Supporting Information

ABSTRACT: Soil fumigation is an important agronomic practice in the production of many high-value vegetable and fruit crops, but the use of chemical fumigants can lead to excessive atmospheric emissions. A large-scale (2.9 ha) field experiment was conducted to obtain volatilization and cumulative emission rates for two commonly used soil fumigants under typical agronomic practices: 1,3-dichloropropene (1,3-D) and chloropicrin. The aerodynamic method and the indirect back-calculation method using ISCST3 and CALPUFF dispersion models were used to estimate flux loss from the treated field. Over the course of the experiment, the daily peak volatilization rates ranged from 12 to 30 μg m^{-2} s^{-1} for 1,3-D and from 0.7 to 2.6 μg m^{-2} s^{-1} for chloropicrin. Depending on the method used for quantification, total emissions of 1,3-D and chloropicrin, respectively, ranged from 16 to 35% and from 0.3 to 1.3% of the applied fumigant. A soil incubation study showed that the low volatilization rates measured for chloropicrin were due to particularly high soil degradation rates observed at this field site. Understanding and quantifying fumigant emissions from agricultural soil will help in developing best management practices to reduce emission losses, reducing adverse impacts to human and ecosystem health, and providing inputs for conducting risk assessments.

INTRODUCTION

Soil fumigation can significantly affect regional air quality.[1] Soil fumigation can lead to toxic substances entering the regional air stream as well as increasing the concentration of potential precursors for photochemical smog, which is formed by the reaction of volatile organic chemicals with nitrogen oxides in the atmosphere. Photochemical smog has become a problem in California during the summer months, and fumigants have been identified as potential precursors. Monitoring indicates that additional efforts are needed to ensure that U.S. EPA's 8-h ozone standard[2] is attained throughout the state.

The fumigant 1,3-dichloropropene (1,3-D) is an effective nematicide used for preplant soil fumigation; however, it is considered a possible carcinogen and is a Clean Air Act substance.[3] The high volatility (vapor pressure = 4.3 kPa[4]) of 1,3-D facilitates its movement, which increases effectiveness, but may also lead to high atmospheric emissions[3,5] and the potential for worker exposure.[6] In 1990, the detection of high 1,3-D concentrations in ambient air samples at multiple sites in California led to a suspension of 1,3-D as a soil fumigant.[7] The suspension remained in effect until 1995, when approaches to mitigate emissions were developed and tested.

Chloropicrin (trichloronitromethane) is effective for controlling soilborne fungi, diseases, and nematodes and was first registered in the United States in 1975.[8] Significant emissions for chloropicrin are possible after soil fumigation due to its high vapor pressure (2.4 kPa[4]). Chloropicrin has been found to be a reactive compound that promotes tropospheric ozone formation if present with other reactive organic compounds in the atmosphere.[9] Even though chloropicrin has been used in soil fumigation for decades, there is much to learn about its fate and persistence in soil and its volatilization from soil into the atmosphere.[10] More importantly, there is a great need to develop methods to control emissions for all soil fumigants.

There is very little published information on field-scale emissions of 1,3-D or chloropicrin. There have been several reported soil column experiments[11−18] that placed 1,3-D emission losses from bare soil in the range of 20−77% of the applied dosage. These studies also revealed that emission rates obtained using laboratory soil columns can have high variability (i.e., μ = 41%, σ = 16%). Total emission rates have been obtained under field conditions using micrometeorological and flux chamber methods. These studies have shown a similar range in total emissions of 12−80%,[19−25] with the highest estimates obtained using flux chambers (μ = 56%, σ = 22%). Flux chambers offer a relatively simple and cost-effective method for determining emission rates. They are also known to suffer from several practical problems, such as sampling a small surface area and the presence of the chamber affecting the tested surface,[26] which can affect the results. Total emission estimates of chloropicrin based on laboratory soil column

experiments place losses in the range of 7−16% of applied fumigant.[16,18] For measurements utilizing flux chambers,[24] the total losses were reported to be 30%.

It is imperative to better understand emissions from fumigated soil at typical agronomic scales to reduce the adverse impacts from soil fumigation. Large-scale field measurement of fumigant emissions provides information regulators require at the appropriate scale while serving as a reference baseline for the development and testing of new methods to reduce emissions.

Continued use of 1,3-D and chloropicrin will likely require extensive information on their environmental fate and transport collected at agronomic scales. The objective of this study was to conduct a field experiment to obtain needed information on the period-averaged and total emissions of 1,3-D and chloropicrin after shank fumigation in a large-scale agricultural field. Emission information is required by state and federal regulators as inputs into risk assessment models for the development of buffer zones to ensure public safety and also benefits the agricultural community by providing science-based information concerning rates of emission.

EXPERIMENTAL METHODS

The 2007 field experiment was conducted in an agricultural field near Buttonwillow, CA, USA, from September 5 to 21. The field soil was classified as Milham sandy loam (fine-loamy, mixed, thermic Typic Haplargids) and had approximately 1% organic matter content in the upper 10 cm, which decreased with depth. Approximately 2 weeks before the start of the experiment, the field was plowed and disked to break up any large soil aggregates and irrigated so that the soil condition was suitable for fumigation, with a water content of approximately 0.2 (cm^3 cm^{-3}). Telone C-35, a mixture of 1,3-D (68.1%) (CAS Registry No. 542-75-6) and chloropicrin (31.9%) (CAS Registry No. 76-06-2) was provided by Dow Agrosciences (Indianapolis, IN, USA) and applied by a commercial applicator using standard fumigation practices. 1,3-D contains two isomers, *cis*-1,3-D and *trans*-1,3-D, in a 50:50 ratio. The fumigation began at 9:35 a.m. (t = 0.40 day) and was completed within 3 h. The injection rig carried a 450 cm tool bar with nine shanks spaced in 50 cm increments laterally across the tool bar. The target depth of application was 46 cm (18 in.), and the fumigant material was applied to a nearly square 2.9 ha area (162 × 178 m). The target application rate was 240 kg/ha (20 gal/acre), and the actual weight of Telone C-35 applied was determined after fumigation (474.5 kg of 1,3-D and 222.3 kg of chloropicrin).

Measurement of 1,3-D and Chloropicrin Concentration. Atmospheric samples of 1,3-D and chloropicrin were obtained using XAD-4 tubes (SKC 226-175, SKC, Inc., Fullerton, CA, USA) followed by a charcoal backup tube (SKC 226-09, SKC, Inc.) to check for 1,3-D breakthrough both in laboratory and field samples. Ambient air was pulled through the sampling tube at a nominal rate of 150 cm^3/min using a vacuum system.

The 1,3-D and chloropicrin concentrations in the atmosphere were collected at 1.5 m above the soil surface at 12 locations surrounding the field site (see Supporting Information, Figure S1). Sample collection began at 8:00 a.m. (i.e., t = 0.33 day) and consisted of 3-h samples during the daytime and a 12-h sample at night. The daytime sampling intervals were increased to 6 and 12 h beginning on days 4 and 10, respectively. Sampling periods were lengthened to ensure that sufficient mass was collected in the sampling tubes for residue analysis as the experiment progressed.

Additional samples of the 1,3-D and chloropicrin concentrations in the atmosphere were collected at 10, 40, and 80 cm above the ground surface at the center of the treated field for use in a direct method of estimating mass flux because a concentration gradient is required. During days 0−5, the measurement periods were 2 h long during daytime and a single nighttime sample was collected. The daytime sampling intervals were increased to 3, 4, and 6 h beginning on days 5, 9, and 12, respectively.

Meteorological Measurements. Wind speed measurements were obtained at 20, 40, 80, and 160 cm above the ground surface using Windsonic 2-D sonic anemometers (Gill Instruments, Ltd.). Fine-wire thermocouples (FW3, Campbell Scientific, Inc.) were placed at 10, 40, and 80 cm above the ground surface to measure the air temperatures and temperature gradient. Relative humidity and temperature (1.5-m height, CS-215, Campbell Scientific, Inc.), net radiation (1-m height, Q-6, Radiation and Energy Balance Systems, Inc.), and barometric pressure (Vaisala PTA-427, Campbell Scientific, Inc.) measurements were also obtained during the experiment. These sensors were located at field center (see the Supporting Information).

Wind speed, wind direction (Wind Monitor, 5305, R. M. Young, Traverse City, MI, USA), and solar radiation (LI-200S, LI-COR, Inc.) were measured at 10-m height, which was positioned in a nearby field. Hourly averaged solar and net radiation measurements were collected yielding a nominal time series of 384 values (i.e., 24 h × 16 daily values). The average and standard deviation were calculated for each hour of the day to represent a typical daily cycle. This resulted in 24 average solar and net radiations and their standard deviations.

Methods for Measuring the Volatilization Rate. Two regulatory approaches were used to obtain the volatilization rate. A back-calculation method using the Industrial Source Complex Short-Term model (ISCST3),[27,28] has been extensively used for regulatory decisions by the California Department of Pesticide Regulations (CDPR) since the 1990s.[29] A different air dispersion model, CALPUFF,[30] was also used. EPA has recently adopted AERMOD[31] as a replacement for ISCST3. In California, due to the extensive historical use and past decisions based on ISCST3, CDPR has not required or recommended use of AERMOD for determining emission estimates from field application. CDPR evaluated AERMOD and found that the new functionality in AERMOD was not related to the area-source components of the model, and therefore replacement of ISCST3 was not warranted.[29]

The emission rates obtained using the back-calculation method involve comparing observed ambient concentrations in the atmosphere surrounding the field to concentrations calculated using an atmospheric dispersion model (e.g., ISCST3 or CALPUFF). The estimated emission rate is obtained by adjusting the ISCST3 model emission rate to produce the best fit to the measured concentration values (i.e., back-calculating the field emission rate).

The estimated emission rate is based on a linear relationship

$$C_{meas} = b + EC_{ISC} \quad (1)$$

where C_{meas} is the measured ambient concentration, E is the unknown actual emission rate, b is a background concentration that occurs when E = 0, and C_{ISC} is a predicted concentration at the receptor. The model parameters are estimated by linear regression using observed ambient concentrations (C_{meas}) at locations surrounding the treated field and the predicted concentrations (C_{ISC}) at each sampling location obtained using an atmospheric dispersion model with a nominal emission rate (E_{nom}). Because the ISCST3 or CALPUFF concentrations are proportional to the unknown emission rate, E can be estimated from

$$\text{flux} = E = mE_{nom} \quad (2)$$

where the intercept, b, and the slope, m, are obtained from linear regression.

All dispersion model simulations used in back-calculation methods used the regulatory default options, rural dispersion, flat terrain, receptor height of 1.5 m, and meteorological inputs using standard methodology.[30] For CALPUFF simulations, the field was split into four quadrants, and fumigant movement and dispersion were followed from each quadrant to the receptors.

For comparison purposes, the aerodynamic method (ADM)[32] was also used to estimate the volatilization rate based on gradients of wind speed, temperature, and fumigant concentration[32] collected over a relatively large and spatially uniform source area. It is customary to place the instruments at heights that are approximately 1−2% of the upwind fetch distance, which for this experiment would be heights up

DOI: 10.1021/acs.jafc.5b01309
J. Agric. Food Chem. 2015, 63, 5354−5363

to 80 cm. The air concentrations at the 80-cm height were found to be unreliable due to an equipment malfunction; therefore, volatilization rates were calculated using the 10 and 40 cm data. More information is provided in the Supporting Information.

The total fumigant mass lost after application, mass, was calculated using

$$\text{mass} = \text{area} \sum_{n} f_z(t_i)\Delta t_i \quad (3)$$

where $f_z(t_i)$ is the ith period volatilization rate (μg m^{-2} s^{-1}), Δt_i is the time interval for period i, n is the total number of periods, and area is the area (m^2) of the treated region of the field.

Chemical Analysis. Chemical analyses followed the same procedures described in Yates et al.[33] In brief, the concentrations of 1,3-D and chloropicrin in solvent extracts were determined by gas chromatography (GC) using an HP 6890 GC (Agilent Technologies, Palo Alto, CA, USA) equipped with an electron capture detector (ECD). The GC conditions were as follows: use of a 30 m × 0.25 mm × 1.4 μm DB-VRX capillary column (J&W Scientific, Folsom, CA, USA) with 240 °C inlet temperature, 290 °C detector temperature, and 1.6 cm^3 min^{-1} column flow rate (He).

RESULTS

Environmental Conditions. Shown in Figure 1 are hourly means and standard deviations of the solar irradiance (Q_{in}) and net solar radiation (Q_{net}). The maximum and average solar flux densities were 861 and 264 W m^{-2}, respectively. The maximum standard deviation was 72 W m^{-2} and occurred at 5:00 p.m.

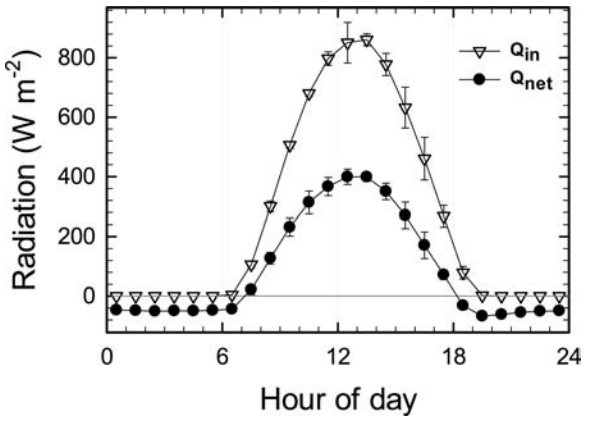

Figure 1. Global solar irradiance (W m^{-2}) and net radiation (W m^{-2}) as a function of time of day. The point values are averages of the hourly radiation over the entire experiment, and the error bars are the standard deviations. Small standard deviations are indicative of relatively uniform clear sky conditions throughout the experiment.

The net radiation was also found to be piecewise smooth during the daytime and was highly uniform at a given time of day during this experiment. The maximum, minimum, and average values were 399 , −67, and 86 W m^{-2}, respectively. The maximum standard deviation for the 24 periods was 44 W m^{-2}.

During the first 8 days of the experiment, the daily maximum temperatures at 1.5 m were similar and ranged from approximately 32 to 35 °C and averaged 33.2 °C (Figure 2A). The daily minimum temperature varied from 15 to 20 °C and averaged 17.3 °C. Starting at day 8, daily maximum temperatures were more variable, ranging from 22 to 31 °C, and averaged 27.3 °C, and the daily minima varied from 12 to 15 °C and averaged 13.1 °C.

The hourly averaged wind speed at 10 m height had a maximum of 5.2 m s^{-1}, and the daily peak 1-h wind speeds had an average and standard deviation of 3.2 ± 0.8 m s^{-1} (Figure 2B). During the nighttime, the daily minimum wind speeds averaged 0.64 m s^{-1} (±0.32), and five values (1.5%) were below 0.5 m s^{-1}, below the starting threshold for the 10-m wind direction sensor.

The wind-rose diagram that summarizes the frequency distribution of the wind speed and direction during the experiment suggests the winds were predominately from the northwest and that there was more variation in wind direction at 10 m compared to measurements taken at the center of the field (1.6 m) (Figure 3). This diagram uses 1- or 2-min averaged wind speed and wind direction data and shows that occasionally winds in excess of 5 m s^{-1} were observed. The length of each wedge provides the frequency that the winds came from that particular direction interval, per unit time. The color sections on each wedge provide frequency information about the wind speed ranges. For example, at 10 m, for approximately 14% of the time during the experiment, the winds were blowing from the north (i.e., 360° ± 11.25°) and about 3.2% of the time the wind speed was within the range of 2.0−2.5 m s^{-1} (i.e., 6.7% − 3.5%). For these short time interval measurements, (i.e., 1−2 min averaging), the maximum observed wind speed was 8.3 m s^{-1}, 1.6% of the measurements exceeded 5 m s^{-1}, and 4.5% were <0.5 m s^{-1}.

Air Concentrations. One air monitoring station was placed 50 m northeast of the field due to a fenced property boundary, and the remaining 11 stations were positioned 30, 90, or 120 m from the field edge. Figure 4 shows the maximum concentrations of *cis*-1,3-D, *trans*-1,3-D, and chloropicrin from the 11 monitoring stations surrounding the field. During periods with steady wind direction, the up-wind air samplers recorded concentrations that were below detectable levels. In general, the highest concentrations occurred during nighttime or early morning hours.

For *cis*-1,3-D, the maximum daily concentrations at the center of the field at height 0.4 m exceeded 1000 μg m^{-3} 14 h after the fumigation was completed. Fumigant labels typically specify a field re-entry period and a buffer setback from the field edge to minimize the potential for bystander exposure. High concentration levels were also observed before sunrise on days 3 (657 μg m^{-3}) and 4 (840 μg m^{-3}). At a distance of 30 m from the field boundary, the daily peak *cis*-1,3-D concentration exceeded 60 μg m^{-3} during the first 2 days after application and the maximum concentrations occurred on days 3−4 (109−112 μg m^{-3}). At greater distances, daily maximum *cis*-1,3-D concentrations were approximately 30 and 35% lower than at 30 m. During the first 24 h after fumigation, the concentrations of *trans*-1,3-D were about 65% less than the *cis*-1,3-D isomer, approximately 20% less than *cis*-1,3-D values for days 3 and 4. After 4 days, *cis*- and *trans*-1,3-D concentrations were similar in magnitude (<10% difference).

Chloropicrin concentrations were generally very low, especially after the first 24 h. The maximum on-field concentration was 60 μg m^{-3} and 15, 13, and 7 μg m^{-3}, respectively, at distances of 30, 90, and 120 m from the field boundary. After approximately 4 days, the maximum chloropicrin concentration levels surrounding the field were low (<1 μg m^{-3}), and after 9.54 days, sampling for chloropicrin ended.

Fumigant Emissions. Transient 1,3-D and chloropicrin volatilization rates using the ISCST3 and CALPUFF methods are shown in Figure 5; the maximum flux rates, the maximum 24-h average flux rates, and the percent total emissions for the

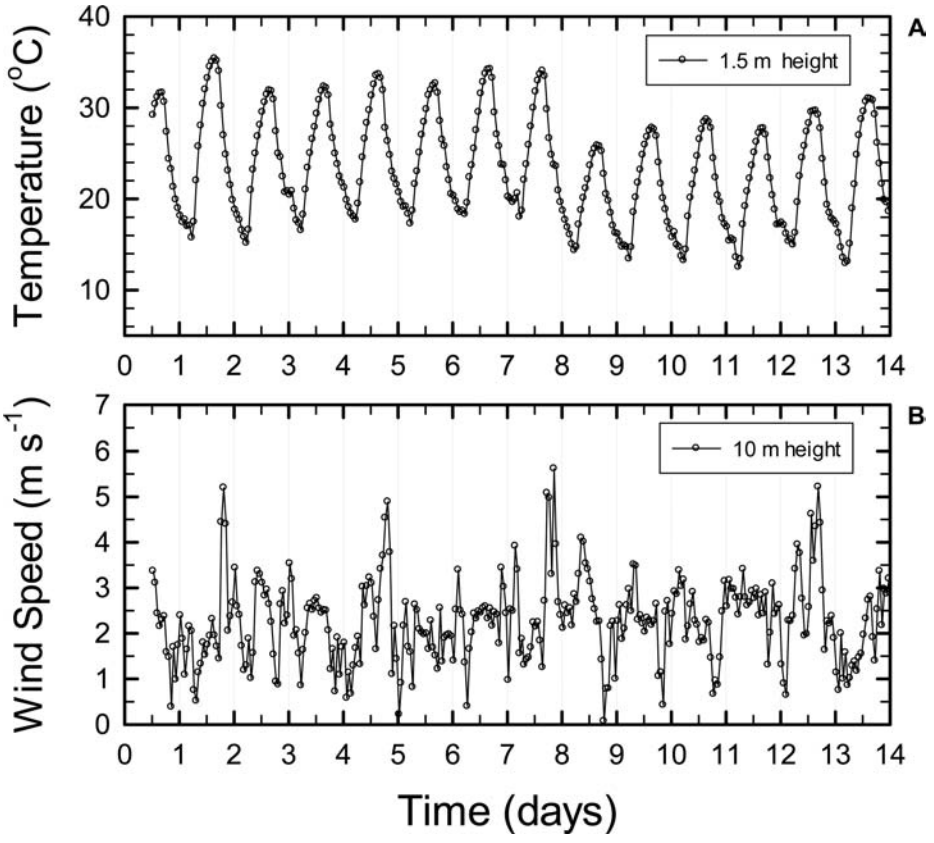

Figure 2. (A) Air temperature (°C) at 1.5 m and (B) wind speed (m s^{-1}) at 10 m above the soil surface during the experiment. Integer values occurred at midnight, and each point is a 1-h sample average.

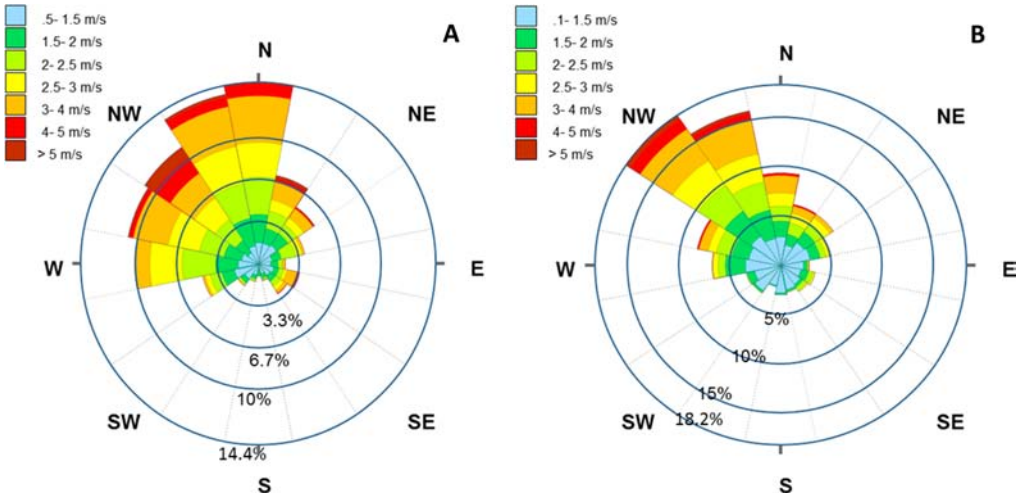

Figure 3. Wind rose diagrams showing the wind direction, wind speed, and frequency that the wind occurred in a specific direction. Two-minute averaged wind speed and direction were used in (A) and 1-min averaged wind speed and direction in (B). In (A), wind measurements at 10 m are shown. In (B), wind measurement at 1.6 m and at field center are shown.

three measurement methods are summarized in Table 1. For CALPUFF and ISCST3, the maximum flux rate for 1,3-D occurred at day 2, and for chloropicrin it occurred during fumigant application. The shaded areas in Figure 5 are the 24-h average flux rates calculated by converting the total mass lost for each day, using CALPUFF, into a flux density. Averaging smooths the short-term fluctuations and more clearly reveals the underlying behavior. The volatilization rates using the ISCST3 model were consistently less than those found using the CALPUFF model. For *cis*-1,3-D and *trans*-1,3-D, the maximum and average ISCST3 flux rates were 59−63% less than CALPUFF rates and for chloropicrin, 74−85% less. For the CALPUFF method, the estimated total volatilization of *cis*-1,3-D, *trans*-1,3-D, and chloropicrin, respectively, was 32, 23, and 0.9% (Table 1). For the ISCST3 model, the estimated total volatilization, respectively, was 19, 13, and 0.3%.

Figure 6 shows time series for 1,3-D and chloropicrin volatilization rates obtained with the aerodynamic method. The maximum emission rates for *cis*-1,3-D, *trans*-1,3-D, and chloropicrin, respectively, were 18, 9.2, and 0.68 μg m^{-2} s^{-1}

DOI: 10.1021/acs.jafc.5b01309
J. Agric. Food Chem. 2015, 63, 5354−5363

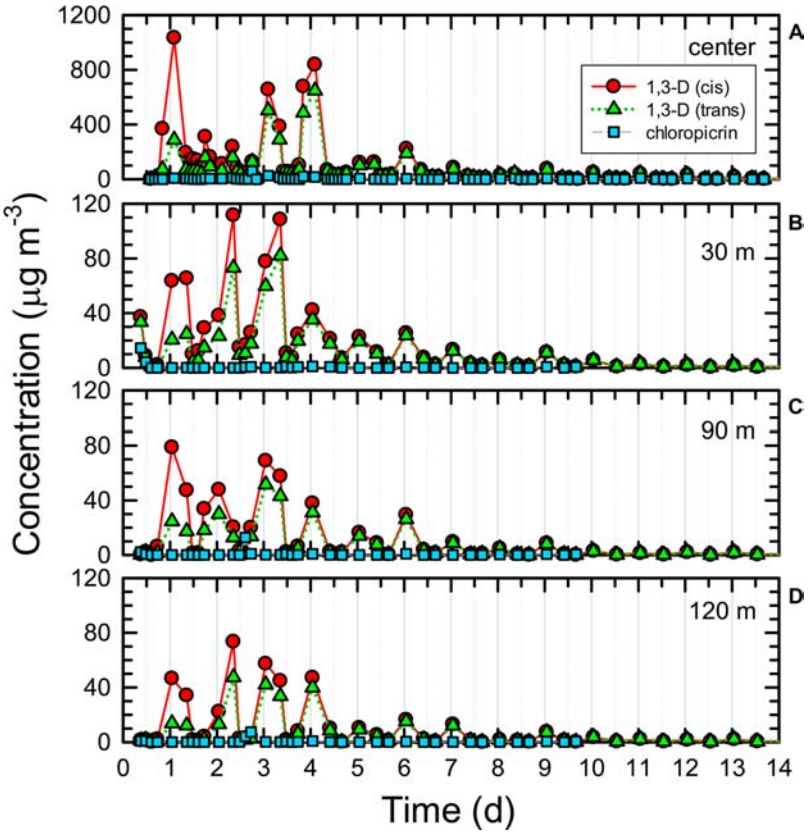

Figure 4. Maximum 1,3-D isomer and chloropicrin concentrations in air at samplers located 30, 90, and 120 m from the edge of field plots (see Supporting Information, Figure S1). Measurements were taken 1.5 m above the soil surface. Time scale begins at midnight September 5, 2007.

(Table 1). For *cis*-1,3-D, the maximum emission rate was within 2% of the back-calculated value using CALPUFF and for *trans*-1,3-D, within 22%. The aerodynamic method yielded total emission estimates of 42, 28, and 1.3% for *cis*-1,3-D, *trans*-1,3-D, and chloropicrin, respectively (Table 1). The aerodynamic method estimates of total emission for *cis*-1,3-D, *trans*-1,3-D, and chloropicrin, respectively, were 33, 25, and 49% higher compared to the back-calculation method using the CALPUFF air dispersion model.

DISCUSSION

Wind Speed, Temperature, and Radiation. Warm temperatures, cloudless conditions, and persistent wind directions are typical weather patterns in the southern San Joaquin Valley in August and September,[33] but wind speeds that produce windblown dust were not observed during the field study. During high wind speeds, windblown dust can reduce visibility and energy inputs, which could affect fumigant emissions. Measurements of solar radiation obtained during a previous experiment that was conducted in late August and early September 2005[33] produced a similar curve as Figure 1, but with slightly lower standard deviations for Q_{in} at 11:00 a.m. and in the early afternoon. The overall low standard deviations shown in Figure 1 indicate that consistent energy inputs were observed during this field experiment and, for comparative purposes, that environmental conditions were similar to a previous experiment conducted in 2005.[33]

Wind speed measurements collected in 2005 in the vicinity of the field experiment using research grade cup anemometers (CWT-1806, C. W. Thornthwaite Associates)[33] indicated that northerly and westerly wind directions are common to this region of California and align with the general orientation of the San Joaquin Valley and surrounding mountains.[33] In 2005, 93% of hourly wind speed measurements during August and September were below 3 m s^{-1} with a maximum of 5.6 m s^{-1} and were predominately from the north-northwest. During this experiment, 78% of the hourly wind speeds were below 3 m s^{-1} and the maximum was 5.6 m s^{-1} (day 8). The average was 2.3 m s^{-1}, the minimum was 0.07 m s^{-1} (day 9), and only six periods were below 0.5 m s^{-1} and only two periods below 0.25 m s^{-1}. Wind direction measured at 1.6 m near the center of the field show similar, but much more consistent, wind direction. This could be partly due to the on-field sensor type, which was a 2-D sonic anemometer consisting of no moving parts and with a threshold measurement of <0.01 m s^{-1}. The mechanical wind direction sensor (10 m) may have been affected by wind buffeting, stalling, and overshoot compared to a high-frequency, nonmechanical device (1.6 m). Even though the field site was flat and had a large uniform surface surrounding the site, near-surface wind directions might also be affected by local topographic effect compared to higher elevation measurements.

Air Concentrations. In general, the highest concentrations occurred during nighttime and early morning hours; this is generally interpreted as a consequence of a stable atmosphere and lower turbulence.[34] The stability of the atmosphere can be estimated from the temperature and wind speed at two heights by calculating the gradient Richardson's number, R_i, and using R_i in an empirical relationship for atmospheric stability, Φ_m (see the Supporting Information). These relationships are described and shown in Figure S2 for a height of 0.6 m. For neutral stability $\Phi_m \approx 1$. Values of $\Phi_m > 1$ indicate a stable atmosphere, which occurred during nighttime and early morning hours of

[a]Percent of total fumigant mass applied; assumes the flux rate is uniform within the field.

the experiment. During the daytime, the atmosphere was generally unstable (i.e., $\Phi_m < 1$). At night, lower wind speed and weaker buoyancy reduced mixing near the surface, allowing emission of gas to accumulate in concentration.

Fumigant concentrations were largest at the start of the experiment due to the high concentrations in the soil immediately following application, rapid diffusion due to soil fractures caused by the fumigation shanks and large initial gradients, and evaporation of fumigant from the injection rig to the atmosphere during application. This behavior was observed at all sampling distances (Figure 4) but is most easily interpreted for the on-field measurements, which were not influenced by wind direction and sample-station positions.

The off-site samples are particularly useful in determining emissions during the application process, before the on-field sensors could be installed. Application losses can occur when the fumigators lift the shanks from the soil as they turn for the next pass down the field. Although the injection valves are closed to minimize waste and emissions, any residue remaining on the shank injectors and tubing evaporates into the atmosphere, increasing fumigant loadings. This is most noticeable at 30 m, during the first two sampling periods (Figure 4B) that were collected during fumigation and is a combination of application losses and losses from soil. The estimated mass lost during fumigation was <1% of applied.

Shank (i.e., a knife-like blade that cuts through soil with the injection nozzle at the lower end) injections tend to produce a more uniform concentration depth profile and higher concentrations near the soil surface compared to methods that do not produce a fracture,[35] but rapid movement along the shank fracture can lead to higher fumigant emissions. New application technology using a coulter and packer purports to reduce fumigant emissions and increase residue levels in soil,[36] on the basis of measurements collected at a depth of 12 cm. Further research is needed to obtain concentration distributions at other depths.

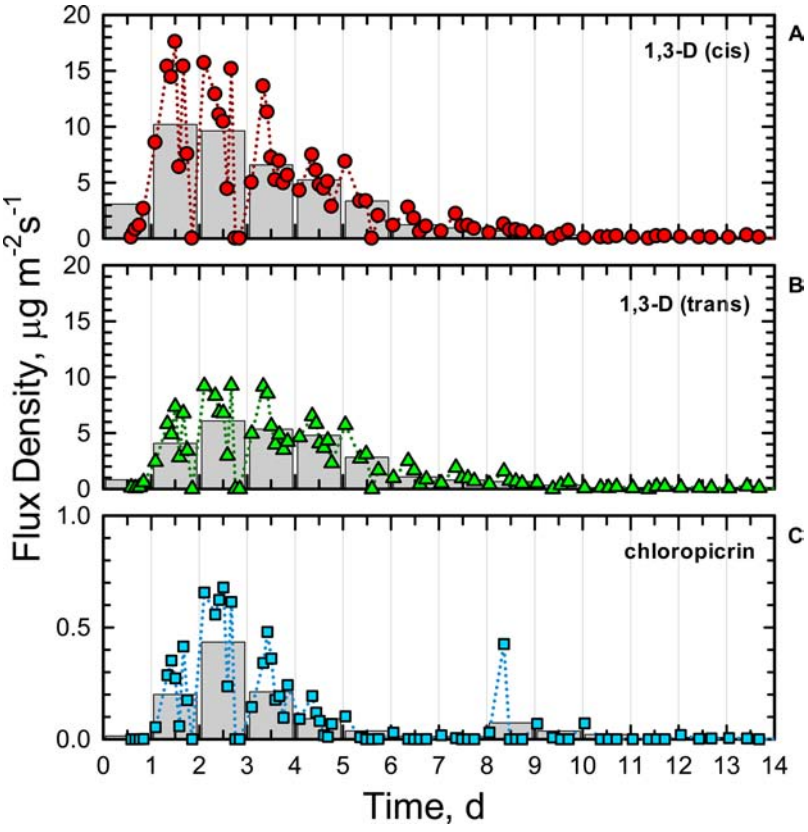

Figure 6. Volatilization rate (i.e., flux density, μg m^{-2} s^{-1}) as a function of time (days) after application for the aerodynamic method. Shaded areas are mass losses for each day converted into daily averaged volatilization rates. For day 0, the shaded area is based on 16 h of available data.

The highest fumigant concentrations were measured near the field center, and progressively lower concentrations were observed at the more distant offsite sample stations. For example, the maximum period-averaged *cis*-1,3-D concentration during the experiment for on-field, 30, 60, and 120 m distances, respectively, were 1035, 112, 79, and 74 μg m^{-3}. The overall behavior of *trans*-1,3-D was similar to that of *cis*-1,3-D, but with slightly lower concentrations (especially at early times). Compared to *cis*-1,3-D, *trans*-1,3-D is known to have an 8.2% higher boiling point (112.6 °C), 6.4% higher solubility (2320 ppm), 33% lower vapor pressure (23 mmHg), and 42% lower dimensionless Henry's law constant (0.037). In concert, these factors may result in a delay in *trans*-1,3-D movement to the soil surface, reduction in peak emission rates, and retardation of the peak emission timing.[13,37] Observed chloropicrin air concentrations were very low for all distances and times after chloropicrin application ended (t > 0.53 day). The higher concentrations during fumigation were most likely due to the application process, as discussed above.

Fumigant Emissions. State and federal regulators are concerned about atmospheric loadings of soil fumigant chemicals, and information on emissions is used to estimate environmental risks and to determine risk related to acute bystander exposure. Information on the total emission rate is useful for determining contributions to regional volatile organic chemicals and for determining risks due to chronic exposure to fumigant chemicals.

The emissions of 1,3-D (*cis* + *trans*) calculated using ISCST3, CALPUFF (Figure 5), and ADM (Figure 6) methods demonstrate a similar overall pattern with higher rates early in the experiment and lower rates about 5−6 days post application. The ISCST3 estimates were found to be consistently lower than estimates obtained using the CALPUFF model (53% lower on average). The largest differences occurred during the morning hours when the ISCST3 emissions were as much as 85% lower than the CALPUFF values. Using ISCST3, the reported total 1,3-D and chloropicrin losses, respectively, were 40 and 64% lower than the CALPUFF values.

During the first 5 days, the short-term volatilization rates follow a consistent cycle where the volatilization rate increases from midnight to midmorning, followed by a steep reduction in the volatilization rate at midday and low values until nighttime. This pattern is consistent with daytime drying of the surface soil, which leads to increased vapor adsorption. Increased adsorption reduces the pesticide vapor density and the vapor gradients,[38−40] which is an important transport mechanism. As water content in soil decreases below a threshold level, the reduction in vapor pressure would cause a reduction in pesticide emissions.[41] Using modeling, the effects of vapor adsorption have been shown to strongly bind volatile pesticides to soil particles in a highly nonlinear process.[42,43]

Whereas the emission measurements vary considerably with time of day, the long-term (e.g., daily averaged) emission rates (shaded areas in Figure 5) show a smoother and more predictable behavior that starts with a steady increase in the emission rate after fumigation, peaks on day 2, and is followed by a long period of decreasing emission rates. In terms of mathematically modeling the emission process, this behavior follows conventional transport theory.[44]

It can be shown that the timing of the maximum emission rate depends on the depth of injection[35] for a shank or point

DOI: 10.1021/acs.jafc.5b01309
J. Agric. Food Chem. 2015, 63, 5354−5363

fumigation (i.e., injection) model. This is due to the time needed for the fumigant to diffuse from the injection depth (46 cm) to the soil surface and volatilize into the atmosphere. For a shank fumigation using *cis*-1,3-D, the model predicts that the peak emission rate would occur at approximately 1−1.3 days after application, assuming a post fumigation soil-disking depth of 15−20 cm. This coincides with the experimental results using the on-field measurements (Figure 6) where the highest daily averaged emissions (shaded area) occur on day 1. For the CALPUFF method (Figure 5), the peak daily averaged emission rate occurs on day 2. It is unclear why the peak flux calculated from CALPUFF occurred at a later time than with the ADM method, but is probably due to differences in the approach for calculating flux values or the temporal nature of wind speed/direction, which are averaged over each sampling duration. For the ADM method, the sampling "footprint" (i.e., area of surface-soil-emissions captured by the sampling equipment) would be a relatively small zone immediately surrounding the sampling equipment, and the time period when the fumigant was injected into this area would have a relatively short duration. For the CALPUFF method, emissions over the entire field and transport from the field boundaries to the surrounding samplers affect the emission rate values. This means that the CALPUFF method could be affected by spatial and temporal averaging of the field emission rates and near-field transport processes.

In Figure 5, the first two flux values were measured during the fumigation period and demonstrate the gas losses occurring during application. Large emission losses during fumigation caused state regulators in California to restrict 1,3-D application from 1990 to 1995[7] to protect people living in fumigation areas. It was not until suitable application guidelines were developed and tested that use of 1,3-D was again allowed in California. During this experiment, losses during application were lower than emissions from soil that occurred later in the experiment and show that current regulations are effectively controlling losses during application.

A laboratory study[45] reported 1,3-D and chloropicrin emissions using Milham sandy loam soil collected from a nearby, nontreated, field in 2005. The stainless steel soil columns (1.5 m long) were placed in a controlled-temperature environment so that the columns were exposed to temperature conditions similar to those observed at the field site. The reported total *cis*-1,3-D emissions 14 days after treatment was 33.1% of applied. The emission rate from the laboratory experiment was within 1% of the CALPUFF *cis*-1,3-D total emission value.

In a follow-up experiment[18] that included 1,3-D and chloropicrin, the total 1,3-D (*cis* + *trans*) and chloropicrin emissions 14 days after injection, respectively, were reported as 40 and 16% of applied. The reported chloropicrin emission losses were much more than observed during this field experiment (e.g., ∼1%). The soil at the field site was found to have relatively high soil degradation rates. Ashworth et al.[18] measured the 1,3-D and chloropicrin half-lives, respectively, as 90 and 2.9 h, at 25 °C. In a subsequent laboratory study Ashworth et al.[46] found that the chloropicrin degradation rate depended on the chloropicrin application rate, with low application rates leading to high degradation rates.

Rapid chloropicrin degradation in soil may have contributed to a reduction in soil concentration levels before sufficient time elapsed to allow significant volatilization, and to test this hypothesis, a mathematical model was used to predict total emissions as a function of soil properties, injection depth, presence of a shank fracture, soil degradation, and surface resistance to volatilization.[35] A feasible explanation for the low chloropicrin emissions observed during the experiment is the soil degradation rate (i.e., $t_{1/2}$ = 2.9 h), which led to predicted total emissions of <1%.

Very few large-scale field measurements of the emissions of 1,3-D and chloropicrin after broadcast application are reported in the literature. There are even fewer reported studies that utilize multiple methods for measuring the emission rate. This is due, in part, because conducting a field campaign is very expensive and requires large investments in time, equipment, and personnel. The current study is unique because it provides a continuous time series of the emissions for 14 days (daytime and nighttime) and involved collection of two independent data sets (i.e., on-field and off-field measurements). These data were then used so that the emission rate was calculated by three methodologies (i.e., ISCST3, CALPUFF, and ADM methods). Comparing the methodologies revealed that the increasing order of the total emissions was ISCST3 < CALPUFF < ADM, and total emissions from CALPUFF are approximately the same as the average of the three methods.

Determining which method provides the most accurate emission rates is not possible with the data currently available, because there is no absolute reference for comparison. Each method encompasses inherent assumptions and/or simplifications that may affect the calculated values under some conditions. For example, ISCST3 is a steady-state atmospheric dispersion model, so results could be compromised for highly variable wind conditions during an hourly time step. CALPUFF is a non-steady-state Lagrangian puff model that tracks chemical movement in a more natural manner, a likely an improvement over ISCST3, but the results depend on the gridding system employed and the representativeness of the meteorological data. The ADM method assumes a well-developed surface layer for measuring gradients (concentration, wind speed, and temperature) and requires evaluation of a correction term for stable and unstable atmospheric conditions, which may introduce uncertainty. It is clear that further research is needed to better understand the accuracy and performance of these methods for calculating fumigant emissions.

Using total emissions from CALPUFF for comparison, the results of this study fall within the range of values reported in the literature for 1,3-D for similar application methodology (25−66%).[24,36,47] The results for chloropicrin were much different from emission values reported in the literature (i.e., 30−60%), which was attributed to the unusually high soil reactivity at the field site.

The results from this study should prove useful for conducting risk assessments. Recent U.S. EPA FIFRA Scientific Advisory Science Panels (SAP) conducted assessments of three fumigant bystander exposure models.[48−50] The SAP and model developers concluded that the availability of appropriate emission rate time series is critical to the effective use of these risk assessment models, because the emission rate defines the source term for fumigants in the airstream that can lead to exposures. Information on emission rates based on multiple and independent estimation methods, and that are applicable to field-scale conditions, provides valuable information for use in risk assessment.

Influence of Free Amino Acids, Oligopeptides, and Polypeptides on the Formation of Pyrazines in Maillard Model Systems

Gustavo Luis Leonardo Scalone,[†,‡] Tatiana Cucu,[†] Norbert De Kimpe,[‡] and Bruno De Meulenaer*[,†]

[†]Department of Food Safety and Food Quality, nutriFOODchem Group, Member of Food2Know, Faculty of Bioscience Engineering, and [‡]Department of Sustainable Organic Chemistry and Technology, Faculty of Bioscience Engineering, Ghent University, Coupure links 653, B-9000 Ghent, Belgium

ABSTRACT: Pyrazines are specific Maillard reaction compounds known to contribute to the unique aroma of many products. Most studies concerning the generation of pyrazines in the Maillard reaction have focused on amino acids, while little information is available on the impact of peptides and proteins. The present study investigated the generation of pyrazines in model systems containing whey protein, hydrolyzed whey protein, amino acids, and glucose. The impact of thermal conditions, ratio of reagents, and water activity (a_w) on pyrazine formation was measured by headspace solid-phase microextraction with gas chromatography/mass spectrometry (HS-SPME−GC/MS. The presence of oligopeptides from hydrolyzed whey protein contributed significantly to an increased amount of pyrazines, while in contrast free amino acids generated during protein hydrolysis contributed to a lesser extent. The generation of pyrazines was enhanced at low a_w (0.33) and high temperatures (>120 °C). This study showed that the role of peptides in the generation of pyrazines in Maillard reaction systems has been dramatically underestimated.

KEYWORDS: *peptides, Maillard, fractions, pyrazines, flavor, model reactions, HS-SPME−GC/MS*

INTRODUCTION

The Maillard reaction comprises a set of complex chemical reactions, which are initiated when a free amino group of an amino acid, peptide, protein, or amine reacts with the carbonyl group of a reducing sugar. This nonenzymatic browning reaction gives rise to modifications in color, aroma, taste, and nutritional value of thermally treated foods and is influenced by many factors, such as temperature, time, pH, type of buffer, water activity, and reactant concentration.[1] The reaction between free amino acids and carbonyl compounds has been extensively studied,[1] whereas the Maillard reaction between peptides and proteins with carbonyl compounds has been less investigated.[2−4] This in fact is quite surprising, as the amount of free amino acids in food is generally very low as compared to the amounts of peptides and especially proteins.[5]

A limited number of studies have investigated the generation of volatiles in protein−carbohydrate models. Nevertheless, these studies were performed under unrealistically severe thermal conditions.[6−8]

Oligopeptides have been recognized as important flavor enhancers and precursors of the Maillard reaction.[2,9−11] Moreover, peptides can be a flavor enhancer as such (umami taste). In addition, the formation of flavor compounds due to reaction between peptides and carbohydrates has mainly been studied in model systems containing glutathione[12−15] and glycine-derived peptides such as diglycine, triglycine, and tetraglycine.[4] In these studies, pyrazines were indeed the most abundant volatiles.

Substituted and unsubstituted pyrazines are specific Maillard reaction products that are known to contribute significantly to the unique roasted, nutty, meaty, earthy, and popcornlike aroma of many heated food products.[16,17] Oh et al.[4] found that the amount of pyrazines formed from diglycine or tetraglycine was considerably lower compared to that formed from either glycine or triglycine. Van Lancker et al.[18,19] studied the formation of pyrazines from di- and tripeptides with different amino acid sequences. The results of these studies showed significant formation of pyrazines from dipeptides compared to free amino acids and less pyrazine formation in tripeptides compared with dipeptides and free amino acids.

The general mechanism of pyrazine formation via the Maillard reaction implies in the first step the reaction of a dicarbonyl compound **1** produced by sugar degradation and an amino acid **2**, which leads to the formation of Strecker aldehydes **6** and α-aminoketones **7**. A crucial step in this degradation reaction is decarboxylation of the intermediate **4** via a cyclic transition state (Figure 1, part I). The second step in pyrazine formation involves two possible pathways that start with the condensation reaction of two α-aminocarbonyl compounds, **7** and **7′**, forming dihydropyrazine **9**. This dihydropyrazine can react in two distinct ways. The dihydropyrazine can oxidize spontaneously with air to the corresponding pyrazine **11** (pathway A). Alternatively, after deprotonation the dihydropyrazine anion **10** can react with a carbonyl compound **6** in an aldol-type reaction (pathway B). Whenever this reacting carbonyl compound is a Strecker aldehyde **6**, amino-acid-specific pyrazines **15** are formed (Figure 1, part II).

Peptides cannot follow the typical Strecker degradation due to the absence of a free carboxyl group at the α-carbon with respect to the free amino group, making the decarboxylation

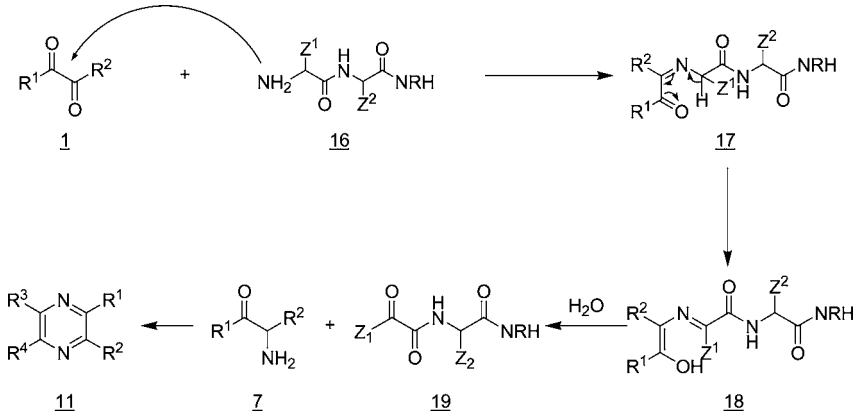

Figure 2. Hypothetical formation mechanism of α-aminoketones from the reaction of peptides with an α-dicarbonyl compound. Adapted from Van Lancker et al.[18]

impossible. Van Lancker et al.[18] have suggested a mechanism of pyrazine formation in model systems containing dipeptides and dicarbonyl compounds as shown in Figure 2. In accordance with the reaction with free amino acids, reaction of α-dicarbonyl compound **1** with the dipeptide starts with formation of an α-ketoimine **17**. Afterward, deprotonation occurs at the α-position of the amide moiety, resulting in a 1,5-H-shift leading to enolization of the carbonyl group of intermediate **17**. Hydrolysis of the imino moiety of 4-hydroxy-2-azadiene **18** produces the α-aminoketone **7**, and instead of forming the Strecker aldehyde, a complex α-ketoamide **19** is formed.[2]

Although it was shown before that peptides may generate pyrazines in the Maillard reaction, their potential contribution to the overall pyrazine formation in food has not been compared to the contribution of amino acids. Therefore, this study aimed to evaluate the impact of trypsinogenic whey hydrolysis products on the formation of pyrazines in a Maillard reaction model, thereby trying to discriminate the role of free amino acids and peptides generated, respectively. In addition the impact of other factors such as heating conditions, ratio of

reagents, and water activity on the formation of pyrazines was investigated.

MATERIALS AND METHODS

Chemicals. DL-Norvaline (99%), L-cysteine (99.5%), L-4-hydroxyproline (99%), DL-valine (99%), DL-alanine (99%), L-tryptophan (99.5%), L-citrulline (99%), sarcosine (99%), DL-histidine (99%), L-isoleucine (99.5%), DL-leucine (99%), and glutamine (99,5%) were purchased from Fluka (Sigma−Aldrich, Bornem, Belgium). DL-Lysine monohydrochloride (98%), DL-methionine (99%), glycine (99.5%), L-arginine hydrochloride (99%), L-phenylalanine (99%), L-glutamic acid (99%), D-(+)-glucose (99.5%), trypsin from porcine pancreas, trypsin−chymotrypsin inhibitor from *Glycine max* (soybean), insulin from bovine pancreas, insulin chain B oxidized from bovine pancreas, cytochrome *c* from equine heart, vitamin B_{12}, Val-Tyr, pyrazine (99%), 2-methylpyrazine (99%), and sodium bromide (99%) were purchased from Sigma−Aldrich (Bornem). L-Lysine (97%), arginine (98%), proline (99%), asparagine monohydrate (99%), 2,5-dimethylpyrazine (99%), 2-ethylpyrazine (98%), 2-ethyl-3-methylpyrazine (99%), 2-ethyl-3,5(6)-dimethylpyrazine (99.5%), and trichloroacetic acid (99%) were purchased from Acros Organics, Thermo-Fisher Scientific (Erembodegem, Belgium). Aspartic acid (99%), DL-threonine (99%), and L-tyrosine (99%) were purchased from Merck (Darmstadt, Germany). DL-Serine, 2,3-dimethylpyrazine (99%), and 2,6-dimethylpyrazine (96%) were purchased from Janssen Chimica (Geel, Belgium). Magnesium chloride hexahydrate (99%), calcium carbonate (99%), potassium iodide (99.5%), and sodium chloride (98%) were purchased from Chemlab Analytical (Zedelgem, Belgium). Whey protein isolate Lacprodan DI-9224 was donated from Arla Foods (Aarhus, Denmark).

Hydrolysis of Whey Protein. Whey protein isolate (84% protein) was dissolved in 0.1 M potassium phosphate buffer, pH 7.8, at a concentration of 5 mg/mL, heated at 95 °C for 5 min, and then cooled down at room temperature. Trypsin was added at a ratio of 1:20 (w/w), and then the mixture was incubated at 37 °C in a water bath for 20 h. The obtained solution was heated at 95 °C for 5 min to inactivate the enzyme and then frozen for later use. The free amino acid content of the hydrolyzed protein was analyzed and reported (Table 1). The nonhydrolyzed whey protein isolate did not contain free amino acids in detectable amounts. The protein hydrolysate was further characterized by gel-permeation chromatography as shown in Figure 3 and outlined below.

Table 1. Free Amino Acid Composition of Native Whey Protein Isolate after Tryptic Hydrolysis

amino acid	content (mg/100 mg of hydrolyzed whey)
lysine	0.9916
leucine	0.1340
valine	0.0960
isoleucine	0.0728
arginine	0.0546
tyrosine	0.0421
threonine	0.0389
tryptophan	0.0359
phenylalanine	0.0297
methionine	0.0218
alanine	0.0104

Size-Exclusion Chromatography. Samples of whey protein and hydrolyzed whey protein were analyzed with an Äkta explorer liquid chromatograph (LC) coupled to a UV detector (GE Healthcare, Zaventem, Belgium) equipped with a Superdex peptide 10/300 GL column (GE Healthcare, Zaventem). Working conditions were as follows: mobile phase, 0.15 M ammonium hydrogen carbonate buffer, pH 7.8; flow, 0.5 mL/min; UV detection, 214 nm.

Free Amino Acid Analysis. Samples of whey protein and hydrolyzed whey protein were treated with a solution of 15% trichloroacetic acid, further centrifuged, filtered, and analyzed by HPLC with fluorescence detection.[20]

Selection of Thermal Reaction Conditions. *Sterilization Conditions.* Samples were mixed in a volumetric flask and the volume was adjusted to 5 mL with 0.1 M potassium phosphate buffer, pH 7.8. Then each sample was transferred to a SPME vial (Gerstel, Mülheim, Germany) and closed with a pressure cap [silicone/poly-(tetrafluoroethylene) (PTFE), 55°, shore A, 1.5 mm, magnetic; Gerstel, Mülheim an der Ruhr, Germany). The vial was heated in a stirring oil bath at 130 °C to obtain an inside temperature of 120 °C, for 2 h, after which the vials were immediately cooled down in an ice bath.

Roasting Conditions. Samples were mixed in a volumetric flask and the volume was adjusted to 5 mL with 0.1 M potassium phosphate buffer pH 7.8. Then each sample was transferred to a SPME vial containing 1.5 g of sand. Subsequently the samples were frozen and freeze-dried in a VaCo5 freeze-dryer (Zirbus Technology, Bad Grund, Germany) to ensure sample homogeneity. Finally, the samples were closed with pressure caps and heated in an oven (Memmert, Fisher Scientific, Erembodegem, Belgium) at 180 °C for 90 min. Preliminary experiments showed that a considerable improvement in reproducibility could be obtained by dissolving, freezing, and freeze-drying instead of dry-mixing the various ingredients.

Reactant Type. Two groups of samples were analyzed to evaluate the yields of pyrazine formation under roasting and sterilization conditions.

Samples containing hydrolyzed whey protein and glucose were prepared at eight different ratios of protein to glucose ranging from 1:1.33 to 1:0.08 (w/w); see Table 2. Samples containing lysine and glucose were prepared at nine different ratios of lysine to glucose ranging from 1:2.53 to 1:0.15 (w/w); see Table 3. Samples were analyzed by headspace solid-phase microextraction with gas chromatography/mass spectrometry (HS-SPME−GC/MS).

Elucidation of the Role of Protein Hydrolysis Products on Formation of Pyrazines. Four groups of model systems were prepared as follows: (1) hydrolyzed whey protein (15 mg) + glucose (7.5 or 15 mg); (2) native whey protein (15 mg) + glucose (7.5 or 15 mg); (3) native whey protein (15 mg) + glucose (7.5 or 15 mg) with addition of a mixture of free amino acids (aa), corresponding to the free amino acid content of the tryptic digestion of whey protein as reported in Table 1; and (4) a mixture of free amino acids (aa), corresponding to the free amino acid content of the tryptic digestion of whey protein as reported in Table 1, and glucose (7.5 or 15 mg).

The reaction mixtures were dissolved in 5 mL of 0.1 M potassium phosphate buffer, pH 7.8, and then transferred to SPME vials containing 1.5 g of sand, freeze-dried, closed with pressure caps, and thermally treated under previously described roasting conditions. Samples were analyzed by HS-SPME−GC/MS.

Impact of Water Activity on Pyrazine Generation from Hydrolyzed Whey Protein. Samples containing 15 mg of hydrolyzed whey protein and 7.5 mg of glucose were dissolved in 5 mL of 0.1 M potassium phosphate buffer, pH 7.8, and transferred to SPME vials containing 1.5 g of sand. Subsequently the vials were freeze-dried and immediately capped. Afterward, the water activity (a_w) values of the samples were determined on a 4TEV dew point water activity meter (Aqualab, Decagon Devices, Pullman, WA) obtaining an initial value of 0.16.

Subsequently, freeze-dried samples were transferred to different hermetic plastic recipients containing saturated solutions of magnesium chloride (32% relative humidity, RH), potassium carbonate (43% RH), sodium bromide (56% RH), potassium chloride (67% RH), and sodium chloride (75% RH). All the samples were incubated in triplicate for 7 days at 30 °C inside an incubator (Memmert, Fisher Scientific, Erembodegem, Belgium) in order to reach the desired water activity in each sample. After reaching equilibrium, all samples were thermally treated under previously described roasting conditions and analyzed by HS-SPME−GC/MS.

Headspace Solid-Phase Microextraction with Gas Chromatography/Mass Spectrometry Analysis. The volatiles produced during the different experimental conditions were extracted by means

[a]Samples containing hydrolyzed whey protein and glucose were prepared at eight different ratios of protein to glucose, ranging from 1:1.33 to 1:0.08 (w/w), and analyzed by HS-SPME−GC/MS. Data points represent mean values of three independent determinations and are given as GC/MS peak area × 10^6. Values in the same row followed by different letters are significantly different ($p < 0.05$). [b]Protein/glucose ratio (w/w). [c]Model reactions were as follows: R, dry glucose and hydrolyzed whey mixtures under roasting conditions (180 °C/90 min); S, aqueous glucose and hydrolyzed whey solutions under sterilization conditions (120 °C/120 min). [d]Identification confirmed by GC retention index and mass spectra of authentic compounds. [e]ND, not detected. [f]Tentatively identified by matching mass spectra library.

of HS-SPME for 30 min at 35 °C with a DVD/Car/PDMS fiber (Supelco, Bornem) with a multipurpose sampler (MPS-2, Gerstel). GC/MS analyses of the SPME extract were performed with an Agilent 6890 GC Plus apparatus coupled to a quadrupole mass spectrometer

J. Agric. Food Chem. 2015, 63, 5364−5372

5973 MSD (Agilent Technologies, Diegem, Belgium) and equipped with a DB-5 capillary column (30 m length × 0.25 m i.d; 0.25 μm film thickness) (Agilent Technologies, Diegem). Working conditions were as follows: transfer line to mass-selective detector (MSD) 250 °C, carrier gas (He) 1.0 mL/min; electron ionization (EI) 70 eV; acquisition parameters, scanned m/z 40−200 (2−10 min), 40−300 (10−20 min), and 40−400 (>20 min); oven temperature started at 35 °C, held 5 min, programmed from 35 to 80 °C at 2 °C/min, held 2 min. Pyrazines were identified by comparison of the mass spectrum with mass spectral libraries (Nist 98, Wiley sixth and HPCH2205) and by comparison of the calculated linear retention indices with literature values.

Generation of pyrazines was followed in a semiquantitative way by considering the absolute peak area of each individual pyrazine.[18,21,22] Although this approach does not allow absolute quantitation of each individual pyrazine, it is generally accepted as suitable to evaluate the pyrazine formation in a reliable way.

Statistical Analysis. All analyses were performed with SPSS Statistics version 22 at a significance level of 95% ($p = 0.050$). Data were normally distributed (Kolmogorov−Smirnov test, $p < 0.050$ for all standardized residuals). Therefore, one-way analysis of variance (ANOVA) was selected for statistical analysis. The Games−Howell correction was applied to control the familywise error rate at 5% for all multiple pairwise comparisons.

RESULTS AND DISCUSSION

Selection of Reaction Conditions and Ratio of Model Systems. In a first series of experiments, the impact of reactant ratio (glucose and hydrolyzed whey protein) on the formation of pyrazines was evaluated for both thermal treatments applied.

The results shown in Table 2 indicate that, under roasting conditions (180 °C/90 min), significant quantities of the following pyrazines were produced in model systems containing hydrolyzed whey protein and glucose: 2-methylpyrazine, 2,5(6)-dimethylpyrazine, 2,3-dimethylpyrazine, 2-ethylpyrazine, 2-ethyl-3-methylpyrazine, 3-ethyl-2,5-dimethylpyrazine, 2-ethyl-3,5-dimethylpyrazine, and 5-ethyl-2,3-dimethypyrazine.

The same reactants under sterilization conditions (120 °C/120 min) yielded mainly 2-methylpyrazine and 2,5(6)-dimethylpyrazine. However, the peak areas of the produced pyrazines were considerably lower compared to those observed during roasting conditions. These observations may be due to the fact that indeed a lower amount of pyrazines was produced, which can be explained by the different reaction conditions: temperature and presence of water in the systems. It should be noted as well, however, that by addition of 2 μg of 2-ethyl-3-methylpyrazine to similar amounts of non-thermally-treated samples, a much higher peak area was observed for the dry (107.89×10^6) versus the wet sample (6.68×10^6). This indicated that partitioning of the pyrazines between samples and headspace is totally different for dry and aqueous sample.

The ratio between glucose and hydrolyzed whey protein played a crucial role in the formation of pyrazines. The generation of pyrazines under dry roasting conditions was low in model systems where glucose was present in low amounts (ratio 1:0.08 and 1:0.16). This effect can likely be explained since the amount of dicarbonyl compounds generated from glucose degradation was low, which had an impact on the formation of pyrazines and resulted in lower peak areas. Higher peak areas were detected for ratios up to 1:0.5 and 1:0.67. At higher protein/glucose ratios, a decrease in the formation of pyrazines was again observed. This may be due to excessive formation of different carboxylic acids such as acetic acid from glucose,[23] which might decrease the pH of the model systems. It is generally known that pH has an impact on the generation of pyrazines,[1] hindering their formation at low pH due to the protonation of the amino groups of the amino acids and peptides. Also, under sterilization conditions, the peak area of the formed pyrazines was affected by the protein/glucose ratio although to a lesser extent.

It is broadly known that, in Maillard reaction models, free amino acids have a high reactivity. In order to compare the reactivity of glucose/hydrolyzed whey protein with a glucose/amino acid mixture, lysine was selected. Pyrazine formation at different lysine/glucose ratios was monitored under both heating conditions (see Table 3). Considerably higher amounts of pyrazines were detected in the lysine-containing reaction systems under both heating conditions when compared to hydrolyzed whey. In addition, the detected pyrazines were more diverse, particulary for the roasted samples. Under roasting conditions, the detected amounts of 2-methylpyrazine and 2,5(6)-dimethylpyrazine were considerably less influenced by the lysine/glucose ratio. However, the lysine/glucose ratio did have a considerable effect on the amount of pyrazines detected. At lower lysine/glucose ratios, formation of pyrazines in roasting conditions decreased considerably, while this tendency was not observed under sterilization conditions. These experiments showed that depending upon the amino compounds participating in the reactions, such as free amino acids or peptides involved in the pyrazine formation, the impact of the amino compounds/glucose ratio on the pyrazine formation will be different.

As it was noticed that considerably more pyrazines were detected under roasting conditions (180 °C/90 min) for both glucose/hydrolyzed whey protein and glucose/lysine models, this heat treatment was used in subsequent experiments.

Elucidation of the Role of Protein Hydrolysis Products on Formation of Pyrazines. From the previous experiments, it was obvious that hydrolyzed whey proteins were able to generate pyrazines in Maillard reaction systems. However, it was not clear if the compounds responsible for the pyrazine generation are the free amino acids produced during hydrolysis (Table 1) or the peptidic fraction or both. Therefore, formation of pyrazines by hydrolyzed whey protein was compared with pyrazine generation in a mixture of nonhydrolyzed proteins to which the free amino acids formed upon trypsinogenic hydrolysis were added according to the amounts reported in Table 1. Nonhydrolyzed whey protein was included as a control. In addition, glucose together with the free amino acids generated upon trypsinogenic hydrolysis of whey was considered as well. Experiments were conducted under dry heating conditions at two protein/glucose ratios.

In model systems containing free amino acids as described in Table 1 and glucose, no pyrazines were detected (data not shown). Most likely the amount of reagents was not sufficient to generate sufficient Maillard products. Model systems containing hydrolyzed whey protein and glucose led to formation of the highest amounts of pyrazines (Table 4). In model systems containing native whey protein and glucose, the generation of pyrazines was significantly lower than in samples of hydrolyzed whey. Native whey protein isolate did not contain any free amino acids, suggesting that the limited generation of pyrazines was due to thermal degradation of the protein under the selected reaction conditions, releasing amino compounds that can react with glucose and form pyrazines. Model systems containing native whey with addition of the mixture of free amino acids (Table 1) and glucose produced comparable and statistically similar amounts of pyrazines as the

Table 3. continued

[a]Samples containing lysine and glucose were prepared at nine different ratios of lysine to glucose, ranging from 1:2.53 to 1:0.17 (w/w), and analyzed by HS-SPME−GC/MS. Data points represent mean values of three independent determinations and are given as GC/MS peak area × 10^6. Values in the same row followed by different letters are significantly different ($p < 0.05$). [b]Lysine/glucose ratio (w/w). [c]Model reactions were as follows: R, dry glucose and lysine mixtures under roasting conditions (180 °C/90 min); S, aqueous glucose and lysine solutions under sterilization conditions (120 °C/120 min). [d]Identification confirmed by GC retention index and mass spectra of authentic compounds. [e]ND, not detected. [f]Tentatively identified by matching mass spectra library.

model systems containing native whey protein isolate and glucose.

These results allowed us to conclude that the amount of free amino acids present in the whey hydrolysate was not sufficient to produce pyrazines in measurable amounts under the heating conditions earlier described. Compared to the results from experiments with hydrolyzed whey, it is obvious that the peptides generated upon hydrolysis played an important role in the generation of pyrazines.

Regarding the pathways that involve the peptidic fraction in the generation of α-aminoketones and their posterior condensation into pyrazines, Oh et al.[4] studied model systems with glycine containing di-, tri-, and tetrapeptides. The authors suggested that tetraglycine could be degraded to diglycine and further degraded into glycine to produce pyrazines. Simultaneously, triglycine was suggested to be degraded to diglycine and glycine. However, these results are limited to glycine-containing peptides. Yang et al.[24] studied peptide bond cleavages during the Maillard reaction, and their results show that some peptide bonds can be more resistant or labile depending on the amino acid sequence in the peptide chain. Therefore, the use of di-, tri-, and tetraglycine can only represent some peptides. The mechanism previously depicted in Figure 2 implies the formation of pyrazines in model systems containing dipeptides and dicarbonyl compounds. The alternative mechanism was suggested since dipeptides cannot follow the typical Strecker degradation due to the absence of a free carboxyl group to form α-aminoketones.

It is obvious that a similar mechanism can be responsible for the formation of pyrazine from oligopeptides as well.

Impact of Water Activity on Pyrazine Generation from Hydrolyzed Whey Protein. Lu et al.[25] studied the effects of water content on volatile generation and peptide degradation in the Maillard reaction, using glycerol to limit the water content of the samples. However, Smarrito-Menozzi et al.[26] reported that glycerol is an underestimated flavor precursor in the Maillard reaction. Therefore, the water content of the samples was controlled by equilibrating them in recipients filled with saturated salt solutions, obtaining atmospheres with fixed relative humidities as described by Greenspan et al.[27] Thus, after equilibration, samples with a particular water activity were obtained.

The results presented in Table 5 show that the model systems incubated with a water activity of 0.33 produced the highest amounts and variety of pyrazines. This may be explained by the potential effect of water activity on peptide degradation. Oliyai et al.[28] studied the chemical stability of a hexapeptide under varying conditions of pH, temperature, and moisture content; they found that higher moisture content significantly degraded the hexapeptide, leading to increased reactivity. In addition, water activity has been pointed out to have an impact on reaction rates[29] since water in food often acts as a plasticizer, leading to enhanced mobility and chemical reactivity as well.[30] However, increasing the water activity to values higher than 0.33 lead progressively to a lower generation of pyrazines, which can be explained by the fact that water is a product of several condensation steps in the Maillard reaction.[31]

This is the first paper systematically evaluating the impact of peptides generated by trypsinogenic hydrolysis on the formation of pyrazines via the Maillard reaction. The results suggest that the contribution of peptides to the generation of pyrazines is considerably high, while the role of free amino

acids is only minor and more than likely less important. The role of peptides in food on the generation of pyrazines has probably been underestimated and requires more attention.

Supporting Information

ABSTRACT: Black currant juices from five different cultivars were analyzed for composition, content, and mean degree of polymerization (mDP) of proanthocyanidins (PA) by UPLC-MS/MS. Juices contained both procyanidins (PC) and prodelphinidins (PD), but the PC-% varied significantly, from 28 to 82% of the total PA. In addition, high PD-% was related to high mDP and total PA content. Enzyme-assisted processing increased significantly total PA (5−14-fold), PD-% (12−65%), and mDP (1.8−6.2-fold) in the juices of all cultivars. Enzymatic treatment increased the contents of large PAs more than those of small PAs. The contents of PA and mDP were positively associated with the mouth-drying and puckering astringent characteristics. However, the PA content did not contribute to the bitter taste. Juices from the most bitter cultivars had the lowest contents of proanthocyanidins regardless of the processing method. This finding indicates the existence of other bitter compounds in black currants in addition to PA.

KEYWORDS: *astringency, bitterness, black currant, juice processing, proanthocyanidins*

INTRODUCTION

Flavonoids are present especially in plant-derived foods and beverages. Proanthocyanidins (PA), often referred to as condensed tannins, form the most common group of tannins in plants. Proanthocyanidins are oligomeric and polymeric tannins composed of different types of flavan-3-ol units. Proanthocyanidins formed from monomeric (+)-catechin and/or (−)-epicatechin units are called procyanidins (PC), whereas the other common group, prodelphinidins (PD), consists of (+)-gallocatechin and/or (−)-epigallocatechin units. Commonly the monomeric units are linked by B-type (C−C; 4α→8 or 4α→6) or A-type (C−O−C) bonds. Proanthocyanidins are generally linked to astringent and bitter sensory properties in foods.

The mechanisms of the astringent sensations have been widely studied, but are not yet well understood.[1−4] A commonly accepted hypothesis is that polymeric tannins binding and precipitating salivary proteins are detected as a drying and rough sensation in the mucous membranes. Astringency is considered as a trigeminal sensation and often dependent on oral movement.[5] The binding to salivary proteins may be affected by the size and molecular flexibility of the tannins tested.[6] Structural characteristics of tannins contribute to different sensory properties. Procyanidins and galloyl glucoses are perceived as more astringent than ellagitannins (hydrolyzable tannins), but the latter have lower thresholds for detection of astringency.[7] Additionally, some astringent compounds do not bind to salivary proteins and thus elicit the sensation by different mechanisms.[8]

The mean degree of polymerization (mDP) of PAs has been associated with astringency.[9−11] However, structural characteristics of the polymeric compounds are more important factors.[12,13] High mDP and high percentage of galloylation in the subfractions activate trigeminal neurons, resulting in high astringency.[5] High galloylation of PA structure may result in a rougher astringent sensation with increased "coarse" attribute.[9] Monomeric flavan-3-ols and low molecular weight PAs have been reported to be more bitter than astringent, whereas higher molecular weight PAs are generally more astringent than bitter.[14,15] The high (−)-epicatechin concentration was significantly more bitter and astringent than the equal concentration of (+)-catechin.[16] In addition to proanthocyanidins, flavonol glycosides and various phenolic acid derivatives have been reported to elicit astringent sensations.[17−22] Compounds belonging to the latter two classes have significantly lower sensory threshold levels for astringency than those of the former.[17,18,20]

Bitter taste is mediated by G protein-coupled receptors of the taste receptor 2 family (TAS2Rs). In general, TAS2Rs are sensitive to several or multiple different bitter compounds. In a recent study, various monomeric flavonoids, including (+)-catechin, (−)-epicatechin, and (−)-epigallocatechin, activated the human bitter taste receptors TAS2R14 and TAS2R39.[23] Soares and co-workers[24] showed that procyanidin trimer C2 (catechin-(4α→8)-catechin-(4α→8)-catechin) and (−)-epicatechin activated TAS2R5 and the latter compound also activated TAS2R4 and TAS2R39. On the other hand, procyanidin dimer B2 (catechin-(4α→8)-catechin) did not activate any receptor in their study.

Black currant (*Ribes nigrum* L.) is used for the production of juices, berry wines, nectars, jams, and nutraceutical ingredients. Pectinolytic enzymes are commonly used in industrial berry processing to increase the juice yield. Simultaneously, the

[a]Total contents of proanthocyanidins (PA total) is the sum of PC (procyanidins) and PD (prodelphinidins) Total and PC:PD ratio are calculated from the total values; PA 1−3 is the sum of monomers, dimers, and trimers (from Supplementary Tables 1 and 2). PA others is the remainder of PA total and PA 1−3 indicating higher level of polymerization. Values after ± show the maximum deviations by the method.[33] Statistically significant differences between averaged processes are based on Student's *t* test ($p < 0.05$). Differences are presented as * higher contents in enzymatic process.

contents of phenolic compounds of juices increases significantly,[25−27] as do the astringent and bitter sensory properties.[28−30] Moreover, a high content of phenolic compounds in a black currant juice may have a negative impact on liking.[30] We have previously examined the roles of sugars, fruit acids, and smaller phenolic compounds, such as anthocyanins, flavonols, and hydroxycinnamic acids, in the sensory profiles of juices produced from various black currant cultivars.[29] Especially, various flavonol glycosides and hydroxycinnamic acid derivatives contribute to astringency in black currant juices.[28−30] In addition to the aforementioned phenolic compounds, black currants contain also significant amounts of proanthocyanidins.[31,32] The aim of the present study was to investigate the proanthocyanidin profiles and contents in black currant juice samples from our previous study.[29] Enzyme-aided processing was compared with nonenzymatic juice pressing using five different black currant cultivars produced at laboratory scale. The second aim was to investigate the contribution of the compounds to the sensory properties of black currant juices and especially examine the contribution of flavan-3-ols to astringency and bitterness in the juices.

MATERIALS AND METHODS

Black Currant Juice Samples. Juice samples were as introduced by Laaksonen et al.[29] Berries were harvested when optimally ripe in 2010 (four commercial cultivars, 'Mortti', 'Mikael', 'Marski', and 'Ola', and a new breed no. 15, 'Breed15') in southern Finland (MTT Piikkiö, Agrifood Research, Finland). Berries were frozen immediately after harvesting and kept at −20 °C before processing. Two juice-processing methods were applied at laboratory scale from berries of each cultivar. The first process was carried out in 2011 without enzymes and the second in 2012 with the aid of commercial enzymes (Pectinase 714L, Biocatalysts Ltd., Cardiff, UK; dosage = 57 mg of enzyme/380 g of berry mash). All juice samples were frozen at −20 °C for further analyses (sensory evaluations in 2011 for nonenzymatic and in 2012 for enzyme-assisted juices; chemical analyses in 2012).

Proanthocyanidin Analyses. Qualitative and quantitative analyses of proanthocyanidins were carried out according to method of Enström et al.[33] Proanthocyanidins were separated with Sephadex LH-20 gel and analyzed with UPLC-MS/MS (Waters Acquity Xevo UPLC-MS/MS, Waters, MA, USA) including a binary solvent manager, a 96-place sample manager, a PDA detector, and a Xevo TQ triple-quadrupole mass spectrometer equipped with an electrospray interface. The column was a Waters Acquity UPLC BEH Phenyl (1.7 μm, 2.1 × 100 mm).

Purified proanthocyanidins were used as external standards.[33] The standards were obtained from dried black currant leaves with Sephadex LH-20 gel chromatography.[34] The Sephadex fractions were further fractionated by semipreparative HPLC using a Waters Delta 600 system equipped with a Fraction Collector III. The column used was Phenomenex Gemini (150 × 21.2 mm, 10 μm, C18, 110 Å). The purified compounds were used with a Waters XEVO triple-quadrupole mass spectrometer to develop compound-specific multiple reaction monitoring (MRM) methods and quantitative calibration curves.[33]

Sensory Evaluations. The sensory evaluation process using generic descriptive analysis and the sensory characteristics of the juice samples are described by Laaksonen et al.[29] The nonenzymatic and enzymatic juice samples were assessed by two separate trained sensory panels ($n = 14$ and $n = 13$, respectively) in controlled sensory laboratory conditions (according to ISO8589). The data were collected using Compusense-*five* software (Compusense Inc., Guelph, Canada). Of the nine attributes examined by Laaksonen et al.,[29] only taste (sourness, sweetness, and bitterness) and two astringency (mouth-drying and puckering) attributes were selected for this study to examine their correlations with proanthocyanidins.

Statistical Analyses. Differences between the processes were analyzed by Student's *t* test ($p < 0.05$; IBM SPSS Statistics; IBM Corp., Armonk, NY, USA). A partial least-squares regression (PLS) method was applied for standardized data with *X*-variables (predictors) as chemical compounds and/or their ratios and *Y*-variables (responses) as the sensory properties. Full cross-validation was used to estimate the number of factors for a statistically reliable model. Multivariate models were conducted using Unscrambler 10.3 (Camo Process AS, Oslo, Norway).

RESULTS AND DISCUSSION

Proanthocyanidins in Juice Samples. Mean degree of polymerization (mDP in Table 1) indicates the average number of flavan-3-ol monomeric units present in the numerous oligomeric and polymeric condensed tannins present in the juice samples analyzed. The mDP value was significantly higher

in the enzyme-aided juices (3.1-fold higher on average) than in the nonenzymatic juices in all cultivars. Cultivar 'Mortti' had the notably lowest value of mDP among the nonenzymatic; this cultivar had the highest increase in mDP when treated with enzymes. In general, black currants have been reported to have higher mDP than several other small edible berries.[32,35] Freezing of berries can have an impact on their chemical composition. The freezing period between sensory evaluations and the chemical analyses may have had some minor impacts on the mDP values of the juice samples.[36] However, the phenolic compounds of black currants have been reported to be more stable than the compounds of other common berries, such as strawberries or bilberries.[37] Additionally, black currant procyanidin contents remain relatively stable during storage at −20 °C.[38]

Condensed tannins in black currant juices consist of procyanidins (PC) and prodelphinidins (PD). The contents of both were significantly higher in the enzymatic than in the nonenzymatic juices (Table 1). Interestingly, the juice of 'Mortti' from the nonenzymatic process had notably more PC than PD, whereas it was vice versa in the corresponding products of 'Ola', 'Mikael', and 'Breed15', which had more PD than PC. The nonenzymatic juice process represented the original berry pulp without seeds or berry skins. On the other hand, the enzyme released various phenolic compounds from the berry skins to the juice. The PC:PD ratio was very similar in all enzyme-aided juices (average 14:86), which indicated the higher PD contents compared to PC in the berry skins across the five cultivars.

Currently, only a few studies have focused on the analysis of the proanthocyanidin (PA) composition in black currants. In the study of Wu et al.[39] the proanthocyanidins were characterized only by chain length. Liu et al.[40] reported PD monomers, dimers, and trimers in black currant leaves and buds. In the current study, we characterized and quantified the whole PA content, including larger oligomers and polymers as well as monomeric, dimeric, and trimeric PAs, by using a novel group-specific MRM technology.[33] Enzyme-aided juices contained more PAs than the juices without enzymatic assistance (Table 1). The proportions of monomeric, dimeric, and trimeric PAs (from Supplementary Tables Tables 1 and 2) of the total PAs varied between 24 and 41% and between 12 and 21% in the nonenzymatic and enzyme-aided juices, respectively. Thus, the majority of the PAs found in black currant juices had a polymerization degree >3. The contents of these compounds (PA others in Table 1 and Figure 1) were 6.9−20.4 times

J. Agric. Food Chem. 2015, 63, 5373−5380

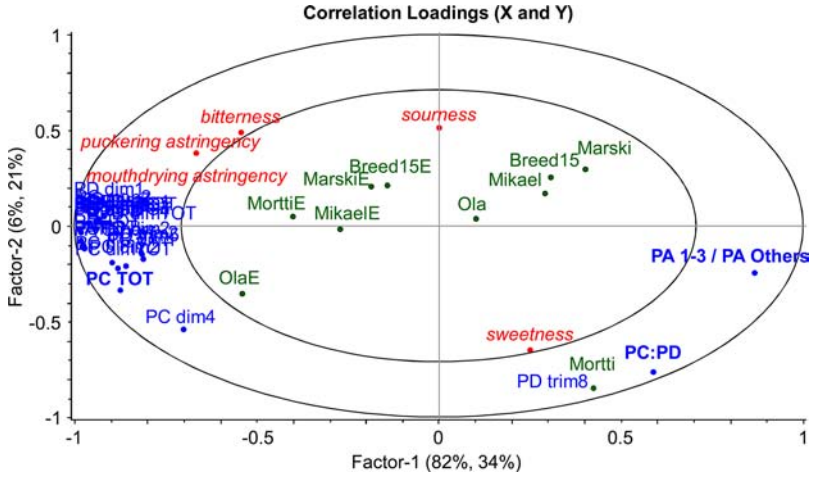

Figure 2. PLS correlation loadings plot of the interaction between taste and astringencies (Y, n = 5) and proanthocyanidin measures (X, n = 35) in all 10 juice samples from both processes. Samples are in green font, sensory attributes are in red italic font, and compounds are in blue. For abbreviations of compounds refer to Table 1 and Supplementary Tables 1 and 2.

higher in enzyme-aided juices than in the juices produced without enzymes.

The individual PAs found in the samples by the compound-specific MRM methods are shown in Supplementary Tables 1 and 2 of the Supporting Information in a fixed order of retention in reverse phase liquid chromatography according to their hydrophilic properties. For example, PC−PC dimer 1 elutes earlier than PC−PC dimer 4. The monomeric PC and PD units of PAs both have two diastereoisomeric configurations ((+)-catechin/(−)-epicatechin and (+)-gallocatechin/(−)-epigallocatechin, respectively) in plants, which results in 12 possible compounds belonging to PC−PC, PC−PD, or PD−PD dimers (Supplementary Table 1). The two PC monomers were identified as (+)-catechin and (−)-epicatechin, respectively. At the same time, PC−PC dimers 1−4 were tentatively identified as catechin-(4α→8)-catechin (trivial name B3), epicatechin-(4α→8)-catechin (B1), catechin-(4α→8)-epicatechin (B4), and epicatechin-(4α→8)-epicatechin (B2), respectively.[41] The same order may be applied for PD−PD dimers, the first being gallocatechin-(4α→8)-gallocatechin, the second epigallocatechin-(4α→8)-gallocatechin, the third gallocatechin-(4α→8)-epigallocatechin, and the fourth epigallocatechin-(4α→8)-epigallocatechin. PD−PD dimers gallocatechin-(4α→8)-gallocatechin and gallocatechin-(4α→8)-epigallocatechin have been previously reported from black currant leaves.[42,43] Additionally, Tits et al.[43] found also a 4α→6 dimer of gallocatechin from the leaves, whereas a 4α→8 bond is more commonly found in edible plants.[35]

In almost all dimers (excluding two PC−PC dimers), the contents were significantly higher in enzyme-aided juices than in nonenzymatic juices (t test, $p < 0.05$; Supplementary Table 1). The PC−PC dimers were less abundant (on average 2.9 and 2.0% of all dimers in nonenzymatic and enzymatic juices, respectively) than the PC−PD (27.3 and 23.3%) and PD−PD dimers (69.8 and 74.8%) in all cultivars and in both processes. Figure 1 shows the abundance of individual monomers, dimers, and trimers in the juices and the comparison of the compound profiles between juice processes. Within PC dimers, compounds 1 (dimer B3) and 3 (B4) were more abundant than compound **2** (B1) or 4 (B2), whereas within PD−PD and PC−PD dimers compounds 2 and 4 were more abundant than compounds 1 or 3 (Figure 1). Within all three dimer types, the proportion of the most abundant dimer (dimer 3 in PC−PC and dimer 4 in PC−PD and PD−PD dimers) was found in significantly higher proportions in enzyme-treated juices. At the same time, the proportion of one dimer (dimer 2 in PC−PC, 3 in PC−PD, and 1 in PD−PD) was higher in nonenzymatic juices than in the enzyme-treated juices. In addition to significant increases in the contents of PAs, the enzyme-assisted juice processing significantly altered the flavan-3-ol composition in the juice by releasing PAs from the berry skins.

Trimers made up of prodelphinidin units only (PD−PD−PD) were found in the juices (Supplementary Table 2). One PD−PD−PD trimer (gallocatechin-(4α→8)-gallocatechin-(4α→8)-gallocatechin) and one PC−PD−PD trimer (catechin-(4α→8)-gallocatechin-(4α→8)-gallocatechin) have earlier been found in black currant leaves.[42,43] The enzyme treatment, again, increased significantly the content of trimeric PAs in the juice. Trimers 3 and 7 were the most abundant in general, and they were significantly more abundant in the juices processed with pectinase. Interestingly, one trimer (PD trimer 8), the most hydrophobic of the PD−PD−PD trimers, was found in the nonenzymatic juice of cultivar 'Mortti' but not in the corresponding enzymatic juice or juices from other cultivars.

Impact of Juice Processing on Sensory Quality. PLS regression model was used to study the interactions between proanthocyanidins and the sensory attributes (Figure 2). PAs in the model are the compounds or compound ratios from Table 1 and Supplementary Tables 1 and 2 (total of 35 X-variables). Three taste attributes (bitterness, sourness, and sweetness) and two astringent qualities (mouth-drying and puckering astringencies) were selected for the model from Laaksonen et al.[29] with a total of five Y-variables. Eighty-eight percent of the variation in X-data explains 55% of the variation in Y with two factors. In the model, proanthocyanidin variation explains 92.4% of the variation (90.0% in validated model) in mouth-drying astringency with one validated factor. Almost all of the X-variables are located on the left side of the plot with the astringency variable. All enzyme-aided juices are located also on the left side of the plot, which indicates that proanthocyanidins have a significant role in the increased mouth-drying astringency in these juices. Especially, a higher degree of polymerization (mDP) and a lower content of PC units in ratio

DOI: 10.1021/acs.jafc.5b01287
J. Agric. Food Chem. 2015, 63, 5373−5380

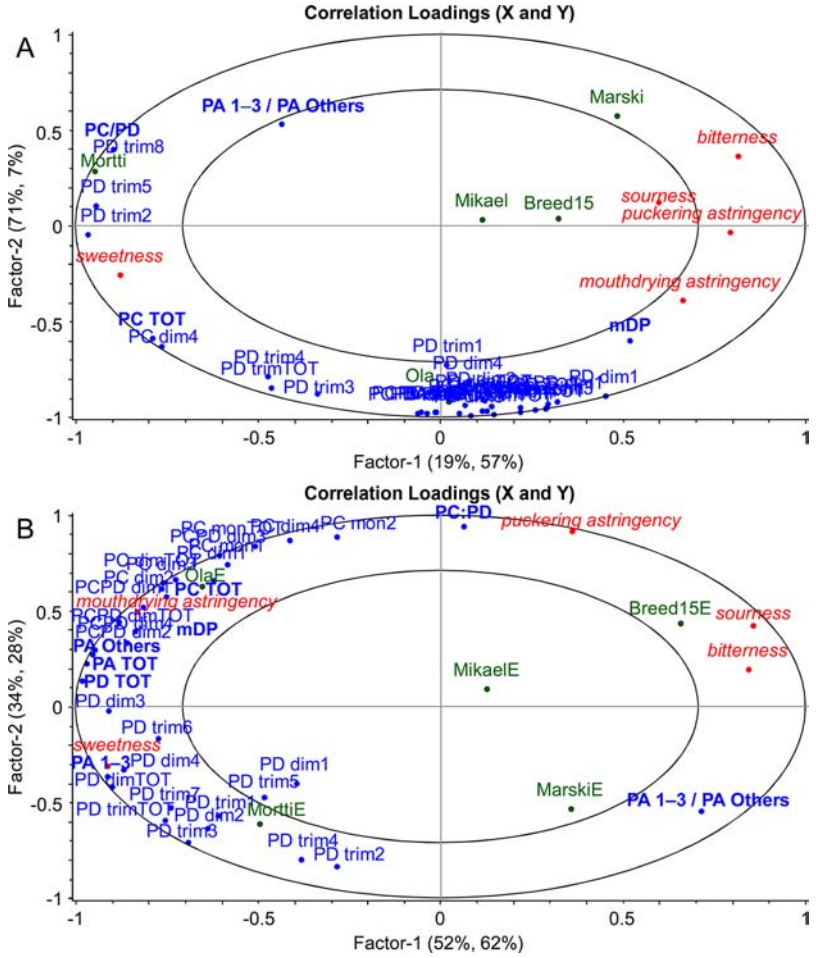

Figure 3. PLS correlation loadings plots of the interaction between taste and astringencies (Y, n = 5) and proanthocyanidin measures (X, n = 35) juice samples from different cultivars within processes: (A) juices without enzymatic assistance; (B) juices with enzymatic (E) assistance. Samples are in green font, sensory attributes are in red italic font, and compounds are in blue. For abbreviations of compounds refer to Table 1 and Supplementary Tables 1 and 2.

to PD contributed to mouth-drying astringency. This suggests that the protein affinity of PAs is enhanced by the increase in PA size, especially if the increase is brought about by a proportionally larger number of phenolic OH units in the additional monomeric building blocks (PDs have 25% more OH units than PCs). In addition, a significant increase in mouth-drying astringent characteristics is caused by the effective breakage of pectin structures in enzyme-aided juice processing.[29] High viscosity and low astringency were observed in our juices without pectinase treatment, which is in agreement with earlier studies.[44,45]

Other sensory attributes were not well explained in the model with the comparison of processes (Figure 2). The X-variables explained only 44.3% (27.9% in the validated model) of variation in puckering astringency with the first factor. However, flavan-3-ols, their dimers and trimers, and polymeric phenolic fractions in red wine have also been reported to have puckering astringent properties.[17,18,46] Besides astringency, the remaining three attributes were poorly explained in the model with the PA contents: only a little of variation in bitterness (10.1%) was explained with the first factor, whereas the variation in sourness or sweetness was not explained at all. The latter findings were as expected; sourness was not different between processes.

Impact of Cultivar on Sensory Quality. Two PLS models were created to examine the sensory contribution of proanthocyanidins in the five juices within processes (Figure 3). Figure 3A presents the model for the samples without pectinase treatment. Ninety percent of the variation in the chemical variable data X explained 64% of the variation in sensory data. However, none of the five sensory attributes was well validated in the full cross-validation. Cultivars 'Mortti' and 'Ola' had the highest contents of proanthocyanidins but were not significantly astringent or bitter in this juice process. Especially nonenzymatic juice from 'Mortti' was the sweetest and the most viscose of the five cultivars.[29] As discussed earlier, the high viscosity due to the high polysaccharide content in these juices masks the astringency of proanthocyanidins. Some correlation can be found between mDP and mouth-drying astringency on the right side of the plot (Figure 3A), which may indicate the role of highly polymerized proanthocyanidins in astringency despite the masking effect of the juice matrix.

A similar model for enzyme-aided juices is shown in Figure 3B with two validated factors. Overall, 86% of the variation in X-data explained 90% of the variation in Y. The best explained Y-variable was mouth-drying astringency with 92.7% (validated 81.1%). Most of the chemical variables, especially variables PA total (total content of proanthocyanidins), PA others (tetramers and larger polymers), and mDP, are located in the

DOI: 10.1021/acs.jafc.5b01287
J. Agric. Food Chem. 2015, 63, 5373−5380

left of the plot with cultivars 'Ola' and 'Mortti' and the mouth-drying astringency. This supports the earlier finding that especially the size of PAs is important in the protein affinity that causes the mouth-drying astringent sensation in the mucosa. In fact, puckering astringency was the second attribute well explained with the model (96.9% explained, but only 56.9% in validated model) in the upper part of the plot. Interestingly, PC−PC and PC−PD dimers are correlated with mouth-drying astringency and cultivar 'Ola', whereas PD dimers and trimers correlate with 'Mortti'. Simultaneously, the PC:PD ratio correlates with the mouth-drying astringency and puckering astringency on factor 2. These findings indicate that variations in the PC:PD ratio may result in different overall astringent properties. The PC:PD ratio being more closely related to puckering astringency suggests that PC-% is more important in causing the puckering sensation, whereas PD-% might be a more important contributor to the mouth-drying sensation together with the size of PA. A high portion of PD in comparison to PC has been previously reported to result in lower "coarse" attribute of astringency.[9] Changes in the PC:PD ratio may result in different overall astringency perception.

Bitterness was poorly explained by the chemical variables in the model (Figure 3B). The compounds studied and their contents did not contribute to bitterness of the juices. These compounds were found in the lowest contents in the bitterest cultivars ('Breed15' and 'Marski'). Additionally, neither total contents of proanthocyanidins, total PD, total PC, nor their ratio contributed to bitterness. However, the ratio between PA 1−3 (sum of monomers, dimer,s and trimers; Table 1) and PA others (degree of polymerization ≥ 4; Table 1) correlated with bitterness on factor 1. In other words, there were more smaller and bitter PAs relative to larger and astringent PAs found in the juice of 'Marski' than in the less bitter juices. As reported by Laaksonen et al.,[29] the flavonols (glycosides or aglycons), hydroxycinnamic acid derivatives, or anthocyanins did not explain the bitterness of the juices. Their contents were the lowest in the bitterest cultivars regardless of the juice production process. All of these compounds, or at least some in each class, activate the human bitter taste receptors.[23,24] These findings suggest that the bitterness in juice of the black currant cultivars may be due to complex interactions among multiple sensory-active compounds. In our previous studies,[29,30] the sugar-to-acid ratio was a more important factor contributing to sweetness than individual sugar components. Similarly, the bitterness of these juices may be due to the ratios between bitter phenolics and sweet sugars and/or sour acids. In our previous study, the bitterest cultivars had high contents of sugars or nonphenolic fruit acids relative to phenolics. Thus, the sugars or acids may affect and mask the astringent properties of the phenolic compounds, but not the bitterness of the juices. On the other hand, bitterness may have been caused by berry components that were not characterized in this study or our earlier investigations.[28−30]

The PC monomers, dimers, and trimers in red wine have been reported to be both bitter and astringent, but the thresholds for bitterness are higher than for astringency.[17,18] According to Hufnagel and Hofmann,[18] the dose-over-threshold (DoT) factors, which indicate the ratio between concentration and taste threshold for the compounds, were <1, indicating their low contribution to bitterness. In the same study,[18] the omission of the PC compounds from a reconstructed wine model resulted in a decrease in bitterness. Therefore, the compounds in subthreshold concentrations may contribute to overall bitterness. By using the same thresholds for the same compounds, PC monomers and PC−PC dimers had also DoT values <1 in this study. However, the contents of PD−PD and PC−PD dimers were notably higher than those of PC−PC dimers.

In conclusion, the proanthocyanidin contents were significantly higher in black currant juices from pectinase-aided processing than in juices without enzyme treatments. The identified compounds contributed to mouth-drying and puckering astringent properties in the juices, especially in juices produced with enzymes. Proanthocyanidin contents did not contribute to bitterness of juices within processes. There may be other bitter-tasting compounds in black currants in addition to PA, flavonols, and hydroxycinnamic acid derivatives. The bitterness may also have been affected by several juice components, especially the ratios between different groups of sensory-active components. Due to the different PA and sensory profiles of the nonenzymatic juices in comparison to enzyme-aided juices, the minimally processed "extra-virgin" type juice processing may have potential in the food industry. Additionally, this study provides important information for farmers and the food industry concerning the interactions between phenolic compounds and sensory characteristics of black currant cultivars.

Supporting Information

ABSTRACT: We report a rapid, direct, and unequivocal spin-chromatographic separation and identification of minor components in the lipid fraction of milk and common dairy products with the use of selective one-dimensional (1D) total correlation spectroscopy (TOCSY) nuclear magnetic resonance (NMR) experiments. The method allows for the complete backbone spin-coupling network to be elucidated even in strongly overlapped regions and in the presence of major components from 4×10^2 to 3×10^3 stronger NMR signal intensities. The proposed spin-chromatography method does not require any derivatization steps for the lipid fraction, is selective with excellent resolution, is sensitive with quantitation capability, and compares favorably to two-dimensional (2D) TOCSY and gas chromatography−mass spectrometry (GC−MS) methods of analysis. The results of the present study demonstrated that the 1D TOCSY NMR spin-chromatography method can become a procedure of primary interest in food analysis and generally in complex mixture analysis.

KEYWORDS: *lipid fraction, totally correlated NMR spectroscopy (TOCSY), spin chromatography, dairy products*

INTRODUCTION

Separation and identification of components from complex mixtures have occupied a central role in the field of natural products and food chemistry research. The classical protocol for the investigation of complex mixtures has been to apply various chromatographic techniques, to isolate a certain amount of a pure product, and to identify its structure using various spectroscopic techniques[1] and/or the use of specialized hyphenated spectroscopic techniques.[2,3] On the other hand, nuclear magnetic resonance (NMR) spectroscopy is increasingly used as an analytical tool for identification and quantification of low-molecular-weight metabolites on unfractionized biological fluids, natural product extracts, and food samples.[1,4−12]

Milk lipids are very important because they confer distinctive textural, nutritional, and organoleptic properties on dairy products. Recent studies have reported that the consumption of saturated fatty acids has been linked to increased risk of cardiovascular disease, whereas the consumption of milk conjugated linoleic acids (CLAs) has beneficial effects, and this issue is still subject to numerous studies.[13] Accurate analysis, therefore, of minor lipids is important for determining the nutritive value and preparing nutritional labeling materials for particular function or application. The analysis of minor lipids, however, is extremely challenging and complex because it can be very slow and laborious and may require various preparation and analysis steps.[14]

The selective 1D TOCSY experiment has become an important NMR technique for establishing ^{1}H−^{1}H connectivity via scalar coupling in small- and medium-sized molecules[15,16] and in the analysis of mixtures of related compounds.[17] However, the method has found limited application in food matrices; to the best of our knowledge, few studies have, thus far, been published, among them in the metabolomics analysis of amino acids in honey[18] and mango juice.[19] In the present study, we report, for the first time, the direct identification of six minor species: (9-*cis*,11-*trans*) 18:2 and (9-*trans*,11-*trans*) 18:2 CLA isomers, caproleic acid (CA), glycerol in 1,2-diglyceride (1,2-DAG), 1-monoglyceride (1-MAG), and 2-monoglyceride (2-MAG) in the lipid fraction of milk and halloumi cheese, without any derivatization steps, with the use of a spin-chromatography procedure based on the spin diffusion process of selective one-dimensional (1D) total correlation spectroscopy (TOCSY) experiment.

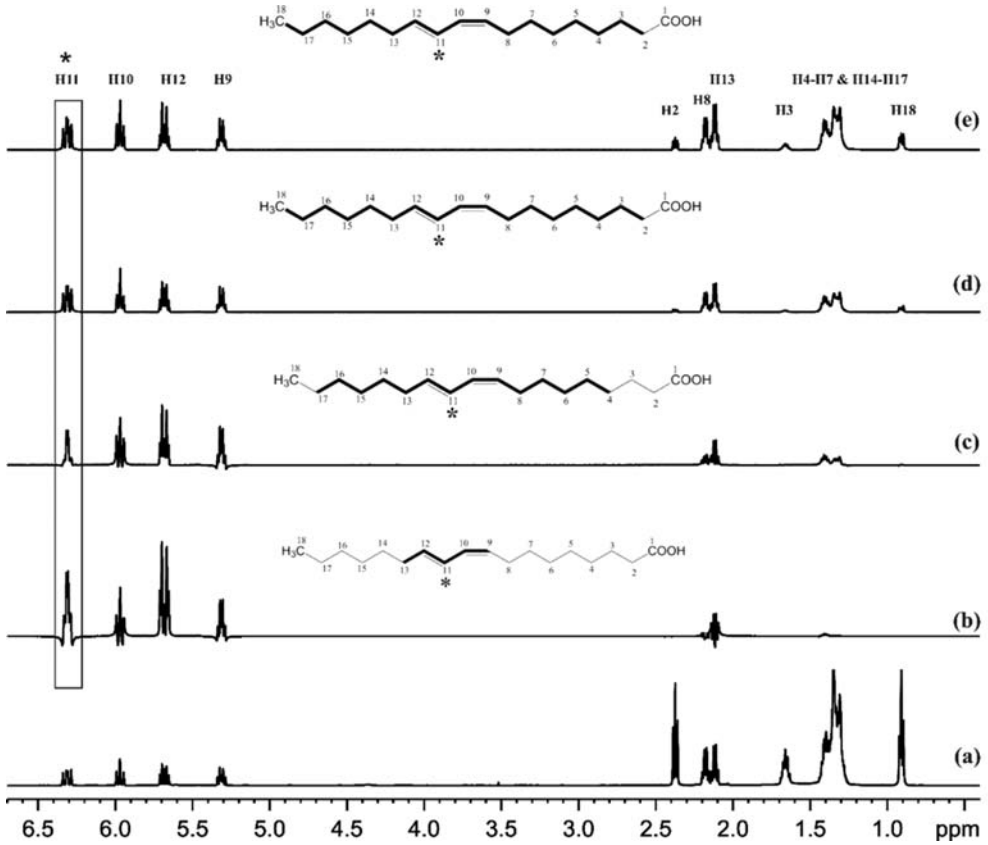

Figure 1. (a) 500 MHz 1D NMR spectrum of 20 mM solution of the (9-*cis*,11-*trans*) 18:2 CLA in $CDCl_3$ (*T*, 298 K; acquisition time, 4.3 s; relaxation delay, 5 s; number of scans, 256; and experimental time, ~25 min). (b–e) Selective 1D TOCSY spectra of the above solution using a mixing time of τ_m = (b) 33 ms, (c) 70 ms, (d) 200 ms, and (e) 400 ms. The asterisk denotes the selected H11 resonance that was excited. For panels b–e, the magnetization transfer network is illustrated.

MATERIALS AND METHODS

Materials. Conjugated (9-*cis*,11-*trans*) 18:2 linoleic acid, purity ≥96% [high-performance liquid chromatography (HPLC) grade], and conjugated (9-*trans*,11-*trans*) 18:2 linoleic acid, purity ≥98% (HPLC grade), were purchased from Fluka. CA, purity ≥96%, was purchased from Sigma-Aldrich. Chloroform and methanol (analytical grade) were obtained from Fisher Scientific (U.K.). $CDCl_3$ (99.8%) was purchased from Deutero (Kastellaun, Germany). The 37 fatty acid methyl ester (FAME) standard mix was purchased from Sigma-Aldrich.

Sample Preparations. The lipid fractions of milk samples were prepared as previously described.[20] The lipid fractions of halloumi cheese were prepared as follows: cheese samples were frozen in liquid N_2 and pulverized in a ceramic mortar. After lyophilization for 2 days, 300 mg of cheese was used for the extraction of the lipid phase, using the Bligh and Dyer method, as previously described.[20]

NMR Instrumentation. NMR experiments were performed on a Bruker AV500 spectrometer (Bruker Biospin, Rheinstetten, Germany) using the Topsin 2.1 suite. The 1D TOCSY experiments were carried out using a standard Bruker pulse program (selmlgp). A shaped pulse length of 20 ms for selective excitation was used, followed by either a MLEV-17 TOCSY spin lock[18] or applying the DIPSI-2 pulse train and incorporating a z filter before acquisition[21] for the suppression of artifacts. The spin lock was adjusted to 7.1 kHz, corresponding to a low power 90° pulse of 35 μs; this allows for safe operation without problems of significant heating of the samples, with spin-lock times up to 400 ms.

Gas Chromatography–Mass Spectrometry (GC–MS) Analysis. FAMEs were prepared by transesterification with methanolic potassium hydroxide according to the ISO 15884:2002 method[22] as previously described.[23] Fatty acid profiles were generated by analyzing the FAME samples on a GC-MS-QP 2010 Plus gas chromatography mass spectrometer (Shimadzu, Duisburg, Germany) equipped with a HT 280 T auto sampler (HTA, Brescia, Italy). Details of the GC–MS analysis are given elsewhere.[20,23]

RESULTS AND DISCUSSION

1D TOCSY of Model Compounds: Effects of Mixing Time. Figure 1 illustrates a series of selective 1D TOCSY spectra of the model (9-*cis*,11-*trans*) 18:2 CLA isomer, where the H11 olefinic proton (δ = 6.27 ppm)[20,24,25] has been selected for excitation using a range of mixing times and, thus, affecting the number of transfers within the spin system.[26] For a mixing time τ_m = 33 ms, the selective 1D TOCSY transfers magnetization to its *J*-coupled partners within the conjugated olefinic protons and the $C(13)H_2$ protons (Figure 1b). Using longer mixing times, the magnetization is transferred throughout the full spin system and, for τ_m values of 200 and 400 ms, resulted in the complete analysis and structure elucidation of the compound (panels d and e of Figure 1). Figure S1 of the Supporting Information illustrates a similar series of selective 1D TOCSY spectra of the (9-*trans*,11-*trans*) 18:2 CLA isomer, where the H10 and H11 (δ = 5.97 ppm) protons have been selected. Again, the 1D TOCSY experiment allows for structural information to be extracted in a time-efficient manner and with high spectral resolution.

Method Application in the Lipid Fraction of Milk and Dairy Products. An important application of the 1D experiment is the selective excitation of a proton sub-spectrum belonging to a single chemical component contained in a complex mixture, thus providing a form of spin chromatography. The selective excitation of a suitable "target" resonance

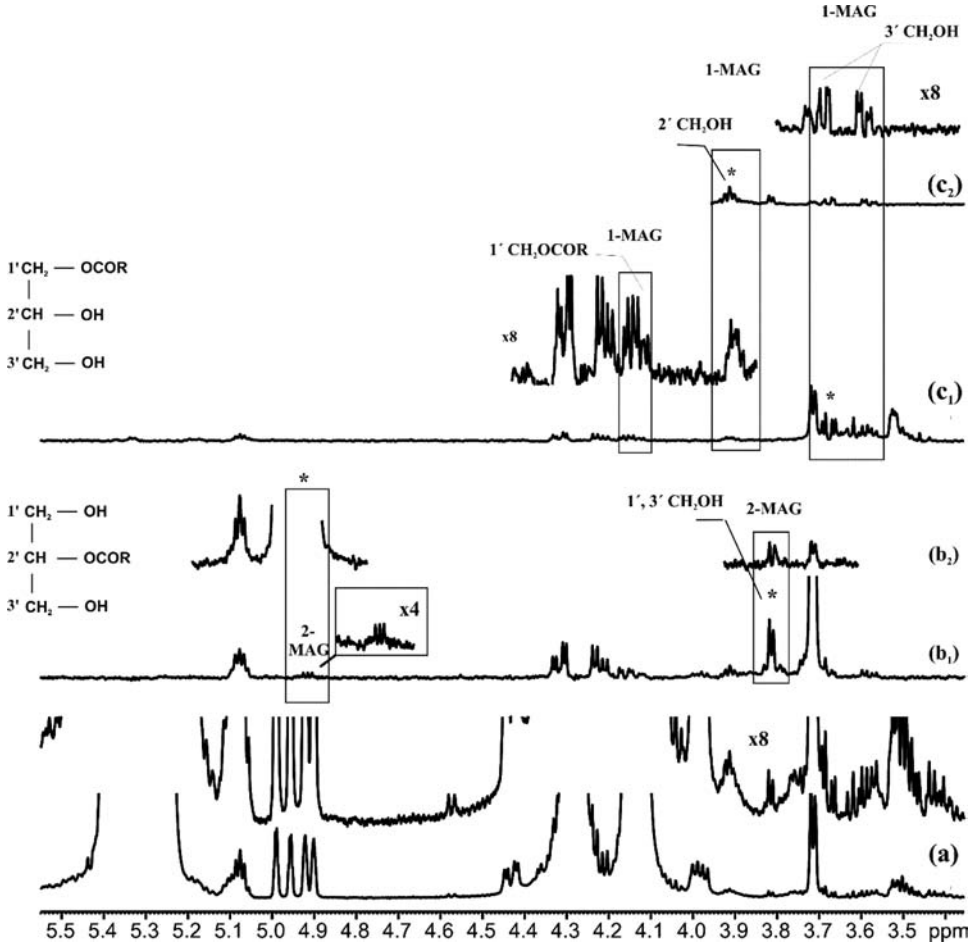

Figure 4. Selected regions of (a) Figure 2a, (b) 1D TOCSY spectrum that demonstrates the spin system of the glycerol moiety in 2-MAG [in panels b_1 and b_2, the selective excitation pulse was set on the 1′,3′-CH_2OH (δ = 3.82 ppm) and 2′-CHOCOR (δ = 4.92 ppm) peaks in 2-MAG, respectively], and (c) 1D TOCSY spectrum of the spin system of the glycerol moiety in 1-MAG [in panels c_1 and c_2, the selective excitation pulse was set on the 3′-CH_2OH (δ = 3.67 ppm) and 2′-CH_2OH (δ = 3.92 ppm) peaks in 1-MAG, respectively].

mixing time, of the H11 proton of the (9-*cis*,11-*trans*) 18:2 CLA isomer (Figure 2b) illustrates effective magnetization transfer from H11 to H2 and from H11 to H18. Therefore, its structure becomes amenable to detailed analysis, although signals from H2 to H8 and from H12 to H18 protons are completely hidden in a conventional 1D ^{1}H NMR spectrum under the resonances of the abundant components from 4 × 10^2 to 3 × 10^3 stronger intensities.

Similar experiments were performed with CA (Figure 2c). Selective TOCSY excitation of the H10a protons at 4.97 ppm with τ_m = 400 ms resulted in the effective magnetization transfer throughout the complete proton spin system, although the signals from H8 to H2 are completely hidden in the conventional 1D ^{1}H NMR spectrum. Selective TOCSY excitation of the doublet at 3.72 ppm reveals the complete spin system of the glycerol moiety in 1,2 DAG at 5.20 ppm (2′-CHOCO), 4.28 ppm, and 4.13 ppm (1′b,1′a-CH_2OCO, respectively) (Figure 2d).

Figure S2 of the Supporting Information illustrates a similar series of selective 1D TOCSY spectra of the lipid fraction of the lyophilized milk sample. Again, the 1D TOCSY allows for the analysis and structure elucidation of minor compounds in a time-efficient manner and with high spectral resolution.

A comparison of the 1D TOCSY spectrum of the model (9-*cis*,11-*trans*) 18:2 CLA isomer to the spectrum obtained from the lipid fraction of the lyophilized halloumi cheese sample illustrates a significant difference of the $C(2)H_2$ spin system (Figure 3). In the model compound, it appears as a triplet (δ = 2.33 ppm, and ^3J = 7.2 Hz) because of coupling with the $C(3)H_2$ protons, while in the spectrum of the extract, it appears at δ = 2.30 ppm with a complex multiplet pattern. This clearly demonstrates that the (9-*cis*,11-*trans*) 18:2 CLA isomer in the extract exists predominantly as an ester and not as a free acid. Because of the asymmetry of the *sn*2 carbon of the glycerol moiety, the $C(3)H_2$ protons become magnetically non-equivalent, thus resulting in a multiplet spin pattern. This result is very important in investigating the hydrolysis products of the ester linkage between an acyl group and the glycerol backbone. The resulting free fatty acids and their catabolic products have been found to be among the primary factors for the aroma of hard cheese, where lipolysis reaches high levels.[24]

Figure 4 illustrates the great potential of the 1D TOCSY experiments in the case of minor species with resonances in overcrowded spectral regions of the 1D ^{1}H NMR spectrum. The spin systems of the glycerol moieties in both 2-MAG (panels b_1 and b_2 of Figure 4) and 1-MAG (panels c_1 and c_2 of Figure 4) were clearly resolved and provided an unequivocal assignment of both species, although the 1-MAG resonances are strongly overlapped in the region of 3.75−3.55 ppm (Figure 4a).

Table 1. Results Obtained Using 1D TOCSY NMR, Conventional 1D ^{1}H NMR, and GC−MS Methods for the Determination of CA in Two Milk Samples

sample	analyte (units)	1D TOCSY[a]	^{1}H NMR[a]	relative deviation[b] (%)	GC−MS	relative deviation[c] (%)
1	CA (mM)	1.02 ± 0.03	0.97 ± 0.02[a]	5.15		
	CA (% of the lipid fraction)		0.26 ± 0.01		0.28	−7.14
2	CA (mM)	1.92 ± 0.06	1.83 ± 0.06[a]	1.75		
	CA (% of the lipid fraction)		0.74 ± 0.01		0.68	8.82

[a]Results are expressed as millimolars of CA [in tube; standard deviation (n = 3)]. [b]Results are expressed as 100[(1D TOCSY$_{value}$) − (1D ^{1}H NMR$_{value}$)]/(1D ^{1}H NMR$_{value}$). [c]Results are expressed as 100[(1D ^{1}H NMR$_{value}$) − (GC−MS$_{value}$)]/(GC−MS$_{value}$).

The excellent selectivity of the 1D TOCSY is demonstrated also in the case of strongly overlapped resonances of the 18:2 CLA geometric isomers. Figure S3 of the Supporting Information illustrates a selected ^{1}H NMR region of the (9,11) 18:2 CLA resonances of the lipid fraction of a lyophilized halloumi cheese sample. The apparent triplet at 5.92 ppm (^3J = 10.9 Hz) has been assigned to the H10 olefinic proton of the (9-*cis*,11-*trans*) 18:2 CLA isomer, and the strongly overlapped minor peak at 5.97 ppm has been assigned to the composite signal of the H10 and H11 protons of the (9-*trans*,11-*trans*) 18:2 CLA isomer. Selective 1D TOCSY of the resonance at 5.97 ppm clearly demonstrates magnetization transfer to H9 and H12 resonances at 5.54 ppm, which are not overlapped with other resonances of the lipid fraction (see Figure S3c of the Supporting Information) and, thus, can be used for the assignment of the (9-*trans*,11-*trans*) 18:2 CLA isomer. A limitation of the method, however, is that, because the identification is based on chemical shifts, the length of the fatty acid and the position of the unsaturation remains ambiguous. For instance, the ^{1}H NMR spectrum of (9-*cis*,11-*trans*) 18:2 has almost identical chemical shifts and J couplings as that from (9-*cis*,11-*trans*) 20:2 and (11-*cis*,13-*trans*) 20:2.

Figure S4 of the Supporting Information illustrates a comparison of the 1D TOCSY spectrum of Figure 2b to the respective extracted column and row in the two-dimensional (2D) TOCSY experiment. It is evident that the 1D TOCSY (i) significantly increases the digital resolution because, in the 2D TOCSY, it is limited by the number of points taken in the indirect dimension, (ii) removes dynamic range issues from the spectrum, (iii) of the whole spin system can be excited even in the region of strong signal overlapping with major components from 4 × 10^2 to 3 × 10^3 stronger NMR signal intensities, and (iv) decreases the experimental time.

Quantification Using 1D TOCSY: Comparison to 1D ^{1}H NMR and GC−MS Methods of Analysis. The excellent sensitivity and digital resolution of the 1D TOCSY experiment allows for the quantification of minor components. The quantitative analysis was based on the standard addition method. Known amounts of CA were added to the sample, and the respective spin chromatograms were recorded with the selective excitation of the H9 proton of the CA. The pulse repetition time (acquisition time + relaxation delay) was set at $5T_1$ (~16 s) of the long relaxation time of the H9 and H10 protons (~3.2 s) of the CA. The results were compared to those obtained by the use of 1D ^{1}H NMR quantitation.

The effect of the mixing time on the quantitation results was studied in detail. Several mixing times were used, more specific 33, 100, and 200 ms (τ_m = 33 ms corresponds to the value of $^1/_2$ ^3J, where ^3J is the coupling of the H9 and H10 protons). The sensitivity of the 1D TOCSY method was higher using smaller mixing time values but at the expense of the quantitation accuracy. Longer mixing times resulted in a moderate decrease of sensitivity, approximately by a factor of 2; however, a significantly improved accuracy of the method was achieved (the relative error was calculated as 31% for τ_m = 33 ms, because of twisted lineshapes,[27] whereas the relative error was calculated as only 2% for τ_m = 200 ms). Moreover, for τ_m = 200 ms, the sensitivity and accuracy of the method were almost equal using either the H9 or the H10 signals (data not shown). It should be pointed out that one of the advantages of the spin-chromatographic procedure is the ability to quantify the analyte of interest using either the excited proton or a nearby proton where the magnetization was transferred.

The 1D TOCSY quantitation was achieved following the procedure described by Sandusky et al.[28] Table 1 provides the quantification data obtained for the milk samples using the 1D TOCSY procedure. A concentration value (in tube) of 1.02 ± 0.03 mmol L^{-1} was determined using the 1D TOCSY and the H9 proton integration (Figure 5 and Figure S5 of the Supporting Information) compared to 0.97 ± 0.02 mmol L^{-1} as determined by using the conventional 1D ^{1}H NMR with an internal standard. For the second milk sample, the respective results were 1.92 ± 0.06 and 1.84 ± 0.06 mmol L^{-1}. The results demonstrate the excellent agreement between the 1D TOCSY method with the conventional 1D ^{1}H NMR method.

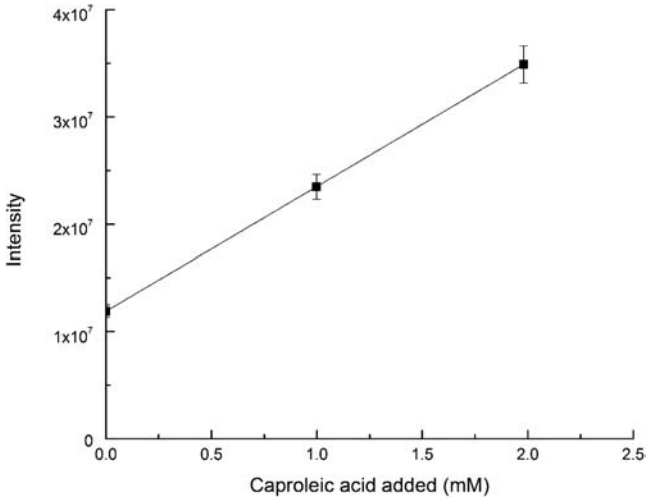

Figure 5. Quantification of CA in the lipid fraction of a lyophilized milk using the 1D TOCSY method (see also Figure S5 of the Supporting Information).

The limit of detection (LOD) for the spin-chromatographic quantitation of CA was calculated by the use of two different methods based on the calibration function[29] or the SNR method.[30,31] By means of the calibration function,[29] a calibration curve of the standard addition method was used; the LOD was found as 0.07 ± 0.01 mmol L^{-1} (in tube) or 0.01

DOI: 10.1021/acs.jafc.5b01335
J. Agric. Food Chem. 2015, 63, 5381−5387

mg g^{-1} for the milk sample. Using the SNR method, the LOD was calculated by applying the 3C/(S/N) equation in a standard sample of CA, where C represents the concentration of the analyte as determined by ^{1}H NMR (data were treated without using a line-broadening exponential function) and the signal-to-noise (S/N) value of the respective 1D TOCSY spectra was calculated. For the concentration levels of 0.97, 2.04, and 2.98 mmol L^{-1} of CA (in tube) the 3C/(S/N) value was calculated as 0.10, 0.11, and 0.08 mmol L^{-1} using the 1D TOCSY spectra and 0.004, 0.007, and 0.010 mmol L^{-1} using the 1D ^{1}H NMR spectra, respectively; thus, the LOD value of CA is 0.10 mmol L^{-1} (in tube) or 0.01 ± 0.001 mg g^{-1} for the milk sample and 0.010 mmol L^{-1} (in tube) or 0.001 ± 0.0001 mg g^{-1} for 1D TOCSY and 1D ^{1}H NMR methods, respectively.

The quantitative results of the spin chromatography and ^{1}H NMR were compared to those obtained with the use of the GC−MS method of analysis (ISO 15884:2002).[22] The results are in accordance with the GC−MS method of analysis; CA was found to be 0.28 and 0.68% of the total lipids when calculated by GC−MS and was measured as 0.26 and 0.74% of the total lipids when calculated by 1D ^{1}H NMR for the first and second milk samples, respectively.

The proposed selective 1D TOCSY spin-chromatographic separation procedure, therefore, is an excellent technique in mixture analysis of minor components, through a careful selection of the spin system to be excited. The method might become of primary interest in food research, including targeting metabolomics[32] because it (i) is rapid, selective, and non-destructive, (ii) allows for the chemical identification of minor components even in strongly overlapped spectral regions, (iii) does not require derivatization steps, and (iv) allows for the quantification of analytes of interest.

ABSTRACT: The objective of this study is to test the feasibility of multi-isotopic and elemental analyses combined with chemometric techniques for differentiating the botanical origins of major honey products in China. The stable isotope and elemental compositions of 57 honey samples from four major floral origins in China (i.e., rape honey, acacia honey, vitex honey, and jujube honey) were analyzed using stable isotope ratio mass spectrometry (IRMS) and inductively coupled plasma mass spectrometry (ICP-MS), respectively. The results showed that hydrogen and oxygen isotopes could be more suitable than the carbon isotope for discriminating the floral origins of major honeys in China. There were significant differences in the contents of most elements between or among different floral origins. The combination of IRMS and ICP-MS methods provides the most effective and accurate approach (in most cases close to 100% accuracy) for classifying Chinese honeys according to their floral origins.

KEYWORDS: *honey, chemometric techniques, floral origins, IRMS, ICP-MS*

INTRODUCTION

Honey is known as a natural substance produced by *Apis mellifera* (bees) from the nectar or honeydew of plants and usually contains no additives or preservatives.[1] It can be divided into various types of honey such as acacia, vitex, rape, jujube, and many more according to their sources and constitutions. Honey contains numerous nutrients and may also show biologically active properties (e.g., antimicrobial) depending on its floral origin, which is considered essential to the health-promoting functions of honey for the human body.[2] Because of the large difference in the prices and yields as well as the quantity demand among different varieties of honey, honey products have frequently been the object of fraud in Chinese and international markets. Fraudulent honey products in markets are often manufactured by combining honey resulting from various floral sources where bees forage for different nectars and honeydews, mixing premium and high-grade quality honey with cheaper and lower quality ones, or adding cheaper sweeteners. Thus, the determination and certification of honey according to their floral origins plays an important role in ensuring fairness and equality for beekeepers, producers, distributors, and consumers as well as regulatory agencies.

To guarantee fair play in markets and combat product fraud, we need appropriate and reliable methods to determine the legitimacy of botanical origins of honey in the markets. Melissopalynoloy, the study of pollen components and load within honey, has conventionally been employed to determine floral origin. However, the limitations of this method include unreliability, expertise, time consumption, etc.[3,4] Several new techniques including physicochemical parameters,[5−7] ICP-MS,[8] liquid chromatography−diode array detection−tandem mass spectrometry,[9,10] infrared spectroscopy,[1,11,12] FT-Raman spectroscopy,[13] NMR,[14] gas chromatography,[15] and gas chromatography−mass spectrometry[7,15−17] have been developed to replace the conventional method.

Stable isotope techniques have been successfully applied to detect the adulteration of honey worldwide.[18−21] For instance, Çinar et al.[18] proved the C_4 sugar value was a useful criteria for identifying the distinctiveness and detecting high-fructose corn syrup (HFCS) adulteration of pine honey. Stable isotope technique has also been employed to discriminate honey of differing geographical origins.[20] Schellenberg et al.[20] revealed that the stable isotopic compositions of honey produced in areas with geographical features and diverse climatic conditions could become reliable geographical origin information.

