $kg^{-1}$ in four samples; these results were highly consistent with our previous study using the LC-MS/MS method.[24] At the

**Table 2. Mean Recoveries and Repeatability of the Developed Method at Three Concentration Levels with LOQs ($n$ = 6)**

| compound | spiking level ($\mu$g kg$^{-1}$) | recovery (%) | RSD (%) | LOQ ($\mu$g kg$^{-1}$) |
|---|---|---|---|---|
| vanillin | 10 | 82.8 | 5.8 | 10 |
| | 50 | 88.5 | 4.2 | |
| | 100 | 94.3 | 3.6 | |
| methylvanillin | 10 | 87.3 | 4.9 | 10 |
| | 50 | 92.6 | 4.1 | |
| | 100 | 107.5 | 3.5 | |
| ethylvanillin | 10 | 85.1 | 5.6 | 10 |
| | 50 | 90.6 | 3.8 | |
| | 100 | 93.4 | 3.3 | |
| coumarin | 10 | 88.6 | 8.9 | 10 |
| | 50 | 93.8 | 6.4 | |
| | 100 | 105.2 | 3.7 | |

same time, methylvanillin was detected at concentration levels ranging from 0.78 to 0.94 mg kg$^{-1}$ in three samples. The detailed results are summarized in Table 3, and the SRM chromatograms of a real positive sample are shown in Figure 5. Vanillin was considered as being added intentionally to the four vanillin-positive samples because the concentration is high. Especially the sample containing 706.8 mg kg$^{-1}$ vanillin, according to previous analysis on Chinese vanillin usage limit, is certainly against China's national standard. These samples should be a matter of concern when applied to infants and even children. Meanwhile, the occurrence of methylvanillin was considered as being contaminated during the production process and not added intentionally, because its concentrations were so small that it could not effectively act as a flavoring ingredient.

**Table 3. Content of Vanillin and Methylvanillin in Infant Formula Samples ($n$ = 3)**

| | vanillin | | methylvanillin | |
|---|---|---|---|---|
| sample | content[a] | RSDs (%) | content[a] | RSDs (%) |
| 1 | 2.4 | 2.5 | 0.85 | 2.8 |
| 2 | 32.6 | 2.1 | 0.78 | 3.1 |
| 3 | 80.3 | 2.3 | 0.94 | 2.4 |
| 4 | 706.8 | 1.8 | *b* | |

[a]Content in mg kg$^{-1}$. Ethylvanillin and coumarin were below LOQ. [b]Contents were below LOQ.

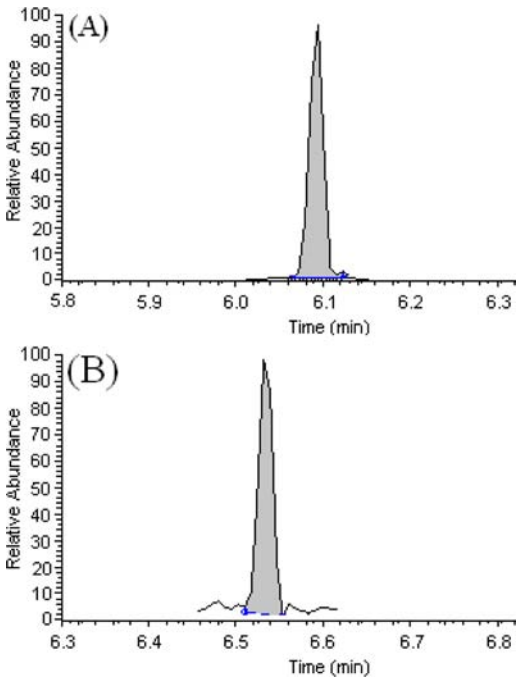

**Figure 5.** SRM chromatograms of a real positive sample: vanillin (A); methylvanillin (B).

The developed method allows the simple, rapid, and sensitive determination of four flavorings in infant formula samples. The method showed good recoveries (82.8−107.5%) and precision (RSDs < 8.9%) and could be applied for the unequivocal simultaneous identification and quantification of target analytes in complex formula samples.

experiments. The same equipment as above was used for this purpose. The solvents were heated for 5 h.

*HPLC Measurements.* Chromatographic measurements were performed using LC/ESI/IT/MS from Finnigan (LCQ Adventage Max) equipped with the ion-trap mass spectrometric system (Thermo-Electron Corp., San Jose, CA, USA) and a diode array detector from Finningan (Surveyer PDA Plus Detector). The column used was a 100 mm × 4.6 mm i.d., 3 $\mu$m, Gemini C18 (Phenomenex, Torrance, CA, USA). Chromatographic separation was performed using gradient elution. Mobile phase A was 25 mM formic acid in water; mobile phase B was 25 mM formic acid in acetonitrile. The gradient program started at 5% B, increasing to 35% for 30 min, next from 35 to 100% B for 5 min, followed by isocratic elution (100% B) for 5 min. The total run time was 40 min at the mobile phase flow rate of 0.4 mL/min.

In each run, PDA spectra in the range of 200−600 nm and MS spectra in the range of $m/z$ 100−1000 were collected continuously. SIM function was used to better visualize the chromatographic separation and to remove the signal connected with the interfering components of the blueberry pulp. The time periods and monitored ions were as follows: 0−9 min, $m/z$ 191; 9−15 min, $m/z$ 371; 15−20 min, $m/z$ 353; 20−21.5 min, $m/z$ 179; 21.5−40 min, $m/z$ 353.

The column effluent was ionized by electrospray (ESI). The ESI needle potential was 4.5 kV in the negative ionization mode. To identify the chlorogenic acid isomers and the chlorogenic acid transformation products, the functions of secondary ($MS^n$) ion fragmentation were applied. The collision energy was chosen individually for each group of the examined compounds.

To identify 5-*O*-caffeoylquinic acid derivatives in the examined samples, LC/ESI/TOF/MS analysis was additionally performed. LC/ESI/TOF/MS analysis was carried out on the Agilent (Agilent Technologies, Palo Alto, CA, USA) liquid chromatography system. MS analysis was performed on the orthogonal TOF/MS equipped with an electrospray interface (Agilent Technologies, Santa Clara, CA, USA). Negative mode using full scan mode in TOF/MS analysis was applied, and the mass range was set at 100−600 Da. Chromatographic separation was performed using the same chromatographic column and the same gradient elution as described for LC/ESI/IT/MS analysis.

Due to the lack of standards of CQA isomers and their hydroxyl derivatives, the amounts of these compounds were calculated by relating their chromatographic responses to the calibration curve for 5-CQA. Quantitative evaluations of all examined compounds were performed on the basis of the signal from the MS detector.

## RESULTS AND DISCUSSION

Figure 1 presents the chromatogram of supernatant from blueberry pulp obtained before (Figure 1A) and after 5 h of thermal processing (Figure 1B). As seen in Figure 1A, the supernatant from unprocessed blueberries contains three main components: 5-CQA and quinic and caffeic acid. They are all known as the main components of blueberries,[11] but they additionally were confirmed on the basis of retention coefficients of their standards and MS and PDA spectra. As shown in Figure 1B, the supernatant from the processed blueberries contains, besides the parent substances, nine additional components formed as a result of 5-CQA transformation and degradation: hydroxyl derivatives of 3-CQA, peaks 4 and 5; hydroxyl derivatives of 5-CQA, peaks 6 and 7; hydroxyl derivatives of 4-CQA, peaks 8 and 9; 3-CQA, peak 10; 4-CQA,

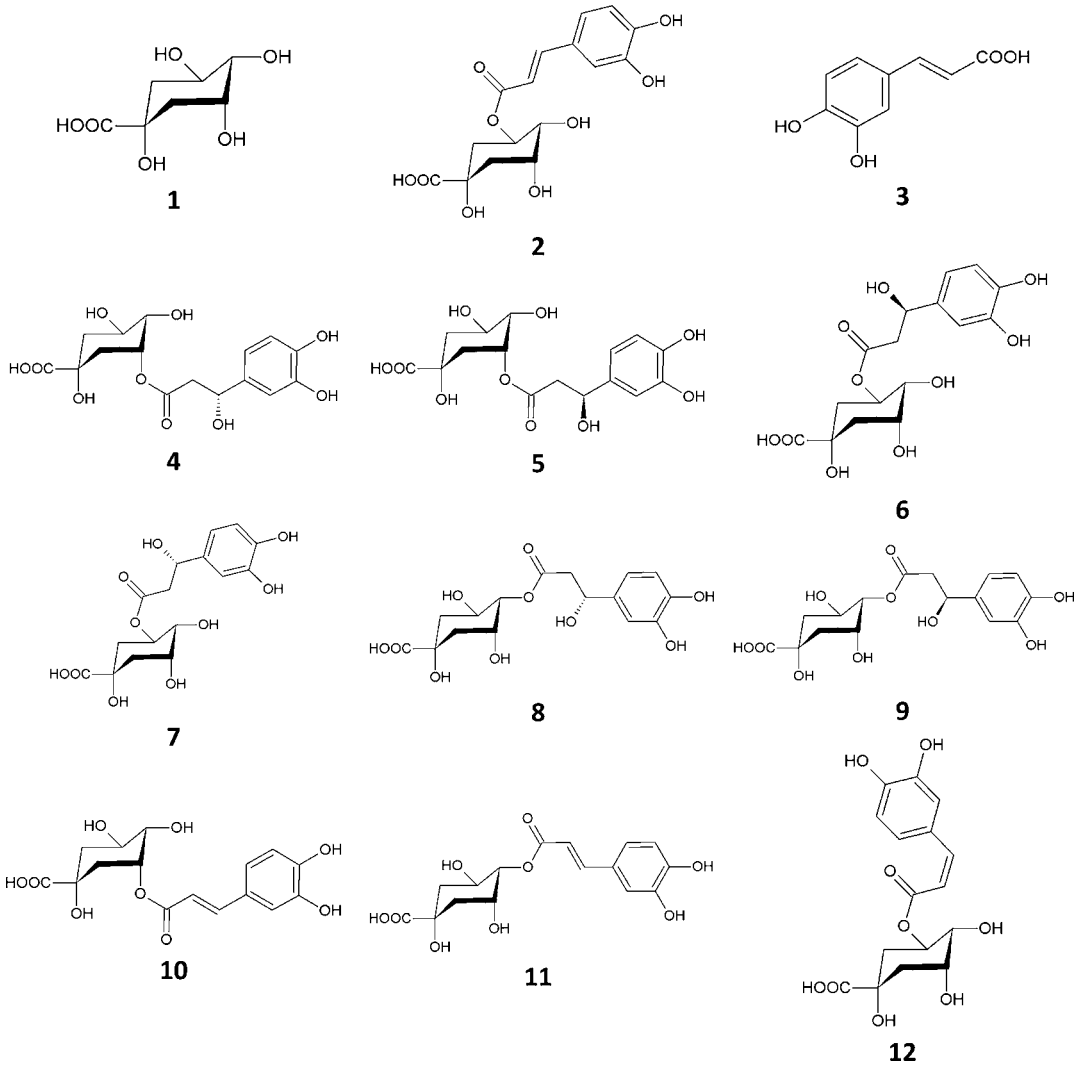

**Figure 2.** Molecular structures of 5-CQA and its transformation products identified in blueberry pulp before and after thermal processing.

peak 11; and *cis*-5-CQA, peak 12. Their presence was identified and confirmed by the PDA, $MS^n$,[10,12,13] and HRMS data. All of these components were reported earlier as transformation and degradation products of 5-CQA in buffered 5-CQA solution,[10] so it turns out that the 5-CQA transformation and degradation in thermally processed blueberry pulp is almost the same as its transformation in the model system. The matrix components have no impact on the process.

For clarity, the names of all the identified compounds, their peak and structure numbers, abbreviations, and chemical structures are collected in Table 1 and graphically presented in Figure 2. The $MS^n$ and HRMS data for the compounds are collected in Tables 2 and 3. To eliminate the concentration differences resulting from the presence of sucrose in the examined samples, the amounts of 5-CQA and its transformation products were recalculated and related to the mass of pure fresh blueberry pulp.

The influence of heating time of the blueberry pulp on the amount of individual formed components is presented in Figures 3−5. Each figure contains three curves. The dash-dotted line corresponds to the processed pulp without sucrose addition, whereas the dotted line and dashed line are the relationships for blueberry pulps with added sucrose at two concentration levels (10 and 30%, respectively). The presented relationships

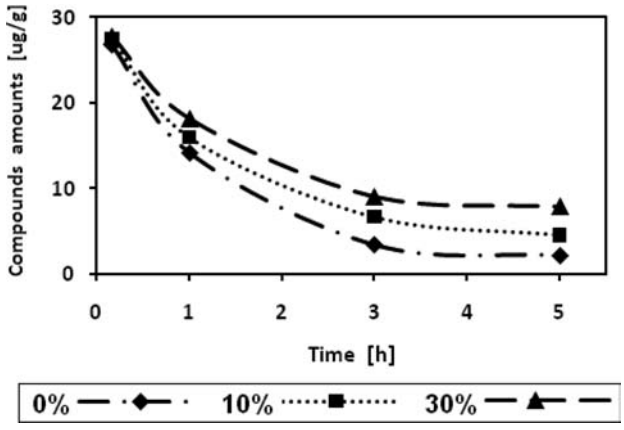

**Figure 3.** Influence of time and sucrose concentration on the amount of 5-CQA in blueberry pulp during its thermal processing.

show the following: (i) The concentration of 5-CQA decreases in the pulp (see Figure 3). This behavior is obvious as 5-CQA is a precursor to other already described products. Significantly, the 5-CQA transformation process was the quickest in the blueberry pulp containing no sucrose. (ii) The concentrations of CQA isomers (3- and 4-CQA), their hydroxyl derivatives

(3- and 4-CQA-OH), and CQA hydrolysis products (QA and CA) increase (see Figure 4). The amounts of QA and CA formed are similar, which agrees with the reaction stoichiometry of 5-CQA hydrolysis. The concentration increase of 3- and 4-CQA-3R/S-OH is consistent with the concentration increase of their precursors, 3- and 4-CQA. In contrast to 5-CQA, the increase of sucrose concentration slows the speed of the formation of these compounds. (iii) The initial increase of the amount of *cis*-5-CQA and hydroxylated 5-CQA derivates (5-CQA-3*R*-OH and 5-CQA-3*S*-OH) is followed by the decrease of their amount (see Figure 5). This shape of the relationships, most evident for *cis*-5-CQA, can be explained by the simultaneous occurrence of two competitive reactions: the formation and degradation of the transformation products. For this group of components, as for the components mentioned previously, the sucrose concentration increase slows the speed of their formation.

The comparative analysis of the presented results and those obtained for 5-CQA transformation in artificial systems[10] leads to the conclusion that the transformation of this acid in the processed blueberry pulp is very similar to that occurring in acidic

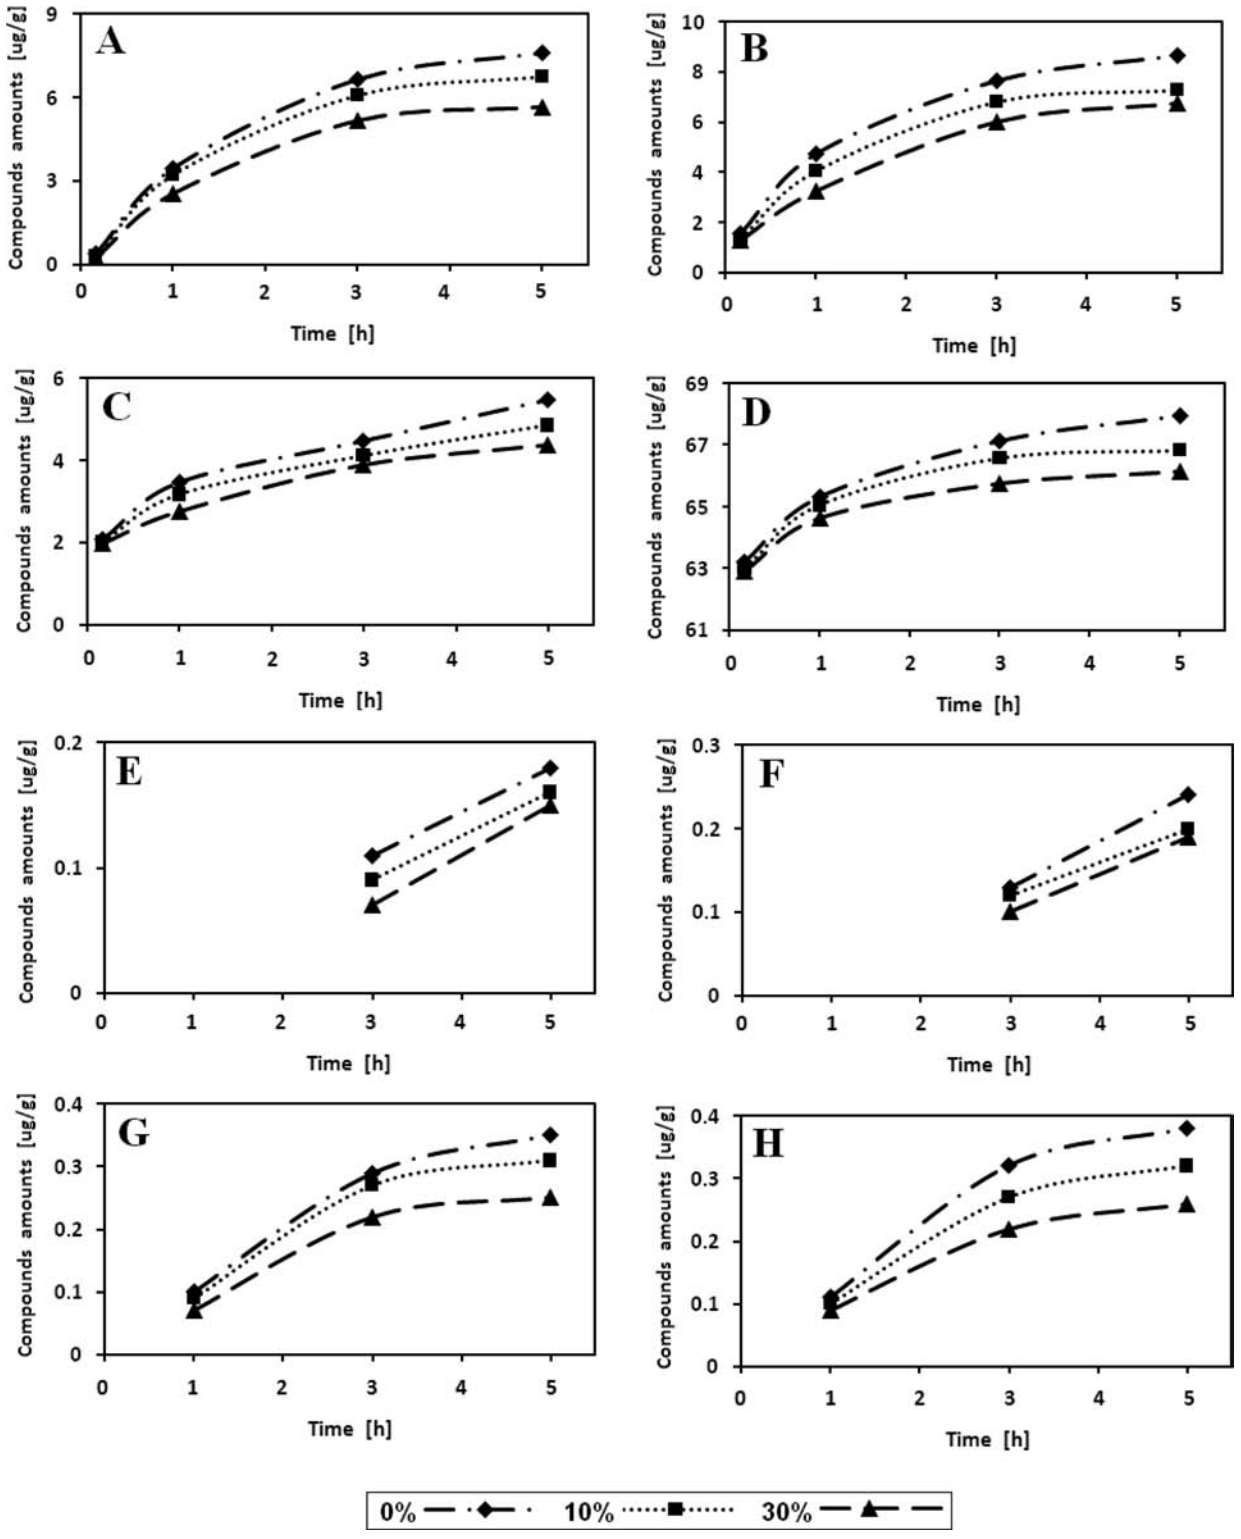

**Figure 4.** Influence of time and sucrose concentration on the amount of 3-CQA (A), 4-CQA (B), CA (C), QA (D), 3-CQA-3*R*-OH (E, F), 3-CQA-3*S*-OH (E, F), 4-CQA-3*R*-OH (G, H), and 4-CQA-3*S*-OH (G, H) forming in blueberry pulp during its thermal processing.

water solution.[10] The experiments concerning 5-CQA transformation in water solution have revealed a larger number of 5-CQA transformation and degradation products[10] than those in the processed blueberries, but the absence of some 5-CQA transformation products in blueberry pulp probably results from the significantly lower concentration level of 5-CQA in the processed fruits than in the previously reported experiments.[10]

Slow transformation and degradation of 5-CQA in the presence of sucrose is the most striking result. To confirm this finding, the transformation of 5-CQA in water solution with and without the addition of sucrose was examined. The experiments were performed using a 5-CQA water solution containing a similar amount of the acid in 1 mL of solvent to 1 g of blueberry pulp. The results of these experiments are collected in Table 4.

| 11 | 4-CQA | 7.12 | 6.13 |
| 12 | *cis*-5-CQA | 0.41 | 0.29 |

As appears from the table, the presence of sucrose clearly slows the transformation speed also in the artificial system. The observed phenomenon can be attributed to the increase of the pulp's viscosity resulting from the presence of the sugar or can be connected with the competition of sucrose and 5-CQA molecules for water molecules.

The presented results prove that high-temperature processing of blueberries causes 5-*O*-caffeoylquinic acid isomerization and transformation. It has been found that as many as 11 components (5-CQA derivatives and its reaction product with water) can be formed from 5-CQA during the processing of blueberries. As results from the experiments, the transformation of this acid in the processed blueberry pulp is very similar to that occurring in acidic water solution.[10] Moreover, the speed of these transformations depends on the sucrose concentration in the processing system, which is another paper novelty. It can be anticipated that 5-CQA, during the high-temperature processing of other fruits and plants containing this acid, is transformed in a similar way.

These results are important not only for food technologists but also for researchers examining plant materials, who may mistakenly treat the 5-CQA transformation products as new components not previously found in examined plants and, thus, erroneously estimate their composition.

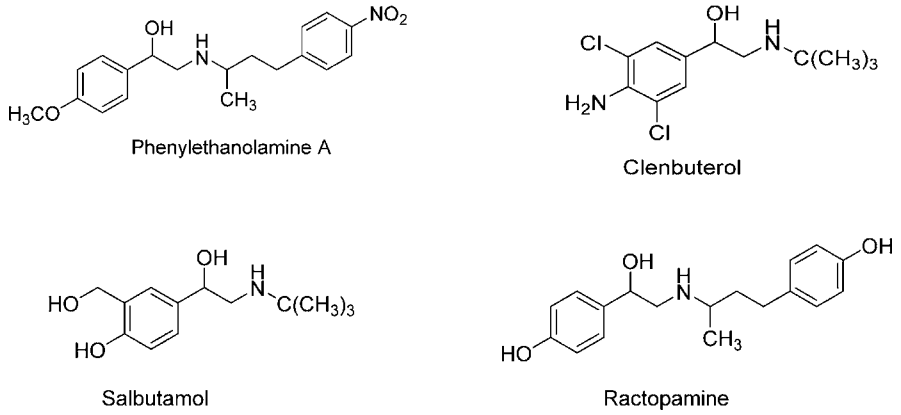

**Figure 1.** Molecular structures of phenylethanolamine A, clenbuterol, ractopamine, and salbutamol.

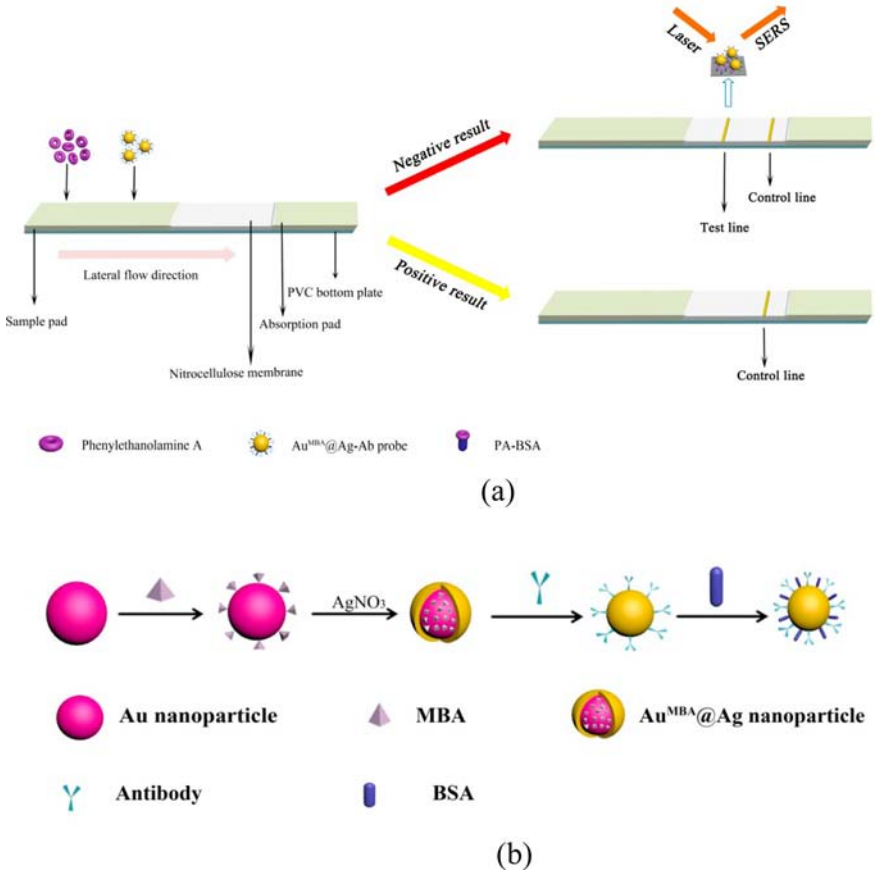

**Figure 2.** (a) Schematic diagrams of the assembly of the ICA strip and the principle of SERS-based ICA for PA detection; (b) preparation of $Au^{MBA}$@Ag-Ab probe.

primary drawback is its time-consuming and laborious incubation washing and rinsing procedures. The electrochemical method is disturbed by many interferents.

Immunochromatography assay (ICA) represents a popular and widely used test principle for point-of-care applications. The main features of the normal Au colloidal particle-based ICA are the user-friendly operation, quickly obtained results, less interference due to chromatographic separation, relatively low cost, and fairly good shelf life.[16] At present, ICA has been widely used for the rapid detection of toxic or harmful substances in many fields such as food safety monitoring[17−20] and point-of-care diagnostics.[21−24] However, although the conventional qualitative analysis can meet the needs of detection of some analytes (e.g., pregnancy testing), it is not suitable in some cases when the quantitative level of an analyte is important.[25] In past years, some attempts of ICA using fluorescence or quantum dots for quantitative analysis were made.[26,27] Nevertheless, a significant limitation of these modified ICA methods is that the results may suffer from optical interference (e.g., photobleaching). Fluorescence ICAs are often complicated by the requirement of an elaborate excitation and detection scheme and by broad emission bands.

Surface-enhanced Raman scattering (SERS) is one of the most sensitive analytical techniques available for the scientist today.[28] Colloidal Au and Ag in solution can render SERS-active by adsorbate-induced particle aggregation.[29,30] Au

dx.doi.org/10.1021/jf503599x | J. Agric. Food Chem. 2014, 62, 10896−10902

colloids have advantages of easy preparation, homogeneity, and biocompatibility with biomolecules such as proteins, antibodies, and DNA, in contrast to Ag NPs, which are not biocompatible and less stable under biological conditions.[31] However, the extinction coefficient of the surface plasmon band of Ag NP is approximately 4 times as large as that for an Au NP of the same size.[32] Currently, the SERS activity of the Ag@Au or Au@Ag core−shell bimetallic nanoparticles were investigated and compared.[33−35] The Au@Ag core−shell nanoparticles were found to have a higher SERS activity mainly due to electronic ligand effect and localized electric field enhancement in core−shell naoparticles.[35] Au@Ag core−shell nanoparticles have been explored for biological applications such as oligonucleotide conjugation and SERS-based immunoassay.[36]

Herein, we describe a novel ICA based on SERS for the detection of PA in urine samples for the first time. The principle and procedures of this approach (Figure 2a) were similar to those based on normal Au colloidal particles. To develop this ICA, a new probe (e.g., $Au^{MBA}$@Ag-Ab) was synthesized (Figure 2b) by immobilizing a polyclonal antibody against PA on the surface of Au/Ag core−shell nanoparticles that have been sandwiched with a Raman reporter (MBA, which is the most common Raman reporter with specific Raman peaks at 1074 and 1583 $cm^{-1}$ applied to the development of a SERS-based immunoassay). After ICA procedures, the specific Raman scattering intensity of MBA on the test line was measured for the quantitative detection of PA. The proposed ICA displayed the properties of high sensitivity, specificity, accuracy, and precision for PA detection.

## MATERIALS AND METHODS

**Materials and Apparatus.** Bovine serum albumin (BSA) and Tween-20 were purchased from Sigma (St. Louis, MO, USA). 4-Mercaptobenzoic acid (MBA) was purchased from Aladdin China Ltd. (Shanghai, China). Chloroauric acid ($HAuCl_4$), silver nitrate ($AgNO_3$, 99%), ascorbic acid (99%), and trisodium citrate were obtained from Sinopharm Chemical Reagent Co., Ltd. (Shanghai, China). Phenylethanolamine A (PA) was bought from Toronto Research Chemicals Inc. (Toronto, ON, Canada). Clenbuterol, ractopamine, and salbutamol were obtained from Zhongmu Pharmaceutical Co., Ltd. (Hubei, China). All other chemicals were of analytical grade. The polyclonal Ab against PA and coating antigen (PA−BSA conjugate) were prepared by our group.[14] Nitrocellulose (NC) membranes were purchased from Whatman (Shanghai, China). PVC sheets, adhesive tape, and filter paper were purchased from Jieyi Biotechnology Co. Ltd. (Shanghai, China). A deionized-RO water machine (Dura 12FV) was purchased from THE LAB Co. (USA). The digital photographs of the samples were taken with a Cannon IXUS 125 HS digital camera (Cannon Inc., Japan). Transmission electron microscopy (TEM) photographs were taken on a Tecnai G220 from USA FEI Co. The portable Raman Analyzer RamTracer-200-HS was obtained from OptoTrace Technologies, Inc. (Suzhou, China).

**Preparation of $Au^{MBA}$@Ag-Ab Probe.** The preparation of the $Au^{MBA}$@Ag-Ab probe is illustrated in Figure 2b. The colloidal gold particles were first prepared according to ref37. Briefly, 1.5 mL of 1% trisodium citrate solution was added rapidly to the boiling aqueous solution of 100 mL of 0.01% $HAuCl_4$ with vigorous stirring. The mixture was kept boiling for 15 min until the color did not change. After the solution cooled down, 10 $\mu$L of 1 mmol $L^{-1}$ MBA solution was added to 10 mL of colloidal gold solution and stirred for 3 h. The MBA modified Au colloids (e.g., $Au^{MBA}$) were purified by centrifugation and resuspension with the same volume of ultrapure water.

After pH adjustment with 0.01 mol $L^{-1}$ HCl, 10 mL of the above $Au^{MBA}$ colloid was mixed with 2 mL of 0.1 mol $L^{-1}$ ascorbic acid in a beaker under stirring. Then 1 mmol $L^{-1}$ $AgNO_3$ was dropwise added into the above mixture. With the continuous addition of $AgNO_3$ solution in amounts of 0.08, 0.12, 0.16, 0.20, 0.25, 0.30, and 0.40 $\mu$mol to 1 mL of $Au^{MBA}$ solution, silver nitrate was reduced by ascorbic acid and the resultant Ag shells continuously grew on the surface of Au seeds. When the purple-red of solution changed to orange-yellow, the solution was further stirred for 30 min and centrifuged at 9000 rpm for 10 min. After removal of the supernatant, the $Au^{MBA}$@Ag NPs were obtained.

The pH value of $Au^{MBA}$@Ag solution was adjusted to 9.0 with 0.1 mol $L^{-1}$ $K_2CO_3$, and then 1 mL of the solution was mixed with Ab against PA for 3.5 h. Finally, 100 $\mu$L of 5% BSA was added to the mixtures and incubated overnight to block the immune complex probes. The final $Au^{MBA}$@Ag-Ab probes were separated from solutions by centrifugation at 8500 rpm for 10 min. Sediment was diluted with an equal volume of phosphate (PB) buffer and stored at 4 °C until use.

**Preparation of ICA Strip.** The ICA strip consisting of an absorbent pad, a nitrocellulose membrane with a test line and a control line, a sample pad, and a PVC bottom plate in a length of 6 cm was assembled (Figure 2a). The test and control lines were formed by spreading 10 $\mu$L of PA−BSA (5.0 mg $mL^{-1}$) and 10 $\mu$L of goat anti-rabbit IgG (1:100 dilution), respectively, and then dried for 20 min at room temperature. The NC membrane was pasted on the center of the PVC bottom plate. The absorbent pad and the sample pad were pasted to both ends of the NC membrane, overlapping it about 1.5 mm. The assembled plate was cut to 4 mm in width. Strips were sealed into glass bottles in the presence of desiccant gel and nitrogen gas and stored at 4 °C until use.

**Procedure of SERS-ICA and SERS Signal Acquisition.** Six microliters of $Au^{MBA}$@Ag-Ab was added onto the sample pad 1.0 cm near the NC membrane, and then 150 $\mu$L of PA standard/sample solution was pipetted onto the sample pad at 0.5 cm from the end of the strip. The standard/sample solutions together with the $Au^{MBA}$@Ag-Ab probes were flowing toward the absorbent pad by capillary action. The color was developed on the test and control zones visually. All ICA procedures were completed within 15 min. The immune complex probes captured by the coating antigen on the test line could be measured with the portable laser Raman Analyzer coupled with a microscope (Eplan, 40 × 0.6). Excitation source was tuned at 785 nm with a laser power of 20 mW at the test line area. The typical integration time used in this assay was 10 s, average with 2 and boxcar with 1. The peak intensity at 1074 $cm^{-1}$ arose from MBA measured from an average of spectra collected at 10 different spots along the middle part of the test line used for quantification.

## RESULTS AND DISCUSSION

**Principle of the SERS-Based ICA.** As illustrated in Figure 2a, the principle of SERS-based ICA is similar to that based on conventional gold colloidal particles. When 150 $\mu$L of PA standard/sample solution was pipetted onto the sample pad at 0.5 cm from the end of the strip, the standard/sample solutions would move toward the absorbent pad and $Au^{MBA}$@Ag-Ab would migrate together with liquid solution. If there was no PA in the standard/sample solution (e.g., negative result), the $Au^{MBA}$@Ag-Ab would be captured by PA−BSA coated on the membrane (test line). Excess $Au^{MBA}$@Ag-Ab would be moved continuously to get the control line and be captured by goat anti-rabbit IgG. Two orange-yellow bands on the test line and control line would appear due to the accumulation of orange-yellow $Au^{MBA}$@Ag-Ab. In contrast, for standard/sample solution containing a large amount of PA (e.g., positive result), the specific antibody binding sites on the probe would be occupied first by PA, leaving no binding sites for PA−BSA. Consequently, no $Au^{MBA}$@Ag-Ab would remain at the PA−BSA location on the NC membrane, but $Au^{MBA}$@Ag-Ab would move continuously to get to the control line and be captured by goat anti-rabbit IgG. In this case, only the orange-yellow band on the control line appeared. Thus, the degree of intensity of

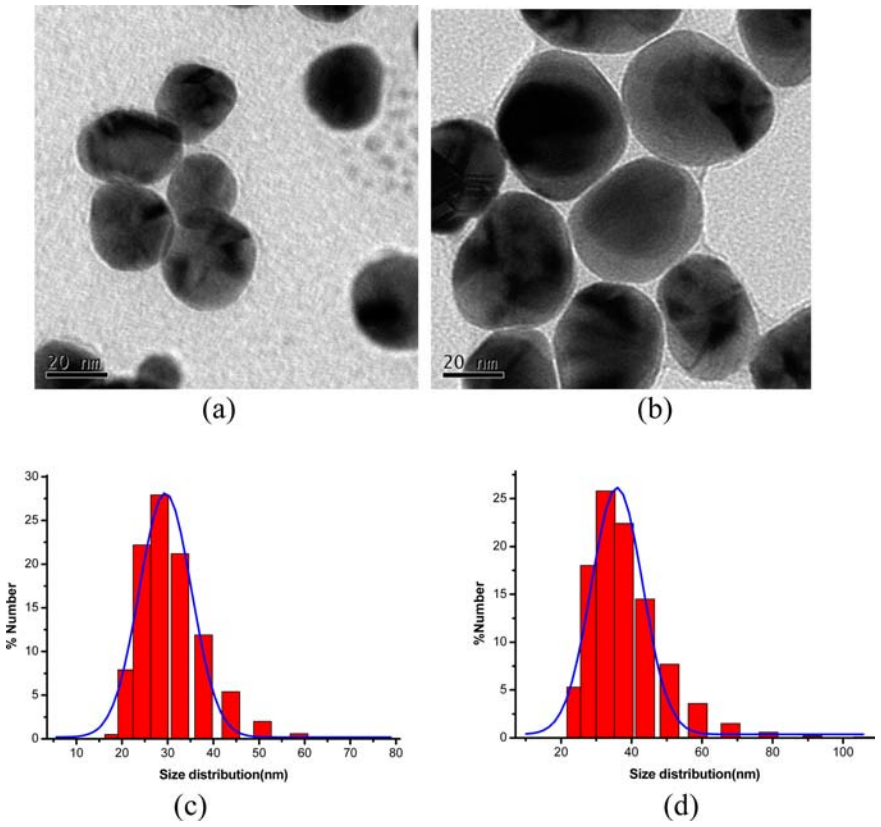

**Figure 3.** (a, c) TEM images and DLS of Au NPs; (b, d) TEM images and DLS of $Au^{MBA}$@Ag NPs with Ag shell thickness of 2.5 nm.

$Au^{MBA}$@Ag-Ab color on the test line was the reverse of the concentration of PA. With the portable Raman analyzer, the SERS scattering intensity arising from the MBA captured on the test line was measured for the quantitative analysis of PA.

**Preparation and Characterization of $Au^{MBA}$@Ag NPs.** The colloidal gold NPs were first prepared and characterized. The TEM images and dynamic light scattering (DLS) of 100 individual Au NPs are shown in Figure 3a,c. The TEM images revealed that the colloidal gold NPs were homogeneous with a diameter size about 30 nm, whereas the DLS results showed that the Au NPs size distribution was in the range of 30 ± 5 nm.

To increase the sensitivity of the SERS-based ICA for PA, it will be desirable to have more MBA sandwiched in the probe. MBA could be easily attached to Au NPs via the thiol group in the MBA molecule. When 10.0 mL of the Au colloids was mixed with different amounts of MBA, more MBA addition to Au colloid solution would make the Au NPs aggregate and even precipitate. We found that 10.0 $\mu$L of MBA solution at the concentration of $1 \times 10^{-3}$ mol $L^{-1}$ was considered the appropriate amount of MBA required to mix with 10.0 mL of the Au colloids to form the $Au^{MBA}$ NPs.

The effect of the amount of $AgNO_3$ in the preparation of $Au^{MBA}$@Ag NPs on the SERS enhancement of MBA was investigated. With the amount of $AgNO_3$ increasing in the range of 0.08, 0.12, 0.16, 0.20, 0.25, 0.30, and 0.40 $\mu$mol to 1 mL of $Au^{MBA}$ solution, silver nitrate was reduced by ascorbic acid and the Ag shells continuously grew on the surface of $Au^{MBA}$ seeds. Accordingly, the color of the resultant $Au^{MBA}$@Ag NPs was gradually changed from purple-red to orange-yellow to yellow (Supporting Information, Figure S1a). The Raman intensity of the $Au^{MBA}$@Ag solutions was tested by the portable Raman Analyzer. As illustrated in Figure S1b, there is a strong dependence of the Raman intensity on the amount of $AgNO_3$ for NPs preparation, for example, on the Ag shell thickness. The maximal Raman intensity was obtained for the $Au^{MBA}$@Ag solution by employing 0.25 $\mu$mol of $AgNO_3$ for NPs preparation. Apparently, the Ag shell of $Au^{MBA}$@Ag NPs plays an important role in enhancing the MBA signals in the SERS detection.

The TEM image and DLS of 100 individual $Au^{MBA}$@Ag NPs using 0.25 $\mu$mol of $AgNO_3$ for NPs preparation are presented in Figure 3, panels b and d, respectively. The TEM image indicated the size of $Au^{MBA}$@Ag NPs was about 35 nm. The DLS results showed that the $Au^{MBA}$@Ag NPs size distribution was in the range of 35 ± 5 nm. Compared with the size of gold NPs, the thickness of the Ag shell in $Au^{MBA}$@Ag NP was estimated to be 2.5 nm.

**Test of Nonspecific Adsorption.** Before PA detection, whether there was nonspecific adsorption was tested. The ICA procedures at zero concentration of analyte in three situations were performed: (a) $Au^{MBA}$@Ag-Ab as a probe, PA−BSA coated on the test line; (b) $Au^{MBA}$@Ag-BSA as a probe, PA−BSA coated on the test line; (c) $Au^{MBA}$@Ag-Ab as a probe, $Na_2CO_3$−$NaHCO_3$ solution spread on the test line. The Raman spectra in the above three situations are illustrated in Figure S2. From Raman spectrum a, it was seen that both specific Raman scattering peaks of the MBA at 1074 and 1583 $cm^{-1}$ with the signal values of 9200 (AU) and 8100 (AU) appeared, which clearly demonstrated that the probe of $Au^{MBA}$@Ag-Ab was specifically bound with PA−BSA at the test line on the membrane. From Raman spectra b and c, there were almost no SERS signals appearing either at 1074 $cm^{-1}$ or

at 1583 $cm^{-1}$, indicating that there was no nonspecific adsorption.

**Optimization of Assay Conditions.** The sensitivity of the SERS-based ICA was improved by optimizing a series of conditions such as the amount of the antibody used for preparing $Au^{MBA}$@Ag-Ab probes, the coating antigen, and the probe utilized on the strip. Here we used the inhibition ratio ($B_0/B_{0.1}$) to evaluate the optimization. $B_0$ and $B_{0.1}$ are the SERS intensities at 1074 $cm^{-1}$ when PA concentrations were at 0 and 0.1 ng $mL^{-1}$, respectively. The bigger the inhibition ratio value, the higher the sensitivity of the assay.

In the preparation of $Au^{MBA}$@Ag-Ab probe, different amounts of antibody were consecutively coupled to 1.0 mL of $Au^{MBA}$@Ag NPs. The effects of the amount of Ab on the inhibition ratio were investigated (Figure S3a). It was found that when different volumes of antibody (at concentration of 2.0 mg $mL^{-1}$) from 0.5 to 3.0 $\mu$L were applied, the highest value of $B_0/B_{0.1}$ was achieved at 2.0 $\mu$L. Thus, the optimal amount of Ab for $Au^{MBA}$@Ag probe preparation was 2.0 $\mu$L.

The amount of coating antigen (PA−BSA) immobilized on the test line and the $Au^{MBA}$@Ag-Ab probe applied in the ICA strip significantly influence the assay sensitivity. As shown in Figure S3b,c, when 10 $\mu$L of PA−BSA at concentrations from 3.0 to 7.0 mg $mL^{-1}$ was applied to the ICA procedure, the highest value of $B_0/B_{0.1}$ was achieved at 5.0 mg $mL^{-1}$, whereas when volumes of $Au^{MBA}$@Ag-Ab from 2.0 to 10 $\mu$L were tested, the highest value of $B_0/B_{0.1}$ was obtained at 6.0 $\mu$L. Therefore, the optimal conditions applied to one ICA strip were 10 $\mu$L of PA-BSA at a concentration of 5.0 mg $mL^{-1}$ and 6.0 $\mu$L of $Au^{MBA}$@Ag-Ab.

**Sensitivity of the Assay.** Under optimal assay conditions, the SERS-based ICA for PA detection was developed. The PA standard solutions were in a range of 0−100 ng $mL^{-1}$. After the addition of 150 $\mu$L of PA standard solution to the sample pad, 15 min later, the color arising from $Au^{MBA}$@Ag-Ab on the test line was visualized by the naked eye (Figure 4a). With PA concentration increasing, the intensity of the color on test lines was gradually decreased. The SERS intensity at 1074 $cm^{-1}$ generated from MBA on the test lines was measured by SERS analyzer. As illustrated in Figure 4b, with PA concentration increasing, the SERS intensity at 1074 $cm^{-1}$ gradually decreased. The standard curve of the SERS-based ICA for PA was constructed in the form of $B/B_0 \times 100\%$ versus log $C$ (Figure 4c), where $B$ and $B_0$ were the SERS intensities when PA solutions were at the standard points and zero concentration. It was seen from Figure 4c that values of $IC_{50}$ and LOD at 3 × SD were 0.064 ng $mL^{-1}$ and 0.32 pg $mL^{-1}$, respectively. The comparison of the $IC_{50}$ and LOD values achieved in this study with those obtained in other immunoassays for PA detection is given in Table S1. It can be seen from Table S1 that $IC_{50}$ and LOD values in this work are 1−3 orders of magnitude lower than those obtained by other immunoassays, indicating the ultrasensitivity of the SERS-based ICA.

**Reproducibility of the SERS Signals.** To investigate the reproducibility of the SERS signals, three strips set up with PA standard solutions at 0, 0.1, and 1.0 ng $mL^{-1}$ after ICA procedures were tested. The SERS intensities at 1074 $cm^{-1}$ from 10 different spots along the middle parts of the test line in the strips were measured and are illustrated in Figure S4a. It was seen that among the three strips, the higher the PA concentration, the lower the SERS intensities; in each strip, the RSD value of the SERS intensities at 10 measurements were

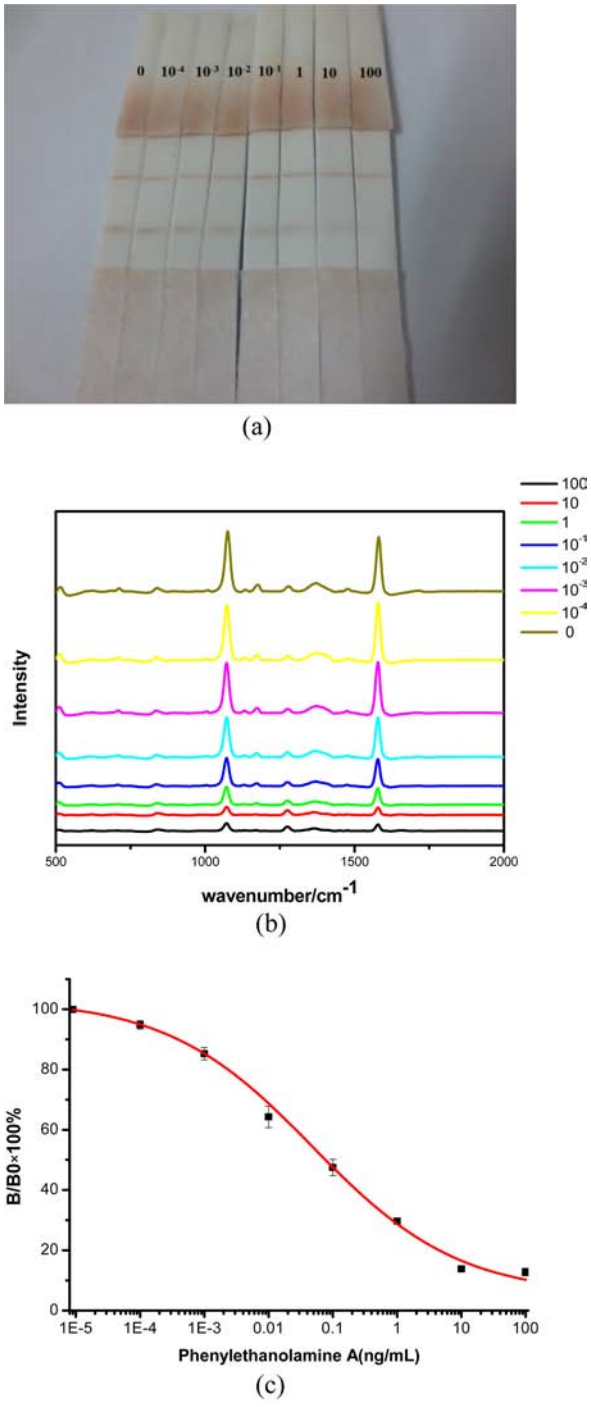

**Figure 4.** (a) Digital photograph of the strips after ICA procedure. The numbers on the test lines are the standard concentration of analyte (ng $mL^{-1}$). (b) Raman spectra arising from MBA on test lines. (c) Standard curve of the SERS-based ICA for PA. The bars represent the standard deviation of the 10 measurements of the intensities of MBA at 1074 $cm^{-1}$ on test lines.

5.17, 7.93, and 5.64%, respectively, indicating high precision of the SERS signal.

**Specificity of the Assay.** The specificity of a competitive immunoassay is often expressed by cross-reactivity (CR) value. Here we chose another three $\beta$-adrenergic agonists (ractopamine, salbutamol, and clenbuterol hydrochloride) to test the specificity of this assay. All compounds including PA were prepared at concentrations of 0, 0.01, 0.1, and 1 ng $mL^{-1}$ and

dx.doi.org/10.1021/jf503599x | J. Agric. Food Chem. 2014, 62, 10896−10902

applied to ICA procedures. The CR values were calculated according to CR (%) = [$IC_{50}$ of PA)]/[$IC_{50}$ of tested compound] × 100%. As shown in Figure S4b, for all three $\beta$-agonists, with the concentration increasing, the SERS intensities were almost constant, suggesting that there was almost no cross-reactivity of this SERS-based ICA with these three $\beta$-agonists, which demonstrated the high specificity of the proposed assay.

**Test of Recovery.** We chose pig urine samples for the spiking experiment. After dilution of the urine to 1:50 with PVP−PBST (polyvinylpyrrolidone−phosphate buffer saline with 0.1% Tween-20, v/v = 1:1, 1%), the urine sample was spiked with PA to concentrations of 0.01, 0.1, and 1.0 ng $mL^{-1}$, then 150 $\mu$L of the diluted urine sample was applied to ICA procedures. The contents of PA in spiked samples were quantified according to the standard curve run in the same day. As shown in Table 1, the recoveries of the PA from spiked samples were 99.9−101.2% with RSD values in range of 3.6−5.8% ($n$ = 3), indicating that this new approach was an applicable method to effectively detect the target analyte in urine samples.

**Table 1. Recoveries of PA from Spiked Urine Samples Measured by SERS-Based ICA**

| concn spiked (ng $mL^{-1}$) | recovery measured (100%) | | | average | RSD (100%) |
|---|---|---|---|---|---|
| 0.01 | 101.9 | 94.7 | 106.3 | 100.9 | 5.8 |
| 0.1 | 97.5 | 101 | 105 | 101.2 | 3.7 |
| 1 | 96.36 | 103.6 | 99.7 | 99.9 | 3.6 |

In conclusion, a novel ICA based on SERS using $Au^{MBA}$@Ag-Ab as a probe for the sensitive and quantitative detection of PA was developed in this study. Under optimal conditions, the $IC_{50}$ and LOD values of this new approach for PA were 0.06 ng $mL^{-1}$ and 0.32 pg $mL^{-1}$, respectively, indicating the ultrasensitivity of the assay. This ICA also displayed high specificity and reproducibility. Furthermore, by sandwich format, the proposed SERS-based ICA might be applied for the detection of macromolecular compounds; and by immobilizing more than two different kinds of coating antigens on the NC membrane as test lines and utilizing corresponding $Au^{MBA}$@Ag-Ab probes, it might be used for multiplex assays. The proposed SERS-based ICA was proven to be a rapid, simple, and ultrasensitive analytical method for PA and might be also applied for the determination of various target analytes in clinical, biological, food, and environmental analyses.

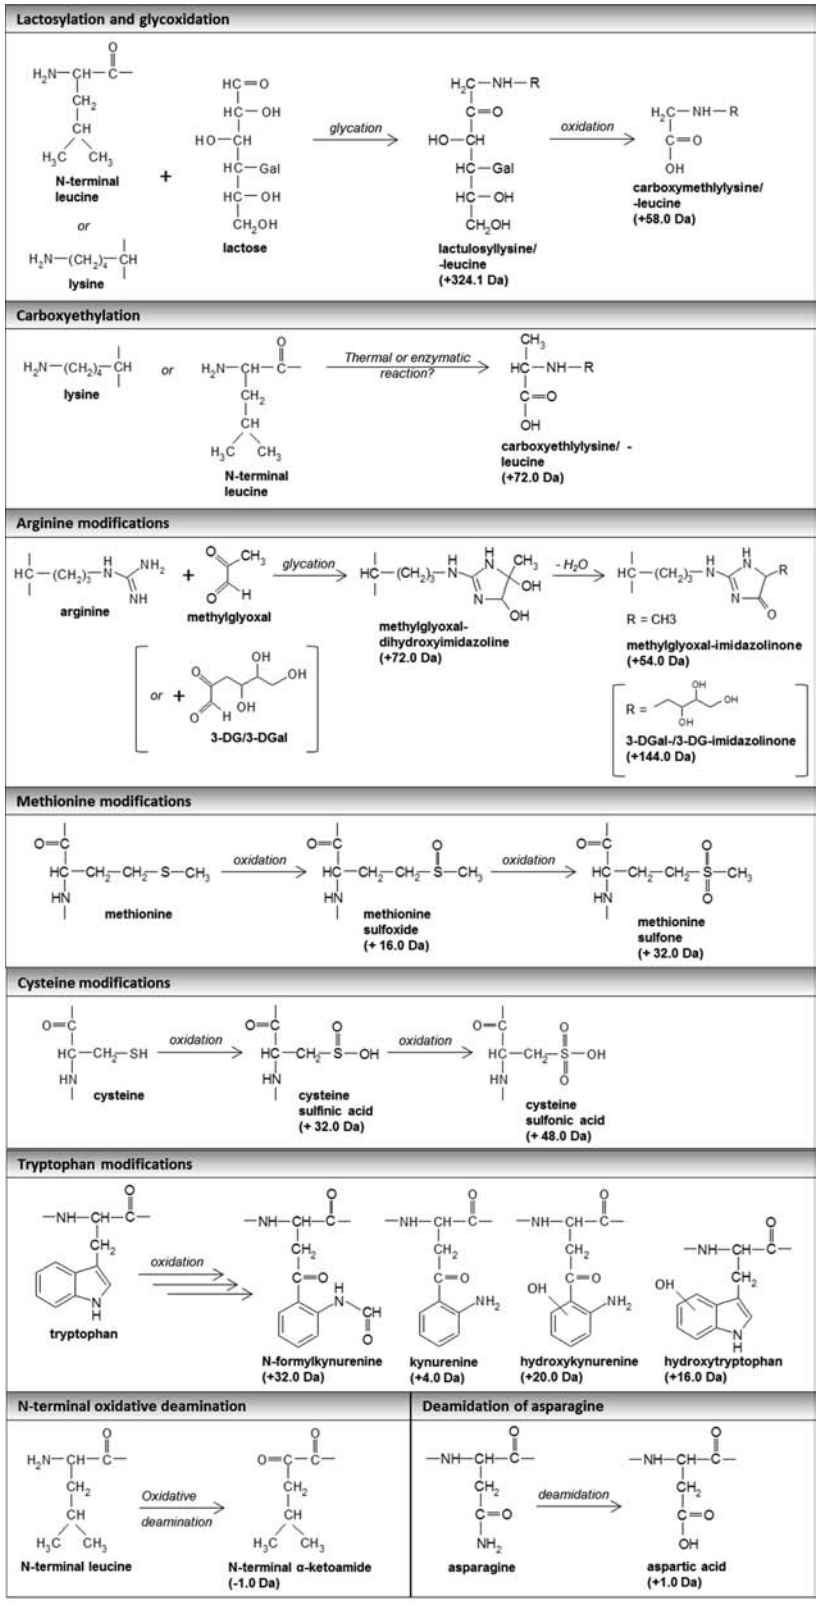

**Figure 1.** Reactions leading to the analyzed protein modifications in heated milk.

quantification of the modified peptides in diverse commercial milk products was performed to confirm their relevance for industrial processes. Furthermore, the data were applied to evaluate the potential of novel marker compounds to reflect milk processing conditions.

## MATERIALS AND METHODS

**Materials.** Formic acid (eluent additive for LC-MS), acetonitrile (LC-MS Chromasolv), disodium phosphate purum p.a., and monosodium phosphate purum p. a. were obtained from Sigma-Aldrich (Taufkirchen, Germany). 1,4-Dithiothreitol (DTT) was purchased from Roth (Karlsruhe, Germany). Endoproteinase GluC was supplied

by Roche (Mannheim, Germany). All water used was ultrapure water (18.2 MΩ cm resistivity).

**Milk Samples.** Raw milk samples ($n$ = 5) were provided by local farmers. Each sample was taken from pooled milk of at least 20 cows. Pasteurized milk ($n$ = 5; 1.5−3.5% fat), extended shelf life (ESL) milk ($n$ = 5; 3.5−3.8% fat), ultrahigh-temperature (UHT) milk ($n$ = 5; 3.5−3.8% fat), evaporated milk ($n$ = 6; 3.0−7.5% fat), and coffee cream ($n$ = 2; 10−12% fat) were purchased at local supermarkets. The day of purchase was generally about 3.5 months (UHT milk), 16 days (ESL milk), and 3−6 days (pasteurized milk) before the respective expiration date, indicating only a moderate storage time between production and purchase. Sterilized milk ($n$ = 1; 1.5% fat) was obtained from a German producer via an Internet shop. All samples were analyzed directly after purchase or kept at −21 °C until analysis.

**Defatting of Raw Milk and Milk Samples.** Fat from raw milk and milk samples was removed by centrifugation in a Hettich (Tuttlingen, Germany) Universal 16/32 R centrifuge for 60 min at 1650$g$ and 4 °C. The upper fat layer was carefully removed with a spatula. Visual evaluation indicated that the major part of the fat had been separated from the aqueous layer. Minor lipid contaminations in the samples did not interfere noticeably with chromatography, enzymatic hydrolysis, or mass analysis. Defatted milk samples were either stored at −80 °C prior to analysis or worked up directly after defatting. Samples were permanently kept on ice during sample preparation to minimize enzymatic activity.

**Heating of Raw Milk.** Aliquots of 25 μL of defatted raw milk were transferred to Eppendorf (Hamburg, Germany) tubes and heated in an Eppendorf thermo mixer at 99 °C for 0, 5, 10, 15, and 23 min. After heating, samples were immediately cooled in ice. All heating experiments were performed in triplicate.

Because industrial heating of milk is more efficient than heating in the laboratory scale, the heating conditions had to be adapted to obtain similar modification pattern as observed in commercial products. As shown later, the applied heating conditions modeled the extent of modifications in industrial products well.

**Specific Enzymatic Hydrolysis.** Milk samples (25 μL each) were transferred to Eppendorf tubes and specifically hydrolyzed by the addition of 75 μL of endoproteinase GluC (0.08 μg/μL) in 25 mM phosphate buffer, pH 7.8. The tubes were shaken in an Eppendorf thermo mixer for 16 h at 37 °C. Hydrolyzed proteins were reduced by adding 10 μL of 1 M DTT. Following 30 min of incubation at room temperature, 890 μL of water was added and samples were filtered (PVDF, 0.22 μm; Roth, Karlsruhe, Germany). Under these conditions, 95−100% of the cleavage sites in β-lactoglobulins were specifically hydrolyzed, which was monitored by targeted analysis of peptides with missed cleavages in full scan chromatograms.

**LC-MS/MS Analysis.** LC-MS/MS experiments were carried out on a Dionex (Germering, Germany) Ultimate 3000 RS UHPLC system from Thermo Scientific, coupled to a QTrap 4000, equipped with an electrospray ionization (ESI) source (AB Sciex, Foster City, CA, USA). Aliquots of 10 μL of the protein hydrolysates were separated on a C18 column (Waters (Eschborn, Germany) Acquity UPLC BEH 300, 2.1 × 100 mm, 1.7 μm) at a flow rate of 0.3 mL/min, with a gradient program as follows: 0 min, 5% B; 5 min, 5% B; 55 min, 50% B; 55.5 min, 95% B; and 60 min, 95% B, using 0.1% formic acid as eluent A and acetontrile as eluent B. Equilibration of the column was performed with initial conditions for 6 min prior to each injection. The column was operated at 30 °C. After 1 min, the LC flow was directed into the mass spectrometer for 54 min. Experiments were carried out in the positive mode with the resolution of the quadrupoles set to unit.

**Scheduled Multiple Reaction Monitoring (sMRM).** A sMRM method was developed as described previously.[6] Briefly, sMRM data were acquired using a list that defined transitions for each single modification (one quantifier and two qualifiers per modified peptide as shown in the Supporting Information), indicating the expected retention times and determining a detection window of 40 s. Target scan time was set to 1.2 s. Collision energies and declustering potentials were optimized for each single transition as detailed in the Supporting Information.

**Calculation of Modification Indices.** Modification indices for each modification were calculated from the extracted ion chromatograms of the sMRM runs as follows:

$$\text{index} = \frac{\text{area extracted ion chromatogram (modified peptide)}}{\text{area extracted ion chromatogram (internal standard)}} \times 100$$

Areas of extracted ion chromatograms were obtained by signal integration, which was performed in Analyst 1.5.1 (AB Sciex). The multiplier of 100 was arbitrarily chosen to obtain easily manageable numbers for the indices. The peptide AA 159−162 (QCHI) from β-lactoglobulin was selected as internal standard because its unreactive amino acids were expected not to be modified during thermal treatment (see below).

**Statistical Data Evaluation.** Statistical data evaluation was performed in Microsoft Office Excel 2007. Variance homogeneity was tested with an $F$ test. Levels of significance were then calculated using an unpaired two-tailed Student $t$ test for homoscedastic or heteroscedastic distribution, respectively. A $p$ value <0.05 was considered as significant.

## RESULTS AND DISCUSSION

The goal of the present study was to investigate if the β-lactoglobulin modifications, which had previously been identified in milk, were indeed formed by thermal processes or if they originated from other mechanisms. Therefore, kinetics of the site-specific formation of protein modifications in β-lactoglobulin during thermal treatment of raw milk was systematically investigated by UHPLC-ESI-MS/MS in sMRM mode after specific enzymatic hydrolysis. β-Lactoglobulin was chosen because the structures and binding sites of nePTMs formed during milk processing are well characterized, which is a prerequisite of the present quantitative studies.[6] The method, however, can easily be adapted to other milk proteins, such as the caseins. To confirm that the results are of relevance for industrial processes, the modifications were also semiquantified in commercially available dairy samples. With the aim to cover a broad range of different industrial heating procedures, the following product types were chosen for analysis: raw milk as unheated control, pasteurized milk, ESL milk, UHT milk, sterilized milk, evaporated milk, and coffee cream. Altogether, 52 modifications were analyzed, with 19 different structures at 26 binding sites. Among these modifications were N-terminal and lysine- or arginine-bound glycation or glycoxidation products, oxidation products of methionine, tryptophan, cysteine, and the N-terminus, and, finally, the hydrolysis product of asparagine. Table 1 gives a detailed overview of analyzed modifications and their position in the amino acid sequence. Figure 1 displays the reactions leading to the corresponding protein modifications in thermally processed milk.

**Semiquantification by Means of an Internal Peptide as Standard for Normalization.** Because absolute site-specific quantification of protein modifications is not practicable in default of available standards, we performed semiquantification by normalizing the peak area of a specific modified peptide to an internal standard peptide released during specific enzymatic hydrolysis from β-lactoglobulin, as applied in previous studies.[20] The peptide AA 159−162 (QCHI) from β-lactoglobulin was selected as internal standard because its unreactive amino acids were expected not to be modified during thermal treatment. When raw milk was heated over 23 min, no significant decrease of signal areas could be observed for the peptide AA 159−162 (Figure 2), confirming that the selected peptide was obviously not significantly modified indeed. Furthermore, the enzymatic digestibility of β-lactoglobulin by GluC was not detectably impaired by thermally induced modification. Thus, it could be

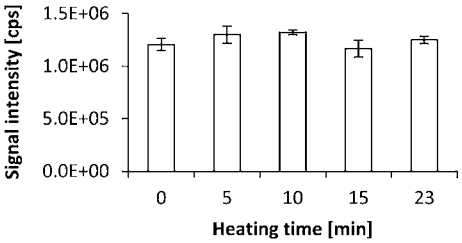

**Figure 2.** Absolute signal intensities of the peptide AA 159−162 (QCHI). $\beta$-Lactoglobulin from raw and heated milk was digested with GluC and analyzed by UHPLC-MS/MS. Intensities were not significantly altered by the heating process. The mean of a triplicate ± standard deviation is displayed.

expected that the normalization of signal areas of the analytes to the signal area of the internal standard peptide compensated for differences in the mass spectrometric performance during different runs. In commercially available dairy products, the concentration of $\beta$-lactoglobulin depends, for example, on the cattle breed or feeding conditions. Industrial processing such as evaporation further influences the protein concentration. Thus, normalizing the signal areas of modified peptides by the signal area of the internal standard peptide also compensates for differences in protein concentrations between different products.

It was expected that protein modifications in milk are present in very small quantities. Therefore, a sensitive sMRM method was developed that considered only the most intense charge state for quantification.[6] Although this approach did not allow for the direct comparison of the modification degree of different modification sites, it provided information on the relative amount of one specific modification site in different samples. Figure 3 summarizes the results obtained for the detected modifications in raw milk heated on a laboratory scale and those found in commercially available milk products.

**Kinetics of N-Terminal Lysine- and Arginine-Bound Glycation Products.** Heating of raw milk at 99 °C resulted in detectable lactosylation of the lysine residues K14, K47, K60, K75/77/83, K91, and K135 (Table 1; Figure 3B−G). Furthermore, glycation of the N-terminal amino group was observed (Figure 3A). Modification indices ranged between 0.99 (K14) and 56.3 (N-terminus). Similar profiles for the formation of the Amadori products were obtained for all affected lysine residues with very low modification rates in raw milk and increasing modification with extended heating. The modification indices of some lysine residues (e.g., K91, see Figure 3F) reached a plateau after prolonged heating. These findings are in very good agreement with previous studies on the kinetics of lactulosyllysine formation in milk proteins, showing a linear function of time in the early phase of milk heating and ending up in a plateau after prolonged heating.[2] It should be noted that the indices do not necessarily correlate with the concentration of modifications, because lower peptide ionization leads to lower modification indices. Nevertheless, it is interesting that only the N-terminus was already remarkably glycated in raw milk (index 16.1), whereas all other Amadori products were of very low intensity in raw milk (indices <1). The presence of the Amadori product in raw milk has been detected before.[7,21] Those initial levels of lactosylated lysine may be formed in vivo or during storage by nonenzymatic, but possibly also by enzymatic reactions. Furthermore, artificial formation during sample workup cannot be fully excluded. However, the background levels in raw milk have been observed not only in the present study but also through the use of other analytical methods including different methods of sample preparation.[7,21] At all lysine residues, a (highly) significant increase of lactulosyllysine was observed after only 5 min of heating, confirming that this modification is a good marker for milk products that underwent a low degree of processing.

In dairy products, clear differences in the modification indices were observed in relation to industrial treatment. In most cases, the glycation degree determined in pasteurized samples was not significantly different from raw milk, whereas ESL treatment led to a significantly higher lactosylation rate at three sites (K60, K75/77/83, K135; Figure 3AA−GG). Depending on the lactosylation site in the amino acid sequence, either sterilized milk and evaporated milk, or coffee cream, or UHT milk showed the highest modification indices. Obviously, the particular sites in protein structures are prone to glycation to variable extent and undergo different subsequent reactions, when the processing conditions vary.[22] It could be concluded from the comparison of evaporated milk with sterilized milk and coffee cream, for example, that the evaporation step led to a particularly severe modification of K47 and K60, whereas K14 and K91 were less affected. The evaporation process leads to a higher concentration of the reactants lactose and lysine residues, which should promote lactosylation in general. However, this effect was not observed for all lysine residues. Most likely, evaporation influenced the conformation of $\beta$-lactoglobulin differently from sole heating. The different process-induced changes of protein conformation may then lead to different molecular environments of the particular lysine residues. The lactosylation of the sites K60, K75/77/83, and K135 reflected moderate heating during the production of ESL milk more sensitively, so that it can be assumed that site-specific analysis of lactulosyllysine may be a more sensitive marker of low-impact heat treatment than the recording of overall lactulosylation as determined, for example, by the furosine method.[21] A previous study already achieved site-specific semiquantification of the Amadori product in $\beta$-lactoglobulin in dairy products by mass spectrometry, applying matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOF-MS) after in-gel digest.[8] However, the former study detected modifications at only three sites (K47, K138/141), probably because the method was less sensitive. The present results of the lactosylation index at K47 in different milk products match former data very well, whereas the present method did not cover K138/141.

CML, the best characterized degradation product of the Amadori product, could be detected in traces in heated raw milk at K8, K14, K69, K70, K75/77, and K101 (Table 1). Higher modification indices of CML, which allowed semiquantifiction, were observed at K47, K60, K91, and K135 (Figure 3H−K). After a lag phase, CML indices increased linearly as a function of heating time and reached final values between 0.03 (K47) and 1.6 (K60). In commercially available milk products, CML was also detected in traces at K83 and K100 as well as at the N-terminus, in addition to the aforementioned sites (Table 1). However, these signals were close to the detection level so that further analyses are required to determine if this observation is indeed related to industrial processing. CML could not be detected at all or only in very low amounts in raw, pasteurized, and ESL milk. All other analyzed milk products showed a clear connection of CML formation to heat treatment (Figure 3HH−KK), with the highest modification indices in sterilized and evaporated milk and coffee cream, which is consistent with previous studies.[4] Thus, it can be

dx.doi.org/10.1021/jf503664y | J. Agric. Food Chem. 2014, 62, 10903–10915

concluded that the presence of CML in milk products is strictly related to thermal treatment during processing. In contrast to lactulosyllysine, different processing conditions did not site-specifically affect the CML formation. As a marker, it may reflect rather intensive heating conditions as applied during UHT treatment and beyond.

CEL was semiquantified in heated milk at K60 (Figure 3L) and detected in traces at K69/70 and K91 (Table 1). The modification index at K60 did not increase significantly during heating at 99 °C, nor could we establish a clear correlation of the modification indices for K60 in commercially available milk products to the heating process (Figure 3LL). On the other hand, CEL at K69/70 and K91 could be clearly detected only in sterilized, evaporated, and UHT milk, but not in coffee cream (Table 1), which may indicate some influence from the processing conditions. It has been shown before that dehydrogenases from *Lactococcus (Streptococcus) lactis* are able to form CEL by reductive alkylation of lysine with pyruvate.[4] Thus, the microbial activity may be a more important source of CEL in some samples than thermal processes. Ahmed et al. measured protein-bound CEL in three samples of raw, pasteurized, and sterilized milk and found significantly higher concentrations in pasteurized and sterilized milk compared to raw milk, but not in sterilized milk compared to pasteurized milk.[23] Altogether, the findings indicate that nonthermal processes may also be an important source of CEL in milk products, so that this modification cannot be used as convincing marker for heat treatment in this product group.

No arginine glycation products could be detected in $\beta$-lactoglobulin from heated raw milk (Table 1), although the presence of methylglyoxal-dihydroxyimidazoline, methylglyoxal-imidazolinone, and 3-deoxygalactosone-/3-deoxyglucosone-imidazolinone has been reported for $\beta$-lactoglobulin after heating with lactose.[6] Due to their relatively low stability, they may react further with other milk ingredients. However, traces of methylglyoxal-dihydroxyimidazoline were detected at R124 in sterilized and evaporated milk (Table 1) and, furthermore, small amounts of methylglyoxal-imidazolinone were shown to be present at R40 and R124 in more severely heated products (Table 1). As with CEL, Ahmed et al. detected protein-bound methylglyoxal-imidazolinone in significantly higher concentrations in pasteurized and sterilized milk samples compared to raw milk, but not in sterilized compared to pasteurized milk.[23] Thus, the present results suggest that methlyglyoxal-derived arginine modifications are formed to some extent upon thermal milk processing, but their relevance is low compared to other protein modifications.

**Kinetics of Oxidation Products.** When defatted milk was heated at 99 °C, we could observe oxidation of methionine to the sulfoxide, of cysteine to the sulfonic acid, and of tryptophan to hydroxytryptophan (Table 1; Figure 3M−P,R,S).

Methionine is very easily oxidized, in a first step yielding methionine sulfoxide, which has already been reported to be present in heated milk and, particularly, in whey protein and caseinate preparation.[8,9] Methionine sulfoxide could be detected in raw milk at all four methionine residues (M7, M24, M107, M145), which may be partially caused by oxidation processes during sample preparation or by enzymatic processes, for example, through lactoperoxidase (Table 1).[24] When raw milk was heated for a short time, relatively low, but significant, increases in the indices of methionine sulfoxide were found at M7, M24, and M145 (Figure 3M−P). However, prolonged heating did not lead to a further increase of methionine oxidation. In the case of M107, in contrast, no formation of methionine sulfoxide was observed as a consequence of thermal treatment. On the other hand, a clear tendency toward higher indices of methionine sulfoxide was observed with increasing severity of the thermal treatment in pasteurized, ESL, UHT, and sterilized milk, and, at all methionine residues, even higher indices were measured in sterilized milk and coffee cream (Figure 3MM−PP). Evaporated milk, in contrast, had surprisingly low indices, indicating further reactions of methionine residues during the concentration step (Figure 3MM−PP). In coffee cream, which has the highest fat content of all samples, the generation of reactive oxygen species during lipid oxidation very likely promoted oxidation of methionine to the sulfoxide.[20] This hypothesis is supported by the results for evaporated milk: the product with the highest fat content (7.5%) had very high indices for methionine sulfoxide at M7 and M24 (0.65 and 0.12, respectively), whereas the other five products were much less affected (0.17−0.28 and 0.02−0.05, respectively) (Figure 3MM,NN). Because lipid oxidation may be an important contributor to the formation of methionine sulfoxide, it can be assumed that heating of whole milk has a greater effect than heat treatment of defatted milk as performed in the present study. Thus, it may be concluded that methionine sulfoxide is a rather poor indicator of thermal impact but may reflect the lipid oxidation rate during processing very well.

Although methionine sulfone could be detected at M107, its index was stable during the heating of raw milk, and the indices measured in commercially available milk samples did not suggest that formation of the sulfone was dependent on the process parameters (Figure 3Q). In evaporated milk, the intensities of sulfone were very low, indicating once more that methionine underwent further reactions during the evaporation processes (Figure 3QQ). Thus, it is likely that methionine sulfone in milk results from enzymatic post-translational modification rather than from chemical modification during thermal treatment.

Oxidation of cysteine to the sulfinic acid during heating of raw milk was detected only in traces at C119 (Table 1). In the peptide used as internal standard (AA 159−162, QCHI), oxidation of cysteine could not be detected.[6] A trend toward higher concentration of sulfinic acid at C119 was observed in commercially available products (Table 1), suggesting heat-dependent oxidation. At C66, significantly higher indices for cysteine sulfonic acid were also found as a result from the heating of raw milk (Figure 3R). However, the analysis of commercial milk products did not confirm these findings, because the products showed high variations of the cysteine sulfonic acid concentration at C66, C119, and C121 without clear correlation with the heat treatment (Table 1; Figure 3RR). Obviously, the nonenzymatic oxidation of cysteine to the sulfonic acid is of minor importance in heated milk products. Cysteine sulfenic acid is not covered by the method because it is reduced by the addition of DTT prior to mass analysis.

When $\beta$-lactoglobulin was heated in a milk-resembling system, hydroxytryptophan, *N*-formylkynurenine, kynurenine, and hydroxykynurenine were reported as oxidation products of tryptophan.[6] Only traces of hydroxytryptophan were detected at W19, when raw milk was heated at 99 °C (Table 1). Semiquantification at W61 revealed that the indices for hydroxytryptophan first significantly increased during heating but that the amino acid approached its initial concentration during prolonged reaction (Figure 3S). Thus, formation of hydroxytryptophan is probably promoted by thermal processing, although the product is not stable, but further degraded. UHT, sterilized, and evaporated milk as well as coffee cream contained

higher levels of hydroxytryptophan than less severely heated milk, confirming heat-dependent oxidation of tryptophan (Figure 3SS). It is interesting to note that the striking variance in the indices of evaporated milk is due to a single sample which contained more fat (7.5%; index 1.75), whereas the five other products with fat contents between 3 and 4% showed indices between 0.45 and 0.75. Probably, lipid-dependent generation of reactive oxygen species led to the higher oxidation degree of tryptophan at W61 observed in the outlier. However, it cannot be excluded that differences in the heating process also contributed to the observed variance.

*N*-Formylkynurenine at W61 was naturally present in raw milk and significantly decreased from an index of 5.4 to 1.2 when the raw milk was heated (Figure 3T). It seems likely that it was further degraded. However, kynurenine, a possible degradation product of *N*-formylkynurenine, also decreased significantly at W19 and W61 during heating (Figure 3U,V) indicating that further/other degradation reactions must be responsible for the decrease of *N*-formylkynurenine and kynurenine. The observation that tryptophan was hydroxylated (see above) and that hydroxykynurenine has been detected in a model system, when $\beta$-lactoglobulin was heated in a milk-resembling system with lactose,[6] gives rise to the assumption that the aromatic rings of *N*-formylkynurenine and kynurenine were oxidized. The oxidized products could, however, not be detected in heated milk (see Table 1) and were apparently below the detection limit of the applied method. The analyzed milk products showed the same trend as heated raw milk, with high contents of *N*-formylkynurenine and kynurenine at W19 and W61, respectively, in mildly treated milk and lower contents in more severely heated products (Figure 3TT−VV).

Altogether, these results lead to the assumption that enzymatic processes probably contribute largely to the presence of tryptophan modifications in raw milk. Additionally, further degradation reactions of primary tryptophan modifications, which have not been elucidated yet, must take place during thermal treatment.

Recently, N-terminal $\alpha$-ketoamide was detected in $\beta$-lactoglobulin in sterilized milk, resulting from the oxidation of the N-terminal amine functional group.[6] The present study revealed that detectable amounts of the $\alpha$-ketoamide were already present in raw milk, with a modification index of 0.2 (Figure 3W). The index increased during heating of raw milk and reached a final value of 0.45. Possibly, reactive intermediate products from the Maillard reaction such as dicarbonylic structures favored the oxidation, as proposed by Akagawa et al.[25] In commercial milk products, significantly higher indices were observed in UHT milk, sterilized milk, and coffee cream, reflecting the heat-dependent formation (Figure 3WW). In evaporated milk, in contrast, the concentrations of the N-terminal $\alpha$-ketoamide were very low. The examined structure has a highly reactive $\alpha$-dicarbonyl group and, probably, underwent further reactions during the industrial concentration of the product.

**Kinetics of the Hydrolysis of Asparagine.** Heating of raw milk resulted in the hydrolysis of asparagine N63 to aspartic acid. The hydrolysis occurred linearly (Figure 3X). Interestingly, the modification index in raw milk was higher (index 2.1) than in milk heated for 5 min at 99 °C (index 1.0). This leads to the assumption that the deamidation in raw milk was partially catalyzed by milk asparaginase during sample preparation. Thermal treatment probably deactivated the asparaginase, preventing any additional deamidation during sample workup of the heated samples. The results obtained for the analyzed milk samples also reflected the heat-dependent hydrolysis of N63, with sterilized milk having the highest modification index (Figure 3XX). Deamidation of N63 has already been observed during the storage of UHT milk[26] and, thus, the presented modification indices might have been partially influenced by different storage periods of the products. Still, the heat-dependent formation is clearly visible and in good accordance with a previous study,[27] providing evidence for the heat-induced deamidation of milk protein.

Previously, it has been shown that a great variety of protein modifications are present in processed milk affecting, for example, lysine, arginine, methionine, cysteine, tryptophan, asparagine, and the N-terminus.[6] The present study performed semiquantitative analyses of these modifications to reveal the origin of the compounds. As expected, lactosylation of lysine and the N-terminus as well as CML formation was observed as consequences of thermal treatment. Additionally, hydroxytrypophan and the ketoamide of the N-terminus as well as deamidation of asparagine were detected as thermal reaction products. The formation of CEL, cysteine sulfonic acid, methionine sulfone, *N*-formylkynurenine, and kynurenine, in contrast, rather seems to depend on enzymatic processes in the raw milk. Further degradation of *N*-formylkynurenine and kynurenine, however, was detected again as thermal reaction. Finally, the formation of methionine sulfoxide reflected heat treatment only to some extent, but was obviously more strongly related to lipid oxidation processes. Thus, product-specific semiquantification of a variety of post-translational modifications helped to shed light on different enzymatic and nonenzymatic processes that occur during the heating and storage of milk. The newly acquired information may be helpful to develop custom-tailored markers for different industrial processes and storage conditions. Additionally, site-specific semiquantification revealed that the site-specific analysis of a modification may lead to highly sensitive markers. For example, lactosylation of K60, K75/77/83, and K135 indicated a difference between pasteurized milk and ESL milk, whereas lactosylation of other lysine residues and the N-terminus did not reflect the minor differences in the thermal impact of these two production processes.

In the future, highly sensitive and truly untargeted methods will be required to comprehensively elucidate all post-translational protein modifications that have escaped identification so far. Furthermore, controlled storage experiments are required to differentiate between storage and heating effects in commercial samples.

deoxyanthocyanidins, which otherwise have only been found in the flowers of sinningia (*Sinningia cardinalis*), the silk tissues of maize (*Zea mays*), and the stalks of sugar cane (*Saccharum* sp.).[17−19]

In sorghum grains, polyphenol compounds can be found in the pericarp (outer seed coat) and the testa (inner layer of tissue between the pericarp and the endosperm). A number of classical loci identified by their effects on grain color and testa presence control the presence or absence of polyphenol compounds in sorghum.[20] Genotypes with dominant alleles at the B1 and B2 loci have proanthocyanidins in the testa. Genotypes with a dominant allele at the spreader (S) locus, as well as dominant alleles at the B1 and B2 loci, have proanthocyanidins in both the pericarp and the testa, often, but not always, resulting in a brown appearance to the grain. The base pericarp color is red, yellow, or white, and these colors are controlled by the R and Y loci. The S locus and additional loci, such as intensifier (I) and mesocarp thickness (Z), modify the base pericarp color, resulting in a range of colors from brilliant white to black with various shades of red, yellow, pink, orange, and brown among sorghum genotypes (see Figure 1). Using mutants for seed color traits, the

**Figure 1.** Natural variation in sorghum grain color. Three accessions (with three seeds of each accession) of grain with the appearance of (A) brown (PI597965, PI533927, PI35038), (B) white (PI533755, PI533845, PI534028), (C) yellow (PI659691, PI656011, PI533776), and (D) red (PI576418, PI534047, PI564165) pericarps. The outer coat has been scraped off of some samples, revealing the presence or absence of a pigmented testa.

biochemical and regulatory pathways underlying flavonoids and flavonoid products have been almost completely elucidated in *Arabidopsis* and maize, and extensively studied in other species (Table S1 in the Supporting Information).[21] Therefore, homology can be used as a guide to discover genes involved in the sorghum flavonoid pathway. The gene underlying the B2 locus was recently cloned and designated *Tannin1*, along with two nonfunctional alleles of *Tannin1*, *tan1-a* and *tan1-b*.[22] *Tannin1* encodes a WD40 protein homologous to the *Arabidopsis* proanthocyanidin regulator *transparent testa glabra1* (*TTG1*). The gene underlying the Y locus has also been cloned and designated *Yellow seed1*. *Yellow seed1* encodes a MYB protein, orthologous to the maize 3-deoxyanthocyanidin regulator *P1*, that is needed for accumulation of 3-deoxyanthocyanidins in the sorghum pericarp.[23] The R locus has been mapped to chromosome 3 between 57 and 59 Mb, and the Z locus has been mapped to chromosome 2 between 56 and 57 Mb,[24] but the underlying genes have not been identified.

While the genetic controls of polyphenol presence/absence have been well-studied using mutant lines and nonfunctional polymorphisms, there has been little study of quantitative natural variation in polyphenols.[25] Polyphenol nonfunctional mutations were strongly selected during cereal domestication, when bitter tasting and/or dark compounds were partly or completely lost in most cereals, including wheat, rice, and maize.[26] However, sorghum provides a valuable resource for polyphenol diversity, as adaptation to different environments has led to extensive phenotypic and genetic diversity in the crop.[13,27] This diversity can be useful for biofortification and crop improvement (e.g., desirable traits can be bred into existing elite varieties), but quantitative phenotyping is needed to identify alleles responsible for quantitative trait variation in grain polyphenols (reviewed by Flint-Garcia[28]). The goals of this study were to quantify the natural variation of two of the major sorghum grain polyphenols (proanthocyanidins and 3-deoxyanthocyanidins) and to identify single-nucleotide polymorphisms (SNPs) that are associated with low or high polyphenol concentrations using genome-wide association studies (GWAS). GWAS are used to map the genomic regions underlying phenotypic variation (known as quantitative trait loci) by scanning the genome for statistical associations between genetic variation and phenotypic variation.[29] In contrast to the biparental linkage mapping approach, GWAS takes advantage of historical recombinations in a diverse panel and linkage disequilibrium between causal variants and nearby SNP markers. Although it has been used extensively to identify putative genetic controls of human disease,[30] it is a relatively new but promising tool in plant genomics.[27,31,32] Here we present a survey of the quantitative natural variation of polyphenols in a diverse worldwide panel of sorghum and a catalog of flavonoid-associated loci across the sorghum genome.

## MATERIALS AND METHODS

**Plant Materials.** We investigated a total of 381 sorghum accessions, comprising 308 accessions from the Sorghum Association Panel (SAP)[33] and an additional 73 accessions selected based on presence of a pigmented testa using the U.S. National Plant Germplasm System's Germplasm Resources Information Network (GRIN).[34] The SAP includes accessions from all major cultivated races and geographic centers of diversity in sub-Saharan Africa and Asia, as well as important breeding lines from the United States. The 73 additional accessions were included to increase the proportion of accessions with high proanthocyanidins.

Seeds were obtained through GRIN and planted in late April 2012 at Clemson University Pee Dee Research and Education Center in Florence, SC. A 2-fold replicated complete randomized block design was used. Panicles from each plot were collected at physiological maturity (signified by a black layer at the base of the seed that normally forms about 35 days after anthesis). Due to differences in maturity among these accessions, harvest occurred between September and October. Once harvested, panicles were air-dried in a greenhouse and then mechanically threshed, and any remaining glumes were removed with a wheat head thresher (Precision Machine Company, Lincoln, NE).

**Phenotyping.** Twenty grams of cleaned whole grain from one replicate was scanned with a FOSS XDS spectrometer (FOSS North America, Eden Prairie, MN, USA) at a wavelength range of 400−2500 nm. To determine reproducibility, duplicates on a subset of 218 accessions available from replicate plots were also scanned. The NIR reflectance spectra were recorded using the ISIscan software (Version 3.10.05933) and converted to estimates of total phenol, proanthocyanidin, and 3-deoxyanthocyanidin concentrations. The spectrometer, software, and calibration curves used in this study were recently described.[35] Samples with unusual reflectance were visually inspected, and near-infrared spectroscopy (NIRS) was repeated. Seventeen samples were removed from further analysis either because they

contained mixed grain (mixed size, shape, or color) or because their readings were outside the range of the available NIRS calibration curve. Total phenol, proanthocyanidin, and 3-deoxyanthocyanidin data are expressed as mg gallic acid equivalents (GAE)/g, mg catechin equivalents (CE)/g, and absorbance (abs)/mL/g, respectively. These were the units used in creating the calibration curves, which measured total phenols with the Folin−Ciocalteu method, 3-deoxyanthocyanidins with the colorimetric method of Fuleki and Francis, and proanthocyanidins with the modified vanillin/HCl assay.[35] For the purposes of this study, we use a cutoff of greater than 10.00 mg CE/g to define proanthocyanidin-containing varieties and greater than 50.00 abs/mL/g to define 3-deoxyanthocyanidin-containing varieties.

Visual appearance of grain was classified independently by two people by visually scoring three seeds per accession as white, yellow, red, or brown. Testa presence was identified with three seeds per accession by cutting a thin layer off the pericarp and examining under a dissecting microscope. The total grain weight of 100 seeds per accession was recorded.

**Genomic Analysis.** Genotypes were available for the 324 accessions that were part of the SAP.[27] Genotyping-by-sequencing (GBS) was performed for the 73 additional accessions by the Institute for Genomic Diversity using the methods by Elshire et al.[36] Briefly, we provided seeds of the 73 additional accessions (the same seeds obtained from GRIN that we used to grow our panel) to the Institute for Genomic Diversity, where the following work was performed: Seedlings were grown to obtain tissue, DNA was isolated using the Qiagen DNeasy Plant kit, genomic DNA was digested individually using ApeKI, 96X multiplexed GBS libraries were constructed, and DNA sequencing was performed on the Illumina Genome Analyzer *IIx*. To extract SNP genotypes from sequence data, the GBS pipeline 3.0 in the TASSEL software package[57] was used, with mapping to the BTx623 sorghum reference genome.[37] Missing genotype calls were imputed using the FastImputationBitFixedWindow plugin in TASSEL 4.0.[38]

GWAS was carried out on 404,628 SNP markers, using the statistical genetics package Genome Association and Prediction Integrated Tool (GAPIT)[39] with both a general linear model (GLM) and a mixed linear model (MLM) with kinship. In a previous study we found that an MLM[40] with kinship (K), which controls for relatedness among the accessions in the panel, performs well to identify causative loci for sorghum polyphenols.[41] Bonferroni correction (family wise *P*-value of 0.01, $P < 10^{-6}$) was used to identify significant associations. Pseudoheritability (proportion of phenotypic variation explained by genotype) was estimated from the kinship (K) model in GAPIT[42] as the *R*-squared of a model with no SNP affects. A previously developed a priori candidate gene list was used, and 35 additional candidate genes were added (see Supporting Information).[41]

## RESULTS

**Quantitative Variation in Grain Polyphenols.** We first sought to determine the reliability of the NIRS estimates across the diverse material in the panel. Phenotypic variation for grain polyphenol concentrations was determined using a diverse association panel with 381 accessions (Figure 2). The standard deviation between the duplicates was similar across all concentrations of polyphenols ($r^2$ = 0.06, $P$ = 0.0001) and proanthocyanidins ($r^2$ = 0.01, $P$ = 0.12), with an average difference of 47% and 4%, respectively. However, the standard deviation between the 3-deoxyanthocyanidin duplicates becomes much larger for samples with higher 3-deoxyanthocyanidin concentrations ($r^2$ = 0.32, $P = 10^{-17}$), with an average difference of 72% (Figure 2C). To determine if the NIRS measurements of proanthocyanidin concentration were concordant with the known distribution of testa and *tan1-a* nonfunctional allele,[22] we plotted proanthocyanidin concentration of accessions with or without a pigmented testa (Figure

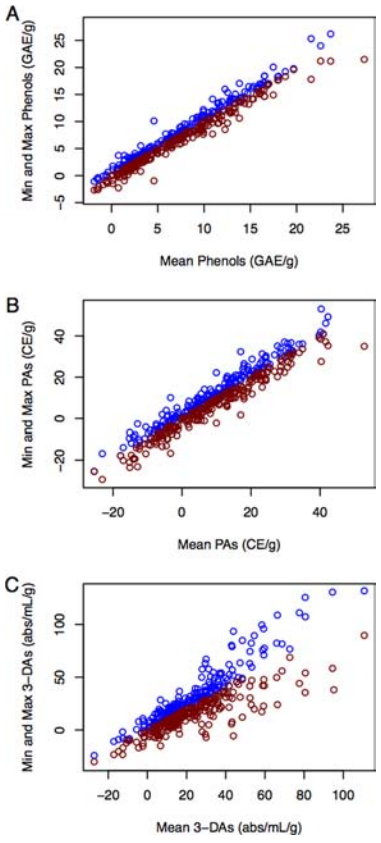

**Figure 2.** Phenotypic variation of grain polyphenol concentrations in 381 sorghum varieties. Samples are ordered on the *x*-axis according to their mean value for the accession. The observed value for each replicate is given on the *y*-axis, with the higher value of the duplicates in red and the lower value of the duplicates in blue. (A) Total polyphenols, (B) proanthocyanidins (PAs), and (C) 3-deoxyanthocyanidins (3-DAs).

S1A in the Supporting Information), and accessions with the wild-type *Tannin1* allele or the *tan1-a* allele (Figure S1B in the Supporting Information). As expected, the absence of a testa and presence of *tan1-a* were primarily found in accessions containing less than 10 mg CE/g of proanthocyanidins. The mean proanthocyanidin concentrations in accessions with a pigmented testa were significantly higher than in accessions without a pigmented testa (18.17 versus 1.45 mg CE/g; $P = 10^{-17}$), and the mean proanthocyanidin concentrations in accessions with the wild-type *Tannin1* were significantly higher than in accessions with *tan1-a* (12.28 versus 0.86 mg CE/g; $P = 10^{-11}$).

Next we investigated the range of total phenol, proanthocyanidin, and 3-deoxyanthocyanidin concentrations and their covariation with each other and grain weight (Figure 3). Overall, proanthocyanidins were detected in 55% of the samples, while only 13% contained 3-deoxyanthocyanidins, and only 6% contained both polyphenols. The mean total polyphenol concentration was 7.00 mg (GAE)/g, the mean proanthocyanidin concentration was 7.73 mg CE/g, and the mean 3-deoxyanthocyanidin concentration was 27.40 abs/mL/g (Table 1 and Figure 3). Pearson's correlations were calculated between total phenols, proanthocyanidins, and 3-deoxyanthocyanidins. There was no significant correlation between proanthocyanidins and 3-deoxyanthocyanidins (0.02, $P$ = 0.7), consistent with independent genetic control. In contrast,

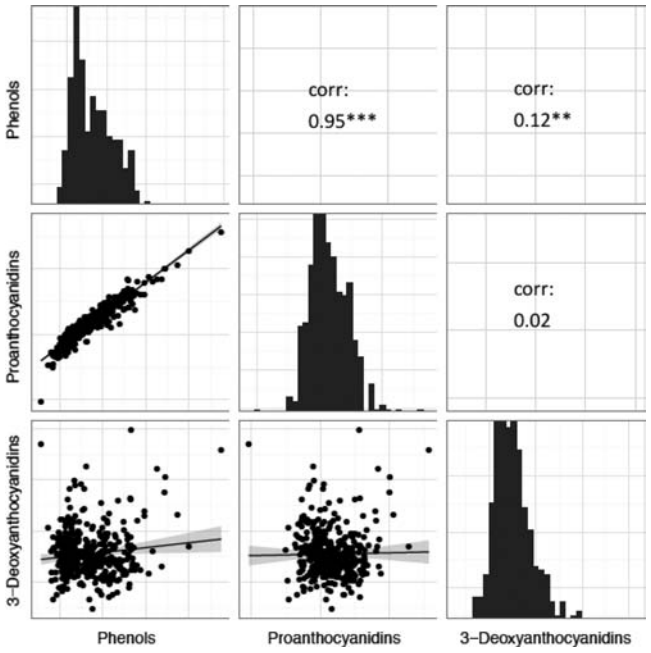

**Figure 3.** Relationship within and between grain polyphenol traits in a global sorghum germplasm collection. The center diagonal presents histograms of the mean concentrations of each trait ($n$ = 381). The lower corner contains scatter plots with regression lines showing the relationships between the traits. The upper corner shows Pearson's correlations between the traits. Units are mg GAE/g for total phenols, mg CE/g for proanthocyanidins, and abs/mL/g for 3-deoxyanthocyanidins.

**Table 1. Polyphenol Concentrations in 373 Sorghum Varieties**

| constituent | mean | range | SD |
|---|---|---|---|
| total phenols (mg GAE/g) | 7.00 | ND−37.46 | 5.92 |
| proanthocyanidins (mg CE/g) | 7.73 | ND−78.51 | 15.45 |
| 3-deoxyanthocyanidins (abs/mL/g) | 27.40 | ND−149.21 | 24.05 |

there were a strong positive correlation between total phenols and proanthocyanidins (0.95, $P < 10^{-15}$) and a weak positive correlation between total phenols and 3-deoxyanthocyanidins (0.12, $P$ = 0.02). Variance in proanthocyanidins accounted for 90% of all the variance in total phenols (Figure 3). Since the seed coat (pericarp and testa) contains most of the polyphenols in the grain, and the ratio of seed coat (surface area) to endosperm is generally greater in smaller grains, we wondered if differences in grain size might be underlying variation in polyphenol concentrations. In other words, are high grain polyphenol concentrations limited to small-grain varieties, which have a high proportion of seed coat to endosperm? No significant correlation was found between grain weight and either proanthocyanidins (−0.02, $P$ = 0.7) or 3-deoxyanthocyanidins (−0.02, $P$ = 0.7), and a small negative correlation was found between grain weight and total polyphenols (−0.10, $P$ = 0.04). Pseudoheritability was 81.7% for proanthocyanidins and 66.5% for 3-deoxyanthocyanidins.

**Population Structuring of Polyphenol Concentrations.** To determine the distribution of polyphenol traits with respect to global genetic diversity, we conducted a principal component analysis and highlighted the variation in polyphenol concentration (Figures S2A and S2B in the Supporting Information), as well as morphological races (Figure S2C in the Supporting Information). At least some high proanthocyanidin accessions were found in most subpopulations, whereas high 3-deoxyanthocyanidin accessions were more restricted (Table 2). Bicolor (21.18 mg CE/g) and guinea-caudatum (17.89 mg CE/g) had the highest mean concentration of proanthocyanidins. Caudatum had moderate concentrations (13.20 mg CE/g), and the other botanical races and intermediate groups showed an average less than 10.00 mg CE/g. The highest mean concentrations of 3-deoxyanthocyanidins were found in bicolor-durra (36.95 abs/mL/g) and guinea (35.63 abs/mL/g) accessions (Table 2). We also determined the mean concentrations by country to better understand the geographic patterns for sorghum polyphenols (Table 3). Accessions from Uganda (19.03 mg CE/g) had the highest mean proanthocyanidin concentrations, accessions from South Africa (12.23 mg CE/g) and Sudan (10.33 mg CE/g) had moderate concentrations, while accessions from the other countries showed an average less than 10.00 mg CE/g. The highest mean concentrations of 3-deoxyanthocyanidins were found in accessions from Nigeria (36.39 abs/mL/g) and Ethiopia (32.87 abs/mL/g).

**Genome-Wide Association Studies.** To investigate the genetic basis of natural variation in sorghum grain polyphenols, we conducted GWAS using 404,628 SNP markers. We were able to obtain genotype data for 373 out of the 381 phenotyped accessions. As a data quality check, we first collapsed the quantitative proanthocyanidin data to qualitative (presence or absence) data, and were able to repeat findings from previous GWAS and linkage studies (Figures S3 and S4 and Tables S2 and S3 in the Supporting Information). Next, to identify novel alleles associated with quantitative variation of proanthocyani-

[a]If a country contained a small sample size (less than 10 accessions), it was not included in this analysis. PA, proanthocyanidins; 3-DA, 3-deoxyanthocyanidins; ND, not detected (absorbance was less than 0.001).

dins, we conducted a GWAS on the 373 accessions (Figure 4; Table S4 in the Supporting Information). A GLM identified 3,272 significant SNPs (Figure 4A), while the MLM identified 24 significant SNPs after accounting for population structure (Figure 4B). The genomic locations of the association peaks were generally similar between methods. A peak on chromosome 4 at ∼61 Mb colocalized with *Tannin1* (Sb04g031730), as well as three a priori candidate genes in the region: a putative *Zm1* homologue (Sb04g031110), a putative *TTG1* homologue (Sb04g030840), and a putative *TT16* homologue (Sb04g031750) (Figure 4C). The GLM identified a peak at 58.6 Mb on chromosome 7 (S7_58603858; $P < 10^{-15}$), which was not present in the MLM.

In order to reduce the effects of known *Tannin1* nonfunctional alleles and identify additional quantitative loci, samples with the *tan1-a* and *tan1-b* alleles were removed and a GWAS was conducted on the remaining samples (Figure 5 and Table S5 in the Supporting Information). The GLM identified 2,641 significant SNPs (Figure 5A). The association peak on chromosome 7 was again identified in the GLM and not in the MLM (Figure 5B). Additionally, there was a peak on chromosome 2 around 8 Mb (S2_8258226; $P < 10^{-11}$) identified in the GLM, near a putative *TT8* homologue (Sb02g006390). Both the GLM and the MLM identified a peak on chromosome 4, again around 61 Mb, and another peak on chromosome 4 between 53 Mb and 55 Mb, close to an F3′H *Pr1* coorthologue.

To further map loci controlling quantitative proanthocyanidin variation, we ran a GWAS only on samples that contained proanthocyanidins (greater than 10.00 mg CE/g) and/or had a visible pigmented testa (Figure 6 and Table S6 in the Supporting Information). With this subset, there were 676 significant SNPs identified in the GLM, but association peaks were more diffuse (Figure 6A). The most significant SNP was on chromosome 6 (S6_56992521, $P < 3 \times 10^{-10}$) near a *TT16* a priori candidate (Sb06g028420). The MLM identified two significant SNPs, with a peak on chromosome 4, again around 61 Mb, and another peak on chromosome 4 between 53 Mb and 55 Mb (Figure 6B). Both the GLM and the MLM identified significant SNPs around 61.1 Mb on chromosome 1, which is near *yellow seed1*.

Next, a GWAS was conducted to identify genetic controls of 3-deoxyanthocyanidin variation among the 373 accessions (Figure 7 and Table S7 in the Supporting Information). The GLM identified 233 significant SNPs, with distinct association peaks on chromosomes 3 and 4 (Figure 7A). The peak on chromosome 3 was between 71 and 72 Mb and colocalized with a gene (Sb03g045170) homologous to both *TT18* (ANS) and *TT6* (F3H). The peak on chromosome 4 was between 53 Mb and 55 Mb, close to *TT1* and *TT2* homologues, and an F3′H *Pr1* coorthologue. While there was not a distinct peak on chromosome 1, the strongest association signal in the GWAS was found in a diffuse peak on chromosome 1 around 55 Mb ($P < 10^{-9}$). The closest a priori candidates were putative *TTG2* (Sb01g032120) and *TT2* (Sb01g032770) homologues. There were no distinct peaks or significant associations identified in the MLM (Figure 7B).

**Grain Color.** Since grain color is commonly used as a visual marker for sorghum polyphenol content, we used our data set to better understand both the correlation between visually scored grain color and polyphenol concentration, and the potential shared genetic basis for these traits. Based on visual assessment of grain appearance, we designated 142 white, 35 yellow, 48 red, and 152 brown grain accessions. An analysis of variance (ANOVA) showed significant variation among the grain color groups, so we conducted a post hoc Tukey test. Grain classified as red contained significantly more 3-deoxyanthocyanidins than brown ($P < 10^{-5}$) or white grain ($P < 10^{-5}$) accessions, but no significant difference was found between red and yellow accessions (Figure 8A and Table 4). Brown grain accessions contained significantly more proanthocyanidins than accessions with red ($P = 0.0001$), white ($P = 0.001$), or yellow ($P = 0.001$) grain (Figure 8B and Table 4). This was expected as most of the sorghums with testa layers were classified as brown (57%). We also compared proanthocyanidin concentrations between grain color in proanthocyanidin-containing (greater than 10.00 mg CE/g or presence of pigmented testa) accessions. Brown grain color classes contained significantly more proanthocyanidins than nonbrown (brown $n = 120$, nonbrown $n = 85$, $P < 10^{-13}$). However, when brown grain color classes were compared to each color class individually, they only contained significantly more proanthocyanidins than white color classes ($P < 10^{-4}$). Red and lemon-yellow grain color classes also contained significantly more proanthocyanidins than white in the proanthocyanidin-containing accessions ($P = 0.001$ and $P = 0.02$).

To identify genes associated with brown grain, we conducted a presence/absence (brown versus nonbrown) GWAS on all 373 of the accessions (Figures S5A and S5B and Table S8 in the Supporting Information) and another presence/absence (brown versus nonbrown) GWAS on the 203 proanthocyanidin-containing accessions (Figures S5C and S5D and Table S9 in the Supporting Information). A distinct association peak on chromosome 8 at 52.9 Mb was observed in both GWAS. The nearest a priori candidate was a putative *TT12* homologue within 400 Kb (Sb08g021640). The GWAS conducted on all 373 accessions identified a peak on chromosome 3 at 63.6 Mb,

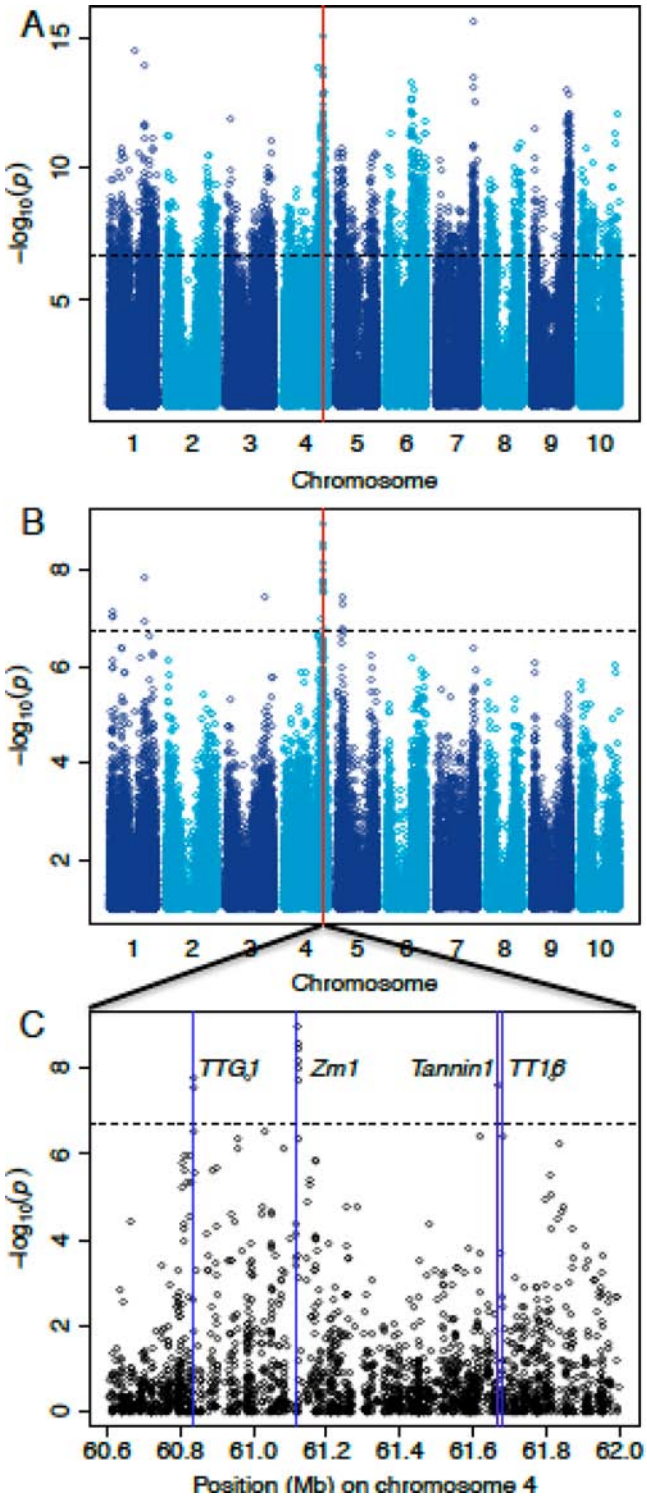

**Figure 4.** GWAS for proanthocyanidin concentration in sorghum grain. Manhattan plot of association results from (A) a GLM analysis, (B) an MLM analysis, and (C) a closeup of the peak on chromosome 4 showing *Tannin1* and other candidate genes in the region, using 404,628 SNP markers and 373 accessions. Axes: the $-\log_{10}$ *p*-values (*y* axis) plotted against the position on each chromosome (*x* axis). Each circle represents a SNP. The dashed horizontal line represents the genome-wide significance threshold as determined by Bonferroni correction. Regions with $-\log_{10}$ *p*-values above the threshold are candidates. The vertical lines indicate the location of *Tannin1* and a priori candidate genes in the *Tannin1* region (~61 Mb).

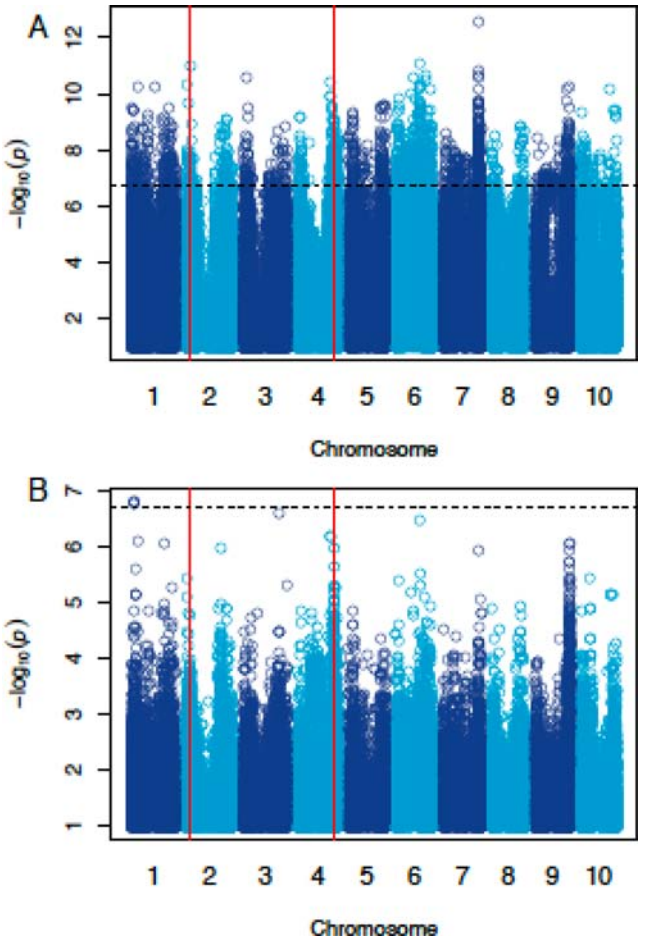

**Figure 5.** GWAS for proanthocyanidin concentration in sorghum grain with accessions containing *tan1-a* and *tan1-b* nonfunctional alleles removed. Manhattan plot of association results from (A) a GLM analysis and (B) an MLM analysis, using 404,628 SNP markers and 312 accessions. Axes: the $-\log_{10}$ *p*-values (*y* axis) plotted against the position on each chromosome (*x* axis). Each circle represents a SNP. The dashed horizontal line represents the genome-wide significance threshold as determined by Bonferroni correction. Regions with $-\log_{10}$ *p*-values above the threshold are candidates. The red vertical lines highlight the location of candidate genes. (TT8 on chrm. 2 and *TTG1*, *Zm1*, and *TT16* on chrm. 4)

within 100 Kb of another putative *TT12* homologue (Sb03g035610), and also a peak on chromosome 6 (S6_56992521, $P < 3 \times 10^{-10}$) near a *TT16* a priori candidate (Sb06g028420) (Figures S4A and S4B in the Supporting Information). The GWAS conducted on the proanthocyanidin-containing accessions identified a peak on chromosome 2 around 69.6 Mb, very near another *TT12* homologue (Sb02g034720) (Figures S5C and S5D in the Supporting Information). This peak was also identified in the GWAS conducted on all 373 accessions, but was more diffuse. There were no peaks on chromosome 4 around *Tannin1* or on chromosome 2 around the Z locus.

To identify genes associated with red grain, we conducted a presence/absence (red versus nonred) GWAS on all of the samples (Figure S6 and Table S10 in the Supporting Information). Two association peaks on chromosome 4 were identified by both the GLM and MLM, in the same region as the peak in the 3-deoxyanthocyanidin GWAS. The first peak, at 54.5 Mb, colocalized with a priori candidate Sb04g024710, the

F3′H *Pr1* coorthologue that was also in one of the 3-deoxyanthocyanidin GWAS peaks. The second peak, at 55.9 Mb, was very close to a priori candidate Sb04g026480, a putative MYB homologue. There was also a peak around 72 Mb on chromosome 3, in the same region as the peak in the 3-deoxyanthocyanidin GWAS, near a priori candidate Sb03g044980, a putative *TT19* homologue. A peak was identified on chromosome 6 between 7 and 8 Mb, which was not near any a priori genes, but was near a putative vacuolar sorting protein gene (Sb06g003780). There were no peaks on chromosome 3 around the R locus.

## DISCUSSION

**Genetic Controls of Sorghum Polyphenols.** The genetic controls of the flavonoid pathway (Figure 9) have been well studied in many economically important food plants, including grape (*Vitis vinifera*), barley (*Hordeum vulgare*), maize (*Zea mays*), rice (*Oryza sativa*), and wheat (*Triticum* spp.).[43] Much of our understanding of flavonoid genetics, including biosynthetic enzymes, transporters, and regulatory proteins, come from analysis of Transparent Testa (TT) mutants in *Arabidopsis*.[44] Transcriptional regulation occurs through a ternary complex made up of *TT2*, *TT8*, and *TTG1*, which encode for MYB, bHLH, and WD40 proteins (MBW complex), respectively.[44] This ternary complex is highly conserved among plant species.[45] In the sorghum proanthocyanidin pathway, the WD40 (*Tannin1*) component of the MBW complex has been identified, as well as a likely candidate for the bHLH; several studies have found a significant linkage and association on sorghum chromosome 2 around 8 Mb, near a putative bHLH transcription factor orthologous to *Arabidopsis TT8*.[22,24,41,46,47] The MYB transcription factor that would complete the ternary complex has not been found in sorghum. The *Zm1* homologue on chromosome 4 at 61.1 Mb (Sb04g031110, 66.8% similarity), which was mapped in all of our proanthocyanidin GWAS, is a possible candidate for the missing MYB. The maize *Zm1* gene is a MYB transcription factor, homologous to classical maize grain pigmentation gene *C1* that can induce transcription of DFR, an essential structural enzyme in the flavonoid pathway.[48]

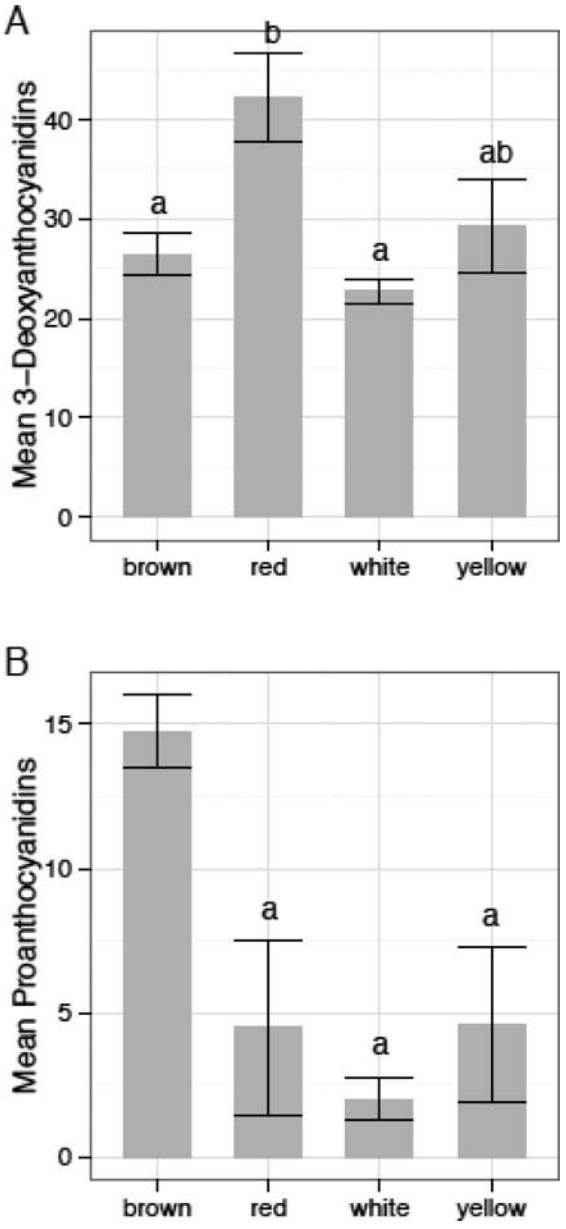

**Figure 8.** Polyphenol differences between grain colors. Mean concentrations of (A) proanthocyanidins and (B) 3-deoxyanthocyanidins in accessions of each grain color. Color categories share the same letter if they are not significantly different from each other, based on a post hoc Tukey HSD test (brown, $n$ = 152; red, $n$ = 48; white, $n$ = 142; yellow, $n$ = 35).

Another possible explanation for the significant SNPs at this location is an indirect association with an undescribed allele at *Tannin-1*.

About two-thirds of the SAP accessions we studied were "converted" tropical accessions, meaning that alleles for reduced height and early flowering have been introgressed so they can be grown in temperate regions.[49] Surprisingly, the proanthocyanidin GWAS association peak on chromosome 7 (~58.6 Kb) precisely colocalizes with *dw3* (Sb07g023730), a dwarfing loci used in the conversion, in conjunction with *dw1*, *dw2*, and *dw4*.[27] Smaller peaks on chromosomes 6 (~39 Kb) and 9 (~57 Kb) were near the *dw2* and *dw1* loci. The association peaks on chromosomes 6, 7, and 9 may be artifacts arising from a lower mean proanthocyanidin concentration in the converted lines (4.4 mg CE/g) which all shared the same *dw* alleles, compared to the unconverted lines (11.0 mg CE/g). Accordingly, when we conducted a proanthocyanidin GWAS using only converted accessions to control for this spurious phenotypic covariation between proanthocyanidin and height, the peaks near *dw1*, *dw2*, and *dw3* disappeared, while the *Tannin1* peak remained (Figure S7 in the Supporting Information).

As a phytoalexin,[15,16] the effect of the environment may make it more difficult to map the genetic basis of 3-deoxyanthocyanidins than the genetic basis of proanthocyanidins. Although the GLM was able to identify significant SNP associations for 3-deoxyanthocyanidins, there were few peaks, and the MLM did not identify any significant associations. Detection of alleles contributing to variance of 3-deoxyanthocyanidins may require a larger sample size, additional replication, a biparental mapping population, or controlled fungal inoculations to induce biosynthesis of polyphenol compounds.[23] However, our results did provide a promising candidate for followup. A *Pr1* orthologue (Sb04g024750) lies within a distinct peak on chromosome 4, about 400 Kb from the top SNP identified in the 3-deoxyanthocyanidin GWAS (S4_54975391; $P < 10^{-8}$), and 100 Kb from the top SNP in the red grain GWAS (S4_54555458, $P < 10^{-13}$). *Pr1* is a maize F3′H enzyme, homologous to *TT7* in *Arabidopsis*. The F3′H enzyme is essential for production of 3-deoxyanthocyanidins, as well as the red phlobaphene pigments visible in maize,[18] and has been implicated in production of these compounds in sorghum (Figure 9).[50] Overall, we observe a 1.6-fold difference in 3-deoxyanthocyanidin concentrations between accessions carrying the high concentration alleles and low concentration alleles for the top red grain-associated SNP ($P$ = 0.001). F3′H is necessary for proanthocyanidin production as well, and, indeed, significant associations with SNPs in the ~54 Mb region on chromosome 4 were also identified in the GWAS with *tan1-a* and *tan1-b* samples removed, as well as the GWAS with only proanthocyanidin-containing samples.

Our study identified many peaks and SNPs significantly associated with proanthocyanidins and 3-deoxyanthocyanidins, hence there appear to be many small effect genes controlling natural variation of these traits. Consequently, a larger association panel, or a targeted biparental mapping population,

**Table 4. Polyphenol Concentrations by Color**

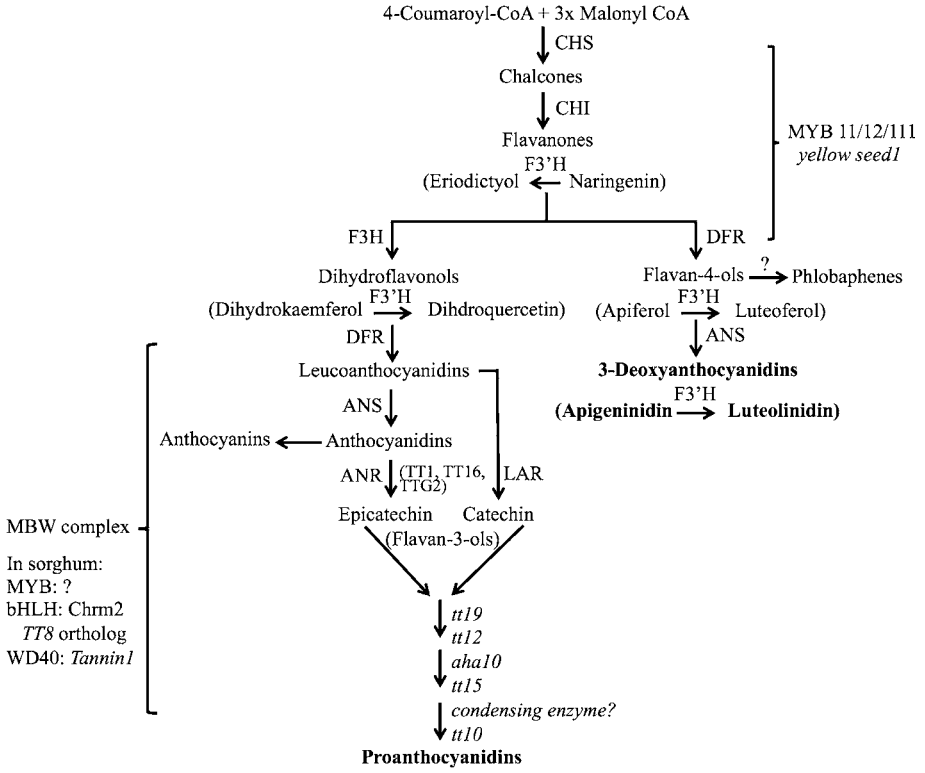

**Figure 9.** Simplified scheme of flavonoid biosynthetic pathway in sorghum grain with candidate genes noted. Enzyme abbreviations are in uppercase letters, while gene abbreviations are in italics. Question marks depict unknown steps. Chalcone synthase (CHS), chalcone-flavanone isomerase (CHI), flavanone 3-hydroxylase (F3H), flavanone 3′-hydroxylase (F3′H), dihydroflavonol-4-reductase (DFR), anthocyanidin synthase (ANS), anthocyanidin reductase (ANR), leucoanthocyanidin reductase (LAR); MYB-bHLH-WD40 (MBW).

may be more effective in precisely identifying causal alleles. Moving forward, sequence analysis and expression analysis of the candidate genes are needed to identify causal polymorphisms and lay the groundwork for the use of polyphenol genetic variation in crop improvement.

**Crop Improvement for Sorghum Polyphenols.** Efforts to characterize polyphenols, with the goal of producing high polyphenol specialty varieties, have been undertaken in several grain crops, including purple wheat,[51] black rice,[52] multicolored maize,[53] multicolored barley,[54] and black sorghum.[55] Our diverse association panel contained a wide range of proanthocyanidin and 3-deoxyanthocyanidin concentrations, and this genetic variation may be useful in breeding programs to produce high polyphenol specialty varieties. Bicolor sorghums had the highest mean proanthocyanidin concentrations, but their grain weight is significantly less (20% less) than that of non-bicolor sorghums ($P < 10^{-9}$). Combined with low yield potential, the small grain size makes it difficult to use bicolor race sorghums in a grain sorghum breeding program, but may still be of interest to breeders wanting to produce specialty varieties. In addition to bicolor sorghums, caudatum and guinea-caudatum sorghums also had high mean proanthocyanidin concentrations, and are promising sources for increasing proanthocyanidin concentrations in sorghum. In particular, among the caudatum and guinea-caudatum sorghums, caudatum sorghums from tropical climates such as Uganda had the highest mean proanthocyanidin concentrations, so they may be good material for breeding high polyphenol sorghums. While bicolor-durra and guinea sorghums had the highest mean 3-deoxyanthocyanidin concentrations, the difference among all the races was not significant, so it may be more important to simply identify unique genotypes across the sorghum collection. Chemical analysis is underway on the samples that were outside of the NIRS calibration curves, and true biological outliers may open up new avenues for future work on sorghum varieties with extreme polyphenol concentrations.

Increasing 3-deoxyanthocyanidin production may be challenging, since, as phytoalexins, they are not constitutively expressed, but rather synthesized by plants under pathogen attack.[15,16] We note in our comparison of 3-deoxyanthocyanidin concentrations from duplicate samples that the difference between duplicates becomes larger for accessions with higher 3-deoxyanthocyanidin concentrations. One possibility is that there is greater technical variation in the 3-deoxyanthocyanidin NIRS estimates, but Dykes et al.[35] demonstrated the same correlation coefficient between the NIRS-predicted values and the values in the validation set for proanthocyanidins ($r = 0.81$) and 3-deoxyanthocyanidins ($r = 0.82$). Therefore, we would not expect to see differences in accuracy of the NIRS predictions for proanthocyanidins and 3-deoxyanthocyanidins in our study. As this was a field study, another possibility is that uncontrolled environmental variation may have contributed to the difference between the duplicate samples. Accessions with the genetic capability to produce grain 3-deoxyanthocyanidins may be producing low or high 3-deoxyanthocyanidin concentrations depending on the exposure to inducing agents on a given panicle. Controlled inoculation studies are needed to further explore this possibility.[23]

The spreader gene is a promising target for increasing grain proanthocyanidin concentrations, and a previous report using a small number of varieties has shown higher proanthocyanidin

concentrations in varieties with a functional spreader.[56] Given that three peak SNP associations in the brown grain GWAS were near putative MATE transporter *TT12* homologues, we propose that the spreader gene may be a *MATE* transporter. A biparental mapping population segregating the spreader gene would be needed to confirm this hypothesis. To get a sense of the effect these loci may have on proanthocyanidin concentrations, we compared concentrations of each allele in proanthocyanidin-containing accessions. There was a 1.8-fold (S3_63633634, $P$ = 0.04), a 1.5-fold (S2_69656067, $P$ = 0.0003), and a 1.7-fold (S8_52906014, $P$ = 0.0002) difference between accessions carrying the high concentration alleles and low concentration alleles. When the three polymorphisms are considered together, accessions with all three high-alleles (S2_69656067 = "A", S3_63633634 = "A", S8_52906014 = "G") have 1.7- to 2.7-fold higher proanthocyanidin concentrations ($P = 10^{-8}$), consistent with an additive effect more than doubling the concentration of proanthocyanidins in sorghum grain.

Appearance of grain color is predominantly due to polyphenols, but can also be influenced by endosperm color and grain weathering. Taken in total, the color classes used for our analysis represent general groups and are not definitive descriptors of any specific trait. For example, it is possible to have a sorghum classified as brown that does not have a testa layer, as well to have a sorghum classified as white that has a testa layer (see Figure 1). However, our results support the use of visual categorization of grain color as a simple assessment of polyphenol concentrations in crop improvement programs; brown grain has significantly higher proanthocyanidin concentrations than nonbrown, red grain has significantly higher 3-deoxyanthocyanidin concentrations than nonred, and white grain has significantly lower concentrations of these polyphenols than nonwhite. Additionally, the genetic architecture of grain color reflects, to an extent, that of the polyphenols with which they are associated. For instance, the red grain GWAS and the 3-deoxyanthocyanidin GWAS produced similar association peaks on chromosome 4 (~54 Mb), which may map to the sorghum *Pr1* orthologue, and chromosome 3 (~72 Mb), which colocalizes with putative homologues of *ANS*, *F3H*, and *TT19*. The brown grain GWAS and the proanthocyanidin-containing GWAS produced similar association peaks on chromosome 6 (~57 Mb) near a priori candidate *TT16*, a key regulatory protein in the proanthocyanidin branch of the flavonoid pathway. Overall, to increase sorghum proanthocyanidin and 3-deoxyanthocyanidin concentrations quantitatively, there are many associated alleles available, but none of them have large effect. This survey of grain polyphenol variation in sorghum germplasm and catalog of flavonoid pathway-associated loci contributes toward the goal of producing sorghum crops that will contribute to marker-assisted breeding of sorghum crops that will benefit human health.

York) at 37 °C in a 5% $CO_2$ incubator with 10 μL of the RES storage solutions for 48 h. A 10 μL portion of DMSO was added to each control group to exclude its effect on cells. In addition, caspase inhibitor (z-VAD-FMK, Beyotime Institute of Biotechnology, Haimen, China) and JNK inhibitor (SP600125, Beyotime Institute of Biotechnology, Haimen, China) were used here to assess the relevant RES signaling pathway.

**Cell Viability and Cytotoxicity Assay.** After 48 h RES treatment, Jurkat cells and NK cells in each group were centrifuged at 1000 × *g* for 5 min, washed with PBS, and resuspended in 600 μL of RPMI-1640 media (IL-2 free). A 20 μL portion of CCK-8 (Cell Counting Kit-8, Dojindo, Japan) was added to a 200 μL cell suspension per well in a 96-well plate in triplicate for each group. The cells were then incubated for 2 h at 37 °C in a 5% $CO_2$ incubator. The optical density (OD) values per well were recorded at 450 nm in microplate reader (BioTek Synergy-4).

The procedure of NK cell cytotoxicity assay was described by Li et al.[12] Briefly, NK cells ($8 \times 10^5$) were separated from each RES treated group, washed three times with PBS, and resuspended in 400 μL of RPMI-1640 (IL-2 free). A 100 μL portion of NK cells ($2 \times 10^5$) was plated into each well of a 96-well plate with 100 μL of K562 cells ($4 \times 10^4$) in triplicate to make the effector-to-target ratio (E:T) at 5:1. The effector control wells contained 100 μL of NK cells ($2 \times 10^5$ cells) and 100 μL of medium. The target control wells contained 100 μL of K562 cells ($4 \times 10^4$ cells) and 100 μL of medium. Plates were incubated at 37 °C in a 5% $CO_2$ incubator. After 4 h coculture, 20 μL of CCK-8 was added to each well, and the plate was then incubated for another 2 h with OD values recorded at 450 nm. Cytotoxicity was determined by evaluating the rate at which NK cells killed K562 cells; the killing rate was calculated as following equation:[13]

$$\text{killing rate (\%)} = [1 - (OD_{e+t} - OD_e)/OD_t] \times 100\%$$

The notation is defined as follows: $OD_e$, average $OD_{450}$ of triplicate wells for NK cell control; $OD_t$, average $OD_{450}$ of triplicate wells for K562 cells control; $OD_{e+t}$, average $OD_{450}$ of triplicate wells for NK cells plus K562 cells.

**mRNA Expression Analysis.** Total RNA was isolated from RES treated NK cells ($1 \times 10^7$) by using TRIzol reagent (Invitrogen, Carlsbad, CA). The mRNA levels of three cytokines, IFN-γ, perforin, granzyme-B, and four receptors related to the cytotoxicity of NK cell, NKG2A, NKG2D, NKp30, and NKp44, were evaluated by relative quantification PCR (RT-qPCR) with SYBR Green random mixing method. Glyceraldehyde-3-phosphate dehydrogenase (GAPDH) was used as the internal control. The $2^{-\Delta\Delta Ct}$ method was used to calculate relative changes in gene expression.[14] All primers used here are shown in Table 1. RT-qPCR was performed as the instructions of the TransStart Top Green qPCR SuperMix kit (TransGen Biotech, Beijing, China). The reaction mixtures were incubated for 30 min at 48 °C, followed by 40 cycles of PCR at 94 °C for 5 s, 55 °C for 15 s, and 72 °C for 10 s. At the end of 40 cycles, a melting curve analysis was performed to confirm the presence of only a single amplified product of the expected size.

**ELISA Assay of IFN-γ, Perforin, and Granzyme-B.** The secretions of IFN-γ, perforin, and granzyme-B were assessed by corresponding ELISA Kits (BD Bioscience, CA). After RES treatment, NK cells ($8 \times 10^5$) were centrifuged and washed with PBS, resuspended in 400 μL RPMI-1640 (IL-2 free), mixed with $1.6 \times 10^5$ K562 cells in 100 μL RPMI-1640 (IL-2 free), and then incubated for 4 h at 37 °C in 5% $CO_2$ incubator (K562 cells were used to activate the cytokine secretion of NK cells according the literature).[15] In the ELISA assay, each condition was performed twice, and OD values were recorded at 450 nm. Curve Expert 13.0 was employed to create the standard curve according to the OD values of standards. The quantities of these cytokine secreted by NK were calculated from these standard curves.

**Apoptosis and Receptor Expression Assay.** AnnexinV-FITC Apoptosis Detection Kit (Beyotime Institute of Biotechnology, Haimen, China) was used to assess the apoptosis of Jurkat cells and NK cells. After treatment with RES in presence or absence of the z-VAD-FMK (caspase inhibitor, 50 μg/mL, Beyotime Institute of Biotechnology, Haimen, China), cells were centrifuged and washed 3 times with PBS, and then labeled with AnnexinV-FITC and PI following the instructions. NK cells treated by RES were centrifuged and washed with PBS, and then divided into 4 groups ($1 \times 10^5$ cells each) and labeled with PE-conjugated mouse antihuman NKG2A (R&D Systems, Minnesota), NKG2D, NKp30, and NKp44 (BD Bioscience, California). All the cells were analyzed using flow cytometry.

**Data Analysis.** Statistical analysis was performed using SPSS 16.0 statistical software (IBM, New York). The data were presented as the mean ± SD. The results were analyzed using the analysis of variance (ANOVA). Multiple comparisons used LSD test to evaluate the significance of differences between groups. Statistical significance was defined as $p < 0.05$.

## RESULTS

**NK Cell Purity.** After 3 weeks of *ex vivo* expansion, primary human NK cells were harvested, stained with CD56-PE and CD3-FITC mAbs, and analyzed by flow cytometry. The percentage of NK cells ($CD56^+CD3^-$) was determined. The mean percentage of NK cells from 12 donors was 91.21 ± 1.78% ($n = 12$).

**Cell Viability.** RES (12.5−50 μM) shows concentration-dependent effects on the viability of both Jurkat cells and NK cells. In the concentration of 50 μM, RES can inhibit the viability of both cells. Figure 1 shows the OD values were significantly reduced, which were 1.94 ± 0.33, 1.8 ± 0.34, 1.79 ± 0.37 1.74 ± 0.23, 1.85 ± 0.26, 1.47 ± 0.21, 1.41 ± 0.36, and 1.18 ± 0.29 in Jurkat cells, and 0.77 ± 0.05, 0.76 ± 0.03, 0.77 ± 0.04, 0.76 ± 0.03, 0.76 ± 0.04, 0.74 ± 0.02, 0.62 ± 0.03, and 0.48 ± 0.03, respectively, in NK cells with the concentration of RES increased from 0 to 50 μM (Figure 1A). It was noticed that when the concentration of RES reduced to 12.5 μM, there was no obvious inhibited effect on NK cells, but the Jurkat cells still could be affected until it reduced to 6.25 μM. This suggested that Jurkat cells are more sensitive than NK cells in response to RES causing cell death. On the other hand, inhibitors were employed here to assess the relevant signaling pathway RES may act with (Figure 1B). After pretreatment by inhibitors (z-VAD-FMK and SP600125), RES (50 μM) no longer showed the inhibited effect on Jurkat cells and NK cells in z-VAD-FMK group. The OD values in z-VAD-FMK group

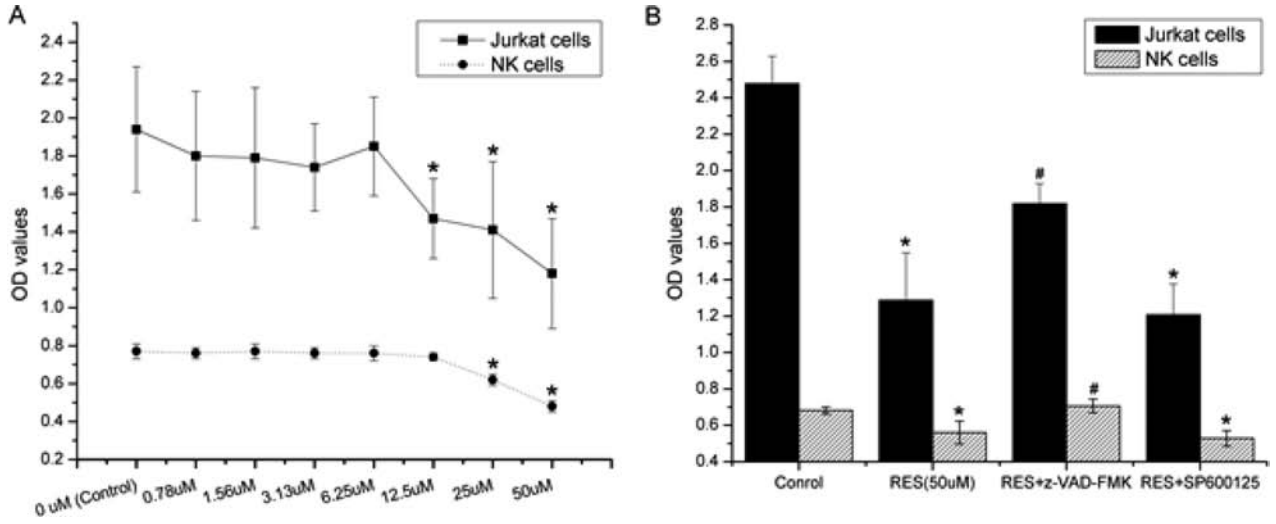

**Figure 1.** OD values of cells treated with RES and inhibitors ($n = 4$). (A) Cells treated with RES in concentration gradient (0−50 $\mu$M) for 48 h. (B) Cells treated with RES (50 $\mu$M) in present or absent of z-VAD-FMK and SP600125 (50 $\mu$M each) for 48 h. Data represent the mean ± SD of four independent experiments. One-way ANOVA and LSD tests were performed: * $p < 0.05$ compared with the control; # $p < 0.05$ compared with the RES treated group.

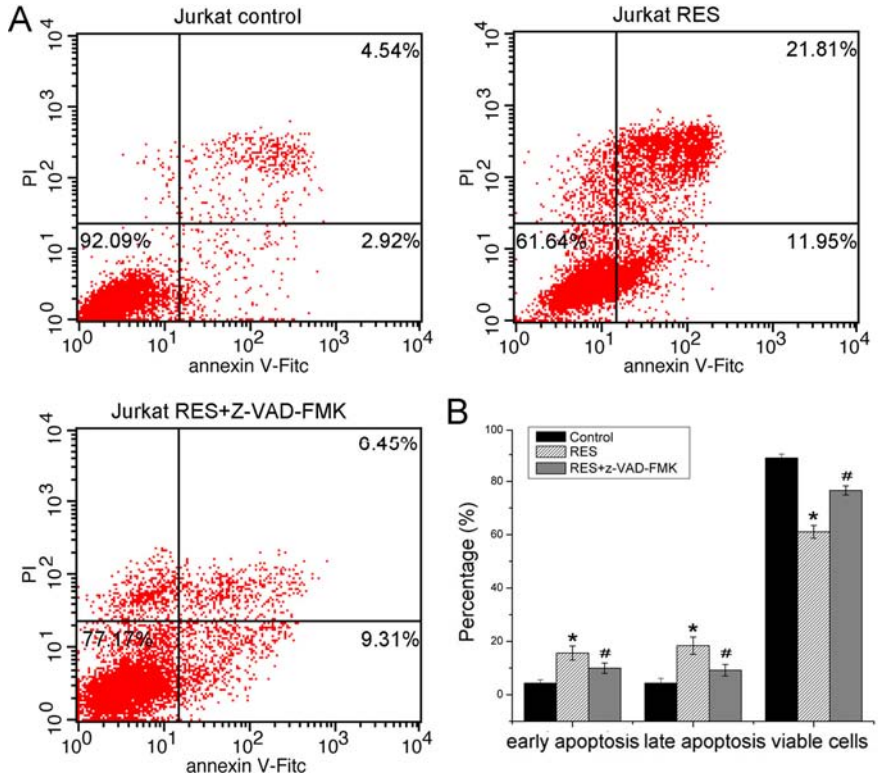

**Figure 2.** Apoptosis and necrosis of Jurkat cells after RES treatment ($n = 4$). (A) A representative flow cytometry plot of Jurkat cells from one donor. The percentages of viable (Annexin $V^-/PI^-$), early apoptotic (Annexin $V^+/PI^-$), and late apoptotic/necrotic (Annexin $V^+/PI^+$) cells are shown. (B) The percentage of apoptosis in these cells is summarized in the bar graph; each column represents the mean ± SD from four independent experiments. Multivariate ANOVA and LSD tests were performed: * $p < 0.05$ compared with the control; # $p < 0.05$ compared with the RES treated group.

were 1.82 ± 0.11 and 0.71 ± 0.04, respectively, compared with the 1.29 ± 0.26 (Jurkat cells) and 0.56 ± 0.06 (NK cells) in RES groups. However, the OD values in SP600125 groups of the two cells showed no significant changes compared with the RES groups. It is suggested that RES may inhibit the viability of cells by causing them apoptosis/death via caspase signal pathway.

**Cell Apoptosis.** Cells stained by AnnexinV and PI after 48 h RES (50 $\mu$M) treatment in presence or absence of z-VAD-FMK were shown in Figures 2 and 3. Apoptosis of both Jurkat cells and NK cells increased comparing with the controls, and the apoptosis of Jurkat cells was more damaged than the latter. Early apoptosis (Annexin$V^+/PI^-$) occurred in 15.9 ± 1.99% in NK cells and 15.59 ± 2.67% in Jurkat cells after RES treated

dx.doi.org/10.1021/jf502950u | J. Agric. Food Chem. 2014, 62, 10928−10935

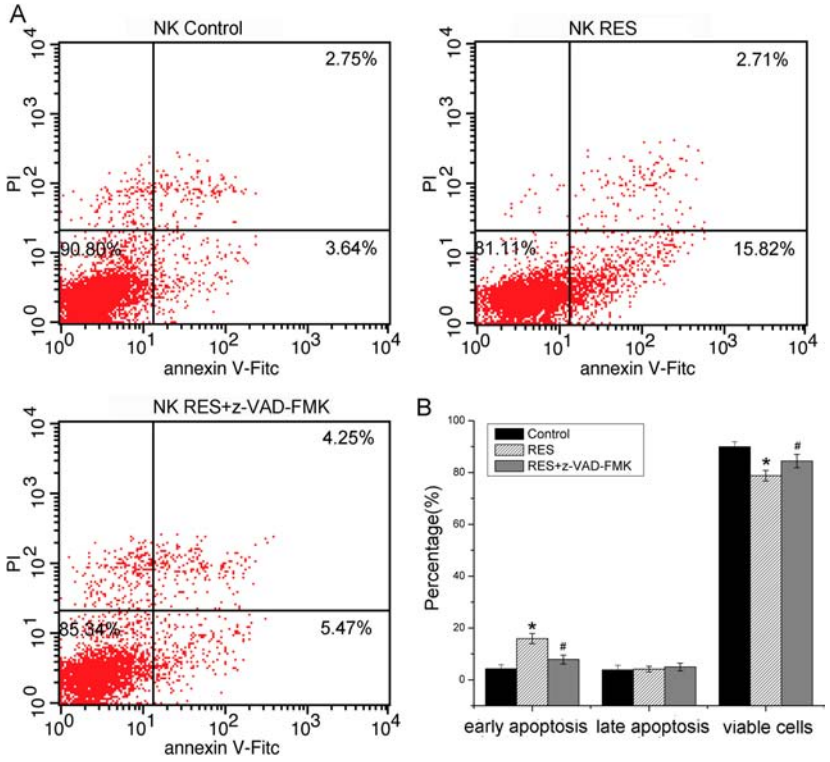

**Figure 3.** Apoptosis and necrosis of NK cells after RES treatment ($n = 4$). (A) A representative flow cytometry plot of NK cells from one donor. The percentages of viable (Annexin $V^-/PI^-$), early apoptotic (Annexin $V^+/PI^-$), and late apoptotic/necrotic (Annexin $V^+/PI^+$) NK cells are shown. (B) The percentage of apoptosis in these cells is summarized in the bar graph; each column represents the mean ± SD from four independent experiments. Multivariate ANOVA and LSD tests were performed: * $p < 0.05$ compared with the control; # $p < 0.05$ compared with the RES treated group.

compared with 4.24 ± 1.57% and 4.29 ± 1.25%, respectively, of the control ($p < 0.05$). Meanwhile, the late apoptosis/necrosis NK cells were 4.12 ± 1.08%, with no significant difference compared with 3.8 ± 1.79% of the control. However, the late apoptosis/necrosis Jurkat cells were 18.35 ± 3.24%, increased significantly compared with the 4.3 ± 1.82% in the control. Correspondingly, the percentages of viable cells were 78.78 ± 2.06% (NK cells) and 61.06 ± 2.4% (Jurkat cells) in RES treated groups compared with 89.98 ± 1.93% (NK cells) and 88.79 ± 1.5% (Jurkat cells) in control, respectively ($p < 0.05$). Furthermore, the RES-induced apoptosis and necrosis of cells were blocked by caspase inhibitor (z-VAD-FMK). After pretreatment by z-VAD-FMK, the apoptosis rates of Jurkat cells and NK cell were reduced partially. These results suggested that RES could induce Jurkat cell and NK cell apoptosis in 50 μM, which may be relevant with caspase signaling pathways. NK cells showed more resistance than Jurkat cells on RES induced apoptosis at dose tested.