Several previous studies have shown that elemental profiling also provides a good prospect for characterizing geographical origins of honey. As demonstrated by Pellerano et al.,[22] the honey in Argentina could be divided into three producing areas according to their geographical origins by analyzing trace elements in multifloral honey from different geographical locations in combination with instrumental neutron activation analysis. Element profiling, especially using metal contents, has

J. Agric. Food Chem. 2015, 63, 5388−5394

been used as another chemical profiling method to determine botanical origins of honey. Because metals are stable in honey over a long time, their concentrations should depend on their botanical origins, the type of soils in which nectar-producing plants grow, and the vegetation conditions in the forage area.[23] For example, Chen et al.[24] analyzed 12 elements in Chinese honey samples of diverse types and successfully differentiated Chinese honey through partial least-squares discriminant analysis and back-propagation artificial neural network. Chudzinska et al.[25] also combined multielement concentration analysis and chemometric analysis to forecast the three different types of honey in Poland.

As reported previously, the identification of geographical and botanical origins of agro-products using multistable isotope and multielement combination with chemometric analysis is an expanding field.[26−29] For example, Branch et al.[26] analyzed the contents of Cd, Pb, Se, Sr, and ^{13}C, ^{15}N for the seeds of 20 local *Triticum aestivum* varieties to separate different cultivars or blends using discriminant analysis. To our knowledge, no research has been performed to classify the botanical origins of Chinese honey on the basis of multistable isotope and element compositions. This study thus aimed at testing the feasibility of multi-isotopic and elemental analyses combined with chemometric techniques to differentiate the botanical origins of major honeys in China.

MATERIALS AND METHODS

Sampling and Preparation. A total of 57 honey samples, including those originated from rape (*Brassica campestris* L.), acacia (*Robinia pseudoacacia* L.), vitex (*Vitex negundo* var. *heterophylla* Rehd.), and jujube (*Ziziphus jujuba* Mill. var. *inermis* (Bunge) Rehd.) (n = 16, 16, 12, and 13, respectively), were collected directly from beekeepers during 2012 and 2013 in different regions of China (Table 1). To avoid the effect of variations of bee species, the honey samples for this study were collected only from the bee hives occupied by *Apis mellifera*.

Table 1. Description of Sampling Regions for Four Major Types of Unifloral Honey in China

floral source	geographical origin	characteristics
rape	Yunnan and Sichuan provinces	white color, white crystals
acacia	Beijing and Shanxi provinces	light white color, no crystals
vitex	Beijing and Shanxi provinces	light amber color, crystals
jujube	Beijing and Shanxi provinces	amber color, no crystals

All honey samples were stored in the absence of light in plastic containers that were acid washed before use and maintained at room temperature (about 25 °C) until further analyses. Samples also were separated for stable isotope analysis. A test portion of about 30 g of honey was taken and liquefied at 45 °C and then homogenized in an ultrasonic bath for 0.5 h prior to both stable isotopic and multielemental analyses.

Stable Isotopic Analysis. The stable isotope analyses were carried out using an isotope ratio mass spectrometer (IRMS) (Finnigan Delta V Plus, Thermo Fisher Scientific Corp, Bremen, Germany) in the IRMS Laboratory of Chinese Academy of Forestry, coupled with an elemental analyzer (EA; Flash EA1112, Thermo Scientific) to measure $^{13}C/^{12}C$ ratios and a pyrolyzer (Finnigan TC/EA, High-Temperature Conversion Elemental Analyzer, Thermo Scientific) to measure $^{2}H/^{1}H$ and $^{18}O/^{16}O$ ratios. To separate the gases, the EA was fitted with a Porapack QS GC column (3 m; 6 × 4 mm, o.d./i.d.) and the pyrolyzer with a molecular sieve 5 Å (0.6 m) GC column. The devices were interfaced with the IRMS through a dilutor (Conflo III, Thermo Scientific) for dosing the sample and reference gases and fitted with an autosampler (Finnigan AS2000, Thermo Scientific). An appropriate cover on the pyrolyzer autosampler allowed continuous flushing with helium to guarantee dryness of the samples during measurement. About 1.0 g samples of honey were diluted to 10 mL with ultrapure water, and 3 μL of diluted solution was then placed into a tin capsule for $^{13}C/^{12}C$ measurements.

For hydrogen and oxygen isotopic analyses, about 200 μg of fresh honey of each sample was transferred into a silver capsule in dupluicate as for the 0.2 mg each of two laboratory standards (P1, P2) with known D/H and $^{18}O/^{16}O$ values. All of these silver capsules were not completely sealed so the samples were equilibrated with laboratory vapor with stable isotopic compositions for at least 3 days before the capsules were closed with tweezers and the samples were analyzed in the TC/EA pyrolyzer for D/H and $^{18}O/^{16}O$. The stable isotope compositions were recalculated from the IRMS results using P1 and P2 as QC materials. In this way, only the nonexchangeable hydrogen of honey was tested for D/H.[30]

Carbon, hydrogen, and oxygen isotope ratios were reported in δ notation in units of per mil or parts per thousand (‰) relative to the accepted international standards, $\delta^{13}C$‰ relative to Pee Dee Belimnite (PDB), whereas $\delta^{2}H$ and $\delta^{18}O$ refers to V-SMOW (Vienna Standard Mean Ocean Water). The delta values were calculated as

$$\delta_x = (R_{samp}/R_{ref} - 1) \times 1000$$

where R_{samp} and R_{ref} are the ratios of heavy to light isotope for the sample and reference material, respectively. The quality control standards for the $\delta^{13}C$, $\delta^{2}H$, and $\delta^{18}O$ analyses were IAEA600 ($\delta^{13}C$ = −27.771‰), USGS43 ($\delta^{2}H$ = −50.3‰), EMA P1 ($\delta^{2}H$ = −25.3‰; $\delta^{18}O$ = 20.99‰), EMA P2 ($\delta^{2}H$ = −87.80‰; 26.9‰), and USGS43 ($\delta^{18}O$ = 14.11‰). The analytical precision was 0.2‰ for $\delta^{13}C$, 2‰ for $\delta^{2}H$, and 0.2‰ for $\delta^{18}O$.

Multielement Analyses. The multielement analysis was performed using an Agilent 7500ce ICP-MS (Agilent Technologies Inc., Santa Clara, CA, USA). The honey samples were measured after the hot acid extraction using a heating block digestion system.[31] Briefly, a ∼1.0 g sample of honey was placed into a 50 mL Teflon digestion vessel with 10 mL of HNO_3 (guarantee reagent) and digested at ambient temperature overnight. The sample was placed on a heating block the next day. The combustion procedure was as follows: (1) at 70 °C for 10 min, (2) at 160 °C for 240 min, (3) at 180 °C for 120 min. The digested solution was diluted to a final volume of 50 mL with ultrapure water, decanted into luer-lock syringes, and then filtered through a Pall PVDF 0.45 μm filter into a plastic flask before further analyses. A blank digest was carried out in the same way. All materials were cleaned by soaking for 48 h in diluted HNO_3 (40% v/v) and rinsed three times with ultrapure water prior to use.[32]

The method performances for determination of 20 elements in the honey samples were evaluated by the tests of blank values, limits of detection (LOD), and spiking recovery. The spiking recoveries for these 20 elements in honey samples range from 90.2 to 109.9%, which suggests that the performance of the method allows accurate measurements of the levels of these elements in our honey samples.

Statistical Analysis. Multiple-comparison ANOVA was used to compare the differences among four honey floral origins using the SPSS software (version 17.0). Principal component analysis (PCA) and linear discriminant analysis (LDA) were applied to differentiate the floral origins of the honey samples using Matrix Laboratory (MATLAB) software (version 7.9.0). PCA minimizes the possibility of losses of the information on data matrix by reducing data set dimensionality, which can preserve most of the original variability through complex combination of their variables. The principal component (PC) could account for most of the variability in data grouping. The multivariate method was chosen to assess the stable isotope and multielement data. LDA, as a supervised technique, provided a discriminant model with respect to the descriptors' previously defined botanical origins of honey and found a rule that allocated unknown origins of honey samples to the correct group as well as studied variable discriminate best among the types of honey. To verify the power and the stability of the model, a "leave-one-out"

DOI: 10.1021/acs.jafc.5b01576
J. Agric. Food Chem. 2015, 63, 5388−5394

cross-validation discriminant analysis was carried out. In this test, known samples were used as "unknowns" to validate the model built on the basis of a reduced set of cases. Effectively, one sample was removed from the data set and then classified on the basis of a model constructed from the remainder. This process was then repeated for each sample in turn and the success of the classification recalculated by comparison with the known origin.[33]

RESULTS AND DISCUSSION

Variations in Stable Isotope Ratios of Honey among Floral Origins. The variations in stable isotopic compositions of the honey with different floral origins are presented in Figure 1. The order of the botanical origins according to the honey $\delta^{13}C$ value was vitex > jujube ≈ acacia > rape (Figure 1a). Despite significant difference in the mean $\delta^{13}C$ value among four floral origin by ANOVA test ($P = 0.05$), there were only slight differences in their ranges, resulting in overlapping among the floral origins. In other words, there was no clear differentiation in the $\delta^{13}C$ values among the four Chinese honey types. The nectar sources of Chinese honey are all from C_3 plants, so no big differences in the $\delta^{13}C$ values of honey were expected due to their botanical origins. However, the differences in the $\delta^{13}C$ values could be explained on the basis of the geographical origins and environmental conditions where the honeys were formed, but to much lesser degree on their botanical origins.[20,34] For example, the rape plants tend to grow in southern and central China where the climate is more humid so their honeys have much lower mean $\delta^{13}C$ values because of larger $\delta^{13}C$ discrimination during photosynthesis in a humid environment,[35] whereas the acacia, vitex, and jujube plants grow in drier regions, resulting in slightly higher mean honey $\delta^{13}C$ values (Figure 1a). Thus, stable carbon ratio alone was not suitable for the determination of botanical origins for Chinese honeys.

There were highly significant differences in the mean values of both hydrogen and oxygen isotope ratios according to the floral origins (all $P < 0.01$ from ANOVA and Duncan's LSD tests). The order of floral origin was acacia > jujube > vitex > rape according to the mean $\delta^{2}H$ value of honey samples (Figure 1b), and for the mean $\delta^{18}O$ value the order was jujube > rape > acacia > vitex (Figure 1c). From a two-dimensional plot of stable hydrogen and oxygen isotope ratios (Figure 2), it was obvious that botanical origins of Chinese honeys could be separated in most cases with only these two isotopic parameters. In general, the jujube honey had high $\delta^{2}H$ and $\delta^{18}O$ values, so they appeared at the top right section of the plot, whereas the acacia honey had high $\delta^{2}H$ but low $\delta^{18}O$ values, so they clustered in the top right section, also (Figure 2). With medium $\delta^{18}O$ but low $\delta^{2}H$ values, the rape honeys were positioned to the middle bottom, whereas the vitex honeys were positioned in the left middle section with medium $\delta^{2}H$ but low $\delta^{18}O$ values, which were overlapped with several acacia or vitex honeys (Figure 2). The stable hydrogen compositions in the honey samples are determined by the isotopic compositions of the water to which the plant has assimilated and conserved during photosynthesis,[20,36] whereas the compositions of stable oxygen isotopes in the honey samples were affected not only by waters available for plants but also atmospheric CO_2. Because of different environmental waters and unique plant isotopic interactions with atmospheric CO_2, the honeys with different floral origins could have distinct hydrogen and oxygen isotopic signals, which could be used as biological markers to discriminate the floral origins in China.

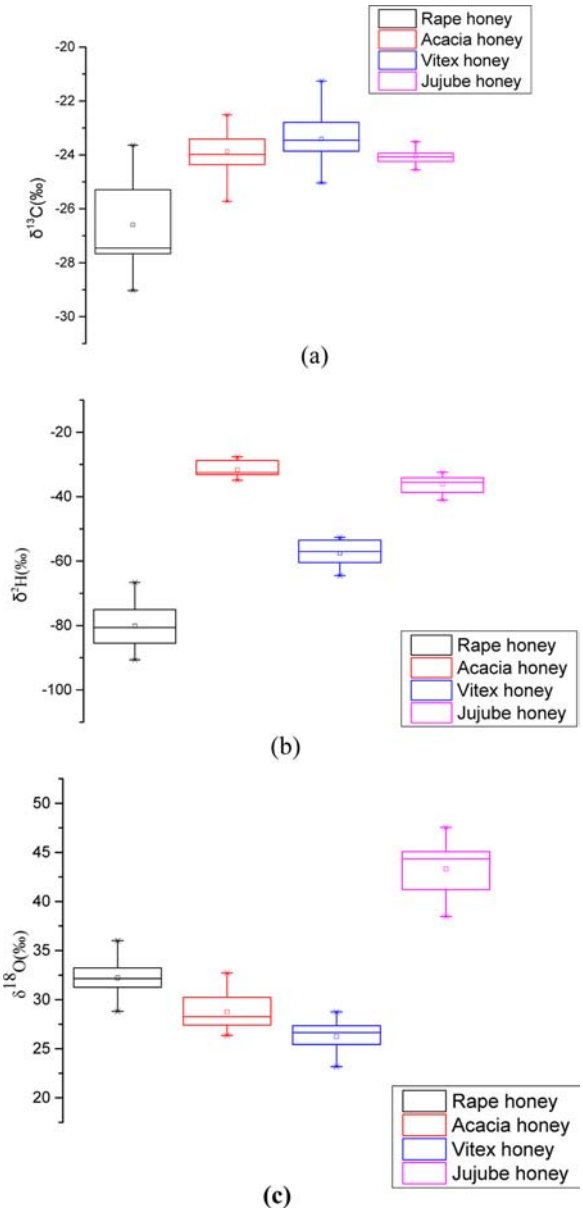

Figure 1. Box plot for carbon isotope ratio ($\delta^{13}C$, a), hydrogen isotope ratio ($\delta^{2}H$, b), and oxygen isotope ratio ($\delta^{18}O$, c) of Chinese honey samples according to floral origins. For each box plot, the boundary of the box closest to zero indicates the 25th percentile, the solid lines within the box mark the mean and median, and the boundary of the box farthest from zero indicates the 75th percentile. Whiskers above and below the box indicate the 90th and 10th percentiles, whereas symbols represent the 5th and 95th percentiles. Significant differences are defined at the 95% confidence level.

Comparisons in Multielement Concentrations of Honey among Floral Origins. As shown in Table 2, there was certain variability of the element compositions in the honey samples tested. Elements grouped as major elements were those having an average concentration of >1 mg/kg in food products.[37] In agreement with previous studies,[23,24,38] K was the most abundant chemical element in Chinese honeys (Table 2). In the honey samples tested, the highest K contents were found in the jujube honey samples, followed by the vitex, acacia, and rape honey samples. Na is the second most common chemical element in honey,[23] and the order of mean Na concentration was jujube honey (46.59 mg/kg) > vitex honey

DOI: 10.1021/acs.jafc.5b01576
J. Agric. Food Chem. 2015, 63, 5388−5394

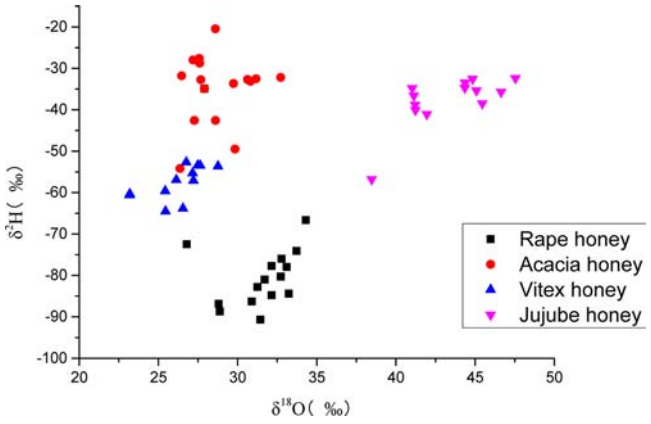

Figure 2. Plot of hydrogen isotope ratio (δ^2H) versus oxygen isotope ratio (δ^{18}O) for Chinese honey samples of four different floral origins.

(31.62 mg/kg) > rape honey (29.71 mg/kg) > acacia honey (22.75 mg/kg). The mineral composition of honey, especially the contents of major elements, correlated with its color. Dark and amber honeys such as the jujube honey contained higher amounts of certain major elements than pale honeys such as the rape and vitex honeys. Indeed, the color of jujube honey was darkest among the four unifloral honey types (Table 1), and the concentrations of K, Na, Ca, and Mg in the jujube honey were exactly the highest among the four botanical origins (Table 2).

The contents of trace elements (usually <1 mg/kg) in Chinese honey samples were quite low (Table 2). The rape honey samples were generally characterized by the highest contents of Ni, Mo, and Ti, but for the acacia honey samples the contents of U were the highest among the four unifloral honey types. The vitex honey samples had higher contents of Cr, As, Se, Ag, and Cd, but in the jujube honey samples none of these trace elements was at high level (Table 2).

Multivariate Analysis of Stable Isotopic and Multielement Compositions. As shown in the above analyses, the compositions of one or two elements either stable isotope ratios or elemental compositions in honey samples provided only an incomplete view with respect to interpretation of honey botanical origins. Thus, it is impossible to assign the botanical origin of an unknown test sample using single-element analysis, and a multivariate evaluation is necessary to improve the overall accuracy of any classification of honey floral origin.

A 3-D plot of first principal component (PC1), second principal component (PC2), and third principal component (PC3) obtained by PCA is shown in Figure 3. The plot

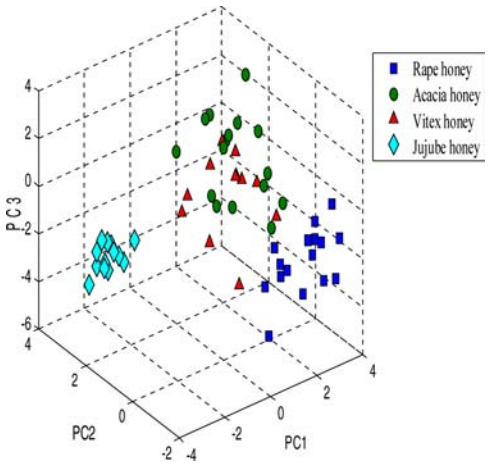

Figure 3. 3-D score plot for the three principal components of Chinese honey samples of four different floral origins.

elucidated the characteristics of four botanical origins of Chinese honeys. The rape honey samples had low values for PC2, the jujube honey samples had low PC1, and both the acacia honey and vitex honey samples had high values for PC2. PC1 explained 30.8% of the variability and high factor loadings on the δ^{18}O, K, Ca, Cu, Sr, Ag, and Ba (Figure 4). Low PC1 values for the jujube honey samples of these components and similar values were found in the rape, vitex, and acacia honey

Table 2. Comparisons of the Contents of Common Elements in Chinese Honeys among Four Floral Origins[a]

element (units)	rape honey (n = 16)	acacia honey (n = 16)	vitex honey (n = 12)	jujube honey (n = 13)
Na (mg/kg)	29.71 ± 16.52a	22.75 ± 30.35a	31.62 ± 38.59ab	46.59 ± 12.71b

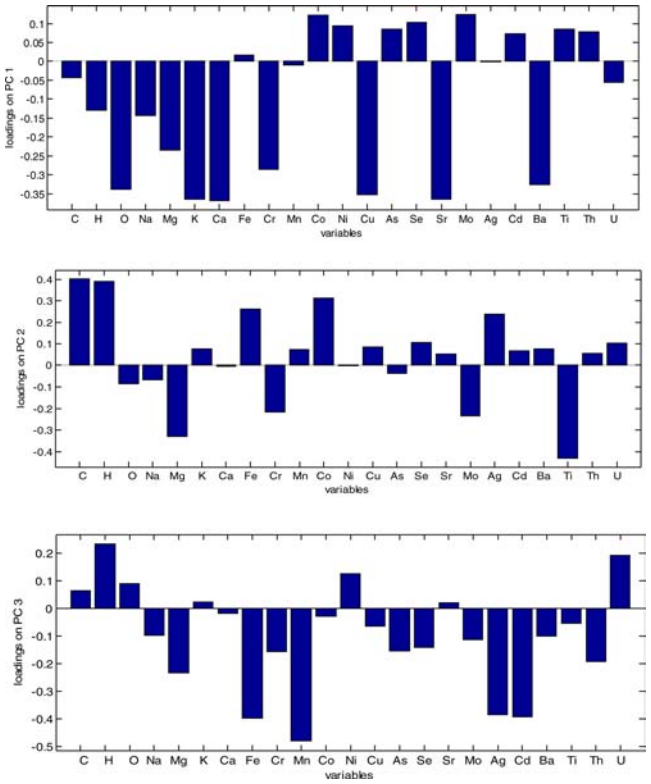

Figure 4. Loadings of the variables on three principal components of PCA analysis (PC1, PC2, and PC3) for Chinese honey samples of four different floral origins.

samples. PC2 explained 14.2% of the variability and high factor loadings on the $\delta^{13}C$, $\delta^{2}H$, Mg, Co, and Ti concentrations (Figure 4). PC3 explained only 9.7% of the variability. Together all three components accounted only for 51.7% of the variation. Intermediate PC2 values were found for the jujube honey samples of these components and low PC2 values for the rape honey samples, but similar PC2 values were found for the vitex and acacia honeys (Figures 3 and 4). Thus, the $\delta^{13}C$, $\delta^{18}O$, $\delta^{2}H$, Mg, K, Ca, Co, Cu, Ag, Sr, Ba, and Ti concentrations were proved to be effective parameters for determining the botanical origins of Chinese honey samples. However, the plot of the PCs for the acacia honey samples overlapped tightly with the vitex honey samples (Figure 3).

For a better analysis of the discriminating botanical origins of honey, LDA was carried out using stable isotope ratios of 3 elements (carbon, oxygen, hydrogen) and contents of all 20 metal elements in 57 Chinese honey samples. LDA was performed as a chemometric technique, and their discrimination models were constructed to classify honey samples according to their botanical origins using the obtained data of $\delta^{13}C$, $\delta^{2}H$, $\delta^{18}O$, Na, Mg, K, Ca, Fe, Cr, Mn, Co, Ni, Cu, As, Se, Sr, Mo, Ag, Cd, Ba, Ti, Th, and U concentrations. The overall correct classification and cross-validation rates from such analysis are shown in Table 3. The LDA with stable isotope data alone gave a reasonable classification rate (ranging from 87.5 to 100%, overall 96.5%) or cross-validation rate (75−100%, overall 87.7%). The LDA using the contents of 20 metal elements resulted in a slightly higher correct classification (91.7−100%, overall 96.5%) but a much lower cross-validation rate (41.7−100%, overall 73.7%). In comparison, the LDA using combination of both isotopic and elemental compositions resulted in the highest successful rates for both correct classification (all cases 100.0%) and cross-validation (100%, except the rape honey samples of 87.5%). Thus, the combination of two analytical techniques performed well, which in most cases could successfully discriminate Chinese honey samples according to their botanical origins. Theoretically, this approach can be applied to other food products, but more feasibility studies are needed.

Table 3. Classification of Chinese Honey Samples with Different Botanical Origins and Percentage of Observations Correctly Classified

	predicted group membership (%)				
	acacia honey	rape honey	vitex honey	jujube honey	overall

Microwave-Assisted Extraction of Phenolic Compounds from Almond Skin Byproducts (*Prunus amygdalus*): A Multivariate Analysis Approach

Arantzazu Valdés,* Lorena Vidal, Ana Beltrán, Antonio Canals, and María Carmen Garrigós

Analytical Chemistry, Nutrition & Food Sciences Department, University of Alicante, 03080 Alicante, Spain

Supporting Information

ABSTRACT: A microwave-assisted extraction (MAE) procedure to isolate phenolic compounds from almond skin byproducts was optimized. A three-level, three-factor Box−Behnken design was used to evaluate the effect of almond skin weight, microwave power, and irradiation time on total phenolic content (TPC) and antioxidant activity (DPPH). Almond skin weight was the most important parameter in the studied responses. The best extraction was achieved using 4 g, 60 s, 100 W, and 60 mL of 70% (v/v) ethanol. TPC, antioxidant activity (DPPH, FRAP), and chemical composition (HPLC-DAD-ESI-MS/MS) were determined by using the optimized method from seven different almond cultivars. Successful discrimination was obtained for all cultivars by using multivariate linear discriminant analysis (LDA), suggesting the influence of cultivar type on polyphenol content and antioxidant activity. The results show the potential of almond skin as a natural source of phenolics and the effectiveness of MAE for the reutilization of these byproducts.

KEYWORDS: *microwave-assisted extraction, phenolic compounds, almond skin, HPLC-DAD-ESI-MS/MS, antioxidant activity, linear discriminant analysis*

INTRODUCTION

Almond (*Prunus amygdalus*) production has increased significantly in recent years, with a worldwide production of about 1.9 million tonnes in 2012.[1] Food applications of almonds such as confectionary and bakery items, snack formulations, cereals, and marzipan require the almonds without the seed coats.[2] The external coating of almonds is industrially removed by using a hot water blanching process, with the brown skin contributing around 6.0−8.4% of the seed weight.[3] Almond skin agricultural byproducts are produced during almonds processing in large amounts. Industries are forced to consider ways of treating or using these residues; most are just incinerated or dumped without control, causing several environmental problems, or used as animal feed.[4]

Almond skin contains 50−75% of the total phenols present in the nut, such as aldehydes and hydroxybenzoic acids, flavanones, isoflavones, flavonol glycosides, phenolic acids, flavonol aglycones, flavan-3-ols, flavonone aglycones, flavonone glycosides, and lignans. Flavanol and flavonol glycosides are the most abundant phenolic compounds, particularly epicatechin, catechin, isorhamnetin-3-*O*-glucoside, isorhamnetin-3-*O*-rutinoside, kaempferol-3-*O*-rutinoside, and naringenin-7-*O*-glucoside.[5,6] Polyphenols have been found to decrease the risk of coronary heart disease and function as anti-inflammatory agents due to their high antioxidant capacity.[6] These compounds can function as natural preservatives for meat products, reducing their lipid oxidation.[7,8] Therefore, almond skin byproducts rich in antioxidant compounds could be reused by food industries as natural additives to control the oxidative process, adding value to this residue. It is of economical and ecological significance to find an efficient method to isolate phenolic compounds from these byproducts. However, cultivar differences may affect almond flavonoid concentration.[3]

Extraction of phenolic compounds from food is one of the most important steps prior to their determination by HPLC.[9] Recently, some novel extraction methods of flavonoids such as microwave-assisted extraction (MAE) were developed showing several advantages over the conventional extraction techniques such as the reduction of solvent used for extraction and energy consumption, moderately high recoveries, good reproducibility, shortened extraction time, and minimal sample manipulation for the extraction process.[10−12] This technique has been successfully used with effectively improved flavonoid yield for the extraction of different food matrices, such as honey, peanut skins, sweet potato, and maize.[13−17]

With regard to the extraction of almond skin antioxidants, conventional extraction is usually performed at reflux by using high temperatures for several hours or maceration with solvent for days at room temperature.[18−20] To our knowledge, no MAE application for the extraction of phenolic compounds from almond skin has been found in the literature. Therefore, the objectives of this study were (1) to optimize a new extraction procedure for the extraction of phenolic compounds in almond skin by MAE using an experimental design in terms of highest total phenolic content (TPC) and antioxidant activity (DPPH); (2) to increase the potential added value of almond agricultural byproducts, reducing costs for the food industry; and (3) to select an almond cultivar with higher antioxidant capacity as a

potential antioxidant source. For these purposes, the determinations of TPC, flavonoids (HPLC-UV-ESI-MS/MS), and antioxidant activity (DPPH, FRAP) were performed on seven different almond cultivars, and the presence of different categories within almond skin samples was studied using stepwise linear discriminant analysis (LDA). This characterization is an essential step for the reutilization of these almond skin byproducts.

MATERIALS AND METHODS

Chemicals and Reagents. Water (ultrapure grade) and ethanol (HPLC grade) were acquired from Merck (Madrid, Spain). Quercetin, sodium carbonate, Folin−Ciocalteu reagent (2 N), 2,2-diphenyl-1-picrylhydrazyl (DPPH), (±) 6-hydroxy-2,5,7,8-tetramethylchromane-2-carboxylic acid (Trolox), HPLC grade acetonitrile, and methanol were supplied by Sigma-Aldrich (Madrid, Spain). All other reagents used were of analytical or chromatographic grade and were purchased from Panreac (Barcelona, Spain). Standard compounds such as (+)-catechin, (−)-epicatechin, quercetin-3-*O*-rutinoside, kaempferol-3-*O*-rutinoside, isorhamnetin-3-*O*-glucoside, isorhamnetin-3-*O*-rutinoside, naringenin-7-*O*-glucoside, naringenin, and daidzein (internal standard) were purchased from Extrasynthese (Genay, France).

Sample Preparation. Seven almond cultivars from the 2011 harvest were selected for this study and were supplied by Almendras Llopis (Alicante, Spain): three Spanish (Marcona, Guara, and Planeta) and four American (Butte, Colony, Carmel, and Padre). The blanching process of almonds (100 g) was carried out at 95 °C for 3 min using 150 mL of deionized water to remove the skins from the kernels by hand.[6] Prior to MAE, the obtained skins were oven-dried for 12 h and ground with a ZM 200 high-speed rotary mill (Retsch, Haan, Germany) to increase the extraction efficiency.[12] Particles passing through a 0.5 mm sieve were used to ensure the homogeneity of the residue powder. The almond skin fraction obtained was dried in an oven at 40 °C for 24 h to reduce its moisture content.

Extraction Procedure. MAE was carried out using a modified M1711N domestic microwave oven (Samsung M1711N, Taiwan), with a hole (18 mm diameter) in the top of the oven, at a frequency of 2450 MHz and 800 W maximum power.[21] The sample was stirred at 300 rpm during extraction using a microwave stirrer (Bel-Art Products, Wayne, NJ, USA). The appropriate weight of homogenized almond skin powder was placed in a 100 mL quartz flask, which was connected to a vapor condenser. The system operated as an open-vessel extraction system, where the solvent is heated and refluxed through the sample, allowing a very efficient heating.[22] Ethanol was selected as an effective extraction solvent for phenolic compounds in food samples.[13,23] Ethanol is also recommended by the U.S. Food and Drug Administration as an environmentally nontoxic food grade organic solvent.[24]

MAE was carried out at different extraction times and microwave powers using 60 mL of 70% (v/v) ethanol. The obtained extracts were centrifuged at 4500 rpm for 5 min, filtered through a 0.45 μm PVDF filter (Teknokroma, Barcelona, Spain), made up to 50 mL, and kept at −20 °C until analysis.

Experimental Design. The extraction of phenolic compounds from almond skin was performed under different extraction conditions according to the experimental design shown in Table 1. The parameters considered during MAE optimization were almond skin weight (0.5, 2.0, 3.5 g), microwave power (100, 200, 300 W), and irradiation time (20, 40, 60 s). The Butte cultivar was selected for the optimization of MAE conditions. The range of studied variables was selected on the basis of results obtained in preliminary experiments. In this sense, at increased microwave power level of 300 W in the screening experiment, rapid heating of the extraction medium and bubbling of the substance occurred due to high cavitation, leading to the entry of the extraction medium into the condenser. A Box−Behnken design (BBD), comprising 16 experimental runs, was used, and experiments were carried out in randomized order.[25] The responses obtained from the experimental design were evaluated in terms of TPC and antioxidant activity (DPPH).

Table 1. Box−Behnken Experimental Design and MAE Results

run	almond skin wt (g)	microwave power (W)	irradiation time (s)	TPC (mg QE)	DPPH (% inhibition)
1	0.5	100	40	15.3	13.4
2	3.5	100	40	86.4	77.3
3	0.5	300	40	15.3	14.2
4	3.5	300	40	68.7	70.7
5	0.5	200	20	12.7	11.5

14	2.0	200	40	42.7	43.6
15	2.0	200	40	40.7	43.1
16	2.0	200	40	47.3	54.5

Regression analysis was used for the experimental data and fitted into the following empirical second-order polynomial model:

$$Y = \beta_0 + \Sigma\beta_i X_i + \Sigma\beta_{ii} X_i^2 + \Sigma\Sigma\beta_{ij} X_i X_j$$

Y is the predicted response, X represents the variables of the system, i and j are design variables, β_0 is a constant, β_i is the linear coefficient, β_{ii} is the quadratic coefficient, and β_{ij} is the interaction coefficient of variables i and j.

HPLC Analysis of Flavonoid Compounds. HPLC-DAD-ESI-MS/MS analysis was performed, in triplicate, using an 1100 series HPLC system (Agilent Technologies, Waldbronn, Germany) coupled to a photodiode array UV−vis detector and an LC/MSD Trap SL ion trap mass spectrometer (Agilent, Stuttgart, Germany) via an electrospray ionization (ESI) source. Mass spectra were recorded in the negative ionization mode (m/z 50−900).[26] The electrospray chamber was operated at 3.5 kV with a drying gas temperature of 350 °C, N_2 pressure, and flow rate on the nebulizer at 50 psi and 10 L/min, respectively; MS/MS collision energies were set at 20 V.

The column used for flavonoids separation (10 μL) was a 4.6 mm × 150 mm i.d., 5 μm, Eclipse XDB-C18 (Agilent Technologies) at 25 °C. The mobile phase consisted of 2% acetic acid in ultrapure water (solvent A) and 2% acetic acid in ultrapure water/acetonitrile (73:25, v/v, solvent B) at a flow rate of 1 mL/min. The linear gradient started with 0 min, 40% B; 25 min, 70% B (hold 5 min); 32 min, 100% B (hold 4 min); back to 40% B (hold 5 min). UV detection of flavonoid compounds was carried out at 290 nm. The identification of the most abundant phenolic compounds was made by comparison of retention times and UV−vis and MS/MS spectra with those of commercially standard compounds and available literature.[26] Quantitation was carried out using an MS/MS detector and daidzein as internal standard (20 mg/kg). Final concentrations of flavonoids were expressed in micrograms per gram of dry almond skin.

Total Phenolic Content. The TPC of almond skin extracts was determined, in triplicate, according to the Folin−Ciocalteu colorimetric method, as reported by Singleton and Rossi,[27] using a Biomate-3 UV−vis spectrophotometer (Thermospectronic, Mobile, AL, USA). Deionized water (30 mL) and Folin−Ciocalteu reagent (2.5 mL) were added to 500 μL of almond skin extract. The mixture was vortexed and incubated for 5 min. Then, 7.5 mL of 20% aqueous Na_2CO_3 and 10 mL of deionized water were added and mixed. The absorbance was measured at 760 nm after 90 min of incubation against deionized water as a blank. Quercetin was used as the reference standard (25−1000 mg/kg), and TPC was expressed as milligrams of quercetin equivalent (QE) per gram of dry almond skin.

J. Agric. Food Chem. 2015, 63, 5395−5402

Determination of Antioxidant Activity. The DPPH assay was used to determine the free radical scavenging activity of almond skin extracts as described by Assimopoulou et al.[29] One hundred microliters of the almond skin ethanolic extract were mixed with 2.7 mL of DPPH solution (10^{-4} M in ethanol). The percentage of free radicals scavenged by DPPH radical was determined at steady state (60 min) at 517 nm.[30,31]

The capacity of almond skin extracts to reduce ferric ions was assessed by using the FRAP method.[32] Two hundred and fifty milliliters of acetic acid buffer (300 mM, pH 3.6), 10 mM 2,4,6-tripyridyl-*s*-triazine (TPTZ) made up in 10 mL of 40 mM HCl, and 10 mL of 20 mM ferric chloride solution were mixed at a 10:1:1 ratio, to make the FRAP reagent. One hundred microliters of the almond skin ethanolic extract was added to 4.9 mL of FRAP reagent. Measurements were performed at 593 nm after 30 min of incubation at 37 °C in darkness. Trolox was used as the reference standard (85−365 mg/kg), and the antioxidant capacity was expressed as micromoles of Trolox equivalent (TE) per gram of dry almond skin.

Both methods were performed in triplicate using a Biomate-3 spectrophotometer (Thermospectronic).

Statistical Analysis. Statgraphics-Plus software 5.1 (Statistical Graphics, Rockville, MD, USA) was employed to generate and analyze the results of the BBD. Graphic analysis of the principal effects and interactions between variables was used for interpretation of results. Response surface methodology (RSM) was used to determine the optimal extraction conditions. Least-squares regression analysis was performed to obtain the coefficients of the quadratic polynomial model previously described. The adequacy of the fitted model was determined by evaluating the lack of fit, the coefficient of determination (R^2), and F test obtained from the analysis of variance (ANOVA). Statistical significance of model parameters was determined at the 5% probability level ($\alpha = 0.05$).

SPSS commercial software, ver. 15.0 (Chicago, IL, USA), was used for statistical analysis of almond cultivar results by means of ANOVA. The Tukey test was used to determine differences between means at a $p \leq 0.05$ significance level. In chemometrics data analysis, pattern recognition methods are a powerful tool in the context of food quality assessment and food composition analysis.[33] The presence of different categories within almond skin cultivars was studied using stepwise LDA as a multidisciplinary approach.[34]

RESULTS AND DISCUSSION

Optimization of Extraction Conditions. A preliminary study was performed to determine the effect of solvent volume and solvent ratio (ethanol in water) on the recovery of TPC and antioxidant activity from almond skin. It was found that 60 mL of 70% (v/v) ethanol provided the maximum TPC and DPPH scavenging activity (data not shown). These conditions were then fixed for further optimization of extraction conditions. The selection of 70% (v/v) ethanol in water was in concordance with results obtained by other authors from the determination of natural phenols in different samples, because extraction efficiency depends on the solubility of the analytes in the extraction solvent.[12,14,22,25] Hughey et al.[5] studied the distribution of polyphenols from almond skin in blanch water as a function of time and temperature, the intrinsic solubility of each polyphenol in water being different depending on its structure. In general, major phenolic compounds present in almond skin are sparingly soluble in hot water. As a consequence, a highest yield extraction of these compounds as the ethanol portion increases can be expected. However, the use of high ethanol contents as solvent extraction could lead to polyphenol degradation and overpressure inside the vessel due to overheating of the sample.[11] In this sense, dipolar rotation and ionic conduction are simultaneously produced during MAE.[26] As the ethanol concentration increases, higher dielectric loss is obtained.[27] As a consequence, the higher capacity of the solvent to absorb microwave energy can lead to a faster rate of solvent heating with respect to the plant material.[12]

With regard to solvent volume, it was found that 60 mL was the more effective volume to be used with a maximum quantity of sample of 3.5 g without the formation of almond skin aggregates in the quartz flask during extraction. In this sense, extraction solvent efficiently absorbs microwave energy and leads to enhanced swelling of food material, which is favorable to increasing the contact surface area between phases.[12] However, a high volume of solvent could decrease the microwave adsorption of material, because more energy was absorbed by the solvent. In this case, the breaking of cell wall material and mass transmission might negatively influence and decrease the phenolics extraction and antioxidant capacity.[28]

There are different factors that can affect the extraction efficiency of MAE, such as microwave power, type and composition of solvent, extraction time, particle size of sample, solvent to solid ratio, soaking time, and extraction cycles.[35] The present study evaluates some of these variables by using a Box−Behnken experimental design. Butte almond skin was used for the experimental design and method optimization assays. The experimental data obtained in terms of TPC and DPPH scavenging activity are presented in Table 1. A statistical analysis of results was performed to estimate the statistical significance of the factors and interactions between them that had the greatest effect on obtaining extracts with high yield of TPC and antioxidant capacity (Figure 1). Among the studied factors, the almond skin weight had the greatest influence on the studied responses, showing a positive effect.

The rest of the investigated parameters had no significant impact on the studied responses. With regard to magnetron power, the increasing microwave energy can favor the penetration of solvent into the food matrix and offer a rapid transfer of energy to the solvent and matrix, increasing

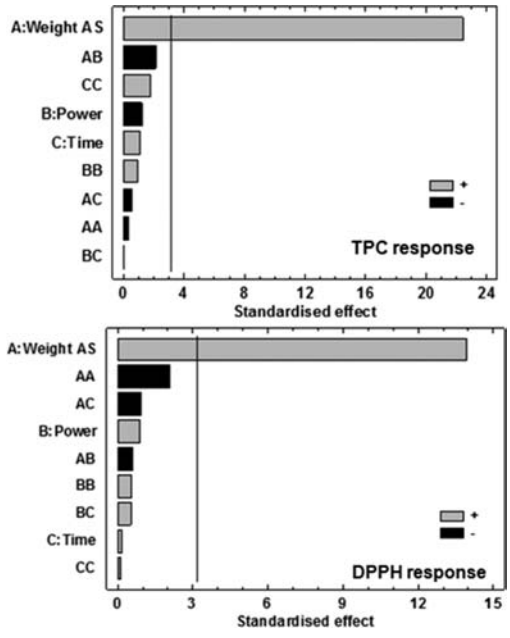

Figure 1. Pareto charts of factors and interactions obtained from the Box−Behnken design for each response: TPC (mg QE/g almond skin) and DPPH scavenging (%). The vertical line indicates the statistical significance at 5% of the effects.

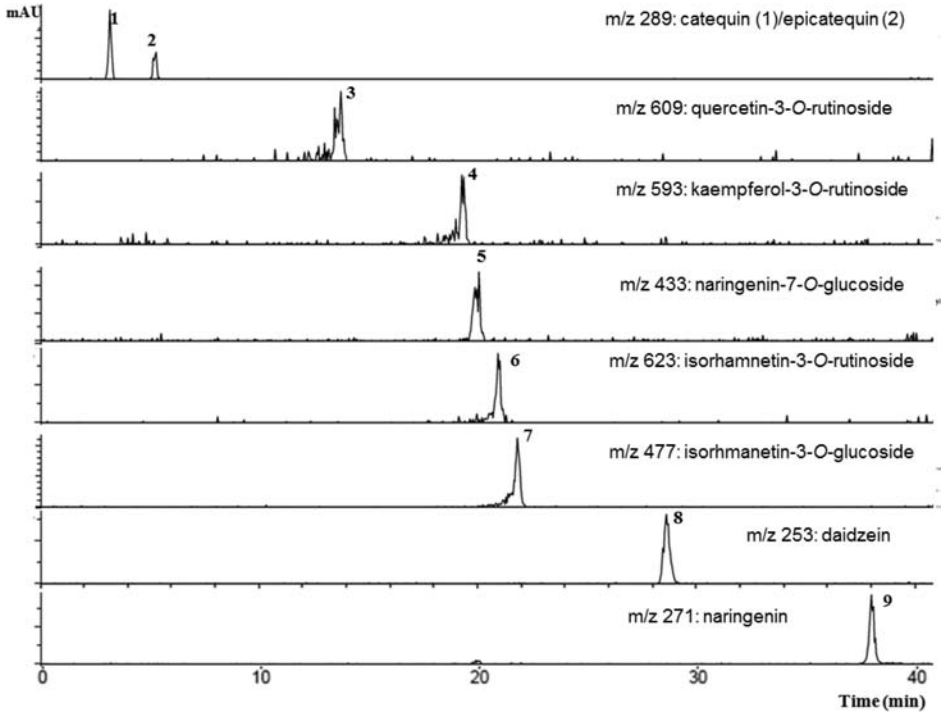

Figure 2. Extracted ion chromatograms of flavonoid standards obtained from $[M - H]^-$ ion by HPLC-ESI-MS/MS analysis (50 mg/kg).

temperature and allowing the dissolution of compounds to be extracted with an increase in the phenolics extraction yield.[26] However, a negative effect with increasing microwave irradiation energy could be observed by thermal degradation of antioxidant compounds and overpressure inside the vessel due to an increase in the extraction temperature.[12] Higher temperatures can also reduce extraction selectivity as matrix materials and nondesired compounds can also be extracted. Microwave power is strongly dependent on time and extraction temperature. In this sense, the increase in microwave power and extraction temperature causes rapid cell rupture, increasing the amount of impurities in extracts, which can affect antioxidant activity. Furthermore, longer exposure with low or moderate power is considered a wiser choice because it results in better purity of the obtained extracts.[11] With regard to irradiation time, this parameter generally has a positive influence on the TPC response.[12] This behavior can be explained by considering that the thermal accumulation within extraction solution due to the absorption of microwave energy promotes the dissolution process of phenolic compounds into the solution.[26] In the present work, the extraction temperature rose to 47 ± 4 °C by using the lower studied power (100 W) and maximum time (60 s). Then, the combination of low microwave power and short extraction time could lead to moderately high temperatures, which could be considered able to extract almond skin antioxidant compounds with high antioxidant activity.

The mathematical models obtained for both studied responses by applying multiple regression analysis on the experimental data were expressed by the following equations:

$$\mathrm{TPC} = 45.10 + 32.70A - 1.73B + 1.55C - 4.41AB - 1.16AC + 0.07BC - 0.69A^2 + 1.99B^2 + 3.65C^2$$

$$\mathrm{DPPH} = 48.57 + 30.045A + 1.87B + 0.34C - 1.84AB + 1.63BC - 2.92AC - 6.35A^2 + 1.71B^2 + 0.36C^2$$

A, B, and C are the coded variables for almond skin weight, microwave power, and irradiation time, respectively.

The computing program showed that the two fitted models were considered satisfactory as the lack of fit was not significant ($p > 0.05$). R^2 is defined as the ratio of the explained variation to the total variation and is a measurement of the degree of fitness.[14] The model can fit well with the actual data when R^2 approaches unity. The R^2 values obtained for TPC and DPPH were 0.9835 and 0.9691, respectively. These values indicated a relatively high degree of correlation between the actual data and predicted values, indicating that both models could be used to predict the studied responses.

Optimal conditions found by prediction of computing program to obtain highest TPC and DPPH values of 89.2 mg CE and 78.4%, respectively, were determined as follows: almond skin weight, 3.5 g; microwave power, 100 W; extraction time, 60 s. As the almond skin weight clearly had a strong significant positive effect, this value was increased until 4 g. The values obtained for TPC and DPPH scavenging after extraction of almond skin under these optimal conditions, in triplicate, were 54 ± 2 mg QE/g almond skin and 90 ± 1%, respectively. As a result, for the extraction of phenolic compounds from almond skin, the best selected extraction conditions were 100 W, 60 s, 4 g, and 60 mL of 70% ethanol.

MAE can be considered a rapid technique showing several advantages compared to conventional extraction methods, which are time-consuming, eventually lead to thermal degradation of antioxidant compounds, and usually require higher quantities of organic solvents, raising process costs and reducing the environmental sustainability. For example, almond skin was extracted during 24 h at 40 °C by using 70% of

aqueous organic solvent (methanol, acetone, or acetonitrile) by Tsujita et al.[36] Also, Hughey et al.[5] extracted almond skin antioxidant compounds during 24 h at 37 °C by using 50% water/methanol with 3.5% (v/v) acetic acid. Finally, Monagas et al.[20] extracted antioxidant compounds from almond skin with 80% (v/v) acetone at a solid to solvent ratio of 1:10 (w/v) during 30 min at 50 °C.

Analysis of Flavonoid Compounds in Almond Skin Cultivars. An adequate separation and good resolution of compounds were obtained for identification and quantitation (Figure 2). According to the unsaturation and oxidation degrees of the three-carbon segment, various families of flavonoids can be distinguished such as flavanones, flavonols, flavones, isoflavones, and anthocyanidins.[9] Peaks 1 and 2 showed a $[M - H]^-$ at m/z 289 and characteristic MS/MS ions at m/z at 245, 205, and 179, respectively, and they were identified as two flavan-3-ols: (+)-catechin and (−)-epicatechin, respectively. Peaks 3, 4, 5, 6, and 7 were identified as five glycosidic compounds: quercetin-3-*O*-rutinoside (m/z 609 with an MS/MS fragment at m/z 300), kaempferol-3-*O*-rutinoside (m/z 593 with an MS/MS fragment at m/z 285), naringenin-7-*O*-glucoside (m/z 433) with an MS/MS fragment at m/z 271, isorhamnetin-3-*O*-rutinoside (m/z 623 with an MS/MS fragment at m/z 315), and isorhamnetin-3-*O*-glucoside (m/z 477 with an MS/MS fragment at m/z 315), respectively. The isoflavone daidzein at m/z 253, with MS/MS fragments at m/z 224 and 135, which was used as internal standard, was identified at peak 8. Finally, peak 9 was identified as the flavanone aglycone naringenin (m/z 271) with MS/MS fragments at m/z 177 and 151. The compounds identified in this work are in agreement with published literature determining the phenolic profile of almond skin.[5,18]

Table 2 summarizes the individual flavonoids content found in the studied almond skin cultivar extracts. Significant differences were obtained among almond skin cultivars regarding their flavonoid profiles. Flavonoids are products of the shikimate pathway from acetate and phenylalanine in plants. The genetic variation in the shikimate pathway of almond cultivars is likely responsible for the different flavonoid profiles between cultivars.[18] For epicatechin, isorhamnetin-3-*O*-glucoside, kaempferol-3-*O*-rutinoside, and isorhamnetin-3-*O*-rutinoside, Guara skin showed the highest content compared to the rest of the studied cultivars. On the other hand, catechin, naringenin-7-*O*-glucoside, quercetin-3-*O*-rutinoside, and naringenin were quantified at higher amounts in Planeta skin.

As has been previously reported, during the blanching process the blanch water will increase in polyphenols, whereas blanched almond skins will decrease in phenolic content.[5,13] The results obtained in this work from the quantitation of flavonoid compounds are in agreement with those found by Hughey et al.[5] As the number of −OH functional groups decreases in the molecule, a higher hydrophobic character and lower solubility in boiling water of the phenolic compound are obtained. As a result, these compounds may present more affinity for an organic phase such as ethanol during MAE.[28] Thus, isorhamnetin-3-*O*-rutinoside, kaempferol-3-*O*-rutinose, isorhamnetin-3-*O*-glucoside, and quercetin-3-*O*-rutinoside, with more than seven −OH groups present in their molecules, were quantified in higher amounts in almond skin cultivars, followed by catechin, epicatechin, and naringenin-7-*O*-glucoside with only five −OH groups. Finally, naringenin was quantified at the lower amount with only three −OH groups in its molecule. Hughey et al.[5] also reported a lower concentration of naringenin in almond skins after blanching. Bolling et al.[37] found the highest and lowest quantities for isorhamnetin-3-*O*-rutinoside and quercetin-3-*O*-rutinoside, respectively, in different almond skin cultivars. Similar results were reported also by Mandalari et al.[4] after lipid removal by almond skin extraction with *n*-hexane and further extraction by sonication. Finally, Garrido et al.[3] reported similar results for the flavonoids quantified in the present work when analyzing almond skin mixtures of Spanish and American cultivars subjected to blanching.

Analysis of Total Flavonoids, TPC, and Antioxidant Activity in Almond Skin Cultivars. The total flavonoids content quantified by HPLC-ESI-MS/MS, TPC results, radical scavenging activity by DPPH, and reducing power by FRAP are shown in Table 3 for all almond skin cultivar extracts. Guara skin showed the highest total flavonoids content (1162 μg/g almond skin), TPC (119 mg QE/g almond skin), and FRAP (556 μmol TE/g almond skin) values. Padre, Butte, and Colony cultivars followed Guara for total flavonoids content and, finally, Planeta, Carmel, and Marcona. With regard to TPC results, Guara was followed by Planeta, Colony, and Carmel and, finally, Marcona, Padre, and Butte. For FRAP, Guara and Marcona did not show statistical differences, with highest antioxidant activity, followed by Padre, Planeta, Carmel, Butte, and, finally, Colony. These results are in accordance with those found in a previous work in which an exhaustive study of the phenolic composition of almond skin was carried out to evaluate their potential application as a functional food ingredient.[38] In this study, TPC and radical scavenging activity results were significantly higher for the almond skin mixture of Spanish varieties than for the American ones. Similar results were also obtained in a previous work in which the polyphenol content and antioxidant activity of seven different almond skin cultivars harvested over three seasons in California were studied.[18] From this work, it was concluded that cultivar had a differential impact on individual polyphenol synthesis, flavonoid content, and antioxidant activity of almonds. With regard to DPPH results, a high radical scavenging activity (>90%) was obtained for all studied cultivars, although no significant differences were obtained among them ($p > 0.05$).

The total flavonoids content found in the present study, which ranged from 46 to 116.2 mg/100 g of almond skin, is higher than the mean value reported for almonds in the USDA flavonoid content database (15.24 mg/100 g almonds), which is based on data from the Food Composition Nutrient Data Laboratory of the USDA.[39] These data were obtained using extracts from whole almonds, whereas in the present study the skin was analyzed, which accounts for 78−98% of the flavonoid content from whole almonds.[19,39,40] On the other hand, differences found in the absolute amount of recovered polyphenols, flavonoid content, and TPC and FRAP results obtained from almond skins between studies may arise from the use of different methods of extraction and analysis.[18,40]

The obtained results clearly showed the efficiency of the optimized MAE method and the high antioxidant potential of almond skin extracts as natural antioxidant sources; Guara skin showed the highest TPC and flavonoids contents. Therefore, it could be concluded that MAE could be considered a potential alternative to conventional extraction methods for the isolation of phenolic compounds from almond skin.

Multivariate Analysis. LDA was applied as a multidisciplinary approach by inserting together all parameters obtained from the determination of TPC, antioxidant activity by FRAP, and individual flavonoid contents quantified by HPLC-ESI-MS/MS as predictors, evaluating the capability of the complete model to discriminate samples according to cultivar. The results obtained for DPPH from almond skin cultivars were not included in the LDA because no significant differences were obtained among samples (Table 3). As a result, 100% of samples were correctly classified, obtaining a λ_w = 0.175, with a good resolution among categories.

Six discriminant functions were obtained, using the variable selection rule for minimizing Wilk's lambda, which account the 61.5, 26.6, 8.1, 3.1, 0.5, and 0.6% of the total variance, respectively. Projections of cultivar scores on the first two determined discriminant functions are shown in Figure 3,

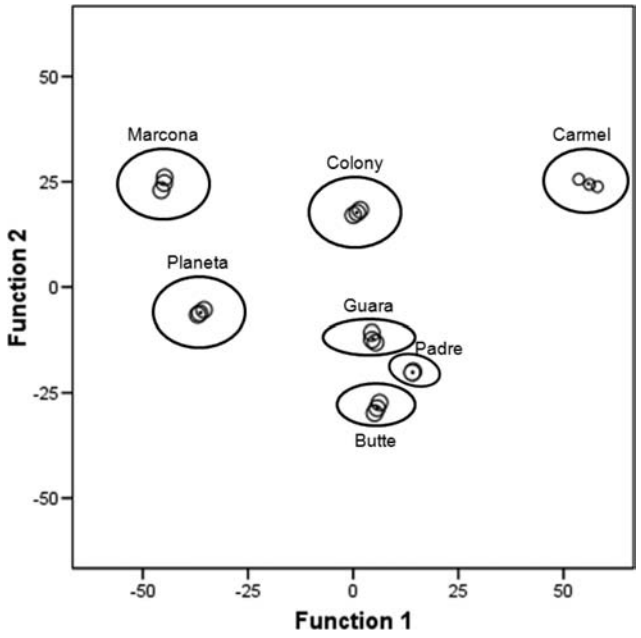

Figure 3. Projections of almond skin cultivar scores on the space determined by the two first discriminant functions obtained by the multidisciplinary approach.

where cultivars appear associated, suggesting seven groups. The first discriminant function showed differences in the discriminant space among the almond skin cultivars. This function was positively affected by TPC and isorhmanetin-3-*O*-rutinoside, kaempferol-3-*O*-rutinoside, and isorhamnetin-3-*O*-glucoside contents. On the other hand, FRAP, quercetin-3-*O*-rutinoside, naringenin-7-*O*-glucoside, naringenin, catechin, and epicatechin predictors negatively affected function 1. With regard to the second discriminant function, it was more affected by TPC, naringenin-7-*O*-glucoside, and isorhamnetin-3-*O*-glucoside contents, whereas the rest of the predictors had a negative influence on it. As a result, the application of the multidisciplinary approach revealed the potential of the obtained model for the discrimination and classification of almond skin cultivars according to the results obtained for TPC, antioxidant capacity (FRAP), and individual flavonoids content (HPLC-ESI-MS/MS). Similarly, Bolling et al.[18] found that canonical discriminant analysis of polyphenols content and antioxidant activity (FRAP) could distinguish almonds from different cultivars harvested in different seasons with 80% confidence. Also, in a previous work, we found that a multidisciplinary LDA approach of structural (FTIR) and thermal parameters (DSC, TGA) could successfully classify and discriminate three different almond cultivars.[34] The obtained results revealed the suitability of the studied techniques combined with LDA for a fast discrimination among different almond skin cultivar residues in food processing.

Characterization of Antibodies and Development of an Indirect Competitive Immunoassay for Detection of Deamidated Gluten

Olivier Tranquet,* Roberta Lupi, Valerie Echasserieau-Laporte, Manon Pietri, Colette Larré, and Sandra Denery-Papini

INRA, UR1268 Biopolymers, Interactions, Assemblies, rue de la Geraudiere, Nantes cedex 03, France

ABSTRACT: Diversification of gluten applications in the food and cosmetics industries was achieved through the production of water-soluble gluten that can be obtained by deamidation. Current analytical methods dedicated to gluten detection failed to detect deamidated gluten. After immunizing mice with the peptide LQPEEPFPE conjugated to keyhole limpet hemocyanin, five mouse monoclonal antibodies (mAbs) were produced and sequences of bound epitopes were determined as XPXEPFPE, where X is Q or E. The mAbs exhibited high specificity for deamidated gliadins and low molecular weight glutenin subunits. A competitive enzyme-linked immunosorbent assay (ELISA) based on INRA-DG1 mAb was developed with an IC50% of 85 ng/mL and a limit of detection of 25 ng/mL. The intra- and interassay coefficients of variation (CV) were <10% except for the interassay CV of the low-level control (40 ng/mL), which was 20%. This assay was capable of detecting three of the four deamidated gluten samples spiked in rice flour at 20 mg/kg.

KEYWORDS: *deamidated gluten, deamidated gliadins, monoclonal antibodies, ELISA*

INTRODUCTION

Wheat, which is adapted to various climate and agronomic conditions, is consumed worldwide as a major supplier of calories. The gluten protein fraction of flour has unique viscoelastic properties that enable the preparation of bread, pasta, and noodles. These functional properties and its low cost as a byproduct of the starch industry make gluten an ingredient that is now included in numerous foods, feed, and cosmetics far beyond its traditional uses.

Gluten is the causative agent of celiac disease (CD)[1] and is also involved in food allergy to wheat.[2−4] To date, there is no curative treatment for these two pathologies and the only solution for patient is a lifelong gluten-free diet. Codex alimentarius states a threshold of 20 mg of gluten/kg in food as safe for CD patients.[5] Below this content, food can be claimed as "gluten-free". Recently, The VITAL Scientific Expert Panel established that a dose of 1 mg of wheat protein did not trigger symptoms in 95% of people allergic to wheat, suggesting that the 20 mg/kg threshold is also suitable for wheat-allergic patients.[6]

Gluten is a complex network of gliadins and glutenins that interacts by covalent and noncovalent bounds. Gliadins are monomeric proteins classified into α/β-, γ-, ω2-, and ω5-subtypes, while glutenins are polymeric proteins classified in low- and high-molecular weight glutenin subunits (LMW-GS and HMW-GS). Gliadins and GS are insoluble in water and characterized by homologous repetitive domains rich in proline and glutamine.[7] The low water solubility of gluten limits its application as a functional ingredient in the food industry.[8] Diversification of gluten applications has been achieved through the production of gluten samples functionalized by chemical or enzymatic processes.

Deamidation is one of the methods used for this purpose. It may be performed by either chemical or enzymatic treatment, resulting in the conversion of the amide groups of glutamine and asparagine to the corresponding carboxyl groups. By introducing one negative charge at the deamidation site, this reaction affects the physicochemical properties of peptides and proteins.[9] Heating gluten under acidic conditions is an effective and simple method of deamidation used on an industrial scale. Concomitantly to deamidation, partial proteolysis of gluten components may occur at various degrees depending on the acid concentration, temperature and time for treatment. These modified gluten samples exhibit enhanced water solubility, foaming, and emulsifying properties while preserving their nutritional properties.[8,10]

Deamidation has an impact on gluten biological activity. It is known that most of the gluten-derived peptides involved in CD need to be deamidated in vivo by tissue transglutaminase to enhance their T-cell activation potential.[11,12] Gliadin fractions deamidated by chemical treatment (heat/acid treatment) have also been shown to exhibit such activity.[13] Early in the 2000s, severe allergic reactions to deamidated gluten (DG) were reported in individuals otherwise tolerant to native wheat.[14] The allergens and epitopes detected by immunoglobulin E (IgE) from these patients were shown to be different from those from patients allergic to classical wheat products. This allergy to DG was a different entity from wheat allergy specifically elicited by DG.[15] More dramatically, DG has been shown to be involved in a sensitization mechanism enabling both hydrolyzed or native proteins to elicit severe skin reactions and food allergy in more than 1300 individuals.[16] In Japan, almost all of these patients were sensitized by the same soap containing the same ingredient consisting of acid-hydrolyzed gluten (Glupearl 19S).[17]

Gluten detection is mainly based on enzyme-linked immunosorbent assay (ELISA) with antibodies that target epitopes among the repetitive domains of gliadins.[18] Repetition of the recognized epitopes allows the establishment of a sandwich ELISA with a single monoclonal antibody (mAb) and sequence homologies of these domains among gliadins enable the simultaneous detection of several gliadins.[19] However, these repetitive sequences, rich in glutamine, are strongly modified by deamidation and thus mAb recognition is reduced or absent. As a consequence, the concentration of DG detected by these kits is drastically underestimated.[20]

Denery-Papini et al. identified dominant epitopes bound by IgE from DG allergic patients. They corresponded to deamidated repetitive peptides of γ and ω2-gliadins containing two or three Glu residues.[15] As the sequences of these deamidated peptides are absent in native gluten or gliadins, we therefore hypothesized that they would be a good target for the specific detection of DG. In this study, we present the production of mAbs and the development of a competitive ELISA that specifically detects deamidated gluten.

MATERIALS AND METHODS

Gliadin and Glutenin Subunit Purification. Gliadins were extracted from wheat flour (cultivar Hardi) using a sequential procedure.[21] Briefly, the albumins/globulins (water/salt soluble proteins from wheat flour) were extracted from flour with a saline buffer. After three washings, the insoluble components were suspended in 70% (v/v) ethanol for 1 h at room temperature, and after centrifugation, the supernatant, i.e. the total gliadins were collected. The gliadin classes (α, γ, ω2, and ω5) were then prepared by ion-exchange chromatography and reversed-phase HPLC[3,22] and lyophylized. LMW-GS were obtained by the procedure of Verbruggen et al.[23] After pre-extraction of gliadins, glutenin subunits were solubilized from flour at 60 °C with 50% propanol containing 1% dithiothreitol. LMW-GS were then selectively precipitated with a final concentration of 85% propanol. Protein content of the fractions was determined by the Kjeldahl method.

Preparation of Deamidated Wheat Protein Fractions. Purified α-, ω2-, and ω5-gliadins, total gliadins, and LMW-GS were deamidated by acidic treatment as previously described.[24] A set of total gliadin fractions deamidated to different extents was also prepared. Gliadins (10 mg) were solubilized in 1 mL of 50% (v/v) ethanol, 0.1 N hydrochloric acid, and heated at 90 °C for 40, 60, 90, and 120 min. At each time, the reaction was stopped by neutralization with 1 mL 0.1 N NaOH. Solutions were dialyzed by ultrafiltration on AMICON centrifugal units with a MWCO at 3000 Da and centrifuged at 10 000 g, and the supernatant was recovered and freeze-dried. The degree of deamidation was calculated as the ratio of the amount of ammonia released from the deamidated sample to the total ammonia in the native sample and expressed as a percentage. Ammonia release was determined according to manufacturer's instructions (K-AMIAR, Megazyme, Ireland) after complete deamidation (3 h in 2 M HCl at 110 °C) of each sample. The deamidated Gliadins (D-Glia) were analyzed by native-PAGE on 10% acrylamide gels and compared with native gliadins.

Native and Functionalized Industrial Gluten Samples. VITAL Gluten (AIT Ingredients ref M120406) has been used as a native gluten reference. Four functionalized gluten samples (FG) described as wheat protein isolates with enhanced solubility in aqueous solution or with high emulsifying properties were selected for this study, referred to hereafter as FG1 to FG4. FG1 and FG2 were acid hydrolyzed gluten samples, already described by Krogshbo et al.[25] (with a deamidation level of 20−30% and 60%, respectively). FG3 and FG4 have been used in cosmetics. FG3 was provided by ALPOL Cosmétique (France), and FG4 was provided by Prof. Moneret-Vautrin (CH Epinal). No information was available about the processes used for neither their preparation nor their degree of deamidation or hydrolysis. Without any availability of the raw gluten used in these processes, measurement of the percentage of deamidation was not possible. They were characterized by native PAGE.

mAb Generation. Three BALB/c mice were injected subcutaneously twice at two-week intervals with 20 μg of the synthetic peptide LQPEEPFPEQC, conjugated to keyhole limpet hemocyanin (Millegen, France) and emulsified in Titermax Gold Adjuvant (SIGMA, CytRx Corporation, France). Three days after the second immunization, the mice were sacrificed. The popliteal lymph nodes were removed, and the lymphocytes were suspended by perfusion and fused with a SP2/0 myeloma cell line using standard hybridoma preparation and limiting dilution cloning procedures. The hybridoma supernatants from the fusion were screened for the presence of antipeptide antibodies using an indirect ELISA. The five selected hybridomas were cloned by dilution and referred to as INRA-DG1 to INRA-DG5. Crude hybridoma supernatants were used as the source of monoclonal antibodies.

Animal experiments were carried out at the INRA facilities, which are authorized by the Local Veterinary Department (authorization no. 44502). mAb production was approved by the Ethical Comity of Pays de la Loire under the number CEEA-2011.26.

Indirect ELISA. Reactivity of the antibodies to gliadins and LMW-GS, either native or deamidated, was assessed by indirect ELISA as described by Battais et al. for sample preparation and coating.[22] Uncoated sites were blocked with 4% defatted skimmed milk in phosphate-buffered saline (PBS) at pH 7.4 for 1 h. Hybridoma supernatants diluted 250 times in PBS containing 0.1% skimmed milk were then added and incubated for 1 h at room temperature. After washing with PBS 0.05% Tween 20, bound antibodies were detected by incubation with horseradish peroxidase antimouse IgG (Bio-Rad, Marnes-la-Coquette, France, 1:3000 dilution) and orthophenylenediamine as the substrate. Color development was stopped with 100 μL of 2 M H_2SO_4, and the absorbance was read at 492 nm.

Epitope Mapping with Solid-Phase Synthetic Peptides (Pepscan). Impact of the deamidation of the immunogenic peptide on mAb interaction was explored with octapeptides prepared by automated spot synthesis and covalently fixed by their C-terminal end on a cellulose membrane (Abimed, Langenfeld, Germany) as previously described.[15] After washing for 5 min with ethanol and three times for 5 min with Tris 50 mM buffer at pH 8.0 containing 0.05% Tween 20 (v/v) (TBS/T), the membrane was blocked with 2.5% (w/v) skimmed dried milk and 5% (w/v) sucrose in TBS/T for 1 h, washed in TBS-T and incubated overnight with mAb supernatant diluted 4000 times. After further washing, horseradish peroxidase antimouse IgG (170-6516, Bio-Rad) diluted 1/100 000 in blocking buffer was added for 1 h and washed. The membrane was then incubated with a chemiluminescent substrate (SuperSignal West Dura Extended Duration Substrate; Pierce, Rockford, IL). mAb binding was revealed by chemiluminescence with a CCD camera (Luminescent Image Analyzer LAS 3000; Fujifilm, Tokyo, Japan).

Competitive Inhibition ELISA. Microtiter plates (Maxisorp, NUNC, Roskilde, Denmark) were coated with LQPEEPFPEQC conjugated to BSA in 10 mM carbonate-bicarbonate buffer (pH 9.6) and left overnight at 4 °C. D-Glia and FGs were solubilized at 1 mg/mL in water or in PBS, taking into account their protein content. They were further diluted from 20 μg/mL to 8 ng/mL in PBS containing 0.1% skimmed milk prior incubation with INRA-DG1 mAb for 2 h at 37 °C. Then, 100 μL of antibody-sample solution was added to plates coated in BSA-LQPEEPFPEQC and incubated for 1 h. After washing, bound mAbs were revealed as previously described by indirect ELISA. Inhibition of antibody binding was expressed as the percentage of the maximal response obtained with antibody in the absence of the competitor according to the following formula:

$$\%\text{inhibition} = 1 - (\text{sample OD}/\text{blank sample OD})$$

Inhibition curves were obtained and fitted with a four parameter logistic regression. IC50 was defined as the analyte concentration that causes 50% inhibition of antibody binding. Limit of detection (LOD) expressed as a percentage of the inhibition unit was calculated with an

DOI: 10.1021/acs.jafc.5b00923
J. Agric. Food Chem. 2015, 63, 5403−5409

absorbance value equal to the mean value of the blank samples −3.3 × SD.

R5 ELISA kits were purchased from R-Biopharm (RIDASCREEN Gliadin competitive kit, Darmstadt, Germany). Samples were extracted in 60% (v/v) ethanol and analyzed according to the manufacturer's instructions. D-Glia and FGs were analyzed in triplicate in the INRA-DG1 competitive assay and in duplicate in the R5 competitive ELISA. FG2 was used in triplicate when chosen as standard.

Analysis of Wheat and Related Species, Maize, Soya, and Rice Flours. Grains of bread wheat (cv. apache), durum wheat (cv. Neodur), einkorn (cv. pays de sault), spelt (cv. rouquin), rye (cv. caroass), barley (cv. vanessa), oat (cv. evora), and triticale (cv. tremplin) were ground in liquid nitrogen. Maize, rice, and soya flour were purchased in food store. Soluble proteins were extracted by suspending flour at 100 mg/mL in PBS for 1 h, at room temperature under continuous agitation. Supernatants were collected after centrifugation (10 min/2500*g*), diluted at 1:20 in PBS containing 0.1% skimmed milk, and applied in the INRA-DG1 competitive ELISA.

Assay Evaluation. Reproducibility and repeatability were determined with three solutions of FG2 solubilized in water at 1 mg/mL and further diluted at 1000, 200, and 40 ng/mL in PBS containing 0.1% skimmed milk. Each solution was analyzed in quadruplicate on three different days by the same manipulator on freshly coated plates and with three independent standard solutions. We prepared contaminated rice flour samples spiked with 20 mg/kg of each FG. A 5 g portin of rice flour were suspended in 49.9 mL of PBS and 100 μL of FGs at 1 mg/mL (100 μg) and incubated for 1 h at room temperature. After centrifugation (2500 g/10 min), supernatants were collected and diluted at 1:20 in PBS 0.1% skimmed milk before analysis in the competitive ELISA.

Statistical Analysis. Mean and standard deviation were calculated with Excel 2010 (Microsoft) software.

RESULTS

MAbs Production and Specificity. MAbs were produced against the peptide LQPEEPFPEQC containing a dominant epitope QPEEPFPE recognized by patients suffering from an allergy to deamidated gluten.[15] The supernatants of the resulting hybridomas were screened by indirect ELISA for their reactivity to the peptide LQPEEPFPEQC conjugated to BSA. Five of them secreting mAbs specific for the immunogenic peptide were selected. They were denoted as mAbs INRA-DG1 to DG5.

Their substrate specificity was explored by indirect ELISA with native or deamidated α-, γ-, ω2-, and ω5-gliadins and LMW-GS. The five INRA-DG mAbs were specific for deamidated samples. They were divided into two groups according to their profiles of reactivity: the first was represented by INRA-DG1 and the second corresponded to INRA-DG2, -DG3, -DG4, and -DG5, which were represented by INRA-DG2 (Figure 1). mAb INRA-DG1 showed similar binding intensities for all deamidated fractions and it bound weakly to the native ω2-gliadins. mAb INRA-DG2 displayed a more restricted profile of reactivity as it only bound strongly to three deamidated fractions: γ-, ω2-, and ω5-gliadins; it exhibited weak reactivity to deamidated α-gliadins and LMW-GS and no binding to the native gluten proteins. The contribution of the number and the position of Glu residues to the binding of mAbs DG1 and DG2 was then investigated by the pepscan technique on a set of 16 peptides representing all the possible Q/E substitutions of the immunogenic peptide QPEEPFPE (Figure 2, peptide no. 2). Both mAbs recognized four deamidated peptides. All of them were deamidated to at least 50%. The position of the Q/E substitution appeared of importance: at position 1, it did not affect binding to the mAbs;

at position 3, it was not essential, but strongly enhanced the binding intensity; Q/E substitutions at position 4 and 8 were absolutely required for peptide recognition. Thus, epitopic sequences were the same for both MAbs and corresponded to peptides XPXEPFPE, where X is Q or E.

Characterization of Deamidated Gliadins and Functionalized Gluten Samples. Deamidated gliadin fractions with levels of deamidation ranging from 15% to 48% (elsewhere referred to as D-Glia-15% to D-Glia-48%) were produced. Their analysis on native PAGE reveals that the apparent mobility of proteins increased with their deamidation

DOI: 10.1021/acs.jafc.5b00923
J. Agric. Food Chem. 2015, 63, 5403−5409

level under these conditions (Figure 3). Contrarily, native gliadins were almost unable to migrate in these conditions.

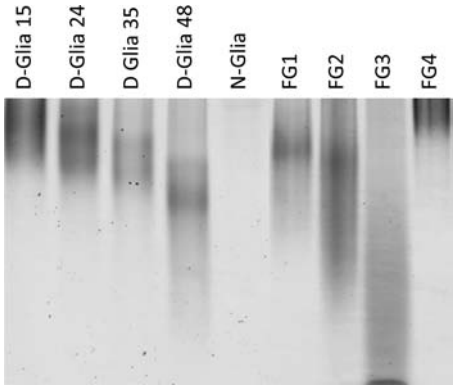

Figure 3. Analysis by native PAGE of deamidated gliadins (D-Glia) at various deamidation levels (15%, 24%, 35%, and 48%), native gliadins (N-Glia), and industrial functionalized gluten samples (FG).

Analysis of these samples illustrated that negative net charge increased proportionally to the duration of acid hydrolysis. Functionalized gluten samples (FG) were subjected to the same analysis by native PAGE. All FG samples were able to migrate along the gel at different distances from the top of the gel revealing that they contained different levels of negative charges. FG1 was very similar to D-Glia-35%. FG2 and FG3 displayed more mobility and a more heterogeneous pattern. The pattern of FG3 suggested that concomitantly with deamidation, strong hydrolysis had occurred. FG4 displayed lower mobility, similar to D-Glia-15%.

Development of Competitive Indirect ELISA. Considering its broad reactivity to deamidated gluten proteins, INRA-DG1 mAb was selected for assay development. Since deamidated gluten may also be cleaved, a competitive format was chosen for the ELISA. Two competitive assays were tested with either deamidated gliadins or the peptide LQPEEPFPEQC conjugated to BSA for coating on the microplates. The similarity of results (data with deamidated gliadins not shown) led us to choose the peptide LQPEEPFPEQC conjugated to BSA for coating the solid phase because it could be easily produced with good reproducibility. Two parameters were then explored to optimize the sensitivity of the ELISA: the concentration for the coating antigen and the antibody dilution. A lower IC50 with D-Glia-48% indicated higher sensitivity. It was reached for a coating performed at 0.75 μg/mL and a dilution of 1:4000 for the DG1 supernatant. Using these conditions, we checked for the reactivity of purified native gliadins and GS. None of them were detected in the competitive assay (data not shown).

Analysis of Samples by Competitive R5 and INRA-DG1 ELISA. Detection of the deamidated gliadin fractions was compared by means of two competitive ELISAs, the first based on the INRA-DG1 mAb, and the second based on the R5 antibody.[26] Increasing percentages of deamidation progressively impaired the detection of gliadins by the competitive R5 assay (Figure 4a). IC50 obtained with D-Glia-15%, −24%, −35%, and −48% were 3, 4, 8, and 50 times lower, respectively, than that of standard in the kit (pepsic/tryptic digest of prolamins from wheat, rye, and barley). The opposite effect of deamidation was observed with the INRA-DG1 assay (Figure 4b) since D-Glia 48% was the better recognized sample while

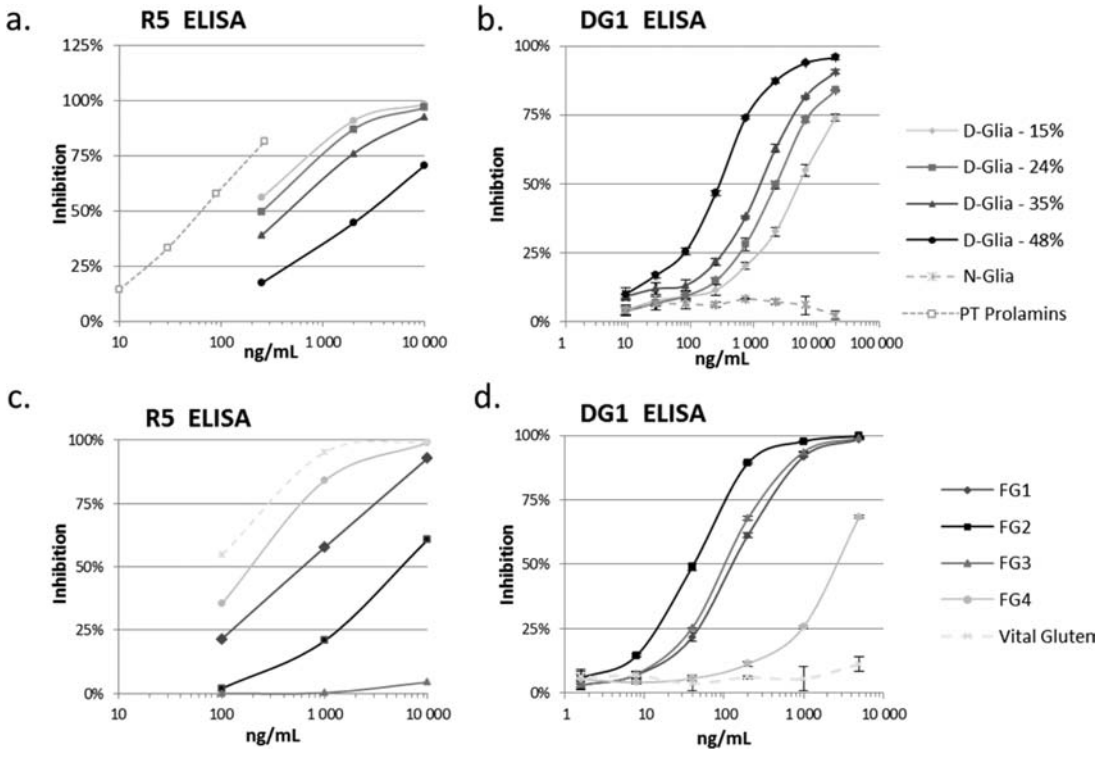

Figure 4. Analysis by indirect competitive ELISA of deamidated gliadins (D-Glia) at various deamidation levels (15%, 24%, 35%, and 48%), native gliadins (N-Glia), industrial functionalized gluten samples (FG), and vital gluten. D-Glia (a) and FG (c) were analyzed by the R5 competitive ELISA. D-Glia (b) and FG (d) were analyzed by the INRA-DG1 Competitive ELISA. Pepsic trypsic digested prolamins from wheat rye and barley (PT-Prolamins).

DOI: 10.1021/acs.jafc.5b00923
J. Agric. Food Chem. 2015, 63, 5403−5409

D-Glia-15% gave the weaker response. Moreover, the absence of response with native gliadins confirmed that deamidation was absolutely required for DG1 binding.

FG samples and vital gluten were then analyzed with both R5 and INRA-DG1 competitive assays. In the competitive R5 ELISA, decreasing responses to FG4, 1, and 2 were observed and were 3, 10, and 100 times lower, respectively, than to vital gluten (Figure 4c). There was no response to FG3. In the competitive INRA-DG1 ELISA vital gluten was not detected while all FG samples were (Figure 4d). In terms of response intensity, FG4, 3, 1, and 2 gave increasing responses in the INRA-DG1 assay. It should be noted that FG3, which was undetected by the R5 assay, was detected similarly to FG1 with the INRA-DG1 competitive ELISA.

Immunoassay Evaluation. Performance evaluation of the competitive ELISA was performed with eight concentrations of FG2 ranging from 3 to 7500 ng/mL in PBS, which were chosen as the standards. A typical standard curve is presented in Figure 5. On the basis of three independent experiments, IC50 and a blank value were calculated as 85 ± 16 and 16 ± 2.8 ng/mL, respectively. Taking into account interassay variation, LOD was set at 25 ng/mL (mean of blank −3.3 × SD), which corresponded to 21% inhibition. Repeatability and reproducibility were assessed with three solutions of FG2 at 40, 200, and 1000 ng/mL in PBS. They were analyzed in quadruplicate in three independent experiments for evaluation of intra- and interassay variations. The intra-assay coefficients of variation (CV) ranged from 2.1% to 6.2%, and the interassay CVs were 7.8%, 5.1%, and 20.3% for the 1000, 200, and 40 ng/mL solutions, respectively (Table 1).

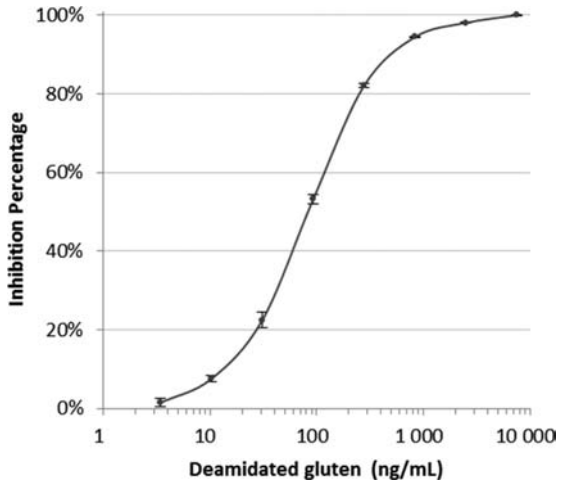

Figure 5. Competitive inhibition curve of FG2.

Soluble proteins extracted from common cereal grains (four wheat species, rye, barley, oat maize, and rice) and from soya seeds were used to check their potential cross reactivity in our assay. None of these extracts caused inhibition over the LOD of the assay (data not shown).

Application to Contaminated Rice Flour (20 mg/kg). Contamination of rice flour was performed with the four FG samples at 20 mg/kg and quantified in the INRA-DG1 ELISA. This level of contamination led to significant percentages of inhibition for FG1, 2, and 3, but not for FG4 (Table 2). Recoveries were then determined using FG2 as standard. Recovery of the FG2 was excellent since it reached 100%. Recoveries of FG1 and FG3 were 42% and 52% respectively.

Table 1. Repeatability and Reproducibility of INRA-DG1 Competitive ELISA Determined at Three FG2 Concentrations

A (ng/mL)	assay	mesured amount (ng/mL)	recovery (%)	intra-assay CV (%)	interassay CV (%)
1000	1	882 ± 54	88	6.1	
	2	1045 ± 31	105	3.0	7.8
	3	1049 ± 62	105	5.9	
200	1	202 ± 12	101	6.2	
	2	222 ± 5	111	2.1	5.1
	3	203 ± 5	101	2.7	
40	1	50 ± 3	124	5.5	
	2	61 ± 4	152	6.1	20.3
	3	64 ± 3	134	4.4	

Table 2. Percentage of Inhibition and Recoveries of FG Samples Spiked at 20 mg/kg in Rice Flour and Analyzed in INRA-DG1 Competitive ELISA

	% inhibition	SD[a]	recovery
FG1	24%	2%	42%
FG2	47%	1%	100%
FG3	29%	2%	52%
FG4	11%	1%	NA

[a]Standard deviation.

These values were expected since FG 1 and FG3 were less recognized than the standard (FG2) by INRA-DG1 mAb.

DISCUSSION

Patients allergic to DG possess IgE specific for peptides derived from the domains containing repetitive sequences of γ- and ω2-gliadins where glutamine has been replaced by glutamic acid. Denery-Papini et al. determined that the peptide QPEEPFPE was a dominant epitope for patients allergic to DG but tolerant to native wheat.[15] Part of this epitope, PEEPFP, has also been found in Japanese patients sensitized by a soap containing DG.[27] After immunizing mice with the synthetic peptide LQPEEPFPEQC, we selected mAbs capable of discriminating between deamidated gluten proteins and their native counterparts. One of them, mAb INRA-DG1, appeared extremely interesting for detection purposes as it bound both deamidated gliadins and deamidated LMW-GS. In accordance with the sequence similarities between the repetitive domains of native gliadins and those of LMW-GS, such cross reactivities are frequent and have already been observed with a large set of mAbs directed toward native domains containing repetitive sequences of gliadins;[28] the same phenomenon was observed after deamidation. We identified four epitopes of mAb INRA-DG1. None of them were present in extenso in all gliadins and LMW-GS. Further exploration is required for complete epitope mapping. When compared to mAbs applied to gluten detection, INRA-DG1 mAb differs from others by its capacity to specifically detect DG with high sensitivity. To date, most of, if not all, commercial kits designed for gluten detection are based on antibodies targeting the repetitive sequences of gliadins.[18] These sequences rich in glutamine are susceptible to deamidation. Kits based on R5, but also on Skerritt's or G12 mAbs[29,30] were incapable of properly detecting deamidated gluten: their binding to gluten deamidated at 52% was abolished for Skerritt's and G12 mAbs or strongly reduced for R5.[20,31] In this study, we demonstrated that the decrease of

DOI: 10.1021/acs.jafc.5b00923
J. Agric. Food Chem. 2015, 63, 5403−5409

R5 binding was a continuous phenomenon directly related to the level of deamidation. Even a low deamidation level, such as 15%, induced a 3-fold decrease for R5 mAb recognition. On the contrary, INRA-DG1 mAb was able to detect gliadins deamidated at levels varying from 15% to 50%. Moreover, the more the gliadins are deamidated, the stronger the binding. The capacity of DG1 to detect weakly deamidated gliadins (15%) added to the fact that the identified epitopes were deamidated at least by 50% suggested that, as a random process, deamidation in acidic condition is heterogeneous and may result in high percentage of deamidation on small portion of the repetitive sequences.

Furthermore, impaired detection by the R5 assay was also observed with the tested FG samples. It should be noted that one of them (FG3) was not even detected. This sample appeared highly hydrolyzed and the remaining fragments should be of smaller length than in the other FG samples. R5 is known to bind sequences as small as the pentapeptide[32] and the competitive format should allow their detection. This absence of detection of FG-3 by R5 might be attributed to the absence of remaining native sequences.

Repetitive sequences of gliadins and GS, which are homologous, are a target of choice for gluten detection. However, these sequences are not identical and are recognized with different affinity by mAbs; therefore, accurate standardization of gluten assays is still a serious issue.[18] Detection of deamidated gluten faces similar difficulties to which possible hydrolysis and heterogeneity in the level of deamidation of the sample are added. The INRA-DG1 competitive assay was capable of detecting contamination as low as 20 mg/kg in rice flour for 3 of 4 of the DGs tested. The particular behavior of FG4 in both assays—low detection by the DG1 assay and good detection by the R5 competitive assay—can be related to a low deamidation level as suggested by weak mobility in native PAGE. In such a case, the R5 and the INRA-DG1 competitive assays appeared fully complementary. With this set of samples with varying degrees of deamidation, we observed that the more a sample is recognized in one assay, the less it would be in the other assay.

In conclusion, the INRA-DG1 mAb assay described here is useful for the detection of deamidated gliadins or gluten with high sensitivity and specificity. Further experiments are required to validate its applicability to incurred processed food and cosmetic samples.

ABSTRACT: *Rhus verniciflua* (*Toxicodendron vernicifluum*) is a medicinal tree popularly used in Asian countries such as China, Japan, and Korea as a food additive or herbal medicine because of its beneficial effects. *R. verniciflua* extract (RVE) contains diverse phenolic compounds, such as flavonoids, as its major biological active constituents. In this study, the pharmacokinetic profiles of eight phenolic compounds were investigated following oral administration of RVE to rats. The eight phenolic compounds were 2,4-dihydroxybenzoic acid, 3,4-dihydroxybenzoic acid, fisetin, fustin, butin, sulfuretin, taxifolin, and garbanzol. The plasma concentrations of the eight compounds were determined by using a liquid chromatography−triple-quadrupole mass spectrometer before and after treatment with β-glucuronidase. When 1.5 g/kg RVE was administered, the eight compounds were all detected in plasma, mainly as conjugated forms. These pharmacokinetic data would be useful for understanding the pharmacological effects of RVE.

KEYWORDS: *Rhus verniciflua Stokes, phenolic compounds, bioanalytical method, pharmacokinetics*

INTRODUCTION

Rhus verniciflua (*Toxicodendron vernicifluum*) is a medicinal tree cultivated in Asian countries, including China, Japan, and Korea. It has been traditionally used as a health food, herbal remedy, or food additive.[1,2] *R. verniciflua* contains medicinal ingredients with diaphoretic, cathartic, antiviral, sedative, and antirheumatic activities.[3] There are many reports on the pharmacological activities of *R. verniciflua* extracts (RVE). These include antioxidant activity,[2,4−9] antiproliferative activity with growth of human lymphoma cells,[1] anti-inflammatory activity,[10] antimutagenic activity,[11] apoptotic effects,[12,13] and antimicrobial activity.[14]

These pharmacological activities of RVE are believed to be attributed to its bioactive ingredients, such as phenolic compounds. In previous chemical studies,[15] diverse phenolic compounds, such as caffeic acid, 2,4-dihydroxybenzoic acid (2,4-DHBA), *p*-coumaric acid, chlorogenic acid, protocatechuic acid, garbanzol, fisetin, kaempferol, kaempferol-3-*O*-glucoside, quercetin, butein, butin, gallic acid, fustin, 2,6,3′,4′-tetrahydroxy-2-benzylcoumaran-3-one, and sulfuretin, have been reported as constituents of RVE. These phenolic compounds have been shown to exhibit various beneficial effects.[8,9,15,16] For example, fisetin exhibited anti-inflammatory activity.[17] Fustin exerted neuroprotection on 6-hydroxydopamine-induced cell death.[18] Butin has a protective effect against hydrogen peroxide-induced apoptosis via its antioxidant properties,[19] 2,4-DHBA showed an antioxidative activity for free radical scavenging,[20] and 3,4-DHBA exhibited antioxidant, anti-inflammatory, antihyperglycemic, and anti-apoptotic activities.[21] Sulfuretin exhibited anti-inflammatory activity and therapeutic value in preventing β-cell damage.[22−24] Garbanzol showed anti-inflammatory and antinociceptive effects,[25] and taxifolin inhibited oxidative stress and cell apoptosis to prevent diabetic cardiomyopathy in vivo and in vitro.[26]

However, to our knowledge, pharmacokinetic studies of the bioactive phenolic compounds in RVE have not been performed, although pharmacokinetics is crucial for providing evidence of biological activity in vivo and for understanding the action mechanisms of functional foods. As for analytical methods for RVE, only a few published methods are available, which are high-performance liquid chromatography (HPLC)-based methods.[15] Furthermore, bioanalytical methods for the quantitation of phenolic compounds of RVE in biofluids or tissues have not yet been reported.

In this study, a precise, accurate, and sensitive method based on liquid chromatography−tandem mass spectrometry (LC-MS/MS) for the simultaneous quantitation of eight phenolic compounds of RVE (Figure 1) in rat plasma was developed. Pharmacokinetic profiling of the phenolic compounds was investigated following oral administration of RVE to rats using the developed method. Subsequently, we presented the pharmacokinetic properties of phenolic compounds of RVE as conjugated metabolites as well as parent forms.

MATERIALS AND METHODS

Chemicals. Sulfuretin and fustin were purchased from Extrasynthese (Genay Cedex, France). Chrysin, fisetin, butin, garbanzol,

at 100 °C and then filtered for removal of impurities. The extract was added to 10% ethanol and 50% dextrin and concentrated through spray-drying. The final desiccated extract was used for the pharmacokinetics experiments.

Calibration and Quality Control (QC) Standards. Each analyte was dissolved in dimethyl sulfoxide at a concentration of 1 mg/mL to make a stock solution. The working standard mixture was prepared by diluting and combining each stock solution with methanol. The internal standard solution (IS; 2.5 μg/mL chrysin) was prepared in methanol. The working standard mixture (50 μL) was spiked into 450 μg/mL of blank rat plasma to prepare calibration (1, 2, 5, 10, 20, 50, 100, 200, 500, and 1000 ng/mL) and QC (2, 100, and 1000 ng/mL) standards. All standard samples were kept in a freezer (−20 °C) until they were analyzed.

Sample Preparation. Fifty microliters of plasma was added to 200 μL of phosphate-buffered saline (PBS; pH 7.2) with IS (5 μL) and 10% ascorbic acid (10 μL) and extracted with 1 mL of ethyl acetate. For β-glucuronidase-treated samples, 50 μL of plasma was added to 200 μL of PBS with β-glucuronidase (1.4 units), and it was incubated for 60 min at 55 °C. After incubation, the mixture was spiked with IS (5 μL) and 10% ascorbic acid (10 μL) and extracted with 1 mL of ethyl acetate. The organic layer was taken and evaporated to dryness. The residue was reconstituted in 70% MeOH (100 μL) and transferred to an LC vial.

LC-MS/MS Analysis. An Agilent 6460 triple-quadrupole mass spectrometer with an Agilent 1260 Infinity HPLC system (Agilent Technologies, Palo Alto, CA, USA) was used for LC-MS/MS analysis. A Poroshell 120 EC-C18 column (50 × 3.0 mm, 5 μm; Agilent) was used, and column temperature was adjusted to 40 °C. The mobile phase was composed of (A) 0.1% formic acid and (B) 90% acetonitrile with 0.1% formic acid. The flow rate was 0.25 mL/min, and gradient elution was used as follows: 10−90% B for 3 min; 90% B for 1 min; and re-equilibrium (10% B) for 4 min. Electrospray ionization was used in negative ion mode. Multiple reaction monitoring (MRM) was employed. The precursor/product ion pairs were m/z 153 → 109 for 3,4-DHBA and 2,4-DHBA; m/z 287 → 109 for fustin; m/z 303 → 285 for taxifolin; m/z 271 → 243 for garbanzol; m/z 285 → 135 for fisetin; m/z 271 → 135 for butin; m/z 269 → 133 for sulfuretin; and m/z 253 → 143 for chrysin (IS). Dwell time for each transition was set at 150 ms.

Method Validation. The analytical method validation was conducted according to the U.S. FDA guideline for bioanalytical method validation (2001).

The calibration curve was generated using eight concentration levels of calibration standards in triplicate. The intraday assay for precision and accuracy was conducted by repeated analyses (n = 5) of QC samples at three concentrations (2, 100, and 1000 ng/mL) for each analyte. The interday assay was performed by repeated analyses on five consecutive days. The precision was presented as percent coefficient of variation (%CV). The accuracy was presented as percentage recoveries to nominal concentration. Freeze-and-thaw stability was tested at three concentrations (20, 100, and 500 ng/mL). The QC samples were frozen at −20 °C for 24 h and thawed completely at room temperature. After this cycle had been repeated two times more, the samples were analyzed. The QC samples were also tested for long-term (−20 °C for 2 weeks) and short-term (room temperature for 4 h) stabilities. Postpreparative stability was tested 24 h after the prepared QC samples had been kept in an autosampler (4 °C).

Animals. Male Sprague−Dawley rats (270−300 g, 8 weeks old) were purchased from NaRa Biotech Co. (Pyungtaksi, Korea). The rats

were housed in a temperature-controlled (23 ± 2 °C) and moisture-controlled (55 ± 10%) room under a 12 h light/dark cycle and allowed access to food and water. The rats were fasted overnight and until 6 h after dosing. All animal care and experimental procedures were approved by the Institutional Animal Care and Use Committee of Hanyang University (2015-0019).

Pharmacokinetic Experiments. RVE (1.5 g/kg) in 3 mL of water was orally administered to the rats. Whole blood samples were collected by cannulating a polyethylene tube (PE-50) into the carotid artery at intervals of 1, 2, 4, 6, 8, 10, 12, and 24 h after dosing. The collected samples were centrifuged at 15000g for 5 min to obtain plasma. The plasma samples were kept frozen at −20 °C until they were analyzed.

RESULTS AND DISCUSSION

LC-MS/MS Method Development. The quantitative method for eight phenolic compounds of RVE, including fisetin, fustin, butin, sulfuretin, taxifolin, garbanzol, 2,4-DHBA, and 3,4-DHBA, was developed using LC-MS/MS. The LC-MS/MS method covering all of these phenolic compounds is not available, but there are several published papers describing the LC-MS/MS condition for each analyte.[15,27,28] Therefore, we referred to and modified those reported methods to optimize our sample preparation method and LC-MS/MS conditions for sensitive, reproducible, and rapid analysis for all analytes. Eepresentative MRM chromatograms obtained from the optimized method are displayed in Figure 2. Subsequently, the method validation was performed regarding the parameters as follows.

Specificity. The specificity of the method was evaluated by comparing MRM chromatograms of 2,4-DHBA, 3,4-DHBA, fisetin, fustin, garbanzol, taxifolin, butin, sulfuretin, and chrysin for blank plasma, plasma spiked with standards, and plasma obtained 1 h after oral administration of RVE. As shown in Figure 2, there was no interfering peak at the retention time for each analyte in blank matrix.

Matrix Effect. The postextraction method was used to evaluate the matrix effect. The test was performed at three concentrations for all analytes: 20, 100, and 500 ng/mL. The percent recovery was >90% at all concentrations for all analytes (data not shown). This indicated that the ion suppression by matrix effect was negligible in the present method.

Linearity and Lower Limit of Quantitation (LLOQ). Good linearity (R > 0.998) was observed in the calibration curves (1−1000 ng/mL) for all analytes. The back-calculated data for all concentration points except LLOQ showed acceptable accuracy (85−115%) and precision (≤15%). The LLOQ was 1 ng/mL for all analytes as the resulting data met the criteria for accuracy within 80−120% and precision of ≤20%.

Precision and Accuracy. For all QC levels, the intraday precision was <12.1% and the accuracy was 86.9−106.9%. The interday precision was <15.0% and the accuracy was 85.0−109.9% (Table 1). Thus, the intra- and interday assay results met the criteria for analytical method validation on the basis of U.S. FDA guidelines, indicating that the present method is accurate and precise.

DOI: 10.1021/acs.jafc.5b01724
J. Agric. Food Chem. 2015, 63, 5410−5416

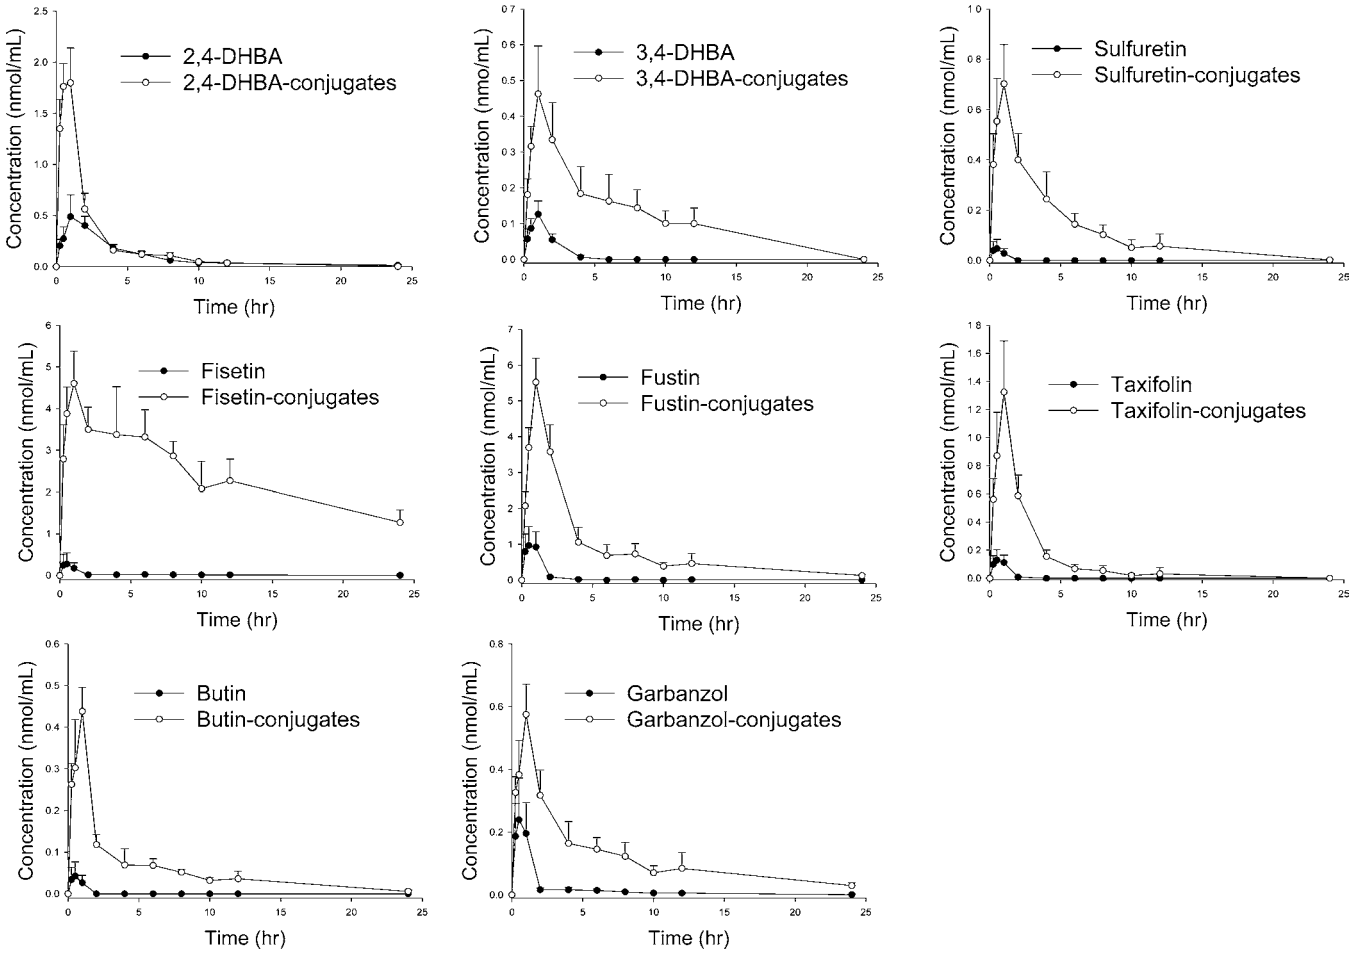

Figure 3. Plasma concentration−time profiles of eight phenolic compounds after oral administration of 1.5 g/kg *Rhus verniciflua* extracts.

Stability. The stability of the eight compounds was evaluated under various storage and process conditions (Table 2). All compounds were stable in rat plasma after three freeze/thaw cycles (91.8−110.6); at room temperature for 4 h (87.1−109.0) and at −20 °C for 2 weeks (85.0−102.0%). In addition, the processed samples were stable in the autosampler for 24 h (85.5−116.7%).

Pharmacokinetic Profile of the Phenolic Compounds and Their Conjugated Metabolites. After oral administration of RVE to rats, the plasma concentrations of the eight phenolic compounds were determined and further analyzed following β-glucuronidase treatment to obtain the plasma concentration profile of the conjugated metabolites. The plasma concentration of the conjugated metabolites was calculated by subtracting that of the free forms from the values of the β-glucuronidase-treated samples. Figure 3 shows the plasma concentration−time curves for the free and conjugated forms of each analyte. The resultant pharmacokinetic parameters are presented in Table 3.

Prior to the pharmacokinetic study, the content of each phenolic compound in RVE was measured by using the developed LC-MS/MS method. The contents of fisetin, fustin, butin, sulfuretin, taxifolin, garbanzol, 2,4-DHBA, and 3,4-DHBA were 4.048, 5.560, 0.457, 0.334, 1.077, 0.769, 0.087, and 0.101 mg/g, respectively. When RVE was orally administered, the plasma concentration level of the free forms was generally low throughout all time points, although the content of each ingredient was different. The C_{max} of the free forms ranged from 0.04 to 1.01 nmol/mL, and the AUC values were between 0.03 and 1.42 nmol·h/mL. In contrast, the plasma concentration level of the conjugated forms was higher than that of the free forms for most of the compounds. The C_{max} of the conjugated forms ranged from 0.44 to 5.53 nmol/mL, and the AUC values were between 1.38 and 57.65 nmol·h/mL. On the basis of the AUC values, the plasma levels of the conjugated forms were approximately 2−100 times greater than that of the corresponding free forms. These results indicate that the phenolic compounds circulate mainly as a conjugated form after being absorbed, which suggests that the conjugated forms might be associated with the biological activity of RVE in vivo.

The pharmacokinetics of phenolic compounds or flavonoids have been extensively investigated. According to the review paper by Manach and Donovan,[29] the pharmacological effects of flavonoids depend on their absorption from the gastrointestinal (GI) tract and subsequent metabolism, and flavonoids show different behaviors in absorption, metabolism, and clearance. Thus, the content of flavonoids in the extracts is not necessarily related to their plasma concentration (or the plasma concentration of their metabolites). In addition, flavonoids undergo extensive first-pass phase II biotransformation processes, such as sulfation, glucuronidation, or methylation, in the small intestine and liver following absorption from the GI tract. Such general pharmacokinetic properties of flavonoids were well observed in our study. In particular, our data indicated that fisetin and fustin were considered the principal bioactive molecules responsible for the pharmacological activity

of RVE in terms of pharmacokinetic properties as well as chemical composition.

In conclusion, we developed and validated an accurate, reliable, and sensitive LC-MS/MS method to determine eight phenolic compounds and their conjugate metabolites in rat plasma. The developed method was applied to investigate the pharmacokinetics of the phenolic compounds of RVE and their conjugate metabolites in rat plasma. The present results provided the pharmacokinetic properties of the phenolic compounds of RVE to investigate the underlying pharmacological mechanisms of RVE.

Supporting Information

ABSTRACT: The grumixama (*Eugenia brasiliensis* Lam.), also known as Brazilian cherry, is a fruit native to Brazil. This study identified the flavonoids in the flesh and seeds and ellagitannin in the flesh of purple and yellow varieties. The physicochemical characteristics and antioxidant capacity of these fruits were also evaluated. Anthocyanins and flavonols were found in high levels in the flesh of purple (32−180 mg 100 g^{-1} FW) and yellow grumixama (13−41 mg 100 g^{-1} FW), respectively. The major flavonoids identified were cyanidin 3-glucoside and quercetin aglycone. Furthermore, ellagitannins were found in high levels in the flesh of purple (82−243 mg ellagic acid equiv 100 g^{-1} FW) and yellow grumixama (92 mg ellagic acid equiv 100 g^{-1} FW) and seeds (2220−2905 mg ellagic acid equiv 100 g^{-1} FW). The ellagitannin profiles of both varieties were first characterized in which pedunculagin isomers, strictinin isomers, and ellagic acid galloyl hexoside were the major ellagitannins identified. In summary, both varieties of the grumixama fruit as well as the seeds could be good sources of bioactive compounds, mainly ellagitannins.

KEYWORDS: *ellagitannins, anthocyanins, grumixama, bioactive compounds*

INTRODUCTION

The grumixama (*Eugenia brasilienses* Lam.) belongs to the Myrtaceae family and is a native fruit of the southern and southeastern regions of the Atlantic Forest of Brazil. It is a fruit similar to a cherry, approximately 2.0 cm in diameter, containing one or many seeds, and is somewhat sweet. Three varieties were recognized by Cambessèdes (1832−1833) according to their fruit colors: The α-variety or purple fruit is the most common and is known as the Brazilian cherry.[1,2] The β-variety has red fruit, and the γ-variety has white fruit, although it was also described by Mattos (1984) as being yellow.[2] Despite belonging to the same species, the yellow and purple varieties show distinct chemotypes with respect to the terpene profiles in the leaves and fruits.[2] Grumixama is rarely consumed as a fresh fruit, but is commonly used to produce fruit juice and frozen pulp, with the pulp frequently containing a mixture of the purple and yellow forms. Although still limited, commercial cultivation has begun in recent years, and this plant represents economic potential due to the attractive sensory attributes and phenolic compounds in its composition, including ellagitannins and flavonoids.[1,4]

In general, fruits belonging to this family are known to be good sources of bioactive compounds.[3−5]The purple grumixama fruit was shown to be rich in anthocyanins, mainly cyanidin-3-glucoside, and carotenoids, mainly monohydroxy carotenoids such as *all-trans*-β-cryptoxanthin.[1,6] High antioxidant capacity[3] and anti-inflammatory activity[1] have been demonstrated. However, no information about phenolic composition, the antioxidant capacity, or other biological activities of the yellow fruit was previously available.

The leaves of grumixama have been used in folk medicine for the treatment of several diseases including arthritis, diabetes, and rheumatism and have showed antidepressant-like[7] and anti-inflammatory activities,[8] which are attributed to their phenolic compounds.

As a member of the Myrtaceae family, in addition to the flavonoids, grumixama would also be expected to be rich in ellagitannins and ellagic acid derivates, another class of phenolic compounds. This class of phenolics is relatively uncommon in dietary fruits and vegetables, although a few berries, such as strawberry, raspberry, blackberry, and pomegranate, have substantial contents of these compounds.[9−11] It has been suggested that ellagitannins as well as flavonoids may prevent chronic diseases such as cancer and cardiovascular diseases. These protective activities are attributed to both classes of phytochemicals, which are thought to provide antiproliferative,[12] anti-inflammatory, and antioxidant activities[11,14−16] and to function as glycemic regulators.[12,13,17]

Therefore, given the importance of bioactive compounds in the promotion of health, the aim of this study was to conduct a systematic analysis of the phenolic compounds, specifically the

ellagitannins and flavonoids, in the purple and yellow grumixama fruits and the seeds of these plants.

MATERIALS AND METHODS

Chemicals. Fluorescein, 2,2′-azobis(2-methyl-propanimidamide) dihydrochloride (AAPH), 2,2-diphenylpicrylhydrazyl (DPPH), trifluoroacetic acid, ytterbium acetate, sucrose, glucose, fructose, catechin, epicatechin, epigallocatechin gallate, gallocatechin gallate, epicatechin gallate, quercetin, gallic acid, ellagic acid, and proanthocyanidin B1 and proanthocyanidin B2 were purchased from Sigma-Aldrich (St. Louis, MO, USA). Quercetin 3-glucoside, myricetin, cyanidin-3-glucoside, cyanidin, and delphinidin were purchased from Extrasynthese (Genay, France). Methanol and acetic acid were purchased from Merck Millipore (Darmstadt, Germany). All other chemicals used were of analytical or HPLC grade.

Plant Materials. The fruits of the yellow and purple grumixama were collected in the southeastern and southern regions of Brazil. Twelve kilograms of purple grumixama was acquired by local producers in the Vale do Paraiba (Sítio do Bello farm) located in São Paulo state, and 4 kg of grumixama was provided by Epagri-Itajaí located in Santa Catarina state. Both samplings were collected in December 2012 and January 2013. Yellow grumixama (4 kg) was acquired by Sitio do Bello farm in December 2012. The fruits of the purple and yellow grumixama were separated into flesh (F) and seed (S) and named F1 and F2 (from São Paulo state), F3 and F4 (from Santa Catarina state), and S1, S2, S3, and S4, respectively. The samples designated F5 and S5 corresponded to the yellow variety. All fruits were harvest at ripening stage and stored at −70 °C until analysis. Samples were thoroughly homogenized by powdering in liquid nitrogen to perform the analysis.

Physicochemical Analyses. The analysis of the protein content was performed according to the Kjedahl method, using the nitrogen conversion factor of 5.75 for vegetable proteins (AOAC, no. 950.48).[18,19] The moisture and lipid contents were analyzed according to the methods described by AOAC (AOAC, no. 925.40 and 948.22, respectively).[18,19] The fiber content was measured according to the method described by AOAC (no. 985.29).[18,19] The soluble solids (°Brix) were determined using a hand-held refractometer (AOAC, no. 932.12).[20]

Soluble Sugars Content. The samples were extracted with 80% ethanol (v/v) at 80 °C for 30 min under stirring. The soluble sugars were analyzed by high-performance liquid chromatography (HPLC) coupled to a pulse amperometric detector (PAD) using a one-Dionex DX500 system (Dionex, Thermo Scientific, Waltham, MA, USA), equipped with a CarboPac PA1 column (4 mm × 250 mm) (Dionex), using a mobile phase consisting of 18 mM NaOH, at a flow rate of 1 mL min^{-1} for 25 min. The quantification was based on an external calibration using sucrose, glucose, and fructose.[21]

Total Phenolic Content, Monomeric Anthocyanins, and Antioxidant Capacity. Three replicate samples (0.5 g) were extracted with 70% methanol containing 5% acetic acid (25 mL) using an ultraturrax (Polytron Kinematica GnbH, Kriens-Luzern, Switzerland), followed by 30 min of stirring at 5 °C and then filtration. These extracts were used to assess total phenolic content, monomeric anthocyanin content, and antioxidant capacity. The assays were carried out in triplicate. The total phenolic content was measured using the Folin−Ciocalteu method, and the absorbance was measured at 763 nm.[22] The results were expressed as gallic acid equivalents per 100 g of sample. The monomeric anthocyanin content was determined using the pH differential method.[23] The monomeric anthocyanin pigment concentration was calculated using the molar absorptivity of cyanidin 3-glucoside (ε = 26900) and expressed as milligrams of cyanidin 3-glucoside equivalents per 100 g of sample. The antioxidant capacity was analyzed using the DPPH[24] and oxygen radical absorbance capacity (ORAC) methods[25] and expressed as millimoles of trolox equivalents per 100 g of sample. All results were expressed as fresh weight.

Ellagitannin Content. The samples were extracted with 80% acetone and dried under nitrogen. An aliquot of the extract was added to 2 M trifluoroacetic acid and hydrolyzed at 120 °C for 120 min, according to the method of Giner-Chávez et al. with a slight modification.[26,27] The hydrolyzed samples were evaporated to dryness under nitrogen, redissolved in methanol, and filtered through a 0.43 μm PTFE filter (Millipore Ltd., Bedford, MA, USA) for HPLC-DAD analysis as described for the phenolic compounds. Ellagic acid (EA) was used to construct the calibration curve, and the results were expressed as milligrams of total EA equivalents per 100 g of sample.

Identification and Quantification of Phenolic Compounds. The samples were extracted with 70% methanol, acidified with 5% acetic acid, using an ultraturrax (Polytron Kinematica GnbH), and filtered. The extract was then concentrated by removal of the methanol under vacuum at 40 °C on a rotary evaporator (Rotavapor RE 120; Buchi, Flawil, Switzerland) prior to application to a solid-phase extraction column. The extract was passed through a polyamide column (1 g) (CC 6, Macherey-Nagel Gmbh and Co., Duren, Germany) previously conditioned with methanol and ultrapure water. The sample was loaded onto the column and washed with ultrapure water. The phenolic compounds were eluted with 0.3% HCl in methanol. The eluates were completely dried using a rotary evaporator under vacuum at 40 °C, resuspended in methanol, and filtered through a 0.45 μm PTFE filter (Millipore Ltd.) for the quantification of flavonoids and phenolic acids by HPLC-DAD analysis.[28]

Analysis of Phenolic Compounds by Reversed-Phase HPLC-DAD. Identification and quantification of the phenolic compounds was performed using a 1260 Infinity Quaternary LC System (Agilent Technologies, USA), with an autosampler and a quaternary pump, coupled to a diode array detector (DAD). The column used was a 5 μm Prodigy ODS3 column (4.60 × 250 mm) (Phenomenex Ltd., UK) with a flow rate of 1 mL/min at 25 °C. The mobile phase consisted of two solvents: solvent A, 0.5% formic acid in water, and solvent B, 0.5% formic acid in acetonitrile. The solvent gradient was applied as follows: 10% B at the beginning, 10% at 5 min, 20% at 15 min, 25% at 25 min, 35% at 33 min, 50% at 38 min, 90% at 43−44 min, and 10% at 45 min. Anthocyanins were detected by monitoring the elution at 525 nm, and other flavonoids were monitored at 270 nm. The phenolic compounds were identified by comparing their retention times, diode array spectral characteristics, and mass spectra, measured using LC-ESI-MS/MS, with the standards and the data available in the literature. The calibration was performed using commercial standards.[28]

Identification of Ellagitannins. Approximately 5 g of sample was extracted with 80% acetone and evaporated to eliminate the acetone. An aliquot of 0.1 M ytterbium acetate was added to the aqueous extract and held overnight at 5 °C. The precipitate (ET-Yb) was centrifuged at 3000*g* for 10 min at 5 °C. The precipitate was washed three times, twice with 80% acetone and once with pure acetone. The precipitate was subsequently dissolved in 10 mM oxalic acid, and the supernatant was dried under nitrogen, resuspended in methanol and filtered using 0.43 μm PTFE membrane filters (Millipore Ltd.) for LC-ESI-MS/MS analysis.[29]

LC-ESI-MS/MS Analysis. The identification of the flavonoids and ellagitannins was performed by LC-ESI-MS/MS using a Prominence liquid chromatograph (Shimadzu, Japan) linked to an ion trap Esquires-LC mass spectrometer (Bruker Daltonics, Billerica, MA, USA) with an electrospray ionization (ESI) interface. The solvent gradient conditions were the same as those used for the HPLC-DAD process. After passing through the DAD, the flow rate was changed to 0.2 mL/min for application to the mass spectrometer. The ESI was used in the positive mode to detect the anthocyanins and in the negative mode for the other classes of flavonoids. The mass spectrometer operating conditions were as follows: collision energies of 4500 and 4000 V were used for the positive and negative mode, respectively, and the capillary temperature was 275 °C. The analysis was carried out using a full scan from m/z 100 to 1500. The compounds were identified according to comparison with the retention times of authentic standards when possible, as well as by absorption spectrum similarity, mass spectral characteristics, and comparison with literature data.[28]

Identification and Quantification of Proanthocyanidin. The freeze-dried samples (0.8 g) were homogeneized with extraction

[a]Results are expressed as g/100 g. ND, not detected; Tr, trace. Values shown are the means (standard deviation). Purple fruit was designated F1, F2, F3, and F4; yellow fruit was designated F5; F1, F2, and F5, from São Paulo state; F3 and F4, from Santa Catarina state. [b]Correction factor for vegetable proteins: 5.75.

solution (acetone/water/acetic acid, 70:29.5:0.5, v/v/v) using an Ultraturrax followed by sonication in an ultrasonic bath for 15 min. The homogenates were centrifuged at 2000*g* for 10 min. The acetone was evaporated under reduced pressure at 35 °C and passed through a Sep-Pack C-18 solid phase extraction cartridge (Waters, Milford, MA, USA) and washed with Milli-Q water. The phenolic compounds were eluted with methanol. The eluates were completely dried using a rotary evaporator under vacuum at 40 °C, resuspended in methanol, and filtered through a 0.45 μm PTFE filter (Millipore Ltd.) for the quantification of proanthocyanidins by HPLC-DAD analysis. For strawberry proanthocyanidin analysis (cv. Camarosa), used to compare proanthocyanidin profile, the same protocols was applied.

Normal Phase HPLC-DAD of Proanthocyanidin Extract. The analysis was carried out as reported previously.[30] The same HPLC equipment described above was used. The column used was a Develosil Diol (4.60 × 250 mm, 5 μm) (Phenomenex Ltd., UK) with a flow rate of 1 mL/min at 25 °C. The mobile phase consisted of two solvents: solvent A, CH_3CN/HOAc (98:2, v/v), and solvent B, CH_3OH/H_2O/HOAc, 95:3:2, v/v/v). The solvent gradient was applied as follows: 0% B at the beginning, 40% at 35 min, and 40% at 45 min. UV detection was set at 280 nm, and fluorescence detection used excitation at 276 nm and emission at 316 nm. The calibration was performed using commercial standards of proanthocyanidin B1 and proanthocyanidin B2.

Statistical Analysis. The results were expressed as the mean values ± standard deviation. Analysis of variance (ANOVA) followed by the Tukey test was performed using Biostat 5.0.

RESULTS AND DISCUSSION

Chemical Composition. Table 1 shows the chemical composition for the flesh of purple grumixama, collected in two different places and times (F1, F2, F3 and F4), and a single sample of the flesh of the rarer yellow variety (F5). According to the °Brix values, all fruits analyzed were at the same ripening stage, but there were slight differences but not significant in the chemical composition among the fruits harvested at different times and places. Glucose was the main sugar found in these fruits, which is compatible with the results for a ripe berry fruit, due to the hydrolysis of sucrose during ripening.[31,32]

Soluble Total Phenolic and Monomeric Anthocyanin Contents and Antioxidant Capacity. Figure 1A shows the results for the soluble total phenolic and monomeric anthocyanin contents for the flesh and seeds. All seeds of purple grumixama, collected in different places and times, presented higher content of total phenolic content (varying from 2.51 ± 0.09 to 3.3 ± 0.12 g 100 g^{-1} fresh weight, FW) than the respective flesh (varying from 0.18 ± 0.01 to 0.75 ± 0.02 g 100 g^{-1} FW). Among the flesh samples, F1 and F4 showed the highest total phenolic, values similar to those found in Brazilian blackberry cultivars (from 0.34 ± 0.01 to 0.50 ± 0.01 g 100 g^{-1} FW).[32] The flesh of purple grumixama contained high contents of the monomeric anthocyanin, varying from 30 to 200 mg 100 g^{-1} FW, where F1 and F4 presented values similar to those founded in Brazilian blackberry cultivar Guarani (*Rubus* sp.) (190 mg 100 g^{-1} FW).[33] Differences in flavonoids and phenolic contents were observed in several vegetables and could be due to agronomic conditions, plant tissue, and varieties. Anthocyanins were not detected in the yellow fruit or in its seeds. The yellow fruit presented the lowest total phenolic content (0.18 ± 0.01 g/100 g FW); however, there was no difference in the phenolic content in the seeds of the two varieties. These results indicate

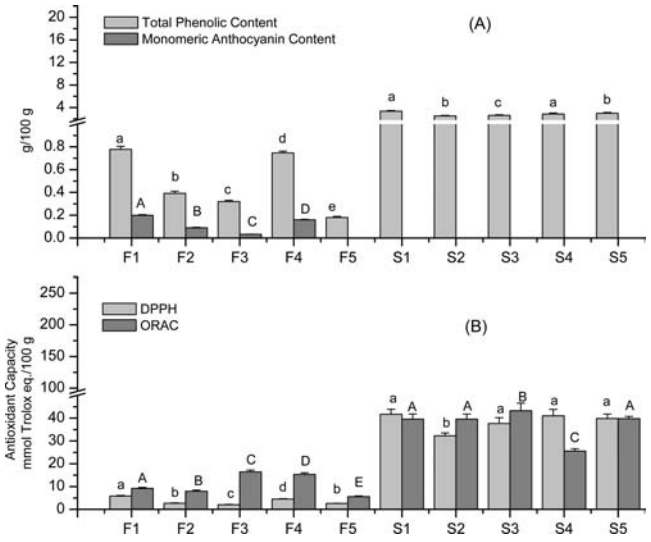

Figure 1. Total phenolic and monomeric anthocyanin contents (A) and antioxidant capacity (B) analyzed by DPPH and ORAC methods for the flesh (F1, F2, F3, F4, and F5) and seeds (S1, S2, S3, S4, and S5) of *Eugenia brasilienses* Lam., purple and yellow fruits. The monomeric anthocyanin and total phenolic contents are expressed as cyanidin-3-glucoside and gallic acid equivalents, respectively. The values are expressed as fresh weight for the flesh. The statistical analyses were performed among the different parts of grumixama. The same letters indicate nonsignificant differences among the samples ($p < 0.05$).

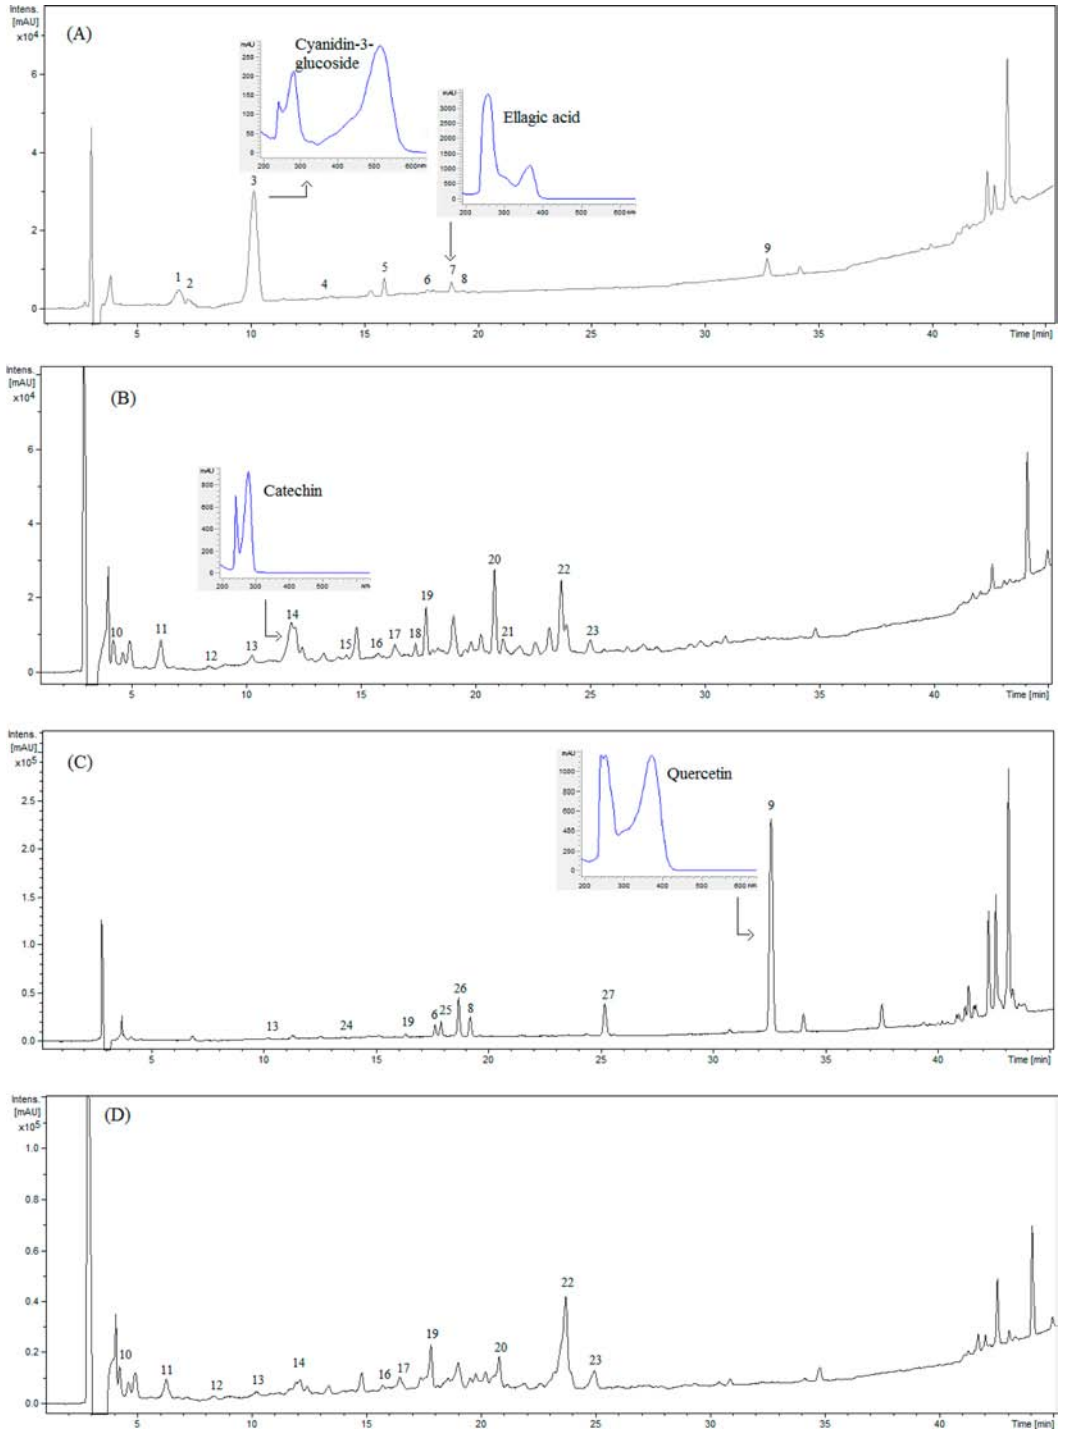

Figure 2. Chromatograms obtained by HPLC-DAD (λ = 270 nm) of the purple (A) and yellow (C) flesh, seeds of purple grumixama (B), and seeds of yellow grumixama (D). The identification of the peaks is given in Table 2.

that the place and time of fruit harvesting do not influence the phenolic or anthocyanin contents of grumixama.

Figure 1B shows the antioxidant capacity evaluated by the DPPH and ORAC methods. The flesh showed the lowest antioxidant capacity values by both methods. No significant differences ($p < 0.05$) with respect to the place or harvest period were observed among the fruits or seeds. Due to their structure, phenolic compounds possess high antioxidant capacities, and these compounds represent one of the main phytochemical classes responsible for the total antioxidant capacity of plant-derived food.[16] Thus, a high correlation (Pearson correlation) was observed between the total phenolic content and the DPPH values (r = 0.93) as well as the ORAC (r = 0.87) values. There was also a strong correlation between the content of monomeric anthocyanins and total phenolic compounds (r = 0.97), suggesting an influence of the phenolic compounds in the antioxidant capacity. In addition, ascorbic acid, an important hydrophilic antioxidant present in fruits, was not detected in the flesh of either the purple or yellow variety.

Identification of Flavonoids and Phenolic Acids. Figure 2 shows the HPLC-DAD chromatograms of the flesh of the purple and yellow grumixama fruits (A and C, respectively) and

[a]RT, retention time. [b]Peaks are numbered according to Figure 2A (flesh of the purple grumixama), Figure 2C (flesh of the yellow grumixama), Figure 2B (seeds of the purple grumixama), and Figure 2D (seeds of the yellow grumixama). [c]Percentage was calculated from the total area of the chromatograms at 525 nm for anthocyanins and 270 nm for the other compounds. [d]Compounds were identified by comparison with retention time of standards and mass fragment profile and UV−vis absorption spectra. [e]Tr, traces, <0.01.

seeds (B and D, respectively), and the respective identification of the compounds by LC-ESI-MS/MS is shown in Table 2.

Fruits. Eight compounds were identified in the flesh of each of the two varieties, the purple and yellow grumixama. In the flesh of the purple fruit, two classes of flavonoids (five anthocyanins and two flavonols) and one phenolic acid were identified. In the flesh of the yellow fruit, two classes of flavonoids (four flavonols and two flavanols) and two ellagic acid derivatives were detected. Among these, two flavonoids were common to both fruits (peak 8, quercetin 3-glucoside at m/z 463, and peak 9, quercetin aglycone at m/z 301). As expected, anthocyanins were detected only in purple grumixama. Specifically, this fruit contained two anthocyanidins, cyanidin and delphinidin, with characteristic molecular ions at m/z 287 and 303, respectively. Peaks 6 (at m/z 615), 10, and 12 (at m/z 633) were identified as ellagitannins, and their identification is further discussed below.

The major class of compounds present in the purple grumixama fruit was anthocyanins (82% of total identified compounds), whereas the yellow fruit was dominated by flavonols (74% of total identified compounds). The major anthocyanins present in the purple grumixama were delphinidin hexoside (peak 1, at m/z 465) and cyanidin-3-glucoside (peak 3, at m/z 449), which were responsible for 30 and 61% of total anthocyanins, respectively. In the yellow grumixama, the major flavonols present were quercetin 3-glucoside (peak 8, at m/z 463) and quercetin aglycone (peak 9, at m/z 301), which were responsible for 25 and 53% of total flavonols, respectively.

Peak 1 had a molecular ion at m/z 465 and two MS/MS fragments at m/z 303 $[M - 162]^+$ and at m/z 229, suggesting that this peak represents a delphinidin linked to a hexoside, where the loss of 162 corresponds to a hexose unit. This compound was probably delphinidin-3-glucoside, also identified in purple grumixama.[6] Peaks 2 and 3 had the same molecular ion at m/z 449 and mass fragments at m/z 287 $[M - 162]^+$ and at m/z 213. Peak 3 was identified as cyanidin 3-glucoside, and its identity was confirmed by coelution with the commercial standard. Thus, considering the elution order in relation to cyanidin 3-glucoside, which was consistent with that expected from the reversed phase elution, peak 2 could be cyanidin 3-galactoside, also identified in the purple grumixama.[1,6]

DOI: 10.1021/acs.jafc.5b01195
J. Agric. Food Chem. 2015, 63, 5417−5427

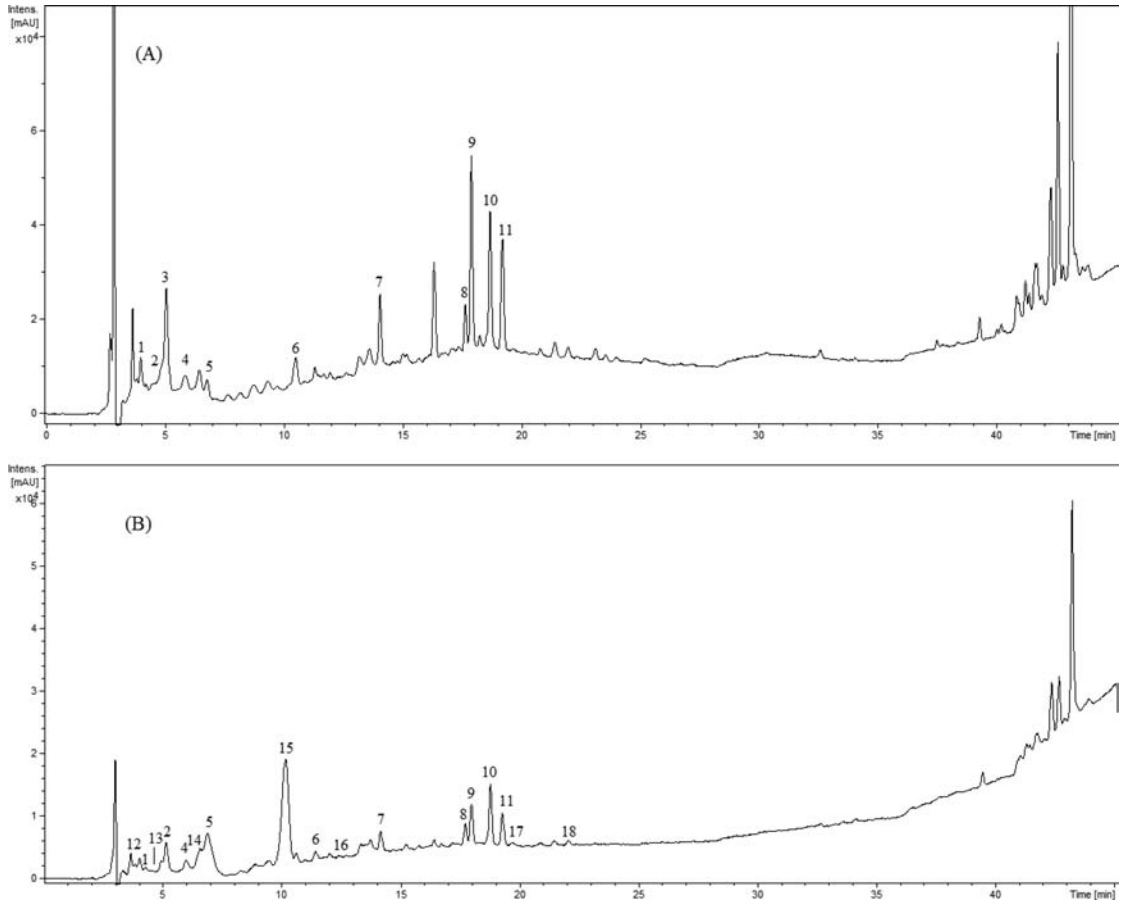

Figure 3. Chromatograms of the ellagitannins extracted using ytterbium acetate obtained by HPLC-DAD (λ = 270 nm) of the flesh of the yellow (A) and purple grumixama (C). The identification of the peaks is given in Table 3.

Peak 4 had a molecular ion at m/z 419 and an MS/MS fragment at m/z 287 $[M - 132]^+$, suggesting that it corresponded to a cyanidin linked to a pentoside: either a xyloside or arabinoside unity.[1] The identity of peak 5 was confirmed by coelution with standard as cyanidin (m/z 287). Peak 7 showed absorption spectra similar to ellagic acid, and its identity was confirmed as ellagic acid (m/z 301) by coelution with commercial standard. Peak 8, identified as quercetin 3-glucoside, had a molecular ion at m/z 463 and one mass fragment at m/z 301, corresponding to quercetin after the loss of a hexose unit (−162 from $[M - H]^-$), and a second fragment at m/z 151. Peak 9, with a molecular ion at m/z 301 and MS/MS fragment at m/z 151, was identified as quercetin aglycone. Quercetin and ellagic acid demonstrated the same characteristic molecular ion at m/z 301. However, on MS/MS analysis, quercetin forms characteristic mass fragments at m/z 179 and 151, whereas the fragments from ellagic acid were observed at m/z 257 and at m/z 229.[34]

In the yellow variety, two flavonols and two flavanols were identified. Peak 27 had a molecular ion at m/z 317, characteristic of myricetin. Peak 19, identified as myricetin hexoside dimeric ion, had a molecular ion at m/z 959 and MS/MS fragments at m/z 479 and at m/z 317 ($[M - H]^- - 162$, corresponding to the loss of a hexose unit).[5,34] Peak 14 showed molecular ions at m/z 579 and at m/z 289 and an MS/MS fragment at m/z 289 ($[M - H]^- - 290$), which suggested it was a catechin dimeric ion. In addition, this compound showed another fragment at m/z 245 (neutral loss of CO_2, 44, from the catechin).[34] A dimeric ion is an ion that is formed by the ionization of a dimer or by the association of an ion with its neutral counterpart such as $[M2]^{\bullet -}$ or $[M - H - M]^-$.[35] Peak 24 had the same molecular ion at m/z 289, characteristic of a catechin isomer, and two mass fragments at m/z 245 and at m/z 203. Peaks 14 and 24 were identified as catechin and epicatechin, respectively, and their identities were confirmed by coelution with the corresponding standards.

The identities of the flavonoids cyanidin-3-glucoside, cyanidin aglycone, quercetin 3-glucoside, quercetin aglycone, and myricetin aglycone, and free ellagic acid were confirmed by coelution with standards and the similarities of the UV−vis absorption spectra and the mass spectral characteristics to those of the standards.

Flavonoids are rarely present in plants as aglycones. Instead, they are usually linked to various sugars.[36,37] It is interesting to observe that high concentrations of the aglycone forms of cyanidin and quercetin were detected in the purple grumixama, and aglycone forms of quercetin and myricetin were detected in the yellow variety of these fruits. No aglycone forms were released when isolated cyanidin-3-glucoside, quercetin-3-glucoside, and quercetin-3-rutinoside were tested in the protocol extraction, excluding the possibility that they were artifacts.

Flores et al.[1] identified nine anthocyanins, of which five were found in the purple grumixama analyzed in this work. In addition, Silva et al.[6] identified three of these and one additional form: cyanidin 3-acetyl-hexoside. However, myricetin, rutin, and kaempferol, also detected by Reynertson et al.[3] in purple grumixama, were not detected in the present study. These differences in the profiles could be due to differences in local

J. Agric. Food Chem. 2015, 63, 5417−5427

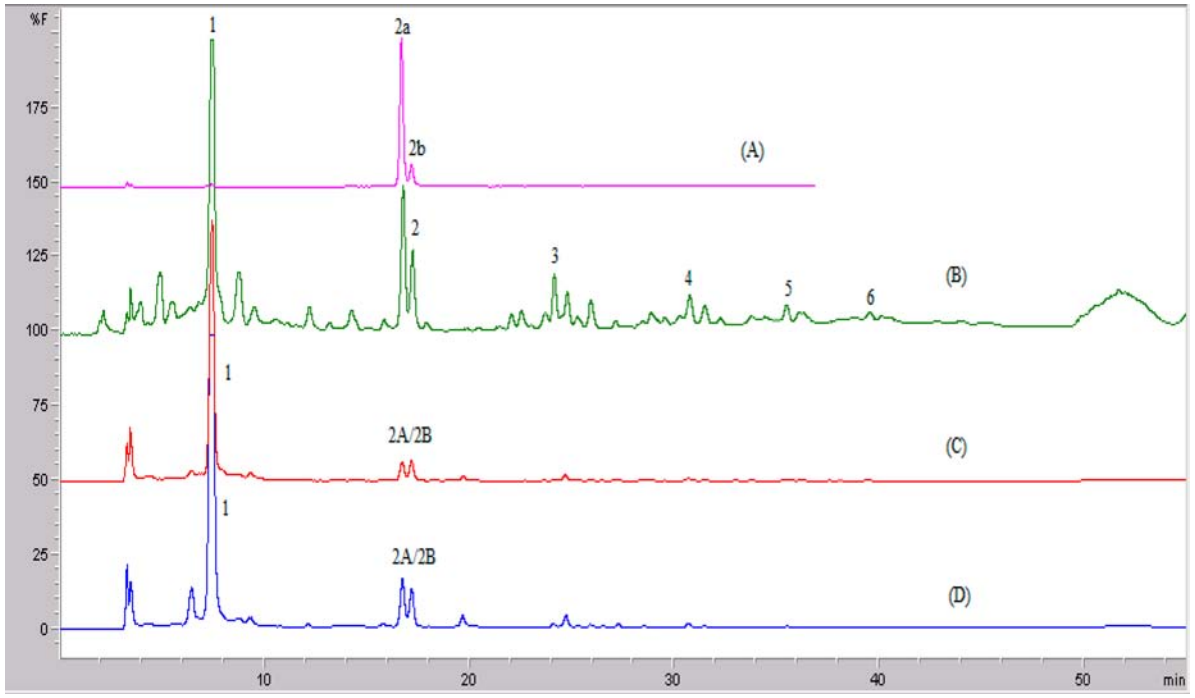

Figure 4. Chromatogram obtained by HPLC-fluorescence of proanthocyanidins in normal phase diol column: (A) proanthocyanidin B1/B2; (B) strawberry extract; (C) yellow grumixama; (D) purple grumixama (cv. Camarosa). The numbers denote the polymerization degree (1, monomers; 2, dimer; 3, timer; etc.). (A) proanthocyanidin B2; (B) proanthocyanidin B1.

plantation and/or agronomic conditions. The phenolic profile of yellow grumixama had not been previously characterized, most likely because this variety is less common than the purple variety. The flavonoid profile of the yellow variety was very different from that of the purple variety. Specifically, the purple and yellow varieties are good sources of anthocyanins and flavonols, respectively.

Seeds. Table 2 presents the compounds identified by LC-ESI-MS/MS in the seeds of the purple and yellow grumixama. The peak numbers in this table refer to the numbered peaks in Figure 2, which identified 12 and 9 phenolic compounds in the seeds of the purple and yellow grumixama, respectively. All compounds identified in the seeds of yellow variety were also found in the purple form. Among the nine compounds present in both seeds, three ellagic acid derivates (peaks 20, 22, and 23, at m/z 927, 489, and 489, respectively), three flavanols (peaks 11, 14, and 16, at m/z 611, 289, and 457, respectively), two flavonols (peaks 17 and 19, at m/z 631 and 959, respectively), and one proanthocyanidin (peak 13, at m/z 577) were identified. In addition to these, in the seed of purple grumixama, four additional compounds were identified: one ellagic acid derivative (peak 18, at m/z 593), two flavanols (peaks 15 and 21, at m/z 457 and 442, respectively), and one flavonol (peak 27, at m/z 317 and 959). Peaks 10 and 12, at m/z 633, were identified as ellagitannins.

The major compounds identified in the seeds of the yellow and purple grumixama were ellagitannins, expressed as total ellagic acid (42 and 38% of the total compounds identified, respectively) and flavanols (28 and 34% of the total compounds identified, respectively).

In addition to myricetin hexoside (at m/z 479), which was also found in the flesh, myricetin galloyl hexoside (peak 17) was identified in seeds of both varieties. Peak 17 showed a molecular ion at m/z 631 and two mass fragments at m/z 479 and 316. The fragment at m/z 479 corresponds to a myricetin hexoside, resulting from the loss of a galloyl group (−152 from $[M - H]^-$).

The phenolic acids or derivatives detected and identified in the grumixama (flesh and seed) have common molecular ions at m/z 301 and 169, which correspond to ellagic acid and gallic acid, respectively. Other structures linked to these phenolic acids included sugars (hexoses and pentoses) and the acetyl group. Examples include ellagic acid hexoside (peak 20, at m/z 463 with an MS/MS fragment at m/z 301) and ellagic acetyl rhaminoside dimeric ion (peak 23, at m/z 489 with an MS/MS fragment at m/z 301), respectively. With the exception of free ellagic acid, all other phenolic acids were identified by comparison with data from the literature.[5,38,39]

Among these compounds (Table 2), catechin, epicatechin, gallocatechin gallate, epigallocatechin gallate, (−)-epicatechin gallate, free ellagic acid, myricetin aglycone, and quercetin aglycone were identified by coelution with the corresponding standards and the similarity of the UV−vis absorption spectra and mass spectra characteristics. The compounds in the seeds had not been previously studied.

Identification of Proanthocyanidin of Fruits. Proanthocyanidin are polymeric flavonoid compounds composed of flavonol-3-ol subunits. Proanthocyandins were the main strawberry phenolics,[30] presenting from dimeric to polymeric forms. Flesh and seed of both grumixama varieties presented dimeric form of proanthocyanidin. None other polymeric form was detected. Peak 13 (Table 2) had a molecular ion at m/z 577 and two MS/MS fragments at m/z 407 and 289, that were identified as proanthocyanidins B1/B2, a dimer of catechin/epicatechin. The identity was confirmed by coelution with the commercial standard (Figure 4).

Identification of Ellagitannins of Fruits. Ellagitannins (ETs) are present in berries and a number of other sources, such as nuts.[10] ETs are hydrolyzable tannins, a class of polyphenols with a structure that consists of esters of

The same letters indicate nonsignificant differences between samples ($p < 0.05$). [b]Delphinidin hexoside was quantified as delphinidin aglycone. [c]Gallocatechin was quantified as catechin. [d]Myricetin derivatives were quantified as myricetin aglycone.

hexahydroxydiphenoyl (HHDP) groups with a polyol core (usually glucose or quinic acid) that often contains galloyl groups.[12,40,41] An ET-enriched fraction was used to identify the ETs by LC-ESI-MS/MS analysis. The ET-enriched fraction was obtained by the precipitation of ETs using ytterbium acetate, which provided an improved separation from other phenolics such as flavonoids.[29]

Figure 3 shows the chromatograms obtained from the flesh of the yellow and purple grumixama (A and C, respectively). The peak numbers indicate the compounds identified, which are listed in Table 3. Seven ellagic acid derivatives were identified in the ET-enriched fraction, as discussed above.

In the flesh of the purple and yellow varieties, 10 and 7 compounds, respectively, were identified as ETs (Table 3). All of the other numbered peaks in the chromatograms were identified as ellagic acid derivatives and flavonoids and are listed in Table 2. Among these, there were six ellagic acid derivatives and cyanidin 3-glucoside in the purple grumixama and four EA derivatives in the yellow one. All of the ETs detected in the flesh of the yellow fruit were also detected in the purple fruit.

Peaks 1 and 3 were identified as C-glycosidic ellagitannins. The molecular ions for both peaks 1 and 3 were at m/z 933, and both produced two mass fragments at m/z 915 and 301 and identified as castalgin/vescalagin isomers. The fragment at m/z 915 resulted from the neutral loss of water ($[M - H]^- - 18$), and the other, at m/z 301, resulted from the neutral loss of 632 (monogalloyl − glucose).[5,42,43] Castalgin/vescalagin isomers were the major ellagitannins in the flesh of the yellow grumixama, corresponding to approximately 61% of the total ETs identified. Peaks 2 and 5 was identified as peduncunlagin isomers (2,3- or 4,6-dihexahydroxydiphenoyl [HHDP]-glucose) with a molecular ion at m/z 783 and three mass fragments: one at m/z 481 resulting from the neutral loss of an HHDP group ($[M - H]^-$ 302) and two others at m/z 301 ($[M - H]^-$ 482, resulting from the loss of an HHDP (302), a glucosyl group (162) and H_2O (18)) and at m/z 257. The fragment at m/z 301 is characteristic of the ellagitannins, and the one at m/z 257 (loss of CO_2) is a typical fragment of ellagic acid.[42−44]

Peaks 4, 12, 13, and 14, identified as strictinin isomers, all had molecular ions at m/z 633 and mass fragments at m/z 481, resulting from the neutral loss of a galloyl group ($[M - H]^- - 152$) and at m/z 301, resulting from the neutral loss of one hexose unity and one molecule of water ($[M - H]^- - 180$ from the loss of glucosyl (162) groups and water (18)) from the fragment at m/z 481.[45] Among these four isomers, only compound **4** was present in both varieties. Peak 8 showed a molecular ion at m/z 615 and MS/MS fragments at m/z 463,

DOI: 10.1021/acs.jafc.5b01195
J. Agric. Food Chem. 2015, 63, 5417−5427

resulting from the loss of a galloyl group from $[M - H]^-$, and at m/z 301, resulting from the loss of one hexose unit (162). Compound **8** was identified as ellagic acid galloyl hexoside. Pedunculagin isomers, strictinin isomers, and ellagic acid galloyl hexoside were the major ellagitannins in purple grumixama, corresponding to 20, 30, and 19%, respectively, of the total ETs identified. Peak 6 had a molecular ion at m/z 935 and yielded MS/MS fragments at m/z 633 ($[M - H]^- - 302$, resulting from the loss of an HHDP group), and at m/z 301 ($[M - H]^- - 634$, resulting from the loss of HHDP (302), gallic acid (170), and glucosyl (162) groups). On the basis of the mass spectra, this peak was identified as a probable casuarictin (galloyl-bis-HHDP-glucoside), an *O*-glucoside isomer.[46]

Isomeric ions have the same numbers of each isotopic atom, but the positions of these atoms differ.[35] Thus, these molecules have different retention times, but the same mass spectra characteristics.

Ten ellagitannins were identified in the flesh of the fruits. Characterization of the ellagitannins had not previously been studied in grumixama. However, the ellagitannins have been studied in other plants from the Myrtaceae family. Various ellagitannins such as telligramadin, pedunculagin, casuarictin, strictinin, vescalagin and castalagin,[5,43,47] including their monomeric forms, were also identified in these studies. However, dimeric ellagitannin forms such as sanguinin H-6 and sanguinin H-10, which are common in berries,[43,46] were not detected in grumixama. Furthermore, oligomeric forms such as melasquanin A, which are common in other species of the Myrtaceae family, were also not identified here.[48]

Quantification of Flavonoids, Phenolic Acids, Proanthocyanidin, and Ellagitannins. The main constituents of the flesh of the purple grumixama were the anthocyanins (32−180 mg of total anthocyanin equiv 100 g^{-1} FW) and ellagitannins, expressed as total ellagic acid (82−243 mg ellagic acid equiv 100 g^{-1} FW) (Tables 4 and 5, respectively). Ellagitannin quantification is based on hydrolysis of these compounds to yield free ellagic acid (EA), which is detected by HPLC. The cyanidin 3-glucoside contributed 82−89% of the total anthocyanin, of which 3−8% was present as cyanidin aglycone. The amount of the anthocyanins found in the flesh by HPLC-DAD analysis is consistent with the monomeric anthocyanin content (Figure 1A). Thus, the anthocyanin concentrations in purple grumixama vary according to harvest time and local plantation. The lowest concentration was similar to those given for several strawberry cultivars, ranging from 23.5 ± 1.9 mg 100 g^{-1} in cv. Aibión to 46.6 ± 2.9 mg 100 g^{-1} FW in cv. Aguedilla,[30] and cranberry (66.7 mg 100 g^{-1}).[43] Also, the highest concentration was similar to that reported for blackberry cultivars, ranging from 80 to 100 mg 100 g^{-1} FW[32] and blueberry (218 mg 100 g^{-1} FW).[43]

The flesh of the yellow grumixama (Table 4) is rich in flavonols (quercetin and myricetin derivatives), corresponding to 41 mg 100 g^{-1} FW with only small amounts of the flavanols (catechin and epicatechin). However, the major components were the ellagitannins (91.72 mg 100 g^{-1} FW) (Table 5).

The flavonoids identified in the seeds were primarily flavonols and flavanols. The total flavanol amounts in seeds varied from 39 to 70 mg 100 g^{-1} FW, whereas the flavonol amounts varied from 14 to 30 mg 100 g^{-1} FW and consisted mainly of myricetin. However, the major compound in seeds was the ellagitannin, expressed as total ellagic acid, contributing 2.22−2.95 g 100 g^{-1} FW.

The flesh of grumixama presented a low concentration of proanthocyanidins B1/B2 (Table 5). The concentration ranged from 0.41 ± 0.04 to 2.01 ± 0.15 mg/100 g FW in the purple grumixama and to 0.79 ± 0.02 mg/100 g FW in the yellow one. These values were lower than reported for several cultivars of strawberry, ranging from 53.9 to 168.1 mg/100 g FW.[30]

The flesh of purple and yellow grumixama fruits was shown to be a good source of anthocyanins and flavonols, respectively, and both were good sources of ellagitannins. Given the biological activities attributed to these classes of compounds (flavonoids and ellagitannins), the purple and yellow fruits show considerable potential as functional foods. The seeds, although inedible, could be used as sources of bioactive compounds, mainly ellagitannins. However, studies regarding the biological activities of these materials are also necessary to elucidate the mechanisms by which the biological effects attributed to this plant could occur.

Table 5. Total Ellagic Acid and Proanthocyanidin Contents in the Flesh of *Eugenia brasiliensis* Lam.[a]

sample	free ellagic acid	total ellagic acid	total proanthocyanidin

Youngiasides A and C Isolated from *Youngia denticulatum* Inhibit UVB-Induced MMP Expression and Promote Type I Procollagen Production via Repression of MAPK/AP-1/NF-κB and Activation of AMPK/Nrf2 in HaCaT Cells and Human Dermal Fibroblasts

Natural Products Research Center, Korea Institute of Science and Technology, Gangneung, Gangwon-do 210-340, Republic of Korea

ABSTRACT: This study investigated the effects of youngiaside A (YA), youngiaside C (YC), and *Youngia denticulatum* extract (YDE) on extrinsic aging and assessed its molecular mechanisms in UVB-irradiated HaCaT keratinocytes and human dermal fibroblasts (HDFs). The results showed that YA, YC, and YDE decreased matrix metalloproteinase (MMP) expression and production in HaCaT cell and HDFs and increased collagen expression and production in HDFs. In addition, YA, YC, and YDE significantly increased antioxidant enzyme expression, thereby down-regulating UVB-induced reactive oxygen species (ROS) production and ROS-induced mitogen-activated protein kinase (MAPK) and activator protein-1 (AP-1) signaling in HaCaT cells. Furthermore, YA, YC, and YDE reduced phosphorylation of IκBα and IKKα/β, blocked nuclear factor-κB (NF-κB) p65 nuclear translocation, and strongly suppressed pro-inflammatory mediators. Finally, YA, YC, and YDE augmented UVB-induced adenosine monophosphate activated protein kinase (AMPK) phosphorylation and YA and YC did not inhibit MMP-1 production in AMPK inhibitor or nuclear factor-erythroid 2-related factor-2 (Nrf2) siRNA-treated HaCaT cells. The results suggest that these compounds could be potential therapeutic agents for prevention and treatment of skin photoaging.

KEYWORDS: *youngiaside, Youngia denticulatum, UV, MMPs, type I procollagen*

INTRODUCTION

Skin photoaging is classified into extrinsic aging and intrinsic aging. Extrinsic aging can be triggered by ultraviolet (UV) radiation, stress, or smoking and is characterized by wrinkles, laxity, and dryness.[1] UV radiation consists of three components, UVA, UVB, and UVC. Whereas UVA and UVB reach the Earth in sufficient amounts to damage the skin, UVC is almost completely absorbed by the ozone layer.[2] UVB is particularly damaging, as it penetrates the epidermis and the upper part of the dermis, where it damages keratinocytes and leads to sunburn, photoaging, and skin cancer.[3] UVB radiation activates activator protein-1 (AP-1) and nuclear factor-κB (NF-κB) in the skin, thereby increasing the production of inflammatory cytokines and matrix metalloproteinases (MMPs) in keratinocytes.[4] These cytokines stimulate fibroblasts to promote the production of MMPs, which degrade the extracellular matrix (ECM).[5]

UVB radiation also promotes the generation of intracellular reactive oxygen species (ROS). ROS induce many harmful effects including DNA damage, inflammatory reactions, and damage to ECM integrity.[6] UVB-induced ROS production triggers growth factor receptors, cell surface cytokines, and mitogen-activated protein kinase (MAPK) cascades such as c-Jun N-terminal kinase (JNK), extracellular signal-regulated kinase (ERK), and p38 kinase, which in turn regulate AP-1.[7] Increased AP-1 activity increases MMP-1 production and decreases type I procollagen production.[8] The transcriptional activity of AP-1, a heterodimer composed of c-Jun and c-Fos, is dependent on the degree of c-Jun phosphorylation and c-Fos expression.[8]

The adenosine monophosphate activated protein kinase (AMPK) cascade is a regulator and sensor of cellular energy status. Stresses that consume cellular ATP, such as oxidative stress, hypoxia, nutrient deprivation, and metabolic poisoning, can activate AMPK.[9] Recently, it was reported that AMPK activation plays an important role in MMP-1 expression in human dermal fibroblasts (HDFs) by regulating the upstream and downstream signaling of AMPK.[10] Thus, AMPK activators could be used to prevent UV-induced skin photoaging.

Nuclear factor-erythroid 2-related factor-2 (Nrf2) and Kelch-like ECH associated protein 1 (Keap1) coordinate the transcriptional induction of a large number of antioxidant-metabolizing enzymes, thus affirming the important role of these two proteins.[11] Nrf2 was recently shown to play a central role in protecting cells from UV-induced apoptosis in vitro and acute sunburn reactions in vivo.[12,13] Furthermore, the Nrf2-Keap1 pathway plays an important role in preventing photoaging by maintaining high levels of antioxidants, such as glutathione, in the skin.[14] Thus, Nrf2 activators may also be beneficial for preventing skin photoaging.

Youngia denticulatum is a plant native to Korea, the early sprouts of which have traditionally been eaten as wild vegetables.[15] *Y. denticulatum* contains many phenolic compounds, including chlorogenic acid, dicaffeoylquinic acid, and chicoric acid, all of which exhibit antioxidant activity.[15−18] We recently reported that youngiasides A, B, and C isolated from

Y. denticulatum induce the detoxification enzymes, quinone reductase and CYP1A1, through activation of Nrf2 and the aryl hydrocarbon receptor (AhR).[19] We also reported that *Y. denticulatum* protects liver and retinal cells from oxidative stress-induced damage in vitro and in vivo.[15,20,21] However, it remains unknown whether *Y. denticulatum* and its constituents prevent skin photoaging in HaCaT and HDF cells. Thus, this study was performed to investigate the effects of *Y. denticulatum* extract (YDE) and its active compounds, youngiasides A (YA) and C (YC), on the production of MMPs and type I procollagen in UVB-irradiated HaCaT cells and HDFs and to determine their underlying mechanisms.

MATERIALS AND METHODS

Chemical Reagents. 2′,7′-Dichlorofluorescin diacetate (DCFH-DA) was purchased from Sigma Chemicals (St. Louis, MO, USA). Antibodies against superoxide dismutase (SOD) 1, heme oxygenase (HO)-1, Nrf2, cyclooxygenase (COX)-2, phospho-Akt, phospho-SAPK/JNK (Thr183/Tyr185), SAPK/JNK (Thr183/Tyr185), phospho-p44/42 MAPK (Erk1/2), p44/42 MAPK (Erk1/2), phospho-p38, p38, phospho-IκBα (Ser32/36), IκBα, phospho-NF-κB p65 (Ser536), NF-κB p65, phospho-IκB kinase (IKK) α/β (Ser176/180), IKKα, phospho-c-Jun (Ser243), c-Jun, phospho-c-Fos (Ser32), phospho-AMPKα (Thr172), AMPKα, phospho-acetyl-CoA carboxylase (Ser79), and β-actin were purchased from Cell Signaling Technology (Beverly, MA, USA). Dulbecco's modified Eagle's medium (DMEM) and fetal bovine serum (FBS) were from HyClone Laboratories (Logan, UT, USA). All other chemicals and reagents used were of analytical grade.

Plant Material and Preparation of YA and YC. Whole plants (the aerial component and roots) of *Y. denticulatum* were collected in August 2011 at the Wild Vegetable Experiment Station, Gangwon ARES, Korea, and were identified by one of the authors (C.Y.K.). A voucher specimen (D-043) was deposited at the Natural Product Research Center, KIST Gangneung Institute, Korea. Isolation of chemical constituents (Figure 1A) from *Y. denticulatum* was performed as previously described.[19]

Cell Culture and UVB Irradiation. HaCaT and HDF cells were purchased from the American Type Culture Collection (Manassas, VA, USA). Cells were cultured in DMEM supplemented with penicillin (120 units/mL), streptomycin (75 μg/mL), and 10% FBS in an atmosphere of 5% CO_2 at 37 °C. HaCaT and HDF cells were maintained until 80% confluence and then pretreated with various concentrations of YDE, YA, and YC. After a 1 h incubation, the culture medium was replaced with 1.5 mL of phosphate-buffered saline (PBS). Cells were then exposed to UVB light (15 mJ/cm^2) with a 312 nm UVB light source (VL-6.LM; Vilber Lourmat, Marne-la-Vallée Cedex 1, France). UV strength was measured with a Waldman UV meter (model 585100; Waldman, Wheeling, IL, USA). After UVB irradiation, cells were treated with various concentrations of YDE (5 or 10 μg/mL), YA, and YC (5 or 10 μM) in serum-free medium.

Cell Viability. Cell viability was determined using a 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) (Sigma-Aldrich, St. Louis, MO, USA) colorimetric assay. HaCaT and HDF cells were maintained until 80% confluence and then pretreated with various concentrations of YDE, YA, and YC. After a 1 h incubation, the cells were exposed to UVB (15 mJ/cm^2) and treated with various concentrations of YDE, YA, and YC for 24 h in serum-free medium. Cell medium was replaced with 200 μL of MTT (0.5 mg/mL) and incubated for an additional 3 h. After washing the cells, the insoluble formazan crystals were dissolved in 200 μL of dimethyl sulfoxide. Absorbance at 540 nm was measured by spectrophotometry using a microplate reader (Bio-Tek Instruments, Winooski, VT, USA).

Western Blot Analysis. HaCaT cells were lysed in RIPA buffer containing protease inhibitors and then incubated on ice for 10 min. Protein concentrations of cell lysates were determined by Bradford protein assay (Bio-Rad Laboratories, Hercules, CA, USA). Equal amounts of protein (30 μg) from each sample were loaded and separated by 10% sodium dodecyl sulfate−polyacrylamide gel electrophoresis and then transferred to nitrocellulose membranes (Whatman GmbH, Dassel, Germany). Membranes were initially blocked with 5% skimmed milk in Tris-buffered saline containing 0.1% Tween-20 for 1 h and then incubated with primary antibodies for 16 h at 4 °C. After three washes in Tris-buffered saline containing 0.1% Tween-20, membranes were incubated with horseradish peroxidase-linked secondary antibodies (Santa Cruz Biotechnology, Santa Cruz, CA, USA) for 2 h. Proteins were detected with enhanced chemoluminescence reagents (Amersham Biosciences, Little Chalfont, UK) and visualized using an ECL Advanced system (GE Healthcare, Hatfield, UK).

Enzyme-Linked Immunosorbent Assay (ELISA). HaCaT and HDF cells were cultured in 24-well plates (1×10^5 cells/well) and pretreated with YDE, YA, and YC for 1 h. After washing with PBS, cells were irradiated with UVB (15 mJ/cm^2) through a thin layer of PBS. After UVB irradiation, HaCaT and HDF cells were incubated with serum-free DMEM containing YDE, YA, and YC. Cell culture medium was collected after 24 h, and MMP-1 and type I procollagen productions were quantified using a human MMP-1 ELISA kit (QIA55; Merck & Co. Inc., Whitehouse Station, NJ, USA) and a procollagen type I C-peptide enzyme immunoassay kit (MK101; Takara, Shiga, Japan), respectively.

Reverse Transcription-Polymerase Chain Reaction (RT-PCR). Trizol reagent (Invitrogen, Carlsbad, CA, USA) was used to isolate total RNA from cell pellets. Total RNA was quantified by spectrophotometry at 260 nm. The cDNA was synthesized in a 20 μL reaction containing 2 μg of total RNA, oligo (dT), and Reverse Transcription Premix (ELPIS-Biotech, Daejeon, Korea). PCR amplification of the cDNA products (3 μL) was performed with PCR premix (ELPIS-Biotech, Daejeon, Korea) and the following primer pairs (Bioneer, Daejeon, Korea): MMP-1 forward, 5′-ATT CTA CTG ATA TCG GGG CTT TGA-3′, and MMP-1 reverse, 5′-ATG TCC TTG GGG TAT CCG TGT AG-3′ (409 bp); MMP-2 forward, 5′-ATT CTA CTG ATA TCG GGG CTT TGA-3′, and MMP-2 reverse, 5′-ATG TCC TTG GGG TAT CCG TGT AG-3′ (409 bp); MMP-3 forward, 5′-TGA GGA CAC CAG CAT GAA CC-3′, and MMP-3 reverse, 5′-ACT TCG GGA TGC CAG GAA AG-3′ (248 bp); MMP-9 forward, 5′- GGG CCG CTC CTA CTC TGC CT-3′, and MMP-9 reverse, 5′-TCG AGT CAG CTC GGG TCG GG-3′ (296 bp); collagen, type I, α1 (COL1A1) forward, 5′-CTC GAG GTG GAC ACC ACC CT-3′, and COL1A1 reverse, 5′-CAG CTG GAT GGC CAC ATC GG-3′ (366 bp); collagen, type III, α1 (COL3A1) forward, 5′-TGG TGC CCC TGG TCC TTG CT-3′, and COL3A1 reverse, 5′-TAC GGG GCA AAA CCG CCA GC-3′ (87 bp); tumor necrosis factor α (TNF-α) forward, 5′-AGC CGC ATC GCC GTC TCC TA-3′, and TNF-α reverse, 5′-CAG CGC TGA GTC GGT CAC CC-3′ (163 bp); prostaglandin-endoperoxide synthase 2 (COX-2) forward, 5′-GCC AGC TTT CAC CAA CGG GC-3′, and COX-2 reverse, 5′-CTC CTG CCC CAC AGC AAA CCG-3′ (220 bp); interleukin 6 (IL-6) forward, 5′-TCG AGC CCA CCG GGA ACG AAA-3′, and IL-6 reverse, 5′-AGG CAA CTG GAC CGA AGG CG-3′ (94 bp); p65 forward, 5′-CGC GCC GCT TAG GAG GGA GA-3′, and p65 reverse, 5′-GGG CCA TCT GCT GTT GGC AGT-3′ (197 bp); p50 forward, 5′-AGC AGC GTG GGG ACT ACG AC-3′, and p50 reverse, 5′-GGC TGG GGT CTG CGT AGG GA-3′ (345 bp); superoxide dismutase 1 (SOD1) forward, 5′-ATG GCG ACG AAG GCC GTG TG-3′, and SOD1 reverse, 5′-GAC CAC CAG TGT GCG GCC AA-3′ (360 bp); heme oxygenase 1 (HO-1) forward, 5′-AGG GAA TTC TCT TGG CTG GC-3′, and HO-1 reverse, 5′-GAC AGC TGC CAC ATT AGG GT-3′ (237 bp); Nrf2 forward, 5′-CAG CGA CCT TCG CAA ACA AC-3′, and Nrf2 reverse, 5′-CAT GAT GAG CTG TGG ACC GT-3′ (464 bp); and β-actin forward, 5′-TCA TGT TTG AGA CCT TCA A-3′, and β-actin reverse, 5′-GTC TTT GCG GAT GTC CAC G-3′ (517 bp). Prior to PCR amplification, primers were denatured at 94 °C for 5 min. Amplification consisted of 28 cycles as follows: 30 s denaturation at 94 °C, 1 min annealing at 56 °C, and 1 min extension at 72 °C, followed by a final 5 min extension at 72 °C. PCR was performed on a GeneAmp PCR System 2700

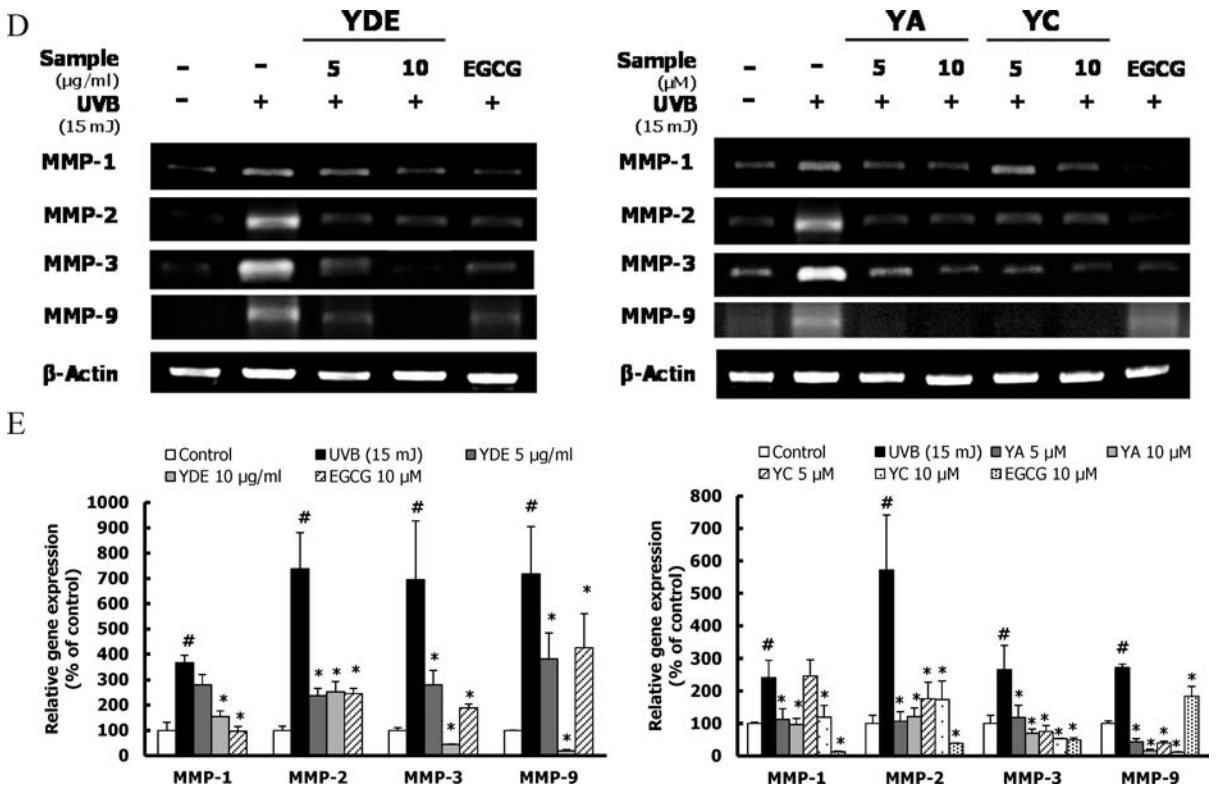

Figure 1. Effects of *Youngia dendiculatum* extract (YDE), youngiaside A (YA), and youngiaside C (YC) on MMP-1 production and MMPs mRNA expression in UVB-irradiated HaCaT cells and human dermal fibroblasts (HDF). (A) Chemical structure of constituents from YDE. HaCaT cells and HDF were treated with different concentrations of YDE and its active compounds, chicoric acid (CRA), 3,5-dicaffeoylquinic acid (DCQA), chlorogenic acid (CA), luteolin 7-*O*-glucuronide (Lute-glu), youngiaside A (YA), youngiaside B (YB), youngiaside C (YC), for 1 h and then exposed to UVB irradiation (15 mJ/cm^2). At 24 h after UVB exposure, (B, C) release of MMP-1 into the culture media was determined by ELISA in HaCaT cell and HDF, respectively. (D, E) mRNA expression of MMP-1, -2 ,-3, and -9 was measured by RT-PCR with regard to YDE, YA, and YC in HaCaT cells. β-Actin was used as an internal control for RT-PCR. Epigallocatechin gallate (EGCG) was used as a positive control. Results are expressed as the mean ± SD (% control) of three independent experiments. (#) $P < 0.05$ compared with vehicle control; (∗) $P < 0.05$ compared with UVB-treated cells.

(Applied Biosystems, Foster City, CA, USA). PCR products were separated by 1.5% agarose gel electrophoresis and visualized with ethidium bromide. β-Actin was used as an internal control. A densitometer was used for RT-PCR on DIG chemiluminescent film (volume of all markers/volume of β-actin).

Measurement of ROS Production. HaCaT cells were pretreated with YDE, YA, and YC for 1 h, washed with PBS, and stained with 40 μM DCFH-DA for 30 min. Cells were then irradiated with UVB (15 mJ/cm^2), and changes in fluorescence intensity were measured using a microplate reader (Bio-Tek Instruments) at excitation and emission wavelengths of 485 and 530 nm, respectively.

siRNA Treatment. The siRNAs targeted against Nrf2 were designed by and purchased from Cell Signaling (Beverly, MA, USA). Transfection of siRNAs (100 pmol) into HaCaT cells was performed with Lipofectamine RNAiMAX (Invitrogen).

Statistical Analysis. All experiments were repeated at least three times, and each experiment was performed in triplicate. Results are presented as the mean ± standard deviation (SD). Statistical analyses were performed using SPSS 12.0 (SPSS Inc., Chicago, IL, USA). Group differences were assessed by one-way analysis of variance (ANOVA), followed by Scheffe's test. A P value of <0.05 was considered statistically significant.

RESULTS

Effects of YDE, YA, and YC on HaCaT and HDF Cell Viability. Potential effects of YDE, YA, and YC on HaCaT and HDF cell viability were evaluated by MTT assay. HaCaT and HDF cells were irradiated with UVB (15 mJ/cm^2) and incubated with YDE, YA, or YC for 24 h. Treatment with YDE (5 or 10 μg/mL), YA, or YC (5 or 10 μM) had no cytotoxic effect on HaCaT and HDF cell viability (data not shown).

Effects of YDE, YA, and YC on MMP-1 Production and MMP mRNA Expression in UVB-Irradiated HaCaT and HDF Cells. Previously we identified and isolated several compounds from YDE.[19] To determine the effect of YDE and these compounds on MMP-1 production, the MMP-1 protein level was examined. YDE inhibited the release of MMP-1 from UVB-irradiated HaCaT cells and HDFs at concentrations of 5 and 10 μg/mL. In addition, we found that YA and YC inhibited MMP-1 production in UVB-irradiated HaCaT cells and HDFs, respectively (Figure 1B,C). Therefore, we selected YA and YC for further study. The results demonstrated that the UV irradiation up-regulated the mRNA levels of collagen-degrading MMPs including MMP-1, MMP-2, MMP-3, and MMP-9. The expression of these genes was down-regulated by treatment with YDE, YA, and YC in UV-irradiated HaCaT cells (Figure 1D,E).

Effects of YDE, YA, and YC on Type I Procollagen Production and COL1A1 and COL3A1 mRNA Expression in UVB-Irradiated HDFs. To investigate the effects of YDE, YA, and YC on type I procollagen production in UVB-irradiated HDFs, cells were exposed to UVB (15 mJ/cm^2), and type I procollagen enzyme activity was measured using a type I procollagen assay kit. Notably, YDE, YA, and YC increased

J. Agric. Food Chem. 2015, 63, 5428−5438

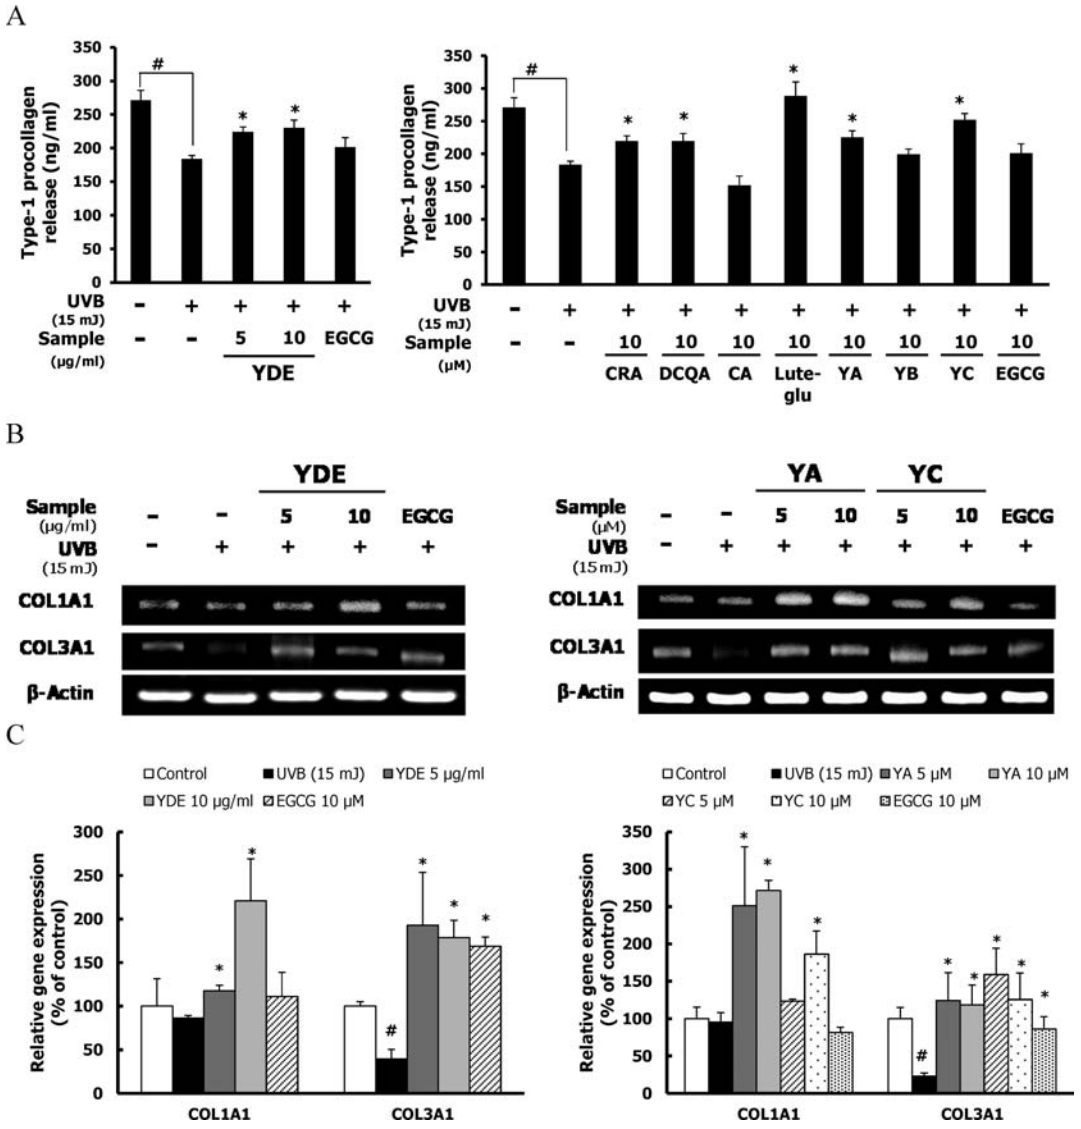

Figure 2. Effects of YDE, YA, and YC on type I procollagen production and COL1A1 and COL3A1 mRNA expression in UVB-irradiated HDF. HDFs were treated with different concentrations of YDE and its active compounds, CRA, CA, DCQA, Lute-glu, YA, YB, and YC, for 1 h and then exposed to UVB irradiation (15 mJ/cm^2). At 24 h after UVB exposure, (A) the amount of type I procollagen secretion into the culture media was determined by ELISA. (B, C) mRNA expression of COL1A1 and COL3A1 was measured by RT-PCR with regard to YDE, YA, and YC. β-Actin was used as an internal control for RT-PCR. EGCG was used as a positive control. Results are expressed as the mean ± SD (% control) of three independent experiments. (#) $P < 0.05$ compared with vehicle control; (*) $P < 0.05$ compared with UVB-treated cells.

type I procollagen protein production and COL1A1 and COL3A1 mRNA levels in HDFs (Figure 2).

Effects of YDE, YA, and YC on UVB-Induced Intracellular ROS Production and Antioxidant Enzyme Expression through Activation of Nrf2 in HaCaT Cells. To study the effects of YDE, YA, and YC on UVB-induced intracellular ROS generation, antioxidant enzyme expression, and Nrf2 activation, we utilized flow cytometry, RT-PCR, and Western blot analyses. Cells treated with YDE, YA, and YC inhibited UVB-induced intracellular ROS levels (Figure 3A) and increased expression of HO-1, SOD1, and Nrf2 (Figure 3B–D) compared to that of the UVB-irradiated control. To further confirm YA- and YC-mediated MMP-1 production through activation of Nrf2, we used Nrf2 RNA interference and treated sulforaphane as an Nrf2 activator. MMP-1 production was inhibited in YA-, YC-, and sulforaphane-treated cells but was not attenuated in Nrf2 siRNA-treated cells (Figure 3E).

Effects of YDE, YA, and YC on UVB-Induced Proinflammatory Mediators and NF-κB Activation in HaCaT Cells. We next investigated the effects of YDE, YA, and YC on UVB-induced expression of inflammatory mediators. Notably, UVB-induced expression of TNF-α, COX-2, IL-6, p65, and p50 was lower in YDE-, YA-, and YC-treated cells than in the UVB-irradiated control (Figure 4A,B).

To examine the mechanism by which YDE, YA, and YC inhibit NF-κB transcriptional activity, we assessed their effects on nuclear translocation and phosphorylation of NF-κB. YDE and YC inhibited UVB-induced nuclear translocation of NF-κB p65 protein (Figure 4C). Furthermore, YDE, YA, and YC inhibited the phosphorylation of IKKα/β and IκB and the degradation of IκB, which regulates nuclear translocation of NF-κB (Figure 4C).

Effects of YDE, YA, and YC on UVB-Induced Phosphorylation/Expression of c-Jun and c-Fos in HaCaT Cells. In this series of experiments, UVB-induced

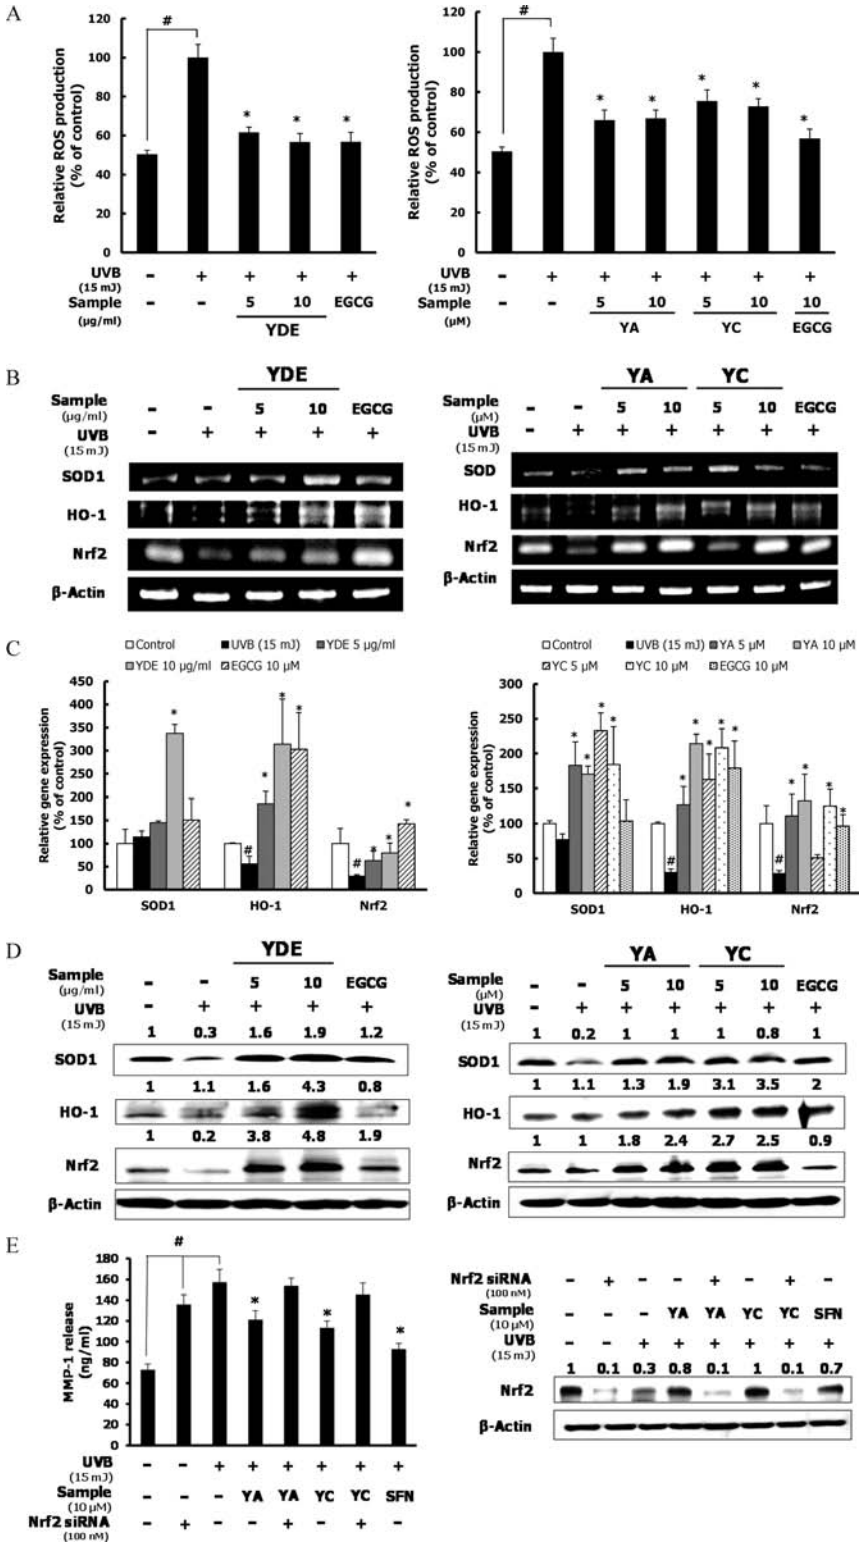

Figure 3. Effects of YDE, YA, and YC on intracellular ROS production, expressions of antioxidant enzymes, and Nrf2-mediated MMP-1 production in UVB-irradiated HaCaT cells. (A) HaCaT cells were pretreated with various concentrations of YDE, YA, and YC for 1 h and then stained with 40 μM 2′,7′-dichlorofluorescein diacetate (DCFH-DA; Sigma-Aldrich) for 30 min. The stained cells were then irradiated with UVB (15 mJ/cm^2). After 30 min, ROS levels were analyzed by flow cytometry. (B−D) HaCaT cells were treated with YDE, YA, and YC for 1 h and then exposed to UVB irradiation (15 mJ/cm^2). At 24 h after UVB exposure, SOD1, HO-1, and Nrf2 expressions were evaluated by RT-PCR and Western blot analysis. (E) HaCaT cells transfected with Nrf2 siRNA were treated with YA and YC for 1 h and then exposed to UVB irradiation (15 mJ/cm^2). At 24 h after UVB exposure, MMP-1 production and Nrf2 expression were measured by ELISA and Western blot analysis, respectively. β-Actin was used as an internal control for RT-PCR and Western blot analysis. EGCG was used as a positive control. Sulforaphane (SFN) was used as a positive control of Nrf2 activator. Results of ROS and MMP-1 production and RT-PCR are expressed as the mean ± SD (% control) of three independent experiments. (#) $P < 0.05$ compared with vehicle control; (∗) $P < 0.05$ compared with UVB-treated cells.

DOI: 10.1021/acs.jafc.5b00467
J. Agric. Food Chem. 2015, 63, 5428−5438

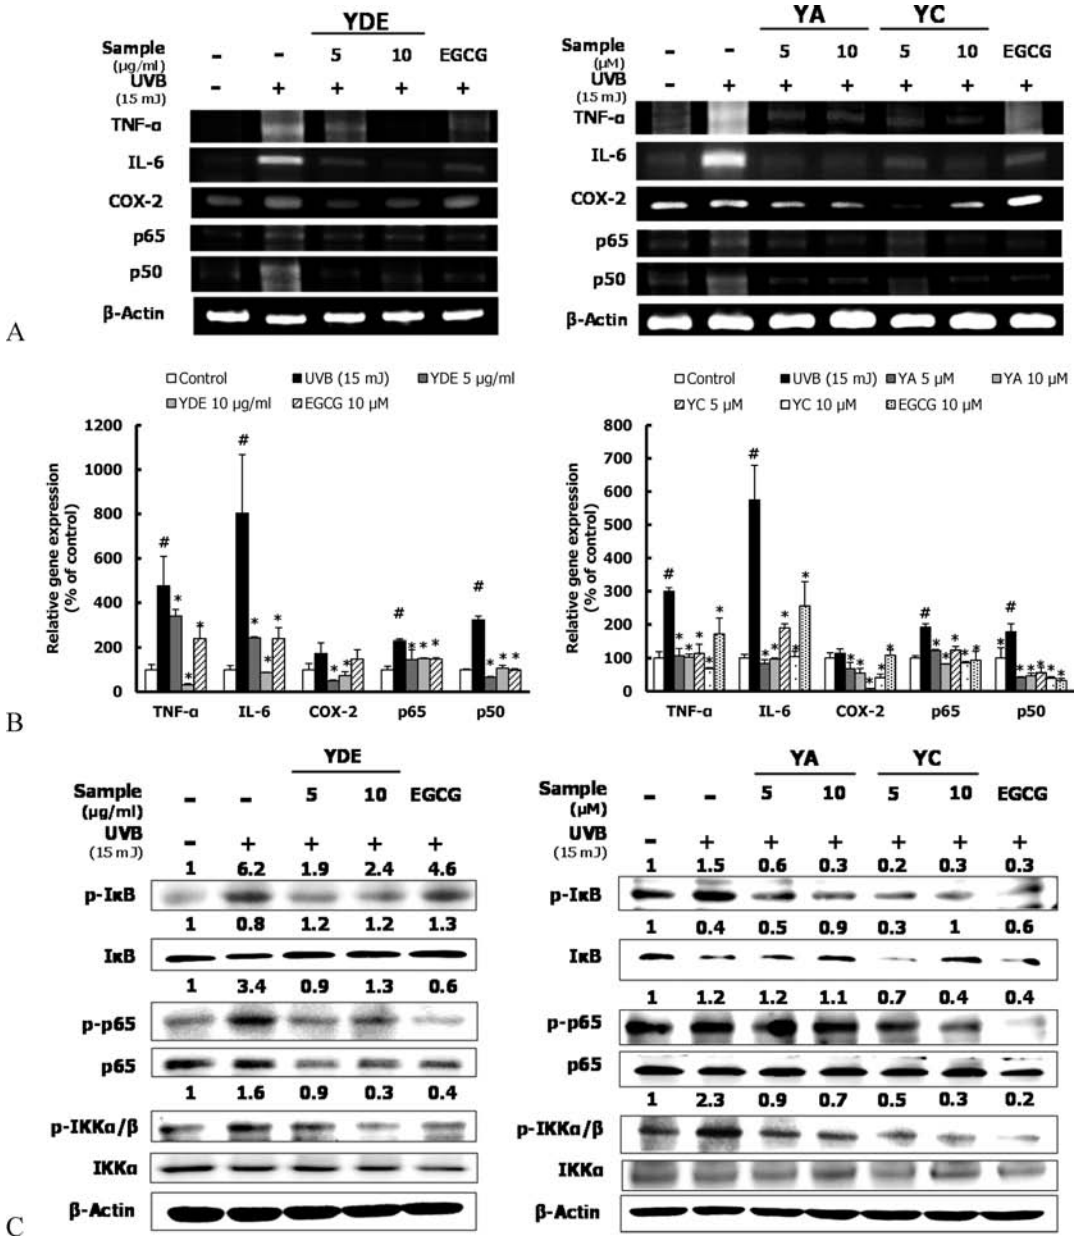

Figure 4. Effects of YDE, YA, and YC on inflammatory mediators and NF-κB activation in UVB-irradiated HaCaT cells. (A, B) HaCaT cells were treated with YDE, YA, and YC for 1 h and then exposed to UVB irradiation (15 mJ/cm^2). At 24 h after UVB exposure, TNF-α, IL-6, COX-2, p65, and p50 were evaluated by RT-PCR. (C) HaCaT cells were treated with YDE, YA, and YC for 1 h and then exposed to UVB irradiation (15 mJ/cm^2). At 30 min after UVB exposure, NF-κB signaling (IκBα, p65, IKKα/β) was assessed by Western blot analysis. β-Actin was used as internal control for Western blot analysis. EGCG was used as a positive control. RT-PCR results are expressed as the mean ± SD (% control) of three independent experiments. (#) $P < 0.05$ compared with vehicle control; (∗) $P < 0.05$ compared with UVB-treated cells.

phosphorylation of Akt, ERK, JNK, and p38 was lower in YDE-treated cells and phosphorylation of Akt and JNK was reduced in YA- and YC-treated cells (Figure 5A), suggesting that YDE, YA, and YC inhibit UVB-induced MMP-1 expression by suppressing MAPK signaling. AP-1 is composed of c-Jun and c-Fos proteins, and increased transcription of AP-1 interferes with the synthesis of the major dermal collagens I and III. Notably, treatment with YDE, YA, and YC inhibited AP-1 transcription (Figure 5B).

Effects of YDE, YA, and YC on AMPK-Mediated MMP-1 Expression. AMPK is known to suppress UVB-induced MMP-1 expression. Therefore, we hypothesized that AMPK activation by YDE, YA, and YC could inhibit UV-induced MMP-1 expression. First, we verified that YDE, YA, and YC increased AMPK phosphorylation in HaCaT cells (Figure 6A). To confirm the role of AMPK activation on UVB-induced MMP-1 expression, we investigated whether YA and YC suppressed MMP-1 production via activation of the AMPK pathway. Treatment with compound **C**, an AMPK inhibitor, and UVB irradiation increased MMP-1 expression. Moreover, MMP-1 expression was inhibited by YA, YC, and AICAR, an activator of AMPK. However, YA and YC did not show inhibitory effects in compound **C**-treated HaCaT cells (Figure 6B).

DISCUSSION

MMPs play an important role in the physiological mechanisms of skin photoaging. UV irradiation alters the connective tissues

DOI: 10.1021/acs.jafc.5b00467
J. Agric. Food Chem. 2015, 63, 5428−5438

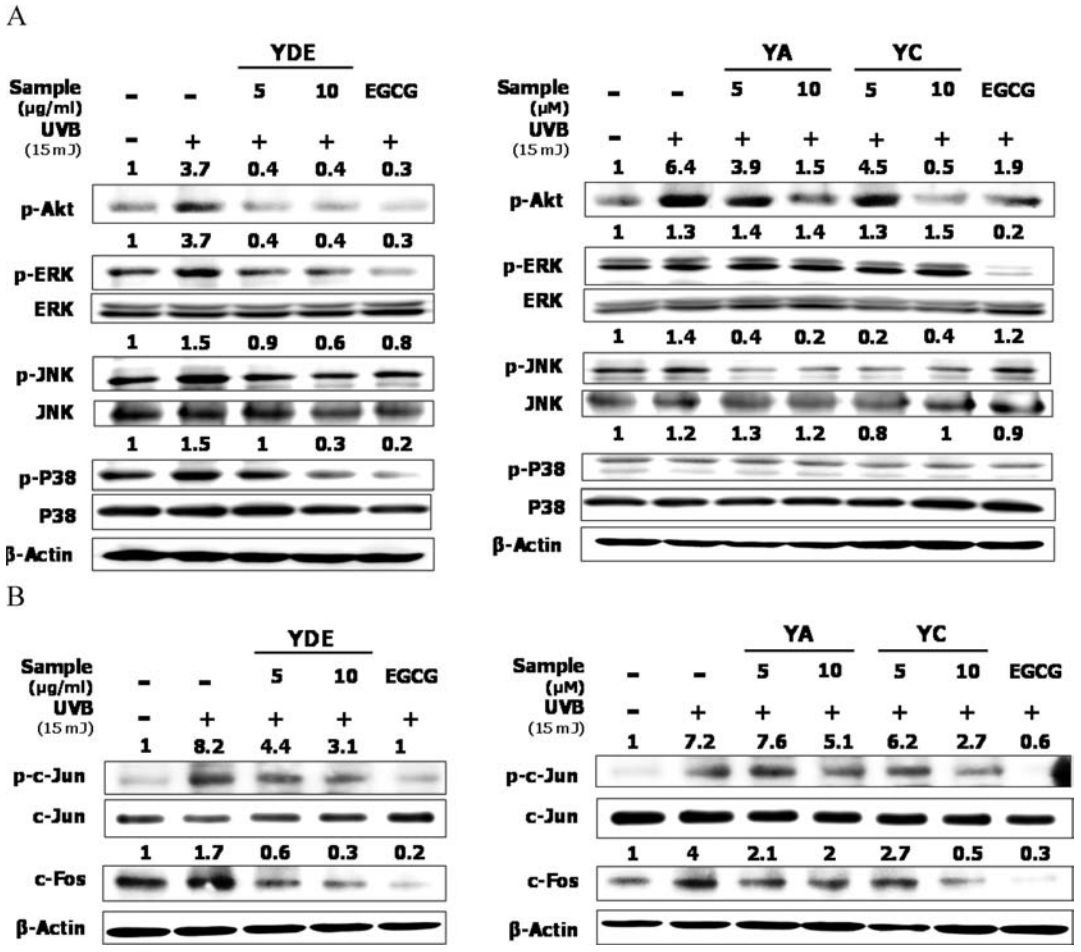

Figure 5. Effects of YDE, YA, and YC on UVB-induced MAPK/AP-1 signaling in UVB-irradiated HaCaT cells. HaCaT cells were treated with YDE, YA, and YC for 1 h and then exposed to UVB irradiation (15 mJ/cm^2). At 30 min after UVB exposure, phosphorylations of (A) Akt, MAPK (ERK, JNK, and p38) and (B) AP-1 (c-Jun and c-Fos) were assessed by Western blot analysis. β-Actin was used as internal control for Western blot analysis. EGCG was used as a positive control.

of the skin by up-regulating the expression of MMPs, which degrade collagen and other ECM proteins.[22−24] MMP-1 is a member of the collagenase subfamily of MMPs. When activated, MMP-1 initiates collagen breakdown by cleaving type I and type III collagen, which are further cleaved by MMP-2 and -9.[25] Latent MMP-1, -2, and -9 derived from dermal fibroblasts or keratinocytes could be greatly activated by MMP-3 and ultimately initiate degradation of type I and III collagens.[25] The gelatinolytic activities of MMP-2 and -9 are the central players in UV-irradiated skin damage and in the formation of wrinkles.[26] One study demonstrated that antioxidants inhibit the activity of UV-induced MMP-9.[27] Therefore, we hypothesized that YDE, YA, and YC, which are known to have antioxidant activities,[15,19−21] affect MMP expression. In the present study, we found that YDE, YA, and YC markedly decreased UV-induced MMP production and expression. Thus, our results clearly show that YDE, YA, and YC down-regulate MMP expression.

Collagens provide resiliency and strength to the skin; therefore, collagen degradation by processes such as photoaging promotes skin aging. Most collagen fibers in the dermis are type I and III collagens.[4] Types I collagen is a fibrillar collagen that is found in extensible connective tissues such as skin, lung, and the vascular system. Type III collagen is a fibrous scleroprotein in bone, cartilage, dentin, tendon, bone marrow stroma, and other connective tissue and yields gelatin on boiling.[4] In this study, YDE, YA, and YC increased type I procollagen protein and mRNA levels of COL1A1 and COL3A1. Because reduced collagen levels in UV-damaged skin may occur via collagen breakdown due to UVB-induced MMPs, the present results indicate that YDE, YA, and YC may prevent or treat UVB-induced ECM damage by inhibiting MMP expression.

In the photoaging process, UV irradiation induces oxidative damage. UV-induced ROS production up-regulates the expression of MMP-1, leading to increased collagen degradation. ROS production also plays an important role in MAPK signaling.[28] Thus, reducing ROS generation is a potentially effective strategy to prevent skin photoaging. Antioxidant agents can mediate decreased ROS production and protect the skin from the effects of UV irradiation. The Nrf2−Keap1 pathway plays a key role in coordinating the transcriptional induction of various antioxidant-metabolizing enzymes that can neutralize the damaging effects of ROS. In a previous study, YDE exhibited antioxidant effects against oxidative stress in hepatocytes and retinal cells by decreasing ROS production and increasing antioxidant enzyme expression.[15,21] In the present study, YDE, YA, and YC significantly reduced intracellular ROS production. Reduced antioxidant enzyme expression in aged and photoaged keratinocytes and fibroblasts can accelerate oxidative damage and promote MAPK signaling to increase the rate of skin aging

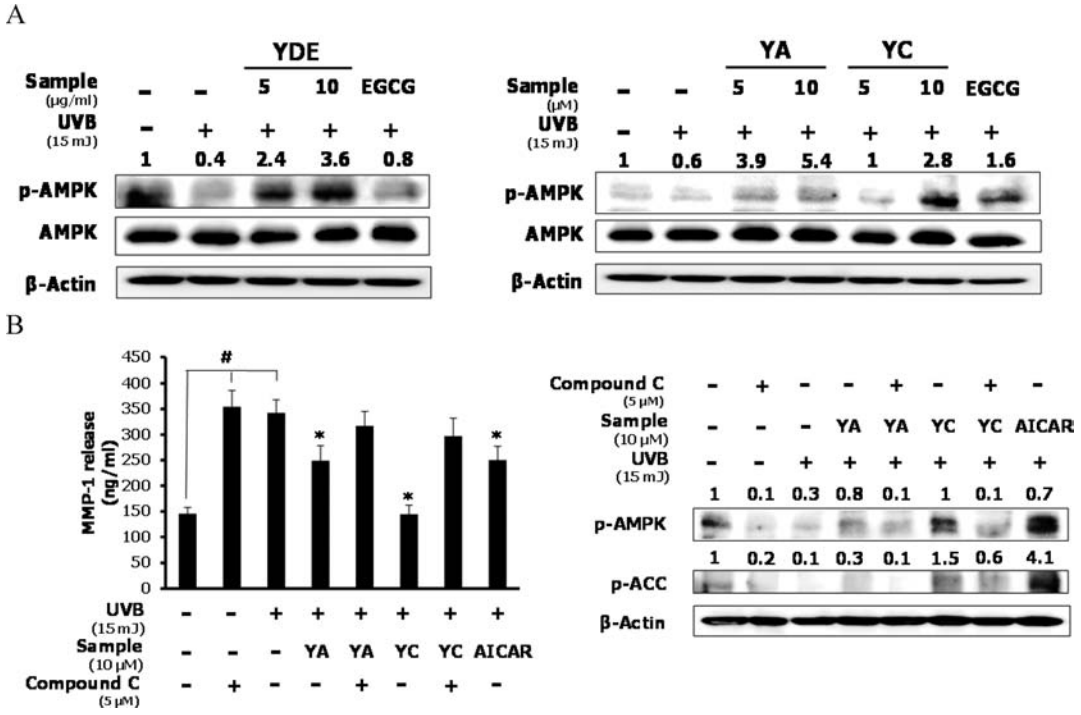

Figure 6. Effects of YDE, YA, and YC on phosphorylation of AMPK and AMPK-mediated MMP-1 production in UVB-irradiated HaCaT cells. HaCaT cells were treated with YDE, YA, and YC for 1 h and then exposed to UVB irradiation (15 mJ/cm^2). At 30 min after UVB exposure, (A) phosphorylation of AMPK and ACC was evaluated by Western blot analysis. HaCaT cells treated with compound **C** were treated with YA and YC for 1 h and then exposed to UVB irradiation (15 mJ/cm^2). At 24 h after UVB exposure, (B) production of MMP-1 and phosphorylation of AMPK and ACC were measured by ELISA and Western blot analyses, respectively. β-Actin was used as an internal control for RT-PCR and Western blot analysis. EGCG was used as a positive control. Compound **C** and AICAR were used as an AMPK inhibitor and activator, respectively. Results of MMP-1 production are expressed as the mean ± SD (% control) of three independent experiments. (#) $P < 0.05$ compared with vehicle control; (∗) $P < 0.05$ compared with UVB-treated cells.

and photoaging.[29] YDE, YA, and YC increased the expression of SOD1, HO-1, and Nrf2 and suppressed MMP-1 production via a Nrf2-dependent pathway. These observed effects indicate that YDE, YA, and YC inhibit UVB-induced alterations in MMP-1 and type I procollagen expression, in part by reducing ROS generation and promoting antioxidant enzyme expression and Nrf2 expression.

MAPK signaling plays a central role in regulating cell proliferation, cell motility, MMP gene expression, and cell survival and death. The three major MAPK subfamilies in mammalian cells include JNK, ERK, and p38.[30] Oxidative stress induced by accumulation of ROS can initiate MAPK signaling by phosphorylation of MAPK proteins.[28] We show in the present study that UVB-induced phosphorylation of ERK, JNK, and p38 was lower in YDE-, YA-, and YC-treated cells. This suggests that YDE, YA, and YC attenuate UVB-induced expression of MMP-1 by inhibiting MAPK signaling. MMP-1 gene expression is regulated by c-Jun and c-Fos, which are components of the AP-1 protein complex. When activated, JNK phosphorylates c-Jun, increasing c-Jun transcriptional activity.[8,31] YDE, YA, and YC inhibited UVB-induced AP-1 activation by reducing c-Jun phosphorylation and c-Fos expression. These results indicate that YDE, YA, and YC reduce UVB-induced c-Jun and c-Fos expression by inhibiting phosphorylation of JNK.

The NF-κB pathway is an important regulator of gene expression associated with immune and inflammatory responses.[32] In addition, NF-κB also increases MMP-1 expression in the dermis.[33] Our results show that YDE, YA, and YC reduced IκBα phosphorylation and NF-κB p65 nuclear translocation.

Pro-inflammatory cytokines and transcription factors, such as TNF-α, COX-2, IL-6, p65, and p50, which affect the aging process, are induced by exposure to UVB radiation. Inflammation, which is mediated by these cytokines, increases the production of ROS, thus amplifying the effects of UV exposure.[34] The antioxidant properties of YDE were confirmed by its ability to increase the antioxidant enzyme activity of hepatocyte and retinal cells under oxidative stress conditions.[15,21] Hence, YDE, YA, and YC may inhibit inflammatory cytokine expression through these factors. Our findings demonstrate that YDE, YA, and YC inhibited TNF-α, COX-2, IL-6, p65, and p50 expression and attenuated UVB-induced expression of pro-inflammatory cytokines.

AMPK regulates UV-induced stabilization of COX-2 mRNA in human keratinocytes.[35] AMPK can also counteract oxidative stress in the vascular endothelium[36] and is a therapeutic target for vascular disease.[37] In a recent study, it was suggested that AMPK activation plays a key role in the suppression of MMP-1.[10] In accordance with these previous studies, we found that treatment with YDE, YA, and YC increases AMPK phosphorylation and inhibits MMP-1 production via AMPK activation. Therefore, we conclude that the AMPK pathway is the major target pathway mediating the effect of YA and YC in HaCaT cells.

The present study is the first to demonstrate that YA, YC, and YDE reduced MMP expression by suppressing UVB-induced oxidative stress and inflammation in HaCaT cells and increased type I procollagen production in HDFs. These

responses may be mediated by inhibition of MAPK, AP-1, and NF-κB and activation of Nrf2 and AMPK pathways in cultured HaCaT cells. Further research using physiologically appropriate skin cell models is needed because keratinocyte cell lines have different biological functions and genetic variations compared with those of primary keratinocytes. These differences may influence cellular responses to UV irradiation such as MMP-1 activation. In addition, it is necessary to elucidate potential anti-aging properties of YA, YC, and YDE in vivo and characterize the underlying mechanisms in animal models.

Isolation of a Hemagglutinin with Potent Antiproliferative Activity and a Large Antifungal Defensin from *Phaseolus vulgaris* cv. Hokkaido Large Pinto Beans

Cuiming Yin, Jack Ho Wong,* and Tzi Bun Ng*

School of Biomedical Sciences, Faculty of Medicine, The Chinese University of Hong Kong, Shatin, Hong Kong, China

Supporting Information

ABSTRACT: Lectins (hemagglutinins) are defined as sugar-binding proteins or glycoproteins with various biological activities. A 60 kDa dimeric hemagglutinin with a blocked N-terminus was isolated in large yield (190 mg/60 g) from the common edible bean *Phaseolus vulgaris* cv. Hokkaido large pinto bean. Its hemagglutinating, antifungal, and antitumor activities as well as the effects of carbohydrate and metal ions on its hemagglutinating activity were examined. It inhibited the proliferation of nasopharyngeal carcinoma (CNE2), human breast cancer (MCF7), and hepatoma (HepG2) cells. The IC_{50} values toward HepG2, MCF7, and CNE2 cells after treatment for 48 h were 8.1, 6.07, and 7.49 μM, respectively, which were relatively low among lectins of different *P. vulgaris* cultivars. From the pinto beans, a 10888 Da antifungal peptide with similarity to plant defensins as revealed by mass spectroscopic analysis was also isolated with a yield of 3.2 mg of proteins from 60 g of beans. The large defensin was capable of inhibiting mycelial growth in *Mycosphaerella arachidicola*, *Setosphaeria turcica*, *Bipolaris maydis*, and *Fusarium oxysporum* but not in *Valsa mali*.

KEYWORDS: *hemagglutinin, antiproliferative, antifungal, defensin*

INTRODUCTION

From ancient times to the present, pathogen invasion is a health hazard to most of living organisms. During the process of evolution, organisms have developed various defense mechanisms to eliminate these potential life-threatening risks. Lectins and defensins are two types of defense proteins that plants secrete for self-protection.[1]

Lectins (hemagglutinins) are sugar-binding proteins with high carbohydrate selectivity, which exist ubiquitously in diverse species of plants, animals, viruses, bacteria, and fungi.[2] Along with a defensive nature, some of them, such as lectins from edible plants, demonstrate a strong capability of inhibiting cancer cell proliferation. For example, concanavalin A (Con A), a mannose- and glucose-binding lectin isolated from jack bean, was found to have considerable potential in anticancer applications.[3] However, apart from it, currently available lectins may have their own limitations for further development and application. Thus, the discovery of more potential targets is of great significance and a worthwhile undertaking.

Phaseolus vulgaris is a leguminous species that produces common edible beans. Different *P. vulgaris* cultivars share the same characteristic; that is, most of them contain a lectin or a phytohemagglutinin as a storage protein. Even though lectins from various cultivars have similar molecular sizes, they may possess different biological activities and vary in the potency of a particular activity. Antifungal proteins such as defensin may or may not be present in a cultivar. Hence, we set out to isolate a lectin and an antifungal protein from *P. vulgaris* cultivar Hokkaido large pinto bean.

MATERIALS AND METHODS

Purification of Hemagglutinin from Hokkaido Large Pinto Bean. Hokkaido large pinto beans were purchased from a Japanese food supermarket in Hong Kong. After soaking in distilled water overnight, 60 g of beans was homogenized in a Waring blender in 500 mL of 20 mM Tris-HCl buffer (pH 7.6). The homogenate was centrifuged at 16000 rpm for 30 min at 4 °C. The supernatant was filtered by using a piece of filter paper before loading onto an Affi-gel blue gel (Bio-Rad) column (18 cm × 5 cm) that had been pre-equilibrated with 20 mM Tris-HCl buffer (pH 7.6). Then, the column was washed with 1 M NaCl in 20 mM Tris-HCl buffer (pH 7.6) to elute the adsorbed proteins. The adsorbed fraction was dialyzed against double-distilled water overnight at 4 °C and lyophilized into powder form. The powder was resuspended (20 mg/mL buffer) in 20 mM NH_4HCO_3 buffer (pH 9.6) before FPLC-anion exchange chromatography on a Mono Q column (GE Healthcare) using an AKTA Purifier (GE Healthcare). Adsorbed proteins were eluted using a 0−1 M NaCl gradient in 20 mM NH_4HCO_3 buffer (pH 9.6). The first peak containing adsorbed materials was collected, dialyzed, lyophilized, resuspended in 20 mM Tris-HCl buffer (pH 7.6) (5 mg/mL), and then subjected to FPLC-gel filtration on a Superdex 75 HR 10/300 column (GE Healthcare). The first major absorbance peak contained purified Hokkaido large pinto bean lectin.

The three chromatographic steps used for purifying defensin from Hokkaido large pinto beans were the same as described above for the purification of hemagglutinin. In the Mono Q purification step, the unbound fraction was collected and dialyzed against double-distilled water, and buffer was added, resulting in a protein solution in 20 mM Tris-HCl buffer (pH 7.6). Then the sample was subjected to FPLC-gel filtration on a Superdex 75 HR 10/300 column (GE Healthcare). The last major absorbance peak contained purified Hokkaido large pinto bean defensin.

Molecular Mass Determination. Sodium dodecyl sulfate−polyacrylamide gel electrophoresis (SDS-PAGE) was carried out using a 15% separating gel and a 5% stacking gel. The protein sample was

diluted with loading buffer containing β-mercaptoethanol (10% glycerol, 0.4% SDS, 0.005% bromophenol blue, and 20 mM EDTA in 0.5 M Tris-HCl, pH 7.5, 5% β-mercaptoethanol) to reduce disulfide bonds in the proteins. The samples were boiled in water for 5 min. Then, electrophoresis was performed at a constant current of 10 mA and a constant voltage of 120 V for about 75 min. After electrophoresis, the gel was stained with Coomassie brilliant blue, and it was put on a shaker to shake for 1 h and then destained with 10% acetic acid overnight.[4]

Determination of N-Terminal Amino Acid. N-Terminal amino acid sequence analysis was carried out using an HP 1000A Edman degradation unit and an HP 1000 HPLC system (Agilent Technologies, Santa Clara, CA, USA).

Mass Spectrum Analysis. The molecular mass of the antifungal protein was verified by performing matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOF MS), using an Applied Biosystems 4700 Proteomics Analyzer.

Matrix-assisted laser desorption/ionization time-of-flight time-of-flight tandem mass spectrometry (MALDI-TOF-TOF-MS/MS) was utilized to fragment sample proteins by MS/MS, and the fragments were identified by top-down proteomic analysis. The defense protein was identified by analysis of MS and MS/MS data using NCBInr and SwissProt databases (Greenplant).[5]

Assay of Hemagglutinating Activity. A 50 μL test sample was subjected to a 2-fold serial dilution with phosphate-buffered saline (PBS) (pH 7.2) in a 96-well microtiter U-plate. Afterward, 50 μL of a rabbit red blood cell suspension (2%) in PBS was added to each diluted sample. PBS (50 μL) mixed with 50 μL rabbit red blood cell was used as a negative control. The plate was incubated at room temperature until the red blood cells in the negative control formed a red dot at the bottom of the well, which means it had fully sedimented. The hemagglutinating activity of each of the test samples was then recorded. One hemagglutination unit or hemagglutination titer is defined as the reciprocal of the highest dilution of the lectin sample that induces hemagglutination. Specific hemagglutinating activity is the number of hemagglutination units per milligram of protein.[6]

Determination of pH Stability and Temperature Stability of Hemagglutinating Activity. To ascertain the effect of pH, solutions/buffers with different pH values from 0 to 14 were prepared as follows: pH 0−1, HCl; pH 2−5, NH_4OAc; pH 6−10, Tris-HCl; pH 11−12, $NaHCO_3$; and pH 13−14, NaOH. The protein sample was mixed with an equal volume (50 μL) of a solution at a specified pH and incubated at room temperature for 30 min. Then, the mixtures were neutralized and assay of hemagglutinating activity was carried out. The hemagglutinating activity remaining was determined.[7]

To test the effect of temperature, the protein sample was heated at different temperatures from 20 to 100 °C, at 10 °C intervals for 30 min. The sample was immediately cooled on ice for another 30 min to terminate the incubation and then warmed up to room temperature. The assay of hemagglutinating assay was carried out as described above. The hemagglutinating activity of the lectin following incubation at room temperature was considered as 100% activity.

Effects of Carbohydrates and Metal Ions on Hemagglutinating Activity. To investigate the carbohydrate specificity of the purified sample, 200 mM solutions of various kinds of sugars including *N*-acetylglucosamine, L-arabinose, D-fructose, D-fucose, D-galactose, D-glucose, lactose, maltose, D-mannose, raffinose, L-rhamnose, and D-xylose were used to dissolve the lyophilized sample to 0.1 mg/mL. Assay of hemagglutinating activity was carried out using the carbohydrate solutions at their particular concentrations for 2-fold serial dilution instead of PBS. The percentage of hemagglutinating activity remaining was calculated.[8]

On the other hand, the effects of metallic chlorides encompassing calcium chloride, manganese chloride, ferrous chloride, magnesium chloride, copper chloride, and zinc chloride on the hemagglutinating activity of Hokkaido large pinto bean hemagglutinin were also tested. First, the hemagglutinating activity of the original hemagglutinin solution was assessed and the fold number of 2-fold serial dilution that caused the test sample solution to begin to lose its hemagglutining activity was recorded. Then the sample solution was diluted with the recorded fold. Then, 25 μL of a 200 mM solution of a specified metallic salt (in 0.9% NaCl) was subjected to a 2-fold serial dilution with 0.9% NaCl in a 96-well plate. Afterward, 25 μL of diluted sample solution was added to each well, and the mixture was incubated at room temperature for 1 h. In the control group, 25 μL of NaCl was used for 2-fold serial dilution instead of the metallic salt. Fifty microliters of a 2% rabbit erythrocyte suspension were then added to each well for another 2 h incubation at room temperature. Hemagglutination was estimated afterward. A second control experiment containing only the metal salt and red blood cells was run concurrently to ascertain the effect of each metal salt on the red blood cells in the assay.

Assay of Antifungal Activity. Antifungal activity assay was carried out for investigating the antifungal potential of Hokkaido large pinto bean hemagglutinin. Different phytopathogenic fungi including *Mycosphaerella arachidicola*, *Setosphaeria turcica*, *Bipolaris maydis*, *Fusarium oxysporum*, and *Valsa mali* were grown in Petri dishes (90 mm × 15 mm) containing 10 mL of potato dextrose agar. A small amount of each fungal species was planted in the middle of the dish and then incubated at room temperature for a few days until it developed into a mycelial colony. Test samples (2 and 1 mg/mL) were added onto sterile blank round paper disks (0.625 cm in diameter), which were placed 0.5 cm away from the edge of the mycelial colony. Sterile buffer was added as control. After that the plates were incubated at room temperature until the mycelia had grown near the disk of the control group. If the mycelium could not grow near the disk and a clear invagination without mycelium was developed, it indicated that the test sample possessed antifungal activity.[9]

For testing the antifungal activity of the purified proteins against *Candida albicans*, 1×10^7 cells were treated with 2 mg of protein and incubated in Sabouraud dextrose broth (pH 5.5, Sigma). In the control, the protein sample was replaced by autoclaved broth. All eppendorf tubes were placed in an orbital shaker at 37 °C with shaking at a speed of 200 rpm and incubated for 6 h. Ten-fold serial dilution of 50 μL of the mixture containing the test protein and cells was performed in broth. Fifty microliters of the fourth and fifth 10-fold diluted solution were spread on agar plates. Cell counting was implemented after incubation of the plates at 37 °C for 24 h.

The method for testing the antifungal activity of Hokkaido large pinto bean defensin was as previously described. Six species of fungi were tested including *M. arachidicola*, *S. turcica*, *B. maydis*, *F. oxysporum*, *V. mali*, and *C. albicans*. For the assay of antifungal activity toward *C. albicans*, the concentration of defensin used was 0.1 mg/mL.

Assay of Antiproliferative Activity. Nasopharyngeal carcinoma (CNE2), human breast cancer (MCF7 and MDA-MB-231), hepatoma (HepG2) cells, and an immortalized normal nasopharyngeal epithelial cell line NP 69 and human embryo liver (WRL 68) cells, from American Type Culture Collection, were suspended in RPMI medium at a cell density of 5×10^4 cells/mL. A 100 μL aliquot of these cell suspensions was seeded and incubated in the 96-well plates overnight. Then, the protein samples at concentrations of 0.49−125 μM (0.49, 0.98, 1.95, 3.91, 7.81, 15.63, 31.25, 62.5, and 125 μM) in 100 μL of RPMI medium were added to the wells, followed by incubation in a humidified atmosphere of 5% CO_2 at 37 °C. After incubation for 24 and 48 h, the medium was discarded, and the wells were washed with PBS. Then, 25 μL of a 5 mg/mL solution of 3-(4, 5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) in PBS was added into each well, and the plates were incubated at 37 °C for 4 h. After incubation, the plates were centrifuged at 2500 rpm for 5 min. The supernatant was carefully removed, and 150 μL of dimethyl sulfoxide (DMSO) was added into the wells to dissolve the MTT (formazan). OD 590 nm was measured within 10 min by using a microplate reader. Percentage inhibition of the MCF7, HepG2, and CNE2 cells was calculated by using the following formula: [(OD 590 nm of the control (without test protein) − OD 590 nm of the well with test protein at a particular concentration)/OD 590 nm of the control] × 100%.[10]

Results were expressed as means ± standard deviation (SD). The median inhibition concentration (IC_{50}) was determined using SPSS 11.0.1 statistical software (SPSS Inc., Chicago, IL, USA). For between-group comparisons, one-way ANOVA was used. Differences with p values of ≤ 0.05 were considered to be statistically significant.

RESULTS

Purification of Hemagglutinin from Hokkaido Large Pinto Bean. Three chromatographic steps were utilized for the purification of hemagglutinin from Hokkaido large pinto bean. Hemagglutinins possess at least one noncatalytic domain that reversibly binds to specific carbohydrate structure. This property enables them to aggregate red blood cells. By using the test for hemagglutinating activity to monitor all of the chromatographic fractions, the target chromatographic fraction possessing hemagglutinating activity was identified and selected for further purification

The first chromatographic step on Affi-gel blue gel separated proteins into an unbound fraction that contained most of the proteins of Hokkaido large pinto bean, as shown in Figures 1A and 2A, and a bound fraction, which appeared as a sharper peak. The bound fraction I was obtained by elution with 1 M NaCl solution in the starting buffer. Both unbound and bound fractions were tested by using the test for hemagglutinating activity.

DOI: 10.1021/acs.jafc.5b00475
J. Agric. Food Chem. 2015, 63, 5439−5448

The bound fraction I was identified as the target chromatographic fraction containing hemagglutinating activity. From the SDS-PAGE gel photo shown in Figure 2A, proteins with a size of 30 kDa constituted the bulk of the adsorbed fraction. The second step was FPLC-cation exchange chromatography of bound fraction I from the Affi-gel blue gel column on Mono Q, which yielded one unadsorbed fraction and two major adsorbed peaks (Figure 1B). Hemagglutinating activity was enriched in fraction II. In the third step, fraction II was loaded to an FPLC-gel filtration Superdex 75 column for the purpose of further purification. A major peak was obtained including fractions A and B, which were collected at 9 and 9.5 mL, respectively (Figure 1C). Totally a yield of 190 mg of protein from fractions A and B was obtained from 60 g of Hokkaido large pinto bean (Table 1).

Table 1. Purification of Hemagglutinin from Hokkaido Large Pinto Bean (60 g)

chromatographic fraction	specific hemagglutinating activity (titer mg^{-1})	total protein (mg)	recovery (%)
crude extract	34854	3294	100.00
Affi-gel blue gel	51200	699	31.21
Mono Q	63212	399	22.00
Superdex 75	102400	190	16.95

From the SDS-PAGE gel photo shown in Figure 2C, a single band with a molecular weight around 30 kDa was observed in fractions A and B, indicating that the target hemagglutinin was eluted in the ninth milliliter. On the basis of the standard calibration curve for the Superdex 75 column (data not shown), the molecular mass of Hokkaido large pinto bean hemagglutinin was about 60 kDa. This indicated that the hemagglutinin is a protein with a molecular mass of about 60 kDa and composed of two subunits.

Determination of Temperature Stability, pH Stability, Carbohydrate Selectivity, and Metal Ion Effect. Hokkaido large pinto bean hemagglutinin exhibited moderate thermostability. Its hemagglutinating activity was maintained at temperatures up to 60 °C but dropped dramatically at 70 °C, when only half of the hemagglutinating activity remained. At 80 °C only 0.39% residual activity was detected, and the activity was completely abolished at 90 °C. Testing for pH stability revealed that it retained full activity in the pH range of pH 2−12, indicating fairly high pH stability. The hemagglutinating activity was halved at both pH 1 and 13 and vanished at pH 0 and 14. For investigation of carbohydrate selectivity, none of the carbohydrates at 200 mM concentration interacted with Hokkaido large pinto bean hemagglutinin including D-galactose, D-fructose, D-xylose, D-glucose, D-mannose, L-rhamnose, L-fucose, L-arabinose, xylitol, glucosamine, glucuronic acid, galactonic acid, maltose, α-lactose, and raffinose, as the hemagglutining activity was not attenuated after the addition of various kinds of carbohydrates.

Testing the effect of metal ions on the hemagglutinating activity of Hokkaido large pinto bean hemagglutinin disclosed that 48.8 μM Cu^{2+} or Fe^{2+} ions, 97.7 μM Mn^{2+} ions, 195.3 μM Zn^{2+} ions, and 781.1 μM Ca^{2+} ions enabled the diluted protein sample solution to regain its hemagglutinating activity, indicating an augmenting effect.

Assay of Antifungal Activity. The mycelia of different phytopathogenic fungi all successfully grew near the disks in the presence of Hokkaido large pinto bean hemagglutinin, as in the case of the negative control, and there was no difference in the cell number of *C. albicans* between the hemagglutinin-treated group and the control group. The data suggest that Hokkaido large pinto bean hemagglutinin had no antifungal effect.

Assay for Antiproliferative Activity. The antiproliferative activity of Hokkaido large pinto bean hemagglutinin against HepG2, MDA-MB-231, MCF7, and CNE2 cancer cells was assessed by MTT assay. Results of the assay disclosed that treatment with Hokkaido large pinto bean hemagglutinin for 24 h did not achieve its maximum inhibitory effect (Figure 3A). At concentrations up to 125 μM, the hemagglutinin did not achieve 50% inhibition of each type of cancer cells after 24 h of treatment. The inhibitory effect against MDA-MB 231 metastatic breast cancer cells was minimal. The lectin achieved only 21% inhibition at the highest tested concentration (125 μM), compared with 43, 45, and 47% inhibition of proliferation of HepG2, MCF7, and CNE2 cancer cells, respectively. However, after uninterrupted incubation with Hokkaido large pinto bean hemagglutinin for 48 h, the inhibitory effect against each type of cancer cells was stronger than that observed after 24 h of treatment, with IC_{50} values of 8.135, 6.067, and 7.492 μM toward HepG2, MCF7, and CNE2 cancer cells, respectively. The IC_{50} value for MCF7 cells was smaller than that for CNE2 cancer cells. A further decline in proliferation rate was obtained in CNE2 cells after treatment with 125 μM hemagglutinin, which was 74% compared to 67%. At 125 μM concentration, Hokkaido large pinto bean hemagglutinin inhibited the growth of MDA-MB-231 cancer cells by 28% (Figure 3B). The hemagglutinin did not affect the viability of normal liver cell line WRL68 at 24 h, but

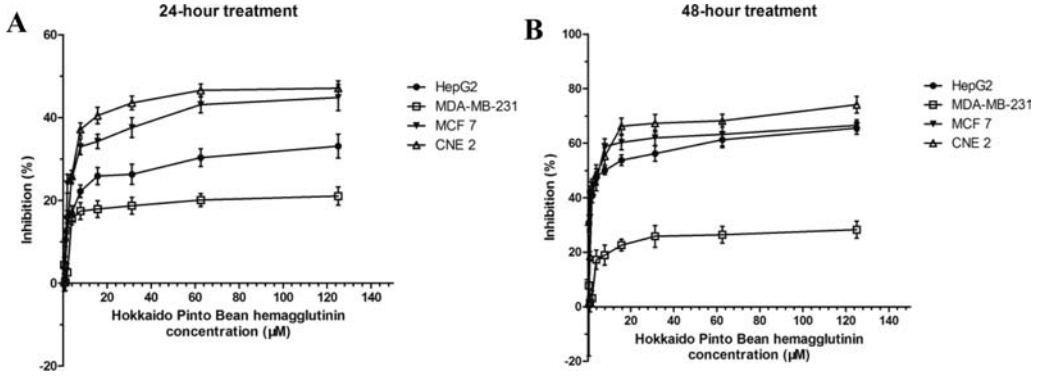

Figure 3. Results of MTT assay for Hokkaido large pinto bean hemagglutinin: MTT assay results after treatment of HepG2, MDA-MB-231, MCF7, and CNE2 cancer cells with different concentrations of Hokkaido large pinto bean hemagglutinin for (A) 24 h and (B) 48 h. Results represent the mean ± SD (n = 3).

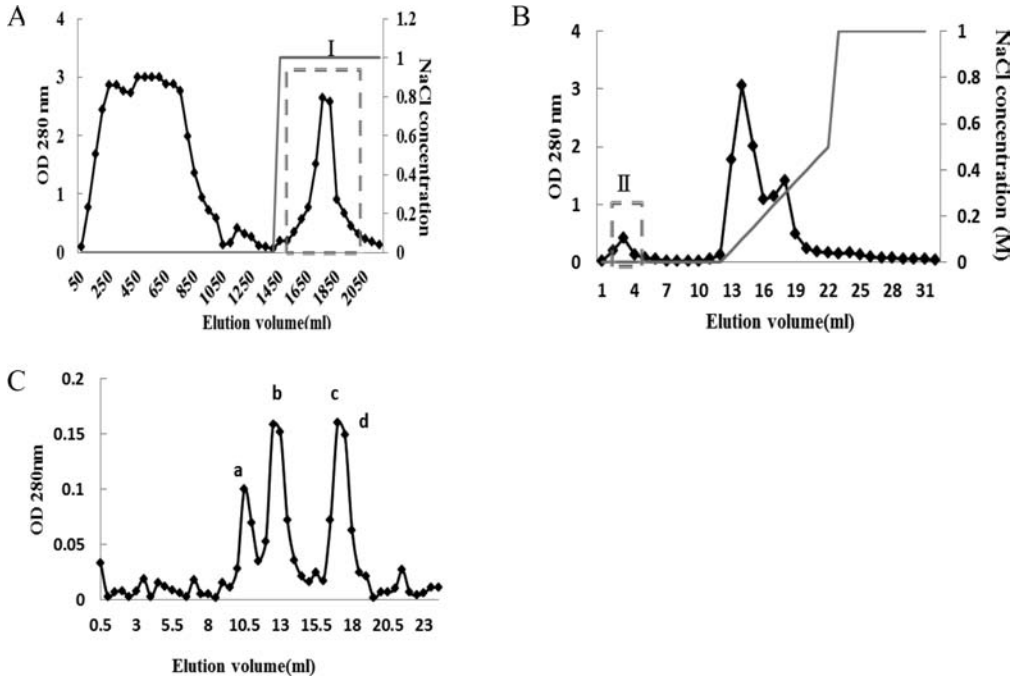

Figure 4. Purification of Hokkaido large pinto bean defensin: (A) affinity chromatography on Affi-gel blue gel; (B) FPLC of Affi-gel blue gel fraction I on Mono Q; (C) gel filtration of Mono Q fraction II on Superdex 75 by FPLC. Fractions a, b, c, and d were collected at elution volumes of 10.5, 12.5, 17, and 17.5 mL, respectively. Regions encircled with dotted lines signify target fractions with antifungal activity, which were collected and selected for the next step of purification.

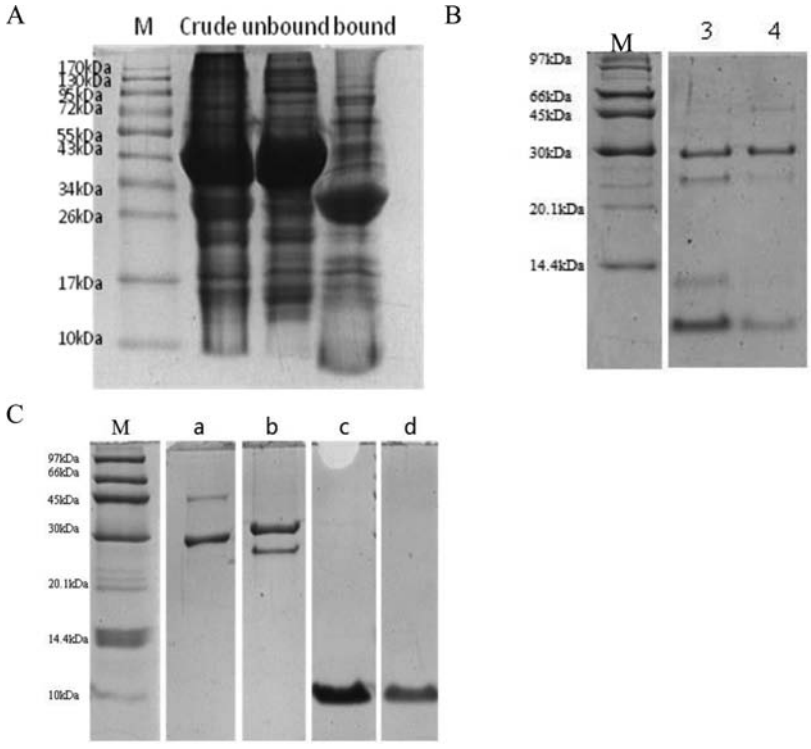

Figure 5. SDS-PAGE results for isolation of Hokkaido large pinto bean defensin: (A) Affi-gel blue gel eluate (crude, crude extract; unbound, unbound fraction; bound, fraction I); (B) Mono Q eluate (M, molecular weight marker; 3 and 4, fraction collected at the 3rd and 4th mL, respectively); (C) M, molecular mass marker; a, b, c, d, fractions collected at elution volumes of 10.5, 12.5, 17, and 17.5 mL, respectively.

caused inhibition when the treatment was lengthened to 48 h (IC_{50} value > 80 μM), and gave rise to an IC_{50} value of 45 μM after treatment for 72 h (Table 3). Yet the effect was much weaker compared with the aforementioned tumor cell lines (IC_{50} values < 10 μM). A comparison of the characteristics of lectins/hemagglutinins from various *P. vulgaris* cultivars is presented in Table 4.

Purification of Hokkaido Large Pinto Bean Defensin. Hokkaido large pinto bean defensin was discovered during the purification of Hokkaido pinto bean hemagglutinin. By

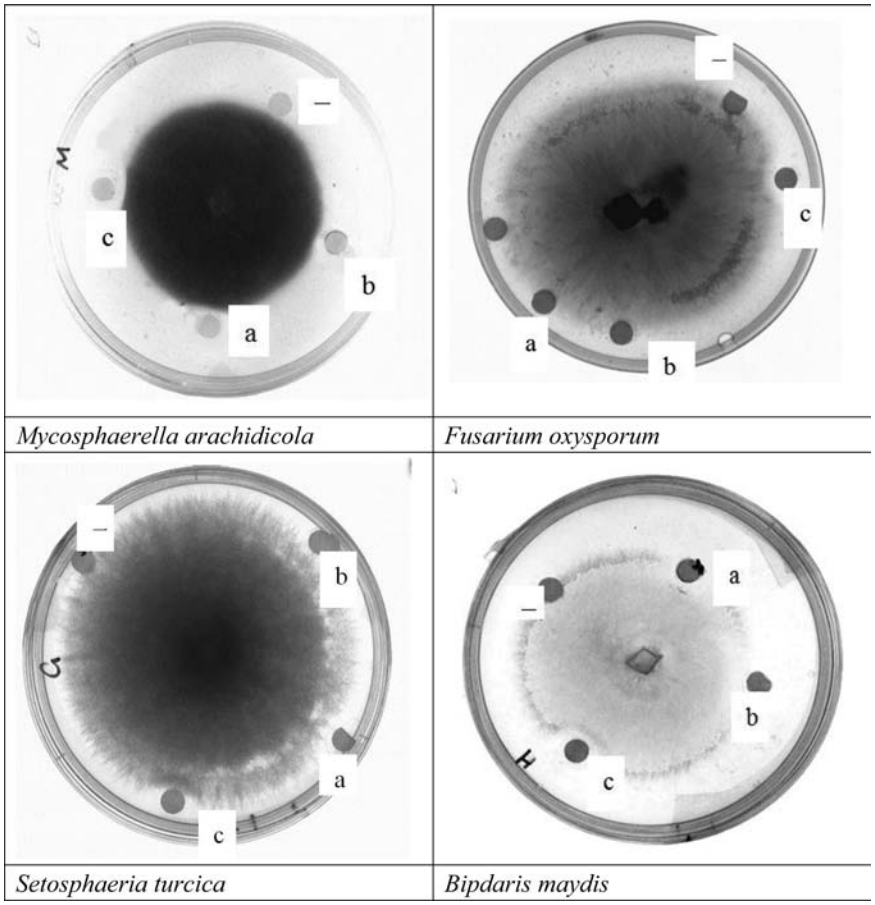

Figure 6. Antifungal activity of Hokkaido large pinto bean defensin toward *Mycosphaerella arachidicola*, *Fusarium oxysporum*, *Setosphaeria turcica*, and *Bipdaris maydis*. (−), negative control (water); a, b, and c refer to fractions a, b, and c, which were collected at elution volumes of 10.5, 12.5, and 17 mL, respectively, during gel filtration on Superdex 75. Antifungal activity was detected only in fraction c.

monitoring the antifungal activity of chromatographic fraction obtained at each purification step with the assay of antifungal activity, it was observed that the crude extract and sample obtained after purification on Affi-gel blue gel (relevant results are shown in Figures 4A and 5A) contained antifungal protein(s), as they both exerted antifungal effect toward *M. arachidicola* (data not shown). In the second chromatographic step using FPLC-cation exchange on Mono Q, the unadsorbed fraction referred to as fraction II in Figure 4B exhibited antifungal activity. The proteins in this fraction (third and fourth milliliter eluted from Mono Q) were checked by SDS-PAGE, as shown in Figure 5B. After further purification of Mono Q fraction II by FPLC-gel filtration on a Superdex 75 column, several main peaks were obtained (Figure 4C). Fractions a, b, c, and d were collected at elution volumes of 10.5th, 12.5th, 17th, and 17.5th mL, respectively. The molecular size and purity of the proteins in the fractions are shown in Figure 5C. After assay of antifungal activity of each fraction, both fractions c and d were found to be effective (Figure 6). Collection of fractions c and d resulted in totally a yield of only 3.2 mg of protein from 60 g of Hokkaido large pinto beans (Table 2).

Mass Spectrum Analysis. The molecular weight of the protein was confirmed by MALDI-TOF MS to be 10888 Da (Supporting Information). An analysis of MS and MS/MS data using NCBInr and SwissProt databases revealed 40% similarity with defensin D1 of *P. vulgaris* protein accession gi|312982410. Hence, the defense protein from fraction c can be regarded as a member of the defensin group.

Antifungal Activity of Hokkaido Large Pinto Bean Defensin. Five fungal species were utilized in the assay of antifungal activity, comprising *M. arachidicola*, *S. turcica*, *B.*

DOI: 10.1021/acs.jafc.5b00475
J. Agric. Food Chem. 2015, 63, 5439−5448

maydis, *F. oxysporum*, and *V. mali*. Distilled water was used instead of protein sample as negative control. The antifungal activity of fractions a, b, and c was tested. It was found that fraction b had no antifungal effect on all five types of fungal species, as the mycelial growth extended to the paper disks. Fraction a had only a weak antifungal effect on *M. arachidicola*. Fraction c was capable of inhibiting the growth of *M. arachidicola*, *S. turcica*, *B. maydis*, and *F. oxysporum*, as distinct crescent-like invaginations could be seen around the paper disks. Yet it could not inhibit the growth of the pathogenic fungus *V. mali* (data not shown). Protein in fraction d had a molecular size identical to that of the protein in fraction c, and it also possessed antifungal activity toward the same types of fungi, suggesting they are the same protein (data not shown). Hokkaido large pinto bean defensin exerted strong activities toward *M. arachidicola* and *B.maydis* and a weaker activity toward *S. turcica* and *F. oxysporum*. The defensin had no antifungal effect on *C. albicans* at the concentration of 0.1 mg/mL (data not shown).

DISCUSSION

Nowadays, many lectins from edible plants with potent antitumor activity have been discovered. For instance, legume lectin Con A induced apoptosis in human melanoma A375 cells.[3] *Momordica charantia* lectin exerted an inhibitory action on nasopharyngeal carcinoma cells.[11] Banana lectin demonstrated a suppressive effect on leukemia (L1210) and HepG2 cells.[12] Broccolini lectin[13] and taro lectin[14], etc., are all potential candidates as anticancer agents. *P. vulgaris* merits research efforts because of its relatively inexpensive price, multiple cultivar sources, and high potential in anticancer activity. As Hokkaido large pinto bean has not been investigated before, we selected it for the present study.

By applying affinity chromatography on Affi-gel blue gel and Blue Sepharose, ion exchange chromatography on SP-Sepharose, Mono Q, and Q Sepharose, and FPLC-gel filtration on Superdex 75 and Superdex 200, etc., a variety of lectins with protential were successfully purified from different organisms, such as lectins from jelly fish *Nemopilema nomurai*,[15] bighead carp *Aristichthys nobilis*,[16] coral *Acropora millepora*,[17] *Annona muricata* seeds,[18] and various *P. vulgaris* cultivars including French bean Indian cultivar,[19] Blue Tiger King,[20] jade bean,[21] northeast red bean,[22] and so on. The purification methods adopted in the present study can be used to obtain the target proteins in a fast and simple way. By using fewer purification steps, the loss of the target protein could be minimized. The purification efficiency and the percentage recovery of lectin, which is calculated using the formula percentage recovery = (total hemagglutinating titer of purified sample/total hemagglutinating titer in crude extract) × 100%, showed the yield of Hokkaido large pinto bean hemagglutinin was noteworthy in that 190 mg of hemagglutinin could be purified from 60 g of beans with 17% recovery. It may be due to the abundant occurrence of this storage protein in Hokkaido large pinto beans and the few steps of purification employed. Many lectins isolated from other cultivars of *P. vulgaris* may not have the same advantages. For instance, the yield of lectin from 100 g of French bean cultivar no. 12 was only 4.8 mg with 18.1% recovery;[23] the corresponding values for Anasazi beans were 26 mg and 14% recovery;[24] and the values for French beans (cultivar no. 1) were 96.25 mg and 18.73% recovery.[7] Although larger amounts of lectin from other cultivars have been reported, for example, 428 mg of brown kidney bean lectin from 100 g of beans with about 57% recovery,[25] other advantages such as performance in assays of various biological activities should also be taken into consideration when assessing the utility/value of a protein.

With respect to structure and molecular size, Hokkaido large pinto bean hemagglutinin shared common characteristics with many lectins of *P. vulgaris*, which are dimeric proteins with a molecular mass of about 60 kDa.[21] Yet there are exceptions, for example, a 94 kDa tetrameric lectin purified from the seeds of the Cacahuate cultivar of *P. vulgaris*.[26] Despite these similar characteristics, hemagglutinins or lectins from different cultivars may perform distinctively regarding many biological activities, which may be due to the differences in their sequences. The N-terminal sequence is important for identifying a protein. By examining the N-terminal sequence, a number of *P. vulgaris* lectins have been identified.[23,27−30] However, in this study no peaks were detected after seven sequencing cycles, indicating that the hemagglutinin most likely possessed a blocked N-terminus. This is not a unique case, as lectins of *Castanea crenata*,[31] *Schizophyllum commune*,[32] and *Sclerotium rolfsii*[33] also had a blocked N-terminus.

Lectins or hemagglutinins from *P. vulgaris* possess different thermal and pH stabilities. For instance, lectin from jade bean had modest pH and heat stability: it was stable only at pH 4.5−9.4 and 30−70 °C,[21] whereas lectins purified from Anasazi bean and the Indian cultivar of French bean manifested high pH and heat stability. They were stable at 80 and 90 °C, respectively, and retained their hemagglutinating activity after treatment with solutions at pH 1−14 and 1−13, respectively.[19,27] The high thermal stability may be due to the absence of disulfide linkages, which become unstable at elevated temperatures or attributed to the absence of heat-sensitive tryptophan residues.[34] Some lectins had poor thermostability and pH stability, such as French bean cultivar no. 35, which retained its hemagglutinating activity at an ambient temperature below 50 °C or at a pH within the range of 6−8.[35] Hemagglutinin purified from Hokkaido large pinto bean was characterized by a modest thermostability and pH stability; it was stable at 30−60 °C and at pH values from 2 to 12. Considering its potential for application, it may be utilized as an agent for injection as it is stable at physiological temperature and pH in plasma. As the pH of gastric fluid ranges from 1 to 3, it still has a potential to be employed as a drug for oral administration even though its activity would be halved at pH 1.