**NK Cells Cytotoxicity.** In this assay, NK cells were treated with RES in concentration gradient for 48 h. The cytotoxicity of the NK cells was tested. As shown in Figure 4, the cytotoxicity of NK cells was significantly decreased when the concentration of RES was above 25 μM, 61.42 ± 3.93% and 71.28 ± 3.55% in 50 and 25 μM treated groups compared with the 90.22 ± 1.43% in the control ($p < 0.05$). Unexpectedly, RES in low concentration (3.13 and 1.56 μM) increased the cytotoxicity of NK cells, 95.86 ± 1.56% and 94.73 ± 1.62% compared with control ($p < 0.05$). Therefore, in the following experiments, the mechanism underlying the increased NK cells cytotoxicity was studied under 3.13 μM treatment of RES.

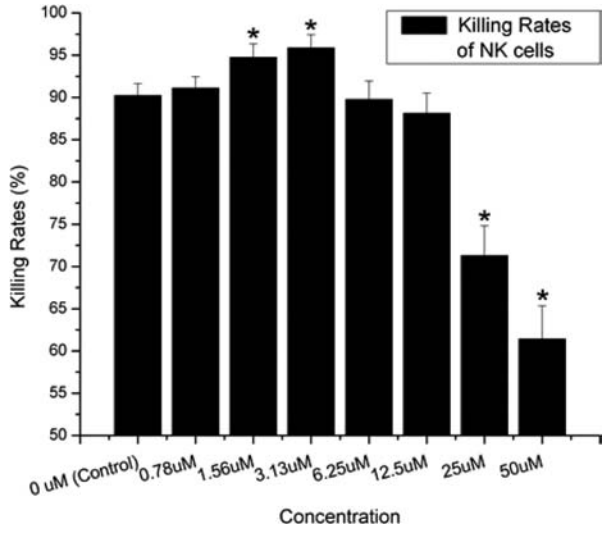

**Figure 4.** Effect of RES on NK cell cytotoxicity ($n = 4$). Each column represents the mean ± SD from four independent experiments. One-way ANOVA and LSD tests were performed: * $p < 0.05$ compared with the control.

**RT-qPCR.** Table 2 depicted the expression profiles of genes involved in NK cell functions after low concentration RES (3.13 μM) treatment. The mRNA level of IFN-γ increased significantly in the RES-treated group to 4.5-fold compared with the control ($p < 0.05$). Meanwhile, the mRNA levels of triggering receptors NKG2D were also up-regulated signifi-

dx.doi.org/10.1021/jf502950u | J. Agric. Food Chem. 2014, 62, 10928−10935

Table 2. RES in Low Concentration Regulated NK Cell Functional Proteins at the mRNA Level ($n$ = 6)[a]

| gene | IFN-$\gamma$ | perforin | granzyme-B | NKG2A | NKG2D | NKp30 | NKp44 |
|---|---|---|---|---|---|---|---|
| compared with control | 4.5(fold)[b] | 2.14(fold) | 1.77(fold) | 0.53(fold) | 6.36(fold)[b] | 1.39(fold) | 1.71(fold) |

[a]SYBR green-based RTq-PCR was used to examine the mRNA levels of genes that are important for NK cell functions. The data represent the mean ± SD of six independent experiments. One-way ANOVA and LSD test. [b]$p < 0.05$ compared with 1.

cantly in the RES treated group, which increased 6.36-fold compared with control ($p < 0.05$).

**ELISA.** The levels of cytokine and cytolytic proteins in the NK cell supernatants are illustrated in Figure 5. It is noticed that the IFN-$\gamma$ level was increased under 3.13 $\mu$M RES treatment, which was increased to 730 ± 41 pg/mL compared with the 400 ± 35 pg/mL in the control ($p < 0.05$). The concentration of perforin was not changed significantly. They were about 800 ng/mL in RES treated and control groups. However, the granzyme-B was hardly detected in the supernatants of two groups.

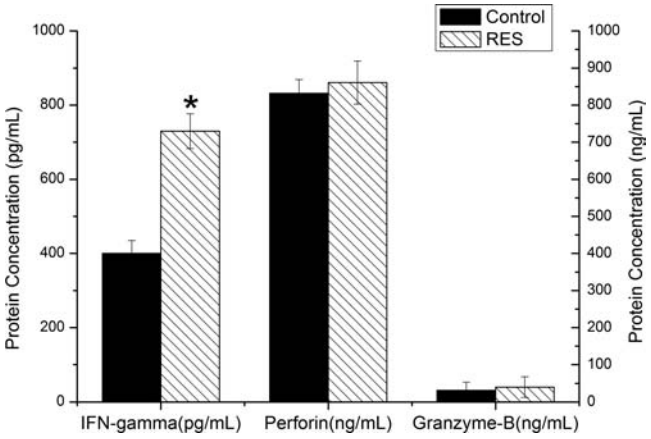

**Figure 5.** IFN-$\gamma$, perforin, and granzyme-B secretion of NK cells after RES treatment. RES (3.125 $\mu$M) treated NK cells were stimulated with K562 cells, supernatants were collected, and then the concentrations of IFN-$\gamma$, perforin, and granzyme-B were detected. Each column represents mean ± SD of four independent experiments. One-way ANOVA and LSD tests were performed: * $p < 0.05$ compared with control.

**Receptor Expression.** Flow cytometry assays indicate that NK cells display a significant up-regulation of NKG2D (Figure 6). The positive percentage of NKG2D increased from 83.52 ± 5.64% in the control group to 94.2 ± 4.67% in RES treated group ($p < 0.05$). The positive percentages of NKG2A, NKp30, and NKp44 were not changed obviously.

## DISCUSSION

As a small polyphenol, RES was found in various plant sources,[16] and has been demonstrated to have many beneficial effects and received a lot of attention in recent years. RES was well-known for use in various areas including anti-inflammatory, antioxidant, antidiabetic, and antiaging.[17−19] Also, it showed the positive effects of triggering cell death in a great variety of human tumor cells, such as colon, prostate, breast, lymphoma, and leukemia.[20−24] For these reasons, RES has been recognized as a potential adjuvant in cancer chemotherapy.[25,26]

NK cells play a pivotal role in innate and adaptive immunity, especially in tumor surveillance. The effect of RES on human NK cells should be assessed carefully if it has been used as antitumor drug. In this study, primary human NK cells were treated by RES with concentration gradient. The viability, apoptosis, and cytotoxicity of NK cells were detected. Jurkat cells were used to assess if there was a sensitivity difference for RES between primary cells and tumor cells.

When RES was employed as a drug or adjuvant to inhibit viability or induce apoptosis on tumor cells *in vitro*, the common working concentrations were 25−200 $\mu$M.[27−30] In the present study we noticed that when the concentration of RES above 12.5 $\mu$M, the significant inhibiting effect was observed on Jurkat cells, but the threshold in NK cells was 25 $\mu$M. It indicated that tumor cell lines such as Jurkat are more sensitive than NK cells to the toxicity effect of RES. Jazirehi et al. reported that, in 10 $\mu$M concentration, RES did not show any toxicity on human PBMCs, but it caused cell death in Roma cell lines.[31] Another study reported that RES reduced the viability and DNA synthesis capability of the promyelocytic leukemia (HL-60) cell;[32] it also inhibited growth of human colon tumorigenic cells mediated by cell cycle arrest.[33] Tumor cells grow more actively than primary cells, the DNA synthesis reduction and cell cycle arrest caused by RES affect the tumor cell proliferation more serious than primary cells, which may explain the sensitivity difference of RES between the two kinds of cells.

Many studies have indicated the biphasic effects of RES on cells. It was reported that RES can promote GH3 cells proliferation at low concentrations (1 $\mu$M) and inhibit it at high concentrations (>10 $\mu$M), and the RES-induced GH3 cell apoptosis was caspase-dependent.[25] Suzuki et al. observed cleavage of caspase-3 and poly(ADP-ribose) polymerase in RES-treated cells, which indicated that RES induces caspase-dependent apoptosis in MT-2 and HUT-102 cells.[34] Our results showed, at the high concentration (50 $\mu$M), RES reduces OD values of both Jurkat cells and NK cells, while caspase inhibitor z-VAD-FMK can prevent RES caused cell death. The flow cytometry assay confirmed these results; after pretreatment by z-VAD-FMK, the early and late apoptosis/necrosis cells caused by RES were reduced significantly, which suggests that RES promotes cell apoptosis via caspase signaling pathway. Kashif et al. reported that RES (4−8 $\mu$M) treatment inhibited the caspase activation, and $H_2O_2$ induced apoptosis in HL60 cells.[35] Another study showed that RES in 2 and 5 $\mu$M increased the percentage of CD19+ cell in human PBMCs. However, 10 $\mu$M RES inhibited the proliferation of B lymphocyte.[36] In our results, RES (in 1.56−6.25 $\mu$M) did not show the promote proliferation or antiapoptosis effects (data not shown) on either Jurkat cells or NK cells, but it actually promoted the cytotoxicity of NK cells in 1.56−3.13 $\mu$M.

The cytotoxicity of NK cells plays a key role in tumor identification and surveillance. NK cells kill malignant cells by secretion of IFN-$\gamma$, perforin, and granzyme-B. NKG2D is the most important triggering receptor on NK cells which trigger cytotoxicity and mediate the secretion of IFN-$\gamma$.[37] RT-qPCR and flow cytometry assays indicated that RES in 3.13 $\mu$M can increase the expression of NKG2D both in mRNA and protein level. Results from Lu et al. show that RES pretreatment increases NK cell cytotoxicity in a dose-dependent (1.56−12.5

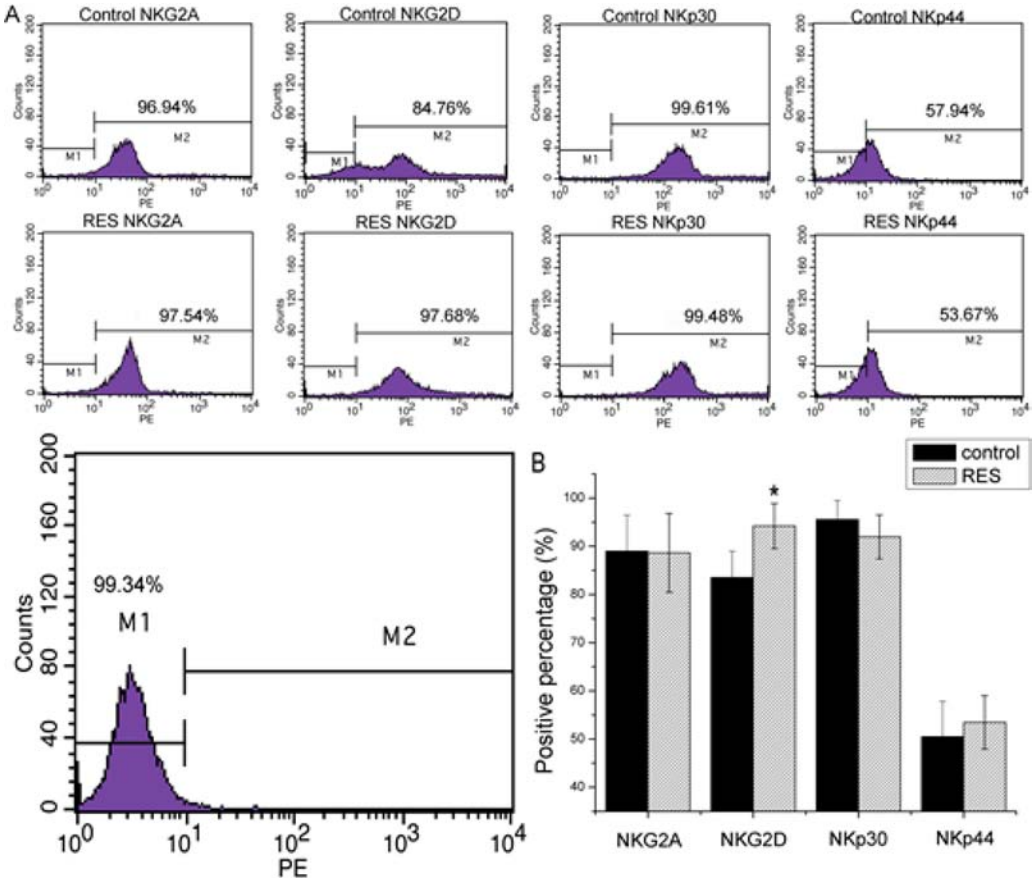

**Figure 6.** Protein expression profiles for the NK cell receptors NKG2A, NKG2D, NKp30, and NKp44 after low concentration RES treatment. (A) NK cells were stained with PE-conjugated mAbs and analyzed by flow cytometry (for example). (B) The bar graph represents the mean ± SD from three independent experiments. One-way ANOVA and LSD test: * $p < 0.05$ compared with control.

$\mu$M) manner by up-regulation of the expression of NKG2D and perforin expression.[38] In our results, the change of perforin expression was not obvious, but the IFN-$\gamma$ expression was up-regulated significantly. Increased expression of NKG2D and IFN-$\gamma$ may be the reason for enhanced cytotoxicity of NK cells. Hu et al. reported that RES treatment also increases the cell-surface expression of NKG2D ligands on human promyelo-blastic leukemia KG-1a cells.[39] It indicated that RES can enhance the CIK (cytokine-induced killer) via up-regulation of the expression of both NKG2D and NKG2D ligands on effector and target cells, respectively.

Thought that the effects of RES on NK cytotoxic activity may be due to partial agonistic activity of RES on aryl hydrocarbon receptor (AhR).[40] They speculated that RES is a partial agonist of human AhR and exerts its effect on NK cells by the mechanism involving activation of JNK (c-Jun N-terminal kinase) and ERK (extracellular-regulated kinase).[38,40] Unlike caspase inhibitor, JNK inhibitor SP600125 did not show the abolished effects on high concentration RES induced NK cell apoptosis in our study. However, JNK may relate to the positive effect of RES on NK cells.

The present study indicated that RES has biphasic effects on human NK cells. Other biphasic effects of RES on tumor cells or several parasitic diseases were also reported (reviewed by Calabrese et al.[41]). In line with these findings, it indicated that RES acts via multiple target pathways (AhR, JNK, and ERK).[42] Due to rapid metabolism in human body, RES may hardly reach the body tissues in sufficient dosage to exert the beneficial health effects by oral consumption.[43] Using RES as one kind of injection may be part of the solution. Therefore, it was very important to confirm and calculate the effective concentration of RES accurately when it was used as a potential antitumor or health product.

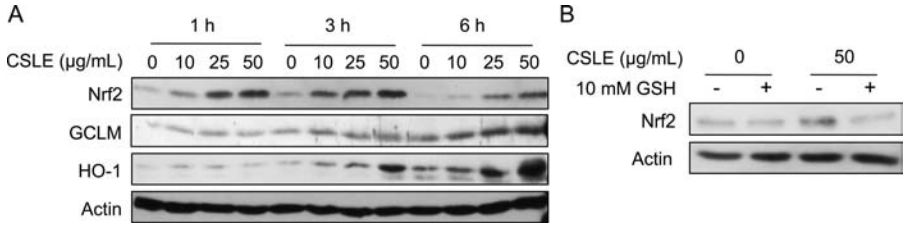

**Figure 1.** CSLE-mediated activation of Nrf2 in HepG2 cells and modification of purified Keap1. (A) Cells were exposed to CSLE (10, 25, or 50 $\mu$M) for 1, 3, or 6 h, and then total cell proteins were subjected to Western blot analysis with the indicated antibodies. (B) CSLE was incubated with GSH (10 mM) for 30 min at room temperature. The cells were treated with GSH-incubated CSLE (50 $\mu$g/mL) for 1 h, and total cell proteins were subjected to Western blot analysis with the indicated antibodies.

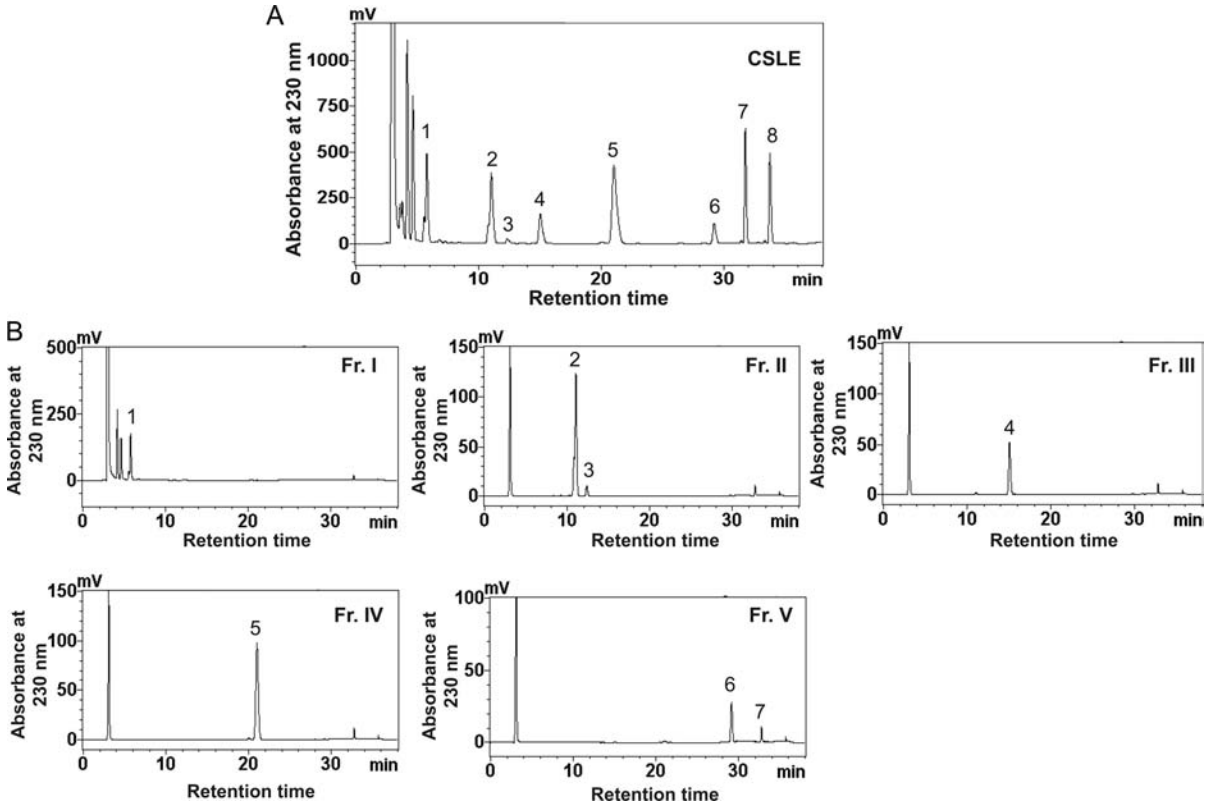

**Figure 2.** HPLC analysis of CSLE (A) and fractions separated by Ultra Pack ODS-S-50B column chromatography (B). Detection at 230 nm.

(Beverly, MA, USA), and Invitrogen (Carlsbad, CA, USA), respectively. All other reagents were of the highest grade available.

**Cell Culture.** HepG2 cells were obtained from RIKEN Cell Bank (Tsukuba, Japan). The cells were cultured in minimal essential medium (MEM; Wako) containing 10% fetal bovine serum, antibiotics (100 U/mL penicillin and 100 $\mu$g/mL streptomycin), and 2 mM L-alanyl-L-glutamine (Invitrogen) in an incubator supplemented with 5% $CO_2$ at 37 °C. In extracting total protein, $8 \times 10^5$ cells were seeded in 35 mm dishes. The cells were preincubated in serum-free medium for 12 h before treatment with compounds.

**CSLE Extraction.** *C. sativum* leaves (78 g) were frozen in liquid nitrogen and transferred to a 1 L flask containing 80 mL of distilled deionized water and 160 mL of *n*-hexane. The flask was refluxed in an oil bath at 80 °C for 2 h, and the *n*-hexane layer was collected using a separating funnel. The *n*-hexane layer was passed over anhydrous sodium sulfate to remove any trace of water and then treated with argon gas. The *n*-hexane layer was evaporated in vacuo to remove *n*-hexane, and the residues were redissolved in acetonitrile or dimethyl sulfoxide (DMSO). Samples were stored at −80 °C prior to use.

**Separation of CSLE.** The CSLE (70 mg) in DMSO was separated into five fractions by preparative column chromatography using an Ultra Pack ODS-S-50B column (300 × 26 mm i.d., 50 $\mu$m; Yamazen Science Inc., Osaka, Japan); elution was with 25% acetonitrile in water at a flow rate of 5 mL/min. Phytochemicals with retention times of 2−60 min (fraction I, 10 mg), 60−100 min (fraction II, 10 mg), 100−150 min (fraction III, 10 mg), 150−220 min (fraction IV, 20 mg), and 220−300 min (fraction V, 10 mg) were collected, evaporated in vacuo, and freeze-dried. Phytochemicals in each fraction were monitored using analytical high-performance liquid chromatography (HPLC) [YMC-Pack, ODS-AM, 250 × 4.6 mm, i.d., 5 $\mu$m (YMC CO Ltd., Kyoto, Japan); mobile phase, acetonitrile/water, 25:75 (v/v); flow rate, 1 mL/min; detection, 230 nm].

**Detection of the Covalent Modification of Keap1 by Electrophiles.** The covalent modification of Keap1 by electrophiles was detected using a BPM-labeling assay as previously described.[22] Recombinant murine Keap1 was expressed as a C-terminal His-tagged fusion protein from BL21-CodonPlus (DE3)-RIPL cells (Stratagene, La Jolla, CA, USA) and purified using Ni-NTA agarose (Qiagen, Valencia, CA, USA).[23] Samples, including Keap1−decenal and −dodecenal adducts, were incubated with 25 $\mu$M BPM for 30 min at 37 °C and then subjected to Western blot analysis with an HRP-linked antibiotin antibody (Cell Signaling Technology).

**Detection of 2-Alkenals Using DAIH Labeling Analysis.** Each sample (17 $\mu$L) was incubated with 85 $\mu$L of a derivatization reagent

dx.doi.org/10.1021/jf5030592 | J. Agric. Food Chem. 2014, 62, 10936−10944

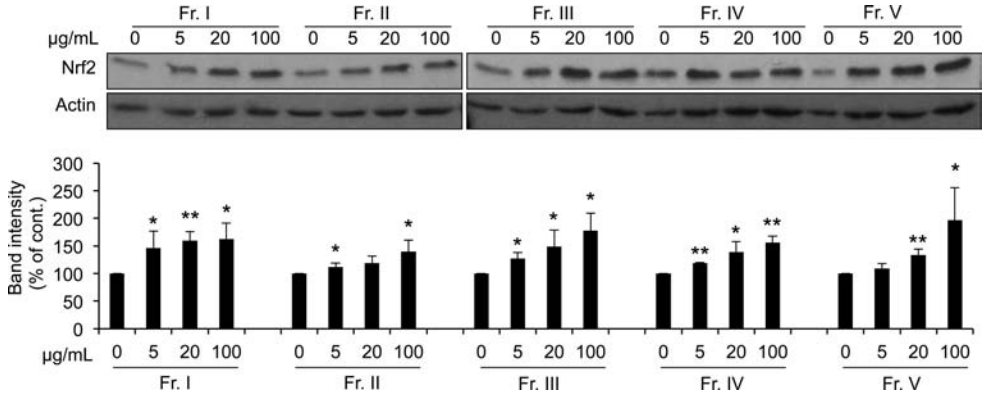

**Figure 3.** Nrf2 activation during exposure of HepG2 cells to the CSLE fractions. The cells were exposed to each fraction (5, 20, or 100 $\mu$M) for 1 h, and then the cell lysates were subjected to Western blot analysis with the indicated antibodies. The bands were quantified using ImageJ software, and the density of each band was normalized to that of actin. Each value is the mean ± SE of three determinations. (*) $p < 0.05$ and (**) $p < 0.01$ versus control.

**Figure 4.** Identification of (*E*)-2-alkenals in CSLE and fractions by UPLC-MS/MS following reaction with DAIH: (A) reaction of (*E*)-2-alkenal with DAIH leading to the dehydrated reaction product [predicted MS numbers of the fragments are $m/z$ 323.13 derived from DAIH and $m/z$ 25.2 + 14$n$ derived from the (*E*)-2-alkenal residue of the (*E*)-2-alkenal-DAIH adduct]; (B) observed MS number of the reaction products with DAIH and fragments derived from the 2-alkenal−DAIH adduct by UPLC-MS/MS analysis.

consisting of 0.06% DAIH, 140 $\mu$M HCl, and 93% acetonitrile for 15 min on ice. A 10 $\mu$L sample of the reaction mixture was analyzed by ultraperformance liquid chromatography (UPLC) and liquid chromatography−tandem mass spectrometry (LC-MS/MS). Briefly, the reaction products were characterized using an Acquity UPLC system (Waters Co., Milford, MA, USA) equipped with an Acquity BEH $C_{18}$ column (2.1 mm × 50 mm i.d., 1.7 $\mu$m) held at 35 °C in the direct injection mode. Mobile phases A [water containing 0.1% (v/v) formic acid] and B [acetonitrile containing 0.1% (v/v) formic acid] were linearly mixed using a gradient program, and the instrument was calibrated immediately prior to each series of experiments. The flow rate was 0.3 $\mu$L/min, and the mobile phase composition was as follows: 15% B for 10 min; linear increase over 20 min to 95% B; maintained at 95% B for 2 min before a linear return to 15% B over 3 min. The total running time, including conditioning the column to the initial conditions, was 35 min. The eluted chemical compounds were then transferred to the electrospray source of the Synapt High Definition MS system (Waters Co.). The system control and analysis of the mass spectra were performed using Waters MassLynx software ver. 4.1. Electrospray ionization was used with a capillary voltage of 2.8 kV and a sampling cone voltage of 35 V. Low (6 eV) or elevated (stepped from 15−60 eV) collision energy was used to generate either intact precursor ions (low energy) or product ions (elevated energy). The source temperature was 80 °C, and the detector was operated in the negative ion mode. Data were collected from $m/z$ 50−1000. All analyses were acquired with an independent reference; leucine enkephalin $[M - H]^-$ ion as lock mass ($m/z$ 554.2615) was infused via the LockSpray ion source to ensure accuracy and reproducibility. Data were analyzed with MassLynx version 4.1 software and MassFragment version 1.1 software.

**Luciferase Assay.** Transient transfection of cDNAs was performed using Lipofectamin 2000 (Invitrogen) according to the manufacturer's instructions. Briefly, HepG2 cells were seeded at 0.5 × $10^5$ cells/cm$^2$ in 12-well plates. After the cells were incubated overnight, 1.6 $\mu$g of ARE-Luciferase cDNA and 0.16 $\mu$g of pRL-TL cDNA or Lipofectamin 2000 reagent were mixed with OPTI-MEM (Invitrogen) in separate tubes and incubated for 20 min at room temperature to allow the

dx.doi.org/10.1021/jf5030592 | J. Agric. Food Chem. 2014, 62, 10936−10944

formation of complexes. These solutions were then added to the cells and incubated for 12 h, followed by a further 12 h of incubation in serum-free medium. The cDNA-transfected cells were then exposed to the samples, washed with phosphate-buffered saline (PBS), and lysed with Passive Lysis Buffer (Promega, Madison, WI, USA). Luciferase activity was measured using a Dual-Luciferase Reporter Assay System (Promega) according to the manufacturer's instructions.

**Western Blot Analysis.** HepG2 cells were exposed to CSLE, butanal (99.85% purity, Sigma-Aldrich, St. Louis, MO, USA), (*E*)-2-butenal (99% purity, Nacalai), (*E*)-2-decenal, or (*E*)-2-dodecenal, washed with ice-cold PBS, and then collected by scraping into a 2% sodium dodecyl sulfate (SDS) solution. After the cells were lysed at 95 °C for 20 min, protein concentrations were determined using the BCA Protein Assay (Piece, Rockford, IL, USA). Each sample was mixed with a half-volume of SDS−polyacrylamide gel electrophoresis (PAGE) loading buffer (62.5 mM Tris-HCl, pH 6.8; 6% SDS; 24% glycerol; 50 mM TCEP; and 0.015% bromophenol blue) and incubated at 95 °C for 5 min. The cellular proteins were then separated using SDS-PAGE and transferred to polyvinylidene difluoride membranes (Bio-Rad Laboratories, Hercules, CA, USA). The membranes were blocked with 5% skim milk in TTBS (20 mM Tris-HCl, pH 7.5; 150 mM NaCl; and 0.1% Tween 20) and then incubated with primary antibody in TTBS. To detect immunoreactive proteins, HRP-conjugated anti-rabbit IgG and an enhanced system (Chemi-Lumi One L; Nacalai, Kyoto, Japan) were used. Representative blots were from three independent experiments.

**Determination of Electrophilicity Index.** The lowest unoccupied molecular orbital energy ($E_{LUMO}$) and highest occupied molecular orbital energy ($E_{HOMO}$) were determined using Gaussian 09 (ver. 8.0) software (Conflex, San Diego, CA, USA). The ground state equilibrium geometries of each structure were calculated with density-functional RB3LYP 6-31G(d). The global hardness ($\eta$) was calculated as $\eta \approx (E_{LUMO} - E_{HOMO})/2$, softness ($\sigma$) was calculated as $\sigma = 1/\eta$, and the electronic chemical potential ($\mu$) was calculated as $\mu \approx (E_{HOMO} + E_{LUMO})/2$. The electrophilicity index ($\omega$) was calculated as $\omega = \mu^2/2\eta$.[24,25]

**Statistical Analysis.** Statistical significance was assessed using Student's *t* test or Dunnett's post hoc test after a one-way analysis of variance with Microsoft Excel for Mac 2011 version 14.4.3; $p < 0.05$ was considered significant.

## RESULTS

**Activation of Nrf2 by CSLE.** Exposure of HepG2 cells to CSLE resulted in activation of Nrf2 and up-regulation of downstream proteins, such as GCLM and HO-1 (Figure 1A); however, CSLE at a concentration of 100 $\mu$g/mL repressed the Nrf2 activation and thus GCLM and HO-1 gene expression. Pretreatment with GSH markedly diminished CSLE-mediated activation of Nrf2 in the cells (Figure 1B), suggesting electrophiles contributed to the activation. Consistent with this, the thiol groups of Keap1, the negative regulator for Nrf2, were modified by CSLE in a concentration-dependent manner as determined by a BPM assay (Supporting Information Figure S1).

**Separation of Nrf2 Activators in CSLE.** As shown in Figure 2A, the CSLE contained eight major compounds detected at 230 nm; compounds **2** and **5** were identical to authentic (*E*)-2-decenal and (*E*)-2-dodecenal, respectively (Figure 2 and Figure S2 in the Supporting Information). The CSLE components were separated into five fractions by Ultra Pack ODS-S-50B column chromatography (Figure 2B), and then the Nrf2 activation potential of each fraction was evaluated in HepG2 cells. Unexpectedly, fractions I−V all activated Nrf2 to a similar extent (Figure 3), suggesting that the observed Nrf2 activation might be due to electrophiles with (*E*)-2-alkenal substituents, as various (*E*)-2-alkenals have been observed previously in a CSLE.[3,9]

**Analysis of (*E*)-2-Alkenals in CSLE.** To investigate whether or not the components in each fraction contained (*E*)-2-alkenal moieties, we performed UPLC-MS/MS analysis in the negative ion mode of the CSLE components after derivatization with DAIH (see Figure 4A).[26]

Authentic (*E*)-2-decenal and (*E*)-2-dodecenal were converted into DAIH derivatives with retention times of 16.61 min ($m/z$ 489.3) and 20.95 min ($m/z$ 517.3), respectively (Figure 4 and Figure S3 in the Supporting Information), whereas no such peaks and corresponding molecular masses were seen without DAIH (Figure S3A). Using the DAIH derivative method, we identified (*E*)-2-alkenal-related chemicals, including (*E*)-2-decenal (compound **2** in fraction II), (*E*)-2-undecenal (compound **4** in fraction III), and (*E*)-2-dodecenal (compound **5** in fraction IV) (Figures 4 and 5). Compound **3** was not an (*E*)-2-alkenal because

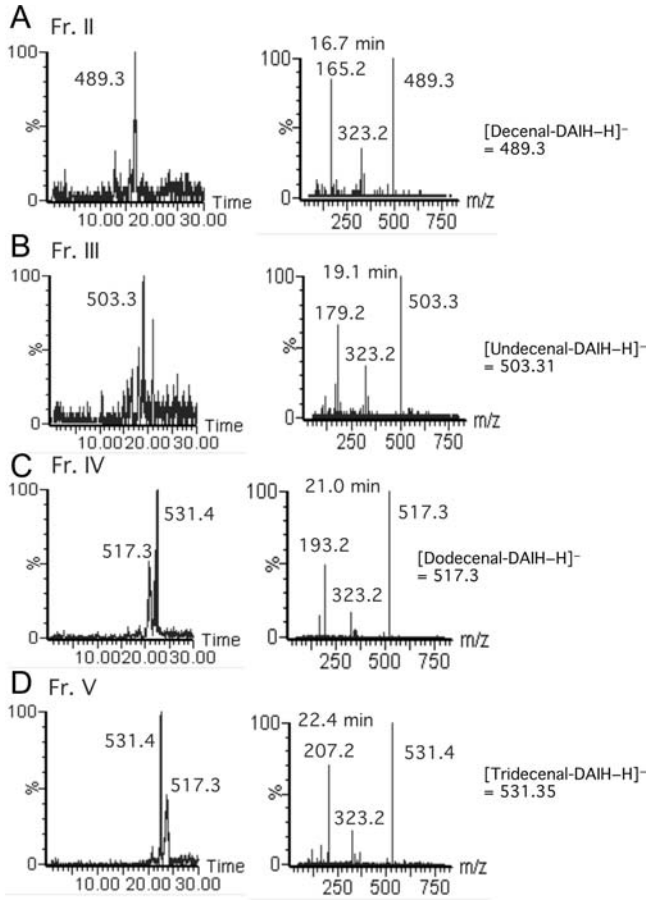

**Figure 5.** UPLC and LC-MS/MS spectra of reaction products after reaction of each fraction with DAIH: (A−D) UPLC/MS chromatograms of derivatives of 2-alkenal with DAIH (left) monitored at $m/z$ 323.1, respectively. The mass spectra were obtained from derivatives with retention times of 16.7 min (A), 19.1 min (B), 21.0 min (C), 22.6 min (C) and 22.4 min (D), corresponding to the DAIH adducts.

this molecule could not be converted to a DAIH derivative (data not shown). Fraction V contained (*E*)-2-tridecenal, although we did not examine whether (*E*)-2-tridecenal is compound **6**, **7**, or **8** (Figures 4 and 5). (*E*)-2-Hexenal, (*E*)-2-tetradecenal, (*E*)-2-pentadecenal, (*E*)-2-hexadecenal, and (*E*)-2-heptadecenal were also detected in the CSLE by DAIH derivatization (Figure 4 and Figure S4 in the Supporting Information). These results suggest that there are a variety of aliphatic electrophiles with an (*E*)-2-alkenal group in the CSLE, which is in agreement with previous studies.[3,9,16]

**Activation of Nrf2 Is Coupled to Covalent Modification of Keap1 by (*E*)-2-Decenal and (*E*)-2-Dodecenal.** Exposure of HepG2 cells to (*E*)-2-decenal and (*E*)-2-dodecenal under

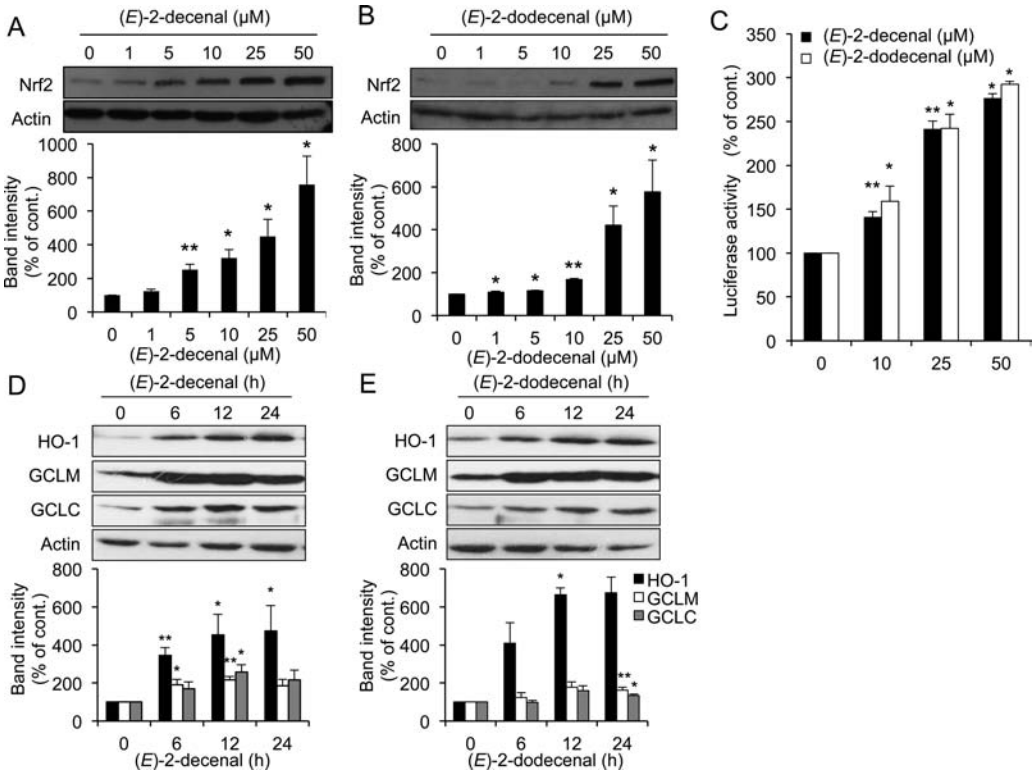

**Figure 6.** (*E*)-2-Decenal- or (*E*)-2-dodecenal-mediated activation of Nrf2 and up-regulation of downstream gene products. (A, B) The cells were exposed to (*E*)-2-decenal (A) or (*E*)-2-dodecenal (B) for 3 h, and total cell proteins were subjected to Western blot analysis with the indicated antibodies. (C) ARE-luciferase and pRL-TK cDNAs were transfected into HepG2 cells. After exposure of the cells to (*E*)-2-decenal or (*E*)-2-dodecenal for 6 h, luciferase activity was measured. (D, E) The cells were exposed to 25 $\mu$M (*E*)-2-decenal (D) or (*E*)-2-dodecenal (E) for 6, 12, or 24 h, and total cell proteins were subjected to Western blot analysis with the indicated antibodies. The bands were quantified using ImageJ software, and the density of each band was normalized to that of actin. Each value is the mean ± SE of three determinations. (*) $p < 0.05$ and (**) $p < 0.01$ versus control.

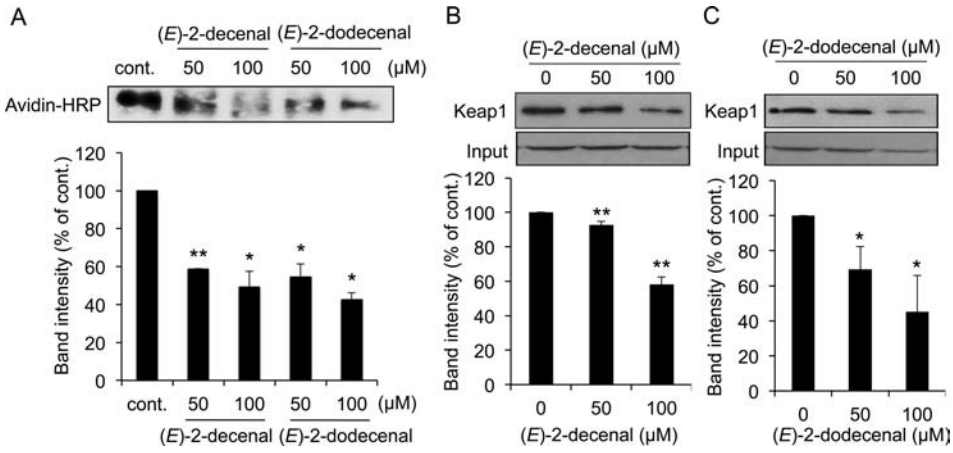

**Figure 7.** Modification of cellular Keap1 and purified Keap1 by (*E*)-2-decenal and (*E*)-2-dodecenal. (A) Recombinant murine Keap1 was incubated with (*E*)-2-decenal and (*E*)-2-dodecenal in 20 mM Tris-HCl (pH 8.5) at 37 °C for 20 min and allowed to react with 25 $\mu$M BPM (30 min at 37 °C). The reaction mixture was subjected to Western blot analysis with avidin−horseradish peroxidase conjugate. The bands were quantified using ImageJ software, and the band densities were normalized to that of Keap1. Each value is the mean ± SE of three determinations. (*) $p < 0.05$ and (**) $p < 0.01$ versus control. (B, C) HepG2 cells were incubated with (*E*)-2-decenal (B) and (*E*)-2-dodecenal (C) for 30 min and then lysed with RIPA buffer. Cell lysates were incubated with BPM (50 $\mu$M) for 30 min and then immunoprecipitated with avidin−agarose. The precipitated proteins were subjected to Western blot analysis with an anti-Keap1 antibody. The bands were quantified using ImageJ software. Each value is the mean ± SE of three determinations. (*) $p < 0.05$ and (**) $p < 0.01$ versus control.

nontoxic conditions (<50 $\mu$M) resulted in Nrf2 activation in a concentration-dependent manner (Figure 6A,B). These (*E*)-2-alkenal-related aliphatic electrophiles were able to transactivate Nrf2, as evaluated by ARE-dependent luciferase activity (Figure 6C), and to up-regulate the downstream gene products GCLC, GCLM, and HO-1 (Figure 6D,E). As shown in Figure 7A, recombinant Keap1 underwent covalent modification by (*E*)-2-decenal and (*E*)-2-dodecenal, as evaluated in the BPM assay. Cellular Keap1 was also modified in HepG2 cells exposed to (*E*)-2-decenal and (*E*)-2-dodecenal (Figure 7B,C).

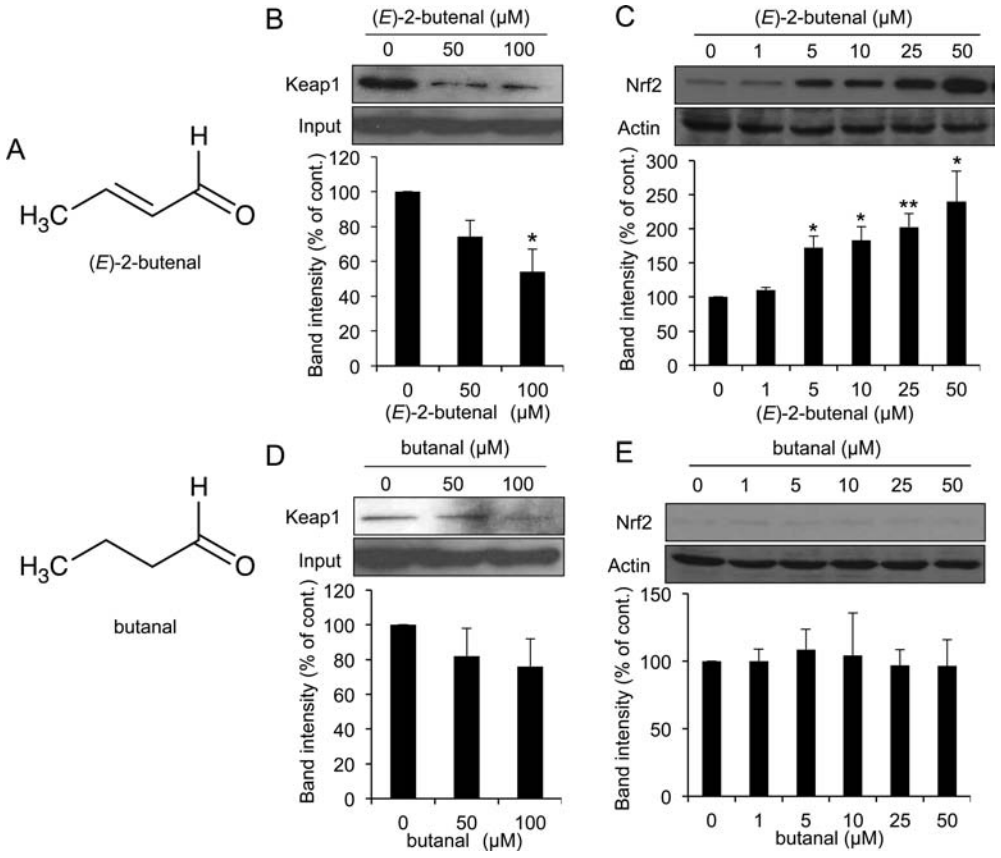

**Figure 8.** S-Alkylation of the cellular Keap1 and activation of Nrf2 during exposure of HepG2 cells to (*E*)-2-butenal or butanal. Panel A shows structures of (*E*)-2-butenal and butanal. (B, D) Cells were incubated with (*E*)-2-butenal (B) or butanal (D) for 30 min and then lysed with RIPA buffer. The cell lysates were incubated with BPM (50 $\mu$M) for 30 min and then immunoprecipitated with avidin−agarose. The precipitated proteins were subjected to Western blot analysis with an anti-Keap1 antibody. (C, E) The cells were exposed to (*E*)-2-butenal (C) or butanal (E) for 3 h, and total cell proteins were subjected to Western blot analysis with the indicated antibodies. The bands were quantified by using ImageJ software. Each value is the mean ± SE of three determinations. (*) $p < 0.05$ and (**) $p < 0.01$ versus control.

**(*E*)-2-Alkenal Structure Is Essential for Nrf2 Activation.** On the basis of the results described above, we postulated that the (*E*)-2-alkenal moiety is required for the covalent modification of Keap1 that leads to Nrf2 activation during exposure of cells to isolated CSLE phytochemicals because of its electrophilic properties. To confirm this hypothesis, we calculated the electrophilicity of (*E*)-2-butenal and butanal as model compounds (Figure 8A). The electrophilicity index of (*E*)-2-butenal, calculated using Gaussian09 (ver. 8.0) software, was 3.23 eV, and the electrophilicity indices of related chemicals were similar (Table 1). These results suggest that the electrophilic potentials of (*E*)-2-alkenals are unaffected by differences in the carbon number of these chemicals. In contrast, butanal was weaker in electrophilicity and harder than (*E*)-2-butenal ($\eta$ = 2.64 eV, $\sigma$ = 0.38, Table 1). Consistent with this, butanal only minimally reacted with the thiol groups of GSH (Supporting Information Figure S5). In HepG2 cells, (*E*)-2-butenal modified intracellular Keap1, as detected by the BPM assay (Figure 8B), and activated Nrf2 in a concentration-dependent manner (Figure 8C), whereas exposure to butanal did not result in Keap1 modification and Nrf2 activation (Figure 8D,E).

**Table 1. Electrophilicity Index ($\omega$), Global Hardness ($\eta$), and Softness ($\sigma$) of Butanal and Various (*E*)-2-Alkenals[a]**

| compound | $\omega$ (eV) | $\eta$ (eV) | $\sigma$ (eV) |
|---|---|---|---|
| butanal | 2.29 | 3.07 | 0.33 |
| (*E*)-2-butenal | 3.23 | 2.64 | 0.38 |
| (*E*)-2-decenal | 3.21 | 2.61 | 0.38 |
| (*E*)-2-undecenal | 3.17 | 2.63 | 0.38 |
| (*E*)-2-dodecenal | 3.17 | 2.63 | 0.38 |
| (*E*)-2-tridecenal | 3.17 | 2.63 | 0.38 |

[a]Calculated as described under Materials and Methods.

## DISCUSSION

The present study indicates that phytochemicals involved in the Nrf2 activation are (*E*)-2-alkenal-related aliphatic electrophiles. Preparative ODS column chromatography and a DAIH labeling assay, followed by UPLC-MS/MS isolated nine phytochemicals from a CSLE that were identified as (*E*)-2-hexenal, (*E*)-2-decenal, (*E*)-2-undecenal, (*E*)-2-dodecenal, (*E*)-2-tetradecenal, (*E*)-2-pentadecenal, (*E*)-2-hexadecenal, and (*E*)-2-heptadecenal (Figure 4B and Figure S4 in the Supporting Information). Supporting our results, (*E*)-2-alkenals have been detected in an extract of *C. sativum* leaves by GC-MS.[3,5] Potter has shown that a pentane extract of the leaves of *C. sativum* contained a series of (*E*)-2-alkenals that accounted for approximately 69% of the *C. sativum* leaf oil, consisting mainly of (*E*)-2-decenal (46.1%) and (*E*)-2-dodecenal (10%).[3] Whereas 4-hydroxy-2-(*E*)-nonenal and acrolein are found to be aliphatic electrohiles, which are able to activate Nrf2,[27−29] to our knowledge there is no report that these compounds are components in *C. sativum* leaf oil. These

dx.doi.org/10.1021/jf5030592 | J. Agric. Food Chem. 2014, 62, 10936−10944

suggest, therefore, that (*E*)-2-alkenals would predominantly participate in CSLE-dependent Nrf2 activation. Matsutani et al.[30] have reported that (*E*)-2-hexenal enhances ARE-dependent luciferase activity in K562 cells, supporting our notion.

It is well-known that oxidative stress-mediated phosphorylation of Nrf2, oxidative modification and covalent modification of Keap1, and proteasome inhibition are associated with substantial Nrf2 activation.[20,31−33] In a preliminary study, we found that (*E*)-2-decenal and (*E*)-2-dodecenal could neither cause proteasome inhibition nor induce oxidative stress under the concentrations examined in the present study (data not shown). As shown in Figure 7 and Figure S1 in the Supporting Information, the BPM-labeling assay revealed that CSLE, (*E*)-2-decenal, and (*E*)-2-dodecenal are able to modify Keap1 through thiol groups, suggesting that these (*E*)-2-alkenals are able to incorporate into the cells presumably by passive diffusion and then modify the cellular proteins. Thus, it seems likely that *S*-alkylation of Keap1 participates in the Nrf2 activation (Figure 9).

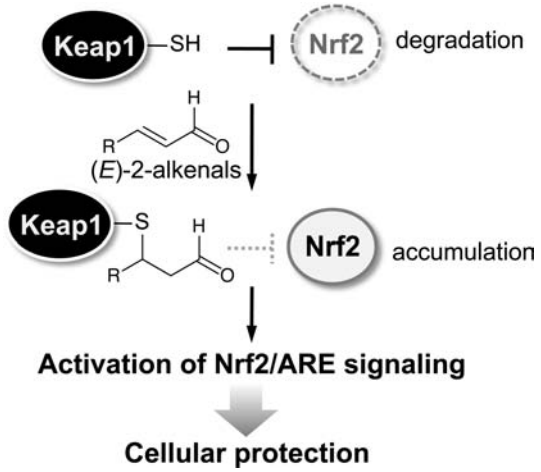

**Figure 9.** (*E*)-2-Alkenals in *C. sativum* leaves activate Nrf2/ARE signaling through covalent modification of Keap1.

(*E*)-2-Alkenals isolated from CSLE activated Nrf2 to a similar degree despite the different carbon numbers of these phytochemicals (Figures 3 and 5). This suggests that the (*E*)-2-alkenal groups are a common substituent required for the activation of Nrf2. Such a hypothesis was well supported by an estimation of the electrophilicity indices for (*E*)-2-alkenals with different carbon numbers (Table 1). Furthermore, experiments with (*E*)-2-butenal as a model of (*E*)-2-alkenals with an $\alpha,\beta$-unsaturated aldehyde group indicated that even (*E*)-2-butenal can modify cellular Keap1, thereby activating Nrf2 in HepG2 cells, whereas butanal had no effect on Keap1 modification and Nrf2 activation (Figure 8). Collectively, our study strongly indicates that CSLE contains several electrophiles, which can easily bind to soft nucleophiles,[34,35] and thus can activate Nrf2 through covalent modification of Keap1 through the (*E*)-2-alkenal group of these chemicals (Figure 9). Acrolein with an $\alpha,\beta$-unsaturated aldehyde is reported to up-regulate downstream protein of Nrf2 such as HO-1 through activation of phosphatidylinositol 3-kinase pathway.[36] Further study is required to clarify whether or not CSLE, (*E*)-2-decenal, and (*E*)-2-dodecenal could activate Nrf2 through activation of other signaling pathways in addition to covalent modification of Keap1 (Figure 7 and Figure S1 in the Supporting Information).

A variety of phytochemicals with different structures are known to have an effect on health through activation of Nrf2.[37,38] For example, sulforaphane in *Brassica oleracea* var. *italica*,[39] curcumin in *Curcuma longa* L., caffeic acid phenyl ester in honey,[37,38] perillaldehyde in *Perilla frutescens* (L.) Britt. and *Artemisia princeps* Pamp.,[30] diallyl trisulfide in *Allium sativum* L.,[40] and now (*E*)-2-alkenal derivatives in *C. sativum* leaves are able to activate Keap1/Nrf2 signaling. This Nrf2 activation results in up-regulation of downstream proteins associated with cellular protection such as phase II xenobiotic detoxification enzymes (GCLM and GCLC), phase III transporters (multidrug resistance-associated proteins), and antioxidant proteins (HO-1 and peroxiredoxin).[16−20] GCLM, GCLC, and HO-1 were induced during exposure of HepG2 cells to (*E*)-2-decenal or (*E*)-2-dodecenal (Figure 6). We have previously reported that sulforaphane can suppress arsenic-induced cytotoxicity through Nrf2 activation and induction of downstream proteins.[16] CSLE and (*E*)-2-alkenals also have a cytoprotective effect on arsenite-induced cytotoxicity (data not shown). (*E*)-2-Alkenals are contained not only in *C. sativum* leaves but also in other plants, including *Eryngium fetidum* L. belonging to the Umbelliferae family.[5,41] (*E*)-2-Hexenal, which is synthesized in green leaves from $\alpha$-linolenic and linolenic acids, is a component of the green odor for various classes of plants.[4] Therefore, we postulate that aliphatic electrophiles, such as (*E*)-2-alkenals in plants, possess a potential cytoprotective effect against environmental pollutants and oxidative stress through activation of electrophilic signaling mediated by the (*E*)-2-alkenal group.

[a]Compound **1** was recorded in pyridine-$d_5$, and the others were in $CDCl_3$.

**Extraction and Isolation.** The air-dried fruits of *C. orbiculatus* (9.0 kg) were powdered and extracted with methanol three times (3 × 54 L) under reflux. The organic solvent was evaporated to afford a crude extract (1.2 kg). The extract was suspended in $H_2O$ (1.2 L) and then partitioned with petroleum ether (5 × 1.2 L) and ethyl acetate (5 × 1.2 L) successively. The ethyl acetate soluble part (190 g) was fractionated by silica gel column chromatography (silica gel, 1.2 kg; column, 9 × 70 cm), using a gradient solvent system of petroleum ether/acetone (100:0, 100:2, 100:4, 100:7, 100:10, 100:15, 100:20, and 100:28, 21 L for each gradient elution), to afford seven fractions ($F_1$−$F_7$) according to the TLC analyses. Fraction $F_3$ (eluted by petroleum ether/acetone, 100:4 and 100:7) was subjected to medium-pressure liquid chromatography (MPLC) over octadecylsilyl (ODS) eluting with a step gradient from 68 to 87% MeOH in $H_2O$ to give seven subfractions ($F_{3\text{-}1}$−$F_{3\text{-}7}$). Subfraction $F_{3\text{-}4}$ was further purified by preparative HPLC (YMC-pack ODS-AM, 250 × 20 mm i.d., 85% MeOH in $H_2O$) to afford compound **1** ($t_R$ = 29 min, 14.7 mg). Fraction $F_5$ (eluted by petroleum ether/acetone, 100:10 and 100:15), using the above MPLC (67−87% MeOH in $H_2O$), provided 12 subfractions $F_{5\text{-}1}$−$F_{5\text{-}12}$, and the following purification of $F_{5\text{-}1}$ by the

[a]Compound **1** was recorded in pyridine-$d_5$, and the others were in $CDCl_3$.

same HPLC system (72% MeOH in $H_2O$) yielded compounds **2** ($t_R$ = 28 min, 13.5 mg) and **7** ($t_R$ = 31 min, 12.7 mg). By the same HPLC system, compound **3** ($t_R$ = 29 min, 40.6 mg) was obtained from subfraction $F_{5\text{-}5}$ (82% MeOH in $H_2O$). The further purification of subfractions $F_{5\text{-}2}$ (78% MeOH in $H_2O$) and $F_{5\text{-}10}$ (88% MeOH in $H_2O$) yielded compounds **4** ($t_R$ = 12 min, 8.7 mg) and **6** ($t_R$ = 48 min, 5.0 mg), respectively. Compounds **5** ($t_R$ = 23 min, 6.0 mg) and **10** ($t_R$ = 25 min, 6.9 mg) were acquired from the subfraction $F_{5\text{-}12}$ (91% MeOH in $H_2O$) with the same HPLC system. Compounds **8** ($t_R$ = 47 min, 4.9 mg) and **9** ($t_R$ = 45 min, 6.6 mg) were isolated from subfraction $F_{4\text{-}2}$ (72% MeOH in $H_2O$), which was obtained from $F_4$ (eluted by petroleum ether/acetone, 100:7 and 100:10) by the above MPLC (67−87% MeOH in $H_2O$).

**Celaspene A (1):** white powder; $[\alpha]_D^{21}$ −21.4 (*c* 0.19, $CH_2Cl_2$); CD ($CH_3CN$) 198 ($\Delta\varepsilon$ −19.3), 222 ($\Delta\varepsilon$ +9.4), 239 ($\Delta\varepsilon$ −13.9) nm; IR (KBr) $\nu_{max}$ 2955, 2917, 2849, 1736, 1602, 1369, 1279, 1229, 1114, 1069, and 1026 cm$^{-1}$; $^{13}$C NMR (100 MHz, pyridine-$d_5$) and $^1$H NMR (400 MHz, pyridine-$d_5$) data, Tables 1 and 2, respectively; ESIMS *m*/*z* 659 $[M + Na]^+$; HR-ESIMS *m*/*z* 659.2466 $[M + Na]^+$, calcd for $C_{35}H_{40}NaO_{11}$, 659.2468.

**Computational Methods.** Details have been previously reported.[11,12]

**Antifungal Activity Assay.** The antifungal activities of the isolated compounds were tested against six pathogenic fungi (*Gibberella zeae*, *Physalospora piricola*, *Alternaria solani*, *Cercospora arachidicola*, *Cladosporium cucumerinum*, and *Phytophthora capsici*) using a mycelium growth inhibition method.[13−17] The test solution (1 mL, 50 $\mu$g/mL) was poured into sterile culture plates (9 cm diameter), and agar culture medium (9 mL) was added. Sterile water (1 mL) and agar culture medium (9 mL) were used as controls. The inocula, 4 mm in diameter, were removed from the margins of actively growing colonies of mycelium, placed in the centers of the above plates, and incubated at 24 °C. After an incubation of 72 h, the diameter of the mycelium was measured. Each treatment was performed in two replicates. The inhibitory rate was used to describe the antifungal activities of compounds:

$$\text{inhibition rate (\%)} = (\text{av hyphal diam in control} - \text{av hyphal diam in treatment})/\text{av hyphal diam in control}$$

## RESULTS AND DISCUSSION

The ethyl acetate-soluble part of the methanol extract of the fruits of *C. orbiculatus* was subjected to silica gel column chromatography and further purified by HPLC to acquire nine new (**1**−**9**) and one known (**10**) compound (Figure 1). The known compound was identified by comparison of spectroscopic data with those reported in the literature as 6$\alpha$-acetoxy-1$\beta$,2$\beta$,9$\beta$-tribenzoyloxy-8$\beta$-nicotinoyloxy-$\beta$-dihydroagarofuran, **10**.[18]

Compound **1** was isolated as a white powder. Its molecular formula was determined as $C_{35}H_{40}O_{11}$ on the basis of HR-ESI-MS spectroscopic data, which were consistent with the NMR data. The $^1H$ NMR spectrum of **1** exhibited six methyl groups [$\delta_H$ 2.18 (3H, s, COC$H_3$-13), 2.17 (3H, s, COC$H_3$-1), 1.59 (3H, s, COC$H_3$-6), 1.57 (3H, s, $H_3$-14), 1.48 (3H, s, $H_3$-15), and 1.06 (3H, d, $J$ = 7.0 Hz, $H_3$-12)], four oxygenated methine protons [$\delta_H$ 5.87 (1H, dd, $J$ = 11.7, 4.7 Hz, H-1), 7.07 (1H, s, H-6), 6.13 (1H, dd, $J$ = 5.6, 3.7 Hz, H-8), and 6.20 (1H, d, $J$ =

dx.doi.org/10.1021/jf503735t | J. Agric. Food Chem. 2014, 62, 10945−10953

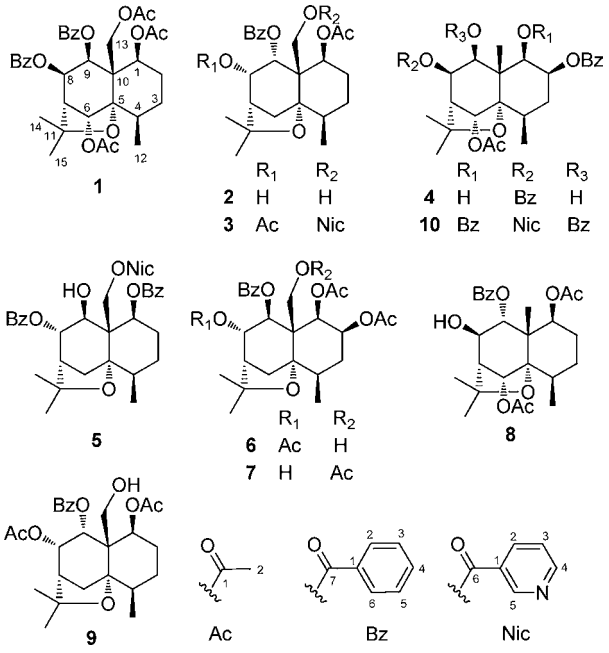

**Figure 1.** Structures of compounds **1**–**10** from *C. orbiculatus*.

5.6 Hz, H-9)], and a pair of methylene protons [$\delta_H$ 5.24 and 5.06 (each 1H, d, $J$ = 13.2 Hz, $H_2$-13)]. Additionally, 10 aromatic protons were also revealed by the $^1$H NMR spectrum. The $^{13}$C NMR spectrum of **1** showed 35 carbon resonances (Table 1). From the $^1$H and $^{13}$C NMR spectra, three acetyl groups and two benzoyl groups were deduced and defined from the above proton signals and the observation of the corresponding carbon signals (Tables 1 and 2).[5] In addition to the above 20 signals for the acyl groups, there are additional 15 resonances displayed for the parent skeleton in the $^{13}$C NMR spectrum. These skeletal carbon signals comprised three methyls [$\delta_C$ 14.9 (C-12), 24.2 (C-14), and 30.1 (C-15)], two methylenes [$\delta_C$ 23.3 (C-2), and 26.5 (C-3)], six methines [$\delta_C$ 79.2 (C-1), 33.5 (C-4), 74.7 (C-6), 53.3 (C-7), 71.4 (C-8), and 73.3 (C-9)], and four quaternary carbons [$\delta_C$ 91.0 (C-5), 51.1 (C-10), and 81.1 (C-11)] on the basis of the HMQC and DEPT spectra. The above spectroscopic features and the 15 skeletal carbons displayed in the $^{13}$C NMR spectrum suggested that compound **1** is a sesquiterpene having five acyloxy groups (three acetoxy and two benzoyloxy groups).[7−10] When the chemical shifts of skeletal carbons of **1** were compared with those of sesquiterpenes reported in the literature,[5,19] the presence of $\beta$-dihydroagarofuran skeleton for **1** was obvious. To corroborate the above deductions and confirm the $\beta$-dihydroagarofuran sesquiterpene skeleton, the HMBC and $^1$H−$^1$H COSY experiments were performed. By interpretation of the HMQC, HMBC, and $^1$H−$^1$H COSY spectra, the $\beta$-dihydroagarofuran sesquiterpene skeleton for **1** was elucidated, where the oxygenated methine and methylene carbon signals at $\delta_C$ 79.2, 74.7, 71.4, 73.3, and 60.8 were assigned to C-1, C-6, C-8, C-9, and C-13, respectively. The locations of the five acyloxy groups were determined via HMBC correlations. The long-range correlation of the proton H-1 ($\delta_H$ 5.87) with the carbonyl signal at $\delta_C$ 169.8 (CO of the acetoxy moiety) revealed the presence of the acetoxy group at C-1. Similarly, the long-range couplings of the protons H-6 ($\delta_H$ 7.07) and $H_2$-13 ($\delta_H$ 5.24 and 5.06), with the carbonyl carbon signals at $\delta_C$ 169.8 and 170.5 evidenced that the remaining two acetoxy groups were attached at C-6 and C-13, respectively. The two benzoyloxy groups located at C-8 and C-9 were verified by the HMBC correlations of H-8 and H-9 to the corresponding carbonyl carbons of two benzoyloxy groups. Further analyses of the 2D NMR spectra (Figure 2) led to the assignments of all the proton and carbon signals, and the planar structure for **1** was thus established.

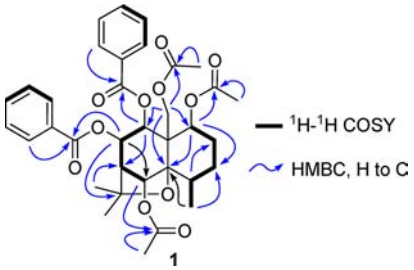

**Figure 2.** Selected HMBC and $^1$H−$^1$H COSY correlations of compound **1**.

The relative configuration of compound **1** was established on the basis of the NOESY spectrum and Chem3D modeling (Figure 3). NOESY correlations observed for $H_3$-12/$H_2$-13, $H_3$-12/H-2$\beta$, $H_2$-13/H-2$\beta$, $H_2$-13/H-6, $H_3$-12/H-6, H-1/H-9, H-9/$H_3$-14, H-8/$H_3$-14, and H-1/H-3$\alpha$ (Figure 3), but not for $H_2$-13/H-1, $H_2$-13/H-9, and $H_3$-12/H-1, and the Chem3D modeling indicated a conformation for compound **1** as shown in Figure 3, where the two six-membered rings B and A were *trans*-fused and existed in a twist-chair and chair conformation, and the furan ring C, almost perpendicular to the six-membered ring B, was located below ring B. The arrangement of the three rings and the NOESY correlations required that the C-12 methyl group and the C-13 methylene group were both $\beta$-axially oriented, the C-1 acetoxy group and the C-9 benzoyloxy group were both $\beta$-equatorially oriented, the C-6 acetoxy group was in an $\alpha$-equatorial position, and the C-8 benzoyloxy group was in a $\beta$-axial position.[5,19] Thus, the relative configuration of **1** was designated as shown in Figure 3. The absolute configuration of **1** was tentatively established by the TDDFT CD calculations[20,21] and substantiated by the CD exciton chirality method.[22] Through the systematic conformational search and optimization and TDDFT CD calculations, the calculated ECD spectra were obtained. The calculated ECD spectrum of **1a** (Figure 4) is agreement with the experimental result, which suggested an absolute configuration of 1*S*,4*R*,5*S*,6*R*,7*R*,8*R*,9*S*,10*S* for compound **1**, whereas the experimental CD spectrum of **1** showed a characteristic Davidoff-type split curve with a first negative Cotton effect at 239 nm ($\Delta\varepsilon$ −13.9) and a second positive effect at 222 nm ($\Delta\varepsilon$ +9.4), due to the couplings of the two benzoyloxy chromophores at C-8$\beta$ and C-9$\beta$, which confirmed the absolute configuration of 1*S*,4*R*,5*S*,6*R*,7*R*,8*R*,9*S*,10*S* unequivocally. On the basis of the above evidence, the structure of **1** was established as (1*S*,4*R*,5*S*,6*R*,7*R*,8*R*,9*S*,10*S*)-1$\beta$,6$\alpha$,13-triacetoxy-8$\beta$,9$\beta$-dibenzoyloxy-$\beta$-dihydroagarofuran, which has been named celaspene A.

Compound **2**, a colorless oil, had a molecular formula of $C_{24}H_{32}O_7$ as deduced from the HR-ESIMS. From the $^1$H NMR spectrum of **2**, four methyl groups, five aromatic protons, three oxygenated methine protons, and a pair of methylene protons were displayed (Table 2). The $^{13}$C NMR spectrum of **2** exhibited 24 carbon resonances. From the $^1$H and $^{13}$C NMR spectra, one acetyl group was apparent from the methyl singlet

dx.doi.org/10.1021/jf503735t | J. Agric. Food Chem. 2014, 62, 10945−10953

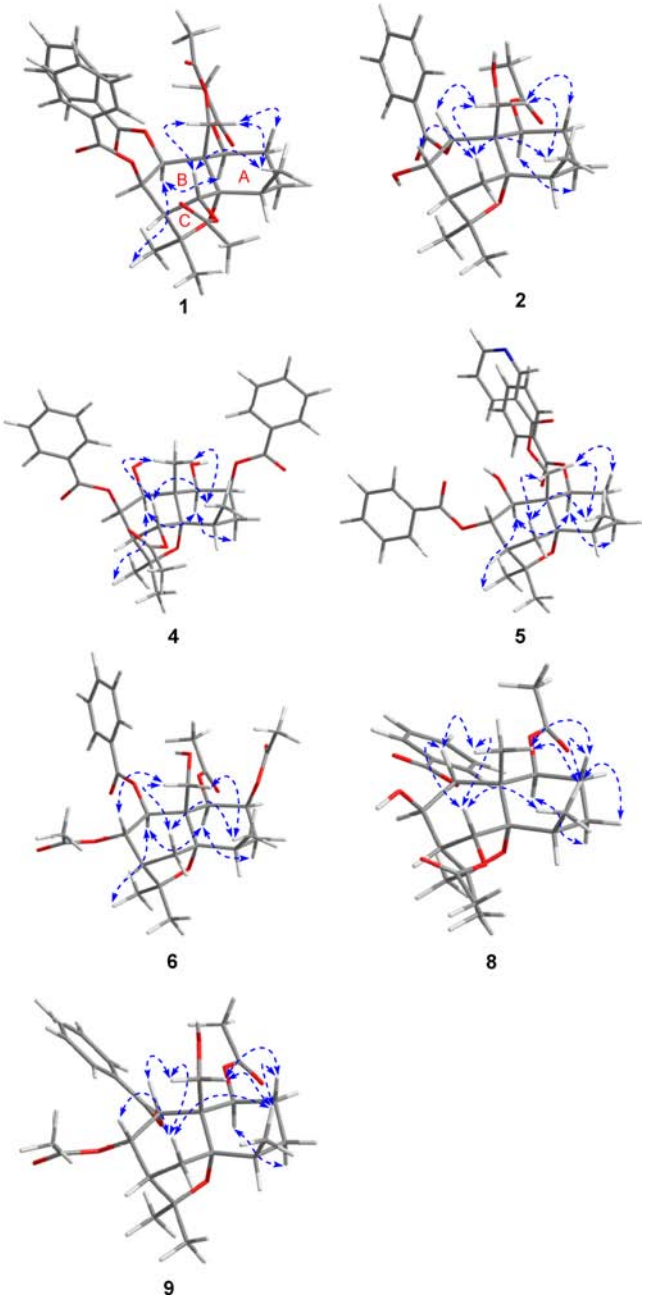

**Figure 3.** Key NOESY correlations of compounds **1**, **2**, **4**−**6**, **8**, and **9**.

and the corresponding carbon signals (Tables 1 and 2). In addition, one benzoyloxy group was also deduced and defined from the observation of the aromatic proton signals (Table 2) and the typical aromatic carbon signals (Table 1).[5−10] Apart from the above nine resonances for the substituent groups, the remaining 15 skeletal carbon resonances indicated in the $^{13}C$ NMR spectrum form a characteristic $\beta$-dihydroagrofuran skeleton.[5] To elucidate the skeleton and assign the substituent groups, the following HMQC, HMBC, and $^{1}H-^{1}H$ COSY experiments were performed. By interpretation of the 2D NMR spectra, the characteristic 1,8,9,13-tetrasubstituted-$\beta$-dihydroagrofuran sesquiterpene skeleton was confirmed, where the oxygenated methylene and methine carbons at $\delta_C$ 75.4, 72.6, 70.8, and 62.5 were ascribed to C-1, C-8, C-9, and C-13, respectively. The HMBC correlations of the protons H-1 ($\delta_H$ 5.60) and H-9 ($\delta_H$ 6.03) with the carbonyl carbons at $\delta_C$ 169.2

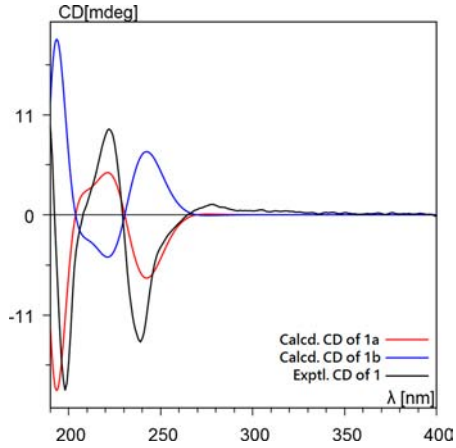

**Figure 4.** Calculated ECD spectra of **1a** (1*S*,4*R*,5*S*,6*R*,7*R*,8*R*,9*S*,10*S*)- and **1b** (1*R*,4*S*,5*R*,6*S*,7*S*,8*S*,9*R*,10*R*)-isomers and the experimental ECD spectrum of **1** in acetonitrile.

and 167.7 demonstrated that the acetoxy group was attached at C-1 and the benzoyloxy group was at C-9, respectively. There were no additional acyloxy groups in compound **2**, so the substituent groups at C-8 and C-13 could only be hydroxy groups, which was confirmed by the HR-ESIMS data. Further analyses of the HMQC, HMBC, and $^{1}H-^{1}H$ COSY spectroscopic data resulted in the assignments of all the proton and carbon signals. The planar structure with a $\beta$-dihydroagrofuran sesquiterpene skeleton for **2** was therefore disclosed. The relative configuration was elucidated on the basis of the NOESY spectrum and the coupling constants. NOESY correlations observed for $H_3$-12/$H_2$-13, $H_3$-12/H-2$\beta$, $H_2$-13/H-2$\beta$, $H_2$-13/H-6$\beta$, $H_3$-12/H-6$\beta$, $H_2$-13/H-9, H-8/H-6$\beta$, and H-1/H-3$\alpha$ (Figure 3), but not for H-1/H-9, $H_2$-13/H-1, $H_3$-14/H-8, H-9/$H_3$-14, and $H_3$-12/H-1, and the Chem3D modeling revealed a conformation for compound **2** as shown in Figure 3, where the C-1 acetoxy group was in a $\beta$-equatorial position and the C-9 benzoyloxy group was in an $\alpha$-axial position. The C-8 hydroxy group was determined as $\alpha$-equatorially oriented, which was supported by the coupling constant between H-9 and H-8 ($J_{8,9}$ = 6.2 Hz).[7,19] Thus, the relative configuration of **2** was characterized as in Figure 3. Considering the biosynthetic origin, the conformations of three skeletal rings, and the same relative configurations for C-4, C-5, and C-10 in compounds **2** and **1**, the absolute configurations of C-4, C-5, and C-10 were established to be 4*R*, 5*S*, and 10*S* and the absolute configurations of C-1, C-8, and C-9, consequently, were determined as 1*S*, 8*S*, and 9*R*.[5] Thus, compound **2** was characterized as (1*S*,4*R*,5*S*,7*S*,8*S*,9*R*,10*S*)-1$\beta$-acetoxy-9$\alpha$-benzoyloxy-8$\alpha$,13-dihydroxy-$\beta$-dihydroagarofuran, which was named celaspene B.

Compound **3** possessed the molecular formula of $C_{32}H_{37}NO_9$ on the basis of the HR-ESIMS. The $^{1}H$ and $^{13}C$ NMR spectra implied that **3** had the same 1,8,9,13-tetrasubstituted-$\beta$-dihydroagrofuran sesquiterpene skeleton as compound **2** and possessed four acyl groups.[5−10,19] Besides one benzoyl and two acetyl groups, an additional nicotinoyl group was deduced and defined on the basis of the proton signals and the typical carbon resonances (Tables 1 and 2).[19,23] The following 2D NMR experiments validated the above deductions. The locations of the acyl groups were elucidated by interpretation of the HMBC data as in the case of **2**. HMBC correlations of the protons at H-1 ($\delta_H$ 5.60), H-8 ($\delta_H$ 5.67), H-

dx.doi.org/10.1021/jf503735t | J. Agric. Food Chem. 2014, 62, 10945−10953

9 ($\delta_H$ 5.94), and $H_2$-13 ($\delta_H$ 4.86 and 4.80) with the corresponding carbonyl carbons at $\delta_C$ 169.6, 169.9, 165.9, and 165.3 indicated that two acetoxy, one benzoyloxy, and one nicotinoyloxy group were attached at C-1, C-8, C-9, and C-13, respectively. By further analyzing the 2D NMR spectra, the planar structure of **3** was established. The relative configuration of compound **3** was elucidated on the basis of the NOESY spectrum and Chem3D modeling as that of compound **2**. The NOESY correlations observed for $H_3$-12/$H_2$-13, $H_3$-12/H-2$\beta$, $H_2$-13/H-2$\beta$, $H_2$-13/H-6$\beta$, $H_3$-12/H-6$\beta$, $H_2$-13/H-9, H-8/H-6$\beta$, and H-1/H-3$\alpha$ (Figure 3), but not for $H_2$-13/H-1, H-1/H-9, H-9/$H_3$-14, and $H_3$-12/H-1, and the Chem3D modeling disclosed a molecular conformation for compound **3** as depicted in Figure 3, where all of the chiral carbons had the same relative configurations as those of compound **2**. On the basis of the above spectroscopic evidence and the biosynthetic standpoint, compound **3** was assigned as (1*S*,4*R*,5*S*,7*S*,8*S*,9*R*,10*S*)-1$\beta$,8$\alpha$-diacetoxy-9$\alpha$-benzoyloxy-13-nicotinoyloxy-$\beta$-dihydroagarofuran and named celaspene C, which is the C-8 isomer of the known compound 1$\beta$,8$\alpha$-diacetoxy-9$\beta$-benzoyloxy-13-nicotinoyloxy-$\beta$-dihydroagarofuran.[24,25]

Analyses of the $^{13}C$ and $^{1}H$ NMR data (Tables 1 and 2) of compound **4** revealed that **4** had the characteristic 1,2,6,8,9-pentasubstituted-$\beta$-dihydroagarofuran sesquiterpene skeketon.[5−10] The same acyl groups as those appearing in compounds **1**−**3** were apparent, which were deduced and determined as one acetyl and two benzoyl groups according to its $^{13}C$ and $^{1}H$ NMR spectra.[19,23] The residual substituent groups could only be hydroxy groups, which were validated by the HR-ESIMS data. Through the same 2D NMR experiments, especially HMBC and $^{1}H-^{1}H$ COSY experiments, as for compounds **1**−**3**, the positions of the substituent groups (one acetoxy and two benzoyloxy groups) of **4** were determined, which suggested that the two benzoyloxy groups were attached at C-2 and C-8, the two hydroxy groups were ascribed to C-1 and C-9, and the acetoxy group was at C-6, respectively. The NOESY spectrum and the coupling constants allowed the relative configuration of **4** to be assigned. The NOESY correlations observed for $H_3$-12/$H_3$-13, $H_3$-13/H-6, $H_3$-12/H-6, H-1/H-9, H-9/$H_3$-14, H-8/$H_3$-14, and H-1/H-3$\alpha$ (Figure 3), but not for $H_3$-13/H-1, $H_3$-13/H-9, $H_3$-12/H-1, and $H_3$-12(13)/H-2, and Chem 3D revealed that the two hydroxy groups attributed to C-1 and C-9 were both $\beta$-equatorially oriented, the two benzoyloxy groups ascribed to C-2 and C-8 were both $\beta$-axially oriented, and the acetoxy attached at C-6 was $\alpha$-equatorially oriented.[5,19] The coupling constants between H-9 and H-8 ($J_{8,9}$ = 4.7 Hz) and H-1 and H-2 ($J_{1,2}$ = 3.6 Hz) also confirmed that the protons H-1 and H-9 were in $\alpha$-axial positions and H-2 and H-8 were in $\alpha$-equatorial positions, respectively. According to the above spectroscopic evidence and the biosynthetic standpoint, the structure of compound **4** was therefore assigned as (1*R*,2*S*,4*R*,5*S*,6*R*,7*R*,8*R*,9*S*,10*S*)-6$\alpha$-acetoxy-2$\beta$,8$\beta$-dibenzoyloxy-1$\beta$,9$\beta$-dihydroxy-$\beta$-dihydroagarofuran,[5] which has been named celaspene D.

The HR-ESIMS provided a molecular formula of $C_{35}H_{37}NO_8$ for compound **5**. The $^{13}C$ and $^{1}H$ NMR spectra (Tables 1 and 3) suggested a 1,8,9,13-tetrasubstituted-$\beta$-dihydroagarofuran sesquiterpene skeketon for **5**.[5−10] The four substituent groups were deduced as two benzoyloxy groups, one nicotinoyloxy group,[19,23] and one hydroxy group according to its $^{13}C$ and $^{1}H$ NMR spectra, which was supported by the 2D NMR and HR-ESIMS data. As in the case of **1**−**4**, the acyloxy groups were positioned by interpretation of the HMBC spectrum. The HMBC correlations of the protons H-1, H-8, and $H_2$-13 with the carbonyl carbons at $\delta_C$ 166.4, 166.1, and 165.4 demonstrated that the two benzoyloxy groups were located at C-1 and C-8, and the nicotinoyloxy group was at C-13, respectively. Consequently, the substituent group at C-9 could only be hydroxy group. The coupling constants and the NOESY spectrum allowed the relative configuration of **5** to be assigned. The coupling constant ($J_{8,9}$ = 9.5 Hz) between H-9 and H-8 suggested that both H-8 and H-9 had an axial orientation, with a nearly 180° dihedral angle between H-8 and H-9.[7,19] The NOESY spectrum displayed the correlations of $H_3$-12/$H_2$-13, $H_3$-12/H-6$\beta$, $H_2$-13/H-6$\beta$, H-6$\beta$/H-8, $H_3$-12/H-2$\beta$, $H_2$-13/H-2$\beta$, $H_2$-13/H-8, H-1/H-9, H-9/$H_3$-14, and H-1/H-3$\alpha$ (Figure 3), but not for $H_2$-13/H-1, $H_2$-13/H-9, and $H_3$-12/H-1. According to the above evidence, the C-1 benzoyloxy group, the C-9 hydroxy group, and the C-8 benzoyloxy group were characterized as $\beta$-equatorial, $\beta$-equatorial, and $\alpha$-equatorial, respectively. The relative stereochemistry of **5** was therefore elucidated, where the orientation of the C-8 substituent group was different from those in compounds **1** and **4**. Also on the basis of the conformations of three skeletal rings and the biosynthetic origin, the absolute configuration of **5** was established as 1*S*,4*R*,5*S*,7*S*,8*S*,9*S*,10*R*.[5] Thus, compound **5** was elucidated as (1*S*,4*R*,5*S*,7*S*,8*S*,9*S*,10*R*)-1$\beta$,8$\alpha$-dibenzoyloxy-9$\beta$-hydroxy-13-nicotinoyloxy-$\beta$-dihydroagarofuran and named celaspene F.

Compounds **6** and **7** had the same molecular formula, $C_{28}H_{36}O_{10}$, on the basis of their HR-ESIMS data. Analyses of the $^{13}C$ and $^{1}H$ NMR spectra (Tables 1 and 3) of the two compounds revealed that compounds **6** and **7** had the same 1,2,8,9,13-pentasubstituted-$\beta$-dihydroagarofuran skeleton and the same substituent groups (one hydroxy, one benzoyloxy, and three acetoxy groups).[5,19] The difference was that the substituent groups in the two compounds were in different positions. Through the same 2D NMR experiments as those for compounds **1**−**5**, the positions of the hydrxoy and acyloxy groups in compounds **6** and **7** were determined. For compound **6**, the three acetoxy groups and the benzoyloxy group were attributed to C-1, C-2, and C-8, and C-9 by the HMBC correlations of H-1, H-2, H-8, and H-9 to the corresponding carbonyl carbons, and the remaining one hydroxy group could only be located at C-13. The following NOESY experiment and the coupling constants led to the elucidation of the relative configuration of **6**. The NOESY correlations observed for $H_3$-12/$H_2$-13, $H_3$-12/H-6$\beta$, $H_2$-13/H-6$\beta$, H-6$\beta$/H-8, $H_2$-13/H-8, H-1/H-9, H-9/$H_3$-14, and H-1/H-3$\alpha$ (Figure 3), but not for $H_2$-13/H-1(2), $H_2$-13/H-9, and $H_3$-12/H-1(2), the coupling constant of H-9 and H-8 ($J_{9,8}$ = 9.5 Hz), and the Chem3D modeling suggested a conformation for **6** as shown in Figure 3, where the C-1 acetoxy group and the C-9 benzoyloxy group were both in $\beta$-positions with an equatorial orientation, the C-2 acetoxy group was in a $\beta$-position with an axial orientation, and the C-8 acetoxy group was in an $\alpha$-position with an equatorial orientation. Compound **7** had the same substituent groups as compound **6**, and their relative locations were assigned by the HMBC spectrum, which demonstrated the three acetoxy groups and the benzoyloxy group were attached at C-1, C-2, C-13, and C-9, respectively. The only hydroxy group supported by the HR-ESIMS data was verified at C-8 by interpretation of the $^{1}H-^{1}H$ COSY spectrum. The same relative configuration for compounds **7** and **6** was inferred on the basis of the analyses

and the careful comparison of the NOESY spectra of **7** and **6**. On the basis of the same conformations of three skeletal rings in compounds **1**−**7** and the biosynthetic origin, compounds **6** and **7** were characterized as (1*R*,2*S*,4*R*,5*S*,7*S*,8*S*,9*S*,10*S*)-1*β*,2*β*,8*α*-triacetoxy-9*β*-benzoyloxy-13-hydroxy-*β*-dihydroagarofuran and (1*R*,2*S*,4*R*,5*S*,7*S*,8*S*,9*S*,10*R*)-1*β*,2*β*,13-triacetoxy-9*β*-benzoyloxy-8*α*-hydroxy-*β*-dihydroagarofuran, which have been named celaspenes G and H, respectively.

Compound **8** possessed the molecular formula of $C_{26}H_{34}O_8$ as determined by the HR-ESIMS. Its $^{13}C$ and $^{1}H$ NMR spectra (Tables 1 and 3) revealed that compound **8** was a 1,6,8,9-tetrasubstituted-*β*-dihydroagarofuran sesquiterpene with two acetyl, one benzoyl, and one hydroxy group, which was supported and confirmed by 2D NMR spectra. The further interpretation of 2D NMR spectra led to the determination of the relative positions of these substituent groups, which verified that the two acetoxy groups were located at C-1 and C-6, the benzoyloxy group was at C-9, and the hydroxy group was at C-8, respectively. By further analyzing the HMQC, HMBC, and $^{1}H-^{1}H$ COSY spectra, all of the proton and carbon signals were assigned unambiguously. On the basis of these assignments, the proton signals for H-8 and H-9 presented in the form of singlet, which implied the different configurations for C-8 and C-9 in **8**. The NOESY correlations of $H_3$-12/$H_3$-13, $H_3$-12/H-6, $H_3$-13/H-6, $H_3$-13/H-9, $H_3$-13/H-2*β*, $H_3$-12/H-2*β*, and H-1/H-3*α* (Figure 3), but not for H-6/H-8, H-1/H-9, H-9/$H_3$-14, $H_3$-13/H-1, and $H_3$-12/H-1, the coupling constant of H-9 and H-8 ($J_{9,8}$ = 0 Hz), and Chem3D modeling suggested that H-8 was *α*-equatorially oriented, H-9 was *β*-equatorially oriented, and H-1 was *α*-axially oriented.[5,19] Thus, the relative configuration of **8** was elucidated. According to the same conformations of three skeletal rings of compounds **1**−**7**, the absolute configuration of **8** was assigned as 1*S*,4*R*,5*S*,6*R*,7*R*,8*R*,9*R*,10*S*.[5,19] Compound **8** was therefore characterized as (1*S*,4*R*,5*S*,6*R*,7*R*,8*R*,9*R*,10*S*)-1*β*,6*α*-diacetoxy-9*α*-benzoyloxy-8*β*-hydroxy-*β*-dihydroagarofuran and named celaspene H, which is the C-9 isomer of the known compound 1*β*,6*α*-diacetoxy-9*β*-benzoyloxy-8*β*-hydroxy-*β*-dihydroagarofuran.[26−29]

Compound **9** possessed a molecular formula of $C_{26}H_{34}O_8$ from its HR-ESIMS. The molecular formula and its $^{13}C$ and $^{1}H$ NMR spectra (Tables 1 and 3) suggested that compound **9** was a 1,8,9,13-tetrasubstituted-*β*-dihydroagarofuran sesquiterpene with two acetoxy, one benzoyloxy, and one hydroxy group. To achieve the assignments of all the proton and carbon signals, the 2D NMR spectra were recorded. By interpretation and analyses of 2D NMR spectra, the planar structure of a 1,8,9,13-tetrasubstituted-*β*-dihydroagarofuran sesquiterpene was established, where the two acetoxy groups and one benzoyloxy group were ascribed to C-1, C-8, and C-9, and the residual hydroxy group was securely assigned to C-13. The coupling constant of H-9 and H-8 ($J_{9,8}$ = 6.4 Hz), Chem3D modeling, and the NOESY correlations of $H_3$-12/$H_2$-13, $H_3$-12/H-6*β*, $H_2$-13/H-6*β*, $H_2$-13/H-9, $H_2$-13/H-8, H-6*β*/H-8, $H_2$-13/H-2*β*, $H_3$-12/H-2*β*, and H-1/H-3*α* (Figure 3), but not for H-1/H-9, H-9/$H_3$-14, $H_2$-13/H-1, and $H_3$-12/H-1, revealed a molecular conformation for **9** as shown in Figure 3.[5] The proton H-1 was in an *α*-position with an axial orientation, H-8 was in a *β*-position with an axial orientation, and H-9 was in a *β*-position with an equatorial orientation. Similarly, from a biosynthetic standpoint, the absolute configuration was also assigned on the basis of the same conformations of the three skeletal rings.[5] Thus, compound **9** was elucidated as (1*S*,4*R*,5*S*,7*S*,8*S*,9*R*,10*S*)-1*β*,8*α*-diacetoxy-9*α*-benzoyloxy-13-hydroxy-*β*-dihydroagarofuran and named celaspene I.

To explore the potential biological effects of these new sesquiterpenes to serve agriculture, these isolated compounds from *C. orbiculatus* were preliminarily investigated for their antifungal activities against six pathogenic fungi (*G. zeae*, *P. piricola*, *A. solani*, *C. arachidicola*, *C. cucumerinum*, and *P. capsici*), which commonly infect crops, leading to severe crop yield reduction and dramatic economic losses in agriculture.[30] Chlorothalonil and carbendazol were used as the corresponding positive controls. At a concentration of 50 *μ*g/mL, all of the evaluated compounds exhibited antifungal activities. Their preliminary antifungal activities are shown in Figure 5

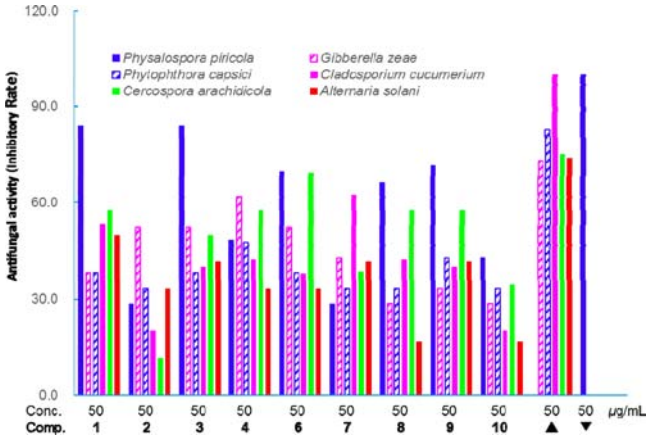

**Figure 5.** Antifungal effects of compounds **1**−**4** and **6**−**10** against six pathogenic fungi. Six common pathogenic fungi (*G. zeae*, *P. piricola*, *A. solani*, *C. arachidicola*, *C. cucumerinum*, and *P. capsici*) were selected to evaluate the antifungal activities of compounds **1**−**4** and **6**−**10**. The biological data presented are the mean scores for each treatment across replicates. The symbols ▲ and ▼ indicate the positive controls chlorothalonil and carbendazol, respectively.

(compound **5** was not assayed for the antifungal effects because of inadequate residual amount). For the pathogenic fungi *A. solani* and *P. capsici*, all of the compounds showed weak or moderate antifungal effects. For the fungus *G. zeae*, compound **4** showed a strong activity with an inhibitory rate of 62%. For the fungus *C. cucumerinum*, compound **7** showed a strong activity with an inhibitory rate of 62%. For the fungus *C. arachidicola*, compound **6** had a stronger activity with an inhibitory rate of 69% than other compounds. Compounds **1**, **3**, **6**, **8**, and **9** showed promising antifungal activities against the fungus *P. piricola* with inhibitory rates of 84, 84, 70, 66, and 71%, respectively. From the above antifungal data, there seem to be no obvious correlations among these activities against the six pathogenic fungi and the selectivity or sensitivity of each pathogenic fungus toward the same compound is different, which implies that the antifungal activity against different pathogenic fungus may have different mechanisms.

In conclusion, nine new and one known sesquiterpene were obtained from the fruits of the plant *C. orbiculatus*. Their structures, especially the stereochemical features, were elucidated by NMR data analyses, TDDFT CD calculations, and the CD exciton chirality method. The subsequent biological screenings exhibited that these isolated compounds showed antifungal activities against six phytopathogenic fungi. The results of our phytochemical investigation further revealed the chemical components of *C. orbiculatus* as an insecticidal and

medicinal plant, and the biological screenings implied that *C. orbiculatus* may be potentially useful to protect crops against phytopathogenic fungi and that the bioactive compounds may probably be considered as candidate agents of antifungal agrochemicals for crop protection products.

carried out in the veterinary area due to the promising overall efficacy of aromatic herbs for the benefit of animals and the quality of animal-derived products. Some authors have even proposed these naturally occurring substances as substitutes for antibiotic growth promoters.[14] In a preliminary study conducted by our group, the bioaccessibility and phase II metabolism of thyme phenols were assessed by an in vitro digestion model combined with Caco-2 and HepG-2 cell models.[15] The results of this study showed different metabolic profiles depending on the phenolic compound. Whereas eriodictyol appeared in both its sulfated and glucuronidated forms after cell incubation, naringenin was only conjugated into its glucuronide form. To complement these studies, it becomes essential to study the microbial conversion of thyme phenolic compounds and the elucidation of their colonic pathways. In this sense, the main aim of the present study was to provide more complete, comprehensive, and convincing results about the gut metabolism of thyme phenolic compounds by using a combination of in vitro and in vivo experiments. For the in vitro fermentation study, the most representative compounds from different subclasses of thyme phenols were selected: (i) the monoterpene thymol and its isomer carvacrol; (ii) the flavonoid eriodictyol; and (iii) rosmarinic acid, a phenolic acid occurring in many common aromatic herbs from the Lamiaceae group. After studying the in vitro gut metabolism pathways of the aforementioned thyme phenols, we investigated their colonic metabolites in human fecal samples obtained before and after a 3 week intervention with a daily administered dose of 25 mL (23 g) of a thyme phenol-enriched olive oil (TPEOO).

## MATERIALS AND METHODS

**In Vitro Colonic Fermentation.** Fecal samples were collected from three healthy volunteers who followed normal dietary habits and declared that they had not taken antibiotics for at least 3 months prior to the sample collection. The fermentation medium was carbonate−phosphate buffer. This was prepared according to a previously described method[16] by mixing (all in g/L) 9.240 $NaHCO_3$, 3.542 $Na_2HPO_4{\cdot}2H_2O$, 0.470 NaCl, 0.450 KCl, 0.227 $Na_2SO_4{\cdot}10H_2O$, 0.055 $CaCl_2$ (anhydrous), 0.100 $MgCl_2{\cdot}6H_2O$, and 0.400 urea with 10 mL/L of added trace element solution (in mg/L) 3680 $FeSO_4{\cdot}7H_2O$, 1159 $MnSO_4{\cdot}H_2O$, 440 $ZnSO_4{\cdot}7H_2O$, 120 $CoCl_2{\cdot}6H_2O$, 98 $CuSO_4{\cdot}5H_2O$, and 17.4 $Mo_7(NH_4)_6O_24{\cdot}4H_2O$). Before its use, the culture medium was maintained in an anaerobic chamber for 48 h, using gas generator bags ($CO_2$) (Becton Dickinson, Sparks, MD, USA) to remove the oxygen. The anaerobic conditions were continuously monitored by using anaerobic indicator strips (Becton Dickinson). Standards of thymol, rosmarinic acid, and eriodictyol were purchased from Extrasynthese (Genay, France), whereas carvacrol was purchased from Sigma-Aldrich (St. Louis, MO, USA). For the selection of the phenolic compounds to carry out the in vitro experiments, we took into consideration the availability of commercial standards and the occurrence of these substances in the TPEOO.

The in vitro fermentation procedure used in this study was adapted from the method proposed by Serra and co-workers.[17] For each volunteer, 15 g of fresh feces was homogenized for 60 s in a stomacher with 300 mL of prereduced culture medium to obtain a 5% fecal slurry. Following the homogenization, the fecal slurry was filtered and left to stand for 30 min. Once done, 10 mL was taken and added to 15 mL disposable tubes. After the addition of the standard (phenol standard final concentration 500 $\mu$M for thymol, carvacrol, and eriodictyiol, and 200 $\mu$M for rosmarinic acid), the disposable tubes were incubated in anaerobic chambers at 37 °C in an orbital shaker (60 strokes/min) to mimic colon conditions (anaerobic conditions were controlled by anaerobic indicator strips). The high initial concentrations (500 and 200 $\mu$M) of the parent compounds were chosen to determine more clearly the microbial metabolites generated, even at relatively low concentrations. Aliquots of the fermented fecal samples (500 $\mu$L) were collected at 0, 2, 6, 12, 24, and 48 h of incubation and stored immediately at −80 °C until the chromatographic analysis. All of the fermentation samples were incubated in triplicate. In parallel, a control sample (fecal slurry without addition of phenolic standard) was prepared for each fermentation time. Also, the phenolic standards without feces (blank 1) were incubated at each time (0, 2, 6, 12, 24, and 48 h) to take into account the possible chemical degradation of phenolic compounds.

**Human Intervention Study.** Fecal samples from 10 volunteers were used to determine thyme phenolic metabolites identified in the in vitro fermentation model. The feces were obtained before and after the consumption (25 mL/day) of a thyme phenol-enriched olive oil (TPEOO) over a period of 3 weeks. The TPEOO was prepared by adding a thyme phenolic extract to an olive oil according to the methodology described by Rubió and co-workers.[18] The main phenolic compounds that were transferred from thyme to the olive oil were flavonoids, such as eriodictyol, thymusin, naringenin, and xanthomicrol, phenolic acids, such as rosmarinic acid, and the monoterpenes thymol and carvacrol (Table 1).

**Table 1. Phenolic Composition of Thyme Phenol-Enriched Olive Oil (TPEOO)[a]**

| compound | mg phenol/kg oil |
|---|---|
| rosmarinic acid | 16.3 ±1.2 |
| flavonoids | |
| eriodictyol | 6.9 ±0.5 |
| luteolin | 8.5 ±0.8 |
| apigenin | 3.8 ±0.2 |
| naringenin | 7.9 ±0.8 |
| thymusin | 48.6 ±3.6 |
| xanthomicrol | 21.3 ±2.2 |
| 7-methylsudachitin | 21.1 ±3.4 |
| monoterpenes | |
| thymol | 25.4 ±2.1 |
| carvacrol | 9.1 ±0.8 |

[a]Values are means ± SD ($n$ = 5) expressed as mg phenol/kg oil.

Prior to the TPEOO intervention, there was a 2 week wash-out period, in which common olive oil (a blend of refined olive oil and a small percentage of virgin olive oil) was the main fat consumed. To avoid an excessive intake of phenolic compounds during the intervention period, the participants were advised to limit the intake of phenol-rich foods. Fecal samples from each volunteer were collected after the wash-out period (pre TPEOO intake) and at the end of the 3 week intervention (post TPEOO intake). The subjects gave their written informed consent before participation (Ethics Committee for Human Research of the IMIM-Hospital del Mar, Barcelona, Spain; CEIC-PSMAR 2009/3347/I). Freshly voided fecal samples were collected by the volunteers into a sterile pot and brought to the laboratory under anaerobic conditions within 2 h of defecation, immediately mixed in a phosphate buffer (PBS; final concentration 10% of fecal sample), and centrifuged for 5 min at 13000 rpm. The supernatant was divided into aliquots of 500 $\mu$L and stored at −20 °C until chromatographic analysis of phenol metabolites.

**Treatment of Fecal Samples and Chromatographic Analysis of Thyme Metabolites.** The in vitro fermentation samples and the supernatants obtained from the human intervention study were slowly thawed in ice, transferred into a disposable tube (15 mL), and acidified with 60 $\mu$L of HCl to inactivate the microbiota. A liquid−liquid extraction was carried out by adding 5 mL of ethyl acetate, and after shaking for 10 min in a vortex, samples were centrifuged (10 min, 8784$g$, at room temperature). The supernatants resulting from two ethyl acetate extractions were combined and evaporated under nitrogen flow at 30 °C. The dry residue was reconstituted with 500 $\mu$L of water/acetonitrile/methanol (86:12:2, v/v/v), filtered with a

0.22 μm nylon syringe filter, and transferred into chromatographic vials for analysis.

The chromatographic analysis of rosmarinic acid, eriodictyol, and their metabolites and thymol and carvacrol metabolites was performed with a Waters Acquity Ultra-Performance liquid chromatography (UPLC-ESI-MS/MS) system (Waters, Milford MA, USA), according to the previously described method.[19] The tandem mass spectrometry (MS/MS) analyses were carried out on a triple-quadrupole detector (TQD) mass spectrometer (Waters) equipped with a Z-spray electrospray interface. The analyses were done in the negative ion mode, and the data were acquired with the selected reaction monitoring mode (SRM). The MS/MS parameters were as follows: capillary voltage, 3 kV; source temperature, 150 °C; cone gas flow rate, 80 L/h; desolvation gas flow rate, 800 L/h; desolvation temperature, 400 °C. Nitrogen (>99% purity) and argon (99% purity) were used as the nebulizing and collision gases, respectively. The cone voltages and collision energies were optimized for each analyte by injection of each standard compound in a mixture of acetonitrile/water (50:50, v/v) at a concentration of 10 mg/L. Two transitions were studied for each compound. The most abundant transition was used for quantification, whereas the second most abundant was used for confirmation purposes. The dwell time established for each transition was 30 ms. Data acquisition was carried out with MassLynx v 4.1 software. Catechol, phenylacetic acid, 4-hydroxybenzoic acid, 3-phenylpropionic acid, 2-(4′-hydroxyphenyl)acetic acid, 2-(3′-hydroxyphenyl)acetic acid, 4-coumaric acid, protocatechuic acid, 2-(3′,4′-dihydroxyphenyl)acetic acid, 3-(4′-hydroxyphenyl)propionic acid, 3-(3′,4′-dihydroxyphenyl)-propionic, caffeic acid, rosmarinic acid, and eriodictyol were quantified using the calibration curves of their respective standards.

Additionally, all samples were subjected to gas chromatography (GC) analyses to identify and quantify the volatile monoterpene thymol and carvacrol in their native forms. These compounds were first extracted from the in vitro fermentation samples and from the human fecal supernatants to the TPEOO intervention by hexane. For this purpose, 500 μL of sample was mixed with 1 mL of hexane and shaken during 1 h and then centrifuged for 10 min at 9000 rpm at room temperature. The volatile material collected from the supernatant was analyzed by gas chromatography (GC) (Agilent 7890A series) coupled to a flame ionization detector (FID) using a capillary column TRB-5SM (Teknocroma, Barcelona, Spain). The column temperature was programmed at 90 °C for 1 min, increased by 15 °C/min to 270 °C, and then maintained at 270 °C for 10 min (total run time of 25 min). Helium was the carrier gas (1 mL/min). Injector temperature was 250 °C, the detector temperature was 280 °C, and 1 μL of the solution was injected into the GC-FID system. Thymol and carvacrol were identified by comparing the retention times to those for the authentic standards and quantified by using the calibration curve of the respective standard.

**Statistical Analysis.** Each sample from the in vitro experiment was analyzed in triplicate (three replicates from three volunteers; $n = 9$), and the data are presented as the mean values of all samples at each time ($n = 9$ per each time) minus the concentration of the compound in the control (fecal culture medium without phenolic compound). In the in vivo study, to compare the baseline with the post-treatment concentration values of the metabolites in human fecal samples, the ANOVA analysis was employed using STAT-GRAPHICS Plus 5.1 software (Manugistics Inc., Rockville, MD, USA). The level of significance was 0.05.

## RESULTS AND DISCUSSION

**Kinetics of Thyme Phenol Colonic Metabolism in in Vitro Fermentation.** Changes in the precursor compounds (thymol, carvacrol, rosmarinic acid, and eriodictyiol) during the in vitro fermentation were monitored from 0 to 48 h. Results are reported as the average of three independent fermentations for each human fecal sample, obtaining nine replicates for each fermentation time (individual values are shown in Tables S1–S4 of the Supporting Information). The amounts of the phenolic compounds and their metabolites were corrected for the endogenous levels detected in the control fermentations (fecal culture medium without phenolic compound) (Human Intervention Study underMaterials and Methods).

**Monoterpenes: Thymol and Carvacrol.** On the basis of the volatile nature of thymol and carvacrol, these compounds were analyzed by GC, whereas colonic metabolites formed during in vitro fermentation were analyzed by liquid chromatography (UPLC-MS/MS). The kinetics of the generated metabolites after thymol and carvacrol fermentation is shown in Figure 1, panels A and 1B, respectively. In general,

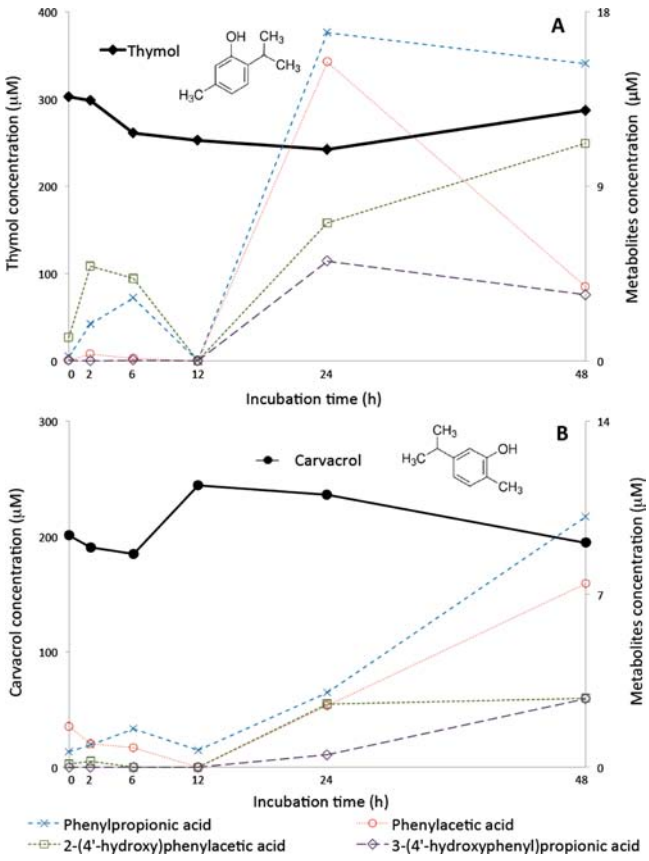

**Figure 1.** (A) Thymol concentration (solid line) and metabolite generation (dotted line) during in vitro fermentation. (B) Carvacrol concentration (solid line) and metabolite generation (dotted line) during in vitro fermentation.

carvacrol and thymol showed a similar behavior during the 48 h incubation, possibly due to the closely related chemical structure. Both compounds were poorly degraded and remained relatively stable until the end-time of the fermentation, indicating the nonexistent or low activity of gut microbiota in terms of monoterpene utilization. However, some metabolites were formed during the in vitro fermentation of thymol (Figure 1A): (i) phenylacetic acid, which reached its maximum concentration (16.91 μM) at 24 h of incubation; (ii) 2-(4′-hydroxyphenyl)acetic acid with a maximum recovery (15.39 μM) also at 24 h of incubation. Furthermore, (iii) phenylpropionic acid and (iv) 3-(4′-hydroxyphenyl)propionic acid reached the maximum concentration at 48 h (11.20 μM) and at 24 h (5.14 μM) of incubation, respectively. Interestingly, low concentrations of carvacrol were found at different times during the thymol fermentation (Supporting Information,

Table S1) but were also detected in thymol standard samples incubated without fecal slurry (blank 1), which may indicate that carvacrol is generated by the medium conditions as a consequence of the isomerization of thymol.

Similar results were observed when carvacrol was fermented. During the fermentation the main metabolites that appeared were (i) phenylpropionic acid (10.13 $\mu$M) and (ii) phenylacetic acid (7.43 $\mu$M), both by the end of fermentation. After the fermentation of carvacrol, (iii) 2-(4′-hydroxyphenyl)acetic acid and (iv) 3-(4′-hydroxyphenyl)propionic acid wer also detected. Both phenolic acids reached their maximum concentrations (2.78 and 2.77 $\mu$M, respectively) at 48 h of fermentation.

In vitro fermentation of monoterpenes using animal intestinal content as inocula also showed low microbial activity.[20,21] Michiels and co-workers have reported that thymol and carvacrol were degraded by 29% after the fermentation of both compounds using piglet cecal as inocula, but no degradation products were specified.[20] Varel and co-workers also observed high stability of thymol and carvacrol after anoxic swine waste fermentation, recovering close to 95% of both monoterpenes at 62 days.[21] Therefore, our results confirm that phenol terpenes remain stable during the fermentation, probably due to the complex carbon skeleton that may hamper their microbial degradation. To the best of our knowledge, there are no data available in the literature about thymol and carvacrol metabolism in human bowel. However, cholesterol and bile acids, which also have a terpenoid lipid structure, are daily exposed to gut microbiota, and their bacterial transformations have been extensively documented in humans. The reduction of the C7 double bond of the cholesterol molecule,[22] the 7$\alpha$-dehydroxylation, and the side chain degradation of functional groups in the case of bile acids are typically caused by bacteria activity, but in any case cholesterol, bile acids, and their metabolites suffer further degradation.[23] Similarly, our results suggest that thymol and carvacrol (phenolic terpenes) may be recalcitrant molecules to biodegradation in the human large intestine, probably as a consequence of the low number of functional groups and/or the lack of intestinal bacteria specialized in their metabolism. Therefore, the appearance of phenolic acids, especially within 24 h of incubation (Figure 1), may be explained by the loss of bacteria cell integrity due to the modification of membrane permeability, which could induce the release of endogenous metabolites into the culture medium. Linked to this, Thapa and co-workers[1] studied the effects of different essential oils and their pure compounds, including thymol, on pathogenic and commensal intestinal bacteria. The results showed that phenolic monoterpenes were the most active class of antibacterial agents and caused a dose-dependent loss of cell integrity in Gram-positive bacteria, probably by modifying the permeability of cellular membranes, thus promoting the loss of ATP and intracellular metabolites or enzymes. Therefore, in our study the release of endogenous microbial material could explain the presence of different phenylacetic and phenylpropionic acids in the thyme and carvacrol fermentation media.

**Rosmarinic Acid and Eriodictyol.** Analyses of the fermentation samples of rosmarinic acid and eriodictyol revealed a full degradation of the parent compounds and a high generation of microbial products over the incubation time (0−48 h). The kinetics of the rosmarinic acid fermentation showed that this compound was insignificant at 12 h of incubation (Figure 2A). The first intermediate microbial metabolite derived from the hydrolysis of rosmarinic acid was

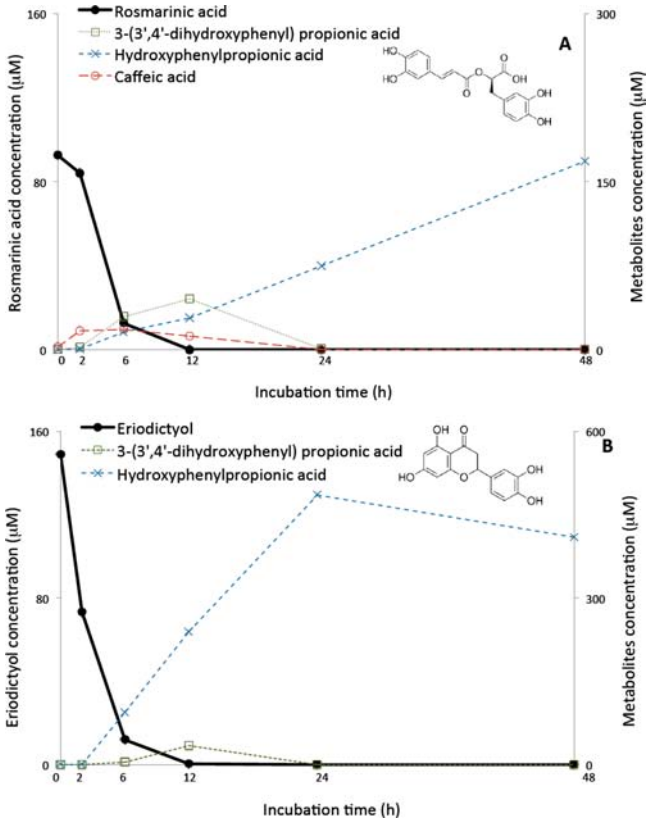

**Figure 2.** (A) Conversion of rosmarinic acid (solid line) during in vitro fermentation into its phenolic catabolites (dotted line). (B) Conversion of eriodictyol (solid line) during in vitro fermentation into its phenolic catabolites (dotted line).

caffeic acid, which reached its maximum concentration at 6 h (17.9 $\mu$M) (Figure 2A) before declining to trace levels at 48 h of fermentation. The gut metabolic pathway of rosmarinic acid is proposed in Figure 3. A previous study has also revealed a rapid transformation of rosmarinic acid when it was fermented in pure cultures of *Lactobacillus johnsonii*,[24] a type of lactic acid bacteria (LAB) commonly found in the human gut.[25] Degradation of rosmarinic acid seems to be mediated by microbial chlorogenate esterases.[24]

The second intermediate metabolite detected in the fecal culture medium was 3-(3′,4′-dihydroxyphenyl)propionic acid, probably formed as a result of the microbial transformation of caffeic acid (Figure 3) by the reduction of the aliphatic double bond of the second ring of the molecule. 3-(3′,4′-dihydroxyphenyl)propionic acid reached its highest peak of concentration at 12 h (24.2 M) coinciding with the decrease in the concentration of caffeic acid in the fermentation medium (Figure 2A). An isomer of 3-(4′-hydroxypehyl)propionic acid was identified as the main metabolite formed by the fermentation of rosmarinic acid, and this reached the highest concentration in the medium (168.2 $\mu$M) at 48 h of fermentation, parallel to the decrease in the concentration of its precursor, 3-(3′,4′-dihydroxyphenyl)propionic acid. The generation of hydroxyphenylpropionic acid probably came from the 4-dehydroxylation of 3-(3′,4′-dihydroxyphenyl)propionic acid, but we were not able to confirm this information. Caffeic acid is a hydroxycinammic acid widely present in foods, in both free and conjugated forms (normally with quinic acid to form chlorogenic acid). Microbial fermentation of free or conjugated caffeic acid has been studied, and our findings seem to be in line

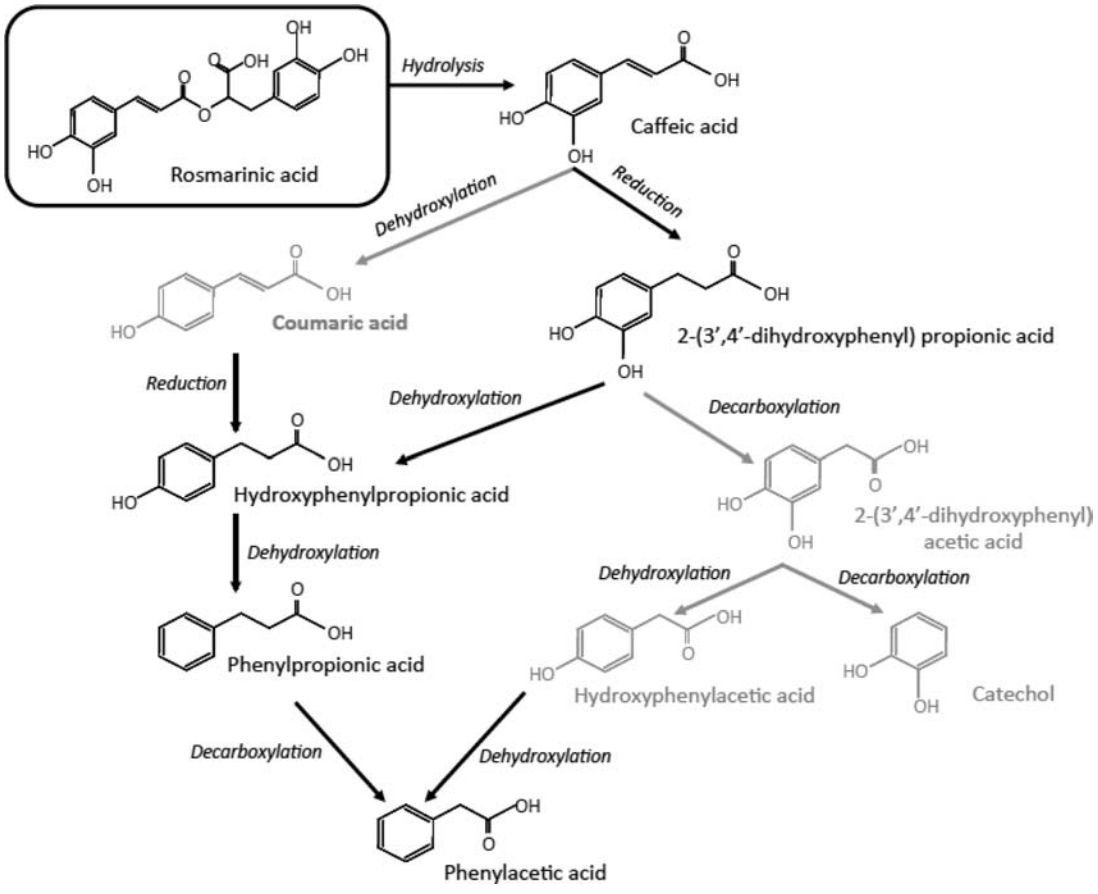

**Figure 3.** Proposed colonic pathway of rosmarinic acid. Compounds in bold were detected in the fermentation medium between 0 and 48 h. Compounds in gray were detected as minor metabolites in the fermentation medium.

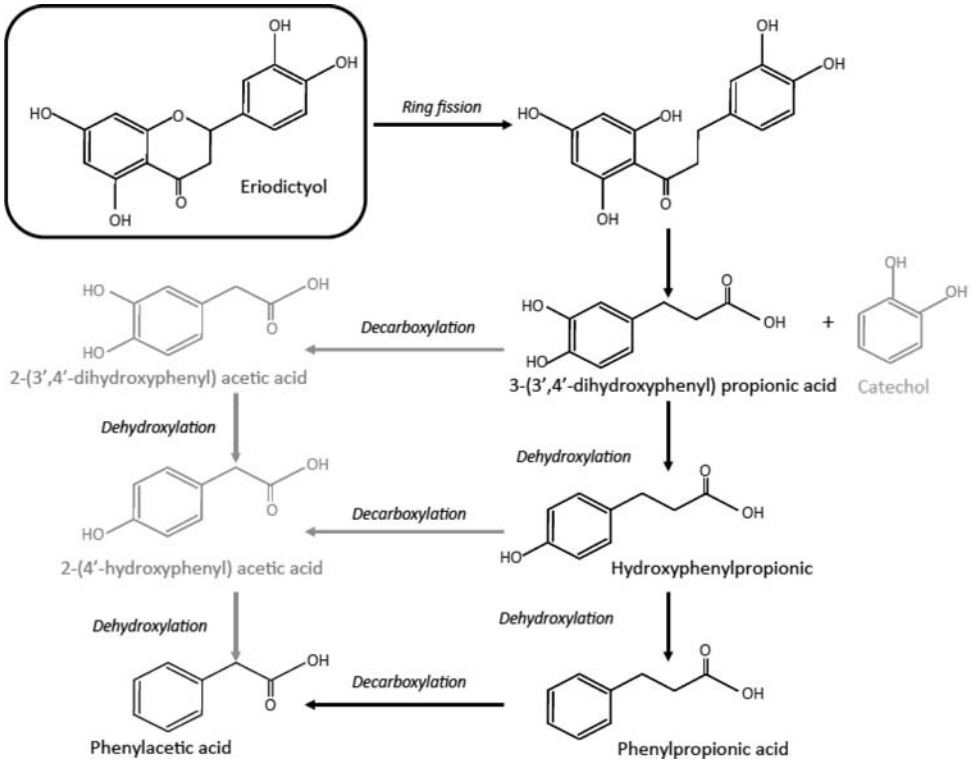

**Figure 4.** Proposed colonic pathway of eriodictyol. Compounds in bold were detected in the fermentation medium between 0 and 48 h. Compounds in gray were detected as minor metabolites in the fermentation medium.

dx.doi.org/10.1021/jf503748y | J. Agric. Food Chem. 2014, 62, 10954−10961

with previous works in which 3-(3′-hydroxyphenyl)propionic acid was recovered as the main bacteria metabolite.[13]

Chemically, rosmarinic acid is an ester of caffeic acid and 3-(3′,4′-dihydroxyphenyl)lactic acid. As a consequence of its hydrolysis, two molecules are released into the medium, but both yield hydroxyphenylpropionic acid as the final metabolite, which could explain the high molar ratio between the parent compound and its formed metabolite. In the proposed rosmarinic acid colonic pathway (Figure 3), other metabolites such as the nonhydroxylated form of phenylpropionic acid, coumaric acid, benzoic acid, and catechol have been described as other possible final metabolites. However, the low and variable amounts of these metabolites detected during the fermentation suggest that they could be attributed to other food precursors, as was reported after an in vitro fermentation of coffee polyphenols.[13]

With regard to the colonic metabolism of eriodictyol, the kinetic response of the generated microbial metabolites is shown in Figure 2B. Complete degradation of eriodictyiol before 48 h of fermentation has been seen in all of the samples analyzed, indicating high microbial activity. Total degradation of eriodictyol has also been reported in previous works using *Eubacterium ramulus*[26] and *Clostridium orbiscindens*[27] as inocula. On the basis of the different metabolic compounds detected at different collection times, we proposed a hypothetical colon degradation pathway for eriodictyol (Figure 4). Heterocyclic C-ring cleavage of eriodictyol was the first evidence of microbial action, yielding 3-(3′,4′-dihydroxyphenyl)propionic acid as an intermediate metabolite probably derived from the B-ring fragment. 3-(3′,4′-dihydroxyphenyl)propionic acid reached its maximum concentration (12.9 $\mu$M) at 12 h and declined thereafter (Figure 2C). Dehydroxylation of 3-(3′,4′-dihydroxyphenyl)propionic acid produced an isomer of hydroxyphenylpropionic acid, which represents the main phenolic end product. There was a progressive increase in the concentration of hydroxyphenylpropionic acid over the time course of fermentation with the maximum peak of concentration at 24 h (344.4 $\mu$M). These results are in line with those reported by other authors, who also detected 3-(3′,4′-dihydroxyphenyl)propionic acid as a fermentation product of eriodictyol.[26,27] However, no hydroxyphenylpropionic acid was described, probably because the experiments were carried out with two types of bacteria, *E. ramulus* and *Cl. orbiscinders*, that may not have dehydroxylation activity.

**Human Intervention Study.** The impact of human intestinal microbiota on the transformation of thyme phenols was investigated in 10 volunteers after the daily consumption of 25 mL of TPEOO over 3 weeks. The feces of the volunteers were analyzed at baseline and after the intervention period to elucidate eventual changes in the profile of the microbial metabolites. Although we observed that thymol and carvacrol were stable over 48 h during the in vitro incubation, only carvacrol was quantified in feces from one of the volunteers after the intake of TPEOO (data not shown). Nevertheless, an increment in the instrumental signal corresponding to the chromatographic peak of carvacrol (Treatment of Fecal Samples and Chromatographic Analysis of Thyme Metabolites under Material and Methods) was observed in 7 of the 10 fecal samples analyzed, although the carvacrol concentration was below to the limit of quantification (data not shown). This is in line with Anderson and co-workers, who failed to detect the aforementioned monoterpenes in pig feces after the intake of a thyme-rich diet.[28] In a similar study, only <10% of limonele was detected in the feces of animals (dog and guinea pig) after a high dose, whereas a high recovery was observed in urine.[29] In a preliminary human intervention study conducted by our research group in which hyperlipidemic adults consumed thyme-enriched olive oil, a high recovery of thymol metabolites (main glucuronide conjugates) in 24 h urine was observed.[30] The findings of the present survey, together with the previous reported data regarding the urinary excretion of monoterpenes,[18] support the hypothesis that phenol monoterpenes are effectively absorbed in the upper part of the gastrointestinal tract, and consequently the trace levels of carvacrol found in fecal samples actually represent only nonabsorbed remnants.

With regard to rosmarinic acid and eriodictyol, these compounds were not detected in the human fecal samples as their native structure after the sustained intake of TPEOO, which is in line with the complete degradation of these compounds observed in the in vitro study. In accordance with the in vitro fermentation, increased in the phenolic acids concentrations of 3-(3′,4′-dihydroxyphenyl)propionic acid, hydroxyphenylpropionic acid (the same isomer of acid reported in the in vitro experiments), 3-phenylpropionic acid, and 2-(4′-hydroxyphenyl)acetic acid were detected in human fecal samples after the intake of TPEOO. 3-(3′,4′-dihydroxyphenyl)-propionic acid and hydroxyphenylpropionic acid were identified in the in vitro colon fermentation study as the intermediate and main metabolites of rosmarinic acid (Figure 3) and eriodictyol (Figure 4). However, the increase in the concentrations of these catabolites was not statistically significant ($p > 0.05$) (Figure 5). Similarly, other in vivo studies also noted an increment in the concentration of hydroxyphenylpropionic acid in feces after the intake of grape seed extract and cranberries.[31,32]

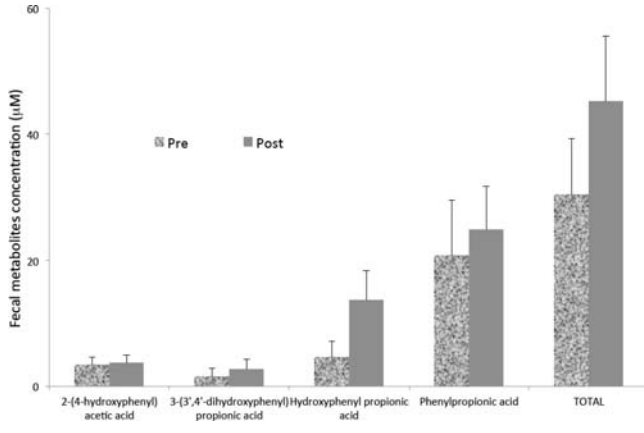

**Figure 5.** Phenolic metabolites detected in human fecal samples before (pre-) and after (post-) intake of thyme phenol-enriched olive oil (TPEOO).

Microbial metabolites produced in the large intestine could carry out their bioactive activity at a local level (intestinal lumen) or, if absorbed, they could be distributed by blood circulation to organs and tissues where they might accumulate or be detoxified by metabolizing enzymes (primarily in the liver) before being excreted in the urine.[8,12] Bioactivity investigations using human or animal cell lines have made extensive use of phenolic microbial catabolites to elucidate their possible mechanisms of action, and experiments have been widely reviewed by Del Rio and co-workers[33] and Rodriguez-Mateos and co-workers,[34] From this recent literature it is

apparent that polyphenols and itheir microbial catabolites do not act simply as antioxidants in vivo and that their diverse effects are, in most instances, based on more complex and specific modes of action, mainly related to cancer and cardiovascular diseases. In this sense, microbial catabolites derived from phenylacetic and phenylpropionic acids, which were also detected in large amounts in fecal samples following TPEOO intake, were proposed as anti-inflammatory agents.[35] Additional experiments were carried out with the advance glycation end products (AGEs) model and pointed to the glucose-mediated pathway as a likely site of action of several microbial catabolites derived from hydroxyphenylacetic acid.[36]

These minor changes in phenol metabolite concentrations observed in feces after the sustained intake of thyme phenols through TPEOO (Figure 5) could indicate a high rate of absorption of thyme phenolic compounds in the upper part of the gastrointestinal tract. There is in vitro evidence that suggests that minor constituents of herb and spice extracts could enhance the rate of absorption of hydrophilic compounds present in the lumen of the small intestine, thus increasing paracellular transport by the transient opening of tight junctions.[37,38]

Recent in vitro studies have proposed that aromatic herbs could inhibit the growth of colon cancer cells,[39] which suggests that these compounds might have antitumoral effects in contact with colon mucosa. Also, a promising use of aromatic herbs as natural antimicrobials of gut pathogens was proposed.[1] However, in our study the thyme phenolic compounds (thymol, carvacrol, rosmarinic acid, or eriodictyol) in their native structures were not detected in human feces.

In conclusion, the results of the present study provide very useful information regarding the gut metabolism of thyme phenols. Although the monoterpenes carvacrol and thymol were poorly metabolized by gut microbiota in the in vitro model fermentation, neither of these compounds, except for one volunteer, was quantified in human feces after the sustained intake (3 weeks) of a daily dose of 25 mL of TPEOO. These results support the idea suggested by other authors that thymol and carvacrol are well absorbed during small intestine passage. In contrast, rosmarinic acid and the flavonoid eriodictyol were extensively metabolized during in vitro colonic fermentation, yielding hydroxyphenylpropionic acid as the main metabolite. In accordance with these results, after the sustained intake of TPEOO, neither rosmarinic acid nor eriodictyol was detected in human feces, observing at the same time an increase in the concentration of hydroxyphenylpropionic and phenylpropionic acids, confirming the effective microbial degradation for these compounds. The most likely effective absorption in the upper part of the gastrointestinal tract, together with the intense colonic metabolism of other representative compounds of thyme phenolic fraction (rosmarinic acid and eriodictyol), opens the possibility of the application of technologic resources, such as microencapsulation, to facilitate the arrival of this type of compound to the colon. Further research is needed to understand the physiological effects of thyme phenols in the gut and their implications when thyme is used as such (dry leaf) or as an essential oil for food flavoring.

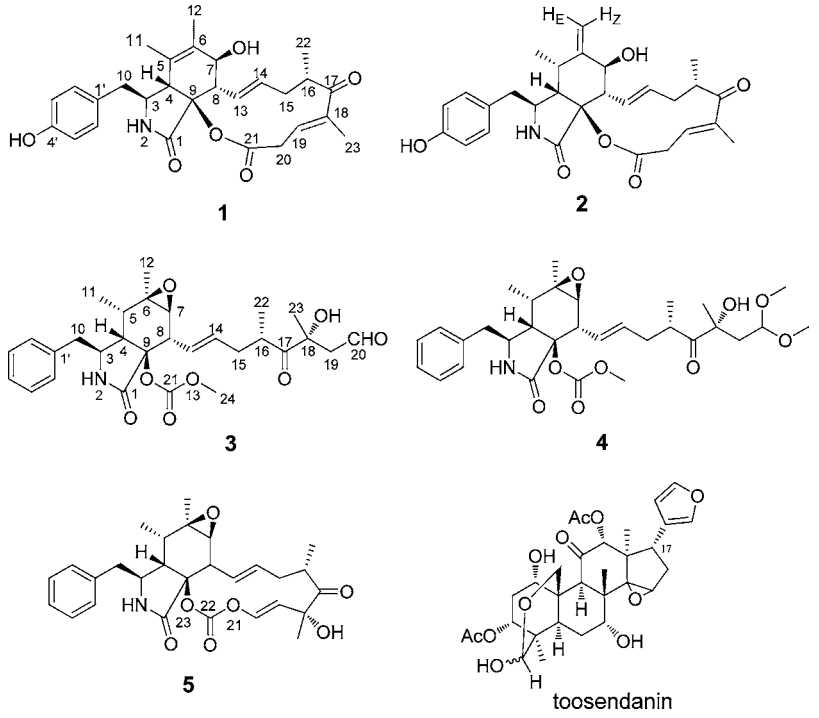

**Figure 1.** Structures of cytochalasins **1**–**5** isolated from *Xylaria* sp. XC16 and toosendanin.

(Mitsubishi Chemical Corp., Tokyo, Japan), Sephadex LH-20 (40–70 μm) (Amersham Pharmacia Biotech AB, Uppsala, Sweden), and Lichroprep RP-18 gel (40–63 μm) (Merck, Darmstadt, Germany). $GF_{254}$ plates (Qingdao Marine Chemical Inc., Qingdao, China) were used for thin-layer chromatography (TLC). High-performance liquid chromatography (HPLC) analysis was performed on an Agilent TC-C18 column (250 mm × 4.6 mm, 5 μm, Agilent Technologies Ltd., CA, USA) on a Waters 1525 instrument (Waters Corp., MA, USA). Brine shrimp eggs (*Artemia* cysts) (Advanced Hatchery Technology Inc., Xiamen, China) were used for bioguided assay.

**Fungal Material.** Plant material was collected in Yangling, Shaanxi province, China, in April 2011. Isolation, maintenance, and preservation of endophytic fungi were performed according to the reported protocols.[21] All isolated fungal strains (28 in total, XC1–XC28) were prescreened for their toxicity toward brine shrimp.[19] The most toxic strain XC16 belonged to the genus *Xylaria*, identified by internal transcribed spacer (ITS) rDNA region sequence comparison, and was designated as *Xylaria* sp.

**Fermentation, Extraction, and Isolation.** All 28 isolated fungal strains (XC1–XC28) were fermented on solid rice medium. Toxicity of the fermented culture (20 μg/mL) against brine shrimp were assayed according to our previously reported protocol.[19] The most toxic strain XC16 was selected to be cultivated on rice medium (40 g rice and 100 mL distilled water, sterilized under 121 °C for 30 min) in 200 Erlenmeyer flasks (500 mL each). The flask cultures were incubated under 28 °C for 3 weeks.

The fungal cultures of *Xylaria* sp. XC16 grown on rice medium were extracted with petroleum ether and EtOAc three times, respectively, and tested by brine shrimp lethality assay. The toxic EtOAc crude extract was fractionated by silica gel CC using $CHCl_3$–MeOH gradient elution to provide five fractions (Fr.1–Fr.5). Fr.2 (4.93 g) indicated the highest activity and was further chromatographed on Sephadex LH-20 eluted with MeOH as an eluent to give two fractions A and B. These two fractions were analyzed by a Thermo BDS Hypersil column (250 × 10 mm, 5 μm, Thermo Fisher Scientific Inc., MA, U.S.), eluted with gradient 60–90% MeOH/$H_2O$ at a flow rate of 2.0 mL/min over 30 min. Then fractions A and B were chromatographed on the same HPLC column, respectively. Fraction A was separated with 70% MeOH/$H_2O$ as eluent to yield compounds **3** (8.7 mg), **4** (5.8 mg), and **5** (3.9 mg). Fraction B was purified with 82% MeOH/$H_2O$ to afford compounds **1** (12.3 mg) and **2** (8.2 mg).

**Computational Section.** MMFF and DFT calculations were run with Spartan 10 (Wave function Inc., Irvine, CA) with standard parameters and convergence criteria. TDDFT calculations were run with Gaussian 09,[22] with default grids and convergence criteria. Conformational searches were run with the Monte Carlo algorithm implemented in Spartan 10 using Merck molecular force field (MMFF). All structures thus obtained were optimized with DFT method using B3LYP functional, using first the 6-31G(d) basis set and then 6-311+G(d,p) basis set. TDDFT calculations were run using B3LYP and CAM-B3LYP functionals and TZVP basis set, including 64 and 42 excited states, respectively. UV and CD spectra were generated using the program SpecDis[23] by applying a Gaussian band shape with 0.3–0.4 eV exponential half-width, from dipole-length rotational strengths.

**Toxicity Bioassay.** All the isolated metabolites were tested for their toxicity activity against brine shrimp (*Artemia* cysts) as previously reported method.[19]

**Phytotoxicity Bioassay.** The seeds of two herbaceous plants, lettuce (*Lactuca sativa*) and radish (*Raphanus sativus*) were used for the bioassay. The procedure was conducted according to the

previously reported protocol.[20,24−26] Glyphosate was selected as the positive control. Triplicate experiments were conducted on 6-well plates, and the phytotoxic effects [response index (RI)] were calculated according to the equation:

$$\text{If } T > C, \text{ then RI} = 1 - C/T; \text{ if } T < C, \text{ then RI} = T/C - 1$$

where $T$ is the length of the treatment, $C$ is the length of the blank control, and RI is the response index. RIs are expressed as averages ± standard deviation (SD) for three replicates.

**Antifungal Bioassay.** All the isolated metabolites were tested in vitro for the antifungal activity against agriculturally important four phytopathogenic fungi: *Fusarium solani*, *Gibberella saubinetti*, *Botrytis cinerea*, and *Alternaria solani*, according to our reported bioassay.[19] All these pathogenic organisms tested were deposited at the College of Science, Northwest A&F University. Antifungal activity was assessed by the microbroth dilution method in 96-well flat-microtiter plates using a potato dextrose (PD) medium. Initial concentrations of compounds tested were made up to 4 mM in DMSO. Two commercial fungicides, carbendazim and hymexazol (Aladdin Chemistry Co. Ltd., Shanghai, China) were used as positive control. A DMSO solution of equal concentration was used as a negative control. The fungi were incubated in the PD medium for 18−36 h at 28 ± 0.5 °C at 150 rpm, and spores of different microorganism concentrations were diluted to approximately $1 \times 10^6$ colony-forming units/mL (CFU/mL) with PD medium. In flat-microtiter plates, tested compounds, fungal suspension, and sterile water were added to made up final concentrations of the compounds in the range of 1.57−200 μM. Cultures were then grown in the dark at 28 ± 0.5 °C for 48 h. Minimum inhibitory concentrations (MICs) were inspected as the lowest concentrations in which no fungal growth could be observed.

## RESULTS AND DISCUSSION

**Identification of the Bioactive Fungal Endophytic Strain XC16.** Brine shrimp test has been proved to be a simple and reliable benchtop bioassay for screening toxicity for natural extracts and synthetic products.[27−29] Twenty-eight strains (XC1−XC28) of endophytic fungi were isolated from the healthy leaves of *Toona sinensis*. All isolates were screened for their toxicity against brine shrimp at 20 μg/mL level. Among the isolates, the secondary metabolites of the two strains XC16 and XC20 exhibited remarkable toxicity to the organism. The culture filtrate from strain XC16 killed all brine shrimp larvae, showing the greatest activity, and was therefore selected for the isolation and characterization of bioactive metabolites. To identify this active strain XC16, a GenBank search with the nuclear ribosomal ITS1 sequence and 18S rDNA of XC16 was

carried out. The results revealed a species of *Xylaria* as the closest match, with sequence identities 99%. The most similar sequence was that of *Xylaria* sp. JW38−4 (accession number GQ906959). On the basis of its ITS and 18S rDNA sequences, the fungus XC16 clearly belongs to the member of the genus *Xylaria*, identified as *Xylaria* sp. XC16, a mycelial fungus under scanning electron microscope.

**Isolation, Purification, and Structure Elucidation.** The active EtOAc extracts of the cultures of this strain *Xylaria* sp. XC-16 were submitted to column chromatography on silica gel to provide five fractions (Fr. 1-Fr. 5). Among these fractions, Fr.2 showed strong toxicity to brine shrimp at 20 $\mu$g/mL level. As a result, Fr. 2 was fractionated through silica gel column chromatography, gel filtration over Sephadex LH-20, ODS column chromatography, and semipreparative HPLC to afford two new cytochalasins **1** and **2**, together with three known cytochalasin derivatives, **3**−**5** (Figure 1). Their structures were elucidated by a combination of spectroscopic analyses (UV, CD, IR, MS, 1D, and 2D NMR) and by comparison to literature data.

Cytochalasin $Z_{27}$, **1**, was obtained as white powder. Its molecular formula was assigned as $C_{28}H_{33}NO_6$ based on the pseudomolecular ion in HR-ESI-MS, requiring 13 degrees of unsaturation. The IR absorptions at 1707, 1667, 1614, and 1516 $cm^{-1}$ indicated the presence of carbonyl and benzene ring groups in the structure. The $^1H$ and $^{13}C$ NMR data of **1** (Table 1) suggested four methyls, three methenes, 12 methines (including seven unsaturated ones), and nine quaternary carbons (including eight unsaturated ones). The unsaturated carbon signals in $^{13}C$ NMR suggested six carbon−carbon double bonds and three C═O groups ($\delta_C$ 205.4, 172.4, and 169.4). In particular, the AA′XX′ spin system [$\delta_H$ 7.30 (*d*, *J* = 8.2 Hz), 7.17 (*d*, *J* = 8.2 Hz)] indicated a 1,4-disubstituted benzene ring in **1**. Apart from the ten degrees of unsaturation due to the unsaturated bonds and the benzene ring, the remaining ones indicated that **1** possesses a tricyclic framework, which was elucidated by means of extensive analysis of the 2D NMR spectra (HSQC, $^1H-^1H$ COSY, and HMBC). All protons directly bonded to the carbon atoms were first assigned on the basis of the HSQC data. Five fragments were deduced from the COSY spectrum (Figure 2). Further detailed HMBC correlations (Figure 2) revealed the whole planar structure of **1**, a 4′-hydroxyl derivative of cytochalasin $Z_{17}$, which was obtained from *Aspergillus flavipes*, an endophytic fungus of the mangrove plant *Acanthus ilicifolius*.[30]

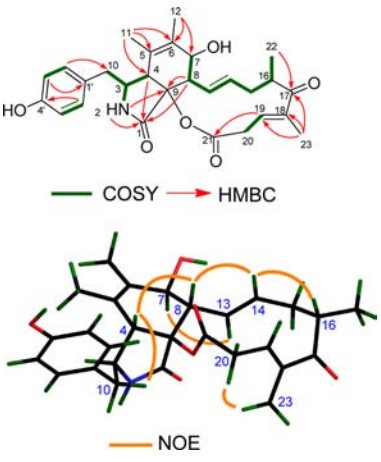

**Figure 2.** Selected HMBC, $^1H-^1H$ COSY, and NOESY correlations of **1**.

The relative configuration of **1** was assigned by $^{13}C$ NMR data in comparison with reported ones, and by NOESY results with the help of molecular modeling. As shown in Figure 2, the observed correlations of H-10a/H-4 and H-4/H-8 indicated that C-10, H-4, and H-8 are on the same side of the molecule and were arbitrarily assigned as $\beta$-oriented. The NOE correlation of H-7/H-13 indicated H-7 to be $\alpha$-oriented. Further confirmation of the stereochemistry at C-7 and C-8 was provided by the NOE correlation of H-8/H-14. Moreover, the NOE correlation H-14/H-16, when checked against molecular modeling results (Figure 2), offered the proof of the $\alpha$-orientation of Me-22. Finally, the 18*E* configuration of the C-18/C-19 double bond was proved by H-20/Me-23 NOE correlation and the absence of H-19/Me-23 correlation. Previous studies suggested that the stereochemistry of the essential elements of cytochalasins skeleton is well retained along the series. These include (1) the stereochemistry of the macrocyclic ring, with a trans C-8/C-9 junction and a cis C-4/C-9 junction;[31,32] (2) the $\beta$ orientation of the oxygen at C-7;[11,33,34] (3) the $\alpha$-orientation of Me-22;[31,32] and (4) the *E* configuration of the C-18/C-19 double bond.[30,34,35] The $^{13}C$ NMR spectrum of **1** (Table 1) showed similar chemical shifts to that of cytochalasin $Z_{17}$,[30] especially of the macrocyclic ring moiety. In particular, the similarities between the chemical shifts of C-7, C-9, and C-16 indicated that the relative configurations of these centers in **1** are consistent with those in cytochalasin $Z_{17}$, as shown in Figure 2. Furthermore, compound **1** showed a CD spectrum (Figure 3A) consistent with that of cytochalasin $Z_{17}$.[35] This is not surprising because of the structural analogy between the two compounds; still, an independent proof of the absolute configuration of **1** was obtained by quantum mechanical calculations of its CD spectrum. It was concluded that **1** has the same configuration of cytochalasin $Z_{17}$, and its structure is determined as (+)-(3*S*,4*S*,7*S*,8*S*,9*S*,13*E*,16*S*,18*E*)-7-hydroxy-5,6,16,18- tetramethyl-10-(4′-hydroxyphenyl)-22-oxa-[12]-cytochalasa-6,13,18-trien-1,17,21-trione.

Molecular modeling of compound **1** was run through a well-established protocol.[36] The most stable energy minima thus obtained had a very similar conformation of the macrocycle (Figure 2), which was in keeping with the NOE correlations discussed above, and differed only for the orientation of the 4′-hydroxyphenylmethyl and the hydroxyl groups. CD calculations were run of DFT geometries with TDDFT method,[37] using B3LYP and CAM-B3LYP functionals and TZVP basis set, and averaged at 300 K using Boltzmann populations. The weighted-average CD spectra (Figure 3B) are in good agreement with the experimental one. In particular, the B3LYP functional performed better in the long-wavelength region, where TDDFT method is intrinsically more accurate.[38] Conversely, the CAM-B3LYP functional reproduced better the short-wavelength region. In conclusion, the absolute configuration of cytochalasin $Z_{27}$ was definitely established as (+)-(3*S*,4*S*,7*S*,8*S*,9*S*,16*S*)-**1**.