With regard to carbohydrate selectivity, selected simple saccharides did not exert any inhibitory effect on the hemagglutinating activity of Hokkaido large pinto bean hemagglutinin. A number of lectins isolated from other *P. vulgaris* cultivars including cultivar 12, cultivar 35, Indian cultivar of French beans, Hokkaido red bean, northeast red bean, etc., also exhibited this common phenomenon.[19,23,34,36] On the other hand, the sugar-binding ability of lectins of some other *P. vulgaris* cultivars has been discovered. For instance, lectin from cultivar no. 1 of French beans bound specifically to glucuronic acid,[22] and lectins from both pinto beans and Extralong Autumn purple beans were galactose-specific.[28] In addition, polysaccharides can also be the binding target of some lectins. For example, lectin isolated from Blue Tiger King bean was polygalacturonic acid-binding specific;[28] meanwhile, the hemagglutinating activity of lectin from red kidney bean was reduced by several glycoproteins.[29]

Lectins are found to be divalent cation-dependent proteins.[20,37] During purification, they may lose ions or become desaturated with ions, which provides a rationale to the assay of the effect of metal ions in this study. Results displayed that metal ions including Ca^{2+}, Zn^{2+}, Mn^{2+}, Cu^{2+}, or Fe^{2+} ions enhanced the hemagglutinating activity of Hokkaido large pinto bean

[a]ND, not determined. [b]N/A, not applicable.

hemagglutinin at different concentrations, whereas Mg^{2+} ions failed to strengthen the diluted hemagglutinin to regain its hemagglutining capacity. Cu^{2+} or Fe^{2+} ions had the most obvious effect at the minimum concentration, followed by Mn^{2+} and Zn^{2+} ions, whereas Ca^{2+} ions were the least effective. It should be remembered that the effect of metal ion was uncertain. It was demonstrated that Ca^{2+}, Zn^{2+}, Mn^{2+}, and Mg^{2+} had no effect on the hemagglutinating activity of *Grifola frondosa* lectin,[38] whereas they restrained the lectin of *Schizophyllum commune*.[39] This may be due to the change of protein structure in the presence of metal ions.[40] For the *P. vulgaris* species, the effect on lectins varies among different cultivars. The activity of Con A, which is a well-known lectin isolated from jack beans, could be enhanced in the presence of Ca^{2+}, Mg^{2+}, and Mn^{2+} ions.[21] The potentiating effect of Ca^{2+} ions was not very commonly found and has been reported only for a few *Phaseolus* lectins, including *P. coccineus* lectin,[41] *P. lunatus* lectin,[42] and *P. acutifolius* lectin,[43] which was probably because Ca^{2+} ions enable the lectins to resist tryptic proteolysis.

For antifungal activity, Hokkaido large pinto bean hemagglutinin did not affect the growth of the tested fungi. To date, it has been found that some lectins possess antifungal activity. For example, *Aleuria aurantia* lectin inhibited the growth of *Mucor racemosus*.[44] French bean no. 35 lectin exhibited antifungal activity against *V. mali*, *F. oxysporum*, and *Rhizoctonia solani*.[35] However, a number of lectins without antifungal effect have been reported, such as lectin from jade bean,[21] Extralong Autumn purple bean,[28] and ground bean[45] etc.

The proliferation of several kinds of cancer cells encompassing hepatoma (HepG2) cells, breast cancer (MCF7) cells, and nasopharyngeal cancer (CNE2) cells was reduced by Hokkaido large pinto bean hemagglutinin in a time- and dose-dependent manner, whereas its antiproliferative effect on MDA-MB-231 breast cancer cell was only meager. The range of tumors cells found to be sensitive to Hokkaido large pinto bean hemagglutinin was large, compared to that of lectin purified from Blue Tiger King bean, which was specific toward HepG2 cells,[20] as well as lectin from French bean cultivar no. 35, which was active toward MCF7 cells but not toward HepG2 cancer cells.[35]

The anticancer effect of Hokkaido large pinto bean hemagglutinin in vitro was potent among many lectins that have been discovered to date. For instance, its IC_{50} values for HepG2, MCF7, and CNE2 cells after a 48 h exposure were 8.14, 6.07, and 7.49 μM, respectively, which were much smaller in magnitude than that of acaconin from seeds of *Acacia confusa* (IC_{50} = 128 ± 9 μM for MCF7 cells);[10] jade bean lectin (IC_{50} = 169 μM for MCF7 cells);[21] and Chinook salmon roe lectin (IC_{50} = 68 μM for HepG2 cells), etc. Some lectins showed a similar antitumor activity, such as lectin from *Lactarius flavidulus* (IC_{50} = 8.9 μM and 6.81 μM for HepG2 and leukemic L1210 cells, respectively);[10] Nagaimo lectin significantly reduced the growth of MCF7, HepG2, and CNE2 cells after 24 h of treatment, with IC_{50} values of 3.17, 7.12, and 19.79 μM, respectively.[46] With the advantages of pH stability and strong anticancer acitivity, Hokkaido large pinto bean hemagglutinin has the potential to be developed as an antineoplastic agent.

A summary of the properties of some *P. vulgaris* lectins (Table 4) revealed that Hokkaido large pinto bean hemagglutinin manifested the advantageous features of a potent antiproliferative effect toward different types of cancer cells, a wider pH range over which it was stable, and a considerably higher yield, which demonstrate its potential as an anticancer candidate.

Three types of chromatography including affinity chromatography, ion exchange chromatography, and FLPC-gel filtration were utilized for purification of defensin from Hokkaido large pinto beans. The protocol resembles purification procedures for some other defensins.[47,48] It has been reported that plant defensins have been discovered to possess an isoelectric point around 8−9.[49] This facilitates isolation of plant defensins by means of ion exchange chromatography: adsorption on cation exchangers and lack of binding to anion exchangers in neutral buffers (e.g., Tris-HCl, pH 7.6) or acidic buffers (e.g., NH_4OAc, pH 4.6).

The yield of the 10888 Da Hokkaido large pinto bean defensin was only 3.2 mg from 60 g of beans. In other studies on purification of defensin, such as the purification of northeast red bean antifungal peptide, 8 mg of antifungal peptide was extracted from 100 g of beans. Higher yields were observed in the purification of defensin from *Legumi secchi* bean and ground bean, which were 43 and 14 mg from 100 g of beans, respectively. However, a lower yield was also encountered in the purification of cloud bean defensin, which was 1.12 mg per 100 g of seeds.

With regard to its biological activity, Hokkaido large bean defensin displayed antifungal activity on different types of fungi including *M. arachidicola*, *S. turcica*, *F. oxysporum*, and *B. maydis*. However, fungi such as *V. mali* and *C. albicans* were resistant to Hokkaido large pinto bean defensin. In addition, most of the previously reported plant defensins were small proteins with a molecular size ranging from 5 to 9 kDa.[49] With a molecular size of 10.888 kDa, Hokkaido large pinto bean defensin is a big defensin. Defensins with a large size also exist in animals. For instance, a 79-residue defensin, which is responsible for host defense, was found in the Japanese horseshoe crab.[50]

To recapitulate, the pinto bean is an edible bean common in the United States and the Far East. The pH-stable and thermostable hemagglutinin, isolated with a remarkable yield

DOI: 10.1021/acs.jafc.5b00475
J. Agric. Food Chem. 2015, 63, 5439−5448

(190 mg/60 g), has potent antiproliferative activity toward various tumor cells including nasopharyngeal carcinoma (CNE2), human breast cancer (MCF7 cells), and hepatoma (HepG2) cells and thus noteworthy health-promoting activity. Currently there are not many publications reporting the action of lectins against nasopharyngeal cancer cells. The isolated defensin has a larger molecular weight than previously reported defensins and antifungal activity toward various phytopathogenic fungi and could be used in the biological control of agriculturally important fungi. It deserves mention that by comparison some antifungal proteins have activity against only one or two fungal species.[51,52]

Metabolomic Analysis Reveals Cyanidins in Black Raspberry as Candidates for Suppression of Lipopolysaccharide-Induced Inflammation in Murine Macrophages

Young-Hee Jo,[†,∥] Hyun-Chang Park,[†,∥] Seulgi Choi,[†,∥] Sugyeong Kim,[†] Cheng Bao,[†] Hyung Woo Kim,[†] Hyung-Kyoon Choi,[‡] Hong Jin Lee,*[,†] and Joong-Hyuck Auh*[,†]

Supporting Information

ABSTRACT: The extracts produced by multisolvent extraction and subfractionation with preparative liquid chromatography of black raspberry (*Rubus coreanus* Miquel) cultivated in Gochang, South Korea, were tested for their anti-inflammatory effects. The metabolomic profiling and analysis by orthogonal partial least-squares discriminant analysis (OLPS-DA) suggested that cyanidin, cyanidin-3-glucoside (C3G), and cyanidin-3-rutinoside (C3R) were key components for the anti-inflammatory responses in the most active fraction BF3-1, where they were present at 0.44, 1.26, and 0.56 μg/mg of BF3-1, respectively. Both BF3-1 and mixture of these cyanidins at the same ratio reduced lipopolysaccharide (LPS)-induced protein level of iNOS expression and suppressed mRNA and protein expressions of tumor necrosis factor (TNF)-α, interleukin (IL)-6, and IL-1β through inhibiting the phosphorylation of mitogen-activated protein kinases (MAPKs) and STAT3 in murine macrophage RAW264.7 cells. Overall, the results suggested that co-administration of cyanidin, C3G, and C3R is more effective than that of cyanidin alone and that the coexistence of these anthocyanin components in black raspberry plays a vital role in regulating LPS-induced inflammation even at submicromolar concentrations, making it possible to explain the health beneficial activity of its extracts.

KEYWORDS: *black raspberry, metabolomic profiling, cyanidin, cyanidin-3-glucoside, cyanidin-3-rutinoside*

INTRODUCTION

There are accumulating studies demonstrating the health beneficial efficacy of black raspberry in chronic diseases such as inflammation, metabolic syndrome, atherosclerosis, and cancer.[1−6] Black raspberry supplementation retarded mammary tumorigenesis by inhibiting the expression of estrogen receptor α (ER-α), reducing carcinogen-induced esophageal cancer by regulating pentraxin-3 expression, and suppressing ultraviolet B (UVB)-induced inflammation and skin tumor development.[2,5,7] In addition, a diet containing 5 or 10% of freeze-dried black raspberries suppressed DSS-induced colon injury through inhibiting cyclooxygenase 2 (COX-2) expression and reducing the level of tumor necrosis factor-α (TNF-α) and interleukin 1β (IL-1β).[4] The potential constituents responsible for the health beneficial efficacy of black raspberries have been identified as anthocyanins, simple phenols such as ellagic acid and quercetin, sterols such as β-sitosterol, vitamins, and minerals.[8] Tulio et al. identified five different anthocyanins including cyanidin-3-glucoside and cyanidin-3-rutinoside and demonstrated that cyanidin-3-rutinoside and cyanidin-3-xylosylrutinoside may act as the key components exerting antioxidant activity in black raspberry.[9] Ferulic acid and β-sitosterol were also reported to show antiproliferative activity in oral cancer cell lines without affecting the normal oral epithelial cells.[10] Although the roles of powder or extract of black raspberry in physiological effects and their potent ingredients have been elucidated, there are few studies considering the actual concentrations or interactions of the key phytochemicals in the extracts of black raspberry. To overcome this hurdle, it is meaningful enough to employ a new approach for profiling the whole metabolites and identifying the set of metabolites exerting the health-promoting effects.

Metabolomics is nontargeted identification and quantification of all metabolites within a given set of conditions.[11] It objectively measures all or a substantial fraction of all metabolites within a sample, quantifies each relative to an absolute index of the sample (per gram, milliliter, etc.), and analyzes hundreds to thousands of small molecular weight metabolites comprehensively within samples according to their molecular weights.[12] Metabolomics is a useful tool for the analysis of the phenotype in food science.[13] Currently, metabolite profiling methods have been established including mass spectrometry (MS)-coupled methods, such as LC-MS, ultraperformance LC (UPLC)-MS, and capillary electrophoresis (CE)-MS, which have wide availability in analytical technology.[14] LC-MS methods are often used with electrospray ionization (ESI), atmospheric pressure chemical ionization (APCI), or matrix-assisted laser desorption/ionization (MALDI) to porovide the samples as ionized state. The ionized metabolites pass through linear TOF-MS, single-quadrupole MS, or Q-TOF to detect the ion mass and intensity[15] commonly by MS-MS or MS^n. Following profiling by LC-MS, all data are analyzed by statistical tools to screen out

critical contributors on the significant variations in the target samples.

In our previous study, metabolomic investigation using MS-coupled method was performed between the fractions separated by multistep solvent extraction, and ellagic acid was successfully identified as a key metabolite in the fraction exerting anti-inflammatory activity in strawberry ('Seolhyang').[16] Recently, it was also reported that ^{1}H nuclear magnetic resonance (NMR)-based metabolomic analyses were developed, by which the bioactive contributors in black raspberry against oxidative stress and proliferation of HT-29 colon cancer cells were identified.[17,18] These results suggested that the metabolomic process could be one of the significant approaches to ascertain the constituents responsible for the physiological efficacy of the active food resources. However, comparative demonstration of active components screening with metabolomic approach along with mechanistic evaluation has been tried to date. In this study, black raspberry cultivated in South Korea was separated into several fractions with organic solvents, and then the most active extract in suppressing lipopolysaccharide (LPS)-induced inflammation was further fractionated. The key contributors were discriminated and identified through multivariate statistical analysis, and their anti-inflammatory activity was validated with the underlying mechanism.

MATERIALS AND METHODS

Materials. Black raspberry (*Rubus coreanus* Miquel) cultivated in Gochang, South Korea, was used for the multistep solvent extraction. Fresh black raspberries were freeze-dried and kept in a deep freezer (−80 °C) before use. LPS, cyanidin, cyanidin 3-glucoside chloride, and cyanidin 3-rutinoside chloride were obtained from Sigma-Aldrich Corp. (St. Louis, MO, USA). Ethyl acetate was purchased from DUKSAN (Ansan, South Korea), methanol from SAMCHUN (Pyung-Taek, South Korea), acetonitrile from J. T. Baker (Phillipsburg, NJ, USA), and formic acid from Sigma-Aldrich Corp.

Extraction of Polyphenol Compounds from Black Raspberry. Polyphenols from black raspberry were extracted by multistep solvent extraction method with ethyl acetate and methanol as described previously.[16,19] Black raspberry (2.5 g) was extracted with ethyl acetate (10 mL) for 30 min at room temperature, and the supernatant was evaporated and resuspended with methanol (BF1). The residue was acidified with HCl (2 M, 1 mL) and then extracted with methanol (BF2), and another supernatant portion was hydrolyzed with HCl in MeOH (0.6 M, 5 mL) for 20 h at 60 °C (BF3) and analyzed by LC-MS/MS.

Subfractionation of BF3 Using Preparative LC. BF3 was further fractionated using preparative liquid chromatography (LC-forte/R, YMC, Kyoto, Japan). Separation was carried out using YMC-DispoPack AT ODS (40 g, 25 μm) (YMC). The solvent system was consisted of a gradient mobile phase from 100% B in 3 min, from 100 to 0% in 24 min, held at 0% over 3 min, and finished at 30 min, where solvent A was 0.1% formic acid in water and solvent B was 0.1% formic acid in methanol. The flow rate was set at 25 mL/min, and UV spectra were measured at 280, 360, and 400 nm. The BF3 was separated into three subfractions according to peak shape, which was detected at 280 nm (Figure 2A).

Metabolite Profiling Using LC-MS/MS Analysis. Profiling of the metabolites in each fraction or the extracts was conducted using a LC-MS/MS system consisting of an Accela HPLC system with a PDA detector (Accela 80 Hz PDA detector, Thermo Fisher Scientific, San Jose, CA, USA) and an LTQ-Velos ion trap mass spectrometer fitted with a heat electrospray ionization interface (Thermo Fisher Scientific).[16] Separation was carried out using a UPLC BEH C18 column (1.7 um, 100 × 2.1 mm i.d., Acquity, Waters, Milford, MA, USA) at 35 °C. Solvent A was 0.1% formic acid in water, and solvent B was 0.1% formic acid in acetonitrile. The solvent system consisted of a gradient mobile phase from 5 to 10% B in 5 min, held at 10% B for 5 min, from 10 to 40% B in 20 min, from 40 to 90% B in 10 min, then returned to the initial conditions (5% B) in 5 min and conditioned at 5% B in 10 min, and finished at 55 min. The flow rate was set at 0.3 mL/min, and UV spectra were measured between 180 and 800 nm. Acquisition was performed in the positive and negative ion mode by electrospray ionization (ESI) source, and the m/z range was 100−1000 Da. The capillary temperature was 275 °C, and the source voltage was set to 5 kV for ionization.

Metabolite Identification. The data acquired by LC-MS/MS were processed for peak detection, alignment, and identification by SIEVE software (Thermo Fisher Scientific, Waltham, MA, USA). The acquired LC-MS/MS spectrum was identified after comparison with those proposed by the MASSBANK database (www.massbank.jp), Human Metabolome Database (www.hmdb.ca), METLIN (http://masspec.scripps.edu), KEGG database (www.Kegg.co.jp), and related papers. Identifications of cyanidin, cyanidin 3-glucoside, and cyanidin 3-rutinoside were confirmed with authentic standard compounds.

HPLC Analysis for Quantification of Metabolites. Quantification of anthocyanins and their metabolites was conducted using a standard curve generated from authentic standards of cyanidin, cyanidin 3-glucoside, and cyanidin 3-rutinoside. Analysis was performed by HPLC (Dionex HPLC-3000, Dionex Corp., Sunnyvale, CA, USA) with a UV detector (Ultimate 3000 diode array detector, Dionex Corp.) using an X-bridge C18 column (3.5 μm, 4.6 × 150 mm, Waters) at 35 °C. The solvents were 10% formic acid in water (phase A) and acetonitrile (phase B) at flow rate of 1 mL/mL. The linear gradient profile was as follows: 5−15% B in 15 min, held at 15% B for 5 min, 15−5% B in 5 min, and finished at 25 min. UV spectra were measured at 520 nm.

Cell Culture. RAW264.7 cells were obtained from the Korean Cell Line Bank (Seoul, Korea) and cultured in DMEM supplemented with 10% fetal bovine serum (FBS), 1% penicillin/streptomycin, and 1% HEPES at 37 °C and 5% CO_2.

Cell Proliferation Assay (MTT Assay). The cells were seeded in a 96-well plate and treated with black raspberry extracts for 24 h. The formazan crystals formed from 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT, Sigma-Aldrich) were dissolved in DMSO, and the absorbance was measured with an ELISA reader at 570 nm (Molecular Devices, Sunnyvale, CA, USA).

Western Blot Analysis. This analysis was described previously.[16] Briefly, the cells were harvested with radioimmunoprecipitation assay (RIPA) lysis buffer, and the protein extract was separated and transferred to a polyvinylidene difluoride (PVDF) membrane (Millipore, Billerica, MA, USA). The primary antibodies against iNOS (Abcam, Cambridge, MA, USA), COX2, IκBα (Santa Cruz Biotech, Santa Cruz, CA, USA), phospho-ERK, phospho-p38, phospho-JNK, phospho-STAT3 (Cell Signaling Technology, Boston, MA, USA), β-actin (Sigma-Aldrich), and secondary antibodies (Santa Cruz) were used. The expression levels of proteins were visualized with EZ capture MG (ATTO, Tokyo, Japan) and quantified with CS Analyzer (ver. 3.0, ATTO).

RNA Extraction and Quantitative RT-PCR Analysis. The cellular RNA was isolated and reverse-transcribed to cDNA using Trizol reagent (Sigma) and a RevertAid First Strand cDNA Synthesis Kit (Theromo Scientific, Lafayette, CO, USA) in Atlas Thermal Cycler (Astec, Fukuoka, Japan), respectively. The cDNA was amplified using TaqMan primers (iNOS, COX-2, TNF-α, IL-1β, interleukin-6 (IL-6), glyceraldehyde-3-phosphate dehydrogenase (GAPDH); Applied Biosystems, Foster City, CA, USA) in ABI Prism 7500 real-time PCR system (Applied Biosystems) and relatively quantified as described in the previous study.[16]

Enzyme-Linked Immunosorbent Assay (ELISA). Following the instructions from the company, the expression of cytokines (TNF-α, IL-6, IL-1β) in culture supernatants was analyzed using an ELISA kit (Koma Biotech Inc., Seoul, Korea).

Data Processing and Statistical Analysis. SIEVE software (Thermo Fisher Scientific) was used for peak/feature picking and deconvolution of raw data. The SIEVE parameters were as follows: mass range, 100−1000 Da; retention time, 1.5−35 min; frame m/z

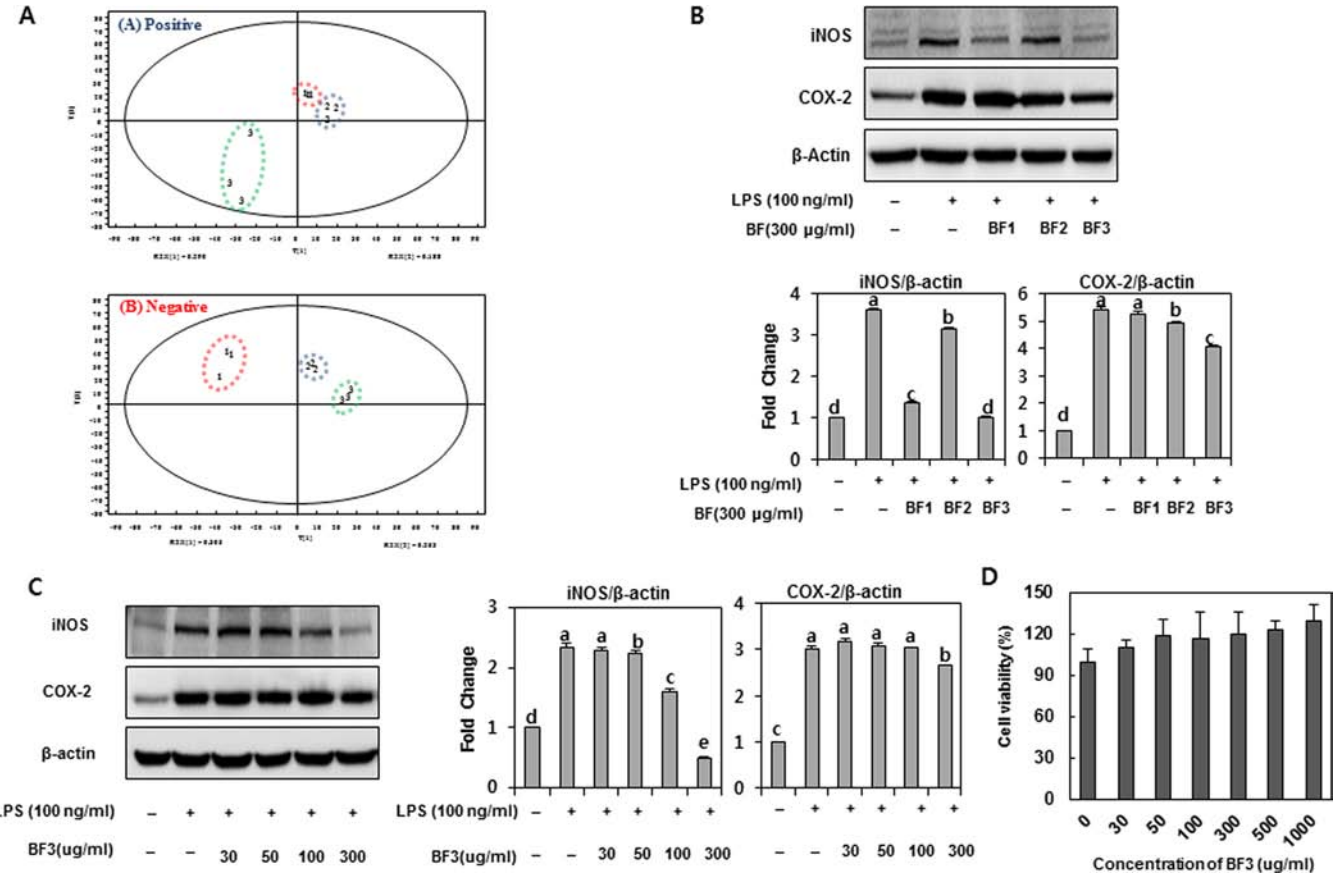

Figure 1. Anti-inflammatory effect of Korean black raspberry fractions in LPS-induced RAW264.7 cells. (A) PCA score plot for the metabolites in each fraction. Fractionation of extract was performed by using multistep solvent extraction and PCA score plot for classifying the distinctive metabolites in extract fractions (1, BF1; 2, BF2; 3, BF3) analyzed by LC-ESI-ion trap MS/MS in positive and negative ion mode. (B) Comparison of anti-inflammatory effects of each fraction. The cells (8×10^5 cells/well in 60 mm dish) were treated with black raspberry fractions (300 μg/mL) together with LPS (100 ng/mL) for 15 h. The protein expression levels of iNOS and COX2 were determined by Western blotting and normalized with β-actin. (C) Anti-inflammatory effect of BF3. The cells (8×10^5 cells/well in 60 mm dish) were treated with BF3 (30, 50, 100, 300 μg/mL) together with LPS (100 ng/mL) for 15 h. iNOS and COX2 protein expression were determined by Western blotting and normalized with β-actin. (D) Effect of BF3 on cell viability. The cells (1×10^4 cells/well in a 96-well plate) were treated with BF3 at the indicated concentrations for 24 h, and cell viability was assessed by MTT assay. Statistical significance was determined by one-way ANOVA with the Duncan test, and differences are indicated with different letters ($p < 0.05$).

width, 0.02 Da; frame time width, 2.5 min. Noise filtering, peak detection, isotope peak removal, alignment of retention time and mass, and peak normalization were conducted. Multivariate statistical analyses, including principal component analysis (PCA) and orthogonal partial least-squares discriminant analysis (OPLS-DA), were performed using SIMCA software (Umetrics, Umea, Sweden). The data sets were mean-centered and pareto-scaled before analysis. For analyzing the data from MTT, Western blot, quantitative RT-PCR, and ELISA assays, one-way ANOVA with Duncan's test was used, and differences were considered statistically significant at $p < 0.05$.

RESULTS

Metabolite Profiling in Fractionated Black Raspberry by LC-ESI-Ion Trap-MS/MS. Black raspberry metabolites were fractionated into three groups (BF1, BF2, BF3) through ethyl acetate and methanol extraction as described under Materials and Methods. PCA clearly indicated that the metabolites in different fractions were separated into different groups as shown in Figure 1A. Differences were mainly contributed by principal component 1 in both negative and positive ion modes. The metabolites in each fraction were analyzed using LC-ESI-MS/MS and summarized (see Supporting Information Table 1). The abundance of all molecular ions was sufficient for further fragmentation into MS^2 and MS^3 analysis for the tentative identification of each metabolite.

Black Raspberry Fraction 1 (BF1). BF1, as ethyl acetate extract, contained *p*-coumaroyl hexose, (epi)catechin-(epi)-catechin, quercetin 3-*O*-rutinoside, quercetin 3-*O*-glucuronide, ellagic acid hexose, kaempferol-deoxyhexose, luteolin 7-glucoside, vanilloyl hexose, myricetin hexose, and hibiscetin tetramethyl ether in positive ion mode. Catechin, ellagic acid, methyl ellagic acid pentose, ellagitannin derivatives, *p*-coumaroylhexose, quercetin, quercetin, quercetin 3-glucoside, quercetin 3-*O*-glucuronide, proanthocyanidin B2 (EC-4,8-C), HHDP-galloyl-glucose, dihydroxybenzoic acid, and hydroxybenzoyl hexose were identified in negative ion mode.

Black Raspberry Fraction 2 (BF2). BF2, as a simple methanol extract, cyanidin 3-glucoside, cyanidin 3-rutinoside, cyanidin 3-sambubioside, cyanidin 3-xylosylrutinoside, (+)-catechin, *p*-coumaroyl hexose, quercetin 3-*O*-glucuronide, quercetin, and pelargonidin 3-rutinoside were identified in positive ion mode. Ellagic acid, ellagic acid-pentose conjugate, quercetin, quercetin glucoside, quercetin 3-*O*-glucuronide, quercetin 3-rutinoside, cyanidin 3-glucoside, malvidin 3-*O*-glucoside, pelargonidin 3-*O*-rutinoside, peonidin glucoside,

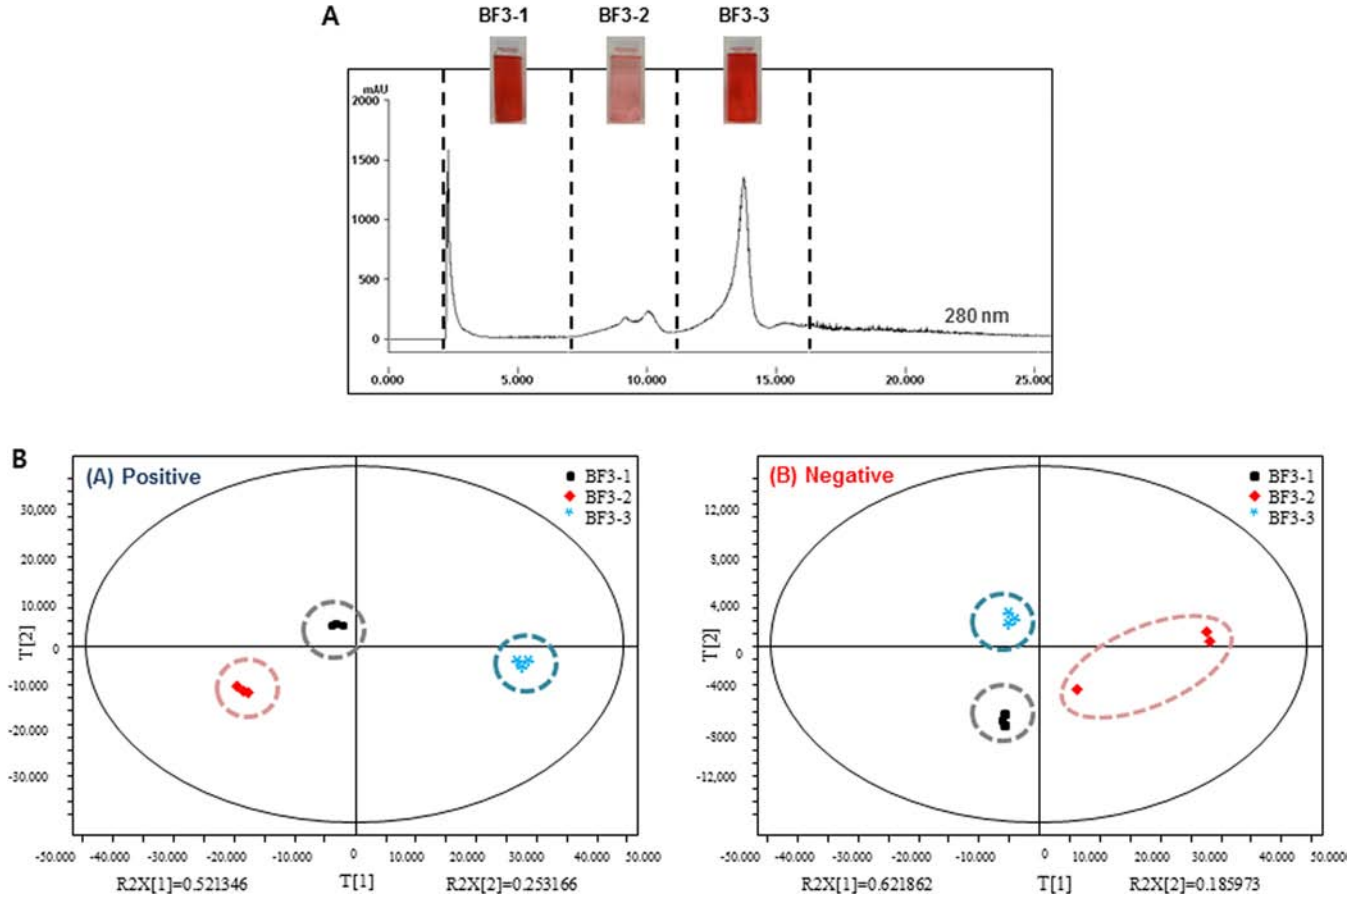

Figure 2. PCA for the metabolites in subfractions of Korean black raspberry extract 3 (BF3). (A) HPLC chromatogram of BF3 by preparative HPLC. BF3 was fractionated into three subfractions (at 280 nm): BF3-1, 2.00−6.84 min; BF3-2, 6.84−10.67 min; BF3-3, 10.67−15.45 min. (B) PCA score plot of Korean black raspberry subfractions analyzed by LC-ESI-ion trap MS/MS in positive (left) and negative ion mode (right).

HHDP-galloyl-glucose, ellagitannin derivatives, galloyl bis-HHDP-glucoside, *p*-coumaroyl hexose, and citric acid were found in negative mode.

Black Raspberry Fraction 3 (BF3). BF3, as the acidic hydrolysate of BF2, cyanidin, cyanidin 3-glucoside, cyanidin 3-rutinoside, cyanidin 3-sambubioside, pelargonidin 3-malonyl-glucoside, pelargonidin 3-rutinoside, and quercetin were found in positive ion mode, whereas cyanidin, cyanidin 3-glucoside, cyanidin 3-rutinoside, isorhamnetin 3-glucuronide, pelargonidin 3-rutinoside, ellagic acid, HHDP-galloyl-glucose, ellagitannin derivatives, kaempferol, and quercetin were identified in negative ion mode.

Black Raspberry Fractions Inhibited LPS-Induced Inflammation in Murine Macrophage Cells. To investigate the effect of black raspberry fractions on regulating inflammation, murine macrophage RAW264.7 cells were treated with extracted fractions (BF1-BF3) at 300 μg/mL concentration, and the protein expression of well-known inflammatory markers iNOS and COX-2 was determined. As shown in Figure 1B, BF3 exerted the most significant inhibition on iNOS expression, followed by BF1, and BF2 did not show suppressive activity. BF3 also reduced the expression of COX-2, but the effect was marginal (Figure 1B). To evaluate the dose dependency of the most potent fraction, RAW264.7 cells were treated with BF3 at different concentrations (30, 50, 100, 300 μg/mL), and we found that BF3 significantly suppressed iNOS expression from 100 μg/mL concentration, with a slight inhibition on COX-2 (Figure 1C). In the MTT assay, BF3 did not affect the cell viability up to 1000 μg/mL, indicating that iNOS inhibition is not derived from the cellular cytotoxicity in the macrophage cells (Figure 1D). On the basis of these results, we chose BF3 for further studies of subfractionation and identification of active metabolites.

Metabolite Phenotyping of Black Raspberry Subfractions. Through prep-LC, BF3 metabolites were fractionated into three subfractions, and then their metabolites were analyzed by LC-ESI-ion trap-MS/MS. PCA indicated that metabolites in subfractions were classified into different groups. In positive ion mode, principal component 1 (explaining 52.1% of the total variance) discriminated the metabolite profiles of subfractions, whereas principal component 2 explained 25.3% of total variance (Figure 2B). In negative ion mode, metabolites in subfractions were discriminated by principal component 1 (explaining 62.2% of total variance), and principal component 2 explained 18.6% of total variance (Figure 2B). The PCA score plots demonstrated the distinctive metabolite phenotypes of subfractions. The metabolites in each subfractions were analyzed using LC-ESI-ion trap-MS/MS and are summarized in the Supporting Information (Table 2). By comparison of retention time and MS^n spectra in positive mode, cyanidin 3-glucoside, cyanidin 3-rutinoside, and cyanidin were identified in BF3-1. Cyanidin 3-glucoside, cyanidin 3-rutioside, pelargonidin 3-rutinoside, quercetin-3-rutinoside, and cyanidin 3-xylosylrutinoside were identified in BF3-3. Cyanidin 3-glucoside, cyanidin 3-rutinoside, cyanidin, and ellagic acid were also identified in BF3-1 in negative mode, and ellagic acid and quercetin were

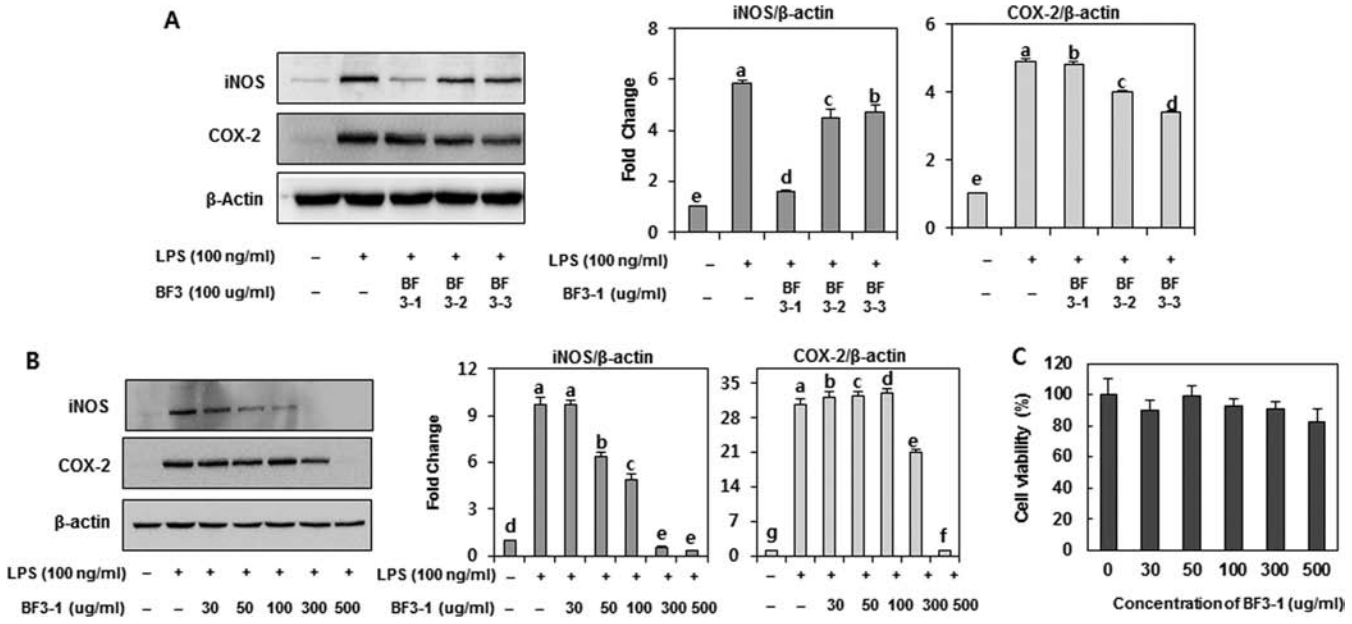

Figure 3. Anti-inflammatory effect of subfractions of BF3 in LPS-induced RAW264.7 cells. (A) Comparison of anti-inflammatory effects of each subfraction. The cells (8×10^5 cells/well in 60 mm dish) were treated with black raspberry subfractions (BF3-1, BF3-2, BF3-3; 100 μg/mL) together with LPS (100 ng/mL) for 15 h. The levels of iNOS and COX2 protein expression were determined by Western blotting and normalized with β-actin. (B) Anti-inflammatory effect of BF3-1. The cells (8×10^5 cells/well in 60 mm dish) were treated with BF3-1 (30, 50, 100, 300, 500 μg/mL) with LPS (100 ng/mL) for 15 h, and iNOS and COX2 protein expressions were determined by Western blotting and normalized with β-actin. (C) Effect of BF3-1 on cell viability. The cells (1×10^4 cells/well in a 96-well plate) were treated with BF3-1 at the indicated concentrations for 24 h, and cell viability was determined by MTT assay. Statistical significance was determined by one-way ANOVA with Duncan's test, and differences are indicated with different letters ($p < 0.05$).

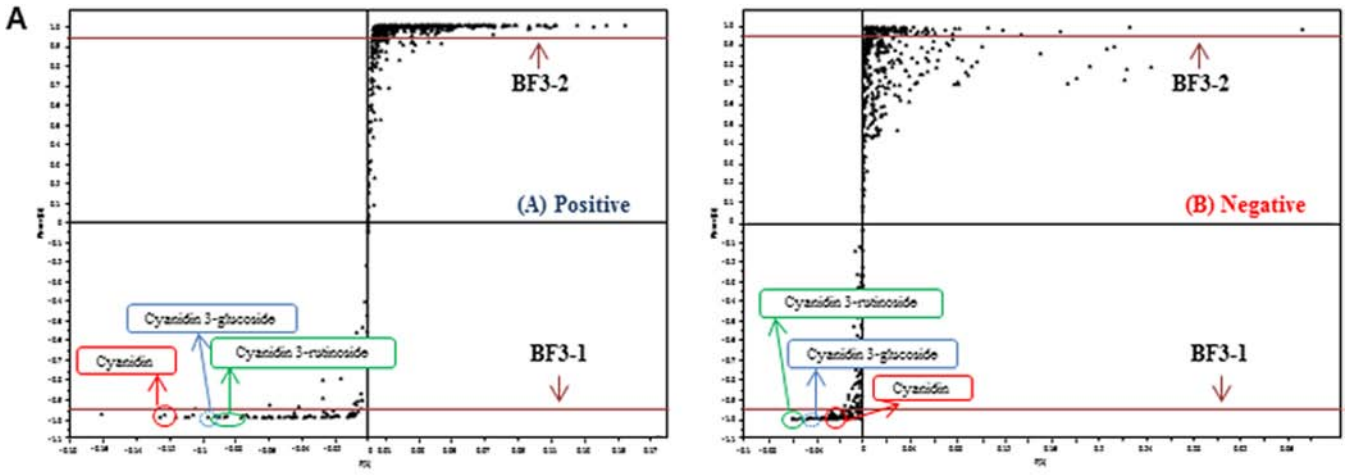

B

No.	Compounds	Quantity (μg/mg of BF3-1)
1	Cyanidin	0.44 ± 0.04
2	Cyanidin 3-glucoside	1.26 ± 0.08
3	Cyanidin 3-rutinoside	0.56 ± 0.06

Figure 4. Analysis for the key compounds in BF3-1. (A) S-plot generated by OPLS-DA for the metabolite in BF3-1 and BF3-2 in positive (left) and negative ion mode (right). (B) Quantification of cyanidin, cyanidin 3-glucoside, and cyanidin 3-rutinoside in BF3-1 by HPLC.

identified in BF3-2 in negative ion mode. Cyanidin 3-glucoside, cyanidin-3-rutinoside, and quercetin-3-rutinoside were found in BF3-3 under negative ion mode of analysis.

Subfractions of BF3 Exerted More Active Efficacy in Regulating Inflammatory Markers in Murine Macrophage Cells. Here, we evaluated the regulatory effects of BF3 subfractions on inflammatory markers iNOS and COX-2 in LPS-induced RAW264.7 macrophage cells. As shown in Figure 3A, BF3-1 (100 μg/mL) strongly inhibited the expression of iNOS induced by LPS treatment, but BF3-2 and BF3-3 exerted

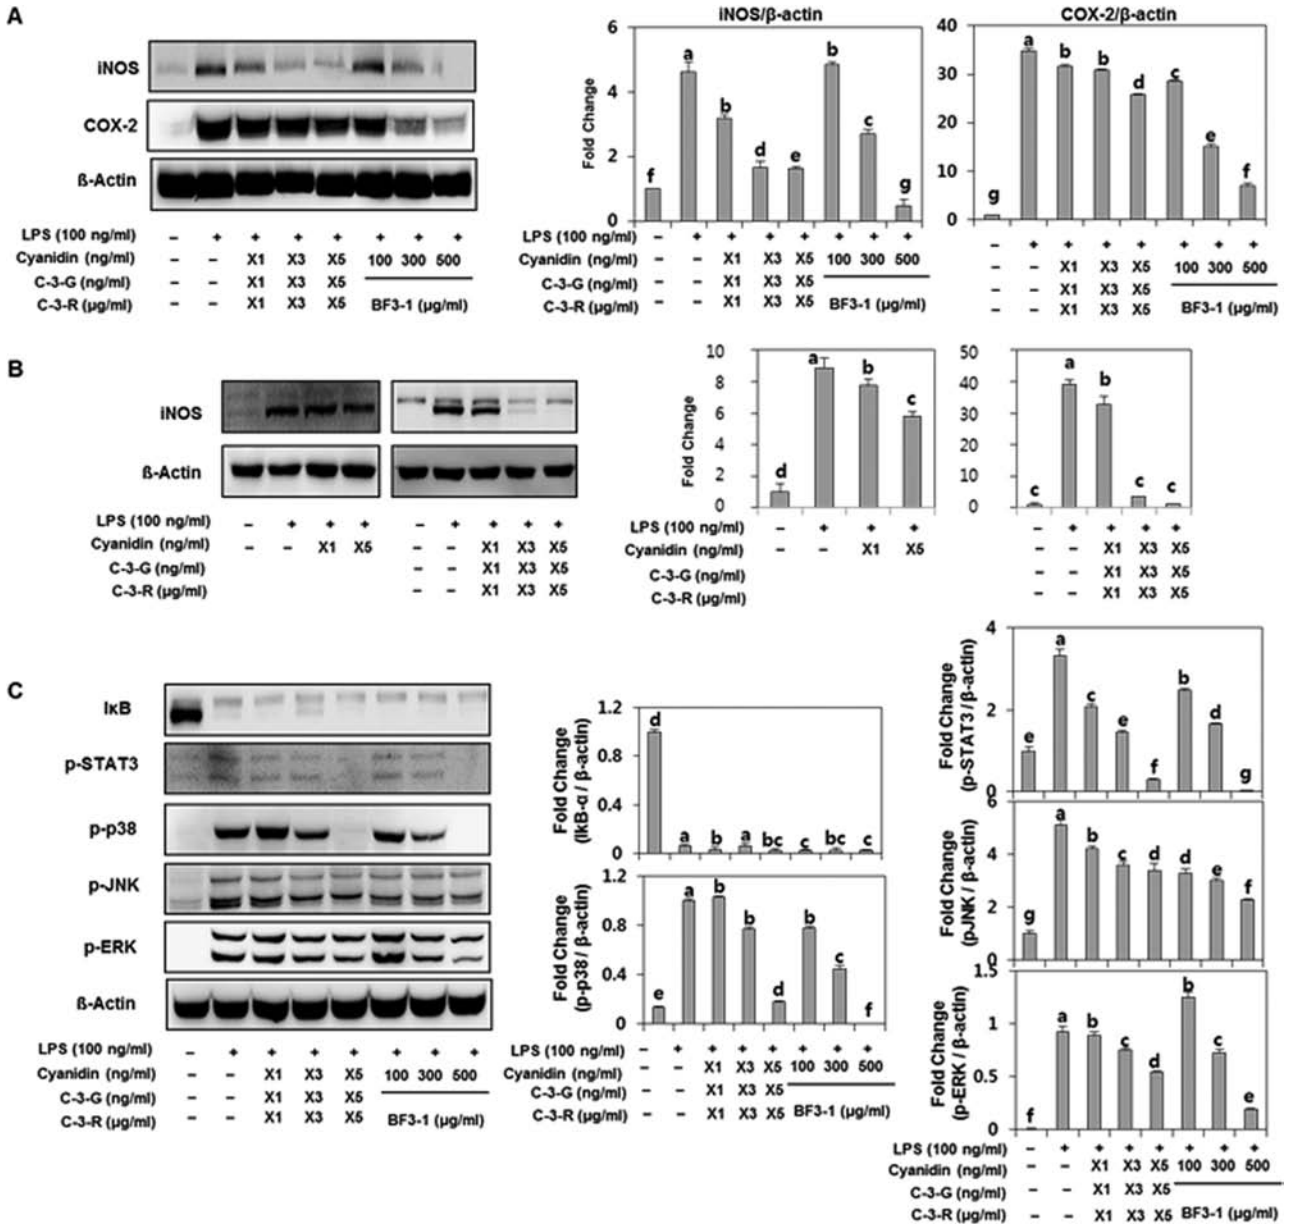

Figure 5. Anti-inflammatory mechanisms of BF3-1 and corresponding key constituents in LPS-induced RAW264.7 cells. (A) The cells (8×10^5 cells/well in 60 mm dish) were treated with the key compounds (cyanidin, C3G, C3R) or BF3-1 (100, 300, 500 μg/mL) with LPS (100 ng/mL) for 15 h. X1 represents 0.15 μM cyanidin, 0.26 μM C3G, and 0.09 μM C3R, respectively, and X3 and X5 represent levels 3 and 5 times higher than X1. The protein expression levels of iNOS and COX2 were determined by Western blotting and normalized with β-actin. (B) The cells (8×10^5 cells/well in 60 mm dish) were treated with cyanidin alone (X1 and X5) and cyanidin mixture (X1, X3, X5) for 15 h. The expression level of iNOS was determined by Western blotting and normalized with β-actin. (C) The cells (8×10^5 cells/well in 60 mm dish) were treated with the key compounds (cyanidin, C3G, C3R) and BF3-1 (100, 300, 500 μg/mL) with LPS (100 ng/mL) for 15 min. The levels of LPS-induced phosphorylation of MAPKs and STAT3 and IκBα degradation were assessed by Western blotting and normalized with β-actin. Statistical significance was determined by one-way ANOVA with Duncan's test, and differences are indicated with different letters ($p < 0.05$).

only slight suppression of iNOS and COX-2. In a concentration dependency test, BF3-1 showed inhibitory efficacy of iNOS from 50 μg/mL and of COX-2 from 300 μg/mL without affecting the cellular viability (Figure 3B,C), suggesting that BF3-1 black raspberry fraction may contain the key components responsible for anti-inflammatory activity.

Screening of Anti-inflammatory Metabolites in BF3-1 and BF3-2 by LC-ESI-Ion Trap MS/MS. All data sets of metabolite profiles of BF3-1 and BF3-2 were analyzed by OLPS-DA. The S-plot visualized the variables that differentiated most in uncoordinated way at the top or bottom in the plot. The variables on the top indicated metabolites in BF3-2, and the ones on the bottom indicated metabolites in BF3-1 in positive and negative ion modes as described in Figure 4A. Cyanidin, cyanidin 3-glucoside (C3G), and cyanidin 3-rutinoside (C3R) were identified as significant variables ($p < 0.05$) specifically found in BF3-1 compared to BF3-2 with regulatory activity on iNOS and COX-2 expression as denoted in Figure 4A. Quantitative analysis on these key molecules revealed that cyanidin, C3G, and C3R were contained in BF3-1 at 0.44, 1.26, and 0.56 μg/mg, respectively (Figure 4B). The critical difference of these compounds in BF3-1 may influence the

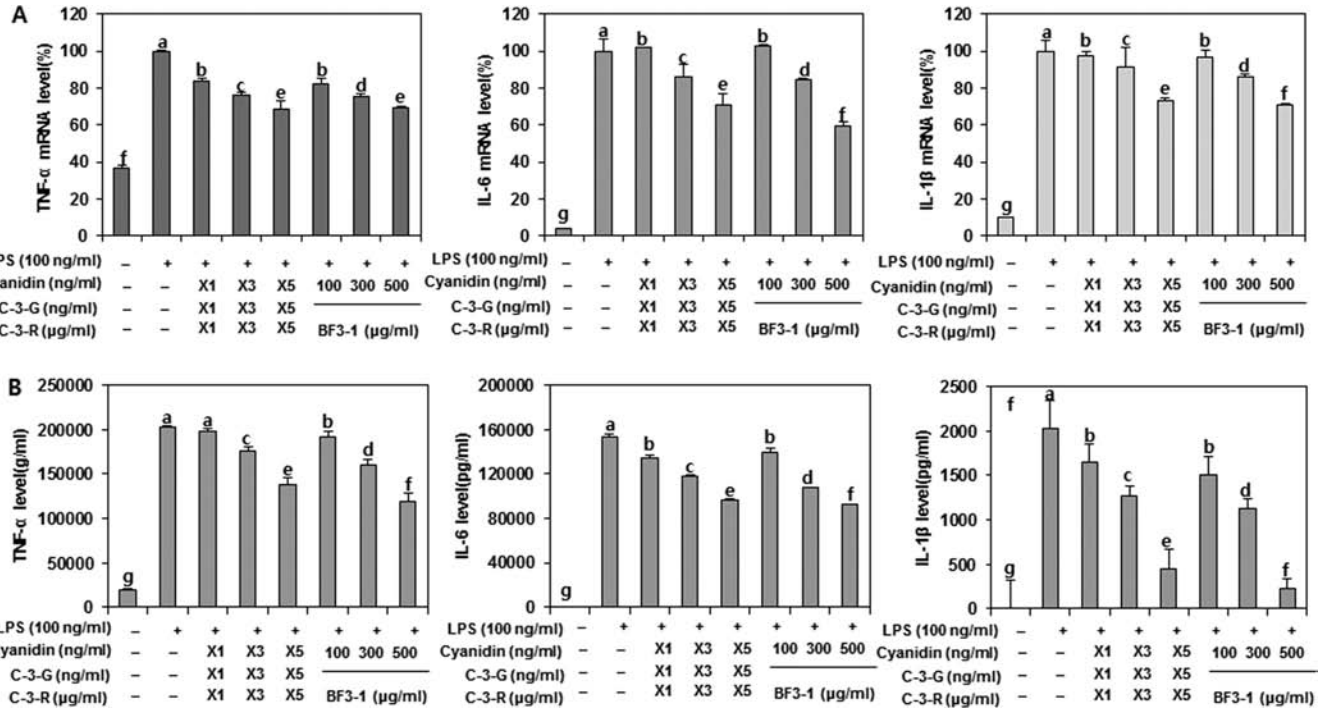

Figure 6. Effect of BF3-1 and key constituents on mRNA and protein expression of cytokines in LPS-induced RAW264.7 cells. The cells (8×10^5 cells/well in 60 mm dish) were treated with the key compounds (cyanidin, C3G, C3R) and BF3-1 (100, 300, 500 μg/mL) with LPS (100 ng/mL) for 15 h. (A) The mRNA levels of cytokines were measured by quantitative RT-PCR. (B) The released cytokine levels in media were measured by ELISA. Statistical significance was determined by one-way ANOVA with Duncan's test, and differences are indicated with different letters ($p < 0.05$).

different anti-inflammatory patterns of BF3-1 and BF3-2 as indicated in Figure 3A.

BF3-1 and Cyanidin Mixture Commonly Suppressed the Inflammatory Markers and Regulated the Same Intracellular Signaling Mediators in Murine Macrophage Cells. Here, we compared the anti-inflammatory activity between the BF3-1 fraction and the cyanidin mixture of the key components, cyanidin, C3G, and C3R, in LPS-induced RAW264.7 cells. On the basis of the quantifications of key components in BF3-1, the actual amounts of cyanidin, C3G, and C3R in BF3-1 at 100 μg/mL were determined as 0.044 μg/mL (~0.15 μM), 0.126 μg/mL (~0.26 μM), and 0.056 μg/mL (~0.09 μM), respectively, which was described as X1 (Figure 5). X3 and X5 represent 3 and 5 times higher amounts of each constituent relative to X1, which are the same amounts present in 300 and 500 μg/mL of BF3-1, respectively. As shown in Figure 5A, the BF3-1 fraction exerted dose-dependent suppression of iNOS expression, and the cyanidin mixture also showed similar activity, although COX-2 inhibition is more significant in BF3-1. In addition, single treatment of cyanidin at the concentrations of X1 (0.044 μg/mL) and X5 (0.22 μg/mL) suppressed LPS-induced iNOS expression only up to 12.8 and 34.7%, respectively, but the treatment of cyanidin mixture exerted iNOS inhibitory activity up to 16.6% and 98.3% (Figure 5B). These results suggest that the regulatory efficacy on iNOS expression by BF3-1 fraction might be derived from the coexistence of cyanidin, C3G, and C3R. To determine whether BF3-1 and the cyanidin mixture share the upstream inflammatory signaling molecules, we tested the expression of inhibitory κB (IκB) and phosphorylation of mitogen-activated protein kinases (MAPKs) and found that the phosphorylations of extracellular signal-related kinase (ERK), c-Jun N-terminal kinase (JNK), and p38 induced by LPS treatment were significantly blocked by both the BF3-1 fraction and cyanidin mixture in a dose-dependent manner (Figure 5B). Interestingly, however, BF3-1 and the cyanidin mixture did not recover the degraded IκB by LPS treatment, indicating that they regulated the LPS-induced inflammation independent of the nuclear factor κB (NF-κB) signaling pathway.

BF3-1 and Cyanidin Mixture Inhibited Expression Level of the Same Cytokines in Murine Macrophage Cells Induced by LPS. Due to critical roles of cytokines during the inflammatory processes,[20] we further investigated the roles of BF3-1 and cyanidin mixture in regulating the expression of well-known cytokines tumor necrosis factor-α (TNF-α), interleukin 1β (IL-1β), and interleukin 6 (IL-6) in RAW264.7 cells. In mRNA expression of cytokines determined by quantitative RT-PCR, both cyanidin mixture and BF3-1 reduced the level of those cytokines most significantly at X5 and 500 μg/mL (Figure 6A). In addition, the amount of the secreted cytokines at protein level was confirmed by ELISA, and it was found to be reduced by cyanidin mixture and BF3-1 treatment, where IL-1β was most strikingly suppressed (Figure 6B). Recently, it was reported that LPS increased the production of cytokines IL-6 and IL-1β through STAT3 activation in murine macrophage cells.[21] Here, we also confirmed that BF3-1 and cyanidin mixture blocked the phosphorylation of STAT3 (Figure 5B), which may lead to reduced LPS-induced expression of IL-6 and IL-1β (Figure 6).

DISCUSSION

Metabolomics is the useful analysis appropriate for profiling a whole set of metabolites and phenotyping the unique metabolome from complicated food and natural resources. This approach has been recently applied to elucidate the relationship between dietary sources and human chronic

DOI: 10.1021/acs.jafc.5b00560
J. Agric. Food Chem. 2015, 63, 5449−5458

diseases and discover new biomarkers by analyzing urine or plasma samples.[22,23] In addition, studies developing the new model system to connect the active metabolites in fruit extracts to bioactivity have been reported.[17,18] Anthocyanin extract from black raspberry was analyzed by NMR spectroscopy and multivariate statistical analysis, and it was found that anthocyanins C3R, cyanidin 3-*O*-xylosylrutinoside (C3X), and C3G were identified as the critical constituents exerting antioxidant activity.[17] Using the same approach, C3R and C3X were also reported to play a predominant role in inhibiting proliferation of human colon cancer cells.[18] In this study, we performed multistep solvent extraction to cover the whole metabolome in black raspberry and further separated the most active fraction inhibiting inflammatory markers with preparative HPLC (Figures 1 and 2). By comparing the metabolites from the fraction with anti-inflammatory effect (BF3-1) to those without the activity (BF3-2) using HPLC-ESI-ion trap MS/MS and OPLS-DA, we successfully identified and quantified the key constituents responsible for the activity, cyanidin, C3G, and C3R (Figures 3 and 4). Most importantly, we validated the mechanistic roles of BF3-1 and the mixture of cyanidin, C3G, and C3R in regulating the same molecular targets during the inflammatory process (Figures 5 and 6).

To investigate the link between the powder or extract of different fruits and vegetables and individual constituents for the prevention of chronic diseases, many studies have evaluated the effects of extracts, identified their components, and finally confirmed the physiological efficacy of several key constituents.[24,25] In some studies, however, a single active component was treated at too high concentration compared to that in the extract,[10,26,27] ranging from 10 to 100 μM in the case of C3G. Here, we quantified the actual concentrations of the cyanidin, C3G, and C3R in the active fraction (BF3-1) and treated the same amount with those in BF3-1, ranging from 0.15 to 0.75 μM cyanidin, from 0.25 to 1.3 μM C3G, and from 0.09 to 0.45 μM C3R, respectively (Figures 5 and 6). The interaction between constituents must also be considered. As many know, it has been reported that synergistic and/or antagonistic effects between different ingredients would influence fatty acid oxidations, antioxidant capacities, tumor cell proliferation, and intracellular molecular target expression.[28−31] In addition, the COX-2 inhibitory activity of the BF3-1 fraction was more dramatic compared to the cyanidin mixture (Figure 5A), which might be explained by the active interactions between other constituents including unknown compounds in BF3-1 fraction.

LPS is known to activate macrophage cells by increasing the pro-inflammatory products including iNOS, COX-2, and cytokines such as TNF-α, IL-6, and IL-1β, and the upstream intracellular signaling by LPS is mediated through the NF-κB pathway regulated by Iκ, and the MAPKs pathway including ERK, JNK, and p38 after binding to Toll-like receptors (TLRs) on the cell membrane.[32−34] Interestingly, a recent finding indicates that LPS led to morphological changes to bigger cell size and increased membrane protein clusters in RAW264.7 cells.[35] Black raspberry powder and extracts have been reported to have regulatory activity of inflammatory markers in different models, for example, iNOS and COX-2 suppression in *N*-nitrosomethylbenzylamine-induced angiogenesis,[36] to inhibit TNF-α, IL-1β, COX-2, and phospho-IκB in dextran solution sulfate-induced ulcerative colitis,[4] and to decrease TNF-α and IL-6 serum levels in patients with metabolic syndrome.[3] Our results in this study also support previous studies in that black raspberry extract regulated LPS-induced phosphorylation of ERK, JNK, p38, and STAT3, resulting in reduction of both mRNA and protein expression of cytokines, TNF-α, IL-6, and IL-1β, in addition to iNOS suppression without cytotoxicity (Figures 5 and 6). The cyanidin mixture containing cyanidin, C3G, and C3R, identified by metabolomic screening and quantified by HPLC analsysis from BF3-1, was validated to have similar efficacy in regulating the inflammatory mediators at submicromolar concentrations (Figures 5 and 6), ascertaining that cyanidin, C3G, and C3R are the critical constituents in black raspberry fraction BF3-1.

The NF-κB, activated by LPS, cytokines (IL-1β or TNF-α), or oxidative stress, is a well-known transcription factor regulating iNOS expression.[37] Berry anthocyanins including cyanidin 3-glucoside have been reported to block the NF-κB activation induced by cytokines and UVB in different models.[27,38,39] In this study, however, neither black raspberry extract (BF3-1) nor corresponding cyanidin mixture induced the recovery of IκB degradation (Figure 5B), which is one of the key events happening during activation of the NF-κB signaling pathway by LSP. This inconsistent result in regulating NF-κB signaling might be from the lower concentration of treated anthocyanins than in other studies. The concentration of the X3 mixture containing cyanidin, cyanidin-3-glucoside, and cyanidin-3-rutinoside in the present study was only 0.678 ug/mL (1.51 μM), whereas other studies used from 8.99 μg/mL (20 μM) to 112.34 μg/mL (250 μM) of cyanidin-3-glucoside.[27,38,39] Instead, BF3-1 and the cyanidin mixture significantly suppressed LPS-induced MAPKs phosphorylation, which can lead to inhibition of the binding of activating protein-1 (AP-1) complex and iNOS expression.[40] These findings suggest that coexistence of anthocyanins even at low concentrations (<1 μM) may exert significant anti-inflammatory activity, although the molecular targets at upstream signaling pathways are different from those at higher concentration treatment.

It is generally known that the bioavailability of anthocyanins is <2%, and their plasma concentrations range from 1 to 100 nM,[41,42] which are relatively lower concentrations compared to that of the cyanidin mixture (0.50−2.52 μM) treated in this study. Interestingly, however, it has been demonstrated that the gastrointestinal tissues absorb the anthocyanins as their intact form, which resulted in higher accumulation of anthocyanins in stomach or intestinal tissues.[43−45] He et al. found that 7.5% of anthocyanins of administered C3G equivalent (27 nmol) were absorbed into intestinal tissues of rat, indicating much more efficient uptake of anthocyanins than those in plasma or urine.[44] In an animal study using a blackberry anthocyanin-enriched diet (14.8 mmol of anthocyanins) for 15 days, the accumulations of C3G equivalent reached 605 nmol/g of tissue in jejunum, whereas the plasma concentration of C3G equivalent was only 0.36 nmol/mL.[45] These studies suggest that the treated concentrations of cyanidin mixture are physiologically relevant to provide a beneficial effect on regulating the local inflammatory processes at least in gastrointestinal tract.

Taken together, we performed a multistep solvent extraction and subfractionation of black raspberry cultivated in South Korea. Metabolomic profiling and OLPS-DA between subfractions determined that cyanidin, C3G, and C3R are the key components responsible for anti-inflammatory activity. We also confirmed that cotreatments of cyanidin, C3G, and C3R at the same concentration with the fraction shared molecular targets, MAPKs and STAT3, which resulted in suppression of iNOS

and cytokines, TNF-α, IL-6, and IL-1β. To our best knowledge, this is the first report to employ a systematic approach using metabolomic analysis to identify and validate the key contributors to anti-inflammatory physiological efficacy. For further study, it is necessary to expand to in vivo studies demonstrating the effect of active compounds on the metabolome in biofluid to clearly elucidate their health beneficial efficacy.

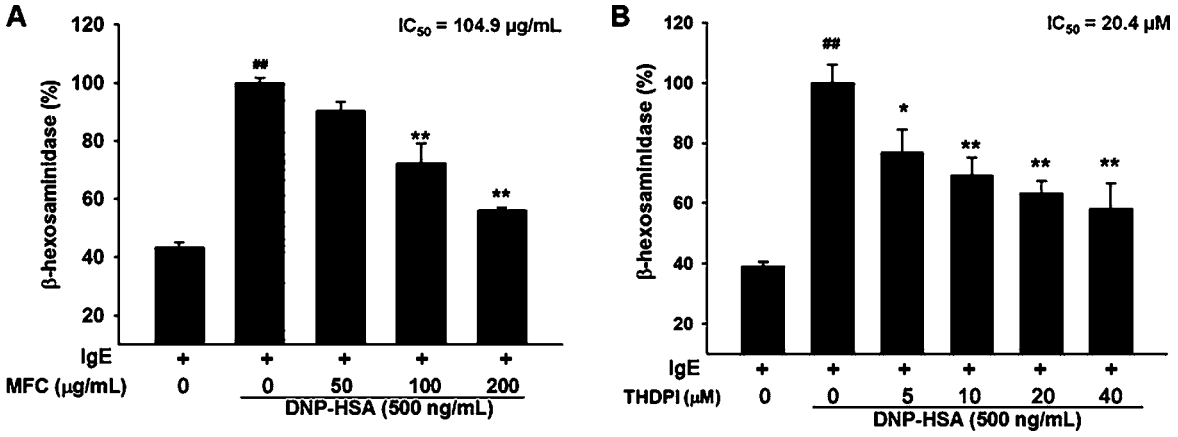

Figure 1. Effect of MFC and THDPI on mast cell degranulation in RBL-2H3 cells. Anti-DNP IgE-sensitized cells were treated with various concentrations of MFC (A) and THDPI (B) for 1 h followed by an antigen stimulation (DNP−HSA) for an additional 1 h. The release of β-hexosaminidase from cells treated with IgE/DNP−HSA was considered to represent 100% degranulation. Data represent the mean ± SD of three independent experiments. (##) $p < 0.01$, compared with IgE-sensitized cells without DNP−HSA; (**) $p < 0.01$, compared with IgE/DNP−HSA-treated cells. THDPI, 5,7,3′,4′-tetrahydroxy-6,8-diprenylisoflavone.

MO, USA). Purified mouse anti-rat FcεRIα-antibody was purchased from BD Biosciences (Franklin Lakes, NJ, USA). *Prime* RT-PCR premix was purchased from Genet Bio (Seoul, Korea), and PRO-PREP protein extraction solution and easy-BLUE total RNA extraction kits were purchased from iNtRON Biotechnology (Kyunggi, Korea). Anti-phospho-Lyn antibody was purchased from Cell Signaling Technology (Danvers, MA, USA). Anti-Lyn, anti-phospho-Syk, anti-Syk, anti-phospho-LAT, and anti-LAT antibody, fluorescent Ca^{2+} probe, Fura 2/AM, FITC-avidin, and FITC-conjugated $F(ab')_2$ goat anti-mouse IgG were purchased from Santa Cruz Biotechnology (Dallas, TX, USA).

Preparation of Methanol Extracts from the Fruits of *C. tricuspidata* (MFC). The fruits of *C. tricuspidata* (Moraceae) were collected from the Korea Forest Research Institute, Southern Forest Research Center (Jinju, Korea). A voucher specimen (accession no. KH1-5-090904) was deposited at the Department of Biosystems and Biotechnology, Korea University (Seoul, Korea). Methanol extract from the fruits of *C. tricuspidata* (MFC) was prepared as follows: The fresh fruits of *C. tricuspidata* (10.7 kg) were sliced and extracted three times with MeOH (10 L × 3) at room temperature. The solvent was evaporated in vacuo to obtain a total MeOH extract (630.95 g).[17]

Ultraperformance Liquid Chromatography (UPLC) Analysis of MFC. The MFC was analyzed using an Acquity UPLC system (Waters, Millford, MA, USA) with an Acquity UPLC BEH C18 column (1.7 μm, 2.1 × 150 mm i.d.). The mobile phase consisted of solvent A (0.05% trifluoroacetic acid in water) and solvent B (acetonitrile). The starting eluent was 40% B at 0 min. The proportion of B was increased linearly to 100% from 0 to 13 min, held constant at 100% until 14 min, returned to the initial composition (40% B) at 14 min, and then held constant for 1 min to re-equilibrate the column. The flow rate was 0.3 mL/min, and the sample injection volume was 2 μL. The column and sample managers were maintained at 35 and 15 °C. The UV detection wavelength was monitored at 280 nm.

Isolation and Identification of Compounds from MFC. The isolation and identification of 10 isoflavones, alpinumisoflavone, 4′-*O*-methylalpinumisoflavone, 5,7,4′-trihydroxy-6,8-diprenylisoflavone, 5,7,3′,4′-tetrahydroxy-6,8-diprenylisoflavone, derrone, erysenegalensein E, isoerysenegalensein E, gancaonin A, warangalone, and osajin, from MFC were described in our previous paper.[17]

Cell Cultures. Rat basophilic leukemia (RBL-2H3) cells (ATCC no. CRL-2256) were cultured at 37 °C and 5% CO_2 in MEM supplemented with 10% (v/v) fetal bovine serum, 100 U/mL penicillin, and 100 μg/mL streptomycin.

Measurement of the Release of β-Hexosaminidase. Mast cell degranulation was determined by β-hexosaminidase release on the basis of a previously described method.[18] Briefly, RBL-2H3 cells (1 × 10^5 cells/100 μL/well) were cultured in 96-well plates and incubated with monoclonal mouse anti-DNP IgE antibody (anti-DNP IgE) (1 μg/mL) for 24 h at 37 °C. The IgE-sensitized RBL-2H3 cells were washed twice with extracellular Hepes buffer (5 mM KCl, 125 mM NaCl, 20 mM Hepes, 1.5 mM $MgCl_2$, 1.5 mM $CaCl_2$). After washing, the cells were treated for 1 h with different concentrations of MFC and isolated compounds in 50 μL of Hepes buffer containing BSA (1%) and glucose (1%) at 37 °C and subsequently stimulated with DNP−HSA (500 ng/mL), a multivalent antigen, for an additional 1 h. Supernatants (40 μL) were transferred to a 96-well plate and incubated with 50 μL of substrate solution (5 mM of 4-nitrophenyl *N*-acetyl-β-D-glucosaminide in 50 mM citric acid buffer, pH 4.5) for 1.5 h at 37 °C. The reactions were stopped by the addition of 50 μL of stop solution (0.5 M Na_2CO_3/$NaHCO_3$, pH 10.0) and the absorbance at 405 nm was measured using a microplate reader (SpectraMax M5, Molecular Devices, Sunnyvale, CA, USA). The activity value measured from cells treated with IgE/DNP−HSA was considered to represent 100% degranulation.

Table 1. Inhibitory Effects of Isolated Compounds from MFC on the Release of β-Hexosaminidase from Mast Cells

compound	β-hexosaminidase release (IC_{50},[a] μM)
(**1**) derrone	>40
(**2**) alpinumisoflavone	>40
(**3**) erysenegalensein E	>40
(**4**) 5,7,3′,4′-tetrahydroxy-6,8-diprenylisoflavone	20.4
(**5**) isoerysenegalensein E	>40
(**6**) gancaonin A	>40
(**7**) 5,7,4′-trihydroxy-6,8-diprenylisoflavone	>40
(**8**) 4′-*O*-methylalpinumisoflavone	>40
(**9**) warangalone	>40
(**10**) osajin	>40
ketotifen (positive control)	23.1

[a]The IC_{50} values were determined in a semilogarithmic graph with four different concentrations of compounds. At least three independent experiments were performed. Ketotifen, a mast cell stabilizer, was used as a positive control compound.

Measurement of Intracellular Ca^{2+}. RBL-2H3 cells (1 × 10^5 cells/100 μL/well) were cultured in black 96-well plates and incubated with anti-DNP IgE (1 μg/mL) for 24 h at 37 °C. Cells were washed with PBS buffer and incubated with Fura 2/AM (20 μM) in 100 μL of Tyrode buffer (5 mM KCl, 130 mM NaCl, 10 mM Hepes, 0.6 mM MgCl, 1 mM $CaCl_2$, 1% BSA, 1% glucose) for 1 h. The cells were washed three times with PBS buffer and treated with different

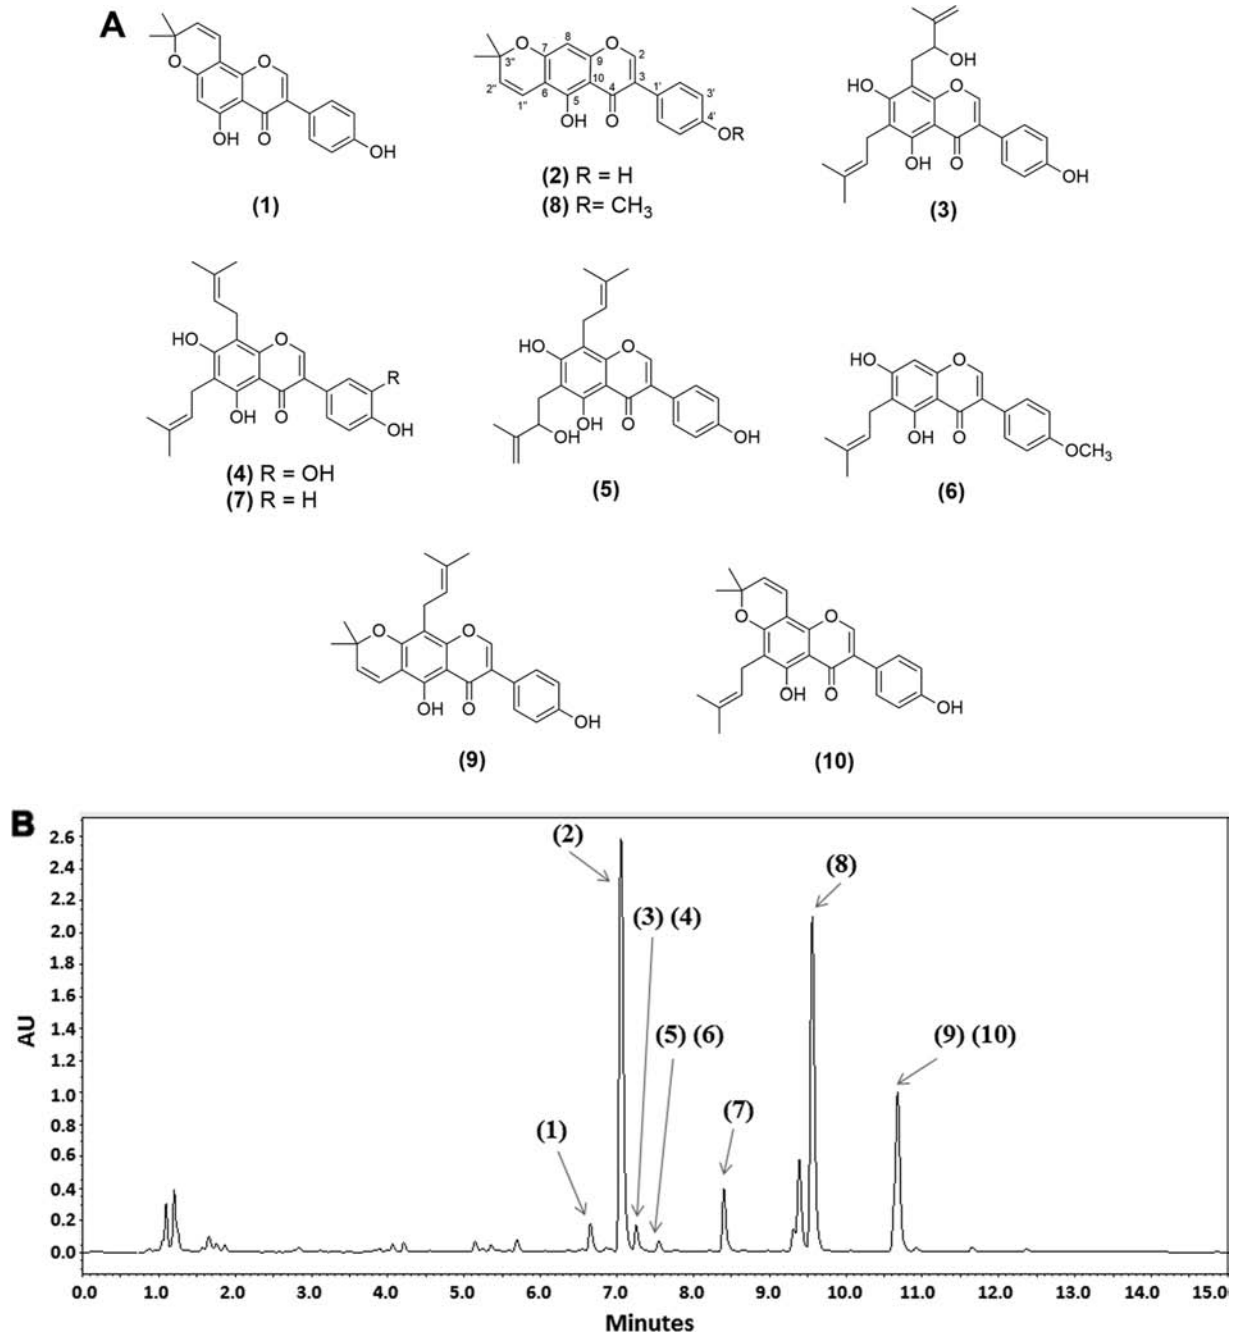

Figure 2. (A) Structures of principal compounds and (B) UPLC chromatogram of MFC. The principal compounds are (**1**) derrone, (**2**) alpinumisoflavone, (**3**) erysenegalensein E, (**4**) 5,7,3′,4′-tetrahydroxy-6,8-diprenylisoflavone, (**5**) isoerysenegalensein E, (**6**) gancaonin A, (**7**) 5,7,4′-trihydroxy-6,8-diprenylisoflavone, (**8**) 4′-*O*-methylalpinumisoflavone, (**9**) warangalone, and (**10**) osajin.

concentrations of MFC and an isolated compound in 100 μL of Tyrode buffer for 15 min and subsequently stimulated with DNP−HSA (500 ng/mL). The fluorescence intensity was recorded for 20 min using a microplate reader (SpectraMax M5, Molecular Devices, Sunnyvale, CA, USA) at an emission of 512 nm and excitation of 340 and 380 nm. The fluorescence ratio (F_{340}/F_{380}) was used as an indication of a rise in the intracellular concentration of Ca^{2+}.[19]

Measurement of Biotinylated IgE Binding to FcεRI. IgE biotinylation (biotinylated IgE) was carried out according to previously reported methods.[20] Briefly, DNP−IgE (0.5 mg) was dissolved in 500 μL of PBS and incubated with 50 μL of 10 mM of succinimidyl-6-(biotinamido) hexanoate (Thermo Fisher Scientific, Waltham, MA, USA) dissolved in DMSO. After 1 h of incubation at 4 °C, 1 mL of Tris (50 mM, pH 8) was added to deactivate residual reactive groups. The biotinylated IgE were dialyzed with PBS at 4 °C, recovered, and stored frozen until use. For binding experiments, RBL-2H3 cells (1×10^6 cells/mL/well) were cultured for 24 h in 12-well plates and washed with PBS containing 0.2% bovine serum albumin. The cells were incubated with biotinylated IgE (2 μg/mL) and MFC and an isolated compound for 1 h at 37 °C, detached by gentle scraping, centrifuged at 4000 rpm for 5 min, suspended in PBS, and stained with 20 μL of FITC-avidin at 4 °C for 30 min. As a background control, untreated cells were stained with FITC-avidin alone. The cells were then washed twice with PBS and subjected to analysis of IgE binding to RBL-2H3 cells using a flow cytometer (FACSCalibur, BD Biosciences, San Jose, CA, USA). Values of florescence intensity were obtained from histogram statistic of CellQuest software (BD Biosciences).

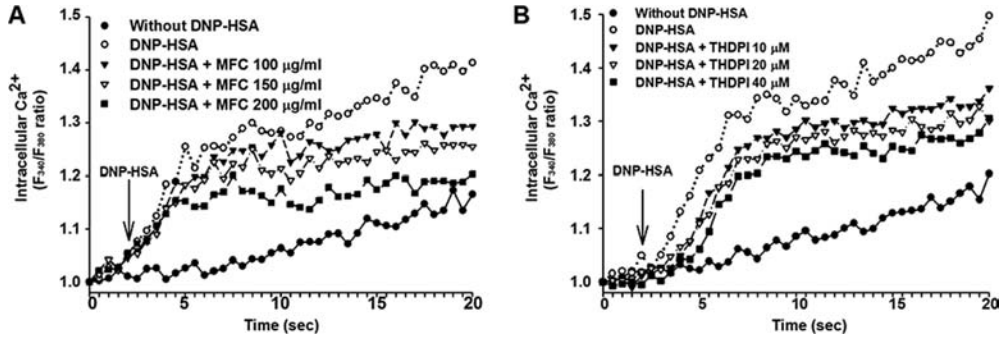

Figure 3. Effect of MFC and THDPI on Ca^{2+} influx in RBL-2H3 cells. Anti-DNP IgE-sensitized cells were incubated with Fura 2/AM for 1 h and thereafter treated with MFC (A) and THDPI (B) for 15 min and subsequently stimulated with an antigen (DNP−HSA, 500 ng/mL). Fluorescence intensity was measured for 20 min (excitation, 340 and 380 nm; emission, 512 nm). Values are expressed as a ratio of the fluorescence at the two excitation wavelengths (F_{340}/F_{380}). The arrow represents the time at which antigen was added.

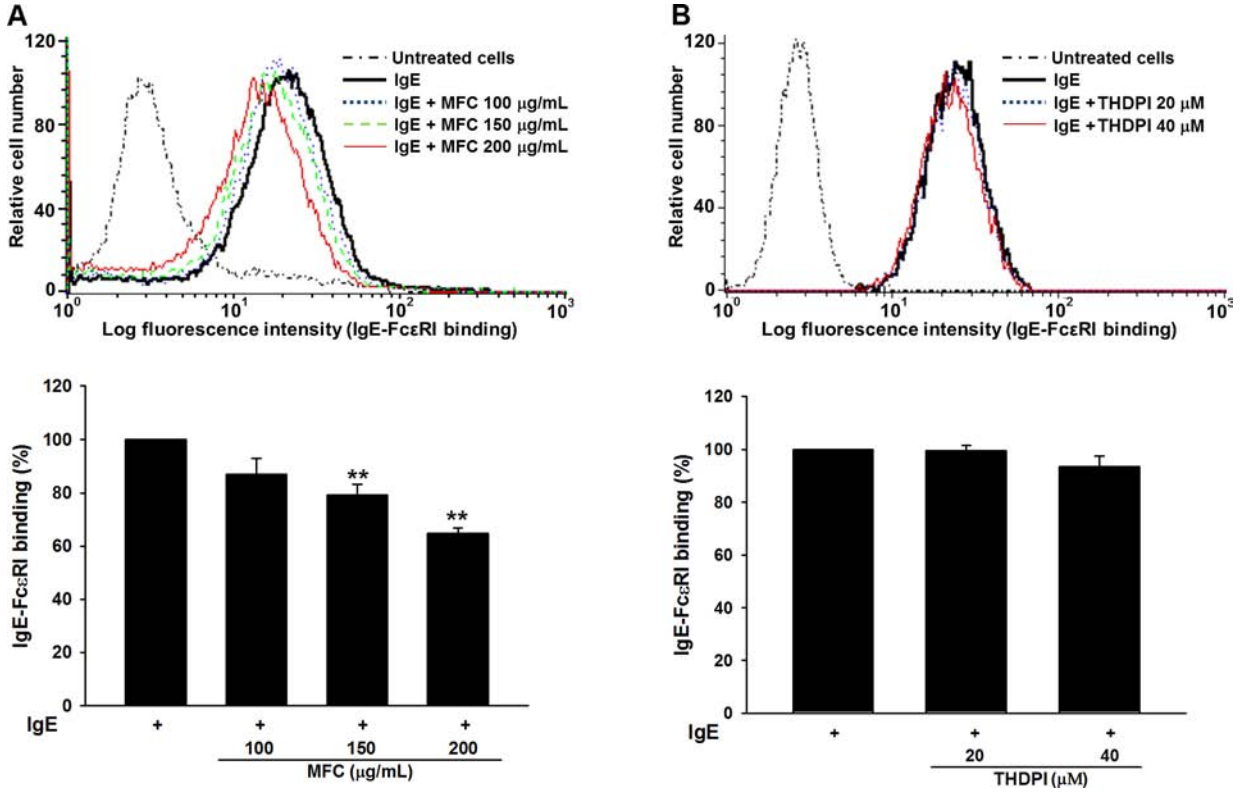

Figure 4. Effect of MFC and THDPI on IgE−FcεRI binding. RBL-2H3 cells were treated with biotinylated IgE (2 μg/mL) and various concentrations of MFC (A) and THDPI (B) for 1 h. The cells were then stained with FITC-avidin for 30 min. IgE bound to FcεRI on RBL-2H3 cells was analyzed by employing flow cytometry. Quantitative comparison of IgE−FcεRI binding between IgE-treated cells and sample-treated cells was made. Values of florescence intensity were obtained from histogram statistic of CellQuest software. Data represent the mean ± SD of three independent experiments. (**) $p < 0.01$, compared with the IgE-treated cells.

Measurement of mRNA Expression. RBL-2H3 cells (5×10^5 cells/500 μL/well) were incubated for 24 h, treated with MFC and an isolated compound for 3, 6, 18, 24 h (time-dependent), and treated with various concentrations of MFC and an isolated compound for 24 h (dose-dependent). The cells were washed twice with PBS, and total RNA was isolated with easy-BLUE (iNtRON Biotechnology, Korea), according to the manufacturer's instruction. cDNA synthesis was performed from 500 ng of total RNA by using a ONE-STEP RT-PCR PreMix kit (iNtRoN Biotechnology, Korea). The following primer pairs were synthesized (Bioneer, Korea):

FcεRIα, 5′-CATTGTGAGTGCCACCATTC-3′, 5′-TTCTTC-CAGCTACGGCATCT-3′;

FcεRIβ, 5′-TTGTCTGCTCCACACTCCAG-3′, 5′-AGGCTG-CCTCTCACCAGATA-3′;

FcεRIγ, 5′-CACCTGTTCTCAGCTGCATT-3′, 5′-GGATCA-GGGAAGGAAAGAGG-3′;

GAPDH, 5′-AGACAGCCGCATCTTCTTGT-3′, 5′-CTTGCC-GTGGGTAGAGTCAT-3′.

The denaturation, annealing, extension, and cycle conditions were performed as follows: 94 °C for 45 s, 62 °C for 45 s, 72 °C for 45 s, and 26 cycles. The PCR reaction was performed with a 2720 Thermal Cycler (Applied Biosystems, USA). Aliquots of the PCR reactions were electrophoresed in 1.5% (w/v) agarose gels and stained with SYBR Safe DNA gel stain (Invitrogen, USA). DNA bands were visualized with LAS 1000plus (FUJIFILM, Japan).

Measurement of p-Lyn, p-Syk, p-LAT, and p-PLCγ Proteins. RBL-2H3 cells (2×10^6 cells/2 mL/well) were cultured in 6-well plates with IgE for 24 h. Cells were then treated with different concentrations

J. Agric. Food Chem. 2015, 63, 5459−5467

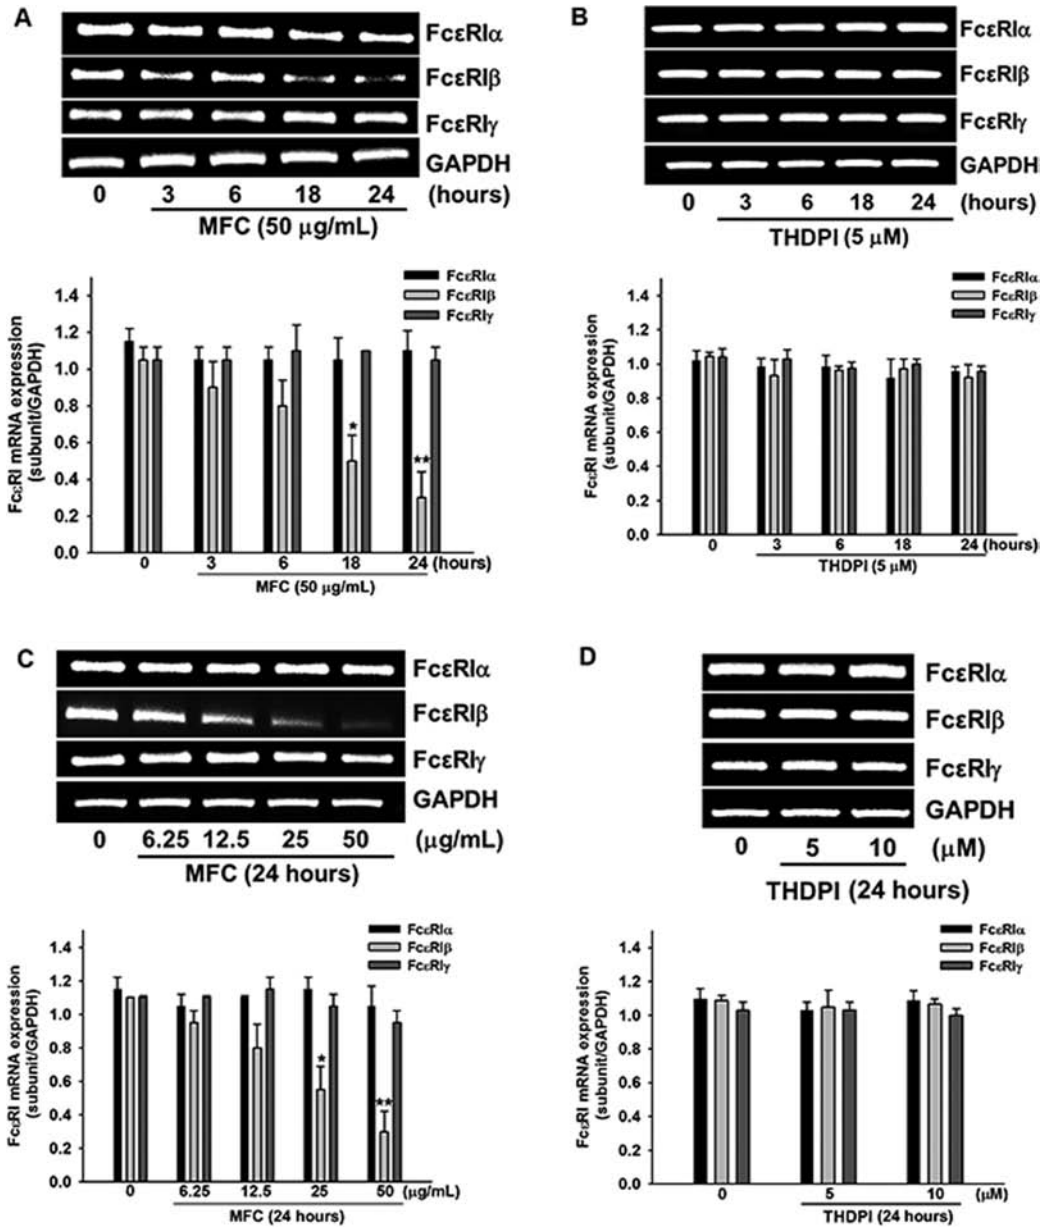

Figure 5. Effect of MFC and THDPI on FcεRI mRNA expression in RBL-2H3 cells. RBL-2H3 cells were treated with MFC and THDPI for different time intervals (0, 3, 6, 18, and 24 h) (A, B). RBL-2H3 cells were treated with various concentrations of MFC and THDPI for 24 h (C, D). The mRNA expression levels of FcεRI-subunit genes, α, β, and γ, were determined by RT-PCR analysis. Quantitative representation of the expression of each subunit of FcεRI and GAPDH mRNA was made using ImageJ software. Data represent the mean ± SD of three independent experiments. (∗) $p < 0.05$ and (∗∗) $p < 0.01$, compared with the non-MFC-treated cells.

of MFC and an isolated compound for 24 h and subsequently stimulated with DNP−HSA (500 ng/mL) for 10 min. Cells were lysed by PRO-PREP protein extraction solution (iNtRON Biotechnology, Korea) for 20 min at −20 °C. After incubation, lysates were centrifuged at 13000 rpm for 10 min at 4 °C for clarification. Approximately 15 μL (30 μg of total protein) of supernatant was subjected to 10% SDS-PAGE and transferred to PVDF membrane (Immobilon-P, Millipore, USA). The membrane was incubated with primary antibodies at 4 °C overnight. After washing, the membranes were probed with secondary antibodies for 1 h and developed with ECL Western blotting detection reagent, WEST-ZOL plus (iNtRON Biotechnology, Korea). Bands were visualized using an image analyzer, LAS 1000plus (FUJIFILM, Japan).

Redistribution of F-Actin Using Confocal Microscopy. RBL-2H3 cells (4×10^4 cells) were cultured in cell culture slides (SPL Lifescience, Korea) and sensitized with IgE (2 μg/mL) for 3 h. Before antigen stimulation, RBL-2H3 cells were treated with different concentrations of MFC, an isolated compound, or piceatannol for 1 h, and then stimulated with DNP−HSA (500 ng/mL) for 15 min. Cell fixation was performed with PBS containing 4% formaldehyde for 30 min and permeabilized twice with PBS containing 0.1% Triton X-100 for 5 min. Staining for F-actin (green) was performed with Alexa Fluor 488 phalloidin (Invitrogen, USA) for 20 min in the dark. 4′,6-Diamidino-2-phenylindole (DAPI) staining was performed to identify all cell nuclei (blue) using a mounting medium containing DAPI (VECTASHIELD Mounting Medium with DAPI, Vector Laboratories, USA) prior to analysis by confocal fluorescent microscopy using a LSM 700 (Carl Zeiss, Germany) and ZEN software for the capture of images (Carl Zeiss, Germany).

Statistical Analysis. Data obtained were expressed as the mean ± standard deviation (SD). Statistical significance was determined using GraphPad Prism (GraphPad Software, USA). The differences among

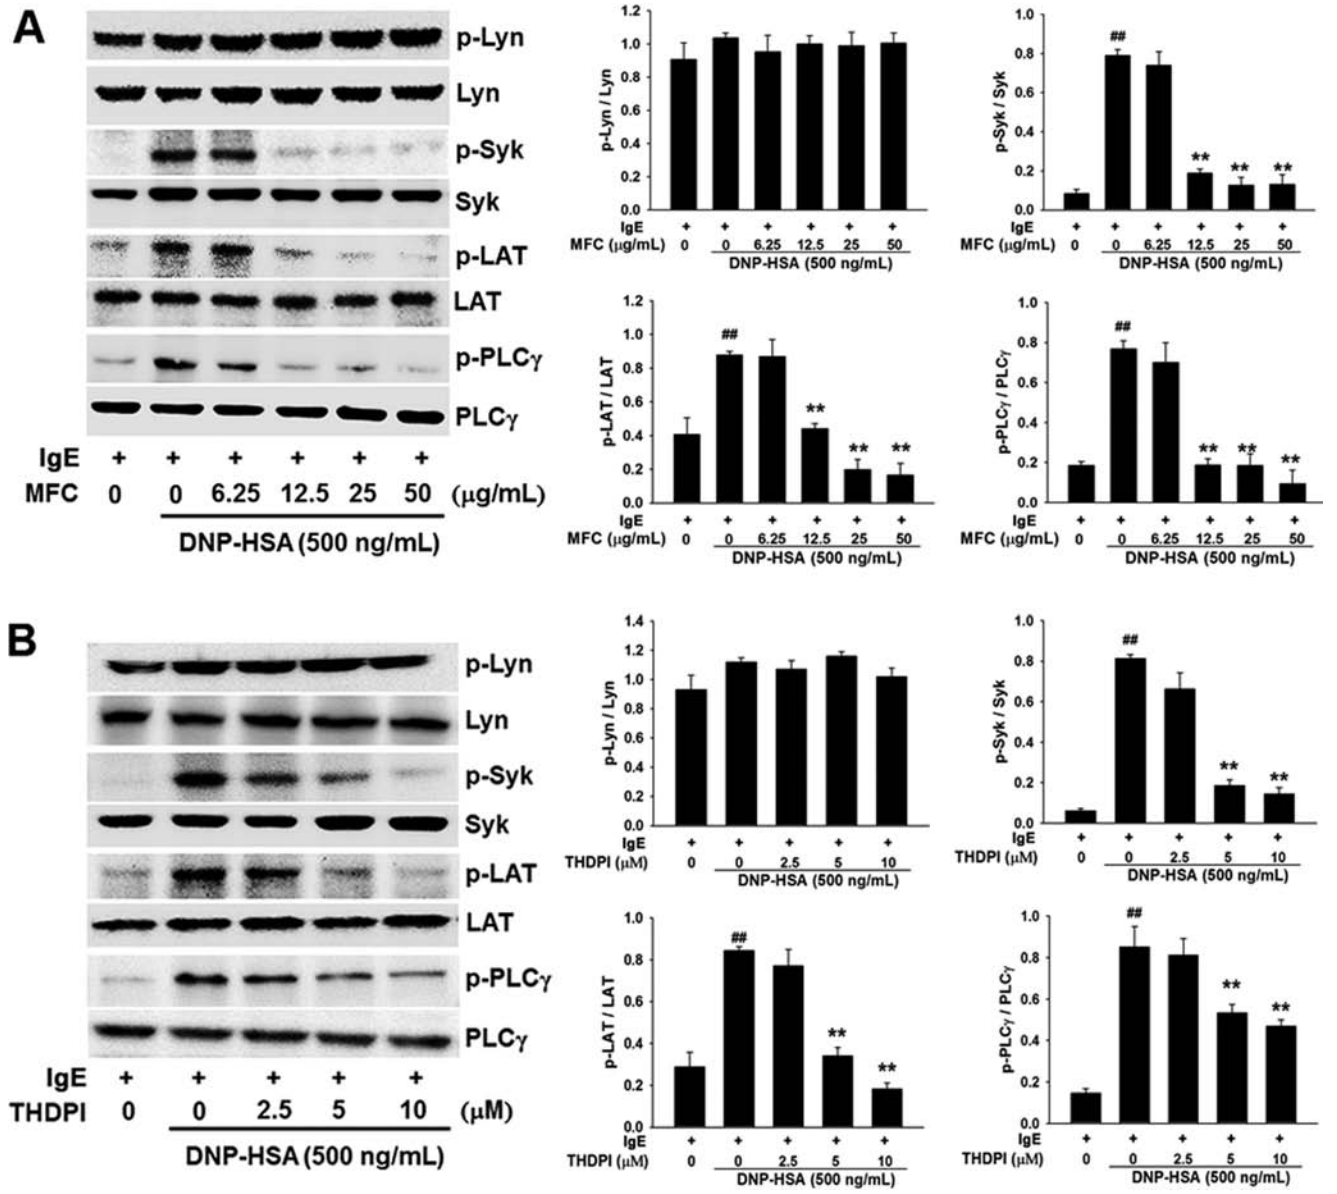

Figure 6. Effect of MFC and THDPI on the FcεRI-mediated phosphorylation of Lyn, Syk, LAT, and PLCγ in RBL-2H3 cells. Anti-DNP IgE-sensitized RBL-2H3 cells were cultured with various concentrations of MFC (A) and THDPI (B) for 24 h followed by antigen stimulation for 10 min. Then, each cell lysate was subjected to immunoblot analysis. p-Lyn, p-Syk, p-LAT, and p-PLCγ represent the phosphorylated Lyn, Syk, LAT, and PLCγ, respectively. Data represent the mean ± SD of three independent experiments. (##) $p < 0.01$, compared with IgE-sensitized cells without DNP-HSA; (**) $p < 0.01$, compared with IgE/DNP-HSA-treated cells.

the groups were evaluated by one-way analysis of variance (ANOVA) with Bonferroni's multiple-comparison method. A p value of <0.05 was considered to be statistically significant. All of the data were obtained from at least three independent experiments.

RESULTS AND DISCUSSION

Mast cells are crucial factors in the regulation of inflammatory and allergic responses due to their ability to produce pro-inflammatory mediators. The major mechanism for the activation of mast cells is the interaction of immunoglobulin E (IgE) with its high-affinity receptor (FcεRI), on the cell surface, which initiates FcεRI signaling through Lyn and Syk to regulate degranulation.[21] In this study, we investigated the inhibitory effects of methanol extract from the fruits of *C. tricuspidata* (MFC) on FcεRI-mediated mast cell activation and identified THDPI as an active compound responsible for the inhibitory action. β-Hexosaminidase has been commonly considered as a useful indicator for the evaluation of the activation of mast cells in various allergic inflammation.[22] As shown in Figure 1A, MFC significantly inhibited the release of β-hexosaminidase in FcεRI-mediated mast cells with an IC_{50} value of 104.9 μg/mL. Major constituents of MFC were identified using UPLC, and 10 compounds were isolated from MFC (Figure 2). Among the 10 isolated compounds from MFC, THDPI attenuated the release of β-hexosaminidase with an IC_{50} value of 20.4 μM, whereas the other compounds revealed no significant effects at concentrations up to 40 μM (Figure 1B and Table 1).

To investigate the mechanism underlying the inhibitory effects of MFC and THDPI on mast cell degranulation, free cytoplasmic calcium levels were examined. The movement of calcium across the membrane into the cytosol, either from an intracellular store such as the endoplasmic reticulum or from the external environment,

DOI: 10.1021/acs.jafc.5b00903
J. Agric. Food Chem. 2015, 63, 5459−5467

plays a crucial role in IgE-mediated mast cell activation and degranulation.[22] Therefore, many antiallergic drugs are known to inhibit calcium influx into the cytosol, resulting in the suppression of the degranulation of mast cells.[23] After the addition of antigen (DNP−HSA) in IgE-sensitized RBL-2H3 cells, the rapid elevation of intracellular calcium influx was observed in the untreated group. However, the treatment of MFC and THDPI decreased the antigen-induced intracellular calcium levels in a dose-dependent manner (Figure 3). These data suggest that MFC and THDPI elicit inhibitory effects on mast cell degranulation at least in part by the inhibition of calcium influx into the cytosol.

Binding of IgE to its receptor, FcεRI, on the surface of mast cells is one of the essential steps to initiate mast cell activation and degranulation. It has been reported that omalizumab, a recombinant DNA-derived humanized IgG1k monoclonal antibody, interferes with the IgE−FcεRI binding and inhibits mast cell degranulation,[24] and it is currently used for the control of allergic asthma and atopic dermatitis.[25] Thus, interfering with IgE binding to FcεRI could be another method to suppress IgE−FcεRI-mediated mast cell activation. When RBL-2H3 cells were treated with MFC at a fixed concentration of IgE, IgE binding levels were decreased to 86.9, 79.3, and 64.7% when treated with MFC at 100, 150, and 200 μg/mL, respectively, compared with control groups treated with IgE alone (Figure 4A). However, the treatment of THDPI showed no significant effects at concentrations up to 40 μM in IgE−FcεRI interaction (Figure 4B).

FcεRI are multimeric immune receptors consisting of one α-subunit, one β-subunit, and two γ-subunits. The α-subunit binds to the Fc portion of IgE, and β- and γ-subunits are thought to account for the cell-activation properties of FcεRI.[26] In FcεRI knockout mice, binding of IgE to mast cells was completely blocked, causing no induction of degranulation following allergic reactions.[27] Therefore, modulation for FcεRI expression could be considered as a therapeutic target for preventing FcεRI-mediated allergic inflammatory diseases. Recently, epigallocatechin gallate (EGCG) has been reported as a possible inhibitor for FcεRI expression by inhibiting mRNA expression of γ-subunit in mast cells.[28] To examine whether MFC and THDPI have an effect on FcεRI expression in mast cells, RBL-2H3 cells were treated with MFC and THDPI for 24 h. MFC inhibited only FcεRI β-subunit mRNA expression significantly; however, mRNA expression of the α- and γ-subunits was not affected (Figure 5A,C). In the group treated with THDPI, however, no inhibitory effect on FcεRI subunits was observed (Figure 5B,D).

Cross-linking of the FcεRI on mast cells activates nonreceptor type protein tyrosine kinases such as Lyn and Syk.[29] Lyn can be constitutively associated with FcεRI and is responsible for the phosphorylation of β- and γ-subunits. These phosphorylation events result in the association of Syk with phosphorylated γ-subunit, thereby promoting the activation of Syk.[30] It has been reported that Syk-deficient mast cells completely abrogated the degranulation, calcium elevation, and activation of the ERK and JNK.[29] LAT is known to be phosphorylated by Syk and is important for activation of PLCγ, which is essential for increasing the intracellular calcium level in the calcium-dependent pathway.[31] In LAT-deficient bone marrow-derived mast cells (BMMCs), tyrosine phosphorylation of FcεRI and Syk was intact following FcεRI engagement; however, activation of PLCγ and calcium mobilization were dramatically reduced.[32] As demonstrated in Figure 6, both MFC and THDPI showed no effect on the phosphorylation of Lyn; however, they suppressed the phosphorylation of Syk as well as its downstream effectors, LAT and PLCγ, in IgE-sensitized RBL-2H3 cells stimulated by antigens. A previous study has reported that piceatannol, a protein kinase inhibitor, reduced the antigen-induced secretion in IgE-sensitized mast cells through the inhibition of phosphorylation of Syk without the inhibition of phosphorylation of Lyn.[33]

The FcεRI-mediated signaling in mast cells leads not only to degranulation and cytokine production but also to actin assembly and various morphological changes in the cells. These morphological changes involve the redistribution of F-actin and are in parallel with degranulation of mast cells.[34] Several studies have demonstrated that these morphological changes are downstream of Syk and are Ca^{2+} dependent.[35,36] It has been also reported that activation of FcεRI induces no or minimal morphological change in $Syk^{-/-}$ cells, but this is reconstituted by stable expression of Syk in these cells.[35] In addition, IgE-mediated redistribution of F-actin is observed only in $Syk^{-/-}$ cells transfected with wild-type Syk.[37] In Figure 7, these morphological changes were observed in RBL-2H3 cells stained with fluorescent phalloidin to visualized F-actin. In unstimulated cells, F-actin (green) was at steady state and concentrated at the cell membrane (Figure 7A). When stimulated with antigen (DNP-HSA), F-actin was redistributed

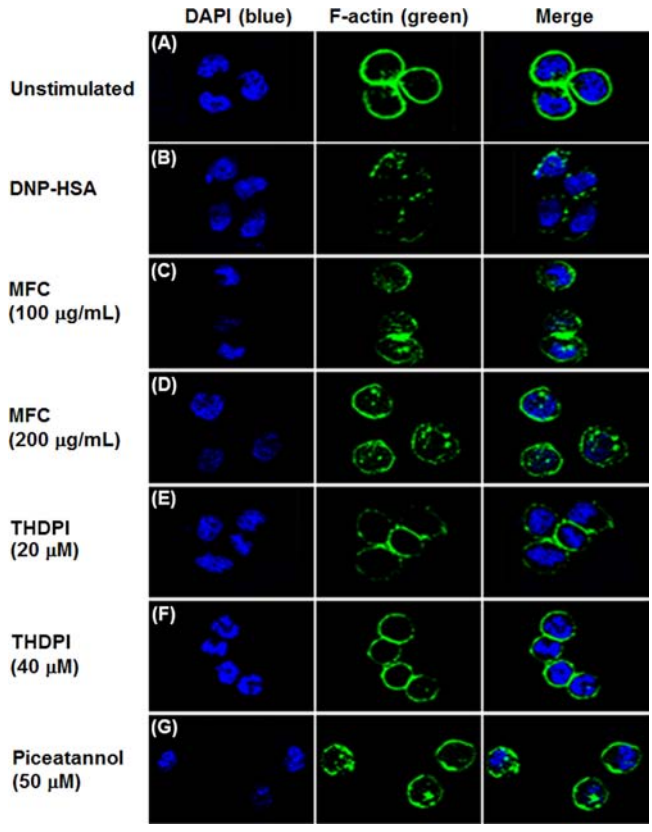

Figure 7. Effect of MFC and THDPI on F-actin assembly in RBL-2H3 cells. IgE-sensitized RBL-2H3 cells were treated with MFC, THDPI, and piceatannol for 1 h followed by antigen stimulation (DNP−HSA, 500 ng/mL) for 15 min. Cells were fixed and then double stained with fluorescent phalloidin for F-actin (green) and DAPI for cell nuclei (blue). Panels show representative images from (A) unstimulated cells, (B) cells stimulated with antigen, (C, D) MFC-treated cells stimulated with antigen, (E, F) THDPI-treated cells stimulated with antigen, and (G) piceatannol-treated cells stimulated with antigen. Original magnification, ×400.

J. Agric. Food Chem. 2015, 63, 5459−5467

and cells were spread (Figure 7B). However, this redistribution of F-actin was markedly inhibited in MFC-treated cells (Figure 7C,D) and in THDPI-treated cells (Figure 7E,F). These inhibitory effects on F-actin redistribution were compared with those of a Syk inhibitor, piceatannol (Figure 7G), which has been reported to inhibit actin assembly, membrane ruffling, spreading, and degranulation in mast cells.[38]

In conclusion, MFC and its active compound, THDPI, inhibited FcεRI-mediated degranulation and the calcium influx. MFC also interfered with IgE−FcεRI interaction and decreased FcεRIβ mRNA expression. THDPI, however, did not show any significant effects on IgE−FcεRI interaction and FcεRI mRNA expression. It is possible that other minor compounds in MFC may be responsible for the inhibitory effects on the affinity of IgE to the receptors and the expression of FcεRIβ mRNA. Further study is required to identify other compounds in MFC responsible for these inhibitory effects. MFC and THDPI inhibited F-actin redistribution and downstream signaling by suppressing FcεRI-mediated Syk activation in mast cells (Figure 8).

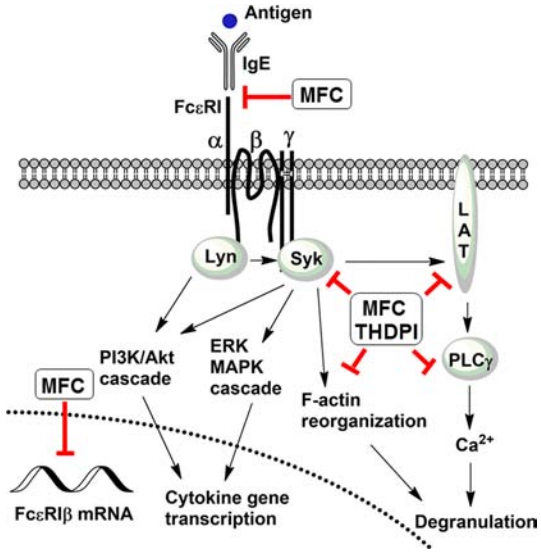

Figure 8. Scheme of the inhibitory effects of MFC and THDPI on FcεRI-mediated signaling in RBL-2H3 cells. MFC and THDPI inhibited mast cell degranulation, calcium influx, and F-actin redistribution. The phosphorylation of Syk, LAT, and PLCγ was inhibited by MFC and THDPI. In addition, MFC inhibited IgE−FcεRI interaction and FcεRIβ subunit mRNA expression.

These findings indicate that MFC and THDPI may have a potential therapeutic benefit for the control of IgE−FcεRI-mediated mast cell activation in inflammatory or allergic processes.

ABSTRACT: Neohesperidin dihydrochalcone (NHDC), a sweetener derived from citrus, belongs to the family of bycyclic flavonoids dihydrochalcones. NHDC has been reported to act against CCl_4-induced hepatic injury, but its mechanism is still unclear. We first discovered that NHDC showed a strong ability to scavenge free radicals. In addition, NHDC induces the phase II antioxidant enzymes heme oxygenase 1 (HO-1) and NAD(P)H/quinone oxidoreductase 1 (NQO1) through the activation of the nuclear factor (erythroid-derived 2)-like 2 (Nrf2)/antioxidant response element (ARE) signaling. Further assays demonstrated that NHDC induces accumulation of Nrf2 in the nucleus and augmented Nrf2-ARE binding activity. Moreover, NHDC inhibits the ubiquitination of Nrf2 and suggests the modification of Kelch-like ECH-associated protein 1 (Keap1) and the disruption of the Keap1/Nrf2 complex. c-Jun N-terminal kinase (JNK) and p38 but not extracellular signal-regulated protein kinase (ERK) phosphorylations were up-regulated by NHDC treatment. Taken together, NHDC showed its protective antioxidant effect against CCl_4-induced oxidative damage via the direct free radical scavenging and indirect Nrf2/ARE signaling pathway.

KEYWORDS: *NHDC, Keap1, HO-1, NQO1, MAPK, liver, ubiquitination*

INTRODUCTION

The liver plays an important role in the detoxification of xenobiotics and drugs prior to excretion. However, these toxic substances can lead to hepatic injury. Carbon tetrachloride (CCl_4) has often been used as a common model of acute liver damage. The toxic mechanism of CCl_4 was identified to involve the excessive production of free radicals. CCl_4 is metabolized into $CCl_3^{\bullet}$ and $CCl_3OO^{\bullet}$ radicals with the participation of cytochrome P4502E1, which initiates the process of lipid peroxidation and ultimately resulting necrosis.[1] In the liver, excess free radicals insult may result in liver failure or liver fibrosis.

Previous studies have illustrated that natural compounds with antioxidant activity are effective in protecting the liver from oxidative damage. In this regard, the use of active antioxidants for the prevention and treatment of liver diseases has drawn much attention. Our previous study indicated the protective effects of neohesperidin dihydrochalcone (NHDC) on CCl_4-induced acute hepatic injury in vivo and in vitro.[2] CCl_4-induced acute hepatotoxicity is the most used experiment model. The remarkable restoring of antioxidant enzymes and the amelioration of oxidative biomarkers suggests an antioxidative activity. However, the exact molecular mechanism of NHDC against CCl_4 insult is quite unveiled.

One of the strategies to avoid free radical-mediated damage is to directly increase the radical scavenging capacity. Numerous studies have suggested that polyphenol compounds show antioxidant effects via a scavenging action on both carbon- and oxygen-centered radicals. The second approach is to regulate intrinsic antioxidant defenses at the transcriptional level. Recent reviews have summarized that natural products upregulate a group of cytoprotective genes via nuclear factor erythroid-derived 2-like 2 (Nrf2) signaling.[3,4] Under physiological conditions, Nrf2 was tightly anchored in the cytoplasm by its negative regulator protein Kelch-like ECH-associated protein 1 (Keap1) that binds tightly to Nrf2, which directs Nrf2 to proteasome degradation. Under certain circumstances, Nrf2 activators trigger the dissociation of Nrf2 from Keap1 and facilitate the translocation of Nrf2 into the nucleus. Nucleic Nrf2 binds to the antioxidant-responsive element (ARE) consensus sequence to initiate the transcription of cytoprotective genes.

Thus, the current study was designed to identify the protective mechanisms of NHDC. We discovered that NHDC showed a significant capacity in free radical scavenging. We also illustrated that NHDC potently induces the activation of Nrf2 signaling. These findings revealed the cytoprotective role of Nrf2 against CCl_4 intoxication in in vitro and in vivo models.

MATERIALS AND METHODS

Materials. NHDC (CAS: 20702-77-6, structure shown in Figure 1), ABTS (2,2′-azinobis-3-ethylbenzothiazolin-6-sulfonic

acid), DPPH (1,1′-diphenyl-2-picryhydrazyl), TPTZ (2,4,6-tripyridyl-*s*-triazine), and luminol were supplied by Aladdin Reagent Database Inc. (Shanghai, China). CCl_4 (≥99.5%) was purchased from Kelong Chemical Co., Ltd. (Chengdu, China). MG132, the proteasome inhibitor, was obtained from Selleck Chemicals (Shanghai, China). The antibodies against Nrf2, heme oxygenase-1 (HO-1), NAD(P)H/quinone oxidoreductase 1 (NQO1), Lamin B, c-Jun N-terminal kinase (JNK), extracellular signal-regulated protein kinase (ERK), and p38 were purchased from Proteintech group, Inc. (Wuhan, China), and antibodies against β-actin, rabbit IgG, the EasyBlot ECL kit, and the nuclear/cytosol fractionation kit were purchased from Sangon Biotech Co., Ltd. (Shanghai, China). The chemiluminescent electrophoretic mobility shift assay (EMSA) kit, Biotin-labeled ARE probe, SP600125 (a JNK inhibitor), PD98059 (an ERK inhibitor), SB203580 (a p38 inhibitor), Western stripping buffer, and protein A agarose beads were obtained from Beyotime Institute of Biotechnology (Nanjing, China). Antibodies against p-JNK, p-ERK, p-p38, and Keap1 were purchased from Biosynthesis Biotechnology Co., Ltd. (Beijing, China). Ubiquitin antibody was from Santa Cruz Biotechnology (Santa Cruz, CA). 3-(4,5-Dimethylthiazol-*z*-yl)-3,5-diphenyltetrazolium bromide (MTT) was purchased from Dingguo Biotechnology Co., Ltd. (Beijing, China). Lipofectamine 2000 transfection reagent was supplied by Promega (Madison, WI). Nrf2 siRNA was synthesized by GenePharma Co., Ltd. (Shanghai, China).

Antioxidant Activity Assays. The free radical scavenging activity of NHDC was determined by ferric-reducing antioxidant power (FRAP), DPPH, ABTS, hydroxyl ($HO^{\bullet}$), and superoxide ($O_2^{\bullet-}$) radical scavenging assays. The FRAP assay is based on the reduction of a ferric 2,4,6-tripyridyl striazine complex (Fe^{3+}-TPTZ) by antioxidants to the ferrous form (Fe^{2+}-TPTZ), which forms a dark blue Fe^{2+}-TPTZ complex with an absorbance maximum at 593 nm.[5] The DPPH assay is based on the reduction of stable radical $DPPH^{\bullet}$ to a yellow product with the incubation of antioxidant. The absorbance was measured at 515 nm.[5] The ABTS assay is based on the ability of an antioxidant to inhibit the generation of a blue-to-green color product, which indicates the reaction of $ABTS^{\bullet+}$ and potassium persulfate. The ABTS radical-scavenging efficiency was measured by spectrophotometry at 750 nm.[5] The superoxide anion scavenging ability was determined by a chemiluminescence method in the pyrogallol−luminol system. The rate of pyrogallol autoxidation was measured at 320 nm.[6] The hydroxyl radical-quenching activity was measured by using the hydroxyl radical generated from Fenton's reaction of $Fe^{2+}-H_2O_2-$luminol chemiluminescence method.[7] All experiments were performed at least three times independently.

Animals, Treatment and Tissue Preparation. Male Kunming mice (22 ± 2 g) were provided by Chongqing Academy of Chinese Materia Medica. All animal studies were approved by the Southwest University Animal Care and Use Committee. Experiments were conducted according to the national institution's guidelines for the care and use of laboratory animals. Animals were kept in an air-conditioned room with a 12 h light and dark cycle with free access to food and water. All animals were adapted in individual plastic cages for a week, then the animals were randomly distributed into four groups with six mice in each group. The control group was administered appropriate vehicles throughout.

The NHDC group was administered NHDC (200 mg/kg body weight/day, dissolved in sodium carboxymethyl cellulose, prepared immediately before use) for 7 continuous days. The CCl_4 group received sodium carboxymethyl cellulose once daily for 7 continuous days. Three hours after the final intragastric administration, the mice were injected with CCl_4 (10 mL/kg body weight, 2% v/v in olive oil). The NHDC + CCl_4 group was treated with NHDC (200 mg/kg body weight/day) for 7 continuous days. Three hours after the final treatment, the mice were injected with CCl_4 (10 mL/kg body weight, 2% v/v dissolved in olive oil). The animals were sacrificed 24 h after the CCl_4 administration. The livers were removed carefully, rinsed twice with ice-cold physiological saline, and then divided into two pieces. One half was prepared for hepatic homogenization, and the others were used for immunohistochemical analysis. All steps were performed at 4 °C.

Cell Culture and Cell Viability Assay. The human hepatoma HepG2 cell line was purchased from the Third Military Medical University (Chongqing, China). HepG2 cells were cultured in DMEM containing 10% (v/v) FBS (HyClone, UT), penicillin (100 U/mL), and streptomycin (100 U/mL) in the humidified incubator at 37 °C under 5% CO_2. HepG2 cells were transferred onto 96-well culture plates at a density of 5×10^3 cells per well. After incubation overnight, the cells were pretreated with various inhibitors for 30 min and replaced with fresh serum-free medium containing NHDC or solvent vehicle for another 1 h. Finally, cells were maintained in 0.5% v/v CCl_4 for 3 h, and then treated with MTT (5 mg/mL final concentration) at 37 °C for 4 h. The supernatant was removed, and 150 μL of DMSO was added, measured spectrophotometrically at 570 nm.

Immunohistochemical Staining. The paraffin-embedded liver sections were deparaffinized and rehydrated; 3% H_2O_2 in methanol was used to block endogenous peroxidase activity for 15 min. Antigen retrieval was measured by 1 mM EDTA buffer (pH = 9.0) in a microwave for 3 min. The nonspecific protein binding was blocked by goat serum for 30 min, then the following steps were followed on the instruction of Histostain-plus and xiaminobenzidine (DAB) substrate kits. The slides were incubated with HO-1, NQO1, or Nrf2 antibodies at 4 °C overnight and incubated with biotin-labeled goat antirabbit IgG for 1 h. 3,3′-DAB solution was used in color development and counterstained with hematoxylin. The images were captured using a light microscope (magnification, 400× , Nikon Eclipse Ti-SR). Representative images are presented.

Preparation of Cytosolic and Nuclear Extracts. Cytosolic and nuclear proteins were extracted by a nuclear/cytosol fractionation kit according to the manufacturer's instructions. The cytosolic and nuclear extractions were stored at −20 and −80 °C, respectively.