Cytochalasin $Z_{28}$, **2**, was obtained as white solid. Its molecular formula $C_{28}H_{33}NO_6$ is the same as **1**, as deduced from the pseudomolecular ion in HR-ESI-MS, suggesting that **2** was an isomer of **1**. Comparison of its $^1H$ and $^{13}C$ NMR data with those of **1** (Table 1) revealed that compound **2** also had a quite similar skeleton to that of **1**. A significant difference was that the two carbon signals at $\delta_C$ 125.4 (C-5, s) and 134.8 (C-6,

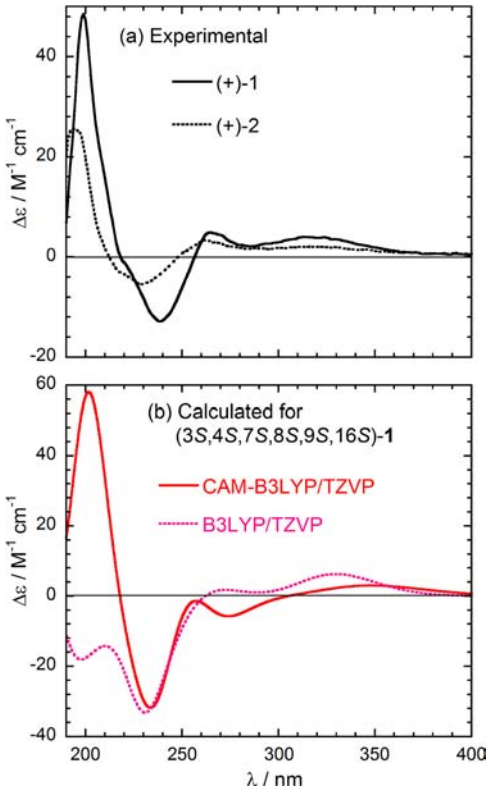

**Figure 3.** (A) Experimental CD spectra of (+)-**1** and (+)-**2** in methanol (0.5 mM, 0.5 mm cell). (B) CD spectra calculated for (3*S*,4*S*,7*S*,8*S*,9*S*,16*S*)-**1** at B3LYP/TZVP//B3LYP/6-311+G(d,p) and CAM-B3LYP/TZVP//B3LYP/6-311+G(d,p) levels as Boltzmanns average on 8 structures. Gaussian band-shape with 0.3 (B3LYP) and 0.4 eV (CAM-B3LYP) exponential width; CAM-B3LYP spectrum red-shifted by 30 nm.

s), attributable to the tetrasubstituted endocyclic double bond in **1**, were replaced by the two exocyclic double-bond carbon signals at $\delta_C$ 151.9 (C-6, s) and 112.7 (C-12, t) in **2**. This portion of the spectrum was also similar to that observed in the $^{13}$C spectrum of 10-phenyl[12]cytochalasin $Z_{16}$.[35] Furthermore, in the $^1$H NMR spectrum of **2**, the C-11 methyl proton signal ($\delta_H$ 1.06, d, $J$ = 6.6 Hz), appearing as a doublet instead of the singlet ($\delta_H$ 1.52, s) as in **1**, was also consistent with a methyl-substituted six-membered ring as seen in cytochalasin $Z_{16}$.[35] This difference between **1** and **2** was further confirmed by $^1$H−$^1$H COSY and HMBC correlations as shown in Figure 4. The similar $^{13}$C NMR data of the macrocyclic rings in **1** and **2** (Table 1) and the consistency of NOESY results (Figures 2 and 4) suggested that the cyclic moieties in both **1** and **2** possess the same relative configurations. Additionally, the relative configuration of the chirality center at C-5 in **2** was assigned through the NOE correlations H-3/$H_3$-11, proving that Me-11 is $\alpha$-oriented.

The absolute configuration of compound (+)-**2** was established by spectroscopic comparison. Compound (+)-**2** has in fact a CD spectrum very similar to that of (+)-**1** (Figure 3A), and also consistent with that reported for cytochalasin $Z_{16}$.[35] It can therefore be assumed that cytochalasins **1** and **2** have the same absolute configuration of the corresponding chirality centers, as established above for (+)-**1**. Thus, the structure of **2** was determined as (+)-(3*S*,4*S*,5*S*,7*S*,8*S*,9*S*,13*E*,16*S*,18*E*)-7-hydroxy-5,16,18-trimethyl-10-(4′-hydroxy)phenyl-22-oxa-[12]-cytochalasa-6-(12),13,18-trien-1,17,21-trione.

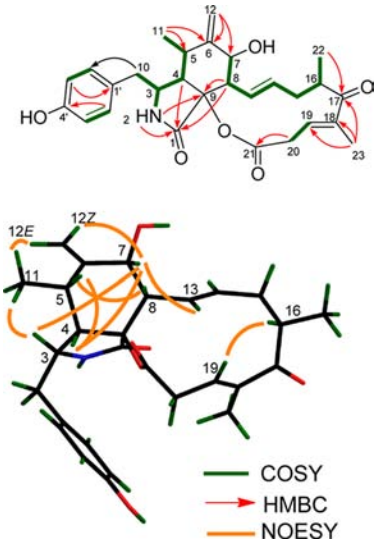

**Figure 4.** Selected HMBC, $^1$H−$^1$H COSY, and NOESY correlations of **2**.

*seco*-Cytochalasin E, **3**, was isolated as colorless oily solid. Its molecular formula was tentatively established as $C_{29}H_{37}NO_8$ based on ESI-MS peak at $m/z$ 550.11 ([M + Na]$^+$) associated with $^{13}$C NMR data. The $^1$H NMR signals (Table 1) at $\delta_H$ 7.15 (2H, d, $J$ = 7.3 Hz), 7.22 (1H, d, $J$ = 7.3 Hz), and 7.30 (2H, *d*, $J$ = 7.3 Hz) indicated a phenyl group in the structure. The large coupling constant ($J$ = 15.6 Hz) at $\delta_H$ 7.15 indicated a trans double bond in the structure. The similar $^{13}$C NMR data of compound **3** and cytochalasin $Z_{18}$ (**4**)[30] revealed a typical octahydro-1*H*-isoindol-1-one moiety of cytochalasin skeleton. Further detailed analysis of HSQC and $^1$H−$^1$H COSY suggested fragments as shown in Figure 5. Connections

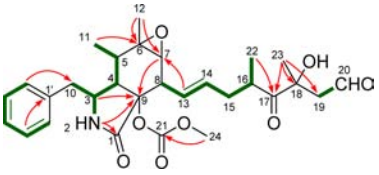

**Figure 5.** Selected HMBC and COSY correlations of **3**.

among the fragments showing COSY cross-peaks, quaternary carbons and methyl groups were further confirmed by HMBC correlations (Figure 5). The whole planar structure was elucidated as *seco*-cytochalasin E, a ring-opened derivative of cytochalasin E, which had been previously obtained as a semisynthetic derivative of **5**,[39] but without detailed spectroscopic data reported in the literature. Herein, all the $^1$H NMR and $^{13}$C NMR data were assigned unambiguously according to the 2D NMR experiments (Table 1). This is the first report of *seco*-cytochalasin E as a natural product.

Compounds **4** and **5** were identified as cytochalasin $Z_{18}$[30] and cytochalasin E,[30,33] respectively, on the basis of their spectroscopic features (NMR, MS) and by comparison with the published data in the literature.

**Biological Activity.** All the compounds **1**−**5** were examined for toxicity against brine shrimp, for phytotoxicity and antiphytopathogens in vitro.

dx.doi.org/10.1021/jf503846z | *J. Agric. Food Chem.* 2014, 62, 10962−10969

**Toxicity to Brine Shrimp.** In the screening assay on brine shrimp, cytochalasin E, **5**, at 50 $\mu$M displayed 100% lethality. In contrast, the other compounds **1**−**4** displayed very weak toxicity toward brine shrimp larvae with lethality below 10%. Compound **5** produced strong toxic effects on brine shrimp in a concentration-dependent manner (0.625−20.0 $\mu$M (Figure 6),

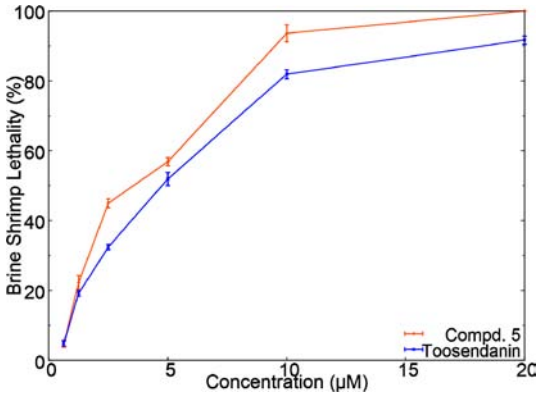

**Figure 6.** Brine shrimp lethality of **5** and the positive control drug toosendanin in concentrations 0.625−20.0 $\mu$M.

with a $LC_{50}$ value of 2.79 $\mu$M, which was comparable to that of the commercial insecticidal agent toosendanin, showing a $LC_{50}$ value of 4.03 $\mu$M. By comparison of the isolated structures of **1**−**5**, the toxicity against brine shrimp of **5** may be rationalized as due to the 13-membered macrocycle with a vinyl carbonate ester group.

**Phytotoxic Activity.** Among the five compounds tested, only cytochalasin E, **5**, bearing a vinyl carbonate ester and an epoxy group, demonstrated the highest seedling growth inhibition on *Lactuca sativa* and *Raphanus sativus* at concentrations in the range of 10−80 $\mu$M (Figure 7). The phytotoxicity of **5** was higher than that of the positive control, glyphosate, a broad-spectrum systemic herbicide in agriculture. In contrast, the remaining compounds **1**−**4** showed no effect on both seedlings even at a concentration of 100 $\mu$M. These

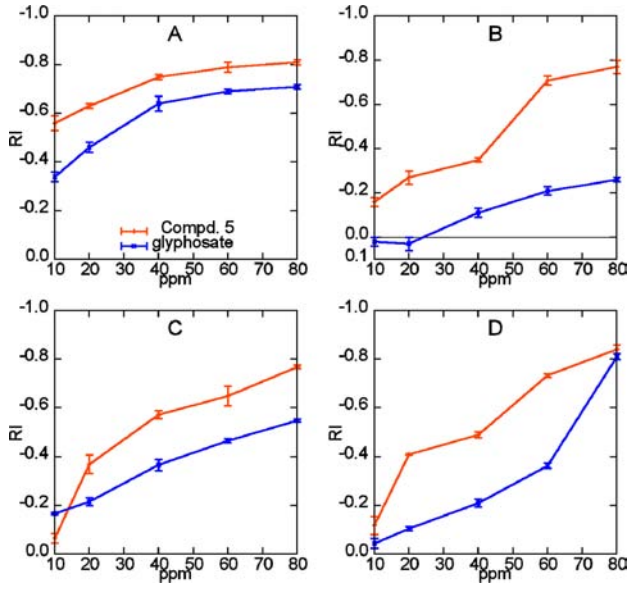

**Figure 7.** Phytotoxic activities of **5** and glyphosate on (A) *Lactuca sativa* root, (B) shoot, (C) *Raphanus sativus* L. Root, and (D) shoot.

findings demonstrated again that the 13-membered macrocyclic vinyl carbonate ester moiety in cytochalasins could be a determinant feature for activity. In fact, the macrocyclic ring opening of **5** to yield *seco*-cytochalasin E, **3**, leads to a loss of activity; 22-oxa[12]cytochalasins (e.g., cytochalasins $Z_{27}$, **1**, and $Z_{28}$, **2**), possessing the secondary hydroxyl group on C-7, were inactive; and open-chain cytochalasins (e.g., *seco*-cytochalasin E, **3**, and cytochalasin $Z_{18}$, **4**) without a perihydroisoindolyl scaffold were also inactive. Interestingly, the bioassay results of cytochalasin E, **5**, show an agreement between phytotoxic and insecticidal activity.

Cytochalasins have been considered as potential mycotoxins, and some of them have been found to be phytotoxic to different plants. Cytochalasin H, a toxic [11]cytochalasan of *Phomopsis* sp. isolated from weevil-damaged pecans, was markedly inhibitory to the growth of the floral development of tobacco plants.[40] Two [11]cytochalasans, pyrichalasin H, produced by the fungus *Pyricularia grisea*, and zygosporin D, isolated from the culture of the insect pathogenic fungus *Metarrhizium anisopliae*, were found to strongly inhibit the growth of rice seedlings.[41,42] Cytochalasin $Z_6$, an 24-oxa[14]-cytochalasan isolated from the culture of *Phoma exigua* var. *heteromorpha*, caused inhibition of rootlet elongation of tomato seedlings.[43] In addition, three 24-oxa[14]cytochalasans, namely cytochalasins $Z_3$, B, F, and an [13]cytochalasan, deoxaphomin, from the culture of *Pyrenophora semeniperda*, a promising mycoherbicide for the biological control of grass weeds, showed a remarkable ability to inhibit root elongation of wheat and tomato seedlings.[44] Of the test cytochalasins B, F, $Z_2$, and $Z_3$, and deoxaphomin, produced by *Phoma exigua* var. *exigua*, a potential mycoherbicide against the perennial weeds *Sonchus arvensis* and *Cirsium arvense*, deoxaphomin demonstrated the highest level of toxicity on leaves of *S. arvensis*, whereas other cytochalasins showed lower activity.[11] These observations promoted structure−activity relationship (SAR) studies leading to the conclusions that a [11] or a [13]carbocyclic or a [14]lactonic macrocyclic ring fused to an intact perihydroisoindolyl-1-one motif is an important feature for toxicity, and that the role played by the hydroxyl group on C-7 also appears crucial in imparting toxicity.[44−48] However, these results are not in accordance with our results, which indicated instead that the presence of 7-OH group in 22-oxa[12]cytochalasin motif has no major role in conferring activity. This discrepancy may depend on different crop species, varying sensitivity, and cytochalasin type. This is the first report of phytotoxicity of the tested cytochalasins, especially, a small type of 21,23-dioxa[13]-cytochalasin containing the unique vinyl carbonate moiety (e.g., **5**), to *Lactuca sativa* and *Raphanus sativus* seedlings.

**Antifungal Activity.** The antiphytopathogenic activity of the isolated cytochalsins was also evaluated on four different pathogens, namely, *Fusarium solani*, *Gibberella saubinetti*, *Botrytis cinerea*, and *Alternaria solani*, and the results are shown in Table 2. The antifungal activity of cytochalsin derivatives strongly depends on the fungal species. Among the compounds tested, only compound **2** showed strong fungicidal effect (MIC of 12.5 $\mu$M) against *G. saubinetti*, compared with that of the positive control hymexazol (MIC of 25 $\mu$M). In contrast, other compounds displayed quite weak properties with MIC values of greater than 50 $\mu$M against the pathogens tested.

In conclusion, five cytochalasins **1**−**5** have been characterized in the endophytic *Xylaria* sp., including two new compounds cytochalasin $Z_{27}$, **1**, and cytochalasin $Z_{28}$, **2**, and one new

**Table 2. Inhibitory Effects of Compounds 1−5 on Phytopathogenic Fungi**

| | phytopathogenic fungi (MIC, μM) | | | |

natural product *seco*-cytochalasin E. To the best of our knowledge, this is the first report of these three types of cytochalasan alkaloids in the genus *Xylaria*.[49] Cytochalasin E was identified as the most active component in brine shrimp toxicity and phytotoxicity potency in the fungal endophyte. The preliminary SAR analysis suggested that cytochalasin E with a characteristic 13-membered macrocyclic vinyl carbonate group could most likely result in strong activity. Fungal endophytes are well-known for their ability to produce a wide range of antimicrobial substances and enhance plant resistance to pathogens and pests. Therefore, a chemical interaction between the endophyte *Xylaria* sp. and the plant *T. sinensis* produces the mycotoxins as chemical defense compounds that could protect the host.

**Bacterial Strains and Growth Media.** *Bifidobacterium dentium* KCTC 3361, *Clostridium leptum* KCTC 5155, *Enterococcus saccharolyticus* KCTC 3643, *Mitsuokella multacida* KCTC 5453, *Pediococcus acidilactici* KCTC 15064, *Clostridium nexile* KCTC 5578, *Clostridium scindens* KCTC 5591, *Ruminococcus gnavus* KCTC 5920, and *Weissella paramesenteroides* KCTC 3531 were purchased from the Korean Collection for Type Cultures. *Megamonas funiformis* JCM 14723 was purchased from the Japan Collection of Microorganisms. *Marvinbryantia formatexigens* DSM 14469 and *Ruminococcus obeum* DSM 25238 were purchased from the Leibniz Institute DSMZ (German Collection of Microorganisms and Cell Cultures). *Lactobacillus acidophilus* ATCC 4356, *Lactobacillus delbrueckii* subsp. *bulgaricus* ATCC 11842, *Lactobacillus fermentum* ATCC 14931, and *Lactobacillus plantarum* subsp. *plantarum* ATCC 14917 were kindly provided by Professor Heping Zhang (Inner Mongolia Agricultural University, China). *Bifidobacterium adolescentis* CICC 6070 was purchased from the China Center of Industrial Culture Collection. *Clostridium perfringens* ATCC 13124 was purchased from the American Type Culture Collection. *Lactobacillus reuteri* CCFM 8217 and *Leuconostoc mesenteroides* CCFM 8220 were obtained from the Culture Collection of Food Microorganisms, Jiangnan University.

The medium used to isolate the bacteria was modified from gut microbiota medium (GMM),[19] which was modified from the supplemented tryptone−yeast−glucose medium by Gordon and co-workers[19] to culture fecal microbiota. The modified GMM contained 4 g of lactulose, 2 g of peptone, 1 g of yeast extract, 2 g of $KH_2PO_4$, 0.002 g of $MgSO_4{\cdot}7H_2O$, 0.08 g of NaCl, 8 mg of $CaCl_2$, 0.73 mg of $FeSO_4{\cdot}7H_2O$, 1.2 mg of hematin, 10 mL of ATCC vitamin mix, 10 mL of ATCC trace mineral mix, 0.5 mL of Tween 80, and 0.5 g of L-cysteine per liter. The pH was adjusted to 7.0 ± 0.1 by use of NaOH, and the medium was sterilized at 115 °C for 20 min. Lactulose was filter-sterilized through a 0.22-$\mu$m filter and added to the autoclaved medium as the sole carbon source. Solid medium was obtained by adding 18 g of agar/L of liquid medium. A total of 15 mL of 0.5% bromocresol purple was added to the GMM agar medium as the indicator of pH change.

**Database Preparation.** Site-specialized protein multifasta (PEP) files for reference genomes can be downloaded from the HMP Data Analysis and Coordination Center. These files record all HMP isolates that have completed sequencing and annotation. The gastrointestinal-tract PEP file (382 rows) was downloaded from http://hmpdacc.org/HMRGD/. A customized script was used to eliminate redundance.

The output of HMP's mothur community profiling of metagenomic 16S rRNA sequence data generated by a low-stringency approach (http://hmpdacc.org/HMMCP/) was also used for reference. One hundred seven of the genera depicted in the mothur community profiling output were not found in the list of reference genomes. Therefore, the 98 available genome coding sequences for these 107 genera were downloaded from the National Center for Biotechnology Information and merged into the gastrointestinal-tract PEP file, followed by BLAST database formatting.

**Genes Responsible for Uptake and Hydrolysis of Galactooligosaccharides.** By use of literature mining, 41 genes were identified as responsible for the transport or catabolism of GOS (Table 1). However, no genes have been reported to be responsible for the metabolism of lactulose. Like lactulose, GOS is formed by a $\beta$-1,4-glycosidic bond. Therefore, the genes related to GOS metabolism were used in this study to predict potential lactulose-metabolizing bacteria.

**Alignment of Transporters and Glycosidases against the Local Protein Database.** BLASTP searches were run against the local protein database with transporters and glycoside hydrolases used as queries. When the alignment length was found to exceed 70% of the transporter/glycoside hydrolase sequence and the identity was greater than 40%, the strain was inferred to have homologous proteins for corresponding functions.

**Isolation and Identification of Lactulose-Metabolizing Bacteria.** Fresh fecal samples were collected from five healthy donors aged 25−29 years. The fecal samples were placed in prereduced 0.1 M phosphate-buffered saline (PBS; 80 g of NaCl, 2 g of KCl, 14.4 g of $Na_2PO_4$, 2.4 g of $KH_2PO_4$, and 0.5 g of L-cysteine per liter; pH 7.0), with 15 mL/g of feces per sample.[19] The samples were dispersed and suspended by vortexing with sterilized glass beads for 5 min. Serial dilution was performed with 0.1 M PBS, and the diluted ($10^{-3}$) samples (0.1 mL) were plated. Six plates were used for each fecal sample, as recommended by Gordon and co-workers,[19] and the medium without lactulose was used for negative controls. The plates were incubated in an anaerobic workstation (Whitley DG250, Don Whitley Scientific Limited, West Yorkshire, U.K.) at 37 °C for 24 h under an atmosphere of 80% $N_2$, 10% $CO_2$, and 10% $H_2$. Colonies

[a]This entry from ref 23.

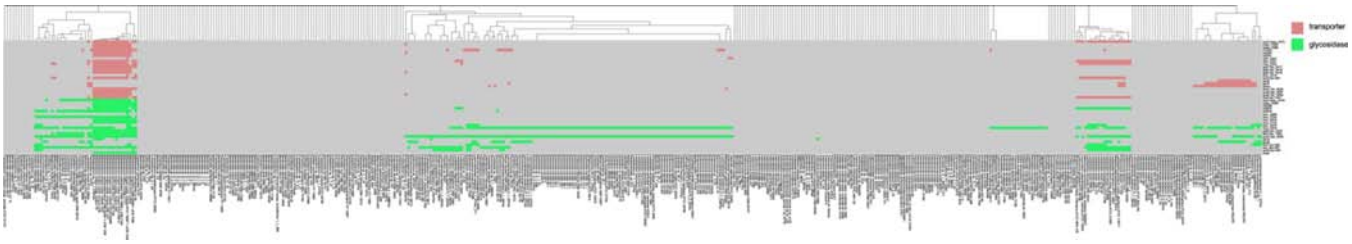

**Figure 1.** Distribution of homologue proteins of transporters and glycosidases for lactulose (vertical axis) among GIT bacteria (horizontal axis). Positive results for transporters and glycosidases are indicated in red and green, relatively.

with yellow surroundings on the GMM plates were picked up, reinoculated into liquid medium, and cultured anaerobically. The bacteria were isolated and purified by the standard streak-plate technique. The isolated bacteria were Gram-stained and identified by amplification and sequencing of 16S rRNA. The polymerase chain reaction (PCR) procedure was as follows: 95 °C for 5 min; 95 °C for 30 s, 50 °C for 30 s, and 72 °C for 1 min 30 s, 30 cycles; 72 °C for 10 min; 12 °C for 10 min. The resulting PCR product was sequenced by Sangon Biotech (Shanghai) Co., Ltd.

**Characterization of Bacterial Growth on Lactulose.** Bacteria were cultured anaerobically in GMM at 37 °C for 24 h, with lactulose as the sole carbon source. Absorbance at 600 nm ($OD_{600}$) and pH were recorded every 2 h to characterize the growth. The amount of lactulose in the culture supernatant was determined by the method developed by Zhang et al.[29]

**Fermentation of Galactooligosaccharides by Lactulose-Metabolizing Bacteria.** Bacteria capable of metabolizing lactulose were inoculated on GMM plates with GOS as the sole carbon source and bromocresol purple as the indicator. GMM plates without GOS were set as negative controls. The bacteria on the GMM−GOS plates that were capable of growing and coloring their surroundings yellow were considered to have the ability to metabolize GOS.

## RESULTS

**Homologous Proteins for Lactulose Transporters and Glycosidases in 453 Gastrointestinal-Tract Bacteria Strains.** The results of aligning the transporters and glycosidases with the local protein database are shown in Figure 1. Surprisingly, homologue proteins for the glycosidases appeared in 222 of the 453 strains, which accounted for 56 of the 114 genera. In contrast, homologue proteins for the transporters were found in only 90 strains, accounting for 29 of the 114 genera. These 90 strains also possessed homologue proteins for the glycosidases. In general, lactulose metabolism requires transporters and galactosidases. In addition to *Bifidobacterium* and *Lactobacillus*, 27 genera with homologue proteins for both transporters and glycosidases were found (Figure 1), indicating that lactulose may not be exclusively a stimulant of probiotics.[30] However, it remains unclear whether the predicted bacteria are able to utilize lactulose; further investigation is required.

**Utilization of Lactulose by *Cronobacter sakazakii*, *Enterococcus casseliflavus*, *Enterococcus faecalis*, and *Klebsiella pneumoniae*.** Compared with GOS, lactulose has an accurate chemical structure and metabolic process, and its purity can reach 99.3%. In the current study, fecal samples collected from five healthy adults were plated on GMM with lactulose as the sole carbon source. Ninety-six strains belonging to 18 species of nine genera were identified (Table 2). To our knowledge, *Cronobacter*, *Enterococcus*, *Klebsiella*, and *Pseudomonas* are first reported in our study to be capable of utilizing lactulose. One strain from each species was selected and its growth on lactulose was characterized (Figure 2). $OD_{600}$ increased during the 24-h culture period, along with a decrease in pH and a reduction in the lactulose amount, which provided direct proof of lactulose utilization.

**Table 2. Identified Lactulose-Metabolizing Bacteria in Healthy Adult Feces[a]**

| genus and species | strains |
|---|---|
| *Cronobacter sakazakii* | CCFM 8305, 8306, 8307, 8308, 8309, 8310, 8311, 8312 |

[a]16S rRNA nucleotide acid sequences of the identified strains are shown in Table S1 in Supporting Information.

In addition, the ability of 21 strains to metabolize lactulose was assessed, and 17 strains were proven to be able to grow on lactulose (Table 3 and Figure 3). Thirteen of the 15 strains with homologue proteins for both transporters and glycosidases were capable of utilizing lactulose, indicating that searching for transporter and glycosidase homology may be an effective method of predicting lactulose-metabolizing bacteria.

**Galactooligosaccharide Utilization by Lactulose-Metabolizing Bacteria.** Due to the structural similarity of lactulose and GOS, the 18 strains isolated (Figure 2) and the 17 strains found to be capable of metabolizing lactulose (Table 3) were tested for their ability to ferment GOS. The results showed that 32 strains were capable of GOS utilization (Table

4). Although lactulose is a disaccharide composed of fructose and galactose, while GOS is a complex with different degrees of galactose polymerization, they may share the same transporters or glycosidases. Moreover, the 17 lactulose-metabolizing strains obtained from the alignment search contained homologue proteins for transporters and glycosidases that have been reported to be responsible for metabolizing GOS. Thus, there seems to be a significant correlation between lactulose and GOS.

## DISCUSSION

Lactulose has generally been regarded as a special substrate used by probiotic bifidobacteria and lactobacilli. However, *Faecalibacterium prausnitzii*, *Bacteroides oralis*, *E. coli*, and *C. perfringens* have also been reported to utilize lactulose in vitro.[10,31] It remains unclear which species are able to utilize lactulose in the gut. The gut is a complex ecosystem, with about $10^{14}$ bacteria categorized into more than 1000 species,[32] and the aim of the current study was to identify lactulose-metabolizing bacteria within this ecosystem.

Transporters and glycosidases are of great importance to the utilization of oligosaccharides. Thus far, however, no encoding genes for lactulose metabolism have been identified. Therefore, the genes for GOS metabolism acquired through literature mining were used instead. Moreover, the unculturability of most gut microbes has limited our understanding of the metabolic characteristics of individual strains. To date, HMP has failed to reach its goal of isolating 3000 reference genomes from human body sites. In the current study, the site-specialized reference genome data provided by HMP were combined with the output of mothur community profiling to build a local protein database. As shown in Figure 1, the genes for lactulose metabolism appeared in 222 GIT bacteria strains, of which 90 strains possessed homologue proteins for both transporters and glycosidases. It is reasonable to infer from the existence of transporters in a given strain that the strain contains corresponding glycosidases. If no corresponding glycosidases were available, the strain would be unlikely to contain transporters.

To identify lactulose-metabolizing bacteria in the gut, 18 species were isolated from fecal samples (Table 2), and 17 strains were proven to have the ability to utilize lactulose (Table 3). This indicates that bioinformatic analysis is an effective tool for predicting lactulose-metabolizing bacteria, thereby narrowing the scope of experimental research. Unlike the results of previous studies,[10,31,33] the findings of the current study indicated for the first time that the genera *Cronobacter*, *Enterococcus*, *Klebsiella*, and *Pseudomonas* are able to utilize lactulose. To the best of our knowledge, *C. sakazakii*, *E. aerogenes*, Enterobacteriaceae bacterium, *E. casseliflavus*, *E. faecalis*, *E. faecium*, *E. gallinarum*, *E. fergusonii*, *K. pneumoniae*, *Klebsiella* sp., *K. variicola*, *P. putida*, *S. anginosus*, *S. equinus*, and *B. pseudocatenulatum* have never been reported to be capable of utilizing lactulose.

Therefore, lactulose was shown to have the potential to stimulate the growth of many commensal bacteria in addition to bifidobacteria and lactobacilli. More gut bacteria capable of utilizing lactulose may exist than previously supposed. Additionally, lactulose exhibited similar metabolic characteristics to GOS (Table 4), which may be derived from lactulose.[34] Therefore, lactulose may be considered a type of GOS with a lower degree of polymerization, and lactulose and GOS may possess similar genes for transporters or galactosidases. In the human gut, competition for limited food takes place among the bacteria, and those capable of utilizing prebiotic substrates might have advantages during the competition with other bacteria.[35]

In conclusion, the combination of a homology search and the traditional isolation method assisted in the identification of lactulose-metabolizing bacteria. Thirty-five species were found, most of which were reported for the first time to be capable of utilizing lactulose. The commensal gut bacteria *Cronobacter*, *Enterococcus*, *Escherichia*, *Klebsiella*, *Pseudomonas*, and *Streptococcus* were found to be able to ferment lactulose. In addition, significant correlations were observed between lactulose and GOS metabolism. This work offers greater insight into the utilization of oligosaccharides by gut bacteria. To further explore the relationship between functional oligosaccharides

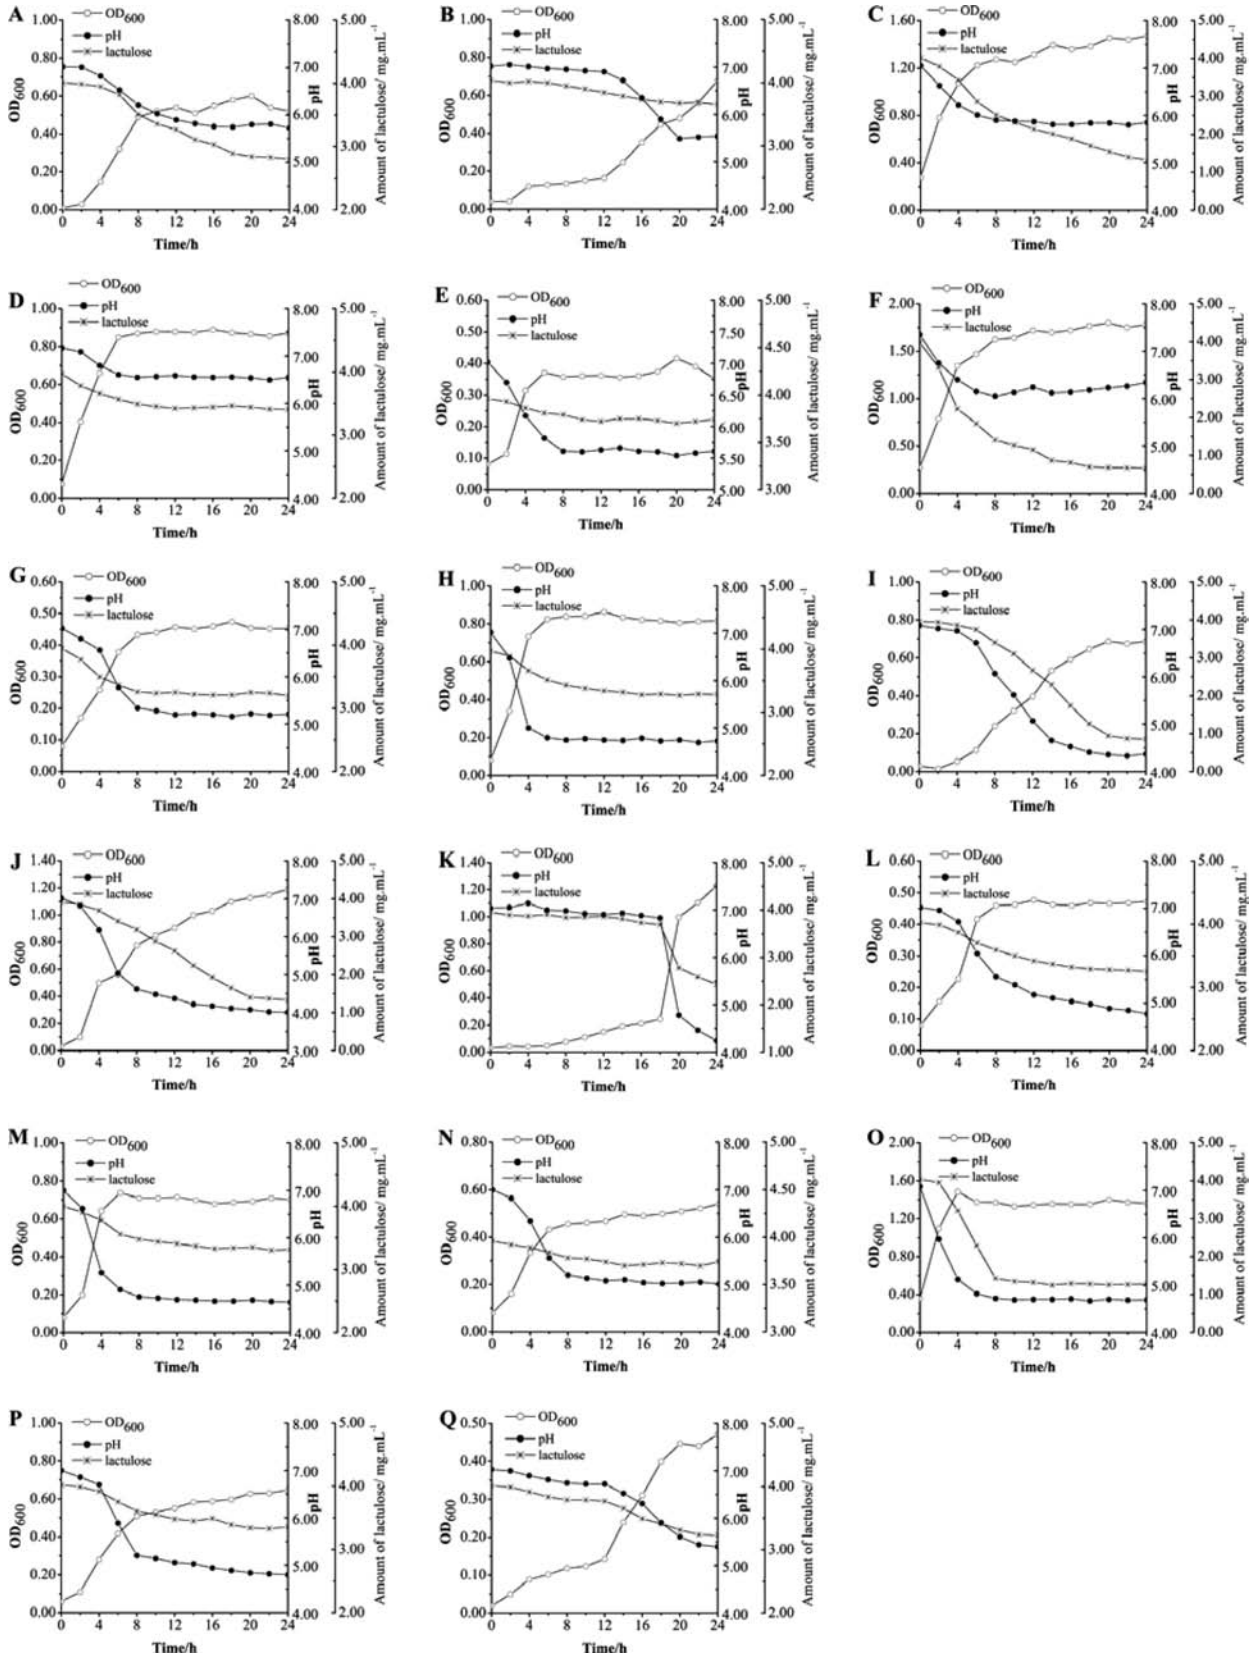

**Figure 3.** Growth of obtained strains on GMM medium with lactulose as the sole carbon source. $OD_{600}$ (○), pH (●), and the amount of lactulose (×) were recorded every 2 h, and the strains are presented as follows: (A) *B. adolescentis* CICC 6070, (B) *B. dentium* KCTC 3361, (C) *C. leptum* KCTC 5155, (D) *C. perfringens* ATCC 13124, (E) *E. saccharolyticus* KCTC 3643, (F) *E. rectale* ATCC 33656, (G) *L. acidophilus* ATCC 4356, (H) *L. delbrueckii* subsp. *bulgaricus* ATCC 11842, (I) *L. fermentum* ATCC 14931, (J) *L. plantarum* subsp. *plantarum* ATCC 14917, (K) *L. reuteri* CCFM 8217, (L) *L. mesenteroides* CCFM 8220, (M) *M. formatexigens* DSM 14469, (N) *M. funiformis* JCM 14723, (O) *M. multacida* KCTC 5453, (P) *P. acidilactici* KCTC 15064, and (Q) *W. paramesenteroides* KCTC 3531.

stem parts in their *C. incanus* herbal teas. As a result, the particle size also varies widely in such products.

So far, some studies have investigated the phenolic compounds in different *Cistus* species, but in these studies only the leaves[19,20] or aerial parts of *Cistus* plants have been analyzed, which presumably consisted of an undefined mixture of leaves and a few stems as well as some blossoms.[2,12,21−23] Especially in some regions in northern Greece, hot water extracts from aerial parts consisting of dominantly woody and less leafy parts of *C. incanus* have been traditionally used as remedies.[3] However, until today no reliable scientific data seem to be available for the distribution of bioactive phenolic compounds in the leaves or the woody stem parts of *C. incanus*.

With regard to the brewing references recommended (by the manufacturers), hot water extractability represents a very critical factor in yielding herbal tea infusions with high concentrations of phenolic compounds. In a previous work, the influence of brewing process factors such as the type of water, temperature, and brewing duration on the phenolic compounds in *C. incanus* infusions was demonstrated.[10] To augment these results, a potential influence of herbal particle size on the extractability of bioactive phenolic compounds in *C. incanus* infusions should be taken into consideration in the current study.

For investigating the presence of bioactive phenolic compounds in *C. incanus* herbal tea, four commercially available products were manually divided into leaves and woody stems. However, there are only a few manufacturers that sell products with a high amount of woody stems, but especially these products are highly advertised for their health-preventive properties. The resulting infusions were analyzed for the presence and concentration of phenolic compounds. Additionally, the separated plant parts were reconstituted into three defined mixtures. As chemical analytical marker, the amount of woody parts of these model samples was determined by cellulose concentrations and sugar profiles.

Furthermore, one *C. incanus* herbal tea was exemplarily separated by the use of a laboratory sieving machine into six fractions of different particle sizes with recognizable leafy and woody parts to investigate the extractability and the influence of particle size on the phenolic substances in the corresponding infusions. By use of LC-DAD-ESI-MS/MS the phenolic compounds were identified, and 22 substances were quantitated by LC-DAD. The chemical reactivity of these quantitated phenolic compounds was estimated using LC-onlineTEAC data published previously for the Trolox equivalent antioxidant capacity (TEAC) of the single compounds in *C. incanus* infusions.[10]

The aim of this study was to investigate the influence of the herbal leaf content and particle size on the concentration of quantitated bioactive phenolic compounds in *C. incanus* infusions. Besides the importance for the consumers with regard to potential health beneficial effects, these data might be of certain importance for a re-evaluation of the persisting *Novel Food* status of *C. incanus* products in the European Community.

## MATERIALS AND METHODS

**Chemicals.** Gallocatechin (≥98%), myricitrin (≥99%), quercitrin hydrate (≥78%), procyanidin B1 (≥90%), *trans*-ferulic acid (99%), copper(II) sulfate pentahydrate (Ph. Eur.), and sodium carbonate (99.5%) were purchased from Sigma-Aldrich Chemie GmbH (Schnelldorf, Germany). Catechin (∼CHR), formic acid (≥98%), D-(+)-xylose (>99%), and D-(+)-glucose (≥99.5%) were purchased from Carl Roth GmbH & Co. KG (Karlsruhe, Germany). Tiliroside (96%) was purchased from PhytoLab GmbH & Co. KG (Vestenbergsgreuth, Germany). Gallic acid (98%) was purchased from Acros Organics BVBA (Geel, Belgium). Ellagic acid (≥98%) and myricetin-3-*O*-galactoside (≥99%) were purchased from Extrasynthese SAS (Genay, France). Ammonia solution (25% p.a.) and petroleum ether (40−60 °C) were purchased from Th. Geyer GmbH & Co. KG. (Renningen, Germany). Acetone, ethanol, sulfuric acid (>95%), boric acid, and bicinchoninic acid were purchased from Fisher Scientific GmbH (Schwerte, Germany). Glacial acetic acid, methanol, and acetonitrile were purchased from VWR International GmbH (Darmstadt, Germany). Potassium tetraborate (99.5%) was purchased from ChemPur GmbH (Karlsruhe, Germany). MCI Gel CA08F was purchased from Mitsubishi Chemical Corp. (Tokyo, Japan). L-Aspartic acid (Ph. Eur.) and amylase was purchased from Merck KGaA (Darmstadt, Germany). Amyloglucosidase was purchased from Roche Diagnostics GmbH (Mannheim, Germany). Polyamide 6 (particle size = 0.05−0.16 mm) was purchased from Macherey-Nagel GmbH & Co. KG (Düren, Germany). All solvents were of LC grade, and water was of Milli-Q-quality.

**Plant Material.** Four commercially available products of *C. incanus* herbal teas were used as a basis for this study. Leaf particles and woody stem parts as well as some blossoms were recognizable in all samples. The average sizes of leaves and stems, the stem diameters, and the country of origin of the four herbal teas are presented in Table 1. For the determination of a possible influence of the leaf and wood contents on the presence of phenolic compounds in the infusions, the four herbal samples were manually sorted into woody stems and leaves. Furthermore, three mixtures of sample 1 were reconstituted exemplarily from the stems (st1; "st" stands for *sorted*) and leaves (st5), resulting in preparations with (st2) 25% (w/w), (st3) 50% (w/w), and (st4) 75% (w/w) leaf content and corresponding woody stem contents of 75% (w/w), 50% (w/w), and 25% (w/w). In Figure 1A samples st1, st3, and st5 are shown for the manually sorted herbal teas. In a second series of experiments, investigating the extractability of the phenolic compounds with regard to particle size, *C. incanus* herbal tea sample 1 was exemplarily separated by use of a laboratory sieving machine Typ 3D from Retsch GmbH (Haan, Germany) into six fractions with the sizes (sample sv1; "sv" stands for *sieved*) 2.5−3.1 mm, (sv2) 2.0−2.5 mm, (sv3) 1.4−2.0 mm, (sv4) 1.0−1.4 mm, (sv5) 0.5−1.0 mm, and (sv6) <0.5 mm. All fractions contained recognizable parts of leaves and stem parts (Figure 1B).

**Sample Preparation.** *C. incanus* herbal tea (1.25 g) was brewed in 45 mL of water at a temperature of 95 °C for 5 min. The brewing time and temperature were used according to manufacturer recommendations for the preparation of the infusions. After centrifugation (centrifuge 5810 R, Eppendorf GmbH, Hamburg, Germany) for 10 min at 3220*g*, an aliquot of 35 mL was taken of the supernatant. Lyophilization of the aliquot using a lyophilizer (Alpha 1-4 LSC,

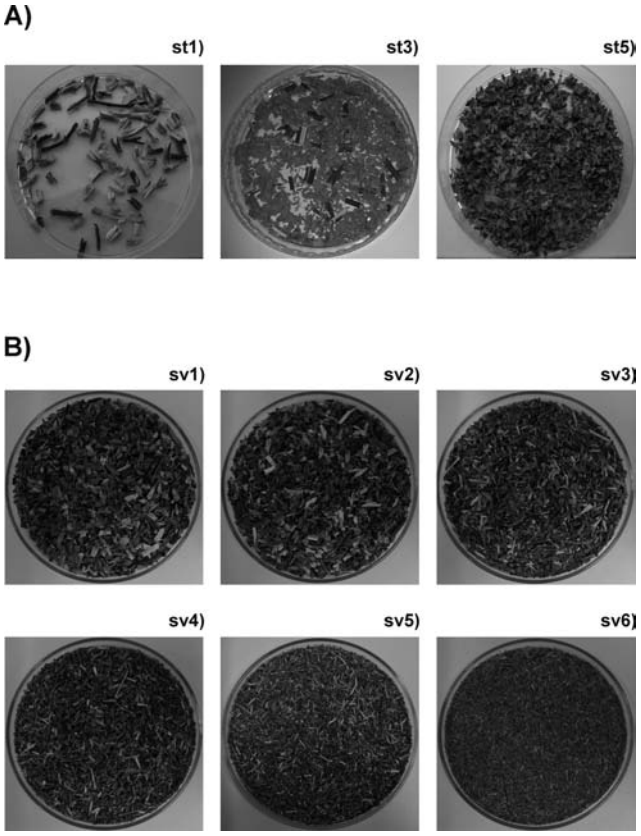

**Figure 1.** (A) Three manually sorted *C. incanus* herbal teas (of sample 1). Plant part composition of samples: (st1) 0% (w/w) leaves and 100% (w/w) woody stems; (st3) 50% (w/w) leaves and 50% (w/w) woody stems; (st5) 100% (w/w) leaves and 0% (w/w) woody stems. (B) Sieved *C. incanus* herbal teas (of sample 1) containing leaves and woody stem parts. Average particle sizes of herb material: (sv1) 2.8 mm; (sv2) 2.3 mm; (sv3) 1.7 mm; (sv4) 1.2 mm; (sv5) 0.8 mm; (sv6) 0.3 mm.

Martin Christ GmbH, Osterode, Germany) and dissolving the dry residues in 4 mL of water followed. The next step in sample preparation included a solid phase extraction (SPE) according to a method of Breitfellner et al.[24] using polyamide 6 as stationary phase and two elutions, one with methanol and one with ammonia containing methanol, for purification and fractionation. After drying under a stream of nitrogen overnight, redissolving in 4 mL of methanol 70%, and syringe filtration (0.45 $\mu$m nylon membrane), the extracts were ready for analyses.[10] The extracted herb was air-dried at room temperature for about 72 h. An accelerated solvent extraction (ASE) with four solvents of different polarities followed for a ful extraction of all soluble substances of herb material. The insoluble cellulose was determined of the fully extracted *C. incanus* herb resulting from the brewing process and ASE. The used methods for ASE and determination of wood sugar and cellulose concentrations are described below.

**Analysis of the Wood Content.** For analyzing the wood content in the sorted leaf and woody stem samples (st1−st5), the cellulose concentrations and sugar profiles of the stems were measured as analytical markers. Following the determination of the dry weight, 0.5 g of each manually sorted sample was extracted in duplicate by use of an accelerated solvent extraction system ASE 200 (Dionex GmbH, Idstein, Germany). Two extraction cycles with 10 mL of solvent were performed for 10 min at 70 °C and 10 MPa for each solvent. The following solvents were used gradually: petroleum ether, acetone/water (9:1), ethanol/water (8:2), and water. After air-drying at room temperature for about 24 h ("climatization") and milling with a laboratory disk mill Typ T 1000 from Siebtechnik GmbH (Mühlheim, Germany), the ASE residues were subjected to a two-stage hydrolysis. For the prehydrolysis 200 mg of the milled material was mixed with 2 mL of 72% sulfuric acid in a reaction tube and hydrolyzed under repeated stirring at 30 °C for 1 h on a thermostat. The reaction was stopped by adding 6 mL of water. Afterward, the prehydrolyzed sample was transferred with 50 mL of water in a 100 mL volumetric flask. For posthydrolysis the pretreated sample was hydrolyzed at 120 °C and 0.12 MPa for 30 min in an autoclave. After cooling, filling to the calibration mark with water and subsequent agitation, filtration over a G4 sintered glass crucible, and washing the hydrolysis residue acid-free with water followed. After drying at 105 °C, the residue was determined gravimetrically. With regard to wood chemistry, this residue represents the acid-insoluble lignin (Klason lignin). The hydrolysates were analyzed with regard to their glucose and xylose contents by borate anion exchange chromatography.[25] Additionally, a test on starch was carried out for the 100% (w/w) woody stem (st1) and the 100% (w/w) leaf sample (st5) to evaluate if the glucose results from cellulose or from starch hydrolysis. For this purpose, the two samples described were finely milled by use of a disk mill, 200 mg was weighed in a 25 mL volumetric flask, and 20 mL of methanol/water (3:1) was added. After shaking thoroughly by hand, the solution was incubated for about 15 h and filtered over a G4 sintered glass filter. The filtration residues were washed with 20 mL of methanol/water (3:1) and climatized for 5 days. Afterward, 25 mg of the residues was incubated with 0.75 mL of enzyme solution (0.05% amylase and 0.05% amyloglucosidase in 0.1 M ammonium acetate buffer, pH 4.7) at 45 °C for 24 h. After filtration of the solutions, the glucose concentration was determined by borate anion exchange chromatography[25] and corrected for an enzyme blank. All monosaccharide and starch concentrations were based on the original raw material under consideration of the various extraction losses. The cellulose content of samples was calculated from the glucose concentration by subtracting the glucose from starch and considering the weight gain due to water addition during hydrolysis (−10%).

**Identification and Quantification of the Phenolic Compounds.** Identification of the phenolic compounds was previously described by Riehle et al.[10] Following SPE cleanup of the *C. incanus* infusions, the phenolic substances in both eluates, one methanolic and one ammonia−methanol eluate, were identified by LC-DAD-ESI-MS/MS.

For the quantitation of the phenolic compounds, stock solutions of standard substances were prepared at a concentration level of 1 mg/mL. For the calibration curves, seven equidistant concentrations of each standard were prepared, and the purity of standard substances was considered in the calculations. A coefficient of determination with $R^2 = 0.99$ resulted for all calibrations curves. As there are no standards commercially available for all compounds, some were quantitated by the use of structural relatives. Thus, methyl gallate was quantitated as gallic acid and gallocatechin−catechin as procyanidin B1, myricetin-*O*-xyloside as myricitrin, myricetin-3-*O*-glucoside as myricetin-3-*O*-galactoside, glycosides of quercetin as quercitrin, hexahydroxydiphenoyl-glucose and ellagic acid-7-*O*-xyloside as ellagic acid, and hydroxyferulic acid-*O*-rhamnosides and hydroxyferuloyl-rhamnose as *trans*-ferulic acid. The corresponding correction factors for the difference in molecular weight were included in the calculation of substance concentrations. For the quantitation of gallocatechin−catechin as procyanidin B1, it has to be considered that the absorption of the gallocatechin subunit was lower compared to the absorption of the catechin subunit in procyanidin B1. Consequently, the absolute results for gallocatechin−catechin concentrations are slightly higher. For the measurements, the LC-DAD method according to Riehle et al.[10] was used. Hydroxybenzoic acids, ellagitannins, and flavanols were detected at a wavelength of 280 nm, hydroxycinnamic acids at 325 nm, and the flavonols at 350 nm.

**Statistical Analysis.** Two *C. incanus* infusions of each sample were brewed and analyzed twice. The standard deviation was calculated, and the averaged values along with the standard deviations are documented in the corresponding figures. The calibration curves for quantitation were also analyzed twice.

## RESULTS AND DISCUSSION

**Identification of the Phenolic Compounds.** *C. incanus* infusions include a wide range of phenolic compounds of different substance classes. According to Riehle et al.,[10] 32 phenolic compounds, belonging to the subclasses of phenolic acids, flavonoids, and ellagitannins, were detected. In addition to the previously identified phenolic compounds, a 4-*O*-rhamnoside and a 5-*O*-rhamnoside of hydroxyferulic acid as well as a hydroxyferuloyl-rhamnose have been tentatively identified by LC-DAD-ESI-MS/MS in this study. Such *O*-glycosylated phenolic acids were also previously identified by Barrajón-Catalán et al.[2] for *Cistus albidus*, another species of the plant family Cistaceae. From the substances identified, the 22 dominant phenolic compounds in the *C. incanus* infusions have been quantitated with LC-DAD. Table 2 gives an overview of these compounds, their retention times, and MS and MS/MS data as well as their distribution in the two SPE eluates.

**Leaf and Wood Contents of the Manually Sorted Samples.** For the investigation of the influence of herbal leaf and wood content on the composition of phenolic compounds in *C. incanus* infusions, four herbal tea samples were manually sorted into woody stems and leaves. Besides sample st1 with 100% (w/w) and st5 with 0% (w/w) woody stem parts, *C. incanus* herbal tea sample 1 was exemplarily reconstituted into three defined mixtures of stems and leaves on the basis of their dry weight: (st2) 75% (w/w), (st3) 50% (w/w), and (st4) 25%

(w/w) woody stem parts. To monitor the biochemical "real" wood contents of these exemplarily sorted *C. incanus* herbal teas, the results from acid hydrolysis and carbohydrate analysis were considered (Table 3). With regard to wood chemistry, the residue from a sulfuric acid hydrolysis represents the acid-insoluble lignin content of the sample (Klason lignin). However, for the various *C. incanus* samples, the hydrolysis residue was always in a similar order of magnitude and did not correlate with the ratio of stem and leaf material. This indicates that other components, for example, protein from the leaves, are as well incorporated into the residue. Accordingly, this value is not suitable to monitor the proportion of leaf and stem material. Alternatively, the polysaccharide components of the material have been considered. The sum of glucose and xylose combines the main components, representing the cellulose and hemicelluloses content of the samples. In addition, the cellulose content was calculated. In Table 3, the corresponding values of the five samples (st1−st5) prepared from the leaves and stems of sample 1, manually separated and then mixed according to fixed ratios, as well as the concentrations of glucose resulting of starch of the 100% (w/w) woody stem (st1), and 100% (w/w) leaf sample (st5) are presented. Strongly linear positive correlating concentrations of glucose and xylose with an increasing amount of woody plant parts ($R^2$ = 0.99) were revealed. The low glucose values of 1% in the starch test indicated that the glucose, which was used for the calculation of cellulose, did not significantly result from starch hydrolysis. On the basis of the starch test results, a correction factor of 1% was included in the calculation of the absolute cellulose concentration. Altogether, the cellulose contents of manually sorted *C. incanus* herbal teas can be used as a valid analytical marker for wood contents.

**Presence of Phenolic Compounds Depending on the Plant Parts of the Herbal Tea Mixture.** The presence of the 22 quantitated phenolic compounds in the resulting infusions brewed from the four herbal tea samples sorted into woody stems and leaves is shown in Table 4. In all four samples higher concentrations of quantitated phenolic compounds were present in the infusions brewed from the sorted leaves compared to the stems. Furthermore, several of the 22 quantitated compounds were not even detectable in the infusions brewed from stems. Especially in sample 1, which included the longest stems with the largest diameters of the four *C. incanus* herbal tea samples analyzed, only gallic acid, catechin, and methyl gallate were detected in infusions brewed from stems. A remarkable exception was the catechin concentration. In the four infusions brewed from *C. incanus* stems, comparatively high concentrations of this phenolic compound from 0.3 to 1.1 mg/100 mL infusion were quantitated. In sample 3, the concentration in the infusion brewed from stems (0.9 mg/100 mL) was even higher compared to the infusion brewed from *C. incanus* leaves (0.6 mg/100 mL). Altogether there were differences in the concentrations of the quantitated phenolic compounds between the infusions brewed from four *C. incanus* herbal teas. These differences were maybe a result from different plant origins, ecophysiological factors, cultivation conditions, or harvest time. For example, the plant materials of samples 1 and 2 were harvested in Greece, sample 4 was from Turkey, and the origin of sample 3 was not available. In the discussion of the varying presence of phenolic compounds in *C. incanus* plant parts, the plant physiological properties and harvest time of these Mediterranean shrubs should be considered, too. These plants have been classified as malakophyllous xerophytes[4,26]

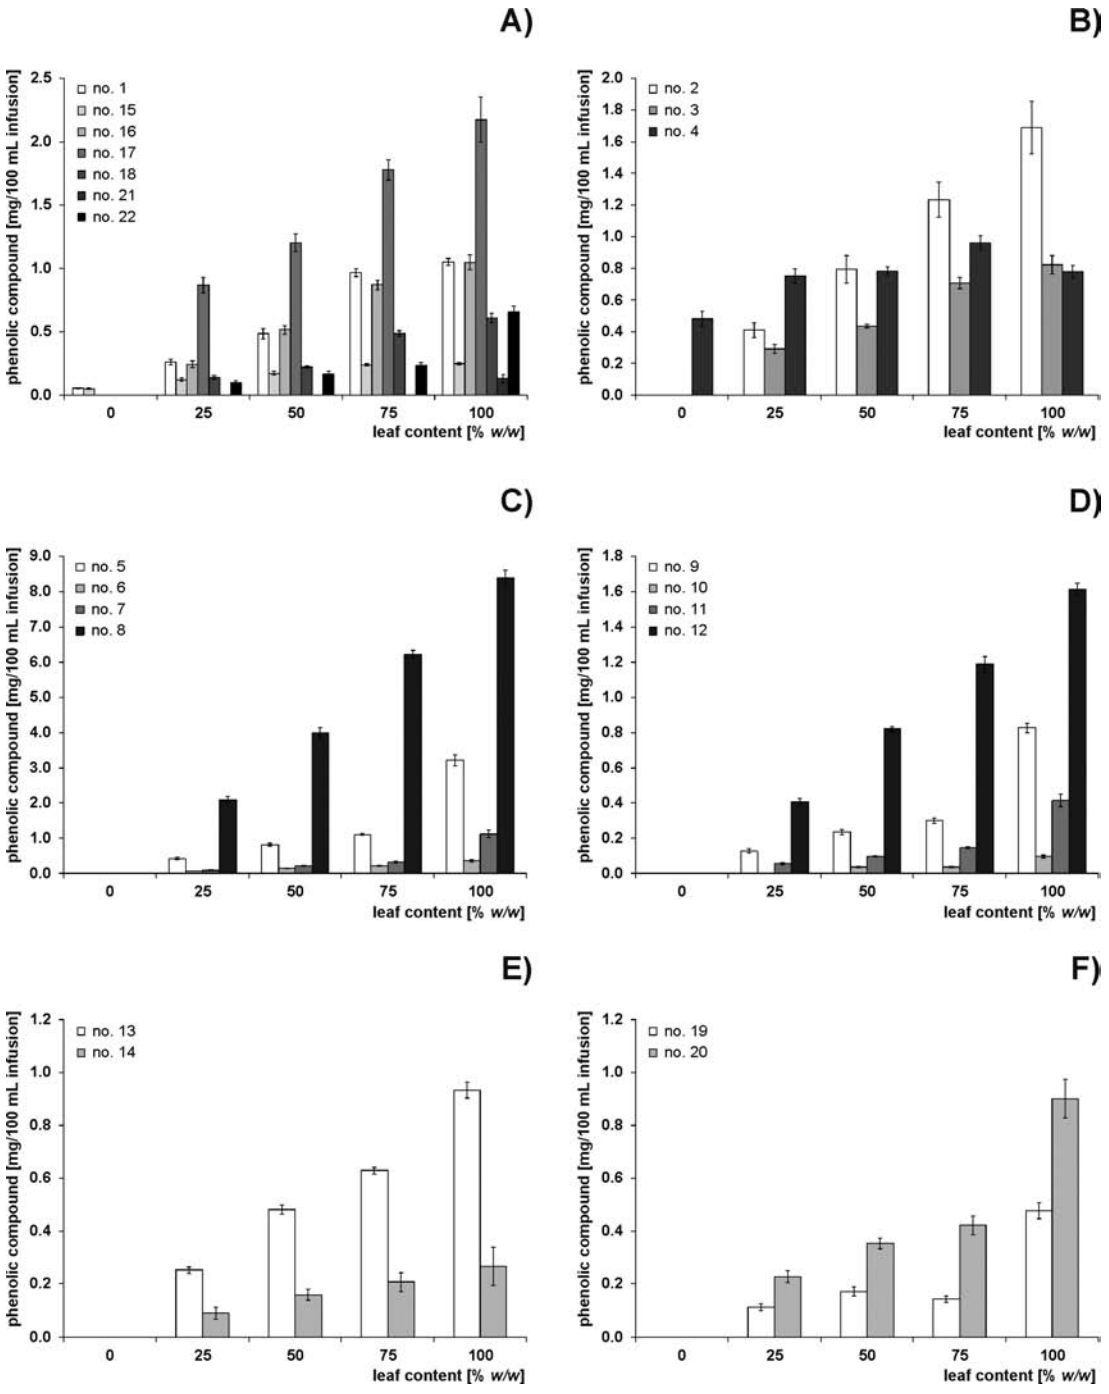

**Figure 2.** Contents of 22 phenolic compounds in five *C. incanus* infusions brewed from herbal mixtures (of sample 1) with leaf contents of 0% (w/w), 25% (w/w), 50% (w/w), 75% (w/w), and 100% (w/w) and corresponding woody stem contents of 100% (w/w), 75% (w/w), 50% (w/w), and 0% (w/w): (A) phenolic acids; (B) flavan-3-ols and dimers; (C) myricetin glycosides; (D) quercetin glycosides; (E) tiliroside isomers; (F) ellagitannins. For compound no. refer to Table 2.

and are drought resistant with seasonal dimorphism of the leaves.[27] The plants of this genus develop small leaves with numerous trichomes during dry summer periods for minimization of transpiration and leaves with only few trichomes in winter.[27] According to Christodoulakis et al.,[28] the prominent feature of *C. incanus* summer leaves is an intense accumulation of phenolic secondary metabolites, whereas in less climatically stressed winter leaves, a lower accumulation can be observed. Similar effects have been already shown for environmental stress factors such as drought, which significantly increased concentrations of bioactive phenolic compounds in *Cistus clusii* leaves, for example.[29] Therefore, investigating the influence of seasonal leaf polymorphism on the presence of phenolic compounds in *C. incanus* can be a scientific basis for further research. Altogether, a tentative indication of the ecophysiological variation in the concentrations of phenolic compounds in different *C. incanus* herbal products and plant parts is represented by the results of the four traditional herbal tea samples of this work.

Subsequently, the concentrations of the 22 quantitated phenolic compounds in the infusions brewed from the mixtures (st1−st5) of *C. incanus* sample 1 are shown along six chosen phenolic substance classes. In Figure 2, the influence of the leaf content on the concentration of phenolic acids (A), flavan-3-ols and their dimers (B), myricetin glycosides (C), quercetin glycosides (D), tiliroside isomers (E), and ellagitannins (F) is shown for *C. incanus* woody stems (st1) and leaves (st5) as well as for the three reconstituted mixtures (samples st2−st4). The strongest correlations in the class of phenolic acids between leaf content and presence of substance resulted for gallic acid ($R^2$ = 0.96) and methyl gallate ($R^2$ = 0.95). Furthermore, these two compounds were present in infusions brewed from the 100% (w/w) woody stem sample (st1), too. Concentrations for both gallic acid derivatives ranged from 0.1 mg/100 mL infusion (st1) to 1.1 mg/100 mL infusion (st5) and for methyl gallate from 0.1 mg/100 mL infusion (st1) to 0.3 mg/100 mL infusion (st5). This result illustrates that up to 11-fold higher concentrations of gallic acid can be yielded when *C. incanus* infusions are brewed from a herbal preparation consisting of 100% (w/w) pure leaves. As shown in a previous work, gallic acid is one of the most reactive phenolic compounds in *C. incanus* infusions, as it is responsible for about 11% of the total TEAC.[10] For the other phenolic acids a similar occurrence in woody stem and leaf parts was observed, too.

With regard to the class of flavan-3-ols (catechins) and their oligomers, the strongest correlation between leaf content of *C. incanus* herbal tea sample 1 and the presence of phenolic substance was found for gallocatechin ($R^2$ = 0.99). The gallocatechin concentrations ranged from 0.0 mg/100 mL infusion (st1) to 1.7 mg/100 mL infusion (st5). For the antioxidant capacity and bioactivity of *C. incanus* infusions, the presence of gallocatechin is an important aspect. This substance contributes 14% of total TEAC.[10]

In contrast to the gallocatechin concentrations, remarkably high catechin concentrations of 0.5 mg/100 mL infusion were quantitated in the sample consisting of 100% (w/w) stems (st1). These comparatively high concentrations of catechin in woody parts of *C. incanus* may also be an argument for the traditional application of the aerial parts, including woody stems, for herbal infusions.[3,30] The presence of catechin and further flavan-3-ol derivatives in stems or bark is known for many other plants of different plant families and orders.[31−33] Besides the occurrence of catechin in woody plant parts, higher concentrations were reported for leaves.[34,35] The presence of catechin in leaves and woody stems of *C. incanus* also explains the quite low correlation of $R^2$ = 0.55 for the influence between the concentrations of this substance and leaf content of reconstituted samples. However, the presence of notable amounts of catechin in infusions brewed from woody stem parts of *C. incanus* is also important for antioxidant capacity. Catechin was responsible for 11% of total TEAC.[10]

Furthermore, for sensory properties of the infusion, the content of phenolic compounds can be important, too. According to Peleg et al.,[36] catechin monomers are responsible as they have a strong bitter taste and elicit a slight astringency. However, Scharbert et al.[37] described the catechin threshold concentration for astringency being approximately 11.9 mg/100 mL aqueous solution. Bitterness and astringency in *C. incanus* infusions therefore should be expected only at levels of 10-fold higher catechin concentrations. Furthermore, black and green teas provide astringency, and the content of catechin is almost similar in *C. incanus* infusions as given in polyphenol databases[14−16] and shown herein. Therefore, the combination and synergisms of different phenolic compounds have been taken into account. Again, Scharbert et al.[37] showed for some flavonol glycosides really low sensory threshold levels.

For the flavor of herbal infusions it should be also considered that an infusion brewed from 100% (w/w) *C. incanus* leaves exhibits a persistent "green odor". This odor arises from volatile compounds based on $C_6$-aldehydes and $C_6$-alcohols.[38,39]

With regard to the presence of flavonols in the five reconstituted herbal tea mixtures, the highest concentrations as well as the strongest correlations between leaf contents and amounts of phenolic compounds in *C. incanus* infusions were observed for myricitrin and quercitrin. Additionally, both can be detected only in samples that contained pure leaves. For myricitrin, the concentrations reached from 0.0 mg/100 mL infusion (st1) to 1.1 mg/100 mL infusion (st5) and for quercitrin from 0.0 mg/100 mL infusion (st1) to 1.6 mg/100 mL infusion (st5). The coefficient of determination for the leaf content of sample and concentrations of myricitrin as well as for quercitrin was $R^2$ = 0.99. Moreover, high concentrations of myricitrin in *C. incanus* infusions seem to be an important marker of bioactivity, as it is highly responsible for the infusion's total antioxidant capacity. This substance contributes to 17% of total TEAC.[10]

A similar distribution in herbal plant material was observed for the isomers of tiliroside. Both isomers were present in samples that contained only leaves (st5), but not in pure woody stems (st1). For the dominant isomer *trans*-tiliroside, concentrations ranged between 0.0 mg/100 mL infusion (st1) and 0.9 mg/100 mL infusion (st5). The correlation coefficient of $R^2$ = 0.99 again suggests a very good linearity between the amount of substance and leaf content in a sample.

With the exception of catechin an exclusive occurrence of all quantitated flavonoids in *C. incanus* infusions brewed from leafy parts was observed in this work for sample 1. In woody stem parts this substance class was not present.

For the presence of the class of ellagitannins, a similar trend but slightly weaker linear correlation was observed in samples st1−st5. For the hexahydroxydiphenoyl-glucose isomers, concentrations of 0.0 mg/100 mL infusion (st1) to 0.5 mg/100 mL infusion (st5) together with a correlation of $R^2$ = 0.76 were detected for the first isomer at a retention time of 27.1 min. Concentrations from 0.0 mg/100 mL infusion (st1) to 0.9 mg/100 mL infusion (st5) together with $R^2$ = 0.90 were analyzed for the second isomer at a retention time of 28.7 min. Both isomers are also important antioxidants. The first isomer is responsible for 6% and the second isomer for 14% of total TEAC in *C. incanus* infusions.[10]

From the results of this study, it can be concluded that most of the phenolic compounds in *C. incanus* are present in the leafy parts. The dominant presence in leaves was generally observed for most of the flavonoids, phenolic acids, and ellagitannins. Nevertheless, for consumer's acceptance, a balanced flavor is of equal importance, besides the amount of bioactive phenolic compounds. Infusions brewed from 100% (w/w) leaf material may be rejected because of an overpowering "green odor". However, there might be some unidentified or under the actual brewing conditions nonextractable compounds in woody stem parts of *C. incanus*. Varying extraction conditions, for example, multiple maceration or use of other solvents, can lead to different results. In this context, it also has to be considered that short-term boiled hot water extracts of the aerial parts have been traditionally used for the therapy of inflammatory skin

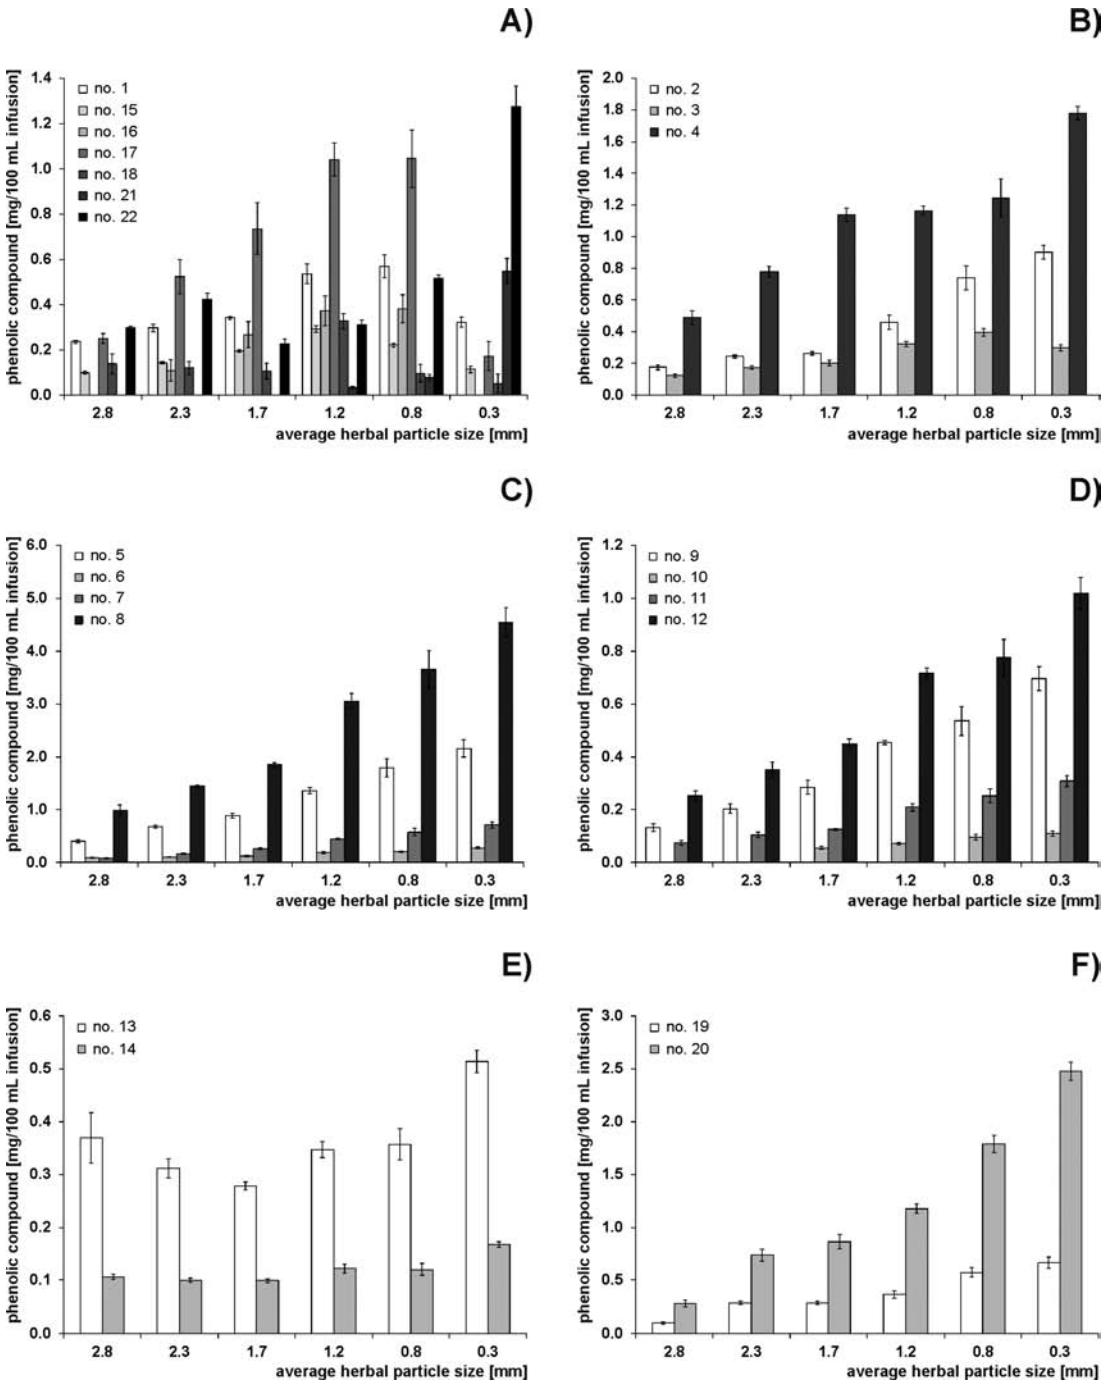

**Figure 3.** Contents of 22 phenolic compounds in six *C. incanus* infusions brewed from herbal material (of sample 1) with average particle sizes of 2.8, 2.3, 1.7, 1.2, 0.8, and 0.3 mm, all including recognizable leaf and stem parts (Figure 1 B): (A) phenolic acids; (B) flavan-3-ols and dimers; (C) myricetin glycosides; (D) quercetin glycosides; (E) tiliroside isomers; (F) ellagitannins. For compound no. refer to Table 2.

diseases, as well as for improved wound healing, whereas hot water extracts boiled for a longer time have been used as antidiarrhetics.[3] For this reason product optimization regarding stem and leaf contents of herbal tea mixtures and preparation guidelines are very important for infusions containing high concentrations of bioactive phenolic compounds with reference to the corresponding physiological property aimed at.

**Influence of Herbal Particle Size on the Extractability of Phenolic Compounds.** Besides the question of the presence of phenolic compounds in leaves or woody stem material of *C. incanus*, the different particle sizes of the herbal material may be also important for the extractability of bioactive compounds during the brewing process. To investigate a correlation between extractability of phenolic compounds and herbal particle size, exemplarily *C. incanus* herbal tea sample 1 was separated by use of a laboratory sieving machine into six fractions with different particle sizes (samples sv1−sv6). As obvious from Figure 1B, all sieved fractions contained recognizable parts of both leaves and woody stem parts. Figure 3 shows the influence of the herbal particle size on the concentration of 22 phenolic compounds in the resulting *C. incanus* infusions. This influence is demonstrated for the

phenolic substance classes of phenolic acids (A), flavan-3-ols and their dimers (B), myricetin glycosides (C), quercetin glycosides (D), tiliroside isomers (E), and ellagitannins (F).

For most of the phenolic acids quantitated in the six measured *C. incanus* infusions brewed from plant material with different average particle sizes from 0.3 to 2.8 mm, concentrations increased with decreasing particle size. For example, the concentration of hydroxyferulic acid-4-*O*-rhamnoside increased gradually from 0.3 mg/100 mL infusion (sv1) up to 1.1 mg/100 mL infusion (sv5). However, the lowest content of 0.2 mg/100 mL infusion for this compound was detected for infusions brewed from 0.3 mm herbal material (sv6). A similar negative correlation between particle size and concentration of phenolic compound was observed for gallic acid, methyl gallate, and hydroxyferulic acid-5-*O*-rhamnoside. For ellagic acid and ellagic acid-7-*O*-xyloside, the highest extraction yields were reached by use of herb material with an average particle size of 0.3 mm (sv6). Additionally, ellagic acid-7-*O*-xyloside only was present in quantitatable amounts in infusions brewed from herbal tea with particle size <1.7 mm (sv3). Furthermore, hydroxyferuloyl-rhamnose reached the highest concentration in the infusion resulting of *C. incanus* herbal tea with an average particle size of 1.2 mm (sv4). Altogether, the coefficients of correlation between particle size and concentration of phenolic compound were very low for phenolic acids in *C. incanus* infusions. However, all results for the extractability were based on actual preparation recommendations of the manufacturer. Longer extraction times or other extraction temperatures can lead to varying concentrations of antioxidant phenolic substances in *C. incanus* infusions, as shown in a recent study.[10]

With regard to the group of flavan-3-ols and dimers, the highest extractability for gallocatechin and catechin was achieved when using herbal tea consisting of an average particle size of 0.3 mm (sv6). Altogether, gallocatechin concentrations ranged from 0.2 mg/100 mL infusion (sv1) to 0.9 mg/100 mL infusion (sv6) and for catechin from 0.5 mg/100 mL infusion (sv1) to 1.8 mg/100 mL infusion (sv6). The correlation coefficients for the influence of the particle size on the concentration of phenolic compound in the infusion were $R^2$ = 0.89 for gallocatechin and $R^2$ = 0.93 for catechin. These results for the extractability of some phenolic compounds were also supported by a study of Lang and Wai,[40] who described the sample particle size being a generally critical factor for a satisfactory extraction in herbal and natural products. In the present work, catechin, which was detected not only in leaves but also in remarkably high contents in woody stem parts, the extraction yield was almost 4-fold higher when extracting out of herbal material with an average particle size of 0.3 mm (sv6) compared to a particle size of 2.8 mm (sv1). However, controversial results were reported for black tea infusions. Astill et al.[41] measured higher catechin concentrations in infusions brewed from whole tea leaves compared to infusions resulting from tea dust. In the case of black tea, a higher degradation of catechin in tea dust due to an enzymatic degradation (e.g., phenoloxidases) is the main explanation.[41] In *C. incanus* herbal teas with small particle sizes, such an endogenous degradation of phenolic compounds seems to be negligible or may be overlaid by higher extraction yields.

A similar extractability was observed for the myricetin and quercetin glycosides. The concentrations of myricitrin reached from 1.0 mg/100 mL infusion (sv1) to 4.6 mg/100 mL infusion (sv6) and for quercitrin from 0.3 mg/100 mL infusion (sv1) to 1.0 mg/100 mL infusion (sv6) with decreasing particle size. This means 5-fold higher concentrations for myricitrin and 3-fold higher concentrations of quercitrin in *C. incanus* infusions brewed from herb material with a comparatively small particle size. The coefficients of correlation between particle size and concentration of phenolic compound were $R^2$ = 0.97 for myricitrin and $R^2$ = 0.96 for quercitrin.

For the tiliroside isomers extractability seems to be different. For both isomers only an approximately 1.5-fold higher amount was extracted from herbal tea with 0.3 mm average particle size (sv6) compared to the infusion brewed from plant material with 2.8 mm herbal particle size (sv1). From all of these results it can be concluded that these acylated flavonol glucosides were extracted very efficiently from plant material even at a rather large particle size.

With regard to the extractability of the ellagitannins, a strong influence of particle size on the concentration in the corresponding infusions was observed for both hexahydroxydiphenoyl-glucose isomers. For the first isomer at a retention time of 27.1 min a 7-fold higher concentration and for the second isomer at a retention time of 28.7 min an 8-fold higher concentration was yielded when the infusion was brewed from herbal tea with a particle size of 0.3 mm (sv6) instead of using material with 2.8 mm average particle size (sv1). The absolute concentrations for the second isomer reached from 0.3 mg/100 mL infusion (sv1) to 2.5 mg/100 mL infusion (sv6). Overall, for ellagitannin-rich *C. incanus* infusions, a small herbal particle size is decisive under the actual brewing recommendations.

Altogether, the herbal particle size should be considered as an important factor for the extractability of phenolic compounds in *C. incanus* infusions. For most of the bioactive phenolic compounds quantitated in this work, infusions brewed from herbal tea with a comparatively small particle size between 0.3 mm (sv6) and 0.8 mm (sv5) contained the highest concentrations.

addition of phytase into the precipitated SPI would make the SPI processing have an additional step (the addition of water for phytase treatment). Therefore, the addition of phytase into the water extract of soybean flour should be the best strategy. In addition, the phytase used in this study is recommended to hydrolyze phytate at 55 °C and pH 5.0, which is well used in the phytase treatment. To examine whether this condition could produce SPI with high quality, the hydrolysis conditions (25−55 °C, pH 5.0−6.5) for phytase were examined, and the optimal condition was selected to prepare SPI samples with different phytate contents by prolonging the hydrolysis time. The effects of phytate content on the yield, components, and physicochemical (solubility, ζ-potential, denaturation temperature, and secondary structure) and functional properties (emulsifying activity, foaming activity, gelation, and in vitro digestibility) of SPI were systematically examined. This study will provide some valuable information for the application of phytase on SPI processing.

## MATERIALS AND METHODS

**Materials.** Defatted low-heat soybean meal (protein content, 52.9%, dry basis; moisture, 7.9%) was purchased from Shandong Wonderful Industrial Group Co., Ltd. (Dongying, China). Phytase from *Aspergillus niger* with an activity of 45000 U/g was purchased from Sukahan Bio-Technology Co., Ltd. (Weifang, China), and hydrolysis condition of pH 5.0 and 55 °C was recommended by the manufacturer. Its activity was about 200000 PU/g after simple purification.

**Purification of Phytase and Determination of Phytase Activity.** The phytase purchased from Sukahan was dissolved in 50 mM sodium acetate buffer (pH 5.5), stirred for 30 min at 4 °C, and then centrifuged (9690*g*, 20 min, 4 °C) to obtain supernatant and precipitate. The supernatant was subjected to ammonium sulfate precipitation (80% saturation) with constant stirring. The precipitate was collected by centrifugation (9690*g*, 20 min, 4 °C) and dissolved in a minimum volume of 50 mM sodium acetate buffer (pH 5.5). The enzyme solution was dialyzed overnight at 4 °C against deionized (DI) water and freeze-dried to obtain purified phytase. Phytase activity was analyzed according to the method described by Quan et al.[19] and Harland et al.[20] with minor modifications, and one phytase unit (PU) was the amount of enzyme that released 1 μmol of inorganic phosphorus from 5 mM sodium phytate in 1 min at pH 5.5 and 37 °C.

**Phytase Treatment.** Defatted soybean meal was ground three times at a 30 s interval and sieved through an 80 mesh sieve to obtain soybean flour. The procedure for extracting soybean protein isolate (SPI) is shown in Figure 1. SPI samples with different contents of phytate were obtained at room temperature (about 25 °C) and pH 5.0 by prolonging hydrolysis time (5, 10, 20, 40, and 60 min). There were two control samples in this study: SPI0 was prepared under the same condition without phytase according to the traditional method; SPI2 was prepared under the same condition with phytase at the optimal condition (pH 5.0, 55 °C) of phytase recommended by the manufacturer. SPI samples were sealed in polythene bags and stored at 4 °C until further analysis.

**Determination of Phytate Content.** Phytate content was determined as described by Gao et al.[21] with minor modifications. Approximately 0.5 g of SPI was extracted with 10 mL of 2.4% HCl, magnetically stirred at 220 rpm for 2 h at room temperature, and centrifuged at 1000*g* at 10 °C for 20 min. Crude extract was transferred into a 25 mL beaker containing 1 g of NaCl, which was magnetically stirred at 350 rpm for 20 min to dissolve the salt and then allowed to settle at 4 °C for 60 min. The mixture was centrifuged at 1000*g* at 10 °C for 20 min, and supernatant was transferred into a 200 mL volumetric flask followed by the addition of DI water to the final volume. The diluted solution (5 mL) was thoroughly mixed with 4 mL of Wade reagent (0.03% $FeCl_3 \cdot 6H_2O$ + 0.3% sulfosalicylic acid) and centrifuged (1000*g*, 10 min, 10 °C). Absorbance of color reaction products for both samples and standards was read at 500 nm. Sodium phytate solutions (0.1−0.5 mg/mL; Sigma-Aldrich, Shanghai, China) were used to make the standard curve ($R^2 > 0.99$).

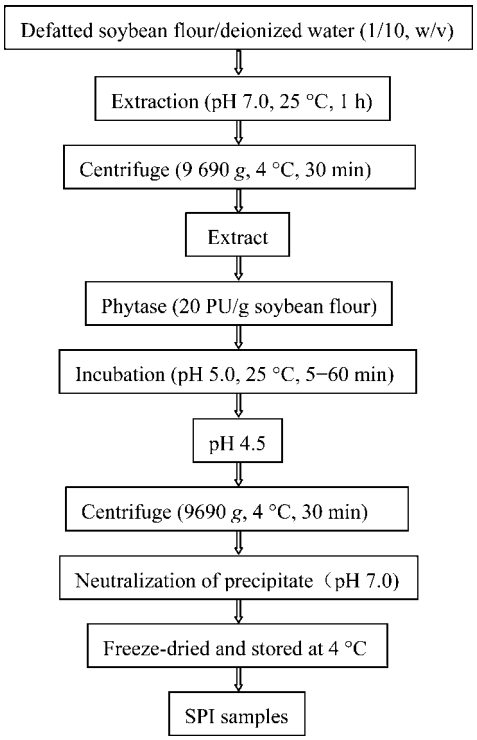

**Figure 1.** Procedure for preparation of soybean protein isolate from defatted low-heat soybean flour.

**ζ-Potential.** The ζ-potentials of SPI suspensions (0.05%, w/v) were measured by using a Zetasizer Nano ZS (Mastersizer X, Malvern Instruments Ltd., Malvern, UK).

**Protein Solubility.** Protein solubility of SPI was determined according to the method of Li et al.[18] with minor modifications. Aliquots (200 mg) of SPI samples were dispersed and stirred in 20 mL of DI water (pH 6.8) at 200 rpm for 30 min at room temperature. Then, the suspensions were centrifuged at 4000*g* for 30 min. Nitrogen contents of the supernatants were measured by using the micro-Kjeldahl method (N × 6.25), and the measurements were performed in duplicate. Percent nitrogen solubility (NS) was calculated as follows (eq 1):

$$\text{NS}\,(\%) = (\text{N in supernatant/total N in 200 mg sample}) \times 100\% \quad (1)$$

**Differential Scanning Calorimetry (DSC).** The thermal characteristics of SPI were examined by using a TA Q100-DSC thermal analyzer (TA Instruments, New Castle, DE, USA), according to the procedure of Wang et al.[22] with some modifications. SPI (10.0 mg) was dispersed into 40 μL of 0.01 M phosphate buffer (pH 7.0), and 10 μL was hermetically sealed into a coated aluminum pan and heated from 20 to 110 °C at a rate of 5 °C/min. A sealed empty pan was used as control. Peak or denaturation temperature ($T_d$) and total enthalpy of denaturation ($\Delta H$, J/g dry matter) were computed from the thermograms by Universal Analysis 2000 software, version 4.7A (TA Instruments-Waters LLC). All experiments were conducted in duplicate. In all cases, the sealed pans were equilibrated at 25 °C for >6 h.

**Measurement of Circular Dichroism (CD).** CD spectra were obtained using an MOS-450 spectropolarimeter (BioLogic Science Instrument, France). The CD spectroscopic measurement was done according to the method of Tang et al.,[23] which was performed in a quartz cuvette of 2 mm with a protein concentration of 0.1 mg/mL in DI water at pH 6.8. The sample was scanned from 190 to 250 nm, and the spectra were an average of eight scans. The following parameters were used: step resolution, 1 nm; acquisition duration, 1 s; bandwidth,

0.5 nm; sensitivity, 100 mdeg. The cell was thermostated with a Peltier element at 25 °C, unless specified otherwise. Recorded spectra were corrected by subtraction of the spectrum of DI water. The secondary structure composition was estimated from the CD spectra using the CONTIN/LL program in CDPro software.

**Emulsifying Activity.** The emulsifying activity index (EAI) and emulsion stability index (ESI) of SPI were determined according to the method of Wang et al.[22] An SPI suspension (9 mL; 0.2% (w/v)) and 3 mL of soybean oil were homogenized using one high-speed homogenizer (FA25, Fluko Co., Germany) for 1 min at 10000 rpm to form an emulsion. An aliquot (50 $\mu$L) of the emulsion was collected from the bottom of the emulsion, immediately (0 min) or 10 min after homogenization, and diluted (1:100, v/v) in 0.1% (w/v) sodium dodecyl sulfate (SDS) solution. After thorough mixing, the absorbance of the diluted emulsion was read at 500 nm.

EAI and ESI values were calculated by using eqs 2 and 3

$$\text{EAI}\ (\text{m}^2/\text{g}) = 2 \times 2.303 \times A_0 \times \text{DF}/[c \times \varphi \times (1 - \theta)] \quad (2)$$

$$\text{ESI}\ (\text{min}) = A_0/(A_0 - A_{10}) \times 10 \quad (3)$$

where DF is the dilution factor (100), $c$ is the initial concentration of SPI (0.2 g/100 mL), $\varphi$ is the optical path (0.01 m), $\theta$ is the fraction of oil used to form the emulsion (0.25), and $A_0$ and $A_{10}$ are the absorbance of the diluted emulsions at 0 and 10 min, respectively. Measurements were performed in triplicate.

**Foaming Activity.** The foam capacity and stability were determined according to the method of Venktesh et al.[24] with slight modifications. Two grams of SPI was dispersed in 100 mL of DI water (pH 6.8). Then, it was whipped in the high-speed homogenizer (FA25, Fluko Co.) at 10000 rpm for 1 min and poured into a 250 mL graduated cylinder. The volume of the foam after 30 s was recorded, and the volume increase was expressed as percent foam capacity. The foam stability was determined by measuring the decrease in foam volume as a function of time up to 30 min.

$$\text{foam capacity}\ (\%) = [\text{vol after whipping}\ (\text{mL}) - \text{vol before whipping}\ (\text{mL})] \times 100/\text{vol before whipping}\ (\text{mL}) \quad (4)$$

Measurements were performed in triplicate.

**Textural Measurements of SPI Gels.** The methods of preparing SPI gels and determining the texture of SPI gels were according to the method of Li et al.[18] Briefly, gels were prepared by heating 15% (w/v) SPI suspension in cylindrical glass molds with an inner diameter of 20 mm and a height of 40 mm. The molds were filled three-fourths full, and the air bubbles in suspension were removed using a vacuum pump. The sample was heated in a 95 °C water bath for 30 min and immediately cooled in an ice water bath. Then the sample was kept at 4 °C for 24 h for further analysis. Then, the gels were taken out of the molds and transferred to a Texture Analyzer (TMS-PRO, Food Technology Corp., USA). A cylinder probe with a diameter of 10 mm was chosen. The probe test speed, starting trigger force, depth, back-off distance, and holding time between two cycles were set as follows: 120 mm/min, 0.05 N, 10 mm, 40 mm, and 0 s, respectively. The tests were performed in triplicate at 25 °C. The hardness was analyzed by Rheology Advantage Data Analysis software.

**In Vitro Digestibility of Protein and Bioavailability of Minerals.** The in vitro digestibility of protein and bioavailability of minerals were respectively evaluated according to the methods of Dinnella et al.[25] and Lestinenne et al.[26] with minor modifications. About 1 g of SPI was precisely weighed in an enzymolysis reactor and dispersed into 20 mL of DI water. After 10 min of conditioning in a shaking water bath at 37 °C, the pH was adjusted to 2.0 with 1 M HCl solution under magnetic stirring. Next, 2% (w/w) of pepsin (Sigma-Aldrich, Shanghai, China) was added, and the mixture was incubated for 2 h. The pH was then increased to about 5.3 with 1 M $NaHCO_3$, 6% (w/w) of bile salts (Sigma-Aldrich) was added, and the pH was adjusted to 7.5 with 1 M NaOH. Then 4% (w/w) of pancreatin (Sigma-Aldrich) was added and incubated for 2 h under low magnetic stirring. Then, the obtained emulsion was divided into two aliquots.

One aliquot (10 g) was mixed with 10 mL of 20% (w/v) trichloroacetic acid (TCA). The mixture was kept for 10 min at room temperature and then centrifuged (4000g, 30 min) to obtain the precipitate. After a washing with 10 mL of TCA (20%, w/v), the final precipitate was obtained by centrifugation at the same parameters above. The nitrogen (N) content was determined by using the Kjeldahl method. The percent N release after the digestion was calculated as

$$\%\ \text{N release} = (N_0 - N_t) \times 100/N_{\text{total}} \quad (5)$$

$N_t$ (mg) is the TCA-insoluble N after digestion, $N_0$ (mg) is the TCA-insoluble N in SPI sample, and $N_{\text{total}}$ (mg) is the total N of SPI sample. Measurements were performed in duplicate.

The other aliquot (10 g) was dialyzed using a cellulose dialysis tube (cutoff 12 kDa) containing 25 mL of NaCl solution (9 mg/mL). The solution was dialyzed under stirring at 37 °C for 2 h. The dialyzed solution in the tube was then removed and stored at 4 °C in an amber bottle under a nitrogen blanket. The amounts of dialyzable calcium (Ca) and zinc (Zn) corresponded to those obtained outside the dialysis membrane (analyzed by atomic absorption spectrophotometer), expressed as percentages of total calcium and zinc present in the test sample, were used as an indicator of mineral bioavailability. Measurements were performed in duplicate.

**Determination of Ca and Zn.** Ca and Zn contents in SPI were measured by atomic absorption spectrophotometer (SperctrAA220/22Z, Varian, USA) according to the method of Kamchan et al.[27] SPI (0.5 g) was weighed into a preweighed porcelain crucible (predried in an oven at 105 °C overnight) and put into a muffle furnace (550 °C, 8 h). The resulting white ash was weighed, dissolved into 3 mL of concentrated nitric acid, and diluted with distilled water in a 25 mL volumetric flask. The solution was used to determine Ca and Zn contents.

**Trypsin Inhibitor Activity (TIA) Assay.** TIA of SPI was measured according to the method of Xu et al.,[28] with slight modifications. For the TIA standard curve, 0−1.0 mL of trypsin inhibitor standard solution (0.01%, w/v) was pipetted into a set of test tubes, and the volume was made up to 2 mL with DI water. The test tubes were placed and warmed in a 37 °C water bath. Then 5 mL of 0.04% (w/v) $N^{\alpha}$-benzoyl-L-arginine 4-nitroanilide hydrochloride (BAPA) in pH 8.2 Tris-HCl buffer (1% dimethyl sulfoxide, v/v; 0.02 M $CaCl_2$), which should be prepared freshly and prewarmed in 37 °C water bath, was pipetted into test tubes followed by 2 mL of 0.01% (w/v) trypsin in 0.04 mM HCl solution. Exactly 10 min later, the reaction was terminated by adding 1 mL of 30% acetic acid (v/v) into each tube. After mixing, the content of each tube was centrifuged at 3000 rpm for 10 min, and the absorbance of the filtrate was measured at 410 nm by using a UV-2100 spectrophotometer (UNICO, WFZ UV-2100) against a reagent blank. The reagent blank was prepared by adding 1 mL of 30% acetic acid (v/v) to a test tube containing trypsin and water before 5 mL of BAPA solution was added. The linearity of the calibration curve was $r = 1$. TIA of SPI should be diluted to the point where 1 mL produces trypsin inhibition of 40−60%. Then 1 mL of diluted sample was added to tubes, and it was done just as above. One TIA unit is arbitrarily defined as an increase of 0.01 absorbance unit at 410 nm per 10 mL of the reaction mixture under the conditions used.

**Statistical Analysis.** Data reported are mean values ± standard deviations. Data were analyzed using SPSS for Windows (version 13.0, SPSS Inc. Chicago, IL, USA) following an analysis of variance (ANOVA) one-way linear model. Mean comparisons were performed using the Duncan test, and the significance level was established for $P < 0.05$.

## RESULTS AND DISCUSSION

**Hydrolysis Condition.** The condition (pH 5.0 and 55 °C) was recommended by the manufacturer for the hydrolysis of phytate by phytase. In the beginning of this study, this condition was used to produce SPI samples, but it was found

that the obtained samples had bad solubility. By increasing the hydrolysis pH (pH 5.0, 5.5, 6.0, and 6.5; 25 °C), the degree of phytate degradation was decreased (Supporting Information Table S1); by decreasing the hydrolysis temperature (55, 45, 35, and 25 °C (room temperature); pH 5.0), it was found that the solubility of SPI sample was increased (Supporting Information Table S2). As a result, two hydrolysis conditions (pH 5.0, 25 °C, 60 min, 20 PU/g soybean flour; pH 5.0, 55 °C, 60 min, 10 PU/g soybean flour) were selected for the following research, and the obtained SPI samples were named SPI1 and SPI2, respectively. In addition, SPI was also produced by the traditional method without phytase (SPI0).

Table 1 shows that SPI0 has a phytate content of 19.86 mg/g, which is in agreement with the results of Saito et al. (20.5 mg/g)[29] and Kumar et al. (1−2%).[1] Phytate contents of SPI1 (0.11 mg/g) and SPI2 (0.11 mg/g) are very low, revealing that phytate also can be efficiently hydrolyzed at 25 °C by increasing the addition of phytase. Table 1 also shows that SPI0 has the highest solubility, EAI, and FC, whereas SPI1 has the highest ESI, FS, and gel hardness; SPI2 shows the worst properties. The results revealed that phytase treatment at 55 °C had bad effects on the properties of low-phytate SPI. Therefore, room temperature (25 °C) was selected for the low-phytate SPI production.

**Table 1. Physicochemical and Functional Properties of SPI with or without Phytase According to the Procedure Described in Figure 1**[a]

| | SPI0[b] | SPI1[c] | SPI2[d] |
|---|---|---|---|
| phytate content (mg/g) | 19.86 ± 0.56a | 0.11 ± 0.06b | 0.11 ± 0.04b |
| protein solubility (%) | 98.89 ± 1.16a | 95.57 ± 0.87b | 72.36 ± 1.07c |
| EAI ($m^2$/g) | 24.99 ± 0.33a | 15.26 ± 0.46b | 4.12 ± 0.45c |
| ESI (min) | 40.01 ± 0.71b | 55.93 ± 1.15a | 15.05 ± 1.02c |
| FC (%) | 75.1 ± 1.5a | 60.2 ± 1.1b | 39.2 ± 1.6c |
| FS (%) | 53.0 ± 2.3b | 70.0 ± 1.3a | 35.0 ± 2.0c |
| hardness of gel (N) | 0.51 ± 0.05b | 0.68 ± 0.06a | 0.25 ± 0.05c |

[a]The data are shown as means ± SD. Means with different letters in the same row are significantly different at the 5% level. [b]SPI0, traditional method. [c]SPI1, pH 5.0, 20 PU/g soy flour, 25 °C, 60 min. [d]SPI2, pH 5.0, 10 PU/g soy flour, 55 °C, 60 min.

**Effects of Phytase-Assisted Processing Method on the Components of SPI.** To systematically examine the effects of phytase-induced phytate degradation on SPI, the water extract of soy flour was respectively hydrolyzed by phytase (pH 5.0, 25 °C, 20 PU/g soybean flour) for 5, 10, 20, 40, and 60 min and acid-precipitated to obtain SPI1 samples. SPI0 was used as control. Table 2 shows that phytate contents of SPI samples are 19.86 (SPI0), 14.58 (5 min), 8.64 (10 min), 4.42 (20 min), 1.89 (40 min), and 0.11 (60 min) mg/g, respectively; interestingly, protein recovery ($R^2$ = 0.781; 52.26−54.83%) and content ($R^2$ = 0.876; 90.57−92.85%) in SPI are linearly and slightly increased, whereas ash content is linearly ($R^2$ = 0.940) and significantly decreased from 5.15 to 3.62% with decreasing phytate content. Two important minerals (Zn and Ca) in SPI are also significantly decreased with prolonged hydrolysis time, which is in good agreement with the behavior of ash content. Ca content in SPI0 (818.6 μg/g) was in agreement with the results of Honig and Wolf[30] (1.05−1.66 mg/g) and Kroll et al.[31] (0.076%, w/w), and the Zn content in SPI0 (21 μg/g) was also consistent with the results of Honig and Wolf[30] (29−36 μg/g).

Generally, the interaction between phytate and protein was electrostatic, and both phytate and soybean proteins were negatively charged at neutral pH.[32] As a result, phytate did not bind to soybean proteins at neutral pH,[31] but the binding of phytate did happen in the presence of $Ca^{2+}$ (or $Zn^{2+}$ and some other divalent ions), which was considered that phytate−mineral ($Ca^{2+}$, $Zn^{2+}$, and some other divalent ions)−protein complexes were formed.[33,34] By phytase treatment, phytate was hydrolyzed to phosphorus and inositol, and mineral−protein complexes remained. By deceasing the pH from neutral pH to acidic pH (acid-precipitation for SPI), the number of bound $Ca^{2+}$ on soybean proteins was decreased,[31] which might be the reason that ash content in SPI1 was decreased with prolonged hydrolysis time. For SPI0, some phytate−mineral complexes (insoluble) might be released from proteins by decreasing the pH, but they would be mixed with soybean proteins in the precipitate, which should be the reason that ash content in SPI0 was still larger than that in SPI0.[35]

Phytate is one kind of salt rich in negative charge, so it was considered that phytate−mineral−protein complexes would be more acidic than mineral−protein complexes, revealing that the former should be more hydrophilic than the latter, which might be one reason for the higher protein recovery induced by phytase.

**ζ-Potential and Protein Solubility.** Figure 2a shows that the ζ-potential value of the SPI suspension is linearly ($R^2$ = 0.793) and significantly increased from −26.1 to −35.4 mV with increasing phytate content, which is consistent with the hypothesis stated above. Figure 2b shows that the protein solubility of SPI is linearly ($R^2$ = 0.983) and slightly increased from 94.81 to 98.89% with increasing phytate content, which is

**Table 2. Components of SPI Treated by Phytase for Different Times (5, 10, 20, 40, 60 min; pH 5.0, 25 °C, 20 PU/g Soybean Flour)**[a]

| | | SPI1 | | | | |
|---|---|---|---|---|---|---|

[a]The data are shown as means ± SD. Means with different letters in the same row are significantly different at the 5% level.

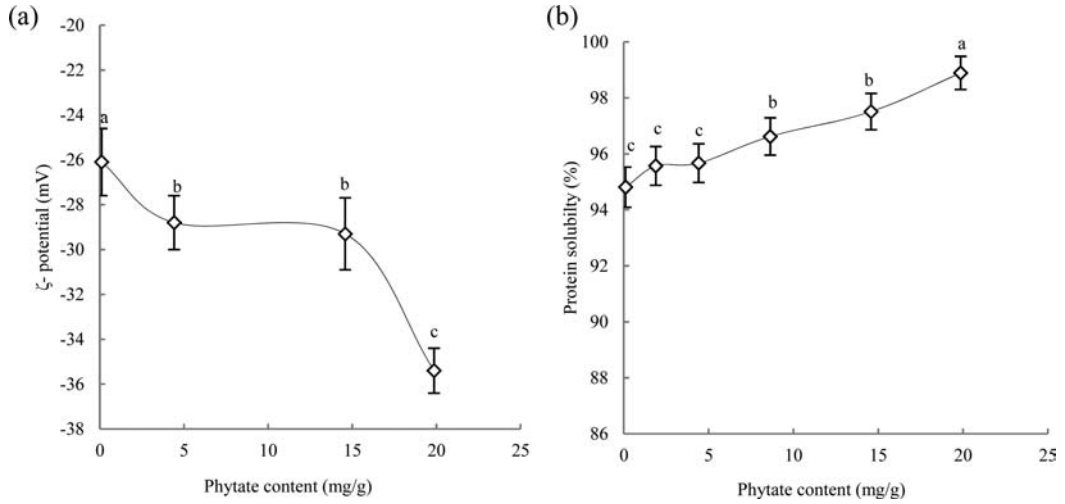

**Figure 2.** Effects of phytate content on ζ-potential (a) and protein solubility (b) of SPI. Means with different letters on the same line are significantly different at the 5% level.

in agreement with the results in Figure 2a. This is because the ζ-potential value reflects the degree of repulsion between the adjoining charged colloids: colloids with higher ζ-potential values are more electrically stable and vice versa. Ishiguro et al.[36] reported that the solubility of soy milk protein was positively correlated with soy milk phytate content and that a greater amount of coagulant was needed to coagulate high-phytate soy milk to form tofu compared to low-phytate soy milk. In addition, Liu and Chang[37] reported similar results as above.

**Thermal Behaviors.** All SPI samples showed typical DSC thermograms of soybean isolates in which two endothermic transitions corresponded to the denaturation of β-conglycinin and glycinin, respectively. $T_{d1}$ (denaturation temperature of β-conglycinin), $T_{d2}$ (denaturation temperature of glycinin), and $\Delta H$ (total enthalpy change of SPI) were obtained from DSC thermograms and are shown in Table 3. β-Conglycinin and glycinin of SPI0 exhibited two endothermic peaks at about 79.4 ($T_{d1}$) and 96.2 °C ($T_{d2}$), and $\Delta H$ was 10.2 J/g. With decreasing phytate content, $T_{d1}$ ($R^2$ = 0.941), $T_{d2}$ ($R^2$ = 0.977), and $\Delta H$ ($R^2$ = 0.963) were all linearly decreased. When SPI had a phytate content of 0.11 mg/g, $T_{d1}$, $T_{d2}$, and $\Delta H$ were 71.2 °C, 92.1 °C, and 9.3 J/g, respectively. These results showed that SPI with higher phytate content had higher denaturation temperatures than that with lower phytate content.

**Table 3. DSC Characteristics of SPI with Different Phytate Contents**[a]

| phytate content in SPI (mg/g) | $T_{d1}$[b] (°C) | $T_{d2}$[c] (°C) | $\Delta H$[d] (J/g) |
|---|---|---|---|
| 19.86 ± 0.61a | 79.4 ± 0.5a | 96.2 ± 0.7a | 10.2 ± 0.5a |
| 14.58 ± 0.20b | 78.5 ± 0.3b | 94.5 ± 0.5b | 9.8 ± 0.6b |
| 4.42 ± 0.51c | 74.8 ± 0.4c | 92.8 ± 0.4c | 9.5 ± 0.4c |
| 0.11 ± 0.10d | 71.2 ± 0.1d | 92.1 ± 0.4d | 9.3 ± 0.1d |

[a]The data are shown as means ± SD. Means with different letters in the same column are significantly different at the 5% level. [b]$T_{d1}$, denaturation temperature of β-conglycicin. [c]$T_{d2}$, denaturation temperature of glycicin. [d]$\Delta H$, total enthalpy change of β-conglycicin and glycicin.

In food processing and biological processes, many kinds of molecules (i.e., proteins, lipids, anions, metal ions, ions, odorant molecules, and others, collectively known as ligands) would bind to proteins, and it was widely accepted that the liganded proteins were more thermally stable than the nonliganded ones. As the hypothesis stated above, the phytate in phytate−mineral−protein complexes was gradually hydrolyzed with prolonged hydrolysis time, and mineral−protein complexes remained. The ash content, including Ca and Zn, in SPI was also decreased with prolonged hydrolysis time (Table 2). These showed that SPI obtained from long hydrolysis time contained lower bound phytate and minerals than that from short hydrolysis time. Scilingo and Anon[38] reported that the Ca content increase could cause an increase in thermal stability of SPI, and Martins et al.[39] reported that the binding of phytate derivatives could also enhance the thermal stability of proteins. Therefore, it was reasonable that SPI with low phytate and ash contents was less thermally stable that that with high phytate and ash contents.

**Secondary Structure of Proteins in SPI.** SPI0 and SPI1 (phytate content, 0.11 mg/g) were selected to be examined by CD spectrometry between 190 and 250 nm. The ratios of α-helix, β-sheet, β-turn, and random coil were calculated from their CD spectra and are shown in Table 4. It was found that the ratios of β-sheet and β-turn were increased, whereas that of random coil was decreased for SPI1 compared to SPI0; the ratio of α-helix was slightly decreased. Phytate could inhibit the activities of many kinds of digestive enzymes, revealing that it might change the conformations of those enzymes.[1] Therefore, it was reasonable that phytate could affect the secondary structure of proteins in SPI.

**Table 4. Ratio of Secondary Structure of Proteins in SPI0 and SPI1 with Phytate Contents of 19.86 and 0.11 mg/g, Respectively**

| | α-helix | β-sheet | β-turn | random coil | total |
|---|---|---|---|---|---|
| SPI0 | 0.324 | 0.167 | 0.199 | 0.308 | 0.998 |
| SPI1 | 0.321 | 0.185 | 0.211 | 0.280 | 0.997 |

Similar to the digestive enzymes, it was considered that soybean proteins should be slightly denatured by the binding of phytate, and Wang et al.[22] reported that the slight denaturation of soybean proteins by high hydrostatic pressure could increase

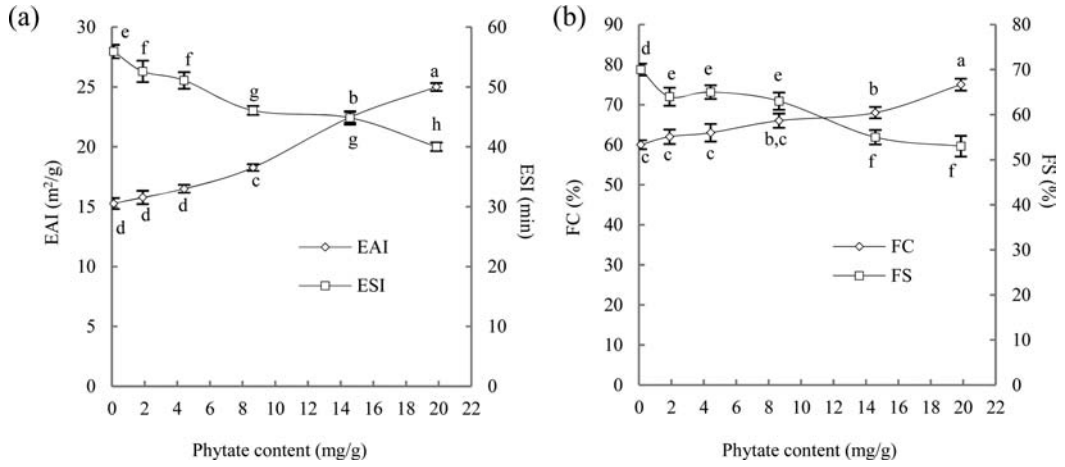

**Figure 3.** Effects of phytate content on EAI and ESI (a) and FC and FS (b) of SPI. Means with different letters on the same line are significantly different at the 5% level.

the denaturation temperatures and solubility, which was consistent with the results in Figure 2b and Table 3. Unfortunately, they did not give the data concerning the secondary structure.

**Emulsifying and Foaming Properties.** Figure 3a shows that the EAI of SPI is linearly ($R^2$ = 0.983) and significantly increased from 15.26 to 25.00 $m^2/g$, whereas the ESI of SPI is linearly ($R^2$ = 0.953) and significantly decreased from 55.93 to 40.01 min, with increasing phytate content. Li et al.[18] reported that high hydrostatic pressure could significantly increase solubility and EAI but significantly decrease ESI of SPI in the ranges of 0−300 MPa and 5−15 min, which was in agreement with the results above. Wang et al.[22] used high hydrostatic pressure to treat SPI and obtained results similar to those of Li et al.[18] It is known that protein solubility is a key factor for its emulsifying activity. Generally, high solubility corresponds to high emulsifying activity and vice versa. Table 3 shows that the denaturation temperature of SPI is increased with increasing phytate content, revealing that the molecular flexibility of SPI is decreased.[40] It is known that molecular flexibility is positively correlated with its emulsion stability. In addition, phytate−mineral−protein complexes (high-phytate SPI) were more hydrophilic than mineral−protein complexes (low-phytate SPI), meaning that the former had larger surface hydrophilicity/hydrophobicity ratios (similar to the hydrophilic−lipophilic balance of a surfactant) than the latter, which could be well evidenced by the results in Figure 2b. Therefore, the balance between protein solubility and flexibility could be used to explain the different behaviors of EAI and ESI of SPI.

Figure 3b shows that the FC of SPI is linearly ($R^2$ = 0.955) and significantly increased from 60 to 75%, whereas the FS of SPI is linearly ($R^2$ = 0.919) and significantly decreased from 70 to 53%, with increasing phytate content. Li et al.[18] reported that high hydrostatic pressure also could significantly increase FC but significantly decrease FS of SPI in the ranges of 200−300 MPa and 5−15 min. Foaming activity, similar to emulsifying activity, belongs to the functional properties related to the protein surface. Therefore, the different behaviors of FC and FS of SPI could be explained by the same theory as above.

**Hardness of SPI Gels.** SPI samples with different phytate contents were used to prepare gels, and the hardness, a typical parameter of gel, was determined and is shown in Figure 4. It was found that hardness was linearly ($R^2$ = 0.893) and significantly decreased from 0.69 to 0.50 N with increasing

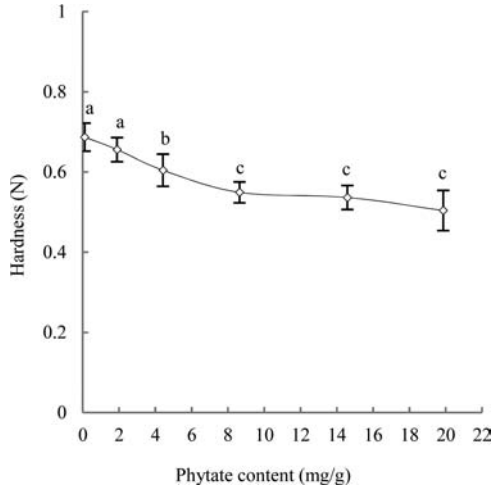

**Figure 4.** Effects of phytate content on hardness of SPI gel. Means with different letters are significantly different at the 5% level.

phytate content. Toda et al.[41] prepared soy milks with different phytate contents by using different soybean varieties, and breaking stress (hardness) of filled tofu (coagulant: low concentration (0.25%) of $MgCl_2$) was highly and negatively ($P$ < 0.001, $r$ = −0.73) correlated with soy milk phytate content. Ishiguro et al.[37] prepared soy milks with different phytate contents by the addition of different levels of phytate, and filled tofu with higher phytate content had lower breaking stress. Hou and Chang[42] prepared soy milks with different phytate contents by using phytase, and it was found that the yield of momen tofu was increased; breaking stress was decreased with decreasing phytate content, showing a different trend from the two research studies above. However, it was considered that the different trend should be induced by the different preparation methods of tofu. For momen tofu, the step of pressing was used to remove the whey fraction, and a lower yield of menon tofu was obtained from high-phytate soy milk compared to low-phytate soy milk, indicating that low-phytate momen tofu had a higher moisture content than high-phytate momen tofu. It was considered that the high-moisture content glossed over the real effects of phytate on the hardness of tofu. Additionally, it is widely accepted that the gel network formation is the result of a combination of hydrophobic and

electrostatic interactions.[43] As stated above, SPI with a high phytate content was more acidic than that with a low phytate content (Figure 2a), revealing that proteins in the former SPI had stronger electrostatic repulsion, and phytate−mineral−protein complexes (high-phytate SPI) had lower surface hydrophobicity/hydrophilicity ratios than mineral−protein complexes. These could be used to well explain the results in Figure 4.

**In Vitro Digestibility of Protein and Bioavailability of Minerals.** Figure 5 shows the in vitro protein digestibility and TIA of SPI with different phytate contents. It was found that the in vitro digestibility was linearly ($R^2$ = 0.96) and significantly decreased from 72 to 59%, whereas the TIA was linearly ($R^2$ = 0.821) and significantly increased from 71934 to 78500 U/g with increasing phytate content. It was calculated that the TIA in SPI with a phytate content of 0.11 mg/g was about 92% of that with a phytate content of 19.86 mg/g, revealing that phytate had some effects on inhibiting the activity of trypsin. Ritter et al.[44] reported that low-phytate SPI obtained from sequential ion exchange process was more digestible than high-phytate SPI, and Knuckles et al.[45] found that the inhibitory effect of the phytate on in vitro digestibility of casein and bovine serum albumin was positively correlated with phytate content. Borowsk et al.[46] found that protein isolates from fava bean and soybean with low phytate contents also had low TIA, and Singh et al.[47] reported that the activity of trypsin could be substantially inhibited by low levels of phytate.

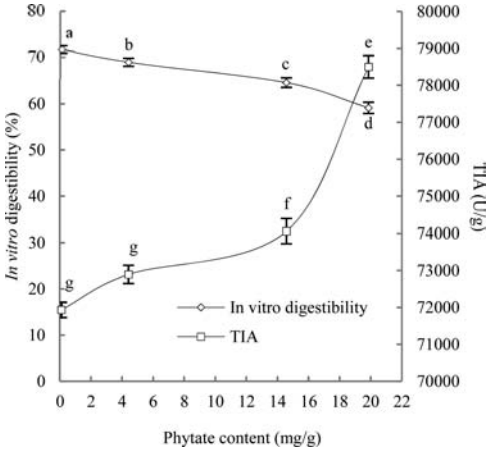

**Figure 5.** Effects of phytate content on in vitro digestibility and TIA of SPI. Means with different letters on the same line are significantly different at the 5% level.

Table 5 shows the dialyzable Ca and Zn in SPI with different phytate contents by simulated gastrointestinal digestion. With increasing phytate content, Zn and Ca contents in SPI are significantly increased from 12.71 to 20.94 μg/g and from 562.2 to 818.6 μg/g, respectively; percentages of dialyzable Zn and Ca are significantly decreased from 15.4 to 2.5% and from 27.64 to 20.13%, respectively; interestingly, the amount of dialyzable Zn is significantly decreased from 1.96 to 0.53 μg/g, whereas that of dialyzable Ca is significantly increased from 155.39 to 164.78 μg/g. These results showed that phytase should be able to increase the amount of bioavailable Zn, although it decreased the Zn content in SPI, and that phytase increased the percentage of bioavailable Ca, but decreased the amount of bioavailable Ca, which should result from the phytase-induced Ca content decrease in SPI. The results were in agreement with many research studies which revealed that the removal of phytate could enhance the bioavailability of minerals.[1] Wise et al.[48] reported that Ca-bound phytate increased chelation with trace minerals, especially Zn, to form coprecipitates that make the Zn unavailable, which might be used to explain the amount decrease of bioavailable Zn with increasing phytate content. This was because Ca content was decreased with decreasing phytate content. In addition, the low percentages of dialyzable Zn (2.5−15.4%) and Ca (20.13−27.64%) may result from the binding of Zn and Ca to protein hydrolysates.[49,50]

In this study, it was found that hydrolysis condition at low temperature (25 °C) and pH 5.0 was better than that (55 °C, pH 5.0) recommended by the manufacturer for retaining the properties of SPI, so the former condition was used to prepare SPI sample with decreasing phytate content by prolonged hydrolysis time. The results showed that protein content, protein recovery, solubility, ζ-potential value, denaturation temperatures, EAI, FC, and TIA were highly and positively correlated, whereas ash content (including Ca and Zn), ESI, FS, gel hardness, and in vitro protein digestibility were highly and negatively correlated with phytate content of SPI. Simulated gastrointestinal digestion and subsequent dialysis showed that the percentages of dialyzable Zn and Ca were increased with decreasing phytate content in SPI but that the amounts of dialyzable Zn and Ca revealed different behaviors: the former was increased and the latter was decreased. CD spectra revealed that the phytase treatment could change the secondary structure of SPI. In all, these results showed that the phytase-assisted processing method could produce low-phytate SPI with better gelling and nutritional properties than the traditional method by slightly losing solubility and partially losing emulsifying activity and foaming activity. It was considered that this kind of SPI would be a good ingredient in the production of sausage and similar products.

**Table 5. Dialyzable Ca and Zn in SPI with Different Phytate Contents by Simulated Gastrointestinal Digestion[a]**

| phytate content (mg/g SPI) | Zn content (μg/g SPI) | dialyzable Zn (μg/g SPI) | dialyzable Zn (%) | Ca content (μg/g SPI) | dialyzable Ca (μg/g SPI) | dialyzable Ca (%) |

anthocyanins including glucoside, galactoside, and arabinoside of delphinidin, cyanidin, peonidin, petunidin, and malvidin.[11] The aim of this study was to establish a routine methodology to assess the possible adulteration of commercial extracts and dietary supplements containing *V. myrtillus*. Thus, the anthocyanin profiles and their relative percentages in the berries of *V. myrtillus* from different countries were analyzed by LC. The resultant information was used as a baseline to evaluate the quality of 14 extracts, 6 dietary supplements, and 6 juices containing bilberry found in marketplaces and herbalist's shops.

## MATERIALS AND METHODS

**Chemicals and Materials.** Standards of cyanidin (Cy)-, delphinidin (D)-, petunidin (Pt)-, peonidin (Pe)-, malvidin (Mv)-, and their 3-*O*-glucoside (glc), Cy-, Pt-, Pe-, Mv-3-*O*-galactoside (gal), Cy-arabinoside (Cy-ara), and Cy-rutinoside (Cy-rut) were purchased from Polyphenols Laboratory (Sandnes, Norway). Potassium chloride, hydrochloric acid, methanol, acetonitrile, and phosphoric and trifluoroacetic acid (TFA) were from Merck (Darmstadt, Germany). Amaranth and ammonium acetate were purchased from Sigma-Aldrich (St. Louis, MO, USA), and water was obtained from a Milli-Q apparatus (Millipore, Milford, MA, USA). Frozen bilberries (*V. myrtillus*) originating from Italy ($n$ = 5), Finland ($n$ = 3), Sweden ($n$ = 1), Germany ($n$ = 3), Croatia ($n$ = 2), Argentina ($n$ = 2), and Slovenia ($n$ = 3) were purchased in local supermarkets and stored immediately at −20 °C. Bilberry extracts (E1−E14) were from different manufacturers, whereas food supplements (S1−S6) and juices (J1−J6) were acquired in herbal shops and local markets. The extracts of berries such as chokeberry (*Aronia melanocarpa*), elderberry, blackberry, black currant, red raspberry, sweet cherry, black beans, and black soybean and the fruits of mulberry (*Morus nigra*) were a gift from Specchiasol (Bussolengo, VR, Italy).

**Sample Preparation.** *Bilberry Fruit.* Approximately 10 g of frozen berries was mixed with 30 mL of a solution of methanol/TFA 2% in water (10:90, v/v) and homogenized by an Ultra-Turrax (IKA-Werke, Staufen, Germany) for 1 min. The homogenate was extracted for 30 min under agitation in the dark at room temperature. The suspension was centrifuged at 1000*g* for 10 min at 4 °C and the supernatant recovered. The residue was extracted again until disappearance of the red color (4 × 20 mL) with a solution of methanol/TFA 2% in water (10:90, v/v) and treated as described above. The supernatants were combined, and the volume was adjusted to 200 mL by solution of 2% TFA in water. All extracts were stored at −20 °C and centrifuged at 3000*g* for 1 min before the LC analysis.

*Bilberry Extracts.* Approximately 100 mg of powder was dissolved in approximately 20 mL of a solution of methanol/water (10:90, v/v), the suspension was sonicated for 5 min and centrifuged at 1000*g* for 5 min, and the supernatant was recovered. The residue, if present, was extracted four times with 15 mL of a methanol/water (10:90, v/v) solution and treated as described above. The supernatants were combined, and then the final volume was adjusted to 100 mL with water.

*Food Supplements and Juices Containing Bilberry Extract.* The contents of 10 capsules were mixed, and approximately 300 mg was dissolved in approximately 5 mL of methanol. This suspension was sonicated for 5 min and centrifuged at 1000*g* for 5 min, and the supernatant was recovered. The residue was extracted three times with 5 mL of water and treated as previously described. The supernatants were combined, and then the final volume was adjusted to 25 mL with water. The juice (2 mL) was diluted in 7 mL of a methanol/water

[a]Mean value (g/100 g FW, RSD% <12). [b]RP, relative percentage (individual compounds reported as percentage of total ACN monitored at 520 nm). [c]–, not found. [d]Contains also cyanidin-rutinoside (RP = 18.3). [e]Contains also cyanidin-xyloside (RP = 1.6). [f]Contains also cyanidin-rutinoside (RP = 4.0).

(10:90, v/v) solution, the suspension was sonicated for 5 min and centrifuged at 1000*g* for 5 min, and the supernatant was recovered. The residue was extracted with 7 mL of water and treated as previously described. The supernatants were combined, and then the final volume was adjusted to 20 mL with water. The sample was stored at 4 °C before the qualitative and quantitative analyses.

**Determination of Total Anthocyanins.** The total content of ACNs was determined spectrophotometrically (PerkinElmer Lambda 20, Waltham, MA, USA) by two methods.

Method A was described by Giusti et al.[22] Extracts were diluted in 0.1% HCl, the absorbance was measured at 520 nm, and the total percentage of ACNs was calculated as

$$\text{total ACNs (\%)} = \frac{A \times \text{MW} \times V \times D}{\varepsilon_{\text{mol}} \times W} \times 100$$

where $A$ = absorbance (AU), $\varepsilon_{\text{mol}}$ = Cy-glc molar extinction coefficient (26900), MW = Cy-glc molecular weight (449 Da), $W$ = sample weight (mg), $V$ = volume (mL), and $D$ = dilution factor.

Method B was described by Lee et al.[13] The absorbance was measured twice for each sample and buffer at the following wavelengths: 520 and 700 nm. The absorbance $A$ was calculated as follows:

$$A = (A_{520\text{nm}} - A_{700\text{nm}})_{\text{pH1}} - (A_{520\text{nm}} - A_{700\text{nm}})_{\text{pH4.5}}$$

The total ACN content (mg ACNs/100 mg) was calculated as described above.

**Anthocyanin Determination by Liquid Chromatography–Diode Array–Mass Spectrometry.** The UPLC system was a model Acquity (Waters, Milford, MA, USA) equipped with a model E-Lambda photodiode array detector (Waters) and a tandem mass spectrometer model Quattromicro (Waters). The separation was carried out by a BEH Shield $C_{18}$ column (150 × 2.1 mm, 1.7 μm, Waters) maintained at 45 °C. The flow rate was 0.5 mL/min, and the eluents were (A) 0.3% TFA and (B) $CH_3CN/CH_3OH$/TFA 0.5% (22:22:56, v/v/v). The elution gradient was linear as follows: 0–20 min, 20% B; 20–30 min, from 20 to 26% B; 30–40 min, from 26 to 30% B; 40–45 min, from 30 to 40% B; 45–47 min, from 40 to 60% B; 47–50 min, from 60 to 90% B; 90% for 3 min. Chromatographic data were acquired from 200 to 700 nm and integrated at 520 nm. Anthocyanin stock solutions (1 mg/mL) were prepared in methanol/TFA 2% (10:90, v/v) and stored at −20 °C. Working solutions ($n$ = 5) were prepared in the range of 2–50 μg/mL, and each analysis was carried out in duplicate. Fifty microliters was injected into the chromatographic system. The concentration of the ACNs not commercially available (D-gal, D-ara, Mv-ara, and Pt-ara) was estimated using the calibration curve equation of the same anthocyanidin linked to glucose. The ACNs were also determined by the Cy-glc curve, and the resulting data were corrected by molecular weight ratio.

Mass analyses were performed in positive scan mode in the range of 100–1000 Da, and the fragmentations were performed using cone voltage, collision energy, and argon gas at 20 V, 30 eV, and $2.0 \times 10^{-3}$ mbar, respectively.

**Amaranth Determination by UPLC-MS/MS.** The UPLC system was a model Acquity (Waters) coupled to a tandem mass spectrometer model Quattromicro (Waters). Separations were performed using a 1.7 μm BEH $C_{18}$ column (100 × 2.1 mm, Waters). The eluent was 1 mM ammonium acetate, pH 4.5/acetonitrile (80:20, v/v). The flow rate was 0.5 mL/min, the column temperature was 35 °C, and the injection volume was 2 μL. The capillary voltage was set to 3.0 kV, the cone voltage was 30 V, the source temperature was 130 °C, the desolvating temperature was 350 °C, the collision energy (CE) was specific for each transition, and argon was used at $2.0 \times 10^{-3}$ mbar to improve fragmentation in the collision cell. Amaranth was determined in multiple reaction monitoring (MRM) mode, and the data were acquired by MassLynx 4.0 software (Waters). The mass spectrometer was operated in the electrospray ionization (ESI) negative mode, and the fragmentation transitions were $(m/z)^-$ 537 → 317 (CE 30), 457 (CE 40), with a dwell time of 0.2 s. Calibration curves were obtained from amaranth stock solutions prepared by dissolving 10 mg of standard powder in 10 mL of methanol, and their quantitative determination was performed in the range of 50–500 ng/mL.

[a]ACN content by HPLC. [b]ACN content by spectrophotometer. [c]Method not reported in the analytical certificate. Method A, spectrophotometric at 520 nm; method B, spectrophotometric (520 nm) at two different pH values; method C, LC-DAD. [d]nr, not reported in the packaging.

**Statistical Analysis.** The statistical analysis was performed by means of Excel software. To demonstrate the similarity or differentiation between the chemical profiling chromatograms between reference (fruits) and target products (extracts, commercial preparations), the total deviation percentage (TD%) was introduced and calculated by using the equation

$$\mathrm{TD\%} = \sum_{i}^{n} \frac{|A_s' - A_t'|}{A_s' n}$$

where TD% = total deviation percentage, $A_s$ = relative percentage of the peak in the reference chromatogram (bilberry fruits), $A_t$ = relative percentage of the peak in the target chromatogram, and $n$ = the number of peaks.

## RESULTS AND DISCUSSION

Anthocyanins in bilberry fruit and their commercial preparations were identified by cochromatography, online UV−vis spectra, molecular weight, and MS/MS fragmentation. The chromatograms relating to fruits, obtained at 520 nm, showed the presence of 15 anthocyanins, whereas the respective aglycones were absent in all of the samples (Figure 1a) and several fruits ($n$ = 3) displayed a lower amount of anthocyanidin glucosides (Figure 1b). Therefore, there were two types of bilberry, which differed in the relative percentages of glucosylated anthocyanidins. Lower percentages of glucosylated ACN have already been found in several cultivars of bilberry[1] and highbush blueberry,[16] but the factors responsible for these differences are not yet clear. They could include differences in the genotype, environment, such as light, temperature, and altitude, or both factors. Table 1 reports the individual and total anthocyanin content in bilberries from different countries. The monomeric anthocyanin pigment content of the analyzed berry samples ranged from 151 to 1310 mg/100 g FW with a mean of 551 mg/100 g (Table 1), and D-, Cy-, Pt-, Mv-, and Pe-glycosides comprised about 39, 24, 18, 14, and 5% of the total ACNs, respectively. The average contents of these ACNs were comparable to those reported by Latti et al.,[1] but lower than those reported by other authors.[17] Quantification of the ACNs was based on authentic standards and by the Cy-glc equivalents, which are the methods generally used in quality control laboratories. The latter type of quantification underestimated the content of D-glycosides by approximately 30%, as shown by Kähkönen et al.[18]

**ACNs in Bilberry Extracts.** Amaranth, a dye used to adulterate the extracts of bilberry, was not detected in any sample analyzed. The quantitative analysis of the standardized bilberry extracts showed marked differences among them (Table 2). The spectrophotometric determinations have provided quantitative data up to 75% higher than those obtained by chromatography, and the differences may be due to the presence of other pigments, polymerized anthocyanins, or both. Despite this, the pH differential method could be used to quickly determine the presence of dyes that do not change color in varying pH conditions, such as amaranth.

The chromatographic analyses showed that 35% of the tested extracts (E2, E4, E7, E9, and E10) did not qualitatively and quantitatively conform to the analytical report provided by the supplier. Extracts E1, E3, E6, E13, and E14 did qualitatively conform, but their content in anthocyanins was lower than declared by the supplier. In particular, the ACN amount found in E6 was lower than about 80%. The remaining extracts (E5 and E11) were qualitatively and quantitatively in accordance with those stated by the manufacturer.

Figure 2 shows the chromatograms, integrated at 520 nm, corresponding to samples E2, E7, and E9. The chromatographic profile of the E2 extract, similar to E4, showed the presence of two main ACNs that seemed to match, separation factor ($\alpha$) = 1, Cy-glc and Pt-glc. The mass spectra showed that peaks 5 and 8 (Figure 2I) had molecular weights of 449 and 595, respectively, and at lower collision energy values these ions gave an ion product with $(m/z)^+$ 287, likely corresponding to the aglycone moiety. Thus, the mass spectrometry data, combined with the UV−vis and chromatographic behavior, suggest that peaks 5 and 8 were Cy-glc and Cy-rut, respectively. The latter compound, Cy-rut, is not normally present in bilberry fruit extracts, but has been found in berries such as *Morus nigra* (black mulberry). Thus, the reference extract of bilberry fruit was spiked with a commercial extract of mulberry, and chromatographic analysis revealed that the E2 and E4 samples contained approximately 50 and 30% mulberry, respectively.

The chromatographic profiles of the E7 and E8 extracts differed significantly from that of the bilberry; they contained three main ACNs corresponding to Cy-gal, Cy-glc, and Cy-ara and two minor compounds identified as Pe-glc and Cy-xyloside (Figure 2II). These ACNs were present in a reference extract of *Aronia melanocarpa* (chokeberry), and they have also been

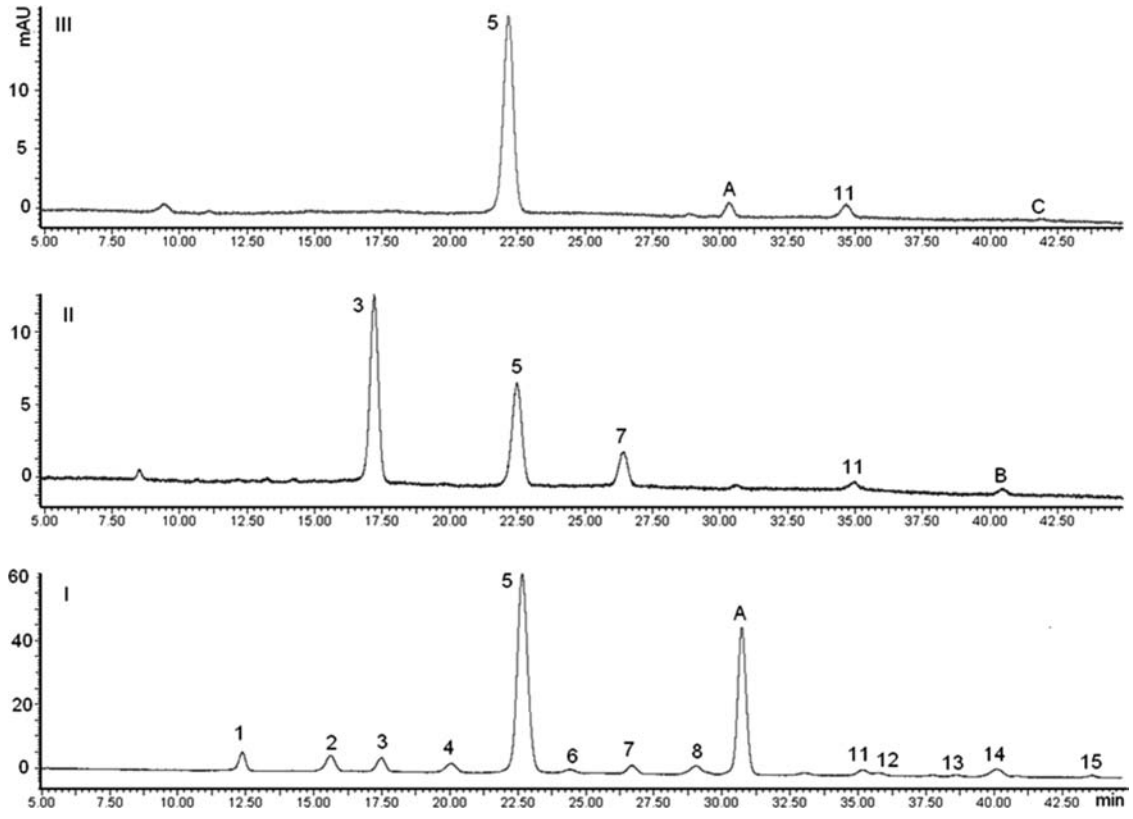

**Figure 2.** Chromatograms integrated at 520 nm of extracts E2 (I), E7 (II), and E9 (III). Peaks: A, Cy-rutinoside ($[M]^+$, $m/z$ 595; MS/MS, $m/z$ 287); B, Cy-xyloside ($[M]^+$, $m/z$ 419; MS/MS, $m/z$ 287); C, Cy-derivative (($[M]^+$, $m/z$ 569; MS/MS, $m/z$ 287). The chromatographic profiles of samples E2, E7, and E9 were comparable to those of mulberry, chokeberry, and blackberry extract, respectively. See Figure 1 for peak attribution.

found in chokeberries by different authors,[19,15] although in different proportions from those present in our chokeberry extracts. Thus, it seems that samples E7 and E8 were extracts of chokeberries and not bilberries. In addition, sample E9 did not contain the 15 typical bilberry ACNs. Indeed, it contained mainly Cy-glc and lower amounts of Cy-rut, Pe-glc, pelargonidin-hexoside, and an unknown anthocyanin (Figure 2III, peak C). The mass spectra showed that peak C had a molecular weight of 569 Da, and at lower collision energy values it gave an ion product with $(m/z)^+$ 287, likely corresponding to the aglycone moiety, thus suggesting that it was a cyanidin derivative. We found these ACNs in an extract of blackberry (*Rubus nigra*). Furthermore, Jacobeck et al.[15] reports a chromatographic profile of the blackberry very similar to that of extract E9. Thus, the sample E9 is not bilberry, but may be a blackberry extract. Finally, extract E10 did not contain ACNs, and the spectrophotometric data revealed significantly less than the declared percentage.

**ACNs in Food Supplements Containing Bilberry.** The ACN spectrophotometric determinations (Table 2) in 12 food supplements have provided quantitative data up to 80% higher than those obtained by chromatography, as already obtained from analyzing the extracts. The LC-DAD-MS analyses showed that the food supplements formulated in capsules (S1−S6) did not qualitatively and/or quantitatively conform (Table 2). In particular, the chromatographic profiles of products S2, S4, and S5 were comparable to those of extracts E2 and E4, identified as black mulberry extracts. The quantitative data suggest that S4, S5, and S2 contain approximately 50, 70, and 70% of mulberry extract, respectively, suggesting that these dietary supplements have been manufactured using an extract of the E2-type. Products S3 and S6 contained bilberry extract, but the ACN content determined by LC-DAD was less than that declared on the label (Table 2). Moreover, sample S6 contained aglycones comprising approximately 20% of the total ACNs, which suggests the use of an extract of lower quality, inadequate/incorrect processing, or both. Product S1 did not contain ACNs, and the package did not report the ACN percentage.

With regard to juices, their chromatographic profiles were comparable to those of the reference extracts except for sample J5. In this product, ACNs were not detected and the chromatographic profile showed a "hump" at about 45 min, which could suggest the presence of polymerized ACNs. The ACN content was only reported on the label of product J5, which was much lower than that determined spectrophotometrically (Table 2). The quantitative data show that the ACN daily intake is in the ranges of 5−33 and 0.5−9.3 mg for products S1−S6 and J1−J6, respectively, which corresponds to <20 g of fresh bilberry fruits containing 0.2% in ACNs. Moreover, it should be pointed out that these quantities are much lower than those demonstrated to be effective in the treatment of some pathologies, such as peripheral vascular disease and venous sensitivity (100−200 mg ACNs)[20] or in reducing the levels of oxidized DNA bases and increasing the resistance to oxidatively induced DNA damage (375 mg ACNs).[21]

Overall, the picture is discouraging and, therefore, it would be appropriate for producers to standardize their extracts and food supplements with chromatographic techniques, as reported in pharmacopoeia, to effectively declare the amounts of anthocyanins.

**Total Deviation Percentage.** The extracts and food supplements showed chromatographic profiles of ACNs similar

Table 3. Chemical Profiling Data of the ACNs in Bilberry Fruits and Commercial Products (Peak Area in Percentage)[a]

to those of fruits with higher glucosylated anthocyanidin contents. Therefore, fruits with a fingerprinting shown in Figure 1a were used as a reference for the determination of the relative percentages of ACNS. Fourteen extracts and 12 finished products were analyzed on the basis of the established chromatographic profiling (Figure 1a), and the normalized peak areas of the typical 15 ACNs are provided in Table 3. The total deviation percentage (TD%) was chosen as the parameter to compare the chromatograms of the reference and target products. The last column of Table 3 shows the TD% values of 26 commercial products versus the reference bilberry. The TD% data for the bilberry extracts suggested that products E1, E3, E5, E6, and E11–14 were similar to the given reference, but the others (about 57%) differed significantly from it. The food supplements in capsules or juice showed higher values of TD% in about 60 and 33% of the products, respectively. The TD% does not provide quantitative data, but it can be a valuable tool to verify the conformity of a product. The limiting value of TD% beyond which the product is not to be considered bilberry remains to be determined.

[a]Rt, retention time; LOD, limit of detection; LOQ, limit of quantification. [b]Peak area from this transition was used for quantification. [c]Identification and confirmation based on molecular weight and MS/MS fragmentation patterns. [d]Compound confirmation based on accurate mass from FT-ICR-MS and structural identification based on MS/MS fragmentation patterns. Response for DHC and curcumin adduct (curcumin−L-cysteine) was assumed to be the same as that for curcumin.

then THC in the presence of nicotinamide adenine dinucleotide phosphate (NADPH).[19] The mechanism of *CurA* is presumed to occur through the reduction of C═C bonds only and not C═O bonds on the heptadienone linkage of curcumin.[19] To gain more information on the metabolism of curcuminoids by gut bacteria, we studied the in vitro interaction of curcuminoids with a pure culture of *Escherichia fergusonii* (ATCC 35469 (E469)) and two strains of *E. coli* (ATCC 8739 (E739) and DH10B (E10B)). These bacteria were chosen as they all contain the YncB gene that encodes for *CurA*. A basic local alignment search tool (BLAST) program revealed that the predicted amino acid sequence of *Escherichia fergusonii* ATCC 35469 (E469) and *E. coli* ATCC 8739 (E739) exhibited 90% and 97% similarity, respectively, to the deduced amino acid sequence of *CurA* from *E. coli* DH10B (E10B). The amount of curcuminoids degraded by the three *Escherichia* bacteria was quantified using liquid chromatography−mass spectrometry (LC-MS) and multiple reaction monitoring (MRM). The breakdown products produced were identified and characterized using tandem mass spectrometry (MS/MS) and high-resolution Fourier Transform-ion cyclotron resonance MS (FT-ICR-MS) and then quantified using MRM.

## MATERIALS AND METHODS

**Materials.** Commercially available curcumin, which consists of a mixture of three naturally occurring curcuminoids, curcumin (80.1%), DMC (15.6%), and Bis-DMC (2.6%), pure standards of two possible breakdown products, THC and FA, and the internal standard (IS) used, $\beta$-estradiol-17-acetate, were purchased from Sigma-Aldrich (Castle Hill, NSW, Australia). Acetonitrile was purchased from Burdick & Jackson (Gillman, SA, Australia), methanol and ethyl acetate were supplied by Merck Pty Ltd. (Kilsyth, Vic, Australia), and all solvents were of HPLC grade. Formic acid and ammonium acetate (analytical grade) were from Ajax FineChem (Waltham, MA, USA). Redistilled deionized water with a resistivity of 18.2 m$\Omega$ was used in all experiments.

Pig cecal fluid (PCF) was sourced from an abattoir (Laverton, VIC, Australia). The PCF was centrifuged at 16000*g* for 40 min (Sorvall RC-6, Thermo Scientific) to remove solid particles, and the supernatant was stored at −20 °C until further use.

**Bacterial Strains.** *Escherichia fergusonii* ATCC 35469 (E469) and *E. coli* ATCC 8739 (E739) from human fecal isolates were obtained from American Type Culture Collection (Manassas, VA, USA). *E. coli* DH10B (E10B) was from Invitrogen (VIC, Australia). All strains were stored at −80 °C in de Man−Rogosa−Sharpe medium (MRS medium; Oxoid; SA, Australia) supplemented with 30% (v/v) glycerol as a cryoprotectant.

**Medium and Growth Conditions for Fermentation Experiments.** Modified medium for colon bacteria (mMCB), which supports the growth of colonic bacteria,[20] was selected for fermentation experiments. The medium consisted of 0.65% (all w/v) bacteriological peptone (Oxoid), 0.5% soy peptone (Oxoid), 0.3% yeast extract (Oxoid), 0.25% tryptone (Oxoid), 0.45% NaCl, 0.2% KCl, 0.05% $MgSO_4 \cdot 7H_2O$, 0.045% $CaCl_2 \cdot 2H_2O$, 0.02% $NaHCO_3$, 0.02% $MnSO_4 \cdot H_2O$, 0.0005% $FeSO_4 \cdot 7H_2O$, 0.0005% $ZnSO_4 \cdot 7H_2O$, 0.04% L-cysteine $HCl \cdot H_2O$ as a reducing agent, and 1.0 mL of resazurin solution (made from 0.01% w/v) as an anaerobic indicator. This growth medium was supplemented with 5% (v/v) PCF for selected experiments. This

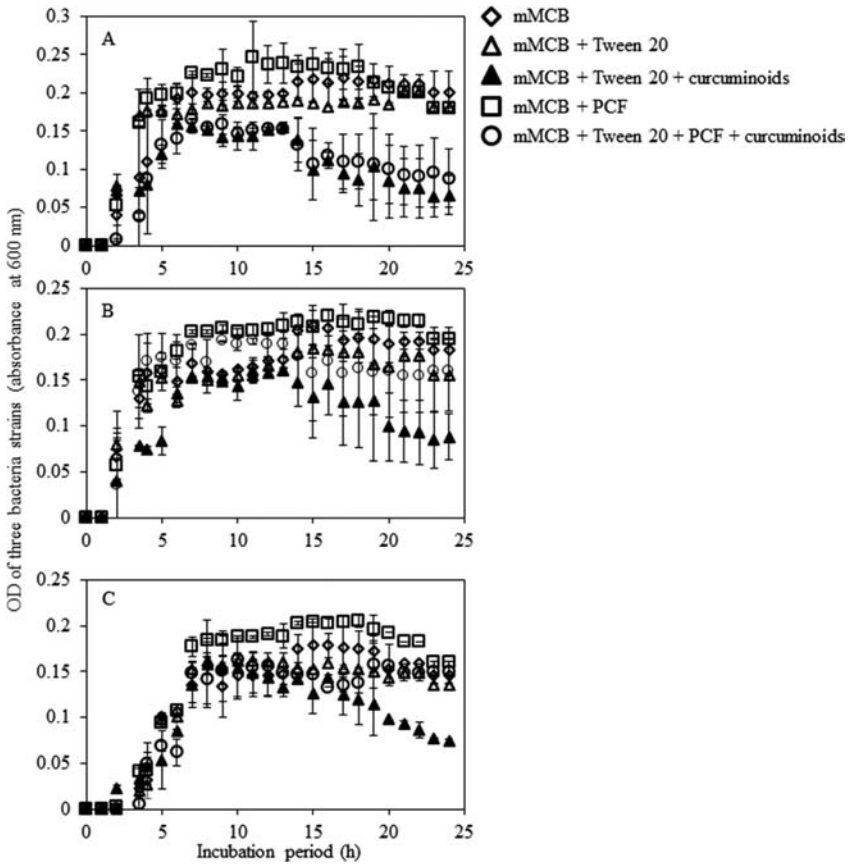

**Figure 1.** Growth of *Escherichia fergusonii* (E469) (A), *E. coli* 739 (E739) (B), and *E. coli* DH10B (E10B) (C) in mMCB with or without Tween 20 and PCF and supplemented with curcuminoids. Each data point is the average of three biological replicates ± SD.

medium was prepared anaerobically and transferred (10 mL) to glass tubes in an anaerobic culturing hood.

For subculture preparations, *Escherichia fergusonii* and *E. coli* were cultured individually on lysogeny agar plates containing 1% (all w/v) tryptone, 0.5% yeast extract, 1% NaCl, and 2% agar (Oxoid). Under these conditions colonies were visible after 24 h of incubation at 37 °C. One colony of each culture was then grown in separate glass tubes containing 10 mL of mMCB, as above, under anaerobic conditions at 37 °C for 2 h.

For fermentation assays, 100 $\mu$L of the subculture was inoculated into separate glass tubes containing 10 mL of mMCB and supplemented with curcuminoids at a concentration of 0.3 mM (solubilized in 3% (v/v) of Tween 20). Blank control samples containing only mMCB or mMCB + PCF but without curcuminoids were also inoculated. The initial pH of the fermentation medium was pH 6.27 ± 0.02. A set of abiotic samples with or without curcuminoids in mMCB or mMCB + PCF were maintained to account for the stability of curcuminoids at the start and end of fermentation. Fermentation temperature was kept constant at 37 °C and maintained for 36 h. Samples were acquired at 12 different time points for further analysis. The fermentation was performed on three separate occasions.

**Bacterial Growth.** The growth curves of bacterial strains were obtained by measuring the optical density (OD) at 600 nm using a Nanodrop 2000C spectrophotometer with a UV−vis detector (Thermo-Fisher Scientific). Triplicate measurements were obtained, and data are presented as the mean ± SD.

**Quenching and Cell Lysis.** Following incubation, bacterial metabolism was quenched by adding 2 mL of cold methanol/water (60%, v/v) solution to 1 mL of cell culture. To lyse the cell, samples were frozen in liquid nitrogen, thawed on dry ice, and then sonicated in a microfuge tube within a sonicator bath for ∼3 min. This lysis procedure was repeated 10 times. The samples were then vortexed and centrifuged at 805*g* for 5 min at 0 °C (Eppendorf centrifuge 5810R) to remove cell debris. The supernatant was kept at −20 °C prior to extraction.

**Curcuminoids and Metabolite Extraction.** The procedure for extraction of curcuminoids and transformed metabolites was adapted and optimized from that of Saradhi et al.[21] Briefly, 0.5 mL of supernatant and 1 mL of ethyl acetate with 100 $\mu$g/mL IS ($\beta$-estradiol-17-acetate) were mixed. The sample was then vortexed and centrifuged at 11000*g* for 5 min (Eppendorf Centrifuge 5424). The upper organic layer (∼1 mL) was transferred to a clean microfuge tube. The same extraction procedure was repeated using the lower aqueous layer. Both upper organic layers were then combined and dried (SpeedVac, Christ RVC 2-33, John Morris Scientific) for about 2 h at 20 °C or until completely dry. The dried extracts were then resuspended in 100 $\mu$L of LC-MS running buffer containing 10 mM ammonium acetate in an acetonitrile/water (50%, v/v) solution, vortexed, and further diluted by combining 10 $\mu$L of resuspended extract and 90 $\mu$L of LC-MS running buffer. This solution was then vortexed and centrifuged at 11000*g* for 5 min, and 80 $\mu$L was transferred to vials, which were capped and ready for LC-MS analysis.

**Identification and Quantification of Extracted Curcuminoids and Metabolites.** Chromatographic separation of curcuminoids and metabolites was performed with an LC 1200 series system (Agilent Technologies, Santa Clara, CA, USA), which consisted of a Binary Pump SL and Hi-P-Autosampler (with injection volume of 2 $\mu$L). Elution was achieved with an Agilent Poroshell 120 EC-C8 column (2.1 × 50 mm, with a particle size of 2.7 $\mu$m). The mobile phases consisted of 10 mM ammonium acetate and 0.1% (v/v) formic acid in water (A) or in acetonitrile (B). A linear gradient was applied as follows with a flow rate of 0.3 mL min$^{-1}$: 0−5 min, 20% B; 5−8.1 min, 80% B; 8.1−10.0 min, 20% B; with a total run time of 10 min. Analysis was performed using a 6460 triple-quadrupole mass spectrometer (Agilent Technologies) equipped with an electrospray ionization (ESI) source operating in negative mode. For the identification and quantification of compounds,

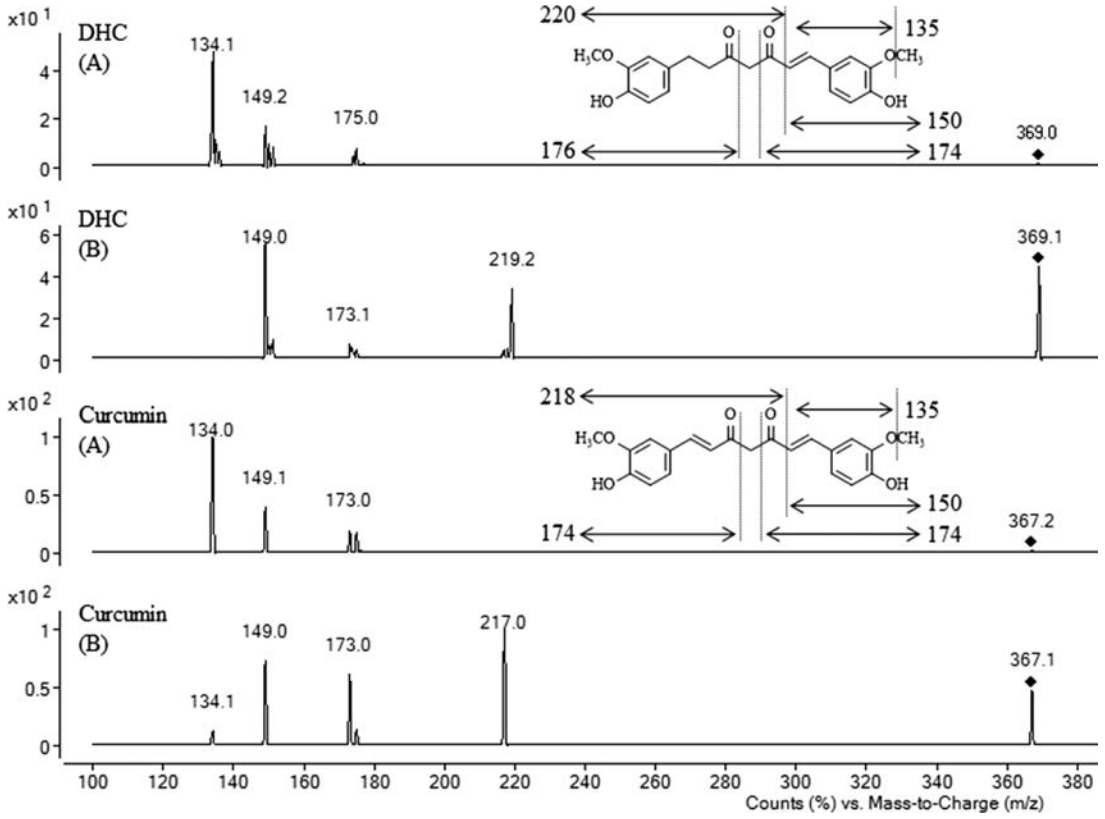

**Figure 2.** MS/MS spectra of DHC and curcumin from triple-quadrupole mass spectrometer operating in negative mode with a fragmentor voltage of 110 V and collision energy of 25 V (A) and 10 V (B) and their neutral chemical structures and fragmentation sites, DHC (top) and curcumin (bottom). The product ions shown on the spectra are the $[M - H]^-$ ions formed by loss of a proton from either of the phenol moieties.

a MRM analysis was employed, tracking the transition indicative of parent and product ion specific for each compound. Previous direct infusion experiments were performed to optimize the fragmentor voltage and collision energy (CE). After infusion had been performed, the following parameters were fixed: drying $N_2$ temperature, 300 °C; gas flow, 7 L $min^{-1}$; nebulizer pressure, 15 psi; sheath gas temperature, 400 °C; sheath gas flow, 10 L $min^{-1}$; capillary voltage, 2000 V; nozzle voltage, 1000 V; cell accelerator voltage, 7 V; dwell time, 20 ms. Detailed transitions of parent molecules and product ions, MS parameters (fragmentor voltage and CE), limits of detection (LODs), and limits of quantification (LOQs) are listed in Table 1.

The concentrations of curcuminoids curcumin, DMC, and Bis-DMC were quantified on the basis of a calibration curve for curcumin. It was assumed that the response factors for DMC and Bis-DMC were the same as that for curcumin. The metabolites THC and FA were also quantified using standards. For the quantification of the metabolite with $m/z$ $[M - H]^-$ 369 and the compound with $m/z$ $[M - H]^-$ 470, it was assumed that these also had the same response factor as curcumin. The area under the curve from the LC-MS spectra of each compound was normalized using the IS and then converted to concentration using the standard calibration curves.

Separate spiking experiments with known quantities of the curcuminoids, and the metabolites THC and FA in mMCB medium were carried out. Recoveries for all five compounds were ∼80%. All values given in the tables and figures were corrected for recovery (assuming 80% for all compounds).

**Identification of Compounds with $m/z$ $[M - H]^-$ 369 and $m/z$ $[M - H]^-$ 470.** LC-MS/MS using a triple-quadrupole mass spectrometer and accurate mass using FT-ICR-MS were used to confirm the identity of compounds with $m/z$ $[M - H]^-$ 369 and $m/z$ $[M - H]^-$ 470.

*LC-MS/MS.* Chromatographic separation conditions were as described above. Analysis was performed using a 6460 triple-quadrupole mass spectrometer (Agilent Technologies) equipped with an ESI ion source operating in negative mode. A product ion scan was employed for confirmation of the metabolite. The acquisition parameters were as follows: CE, 10, 20, and 35 V; fragmentor voltage, 110 V; MS scan range from 50 $m/z$ (min) to 500 $m/z$ (max); drying $N_2$ temperature, 300 °C; gas flow, 7 L $min^{-1}$; nebulizer pressure, 15 psi; sheath gas temperature, 400 °C; sheath gas flow, 10 L $min^{-1}$; capillary voltage, 2000 V; noozle voltage, 1000 V.

*FT-ICR-MS.* A Bruker Daltonics (Bremen, Germany) SolariX 7 T Hybrid MALDI/ESI-FT-ICR-MS was used for isolation and high mass resolution analysis. The instrument was operated in ESI negative ionization mode with TD acquisition = 1M, MS detection (resolution 260000 at $m/z$ 400) using an external calibration of sodium trifluoroacetate solution, and MS/MS detection (resolution 45000 at $m/z$ 400). The sample was infused at a rate of 2 $\mu$L $min^{-1}$ using the syringe pump, and a total of 20 scans were collected and averaged. The following general instrument conditions were set: capillary voltage, 4200 V; drying gas flow, 4.0 L $min^{-1}$; drying gas temperature, 180 °C; nebulizer gas flow rate, 0.8 bar; source accumulation, 0.001 s; ion accumulation, 0.5 s; ion cooling time, 0.01 s; flight time, 0.001 s. Various collision voltages were used with a collision gas flow rate of 40%. Data were analyzed using Bruker Compass Data Analysis 4.2 (Build 383.1) software.

**Statistical Analysis.** Statistical analysis was performed using the statistical package Minitab for Windows (version 17). Differences in the data were analyzed using one-way analysis of variance (ANOVA). The effect of two different treatments, (i) without PCF and (ii) with PCF, on the ability of the three bacterial strains to degrade curcuminoids at 36 h of fermentation was also tested. Tukey pairwise comparisons were used to identify the differences and statistical significance defined as $p < 0.05$.

## RESULTS AND DISCUSSION

**Growth of *Escherichia fergusonii* and Two *E. coli* Strains.** The three *Escherichia* bacterial strains demonstrated a

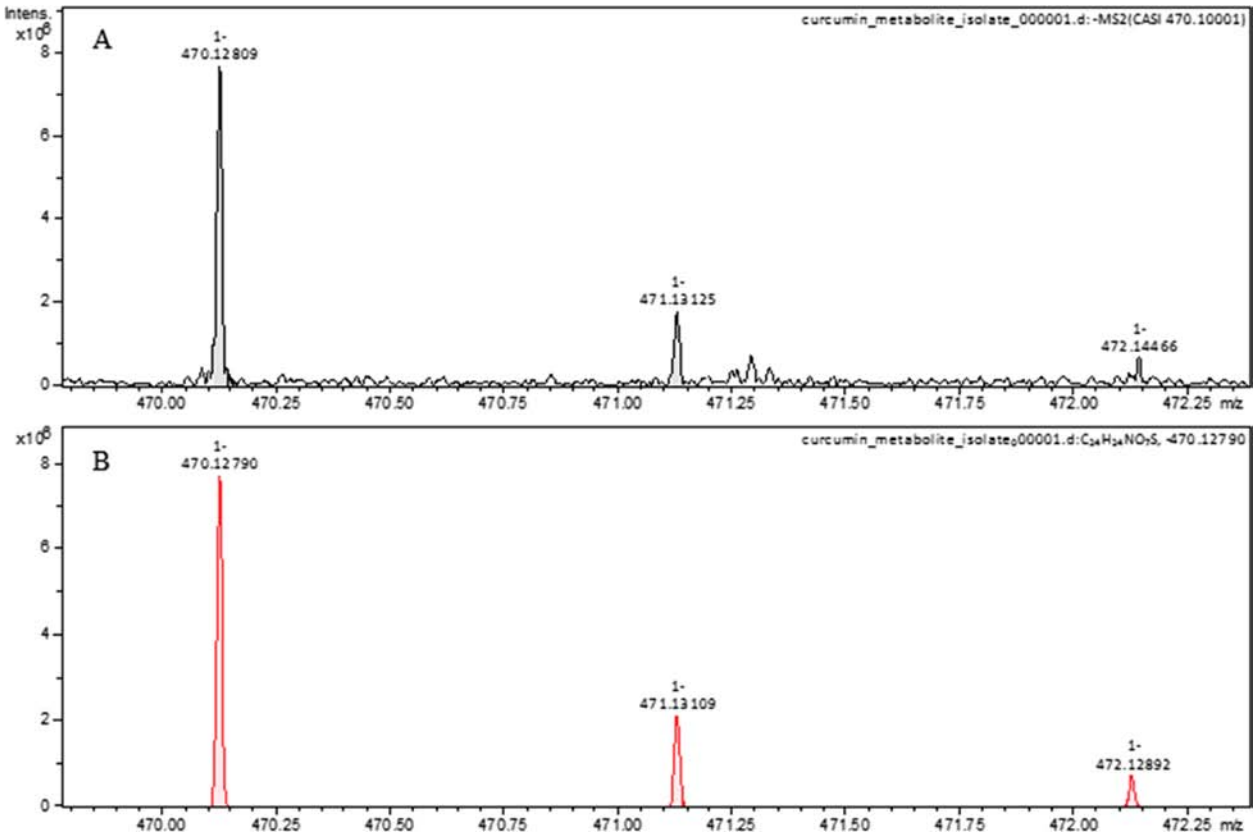

**Figure 3.** Full scan MS mass spectra of isolated curcumin adduct displaying isotopic profile (A) and the calculated isotopic profile of the predicted $C_{24}H_{25}NO_7S$ compound (B).

growth curve typical of batch culture in mMCB media, with a lag phase of around 2−3 h followed by exponential growth and a stationary phase beyond 8 h (Figure 1). The growth of all strains was not markedly affected by the addition of Tween 20 to solubilize the curcumin (3%, v/v) (Figure 1). Others have observed that Tween 20 (0.5%, w/w) in 0.1 M phosphate buffer disintegrated the cell wall and cytoplasmic membrane of *Listeria monocytogenes* and *Salmonella typhimurium*.[22] It is likely that differences in the responses of bacteria to curcumin may vary with growth medium and microbial species. Indeed, the addition of medium was observed to counter the nonreversible damage caused to cells grown in buffer.[23]

The addition of PCF (5%, v/v) slightly increased bacterial growth and the $OD_{600\ nm}$ increased by ∼0.02−0.05 units (Figure 1). PCF is known to assist the growth of facultative anaerobic bacteria. Similar findings were observed previously when media containing either ruminal fluid or pig cecal extract supported the growth of a larger number of gut bacteria compared to a medium rich in nutrients.[24]

The growth of E469, E739, and E10B in the first 8 h of fermentation was not affected by the supplementation of 0.3 mM curcuminoids, as shown by the profiles (Figure 1). However, a decline in $OD_{600\ nm}$ was observed for E469 and E10B during the stationary phase, indicating a change in metabolism. A similar decline was observed for E469 in the presence of PCF and Tween 20.

The pH values at the start and end of the fermentation were 6.27 ± 0.02 and 6.00 ± 0.05, respectively. Curcumin is stable at these pH values, but at alkaline pH >7.5, it degraded chemically within 30 min to ferulic acid, feruloylmethane, and vanillin.[25,26] Therefore, changes in curcumin are likely to be due to bacterial metabolism.

**Identity of Compounds Formed in Fermentation Cultures with Curcumin.** The upper organic and lower aqueous fractions for all extracted samples were examined by LC-MS using a full MS scan operating in both negative and positive modes from $m/z$ 50 to 800 (method S1, Supporting Information).

Four compounds, in addition to the curcuminoids added, were identified from the full scan LC-MS spectra of the upper organic fraction of inoculated samples supplemented with curcuminoids. The full scan LC-MS spectra showing the total ion chromatogram of sample with 0.3 mM curcuminoids inoculated with E469 in mMCB and the extracted full mass spectra of one of the compounds are shown in Figure S1 (Supporting Information). Two of these additional compounds, THC and FA, were identified by comparison to standards. The other two compounds with $m/z$ (all in $[M - H]^-$) 369 and 470 were identified using LC-MS/MS and FT-ICR-MS, respectively. Compounds with $m/z$ $[M - H]^-$ 369 and 470 were confirmed to be dihydrocurcumin (DHC) and a curcumin adduct (curcumin−L-cysteine), respectively, as discussed below. No metabolites could be identified in the lower aqueous fractions.

*Confirmation of Compounds with m/z [M − H]⁻ 369.* Full scan LC-MS of samples grown in the presence of curcuminoids gave rise to product ion with $m/z$ $[M - H]^-$ 369 (data not shown), consistent with the $[M - H]^-$ ion of DHC (370 MW). To ensure that this compound putatively identified as DHC was not an isotope of curcumin, LC-MS/MS of DHC and curcumin in negative mode were performed and their spectra together with neutral chemical structures are shown in Figure 2. A fragmentor

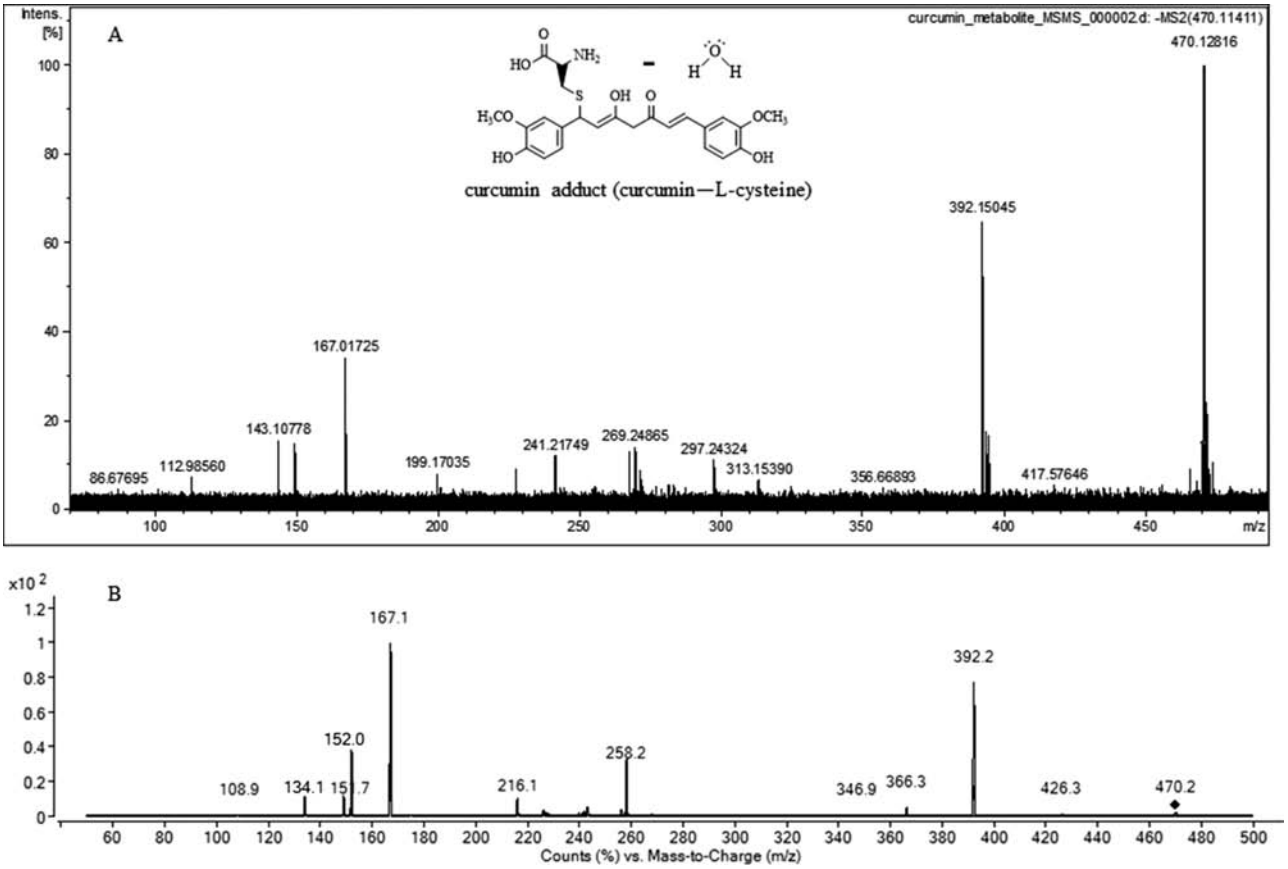

**Figure 4.** MS/MS analysis of curcumin adduct (curcumin−L-cysteine) from FT-ICR-MS (A) and triple-quadrupole mass spectrometer (B) and the proposed chemical structure of the adduct. MS/MS fragmentation patterns of curcumin adduct (curcumin−L-cysteine) from both instruments showed two intense fragment ions at nominal masses of 392 and 167.

voltage of 110 V and CE of 25 and 10 V were applied to both compounds, producing product ions of $m/z$ 134, 149, 173, 175, and 219 for DHC and $m/z$ 134, 149, 173, and 217 for curcumin (Figure 2).

Differences between the product ions of DHC and curcumin were attributed to their chemical structures. Curcumin possesses two alkenyl C═C bonds within the heptadienone backbone,[1] whereas DHC is the reduced form of curcumin in which one of the alkenes has been reduced.[19] DHC has been previously reported as the intermediate breakdown product of curcumin by the enzyme *CurA*, through the reduction of an alkene present on the heptadienone chain.[19] The common product ions of both curcumin and DHC can be rationalized through the presence of at least one C═C bond, where the observed $[M - H]^-$ product ions $m/z$ 134 and 149 correspond to fragmentation across the enone functionality (149) with a further loss of a single methyl group (134) (Figure 2). The other product ions for curcumin, 173 and 217, correspond to fragmentation at the ketone functionality. For DHC, which possesses a reduced alkene with two hydrogen atoms, the corresponding mass shifted product ions 175 and 219 were observed (Figure 2). The product ion 173 was also observed for DHC, where the presence of a single alkene functionality and corresponding fragmentation at the ketone produce an identical product ion to that of curcumin.

*Confirmation of Compound with m/z [M − H]⁻ 470.* To putatively identify the compound with $m/z$ $[M - H]^-$ 470, high mass accuracy FT-ICR-MS mass spectra of the compound were collected. Direct infusion of the crude culture media provided a complex signal; further isolation of a narrow mass range (10 $m/z$) centered around $m/z$ of 470 found a single peak at $m/z$ $[M - H]^-$ 470.12809 as shown in Figure 3. Calculation of the molecular formula from the accurate mass gave only a single possible formula, $C_{24}H_{25}NO_7S$ (calculated $m/z$ $[M - H]^-$ 470.12789), with a very low mass error of −0.41 ppm, as shown in Table 2. The isotopic pattern of the compound with $m/$

dx.doi.org/10.1021/jf5031168 | J. Agric. Food Chem. 2014, 62, 11005−11015

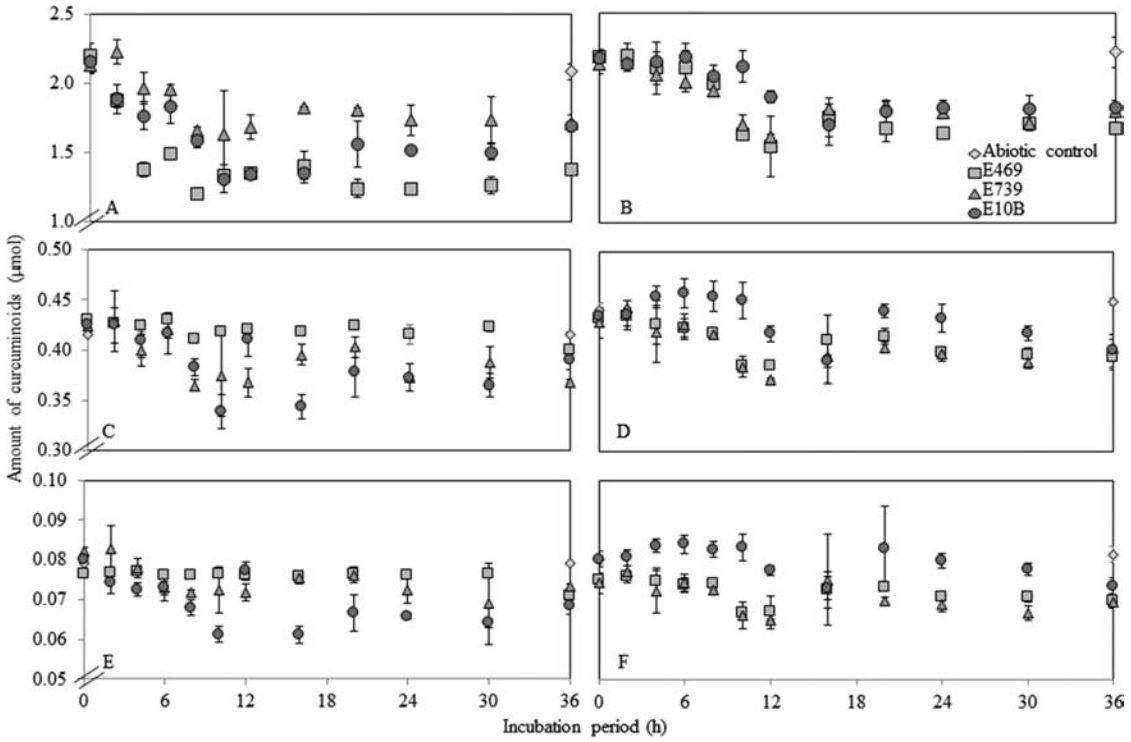

**Figure 5.** Amount of curcuminoids: curcumin (A, B), DMC (C, D), and Bis-DMC (E, F) measured during fermentation with *Escherichia fergusonii* (E469), *E. coli* 739 (E739), and *E. coli* DH10B (E10B) in mMCB without PCF (A, C, E) or with PCF (5%, v/v) (B, D, F). The amount of curcuminoids in the upper organic extracts was quantified using LC-MS/MS and expressed as total micromoles in the original experimental broth of 10.1 mL. The amounts of curcuminoids in the control (abiotic) samples were measured at 0 and 36 h. Each data point is the average of three biological replicates ± SD.

$z$ $[M - H]^-$ 470 from FT-ICR-MS is similar to the calculated isotopic peak spacing of the compound, as shown in Figure 3.

L-Cysteine was present in the growth medium (mMCB) to reduce the oxido/reduction potential. The amount added far exceeds that required for the formation of the curcumin−L-cysteine adduct. The predicted formula of the metabolite matches an addition product of curcumin ($C_{21}H_{20}O_6$) and L-cysteine ($C_3H_7NO_2S$) with a loss of water. We propose an initial 1,4-addition product, curcumin adduct (curcumin−L-cysteine), with a possible chemical structure as shown in Figure 4, which undergoes dehydration either in vitro or within the MS source. In support of our putative assignment, curcumin possesses two $\alpha,\beta$-unsaturated ketone moieties that can act as Michael acceptors to nucleophilic attack through a Michael-type addition reaction mechanism.[27] Furthermore, curcumin has previously been found to bind covalently to nucleophilic sulfhydryls and the selenol moiety of selenocysteine.[28,29] Thioredoxin reductase, a selenocysteine-containing enzyme, was irreversibly inhibited by curcumin through a Michael-type addition reaction only in the presence of NADPH, with inhibition persisting after the removal of curcumin.[28]

To explore the mechanism of formation of the putatively identified curcumin adduct, we performed a separate experiment by incubating mMCB with and without 0.3 mM curcuminoids at 37 °C for 24 h and removed the bacterial cells to produce spent media. Both spent media samples were further supplemented with 0.3 mM curcuminoids and incubated for another 24 h. The curcumin adduct was observed only in spent media where curcuminoids were co-incubated with mMCB (data not shown). This suggests that the curcumin adduct is formed only in the presence of bacteria. We propose that this curcumin adduct may be formed through a Michael-type addition, possibly in the presence of NADPH. It is probable that NADPH was produced in the fermentation cultures in this study through bacterial synthesis or another biological reductant may be employed.

Additional MS/MS analysis by FT-ICR-MS and triple-quadrupole MS showed two intense fragment ions at nominal masses of 392 and 167, as demonstrated in Figure 4. Accurate mass analysis gave masses of 392.15045 and 167.01725 with calculation of the molecular formula indicating empirical formulas of $C_{23}H_{22}NO_5^-$ (calculated, 392.15035; mass error, −0.26 ppm) and $C_8H_7O_2S^-$ (calculated mass, 167.01722; mass error, −0.14 ppm) as probable fragmentation products of a curcumin−L-cysteine adduct, as shown in Table 2. Although isolation and elucidation of the exact chemical structure is beyond the scope of the current study, data presented here can be used to assist in future determination of the exact chemical structure of the compound with $m/z$ $[M - H]^-$ 470.

**Quantification of Compounds Formed in Fermentation Cultures with Curcumin.** *Change in Curcuminoid Concentrations during Fermentation.* The extent to which the three curcuminoids (curcumin, DMC, and Bis-DMC) were degraded by the bacteria E469, E739, and E10B during batch fermentation for 36 h was determined using LC-MS. The effect of supplementing the media with PCF (5%, v/v) on the ability of all three strains to degrade curcuminoids was examined. Blank control samples containing only mMCB or mMCB with PCF without curcuminoids showed no or negligible signal interference in the LC-MS spectra of curcuminoids and metabolites.

The amounts of curcuminoids (curcumin, DMC, and Bis-DMC) present in abiotic control samples in mMCB (Figure 5A,C,E) and in mMCB with PCF (Figure 5B,D,F) did not change at the start and end of fermentation. This may be expected as curcumin is stable at the pH of the fermentation

[a]The values for the amounts have been corrected for the recoveries of compounds and represent the amount present in 10.1 mL of fermentation medium. This was 80% for curcumin, DMC, Bis-DMC, and FA, as determined from separate spiking experiments. As curcumin−L-cysteine was not commercially available, spiking experiments could not be carried out, and the values are those as determined without correction for recovery. Means with the same letters within the same row are not significantly different. [b]Curcuminoid equivalents (equiv) were calculated assuming the following: (i) 1 mol of curcumin gives 2 mol of FA and 1 mol of DMC gives 1 mol of FA. (ii) The initial curcuminoid mixture contained 80.1:15.6 (curcumin/DMC); therefore, FA obtained from this mixture on a molar basis would be 1.837. [c]Curcuminoid equivalents (equiv) were calculated assuming 1 mol of curcumin gives 1 mol of curcumin−L-cysteine. [d]Percent curcuminoids accounted for {[$\mu$mol of remaining curcuminoids + $\mu$mol FA/1.837) + $\mu$mol curcumin−L-cysteine)]/(initial $\mu$mol curcumin + initial $\mu$mol DMC + initial $\mu$mol Bis-DMC)} × 100.

media (pH 6.00−6.27 over the fermentation course of 36 h). It is only at pH >7.5 that curcumin is unstable.[25,26] The absence of an observable change in abiotic samples shows that there is no chemical degradation of curcuminoids over this time and confirms that any change in curcuminoids in the presence of the cultures is the result of bacterial metabolism.

The degradation profiles of curcuminoids (curcumin, DMC, and Bis-DMC) in the presence of bacteria over the 36 h fermentation period are also shown in Figure 5. In the absence of PCF, a decrease in curcumin was observed until about 8−10 h, coincident with the onset of the stationary phase (Figure 1); the level of curcumin then stayed relatively constant until 36 h (Figure 5A), whereas with PCF, the level of curcumin decreased until around 12 h and then stayed relatively constant until 36 h (Figure 5B). A slight decrease was also observed in the amounts of DMC and Bis-DMC following 36 h of fermentation, as demonstrated in Figure 5C,D and E,F, respectively.

The initial measured amounts of curcuminoids in fermentation cultures at 0 and 36 h are given in Table 3. The significant differences between the ability of the three bacterial strains to degrade curcuminoids in mMCB with or without PCF at 36 h were compared. The ability of all three strains to convert curcumin, in mMCB media with or without PCF, was in the order E469 > E10B ∼ E739. Whereas E469 degraded 37.3% of curcumin, which is significantly higher ($p < 0.05$) than that with E739 (19.9%) and E10B (20.8%), there were no significant differences ($p > 0.05$) between degradation by E739 and E10B in the absence of PCF. Similar results were obtained in the presence of PCF, where curcumin conversion was significantly higher ($p < 0.05$) with E469 (23.2%) compared to E739 (15.8%) and E10B (16.1%). The effects of PCF addition on curcumin degradation were strain dependent. In the presence of PCF, the degradation of curcumin by E469 was significantly reduced ($p < 0.05$). However, the addition of PCF had no significant effect ($p > 0.05$) on the ability of E739 and E10B to degrade curcumin.

The amounts of DMC altered in the fermented cultures for all strains in mMCB were not significantly different ($p > 0.05$). This was also the case for all strains in mMCB with added PCF (Table 3). The change in the amount of DMC in the presence of E739 was significantly higher ($p < 0.05$) in mMCB (16.3%) than in mMCB with added PCF (5.7%), but changes in DMC amounts were not significantly affected by the addition of PCF ($p > 0.05$) when E469 or E10B was used.

The amount of Bis-DMC in mMCB changed by E10B (14.8%) was significantly higher ($p < 0.05$) than that changed by E469 (7.2%), but there were no significant differences ($p > 0.05$) between E739 and E469. The ability of all three strains to convert curcumin in mMCB was in the order E10B > E739 ∼ E469. The changes in the amounts of Bis-DMC in the presence of all three strains were not significantly different ($p > 0.05$) in mMCB with

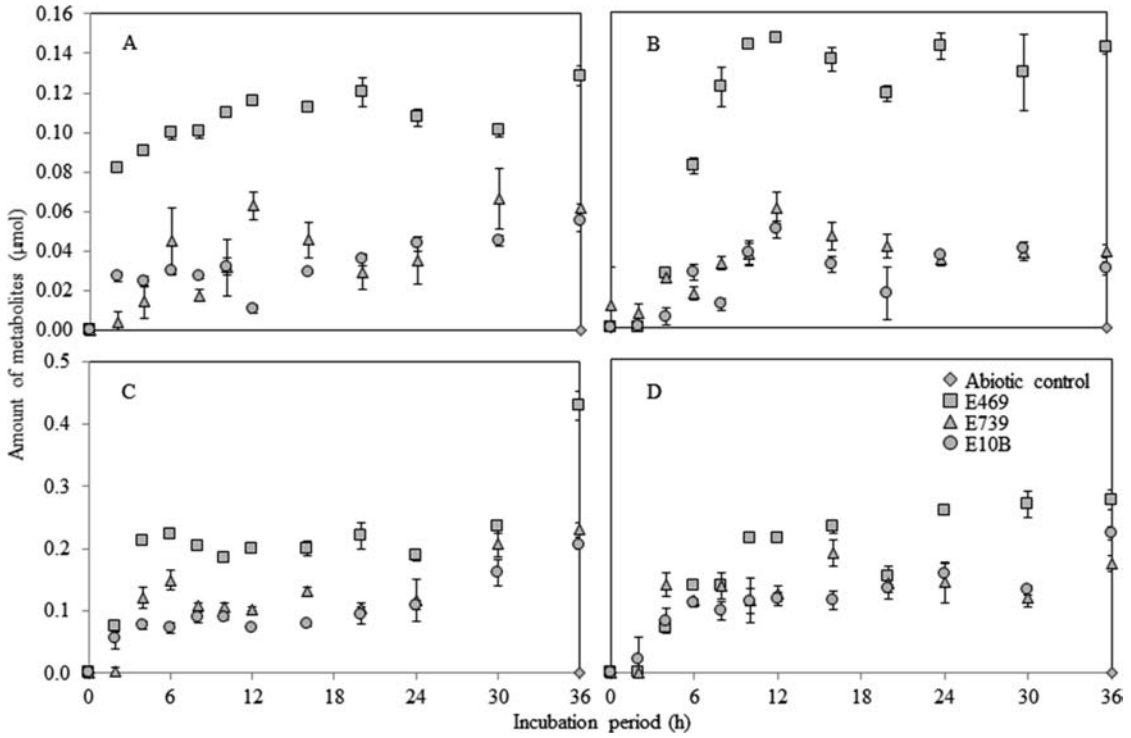

**Figure 6.** Measured amounts of FA (A, B) and curcumin adduct (curcumin−L-cysteine) (C, D) during fermentation with *Escherichia fergusonii* (E469), *E. coli* 739 (E739), and *E. coli* DH10B (E10B) in mMCB without PCF (A, C) or with PCF (5%, v/v) (B, D). The amount of FA and curcumin adduct (curcumin−L-cysteine) in the upper organic extracts were quantified using LC-MS/MS and expressed as total micromoles in experimental broth of 10.1 mL. Each data point is the average of three biological replicates ± SD.

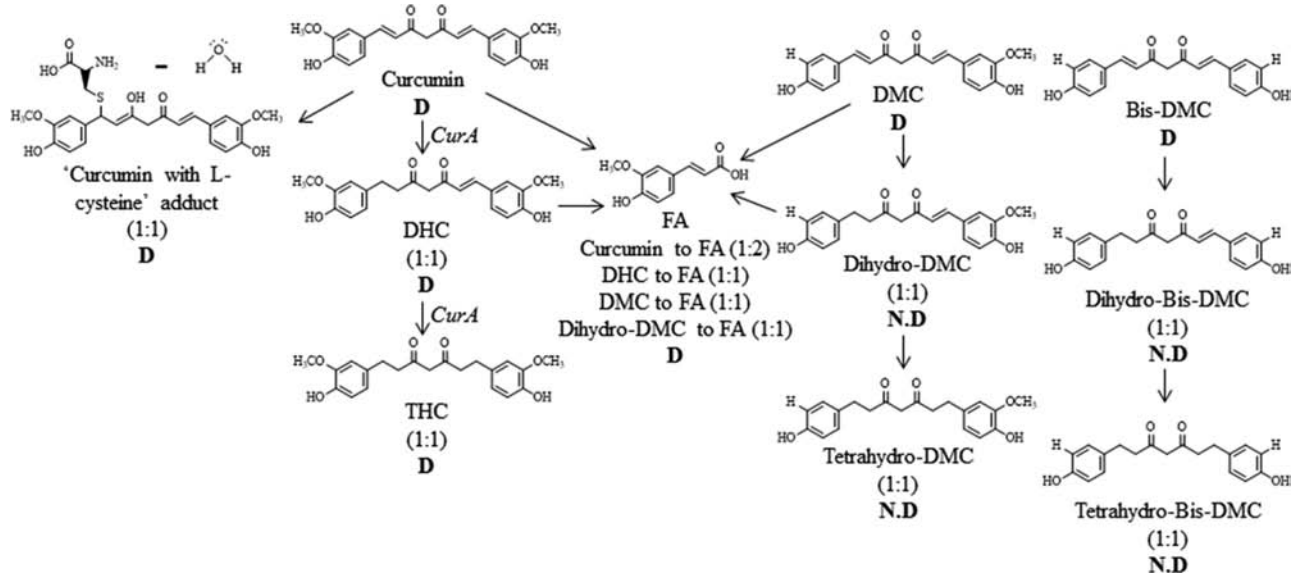

**Figure 7.** Proposed degradation of the three curcuminoids (curcumin, DMC, and Bis-DMC) and breakdown products formed by *Escherichia fergusonii* (E 469), *E. coli* 739 (E739), and *E. coli* DH10B (E10B). Numbers in parentheses represent the theoretical conversion of curcuminoids to metabolites. D, detected; N.D, not detected in this study.

added PCF. The ability of E469 and E739 to convert Bis-DMC was not significantly affected by the addition of PCF ($p > 0.05$). However, a significant increase ($p < 0.05$) was observed for changes in Bis-DMC when PCF was not added to mMCB in the presence of E10B (14.8% compared from 9.6%).

*Quantification of Compounds Formed in Fermentation Cultures with Curcumin.* DHC and THC were minor metabolites of curcumin degradation, and they constitute <1% of the total metabolites recovered. The formation of FA and curcumin−L-cysteine during fermentation is shown in Figure 6, and the amounts quantified after 36 h are given in Table 3. In mMCB without PCF, the formation of FA by E469 (0.07 μmol) was significantly higher ($p < 0.05$) than the amounts formed by E739 and E10B (0.03 μmol), but there were no significant differences ($p > 0.05$) between E739 and E10B. In mMCB with PCF, the formation of FA by E469 (0.08 μmol) was also significantly higher ($p < 0.05$) than that by E739 and E10B (0.02 μmol), but there were no significant differences ($p > 0.05$)

dx.doi.org/10.1021/jf5031168 | J. Agric. Food Chem. 2014, 62, 11005−11015

between E739 and E10B. The formation of FA by E469 in the presence of PCF (0.08 μmol) was significantly higher ($p < 0.05$) than in mMCB alone (0.07 μmol). The formation of FA by E739 and E10B in the presence of PCF (0.02 μmol) was significantly lower ($p < 0.05$) than in mMCB alone (0.03 μmol).

In mMCB without PCF, the formation of curcumin−L-cysteine by E469 (0.43 μmol) was significantly higher ($p < 0.05$) than those by E739 (0.23 μmol) and E10B (0.21 μmol), but there were no significant differences ($p > 0.05$) between E739 and E10B. In mMCB with PCF, the formation of curcumin−L-cysteine by E469 (0.28 μmol) was significantly higher ($p < 0.05$) than those by E10B (0.22 μmol) and E739 (0.17 μmol). In the same medium, the formation of curcumin−L-cysteine by E10B was also significantly higher ($p < 0.05$) than that by E739. The formation of curcumin−L-cysteine by E469 and E739 in the absence of PCF (0.43 and 0.23 μmol, respectively) was significantly higher ($p < 0.05$) than in the presence of PCF (0.28 and 0.17 μmol, respectively). The formation of curcumin−L-cysteine by E10B was not significantly different ($p > 0.05$) in the absence (0.21 μmol) or presence of PCF (0.22 μmol).

*Accountability for Curcuminoids.* The amount of curcumin accounted for was also calculated and found to be 87−94%. The amount of curcumin accounted for was not significantly different ($p > 0.05$) between the three *Escherichia* bacteria in mMCB or mMCB with PCF (Table 3). However, the amount of curcumin accounted for E469 in the presence of PCF (92.6%) was significantly higher ($p < 0.05$) than in the absence of PCF (86.8%), but there were no significant differences ($p > 0.05$) for E739 and E10B in the presence or absence of PCF. The level of accountability, which represents remaining curcuminoids (curcumin, DMC, and Bis-BMC) and curcuminoid equivalents for conversion into ferulic acid and curcumin−L-cysteine, is high. In a different system, when curcuminoids were incubated with rat liver slices, there was ∼50% of curcumin and DMC and ∼75% for Bis-DMC accounted for.[11] These authors attributed the lack of accountability for the total amount of curcuminoids to possible spontaneous chemical degradation in aqueous solution and conversion to other breakdown products that were not detected by the methods used.[11]

**Proposed Pathways of Degradation of Curcuminoids by Bacterial Strains Examined.** The proposed pathways of degradation of the three curcuminoids are demonstrated in Figure 7. Curcumin is converted to DHC and then THC by the enzyme *CurA*, through the reduction of C═C bonds on the heptadienone chain.[19] In studies involving ingestion of curcumin in humans and animals it was found that this pathway was rapid and that curcumin and metabolites were subsequently glucuronidated or sulfated by enzymes present in the liver.[10,11]

Both curcumin and DHC can also be converted to FA, as shown in Figure 7. FA was found to be one of the major metabolites in the serum, urine, and feces of humans after consumption of encapsulated curcumin in bread, and the authors suggested that the presence of FA was probably as a result of gut bacteria metabolism.[12] Our data are consistent with this hypothesis.

In our in vitro system, the presence of a curcumin adduct, curcumin−L-cysteine, was also found. This adduct was observed only in fermented samples in the presence of curcuminoids and bacteria and not present in abiotic samples. The adduct was also observed only in spent media where curcuminoids were co-incubated with mMCB, confirming that the presence of bacteria was necessary for the formation of the curcumin adduct. However, from these studies alone it is not possible to assign this to bacterial transformation. It is possible that under the conditions used in this study, the formation of the adduct was due to a chemical reaction induced by the presence of the changed composition of the media due to the formation of bacterial metabolites.

DMC and Bis-DMC follow the same pathway as curcumin, with similar reductive products.[11] Therefore, DMC is predicted to be converted to dihydro-DMC and then tetrahydro-DMC (Figure 7). DMC and dihydro-DMC can also be converted to FA as shown in Figure 7. Furthermore, Bis-DMC is converted to dihydro-Bis-DMC and then tetrahydro-Bis-DMC (Figure 7). Metabolites from DMC and Bis-DMC degradation were not detected in this study, probably due to the lower concentration of these compounds in the starting material.

Pure culture experiments provide insights into possible products formed by bacteria in the presence of curcuminoid. Our studies have demonstrated that the metabolism of curcuminoids (curcumin, DMC, and Bis-DMC) by three different *Escherichia* bacteria in vitro in batch culture resulted in the metabolism of curcumin to DHC, THC, and FA. In addition, the formation of a curcumin adduct (curcumin−L-cysteine) was also observed. Although the result obtained is fundamental, it is limited to the capability of *Escherichia* bacteria to metabolize curcuminoids. Further in vitro studies should be expanded to include the incubation of curcuminoids with a complex microbial population such as fecal samples to determine any differences in metabolism and metabolite production. It is also necessary to carry out in vivo trials to ascertain whether similar microbial metabolites and a curcumin adduct are formed under conditions in the body where there is consortia of microbes in the lower gut environment. Our data contribute to a possible map of curcumin breakdown products and show the relative abundance of different curcumin metabolites. The methods presented here will facilitate further studies of these pathways, including the flux of metabolite production under biologically relevant conditions.

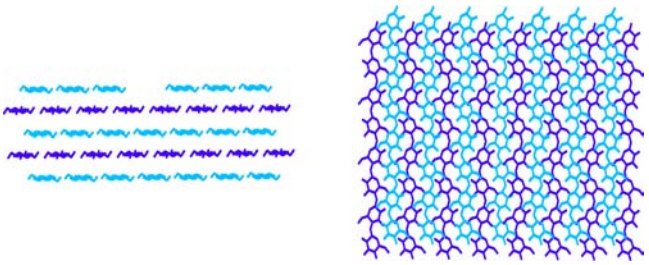

**Figure 1.** End-on (left) and "bottom" (right) views of the initial structure of the cellulose microcrystallite simulated in this study. As one can see from the end view, the center chain on the upper 100 surface has been removed. The analysis of the water structuring over the 100 surface reported here thus was confined to the uninterrupted "bottom" surface.

## EXPERIMENTAL PROCEDURES

The MD simulations reported here were conducted in the *NPT* ensemble using the CHARMM molecular mechanics program.[11,12] The sugar atoms were modeled using parameters specifically developed for carbohydrates, denoted as CSFF.[13,14] Water molecules were represented using the modified TIP3P force field.[15,16]

The initial cellulose structure for the simulations was taken from the reported native cellulose I$\beta$ crystal structure.[6] It thus differs significantly from that apparently used by Biermann et al. in that all exocyclic C6 primary alcohol groups were initially set in the TG conformation.[1] The cellulose model consisted of 36 chains, each with a degree of polymerization of eight, arranged into a small microcrystallite as shown in Figure 1. This microcrystallite consisted of five layers of parallel chains, with three even layers and two odd layers. The two odd layers contained eight chains each, and two of the even layers had seven chains each; the third consisted of only six chains, with the central chain removed, to model the effects on solvent structuring from the removal of a single chain, which might occur in the hydrolysis conducted by a processive exocellulase. In this model, the "top" and "bottom" of the microcrystallite consisted of approximately planar 100 surfaces, which permitted an analysis of how water interacts with this hydrophobic surface. Deletion of the middle chain of the "top" 100 even layer created a trough ~8 Å wide and ~4 Å deep that ran the length of the crystal. Chain numbers were assigned as chains 1−36 from the left on the first layer of the cellulose crystal. The constructed microcrystallite was placed in an equilibrated cubic box of TIP3P water molecules with a box length of 73.8 Å. All those water molecules that overlapped with the carbohydrate heavy atoms were deleted. The simulation contained 11821 water molecules and 41619 atoms in total. For the purpose of comparison, a simulation of $\beta$-D-glucopyranose in aqueous solution using the same carbohydrate force field and water model was also conducted to analyze how water molecules orient over an individual glucose monomer.

Chemical bonds to hydrogen atoms were kept fixed using the general constraint algorithm SHAKE.[17,18] van der Waals interactions were smoothly truncated on an atom-by-atom basis using switching functions from 12.0 to 14.0 Å.[11] Electrostatic interactions were treated using the particle-mesh Ewald method[19] with a real space cutoff of 15 Å and a $\kappa$ value of 0.3 Å$^{-1}$. The simulation was run at a constant temperature of 300 K and a constant pressure of 1 atm, maintained using a Hoover constant pressure/temperature algorithm, with a Hoover piston mass of 2000 amu.[20−22] Initial velocities were assigned from a Boltzmann distribution at 300 K, and the trajectories were run for 11 ns with a step size of 1 fs using full periodic boundary conditions. The last 10 ns of the simulation time was used for analysis. This simulation time is more than adequate to allow complete convergence of the water structuring[23] but is not long enough to allow the crystallite to undergo the structural transition that is known to occur with all of the highly developed carbohydrate force fields.[24]

Molecular graphics were generated with Visual Molecular Dynamics (VMD1.9),[25] and atomic density analyses of the trajectories were calculated using this program.[25] For each saved frame of the trajectory, a coordinate transformation was conducted so that the positions of the water molecules could be specified relative to the crystal surfaces in a coordinate frame fixed on its center of mass. The solvent density was then averaged relative to bulk solvent density. Average orientational and distributional properties were analyzed for those water molecules located in cylinders above the 100 crystal face with positions defined and located as shown in Figure 2, to evaluate the structuring influences

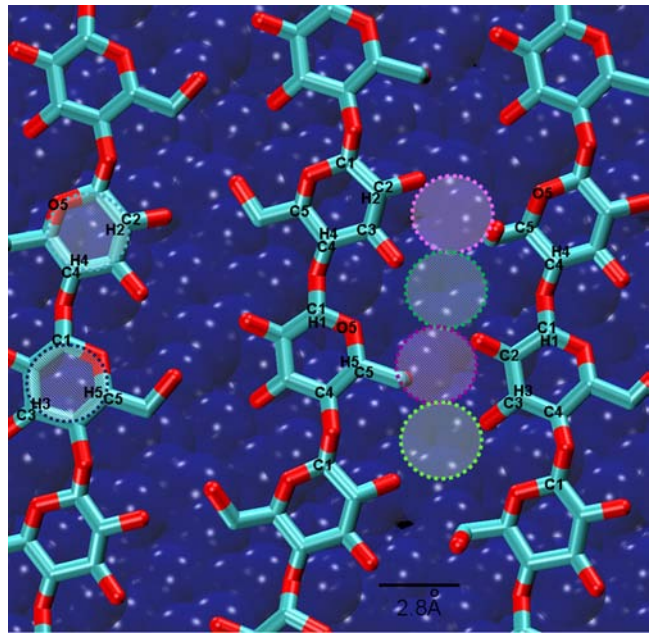

**Figure 2.** Illustration of the central portion of the "bottom" surface of the simulated microcrystal, illustrating the atom labeling employed as well as the footprints of the six cylindrical volumes for which orientational structuring was computed. Only carbon and oxygen atoms are shown for the sake of clarity, but the locations of the nonpolar H1, H2, H3, H4, and H6 hydrogen atoms are indicated by labels located on the appropriate carbon atoms. Also indicated is the coloring scheme used to distinguish these regions in subsequent figures: black, above the glucose H1−H3−H5 plane; turquoise, above the glucose H2−H4 atoms; dark purple, between two residues (O5−C5−C2−C3); pink, between two residues (C2−C3−O5−C5); dark green, among four residues (C4−C1−C4−C1); light green, among four residues (C4−C1−C4−C1).

of different features on the surface, including directly over both types of faces in the chains and over several positions in the more polar grooves between the chains. The same color schemes used in Figure 2 for these different regions are employed in Figures 5 and 7 to distinguish the behaviors of water molecules over the various parts of the surface.

## RESULTS AND DISCUSSION

Because the chains that make up the microcrystallite were completely unconstrained in these simulations, the entire crystal quickly developed a twist as the individual chains distorted away from the flat 2-fold screw geometry of the crystal structure (Figure 3). Such twisting has been observed in previous simulations of this crystal structure with all three of the most commonly used molecular mechanics force fields (CHARMM, GLYCAM, and GROMACS).[8,24,26] To minimize edge effects on the calculated local density profiles, only the volume above the middle three chains of the 100 face was used, and only for the middle four residues of these chains, as shown in Figure 2. Over this approximately square area, the solvent

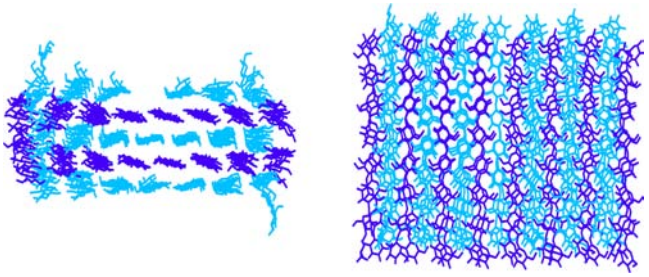

**Figure 3.** End-on (left) and "bottom" (right) views of the instantaneous final structure of the cellulose microcrystallite simulated in this study, illustrating the twist that developed in the crystal.

density and orientation were characterized in various cylindrical subvolumes centered over specific locations on the surface, as indicated in Figure 2. These volumes were selected to sample the effects of both types of faces of the monomer rings, as well as different portions of the hydrophilic, hydrogen-bonded groove between the chains. Because the twist in the substrate surface is minimal over the center of the surface, its effects on the calculated densities are also minimal and would primarily arise at long distances, where the overlap with the edges of similar adjacent cylinders would be greatest, but are of less interest because of the distance from the surface.

As one would expect for this topologically complex surface, the average density of neighboring water molecules varied with position over the surface as well as with distance from the surface. Figure 4 illustrates examples of the variation in solvent density as a function of distance from the surface in cylinders located at various places in the crystal face, including over the H2−H4 face (Figure 4a), over the H1−H3−H5 face (Figure 4b) of a glucose ring, and over two different spots between different chains (Figure 4c,d). Even within most of these cylindrical volumes, the density varies across the diameter of the cylinder, reflecting the changes in the underlying molecular geometry. For example, for the cylinder over the H2−H4 face (Figure 4a), it can be seen in the figure that the water molecules approach the ring more closely over the O5 atom on the right side of the cylinder, to which they can weakly hydrogen bond, than they do over the nonpolar H2 and H4 atoms that point directly up and prevent the closer approach of solvent.

The density over the H1−H3−H5 face is more uniform (Figure 4b) and clearly indicates two pronounced nearby layers, as does the density over the H2−H4 face, with a clear minimum between layers. The decreased density between the second and third layers is harder to detect in these figures. The density between the O2−O6 interchain hydrogen bond penetrates most closely between the hydroxyl groups (Figure 4c), as would be expected. The density between the chains, but not centered over any hydroxyl groups (Figure 4d), is more complex. Note that the fact that the edges at longer distances do not exhibit higher densities in any of these cylinders indicates that the twist of the surface is not significantly affecting the calculated densities.

Figure 5 displays the averaged solvent density in the various cylinders whose bases are illustrated in Figure 2 as a function of distance above the average plane defined by the sugar rings. As one can see, these distributions fall into three groups: those centered over the glucose rings, with first peaks located around 3.7 Å, those centered between the O2 and O6 groups of different chains, and those centered between the O2 and O3 groups of different chains, where the water molecules can

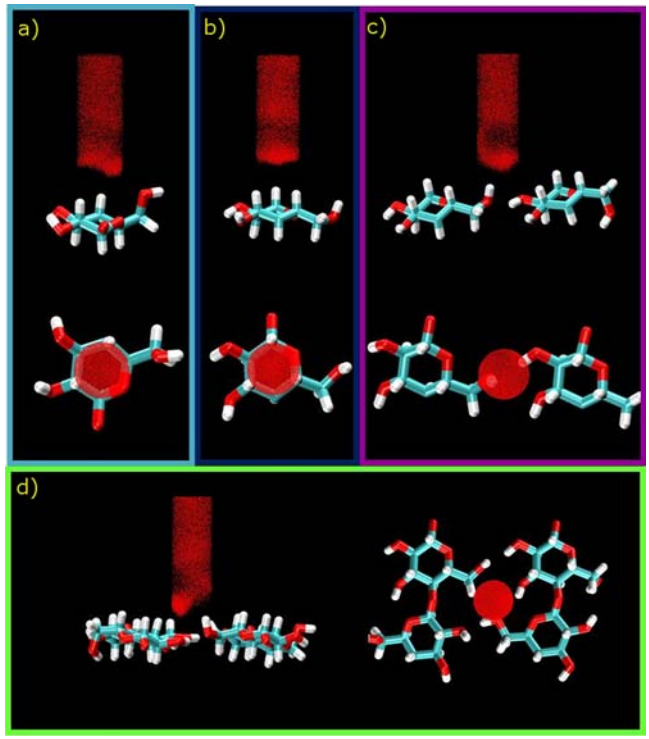

**Figure 4.** Examples of the variation in density in selected cylinders located over different positions in the surface, as seen from top and sides: (a) centered over the H2−H4 face of a glucose monomer, (b) centered over the H1−H3−H5 surface of a glucose ring, (c) centered over the HO2−O6 hydrogen bond between chains, and (d) centered over a region between the interchain hydrogen bonds. The red dots represent water oxygen positions at regular intervals over the entire simulation.

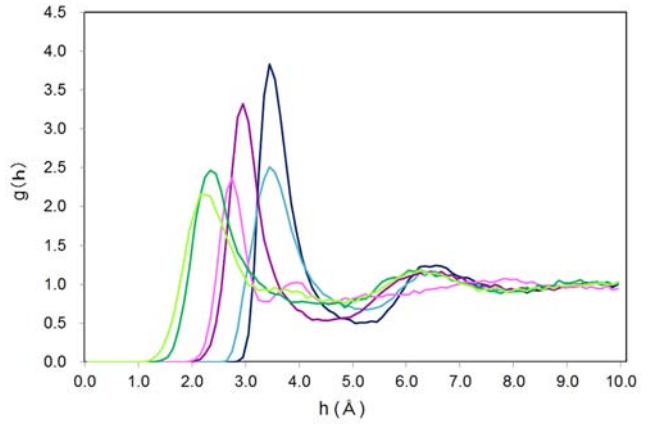

**Figure 5.** Solvent density profiles in the cylinders centered over various positions in the average crystal face: black, above the glucose H1−H3−H5 plane; turquoise, above the glucose H2−H4 atoms; dark purple, between two residues (O5−C5−C2−C3); pink, between two residues (C2−C3−O5−C5); dark green, among four residues (C4−C1−C4−C1); light green, among four residues (C4−C1−C4−C1).

approach much more closely, with first peaks centered around 2.0−2.2 Å. Note that all of these distributions exhibit distinct second peaks but with significantly lower amplitudes, and no longer-range structure. Uniquely among these distributions, that for the cylinder centered between the O2 hydroxyl of the center chain and the O6 hydroxyl of the outer chain, colored pink, exhibits a significant additional peak around 4.0 Å that

dx.doi.org/10.1021/jf501763r | J. Agric. Food Chem. 2014, 62, 11017−11023

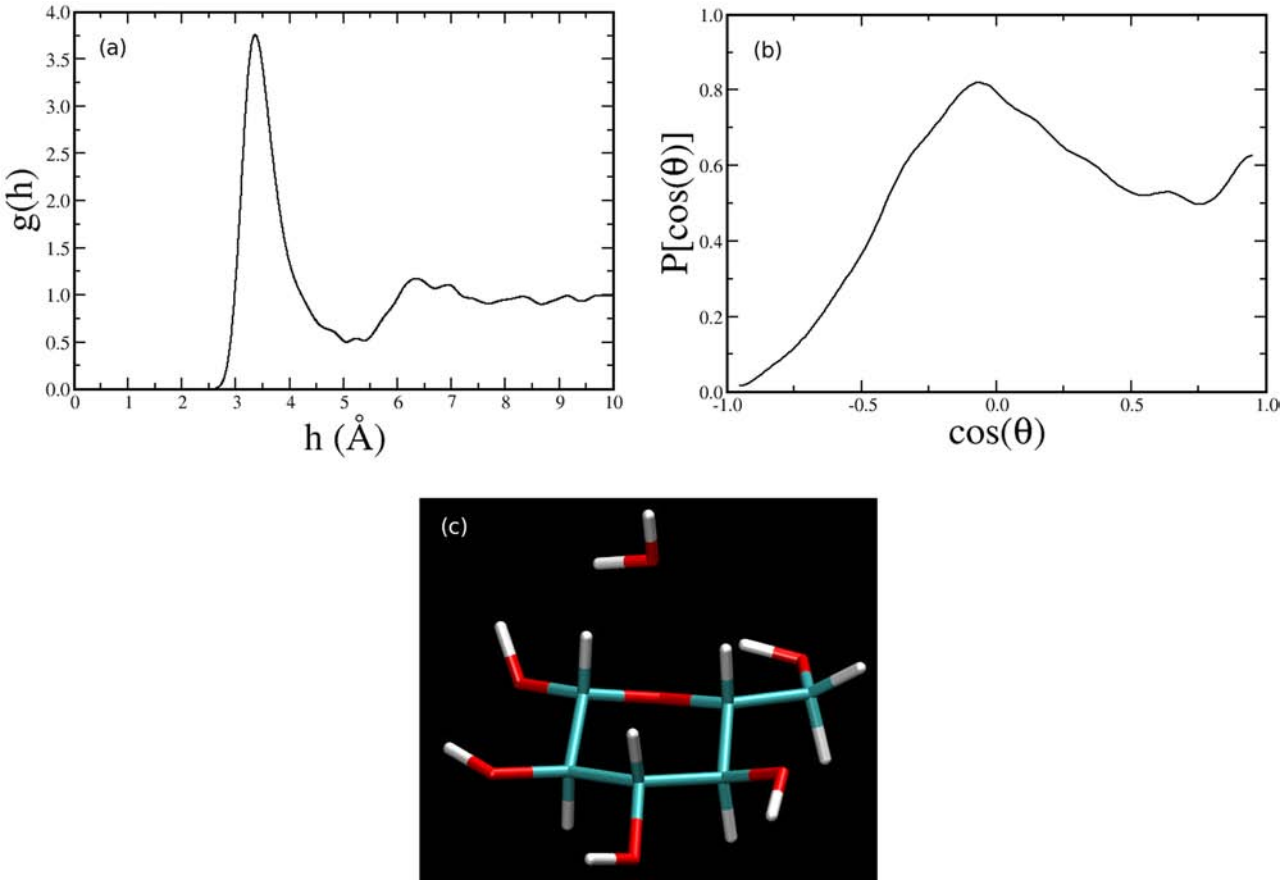

**Figure 6.** (a) Density distribution as a function of distance above the average H1−H3−H5 plane and (b) angular orientational distribution function for water molecules in a cylinder centered over the H1−H3−H5 face of $\beta$-D-glucopyranose in aqueous solution. (c) Typical example of a water molecule over this face with one of its protons pointing directly away from the face.

apparently represents first peak water molecules from the adjacent cylinder centered between the O3 and O2 hydroxyl groups of the same chains. The cylinder centered in this groove between the O2 hydroxyl of the center chain and the O3 group of the outer chain, colored light green, also exhibits a similar but less distinct shoulder at the same distance. In general, sharp narrow peaks in radial distribution functions are a signature of hydrogen bonding, while lower-magnitude, broader peaks generally are taken to indicate nonspecific packing (it should be remembered, however, that the density profiles shown in Figure 5 are not radial distribution functions). None of the density distributions seen in Figure 5 display the conventional structure of either hydrophilic or hydrophobic radial distribution functions.

Recent theories of the hydration of nonpolar species have found that extended planar surfaces should hydrate in a manner different from that of smaller hydrophobic molecules.[27−31] For hydrophobic solutes with a small spatial extent and a high convex curvature, such as methane or methylene, water molecules in the first "hydration shell" can straddle the solute to make hydrogen bonds to other water molecules off to the sides, with neither their protons nor lone pairs directly pointing at the solute, which would involve the loss of a hydrogen bond.[32] The cost of this structuring is entropic, because the translational and rotational freedom of the water molecules is restricted. As a result, such species are driven to aggregate in aqueous solutions,[33] which liberates water molecules to regain their motional freedom. The calorimetric signature of this type of hydrophobic aggregation at room temperature is that it is entropy-driven, with a heat capacity change that is negative, because the initial solvation of such hydrophobic species is accompanied by an increase in the level of solvent structuring and thus heat capacity.

However, as the spatial dimensions of hydrophobic species increase, it becomes impossible for water molecules to straddle the hydrophobic surface and still make hydrogen bonds to other water molecules off to its sides.[9,34−37] Under these conditions, the water molecules point one hydrogen atom or lone pair directly at the hydrophobic surface,[9] because the resulting loss of one hydrogen bond is nevertheless energetically better than the loss of the two or three hydrogen bonds that would result if they adopted the orientation of waters adjacent to a methane molecule.[9,29,34,37,38] The aggregation of such extended surfaces in aqueous solution would then be enthalpically dominated, because the pairing of two such surfaces would allow the liberated water molecules to regain their lost hydrogen bonds as well as their motional freedom. Orientational structuring of this type has been observed in simulation studies of extended featureless surfaces as well as of benzene and silica.[9,31,33,35,39] It has been demonstrated that there is a gradual transition from entropic to enthalpic domination of the solvation free energy as a function of size for the case of a spherical cavity, with a characteristic length scale for the transition of ∼1 nm.[28,29] This type of hydration also results in a depletion of water molecule density close to the hydrophobic surface, unlike the case for the small spherical

solutes such as methane, where there is a peak in water density at approximately the contact distance,[38] so that the hydration of these surfaces is characterized by a dewetting, with a more extended zone from which water is excluded.[29,31]

The nonpolar H1−H3−H5 triad face of a single glucose molecule in the $^4C_1$ conformation presents a rather limited hydrophobic surface to adjacent water molecules, with the average length of the sides of this triangle being only ∼2.5 Å. Thus, water molecules directly over this face can straddle this hydrophobic surface much as they would a smaller convexly curved nonpolar species like methane, making hydrogen bonds to other water molecules off to the side of the sugar ring, including those that might also be hydrogen bonding to the sugar's hydroxyl groups, and thus approach the surface more closely. This similarity to the hydration of methane can be seen in the density distribution function for water oxygen atoms above the H1−H3−H5 plane (Figure 6a), which strongly resembles the radial density distribution function for water molecules above the approximately spherical methane.

As is also the case for water molecules around a hydrated methane,[38] the first neighbor water molecules in the simulation of a single β-D-glucopyranose molecule in solution tend to point one of their protons directly away from the surface as shown in Figure 6c for a typical instantaneous "snapshot" example. This tendency can be characterized quantitatively using an orientational probability distribution function for the O−H bonds of the water molecules, calculated as the probability of observing an angle $\theta$ between the bond vector and the normal to the surface from the oxygen atom. Figure 6b displays this orientational distribution function $P[\cos(\theta)]$ [plotted as a function of $\cos(\theta)$ to eliminate cosine law effects], which exhibits a peak at +1 (i.e., $\theta = 0$), indicating a proton pointing directly away from the surface, with the other proton then oriented at a tetrahedral angle, producing the broad central peak in the distribution centered between −0.33 (the tetrahedral angle) and 0. The weakness of the peak at +1, and both the broadness and shift toward 0 of the maximum of the position of the central peak of the distribution, as compared to a more classical nonpolar distribution for solutes like argon or methane,[38] are a reflection of the larger extent of the flat hydrophobic surface here, compared to that of methane, requiring the water molecules to shift off-center and tilt to accommodate the hydrogen bonds to other water molecules. Nonetheless, this orientational behavior for a single glucose molecule qualitatively strongly resembles that for solvated methane and hydrocarbon chains.

Embedding such a glucose monomer in a cellulose chain, however, and then packing that chain into a 100 face of a cellulose crystal, presents the nearest neighbor water molecules with a significantly different topological landscape. The effects of this different surface have been characterized previously in terms of the anisotropic density distribution of water molecules over the surface,[8] but not in terms of their orientations. In the troughs between the chains, made up of the hydrogen-bonding hydroxyl groups, water molecules can approach more closely as they also attempt to hydrogen bond to these groups, as reflected in the density distributions illustrated in Figure 5. Angular orientational distribution functions for water molecules in the cylinders centered over different regions of the cellulose surface were calculated for those first-layer water molecules closer to the surface than the first minimum in each individual distance distribution, as shown in Figure 5, and are plotted in Figure 7. As one can see in this figure, the water molecules

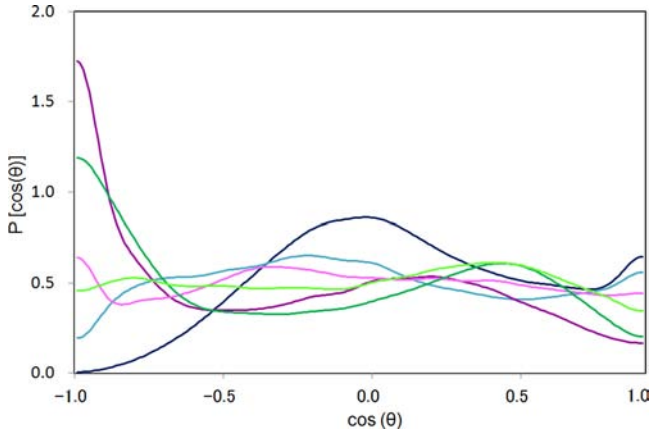

**Figure 7.** Orientational distribution function $P[\cos(\theta)]$ as a function of $\cos(\theta)$ for water molecules in selected regions above the 100 surface of the crystallite: black, above the glucose H1−H3−H5 plane; turquoise, above the glucose H2−H4 atoms; dark purple, between two residues (O5−C5−C2−C3); pink, between two residues (C2−C3−O5−C5); dark green, among four residues (C4−C1−C4−C1); light green, among four residues (C4−C1−C4−C1).

centered over the H1−H3−H5 face of the cellulose monomers exhibit the same sort of hydrophobic orientational structuring as for the free glucose molecule (Figure 6), which again qualitatively resembles that for methane, indicating that these ribbons of hydrophobicity are not acting like more extended hydrophobic surfaces (where a proton would be pointing directly at the surface), but more like the hydrocarbon chains of a fatty acid. Qualitatively similar behavior is seen for the H2−H4 face, but with a lower peak maximum at +1; in this case, the orientational structuring is even weaker.

For water molecules located in some of the cylinders centered between the chains, over the hydrophilic troughs occupied by the hydroxyl groups, strong orientational structuring is seen, particularly for the cylinders indicated in Figure 7 by purple and green, while for the other two there is very little structuring. This is somewhat surprising because these volumes are essentially equivalent positions. In these distributions, a hydrogen atom is directed down toward the surface to make a hydrogen bond to one of the glucose hydroxyl groups, as indicated by the peaks in the angular distribution function at $\cos(\theta) = -1$, the opposite of that seen in Figure 6. This orientational effect is much stronger than the nonpolar structuring, because of the strength and geometric requirements of the hydrogen bonds to the cellulose.

Recently, we demonstrated that the special water solvent structuring above extended flat surfaces is a dominant factor in the aggregation of the planar purine molecule caffeine in aqueous solution.[36] Although caffeine is <1 nm in size, in a narrow volume over the center of the molecular plane, water molecules indeed are unable to straddle the plane and make hydrogen bonds to water molecules around the periphery of the ring. Solvent molecules in this small volume point one hydrogen atom or lone pair directly at the center of the caffeine solute, even though this entails the loss of a hydrogen bond. The liberation of this structured water molecule when the face of caffeine binds to another molecule drives the association of caffeine with hydrophobic solutes, including other caffeine molecules, and from calorimetry, it is known that such aggregation is enthalpically dominated.[40,41]

Another study has found that in MD simulations of β-D-glucopyranose, the monomer repeat unit of cellulose, interacting in aqueous solution with indole, the side chain of the amino acid tryptophan, and the triad of H1−H3−H5 hydrophobic protons in glucose exhibited a pronounced tendency to bind to the flat hydrophobic face of the indole, with an association energy of approximately 1.2 kcal/mol.[42] Similar binding of glucose to caffeine has also been observed, with a very similar binding energy,[43] and glucose has been shown to bind to tryptophan side chains in cellulases and other proteins.[42,44−46] Thus, the hydration of planar surfaces like those in tryptophan, phenylalanine, and tyrosine may play an important part in molecular recognition involving protein−carbohydrate interactions. However, from these results, it appears that this is a property of these larger planar surfaces alone but is not a characteristic of the H1−H3−H5 hydrophobic triad of the $^4C_1$ conformation of the β-D-glucopyranose monomer that constitutes the largest part of the hydrophobicity of the cellulose 100 surface. As evidence of this observation, it should be noted that at normal biological concentrations glucose molecules do not exhibit any significant tendency to self-associate, and to the extent that they do interact at high concentrations (1.5 mol $kg^{-1}$), it tends to be by hydrogen-bonding interactions rather than by pairing of these triad faces.[47]

A significant factor contributing to the insolubility of cellulose is the fact that the chains exhibit considerable hydrophobicity, with nonpolar "tops" and "bottoms" in the extended 2-fold screw conformation of the reported crystal structure. These hydrophobic faces constitute the bulk of the exposed area of the 100 crystal surface. However, while the total surface of a crystalline cellulose fibril can be extensive, with diameters in the tens of nanometers, these surfaces are structurally very complex, and predominantly hydrophilic, with the hydrophobic 100 faces constituting only a portion of the fibril surface. Even this 100 surface is not completely hydrophobic, because the grooves between the chains are lined with the hydrogen-bonding hydroxyl groups of the monomers. Thus, the 100 surface exhibits a complex character with alternating hydrophobic and hydrophilic bands, rather than a single extended hydrophobic plane, and with the hydrophobic bands raised slightly higher than the average surface plane and the hydrophilic bands recessed slightly lower. Although the fibrils are quite large, the hydrophobic nature of their interactions with water more resembles that of the hydration of lipids than that of larger hydrophobic surfaces, as characterized by the orientational effects of these hydrophobic regions on the adjacent water molecules, and apparently does not involve the form of structuring seen in planar hydrophobic species like indole and the purines, in spite of its larger size. These results also might seem to suggest that the aggregation of cellulose chains and microfibrils by hydrophobic association would be dominated by entropy, as is the case of methane and lipids, rather than enthalpy, as is the case for caffeine aggregation. However, in the case of the aggregation of cellulose chains into layers such as those seen in the reported crystal structure, the water molecules hydrogen bonded to the hydroxyl-lined grooves between the chain would also be excluded by the aggregation, with the enthalpic cost due to the loss of these hydrogen bonds disfavoring aggregation. Because cellulose is not soluble, this factor is evidently smaller than the hydrophobic contribution, but this contribution to the energetic balance sheet for cellulose chain aggregation was not examined in our previous calculation of the factors contributing to cellulose insolubility.[2]

Finally, it should be remembered that the system simulated here is highly idealized; it is quite small and does not have the quasi-cylindrical cross section that might be expected for a real microfibril. In addition, any rotations of the primary alcohol groups to the GG orientation, perpendicular to the ribbon plane, particularly if they are randomly distributed, would significantly complicate the surface hydration patterns, as described by Biermann et al.[1] Additionally, real *in vivo* microfibrils might interact not only with other cellulose microfibrils but also with hemicellulose and lignin in ways that would further complicate hydration patterns. The hydration patterns seen here may help rationalize how such interactions arise.

the farm and its surroundings was conducted daily. All experiments with ostriches were performed according to protocols approved by the Huazhong Agricultural University Animal Care and Utilization Committee.

**Experimental Diets and Nutrient Levels.** The ostriches were fed with a blend of custom-made premix diet and pak choi based on their physiological needs, developmental stage, and breeding experience.[15] Moreover, to aid in digestion, some sand must be added in sufficient but not excessive quantities.[16] The nutrient composition of the diets and of each ingredient is reported in Table 1.

**Table 1. Ingredients and Composition of the Basal Diets[a]**

| ingredients | content (g/kg) | chemical composition | content (g/kg) |
|---|---|---|---|
| custom-made premix | 670 | crude protein | 193 |
| pak choi | 330 | lysine | 10.0 |
| | | cystine | 3.90 |
| | | crude fiber | 76.5 |
| | | crude fat | 29.1 |
| | | methionine | 3.41 |
| | | ash | 87.8 |
| | | metabolic energy | $2.94 \times 10^3$ kcal |
| | | boron in premix | 1.78 mg |
| | | boron in pakchoi | 2.45 mg |

[a]Supplied per kilogram of diet: 6.30 g of phosphorus, 14.7 g of calcium, 80.0 mg of manganese, 500 mg of magnesium, 11.0 mg of copper, 87.0 mg of zinc, 0.27 mg of selenium, 3.00 mg of iodine, 150 mg of ferrum, 12 000 IU of vitamin A, 3000 IU of vitamin $D_3$, 3.50 mg of vitamin K, 100 IU of vitamin E, 3.50 mg of vitamin $B_1$, 8.10 mg of vitamin $B_2$, 4.00 mg of vitamin $B_6$, 50.4 mg of niacin, 20.9 mg of pantothenic acid, 2.00 mg of folic acid, 0.20 mg of biotin, 1500 mg of choline, and 0.01 mg of vitamin $B_{12}$.

**Sample Collection and Processing.** At 90 days of age, the birds were weighed after a fasting period of 24 h, and cumulative weight gain and feed intake were determined. Using these values, cumulative feed to gain ratios were calculated. Following these measurements, the birds were electrically stunned and terminated in an ostrich abattoir. The iliofibularis muscles were removed from the left and right legs of each carcass, after removal of the external fat and the epimysium. The muscle samples of every ostrich were divided in two; one was kept at 4 °C until the completion of the physical analysis, and the other was frozen at −20 °C for further chemical analysis. Each sample was ground, homogenized, and vacuum-packed in plastic bags.

**Meat Physical Analyses.** At 24 h post-mortem, meat pH was measured on the iliofibularis muscles with a Testo 205 pH meter (Testo AG, Germany), equipped with an insertion glass electrode (calibrated at pH 4.01 and 7.00 at the abattoir temperature). Three readings were made on each sample, and the mean was recorded.

Meat color was measured on 4 cm thick muscle slices (cut 24 h post-mortem), according to the CIE $L^*a^*b^*$ color system (where $L^*$ measures relative lightness, $a^*$ measures relative redness, and $b^*$ measures relative yellowness) using a Colorgard System 2000 colorimeter (Pacific Scientific, Silver Spring, MD). Three measurements were taken per sample at random positions to determine $L^*$, $a^*$, and $b^*$ values; the average of the three readings was used in the statistical analysis.

Drip loss (%) was determined according to the method described by Zhang et al.[17] Briefly, the muscles were cut into 2 × 2 × 2 cm thick slices, weighed, and suspended in individual plastic bags. After storage for 24 h at 4 °C, the samples were removed from their individual bags, dried with absorbent paper, and weighed again. Drip loss was calculated as weight loss expressed as a percentage of the initial weight of the sample.

Cooking loss (%) was determined by placing weighed samples of approximately 100 g into sealed plastic bags and immersing in water at 75 °C (for the sufficient heat penetration without causing excessive denaturation of the collagen present in the meat). Samples were then removed from the water; the bagged samples were allowed to cool in running water to ±25 °C, and then the samples were blotted dry with tissue paper and reweighed. Cooking losses were then calculated by measuring the weight difference before and after cooking, and values were expressed as a percentage of the fresh (uncooked) sample weight.

Warner−Bratzler shear force (WBS) was determined on the same samples used for the cooking loss determination. Cooked muscle was cooled to room temperature, and three cylindrical cores were randomly removed from each cooked sample using a 1.27 cm diameter bore to determine Warner−Bratzler shear force values.[18] The samples were cut parallel to the direction of the muscle fiber to measure the influence of the myofibrillar proteins. Maximum shear force values were recorded for each cylindrical core of cooked muscle (repeated three times), and the mean values attained from the three samples were used in the statistical analysis. A larger value (kg) indicated a greater shear force and therefore tougher meat.

**Meat Chemical Analyses.** Chemical analyses were carried out on meat samples stored at −20 °C. Moisture, fat, protein, and ash contents were assessed according to AOAC standard techniques[19] on minced meat samples after 24 h of thawing at 4 °C.

For fatty acid composition, lipid was extracted according to the method used by Folch et al.[20] on *M. iliofibularis* (5 g of ground meat), after which the lipids were analyzed for fatty acids. Fatty acids were quantified as methyl esters, prepared according to the method described by Butte.[21] Methyl esters were separated on an Agilent model GC-6400 gas chromatograph equipped with a DB-23 capillary column (length 60 m, internal diameter 0.25 mm, film thickness 0.25 μm). The GC program was set to the following conditions: a helium flow rate of 1 mL/min, FID detector at 250 °C, split−splitless injector at 220 °C, and an injection volume of 0.5 mL. The fatty acid methyl esters (FAME) were identified by comparison of the retention times to those of the FAME standards. Fatty acids were expressed as a percentage of total methylated fatty acids.

The determination of cholesterol was performed using the method of Duckett and Wagner.[22] This method involved direct saponification of the samples and extraction of the unsaponifiable compounds with cyclohexane. Samples were separated using a Drug Three Mega bore column (10 m, 0.53 mm) maintained at a constant temperature of 285 °C, with the injector temperature set at 300 °C and detector temperature at 320 °C. Helium was the carrier gas (flow rate: 12 mL/min). The content of cholesterol was quantified using regression equations obtained from cholesterol standards and then corrected using stigmasterol (50 μg/mL) as an internal standard; cholesterol content was expressed as mg/100 g of meat.

**Statistical Analysis.** All of the samples were measured in triplicate; the average of the three values was used in the statistical analysis. Data were analyzed using the SPSS 17.0 software (SPSS Inc., Chicago, IL). A one-way analysis of variance (ANOVA) was used to evaluate the effects of different concentrations of boron on the performance and meat quality of the African ostrich chicks. Duncan's multiple range tests were performed to denote differences between the groups when differences were significant (a probability level of 5% was considered significant ($p < 0.05$) for all tests). All values were expressed as the means ± standard deviations.

## RESULTS AND DISCUSSION

**Growth Performance.** The results of the growth performance of the birds are presented in Table 2. The final BW of the birds fed 160 mg/L boron was significantly higher than that of the control group (0 mg/L) ($P < 0.05$), and the addition of 320 and 640 mg/L boron significantly decreased the final BW of the ostrich chicks when compared to the other groups ($P < 0.05$). The ADFI of the birds was significantly increased by 160 mg/L supplemental boron in drinking water ($P < 0.05$); however, the other boron levels had no significant effect on ADFI. Adding 80 and 160 mg/L boron significantly increased the ADG of the birds, and 320 and 640 mg/L boron significantly decreased the ADG of the birds ($P < 0.05$). Boron had no effect on feed conversion.

In the present study, final BW, ADFI, and ADG of the birds significantly increased ($P < 0.05$) with supplementation of boron at 160 mg/L level (Table 2). Similar results were obtained in broilers fed 60−120 mg/kg boron[8] and hens fed 100 and 200 mg/kg boron.[23] Final BW and ADG were depressed by the higher levels of boron (320 and 640 mg/L) (Table 2), agreeing with results obtained in broilers fed 300 mg/kg boron,[8] layers fed 400 mg/kg boron,[9,23] hens fed 400 mg/kg boron,[24] and Japanese quails fed 10, 60, 120, and 240 mg/kg boron.[25] However, there were no differences in feed conversion between the groups (Table 2). In previous studies, feed conversion was not affected by 80 mg/kg boron in broilers,[26] by 5, 10, 50, 100, 200, and 400 mg/kg boron in the hens,[24] or by 5 and 15 mg/kg boron in pigs.[27] The results (Table 2) of this study indicated that 160 mg/L boron supplementation improved growth performance in ostrich chicks, but 320 and 640 mg/L boron supplementation inhibited growth performance.

**Physical Meat Quality Parameters.** The effects of different concentrations of boron on the physical meat quality parameters of the ostrich chicks are reported in Table 3. The drip loss and cooking loss of meat were significantly decreased by supplemental boron at 160, 320, and 640 mg/L. Further, the addition of 160, 320, and 640 mg/L boron to drinking water significantly increased the pH value of the meat ($p < 0.05$). The color and WBS values of meats did not differ among the birds administered different boron levels ($P > 0.05$).

To the best of our knowledge, there are no reports of the effect of boron on physical meat quality parameters. The data clearly showed that the pH value of the meat was significantly increased by supplemental boron at 160, 320, and 640 mg/L ($P < 0.05$) (Table 3). The pH value of meat depends on the content of lactic acid in the muscles, and after the slaughter, muscle glycogen glycolysis is the main source of lactic acid.[28] It is widely accepted that there is a close correlation between muscle pH values and glycogen.[29] The high ultimate pH of the meat is a consequence of depleted muscular glycogen reserves prior to slaughter and greatly affects meat quality.[30] Boron has a major role in controlling certain metabolic pathway processes using hydrolases or oxidoreductases.[4,31] These enzymes need pyridine or flavin nucleotides (NAD+, NADP, or FAD) to promote the enzyme activity. Boron reversibly inhibits their activity by forming transition state analogs or competing for NAD or FAD.[4,31] Boron can also inhibit NAD directly to affect enzyme activity.[32−34] NAD is an important reaction substrate of glycolysis; boron inhibits the glycolytic pathway by acting on NAD, thus reducing the lactic acid content of muscle and increasing pH value. Geyikoğglu and Türkez[35] reported that high boric acid doses (3.375 and 4.5 mmol B/kg b.wt.) caused decreased metabolite concentrations (glucose, glycogen, lactate, and ATP) in breast muscle of broiler chickens, thus increasing the muscle pH value. In the present study, the pH value of the meat was significantly increased by 160, 320, and 640 mg/L boron in the drinking water, which could be due to the additional boron reducing lactic acid and glycogen content in the muscles.

The drip loss and cooking loss were significantly decreased by supplemental boron at 160, 320, and 640 mg/L ($P < 0.05$) (Table 3). Meat that has a higher pH has a stronger water holding capacity (WHC) and lower moisture loss.[36] Lower drip loss and cooking loss were, therefore, expected for the samples of groups 4, 5, and 6. The results confirmed that the drip loss and cooking loss of these groups were significantly decreased as compared to those of the control group ($P < 0.05$). The significant increase in the ultimate pH of groups 4, 5, and 6 could account for this finding.

There were no significant differences between treatments with regard to meat color or shear force values ($P > 0.05$) (Table 3). At a higher meat pH, protein can bind more strongly with water, allowing less free water; therefore, meat will be darker in color because there is less free water to reflect light.[37] Although not significant, groups 4, 5, and 6 had lower $L^*$ values. Lanza et al.[38] reported that there was a negative correlation ($r = -0.41$; $P < 0.05$) between shear force values and ultimate pH, but in this study, no significant changes were detected for the shear force values with increasing pH value, suggesting that the inclusion of boron in the drinking water of

ostrich chicks does not have any effect on the tenderness of meat.

**Chemical Meat Quality Parameters.** The effects of different levels of boron on chemical meat quality parameters of ostrich chicks are reported in Table 4. The parameters that differed in the current study were protein, ash, C18:1, and C18:3$\omega$3; significantly lower protein was found in the treatments of 320 and 640 mg/L boron; lower C18:1 and C18:3$\omega$3 were found with the dose of 640 mg/L boron, and higher ash was found with the 640 mg/L boron ($p < 0.05$) dose. No significant effects of the boron treatment for moisture, fat, SFA, or cholesterol of meat were found for any birds in the trial.

The moisture of muscle was decreased with increasing dosages of the boron supplement in the drinking water, but no significant difference ($P > 0.05$) was observed between the treatment groups. Eren et al.[25] reported that boron had no effect on the moisture of Japanese quail meat, which was consistent with our results.

Eren et al.[25] also reported that fat in the meat of male Japanese quails was increased with boron supplements of 10, 60, 120, 240 mg/kg, and in females, 120 and 240 mg/kg boron increased fat percentages in the meat ($P < 0.05$). In the present study, the fat of the muscle increased with increasing doses of boron, but it was not significant ($P < 0.05$). This trend for fat was similar to previous research.

The ash content of muscle is representative of mineral and trace element content.[39] Boron has a regulatory role in the metabolism of several minerals such as magnesium, phosphorus, molybdenum, and calcium.[23] Shang et al.[40] showed that the addition of boron in drinking water could improve the contents of iron and zinc in chicken meat. Similarly, Eren et al.[25] reported that 240 mg/kg boron increased ash percentages in the meat of Japanese quails ($P < 0.05$). Our results also showed that ash of muscle was increased with increasing dosage of boron, and ash content was significantly ($P < 0.05$) higher at the high dose (640 mg/L) than at the low doses (0, 40, 80, 160, 320 mg/L). The ash content increased gradually due to the boron raising the mineral content of the muscle, but more research is needed to further quantify this.

As mentioned above, boron can inhibit the activity of NAD,[32−34] and, because serine proteases require pyridine or flavin nucleotides ($NAD^+$, NADP, or FAD), boron can inhibit the activity of serine proteases. Serine proteases are one of the most abundant groups of proteolytic enzymes; they are involved in many physiological processes through the proteolytic activation of precursor proteins.[41] The addition of boron inhibited the activity of serine proteases, so that macromolecule proteins cannot be broken down into smaller proteins, resulting in the relatively low protein content of the ostrich meat. This may be the cause of the decrease in muscle protein with increasing doses of boron supplementation.

Hall et al.[42] reported that when boron was orally administered (8 mg/kg/day) to rats, daily for 14 days, TG levels and LDL cholesterol decreased. Basoglu et al.[43] suggested that boron had positive effects on hepatic steatosis and visceral fat by affecting the lipid profile and reducing oxidative stress. The administration of sodium borate decreased concentrations of total cholesterol, triglyceride, high-density lipoprotein, low-density lipoprotein, and nonesterified fatty acids in the blood.[3] Several studies have indicated that boron could improve lipid metabolic profiles. Until now, the research has only been conducted in serum; there is no literature reporting changes of lipid substances in the muscle when boron is administered. Our experiment showed that boron had no influence on the percentages of SFA and cholesterol in meat, but the proportion of C18:1 and C18:3$\omega$3 significantly ($P < 0.05$) decreased at the highest dosage (640 mg/L).

In conclusion, we investigated the effect of boron on the growth performance and meat quality of African ostrich chicks, and our results showed that additional boron improved these parameters, but a high dose of boron had a negative effect.

According to our results, 160 mg/L boron was the optimal dosage for growth performance and meat quality of African ostrich chicks.

**Figure 1.** Chemical structure of purified saponins (**1**−**12**) and sapogenins (**13**−**15**) used in this investigation (I, hederagenin; II medicagenic acid; III, zanhic acid; and IV, soyasapogenol B).

has been extensively investigated.[17,20−22] In some cases, their structure−activity relationship has been assessed.[16,23] In addition, the main genes involved in their biosynthesis have been identified.[24−27]

In the present study, data on the antifungal properties of saponin extracts from alfalfa (*Medicago sativa* L.) against the causal agent of rice blast *P. oryzae* were obtained. The *P. oryzae* strains used in these investigations were isolated from five different rice varieties cultivated in Lombardy, in the Po valley, a typical Italian area of rice production. Saponins from *M. sativa* tops and roots, the corresponding mixture of prosapogenins, and pure saponins and sapogenins were tested against *P. oryzae* isolates in *in vitro* experiments. A prosapogenin mixture from alfalfa leaves was used to evaluate their antifungal activity by means of the *in planta* tests. These assays were performed in controlled conditions, using three different rice cultivars known to possess high, medium, and low pathogen resistance, infected with a mixture of the isolated strains of *P. oryzae*. Results of the antifungal properties of saponins from *M. sativa* are also discussed on the basis of their structure−activity relationship. To our knowledge, no previous investigations have been reported on the antifungal activity of saponins from *M. sativa* against the rice pathogen *P. oryzae* in both *in vitro* and *in planta* tests.

## MATERIALS AND METHODS

**Chemicals and Reagents.** Ethanol (EtOH) and penicillin G were purchased from Sigma-Aldrich s.r.l. (Milan, Italy). Water was deionized by a filter through a Direct-Q system (Millipore, Bedford, MA). Potato dextrose agar (PDA) was purchased from BioLife (Milan, Italy).

**Extraction and Purification of *M. sativa* Saponins and Preparation of Prosapogenins and Sapogenins.** Alfalfa (*M. sativa* cv. Equipe) plants were grown in an open field at CRA-FLC (Lodi, Italy). Leaf samples (collected at anthesis) and roots (collected in autumn) were oven-dried at 50 °C for 2 days, ground, and used for saponin extraction. Saponins used in this study were newly extracted and purified, following general procedures previously reported.[16,21,22,28,29] Pure saponins, compounds **1**−**12** (Figure 1), were obtained by a combination of chromatographic separation steps [silica gel open-column chromatograpy and semi-preparative reversed-phase high-performance liquid chromatography (RP-HPLC)] from the crude saponin mixtures from leaves and roots as described.[21,22,28] The saponin mixture from leaves was used to prepare prosapogenins and

dx.doi.org/10.1021/jf5049063 | J. Agric. Food Chem. 2014, 62, 11030−11036

sapogenins. Prosapogenins were obtained after basic hydrolysis,[19,30] and acid hydrolysis afforded the related sapogenins, compounds **13**−**15** (Figure 1), that were obtained in a pure form after silica gel open-column chromatography.[16,31]

**Analysis of Saponin Extracts.** Purified mixtures of saponins were obtained as whitish powder in a purity of 90−95% and analyzed by silica gel 60H ready-to-use thin-layer chromatography (TLC) plates (Merck, Darmstadt, Germany) as previously described[20] and by high-performance liquid chromatography (HPLC) as reported.[21,22,28] Purified saponin and prosapogenin mixtures were characterized for their quantitative aglycone composition by gas chromatography−flame ionization detection (GC−FID) and gas chromatography−mass spectrometry (GC−MS) analyses of derivatized sapogenins.[20,32] Detailed structural elucidation of pure saponins, compounds **1**−**12**, and sapogenins, compounds **13**−**15**, was obtained by nuclear magnetic resonance (NMR) and electrospray ionization−tandem mass spectrometry (ESI−MS/MS) analysis.[17,21,22,27−29] Evaluation of the saponin composition in the plant extracts was also performed by liquid chromatography−tandem mass spectrometry (LC−MS/MS) experiments.

**Saponin Preparation for *in Vitro* and *in Planta* Bioassays.** For the *in vitro* tests, crude saponin mixtures from alfalfa leaves and roots, prosapogenins, and pure saponins, compounds **1**−**12**, were dissolved in EtOH/$H_2O$ solutions (from 30 to 70% EtOH according to their solubility), while pure sapogenins, compounds **13**−**15**, were dissolved in 100% EtOH. All samples were prepared in a final concentration of 0.5 mg/mL. Serial dilutions (2-fold) were prepared from the starting standardized stock solutions to obtain a concentration range from 500 to 15.625 μg/mL for each sample. Sonication of each sample was generally adopted to facilitate solubilization of the metabolites. A series of EtOH/$H_2O$ control solutions at different concentrations were also tested against *P. oryzae*. For the *in planta* bioassays, under controlled conditions, prosapogenins were dissolved at 1% (w/v) in water with added 0.5% (w/v) gelatin, which is used in the rice infection standard protocol, with mild heating to facilitate solubilization. Prosapogenins were also tested in the same water/gelatin mixture at the same concentration in the *in vitro* experiments.

**Microorganism Growth Conditions.** Antifungal activity was tested against different isolates of *P. oryzae* [formerly called *Pyricularia grisea* (Cooke) Saccardo],[33] obtained from leaf lesions of the following rice Italian varieties: Augusto, Nembo, Italico, Karnak, and Vialone Nano, with isolate number PatVeg 202 a, b, c, d, and e, respectively, included in a large collection of *P. oryzae* partially used for the study of the genetic structure of the Italian pathogen population. The isolates were maintained in the Laboratory of Mycology of the University of Pavia and grown on potato dextrose agar or rice seed flour medium, adding 500 000 units of penicillin G. Petri dishes with the cultures were maintained at 25 °C in a growth chamber with a 12 h photoperiod for 7−9 days before the antifungal assays.[34] Each of the five *P. oryzae* isolates from the above-cited rice varieties were individually used for the *in vitro* tests and further used as a mixture (50 000 conidia/mL each) for the *in planta* experiments.

***In Vitro* Antifungal Assay.** The *in vitro* antifungal activities of all of the tested saponins were determined as the minimum inhibitory concentration (MIC) and the minimum fungicidal concentration (MFC) against the *P. oryzae* isolates described above, following reported procedures,[35−37] with some modifications. MIC was defined as the lowest drug concentration that completely inhibited the growth of the test fungal pathogens after 7 days of incubation at 25 °C. To determine the lowest concentration required to kill completely the test fungus (MFC), the initial inoculum was sub-cultured from 7-day-old microwell plates containing the extract where no fungal growth was observed (100% of inhibition) in a fresh cultural medium free of the extract and examined at 24 h intervals for 10 days. The MFC was defined as the lowest drug dilution, allowing for a total reduction (99.9%) of the initial inoculum on the culture medium.[38] MIC and MFC values were determined by a 2-fold serial broth microdilution method in multi-well plates. All of the tested samples were diluted in a Sabouraud culture medium to the following final concentrations (1 mL final volume): 0.500, 0.250, 0.125, 0.060, 0.030, 0.015, and 0.0075 mg/mL. Flutriafol Pestanal, containing the antifungal compound (*R*,*S*)-2,4-difluoro(1*H*-1,2,4-triazol-1-ylmethyl)benzhydryl alcohol, was used at the following concentrations: 0.250, 0.125, 0.060, 0.030, 0.015, and 0.0075 mg/mL. The MIC and MFC of the EtOH/$H_2O$ solutions were also recorded at the concentrations described above to exclude any antifungal effect because of the solvent. All bioassays were performed in triplicate.

***In Planta* Antifungal Assays.** Two *in planta* bioassays were performed. The first experiment aimed to compare the *in vitro* results and was performed using the Italian rice (*O. sativa* L. ssp. *japonica*) cultivar Maratelli, highly susceptible to rice blast. The protection against the disease exerted by prosapogenins was compared versus that of commercial fungicide Flutriafol Pestanal. In a second assay, the prosapogenin effect on rice genotypes was evaluated using the rice cultivars Baldo and Selenio, characterized by medium and low susceptibility to blast disease, respectively. The resistance/susceptibility to *P. oryzae* of the three rice cultivars has been reported[39] and was confirmed by previous pathogenicity assays (data not shown).

In both assays, rice plants were grown from seeds in trays filled with compost kept in a greenhouse under a daytime temperature of 27 °C and a nighttime temperature of 22 °C, with a 12 h photoperiod and 60% humidity. Nitrogen fertilization with 8.6 g of nitrogen equivalent (corresponding to standard levels used during rice crop cultivation) was applied 2 days before inoculation with the fungus. The fungal conidia suspension used to infect the rice plants was obtained by mixing the same amounts of the five isolates of *P. oryzae* (50 000 conidia/mL each) with 0.5% (w/v) gelatin to ensure conidial adhesion on rice leaves. Inoculation was performed as described,[40] by spraying 30 mL of conidia suspension on a block of 150 rice seedlings 4 weeks after sowing. Prosapogenin treatments were performed by spraying a solution [50 mL of 10 g/L in 0.5% (w/v) gelatin]. The Flutriafol Pestanal formulation was applied at field dosage (125−150 g/ha). All treatments (prosapogenin and fungicide) were applied at two different times, viz., 24 h before and 3 days after inoculation of rice plantlets with *P. oryzae*. Positive control plants were sprayed with conidial suspensions (30 mL as above) without further treatment. All bioassays were performed in three replicates. After 7 days, the macroscopic disease symptoms on the second rice leaf were scored on all plants to assess the effect of the treatments. The disease severity (DS) was estimated on the basis of a visual 5-level scale from 1 (no disease) to 5 (serious disease), as described in Figure 2. Efficacy classes were then created by merging DS score levels as follows: DS1 and DS2 were associated with high efficacy of the treatment, and the corresponding efficacy class was "protection" (P), with no reduction of the grain yield; DS3 was considered of moderate efficacy, and the class was "medium protection" (MP), with reduction of the grain yield; and DS4 and DS5 were associated with low efficacy of the treatment, and the efficacy class was "no protection" (NP), with considerable grain loss. Efficacy classes were subsequently used in the statistical analysis.

**Statistical Analysis.** For each cultivar, treatment, and replicate, the frequency of the three efficacy classes was computed as a percentage of evaluated plants. The angular transformation was applied to the percentage values, and the transformed data were subjected to analysis of variance (ANOVA).[41] A first ANOVA compared the frequency of the three efficacy classes in each treatment of each individual cultivar (Table 2). In a second ANOVA, the effect of treatments on plant protection was assessed by comparing, within each cultivar, the frequency of plants from different treatments within each efficacy class (Figure 3). In both ANOVAs, mean values were compared by Duncan's multiple range test (at $p < 0.05$) when the $F$ test from the analysis was significant at $p < 0.05$.

## RESULTS AND DISCUSSION

The saponin composition from alfalfa extracts was evaluated by TLC and HPLC analyses as previously reported.[21,22,28] LC−MS/MS analyses of the total extracts were also performed, and several mass peaks corresponding to the different saponins were identified (data not shown). GC−FID and GC−MS analyses of the aglycone moieties, obtained by acid hydrolyses from the

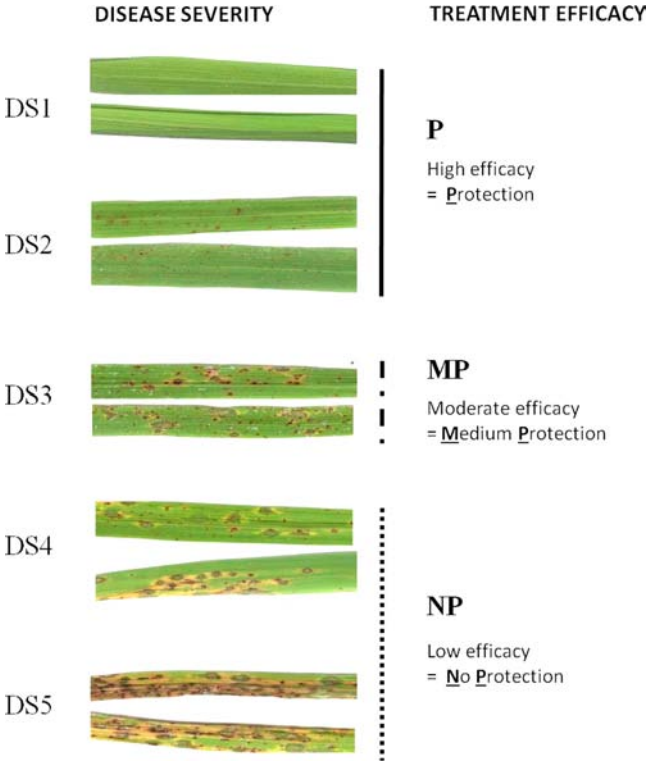

**Figure 2.** DS scale of rice leaves based on a visual 5-level scale: DS1, highly resistant (no symptoms); DS2, resistant (necrotic spots); DS3, partially resistant (mixture of necrotic spots and small gray lesions); DS4, susceptible (typical diamond-shaped blast lesions, lengthened, gray inside and brown outside, and yellow edges); and DS5, highly susceptible (blast lesions with wide yellow edges on the whole leaf surface). The treatment efficacy classes were then created by merging DS score levels: (P) DS1 and DS2, (MP) DS3, and (NP) DS4 and DS5.

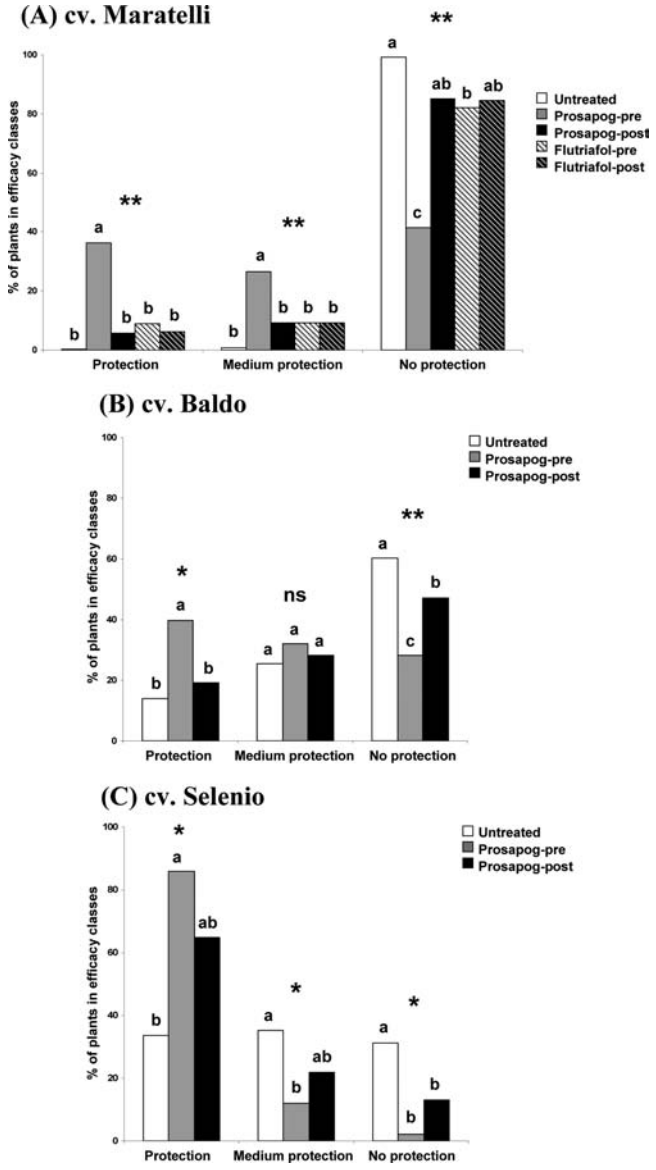

**Figure 3.** Frequency of plants (percentage of evaluated plants) classified in three efficacy classes (protection, medium protection, and no protection) after treatments against *P. oryzae* infection (untreated control and application of prosapogenins or Flutriafol Pestanal fungicide before and after plant inoculation with the pathogen) in three rice cultivars. For a symptom description of efficacy classes, see Figure 2. ns, ∗, and ∗∗, variation among treatments within each cultivar and efficacy classes not significant and significant at $p < 0.05$ and $p < 0.01$, respectively. In each cultivar and efficacy class, treatment mean values followed by different letters are different at $p < 0.05$ according to Duncan's multiple range test.

corresponding saponin mixtures, showed that saponins from alfalfa leaves are characterized by a high concentration of medicagenic acid (51% of the total sapogenins), followed by zanhic acid (25%), soyasapogenol B (16%), bayogenin (3%), hederagenin (1%), and soyasapogenol A (1%), while saponins from alfalfa roots are characterized by the presence of medicagenic acid (68%), hederagenin (18%), soyasapogenol B (6%), bayogenin (3%), and zanhic acid (2%) (Figure 1). Composition of purified saponin mixtures used in these assays was consistent with previously obtained results.[19,20,29] From the TLC and HPLC analyses, a different saponin composition was confirmed for the two plant organs, e.g., the presence of compound **4**, the 3-*O*-$\beta$-D-glucopyranosyl derivative of medicagenic acid (Figure 1), only in roots.[17] In addition, monodesmosidic saponins, compounds **2**, **4**, and **12**, were found to be more abundant in alfalfa root extracts, representing about 45% of the total saponins, while saponins from tops were predominantly composed of bidesmosidic compounds **1**, **3**, and **5**−**11**, accounting for about 80% of the total saponins (data not shown). Prosapogenins that were obtained from the leaf saponin mixture after basic hydrolyses showed the same chemical aglycone composition of the saponins from which they were prepared, but they were entirely composed of monodesmosidic compounds. Individual pure saponins, compounds **1**−**12**, and sapogenins, compounds **13**−**15**, were obtained by means of chromatographic purification steps, and their chemical structure (Figure 1) was determined by LC−MS/MS and NMR experiments.

The *in vitro* biological effects of saponin extracts from alfalfa leaves and roots, single purified saponins, prosapogenins, and sapogenins were investigated for activity against five strains of the rice fungal pathogen *P. oryzae* isolated from five different Italian rice varieties. All of these isolates showed a similar response (in terms of MIC/MFC) to the different tested compounds. Results from these bioassays are reported as MIC and MFC values in Table 1. All of the tested compounds showed a broad spectrum of antifungal activity. The lowest

[a]Flutriafol Pestanal was tested as a positive control. For chemical structures, see Figure 1.

activity (MIC = 2.0 mg/mL) was observed for the saponin mixture from alfalfa leaves, while the corresponding prosapogenins showed the highest inhibition activity, with MIC and MFC values of 0.03 and 0.25 mg/mL, respectively. Intermediate values (MIC = 0.25 mg/mL, and MFC = 0.5 mg/mL) were instead recorded for pure saponins, compounds **1**−**12** (Table 1). Among pure saponins, the bidesmosidic hederagenin derivatives, compounds **1** and **3** (Figure 1), did not show any antifungal activity (MIC and MFC values of >0.5 mg/mL) against *P. oryzae*, while a moderate inhibition (MIC and MFC values from 0.125 to 0.5 and from 0.125 to >0.5 mg/mL, respectively) was in general observed for the bidesmosidic saponins of medicagenic and zanhic acid (compounds **5**−**10**). The only exception was saponin **11**, a bidesmoside of zanhic acid, which revealed no activity (MIC and MFC values of >0.5 mg/mL). A moderate inhibition (MIC = 0.25 mg/mL) was observed for saponin **2**, a trisaccharide monodesmoside of hederagenin, while a strong inhibition was observed for compound **4**, the 3-*O*-*β*-D-glucopyranosyl derivative of medicagenic acid, for which a MIC of 0.03 mg/mL and a MFC of 0.125 mg/mL were recorded. As expected, no growth inhibition was instead observed for compound **12**, a saponin of soyasapogenol B, that is known for its very low or null antifungal activity.[17] A similar trend (Table 1) could also be observed for the three pure sapogenins **13**−**15**: no activity was recorded for hederagenin **13** (MIC and MFC values of >0.5 mg/mL); a moderate activity was observed for zanhic acid **15** (MIC and MFC values of 0.25 mg/mL); and a high antifungal activity was observed for medicagenic acid **14** with a MIC = 0.01 mg/mL and MFC = 0.03 mg/mL. Among all of the tested compounds, this last sapogenin and its 3-*O*-*β*-D-glucopyranosyl derivative, compound **4**, showed the highest antifungal activity similar to that of the Flutriafol Pestanal, which is a systemic fungicide currently applied in rice fields to control the blast disease and, hence, assayed as a standard for *P. oryzae* positive control.

Previous investigations on the structure−activity relationship of saponins have led to contrasting results:[16,42,43] some authors suggested that sugar moieties are important for their antifungal effects, while according to others, sapogenins are more active. The data reported here clearly demonstrate that medicagenic acid, the main aglycone among *M. sativa* saponins, and its derivatives are responsible for the highest antifungal inhibition against *P. oryzae* (in comparison to hederagenin and zanhic acid saponins). In addition, as previously stated,[16,17,42,43] the monodesmosidic compounds (prosapogenins from *M. sativa* tops and compound **4**) are, in general, more active against rice blast pathogen than the corresponding bidesmosides.

Concerning the mechanism of action of these antifungal compounds, some considerations on their biocidal activities can be deduced. It is known that Flutriafol Pestanal is a triazole derivative, and it is able to inhibit the ergosterol biosynthesis, causing the rupture of fungi cell membranes.[44] In addition, there is evidence that saponins are able to alter membrane permeability, to complex cholesterol or other membrane components, leading to the rupture of the cell.[15,45] The results obtained in our experiments show that monodesmosides of medicagenic acid and compound **4** are as bioactive as Flutriafol and support a mechanism of action affecting the cell membrane integrity.

On the basis of the highest antifungal activity shown in the *in vitro* tests by the monodesmosidic prosapogenins, these compounds were employed for the *in planta* assays on three Italian rice varieties, Maratelli, Baldo, and Selenio, chosen for their different levels of susceptibility to the pathogen. The *in planta* assays confirmed the different degrees of susceptibility to the disease shown by the three cultivars evaluated. The frequency of highly symptomatic plants (represented by the efficacy class "no protection") was indeed generally very high in cv. Maratelli, regardless of the applied treatment, moderate or low in cv. Selenio, and somewhat intermediate between the previous two in cv. Baldo (Table 2). In the tolerant cv. Selenio, the frequency of the three efficacy classes (protection, medium protection, and no protection) did not differ in the inoculated untreated condition, whereas with either application of prosapogenins, the frequency of "protection" was significantly greater ($p < 0.05$) than those of the two other classes (Table 2). Interestingly, in both the susceptible cv. Maratelli and the moderately susceptible cv. Baldo, the three efficacy classes did not differ under the pre-inoculation prosapogenin application, as a consequence of an increase of frequency of protected plants and a decrease of frequency of non-protected plants, in comparison to the other treatments in each cultivar (Table 2).

The latter finding is shown better in Figure 3, where the results of the second ANOVA are graphically reported. In particular, in Figure 3A, it is evident that, for cv. Maratelli, the pre-inoculation application of prosapogenins enhanced remarkably the frequency of plants with "protection" and "medium protection" and reduced the frequency of those with "no protection" compared to the control and all other treatments. Similarly, the application of saponins before the inoculation also increased the frequency of protected plants and decreased that of non-protected plants in cv. Baldo compared to the control and post-inoculation application (Figure 3B). Only in the tolerant cv. Selenio was the post-inoculation application of prosapogenins able to exert some protective efficacy against the

**Table 2. Comparison among Efficacy Classes within Individual Treatments against *P. oryzae* Infection (Untreated Control and Application of Prosapogenins or Flutriafol Pestanal before and after Plant Inoculation with the Pathogen) in Three Rice Cultivars[a]**

| | | treatment efficacy class[b] | | |
|---|---|---|---|---|
| treatment | *F* test probability[c] | protection | medium protection | no protection |
| | | cv. Maratelli | | |
| untreated | 0.0001 | 0.2 b | 0.7 b | 99.1 a |
| prosapogenins pre-inoculation | ns | 36.3 a | 26.5 a | 41.5 a |
| prosapogenins post-inoculation | 0.05 | 5.8 b | 9.2 b | 85.0 a |
| Flutriafol pre-inoculation | 0.01 | 8.9 b | 9.1 b | 82.0 a |
| Flutriafol post-inoculation | 0.01 | 6.3 b | 9.2 b | 84.5 a |
| | | cv. Baldo | | |
| untreated | 0.05 | 14.1 b | 25.6 b | 60.3 a |
| prosapogenins pre-inoculation | ns | 39.8 a | 32.0 a | 28.2 a |
| prosapogenins post-inoculation | 0.05 | 19.2 c | 33.7 c | 47.1 a |
| | | cv. Selenio | | |
| untreated | ns | 33.5 a | 35.2 a | 31.2 a |
| prosapogenins pre-inoculation | 0.05 | 85.9 a | 11.9 a | 2.2 b |
| prosapogenins post-inoculation | 0.05 | 64.8 a | 22.0 a | 13.2 b |

[a]Values are percentages of plants recorded in each class for each treatment and cultivar. For a symptom description of efficacy classes, see Figure 2. [b]In each cultivar and treatment, class values followed by different letters are different at $p < 0.05$ according to Duncan's multiple range test. Analysis was carried out after angular transformation of original percentage values reported in the table for the sake of clarity. [c]Among efficacy classes within each treatment; ns, not significant.

fungus, while the pre-inoculation treatment had the same positive effect exhibited for the two other cultivars (Figure 3C).

The results reported herein indicate that prosapogenins are active compounds against *P. oryzae*, especially in prevention of the fungal attack, and they were active against all five *P. oryzae* isolates used in both the *in vitro* and *in planta* experiments. The toxicity of the commercial formulation Flutriafol Pestanal has been poorly described.[46,47] Nevertheless, this compound is extremely persistent in soil, possesses high mobility potential, and is considered a groundwater contaminant.[48] Therefore, saponins from *M. sativa* could represent, if properly formulated, a promising and environmentally friendly treatment for control of rice blast.

In conclusion, data presented here make a point about the potential use of saponins, related prosapogenins, or aglycones from *M. sativa* for new fungicidal formulations. The highest antifungal activity shown by prosapogenins makes these saponin-derived compounds good candidates for practical use in agriculture. The large biomass produced by alfalfa, together with the selection of new varieties with high content of selected saponins with a defined chemical structure,[49] should make the industrial extraction of saponins economically viable.

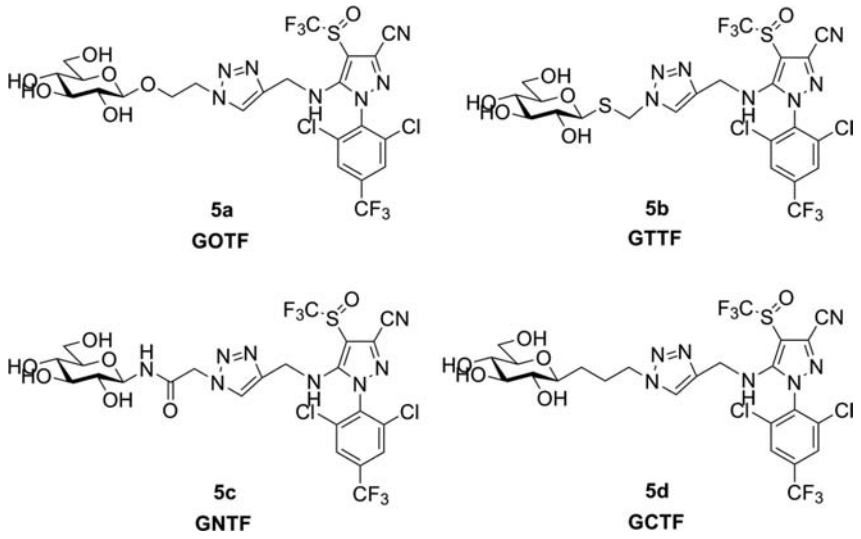

**Figure 1.** Chemical structures of O-, S-, N-, and C-glycosidic bonds in glucose−fipronil conjugates.

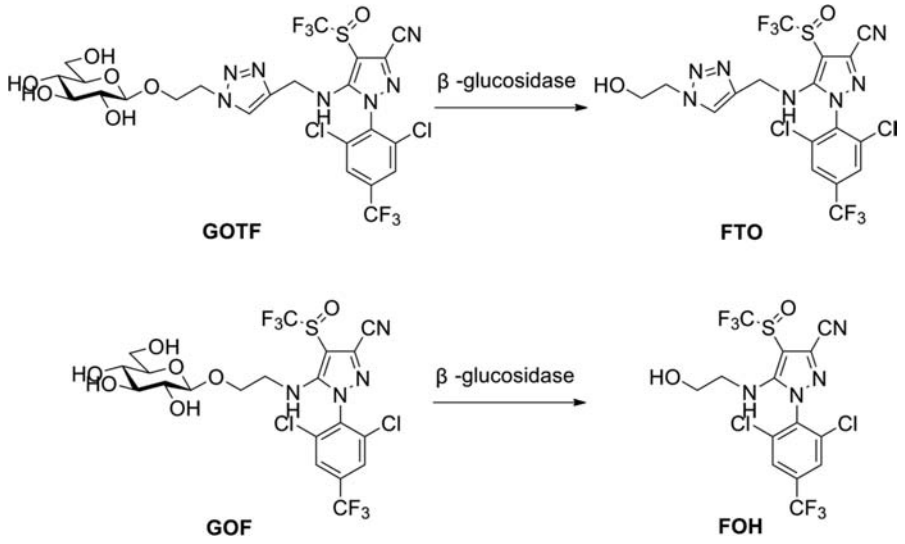

**Figure 2.** Metabolism of O-glycosidic bond in glucose−fipronil conjugates as catalyzed by $\beta$-glucosidase.

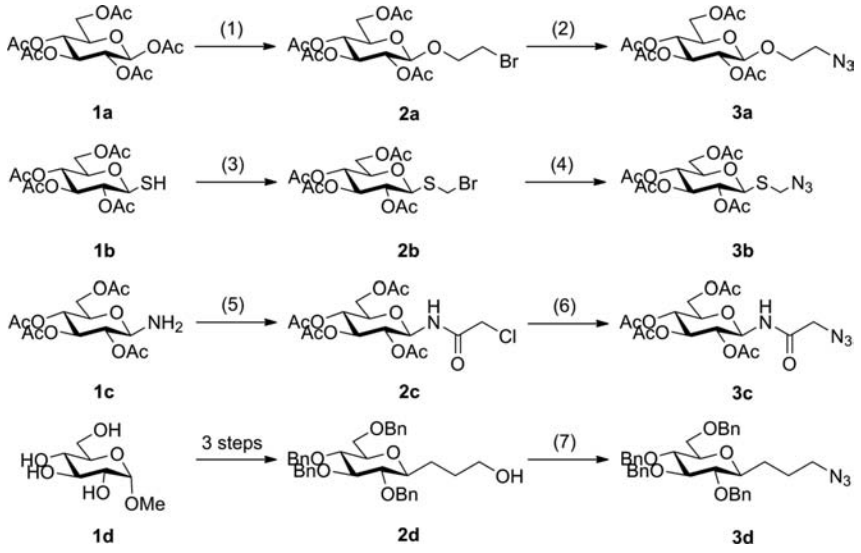
be recognized and hydrolyzed by endogenous $\beta$-glucosidases to bioactivate aglycons and control pests, which are also performed by plant defense systems. Secondary plant metabolites are glycosylated within plants to O (OH− and COOH−), N, S, and C atoms by glycosyltransferases.[16−18] In this study, we synthesize O-, S-, N-, and C-glycosidic bonds of glucose−fipronil conjugates (Figure 1) to investigate their metabolisms in vitro and in vivo. To verify metabolism and insecticidal activity, we introduce another synthesized O-glycosidic bond conjugate *N*-{3-cyano-1-[2,6-dichloro-4-(trifluoromethyl)phenyl]-4-[(trifluoromethyl)-sulfinyl]-1*H*-pyrazol-5-yl}-2-aminoethyl-$\beta$-D-glucopyranoside (GOF; Figure 2), which possesses moderate phloem mobility.[6] This study aimed to determine metabolic differences between four glycosidic bond conjugates and the activity of endogenous $\beta$-glucosidase, which is involved in the hydrolysis of exogenous glucose−pesticide conjugates in the plant. The results can help establish methods of circumventing the mutual exclusivity of phloem mobility and biological activity through the hydrolysis of endogenous $\beta$-glucosidases.

## MATERIALS AND METHODS

**General Information on Synthesis.** All reagents and solvents were purchased from a commercial company. $^1$H NMR and $^{13}$C NMR spectra were obtained with a Bruker AV-600 instrument. Chemical shifts were expressed in parts per million with TMS as internal standard. High-resolution electrospray ionization mass spectra (HR-ESI-MS) were recorded on a Bruker maXis impact ESI-Q-TOF instrument. Analytical thin-layer chromatography (TLC) was carried out on precoated plates (silica gel $GF_{254}$), and spots were visualized with a ZF-20D ultraviolet (UV) analyzer. Silica gel (200−300 mesh) was used for column chromatography.

*Synthesis of 2,3,4,6-Tetra-O-acetyl-(2-azidoethyl)-$\beta$-D-glucopyranoside (**3a**; Scheme 1).* $\beta$-D-Glucose pentaacetate (5 g, 12.81 mmol) and 2-bromoethanol (3.2 g, 25.62 mmol, 2 equiv) were dissolved in 25 mL of anhydrous $CH_2Cl_2$. The solution was stirred under nitrogen and cooled to 0 °C, and then $BF_3{\cdot}Et_2O$ (2.1 mL, 16.65 mmol, 1.3 equiv) was added dropwise over a period of 30 min. The reaction was stirred for 1 h at 0 °C and overnight at room temperature. After dilution with $CH_2Cl_2$ and washing with cold water and saturated aqueous $NaHCO_3$, the organic phase was dried over anhydrous $Na_2SO_4$ and evaporated under reduced pressure to yield **2a** (4.55 g, 78%) as colorless oil. The product was subjected to the next step without further purification.

**Scheme 1**[a]



[a]Reagents and conditions: (1) 2-bromoethanol, $BF_3{\cdot}Et_2O$, and $CH_2Cl_2$ overnight; (2) $NaN_3$, 2:1 acetone/$H_2O$, and reflux for 20 h; (3) $CH_2Br_2$, $K_2CO_3$, 6 h; (4) $NaN_3$ and DMF at 90 °C for 12 h; (5) $(ClCH_2CO)_2O$, TEA, $CH_2Cl_2$, 0 °C and room temperature for 2 h and overnight, respectively; (6) $NaN_3$ and DMF at 90 °C for 12 h; (7) DPPA, DBU, and DMF at 100 °C for 4 h; $NaN_3$ at 100 °C for 12 h.

$NaN_3$ (3.25 g, 50 mmol, 5 equiv) was added to a solution of **2a** (4.55 g, 10.0 mmol) in acetone (20 mL) and water (10 mL). The reaction mixture was heated under reflux for 20 h, diluted with $CH_2Cl_2$, and sequentially washed with saturated aqueous $NaHCO_3$, water, and brine. The organic layer was dried over anhydrous $Na_2SO_4$ and evaporated to a residue, which was purified by column chromatography (hexane/EtOAc 3:2) to afford 2-azidoethyl glycoside (**3a**) (3.75 g, 85%) as a clear glass: $^1$H NMR ($CDCl_3$) $\delta$ 5.18 (t, $J$ = 9.5 Hz, 1H), 5.06 (t, $J$ = 9.7 Hz, 1H), 4.99 (t, $J$ = 8.8 Hz, 1H), 4.57 (d, $J$ = 8.0 Hz, 1H), 4.22 (dd, $J$ = 12.3, 4.7 Hz, 1H), 4.13 (dd, $J$ = 12.3, 2.0 Hz, 1H), 4.00 (dt, $J$ = 10.5, 4.1 Hz, 1H), 3.72−3.63 (m, 2H), 3.46 (ddd, $J$ = 11.7, 7.6, 3.3 Hz, 1H), 3.26 (dt, $J$ = 13.4, 4.0 Hz, 1H), 2.06 (s, 3H), 2.02 (s, 3H), 1.99 (s, 3H), 1.97 (s, 3H); $^{13}$C NMR ($CDCl_3$) $\delta$ 170.65, 170.26, 169.41(2C), 100.69, 72.81, 71.96, 71.10, 68.58, 68.36, 61.87, 50.55, 20.75, 20.69, 20.61 (2C). HRMS (ESI) calcd for $C_{16}H_{23}N_3NaO_{10}$ $(M + Na)^+$ 440.1281, found 440.1276.

*Synthesis of Bromomethyl 2,3,4,6-Tetra-O-acetyl-1-thio-β-D-glucopyranoside (**2b**; Scheme 1).* 2,3,4,6-Tetra-*O*-acetyl-β-D-1-thio-glucopyranosyl[19] (**1b**) was synthesized as previously described.

$K_2CO_3$ (3.03 g, 21.9 mmol, 2 equiv) was added to a stirred solution of **1b** (4 g, 10.95 mmol) in $CH_2Br_2$ (20 mL), and the mixture was stirred at room temperature. TLC was used to determine the disappearance of the starting material (about 6 h), and then the solid was removed by filtration and the filtrate was concentrated. The residue was purified by column chromatography (hexane/EtOAc 3:2) to afford product **2b** (3.51 g, 70%) as a clear glass: $^1$H NMR ($CDCl_3$) $\delta$ 5.28 (t, $J$ = 9.4 Hz, 1H), 5.13−5.06 (m, 2H), 4.81 (d, $J$ = 10.2 Hz, 1H), 4.76 (d, $J$ = 11.0 Hz, 1H), 4.55 (d, $J$ = 11.0 Hz, 1H), 4.25 (dd, $J$ = 12.5, 5.0 Hz, 1H), 4.17 (dd, $J$ = 12.4, 2.3 Hz, 1H), 3.78 (ddd, $J$ = 10.1, 5.0, 2.3 Hz, 1H), 2.08 (s, 3H), 2.05 (s, 3H), 2.03 (s, 3H), 2.00 (s, 3H); $^{13}$C NMR ($CDCl_3$) $\delta$ 170.71, 170.22, 169.54, 169.50, 82.05, 76.39, 73.86, 69.91, 68.34, 62.01, 32.11, 20.86, 20.75, 20.71, 20.70. HRMS (ESI) calcd for $C_{15}H_{21}BrNaO_9S$ $(M + Na)^+$ 478.9988, found 478.9982.

*Synthesis of Azidomethyl 2,3,4,6-Tetra-O-acetyl-1-thio-β-D-glucopyranoside (**3b**; Scheme 1).* $NaN_3$ (2.13 g, 32.8 mmol, 5 equiv) was added to a solution of **2b** (3.0 g, 6.56 mmol) in 30 mL of DMF. The reaction mixture was stirred at 90 °C for 12 h, diluted with $CH_2Cl_2$, and washed with saturated aqueous $NaHCO_3$, water, and brine. The organic layer was dried over anhydrous $Na_2SO_4$ and evaporated under reduced pressure. The residues was purified by column chromatography (hexane/EtOAc 2:1) to afford product **3b** (2.48 g, 90%) as a white amorphous solid: $^1$H NMR ($CDCl_3$) $\delta$ 5.23 (t, $J$ = 9.4 Hz, 1H), 5.10 (t, $J$ = 9.8 Hz, 1H), 5.06 (t, $J$ = 9.7 Hz, 1H), 4.70 (d, $J$ = 10.1 Hz, 1H), 4.41 (d, $J$ = 13.5 Hz, 1H), 4.32 (d, $J$ = 13.5 Hz, 1H), 4.23 (dd, $J$ = 12.4, 4.9 Hz, 1H), 4.14 (dd, $J$ = 12.4, 2.2 Hz, 1H), 3.74 (ddd, $J$ = 10.1, 4.9, 2.3 Hz, 1H), 2.06 (s, 3H), 2.05 (s, 3H), 2.01 (s, 3H), 2.00 (s, 3H); $^{13}$C NMR ($CDCl_3$) $\delta$ 170.71, 170.21, 169.53, 169.45, 81.81, 76.31, 73.79, 70.12, 68.18, 62.05, 51.12, 20.81, 20.74, 20.69, 20.68. HRMS (ESI) calcd for $C_{15}H_{21}N_3NaO_9S$ $(M + Na)^+$ 442.0896, found 442.0891.

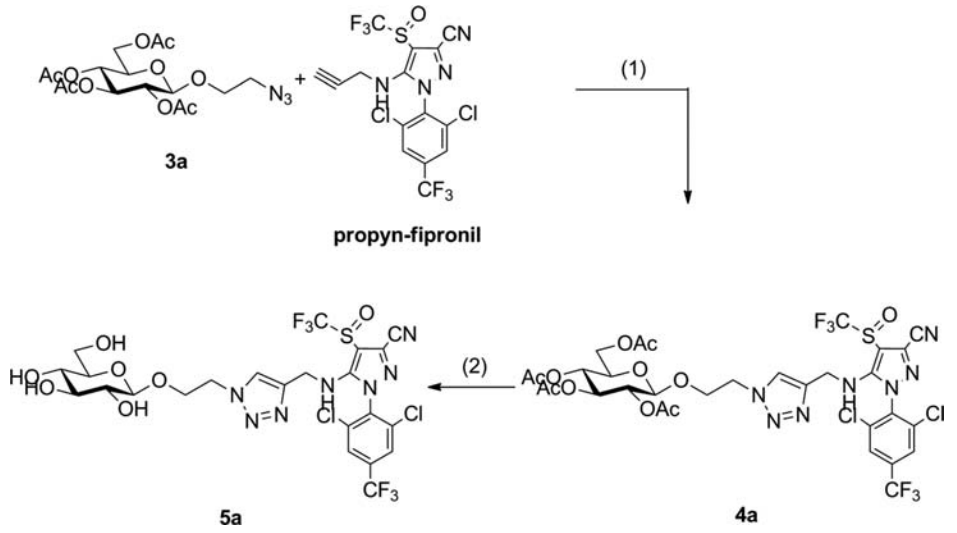
*Synthesis of 2,3,4,6-Tetra-O-acetyl-N-chloroacetyl-β-D-glucopyranosylamine (**2c**; Scheme 1).* 2,3,4,6-Tetra-*O*-acetyl-β-D-glucopyranosylamine[20] (**1c**) was synthesized as previously described.

The solution of **1c** (1.74 g, 5.0 mmol) in anhydrous $CH_2Cl_2$ (30 mL) was cooled to 0 °C, anhydrous TEA (1.4 mL, 10.0 mmol, 2 equiv) was added dropwise, and then chloroacetic anhydride (1.28 g, 7.5 mmol, 1.5 equiv) was added to the solution in portions. The reaction mixture was stirred for 2 h at 0 °C, followed by stirring at room temperature overnight. After dilution with $CH_2Cl_2$ and washing with cold water and saturated aqueous $NaHCO_3$, the organic phase was dried over anhydrous $Na_2SO_4$ and evaporated in vacuo. The residues were purified by column chromatography (hexane/EtOAc 1:1) to afford the product **2c** (1.17 g, 55%) as a white solid: $^1$H NMR ($CDCl_3$) $\delta$ 7.31 (d, $J$ = 8.9 Hz, 1H), 5.32 (t, $J$ = 9.5 Hz, 1H), 5.20 (t, $J$ = 9.2 Hz, 1H), 5.07 (t, $J$ = 9.7 Hz, 1H), 5.00 (t, $J$ = 9.6 Hz, 1H), 4.29 (dd, $J$ = 12.5, 4.4 Hz, 1H), 4.13−3.95 (m, 3H), 3.83 (ddd, $J$ = 10.1, 4.3, 2.1 Hz, 1H), 2.08 (s, 3H), 2.05 (s, 3H), 2.03 (s, 3H), 2.02 (s, 3H); $^{13}$C NMR ($CDCl_3$) $\delta$ 170.88, 170.69, 169.97, 169.60, 166.95, 78.63, 73.92, 72.68, 70.38, 68.21, 61.69, 42.36, 20.83−20.68 (4C). HRMS (ESI) calcd for $C_{16}H_{22}ClNNaO_{10}$ $(M + Na)^+$ 446.0830, found 446.0824.

*Synthesis of 2,3,4,6-Tetra-O-acetyl-N-azidoacetyl-β-D-glucopyranosylamine (**3c**; Scheme 1).* $NaN_3$ (650.0 mg, 10.0 mmol, 5 equiv) was added to a solution of **2c** (847.6 mg, 2 mmol) in 20 mL of DMF. The reaction mixture was stirred at 90 °C for 12 h, diluted with $CH_2Cl_2$, and washed with saturated aqueous $NaHCO_3$, water, and brine. The organic layer was dried over anhydrous $Na_2SO_4$ and evaporated under reduced pressure. The residue was purified by column chromatography (hexane/EtOAc 2:1) to afford product **3c** (780 mg, 91%) as a white amorphous solid: $^1$H NMR ($CDCl_3$) $\delta$ 7.11 (d, $J$ = 9.1 Hz, 1H), 5.31 (t, $J$ = 9.5 Hz, 1H), 5.22 (t, $J$ = 9.3 Hz, 1H), 5.07 (t, $J$ = 9.8 Hz, 1H), 4.97 (t, $J$ = 9.6 Hz, 1H), 4.29 (dd, $J$ = 12.5, 4.4 Hz, 1H), 4.09 (dd, $J$ = 12.5, 2.1 Hz, 1H), 4.03−3.90 (m, 2H), 3.83 (ddd, $J$ = 10.1, 4.3, 2.1 Hz, 1H), 2.08 (s, 3H), 2.05 (s, 3H), 2.03 (s, 3H), 2.02 (s, 3H); $^{13}$C NMR ($CDCl_3$) $\delta$ 170.96, 170.68, 169.96, 169.62, 167.57, 78.25, 73.90, 72.71, 70.58, 68.22, 61.71, 52.69, 20.81,

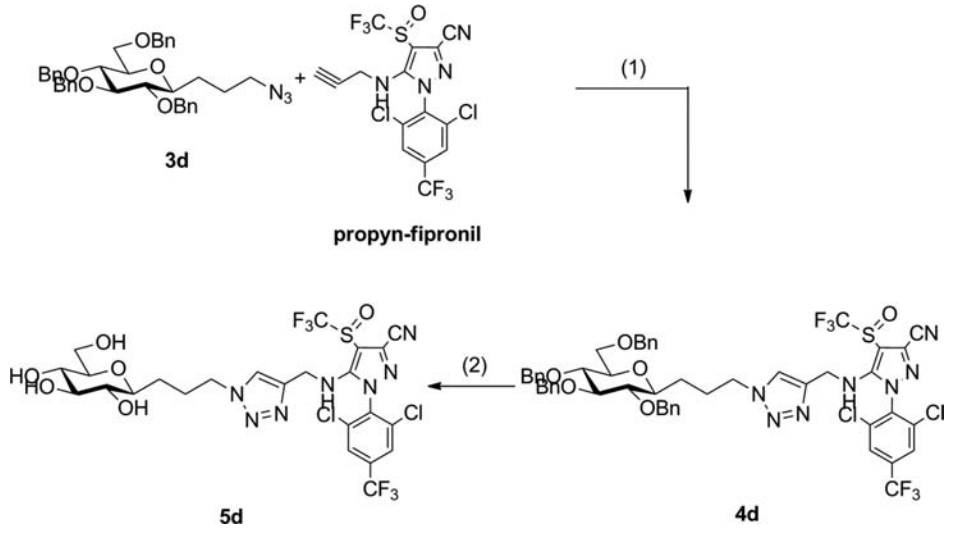
dx.doi.org/10.1021/jf5034575 | J. Agric. Food Chem. 2014, 62, 11037−11046

**Scheme 2**[a]



[a]Reagents and conditions: (1) $CuSO_4 \cdot 5H_2O$, sodium ascorbate, and 1:1 t-BuOH/$H_2O$ at 60 °C for 3 h; (2) 1 M NaOMe/MeOH at room temperature for 30 min.

**Scheme 3**[a]



[a]Reagents and conditions: (1) $CuSO_4 \cdot 5H_2O$, sodium ascorbate, and 1:1 t-BuOH/$H_2O$ at 60 °C for 3 h; (2) anhydrous $FeCl_3$ and $CH_2Cl_2$ at room temperature.

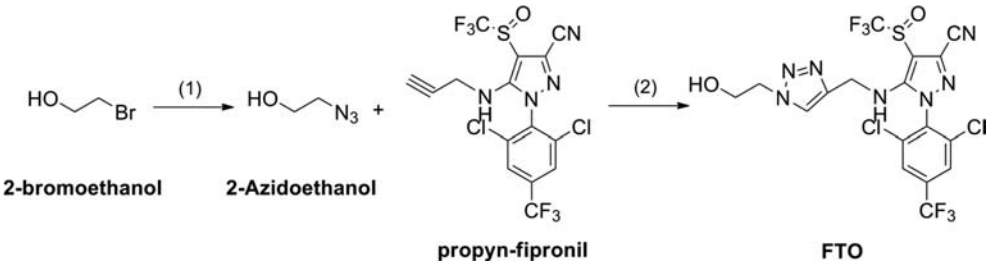
20.70, 20.66 (2C). HRMS (ESI) calcd for $C_{16}H_{22}N_4NaO_{10}$ $(M + Na)^+$ 453.1234, found 453.1228.

*3-(2,3,4,6-Tetra-O-benzyl-β-D-glucopyranosyl)-1-propanol*[21] ***(2d; Scheme 1).*** **2d** was synthesized as previously described to afford the compound as a white amorphous solid: $^1$H NMR ($CDCl_3$) $\delta$ 7.35−7.26 (m, 18H), 7.15−7.10 (m, 2H), 4.93 (d, $J$ = 10.9 Hz, 1H), 4.80 (dd, $J$ = 14.1, 10.9 Hz, 2H), 4.70 (d, $J$ = 11.7 Hz, 1H), 4.61 (dd, $J$ = 11.8, 10.1 Hz, 2H), 4.48 (dd, $J$ = 18.7, 11.5 Hz, 2H), 4.07−4.00 (m, 1H), 3.80−3.53 (m, 9H), 1.82−1.77 (m, 2H), 1.72−1.58 (m, 2H); $^{13}$C NMR ($CDCl_3$) $\delta$ 138.86, 138.42, 138.30, 138.07, 128.58−127.74 (20C), 82.54, 80.36, 78.39, 75.60, 75.17, 74.52, 73.66, 73.30, 71.32, 69.33, 62.54, 29.39, 21.10. HRMS (ESI) calcd for $C_{37}H_{42}NaO_6$ $(M + Na)^+$ 605.2879, found 605.2874.

*Synthesis of 3-(2,3,4,6-Tetra-O-benzyl-β-D-glucopyranosyl)-1-azidopropyl* ***(3d; Scheme 1).*** Compound **2d** (582.73 mg, 1 mmol) was dissolved in anhydrous DMF (15 mL), DPPA (650 μL, 3 mmol, 3 equiv), and DBU (150 μL, 1 mmol, 1 equiv) added dropwise. The solution was stirred at 100 °C for 4 h and then cooled to room temperature. Sodium azide (195 mg, 3 mmol, 3 equiv) was added to the solution in one portion, and the reaction mixture was stirred at 100 °C for an additional 12 h. After cooling to room temperature, the solution was diluted with diethyl ether (100 mL). The organic phase was then washed with $H_2O$ (100 mL) and saturated aqueous NaCl (100 mL), dried over anhydrous $Na_2SO_4$, and then evaporated in vacuo. The residue was purified by column chromatography (hexane/EtOAc 8:1) to afford **3d** (2.48 g, 90%) as a colorless oil: $^1$H NMR ($CDCl_3$) $\delta$ 7.43−7.27 (m, 18H), 7.16−7.07 (m, 2H), 4.92 (d, $J$ = 10.9 Hz, 1H), 4.80 (dd, $J$ = 10.8, 4.7 Hz, 2H), 4.71 (d, $J$ = 11.7 Hz, 1H), 4.66−4.55 (m, 2H), 4.47 (dd, $J$ = 11.4, 7.1 Hz, 2H), 4.05−3.91 (m, 1H), 3.82−3.21 (m, 9H), 1.85−1.67 (m, 3H); $^{13}$C NMR ($CDCl_3$) $\delta$ 138.88, 138.38, 138.32, 138.16, 128.61−127.75 (20C), 82.59, 80.25, 78.29, 75.63, 75.21, 73.91, 73.68, 73.43, 71.35, 69.22, 51.31, 25.16, 22.01. HRMS (ESI): calcd for $C_{37}H_{41}N_3NaO_5$ $(M + Na)^+$ 630.2944, found 630.2938.