EMSA. Nrf2/ARE binding activity was determined by EMSA using the Chemiluminescent EMSA Kit. The double-stranded oligonucleotides were designed according to the sequences of biotin-labeled ARE probe 5′-ACT GAG GGT GAC TCA GCA

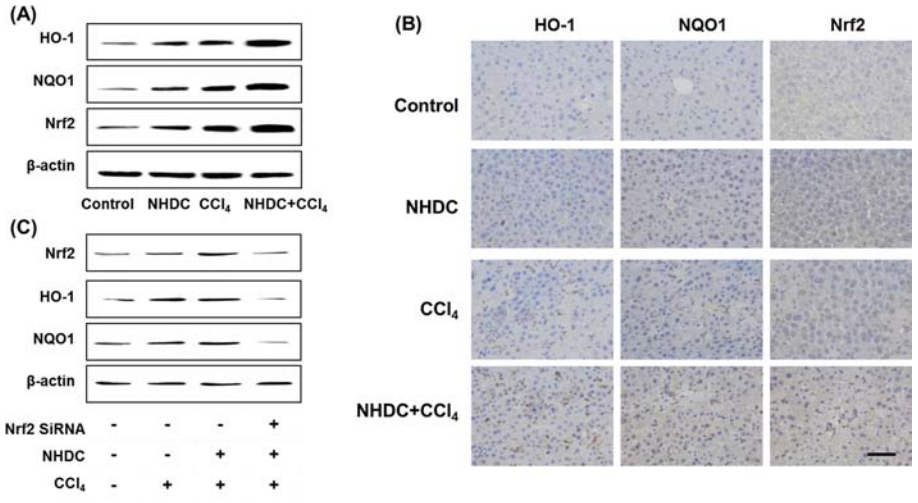

Figure 2. Effects of NHDC on the expression of HO-1, NQO1, and Nrf2. (A) NHDC stimulates HO-1, NQO1, and Nrf2 expressions by Western blot assay. Animals were treated with NHDC or CCl_4 as described in the Materials and Methods section. The test was repeated three times, and representative blots are shown. β-Actin served as a control. (B) Effects of NHDC on the expressions of HO-1, NQO1, and Nrf2 with the immunohistochemical method. Animals were treated with NHDC or CCl_4 as described in the Materials and Methods section. Bar = 50 μM. (C) Nrf2 siRNA down-regulates Nrf2, HO-1, and NQO1 protein expressions. HepG2 cells were transfected with a specific Nrf2 siRNA as described in the Materials and Methods section and pretreated with NHDC (30 μM) for 1 h. The cells were then subjected to a CCl_4 (0.5%, v/v) challenge. After 6 h of CCl_4 treatment, the levels of Nrf2, HO-1, and NQO1 were measured by Western blot analysis. The results are from three independent experiments.

AAA TC-3′ and 3′-TGA CTC CCA CTG AGT CGT TTT AG-5′. Briefly, 5 μg of nuclear protein was incubated with the biotin-labeled ARE probe (10 ng/μL) in the binding buffer at 25 °C for 30 min. The mixtures were fractionated on 6.5% polyacrylamide gels, and then transferred onto a Magmaprobe nylon membrane (Dingguo, Beijing, China). The membrane was incubated with a blocking buffer for 30 min at room temperature and immersed in blocking buffer containing streptavidin-HRP conjugate for 20 min. The membrane was washed four times at room temperature with washing buffer. Western blotting reagents were visualized with the EasyBlot ECL kit (ECL) that showed the gel shifts.

Transfection of Small Interfering RNA (siRNA). Predesigned siRNA against human Nrf2 was purchased from GenePharma Co., Ltd. (Shanghai, China). Transfection of siRNA was performed as previously described.[8] Briefly, HepG2 cells were transferred onto the 6-well culture plates and transfected with 100 nM siRNA against Nrf2 by Lipofectamine 2000. After 6 h of incubation, they were added to the fresh medium, and the cells were cultured for another 24 h. The cells were then pretreated with 30 μM NHDC for 1 h and treated with CCl_4 (0.5% v/v) an additional 6 h for the Western blot assay.

Immunoprecipitation. After treatment with NHDC, the cells were lysed with RIPA lysis buffer (50 mM Tris−HCl, pH = 7.4, 150 mM NaCl, 0.5% sodium deoxycholate, 1% NP-40, 1 mM PMSF, 0.1% SDS, and a proteinase inhibitor cocktail). The lysates were incubated on ice for at least 30 min and homogenized with an ultrasonicator for 10 min. The homogenates were centrifuged at 13 000 rpm at 4 °C for 10 min. The supernatants were collected, the concentrations of proteins were detected using the Bradford Protein Assay Kit. Whole cell lysates were precleared with protein A agarose beads for 10 min. The solutions were incubated with 2 μg of Keap1 or Nrf2 antibody at 4 °C overnight and further incubated with 30 μL of protein A agarose beads at 4 °C for 3 h, then the solution was centrifuged, and the beads were washed five times with lysis buffer. The complexes were mixed with 15 μL of loading buffer, heated at 98 °C for 10 min, and subsequently analyzed by Western blotting.

Western Blotting. The whole cell lysates and the immunoprecipitation products were separated by 8% or 10% SDS-PAGE and transferred onto the PVDF membrane. The membranes were blocked with 5% nonfat milk for 2 h then incubated with different primary antibodies at 4 °C overnight. The membranes were incubated with the secondary antibody for 2 h, followed by visualization using the ECL system. Representative blots were chosen from three or four separate experiments that showed similar results.

Redox Western Blotting. Redox Western blotting for Keap1 was performed on the basis of our previously reported method.[9] Briefly, HepG2 cells were treated with NHDC (0−30 μM) for 6 h. Cells were lysed with lysis buffer containing 50 mM Tris−HCl (pH 7.4), 150 mM NaCl, 0.25% sodium

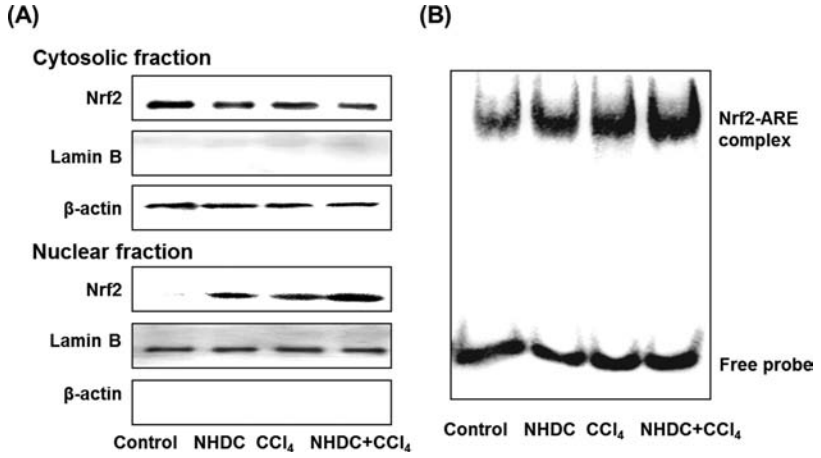

Figure 3. Effects of NHDC on nuclear Nrf2 accumulation and Nrf2-ARE binding activity. (A) Western blot analysis of the Nrf2 protein in cytosol and the nucleus, respectively. β-Actin and Lamin B were tested as loading controls in both the cytosolic and nuclear fractions. (B) EMSA detected for the Nrf2-ARE binding activity. Data were representative of three separate experiments showing similar results.

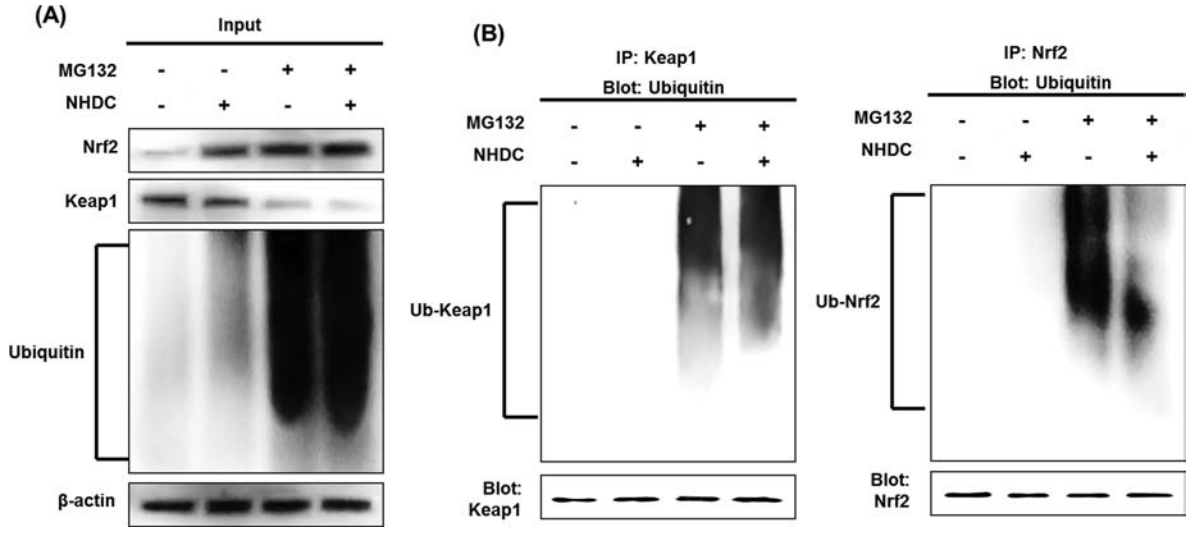

Figure 4. Effects of NHDC on the ubiquitination of Keap1 and Nrf2. (A) Western blot analysis of endogenous Keap1, Nrf2, and ubiquitin. HepG2 cells were treated with MG132 (10 μM) for 1 h and then treated with or without 30 μM NHDC for 6 h. Whole cell lysates were used to investigate Nrf2, Keap1, and ubiquitin with their antibodies. (B) The levels of Keap1 and Nrf2 ubiquitination. The proteins were immunoprecipitated with Keap1 and Nrf2 antibodies, then the precipitated proteins were visualized by Western blot analysis with ubiquitin antibody. Results are representative of three or four experiments.

deoxycholate, 1% NP-40, EDTA, 1 mM PMSF, sodium fluoride, sodium orthovanadate, and leupeptin protease inhibitor. The cell lysates were centrifuged at 12 000 rpm at 4 °C for 10 min, and the supernatant was collected as the redox cell extracts. Half of the extracts were diluted in the buffer containing β-mercaptoethanol (βME). After heat denaturation, the extracts were separated by 8% SDS-PAGE, and then Keap1 was detected by Western blotting.

Statistical Analysis. Values are expressed as the mean ± SD. Statistical analysis was performed using SPSS 18.0. Differences between the means of data were compared by the one-way variance analysis test, and post hoc analysis of group differences was performed by least significant difference test. A P value of <0.05 was considered to be statistically significant.

RESULTS AND DISCUSSION

NHDC Direct Scavenges Free Radicals. As shown in Table 1, NHDC has shown significant free radical scavenging activities in the range of 0.05−500 μM. In the FRAP assay, the

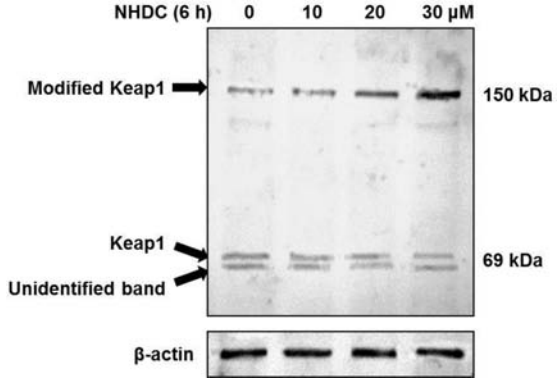

Figure 5. NHDC induces the modification of Keap1. Cells were treated with the indicated concentrations of NHDC for 6 h, analyzed by Western blot with Keap1 antibody and β-actin as a loading control. Data are representative of three separate experiments.

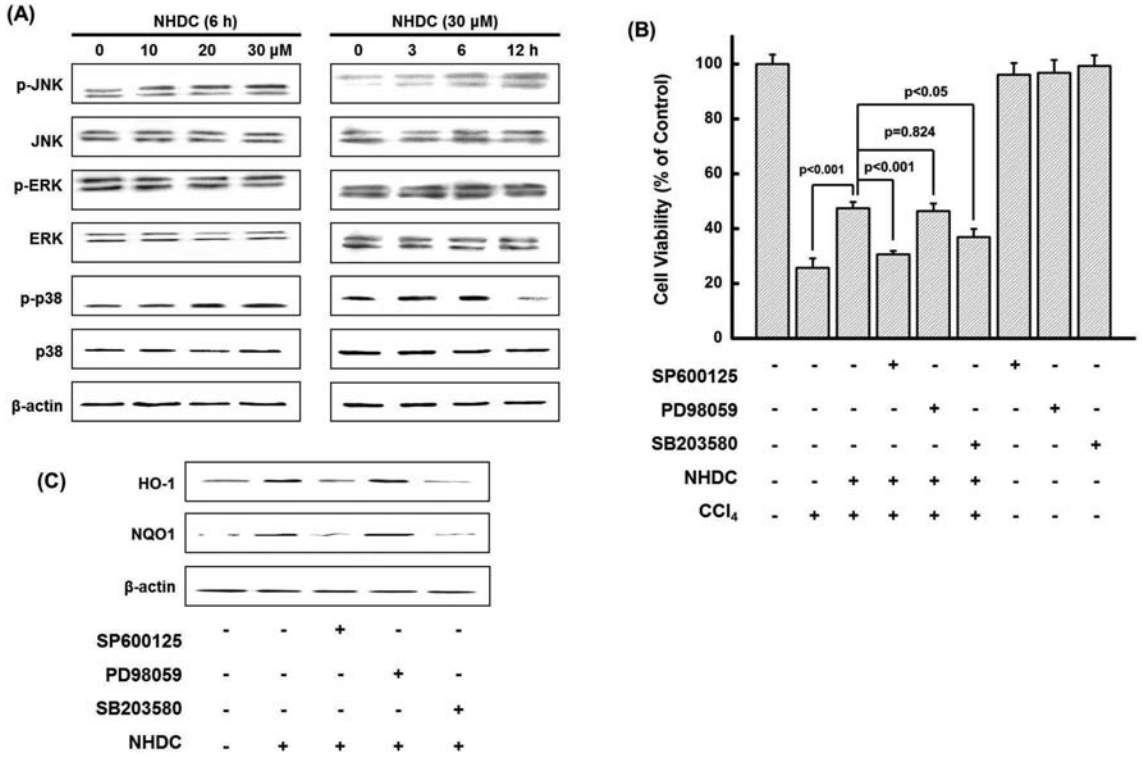

Figure 6. The cytoprotective effect of NHDC involves JNK and p38 MAPK signaling. (A) Concentration and time response of NHDC on the activation of JNK and p38 signaling. HepG2 cells were treated with NHDC at the indicated concentrations or times, and then the proteins were detected by Western blot analysis. (B) The pretreatment of JNK and p38 inhibitors, but not the ERK inhibitor, blocks the cytoprotective effect of NHDC. HepG2 cells were pretreated with 10 μM JNK inhibitor (SP600125), ERK inhibitor (PD98059), or p38 inhibitor (SB203580) for 30 min prior to incubation with 30 μM NHDC for another 1 h, then CCl_4 was introduced to induce cell damage. A MTT assay was performed to investigate the cell viability. Data from three independent experiments are expressed as means ± SD. (C) The pretreatment of JNK and p38 inhibitors, but not the ERK inhibitor, blocks the expressions of HO-1 and NQO1. Cells were treated with 10 μM SP600125, PD98059, or SB203580 for 1 h and then exposed to 30 μM NHDC for another 6 h. Total cell extracts were prepared and analyzed by Western blot analysis for the detection of the levels of HO-1 and NQO1. Data are representative of four separate experiments.

ability of NHDC to reduce Fe^{3+} to Fe^{2+} was increased concentration-dependently. The FRAP values were varied from 37.3 ± 0.9 to 1292.5 ± 56.1 μM at a concentration range of 0.05−500 μM. DPPH is a nitrogen-centered free radical that has been widely used in assessment of free radical quenching capabilities of antioxidants. NHDC possess concentration-dependent scavenging activities against the DPPH radical. According to a previous report, IC_{50} values for butylated hydroxyanisole (BHA), butylated hydroxytoluene (BHT), α-tocopherol, and trolox on the DPPH radical were found to be 61, 220, 31, and 50 μM, respectively.[10] Therefore, the DPPH radical-scavenging efficiency of NHDC is on the same order of magnitude as BHA, α-tocopherol, and trolox and one magnitude higher than BHT. In the ABTS assay, NHDC exhibited a concentration-dependent scavenging activity, and the highest concentration of NHDC (500 μM) scavenged the ABTS radical almost completely (99.1 ± 0.2%). $O_2^{\bullet-}$ is an important oxygen-center radical that can occur during in vivo metabolism, and the basal level of $O_2^{\bullet-}$ may be upregulated under certain pathological conditions.[11] The toxicity of $O_2^{\bullet-}$ has often been identified from neurodegenerative patients or an experimental model, which have relatively low SOD activities.[12] In the current study, pyrogallol was autoxidized to generate $O_2^{\bullet-}$, which can be detected by luminol. $HO^{\bullet}$ is the most reactive oxygen radical, which readily reacts with biomacromolecules and resulting the denaturation of proteins, lipid peroxidation and DNA modification.[13] Here, the generation of $HO^{\bullet}$ was performed by reaction of Fe^{2+} and H_2O_2. The scavenging effects of NHDC on superoxide and the hydroxyl radical are shown in Table 1. Our result indicated 30.4 ± 1.2% of the superoxide generated by a pyrogallol autoxidation system and 45.7 ± 2.4% of the hydroxyl radical generated by a Fenton's reaction were inhibited by 500 μM NHDC, respectively. Together, our results demonstrate that NHDC is a potent antioxidant with high antioxidant capacity, which is consistent with previous investigations.[14,15]

NHDC Enhances the Protein Levels of HO-1, NQO1, and Nrf2 in Mice. Our previous studies have demonstrated that NHDC plays an important role in the attenuation of CCl_4-induced liver injury in vivo and in vitro,[2] but the specific mechanism is still unclear. HO-1 is an endogenous, cytoprotective enzyme, that has both antioxidative and anti-inflammatory effects by catalyzing the first and rate-limiting step in the catabolism of the prooxidant heme to carbon monoxide, biliverdin, and free iron.[16] NQO1 is a cytosolic flavoprotein that catalyzes two-electron reduction and detoxification of quinones and other redox cycling endogenous and exogenous chemicals.[17] Growing evidence indicates that natural antioxidants play important roles in the activation of HO-1 and NQO1.[18] In the present study, the levels of HO-1 and NQO1 expression showed significant increases in the NHDC group (Figure 2A, lane 2 vs 1, lane 4 vs 3). Interestingly, the CCl_4 group also showed the upregulation of these two gene expressions (Figure 2A, lane 3 vs 1), which is consistent with

DOI: 10.1021/acs.jafc.5b01750
J. Agric. Food Chem. 2015, 63, 5468−5475

a previous study;[19] however, controversial results have also been reported. For example, Lee et al. showed that the NQO1 protein level in the CCl_4 group was significantly reduced compared with that in the control group.[20] Although there are disputable effects of CCl_4, it is widely accepted that antioxidants upregulated the expressions of these protective genes.

The activation of Nrf2 signaling and the upregulation of downstream antioxidant/detoxifying enzymes are important to inhibit oxidative stress and maintain the cellular homeostasis.[21] In view of these, we investigated whether NHDC activates HO-1 and NQO1 expression through the Nrf2 pathway. As shown in Figure 2A, the Western blot assay clearly indicated that Nrf2 has markedly increased after treatment with NHDC, which suggested a post-transcriptional regulation mechanism of Nrf2. Furthermore, we investigated the level of HO-1, NQO1, and Nrf2 by immunohistochemical staining. Consistently, HO-1, NQO1, and Nrf2 immunopositive cell numbers were markedly increased in NHDC-treated animals compared with the control or CCl_4 group (Figure 2B).

To further confirm that NHDC-induced HO-1 and NQO1 expression is mediated through Nrf2 activation, HepG2 cells were transfected with Nrf2 siRNA for 6 h, followed by CCl_4 stimulation or NHDC + CCl_4 cotreatment. Transfection of Nrf2 siRNA reduced the expression of Nrf2 as well as NHDC-induced HO-1 and NQO1 expression (Figure 2C). Together, these findings suggest that the protective mechanism of NHDC against CCl_4-induced hepatic injury is associated with the activation of Nrf2 signaling.

NHDC Induces the Translocation of Nrf2 and ARE Binding in HepG2 Cells. Nrf2 is an important transcription factor that is sequestered by the actin-binding protein Keap1 in the cytosol under homeostatic or nonstressed conditions. Cytosolic Nrf2 was subjected to ubiquitination and subsequent proteasomal degradation; thus, Nrf2 is inactive in cytosol.[22] However, once it translocates into the nucleus, Nrf2 heterodimerizes with a small musculo-aponeurotic fibrosarcoma protein and then binds to ARE. We therefore examined whether NHDC facilitates the translocation of Nrf2 from cytosolic into the nucleus. As shown in Figure 3A, Nrf2 in the cytosol fraction was reduced; in contrast, the amounts of nuclear Nrf2 were significantly increased after NHDC, CCl_4, or NHDC + CCl_4 treatment. Housekeeping genes Lamin B and β-actin have not been identified in the cytosolic and nucleus fractions, respectively, indicating the purity of these two fractions. To evaluate the effect of NHDC on Nrf2-ARE binding, EMSA was performed. In Figure 3B, our result suggested that the treatment of NHDC increased the ARE binding activity of Nrf2 in the nuclear fraction. Together, our results suggest that NHDC increased the translocation of Nrf2 and ARE-binding activity.

NHDC Inhibits the Ubiquitination of Nrf2 in HepG2 Cells. Previous studies have revealed that under homeostatic conditions, Nrf2 is rapidly degraded through the ubiquitin-dependent proteasome pathway.[23] To determine whether the up-regulation of Nrf2 by NHDC is due to the inhibition of Nrf2 ubiquitination, we detected the ubiquitination of Nrf2 through immunoprecipitation after treatment with MG132, a proteasome and protease inhibitor that allows the detection of ubiquitinated proteins. The treatment with MG132 also resulted in an increased association of Nrf2 with Keap1 in the cytoplasm.[24] As shown in Figure 4A, the Nrf2 protein level was increased after treatment with NHDC or MG132 alone or in combination; interestingly, the level of Keap1 was reduced by such treatment. Meanwhile, the treatment of MG132 caused an enhancement in the ubiquitin level, whereas NHDC has no effect on the ubiquitin level. Interactions between ubiquitin and Keap1 or Nrf2 were analyzed by immunoprecipitation with anti-Keap1 or anti-Nrf2 antibodies, respectively, followed by blotting with antiubiquitin (Figure 4B). NHDC showed no effect on the level of ubiquitinated Keap1 (left panel, lane 4 vs 3); however, a significant reduction of the ubiquitinated Nrf2 was observed in HepG2 cells cotreated with MG132 and NHDC (right panel, lane 4 vs 3). These results suggest that NHDC-enhanced Nrf2 is, at least partially, due to an inhibitory effect of the ubiquitination of Nrf2. Similarly, quercetin[8] and isothiocyanate sulforaphane[25] inhibit Nrf2 ubiquitination without inducing Keap1 ubiquitination. However, quinone-induced oxidative stress enhances ubiquitination of Keap1, which increases the level of Nrf2 correspondingly.[26,27] Our recent study also demonstrated that halogenated quinone, tetrachlorobenzoquinone, induces an ubiquitination switch from Nrf2 to Keap1.[9] The upregulation of Keap1 ubiquitination may interrupt the ability of Keap1 to assemble into a Cullin-dependent E3 (Cul3) ubiquitin ligase complex, which is critical for the control steady-state levels of Nrf2.[26] Although quinone or oxidative stress-mediated Nrf2 activation is independent of the dissociation of Keap1-Cul3 complex, oxidized fatty acids induces the dissociation of Keap1 from Cullin3, thereby inducing the activation of Nrf2 signaling.[28] These differences in the activation of Nrf2 signaling may suggest a structure−activity relationship between these inducers.

NHDC Induces the Modification of Keap1 in HepG2 Cells. Keap1 contains 25 and 27 cysteine residues in mouse and human homologues, respectively.[23] Because of the high activity of these cysteine residues, inducers are able to binding with Keap1 at different cysteine sites. For example, cysteine 151 is important for the binding of Keap1 to Cul3, and the modification of cysteine 151 causes a conformational change of Keap1, which results in the dissociation of Keap1 from Cul3 and the inhibition of Nrf2 ubiquitination.[27] A number of studies have indicated that some electrophilic compounds induce the formation of Keap1 dimer via S-alkylation[29] or intramolecular disulfide bond formation.[9,30]

To determine whether modification of Keap1 might occur with NHDC, the migrations of Keap1 were evaluated by SDS-PAGE analysis. As shown in Figure 5, Keap1 protein with a molecular mass of 69 kDa has been designated as "normal" Keap1. However, the intensities of the 69 kDa band were slightly decreased in the NHDC groups, whereas a band with slower migration appeared in a concentration-dependent manner. This band, which has an approximate molecular mass of 150 kDa, could be referred to as "modified" Keap1. Hong et al. demonstrated that a typical Nrf2-inducer *tert*-butyl hydroquinone (*t*BHQ) and a thiol-reactive electrophile, *N*-iodoacetyl-*N*-biotinylhexylenediamine (BMCC) generated high-molecular-weight Keap1 forms (>150 kDa), which were identified as K-48-linked polyubiquitin conjugates.[31] However, 1-biotinamido-4-(4′-[maleimidoethyl cyclohexane]-carboxamido)butane (IAB)[31] and sulforaphane[32] have no effect on the ubiquitination of Keap1. Thus, IAB and sulforaphane display a pattern of Keap1 modification different from that of *t*BHQ or BMCC. Combined with the result of unaffected ubiquitination of Keap1 upon NHDC treatment in Figure 4B, we concluded that NHDC may share the same mechanism with IAB and sulforaphane. Interestingly, sulforaphane modified Keap1 most readily in the Kelch domain, but IAB modified

Keap1 in the central linker domain. However, whether NHDC induces Keap1 modification in Kelch or the central linker domain needs further investigation.

The Activation of JNK and p38 Signalings Involved in the Cytoprotective Effect of NHDC. The mitogen-activated protein kinase (MAPK) signaling cascade can be activated by various extracellular signals. Interestingly, previous studies have indicated that Nrf2 inducers have the ability to modulate MAPK activities. For instance, Yu et al. reported *t*BHQ and sulforaphane upregulate the activity of ERK2 and p38 but not JNK1; however, the inhibition of ERK2 or p38 activity blocked the induction of phase II detoxifying enzyme and the ARE-linked reporter gene.[33,34] In our study, NHDC treatment for 6 h up-regulated the phosphorylation of JNK and p38, but not ERK in HepG2 cells, in a concentration-dependent manner, Figure 6A. Time-dependent analysis indicated the phosphorylation of JNK increased time-dependently, but the phosphorylation of p38 reached the maximum at 6 h. To further confirm that the activation of JNK and p38 was involved in the cytoprotective effects related to NHDC, cells were pretreated with the JNK inhibitor (SP600125), ERK inhibitor (PD98059), or p38 inhibitor (SB203580) for 1 h prior to addition of NHDC. We found that JNK and p38 inhibitors, but not ERK inhibitor, attenuated the protective effects of NHDC against CCl_4-induced HepG2 cells damage (Figure 6B). We also detected the expressions of antioxidant enzyme by Western blotting analysis. As expected, the inhibition of JNK and p38, but not ERK, strongly decreased the NHDC-induced expressions of HO-1 and NQO1. These results indicated that JNK and p38 MAPK are involved in Nrf2-mediated expressions of HO-1 and NQO-1, and the cytoprotective function of NHDC possibly link with the activation of JNK and p38 MAPK signaling pathways.

ABSTRACT: Recently, new lines of yellow-seeded (CS-Y) and black-seeded canola (CS-B) have been developed with chemical and structural alteration through modern breeding technology. However, no systematic study was found on the bioactive compounds, chemical functional groups, fatty acid profiles, inherent structure, nutrient degradation and absorption, or metabolic characteristics between the newly developed yellow- and black-seeded canola lines. This study aimed to systematically characterize chemical, structural, and nutritional features in these canola lines. The parameters accessed include bioactive compounds and antinutrition factors, chemical functional groups, detailed chemical and nutrient profiles, energy value, nutrient fractions, protein structure, degradation kinetics, intestinal digestion, true intestinal protein supply, and feed milk value. The results showed that the CS-Y line was lower ($P \leq 0.05$) in neutral detergent fiber (122 vs 154 g/kg DM), acid detergent fiber (61 vs 99 g/kg DM), lignin (58 vs 77 g/kg DM), nonprotein nitrogen (56 vs 68 g/kg DM), and acid detergent insoluble protein (11 vs 35 g/kg DM) than the CS-B line. There was no difference in fatty acid profiles except C20:1 eicosenoic acid content (omega-9) which was in lower in the CS-Y line ($P < 0.05$) compared to the CS-B line. The glucosinolate compounds differed ($P < 0.05$) in terms of 4-pentenyl, phenylethyl, 3-CH_3-indolyl, and 3-butenyl glucosinolates (2.9 vs 1.0 μmol/g) between the CS-Y and CS-B lines. For bioactive compounds, total polyphenols tended to be different (6.3 vs 7.2 g/kg DM), but there were no differences in erucic acid and condensed tannins with averages of 0.3 and 3.1 g/kg DM, respectively. When protein was portioned into five subfractions, significant differences were found in PA, PB1 (65 vs 79 g/kg CP), PB2, and PC fractions (10 vs 33 g/kg CP), indicating protein degradation and supply to small intestine differed between two new lines. In terms of protein structure spectral profile, there were no significant differences in functional groups of amides I and II, α helix, and β-sheet structure as well as their ratio between the two new lines, indicating no difference in protein structure makeup and conformation between the two lines. In terms of energy values, there were significant differences in total digestible nutrient (TDN; 149 vs 133 g/kg DM), metabolizable energy (ME; 58 vs 52 MJ/kg DM), and net energy for lactation (NEL; 42 vs 37 MJ/kg DM) between CS-Y and CS-B lines. For in situ rumen degradation kinetics, the two lines differed in soluble fraction (S; 284 vs 341 g/kg CP), potential degradation fraction (D; 672 vs 590 g/kg CP), and effective degraded organic matter (EDOM; 710 vs 684 g/kg OM), but no difference in degradation rate. CS-Y had higher digestibility of rumen bypass protein in the intestine than CS-B (566 vs 446 g/kg of RUP, $P < 0.05$). Modeling nutrient supply results showed that microbial protein synthesis (MCP; 148 vs 171 g/kg DM) and rumen protein degraded balance (DPB; 108 vs 127 g/kg DM) were lower in the CS-Y line, but there were no differences in total truly digested protein in small intestine (DVE) and feed milk value (FMV) between the two lines. In conclusion, the new yellow line had different nutritional, chemical, and structural features compared to the black line. CS-Y provided better nutrient utilization and availability.

KEYWORDS: *bioactive compounds, nutrition and antinutrition profile, protein structure, fatty acid, energy value, biodegradation and digestion*

INTRODUCTION

Oilseeds and their products are the most valuable agricultural crops in world trade. Nowadays, canola is considered the second most abundant source of edible oil in the world,[1] and canola meal is widely used as a protein source in livestock feeding.[2] Canadian breeders in 1970s developed canola,

containing low "erucic acid" in the oil portion (<2% of total fatty acids in the oil) and "glucosinolates" in the meal portion (<30 μmol of any one or any combination of the four aliphatic glucosinolates in its defatted meal).[3]

The high erucic acid, glucosinolates, and condensed tannins in rapeseed could have adverse effects on animal health. Specifically, erucic acid, a fatty acid with the configuration C22:1 n-9, has been known to cause heart lesions in experimental animals.[4] If animals eat high amounts of this acid, it can result in "fat deposits infiltrating their heart walls".[5] On the other hand, glucosinolates have a negative impact on palatability, feed efficiency, iodine uptake, and weight gain in animals.[6] As to condensed tannins, the high content of condensed tannin affects biological functions such as intake and digestion.

At the same time, the improvement of the quality of canola seed and its byproducts (i.e., canola meal) has been attempted, by increasing the digestibility of the hull and/or reducing the hull proportion in the meal.

Canola varieties consist of yellow-seeded and black (dark brown)-seeded varieties. Hulls from yellow-seeded varieties have lower fiber but higher protein and oil than the black-seeded.[7,8]

Apart from the chemical composition of oilseed crops, their protein secondary structure profiles may also influence the quality and absorption of protein.[9−12] Therefore, to understand a crop's digestive behavior and nutritional value, it is important to look at the protein structure, for example, the secondary structure.[10]

However, studies aiming at evaluating the nutritional value, for ruminants, of *Brassica napus* yellow-seeded varieties, especially their degradation kinetics and protein molecular structure, are scarce. In our study, we hypothesized that these newly developed yellow and black canola seed varieties might be different in terms of their nutritional value and nutrient degradation characteristics as well as their protein's inherent molecular structural makeup.

This study aimed to systematically characterize the chemical, structural, and nutritional features in these yellow- and black-seeded canola lines. The parameters assessed include bioactive compounds and antinutrition factors, functional groups, detailed chemical and nutrient profiles including fatty acid profiles, energy value, nutrient fractions, protein structure, degradation kinetics, intestinal digestion, protein supply, and predicted feed milk value.

MATERIALS AND METHODS

New Lines of Yellow-Seeded and Black-Seeded Canola. Yellow and black canola seeds (*Brassica napus*) were supplied by Agriculture and Agri-Food Canada, Saskatoon Research Center, Canada, and used as feed sources. The yellow-seeded line was called YN01-429, and the black seeded line was a breeding line named N07-1374, which has a contrasting pedigree to YN01-429. Seeds were harvested from plots grown in 2010 and 2011 in adjacent trials about 1500 m apart at the Agriculture and Agri-Food Canada Saskatoon Research Centre in Saskatoon, Canada.

For the black-seeded line, a plot size of 1.9 m^2 had approximately 100 seeds planted mid-May each season. At maturity, seeds were directly combined from the plot. A plot size of 7.4 m^2 was used to grow the yellow-seeded line from approximately 800 seeds planted in mid-May, and plots were combined about 2 weeks after swathing. Seeding dates were 4 and 1 day apart for the two different trials in 2010 and 2011, respectively. For all samples, seeds from two different replications in each experiment of the same line were combined to form the samples used in this study. Adjusted yields ranged from 2200 to 3950 kg/ha for N07-1374 and from 2400 to 2700 kg/ha for YN01-429 in 2010 and 2011, respectively. Agronomically, the lines were very similar with flowering times and maturity ratings ranging from 1 to 3 days and from 2 to 6 days, respectively, with N07-1374 having a slightly later maturity rating.

Rumen in Situ Incubation and Degradation Kinetics. The Animal Care Committee at the University of Saskatchewan approved this trial.[13] The detailed "gradual addition/all out" procedure was reported previously.[14]

In situ degradation kinetics of different nutrients (DM, CP, OM, NDF) were determined.[15−18]

Digestibility of Rumen Bypass Protein in the Small Intestine. The digestibility of rumen bypass crude protein was determined according to the three-step in vitro procedure as described by Calsamiglia and Stern.[19]

Chemical Profiles. The residues of the nylon bags, from both experimental runs, were collected and pooled according to the incubation time, treatment, and run. Samples were analyzed for chemical and nutritional profiles using the methods from AOAC[20] and Van Soest et al.[21]

To prevent inaccurately high NDF value, the samples was incubated in acetone for 2 h to extract fat. The methods for determining the contents of soluble crude protein (SCP) and non-nitrogen protein (NPN) were previously described by Theodoridou and Yu.[22]

Oil and Fatty Acids. Oil content was analyzed using AOAC method 920.39 and fatty acid profile using method 969.33 for preparation and method 996.06 for qualification. Briefly, accurately weighed ground seed samples (0.40g) were put into a labeled Mojonnier flask, and then 110 mg of pyrogallic acid, 2.0 mL of C21:0 (internal standard), 2.0 mL of ethanol, and 10.0 mL of HCl (8.3 M) were added. For complete extraction, the solution was mixed well every 10 min on a vortex mixer and then cooled to room temperature (25 °C). As for the methylation procedure, chloroform (3 mL) and diethyl ether (3 mL) were used to dissolve the extracted fat and then evaporated again in the water bath (40 °C) under a N stream in a glass vial. After dryness was reached, the vial was cooled to room temperature (25 °C), and H_2O (5.0 mL), hexane (1.0 mL), and Na_2SO_4 (1 g) were added to allow layer separation. The top layer was transferred to another vial containing 1 g of Na_2SO_4 for gas chromatography analysis (Agilent 6890, Agilent Technologies Inc., Santa Clara, CA, USA). The column used in this study was a DB 225 capillary column (0.10 mm i.d., 10 min length, and 0.10 μm film thickness). The column temperature program was set up as follows: initial temperature, 35 °C, raised at 25 °C/min to 195 °C, raised at 3 °C/min to 205 °C, and raised at 8 °C/min to 230 °C. The detector temperature was 250 °C. The analysis was repeated if the error was >5% between two replications.

Glucosinolates, Polyphenols, and Condensed Tannins. Glucosinolate profiles in the samples were analyzed using the CGA method.[23,25] Total polyphenols and condensed tannins (CT, HCl-butanol procedure) in samples were determined according to the methods of Slinkard and Singleton[26] and Reed.[27] All samples were analyzed in duplicate; the analysis was repeated if the error was >5%.

Energy Values and Protein Subfractions. Energy values were estimated using a summative approach as suggested by the NRC 2001 dairy.

The Cornell System of CNCPS was applied to partition protein fractions.[28]

Molecular Structure Profile Explored Using Molecular Spectroscopy. Molecular spectroscopic experiments were performed at the Molecular Spectroscopy Lab in the Feed Science Division at APS of the University of Saskatchewan. Attenuated total reflectance-Fourier transformed infrared-vibration spectroscopy (JASCO FT/IR-ATR-4200, Jasco Inc., Easton, MD, USA) was carried out. Samples were placed in the refrigerator to minimize sticking while grinding. Later they were fed slowly into the grinder to further prevent sticking during the grinding process and were finely ground using a fit with a 0.5 mm screen. Five subsamples from each sample were analyzed with 32 scans per sample in the 4000−800 cm^{-1}. The functional spectral

DOI: 10.1021/acs.jafc.5b01577
J. Agric. Food Chem. 2015, 63, 5476−5484

bands and their intensity of ratio calculation (i.e., amide I, II, secondary structures) were according to the previously published study.[29]

Using the Dutch System To Predict Potential Protein Nutrient Supply and Feed Milk Value (FMV). Potential protein nutrient supply was predicted on the basis of the Dutch system[30−33] The FMV was determined on the basis of the metabolizable protein from the NRC 2001 model.

Statistical Analysis. The data were statistically analyzed using the Mixed Model procedure of SAS (version 9.3) (SAS Institute, 1999). For chemical and nutrient data, the model was $Y_{ij} = \mu + V_i + e_{ij}$. The model used for rumen and intestinal data was $Y_{ijk} = \mu + V_i + R_k + e_{ijk}$, where Y_{ijk} is the dependent variable ijk, μ is the population mean, V_i was the fixed effect of canola seed type, R_k was a random effect of the in situ run, and e_{ijk} was the random error. For all statistical analyses, significance was declared at $P < 0.05$ and trends at $P \leq 0.10$.

RESULTS AND DISCUSSION

Chemical Characterization. The results on the chemical profiles of the yellow-type (CS-Y) and black-type (CS-B) canola seeds are presented in Table 1. No significant differences were found between CS-Y and CS-B for the basic nutrients. For carbohydrate profiles, CS-Y was lower in ADF (60.7 vs 98.6 g/kg DM) and ADL (8.1 vs 43.5 g/kg DM) and tended to be lower in NDF (122.1 vs 154.5 g/kg DM) ($P \leq 0.10$) (Table 1). It has been reported that dietary fiber content in yellow-seeded samples was significantly lower than in the black-seeded types, and this is due to "the bigger seed size, the lower contribution of the hull fraction to the total seed mass, and the lower fiber content of the hull fraction for the yellow seeded canola".[7] Moreover, Abraham and Bhatia[34] mentioned that yellow-seeded *Brassica* genotypes "have a thinner and translucent seed coat, resulting in a lower hull proportion with a bigger embryo and consequently greater oil and protein contents in the seeds". Moreover, hulls consist of low molecular weight carbohydrates cellulose, pectin, lignin, and other compounds.[35] Therefore, in this study the significantly notably lower ADL in CS-Y compared to CS-B could be due to the higher digestible hull in the yellow seed.

With regard to the protein profile of the feedstuffs used in this study, CS-Y had lower ($P < 0.05$) NPN (g/kg DM or g/kg SCP) and ADICP (g/kg DM). A trend toward significance was observed when ADICP was expressed as g/kg CP, and in that

significant amounts of essential fatty acids.[37] In this study, there was no difference in the erucic acid level. Among the fatty acids the C20:1 eicosenoic acid content (omega-9) was lower ($P < 0.05$) for the CS-Y than for the CS-B.

There are many studies focusing on the phenolic compounds in crops such as soybean, sunflower, and sorghum; however, knowledge of these compounds in canola remains fragmentary, even though canola contains about 5 times as much phenolic compounds as soybeans.[38] The predominant phenolic groups present in canola seed are phenolic acids and condensed tannins. The last one is present from 150 to 300 g/kg DM, with higher levels in black-seeded varieties.[39,40] In this study, there were no significant differences in the CT content, whereas the total polyphenols tended to be lower for the yellow- than for the black-seeded varieties (6.3 vs 7.2 g/kg DM). According to Shahidi et al.,[41] phenolic compounds (i.e., CT) contribute to the dark color of canola seed and their byproducts.

Glucosinolates are natural antinutritional compounds found in most brassica seeds and plants such as mustard, Brussels sprouts, cabbage, and cauliflower. The presence of relatively high levels of certain glucosinolates in traditional types of rapeseed hindered the use of rapeseed meal as a protein supplement in animal nutrition. The composition of glucosinolates in canola seeds depends on the seed variety.[3,42] Our study found specific glucosinolate compounds present in higher amounts in the yellow than in the black canola seeds. 3-Butenyl, phenylethyl, and 3-CH_3-indolyl exist in a significantly higher amount in CS-Y compared to in CS-B.

Fractionation of Protein. Protein and subfractions are shown in Table 3. Canola yellow type was significantly lower in the PA (3.9 vs 5.8 g/kg CP) and the unavailable PC fraction[24] (10.1 vs 33.2 g/kg CP) compared to the black one. Because the PC fraction in the feed represents the unavailable part of the protein, which cannot be used effectively by the ruminants, our results implied that the yellow canola seeds were expected to show comparatively better protein utilization than the brown seeds.

Energy Values in Newly Developed Lines. Truly digestible nutrients[18] and energy content of yellow and black canola varieties are summarized in Table 4. CS-Y was higher ($P < 0.05$), compared to CS-B, in total digestible nonfiber carbohydrate (367.1 vs 277.3 g/kg DM) and total digestible nutrients (149.4 vs 133.5 g/kg DM). The total digestible NDF tended to be higher for the CS-Y compared to the CS-B (21.1 vs 7.8 g/kg DM).

On the other hand, the energy values ($DE_{1\times}$, $DE_{3\times}$, $ME_{3\times}$, $NE_{L3\times}$) were higher ($P < 0.05$) for the yellow-seeded compared to the black-seeded canola. This result might be due to the

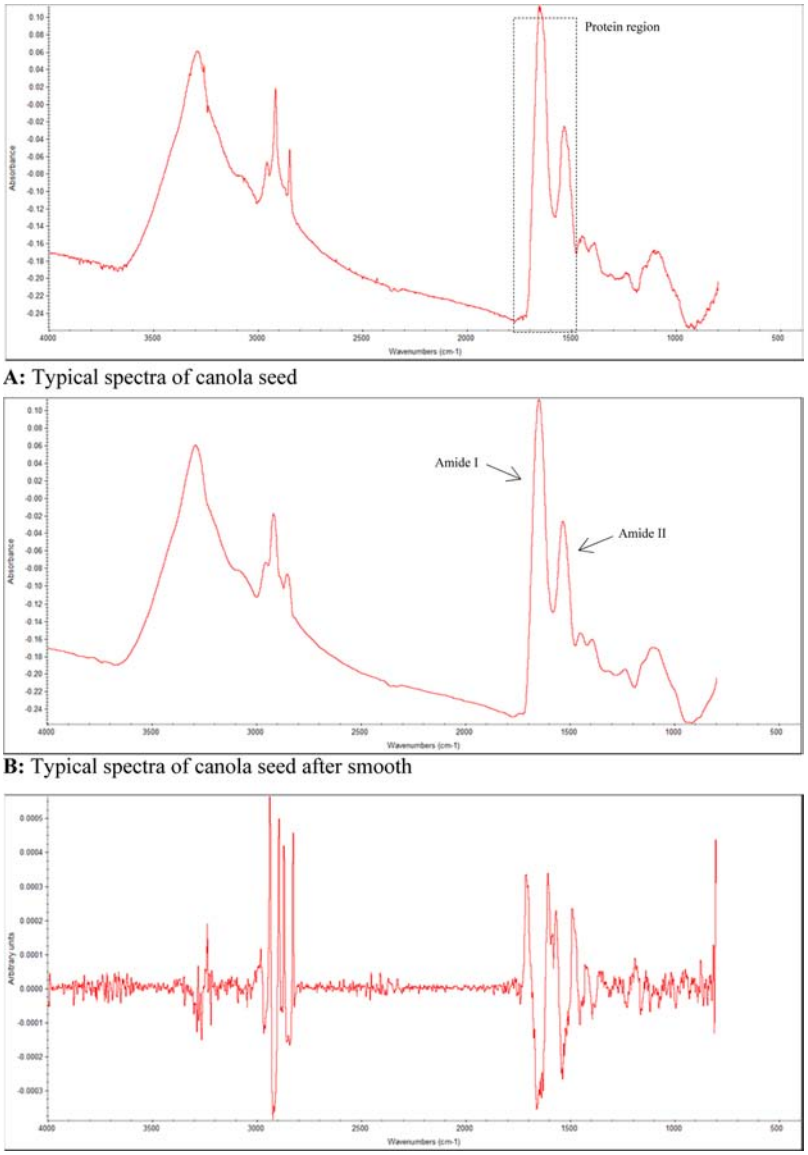

Figure 1. Typical biomolecular spectrum of canola seed in the region from ca. 4000 to 800 cm^{-1}, showing the chemical functional group of protein amides I and II.

tendency for lower fiber content and reduced hull of CS-Y compared to CS-B.

In Situ Rumen Incubation. The effect of canola seed variety on rumen fractions, rate of degradation, and effective degradability of nutrients is presented in Table 5. When CS-Y was compared with CS-B, there were no differences in rumen degradability, soluble fraction, and degradation rate of dry matter. However, the *D* fraction of dry matter in yellow-seeded canola (727.6 g/kg DM) was higher than in the black one (650.7 g/kg DM). The degradable fraction of organic matter (Table 5) was higher for CS-Y compared to CS-B (799.0 vs 642.8 g/kg OM).

The results on the in situ rumen protein degradation study showed that the EDCP (g/kg CP) of CS-Y was similar to that of CS-B. However, the potential soluble fraction was lower ($P < 0.05$) and the degradable fraction was higher ($P < 0.05$) for the yellow-seeded compared to the black-seeded canola.

The NDF degradability depends on the proportion of its main components (i.e., cellulose, hemicellulose, and lignin). Lignin, as well as cellulose and hemicellulose that are associated with it, is known to be highly indigestible.[20] In our study, the lower ($P < 0.05$) ADF and ADL content of yellow-seeded canola and the tendency of the NDF content to be lower, compared to the black one, was expected to be in accordance with a higher EDNDF (g/kg NDF) for CS-Y. However, there was no difference between CS-Y and CS-B concerning the degradation characteristics of neutral detergent fiber.

Intestinal Digestibility of Rumen Undegradated Protein. The in vitro crude protein intestinal digestibility of CS-Y was higher ($P < 0.05$) compared to that of CS-B (565.9 vs 445.6 g/kg CP of rumen undegradable protein) (Table 6). The lower undegradable protein fraction (PC) and the higher intestinal protein digestibility of yellow canola compared to the black-seeded one implies that the yellow type is a better source of intestinally digestible proteins for ruminants.

The absorbance of crude protein in the ruminant's small intestine has been reported to be negatively correlated ($r = -0.81$) with the acid detergent insoluble N content in canola meal.[43] This is in agreement with the results obtained in our study, where the higher protein intestinal digestibility of CS-Y,

DOI: 10.1021/acs.jafc.5b01577
J. Agric. Food Chem. 2015, 63, 5476−5484

compared with the CS-B, was in accordance with its lower ($P < 0.05$) ADICP value.

Protein Metabolic Characteristics and Feed Milk Value. The protein metabolic characteristics and the feed milk value are shown in Table 7. As described before, the microbial protein production is estimated on the FOM basis in the Dutch system. Therefore, similarity in FOM between the yellow and black resulted in similar values of MCP_{FOM} and AMCP.

In comparison with the black-seeded canola, the microbial protein that synthesized in the rumen and was based on the rumen degraded feed protein was significantly lower for the CS-Y in accordance with its trend ($P < 0.10$) for lower OEB value.

In our study, the fact that the OEB value[30] tended to be lower ($P < 0.10$) for the yellow-seeded canola indicates this seed type may result in a better nitrogen availability and utilization by the animals.

The feed milk values for both types of canola seed were not different ($P > 0.05$), so both are expected to have similar efficiencies for milk production.

Protein Molecular Structures of Yellow- and Black-Seeded Canola. The profiles of protein molecular structure of yellow- and black-seeded canola as defined with ATR-FT/IR are presented in Table 8. The research shows that protein secondary structure affects the protein by changing protein quality and biofunctions.[29,44−49] Depending on the α-helix to β-sheet ratios, tissues of the same protein content may differ in their nutritional value.

Figure 1 shows typical spectra, smoothed spectra, and second-derivative spectra of CS-Y and CS-B revealed by ATR-FT/IR molecular spectroscopy. In the present study, no significant differences were observed for the protein's inherent molecular structural makeup between CS-Y and CS-B.

In contrast with our results, Theodoridou et al.[50] concluded that the amide I and II areas, the β-sheet, and the ratio of amide I to amide II were higher ($P < 0.05$) for black-seeded compared to yellow-seeded canola. One possible reason for this variation between the two studies might be the fact that another analytical technique, called synchrotron-based vibrational FTIR microspectroscopy (SR-FTIRM),[51,52] has been employed in their study.

In summary, the results of this study indicated that the yellow-seeded canola was lower in ADF, ADL, NPN, and ADICP content compared to the black one. The yellow-seeded canola had higher values in the total digestible nutrients content, net energy, and digestible and metabolizable energy. There were no differences for the protein's inherent structural spectral characteristics. The findings of the present study show that the breeding of yellow-type canola is a promising route to reducing fiber and hull contents while at the same time increasing the level of oil. The feed protein availability and utilization by the animal might be higher when yellow-type canola is fed to animals, because the in vitro intestinal digestibility was found to be higher for the yellow-seeded canola compared to the black one. On the other hand, the yellow-seeded canola tended to have a lower degraded balance, compared to the black one, which suggests a better nutrient utilization and less output of potentially polluting nitrogen. This needs to be consider because environmentally friendly rations are nowadays very important in animal nutrition.

MATERIALS AND METHODS

Plant Materials and Germination Assay. The sweet corn (Yuetian 13) seeds were brought from Guangdong King Zuo Agricultural Science and Technology Company. The seeds were artificially aged under high temperature and humidity (45 °C and 100% relative humidity) conditions. Seeds were surface-sterilized. Seed germination was tested on moist filter paper. In each Petri dish (90 mm diameter), 20 seeds were randomly placed on the filter paper and then 10 mL of deionized water was added. The seeds were germinated for 4 days under dark conditions in a controlled (30 °C) growth chamber. Germination was considered when the coleoptiles were longer than 2 mm. Three replicates were carried out for each treatment.

RNA Isolation. The seeds were artificially aged under high temperature and humidity (45 °C and 100% relative humidity) conditions for 2 days.[29] Seeds that non-artificially aged (0 days) were used as a control (CK). We cut the pericarp and endosperm off the seeds with a knife carefully, and then the samples were immediately frozen in liquid nitrogen and stored at −80 °C. Total RNA was extracted using Trizol reagent (Invitrogen, Carlsbad, CA) following the procedure of the manufacturer.

Small RNA Library Construction, Sequencing, and Sequencing Data Analysis. The total RNA was used for Solexa sequencing. Four libraries were constructed: two sets were from seeds non-artificially aged (CK), the other two sets were from seeds artificially aged for 2 days. According to Illumina's TruSeq Small RNA Sample Preparation Guide, small RNA libraries were constructed using Illumina's TruSeq Small RNA Preparation Kit (Illumina, San Diego, CA).[30] Small RNAs were ligated to a 3′ RNA adapter and a 5′ RNA adapter. The purified cDNAs after reverse transcription and polymerase chain reaction (PCR) were sequenced by the Illumina Hiseq2000 (Illumina, San Diego, CA). Raw sequencing reads were obtained using Illumina's Sequencing Control Studio software, version 2.8 (SCS, version 2.8) (Illumina, San Diego, CA). After quality control using a common pipeline filter, clean reads were directly used for further bioinformatics analysis with ACGT101-miR (LC Sciences, Houston, TX).[31] Then, unique sequences (18−25 nucleotides) were mapped to specific species precursors in the miRNA database (miRBase 20 released) in maize (http://www.mirbase.org) by BLAST search to identify known miRNAs and novel 3p- and 5p-derived miRNAs. New candidate miRNAs were identified by extracting 250 nucleotides of the sequence flanking genome sequence of unique small RNAs using MIREAP (http://sourceforge.net/projects/mireap/), followed by the prediction of secondary structures by the Mfold program. The new candidate miRNA were identified on the basis of the criteria as described.[3]

Degradome Library Construction. The degradome cDNA library was constructed on the basis of the method described previously[32] using sliced ends of polyadenylated transcripts from sweet corn seeds. Identification of the potentially sliced targets of the known and novel miRNA identified by high-throughput sequencing and degradome analysis were processed using the publicly available CleaveLand 3.0 software package and the ACGT301-DGE, version 1.0 program (LC Sciences, Houston, TX).[33]

Quantitative Real-Time (qRT)-PCR. Total RNA was extracted from the sweet corn seeds artificially aged for 0 and 2 days with Trizol reagent (Invitrogen) following the instructions of the manufacturer. These samples were treated under the same conditions as those for miRNA and degradome sequencing. The total RNA (1 μg) was reverse-transcribed using miRNA-specific stem-loop primers. Next, qRT-PCR was performed using Rotor-Gene Q (QIAGEN). The primers used are listed in Table S11 of the Supporting Information. The relative expression ratio was calculated using the $2^{-\Delta\Delta C_t}$ method with 5S rRNA as the reference gene. All of the gene expression data were obtained from three individual biological replicates and processed according to strict statistical methods.

RESULTS AND DISCUSSION

Seed Vigor Changes under Artificial Aging Treatment. Germination percentage reflects seed vigor. With sustained artificial aging under 45 °C and 100% RH conditions, seed vigor decreased gradually. The germination percentage reduced to about 50% after 2 days of aging (Figure 1).

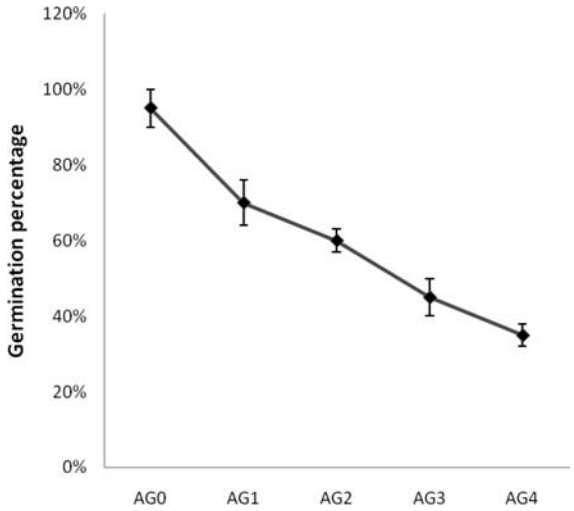

Figure 1. Germination percentage of Yuetian 13 under artificial aging treatment. AG0 means non-artificially aged; AG1 means artificially aged for 1 day; AG2 means artificially aged for 2 days; AG3 means artificially aged for 3 days; and AG4 means artificially aged for 4 days.

Overview over Deep-Sequencing Results. To study the possible miRNAs related with sweet corn seed vigor, we profiled miRNA accumulation during seed artificial aging. We constructed four maize small RNA libraries using mixed RNAs obtained from seeds non-artificially aged (CK) and artificially aged for 2 days. Deep sequencing generated a total number of 9 218 636 and 7 784 067 raw reads from libraries of seeds non-artificially aged named AG0a and AG0b and 7 203 021 and 8 043 385 raw reads from libraries of seeds artificially aged for 2 days named AG2a and AG2b. After removing sequences that 3′ adapter was not found and reads with lengths of <18 and >25 nucleotides, junk reads, there were 6 264 835, 5 943 490, 5 107 877, and 5 791 540 mappable reads obtained for AG0a, AG0b, AG2a, and AG2b libraries, respectively (see Table S1 of the Supporting Information). Most of these miRNAs were 20−24 nucleotides. The length distribution of these small RNA sequences showed that the most abundant sequences were 24 nucleotides long, followed by 22 nucleotides long and 21 nucleotides long (Figure 2). This was consistent with most plant mature small RNAs.[34−36] The mappable reads were then searched against the Rfam (http://rfam.janelia.org), mRNA (ftp.jgi-psf.org/pub/compgen/phytozome/v9.0/Zmays/annotation/), and repeat (http://www.girinst.org/repbase) databases. Finally, after excluding sequences that aligned to those databases, 5 037 856, 4 796 100, 4 269 398, and 4 951 734 sequences remained in the AG0a, AG0b, AG2a, and AG2b libraries, respectively (see Tables S2 and S3 of the Supporting Information).

Identification of Known miRNAs in Seeds of Sweet Corn. To identify the miRNAs in our data set, sRNA sequences identified by deep sequencing were Blastn-searched against the currently known mature plant miRNAs in the miRNA database miRBase. There are currently 172 pre-miRNAs listed that

DOI: 10.1021/acs.jafc.5b00522
J. Agric. Food Chem. 2015, 63, 5485−5491

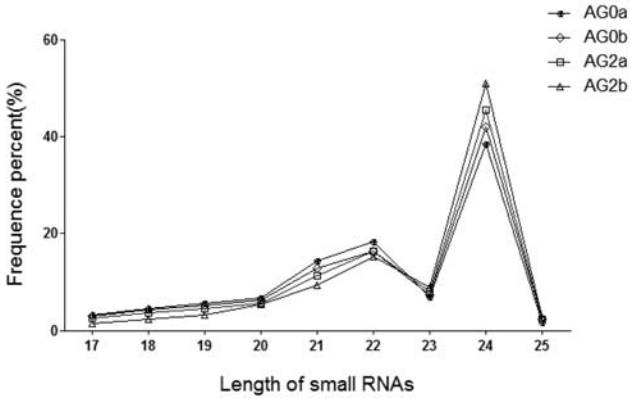

Figure 2. Length distribution of unique sRNAs of sequ-seqs type in four libraries.

correspond to 321 mature miRNAs of *Z. mays* in miRBase. In the present research, there were 146 pre-miRNAs corresponding to 130 mature miRNAs detected, 33 new mature 5′- or 3′-miRNAs corresponding to *Z. mays* pre-miRNAs detected for the first time, and 93 mature miRNAs corresponding to *Z. mays* pre-miRNAs detected confirming miRNA sequences in miRBase but different sequences in our study (see Table S4 of the Supporting Information). Both libraries identified 27 conversed miRNA families, which were 3 conversed miRNA families more than that in dry and imbibed maize seeds, including miR395, miR2118, and miR2275.[4] There were 12 novel pre-miRNAs corresponding to 18 mature miRNAs originating from other species but can be mapped to the *Z. mays* genome. Among the 18 mature miRNAs, 13 new mature 5′- or 3′-miRNAs were detected in *Z. mays* for the first time and 4 mature miRNAs were detected confirming miRNA sequences in miRBase but different sequences in our study (see Table S5 of the Supporting Information). There were 31 novel miRNAs originating from 31 pre-miRNAs that could not be mapped to the *Z. mays* genome; these were mapped to other plant species genomes, and the extended sequences at the mapped positions of the genome potentially form hairpins (see Table S6 of the Supporting Information). Another 4 novel miRNAs identified to originate from pre-miRNAs that could not be mapped to the *Z. mays* genome but were mapped to other plant genomes failed in hairpin structure prediction for extended sequences at the mapped positions (see Table S7 of the Supporting Information).

Identification of New Candidate miRNAs in Seeds of Sweet Corn. Reads that cannot be mapped to the miRBase were used to query the Rfam, the mRNA database, and the repeat Repbase. After removal of mapped reads, the rest of the reads were predicted for potential stem-loop structure. In total, 141 pre-miRNAs corresponding to 137 unique miRNAs were first identified in our study (see Table S8 of the Supporting Information). The 137 candidate miRNAs were 18−24 nucleotides long, with 69.34% of them 24 nucleotides long. Most of the candidate miRNAs were expressed at a low level. However, 6 of the candidate miRNAs were expressed at a high level. Those miRNAs were PC-5p-142680_20, PC-5p-6996_405, PC-3p-144850_17, PC-5p-608_3876, and PC-3p-78961_35; they had more than 20 reads in four libraries.

miRNAs That Related with Sweet Corn Seed Vigor. To identify miRNAs related with sweet corn seed vigor, the reads obtained from the high-throughout sequencing were used for differential expression analysis. With the selection of p value < 0.05, 27 miRNAs were identified to be differentially expressed between the four libraries; 17 miRNAs were upregulated, and 10 miRNAs were downregulated (Table 1). Of the 15 *Z. mays*-specific miRNAs, 9 miRNAs were upregulated and 6 miRNAs were downregulated. Zma-miR319a-3p_R+1, the miRNA that had the highest expression abundance in the four libraries, was upregulated when the sweet corn seed vigor was down. A *Brachypodium distachyon*-specific miRNA, bdi-miR159-3p, was downregulated when the sweet corn seed vigor was down. A total of 11 candidate miRNAs were differentially expressed between the four libraries: 8 were upregulated, and 3 were downregulated. To validate conserved miRNAs identified and novel miRNAs predicted, we selected 10 differential expressed miRNAs for stem-loop qRT-PCR. The expression trends of these miRNAs were consistent with the high-throughout sequencing results. Figure 3 showed that the 10 miRNA expression profiles by qRT-PCR were consistent with those by deep sequencing, indicating the reliability of these methods.

Targets of miRNAs in Seeds of Sweet Corn. To understand the function of the novel miRNAs from seeds of sweet corn, targets of novel miRNAs were predicted using recently developed degradome sequencing technology. In total, 13 621 118 (99.47%) mappable reads were obtained, including 3 986 470 unique mappable reads, while 7 343 113 (99.46%) transcript mapped reads, including 2 282 963 unique transcript mappable reads, were obtained (see Table S9-1 of the Supporting Information). The target transcripts were sorted into five categories according to the relative abundance of the tags at the target mRNA sites. Briefly, category "0" is defined as >1 raw read at the position, with abundance at a position equal to the maximum on the transcript and with only one maximum on the transcript. In category "1", the expected cleavage signature was equal to the maximum on the transcript and more than one maximum position on the transcript. For category "2", abundance at the position was less than the maximum but higher than the median for the transcript. The abundance at the position equal to or less than the median for the transcript was grouped into category "3", and category "4" showed only one raw read at the position. Figure 4 showed the typical five categories of the target transcripts. A total of 1142 targets that were potentially cleaved by 131 miRNAs were identified (see Table S9-2 of the Supporting Information). Meanwhile, 26 genes were identified to be targeted by 9 differentially expressed miRNAs in both degradome analysis and bioinformatics analysis (see Table S9-3 of the Supporting Information). Notably, the targets of miR319, miR156, miR160, and miR167 were identified as transcription factors, such as MYB, TCP, SBP, and ARF, respectively, which have been experimentally validated by the previous studies.[19−21] This demonstrated the high reliability of target identification in the present research.

Gene Ontology (GO) Analysis and Pathway Analysis of Targets. To gain a better understanding of the functional roles of the miRNAs, we did GO and KEGG pathway analysis on putative targets. The targets were annotated using the GO annotations available from B73 RefGen_v2. GO analysis is commonly used to describe the function of genes and gene products, while the KEGG analysis is used to provide the pathway of annotated targets. Figure 5 showed the GO functional classification of novel miRNA targets in the sweet corn seeds. Novel targets covered a broad range of functional categories. Obviously, targets of ATP-binding, regulation of

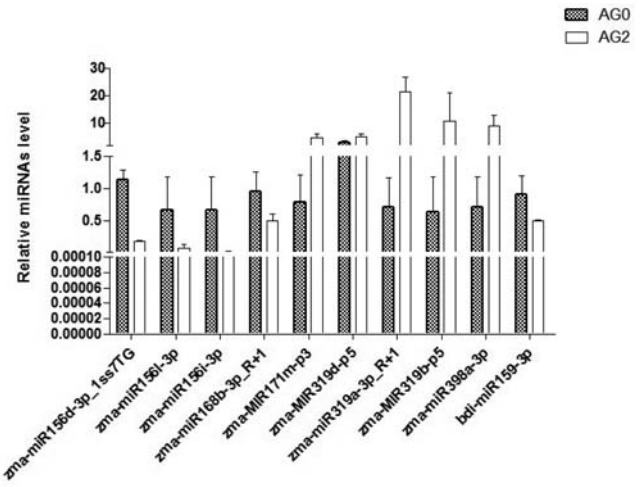

Figure 3. Detection of selected miRNA expression in AG0 and AG2 sweet corn seeds using qRT-PCR. AG0 means non-artificially aged, while AG2 means artificially aged for 2 days. The 5S rRNA was chosen as an endogenous control. The results were obtained from three biological replicates, and the error bars indicate the standard error of the mean.

transcription, DNA-dependent, and nucleus- and membrane-related genes were specifically enriched. This suggested that those genes may play an important role in sweet corn seeds. The pathways of all the miRNAs and targets involved were listed (see Tables S10-1 and S10-2 of the Supporting Information). There were 157 pathways that targets involved, while purine metabolism, cell cycle, and phenylalanine metabolism pathways owned most targets. However, there were only 13 miRNAs found to be involved in pathways, including mitogen-activated protein kinase (MAPK) signaling pathway, endocytosis, spliceosome, and others.

Function of Differentially Expressed miRNAs. Although 27 miRNAs were differentially expressed related with sweet corn seed vigor, only 26 genes targeted by 9 miRNAs were identified in both degradome analysis and bioinformatics analysis, including 10 MYB proteins, 2 TCP family transcription factors, 1 membrane-anchored ubiquitin-fold protein 6 precursor (MUB6), 1 heat stable protein, 3 peroxidase superfamily proteins, 1 selenium-binding protein (SBP), and 6 unknown transcription factors. The function of the MYB protein has been previously identified. MYB proteins are key factors in regulatory networks controlling development, metabolism, and responses to biotic and abiotic stresses.[37] In *Arabidopsis* and rice (*Oryza sativa*), MYB33 and MYB101 targeted by miR159 were ABA-positive regulators, which play a vital role in seed germination. The role of MYB protein in seed vigor is still unknown. In our study, MYB domain proteins 65/33/101 were targeted by bdi-miR159-3p and zma-miR319a-3p_R+1. This suggests that MYB protein may participate in seed vigor regulation through chromatin binding. Loss of seed vigor brings abnormal physiological and biochemical activities in cells, such as free radical lipid peroxidation, chromosome aberration, and non-enzymatic glycosylation (NEG). Peroxidase (POD) is a scavenger of reactive oxygen, which can maintain the stability and integrity of the membrane of the cells. POD superfamily proteins play roles in the oxidation−reduction process and response to oxidative stress, which protect seeds from oxidative damage during artificial aging. This suggests that PC-5p-213179_17 may prevent sweet corn seeds from free-radical lipid peroxidation by participating in the

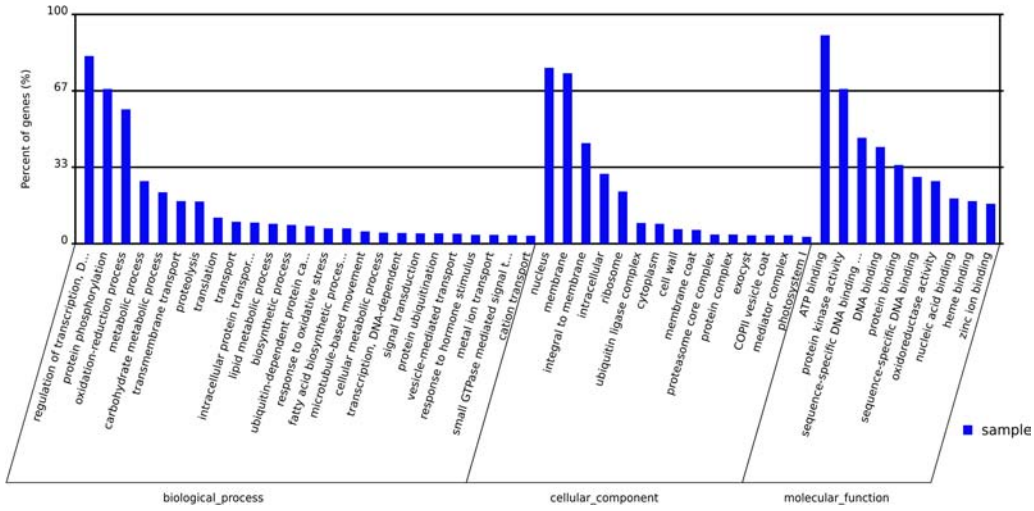

Figure 5. GO functional classification of novel miRNA targets in the sweet corn seeds.

peroxidase activity, oxidation−reduction process, and response to oxidative stress. The function of MUB6 in seed vigor is still unclear, but researchers have proven that MUB6 expressed in seeds associated with plant structure in *Arabidopsis*. Seed aging will destroy the integrity of the membrane. Here, we report a MUB6 in sweet corn seeds regulated by PC-3p-477790_3, which may be a new direction in the research of seed vigor. Heat-stable protein also targeted by PC-3p-477790_3 may be involved in ameliorating the effects of artificial aging on seed vigor by repairing protein damage. Therefore, we propose that miRNAs participate in seed vigor of sweet corn by regulating some genes controlling the process.

at 37 °C and 200 rpm. Gentamicin was added to a final concentration of 25 μg/mL for plasmid maintenance.

General Molecular Biological Techniques. Routine molecular biological techniques were performed according to Sambrook et al.[19] The restriction enzymes and T4 DNA ligase used were purchased from Fermentas (St. Leon-Rot, Germany). Pfu DNA polymerase (Transgen, Beijing, China) was used for PCR amplification of the insets, and Taq PCR MasterMix (Zoman, Beijing, China) was used for the test PCR reactions. The primers used in this study are listed in Table 1. Transformation of *G. oxidans* was performed by triparental mating, essentially as described by Hölscher et al.[20]

Site-Directed Mutagenesis to Construct an Improved pBBR1MCS-5 Series. Site-directed mutagenesis upstream of the gene *rep* in pBBR1MCS-5 was performed, including the −10 and −35 region of the promoter and the ribosome binding site (RBS), using a TOYOBO KOD-Plus-Mutagenesis Kit (Tokyo, Japan) according to the manufacturer's instructions. The primers used for each mutation are listed in Table 1. The pBBR1MCS-5 plasmid was mutated to generate pBBR-10, pBBR-35, pBBR-3510, pBBR-RBS, pBBR-R10, pBBR-R35, and pBBR-R31. Among the resulting plasmids, pBBR-10 was mutated at the −10 region (CATAAT to TATAAT) using the primers M10-F and M10-R. pBBR-35 was mutated at the −35 region (TTGACT to TTGACA) using the primers M35-F and M35-R. pBBR-3510 was created using two rounds of mutagenesis using the primer pairs M35-F and M35-R and M10-F and M10-R consecutively. pBBR-RBS was mutated at the ribosome binding site (GGAGA) of the rep gene (to GGAGGAAA) using the primers Mrbs-F and Mrbs-R. pBBR-R10 was created using two rounds of mutagenesis using the primer pairs M10-F and M10-R and Mrbs-F and Mrbs-R consecutively. pBBR-R35 was created using two rounds of mutagenesis using the primer pairs M35-F and M35-R and Mrbs-F and Mrbs-R consecutively, and pBBR-R31 was created using three rounds of mutagenesis using the primer pairs M35-F and M35-R, M10-F and M10-R, and Mrbs-F and Mrbs-R consecutively.

Construction of Recombinant Plasmids. The fragments of the *G. oxidans tufB* promoter and the *ga2dh* gene were amplified with PCR using the primer pairs PtufB-F and PtufB-R and ga2dh-F and ga2dh-R, respectively, using chromosomal DNA as the template. The resulting fragment of the *tufB* gene was digested using *Sac*I/*Xba*I and was ligated into pBBR1MCS-5 digested with the same enzymes to produce the recombinant plasmid pBBR1MCS-*tufB*. The fragment of *ga2dh* was digested using *Xba*I/*Bam*HI and was cloned into pBBR1MCS-*tufB* digested with the same enzymes to generate pBBR-*ga2dh*. The plasmids pBBR-10-*ga2dh*, pBBR-35-*ga2dh*, pBBR-RBS-*ga2dh*, pBBR-3510-*ga2dh*, pBBR-R10-*ga2dh*, pBBR-R35-*ga2dh*, and pBBR-R31-*ga2dh* were constructed in the same manner. All of the resulting recombinant plasmids were confirmed by sequencing, and these plasmids were transformed into *G. oxidans* DSM 2003 through triparental mating.[20]

Real-Time PCR. The plasmid copy number and level of gene transcription were determined using RT-qPCR. The StepOnePlus Real-Time PCR System (Applied Biosystems, California, United States) was used for qPCR amplification and detection. The qPCR analyses were conducted in a total volume of 20 μL using the CWBIO FastSYBR Mixture (with Rox) (Beijing, China) according to the manufacturer's recommendations. All of the reactions were performed in triplicate.

The recombinant *G. oxidans* cells were cultured at 30 °C and 220 rpm for 22 h. Plasmid DNA was collected from 3 mL cultures according to the Biomiga Plasmid Miniprep Kit protocol (San Diego, CA, United States). The extracted plasmids were used as templates, and the cryptic plasmid pGOX3 was used as the internal single-copy reference. The primer pairs qpBBR-F and qpBBR-R and qpGOX3-F and qpGOX3-R were used in the respective reactions.[21]

Total RNA was isolated from 15 mL cultures using Takara RNAiso Plus (Dalian, China) following the manufacturer's instructions. A 1 μg sample of RNA was reverse transcribed into cDNA using the Takara PrimeScript RT reagent kit including gDNA Eraser (Dalian, China). The relative abundance of the *ga2dh* transcripts in the recombinant strains was analyzed using RT-qPCR with the primers qga2dh-F and qga2dh-R. The 16S rRNA gene was used as the internal standard and detected with the primers q16S-F and q16S-R.

Preparation of Membrane Fractions. The *G. oxidans* cells were harvested by centrifugation at 8 000 rpm for 10 min and washed twice with 20 mM potassium phosphate buffer (pH 7.5). The washed cells were resuspended with the same buffer at a cell wet weight (CWW) concentration of 0.1 g/mL and then disrupted using an ultrasonifier (Xinzhi, Ningbo, China) for 99 cycles (300 W, 5 s sonication, 5 s pause on ice). After centrifugation at 8 000 rpm for 15 min to remove the cell debris, the supernatants were centrifuged at 40 000 rpm for 60 min. The sediments were collected and designated the membrane fractions, which were resuspended into 100 mM NaAc buffer (pH 5.5) on ice subsequently.

Enzyme Activity Assay and Protein Concentration Determination. GA2DH activity was determined at 30 °C by measuring the initial reduction rate of 2,6-dichlorophenolindophenol (2,6-DCIP, Sigma, St. Louis, MO, United States) at 600 nm on a SpectraMax 190 instrument (Molecular Devices, California, United States), and a molar extinction coefficient of 10.8 mM^{-1} cm^{-1} for DCIP was used for the calculation.[22] The basal reaction mixture consisted of 5 mM DCIP and 6.5 mM phenazine methosulfate (PMS, Sigma, St. Louis, MO, United States) in 50 mM potassium phosphate buffer (pH 6.0) and was

DOI: 10.1021/acs.jafc.5b01652
J. Agric. Food Chem. 2015, 63, 5492−5498

prepared just before the assay. The reaction mixtures (200 μL) for enzyme assay containing 80 μL of basal reaction mixture and 0.015 mg of protein in 50 mM potassium phosphate buffer (pH 6.0) was incubated at 30 °C for 5 min, and the reactions were started by adding 50 mM prewarmed GA. One unit of GA2DH activity was defined as the amount of the enzyme that catalyzes the reduction of 1 μM DCIP per min at 30 °C. Protein concentration was determined by the method of Bradford,[23] using bovine serum albumin as a standard.

Relative 2KGA Production by the Different *G. oxidans* Strains. The relative level of 2KGA production was evaluated in the different *G. oxidans* strains by determining the concentration of 2KGA after 2 h of catalysis. The *G. oxidans* strains were cultivated for 22−24 h, after which the cells were collected by centrifugation at 7 000 rpm for 20 min. The reaction system contained 10 g CWW/L resting cells and 40 g/L GA in 50 mL shaking flasks with a working volume of 10 mL. The reactions were performed at 30 °C and 200 rpm using a rotary shaker. All of the experiments were conducted in triplicate.

Biotransformation of GA to 2KGA. Biotransformation of GA to 2KGA was performed in a 7 L fermenter with a working volume of 1.5 L at 30 °C and 600 rpm, with the pH maintained at 5.8 using NaOH. The *G. oxidans* cells were cultivated for 22−24 h, after which the cells were collected by centrifugation at 7 000 rpm for 20 min. The reaction solutions contained 30 g CWW/L resting cells and 320 or 480 g/L GA. Filtered air was injected at a flow rate of 8 L/min to provide dissolved oxygen for the reaction.

Quantification of GA and 2KGA. Quantification of GA and 2KGA was performed using high-performance liquid chromatography (HPLC). The substances were separated using an ICSep COREGEL-87H3 column (Transgenomic, New Haven, CT, United States) at 35 °C, using 0.008 N H_2SO_4 as the mobile phase at a flow rate of 0.35 mL/min, with UV absorption evaluated at 210 nm.

RESULTS AND DISCUSSION

Construction of Mutant Derivatives of Plasmid pBBR1MCS-5. The plasmid used as the template for mutagenesis was the broad-host-range vector pBBR1MCS-5,[18] which has been used to express genes of interest in *Acetobacter* and *Gluconobacter* strains.[24−28]

The replication control region of pBBR-based plasmids is the *rep* gene.[29,30] Tao et al. performed localized random mutagenesis in the replication control region of a pBBR-based plasmid pBHR1 and showed that single amino acid change of serine to leucine at codon 100 of the replication protein and single nucleotide change of C to T at 46 bp upstream of the rep gene caused the increase of plasmid copy number by 3−7 fold.[31] The promoter and the ribosome binding site located in the upstream region of *rep* gene regulate the expression of *rep* gene. Thus, based on the pBBR1MCS-5, the mutant plasmids pBBR-10, pBBR-35, and pBBR-3510 were constructed by mutagenesis of −10 and −35 promoter regions to improve the expression of *rep* (Figure 1). Plasmid pBBR-10 contained a C to T (C1707T) mutation at 86 bp upstream of the *rep* gene, generating a CATAAT to TATAAT mutation in the −10 promoter region. The plasmid pBBR-35 contained a T to A (T1689A) mutation at 104 bp upstream of the *rep* gene, generating a TTGACT to TTGACA mutation in the −35 promoter region. pBBR-3510 contained two mutations, C1707T and T1689A. These mutations made the promoter equipped with conserved −35 and −10 hexamers sequences,[32] thus increasing the promoter activity and the expression level of the *rep* gene. Jacob et al. previously observed that increasing the base complementarity of the ribosomal binding site and the 3′ end of the gene encoding the 16S rRNA enhanced the binding of the mRNA to the ribosome.[33−37] An insertion of GAA (GAA1786ins) at 7 bp upstream of the *rep* gene in pBBR1MCS-5 was generated, yielding the mutant plasmid pBBR-RBS. pBBR-RBS had a GGAGA to GGAGGAAA mutation in the ribosomal binding site of pBBR1MCS-5. A combination of mutations at −10 and −35 of the promoter region and the ribosomal binding site generated the mutant plasmids pBBR-R10, pBBR-R35, and pBBR-R31 (Figure 1). After being transformed into *G. oxidans* DSM 2003, six of the seven mutant plasmids, with the exception of pBBR-R10, were found to be capable of stable replication.

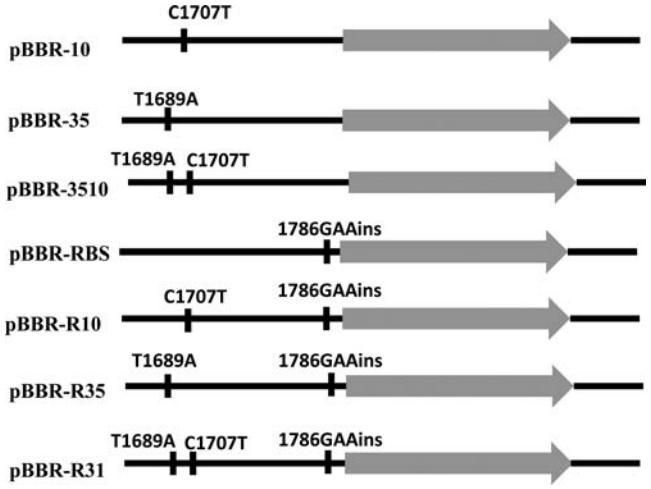

Figure 1. Maps showing the mutations created in the pBBR1MCS-5 plasmid derivatives. The mutations were numbered according to the corresponding base pair positions in pBBR1MCS-5. The nucleotides listed in front of the numbers indicate the wild-type sequences. The nucleotides listed after the numbers indicate the mutated sequences. "GAAins" after the numbers indicates that GAA was inserted at that position.

Determination of the Relative Plasmid Copy Number of the Mutant Plasmids in *G. oxidans*. The relative plasmid copy numbers were determined by qPCR using the total plasmids isolated from recombinant *G. oxidans* DSM 2003 as the templates. The cryptic plasmid pGOX3,[9] which is a low copy-number plasmid in *G. oxidans* with a large size of 14 547 bp, was used as the internal single-copy reference.[21] The relative plasmid copy numbers were calculated from the threshold cycle (C_T) using the $2^{\Delta CT}$ method as described by Zhang et al.[21] The C_T values are calculated automatically by the instrument according to the amplification plot, while ΔC_T is the difference between the C_T value of the single-copy reference and that of the plasmids. The results showed that the relative plasmid copy numbers of pBBR1MCS-5, pBBR-10, pBBR-35, pBBR-RBS, pBBR-R35, pBBR-3510, and pBBR-R31 in *G. oxidans* were 24 ± 6, 37 ± 8, 43 ± 8, 28 ± 8, 59 ± 5, 36 ± 7, and 43 ± 3 greater than that of pGOX3, respectively, demonstrating that the plasmid copy numbers of all the engineered plasmids in *G. oxidans* were higher than that of pBBR1MCS-5 plasmid (Table 2). The copy numbers of the plasmid derivatives with mutations in the −10 or/and −35 region were increased by 50−104% compared to the copy number of the control plasmid. A single insertion of GAA at nucleotide 1786 of pBBR1MCS-5 had little effect on plasmid copy number.

Overexpression of the *ga2dh* Gene in *G. oxidans* Using Different Mutant Vectors. To demonstrate the utility of the mutant plasmids for engineering *G. oxidans*, the key enzyme involved in 2KGA formation, GA2DH, was overexpressed in *G. oxidans* DSM 2003 using the mutant vectors

pBBR-R31	19.94 ± 0.01	14.53 ± 0.10	43 ± 3	1.79 ± 0.13

[a]The $2^{\Delta CT}$ method was used for quantitation. Plasmid pBBR1MCS-5 was used as the control sample. The relative copy numbers were determined by comparing the value of the plasmids to that of the cryptic plasmid pGOX3. Ratio refers to the ratio of the copy number of plasmids to that of pBBR1MCS-5.

under the control of the *G. oxidans tuf B* promoter, which has been widely used in *G. oxidans*.[25−27] The parental plasmid pBBR1MCS-5 was used as the control for *ga2dh* expression. The relative copy numbers of plasmids harboring *ga2dh* gene in *G. oxidans* were also detected. As shown in Table 3, the

Table 3. Results of the Relative Copy Number of Plasmids Harboring *ga2dh* Gene Using Real-Time PCR[a]

plasmid	C_T-pGOX3	C_T-pBBR	relative copy number	ratio
pBBR-ga2dh	15.91 ± 0.03	11.96 ± 0.05	15 ± 1	1.00 ± 0.07
pBBR-10-ga2dh	15.77 ± 0.34	11.24 ± 0.10	23 ± 8	1.53 ± 0.54
pBBR-35-ga2dh	17.23 ± 0.12	12.14 ± 0.19	34 ± 8	2.27 ± 0.53
pBBR-RBS-ga2dh	15.56 ± 0.06	11.11 ± 0.03	22 ± 1	1.47 ± 0.06
pBBR-R35-ga2dh	15.47 ± 0.13	10.17 ± 0.05	39 ± 6	2.60 ± 0.40
pBBR-3510-ga2dh	15.01 ± 0.03	9.48 ± 0.11	46 ± 5	3.07 ± 0.33
pBBR-R31-ga2dh	15.13 ± 0.14	10.24 ± 0.11	30 ± 5	2.00 ± 0.33

[a]The $2^{\Delta CT}$ method was used for quantitation. Plasmid pBBR-ga2dh was used as the control sample. The relative copy numbers were determined by comparing the value of plasmids to that of the cryptic plasmid pGOX3. Ratio refers to the ratio of the copy number of plasmids to that of pBBR-ga2dh.

plasmids copy numbers were affected by *ga2dh* overexpression, and the relative plasmid copy numbers of mutant plasmids harboring *ga2dh* gene were higher than that of pBBR-ga2dh, which was similar to the result of empty vectors. However, instead of pBBR-R35-ga2dh, the copy number of plasmid pBBR-3510-ga2dh (46 ± 5) was the highest, increased by 207% compared to that of pBBR-ga2dh (15 ± 1).

To validate the relative transcription level of the *ga2dh* gene between the recombinant *G. oxidans* strains harboring the various plasmids, the *ga2dh* mRNA levels were assessed using real-time PCR. Using 16S rRNA as the internal standard, it was clearly demonstrated that the highest abundance of *ga2dh* transcripts was observed in the *G. oxidans*/pBBR-3510-ga2dh strain, which was approximately 22-fold higher than that of the control strain *G. oxidans*/pBBR1MCS and approximately 6-fold higher than that of the *G. oxidans*/pBBR-ga2dh strain (Figure 2).

GA2DH is a membrane-bound protein and is responsible for the oxidation of GA to 2KGA. Membrane fractions of different

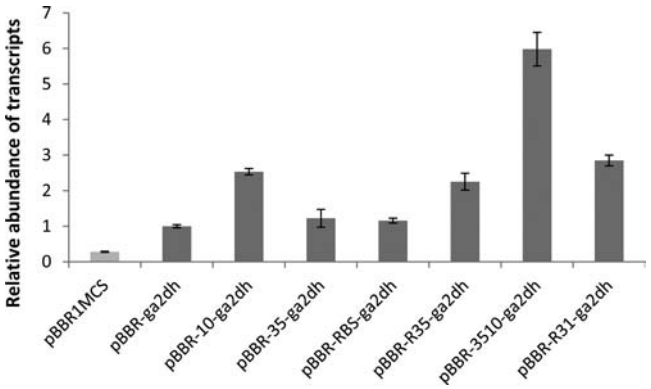

Figure 2. Relative abundance of *ga2dh* transcripts in the different *G. oxidans* strains. All of the cells were cultured in sorbitol-containing medium for 22 h and were harvested for total RNA isolation. The relative transcription levels of the *ga2dh* gene were determined using real-time PCR. The values were compared to that of the strain *G. oxidans*/pBBR-ga2dh.

G.oxidans strains were prepared and used to determine the GA2DH activities toward GA. As shown in Table 4, compared

Table 4. Activities of the Membrane-Bound GA2DH of Different *G. oxydans* Strains[a]

strains	GA2DH activity (U/mg protein)
G. oxidans/pBBR1MCS	0.43 ± 0.06
G. oxidans/pBBR-ga2dh	1.28 ± 0.09
G. oxidans/pBBR-10-ga2dh	1.60 ± 0.11
G. oxidans/pBBR-35-ga2dh	2.10 ± 0.10
G. oxidans/pBBR-3510-ga2dh	3.95 ± 0.07
G. oxidans/pBBR-RBS-ga2dh	1.97 ± 0.28
G. oxidans/pBBR-R35-ga2dh	3.35 ± 0.23
G. oxidans/pBBR-R31-ga2dh	2.90 ± 0.11

[a]Each value represents the average value and standard deviation of three independent experiments.

to the strain *G. oxidans*/pBBR-ga2dh, the GA2DH activities of the obtained constructs using the mutant vectors were increased. Among these strains, *G. oxidans*/pBBR-3510-ga2dh displayed the highest GA2DH activity (3.95 ± 0.07 U/mg protein).

The seven recombinant strains were used to catalyze GA in shaking flasks, and their 2KGA production in 2 h were determined to compare their productivities of 2KGA. The 2KGA concentration achieved by the *G. oxidans* strain containing pBBR1MCS-5 was set as the control value. As shown in Figure 3, all of the *ga2dh*-overexpressing strains

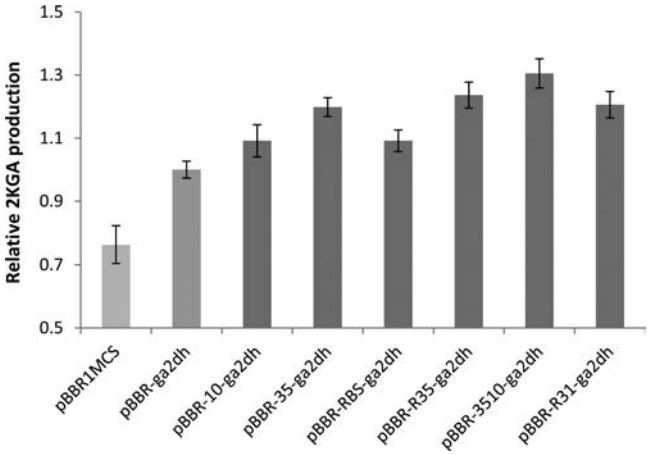

Figure 3. Levels of 2KGA production by *G. oxidans* strains containing various plasmids. The catalytic reactions were performed under the same conditions. The values were compared to that of the strain *G. oxidans*/pBBR-ga2dh.

produced concentrations of 2KGA higher than that of the control strain (*G. oxidans*/pBBR1MCS). More 2KGA was produced by the recombinant strains containing mutant plasmids compared to the 2KGA production of *G. oxidans*/pBBR-ga2dh. Among these strains, *G. oxidans*/pBBR-3510-ga2dh exhibited the highest level of 2KGA production, corresponding to the highest relative transcription level of the *ga2dh* gene and highest GA2DH activity.

Biotransformation of GA to 2KGA by the Recombinant *G. oxidans*/pBBR-3510-ga2dh Strain. To assess the potential industrial use of *G. oxidans*/pBBR-3510-ga2dh, which exhibited the greatest increase in 2KGA production, scaled-up biotransformation of GA was performed in a 7 L fermenter with a continuous air supply. The reaction system contained 30 g CWW/L resting cells and 320 g/L GA. To exclude the effects of the empty vector, *G. oxidans*/pBBR1MCS was also included in the analysis. The level of 2KGA production by the three *G. oxidans* strains harboring pBBR-3510-ga2dh, pBBR-ga2d, or pBBR1MCS-5 is summarized in Figure 4. Time course analysis of GA oxidation by *G. oxidans*/pBBR-3510-ga2dh revealed that approximately 320 g/L 2KGA accumulated from 320 g/L GA in 17 h, generating a productivity of 0.63 g/g CWW/h. In contrast, the *G. oxidans*/pBBR-ga2dh and *G. oxidans*/pBBR1MCS strains required more time to complete this reaction, leading to the productivities of 0.40 g/g CWW/h and 0.22 g/g CWW/h, respectively.

Thus, the overexpression of *ga2dh* in *G. oxidans* with the mutant plasmid pBBR-3510 significantly accelerated the oxidative reaction and resulted in increased 2KGA production, which was enhanced by approximately 58% and 186% compared to that of *ga2dh*-overexpressing *G. oxidans* harboring the control plasmid pBBR1MCS-5 or the parental strain containing the empty vector, respectively.

When the initial GA concentration was increased to 480 g/L, 30 g CWW/L of resting *G. oxidans*/pBBR-3510-ga2dh cells still completely exhausted the supplied GA and produced 474 g/L 2KGA when a continuous air supply was provided, although the conversion time was extended to 96 h, corresponding to a productivity of 0.16 g/g CWW/h (Figure 5). This reaction could not be completed by the *G. oxidans*/pBBR1MCS or the *G. oxidans*/pBBR-ga2dh strain (data not shown). In addition to substrate or product inhibition, we observed that an insufficient

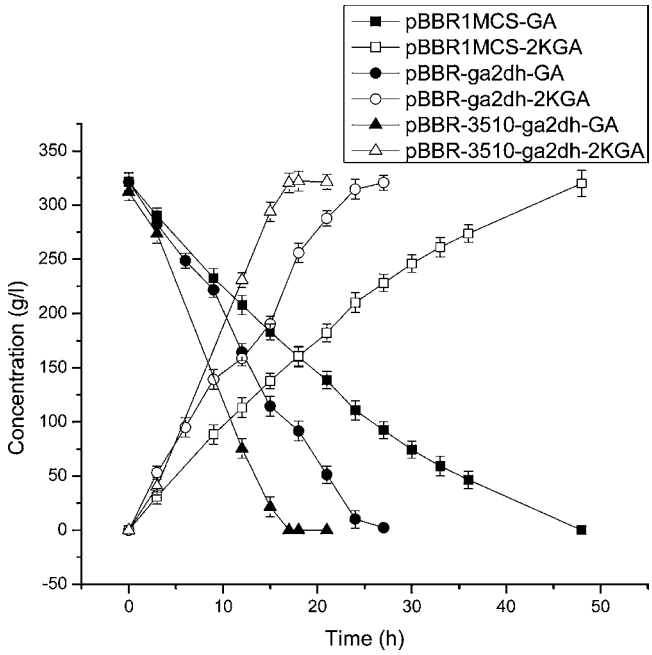

Figure 4. Comparative 2KGA production and GA consumption of *G. oxidans*/pBBR1MCS, *G. oxidans*/pBBR-ga2dh, and *G. oxidans*/pBBR-3510-ga2dh in a 7 L fermenter supplied with 320 g/L GA.

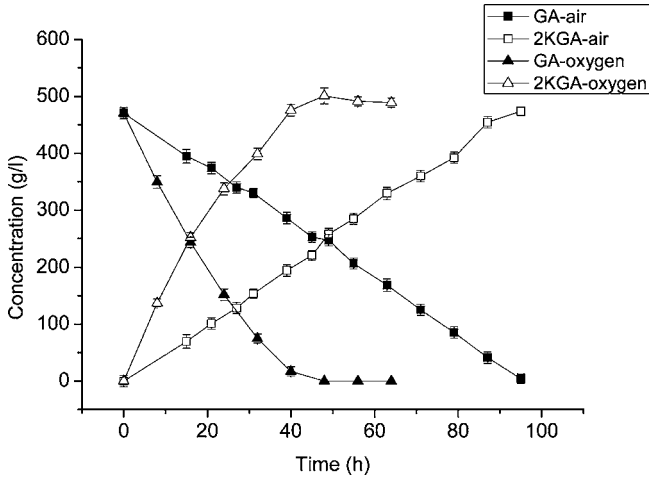

Figure 5. Time course of the oxidation of GA by the engineered strain *G. oxidans*/pBBR-3510-ga2dh.

oxygen supply had a negative impact on the performance of *G. oxidans*/pBBR-3510-ga2dh. During the entire reaction process, the DO level in the fermenter remained less than zero despite the fact that the agitation speed and aeration rate were maintained as high as possible. Thus, oxygen instead of air was supplied continuously to support the oxidation of 480 g/L GA. As expected, 45 h after initiating the reaction, nearly all of the supplied GA had been exhausted by *G. oxidans*/pBBR-3510-ga2dh and approximately 486 g/L 2KGA had been accumulated, corresponding to a productivity of 0.36 g/g CWW/h. Compared to the results of previous studies,[8] the *G. oxidans*/pBBR-3510-ga2dh strain created in this study showed the highest level of 2KGA production and a relatively high productivity level.

list of compounds for which methods of analysis are standardized and authorized by the International Olive Council (IOC).[30] Their response to even some of the most influential sources of variability is practically unknown. Only a few reports studying their intervarietal variability have been published, focusing only on particular major compounds.[27,28,31] No experimental evidence on the effect of ripening on 4-monomethyl- and 4,4′-dimethylsterols in olive oil can be found in available literature; to date, only their behavior in olive fruit has been investigated,[2,3] which can differ significantly. There are no published data on the interdependence and the interactive effect of variety and ripening on 4-monomethyl- and 4,4′-dimethylsterol concentrations. Among the olive oil research and expert community, investigations on indicators of olive oil aging are the focus of interest, mainly because olive oil quality deteriorates with storage, which is directly related to its market categorization and price. Such research is currently in full swing[32] but not a single study to date has addressed the effect of storage temperature and storage in general on the contents of 4-monomethyl- and 4,4′-dimethylsterols in any vegetable oils.

The aim of this study was to investigate the variability of the contents of major 4-monomethyl- and 4,4′-dimethylsterols in olive oil as a result of three key factors, variety, ripening degree, and storage, including the effect of storage temperature. Besides providing new knowledge about the chemistry of olive oil and its important constituents in general, the objective was to assess whether 4-monomethyl- and 4,4′-dimethylsterols have the potential for satisfactory multivariate discrimination and could be used as indicators for each of the mentioned factors of variability. Reliable and stable indicators among these constituents could contribute to the ever-growing scientific area of research on olive oil quality and authenticity and could be used for more reliable characterization, differentiation, authentication, and certification of olive oils of specific origin and attributes. It is expected that the results obtained in this work could have practical application and be useful for producers to optimize individual steps in production to obtain olive oils with targeted 4-monomethyl- and 4,4′-dimethylsterol composition.

MATERIALS AND METHODS

Sampling and Harvesting. Three important autochthonous varieties in the Istria region of Croatia were chosen for the investigation: Buža, Črna, and Rosinjola. In the crop year 2006/2007, nonirrigated trees were identified and carefully marked on different plots located in the corresponding characteristic production zone of each variety. The plots were located in the region of Istria (Croatia) within a radius of approximately 18 km and were characterized by similar pedoclimatic conditions.

Olives were harvested at three ripening degrees denoted as green (RD1), spotted (RD2), and ripe (RD3). For Buža variety, ripening indexes were 1.4, 2.8, and 3.8; for Črna, 1.9, 2.8, and 4.1; and for Rosinjola, 1.5, 3.2, and 3.8, respectively. Each batch of olive fruits giving a single olive sample comprised olives handpicked from three single trees of a given variety at the determined stage of ripeness. Ripening index (RI) was determined from 100 olive fruits, randomly taken from each olive fruit batch. This parameter is a function of fruit color in both skin and pulp and was determined according to Beltrán et al.[33]

Oil Extraction. Each oil sample was extracted from approximately 100 kg of olive fruits transported to the mill immediately after harvest and processed within 24 h. Oils were obtained by the continuous cold automatic olive oil extraction system Oliomio Cultivar 500 (Toscana Enologica Mori Snc., Italy). Olives were washed and crushed with a stainless steel hammer crusher. For each sample, the olive paste was transported to the vertical unit where it was malaxed for 35 ± 2 min at a temperature below 27 °C. Oils were obtained by separation in a horizontal two-phase centrifuge. Oils were filtered through cotton wool to eliminate larger impurities. Samples were stored in amber glass 125 mL bottles. Nine oil samples, representing combinations of three varieties and three ripening degrees, were analyzed within a month of oil extraction (fresh oil samples).

Storage Conditions. In total, 27 oil samples representing each variety/ripening degree combination were stored in the dark for a period of 12 months under three different temperature conditions. Besides variable room temperature (VR, 10−28 °C), which was supposed to simulate common stock and domestic conditions, refrigeration (RE, 4 °C) and freezing (FR, −20 °C) temperatures, which are usually applied for conservation of various other foodstuffs and were recently found to preserve olive oil quality,[34] were also included. Stored samples were analyzed within a month after the 12 month storage period.

Extraction of 4-Monomethylsterols and 4,4′-Dimethylsterols. 4-Monomethylsterol and 4,4′-dimethylsterol analysis was conducted according to the method proposed by IOC[30] and the modified method for the determination of aliphatic alcohols adopted by EEC regulations.[35] Five grams of olive oil was added to 1-eicosanol (5 mg/100 g of olive oil) (Supelco, Bellefonte, PA), used as internal standard, and were saponified with 50 mL of potassium hydroxide ethanolic solution. After the sample was boiled, 50 mL of distilled water was added, the flask was cooled to approximately 30 °C, and the content was quantitatively transferred to a 500 mL separating funnel by use of distilled water portions of a total volume of 50 mL. The extraction of unsaponifiable fraction was carried out with three portions of diethyl ether (80 mL + 70 mL + 70 mL) by vigorous shaking. The ethyl ether extracts were combined in a separating funnel and washed with distilled water (50 mL at a time) until the washing water gave a neutral reaction. Following purification with water and drying over sodium sulfate, diethyl ether was evaporated under vacuum and nitrogen and then completing drying in an oven at 100 °C for 15 min. Unsaponifiable fraction was dissolved in chloroform, and approximately 20 mg was loaded on a basic silica thin-layer chromatography (TLC) plate (Fluka, Buchs, Switzerland). The 4-monomethylsterol and 4,4′-dimethylsterol fraction (the sum of free and esterified forms without glycosides) was separated by elution with a mixture of hexane and diethyl ether (65:35 v/v). The corresponding bands were visualized under UV light after being sprayed with 2′,7′-dichlorofluorescein 0.2% ethanolic solution, then scraped off with a spatula and extracted with chloroform and diethyl ether. After the extract was evaporated to dryness, 4-monomethylsterols and 4,4′-dimethylsterols were converted to trimethylsilyl ethers by addition of pyridine/hexamethyldisilizane/trimethylchlorosilane (9:3:1 v/v/v) (Supelco, Bellefonte, PA), left for 15 min, and then centrifuged at 3500 rpm for 5 min.

Identification of 4-Monomethyl- and 4,4′-Dimethylsterols. Identification of 4-monomethyl- and 4,4′-dimethylsterols as trimethylsilyl ethers was carried out by gas chromatography/mass spectrometry (GC-MS) on a Varian 3900 gas chromatograph coupled with a Varian Saturn 2100T ion trap mass spectrometer (Varian Inc., Harbour City, CA). The fused silica column used was a 30 m × 0.25 mm i.d. × 0.25 μm film thickness Varian VF-5 ms capillary column (5% phenylpolysiloxane/95% dimethylpolysiloxane). Injector temperature was 280 °C. The GC oven parameters were as follows: initial temperature was 180 °C, increased at 2 °C/min to 280 °C, and then kept at 280 °C (total run time approximately 65 min). Transfer line, manifold, and ion trap temperatures were 285, 80, and 220 °C, respectively. Helium was used as a carrier gas with a constant flow of 1.2 mL/min. One microliter of the analytical sample was injected in split mode (1:50). Mass spectra were acquired in the electron impact mode (70 eV) at 1 scan/s, using full scan with a mass acquisition range of 30−650 m/z. Identification of compounds was performed by careful interpretation of retention data and mass spectra and by comparisons with retention and mass spectral data from the literature[1,5,6,8−13,36−39] and NIST05 library when available (trimethylsilyl ethers or acetates).

[a]For trimethylsilyl ethers of 4-monomethylsterols and 4,4′-dimethylsterols identified in olive oils by GC-MS analysis.

The obtained retention time and mass spectrometric data for the corresponding trimethylsilyl ethers are reported in Table 1. Four major 4-monomethylsterols (obtusifoliol, gramisterol + cycloeucalenol, and citrostadienol) and five major 4,4′-dimethylsterols (δ-amyrin, β-amyrin, butyrospermol, cycloartenol, and 24-methylenecycloartanol) were identified. The identity of β-amyrin and cycloartenol was confirmed by comparison of their retention times and mass spectra to those of pure standards [β-amyrin analytical standard, ≥98.5%, Fluka (Buchs, Switzerland); cycloartenol, ≥90.0%, Sigma–Aldrich (St. Louis, MO)], which were the only standards of 4-monomethyl- and 4,4′-dimethylsterols analyzed in this work commercially available.

Quantitative Determination of 4-Monomethyl- and 4,4′-Dimethylsterols. Quantitative determination of 4-monomethyl- and 4,4′-dimethylsterols as trimethylsilyl ethers was carried out by capillary gas chromatography with flame ionization detection (GC-FID) on a Varian 3350 GC (Varian Inc., Harbour City, CA) equipped with the same column described above. Injector and oven were the same as described above, while detector temperature was 290 °C, for approximately 65 min. Helium was used as a carrier gas with a flow rate of 1.27 mL/min. One microliter was injected in split mode (1:50). A typical GC-FID chromatogram of 4-monomethyl- and 4,4′-dimethylsterols as trimethylsilyl ethers is presented in Figure 1. 4-Monomethyl- and 4,4′-dimethylsterol concentrations were expressed as milligrams per 100 g of internal standard, with an assumed response factor equal to 1. Relative amounts of individual compounds were expressed as percentages of total 4-monomethyl- + 4,4′-dimethylsterol peak area (all nine compounds).

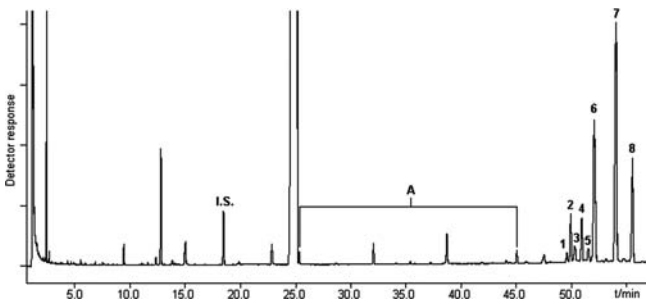

Figure 1. GC-FID chromatogram of trimethylsilyl ethers of 4-monomethyl- and 4,4′-dimethylsterols in Buža olive oil (green olives, RD1). Peak identification: I.S., internal standard (1-eicosanol); A, aliphatic alcohols; 1, δ-amyrin; 2, obtusifoliol; 3, β-amyrin; 4, butyrospermol; 5, gramisterol + cycloeucalenol; 6, cycloartenol; 7, 24-methylenecycloartanol; 8, citrostadienol.

Analyses were performed in duplicate, and average values were used in further data elaboration. The precision of the method was high, with relative standard deviations (n = 2) generally not surpassing 7% and in the case of major compounds, such as citrostadienol, butyrospermol, cycloartenol, and 24-methylenecycloartanol, not surpassing 4%.

To determine linearity, three replicate analyses of a sample spiked with three different concentrations of chemical standards of β-amyrin (2, 5, and 10 mg/100 g of oil) and cycloartenol (10, 30, and 50 mg/100 g of oil) were performed. Correlation coefficients were satisfactory: 0.997 for β-amyrin and 0.993 for cycloartenol. The same data were used for determination of recovery, which ranged from 92% to 103% with an average of 96% for β-amyrin (n = 9) and from 94% to 100% with an average of 98% for cycloartenol (n = 9).

Limits of detection (LOD) were estimated as 3 times the baseline noise and ranged from 0.056 mg/100 g for obtusifoliol to 0.092 mg/100 g for β-amyrin. Limits of quantification (LOQ) were estimated as 10 times the baseline noise and ranged from 0.185 mg/100 g for obtusifoliol to 0.306 mg/100 g for β-amyrin. Since LOD and LOQ for individual compounds change depending on FID sensitivity, average detection limits registered during method validation and analyses were reported.

Analysis of 4-Desmethylsterols. Analysis of 4-desmethylsterols was described in a previous study.[29] Only total concentrations of 4-desmethylsterols (milligrams per 100 g), obtained as the sums of concentrations of individual 4-desmethylsterols, are reported in this work.

Statistical Analysis. Duplicate analysis results were used to calculate average values, which were used in further data elaboration. Variables used for statistical analysis were average values of concentration (milligrams per 100 g) and relative amount (percent) of all analyzed compounds. These data are presented in Tables 3 and 4 without the corresponding deviations. The main-effect three-way analysis of variance (ANOVA) without replication (σ-restricted parametrization, effective hypothesis decomposition)[40] was selected to evaluate the effect of factors variety, ripening degree, and storage temperature on the content of individual and total major 4-monomethyl- and 4,4′-dimethylsterols in olive oil. The results for total 4-desmethylsterols are also presented. Because it was a nonreplicated experiment, the effects of all first- and second-order interactions were treated as random and pooled into error term. The majority of variables exhibited low variability with no statistically significant differences between means for the storage temperature factor (Table 2), so their values were not reported. Mean values for the factors variety and ripening degree are expressed together with the corresponding standard errors. Statistically significant differences were determined by Tukey's honest significant difference (HSD) posthoc analysis. Statistical significance was set at $p < 0.05$ (Tables 3 and 4).

[a]Main-effect three-way analysis of variance (ANOVA) without replication for concentrations (milligrams per 100 grams) and relative amounts (percent) of 4-monomethylsterols and 4,4′-dimethylsterols in olive oils, with variety, ripening degree, and storage condition as variable factors. $p < 0.050$ is statistically significant.

Before being subjected to unsupervised (principal component analysis, PCA) and supervised (stepwise linear discriminant analysis, SLDA) multivariate statistical analysis, GC data were standardized (centered) via the autoscale procedure, in which a variable is subtracted from its mean value and the obtained difference is divided by the standard deviation of this variable throughout the data set. For the factors variety and ripening degree, unrotated PCA was carried out by use of variables selected according to their high *F*-statistic values. Kaiser's rule was followed for selection of the number of principal components (PCs), and only factors with eigenvalues higher than 1.00 were retained. PCA models with the best separation capacity are presented. For a valid statistical classification of olive oil samples into categories according to variety or ripening degree, forward SLDA was applied, with Wilk's λ as a selection criterion and an *F*-statistic factor to establish the significance of the changes when a new variable is tested. The value of *F* for a variable to enter the differentiation model was fixed at 1.00, and minimum tolerance was set at 0.01. For presentation of changes as a result of storage by SLDA, variables were previously standardized through all levels of each single subject separately (the same sample fresh and stored at three temperatures) to eliminate the effect of variety and ripening degree. In this way relative changes, expressed as an increase or a decrease, are presented.

Statistical data elaboration was carried out with Statistica v 8.0 software (Stat-Soft Inc., Tulsa, OK).

RESULTS AND DISCUSSION

Results of three-way analysis of variance (ANOVA) for individual (milligrams per 100 g and percent) and total 4-monomethyl- and 4,4′-dimethylsterols in different samples of olive oil, with variety, ripening degree, and storage condition as factors, are presented in Table 2. A significant effect of variety ($p < 0.05$) was determined for the majority of compounds. The highest *F*-statistic values were found for concentrations of *β*-amyrin, butyrospermol, citrostadienol, and cycloartenol, as well as for relative amounts of *β*-amyrin, cycloartenol, and 24-methylenecycloartanol. A significant effect of ripening degree ($p < 0.05$) with the highest *F* values was found for concentrations of 24-methylenecycloartanol and for relative amounts of citrostadienol, 24-methylenecycloartanol, and *δ*-amyrin. Total 4-monomethylsterols were found to be more affected by variety, while total 4,4′-dimethylsterols varied more significantly due to ripening degree. Evidently, variability arising from the effect of storage was much lower than that caused by the other two factors. For this reason, mean values for the storage condition factor are not reported in Tables 3 and 4 together with those for variety and ripening degree.

Variability as a Result of Olive Variety. Buža variety was found to contain the lowest concentrations and relative amounts of 4-monomethylsterols, while Rosinjola had the highest citrostadienol level (Table 3). Among 4,4′-dimethylsterols, Buža was characterized by the highest 24-methylenecycloartanol and the lowest butyrospermol levels. Rosinjola was the most abundant in *β*-amyrin and cycloartenol, and it exhibited the lowest 24-methylenecycloartanol content. The lowest content of *β*-amyrin was found in Črna oils (Table 4). The differences in total 4,4′-dimethylsterols between mean values for the investigated varieties were not significant (Table 2).

When PCA was applied on the data set comprising 36 cases (olive oil samples) and variables with the highest *F* values for the variety factor (Table 2), a model with butyrospermol (milligrams per 100 g), citrostadienol (milligrams per 100 g), *β*-amyrin (percent), and cycloartenol (percent) as variables was found to have the best separation capacity (Figure 2). [a]Olive oils are Buža, Črna, and Rosinjola varieties obtained from green, spotted, and ripe olives (control, CO) and stored for 12 months at variable room temperature (VR, 10−28 °C), refrigeration (RE, 4 °C), and freezing (FR, −20 °C) temperatures. Different letters within a group represent statistically significant different means at $p < 0.05$ for the variety and ripening degree factors obtained by main-effect three-way ANOVA and Tukey HSD posthoc test. Mean values are reported together with the corresponding standard errors. Mean values for the storage temperature factor are not reported because of low variability with no statistically significant differences for the majority of compounds. Average values of two GC determinations for each variety/degree of ripening/storage temperature combination are represented without standard deviation.

principal components (PCs) were extracted, explaining 86.9% of total variance of the set. Figure 2a shows the projection of olive oil samples along the directions of PC1 and PC2, while the corresponding factor loading plots that establish relative importance of the variables are reported in Figure 2b. Rosinjola oils were differentiated from Buža and Črna along the direction of PC1 by higher percentages of β-amyrin and cycloartenol. Črna oils were associated with higher concentrations of butyrospermol and were differentiated from Buža and Rosinjola oils by PC2.

SLDA was applied on the whole data set (36 cases, 16 variables) and succeeded in classifying oils according to varietal origin correctly. Seven variables were selected according to Wilks' λ criterion. β-Amyrin (percent) entered the model as the first variable and classified 100% of Rosinjola oils correctly. Inclusion of butyrospermol (percent) and δ-amyrin (percent) resulted in 100% correct classification of all 36 oils. Gramisterol + cycloeucalenol (percent), cycloartenol (percent), obtusifoliol (milligrams per 100 g), and citrostadienol (milligrams per 100 g) additionally improved the differentiation capacity of the model.

Single variables (milligrams per 100 g and percent) or their combination, which were found to account for the most variability arising from varietal origin, could be considered as relatively stable indicators of variety, since the intravarietal variability due to ripening degree and storage condition did not compromise their differentiating power. 4-Monomethyl- and 4,4′-dimethylsterols, mostly the major components 24-methylenecycloartanol, cycloartenol, and citrostadienol, were previously found to be useful for characterization and differentiation of monovarietal olive oils, but only in combination

[a]Olive oils are Buža, Črna, and Rosinjola varieties obtained from green, spotted, and ripe olives (control, CO) and stored for 12 months at variable room temperature (VR, 10−28 °C), refrigeration (RE, 4 °C), and freezing (FR, −20 °C) temperatures. Different letters within a group represent statistically significant different means at $p < 0.05$ for the variety and ripening degree factors obtained by main-effect three-way ANOVA and Tukey HSD posthoc test. Mean values are reported together with the corresponding standard errors. Mean values for the storage temperature factor are not reported because of low variability with no statistically significant differences for the majority of compounds. Average values of two GC determinations for each variety/degree of ripening/storage temperature combination are represented without standard deviation.

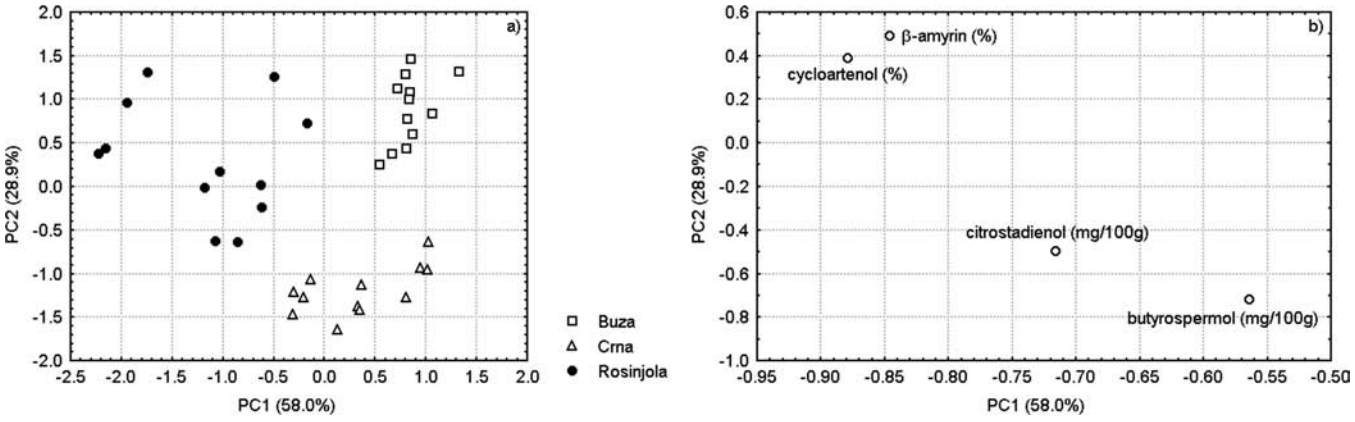

Figure 2. (a) Separation according to variety of olive oils from Buža, Črna, and Rosinjola varieties, harvested at three different ripening degrees and stored for 12 months, along the directions of principal components PC1 and PC2. (b) Factor loadings of selected variables (concentrations in milligrams per 100 g and relative amounts in percent of 4-monomethyl- and 4,4′-dimethylsterols) on PC1 and PC2.

with other constituents and without considering intravarietal variability due to ripening degree and storage.[27,28,31]

Throughout the investigated period of ripening, the major 4-monomethylsterol was citrostadienol, while the most abundant 4,4′-dimethylsterols were 24-methylenecycloartanol and cycloartenol (Tables 3 and 4). The same compounds were also the most abundant in oils from Picholine and Sayali varieties cultivated in Tunisia,[2,41] in Italian varieties Bosana, Coratina, Dritta, Frantoio, Moraiolo, Provenzale, and Leccino,[27,31] and in Spanish olive oils,[4] but with different relative proportions. In two of the most comprehensive and detailed studies on triterpenoids in olive fruit, Stiti and Hartmann[5] and Stiti et al.[3] identified a very large number of major and minor sterol and non-sterol compounds including 4-monomethyl- and 4,4′-dimethylsterols, with triterpenic acids as the most abundant. They used a pattern for the classification of triterpenoids into chemical groups according to their molecular structure which was different from that applied in this work and by other authors. In addition, Stiti et al.[3] did not report quantitative data for all compounds and reported the amounts of free and esterified forms separately. All the aforementioned reasons made these data hard to interpret and compare in terms of olive oil relative composition.

In this work, the level of total 4,4′-dimethylsterols was approximately 4−6 times higher than that of 4-monomethylsterols at different ripening stages, which reasonably corresponds to literature data where Sakouhi et al.[2,41] reported an average ratio of approximately 3:1.

Variability as a Result of Ripening Degree. The average concentrations (milligrams per 100 g) of 4-monomethylsterols, as well as of δ- and β-amyrin and butyrospermol, were found to be stable throughout ripening or slightly increased in oils produced from ripe olives. However, the patterns were not quite uniform for all varieties (Tables 3 and 4). 24-Methylenecycloartanol and cycloartenol increased constantly from RD1 to RD3, which was more pronounced in the case of the latter constituent. Such an increase has caused a significant drop in the relative amounts of other 4-monomethyl- and 4,4′-dimethylsterols in olives produced from spotted (RD2) and especially ripe (RD3) olives (Table 4). The increase in 24-methylenecycloartanol and cycloartenol contributed the most to the increase in total 4,4′-dimethylsterol concentration (Table 4). A constant increase in 4-monomethyl- and 4,4′-dimethylsterols (free + esterified) during olive fruit ontogeny was reported by Stiti et al.[3] The same authors observed a significant rise in 24-methylenecycloartanol and cycloartenol concentration at the moment olive epidermal color began to change from green to spotted, coinciding with the start of the synthesis of anthocyanins and loss of chlorophylls. This phenomenon was explained as a result of a redirection of carbon flux from the triterpenoid toward the sterol pathway, with cycloartenol being a precursor to 24-methylenecycloartanol and a major early

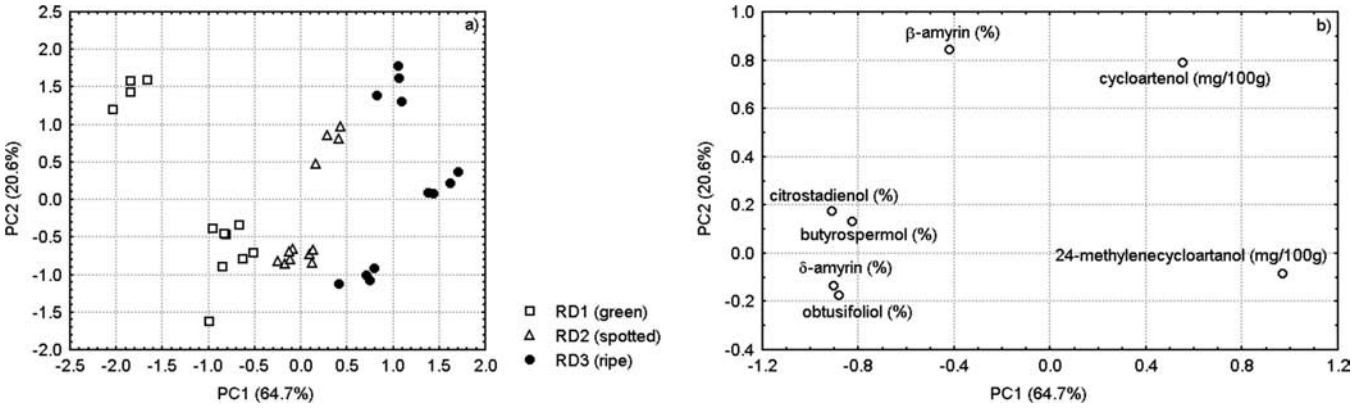

Figure 3. (a) Separation according to ripening degree of olive oils from Buža, Črna, and Rosinjola varieties, harvested at three different ripening degrees (RD1−RD3) and stored for 12 months, along the directions of principal components PC1 and PC2. (b) Factor loadings of selected variables (concentrations in milligrams per 100 g and relative amounts in percent of 4-momomethyl- and 4,4′-dimethylsterols) on PC1 and PC2.