**General Procedure for the Synthesis of Title Compounds (4a−4d; Schemes 2 and 3).** The propyn-fipronil donor[5] was synthesized as previously described. Compounds **3a−3d** (1 mmol) were added to a solution of propyn-fipronil donor (1 mmol) in 3 mL

**Scheme 4**[a]



[a]Reagents and conditions: (1) $NaN_3$ and water at 85 °C for 16 h; (2) $CuSO_4{\cdot}5H_2O$, sodium ascorbate, and 1:1 t-BuOH/$H_2O$ at 60 °C for 3 h.

of *tert*-butyl alcohol. Then, a solution of $CuSO_4{\cdot}5H_2O$ (100 mg, 0.4 mmol) and sodium ascorbate (173 mg, 0.8 mmol) in distilled water (3 mL) was further added. The yellow solution was vigorously stirred at 60 °C for 3 h and quenched by adding water (10 mL). The aqueous layer was extracted with $CH_2Cl_2$ (10 mL × 3). The combined organic extracts were washed with aqueous sodium hydrogen carbonate and brine, dried with anhydrous $Na_2SO_4$, filtered, and evaporated in vacuo. The residues were purified by column chromatography (hexane/EtOAc 1:1) to afford the desired products as solids.

*N-{3-Cyano-1-[2,6-dichloro-4-(trifluoromethyl)-phenyl]-4-[(trifluoromethyl)sulfinyl]-1H-pyrazol-5-yl}-1-[2,3,4,6-tetra-O-acetyl-(2-triazolethyl)-β-D-glucopyranoside]-1H-1,2,3-triazole-4-methanamine (**4a**):* white solid; yield 85%; $^1$H NMR ($CDCl_3$) $\delta$ 7.75 (d, $J$ = 10.2 Hz, 2H), 7.53 (s, 1H), 6.24 (t, $J$ = 5.6 Hz, 1H), 5.16 (t, $J$ = 9.5 Hz, 1H), 5.03 (t, $J$ = 9.7 Hz, 1H), 4.86 (dd, $J$ = 9.5, 7.9 Hz, 1H), 4.50 (t, $J$ = 4.9 Hz, 2H), 4.46 (d, $J$ = 7.8 Hz, 1H), 4.37 (ddd, $J$ = 30.0, 14.7, 5.6 Hz, 2H), 4.21 (dd, $J$ = 12.4, 5.0 Hz, 1H), 4.17−4.10 (m, 1H), 4.08 (dd, $J$ = 12.4, 2.3 Hz, 1H), 3.91 (dt, $J$ = 10.8, 5.4 Hz, 1H), 3.68 (ddd, $J$ = 9.9, 4.9, 2.3 Hz, 1H), 2.03 (s, 3H), 2.01 (s, 3H), 2.00 (s, 3H), 1.89 (s, 3H); $^{13}$C NMR ($CDCl_3$) $\delta$ 170.64, 170.11, 169.60, 169.47, 151.24, 142.78, 136.66, 136.53, 135.48, 135.06 (q, $J$ = 34.4 Hz), 127.32, 126.49, 126.32, 125.46 (q, $J$ = 336.3 Hz), 123.77, 121.93 (q, $J$ = 274.1 Hz), 110.53, 100.70, 96.18, 72.32, 72.14, 71.10, 68.26, 67.84, 61.79, 50.37, 41.21, 20.71, 20.62 (2C), 20.59. **General Procedure for the Synthesis of Title Compound 5d (Scheme 3).** Anhydrous $FeCl_3$ (12 mmol) was added to a stirred solution of compound **4d** (1 mmol) in dry $CH_2Cl_2$ (10 mL) at room temperature under nitrogen. The reaction was left undisturbed until the color of the reaction mixture became brown. The solution was then evaporated under reduced pressure, and the residue was purified by column chromatography (chloroform/methanol 15:1) to afford the desired product **5d** as a white solid.

*N-{3-Cyano-1-[2,6-dichloro-4-(trifluoromethyl)phenyl]-4-[(trifluoromethyl)sulfinyl]-1H-pyrazol-5-yl}-1-(β-D-glucopyranosyl)-propyl-1H-1,2,3-triazole-4-methanamine (**5d**):* white solid; yield 55%; $^1$H NMR (MeOD) $\delta$ 8.08 (s, 2H), 7.87 (d, $J$ = 2.3 Hz, 1H), 4.61 (dd, $J$ = 16.1, 3.8 Hz, 1H), 4.50−4.36 (m, 3H), 3.93−3.87 (m, 1H), 3.78 (dd, $J$ = 11.8, 2.1 Hz, 1H), 3.59 (ddd, $J$ = 15.3, 10.6, 6.0 Hz, 2H), 3.47 (t, $J$ = 9.0 Hz, 1H), 3.36−3.32 (m, 1H), 3.24−3.17 (m, 1H), 2.13−2.02 (m, 1H), 1.96−1.85 (m, 1H), 1.74−1.58 (m, 2H); $^{13}$C NMR (MeOD) $\delta$ 151.87, 145.11, 137.88 (2C), 136.14, 136.13 (q, $J$ = 34.6 Hz), 127.97, 127.85, 126.94 (q, $J$ = 335.8 Hz), 123.98 (2C), 123.62 (q, $J$ = 272.9 Hz), 112.17, 97.60, 76.66, 75.18, 74.67, 72.94, 72.35, 63.24, 51.23, 41.18, 27.78, 22.65. HRMS (ESI): calcd for $C_{24}H_{24}Cl_2F_6N_7O_6S$ $(M + H)^+$ 722.0790, found 722.0785.

*Synthesis of N-{3-Cyano-1-[2,6-dichloro-4-(trifluoromethyl)-phenyl]-4-[(trifluoromethyl)sulfinyl]-1H-pyrazol-5-yl}-1-ethanol-1H-1,2,3-triazole-4-methanamine (FTO; Scheme 4).* 2-Bromoethanol (3.2 g, 25.62 mmol) was dissolved in water (12 mL), and sodium azide (2.5 g, 38.5 mmol, 1.5 equiv) was added to the solution. The reaction mixture was stirred at 85 °C for 16 h and quenched by adding cold water (10 mL). Diethyl ether (50 mL) was added, and the organic layer was washed with saturated aqueous $NaHCO_3$, water, and brine. The organic layer was dried over anhydrous $Na_2SO_4$ and evaporated under reduced pressure to yield 2-azidoethanol (1.56 g, 70%) as a colorless oil. The product was subjected to the next step without further purification.

2-Azidoethanol (0.5 g, 5.74 mmol) was added to a solution of propyn-fipronil (2.72 g, 5.74 mmol) in 15 mL of *tert*-butyl alcohol. Then, a solution of $CuSO_4{\cdot}5H_2O$ (575 mg, 2.3 mmol, 0.4 equiv) and sodium ascorbate (911.3 mg, 4.6 mmol, 0.8 equiv) in distilled water (15 mL) was added. The yellow solution was vigorously stirred at 60 °C for 3 h and then quenched by adding water (10 mL). The aqueous layer was extracted with $CH_2Cl_2$ (15 mL × 3). The combined organic extracts were washed with aqueous sodium hydrogen carbonate and brine, dried with anhydrous $Na_2SO_4$, filtered, and evaporated in vacuo. The residues were purified by column chromatography (hexane/EtOAc 2:3) to afford FTO (2.64 g, 82%) as a white solid: $^1$H NMR ($CDCl_3$) $\delta$ 7.76 (d, $J$ = 2.6 Hz, 1H), 7.60 (s, 1H), 6.04 (t, $J$ = 5.6 Hz, 1H), 4.47−4.44 (m, 1H), 4.40 (dd, $J$ = 15.1, 6.2 Hz, 1H), 4.28 (dd, $J$ = 15.1, 5.8 Hz, 1H), 4.08−4.01 (m, 1H), 2.23 (s, 1H); $^{13}$C NMR ($CDCl_3$) $\delta$ 153.75, 146.32, 137.81 (2C), 136.59, 136.03 (q, $J$ = 34.6 Hz), 129.81, 127.53, 126.78 (q, $J$ = 334.6 Hz), 125.79 (2C), 122.13 (q, $J$ = 272.8 Hz), 110.90, 96.81, 60.58, 48.74, 43.17. HRMS (ESI): calcd for $C_{17}H_{12}Cl_2F_6N_7O_2S$ $(M + H)^+$ 562.0055, found 562.0049.

**β-Glucosidase Enzymes.** β-Glucosidase from almonds was purchased from Sigma-Aldrich. A 10 U/mL solution was prepared.

**Growth of Plants.** This procedure is reported in detail elsewhere.[22,23] Six-day-old castor bean seedlings were selected for cotyledon absorption experiments. Adult plants of castor bean were grown in half-strength Hoagland's solution for 3−4 weeks until they possessed four true leaves. The cotyledons and primary leaves were cut, and the plants were tested 2−3 days later.

**Glucoside Metabolism Assays in Vitro.** A modification of the phosphate-based method of Masayuki[24] was used for glucoside metabolism assays. Glucosides were hydrolyzed in 0.1 M citrate−0.2 M phosphate buffer (pH 5.5) containing 1 unit of β-glucosidase, and the volume was brought up to 1 mL. Then, 5 μL of 20 mM concentrated standard solution was added to these centrifugal tubes. After incubation at 37 °C for 1 h, the reaction was stopped by boiling for 3 min.

The reaction mixture was analyzed with an Agilent 1100 HPLC system on a $C_{18}$ reversed-phase column (5 μm; 250 × 4.6 mm i.d.; Agilent Co.) with a flow rate of 1.0 mL min$^{-1}$ at 30 °C, and the eluent was made of water and acetonitrile (50:50, v/v). Glucoside and aglycon were detected by UV absorption at 210 nm.

For the identification of reaction products, UHPLC-HRMS analyses were performed. The UHPLC system consisting of an autosampler, a binary pump, and a diode array detector (Agilent Technologies 1290 infinity) was interfaced to a time-of-flight (TOF) mass spectrometer (Bruker Maxis, Germany). SB-$C_{18}$ RRHD (1.8 μm, 50 × 2.1 mm, Agilent Technologies) was used for the separation. Column temperature was set at 30 °C, and injection volume was 5 μL. The binary mobile phase consisted of (A) 100% water and (B) 100% acetonitrile, and the 8 min gradient was described as follows: 0−1 min, 10% B isocratic; 1−4 min, 90% B; 4−8 min, 10% B, at a flow rate of 0.2 mL min$^{-1}$. The detection wavelength was 210 nm. Electrospray ionization in positive mode was performed under the following conditions: nebulizer, 0.3 bar; drying gas, 4.0 L min$^{-1}$; drying temperature, 180 °C; and capillary, 3500 V. The full scan mass spectra of the compounds were recorded within $m/z$ 50−1000.

**Glucoside Metabolism Assays in Vivo.** These assays were performed following a previous method.[25] In a typical procedure, an aqueous solution (10 mM, equal volumes of 10 μL in each petiole) was injected into the petioles of the two mature leaves using a 10 μL microsyringe. After the application of glucosides, the plants were grown for 4 h, and then the blades of the mature leaves were separated from the plants.

The compounds were extracted from the leaves (2.0 g) by grinding in 10 mL of methanol with a glass mortar and pestle. After ultrasonic treatment for 20 min, a portion (2.0 mL) of the extract was centrifuged at 15000 rpm for 5 min and the supernatant passed through a 0.22 μm filter. Then, the treated solutions were analyzed by HPLC. Recoveries of parent compound were >85% conducted by adding known amounts of glucosides with three replicates.

**Insects.** Larvae of *S. litura* F. were obtained from the Guangzhou Biological Control Station and raised with artificial feed under cage conditions for three generations. Healthy larvae of *P. xylostella* L. were collected from the experimental farm of Dongguan Agricultural Science Research Center, Guangdong, China, and reared on Chinese cabbage (*Brassica rapa*) under cage conditions for three generations. The feeding conditions were as follows: temperature, 26 ± 2 °C; relative humidity, 70%; and photoperiod, 16:8 h (light/dark).

**Insecticidal Activity.** To investigate the insecticidal activities of FTO (Scheme 4) and FOH,[6] we synthesized the aglycons beforehand. The insecticidal activities of the compounds GOTF, FTO, GOF, FOH, and fipronil against *P. xylostella* L. and *S. litura* F. were evaluated by leaf disk dipping assay.[26] The leaf disks (1.8 cm diameter) were cut from fresh cabbage grown in a greenhouse. The compounds were dissolved in acetone and suspended in distilled water containing Tween 80 (0.1%). Leaf disks were dipped in each test solution for 30 s and allowed to dry for 2 h. After air-drying, the treated leaf disks were placed in Petri dishes (9 cm diameter) lined with filter paper, and then the second-instar larvae of *P. xylostella* L. and *S. litura* F. were transferred to a Petri dish. Three replicates (10 larvae per replicate) were carried out. Fipronil was used as a standard. Petri dishes were kept in an incubator at 26 °C and 85% relative humidity under a photoperiod of 16:8 h (light/dark). Mortalities were determined 24 h after treatment.

## RESULTS AND DISCUSSION

**Synthesis and Characterization.** Click chemistry[27] was performed to create four glucose−fipronil conjugates, **4a−4d** (Figure S1). $CuSO_4{\cdot}5H_2O$/sodium ascorbate and CuI/DIPEA are commonly used as catalysts for this method. The $CuSO_4{\cdot}5H_2O$/sodium ascorbate system[28] was selected to optimize the reaction yield (>85%) and ensure the stability of conjugates. Compounds **4a−4c** were deprotected using 1 M NaOMe in

MeOH to yield products **5a**–**5c** with 60% yields. The structures of **4a**–**4c** and **5a**–**5c** were confirmed by $^{1}$H NMR, $^{13}$C NMR, and mass spectrometry. The acetyl groups of **4a** exhibited characteristic signals at 1.89, 2.00, 2.01, and 2.03 ppm in the $^{1}$H NMR spectra, as well as 20.59, 20.62, and 20.71 ppm in the $^{13}$C NMR spectra. However, the characteristic $^{1}$H NMR and $^{13}$C NMR spectrum signals of **5a** were not observed. The acetyl groups of **4a** disappeared after deprotection.

Generally, palladium-catalyzed hydrogenolysis was used to deprotect benzyl ether. However, **4d** exhibited a sulfur atom in sulfinyl that could cause permanent catalytic poisoning. Accordingly, $FeCl_3$ was introduced to synthesize **5d** with 55% yield because of its high efficacy.[29] The structures of **4d** and **5d** were confirmed by $^{1}$H NMR, $^{13}$C NMR, and mass spectrometry. Debenzylation was proved by $^{1}$H and $^{13}$C NMR spectra. The characteristic peaks between 7.35 and 7.1 ppm in the $^{1}$H NMR spectra, as well as the peaks at 128.65–127.76, 137.99, 138.08, 138.18, and 138.65 ppm in the $^{13}$C NMR spectra, were not observed after deprotection.

**Hydrolysis of Glucosides.** To examine the ability of *β*-glucosidase to hydrolyze glucose–pesticide conjugates in vitro, 1 mL of buffer solutions containing 1 unit of almond *β*-glucosidase was individually incubated with four glucose–fipronil conjugates for 1 h. Each solution was analyzed by HPLC upon termination of the reaction to detect potential hydrolysis products. Figure 3A shows that GOTF solution displayed a novel peak, and the original peak at the GOTF position cannot be clearly detected. This result indicated that 1 unit of *β*-glucosidase could hydrolyze nearly all GOTF within 1 h. However, no peak was observed from the other conjugate solutions, indicating that these analogues could not be hydrolyzed by *β*-glucosidases under experimental conditions (Figure 3B–D). In the absence of enzymes, hydrolysis was not observed in the control reaction, demonstrating the stability of glucosides. Considering the metabolite accumulation caused by the *β*-glucosidase-mediated degradation of GOTF, the single metabolite observed in the in vitro assay was analyzed by UHPLC-HRMS to determine its structure and define the enzymatic reactions (Figure 4A,B). The GOTF metabolite in the positive-ion mode resulted in pseudomolecular $[M + Na]^+$ at $m/z$ 583.9904, which was consistent for its reduced mass (mass loss = 162) indicating the removal of a single glucose molecule. This result determined the chemical structure (FTO) of the metabolite (Figure 2). The identity of the GOTF metabolite was verified by $^{1}$H NMR (Figure S2). These data indicated that the almond *β*-glucosidase hydrolyzed GOTF to FTO and exhibited high specificity for the O-glycosidic bond.

The in vitro activity of *β*-glucosidases implied that it could hydrolyze glucose–fipronil conjugates in vivo. To confirm this result, tests were conducted in adult *Ricinus communis* L. A peak was detected by HPLC in the leaf extracts when 20 *μ*L of a 10 mM GOTF solution was injected into the petioles after 4 h (Figure 3A). The retention time of the metabolic product suggested that for GOTF the observed products of castor bean in vivo were similar to those generated from the in vitro assays using *β*-glucosidase solutions (UHPLC-HRMS, Figure 4C–E). GOTF was also identified in the leaf extract (Figure 4C,D). By contrast, peaks were undetected in the extracted solution by HPLC when analogues were treated under the same experimental condition (Figure 3B–D). Thus, the analogues were stable within 4 h of injection, but we cannot rule out the possibility of other metabolism mechanisms occurring within the plant with prolonged time. Given the results of in vivo and

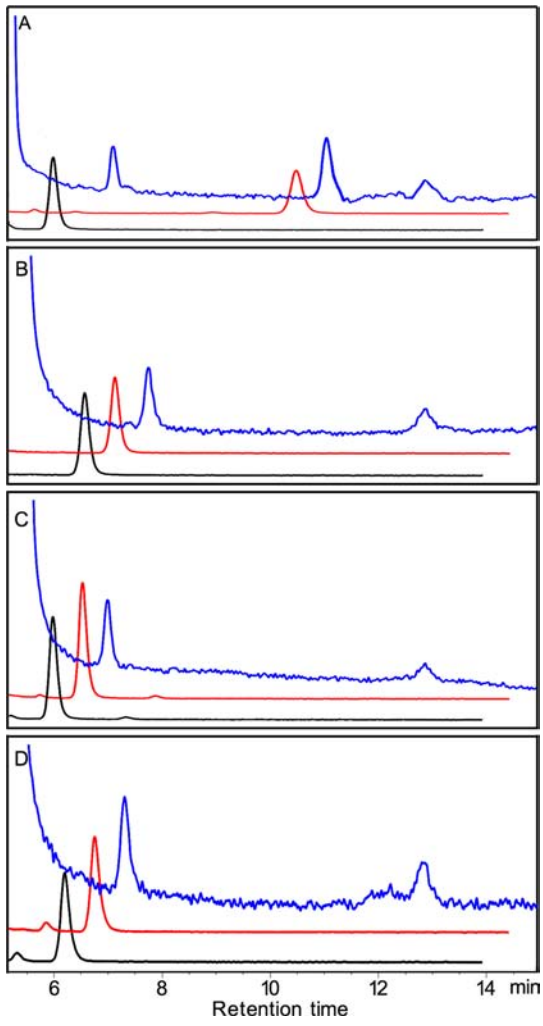

**Figure 3.** HPLC chromatograms of four glucosides measured at 210 nm for (A) GOTF, (B) GTTF, (C) GNTF, and (D) GCTF. Lane 1 (black line) describes the standard solutions of the corresponding glucosides. Lane 2 (red line) represents the glucosides incubated in buffer solutions containing of 1 unit of *β*-glucosidase for 1 h. Lane 3 (blue line) corresponds to the leaf extraction of castor bean at 4 h after injection.

in vitro assays, *β*-glucosidase was associated with the metabolism of glucose–fipronil conjugates in the body of adult castor beans and was specific for the hydrolysis of O-glycosidic bonds.

*β*-Glucosidase mediated the hydrolysis of glucose–pesticide conjugates, in which glucose was tethered to pesticides by O-glycosidic bonds. To verify this result, another glucose–fipronil conjugate, GOF, was selected for additional tests under the same experimental condition; this conjugate has been synthesized, and its phloem mobility in the castor bean system has been examined.[6] After 1 h of incubation with *β*-glucosidase, a peak in the HPLC chromatogram was observed and analyzed by UHPLC-HRMS (Figure 5A). Results showed that GOF (molecular mass = 642.0177) had $[M + Na]^+$ at $m/z$ 665.0077 (calculated for $C_{20}H_{18}Cl_2F_6N_4NaO_7S$; Figure 5B). The hydrolysis products (FOH) indicated a reduction in glucose molecule, and the majority of these displayed $[M + H]^+$ at $m/z$ 480.9733 (calculated for $C_{14}H_9Cl_2F_6N_4O_2S$; Figure 5C). The glucose–pesticide conjugate was metabolized within the body of an adult castor bean 4 h after injection. The reaction

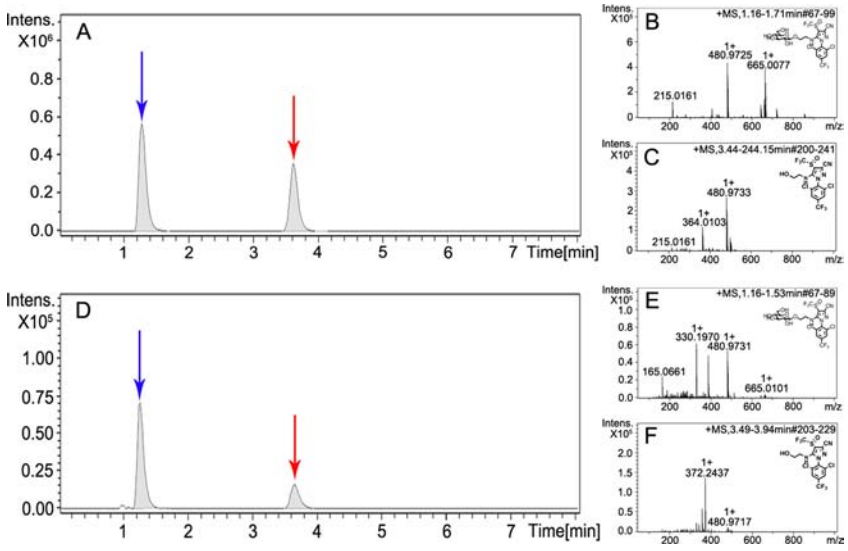

**Figure 5.** UHPLC-HRMS analysis of metabolites present in the buffer solution of $\beta$-glucosidases and leaf extract after treatment with GOF: (A) GOF solution incubated with $\beta$-glucosidases in vitro; (B) positive-ion ESI mass spectrum of the peak in panel A (blue arrow) showing $[M + Na]^+$ at $m/z$ 665.0077, which corresponds to the mass of GOF; (C) positive-ion ESI mass spectrum of the peak in panel A (red arrow) showing the reduced mass of the hydrolysis products to remove the glucose molecule; $[M + H]^+$ is located at $m/z$ 480.9733; (D) UV chromatogram of the leaf extracts; (E) positive-ion ESI mass spectrum of the peak in panel D (blue arrow) indicating $[M + Na]^+$ at $m/z$ 665.0101; (F) positive-ion ESI mass spectrum of the peak in panel D (red arrow) showing $[M + H]^+$ at $m/z$ 480.9717, which corresponds to the metabolite in vitro.

products identified by UHPLC-HRMS (Figure 5D–F) were similar to those of $\beta$-glucosidase hydrolysis in vitro. These data demonstrated that $\beta$-glucosidase was associated with the hydrolysis of GOF within the plant and the O-glycosidic bond.

To determine whether the O-glycosidic bond conjugates GOTF and GOF would be hydrolyzed in epidermal or mesophyll cells before reaching the phloem, a cotyledon absorption experiment was performed using castor bean seedlings (Supporting Information, Materials and Methods). After 15 min of incubation, both GOTF and GOF were hydrolyzed. GOTF was almost entirely hydrolyzed to be FTO within the cotyledons, whereas about 75% of GOF was hydrolyzed (Figure S3). Combined with in vitro and in vivo hydrolysis, GOF can be speculated to be not as readily hydrolyzed as GOTF. Given that the phloem mobility of GOF has been confirmed,[6] the slow hydrolysis and moderate phloem mobility of GOF is considered to be preferred over GOTF to be loaded in the phloem and achieve the slow release of insecticidal activities. The difference in hydrolyzing degree between GOF and GOTF may be due to the distinction of $\beta$-glucosidase affinity. Thus, the effects of different glucose–pesticide conjugates' chemical construction on hydrolyzing degree is worthy of further investigation.

A pro-drug was designed to solve the incompatibility between phloem mobility and activity. This material could be cleaved inside the plant or pest organism by spontaneous chemical conversion or enzyme-catalyzed metabolism. The enzyme unique to the plant crucially determines the proper approach to the preparation of pro-drugs.[2,30] Related works have achieved this enzyme through engineering mechanisms to release the active molecule within the plants. For instance, a sulfonylurea pro-herbicide can be activated in transgenic

dx.doi.org/10.1021/jf5034575 | J. Agric. Food Chem. 2014, 62, 11037–11046

tobacco using the TA29 promoter to express a bacterial P450 gene in a tissue-specific manner.[31] Tobacco could hydrolyze oxamyl glucuronide into its active compound by expressing the gene of *E. coli* β-glucuronidase in the root meristem and central cylinder.[2] However, the environmental effects of genetically modified crops could limit the use of this approach.[32] Plants contain endogenous β-glucosidases that catalyze the hydrolysis of glucosidic bonds to bioactivate plant glucosides (e.g., pro-hormones and phytoanticipins) and design parts as special active sites.[33] Although the importance of β-glucosidase in catalyzing glucoside hydrolysis is well documented, few studies have focused on the utilization of endogenous β-glucosidase to hydrolyze exogenous glucosides. This study revealed the involvement of endogenous β-glucosidase in the hydrolysis of glucose−pesticide conjugates. Furthermore, tethering of the mobility-conferring glucose to the pesticide through O-glycosidic bonds can circumvent the conflicting functions of mobility and activity.

**Insecticidal Activity.** The insecticidal activities of GOTF, FTO, GOF, and FOH were evaluated and compared with those of fipronil over a wide range of concentrations (Tables 1 and 2). GOTF and GOF exhibited negligible insecticidal activities against the second-instar larvae of *P. xylostella* L. and *S. litura* F. (mortality rate at 500 mg $L^{-1}$, <20%; Table 1). The low insecticidal activity of glucose−fipronil conjugates verified the theory of Hsu et al.,[2] in which the incompatibility between mobility and activity was observed. However, FOH (aglycon of GOF) exhibited excellent activity comparable to that of commercialized fipronil (Tables 1 and 2). $LC_{50}$ value (95% confidence limits, CL) after 24 h was found to be 31.49 mg $L^{-1}$ (18.19−54.49 mg $L^{-1}$) against the larvae of *P. xylostella* L., which was analogous to that of fipronil (25.50 mg $L^{-1}$ (16.10−40.40 mg $L^{-1}$)). Meanwhile, the $LC_{50}$ (95% CL) of FOH was 36.34 mg $L^{-1}$ (26.15−50.52 mg $L^{-1}$) against the second-instar larvae of *S. litura* F; the $LC_{50}$ for fipronil was 33.87 mg $L^{-1}$ (25.81−44.45 mg $L^{-1}$). FTO (the aglycon of GOTF) exhibited unsatisfactory insecticidal activity at 500 mg $L^{-1}$, with mortality rates of only 30% against *P. xylostella* L. and 9.7% against *S. litura* F. after 24 h (Table 1). Thus, we inferred that triazolyl could significantly reduce the insecticidal activity of fipronil. However, the results of this study should be further analyzed.

Overall, four glucose−fipronil conjugates were designed and synthesized by click chemistry. Metabolic assays of conjugates in vitro and in vivo were performed. Results demonstrated that the O-glycosidic bond could be recognized and hydrolyzed only by β-glucosidases. Another O-glycosidic bond conjugate GOF was metabolized in *R. communis* L., which released the aglycon FOH with highly analogous efficacy to the commercialized fipronil against *P. xylostella* L. and *S. litura* F. However, further analyses of the location and rate of GOF hydrolysis are required. These results conformed to our initial hypothesis that endogenous β-glucosidases were involved in the hydrolysis of exogenous phloem-mobile conjugates and the release of active aglycons, which can reasonably and feasibly achieve phloem mobility and biological activity of pesticides.

**Table 1. Insecticidal Activities of GOTF, FTO, GOF, FOH, and Fipronil against *P. xylostella* L. and *S. litura* F.**

| | toxicities against *P. xylostella* L. | | toxicities against *S. litura* F. | |

controlled, and more comprehensive research should be conducted.

In this Article, field experiments of penconazole were conducted, and then cucumber, tomato, head cabbage, and pakchoi samples were collected for analysis. A simple pretreatment method was adopted on the basis of buffered QuEChERS (quick, easy, cheap, effective, rugged, and safe) for the extraction, cleanup, and preconcentration of penconazole.[27,28] The chiral analysis method of penconazole was established by liquid chromatography−tandem mass spectrometry (LC−MS/MS) equipped with a Lux Cellulose-2 chiral column. Finally, the result suggested that penconazole showed enantioselective dissipation in head cabbage and pakchoi, but not in the cucumber and tomato samples. The results in this Article might also provide some sufficient information on penconazole during the food and environment risk assessment.

## MATERIALS AND METHODS

**Chemicals and Materials.** The analytical standard of (±)-penconazole (purity 99.0%) was purchased form Dr. Ehrenstorfer (Augsburg, Germany). The commercial product of penconazole-EC (10% of (±)-penconazole) was obtained from the Hangzhou Udragon Chemical Co. Ltd. (Zhejiang, China). Purified water was prepared by using a Milli-Q water purification system (Millipore Corp., Billerica, U.S.). LC grade methanol ($CH_3OH$) and acetonitrile ($CH_3CN$) were obtained from Merck (Darmstadt, Germany). Formic acid and ammonium acetate were obtained from TEDIA (Fairfield, U.S.). Acetic acid was obtained from Sigma-Aldrich (St. Louis, U.S.). Silica-based sorbents including $C_{18}$ (40 μm particle size) and primary secondary amine (PSA) (40 μm particle size) were obtained from Agilent (Wilmington, U.S.). All other chemicals and solvents were of analytical grade and were purchased from commercial sources.

**Field Experiments.** The vegetable (cucumber, tomato, head cabbage, and pakchoi) seeds purchased from Longda Seeds (Hangzhou, China) were sown in greenhouse conditions on 7 February 2012. The field experiments were conducted from March to May 2012 in Zhejiang Academy of Agricultural Sciences (Hangzhou, China). Every experiment treatment for a vegetable contained three replicate plots and a control plot without penconazole. The area of each plot was 30 (10 × 3) $m^2$, and the buffer zone was set up between plots. These plots had never been treated with penconazole for more than 3 years. (±)-Penconazole 10% EC was applied as foliar spray at the dose of 47.6 g a.i. $ha^{-1}$ (gram of active ingredient per hectare), dissolving in 2 L of water. Approximately 2 kg of vegetable samples was collected from nine randomly selected sampling points within each plot, at 0 (1 h after spraying), 1, 2, 3, 5, 7, 10, 14, and 21 days after spray. All vegetable samples were homogenized by a blender (Philips, China), and then stored at −20 °C until further analysis.

**Enantioselective LC−MS/MS Analysis.** LC−MS/MS analyses were performed on a Surveyor liquid chromatograph equipped with a TSQ Discovery triple quadrupole mass spectrometer (Thermo Fisher Scientific, U.S.). Thermo Fisher Xcalibur software (version 2.0.7) was used for data quantitation and documentation.

A satisfactory enantioseparation of penconazole was performed on a Lux Cellulose-2 chiral column (150 mm × 2.0 mm i.d., 3 μm, Phenomenex, U.S.) packed with cellulose tris (3-chloro-4-methylphenylcarbamate). The analysis was isocratic at 0.2 mL $L^{-1}$ flow rate using mobile phase A (LC grade methanol) and mobile phase B (0.1% formic acid and 2 mM ammonium acetate in water) in a 70:30 v/v ratio. The column temperature was kept at 25 °C, and the autosampler temperature was set at 4 °C. The sample injection volume was 10 μL, and the total run time was 25 min.

The ESI−MS/MS (electrospray ionization coupled with tandem mass spectrometry) was performed in positive ion mode, and the monitoring conditions were optimized for penconazole. The typical ESI source conditions were as follows: ion spray voltage, 4200 V; ion capillary temperature, 350 °C; sheath gas flow ($N_2$), 35 (arbitrary) units; aux gas flow ($N_2$), 8 U; collision gas pressure (Ar), 1.5 mTorr. Multiple reactions monitoring (MRM) mode was applied to determine the fragmentation of the protonated pseudomolecular ions of penconazole. The transitions $m/z$ 284 > 159 and $m/z$ 284 > 70 were used for quantification and confirmation, respectively. The corresponding collision energies were 15 and 20 eV.

**Elution Order Determination of Penconazole Enantiomers.** The optical rotation dispersion (ORD) signal of (+) or (−) was used to distinguish the elution order of the enantiomers by an Agilent 1200 HPLC system equipped with a G1315B diode array detector (Wilmington, U.S.) and online CHIRALYSER-MP optical rotation detector (IBZ Messtechnik, Germany). The signal was received and processed by Agilent 1200 chemstation and N2000 SP1 chromatographic chemstation (Zhida, China) software. The chiral separation was performed under the same LC conditions as LC−MS/MS, but the injection volume was 20 μL and the flow rate was set at 1.0 mL/min with the UV detection at 230 nm.

**Sample Preparation.** Samples were thawed previously at room temperature. A 15 g triturated vegetable sample was weighed into a 50 mL polypropylene centrifuge tube, and 15 mL of acetonitrile containing 1% of acetic acid was added. The mixture was shaken by a vortex mixer for 1 min and then sonicated for 15 min. Subsequently, 6 g of anhydrous magnesium sulfate and 1.5 g of anhydrous sodium acetate were added, and the tube was shaken vigorously by hand for 5 min and centrifuged at 6000 rpm for 5 min. A 1 mL aliquot of upper acetonitrile supernatant was transferred into a 2 mL centrifuge tube containing 50 mg of PSA sorbent, 50 mg of C18 sorbent, and 150 mg of anhydrous magnesium sulfate for cleanup. The tube was shaken by vortex mixer for 1 min and centrifuged at 6000 rpm for 5 min. A 0.5 mL portion of the upper extracts was transferred into a 2 mL centrifuge tube containing 0.5 mL of water. The resulting solution was filtered through a 0.22 μm Teflon syringe filter for LC−MS/MS analysis.

**Method Validation.** A series of working standard solutions and matrix-matched calibration standard of (±)-penconazole for linearity of the method were prepared at 0.5, 1, 2.5, 5, 25, 100, and 500 μg $L^{-1}$ for each enantiomer. The calibration curves were generated by plotting the peak area of quantification ion transition versus the concentration of each enantiomer. Linear regression analysis was performed using Microsoft Excel 2007, and the correlation coefficient was used to evaluate linearity of the method.

The accuracy and precision of the method were investigated to evaluate its reliability. The blank vegetable samples obtained from the field experiment were fortified with standard solutions of each enantiomer at three levels (2.5, 50, and 500 μg $kg^{-1}$). Recovery experiments were carried out with five replicates for each level, and fortified samples were equilibrated for 1 h at room temperature prior to extraction as described above. The precision of the method was investigated by the repeatability (intraday assays) and reproducibility (interday assays), expressed by relative standard deviation (RSD). The repeatability assays were measured in five replicates at three concentration levels on the same day, with the same instrument and by the same operator. The reproducibility assays were evaluated in five replicates at the earlier stated concentration levels on three different days, with the same instrument but by different operators.

The limits of detection (LODs) for each enantiomer were calculated as 3 times the signal-to-noise (peak to peak) ratio of the quantitative ion transition by the lowest spiked analytes concentration assayed with five replicates. The limits of quantification (LOQs) were defined as the lowest concentration with acceptable accuracy for 70−120% and precision for 15% variability.

## RESULTS AND DISCUSSION

**Enantioseparation and Identification Elution Order of Penconazole.** Under the LC−MS/MS condition, the enantiomers of penconazole were separated completely on a Lux Cellulose-2 column (as shown in Figure 4). In this work, an online ORD was used to distinguish the elution order information on penconazole enantiomers based on the difference of the refractive index between left (−) and right

Table 1. Comparison of Matrix-Matched Calibration and Solvent Calibration (0.5−500 $\mu$g $L^{-1}$)

| compound | matrix | standard linear equation | $R^2$ | slope of matrix/slope of solvent |
|---|---|---|---|---|
| (+)-penconazole | solvent | $Y = 130131X + 50683$ | 0.9983 | |
| | cucumber | $Y = 128910X + 23523$ | 0.9998 | 0.991 |

| | P | 79.6 (6.5, 9.6) | 84.6 (4.9, 6.3) | 87.9 (5.8, 6.0) |

[a]RSD represents the relative standard deviation of intraday ($n$ = 5). [b]RSD represents the relative standard deviation of interday ($n$ = 15). [c]C represents cucumber. T represents tomato. H represents head cabbage. P represents pakchoi.

(+) linearly polarized lights. The results showed that the first eluted enantiomer was confirmed as (+)-penconazole, while the second eluted enantiomer was (−)-penconazole under the LC condition described above.

**Method Development and Validation.** The sample extraction and cleanup procedure for penconazole enantiomers in vegetables followed the buffered QuEChERS method. Validation of the proposed method included linearity, recovery, and precision. Good linear calibration curves for both enantiomers were obtained over the range of 0.5−500 $\mu$g $L^{-1}$. The linear equations for each enantiomer in standard solutions and matrix-matched solutions are listed in Table 1. The matrix effect was calculated by comparing the slope of matrix-matched standard curve with the slope of solvent standard calibration curve.[29] The slope ratios of matrix-matched to solvent-based calibration listed in Table 1 were in the range of 0.928−0.998, which implied no significant matrix effect for enantiomers of penconazole in the four vegetable matrixes.

The recoveries of penconazole enantiomers in vegetable matrixes at three spiked levels ranged from 78.5% to 102%, and the RSDs of repeatability and reproducibility ranged from 2.8% to 11.5% (see Table 2). The results of recoveries and precisions obtained in the method validation portion proved that the method was efficient and reliable to determine the enantiomers of penconazole in the four vegetables with LC−MS/MS. The LODs for both enantiomers in the tested vegetables were estimated to be 0.5 $\mu$g $kg^{-1}$, while the LOQs of enantiomers in vegetables were 2.5 $\mu$g $kg^{-1}$ based on the lowest fortified level in the tested vegetables.

**Residues Dissipation of Penconazole in Cucumber and Tomato.** Penconazole residue dissipation in cucumber and tomato was investigated under field conditions. In Figure 2, the data were plotted from cucumber and tomato as normalized concentrations ($100C/C_0$) versus treatment time. Figure 2 shows that the residues of penconazole decreased quickly with time in cucumber and tomato when the (±)-penconazole was sprayed, and the dissipation processes followed first-order kinetics. The depletion rate constant were obtained by fitting the enantiomer of penconazole residue data from each experiment to the first-order kinetic equation $\ln(C/C_0) = -kt$, where $C_0$ is the initial concentration of the enantiomer ($\mu$g $kg^{-1}$), $C$ is its concentration ($\mu$g $kg^{-1}$) at time $t$ (days), $k$ is the depletion rate constant, and the corresponding half-lives ($t_{1/2}$) were calculated as $t_{1/2} = \ln 2/k = 0.693/k$.[30] The depletion rate constant, half-life, and correlation coefficient ($R^2$) of the two enantiomers are shown in Table 3, and the data show that the depletion rates of the two enantiomers in cucumber and tomato were similar to $t_{1/2}$ ranging from 1.52 to 1.98 days.

In this study, the enantiomeric ratio (ER) was used as a measure of the enantioselectivity of the residues dissipation of penconazole in vegetables. The ER value was defined as the concentration of the first eluting (+)-enantiomer divided by the concentration of the later eluting (−)-enantiomer.[31] It was shown in Figure 3 that the ER values of (±)-penconazole were constant with time in cucumber and tomato. Student's $t$-tests were made to compare the mean ER values of (±)-penconazole in the two vegetables with ER = 1 at a 95% confidence interval. The statistical test results indicated that the dissipation of penconazole enantiomers was not enantioselective either in cucumber ($p$ = 0.17) or in tomato ($p$ = 0.30).

**Residue Dissipation of Penconazole in Head Cabbage and Pakchoi.** The residue dissipation of penconazole enantiomers in head cabbage and pakchoi was investigated under field conditions with (±)-penconazole foliage sprayed. Generally, the residues of both enantiomers of penconazole decreased quickly with time elapsed in the head cabbage and

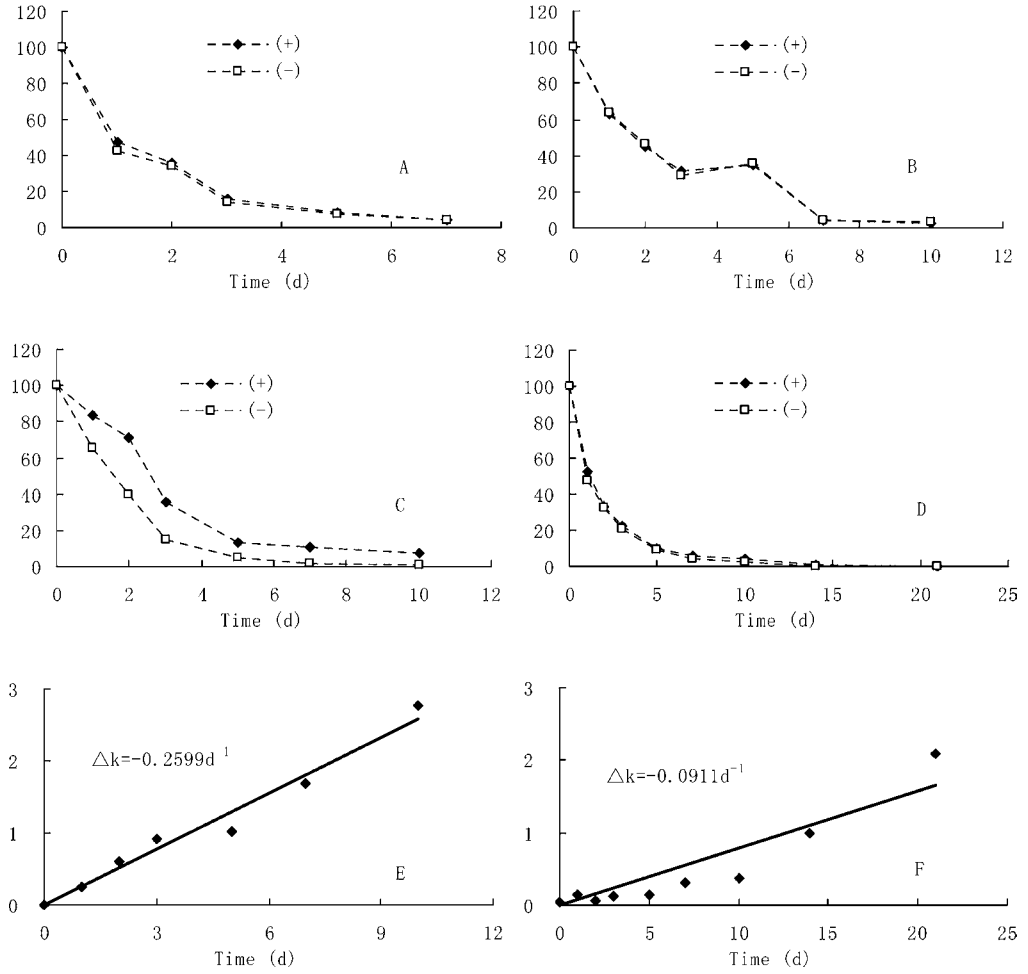

**Figure 2.** Degradation of penconazole enantiomers in (A) cucumber, (B) tomato, (C) head cabbage, and (D) pakchoi. Normalized concentrations ($100C/C_0$) are plotted versus treatment time (d). Note the faster degradation of the (−)-enantiomer. Plot of ln(ER) from (E) head cabbage and (F) pakchoi after treatment with (±)-penconazole versus treatment time showing a linear relationship.

**Table 3. First-Order Depletion Rate Constant ($k$), Initial Concentration ($C_0$), Half-Life ($t_{1/2}$), and Correlation Coefficient ($R^2$) for the Enantioselective Dissipation of Penconazole**

| experiment | compound | $k$ (day$^{-1}$) | $C_0$ ($\mu$g kg$^{-1}$)[a] | $t_{1/2}$ (day)[a] | $R^2$ |
|---|---|---|---|---|---|
| cucumber | (+)-penconazole | 0.4536 | 39.3 ± 3.6 | 1.53 ± 0.07 | 0.9756 |
| | (−)-penconazole | 0.4547 | 43.1 ± 1.9 | 1.52 ± 0.09 | 0.9667 |
| tomato | (+)-penconazole | 0.3636 | 49.6 ± 4.0 | 1.90 ± 0.12 | 0.9117 |
| | (−)-penconazole | 0.3491 | 50.9 ± 1.9 | 1.98 ± 0.06 | 0.9025 |
| head cabbage | (+)-penconazole | 0.2899 | 119.6 ± 7.7 | 2.39[b] ± 0.05 | 0.9165 |
| | (−)-penconazole | 0.5497 | 118.4 ± 5.1 | 1.26[b] ± 0.11 | 0.9895 |
| pakchoi | (+)-penconazole | 0.2720 | 449.3 ± 8.7 | 2.55[b] ± 0.03 | 0.9553 |
| | (−)-penconazole | 0.3632 | 435.0 ± 6.7 | 1.91[b] ± 0.07 | 0.9861 |

[a]Values represent the means ± SDs ($n$ = 3). [b]Significantly different from each other, $p < 0.05$ (paired $t$ test).

pakchoi (see Figure 2), and the typical LC−MS/MS chromatograms are shown in Figure 4. In Figure 2C and D, the data were plotted from head cabbage and pakchoi as normalized concentration ($100C/C_0$) versus time, and it was obvious that the second-eluted (−)-enantiomer dissipated more rapid than the other enantiomer, leading to residues enriched in (+)-form. By calculation, the depletion rate constant followed first-order kinetics and the half-life of each enantiomers is listed in Table 3, and these data also demonstrated that (−)-enantiomer ($t_{1/2}$ = 1.26 and 1.91 days, respectively) degraded faster than (+)-enantiomer ($t_{1/2}$ = 2.39 and 2.55 days, respectively) in the two tested vegetables. The statistical analysis was also performed, and the result suggested that the difference of the two enantiomers was significant ($p < 0.05$, student's paired $t$ test).

In Figure 3C and D, the variation curve of ER value was plotted versus time from head cabbage and pakchoi, and it could be found that the ER values of penconazole consistently increased with time in both vegetables. Student's $t$ tests were made to compare the mean ER values of (±)-penconazole in the two vegetables with ER = 1 at a 95% confidence interval. The statistical test results indicated there was substantial enantioselectivity on the dissipation of (±)-penconazole in

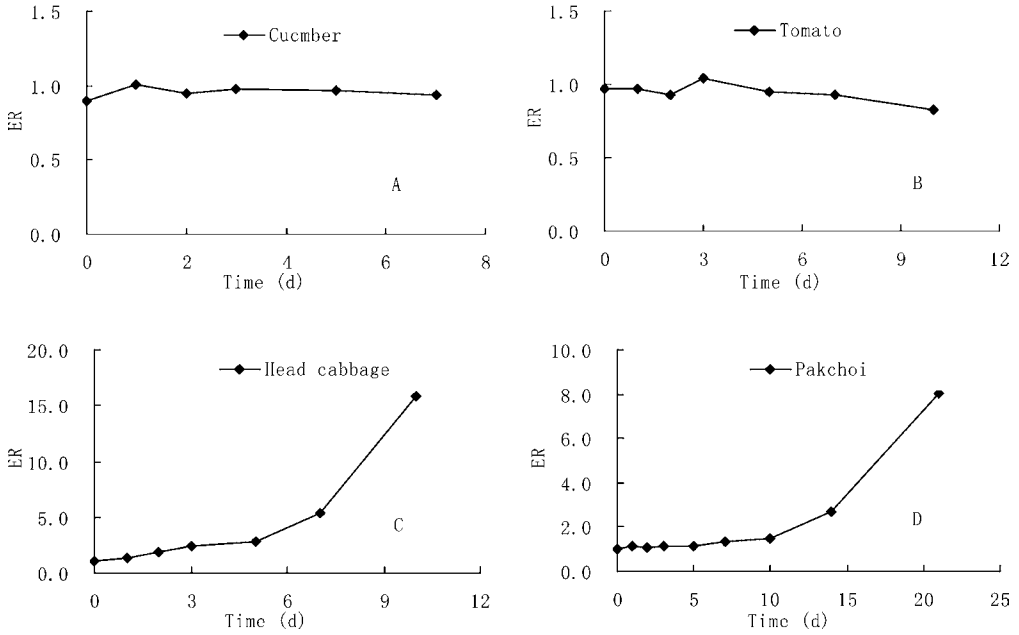

**Figure 3.** Enantiomeric ratio (ER) of penconazole residues in (A) cucumber, (B) tomato, (C) head cabbage, and (D) pakchoi.

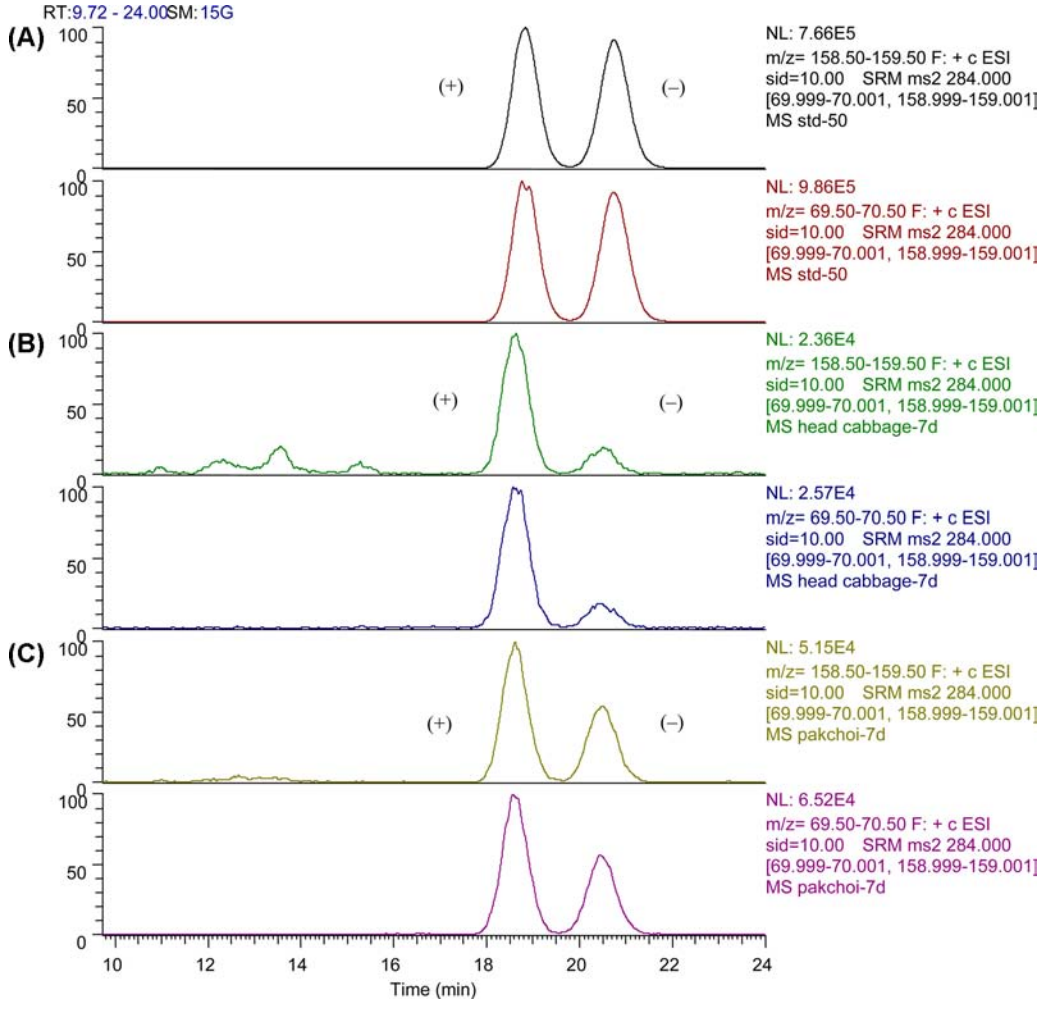

**Figure 4.** Representative chromatograms of (A) (±)-penconazole standard (50 $\mu$g L$^{-1}$), (B) extract from head cabbage at 7 d after treatment with (±)-penconazole, and (C) extract from pakchoi at 7 d after treatment with (±)-penconazole.

dx.doi.org/10.1021/jf5034653 | J. Agric. Food Chem. 2014, 62, 11047−11053

head cabbage ($p$ = 0.005) and pakchoi ($p$ = 0.016) under the field experiments.

The dissipation processes of penconazole enantiomers in the test vegetables followed first-order kinetics with a depletion rate constant of $k_{(+)}$ for the (+)-enantiomer, and a depletion rate constant of $k_{(-)}$ for the (−)-form; ER may be expressed as an equation of time ($t$) in the following relationship:[32,33]

$$ER_t = [+]/[-] = ER_0 \times e^{\{k_{(-)} - k_{(+)}\}} = ER_0 \times e^{\Delta k} \quad (1)$$

where $ER_0$ is the initial ER value at 1 h after spraying with (±)-penconazole in head cabbage and pakchoi, [+] and [−] are the concentrations of (+)-enantiomer and (−)-enantiomer at time $t$, respectively, and $\Delta k$ is the difference from $ER_0$ over time. The above relationship can be further expressed in a linear form after logarithmic transformation of ER:

$$\ln(ER_t) = \ln(ER_0) + \Delta k \quad (2)$$

Equation 2 indicated a linear relationship between $\ln(ER_t)$ and time ($t$), and we showed the data plotted in Figure 2E and F, which could be used to determine the rate difference $\Delta k$ and thus enantioselectivity. The $\Delta k$ calculated from these plots for head cabbage and pakchoi is 0.2599 and 0.0911 $d^{-1}$, respectively. The results also suggested that greater enantioselectivity of penconazole occurred in head cabbage than that in pakchoi.

In the present study, the dissipation of the two enantiomers of penconazole was investigated in the four test vegetables. The results showed that the (−)-penconazole degraded faster than the (+)-isomer in head cabbage and pakchoi, which meant enantioselectivity happened. However, no obvious enantioselectivity of dissipation behavior existed in cucumber and tomato. Some studies[16,17,20,23,24] verified that other triazole fungicides, such as hexaconazole, tebuconazole, and myclobutanil, exhibited stereoselectivity of degradation in cucumber or tomato. Many researchers[34−38] indicated that whether enantioselective behavior occurred or not may be related to the metabolic enzyme system in plant during the process of chiral pesticide biotransformation. Further research should be done to identify the metabolic enzyme systems related to penconazole biotransformation in vegetables. Meanwhile, research concerning the bioactivities and toxicities of individual enantiomer of penconazole also should be conducted to provide adequate information for further food safety risk evaluation of penconazole enantiomers.

**X-ray Diffraction.** A colorless crystal **Ig** suitable for X-ray diffraction study was cultivated in the test tube from DMSO by self-volatilization. A crystal with dimensions of 0.20 mm × 0.15 mm × 0.10 mm was mounted on a Bruker SMART 1000 CCD diffractometer equipped with a graphite-monochromatic Mo K$\alpha$ radiation ($\lambda$ = 0.71073 Å). Intensity data were collected at 293(2) K by using a multiscan mode in the range of 3.05° ≤ $\theta$ ≤ 25.50° with the following index ranges: −16 ≤ $h$ ≤ 16, −16 ≤ $k$ ≤ 16, and −27 ≤ $l$ ≤ 26. A total of 31784 reflections were collected, and 4768 were independent ($R_{int}$ = 0.0441), of which 4091 with $I > 2\sigma(I)$ were observed. X-ray single-crystal diffraction is shown in Figure 2 with the following

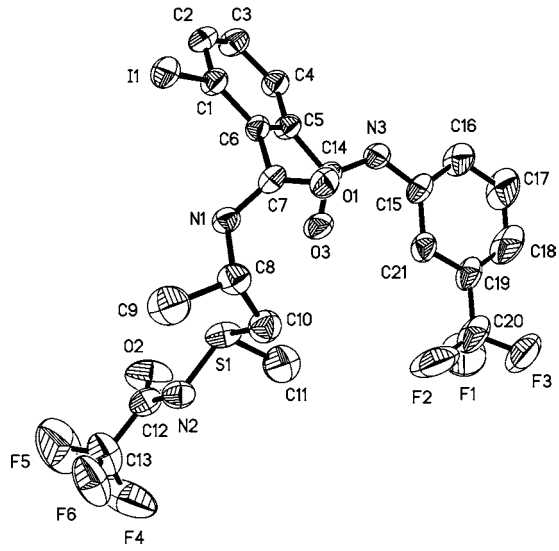

**Figure 2.** Crystal structure of compound **Ig**.

crystallographic parameters: $a$ = 13.998(2) Å, $b$ = 13.998 (2) Å, $c$ = 22.660(5) Å, $\alpha$ = 90°, $\beta$ = 90°, $\gamma$ = 120°, $V$ = 3845.4(11) Å$^3$, $Z$ = 4, $D_c$ = 1.644 mg m$^{-3}$, $\mu$ = 1.401 mm$^{-1}$, $F$ (000) = 1878, $R$ = 0.0539, $w_R$ = 0.1349, final $R$ factor = 4.54%, final $w_R$ factor = 12.87%, absolute structure parameter = −0.02 (3). The crystal structure was solved by direct methods with SHELXS-97[28] and refined by full-matrix least-squares refinements based on $F^2$ with SHELXL-97. All non-hydrogen atoms were refined anisotropically, and all hydrogen atoms were located in the calculated positions and refined with a riding model.

**Biological Assay.** All bioassays were performed on representative test organisms reared in the laboratory. The bioassay was repeated at 25 ± 1 °C according to the statistical requirements. Assessments were made on a dead/alive basis, and mortality rates were corrected using Abbott's formula.[29] Evaluations were based on a percentage scale of 0−100, in which 0 = no activity and 100 = total control. The standard deviations of the tested biological values were ±5%. $LC_{50}$ values were calculated by probit analysis.[30]

**Larvicidal Activity against Oriental Armyworm (*Pseudaletia separata* Walker).** The larvicidal activity of title compounds and the standard flubendiamide against oriental armyworm was tested according to the leaf-dip method using the reported procedure.[31] The insecticidal activity is summarized in Table 1. $LC_{50}$ values of compounds **Ia,b,d**, **IIb,d,f**, **IIIa,b**, **IVa**, and flubendiamide against oriental armyworm are listed in Table 2.

**Larvicidal Activity against Diamondback Moth (*Plutella xylostella* L.).** The larvicidal activity of title compounds and flubendiamide against diamondback moth was tested by the leaf-dip method using the reported procedure.[32,33] The insecticidal activity is summarized in Table 3.

## RESULTS AND DISCUSSION

**Synthesis.** The synthesis of *N*-trifluoroacetyl sulfilimines was achieved by the key intermediates *N*-cyano sulfilimines as shown in Scheme 1. The *N*-cyano group was proved to be easily cleaved upon treatment with TFAA at room temperature. Compared with *N*-cyano sulfilimines, these *N*-trifluoroacetyl sulfiliminyl derivatives displayed better solubility and improved hydrophobicity.

The novel structures of these title compounds were characterized by melting point, $^1$H NMR, elemental analysis (or high-resolution mass spectrometry), and optical polarimetry. The chemical shifts of the active proton signals in the anilide moiety were at 10.01−10.22 ppm in DMSO-$d_6$. However, the active proton signals of −NHCO− on the amide bridge in the aliphatic amide moiety were observed at $\delta$ 8.67−9.05 and $\delta$ 8.70−8.89 in DMSO-$d_6$, respectively.

**Crystal Structure Analysis.** The molecular structure of the title compound is shown in Figure 2. Generally, the average bond lengths and bond angles of the benzene ring, amide group, $CF_3$ group, or other bonds are within normal ranges.[34−38] The S(1)═N(2) bond [1.679(6)Å] is longer than the general C═N double-bond length of 1.27 Å. The torsion angle of N(2)−S(1)−C(10)−C(8) is −93.4(6)°. As shown in Figure 2, the two phenyl rings are nearly vertical with a quite small dihedral angle ($\theta$) of 40.8°. In the intermolecular face-to-face $\pi-\pi$ stacking pattern of the title compound, it is worth mentioning that the two molecules of each stacking unit (C15−C21) are cetro-symmetric, which can be proved by the

relative position of the two phenyl rings of the two molecules. The crystal packing structure demonstrates the existence of three intermolecular hydrogen bond and an intramolecular hydrogen bond: N−H---O and N−H---I. These interactions are estimated to play a role in stabilizing the crystal structure.

**Structure−Activity Relationship (SAR).** *Larvicidal Activity against Oriental Armyworm.* The larvicidal activity of compounds **Ia−f**, **IIa−f**, **IIIa−c**,**e**, and **IVa−c**,**e** against oriental armyworm are listed in Table 1. Most title compounds exhibited good to excellent activity against oriental armyworm. Generally speaking, these stereoisomers exhibited different impacts on biological activity following the sequence (Sc, Ss) ≥ (Sc, Rs) ≫ (Rc, Rs) > (Rc, Ss), which is not in accordance with *N*-cyano sulfiliminyl structures reported in our previous publication as ((Sc, Ss) ≥ (Sc, Rs) ≫ (Rc, Ss) > (Rc, Rs)).[19] As shown in Table 1, for example, **IIa** (Sc, Ss) showed 60% insecticidal activity at 0.1 mg $L^{-1}$, whereas **IIIa** (Rc, Ss) gave a death rate of 10% at only 0.5 mg $L^{-1}$. As seen in Rs configurations, **Ia** (Sc, Rs) (100%) showed better insecticidal activity than **IVa** (Rc, Rs) (20%) at a concentration of 0.25 mg $L^{-1}$. These observations indicated that activities varied significantly depending upon carbon and sulfur chirality. As seen in comparison with other structures in the four configurations, **II** (Sc, Ss) was most active, followed by **I** (Sc, Rs) and **IV** (Rc, Rs), whereas **III** (Rc, Ss) was almost inactive. It was further concluded that a reasonable coordination of both carbon and sulfur chirality accounted for the improvement of insecticidal activity and that a possible synergistic effect was involved.

In comparison, in some cases these diastereoisomers with Sc configurations (**Ia** vs **IIa**, **Ib** vs **IIb**, and **Ic** vs **IIc**), Rc configurations (**IIIb** vs **IVb** and **IIIe** vs **IVe**) showed similar activities. Whereas **IIf** (Sc, Ss) displayed 30% insecticidal activity at 0.1 mg $L^{-1}$, the larvicidal activity of **If** (Sc, Rs) was 70% at 1 mg $L^{-1}$, and **IId** (Sc, Ss) showed better activity than **Id** (Sc, Rs). These observations showed that Ss configurations gave higher activity than Rs counterparts in these Sc configurations. However, in other cases, Rs configurations showed better activity than Ss counterparts in these Rc configurations, such as **IVa** versus **IIIa**, **IVb** versus **IIIb**, and **IVc** versus **IIIc**. Carbon chirality has a stronger influence on the activity than sulfur, as shown in Rs configurations (**Ia** vs **IIIa**, **Ib** vs **IIIb**, **Ic** vs **IIIc**, and **Ie** vs **IIIe**) and in Ss configurations (**IIa** vs **IVa**, **IIb** vs **IVb**, **IIc** vs **IVc**, and **IIe** vs **IVe**).

As shown in Table 1, all compounds showed a mortality of 100% at 10 mg $L^{-1}$, except **IIe**, **IIIb**, **IIIe**, **IVb**, and **IVe**. Particularly, **Ia**, **Ic**, **IIa**, **IIc**, **IIf**, and **IVa** exhibited 100% larvicidal activities even at 1 mg $L^{-1}$. It is worth noting that **Ia**, **IIa**, and **IIf** showed activities as excellent as that of flubendiamide. Furthermore, the iodine substituent in each configuration showed the best larvicidal activity, which was consistent with the previous paper.[26] Br substituent as well as Cl, $NO_2$, F, and H possessed inferior insecticidal activity against oriental armyworm. Compared with *N*-cyanosulfilimines,[19] the results of larvicidal activity against oriental armyworm implied that the introduction of the *N*-trifluoroacetyl group was essential for improvement of larvicidal activity. This is probably due to these *N*-trifluoroacetyl sulfiliminyl derivatives displaying better solubility and improved hydrophobicites. In comparison with our previous research,[39] *N*-trifluoroacetyl sulfilimines with one methyl group in the aliphatic amido moiety gave better activity than those corresponding structures with two methyl groups, so it was concluded that the conventional second methyl group in the aliphatic amido side chain of dicarboxamide might not be requisite during our molecular design stragety.

From Table 2, it was found that the $LC_{50}$ value of **IIa** was 0.1052 mg $L^{-1}$, slightly lower than that of flubendiamide (0.1230 mg $L^{-1}$). In addition, the $LC_{50}$ values of compounds **Ia**, **IIb**, and **IIf** were 0.1374, 0.3374, and 0.1476 mg $L^{-1}$, respectively.

*Larvicidal Activity against Diamondback moth.* The larvicidal activities of compounds **Ia**, **If**, and **IIa−c** and flubendiamide against diamondback moth are listed in Table 3. From that table, we observed that most compounds exhibited excellent activities. Compared with different substituents I, F, and Cl in the phthaloyl moiety of the title compounds, Br revealed the best activity, a death rate of 100% at $10^{-6}$ mg $L^{-1}$, which is a much better activity than that of flubendiamide (0% at $10^{-4}$ mg $L^{-1}$) with a striking difference of >100-fold. Also, **IIa** and **IIc** gave higher activity than flubendiamide; the larvicidal activities of **IIa** and **IIc** were 40% at $10^{-5}$ mg $L^{-1}$ and 80% at $10^{-6}$ mg $L^{-1}$, respectively, better than that of flubendiamide. Whereas **Ia** and **IIb** reached the same activity level as flubendiamide. The bioassay results indicated that chiral dicarboxamide scaffolds containing *N*-trifluoroacetyl sulfiliminyl moiety were favorable to improve the larvicidal activity toward the diamondback moth.

**CoMFA Analysis by SYBYL.** The CoMFA method is widely used in drug design because it allows for rapid prediction of QSAR of newly designed molecules.[40−43] Using SYBYL,[44] a brief CoMFA is taken for two data sets. Compounds in data set 1 are **Ia**,**b**,**d**, **IIb**,**d**,**f**, **IIIa**,**b**, and **IVa**. In addition to compounds in data set 1, compounds with *N*-cyano sulfiliminyl substituted in the aliphatic amide moiety are included in data set 2. The conformations of all molecules are optimized with Tripos force field and Gasteiger−Hukel charges, whereas the activity data are reported as the negative logarithms of $LC_{50}$. Detailed CoMFA results for the two data sets are shown in Figures 3 and 4, respectively.

The result for data set 1 draws similar conclusions as in a previous paper.[19] The green area near the I substituent suggests that a bulkier group is favorable. The small yellow area indicates a less bulky substituent enhances activity. Thus, the molecules

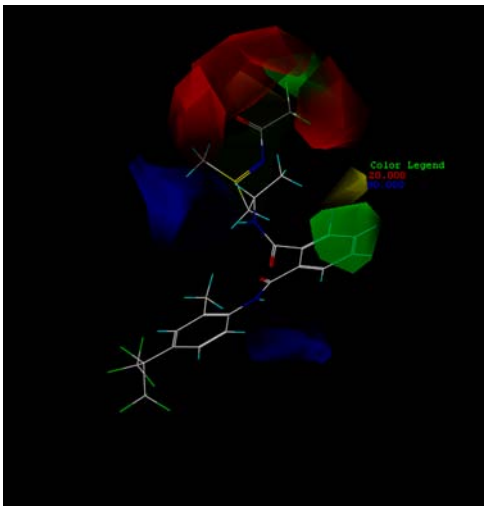

**Figure 3.** CoMFA results for data set 1. The molecule shown in this figure is **Ia**.

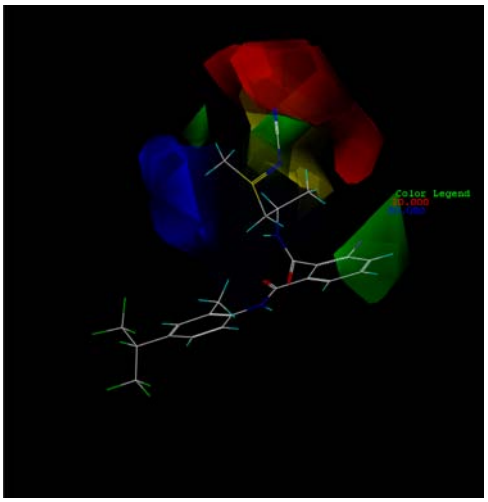

**Figure 4.** CoMFA results for data set 2. The molecule shown in this figure is the (Sc, Rs) configuration of **D** (Figure 1).

with Sc configurations (**I** and **II**) have a better activity than Rc configurations. Finally, the red area surrounding the $COCF_3$ group indicates that more electronegativity is favorable here.

Compared with the results from data set 2, molecules with a $COCF_3$ group in the aliphatic amide moiety give a similar conclusion. The similarity between Figures 3 and 4 indicates that the structure−activity relationship reported in a previous paper[19] is also suitable for these $COCF_3$-substitued molecules.

A partial least-square analysis gives an excellent linear relationship between predicted and actual activities ($R_2$ = 1.000), which indicates a valid CoMFA model.

In summary, this is the first report of chiral *N*-trifluoroacetyl sulfilimines. Four series of phthalamides were designed, synthesized, and evaluated against oriental armyworm and diamondback moth for insecticidal activity. These *N*-trifluoroacetyl sulfilimines exhibited a sequence of activity against oriental armyworm of (Sc, Ss) ≥ (Sc, Rs) ≫ (Rc, Rs) > (Rc, Ss), whereas carbon chirality influenced the activities more strongly than sulfur. For diamondback moth, compounds **If**, **IIa**, and **IIc** exhibited much stronger activity than flubendiamide. CoMFA calculation indicated that stereoisomers with Sc configurations containing more electronegative groups such as $COCF_3$ are favorable to attain their high activity. It was further concluded that the conventional second methyl group in the aliphatic amido side chain of dicarboxamide might not be a requisite in search of novel sulfiliminyl insecticides.

of antibiotics in various crops. Findings from this study would facilitate a better understanding of the transfer of antibiotics to the soil−plant system and the potential ecological and human risks through exposure to antibiotic contamination.

## MATERIALS AND METHODS

**Antibiotics and Chemicals.** Target antibiotic compounds were selected mainly based on their frequent usage in human and livestock in the PRD and other regions as well as their environmental behaviors.[25−27] Tetracycline (TC), sulfamethazine (SMZ), norfloxacin (NOR), erythromycin (ERY), and chloramphenicol (CAP), which belong to five different antibiotic types, were examined in this study (Table 1). All standards and some internal standards (SMZ-$d_4$, NOR-$d_5$, and ERY-$^{13}C_2$) were obtained from Sigma-Aldrich (USA), CAP-$d_5$ was purchased from Dr Ehrenstorfer GmbH (Germany), and TC-$d_6$ was obtained from Toronto Research Chemicals (Canada). Oasis HLB extraction cartridges (6 mL, 500 mg) (Waters Corporation, USA) were used for the extraction and purification of the target compounds. All the organic solvents used were of HPLC grade and purchased from Merck Corporation (Germany). Individual stock solutions and internal standards were prepared at 100 mg/L in methanol and stored in an amber glass vial at −20 °C.

**Sampling Sites.** Six locations (Huizhou, Foshan, Zhongshan, Guangzhou, Dongguan, and Shenzhen) in the PRD region were sampled. The region contains more than 11 million hectares of arable land, and the sampling sites were representative regarding farming practice and had long history (>20 y) of wastewater reuse. The irrigation water in Huizhou, Foshan, Zhongshan, and Guangzhou was mainly domestic wastewater that was largely untreated and discharged directly into open ditches or nearby rivers, while fishpond water was used for irrigation in Dongguan and Shenzhen (Figure 1).

Irrigation water, soil, and crops were sampled in July 2013. Water samples were collected in 1 L amber glass bottles, with 50 mL of methanol immediately added and pH adjusted to 3.0 using 4 M $H_2SO_4$ to preserve the aqueous samples (five replicates per sampling site). Soil and crop samples were collected from five random plots (100 × 100 $m^2$) on each sampling site. Soil samples were collected at two depths: 0−10 cm and 10−20 cm. An adjacent plot without cultivation served as the control with no antibiotic contamination. Soil samples were characterized, and their physicochemical properties are given in Table S1 in the Supporting Information. Chinese white cabbage, water spinach, Chinese radish, corn, and rice were harvested around the soil-sampling sites when the crops reached marketable size. Five whole crops were randomly collected from each plot, which were pooled to form a bulk sample to result in five replicates per site. Crops cultivated in a greenhouse without wastewater irrigation were used as control crops. Once in the laboratory, the water samples were passed through 0.7 μm glass fiber filters (Whatman GF/F, U.K.), and extraction was carried out within 3 days. Soil samples and fresh crops were rinsed

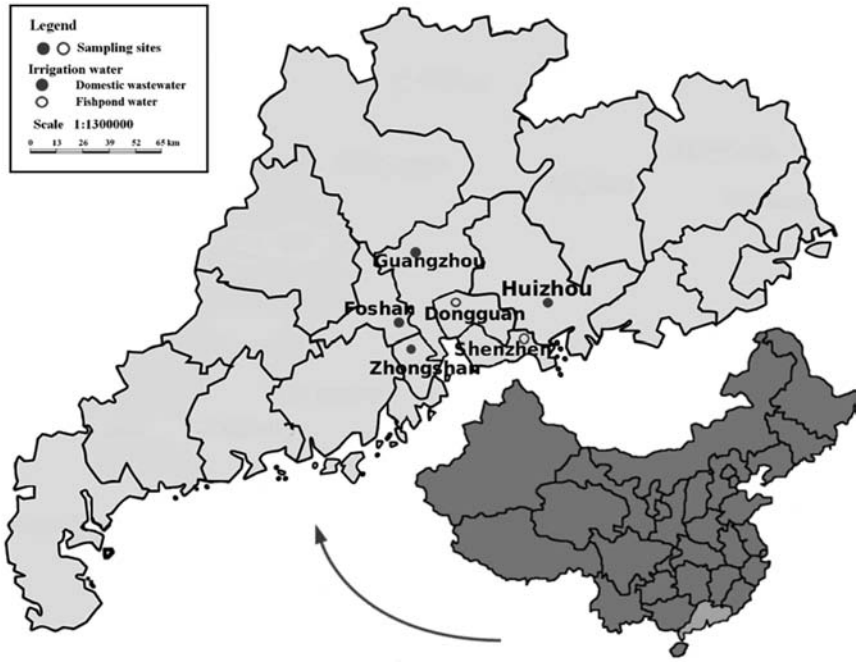

**Figure 1.** Information on the sampling sites in the Pearl River Delta, southern China.

with deionized water and freeze-dried. The dried samples were then ground to powder and stored at −20 °C until extraction.

**Extraction.** *Water Samples.* The target antibiotics in the water samples were extracted by solid phase extraction (SPE) using Oasis HLB cartridges. The internal standards (100 ng) and 0.2 g of disodium ethylenediaminetetraacetate ($Na_2EDTA$) were spiked into each water sample (1 L). The SPE cartridges were preconditioned with 10 mL of methanol and 10 mL of Milli-Q water, after which the water samples were passed through the cartridge at a flow rate of 10 mL/min. The analytes were eluted from the cartridge with 10 mL of methanol, concentrated under a gentle nitrogen stream, and then redissolved in 1 mL of methanol. The final extract was filtered through a nylon syringe filter into a 2 mL amber glass vial and stored at −18 °C before the LC−MS/MS analysis.

*Soil Samples.* One gram of freeze-dried soil was ground up and spiked with 100 μL of each internal standard (1.0 mg/L). The soil samples were extracted three times with 30 mL of acetonitrile and 0.2 M citric acid buffer (pH 4.4) (v:v = 1:1) by vortex (60 s each time) and ultrasonication (15 min each time). The mixture was centrifuged in air-cooled conditions at 1370 g for 10 min and concentrated; the extract for each soil sample was evaporated to near dryness, 0.2 g of $Na_2EDTA$ was added, and the mixture was diluted to 200 mL with Milli-Q water. Each cartridge was preconditioned with 10 mL of methanol and 10 mL of Milli-Q water, and the extracts were passed through HLB cartridges for purification. The analytes were eluted from the cartridge with 10 mL of methanol and dried under a gentle nitrogen stream. Finally, the residue was redissolved in 1 mL of methanol for analysis.

*Crop Samples.* One gram of each freeze-dried crop tissue was ground and spiked with 100 μL of each internal standard (1.0 mg/L). The crop samples were extracted three times with 30 mL of mixed solution of acidified acetonitrile (pH 3) and acetone (v:v = 1:1) by vortex mixing (60 s each time) and ultrasonication (15 min each), followed by centrifugation in air-cooled conditions at 12000*g* for 15 min. The combined extractions were pipetted into a 200 mL round-bottom flask and evaporated to remove the organic solvent; 0.2 g of $Na_2EDTA$ was added, and the mixture was diluted to 200 mL with Milli-Q water and passed through the preconditioned HLB cartridges for purification. The analytes were then eluted from the cartridge with 10 mL of methanol and dried under a gentle nitrogen stream. Finally, the residue was redissolved in 1 mL of methanol for analysis.

**Liquid Chromatography Mass Spectrometry Analysis.** The target antibiotic compounds were analyzed by HPLC−MS/MS (Agilent Liquid Chromatography 1100 series HPLC system coupled to an Agilent 6410 triple quadrupole MS) equipped with an electrospray ionization (ESI) source (Agilent, USA) in multiple-reaction monitoring (MRM) mode. The analyses were performed in negative mode for CAP and in positive mode for the other antibiotics. Nitrogen gas was used as the drying and collision gas. The chromatographic column was an Agilent Eclipse XDB-C18 (3.0 × 75 mm, 3.5 μm) column with a Poroshell 120 precolumn filter (3.0 mm, 0.2 μm). The column temperature was maintained at 40 °C for the analysis of the antibiotics.

For ESI+, 0.01% formic acid was used as mobile phase A and acetonitrile as mobile phase B. Gradient conditions were set as follows: 0 min, 20% B; 3 min, 40% B; 6 min, 60% B; 8 min, 80% B; 9 min, 95% B and 13 min, 20% B. For ESI−, Milli-Q water was used as mobile phase A and acetonitrile as mobile phase B (v:v = 15:85) with isocratic elution. The injection volume was 10 μL, and the flow rates of the mobile phases were 0.3 mL/min and 0.35 mL/min for the positive and negative modes, respectively.

Mass spectrometric conditions were optimized using Optimizer (Agilent, USA) for fine-tuning of the fragmentor voltage, collision energy (CE), and multiple reaction monitoring mode (MRM) transitions for each antibiotic (Table S2 in the Supporting Information). The following optimized parameters were selected: drying gas temperature 350 °C, drying gas flow rate 9 mL/min (ESI+), 11 mL/min (ESI−), capillary voltage 3500 V. The system was re-equilibrated for 5 min between runs.

**Estimation of the Bioconcentration Factor and Dietary Intake.** The ability of a plant to accumulate antibiotics from the soil was estimated using the bioconcentration factor (BCF), which was calculated as the ratio of the chemical concentration in the crop tissue to the chemical concentration in the soil (all based on dry weight):

$$\mathrm{BCF} = \frac{\text{concentration in crop tissue (μg/kg)}}{\text{concentration in soil (μg/kg)}}$$

An exploratory assessment of the potential human exposure to antibiotics through the consumption of edible crops was conducted. The level of human exposure was calculated as

$$\text{human exposure} = C \times D \times W \times T$$

where $C$ is the concentration of antibiotics in the edible tissue (ng/g wet weight), $D$ is the average daily consumption of edible crops (g wet weight/kg body weight day), $W$ is the body weight (kg) of the person consuming the crops, and $T$ is the exposure time (day). The concentrations of antibiotic in crop were converted to a fresh weight basis using the average water content of each crop (95.3% for Chinese white cabbage, 91.4% for water spinach, 95.3% for Chinese radish, 76.0% for corn, and 11.6% for rice).[28] The annual exposure of a 70 kg individual was estimated using the average daily consumption of edible crops (11.8, 0.6, 0.5, 9.2, and 24.0 g wet weight/kg body weight-day for Chinese white cabbage, water spinach, Chinese radish, corn, and rice, respectively).[29]

**Quantification and Quality Control.** To account for the potential analyte loss, a reagent blank, method blank, and spiked matrices were analyzed together with the water, soil, and crop samples. None of the analytes were detected in the blank controls for water, soil, and crop samples. Quantification of each antibiotic compound was obtained using the internal standard method. Analytical precision was measured by analyzing one sample in triplicate for every 10 samples, and the calculated relative standard deviation was less than 10%.[28] The recoveries of the target compounds ranged between 70% and 120% (Table S3 in the Supporting Information). Limit of detection (LOD) and limit of quantification (LOQ) of the antibiotics were calculated with signal/noise ratios (S/N) of 3 and 10, respectively. The S/N ratios were obtained by using the software Masshunter (Agilent, USA). The LOQ of the target compounds ranged from 0.40 to 1.13 ng/L for the water samples, 0.70 to 4.63 ng/g for the soil samples, and 0.80 to 4.40 ng/g for the crop samples (Table S3 in the Supporting Information). Ten concentrations (0.5, 1, 2, 5, 10, 20, 50, 100, 200, and 500 ng/L) of individual antibiotics were used to calculate the calibration curves ($r^2 > 0.999$). Recoveries of the study compounds were performed by spiking the standard solutions to DI water, soil, and crop tissue samples. Ion suppression and enhancement are considered as the major sources of inaccurate quantitative results in complex matrices.[22,30] Initial recovery was done using the internal standards and standard solutions to correct for matrix effects, spiking 100 $\mu$g/L of each standard into the sample extracts and comparing the obtained concentration in matrix to the concentration in solvent. Values of smaller or greater than 100% indicate signal suppression and enhancement, respectively.[31]

## RESULTS AND DISCUSSION

**Antibiotics in Irrigation Water.** The target antibiotics were detected at concentrations above the LOQ in the irrigation water samples (Figure 2). The highest concentration was 69.3−234.0 ng/L for TC, and the lowest was 4.0−58.2 ng/L for SMZ. These results were in general agreement with those for agricultural irrigation water.[32,33] The wastewaters in Dongguan and Shenzhen contained significantly higher concentrations of antibiotics (ranging 12.9−234.0 ng/L and 10.5−184.0 ng/L, respectively) than those in the other regions ($p < 0.05$). This can be attributed to the common practice of directly adding antibiotics to water or in medicated feeds to control bacterial diseases in farmed fish.[34] In the irrigation waters from Foshan, Zhongshan, and Guangzhou, TC and CAP were found at relatively high concentrations. The wastewater used for crop irrigation in Huizhou had the lowest concentrations of the various antibiotics. The cropland in Huizhou is located on the upper-middle reaches of the Danshui River and has less interference from human activities.

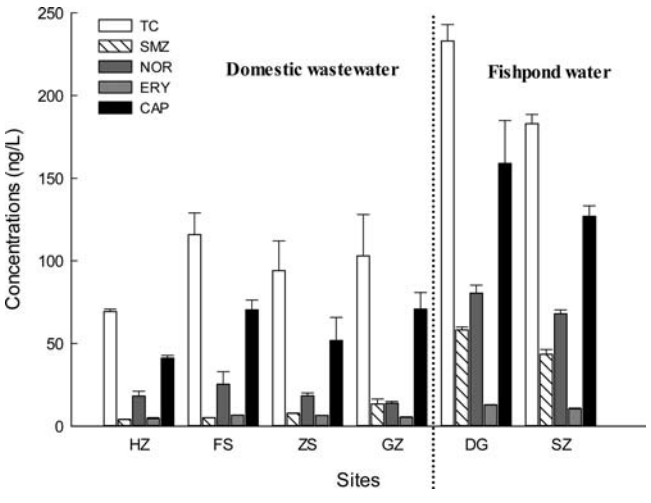

**Figure 2.** Concentrations (ng/L) of antibiotics in irrigation water in the Pearl River Delta, China (mean ± SD, $n = 5$).

**Antibiotics in Soils.** TC, SMZ, NOR, ERY, and CAP were all detected in the surface layer (0−10 cm) irrigated soil samples from the six sites (Table 2). TC, NOR, and CAP in most cases had significantly higher concentrations in soils irrigated by fishpond water than those by domestic wastewater ($p < 0.05$). TC, NOR, and CAP showed a similar trend in concentration in the corresponding irrigation waters ($r = 0.93$, $p < 0.05$). All five target antibiotics detected in the irrigation water could be found in the irrigated soils. Both the irrigation water and irrigated soil samples from Dongguan and Shenzhen had significantly higher concentrations than the other sampling sites, especially for TC and CAP ($p < 0.05$), suggesting that the irrigation water (domestic wastewater and fishpond water) was the major contributing source.

Antibiotics persist in the environment after they are released into the soil from irrigation water.[35] Although wastewater is also used for irrigation in other countries, few studies have examined the presence and accumulation of antibiotics in irrigated soils and crops.[5,36,37] Kinney et al. (2006)[36] detected ERY in reclaimed water and wastewater-irrigated soils at concentrations of 177−611 ng/L and 0.02−15 $\mu$g/kg, respectively. Chen et al. (2011)[5] found TC, NOR, and CAP in the soils of Hebei, China, under wastewater irrigation for approximately 50 years. The present study found that the concentrations of TC, SMZ, NOR, and CAP in soil samples were significantly higher in Dongguan than in the other sites ($p < 0.05$), which corresponded to their higher concentrations in the irrigation water. NOR was frequently found at concentrations as high as 66.7 $\mu$g/kg in the irrigated soils. NOR is one of the most frequently detected antibiotics in various environmental media including water, soil, and plants,[17,38] which could be related to its extensive medical and veterinary use. It may also come from animal manure,[39] which was commonly applied in these areas. It is not surprising that NOR was consistently found at high concentrations in wastewater irrigated soils in the PRD. TC (5.0−21.9 $\mu$g/kg), SMZ (1.3−4.2 $\mu$g/kg), ERY (1.1−4.4 $\mu$g/kg), and CAP (3.2−22.3 $\mu$g/kg) were also found in the six sampling sites. TC had higher concentrations in soil irrigated with fishpond water than that with domestic wastewater. TC was detected at higher concentrations in 0−10 cm soils than in 10−20 cm soils, which is in line with its strong tendency to sorb onto soils due to their high $K_{oc}$ values (Table 1). SMZ have similarly low concentrations in the two soil depths. Sorption of SMZ to soils was influenced by its physicochemical properties and soil pH. The average soil pH in the six sampling sites was 7.51. According to the p$K_a$ values of SMZ, the fraction of deprotonated species would be increased, which would have decreased its sorption to the soil.[33,40] Therefore, SMZ is very

mobile and its concentrations were similar in the two soil layers at all sampling sites. Although most of the antibiotics were found in the two soil layers, the concentrations were higher at 0−10 cm than 10−20 cm due to their sorption and migration upon continuous irrigation. Chen et al. (2011)[5] detected TC at higher concentrations in the upper layer soil in wastewater irrigated plot in Hebei Province. The distribution of the target antibiotics in the soil profiles indicates that they were preferably retained in soil, which may lead to further contamination of plants. Nevertheless, the concentrations of antibiotics in this study were significantly lower than those reported in other studies. For example, Hu et al. (2010)[41] detected TC in wastewater-irrigated soils at concentrations of 2.5−105 $\mu$g/kg, which could be attributed to the control of antibiotic use by the Chinese government in recent years.[38,41]

**Antibiotics in Crops.** NOR was consistently found at the highest concentrations (4.6−23.6 $\mu$g/kg) in crop tissues, followed by CAP (2.6−22.4 $\mu$g/kg) and TC (4.0−10.1 $\mu$g/kg) (Table S4 in the Supporting Information), which is similar to the results of Hu et al. (2010).[41] However, SMZ and ERY were not detected in most of the vegetable crops. The leaves of Chinese white cabbage and water spinach were found to contain a variety of antibiotics, e.g., three out of the five antibiotics with concentrations of 2.6−23.6 $\mu$g/kg in Chinese white cabbage. Three antibiotics were found in water spinach leaves, though mostly at a lower concentration (5.5−21.8 $\mu$g/kg). SMZ and ERY were only found in the roots of Chinese radish and Chinese white cabbage. SMZ was not liable to be retained in the surface soil and absorbed by crops as indicated by its small $K_d$ value, even though SMZ was present in most of the irrigated soil samples. Furthermore, ERY was rapidly adsorbed onto clay particles where protonation occurred.[42] It is difficult for ERY to be absorbed through the cellular membranes and translocate into crops as it has a greater molecular weight than the other compounds.[43] SMZ and ERY also have a shorter degradation time than the other three.[40] Therefore, these antibiotics are not easily absorbed by crops and tend not to accumulate in the plant tissues. Residue degradation, soil-binding, and leaching are other factors that can limit the availability of antibiotics for uptake by crops.[41]

**Bioconcentration Factor of Antibiotics in Crops.** The mean BCF values for different crops from the six sites are shown in Figure 3. The reported BCF values represent the minimum values due to biodegradation under the field conditions.

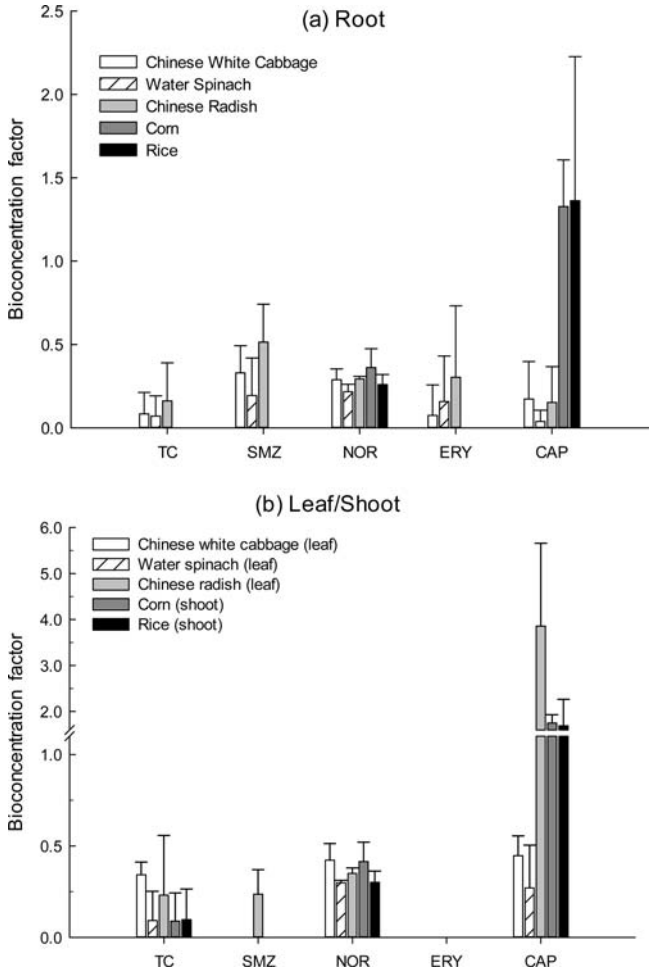

Figure 3. Bioconcentration factor (BCF) values of antibiotics in different crops (mean ± SD, $n$ = 5).

The $BCF_{root}$ values for CAP in the roots of corn and rice were 1.33 and 1.36, respectively, and the values for the other compounds were below one. CAP was also found in the shoots of Chinese radish, corn, and rice, which had $BCF_{leaf/shoot}$ values of 3.86, 1.75, and 1.69, respectively. In the five crops, the values of $BCF_{leaf/shoot}$ for TC, NOR, and CAP were larger than those for $BCF_{root}$. In contrast, the $BCF_{root}$ values for SMZ and ERY were larger than their $BCF_{leaf/shoot}$ because SMZ and ERY were not detected in most crop tissues. Moreover, the $BCF_{root}$ and $BCF_{leaf/shoot}$ values for TC, SMZ, NOR, and ERY were less than

one, indicating that they were not readily absorbed and the plants did not accumulate the antibiotics.

The uptake and translocation of antibiotics varied among the crop species. For example, although CAP was found in the roots of corn and rice ($BCF_{root}$ 1.33−1.36), it showed limited accumulation in the roots of Chinese white cabbage, water spinach, and Chinese radish ($BCF_{root}$ 0.03−0.17). In addition, all except ERY were present in the leaves of Chinese radish, and the $BCF_{leaf/shoot}$ of CAP in Chinese radish was the highest. Herklotz et al. (2010)[22] reported high concentration of sulfamethoxazole in cabbage (23.6−3200 ng/g, dry weight) under ideal hydroponics conditions. However, another study only found low concentrations of ionic compounds in crops, probably due to the repulsion of the anions by the negative electrical potential of the plant cell membrane.[44] The average soil pH was 7.5, and as SMZ existed primarily in anionic form, it was difficult for the crops to absorb. Therefore, SMZ showed limited accumulation in both roots and shoots, which is comparable to the findings of Wu et al.(2013).[7] In all, the differences in the uptake and accumulation of antibiotics are governed by the crop species, harvest time, and environmental conditions.

**Translocation of Antibiotics within Crops.** The distribution of TC, NOR, and CAP in Chinese white cabbage, water spinach, Chinese radish, corn, and rice was in the descending order of fruit > shoot/leaf > root, which suggests that the three antibiotics were transported in the transpiration stream within the xylem of the plants. In contrast, the concentrations of SMZ and ERY followed the order of root > shoot/leaf > fruit. The concentration of sulfamethoxazole in roots was about 10 times that in leaves of greenhouse grown vegetable (lettuce, cucumber, pepper, and spinach).[7] Migliore et al. (1998)[45] also found that the concentration of sulfonamides in roots was higher than that in leaves for wheat and corn. The translocation of antibiotics in crops depends on the physicochemical properties of antibiotics and crop species as well as the concentrations of antibiotics in soil.[46] The species type and the growth stage can affect the accumulation and distribution of antibiotics in crops.[15] According to the reported inhibitory concentrations of antibiotics on plants,[47] crop growth would not be significantly affected at the antibiotic concentrations detected in this study.

The translocation factor (TF) represents the translocation of antibiotics from the roots to the leaves and/or shoots, and is calculated simply as the ratio of the leaf to root concentration ([leaf]/[root]). The uptake by plants is considered to occur by passive transport. Once a chemical is taken up by roots, translocation driven by the transpiration process will distribute the chemical to other parts of the plant, and the ratio of root to leaf concentrations is dependent on the amount of water transpired and the growth rate of the plants.[48] In this study, all of the antibiotics were found in the leaves and/or shoots, except ERY, which was not detected in leaves and/or shoots. Thus, the TF for ERY cannot be calculated; TF for SMZ could only be calculated in Chinese radish.

The TF for NOR was generally larger than 1 in all five crops, indicating that NOR was preferentially transferred from the roots to the shoots (Table 3). The TFs for CAP in water spinach, rice, and corn were also larger than 1. Other antibiotics, especially ERY and SMZ, were found to accumulate in roots (TF < 1). The translocation of sulfonamides agreed with the findings of previous reports for cabbage, lettuce, cucumber, and pepper.[19,22] For example, Herklotz et al. (2010)[42] found that the concentration of sulfamethoxazole in roots was 135 times that in the leaves of cabbages grown in a nutrient solution, and the fraction of sulfamethoxazole in cabbage roots accounted for 98.4% of the total uptake. The translocation of organic compounds within plants is affected by several factors, e.g., hydrophilicity.[49] It was found that the TF was at a maximum for compounds having log $K_{ow}$ from −1.03 to 0.92, except for SMZ. Ionization could reduce the translocation of ionized organic compounds to shoots.[50] This may happen in SMZ under the present environmental conditions (existed predominantly as anion) coupled with their low root cell membrane permeability to ionized SMZ. Nonionic compounds that are highly hydrophilic were less able to cross the hydrophobic membranes, while highly lipophilic compounds were less likely to be transferred to shoots because they were retained in the root lipids.[50] In the present study, the five antibiotics have similar log $K_{ow}$ that could not distinguish the importance of hydrophilicity on the translocation and accumulation of organic compounds in crops. Moreover, uptake was species specific, even when the crops shared the same irrigated soil.[20,44] Therefore, antibiotics demonstrate different translocation behaviors in different plants according to their physicochemical properties as well as plant species, growth, and transpiration rates.

**Table 3. Translocation Factor (TF) Values of Antibiotics in Different Crops (Mean ± SD, $n$ = 5)[a]**

| | TC | SMZ | NOR | CAP |
|---|---|---|---|---|
| Chinese white cabbage | 0.5 ± 0.1 | | 1.5 ± 0.2 | 0.8 ± 0.2 |
| water spinach | 0.4 ± 0.2 | | 1.4 ± 0.4 | 1.2 ± 0.7 |
| Chinese radish | 0.7 ± 0.3 | 0.2 ± 0.1 | 1.2 ± 0.03 | 0.8 ± 0.2 |
| corn | | | 1.2 ± 0.1 | 1.4 ± 0.3 |
| rice | | | 1.2 ± 0.03 | 1.4 ± 0.5 |

[a]TF for ERY could not be calculated.

**Human Exposure Implications.** On average, the level of daily human exposure to the five antibiotics through the consumption of edible crops ranged from 0.003 to 21.8 μg (Table 4). SMZ and ERY were only detected in Chinese radish, indicating that there would be negligible risk associated with the consumption of these crops. However, the levels of TC, NOR, and CAP were relatively high, especially for corn and rice (daily human exposure was 0.34−2.77 and 11.0−21.8 μg, respectively). The annual human exposure has been estimated based on the daily consumption of these five edible crops (1.1 to 7950 μg). Moreover, the United Nations Food and Agriculture Organization has established acceptable daily intake (ADI) levels for TC (0−30 μg/kg bw) and ERY (0.0−0.7 μg/kg bw). Assuming that the body weight of an average adult is 70 kg, the maximum permissible intake of TC is 2100 μg/day while that for ERY is 49 μg/day. Although the estimated values of daily human exposure in this study were much lower than the minimum therapeutic doses (typically in the 20−200 mg range) and below the recommended ADI values, antibiotic-resistant bacteria or their corresponding resistance genes have been shown to spread to humans via the food chain.[51] Thus, further research is needed to assess the accumulation of these antibiotics in the food chain to determine the safe concentrations for human consumption.

The results of this study indicate that the use of wastewater and fishpond water to irrigate croplands could lead to the accumulation of antibiotics in soils and edible crops. However,

Table 4. Human Exposure to Antibiotics in Chinese White Cabbage, Water Spinach, Chinese Radish, Corn, and Rice, Calculated from the Concentrations of These Compounds in the Edible Tissues

| | TC | | SMZ | | NOR | | ERY | | CAP | |
|---|---|---|---|---|---|---|---|---|---|---|
| human exposure ($\mu$g) | daily | annual | daily | annual | daily | annual | daily | annual | daily | annual |
| Chinese white cabbage (leaf) | 0.23 | 84.6 | | | 0.59 | 216 | | | 0.21 | 75.2 |
| water spinach (leaf) | 0.01 | 2.8 | | | 0.05 | 18.5 | | | 0.02 | 6.8 |
| Chinese radish (root) | 0.01 | 2.0 | 0.01 | 1.9 | 0.02 | 6.8 | 0.003 | 1.1 | 0.004 | 1.6 |
| corn (fruit) | 0.34 | 125 | | | 2.27 | 830 | | | 2.77 | 1011 |
| rice (fruit) | 11 | 3998 | | | 17.2 | 6266 | | | 21.8 | 7955 |

significant disparities were observed in the potential root uptake and subsequent accumulation of the different antibiotics in relation to their physicochemical properties (e.g., ionization, degradation time, and molecular size) and the environmental conditions. SMZ and ERY preferentially accumulated in roots as they have difficulties in moving up the crops, while TC, NOR, and CAP were more prevalent in leaves/shoots and fruits. More experimental data on other types of antibiotics or organic compounds are needed for verification. Although the levels of antibiotics ingested through the consumption of edible crops were much lower than the minimum therapeutic doses or ADI levels, the findings from this study provide basic information on the accumulation of antibiotics in edible crops and help evaluate human exposure to antibiotics through crop consumption. Further research on the potential long-term health effects of ingesting different types of antibiotics through dietary uptake is necessary.

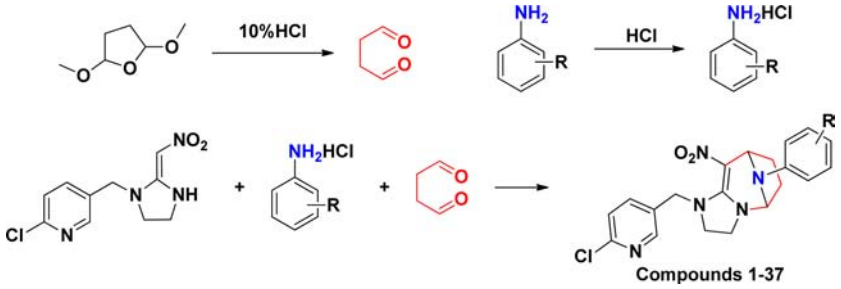
**Scheme 1. Synthetic Routes of Compounds 1−37**



## MATERIALS AND METHODS

**Instruments.** All melting points were obtained with a Büchi Melting Point B540 and are uncorrected. Nuclear magnetic resonance spectra were recorded on a Bruker AM-400 spectrometer with $CDCl_3$ or DMSO-$d_6$ as the solvent ($^1$H at 400 MHz and $^{13}$C at 100 MHz) and TMS as the internal standard. Chemical shifts are reported in parts per million ($\delta$). Coupling constants ($J$) are reported in hertz (Hz). High-resolution electron mass spectra (ESI-TOF) were performed on a Micromass LC-TOF spectrometer. Analytical thin-layer chromatography (TLC) was carried out on precoated plates (silica gel 60 $F_{254}$), and spots were visualized with ultraviolet (UV) light.

**General Synthetic Procedure for the Substituted Aniline Hydrochloride.** The corresponding aniline (10 mmol) in ethyl acetate (15 mL) was cooled to 0 °C. A solution of concentrated HCl was dropwise added and the pH value of the reaction mixture adjusted to 1−2. After the addition was completed, precipitate was filtered and washed with less concentrated HCl and ethyl acetate. After drying under vacuum, the obtained corresponding aniline hydrochloride could be used without further purification.

**Preparation of the Solution of Succinaldehyde.** A mixture of 2,5-dimethoxydihydrofuran (0.290 g, 2.2 mmol) and 0.4 mL of 10% aqueous HCl was stirred at room temperature. After 12 h, the pH value of the mixture was adjusted to 2−3 by saturated aqueous $NaHCO_3$. The solution could be used directly in the next step.

**General Synthetic Procedure for Compounds 1−37.** A mixture of starting material **B** (2 mmol) and corresponding aniline hydrochloride (2.5 mmol) in acetonitrile (20 mL) was stirred at 0 °C. Then the solution of succinaldehyde was slowly added, and the reaction was monitored by TLC. After 1.5 h, the pH value of the mixture was adjusted to 7−8 by saturated aqueous $NaHCO_3$, and the solvent was removed under reduced pressure. Then, water was added, the mixture was extracted with dichloromethane (3 × 50 mL), and the organic layer was washed with brine, dried over anhydrous sodium sulfate, filtered, and concentrated. The residue was purified by silica gel column chromatography to afford the corresponding product.

**X-ray Diffraction Analysis.** Compound **1** was recrystallized by slow evaporation from a mixture of acetone, dichloromethane, and cyclohexane (1:1:1, v/v/v) to afford a suitable single crystal. Yellow blocks of compound **1** (0.29 mm × 0.21 mm × 0.14 mm) were mounted on a quartz fiber. Cell dimensions and intensities were measured at 293 K on a Bruker SMART CCD area detector diffractometer with graphite monochromated Mo K$\alpha$ radiation ($\lambda$ = 0.71073 Å); $\theta_{max}$ = 25.99°; 10716 measured reflections; 3627 independent reflections ($R_{int}$ = 0.0475). Data were corrected for Lorentz and polarization effects and for absorption ($t_{min}$ = 0.7050 and $t_{max}$ = 1.0000). The structure was solved by direct methods using SHELXS-97;[11] all other calculations were performed with a Bruker SAINT System and Bruker SMART programs.[12] Full-matrix least-squares refinement based on $F^2$ using the weight of $1/ [\sigma^2 (F_0^2) + (0.0613P)^2 + 0.0371P]$ gave final values of $R$ = 0.0542, $\omega R$ = 0.1462, and GOF ($F$) = 1.022 for 253 variables and 3627 contributing reflections. Maximum shift/error = 0.000(3) and max/min residual electron density = 0.530/−0.519 e Å$^{-3}$. Hydrogen atoms were observed and refined with a fixed value of their isotropic displacement parameter.

**Biological Assay.** All bioassays were performed on representative test organisms reared in the laboratory. The bioassay was repeated at 25 ± 1 °C according to statistical requirements. All compounds were dissolved in *N*,*N*-dimethylformamide (AP, Shanghai Chemical Reagent Co., Ltd., Shanghai, China) and diluted with distilled water containing Triton X-100 (0.1 mg L$^{-1}$) to obtain series concentrations of 20 and 4 mg L$^{-1}$ and others for bioassays. For comparative purposes, IMI and CYC were tested under the same conditions.

**Insecticidal Test for Cowpea Aphid (*A. craccivora*).** The insecticidal activity of synthetic compounds against cowpea aphid was tested by using the leaf-dip method.[13,14] Horsebean plant leaves with 30−40 apterous adults were dipped in diluted solutions of the chemicals containing Triton X-100 (0.1 mg L$^{-1}$) for 5 s, and the excess dilution was sucked out with filter paper; the burgeons were placed in the conditioned room (25 ± 1 °C, 50% realtive humidity). Water containing Triton X-100 (0.1 mg L$^{-1}$) was used as control. The mortality rates were evaluated 24 h after treatment. Each treatment had three repetitions, and the data were adjusted and subjected to probit analysis as before.

**Insecticidal Test for Armyworm (*Pseudaletia separata* Walker).** The insecticidal activity against armyworm was tested by foliar application.[15−17] Individual corn (*Zea mays*) leaves were placed on moistened pieces of filter paper in Petri dishes. The leaves were then sprayed with the compound solution and allowed to dry. The dishes were infested with 10 third-instar larvae and placed in the conditioned room. The mortality rates were evaluated 48 h after treatment. Each treatment had three repetitions, and the data were adjusted and subjected to probit analysis as before.

**Insecticidal Test for Brown Planthopper (*N. lugens*).** The insecticidal activity against brown planthopper was tested by foliar application. Rice seedlings were placed on moistened pieces of filter paper in Petri dishes. The dishes were infested with 30−40 third-instar larvae and then sprayed with the compound solutions (2.5 mL) using a Potter spray tower (pressure, 5 lb/in$^2$; settlement, 4.35 mg/cm$^2$). Samples were placed in the conditioned room. The mortality rates were evaluated 48 h after treatment. Each treatment had three repetitions, and the data were adjusted and subject to probit analysis as before.

## RESULTS AND DISCUSSION

**Synthesis.** To synthesize azabridged neonicotinoid compounds, the major obstacle was the synthetic methodology. Through comparison of the structures of the 1,3-dicarbonyl derivative and our starting material **B** (cyclic $\beta$-nitroenamine), similar nucleophilic centers were found in these two types of substances, which implied that the target compounds can be constructed in an intermolecular way involving primary amine hydrochlorides and dialdehydes.[10] Consequently, the commercialized glutaraldehyde was first chosen to synthesize eight-membered azabridged neonicotinoid analogues. Therefore, to obtain seven-membered azabridges, the preparation of succinaldehyde was the main task in this work.

Hitherto, various methods of acidic[17−23] and nonacidic hydrolysis[24] were reported to prepare succinaldehyde from commercially available and synthetic equivalent 2,5-dimethoxydihydrofuran (DMTHF). Furthermore, according to our previous study of eight-membered azabridges,[10] it was found that an acidic environment was conducive to the formation of azabridged neonicotinoid compounds. Thus, compound **3** was chosen to study the influence of the pH value, and the results are listed in Table 1.

**Table 1. Optimization of Compound 3**

| entry | hydrolyzed succinaldehyde | time (h) | yield[a] (%) |
|---|---|---|---|
| 1 | pH 1−2 | 1.5 | 66.0 |
| 2 | pH 2−3 | 1.5 | 82.5 |
| 3 | pH 6−7 | 1.5 | 44.2 |
| 4 | pH 8−9 | 1.5 | tr[b] |
| 5 | pH 2−3 | 0.5 | 45.5 |
| 6 | pH 2−3 | 5.0 | 26.2 |
| 7 | pH 2−3 | 10.0 | 20.0 |
| 8 | nonacidic[c] | 1.5 | 60.1 |

[a]Isolated yields. [b]tr, trace. [c]See ref 24.

To begin with, the solution of succinaldehyde was used immediately after acidic hydrolysis of DMTHF. The reaction was monitored by TLC, and the target compound **3** was successfully acquired in a good yield (Table 1, entry 1), which encouraged us to optimize the pH value of succinaldehyde solution before it was used in the next step. From the experimental data in Table 1, it was observed that the pH value below 2 or above 3 would display relatively low yields (Table 1, entries 1−4). These results demonstrated that the pH value at 2−3 was more suitable to synthesize seven-membered azabridged compounds.

On the basis of this optimal condition, the reaction time was also investigated. The corresponding yields were increased, but decreased with the extension of time (Table 1, entries 2 and 5−7). Therefore, the reaction was carried out in 1.5 h, because the decomposition rate of our target compound was more rapid than the formation rate after a period of time. Eventually, the nonacidic condition was also studied (Table 1, entry 8). The succinaldehyde was prepared following literature procedures;[24] however, the corresponding yield was still lower than that of acid condition.

**Crystal Structure Analysis.** To provide more evidence for the proposed molecular structure and establish the conformation of the target compounds, compound **1** was recrystallized by slow evaporation and its single-crystal structure was determined by X-ray crystallography as illustrated in Figure 3.

Unlikely eight-membered compounds, the pyridine ring, and benzene ring of compound **1** pointed to the same direction. Compared with the *trans*-configuration of nitro in the crystal structure of IMI,[26] the nitro groups of compound **1** was in *cis*-configuration as anticipated. There are some characteristics of the bond lengths. For example, the bond lengths of C(9)—N(2) (1.35 Å) and C(9)—N(3) (1.34 Å) were obviously shorter than the typical C—N single bond (1.47 Å) but close to that of C=N (1.33 Å), owing to the transfer of the lone-pair electrons on the amines to C(10)=C(9) and the delocalization of the electrons extended as far as the electron-withdrawing

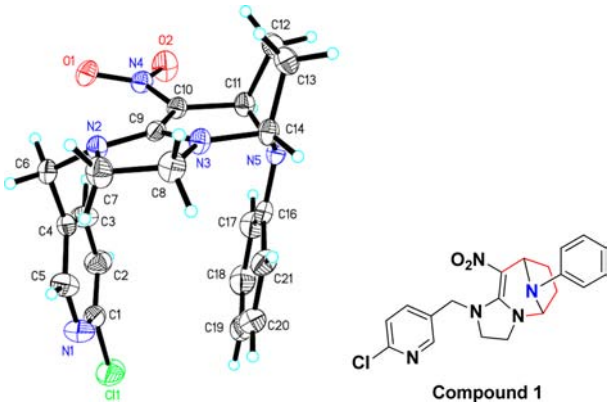

**Figure 3.** Crystal and chemical structures of compound **1**.

group ($-NO_2$), forming a coplanar olefin−amine $\pi$-electron network.[25,26] Moreover, it also made the bond lengths of C(10)═C(9) (1.41 Å) and C—$NO_2$ (C(10)—N(4); 1.36 Å) longer than that of normal C═C (1.34 Å) and shorter than that of typical C—$NO_2$ (C—N; 1.49 Å), respectively.

**Insecticidal Activity.** Table 2 lists the insecticidal activities of the title compounds against cowpea aphid (*A. craccivora*), brown planthopper (*N. lugens*), and armyworm (*P. separata* Walker). Most of the compounds exhibited significant insecticidal activities against these three species of pests. Compound **1** with no substituent on the phenyl group presented similar insecticidal activities against cowpea aphid and brown planthopper, but lower bioactivity against armyworm, compared with seven-membered oxabridged compound CYC (Table 3). Then, the substitution effect on insecticidal activities was investigated.

The compounds with various types of substitutions on position 4 of the phenyl group were first synthesized (**2**–**9**). The bioassay showed that introducing an electron-donating group (OMe and Me) (**3** and **5**) and a fluorine atom (**4**) could contribute to great improvement of activity against armyworm while presenting considerable activities against brown planthopper and cowpea aphid. Meanwhile, bringing in an electron-withdrawing group ($CF_3$, CN, $NO_2$) (**6**, **7**, and **9**), a bromine atom (**2**), or a chlorine atom (**8**) on the phenyl ring would decrease the activities against brown planthopper and cowpea aphid but increase the bioactivity against armyworm, compared with compound **1**.

On position 2 of the phenyl group, the compound with a cyano group (**15**) displayed relatively low insecticidal activities and the others (**10**–**14**) exhibited excellent bioactivities against the three species of pests, which confirmed that position 2 was the key substitution site for structural derivation to obtain high-activity molecules. Moreover, on the basis of the $LC_{50}$ value in Table 3, with the radius of the halogen atom increasing (**10**–**12**), the insecticidal activities showed decreasing tendency against armyworm, but still higher than that of CYC and IMI. Notably, compounds **12** and **13** demonstrated the relatively higher bioactivities among the structures with substitution on position 2.

The insecticidal activities of all the compounds with a substituent on position 3 (**16**–**21**) were lower than that of compound **1** against brown planthopper and cowpea aphid. However, among these, compounds **16** and **21** presented relatively high bioactivities against the three species of pests. Combined with the discussion above, we could preliminarily conclude that introducing a methyl group and a fluorine atom on any site of the phenyl group was favorable to increase the insecticidal activities and that position 2 was an important site for obtaining high-activity compounds.

[a]At 4 mg $L^{-1}$, the mortality of all compounds against brown planthopper (*Nilaparvata lugens*) was 100%.

Therefore, further SAR study of two substitutions on the phenyl group was carried out. Initially, the combinations of fluorine atom with methoxy group (**22**) and methyl (**23**) were carried out. Unfortunately, the insecticidal activities against cowpea aphid and armyworm were decreased dramatically, which was not a good result for exploring a potential neonicotinoid insecticide with superior bioactivities against the three species of pests. Then, we turned our attention to dimethyl substitution on the phenyl group.

2,3-Dimethyl (**27**), 2,4-dimethyl (**28**), and 2,5-dimethyl groups (**29**) were introduced into the phenyl group; owing to the sterically hindered effect of the substituent, the

[a]Not tested.

compound with a 2,6-dimethyl group could not be synthesized. Excitingly, compounds **28** ($LC_{50}$ = 0.039 mg $L^{-1}$) and **29** ($LC_{50}$ = 0.054 mg $L^{-1}$) displayed an improvement of about 1 order of magnitude over CYC ($LC_{50}$ = 0.383 mg $L^{-1}$) in insecticidal activity against brown planthopper and an activity similar to that of **13** against cowpea aphid. Furthermore, the insecticidal activity of compound **29** was 7-fold higher than that of IMI against armyworm. Thus, we replaced the 2,5-dimethyl with 2,5-dimethoxy (**26**), 2,5-dichloro (**30**), and 2,5-difluoro (**33**) to study the variations of bioactivities. Compounds **26**, **30**, and **33** showed comparable activity against brown planthopper, but lower activities against armyworm and cowpea aphid, respectively, which implied that introducing disubstitution on positions 2 and 5 of the phenyl group could obtain a molecule with high activity against brown planthopper.

Difluoro- and multifluoro-substituted compounds were also studied (**24**, **33**−**37**). Compared with compound **12**, introducing multiple fluorine atoms into the phenyl group could not lead to the increase of bioactivities against three species of pests. Therefore, the substitution of a methyl group on the phenyl group was more favorable for the improvement of insecticidal activities than that of fluorine atoms.

Table 4 lists the comparison of insecticidal activities between eight-membered[10] and seven-membered compounds. At low concentration (4 and 20 mg $L^{-1}$), most seven-membered azabridged compounds showed apparently higher bioactivities than eight-membered compounds against the three species of pests. These results indicated that the ring size played a very important role in increasing the insecticidal activities.

**Docking Study.** A docking study was performed to explore the binding modes of our compounds. The crystal structure of the *Aplysia californica* acetylcholine binding protein (*Ac*-AChBP) complexed with IMI (PDB code 3C79) was selected to construct the binding models,[27] which showed high affinity with neonicotinoids and was a good prototype for investigating the binding mode of neonicotinoids.[28] For comparison, compounds **1** and **29** were built, minimized, and docked into

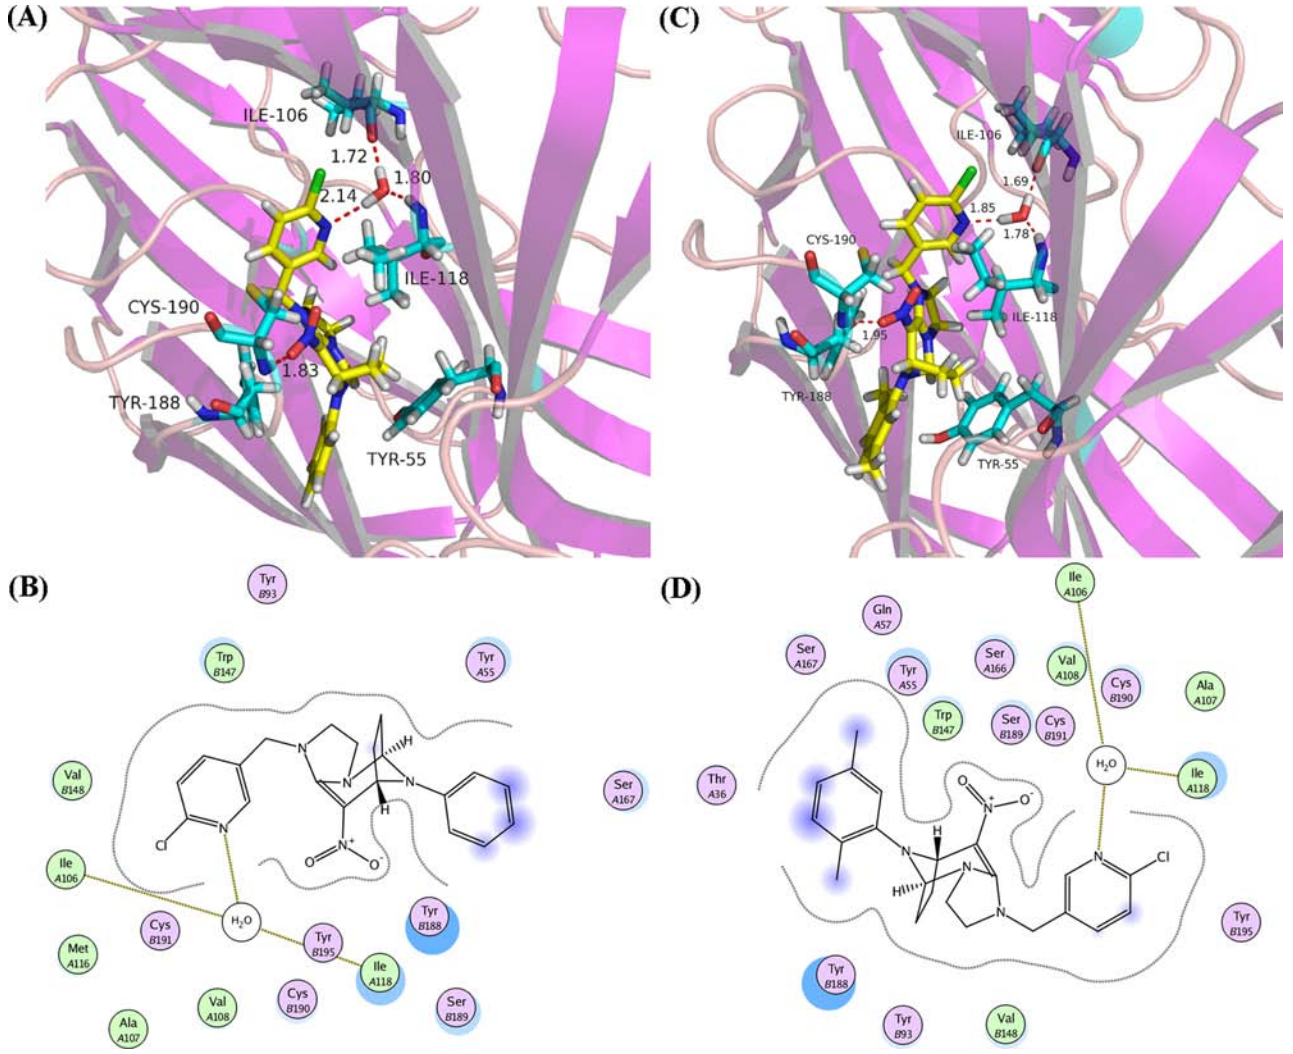

**Figure 4.** Binding modes of compounds **1** (A, B) and **29** (C, D).

the ligand binding pocket of *Ac*-AChBP by using the Induced Fit Docking approach, of which the IFDScore scoring function was selected to evaluate the docking results. All atoms within 20 Å around IMI in the 3C79 structure were selected as binding pocket and considered in the docking study. All computational studies were performed using Maestro 9.0 (Schrödinger, LLC, 2013).

The docking poses of compounds **1** and **29** were depicted in Figure 4. It was found that water bridged hydrogen bonding network played key roles for the ligands recognition, which has also been reported for the binding of IMI and other neonicotinoid compounds.[27,28] Also, N−H···O hydrogen bonds were observed between the peptide N−H of Cys190 and the nitro groups of compounds. The phenyl group inserted into the interspace between loop C and the adjacent subunit, and located between the Tyr188 and Tyr55. Comparing with compound **1**, the methyl group introduced into position 2 of phenyl group in compound **29** could improve the hydrophobic interactions with receptor (Figure 4B and 4D), which might be one of the reasons for the improvement of insecticidal activity.

In conclusion, 37 novel seven-membered azabridged neonicotinoid analogues were designed and synthesized. The pH value at 2−3 of hydrolyzed succinaldehyde solution was an optimized condition to synthesize target compounds in excellent yields. The bioassays showed that most of the compounds presented superior bioactivities to IMI and seven-membered oxabridged compound CYC against cowpea aphid, brown planthopper, and armyworm. Compared with IMI, compound **29** with 2,5-dimethyl group, displayed 7 fold and 20 fold higher activities against armyworm and brown planthopper, respectively. Moreover, seven-membered compounds showed much higher bioactivities against three species of pests than that of eight-membered azabridge neonicotinoids, which implied that the framework of a seven-membered azabridge could significantly improve the insecticidal activity of neonicotinoid analogues and was a very good lead structure to discover potential pesticides. Further studies on field testing of the title compounds are in progress.

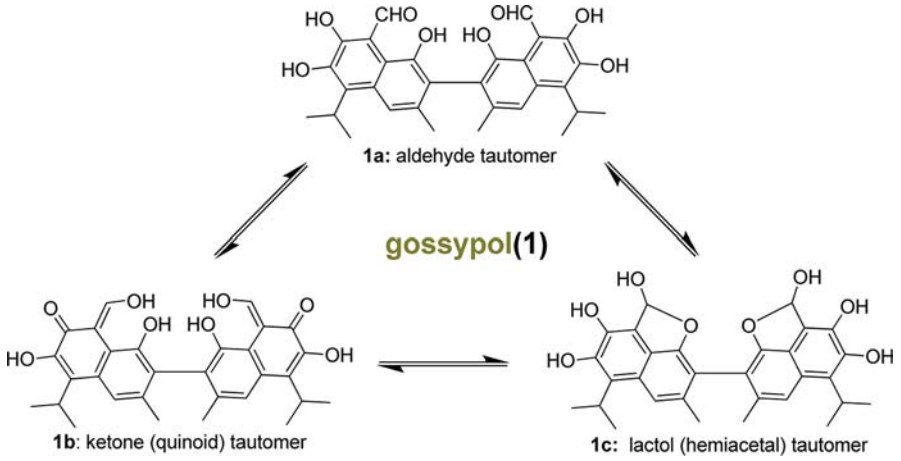

**Figure 1.** Structures of gossypol and its tautomeric forms.

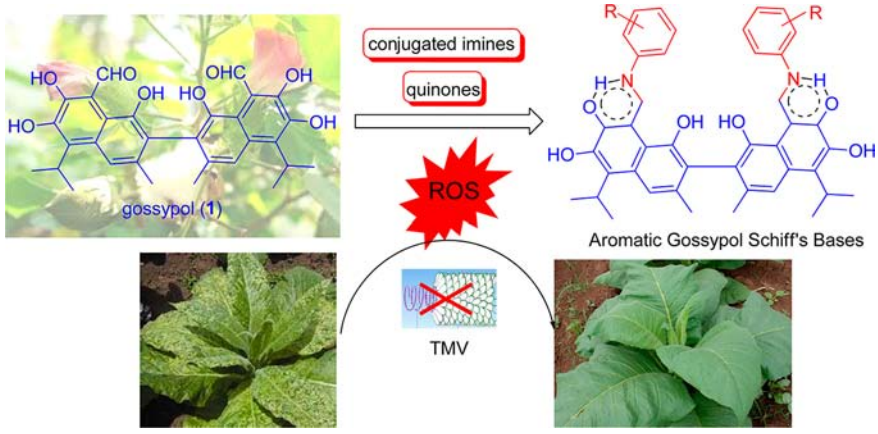

**Figure 2.** Design of compounds **3**–**25**.

gossypol and aromatic amines are expected to adjust gossypol to produce ROS and thus modulate the anti-TMV activity level. (Figure 2) In this contribution, a family of aromatic gossypol Schiff base derivatives has been synthesized and their anti-TMV activities have been determined using both in vitro and in vivo test methods. The structure–activity relationships of these derivatives were discussed as well. Field trial and toxicity evaluation were also conducted for the compound with high anti-TMV activity primarily to assess its potential as an antivirus candidate. Additionally, the synthesized derivatives were also investigated for their potential as fungicidal, insecticidal, or herbicidal reagents (see the Supporting Information).

## MATERIALS AND METHODS

**General.** Reagents were purchased from commercial sources and were used as received. All anhydrous solvents were dried and purified by standard techniques just before use. Reaction progress was monitored by thin-layer chromatography on silica gel GF-254 with detection by UV. Melting points were determined on an X-4 binocular microscope melting point apparatus and are uncorrected. $^{1}$H NMR and $^{13}$C NMR spectra were recorded on a Bruker Ascend 300/400 MHz spectrometer. Chemical shift values ($\delta$) are given in parts per million and downfield from internal tetramethylsilane. High-resolution mass spectra (HRMS) were recorded on FT-ICR MS (Ionspec, 7.0 T).

**General Procedure for the Synthesis of Aromatic Gossypol Schiff Bases 3–10, 12–14, 19, 21, 22, 24, and 25.** A solution of gossypol acetic acid (**2**, 0.50 g, 0.86 mmol) and aromatic amine (1.73 mmol) in ethanol (50 mL) was stirred and refluxed for 5 h, and then the reaction mixture was cooled to room temperature. The resulting solid was filtered, washed with ethanol, and recrystallized to give the desired gossypol derivatives.

**General Procedure for the Synthesis of Aromatic Gossypol Schiff Base Derivatives 11 and 23.** A mixture of aromatic amine (1.73 mmol), NaOH (2.59 mmol), and ethanol (50 mL) was stirred and refluxed for 1 h. Then gossypol acetic acid (**2**, 0.50 g, 0.86 mmol) was added, and the reaction liquid was refluxes for a further 5 h. The reaction mixture was cooled to room temperature, and then the resulting solid was filtered, washed with ethanol, and then recrystallized to give the desired gossypol derivatives.

**General Procedure for the Synthesis of Aromatic Gossypol Schiff Bases 15–18 and 20.** A solution of gossypol acetic acid (**2**, 0.50 g, 0.86 mmol) and aromatic amine (3.46 mmol) in ethanol (50 mL) was stirred and refluxed for 5 h and then the reaction mixture was cooled to room temperature. The resulting solid was filtered, washed with ethanol, and then recrystallized to give the desired gossypol derivatives.

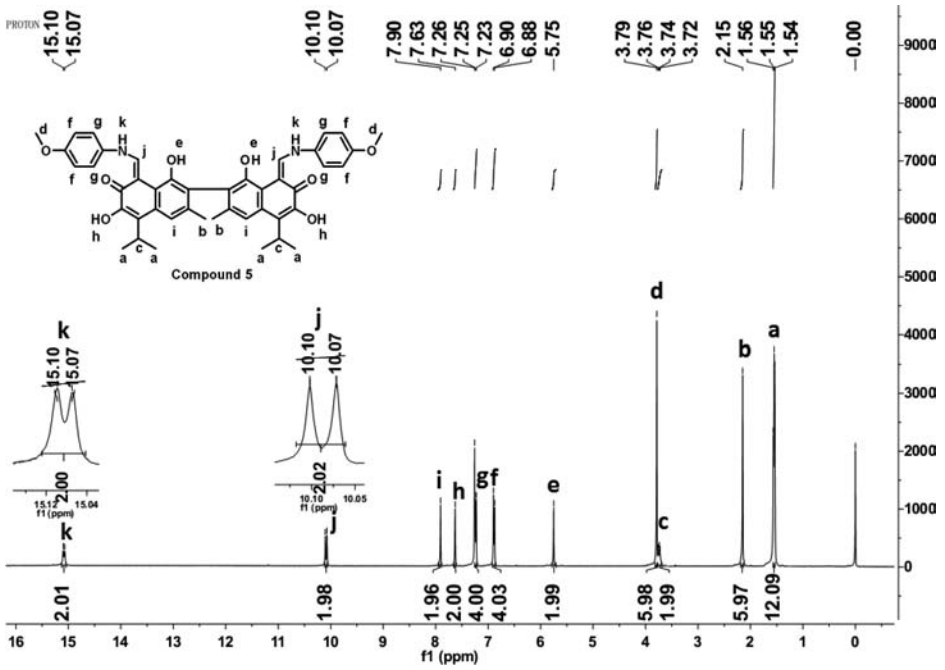

**Figure 3.** $^1$H NMR spectra of compound **5**.

**Biological Assay.** The anti-TMV activity of all compounds was tested using our previously reported methods.[22]

The field trials were carried out in the trial area of the Institute of Agricultural Environment and Resource, Yunnan Academy of Agricultural Sciences, Kunming City, China, between June and July 2014. The formulation of compound **19** (1% emulsifiable concentrates (EC)) was prepared in our research group. It was diluted to 750 L/ha before use.

The rat oral gavage acute toxicity of pesticides was performed in Xu He (Tianjin) Pharmaceutical Technology Co., Ltd. in May 2014. Sixteen rats, half males and half females, were divided randomly into four groups. The samples were respectively configured to 5 and 50 mg/mL.

## RESULTS AND DISCUSSION

**Chemistry.** Gossypol (**1**) was obtained using our previously reported method.[23] Gossypol acetic acid (**2**) was purchased from commercial sources. A series of Schiff bases of gossypol (**3**−**25**) were prepared by treating **2** with the corresponding amines in ethanol (Scheme 1). The Schiff bases had poor solubility in ethanol, so they were simply collected by filtration. Recrystallization of the products from suitable solvents could give purer samples. Unfortunately, recrystallization was not fit for compounds **15**−**18** and **20**. However, they were obtained via the employment of excess amine when the preparation was repeated. For compounds **11** and **23**, the sulfonic sodium salts of corresponding amines were prepared from homologous aminobenzenesulfonic acid and NaOH, for which were used 3 equiv of gossypol to ensure them a sodium sulfonate group. It is worth mentioning that if there are multiple electron withdrawing groups on the ortho and para positions of aromatic amine, such as 2,4-dinitroaniline and 2-nitro-4-(trifluoromethyl)aniline, the corresponding Schiff base of gossypol could not be achieved but the dehydration product of gossypol, anhydrogossypol,[24] was obtained. All of our synthetic gossypol Schiff bases exist in the enamine−enamine form[15,25] in solution as determined by $^1$H NMR. For compound **5**, for example, the structure can be interpreted by the $^1$H NMR spectrum (Figure 3). The signal peaks of symmetrical protons should appear at the same position and have identical coupling constants because of the axial symmetry of the structure. The presence of doublet peaks with the coupling constant of 12.0 Hz in the $^1$H NMR spectrum can be attributed to the signals of **H**—C═C proton (j) and **H**—NAr proton (k). This behavior can be rationally explained by the fact that two protons are adjacent and coupled with each other.

**Antiviral Biological Assay.** Compounds **1**−**25** were initially tested for their phytotoxic activities against the test plant, *Nicotiana tabacum* L. The results indicated that these natural product-based compounds showed no phytotoxic activity at 500 $\mu$g/mL. In other words, the compounds caused no harm to the test plant; therefore, there would be no interference with the determination of anti-TMV data.

The antiviral bioassay of the compounds against TMV was carried out, and the antiviral results are listed in Tables 1 and 2. To make a judgment on the antiviral potency of the synthesized compounds, the commercially available plant virucide ribavirin[24] was used as the control.

The in vitro anti-TMV activities of compounds **1**−**25** and the contrast compound ribavirin are shown in Table 1. The results indicate that these target compounds exhibit moderate to excellent activities against TMV. Among these compounds, gossypol (**1**) and gossypol acetic acid (**2**) displayed similar in vitro anti-TMV activities (**1**, 32%; **2**, 28%); however, they were less effective than ribavirin (38%) at 500 $\mu$g/mL. In contrast, except for **6**, **22**, and **24**, other aromatic gossypol Schiff bases of **3**−**25** showed equivalent or even higher antiviral activities than ribavirin (38%); especially compounds **5**, **9**, **10**, **12**, **15**, **17**, **19**, and **23** displayed obviously higher anti-TMV activities at a concentration of 500 $\mu$g/mL, and the antiviral activities of compounds **9** and **19** at 100 $\mu$g/mL even reach the level of ribavirin at 500 $\mu$g/mL.

On comparison with the parent dianilinogossypol (**3**), except for *p*-hydroxy compound **6**, the activities of Schiff bases **4**−**12** with different substituent groups on the para position of aniline are higher. However, they displayed distinctly different activity levels against TMV in vitro. Compounds with methoxy (**5**),

nitro (**9**), trifluoromethyl (**10**), and trifluoromethoxy (**12**) showed excellent activities (48, 50, 57, and 52%, respectively). To investigate the influence of the position and the number of substituents on the activities, **13**−**23** were synthesized. Compared with their para-substitutional substrates, corresponding substituent groups on the ortho position were beneficial to the increase of their anti-TMV activities, whereas the substituent groups on meta positions were unfavorable to the anti-TMV activities (MeO, **15** > **5** > **16**; $CF_3$, **19** > **10** >**20**; $NO_2$, **9** > **22**). However, the substituent group of the hydroxyl was an exception, as the *o*-hydroxyl compound **13** and *m*-hydroxyl compound **14** had higher activities than *p*-hydroxyl compound **6**. Furthermore, the level of the anti-TMV activities could not be improved by increasing the number of substituent groups. Among methoxy-substituted compounds **5** and **15**−**18**, **15** with only one substituent group on the ortho position displayed the best inhibitory effect. However, **23** (18%) with *o*-methoxy and *m*-sodium sulfonate substituent groups exhibited better inhibitory effect than **11** (0%) and **15** (14%) at 100 μg/mL. The Schiff bases of naphthylamines were synthesized as well, and their anti-TMV activities were performed. Compound **25** (44% at 500 μg/mL), obtained by the condensation of gossypol and 1-naphthylamine, displayed a better inhibitory

dx.doi.org/10.1021/jf504411g | J. Agric. Food Chem. 2014, 62, 11080−11088

effect than dianilinogossypol (**3**, 32% at 500 μg/mL). At variance with **25**, the activity of 2-naphthylamine Schiff base **24** (25% at 500 μg/mL) was relatively lower than that of **3**.

Due to their well-performed behaviors of in vitro antiviral activities against TMV, the in vivo antiviral activities of these compounds deserve to be exploited further. As shown in Table 2, the majority of the compounds also displayed equivalent or higher in vivo activities than the control ribavirin at a concentration of 500 μg/mL. In particular, Schiff bases **12**, **15**, **17**, and **19** exhibited obviously higher anti-TMV activities than ribavirin at 500 μg/mL, of which compound **19** with an *o*-trifluoromethyl group showed the best activity (inactivation activity, 60%/500 μg/mL and 23%/100 μg/mL; curative activity, 57%/500 μg/mL and 30%/100 μg/mL; and protection activity, 62%/500 μg/mL and 26%/100 μg/mL), confirmed by the in vivo inactivation tests, curative tests, and protection tests. Additionally, the in vivo curative activities of these compounds displayed structure−activity relationships similar to the activities in vitro. More importantly, compound **9** with a *p*-nitro group showed a better effect at 100 μg/mL (40%), which is even higher than that of ribavirin at 500 μg/mL (37%).

Interestingly, the in vivo inactivation and protection activities of dianilinogossypol (**3**) displayed excellent inhibitory effects (inactivation activity, 52%/500 μg/mL and 27%/100 μg/mL; protection activity, 44%/ 500 μg/mL and 27%/100 μg/mL). However, only **12**, **15**, **17**, **19**, and **20** exhibited obviously better in vivo curative and protection activities at 500 μg/mL than parent dianilinogossypol (**3**). These results indicated the introduction of trifluoromethoxy, methoxy, and trifluoromethyl on the aromatic ring of aniline could increase the anti-TMV activities level of parent dianilinogossypol. Further analysis of the relationship between the positions of substituents and anti-TMV activities indicated that the order of methoxy and trifluoromethyl is ortho > meta > para position (**15** > **16** > **5**, **19** > **20** > **10**). Other groups and the number of them displayed similar SAR to anti-TMV activities in vitro. The derivatives of naphthylamines (**24** and **25**) had lower inhibitory effect than dianilinogossypol (**3**), but 1-naphthylamine (**25**) is relatively higher than that of 2-naphthylamine (**24**).

**Evaluation of Anti-TMV Activity of 19 in the Field.** Compound **19**, which had exhibited the best anti-TMV activity both in vitro and in vivo in the laboratory, was employed to evaluate the antiviral activity in the field. A 1% EC solution of **19** was prepared and evaluated for the control of TMV in Tengchong county of Yunnan province (southern China). The results of the field trials are shown in Table 3, which indicated that **19** at the amount of 10 g ai/ha had the same control effect (about 66%) as 5% amino glycan at 100 g ai/ha and 20% moroxydine hydrochloride−cupric acetate at 600 g ai/ha at 10 days after spraying. Therefore, it was suggested that **19** could be considered as an alternative to the employed plant virus inhibitor for further development on the basis of the field trials.

**Table 3. Anti-TMV Effect in the Field in 2014**

| compd | amount (g ai/ha) | controlled effect (%) |
|---|---|---|
| **19** | 10 | 66.61 |
| | 50 | 83.88 |
| | 100 | 94.56 |
| 5% amino glycan | 100 | 65.70 |
| 20% moroxydine hydrochloride−cupric acetate | 600 | 66.57 |

**Rat Oral Gavage Acute Toxicity of Gossypol and 19.** To balance the toxicity versus efficacy of compound **19**, we next explored the tolerated dose of **19** and gossypol using a group of rats. They were treated with a single dose of 500 or 50 mg/kg and observed for a period of 14 days, monitoring morbidity (body weight loss) and mortality. All rats were alive after 14 days. The weight of the rats that were treated with gossypol at 500 mg/kg slightly declined over the first 6 days. There is no obvious weight difference between any other two groups (Figure 4). Therefore, gossypol and **19** display low toxicity to rats, but the toxicity of **19** is lower.

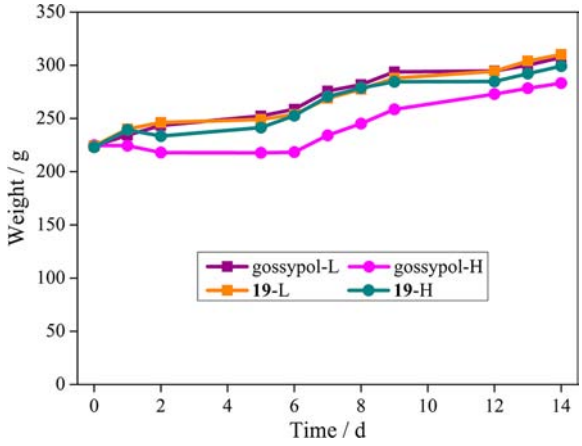

**Figure 4.** Average weight of rats. Gossypol-L, dosage of gossypol is 50 mg/kg; gossypol-H, dosage of gossypol is 500 mg/kg; **19**-L, dosage of **19** is 50 mg/kg; **19**-H, dosage of **19** is 500 mg/kg.

In summary, to eliminate the toxicity caused by the aldehyde group, retain the electron transfer functionalities to generate ROS, and adjust the anti-TMV activity level of gossypol, a series of aromatic gossypol Schiff bases **3**−**25** were prepared and investigated for their anti-TMV activity for the first time. The bioassay results indicated that most of these Schiff bases showed moderate to excellent activities against TMV and were more effective than gossypol (**1**) and gossypol acetic acid (**2**). The introduction of methoxy, trifluoromethyl, or trifluoromethoxy groups, positioned ortho to amine of enamine, could significantly increase the anti-TMV activity levels. Among all of the compounds, compound **19** with an *o*-trifluoromethyl group showed the best anti-TMV activities both in vitro and in vivo in the laboratory. Furthermore, the compound at 10 g ai/ha in the field trial had the same control effect as 5% amino glycan at 100 g ai/ha and 20% moroxydine hydrochloride−cupric acetate at 600 g ai/ha. More importantly, it showed lower toxicity to rats than gossypol. Because of the easy preparation, good anti-TMV activity, and low toxicity, the *o*-trifluoromethylaniline Schiff base (**19**) is expected to be developed as a promising candidate as an inhibitor of plant virus. Further studies on structural optimization and mechanism of action are currently underway in our laboratory.

## MATERIALS AND METHODS

**Samples and Irradiation.** Dried spices (turmeric, oregano, and cinnamon) packed in polyvinyl chloride (PVC) film were purchased from a local market in Daegu, South Korea, and stored in a refrigerator at 5 °C. These spices were handpicked from carefully selected crops and air-dried before being ground to the perfect texture by accurately calibrated machines during the process of manufacturing. The samples were $\gamma$-irradiated (1 and 10 kGy at a dose rate of 2.1 kGy/h) at room temperature using a Co-60 $\gamma$-ray source (AECL, IR-79, MDS Nordion International Co. Ltd., Ottawa, ON, Canada) at the Korean Atomic Energy Research Institute (KAERI), in Jeongeup, Korea. The absorbed doses were confirmed using alanine dosimeters with a diameter of 5 mm (Bruker Instruments, Rheinstetten, Germany). The free-radical signals were measured using a Bruker EMS 104 EPR analyzer (Bruker Instruments, Rheinstetten, Germany). After irradiation until EPR measurements the spice samples were stored at normal laboratory conditions, temperature (23 ± 3 °C), and relative humidity (58−64%) in the dark. However, the sample pretreatments were carried out in normal white fluorescent illumination of laboratory.

**Moisture Contents Determination.** The moisture contents of the spices samples were measured after various sample pretreatments. One gram of the powder sample was placed in an aluminum disc and kept in an electrically heated dry oven at 105 °C for 2−3 h under normal atmospheric pressure. The samples were then transferred to a desiccator for 30 min followed by weight measurements within 2 min time to cool to ambient temperature. Finally, the moisture content was calculated until their absolute differences did not exceed 0.002 g. For each sample, three determinations were carried out.