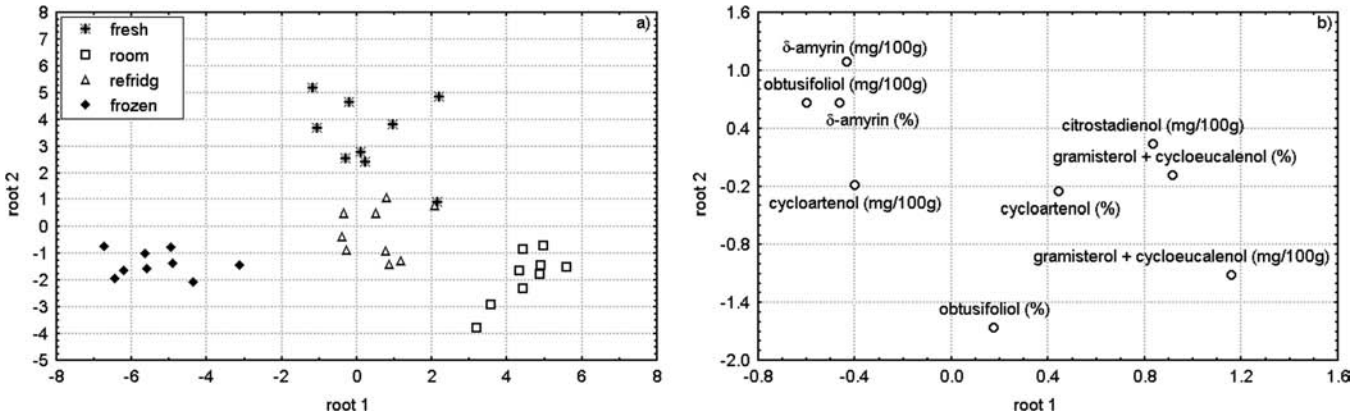

Figure 4. (a) Separation according to storage conditions of olive oils from Buža, Črna, and Rosinjola varieties, harvested at three different ripening degrees and stored for 12 months, along the directions of two discriminant functions. (b) Projection of standardized coefficients of selected variables (concentrations in milligrams per 100 g and relative amounts in percent of 4-methylsterols and 4,4′-dimethylsterols) in two-dimensional space.

biosynthetic intermediate in 4-desmethylsterol synthesis. In this work, the highest average total 4-desmethylsterol concentration was found in oils produced from spotted olives (RD2), which was possibly a result of increased carbon flux toward sterol biosynthesis. The mean values were (in milligrams per 100 g) for Buža, RD1 111.33, RD2 135.65, and RD3 122.16; for Črna, RD1 199.11, RD2 206.61, and RD3 197.16; and for Rosinjola, RD1 135.16, RD2 174.74, and RD3 138.19. Near the end of the olive ripening process, Stiti et al.[3] observed a specific accumulation of 24-methylenecycloartanol, indicating a slowing down of the metabolic flux through the sterol pathway. A sharp increase in 24-methylenecycloartanol concentration (Table 4) together with a drop in total 4-desmethylsterol concentration in RD3 oils were observed in this investigation and are in line with such findings. 4-Monomethyl- and 4,4′-dimethylsterols are components of surface waxes of olive fruit.[5] Therefore, the increase in their concentration in oils made from ripe olives (RD3) is possibly partly a result of a more fragile exocarp that fragments better during milling, as reported by Sánchez Casas et al.[42] Sakouhi et al.[2] noted quite a different behavior of 4-monomethyl- and 4,4′-dimethylsterols during olive ripening, which included much more fluctuation of their content, with the concentrations of cycloartenol and 24-methylenecycloartanol inversely proportional throughout the whole ripening period.

In PCA, the most successful separation between groups of olive oil samples produced at different ripening degrees was achieved by the model that included 36 cases and seven variables: citrostadienol (percent), *δ*-amyrin (percent), *β*-amyrin (percent), obtusifoliol (percent), butyrospermol (percent), 24-methylenecycloartanol (milligrams per 100 g), and cycloartenol (milligrams per 100 g). Two principal components (PCs) were extracted, explaining 85.3% of total variance. The groups were separated along the direction of PC1 (Figure 3). Citrostadienol, *δ*-amyrin, *β*-amyrin, obtusifoliol, and butyrospermol were loaded on the negative side of PC1 and were characteristic for RD1 oils. RD3 oils were associated with higher concentrations of 24-methylenecycloartanol and cycloartenol, which had positive PC1 loadings. RD2 oils were scattered between other two groups in all four quadrants, gravitating toward the intersection of PC1 and PC2. Interestingly, on the scatterplot, three subgroups each comprising four cases/samples could be observed within each of the three groups of oils separated according to ripening degree (Figure 3a). These subgroups corresponded to different varieties, confirming that certain variables can exhibit high variability as a result of both varietal origin and ripening degree.

SLDA, applied on the whole data set (36 cases, 16 variables), classified 97.22% of oil samples correctly according to ripening degree. 24-Methylenecycloartanol (milligrams per 100 g) entered the model as the first variable, which resulted in the

DOI: 10.1021/acs.jafc.5b01638
J. Agric. Food Chem. 2015, 63, 5499−5508

correct classification of 94.44% of all samples. Other variables included were cycloartenol (percent), β-amyrin (milligrams per 100 g), δ-amyrin (percent), and obtusifoliol (percent).

Variability as a Result of Storage Temperature. The results presented in Tables 3 and 4 suggest that 4-monomethyl- and 4,4′-dimethylsterols in oils have undergone certain changes during storage. Among the probable causes are chemical and microbial transformations involving oxidation,[43] cleavage of glycosides into free 4-monomethyl- and 4,4′-dimethylsterol aglycons by acid or enzymatic hydrolysis, and further transformation of reactive sterol precursors such as squalene and (3*S*)-2,3-oxidosqualene.[7] Upon comparison to the magnitude of variability of 4-monomethyl- and 4,4′-dimethylsterols caused by variety and ripening degree, it can be stated that their levels were relatively consistent after the storage period. The concentration of obtusifoliol was the only variable for which a significant effect of storage condition factor was determined by three-way ANOVA. However, certain subtle, and more important, regular patterns were observed after the application of SLDA to the normalized data set (36 cases, 16 variables). The obtained SLDA model classified 100% of all samples according to storage temperature correctly. Nine variables were selected, and 100% correct classification was obtained by the first four variables: gramisterol + cycloeucalenol (percent and milligrams per 100 g), obtusifoliol (percent), and δ-amyrin (milligrams per 100 g). The prediction capacity of the model was evaluated by leave-one-out cross-validation, where each oil sample was removed from the model and classified by the functions derived from all samples other than that sample. Average percentage of correct prediction was 94.44%, with the origin of only two samples not correctly predicted. As seen in Figure 4, very good and clear SLDA differentiation of olive oils was obtained. Fresh oils were discriminated from others along the second discriminant function by higher δ-amyrin (milligrams per 100 g and percent) and obtusifoliol (milligrams per 100 g) and lower gramisterol + cycloeucalenol (milligrams per 100 g) and obtusifoliol (percent) amounts. The first function discriminated samples stored at room temperature and at freezing temperatures from each other as well as from fresh and refrigerated samples, characterizing the former by higher amounts of δ-amyrin (both milligrams per 100 g and percent), obtusifoliol (milligrams per 100 g), and cycloartenol (milligrams per 100 g) and the latter by higher amounts of gramisterol + cycloeucalenol (milligrams per 100 g and percent) and citrostadienol (milligrams per 100 g). It can be said that the composition of oils stored at refrigeration temperature was generally the most similar to that of the fresh oils since Mahalanobis distances between these groups were the shortest (data not shown).

The present investigation demonstrated that olive variety and ripening degree are important sources of variability of 4-monomethyl- and 4,4′-dimethylsterol content in olive oil. Relative amounts of β-amyrin, cycloartenol, and 24-methylenecycloartanol accounted for the most variation due to varietal origin, while the largest influence of ripening degree was observed for relative amounts of citrostadienol and concentrations of 24-methylenecycloartanol. The total concentration of 4,4-dimethylsterols was found to increase during ripening and peak in oils obtained from ripe olives. It should be mentioned that this is the first experimental evidence on the effect of ripening on 4-monomethyl- and 4,4′-dimethylsterols in olive oil. Another novel finding is that the complex interactive effect of variety and ripening degree, which can complicate olive oil characterization, can be overcome by selecting appropriate 4-monomethyl- and 4,4′-dimethylsterols by use of chemometric tools, similarly as recently reported by our group for 4-desmethylsterols[29] and aliphatic alcohols.[22] Successful differentiation of olive oils achieved by multivariate PCA and SLDA models pointed to their potential use as indicators of varietal origin that are independent of ripening degree and vice versa, applicable for both fresh and stored oils. It practically means that there are 4-monomethyl- and 4,4′-dimethylsterols which are more dependent on variety and those which depend more on ripening degree, which is, to our knowledge, the first finding of this type. The presented approach also has practical relevance. It could be especially useful for technical and scientific studies aiming at the authentication and certification of olive oil varietal origin, which often overlook the impact of olive maturity, and vice versa. For example, the approach tested in this work could be utilized for developing more robust olive oil chemical composition specifications for various protected designations, because it considers the interrelationship between three factors of variability and extracts only the most robust and useful indicators. The results obtained in this work could be useful for producers to optimize individual steps in production to obtain olive oils with targeted 4-monomethyl- and 4,4′-dimethylsterol composition.

Variability as a result of storage temperature and storage in general was of a much smaller magnitude. It suggests that olive oil essentially retains its original characteristics and provides health benefits related to 4-monomethyl- and 4,4′-dimethylsterols throughout its shelf life. It also means that, despite the notorious loss of phenols and tocopherols during ripening and storage, oils obtained from ripe olives, even the aged ones, are not inferior with respect to all valuable phytonutrients. Regardless of their small absolute magnitude, relative changes caused by storage were specific for each investigated storage temperature and were found useful in discriminating stored from fresh oils as well, which has not been accomplished by applying the same approach for 4-desmethylsterols[29] and aliphatic alcohols.[22] A clear and regular dependency of 4-monomethyl- and 4,4′-dimethylsterol composition on storage temperature, identified for the first time in our investigation, offers new possibilities for tracking new reliable markers of olive oil age and quality.

The tomato genome encodes well-defined proteins for the three-layer phospho-relaying MPK cascades and contains 16 SlMPKs (often previously named LeMPKs), 5 SlMPKKs, and 89 SlMPKKKs,[14,15] some of which have been functionally characterized for their possible roles in regulating defense responses against biotic and abiotic stresses. SlMPK1/2/3 could be activated by the wound-signaling peptide systemin, oligosaccharide elicitors, UV−B radiation, and pathogen infections.[16−18] Silencing the *SlMPK1*, *SMPK2*, *SlMPK3*, and *SlMPK4* can reduce the drought tolerance of tomato plants to varying degrees and enhance the susceptibility to *B. cinerea*.[19,20] Furthermore, SlMPK1/2/3 have been reported to be involved in systemin-mediated defense response against herbivorous insects in tomato plants.[21] *SlMKK2* and *SlMKK4* were found to activate *SlMPK1* and *SlMPK2* in vitro and contribute to disease resistance against *B. cinerea*.[22] The *SlMKK2* and *SlMPK2* genes contributed disease resistance to *Xanthomonas campestris pv Vesicatoria* in tomato plant.[23] Although *SlMPK1/2/3* have been associated with the defense response in tomato plants, whether *SlMPK1/2/3* can regulate basal defense in tomato fruit remains to be studied.

MAPK cascades are implicated in multiple defense responses in cooperation with plant hormones and reactive oxygen species (ROS). Recent studies indicate that plant hormones, such as auxin indole acetic acid (IAA), abscisic acid (ABA), gibberellic acid (GA), and methyl jasmonate (MeJA) are implicated in plant defense signaling pathways.[24] IAA, ABA, and GA negatively regulate plant defense against *B. cinerea*.[25−28] Conversely, MeJA plays a positive role in tomato fruit disease resistance against *B. cinerea*.[7] ROS and oxidative enzymes are known to accumulate in response to pathogen attacks,[3,29] and they are involved in MAPKs signaling. Silencing of either *SlMPK1* or *SlMPK2* abolishes brassinosteroid-induced H_2O_2 accumulation in tomato plants.[30] However, whether plant hormones and ROS participate in SlMPK disease response in tomato fruit is still not clear.

To study the function of SlMPK1/2/3 in tomato fruit's innate immunity, we used a specific inhibitor of MAPKK, U0126 (1,4-diamino-2,3-dicyano-1,4-bis(*o*-aminophenylmercapto)butadiene), to treat tomato fruit. The U0126 could bind directly to endogenously active MAPKKs and thus prevent the activation of MAPKs.[31] The results demonstrated that the inhibition of SlMPK1/2/3 in tomato fruit led to increased susceptibility to *B. cinerea*, and that plant hormones and ROS were involved in the immune response of SlMPK1/2/3.

MATERIALS AND METHODS

Fruit Materials and Treatments. Tomato (*Solanum lycopersicum* cv. Lichun) fruit was harvested at the mature green stage from a greenhouse at Xiaotangshan Geothermal Special Vegetable Base, Beijing, China, and immediately transported to the laboratory. The tomato was grown under field conditions. Good cultural practices were followed with adequate and consistent watering. The fruit was tagged at 2 days postanthesis (dpa) and harvested at 45 dpa for mature green fruit. The mature green stage of the fruit was confirmed by the color, size, and texture. Fruit of a uniform size and free of visible blemishes or disease was selected for the experiments. The tomato fruit were then surface-disinfected with 2% (v/v) sodium hypochlorite for 2 min, washed with distilled water, and air-dried. The fruit were then immersed in distilled water containing 0.07 mL/L dimethyl sulfoxide (the control), and 2, 5, 10, or 20 μM U0126 (U0126 was dissolved in 0.07 mL/L dimethyl sulfoxide) solutions. The fruit in the solutions were immediately vacuumed under −35 kPa for 0.5 min, and then kept in the solution under air pressure for 2 min. After being air-dried, the fruit were stored at 25 ± 1 °C with a relative humidity of 85−90%. The fruit were sampled at 0, 0.5, 1, 4, 8, 16, and 24 h and at 2, 3, 4, 5, and 6 d (still at mature green stage) for measurements of *SlMPK1/2/3* gene expression, defense enzyme activities, hormone concentration, H_2O_2 content and antioxidant enzyme activities. Ten tomato fruit pericarps from each treatment were cut (all seed was removed), sliced horizontally from the middle third, diced prior to being frozen in liquid nitrogen, and stored at −80 °C. Before analysis, frozen pericarp tissues were ground to a fine powder in a grinding container (A11 basic, IKA, German), which had been precooled with liquid nitrogen. Each treatment was replicated three times.

Pathogen Inoculation and Measurement of Disease Symptoms. The pathogen *B. cinerea* (ACCC 36028) was purchased from Agricultural Culture Collection of China (Haidian, Beijing) and cultured on potato dextrose agar medium at 25 °C. Spore suspensions (2×10^6 conidia mL^{-1}) were prepared with 10-day-old cultures using sterile, distilled water containing 0.01% Tween-80. Twenty-four hours after treatment, 30 fruits were inoculated with 10 μL of spore suspension of *B. cinerea* into the wound (2 mm wide ×4 mm deep) at two points on the equator of each fruit using a pipet. The fruit were placed in plastic bags without sealing to avoid interaction with other fruit, and stored at 25 ± 1 °C. The relative humidity in the storage room was maintained at 90−95%.

Disease incidence and lesion diameter were recorded daily after inoculation. Disease incidence was calculated as the percentage of fruit showing disease symptoms. The lesion area was calculated as $3.14 \times (\text{lesion diameter}/2)^2$. The inoculated tomato fruit were used only for measurement of disease symptoms.

Quantitative Real-Time PCR (qRT-PCR) Analysis. A 100 mg sample of frozen pericarp tissue in powder form was used to extract the total RNA with *EasyPure* Plant RNA Kit (Beijing Transgen Biotech Co. Ltd., Beijing, China). The total RNA was dissolved in 20 μL of RNase-free water, quantified by microspectrophotometry, and stored at −80 °C. Reverse transcription was completed to synthesize the first strand of cDNA with 1 μg of total RNA, according to the instructions from GoScript Reverse Transcription System (Promega, Madison, WI, USA).

All qRT-PCR was run with GoTag qRT-PCR Master Mix (Promega), 0.2 μM specific primer (Table 1), and 100 ng of cDNA in a 20 μL final volume per reaction. The PCR amplifications were carried out using the Chromo4 Real-Time PCR Detection System (Biorad, Hercules, CA, USA) with the following thermal cycling conditions: 94 °C for 2 min, followed by 40 cycles at 94 °C for 15 s,

and 60 °C for 20 s. We calculated primer efficiencies using 2-fold cDNA dilutions (1:1, 1:2, 1:4, 1:8, and 1:16) in duplicate, and we checked for amplification in a negative control without cDNA. The efficiencies of the primer sets used in this study were above 90%. The specificity of the primers was checked by analyzing the dissociation curves ranging from 55 to 94 °C. The relative gene expression for each sample was normalized and calibrated to the UBI3 Ct value and calculated using the $2^{-\Delta\Delta Ct}$ method. All experiments were run in triplicate with different cDNAs synthesized from three biological replicates.

Measurement of Phytohormone Concentrations: Indole Acetic Acid, Abscisic Acid, Gibberellic Acid, and Methyl Jasmonate. An indirect competitive enzyme-linked immunosorbent assay (icELISA) was used to quantify the contents of IAA, ABA, GA, and MeJA according to the methods of Yang et al.[32] and Deng et al.[33] with some modifications. A 0.5 g portion of frozen pericarp tissue in powder form was dispersed with 4 mL of extraction buffer (80% methanol, containing 1 mM 2,6-di-*tert*-butyl-4-methylphenol) using an IKA Disperser (T10 basic, IKA, German). The homogenate was centrifuged at 12000*g* for 15 min at 4 °C, and the supernatant was collected for analysis. The supernatant was passed through a C18-SepPak classic cartridge (Waters, Milford, CT, USA), dried by nitrogen, and dissolved with 2 mL of 0.1 mM phosphate buffered saline (PBS, pH 7.5, containing 1% (v/v) Tween-20 and 1% (w/v) gelatin) for hormone determination with icELISA. The absorbance was recorded in the microplate reader at 492 nm.

Assay of Defense Enzymes. To determine activities of β-1,3-glucanases (GLU, EC 3.2.1.39) and Chitinase (CHI, 3.2.1.14), 1 g of frozen pericarp tissue in powder form was extracted with a 5 mL of 100 mM acetic acid buffer (pH 5.2). The powder (1 g) was homogenized with 5 mL of 0.2 mM boric acid buffer (pH 8.8, containing 10% (w/v) polyvinylpyrrolidone and 1 mM EDTA) for phenylalanine ammonia lyase (PAL, EC 4.3.1.5). For polyphenol oxidase (PPO, EC 1.10.3.2) activity, 1 g of frozen pericarp tissue in powder form was extracted with a 5 mL of 100 mM PBS (pH 6.8). All extraction procedures were conducted at 4 °C. The homogenates were centrifuged at 12000*g* for 15 min at 4 °C, and the supernatants were collected. The activities of defense enzymes were determined by a spectrophotometer (Shimadu, Japan) according to Zheng et al.[34]

Assay for H_2O_2 Content and Antioxidant Enzymes. For analysis of H_2O_2, catalase (CAT, EC 1.11.1.6), ascorbate peroxidase (APX, EC 1.11.1.11), and peroxidase (POD, EC 1.11.1.7), frozen pericarp tissue in powder form (3 g) was homogenized with 6 mL of 100 mM PBS (pH 7.0) using an IKA Disperser. All extraction procedures were conducted at 4 °C. The homogenates were centrifuged at 12000*g* for 15 min at 4 °C, and the supernatants were collected. H_2O_2, CAT, and POD assay kits (Nanjing Jiancheng Bioengineering Institute, Jiangsu, China) were used to measure the H_2O_2 content and CAT and POD activities.

The APX activity was determined by the method of Nakano et al.[35] with some modifications. One unit of APX activity was defined as the amount of enzyme that caused a decrease in absorbance of 0.01 min^{-1} at 290 nm.

Statistical Analysis. The data were expressed as the mean ± standard deviation (SD). One-way analysis of variance and Duncan's multiple range tests were used for statistical evaluations by SPSS 18.0 (IBM Corp., Armonk, NY) with differences considered significant if $P < 0.05$. Pearson's regression analysis was performed to determine the correlation between the hormone concentrations, enzyme activities and H_2O_2 accumulation.

RESULTS AND DISCUSSION

Analysis of *SlMPK1/2/3* Relative Expression with qRT-PCR. U0126 is a stong inhibitor of *MAPKK1/2*.[31] Because there is no specific MAPK inhibitor, U0126 is usually used as a MAPK inhibitor. To examine the inhibitory effects of U0126 on the relative expression of *SlMPK1/2/3*, four different concentrations of U0126 were used: 2 μM and 5 μM U0126 partly inhibited the expression of *SlMPK1*, *SlMPK2*, and *SlMPK3*, whereas 10 μM and 20 μM U0126 significantly inhibited the transcript levels of *SlMPK1*, *SlMPK2*, and *SlMPK3* ($P < 0.05$) (Table 2). However, the inhibitory effects between 10 μM U0126 and 20 μM U0126 showed no significant difference in most comparisons. On the basis of these results, we chose 10 μM U0126 for further study.

The expression of *SlMPK1*, *SlMPK2*, and *SlMPK3* reduced rapidly after the 10 μM U0126 treatment (0.5 h), and it remained at low levels until the last sampling time. The expression levels of *SlMPK1* and *SlMPK2* in the control fruit peaked at 16 h. However, the peak values of expression levels for *SlMPK1* and *SlMPK2* in the control fruit were detected 8 h after treatment in our previous report,[34] which might be due to the different tomato cultivars we used in that study. The expression pattern of *SlMPK3* was different from that of *SlMPK1* and *SlMPK2*. The expression of *SlMPK3* reached the peak values at 4 h. The expressions for *SlMPK1* and *SlMPK2* were similar in the control and in the 10 μM U0126-treated tomato fruit. *SlMPK1* and *SlMPK2* show high sequence

homology at the amino acid level, and they could be activated concurrently, which may explain the similar results we obtained. Holley et al.,[17] also reported that *SlMPK1* and *SlMPK2* were activated in response to systemins and to UV−B radiation at the same time. The increased expression of *SlMPK1*, *SlMPK2*, and *SlMPK3* in the control group of tomato fruit may be attributable to the osmotic stress response caused by the vacuum infiltration method. When a vacuum infiltrated, tomato fruit was exposed to a high osmotic stress that could induce the rapid activation of SIPK.[36] SIPK has been shown to exhibit a very high sequence homology to SlMPK1/2.

Effects of U0126 (10 μM) on Plant Hormones: Indole Acetic Aci, Abscisic Acid, Gibberellic Acid, and Methyl Jasmonate. MAPKs' inhibitor increased the concentrations of IAA, ABA, and GA, but decreased the concentration of MeJA (Figure 1). The concentration of IAA showed a fluctuating decrease in both the control and in the U0126-treated fruit. The concentrations of IAA were 26.6%, 21.6%, 10.5%, 30.2%, 14.2%, and 22% higher after the U0126 treatment than that in the controls on days 1, 2, 3, 4, 5, and 6, respectively (Figure 1A). Changes in ABA concentration in response to MAPKs' inhibitor U0126 showed a pattern that was different from that in the IAA concentration (Figure 1B). The concentration of ABA rapidly increased during the first 3 days, and then decreased. Treatment with U0126 showed a higher ABA concentration during the entire storage period. The GA concentration showed a little variation in the control fruit, but in the U0126-treated fruit, the GA concentration rapidly accumulated on day 5 and reached a peak value of 42.76 ng/gFW (Figure 1C). The concentration of MeJA in the control fruit increased on the first day, then decreased slowly through the remaining storage period (Figure 1D). Treatment with U0126 significantly decreased the MeJA concentration compared to that of the control fruit during the entire storage period ($P < 0.05$).

Plant hormones, such as IAA, ABA, GA, and MeJA, have been thoroughly documented to regulate plant development and growth. They have recently emerged as key regulators of plant disease resistance.[37] Pretreatment with IAA enhanced disease caused by *B. cinerea*, suggesting that IAA played a negative role in plant disease resistance.[28] Our study showed that MAPKs' inhibitor increased IAA concentration (Figure 1A) and promoted the susceptibility of tomato fruit to *B. cinerea* (Figure 4). The ABA-deficient mutant *sitiens* could enhance tomato resistance to *B. cinerea*.[25,38] This resistance effect depends on timely production of H_2O_2,[39] changes in cuticle permeability, and pectin composition.[40] The increased ABA level caused by the MAPKs' inhibitor (Figure 1B) increased tomato fruit disease symptoms (Figure 4). GA enhanced the hemibiotroph susceptibility partly by suppressing JA-mediated defenses.[41] MAPKs' inhibitor increased the GA concentration (Figure 1C), resulting in susceptibility to *B. cinerea* (Figure 4). Zhu et al.[7] reported that MeJA promoted the resistance response of tomato fruit to *B. cinerea*, which was consistent with our results that a lower MeJA concentration in U0126-treated fruit (Figure 1D) resulted in a lower resistance to *B. cinerea* (Figure 4). On the basis of these results, we suggest that IAA, ABA, GA, and MeJA may be involved in the

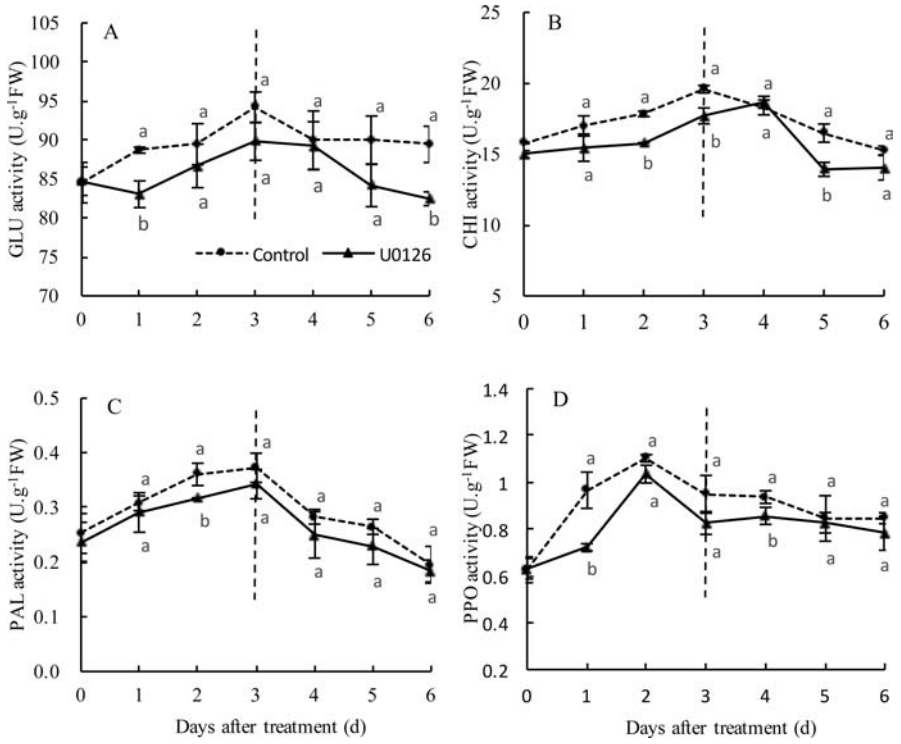

Figure 2. Effects of U0126 (10 μM) treatment on the activities of defense enzymes: β-1,3-glucanase (A), chitinase (B), phenylalanine ammonia lyase (C), and polyphenol oxidase (D). Vertical bars represent the standard errors of the means of triplicate assays. Values followed by different letters on the same day indicate a significant difference, according to Duncan's multiple range test ($P < 0.05$).

defense signaling of SlMPKs that influence tomato resistance to *B. cinerea*.

Effects of U0126 (10 μM) on β-1,3-Glucanases, Chitinase, Polyphenol Oxidase, and Phenylalanine Ammonia Lyase Activities. GLUs are abundant in plants, and they can defend plants against fungal pathogens either alone or in association with CHI and other defense enzymes.[42] GLU activity in U0126-treated tomato fruit was lower than that in the control fruit during the entire storage period (Figure 2A). GLU activity significantly decreased after MAPKs' inhibitor treatment on days 1 and 6 ($P < 0.05$). U0126 treatment decreased the CHI activity, except for day 4 (Figure 2B).

The PAL activity of both the control and U0126-treated fruit increased during the early stage after treatments and then decreased and reached a maximum on day 3; however, PAL activity was inhibited by MAPKs' inhibitor U0126 and showed a significant difference compared with the control on day 2 (Figure 2C).

Changes in PPO activity in response to MAPKs' inhibitor U0126 showed a pattern similar to PAL activity. The PPO activity in both control and U0126-treated fruit increased within 2 days and then decreased. PPO activity reached a maximum on day 2, 1 day earlier than PAL activity (Figure 2D). PPO activity in U0126-treated fruit was lower than that of the control fruit during the entire storage period.

The same trends were observed in GLU, CHI, PAL, and PPO activities in response to MAPKs' inhibitor (Figure 2). Disease enzymes increased during the early stage of storage and then decreased, but they peaked on different days, possibly because different enzymes respond to pathogen attacks at different times. Disease enzymes in the U0126-treated fruit were lower than that in the control fruit, which suggests that there was an intermediate role of SlMPKs in the disease response to *B. cinerea* in postharvest tomato fruit.

Generally, plants have evolved a large variety of defense responses against pathogen infection, including the synthesis of pathogenesis-related (PR) proteins, the enhanced activities of various defense enzymes, and up-regulation of expression of defense genes expression.[3,5,43] CHI and GLU belong to the PR-2 and PR-3 families, respectively. CHI and GLU destroy fungi cell walls by catalyzing the hydrolysis of chitin and β-1,3-glucan.[42] PAL is a key enzyme in the phenylpropanoid pathway of higher plants.[44] Products of the phenylpropanoid pathway are key contributors to disease resistance.[45] Thus, PAL activity can indirectly reflect disease resistance in plants. PPOs are ubiquitous among higher plants, and they are assumed to be involved in plant defense against pathogens. Quinones produced by PPOs may possess direct antibiotic and cytotoxic activities to pathogens. Li et al.[46] found that overexpression of polyphenol oxidase in transgenic tomato plants resulted in enhanced bacterial disease resistance. The effect of U0126 on defense enzymes is possibly a dynamic, unstable process, which has been validated by Melvin et al.[47] They found that pathogen inoculation significantly increased the activities of defense enzymes and that U0126 had no significant influence on the activities of defense enzymes, but U0126 could significantly abolish the activities of defense enzymes induced by pathogen inoculation.[47] So we assume that although there were no large decreases in the activities of GLU, CHI, PAL, and PPO in U0126-treated tomato fruit, when tomato fruit is attacked by pathogens, U0126 may abolish the activities of defense enzymes induced by the pathogen, which leads ultimately to a more serious decay.

Effects of U0126 (10 μM) on H_2O_2, Catalase, Ascorbate Peroxidase, and Peroxidase. The H_2O_2 content peaked on

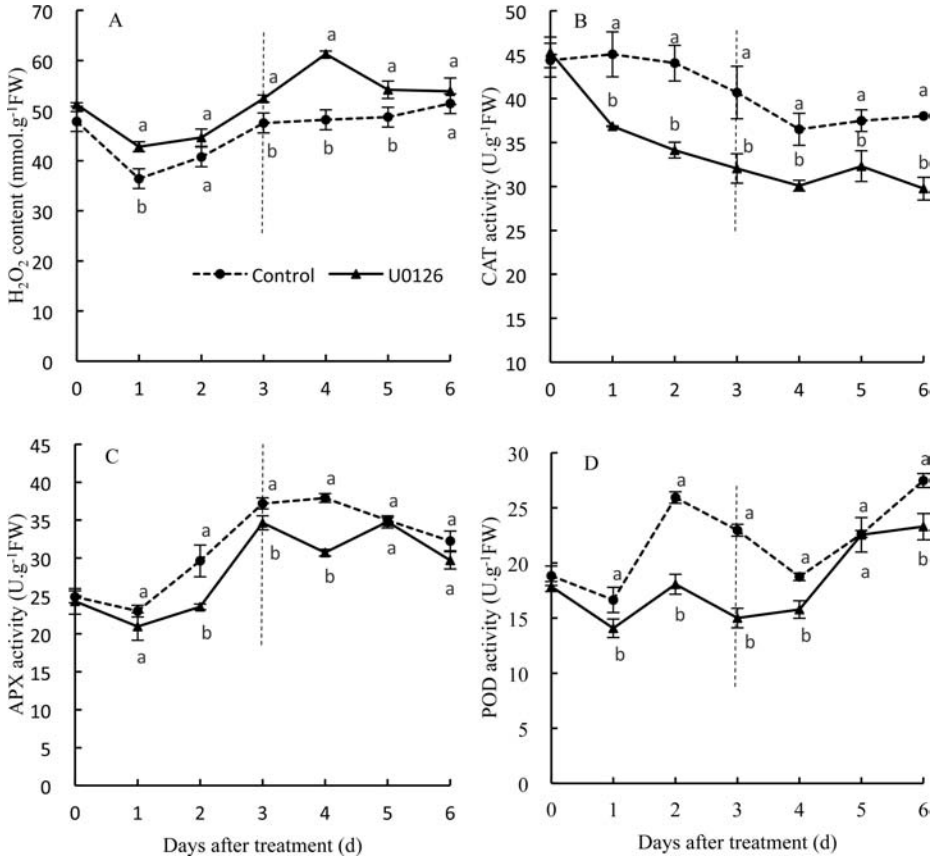

Figure 3. Effects of U0126 (10 μM) treatment on H_2O_2 content (A), catalase (B), ascorbate peroxidase (C), anmd peroxidase (D) in "Lichun" tomato fruit. Vertical bars represent the standard errors of the means of triplicate assays. Values followed by different letters on the same day indicate a significant difference, according to Duncan's multiple range test ($P < 0.05$).

day 4 in the U0126-treated fruit. Treatment with MAPKs' inhibitor U0126 regulated the level of H_2O_2. The H_2O_2 content in the U0126-treated fruit was significantly lower than that of the control at 3−5 days of storage ($P < 0.05$) (Figure 3A).

CAT, APX, and POD activity in U0126-treated fruit were lower than those in control fruit during the entire storage period (Figure 3B, C, and D). CAT activity reached a minimum value on day 4 in the control fruit (Figure 3B), which was consistent with the peak in H_2O_2 content (Figure 3A). CAT activity in U0126-treated fruit showed a fluctuating decrease and was significantly lower than that in the control fruit. Changes in the APX activity (Figure 3C) were different from that of CAT. APX activity in the control fruit increased with some fluctuation during the first 4 days, then decreased. Treatment with U0126 significantly reduced APX activity on days 2, 3, and 4 ($P < 0.05$). POD activity in the U0126-treated fruit significantly decreased compared with the control, except for day 5 ($P < 0.05$). After 6 days, POD activity in the control fruit reached a maximum, with a value of 27.48 U g^{-1} FW, which was 17.9% higher than that of the U0126-treated fruit.

H_2O_2 is one of the most important ROS that have been recorded in the signaling pathway leading to resistance against plant disease.[48] Previous research has indicated that MAPK cascades could mediate the defense response as a downstream component of H_2O_2 signaling, and H_2O_2 was a potent activator of MAPK. Meanwhile, activation of MAPK also enhanced the H_2O_2 content, forming a positive feedback loop.[48,49] Wang et al.[50] found that pretreatment with U0126 could accelerate H_2O_2 production and that it eventually enhanced cell death. We noted a similar change in H_2O_2 production in the U0126-treated tomato fruit, and this finally enhanced the susceptibility to *B. cinerea*.

CAT, APX, and POD, the important antioxidant enzymes downstream of H_2O_2 signaling, serve as efficient scavengers of ROS to avoid oxidative damage. A number of studies have shown that disease resistance to pathogens was accompanied by an increase in CAT, APX, and POD activity.[51] Our results showed that MAPKs' inhibitor (U0126) decreased the activity of CAT, APX, and POD (Figure 3B, C, and D). These results could partly illustrate that H_2O_2, CAT, APX, and POD are involved in the MAPKs pathway, which contributes to the resistance of tomato fruit to invasion and expansion of *B. cinerea*. ABA and H_2O_2 could activate MAPK, enhance the activities of the antioxidant enzymes, and accelerate H_2O_2 production, but U0126 could abolish these effects by ABA and H_2O_2.[48]

Effects of U0126 (10 μM) on Disease Incidence and Lesion Area. *B. cinerea* was used as a model necrotrophic fungal pathogen to investigate whether inhibition of *SlMPK1/2/3* expression in tomato fruit would result in an increased susceptibility to pathogen attacks. The disease incidence and lesion area directly reflected the degree of development of disease symptoms; these measures are used widely in the study of plant defense response.[22] U0126 (10 μM) significantly increased the disease incidence and lesion area in tomato fruit after inoculation with *B. cinerea* when compared with the control ($P < 0.05$). The disease incidence in the U0126-treated fruit increased by 77.3%, 48.0%, 28.2%, and 10.7% on days 1, 2,

DOI: 10.1021/acs.jafc.5b00437
J. Agric. Food Chem. 2015, 63, 5509−5517

3, and 4 after inoculation with *B. cinerea*, respectively (Figure 4A). All fruit in the U0126-treated group showed typical symptoms of *B. cinerea* on the fourth day after inoculation, but 9.67% of the control fruit were still not infected with gray mold disease. The lesion area in the U0126-treated tomato fruit was significantly larger than that of the control fruit. The lesion area in the U0126-treated fruit increased by 189.1%, 145.1%, and 105.1% compared with the control fruit (Figure 4B). Although most of the fruit showed symptoms of decay after inoculation with *B. cinerea*, the symptoms diffused faster in the U0126-treated fruit than in the control fruit. The higher diffusion rate in the treated fruit might result from a disturbance of the fruit's innate system by the MAPKs' inhibitor, which promoted the susceptibility of the tomato fruit to *B. cinerea*. These results indicate that MAPK signaling cascades played a crucial role in the regulation of defense response in the tomato fruit.

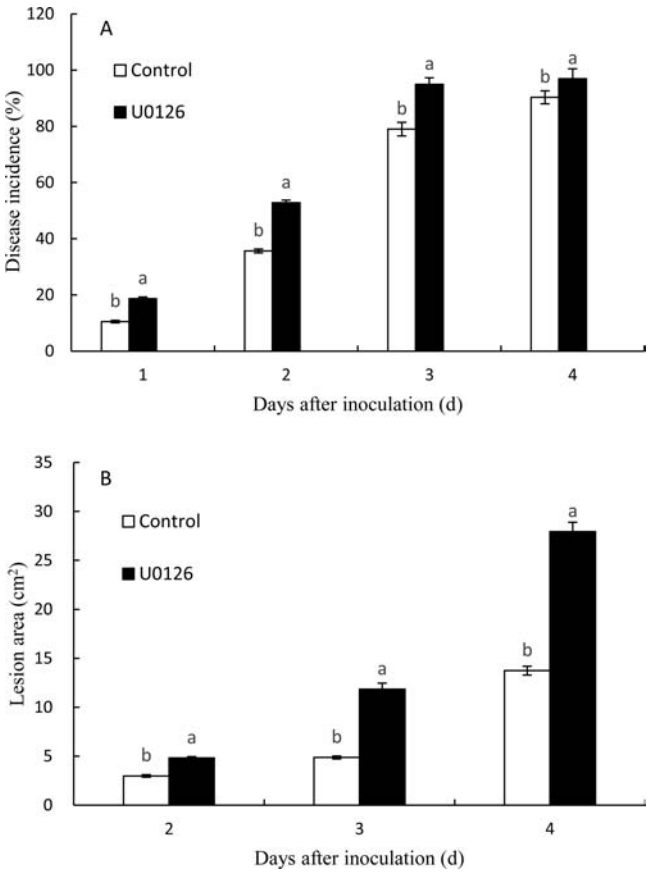

Figure 4. Effects of U0126 (10 μM) treatment on disease incidence (A) and lesion area (B) caused by *B. cinerea* in "Lichun" tomato fruit. Vertical bars represent standard errors of means and different lowercase letters on the same day above the bars are significantly different at $P < 0.05$, according to Duncan's multiple range tests.

Comparison of The Hormone Concentrations, Enzyme Activities and H_2O_2 Accumulation. The correlation coefficients for H_2O_2, POD, CAT, APX, GLU, PAL, CHI, PPO, IAA, GA, ABA, and MeJA are shown in Table 3. Significant correlations were observed among IAA−CAT, ABA−CAT, ABA−APX, GA−MeJA, and GLU−CHI after U0126 treatment ($P < 0.05$); however, no significant correlations were observed between H_2O_2 accumulation and hormone concentrations, and enzyme activities ($P > 0.05$). The significant correlations between ABA−CAT and ABA−APX may be due to that the activities of CAT, and APX could be induced by ABA.[48] The close relationship between GLU and CHI ($R = 0.9$) could possibly be attributed to the fact that both GLU and CHI are PR proteins.

The change profiles of hormone concentrations, enzyme activities, and H_2O_2 content were different between the first 3 days and the last 3 days of treatments. This can be well reflected by the following results: (1) During the first 3 days, the ABA increased rapidly, but decreased during the last 3 days (Figure 1B). (2) GA showed a small variation during the first 3 days, but accumulated sharply during the last 3 days (Figure 1C). (3) The activities of the defense enzymes (GLU, CHI, and PAL) increased during the first 3 days, but decreased during the last 3 days (Figure 2). (4) The H_2O_2 content was higher during the last 3 days than that during the first 3 days (Figure 3A). (5) The activity of CAT rapidly decreased during the first 3 days, but showed a stable and low activity during the last 3 days (Figure 3B). These results illustrate that the effects of U0126 treatment on defense responses were more important during the early stage than the late stage. These may explain why the differences were not large (although significant) in disease symptoms of the control and U0126-treated fruit during the last days of infection.

In conclusion, 10 μM of U0126 significantly inhibited the gene expression of *SlMPK1*, *SlMPK2*, and *SlMPK3*, which resulted in an increase in disease symptoms after inoculation with *B. cinerea*. The balance of hormones (IAA, ABA, GA, and

MeJA) were interfered by the MAPKs' inhibitor, suggesting that plant hormones were involved in the defense signaling pathway of SlMPKs. In addition, the increase in disease symptoms caused by MAPKs' inhibitor may be due to the decrease in the activity of GLU, CHI, PAL, and PPO, which are the primary defenders against fungal pathogens. Moreover, the H_2O_2 content increased, and CAT, APX, and POD activities decreased in MAPKs' inhibitor-treated fruit compared with that of the control fruit, which suggested that SlMPKs might act as defense signaling molecules, partly through the ROS signal. Thus, recognition of the role of *SlMPK1/2/3* in innate immunity can be useful in culturing *SlMPK1/2/3* overexpression in tomatoes to reduce pathogen losses during tomato plant growth and fruit storage.

J. Agric. Food Chem. 2015, 63, 5509−5517

The total antioxidant capacity (TAC) of aqueous extracts and the Trolox equivalent antioxidant capacity (TEAC) of the target compounds were assessed using the 2,2-diphenyl-1-picrylhydrazyl radical (DPPH$^{\bullet}$) scavenging and oxygen radical absorbance capacity (ORAC) assays. These assays were selected as they are commonly used by extract manufacturers in South Africa for product specification and quality control of natural plant extracts. The TEAC of the minor benzophenone, maclurin-3-*C*-glucoside, was also calculated to determine the impact of increased B-ring hydroxylation on the antioxidant activity of the benzophenones.

MATERIALS AND METHODS

Chemicals. HPLC gradient-grade methanol was purchased from Merck Millipore (Darmstadt, Germany). Acetonitrile and acetic acid (≥99.8%) were obtained from Riedel-de Haën (Sigma-Aldrich, St. Louis, MO, USA). Analytical grade reagents and chemicals, i.e., 2,2-diphenyl-1-picrylhydrazyl (DPPH), 2,2′-azobis(2-methylpropionamide) dihydrochloride (AAPH), (±)-6-hydroxy-2,5,7,8-tetramethylchromane-2-carboxylic acid (Trolox), potassium dihydrogen phosphate (KH_2PO_4), potassium hydroxide (KOH), and ascorbic acid, were supplied by Sigma-Aldrich. Fluorescein sodium ($C_{20}H_{10}Na_2O_5$) was obtained from Fluka (Sigma-Aldrich). Ethanol was analytical grade (99%) and sourced from Servochem (Cape Town, South Africa). HPLC-grade water was prepared using Elix and Milli-Q Academic (Merck Millipore) water purification systems in series.

Authentic reference standards with purities >95% were supplied by Sigma-Aldrich (mangiferin, hesperidin, iriflophenone-3-*C*-glucoside), Extrasynthese (Genay, France; eriocitrin, narirutin), Chemos GmbH (Regenstauf, Germany; isomangiferin) and Phytolab (Vestenbergsgreuth, Germany; vicenin-2). Maclurin-3-*C*-glucoside (95%) and iriflophenone-3-*C*-glucoside-4-*O*-glucoside (99%) were isolated from *C. genistoides*.[6] Phloretin-3′,5′-di-*C*-glucoside, isolated from *C. subternata* to a purity of 94% (as assessed by liquid chromatography coupled with diode-array and electrospray ionization mass spectrometric detection, LC-DAD-ESI-MS), was unambiguously identified by nuclear magnetic resonance spectroscopy. Stock solutions of the phenolic standards were prepared in dimethyl sulfoxide (DMSO) at concentrations of ca. 1 mg/mL, diluted with water as required, and filtered through 0.22 μm pore size Millex-GV syringe filters (4 mm diameter; Merck Millipore) prior to use.

Thermal Degradation Kinetics Modeling. The levels of the major benzophenones, iriflophenone-3-*C*-glucoside-4-*O*-glucoside and iriflophenone-3-*C*-glucoside, and the major xanthones, mangiferin and isomangiferin, in *Cyclopia genistoides* plant material were monitored during high-temperature oxidation to establish kinetic parameters governing their degradation. Experiments were conducted on a small scale under highly controlled conditions. The two temperature−time combinations investigated, i.e., 80 °C/24 h and 90 °C/16 h, are representative of the optimum temperature−time regiments recommended to the honeybush industry for the production of the oxidized herbal tea product.

The shoots (leaves and fine stems) from a single *C. genistoides* (L.) Vent (Overberg type) bush were harvested from a commercial plantation near Pearly Beach (Western Cape, South Africa; GPS coordinates −34.702, 19.618). The shoots were dried intact in a forced-air laboratory oven at 40 °C to a moisture content of <10%, whereafter the plant material was pulverized using a Retsch rotary mill (Retsch GmbH, Haan, Germany). A subsample was then sieved to obtain the fraction <50 mesh to ensure a homogeneous sample. The sieved plant material (ca. 80 mg) was weighed off into 4 mL clear glass vials (n = 4 for each time point), followed by addition of 130 μL of deionized water to achieve a final moisture content of ca. 65% and water activity (a_w) of ca. 0.97. The a_w value of the wetted plant material was measured using a Labmaster a_w meter (Novasina AG, Lachen, Switzerland). The vial contents were vortexed, the vials were placed in preheated water baths at 80 and 90 °C, and the required number of vials was removed at each time point. Samples were taken hourly until 16 h for both the 80 and 90 °C trials, followed by sampling at 2 h intervals until 24 h for the 80 °C trial. The control samples received no treatment.

The samples were cooled to room temperature, followed by the addition of 4 mL of 40% aqueous ethanol (v/v) and sonication for 30 min (ultrasonic bath, Branson Ultrasonic Corp., Danbury, CT, USA). The extracts were cooled and filtered (0.45 μm pore size, 33 mm diameter Millex-HV syringe filters; Merck Millipore) and an aliquot of each was diluted 10 times with deionized water. Sample extracts were prepared for high-performance liquid chromatographic (HPLC) analysis by adding 100 μL of 10% aqueous ascorbic acid to 1 mL of the diluted extract.

HPLC-DAD analyses were performed in duplicate on an Agilent 1200 series instrument according to the validated method of Beelders et al.[1] The target benzophenones and xanthones in the sample extracts were identified by coelution with the authentic reference standards and were quantified at 280 and 320 nm, respectively. Due to a limited quantity of the isomangiferin standard available, this compound (**5**) was quantified using a previously determined response factor relative to mangiferin (1.1197). Calibration curves for iriflophenone-3-*C*-glucoside-4-*O*-glucoside (**1**), iriflophenone-3-*C*-glucoside (**3**), and mangiferin (**4**) were constructed weekly (R^2 > 0.9999) with on-column levels in the ranges 0.0166−3.3261, 0.0512−1.4906, and 0.0734−2.1173 μg, respectively.

Modeling of benzophenone and xanthone degradation was performed using quantitative data for the period 0−16 h. For each oxidation temperature, a completely randomized experimental design was used with 4 replications for each of the 16 treatment times. Univariate analysis of variance (ANOVA) using SAS, version 9.2 (SAS Institute, Cary, NC, USA), was performed for each oxidation temperature separately, using the General Linear Models Procedure. The Shapiro−Wilk test was performed to test for normality. Outliers were removed when the residual for an observation deviated more than 3 standard deviations from the standardized model value. Fisher's least significant difference was calculated at the 5% level (P < 0.05) to compare treatment means.

Regression analysis with time (h) as independent variable was performed for the data of each temperature treatment to describe the decrease in compound concentration over time. The order of the thermal degradation reaction of the xanthones and benzophenones was predicted using the model

$$\frac{dC}{dt} = -K_D(C)^n \quad (1)$$

where K_D is the degradation rate constant, n is the reaction order, C is the concentration (g of compound/100 g of plant material), and t is the treatment time (h). The order of the degradation reactions was determined by setting component n in eq 1 to 0, 1 and 2, followed by comparing the coefficients of determination (R^2). The integrated forms of zero-, first-, and second-order kinetic models are given in eqs 2−4, with C_0 equal to the initial concentration of the compound (g/100 g plant material) at t = 0 h:

$$\text{zero order:} \quad C = C_0 - K_D t \quad (2)$$

$$\text{first order:} \quad \ln C = \ln C_0 - K_D t \quad (3)$$

$$\text{second order:} \quad \frac{1}{C} - \frac{1}{C_0} = K_D t \quad (4)$$

The temperature dependence of the degradation rate constants was evaluated by calculating the temperature coefficient (Q_{10}) according to[11]

$$Q_{10} = \frac{K_D(T+10\,^{\circ}C)}{K_D(T)} \quad (5)$$

where K_D is the degradation rate constants at temperatures T and T + 10 °C.

Evaluation of the Thermal Degradation Kinetic Model. The developed kinetic model was subsequently applied to predict the levels

DOI: 10.1021/acs.jafc.5b01657
J. Agric. Food Chem. 2015, 63, 5518−5527

of benzophenones and xanthones remaining when coarsely cut plant material (leaves and stems) was oxidized at 90 °C/16 h under upscaled conditions. This tested the robustness of the kinetic model by incorporating additional variation, i.e., heterogeneity of the plant material due to the coarse cut and batch size.

The shoots from 10 individual *C. genistoides* bushes were harvested from the same commercial plantation stated previously. The fresh shoots from each bush were mechanically shredded (≤3 mm), mixed thoroughly, and divided into two sub-batches for the preparation of unoxidized (control) and oxidized plant material to provide content values for 0 and 16 h processing times, respectively. For the latter, the cut plant material (1 kg) was moistened to a moisture content of ca. 65% and oxidized at 90 °C/16 h.[12] Both the control and oxidized samples were dried at 40 °C/6 h and coarsely sieved,[12] followed by the preparation of freeze−dried hot water extracts as described by Beelders et al.[1]

For HPLC analyses, the freeze−dried extracts were reconstituted in deionized water (ca. 6 mg/mL), followed by the addition of 10% aqueous ascorbic acid (v/v, final concentration 9 mg/mL). Samples were filtered using 0.45 μm pore size Millex-HV syringe filters (33 mm diameter; Merck Millipore) and analyzed. The target xanthone and benzophenone constituents were quantified as described in the previous section.

Other phenolic compounds present in the extracts were also quantified to provide further insight into the quantitative changes that occur during high-temperature oxidation, with emphasis on structure−stability relationships. Maclurin-3-*C*-glucoside (**2**), vicenin-2 (**6**), eriocitrin (**7**), phloretin-3′,5′-di-*C*-glucoside (**8**), and hesperidin (**9**) in the sample extracts were identified by coelution with the authentic reference standards. Additionally, compounds **A**−**I** in the sample extracts were identified by taking their characteristic UV−vis spectra and relative elution order into account, in accordance with LC-DAD-MS results presented by Beelders et al.[1] (Table S1, Supporting Information). Maclurin-3-*C*-glucoside and vicenin-2 were quantified at 320 nm, and calibration curves were constructed over the following ranges (μg on-column): 0.0157−0.6905 and 0.0721−0.9008, respectively. The flavanones eriocitrin and hesperidin were quantified at 288 nm, and the ranges for the calibration curves were 0.0200−0.2500 and 0.0776−0.9700 μg on-column, respectively. Due to the limited quantity of the purified phloretin-3′,5′-di-*C*-glucoside standard available, this compound was quantified using a previously determined response factor relative to hesperidin (0.7902). Compounds **A**−**I** were quantified using calibration curves of the most closely related reference standard. For this purpose, an additional calibration curve for narirutin was constructed at 288 nm over a range of 0.0200−0.3340 μg on-column. The correlation coefficients (R^2) of all calibration curves were larger than 0.9999.

Quantitative data generated for extracts prepared from the unoxidized and oxidized plant material (n = 10) were subjected to ANOVA with Fisher's least significant difference calculated at the 5% level to compare treatment means.

Antioxidant Capacity of Selected Xanthones and Benzophenones and the Effect of High-Temperature Oxidation on TAC of Aqueous Extract. The TAC of the reconstituted freeze−dried extracts (n = 10) was determined in triplicate using the DPPH• scavenging[13] and ORAC[14] assays in 96-well microplate format. Corresponding absorbance and fluorescence values were measured using a BioTek SynergyHT microplate reader fitted with a dispenser (BioTek Instruments, Winooski, VT, USA). TAC data were subjected to ANOVA with Fisher's least significant difference calculated at the 5% level to compare treatment means.

Trolox equivalent antioxidant capacity (TEAC) of the target benzophenones and xanthones were determined to calculate their individual contributions to the TAC of aqueous extracts prepared from unoxidized *C. genistoides* and to quantify the impact of their degradation based on the TAC of aqueous extracts prepared from the oxidized plant material. The TEAC value of the minor benzophenone, maclurin-3-*C*-glucoside, was also determined to provide insight into structure−activity relationships.

Dose−response curves were constructed for the aforementioned compounds and Trolox by plotting graphs of concentration (μM) vs percent DPPH• scavenged (DPPH assay) and net area under curve (ORAC assay). The concentration ranges of the standard compounds were selected to ensure that the antioxidant dose−response curves remained linear. TEAC values for each individual compound were then calculated as follows:

$$\mathrm{TEAC}_{\mathrm{compound}} = \mathrm{slope}_{\mathrm{compound}}/\mathrm{slope}_{\mathrm{Trolox}} \quad (6)$$

RESULTS

Thermal Degradation Kinetics Modeling. The high-temperature oxidation process significantly ($P < 0.05$) reduced the mean content values of the target compounds over the evaluated time−temperature combinations, and these losses were more pronounced at 90 than at 80 °C (Table S2, Supporting Information).

The decrease in the contents of these compounds over a 16 h period, as affected by temperature and chemical structure, is depicted in Figure 1. Analysis of the kinetic data at both temperatures indicated first-order degradation reactions ($0.898 < R^2 < 0.970$), with the exception of iriflophenone-3-*C*-glucoside-4-*O*-glucoside at 80 °C ($R^2 = 0.111$) (Table 1). The mean content value of the latter compound did not change significantly over 16 h at 80 °C ($P \geq 0.05$; Table S2, Supporting Information), which explains the poor correlation. Straight lines were obtained for plots of ln C vs t for each of the assessed compounds at each temperature (Figure 2), where the individual slopes are representative of the first-order degradation rate constants (K_D) (Table 1).

Iriflophenone-3-*C*-glucoside-4-*O*-glucoside was the most thermally stable compound, with a K_D(90 °C) value of 0.0061 h^{-1} (Table 1). Isomangiferin was the second most thermally stable compound at 80 °C (K_D(80 °C) = 0.0116 h^{-1}), while its degradation rate was influenced the most by increased temperature (Q_{10} = 2.70, Table 1). Iriflophenone-3-*C*-glucoside and mangiferin had comparable degradation rate constants of 0.0224 and 0.0248 h^{-1}, respectively, at 80 °C (Table 1). The degradation rate constants for these compounds respectively showed 1.40- and 1.72-fold increases with an increase in temperature from 80 to 90 °C (Table 1).

Evaluation of the Thermal Degradation Kinetic Model. Predicted content values for the target benzophenones and xanthones in aqueous extract prepared from oxidized plant material, based on their contents in aqueous extract prepared from the unoxidized plant material and their first-order K_D(90 °C) values, were calculated for comparison with their actual content values in aqueous extract prepared from the oxidized plant material (Table 2).

The first-order kinetic model provided excellent (error <5%) prediction of iriflophenone-3-*C*-glucoside-4-*O*-glucoside and mangiferin degradation, while it was acceptable (error <10%) for isomangiferin (Table 2). However, a poor fit was obtained for iriflophenone-3-*C*-glucoside, as the kinetic model greatly underestimated the degradation of this compound following oxidation at 90 °C for 16 h (Table 2).

Effect of High-Temperature Oxidation on the Levels of Individual Phenolic Compounds in Hot Water Extracts. Oxidation significantly decreased the content values of most phenolic compounds present in *C. genistoides* hot water extracts (refer to Figure 3 for a typical HPLC chromatogram), but some compounds either remained stable or showed a significant increase (Table 3).

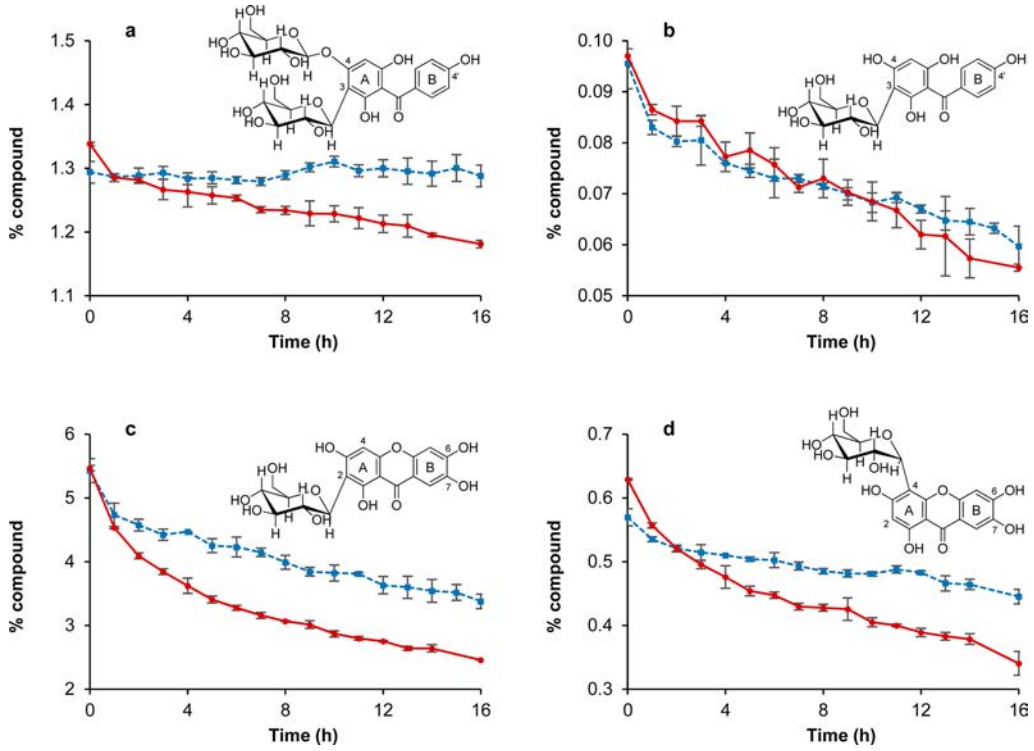

Figure 1. Changes in the mean percentage of compound in *Cyclopia genistoides* (g of compound/100 g of plant material ± standard deviation) for (a) iriflophenone-3-*C*-glucoside-4-*O*-glucoside, (b) iriflophenone-3-*C*-glucoside, (c) mangiferin, and (d) isomangiferin as a function of oxidation temperature over 16 h: (blue dotted curves) 80 °C; (red solid curves) 90 °C.

The *C*-glucosylxanthone mangiferin (**4**) was the major phenolic constituent of freeze-dried hot water extracts prepared from unoxidized (11.80%) and oxidized (6.04%) *C. genistoides* plant material (Table 3). Isomangiferin (**5**) represented the third most abundant phenolic constituent of *C. genistoides* at 1.54% and 0.91% of the unoxidized and oxidized extracts, respectively (Table 3). The mean content values of mangiferin and isomangiferin decreased by 49% and 41%, respectively, with oxidation (Table 3).

The second most abundant phenolic constituent of *C. genistoides* hot water extracts was the novel benzophenone iriflophenone-3-*C*-glucoside-4-*O*-glucoside (**1**), and its mean content value was not significantly affected by processing ($P \geq 0.05$) (Table 3). Iriflophenone-3-*C*-glucoside (**3**) represented the fourth and fifth most abundant phenolic constituent of aqueous extract prepared from the unoxidized (1.12%) and oxidized (0.42%) plant material, respectively. In contrast to the case for compound **1**, the mean content value of iriflophenone-3-*C*-glucoside showed a significant ($P < 0.05$) decrease with oxidation (62%; Table 3).

In addition to these 4 major compounds, 14 additional compounds were also quantified to provide insight into the changes that occur during oxidation (Table 3 and Figure 3). Maclurin-3-*C*-glucoside (**2**) and its glycosylated derivative, maclurin-di-*O*,*C*-hexoside (**A**), were quantified at levels of 0.31% and 0.13%, respectively, in extracts prepared from the unoxidized plant material. The former compound was extremely prone to degradation during the high-temperature oxidation process, exhibiting a decrease of 83%.

A tetrahydroxyxanthone-*C*-hexoside dimer (**C**), a tetrahydroxyxanthone-di-*O*,*C*-hexoside (**D**), and a tetrahydroxyxanthone-*C*-hexoside isomer (**J**) were also quantified as minor constituents of the *C. genistoides* extracts (Table 3). The mean content values of compounds **D** and **J** showed a reduction of 35−40% with oxidation, while the xanthone dimer (compound **C**) was only quantifiable in extracts prepared from the oxidized plant material.

Vicenin-2 (apigenin-6,8-di-*C*-glucoside, compound **6**) represented the sixth and fourth most abundant phenolic constituent of hot water extracts prepared from unoxidized (0.50%) and oxidized (0.45%) *C. genistoides* plant material, respectively. This represents a slight but significant ($P < 0.05$) decrease with oxidation (ca. 10%).

The effect of oxidation on the flavanones was found to differ. The average content of eriocitrin (**7**) in the aqueous extract was not significantly ($P \geq 0.05$) affected by oxidation, while the hesperidin (**9**) and eriodictyol-*O*-hexose-*O*-deoxyhexoside (**E**) contents were significantly ($P < 0.05$) reduced. The average content of naringenin-*O*-hexose-*O*-deoxyhexoside (**G**) also showed a significant ($P < 0.05$) decrease with oxidation (57%), which was accompanied by a significant ($P < 0.05$) increase in the content of another naringenin-*O*-hexose-*O*-deoxyhexoside derivative (compound **F**; 34%).

The mean content values of the dihydrochalcone phloretin-3′,5′-di-*C*-glucoside (**8**) and its hydroxylated derivative, 3-hydroxyphloretin-3′,5′-di-*C*-hexoside (**H**), were both significantly ($P < 0.05$) reduced with oxidation. The former compound presented a decrease of 56%, while the latter was degraded more extensively (84%; Table 3).

Antioxidant Capacity of Selected Xanthones and Benzophenones and the Effect of High-Temperature Oxidation on TAC of Aqueous Extract. Oxidation significantly ($P < 0.05$) lowered the mean TAC of the extracts as assessed using the DPPH$^{\bullet}$ scavenging assay (TAC_{DPPH}; Table 3). Conversely, the TAC_{ORAC} value of extracts was only slightly, but not significantly ($P \geq 0.05$), reduced with oxidation (Table 3).

Assessment of the TEAC of selected benzophenones and xanthones provided some insight into the relative importance of these constituents in terms of the TAC of the extract. $TEAC_{DPPH}$ values for the individual compounds (Table 4) indicated that maclurin-3-*C*-glucoside was the most efficient scavenger of DPPH•. Its $TEAC_{DPPH}$ value (2.19) was ca. 3-fold higher than that of iriflophenone-3-*C*-glucoside (0.65) (Table 4). Despite the low concentration of maclurin-3-*C*-glucoside in the unoxidized *C. genistoides* extract (Table 3), it almost contributed equally to the average TAC of the unoxidized extract in comparison to the much more abundant iriflophenone-3-*C*-glucoside (Table 4). The radical scavenging ability of iriflophenone-3-*C*-glucoside-4-*O*-glucoside toward DPPH• (0.01) was lower than that of its mono-*C*-glucosylated derivative, iriflophenone-3-*C*-glucoside and was also the lowest overall (Table 4).

Both mangiferin and isomangiferin exhibited moderate DPPH• scavenging activity with TEAC values of 1.79 and 1.69, respectively. These xanthones were the major contributors to the TAC of *C. genistoides* hot water extracts, collectively responsible for 41.7% and 25.2% of the TAC_{DPPH} of the extracts prepared from unoxidized and oxidized plant material, respectively (Table 4).

With regard to the ORAC assay, an entirely different ranking of phenolic antioxidants was obtained. The fluorescein fluorescence decay curve of iriflophenone-3-*C*-glucoside-4-*O*-glucoside showed a very different profile in comparison to those of the reference antioxidant, Trolox, and maclurin-3-*C*-glucoside (Figure S1, Supporting Information). Iriflophenone-3-*C*-glucoside-4-*O*-glucoside exhibited the highest $TEAC_{ORAC}$ value (4.76), followed by iriflophenone-3-*C*-glucoside (4.06) (Table 4). Due to both its relative potency and high concentration in the *C. genistoides* extracts (Table 3), iriflophenone-3-*C*-glucoside-4-*O*-glucoside represented a major contributor (>10%) to the average TAC_{ORAC} value of the extracts. Conversely, the contribution of this compound to the TAC_{DPPH} of the extracts was almost negligible (ca. 0.1%) (Table 4). Maclurin-3-*C*-glucoside exhibited a moderate antioxidative effect in the ORAC assay (3.31), comparable to that of isomangiferin (3.38) and notably higher than that of mangiferin (2.80) (Table 4).

DISCUSSION

Thermal Degradation Kinetics Modeling and Evaluation of the Model. The thermal stabilities of iriflophenone-3-*C*-glucoside-4-*O*-glucoside, iriflophenone-3-*C*-glucoside, mangiferin, and isomangiferin were determined, as these compounds represent the major phenolic constituents of *C. genistoides*. Due to the low levels of maclurin-3-*C*-glucoside present in the plant material, its thermal degradation behavior could not be assessed kinetically. An isothermal method was used to estimate reaction kinetics, as the ramp-up time in the thin-walled glass vials was assumed to be negligible in comparison to the length of the holding phase. The kinetic data provided a good fit for first-order degradation reactions, which is in line with the literature on the isothermal degradation of cloudy apple juice phenolic constituents,[15] anthocyanins,[16] and carotenoids,[17] among others.

Addition of an *O*-linked glucopyranosyl moiety at C-4 conferred higher thermal stability to iriflophenone-3-*C*-glucoside-4-*O*-glucoside in comparison to iriflophenone-3-*C*-glucoside during high-temperature oxidation of *C. genistoides* plant

[a]Activity of compound relative to that of Trolox: i.e., concentration of Trolox solution in μM with equivalent antioxidant activity to a 1 μM concentration of the compound under investigation. [b]The concentration range of a specific compound used in the dose−response curves (final concentrations in the reaction volume). [c]Calculated on the basis of content (Table 3) and TEAC values. [d]Oxidation conditions: 90 °C/16 h. [e]Trolox assessed over a concentration range of 5.0−40.0 μM with an average slope (n = 3) of 2.2670 and R^2 = 0.997. [f]Trolox assessed over a concentration range of 0.6−3.7 μM with an average slope (n = 6) of 4.2240 and R^2 = 0.999. TEAC values for the xanthones and benzophenones were determined in duplicate (% RSDs ≤ 5.6).

aglycone.[18,19] This observation was attributed to the blockage of the 3-hydroxyl group in the C ring by the sugar moiety, which prevents the formation of the carbanion.[18] It is thus possible that the hydroxyl group at C-4 on the diphenyl ketone structure is a key parameter with respect to thermal degradation of benzophenones. Similarly, a study of the thermal stability of quercetin-*O*-glycosides demonstrated that the position of glycosylation and type of sugar determined susceptibility to deglycosylation.[20] Zielinski and co-workers[21] have demonstrated slight differences in the stability of the flavone *C*-glucosides vitexin (apigenin-8-*C*-glucoside; 72% degradation) and isovitexin (apigenin-6-*C*-glucoside; 84% degradation) in buckwheat groats during roasting.

In the current study, an increase in oxidation temperature from 80 to 90 °C increased the rate of degradation for all target compounds, as expected. Of interest is that this effect was more pronounced for iriflophenone-3-*C*-glucoside-4-*O*-glucoside, which was stable under oxidative conditions at 80 °C for 16 h but exhibited a decrease of 11.7% following oxidation at 90 °C after the same time period. The effect of temperature on the degradation rate constants was estimated by calculating the temperature coefficient (Q_{10}). The significance of this value is clear when considering the thermal degradation of isomangiferin. This compound had the lowest degradation rate constant at 80 °C, which by itself would imply that this compound is more stable than mangiferin and iriflophenone-3-*C*-glucoside. However, the degradation rate of isomangiferin showed a 2.7-fold increase with an increase in temperature from 80 to 90 °C, which implies greater susceptibility of this compound toward degradation at elevated temperature than mangiferin and iriflophenone-3-*C*-glucoside.

The kinetic parameters derived for the first-order degradation reactions were subsequently used to predict the amounts of major compounds remaining in *C. genistoides* (n = 10) following oxidation (90 °C/16 h) of the coarsely cut plant material under conditions similar to those used in the industrial oxidation process. In spite of the procedure being less "controlled" than the oxidation process carried out with very small quantities of homogeneous material, the degradation kinetic model provided excellent estimates for the average amounts of iriflophenone-3-*C*-glucoside-4-*O*-glucoside and mangiferin in hot water extracts prepared from the oxidized plant material. The model, however, greatly underestimated the degradation of iriflophenone-3-*C*-glucoside, and the reason for this still has to be established. In light of the apparent bitterness of *C. genistoides* infusions, associated with a high mangiferin content,[22] the model could potentially be used to estimate the processing time needed to decrease the mangiferin content to a level where the infusions are not perceived as bitter, without causing unnecessary losses in bioactivity. Another potential application is to "screen" new *C. genistoides* selections of the ongoing Cultivar Development Programme of the Agricultural Research Council of South Africa for an unacceptable bitter taste by predicting the mangiferin content of the processed herbal tea.

Effect of High-Temperature Oxidation on the Levels of Individual Phenolic Compounds in Hot Water Extracts. It is well-known that the high-temperature oxidation process has a significant impact on the individual phenolic content values of *Cyclopia* extracts. Previous studies have, however, mostly been limited to a small data set of randomly selected or paired-processed samples and/or a limited number

DOI: 10.1021/acs.jafc.5b01657
J. Agric. Food Chem. 2015, 63, 5518−5527

of quantifiable compounds.[1,10,23] In the present study, quantitative data were generated for 9 known compounds and 9 additional compounds in 10 individual batches of *C. genistoides* plant material.

The high-temperature oxidation process (90 °C/16 h), required for the development of the desirable sensory properties of honeybush herbal tea, significantly reduced the mean content values of most phenolic compounds of the aqueous extracts. The thermal stability of a number of minor compounds is worth highlighting. The tetrahydroxyxanthone-*C*-hexoside dimer (compound **C**) could only be quantified in extracts prepared from the oxidized plant material. On the basis of related studies regarding the dihydrochalcone aspalathin,[24,25] it is probable that this xanthone dimer is formed by the nonenzymatic, oxidative coupling of two tetrahydroxyxanthone-*C*-hexoside monomers during high-temperature processing. The dimeric xanthone may be linked through either a rotatable or atropisomeric biaryl C−C bond or a biaryl ether C−O−C linkage.[26] Storage of (−)-epigallocatechin gallate in solid-state samples at elevated temperatures (80 °C) has also been shown to induce auto-oxidation with the formation of B-ring dimers.[27]

Two naringenin derivatives, compounds **F** and **G**, also exhibited interesting behavior during the oxidation process. A significant reduction in the mean content value of compound **G** was accompanied by a significant increase in the mean content value of compound **F**. These flavanones are potential isomers, and it is herein postulated that compound **G** is converted to the more stable structure of compound **F** during the oxidation process. Similar observations have been made with regard to the irreversible conversion of isoorientin to orientin via a Wessely−Moser rearrangement during incubation in phosphate buffer at 37 °C for 48 h.[28]

In this study, phloretin-3′,5′-di-*C*-glucoside (**8**) was more stable than 3-hydroxyphloretin-3′,5′-di-*C*-hexoside (**H**) during oxidation at 90 °C/16 h. The presence of an extra hydroxyl group on the B ring of the basic dihydrochalcone structure therefore decreased thermal stability. This effect was also prominent for iriflophenone-3-*C*-glucoside (**3**; 62% reduction) and its C-3′ hydroxylated derivative, maclurin-3-*C*-glucoside (**2**; 82% reduction). Maini and co-workers[29] found that the stability of flavonols in different cell culture media, and their stability to UVA irradiation, decreased with increasing B-ring substitution. Conversely, De Paepe et al.[15] demonstrated a slight decrease in the K_D value with the presence of an additional hydroxyl group at C-3′ on the A ring of the dihydrochalcone structure. These results therefore suggest that both the degree of hydroxylation and the position of hydroxylation, in particular, are key factors affecting the thermal stability of dihydrochalcones.

Antioxidant Capacity of Selected Xanthones and Benzophenones and Effect of High-Temperature Oxidation on TAC of Aqueous Extract. While a reduction in the contents of mangiferin and isomangiferin, for instance, may be desirable from a sensory perspective, the antioxidant activity of the extracts may also consequently be reduced. Given demonstration of the similar antioxidant capacity of three of these compounds in an online HPLC-ORAC assay,[4] their degradation was expected to have a major impact on the TAC value of hot water extracts of *C. genistoides*. This type of extract is of interest due to its use as an ingredient in food and nutraceutical products.

High-temperature oxidation significantly lowered the average TAC_{DPPH} value of the aqueous extracts, while their average TAC_{ORAC} value was only slightly reduced. These observations are in line with data presented by Joubert et al.,[10] in which oxidation significantly reduced the average antioxidant activity of six paired-processed samples of various *Cyclopia* species (as assessed using the $ABTS^{\bullet+}$ scavenging, ferric reducing antioxidant power (FRAP), and lipid peroxidation assays). The same study showed, however, that the ability of the hot water extract of *C. genistoides* to inhibit lipid peroxidation was not affected.[10] It is therefore possible that unknown degradation products may also possess antioxidant activity and thus could have contributed to the TAC_{ORAC} values of extracts prepared from the oxidized plant material. Buchner et al.[19] and Murakami et al.[30] have previously demonstrated antioxidant activity for flavonol and other polyphenolic degradation products.

The higher $TEAC_{DPPH}$ value of maclurin-3-*C*-glucoside in comparison to that of iriflophenone-3-*C*-glucoside may be attributed to the presence of an extra hydroxyl group at C-3′ on the diphenyl ketone structure, which imparts a catechol-type structure to maclurin-3-*C*-glucoside, one of the structural features responsible for antioxidant activity of polyphenols.[31,32] An increase in the degree of glucosylation was found to reduce the reactivity of the benzophenones toward $DPPH^{\bullet}$, as previously observed for flavonoids.[31] The reduced reactivity of iriflophenone-3-*C*-glucoside-4-*O*-glucoside could possibly be attributed to the substitution of an active phenolic OH group, responsible for free radical scavenging. Furthermore, the additional glucopyranosyl moiety can impede access of the remaining free phenolic OH groups to the hindered radical site of $DPPH^{\bullet}$, thereby reducing reactivity.[33]

While data from the $DPPH^{\bullet}$ scavenging assay inferred that iriflophenone-3-*C*-glucoside-4-*O*-glucoside is ineffective as a radical scavenger, this compound had the highest $TEAC_{ORAC}$ value among the five compounds assessed in this study. The difference in ranking of phenolic antioxidants in the ORAC assay in comparison to the DPPH assay may be related to the differences in the reaction mechanisms of the two assays, which underlines the importance of using more than one assay to assess the antioxidant capacity of natural extracts and/or phenolic compounds. To our knowledge, this is the first report on the antioxidant capacity of iriflophenone-3-*C*-glucoside-4-*O*-glucoside and maclurin-3-*C*-glucoside. Further research is thus required to understand the reaction mechanisms of these benzophenones with free radicals.

Similarly, the effect of glucosylation position on the antioxidant activity of the xanthones differed between the two antioxidant assays. Mangiferin exhibited slightly higher reactivity toward $DPPH^{\bullet}$ than its C-4 regioisomer, isomangiferin, while the $TEAC_{ORAC}$ value of isomangiferin was slightly higher than that of mangiferin. These observations are in line with results presented by Malherbe et al.[4] using online HPLC-DPPH and -ORAC assays. Similar antioxidant activities have also been demonstrated for positional isomers of chlorogenic acid.[34]

Collectively, the four major compounds and maclurin-3-*C*-glucoside contributed 44.3% and 26.1% to the TAC_{DPPH} of extracts prepared from unoxidized and oxidized plant material, respectively. Mangiferin was the major contributor, and this could be ascribed to both its high concentration in the sample extracts and its relatively high scavenging ability toward $DPPH^{\bullet}$. It is also clear that, when the DPPH assay was used, the contribution of the benzophenones to the TAC of the extracts was low and that their degradation during oxidation

DOI: 10.1021/acs.jafc.5b01657
J. Agric. Food Chem. 2015, 63, 5518−5527

would thus have little impact on the TAC_{DPPH} value. Using the ORAC assay, the same five compounds could only explain 34.0% and 22.8% of the TAC of extracts prepared from unoxidized and oxidized *C. genistoides* plant material, respectively. Here, mangiferin and iriflophenone-3-*C*-glucoside-4-*O*-glucoside contributed almost equally to the TAC_{ORAC} of extracts prepared from the oxidized plant material. The remarkable stability of iriflophenone-3-*C*-glucoside-4-*O*-glucoside during high-temperature oxidation was therefore paramount to retaining high TAC_{ORAC} of the extracts, even after processing. A large percentage of the TAC of the hot water honeybush extracts still remains unaccounted for, and this may be ascribed to the antioxidant capacities of other phenolic constituents and other types of compounds present in the extracts (both known and unidentified compounds) which were not assessed in the current study.

In conclusion, the high-temperature oxidation process decreased the antioxidant capacity and individual content values of most phenolic compounds present in *C. genistoides* hot water extracts. Decreases in the individual phenolic contents were compound-specific, with factors such as the degree of hydroxylation and the degree and position of glucosylation playing key roles. Insight into the thermal stability of selected xanthones and benzophenones was obtained for the first time in this study, with the application of thermal degradation kinetics modeling. This includes kinetic data on the novel *Cyclopia* constituent iriflophenone-3-*C*-glucoside-4-*O*-glucoside. Understanding these complex reaction mechanisms is a prerequisite to gain further insights into the chemical pathways during the high-temperature oxidation of *C. genistoides* plant material. Future studies will include assessing the thermal stability of the compounds in model solutions as opposed to the plant material, thereby eliminating matrix effects and interactions between phenolic constituents. Such degradation models will be useful to predict the stability of these compounds during pasteurization/sterilization of ready-to-drink herbal tea beverages, for instance.

on extractable anthocyanin content and changes in the content of these compounds, along with other phenolics, as a way to estimate the composition of bioactives in processed maize.[15−17] However, no studies have yet investigated the potential impact of anthocyanin composition of maize on the stability of color in product (in situ) during thermoalkaline processing. Given that visual color is a primary quality factor for processed foods, identifying pigmented maize varieties that retain their visual appeal during processing is important. In this study, we use a diverse set of genetically distinct pigmented maize hybrids to investigate the effect of pigment composition on color stability during nixtamalization and tortilla chip processing.

MATERIALS AND METHODS

Materials. *Maize Samples.* Twenty-four pigmented maize hybrids with various genetic backgrounds from four different color classes [red, blue, purple (also identified as maiz morado), and red/blue] developed by the Texas A&M University Quantitative Genetics and Maize Breeding Program were used. To create each colored hybrid two corn inbred lines, with one or both parents being colored, were crossed to obtain the experimental hybrid seed. The grain samples used in this study were obtained by self-pollinating plants grown from this hybrid seed in two different environments [College Station, TX, 2013 (CS13), and Weslaco, TX, 2011 (WE11); College Station, TX, 2011, was used instead of WE11 for samples 4, 5, 8, and 19 because of insufficient seed quantity]; self-pollination allowed these grain samples to be genetically pure as would be obtained in a farmer's field. The maize genetic variety, color class, and growing location/year are listed in Table 1, and additional information can be found in Mahan et al. (2013).[18] The pigments in red, purple, and red/blue color classes are located mainly in the pericarp and are maternally inherited, whereas the pigments in the blue color class are in the aleurone layer. Prior to analysis, whole grain samples were preground using a coffee grinder (Cuisinart, model DCG-20N series), ground with a UDY cyclone sample mill equipped with a 0.1 mm screen (model 3010-030, UDY Corp., Fort Collins, CO, USA), and stored in a freezer at −20 °C until extraction. A moisture analyzer (model HB43-S, Mettler-Toledo, LLC, Columbus, OH, USA) was used to determine the moisture contents of the ground samples, which were confirmed using the AACC air-oven method of moisture content determination (method 44-15.02, AACC International, 1999).

Chemicals and Reagents. All reagents used were of analytical grade. Cyanidin chloride and pelargonidin chloride standards were purchased from Extrasynthese Natural Products, Genay, France. Ferulic acid and caffeic acid were purchased from Spectrum Chemical Manufacturing Corp., Gardena, CA, USA; and *p*-coumaric acid was purchased from Sigma-Aldrich Chemicals, St. Louis, MO, USA.

Methods. *Alkaline Processing of Pigmented Maize.* Thirty grams of maize was added to large glass tubes containing 90 mL of distilled water (1:3 w/w, maize/water) and either 0% (control), 0.5%, or 1.0% lime (weight of lime per weight of maize). The samples were cooked in a medium kettle filled with water on a DuxTop induction cooktop (Secura, Appleton, WI, USA) for 50 min at approximately 100 °C. The cooked samples were steeped for 14 h in a covered water bath that was previously heated to 80 °C and shut off prior to sample entry. After steeping, the pH of the cooking liquor (nejayote) was measured, and the liquid was then discarded. The cooked maize (nixtamal) was not washed, as is traditionally done after steeping to remove excess lime and partially remove pericarp, due to the fact that the majority of the anthocyanins are present in the pericarp and aleurone layers, and so pigments would be partially lost through this step. The nixtamal was then ground into masa using a coffee grinder (Cuisinart, model DCG-20N series), and the masa was rehydrated on the basis of moisture content to achieve suitable masa consistency for tortilla production. Pieces of masa (14 g) were then pressed into tortillas using a manual press, and these tortillas were baked on a hot griddle (190 °C) for 30 s on each side for a total of 2 min. The tortillas were left to equilibrate to room temperature and then fried at 198 °C for 50 s using an electric deep fryer (Presto, "Fry Daddy Elite" stock no. 05426). The maize tortilla chips were then stored at −20 °C until further analysis.

Extraction. Ground maize flour (5 g) was extracted in 1% HCl in methanol (10 mL) with continuous shaking for 2 h at room temperature. The samples were then centrifuged at 9900*g* for 8 min (HeraeusMegafuge 11R, Thermo Fisher Scientific, Asheville, NC, USA), and the supernatants were collected. A portion of each supernatant was then passed through a syringe filter with a 0.45 μm

DOI: 10.1021/acs.jafc.5b00798
J. Agric. Food Chem. 2015, 63, 5528−5538

nylon membrane before being injected (3 μL) onto the HPLC column.

The fried maize tortilla chips were ground and defatted using hexanes (1:3, samples/hexanes) for 1.5 h with agitation. This process was repeated five times to remove all residual oil, with the saturated hexanes being discarded and fresh hexanes added each time. Defatted samples were stored open in a fume hood overnight until the hexanes had evaporated. These samples were subsequently extracted as described for grain in the preceding paragraph.

HPLC Analysis. Individual anthocyanins and other phenolics were separated and quantified using an Agilent 1200 HPLC system (Agilent Technologies, Santa Clara, CA, USA) equipped with a ZORBAX Stable Bond Eclipse XDB-C18 column (4.6 × 150 mm, 5 μm; Agilent Technologies), with a guard column (4.6 × 12.5 mm, 5 μm). The mobile phase comprised 2% formic acid in water (A) and 2% formic acid in acetonitrile/methanol (50:50) (B). The elution gradient (B) was 0−2 min, 10% isocratic; 2−4 min, 10−20%; 4−24 min, 20−50%; 24−28 min/ 50% isocratic; 28−30 min, 50−10%; and 30−37 min, 10% isocratic. Separation was achieved at a flow rate of 1 mL/min with the column thermostat held at 40 °C. Compounds were monitored at 280, 320, and 360 nm (for other phenolics) and at 520 nm (for anthocyanins) using a diode array detector.

UPLC-ESI/MS Analysis. Analysis was carried out using a Waters-ACQUITY UPLC/MS system (Waters Corp., Milford, MA, USA), which was equipped with a binary solvent manager, sample manager (autosampler), column heater, and photodiode array eλ detector (PDA). This was interfaced with a mass spectrometer equipped with a tandem quadrupole (TQD) electrospray ionization (ESI) detector. A Kinetex C18 column (150 mm × 2.10 mm, 2.6 μm, Phenomenex, Torrance, CA, USA) was utilized for separation with a column temperature of 50 °C for anthocyanins, which were monitored at 520 nm, and a temperature of 40 °C for other phenolics, which were monitored at 280, 320, and 360 nm. Mass spectrometric data for anthocyanins were acquired in positive mode and in negative mode for other phenolics as previously described.[19] Empower 2 software (Waters Corp.) was employed to obtain and analyze the data. The MS scan was recorded in the range of 100−1000 Da for anthocyanins and other phenolics. Nitrogen was the drying and nebulizing gas used, and argon was used as the collision gas (AOC, Bryan, TX, USA). The nitrogen gas flow conditions were 800 and 50 L/h for desolvation and at the cone, respectively. Source block temperature and desolvation temperature were set at 150 and 400 °C, respectively. The intensity of the mass signals of protonated/deprotonated molecules and aglycone fragments was used for optimization of ionization conditions and was performed for each individual compound/peak detected. Mass parameters were optimized as follows: capillary voltage, 3.5/3.0 kV; and cone voltage, 40/30 V for positive/negative ionization, respectively. The MS/MS scan was optimized as follows: cone voltage, 40/30−55 V; and collision energy, 20/15−35 V for anthocyanins/other phenolics, respectively.

Samples were prepared in identical fashion to those for HPLC analysis, but the final filtration prior to injection was through 0.2 μm PTFE filters, with 1 μL injected onto the LC column for analysis. The solvents used were 2% formic acid in water (solvent A) and acetonitrile (solvent B) for anthocyanin analysis and 0.05% formic acid in water (solvent A) and acetonitrile (solvent B) for the other phenolics. The gradient, at a flow rate of 0.4 mL/min, was as follows: 5% B from 0 to 2 min, 5−75% B from 2 to 27 min, 75% B isocratic from 27 to 30 min, 75−5% B from 30 to 31 min, followed by 5% B isocratic for 5 min to allow for column equilibration before the next injection.

Quantification of Major Anthocyanins and Other Phenolics. Major anthocyanins and other phenolics were quantified on the basis of standard curves calibrated using pure standards. However, when standards were not available, content was determined using a molecular weight correction factor and based on the assumption that derivatives possess molar absorptivities similar to those of their aglycones. Cyanidin and pelargonidin were used to estimate their respective glycosides/acyl-glycosides, whereas cyanidin was used to estimate peonidin derivatives. Phenolic amides were quantified on the basis of molar absorptivities of their respective phenolic acid substituents; their UV profiles were essentially identical to the parent phenolic acid components, as previously demonstrated.[20] Concentrations of identified compounds were expressed as micrograms per gram, dry basis.

Determination of Total Anthocyanin Content and Proportion of Monomeric Anthocyanins. Total anthocyanin content (TAC) and total monomeric anthocyanin content (TMA), as well as proportion of monomeric anthocyanins, were determined using the pH differential method as described by Lee et al.[21] Samples were extracted in 1% HCl in methanol (5 g of sample/10 mL of MeOH) and diluted appropriately to reach A_{520} of around 1.0 using pH 1.0 buffer. Using this determined dilution factor, two dilutions of the sample were prepared (one with pH 1.0 buffer and one with pH 4.5 buffer). Samples were scanned from 800 to 200 nm using a UV−vis spectrophotometer (Shimadzu Scientific Instruments, Columbia, MD, USA), and absorbance data were collected at 520 and 700 nm. The proportion of monomeric anthocyanins was determined for only a subset of purple and red/blue samples. The remaining samples had total pigment contents that were too low, so the proportion monomeric could not be determined. All data were reported in micrograms per gram (dry basis).

Measurement of Visual Color Parameters. Visual color parameters were measured using a Minolta Chroma Meter (model CR-300, Ramsey, NJ, USA). The colorimeter was calibrated prior to each use with a standard white tile. Lightness (L^*), degree of redness (a^*), and degree of yellowness (b^*) were the parameters directly measured by the instrument. Measurements were taken in triplicates. Measurements were taken on masa and tortilla chips for each sample and treatment. These values were then converted into total color difference (ΔE) and chroma (C^*) as follows:

$$\Delta E = ((\Delta L^*)^2 + (\Delta a^*)^2 + (\Delta b^*)^2)^{1/2}$$

$$C^* = ((a^*)^2 + (b^*)^2)^{1/2}$$

These color parameters can assist in relating instrumental data to visual perception. Chroma indicates the strength of chromatic response, essentially the saturation of the color, lightness gives the brilliance of the color, and total color difference/change gives the overall magnitude of change of the sample in relation to the control.[22]

Statistical Analysis. Data analysis was carried out using one-way ANOVA to detect differences among the means, and Fisher's least significant difference was used to separate means with $P < 0.05$. Statistical analysis was done using JMP Pro (version 10.0.0, SAS Institute, Cary, NC, USA).

RESULTS AND DISCUSSION

Anthocyanin Composition of the Different Pigmented Maize Color Classes. The anthocyanins identified in the diverse set of pigmented maize samples analyzed in this study (Figure 1) were generally similar to those previously reported.[11,14] The seven major anthocyanins identified were cyanidin-3-glucoside, pelargonidin-3-glucoside, peonidin-3-glucoside, cyanidin-3-(3″-malonylglucoside), cyanidin-3-(6″-malonylglucoside), pelargonidin-3-malonylglucoside, and peonidin-3-malonylglucoside (Figure 1). The malonylglucoside isomers of cyanidin were distinguished mainly on the basis of LC elution profiles, by comparison to published literature.[12−14] The cyanidin-3-(6″-malonylglucoside) elutes later than cyanidin-3-(3″-malonylglucoside) under conditions used in this study.[13,23] The two dominant anthocyanins in all color classes were cyanidin-3-glucoside (m/z 449, positive mode) and cyanidin-3-(6″-malonylglucoside) (m/z 535). On average, these two major pigments together accounted for approximately 80% of HPLC resolved anthocyanin peaks (Table 2). We did not detect any of the condensed flavonoid−anthocyanin dimers previously reported in some maize

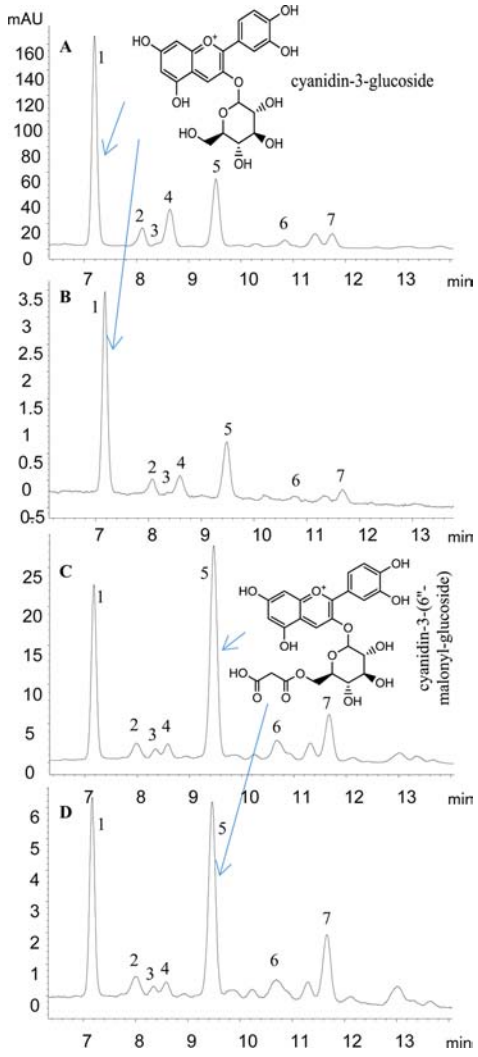

Figure 1. Representative HPLC chromatograms from the Weslaco, TX, 2011, set of samples depicting the differing anthocyanin profiles of a purple maize sample (Wenwei1 R5 × Maize Morado R11) (A) and a red maize sample (Wenwei2 R6 × LH287 R8) (B) versus a red/blue maize sample (Wenwei2 R6 × Lfy Blue R1) (C) and a blue maize sample (Lfy Blue R1 × Ethiopia Blue2 R9) (D) monitored at 520 nm. Numbers identify anthocyanins present: 1 = cyanidin-3-glucoside; 2 = pelargonidin-3-glucoside; 3 = cyanidin-3-(3″-malonylglucoside); 4 = peonidin-3-glucoside; 5 = cyanidin-3-(6″-malonylglucoside); 6 = pelargonidin-3-malonylglucoside; 7 = peonidin-3-malonylglucoside.

varieties[24] in the diverse set of samples we investigated. Such condensed pigments provide far more stable color quality parameters over a wide pH range than their noncondensed analogues.[25] Thus, lines that contain these compounds may provide interesting genetic resources for potential improvement of anthocyanin functionality in maize products.

Major differences in pigment profile were observed between the purple and red color classes, on the one hand, and the red/blue and blue color classes, on the other hand (Figure 1). The main difference between these two groups was the proportion of the two major pigments cyanidin-3-glucoside versus the proportion of cyanidin-3-(6″-malonylglucoside). Overall, the purple and red color classes possessed a higher proportion of monomeric cyanidin-3-glucoside, whereas the red/blue and blue color classes contained a higher proportion of acylated cyanidin-3-(6″-malonylglucoside). The acylated anthocyanins on average accounted for 60% of HPLC resolved pigments in blue and red/blue samples, whereas they accounted for only about 42% of the red and purple sample pigments (Table 2). This is an important observation, because the acylated anthocyanins are more stable to food processing conditions; our findings suggest that color class can be used as one component of a selection criteria for breeding maize to enhance accumulation of stable food colorants.

On the basis of the observed difference in anthocyanin profiles, it was hypothesized that the blue and red/blue color classes would maintain more color through thermoalkaline processing due to the higher proportion of the more stable, malonated derivatives in these color classes. Growth environment had minimal effect on anthocyanin profile within a color class, suggesting that genetic background has the dominant effect on determining anthocyanin composition in pigmented corn.

Color class was also predictive of total anthocyanin content of the maize samples (Table 3). Even though the differences among many hybrids within a color class were significant, a clear pattern based on color class was observed. All samples within the purple color class had significantly higher total anthocyanin content than the other color classes (blue, red/blue, and red). Anthocyanin contents (as cyanidin-3-glucoside equivalents, UV−vis spectroscopy) of purple samples ranged from 890 to 3312 μg/g, whereas the other three color classes had much lower anthocyanin contents (8.9−540 μg/g). Among the nonpurple color classes, the red color class had the lowest pigment content, ranging from 8.9 to 127 μg/g, followed by red/blue (69−368 μg/g) (Table 3). The values were generally within ranges reported for different pigmented maize based on a similar method.[11,14,26]

An interesting observation was that anthocyanin content within each color class appeared to be distinctly influenced by the environment (Table 3). All nonpurple phenotypes (red, red/blue, and blue) had significantly ($p < 0.05$) higher anthocyanin accumulation in Weslaco 2011 than in College Station 2013 samples. In fact, on average, Weslaco 2011

samples had 2.3−4 times higher anthocyanins than College Station 2013 samples among the three color classes. The average anthocyanin content for red samples from Weslaco 2011 was 57.8 μg/g, whereas for College Station 2013 the average was 14.7 μg/g. The average anthocyanin contents for red/blue samples grown in Weslaco 2011 and College Station 2013 were 268 and 101 μg/g, respectively. For the blue phenotype anthocyanin contents averaged 429 μg/g for Weslaco 2011 and 186 μg/g for College Station 2013. Among the purple phenotype, the College Station 2013 samples generally had higher anthocyanin (average 2463 μg/g) content than Weslaco 2011 samples (1905 μg/g), but the pattern was not as clear-cut as with the other color classes. Whereas the way in which the specific growth environments affect the accumulation of anthocyanins was not a subject of this study, the fact that growth environment can have such a distinct impact on anthocyanin content of maize is important. Growth environments could potentially be selected or optimized to maximize anthocyanin accumulation in maize for various uses.

Major Copigment Composition of the Maize Samples. A question that remains is how much the appearance of pigmented maize is merely a function of the anthocyanin content, given the LC profiles of anthocyanins were fairly similar among the diverse set of samples. UV−vis spectroscopy of crude extracts at pH 1.0 revealed minor differences in visible λ_{max} among the color classes, except for the red color class (average 516 nm); the blue, red/blue, and purple samples had mean λ_{max} values of 528, 527, and 526 nm, respectively (data not shown). Due to the fact that the two dominant anthocyanins in all samples (cyanidin derivatives) (Figure 1) have similar absorbance maxima, the differences in λ_{max} for the various color class crude extracts may be partly attributed to the profile of copigments that coextract with the pigments. Also, in view of the significant overlap in anthocyanin contents among the nonpurple color classes (Table 3), it is apparent that appearance is not affected by merely content but possibly inherent copigment profile, as well as other factors.

To determine the possible effect of extracted copigments on crude anthocyanin color, we characterized the major phenolics that were extracted along with the anthocyanins. The major extractable phenolic compounds identified in all of the maize samples were three phenolic amides; *N*,*N*′-dicoumaroylspermidine, *N*-coumaroyl-*N*′-feruloylputrescine, and *N*,*N*′-diferuloylputrescine (Tables 4 and 5). These phenolic amides have been identified as significant components of methanolic extracts from maize, especially in the bran fraction,[20,27,28] and were suggested to be associated with insect resistance in grain[29] and may have interesting bioactive properties.[30] The concentrations of the phenolic amides in the maize samples were relatively high in comparison to the literature values (Table 5).

Important differences were observed in phenolic amine profiles of the samples (Table 5). The red color class had on

[a]Refer to Table 1 for sample genetic background. All data expressed as mean ± SD of duplicates on a dry weight basis. Values within the same column with no letters in common are significantly different ($p < 0.05$). [b]Sample from College Station 2011. [c]na = sample not available.

average much higher content of extractable putrescines (average 574 μg/g) compared to other color classes (average 134−379 μg/g); the red/blue had the second highest content (379 μg/g). On the other hand, the red samples had the lowest average spermidine content (191 μg/g), whereas the blue samples had the highest (351 μg/g). The specific effect of the phenolic amides on anthocyanin color cannot be conclusively determined from these data. However, the different patterns of putrescines (higher in red color) and spermidine (higher in blue color) content in the different color classes suggest that copigments in colored maize likely contribute to shifts in anthocyanin absorption maxima in a way that may influence color appearance of pigmented maize. This is especially important because, as discussed under the thermoalkaline processing section below, the initial color hue has a major impact on visible color changes during processing.

An array of other phenolic compounds, mostly phenolic acids (ferulic, caffeic, and *p*-coumaric) and their glycerol esters (Table 4) were also present in minor quantities in all sample extracts. Interestingly, the glycerol esters of phenolic acids are abundant in sorghum[31,32] but have not been previously reported in maize. No clear pattern was observed for these minor phenolics in the samples; thus, their contribution to anthocyanin color could not be inferred.

Effect of Thermoalkaline Processing on Color Parameters. For processing, samples with yellow endosperm were excluded from tristimulus color analysis to remove this as a confounding variable. Alkaline pH and high temperature are two of the main factors that lead to transformation and degradation of anthocyanins.[33] In the nixtamalization process used in this study, the pH during processing was 4.82 ± 0.34 at 0% lime (control), 9.06 ± 0.52 at 0.5% lime, and 10.74 ± 0.76 at 1% lime (these measurements were taken on the nejayote after cooking and steeping). Additionally, the samples were lime-cooked in a water bath at approximately 100 °C, so the two harsh conditions were combined in nixtamalization and tortilla chip processing, which promoted the degradation of anthocyanins and subsequent color loss/change.

Lightness plays a substantial role in visual color perception. If a sample is too light or too dark, changes in chroma or hue may be imperceptible. The lightness was expected to decrease with an increase in pH due to the fact that in alkaline pH, anthocyanins become blue/purple/black in color from the predominance of quinoidal bases, which produces a dull appearance.[34] This trend was observed in the red/blue, blue, and red color classes (Figure 2; Table 6). Samples from the purple color class appeared and behaved differently from samples of the other three color classes throughout processing

Figure 2. Effect of increasing lime concentration on visual appearance of the four color classes of maize: (A) red/blue; (B) blue; (C) red; (D) purple maize. The left column is 0% lime, 0.5% lime is in the middle, and 1.0% lime is in the far right column.

because they were essentially too dark to detect many differences with the colorimeter. As expected, lightness values of masa were relatively high compared to those of nixtamal (Table 6) due to the exposure of the white endosperm from the grinding step. The red and red/blue color classes generally had the most dramatic change in color of masa as lime concentration increased (Table 6), which was supported by visual appearance of their respective nixtamals (Figure 2). The formation of dark blue quinoidal bases that increase with rising pH at the expense of reddish/yellow hues[33,34] was mostly responsible for this observation. This was confirmed by the large decrease in a^* and b^* color parameters for nixtamal of these two color classes compared to the blue and purple color classes (Table 6). For the tortilla chips, the L^* values did not follow a pattern due to a confounding effect of pillowing or puffing that occurred when frying, which caused the chips to appear brighter, especially at higher lime concentration. More pillowing occurred at higher lime concentrations because the pericarp was more solubilized and thus helped seal the masa surface, trapping moisture and creating pillows when the chips were fried.

In agreement with the visual evidence (Figure 2), the chroma values for red and red/blue sample nixtamal experienced the most dramatic changes, dropping from 27.4 (control) to 12.0 (0.5% lime) and 13.5 (1% lime) for red/blue and from 24.8 (control) to 4.0 (0.5% lime) and 2.3 (1% lime) for red samples (Figure 3) due to the darkening effect of high pH on anthocyanin color. The much larger change in chroma of red compared to red/blue samples can be partly explained by the average loss of anthocyanins to the steep water (nejayote) during nixtamalization. The red sample retained the most pigments at both lime concentrations (Figure 4); the retained pigments contributed to the darker color (and thus lower chroma) at higher pH. The higher pigment retention in the red samples was mostly attributed to the fact that these samples had a visually tougher pericarp, which did not break down as easily

[a]Values are averages within each color class; all data expressed as mean ± SD.

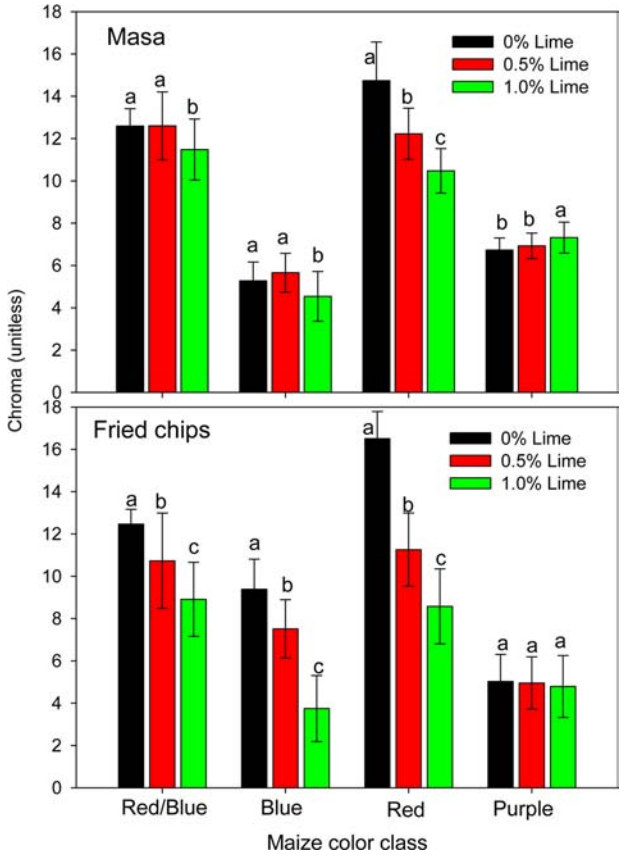

Figure 3. Effect of increasing lime concentration on chroma of red/blue, blue, red, and purple maize samples processed into masa (top) and fried chips (bottom). Data are expressed as mean ± SD; values are averaged for samples from both locations. Columns with different letters within color class are significantly different ($p < 0.05$, Tukey HSD).

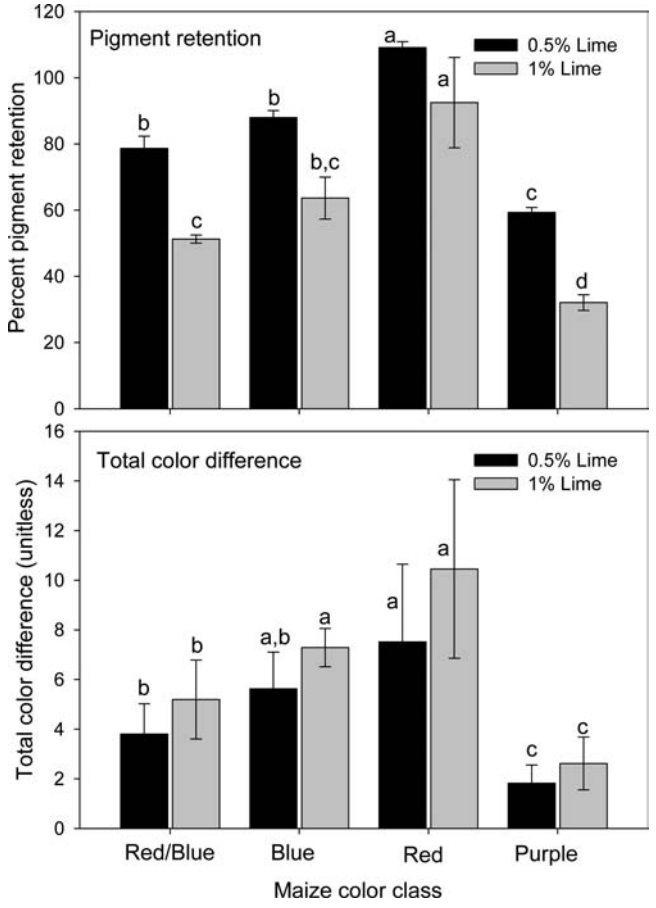

Figure 4. Effect of lime concentration on pigment retention (top) and total color difference (bottom) in processed pigmented maize chips. Values are relative to respective samples processed without any lime. Anthocyanin pigment retention was determined using UV−vis spectrophotometry method; total color differences were calculated from tristimulus color parameters as described under Materials and Methods. Data are expressed as mean ± SD; values are averaged for samples from both locations. Columns with different letters are significantly different ($p < 0.05$, Tukey HSD).

as the other samples during nixtamalization and thus protected most of the pigments from leaching into the nejayote. On the other hand, the blue samples actually showed increasing chroma from 8.1 (control) to 18.8 (0.5% lime) and 14.0 (1% lime). This can be explained by two possible causes; (i) because

[a]Cy = cyanidin, Glu = glucoside, Mal = malonyl. Anthocyanin levels in processed red samples were too low to resolve on HPLC. [b]Based on resolved anthocyanin peaks monitored at 520 nm.

the dark blue color hue of these samples closely matches the quinoidal base hues, a darkening effect of alkaline pH was not as apparent, and (ii) partial loss of anthocyanins during the nixtamalization process led to a brighter nixtamal that partially overcame the darkening effect of the rising pH. However, the fact that the blue samples were the only color class without pigments in the pericarp (all pigment in the aleurone layer) may have also contributed to the observations. The aleurone layers may protect the anthocyanin color quality better than the pericarp during alkaline cooking. This is because the alkaline-induced partial solubilization of the pericarp will lead to release of the anthocyanins and other reactive compounds from the cellular matrix. Interactions of the freed anthocyanins with other released compounds would likely contribute to altered anthocyanin color properties.

A clear trend of decreasing chroma was observed in masa from the red color class, but masa from the other three color classes experienced only modest changes in chroma at either lime concentration (Figure 3). Again, because the red samples retained most of their pigments during the nixtamalization process, the darkening effect of high pH on anthocyanins would be most apparent in their masa. In the chips, a trend of decreasing chroma with increasing lime concentration was more easily observed (Figure 3). All color classes (except purple) showed a significant decrease in chroma when the control chip was compared to the lime treatments. Samples from the purple color class had insignificant changes in chroma likely due to the extreme darkness of the chips at all lime concentrations, which made differences not easily distinguishable instrumentally or even visually. Among the nonpurple samples, red and blue chips showed the largest decline in chroma as lime concentration (and pH) increased. The red/blue chips had relatively high chroma values and showed the lowest magnitude of change in chroma as lime concentration increased. These samples produced chips that were more visually appealing because they were less dull compared to all other chips and were closer in appearance to the starting raw material than the red and blue samples.

Effect of Thermoalkaline Processing on Anthocyanin Content and Profile. As hypothesized, samples from the red/blue and blue color classes, which contain higher proportions of cyanidin-3-(6″-malonylglucoside), retained proportionately more anthocyanins than the purple sample at both lime concentrations (Figure 4). HPLC analysis of anthocyanins retained during thermoalkaline processing confirmed the UV–vis data (Table 7). The red and red/blue samples retained 37–81% of measurable anthocyanins, whereas the purple maize retained 3.4–53% of the measurable anthocyanins after processing into chips compared to raw maize (Table 7). Higher lime concentration generally resulted in lower anthocyanin retention in the chips, likely due to adverse effect of higher pH on anthocyanin stability. Anthocyanin retention in the chips was much higher than those previously reported for red and blue maize samples.[17] This is mainly due to the fact that the vast majority of anthocyanin loss during thermoalkaline processing is due to the initial cooking and steeping, which leads to pigments leaching into steep water (usually discarded) as previously demonstrated.[17] In our study, we used just enough water to cook and steep the maize, and thus little steep water was lost. In fact, de la Parra et al.[17] showed (and our data confirm) that the thermal processes involved in baking and frying steps of tortilla chips are too short to result in meaningful anthocyanin degradation. This shows that anthocyanins can be retained much better in pigmented maize during processing by reducing steeping losses.

It was interesting to note that thermoalkaline processing resulted in a higher proportion of monomeric anthocyanins retained compared to acylated anthocyanins in all processed samples, relative to raw maize (Table 7). This was counter to our expectation that the acylated anthocyanins would be retained more. A likely explanation is that the alkaline pH, in combination with heat, resulted in deacylation of some of these anthocyanins into their monomeric forms. Acyl ester bonds are alkaline labile, whereas the glycosidic linkages are more sensitive to acidic pH. Another possible explanation is that the acylated anthocyanins self-associated or polymerized more readily under the conditions used in this study into complexes that did not resolve in HPLC. This may explain why the high-anthocyanin purple maize showed such a dramatic decline in measurable anthocyanins, especially acylated forms, during processing (Table 7), which did not match visual color observations (Figure 2). Anthocyanin self-association and

DOI: 10.1021/acs.jafc.5b00798
J. Agric. Food Chem. 2015, 63, 5528–5538

aggregation increase significantly as their concentration increases,[35] especially at neutral to higher pH.[36] Thus, anthocyanin "retention" in processed samples must be interpreted in the context of the limitations of the detection methods used.

However, it is worth noting that total pigment retention (Figure 4; Table 7), which has been the major target of published investigations in this subject area, was not a good predictor of color performance during processing. How the retained anthocyanins maintain desirable color properties is more important, and this may be a function of anthocyanin structure, content, and composition and copigment profile, as well as the location and interaction of the anthocyanins with nonphenolic constituents in the grain. The total color difference generally agreed with chroma data and supported our own observations. Among the nonpurple samples, the chips from the red/blue samples had the lowest color difference, whereas the red ones had the highest color difference in lime treatments compared to control (Figure 4). Also worth noting is the fact that, even though total color difference generally positively correlated with pigment retention (r = 0.41), this correlation was weak and disappeared when samples were compared within color class (data not shown), indicating that color performance is more complex than mere changes in measurable anthocyanin pigments.

The fact that 2−4 times higher pigments were accumulated in nonpurple maize in one location than the other suggests that specific environmental parameters have a significant nonrandom impact on anthocyanin biosynthesis in maize; this warrants further investigation. Also, the differential color class responses in the two environments suggest that specific genetic traits are more responsive to the environment. Thus, maize with desirable accumulation of high-value pigments and other bioactive compounds for food use could be developed for specific environments. The implications of the high level of phenolic amide in the maize lines used in this study on potential health benefits of the pigmented maize also warrant investigation.

A major concern to food manufacturers when using natural pigments is color predictability in the final product. Often raw materials are selected with the assumption or expectation that they will retain desirable color attributes in the final product. Thus, predictable performance with minimal changes in color during processing, and not just the final product color, is an important advantage in raw material selection. The red/blue samples seem to have an advantage over other color classes for direct thermoalkaline processing into snacks; they retained their appearance and brilliance the best during processing. Even though acylation improves the stability of anthocyanin pigments to color degradation in solution, such stability is not necessarily predictive of performance of the pigments in situ in products. In all, it is apparent that targeted genetic improvement efforts can produce colored maize with improved performance for thermoalkaline processing. This would eventually lead to expanded demand for such products and, perhaps, healthier grain-based snack offerings.

visceral fat deposition, serum triacylglycerols, and blood glucose in mice and rats.[8]

Sterols oxidize when subjected to heating treatments and/or high temperatures. The effects of culinary processes (such as frying and oven cooking) have been imitated by choosing 180 °C as the heating temperature for most investigations.[14] After 1 h of heating in a conventional oven at this temperature, Menéndez-Carreño et al.[9] found a progressive decrease in stigmasterol content, as well as formation and subsequent degradation of POPs. Xu et al.[15] investigated the oxidative stability of β-sitosterol in a mix with edible oils heated at 180 °C in an oven; after 120 min of heating, a 75% degradation of β-sitosterol was observed. The same research group, Xu et al.,[16] used a mix of β-sitosterol and triacylglycerols with different fatty acid profiles, observing that heating at 180 °C for 120 min led to 85% degradation of β-sitosterol; it seems that the surrounding fatty acids affected sterol oxidation in a time-dependent manner and their effect was unlikely related to their degree of unsaturation. Other studies have shown how the interaction between the conditions used (diverse temperature exposure, heating time, and lipid matrices) can drastically impact PS stability, especially the type of oxidation products, their content and the reaction pathways of oxidation.[17,18]

Among the different cooking techniques, the use of microwave (MW) heating has widely spread in the past two decades at both the domestic and catering levels for cooking, reheating, or thawing food, as it is a fast and easy technique to be employed for the consumption of processed and frozen foods. MW heating of food results from two types of interactions between food components with microwaves: ionic conduction and dipolar rotation.[19] The MW cooking/heating time will thus be greatly influenced by the food dielectric properties (dielectric constant and dielectric loss factor), which are related to the food composition.[20] Despite the large utilization of MW heating, to the best of our knowledge, there are no available data on PS oxidation during microwaving; in fact, only the influence of frying, boiling, and oven heating on sterol oxidation in model systems[14,17,21,22] and food[23−25] has been studied. For a better understanding of how MW heating could impact PS stability, it would therefore be important to first assess PS behavior in a model system during microwaving.

The aim of this study was to evaluate the oxidative stability of PS during MW heating, using two different model systems (a solid film made with a phytosterol mixture (PSF) and a liquid mixture of phytosterols and triolein (PS + TAG (triacylglycerol), 1:100, w/w).

MATERIALS AND METHODS

Reagents and Solvents. All solvents used were of analytical grade. Reagents were supplied by Carlo Erba Reagenti (Rodano, Italy) and Merck (Darmstadt, Germany). β-Sitosterol was purchased from Santa Cruz Biotechnology Inc. (Heidelberg, Germany) (purity 41% β-sitosterol, 23% campesterol, 23% stigmasterol). Triolein was supplied by Nu-Check (Elysian, MN). 5α-Cholestan-3β-ol (dihydrocholesterol, IS; purity 95%), cholest-5-en-3β,19-diol (19-hydroxycholesterol, 19-HC; purity 99%), cholest-5-en-3β,7α-diol (7α-hydroxycholesterol, 7α-HC; purity 99%), cholest-5-en-3β,7β-diol (7β-hydroxycholesterol, 7β-HC; purity 90%), 5α,6α-epoxycholestane-3β-ol (α-epoxycholesterol, α-CE; purity 87%), 5β,6β-epoxycholestan-3β-ol (β-epoxycholesterol, β-CE; purity 80%), cholestane-3β,5α,6β-triol (cholestanetriol, triol; purity 99%), cholest-5-en-3β-ol-7-one (7-KC; purity 99%), and 5-cholestene-3β,25-diol (25-HC; purity 98%) were purchased from Sigma (St. Louis, MO). Glass thin-layer chromatography (TLC) silica plates (20 cm × 20 cm × 0.25 mm film thickness) were supplied by Merck (Darmstadt, Germany). Silica solid-phase extraction (SPE) cartridges (500 mg/3 mL Strata cartridges) from Phenomenex (Torrence, CA) were utilized for POP purification. The silylation mixture was prepared with dried pyridine, hexamethyldisilazane, and trimethylchlorosilane at a ratio of 5:2:1 by volume.

Experimental Design. Two different model systems were used: (a) A phytosterol film (PSF) was prepared with a solution of PS in chloroform (1 mg/mL, composed of 41% β-sitosterol, 23% campesterol, and 23% stigmasterol). An aliquot of 1 mL was transferred to a previously weighed vial (5 mL, 22.00 × 38.25 mm) and taken to dryness under nitrogen flow. (b) A mixture of phytosterols and triolein (PS + TAG) was prepared with a solution of PS in chloroform (1 mg/mL, composed of 41% β-sitosterol, 23% campesterol, and 23% stigmasterol). An aliquot of 1 mL was transferred to a previously weighed vial (5 mL, 22.00 × 38.25 mm), taken to dryness under nitrogen flow, weighed again, added to about 100 mg of triolein, and thoroughly mixed by vortexing.

A domestic multimodal MW oven was used for sample heating (Panasonic NN-CT756, Domestic MW, Bracknell, U.K.). Samples in the opened vials (n = 4 for each model system, 3 of which were for sampling and 1 of which was for temperature control) were placed at the center of the rotatory turntable plate of the oven and exposed (without caps) at a power of 1000 W. Samples were independently heated for 1, 1.5, 3, 6, 12, 20, and 30 min. All heated samples were allowed to cool at room temperature (23 ± 1 °C) after thermal treatment. For each run time, a vial, with triolein or film, was used to measure the temperature of the system. The temperature of the samples was measured immediately after MW exposure, by inserting a thermocouple (K-type; Ni/Al−Ni/Cr) connected to an acquisition system (HI 98804, Hanna Instrument, Villafranca Padovana-PD, Italy) at approximately the geometrical center of the control sample. A 1 mL volume of chloroform was added to each tube, and the tubes were shaken vigorously for 40 s and kept at −20 °C until analysis.

Qualitative TLC of Oxidized Model Systems. Qualitative silica TLC was carried out to verify the formation of polymerization products in the PS + TAG system after oxidation in the MW oven. About 100 mg of the oxidized PS + TAG system was placed in an open vial and heated in the MW oven for 30 min. The sample was then resuspended in 1 mL of chloroform, and an aliquot (0.2 mg/20 μL) was spotted on a 10 cm × 20 cm silica TLC plate. A triolein standard was also loaded as a reference spot (0.2 mg). The mobile phase was a mixture of diethyl ether/n-hexane (35:65, v/v); the TLC plate was developed at 4 °C for 20 min. The TLC bands were visualized by spraying a phosphomolybdic acid solution (20 wt % in ethanol) and then were charred in an oven at 180 °C for 20 min.

Purification and Quantification of PS. PS purification was achieved by using the silica solid-phase extraction (SPE) method described by Bortolomeazzi et al.[26] A known amount of 5α-cholestan-3β-ol (internal standard; 500 μL from a 2 mg/mL solution in n-hexane/2-propanol (3:2, v/v)) was added to 1/10 of the sample for PS quantification. Briefly, apolar lipids were removed by 5 mL of n-hexane/diethyl ether (8:2, v/v), while the polar fraction that contained PS was eluted with an n-hexane/diethyl ether solution (1:1, v/v) and methanol. The eluted fraction was taken to dryness under nitrogen flow, and the PS were silylated at 40 °C for 30 min.[27] The silylated samples were dried under nitrogen flow at 40 °C and dissolved in 1 mL of n-hexane.

The GC determination of sterols was performed with a GC HRGC 5300 (Carlo Erba, Milan, Italy) instrument, equipped with a split−splitless injector, a flame ionization detector (FID), and a computerized data acquisition system (Turbochrom Navigator software, version 6.1.1.0.0:K20, PerkinElmer, Norwalk, CT). The separation of the silylated sterols was performed with a CP-SIL 5CB Low Bleeds/MS column (30 m × 0.32 mm i.d. × 0.25 μm film thickness) (Varian Chrompack, Middelburg, The Netherlands), coated with 100% dimethylpolysiloxane. The oven temperature was programmed from 265 to 280 °C at 0.5 °C/min and then from 280 to 325 °C at 4 °C/min; the injector and detector temperatures were

DOI: 10.1021/acs.jafc.5b00961
J. Agric. Food Chem. 2015, 63, 5539−5547

both set at 325 °C. Helium was used as the carrier gas at a flow of 2.9 mL/min; the split ratio was 1:15. The analysis was run in triplicate.

Sterols were identified by comparing their retention times with those of solutions of silylated sterol standards and further confirmed by injection into a fast gas chromatography−mass spectrometry (Fast GC−MS; same conditions as used for POP analysis) system. Sterols were quantified with the internal standard method, using 5α-cholestan-3β-ol. Their response factors were evaluated with respect to the internal standard.