**EPR Spectroscopy.** To investigate the radiation-induced free radicals in the dried spice samples, three different sample pretreatments were conducted to decrease the moisture content of the spices prior to the EPR measurements:

(i) FD: Freeze-drying (Bondiro, Ilsin Bio Base, Yangju, Kyunggido, Korea) of the samples.[16]
(ii) OD: Oven-drying (HB-502M, Hanbaek Scientific Co., Bucheon, Kyunggido, Korea).[17]
(iii) AE: Alcoholic extraction of the samples was carried out as described by de Jesus et al.[19] Approximately 6 g of the spice samples was put into a beaker containing 40 mL of an 80% ethyl alcohol solution in deionized water. The samples were mixed adequately using a glass rod and kept for 30 min at ambient temperature (23 ± 3 °C). The solid fraction was then separated by filtration, pressed further to reduce the moisture, and then dried in air for 1 h at ambient temperature before being put into the EPR tube.
(iv) WAE: Washing of the finely chopped sample for 20 min with distilled water using a nylon sieve (150 mm). The residues were used after alcoholic extraction as described above.[20,21]

The sample (approximately 0.1 g after the pretreatments) was placed in a quartz EPR tube (5 mm diameter). The open end of the sample tube was then sealed with plastic film. EPR was performed after 15 days of irradiation in accordance with the European standard, EN 1787,[10] using a X-band EPR spectrometer (JES-TE200, Jeol Co., Tokyo, Japan) at room temperature under the following conditions: power, 0.4 mW; frequency, 9.10−9.21 GHz; center field, 324 ± 2 mT; sweep width, 10−25 mT; modulation frequency, 100 kHz; modulation width, 1−2 mT; amplitude, 50−400; sweep time, 30 s; and time constant, 0.03 s. All analyses were conducted in triplicate ($n$ = 3), and the mean values (±standard deviation) are reported. Microsoft Excel (Microsoft Office 2010 version) and Origin (version 8) software were used for data analysis and presentation. The EPR signal height was computed using ESPRIT-425 software (Jeol Co.) as the peak-to-peak amplitude of the first derivative spectrum, whereas the signal intensity was presented in arbitrary units per unit sample weight (AU/mg). The $g$-values were determined using an internal Mn(II) standard attached to the EPR cavity. In addition, $g$ values were also confirmed by calculation using the relation $g$ = 71.448 × microwave (GHz)/magnetic field (mT). This relation was obtained by substituting the values of Bohr magneton ($\beta_e$) and Planck's constant ($h$) in appropriate units into the EPR resonance equation.

## RESULTS AND DISCUSSION

**Spectral Features of the Nonirradiated Samples.** Figure 1 shows the EPR spectra of all of the nonirradiated spice samples subjected to different extraction techniques. The spectra were invariably characterized by a central line at $g_0$ = 2.006 with a line width ($\Delta B_{pp}$) of 0.63 mT as a native signal, plausibly attributable to the photooxodation of the existing polyphenols. Experimental parameters of the spectrometer were kept identical during

measurements of all of the samples. Several reports have suggested that these free radicals are semiquinone radicals produced by the oxidation of plant polyphenolics[22] or lignin.[23] The intensity of the singlet ($g_0$ = 2.006) was almost identical for the spice samples subjected to FD, OD, AE, and WAE. Recently, Akram et al. reported changes in the signal intensity of sauce

samples subjected to different sample pretreatments.[21] However, no such effect was observed for the present spice samples, suggesting that the stability of the existing paramagnetic centers depends on the type of food. Thus, complex matrixes of all of the

were observed, with an increase in the signal intensity of the existing weak singlet ($g$ = 2.006). Raffi et al. and Ahn et al. previously reported similar observations, where an intense signal was noticed in the spectrum of irradiated spice and vegetable; the relatively high intensity was attributed to irradiation treatment.[24,25] The line width ($\Delta B_{pp}$) of the EPR signal was observed to increase from 0.74 to 0.91 mT, and was possibly due to the induction of multiple paramagnetic centers in the matrix of the spice samples. In addition, a radiation specific triplet signal with a hyperfine coupling constant (hfcc) of 3 mT was observed for all samples and identified as originating from the cellulose radical. The triplet was characterized by $g_0$ (central line) at 2.006, $g_1$ (left line) at 2.024, and $g_2$ (right line) at 1.986. Deighton et al.[26] reported that the left line is strictly due to radiation-induced cellulose radicals, whereas the right line, induced by lignin radicals, is sensitive to irradiation as well as the drying processes.[27] The triplet signal of the cellulosic radical is a well-established signature of radiation processing of foods.[12] In case of the irradiated turmeric, an additional weak line at the extreme right of the central signal was observed after FD, AE, and WAE pretreatments as depicted in Figure 2. This signal was possibly because of the axially symmetric radiation-induced doublet of carbohydrate radicals and was masked in case of OD samples. A similar observation has recently been reported in case of the irradiated medicinal plant products where irradiated EPR spectra were the superposition of three paramagnetic centers of polyphenols, cellulose, and carbohydrate radicals.[7] Therefore, in case of turmeric, all three sample pretreatments, FD, AE, and WAE, were successful in identifying radiation-specific radicals beyond doubt.

**Characteristics of EPR Spectra of the Irradiated Spices after Drying Treatments.** To enhance the distinct visibility of the radiation-specific EPR lines for the spices, the samples were subjected to various pretreatments (OD, FD, AE, and WAE) prior to EPR analysis. The intensity of the central signal ($g_0$) of all of the irradiated spice samples was enhanced. The most prominent increase in intensities was observed for FD and OD samples (Figures 2, 3, and 4). However, in case of OD samples, the spectral profile changed minimally following irradiation, although the two radiation-induced side lines ($g_1$ = 2.024 and $g_2$ =

1.986) were still apparent for all of the samples at a radiation dose of 1 kGy. Table 1 shows that the $g$-values ($g_1$ = 2.024, $g_0$ = 2.006, and $g_2$ = 1.986) and the distance ($g_1-g_2$ = 6.0 ± 0.1 mT) between the two satellite lines did not vary significantly with variation of the samples and the pretreatments, which indicates that the radiation-induced free radicals remained unchanged following different pretreatments. In other words, the detection marker identified as cellulose radicals was apparent for all samples and indicated the irradiation history as per EN 1787.[12] However, the intensity of the signal varied detectably with different pretreatment procedures. The side lines were not prominent, especially for the 1 kGy-irradiated OD samples. The signal intensity of the side EPR lines of the cellulose radical increased significantly in the case of all of the AE samples (Figures 2, 3, and 4). However, no further enhancement in the signal intensity was observed after the incorporation of the water-washing step, as reported by Akram et al. in the case of sauce samples.[21] In the case of the irradiated sauce samples, an enhancement in the central line signal intensity after sample pretreatment has also been reported. However, in the present case of the spices, no such increase in the central line intensity was observed, probably because of the considerable differences in the moisture contents between the samples subjected to conventional drying methods (FD, OD) and alcohol assisted extraction treatments (AE and WAE) as shown in Table 2. After alcoholic extraction, both the nonirradiated and the irradiated samples showed an increase in moisture content enhancing the chance of recombination of the paramagnetic centers in the spice moiety. The low starch content (ca. 7−12%) may also influence the EPR spectral profile.[28] It has recently been reported that the presence of starch and the initial water content of a food sample are responsible for the observed differences between the initial and final spectra of the irradiated samples.[7] In the case of cereals, the water content was shown to affect the initial spectra, particularly during irradiation, but the

final spectra were independent of hydration.[29] Table 3 shows the ratio of the signal intensities of the central line ($g_0$) and right line ($g_2$) to the intensity of the left line ($g_1$). The signal ratios were also observed to vary with the irradiation doses and the sample types. The ratio of the intensity of the side signals (corresponding to radiation-induced cellulose radicals) to the total intensity of the central EPR signal was reported to be ca. 5% for irradiated *Foeniculi fructus* and 50% for irradiated citrus fruits.[30,31] In general, the signal intensity ratio of the OD and FD samples was 1:6:1 and 1:7:1, respectively. However, the ideal signal intensity ratio in case of radiation-induced cellulose radicals has been reported as 1:2:1.[32] The ratio of the signal intensity of the right line to that of the left line was observed to be higher for the OD samples in comparison with that of other pretreated samples, and the maximum value was obtained for cinnamon. However, the spectra of the OD and FD samples were not as clear as those of the AE and WAE samples, and thus identification was difficult for the 1 kGy-irradiated sample. The samples subjected to AE and WAE exhibited improved and distinct radiation-induced triplets, as shown in the cases of turmeric (Figure 2b), oregano (Figure 3b), and cinnamon (Figure 4b), possibly because of the removal of the short-lived polyphenolic radicals ($g$ = 2.006) during the sample pretreatments. Consequently, the intensity of the central lines for AE and WAE treated spice samples was found to be reduced, resulting in relative enhancement of the cellulosic triplet as depicted in Figures 2a, 3a, and 4a. The intensity ratio of the central signal to the left signal of all of the AE samples was observed to be less than that of the OD samples, confirming the aforementioned behavior of the EPR signals as demonstrated in Table 3. The behavior of the EPR lines ($g_1$ and $g_0$) with increase in dose from 1 to 10 kGy after different sample pretreatments was also studied. A dose-dependent increase in the radiation-induced cellulose radical signals in the flesh of irradiated vegetables after different sample pretreatments has already been reported by de Jesus et al.[33] In case of the spice samples, the signal intensities were measured by the peak to peak amplitude of the EPR lines. To take into account the variable sample quantities in EPR tubes, the signal intensities in arbitrary unit (AU) of each aliquot were divided by the respective sample weight. The percentage EPR signal intensity was then calculated by normalizing the intensities with respect to 100 as shown in Figure 5. In the case of the OD and FD spice samples, the percentage intensity of the $g_0$ line showed a sharp increase at 1 kGy, followed by a slower enhancement up to 10 kGy. On the contrary, in most of the irradiated food samples sharp enhancements in signal intensities have been observed with increasing dose because food samples have not been subjected to any postirradiation treatments prior to EPR measurements.[7,34] Therefore, in those food samples, the radiation-induced radicals at $g_0$ responsible for intensity enhancement have not been removed. In this study, the spice samples were subjected to postirradiation pretreatments (FD, AE, and WAE) to eliminate the radiation-induced paramagnetic centers at $g_0$ to enhance the signatures of the radiation-specific radicals in EPR spectra. In case of AE and WAE samples, the intensities of the $g_0$ line did not show any sharp enhancement with the increasing dose because the majority of the radiation-induced polyphenolic radicals were eliminated during chemical extraction processes as depicted in Figure 5. A similar observation of a slow increase in EPR signal intensity in case of irradiated sea vegetables after pretreatments has recently been reported in our earlier communication.[35] In addition, at very high dose the intensity normally showed saturation probably because of the increased recombination rate

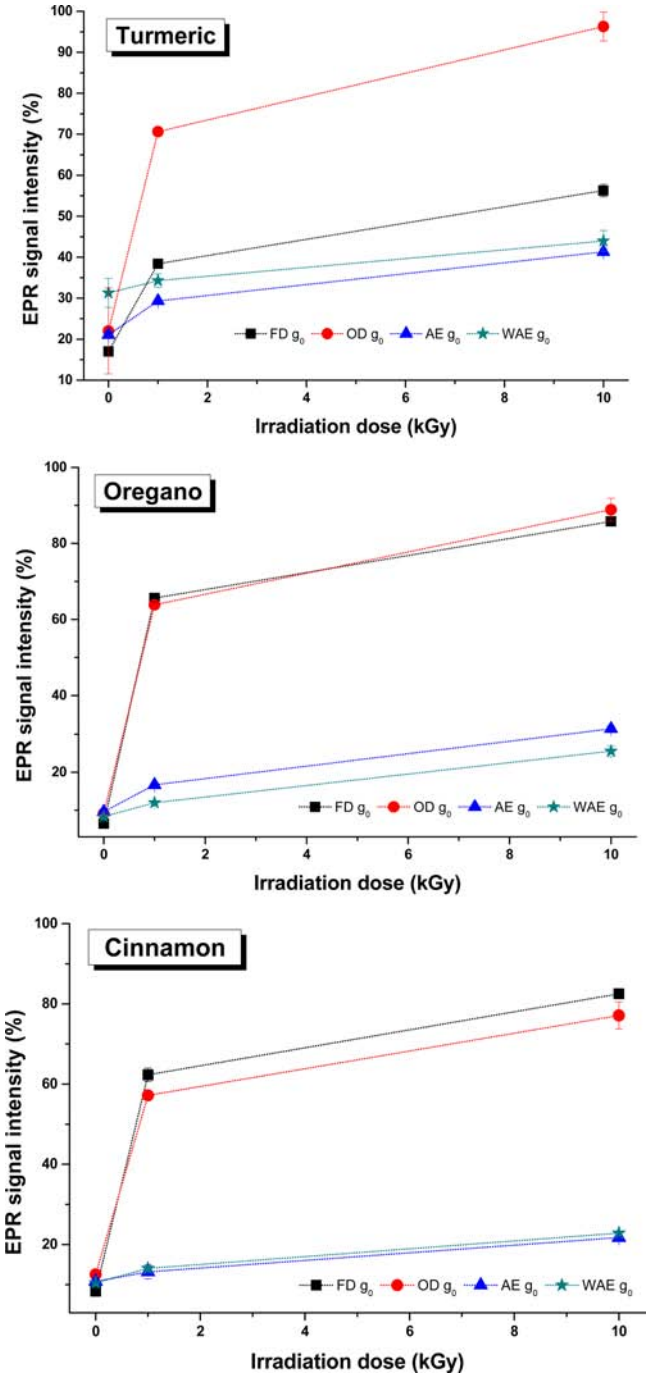

**Figure 5.** Response of the EPR signal intensity with increasing radiation dose for the spices (turmeric, oregano, and cinnamon) after different sample drying pretreatments (FD, freeze-drying; OD, oven-drying; AE, alcoholic extraction; WAE, water washing and alcoholic extraction). The percentage EPR signal intensity was calculated by dividing the weight normalized EPR intensities by 100.

of the radiation-induced radicals due to the enhanced spin density. A similar observation has been reported in the case of irradiated guar gum samples, where the EPR signal intensity did not exhibit any distinct trend with increasing dose, possibly because of the fast recombination of the induced free radicals.[36] However, the qualitative detection of irradiation features was possible for all of the irradiated spice samples on the basis of changes in EPR spectra, and the change was most prominent in the case of the samples subjected to AE pretreatment.

dx.doi.org/10.1021/jf502258r | J. Agric. Food Chem. 2014, 62, 11089−11098

In conclusion, an advanced approach to the EPR analysis of irradiated food samples incorporating the alcoholic-extraction process resulted in improvement in the identification of irradiation status for irradiated spice samples relative to samples pretreated with conventional oven and freeze-drying protocols. The alcoholic-extraction method gave rise to enhanced EPR spectral features, and particularly improved signal intensity, and thus enabled clear detection of irradiation. An addendum water-washing step (in addition to the alcoholic extraction) produced no further enhancement of the EPR spectra. These results suggest that the signature of the paramagnetic radicals in cellulose, produced by irradiation, can be enhanced by the alcoholic extraction process, and this protocol is useful for the identification of $\gamma$-irradiated spices.

analogues, which possess several characteristics that allow them to interact with analytes and serve as chiral selectors.[10−13] The most enantioselective separations of amino acids were carried out on teicoplanin or teicoplanin aglycone chiral stationary phases. The retention occurs when the teicoplanin ammonium group interacts with the carboxylate group of the amino acid or the ammonium group of the amino acid interacts with teicoplanin carboxylate, whereas chiral discrimination results from a complex interaction between analyte and tertiary teicoplanin structure.[13] The retention and chiral resolution can be optimized by changing the concentration and nature of the organic modifier in the mobile phase and enhancing steric conformation of the chiral stationary phase by adjusting pH, ionic strength of the mobile phase, and column temperature.[12−15]

Up to date, there are few papers dealing with the determination of amino acids in hydrolyzed protein fertilizers (HPFs).[16−18] Alarcón-Flores and co-workers[16] developed an ultrahigh-performance liquid chromatography−tandem mass spectrometry (UHPLC−MS/MS) method for the non-chiral determination of 19 underivatized protein amino acids in HPF samples. All amino acids were separated in 8 min by reversed phase, with the addition of the mobile-phase pentadecafluorooctanoic acid as the ion-pairing reagent. Cavani et al.[17] described the separation of protein amino acids derivatized with dansyl chloride by micellar electrokinetic chromatography and direct ultraviolet (UV) detection, employing $\beta$-cyclodextrin as the chiral selector. However, only one amino acid (dansylated D-/L-alanine) was considered, and its degree of racemization was calculated. More recently, Sánchez-Hernández et al.[18] have proposed a capillary electrophoresis−tandem mass spectrometry technique using cyclodextrins as chiral selectors to determine the degree of racemization of the free amino acids in HPFs. The enantiomeric separation of up to 14 amino acids was achieved in about 60 min with resolutions above 1.0.

In this study, a rapid and selective HPLC method based on chiral teicoplanin stationary phase and coupled with tandem mass spectrometry was developed and applied for the first time to the enantioselective determination of free amino acids in HPFs. Under optimized conditions, enantiomeric separation of 15 amino acids was achieved with a run time of 15 min. The method was validated and successfully applied to the analysis of five commercially available HPF samples.

## MATERIALS AND METHODS

**Chemicals and Reagents.** Amino acids L-alanine, L-arginine, L-asparagine, L-aspartic acid, L-cysteine, glycine, L-glutamine, L-glutamic acid, L-histidine, L-leucine, L-isoleucine, L-lysine, L-methionine, L-phenylalanine, L-proline, L-serine, L-threonine, L-tryptophan, L-tyrosine, and L-valine were purchased from Sigma-Aldrich (St. Louis, MO) as the L-amino acid kit. D-amino acids D-alanine, D-arginine, D-asparagine, D-aspartic acid, D-cysteine, D-glutamine, D-glutamic acid, D-histidine, D-leucine, D-lysine, D-methionine, D-phenylalanine, D-proline, D-serine, D-threonine, D-tryptophan, D-tyrosine, and D-valine were purchased separately also from Sigma-Aldrich (St. Louis, MO). Stock standard solution was made at 1 g/L concentration level in 1 mol/L aqueous formic acid solution and kept at 4 °C, in amber glass containers. Working standard solutions were made by appropriate dilution of stock standards in methanol/water solution (50:50, v/v) and kept at 4 °C temperature in amber glass vials prior to analysis. Ultra liquid chromatography−mass spectrometry (LC−MS) acetonitrile was purchased from Carl Roth GmbH & Co. (Karlsruhe, Germany), and ammonium acetate, formic acid, acetic acid, ethanol, and methanol (all LC−MS grade) were purchased from Sigma-Aldrich (St. Louis, MO). Purified water was obtained with a Milli-Q apparatus (Millipore, Bedford, MA).

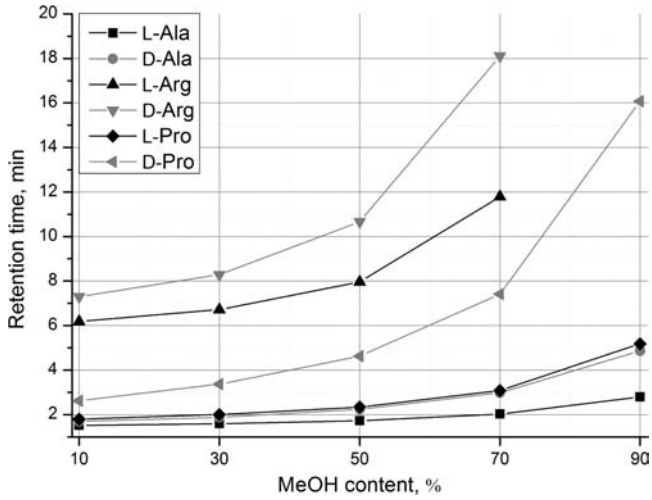

**Figure 1.** Effect of the methanol content in the mobile phase on the retention times of D-/L-Ala, D-/L-Arg, and D-/L-Pro enantiomers ($n$ = 2).

**HPLC−MS/MS Analyses.** Chromatographic separations were performed using an Agilent 1290 Infinity LC system coupled with a triple quadrupole 6410 tandem mass spectrometer equipped with an electrospray ionization (ESI) interface (Agilent Technologies, Santa Clara, CA). The column used was a 150 × 2.1 mm inner diameter, 5 $\mu$m, Astec CHIROBIOTIC T2 purchased from Sigma-Aldrich (St. Louis, MO). Data acquisition and processing were performed with Mass Hunter 5.0 software (Agilent Technologies, Santa Clara, CA). The mobile phase flow rate was 0.3 mL/min; the column was maintained at 15 °C temperature; and the sample volume was 2 $\mu$L. A binary mobile phase with gradient elution was used. Solvent A was water with 10 mmol/L ammonium acetate (pH 4.2), and solvent B was methanol/water (95:5, v/v) with 10 mmol/L ammonium acetate (pH 4.2). The gradient program was set as follows: 0−5 min, 5−50% A; 5−12 min, 50% A; and 12−13 min, 50−5% A. This was followed by a 2 min equilibration period prior to the injection of next sample. The total run time was 15 min.

MS/MS detection was performed in multiple reaction monitoring (MRM) mode. The ESI ion source was set for positive ionization at the following setup: capillary voltage, 4 kV; gas temperature, 300 °C; gas flow, 8 L/min; and nebulizer gas pressure, 30 psi. Cell accelerator voltage and dwell time were kept constant for all analytes and were set at 6 eV and 20 ms, respectively.

**Sample Preparation.** Five commercially available HPF products, namely, Aminocat 30% (sample A), Terra Sorb Complex (sample B), ILSA Drip Forte (sample C), Protifert LMW8 (sample D), and Rutter (sample E), were obtained from local suppliers. These HPF concentrates are viscous liquids containing free amino acids. All samples were prepared according to the procedure suggested by Alarcón-Flores et al.[16] An aliquot of fertilizer was weighed (100 mg), and 10 mL of water solution was adjusted to pH 1.5 with heptafluorobutyric acid. The mixture was thoroughly vortexed for 1 min and centrifuged for 15 min at 3000 rpm. After centrifugation, supernatant was filtered through a nylon 0.20 $\mu$m filter (Carl Roth GmbH & Co., Karlsruhe, Germany), 20 $\mu$L of the filtrate was transferred into the vial, 980 $\mu$L of initial mobile phase was added, and the final solution was taken for HPLC−MS/MS analysis. Because of the large amount of glutamic acid in sample A, the quantitation of D-/L-Glu in this sample was performed separately from 10 times extra-diluted extract.

## RESULTS AND DISCUSSION

**HPLC Separation Optimization.** Macrocyclic antibiotic-based chiral stationary phases are compatible with both organic and aqueous mobile phases. This makes Chirobiotic T2 the ideal stationary phase for resolving polar compounds, such as amino acids. Several parameters, such as nature and content of

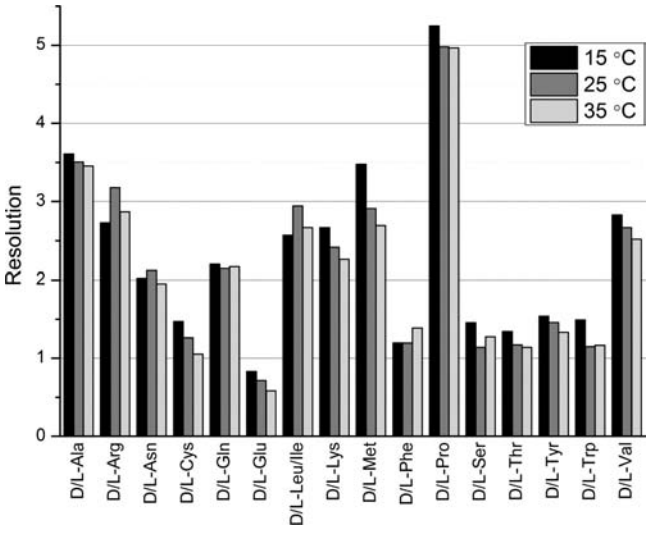

**Figure 2.** Effect of the temperature on the enatiomeric resolution of amino acids obtained in gradient elution mode ($n$ = 2).

the organic modifier in the mobile phase, mobile phase pH, and column temperature, were tested to find the optimum conditions allowing for the highest enantiomeric resolution of the analytes. Typically, the resolution of amino acids is influenced by the nature of organic modifier.[19,20] Three organic modifiers, namely, acetonitrile, ethanol, and methanol, were tested in the current study. Acetonitrile provided the best resolution for isobaric D-Leu/D-Iso and L-Leu/L-Iso pairs, but enantiomeric resolution of the rest of the D-/L-amino acids was reduced significantly. It was shown that the resolution can be improved with the increase of the organic modifier chain length.[21] However, the use of ethanol as the organic modifier increased the system back pressure and considerably decreased peak efficiency. Therefore, methanol was chosen for further optimization. For some analytes in reversed-phase separation mode, macrocyclic glycopeptide-based stationary phases exhibit U-shaped retention versus mobile-phase composition plots.[22−24] The increase in retention with decreasing the MeOH concentration at water-rich mobile-phase compositions is usually observed when hydrophobic interactions between analytes and stationary phase are dominant. At organic-rich mobile-phase compositions, an opposite trend is observed, which can be attributed to the lower solubility of the analytes in less polar mobile phases. The analytes therefore favored the stationary phase, which resulted in a stronger retention at a higher MeOH amount.[24] Figure 1 shows the plots of the retention times for three representative enantiomer pairs as a function of the MeOH concentration in the mobile phase. In this case, the gradually decreasing retention times with the decrease in the amount of MeOH in the mobile phase is not followed by a retention increase at water-rich mobile-phase compositions. The retention times are substantially unaffected by changes in mobile-phase composition for MeOH concentrations lower than 30% (v/v). Obtained results suggest that, for very hydrophilic compounds, such as amino acids, hydrophobic interactions are not the driven retention forces even at water-rich mobile phases.

It was reported earlier[21,25,26] that the discrimination of D-/L-amino acid enantiomers is also influenced by teicoplanin conformation, which can be affected by mobile-phase pH and temperature. Ammonium acetate, which exhibits adequate buffering capacity over the working pH range (3.8−6.8) of the stationary phase, was employed for mobile-phase pH adjustment. No significant effect on enantioselectivity within the pH range of 4−6 was observed, and only slightly better resolution was achieved at lower pH values. Teicoplanin contains a single primary amine ($pK_a \approx 9.2$) and a single carboxylic ($pK_a \approx 2.5$) group, which are mainly responsible for chiral recognition.[27] Thus, the variation of the pH between 4 and 6 does not change the charge state of the amino group and only slightly (at pH < 4.5) affects the charge state of the carboxylic

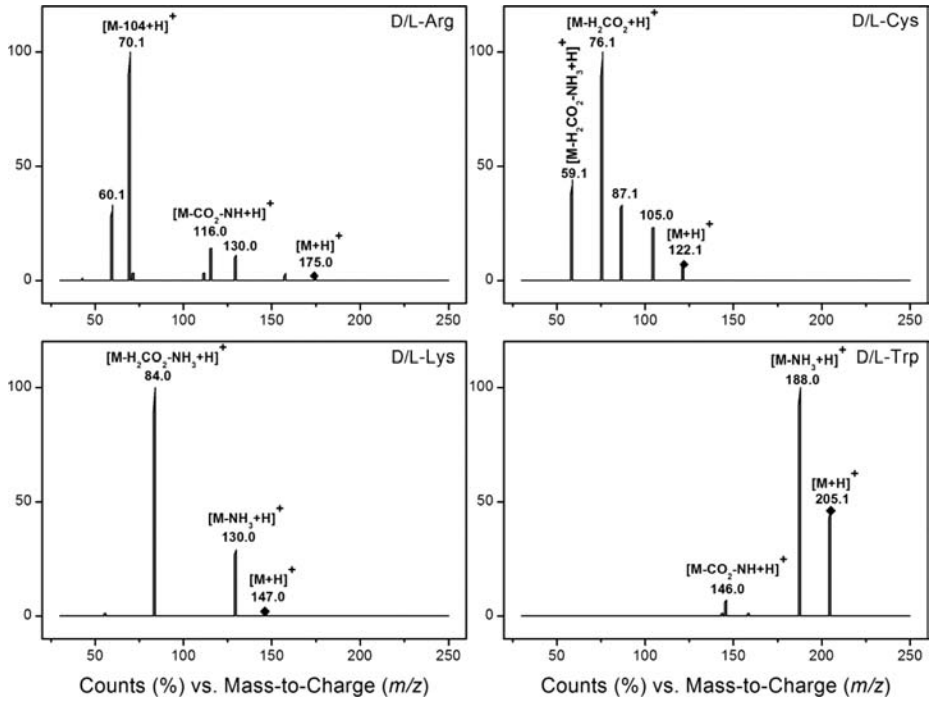

**Figure 3.** Product ion scan mass spectra of representative D-/L-amino acids (100 $\mu$g/L) obtained by direct infusion.

[a]Quantitation transitions are in bold.

group. However, amino acids with pI values lower than 4, namely, D-/L-aspartic acid (pI = 2.98) and D-/L-glutamic acid (pI = 3.08) were only partially resolved under these conditions. Because of the limited stationary-phase pH working range, it was impossible to try to resolve them in their fully protonated form. On the basis of the obtained results, mobile phase with pH 4.2 was chosen for further experiments. It should be noted that more acidic mobile phase is favored over positive ESI ionization mode for better signal response.

From the temperature dependence obtained in gradient elution mode, it was observed that, for most amino acids at the lower temperature, the resolution of the enantiomers increases (Figure 2). A lower temperature generally results in better enantioselectivity ($\alpha$) on most macrocyclic glycopeptide-based chiral stationary phases employed in reversed-phase mode because of the negative enthalpy difference [$\Delta(\Delta H^\circ)$] for the transfer of enantiomers from the mobile phase to the stationary phase.[22,24] All investigated amino acid enantiomers, except for D-/L-Asn, gave negative $\Delta(\Delta H^\circ)$ values, with correlation coefficients higher than 0.98 (results not shown). However, resolution does not always follow the same trend of selectivity. As observed from Figure 2, some D-/L-amino acid pairs exhibited slight $R_s$ improvement with increase of the temperature. Raising the temperature most often is associated with an increase in peak efficiency. Thus, because the resolution factor combines both retention differences and efficiency, the higher contribution to the resolution for these acids most likely came from the increase in efficiency.

Several other parameters, such as buffer concentration, flow rate, and sample volume, were also briefly tested to improve chromatographic performance, but no obvious improvement in the enantiomeric resolution was observed.

**Tandem Mass Spectrometry.** Ion source and MS parameters were optimized manually via direct infusion of a standard solution of 100 $\mu$g/L of each amino acid at 3 $\mu$L/min flow rate. The standard solutions were prepared in water/MeOH (50:50, v/v) containing 10 mmol/L formic acid. Full-scan MS spectra showed the most abundant protonated $[M + H]^+$ molecular ion for all amino acids in positive ESI mode. First quadrupole was set to single ion monitoring mode

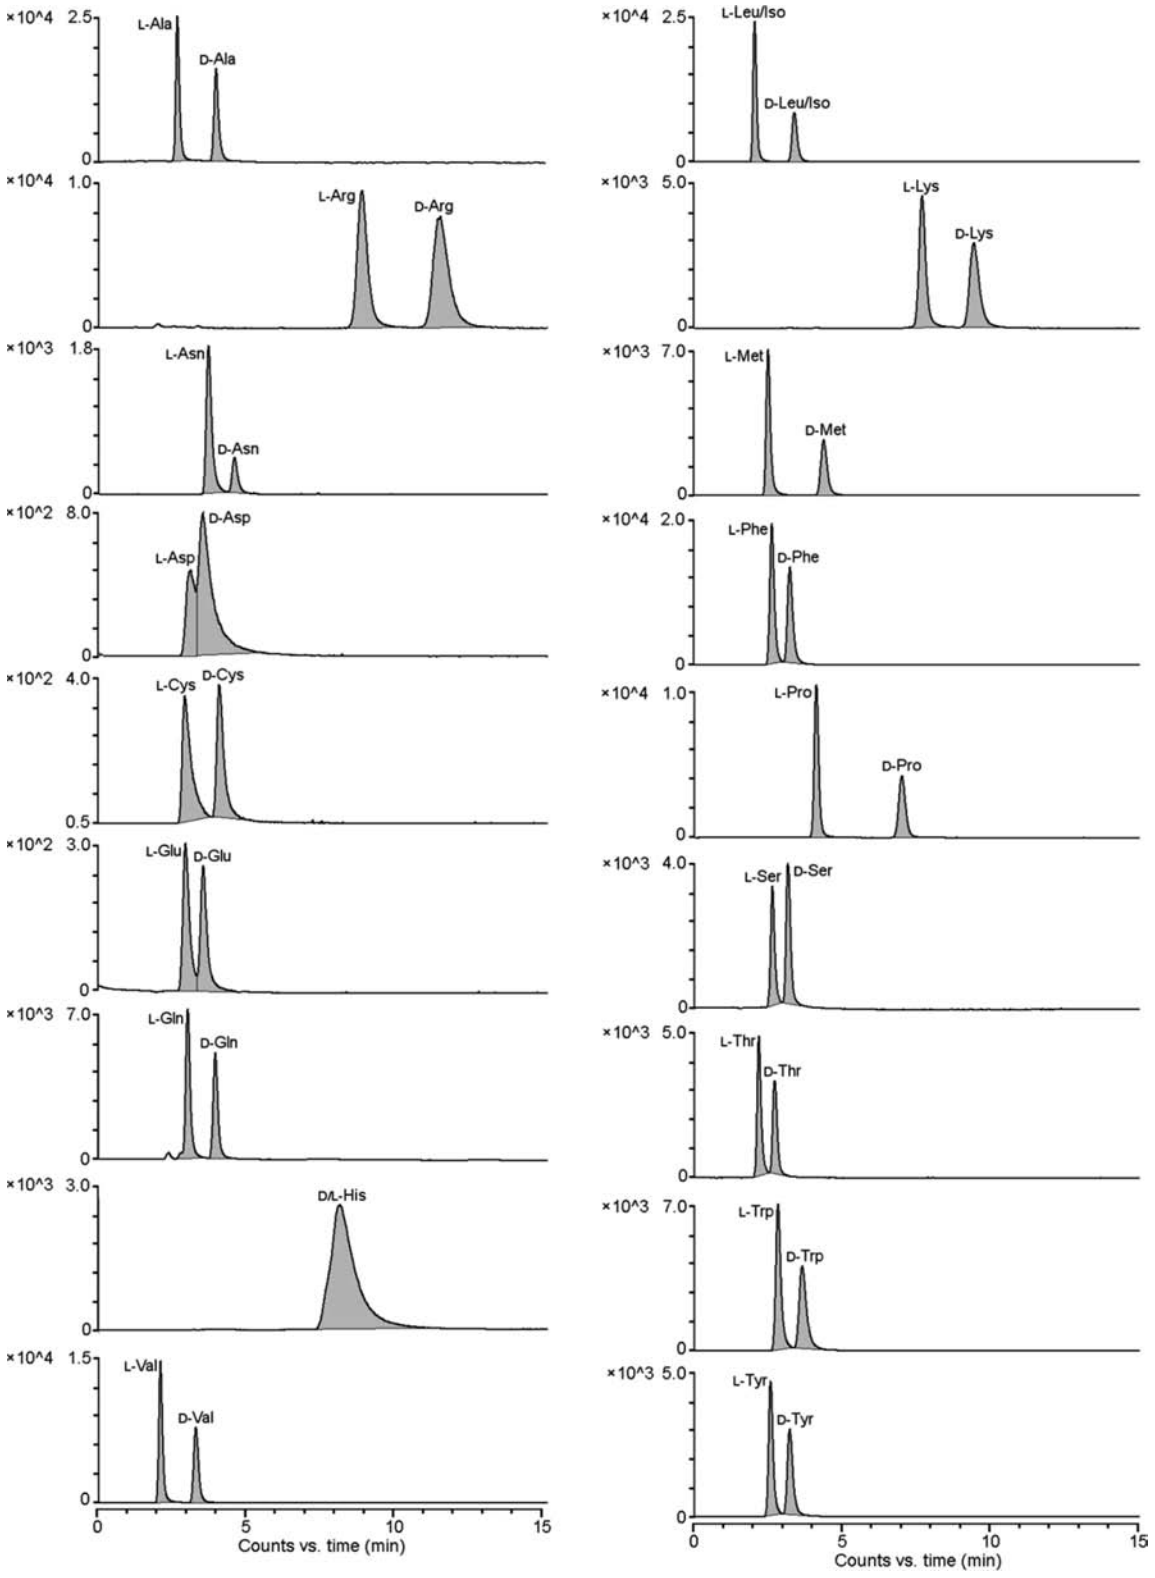

**Figure 4.** MRM chromatograms (transitions used for quantitation) of the amino acid standard mixture at the 50 $\mu$g/mL level obtained under optimized HPLC−MS/MS conditions.

for the selected protonated precursor ion, and the fragmentor voltages (from 50 to 150 V) were tuned individually to each amino acid. Then, product ion MS spectra were acquired, and from the collision-induced dissociation (CID) experiments, the most abundant transition ions were selected. Only one transition was monitored for alanine and proline because of their low molecular weights. The rest of the amino acids produced quantitative and qualitative MRM transitions each. Most of the amino acids gave quantitative MRM transitions corresponding to the loss of formic acid $[M - HCOOH + H]^+$ or formic acid and ammonia $[M - HCOOH - NH_3 + H]^+$, whereas Arg and Trp led to the formation of $[M - 104 + H]^+$

[a]ND = not detected.

and $[M - NH_3 + H]^+$ ions, respectively (Figure 3). The CID collision energies were also tuned manually by monitoring product ion intensity in MRM mode in the range from 2 to 30 eV. All optimal transitions as well as fragmentor voltages and collision energies for investigated amino acids are presented in Table 1.

MRM chromatograms (only transitions used for quantitation) of the amino acid standard mixture at the 50 μg/mL level obtained under optimized HPLC–MS/MS conditions are presented in Figure 4. As can be observed, complete enantiomeric separation of 15 amino acids was achieved in about 15 min. D-/L-Glu and D-/L-Asp pairs were partially resolved, and only for D-/L-His enantiomers was no resolution obtained.

**Method Validation.** The proposed method was validated in terms of linearity, limit of detection (LOD), limit of quantitation (LOQ), accuracy, and precision, following the ICH harmonized tripartite guideline.[28] All HPF samples from the point of composition (provided by the manufacturer) and brief visual evaluation looked similar, but preliminary investigations showed that sample A contains the highest total amount of free amino acids. Consequently, this sample was chosen as the model matrix for validation.

One significant drawback of ESI–MS is that the ionization process is greatly affected by the co-eluting matrix compounds.[29] The matrix effect typically results in the suppression or, less frequently, enhancement of the analyte signal. Isotopically labeled internal standards or matrix-matched calibration are the two common approaches that have been widely used to eliminate or correct matrix effects in LC–MS/MS analyses. However, neither the blank matrix of analyzed fertilizers nor isotopically labeled standards for all investigated amino acids are unavailable. Therefore, in this study, matrix effects were evaluated by the standard addition method. The signal suppression/enhancement observed with each analyte was calculated as the percentage difference in signal intensity measured in the sample extract versus that measured in the pure solvent

$$\text{percentage difference (\%)} = (A_{\text{spiked}} - A_{\text{unspiked}})/A_{\text{solv}} \times 100\%$$

where $A_{\text{spiked}}$ is the analyte peak area in the spiked sample, $A_{\text{unspiked}}$ is the peak area without spiking, and $A_{\text{solv}}$ is the peak area in pure solvent.

A value of 100% is indicative if no signal suppression/enhancement is observed. The aliquots of 10 μL sample extracts were spiked at two concentration levels (100 and 500 μg/mL),

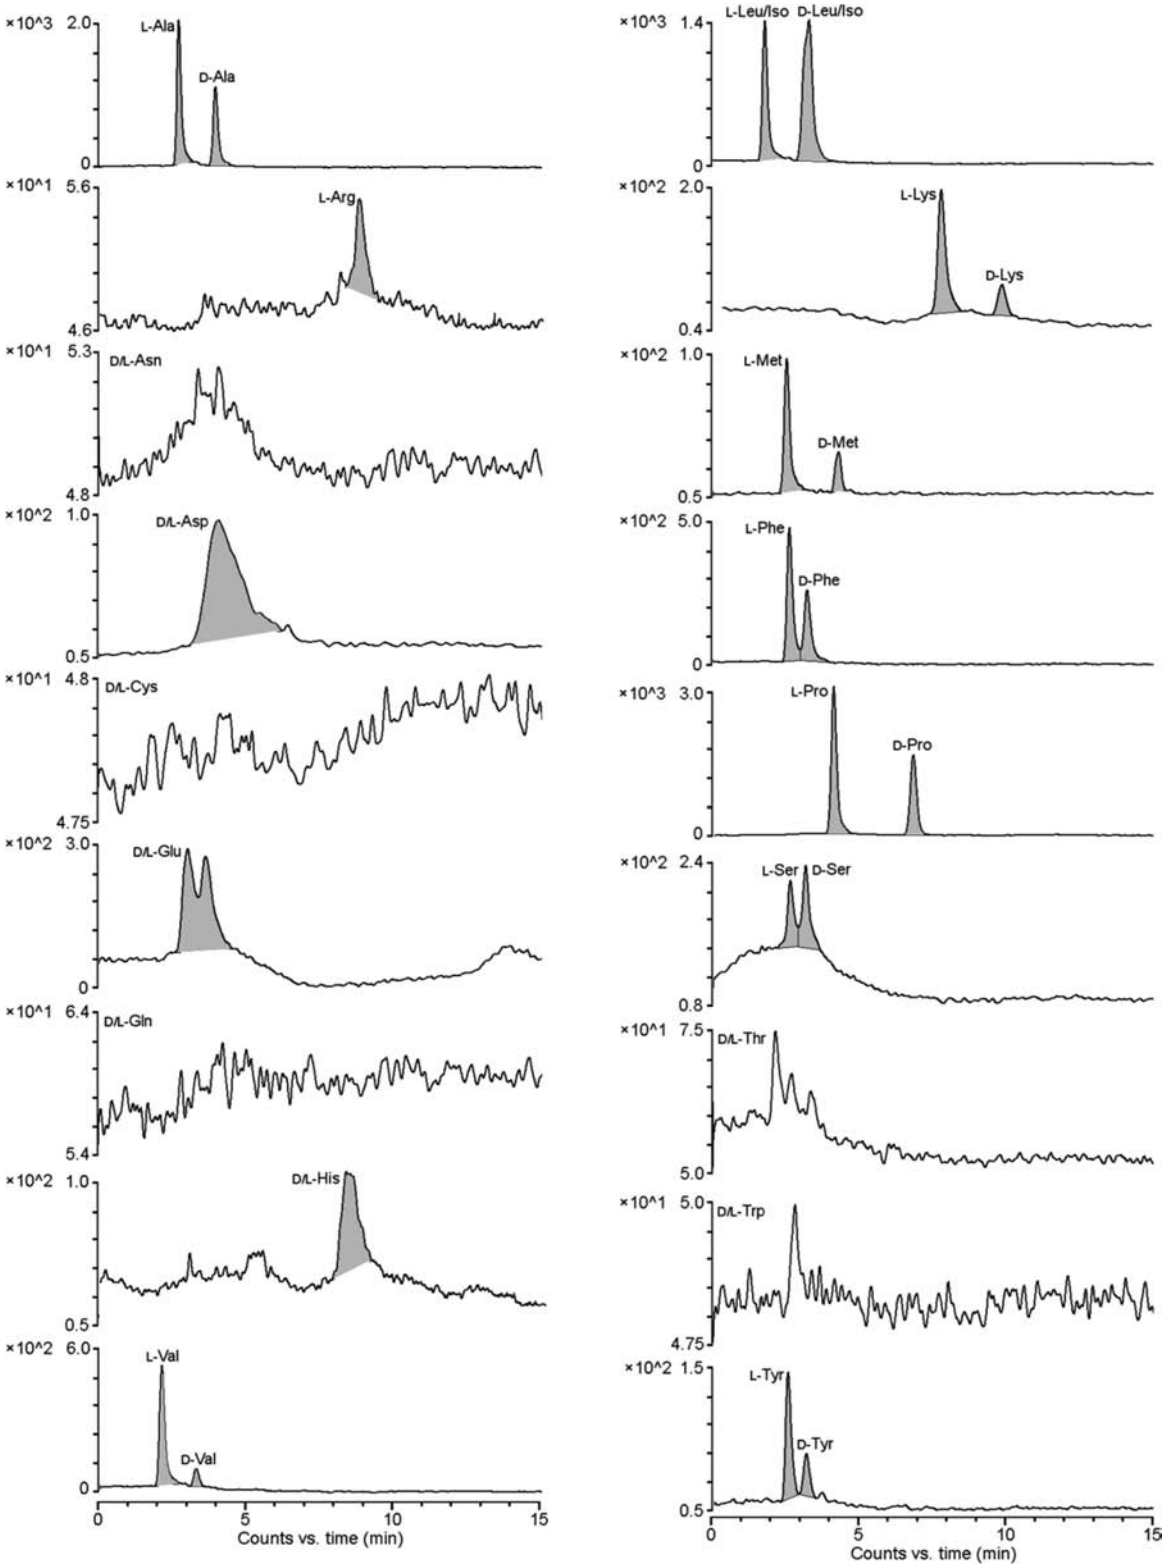

**Figure 5.** MRM chromatograms (transitions used for quantitation) obtained for sample D (Protifert LMW8).

diluted by a factor of 100, and analyzed. Because of high dilution factor of the extracts, signal suppression was not crucial and was in the range of 90.2−117.1% (see Table S1 of the Supporting Information). Nonetheless, to ensure bias-free results, the standard addition protocol was employed for quantitation.

LODs and LOQs were determined (see Table S1 of the Supporting Information) from standard addition experiments (for sample A) based on the standard deviation of the response and the slope, expressed as follows:

$$\text{LOD} = 3.3\sigma/S \quad \text{and} \quad \text{LOQ} = 10\sigma/S$$

where $\sigma$ is the standard deviation of $y$ intercepts of regression lines and $S$ is the slope estimated from the regression curve.

Table 4. Declared and Determined Amounts of Free Amino Acids in Commercial HPF Samples ($n$ = 3)

| sample | brand | declared amount (w/w) of amino acids | determined amount[a] (w/w) of L-amino acids (%) (±SD) | determined amount (w/w) of D-amino acids (%) (±SD) |
|---|---|---|---|---|
| A | Aminocat 30% | contains 30% free L-amino acids + glycine | 27.0 (1.4) | <0.1 |
| B | Terra Sorb Complex | contains 20% free L-amino acids + glycine | 18.5 (2.2) | 0.3 |
| C | ILSA Drip Forte | total amino acids of >50%; contains free amino acids, mainly in the L form | 1.4 (0.2) | 0.2 |
| D | Protifert LMW8 | total amino acids of 50% and free amino acids of 15%; no information on polarization | 12.3 (0.2) | 4.2 (0.2) |
| E | Rutter | no information | 6.1 (0.6) | 0.5 (0.1) |

[a]Amounts of enantiomerically unresolved amino acids and glycine were included to L-amino acids.

Because of the high number of closely eluting analytes, the time segmentation for MRM analysis was not employed and the dwell time for each MRM transition was set to 20 ms. Although this led to reduced detectability and narrower linear ranges, obtained sensitivity was still acceptable for HPF samples.

Because of the absence of reference materials, method trueness was evaluated by spiking/recovery experiments. Fertilizer aliquots (100 mg) were spiked with an approximately 50 $\mu$g/mL standard of L- and D-amino acids, and the sample preparation procedure was applied. The recovery values ranged from 73.4% for D-threonine to 115.3% for D-asparagine, with relative standard deviations (RSDs) lower than 20%, except for L-methionine (21.7%) and D-tyrosine (21.9%). Precision was evaluated in terms of repeatability and reproducibility. Interday repeatability was evaluated for the sample without spiking and spiked at two concentration levels: 0.5 and 5.0 $\mu$g/mL. This procedure was also performed for interday precision experiments within 4 sequential days. Recovery and precision data are summarized in Table 2.

**Sample Analysis.** Five commercially available HPF samples were analyzed under optimized HPLC−MS/MS conditions.

As already mentioned above, samples were prepared according to the recently published procedure;[16] therefore, no additional optimization of this step was performed. Only stability of the analytes was checked, and no racemization during the extraction procedure was observed. Because of low or no enantiomeric resolution, aspartic acid, glutamic acid, and histidine were determined as the sum of D and L enantiomers, whereas for unresolved isobaric D-Iso/D-Leu and L-Iso/L-Leu, only the sum of L-Iso and L-Leu as well as D-Iso and D-Leu amounts was measured. As an example, MRM chromatograms of sample D are presented in Figure 5. Determined concentrations of the individual amino acid enantiomers are summarized in Table 3. Finally, the obtained total amounts of D- and L-amino acids were compared to those declared by the manufacturer (Table 4). Unfortunately, composition of sample E was not specified. As seen, for samples A, B, and D, the determined values agree well with the amounts provided by manufacturers. The majority of the amino acids in sample C most likely exist in bonded form. Samples A and B had the highest enantiomerical purity, whereas in sample D, at least one-fourth of the total amino acid amount was the D enantiomer.

luteolin, quercetin, apigenin, rutin, and kaempferol), which are the constituents responsible for its free radical scavenging activity.[16]

Resorcinol is known as a fluorescent compound (molar fluorescence coefficient, $\varepsilon = 1.59 \times 10^7$ $M^{-1}$ $cm^{-1}$), and its fluorescence intensity decreases as a result of its sequential chlorination with HOCl.[17] Heasley et al. reported that the non-fluorescent monochloro- to dichloro- and to trichlororesorcinol products are formed.[18] The HOCl scavenging activity of the tested polyphenols (as $IC_{25}$ values) is directly linked to the decrease in resorcinol fluorescence under HOCl attack in the presence of polyphenols. The scavenging activity of the polyphenols was also measured with the KI/taurine assay chosen as a reference method.[19]

In this study, the HOCl scavenging activities of polyphenols (flavonoids, simple hydroxybenzoic and hydroxycinnamic acids, etc.) individually and in mixtures (e.g., in herbal teas) were determined with the developed method for the first time. In the preparation of herbal teas for analysis, the method of microwave extraction was used, having distinct advantages of reduced cost and time and increased reproducibility over classical extraction methods (such as Soxhlet extraction, liquid−liquid extraction, column chromatography, and preconcentration techniques). The results obtained with the developed method for polyphenolic compounds and herbal teas were statistically compared [using the analysis of variance (ANOVA) test] to those found by the reference methods KI/taurine and HPLC. As a result, the advantages of the optimized sample preparation (microwave extraction) and fluorometric determination (HOCl scavenging activity measurement) procedures were clearly stated.

## MATERIALS AND METHODS

**Reagents and Apparatus.** The following chemical substances of analytical reagent grade were supplied from the corresponding sources: methanol (MeOH), ethanol (EtOH), quercetin (QR), kaempferol, myricetin, rutin (RT), chlorogenic acid (CHA), naringenin, luteolin (LT), apigenin, gallic acid, and taurine (2-aminoethanesulfonic acid) from Sigma (Taufkirchen, Germany), 4-chlororesorcinol, *p*-coumaric acid, chrysin, and rosmarinic acid from Aldrich (Taufkirchen, Germany), sodium hypochlorite (NaOCl) from Merck (Darmstadt, Germany), acetic acid and potassium iodide from Riedel-de Haën (Taufkirchen, Germany), and resorcinol, hesperetin, (+)-catechin (C), (−)-epicatechin (EC), (−)-epigallocatechin (EGC), (−)-epigallocatechin gallate (EGCG), and ellagic acid from Fluka (Buchs, Switzerland). Herbal material leaves (green tea, sage, yarrow, and alchemilla) were obtained from a local market.

The fluorescence intensity and absorption measurements were performed using a Varian (Mulgrave, Victoria, Australia) Cary Eclipse model spectrofluorometer and a Cary 100 model ultraviolet−visible (UV−vis) spectrophotometer, respectively. The ETHOS-One (Milestone, Shelton, CT) closed vessel oven system was used for microwave-assisted extraction (MAE). Distilled water was supplied from Simpak1 Synergy purification system (Millipore, Billerica, MA). A Waters Breeze 2 model HPLC system (Milford, MA) consisting of a 2998 photodiode array detector and Empower PRO software was used for chromatographic separation, detection, and data acquisition.

**Preparation of Solutions.** The HOCl solution was prepared daily from a commercial solution (0.5%, v/v) by acidification with diluted sulfuric acid to pH 6.2. This stock solution was diluted 10-fold, and its concentration was determined using constant molar absorptivity ($\varepsilon$ = 100 L $mol^{-1}$ $cm^{-1}$) at 235 nm.[20] The fluorogenic resorcinol probe, potassium iodide, and taurine solutions were prepared in distilled water at 50 $\mu$M, 2.0 M, and 0.15 M concentrations, respectively. The polyphenolic solutions were freshly prepared in absolute ethanol. Methanol and 1.0% (v/v) acetic acid were used as the mobile phase for HPLC analysis.

**MAE of Herbal Teas.** The ETHOS-One (Milestone, Shelton, CT) closed vessel oven system equipped with 12 Teflon [polytetrafluoroethylene (PTFE)] vessels and an automatic fiber optic temperature control system were used for MAEs. Extractions were performed at 500 W and 80 °C, and a magnetic stirring rod was added in each vessel. The cut herbal materials were extracted using the following method: a 10 mL ethanol (80%) solution was added to 0.5 g of dried sample powder placed in an inner vessel. The vessels were placed symmetrically in the oven system. The herbal material in EtOH was microwave-irradiated as follows: 3 min for heating to the desired temperature (80 °C), 3 min for balancing at 80 °C, and 5 min for cooling. All herbal extracts were diluted (1:100) with 80% ethanol. The ethanolic extracts were filtered through a filter paper and membrane media (0.45 $\mu$m) successively before analysis.

**Resorcinol Assay.** The fluorometric resorcinol assay was performed as described by Özyürek et al.,[21] with some modifications. The reaction mixture contained polyphenol solution or herbal extract at a proper concentration, 0.5 mL of 0.15 mM HOCl for starting the reaction, and water was added to make the final volume of 4.0 mL. After incubation for 10 min at 37 °C, 1.0 mL of resorcinol (50 $\mu$M) was added to the reaction mixture and incubated for 5 min. At the end of the incubation period, the fluorescence intensity of the remaining resorcinol was measured at 304 nm ($\lambda_{ex}$ = 277 nm). Maximal fluorescence reduction (i.e., intensity difference) of resorcinol took place under HOCl attack without antioxidants, and this difference was reduced in the presence of polyphenols, enabling the HOCl scavenging activity measurement. The HOCl scavenging activity was calculated with the aid of eq 1, where $I_o$ is the fluorescence intensity of the resorcinol probe initially (i.e., prior to HOCl attack) and $I_1$ and $I_2$ are the fluorescence intensities of the resorcinol probe after chlorination in the absence and presence of polyphenolic scavenger, respectively.

$$\text{inhibition ratio (\%)} = 100[(I_2 - I_1)/(I_0 - I_1)] \quad (1)$$

The $IC_{25}$ values of the polyphenols were calculated using a plot of inhibition percentage as a function of $C_{scavenger}$. Because the fluorescence intensity of the reaction mixture was derived from the resorcinol probe alone, possible interferences from scavenger compounds or real sample constituents were absent.

**KI/Taurine Assay.** HOCl scavenging activity of polyphenols and herbal materials was determined using the spectrophotometric KI/taurine reference method described by Soobrattee et al.[19] The reaction mixture contained 1.0 mL of pH 7.4 phosphate buffer, 0.5 mL of taurine, 0−2.0 mL of scavenger solution at a proper concentration, 0.2 mL of HOCl, and water added to make the final volume of 3.7 mL. After the formation of taurine chloramine, potassium iodide (0.5 mL) was added and absorbance was measured at 350 nm ($\varepsilon = 2.29 \times 10^4$ $M^{-1}$ $s^{-1}$).[22] The herbal tea extracts were used by diluting at a ratio of 1:100 so as not to yield any absorbance interference at 350 nm.

The HOCl scavenging activity was calculated with respect to eq 2, where $A_o$ and $A$ are the absorbances of the reaction mixture in the absence and presence of polyphenol, respectively.

$$\text{inhibition ratio (\%)} = 100[(A_o - A)/A_o] \quad (2)$$

**HPLC Assay.** A gradient elution system was used for the determination of the resorcinol probe. The initial composition of the mobile phase (50% A/50% B) was modified using a linear gradient to (slope of 1.0) 60% A/40% B at 5 min, 70% A/30% B at 8 min, 80% A/20% B at 11 min, and a final composition of 90% A/10% B at 14 min. The mobile phases A and B were methanol and 1% (v/v) acetic acid, respectively. The chromatograms were obtained using a reverse-phase Agilent Eclipse XDB C18 column (4.6 × 250 mm, 5 $\mu$m particle size), with the following parameters: $V_{sample}$, 20 $\mu$L; flow rate, 1.0 mL $min^{-1}$; and $\lambda_{resorcinol}$, 275 nm. The retention time of 4-chlororesorcinol, a chlorination product, was found with the aid of a standard.

**Statistical Analysis.** All data were entered in an Excel database and analyzed with SPSS software for Windows. The data obtained

from the resorcinol and KI/taurine assays were compared to the aid of the ANOVA test at a selected confidence level of 95%.[23]

## RESULTS AND DISCUSSION

The HOCl scavenging activity of polyphenols (i.e., flavonoids and simple hydroxybenzoic and hydroxycinnamic acids) individually and in mixtures was evaluated by our recently developed resorcinol fluorometric method.[21] In the preparation of herbal extracts for analysis, the method of microwave extraction was used, having distinct advantages of reduced cost and time and increased reproducibility over classical extraction methods (such as Soxhlet extraction, liquid–liquid extraction, column chromatography, and preconcentration techniques). While MAE enables the reduction of the extraction time (because of its fast and multiple extraction capability) and solvent volumes, sonication may require a longer time and larger solvent volumes and sometimes repeated extractions.[24] The scavenging activity measurements using the resorcinol method were statistically compared to those obtained with KI/taurine and HPLC.

The fluorescence intensity of resorcinol was followed between 0 and 20 min (Figure 1) with and without scavenger

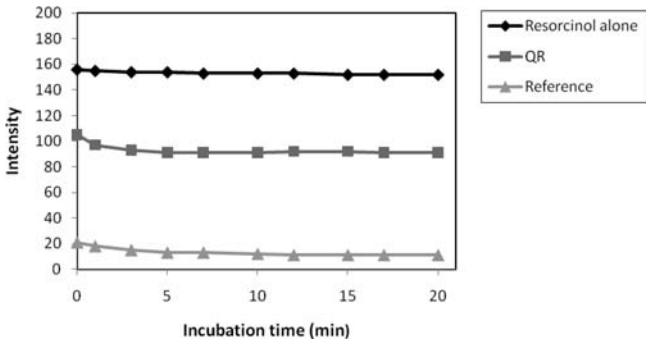

**Figure 1.** Fluorescence intensity as a function of time: (◆) resorcinol alone and resorcinol exposed to HOCl in the (▲) absence and (■) presence (3 $\mu$M QR) of a scavenger.

(i.e., QR). Standing under incubation conditions, the resorcinol probe did not lose its original fluorescence intensity, while upon HOCl oxidation, this intensity was greatly attenuated because of the formation of chlorination products. This fluorescence attenuation was decreased in the presence of an antioxidant polyphenol, such as QR, because of its competition with resorcinol for HOCl quenching. The optimal incubation time was chosen as 5 min, which was sufficient to reach a plateau in intensity (Figure 1).

Figure 2 shows the fluorescence spectra of resorcinol with varying QR concentrations. The maximal decrease in fluorescence intensity of resorcinol was observed under HOCl exposure in the absence of a scavenger as a result of conversion to non-fluorescent products. In comparison to the behavior of the resorcinol probe under HOCl exposure, the fluorescence intensity at 304 nm rose with increasing scavenger concentration (2.0–8.0 $\mu$M QR). This fluorescence increase is related to the scavenging activity of the scavenger. HOCl scavenging activity can be calculated using this intensity difference of resorcinol recorded in the presence and absence of a scavenger at varying concentrations.

**Optimization of MAE Conditions.** MAE conditions were optimized by measuring the HOCl scavenging activity (inhibition percentage) with the use of the resorcinol method

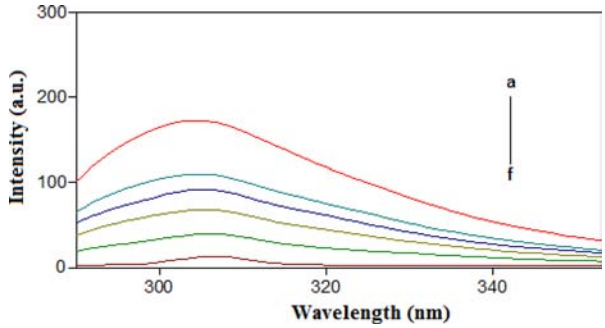

**Figure 2.** Fluorescence spectra of the resorcinol probe at varying scavenger (QR) concentrations [a, 10 $\mu$M resorcinol (alone); b, 8.0 $\mu$M QR; c, 6.0 $\mu$M QR; d, 4.0 $\mu$M QR; e, 2.0 $\mu$M QR; and f, 0 $\mu$M QR (reference)].

(Figure 3). Green tea was chosen as a representative sample for the optimization MAE technique. The effect of the extraction time (0–10 min), temperature (50–100 °C), type of solvent (ethanol, methanol, or water), composition of solvent (ethanol/water at 20, 40, 60, 80, and 100%), and liquid/solid ratio (10–40) on MAE efficiency were determined.

The effect of the extraction temperature and time are shown in Figure 3a. It can be observed that increasing the temperature of the solvent from 50 to 100 °C significantly increased the extraction efficiency up to 3 min, because of the increase in solubility with the temperature.[25] The inhibition percentage slightly decreased when the temperature and time were higher than 80 °C and 3 min, respectively. Therefore, 80 °C and 3 min were chosen as the optimal temperature and time for effective MAE.

Figure 3b shows that the extraction of green tea was greatly influenced by the ethanol concentration in water. The inhibition percentage of green tea extract increased with an increase in the ethanol concentration up to 80% (v/v), beyond which a decrease in HOCl scavenging activity was observed. The possible reasons are (i) highest solubility of lipophilic and hydrophilic antioxidants at this solvent composition and (ii) expansion of the contact surface area with some amount of water.[25] Therefore, 80% (v/v) ethanol concentration in water was chosen as optimal for effective MAE.

Figure 3c shows that the maximum extraction efficiency was obtained using methanol among the pure solvents tested. However, when water was added to pure solvents, 80% ethanol (v/v) was the most appropriate leachant solvent for effective MAE, probably because of the maintenance of a lipophilic/hydrophilic balance of dissolved antioxidants.

Figure 3d shows the effect of the liquid/solid ratio on the MAE of green tea. The HOCl scavenging activity of green tea increased with an increase in the liquid/solid ratio up to 20:1 (mL $g^{-1}$), beyond which the activity decreased because of unnecessary dilution of antioxidants. Therefore, the optimal liquid/solid ratio was determined as 20:1 (mL $g^{-1}$) to reach a high extraction efficiency.

**Testing of Incubation Reaction Products with the Resorcinol Assay.** It is apparent that neither QR nor chlorination products of QR (QR + HOCl) upon HOCl attack exhibit a fluorescence intensity at 350 nm (spectra e and f of Figure 4), meaning that QR competition with the resorcinol probe for HOCl can be followed simply by observing the changes in the resorcinol probe without interference from QR. In other words, the only constituent giving rise to a change

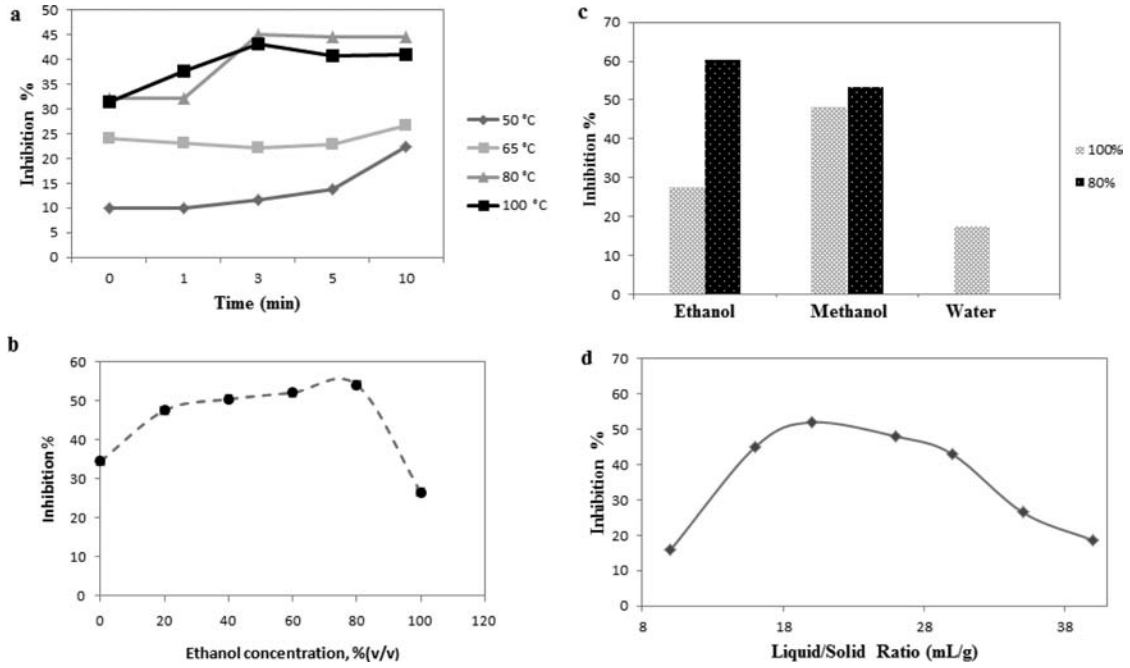

**Figure 3.** Effects of MAE conditions on the inhibition percentage of green tea extract: (a) effect of the extraction time and temperature, (b) effect of the ethanol composition, (c) effect of the solvent type, and (d) effect of the liquid/solid ratio (average of $N = 3$ measurements for each data point).

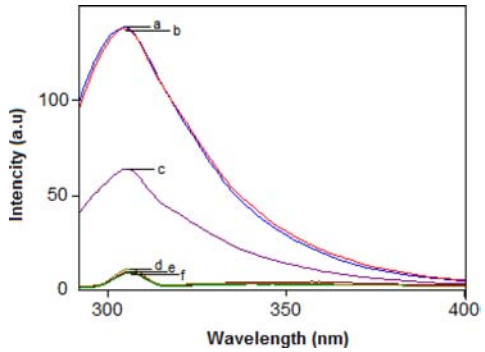

**Figure 4.** Fluorescence spectra of the resorcinol probe: (a) 0.5 mM resorcinol (initial concentration), (b) resorcinol + QR, (c) resorcinol + QR + HOCl, (d) resorcinol + HOCl, (e) QR + HOCl, and (f) QR ($\lambda_{ex}$ = 277 nm).

in fluorescence intensity in the system is the resorcinol probe (spectra a–d of Figure 4). Because QR scavenges some of the HOCl in the incubation system, the intensity increases (relative to that of the chlorinated probe) as a result of this competition with QR (spectra c of Figure 4).

**Analysis of the Results of Resorcinol and KI/Taurine Methods.** The scavenging activity of polyphenols was evaluated by a fluorometric resorcinol assay recently developed in our laboratory.[21] This method evaluates the activity of a scavenger to inhibit the hypochlorite-mediated chlorination of resorcinol, producing non-fluorescent products. The diminution of fluorescence intensity is related to the HOCl scavenging activity of the scavenger. The proposed method was compared to the spectrophotometric KI/taurine method in Table 1.

Quercetin exhibits a high antioxidant[26] and radical scavenging activity,[27] which depend upon the 5-hydroxy-4-keto substitution in the A ring, the 2,3 double bond promoting conjugation between the rings, and 3′,4′-dihydroxy catechol substitution in the B ring. Gomes et al.[28] reported that

**Table 1. HOCl Scavenging Activity of Polyphenols Determined by the Resorcinol and KI/Taurine Methods ($N$ = 4 or 5)[a]**

| HOCl scavenger | $IC_{25}$ value with respect to the resorcinol method ($\mu$M) | $IC_{25}$ value with respect to the KI/taurine method ($\mu$M) |
|---|---|---|
| | Phenolic Acids | |
| rosmarinic acid | 1.26 | ND[b] |
| gallic acid | 1.44 | 2.52 |
| 3-coumaric acid | 2.18 | ND |
| ellagic acid | 2.92 | 3.27 |
| chlorogenic acid | 7.20 | 5.79 |
| | Flavonoids | |
| (−)-epigallocatechin gallate | 0.10 | 0.14 |
| quercetin | 1.19 | 1.64 |
| apigenin | 1.22 | ND |
| chrysin | 1.36 | ND |
| (−)-epigallocatechin | 1.41 | 2.58 |
| hesperetin | 1.58 | 12.14 |
| naringenin | 1.73 | 12.19 |
| rutin | 2.05 | 4.69 |
| myricetin | 2.29 | 2.27 |
| (−)-epicatechin | 2.34 | 2.47 |
| (+)-catechin | 2.52 | 2.49 |
| kaempferol | 2.64 | 4.33 |
| luteolin | 3.56 | ND |

[a] $p = 0.05$; $F_{exp} = 3.788$; $F_{crit(table)} = 4.747$; and $F_{exp} < F_{crit(table)}$. [b] ND = $IC_{25}$ value within the studied concentration range could not be determined.

quercetin ($IC_{50}$ = 1.1 $\mu$M) was the most effective scavenger of HOCl, followed by apigenin and chrysin with an equal $IC_{50}$ ($IC_{50}$ = 3.9 $\mu$M) and luteolin ($IC_{50}$ = 7.1 $\mu$M). The $IC_{25}$ values found with the fluorometric resorcinol method concur with this order of activities (Table 1). The 5,7-dihydroxylated A ring and C3–OH substitution contribute significantly to the HOCl

scavenging activity.[28] When quercetin was subjected to HOCl, chlorination occurred only at two sites (C6 and C8) of the A ring. Binsack et al.[29] detected the chlorination products of quercetin as 6-chloroquercetin and 6,8-dichloroquercetin by HPLC and nuclear magnetic resonance (NMR) techniques.

The hierarchy for HOCl scavenging activity of the flavonol aglycones with respect to the resorcinol assay was quercetin > myricetin > kaempferol (Table 1). Soobrattee et al.[19] reported that the antioxidant capacity of these flavonols is also connected to the number of hydroxyl groups present. The presence of a third hydroxyl group in the B ring at the C-5 position does not contribute to an extra effectiveness of myricetin compared to that of quercetin simply having an *o*-diphenolic structure. Firuzi et al. reported that rutin (quercetin 3-rutinoside; $IC_{25}$ = 22.7 $\mu$M) has lower HOCl scavenging activity than its corresponding aglycone (quercetin; $IC_{25}$ = 8.8 $\mu$M).[30] This is supported by data in Table 1 that the glycosylation of flavonoids reduces their HOCl scavenging activity ($IC_{25}$ values of rutin and quercetin were 2.05 and 1.19 $\mu$M, respectively).

HOCl scavenging activities of flavan-3-ols using the resorcinol method were observed for epigallocatechin gallate (8 OH; 0.10 $\mu$M), epigallocatechin (6 OH; 1.41 $\mu$M), epicatechin (5 OH; 2.34 $\mu$M), and catechin (5 OH; 2.52 $\mu$M) in this order, with the values in parentheses showing the number of hydroxyl groups per molecule and the $IC_{25}$ value, respectively. An increase of HOCl scavenging activities of flavan-3-ols correlated with the number of hydroxyl groups. Similarly, Soobrattee et al.[19] reported that the antioxidant activities of flavan-3-ols decreased with a decrease in hydroxyl groups (EGCG > ECG > EGC > EC > C). Particularly, the three adjacent phenolic −OH groups on both the B ring (at 3′, 4′, and 5′ positions) and the gallate moiety of EGCG give a higher stability to the radical structure emerging from HOCl oxidation by increasing electron delocalization over the whole molecule.[31,32] In our study, EGCG ranked as the strongest HOCl scavenger in both the resorcinol and KI/taurine assays (Table 1), but Soobrattee et al. surprisingly reported close HOCl scavenging activities for EGCG and EC using the KI/taurine assay, despite the fact that epicatechin is devoid of *o*-dihydroxy substitution in the B ring.[19]

It has been reported in the literature that simultaneous light absorption of the probe and scavengers may give rise to problems in the KI/taurine spectrophotometric method. For example, the HOCl scavenging activity of the oxicam group non-steroidal anti-inflammatory drugs could not be determined with KI/taurine because of the strong absorption in the range of 200−420 nm.[33] Similarly, because flavones have a strong absorption band (apigenin, 337 nm; chrysin, 313 nm) in this range,[34] HOCl scavenging activity of flavones could not be evaluated by the KI/taurine method.

The two-way ANOVA test was used for statistical analysis.[23] ANOVA showed that the experimentally found results (consisting of 13 HOCl scavengers excluding the values for compounds that could not be evaluated by the KI/taurine method) with both methods were statistically alike at a 95% confidence level ($F_{exp}$ = 3.788; $F_{crit(table)}$ = 4.747; and $F_{exp} < F_{crit(table)}$ at $p$ = 0.05). Thus, the fluorometric resorcinol method was validated against the KI/taurine method for HOCl scavenging activity assessment of polyphenols.

**Analysis of the Results Obtained by Resorcinol and HPLC Methods.** The initial and remaining amounts of resorcinol probe undergoing HOCl attack were determined by fluorometric and HPLC methods in the presence and absence of a complex scavenger matrix (i.e., green tea extract). The retention times for resorcinol and its chlorination product 4-chlororesorcinol (detected at 275 nm) were 3.10 and 4.60 min, respectively. The chromatograms showed that more resorcinol remained in the reaction medium with increasing volumes of green tea extract because of less conversion to chlorination products. This situation can be clearly observed from the increasing peak heights of the resorcinol probe. For example, approximately 46.5% of resorcinol was converted into its chlorination products in the absence of a scavenger. In the presence of a potent scavenger solution, such as 0.5 and 1.0 mL volumes of green tea extract, the conversion ratio of resorcinol was considerably smaller (27.0 and 7.5%, respectively).

Table 2 shows the concentration of the remaining resorcinol probe in the incubation mixture with respect to the resorcinol and HPLC assays. The remaining resorcinol concentrations (mM) were calculated with the aid of the corresponding calibration curves and correlated well among themselves ($r$ = 0.9973).

**Table 2. Analysis of Resorcinol before and after Incubation with HOCl in the Presence and Absence of Green Tea Extract (Reference) Using Resorcinol and HPLC Methods ($N$ = 3)[a]**

| mixture | concentration of remaining resorcinol with respect to the resorcinol assay (mM) | concentration of remaining resorcinol with respect to the HPLC assay (mM) |
|---|---|---|
| reference | 1.03 ± 0.05 | 1.07 ± 0.05 |
| 0.3 mL of green tea extract | 1.10 ± 0.05 | 1.19 ± 0.03 |
| 0.5 mL of green tea extract | 1.38 ± 0.03 | 1.46 ± 0.02 |
| 0.8 mL of green tea extract | 1.57 ± 0.05 | 1.68 ± 0.04 |
| 1.0 mL of green tea extract | 1.78 ± 0.08 | 1.85 ± 0.06 |

[a] $[\text{Resorcinol}]_{FL} = 1.03[\text{resorcinol}]_{HPLC} + 0.03$ ($r$ = 0.9973).

**Application of the Resorcinol Method to Some Herbal Extracts.** The resorcinol assay was applied to herbal extracts, and the results were compared to the KI/taurine assay as inhibition percentage values. The obtained results demonstrate that green tea extract exhibited the highest HOCl scavenging activity by a large difference in both assays. This is not surprising in view of the fact that green tea is distinguished by its remarkable content of polyphenols, especially catechins, such as epicatechin, epigallocatechin, epicatechin gallate, and epigallocatechin gallate,[35] all of which exhibited high HOCl scavenging activities with respect of the spectroflorometric resorcinol assay (Table 1). The results are also in accordance with those reported by Valentão et al.,[36] indicating that green tea infusion exhibited higher HOCl scavenging activity than small centaury (*Centaurium erythraea* L.)-lyophilized infusion. The inhibition percentages measured with the resorcinol and KI/taurine methods are shown in a bar diagram (Figure 5). The hierarchy for HOCl scavenging activity of herbal teas with respect to the resorcinol assay was green tea > sage tea > yarrow > lady's mantle.

In comparison of the resorcinol and KI/taurine assays in the HOCl scavenging activity measurement, it was observed that the fluorometric resorcinol assay can be securely used without interference from polyphenols or herbal tea constituents, while real sample components or scavengers may show strong absorption in the 200−400 nm range, thereby potentially interfering with the KI/taurine assay.

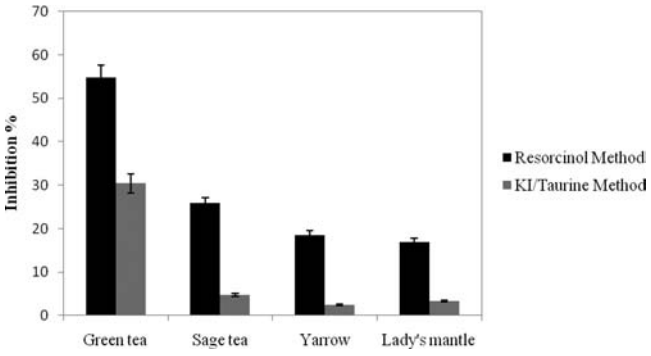

**Figure 5.** Inhibition percentage of some herbal teas (1:100 diluted extract) calculated with the resorcinol assay in comparison to the KI/taurine assay.

**Possible Advantages and Drawbacks.** In principle, the proposed resorcinol assay may be susceptible to interferences, arising from the fact that the excitation and emission wavelengths fall in the UV region. However, no such interference has experimentally been observed in this study, because the possible scavengers, taken for analysis at relatively small concentrations compared to the probe, did not cause any change in the fluorescence intensity of resorcinol. ROS scavenging methods using fluorogenic probes generally provide a superiority of simplicity, selectivity, and sensitivity over other similar spectroscopic methods.[37] The existing methods for quantifying HOCl scavenging activity have some limitations, such as possible UV absorption in the KI/taurine assay. The widely used TNB method, on the basis of the prevention of TNB oxidation in the presence of HOCl scavengers, may suffer from the extra capability of thiols to directly reduce 5,5′-dithiobis-(2-nitrobenzoic acid) (DTNB) to TNB without involvement of any scavenger. The fluorometric resorcinol assay overcomes all of these disadvantages by rendering the relatively specific detection of HOCl and is reliably applied to scavenging activity estimation of polyphenols and herbal materials.

In addition, the resorcinol probe is a right choice for the HOCl assay, because other common oxidants and radical species (except hydroxyl radicals) may not oxidize resorcinol by limitation of their standard redox potentials, thereby supporting selectivity of the proposed assay. This method has been successfully validated against reference assays (KI/taurine and HPLC).

very important significance to the fast and exact detection of ZEN. Recently, immunogen was obtained by coupling 5-aminozearalenone with bovine serum albumin (BSA) through the amino group at the C-5 position of the compound and conjugated to carrier protein by the Mannich reaction.[16−18] Although the specificity of the antibody had been improved somewhat, the sensitivity with ZEN was not as good as those with antibodies produced using CMO-ZEN as immunogen.

In the current study, a highly specific anti-ZEN monoclonal antibody of high titer was produced using a new immunogen, which was made using a different method of conjugating the hapten to protein carrier. The monoclonal antibody-based competitive ELISA test (microwell plate) and colloidal gold immunoassay (membrane-based) was developed to analyze ZEN in corn samples.

## MATERIALS AND METHODS

**Chemicals and Materials.** ZEN, ZAN, α-ZOL, β-ZOL, α-ZAL, β-ZAL, Freund's incomplete adjuvant (FIA), Freund's complete adjuvant (FCA), gold chloride trihydrate, 1,4-butanediol diglycidyl ether, RPMI-1640, hypoxanthine aminopterin thymidine (HAT), hypoxanthine thymidine (HT), 1-(3-(dimethylamino)propyl)-3-ethylcarbodiimide hydrochloricde (EDC), and a mouse monoclonal antibody isotyping kit were purchased from Sigma (St. Louis, MO, USA). BSA and ovalbumin (OVA) were bought from BDH (VWR International Ltd.). Goat anti-mouse IgG antibody (whole molecule) was from Sino-American Biotechnology Co. (Luoyang, China). PEG1500 was from Roche (Mannheim, Germany). Ninety-six-well culture plates were bought from Nunc (Roskilde, Denmark). Protein G affinity columns were bought from Amersham Biosciences. Nitrocellulose membrane, filter membrane, glass fiber, and absorbent pad were purchased from Millipore (Bedford, MA, USA). Eight-week-old female BALB/c mice were obtained from the Laboratory Animal Center, Zhengzhou University, China, and raised under strictly controlled conditions. The other reagents and solvents were of analytical grade or higher. Murine myeloma $NS_0$ cells were kindly provided by Dr. Howard, Institute for Animal Health, UK, and maintained in RPMI-1640 medium (Invitrogen, Carlsbad, CA, USA) supplemented with 10% (v/v) fetal bovine serum (Invitrogen) in our laboratory.

**Apparatus.** The Microplate Reader 550 was from Bio-Rad (Richmond, CA, USA). Milli-Q water was obtained from Millipore (Bedford, MA, USA). An XYZ Biostrip Dispenser, CM 4000 Cutter, and TSR3000 membrane strip reader were all purchased from Bio-Dot (Richmond, CA, USA).

**Preparation of Immunogens and Coating Antigens.** The hapten of ZEN was coupled to the carrier proteins BSA or OVA by 1,4-butanediol diglycidyl ether to generate ZEA−BSA or ZEN−OVAconjugates.[19−21] ZEN−BSA conjugate was used as immunogen, and ZEN−OVA conjugate was employed as coating antigen in ELISA. The procedure included two steps, which are shown in Figure 1. First, 7 mg of BSA/OVA was dissolved in 1 mL of DDW, and 1 mol/L sodium hydroxide was used to adjuste the pH to 10.8. Butane-1,4-diol diglycidyl ether (6 μL) was added, and the solution was placed at room temperature under a nitrogen atmosphere for 20 h; 1.5 mL of 0.5 mol/L sodium hydroxide was degassed using nitrogen, in which 5 mg of ZEN was dissolved, and then added to the epoxy-activated BSA/OVA solution. The reaction mixture was placed at room temperature under a nitrogen atmosphere for 20 h. The conjugates were purified by dialysis against 0.01 mol/L phosphate-buffered saline (PBS, pH 7.4), and the immunogen was stored at −20 °C.

**Immunization.** Six female 8-week-old BALB/c mice were injected subcutaneously four times with ZEN−BSA conjugate. The first dose consisted of 10 μg of immunogen as an emulsion of PBS and FCA. The three subsequent injections were given at 3 week intervals with the same dosage of immunogen emulsified in FIA. Sera were collected 2 weeks after the fourth immunization and screened for anti-ZEN activity by ELISA.[22] One mouse that produced a high titer of antibodies and showed competitive inhibition with ZEN was used for fusion. The mouse selected as the spleen donor for hybridoma production received a final intraperitoneal injection of 50 μg of conjugate in PBS 4 days before cell fusion.[23,24]

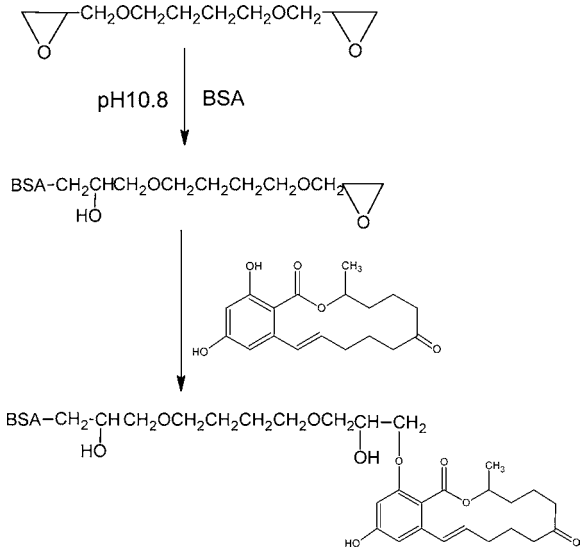

**Figure 1.** Synthetic scheme of ZEN immunogen.

**Cell Fusion and Hybridoma Screening.** Spleen cells from the immunized mouse were fused with NS0 cell using PEG1500.[25] Ten days after fusion, supernatants of hybridoma colonies were recovered and screened by ELISA antibody binding to ZEN. The selected wells were subcloned by limiting dilution. Ascites fluids were produced in paraffin-primed BALB/c mice and the mAbs purified using a protein A affinity column.

**Monitoring of Antibody Titers.** Antibody titer was monitored by ELISA. Microplates were coated with 50 μL/well of ZEN−OVA (2 μg/mL) in 0.05 M carbonate−bicarbonate buffer (pH 9.6) and then incubated at 37 °C for 2 h. After a washing with PBST [PBS containing 0.05% Tween 20 (v/v), pH 7.4], the wells were blocked with 200 μL of 5% normal swine serum in PBST (blocking buffer) and then incubated at 37 °C for 1 h. After another washing step, 50 μL/well with 2-fold serially diluted antibody in blocking buffer was added and incubated for 15 min at 37 °C. Following a washing step, goat anti-mouse−HRP conjugate (1:1000 in PBST, 50 μL/well) was added and incubated for 30 min at 37 °C. The plates were washed again, and 50 μL/well of TMB in chromogen buffer was added; color development was stopped after 10 min with 2 mol/L $H_2SO_4$ (50 μL/well). The optical densities (OD) were measured at 450 nm with an ELISA plate reader.

**Competitive ELISA.** Microplates were coated with ZEN−OVA as above, then 50 μL/well of ZEN serially diluted in PBS at 0, 0.625, 1.25, 2.5, 5, 10, or 20 ng/mL (for the ZEN analogues higher concentrations were used) was added, with 50 μL/well ant-ZEN mAbs (50000-fold diluted in PBS) and incubated for 15 min at 37 °C. Following a washing step, goat anti-mouse−HRP conjugate (1:1000 in PBST, 50 μL/well) was added, and plates were incubated for 30 min at 37 °C. The plates were washed again, and 50 μL/well of HRP substrate was added; color development stopped after 10 min with 2 mol/L $H_2SO_4$ (50 μL/well). The optical densities (OD) were measured at 450 nm with an ELISA plate reader. From the titration curve, the concentration of ZEN giving half-maximal inhibition ($IC_{50}$) was obtained and used for the calculation of cross-reactivity.[26]

To determine the specificity of the antibody inhibition of binding of the anti-ZEN antibody with zearalanone, α-zearalenol, β-zearalenol, α-zearalanol, and β-zearalanol were determined. Cross-reactivity was determined according to the following formula:[27]

Table 1. Immunological Properties of ZEN mAb Detected by ELISA

| mAb | titer | $IC_{50}$(ng/mL) | $K_a$ (L/mol) | eq of linear regression | $R^2$ |
|---|---|---|---|---|---|
| 3G10 | $1:1.28 \times 10^5$ | 1.297 | $4.5 \times 10^{10}$ | $y = -0.5636x + 2.2545$ | 0.9919 |
| 4A3-A10 | $1:1.024 \times 10^6$ | 1.165 | $9 \times 10^{10}$ | $y = -0.5058x + 2.0413$ | 0.9920 |
| 4A3-F9 | $1:5.12 \times 10^5$ | 1.115 | $3 \times 10^{11}$ | $y = -0.53x + 2.1253$ | 0.9946 |
| 4F11-H5 | $1:1.024 \times 10^6$ | 1.309 | $6.5 \times 10^{10}$ | $y = -0.5258x + 2.1389$ | 0.9946 |

$$\text{cross-reactivity}(\%) = \frac{\text{concn of standard ZEN inhibiting 50\% of antibody binding}}{\text{concn of other compounds inhibiting 50\% of antibody binding}} \times 100\%$$

**Preparation of Colloidal Gold Conjugate of the Anti-ZEN Monoclonal Antibody.** Gold chloride was reducted by 1% sodium citrate to produce colloidal gold, of which the mean particle diameter was 24 nm.[28,29] $K_2CO_3$ (0.2 mol/L) was used to adjust the colloidal gold solution to pH 8.2. Thirty microliters of anti-ZEN mAb solution was 2-fold serially diluted in DDW and then mixed with 125 μL of colloidal gold solution to determine the most appropriate protein concentration for conjugation; 125 μL of a 10% NaCl solution was added following incubation for 5 min at room temperature. As the concentration of mAb decreased, the color of samples changed from brilliant red to blue. The most appropriate concentration of mAb for colloidal gold labeling was the lowest concentration of mAb solution that produced a change in color.[30]

One hundred microliters of mAb solution at 0.1 mg/mL in DDW (optimum protein concentration)was dripped into 100 mL of colloidal gold solution (pH 8.2). After 70 min of gentle mixing, 10 mL of 10% BSA solution was added, and after 10 min, the mixture was centrifuged at 12000*g* for 30 min at 4 °C. The supernatant was discarded, and the pellet was washed two times with 20 mmol/L borate buffer (pH 9.0) containing 1% BSA. The final pellets were suspended in 50 mL of TB [20 mmol/L borate buffer (pH 9.0) containing 1% BSA, 3% sucrose, and 0.03% sodium azide] and stored at 4 °C.[30]

**Preparation of Immunochromatographic Test Strips.** Generally, an immunochromatographic test strip consisted of a nitrocellulose (NC) membrane and three pads (sample, conjugate, and absorbent pads). The NC membrane was pasted at the center of a semirigid polyethylene sheet, and the conjugate pad and the absorbent pad were attached with overlaps of 2 and 3 mm, respectively, with the NC membrane. The sample pad was pasted with a 3 mm overlap on the conjugate pad.[31] The test strip was prepared by applying ZEN−OVA (0.3 mg/mL) and Protein A (0.5 mg/mL) to the nitrocellulose membrane (NC) as the test and control lines, respectively, situated 0.5 cm apart at the center of the membrane. The reagents were applied as dots at 1 μL/cm. After drying for 4 h at 50 °C, the prepared membrane was stored under dry conditions. The conjugate pad was saturated with 5 μL/cm of mAb−gold conjugate and dried at 37 °C for 40 min. The sample pad (40 × 300 mm) was treated with 100 mmol/L PB (pH 7.4) containing 1% BSA, 0.3% Tween 20, 5% sucrose, and 0.05% sodium azide and then dried at 45 °C for 4 h.

**Test Procedure and Principle.** One hundred and twenty microliters of ZEN standard solution or sample extract was applied to the sample pad, which was allowed to flow toward the absorbent pad. After 5−10 min, ZEN was nonexistent in the sample, and all of the mAb−gold conjugate would be trapped by the capture reagents to form a test line, which was vivid red to be seen obviously (negative). When ZEN existed in the sample, it would compete with the immobilized capture reagents for the limited amount of mAb−gold conjugate. Hence, the more ZEN existed, the more shallow the test line colored. If there was more than enough ZEN, there would be no visible test line because the reaction of mAb−gold conjugate and the capture reagents was blocked completely. The control line was colored red to ensure that the strip and the test procedure were correct. If no color appeared at the control line, it would mean that the test procedure was either improperly conducted or the strip was invalid, and the sample should be tested again using a new strip.[14]

**Preparation of Cereal and Feed Samples.** For corn, barley, oat, rice, and wheat, 5 g samples were mixed with 2 mL of 1 N HCl and extracted for 5 min, then 5 mL of methylene chloride was added, and the mixture was violently shaken for 15 min. After filtering, the upper water phase was abandoned, and the lower phase was mixed with an equal volume of 0.13 mol/L $NaHCO_3$ and violently shaken for 15 min. After centrifugation for 10 min at 6000 rpm, the upper clear liquid was used directly for analysis without further cleanup. Before the spiking and recovery studies, it was verified by HPLC that each test sample did not contain ZEN.

**Identification of the Test Strip Performance.** ZEN-free corn extracts spiked with ZEN (0, 1, 2, 5, 10, and 20 ng/mL) were presented to the test strip to estimate the sensitivity of the assay. As the method described above, three replicates of each sample were tested. A TSR3000 membrane strip reader (Bio-Dot) was used to measure the relative optical density (ROD) of the test line. The standard curve was constructed by plotting the G/D×A-ROD (pixel) values obtained from the standard samples against its logarithm concentrations. The linearity was assessed by the coefficient of determination ($R^2$). The lower detection limit (LDL) of the test strip using the instrumental measurement was defined as the amount of ZEN in the standard sample solution that caused a 10% decrease of the peak−ROD or G/D×A of that produced by the 0 ng/mL ZEN sample. The sensitivity with the naked eye was set at the lowest concentration of ZEN presenting no color at the test line.

To determine the accuracy, corn samples containing 2, 5, and 10 μg/kg of ZEN were tested. Three replicates of each sample were tested with the same batch of test strips. The optical density of the test line was measured using the test strip reader, and sample values were calculated from the standard curve.

**HPLC Analysis.** Twenty gram samples of cereals or feed were finely ground in a mortar with sodium chloride (2 g). For the method validation, ZEN at 25, 50, 100, 200, 400, 600, and 800 μg/kg was added to 20 g of ground corn samples. The sample was extracted with 50.0 mL of acetonitrile/water (90:10 (v/v)) and shaking for 30 min on a horizontal shaker before filtration through an Ederol folded filter paper. A 10.0 mL sample of the extract was diluted with 40.0 mL of water and filtered through a 0.2 μm filter membrane before HPLC analysis. The excitation wavelength ($\lambda_{ex}$) and emission wavelength ($\lambda_{em}$) were set at 274 and 440 nm, respectively.[32]

## RESULTS AND DISCUSSION

**mAb Production.** Twelve days after fusion, a total of 120 hybridomas secreting specific mAb against ZEN were obtained by ELISA screening with ZEN−OVA antigen. Eight of these hybridomas were cloned by limiting dilution and further expanded for characterization, and four of these clones, identified as 3G10, 4A3-A10, 4A3-F9, and 4F11-H5 were used for the preparation of ascites fluid. The interaction of each mAb with ZEN was analyzed by ELISA. Isotyping showed that all of them belonged to the IgG1 subclass. The immunological properties of the four monoclonal antibodies detected by ELISA are shown in Table 1.

All of the mAbs were highly specific for ZEN with 4A3-F9 as marginally the most sensitive hybridoma, and this antibody was selected for developing the test strip. To determine the specificity of the optimized competitive ELISA and the mAb 4A3-F9, testing for cross-reactivity with a number of closely related compounds was undertaken. As shown in Table 2, the

Table 2. Cross-Reaction of Monoclonal Antibody 4A3-F9 with ZEN and Its Analogues

| Ag | Structures | $IC_{50}$ (ng/mL) | Cross-reactivity (%) |
|---|---|---|---|
| Zearalenone |  | 1.115 | 100 |
| Zearalanone |  | 2.099 | 53.121 |
| α-zearalenol |  | 44.618 | 2.499 |
| β-zearalenol |  | 39.827 | 2.800 |
| α-zearalanol |  | 28.933 | 3.854 |
| β-zearalanol |  | 65.259 | 1.709 |

highest cross-reactivity was 53.121%, obtained for zearalanone; the other test compounds gave a cross-reactivity of <4%.

**Sensitivity of the Test Strip.** As shown in Figure 2, the sensitivity of the test strip was confirmed to be 20 ng/mL by unaided visual assessment, which could be understood to indicate that if the test strip was assumed positive, the ZEN concentration of corn was ≥20 μg/kg. Test line measurements using a Bio-Dot TSR3000 Membrane Strip Reader gave G/peak and G/D×A (area) of the relative optical density (ROD) decreasing as the ZEN concentration in the standard samples increased. The sigmoidal dose−response curve produced by the concentration of standard ZEN and the G/D×A ROD showed good linearity ($y = -0.6536x + 0.8526$, $R^2 = 0.9898$) in the range of 0−20 ng/mL of ZEN with the $IC_{50}$ calculated as 3.4 ng/mL. The LDL of the test strip was 0.84 μg/kg by the test strip reader and was 1 μg/kg by unaided visual assessment (Figure 2).

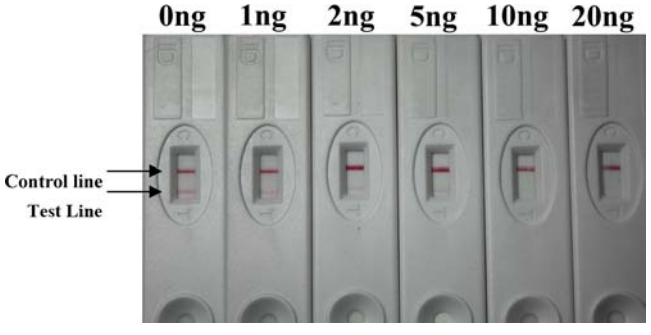

Figure 2. Standard ZEN corn samples were tested using the test strips and the test lines with the naked eye.

**Recovery of ZEN in Corn Samples.** Recoveries for intra-assay reproducibility ranged from 91.30 to 95.27%, and the highest coefficient of variation (CV) was 5.32%. For interassay reproducibility, the test strips of three different batches were used for three replicate testings of the samples, and recoveries ranged from 92.73 to 97.07%. The highest CV was 4.84%. The results are shown in Table 3.

Table 3. Recovery and Intra-assay and Interassay Precision of the Test Strips for ZEN Spiked in Corn Samples[a]

| | intra-assay | | | interassay | | |
|---|---|---|---|---|---|---|
| spiked ZEN (μg/kg) | mean ± SD (μg/kg) | recovery (%) | CV (%) | mean ± SD (μg/kg) | recovery (%) | CV (%) |
| 2 | 1.88 ± 0.10 | 94.16 ± 4.75 | 5.32 | 1.85 ± 0.06 | 96.17 ± 1.26 | 3.24 |
| 5 | 4.76 ± 0.07 | 95.27 ± 1.47 | 1.47 | 4.75 ± 0.23 | 97.07 ± 1.10 | 4.84 |
| 10 | 9.13 ± 0.06 | 91.30 ± 0.62 | 0.66 | 9.27 ± 0.16 | 92.73 ± 1.61 | 1.73 |

[a]Extracts of corn spiked with ZEN at 2, 5, and 10 μg/kg were tested using the strips, the optical density of the test line was measured using the strip reader, and the sample values were calculated from the standard curve. Intra-assay precision was estimated by using one batch of the test strips ($n$ = 3). For interassay precision, three batches of the test strips were used to detect the given samples. The recoveries and coefficients of variation are calculated from triplicate assays in all cases.

**Simultaneous Detection of ZEN in Natural Samples.** The ZEN concentrations of 50 corn samples were analyzed by the test strips, competitive indirect ELISA, and HPLC, and the results were compared. Table 4 shows the summarized results

Table 4. Results of Positive Corn Sample Analyzed with Different Methods

| | ZEN positive samples by | | | |
|---|---|---|---|---|
| | test strip | | ELISA | HPLC |
| corn sample | unaided visual[a] | strip reader (μg/kg) | (μg/kg) | (μg/kg) |
| 1 | − − − | 3.4 ± 0.5 | 4.0 ± 0.9 | 3.6 |
| 6 | + + + | 231.1 ± 49.8 | 190.7 ± 20.9 | 217.2 |
| 18 | + − − | 20.8 ± 2.8 | 14.3 ± 1.6 | 18.8 |
| 23 | + + + | 1691.3 ± 73.2 | 1089.4 ± 50.9 | 1589.4 |
| 25 | + + + | 210.0 ± 34.2 | 189.7 ± 20.8 | 193.6 |
| 32 | + + + | 4168.4 ± 782.6 | 3982.1 ± 590.3 | 3218.6 |
| 38 | + + + | 90.7 ± 17.1 | 89.9 ± 12.3 | 78.5 |
| 43 | + + + | 364.7 ± 41.3 | 293.4 ± 31.2 | 310.5 |
| 47 | + + + | 757.8 ± 79.5 | 589.0 ± 41.6 | 893.3 |
| 49 | + + + | 854.3 ± 103.2 | 683.3 ± 30.2 | 829.6 |

[a]+, positive, ZEN content in the sample is >20 μg/kg; −, negative, ZEN content in the sample is <20 μg/kg.

of the three analytical methods. The three methods showed the same 10 of 50 corn samples to be contaminated with ZEN. Most of the remaining corn samples were also contaminated with ZEN but at levels of mycotoxin of <0.1 μg/kg. The samples that showed positive by competitive indirect ELISA and test strips were confirmed for the accurate quantity by HPLC. The results of ZEN determination in naturally contaminated corn samples by the competitive indirect ELISA and the test strips were consistent with those by HPLC (Table 4).[31] To guarantee the accuracy of the result, analysis by test strips with unaided visual assessment should be done three times at least. The testing time and procedures of the test strips were shorter and more convenient than other methods, and the determination of inspection results were obtained by unaided visual assessment; the test strip is going to be a significant method for on-site and rapid detection of ZEN in corn samples.

**Conclusions.** Our results have demonstrated a methodology for the preparation of rapidly induced antibodies of high specificity and titer against ZEN by using a ZEN−BSA conjugate prepared using 1,4-butanediol diglycidyl ether as the linker,[33] which ensured the preservation of the 7-oxo substituent characteristic of ZEN as an antigenic determinant. The selected anti-ZEN monoclonal antibody showed lower cross-reactivity with the five ZEN analogues. A competitive ELISA and an immunochromatographic test strip for the determination of ZEN contamination in corn samples has been developed using this specific mAb. In summary, the antibody specificity for a ZEN epitope resulting in a very low reactivity with the five ZEN analogues has overcome previous problems in the immunodetection of this contaminant. The competitive indirect ELISA and an immunochromatographic test strip developed in this study are ideally suited for the specific quantitative detection of ZEN contamination in corn.

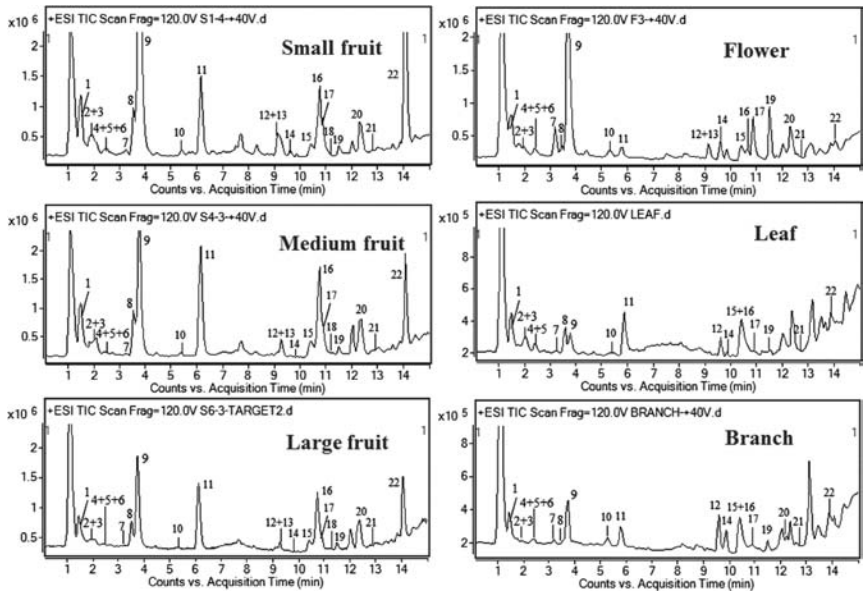

**Figure 1.** Total ion chromatograms (TIC) of different parts (fruit, flower, leaf, and branch) of CGT by RRLC-MS in positive ion mode. Detection was set in positive ion mode with a 120 V fragmentor. Peak numbers of compounds are in accordance with those in Table 1.

30 min at 100 Hz. The supernatants were centrifuged at room temperature for 10 min at 16200*g*, and different samples were diluted different times (6 times for small fruits and flowers and 3 times for medium and large fruits) with methanol before use. An aliquot of 2 $\mu$L of the filtrate was injected for RRLC analysis and 1 $\mu$L for MS analysis.

Standard stock solutions of naringin, rhoifolin, meranzin hydrate, and isoimperatorin were prepared at concentrations of 1000, 800, 200, and 200 $\mu$g/mL, respectively, and stored at −20 °C. Prior to injection, stock solutions were appropriately diluted with methanol to a series of appropriate concentrations used as working solutions.

**RRLC-ESI-MS/MS Analysis.** Analysis was performed on an Agilent 1260 series HPLC system coupled with a 6530 Accurate-Mass Q-TOF system with a Dual AJS ESI source (Agilent Technologies, Palo Alto, CA, USA). Samples were separated on an Agilent ZORBAX SB-C18 column (4.6 mm × 50 mm, 1.8 $\mu$m) at 25 °C. The mobile phase consisted of 0.1% aqueous formic acid (A) and acetonitrile (B) using a gradient program of 25% B in 0−3 min, 25−90% B in 3−14 min, and 90−100% B in 14−15 min. The flow rate was 0.5 mL/min.

The conditions of the ion source were as follows: nebulizer gas setting at 45 psig, capillary voltage at 3000 V, fragmentor voltage at 120 V, drying gas ($N_2$) flow rate and temperature at 10 L/min and 325 °C, and sheath gas flow rate and temperature at 11 L/min and 350 °C. MS acquisition was performed by using electrospray inonization (ESI) in positive ion mode. Collision energy was set at 20 V. All of the data were acquired using the extended dynamic range mode (2 GHz), and the mass range was set at 100−1000 Da in centroid mode. The TOF was calibrated every day before sample analysis and, subsequently, used reference masses at $m/z$ 121.0508 and 922.0098 to obtain high-accuracy mass measurements.

**RRLC-DAD Analysis.** *Instrument and Chromatographic Conditions.* Quantitative analysis was performed on an Agilent 1260 Infinity LC system equipped with a photodiode array detector. Samples were separated on an Agilent ZORBAX SB-C18 column (4.6 × 50 mm$^2$, 1.8 $\mu$m) at 25 °C. Mobile phase consisted of 0.1% aqueous formic acid (A) and methanol (B) using a gradient program of 35−39% B in 0−3 min, 39−39% B in 3−5 min, 39−55% B in 5−12 min, 55−90% B in 12−21 min, and 90−100% B in 21−23 min. The flow rate was 0.5 mL/min. Different detection wavelengths were performed for different periods of time: 283 nm for 0−9 min, 330 nm for 9−18 min, and 310 nm for 18−23 min.

*Method Validation.* An aliquot of 2 $\mu$L of working solutions were injected into RRLC for analysis; the calibration curves were constructed by plotting the peak areas versus the concentration of each analyte. The limit of detection (LOD) and limit of quantification (LOQ) for each analyte were defined by the concentrations that generated peaks with signal-to-noise values ($S/N$) of 3 and 10, respectively.

The precision of the developed method was determined by the intra- and interday variations. For the intraday test, the samples were analyzed six times within the same day, while for the interday test, the samples were examined in duplicates for 3 consecutive days.

To confirm the repeatability, six replicates of the same samples were extracted and analyzed. For the stability test, the same sample was stored at room temperature and analyzed by replicate injection at 0, 2, 4, 8, 16, and 24 h. The RSDs were used to evaluate the method repeatability and stability. Accuracy was calculated as the percentage of recovery. Recovery tests were performed by spiking a known amount of the four standards to 0.25 g of powder and then extracted and analyzed with the same procedures. Six replicates were performed for the test.

**Determination of Total Phenolics.** Total phenolic contents (TPC) of each sample were determined by using the Folin−Ciocalteu reagent according to Singleton and Rossi with slight modifications.[15,16] Gallic acid was used to prepare a standard curve, and final values were expressed in milligrams of gallic acid equivalents (mg of GAE/g). Diluted CGT extracts were incubated with Folin−Ciocalteu phenol reagent. The color was developed by adding sodium carbonate (10%), and absorbance was measured at 765 nm.

**Antioxidant Assays.** *Free Radical Scavenging Capacity.* The free radical scavenging capacity was analyzed by the DPPH assay.[17,18] DPPH is a stable organic nitrogen radical with purple color. Upon reduction by an antioxidant, the solution color faded and the reaction could be monitored by a spectrophotometer at 517 nm. The decrease in absorbance was proportional to the antioxidant capacity and could be measured in comparison to Trolox as standard. All samples and standard were diluted in methanol. A 100 $\mu$L aliquot of CGT extracts was mixed with 100 $\mu$L of DPPH (0.2 mM) in methanol, and the change in optical density (517 nm) was monitored after 30 min using a microplate reader. Results were expressed as $\mu$M Trolox equivalents (TE)/g.

*Ferric Reducing Antioxidant Power Assay.* The FRAP assay was carried out by a commercial kit (Beyotime) following the instruction manual.[19,20] Under acidic conditions, antioxidants can restore ferric tripyridyltriazine ($Fe^{3+}$-TPTZ) into blue $Fe^{2+}$-TPTZ. The total antioxidant activity of antioxidants can be reflected by the absorbance of $Fe^{2+}$-TPTZ at 593 nm. Absorbance was measured at 593 nm using a

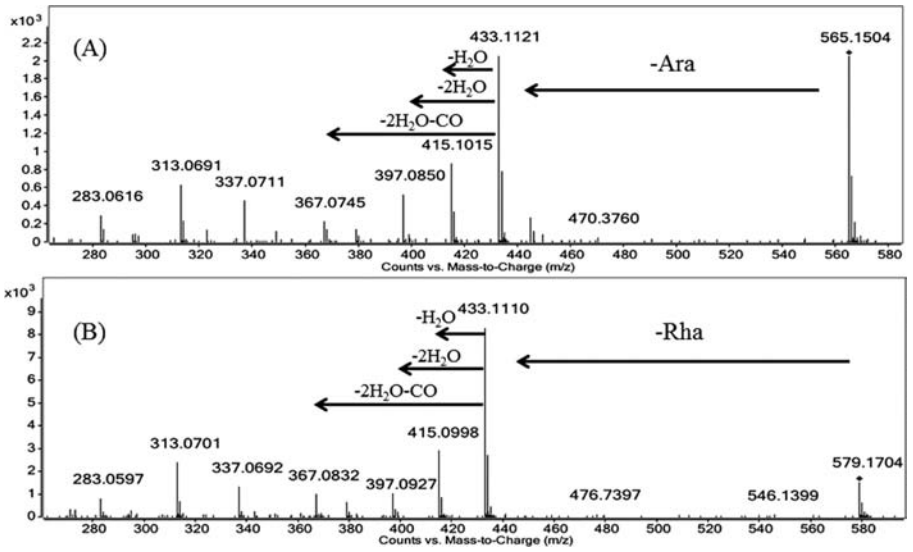

**Figure 2.** MS/MS spectra of (A) compound **2** and (B) compound **3** in positive ion mode with 20 V collision energy.

microplate reader, with $FeSO_4$ as the antioxidant standard. The results of the FRAP assay were calculated as mM $FeSO_4$/(g of powder).

*ABTS Radical Scavenging Activity Assay.* The ABTS assay was performed by a commercial kit (Beyotime) following the instruction manual.[21,22] With the appropriate oxidants, ABTS can be oxidized into green $ABTS^{\cdot+}$, while antioxidants can inhibit this process. The total antioxidant activity of antioxidants can be reflected by the absorbance of $ABTS^{\cdot+}$ at 734 nm. Absorbance was measured at 734 nm using a microplate reader, with Trolox as an antioxidant standard. The results were calculated as $\mu$M TE/(g of powder).

**Statistical Analysis.** All determinations of antioxidant capacity were conducted in triplicates. The values expressed were the mean of three measurements. Statistical comparisons of the results were performed by one-way ANOVA using SPSS 11.5 (Chicago, IL). Significant differences ($p < 0.05$) between the different kinds of samples were analyzed by Duncan's multiple range test.

## RESULTS AND DISCUSSION

**Comparison of Chemical Constituents of Different Parts of CGT.** The profiling of CGT chemical constituents was analyzed by RRLC-ESI-QTOF/MS method (Figure 1). Based on their retention time and MS fragmentation behavior, a total of 22 compounds, including flavanone *O*-glycosides (peaks 6, 7, 9, and 10), flavanone aglycone (peak 12), flavone *C*- (peaks 1, 2, 3, and 5) and *O*-glycosides (peaks 4 and 8), coumarins (peaks 11, 13−16, 21, and 22), and limonoids (peaks17−20) were identified or tentatively characterized (Table 1).

Flavonoid glycosides are divided into two categories: flavonoid *O*- and *C*-glycosides. Favonoid *O*-glycosides ruptures are easily induced by loss of the sugar moiety, while fragmentations in *C*-glycosides focus preferentially on the glycidic moiety.[23,24] At low collision energies, the main fragments of flavonoid *C*-glycosides were due to the loss of water ($[M + H - nH_2O]^+$), and loss of the glucosidic methylol group as formaldehyde ($[M + H - CH_2O - 2H_2O]^+$).[25] In this work, 10 compounds were elucidated as flavonoid glycosides in CGT. Noteworthily, compounds **2** and **3** were identified in CGT for the first time. Figure 2 shows the MS/MS spectra of compounds **2** and **3** in positive ion mode with 120 V fragmentor voltage and 20 V collision energy. Compound **3** yielded a $[M + H]^+$ at $m/z$ 579.1704 and a predominant fragment ion at $m/z$ 433, corresponding to the loss of a terminal rhamnose from the protonated molecule. The product ion at $m/z$ 433 further undertook an inner sugar cleavage to yield the following fragments at $m/z$ 415 ($[M + H\text{-}145 - H_2O]^+$), 397 ($[M + H\text{-}145 - 2H_2O]^+$), 379 ($[M + H\text{-}145 - 3H_2O]^+$), and 367 ($[M + H\text{-}145 - 2H_2O - CH_2O]^+$). The preceding typical fragments were in agreement with 8-*C*-glucosyl apigenin (vitexin) or 6-*C*-glucosyl apigenin (isovitexin).[25] Therefore, compound **3** was proposed to be *O*-pentosylvitexin or -isovitexin. According to the literature data, the possible chemical structure of compound **3** was apigenin-8-*C*-glucoside-*O*-rhamnoside or apigenin-6-*C*-glucoside-*O*-rhamnoside, which has been detected in citrus species.[26−28] Compound **2** exhibited a $[M + H]^+$ at $m/z$ 565.1504, showing a similar MS/MS fragmentation pattern with compound 3. The same ion at $m/z$ 433 due to the loss of a terminal arabinose from precursor ion was also observed. Compared with compound **3**, compound **2** was plausibly identified as apigenin-8-*C*-glucoside-*O*-arabinoside or apigenin-6-*C*-glucoside-*O*-arabinoside.

Coumarin compounds are generally distributed throughout the *Citrus* species.[10] In the present work, a total of seven coumarins were detected and elucidated in CGT. Most coumarins exhibited quasi-molecular ions $[M + H]^+$, $[M + Na]^+$, and fragment ions $[M - CO + H]^+$, $[M - 2CO + H]^+$, $[M - CO_2 + H]^+$, and $[M - CO_2 - CO + H]^+$.

Citrus limonoids have attracted much more attention in recent years because of their health benefits.[29,30] By comparing their quasi-molecular weights, fragment ions, and chromatographic properties with the reported compounds in citrus fruits, we tentatively elucidated four limonoids in CGT, namely, limonin, nomilin, isoobacunoic acid, and obacunone.[31,32]

It has been widely reported that chemical constituents of Citrus species were dominated by flavonoids and limonoids.[31] However, our results showed that CGT contained various courmarins, such as meranzin hydrate, bergaptan, imperatorin, and isoimperatorin. We also observed that chemical constituents were more abundant in fruits and flowers than in leaves and branches. Different sizes of fruits had almost the same chemical constituents profile and yet varied in contents (Table 1), indicating that the harvesting time had no significant effect on the composition of chemical constituents. Isoobacunoic acid was only detected in fruits but not in other parts of CGT. The

compound obacunone was not detected in leaves, but we found abundant obacunone in fruits and flowers.

In summary, the composition and content of chemical constituents varied in different parts of CGT. The most abundant constituents in CGT, calculated by peak area in the MS spectrum, were rhiofolin, naringin, meranzin hydrate, and isoimperatorin.

**Quantitative Evaluation of Chemical Constituents Contents.** In order to develop a feasible and rapid method for quantitative analysis, different mobile phase systems (ACN−-water and methanol−water) were examined and compared. It was shown that a good separation can be obtained in the methanol−water system; however, rhiofolin and naringin were not satisfactorily separated (resolution < 1.5) in the ACN−water system. Finally the methanol−water system was used for the following experiment, considering the appropriate resolution.

To further and truly understand the content of chemical constituents in different tissues of CGT plants (fruits, leaves, flowers, and branches), four major compounds in CGT were quantified by RRLC combined with segmental monitoring strategy, including two flavonoids (rhiofolin and naringin) and two coumarins (meranzin hydrate and isoimperatorin). The naringin showed distinct maximal UV absorption at 283 nm, the rhiofolin and meranzin hydrate had maximal absorptions at 330 nm, and the isoimperatorin had maximal absorptions at 310 nm. To analyze them at one run, we divided the chromatographic fingerprinting into three segments according to the retention time of the four target compounds and set a specific detection wavelength for each segment. Therefore, the UV detector was monitored at 283 nm for 0−9 min, 330 nm for 9−18 min, and 310 nm for 18−23 min.

*Method Validation.* As the results summarized in Supporting Information (Table S1 and Table S2) show, all of the calibration curves exhibited good linearity ($r^2 \geq 0.9998$) within the test range. The LODs and LOQs were less than 0.19 μg/mL and 0.52 μg/mL, respectively. The intra- and interday variations (RSDs) of peak area for four analytes were less than 1.38 and 1.95%, respectively. The repeatability presented as RSDs were in the range from 1.36 to 2.20%. The stability presented as RSDs were less than 1.97%. The recoveries varied between 96.93% and 103.46%. The preceding data were considered to be satisfactory for subsequent analysis of all of the samples.

*Comparison of Main Chemical Constituents in Different Parts of CGT.* The RRLC-DAD assay method was subsequently applied to the simultaneous determination of the two flavonoids and two coumarins (Figure 3) in different parts (fruits, leaves, flowers, and branches) of CGT. The representative RRLC chromatograms of different parts of CGT are shown in Figure 4, and their contents are summarized in Table 2. Values are expressed as mean ± SD ($n$ = 3) in mg/(g of dried weight).

All of the fruit samples tested showed similar phytochemical profiles, but the content levels of the main compounds varied significantly. Among these parts, the small fruits had the highest contents of naringin, rhifolin, and isoimpertorin (256.48, 12.76, and 2.18 mg/g on average, respectively) except meranzin hydrate. Significant differences in contents of the main constituents among different sizes of fruits suggested that the ripening process may influence the quality of the fruits. It was clearly observed that the flower, an alternative source of flavonoids, had high amounts of naringin (135.75 mg/g on

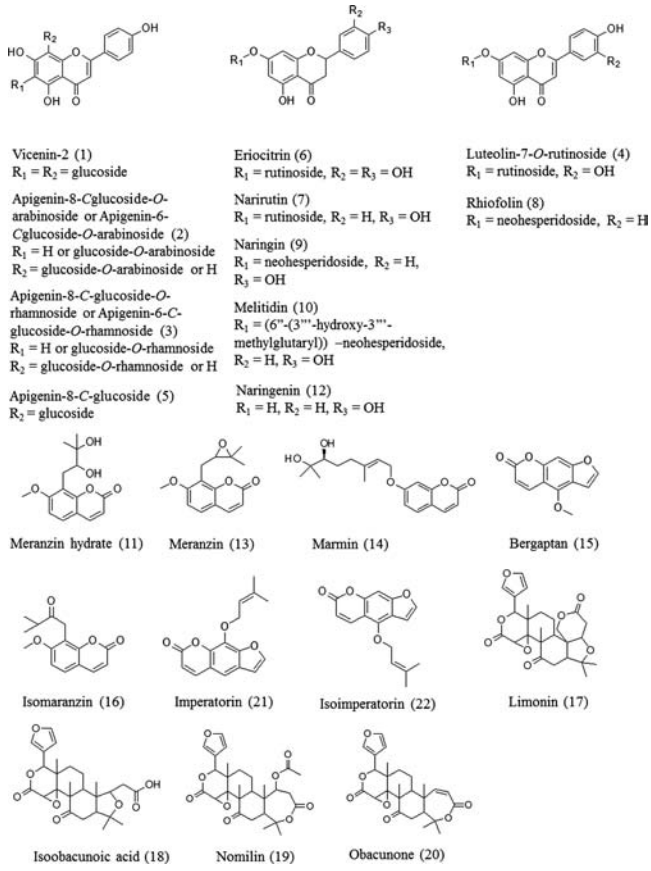

**Figure 3.** Chemical structures of the four quantitative analytes.

average). On the whole, naringin was found to be the predominant compound in different sizes of fruits and other parts of CGT. CGT leaves were found to have almost the same amount of naringin and rhoifolin, with the amount at 1.93 and 1.87 mg/g, respectively. Interestingly, the concentration of naringin in branches was nearly 2 times greater than that in leaves. The two coumarins were not detected in CGT leaves, isoimperatorin was present in a low content, and meranzin hydrate was not detected in CGT branches.

**Determination of Total Phenolic Contents.** Phenolic compounds are considered as the most important antioxidative components of herbs and other plant materials. In the present study; TPC of fruits, flowers, leaves, and branches in CGT, determined by Folin−Ciocalteu reagent, are shown in Figure 5a. The phenolic content of small fruits was significantly higher ($p$ < 0.05) than those of other parts (1.9−9.4-fold). The content of total phenolic varied widely in different parts of CGT and ranged from 11 (for branch) to 123 (for small fruit) mg of GAE/g. Flowers also contained relatively high content of total phenolic, following small fruits. No significant differences were found between medium fruits and large fruits, neither between leaves and branches.

**Determination of Antioxidant Activity.** The antioxidant activity of plant samples can be analyzed using a variety of *in vitro* assays. In the present study, the antioxidant activities of different parts of CGT were determined by DPPH, ABTS, and FRAP assay. It is quite clear that, as shown in Figure 5b−d, small fruit extracts showed the highest antioxidant capacity on average. The antioxidant activity values in three assays showed a similar tendency: small fruit > flower ∼ medium fruit > large fruit > leaf ∼ branch. Phenolic compounds were usually

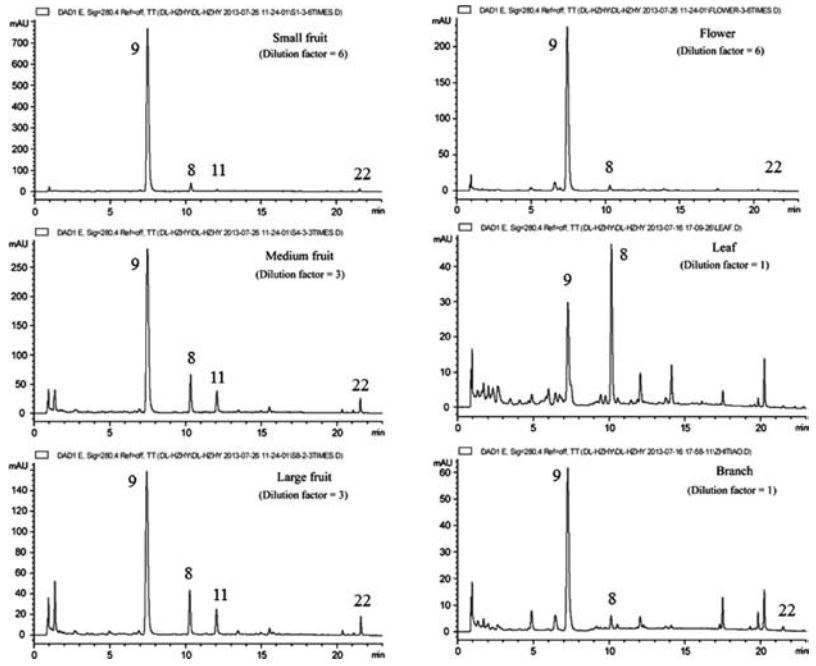

**Figure 4.** Representative RRLC chromatograms of different parts of CGT. Peak numbers of compounds are in accordance with those in Table 1.

[a]S1−8 represent small fruit; M1−6 represent medium fruit; L1−6 represent large fruit; F1−3 represent flowers. [b]Values are expressed as mean ± SD ($n$ = 3) in mg/(g of dried weight). [c]Less than the limit of quantitation.

considered as the basis of antioxidant activity due to their hydroxyl group.[33] Similarly, our results revealed a positive relationship between contents of total phenolic and antioxidant activity. In the market, only fruits of CGT were consumed as food and health supplement. However, our study showed that other parts of CGT, especially flowers, might be used as an alternative dietary supplement.

In conclusion, we compared the chemical constituents profiles of different parts of CGT by RRLC-ESI-QTOF/MS and 22 compounds were identified or tentatively characterized. Of these, two *C*-glucosyl flavones (compounds **2** and **3**) were found, to our best knowledge, for the first time in CGT. This may give us some new insights into CGT, especially leaves and branches which have not been studied before. The

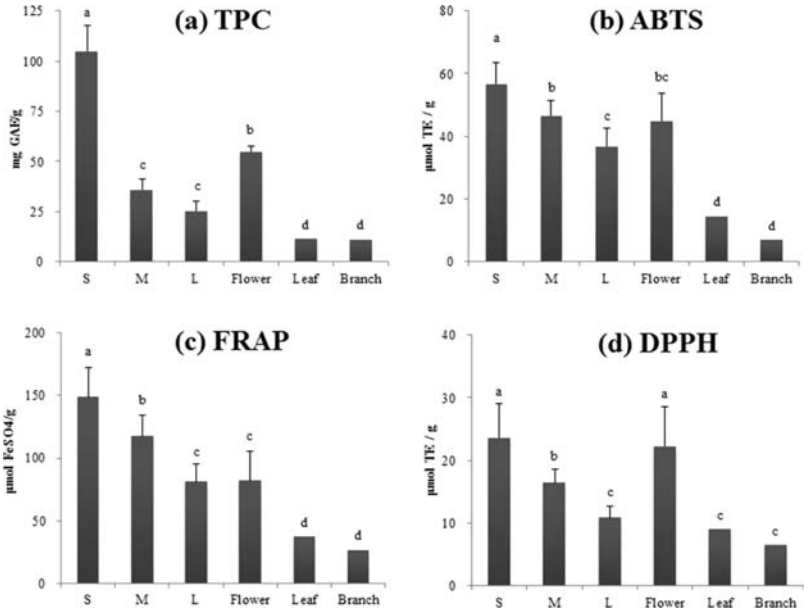

**Figure 5.** (a) Total phenolic contents (TPC) and (b) ABTS, (c) FRAP, and (d) DPPH, antioxidant activity of fruits, flowers, leaves, and branches of CGT. Values of fruits and flowers represent means ± SD (small fruits (S), $n = 8$; medium fruits (M), $n = 6$; large fruits (L), $n = 6$; flower, $n = 3$), while values of leaves and branches represent the antioxidant activity of only the one batch we collected.

quantification of four major compounds by RRLC combined with segmental monitoring strategy demonstrated that the contents of these compounds decreased with ripening of fruits. Fruits and flowers were found to be rich in phenolic compounds and had strong antioxidant activities. In particular, the discarded parts of CGT, leaves and branches, also contained some bioactive compounds and might be used as an alternative dietary supplement. We hope the results may provide useful information for future utilization of CGT.

number of studies using SPE pretreatment in cooperation with liquid chromatography coupled to triple-quadruple tandem mass spectrometry (LC−MS/MS) to quantify BPs in foodstuffs because this method is highly sensitive, has a wide range of applicability, and consumes less solvent. However, the traditional SPE sorbents generally retain analytes by nonselective hydrophobic or polar interactions that lead to partial coextraction of interferences, resulting in suppression of the analyte signal.[19,20] In order to enhance the selectivity of the extraction, molecularly imprinted polymers (MIPs), based on specific recognition of the template molecule, allowing a selective extraction of a target molecule or its structural analogues, were developed.[21−23] In the past few years, MIPs were widely used as a new selective sorbent for cleaning up SPE and for extracting trace levels of compounds from complex matrices.[24−26] Several approaches have been used to prepare BPA imprinted polymers and have been applied to analyze foodstuffs.[27,28] However, the application of MIP for the determination of structurally related BP analogues in foodstuffs has been limited to date.

In this study, we aim to develop a method for the group-selective extraction of seven BPs (BPS, BPF, BPA, BPB, BPAF, TCBPA, and TBBPA) in beverage and canned food samples based on MIP-SPE with LC−MS/MS analysis. The high selectivity of MIP-SPE was compared with the selectivity of the traditional HLB SPE cartridge. In addition, the validated method was used to determine the target compound concentrations in beverage and canned food samples that were collected from a supermarket in Beijing. To our knowledge, this is the first study in which seven bisphenols were included together as target compounds in the development of an analytical method based on MIP-SPE for analyzing foodstuffs.

## MATERIALS AND METHODS

**Reagents and Chemicals.** For this experiment, BPS (purity >98%), BPF (purity >99%), BPA (purity 98.5%), BPA-$d_4$ (purity >97.8%), BPB (purity >98%), and BPAF (purity 98%) were purchased from Tokyo Chemical Industry Co. Ltd. (Tokyo, Japan). BPF-$d_{10}$ and BPS-$^{13}C_{12}$ (purity >99%) were purchased from Toronto Research Chemical Inc. (Ontario, Canada), and BPAF-$d_4$ was purchased from CDN Isotopes Inc. (Quebec, Canada). TCBPA (purity >99%), TCBPA-$^{13}C_{12}$ (purity >99%), TBBPA (purity >99%), and TBBPA-$^{13}C_{12}$ (purity >99%) were obtained from Cambridge Isotope Laboratories Inc. (Andover, MA). In addition, water, acetonitrile (MeCN, water <0.01%), and methanol (MeOH, water <0.01%) were purchased from Sigma−Aldrich (LC−MS-grade, St. Louis, MO). Furthermore, the formic acid and ammonium hydroxide for analysis (28−30 wt % solution of $NH_3$ in water) were supplied by Acros Organics (Morris Plains, NJ). The molecularly imprinted polymers (product code AFFINIMIP SPE bisphenol A cartridges) were provided by Polyintell (Val de Reuil, France). Oasis HLB cartridges (200 mg, 6 mL) were purchased from Waters (Milford, MA), and the stock standard solutions (1000 mg/L) were individually prepared by dissolving in MeOH and were stored at −20 °C. Working solutions were prepared by serial dilution of stock solutions with MeOH/water (50:50 v/v).

**Sample Collection.** Fourteen beverage samples [7 pairs; in each pair one is packed in cans and another in poly(ethylene terephthalate) (PET) or Tetra Pak] and four canned foods from different brands, commonly consumed by the local population, were purchased from a supermarket in Beijing, China. They contained soda, tea drink, juice, vegetable, and meat. Purchasing of the samples was carried out in February 2014. All samples were stored at room temperature and opened only at the moment of analysis.

**Sample Preparation and Solid-Phase Extraction Procedure.** After the samples had been opened, the carbonated beverage samples were degassed by sonication for 30 min to form the loading solution for SPE procedures. Juice and milk samples were centrifuged at 9000$g$ for 5 min to avoid blocking of the cartridges. Regarding the canned food, a total of 1 g of each homogenized sample was added to 5 mL of MeCN for extraction. Following sonication for 20 min, the mixtures were centrifuged at 9000$g$ for 5 min, and the supernatants were collected. Subsequently, 5 mL of hexane was added to remove the fat by liquid−liquid extraction. The MeCN layer was collected and evaporated to 1 mL under a gentle nitrogen stream, which was diluted to 10 mL with LC−MS-grade water to form the loading solution.

A diagram of the MIP-SPE procedure is shown in Figure 1. Briefly, the pretreated loading solutions were loaded onto the MIP-SPE

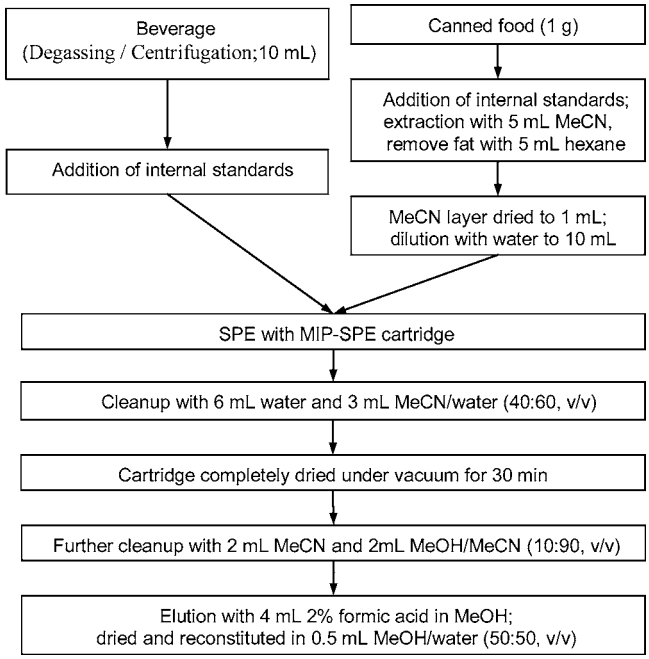

**Figure 1.** Diagram of MIP-SPE procedure for analysis of target BPs in beverage and canned food.

cartridges at a flow rate of 1 mL/min. The MIP-SPE cartridges had been previously conditioned with 3 mL of MeOH, 3 mL of MeCN, and 3 mL of water. After the loading step, the sorbents were cleaned up with water and MeCN/water (40:60 v/v). Next, the sorbents were completely dried and further washed with MeCN and MeOH/MeCN (10:90 v/v). After elution, the eluates were evaporated to dryness and the residues were reconstructed in 500 $\mu$L of a MeOH/water (50:50 v/v) solution for LC−MS analysis.

The protocol for HLB cartridges was conducted according to our previous report.[29] Briefly, the HLB cartridges were conditioned with 6 mL of MeOH and 6 mL of water. After loading of the samples, the cartridges were washed with 6 mL of MeOH/water (50:50 v/v) to remove interference. In addition, the extracts were eluted with 6 mL of 2% ammonia in 100% MeOH. The eluates were evaporated and reconstructed in 500 $\mu$L of a MeOH/water (50:50 v/v) mixture before LC−MS analysis.

**LC−MS Analysis.** The target analytes were separated with an Acquity ultraperformance liquid chromatography system (Waters, Milford, MA). The analytical column was an Acquity ethylene bridged hybrid (BEH) C18 column (2.1 mm × 100 mm; 1.7 $\mu$m; Waters). The mobile phase consisted of a MeOH−water isocratic mixture (40:60 v/v), which was held for 1 min, and a linear gradient from 40% to 80% MeOH that was held for 5 min. The MeOH content was increased to 100% at 6.1 min, held for 2.0 min, and returned to the initial conditions for equilibration. The flow rate was 0.3 mL/min and the injection volume was 5 $\mu$L.

A Xevo TQ-S triple-quadrupole mass spectrometer (Waters, Milford, MA) was used to determine the analyte concentrations. The MS/MS acquisition was operated in negative-ion mode with multiple reaction monitoring (MRM). The source operating conditions were as follows: a capillary voltage of 2.9 kV; source and desolvation temperatures of 150 and 400 °C, respectively; and a desolvation gas flow rate of 1000 L/h. For each analyte, identification was based on the retention time of the quantification and conformation ions. The corresponding cone voltage and collision energies were optimized for maximum intensity (see Supporting Information for optimized MS/MS parameters).

**Method Validation.** Three types of foodstuffs (orange juice, red wine, and canned fish) were used to evaluate the analytical characteristics of the procedure based on the use of MIP-SPE as a selective sorbent prior to chromatographic analysis. This method was evaluated in terms of linearity, accuracy, precision, and sensitivity. In the present study, isotopic internal standards were employed to compensate for the matrix effects and the loss during analysis. Calibration curves were constructed by plotting the peak area ratios of the pure analytes to the internal standards against the analyte concentrations (linearity ranges for BPF, BPB, and TBBPA were 0.2, 0.5, 1, 2, 5, 10, and 20 ng/mL; for BPA and TCBPA, 0.1, 0.25, 0.5, 1, 2.5, 5, and 10 ng/mL; and for BPS and BPAF, 0.02, 0.05, 0.1, 0.2, 0.5, 1, and 2 ng/mL). BPA-$d_4$ was selected as an internal standard for BPB because no commercially labeled standards are available. For assessment of accuracy and precision, the whole MIP-SPE procedures were applied to orange juice, red wine, and canned fish samples spiked with seven BPs at three fortification levels. Analyses of six replicates were conducted to evaluate the precision of the method (expressed as the relative standard deviation, RSD %) and to evaluate the accuracy (expressed as absolute recovery).

The limits of quantification (LOQ) and the limits of detection (LOD), through the proposed method, were determined on the basis of the signal-to-noise (S/N) ratio of the actual analyte peak and the baseline close to the peak. This procedure was performed by successive analyses of spiked noncontaminated samples with decreasing amounts of the analytes until an S/N ratio of 10:1 (LOQ) or 3:1 (LOD) was reached.[13,15] LOQ of BPA in canned food could not be measured because of high background levels in all of these samples, and the corresponding LOQ was estimated by BPA-$d_4$ in the present study.

**Quality Assurance and Quality Control (QA/QC).** Different authors have reviewed the challenge of accurately detecting BPA at ultralow concentrations.[18,30] Background contamination can easily occur at trace levels because the target analytes are inherently ubiquitous in the laboratory environment. In this study, heat-treated glassware, LC−MS-grade solvents, and solvent-washed materials were used to prevent background contamination. In addition, one key problem associated with the development of an MIP-SPE method occurs because the residual template is not completely removed from the polymeric matrix and leaking occurs during the SPE procedure, which results in a false-positive result when the same molecule is used as the template. The template of the MIP sorbent that was used in this experiment is a dummy template that was synthesized commercially and contains two aromatic rings that are similar to BPA, one of which is a phenol. The template is removed by thoroughly washing and does not interfere with the target analytes. Furthermore, a procedural blank containing LC−MS water in place of the foodstuff samples was subjected to the same extraction protocol as the actual samples and was analyzed to evaluate the contamination levels for the entire procedure. Only trace levels of BPA (S/N < 5) and BPS (S/N < 2) were found in the procedural blank (see Supporting Information). The corresponding peak areas were deducted from the analysis results. Quantification was based on the internal calibration curves constructed by injection of seven calibration standards. A midpoint calibration standard was injected to check instrumental drift in sensitivity, and pure MeOH was injected to monitor sample carryover after every 10th sample analysis.

## RESULTS AND DISCUSSION

**Development of the Molecularly Imprinted Polymer Solid-Phase Extraction Procedure.** In this study, the MIP-SPE procedure was optimized on the basis of the manufacturer's instructions (AFFINIMIP SPE bisphenol A cartridges) to develop an MIP-SPE method that was suitable for simultaneous extraction of related BP analogues in beverage and canned food samples. First, the loading solutions were kept in an aqueous environment with less than 10% organic solvent, which resulted in complete retention of the analytes on the MIP-SPE through nonspecific interactions, such as hydrophobic or ion-exchange interactions. For the washing step, 6 mL of pure water was used to eliminate salts and hydrophilic interference. Next, 3 mL aliquots of the different MeCN/water solvent compositions (40:60, 50:50, and 60:40 v/v) were assessed to select a suitable solvent for removing the nonselectively bound polar matrix interference. A washing solvent consisting of 3 mL of MeCN/water (40:60 v/v) was optimal for cleaning and did not compromise recovery of the analytes.

To enable the polymer to selectively interact with the analytes, a complete drying step was necessary for the sorbents to shift from the aqueous to the nonaqueous washing step. After the drying step, 2 mL of MeCN (a polar nonprotic solvent) was used to induce the formation of specific interactions through hydrogen bonds between the analytes and the MIP monomers. Next, 2 mL of a MeOH/MeCN (10:90 v/v) mixture was applied to the cartridges to elute nonspecifically bound apolar matrix interference. As shown in Figure 2, recovery was closely associated with MeOH content

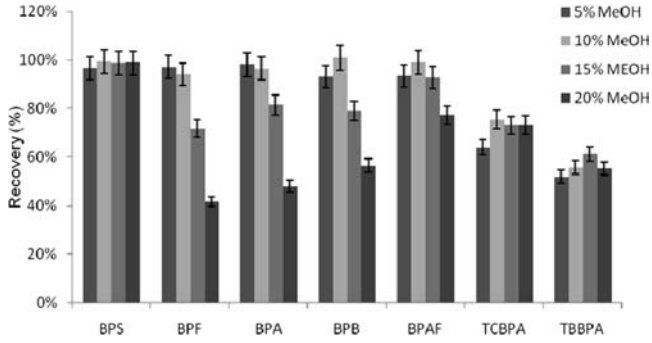

**Figure 2.** Comparison of analyte recoveries for use of different MeOH concentrations in MeCN during the washing step ($n$ = 3).

in the MeCN that was used in the washing step, and more than 10% MeOH in the MeCN resulted in significant losses of BPF, BPA, and BPB but not the other BPs. The presence of a higher portion of protic solvent, such as MeOH, would break the specific interactions, and these compounds with lower affinities for MIP were more easily removed during the washing step. When optimizing the elution conditions, we found that TCBPA and TBBPA were difficult to elute from the cartridge when 100% MeOH was used as the solvent. The desorption of these two compounds was achieved by percolating 100% MeOH with the addition of 2% formic acid, which was effective for disrupting the interactions between analytes and sorbents and for obtaining satisfactory recoveries.

During the SPE process, breakthrough potentially occurred due to the large loading sample volume or the high analyte concentration, which would decrease the recovery of the

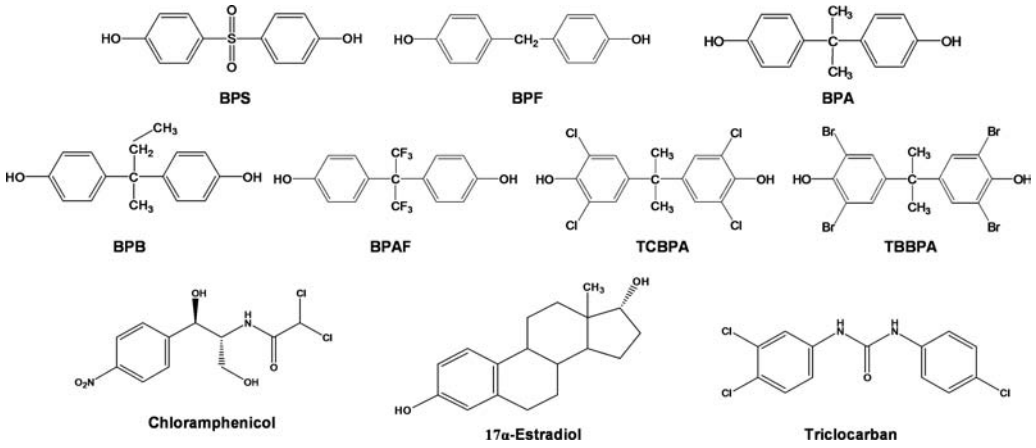

**Figure 3.** Structures of the seven analytes and the other three compounds used in selectivity binding tests.

method. Therefore, the breakthrough was assessed by extracting spiked orange juice (BPF, BPB, and TBBPA, 0.5 ng/mL; BPA and TCBPA, 0.25 ng/mL; BPS and BPAF, 0.05 ng/mL) with different sample loading volumes (5, 10, 20, 40, and 80 mL). No breakthrough occurred in these tests, and all analytes maintained a stable recovery as the sample volume increased from 5 to 80 mL, which indicated the preconcentration potential of the MIP-SPE. In this study, a 10 mL sample volume was selected because lower preconcentration times were needed, lower matrix interferences were introduced, and the sensitivity was sufficient for routine analysis.

**Selectivity of Molecularly Imprinted Polymer Solid-Phase Extraction.** To evaluate the selectivity of the MIP-SPE method, a comparison with the hydrophobic−lipophilic balance (Oasis HLB) SPE cartridge, which is one of the most widely employed reverse-phase cartridges for determining BPA concentrations in foodstuffs,[31−33] was conducted. The group-selective potential of the MIP-SPE procedure was tested by spiking the water with analytes and three other compounds (chloramphenicol, 17$\alpha$-estradiol, and triclocarban) belonging to the same range of polarity as the target analytes (Figure 3). The results obtained by the MIP-SPE procedure were compared with those obtained by the Oasis HLB. As shown in Figure 4, less than 10% of the chloramphenicol was retained by the MIP-SPE cartridge because its chemical structure shared less similarity with the bisphenols and was removed by the washing step. In addition, the lack of retention for triclocarban on the MIP-SPE was observed in the test even if it was a more hydrophobic compound. However, 17$\alpha$-estradiol was an exception to this behavior; it presented an extraction recovery of approximately 50% on the MIP-SPE cartridge. This recovery is explained by the similar arrangement of phenolic hydroxyl groups to the BP analogues. In contrast, the HLB was expected to be less selective than MIP-SPE because all of the compounds with a wide range of polarities were well retained after the loading and rinsing steps.

On the basis of the comparison above, it was shown that the presence of cavities in the MIP occurred. However, this result was not sufficient for demonstrating the real selectivity of the MIP for its application to real samples. Optimal selectivity necessitates the presence of a cleaner baseline or less matrix suppression for real sample analysis. In this study, two types of matrices (orange juice and canned fish) were spiked at the same concentrations and were passed through the MIP-SPE and HLB cartridges for analysis. After extraction and purification by

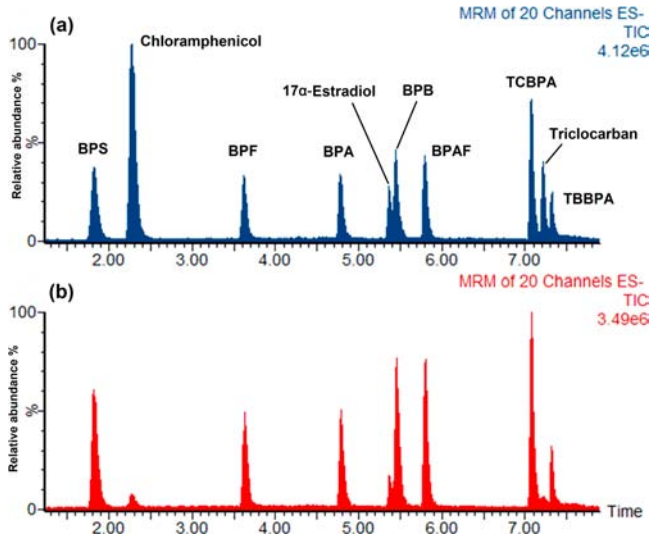

**Figure 4.** Chromatograms obtained from selectivity tests between (a) Oasis HLB and (b) MIP-SPE. The lack of chloramphenicol, 17$\alpha$-estradiol, and triclocarban retention on MIP demonstrates the selectivity of the extraction procedure on MIP-SPE.

the MIP-SPE and HLB cartridges, the chromatograms that corresponded to each analyte are shown in Figure 5. Using the MIP-SPE instead of the Oasis HLB for the extraction and purification process resulted in a cleaner baseline and in less matrix suppression for most of the analytes. In addition, another advantage of MIP-SPE is its ability to remove the majority of the pigment from the sample matrix to obtain cleaner extracts (see Supporting Information).