Purification and Analysis of POPs. Regarding the determination of POPs, the remaining 9/10 of the initial sample solution was purified by silica SPE (Supelclean LC-Si, 500 mg/3 mL) (Supelco, Bellefonte, PA), according to the method suggested by Guardiola et al.[28] A 20 μL volume of internal standard 19-hydroxycholesterol (0.5 mg/mL of *n*-hexane/2-propanol (4:1, v/v)) was added to the sample, dried under nitrogen flow, and redissolved in *n*-hexane/diethyl ether (95:5, v/v) before sample purification. The SPE cartridge was previously activated with 5 mL of *n*-hexane before sample loading and then washed with *n*-hexane (5 mL) and different solvent mixtures of *n*-hexane/diethyl ether (10, 30, and 10 mL of 95:5, 90:10, and 80:20, v/v, mixtures, respectively). The POP fraction was finally eluted with 10 mL of acetone, subjected to silylation, and dissolved in 0.5 mL of *n*-hexane.

POPs were determined and quantified by fast GC−MS. A Shimadzu QP 2010 Plus gas chromatograph (Kyoto, Japan) equipped with a split−splitless injector and coupled to an electron impact (EI) mass spectrometric detector was used. The separation was carried out by a fused-silica capillary column, Restek RTX-5 (10 m × 0.1 mm i.d. × 0.1 μm film thickness; Bellafonte, PA), coated with 95% dimethyl- and 5% diphenylpolysiloxane. A nonsilanized standard split liner (95 mm × 5 mm o.d. × 3.4 mm i.d.) was utilized. The temperature was programmed from 210 to 325 °C at 15 °C/min and kept for 5 min at 325 °C. The injector, the ion source, and the transfer line temperatures were set at 340, 200, and 340 °C, respectively. The injection was performed in the split mode (1:50). Helium was used as the carrier gas at a linear velocity of 47.7 cm/s. The electron energy was 70 eV. A mass range from 40 to 650 *m*/*z* was scanned at a rate of 2500 amu/s. The acquisition and integration modes were full-scan total ion current (TIC) and single ion monitoring (SIM), respectively. Identification of POPs was performed by comparing their retention times and mass spectra with those reported in previous studies.[29−31] POPs were recognized and quantified by their corresponding characteristic ions with a high abundance obtained in the SIM mode (*m*/*z*): IS (19-hydroxycholesterol) (353), 7α-hydroxycampesterol (470), 7α-hydroxystigmasterol (482), 7α-hydroxysitosterol (484), 7β-hydroxycampesterol (470), 7β-hydroxystigmasterol (482), 7β-hydroxysitosterol (484), 6β-hydroxycampesterol (417), 6β-hydroxystigmasterol (429), α-epoxysitosterol (412), β-epoxysitosterol (412), α-epoxystigmasterol (253), β-epoxystigmasterol (253), 7-ketocampesterol (381), 7-ketostigmasterol (386), 6-ketositosterol (473), 7-ketositosterol (500). Considering that most POP standards are not commercially available and assuming that POP fragmentation is similar to that of cholesterol oxidation products (COPs), the quantification of POPs was carried out using calibration curves of oxycholesterols built by quantificator ions with relative abundances similar to those of the ions chosen for oxyphytosterol quantification.[32] Three independent replicates were run per sample.

Statistical Analysis. The mean and standard deviation of each sample's data were calculated. One-way analysis of variance (ANOVA), with Tukey's post hoc multiple comparisons test ($p < 0.05$), was applied to evaluate the significant differences on PS and POP amounts over the MW heating time and between the PSF and PS + TAG models throughout the MW heating process. The SPSS 15.0 program (SPSS, Inc., Chicago, IL) was used for the statistical analysis of the data.

For the kinetic evaluation of PS degradation, a first-order regression analysis of the data was performed using Excel 2008, and the fitting goodness was evaluated on the basis of the regression coefficient (R^2) and the associated *p* value.

RESULTS AND DISCUSSION

Table 1 reports the temperatures reached at each heating time during the two MW experiments, showing that they varied according to the type of model system. The temperature recorded for PSF was lower than that of PS + TAG. This could be mostly attributed to their different compositions and physical status (PSF was a solid film, while PS + TAG was a liquid), as well as the specific heat of triolein, which could have affected their dielectric properties and thus their heating capacities. Another factor that might have partly contributed is the technology of the multimodal domestic MW oven, since the electromagnetic waves enter the cavity, move, and bounce off the walls, generating pockets (called modes) of high and low energy that create a nonuniform microwave field. Moreover, this type of MW oven is unable to deal with power variations and to maintain a constant temperature as unimodal microwave ovens do.

Table 1. Temperature Reached by the Model Systems during Heating in a Multimodal Microwave Oven

	temperature (°C)			temperature (°C)	
time (min)	PSF	PS + TAG	time (min)	PSF	PS + TAG
1.5	43.9	47.5	12	117.05	160.4
3	68.8	61.6	20	140.9	161.9
6	90.5	105.9	30	151.8	159.5

Unreacted PS Trends during MW Heating. The presence of crystals was observed in the PS + TAG model after 20 and 30 min of heating, so silica TLC was performed to verify the occurrence of polymerization products in the mixture, as they could modify the stationary phase of the GC column and affect its peak resolution capacity. Figure 1 shows the TLC plate of the PS + TAG model after 30 min of heating, which qualitatively evidenced a higher degree of polymerization with increasing heating time. Therefore, silica SPE was run for all samples before GC analysis of PS, to remove apolar lipids and polymerization products.

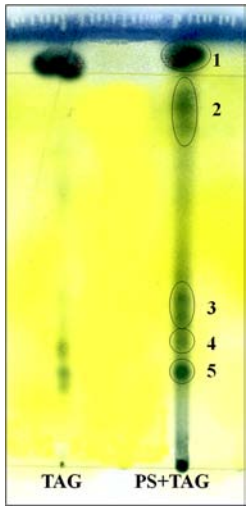

Figure 1. TLC plate of a PS + TAG mixture after 30 min of MW heating. Peak identification: 1, triolein; 2, polymerization products (three bands); 3, free fatty acids; 4, diacylglycerols; 5, phytosterols.

Figure 2 reports the amounts of remaining PS in both model systems after MW heating (0−30 min); the full data with the corresponding statistical treatment are reported in the table in the Supporting Information. In the PSF system, a marked PS degradation (∼30%) was noted in the first 1.5 min of microwaving, which remained almost constant up to 6 min of heating; thereafter, PS showed a continuous, fast drop rate, and at the end of 30 min heating, only about 24% of the initial PS content was observed. The single PS displayed a similar degradation trend, being slightly more pronounced for campesterol than for the other two PS. These results are similar to those obtained by Barriuso et al.,[14] who found the following sterol susceptibility to degradation: campesterol ≈ β-sitosterol ≥ stigmasterol. The authors reported that the experimental heating conditions (temperature/exposure time, modality (e.g., MW, convection, conduction), initial PS amount, sample area/container volume ratio, open/closed container during heating) and PS composition (single PS or mixtures with diverse relative percentages) can differently affect the extent of PS degradation. In PSF, the extent of PS degradation was lower (∼76%) than that observed (∼88%) at 180 °C after 30 min of heating in a thermoblock;[14] such differences could be mainly ascribed to both the diverse temperatures and heating modalities applied (MW vs conduction), as they led to different real sample temperatures. Xu et al.[15] found ∼50% degradation of β-sitosterol when it was heated in a conventional oven at 180 °C for 60 min, being higher than sterol degradation at 150 and 120 °C for 60 min, while Menéndez-Carreño et al.[9] observed ∼38% degradation of the initial stigmasterol at 180 °C after 1 h in a Termaks oven. Derewiaka et al.[33] heated cholesterol at different temperatures (from 120 to 220 °C) and exposure times (from 30 to 180 min); the authors found similar cholesterol concentrations after heating at 150 and 180 °C and the most intense losses at 220 °C, confirming that thermoxidation of cholesterol rapidly increased above its melting point.

Regarding the PS + TAG system, PS also greatly degraded (about 25%) in the first 1.5 min of heating, remaining almost constant up to 12 min. Thereafter, as for the PS + TAG system, a gradual PS drop was noted and about 32% of the initial PS content was detected after 30 min of heating. In this case, all PS exhibited an analogous degradation behavior. However, the extent of PS degradation was much higher (∼68%) than that found (∼21%) when cholesterol + triolein was heated at 180 °C for 30 min in a conventional oven;[21] this distinctive behavior might be attributed to the different heating modalities (MW vs convection), whose influence is more evident in a liquid system than in a solid one. After 30 min of microwaving, only 32% of the PS remained in the PS + TAG system, being in agreement with the amount found in a model system made of stigmasterol, cholesterol, and sunflower oil, and heated at 180 °C for 180 min.[34] This result showed how diverse experimental conditions and temperatures can have a different impact depending on the surrounding matrix. When comparing the two model systems, PS degraded faster when they were microwaved alone than in the presence of TAG, displaying different trends at both the initial and prolonged times of heating. These results are in agreement with those of Soupas et al.,[17] who reported that at high temperature the unsaturated matrix was more quickly oxidized, protecting sterols as observed in the PS + TAG model. In the PS system, the only reactive lipids are phytosterols, so they react more readily following the typical radical chain reaction mechanism of oxidation. Table 2 reports the sterol loss rate throughout the MW heating process in terms of the observed first-order rate constants. All data satisfactorily fit the kinetic model with very high determination coefficients. All sterols in the PS + TAG model exhibited similar degradation rates (k values of 0.03), which were lower than those of the PSF model (0.04), thus confirming that sterol degradations within the same models were similar; furthermore, their degradation was slower in the PS + TAG system.

J. Agric. Food Chem. 2015, 63, 5539−5547

The behavior described in the previous paragraph could be attributed to the physical/steric protection of TAG toward PS, combined with the dilution effect, which led to a lower air contact, thus hampering oxidation.[35] Moreover, triolein used as the in the model system may have also competed with PS for oxidation. Similar results were found when the influence of the degree of unsaturation of different TAGs on cholesterol oxidation was evaluated at 180 °C in an conventional oven;[21] in this study, both the presence of TAGs and their unsaturation degrees inhibited cholesterol thermoxidation. Other researchers found that the sitosterol oxidation rates in phytosteryl ester- and free phytosterol-enriched rapeseed oils subjected to pan-frying at 160 °C for 10 min were ≤0.4%.[36] However, in our study, 5- and 23-fold higher orders of magnitude of the total phytosterol oxidation rate were noted at 12 min of microwaving for the PS + TAG and PSF systems, respectively. Such differences in sterol oxidation rate could be attributed to the presence of higher unsaturated lipid molecules, which may have exerted a protective effect toward PS through different possible mechanisms (such as competition for oxidation, dilution, and physical protection). When Xu et al.[16] evaluated the interaction of fatty acids with β-sitosterol oxidation, they noted ∼15% degradation of the initial β-sitosterol in the presence of oleic acid if heated at 180 °C for 30 min in an oven. When the heating time increased to 60 min at 180 °C, the four fatty acids (with 18 C atoms and different degrees of unsaturation) accelerated the β-sitosterol degradation (∼70% decrease), and thereafter, their oxidation-promoting effect became weaker or diminished; the authors concluded that the surrounding fatty acids affected the PS oxidation in a time-dependent manner and their effect was unlikely related to their level of unsaturation. This conclusion is in agreement with our study, in which different degradation trends were observed depending on the system considered. In the PS + TAG system, after the drastic PS drop at 3 min of microwaving, no degradation change was noticed between 3 and 12 min, and thereafter, a weak decline occurred.

Another aspect to consider is that, at elevated temperatures (>150 °C), polymerization, dehydration, and formation of midpolar and polar compounds can occur.[9,18,37−40] PS can also generate volatile compounds during oxidation, which may arise from breakdown of the side chain followed by molecular rearrangement.[18] In the present study, PS + TAG reached 161.9 and 159.5 °C after 20 and 30 min of MW heating, respectively, so polymerization could take place, as evinced by TLC fractionation (Figure 1). The proportion of the different polymerization products depends on the conditions used; Dobarganes[37] reported that only dehydrodimers have been found in significant amounts at 150 °C, while mono-, bi-, and tricyclic dimers are mainly generated above 250 °C. Some authors have reported that the average polymerization temperature of polar sterol oxides is approximately 180 °C.[9,40,41]

POP Formation. The trimethylsilyl (TMS) derivatives of POPs were analyzed by Fast GC−MS. The characteristic mass fragmentation pattern produced by EI (Table 3) was used to identify the main POPs, on the basis of those reported in previous studies.[29,30,42] As reported in Table 3, 16 POPs were identified and a specific ion was selected for each POP, on the basis of abundance and specificity. In particular, 7-hydroxysterols (α and β), 6β-hydroxysterols, epoxysterols (α and β), and 7-ketosterols originated from oxidation of the main phytosterols (β-sitosterol, stigmasterol, and campesterol) were formed in both systems.

Table 3. Characteristic Mass Fragmentation Pattern of the Main POPs and the Selected Ions for Their Quantification

phytosterol oxidation product	retention time (min)	m/z[a]	characteristic fragmentation
7α-hydroxycampesterol	8.611	470	129, 233, 455, 470, 471, 472, 560

7-ketositosterol	12.201	500	129, 161, 395, 410, 483, 500, 501, 502

[a]The m/z column reports the ions selected for POP quantification purposes.

All PS examined in this study (campesterol, stigmasterol, and β-sitosterol) produced detectable and quantitative amounts of hydroxy, epoxy, and keto derivatives in the ring structure. The phytosterol oxides found are analogous to the major cholesterol oxidation products obtained by autoxidation and thermoxidation, following similar reaction pathways. The major site of POP formation is at C-7 on the second ring, where hydroperoxides and hydroxy and keto sterols are formed. Other major oxidation products that can be produced in the ring structure are epoxides and triols. The formation of epoxides by autoxidation occurs by a bimolecular mechanism that involves one hydroperoxy radical and one unoxidized sterol molecule.[1]

Table 4 reports the single and total POP contents (expressed as micrograms per milligram of phytosterols) of the PSF and PS + TAG models heated in a multimodal MW oven. The evolution of 16 different POPs was followed in this study. In our experimental conditions, with a time lapse from 6 to 12 min, POP formation in both model systems was observed just after 12 min of MW heating; prior to that time, no detectable amounts of POPs were found, which does not exclude the possibility that POPs might have formed in the time lapse between 6 and 12 min. This result is opposite to that reported by Menéndez-Carreño et al.,[25] since they found that the highest POP level in phytosterol-enriched milk was formed in the first 1.3 min of heating in a microwave oven at 900 W and 69 °C. Such differences between these two studies could be mainly attributed to the high water content of milk (about 87−88%), which can greatly favor heat generation during microwaving by means of the dipolar rotation mechanism, and thus affect phytosterol oxidation; in addition, the manufacturing processes used for dairy products (e.g., high pressures) and their storage

[a]From 0 to 6 min of heating, no POPs were detected. Each value in the last three columns represents the mean ± standard deviation of three replicates. Different lowercase letters within the same row denote significant differences ($p < 0.05$) among different heating times. For the total of individual oxidized sterols (β-sitosterol, stigmasterol, and campesterol) and total POPs, different capital letters within the same column denote significant differences ($p < 0.05$) for each time among different systems. nd = not detected.

conditions could also influence the initial oxidative status of milk before microwaving, thus impacting POP formation during the heating treatment. However, it must be noted that Menéndez-Carreño et al.[25] found a significant decrease of POP content in phytosterol-enriched milk after 2 min of treatment (304.71 vs 265 μg/mg of fat after 1.5 and 2 min of treatment, respectively).

In our study, an increase of the total amount of POPs was observed at 12 min of treatment, following different trends depending on the model system. In the PSF, the POP content did not significantly change from 12 min until 30 min of heating, remaining around 100 μg/mg of phytosterols. The PS + TAG system displayed a sinusoidal behavior in which a small amount of POPs (22.66 μg/mg of phytosterols) was observed at 12 min of microwaving, and thereafter, an exponential increase was noticed from 20 min of MW heating onward. At 12 min of heating, the POP level in PSF was higher than that in PS + TAG (90.96 vs 22.66 μg/mg of phytosterols), but at 30

DOI: 10.1021/acs.jafc.5b00961
J. Agric. Food Chem. 2015, 63, 5539−5547

min the POP content showed the opposite trend; in fact, the maximum POP levels reached at the end of heating were 107.00 and 159.00 μg/mg of phytosterols for PSF and PS + TAG, respectively. To our knowledge, other studies reported the time course changes of the POP content deriving from thermoxidation of phytosterols with a diverse matrix environment. Xu et al.[16] reported that the fatty acids accelerated β-sitosterol oxidation for the first 60 min of treatment as compared to the control; indeed, changes in the total β-sitosterol oxidation products of >10% and <5% were reported for the system with fatty acids and just β-sitosterol; starting at 90 min and thereafter, their levels were slightly higher in the system with β-sitosterol alone than the sample with fatty acids. This study emphasizes that pure fatty acids might promote the formation of β-sitosterol oxides in an initial phase of oxidation. Another research paper demonstrated that frying oil/fat decreased β-sitosterol oxides up to 50% when heated for 60 min at 180 °C, probably due to antioxidants naturally occurring in the oil.[15] Barriuso et al.[14] reported that the content of sterol oxidation products increases during the first 5−10 min of heating at 180 °C, and subsequently, their degradation rate was higher than their formation one.

As stated before, the MW heating of edible oils, which are commonly used as a heat transfer medium in complex foods, accelerates their oxidation, causing polymerization and thermal oxidative decomposition of sterols in foods.[20] The higher content of POPs in PS + TAG observed between 20 and 30 min of MW treatment could have been affected by the TAG used as the lipid medium. At this temperature (∼160 °C), fatty acids could have undergone oxidation and produced hydroperoxy radicals, which in turn could have accelerated the degradation of phytosterol. It is well-known that MW heating produces fatty acid hydroperoxides at 2−3 times higher rates than conventional heating.[43] On the other hand, the TAG might have exerted a protective effect against phytosterol oxidation for the first 20 min. Ansorena et al.[21] found that cholesterol alone degraded faster than TAG + cholesterol at 180 °C, concluding that the TAG seemed to provide physical protection to the sterol against oxidation. In the present study, it appears that the TAG diluted the PS during heating transfer and exerted physical protection, thus slowing their oxidation as compared to the PSF system, where PS were directly exposed to MW heating. This behavior can be observed in PS degradation (Figure 2), which reflects on the lack of change in the POP levels in the PS + TAG system between 3 and 12 min. In the PSF system, the stable content of total POPs observed from 12 to 30 min could depend on the equilibrium reached between their thermoformation and further degradation into volatile compounds[18] and further evaporation of the oxides formed[44] and/or conversion into high-molecular-weight oxidation compounds (oligomers and/or polymers).[40] Other factors may impact their formation and differences in total POP contents, such as temperature, physical state, and sterol composition.

As for the generation of oxyphytosterols from the different PS, β-sitosterol oxides were the most abundant, followed by those of campesterol and stigmasterol. This is mainly caused by the relative PS concentrations in the original mixture (41% β-sitosterol, 23% campesterol, and 23% stigmasterol). Regarding the total POP content of each sterol, there were no significant modifications during heating of PSF, while a significant difference was observed in PS + TAG between 12 and 20 min of heating. Comparing the time course of total POPs from each sterol between the two systems, the major POP formation observed at 12 min was in the PSF. From 20 to 30 min of heating, contrasting data trends were found, since PS from the PS + TAG system had the highest oxide content. In fact, the behavior of the POPs originated by the single sterols reflects that observed for the total POPs in each model system.

It is generally expected that the main oxidation products of phytosterols and cholesterol are the 7-hydroxy and 7-keto derivatives,[45] at least during the early stages of oxidation. In the PSF system (Table 4), POPs from all phytosterols contained in the mix were found, the 7-keto oxide being the predominant one (42% of total POPs at 30 min of heating), followed by the 7-hydroxy derivative (7% of total POPs).

The content of total POPs generated from β-sitosterol oxidation showed a nonsignificant increasing trend with heating time (50.89, 58.29, and 63.02 μg/mg of phytosterols for 12, 20, and 30 min, respectively). The 7-keto derivative of this sterol was the predominant POP formed during microwaving, which exhibited a significant rise directly correlated with the treatment time (29.46, 35.76, and 43.67 μg/mg of phytosterols for 12, 20, and 30 min, respectively). As illustrated by Rodriguez-Estrada et al.,[10] 7-ketocholesterol is easily formed, and its content could be >30% of the total cholesterol oxidation products; hence, it is often the most representative oxysterol. However, the trend of this oxidation marker could change depending on the time/temperature conditions and interactions with the system (model or food) or with other oxidation compounds.[10,45] According to mathematical predictive models applied to PS oxidation in PS-enriched beverages as a function of the storage time, 7-ketositosterol and 7-ketocampesterol could be used as markers of the PS oxidation level as they showed the highest R^2 value (percentage of variability explained by the model).[45] Other β-sitosterol POPs, such as 7α-OH and 7β-OH, did not significantly change ($p > 0.05$) during heating; between these two epimers, 7β-OH was predominant (about 10 μg/mg of phytosterols). Regarding campesterol and stigmasterol, total POPs formed after 12 min of microwaving, without showing significant differences during the rest of the heat treatment. The total amounts of POPs originated from each sterol were about 20 μg/mg of phytosterols. The individual POPs generated from these phytosterols exhibited the same trend as β-sitosterol's POPs but with different ratios, reflecting the PS concentrations of the original mixture. No epoxy derivatives of campesterol were detected though. Barriuso et al.[14] investigated the formation and degradation pattern of polar POPs during heating at 180 °C for up to 6 h in a conventional oven. The maximum level of POPs was observed between 5 and 10 min of heating, depending on the individual PS, with the highest concentration of total campesterol and β-sitosterol oxides. In particular, at 5−10 min, the 7-keto derivative was the predominant POP, followed by 7α-hydroxy epimers, epoxides, and triol in a lower amount.

In the PS + TAG model (Table 4), different amounts of 7-hydroxy and 7-keto derivatives were found, which accounted for less than 10% and 20% of the total POPs at 30 min of heating, respectively. The content of total POPs generated from degradation of β-sitosterol displayed an increasing tendency with increasing heating time. A significant, rapid change was observed between 12 and 20/30 min of microwaving; this behavior was also observed for single and total campesterol and stigmasterol oxides (Table 4). The total amounts of stigmasterol oxides generated after 30 min of heating were higher compared to those of campesterol oxides; this could be

DOI: 10.1021/acs.jafc.5b00961
J. Agric. Food Chem. 2015, 63, 5539−5547

partly ascribable to the formation of both epoxy derivatives from stigmasterol, which were not found among campesterol's POPs. The epoxidation of the 5,6-double bond of the sterol comes from a bimolecular reaction mechanism between a hydroperoxy radical and an unoxidized sterol. The additional double bond on the side chain of stigmasterol as compared to the other sterols represents a further attack point for free radicals, which can promote hydroperoxide formation at 100 and 180 °C[46] and may thus affect the rate of oxidation of this sterol.[14] Ansorena et al.[21] found that the concentration of COPs in a cholesterol−TAG system model heated in a conventional oven at 180 °C displayed an increasing tendency at different heating times depending on the TAG unsaturation degree.

It must be noted that, in any case, the most abundant POPs were similar in both model systems and that the main differences were due to the relative oxide concentrations. In the PSF system, the concentrations of individual POPs were greatest for the 7-keto derivative, almost twice as much as in the other model system after 30 min of microwaving (43.67 vs 27.00 μg/mg of phytosterols). In PS + TAG, the 7-hydroxy derivatives (α and β) were present in the same proportion, and their contents were higher than in the PSF system, where 7β-hydroxy derivatives were predominant. In both systems, the epoxy derivatives (α and β) from sitosterol and stigmasterol were formed; however, in the presence of a TAG, β-epoxy was more abundant than the corresponding α epimer.

The correlation analysis mainly emphasized the differences between the two systems, PSF and PS + TAG, as related to the temperature reached during microwaving. In the PSF system, the temperature was directly correlated with POP formation (r = 0.999, p = 0.026), while it was inversely correlated with the sterol content (r = −0.933, p = 0.007). Although β-sitosterol was the most abundant in the phytosterol mixture, total POPs were only positively correlated with the total oxidation products of stigmasterol (r = −0.999, p = 0.033) and campesterol (r = 0.999, p = 0.022). In addition, 7-ketostigmasterol formation was inversely correlated with the sterol content (r = −0.999, p = 0.029). In the PS + TAG system, POP formation was not related to the temperature (r = −0.097, p = 0.938), which further confirms the important "protective/dilution" role of the TAG toward PS oxidation, despite the prooxidizing effect of temperature actually detected in PSF.

In conclusion, free phytosterols displayed a different oxidative stability during MW heating which varied according to the model system. Up to 6 min of microwaving, no POPs were detected in both systems; at 12 min of heating, the POP content reached a higher level in PSF (90.96 μg/mg of phytosterols) than in PS + TAG (22.66 μg/mg of phytosterols). However, at the end of the MW treatment (30 min), a trend changed was noted as the POP content was highest in PS + TAG (159 μg/mg of phytosterols). In this case, the presence of the TAG greatly impacted the PS stability in the first heating period, exerting a protective effect through different possible mechanisms (such as dilution, physical protection, and competition for oxidation).[21] Although household MW heating and cooking does not usually require high exposure times and temperatures, these results prove that MW treatment can differently affect the oxidative stability of free sterols according to the medium composition. This aspect should not be disregarded for food products intended to be cooked in a MW for long time periods (>12 min at the power and temperature settings here tested), as it can potentially impact their quality, nutritional value, and safety. Further studies on MW effects are required using more complex systems, including phytosterol esters (largely employed in PS-enriched food), matrices with diverse unsaturation degrees, and natural antioxidants, as they can greatly affect the extent of PS oxidation.

have unique isotopic fingerprints, stable isotope composition analysis could provide information about ecological and geographical origin of biological products, thereby helping discrimination of food. The utilization of isotope ratio mass spectrometry in distinguishing the geographical origin of food samples has been established. Although this technique is extensively discussed for authenticating food products such as meat, wine, fruit juice, honey, and dairy products,[7] its utility in inferring the geographical origin and authentication of fish, shrimp, and seafood species is scarce.[6] On the other hand, molecular tools, based on protein and DNA biomarkers, have been proposed as suitable strategies for identification of fish and crustacean species. In the case of processed products, due to the lack of stability of the polypeptide targets, electrophoretic and immunological methods are unreliable. However, due to its remarkable stability, DNA analysis circumvents these problems. Among the DNA targets considered for species identification, 12S rRNA, 16S rRNA, tRNAVal, and, to a lesser extent, cytochrome oxidase I (COI) and cytochrome *b* genes have been proposed as useful molecular markers for fish and crustacean species.[4]

Authentication, verification of the geographic origin of a product, and pertinent labeling provide consumers with correct, complete, and transparent information. This enables the consumer to make an informed choice on the type and origin of fish purchased. There has been growing consumer enthusiasm for high-quality food with a clear regional identity. There is also an increased public awareness regarding the means by which it has been produced. This study investigates the applicability of stable isotopic values (δ^{13}C and δ^{15}N) as well as cytochrome *c* oxidase gene I as convergent tools to identify hairtail fish and shrimp and to verify their geographic origin. This would abate counterfeit labeling and help traceability of marketed products.

MATERIALS AND METHODS

Sample Collection. Marketable-sized hairtail fish and shrimp were chosen for the present study. Domestic samples were collected from a seafood market, and their area of catch was confirmed. Imported fishes were obtained from the national seafood quarantine agency after verifying their catchment area and country of origin. In each case, five authentic samples were evaluated.

Stable Isotope Analysis. All samples were brought to the laboratory immediately after collection. They were subsequently separated on the bases of commercial name of the species, country of its origin, body weight, and total length. Dorsal muscle tissue of hairtail fish samples and white muscle tissue of shrimp samples were dissected and stored in the deep freezer (−80 °C). The samples were analyzed according to the method stated by Kim et al.[7] Stable isotope analysis was carried out by use of an elemental analyzer (CHNS-O, Euro Vector) combined with a stable isotope mass spectrometer (Isoprime 100, Isoprime Ltd). The δ^{13}C and δ^{15}N (‰ deviations from Vienna Pee Dee Belemnite, VPDB, and atmospheric N_2, respectively) are expressed as follows:

$$\delta^{13}\mathrm{C}\ (‰) = [(^{13}\mathrm{C}/^{12}\mathrm{C})_{\mathrm{sample}}/(^{13}\mathrm{C}/^{12}\mathrm{C})_{\mathrm{standard}} - 1] \times 1000$$

$$\delta^{15}\mathrm{N}\ (‰) = [(^{15}\mathrm{N}/^{14}\mathrm{N})_{\mathrm{sample}}/(^{15}\mathrm{N}/^{14}\mathrm{N})_{\mathrm{standard}} - 1] \times 1000$$

Two international standards, CH-6 and N-1 of International Atomic Energy Agency (IAEA), were used for calculating the isotope ratios, and the δ^{13}C and δ^{15}N values were reported. In case of both carbon and nitrogen isotope ratios, the analytical precision (standard deviation) was <±0.3‰. An internal standard was run for every 10 samples.

Molecular Analysis. *Genomic DNA Extraction.* Genomic DVA (gDNA) was extracted from muscle tissue by use of the DNeasy blood and tissue kit (Qiagen, Hilden, Germany) as per the protocol described by the manufacturer. The gDNA concentration was measured on a Nanodrop ND-1000 spectrophotometer (Thermo-Fisher Scientific Inc., Waltham, MA). The extracted gDNA was used directly for polymerase chain reaction (PCR) and real-time PCR analysis. Several gDNAs were diluted (1/10), from 10 ng/μL to 0.01 pg/μL, in order to confirm the detection limit of the real-time PCR assay.

DNA Amplification and Sequencing. Mitochondrial cytochrome *c* oxidase I (COI) was selected as the target gene. The COI gene was amplified by use of the following primers, where V indicates vertebrate, F is forward, R is reverse, and In indicates invertebrate:

COI-V-F 5′-TCAACCAACCACAAAGACATTGGCAC-3′
COI-V-R 5′- TAGACTTCTGGGTGGCCAAACAATCA-3′
COI-In-F 5′- GTTCAACAAATCATAAAGATATTGG-3′
COI-In-R 5′- TAAACTTCAGGGTGACCAAAAAATCA-3′

Compatibility of the primer set was confirmed by comparing the full sequence of COI genes of hairtail fish and shrimp with the NCBI database (www.ncbi.nlm.nih.gov). Pre-PCR reaction mixtures were treated in a TaKaRa PCR thermal cycler (TaKaRa Bio Inc., Shiga, Japan), wherein the total volume of 20 μL contained 10 μL of Premix Taq (TaKaRa Bio), 2 μL of primer mix (10 pmol/μL), 1 μL of 5 M betaine, 6 μL of distilled water, and 1 μL of gDNA. Thermal cycling conditions were programmed for initial denaturation at 95 °C for 11 min, followed by a reaction cycle (94 °C for 1 min, 50 °C for 1 min, and 72 °C for 1 min) repeated 35 times, with a final extension step of 72 °C for 5 min. PCR products were analyzed by 1% agarose gel electrophoresis and direct sequencing to identify the sequences accurately (Solgent Inc., Daejeon, Korea).

Primer and Probe Design for Real-Time PCR. Specific primers and probes for the real-time PCR kit were designed from direct sequencing data by use of Primer Express software (Applied Biosystems, Foster City, CA) and web-based software (www.genscript.com, GenScript Inc., Piscataway Township, NJ). Primer and probe sequence information is listed in Tables 1 and 2.

Real-Time Polymerase Chain Reaction and Analysis. Real-time PCR was performed in triplicate in 384-well plates. A 384-well

high-throughput analysis was performed with the ABI Prism 7900 sequence detection system (Applied Biosystems); here, white-colored 384-well plates (Applied Biosystems) were used to intensify the fluorescent signals by a factor of 3. This system operated with a thermal cycler and a laser that was directed via fiber optics to each of the 384 sample wells. Fluorescence emission from each sample was collected by a charge-coupled device camera. Single real-time PCR reaction mixtures contained 10 μL of TaqMan universal master mix II, no UNG (Applied Biosystems), 1 μL of primer mix (10 pmol/μL), 0.5 μL of probe 3 (10 pmol/μL), 7.5 μL of distilled water, and 1 μL of gDNA. Multiplex real-time PCR reaction mixtures contained 10 μL of TaqMan universal master mix II, no UNG (Applied Biosystems), 2 μL of primer mix (10 pmol/μL), 0.25 μL of probe 1 (10 pmol/μL), 0.5 μL of probe 2 (10 pmol/μL), 6.25 μL of distilled water, and 1 μL of gDNA. Thermal cycling conditions for hairtail fish were an initial denaturation at 95 °C for 10 min, followed by a reaction cycle (95 °C for 15 s and 60 °C for 1 min) repeated 40 times. Thermal cycling conditions for shrimp were an initial denaturation at 95 °C for 10 min, followed by a reaction cycle (95 °C for 15 s and 50 °C for 1 min) repeated 40 times. Data were analyzed by use of SDS software v 2.3 (Applied Biosystems).

Phylogenetic Analysis. Phylogenic and molecular evolutionary analyses were conducted with MEGA version 4.[8] The evolutionary history was inferred by use of the neighbor-joining method.[9] The phylogenetic tree was linearized with the assumption of equal evolutionary rates in all lineages.[10] The tree is drawn to scale, with branch lengths in the same units as those of the evolutionary distances used to infer the phylogenetic tree. The evolutionary distances were computed by the maximum composite likelihood method[11] and are in units of number of base substitutions per site.

Statistical Analysis. Data are presented as mean ± standard deviation (SD). Data were analyzed by one-way analysis of variance (ANOVA), and significant differences were determined by Tukey's posthoc test. Linear discriminant analysis (LDA) was used to calculate the discriminant function that classified each group, while leave-one-out cross-validation (LOOCV) was used to examine data among the test samples.

RESULTS

The mean isotopic values and standard deviation [when the number of authentic samples (n) was ≥5] are provided in Figure 1a. As evidenced in Figure 1a, distinct carbon and nitrogen isotopic values of hairtail fish samples of various geographic origins were obtained; that is, the δ^{13}C and δ^{15}N (‰) values of the fish differed significantly based on their origin.

The δ^{13}C values of the five Korean hairtail fish ranged from −17.16‰ ± 0.56‰ to −18.03‰ ± 0.27‰, whereas the δ^{13}C values of other, non-Korean hairtail fish were −15.55‰ ± 0.46‰ (Canadian), −17.90‰ ± 0.23‰ (Chinese), −15.43‰ ± 0.56‰ (Japanese), −15.73‰ ± 0.32‰ (Senegalese), and −17.80‰ ± 0.14‰ (Thai). On the other hand, nitrogen isotope (δ^{15}N) values of the Korean hairtail fish ranged from 11.66‰ ± 0.16‰ to 13.08‰ ± 0.65‰, while the values for

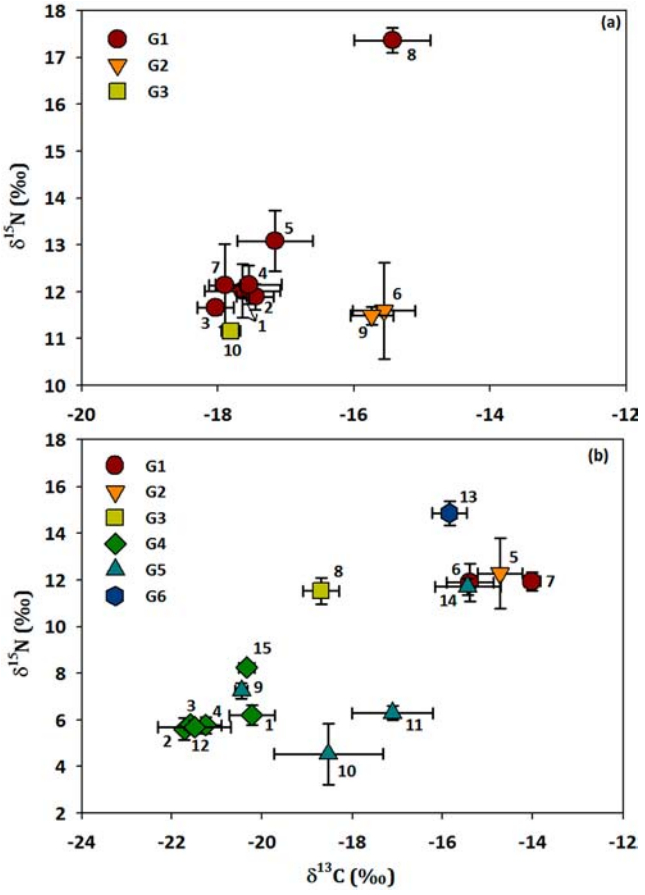

Figure 1. Biplots of δ^{13}C and δ^{15}N values (mean ± SD) of (a) hairtail fish and (b) shrimp based on their geographical origin. Grouping was carried out based on the LDA analysis. Data represent the mean ± SD of five replicates. (a) Group 1 (G1, red circles) represents samples from three countries: Korea [South Sea ID 102 (1), South Sea ID 110 (2), South Sea ID 234 (3), Mokpo (MP) (4), and Gunsan (GS) (5)], China (7), and Japan (8). Group 2 (G2, orange inverted triangles) represents samples from Canada (6) and Senegal (9). Group 3 (G3, yellow squares) represents samples from Thailand (10). (b) Group 1 (G1, red circles) represents wild samples from Korea [Taean (TA) (6) and Gunsan (GS) (7)]. Group 2 (G2, orange inverted triangles) represents wild samples from Korea Guje (GJ) (5). Group 3 (G3, yellow squares) represents wild samples from Yeosu (YS), Korea (8). Group 4 (G4, green diamonds) represents aquacultured samples from Korea [Gunsan (GS) (1), Anmyoendo (AM) (2), Mokpo (MP) (3), and Ansan (AS) (4)] as well as wild samples from Ecuador (12) and Malaysia (15). Group 5 (G5, light blue triangles) represents wild samples from India (9), Indonesia (10), Thailand (11), and Netherlands (14). Group 6 (G6, dark blue hexagons) represents wild samples from Argentina (13).

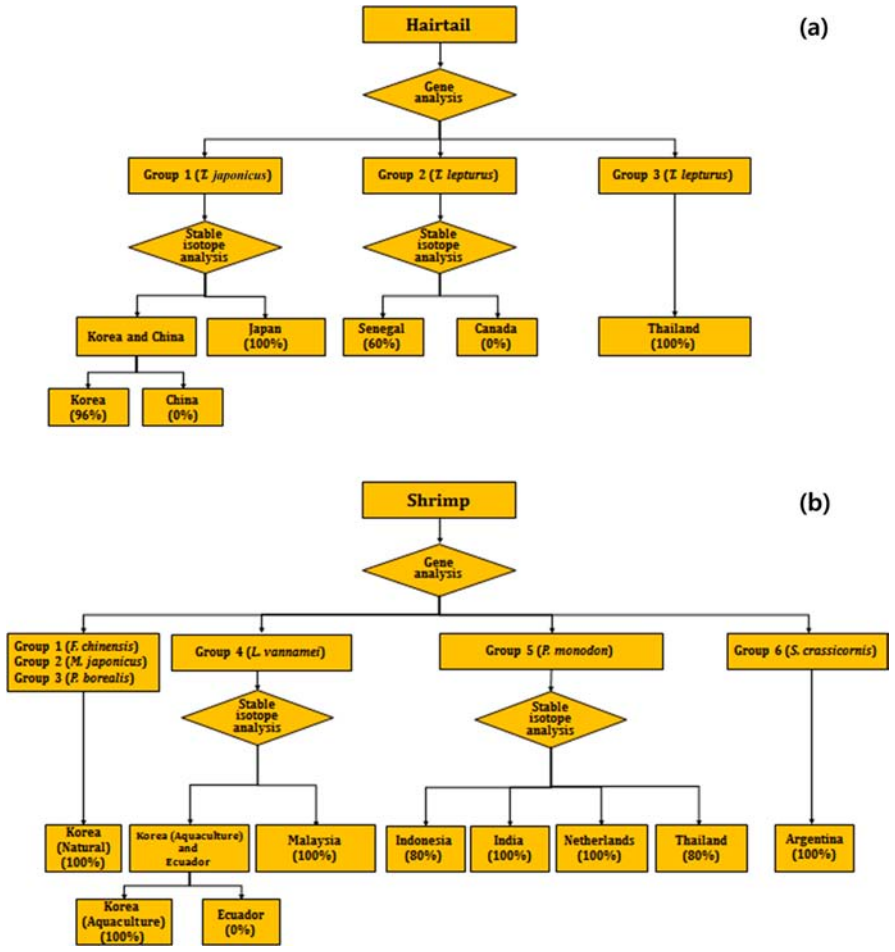

Figure 2. Grouping of (a) hairtail fish and (b) shrimp based on LDA of stable isotopes (δ^{13}C and δ^{15}N). Values in parentheses represent percentage similarity.

other, non-Korean hairtail fish were 11.59‰ ± 1.03‰ (Canadian), 12.14‰ ± 0.88‰ (Chinese), 17.36‰ ± 0.26‰ (Japanese), 11.49‰ ± 0.19‰ (Senegalese), and 11.16‰ ± 0.15‰ (Thai) (Figure 1). LDA of stable isotopes in the hairtail fish samples helped filter the samples into groups (Figure 2a). LOOCV evaluation of the stable isotope data demonstrated approximately 64.7% accuracy in classifying the hairtail fish samples. Here the Korean and Japanese samples were classified with good accuracy (with similarity of 96% and 100% respectively); they varied distinctly from each other.

Aquacultured shrimp samples collected from four different sites in Korea had δ^{13}C values ranging from −20.23‰ ± 0.50‰ to −21.72‰ ± 0.11‰, whereas the δ^{13}C values of wild Korean shrimp ranged from −14.02‰ ± 0.18‰ to −18.69‰ ± 0.40‰. The δ^{15}N (‰) values of aquacultured shrimp ranged from 5.60‰ ± 0.47‰ to 5.80‰ ± 0.14‰, which was quite different from the values for their wild counterparts (from −11.53‰ ± 0.57‰ to −12.82‰ ± 1.51‰). The δ^{13}C values of other, non-Korean shrimp were −20.46‰ ± 0.14‰ (Indian), −18.53‰ ± 1.20‰ (Indonesian), −17.11‰ ± 0.89‰ (Thai), −21.50‰ ± 0.81‰ (Ecuadorian), −15.85‰ ± 0.38‰ (Argentinian), −15.44‰ ± 0.73‰ (Dutch), and −20.3‰ ± 0.18‰ (Malaysian), and their corresponding δ^{15}N values were 7.24‰ ± 0.32‰, 4.54‰ ± 1.31‰, 6.28‰ ± 0.30‰, 5.68‰ ± 0.27‰, 14.87‰ ± 0.51‰, 11.71‰ ± 0.35‰, and 8.23‰ ± 0.21‰, respectively (Figure 1b). The shrimp stable isotope data were filtered to build a LDA model. Model evaluation, carried out via LOOCV, demonstrated an overall accuracy of 75.29% in the case of shrimp. Argentinian and Malaysian shrimp were distinctly classified by this method. Additionally, Indonesian shrimp demonstrated 80% similarity; besides, Thai samples were also classified accurately (80% similarity). All the samples of Korean farmed shrimp resembled each other, and moreover, the Korean natural shrimp also resembled each other; they were classified with 100% accuracy. However, the Korean and natural shrimp distinctly varied from each other (Figure 2b).

PCR amplification was performed by employing mitogenic COI gene primers from isolated total genomic DNA from different samples of hairtail fish and shrimp. PCR products were used for DNA sequencing analysis. Multiple alignments were performed for sequences obtained from DNA sequencing. Here, no insertion, deletion, or stop codons were observed in any sequences. Molecular phylogenetic clustering was undertaken for grouping closely related species or well-identified species enduring on the same clade or sister clades. Phylogenetic analysis revealed identical phylogenetic relationships among the species. Particularly, in the case of hairtail mitochondrial COI sequences, three major clades were obtained (Figure 3a). The first clade, comprising Korean, Japanese, and Chinese hairtail fish samples, formed four clusters. In addition, sequence alignment revealed more similar sequences in hairtail species. From DNA barcoding carried out on the basis of sequencing of a standardized region of the

J. Agric. Food Chem. 2015, 63, 5548−5556

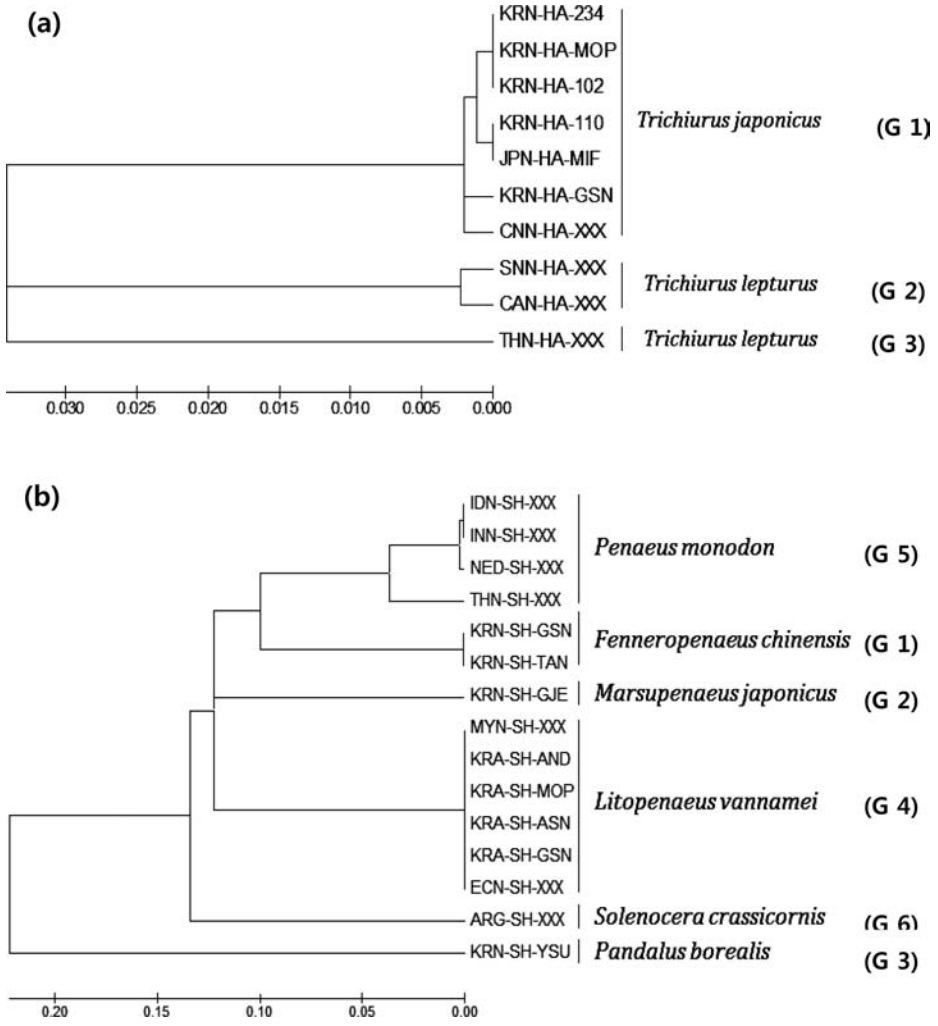

Figure 3. Evolutionary relationships of (a) 10 taxa (linearized) of hairtail fish and (b) 15 taxa (linearized) of shrimp, and neighbor-joining (NJ) phylogenetic trees inferred from DNA sequences of mitochondrial gene COI.

cytochrome *c* oxidase I (COI) gene, the hairtail fish samples from Korea, Japan, and China were identified as *Trichiurus japonicus*, while the hairtail fish samples from Senegal, Canada, and Thailand were identified as *Trichiurus lepturus*.

Phylogenetic analysis of the shrimp samples also displayed identical phylogenetic relationships among the species. Six major clades were obtained from shrimp mitochondrial COI sequences of samples collected from various locations (Figure 3b). In the first clade (G5), two clusters were formed by the species collected from India, Indonesia, and The Netherlands as well as samples from Thailand. The second clade (G1) comprised natural shrimp from Korea. The third phylogenetic clade (G2) (Guje, Korea) was closely related to the second and forth clades. The fourth clade (G4) was formed by the group of shrimp from Korea, Malaysia, and Ecuador. The fifth (G6) and sixth clades (G3) comprised samples from Argentina and Yeosu Korea.

On the basis of DNA barcoding of COI, the shrimp samples from Yeosu and Guje (Korea) were identified as *Pandalus borealis* and *Marsupenaeus japonicus*, respectively, while samples from Gunsan and Taean (Korea) were identified as *Fenneropenaeus chinensis*. The Korean aquacultured shrimp as well as the Malaysian and Ecuadorian shrimp were identified as *Litopenaeus vannamei*, whereas the samples from India, The Netherlands, Thailand, and Indonesia belonged to *Penaeus monodon*. The shrimp from Argentina were *Solenocera crassicornis*.

■ DISCUSSION

Fishery products are considered as a staple food in Korea. In fact, the per capita seafood consumption here is considerably larger than average. In the fish industry, regulations regarding labeling, product quality, and origin have been tightened. Therefore, it is mandatory that fish processing firms must produce proof of origin and traceability. This makes it absolutely essential to formulate an effective traceability system to track fish products throughout the supply chain (harvesting, processing, and marketing). However, identification becomes a rather daunting task in the case of analogous (closely related) fish species. Proper identification of hairtail fishes and their origin is relatively difficult due to their morphological similarities. In Japan, consumer preference for Tachiuo and Tenjikutachi vary with regard to organoleptic characteristics; however, fresh ones are mainly used for raw consumption (sashimi).[12] In addition, most of the morphological characteristicss that are used for species identification (such as head pattern, presence or absence of pectoral fin, dorsal and anal fin ray counts) are lost upon processing; thus, identification of fish species in processed fillets is extremely difficult. This also holds

DOI: 10.1021/acs.jafc.5b01469
J. Agric. Food Chem. 2015, 63, 5548−5556

true for fish sold in parts. Further, shrimp too are often difficult to identify owing to their phenotypic similarities and to the frequent removal of external carapace during processing.[12]

Analytical techniques based on measurement of stable isotopes and DNA-based techniques are suitable for identification of closely related species (both fresh and processed).[5,12] Consequently, they are powerful tools for the detection of counterfeit. This investigation focused on the utility of carbon and nitrogen isotopes, as well as molecular markers, for deriving the geographic origin of hairtail fish and shrimp.

The present study validates the fact that isotopic values of fish vary depending upon the species[13] (Figure 1a). Strikingly distinct δ^{13}C and δ^{15}N values were obtained for hairtail fish of different origin. From a stable δ^{13}C and δ^{15}N biplot for hairtail fish, they could be classified into three groups, wherein samples 1−5, 7, and 10 fell under one group, samples 6 and 9 formed another group, and the remaining sample 8 formed an individual group. Isotopic values (both δ^{13}C and δ^{15}N) of the hairtail fish collected from various sites in Korea differed significantly [$p < 0.05$, Tukey's honestly significant difference (HSD)] from their international counterparts. Moreover, the δ^{13}C and δ^{15}N values of hairtail fish collected from the Asian nations (Korea, China, Japan, and Thailand) were distinctly different ($p < 0.05$, Tukey's HSD) from their Canadian and Senegalese counterparts. Differences in the hydrogeomorphic characteristics between the basins lead to differences in the C signatures of fish.[14] Reports suggest that, in the case of C, isotope ratios of consumers are usually similar to isotope ratios of their diets.[15] On this accord, Gómez-Requeni et al.[16] described that marine fish diets (comprising macroalgae and phytoplankton, which form the lower trophic levels of the marine food web) are isotopically heavier due to their source of carbon (dissolved inorganic carbon pool, δ^{13}C ∼ 0‰), as compared with terrestrial plant photosynthesis from atmospheric CO_2 (δ^{13}C ∼ −7.8‰). Tanaka et al.[17] reported higher (more enriched) δ^{13}C and δ^{15}N ratios in the case of anchovy sampled from inshore habitats as compared to offshore habitats (where lower depleted values were obtained for both). They surmised that higher carbon isotope ratios (in the inshore regions) may reflect a carbon source from benthic primary producers in addition to phytoplankton.[17] Precipitation and temperature variations can also affect the stable isotope ratio of organisms.[18] With respect to the global ocean environment, there is generally a positive correlation between decreasing seawater temperature and lighter δ^{13}C values of particulate organic matter (POM) in cases of high latitude.[19] The geographically classified δ^{13}C values of hairtail fish obtained in this investigation could be attributed to differences in seawater temperature.

The remarkable similarity obtained between the δ^{13}C values of hairtail fish samples collected from various sites within Korea confirm that these values could essentially help traceability of hairtail fish originating from Korea. Nominal variations encountered in the δ^{13}C values of the samples within Korea (in the present investigation) could probably be due to their seasonal and dietary preferences. On this stand, Schell et al.[20] attributed oscillation in carbon isotope ratios of bowhead whale (*Balaene mysticetus*) to seasonal fluctuations of the variety of different zooplankton in the area of study. According to France,[21] the δ^{13}C values of offshore fishes ranged from −20 to −11, while sea grass fishes showed a greater range from −20 to −8. This occurred because a substantial proportion of the fishes collected from sea grass meadows ultimately got their carbon from the plankton-based food web, rather than the benthic-based food web. There are pronounced δ^{13}C isotopic differences between different species. For example, *Geukensia demissa* mussels and *Crassostrea virginica* oysters are isotopically more similar to plankton than to *Spartina* cordgrass, whereas *Orchelimum fidicinium* katydids and *Littorina irrorata* sea snails are isotopically similar to *Spartina*.[22] The δ^{13}C values of the Chinese and Thai hairtail fish (−17.90 and −17.80‰) obtained in this study concurred with the δ^{13}C value of POM reported from China (−19‰).[23] However, the δ^{13}C values obtained for Chinese and Thai samples differed remarkably from those of Canadian, Japanese, and Senegalese hairtail fish (Figure 1a).

During dietary assimilation, nitrogen is more strongly fractionated than carbon, with a mean trophic increase of ∼3‰, as compared to ∼1‰ in carbon.[24] Nitrogen undergoes a 2−4‰ increase in heavier isotope enrichment with each trophic level; it can serve as a tool for determining dietary shifts.[25] Variations in the nitrogen stable isotope ratio reflect not only differences in the trophic level of prey species but also variations in the baseline level of food webs.[17] Measurement of δ^{15}N values allows determination of trophic relationships in complex food webs. These values generally vary with species, diet, and stress. Although the most important application of nitrogen stable isotopes is to determine the trophic level of a species, these values could also indicate an important seasonal change in the marine nitrogen cycle. High anthropogenic inputs on estuarine food webs have also been reported to result in ^{15}N-enriched stable isotope ratios in the community inhabiting the Westerschelde (The Netherlands).[26] In this study, the δ^{15}N value of hairtail fish from China was similar to the report by Wan et al.,[27] who reported δ^{15}N values of 12.9‰ for Chinese hairtail fish. The δ^{15}N values of Japanese hairtail fish in this study were similar to the reports of Shibata et al.[28] and Takai and Mishima;[29] they reported δ^{15}N values of ∼17.5‰ and 17.8‰, respectively, for hairtail fish. Nevertheless, the δ^{13}C and δ^{15}N values of hairtail fish species *T. lepturus* from Brazil (−16.8‰ and 15 ‰)[30] differed from the values obtained for the samples analyzed in this study.

The δ^{13}C values of Korean hairtail fish (−17.16‰ to −18.03‰) were proximate to the δ^{13}C values of POM (−20.2‰) reported by Lee et al.[31] in Korea. The δ^{13}C and δ^{15}N values for Chinese (−17.90‰ and 12.14‰), Japanese (−15.43‰ and 17.36‰), and Thai (−17.80‰ and 11.16‰) hairtail fish were also in compliance with the δ^{13}C and δ^{15}N values of POM in Chinese (−19‰ and 9.8‰), Japanese (−19‰ and 7.3‰), and Thai seawater (−23‰ to −17‰ and 5.7‰ to 8.4 ‰).[23,32,33]

The stable δ^{13}C and δ^{15}N biplot for shrimp classified them into six groups. Here, G1 comprised samples 6 and 7. G2 comprised sample 5, while G3 comprised sample 8. G4 comprised samples 1−4, 12, and 15, while G5 comprised samples 9−11 as well as 14. The remaining sample 13 formed G6 (Figure 2b). Distinct δ^{13}C and δ^{15}N of various species of shrimp collected from different countries showed significant differences. The δ^{13}C and δ^{15}N signatures are known to vary from species to species: for example, the respective δ^{13}C and δ^{15}N values for *Farfantepenaeus indicus* are −16.87‰ and 10.7‰; for *Farfantepenaeus merguiensis*, −16.26‰ and 9.71‰; for *Farfantepenaeus notialis*, −17.15‰ and 9.26‰; for *L. vannamei*, −11.72‰ and 8.9‰; for *P. borealis*, −18.07‰ and 10.78‰; for *P. monodon*, −18.90‰ and 9.66‰; and for *Pleoticus muelleri*, −16.12‰ and 16.86‰).[6] In addition, these

DOI: 10.1021/acs.jafc.5b01469
J. Agric. Food Chem. 2015, 63, 5548−5556

stable isotopic values also vary with the country of origin; for example, the shrimp *P. borealis* from Greenland has different $\delta^{13}C$ and $\delta^{15}N$ values (−18.1‰ and 10.3‰)[34] compared to shrimp from the Mid-Atlantic Ridge (−10.9‰ and 7‰) and Japan (−14.7‰ and 15.8‰).[29,35] Ortea and Gallardo[6] reported unique $\delta^{13}C$ and $\delta^{15}N$ values of shrimp species from Argentina (16.12‰ and 16.86‰), North Atlantic (−18.07‰ and 10.78‰), Mozambique (−16.77‰ and 10.55‰), Nigeria (−17.87‰ and 10.34‰), and Senegal (−16.80‰ and 8.72‰). These reported $\delta^{13}C$ and $\delta^{15}N$ values of various shrimp species from different countries differed significantly from the values of shrimp obtained in our study. This reveals that stable isotopic values could positively indicate the origin of shrimp.

In the present investigation, shrimp from the natural environment showed higher isotopic variability and their mean $\delta^{13}C$ and $\delta^{15}N$ values were statistically different than the farmed ones. The $\delta^{13}C$ values of Korean aquacultured shrimp ranged from −20.23‰ to −21.72‰, whereas the $\delta^{13}C$ values of Korean natural shrimp ranged from −14.02‰ to −18.69‰. In contrast, the $\delta^{15}N$ values of aquacultured shrimp (5.60−6.20‰) were lower than the $\delta^{15}N$ values (11.53−12.28‰) of natural shrimp; this was probably because of differences in diet. Gamboa-Delgado et al.[36] also reported distinct $\delta^{13}C$ and $\delta^{15}N$ values for the shrimp species *L. vannamei* from Ecuador (open sea −16.6‰ and 9.76‰, estuary −18.32‰ and 4.25‰, semi-intensively farmed −19.86‰ and 6.02‰) and *L. vannamei* from the Gulf of Mexico (open sea −17.14‰ and 12.19‰, estuary −18.59‰ and 5.88‰, semi-intensively farmed −19.69‰ and 8.32‰, intensively farmed −21.56‰ and 8.69‰). Aquaculture feeds are frequently formulated with varying dietary levels of plant meals. These plant meals are mostly derived from terrestrial plants having C3 photosynthesis and are less enriched in ^{13}C (mean $\delta^{13}C_{VPDB}$ = −29‰) as compared to C4 plants (mean $\delta^{13}C_{VPDB}$ = −13‰).[36] Also, the C3 plants are less enriched as compared to several marine-derived ingredients such as fish meal ($\delta^{13}C_{VPDB}$ = −17‰). For example, some shrimp feeds used in Mexico have $\delta^{13}C_{VPDB}$ values ranging from −23.6‰ to −22.3‰ and $\delta^{15}N$ values ranging from 5.8‰ to 9.7‰; the $\delta^{13}C_{VPDB}$ values of feed are transferred to the farmed organisms, thereby causing contrasting $\delta^{13}C$ values (more isotopically depleted) as compared to the wild type.[36] Thus, stable isotopic values could help distinguish farmed and natural shrimp.

The unique isotopic values obtained for hairtail fish and shrimp obtained from various regions, viewed through the present study, assert that $\delta^{13}C$ and $\delta^{15}N$ could be used as discriminatory variables to distinguish between various geographic origins.

Although several schematic reports and strategies have been outlined to identify fishery products, determine their geographical origin, and preserve domestic fishery products without adulteration, most of the techniques involved discuss animal meat (beef and lamb). But this study brings forth the applicability of isotopic analysis in the traceability of marine fish products. The identified differences in isotopic patterns of samples from various origins obtained in this study elucidate the potential of stable isotope analysis for validation of geographic authenticity. However, the identified patterns will have to be confirmed in another detailed study comprising a larger number of samples from certified origins and over a time course. Nevertheless, it is a fact that isotopic ratios of fishes are bound to be more stable as compared to other smaller life forms such as phytoplankton. But it is essential to carry out climate, seasonal, and age- and diet-related studies on isotopic ratios in order to derive a better equation. This study positively suggests the reliability of using isotopic ratios of fishes for determining geographic traceability.

DNA barcoding favorably assists identification of seafood species and determination of its origin (i.e., traceability). Here, three gene regions—relatively slowly evolving genes cytochrome *b* (cyt *b*, specified in 72.5% of responses), cytochrome oxidase I (COI, 27.5%), and 16S rDNA (16S, 17.5%)[37]—are proved to be the markers of choice. The COI or *COX1* region demonstrates a good discriminatory power in the identification of fish species. Ward et al.[38] showed 98% of probed marine fish and 93% of freshwater fish were successfully identified from the *COX1* region. DNA barcoding based on partial sequence information from the COI gene has been widely used for species identification of fishes.[39] It provides a paradigm for the development of simple, inexpensive PCR-based assays that can clearly differentiate virtually all fish species. Our results also confirm that the COI barcode is an effective marker for identification of hairtail fish and shrimp; it outright segregates the organisms based on their country of origin (Figure 3).

Investigation of the COI of hairtail fish helped separate the species based on their country of origin. The samples of hairtail fish collected from Korea, Japan, and China were identified as *T. japonicus*, while the samples from Senegal, Canada, and Thailand were identified as *T. lepturus*. Tzeng and Chiu[40] identified 12 cutlass fish species using mitochondrial cytochrome *c* oxidase subunit I (COI) gene of each species and the standard barcode sequences. They illustrated high interspecific differences between the samples of fish, together with high within-species similarities (>95% similarity). These authors explained the degree of interspecific differences was due to the age of phylogenetic origin, and thus, barcode differences were genetically comprehensive.[39] In our study, a clear segregation of patterns of COI was also observed on the basis of geographic origin and species. This validates the effectiveness of the DNA barcoding technique in identifying shrimp as well as hairtail fish and also ascertains its reliability in determining geographic origin. Thus, this particular procedure could be put to use for conservative fisheries management as well as governmental scrutiny of fishery products.

In order to improve the reliability of seafood authentication via statistical analysis, stable isotope ratios as well as the DNA barcoding were combined in this study. The stable isotope data were processed by use of the LDA model. On the basis of this LDA, the hairtail fish (Figure 2a) were segregated into groups. Group 1 consisted of two subgroups; the first clustered together the Korean (with 96% similarity within them) and the Chinese hairtail fish (which had 0% similarity within them), while the second subgroup comprised the Japanese hairtail fish (with 100% match within themselves). LDA of the stable isotope data categorized group 2 as the Senegal (with 60% similarity within them) and Canadian hairtail fish (with 0% similarity within themselves).

The LDA of stable isotopes in shrimp helped subcategorize the Group 4 shrimp into two subgroups. The first subgroup comprised Korean aquacultured shrimp (100% similarity within themselves; 100% accuracy) and natural Ecuador shrimp (0% similarity within themselves), while the second subgroup comprised Malaysian shrimp (having 100% similar profiles). LDA of stable isotopes helped subcategorize group 5 into four subgroups based on the country of origin, wherein the

DOI: 10.1021/acs.jafc.5b01469
J. Agric. Food Chem. 2015, 63, 5548−5556

subgroups comprising Indonesian, Indian, Dutch, and Thai shrimp were identified accurately (as they had 80%, 100%, 100%, and 80% similarity, respectively). Group 6 comprised Argentinian shrimp; the members demonstrated 100% similarity between themselves.

Nowadays, consumers are increasingly interested in validating the reliability of fish products and determining if it is of natural (wild) origin. Nevertheless, international fishery and seafood trade are bound by food safety regulations, which insist on traceability (through all stages of production, processing, and distribution). These regulations aim to promote resource sustainability, quality distinction, and product safety. In fact, the FAO have outlined several analytical approaches for species authentication (NMR analysis, isotope analysis, fingerprints, electrophoresis, peptide mapping, immunological techniques analyzing proteins, target recognition, and blot hybridization), verification of geographic origin (NMR analysis, stable isotope and trace element analysis), and determining if the product is wild or cultivated. This study evaluates two of these techniques: stable isotope analysis and COI sequencing. Both these analyses harmonized in authenticating and tracing the origin of hairtail fish and shrimp from various origins.

Stable isotopes (δ^{13}C and δ^{15}N) and COI gene sequencing have been used to authenticate, discriminate, and trace various food products. But their use in determining the provenance of fish has not been prevalent. On the basis of the present study, we can summarize that COI sequencing helped identify the species of hairtail fish and shrimp. The LDA of stable isotopes helped in further categorizing each species into subgroups, based on the country of origin. Moreover, the stable isotope values distinctly differentiated natural and farmed shrimp from the same country. Thus, this study on hairtail fish and shrimp validates the utility of these tools in identifying these species and establishing their geographical origin.

formed, as well as to investigate the extent of absorption and excretion, tissue distribution and metabolism.[21] Radio-LC-MS is an on-line analytical system that is composed of liquid chromatography (LC), ultraviolet absorbance detection (UV), radioactivity monitoring (RAM), and mass spectrometry (MS). This system, which combines the high separation ability of LC, the structural analysis of MS, and the high sensitivity and specificity of RAM, has become a unique scientific tool for the analysis of radiolabeled drugs.[22−24]

In the present study, the mass balance, metabolism, tissue distribution, and depletion of CYA were investigated in pigs, chickens, carp, and rats following oral administration of ^{3}[H]-CYA using high-performance liquid chromatography combined with radioactivity monitoring and IT/TOF mass spectrometry (LC-RAM-MS-IT-TOF). The comparative in vivo metabolic disposition and tissue depletion of CYA in pigs, chickens, carp, and rats in different organs, tissues, and fluids are reported for the first time. On the basis of these results, the main metabolites, the marker residue, and the target tissue of CYA in animals were identified. This study provides comprehensive information about the disposition and tissue depletion of CYA in animals, which will improve the food safety evaluation of CYA in food animals.

MATERIALS AND METHODS

Chemicals. CYA (≥98%) was synthesized by the Institute of Veterinary Pharmaceuticals of Huazhong Agricultural University (Wuhan, People's Republic of China). 4-[^{3}H]-*O*-nitroaniline ([^{3}H]-ONA) was provided by the Shanghai Institute of Applied Physics, Chinese Academy of Sciences. *O*-Nitroaniline (ONA, ≥99.0%), 10% Pd/C, NaOH, NaClO (5%), pyruvaldehyde dimethylacetal (PDA), and pyrrolidine were purchased from Sinopharm Chemical Reagent Co., Ltd., Shanghai, People's Republic of China. Benzofuroxan (BFO, 99.5%), 2-formylquinoxaline-1,4-dioxide dimethylacetal (FQDDA, 99.7%), and cyanoacetylhydrazine (99.7%) were provided by the Institute of Veterinary Pharmaceuticals (Wuhan, People's Republic of China). Monophase-S was purchased from PerkinElmer Life and Analytical Sciences. ULTIMA GOLD liquid scintillation cocktail and SOLVABLE were purchased from PerkinElmer. StopFlow AD liquid scintillation cocktail was purchased from Aim Research Co. (Hockessin, DE, USA). All chemicals were of reagent grade.

[^{3}H]-CYA was synthesized as previously described.[25] In brief, [^{3}H]-ONA was deoxidized with 2-propanol and NaClO at 25 °C with constant stirring for 2 h to give [^{3}H]-BFO. Next, [^{3}H]-BFO was reacted with PDA and pyrrolidine in an ice bath for 4 h followed by stirring for another 12 h at 17−20 °C and thereafter maintained at 4 °C for 1 h to give [^{3}H]-FQDDA. Finally, [^{3}H]-CYX was obtained by reacting [^{3}H]-FQDDA with cyanoacethlhydrazine in a solution of methanol and concentrated hydrochloric acid at 25 °C with constant stirring for 4 h. The radiochemical purity of the final labeled product was 99.2%. The specific activity of [^{3}H]-CYA was 1.13 mCi/mg by comparing the total radioactivity of 10 mg of [^{3}H]-CYA with the mass (10 mg). The radiochemical purity of [^{3}H]-CYA remained unchanged for 3 months in DMSO solution. A stock solution of [^{3}H]-CYA with a specific activity of 113 mCi/g was prepared 2 weeks before dosing and diluted with 1% aqueous carboxymethyl cellulose to obtain a final dosing suspension of 10 mg/mL with specific activity of 11.3 mCi/g for animal study. When the tritium label compound was used or analyzed during the whole study, the operator was protected with a respirator, gloves, and cottony working clothes to avoid direct contact with tritium.

Animals. Male and female pathogen-free Wistar rats (7 weeks, 200 ± 20 g) were purchased from the Hubei Experimental Animal Research Center (Wuhan, People's Republic of China). Healthy castrated crossbred (Duroc × Large white × Landrace) pigs (weight 15−20 kg) were purchased from the Livestock and Poultry Breeding Center of Hubei Province (Wuhan, People's Republic of China). Cobb 500 chickens (weight 1.0−1.5 kg) were purchased from Wuhan Chai Tai Co., Ltd. (Wuhan, People's Republic of China). Carp (weight 0.4−0.6 kg) were purchased from Wuhan Fish Breeding Farm (Wuhan, People's Republic of China). The animals were fed a basal diet without antimicrobial agents/compounds and acclimatized for 1 week before the experiment. The animals and fish were maintained under standard environmental conditions using the routine methods of animal husbandry and aquaculture. Pigs and broilers were housed singly in all-steel metabolism cages specifically designed for the separate collection of urine and feces in a temperature-controlled room (20 ± 2 °C) with a 12 h light/dark cycle. Carp were held separately in a standalone water tank in the same temperature-controlled room (20 ± 2 °C). Throughout the study period, feed was withheld approximately 12 h before through 4 h after drug administration, while water was available ad libitum. The experimental procedures involving the animals in this study were approved by the Animal Care Center, Hubei Academy of Medical Sciences. All of the in vivo experiments complied with the policy on the care and use of laboratory animals.

Feed. The feed used in this study was purchased from Wuhan Lvhong Bioscience and Technology Co., Ltd. (Wuhan, People's Republic of China). The feed formula was strictly in accordance with the recommended formula of the U.S. National Research Council. Premixed (5%; 3.0 g/kg CYA concentration) and complete feed (150 mg/kg CYA concentration) were initially prepared. The blank feed and the medicated feed were analyzed using the HPLC method described by Wu et al.[22] to determine the drug content. The results indicated that no quinoxaline compound was detected in the blank feed, and only CYA (150 ± 8 mg/kg feed, n = 9) was found in the medicated feed.

Mass Balance Study. Six rats (three male and three female), six chickens, six carp, and four pigs were administered a single oral dose of [^{3}H]-CYA (11.3 mCi/g) by gavage at 20 mg/kg bw (30 mg/kg bw for rats), respectively. Urine and feces samples were collected in preweighed dry ice cooled containers protected from light before dosing at intervals of 0−6, 6−12, and 12−24 h after dose administration and then daily until two consecutive samples from urine and feces had <1% of the total administered radioactivity. At the end of the collection period, the cages were rinsed with water followed by methanol. The cage washings were retained with the excreta. Seven days after the dose administration, all animals were anesthetized and killed, and the pigs were slaughtered using captive bolt stunning equipment and exsanguinated on the basis of guidelines provided by the American Veterinary Medical Association for euthanasia.[26] The samples were stored at −80 °C prior to analyses.

Aliquots of urine (0.2 mL) from the animals at each sampling time were mixed directly with 10 mL of liquid scintillation solution and assayed by liquid scintillation counting (LSC; TriCarb 2900, PerkinElmer Life and Analytical Sciences, Waltham, MA, USA). Aliquots of homogenized feces samples (0.2 g) were first digested with sodium hypochlorite solution (2 mL) for 2 h in a 55 °C water bath. The digested solution was cooled to room temperature and mixed with 0.1 M EDTA (0.2 mL) and 30% H_2O_2 (0.2 mL). The mixture was heated for 30 min in a 55 °C water bath for depigmentation. The efficiency of digestion was confirmed by the digestion of radiochemical standards (^{3}H-Spec-Chec; PerkinElmer Life and Analytical Sciences) for every 10−15 samples and was between 96% and 98%. A correction factor was used accordingly. All of the samples were prepared in 10 mL of scintillation fluid (Ultima Gold) and incubated at room temperature overnight in a dark environment prior to LCS analyses.

Duplicate samples were analyzed by liquid scintillation counting until a statistical error (2σ) of 0.5% was obtained, with a counting time of 5 min, together with representative blank samples. LSC was performed using a Packard Tri-Carb 2900 liquid scintillation analyzer with automatic quench correction using an external method (PerkinElmer Life and Analytical Sciences) to detect the retained [^{3}H] radioactivity.

Metabolism Study. Animals were dosed and sampled as in the mass balance study. In addition to the urine and feces, the blood and bile of the animals were sampled at 6, 12, 24, 48, 72, and 96 h.

DOI: 10.1021/acs.jafc.5b01745
J. Agric. Food Chem. 2015, 63, 5557−5569

Extraction of Radioactive Substances. Urine (2 mL), plasma (2 mL), and bile (1 mL) collected at intervals of 0−6, 6−12, or 12−24 h and then over 24 h periods up to 72 h after dosing were analyzed for each subject. The weight of each aliquot was 0.1% of the total fraction weight (0.25% for urine). Each sample was centrifuged at 4 °C for 5 min at 1500*g*. The supernatant was collected and purified with offline SPE on an Oasis HLB cartridge. The column was activated with methanol (6 mL) and water (6 mL) in sequence and dried by purging the air at a rate of 10 mL/min. Then, the supernatant was loaded onto the SPE column at a flow rate of 1 mL/min, followed by rinsing with 6 mL of water. The analytes were eluted with 6 mL of methanol at a flow rate of 1.0 mL/min. The eluent was evaporated to dryness under a stream of nitrogen at 40 °C. The residues were dissolved with 1 mL of the mobile phase and mixed for 30 s. A fraction of the mixture (0.2 mL) was transferred to a separate tube, and 10 mL of liquid scintillation solution was placed in the tube. The mixture was detected by LSC to quantify the extracted radioactivity. The extraction efficiency of the radioactive substance in the samples was calculated by comparing the extracted radioactivity with the total released radioactivity. The extraction efficiencies of the related compounds in the urine, plasma, and bile were 92.7%, 91.8% and 90.6%, respectively. A portion of the mixture (0.3 mL) was centrifuged at 2000*g* for 5 min. The supernatant was prepared for LC MS ion trap time of flight (LC-MS-IT-TOF) analysis.

Aliquots of the homogenized feces (2 g) were mixed with 5 mL of acetonitrile, sonicated for 2 min, and centrifuged at 4 °C for 5 min at 1500*g*/min. The extraction solution (1) was collected. The residual material was extracted with another 5 mL of ethyl acetate, followed by sonication and centrifugation. The extraction solution (2) was combined with solution (1). Then, the residual precipitate was suspended in 5 mL of NaOH solution (3 mol/L). The mixtures were hydrolyzed in a water bath at 95−100 °C for 30−40 min and then cooled to room temperature. Concentrated HCl (2 mL) was added to the alkaline hydrolysate. The aqueous phase was extracted twice with 10 mL of ethyl acetate by sonicating for 2 min followed by centrifuging for 5 min at 1500*g*/min. The resulting organic phase was combined with solutions (1) and (2). The mixed solutions were evaporated to dryness under a stream of nitrogen in 40−45 °C water baths. The residue was dissolved in 20% MeOH/water (0.5 mL) and analyzed by LC-MS-IT-TOF and a νARC 2.0 Radio-LC assay system with Detector RS232 (AIM Research Co.).

Separation and Identification of Radioactive Substances. The HPLC system (Shimadzu) was equipped with a solvent delivery pump (LC-20AD), an autosampler (SIL-20AC), a DGU-20A3 degasser, a photodiode array detector (PDA; SPD-CY20A), a communication base module (CBM-20A), and a column oven (CTO-20AC). The separation was performed on a Hypersil Gold column (100−2.1 mm i.d.; particle size 5 μm) using a gradient elution consisting of mobile phase A (0.1% formic acid in water) and mobile phase B (acetonitrile). The gradient was as follows: 0−5 min, 8% B; 5−18 min, a linear gradient to 28% B; 18−23 min, a linear gradient to 90% B; 23−26 min, 90% B; 26−26.1 min, a linear gradient back to 8% B. The injection volume was 20 μL, the flow rate was 0.2 mL/min, and PDA detection was performed from 200 to 400 nm. The sample chamber in the autosampler was maintained at 4 °C, while the column was set to 40 °C. The whole analysis lasted for 30 min. Radiochemical detection was performed using the νARC 2.0 Radio-LC system Detector RS232 equipped with a 750 μL detector cell. The instrument was operated in the dynamic liquid scintillation flow mode, and the HPLC eluent was mixed 1/5 with Stop Flow AD scintillation liquid. After radiochemical detection, the total effluent from the detector was transferred directly to the hybrid IT/TOF mass spectrometer without splitting.

The IT-TOF-MS instrument was equipped with an electrospray ionization (ESI) source operated in the positive ionization mode. Mass spectroscopic analyses were carried out on a full-scan mass spectrometer with a mass range of 100−500 Da. Liquid nitrogen was used as the nebulizing gas at a flow rate of 1.5 L/min. The interface and detector voltages were set at 4.5 and 1.6 kV, respectively. The curved desorption line (CDL) and heat block temperatures were both 200 °C. The MS2 spectra were produced by collision-induced dissociation (CID) of the selected precursor ions with Ar as the collision gas. The ion accumulation time and relative collision energy were set at 50 ms and 50%, respectively. Data acquisition and processing were carried out using LCMS solution software version 3.41, supplied with the instrument. The mass numbers corresponding to the particular elemental compositions were also calculated by the formula predictor and generated more than one formula proposed by the software. Therefore, an accuracy error threshold of 5 mDa was set as the limit for the calculation of possible elemental compositions. Hydrogen/deuterium (H/D) exchange was performed to identify the active hydrogen atoms. The extracted samples were dissolved in tritiated water and separated using the mobile phase consisting of acetonitrile and tritiated water.

Distribution and Depletion Study. Each of 30 rats, chickens, and carp and 24 pigs was administered a [^{3}H]-CYA suspension at a single dose of 12 mg/kg bw (rats 16 mg/kg bw) by oral gavage for 7 consecutive days. Four pigs and six rats, chickens, and carp were randomly selected to be slaughtered by exsanguination at 0.25, 1, 3, 7, and 14 days after dosing, respectively. Before slaughter, each animal was anesthetized following the guidelines provided by the American Veterinary Medical Association (AVMA, 2001). The blood, bile, organs, and tissues, including the livers, kidneys, gastrointestinal tracts, hearts, spleens, lungs, muscles, fat, skin, brains, gonads, adrenal glands, and bladders, were collected separately and stored at −80 °C until analysis. Another six rats, pigs, and chickens were administered solvent (1% aqueous carboxymethyl cellulose) at exactly the same amount as the dosed animals. At each time point, one animal was slaughtered and sampled as described for the dosed animals to obtain the blank samples. The weight of each sample was recorded.

All of the samples were homogenized separately and then divided into two parts. One part was prepared and detected by LSC as described in Mass Balance Study for the determination of the total radioactivity. The other part was prepared and analyzed as described in Mass Balance Study for metabolite analysis. The blood and bile were prepared using the same procedure as described for the urine, while organs and tissues were prepared as described for the feces, respectively.

Validation of the Quantitation Methods. All of the samples were quantitated by LSC. The limit of quantitation (LOQ) of LSC was detected by evaluating a series of [^{3}H]-CYA working solutions with different radioactivities; the lowest concentration resulting in a deviation of 5% was designated as the LOQ. The LOQ of [^{3}H]-CYA in the different samples was 10 μg/kg. Two microliters of [^{3}H]-CYA stock solution were diluted 10^9 times with methanol, and then, 20 μL, 40 and 80 μL of diluted [^{3}H]-CYA was added to the blank pig urine, feces, blood and tissues, respectively. The samples were prepared as described above, followed by the determination of the radioactivity of the extracted samples with LSC and LC/LSC. All radioassays were performed in triplicate. On comparison of the extracted radioactivity with the total radioactivity of the diluted solution, the accuracy of [^{3}H]-CYA quantitation in the different samples ranged from 82.6% to 105.2%, with a relative standard deviation of less than 10%. Nine diluted [^{3}H]-CYA stock solutions with different radioactivities were detected by LSC and LC/LSC, and each sample was measured in triplicate. The correlation equation between LSC and LC/LSC was determined to be $y = 4.4579x - 155.87$ ($r = 0.9997$). To calculate the content of volatile radioactivity, such as [^{3}H]-H_2O, another duplicate set of samples was freeze-dried and reconstituted in water ("dry samples") prior to analysis. All radioassays were performed in triplicate. The ^{3}H water exchange in the excretions was between 0.2% and 2.5%.

Data Analysis. The concentrations of radioactive substances were quantitated by reversed-phase HPLC with radiochemical detection. The linear relationship between the cpm (X), which was obtained from the νARC detector, and dpm (Y), which was obtained from the Tricarb 2900TR, was $y = 4.45x - 156$ ($r = 0.9997$). The total residue concentrations and concentrations of the main metabolites were subjected to logarithmic transformation and regressed with the time. The depletion equation and the half-life ($t_{1/2}$) of the total residues and main metabolites were described as $C = C_0e^{-kt}$ and $t_{1/2} = 0.693/k$,

cage rinse	0.2 ± 0.01		0.2 ± 0.01	0.3 ± 0.05		-
total recovery	96.1 ± 3.8		95.3 ± 0.7	94.8 ± 0.5		97.4 ± 3.7

respectively. The percentages of the individual metabolites within the total residues were calculated as follows:

$$X = \mathrm{AUC_M}/\mathrm{AUC_T} \times 100\%$$

X is the percentage of individual radioactive substances within the total radioactive residues. $\mathrm{AUC_M}$ is the area under the curve of the individual radioactive substances in the specific samples. $\mathrm{AUC_T}$ is the area under the curve of the total radioactive residues in the specific samples.

RESULTS

Radioactivity Excretion. Following a single oral dose of [^{3}H]-CYA, CYA was rapidly excreted in all of the studied animals (Table 1). Nearly 64.4−81.5% of the radioactivity was excreted within 24 h, and more than 90% of the radioactivity was excreted within 72 h in all species after dosing, indicating that CYA could be excreted rapidly by the animals. The mean cumulative recovery of excretion, including that of the cage washings within 12 days, ranged from 95.9% to 98%, indicating that the excretions of CYA in the four animal species were quite similar. For pigs and rats, 51.6% and 66.2% of the total radioactivity was excreted from the feces, respectively, whereas 44.3% and 28.35% was detected in the urine, indicating that the major elimination route of CYA was via feces.

Mass Spectrometric Identification of Radioactive Substances (Metabolites). In addition to the intact parent drug, 15 radioactive peaks in total were characterized by HPLC-νARC and identified by LC-MS-IT-TOF in rats, pigs, chickens, and carp. The detailed LC-MS-MS characterization of seven metabolites, including Cy1, Cy2, Cy4, Cy5, Cy10, Cy13, and Cy14, has been reported previously.[11] Eight new in vivo metabolites of CYA were first characterized as follows. The proposed metabolite structures and supporting spectral data for all matrices are shown in Table 2.

Metabolite Cy3. This radioactive peak indicated that it was a main metabolite in the urine at 6 h. The protonated molecular ion was at m/z 232 (M + H), suggesting that Cy3 is a glycine conjugate of Cy6. The predominant fragment ion at m/z 186 was formed by the loss of a carboxyl from the ion at m/z 232. The fragment ion at m/z 159 was formed by the cleavage of the amide bond and loss of CO to form m/z 131. Exchangeable hydrogen atoms are usually bound to N, O, or S atoms in functional groups, such as OH, NH, NH_2, and COOH. Cy3 has two exchangeable atoms. The m/z of Cy3 should be 235 after H/D exchange. The results were consistent with this speculation. Therefore, Cy3 was identified as 2-(quinoxaline-2-carboxamido) acetic acid (Figure 2).

Metabolite Cy6. The protonated molecular ion was at m/z 175 (M + H), which generated m/z 158 and 129. The retention time and fragment ions were identical with those of synthesized Cy6. The mass spectra of the standard were consistent with the corresponding compounds in the samples. Based on these observations, Cy6 was identified as quinoxaline-2-carboxyl (Figure 2).

Metabolites Cy7 and Cy8. Both compounds were minor metabolites of CYA and were detected in urine but not in tissues. Both metabolites showed a protonated molecular ion at m/z 256, which was consistent with Cy2 and Cy10. However, the MS-MS fragment ions of Cy7 and Cy8 were not identical with those of Cy2 and Cy10. The main fragment ions of Cy7 at m/z 189, 172, and 160 were all 17 Da higher than the fragment ions of Cy2 at m/z 172, 155, and 143. Therefore, it was assumed that Cy7 was hydroxylated on the quinoxaline ring. The fragment ion at m/z 131 was found in the MS-MS of Cy8, suggesting that hydroxyl was not on the quinoxaline ring. Furthermore, Cy7 was eluted before Cy2, near the retention time of Cy16 (only found in vitro). Cy8 was eluted behind Cy2, near the retention time of Cy1. The polarity of Cy16 was higher than that of Cy2 due to the hydroxyl on the quinoxaline ring. The results of H/D exchange showed that the m/z values of Cy7 and Cy8 were 261 and 260, respectively. Cy7 has four exchangeable hydrogen atoms, while Cy8 has three exchangeable hydrogen atoms. Hence, Cy7 was identified as 3-hydroxy-2-formylcyanoacetyl hydrazone quinoxaline, and Cy8 was identified as N'-hydroxy-2-formylcyanoacetyl hydrazone quinoxaline (Figure 2).

Metabolite Cy9. The protonated molecular ion was at m/z 258, 2 Da higher than m/z 256, suggesting that Cy9 may be a hydrogenated product of CYA monoxide. The fragment ion at m/z 174 was formed by the loss of $C_3H_3N_2O$ from that at m/z 258. The loss of CO from the ion at m/z 174 generated an ion at m/z 146. In parallel, the ion at m/z 258 could lose $C_3H_4N_3O$ to give m/z 159, and the loss of CO from the ion at m/z 159 yielded m/z 131, suggesting that the hydrogen atoms were not on the quindoxaline ring, according to the identification of Cy4. Cy9 has four exchangeable hydrogen atoms. The m/z value of Cy9 should be 263 after H/D exchange. The detected results were consistent with this speculation. Therefore, Cy9 was identified as N'-(quinoxaline-N1-oxygen-2-methyl)cyanide acetylhydrazine (Figure 2).

Metabolite Cy11. The protonated molecular ion was at m/z 231. According to the accurate mass measurement, Cy11 was formed by the cleavage of the cyano group after the deoxidation of CYA. The fragment ion at m/z 173 was formed by the loss of $C_2H_2O_2$ from m/z 231. The fragment ion at m/z 231 lost $C_2H_5NO_2$ to form m/z 156. Because Cy11 has one hydrogen exchangeable atom, the m/z of Cy11 should be 233 after H/D exchange. The detected results were consistent with this speculation. Therefore, Cy11 was identified as 2-formylacetylhydrazine-quinoxaline N1-oxide (Figure 2).

Table 2. Metabolite Information of CYA in Pigs, Chickens, Carp, and Rats

Compound	Chemical Name	[M+H] (Da)	Elemental composition	Proposed structure	Major fragment ions
Cy0	2-formyl cyano acetyl hydrazone-quinoxaline N^1,N^4-dioxide	272	$C_{12}H_{10}N_5O_3^+$		238,225,198,187,174,170,163,146,143,131,116
Cy1	2-formyl cyano acetyl hydrazine-quinoxaline	240	$C_{12}H_{10}N_5O^+$		199,173,156,143
Cy2	2-formyl cyano acetyl hydrazine-quinoxaline-N1 -oxide	256	$C_{12}H_{10}N_5O_2^+$		239,215,189,172,171,155,144,143,131,129,116,104,102
Cy3	2-(quinoxaline-2-carboxamido)acetic acid	232	$C_{11}H_{10}N_3O_3^+$		186,159,131
Cy4	N'(quinoceline-2-methyl) cyanide acetyl hydrazine	242	$C_{12}H_{12}N_5O^+$		225,158,131
Cy5	2-hydroxy methyl-quinoxaline	161	$C_9H_9N_2O^+$		143,132
Cy6	Quinoxaline-2-carboxylic acid	175	$C_9H_7N_2O_2^+$		157,129
Cy7	3-hydroxy-2-formyl cyano acetyl hydrazone-quinoxaline	256	$C_{12}H_{10}N_5O_2^+$		189,172,160
Cy8	N'-Hydroxy-2-formyl cyano acetyl hydrazone-quinoxaline	256	$C_{12}H_{10}N_5O_2^+$		189,172,160,131,
Cy9	N'-(quinoxaline-N1- oxygen-2-methyl)-cyanide acetyl hydrazine	258	$C_{12}H_{12}N_5O_2^+$		174,159,146,131
Cy10	2-formyl cyano acetyl hydrazine-quinoxaline-N4 -oxide	256	$C_{12}H_{10}N_5O_2^+$		215,189,172,171,155,143,129,117,102
Cy11	2-formyl acetyl hydrazine-quindoxaline-N1-oxide	231	$C_{11}H_{11}N_4O_2^+$		173,156,146
Cy12	2-hydroxymethyl-3-hydroxy quindoxaline	177	$C_9H_9N_2O_2^+$		159
Cy13	2-formyl hydrazone-quinoxaline N1,N4-dioxide	205	$C_9H_9N_4O_2^+$		176,159
Cy14	2-formyl hydrazone-quinoxaline N1-oxide	189	$C_9H_9N_4O^+$		172,144,117
Cy15	N'-(quinoxaline evil morpholine-2-methyl)- acetyl hydrazine	217	$C_{11}H_{13}N_4O^+$		171,144

Metabolite Cy12. The protonated molecular ion was at m/z 177, 16 Da higher than Cy5. There was only one fragment ion at m/z 159, 16 Da higher than m/z 143. The characteristic ions were at m/z 143 and 131, indicating that the hydroxy group was not on the quinoxaline ring. Moreover, the retention time of Cy12 was before that of Cy5, suggesting that the polarity of Cy12 was higher than that of Cy5. Cy12 has two exchangeable hydrogen atoms. The result of H/D exchange showed that the

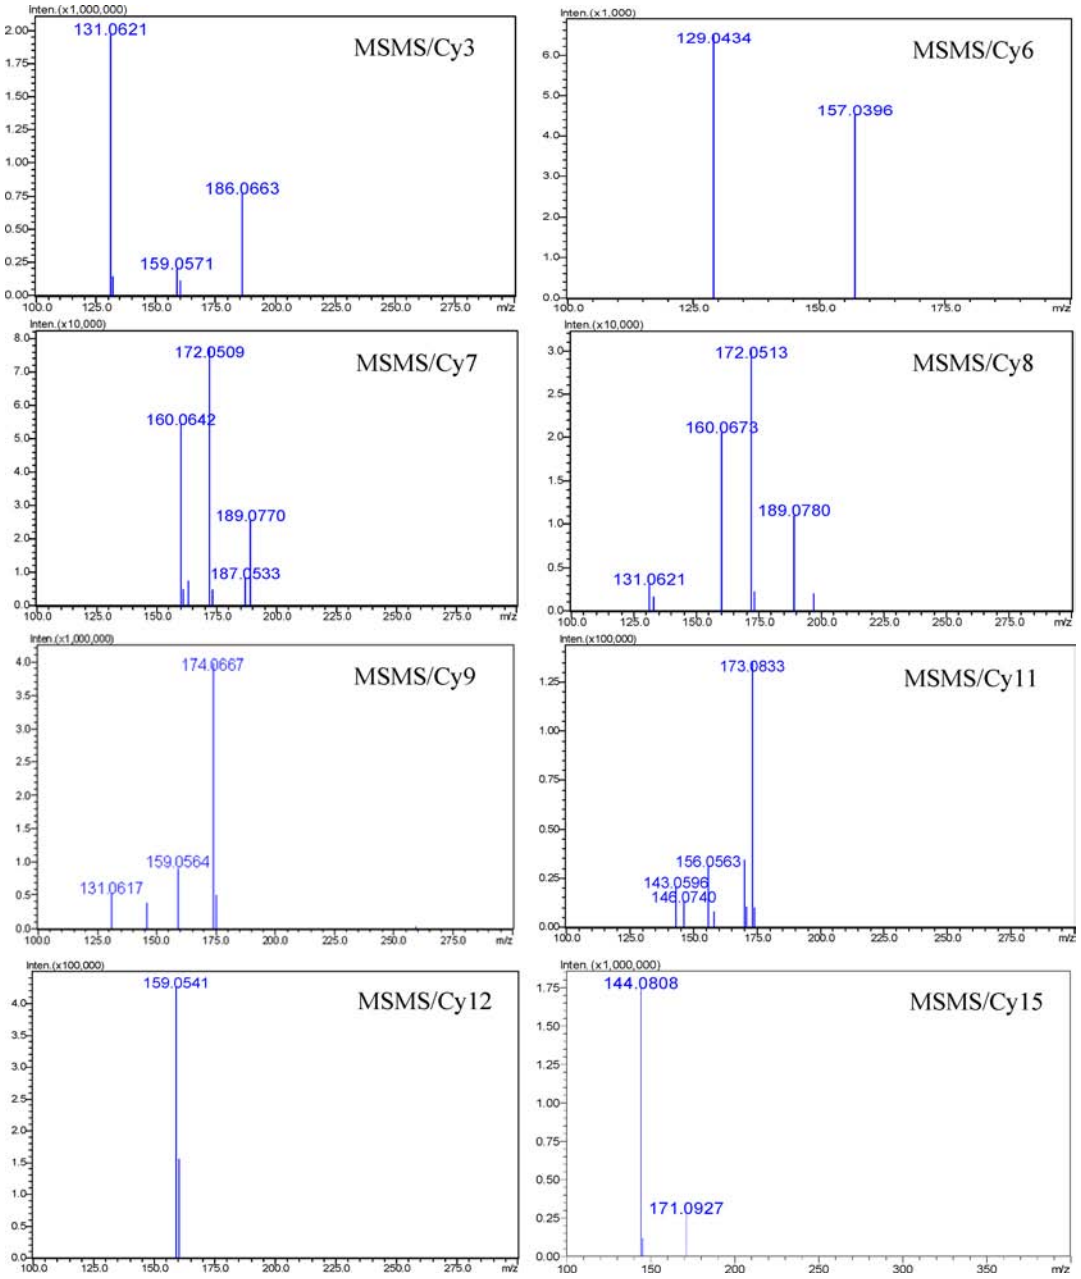

Figure 2. Accurate MS2 spectra of Cy3, Cy6, Cy7, Cy8, Cy9, Cy11, Cy12, and Cy15.

m/*z* value of Cy12 was 180. Hence, Cy12 was identified as 2-hydroxymethyl-3-hydroxyquinoxaline (Figure 2)., and the retention time and mass fragmentation pattern were consistent with those of the synthesized standard.

Metabolite Cy15. The protonated molecular ion was at *m*/*z* 217, 14 Da less than Cy11, suggesting that one oxygen atom was removed from Cy11 and two hydrogen atoms were added to the side chain. The fragmentation ion at *m*/*z* 171 was obtained by the loss of 46 Da from the ion at *m*/*z* 217. Then, the ion at *m*/*z* 144 was formed through the loss of CHN from the ion at *m*/*z* 171. Cy15 has two exchangeable hydrogen atoms. The result of H/D exchange showed that the *m*/*z* value of Cy15 was 220. Therefore, Cy15 was identified as *N*′-(quinoxaline-morpholine-2-methyl)acetyl hydrazine (Figure 2).

Five predominant metabolite standards of CYA were also synthesized and matched the metabolites (Cy1, Cy2, Cy4, Cy10, and Cy12) in the tissues and bodily fluids on the basis of their retention times and mass fragmentation patterns.

Metabolic Profile of CYA in Different Species. Eight metabolites were identified in rats (Table 3). No parent drug could be detected in the urine at any sampling time point, while six metabolites were detected at 12 h after dosing, of which Cy4 and Cy9 represented 29.89% and 32.25%, respectively. Only Cy1 was detected at 48 h, and no metabolites were detected thereafter. The parent drug and seven metabolites were detected in the feces at 12 and 24 h postdosing. Only Cy1 and Cy6 were detected over the 48−72 h time period. No parent drug was detected in the plasma, even at 6 h, but five metabolites could be detected instead.

Thirteen metabolites were observed in pigs (Table 3). The parent drug (Cy0) and 13 metabolites were detected in the urine from 6 to 12 h postdosing, with Cy1, Cy4, and Cy9 being the largest three metabolites, accounting for 11.77%, 26.10%,

detected in the urine up to 72 h. In the feces, the parent drug and 11 metabolites were detected from 0 to 24 h after administration. The amounts of Cy0, Cy1, Cy3, Cy4, and Cy9 were higher than those of the other metabolites. At 48 h, Cy7, Cy8, and Cy11 were undetectable. Thirteen metabolites were found in the bile at 6 h postfinal dosing. At 24 h, Cy7, Cy8, and Cy12 were not detected. At 72 h, no metabolite was characterized in the bile. Eleven metabolites were identified in the blood at 6 h postdosing, but no parent drug was observed (Figure 3).

J. Agric. Food Chem. 2015, 63, 5557−5569

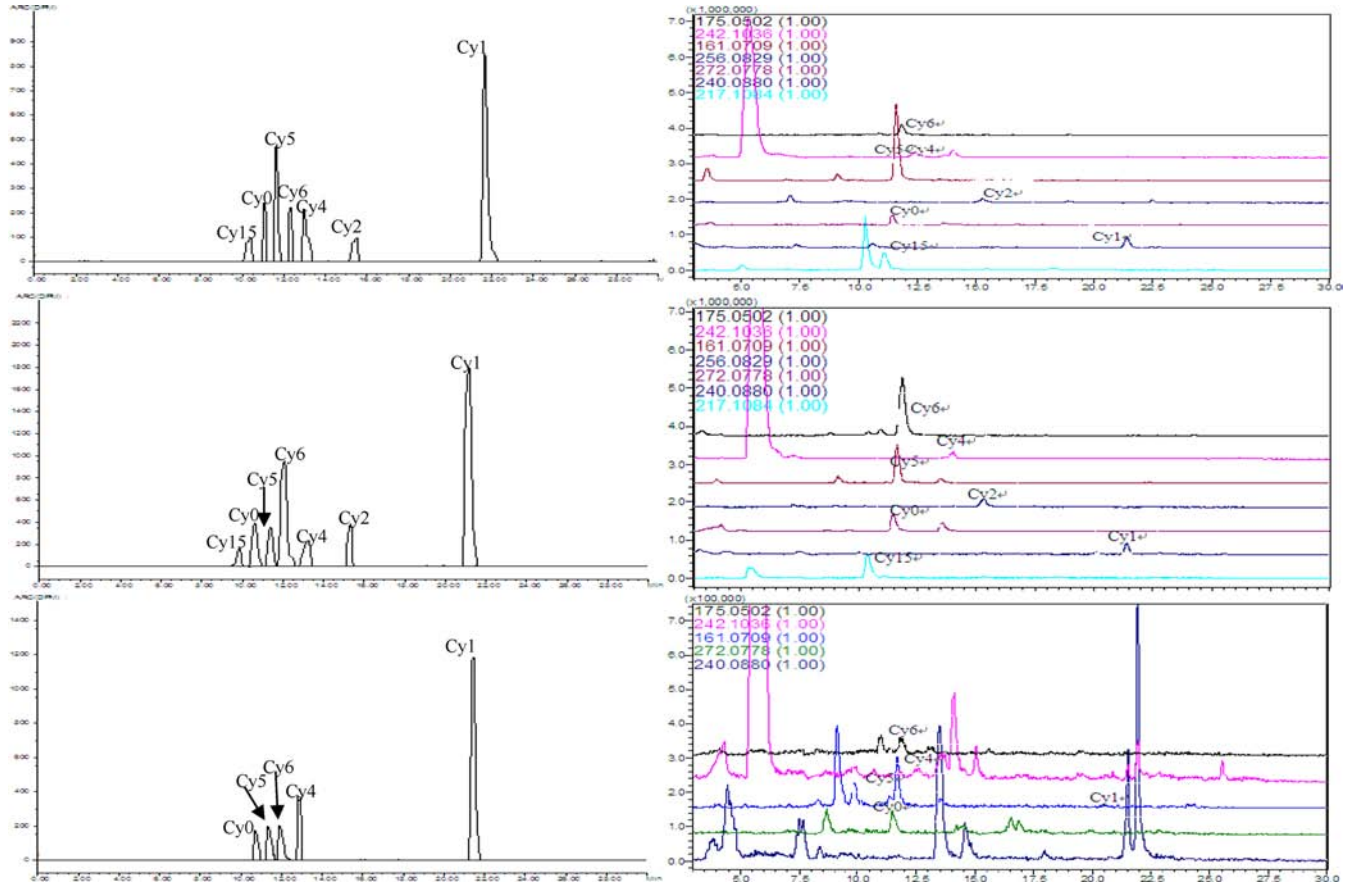

Figure 6. Radioactive chromatography and accurate EIC of CYA and its metabolites in liver, kidney, and muscle of chickens after a single oral dose of [^{3}H]-CYA at 20 mg/kg bw.

Ten metabolites were identified in chickens (Table 3). The parent drug and seven metabolites were detected in the feces at 6 h postdosing, of which Cy0, Cy1, and Cy6 were the main metabolites, with ratios of 29.63%, 23.48%, and 11.49%, respectively. Four metabolites (Cy1, Cy2, Cy5, and Cy6) and the parent drug were found in the feces at 24 h, and Cy0 and Cy1 represented 39.83% and 31.08%, respectively. Only the parent drug and Cy1, Cy2, and Cy6 were detected at 48 h. In the bile, the parent drug and seven metabolites were detected at 12 h postdosing, and Cy13 was not detected in the feces. The parent drug and Cy1, Cy2, and Cy5 were still detectable at 48 h, while only Cy2 and Cy5 were found at 72 h. Four metabolites were identified in the blood at 6 h postdosing.

Four metabolites were identified in carp (Table 3). The parent drug and two metabolites were found in the excreta at 12 h postdosing, and only Cy13 was detected at 24 h. The parent drug and four metabolites were detected in the bile at 6 h, but only Cy0 and Cy2 were found at 24 h. No metabolites were found after 24 h. Three metabolites were detected in the blood at 6 h postdosing.

CYA was metabolized more extensively in pigs than in rats, chickens, and carp because the most metabolites were observed in pigs, and nearly all of the metabolites found in rats, chickens, and carp were observed in pigs, except for Cy15, which was only detected in chickens. Moreover, Cy3 was only observed in pigs and was not observed in the other three species. Carp had a comparatively low metabolic ability for CYA, because only four metabolites were detected in carp during the whole observation. On the basis of the structures and persistence of the metabolites, the metabolic scheme of CYA in animals is proposed in Figure 4.

Tissue Distribution of the Total Radioactivity and Individual Metabolites. Similar trends in the distribution profiles were displayed among the four species (Figure 5). CYA-derived radioactivity underwent a rapid and wide distribution across the various tissues and fluids. Radioactivity was observed in all of the assayed tissues and organs and reached the highest concentration at the first collection time point (6 h) for all of the analyzed matrices after 7 consecutive days of oral exposure to [^{3}H]-CYA. The highest total radioactivity residue (TRR) levels were observed in the bile (14−15 mg/kg) in pigs and chickens and then in the kidneys, livers, and intestines, and the TRR level in the fat was found to be the lowest (less than 1.0 mg/kg) at the withdrawal time of 6 h in the four species. However, the TRR level in the bile of carp was at an extremely low concentration in comparison with that in pigs and chickens.

No parent drug was detected in all of the edible tissues of pigs and rats, even at the earliest withdrawal time of 6 h. The parent drug was detected in the edible tissues of chickens only at the early withdrawal time of 6 h, while it was observed in all of the detected tissues of carp, with a comparably long persistence time of 72 h in the livers and intestines. In rats, five metabolites were detected in the livers, kidneys, and muscles, and Cy11 was additionally detected in the livers at 6 h after final dosing. Cy1, Cy4, and Cy5 persisted for 72−168 h in the livers, kidneys, and muscles of rats, respectively. In pigs, eight metabolites were observed in the livers and kidneys at 6 and 24

A dash (–) denotes that the compound depletes too rapidly for calculation of the AUC.

h following the last administration. Most of those metabolites were also detected in the muscle and fat, except for Cy2. Cy1 was the only metabolite that was detected both in the livers and kidneys at 168 h. In chickens, six metabolites were detected in the livers and kidneys (Figure 6), but Cy2 and Cy15 were only detected at 6 h postfinal dosing. Cy1, Cy4, Cy5, and Cy6 were detected in the muscles at 6–24 h, of which Cy1 was still detected at 72 h following the final dosing. In carp, five metabolites were found in the livers, kidneys, and intestines, and Cy6 was detected additionally in the kidneys and intestines at 6 h postfinal dosing. Cy1 and Cy2 persisted for 72–168 h in the livers, kidneys, and intestines.

On the basis of a comparison of the area under the concentration–time curve (AUC) of the metabolites and the TRR (Table 4), Cy1, Cy3, and Cy6 were found to be the predominant metabolites of CYA in the edible tissues of pigs because they composed 32.2–33.6%, 18.9–54.2%, and 16.1–20.4% of the metabolites, respectively. Cy1 was the most predominant metabolite of CYA in chickens, with an extremely high percentage of more than 60% of the total residues. The parent drug occupied 24.9–29.0% of the total residue in the livers and intestines of carp, and Cy1, Cy2, and Cy4 were found to be the main metabolites, with comparatively high percentages ranging from 19.5% to 59.6% in different tissues. In comparison with the food animals, Cy4 and Cy5 were present at an extremely high percentage of 51.6–64.5% in rats. Cy1 and Cy6 were also considered to be the main metabolites, with percentages of more than 10%.

Depletion of the Total Radioactivity and Main Metabolites. The TRR was observed in nearly all of the detected matrices of the four species within 3 days following the withdrawal of the drug and was still detected in most of the matrices of rats and several tissues in pigs, such as the livers, kidneys, hearts, spleens, lungs, and stomachs, at the seventh day following the last dosing. However, TRR was only detected in the livers and kidneys of chickens and carp, at concentrations ranging from 23 to 98 μg/kg at the seventh day after the last administration. In contrast, TRR was still detected in the livers and kidney of pigs and rats even at the 14th day following the last administration. Therefore, TRR underwent a comparatively rapid depletion in the tissues of chickens and carp, with $t_{1/2}$ ranging from 0.63 to 2.38 and from 0.51 to 1.24 days, respectively, in comparison with the slower depletion in the tissues of pigs, with $t_{1/2}$ ranging from 0.57 to 2.83 days. The $t_{1/2}$ values of the TRR in the livers of pigs, chickens, and rats were 2.39, 1.38, and 1.14 days, respectively, whereas the $t_{1/2}$ values of the TRR in the kidneys of pigs, chickens, and rats were 2.83, 2.38, and 0.59 days, respectively (Table 5). These results demonstrate that TRR persists the longest in the kidneys of pigs and chickens and in the livers of carp, suggesting that the

residual target tissue of CYA in pigs and chickens could be the kidney and that in carp could be the liver. In comparison with the depletion of TRR in the kidneys of pigs and chickens, the $t_{1/2}$ values of Cy1 in the kidneys of pigs and chickens were 2.67 and 2.17 days, respectively, which were quite similar to that of TRR. Thus, Cy1 could be the marker residue of CYA in food-producing animals.

DISCUSSION

CYA was rapidly excreted in the four species, with more than 90% of the radioactivity recovered in the excreta of the animals within 3 days after dosing. CYA-related compounds were excreted more rapidly in chickens than in the other species, with a high recovery of 91.5% within 24 h due to the shorter intestinal tract, and was excreted relatively slowly in carp, with a low recovery of 64.3% within 24 h due to the lower basic metabolic rate of carp. CYA showed a rapid excretion similar to that of carbadox and olaquindox, the congeners of CYA, in animals, which are recovered at rates of nearly 91% and 95% from the excreta within 72 h when they are fed to pigs.[27,28] Fecal excretion was the primary route of CYA in animals, with a comparatively high percentage of 66.2% and 51.6% for rats and pigs, respectively.

Metabolite profile analysis indicated that CYA underwent extensive metabolic reactions in the four species. Overall, 8, 13, 10, and 7 metabolites were characterized in rats, pigs, chickens, and carp, respectively. Most of the metabolites remained consistent in the four species. The main metabolic pathway for CYA in animals involved a N−O reduction on the benzene ring, C═N cleavage on the side chain, followed by the hydroxylation and oxidation of the side chain, and C═N hydrogenation and hydrolysis of the amido linkage on the side chain. The N−O reduction and cleavage of the side chain were in accordance with the metabolism of quinoxalines in pigs, as previously reported,[27,29] while C═N hydrogenation is a novel and unique metabolic pathway of CYA in animals. On the basis of the in vitro metabolism, abundant deoxidation metabolites (Cy1, Cy2, and Cy10) and hydrolysis metabolites (Cy13 and Cy14) could be detected in both the liver microsomes and the intestines of pigs and chickens,[12,30] indicating that the liver and intestine are the main metabolic organs of CYA in animals. The cytochrome b5 reductase, cytochrome P450, and heme11 in the liver microsomes and the aldehyde oxidase and xanthine oxidase in the cytosol in the livers and intestines, were closely associated with the formation of deoxidation metabolites.[31−33] No hydrogenated metabolites were detected in the liver microsomes of animals, but Cy4, the main hydrogenation product of CYA, was detected in the colon microflora of pigs and chickens with an extremely high percentage of 51.5−73.7%,[12] indicating that the hydrogenation of CYA could be performed in the intestinal microflora. It has been shown that hydrogenase in the intestinal bacteria catalyzes the hydrogenation of the C═N double bond, and hydrazone dehydrogenase in the microflora ruptures the C═N bond of CYA to form 2-hydroxymethylquinoxaline, followed by the formation of carboxylic acid-2-quinoxaline (QCA).[34]

Although the main metabolic pathways of CYA in the four species were the same, several metabolites showed obvious different distribution patterns. First, Cy3 was detected only in pigs and was not observed in the other species. Cy3 is the glycine conjugation of QCA, and its production should be catalyzed by glycine *N*-acyltransferase. Early studies showed that the ratio and activity of glycine *N*-acyltransferase in different species were significantly different, and the glycine *N*-acyltransferase in the livers and bile of pigs were predominantly higher than in the other animals, whereas glycine conjugation was formed in rats only when rats were fed pectin.[35−37] Our results demonstrate that the formation of Cy3 in animals is closely associated with the amount and activity of glycine *N*-acyltransferase in animals. Second, Cy4 and Cy9 were detected in the urine of pigs and rats, with predominantly high percentages ranging from 19.78% to 29.89%, but only a comparatively small amount of Cy4 was detected in chicken feces, while these metabolites were not observed in any excreta or tissues of carp. Both Cy4 and Cy9 are produced by the hydrogenation of desoxycyadox, which is mainly catalyzed by hydrogenase. Hydrogenases are microbial enzymes that catalyze either $_{H}2$ oxidation or production.[38] A high ratio of these two metabolites in pigs and rats indicates that the amounts or activities of hydrogenases in pigs and rats could be higher than those in chickens and carp, which remains to be investigated further. Moreover, Cy4 and Cy9 were not observed in the liver microsomes of pigs and rats,[11] but a large quantity of these metabolites was detected in both the urine and bile, demonstrating that Cy4 and Cy9 could be produced in the intestine by bacteria and then absorbed into systemic circulation.

CYA may be widely distributed in various organs and tissues because the total radioactivity was observed in all of the detected tissues, suggesting that CYA might be effective for systemic infection. The concentrations of the total radioactivity in the pig intestines, livers, and kidneys were comparatively higher than those in the other tissues. The accumulation of CYA in the pig intestines contributes to its excellent antibacterial effects on the harmful microflora in the pig intestines and growth performance[3−5] but also raises concerns about its impact on the human intestinal flora and resistance.[39,40] High radioactivity levels in the livers and kidneys indicated that the livers and kidneys were slow-release depots for CYA and its metabolites, which resulted in obvious organ injury in the livers and kidneys after dosing the rats with a high level of CYA in the feed.[41,42]

Cy1, Cy4, and Cy5 were distributed in nearly all tissues in the four species, suggesting that they were the common metabolites of CYA in edible tissues. Of these, Cy1 was the most common and main metabolite of CYA in the edible tissues of the four different species, with the highest concentration and longest persistence, indicating that it could be the key metabolite for food safety control and toxicology concerns. Cy1 was the *N*-oxide reduction metabolite of CYA by reducing the oxygen atoms on both the N1 and N4 sites on the benzene. Because *N*-oxide reduction is driven by single-electron reductases,[11] while single-electron reduction of quinoxaline *N*,*N*-dioxides leads to DNA damage by radical intermediate production,[43] it could be speculated that the formation of Cy1 may lead to the production of some radical intermediates and then cause QdNO-induced pathological damage.[8,44] Moreover, it has been shown that bisdeoxycarbadox, the bisdeoxy metabolite of carbadox, was positive in the Ames test and cell transformation test, and its tumorigenic potential was apparently greater than that of the parent drug.[27,28] On the basis of the structural similarity with bisdeoxycarbadox and the high proportions in the edible tissues in all species, the toxicology of Cy1 should be a primary concern. Cy4 and Cy5 were the predominant metabolites of CYA in various tissues of rats and the muscle of carp, with high percentages over 50% of

DOI: 10.1021/acs.jafc.5b01745
J. Agric. Food Chem. 2015, 63, 5557−5569

the total residues. Theoretically, the toxicity of Cy4 should be lower than that of Cy1 because Cy4 is the hydrogenated product of Cy1. It has been shown that the hydrogenation of compounds can reduce their toxicity.[45,46] Cy5 is the alcohol form of Cy6 and is formed by the cleavage of the side chain followed by an oxidation reaction. Because no toxic perssad was introduced during this process, it could be speculated that the toxicity of Cy5 is similar to that of Cy6. Nevertheless, because such high proportions of Cy4 and Cy5 were observed in the livers and kidneys of rats, they may have important contributions to the pharmacology and toxicology of CYA in rats. Therefore, further studies on the toxicology of Cy1, Cy4, and Cy5 need to be performed.

Cy3 and Cy6 were found to be the main metabolites in pigs, with an extensive distribution and high proportion of the TRR. Cy6 (quinoxaline-2-carboxylic acid, QCA), the final metabolite of carbadox, has been shown to be negative in various toxicology studies, including those for genotoxicity and carcinogenicity,[27,28] and showed relatively lower oxidative stress toxicity than its parent molecules.[8] Cy3, the glycine conjugate of Cy6, is a phase II metabolite with increased water solubility for easy excretion and thus had a toxicity lower than that of Cy6. Hence, Cy3 and Cy6 pose little threat to the food safety of CYA.

The elimination rate of CYA and its metabolites in food animals was closely related to its food safety. The designation of marker residue and target tissue is essential for the food safety monitoring of CYA. The tissue in which the drug persists for the longest time is considered to be the marker tissue, and the compound that persists for the longest period of time in the target tissue is considered to be the marker residue. That means if the marker residue was depleted to a safe amount in the target tissue, there would be no other drug residues in any of the tissues, and the product would be considered definitely safe for the consumer. Hence, the kidney is suggested as the target residue tissue of CYA in pigs, chickens, and rats in light of the total radioactive depletion rate in all tissues. Cy1, Cy3, Cy4, and Cy6 were the main metabolites in the kidneys at 6 h following the final dose, but only Cy1 persisted for the longest time and showed a depletion similar to that of TRR with a similar elimination half-life. Accordingly, the marker residue of CYA was Cy1 in pigs, chickens, and carp.

In summary, CYA was excreted rapidly from the animals after a consecutive oral dosage, and fecal excretion was the major elimination route of CYA in animals, whereas renal elimination was the minor route. CYA was extensively metabolized in rats, pigs, chickens, and carp, primarily involving N−O group reduction, C═N cleavage, and hydrogenation and hydrolysis on the side chain. The major metabolites of CYA were Cy1, Cy3, and Cy6 in pigs, Cy1, Cy5, and Cy6 in chickens, Cy1, Cy2, and Cy4 in carp, and Cy1, Cy2, Cy4, and Cy5 in rats. Cy1 was suggested to be the marker residue, and the kidney was designated as the target tissue. The toxicity of Cy1, Cy4, and Cy5 needs to be investigated further on the basis of their structures and amounts in the edible tissues of food animals. These results provide significant information on the disposition of CYA in animals, which will improve the understanding of the pharmacology and toxicology of CYA in animals and provide comprehensive evidence for the food safety controls of CYA in animal products.

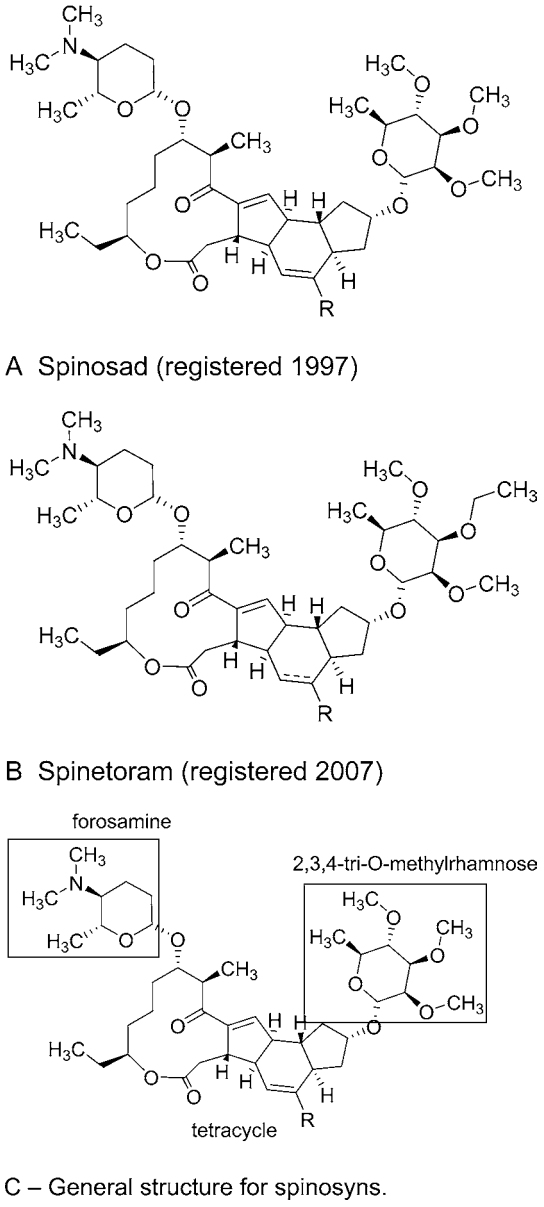

Figure 1. Structures of spinosad, spinetoram, spinosyns: (A) spinosad (primary component spinosyn A (R = H), minor component spinosyn D (R = Me)); (B) spinetoram (primary component 5,6-dihydro-3′-*O*-ethyl spinosyn J (R = H, 5,6 single bond), minor component 3′-*O*-ethyl spinosyn L (R = Me, 5,6-double bond)); (C) general structure of the spinosyns (R = H or Me, boxes highlight the two sugar moieties).

MATERIALS AND METHODS

Synthesis of Spinosyn Analogues. Unless otherwise indicated, all commercial reagents were used without purification. Solvents were of reagent grade. Benzyl alcohol precursors were available commercially or were prepared using published routes. Purity was established as >95% by ^{1}H NMR spectroscopy and LC-MS. Mass spectral data were obtained by electron ionization on one of several systems including a series 1100 mass selective detector (MSD) (Hewlett-Packard, Palo Alto, CA, USA) or a 5890 series II (Hewlett-Packard) with a 5890A mass spectrometer (Hewlett-Packard) or a 6890 series GC system with a 5973 MSD (Hewlett-Packard). Mass spectral data were also obtained by LC-MS analysis using a 215 liquid handler (Gilson, Middleton, WI, USA) for injection coupled to a 1100 chromatography system (Agilent Technologies, Santa Clara, CA, USA) composed of a quaternary pump system and photodiode array detector linked to a 50/50 splitter going simultaneously to a 2000 evaporative light scattering detector (Alltech Associates, Inc., Deerfield, IL, USA) with impactor on and to a ZQ mass spectrometer detector (Waters Corp., Milford, MA, USA) or by a second LC-MS (Waters Corp.) composed of a 2777 autosampler, 1525 μL binary pumps with 100 μL pump heads, and a 2996 photodiode array detector linked to a 50/50 splitter going simultaneously to a 2420 evaporative light scattering detector (Alltech Associates, Inc.) and a ZQ mass spectrometer detector (Waters Corp.). Masses are detected by electrospray ionization (ESI) on both systems. The main method consists of a linear gradient from 5 to 95% organic in 5 min. Solvents are 94.9% H_2O with 5% acetonitrile (aqueous) and 99.9% acetonitrile (organic) both spiked with 0.1% acetic acid. The column used was a 4.6 mm × 50 mm i.d., 5 μm, Sunfire Prep C18 OBD (Waters Corp.). Reverse phase high-performance liquid chromatography (RP HPLC) was conducted on a liquid handler 215 (Gilson) with HPLC grade acetonitrile and water (both with 0.1% acetic acid). ^{1}H NMR spectroscopy data were collected using chloroform-*d* solvent with tetramethylsilane as internal standard.

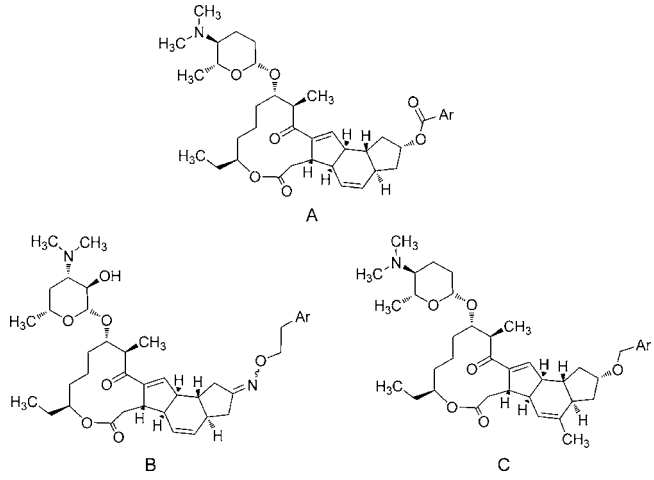

Figure 2. Spinosyn analogues containing rhamnose replacements at C-9: (A) 9-*O*-benzoyl analogues; (B) 9-(*O*-aralkyl) oxime analogues; (C) 9-*O*-benzyl analogues.