**Validation of Molecularly Imprinted Polymer Solid-Phase Extraction Method.** The calibration curves were constructed from the peak area ratio of the analyte to the internal standards (BPA-$d_4$, TCBPA-$^{13}C_{12}$, TBBPA-$^{13}C_{12}$, and BPF-$d_{10}$, 5 ng/mL; BPS-$^{13}C_{12}$ and BPAF-$d_4$, 0.5 ng/mL) versus the analyte concentrations and were linear with a correlation coefficient of >0.99 in the concentration ranges evaluated. Table 1 illustrates the recoveries and the RSDs of the analytes in the spiked orange juice, red wine, and canned fish. The results showed that the recoveries were in the 50−103% range, with RSD values of less than 15% for all of the analytes. The LOQ, obtained after the MIP-SPE procedures of 10 mL beverage samples or 1 g canned food samples, varied from 0.002 to 0.15 ng/mL in the beverage samples and from 0.03 to

1.5 ng/g in the canned food samples. These results provided lower LOQs for BPA and its analogues relative to the LOQs reported in previously published methods[33−37] (see Supporting Information for comparison with other methods).

**Application of the Method.** To demonstrate the applicability of the developed method, several beverage samples and canned foods were randomly purchased from local supermarkets in Beijing. Figure 6 shows the typical LC−MS/MS chromatograms that corresponded to canned pork luncheon meat, in which BPS, BPF, and BPA were detected. The analyte concentrations are summarized in Table 2. BPB, TCBPA, and TBBPA were not detected in any of the samples, and the concentrations of the other BPs in the beverage products were generally low. BPA and BPF were the most frequently detected BPs in the beverage samples and varied from ND to 12 ng/mL and from ND to 0.39 ng/mL, respectively. These levels are similar to the levels that were observed in beverages by Geens et al.[33] (BPA, <LOQ−8.1 ng/

[a]BPB, TCBPA, and TBBPA were not detected in any of the samples.

mL), Cao et al.[34] (BPA, 0.032−4.5 ng/mL), Cacho et al.[14] (BPF, ND−0.26 ng/mL), and Gallart-Ayala et al.[35] (BPF: ND−0.22 ng/mL). Compared with BPA and BPF, less than 25% of the samples contained BPS and BPAF above the LOQ in the beverages, which indicated their minor use in food contact materials.

Influences of the packaging materials were evaluated by comparing the BP concentrations in seven paired beverage samples. The only difference in each pairs is that one was packed in cans and the other in PET or Tetra Pak. As shown in Table 2, beverages in the packing materials with PET or Tetra Pak had lower BPA and BPF contamination or detection rates relative to the same beverages packed in cans. This result indicated that the BPA and BPF in these types of foods primarily originated from the can's inner coating.

For the canned food samples, BPS, BPA and BPF concentrations were comparable to the BP concentrations that were recently reported for canned food[13,33,36,37](see Supporting Information) and were approximately 1 order of magnitude greater than those in the canned beverages. The higher concentrations in canned food most likely occurred because the chemicals preferred a more lipophilic environment than the aqueous phase or resulted from differences in sterilization conditions and coating types.[33]

In conclusion, the above-mentioned applications proved that this MIP-SPE method is a powerful method to make group-selective extraction and purification in a single step and provide cleaner extracts. The method offers many advantages such as high selectivity, low solvent consumption, and ease of use, which make it possible to replace traditional SPE methods for the analysis of bisphenol analogues in complex matrices.

neous internal distribution of binding sites, the mass transfer of target molecules from solution to cavities is obstructed by the adsorption of the template on the surface of MIPs, which causes low binding affinity.

To overcome these problems, a surface-imprinting technique combined with magnetic nanoparticles [superparamagnetic MIPs (M-MIPs)] has been applied recently,[19−21] in which most of the binding sites on the surface of polymers are exposed to facilitate the recognition and removal of the template. In addition, magnetic support can be easily isolated from the real samples using a magnet. However, traditional polymerization processes of MIPs are conducted in organic phase, thereby restricting its application in aqueous systems. In recent years, water-compatible MIPs have been developed. For example, tramadol-imprinted polymers embedding $SiO_2$−$Fe_3O_4$ nanoparticles were prepared in double-distilled water and then used to separate tramadol from human urine samples. The obtained MMIPNPs exhibit high sensitivity and low detection limits.[22] Tao Jing et al.[23] prepared lysozyme-imprinted magnetic nanoparticles immersed in phosphate buffer (0.2 mol $L^{-1}$, pH 6.2) and reused them 5 times. The high adsorption capability and high saturation magnetization of the lysozyme-imprinted magnetic nanoparticles enable their efficient separation from the crude sample. However, to the best of our knowledge, only a few studies on M-MIPs of vanillin have been conducted.

In this paper, we report the use of a simple method to prepare core−shell M-MIPs in a methanol−water reaction system. The obtained M-MIPs were used for the separation and pre-concentration of vanillin. The $Fe_3O_4$ nanoparticles were synthesized by the alkaline co-precipitation method and then coated by a $SiO_2$ layer, in which the surface was modified by 3-methacryloxypropyltrimethoxysilane (MPS) to form end vinyl bonds that provided reaction sites to induce the occurrence of imprinted polymerization on the surface of the $Fe_3O_4$@$SiO_2$@MPS. Finally, M-MIP particles were prepared for the separation and enrichment of vanillin from the aqueous solution before further HPLC−UV analysis. These M-MIPs are water-compatible and highly selective, and they exhibit fast binding kinetics and can be rapidly separated.

## EXPERIMENTAL SECTION

**Reagents and Materials.** Vanillin, methyl vanillin, ethyl vanillin, ferrous sulfate heptahydrate ($FeSO_4·7H_2O$), anhydrous ferric chloride ($FeCl_3$), ammonia ($NH_3·H_2O$), ethanol, methanol, and acetic acid were all purchased from Sinopharm Chemical Reagent Co., Ltd. (Shanghai, China). Methacrylic acid (MAA), ethylene glycol dimethacrylamide (EGDMA), 2,2-azobis(isobutyronitrile) (AIBN), and MPS were obtained from Sigma (Shanghai, China). Tetraethoxysilane (TEOS) was obtained from Aladdin (Shanghai, China). All of these chemicals were of analytical reagent grade.

**Preparation of $Fe_3O_4$@$SiO_2$ Nanoparticles.** The $Fe_3O_4$ magnetic nanoparticles were synthesized via the alkaline co-precipitation method. Briefly, 1.63 g of $FeCl_3$ and 1.45 g of $FeSO_4·7H_2O$ were dissolved in 100 mL of distilled water with vigorous stirring for 20 min under a nitrogen atmosphere. When the temperature was increased to 60 °C, 5 mL of $NH_3·H_2O$ (25−28%, w/w) was injected into the mixture rapidly, and then the solution immediately turned black. The reaction was allowed to proceed for 60 min under a nitrogen atmosphere. The black product was separated from the liquid using a permanent magnet and then washed with distilled water several times until the pH of the washing water was neutral.

The obtained $Fe_3O_4$ nanoparticles were dispersed homogeneously into 100 mL of distilled water by sonication for 20 min. The magnetic dispersion (10 mL) was mixed with 80 mL of ethanol, followed by the addition of 5 mL of ammonia (25−28%, w/w). Subsequently, 1 mL of TEOS was added drop by drop, and the reaction was maintained for 6 h at 40 °C. The obtained $Fe_3O_4$@$SiO_2$ particles were collected using a magnet, rinsed alternately with ethanol and water 3 times, and then dried under vacuum for 24 h.

MPS, a silane coupling agent, was used to modify the silica surface to enhance the binding capacity between the magnetic particles and the MIPs. In this procedure, 500 mg of $Fe_3O_4$@$SiO_2$ particles was dispersed in 50 mL of anhydrous toluene by sonication for 20 min, followed by the addition of 10 mL of MPS. The reaction was conducted with reflux for 24 h at 50 °C under a nitrogen atmosphere. The resulting $Fe_3O_4$@$SiO_2$−MPS was thoroughly washed with toluene and dried under vacuum.

**Preparation of M-MIPs.** The M-MIPs were synthesized by dissolving 0.68 mmol of vanillin (as template) and 2.72 mmol of MAA (as a functional monomer) in 30 mL of methanol/water (9:1, v/v) solution. After vortex oscillation, the mixture was stored under refrigeration at 4 °C overnight to form hydrogen bonds between vanillin and MAA. Subsequently, 100 mg of modified $Fe_3O_4$@$SiO_2$, 6.8 mmol of EGDMA (as a cross-linker), and 30 mg of AIBN (as an initiator) were dispersed in 20 mL of methanol/water (9:1, v/v) by sonication for 25 min, followed by the addition of the vanillin−MAA mixture. After nitrogen gas injection, the solution was mixed at 50 °C for 8 h, then kept at 60 °C for 24 h, and further aged for 6 h at 80 °C. The polymer products were eluted with methanol/acetic acid (9:1, v/v) in a Soxhlet extractor for 48 h to remove the templates. Finally, the obtained M-MIPs were dried under vacuum for 24 h. Superparamagnetic non-MIPs (M-NIPs, as a control) were prepared using the method described previously without the addition of vanillin.

**Characterization.** Fourier transform infrared (FTIR) spectra were recorded using the FTIR spectrophotometer (Nicolet 5700, Thermo Electron Corporation, Waltham, MA). X-ray powder diffraction (XRD) patterns were recorded using an XRD analyzer (D8-FOCUS, Bruker, Karlsruhe, Germany). Transmission electron microscopy (TEM) images were obtained on a JEOL (JEM-2010HR, Japan) transmission electron microscope. The magnetic properties were examined by vibrating sample magnetometry (VSM, 7407, Lakeshore, Westerville, OH). The amounts of analytes were determined by a HPLC−UV (Agilent Technologies 1260 Infinity) method. The ZORBAX SB-C18 column with a 250 × 4.6 mm inner diameter was used as the analytical column. HPLC−UV conditions employed were as follows: mobile phase, methanol/water/acetic acid (3:7:0.05, v/v/v); flow rate, 0.3 mL $min^{-1}$; and detection wavelength, 279 nm, under room temperature.

**Binding Experiment.** To evaluate the adsorption capacity of M-MIPs or M-NIPs, 10 mg of particles was dispersed in 5 mL of vanillin solution with concentrations from 0.04 to 0.15 mmol $L^{-1}$. The mixture was incubated at room temperature for 24 h and then separated by a magnet to determine the concentration of vanillin in supernatant solution.

The M-MIPs or M-NIPs (20 mg) were added to 30 mL of 0.08 mmol $L^{-1}$ vanillin solution to investigate their kinetic adsorption properties. The mixture was incubated in a shaker at room temperature, and samples were obtained at different times. The microspheres were then separated by a magnet to determine the residual concentration of vanillin using a UV spectrophotometer at 279 nm.

Selectivity experiments were conducted using vanillin, methyl vanillin, and ethyl vanillin as structural analogues. M-MIPs (20 mg) or M-NIPs (20 mg) were dispersed into 2.0 mL methanol−water solutions containing 0.08 mmol $L^{-1}$ vanillin, methyl vanillin, and ethyl vanillin. The amount of vanillin, methyl vanillin, and ethyl vanillin in the supernatant were determined by UV after shaking for 12 h at room temperature. The recognition ability of M-MIPs was evaluated using the imprinting factor ($\alpha$), which is defined in the following equation:

$$\alpha = Q_{MIP}/Q_{NIP}$$

where $Q_{MIP}$ and $Q_{NIP}$ are the adsorption amounts of the templates or analogues on M-MIPs and M-NIPs, respectively.

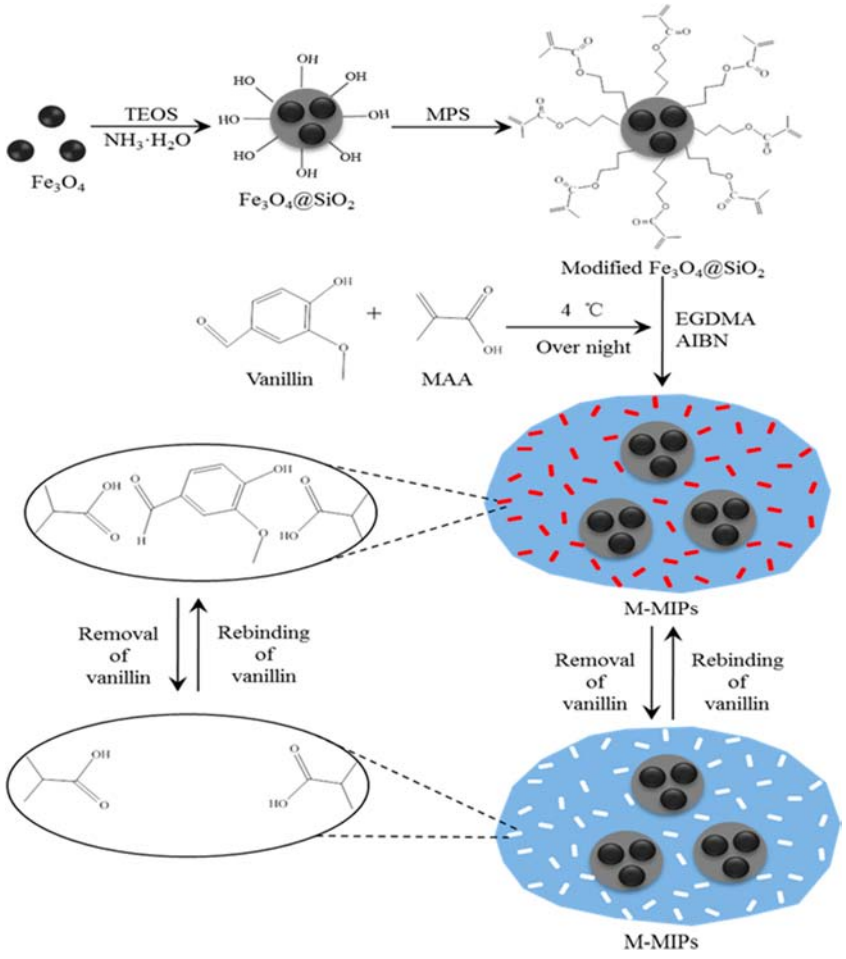

**Figure 1.** Synthesis schematic of M-MIPs.

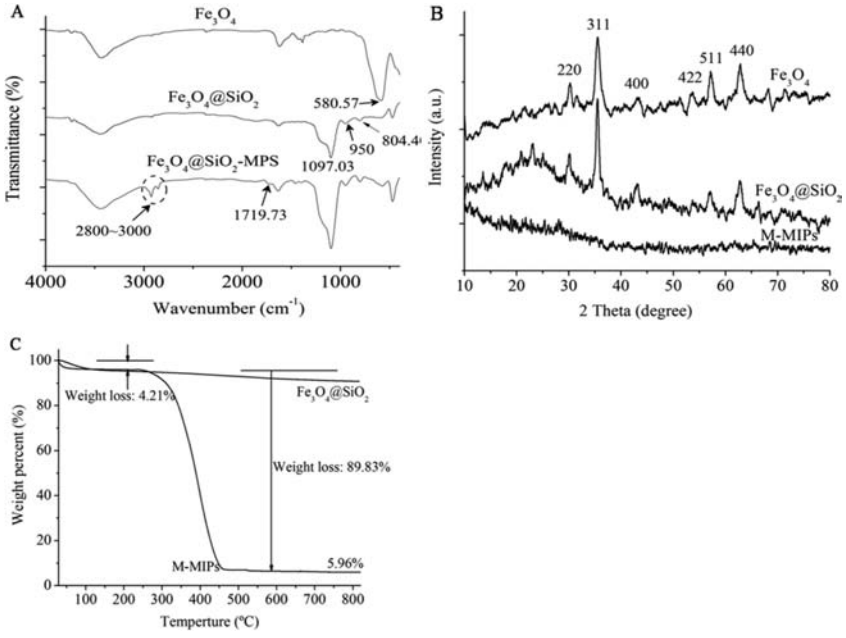

**Figure 2.** (A) FTIR spectra of $Fe_3O_4@SiO_2$, MPS, and $Fe_3O_4@SiO_2$–MPS, (B) XRD of $Fe_3O_4$, $Fe_3O_4@SiO_2$, and M-MIPs, and (C) thermogravimetric curves of $Fe_3O_4@SiO_2$ and M-MIPs.

**Analysis of Vanillin in Real Samples.** Several commercial food samples (bread, milk powder, biscuit, and chocolate) were purchased from the local market in Nanchang. The food samples were ground to a fine powder using a mortar and pestle. Food samples (2 g) unspiked or spiked with different concentrations of vanillin standard solutions (2 mL or 0.01, 0.04, or 0.08 mmol $L^{-1}$) and using water (20 mL) were

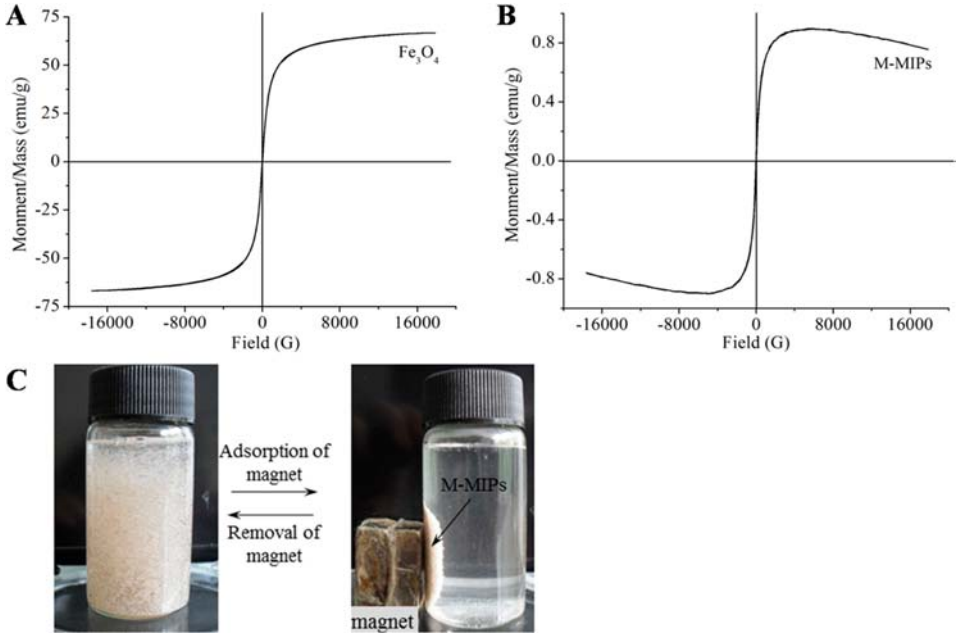

**Figure 3.** Hysteresis loops of the (A) $Fe_3O_4$ nanoparticle and (B) M-MIPs and (C) magnetic separation picture of M-MIPs.

extracted for 30 min. The solutions were then centrifuged and filtered to obtain the extract solution. The M-MIP particles (20 mg) were added to the extract solution, which was then shaken at room temperature for 1 h. A magnet ($N_{35}$ model) was used to separate the M-MIP particles from the solution. The supernatant was measured by HPLC−UV and determined the amount of vanillin. The food sample without spiking was used as a control group. Thus, the recovery of food samples with spiking has been subtracted by the level of vanillin in the control group. The vanillin adsorbed onto the M-MIP sorbent was subsequently eluted with 2 mL of methanol/acetic acid (9:1, v/v). After desorption for 2 h, the template molecule vanillin and adsorbent were easily and rapidly separated using a magnet. The solution containing the template molecule vanillin was dissolved in 2 mL of acetonitrile solvent. The recovery amounts of vanillin in food samples were then determined by HPLC−UV. All of the tests were conducted in triplicate, and the data were reported as the mean values. In addition, matrix interferences could be excluded using selective M-MIPs as the extracting agent. The absorbance values were measured by deducting the absorbance of blank samples.

## RESULTS AND DISCUSSION

**Preparation of M-MIPs.** The water-compatible M-MIPs of vanillin were synthesized via a multi-step polymerization method, as illustrated in Figure 1. Superparamagnetic $Fe_3O_4$ nanoparticles were produced using the co-precipitation method[24] and then coated with a thin film of silica to enhance the dispersibility of magnetic particles and prevent oxidation. MPS was then allowed to react with the hydroxyl of $Fe_3O_4$@$SiO_2$ to introduce vinyl groups, which induced the copolymerization of MIPs to occur on the surface of the microspheres upon the addition of MAA. On the other hand, TEOS has a lot of −OH groups, which can make MPS graft easily onto the $Fe_3O_4$−$SiO_2$ surface. Finally, the M-MIPs were prepared after the templates were eluted with methanol/acetic acid solution. The obtained M-MIPs enabled the easy recognition, separation, and enrichment of the template from complex food sample samples.

**FTIR Spectroscopy.** Figure 2A shows the FTIR spectra of $Fe_3O_4$, $Fe_3O_4$@$SiO_2$, and $Fe_3O_4$@$SiO_2$−MPS. The characteristic peak of $Fe_3O_4$ was observed at 580.57 $cm^{-1}$. The peaks at

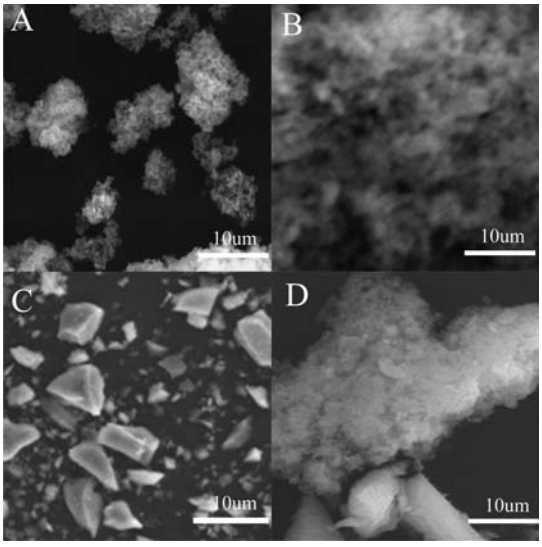

**Figure 4.** SEM images of (A and B) M-MIPs and (C and D) M-NIPs.

1097.03, 950.00, and 804.40 $cm^{-1}$ were attributed to the stretching vibrations of Si−O−Si, Si−O−H, and Si−O, respectively, indicating the formation of the silica shell. The absorbance peaks from 2800 to 3000 $cm^{-1}$ were attributed to the stretching vibrations of the C−H bond from the methyl and methylene groups. The peak at 1719.73 $cm^{-1}$ was attributed to the stretching vibration of the carbonyl group, which indicated the successful modification of MPS.

**Crystalline Structure Analysis.** Figure 2B shows the XRD patterns of $Fe_3O_4$, $Fe_3O_4$@$SiO_2$, and M-MIPs. A series of characteristic peaks for $Fe_3O_4$ in the $2\theta$ range of 10−80° were observed at $2\theta$ = 30.32°, 35.42°, 43.39°, 53.60°, 57.22°, and 62.79°. These peaks were indexed to the (220), (311), (400), (422), (511), and (440) crystalline planes, respectively, which matched well with the data for magnetite [Joint Committee on Powder Diffraction Standards (JCPDS) card 19-629]. However, a few $\gamma$-$Fe_2O_3$ particles were obtained because of the

oxidation of $Fe_3O_4$ during the co-precipitation and silanization processes.[25−27] This finding was not considered in this study, because these particles exhibited similar magnetic properties and either phase allows for the growth of the silica shell on its surface.[28] Furthermore, by comparing the XRD patterns of $Fe_3O_4$ and $Fe_3O_4$@$SiO_2$, some other characteristic peaks for $SiO_2$ were observed in the $2\theta$ range of 10−35°. Meanwhile, a few peaks could be observed in the M-MIP curve for thick MIPs, which significantly decreased the content of $Fe_3O_4$@$SiO_2$ in all of the samples. This inference can be validated by the results of thermogravimetric analysis (TGA) and VSM.

**TGA.** The thermogravimetric curves of $Fe_3O_4$@$SiO_2$ and M-MIPs are shown in Figure 2C, which quantified the encapsulation efficiency of the $Fe_3O_4$@$SiO_2$ particles that were covered with the M-MIPs. When the temperature increased to 200 °C, the weight of both samples decreased by approximately 4.21%, because of dehydration of the physically adsorbed water or solvent residues. A flat curve of $Fe_3O_4$@$SiO_2$ was then observed from 200 to 800 °C. However, the MIPs decomposed rapidly at temperatures of >800 °C. The decrease in mass was 89.83%, especially from 300 to 500 °C. The residual weight (5.96%) was attributed to the thermostable $Fe_3O_4$@$SiO_2$.

**Magnetic Properties of $Fe_3O_4$ and M-MIPs.** The magnetic properties of $Fe_3O_4$ and M-MIPs were determined using VSM at room temperature. The magnetic hysteresis loop of the dried samples is shown in Figure 3. The saturation magnetization ($M_s$) value of the M-MIPs was significantly decreased to 0.90 emu $g^{-1}$, in comparison to pure $Fe_3O_4$ (66.80 emu $g^{-1}$). The decrease in the magnetization value was due to the formation of thick polymers that covered the M-MIP particles. Moreover, hysteresis did not occur, and remanence and coercivity were zero; thus, both samples were superparamagnetic. As such, the M-MIPs with low $M_s$ values could be easily attracted to an external magnetic field at the wall of the vial (Figure 3C). When the magnet was removed, the M-MIPs were re-dispersed into the solution.

**Morphology Analysis.** Figure 4 shows the SEM images of the M-MIPs and M-NIPs. In comparison to the irregular and compact structure of the M-NIPs, the structure of the M-MIPs

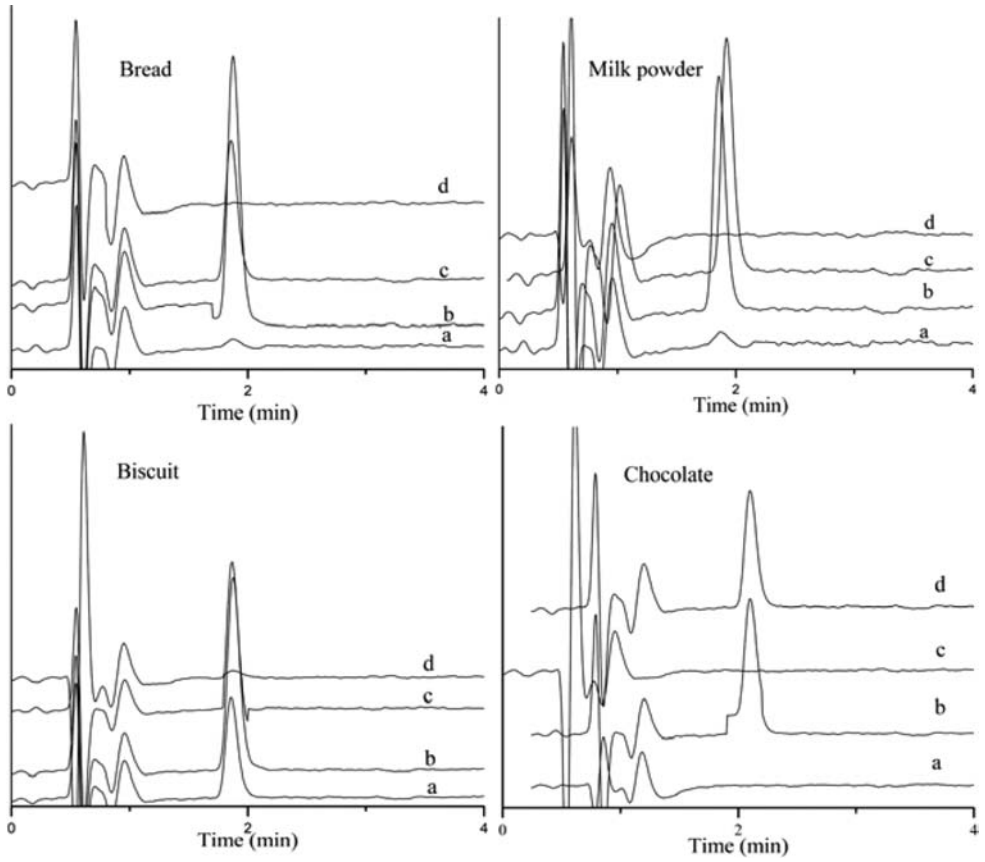

**Figure 6.** HPLC–UV chromatograms of bread, milk powder, biscuit, and chocolate samples. The samples were (a) not spiked, (b) spiked with 0.01 mmol $L^{-1}$ vanillin and without extraction, (c) spiked with 0.01 mmol $L^{-1}$ vanillin and with M-MIP extraction, and (d) spiked with 0.01 mmol $L^{-1}$ vanillin and the remaining solution after extraction.

was loose and porous with many cavities, which facilitated the mass transport and binding kinetics of the template molecules.

**Binding Properties of the M-MIPs.** To estimate the adsorption capability of the M-MIPs and M-NIPs, static adsorption experiments were conducted using different initial concentrations of vanillin solution. Figure 5A shows that the binding amount of the M-MIPs and M-NIPs for vanillin was increased with the increase in the vanillin concentration. Moreover, the amount of vanillin bound to the M-MIPs was much higher than that bound to the M-NIPs. The Scatchard equation was adopted to evaluate the binding ability of the M-MIPs and M-NIPs.[29] The Scatchard equation is expressed as follows:

$$\frac{Q}{C} = \frac{Q_{max}}{K_d} - \frac{Q}{K_d}$$

where $Q$ is the amount of vanillin bound to M-MIPs at equilibrium, $Q_{max}$ is the apparent maximum binding amount, $C_0$ is the initial concentration of vanillin, $C$ is the concentration of the supernatant at equilibrium, and $K_d$ is the dissociation constant.

As shown in Figure 5C, the Scatchard plot for the M-MIPs was a single straight line with a good linear relationship ($R^2$ = 0.981), which indicated that the binding sites in the M-MIPs were almost homogeneous. As a control, the M-NIPs with nonlinear correlation possessed fewer homogeneous binding sites. The linear regression equation for the M-MIPs was $Q/C = 1.090 - 0.017Q$. The $Q_{max}$ and $K_d$ were calculated to be 64.12 $\mu$mol $g^{-1}$ and 58.82 $\mu$mol $L^{-1}$, respectively, on the basis of the slope and intercept of the Scatchard plot. These values confirmed the high affinity of the M-MIPs to vanillin.

Kinetic adsorption experiments for M-MIPs and M-NIPs were carried out to investigate the binding process. As shown in Figure 5B, the adsorption capacity of M-MIPs was much higher than that of M-NIPs. The adsorption amount of M-MIPs increased rapidly in the first 30 min, and the curve became relatively flat until reaching equilibrium after approximately 100 min. A similar behavior was observed for the M-NIPs in Figure 5B. Cavities with recognition sites on the surface of the M-MIPs were occupied rapidly by template molecules, which increased the difficulty of transferring vanillin into the inner sites. Given that no specific recognition sites matched vanillin in terms of shape, size, and functional groups in the M-NIPs, the binding amount of the M-NIPs was obviously lower than that of the M-MIPs.

To investigate the binding specificity of the M-MIPs, a selectivity test was conducted using structural analogues of vanillin, methyl vanillin, and ethyl vanillin as control compounds. As shown in Figure 5D, the adsorption capacity of the M-NIPs is similar and non-selective for the three compounds because selective recognition sites are absent in the M-NIPs. However, the M-MIPs showed a significantly higher binding capacity for vanillin than methyl vanillin and ethyl vanillin. The binding capacities of the M-MIPs for vanillin, methyl vanillin, and ethyl vanillin were 31.4, 17.4, and 18.6 $\mu$mol $g^{-1}$, respectively. Accordingly, the imprinting factor values ($\alpha$) of the M-MIPs for vanillin, methyl vanillin, and ethyl vanillin were 2.66, 1.78, and 1.74, respectively. These results

indicated that the M-MIPs exhibited highly specific recognition ability for vanillin. The high selectivity for vanillin may be based on two factors: (1) the first factor is the difference in chemical structures between vanillin, methyl vanillin, and ethyl vanillin, and (2) only vanillin can specifically match the binding sites of the template in terms of size and shape.

**Method Validation and Application to the Analysis of Vanillin in Food Samples.** To assess the practical applicability of the M-MIPs, four food samples (bread, milk powder, biscuit, and chocolate) were used as real samples in the analysis. At the three spiked vanillin concentrations of 0.01, 0.04, and 0.08 mmol $L^{-1}$, the extraction recoveries of the M-MIPs were 83.39−95.58% with relative standard deviations of 2.48−5.17% (Table 1.). The determined limits of detection and quantification were 2.67 and 8.0 $\mu$mol $L^{-1}$ at signal-to-noise ratios of 3 and 10, respectively. The regression equation was attained, $A_{(279\ nm)} = 8.33021x + 2.77378$ ($R^2 = 0.9996$) within 0.1−5.0 mmol $L^{-1}$. Moreover, the separation process was finished within 10 s when a magnet was used. The results of HPLC−UV chromatograms (Figure 6) also indicated that M-MIPs had high selectivity and enrichment ability.

In summary, novel superparamagnetic particles coated with vanillin-imprinted polymer were synthesized using MAA as the functional monomer and EGDMA as the cross-linker. The resultant M-MIPs showed some attractive characteristics, such as higher binding capacity, faster binding kinetics, and quicker separation. The analytical method based on M-MIPs was successfully applied to vanillin analysis in spiked food samples with higher selectivity and concentration. Thus, the approach offers a simple and straightforward technique for selective separation and fast enrichment of vanillin from complicated food matrices.

[a]Anhydrous (+)-catechin was used for antioxidant capacity tests and (+)-catechin hydrate for ZI studies.

Thus, although spices and herbs are typically rich in bioactive essential oils containing simple phenols, terpenoids, and other bioactive compounds,[16] such volatile compounds were excluded from the scope of the present work because of their strong flavors and odors.

In the present study a major goal was to identify natural extracts that could be used for shelf-life extension of fresh (refrigerated/chilled) fish and lamb by controlling their spoilage bacteria. Extracts from different materials have heterogeneous compositions and thus tend to differ in regard to their abilities to inhibit different bacteria. We focused on nonvolatile extracts from natural products in order to minimize cost and toxicology compliance issues as well as to mitigate any possible changes in the organoleptic properties (the effects on organoleptic properties of different extracts will depend on the amount migrating to the food and the type of food item and

should be tested as part of shelf-life trials). The search was narrowed down to extracts from byproducts of fruit processing industries[2,3,5−8] and tannins derived from different wood components that could be made readily available in New Zealand. The wider bioeconomy would benefit from adding value to agricultural byproducts while health-conscious consumers also tend to prefer natural antioxidants and antibacterial agents.

The major spoilage organisms of chilled fish and lamb are psychrotolerant bacteria. *Shewanella putrefaciens* is a major white fish and chilled lamb spoilage bacterium; very low numbers produce enough $H_2S$ and other sulfur volatiles for a highly offensive rotten-egg odor, as well as trimethylamine and other off-flavor compounds.[18] *Photobacterium phosphoreum* and *Pseudomonas fluorescens* are also able to rapidly spoil fish and/or lamb, when present. The facultative anaerobe *Brochothrix thermosphacta* is a concern for aerobically stored, vacuum-packed or MAP chilled red meats. In anaerobic conditions psychrotrophic Clostridia spp. such as *Clostridium estertheticum* can spoil these products as well.[19] Lactobacilli typically produce a fermentative yeasty odor, but their impact on sensory properties depends also on the food. In some cases lactobacilli may be considered beneficial if they inhibit other, more potent bacteria such as Clostridia. The main spoilage bacteria for fresh New Zealand fish[18,20,21] and lamb[22] are summarized in Table 1. In addition to the bacteria already mentioned, they include several Enterobacteriaceae species, and all were included in the current study except for *Rahnella*. In selecting the target bacteria we aimed to include the food-borne bacteria that are mostly linked to outbreaks worldwide, as well as those associated with spoilage of different sources of food and having different phenotypic characteristics which might be expected to have differences in susceptibility (e.g., Gram-positive and Gram-negative bacteria).

A second goal of the study was to determine the potential suitability of the natural extracts for use in dietary antioxidant supplements. Manufacturers typically claim that antioxidant dietary supplements possess antiaging properties and offer protection against various diseases. The potential benefits of such supplements are uncertain, and high doses of some antioxidant supplements such as vitamin A, vitamin E, and beta-carotene have even been linked to increased all-cause mortality.[23] On the other hand, the many health-promoting effects of fruits are seldom contested and are largely attributed to the antioxidant properties of their phenolic compounds.[24,25]

In this study we evaluated the antibacterial and antioxidant properties of nonvolatile extracts from byproducts of fruit processing industries[2,3,5−8] and tannins derived from trees. To assist with future regulatory acceptance, we have also identified the main phenolic compounds in eight of the most promising extracts.

## MATERIALS AND METHODS

**Materials.** The raw materials and reference compounds used for this study are listed in Table 2. Most of the fruit skins and seeds came from ripe fresh whole fruits obtained from local fruit vendors. The berry fruits were purchased frozen from a local supermarket. Avocado skins and seeds were recovered from fresh avocado processing residue supplied by Fressure Foods, NZ, and processed in-house to generate the extracts used in the study. Reference and standard compounds (ascorbic acid, (+)-catechin, gallic acid, and Trolox), solvents, and reagents were of analytical grade and from Sigma-Aldrich except for acetone, which was from Merck, Darmstadt, Germany. Tannic acid (TaAc) was purchased from BDH Laboratory Supplies, Poole, England. Grape seed extract was obtained from NZ Extracts Ltd., NZ. African mango seed extract (not the mango seed extract in Table 2, which was produced by the authors and used for antibacterial and antioxidant tests) came from Hanzhong TRG Biotech Co. Ltd., Hanzhong City, China. Mimosa tannin and cationic mimosa tannin were supplied by Christian D. Markmann GmbH, Hamburg, Germany. Pine tannin was an in-house product of Scion, NZ (see Processing).

**Processing.** For most of the fruits, skins and seeds were separated from pulp manually, then scraped, and rinsed clean of most pulp and juice/oil residues. Berry fruits (frozen) and tomatoes were juiced at room temperature with a low-temperature Ultem auger juicer (Oscar DA1000, Oscar Juicers, NZ); the juicing residues consisted of the skins and seeds of the fruits. After segregation of the fruit components, the parts to be extracted were immediately frozen at −82 °C, then lyophilized, and ground into powder through a 1 mm mesh using a Wiley mill. Tannic acid is extracted from the leaves, gallnuts, and pods of a range of wood species (Table 2) using water, organic solvents, or their mixtures; the grape seed extract originated from a water-based extraction process; mimosa tannin is commercially extracted from the bark of various acacia species; cationic tannin is a flocculant for pulp mill effluents produced from mimosa tannin by the Mannich reaction; pine tannin originated from alkali extraction of radiata pine (*Pinus radiata*) bark.

**Extraction.** A portion (12−100 g) of fruit skin or seed powder was placed in a Schott bottle (0.5 or 1 L) and extracted with acetone−water (80:20, v/v) at a consistency of 10% for 90 min at 50 °C while the bottle was shaken at 180 rpm. The mixture was then centrifuged (3000 rpm, 5 min) and the supernatant collected by decanting and/or pipetting. The particle residue was washed twice with water, and all the supernatants were combined. The acetone was evaporated from the supernatant under reduced pressure at room temperature, after which the water phase was frozen at −82 °C and lyophilized. The particle residue from the extraction was then re-extracted as described above, and the lyophilized extract powders from both extractions were combined to give the final extract. The extracts were stored in a freezer at −20 °C pending use.

**Thermal Modification of Tannic Acid (TaAc).** For the thermal modification of TaAc,[26] 10.0 g of TaAc was dissolved in 90.0 g of deionized water. The solution was decanted into the Teflon insert of a calorimetric bomb, which was then halfway immersed into an oil bath at 200 °C. After 260 min, the bomb was removed from the bath and allowed to cool overnight. The minor amount of insoluble material found at the bottom of the inset was discarded, and the solution was lyophilized, yielding a brown powder similar in appearance to the starting material.

**Chemical Assays.** *Total Phenol Content (TPC).* Total phenol content of extracts was determined by the Folin−Ciocalteu method according to Kähkonen et al.[27] Absorption was measured at 765 nm using a Cary 300 Bio UV−visible spectrophotometer. A calibration curve (linear fit $R^2$ = 0.9985; 0.005−0.018 mg/mL gallic acid; $A_{765}$ = 0.5−1.6) was constructed with gallic acid, and the sample TPCs (mean of three or more replicates) were expressed as gallic acid equivalents (mg GAE/g) on dry extract weight basis. Anhydrous (+)-catechin was used to check the accuracy of the method.

*Total Flavonoid Content (TFC).* Total flavonoid content was determined using the colorimetric assay described by Dewanto et al.[28] A Cary 300 Bio UV−visible spectrophotometer was used to measure the absorbance at 510 nm. (+)-Catechin hydrate was used for the calibration curve (linear fit $R^2$ = 0.9995; 0.01−0.04 mg/mL catechin; $A_{510}$ = 0.34−0.92), and the results were expressed as catechin equivalents (mg CE/g) on dry extract weight basis. Samples were analyzed in three or more replicates and the results averaged.

*Identifying Phenolic Compounds.* Eight of the extracts with the highest phenol content, excluding CaTa, were also analyzed by LCMS. To extract the phenolic compounds, 1.0 mL of ethanol/Milli-Q water/formic acid (80/20/1, v/v/v) was added to approximately 50 mg of extract, and the mixtures were vigorously agitated using a vortex mixer. Samples were then stored overnight at 4 °C, centrifuged, and diluted 10-fold with methanol before analysis by ultrahigh performance liquid chromatography−high resolution mass spectrometry (LCMS) using a

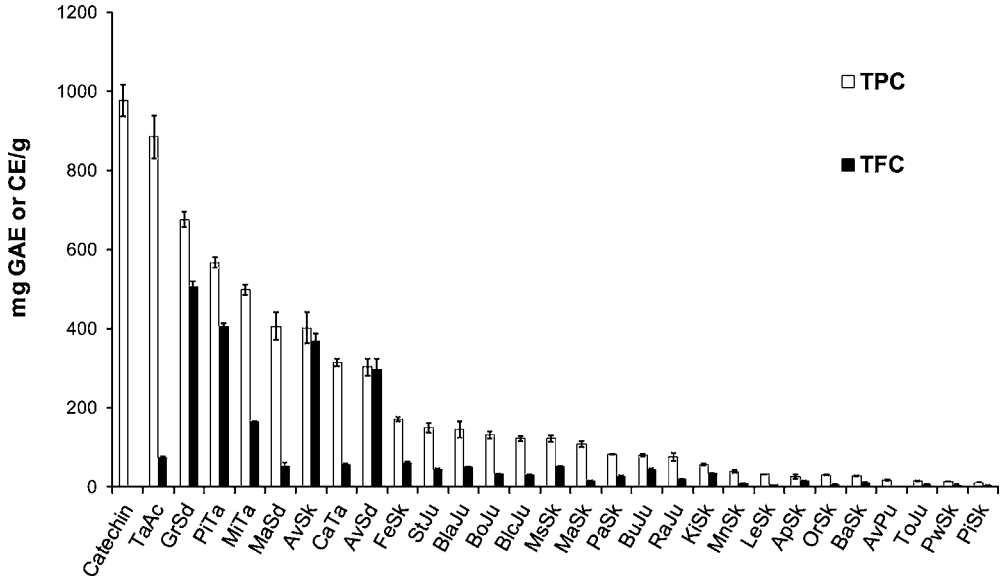

**Figure 1.** Total phenol content (TPC as gallic acid equivalents) and total flavonoid content (TFC as catechin equivalents) of extracts and catechin (external standard). See Table 2 for abbreviations.

Dionex Ultimate 3000 Rapid Separation LC and a micrOTOF QII mass spectrometer (Bruker Daltonics, Bremen, Germany) fitted with an electrospray ion source. Component separation by LC was achieved using two UHPLC Zorbax SB-C18 2.1 × 100 mm, 1.8 μm columns (Agilent, Melbourne, Australia) connected in series. The columns were maintained at 60 °C with a mobile phase flow rate of 350 μL/min. The solvents were A, 100% acetonitrile, and B, 0.2% formic acid, with a solvent gradient of 10% A, 90% B, 0−0.5 min; linear gradient to 45% A, 45% B, 0.5−18 min; linear gradient to 100% A, 18−25 min; 100% A, 25−28 min; linear gradient to 10% A, 90% B, 28−28.2 min; 10% A, 90% B until the next sample injection at 31 min. Injection volumes were 1 μL. The micrOTOF QII parameters were 225 °C; drying $N_2$ 6 L/min; nebulizer $N_2$ 1.5 bar, end plate offset −500 V, mass range 100−1500 Da, acquisition rate 2 scans/s. Negative ion electrospray was used with a capillary voltage of +3500 V. Postacquisition internal mass calibration used sodium formate clusters with the sodium formate delivered by a syringe pump at the start of each chromatographic analysis. Each sample was analyzed in standard HRMS mode and then reanalyzed in HR/MS/MS mode to obtain information about the molecular fragments. mSigma values were calculated to compare measured isotope ratio matches with expected ratios. An automated MS/MS routine was used where the most intense ion present in a survey scan was isolated and then fragmented in the collision chamber in subsequent scans.

*Antioxidant Capacity Assays.* The antioxidant capacity of samples was determined by the DPPH (2,2-diphenyl-1-picrylhydrazyl) radical scavenging method. The steady state measurement variant of the method, based on different dilutions of the sample, was used as described by Buthkup et al.[29] with some modifications: 80% acetone was used as the solvent for DPPH samples and as the blank, and the control was 3.9 mL of DPPH solution + 0.1 mL of 80% acetone. A Cary 300 Bio UV−visible spectrophotometer was used to measure the absorbance at 517 nm; the maximum time before absorption measurement was 120 min. The results were expressed as the effective concentration $EC_{50}$, defined as the amount of antioxidant necessary to decrease DPPH radical absorbance by 50%. A more powerful antioxidant will thus have a lower $EC_{50}$ value. The assays were performed in triplicate and the results averaged.

**Antibacterial Assays.** *Bacterial Strains.* *Listeria monocytogenes* ScottA, *Staphylococcus aureus* ATCC 25923, *P. fluorescens*, *Serratia liquefaciens*, *Salmonella* Enteritidis, *P. phosphoreum*, *Hafnia alvei*, *Salmonella* Typhimurium, *S. putrefaciens*, *Yersinia enterocolitica*, and *Lactobacillus* sp. were obtained from The NZ Institute for Plant & Food Research Limited culture collection, NZ. *Escherichia coli* O157:H7, methicillin-resistant *S. aureus*, and *B. thermosphacta* were purchased from the Environmental Science & Research Centre, NZ. *C. estertheticum* and *Serratia proteomaculans* were kindly supplied by AgResearch, NZ. Bacterial strains were recovered in Brain Heart Infusion (BHI, Difco, NZ) and kept in blood agar plates (Fort Richard, NZ) at 4 °C for storage until the experimental day. Bacteria were grown in Mueller−Hinton broth (MHB, Difco) except for *L. monocytogenes* (grown in Trypticase Soya Broth supplemented with 0.6% of yeast extract, TSBYE, Difco) for 24−48 h prior to the experiments. Each bacterium was incubated at its optimal growth temperature to achieve $1 \times 10^8$ to $1 \times 10^9$ colony-forming units/mL (CFU/mL).

*Preparation of Compounds for Antibacterial Assays.* Extracts were weighed in sterile vials and kept at −20 °C. On the experimental day appropriate dilutions were performed to achieve the final concentration desired. Most of the compounds (Table 2) were diluted in sterile water, while PiTa, gallic acid, catechin, and CaTa were diluted in 80% acetone (ECP, NZ) to facilitate their dissolution.

*Gel Diffusion Assays.* The gel diffusion assays were carried out according to Eseifeka et al.[30] with some modifications. Compounds tested were solubilized as described above and prepared at a final concentration of 10 mg/mL. Bacteria were grown as described above and then centrifuged for 5 min at 4,000 rpm, washed twice with phosphate buffered saline solution, and resuspended in 10 mL of 1% salt peptone water (SPW: 1% NaCl, 0.1% Difco peptone) to achieve a final concentration of $1 \times 10^5$ to $1 \times 10^6$ CFU/mL. An aliquot (1 mL) of each bacterium suspension was placed into a Petri dish and immediately mixed with 18 mL of melted Mueller−Hinton agar (MHA) or Trypticase soya agar supplemented with 0.6% yeast extract (TSAYE, Difco) for *L. monocytogenes*. The plate was then gently swirled and the agar left to solidify in the laminar flow for ca. 30 min. Using a sterile 6 mm core borer, wells were made into the agar, and 35 μL of test compound solution was deposited into them. Appropriate diluent controls were included in all plates. Each of the bacteria was incubated at its optimum growth temperature (from 20 to 37 °C) for 24 to 48 h. The zones of (growth) inhibition (ZIs) surrounding the wells were measured with a digital caliper. A control disk containing 35 μL of 80% acetone was included in each tested plate. Three independent experiments were conducted in triplicate.

*Minimum Inhibitory Concentration (MIC) (NCCLS, 1993).*[31] The determination of MIC was only performed for some of the compounds, the selection being mainly based on the results of the ZI assays. The bacterial strains were prepared as described above with minor modifications. Bacteria were grown in MHB or TSBYE for 24−

[a]Delta (mDa) difference between the measured and calculated $m/z$ values for the assigned formula. [b]mSigma: numerical expression for the difference in the measured and calculated isotope pattern of a compound; low values indicate a good match. [c]Identification. [d]1. Positive identification: retention time, calculated elemental composition, mSigma value, and fragment ion masses all correspond to an authentic standard. 2. Tentative identification: elemental formula calculated with mSigma value support; possible structure identified in chemical databases (e.g., ChemSpider); fragment ion mass data supports the proposed molecular structure. 3. Possible identification: elemental formula calculated with mSigma value support; possible structure identified in chemical databases, but no support from fragment ion mass data. 4. Elemental identification: elemental formula calculated with mSigma values support but no suitable compound found in chemical database. 5. No identification: no reasonable calculated elemental formula fits the measured mass data. [e]Double charged ion [2−].

48 h. The cultures were then centrifuged for 5 min at 4,000 rpm, washed twice with phosphate buffered saline solution, and resuspended in 10 mL of 1% SPW. The test compounds were prepared as described previously to obtain a final concentration of 20 mg/mL. In a 96-well plate, an aliquot (120 $\mu$L) of MHB or TSBYE broth was distributed. Each bacterium was inoculated (5 $\mu$L) in duplicate into the wells. After that, compounds were 2-fold serially diluted (10 to 0.078 mg/mL) and added to the inoculated wells (125 $\mu$L). Absorbance measurements (OD 595 nm) were taken once the dilution was completed ($T_0$). Plates were incubated at the optimum growth temperatures of each bacterium. Final absorbance readings were taken after 24 h, and the level of growth inhibition was determined by comparing them with the readings at $T_0$ and subtracting control backgrounds. The MIC values were taken as the lowest concentration of compounds that completely inhibited the growth of the microorganisms after 24 h of incubation. Four independent experiments were conducted in duplicate. If a given replicate did not prevent growth at 10 mg/mL, a value of 20 mg/mL for the MIC was used to calculate means and standard errors.

## RESULTS AND DISCUSSION

**Phenolic Composition of Extracts.** The TPC and TFC of extracts are shown in Figure 1. The extracts contain some moisture (typically 5−10%), which was not considered in the TPC and TFC results. Anhydrous (+)-catechin, the external standard for checking the accuracy of the TPC assay, yielded the expected result of ∼1000 mg GAE/g. The extracts with high TPC values (>300 mg GAE/g) were either tannins or seed extracts, AvSk being the only exception. The mass data and identification attempts for the most abundant compounds (with retention times of 2−18 min) in each extract are shown in Table 3 (see Table 3 footnote for the definition of the different levels of identification).

The phenols of AvSk and AvSd consisted mostly of flavonoids, as shown by their high TFC/TPC ratios. Their TPC values were much higher than those reported by Rodríguez-Carpena et al.,[32] who extracted fresh avocado skins and seeds with 70% acetone. This may be due to differences in material preparation and extraction methods. The base peak chromatographs (BPCs) of AvSk and AvSd showed that these extracts contained a large number of compounds. Many of the compounds detected in these extracts were identified at levels 1−3 as procyanidin monomers, dimers, or oligomers. Phenolic acids were also detected in the avocado extracts. These results

are in agreement with the work of Rodríguez-Carpena et al.,[32] who found that the phenolic compounds in Hass avocado skins and seeds were predominantly procyanidins.

The condensed tannins (PiTa, MiTa, and CaTa) showed quite different TFC/TPC ratios. For PiTa it was high, which is supported by the LCMS results. Its BPC was relatively simple with only seven compounds. Dihydroquercetin and five procyanidins were identified with a high level of certainty (level 1 or 2). A much lower TPC of 363 mg GAE/g was reported for a commercial pine bark extract from *Pinus maritima*.[37] Regarding MiTa, its tannin content of ca. 77% of the dry matter (according to its technical datasheet) is somewhat higher than expected based on its TPC, even allowing for a moisture content of 10%. Since condensed tannins are proanthocyanidins, the rather low TFC/TPC ratio of MiTa is also surprising. However, the LCMS analysis showed that its main components are flavonoids. Cationic tannin is produced from mimosa tannin by the Mannich reaction, which introduces quaternary amino groups into the tannin. Based on the TPC and TFC values of CaTa and MiTa, this reaction reduces both TPC and the TFC/TPC ratio.

The high TPC and low TFC/TPC ratio of TaAc and MaSd are consistent with gallotannins. This is supported by the LCMS data showing the presence of polygalloyl glucoses containing 5−9 (TaAc) or 5−8 (MaSd) galloyl units, identified at level 3. The BPCs of the two extracts also had many similarities. Aragbo[1] found ca. 75% of tannin-related substances in mango seed to be gallotannins and 25% related to condensed tannins, while Kabuki et al.[34] found mango seeds to contain 79.5% of unspecified polyphenols. Engels et al.,[35] who extracted mango seeds with 80% acetone, found the seed extracts to contain galloyl glucoses with 4−12 galloyl groups.

Grape seed extracts have high TPC,[5] which was also the case for the one used in this investigation (GrSd). According to Nakamura et al.,[36] the phenolic substances in grape seed extracts are mainly oligomeric and polymeric proanthocyanidins with minor amounts of low molecular weight procyanidins and gallic acid. Our LCMS results gave similar results, although the most prominent components were identified as catechin and epicatechin at level 1. The BPC of GrSd resembled that of AvSk; some of their identified major components were also the same.

The extracts from berry juicing residues and some of the fruit skin extracts had moderate TPCs (57−172 mg GAE/g), their TFC/TPC ratios ranging from 0.24 to 0.61. The LCMS data show that FeSk phenols comprised flavonoids, ellagitannins, and phenolic acids. They often contained a pentoside or hexoside moiety and were identified at level 1 or 2. Earlier reports have shown that commonly eaten berries such as those included in this study contain the same types of phenols.[37]

The skins of most other fruits and AvPu gave low TPC values (<40 mg GAE/g), a result that agrees with earlier studies.[5,38] In the case of citrus fruit skin extracts, they have been reported to contain low amounts of flavonoids (glycosylated flavanones, flavones, and bound flavonols) and bound phenolic acids.[38]

**Antioxidant Capacity of Samples.** The $EC_{50}$ values of some reference compounds (Table 4), derived from the DPPH radical assay, were somewhat higher than those reported with methanol as the solvent by Mishra et al.[39] This could be due to the different solvents used in the studies. To enable comparison of reference compounds and extracts the $EC_{50}$ values were expressed as μg/mL in Figure 2. Only the extracts that yielded

**Table 4. Antioxidant Capacity of Reference Compounds**

| | $EC_{50}$, μmol of compound/μmol of DPPH | |
|---|---|---|
| compound | this study | Mishra et al. (2012)[39] |
| ascorbic acid | 0.29 ± 0.02 | 0.17 ± 0.01 |
| gallic acid | 0.09 ± 0.01 | 0.07 ± 0.01 |
| (+)-catechin, anhydrous | 0.25 ± 0.02 | n/a |
| (+)-catechin hydrate | 0.29 ± 0.02 | n/a |
| ferulic acid | 0.57 ± 0.05 | 0.36 ± 0.04 |
| Trolox | 0.32 ± 0.00 | n/a |

$EC_{50}$ values <50 μg/mL are included in Figure 2; the other extracts in Table 2 showed relatively weak antioxidant properties ($EC_{50}$ from 130 to 600 μg/mL). The ten extracts with the lowest $EC_{50}$ values and the highest TPCs are the same, showing that TPC is a good predictor of antioxidant capacity.[33] In fact, the Folin−Ciocalteu method used for TPC determination is also an antioxidant assay. Any nonphenolic antioxidants such as ascorbic acid, if present, would thus also contribute to the TPC value. The large variability of the TFC/TPC ratios between these extracts implies that, for the majority of them, it is the quantity rather than the type (flavonoid vs nonflavonoid) of phenols that matters for antioxidant capacity. However, the antioxidant capacity of the mainly nonflavonoid extract MaSd was higher than those of the mainly flavonoid-type GrSd and PiTa, which had higher TPCs. Flavonoid-type phenols are known to possess significant antioxidant activity.[40] Arogba's finding[1] of more tannin-related compounds in mango seed meal than condensed tannins suggests that gallic acid units (three hydroxyls per aromatic ring), which may be free (gallic acid) or esterified (e.g., polygalloyl glucoses in TaAc), contribute more to antioxidant capacity than catechin, epicatechin, or other flavonoid units (typically 1−2 phenolic hydroxyls per aromatic ring). This hypothesis is corroborated by the very high antioxidant capacity of TaAc and a comparison of the antioxidant capacities of gallic acid and catechin (Table 4), representing gallotannins and condensed (flavonoid-type) tannins, respectively. The high antioxidant capacities of TaAc and MaSd can thus be traced back to their similar phenolic structures and high TPCs. The antioxidant capacity of TaAc exceeded those of the nonphenolic antioxidants ascorbic acid and Trolox (a synthetic, water-soluble variant of vitamin E).

The extract from mango (MaSd) also compares favorably with the commercial grape seed extract (GrSd), a dietary supplement, and the other berry extracts. Avocado extracts (AvSk and AvSd) also performed well, better than the berry extracts. As mentioned earlier, the phenolic profiles of GrSd and AvSk are rather similar. Condensed tannins and kiwifruit extracts are also found in some dietary supplements. African mango seed extract is commercially available; however, a sample obtained for the present study showed a very low TPC of 23 ± 2 mg/g GAE. No commercial avocado skin or seed based dietary supplements seem to be available. Since mango seeds and avocado skins/seeds are produced in large quantities as byproducts of the mango juice and avocado oil[4] industries, respectively, these fruit parts could potentially be exploited to a greater extent for dietary supplement production in a similar fashion to the grape seed extracts currently used.

**Antibacterial Activity of Extracts.** ZI assays were carried out on 18 extracts with high TPCs, and the results are shown in Table 5. Thermally modified TaAc (mTaAc) proved to have the highest antibacterial activity in terms of ZI diameter and range of bacteria affected. The purpose of the thermal

modification was to find out whether compounds such as pyrogallol, produced during the treatment, would enhance the antibacterial activity of TaAc.[26] According to Kim et al.,[26] the antibacterial activity measured by the formation of zone of growth inhibition ZI data of mTaAc against several Gram-positive and Gram-negative bacteria increased with an increase in treatment temperature. The increase was attributed to production of gallic acid and pyrogallol, which were found to have greater antibacterial activity than unmodified tannic acid. The product obtained at the highest treatment temperature

(200 °C) also showed greater antibacterial activity than gallic acid but not as great as pyrogallol. The results of our ZI assay (mTaAc > TaAc > gallic acid; pyrogallol was not investigated) are partly in line with Kim's findings.[26] In general, the extracts with a high or moderately high antioxidant capacity produced large ZIs with most bacteria. The monomeric reference compounds gallic acid and catechin, however, had much lower antibacterial activity than the extracts rich in polygalloyl glucoses (TaAc, MaSd) or procyanidins of different sizes and monomeric flavanols (PiTa, GrSd). Our findings agree with those of Chung et al.,[41] who reported tannic acid to be a more potent antibacterial agent than gallic acid against food-borne bacteria.

The MIC assays were only carried out for selected extracts (Table 6) based on their performance in the ZI assays and potential availability as byproducts. The best-performing extracts in the ZI and MIC assays were clearly MaSd and TaAc, followed by mTaAc and FeSk. According to Engels et al.,[35,42] the antibacterial activity of mango seed extracts is due to the iron-chelating ability of the gallotannins with steric effects making the smaller gallotannins somewhat more effective than the larger ones. Other antibacterial chelating compounds such as mangiferin[43] (a tetrahydroxyxanthone glucoside) worked synergistically with the gallotannins. A tetrahydroxyxanthone glucoside was also identified in MaSd at level 3. The fact that MaSd and TaAc exhibited similar antibacterial activities despite the large difference in their TPC could thus be largely due to the presence of mangiferin (and/or other chelating compounds). Their different gallotannin size distributions, resulting in different degrees of steric hindrance, could also affect their relative antibacterial activities.[42] The weak antibacterial effects of gallic acid compared to TaAc and MaSd are likely due to the fact that the iron ($Fe^{3+}$) chelates formed by the extracts are able to form lattices by coordinating with up to three *o*-dihydroxyphenyl moieties, possibly from different molecules, until the complexes get large enough to precipitate out of the solution.[42] In general, the highest levels of antibacterial activity were seen against the Gram-positive bacteria: *S. aureus*, *C. estertheticum*, *B. thermosphacta*, and *L. monocytogenes*. The Gram-negative bacterium *S. putrefaciens* and *Lactobacillus* sp. (Gram-positive) were more difficult to inhibit than Gram-positive bacteria as only AvSk and AvSd showed low MICs against them. Gram-negative bacteria are usually more resistant to antibacterial agents than Gram-positive because of their protective polysaccharide layer,[44] as it was also observed in the present study. This becomes important as many pathogenic and spoilage bacteria are Gram-negative.

A comparison of the MIC values with the spoilage bacteria information in Table 1 shows that MaSd and TaAc in particular are able to provide significant inhibition of several major fish and lamb spoilage bacteria while also inhibiting many pathogenic bacteria. Kabuki et al.[34] found that the MIC profile of ethanolic mango seed extract was different from those of flavonoid-based ethanolic extracts (tea catechins and theaflavins). Also FeSk and mTaAc gave relatively low MIC values against several of the bacteria tested. Based on the MIC and ZI results, these four extracts proved the most promising candidates for antibacterial packaging films able to extend the shelf life of chilled fish and lamb. As for the other compounds, their MIC values may be too high for such applications despite their ZI activity at the dose investigated. This is the case especially when activity against a broad range of bacteria is desired. Before any packaging materials containing these compounds may be used for food transport, however, the migrating compounds and the packaging material (at least its food contact layer) must comply with strict toxicity criteria. These depend on the type of compound and the expected level of migration. For any novel compounds or packaging materials, nontoxicity must be demonstrated unless exclusion from toxicity testing has been granted. Migration limits include compound-specific limits and maximum limits applying to all compounds (e.g., 60 mg/kg food in the EU) regardless of toxicity. Compliance with these issues should be an integral part of antimicrobial packaging design from the outset. Using compounds (of natural origin where possible) and packaging materials approved for food contact by European Food Safety Authority (EFSA), the US Food and Drug Administration (FDA), and other food safety authorities can significantly reduce testing requirements and improve the chances of finding feasible antibacterial packaging solutions.

To sum up, based on our in vitro assays, the most promising natural extracts for antibacterial packaging films were MaSd and TaAc, i.e., the extracts rich in polygalloyl glucoses and with the highest antioxidant capacity. However, the TPC and LCMS

analyses indicate that TaAc is higher in polygalloyl glucoses than MaSd, whose antibacterial activity was somewhat higher. This could be due to the different polygalloyl (penta- to nonagalloyl) glucose size distributions in the two extracts or other components in MaSd working synergistically with polygalloyl glucoses and/or showing high antibacterial activity on their own. Extracts rich in flavonoid type phenols showed a moderate level of antibacterial activity while those with low total phenol content displayed low activity. Further work should be carried out on the extracts based on polygalloyl glucoses, particularly relating to the economics of using them in supplement and packaging applications and in relation to their safety for human consumption.

evaluated. The primary structure−activity relationship of the MGDGs was also discussed.

## MATERIALS AND METHODS

**Chemicals.** Spectral-grade solvents for spectroscopic measurements were obtained from Sigma-Aldrich. High-performance liquid chromatography (HPLC)-grade solvents were obtained from Merck, Inc. (Merck KgaA, Darmstadt, Germany). All of the other solvents were of analytical grade (Yuwang Reagent Company, Shandong, China).

Cell culture materials, such as Dulbecco's modified Eagle's medium (DMEM), fetal bovine serum (FBS), trypsin, glutamine, and penicillin/streptomycin (PES), were obtained from Gibco. Dexamethasone, 3-isobutyl-methylxanthine, insulin, and dimethyl sulfoxide (DMSO) were obtained from Sigma-Aldrich. The TG kit was purchased from BioSino Biotechnology and Science, Inc., China, and the NEFA-C kit was purchased from NEFA C-test Wako, Japan.

**General Experimental Procedures.** Optical rotation was measured on a PerkinElmer model 241 polarimeter (Norwalk, CT). $^1$H and $^{13}$C nuclear magnetic resonance (NMR) spectra were recorded on JEOL JNM-ECP 600 spectrometers using tetramethylsilane (TMS) as the internal standard, and chemical shifts were recorded as $\delta$ values. Silica gel (100−200 and 200−300 mesh, Qingdao Haiyang Chemical Co., Ltd., Qingdao, China) and Sephadex LH-20 (GE Healthcare Bio-Sciences AB, Uppsala, Sweden) were used for column chromatography. Thin-layer chromatography (TLC) silica gel $GF_{254}$ plates (Yantai Zi Fu Chemical Co., Ltd., Yantai, China) were used for TLC analysis.

**Plant Material.** Fronds of *S. horneri* (Turner) C. Agardh were collected from Changdao in Shandong, China, in October 2010. The original seaweed was identified by Prof. Xiaoqi Zeng (College of Fisheries, Ocean University of China), and a voucher specimen was deposited at the School of Medicine and Pharmacy, Ocean University of China. The alga was washed using water after its collection, dried thoroughly, and stored at room temperature.

**Extraction and Isolation.** *S. horneri* (1170.8 g) was powdered and repeatedly refluxed 3 times with 70% alcohol to obtain a hydroalcoholic solution. The solution obtained was concentrated under reduced pressure, and the remaining aqueous suspension was extracted with the same volume of ethyl acetate (EtOAc) to obtain an EtOAc extract.

The EtOAc extract (4.25 g) was fractionated using vacuum liquid chromatography (VLC) over silica gel by gradient elution using $CH_2Cl_2$/MeOH. The sixth fraction (95:5 $CH_2Cl_2$/MeOH, 853.6 mg) was subsequently separated over Sephadex LH-20 with $CH_2Cl_2$/MeOH (1:1), followed by flash silica gel column chromatography with $CH_2Cl_2$/MeOH (96:4) to obtain a mixture of MGDGs (white powder, 153.4 mg).

The purity of the MGDGs was analyzed using TLC developed with three solvent systems (I, 93:7 $CH_2Cl_2$/MeOH; II, 1:2 $CH_2Cl_2$/EtOAc; and III, 1:1 $CH_2Cl_2$/$Me_2CO$). Only one purplish pink spot was visualized using a 5% methanolic sulfuric acid spray, followed by heating at 115 °C.

**Structure Elucidation of MGDGs.** White amorphous powder. $^1$H NMR (600 MHz, $CDCl_3$) $\delta$: 4.39 (1H, dd, $J$ = 3.1 and 12.0 Hz, H-1), 5.29 (1H, m, H-2), 3.91 (2H, dd, $J$ = 5.4 and 11.1 Hz, H-3), 4.26 (1H, d, $J$ = 7.6 Hz, H-1′), 3.66 (1H, m, H-2′), 3.59 (1H, m, H-3′), 3.69 (1H, m, H-4′), 3.54 (1H, t, $J$ = 5.3 Hz, H-5′), 3.84 (1H, dd, $J$ = 4.4 and 11.8 Hz, H-6′), 3.71 (1H, m, H-6′), 1.25−1.35 [brs, $(CH_2)_n$], 0.87 (6H, t, $J$ = 7.0 Hz, $CH_3$). $^{13}$C NMR (150 MHz, $CDCl_3$) $\delta$: 63.0 (C-1), 70.3 (C-2), 68.2 (C-3), 104.2 (C-1′), 71.4 (C-2′), 73.6 (C-3′), 69.2 (C-4′), 74.7 (C-5′), 62.0 (C-6′), 174.0 and 173.6 (−CO−), 27.3−34.4 [$(CH_2)_n$], 14.3 ($CH_3$). This powder was identified to be 1,2-*O*-diacyl-3-*O*-$\beta$-D-galactopyranosylglycerol (MGDG) by comparing NMR data to the literature.[14]

**Alkaline Hydrolysis.**[15−17] A solution of the total MGDGs (35 mg) in MeOH (3.5 mL) was treated with 5% NaOMe/MeOH (3.5 mL) under stirring at room temperature for 10 min. The mixture was extracted with hexane 3 times. The hexane layer was washed with $H_2O$, dried over anhydrous $Na_2SO_4$, and evaporated to yield a mixture of fatty acid methyl esters (FAMEs). The MeOH layer was neutralized with 2 N HCl/MeOH and evaporated to give a solid residue, which was purified using flash silica gel column chromatography with $CH_2Cl_2$/MeOH (16:9) to obtain monogalactosylglycerol. The optical rotation of the monogalactosylglycerol was then measured to resolve the absolute configuration of glycerol.

**Gas Chromatography−Flame Ionization Detector (GC−FID) Analysis.** GC analysis was performed using a HP 5890 series II chromatograph (Hewlett-Packard, Avondale, PA) equipped with a flame ionization detector (FID), and a SGE 30QC3/AC 20-0.5 capillary column (30 m × 0.32 mm, 0.5 $\mu$m, SGE Analytical Science, Ringwood, Australia) was used for separation. Nitrogen was used as the carrier gas at a flow rate of 1.0 mL/min. The oven temperature was held at 150 °C for 1 min, increased by 15 °C/min to 200 °C, and then increased by 2 °C/min to 250 °C. The injector temperature was set at 270 °C, and the detector temperature was 270 °C. The injection volume was 0.6 $\mu$L.

**Identification of the Molecular Species in MGDGs.** High-performance liquid chromatography−tandem mass spectrometry (HPLC−MS/MS) analysis was performed using a Waters ACQUITY liquid chromatography system (Waters Corp., Milford, MA) coupled with a diode array detector (DAD) and an Amazon SL mass spectrometer (Bruker Daltonics, Bremen, Germany). The HPLC separation used a YMC ODS Pack-A C18 column (250 × 4.6 mm inner diameter, 5 $\mu$m, Tokyo, Japan). The mobile phase was a mixture of water (A) and methanol (B) as follows: 0−40 min, 96 → 100% B; and 40−50 min, 100% B. A flow rate of 1.0 mL/min with detection at 203 nm was used. The injection volume was 10 $\mu$L, and injections were performed using the autosampler.

Electrospray ionization−quadrupole ion trap mass spectrometry (ESI−QITMS) in positive-ion mode was used. The parameters of the ESI interface were as follows: high-voltage (HV) capillary, 4500 V; HV end plate offset, −500 V; MS/MS isolation width, 4.0 units; and collision gas, helium. All skimmer collisionally activated dissociation (CAD) and MS/MS spectra represent averages of five scans. In the MS/MS experiment, the data-dependent MS/MS scan mode was used. The scan mass range was $m/z$ 100−1000.

**Preparation of Major MGDG Molecular Species.** Semi-preparative HPLC was performed on a Shimadzu LC-6AD (Tokyo, Japan) coupled to a photodiode array detector (SPD-M20A). The semi-preparative HPLC column (250 × 10 mm inner diameter, 5 $\mu$m) was prefilled with C18 (YMC ODS Pack-A, Tokyo, Japan), and a linear gradient of $H_2O$ (A) and MeOH (B) was used at a flow rate of 4.0 mL/min. The following elution program was used for separation: 0−40 min, 96 → 100% B; 40−50 min, 100% B; and 50−55 min, 100 → 96% B. The detection wavelength was 203 nm. This preparation yielded compounds **1** (3.1 mg), **3** (1.7 mg), **5** (3.4 mg), **9** (6.4 mg), and **10** (26.2 mg) as well as a mixture of compounds **7** and **8** (12.1 mg).

**Bioassay.** The inhibitory effect on lipid accumulation was assessed in 3T3-L1 adipocytes by measuring the intracellular contents of TG and FFAs. 3T3-L1 preadipocytes were cultured and induced to differentiate into adipocytes as previously described.[18−20] Briefly, confluent 3T3-L1 preadipocytes after 1 day were treated with 1 $\mu$mol/L dexamethasone, 0.5 mmol/L 3-isobutyl-methylxanthine, and 10 $\mu$g/mL (270 munits/mL) insulin for 3 days in high-glucose DMEM containing 10% FBS. At the same time, cells of compound-treated groups were treated with 10 $\mu$M MGDGs **1**, **3**, **5**, **7** + **8**, **9**, or **10** dissolved in DMSO (final DMSO concentration of 0.5%, v/v), respectively. While for the control group, cells were cultured without compounds. Cells were then switched to 10% FBS/DMEM containing only 5 $\mu$g/mL (135 munits/mL) insulin for 3 more days and then switched to 10% FBS/DMEM without insulin. In a normal group, cells were cultured without induction medium or any compounds.

At 14 days after induction of differentiation, 3T3-L1 cells in 48-well plates were lysed and analyzed using the TG kit and the NEFA-C kit according to the protocols provided by the manufacturers. The TG and NEFA values were corrected by their protein content.

**Statistical Analysis.** Values are expressed as the mean ± standard deviation (SD). Statistical analysis was performed with SPSS 11.0. Significant differences between means were evaluated by one-way analysis of variance (ANOVA), and Tukey's studentized range test was used for post-hoc evaluations. $p < 0.05$ was considered to indicate statistical significance.

## RESULTS

**Isolation and Structure Elucidation of MGDGs.** The EtOAc extract of *S. horneri* was chromatographed repeatedly over silica gel and Sephadex LH-20 to obtain a mixture of MGDGs as white powder (Figure 1). The $^1$H NMR spectrum

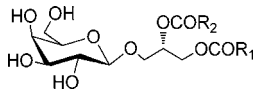

**Figure 1.** Structure of MGDGs.

showed the following characteristic signal pattern because of glycoglycerolipid: a triplet at $\delta_H$ 0.87 (6H, t, $J$ = 7.0 Hz, terminal methyl in fatty acyl), a broad signal centered at $\delta_H$ 1.27 (methylene in the fatty acyl), a mass of signals between $\delta_H$ 3.5 and 5.3 (12H, sugar and glycerol moiety), and a doublet signal at $\delta_H$ 4.26 (1H, d, $J$ = 7.6 Hz, anomeric proton). The $^{13}$C NMR spectrum revealed one anomeric carbon at $\delta_C$ 104.2 and two carbonyl carbons at $\delta_C$ 174.0 and 173.6. The spectrum was identified as MGDGs by comparison of the NMR spectra to previously reported data.[14] To determine the absolute configuration of C-2 in the glycerol moiety, an alkaline hydrolysis experiment was performed. The monogalactosylglycerol from the MeOH layer was identified as (2*R*)-1-*O*-*β*-D-galactopyranosylglycerol with $[\alpha]_D^{25}$ 7.7° (*c* 0.8, $H_2O$) (9.0°,[15] 10.1°,[16] or 7.9°[21]). The optical rotation of (2*S*)-1-*O*-*β*-D-galactopyranosylglycerol was reported to be +6.2°.[17]

The composition of fatty acids was identified through GC–FID analysis for FAMEs, which was derived from an alkaline hydrolysis experiment. The following composition was identified: a mixture of myristate (14:0), palmitate (16:0), palmitoleate [16:1(*ω*-7)], oleate [18:1(*ω*-9)], linoleate [18:2(*ω*-6)], and linolenate [18:3(*ω*-3)] in the ratio of 21.1:29.3:8.0:9.4:12.5:19.6.

**Identification of the MGDG Molecular Species.** The composition of molecular species of MGDGs in *S. horneri* was clarified through HPLC–MS/MS. A total of 10 MGDGs were found under the optimized HPLC condition (Figure 2), and their identities are shown in Table 1 (MS/MS spectrum; see the Supporting Information). The molecular weight of each MGDG was determined by $[M + Na]^+$ and $[M + NH_4]^+$ ions in positive ESI–MS. In the following MS/MS, the precursor $[M + NH_4]^+$ ions produced fragment ions, namely, $[M + H - 180]^+$ and $[M + H - 162]^+$, because of the loss of a galactosyl moiety, and the precursor also produced $[R_xCO + 74]^+$ ions because of the loss of the neutral fatty acid. In addition, the precursor $[M + Na]^+$ ions yielded a pair of abundant fragment ions, namely, $[M + Na-R_xCOOH]^+$, which were derived from the neutral loss of free fatty acid from the *sn*-1 ($x$ = 1) or *sn*-2 ($x$ = 2) position. These two ions were easy to distinguish in MS/MS spectra because of their high peak intensity. Most importantly, the peak intensity of $[M + Na-R_1COOH]^+$ was always greater than that of $[M + Na-R_2COOH]^+$,[22−24] which was used to determine the fatty acyl attachments in each MGDG.

For example, MGDG **10** (Figure 3) had a molecular formula of $C_{43}H_{80}O_{10}$ and was assigned on the basis of $m/z$ 779 (100%, $[M + Na]^+$) and 774 (35%, $[M + NH_4]^+$) as well as relevant ions $m/z$ 595 (11%, $[M + H - 162]^+$) and 577 (19%, $[M + H - 180]^+$). The base peak at $m/z$ 523 (100%, $[M + Na-R_1COOH]^+$) and the minor peak at $m/z$ 497 (37%, $[M + Na-R_2COOH]^+$) in the MS/MS spectra indicated that hexadecanoyl (palmityl, 16:0) was linked to the *sn*-1 position and that octadecadienoyl (18:1) was linked to the *sn*-2 position. In combination with the GC analysis results, the 18:1 fatty acyl was determined as oleoyl [18:1(*ω*-9)].

On the basis of the above findings, 10 molecular species of MGDGs were identified (Figure 1 and Table 1).

**Preparation of Major MGDG Molecular Species.** The major MGDGs (**1**, **3**, **5**, **9**, and **10** as well as a mixture of **7** and **8**) were subsequently obtained using semi-preparative HPLC. This study was the first report on the MGDG molecular species **3**, **5**, **9** and **10** isolated from *S. horneri*.

**Effect of MGDG Molecular Species on TG and FFA Levels in Mature 3T3-L1 Adipocytes.** 3T3-L1 preadipocytes were treated with compounds **1**, **3**, **5**, **9**, and **10** as well as the mixture of compounds **7** and **8** at a concentration of 10 $\mu$M.

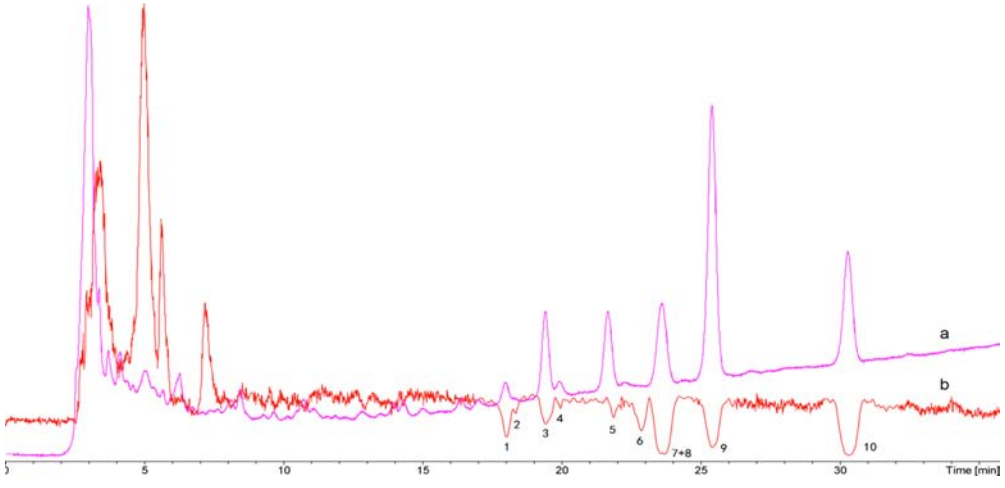

**Figure 2.** HPLC–MS analysis of MGDGs from *S. horneri*: (a) high-performance liquid chromatography–diode array detection (HPLC–DAD) chromatogram at 203 nm and (b) total ion chromatogram (TIC).

**Table 1. HPLC−MS/MS Analysis of MGDGs 1−10**

| MGDG | *sn*-1/*sn*-2 | molecular formula | molecular weight | MS data $[M + Na]^+$ | MS/MS data $[M + Na-RCOOH]^+$ | retention time (min) |
|---|---|---|---|---|---|---|
| **1**[a] | 14:0/16:1 | $C_{39}H_{72}O_{10}$ | 700 | 723 (100) | 495 (100), 469 (38) | 17.9 |
| **2** | 16:0/14:1 | $C_{39}H_{72}O_{10}$ | 700 | 723 (100) | 467 (100), 497 (41) | 18.4 |
| **3**[a] | 14:0/18:2 | $C_{41}H_{74}O_{10}$ | 726 | 749 (100) | 521 (100), 469 (42) | 19.5 |
| **4** | 16:0/16:2 | $C_{41}H_{74}O_{10}$ | 726 | 749 (100) | 493 (100), 497 (39) | 20.0 |
| **5**[a] | 16:0/18:3 | $C_{43}H_{76}O_{10}$ | 752 | 775 (100) | 519 (100), 497 (40) | 21.4 |
| **6** | 14:0/16:0 | $C_{39}H_{74}O_{10}$ | 702 | 725 (100) | 497 (100), 469 (52) | 22.8 |

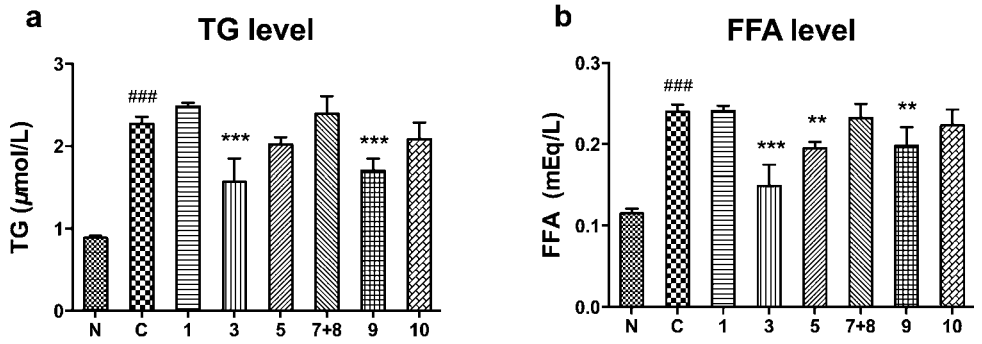

**Figure 4.** Effects of MGDGs on TG and FFA levels in 3T3-L1 adipocytes. The following groups were analyzed: N, normal groups, cells were cultured without induction medium or any samples; C, control groups, cells were cultured with induction medium for 14 days; compound-treated groups, cells were cultured with induction medium and treated with 10 μM MGDGs **1**, **3**, **5**, **7** + **8**, **9**, and **10** for 14 days. At 14 days after induction of differentiation, the cells were lysed using an Omni Ruptor and analyzed using the TG and NEFA kits according to the protocols provided by the manufacturers. Data represent the means ± SD of six determinations. (###) $p < 0.001$ versus the normal group. (**) $p < 0.01$ and (***) $p < 0.001$ versus the control group.

At this concentration, there were no treatment-related changes in cell viability [3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) method; data not shown].

In comparison to untreated cells (Figure 4), compounds **3** [*sn*-1/*sn*-2 14:0/18:2(ω-6)] and **9** [*sn*-1/*sn*-2 16:0/18:2(ω-6)] significantly suppressed the accumulation of TGs in mature 3T3-L1 cells with TG levels of 1.568 ± 0.2808 and 1.701 ± 0.1460 μmol/L, respectively. In contrast, compounds **1** [*sn*-1/*sn*-2 14:0/16:1(ω-7)], **7** [*sn*-1/*sn*-2 14:0/18:1(ω-9)] and **8** [*sn*-1/*sn*-2 16:0/16:1(ω-7)], and **10** [*sn*-1/*sn*-2 16:0/18:1(ω-9)] did not effectively suppress the accumulation of TG levels, with TG levels of 2.484 ± 0.0460, 2.395 ± 0.2148, and 2.084 ± 0.2015 μmol/L, respectively (Figure 4a). The FFA content in mature 3T3-L1 cells was also determined. Compounds **3**, **5**, and **9** showed inhibitory effects on FFA accumulation, with FFA levels of 0.149 ± 0.0258, 0.195 ± 0.0079, and 0.198 ± 0.0229 mequiv/L, respectively (Figure 4b). As a result, the pattern of inhibitory effects on FFA levels was similar to that on TG accumulation. These results indicated that some MGDG molecular species from *S. horneri* reduced the TG and FFA

levels in lipid metabolism, and these results also indicated that linoleyl [18:2(ω-6)] at the *sn*-2 position was an essential group for these activities.

## DISCUSSION

The present study showed that palmitic acid (16:0) was the most abundant fatty acid (FA) in the MGDGs of *S. horneri*. This result agreed with Terasaki et al.[25] and Airanthi et al.,[26] who reported that 16:0 is the major FA in the total lipids of the same species. The major unsaturated fatty acids (UFAs) found in our study were $C_{18}$ UFAs [including 18:3(ω-3), 18:2(ω-6), and 18:1(ω-9)], which differed from the study by Hossain et al.,[27] who reported that $C_{20}$ UFAs are the major UFAs in this species. The FA composition is influenced by species[28,29] and environmental factors.[29−31] Seasonal variation is an important factor for the difference in polyunsaturated fatty acid (PUFA) species. Sanina et al.[30] reported that partial substitution of $C_{20}$ by $C_{18}$ PUFAs in glycolipids occurs from summer to winter in marine macrophytes. Our results supported this view because the seaweed used in the present study was collected in October, but $C_{20}$ UFAs were not detected. This result was due to the extraction and isolation process, which is often used for studies on chemical constituents of traditional Chinese medicine (TCM). Procedures using classic lipid extraction methods[32,33] as well as anti-enzyme and antioxidant measures should be used in future studies.

MGDGs identified in the present study contained mainly $C_{14}$ and $C_{16}$ saturated FAs at the *sn*-1 position as well as $C_{18}$ and $C_{16}$ unsaturated FAs at the *sn*-2 position of the glycerol backbone. The eukaryotic pathway consists of two reactions involving glycoglycerolipid synthetase in the plastid and endoplasmic reticulum (ER). The synthetase in the plastid mainly generates glycoglycerolipids containing 16 carbon atoms at the *sn*-2 position, and the synthetase in the ER generates glycoglycerolipids containing 18 carbon atoms at the *sn*-2 position.[34,35] Our data suggested that the glycoglycerolipid synthetase in *S. horneri* exists in both the plastid and ER.

Compounds **3** and **9** with linoleyl [18:2(ω-6)] at the *sn*-2 position of the glycerol backbone showed stronger inhibitory effects on TG and FFA accumulation than the other compounds. Saturated fatty acyl (14:0 and 16:0) at the *sn*-1 position contributed to the inhibitory effect. As a well-known essential fatty acid, linoleic acid [18:2(ω-6)] functions as a precursor of arachidonic acid [20:4(ω-6)] and a series of pro-inflammatory eicosanoids. Linoleic acid can regulate low-density lipoprotein cholesterol (LDL-C) metabolism by downregulating LDL-C production and enhancing its clearance.[36] Studies have demonstrated that linoleic acid also suppresses sterol regulatory element-binding protein 1c (SREBP-1c) expression[37] and activates peroxisome proliferator-activated receptor (PPAR) α and γ,[38,39] thus leading to lipid degradation.

Metabolic disorders, such as obesity, type-2 diabetes, and metabolic syndrome, can occur when TG and FFA accumulate in adipocytes.[19] Our results introduced a new chemical structure type of MGDGs with linoleyl in the *sn*-2 position that can reduce the levels of TG and FFA in adipocytes, which might be beneficial for lipid metabolism improvement. Because lipid metabolism disorders are an important risk factor of CVDs, our findings also indicated that MGDGs in *S. horneri* might be important effective components associated with the anti-CVD function of this edible seaweed.

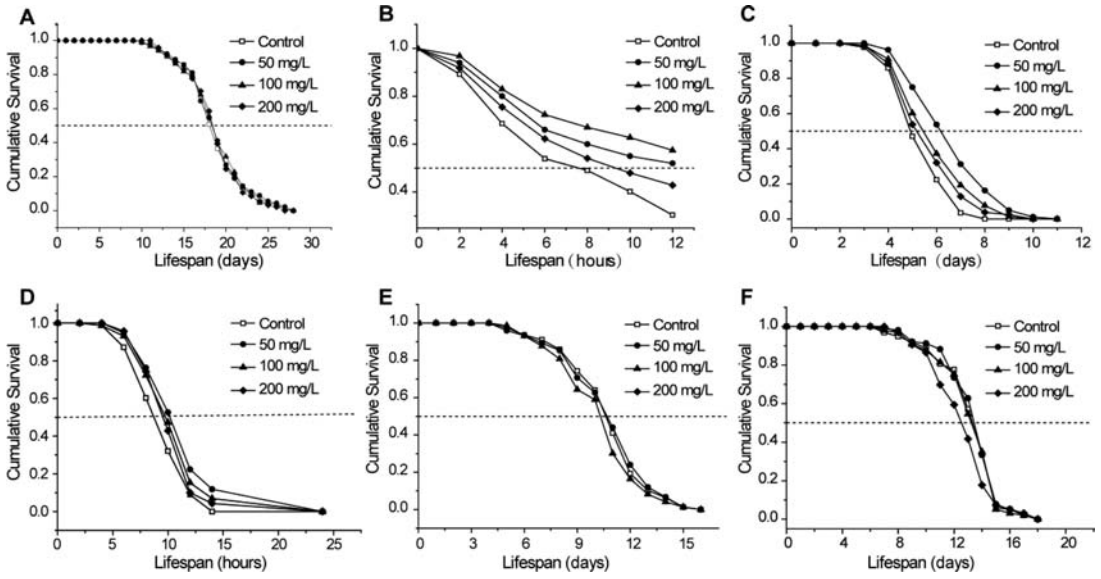

**Figure 1.** BTE treatment results in the alterations of stress response to specific environmental stimuli. (A) Effect of BTE on the lifespan of wild type N2 nematodes under normal culture conditions at 25 °C. (B) Survival of wild type N2 nematodes during 12 h of exposure in 500 mM NaCl. (C) BTE effects of UV irradiation at a dose of 2000 J/m$^2$. (D) Survival of wild type N2 nematodes at 35 °C until all worms are dead. (E) BTE-pretreatment effects on acute $MnCl_2$-induced toxicity. (F) BTE-post-treatment effects on acute $MnCl_2$-induced toxicity.

adding 0.5 L of boiling deionized water to the black tea for 30 min, and subsequently filtering through cotton wool. Each infusion was mixed and freeze-dried. BTE was stored at −20 °C and dissolved in water before use. The composition of BTE was shown in Table S1.

***Caenorhabditis elegans* strains and maintenance.** Wild type N2, TK22 (*mev-1(kn1)*), and VC199 (*sir-2.1 (ok434)*) strains were used in the experiments. The University of Minnesota *C. elegans* Genetics Center (CGC) provided all strains. Strains were maintained at 20 °C on standard nematode growth medium (NGM) with dead *E. coli* OP50 (killed by UV, 9999 J/m$^2$) (as shown in Figure S1) as food source. Age-synchronized nematodes were propagated using the sodium hypochlorite/NaOH method,[10] and cultured on Ø60 mm Petri dishes at 20 °C. All assays were performed at 25 °C unless otherwise stated, and plates in stress resistance assays contained 50 $\mu$M 5-fluoro-2′-deoxyuridine (FUDR) (Sigma-Aldrich, St. Louis, MO, USA). All tested *C. elegans* strains were assessed in triplicate, and three replicates of all trials were performed. BTE (50, 100, or 200 mg/L) was diluted into a suspension of dead *E. coli* OP50, which corresponded to the BTE concentrations we evaluated, and then added to the surface of the NGM plates to the final indicated concentrations. All lifespan and stress assays were conducted in a double-blind manner.

**Lifespan assays.** All lifespan assays were performed according to standard protocols.[11] In brief, age-synchronized wild type N2 (4 days old) nematodes were transferred to NGM plates with BTE or controls to establish the entire nematode lifespan. The number of individuals alive was counted every day, and mortality was recorded until 100% mortality was achieved. Lifespan assay of *mev-1* nematodes (5 days old) was conducted under the same culture conditions.

**Stress assays.** For stress assays, age-synchronized wild type N2 and VC199 (4 days old) nematodes were treated with BTE for 2 d, or controls in the absence of BTE; then nematodes were subsequently transferred to high-salt plates containing 500 mM NaCl (Sinopharm Chemical Reagent, CO, Shanghai, China), 35 °C, UV irradiated in a UVP CL-1000 Ultraviolet Cross-linker (Cambridge, UK) with a dose of 2000 J/m$^2$ and acutely exposed for 30 min to 35 mM manganese chloride ($MnCl_2$) (Sinopharm Chemical Reagent, CO. Shanghai, China), which corresponded to LD25 for $MnCl_2$.[12] The mortality rate was determined by recording the number of dead nematodes over a 1 or 2 h period in heat shock and osmotic stress assays. The survival rate was scored for 1 or 2 h until the controls reached approximately 50% mortality, and once per day in UV and $MnCl_2$ stress assays by touch-provoked movement; animals that failed to respond were considered dead.

The acute $MnCl_2$ treatments assay was also conducted as below; age-synchronized N2 (4 days old) nematodes were acutely exposed for 30 min at 25 °C to 35 mM $MnCl_2$.[12] Then the nematodes were subsequently washed and placed on the control or BTE plates.

**Measurement of reactive oxygen species.** Intracellular reactive oxygen species (ROS) in *C. elegans* were determined by dichloro-fluorescin diacetate (DCF-DA). Nematodes were collected and lysed in 48 h of treatment. Samples were analyzed immediately after lysis. The analysis was performed according to a commercially available kit (Beyotime Institute of Biotechnology, China) as previously described.[13−15] Samples were read every 20 min for 2 h at excitation 488 nm and emission 525 nm.

**Activities of superoxide dismutase (SOD), catalase (CAT), and glutathione peroxidase (GSH-PX).** SOD, CAT, and GSH-PX activities were measured spectrophotometrically using commercially available kits (Nanjing Jiancheng Bioengineering Institute, China) according to the manufacturer's instructions, respectively. The protein contents were determined by a commercially BCA kit (Auragene, China).

**Quantitative RT-PCR.** Total RNA was isolated using Trizol (Invitrogen, USA), and cDNA was synthesized using a cDNA synthesis kit (Takara, Dalian, China). qRT-PCR was carried out using SYBR Premix Ex Taq (Takara, Japan) and the Rotor Gene Q (Qiagen, Germany). qRT-PCR was performed for *sod-3*, *daf-16*, *sir-2.1*, *osr-1*, *skn-1*, *hsf-1*, and *sek-1* and normalization of transcript quantity was carried out using the *actin* genes. Samples were run in triplicate ($n$ = 3), and the primers were shown in Table S2.

**Statistical analyses.** Data were expressed as means ± SD (standard deviation). Lifespan assays were processed using the Kaplan-Meir test, and the log rank test was applied to determine significant differences among group scored data using SPSS 18.0 (Demo version, Armonk, NY). One-way Analysis of Variance (ANOVA), followed by $t$-tests, was used to ascertain significant differences between the controls and BTE treated groups in the Origin 8.0 software (Demo version, Northampton, MA). Differences were considered significant at the $P \leq 0.05$ level.

## RESULTS

### BTE increased resistance of the wild type N2 to high osmotic stress, severe heat shock, and UV irradiation,

**but did not affect lifespan and attenuated $MnCl_2$-induced toxicity.** BTE did not affect the worm lifespan. Compared with the control (the mean lifespan (ML) = 18.7 d, $N$ = 85), the BTE-treatment groups at 50 mg/L (ML = 18.9 d, $N$ = 90), 100 mg/L (ML = 18.8 d, $N$ = 88), and 200 mg/L (ML = 18.8 d, $N$ = 94) showed no effects in the worms' mean lifespan (Figure 1A).

BTE protected N2 nematodes against high NaCl toxicity compared to untreated controls (Figure 1B). Following 12 h of exposure to 500 mM NaCl, the surviving control population reduced to 30.4% ($N$ = 102) of the initial study population; however, 52.0% (50 mg/L, $N$ = 100), 57.4% (100 mg/L, $N$ = 94), and 42.9% (200 mg/L, $N$ = 98) of the initial BTE treated nematode population survived ($P < 0.01$).

N2 nematodes were incubated in BTE under UV irradiation, and the mean lifespan was 6.7 d (50 mg/L, $P < 0.01$, $N$ = 80), 6.2 d (100 mg/L, $P < 0.01$, $N$ = 78), and 6.0 d (200 mg/L, $P$ = 0.05, $N$ = 78) instead of 5.6 days in the control group ($N$ = 85), which represented a significant resistance and reparation (Figure 1C). The nematode lifespan was significantly extended by 21.6%, 10.7%, and 7.1%.

Results showed BTE increased survival rates of *C. elegans* exposed to thermal stress (Figure 1D). The data showed that the mean lifespan pretreated with BTE was 12.1 h (50 mg/L, $P < 0.01$, $N$ = 77), 11.2 h (100 mg/L, $P$ = 0.01, $N$ = 72), and 10.8 h (200 mg/L, $P < 0.05$, $N$ = 70) instead of 9.7 h in the control group ($N$ = 78), indicating enhanced capacity to tolerate heat shock, resulting in increased survival rate based on BTE.

BTE pretreatment did not increase lifespan under $MnCl_2$ stress. The mean lifespan was 10.9 d (50 mg/L, $N$ = 75), 10.4 d (100 mg/L, $N$ = 73), 10.5 d (200 mg/L, $N$ = 79), and 10.8 d (control, $N$ = 78) (Figure 1E). Also, BTE post-treatment at 50 and 100 mg/L did not decrease mortality induced by $MnCl_2$. The mean lifespan under $MnCl_2$ conditions was 13.5 d (50 mg/L, $N$ = 102) and 13.2 d (100 mg/L, $N$ = 97). While the higher BTE concentration significantly accelerated their nematode mortality, with a mean lifespan of 12.8 d (200 mg/L, $P < 0.05$, $N$ = 95). The control group mean lifespan was 13.3 d ($N$ = 98) (Figure 1F).

**BTE diminished ROS levels dependent on concentration in *C. elegans*.** Dose-dependent attenuation of ROS levels in the wild type nematodes fed with BTE is shown in Figure 2. Significant differences were observed for BTE treatments compared with control (50 mg/L, $p < 0.01$; 100 mg/L, $P < 0.001$ and 200 mg/L, $P < 0.001$ at 100 min).

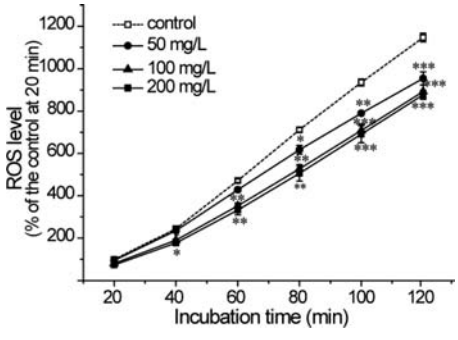

**Figure 2.** BTE decreased ROS accumulation in *C. elegans* under normal culture conditions, detected in a 120 min course. *$P < 0.05$; **$P < 0.01$; ***$P < 0.001$.

**BTE increased GSH-PX activity but not CAT and SOD activity.** The activities of various antioxidant enzymes were analyzed in control and pretreated batches of *C. elegans*. Our results showed that with increasing concentration of BTE (50 mg/L, 100 mg/L, or 200 mg/L), as shown in Figure 3, GSH-PX activity was significantly increased by 55.9% ($P < 0.05$), 98.7% ($P < 0.01$), and 87.3% ($P < 0.01$) (Figure 3A). Interestingly, CAT activity was significantly decreased by 30.0% ($P < 0.05$), 80.4% ($P < 0.01$), and 75.1% ($P < 0.01$) (Figure 3B). In addition, the BTE pretreatment did not induce the activity of SOD compared to the control (Figure 3C).

**BTE up-regulated the mRNA levels of stress-responsive genes.** We first measured changes of the mRNA levels of several stress-responsive transcription factors, including *daf-16*, *hsf-1*, and *skn-1*. BTE did not affect the three genes expression compared with controls. Then, we tested some other regulators of lifespan and stress markers, such as *sir-2.1*, *sod-3*, and *gsh-px*. The expressions of *sir-2.1* were enhanced by 2.19- (50 mg/L), 2.35- (100 mg/L), and 2.69-fold (200 mg/L) (both $P < 0.001$). The *sod-3* expression was up-regulated 2.14- (50 mg/L) ($P < 0.001$) and 1.87-fold (100 mg/L) ($P < 0.01$). The *gsh-px* expression was up-regulated 1.57- (50 mg/L) ($P < 0.01$) and 1.87-fold (100 mg/L) ($P < 0.001$). 200 mg/L BTE did not significantly regulate the *sod-3* and *gsh-px* expression (Figure 4).

Osmotic stress might have independent pathways to other stress in *C. elegans*.[9] So we measured the mRNA levels of *osr-1* and *sek-1* in the osmotic stress response pathway.[16,17] Our results indicated that BTE up-regulated *sek-1* expression by 2.36- (50 mg/L) ($P < 0.001$), 2.20- (100 mg/L) ($P < 0.001$), and 1.57-fold (200 mg/L) ($P < 0.01$). However, BTE did not affect the expression of *osr-1* (Figure 4).

**BTE slightly reduced internal oxidative stress and increased mean lifespan in mev-1 mutant under normal culture conditions without significance.** The BTE treated group survival rate showed a slightly increased trend without significant extent in the hypersensitive mutant *mev-1* at 25 °C compared to the control, demonstrating the following increased mean lifespan due to BTE treatment: 13.6 d (control), 14.0 d (50 mg/L), 14.4 d (100 mg/L), and 14.5 d (200 mg/L) (Figure 5).

**BTE did not affect the survival rate of the sir-2.1 mutant under heat and UV stress, but increased the survival rate under osmotic stress.** BTE protected *sir-2.1* mutants against 500 mM NaCl stress compared to controls (Figure 6A). Following 12 h of exposure to high NaCl, the surviving control population was reduced to 30.7% ($N$ = 114) of the initial study population; however, 42.7% (50 mg/L, $N$ = 110), 52.4% (100 mg/L, $N$ = 103), and 44.2% (200 mg/L, $N$ = 104) of the initial BTE treated nematode population survived ($P < 0.01$).

BTE pretreatment did not increase lifespan under UV and heat stress. The mean lifespan was 5.6 d (50 mg/L, $N$ = 87), 5.7 d (100 mg/L, $N$ = 85), 5.5 d (200 mg/L, $N$ = 71), and 5.6 d (control, $N$ = 96) under UV stress (Figure 6B). The mean lifespan was 9.9 h (50 mg/L, $N$ = 84), 9.8 h (100 mg/L, $N$ = 90), 9.7 h (200 mg/L, $N$ = 79), and 9.6 h (control, $N$ = 84) under heat stress (Figure 6C).

## DISCUSSION

In the present study, we observed that BTE increased *C. elegans* survival during high NaCl, UV, and acute heat stress. However, BTE had no effects on lifespan-extension under normal culture

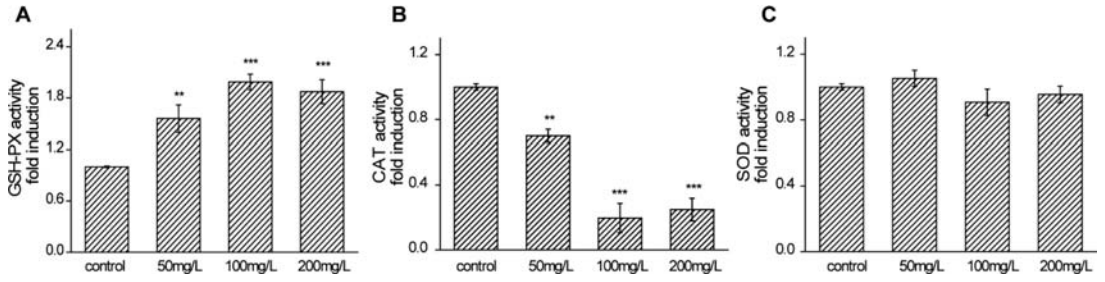

**Figure 3.** Effects of BTE treatment on the activities of GSH-PX (A), CAT (B), and SOD (C) in wild type N2 nematodes. *$P < 0.05$; **$P < 0.01$; ***$P < 0.001$.

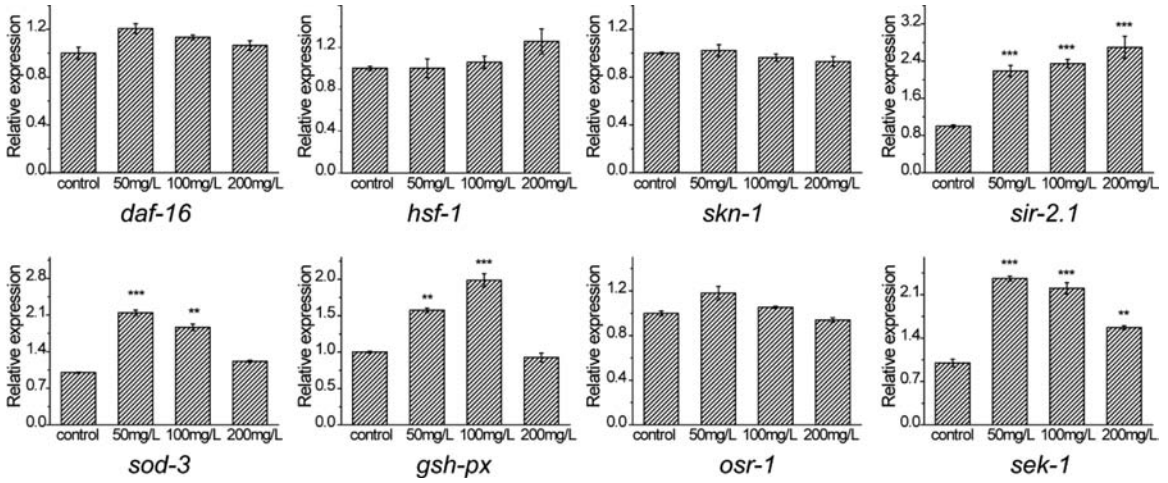

**Figure 4.** Relative mRNA level of *daf-16*, *hsf-1*, *skn-1*, *sir-2.1*, *sod-3*, *gsh-px*, *osr-1*, and *sek-1* after 48 h of BTE treatment. *$P < 0.05$; **$P < 0.01$; ***$P < 0.001$.

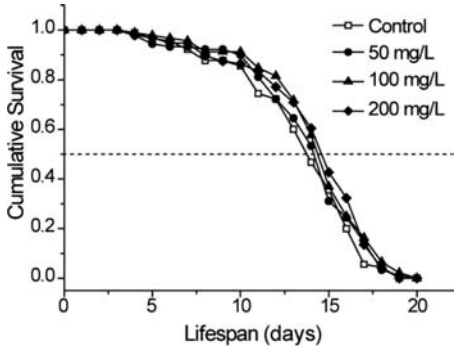

**Figure 5.** Effects of BTE on mutant *C. elegans* strain *mev-1* lifespan.

conditions and prolonging nematode survival from $MnCl_2$ treatment at the concentrations we used. These results suggest that BTE treatment selectively enhances nematodes' resistance to environmental stresses, which notably broadens our knowledge of the biological effects of black tea. The results of this study showed *C. elegans* treated with BTE were resistant to some stressors; therefore, it is conceivable that BTE elicited the response of the stress resistant system.

Multiple studies have demonstrated that polyphenol-rich botanical extracts have been shown to have differential stress resistance in nematodes.[17−20] Blueberry extract increases thermotolerance but is not protective against paraquat-induced oxidative stress.[17] Cranberry extract containing abundant flavonoids promotes survival of *C. elegans* to heat shock and does not improve nematodes' resistance to oxidative stress or

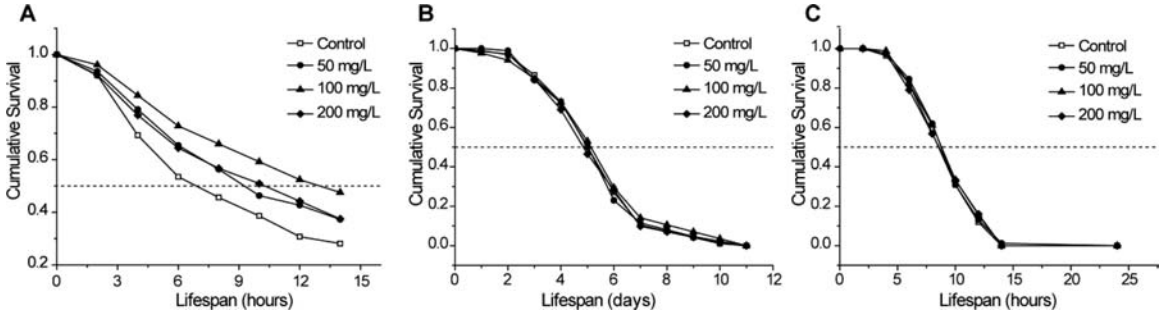

**Figure 6.** Effects of BTE on *sir-2.1* mutants under stress resistance. (A) Survival of VC199 worms during 12 h of exposure in 500 mM NaCl. (B) BTE effects on VC199 worms under UV irradiation at 2000 J/m$^2$. (C) Survival of VC199 worms at 35 °C.

UV irradiation and even renders them more sensitive to osmotic stresses of *C. elegans*.[20] Similarly, BTE contains a high number of polyphenols, which might be one of the most important contributors to the stress resistance of *C. elegans*. Black tea polyphenol has been shown to promote longevity and stress resistance in Drosophila,[6] and a large number of polyphenols in tea have demonstrated beneficial effects to *C. elegans*.[13−15,21−25] In addition, BTE contains a high level of caffeine, which is the main component (Table S1). Caffeine extends lifespan, improves healthspan, and delays age-associated pathology in *C. elegans* up to 97.1 mg/L (500 $\mu$M),[26] which is a relatively high bioactive concentration compared to polyphenols. However, postirradiation exposure to 19.4−1942 mg/L (0.1−10 mM) of caffeine did not create a modifying effect in *C. elegans*.[27] Moreover, the other phytochemicals in black tea may contribute to increased ability of *C. elegans* to stress resistance, such as theanine,[28] organic acids, and metals. A number of experiments have shown that different phytochemicals may interact and synergize to exert their biological functions.[29] Considering complex bioactive constituents, BTE-induced stress resistance may be due to the synergistic effects generated by the interaction of unique black tea phytochemicals.

We further observed that despite the fact that BTE could protect *C. elegans* against stress challenge, concentration is an important factor. Our findings indicated that BTE increased survival in a negative dose-dependent manner under heat and UV stress. The most effective concentration was 100 mg/L under osmotic stress. Also, toxic effects were observed at 200 mg/L under $MnCl_2$ post-treatment. Similarly, the concentration of whole apple extracts played an important role in increasing the resistance to different stresses in *C. elegans*.[18] Tannic-, gallic-, and ellagic-acids, and catechin, which are phytochemicals, exhibited variable effects on stress resistance based on concentration.[30] Compounds such as myricetin, quercetin, kaempferol, and naringenin are accumulated in a concentration-dependent manner in *C. elegans*.[23] Therefore, different concentrations of BTE exerted different effects under different environmental stresses. However, we did not exclude the possibility of the hormetic mechanisms on the dose−response curves for BTE. Multiple studies have found many plant extracts or phytochemicals exerted hormetic effects.[19,26,30−33] By acting as a moderate stress-stimulus, it can be hypothesized that compounds in BTE at lower levels, such as caffeine,[26] quercetin,[33] and tannic acid,[30] modulated an adaptive response, leading to an enhancement in stress resistance. It is therefore important to evaluate the possible effects of BTE at higher concentrations for future study.

Multiple studies have found an inverse relationship between black tea consumption and the risk of age-related diseases in mammals, including in human.[1,5] To exert any effects, absorption and biotransformation of chemical ingredients in BTE were taken into account. Some compounds contained in both green tea and black tea, such as catechins, were relatively well established in mammals, including in human.[5] Absorption and biotransformation of epicatechin and quercetin have already been evaluated in *C. elegans*.[24,34] Differential uptake and biotransformation of quercetin and quercetin-3-*O*-glucoside (Q3Glc) produced different effects to the lifespan of *C. elegans*, because Q3Glc was taken up to a greater extent than quercetin.[35] Therefore, the effects of absorption and biotransformation of compounds in BTE on the stress resistance in *C. elegans* should be considered. However, little information about the uptake and metabolism of unique polyphenols in black tea is available due to difficulties in determination of specific constituents of black tea—theaflavins or thearubigins.[5]

Black tea is known to have antioxidant capacity.[1] Also, ROS are generated by environmental threats such as UV, heat, and metal ions.[9] To understand whether BTE increased stress resistance by its antioxidant activity, we measured the ROS levels in *C. elegans* after 48 h of BTE-treatment. Our results indicated that BTE indeed decreased ROS in *C. elegans*. To see whether this inhibition of ROS formation due to BTE treatment might affect antioxidant systems, we quantified the activities of SOD, CAT, and GSH-PX and the mRNA levels of *sod-3* and *gsh-px*. While no induction of SOD activity was observed at the concentrations we evaluated, the GSH-PX activity was found to be significantly increased in *C. elegans* treated by BTE. However, CAT activity was decreased significantly after BTE treatment, which surprised us. A previous study found that EGb761, an extract of *Ginkgo biolba*, reduced catalase transcripts.[36] Resveratrol also reduced the total catalase activity in MRC-5 cells.[37] Future experiments are needed to investigate why and how BTE reduced CAT activity. Then we found that *gsh-px* and *sod-3* expression was up-regulated by BTE. Superoxide dismutase (SOD) is one important antioxidant enzyme, responsible for the conversion (dismutation) of superoxide detoxification.[38] *C. elegans* has two isoforms of mitochondrial SOD (encoded by *sod-2* and *sod-3*), two cytosolic SODs (*sod-1* and *sod-5*), and one extracellular SOD (*sod-4*).[38] *sod-1* contributes most of the SOD activity, and the relative contribution of *sod-3* was very small.[39] So this might be the reason for the inconformity between the mRNA level of *sod-3* and the SOD activity.

To further identify the antioxidant capacity of BTE, we performed the lifespan assay of *mev-1* mutants. *mev-1* nematodes, which possess a mutation in the Cytochrome *b* large subunit of the mitochondrial complex II, have been used to examine whether plant extracts protect against chronic oxidative stress.[40,41] ROS accumulation was 2-fold greater in *mev-1* nematodes relative to the wild type; consequently, *mev-1* individuals showed increased oxidative stress, accelerated aging, and reduced lifespan.[9] Our results showed that BTE only slightly extended the mean lifespan of *mev-1* mutants. In addition, BTE could not increase lifespan under normal conditions at the concentrations we used. Our finding indicated antioxidant capacity was not predictive of lifespan benefits,[31] even in a mutant containing high ROS levels. The causal relationship between antioxidant and antiaging has been long debated in the field. Many medicinal plant studies in *C. elegans* showed no clear and direct correlation between antioxidant capacity and longevity.[32] Based on these results, the antioxidant activity of BTE might be necessary but not sufficient to protect against aging to *C. elegans*.[42]

*C. elegans sir-2.1* can regulate lifespan and stress responses.[43] Nematodes overexpressing SIR-2.1 were resistance to stress, and *sir-2.1* loss-of-function mutants were stress sensitive.[44] We found that BTE could up-regulate expression of *sir-2.1*. Confirming the crucial role of *sir-2.1*, we observed that the protective effects induced by BTE were dependent on the expression of *sir-2.1* under UV and heat stress, not osmotic stress. *C. elegans* SIR-2.1 protein can function in a stress-response pathway of longevity,[44] and this effect is dependent on *daf-16*.[43] BTE did not affect the *daf-16* gene expression but increased expression of the *daf-16* target *sod-3*. Components in BTE, such as epigallocatechingallate (EGCG) and quercetin,

have been identified to induce a translocation of DAF-16 from the cytoplasm to the nucleus.[21,45] So BTE might induce translocation of DAF-16 to the nucleus to modulate an adaptive response to environmental changes.[46] Therefore, BTE might increase stress resistance through a *sir-2.1/daf-16/sod-3* signaling pathway.

Osmotic regulatory genes controlled osmotic stress resistance independent of temperature and oxidative stress response mechanisms.[47] OSR-1 coupled with SEK-1/MAPKK regulates the resistance of *C. elegans* to hyperosmotic stress.[16] Blueberry extracts increased longevity through the OSR-1/SEK-1 pathway in *C. elegans*,[17] while SEK-1, but not OSR-1, are required for quercetin-induced lifespan-extending in *C. elegans*.[48] Our results showed that BTE significantly up-regulated the expression of *sek-1*, not *osr-1*, which partly indicated how BTE increased survival of *C. elegans* under an osmotic environment. To get a mechanistic insight, further systematic studies are warranted to identify the underlying mechanisms of BTE's differential effects on stress resistance in *C. elegans*.

Here we provide a report of the efficacy in BTE to increased osmotic stress, heat shock, and UV irradiation resistance in *C. elegans*. However, BTE did not attenuate $MnCl_2$-induced mortality and increased lifespan under normal cultural conditions. Our results suggested BTE improved heat and UV stress resistance, not osmotic stress, in a *sir-2.1* dependent manner. In addition, BTE concentration is very important for nematode stress resistance. It is important to elucidate the mechanisms of black tea extracts to further clarify the understanding of stress response processes, and evaluate the health benefit of this worldwide beverage.

[a]Gallic acid equivalents. [b]Catechin equivalents. Values are mean ± SD of triplicates. [c]Significantly different from native grain ($P < 0.05$).

*glaucum*).[15] The most common forms of domestic processing are sprouting, roasting, pressure-cooking, open-pan boiling, and microwave heating, which may bring about several changes in the nutritional quality of food. Hence, the present investigation was carried out to determine the extent to which domestic processing influences phenolic profile and bioaccessibility of polyphenols from commonly consumed cereals (wheat and sorghum) and legumes (green gram and chickpea).

## MATERIALS AND METHODS

**Materials.** Sorghum (*Sorghum bicolor L. Moench*), wheat (*Triticum aestivum L.*), green gram (*Vigna radiata L.*), and chickpea (*Cicer arietinum L.*) were procured from the National Seeds Corporation (Mysore, Karnataka, India). Standard phenolic compounds, pepsin, pancreatin, and bile extract (porcine origin), were procured from Sigma-Aldrich Chemical Co. (St. Louis, MO, USA). HPLC-grade solvents were from Qualigens Chem. Co. (Mumbai, India). All other chemicals and reagents used were of analytical grade.

**Processing of Grain Samples.** A known amount of grain samples was subjected to various types of domestic processing in triplicates as described below.

*Sprouting.* After soaking the grains overnight (30 g in 90 mL), water was decanted, and samples were allowed to germinate for a period of 48 h under ambient conditions (25 °C), while keeping them wet by intermittently spraying water. The sprouted grains were dried under shade, powdered, and used for extraction.

*Heat Processing.* (i) Pressure-cooking: Powdered grain samples were pressure-cooked (15 p.s.i.) in triple-distilled water (10 g in 30 mL) for 15 min. (ii) Open-pan boiling: Powdered grain samples were boiled in triple-distilled water (10 g in 50 mL) on a hot plate for 10 min. (iii) Microwave heating: Powdered grain samples were microwave heated in triple-distilled water (10 g in 50 mL) for 4 min in a household microwave system (SAMSUNG Trio, Combi-CE1031LAT; Samsung Electronics Co. Ltd., Suwon, Korea) at 450 W. Cooked samples were used for further studies. (iv) Roasting: Known quantity of each sample (30 g) was roasted on preheated acid-washed sand at 150 °C ± 2 °C for 5 min (until the sample gave a characteristic aroma and color). Roasted sample was cooled to room temperature, powdered, and stored in airtight pouches in dark at 4 °C until future studies.

**Analysis of Polyphenols.** *Extraction of Polyphenols.* Extraction of polyphenols was carried out by refluxing the grain samples (2 g) in acidified methanol for 2 h.[16] Total polyphenols, total flavonoids, and tannins were analyzed in the filtered extracts as described below.

*Total Polyphenols.* Total polyphenol content was estimated by Folin−Ciocalteu method as described by Singleton et al.,[17] with slight modifications. Briefly, an aliquot of acidified methanolic extract was appropriately diluted with water to 3.0 mL, mixed with 1 mL each of 1N Folin−Ciocalteu reagent and 20% sodium carbonate, and incubated for 30 min at room temperature. The absorbance was recorded in a spectrophotometer (UV-1800, Shimadzu Corporation, Kyoto, Japan) and compared with those of known standard gallic acid concentrations ($R^2$ = 0.999). The total polyphenol content was computed as mg equivalent gallic acid per g of sample.

*Total Flavonoids.* Total flavonoid content was determined according to the method of Zhishen et al.[18] Acidified methanolic extract (0.1 mL) was diluted with 4.9 mL of distilled water and mixed with 0.3 mL of (5% w/v) $NaNO_2$. After 5 min, 0.3 mL of (10% w/v) $AlCl_3$ and 2 mL of 1 M NaOH were added. The sample was then diluted with distilled water to a total volume of 10 mL. The mixture was vortexed and the absorbance was read at 510 nm. Standard catechin was used to prepare a calibration curve ($R^2$ = 0.999). The flavonoid concentration was expressed as mg catechin equivalents per g of sample.

*Tannins.* Tannin content was determined by the modified vanillin−HCl method.[19] An aliquot of acidified methanolic extract was appropriately diluted to 1 mL with distilled water and was mixed with 5 mL of vanillin−HCl reagent. The samples were allowed to stand at room temperature for 20 min and the color developed was recorded at 500 nm. The absorbance was also recorded for standard catechin solution ($R^2$ = 0.998) and the tannin concentration was expressed as mg catechin equivalents per g of sample.

*HPLC Analysis.* Phenolic extracts of native and processed samples were analyzed by HPLC to obtain a profile of individual phenolic compounds.[20] Analysis was carried out in an HPLC system (Agilent 1200 Series; Agilent Technologies Inc., Santa Clara, CA, USA) equipped with a diode array detector. Filtered samples (20 μL) were analyzed for polyphenols using a C18 analytical column (250 × 4.6 mm; 5 μm; Agilent Technologies Inc., USA) with the mobile phase consisting of 0.1% trifluoroacetic acid as solvent A and 100% methanol as solvent B. The total run time was 60 min with a flow rate of 1.0 mL/min with the gradient program as follows: initial B concentration of 20% to 40% in 40 min which was maintained for 10 min and then again to 20% B in the next five min and 5 min of postrun for reconditioning. Peaks were recorded simultaneously at 280 and 320 nm.

**Bioaccessibility of Polyphenols.** Bioaccessibility of polyphenols was determined by an in vitro method as described by Luten et al.,[21] involving simulated gastrointestinal digestion with suitable modifications. Initially, simulated gastric digestion was carried out by incubating the powdered samples (10 g) with pepsin at pH 2.0 and a temperature of 37 °C for 2 h. At the end of gastric digestion, titratable acidity was determined in an aliquot of gastric digest as the amount of 0.2 M sodium hydroxide required to attain a pH of 7.5 in the presence of a mixture of pancreatin and bile extract dissolved in 0.1 M sodium bicarbonate (4 g of pancreatin and 25 g of bile extract per L).

Subsequently, intestinal digestion was simulated by suspending segments of dialysis tubing (molecular mass cutoff: 10 kDa) containing 25-mL aliquots of sodium bicarbonate solution, being equivalent in moles to the titratable acidity (sodium hydroxide needed to neutralize the gastric digest), in Erlenmeyer flasks containing the gastric digest and incubated at 37 °C with shaking until the pH of the digest reached 5.0. Pancreatin−bile extract mixture (5 mL) was then added and

**Table 2. Total Polyphenol and Flavonoid Content and Their Bioaccessibility in Sorghum as Influenced by Domestic Processing**

| type of processing | total polyphenol content[a] (mg/g) | bioaccessible polyphenol content[a] (mg/g) | percent bioaccessibility | total flavonoid content[b] (mg/g) | bioaccessible flavonoid content[b] (mg/g) | percent bioaccessibility | tannins (mg/g) |

[a]Gallic acid equivalents. [b]Catechin equivalents. Values are mean ± SD of triplicates. [c]Significantly different from native grain ($P < 0.05$).

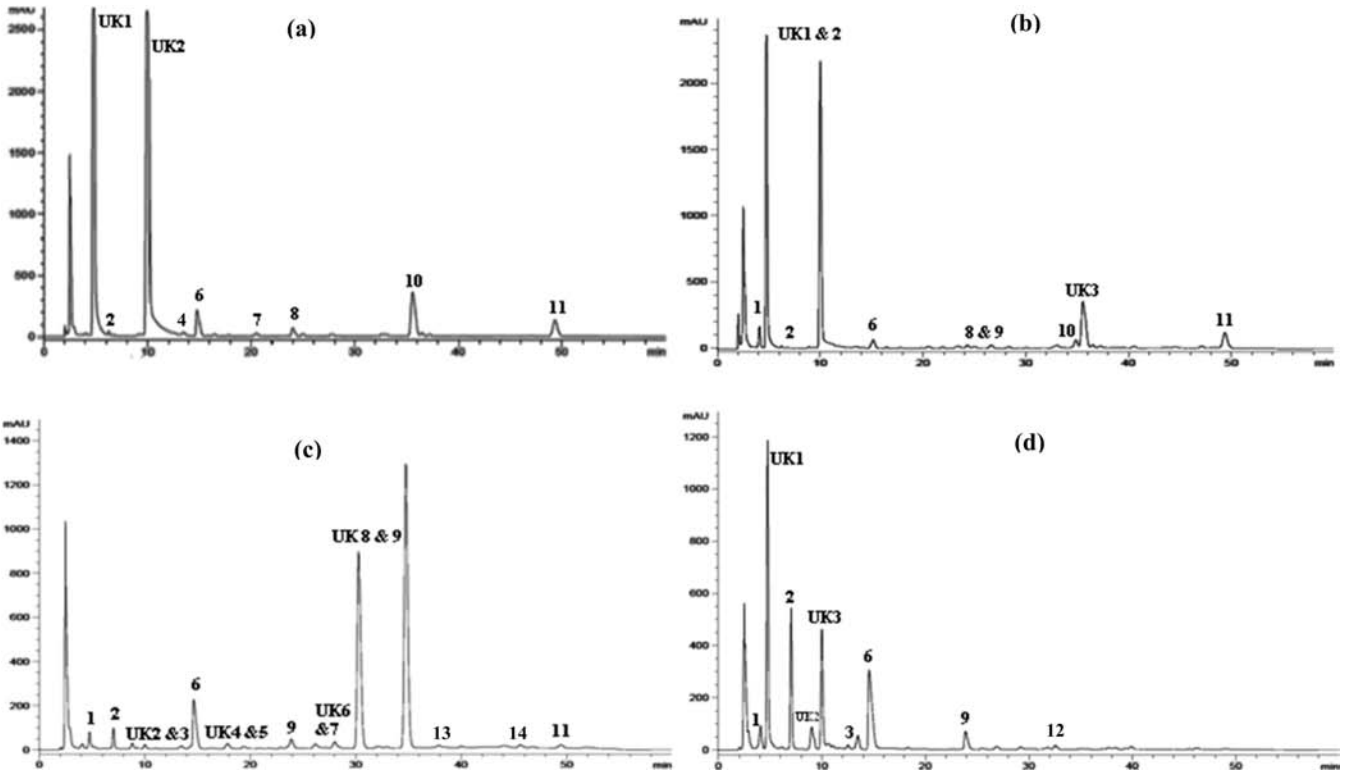

**Figure 1.** HPLC profiles of polyphenols from (a) wheat, (b) sorghum, (c) green gram, and (d) chickpea. 1: Gallic acid; 2: protocatechuic acid; 3: *p*-hydroxy benzoic acid; 4: vanillic acid; 6: syringic acid; 7: *p*-coumaric acid; 8: ferulic acid; 9: sinapic acid; 10: salicylic acid; 11: *t*-cinnamic acid; 12: luteolin; 13: rutin; 14: quercetin; UK: unknown phenolic compound.

incubation was continued for 2 h or longer until the pH of the digest reached 7.0. At the end of this simulated gastrointestinal digestion, the dialyzate was analyzed for polyphenols by both spectrophotometry and HPLC as described in previous paragraphs. The bioaccessible polyphenol present in the grain sample is the dialyzable portion of the total polyphenol, which is expressed as percent bioaccessibility.

**Statistical Analysis.** All determinations were made in three replicates, and the average values are reported. Statistical analysis was carried out using Graphpad INSTAT, Version 3.06, Graphpad software. Data were analyzed by applying one-way analysis of variance (ANOVA) and the differences between means were assessed by Dunnet's test and considered significant when $P < 0.05$.

## RESULTS

Phenolic extracts of native and variously processed cereals and legumes, as well as of dialysates obtained after simulated gastric digestion of these samples, were analyzed for total polyphenols, flavonoids, tannins, and individual polyphenol profile.

**Total Polyphenol, Flavonoid, and Tannin Content of Cereal Grains.** Total polyphenol content, total flavonoid content, and tannin content of wheat are given in Table 1. Total polyphenol content of unprocessed wheat was 1.20 mg/g, which significantly increased on sprouting (by 19%) and roasting (by 20%) ($P < 0.05$). Drastic reduction in polyphenol content was observed on pressure-cooking (by 27%), open-pan boiling (by 18%), and microwave heating (by 34%) ($P < 0.05$). Total flavonoid in native wheat was 0.84 mg/g, which increased by 50% on roasting. Open-pan boiling and microwave heating had deleterious effect (4-fold decrease) on total flavonoid content of wheat, whereas pressure-cooking and sprouting did not alter this much. Native wheat had a total tannin content of 0.45 mg/g which increased significantly on sprouting and roasting (by 33% and 73%, respectively) ($P < 0.05$). Pressure-cooking reduced tannin content of wheat to 0.17 mg/g, while open-pan boiling and microwave heating had even higher

Table 3. Concentrations ($\mu$g/g) of Identified Phenolic Compounds in Native and Processed Wheat[a]

[a]Values are means of triplicates.

deleterious effect, making tannin content below detectable limits.

Total polyphenol, total flavonoid, and tannin content of native and processed sorghum are presented in Table 2. Total polyphenol content of native sorghum was 1.12 mg/g which significantly reduced (by 43−51%) ($P < 0.05$) on heat treatment except roasting, where there was a significant increase (49%) ($P < 0.05$). Sprouting did not cause any significant change in the total phenol content. Significant reduction of total flavonoid content (0.89 mg/g) was observed after sprouting (38%) and heat treatments (27−52%) ($P < 0.05$). Tannin content of unprocessed sorghum was 0.62 mg/g which significantly increased on sprouting (2-fold increase) and roasting (3-fold increase) the cereal ($P < 0.05$). Open-pan boiling drastically reduced (55%) the tannin content ($P < 0.05$).

**HPLC Profile of Phenols of Cereal Grains.** The profile of individual phenolic compounds of wheat is shown in Figure 1a. About 17 compounds have been detected in native form and two unidentified compounds are the major phenolics (Supporting Information (SI) Table 1). The identified compounds found in native wheat are protocatechuic acid, vanillic acid, syringic acid, *p*-coumaric acid, ferulic acid, salicylic acid, and *t*-cinnamic acid. Concentrations of individual identified phenolic compounds are given in Table 3. Among the identified compounds, concentration of salicylic acid (459 $\mu$g/g) was highest followed by syringic acid (58 $\mu$g/g). No significant effect was seen after sprouting the wheat, while there was an increase after roasting (592−904 $\mu$g/g) ($p < 0.05$). Pressure-cooking, open-pan boiling, and microwave heating reduced the concentration of identified compounds to about 50%. Interestingly, protocatechuic acid appeared in profiles of native, sprouted, and roasted samples, while sinapic acid was observed only in pressure-cooked, open-pan boiled, and microwave heated samples.

The profile of individual polyphenolic compounds in native sorghum is shown in Figure 1b. Native sorghum contained a total of 16 compounds out of which 9 compounds are identified as gallic acid, protocatechuic acid, caffeic acid, syringic acid, *p*-coumaric acid, ferulic acid, sinapic acid, salicylic acid, and *t*-cinnamic acid (SI Table 2). Concentrations of various phenolic compounds in native and processed sorghum are given in Table 4. Two unidentified phenolic compounds were major compounds in native sorghum, equally contributing together to more than 75% of the total peak area. They are probably hydroxybenzoic acids since they showed maximum absorbance at 280 nm. Unidentified phenol (UK2) was affected significantly by pressure-cooking, open-pan boiling, and

microwave heating, which reduced from 38.5 to 6.1, 1.1, and 6.7% respectively. Concentration of salicylic acid (64 $\mu$g/g) was highest among identified phenolics of sorghum followed by gallic acid (46 $\mu$g/g). Roasting (630 to 170 $\mu$g/g) showed extremely higher concentrations of identified phenolic compounds. Sprouting (170 to 144 $\mu$g/g) reduced the concentration of identified phenolics significantly. Drastic reduction of identified compounds was observed on pressure-cooking (170 to 69 $\mu$g/g), open-pan boiling (170 to 57 $\mu$g/g), and microwave heating (170 to 148 $\mu$g/g). Gallic acid concentration was much affected by all forms of processing especially sprouting and pressure-cooking, wherein concentration was either below detectable limit or there was a complete absence of gallic acid. Significant increase of salicylic acid concentration (3-fold) was seen in the roasted sample.

**Bioaccessibility of Polyphenols from Cereal Grains.** Bioaccessible polyphenol content from native wheat was 0.96 mg/g (Table 1). Roasting (26%), pressure-cooking (21%), and microwave heating (20%) reduced bioaccessible flavonoid content significantly ($P < 0.05$), whereas no significant change was noticed on sprouting and open-pan boiling. Bioaccessible flavonoid content of native wheat was only 0.04 mg/g, which did not alter much by any of the domestic cooking processes.

Bioaccessible total polyphenol and total flavonoid in native and processed sorghum is given in Table 2. Bioaccessible polyphenol content from native grain was 0.60 mg/g, which reduced significantly ($P < 0.05$) on roasting, open-pan boiling, and microwave heating (15, 12, and 23%, respectively). Sprouting and pressure-cooking did not show any significant effect on total bioaccessible polyphenol. Total bioaccessible flavonoid content from native grain was 0.09 mg/g, which constituted only about 2.5% of total flavonoid content. No significant changes in bioaccessible flavonoid content were observed in any forms of processing except microwave heating (56% reduction).

*HPLC Profile of Bioaccessible Polyphenols of Cereal Grains.* The profile of bioaccessible polyphenols from native wheat showed that not all compounds were bioaccessible; out of 17 compounds, only 4 phenolic compounds were found to be bioaccessible (chromatogram not shown). The major bioaccessible phenolic compound was an unidentified polyphenol constituting about 90% of the total area percentage of the native grain. Concentrations of identified phenolics are

given in Table 5. Gallic acid, which was not bioaccessible from the native grain, was bioaccessible from sprouted, roasted, and pressure-cooked samples. Similarly, syringic was bioaccessible from roasted, pressure-cooked, and microwave heated samples.

The HPLC profile of dialysate of native sorghum showed that not all compounds are bioaccessible; out of 16 compounds, only 5 compounds were bioaccessible (chromatogram not shown). The major compound in native and processed samples was an unidentified compound, while the identified compounds were *p*-hydroxy benzoic acid, *p*-coumaric acid, ferulic acid, sinapic acid, and salicylic acid. Concentrations of identified phenolic compounds are given in Table 6. Among the identified phenolic compounds, salicylic acid was the major compound in native grain. Sprouting and roasting significantly increased the concentration of identified compounds (48 to 112 and 176 μg/g, respectively) ($P < 0.05$), while pressure-cooking, open-pan boiling, and microwave heating did not make any significant difference. The concentration of vanillic acid (which was originally not present in this grain) was particularly increased on processing, except microwave heating.

**Total Polyphenol, Flavonoid, and Tannin Content of Legumes.** Total polyphenol, total flavonoid, and tannin content of native and processed green gram are given in Table 7. Total polyphenol content of native green gram was 4.03 mg/g. Significant reduction of total polyphenol content was observed on sprouting (30% decrease) and microwave heating (25% decrease). Pressure-cooking and open-pan boiling of green gram did not alter the polyphenol content. Total flavonoid content of native green gram was 1.56 mg/g, which reduced significantly on open-pan boiling and microwave heating (about 30% decrease in each case). Sprouted, roasted, and pressure-cooked samples did not show any significant difference in total flavonoid content. Tannin content was reduced from 4.05 to 1.41 mg/g on sprouting, while roasting (87%) and open-pan boiling (76%) increased the same which correlated with the increase in total polyphenol content.

Total polyphenol content of native chickpea was 1.54 mg/g, which increased on pressure-cooking (53%), open-pan boiling (64%), and microwave heating (by >2-fold increase) (Table 8). Total flavonoid content of native legume was 1.47 mg/g, which drastically reduced on pressure-cooking (80%), open-pan boiling (84%), and microwave heating (78%). Sprouted and roasted samples did not show any difference in total polyphenol or total flavonoid content. Tannin content of native chickpea was 0.68 mg/g, which reduced significantly on roasting (62%). Pressure-cooking (>2-fold), open-pan boiling, and microwave heating (both >3-fold) increased total tannin to a large extent.

**HPLC Profile of Phenols of Legumes.** Native green gram showed a total of 20 polyphenols on HPLC, out of which 9 were identified (SI Table 3). HPLC profile showed gallic acid, protocatechuic acid, vanillic acid, caffeic acid, syringic acid, sinapic acid, *t*-cinnamic acid, rutin, and quercetin among identified phenolic compounds (Figure 1c), while the two major phenolics were not identified. Concentrations of

[a]Values are means of triplicates.

identified compounds are represented in Table 9. Total concentration of identified phenolic compounds in native green gram was 252 $\mu$g/g. Open-pan boiling drastically reduced the concentration of identified phenolic compounds (from 252 to 151 $\mu$g/g). No significant difference was observed in other types of processing.

Phenolic compounds identified from the HPLC profile of native chickpea were gallic acid, protocatechuic acid, *p*-hydroxy benzoic acid, gentisic acid, vanillic acid, syringic acid, and luteolin (Figure 1d). The major phenolic of chickpea could not be identified, while among identified compounds, syringic acid followed by protocatechuic acid were major compounds (SI Table 4). Concentration of identified compounds in native legume was 748 $\mu$g/g, which drastically reduced to about 50% upon sprouting (Table 10). Other processing methods did not significantly influence the concentration of identified polyphenol compounds.

**Bioaccessibility of Polyphenols from Legumes.** Bioaccessible portion of total polyphenols, total flavonoids, and tannins from native and processed green gram are given in Table 7. Total bioaccessible polyphenol content in native green gram was 2.71 mg/g, which did not alter significantly on sprouting, pressure-cooking, or open-pan boiling. Roasted green gram showed higher (11%) total bioaccessible content while microwave-heated sample showed decreased content (16%) compared to native grain. Total bioaccessible flavonoid content from native green gram was 0.21 mg/g and an increase of 33% of the same was observed in sprouted sample. Heat processing generally did not change the total bioaccessible flavonoid content of green gram.

Bioaccessible polyphenol content of native chickpea was 1.49 mg/g (Table 8). Significant increase in bioaccessible total polyphenol content was seen in roasted samples (17%), while reduction of the same was observed in pressure-cooked (11%) and open-pan boiled samples (10%). Bioaccessible total flavonoid content of native legume was only 100 $\mu$g/g, which remained unaltered in all the processed samples.

*HPLC Profile of Bioaccessible Polyphenols of Legumes.* HPLC profile of bioaccessible polyphenols of native green gram (not shown) revealed a total of 11 compounds, out of which identified ones are gallic acid, protocatechuic acid, *p*-coumaric acid, and sinapic acid. Three major unidentified compounds constituted about 96% of the total bioaccessible phenolics. As given in Table 11, concentration-wise, gallic acid was highest (58 $\mu$g/g) followed by sinapic acid (26 $\mu$g/g). Concentration of total identified bioaccessible polyphenols increased >2-fold on sprouting. Significant reduction of identified polyphenols was seen on pressure-cooking (17%) ($P < 0.05$).

Bioaccessible polyphenols from native chickpea consisted of 9 compounds, out of which 4 were identified as gallic acid, protocatechuic acid, salicylic acid, and rutin. Not all compounds found in the native grain were bioaccessible (HPLC profile not

shown). Concentrations of different phenolic compounds bioaccessible from native and processed chickpea are given in Table 12. Concentration of total bioaccessible identified polyphenol from native sample was 477 $\mu$g/g, which reduced to about 55% on sprouting. On the other hand, significant increase of the same was noticed after roasting (45%), pressure-cooking (25%,) and microwave heating (30%) ($P < 0.05$), while open-pan boiling produced no significant change.

## DISCUSSION

Cereals and legumes are important food components in vegetarian populations because of their high nutritional quality, and these are generally consumed after some form of processing. It is well-known that processing may affect the composition of cereals and legumes to a significant extent. Knowledge on the bioaccessibility of polyphenols as influenced by domestic processing is limiting. The present investigation was aimed to assess the total and bioaccessible polyphenol content of the common cereals (wheat and sorghum) and legumes (green gram and chickpea) as influenced by various domestic processing methods.

Total polyphenol content of native sorghum observed in the present study viz., 1.12 mg/g, is similar to the value reported in literature.[22] Sorghum showed higher amount of total flavonoid content in both native and processed forms compared to wheat. Sprouting increased total polyphenol content in wheat. It is reported that sprouted waxy wheat variety has better nutritional composition, with higher total phenolic content along with higher dietary fiber and free amino acids, than the unsprouted wheat.[23,24] As seen in the earlier reports, our study also showed higher amount of tannins in sorghum when compared to wheat, which increased considerably on sprouting and roasting. There is evidence of possible health benefits of tannins, which has led to the research on sorghum tannins.[25,26] Pressure-cooking, open-pan boiling, and microwave heating significantly reduced total polyphenol, total flavonoid, and tannin content in both sorghum and wheat.

Green gram provides appreciable amounts of total polyphenol compared to chickpea (4.03 vs 1.54 mg/g) among the two legumes studied, however, these values are higher than those reported by Shweta et al.[27] The observed reduction in total polyphenol content during sprouting agrees with the report of Antu and Sudesh.[28] Interestingly, total polyphenol content increased significantly after pressure-cooking, open-pan boiling, and microwave heating in chickpea. This may be due to the disruption of matrix of legume in the presence of excess of water and temperature. This is interesting in the context of antihyperglycemic activity along with antioxidant properties of chickpea being attributable to its polyphenols.[29] Sprouting caused a significant reduction in total polyphenols of green gram, but not in the case of chickpea. It may also be noted that germinated chickpea is reported to be effective in reducing cholesterol levels in rats,[30] and diets containing roasted chickpea had a beneficial effect on both triglyceride and cholesterol levels in rats.[31] The effect of pressure-cooking, open-pan boiling, and microwave heating on the total flavonoid content was more in the case of chickpea as compared to green gram. Total tannin content of green gram was comparatively higher than in chickpea.

The number of phenolic compounds present in chickpea was found to be more when compared to green gram, wheat, and sorghum. As observed in our previous study,[15] roasting increased the concentration of phenolic compounds irrespective of the grains studied. In the case of sprouting, the concentration of identified polyphenols increased significantly in sorghum and chickpea. When individual phenolic compounds were considered, concentration of vanillic acid and ferulic acid increased in sprouted wheat, as observed by Yang et al.[32] Vanillic acid concentration increased significantly after roasting of all the grains except chickpea. Syringic acid concentration increased significantly in all the grains on microwave heating. Reduction in the concentration of phenolic compounds was observed after pressure-cooking, open-pan boiling, and microwave heating in wheat, sorghum, and green gram.

Wheat provided comparatively more bioaccessible polyphenols than sorghum. Roasting and microwave heating decreased total bioaccessible polyphenol content from both sorghum and wheat. Total bioaccessible flavonoid content from both these cereals was very low (1−20% bioaccessible) compared to bioaccessible total polyphenol content. Bioaccessible polyphenol content from legumes was more than that found from the cereals. However, bioaccessible polyphenol from green gram was comparatively more than the bioaccessible total polyphenol from chickpea. Similar trend was seen in the case of bioaccessible flavonoid content from green gram and chickpea. Domestic processing methods did not show any effect (except sprouting and microwave heating) on the bioaccessible flavonoid content from both the legumes and cereals. Although there was a seemingly increase in the total polyphenol content after pressure-cooking, open-pan boiling, and microwave heating in chickpea, this was not consequent in the total bioaccessible polyphenol content.

Phenolic acids, both hydroxybenzoic and hydroxycinnamic acids, were most common polyphenolic compounds detected in all the grains analyzed. Generally, not all the phenolic compounds (revealed by HPLC), were bioaccessible from the grains analyzed. An unidentified phenolic compound which constituted about 38% of native sorghum was less than 2% bioaccessible. The number of phenolic compounds bioacces-

sible from green gram was more than that from all other grains. Wheat showed comparatively lesser number of bioaccessible polyphenols than sorghum. Roasting had a notable effect on the polyphenol content in wheat as compared to any other processing methods. Sprouting increased the concentration of bioaccessible polyphenols especially in sorghum and green gram. It has been shown that cereals which fulfill the nutritional principles of whole grains, on sprouting become more nutritious in terms of phenolic compounds, vitamins, and minerals when compared to their native form as grain's mobilized energy reservoir becomes readily available in its active form.[33] Concentration of bioaccessible ferulic acid was particularly increased on sprouting, roasting, and microwave heating of sorghum. Ferulic acid, a common phenolic acid has been reported to elevate the activities of detoxifying enzymes, namely glutathione-*S*-transferase, and lower the incidence of colonic carcinomas induced by azoxymethane in vivo.[34] Concentration of protocatechuic acid increased significantly after domestic processing in green gram and chickpea. Protocatechuic acid, which is structurally similar to gallic acid, has been associated with a large number of pharmacological properties.[35]

As reported earlier in finger millet and pearl millet, it appears that polyphenols present at higher concentration in the grain are not necessarily more bioaccessible.[15] Composition of bioaccessible phenolic compounds varied among wheat and sorghum when compared to finger millet and pearl millet. Sprouting and roasting had a beneficial effect on the concentration of polyphenols in all the grains as observed in the case of finger millet and pearl millet. Among the cereals studied, wheat stands next to pearl millet in terms of bioaccessible polyphenols.

Significant difference was observed in the polyphenol content among the grains studied. Even though cereals and legumes possessed appreciable amounts of polyphenols, the amount of bioaccessible polyphenols was considerably low. Domestic processing had a marked effect on the phenolic profiles of cereals and legumes studied, with the effect depending mainly on the food matrix. Typically, sprouting, which increased the concentration of bioaccessible polyphenols in green gram, drastically reduced the same in the case of chickpea. Sprouting and roasting had a more advantageous effect over other domestic processing methods. Use of sprouted and roasted grains as ingredients in the functional foods could provide a higher amount of bioaccessible polyphenols/flavonoids in order to maximize the potential health benefits from them.

times.[21] Several ANCs could be detected in the whole eyeball of pigs[1] fed 2.4−12 mg ANC/kg body weight in blueberries for up to 8 weeks and where the concentration in the whole eye appeared to be correlated with blueberry dose. Human intake of ANC is estimated at approximately 200 mg daily in the North American population[22] or approximately 2.7 mg/kg body weight for a 72 kg person.

Despite the volume of research surrounding ANC effects on vision and their ability to become localized in ocular tissues, there is still a paucity of solid clinical evidence to support existing commercial claims of improvement in night vision to normal-sighted individuals associated with the consumption of blueberries and other ANC-containing foods. This paper describes the results of two placebo-controlled, randomized crossover studies that tested a normal-sighted middle-aged human population for blueberry ANC effects on dark adaptation, scotopic vision, and recovery from photobleaching of the retina.

## MATERIALS AND METHODS

**Study Design and Participants.** Two prospective, placebo-controlled, double-blind, crossover studies, S2 (short duration, two products) and L1 (long duration, one product), were conducted to examine human visual function after intake of blueberry products. Vision testing was conducted under reduced light at specific intervals after the consumption of blueberry products, placebo, or nothing (washout). In S2 the assignment of the 72 subjects to two crossover groups was balanced between testing sites (2), gender (2) and age (3) (Table 1). Similarly, in L1 the assignment of the 59 subjects to two crossover groups was balanced between testing sites (2), gender (2), and age (2) (Table 1). There were no drop-outs from S2, whereas in L1 there were two. Partial results of drop-outs were removed from the L1 analysis. Both studies were approved by the research ethics review board of Dalhousie University (Canada) and were in accordance with the tenets of the Declaration of Helsinki. The Clinicaltrials.gov identifier for both S2 and L1 is NCT01942746.

One hundred and twenty individuals were recruited using printed advertisements posted in two rural communities of Nova Scotia, Canada. Inclusion criteria were male or female, age 35−65 years, with no ocular history other than refractive glasses. The minimum criteria for visual function required for inclusion were (1) visual acuity better than 6/7.5 on EDTRS acuity chart (VectorVision, Greenville, OH, USA) at 2.5 m, (2) contrast sensitivity within normal range to all spatial frequencies tested on Visteck 3000 (VectorVision) at 2.5 m, (3) stereoacuity better than 80 s of arc on Frisby stereoacuity test (Clement Clarke International Ltd., Essex, UK), and (4) intraocular pressure lower than 21 mmHg from the average of three measures using a Mentor tonopen-XL (Innova Medical Ophthalmics, Toronto, Canada).

In the process of eliminating amblyopia (dimness in vision), candidates were examined for manifest strabismus (unable to focus both eyes on one spot) and anisotropia (nonuniform responsiveness between both eyes). Ophthalmologic examination also included direct retinoscopic assessment of retinal pigment epithelium and retina as well as a slit lamp examination of anterior segment. Family and medical history excluded subjects with family history of retinal degeneration, glaucoma, diabetes, hypertension, cataract, and amblyopia. On the basis of these criteria, 72 and 59 subjects were recruited for S2 and L1, respectively, and were assigned to groups that were age and gender-matched (Table 1). All 59 participants of L1 had previously participated in S2. The S2 was completed approximately 7 months before the commencement of L1.

During the intervention and the washout period of both S2 and L1, subjects were instructed to abstain from ANC-containing foods and were provided with a list of alternative fruit choices, such as melons, green grapes, kiwi fruit, green-peeled apples. Compliance to the dietary restriction was assessed using a questionnaire. All subjects were considered to be well-nourished before and during the study. During the study their diet was modified only by the restriction on intake of nonapproved ANC-containing products.

**Table 1. Summary of Two Clinical Trials, S2 and L1, That Examine Blueberry Anthocyanin Effects on Dark Vision**

| | | clinical trial | |
|---|---|---|---|
| | | short trial with two blueberry products (S2) | long trial with one blueberry product (L1) |
| study design | randomized, double-blind | double crossover | single crossover |
| vision testing | sites | 2 | 2 |

[a]C3g eq, cyanidin 3 glucoside equivalents.

**Test Products.** In both S2 and L1 blueberry intake was standardized for ANC content, which was consumed in the form of single-strength blueberry juice (BJ) and in S2 also as a freeze-dried BJ powder. BJ was produced using a commercial process (VanDyks Health Products, Caledonia Nova Scotia, www.vandykblueberries.ca) using previously frozen blueberries that were equal proportions of the cultivars 'Tifblue' (*V. asheii* Reade) and 'Rubel' (*V. corymbosum* L.). The composition of these blueberry cultivars has been reported.[23] Pasteurized juice was stored in 350 mL clear glass bottles, kept refrigerated, and stored in the dark until delivery to subjects and for no longer than 3 months.

In S2 colorimetric analysis of ANCs[24] at the time of BJ production indicated an ANC concentration of 6.04 (SD = 0.18) mg of C3g eq/g dry weight. In L1, BJ had an ANC concentration of 6.83 (SD = 0.20) mg C3g eq/g dry weight at the time of production that declined by 19% to 5.52 (SD = 0.09) mg C3g eq/g dry weight by the end of 3 months of refrigerated storage. In both S2 and L1, 300 mL of BJ and in L1 300 mL of placebo juice composed of food grade ingredients (Table 2) were consumed daily. The BJ provided subjects in S2 with a daily ANC dose of 271 mg C3g eq and in L1 with 346 mg C3g eq (Table 1). The BJ powder used in S2 was produced from freeze-dried BJ and packaged in gelatin capsules. Each capsule contained 2.37 mg C3g eq per capsule; three capsules were consumed for a total daily ANC intake of 7.11 C3g eq. In S2 the placebo was freeze-dried red beet powder in gelatin capsules. Red beet color is due to betalain pigments. Red beets do not contain ANCs; their nutrient composition

**Table 2. Composition of Blueberry Juice Placebo Used in Trial with Long Intervention and One Blueberry Test Product (L1)**

| ingredient | percent (w/w) |
|---|---|
| water | 88.37 |

| xanthum gum | 0.015 |
| total | 100.00 |

has been described.[25] Subjects were instructed to consume their test product before noon.

Dietary compliance was assessed in L1 using a questionnaire where full compliance for test product consumption was defined as having taken a total 300 mL of BJ or placebo at least 5 days per week. Full compliance to the ANC-free dietary restriction was defined as two or fewer servings of ANC-containing food per week. No adjustment was made to account for missed doses of product or noncompliance to the ANC-free diet.

**Product Intake and Vision Testing.** In S2 vision was tested two times and in L1 vision was tested three times before the diet intervention commenced so that subjects could become accustomed to the way in which the vision tests were conducted. In S2 after this pretreatment testing, subjects consumed BJ products or placebo daily for 3 weeks. Randomization was carried out to assign the order of dietary treatment to each subject. In S2 each subject had their vision tested after 3 weeks of product intake and then again after 3 weeks of washout until all three products (BJ, BJ capsule, placebo) were tested. This 3 week cycle to test three products each took 18 weeks. In L1 after pretreatment testing and randomization, vision was tested after 8 and 12 weeks of daily BJ or placebo intake and after 4 and 8 weeks of washout. In L1 this cycle of two products and two washouts took 40 weeks. Vision was tested at the same time of the day (±2 h) within an individual to avoid possible diurnal effects on vision. No attempt was made to schedule vision testing at a fixed period after consumption of BJ, BJ capsules, or placebos. Vision was always tested by the same person and at the same location (Table 1).

A vision testing session lasted <90 min. The vision tests were always performed in the same order, starting with dark adaptation (DA) followed by scotopic visual acuity (VA), contrast sensitivity (CS), and finally the test for macular stress recovery (MSR) time. The tests were generated by computerized systems (VPixx v.3.0, VPIXX Technologies, St. Bruno, Canada) on a Macintosh computer and displayed on a high-resolution (1960 × 1280 pixels) calibrated CRT monitor (model G90f, ViewSonic, Walnut, CA, USA) using custom-made protocols. Calibration (LS-110 photometer, Minolta, Ramsey, NJ, USA) of the CRT monitor for each workstation was carried out at the start of the study, and the calibration results were verified at the end of the study to ensure stability of the monitor output.

**Vision Testing.** *Dark Adaptation (DA) Testing.* In S2, subjects were first asked to look at a diffuse light of 12000 lx for 120 s to achieve controlled photobleaching of their retinal pigment. Room lights were then turned off and the 30 min DA test was performed in the dark. A red fixation target was presented on the right-hand side of the computer monitor. For the right eye, a dim white stimulus light was randomly presented in the upper or lower part of the left side of the monitor, at a distance of 15° nasal to the fixation point. The intensity of the light stimulus was increased until the subject could identify the position of the light stimulus. Up to 20 s was allowed for the subject to determine the position of the light stimulus on the monitor (upper or lower portion). This task was repeated once every minute for 30 min. To compensate for the limitations of the monitor's range of light intensities as subjects became dark adapted, subjects wore neutral density filtered goggles as their DA progressed in both S2 and L1. Goggles were applied when the monitor's intensity was close to the minimum range, where linearity in luminosity was more variable.

In L1 standard retinal photobleaching before DA testing employed a light intensity of 25000 lx for 120 s. In contrast to S2 DA testing, in the L1 the intensity of the dim light was decreased until it could no longer be perceived. Although these two strategies (increasing vs decreasing light intensity) yielded different absolute threshold values between S2 and L1, there was no impact on the DA dynamic changes.

*Visual Acuity (VA) Testing.* To test scotopic VA after the 30 min DA test, subjects continued to wear the light attenuation goggles while single black optotypes of varying size with crowding bars against a white background were presented to them. There were eight different optotypes (letters) of similar discrimination difficulties.[26] Optotype light intensity was 100 cd/m$^2$ for the background and 0.316 cd/m$^2$ for the black letters. Optotypes were first shown at a small size and then their size was increased until the subject could correctly identify the letter. The VA values were measured as the minimum size of the optotype that was correctly perceived through a staircase threshold approach with the third to the sixth reversals averaged for a final value. With this method the threshold scotopic VA was measured 12 times per session.

*Contrast Sensitivity (CS) Testing.* While still in darkness and with the subject wearing the light attenuation goggles, sine wave gratings of three spatial frequencies (1, 3, and 10 cycles/degree) were presented at various levels of contrast, starting at 50% of full black/white contrast using the Michaelson contrast equation.[27] A staircase method was used to determine the minimum contrast discernible. The three spatial frequencies were randomized, and the subject had to correctly determine the orientation of the grating on the monitor (−30, 0, or 30°). Following a correct answer the tester decreased the contrast, whereas after an incorrect answer, the tester increased the contrast. The mean of eight final reversals was considered as the CS threshold for each of the spatial frequencies. In our statistical analysis, we retained only the CS threshold, expressed in percent contrast, for one of the three spatial frequencies used (3 cycles/degree).

*Macular Stress Recovery (MSR) Testing.* For the MSR test, the light attenuation goggles were removed. Then VA was measured as the smallest readable optotype from a computerized five-line, five-letter chart similar to EDTRS charts with a white background intensity set at 100 cd/m$^2$. After VA was established in those conditions, retinal photobleaching was achieved when one eye was exposed to a diffuse light of $3.5 \times 10^4$ cd/m$^2$ (intensity measured at the cornea) for 20 s in S2 or, in L1, to $8.0 \times 10^4$ cd/m$^2$ for 20 s. After this bleaching exposure, the subject was presented again with the EDTRS chart, and the time was measured to recover VA to one line above the smallest optotype before retinal photobleaching. To ensure minimal bias, EDTRS charts presented after bleaching were different from those presented before bleaching, however, with letters of the same reading difficulty level. Due to the nature of the bleaching process, the test could be conducted only once during a vision testing session.

**Statistical Analysis.** *Experimental Design.* Data were analyzed using the ANOVA procedure in GenStat.[28] S2 and L1 employed a crossover design that was balanced between testing sites, age, and dietary treatment. In both trials all participants were tested with every dietary treatment and with washout periods between each treatment.

In both S2 and L1 all data were evaluated for normality and, when necessary, data were converted to $\log_{10}$ to achieve normal distribution of variation. In S2 the analysis model was product (i.e., placebo, BJ, and BJ capsule) for fixed effects and test site, week, and age for random effects. In L1 the analysis model was product (i.e., BJ and placebo) for fixed effects and week and age for random effects. In both S2 and L1 covariation for each subject's performance on vision tests before the study began (pretreatment) was identified and corrected. In S2 the

second pretreatment test results were used for this correction, whereas in L1 the third pretreatment test results were used. Covariate correction was also applied to adjust for possible carry-over effects due to the order of the products taken. In S2 this was the specific order of BJ, BJ capsule, or placebo capsule, whereas in L1 it was the order of BJ or placebo.

*DA Curve Fitting and Variates.* For DA measurements in S2 and L1 raw data were first corrected for the discrepancy point(s) created by the use of neutral density filter goggles that subjects wore once the minimum monitor intensity was too great. Once corrected, the resulting scatterplot was fitted with two exponential functions (Figure 1). The first curve corresponded to the sensitivity gain of the cone photoreceptors, whereas the second curve corresponded to the sensitivity gain of the rod photoreceptors. The time (min) at the intersection of the two curves was defined as the cone−rod transition ($DA_{CRT}$) (Tables 3 and 4).

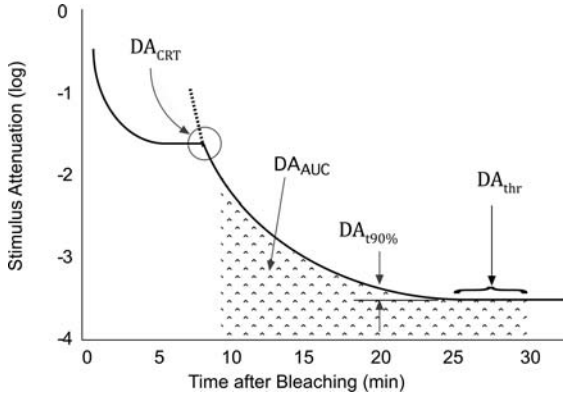

**Figure 1.** Exponentially fitted curves for the early (cone) and late (rod) portion of the dark adaptometry function. The intersection of the two curves indicates the time (min) of the rod/cone transition, $DA_{CRT}$. Measures of dark adaptation included (1) the area under the curve between 9 and 30 min ($DA_{AUC}$), (2) time (min) at 90% of the asymptote ($DA_{t90\%}$) on the second curve, and (3) the final dark threshold ($DA_{thr}$) as defined by $log_{10}$ light intensity during the last 5 min of the 30 min test.

From the second curve two measures were developed to assess the rate of DA. First the area under the DA curve between 9 and 30 min was calculated ($DA_{AUC}$). A lower $DA_{AUC}$ reflects more rapid and more complete dark adaptation. Another measure of DA was the time (min) to reach 90% of the asymptote of the 9−30 min curve, which was defined as $DA_{t90\%}$. Fewer minutes to reach $DA_{t90\%}$ indicated more rapid dark adaptation. To determine the lowest level of light perceived, that is, the dark threshold ($DA_{thr}$), the mean light intensity during the last 5 min of the DA test (25−30 min) was determined from the second fitted curve.

MSR test results were log transformed to normalize variation for ANOVA, whereas their back-transformed decimal values are reported on a log scale for ease of presentation (Figures 2 and 3).

Results of selected vision tests including ($DA_{thr}$), scotopic CS, scotopic VA, and the MSR time were used to investigate their possible relationships with dietary treatments using a principal component analysis (PCA). A correlation matrix was used to identify relationships and is presented as a two-dimensional biplot for S2 (Figure 4A) and L1 (Figure 4B).

## RESULTS

In S2 and L1 there were no reports about adverse effects related to the treatment products. Dietary compliance, where full compliance was ≥5 full doses of study products per week, was reported by 89% of the respondents. Full compliance to diet restrictions, which was ≤2 servings of other ANC-containing food per week, was 60%. Overall response to the compliance questionnaire was 80%.

[a]$DA_{CRT}$, dark adaptation cone rod transition. [b]$DA_{AUC}$, area under the curve, 9−30 min. [c]$DA_{t90\%}$, time to reach 90% of asymptote. [d]$DA_{thr}$, final dark threshold, last 5 min. [e]cd/m$^2$ candela per square meter.

**Vision Test Results.** In general, ANC had no effect on measures of DA or night vision in either S2 or L1. In neither S2 nor L1 was there an effect of blueberry ANC intake on the time (min) to the rod cone conversion, that is, $DA_{CRT}$ (Tables 3 and 4). In S2 there was no effect of dietary treatment on the $DA_{AUC}$ or the $DA_{t90\%}$ (Table 3). In S2, however, the threshold light intensity, that is, the average $DA_{thr}$, was greater in the placebo group (i.e., required a higher light intensity) than either the BJ or the BJ capsule ($P = 0.004$) group (Table 3). In L1 there were no treatment effects (BJ vs placebo) on any of the four measures of DA including $DA_{RCT}$, $DA_{AUC}$, $DA_{t90\%}$, or $DA_{thr}$ (Table 4). In S2 and L1 there were no effects of blueberry product intake on VA or CS in the dark-adapted subjects (Tables 5 and 6).

The MSR test that measured the time (s) to recover visual acuity after exposure of the retina to bright light showed significantly shorter recovery times after BJ versus placebo in both S2 (Figure 2) and L1 (Figure 3). In S2, which employed a 3 week intervention, blueberry-fed subjects had a reduced MSR time compared to placebo ($P = 0.033$). Also, there was no statistical difference between the two ANC daily doses (271 and 7.11 mg C3g eq) employed in S2; both doses reduced MSR time compared to the placebo ($P = 0.014$). In S2 after 3 weeks of washout, there was no significant difference between BJ and placebo, although the trend for a shorter MSR time was still apparent (Figure 2). In L1 the daily consumption of 346 mg C3g eq in BJ reduced the recovery time after photobleaching of the macula; this effect was observed at 8 weeks ($P = 0.027$) and 12 weeks ($P = 0.030$). Whereas the trend for a reduced MSR time persisted after 4 weeks of washout, neither

[a]$DA_{CRT}$, dark adaptation cone rod transition. [b]$DA_{AUC}$, area under the curve, 9−30 min. [c]$DA_{t90\%}$, time to reach 90% of asymptote. [d]$DA_{thr}$, final dark threshold, last 5 min. [e]cd/m$^2$, candela per square meter.

the 4 or 8 week washout was significantly different from the placebo (Figure 3).

PCA biplots were used to collectively illustrate possible relationships among the vision test results and dietary treatments. The S2 biplot accounted for 93% of the total variation (Figure 4A) with 63% in the first score (vertical axis) and 30% in the second score (horizontal axis). The L1 biplot accounted for 81% of the variation with 52% in the first score and 29% in the second score (Figure 4B). In both S2 and L1 the vector distances from each vision test (CS, $DA_{thr}$, MSR, and VA) to the origin were quite similar, indicating that each of the four vision tests contributed roughly equally to the total variation illustrated by the biplots.

In S2 the Euclidian distances between the dietary treatments distinguished the low-dose blueberry capsule (C) and the high-dose BJ (B) from the placebo (P) along the MSR axis (Figure 4 A; solid line ellipse for blueberry products and washouts, dashed line ellipse for placebo treatment and washout). The capsule washout ($C_w$) and BJ washout ($B_w$) were also associated with low MSR values, suggesting a persistence of the effect during the washout. In the L1 biplot, the BJ and placebo treatments were well separated along the MSR axis (Figure 4A; solid line ellipse for BJ and BJ washout results, dashed line for placebo and placebo washout results). In both S2 and L1 the blueberry-related coordinates occurred in the negative quadrant of the biplot because improved MSR was due to a more negative (lower) recovery time. In S2 especially, but also in L1, the placebo and placebo washout coordinates occurred on the periphery of the biplot, indicating high variation because these treatments were inactive.

In both S2 and L1 the angle created by the CS and MSR vectors was smaller than the angle created by other pairs of vision test vectors (Figure 4). This suggests that, among the four vision tests included in the plot, MSR and CS were more strongly and positively correlated to each other. Also, the MSR and CS vector angles were similar in S2 and L1 despite the fact that the position of the CS coordinates differed by >90° between the two trials. The perpendicular line segment distances for the blueberry products were shorter in S2 than in L1, suggesting a closer relationship between CS and blueberry intake in S2, which used a shorter intervention.

The effect of blueberry ANC on DA is of great interest to the field, and in this paper DA performance is indicated in the biplot as $DA_{thr}$, the final dark threshold. In both S2 and L1 $DA_{thr}$ was strongly associated with the first PCA score, because its cosine angle was small in relation to score 1. Score 1 contributed the greatest percentage (63% in S2; 52% in L1) of the variation illustrated by the biplot, indicating that the $DA_{thr}$ was associated with high variation (Figure 4). The length of the perpendicular line segments from the dietary treatments to the $DA_{thr}$ vector varied, suggesting no real pattern in the $DA_{thr}$ response in relation to the diet treatment. VA also contributed strongly to score 1, particularly in L1. VA and $DA_{thr}$ were strongly and negatively correlated.

## DISCUSSION

Results of the S2 and L1 trials contribute to a body of research investigating the action of ANC in vision physiology (for a review, see Tremblay and Kalt[29]) and especially in relation to night vision and bilberry ANC (for a review, see Canter and Ernst[2]). Although S2 and L1 employed nonpurified blueberry products, the hypothesis underlying the design of the trials was that ANC was the blueberry component that could affect human vision because other abundant BJ components, including organic acids, simple sugars, and polysaccharides, have no demonstrated effect on vision.

**Dose and Treatment Regimen.** Together the S2 and L1 studies spanned a wide range of exposure to ANCs. The S2 trial delivered in BJ 5.69 g C3g eq of ANC in 21 days, whereas the capsule delivered 199 mg C3g eq (or 3.4% of BJ dose) in the same period. In L1, BJ delivered a total of 29.1 g of ANCs in 84 days. The high daily dose of BJ in S2 and L1 (Table 1) is comparable to ANC doses used in other studies.[30,31] The design of S2 and L1 did not test for acute effects because the time between product ingestion and vision testing was not controlled.

Whether subjects were aware of the test product identity should be considered, because vision testing is psychophysical and can be susceptible to bias. In S2, subjects were informed that the BJ and the BJ powder capsule were the same product in two formulations and doses. Also in S2, the BJ powder in the capsule was deemed indistinguishable from the red beet powder capsule placebo. Many subjects in S2 and L1 had never previously consumed single-strength BJ and were not familiar with its sensory qualities. There was at least 8 weeks between when subjects consumed BJ or the placebo juice. Subjects had no opportunity to consume BJ and placebo juice at the same time.

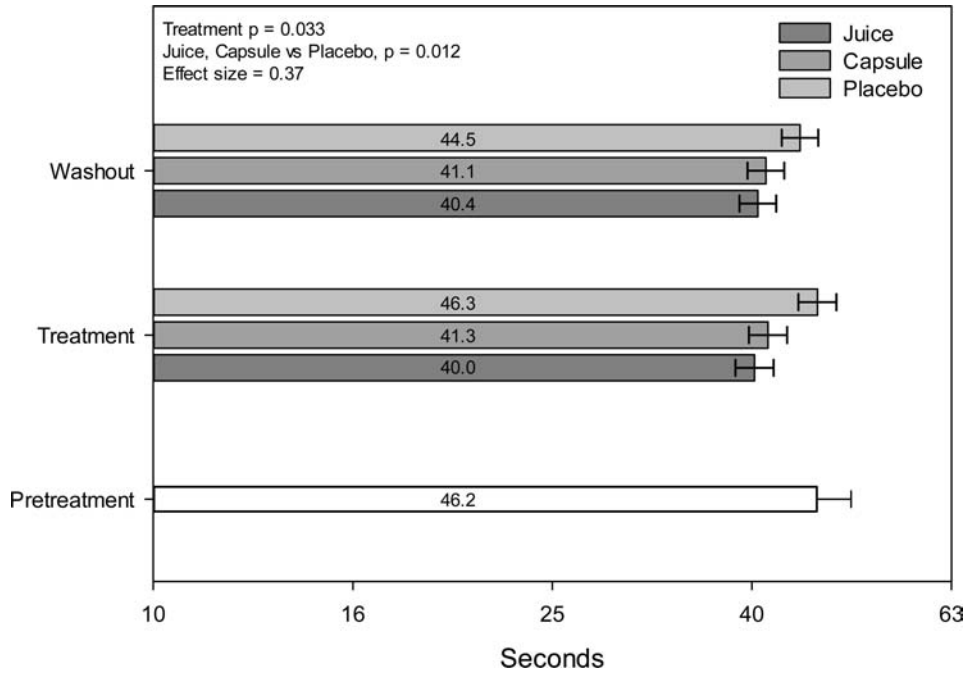

**Figure 2.** Macular stress recovery (MSR) test results defined as time (s) to recover visual acuity after retinal photobleaching in a short trial testing two blueberry products and placebo (S2) with $n = 72$. Mean MSR times ± SEM are shown for the pretreatment (no dietary products) and then after 3 weeks of dietary intervention and 3 weeks of washout. Means are back-transformed from log values which were used for ANOVA. These back-transformed values are plotted on a log scale with back transformed values shown.

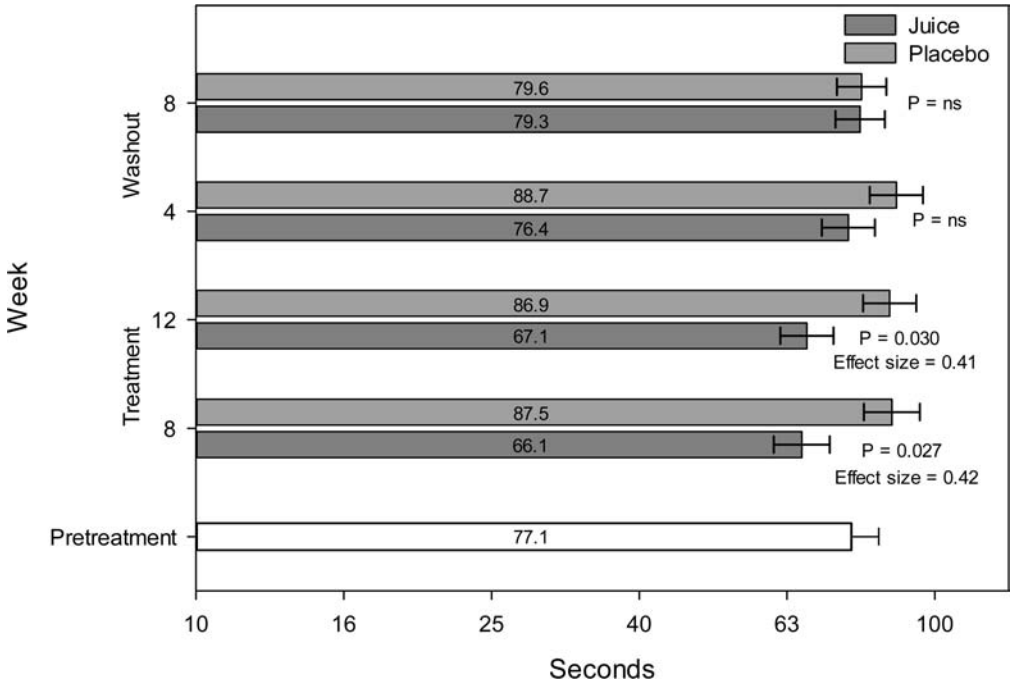

**Figure 3.** Macular stress recovery (MSR) test results defined as time (s) to recover visual acuity after retinal photobleaching in a long trial testing one blueberry product and placebo (L1) with $n = 59$. Mean MSR times ± SEM are shown for the pretreatment (no dietary products) and then after 8 and 12 weeks of dietary intervention and 4 and 8 weeks of washout. Means are back-transformed from log values which were used for ANOVA. These back-transformed values are plotted on a log scale with back transformed values shown.

**Vision Tests.** *DA.* There was no evidence of improved DA with ANC intake in either S2 or L1. In S2 however, a significant treatment effect on $DA_{thr}$ (Table 3) supported some previous studies[11,32−34] wherein ANC intake reduced the final dark threshold light intensity. Although not significant, the 3 week washout in S2 also supported this trend (Table 3). Whereas this suggests that ANC improved the sensitivity of the dark-adapted retina, the effect size (0.5 for treatment period; 0.25 for washout) was moderate. Also, there were no improvements in any other correlated measures of DA ($DA_{RCT}$, $DA_{AUC}$, $DA_{t90\%}$). Furthermore, the L1 trial failed to show a similar trend for $DA_{thr}$, despite a longer intervention with a high ANC dose. It is

worth noting that this improvement in the $DA_{thr}$ in S2 was approximately 0.05 $log_{10}$ cd/$m^2$ (Tables 3 and 4) and is a difference that can be detected only under controlled conditions and would be imperceptible in real life. Variation in the $DA_{thr}$ means in S2 (SEM = 0.014) and L1 (SEM = 0.024) was of the same order of magnitude, suggesting that differences in the DA testing method were not a factor in the difference in $DA_{thr}$ values between the two trials (Tables 3 and 4).

Together the S2 and L1 $DA_{thr}$ results do not support the early European literature that report improvement in DA parameters with ANCs,[11,32−34] results which Canter and Ernst[2] suggest may be influenced by weak experimental design. When Levy[5] used double-blinded, crossover, randomized control protocols, they failed to show improvement in DA among young normal-sighted men in a study using different ANC doses and durations. Muth et al.[7] also used rigorous protocols and found no effects among young normal-sighted men in other attributes of scotopic vision (VA and CS), but they did not test DA specifically. The S2 and L1 trials were designed to test for ANC effects on DA, CS, and VA in a population spanning 30 years in age (35−65, Table 1) across both genders. Subjects older than 65 years were not included in the study because the incidence of confounding vision health conditions such as subclinical cataracts and retinal dysfunctions is more common in this population group.

*CS and VA.* The lack of an ANC effect on either CS or VA in both S2 and L1 may not be surprising because both of these tests rely more on the photoreceptor density and their underlying synaptic circuitry and less on mechanisms where ANC have been shown to be influential.[35,36] A few studies have proposed an effect of ANCs on VA and CS,[17,37] whereas randomized controlled design studies report negative results for ANC effects on CS[6−8] and on VA.[7] Notably, symptoms of asthenopia (visual fatigue) that can relate to changes in VA and CS were reported to be reduced, on the basis of a subjective assessment.[3]

*MSR.* The MSR test, which measured the recovery time of visual acuity after controlled photoreceptor bleaching, depends heavily on the regeneration of rhodopsin[38] in a way that is similar to DA. The degree of photoreceptor bleaching for the MSR test was greater than for DA testing in both S2 and L1. The MSR test measures the recovery of prebleaching acuity involving cone photoreceptors, whereas the DA test assesses the sensitivity of rod photoreceptors. Although photostress recovery time increases with subject age, it is independent of pupil size, ametropia (refractive error), and VA.[38] The MSR test, which is also known as the retinal dazzling or blinding test, has been used clinically to discriminate retinal diseases from conditions of the optic nerve.[39−41]

In S2 and L1 ANC intake significantly reduced the MSR time; however, the effect size was moderate, ranging between 0.37 and 0.42. In S2 the improvement in MSR was observed in just 3 weeks, and this trend persisted during the 3 week washout. MSR improvement in S2 was found with both the high (271 mg C3g eq daily) and a low (7.11 mg C3g eq daily) ANC dose (Table 1; Figure 2). In L1, which used a high ANC dose (346 mg C3g daily), a similar reduction in MSR time was seen at 8 weeks ($P$ = 0.027) and at 12 weeks ($P$ = 0.03) and with a nonsignificant trend persisting at 4 weeks of washout.

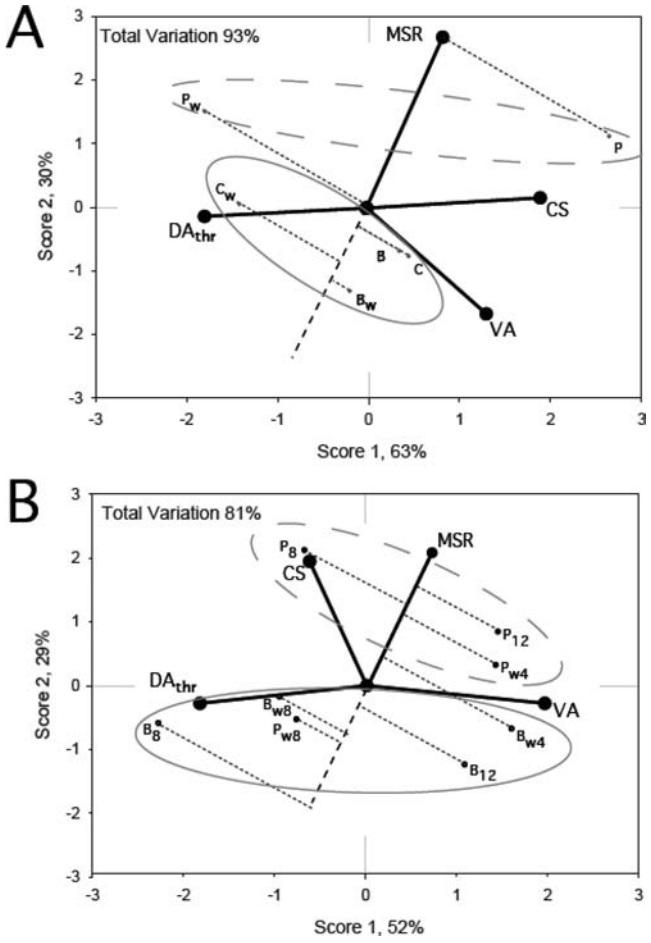

**Figure 4.** Principal component analyses for two clinical trials comparing results for measures of night vision. One trial used a short (3 weeks) intervention and tested two blueberry products (S2) (A); the other trial used a longer intervention (up to 12 weeks) and tested one blueberry product (L1) (B). Panel A and B abbreviations for vision tests: $DA_{thr}$, dark threshold; CS, contrast sensitivity; MSR, macular stress recovery; VA, visual acuity. Panel A interventions: B, blueberry juice, 3 weeks; $B_W$, blueberry juice, 3 week washout; C, blueberry capsule, 3 weeks; $C_W$, blueberry capsule, 3 week washout; P, placebo, 3 weeks; $P_W$, placebo, 3 week washout. Panel B interventions: $B_8$, blueberry juice, 8 weeks; $B_{12}$, blueberry juice, 12 weeks; $B_{w4}$, blueberry juice, 4 week washout; $B_{w8}$, blueberry juice, 8 week washout; $P_8$, placebo juice, 8 weeks; $P_{12}$, placebo juice, 12 weeks; $P_{w4}$, placebo juice, 4 week washout; $P_{w8}$, placebo juice, 8 week washout.

Together the results suggest that ongoing exposure to even a small ANC dose improved MSR time and that the effect persisted for a time after the cessation of ANC intake. This result may be related to the occurrence of ANC glycosides in tissues[42] including eye tissues[1,21] and the persistence of ANC metabolites in enteric circulation.[43] A diverse array of phase II metabolites of ANC have recently been reported to persist in urine.[43] It is not known whether phase II metabolites of ANC affect MSR.

**Multivariate PCA.** The multivariate PCA explained the MSR test results with respect to the variation accounted for in S2 (Figure 4A) and L1 (Figure 4B). The MSR vector correlated poorly with the other three vision test vectors that together contributed to a large proportion of the total variation. Whereas all four vision tests ($DA_{thr}$, MSR, VA, and CS) were poorly correlated, the coordinates of the blueberry treatment groups (solid line ellipse) were clustered along the MSR axis in both S2 and L1. Furthermore, the quite random positioning of the blueberry treatment groups along the $DA_{thr}$, VA, or CS vectors in both S2 and L1 suggests that the absence of statistical significance for these three vision tests is not due to an unpowered study but rather to the absence of correlation between these three vision tests and the intake of ANC.

**Study Design.** Canter and Ernst[2] cited the need for rigorous clinical research designs and controls to examine possible ANC effects on vision, which the S2 and L1 trials attempted to do. Study volunteers were middle-aged and had undergone detailed prescreening prior to enrollment to ensure that the study population was made up of normal-sighted individuals who were free of vision conditions or pathologies that could influence the vision testing. Rigor in the S2 and L1 study designs included double-blinding by vision testers (to the current usage) and subjects (to the identity) of test products or washouts. The use of a complete crossover and the use of a placebo also contributed to the strength of the study design. Conducting vision testing before the start of the dietary intervention (pretreatment) mitigated any effect of the subject learning the new vision tests, and in L1 subjects were already familiar with the tests due to their prior participation in S2. Covariate correction addressed possible effects unrelated to the dietary intervention that may have affected vision test performance.

A challenge in investigating phytochemical interventions is that beneficial effects may not occur in healthy well-nourished populations who have access to a variety of plant-based foods, whereas effects may be still be demonstrable in a phytochemically deficient population. And within the well-nourished Western population, volunteers for nutritional studies are more likely to be nutrition-conscious and consuming a diet containing fruits and vegetables. Results of our study thus contribute to the evidence that nutritional studies related to vision should either target more vulnerable populations or utilize other investigational strategies. ANC intervention studies that target a population with an existing vision pathology may yield more positive outcomes; examples can already be found in relation to glaucoma symptoms[44,45] and vascular pathologies.[46,47] The notion that suboptimal vision may be improved by dietary ANCs has been proposed recently by Shin et al.[48] We are currently investigating ANC intake effects in individuals with impaired vision. Also, large-scale epidemiological studies have associated ANC intake with risk reduction for cardiovascular factors[49,50] and type 2 diabetes,[51] and therefore such an approach is warranted to examine vision health and performance.

Although S2 and L1 failed to demonstrate functional ANC benefits, we have recently reported a potent action of ANC in protecting rats from retinal injury created by exposure to intense light.[19] In this study retinal damage, which was measured objectively by electroretinography and retinal tissue histology, was reduced from 60% in the placebo-fed rats to 20% in BJ-enriched diet. Animal studies benefit significantly from their control of genetics, lifestyle, diet, and the availability of many more research models. Furthermore, laboratory animals that have had limited or no previous exposure to ANCs may be predisposed to greater ANC action compared to humans, where ANC may be consumed regularly and persist in vivo for a long period.[42,43]

The S2 and L1 trials were rigorously designed to test for ANC effects on the performance of subjects in common

psychophysical tests that measure visual function in the dark. ANC intervention had, at best, a moderate effect on the rate of recovery after retinal photobleaching. The magnitude of the effect would not likely translate into subjectively detectable improvement in everyday visual performance. There was no effect of ANC intake on dark adaptation and scotopic vision. At this juncture, with the limited positive results from well-designed human interventional studies in normal populations, it may be useful to investigate the role of ANC in vision using an epidemiological approach or in interventional studies that target specific pathologies or experimental models.

accumulation of native flavanols and microbial metabolites. Flavanol monomers and PCs (as well as other classes of flavonoids) appear to be metabolized to a small pool of a few dozen common microbial metabolites.[15,35] This raises the question of whether the qualitative profile of native flavanols is relevant for modulating the profile of metabolites accumulated in the colon. Very few studies have compared the colonic tissue accumulation of native flavanols and microbial metabolites from distinct dietary profiles of native flavanols;[36] the majority of studies focus on metabolism and accumulation of single compounds or a single flavanol-rich food. Furthermore, the majority of the data on microbial metabolism of flavanols pertains to catechin monomers and small PCs (dimers, trimers, etc.). Very little is known about the metabolism of larger PCs, as these compounds have been studied in matrices that are also rich in smaller compounds (cocoa, apples, GSE, etc.) but have not yet been studied individually. Due to this lack of data, the metabolic fate of large PCs in the gut remains largely unknown.

The objectives of this study were to (1) determine the quantitative and qualitative profile of flavanols and their microbial metabolites accumulated in the colon during habitual exposure to flavanol-rich cocoa extract and (2) compare profiles accumulated in the colon during habitual exposure to distinct profiles of dietary flavanols (monomer-rich, oligomer-rich, and polymer-rich fractions). We hypothesize that administration of equal amounts of flavanols with distinct qualitative profiles to

mice would result in colonic tissue accumulation of distinct qualitative and quantitative profiles of both native flavanols and their microbial metabolites in the colon tissue. Specifically, we hypothesize that (1) administration of cocoa flavanols will increase colonic tissue levels of flavanols and metabolites compared to a low-flavanols control diet and (2) administration of cocoa oligomers and polymers will result in reduced colonic tissue levels of monomeric flavanols and metabolites compared to cocoa extract or cocoa monomers.

## MATERIALS AND METHODS

**Chemicals and Standards.** Milli-Q water was prepared using a Millipore Milli-Q Gradient system (Billerica, MA, USA). Ascorbic acid, (+)-catechin hydrate (C), (−)-EC, epigallocatechin [(−)-(EGC)], epicatechin gallate [(−)-ECG], epigallocatechin gallate [(−)-(EGCG)], *p*-coumaric acid, *m*-coumaric acid, ferulic acid, isoferulic acid, caffeic acid, protocatechuic acid, 3-hydroxybenzoic acid, 4-hydroxybenzoic acid, vanillic acid, homovanillic acid, gallic acid, 4-hydroxymandelic acid, pyrogallol, catechol, phenylacetic acid, 2-(3′-hydroxyphenyl)acetic acid, 2-(4′-hydroxyphenyl)acetic acid, 3-(3′,4′-dihrdroxyphenyl)acetic acid, 3-phenylpropionic acid, 3-(4′-hydroxyphenyl)propionic acid, 5-phenyl-valeric acid, phloretin, hippuric acid, 3-(3′-hydroxyphenyl)propionic acid, and 3-(3′,4′-dihydroxyphenyl)propionic acid were obtained from Sigma (St. Louis, MO, USA). PC dimer $B_2$ and trimer $C_1$ were obtained from ChromaDex (Irvine, CA, USA). Purified PC dimer $B_1$, dimer $B_2$-gallate, dimer $B_5$, trimer $T_2$, tetramer $A_2$, and pentamers (DP 5) through decamers (DP 10) were obtained from Planta Analytica (Danbury, CT, USA). Solvents for extraction, fractionation, and normal-phase HPLC were of ACS grade or better (Fisher, Pittsburgh, PA, USA,or VWR, Radnor, PA, USA). Solvents for UPLC-MS/MS were of LC-MS grade (VWR).

**Cocoa Flavanols.** A flavanol-rich cocoa extract (CE) was produced and separated into fractions with distinct flavanol compositions (monomer-, oligomer-, and polymer-rich fractions). Procedures for extraction, fractionation, and characterization of CE and the fractions were described previously.[23] The levels of total flavanol monomers, dimers, and larger PCs in the CE and cocoa monomer, oligomer, and polymer fractions are presented in Table 1. The levels of individual compounds are presented in the Supporting Information (Table S1). Compared to CE, the monomer-rich fraction is highly enriched for monomers, slightly enriched for dimers, reduced in PCs DP 3−6, and depleted of PCs DP 7−10. The oligomer-rich fraction is highly depleted of monomers, greatly enriched for dimers and PCs DP 3−6, and slightly enriched for DP 7−10. The polymer-rich fraction is highly depleted for monomers, dimers, and PCs DP 3−6 and slightly enriched for PCs DP 7−10. It should be noted that these values are from reverse-phase UPLC analysis that quantified PCs only up to DP 10; the composition of larger PCs that make up a large portion of CE and the majority of the polymer fraction (see Figure S1) are not reflected in the total composition values in Table 1. The normal-phase HPLC flavanol profiles of CE and cocoa PC fractions are shown in Figure S1. By comparing relative peak heights and retention times (retention time roughly correlates to degree of polymerization in normal-phase analysis of flavanols) within each chromatogram, the monomer-, oligomer-, and polymer-rich fractions were indeed relatively enriched for flavanol monomers, oligomers, and polymers, respectively, compared to CE and each other.

**Animals.** Animal experiments were approved by the Institutional Animal Care and Use Committee (IACUC) at Virginia Polytechnic Institute and State University (protocol 13-099-FST). Male C57BL/6J mice ($N = 54$, ∼25 g) were obtained from Jackson (Bar Harbor, ME, USA). Following arrival, mice were maintained on standard rodent chow for 2 weeks under standard conditions (3 mice/cage, 12 h light/dark cycle, 30−70% relative humidity, 20−26 °C) to acclimatize to the vivarium. To reduce coprophagy, bedding was changed twice per week throughout the study. Mice were provided food and water ad libitum unless otherwise specified.

**Diets.** Mice were assigned to one of five diet/treatment combinations ($n = 9$/group). Animals were fed a basal high-fat diet (60% kcal from fat) from the diet-induced obesity model series (D12492, Research Diets, Inc., New Brunswick, NJ, USA). This a semipurified diet with the minimal polyphenol or phenolic background level that is practically attainable; the composition of this basal diet was reported previously[23] and is presented in Table S4 in the Supporting Information. The diet was provided alone (control) or supplemented with CE or one of the three cocoa fractions. The diets containing CE or cocoa fractions were formulated (262.53 mg/kg diet) to provide doses of 25 mg/kg body weight (BW)/day based on an estimated daily food consumption of 95.23 g food/kg BW/day for male C57BL/6J mice from previous studies in our laboratory (data not shown). Diets were maintained at −20 °C throughout the study to prevent degradation of lipids or cocoa compounds. To maintain freshness and prevent degradation of fat or cocoa compounds, food was replaced twice per week for all cages. Animals were maintained on diets for 12 weeks. Food intake for each cage was measured twice per week by weighing food provided and weighing leftover food prior to replacement with fresh food. Food intake did not differ between treatment groups (data not shown).[23]

**Animal Procedures.** Animal body weights (weekly), body composition (weeks 1, 5, 8, and 11), glucose tolerance (week 10), and insulin tolerance (week 11) were measured. These results have been described previously.[23]

**Euthanasia and Necropsy.** At the end of week 12, mice were fasted overnight and euthanized by $CO_2$ (following AVMA Guidelines on Euthanasia) followed by bilateral pneumothorax. Following euthanasia, the abdominal cavity was opened ventrally, and the intestines were removed by cutting through the rectum and gently removing the intestinal tract from the distal end. The colon (between the cecum and rectum) was excised and thoroughly flushed with prechilled 1× phosphate-buffered saline (PBS, VWR) and immediately snap-frozen in liquid $N_2$. Samples were stored at −80 °C prior to sample preparation.

**Extraction of Flavanols and Microbial Metabolites.** Sample preparation and extraction was performed using our previously published method with modifications.[30] Tissue samples were freeze-dried for >24 h using a FreeZone 1 L freeze-dryer (Labconco, Kansas City, MO, USA). Zirconium oxide tissue homogenization beads (∼100 mg, 0.5−1 mm, Next Advance, Averill Park, NY, USA) were added to each sample (25−35 mg dry tissue) along with 50 μL of Milli-Q water and 50 μL of a 1% (w/v) aqueous ascorbic acid solution. Samples were homogenized in a Bullet Blender (Next Advance, speed 7, 1 min, 4 °C). Liquid−liquid extraction was performed by adding 1 mL of ethyl acetate and blending in a Bullet Blender (5 min, speed 9, 4 °C, Next Advance). Samples were centrifuged (5 min, 17000*g*, room temperature), and the organic supernatant was collected. The extraction was repeated on the resulting pellet, and the supernatants were pooled for each sample and dried under a gentle stream of $N_2$ (35 °C). Following liquid−liquid

extraction, solid-phase extraction (SPE) was performed on the remaining pellet. An extraction solution (1 mL acetone/water/glacial acetic acid, 70:28:2 v/v/v) was added to each sample along with 100 $\mu$L of 4% aqueous phosphoric acid. Samples were homogenized in a Bullet Blender (5 min, speed 9, 4 °C) and centrifuged (5 min, 17000*g*, room temperature), and the supernatant was collected. The extraction was repeated, and the supernatants were pooled for each sample. The pooled extracts were diluted with 12 mL of water. Oasis HLB SPE cartridges (1 $cm^3$, 30 mg sorbent, Waters, Milford, MA, USA) were preconditioned with 1 mL of methanol (MeOH) followed by 1 mL of water. The diluted samples (2 mL of pooled extracts + 12 mL of water) were loaded onto the cartridges using a vacuum manifold. Cartridges were washed sequentially with 1 mL of acidified water (0.1% formic acid, v/v) followed by 0.5 mL of 5% (v/v) aqueous MeOH containing 0.1% formic acid (v/v). Cartridges were eluted sequentially with 2 mL of acidified MeOH (0.1% formic acid, v/v) followed by 2 mL of acetone/water/glacial acetic acid (70:28:2) and collected into the tubes containing the dried ethyl acetate extracts from the same sample. Samples were dried under vacuum in a Speed-Vac (45 °C) to remove acetone and MeOH, then frozen on dry ice and freeze-dried for >24 h to remove water and acetic acid. Dried samples were resolubilized in 1 mL of 0.1% formic acid in water/0.1% formic acid in acetonitrile (ACN) (95:5 v/v), sonicated in ice water (25 min), and then filtered into certified LC-MS vials (Waters) using a Samplicity filtration system (0.2 $\mu$m PTFE Philic Millex Samplicity filters, Millipore). Filtered samples were analyzed immediately. The extraction recovery of native flavanols and metabolites by this method was validated in our previous method paper.[30]

For extraction of the diet, 3 g samples of each diet were weighed in triplicate and defatted using hexane. Samples were vortexed with 20 mL of hexane, sonicated on ice (10 min), and centrifuged (5 min, 3500*g*, room temperature), the supernatant was discarded, and the procedure was repeated. An extraction solution (10 mL of acetone/water/glacial acetic acid, 70:28:2 v/v/v) was added to each sample. Samples were then vortexed for 30 s and sonicated on ice for 10 min. Samples were centrifuged (5 min, 3500*g*, room temperature), and the supernatant was collected. The extraction was repeated. The supernatants were pooled for each sample, and 2 mL was diluted with 12 mL of water. Oasis HLB SPE cartridges (1 $cm^3$, 30 mg sorbent, Waters) were preconditioned as described above. The diluted samples (2 mL of pooled extracts + 12 mL of water) were loaded onto the cartridges using a vacuum manifold. Cartridges were washed and eluted as described above into tubes containing the dried ethyl acetate extracts from the same sample. Samples were dried under vacuum in a Speed-Vac (45 °C) to remove acetone and methanol, then frozen on dry ice and freeze-dried for >24 h to remove water and acetic acid. Dried samples were resolubilized, sonicated, and filtered into LC-MS vials as described above. Filtered samples were analyzed immediately.

**UPLC-MS/MS Analysis of Flavanols and Microbial Metabolites.** UPLC-MS/MS analysis was performed using our previously published method with modifications.[30] Details of the methodology are found in the Supporting Information.

**Folin−Ciocalteu Assay.** To extract phenolics from the diet, samples of each diet were weighed in triplicate, defatted twice, and extracted twice as described above. For the Folin assay, 200 $\mu$L of each sample was combined with 2.5 mL of 0.2 N Folin−Ciocalteau reagent. Then, 2.0 mL of saturated aqueous $Na_2CO_3$ was added to each sample, and samples were incubated at room temperature for 2 h. The absorbance was then read at 765 nm. The standard curve was prepared using gallic acid, and total phenolics were calculated as milligrams of gallic acid equivalents (GAE) per gram of material.

**Data and Statistical Analysis.** Outliers were identified and removed using Dixon's *Q* test at the $\alpha = 0.05$ level if necessary. Data were analyzed by one-way ANOVA to determine overall significance of treatment. If significance was detected, Tukey's HSD post hoc test was then performed to compare all treatment means. Significance was defined as $P < 0.05$.

## RESULTS AND DISCUSSION

**Dietary Levels of Native Flavanols.** Levels of native cocoa catechins and PCs in the diet are presented in Figure S2 in the Supporting Information. UPLC-MS/MS analysis of the diets showed that the profile of native flavanols in the diet matched those of the pure extracts. As seen in Figure S2A, the amount of total native flavanols (catechins and PCs) in the control diet is negligible, including an undetectable level of oligomers. This demonstrates that there is essentially no background contribution of catechins or PCs (that can be measured by our UPLC-MS/MS method, i.e., DP 1−10) in the basal control diet and that the only source of catechins and PCs in each diet is the CE or the cocoa fraction added to the basal diet. Panels B−D of Figure S2 show that the monomer- and oligomer-supplemented diets were enriched with monomeric and oligomeric flavanols, respectively, at levels that are significantly higher than those in the other fractions. Overall, the total amount of native flavanols that can be measured by our UPLC-MS/MS method (DP 1−10) found in the polymer diet was lower than in the diets supplemented with CE, monomers, or oligomers, as seen in Figure S2A. This is due to the fact that the larger PC compounds (DP > 10) that make up a large portion of the polymer fraction (see Figure S1) are not resolved or detected with this method as previously shown. Therefore, the measured levels are not reflective of all compounds present in the polymer fraction, but rather those that can be accurately measured using the present UPLC-MS/MS method. These data demonstrate that the vast majority of native flavanols in the diet are from the cocoa fractions and not the basal diet itself.

**Dietary Levels of Metabolites.** Background levels of metabolite compounds (compounds that we identified as microbial metabolites of catechins and PCs but that were present in the diets before being administrated to mice) present in the diets are shown in Figure S3 in the Supporting Information. There was a significant concentration of these compounds in the basal control diet (1.13 ± 0.0273 mg/g, Figure S3A); supplementation of the basal diet with CE or cocoa fractions did not significantly alter the levels present in the diet (1.23 ± 0.0402−1.71 ± 0.292 mg/g). The majority of the metabolites present in the diets are compounds other than the phenylalkyl and benzoic acid derivatives (Figure S3D), such as ferulic acid. These compounds are common in plant materials[37] and are likely introduced from plant-based ingredients in the semipurified diet (Table S4). There were somewhat higher (but not statistically different) levels of phenylalkyl and benzoic acid derivatives in the monomer-supplemented diet (Figure S3B−C). This is potentially due to fractionation, which may cause phenylalkyl and benzoic acids occurring in cocoa to elute with the monomer fraction during SPE. It should be noted that we have previously observed appreciable levels of these metabolites in intestines of rats fed a semipurified basal control diet;[30] these compounds appear to be unavoidable background components in plant-based rodent diets. Overall, these data show that there is no significant contribution of metabolite compounds by the CE or cocoa fractions above levels present in the basal diet alone and that levels of metabolites present in the diets are similar across treatment groups.

On the basis of analysis of the diets, differences in the levels of native flavanols (catechins and PCs) and their microbial metabolites in the colon of mice fed these diets would be expected to be due solely to the composition of the CE or fraction with which each diet was supplemented.

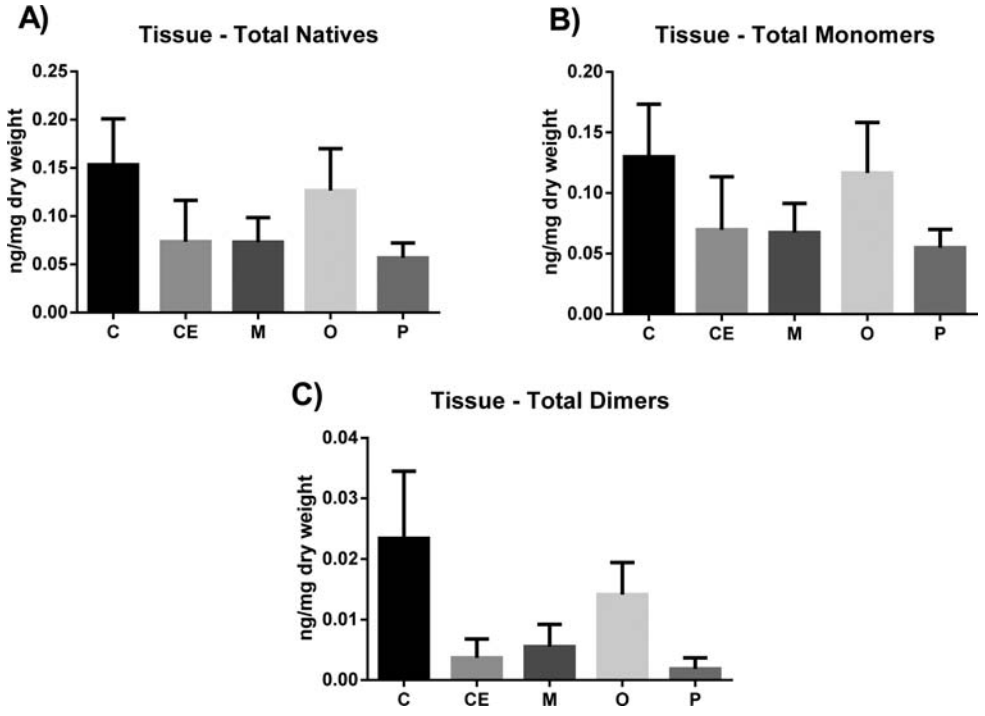

**Figure 3.** Tissue levels of total native compounds (A), total monomers (B), and total dimers (C) in mouse colon tissue following 12 weeks of exposure to the experimental diets. Mice were fasted for 12 h prior to euthanasia and collection of colon tissue. Data are presented as the mean ± SEM from $n = 9$ animals. No significant differences were detected between treatments for total native compounds, total monomers, or total dimers (one-way ANOVA with Tukey's HSD post hoc test, significance defined as $P < 0.05$). Treatments: mice fed basal control diet (C), mice fed control diet supplemented with cocoa extract (CE), mice fed control diet supplemented with cocoa monomers (M), mice fed control diet supplemented with cocoa oligomers (O), and mice fed control diet supplemented with cocoa polymers (P).

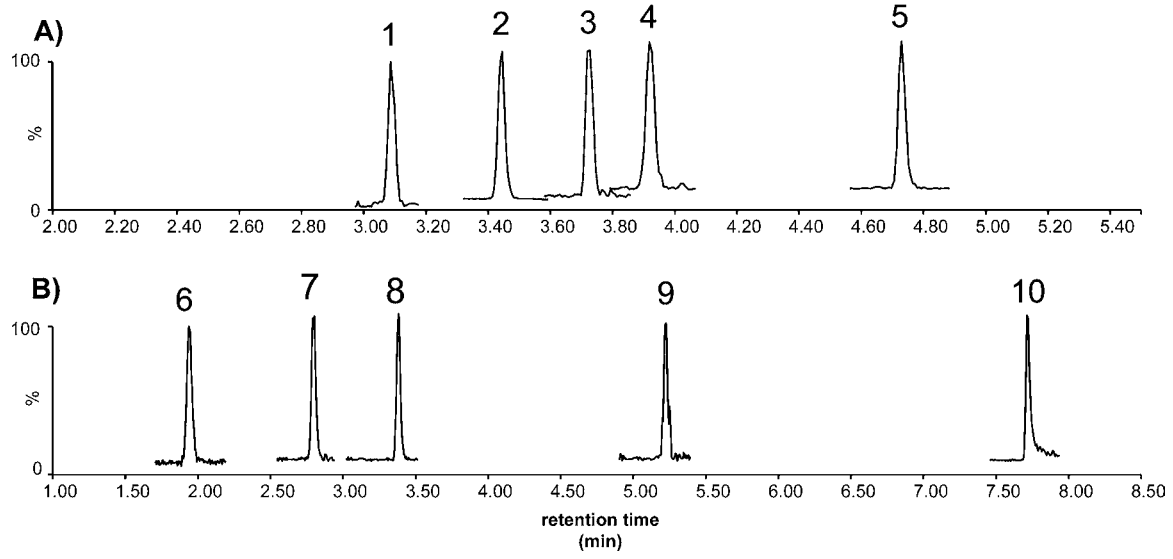

**Figure 4.** Representative UPLC-MS/MS multireaction monitoring (MRM) chromatograms of detected native flavanols (A) and microbial metabolites (B) in the colon tissue of a mouse fed a basal diet supplemented with cocoa oligomers for 12 weeks. All chromatograms are normalized to equal height (100% relative intensity). All chromatograms are from the same animal. Compound identities: (1) catechin; (2) PC $B_2$; (3) (−)-epicatechin; (4) PC $C_1$; (5) PC $B_5$; (6) 3,4-dihydroxybenzoic acid; (7) 4-hydroxybenzoic acid; (8) 3-hydroxybenzoic acid; (9) phenylacetic acid; (10) unknown metabolite [an isomer of 5-(3′,4′-dihydroxyphenyl)valeric acid].

**Colon Tissue Levels of Native Flavanols.** The levels of native flavanols detected in mouse colons are shown in Figure 3. Supplementation of the basal control diet with flavanols did not increase the colonic tissue accumulation of these compounds compared to the basal control diet alone. Whereas tissue accumulation levels of native flavanols were extremely low, the chromatograms shown in Figure 4A demonstrate that the peaks are large, accurately measurable peaks, as opposed to very small peaks and/or baseline noise. Furthermore, quantified peaks were found to be above the signal-to-noise ratio limit of 10:1 for lower limit of quantification. These data suggest that there was very little tissue accumulation of native flavanols in the colon during

dx.doi.org/10.1021/jf503838q | J. Agric. Food Chem. 2014, 62, 11190−11199

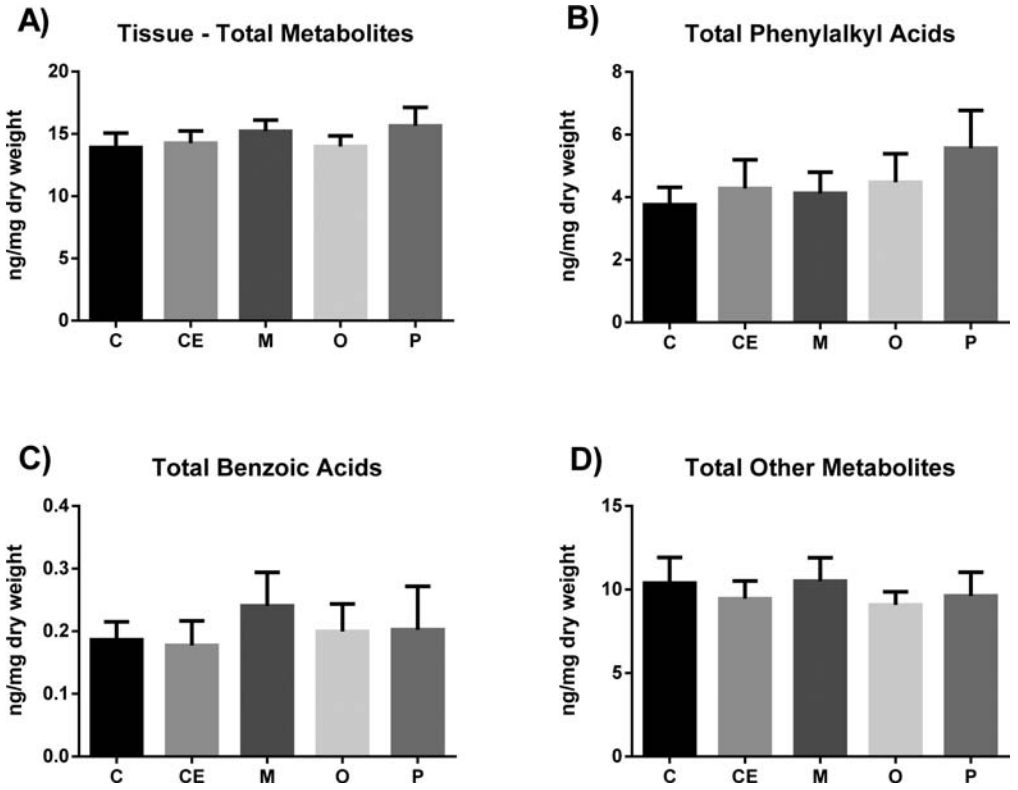

**Figure 5.** Tissue levels of total metabolites (A), total phenylalkyl (phenylacetic, phenylpropionic, and phenylvaleric) acid derivatives (B), total benzoic acid derivatives (C), and total other metabolites (D) in mouse colon tissue following 12 weeks of exposure to the experimental diets. Mice were fasted for 12 h prior to euthanasia and collection of colon tissue. Data are presented as the mean ± SEM from $n = 9$ animals. No significant differences were detected between treatments for total native compounds, total monomers, or total dimers (one-way ANOVA with Tukey's HSD post hoc test, significance defined as $P < 0.05$). Treatments: mice fed basal control diet (C), mice fed control diet supplemented with cocoa extract (CE), mice fed control diet supplemented with cocoa monomers (M), mice fed control diet supplemented with cocoa oligomers (O), and mice fed control diet supplemented with cocoa polymers (P).

the 12 week feeding period, but tissue accumulation was measurable. Our data differ from the results of previous studies of colonic tissue accumulation that have used much higher doses (125−1000 mg/kg) and found significant colonic tissue accumulation of flavanols.[11,29,30] This finding could be due to the comparatively low dose (25 mg/kg) or the 12 h fast before euthanasia. Both of those factors contribute to the accumulation and retention of these native flavanols in coloninc tissues. However, the 12 h fast alone would not result in significant depletion of ingested native flavanolss and their metabolites, partly due to the gastrointestinal (GI) transit time required to reach the colon [a portion of food ingested in the hours prior to fasting would still be in the lower GI tract at 12 h, as reflected by the fact that about half of the mouse colons contained fecal matter at the time of sacrifice in the present study (data not shown)]. Furthermore, acute studies have shown appreciable levels of native flavanols and their metabolites in the colon at from 8 to 18 h postadministration of flavanols,[11,28,30] albeit with much higher doses administered.

The finding that chronic feeding of flavanols did not elevate levels of intact flavanols in the colon was completely unexpected, due to the fact that the basal diet had roughly $10^5$−$10^6$-fold lower levels of native flavanols than any of the cocoa-supplemented diets (Supporting Information Figure S2A). One possible explanation for this is that the 12 week feeding of the cocoa-supplemented diet may have stimulated the gut microbiota in these animals to adapt and become extremely efficient at metabolizing native flavanols; the gut microbiota in animals fed the basal control diet would have had little stimulus to increase their metabolism of the native flavanols. The net effect of a 12 week feeding of flavanols would be to accumulate less of the native flavanols in the colon, despite higher dietary levels. Another possibility is that chronic exposure to flavanols could have unregulated detoxification pathways in the gut epithelium (phase-I/II enzymes and apical efflux transporters such as multidrug-resistant proteins (MRPs) and P-glycoprotein (Pgp)].[38,39] Similar to the first possibility, the gut epithelium in animals fed a semipurified (and largely polyphenol-free) diet would have had little stimulus to increase their metabolism of the native flavanols. Phase-I/II metabolites were not analyzed in the present study due to the sheer number of compounds measured. Provocative data have shown that chronic dosing of grape flavanols for 10 days up-regulates both phase-II metabolism of catechins and depolymerization of procyanidins (likely by the gut microflora) from an acute dose compared to an acute dose without prior chronic dosing, although this study reported only blood levels.[40] This suggests that both mechanisms may be responsible for our data. Future studies could employ various strategies to quantify phase-I/II metabolites of flavanols.[41] For example, parallel analyses could be performed on the same tissue, with one sample first incubated in $\beta$-glucuronidase/sulfatase prior to extraction and the other sample extracted without enzymatic deconjugation, with the difference in measured native flavanols between the two assays representing the extent of glucuronidation and sulfation. Assessment of *O*-methylated metabolites is more challenging, as enzymatic deconjugation is

not feasible and *O*-methyl derivatives must be measured directly, doubling or tripling the number of compounds to monitor.

Interestingly, no PCs larger than trimers (DP 3) were detected above the lower limit of detection (LLOD) in the colon tissue, despite the fact that these larger compounds made up significant portions of the oligomer- and polymer-supplemented diets (Table 1; Figures S1 and S2D) and were easily detectable using our UPLC-MS/MS method. Therefore, it appears that larger PCs are particularly affected by alterations to colonic metabolism occurring during chronic flavanol exposure.

**Colon Tissue Levels of Metabolites.** The levels of microbial metabolites detected in mouse colons are shown in Figure 5. Similar to the native flavanols, the UPLC-MS/MS peaks for the predominant metabolites (Figure 4B) were sizable and not merely "noise", confirming the accuracy and reliability of these data. Mean tissue accumulation levels of microbial metabolites were notably greater than accumulation of native flavanols (13.9−15.2 vs 0.0568−0.153 ng/mg tissue, respectively). However, there were no statistically significant differences in the accumulated levels of total metabolites or in any subclass of metabolites (Figure 5B−D) between treatments. Considering only the four treatments supplemented with CE or cocoa fractions, the data suggest that no matter the source or size (DP) of flavanols, they are all metabolized into similar qualitative and quantitative profiles of compounds during chronic exposure. The finding that the levels of microbial metabolites were not elevated in the flavanol-supplemented diets compared to control was quite surprising, given the differences in dietary levels of flavanols between the diets (Supporting Information Figure S2). Our hypothesis that extensive microbial metabolism of native flavanols potentially led to their low tissue levels (Figure 3) would suggest that extremely high levels of the resulting metabolites should be found in the colon of flavanol-fed mice compared to basal control; clearly this was not the case. Therefore, the reason for the similarity in colonic levels of native flavanols and microbial metabolites between basal control and flavanol-fed mice remains unclear.

**Folin−Ciocalteu Assay.** The surprising finding that total levels of accumulated metabolites were similar for the basal control diet and diets supplemented with cocoa flavanols suggested the possibility that the basal diet contained other phenolics that were not detected by the UPLC-MS/MS assay. UPLC-MS/MS was specific for common catechin monomers and B-type PCs; the presence of other phenolics in the diets that could be metabolized to the few dozen common metabolites could explain the data in Figure 5. Therefore, the Folin−Ciocalteu assay was performed on the diets to determine the total concentration of phenolics that could have been metabolized to the common metabolites measured by UPLC-MS/MS. As shown in Figure S4 in the Supporting Inforamtion, the concentrations of total phenolics in all diets supplemented with CE or the cocoa fractions were significantly higher than that of the basal control diet. These data are in agreement with UPLC-MS/MS data showing that supplementation of the basal control diet with cocoa flavanols significantly increased the phenolic content of the diet and the available substrates for microbial metabolism. However, the magnitude of the differences in levels of phenolic compounds between basal control and supplemented diets differed greatly for the two assays (~2.2-fold for the Folin assay vs $\sim 10^5-10^6$-fold for the UPLC-MS/MS assay). It should be noted that the Folin assay more accurately represents the total antioxidant activity, including nonphenolic constituents[42]). Nevertheless, both measures confirm significantly greater levels of phenolics available for microbial metabolism in flavanol-supplemented diets compared to control, but these differences are not reflected in tissue accumulation of microbial metabolites in the colon tissue (Figure 5). Therefore, similarities in colon metabolite levels between control and flavanol-supplemented mice are not due to large levels of undetected phenolics in the background diet but rather due to colonic metabolism and clearance of native flavanols in flavanol-supplemented mice. Lignins are a potential source of the same metabolites that are produced by metabolism of flavanols, but which may not have been accounted for by the Folin assay. Lignins are found in virtually all plant materials used for animal feeds,[43] as well as cacao beans.[44] However, lignins in the diets used for the present study would likely be almost exclusively from the basal control diet, as lignin would not be appreciably extracted from the cocoa (efficient lignin extraction generally requires high heat, whereas our extractions were performed at room temperature).[45−47] These compounds were not measured by our specific UPLC-MS/MS method, and therefore would not be accounted for in our analysis of native flavanols. It is unknown if the levels of lignins present in the basal control diet contributed to the measured Folin values. Lignins have Folin activity,[48,49] but it is inversely proportional to lignin DP.[50] Therefore, large lignins would have contributed little to observed Folin values. Anaerobic microbial metabolism of lignins results in the formation of several phenolic metabolites also formed by metabolism of flavanols,[51] including phenylacetic acid, benzoic acid, 3-phenylpropionic acid, acid, vanillic acid, ferulic acid, caffeic acid, and catechol. Therefore, the presence of high levels of large lignins in the basal control diet could partly explain why this diet produced similar levels of phenolic metabolites compared to flavanol-supplemented diets (assuming that supplementation with flavanols did not significantly increase the level of precursor compounds above that present in the basal diet).

One limitation of the present study is that the mice were fed a high-fat, low-carbohydrate diet (60 and 20% kcal from fat and carbohydrates, respectively; Supporting Information Table S4).[23] It is unknown how the high-fat diet affected gut microflora composition and subsequent metabolism and tissue accumulation of flavanols. Future work is required to examine the colon tissue accumulation during low-fat (~10% kcal from fat) feeding. However, the present data are relevant, as there is interest in using cocoa flavanols to combat obesity and type-2 diabetes,[22,23] which typically occur in the context of a high-fat diet.

To the best of our knowledge, the present study represents the longest known chronic flavanol feeding study for which colonic tissue accumulation data are reported. Although colonic tissue accumulation levels may be transient (compounds present in the tissue may be metabolized inside cells and/or effluxed into circulation or back into the lumen over time), these levels represent the typical profile of flavanols and their metabolites to which the colon tissue is exposed during chronic flavanol intake.

Our findings, and those of Wang et al.,[40] highlight the pronounced differences observed between single acute doses in animals not previously exposed to flavanols[11] and chronic low doses to which the gut microbiota and epithelium adapt. The results from the present study indicate that we do not yet fully understand the fate of ingested flavanols in the colon during chronic dietary exposure to these compounds. There have been comparatively few studies that characterize the fate of flavanols during long-term chronic exposure to these compounds. Our data demonstrate that these factors (time and dose) warrant further consideration in future studies comparing various doses

and various exposure times. The rationale for these studies is that chronic, low-dose exposure to flavanols is more relevant to human health than high-dose, acute exposure in animals not previously exposed to flavanols.

Additionally, due to the unexpected findings of this study, little is still known regarding the metabolism of larger PCs. We hoped that feeding oligomeric and polymeric PCs would provide data regarding their metabolism. It is known that PC dimers can be metabolized by microflora to dimeric ring-opening intermediates without depolymerization.[13] This key discovery suggests that larger PCs may also be incrementally metabolized from the ends inward and are not necessarily depolymerized prior to ring-opening and other reactions. However, it is still unknown how the dimeric intermediates are further metabolized. Potential metabolic fates of larger PCs include formation of similar intermediates by ring opening (trimers → trimeric intermediates, tetramers → tetrameric intermediates, etc.) and depolymerization to smaller PCs and monomers (this has been shown to be minimal in the stomach and small intestine, but occurrence in the colon remains unknown) prior to further metabolism;[40] alternatively, these larger PCs compounds may remain largely intact and unmetabolized.

Therefore, studies are warranted to compare colonic metabolism and tissue accumulation of flavanols, as well as blood pharmacokinetics,[40] during acute versus chronic exposure. Such studies should compare the quantitative and qualitative profiles of native flavanols and their microbial metabolites in the colon at relevant time points of dietary flavanol exposure. Relevant time points for such studies would likely follow a single acute dose without prior exposure, 1 week chronic exposure, 1 month chronic exposure, and so forth. Such studies are necessary to generate data relevant to human use, where flavanols are typically ingested throughout the lifespan from foods as well as dietary supplements. Additionally, the correlation between colonic tissue accumulation profiles and colonic activity resulting from distinct dietary flavanol profiles warrants further consideration. We have previously shown that distinct flavanol profiles result in distinct biological activities, but the impact of small versus large PCs on colon health remains poorly understood. This study suggests that differences in colon tissue activities would not be predicted by differences in accumulation profiles.

BBCH (Biologische Bundesanstalt, Bundessortenamt and Chemical Industry) scale (system for a uniform coding of phonologically similar growth stages of all monodicotyledonous plant species).

**Sample Preparation.** The aerial parts of winter wheat, *T. aestivum* L. var. Legenda, voucher specimen 4 (BBCH 47), were harvested at principal growth stage in July 2012. The plant material directly after harvesting was frozen in the laboratory freezer (−18 °C), and then lyophilized using freeze-dryer Gamma 2-16 LSC from Martin Christ Gefriertrocknungsanlagen GmbH, Germany (time, 3 days; pressure, 1 mbar). *T. aestivum* L. aerial parts were powdered using an Ultra Centrifugal Mill ZM 200 (Retsch), a modern grinder, which does not cause sample warmup (12-tooth rotor; sieve size, 0.50 mm), and defatted in a Soxhlet extractor with chloroform. The plant material was then used for extraction.

**Chemical Reagents.** Solvents used in the study (methanol, acetonitrile, formic acid, toluene, chloroform, ethyl acetate, 85% orthophosphoric acid, and acetic acid) were of the analytical purity grade, purchased from J. T. Baker (Deventher, The Netherlands). D-Glucose, D-glucuronic acid, D-ribose, L-cystein methyl ester hydrochloride, *o*-toryl isothiocyanate, and 2,2-diphenyl-1-picrylhydrazyl radical (DPPH$^{\bullet}$) were obtained from Sigma-Aldrich Chemical Co. (St. Louis, MO, USA). Fractions were analyzed by TLC (25DC, Alufilien, 20 cm × 20 cm cellulose, Merck, Darmstadt, Germany). The TLC-DPPH$^{\bullet}$ test was performed on the surface of aluminum-backed silica gel 60 $F_{254}$ plates (Merck). Other chemicals were obtained from POCH S.A. (Gliwice, Poland). Phenolic standard solutions were prepared at a concentration of 1 mg/mL.

**Extraction and Fractionation of Crude Wheat Extract.** Defatted aerial parts of winter *T. aestivum* L. var. Legenda (250 g) were subjected to triple extraction with boiling 70% aqueous methanol solution (v/v; 2.5 L; 1 h) under reflux. The collected extracts were combined and filtered through a filter funnel, concentrated using a rotary evaporator (Heidolph), and freeze-dried. The crude extract (40 g) was fractionated using vacuum liquid chromatography; it was suspended in water, and the solution was applied to a 6 cm × 10 cm, 40−63 μm, LiChroprep RP-18 (Merck) preparative column, previously preconditioned with water. The column was washed first with water to remove sugars and then with 40% methanol to elute phenolics. The fraction washed out with 40% methanol was used in the next step of the purification procedure, because it was shown by UHPLC-PDA-ESI-MS/MS analyses to contain numerous phenolic compounds, mainly phenolic acids and flavonoids. Ultrahigh-performance chromatographic separations were performed on an Acquity UPLC System chromatograph (Waters Corp., Milford, MA, USA), equipped with a PDA and a triple-quadrupole mass detector (Acquity TQD, Waters). The crude wheat extract and phenolic fraction were separated on an Acquity HSS C18 (100 × 2.1 mm, 1.8 μm; Waters) column, maintained at 40 °C. The elution (400 μL/min) was carried out with a gradient of solvent B (acetonitrile with 0.1% formic acid) in solvent A (water with 0.1% formic acid): 0−4 min, 7% B; 4−22 min, 7−17% B; 22−24.95 min, 17−45% B; 24.95−25 min, 45−95% B; 25−27 min, 95% B; 27−27.05 min, 95−7% B; 27.05−30 min, 7% B. One microliter of a sample was injected for analysis. The PDA was operated in the range of 220−480 nm (3.6 nm resolution). Mass analyses were performed in the negative ionization mode, using the following conditions: capillary voltage, 2.8 kV; cone voltage, 35 V; source temperature, 140 °C; desolvation temperature, 350 °C; cone gas flow (nitrogen), 100 L/h; desolvation gas flow, 800 L/h; collision gas (argon) flow, 0.1 mL/min. All data were acquired and processed using Waters MassLynx 4.1 software.

**Purification of Phenolic Compounds.** The fraction washed out with 40% methanol was used for isolation of phenolics according to a previously used protocol but with slight modifications.[16] In short, the 40% methanol fraction was condensed nearly to dryness in vacuo, redissolved in distilled water, and loaded onto a preparative column (4 cm × 50 cm, 40−63 μm, LiChroprep RP-18, Merck). The column was washed with water and then with increasing concentrations of methanol in water (5% increments from 0 to 100% methanol). Ten milliliter fractions were collected and checked by TLC on cellulose plates (15:85 acetic acid/water; 25DC, Alufilien, 20 cm × 20 cm cellulose; Merck), and spots were visualized under UV at 366 nm. Fractions showing similar TLC patterns (41 fractions) were combined, evaporated, dissolved in water, freeze-dried, and further analyzed by HPLC. HPLC analyses were performed on a Waters system equipped with a model 616 pump, a model 600s controller, and a model 996 PAD detector. Millenium Chromatography Manager software (Waters Corp.) was used to monitor chromatographic parameters and to process the data. Twenty microliters of each fraction was injected for analysis. Fractions were applied to a Eurospher-100 C18 column (Knauer, Germany) (0.4 cm × 25 cm i.d., 5 μm) and eluted at 1 mL/min with a linear gradient of 1% $H_3PO_4$ in water/60% methanol in 1% aqueous $H_3PO_4$ (80:20%), increasing to 0:100% over 60 min. The column was maintained at 50 °C. Fractions possessing one compound were combined and evaporated to dryness. Fractions containing more than one compound were further purified on a C18 glass column (2 cm × 50 cm, 25−40 μm, Merck) using an isocratic system (methanol/1% $H_3PO_4$).

Semipreparative HPLC was used for purification in the case of fractions obtained in small amounts. This system was equipped with Gilson 321 pump, a liquid handler Gilson GX-271 with a 2 mL sample loop, a Gilson Prep ELSTM II detector, and a semipreparative reserved phase Atlantis Prep T3 (250 mm × 10 mm i.d., 5 μm) column and an Agilent Eclipse Plus C18, (150 mm × 4.6 mm i.d., 3.5 μm) analytical column. The choice of the column depended on the amount of purified fraction. Solvent system (A, $H_2O$ containing 0.2% HCOOH; B, $CH_3CN$ containing 0.2% HCOOH) was optimized individually for each fraction. The column temperature was maintained at 30 °C.

In this way 14 pure phenolic compounds were isolated.

**Mass Analyses of Purified Compounds.** Exact masses of wheat phenolics were determined by direct infusion electrospray high-resolution (Q-TOF) mass spectrometry (HRESI-MS), using a SYNAPT G2-S HDMS mass spectrometer (Waters, Manchester, UK).

Fragmentation analyses were performed by direct infusion electrospray mass spectrometry, using an Acquity TQD mass spectrometer (Waters Corp., Milford, MA, USA).

**NMR Analysis.** NMR spectra were acquired in 650 μL of methanol-$d_4$ at 25 °C or DMSO-$d_6$ at 70 °C on a Bruker Avance III HD 500 MHz instrument (Bruker BioSpin GmbH, Rheinstetten, Germany) equipped with a 5 mm probe ($^1$H, 500.18 MHz; $^{13}$C, 125.79 MHz). Standard pulse sequences and parameters were used to obtain 1D $^1$H, 1D selective TOCSY, 1D selective ROESY, 1D $^{13}$C, and DEPT-135, gCOSY, ROESY (mixing time = 250 ms), gHSQC, gHSQC-TOCSY (mixing time = 80 ms), gHMBC spectra. Chemical shift referencing was carried out using the internal solvent resonances at $\delta_H$ 3.31 and $\delta_C$ 49.0 for methanol-$d_4$ and at $\delta_H$ 2.50 and $\delta_C$ 39.51 for DMSO-$d_6$ (calibrated to TMS at 0.00 ppm).

**Determination of the Absolute Configuration of Sugars.** The absolute configuration of sugars was determined according to a modified method of Tanaka et al.[17] Flavonoids were subjected to acid hydrolysis (1 mL of 2 M HCl, 2 h, 100 °C). Aglycones or partially hydrolyzed *C*-glycosides were then extracted with ethyl acetate (3 × 1 mL), and sugar-containing aqueous layers were neutralized with Amberlite IRA-400 (OH− form). After drying, the samples were used to determine the absolute configuration of the constituent monosaccharides. Samples of monosaccharides obtained after acid hydrolysis of flavonoids were dissolved in 100 μL of anhydrous pyridine, containing 0.5 mg of L-cysteine methyl ester hydrochloride, and heated at 60 °C for 1 h. Then 100 μL of *o*-toryl isothiocyanate (0.5 mg) solution in pyridine was added, and the mixture was heated for another hour, at 60 °C. After cooling, samples were analyzed by UPLC-ESI-MS/MS. Chromatographic separations were carried out on an Acquity BEH C18 column (100 × 2.1 mm, 1.7 μm; Waters). Mass spectrometry analyses were performed in positive ionization mode, using the SRM method. Details of the analysis can be found in the work of Pérez et al.[18] D-Glucose (Glc), D-glucuronic acid (GlcA), and D-ribose (Rib) were identified on the basis of retention time and $m/z$ values of authentic standards, derivatized in the same way.

**TLC-DPPH$^{\bullet}$ Test.** The ability of isolated wheat phenolic compounds to scavenge DPPH$^{\bullet}$ radicals was determined using a

TLC rapid test. Briefly, standard solutions (1 mg/mL) of the purified phenolic acids, flavonoids, and rutin (positive control) were prepared. Aliquots of the standard solutions (5 μL) were applied to aluminum-backed silica gel chromatographic plates by means of a micropipet with a scale. All of the samples were applied bandwise (5 mm wide), with a distance of 10 mm between them, and a 10 mm distance from both the left and low edge of the plate. The plates were developed in vertical chambers presaturated for 15 min with the optimized mobile phase: acetonitrile/water/chloroform/formic acid (60:15:10:5, v/v/v/v). The plates were developed to a distance of 90 mm and dried in a hood for 10 min before derivatization. TLC plates were immersed for 5 s in freshly prepared 0.2% (w/v) methanolic DPPH• solution. After removal of excess DPPH•, plates were kept in the dark for 30 min and then scanned by means of flatbed scanner. The test was performed in triplicate.

**Image Processing Procedure.** Videoscans saved as JPG files were processed by means of a Sorbfil TLC Videodensitometer, a program elaborated by Sorbpolymer JSC (Sorbpolymer JSC, Krasnodar, Russian Federation, 2006; http://www.sorbfil.com). A detailed description of the procedure can be found in a previous publication.[19] First the background was corrected using the option "Background approximation"; for this purpose 50 marker points were placed on the brightness map generated after choosing the aforementioned option. Then the "Correct background" option was chosen to obtain uniform background brightness required to correctly evaluate the free radical scavenging activity of the isolated compounds. As the bands of active polyphenols appear as bright zones against a darker background, it is crucial to chose "Bright spots" option from the program toolbar. Finally, the tracks were assigned, each track corresponding to a given compound. There were 15 tracks, in total, 14 corresponding to all of the isolated polyphenols and one for rutin, which was used as a standard, with well recognized free radical scavenging activity. The bands of active compounds were converted to corresponding peaks, as also seen in Figure 3. The area under the peak of each individual compound was related to the area under the peak of rutin, developed and derivatized under the same conditions.

**Quantification of Wheat Phenolics.** Phenolic compounds were quantified in crude extract prepared at a concentration of 1 mg/mL using chromatographic conditions presented under Extraction and Fractionation of Crude Wheat Extract. These determinations were carried out using the external standard method. Phenolic acids were quantified using 5-caffeoylquinic acid (chlorogenic acid) as a group standard, and UV detection was performed at 325 nm. Flavonoids were quantified using rutin as a group standard, and UV detection was performed at 255 nm.

**Chemical Data of New Wheat Flavonoids. 15**: luteolin 6-*C*-[$6_{Glc''}$-*O*-*E*-caffeoyl-*β*-D-glucopyranosyl(1″→2)-*β*-glucopyranoside] (2 mg), yellow solid; UV (UPLC-PDA) $\lambda_{max}$ (nm) 271, 335; HRESI-MS (Q-TOF), *m*/*z* 771.1770 $[M - H]^-$ (calcd for $C_{36}H_{35}O_{19}^-$ = 771.1778); ESI-MS/MS (TQ), *m*/*z* 773 $[M + H]^+$, 611 $[M + H - 162]^+$, 449 $[M + H - 162 - 162]^+$, 329 $[M + H - 162 - 162 - 120]^+$, 287 $[Y^0 + H]^+ = [M + H - 162 - 162 - 162]$, 325 $[Caf + H + 162 - 18]^+$, 163 $[Caf + H - 18]^+$ (NMR data are presented in Table 1).

## RESULTS AND DISCUSSION

**Analysis of Phenolics.** UHPLC analysis of the methanol extract from wheat green aerial parts revealed the presence of numerous phenolic compounds (Figure 1). Separation of the compounds by low-pressure liquid chromatography followed by purification of fractions on a semipreparative C18 column afforded 14 single isolated compounds (**2**, **3**, **5**, **6**, **9**, **11**–**19**), for which structures were determined by spectrometric and spectroscopic techniques. Additionally, compounds **1**, **4**, **7**, **8**, and **10** were identified on the basis of the obtained UV spectra and fragmentation pathways. To the best of our knowledge, flavonoids **15**, **17**, and **19** are novel structures and have never been reported in the plant kingdom.

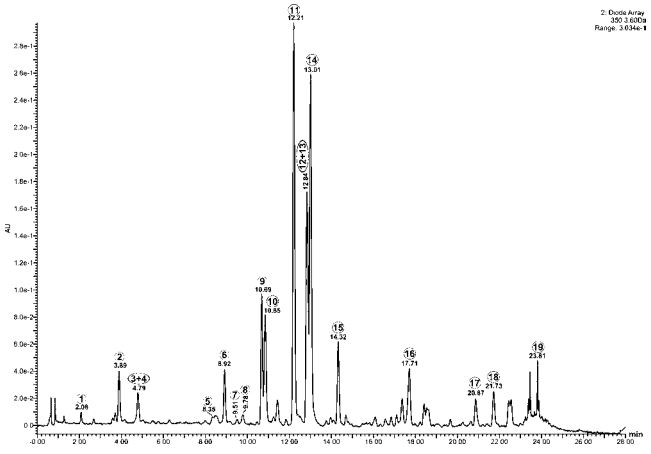

**Figure 1.** UPLC-UV (350 nm) chromatogram of the crude extract from the aerial parts of wheat (*Triticum aestivum* L.). Peak numbers correspond to the numbering of compounds in the text.

Six compounds visible in the UV chromatogram displayed maximum absorption typical for caffeic acid derivatives ($\lambda_{max}$ = 325 nm) and were identified on the basis of their ESI-MS/MS fragmentation patterns as 3-*O*-caffeoylquinic acid (**1**), 5-*O*-caffeoylquinic acid (**2**), 4-*O*-caffeoylquinic acid (**3**), 3-*O*-feruoylquinic acid (**4**), 5-*O*-feruoylquinic acid (**7**), and 4-*O*-feruoylquinic acid (**8**).[20] Compound **5** possessed a UV spectrum ($\lambda_{max}$ = 310 nm) and mass to charge ratio ($m/z$ 163) characteristic for *p*-coumaric acid. The remaining 12 compounds showed UV spectra typical for flavones. Hydrolysis of the purified flavonoids, followed by determination of absolute configuration of monosaccharides, showed that these were D-Glc, D-Xyl, D-GlcA, D-Rib, L-Ara, and L-Rha. Chromatographic separation of the extract afforded numerous flavonoids, including five known flavonoid glycosides, identified on the basis of their ESI-MS/MS and NMR analyses, namely, isoorientin 6″-*O*-$\beta$-D-xylopyranoside (**10**), isoorientin (luteolin 6-*C*-$\beta$-glucopyranoside) (**11**), isoschaftoside (apigenin 6-*C*-$\alpha$-arabinopyranoside 8-*C*-$\beta$-glucopyranoside) (**13**), isoscoparin 2″-*O*-$\alpha$-L-rhamnopyranoside (**16**), and tricin 7-*O*-rutinoside (**18**) (Figure 2).[21−24] NMR spectroscopy data included various 1D [$^1$H, proton-decoupled $^{13}$C and DEPT-135, selective excitation 1D-TOCSY and 1D-ROESY (mixing times of 120 and 250 ms, respectively) and 2D [$^1$H−$^1$H *g*COSY (magnitude mode), $^1$H−$^1$H TOCSY, $^1$H−$^1$H ROESY, $^1$H−$^{13}$C *g*HSQC, $^1$H−$^{13}$C *g*HSQC-TOCSY (mixing time of 80 ms), and $^1$H−$^{13}$C *g*HMBC ($^nJ_{CH}$ = 8 Hz)] spectra. Peaks 6, 9, 12, and 14 visible in the UV chromatogram were tentatively identified on the basis of their UV spectra and ESI-MS/MS fragmentation patterns as luteolin *C*-hexoside *O*-hexoside, luteolin *C*-(pentosyl-hexoside), apigenin *C*-hexoside *C*-pentoside, and luteolin *C*-hexoside *O*-deoxyhexoside, respectively.[25]

Compounds **15** and **17** had UV spectra typical for flavones, and positive ESI-MS analyses showed that their protonated molecules had $m/z$ values of 773 and 757, respectively. The collision-induced dissociation (CID) of these precursor ions revealed their monodesmosidic character. The MS/MS spectrum of **15** showed the presence of a fragment ion of $m/z$ 611 $[M + H - 162]^+$, suggesting the loss of caffeic acid, which is supported by dehydrated protonated caffeic acid ions at $m/z$ 163 $[Caf + H - 18]^+$ and 325 $[Caf + H + 162 - 18]^+$. Further fragment ions at $m/z$ 449 $[M + H - 162 - 162]^+$ and 287 $[M + H - 162 - 162 - 162]$ corresponded with the loss of two consecutive hexoses. Likewise, the MS/MS spectrum of **17** showed the presence of a fragment ion of 449 $[M + H - 176 - 132]^+$, suggesting the loss of pentose and ferulic acid, which is supported by dehydrated protonated ferulic acid ions at $m/z$ 177 $[Fer + H - 18]^+$ and intensive 309 $[Fer + H + 132 - 18]^+$. Further fragment ion at $m/z$ 287 $[M + H - 176 - 132 - 162]^+$ corresponds with luteolin $[Y^0 + H]^+$ and the loss of a hexose unit. A precise structure elucidation was possible after 1D and 2D NMR analyses of these compounds. $^1$H NMR spectra of **15** and **17** performed at 25 °C showed the presence of duplicated signals, corresponding with two rotameric conformers. Therefore, all of the 1D and 2D spectra were performed at 70 °C. The $^{13}$C NMR spectrum of **15** showed 36 signals, sorted by $^{13}$C and DEPT-135 experiments into 2 $CH_2$, 20 CH, and 14 quaternary carbon atoms. The $^1$H NMR spectrum revealed the presence of a 6-*C* substituted luteolin as characterized by signals at $\delta$ 7.33 (d, $J$ = 2.2 Hz; H-2′), 7.25 (dd, $J$ = 8.4, 2.2 Hz; H-6′), and 6.85 (d, $J$ = 8.4 Hz; H-5′) in accordance with the AMX system and two singlets at $\delta$ 6.42 (H-3) and $\delta$ 6.39 (H-8) and the absence of an H-6 signal. The carbohydrate region showed the presence of two anomeric proton signals at $\delta$ 4.74 (d, $J$ = 9.9 Hz; H-$1_{Glc}$) and 4.28 (d, $J$ = 7.9 Hz; H-$1_{Glc''}$), characterizing the presence of two sugar units. On the basis of the values of coupling constants ($J$ > 7 Hz) and the analysis of $^1$H, and $^{13}$C

dx.doi.org/10.1021/jf5038689 | J. Agric. Food Chem. 2014, 62, 11200−11208

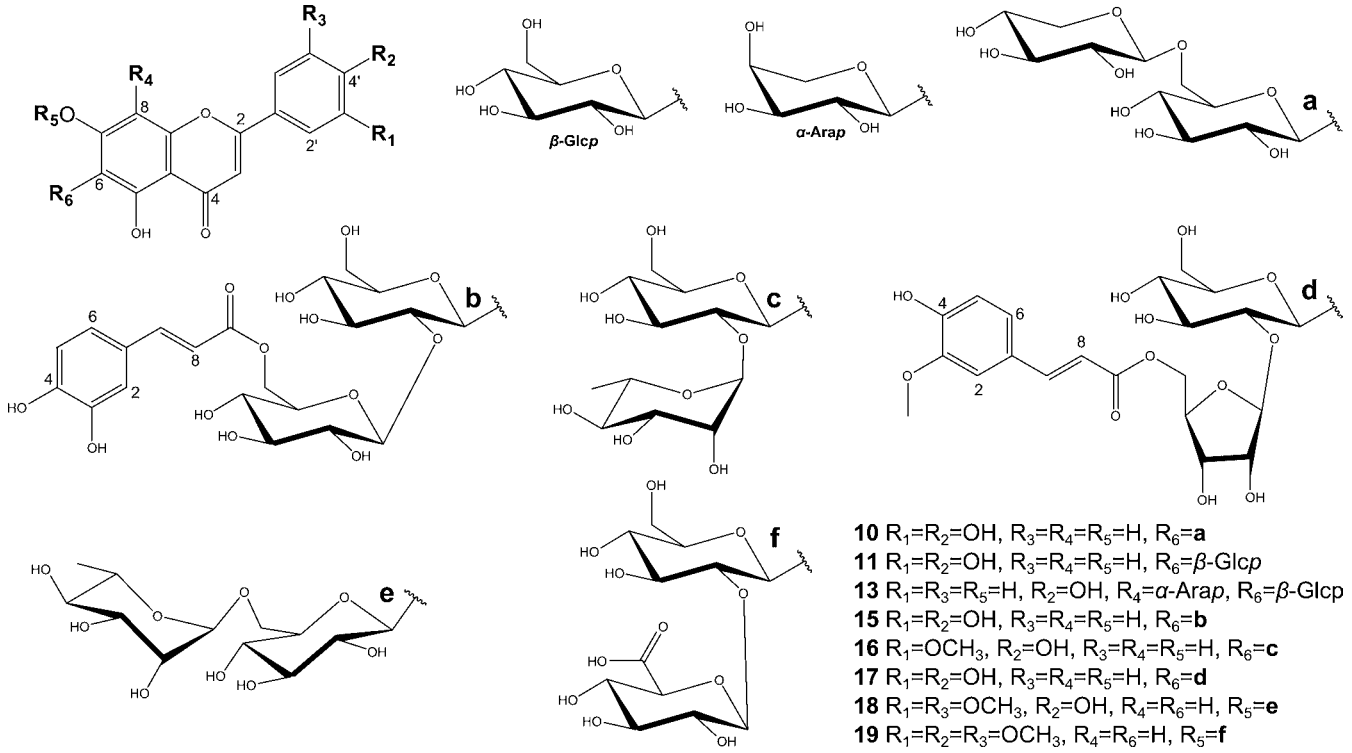

**Figure 2.** Structures of flavone glycosides isolated from the aerial parts of wheat (*T. aestivum* L.).

NMR spectra and 1D TOCSY, COSY, HSQC, HSQC-TOCSY, and HMBC data, the two sugar units were elucidated as *β*-glucopyranoside $\delta_{H/C}$ 4.74 (H-$1_{Glc}$)/71.0 (C-$1_{Glc}$) and *β*-glucopyranoside $\delta_{H/C}$ 4.28 (H-$1_{Glc''}$)/104.8 (C-$1_{Glc''}$) (Table 1). The long-range correlations observed in the HMBC spectrum between the anomeric proton of the glucose ($\delta_H$ 4.28, H-$1_{Glc''}$) and C-2 of glucose ($\delta_C$ 80.8) indicated the presence of interglycosidic linkage between these hexosyl units (1→2). This was further supported by the NOE effect detected in the rotating frame nuclear Overhauser effect spectroscopy spectrum (ROESY) between H-$1_{Glc''}$ and H-$2_{Glc}$. The 6-*C* glycosidation site was determined by the correlation observed in the HMBC spectrum from anomeric proton at $\delta_H$ 4.74 (H-$1_{Glc}$) to carbon C-6 ($\delta_C$ 107.7). Additionally, the aromatic region of the $^1$H and COSY spectra of **15** contained sets of resonances characteristic for an *E*-($J_{\alpha,\beta}$ = 15.9 Hz) olefinic moiety, and the AMX system corresponded to a 3,4-dihydroxyphenyl group at $\delta_H$ 6.97 (d, *J* = 1.9 Hz, H-$2_{Caf}$), 6.76 (d, *J* = 8.1 Hz, H-$5_{Caf}$), and 6.83 (dd, *J* = 8.2, 1.7 Hz, H-$6_{Caf}$); it was identified as an *E*-caffeoyl group. Protons H-$6_{Glc''}$ in compound **15** were downfield shifted to $\delta_H$ 3.85 (br d, *J* = 12.0 Hz) and 3.74 (br d, *J* = 12.0 Hz) and exhibited correlations in the HMBC spectra with the carbonyl carbon resonating at $\delta_C$ 165.6, corresponding with C-$9_{Caf}$. Therefore, **15** was luteolin 6-*C*-[$6_{Glc''}$-*O*-*E*-caffeoyl-*β*-D-glucopyranosyl(1″→2)-*β*-glucopyranoside], a new acylated flavonoid.

Compound **17**, according to the ESI-MS/MS fragmentation pattern, similar to **15**, was acylated with phenolic acid, and $^1$H and $^{13}$C NMR spectra were in agreement with a 6-*C* substituted luteolin nucleus. The carbohydrate region showed the presence of two anomeric proton signals at *δ* 4.72 (d, *J* = 9.9 Hz; H-$1_{Glc}$) and singlet at *δ* 5.16 (H-$1_{Rib''}$), characterizing the presence of two sugar units. On the basis of the analysis of $^1$H and $^{13}$C NMR spectra and 1D TOCSY, COSY, HSQC, HSQC-TOCSY, and HMBC data, the two sugar units were elucidated as *β*-glucopyranoside $\delta_{H/C}$ 4.72 (H-$1_{Glc}$)/71.2 (C-$1_{Glc}$) and *β*-ribofuranoside $\delta_{H/C}$ 5.16 (H-$1_{Rib''}$)/107.6 (C-$1_{Rib''}$), which is reported for the first time as a constituent in glycosylated flavonoids. The long-range correlations observed in the HMBC spectrum between the anomeric proton of the ribose ($\delta_H$ 5.16, H-$1_{Rib''}$) and C-2 of glucose ($\delta_C$ 74.4) indicated the presence of an interglycosidic linkage between these units (1→2). This was further supported by the NOE effect detected in the rotating frame nuclear Overhauser effect spectroscopy spectrum (ROESY) between H-$1_{Rib''}$ and H-$2_{Glc}$. The 6-*C* glycosidation site was determined by the correlation observed in the HMBC spectrum from the anomeric proton at $\delta_H$ 4.72 (H-$1_{Glc}$) to carbon C-6 ($\delta_C$ 108.2). The aromatic region of the $^1$H and COSY spectra of **17**, similar to **15**, contained sets of resonances characteristic for an *E*- ($J_{\alpha,\beta}$ = 15.9 Hz) olefinic moiety and an AMX system at $\delta_H$ 7.22 (d, *J* = 2.2 Hz, H-$2_{Fer}$), 6.81 (d, *J* = 8.1 Hz, H-$5_{Fer}$), and 7.01 (dd, *J* = 8.2, 1.6 Hz, H-$6_{Fer}$), and it was identified as an *E*-feruoyl group. Protons H-$5_{Rib''}$ in compound **17** were downfield shifted to $\delta_H$ 3.82 (ddd, *J* = 11.6, 5.4, 5.4 Hz; 2H) and exhibited correlations in the HMBC spectra with the carbonyl carbon resonated at $\delta_C$ 165.7, corresponding with C-$9_{Fer}$. Therefore, **17** was luteolin 6-*C*-[$5_{Rib''}$-*O*-*E*-feruoyl-*β*-D-ribofuranosyl(1″→2)-*β*-glucopyranoside], a new acylated flavonoid.

Compound **19** presented a UV spectrum corresponding with a 5,7-dihydroxy-3′,4′,5′-trimethoxyflavone skeleton at $\lambda_{max}$ 270 and 328 nm.[26] ESI-MS analysis showed that its protonated molecule had an *m*/*z* value of 683. The collision-induced dissociation (CID) of this precursor ion revealed its monodesmosidic character. The MS/MS spectrum of **19** showed the presence of a fragment ion of *m*/*z* 507 $[M + H - 176]^+$, suggesting the loss of a hexuronic acid, and *m*/*z* 345 $[M + H - 176 - 162]^+$, corresponding to the 3′,4′,5′-*O*-trimethyltricetin ion $[Y^0 + H]^+$. The $^{13}$C NMR spectrum of **19** showed 30 signals, sorted by $^{13}$C and DEPT-135 experiments

dx.doi.org/10.1021/jf5038689 | J. Agric. Food Chem. 2014, 62, 11200−11208

into 3 $CH_3$, 1 $CH_2$, 15 CH, and 11 quaternary carbon atoms. The $^1$H NMR spectrum revealed the presence of a 7-*O* substituted 3′,4′,5′-*O*-trimethyltricetin as characterized by two doublets at $\delta$ 6.90 ($J$ = 1.9 Hz; H-8) and 6.54 ($J$ = 2.0 Hz; H-6), and four singlets at $\delta$ 6.76 (H-3), $\delta$ 7.30 (2H, H-2′/6′), $\delta$ 3.96 (6H, 3′,5′-di-*O*-$CH_3$) and $\delta$ 3.85 (3H, 4′-$OCH_3$). The carbohydrate region of the $^1$H NMR spectrum showed the presence of the oxymethine protons in the range $\delta$ 3.30−3.93. Moreover, two anomeric proton signals at $\delta_H$ 5.33 (d, $J$ = 7.1 Hz; H-$1_{Glc}$) and 4.71 (d, $J$ = 7.8 Hz; H-$1_{GlcA''}$) were also observed, indicating the presence of two sugar units. On the basis of the values of coupling constants ($J$ > 7 Hz), and the analysis of $^1$H and $^{13}$C NMR spectra and 1D TOCSY, COSY, HSQC, HSQC-TOCSY, and HMBC data, the two sugar units were elucidated as $\beta$-glucopyranoside $\delta_{H/C}$ 5.33 (H-$1_{Glc}$)/100.2 (C-$1_{Glc}$) and $\beta$-glucuropyranoside $\delta_{H/C}$ 4.71 (H-$1_{GlcA''}$)/104.9 (C-$1_{GlcA''}$) (Table 2). The long-range correlations observed in the HMBC spectrum between the anomeric proton of the glucuronic acid ($\delta_H$ 4.71, H-$1_{GlcA''}$) and C-2 of glucose ($\delta_C$ 83.5) indicated the presence of an interglycosidic linkage between these hexosyl units (1→2). This was further supported by the NOE effect detected in the ROESY spectrum between H-$1_{GlcA''}$ and H-$2_{Glc}$. The 7-*O* glycosidation site was determined by the correlation observed in the HMBC spectrum from the anomeric proton at $\delta_H$ 5.33 (H-$1_{Glc}$) to carbon C-7 ($\delta_C$ 164.8) and the NOE effect visible in the ROESY spectrum between H-$1_{Glc}$ and H-6/8. Therefore, compound **19** was identified as 3′,4′,5′-*O*-trimethyltricetin 7-*O*-[$\beta$-D-glucuropyranosyl(1″→2)-$\beta$-D-glucopyranoside], a new flavonoid. Among the newly isolated compounds, flavonoids **15** and **17** were acylated with hydroxycinnamic acids. As acylation influences the spectroscopic characteristics of flavones, by increasing their UV-B-absorbing capacity, it is important in shielding plants against UV-B radiation.[27,28]

Flavones, in particular the C-glycosyl-flavones, are the most common type of flavonoids found in grasses. The first flavone to be characterized in wheat was tricin, which was identified as a rust resistance factor in wheat leaves. Flavonoid research on the Poaceae reported the presence of flavone-*C*-glycosides, tricin 5-glucoside, tricin 7-glucoside, isovitexin, iso-orientin glycosides, and lucenin 7-methyl ether.[29] Moreover, the soluble phenolic compounds including flavonols were considered in *T. aestivum* L.[30] Two new flavonoid-*C*-glycosides named triticuside A and triticuside B were isolated from the bran of this species.[31] Olenichenko et al.[32] reported 15 phenolic compounds, most of them (90%) being flavonoids and their derivatives, mainly *C*-glycosides of two flavones (apigenin and luteolin) and their *O*-derivatives. The major component of the phenolic complex in winter wheat leaves (cv. Moskovskaya 39) was isoorientin, identified also in our study (compound **11**).

**Phytochemical Analysis.** Qualitative study revealed that *T. aestivum* L. contained large amounts of flavones. The concentration of particular phenolics in *T. aestivum* L. was determined in this study. 5-Caffeoylquinic acid for phenolic acids and rutin for flavones were used as standards for quantitative determination. The total phenolics concentration in wheat determined with UPLC was 181.71 ± 11.18 mg/g of aerial part dry matter (isolated compounds: 162.78 ± 10.01 mg/g dry weight) (Table 3). Most of them (86.6%) were flavonoids and their derivatives. Luteolin and its derivatives represented 68.4% of total phenolics content in *T. aestivum* L. aerial parts. The predominant compound was flavone **11**, the content of which was 39.41 ± 2.66 mg/g dry weight (dw). Also,

**Table 3. Concentration of Identified Phenolics in *Triticum aestivum* L. Extract**

| retention time (min) | compd | concn (mg/g dw ± SD, $n$ = 3) |

| total | | 181.71 ± 11.18 |

phenolic **14** was present in high amount (32.90 ± 2.21 mg/g dw). Concentrations and profiles of these compounds may be affected by many factors, such as environment, cultivar, soil conditions, cropping year, growth location, species, and plant organs used in the analysis. According to Zagoskina et al.,[33] winter wheat leaves contained higher amounts of soluble phenolic compounds than crowns and roots. In general, phenolic compounds play an important role in winter wheat adaptation to low temperature. Changes in phenolic compound metabolism, manifested in the accumulation of phenylpropanoids and flavonoids (predominantly flavones) in plant leaves, can contribute to plant resistance to cold stress.[32]

**DPPH• Scavenging Activity of Isolated Compounds.** Plant polyphenols are known for their antioxidant properties and beneficial effects on human health. Several papers have been published reporting on the antioxidant effect of the whole *T. aestivum* L. extract, indicating its beneficial effect in some pathological processes.[34,35] The free radical scavenging activity of polyphenols strongly depends on their chemical structure; the amount and position of free hydroxyl groups influence the observed activity.[36,37] The compounds isolated from *T. aestivum* L. can be classified into one of the following groups of polyphenols: phenolic acids, flavone glycosides, or acylated flavone glycosides. The free radical scavenging activity of these compounds was tested in a simple and rapid TLC-DPPH• test with image processing (Figure 3). The analyzed plant species contains two common hydroxycinnamic acids, caffeic and ferulic acid, esterified with quinic acid, which were proved to be more potent free radical scavengers when compared to rutin (Figure 3a). Caffeic acid derivatives can be considered as the main free radical scavenging polyphenols present in *T. aestivum* L. and responsible for terminating radical chain reactions. All of the isolated and active phenolic acids were present in esterified form, but with free hydroxyl groups responsible for free radical scavenging activity. This is in accordance with a review by Rice-Evans et al.,[37] who stated that hydroxycinnamic acids are usually present in plants as simple esters but not glycosylated at the

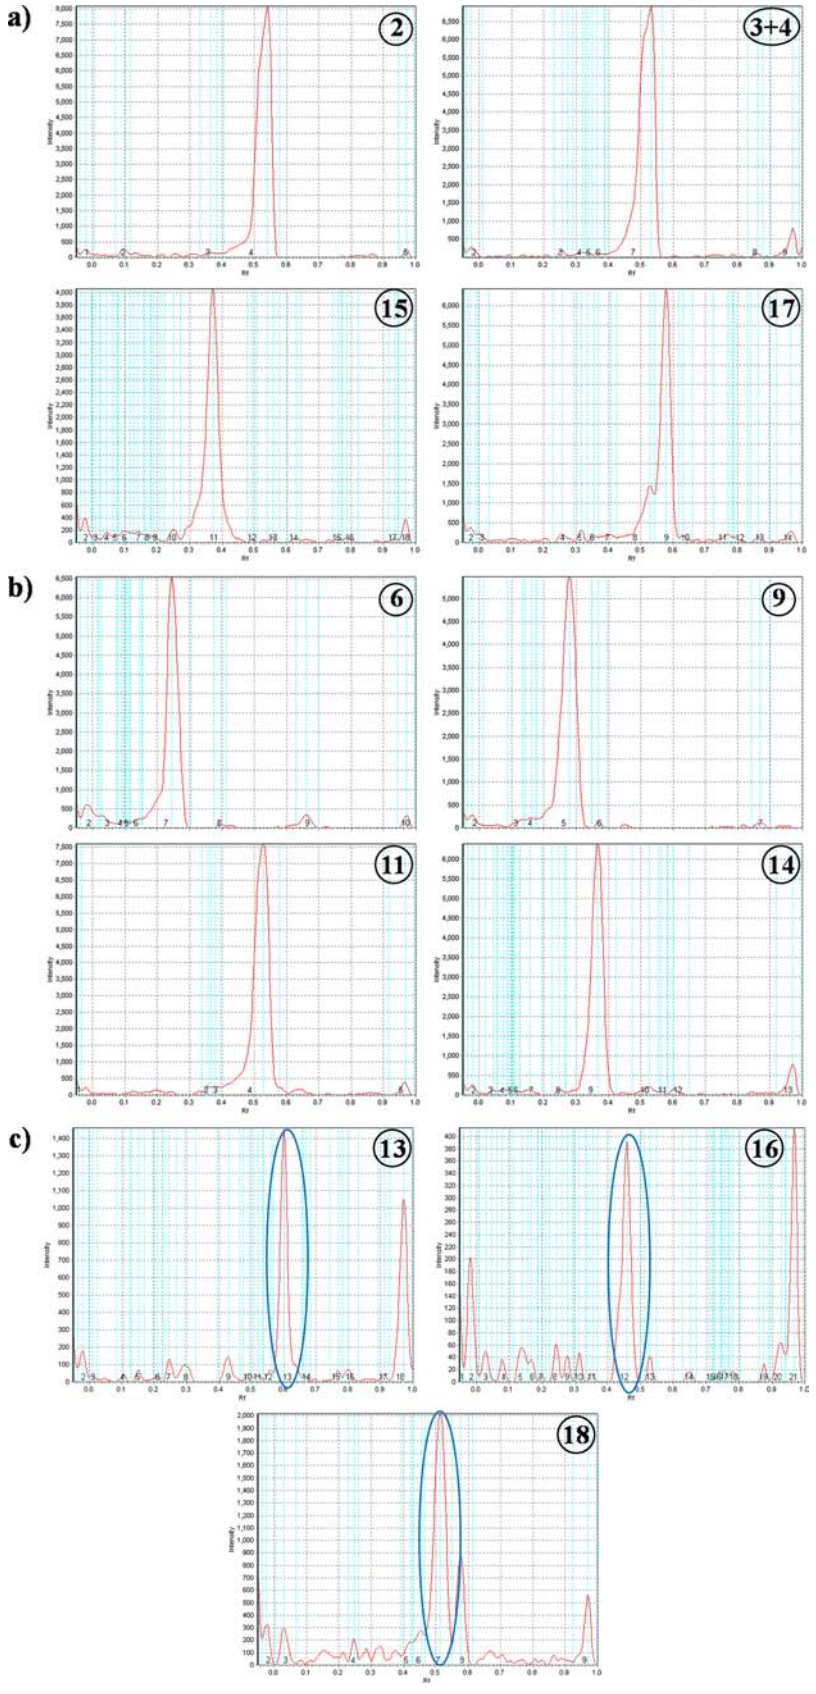

**Figure 3.** Line profile plots, obtained with the use of the image processing procedure, for isolated compounds with free radical scavenging activity: (a) phenolic acids and acylated flavone glycosides; (b) luteolin glycosides; (c) flavone glycosides characterized with relatively weak activity.

phenolic hydroxyl groups. These acids were also identified as acylating agents (compounds **15** and **17**).

*T. aestivum* L. was found to be rich in flavones, especially in luteolin derivatives. No flavonols were identified in the analyzed

dx.doi.org/10.1021/jf5038689 | *J. Agric. Food Chem.* 2014, 62, 11200−11208

species, which confirms that there is a mutual exclusion between flavones and flavonols in many plant species.[37] Flavonols have been proven to be more potent free radical scavengers when compared to flavones, due to the presence of a hydroxyl group at the C3 position in the former group of polyphenols. In the present study all of the isolated luteolin derivatives were found to be potent free radical scavengers (Figure 3b). Noteworthy is the fact that all of the isolated luteolin derivatives were not glycosylated at position C7. Musialik et al. proved that a hydroxyl group at this position is the most acidic site in flavonoids.[38] Due to the acidic properties, this group participates in radical reactions via the SPLET (sequential proton-loss electron-transfer) mechanism, in polar solvents, enabling fast scavenging of the DPPH• radical.[38] Luteolin derivatives glycosylated at the C7 position were found to be weak free radical scavengers.[37] Relatively high free radical scavenging activity of luteolin glycosides can be ascribed not only to the presence of free hydroxyl group at the C7 position but also to the catechol moiety in the B ring. All other isolated flavones were less active, or the activity was not observed even in the presence of free hydroxyl group at the C7 position, for example, apigenin *C*-hexoside *C*-pentoside (not active; **12**), isoschaftoside (weak activity; **13**), or isoscoparin 2″-*O*-α-L-rhamnopyranoside (weak activity; **16**). All of these compounds lack two free hydroxyl groups in the ortho position in the B ring. Tricin 7-*O*-rutinoside (**18**) was also found to be less active than rutin and luteolin derivatives (Figure 3c).

To sum up it can be underscored that caffeic acid derivatives and luteolin glycosides, with a free hydroxyl group in the C7 position, are mainly responsible for the free radical scavenging activity of *T. aestivum* L. phenolic fraction. This species, although not synthesizing potent flavonol antioxidants, as the products of secondary metabolism, may use flavone *C*-glycosides with a free acidic hydroxyl group to terminate radical reactions.

**Site-Directed Mutagenesis.** Site-directed mutagenesis was performed using a one-step PCR method with plasmid *cgt*/pST as the template and a pair of complementary primers (Table 1). The PCR products were treated with *Dpn*I and then used to transform *E. coli* JM109 cells. The intended mutations were confirmed by DNA sequencing. To generate expression strains, the resulting (mutant) plasmids were used to transformed *B. subtilis* WB600 competent cells.

**Table 1. Primers Used for Site-Directed Mutagenesis**

| desired mutation | primer sequence (5′−3′)[a] | DNA template |
|---|---|---|
| D577E | GCAATGTGTATGAAAACTTCGAG | *cgt*/pST |
| | CTCGAAGTTTTCATACACATTGC | |
| D577R | GCAATGTGTATCGTAACTTCGAG | *cgt*/pST |
| | CTCGAAGTTACGATACACATTGC | |
| D577K | GCAATGTGTATAAGAACTTCGAG | *cgt*/pST |
| | CTCGAAGTTCTTATACACATTGC | |
| D577H | GCAATGTGTATCATAACTTCGAG | *cgt*/pST |
| | CTCGAAGTTATGATACACATTGC | |

[a]Nucleotide sequences corresponding to the mutated amino acids are underlined.

**Production and Purification of CGTase Proteins.** A single colony of *B. subtilis* WB600 harboring *cgt*/pST (wild type or mutant) was inoculated into 50 mL of Luria−Bertani medium containing 5 μg/mL kanamycin and grown at 37 °C overnight. A 2 mL portion of this overnight culture was then diluted into 50 mL of terrific broth containing 5 μg/mL kanamycin and incubated on a rotary shaker (200 rpm) at 37 °C for 48 h. The CGTase present in the supernatant was purified to homogeneity, as previously described.[11] The purified enzymes were aliquoted and stored at −80 °C. The protein concentration was determined using the Bradford assay,[16] with reagents obtained from the Bio-Rad protein assay reagent kit (Bio-Rad, Hercules, CA). Bovine serum albumin was used as the standard.

**Enzyme Assays.** All assays were measured by incubating 0.1 mL of appropriately diluted purified CGTase with 0.9 mL of 1% (w/v) maltodextrin (DE = 3, Roquette Frères, Lestrem, France) in 10 mM phosphate buffer (pH 6.5) at 50 °C for 10 min. The concentrations of α-, β-, and γ-cyclodextrin formed were determined using the methyl orange,[17] phenolphthalein,[18] and bromocresol green[19] methods, respectively. One unit of each activity was defined as the amount of enzyme that produced 1 μmol of the corresponding cyclodextrin per minute.

**High-Performance Liquid Chromatography (HPLC) Product Analysis.** The formation of cyclodextrins under conditions resembling an industrial production process was performed by incubating 0.1 unit/mL CGTase (β-cyclization activity) with 5% (wet basis, w/v) soluble starch solution in 10 mM phosphate buffer (pH 6.5) at 45 °C for 24 h. At regular time intervals, samples were taken and boiled for 20 min. The concentrations of α-, β-, and γ-cyclodextrin in the reaction mixture were determined by HPLC, as described in previous reports.[12,20,21]

**Structure Modeling of the (Mutant) CGTase.** The X-ray crystal structure of the wild-type CGTase from *B. circulans* was obtained from the Research Collaboratory for Structural Bioinformatics (RCSB) Protein Data Bank (PDB accession code 1CXI).[22] Homology models of the mutant CGTases were constructed using the SWISS-MODEL protein-modeling server (http://www.expasy.ch/swissmod/SWISS-MODEL.html).[23] The PyMol molecular graphics system (http://www.pymol.org) was used to visualize and analyze the model structure.

## RESULTS

**Expression and Purification of the Wild-Type and Mutant CGTases.** *B. circulans* β-CGTase mutants D577E, D577R, D577K, and D577H were successfully constructed using site-directed mutagenesis. The wild-type and mutant CGTases were expressed in *B. subtilis* WB600, and the secreted proteins were isolated from the culture medium. There were no obvious differences in the levels of expression among the recombinant wild-type and mutant CGTases, with 20−25 mg of each of the CGTase proteins produced per liter in shake-flask cultures. The mutant CGTase proteins were purified to apparent homogeneity using a combination of anion-exchange and hydrophobic chromatographies. The purity and molecular weight of the wild-type and mutant CGTase proteins were verified using sodium dodecyl sulfate−polyacrylamide gel electrophoresis (SDS−PAGE) (data not shown).

**Cyclization Activities of Wild-Type and Mutant CGTases.** The CGTase enzymes were assayed to determine α-, β- and γ-cyclization activities (Table 2). None of the mutations had a substantial effect upon the ratio of β-cyclization activity to total cyclization activity. These ratios varied from 74.6% (D577E) to 76.6% (D577K), with D577H, D577R, and the wild type having intermediate values, in that order. However, the D577E mutant displayed a 14.0% increase in total cyclization activity and an 11.2% overall increase in the β-cyclization activity when compared to the wild-type CGTase. More interesting, the D577R mutant displayed an even larger enhancement of total cyclization activity (32.5%), resulting in a 30.7% overall increase in β-cyclization activity, compared to that of the wild-type CGTase. In contrast, the D577K mutant showed only a 1.3% increase in the total cyclization activity and a 1.5% increase in β-cyclization activity. Finally, the D577H mutant displayed slight decreases in the total cyclization activity and β-cyclization activity compared to wild-type CGTase.

**Starch Conversions of the Wild-Type and Mutant CGTases under Conditions Resembling Industrial Production Processes.** To assess the performance of the mutant CGTases under conditions resembling those used in the industrial production of β-cyclodextrin, each enzyme was assayed in a reaction mixture containing CGTase protein (0.1 unit/mL β-cyclization activity) and 5% (wet basis, w/v) soluble starch. The reaction mixtures were incubated at 45 °C and sampled over a 24 h time course. Although small amounts of α- and γ-cyclodextrin were produced, β-cyclodextrin was the main product for all CGTases (Figure 1). After 24 h of incubation, the wild-type enzyme converted 45.4% of the starch into cyclodextrins, of which the majority (69.2%) was β-cyclodextrin (Table 3).

**Table 2. Cyclization Activities of the Wild-Type and Mutant CGTases from *B. circulans* STB01[a]**

| CGTase | α-cyclization activity (units/mg) | β-cyclization activity (units/mg) | γ-cyclization activity (units/mg) | total (units/mg) |
|---|---|---|---|---|
| wild type | 31.6 ± 0.3 ab (10.4) | 231.6 ± 1.9 b (76.5) | 39.6 ± 0.8 a (13.1) | 302.8 b |
| D577E | 36.9 ± 0.5 d (10.7) | 257.6 ± 2.6 c (74.6) | 50.7 ± 0.7 b (14.7) | 345.2 c |
| D577R | 31.1 ± 0.3 a (7.7) | 302.8 ± 2.3 d (75.5) | 67.4 ± 0.9 c (16.8) | 401.3 d |
| D577K | 32.2 ± 0.4 b (10.5) | 235.0 ± 2.2 b (76.6) | 39.6 ± 0.4 a (12.9) | 306.8 b |
| D577H | 33.2 ± 0.4 c (11.2) | 222.3 ± 1.8 a (75.0) | 41.0 ± 0.3 a (13.8) | 296.5 a |

[a]Numbers in parentheses indicate the ratio in specific activities for the formation of the different cyclodextrins. Each value represents the mean of three independent measurements, and means with different letters within the same column are significantly different ($p < 0.05$).

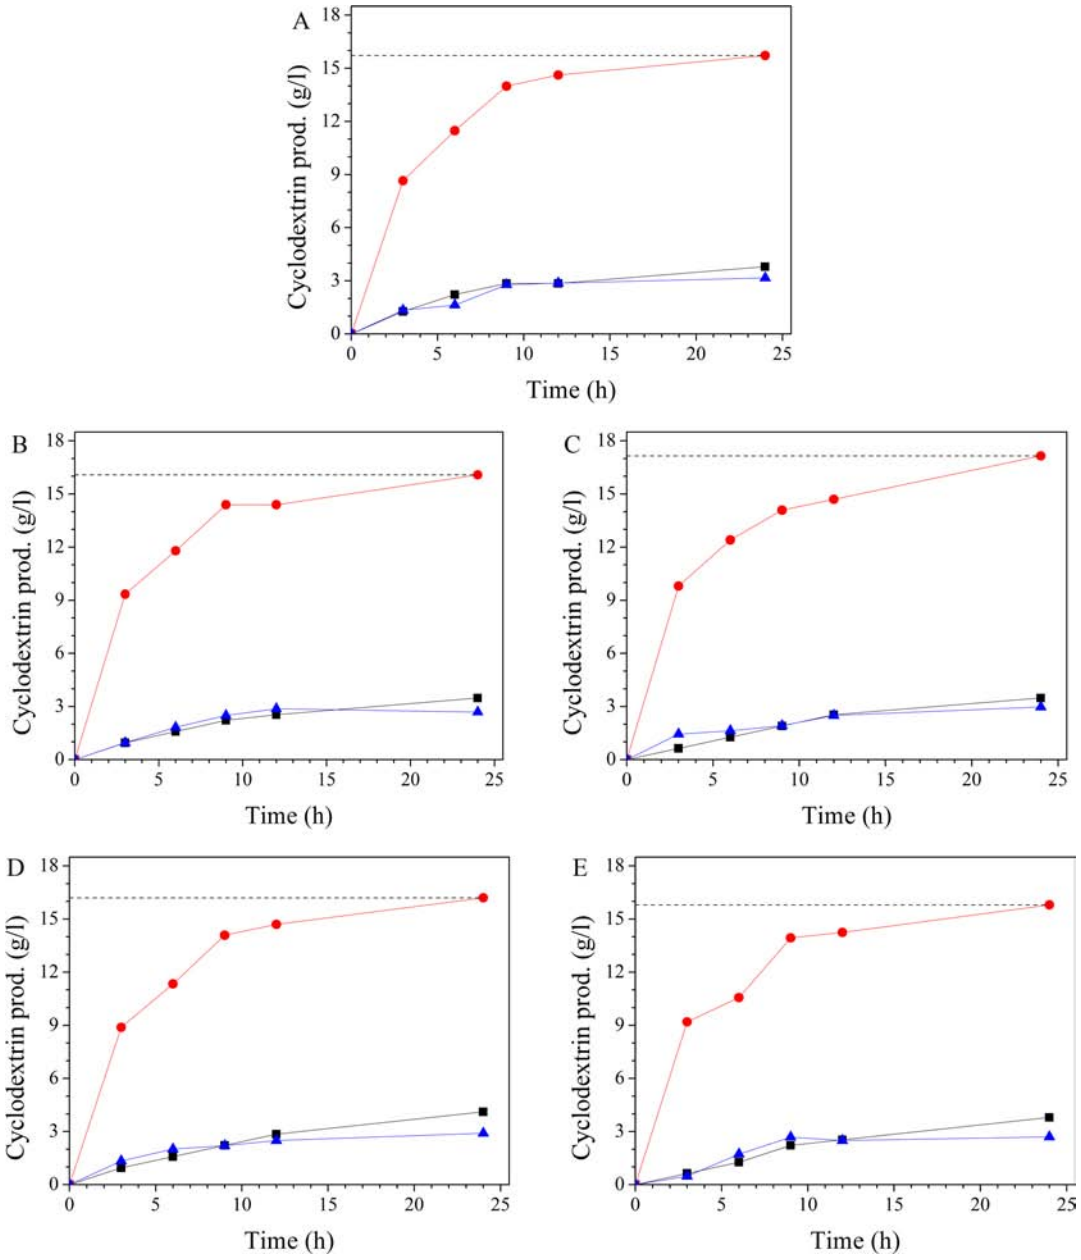

**Figure 1.** Cyclodextrins formed during incubation of the (mutant) CGTases from *B. circulans* STB01 (0.1 unit/mL $\beta$-cyclization activity) with 5% (wet basis, w/v) soluble starch solution in 10 mM phosphate buffer (pH 6.5) at 45 °C for 24 h: (black line) $\alpha$-cyclodextrin, (red line) $\beta$-cyclodextrin, and (blue line) $\gamma$-cyclodextrin for (A) wild-type CGTase, (B) mutant D577E, (C) mutant D577R, (D) mutant D577K, and (E) mutant D577H.

**Table 3. Starch Conversions of the Wild-Type and Mutant CGTases from *B. circulans* STB01**[a]

| | | product (g/L) | | |
|---|---|---|---|---|
| CGTase | conversion of starch into cyclodextrins (%) | $\alpha$ | $\beta$ | $\gamma$ |
| wild type | 45.4 | 3.8 ± 0.1 ab (16.7) | 15.7 ± 0.2 a (69.2) | 3.2 ± 0.1 b (14.1) |
| D577E | 44.6 | 3.5 ± 0.2 a (15.7) | 16.1 ± 0.1 b (72.2) | 2.7 ± 0.1 a (12.1) |
| D577R | 47.4 | 3.5 ± 0.1 a (14.8) | 17.2 ± 0.1 c (72.6) | 3.0 ± 0.2 ab (12.6) |
| D577K | 46.4 | 4.1 ± 0.1 b (17.7) | 16.2 ± 0.2 b (69.8) | 2.9 ± 0.1 a (12.5) |
| D577H | 44.6 | 3.8 ± 0.2 ab (17.0) | 15.8 ± 0.1 a (70.9) | 2.7 ± 0.1 a (12.1) |

[a]CGTase proteins (0.1 unit/mL $\beta$-cyclization activity) were incubated with 5% (wet basis, w/v) soluble starch solution at pH 6.5 and 45 °C for 24 h. Numbers in parentheses indicate the percentage of each cyclodextrin present in the product mixture. Each value represents the mean of three independent measurements, and means with different letters within the same column are significantly different ($p < 0.05$).

The mutant CGTases produced somewhat more $\beta$-cyclodextrin under the same reaction conditions (Figure 1 and Table 3). The D577R mutant showed the greatest enhancement in $\beta$-cyclodextrin production, converting 47.4% of the starch into cyclodextrins, of which 72.6% was $\beta$-cyclodextrin. This represents a 9.5% enhancement in $\beta$-cyclodextrin production.

dx.doi.org/10.1021/jf503523z | J. Agric. Food Chem. 2014, 62, 11209−11214

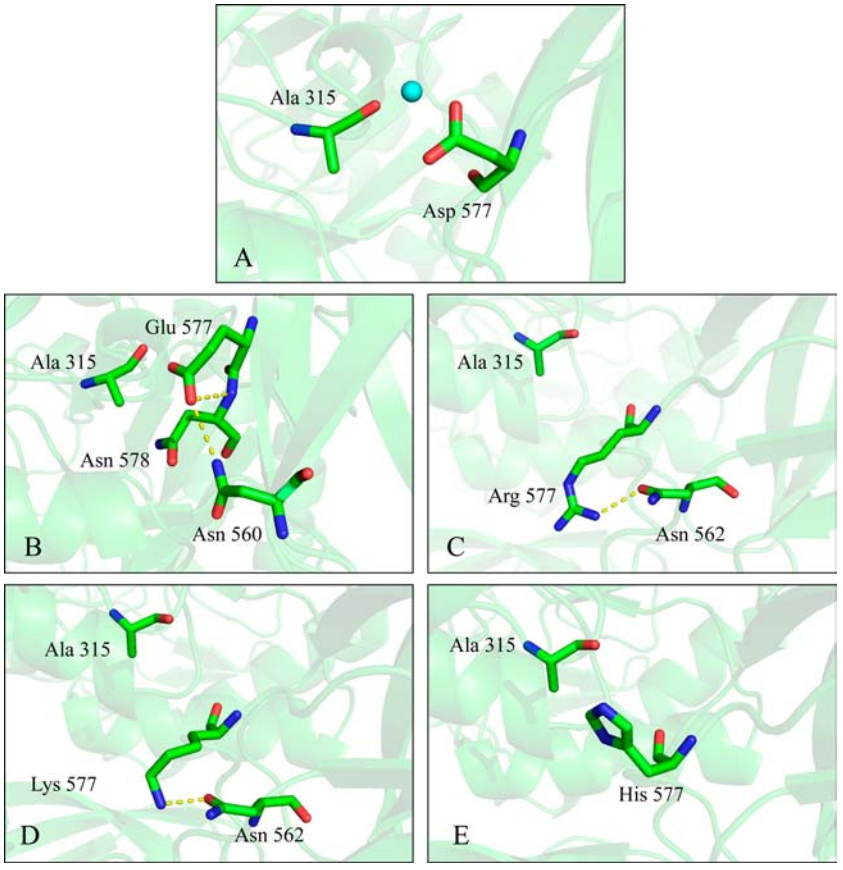

**Figure 2.** Models of the (mutant) CGTases from *B. circulans* STB01: (yellow dashed line) hydrogen bond, (cyan ball) $Ca^{2+}$ in site CaIII, (green) carbon, (red) oxygen, and (blue) nitrogen for (A) wild-type CGTases, (B) mutant D577E, (C) mutant D577R, (D) mutant D577K, and (E) mutant D577H.

The D577K mutant showed a 3.1% increase in $\beta$-cyclodextrin production, converting 46.4% of the starch to cyclodextrins, of which 69.8% was $\beta$-cyclodextrin. Although the D577E mutant showed a slight decline in starch conversion, the mutation resulted in a 2.5% increase in $\beta$-cyclodextrin production, which came at the expense of $\alpha$-cyclodextrin and $\gamma$-cyclodextrin production. The D577H mutant had a slightly lower starch conversion and almost the same $\beta$-cyclodextrin production when compared to the wild-type CGTase.

**Homology Modeling of the Mutant $\beta$-CGTases.** A structural model of each of the mutant CGTases was prepared using the SWISS-MODEL protein-modeling server (Figure 2).[23] Substitution of aspartate for glutamate conserves the negative charge but adds an additional aliphatic carbon and increases the chain length. Comparing the homology model of D577E (Figure 2B) to the structure of the wild-type $\beta$-CGTase (Figure 2A) suggests that the glutamate residue forms additional hydrogen bonds with residues Asn560 and Asn578. Substitution of the negatively charged aspartate with a positively charged residue, such as arginine (Figure 2C) or lysine (Figure 2D), changes the ionic character of this residue and may also introduce a hydrogen bond with Asn562. Substitution of aspartate by histidine (Figure 2E) also changes the ionic character of the residue, but in this case, no additional hydrogen bonds are predicted.

## DISCUSSION

Biochemical studies have revealed calcium-binding sites in the protein molecules of this family.[24,25] Previous reports about calcium-binding sites had showed that the amino acid residues within these regions related to the catalytic activity and thermal stability of $\alpha$-amylase.[26−28] Although there are some differences between CGTase and $\alpha$-amylase in these regions, it was also indicated that the mutation of the amino acid residues at calcium-binding sites could affect the CGTase activities.[29,30] This suggested that the calcium-binding sites might have a critical function to CGTase. The results supported this hypothesis, demonstrating that mutations at the site CaIII of $\beta$-CGTase from *B. circulans* strain STB01, specifically replacement of Asp 577 with glutamate, arginine, or lysine, could have a beneficial effect on $\beta$-cyclization activity; the mutants enhanced the $\beta$-cyclization activity in the order D577R > D577E > D577K.

The homology modeling results appeared to support the hypothesis that the enhancement in $\beta$-cyclization activity of $\beta$-CGTase was related to a conformational stabilizing effect, because all of the mutants with a newly introduced hydrogen bond by mutations of Asp577 showed higher $\beta$-cyclization activities (Figure 2 and Table 2). A possible explanation was that the increase of enzyme stability was more conducive to the synthesis of the main product in the enzyme-catalyzed reaction. However, the enhancement in the $\beta$-cyclization activity might not completely depend upon the conformational stabilizing effect. The structural changes suggested that D577E gave the greatest increase in the number of interactions between the side chain at residue 577 and the other residues in domain D, followed by D577R and D577K. The order in which the substitutions enhanced the $\beta$-cyclization activity did not correlate with the changes in structure predicted by homology modeling. Previous studies have shown that domain D might be involved in positioning domain E in the correct orientation.[31] Furthermore, domain E has an important role in adsorbing starch granules.[32]

Therefore, to identify the molecular bases for the effects seen here, future studies must resort to more sophisticated modeling approaches.

In addition, under the same reaction conditions resembling industrial production processes, the mutants with enhanced $\beta$-cyclization activities could produce more $\beta$-cyclodextrin in the order D577R > D577K > D577E. The D577R mutant demonstrated a substantial enhancement in $\beta$-cyclodextrin production. More importantly, because of a higher $\beta$-cyclization activity, the amount of D577R protein in the reaction mixture could be reduced by 30.7% when compared to the wild-type CGTase. Although the D577E mutant showed only a 2.5% increase in $\beta$-cyclodextrin production, the amount of mutant protein was also reduced by 11.2%. Thus, these mutations of Asp577 resulted in the increased $\beta$-cyclodextrin production and reduced amount of CGTase required during the reaction process.

In conclusion, Asp577, which is located on the periphery of domain D and is a key residue within calcium-binding site CaIII, played an important role in cyclization activity. The mutations D577R and D577E could obviously enhance the total cyclization activity and $\beta$-cyclization activity. Furthermore, under conditions resembling industrial production processes, the D577R and D577E mutants displayed increased $\beta$-cyclodextrin production; the higher $\beta$-cyclization activities resulted in the significant reduction in the amount of mutant protein required during the process. Thus, the two mutants were much more suitable for the industrial production of $\beta$-cyclodextrin than the wild-type enzyme.

molecule (noncovalent approach). The spatial assembly of these interaction sites is subsequently fixed through polymerization in the presence of a cross-linking agent. After removal of the template, binding cavities capable of recognizing and rebinding the template molecules are obtained. The binding pockets are more or less complementary to the template regarding size, shape, and arrangement of the functionalities within the cavity.[22−24] Molecularly imprinted materials offer an interesting alternative as controlled release systems; some examples are described in the bibliography, although the majority of them are focused on pharmaceutical applications.[25,26] In the present study the molecularly imprinted polymer (MIP) technology was applied to develop active food packaging for the controlled release of ferulic acid.

Ferulic acid is a phenolic acid that belongs to the hydroxycinnamic acids and occurs widely in the plant kingdom. It is a strong antioxidant, excellent at neutralizing free radicals, especially the free radicals known as "superoxide", "hydroxyl radical", and "nitric oxide". It also acts synergistically with other antioxidants to increase their efficacy.[27] In addition to its low toxicity, this phenolic acid presents biological properties such as antimicrobial, antioxidant, and anti-inflammatory activities among others. Besides, it has been used by the food industry in many applications (e.g., production of vanillin, as a cross-linking agent, as a preservative, etc.).[28,29]

The kinetic release of ferulic acid from the ferulic acid-imprinted polymers developed into food simulants and into real food samples was studied. A mathematical modeling based on Fick's second law was used to determine the key parameters of the diffusion process and the partition and diffusion coefficients.

## MATERIALS AND METHODS

**Chemicals and Standard Solutions.** All reagents used were of chromatographic grade and used without further purification. Ultrapure water from a Milli-Q water purification system (Millipore, Bedford, MA, USA) was used. Ferulic acid (FA, 99%), 2-hydroxyethyl methacrylate (HEMA, 97%), ethylene glycol dimethacrylate (EDMA, 98%), 2-(dimethylamino)ethyl methacrylate (DMAEMA, 99%), and dimethyldichlorosilane (99.0%) were all from Sigma-Aldrich (St. Louis, MO, USA). Methanol (MeOH, gradient grade for liquid chromatography and hypergrade for LC-MS), ethanol (EtOH, absolute for analysis), and isooctane (for analysis) were obtained from Merck (Darmstadt, Germany). Acetic acid solution (puriss, p.a. for HPLC) was obtained from Sigma-Aldrich (Steinheim, Germany).

The chemical structure and the physicochemical characteristics of ferulic acid (CAS Registry No. 1135-24-6) are presented in Table 1. Data were acquired from the Scifinder database.

A stock solution of ferulic acid was prepared in MeOH, with a known concentration of 1000 $\mu$g/mL. From this stock solution an intermediate solution of 100 $\mu$g/mL was prepared. Calibration standard solutions of ferulic acid were prepared by carrying out diverse dilutions with MeOH. The concentrations of these solutions ranged from 0.05 to 10 $\mu$g/mL. Solutions were stored at 4 °C and protected from light.

**Table 1. Chemical Structure and Physicochemical Properties of Ferulic Acid**

| Chemical structure | Physico-chemical properties |
|---|---|
|  | Molecular weight (MW) 194.185<br>Boiling point (BP) 372.3±27.0 °C<br>log P (octanol-water) 1.51 |

**Molecularly Imprinted Hydrogel Preparation.** Molecularly imprinted hydrogels were prepared according to the method of Benito-Peña et al.[30] Briefly, to obtain the imprinted hydrogel, the template hydroferulic acid (200 mM) and the functional monomers DMAEMA (400 mM) and HEMA (7400 mM) were mixed and placed in a 5 mL glass vial. The mixture was left in contact for several minutes and then, after the addition of EDMA (530 mM) and ABDV (10 mM), cooled and purged with nitrogen for 15 min to remove dissolved oxygen. The prepolymerization mixture solution was injected into molds constituted by two glass plates pretreated with dimethyldichlorosilane and separated by a 0.9 mm thick silicone frame. The molds were placed in an oven at 50 °C for 12 h and later at 70 °C for 24 h more. The hydrogels were removed from the molds and immersed in boiling water for 15 min to remove unreacted components and subsequently rinsed with EtOH 96%, and supernatants were monitored by HPLC-DAD until the removal of the template (HFA) was 99.9%. Finally, the hydrogels were dried and stored.

**Foodstuff.** Chicken roast samples stuffed with ham and cheese were kindly supplied by Nutreco (Nutreco, España, S.A.). The nutritional composition according the supplier was protein, 20.4%; total fat, 6.2%; and total carbohydrate, 0.6%.

**Migration Test: Overall Migration.** Ferulic acid-imprinted polymers were cut in pieces of 2 × 5 cm$^2$ and accurately weighed. These materials were put in contact with the selected food simulants (10% EtOH (v/v), 50% EtOH (v/v), 3% acetic acid (w/v)) and substitutes (95% EtOH (v/v) and isooctane). According to the current legislation,[31] food simulants can be replaced by substitute food simulants if there is scientific evidence that the substitute food simulants overestimate migration compared to the regulated food simulants. Isooctane and 95% ethanol (v/v) are substitutes for fat foods, widely used under the previous legislation and with extensive usage as food simulants. All of the materials were placed so that the whole surface remained in contact with the solvent. The volume used was 20 mL, and all assays were done in triplicate.

Time and temperature conditions were 10 days at 40 °C for 10% EtOH (v/v) 50% EtOH (v/v), 95% EtOH (v/v), and 3% acetic acid (w/v) and 2 days at 20 °C for isooctane. After this time, solvents were placed in glass Petri plates, previously dried and weighed a minimum of five times, and evaporated to dryness using a bath. The residue was determined gravimetrically using the weight difference of the Petri plates, and all of the values were expressed in mg/dm$^2$.