Preparation of 3,4,5-Trimethoxybenzyl Bromide. In a 1 dram vial equipped with a magnetic stir bar were added 0.198 g of 3,4,5-trimethoxybenzyl alcohol (1.00 mmol), 1.5 mL of 9:1 dichloromethane/diethyl ether, and hydrogen bromide (40% aqueous solution). The reaction mixture was stirred for 4.5 h. The reaction mixture was poured into a 25 mL vial containing water and ice. This mixture was extracted three times with ethyl acetate, dried over magnesium sulfate, filtered, concentrated under reduced pressure and low heat, and then stored in the freezer.

Preparation of 9-*O*-Benzyl Spinosyn D Analogues. *Method A: Preparation of 9-O-(3,4,5-Tri-O-methylbenzyl)spinosyn D,* ***6q.*** In a 1 dram vial equipped with a magnetic stir bar were added 0.144 g of 3,4,5-trimethoxybenzyl bromide (0.55 mmol), 0.10 g (0.18 mmol) of spinosyn L C-9 pseudoaglycone, 0.150 g of powdered 10:1 potassium hydroxide/tertrabutylammonium hydride (excess), and 3.0 mL of dichloromethane. The reaction mixture was stirred overnight at room temperature. The reaction mixture was diluted with ether and then passed through a 10 mL Celite cartridge. The eluent was concentrated under vacuum. Purification using a Redi Sep 10 g flash column (Isco, Inc., Lincoln, NE, USA), eluting with ethyl acetate/hexanes/dichloromethane/methanol (10:10:10:1, v/v/v/v), yielded 0.066 g (50% yield) of **6q** as a solid foam.

Method B: Preparation of 9-O-(2-Isopropylbenzyl)spinosyn D, ***6d.*** In a 1 dram vial equipped with a magnetic stir bar were added 0.050 g of 1-(bromomethyl)-2-isopropylbenzene (0.21 mmol), 0.020 g (0.036 mmol) of spinosyn L C-9 pseudoaglycone, 0.10 g of powdered 10:1 potassium hydroxide/tertrabutylammonium hydride (excess), and 1.5 mL of dichloromethane. The reaction mixture was stirred overnight at room temperature. The supernatant solution was then

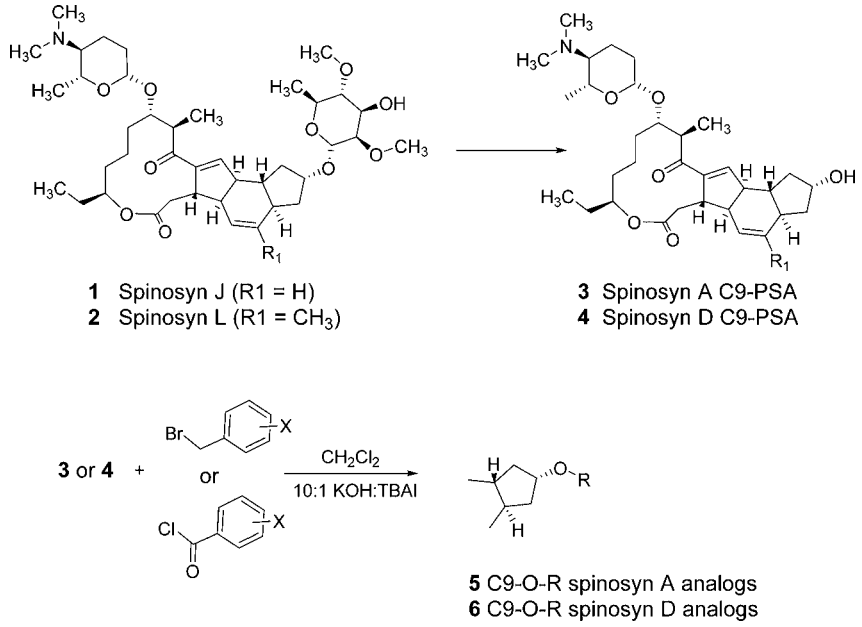

Figure 3. Synthesis of spinosyn D C9 pseudoaglycone and spinosyn D analogues with rhamnose replacements.

added directly to the top of a Redi Sep 2.5 g flash column (Isco, Inc.) and eluted, first with 25 mL of dichloromethane, then with 25 mL of 1% methanol in dichloromethane, and finally with 25 mL of 2% methanol in dichloromethane, which resulted in elution of the desired 9-*O*-benzyl product. Removal of solvent furnished 0.0205 g (79%) of **6d** as a solid foam.

Molecular Modeling Overlays. The spinosyn D and the benzyl and benzoyl structures were built by hand in Sybyl-X 2.1 (Certata, Princeton, NJ, USA) starting from the minimized X-ray structure of spinosyn A. The structures were then minimized and flexibly fit to the minimized X-ray structure of spinosyn A. All of the molecules were initially geometry optimized using the Tripos force field[29] and Gasteiger–Huckel charges[30,31] (Tripos Associates, St. Louis, MO, USA). The shape-based flexible fit of spinosyn D and the benzyl and benzoyl structures was done using Surflex-Sim v2.706 distributed with Sybyl-X 2.1. The top-scoring conformer of each compound from Surflex-Sim was used in the overlay.

Insecticide Bioassays. Dose–response data for each compound against two susceptible laboratory strains of the lepidopteran species *Spodoptera exigua* or *Helicoverpa zea* was determined with a diet-based bioassay using 128-well diet trays (Bio-Serv, Frenchtown, NJ, USA). Three to five second-instar larvae of either lepidopteran were placed in each well (3 mL) of the diet tray that had been previously filled with 1 mL of artificial diet. Selected dosages (12.5, 3.125, 0.78, 0.195, 0.049 μg/cm^2) of the test compound (dissolved in 50 μL of 90:10 acetone/water mixture, v/v) were then applied to the diet in each of 16 wells, allowed to dry, and covered with a clear self-adhesive cover. Controls received solvent only. All treatments were held at 25 °C and 14:10 h light/dark for 6 days. Each well was recorded as a unit (all alive or all dead), the activity across the 16 wells (for each dose) was then averaged. The lethal concentration for 50% of the test population (LC_{50}) and 95% fiducial limits for each compound, with correction for mortality in the controls, were determined using probit analysis.[32]

Bioassays against a susceptible laboratory strain of *Aphis gossypii* (cotton aphid) were conducted as described previously.[33] Briefly, 1-week-old summer crookneck squash seedlings, *Cucurbita pepo*, were pruned to a single cotyledon. A mixed population (immatures and adults) of *A. gossypii* was transferred to the cotyledons 16–24 h prior to the application of test materials. Test compounds were dissolved in 90:10 acetone/ethanol, v/v, to form a stock solution, from which an appropriate amount was diluted in water containing 0.05% Tween 20 to form the spray solution of 50 and 200 ppm. Application was made using a hand-held DeVilbiss airbrush sprayer on aphid-infested plants spraying both leaf surfaces until runoff. There were four replicates (plants) for each treatment, whereas controls consisted of eight replicates treated with a solvent blank. Following treatment, plants were held at 23 °C and 40% RH with a 24 h photoperiod prior to grading. Grading occurred at 72 h post-treatment and consisted of live aphid counts (all nonwinged stages) on each of the replicates compared to the averaged aphid population on the solvent blank controls to estimate a percent mortality.

RESULTS AND DISCUSSION

Synthesis. Rhamnose replacement analogues were made by first deglycosylating spinosyns J, **1**, and L, **2** (Figure 3), to form the pseudoaglycones **3** and **4**, respectively, as described previously.[34] A free C-9 hydroxyl group was then available to prepare benzylated or benzoylated derivatives. Twenty-eight benzyl bromides were selected on the basis of diverse steric and electronic properties. Some of these were available commercially, with the remainder prepared as shown in Figure 3. Commercially available benzyl alcohols were converted into the bromides using hydrogen bromide in dichloromethane/ether. When the benzyl alcohols themselves were unavailable, they were prepared either from the corresponding aldehyde, for **6x**, or acid, for **6l**, by reduction with sodium borohydride or lithium aluminum hydride ($LiAlH_4$), respectively. The substituted aryl methyl bromides were then reacted with **3** or **4**, using individual 1 dram vials with powdered potassium hydroxide/tetra-*n*-butylammonium iodide as the basic catalyst to produce the desired targets **5** and **6** (Figure 3). In addition to exhibiting the expected mass parent ion by LC-MS, the 9-*O*-benzyl products were also characterized by the presence of a $-OC\underline{H}_2-$ signal in the proton NMR between 4.4 and 4.56 ppm, in addition to the expected aromatic signals. This methylene peak was usually a singlet; however, due to its diastereotopic nature, it was sometimes observed as a doublet of doublets. Isolated yields were usually in the range of 50–85%, except when highly electron-rich benzyl bromides such as 2,4-dimethoxy, 2-methoxy, and 4-methoxy were used; in these cases, quaternization of the tertiary amine predominated under the conditions used for this reaction. Structures and selected

Insecticidal Activity. Earlier work using C9-benzoyl derivatives had evaluated 2-, 3-, and 4-methoxy benzoyl analogues,[27] as well as a C9-*O*-methyl. Because of the high reactivity of *o*- and *p*-methoxy-substituted benzyl bromides, which led to the formation of quaternary salts under our reaction conditions, the initial study focused on 3-methoxy analogues of spinosyns A and D, **5b** and **6b**, respectively (Table 2). These compounds were evaluated for insecticidal efficacy against two lepidopteran species, *S. exigua* and *H. zea*. As shown in Table 2, the C9-*O*-(3-methoxybenzyl) derivatives of spinosyns A and D, **5b** and **6b**, were more active than the corresponding C9 pseudoaglycones or the respective C9-*O*-benzoyl derivatives, **5a** and **6a**. However, neither **5b** nor **6b** was as potent as spinosyn A or D (Table 2).

Molecular Modeling Overlay. The 3-methoxybenzoyl, **6a**, and 3-methoxybenzyl, **6b**, derivatives of spinosyn D were overlaid on the structure of spinosyn D. As shown in Figure 4,

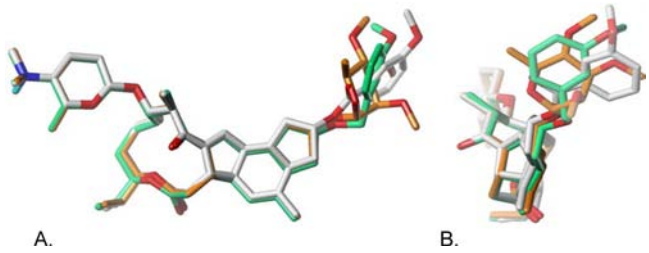

Figure 4. Overlays of C9 3-*O*-methylbenzyl, **6a** (green), and 3-*O*-methylbenzoyl, **6b** (light gray), spinosyn D derivatives, with spinosyn D (orange): (A) side view; (B) end-on view with the C9-benzyl and benzoyl bioisosteres in the foreground.

the benzyl derivative, **6b**, fits into the space of the rhamnose sugar better than the benzoyl derivative, **6a**. The better fit of the benzyl derivatives into the space of the rhamnose (Figure 4) may partially explain their improved insecticidal activity compared to the corresponding benzoyl derivatives (Table 2).

The above results prompted a more comprehensive evaluation of C9-*O*-benzyl analogues. For this study, spinosyn D analogues were prepared due to the availability of gram quantities of the corresponding 9-OH precursor. As noted in Table 2, the relative potencies of A and D analogues are similar. Although the C9-*O*-benzyl analogues displayed a wide range of insecticidal activity (Table 3), all of the analogues were less potent than spinosyn D. A few of the substitutions exhibited insecticidal activity against *S. exigua* that was within 5−15 times that of spinosyn D, whereas most were 20−200-fold less active than spinosyn D. The 2-isopropyl analogue, **6d**, was the most potent against *S. exigua* followed closely by the 3-*O*-methylethoxy, **6n**, 4-methyl, **6t**, 3,5-dimethoxy, **6p**, and benzofuran-2-yl, **6x**, analogues. For larvae of *H. zea*, the most active substitution was only about 3-fold less active than spinosyn D, with the majority being 20− 100-fold less active against *H. zea* than spinosyn D. The most effective substitution against larvae of *H. zea* was the 2-isopropyl, **6d**, followed closely by the 3,5-dimethoxy, **6p**, 4-Cl, **6r**, and 4-CN, **6s** (Table 3). All of the C9-*O*-benzyl analogues were also evaluated against *A. gossypii*. However, no insecticidal activity was observed against *A. gossypii* for any of the analogues at either the 50 or 200 ppm dose (data not shown).

Modifications of the spinosyn structure can greatly alter the insecticidal activity with significant improvements possible over the naturally occurring spinosyns.[13,17,35,36] As such, there has

Table 2. Insecticidal Activity of 9-*O*-Benzyl and 9-*O*-Benzoyl Spinosyns

been interest in exploring further alterations[27,28,33,34,37−41] and especially simplification of some components or the core macrolides tetracycle as a potential means for further exploration of these novel, complex, macrolides.[13,38,41,42] As noted in prior studies, deviation from the 2′,3′,4′-tri-*O*-methyl-*β*-L-rhamnose, whether by removing it, altering the stereochemistry, removing one or more *O*-alkyl groups, or replacing it with D- sugars, furanose sugars, or nonsugars,[13,27,35,36] all result in a large reduction (usually >100-fold) in insecticidal activity. Interestingly, the C9-*O*-benzyl ethers evaluated in the present study retained a significant level of insecticidal potency, demonstrating that, at least to some degree, a substituted benzylic group is better able to mimic the size and placement of the tri-*O*-rhamnosyl group. However, efforts to more closely mimic the shape or electronics of the rhamnose through incorporation of methoxy substituents met with limited success. For example, although the 3,5-dimethoxybenzyl substitution, **6p**, was among the most potent analogues against *S. exigua* larvae, several other simple substitutions, including 4-CN, **6s**, 4-Me, **6t**, 2-isopropyl, **6d**, 4-Cl, **6r**, and 3-methoxyethoxy, **6n**, were equally or more active. Two of the larger moieties, the benzofuran-2-yl, **6x**, and 6-fluoro-4*H*-benzo[1,3]dioxin-8-yl, **6w**, were also insecticidal against *S. exigua* larvae (Table 3), suggesting that to some degree larger moieties can be tolerated as replacements for the 2′,3′,4′-tri-*O*-methyl rhamnose. In general, the analogues showing the greatest potency against *S. exigua* were also among the most active against *H. zea* larvae, with the exception of the larger analogues, **6x** and **6w**.

In contrast to their excellent lepidopteran insecticidal activity, the spinosyns typically are weak against many sap-feeding insects such as aphids.[13,16] For example, spinosyn D is only weakly active (LC_{50} = 50 ppm) against *A. gossypii* compared to commercial aphicides such as imidacloprid (0.06 ppm).[14] None of the C9-*O*-benzyl analogues exhibited any activity against this aphid at the highest dose tested (200 ppm). Thus, the rhamnose bioisosteres were unable to improve on the activity of the spinosyns toward aphids relative to spinosyn D.

Although none of the rhamnose bioisostere-based spinosyns in the present study were as insecticidally active as spinosyn D, several analogues were within 3−15 times, depending on the insect species. Thus, the analogues exhibiting insecticidal activity close to that of spinosyn D demonstrate that an *O*-benzyl moiety can be a reasonable bioisostere for the 2′,3′,4′-tri-*O*-methyl rhamnose. Therefore, as demonstrated by the present and previous studies, the replacement of the sugars on macrolides such as the avermectins, and potentially the spinosyns, with nonsugar bioisoteres is further demonstrated to be a viable approach to developing new insecticidal chemistries.

[a]Values are in mg kg^{-1} DM or % of DM.

Most organic fertilizers contain all essential nutrients required for plant growth and development, but at varying concentrations, and most of them have to be mineralized prior to plant uptake.[5,6] Thus, the availability of nutrients for plant uptake may not be instantaneous and depends on, among other factors, temperature and humidity.[19] Therefore, plants may not necessarily receive adequate amounts of nutrients during the active phases of growth, and an imbalance between nutrient release from organic fertilizers and plant uptake may lead to leaching.[20] With increasing concern for the environment and food safety, fertigation (irrigation with a nutrient solution) is considered a viable option to overcome leaching by synchronizing nutrient demand and supply to the plant. However, optimal nutrient supply through fertigation with organic fertilizers is difficult due to varying rates of mineralization and the lack of organic fertilizers with only one or a few nutrients.[21] Thus, the choice of suitable organic fertilizers for fertigation is imperative to prevent plant nutrient deficiency and to increase the yield and quality of organic strawberries grown in inert growing media.

The effects of organic fertilizers applied via drip irrigation combined with different solid organic fertilizers on the yield, quality, and nutritional status of strawberries are poorly understood as only a very limited amount of research has been conducted within this area. In this context, we hypothesized that fertigation with organic fertilizers results in similar yields and quality of strawberries compared to fertigation with inorganic fertilizers. However, a very limited number of certified organic liquid fertilizers are available in Denmark. The study aimed at elucidating the combined effect of two different solid and two liquid organic fertilizers on the yield, quality, nutrient status, and DM content of leaf tissue and fruit. In addition, the effects on leaf chlorophyll content and pH, electrical conductivity (EC), and nutrient content of drainage water were studied.

MATERIALS AND METHODS

Plant Material and Growth Conditions. The experiment was conducted from early July to late September 2011 in an open plastic tunnel at the Department of Food Science, Aarhus University, Aarslev, Denmark (10°27′ E, 55°18′ N). The mean temperatures outside the tunnel were 16.5, 16, and 14 °C in July, August, and September, respectively. Cold-stored strawberry tray plants (*Fragaria* × *ananassa* Duch. cv. 'Sonata') with 9−15 mm crown diameter were planted in plastic pots (1.4 L) on July 4, 2011. After planting, pots were placed on wooden benches (tabletops) with a distance between benches of 120 cm and a distance between plants of 20 cm, giving 4.2 plants per square meter.

Biological control of aphids, spider mites, and thrips was applied every 2 weeks. In addition, 4 weeks after planting, Nemasys, a biological control agent containing the nematode *Heterorhabditis* spp., was applied against root cutworms. Then, from 5 weeks after planting, plants were sprayed with a 0.3% sulfur solution four times at an interval of 1 week to reduce powdery mildew (*Sphaerotheca macularis*) attack.

Fertilizer Treatments. Pots were filled with peat (Pindstrup substrate 2 standard mix (1 kg m^{-3} 16−6−20 NPK + micronutrients, 0.4 kg m^{-3} powdered superphosphate ($Ca(H_2PO_4)_2$ + $2CaSO_4$), and 0.05 kg m^{-3} Micromax); Pindstrup Mosebrug A/S, Denmark) for the inorganic treatment and the same product without macro- and micronutrients was used for the organic treatments.

Five treatments, one inorganic (IN) and four organic (Table 1), were established in four replicates in a completely randomized layout with four plants per replicate. The organic treatments were combinations of two solid organic fertilizers, composted chicken manure (2−1−2 NPK, Farmergødning, Denmark) and Monterra Malt (4−1−5 NPK, Borregaard BioPlant ApS, Denmark), and two organic liquid fertilizers, broad bean (0.51−0.09−0.41 NPK, Farmergødning, Denmark) and Pioner (Hi-Fruit 4−1−5 NPK or K-Max 3−1−7 NPK, Azelis, Denmark). The broad bean fertilizer was chosen among a very limited number of certified organic fertilizers available in Denmark. Pioner Hi-Fruit and Pioner K-Max are not from organically certified source material but are allowed for organic production. Before planting, either 66 g of chicken manure or 33 g of Monterra Malt was placed into the planting hole just underneath the root system. The nutrient content of the growing media was analyzed by a commercial laboratory (Agrolab, Germany) and is shown in Table 2. Plants were drip fertigated with one dripper per plant. Before the green fruit stage, which occurred 28 days after planting (DAP), plants were supplied with inorganic fertilizer with high N (130 ppm of N) and low K and Ca concentrations, broad bean, or Pioner Hi-Fruit. From 28 DAP plants were fertigated with inorganic fertilizer with low N (90 ppm of

N) and high K and Ca concentrations, broad bean, or Pioner K-Max (Tables 1 and 3). All fertigation solutions were made up to contain approximately the same amount of total (organic + inorganic) nitrogen (N) on the basis of the certificates obtained with the fertilizer products along with all other nutrients in nonequimolar concentrations. The actual contents of NO_3^--N, NH_4^+-N, and other nutrient elements in the fertigation solutions were analyzed by a commercial laboratory (Eurofins, Denmark) and are shown in Table 3. Each plant received 105, 210, and 315 mL of fertigation solution daily 0−7, 8−42, and 43−85 DAP, respectively, and each plant received approximately 3 g of N through fertigation during the experiment.

Nutrient Analyses of Drainage Water. EC and pH were measured by a pH and EC meter (HANNA Instruments Inc. model no. HI 9813, Romania) in drainage water from each replicate once a week from 15 to 85 DAP and are referred to as EC_{dw} and pH_{dw}, respectively. Plastic saucers were placed underneath the pots to collect drainage water after fertigation. Samples of drainage water were sent to a commercial laboratory (Eurofins, Denmark) for nutrient analyses 23 and 65 DAP.

Chlorophyll Content of Leaves. The leaf chlorophyll (Chl) content was estimated once a week starting 10 DAP on young fully developed leaves using an SPAD-502 meter (Spectrum Technologies, Inc., Plainfield, IL, USa). SPAD measurements were taken at three different areas per leaf so that major veins did not interfere with the measurement.

Multielement Analysis of Fruits and Leaves. The contents of macronutrients P, K, Ca, Mg, and S and micronutrients B, Cu, Fe, Mn, and Zn in fruit and leaf samples were analyzed by inductively coupled plasma−optical emission spectroscopy (ICP-OES). Fruit was collected 66 DAP, and fully expanded young leaves were collected 24 and 66 DAP and stored at −20 °C. Fruit and leaf samples were freeze-dried for 90 and 48 h, respectively, prior to multielement analysis. Samples were homogenized into a fine powder using a ball mill equipped with containers and balls coated with zirconium to avoid metal contamination (Retsch mm301, Retsch, Haan, Germany). A 250 mg portion of each sample was digested as described by Husted et al.[22] in an open-vessel system. Samples were subsequently diluted to 3.5% v/v HNO_3 with Milli-Q water and analyzed as described by Laursen et al.[23] Data quality was evaluated using two different certified reference materials, namely, apple leaves (NIST 1515, National Institute of Standards and Technology, Gaithersburg, MD, USA) and spinach leaves (NCS ZC73013, China National Analysis Center for Iron and Steel, purchased from LGC Standards, London, UK). Data were rejected if below the limit of detection (LOD). The LOD was determined as 3 times the standard deviation of a minimum of 7 blanks. Furthermore, data were accepted only if the accuracy for each element was >90% of the certified reference value. The concentrations of N and C were measured using IRMS (ANCA-SL elemental analyzer coupled to a 20−20 Tracermass mass spectrometer, Sercon Ltd., Crewe, UK). Quality assurance was performed by analysis of Certified Reference Materials (NIST 1515, NIST 8436, and 141d acetanilide $CH_3CONHC_6H_5$, National Institute of Standards and Technology) as previously described by Laursen et al.[23]

Fruit Harvest, Yield, and Quality. Fruit was harvested two times a week after full color developed, beginning at 43 DAP (in total, 12 times). Fruit of marketable and nonmarketable quality was weighed and counted. Nonmarketable fruit was distinguished from marketable fruit on the basis of size (<20 mm diameter) and surface characteristics. The surface characteristics included signs of decay due to disease or insect incidences and malformations. The total yield and percentage of marketable fruit was calculated.

Total soluble solids (TSS), titratable acid (TA), dry matter (DM), and firmness were measured on fruit of marketable quality two times (56 and 70 DAP) during the experiment. Firmness was measured as maximum penetration force (N) of fruit using a Fruit Texture Analyzer (FTA 264, Guss, South Africa) fitted with a 5 mm diameter convex puncture probe. The metal cylinder was set to a trigger threshold of 1.1 N and run with a forward speed of 30 mm s^{-1}, measuring speed of 10 mm s^{-1}, reverse speed of 30 mm s^{-1}, and measuring distance of 8 mm. The DM content was measured after oven-drying of fruit samples for 72 h at 60 °C. TSS and TA were determined on homogenates. After removal of the calyxes, fruit was liquidized with 50% demineralized water (w/w) until uniform. The samples were then centrifuged at 12000 rpm for 10 min, and the supernatant was poured into glass vials. TSS was measured by a digital refractometer (RFM 712, Bellinghum Stanley, UK) on 1−2 drops and expressed as degrees Brix (°Brix), which is equivalent to TSS (g 100 g^{-1}) of the sample. For TA, 7−9 g of the supernatant was weighed off and titrated with 0.1 N NaOH to an end point of pH 8.1 using an automatic Tritino 719 S titrator (Ω Metrohm, Switzerland). Results were expressed as citric acid equivalents (mg g^{-1}) fresh weight. All measurements were performed in duplicate.

Biomass Distribution. For DM calculation, runners and other plant parts were separated and oven-dried for 24 h at 60 °C. Runners were also cut three times during the experiment, weighed, and oven-dried for calculation of total above-ground biomass.

Statistical Analysis. The statistical data analysis was done using the GLM procedure of SAS (Statistical Analysis System, version 9.2, SAS Institute, Cary, NC, USA). Tukey's studentized range test was applied to determine significant differences between treatments at a $P < 0.05$ level of significance for fruit yield, quality parameters, nutrient

J. Agric. Food Chem. 2015, 63, 5578−5586

concentrations of leaves and fruit, EC_{dw}, pH_{dw}, and chlorophyll content of leaves.

RESULTS

pH, EC, and Nutrient Concentration of Drainage Water. Throughout the experiment, the pH_{dw} was higher in all organic fertilizer strategies than in the inorganic strategy (Figure 1a). Between 22 and 36 DAP, the pH_{dw} decreased by approximately 1 unit in the organic strategies, but not in the inorganic. Between 43 and 64 DAP, the pH_{dw} increased approximately 1 unit in all treatments, and in the same period the EC_{dw} also increased in all treatments (Figure 1b). Incorporation of Monterra Malt resulted in a slightly higher EC_{dw} than did chicken manure during the first 3 weeks; thereafter, similar or slightly higher EC_{dw} values from chicken manure were measured. From 29 DAP, the EC_{dw} from plants given Pioner High-K/K-max was higher than for plants given broad bean fertigation (Figure 1b). The EC_{dw} for the inorganic fertilizer strategy was between 1.5 and 2 dS m^{-1} for the first 6 weeks, and thereafter it increased in a similar pattern as in the organic strategies.

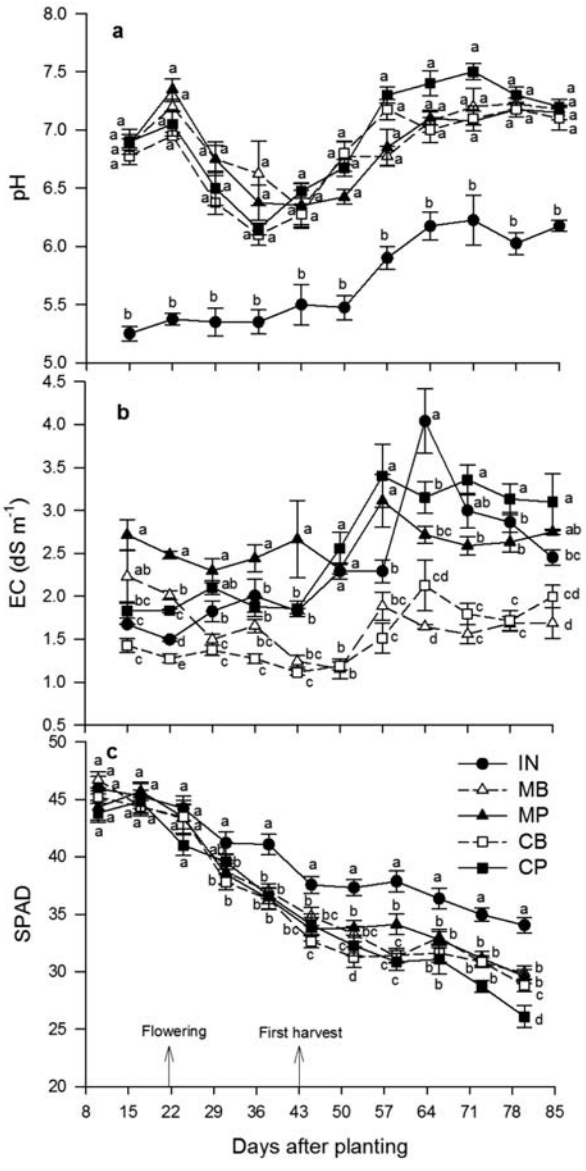

Figure 1. Effect of inorganic (IN) and different organic fertilizer strategies Monterra Malt + broad bean (MB), Monterra Malt + Pioner (MP), chicken manure + broad bean (CB), and chicken manure + Pioner (CP) on (a) pH, (b) EC measured in drainage water 15−85 days after planting, and (c) SPAD measurements on the youngest fully expanded leaves. Bars indicate standard error of the mean (n = 4), and different letters indicate statistically significant differences between strategies within a week (P < 0.05).

Three weeks after planting (23 DAP), almost all nitrogen in the drainage water was in the form of NO_3^- in the inorganic and NH_4^+ in the organic treatments (Table 4). Nine weeks after planting (65 DAP), the NH_4^+ concentration was low in drainage from all treatments, whereas the NO_3^- concentration was high in the inorganic treatment, medium high when fertigated with Pioner K-max, and very low when fertigated with broad bean. The potassium concentration was higher in drainage water from plants fertigated with Pioner Hi-Fruit/K-max compared with broad bean, and 23 DAP more potassium was available from Monterra Malt than from chicken manure. Both potassium and sodium accumulated over time when Pioner Hi-Fruit/K-max was applied, but also to some extent when inorganic fertilizer was given. Concentrations of phosphorus, magnesium, calcium, manganese, zinc, copper, and boron were in general higher in the inorganic treatment.

SPAD. Until 24 DAP, no differences in SPAD values were observed for young fully developed leaves, but after that date the inorganic treatment showed significantly higher SPAD values than the organic treatments (Figure 1c). The observed SPAD values decreased from the beginning of the experiment toward the end in all fertilizer strategies.

DM Distribution. Similar amounts of fruit DM were found in all treatments, whereas more DM was found in leaves and runners of plants receiving inorganic fertilizer (Figure 2a). Therefore, a larger percentage of the accumulated above-ground DM was allocated to fruit in the organic treatments (62−66% of total DM) compared to the inorganic treatment (52% of total DM) (Figure 2b). The total DM per plant was also significantly higher in the inorganic treatment. The biomass of leaves and runners from the different organic treatments was not statistically different. Similar percentages of DM were allocated to leaves (33−39%) in all treatments, but more to runners in plants given inorganic (9%) than in those given organic fertilizer (1−3%).

Nutrient Concentrations in Leaves and Fruits. On day 24 after planting, the leaf concentrations of N, K, Mg, and Ca were within the recommended levels for strawberry growth[14] in all treatments, although for N, K, and Mg relatively high values were found (Table 5). The P concentrations in leaves from the inorganic and chicken manure treatments were in excess of the recommended values at 24 DAP, whereas the P concentration was similar in leaves and fruits given Monterra Malt or chicken manure at 66 DAP. On the other hand, leaf S and Cu levels were deficient in all treatments. In general, the concentrations of all micronutrients were lower in leaves from plants given organic fertilizers compared with the inorganic fertilizer (Table 5). Midway through the picking period (66 DAP) a similar pattern in leaf nutrient concentration was seen as at 24 DAP, but the leaf N levels were slightly lower in all treatments and the N concentration in the inorganic treatment was higher than in the organic treatments. The leaf Ca was highest in the inorganic treatment and low but still within the recommended range in the organic treatments. The S concentration in leaves at 66 DAP was about 3-fold higher than at 24 DAP for all

treatments. In fruit, the highest contents of all nutrients were seen in the inorganic treatment, but the magnesium concentration did not differ between treatments at day 66 after planting (Table 6).

Fruit Yield and Quality. The five fertilization strategies influenced fruit weight and total and marketable fruit yield per plant. The inorganic strategy resulted in the highest total yield, marketable yield, and fruit weight, but except for the fruit weight these parameters did not differ significantly from the Monterra Malt combined with broad bean treatment (Table 7). When the organic strategies were compared in a separate statistical analysis, the broad bean fertigation resulted in a higher marketable and total yield than fertigation with Pioner Hi-Fruit/K-max, whereas the two solid fertilizers incorporated in the growing media resulted in similar yields. The fruit weight did not differ among the organic fertilizer strategies. No statistical differences were found in the percentage of marketable fruit among the five treatments (Table 7).

Fruit TSS and TA were generally higher in plants given Pioner Hi-Fruit/K-max compared with broad bean fertilizer (Table 8), but for fruit harvested 56 DAP TSS contents were similar in all treatments. Fertigation with broad bean fertilizer resulted in similar TSS and TA contents as inorganic fertilizer.

In general, fruit from the organic treatments was noticeably firmer than fruit from the inorganic treatment, and plants supplied with chicken manure tended to produce firmer fruit than plants given Monterra Malt. No significant difference was found between treatments with regard to fruit DM content, but fruit from the organic strategies tended to have a higher percentage DM.

DISCUSSION

Fruit Yield and DM Distribution. The fruit yield and quality of strawberries grown under organic conditions may differ from conventional production systems.[4−7] Furthermore, different forms of organic fertilizer may affect the yield, quality, and nutrient content of strawberry fruit differently.[6,24] In our study, differences in fruit yield were primarily due to differences in fruit weight rather than the number of fruits per plant, indicating that deficient or excess levels of nutrients or other growing conditions have not caused flower abortion as fruit number was determined during flower induction the previous year.[25] The observed reductions in fruit yield and fruit weight from organic treatments may be due to a combination of the following conditions in the root zone: (1) high pH and high NH_4^+/NO_3^- ratio; (2) high EC and/or high NaCl concentration; (3) cation imbalance; and (4) nutrient deficiency.

High pH and High NH_4/NO_3 Ratio. In accordance with previous investigations,[26,27] the pH_{dw} from plants supplied with organic fertilizers was higher than for plants receiving inorganic fertilizers. The higher root zone pH could be responsible for the lower fruit yield in the organic treatments because it influences root growth and nutrient solubility/availability and uptake.[6,16] Also, a high pH may cause precipitation of carbonates of Ca^{2+}, Mg^{2+}, and other cations.[28,29] That $CaCO_3$ precipitation took place is supported by the lower Ca concentrations in drainage water and leaves from the organic treatments, although the Ca^{2+} concentrations in the given organic fertigation solution were similar to the inorganic fertigation solution (Table 3). Furthermore, the availability of micronutrients in the root zone may be decreased at a soil pH >6.5, even in nutrient-rich conditions, due to tight binding with organic matter, clay, and other negatively charged particles.[10,15−17]

In addition to high pH, a high concentration of NH_4^+ in the root zone may have reduced the fruit yield from organic treatments. Tabatabaei et al.[30] reported that a high concentration of NH_4^+ inhibited photosynthesis, growth, and yield in strawberry, and a high ratio of NH_4^+ to NO_3^- has been shown to reduce the biomass allocation to vegetative plant parts.[31] In accordance with this, a larger proportion of total plant DM accumulated in fruit from the organic treatments despite a lower fruit yield in three of the four organic combinations compared with inorganic fertigation (Figure 2).

High EC and/or High NaCl. In the present study, the reduced yield and fruit weight from plants receiving Pioner Hi-fruit/K-max could also be due to high EC_{dw} as values were higher than the optimum level recommended for strawberry

growth.[32−34] It was shown that EC levels >1.71 dS m^{-1} decreased the fruit yield and fruit weight;[34] however, the sensitivity to high EC depended on cultivar and types of dissolved solutes.[32,34,35] Moreover, the lower yield due to the Pioner fertigation may be the result of high concentrations of Na^+ and Cl^- in the root zone. Strawberry plants are considered sensitive to high concentrations of NaCl, although some cultivars are more tolerant than others.[35,36] Previous studies have reported that NaCl stress can reduce fruit yield in both salt-tolerant and -intolerant strawberry cultivars[36] if the EC value of the nutrient solution is >2.5 dS m^{-1}.[32] In susceptible cultivars leaf symptoms are visible at 6 mM NaCl, but not in tolerant cultivars.[35] In the present study, concentrations of Na^+ and Cl^- in the drainage water reached maximum concentrations of 8.1 and 6.0 mM, respectively, when chicken manure + Pioner fertigation was given; however, visual symptoms were not noticed in leaves (Table 4). Therefore, we cannot exclude a minor negative effect on fruit yield of NaCl, but it is not likely to be the main cause of the lower yield when organic fertilizers were given.

Cation Imbalance. An imbalance between cations in the root zone could also contribute to the reduced fruit yield from organic treatments. It has been shown for several plant species that the concentration ratios of K^+, Ca^{2+}, and Mg^{2+} within the plant are linearly correlated with the corresponding ratios of cation activities (a_K, a_{Ca}, and a_{Mg}) of the soil solution.[37] Nutrient analyses of drainage water revealed very high K^+/Ca^{2+} and K^+/Mg^{2+} ratios in the organic fertilization strategies, especially when Pioner Hi-fruit/K-max was applied (Table 4), and this resulted in decreased concentrations of Ca and Mg in the leaves. High K^+/Ca^{2+} and K^+/Mg^{2+} ratios in the fertigation solution reduce fruit number, fruit weight, and yield in strawberries.[38] Also, the high levels of NH_4^+ in the root zone may have competed with Ca^{2+}, Mg^{2+}, and K^+ during root uptake and resulted in lower leaf concentrations of Ca, Mg, and K and lower fruit concentrations of Ca and K.[31]

Nutrient Deficiency. Low levels of available N and P in the root zone, especially at the end of the fruiting period, could also have caused the reduced fruit yield and fruit weight when plants were supplied with organic fertilizer. Leaf and fruit analyses showed that N and K were the predominant nutrients, which is in agreement with previous findings.[8,31] In all treatments, the leaf N concentrations were between 2.7 and 3.6% of DM, which

are within the optimum tissue level for strawberry growth (Table 5).[14] When comparing the leaf N concentration in the organic and inorganic treatments, we observed similar concentrations 24 DAP, whereas a lower concentration was found in leaves from the organic treatments 66 DAP. This demonstrates that incorporation of composted chicken manure or Monterra Malt, which increased total N in the growing media considerably, could supply sufficient N in the beginning of the growing period, whereas the organic fertigation solutions were both insufficient in N supply. The N concentration in fruit was also higher in the inorganic than in the organic treatments when composted chicken manure was incorporated prior to planting. Insufficient N supply may have decreased both total plant biomass and total fruit yield due to a reduced chlorophyll content and photosynthesis, which was indicated by lower SPAD values in the organic treatments (Figure 1c). In our study, the K concentration in the Pioner Hi-Fruit fertigation solution was 2 and 2.5 times higher than in the inorganic and broad bean solutions, respectively. However, only minor differences in leaf K were seen, and fruit K concentrations were generally lower in the organic treatments. Also, the leaf Ca concentration was lower in the organic treatments compared with the inorganic treatments, and the level was deficient according to Reuter and Robinson.[14] As previously mentioned, this could be due to $CaCO_3$ precipitation in the alkaline growing medium.[29] Similarly, the low concentrations of Fe, Mn, B, and Zn in the root zone of the organic treatments may be due to complexing with hydroxides, phosphates, and carbonates at the high pH.[39,40] These low levels of micronutrients in the root zone were also reflected by leaf and fruit tissue concentrations in the deficient range of the same micronutrients[14] and may have negatively influenced both the vegetative and generative growth in the organic treatments. Previous studies have also shown that the nutrient concentrations of applied fertilizers are not the only determinant of mineral uptake in strawberry plants and fruits because soil properties such as pH, EC, NaCl, and microbial activity greatly determine nutrient uptake by plants.[6,15]

Fruit Quality. In our study, we considered TSS, TA, firmness, and DM as important parameters for the eating quality of fruits. TSS and firmness were higher in fruit harvested 70 DAP than in fruit harvested 56 DAP, and these differences could be due to the decreasing temperature and the smaller fruit size of secondary and tertiary fruits and thereby an up-concentration of the soluble solids.[41−43] At the last harvest (70 DAP), TSS and TA in fruit supplied with Pioner fertigation

DOI: 10.1021/acs.jafc.5b01366
J. Agric. Food Chem. 2015, 63, 5578−5586

were higher compared with fruit supplied with inorganic fertigation, and fruit from the broad bean treatments were intermediate. Our finding is in agreement with Reganold et al.,[8] and Shehata et al.,[24] as they also observed higher TSS in organically grown fruit than in inorganically grown fruit. Also, the fruit DM content tended to be higher in the organic treatments, indicating that the higher TSS could be due to lower fruit water content as seen in other studies.[8] In our study, plants from the Pioner fertigation were smaller, which may have allowed more light penetration due to less self-shading effect. Hargreaves et al.[6] and Watson et al.[44] reported that plants exposed to a higher light integral contained more sugar in their fruit. The higher availability of nitrogen in the inorganic treatment may also explain the lower TSS in fruit as Cantliffe et al.[12] reported that increasing amounts of nitrogen fertilizer reduced fruit TSS. The fruit firmness and DM content tended to be higher in the organic fertilization strategies, which is in agreement with the findings of Reganold et al.,[8] and may be due to a higher proportion of cell wall content in the small-sized organic fruits compared to the large-sized inorganic fruits[45] as a result of the lower N level in organic fruit.[46]

In conclusion, incorporation of Monterra Malt in a limed peat-based growing medium combined with broad bean fertigation resulted in similar marketable fruit yield and quality, except for slightly smaller fruits, compared to an inorganic fertilizer strategy. A minor increase in quality parameters of fruits (firmness, TSS, and TA) was seen at the end of the fruiting period when plants were fertigated with Pioner High Fruit/K-max, which was probably due to reduced fruit size. Organic fertilizer combinations resulted in high pH, EC, and/or NaCl concentration and NH_4^+/NO_3^- ratio, cation imbalance, and nutrient deficiency in the root zone, which may be responsible for the lower fruit yield and fruit weight relative to organic treatments.

sized compounds displayed nanomolar potency toward *At*HPPD. In addition, some compounds exhibited promising and broad-spectrum herbicidal activity at the rate of 150 g ai/ha as well as selectivity to several crops, such as maize, wheat, or rice.

MATERIALS AND METHODS

Detailed information for the synthesis of compounds **I**–**VI** is shown in Figures 1–4.

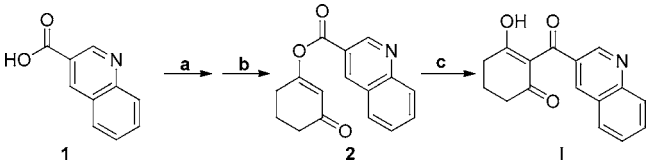

Figure 1. Synthetic route for lead compound **I**. Reagents and conditions: (a) $(COCl)_2$, CH_2Cl_2, −5 °C; (b) 1,3-cyclohexanedione, CH_2Cl_2, 0 °C; (c) acetone cyanohydrin, Et_3N, CH_2Cl_2, room temperature.

X-ray Diffraction. Compound **III-d** was recrystallized from a mixture of acetone and *n*-hexane to afford a suitable single crystal. Light brown crystals of **III-d** (0.20 mm × 0.20 mm × 0.20 mm) were mounted on a quartz fiber with protection oil. Cell dimensions and intensities were measured at 298 K on a Bruker SMART APEX DUO area detector diffractometer (Bruker AXS, Madison, WI, USA) with graphite monochromated Mo Kα radiation (λ = 0.71073 Å); θ_{max} = 28.00; 14889 measured reflections; 4658 independent reflections (R_{int} = 0.0484). The data sets were integrated and reduced using the SAINT Plus program.[24] Data were corrected for Lorentz and polarization effects and for absorption (T_{max} = 0.9821; T_{min} = 0.9821). The structure was solved by direct method using SHELXS97 and refined with SHELXL970.[25] Full-matrix least-squares refinement based on F^2 using the weight of $1/[\sigma^2(F_0^2) + (0.0976P)^2 + 0.2989P]$ gave final values of R_1 = 0.0690, ωR_2 = 0.1652, and GOF(F) = 1.128 for 265 variables, 265 parameters, and 4658 contributing reflections. Maximum shift/error = 0.000, and maximum/minimum residual electron density = 0.614 per −0.329 e Å^{-3}. Hydrogen atoms were observed and placed at their ideal positions with a fixed value of their isotropic displacement parameter.

Compound **III-f** was recrystallized from a mixture of acetone and *n*-hexane to afford a suitable single crystal. Light yellow crystals of **III-f** (0.12 mm × 0.10 mm × 0.10 mm) were mounted on a quartz fiber with protection oil. Cell dimensions and intensities were measured at 298 K on a Bruker SMART APEX DUO area detector diffractometer with graphite monochromated Mo Kα radiation (λ = 0.71073 Å); θ_{max} = 30.00; 15593 measured reflections; 4396 independent reflections (R_{int} = 0.1064). The data sets were integrated and reduced using the SAINT Plus program.[24] Data were corrected for Lorentz and polarization effects and for absorption (T_{max} = 0.9904; T_{min} = 0.9885). The structure was solved by direct method using SHELXS97 and refined with SHELXL970.[25] Full-matrix least-squares refinement based on F^2 using the weight of $1/[\sigma^2(F_0^2) + (0.0886P)^2 + 0.2528P]$ gave final values of R_1 = 0.0514, ωR_2 = 0.1438, and GOF(F) = 1.067 for 211 variables, 211 parameters, and 4396 contributing reflections. Maximum shift/error = 0.000, and maximum/minimum residual electron density = 0.869 per −0.369 e Å^{-3}. Hydrogen atoms were observed and placed at their ideal positions with a fixed value of their isotropic displacement parameter.

Crystallographic data for compounds **III-d** and **III-f** have been deposited with the Cambridge Crystallographic Data Centre as a supplementary publication with the deposition no. 1040193 and 977357, respectively. These data can be obtained free of charge from http://www.ccdc.cam.ac.uk/.

Plasmid Construction, Protein Expression and Purification, Activity Assays, and Kinetic Inhibition Studies. *At*HPPD was constructed by PCR using cDNA of HPPD in pMD19-T Simple (Hangzhou BIOSCI Biotechnology Company, Hangzhou, China) as the template. The primers used here were 5′-CATGCCATGGGCC-ACCAAAACGCCGC-3′ (Nco*I*) and 5′- CGCGGATCCTCAGTG-GTGGTGGTGGTGGTCCCACTAACTGTTT-3′ (*Bam*HI). PCR conditions were 35 cycles at 94 °C for 30 s, 55 °C for 30 s, and 68 °C for 1.5 min. The amplion was introduced into the expression vector pET-15b and subsequently transformed into *Escherichia coli* BL-21(DE3). The DNA sequences of the positive clones were confirmed by DNA sequencing with Shanghai SANGON Company.

Recombinant *At*HPPD was overexpressed in *E. coli* BL-21 (DE3) cells with pET-15b-HPPD plasmid. Recombinant homogentisate 1,2-dioxygenase (HGD) from human was overexpressed in *E. coli* BL-21 (DE3) cells with pET-28a-HGD plasmid. The cells were grown at 37 °C in Luria–Bertani broth supplemented with 50 μg/mL kanamycin (pET-28a plasmid) or 100 μg/mL antimycin (pET-15b plasmid) according to a previous publication.[26] Expression of the *At*HPPD plasmid was incubated at 37 °C for 12 h. HGD was induced by 0.5 mM isopropyl β-D-1-thiogalactopyranoside (IPTG) when bacterial grown reached an A_{600} of 0.6, and then the cells were incubated for another 40 h at 15 °C. After harvesting by centrifugation (5000*g*, 30 min), the pellet was resuspended in buffer (20 mM HEPES, 20 mM NaCl, pH 7.0) and washed twice, followed by sonication using a cell

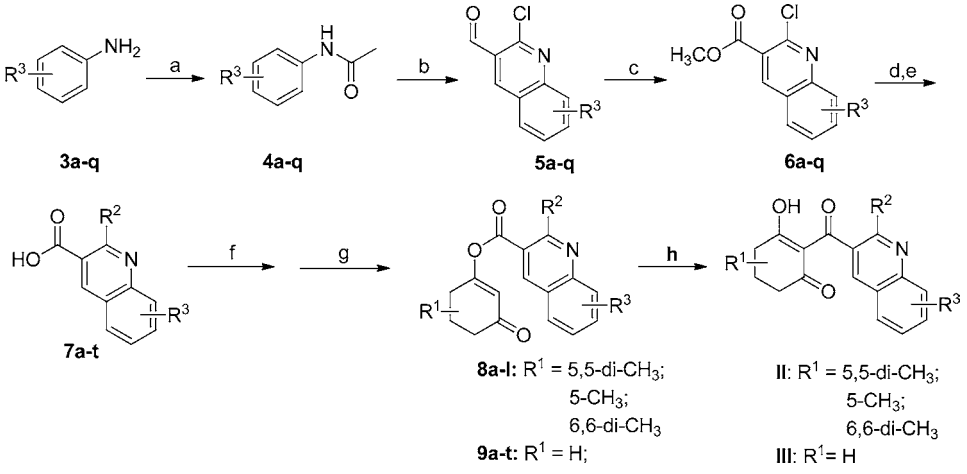

Figure 2. Synthetic route for compounds **II** and **III**. Reagents and conditions: (a) $(CH_3C)_2O$, Et_3N, CH_2Cl_2, 0 °C–room temperature; (b) DMF, $POCl_3$, 0–80 °C; (c) K_2CO_3, CH_3OH, I_2, reflux; (d) Na, alcohols, reflux; (e) H_2O, citric acid; (f) $(COCl)_2$, CH_2Cl_2, −5 °C; (g) (substituted) 1,3-cyclohexanedione, CH_2Cl_2, 0 °C; (h) acetone cyanohydrin, Et_3N, CH_2Cl_2, room temperature.

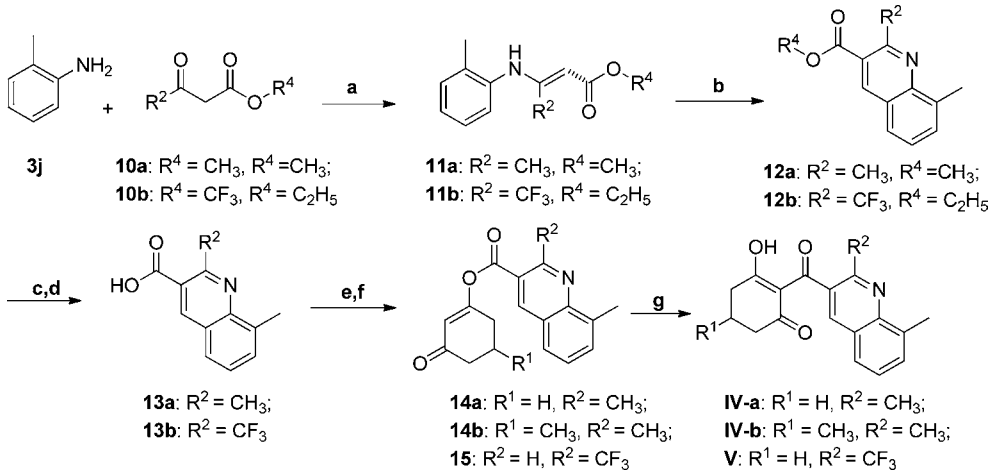

Figure 3. Synthetic route for target compounds **IV** and **V**. Reagents and conditions: (a) *p*-toluenesulfonic acid (*p*-TSA), cyclohexane, reflux; (b) DMF, $POCl_3$, DCE, 70−80 °C; (c) $LiOH{\cdot}H_2O$, methanol, H_2O, reflux; (d) citric acid; (e) $(COCl)_2$, CH_2Cl_2, 0 °C; (g) (substituted) 1,3-cyclohexanedione, Et_3N, CH_2Cl_2, 0 °C; (h) acetone cyanohydrin, Et_3N, CH_2Cl_2, room temperature.

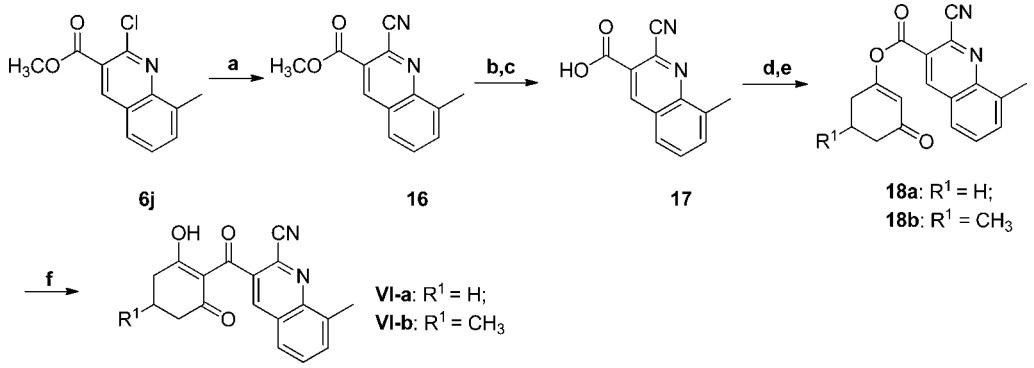

Figure 4. Synthetic route for target compounds **VI**. Reagents and conditions: (a) CuCN, DMF, reflux; (b) $LiOH{\cdot}H_2O$, methanol, H_2O, reflux; (c) citric acid; (d) $(COCl)_2$, CH_2Cl_2, 0 °C; (e) (substituted) 1,3-cyclohexanedione, Et_3N, CH_2Cl_2, 0 °C; (f) acetone cyanohydrin, Et_3N, CH_2Cl_2, room temperature.

disruptor. A crude cell-free supernatant was obtained by centrifugation at 20000 *g* for 30 min.

*At*HPPD was purified in two chromatographic steps. The crude cell-free supernatant was loaded onto a Ni-NTA column (Qiagen, Canada), equilibrated with 20 mM HEPES, pH 7.0. Then, HPPD was eluted with 20 mM HEPES, pH 7.0, 150 mM NaCl, and 250 mM imidazole. The fractions containing HPPD were concentrated, and the buffer was exchanged for 20 mM HEPES, pH 7.0, by ultrafiltration in Ultrafree filter devices (Millipore, Bedford, MA, USA). To further purify the recombinant HPPD, anion exchange chromatography was carried out on Q resin (Amersham-Pharmacia Biotech, Germany) in 20 mM HEPES, pH 7.0. Elution of the recombinant HPPD was carried out in a linear gradient from 0 to 250 mM NaCl. Again, the HPPD-containing fractions were collected and the buffer was exchanged to 20 mM HEPES, pH 7.0.

The in vitro activity and inhibition of *At*HPPD were measured by a modification of coupled enzyme assay methods previously reported in the literature.[27] Assays were performed in 96-well plates at 30 °C using a UV−visible plate reader (Biotech, Winooski, VT, USA) to monitor the formation of maleylacetoacetate at 318 nm (ε_{330} = 13500/M/cm). The reaction mixture in a total assay volume of 200 μL contained appropriate amounts of HPPA, 100 μM $FeSO_4$, 2 mM sodium ascorbate, 20 mM HEPES buffer (pH 7.0), HPPD, and HGD. Before assays were conducted, all reaction components were pre-equilibrated at 30 °C for at least 10 min. The amount of HGD activity was predetermined to be in large excess of the HPPD activity to ensure that the reaction was tightly coupled (the K_m of HGD for HGA was 25 μM). Each experiment was repeated in at least three duplicates, and the values were averaged. HPPD inhibitors were dissolved in dimethyl sulfoxide (DMSO) for stock solution and diluted to various concentrations with reaction buffer just before use. The inhibition constant (K_i), the indication of an inhibitor's potency, was obtained from the Dixon plot of plotting $1/v$ against concentration of inhibitor at certain concentrations of substrate. Bovine serum albumin is usually added up to 0.5% of the total reaction volume for coating of the target enzyme during the incubation. In our assay, no obvious effect from bovine serum albumin on the activity of the compounds has been found, which indicated that the new compounds selectively inhibited the target enzyme but did not interact with bovine serum albumin.

Computational Modeling and CoMSIA Analysis. The crystal structure of *At*HPPD was taken from the PDB data bank (PDB ID 1TFZ). Compounds were constructed and optimized by using SYBYL 7.0 (Tripos Inc.), and Gasteiger−Huckel charges were calculated for them. Docking calculations were performed on the two molecules by using AutoDock 4.0. The protein and ligand structures were prepared with AutoDock Tools. A total of 256 runs was launched for each molecule. Each docked structure was scored by the built-in scoring function and was clustered by 0.8 Å of RMSD criterions. The best binding modes were determined by docking scores and also the comparison with available complex crystal structure of DAS645 with *At*HPPD (PDB entry 1TG5) as reference.[28] Standard Amber ff99 force field parameters were assigned to protein, and general AMBER force field (gaff) was assigned to ligands. The partial atomic charges of ligands were calculated using the AM1-BCC method, and the system was solvated in an octahedral box of TIP3P water with the crystallographic water molecules kept. The edge of the box was at

[a]Herbicidal activity was tested at the rate of 150 g ai/ha. [b]Abbreviations: EC, *Echinochloa crus-galli*; SF, *Setaria faberii*; DS, *Digitaria sanguinalis*; AR, *Amaranthus retroflexus*; EP, *Eclipta prostrata*; AJ, *Abutilon juncea*. [c]Inhibition constant of the enzyme reaction.

least 8 Å from the solute, and appropriate counterions were added to the system to preserve neutrality. In each step, energy minimization was first performed by using the steepest descent algorithm for 1000 steps and then the conjugated gradient algorithm for another 2000 steps.

We selected the majority of the new molecules that show different activities to perform 3D-QSAR. All molecular modeling and 3D-QSAR studies were performed using SYBYL7.3 with TRIPOS Force Field. The 3D structures of all compounds were built by using default setting of SYBYL, and the molecules were subjected for energy minimization at a gradient of 1.0 kcal/mol with delta energy change of 0.05 cal/mol. The CoMFA descriptors and steric and electrostatic field energies were calculated using the SYBYL default parameters: 2.0 Å rid points spacing, an sp^3 carbon probe atom with +1 charge, a minimum σ (column filting) of 2.0 kcal/mol, and an energy cutoff of 30.0 kcal/mol.

Herbicidal Activities. The postemergent herbicidal activities of compounds **I–VI** against *Echinochloa crus-galli* (EC), *Setaria faberi* (SF), *Digitaria sanguinalis* (DS), *Amaranthus retroflexus* (AR), *Eclipta prostrata* (EP), and *Abutilon juncea* (AJ) were evaluated according to the previously reported procedure;[14−16,29] the commercial triketone herbicide mesotrione was selected as a positive control. All test compounds were formulated as 100 g/L emulsified concentrates by using DMF as solvent and Tween-80 as emulsification reagent. The concentrates were diluted with water to the required concentration and applied to pot-grown plants in a greenhouse. The soil used was a clay soil, pH 6.5, 1.6% organic matter, 37.3% clay particles, and CEC 12.1 mol/kg. The rate of application (g ai/ha) was calculated by the total amount of active ingredient in the formulation divided by the surface area of the pot. Plastic pots with a diameter of 9 cm were filled with soil to a depth of 8 cm. Approximately 20 seeds of the tested weeds were sown in the soil at the depth of 1−3 cm and grown at a temperature of 15−30 °C in a greenhouse. The air relative humidity was 50%. The diluted formulation solutions were applied for postemergence treatment. Broadleaf weeds were treated at the two-leaf stage, and monocotyledon weeds were treated at the one-leaf

J. Agric. Food Chem. 2015, 63, 5587−5596

stage. The postemergence application rate was 150 g ai/ha. Untreated seedlings were used as the control group, and the solvent (DMF + Tween-80)-treated seedlings were used as the solvent control group. Herbicidal activity was evaluated visually at 15 days post-treatment (Tables 1 and 2), with three replicates per treatment.

Crop Selectivity. The conventional rice, soybean, cotton, wheat, canola, and maize were planted separately in pots (12 cm diameter) containing test soil and grown in a greenhouse at 20−25 °C.[23] After the plants had reached the four-leaf stage, the spraying treatment was conducted at the dosage of 150 g ai/ha. The visual injury and growth state of the individual plants were observed at regular intervals. After 15 days, the final results of crop safety were determined (Table 3), using three replicates per treatment.

RESULTS AND DISCUSSION

Chemistry. According to the substituents at R^2, the target compounds **I**−**VI** were prepared by four different synthetic routes. When R^2 is a hydrogen atom, the synthetic details for compound **I** are shown in Figure 1; when R^2 is an alkoxy or aryloxy group, the synthetic routes for compounds **II** and **III** are outlined in Figure 2; when R^2 is a methyl or trifluoromethyl group, the detailed synthetic routes for compounds **IV** and **V** are shown in Figure 3; when R^2 is a cyano group, the detailed synthetic route for compounds **VI** is outlined in Figure 4. The lead compound **I** can be obtained by a three-step synthetic route using the commercially available quinoline-3-carboxylic acid **1** as the starting material (Figure 1). The carboxylic acid **1** was very sensitive to $SOCl_2$, $POCl_3$, PCl_5, and PCl_3 because of the high reactivity of the hydrogen at the 2-position on the quinoline ring. To our delight, by using 1.2 equiv of oxalyl chloride as the chloroformylation reagent and CH_2Cl_2 as the reaction solvent, the corresponding acid chloride can be successfully synthesized. The acid chloride thus obtained was very unstable, so it was used in the next step without further purification. Subsequently, the acid chloride reacted with 1,3-cyclohexanedione, and the enol ester **2** can be obtained in a yield of 78%. Finally, by using acetone cyanohydrin as the Fries catalyst, lead compound **I** was synthesized in a yield of 66%.

Because no carboxylic acids **7a**−**q** are commercially available, the reported methods were applied to synthesize them.[30−32] As seen in Figure 2, the target compounds **II** and **III** were synthesized by an eight-step synthetic route using (substituted) anilines **3a**−**q** as the starting materials. After reaction with acetic anhydride, the corresponding (substituted) *N*-phenylacetamides **4a**−**q** can be synthesized in high yields. Subsequently, the corresponding intermediates **5a**−**q** were obtained in yields of 30−80% via the Vilsmeier−Haack reaction. It was found that the substitutions of R^3 have a big impact on reactivity at this reaction step; if R^3 was an electron-withdrawing group, the reaction yields were very low or there was no reaction at all. **5a**−**q** were then oxidized by iodine in methanol, and compounds **6a**−**q** were synthesized in yields of 70−98%. Various carboxylic acids **7a**−**q** were prepared by a three-step one-pot method. More specifically, **6a**−**q** first reacted with sodium alkoxides or aryloxides, and then water was added to the reaction solution to hydrolyze the methoxycarbonyl group. After treating the residue with citric acid, the corresponding **7a**−**q** were obtained in yields of 64−98%. Followed by chloroformylation and esterification reactions, the enol esters **8a**−**l** and **9a**−**t** were obtained in yields of 42−90%. Finally, by using the same method as the synthesis of **I**, the title compounds **II** and **III** can be afforded in yields of 52−84%.

The key intermediates **11a** and **11b** were prepared by reaction of methyl acetoacetate **10a** or ethyl trifluoroacetoacetate **10b** with *o*-toluidine **3j** in the presence of 4-methylbenzenesulfonic acid as the catalyst (Figure 3). Then, **11a** and **11b** reacted with *N*,*N*-dimethylformamide (DMF) and $POCl_3$ in dichloroethane (DCE), and the corresponding **12a** and **12b** were obtained in yields of 90 and 50%, respectively. Alkaline hydrolysis of **12a** and **12b** with $LiOH{\cdot}H_2O$ in the presence of methanol and water furnished the hydroxyacids **13a** and **13b**. The syntheses of the target compounds **IV** and **V** from **13a** and **13b** were the same as the preparation of compound **I**. Similarly, compounds **VI** can be obtained by a six-step reaction route using methyl 2-chloro-8-methylquinoline-3-carboxylate **6j** as the starting material; after cyanation reaction with CuCN, the key intermediate **16** was synthesized in a yield of 88%. Then followed by hydrolysis, chloroformylation, enol esterification, and rearrangement reactions, the target compounds **VI** can be successfully obtained.

The chemical structures of all of the synthetic triketone−quinoline hybrids (**I**−**VI**) were confirmed by ^1H NMR and ^{13}C NMR spectroscopic and HRMS spectrometric data. Furthermore, the structures of compounds **III-d** and **III-f** were verified by X-ray analysis (Figure 5).

HPPD Inhibition and SAR. The K_i value of the designed lead compound **I** against *At*HPPD was about 0.075 μM, suitable for further optimization (Table 1). Molecular modeling was performed to guide us in rational structural optimization. Because no crystal structure of compound **I** with *At*HPPD was available, we used the reported binding mode of DAS645 with *At*HPPD (PDB entry 1TG5) as reference.[33] There were two major interactions of compound **I** with the *At*HPPD active site (Figure 6). The triketone part of compound **I** can form a

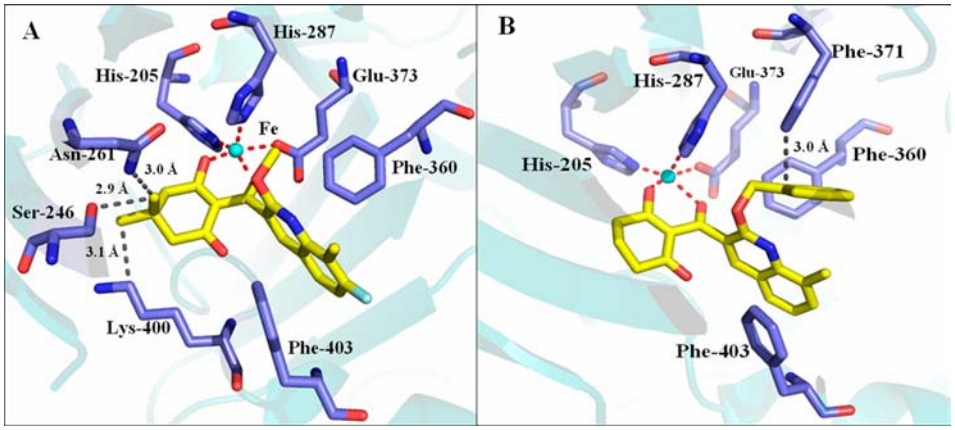

Figure 7. Simulated binding mode of compounds **II-g** (A) and **III-t** (B) with *At*HPPD. The ferrous iron is shown as a cyan sphere, the structures of compounds **II-g** and **III-t** are shown in yellow sticks, and the key residues surrounding the active site are shown in light blue.

bidentate interaction with the active site iron^{II}, whereas the quinoline motif can form $\pi-\pi$ interaction with Phe360 and Phe403. Furthermore, there was no significant interaction of compound **I** with the active site of *At*HPPD (around 4 Å residues), which indicated that a variety of substituent groups might be introduced to compound **I** to increase its interaction with the enzyme. To obtain new compounds with improved *At*HPPD inhibitory activity, we then designed compounds **II**−**VI** on the basis of the core structure on lead compound **I**.

The substituents at R^1 have a significant impact on the activity (Table 1). In most cases, compounds with a 5,5-di-CH_3 at R^1 had decreased HPPD inhibitory activity compared to lead compound **I**. Although the K_i value of compound **II-i** was 0.041 μM, it showed a slightly more potent activity than compound **I**; however, its activity is still far from sufficient when compared with that of mesotrione. For further optimization, compound **II-g** was chosen as a representative to investigate the binding modes. The trikeone part of compound **II-g** can form a bidentate association with the ferrous iron active site, and the quinoline ring can form $\pi-\pi$ interaction with Phe360 and Phe403, respectively (Figure 7A). When the two methyl groups were introduced to the 5-position of the 1,3-cyclohexane ring, the distances between the methyl groups and the surrounding residues would be reduced to lead to steric hindrance. The distances from the two methyl groups on the cyclohexanedione ring of compound **II-g** to residues Asn261, Ser246, and Lys400 are 3.0, 2.9, and 3.1 Å, respectively (Figure 7A). The loss of activity might due to the spatial repellence caused by the methyl groups at the 5-position of the 1,3-cyclohexane ring. Therefore, we proposed that the removal of steric hindrance at this position may be favorable to activity. After one methyl group was removed from this position, the activity of compound **II-k** was greatly improved compared with that of its parent compound **II-j**; however, its activity was still inadequate. This suggests that removing the remaining methyl group would further improve the activity of these molecules.

On the basis of the above analysis, another methyl group was also removed from the 5-position of the 1,3-cyclohexane ring of compound **II-j**. The K_i value of compound **III-a** was as low as 0.009 μM, about 10 times more potent than its parent compound **II-k** and slightly more potent than the commercial mesotrione (K_i = 0.013 μM). Encouraged by these results, we further optimized the structure and studied the activity of this series of compounds. As the steric effects at R^1 had a big impact on activity, compounds **III-b**—**III-d** were synthesized to test the contribution of R^2 to activity. The sterically bulk groups at R^2 were also detrimental to activity; for example, compound **III-a** with a methoxy group at R^2 displayed enhanced activity relative to compounds **III-b**—**III-d** (**III-a** > **III-b** > **III-c** > **III-d**). To understand the structural basis, compound **III-d** was used as a representative for further binding mode investigation. The distance of the benzyl group between Phe371 is 3.0 Å, showing strong steric repulsion effect (Figure 7B).

On the basis of above observation, the methoxy group at R^2 was retained and another set of compounds **III-e**−**III-t** were synthesized to further investigate their HPPD inhibitory activity (Figure 2). All newly synthesized compounds displayed inhibitory constants at the nanomolar range, some of them even showing slightly more potential than mesotrione (Table 1). The position of a single group at R^3 has a big influence on activity. For example, when a methyl group was introduced at the 6-position (**III-f**), the 7-position (**III-g**), or the 8-position (**III-a**) on the quinoline ring, compound **III-a** would have better activity than compounds **III-g** and **III-f** (**III-a** > **III-g** > **III-f**). A similar SAR can also be applied to those with methoxy-substituted analogues (**III-i** > **III-h**) and chloro-substituted analogues (**III-k** > **III-j**). It appeared that the steric bulky groups at R^3 were also detrimental to activity (**III-a** > **III-m** > **III-n**). As to the multisubstituted analogues, compounds with substituents at the 7,8-positions showed improved activity relative to those equivalent substitutions at the 5,8- and 6,8-positions (**III-q** > **III-p** > **III-o**). It seemed that the electron-withdrawing groups at R^3 would produce enhanced effects compared to those with electron-donating groups, although there may be a few exceptions.

Herbicidal Activity and SAR. The postemergence herbicidal activities of the newly prepared compounds were tested against monocotyledon weeds (*E. crus-galli*, *S. faberii*, and *D. sanguinalis*) and broadleaf weeds (*A. retroflexus*, *E. prostrata*, and *A. juncea*) in the greenhouse experiments. The commercial herbicide mesotrione was used as a control; the results are listed in Tables 1 and 2. The treated weeds had developed unique whitening symptoms in light, which indicated that these compounds inhibited HPPD in planta. Some of the synthesized compounds displayed promising and broad-spectrum herbicidal activities at the rate of 150 g ai/ha. Compound **III-l** even exhibited a broader spectrum of weed control (inhibition > 80%) than mesotrione at the rate of 75 g ai/ha.

In most cases, introducing substitutions at R^1 was detrimental to herbicidal activity (Table 1). Notably,

DOI: 10.1021/acs.jafc.5b01530
J. Agric. Food Chem. 2015, 63, 5587−5596

compounds with sterically bulky groups at R^2 also displayed decreased herbicidal activity effects (**III-a** > **III-6b** > **III-c** > **III-d**). These results were consistent with in vitro HPPD inhibitory activity. Furthermore, an interesting structure−activity relationship was observed with respect to the R^3 substitution. For example, when a single substitution was introduced at different positions on the quinoline ring, compounds with substituents at the 7-position would have a broader spectrum of weed control than compounds with substituents at the 8- and 6- positions (**III-g** > **III-a** > **III-f**). It seemed that bulky groups on the quinoline ring were favorable to herbicidal activity (**III-n** > **III-m** > **III-a**). In most case, compounds with electron-withdrawing groups at R^3 were found to exhibit higher herbicidal activity than those with electron-donating groups (**III-k** > **III-g**). Surprisingly, compounds **II-d** and **III-l** with methylthio group at R^3 also displayed excellent herbicidal activity at the rate of 150 ai/ha; even at a dosage as low as 37.5 g ai/ha compound **III-1** still showed >80% control against tested broadleaf weeds and >65% inhibition against monocotyledon weeds (Table 2). A possible explanation for the enhanced herbicidal activity of compounds **II-d** and **III-l** is that the unique properties of the methylthio group make compounds more easily absorbed by plants.[33]

In this work, some of the synthesized compounds had good HPPD-inhibiting activity; however, their herbicidal activities were not satisfactory. For example, compound **III-a** (K_i = 0.009 μM) showed a slightly higher HPPD inhibitory activity than mesotrione (K_i = 0.013 μM); however, its herbicidal activity still could not compete with that of mesotrione. As far as we know, there are many reasons for a compound to have good in vitro inhibitory activity without displaying promising herbicidal activity, such as the absorption, distribution, metabolism, and excretion (ADME) properties. As there is a methoxy group at the 2-position on the quinoline ring of compound **III-a**, we inferred that the methoxy group of compound **III-a** might be easily metabolized by plants.[34] This is because the unique chemical properties of quinoline make its 2-position very active compared with other positions. Therefore, a series of compounds with different metabolism blocking groups were synthesized to verify this hypothesis (Figures 3 and 4). As indicated in Table 1, among the newly prepared compounds **IV** and **VI**, compounds with an electron-withdrawing group at R^2 were found to be detrimental to herbicidal activity. Promisingly, compounds **IV-a** and **IV-b** displayed significantly enhanced herbicidal activity relative to their parent compounds **III-a** and **II-k**, respectively. Therefore, the SAR of R^2 can be summarized as follows: CH_3 > CF_3> OCH_3 > CN > OCH_2H_3, $OCH_2CH_2H_3$ > OCH_2Ph.

Crop Selectivity. As mentioned in the Introduction, crop selectivity is one of the main concerns in herbicide discovery. Compounds **III-l**, **III-m**, and **III-n** with promising herbicidal activity were chose as representatives for further crop selectivity studies. Maize displayed high tolerance to compound **III-l** after postemergence application at the rate of 150 g ai/ha (Table 3). The promising results indicated that compound **III-l** might be developed as a potential herbicidal for maize fields. Most promisingly, compound **III-m** was found to be "selective" to maize, rice, and wheat at the dosage of 150 g ai/ha; however, the commercial mesotrione was found to be "nonseletive" to rice and wheat at the same rate. These results showed that there is a great potential for **III-m** to be developed as a herbicide for weed control in maize, rice, and wheat fields. Furthermore, compound **III-n** was safe for maize at the dosage of 150 g ai/ha, indicating that **III-n** might be developed as a potential herbicide for maize fields.

CoMFA analysis. To further understand the substituent effects on *At*HPPD inhibition, we performed a brief CoMFA analysis of 31 representative compounds with SYBYL.[29] The predicted CoMFA model was established with the conventional coefficient r^2 = 0.974, the cross-validated coefficient q^2 = 0.806, and the predicted non-cross-validated coefficient r^2(pred) = 0.854. The calculated activity values and the plots of the predicted versus the actual activity values for the selected compounds are shown (Table 4). The contour map of the steric contributions was marked in green and yellow areas (Figure 8A). The yellow contour means a bulky substituent in this area is unfavorable for the inhibition activity of *At*HPPD. For example, the compound **II-b** (R^1 = 5,5-diCH_3, K_i = 0.304 μM) is less active than compound **III-i** (R^1 = H, K_i = 0.029 μM), although they have the same R^2 and R^3 groups, which is similar to **II-e** and **III-m**, **II-f** and **III-n**, and **II-j** and **II-k**. On the contrary, the green region highlights positions where a bulky group would be favorable for HPPD inhibition activity. The electrostatic contour map is shown in Figure 8B. The blue color represents that the electro-positive group will be advantageous to the bioactivity of HPPD inhibitors. The electro-negative groups is marked by a red area, which is closed

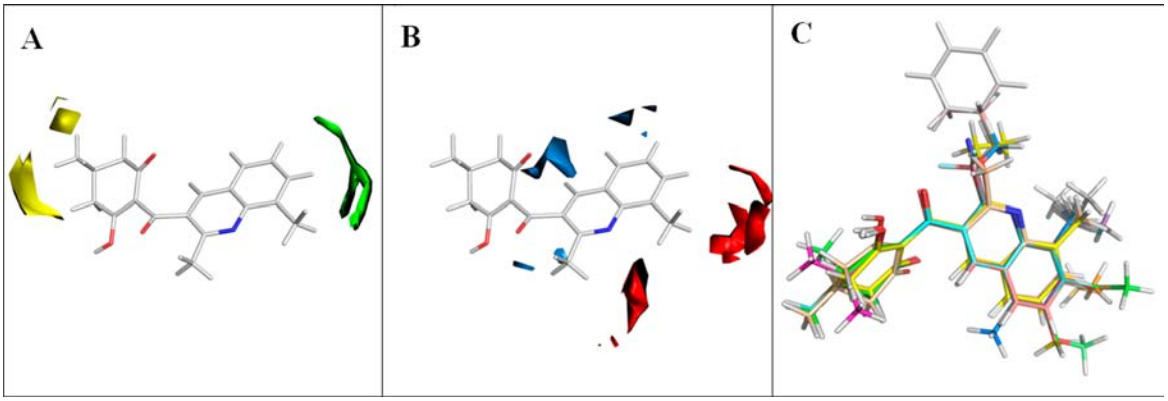

Figure 8. (A) CoMFA map for steric contribution. Compound **IV-b** is shown inside the field. Green polyhedra represents the sterically favored areas where bulkier substituents favor activity, and yellow polyhedra represents the disfavored areas where less bulky substituents favor activity. (B) CoMFA map for electrostatic contribution. Compound **IV-b** is shown inside the field. Blue contours mean the increase of positive charge in these areas will promote the activity; on the contrary, it will enhance the activity if we increase negative charges in the red contour areas. (C) Alignment of 24 compounds of the training set.

to the region of R^2 group and the 7,8-positions on the quinoline ring. Therefore, we can infer that the compound which bears an electron-withdrawing group at R^2 and R^3 (7- and 8-positions) will show higher activity. The experimental values are consistent with our calculation results; for example, the activities of **III-r** (R^3 = 7-F-8-CH_3, K_i = 0.011 μM) > **III-s** (R^3 = 7-Cl-8-CH_3, K_i = 0.014 μM) > **III-t** (R^3 = 7-Cl-8-CH_3, K_i = 0.014 μM), **III-b** (R^3 = OCH_2H_3, K_i = 0.025 μM) > **III-c** (R^3 = O-*n*-Pr, K_i = 0.171 μM) > **III-d** (R^3 = OCH_2Ph, K_i = 0.213 μM) and the activities of compounds **VI-a** and **VI-b** are higher than those of most of other compounds in Table 4 because of the cyano group at the R^2 position.

In conclusion, a series of novel triketone−quinoline hybrids were rationally designed and identified as potent HPPD inhibitors for herbicide discovery. Most of the synthesized compounds displayed excellent HPPD inhibitory activity, and some of them were even superior to the commercial herbicide mesotrione. To our delight, compounds **III-l**, **III-m**, and **III-n** displayed promising herbicidal activity at the rate of 37.5−150 g ai/ha. Especially, compound **III-l** displayed a broader spectrum of weed control than mesotrione. In addition, compounds **III-l** and **III-n** were highly "selective" to maize, and **III-m** was safe for maize, rice, and wheat by postemergence application at the rate of 150 g ai/ha. These results indicated that triketone−quinoline hybrids could be novel lead compounds for novel herbicide discovery. Further field trials and structure optimization of compounds **III-l**, **III-m**, and **III-n** are underway.

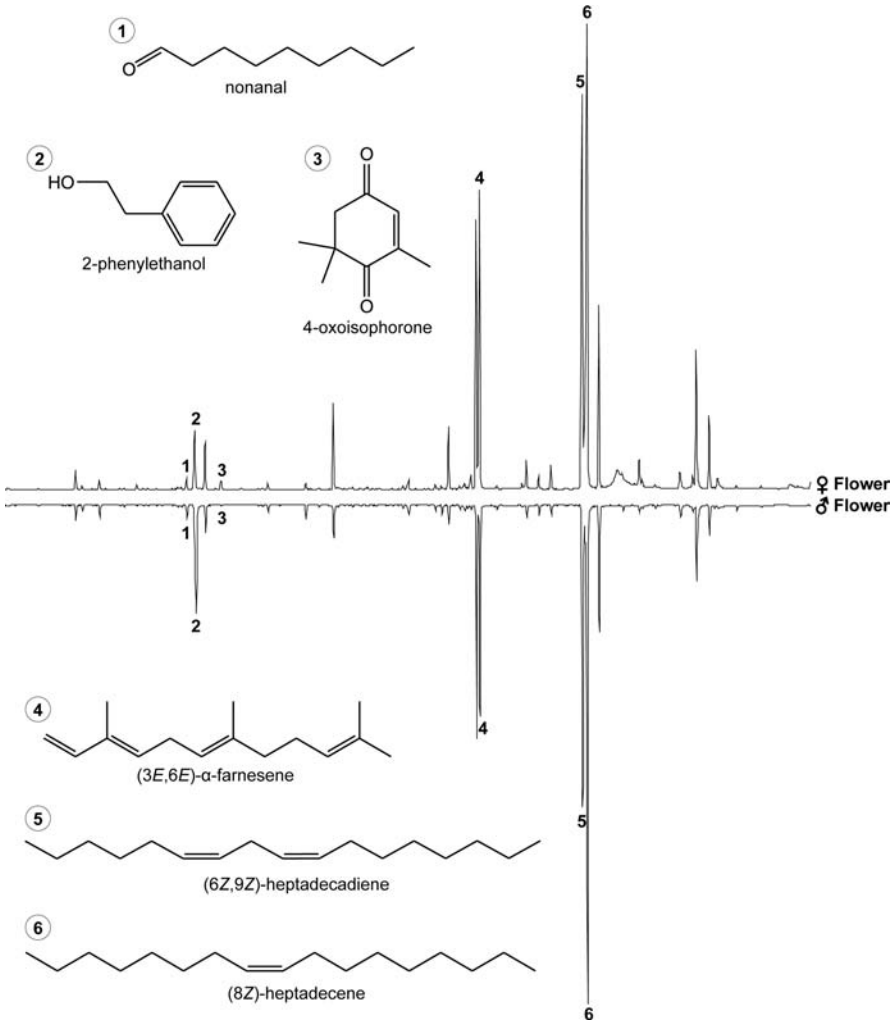

Figure 1. GC-MS chromatograms of kiwifruit floral volatiles from pooled male flower and pooled female flower headspace. The numbered peaks correspond to the antennally active compounds.

from apple skins, obtaining 98% chemical purity. (6Z,9Z)-Heptadecadiene was also not commercially available, so we synthesized it from linoleic acid (99%) using reductive radical decarboxylation.[27] (8Z)-Heptadecene was also synthesized from oleic acid (99%) according to this method to give 94% isomeric purity by GC.

Headspace Sampling of Kiwifruit Flowers. *Actinidia deliciosa* flowers from male (n = 6) and female (n = 10) 'Hayward' vines were individually encased in situ on the vine using custom-made two-piece cylindrical glass chambers (radius = 20 mm, length = 60 mm). The glassware was conditioned in a hot air oven at 150 °C overnight before use. The chamber was joined around the flower, with the stem passing through a small groove in the glass that was then gently sealed with polytetrafluoroethylene tape to avoid any damage to plant tissue. A constant flow rate of 500 mL/min was used, with air entering the chamber through a charcoal filter and leaving the chamber by passing through 60 mg of Tenax#-GR 35/60 (Grace Davison Discovery Sciences, VIC, Australia). The Tenax was conditioned at 250 °C for 3 h under nitrogen before use. Controls were an empty chamber (n = 2) and a chamber containing a leaf (n = 2) set up as outlined above for male and female flowers. Two-hour volatile collections were made between 11:00 a.m. and 1:00 p.m. in a Waikato NZ kiwifruit orchard (37°44′38.12″ S, 175°38′45.49″ E) when large numbers of bee foragers were flying. The Tenax was then eluted with 1 mL of hexane and stored at −80 °C until analysis.

Gas Chromatography–Electroantennogram Detection (GC-EAD). Honey bee antennal depolarizations in response to kiwifruit floral volatiles were recorded using GC-EAD. Honey bees were collected as they left the hives at Plant & Food Research's Lincoln (NZ) apiary (43°38′20.99″ S, 172°28′19.53″ E) with whole head mounts (or alternatively excised antenna) used for recordings. The freshly excised head (or antenna) of an anesthetized honey bee (n = 10 for female flower, n = 8 for male flower) was mounted between silver electrodes containing either salt solution or Spectra 360 electrode gel (Parker Laboratories Inc., Fairfield, NJ, USA). One hundred microliters of each female flower extract was taken, pooled, and then concentrated 10 times under a stream of argon; this was then repeated for the male flowers. The concentrated, pooled sample was then injected into a Varian 3800 GC (Varian, Walnut Creek, CA, USA) coupled to a Syntech EAD recording unit (Syntech Research and Equipment, Hilversum, The Netherlands). Injections were splitless for 0.6 min, and helium was used as a carrier gas with a constant flow of 1 mL/min. A 1:1 split of the column effluent to the antenna and flame ionization detector (FID) was maintained for the duration of the experiment. The GC was equipped with a DB-5 ms column (J&W Scientific, Folsom, CA, USA), 30 m × 0.25 mm i.d. × 0.25 μm film thickness. The injector temperature was 250 °C, and the column oven was programmed from 40 °C (held for 2 min) to 280 °C at 10 °C/min. The transfer line to the antennal preparation was maintained at 250 °C.

Gas Chromatography–Mass Spectrometry (GC-MS). Volatile collections, reaction products, and synthetic compounds were analyzed using a Varian 3800 GC coupled to a Saturn 2200 MS (Varian). Injections were splitless for 0.6 min, and a constant flow of 1 mL/min

Table 1. Summary of Honey Bee Electroantennogram Responses to Volatiles Released from Male and Female Kiwifruit Flowers

compound showing antennal activity	Kovats index DB-5 ms (DB-wax)	response to male flowers (mV)	response to female flowers (mV)	male flower extract (ng)[a]	female flower extract (ng)[a]
nonanal	1105 (1404)	−1.8 ± 1.0	−1.7 ± 0.2	4	4
2-phenylethanol	1111 (1927)	−2.7 ± 0.6	−3.0 ± 0.4	62	25
4-oxoisophorone	1144 (1708)		−1.5 ± 0.3	tr[b]	3
(3*E*,6*E*)-α-farnesene	1503 (1758)	−1.2 ± 0.5	−1.5 ± 0.4	79	111
(6*Z*,9*Z*)-heptadecadiene	1669 (1765)	−1.4 ± 0.3	−3.4 ± 0.9	104	142
(8*Z*)-heptadecene	1678 (1722)	−1.6 ± 0.2	−3.1 ± 0.7	155	169

[a]Estimation of quantity of volatile perceived at the antenna based on comparison with external standards. [b]tr, trace.

of helium was used as the carrier gas. The GC oven was equipped with two columns: a DB-5 ms and a DB-wax, both with dimensions of 30 m × 0.25 mm i.d. × 0.25 μm film thickness. The GC oven temperature programs were 40 °C (held for 2 min) to 280 °C at 10 °C/min for the DB-5 ms column and 40 °C (held for 2 min) to 240 °C at 10 °C/min for the DB-wax column. The injector temperatures were 250 and 220 °C, whereas the transfer line was maintained at 280 and 250 °C for the DB-5 ms and DB-wax columns, respectively. All MS analysis was carried out in electron impact mode at 70 eV and a mass range of m/z 29−399.

Microchemical Derivatization. Hydrogenation of the extract was carried out using 150 μL of the volatile collection solution in combination with 1 mg of 10% Pd/C under a hydrogen atmosphere. The solution was filtered before analysis by GC-MS. For location of the double bond in the heptadecene, dimethyl disulfide (DMDS) derivatization[28] was used. Twenty microliters of the extract was blown down under argon and reacted with DMDS and iodine in diethyl ether for 2 h at 40 °C. The reaction was quenched with a $Na_2S_2O_3$ solution, extracted with pentane, and dried over $MgSO_4$. For identification of the heptadecadiene double-bond locations, the extract was subjected to partial reduction and DMDS derivatization. The partial reduction followed the method of Jham et al.[29] using hydrazine and hydrogen peroxide. Fifty microliters of the extract was concentrated under a stream of argon and then reacted with 150 μL of 10% N_2H_4 in methanol and 150 μL of 4% H_2O_2 in methanol for 2 h at 60 °C. The reaction was quenched with 100 μL of 30% HCl solution, and the organics were then extracted with pentane, washed with water, and dried over $MgSO_4$. The organic products of this partial reduction were subject to reaction with DMDS as outlined above. The extract was also reacted with 4-methyl-1,2,4-triazoline-3,5-dione (MTAD)[30] to test for conjugation. Twenty microliters of the extract was blown down to dryness under a stream of argon and then dissolved in a solution of MTAD, 1.2 mg/mL, in dichloromethane. This solution was injected directly into the GC-MS for analysis.

Synthesis of (6*Z*,9*Z*)-Heptadecadiene. For acid chloride formation, 280 mg of linoleic acid (1.00 mmol) was dissolved in 5 mL of chloroform, and a drop of dimethylformamide was added. Oxalyl chloride (94 μL, 1.09 mmol) dissolved in 1 mL of chloroform was added to the acid solution dropwise at room temperature under argon. After 1 h, the reaction mix was heated and refluxed for 3 h. For Barton decarboxylation, 179 mg of 2-mercaptopyridine *N*-oxide, sodium salt (1.2 mmol), and 1 mg of 4-(dimethylamino)pyridine (0.008 mmol) were dissolved in 5 mL of chloroform. The mixture was heated to reflux, and the crude acid chloride was added dropwise from above with simultaneous irradiation by a tungsten lamp (240 V, 500 W). After 2 h, the reaction mix was cooled to room temperature and added to a separatory funnel containing 20 mL of 1 M HCl and 20 mL of dichloromethane. The organic layer was washed with brine and dried over $MgSO_4$. The solvent was removed, and the crude product was purified by column chromatography (SiO_2, pentane) to give 86 mg of the diene (0.36 mmol, 36% yield, 99% chemical purity, 89% isomeric purity by GC) as a clear, colorless oil: ^{1}H NMR (500 MHz, $CDCl_3$) δ 5.37 (m, 4H, $-CH_2C\underline{H}{=}C\underline{H}CH_2C\underline{H}{=}C\underline{H}CH_2-$), 2.78 (t, 2H, J = 6.56 Hz, $=CHC\underline{H}_2CH=$), 2.05 (q, 4H, J = 6.89 Hz, $=CHC\underline{H}_2CH_2CH_2CH_2CH_3$, $=CHC\underline{H}_2CH_2CH_2CH_2CH_2CH_2CH_3$), 1.40−1.25 (br m, 16H, $=CHCH_2C\underline{H}_2C\underline{H}_2C\underline{H}_2CH_3$, $=CHCH_2C\underline{H}_2C\underline{H}_2C\underline{H}_2C\underline{H}_2C\underline{H}_2CH_3$), 0.89 (t, 3H, J = 6.97 Hz, $-CH_3$), 0.88 (t, 3H, J = 7.13 Hz, $-CH_3$); ^{13}C NMR (125.8 MHz, $CDCl_3$) δ 130.20 (C6 and C10), 127.96 (C7 and C9), 31.88 (C3), 31.54 (C15), 29.70 (C12), 29.36 (C4), 29.30 (C13), 29.23 (C14), 27.25 (C5 or C11), 27.21 (C11 or C5), 25.64 (C8), 22.68 (C2), 22.58 (C16), 14.10 (C1 or C17), and 14.06 (C17 or C1); MS data 70 eV, m/z (relative intensity) 236 (9, M^+), 152 (3), 138 (7), 124 (11), 109 (25), 95 (55), 81 (78), 67 (100), 55 (26), and 41 (37).

Proboscis Extension Response (PER). The general methodology based on Pavlovian conditioning and reviewed by Matsumoto et al.[25] was followed. The synthetic flower mixtures used for PER were made up of the six antennally active compounds at the ratios present in the natural flower extracts (Figure 1). 1-Nonanol was chosen as the untrained control compound as it is readily detected by honey bees over a range of concentrations[31] (from ng to mg) and is a standard control compound for PER experiments.[25]

Honey bees were collected in the morning and harnessed in small cylindrical tubes of 8 mm i.d. Bees were then fed 4 μL of 50% sucrose solution and left for 3 h before training. Bees were set 5 cm in front of a syringe containing 1 μg of a synthetic mixture from either male or female kiwifruit flowers deposited on filter paper. Bees had a 15 s settling time before being exposed to 30 mL of air containing the odor over 4 s. This corresponds to the conditioned stimulus (CS+). After 3 s of odor exposure, bees' antennae were gently touched with a toothpick soaked in 50% sucrose solution and once the proboscis was extended in response, a sugar reward was given corresponding to the unconditioned stimulus (US).

The association in time of the CS+ with the US is expected to trigger the formation of a memory of the odor cues with the presence of the reward. Each bee was trained four times, with 10 min intervals between training. Bees were rested for 1 h before testing in a random order to three odor blends: 1 μg of the synthetic flower mix on which they were trained, 1 μg of the correspondingly sexed flower extract, and an untrained control compound, 100 μg of 1-nonanol. In the absence of sugar reward, bees' responses to the presentation of each odor were recorded as 1 if they showed a PER or as 0 if they did not show a PER. If bees responded positively to the synthetic flower mix as well as the natural extract, we considered that this was a demonstration that the synthetic flower mix was perceived as similar to the natural flower extract. The ability of bees to discriminate between the male or female flower extract when trained on the synthetic mix of either sex was also tested.

Statistical Analysis. In total, 75 bees were trained with the PER. Thirty-seven bees were trained and tested with the kiwifruit female flower synthetic mix, and 38 bees were trained and tested with the kiwifruit male flower synthetic mix. Among those, seven bees were excluded from the final analysis because of death or lack of hunger. A chi-square test was used to compare the observed proportions of bees responding or not to the odors for each test to the calculated expected values if the null hypothesis of independency was assumed. p values of <0.05 reject the hypothesis of independence of proportions and therefore suggest that proportions are similar.

RESULTS

Honey Bee Response to Floral Volatiles with GC-EAD.

Honey bees gave consistent antennal responses to six compounds in the kiwifruit flower headspace, marked in Figure

DOI: 10.1021/acs.jafc.5b01165
J. Agric. Food Chem. 2015, 63, 5597−5602

1. Only compounds to which ≥80% of the bees responded were counted as provoking active responses in the antenna. Quantities of each compound and average antennal responses are shown in Table 1. For female flowers 100% of the foragers responded to nonanal, 2-phenylethanol, 4-oxoisophorone, and (8*Z*)-heptadecene, whereas 90% responded to (3*E*,6*E*)-α-farnesene and (6*Z*,9*Z*)-heptadecadiene. For male flowers, 100% of honey bee foragers responded to 2-phenylethanol, (3*E*,6*E*)-α-farnesene, and (6*Z*,9*Z*)-heptadecadiene, 88% responded to (8*Z*)-heptadecene, and 63% responded to nonanal. Nonanal was included for the male flower as a positive response because of the 100% response in the female extract, which had a similar quantity of nonanal. The 4-oxoisophorone evoked no responses in the male extract as it was thought to be below the detection threshold of the bee.

Analysis of Kiwifruit Flower Volatiles. Pooled samples of male and female flower volatiles of *Actinidia deliciosa* showed no qualitative differences by GC analysis, but there were some quantitative differences, as shown in Table 1. Of the six antennally active compounds in Figure 1, three have previously been identified in kiwifruit flowers:[9] nonanal, 2-phenylethanol, and (3*E*,6*E*)-α-farnesene. These were confirmed with synthetic and isolated standards. 4-Oxoisophorone was identified by mass spectra library match and confirmed by comparison with a synthetic standard. Heptadecene and heptadecadiene were first tentatively identified by their mass spectra, before other confirmatory tests. The double-bond location for the heptadecene was confirmed as the 8-position via DMDS reaction, with the pooled sample giving an adduct with a molecular ion at *m*/*z* 332 and diagnostic ions at *m*/*z* 159 and 173. The geometry of the double bond was confirmed as *Z* using a synthetic standard of 8-heptadecene containing 85% of the *Z* isomer and 15% of the *E* isomer. For identification of the double-bond positions in the diene, the pooled sample was first partially reduced to give the corresponding monoenes, which were then reacted with DMDS. The DMDS adducts both had molecular ions at *m*/*z* 332, with diagnostic ions at *m*/*z* 159, 173, and *m*/*z* 131, 201, corresponding to a double-bond position of 8 or 9 and 6 or 11, respectively. To rule out the possibility of the double bonds being conjugated, an MTAD test was done. Because the pooled extract did not react with the MTAD solution, the double bonds could not be conjugated, meaning the positions had to be 6 and 9. The geometry of the double bonds in the diene was confirmed as (6*Z*,9*Z*)-heptadecadiene via synthesis of the molecule, co-injection with the pooled sample on both DB-5 ms and DB-wax columns, comparison with literature ^{13}C NMR,[32] and electroantennogram testing of the synthetic material with the insect.

Training and Response of Honey Bees with Synthetic Floral Odors. After four training sessions, 85% of bees consistently extended their proboscis in expectation of the reward when the odor was presented. When the bees' memories were tested 1 h after training to the synthetic floral mix, 98 and 93% of bees responded to the male and female synthetic floral mixes, respectively (Figure 2). When presented with the natural extract of the corresponding male and female flowers, bees were also highly responsive, with 97 and 90% PER. However, when bees were presented with a new compound, 1-nonanol, only 28 and 44%, respectively, exhibited PER. For both sexes, the PER responses of bees between the synthetic floral mixtures and the natural extract were similar (chi-square = 21.17, df = 1, $p < 0.0001$, null hypothesis of independence rejected), whereas bees' responses to the synthetic floral mixtures were independent from their responses to the new compound, 1-nonanol (chi-square = 0.22, df = 1, $p = 0.63$). When bees were trained to the synthetic floral mix of either sex (male or female), they responded similarly to the natural extract of both sexes (70%, chi-square = 26.17, df = 1, $p < 0.001$).

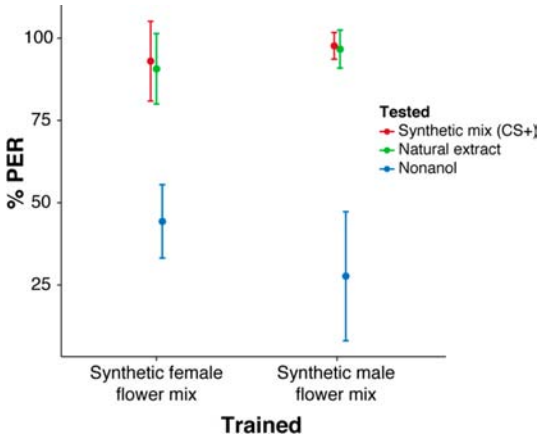

Figure 2. Mean percentage (±SD) of honey bee showing the proboscis extension response (PER) after being trained to synthetic mixes of volatiles from male (n = 37) or female (n = 38) kiwifruit flowers.

DISCUSSION

Our volatile profile for the flowers showed some differences from those previously reported for kiwifruit species.[9−12] The major peaks were the hydrocarbons (6*Z*,9*Z*)-heptadecadiene and (8*Z*)-heptadecene and the sesquiterpene (3*E*,6*E*)-α-farnesene shown in Figure 1. Earlier work on floral volatiles from kiwifruit flowers by Tatsuka et al.[9] found that (3*E*,6*E*)-α-farnesene was the most abundant, whereas hydrocarbons with Kovats indices similar to the ones we identified were in lower abundance and remained unidentified.[9] Others have reported high concentrations of terpenes and their derivatives in the headspace of kiwifruit flower species.[10−12] All aforementioned work has used cut flowers for volatile analysis,[9−12] which provides the benefit of having large concentrated samples but adds plant-wounding volatiles. When plants are cut or wounded, volatile compounds released by the plant change.[33] This can be part of a defense mechanism to deter herbivory by insects[34] or attack by microbes or simply as a result of cellular material being released as a result of the wounding. To avoid this complication, we sampled undamaged flowers in situ on the vine, collecting real-time volatile emissions when the bees were foraging.

Honey bees consistently detected six floral odor compounds from the headspace of the intact kiwifruit flowers. Previous publications on kiwifruit flower headspace report up to 70 floral volatiles.[9−12] This suggests honey bees are using only a few volatiles from the floral mixture for olfactory recognition of the flower. These results are similar to those reported for sunflower extracts collected by Thiery et al.,[13] which contained >100 volatile components, with up to 24 compounds giving EAD response but only 4 compounds were detected by 100% of the bees.[13] The seven Brassicaceae crops tested by Kobayashi et al.[15] contained 52 compounds across the species, but only 14 compounds were physiologically active. Blight et al.[16] found 16 behaviorally active compounds in *Brassica napus*. Of these active compounds, kiwifruit shared 2-phenylethanol and

DOI: 10.1021/acs.jafc.5b01165
J. Agric. Food Chem. 2015, 63, 5597−5602

(3*E*,6*E*)-α-farnesene with some of the Brassicaceae species and none with the sunflower, whereas sunflower and Brassicaceae shared 1,8-cineole and β-elemene as bee-active compounds.

Honey bees have evolved over millions of years alongside angiosperms, acting as generalist pollinators for a multitude of flowers in many different environments. It does not come as a surprise to find that they are cueing in on only some of the floral compounds in a particular flower species and that there are common cues between plant species.[35] Nonanal, 2-phenylethanol, 4-oxoisophorone, and (3*E*,6*E*)-α-farnesene are all well-reported plant volatiles and insect attractants.[35] (8*Z*)-Heptadecene is reported as a plant volatile for boronias[36] and blue roses[37] as well as an attractant across many insect orders.[35] To our knowledge this is the first report of (6*Z*,9*Z*)-heptadecadiene as a floral compound, but it is previously reported as a VOC from astigmatid mites, oribatid mites, and geometrid moths.[35]

The large EAD response by honey bees to (8*Z*)-heptadecene and (6*Z*,9*Z*)-heptadecadiene may not be adapted from a floral origin. (8*Z*)-Heptadecene has been reported as a compound associated with bee larvae,[38] nurse bees,[39] and pollen foragers,[40] but its behavioral function is not yet known. (6*Z*,9*Z*)-Heptadecadiene may also be a honey bee-produced compound, but remains to be identified as such for *Apis mellifera*. Nonetheless, (6*Z*,9*Z*)-heptadecadiene provides an excellent species-specific floral odor for training bees to kiwifruit flowers.

Honey bees trained to the synthetic floral mix responded similarly to the natural extract, indicating that recognition of kiwifruit flower odor may be reliant on only a few key odor compounds of the floral headspace. This is in line with the work of Reinhard et al.,[17] who showed that honey bees learn a few key compounds in recognition of complex volatile mixtures. In addition, honey bees did not seem to discriminate between male and female flower extracts when trained to either floral sex synthetic mix. Differences in visitation rate between male and female flowers reported by Goodwin and Steven[7] cannot be explained by odor cues, but instead may be based on visual cues potentially including the abundance of pollen in the male flower.

Several field trials have been carried out to encourage honey bees to visit more kiwifruit flowers, but with little success.[41,42] In NZ kiwifruit orchards, Goodwin et al.[43] have shown that providing in-hive feeders of sugar solution during the flowering period increases the amount of kiwifruit pollen collected by those hives. However, kiwifruit still need high hive densities to achieve sufficient pollination rates, and further behavioral manipulations at the colony level will be required for more efficient pollination.

This study has highlighted that only a few odors from kiwifruit flowers are likely to be implicated in bee foraging behavior. A better understanding of how honey bees perceive and respond to floral odors at the hive level will be needed before any behavioral manipulation to improve pollination can be undertaken, but this study has enabled the next step in this process.

δ-zein, with a minor fraction of 10 kDa; and (iv) γ-zein (5−10%), with a MW of 27 kDa.[19,20] Zein is an amphiphilic protein, possessing high percentages of hydrophobic amino acids such as leucine (20%), proline (10%), and alanine (10%).[19,20] Due to this amino acid composition, zein is insoluble in water, and, thus, the resulting devices (e.g., films, nanoparticles) display a hydrophobic character with interesting properties that control the release of the loaded compound.[20,21] In addition, as for other nanocarriers of protein origin, these devices are biodegradable and can accommodate a great variety of compounds in a nonspecific way.[22]

Therefore, the aim of this work was to prepare, characterize, and evaluate a resveratrol nanoparticulate formulation based on zein and to study its oral bioavailability and anti-inflammatory effects in a mouse model of induced endotoxic shock.

MATERIALS AND METHODS

Chemicals. Zein, resveratrol, lysine, mannitol, sodium ascorbate, poly(ethylene glycol) 400 (PEG 400), and Tween 20 were purchased from Sigma-Aldrich (Steinheim, Germany). Resveratrol-3-*O*-D-glucuronide (Rsv-O-glu) was from @rtMolecule (Poitiers, France). Ethanol, methanol, acetic acid, and acetonitrile of HLPC grade were obtained from Merck (Darmastadt, Germany). Lipopolysaccharide (LPS) from Salmonella *enterica* serovar Minnesota was purchased from Sigma, (St. Louis, MO, USA). Deionized reagent water (18.2 MO resistivity) was prepared using a water purification system (Wasserlab, Spain). All reagents and chemicals used were of analytical grade.

Preparation of Resveratrol-Loaded Nanoparticles (Rsv-NP-Z). Nanoparticles were prepared by a desolvation method followed by an ultrafiltration purification step and subsequent drying in a spray-dryer apparatus. Briefly, 600 mg of zein and 100 mg of lysine were dissolved in 60 mL of an ethanol/water mixture (65% ethanol by vol). In parallel, 100 mg of resveratrol was dissolved in 10 mL of ethanol, and 6 mL of this solution was transferred to the zein solution. In addition, 6 mg of sodium ascorbate was added to minimize the oxidation of the polyphenol. The mixture was magnetically stirred in the dark for 10 min at room temperature. Nanoparticles were obtained by the continuous addition of 60 mL of purified water. The suspension was purified and concentrated by ultrafiltration using a membrane cartridge with a 50 kDa pore size polysulfone (Medica SPA, Italy). Then, 15 mL of purified water containing 1.2 g of mannitol was added to the resulting suspension of nanoparticles to prevent aggregation and irreversible interactions among the nanoparticles during the drying process. Finally, the suspension was dried in a Büchi Mini Spray Dryer B-290 apparatus (Büchi Labortechnik AG, Flawil, Switzerland) under the following experimental conditions: (i) inlet temperature, 90 °C; (ii) outlet temperature, 45−50 °C; (iii) air pressure, 4−6 bar; (iv) pumping rate, 5 mL/min; (v) aspirator, 100%; and (vi) air flow, 400−500 L/h.

Control formulations (NP-Z) were prepared as described above but in the absence of resveratrol.

Preparation of Resveratrol Conventional Formulations. Two different formulations of resveratrol were also prepared. The first one, a solution of the polyphenol in a mixture of PEG400 and water (1:1 by vol), was prepared by dissolving 37.5 mg of resveratrol in 5 mL of PEG400 under magnetic stirring. Then 5 mL of purified water was added, and the final mixture was agitated in the dark for 10 min. This formulation was named Rsv-sol.

The second one was an extemporary suspension of resveratrol in purified water (Rsv-susp). Briefly, 37.5 mg of resveratrol was dispersed in 10 mL of purified water under magnetic agitation for 10 min. The size of the resulting suspension was 21.4 ± 9.2 μm. The suspension was used after inspection for the absence of aggregates.

Characterization of Nanoparticles. *Size, Zeta Potential, and Morphology.* The mean hydrodynamic diameter and the zeta potential of the nanoparticles were determined by photon correlation spectroscopy (PCS) and electrophoretic laser Doppler anemometry, respectively, using a Zetamaster analyzer system (Malvern Instruments Ltd., Worcestershire, UK). The diameter of the nanoparticles was determined after dispersion in ultrapure water (1:10) and was measured at 25 °C with a scattering angle of 90 °C. The zeta potential was measured after dispersion of the dried nanoparticles in 1 mM KCl solution.

The morphology of the nanoparticles was studied by field-emission scanning electron microscopy (SEM) using a Zeiss DSM940 digital scanning electron microscope (Oberkochen, Germany) coupled with a digital imaging system (Point Electronic GmBh, Germany). The yield of the process was calculated by gravimetry as described previously.[22]

Resveratrol Analysis. The amount of resveratrol loaded into the nanoparticles was quantified by HPLC-UV using a previously described analytical method[23] with minor modifications. Analyses were carried out in an Agilent 1100 series LC system coupled to a diode array detector set at 306 nm. The data were analyzed using ChemStation G2171 v. B.01.03 software (Agilent, USA). The chromatographic system was equipped with a reverse C18 Alltima column (150 mm × 2.1 mm, particle size = 5 μm; Alltech, USA) and a Gemini AJO-7596 C18 precolumn. The mobile phase, pumped at 0.25 mL/min, was a mixture of water/methanol/acetic acid under gradient conditions. The column was heated to 40 °C, and the injection volume was 10 μL. Under these conditions, the retention time for resveratrol was 22.8 ± 0.5 min. Calibration curves in 75% ethanol were designed over the range of 1−100 μg/mL ($R^2 \geq 0.999$). Under these experimental conditions, the limit of quantitation was calculated to be 200 ng/mL.

For analysis, 10 mg of nanoparticles was dispersed in 1 mL of water and centrifuged at 30500*g* for 20 min. The amount of encapsulated resveratrol was calculated by dissolution of the pellets in 1 mL of 75% ethanol. Each sample was assayed in triplicate, and the results are expressed as the amount of resveratrol (μg) per milligram of nanoparticles.

The encapsulation efficiency (EE) was calculated as

$$\mathrm{EE}\ (\%) = \frac{\mathrm{Rsv_p}}{\mathrm{Rsv_t}} \times 100 \quad (1)$$

where $\mathrm{Rsv_t}$ is the total amount of resveratrol in the formulations and $\mathrm{Rsv_p}$, the amount of resveratrol quantified in the pellet.

In Vitro Release Study. Release experiments were conducted under sink conditions at 37 °C using simulated gastric fluid (SGF; pH 1.2) and intestinal fluid (SIF; pH 6.8),[22] containing 0.5% Tween 20 as a surfactant to increase the aqueous solubility of resveratrol. The studies were performed under agitation in a Slide-A-Lyzer Dialysis Cassete with a 10000 MWCO (Thermo Scientific, Rockford, IL, USA). For this purpose, the cassette was filled with 3 mg of resveratrol nanoparticles previously dispersed in 5 mL of water and then introduced into a vessel containing 500 mL of SGF (pH 1.2; 37 °C) under magnetic stirring. After 2 h in the SGF, the cassette was introduced into another vessel containing 500 mL of thermostated SIF (pH 6.8; 37 °C, under agitation). At different time points, samples were collected and filtered through filters with a 0.45 μm pore size (Thermo Scientific) before quantification by HPLC. Calibration curves for resveratrol in SGF and SIF (0.05−6 μg/mL; $R^2 \geq 0.999$ in both cases) were generated.

To ascertain the resveratrol release mechanism, the obtained data were fitted to the Korsmeyer−Peppas and Peppas−Sahlin models. The Korsmeyer−Peppas model is a simple semiempirical approach, which exponentially relates drug release with the elapsed time as expressed in the equation[24]

$$\frac{M_t}{M_\infty} = K_{\mathrm{KP}} \times t^n \quad (2)$$

where M_t/M_∞ is the drug release fraction at time t, K_{KP} is a constant incorporating the structural and geometric characteristics of the matrix, and n is the release exponent indicative of the drug release mechanism.[25] Values close to 0.5 indicate a case I (Fickian) diffusion mechanism, and values between 0.5 and 0.89 indicate anomalous (non-Fickian) diffusion. Values of n between 0.89 and 1 indicate case II transport, erosion of the matrix.

DOI: 10.1021/jf505694e
J. Agric. Food Chem. 2015, 63, 5603−5611

The contributions of Fickian and non-Fickian release were also evaluated by using the Peppas–Sahlin model equation[26]

$$\frac{M_t}{M_\infty} = K_D \times t^{1/2} + K_E \times t \quad (3)$$

where the first term of the right-hand side is the Fickian contribution (K_D is the diffusional constant) and the second term is the case II erosional contribution (K_E is the erosional constant). K_D and K_E values were used to calculate the contribution percentage of diffusion (D) and erosion (E) as follows:[26]

$$D = \frac{1}{1 + \frac{K_E}{K_D} \times t^{0.5}} \quad (4)$$

$$\frac{E}{D} = \frac{K_E}{K_D} \times t^{0.5} \quad (5)$$

Only one portion of the release profile ($M_t/M_\infty \leq 0.6$) was used to fit the experimental data to the previous equation.

In Vivo Pharmacokinetic Studies in Wistar Rats. *Pharmacokinetic Studies.* Pharmacokinetic studies were performed in male Wistar rats (200–250 g) obtained from Harlan (Barcelona, Spain). The studies were approved by the Ethical Committee for Animal Experimentation of the University of Navarra (protocol 028-11) in accordance with European legislation on animal experiments.

Prior to the oral administration of the formulations, animals were fasted overnight to avoid interference with absorption, but were allowed free access to water. For the pharmacokinetic studies, rats were randomly divided into four groups of six animals each. The three experimental groups were (i) aqueous resveratrol suspension (Rsv-susp), (ii) resveratrol in a PEG400/water mixture (Rsv-sol), and (iii) resveratrol-loaded zein nanoparticles (Rsv-NP-Z). As a control, a group of animals was treated intravenously with the PEG400/water (1:1 by vol) solution of resveratrol. Each animal received the equivalent amount of resveratrol at a dose of 15 mg/kg body weight either by oral gavage or intravenously via the tail vein.

Blood samples were collected at set times after administration (0, 10, and 30 min and 1, 2, 4, 6, 8, 24, and 48 h) in specific plasma tubes (Microvette 500 K3E, SARSTEDT, Germany). Samples were immediately centrifuged at 9400*g* for 10 min, and plasma aliquots were kept frozen at −80 °C until HPLC analysis of both resveratrol and resveratrol-3-*O*-D-glucuronide.

Determination of Resveratrol and Resveratrol-3-O-D-glucuronide Plasma Concentration by HPLC. The amount of resveratrol was determined by HPLC-UV using a previously reported analytical method[27] with minor modifications. Analyses were carried out using an Agilent 1100 series LC and a diode array detector set at 306 nm. The data were analyzed in a ChemStation G2171 program (B.01.03). The chromatographic system was equipped with a reverse-phase Kromasil C18 column (250 mm × 2.1 mm, particle size = 5 μm) and a Gemini AJO-7596 C18 precolumn. The mobile phase, pumped at 0.5 mL/min, was a mixture of water, methanol, and acetic acid (50:45:5 by vol) under isocratic conditions. The column was thermostated at 30 °C, and the injection volume was 30 μL. Under these conditions, the retention times for resveratrol-3-*O*-D-glucuronide and resveratrol were 6.2 ± 0.5 and 12.6 ± 0.5 min, respectively.

For analysis, a 100 μL aliquot of plasma was mixed with 50 μL of 0.1 N HCl and 500 μL of acetonitrile (for protein precipitation) followed by vigorous shaking. The samples were then centrifuged at 4000 rpm for 10 min, and the obtained supernatants were evaporated under vacuum in a Speed Vac system (Holbrook, NY, USA) at 25 °C for 30 min. Finally, 100 μL of a mixture of acetonitrile and water (1:1 by vol) was added and vigorously stirred by vortexing for 10 min. The samples were then filtered through a 0.45 μm filter (Thermo Scientific) prior to injection.

For quantification, calibration curves were prepared over the ranges of 2–70 μg/mL for the metabolite and 50–3000 ng/mL for resveratrol ($R^2 \geq 0.99$). All of the calibration standards were obtained by adding either resveratrol or resveratrol-3-*O*-D-glucuronide in acetonitrile (500 μL) to 100 μL of plasma from nontreated animals. The polyphenol or its metabolite was then extracted using the same protocol as described above.

Under these experimental conditions, the limits of quantification were calculated to be 70 ng/mL for resveratrol and 4 μg/mL for the metabolite. Linearity, accuracy, and precision values on the same day (intraday assay) at low, medium, and high concentrations of both resveratrol and the metabolite were always within the acceptable limits (relative error and coefficient of variation of <15%).

Pharmacokinetic Data Analysis. The resveratrol plasma concentration was plotted against time, and the pharmacokinetic analysis was performed using a noncompartmental model within WinNonlin 5.2 software (Pharsight Corp., USA). The following parameters were estimated: the maximal serum concentration (C_{max}), the time in which C_{max} is reached (t_{max}), the area under the concentration–time curve from time 0 to the last sampling time point (48 h) (AUC), the mean residence time (MRT), the clearance (Cl), the volume of distribution (V), and the half-life in the terminal phase ($t_{1/2}$). Furthermore, the relative bioavailability (Fr, %) of resveratrol was estimated by the equation

$$\text{Fr}\ (\%) = \frac{\text{AUC}_{oral}}{\text{AUC}_{iv}} \times 100 \quad (6)$$

where AUC_{iv} and AUC_{oral} are the areas under the curve for the iv and oral administrations, respectively.

In Vitro/in vivo Correlation (INVIC). The eventual correlation between the in vitro and in vivo results was determined by point-to-point plotting of the amount of resveratrol released from the nanoparticles versus the fraction of resveratrol absorbed (FRA), calculated from the mean plasma concentration–time inputs using the Wagner–Nelson equation[28]

$$\text{FRA} = \frac{C_t + k \times \text{AUC}_{0-t}}{k \times \text{AUC}_{0-\infty}} \quad (7)$$

where C_t is the plasma concentration of resveratrol at time t, k is the elimination rate constant of the polyphenol, AUC_{0-t} is the area under the resveratrol concentration versus time curve from 0 to time t, and $AUC_{0-\infty}$ is the area under the curve from 0 to infinity.

Linear regression analysis was applied to the in vitro/in vivo correlation plot, and the coefficient of determination (R^2) was calculated.

Anti-inflammatory Efficacy Study. *Animal Model.* Four-week-old (20–22 g) C57BL/6J female mice were purchased from Harlan (Barcelona, Spain) and housed in standard animal facilities (six animals per cage with free access to food and drinking water). Housing conditions were maintained with controlled temperature and humidity and with 12 h on/off light cycles. Animals were allowed to acclimate for 1 week before the experiment.

In vivo anti-inflammatory studies were evaluated in an endotoxic shock model set up by intraperitoneal (ip) administration of LPS at a dose of 40 μg per mouse.[29] Before administration, the LPS was dissolved in PBS and vortexed for 30 min to complete homogenization.

On day 1, mice were randomly distributed into four groups. The first group of animals received an oral dose of 15 mg/kg resveratrol daily as an oral solution (Rsv-sol) for 7 days. The second group of animals received the same posology of polyphenol (15 mg/kg resveratrol daily for 7 days) but within the zein nanoparticle formulation (Rsv-NP-Z). As controls, a group of animals received LPS treatment (positive-control group), and another group received neither LPS nor resveratrol (negative-control group).

Twenty-four hours after the last dose of resveratrol (day 8), the animals were challenged with 40 μg of LPS by the ip route. Throughout the study, the rectal temperature of the mice was measured until 24 h after challenge. Clinical anaphylactic reactions were scored 6 h postchallenge by two independent observers. Piloerection was scored as follows: (−) normal mouse, (+) weak reaction and/or scratching of the nose and head, (++) moderate piloerection, and (+++) strong piloerection. Depending on the activity

Rsv-NP-Z	307 ± 3	0.10 ± 0.01	−51.1 ± 1.55	80.2 ± 3.26	82.1 ± 4.12

[a]NP-Z, empty zein nanoparticles; Rsv-NP-Z, resveratrol-loaded zein nanoparticles; PDI, polydispersity index. The data are expressed as the mean ± SD (n = 6). [b]Determination of volume mean diameter by photon correlation spectroscopy. [c]Determination of resveratrol content by HPLC-UV. [d]Encapsulation efficiency (%).

of the animals, their mobility was classified as very low (no reaction after pushing), low (arched back and low movements) or normal.

In addition, 90 min after challenge, blood samples were collected into EDTA-K vials (Microvette 500 K3E, SARSTEDT, Germany) from the retro-orbital cavity, centrifuged at 8000g for 10 min for serum collection, and stored at −20 °C until use.

Measurement of Plasma TNF-α. The concentration of circulating TNF-α in the serum was determined using an enzyme-linked immunosorbent assay kit (Mouse TNF-alpha Quantikine ELISA Kit, MTA00B, R&D Systems, Minneapolis, MN, USA) according to the manufacturer's instructions.

Statistical Analysis. The data are expressed as the mean ± standard deviation (SD) of at least three experiments. The nonparametric Kruskal−Wallis test followed by the Mann−Whitney U test with Bonferroni correction was used to investigate significant differences. In all cases, $p < 0.05$ was considered to be statistically significant. All data processing was performed using GraphPad Prism statistical software.

RESULTS

Preparation and Characterization of Nanoparticles. Table 1 shows the physicochemical characteristics of the nanoparticles used in this study. Overall, the mean diameter of empty nanoparticles was smaller than that of nanoparticles loaded with resveratrol. When resveratrol was encapsulated, zein nanoparticles displayed a mean size of approximately 310 nm, whereas the polydispersity index (PDI) was found to be <0.2, indicating a homogeneous nanoparticle formulation. Furthermore, the zeta potential of the nanoparticles was negative (−51 mV); however, when resveratrol was encapsulated, the resulting nanoparticles were slightly more negative than empty ones were (Table 1). Additionally, the resveratrol loading was calculated to be approximately 80 μg/mg nanoparticles, with an encapsulation efficiency close to 82%.

Figure 1 shows the morphology and shape of the resveratrol-loaded nanoparticles. In all cases, the nanoparticles consisted of homogeneous populations of spherical particles with a smooth surface. In addition, the size of the nanoparticles, as observed by SEM, was slightly smaller than the value determined by PCS (Table 1). This observation is related to the fact that nanoparticles composed of macromolecules (such as proteins or polysaccharides) tend to swell when they are dispersed in an aqueous medium.

In Vitro Release Profile. Figure 2A represents the profile of resveratrol release from nanoparticles, expressed as the cumulative percentage of drug released versus time. In all cases, the release of resveratrol from zein-based nanoparticles was found to be independent of the pH conditions. During the first 2 h, under SGF conditions (pH 1.2), approximately 20% of the loaded resveratrol was released from the zein nanoparticles. Then, 6 h later (during incubation under SIF conditions), the amount released was close to 60% of the total resveratrol content. After 48 h, all of the loaded resveratrol had been released from the nanoparticles.

The profile of resveratrol release from the nanoparticles was fitted to different mathematical release models. Using the Korsmeyer−Peppas equation, R^2 values were high ($R^2 > 0.96$),

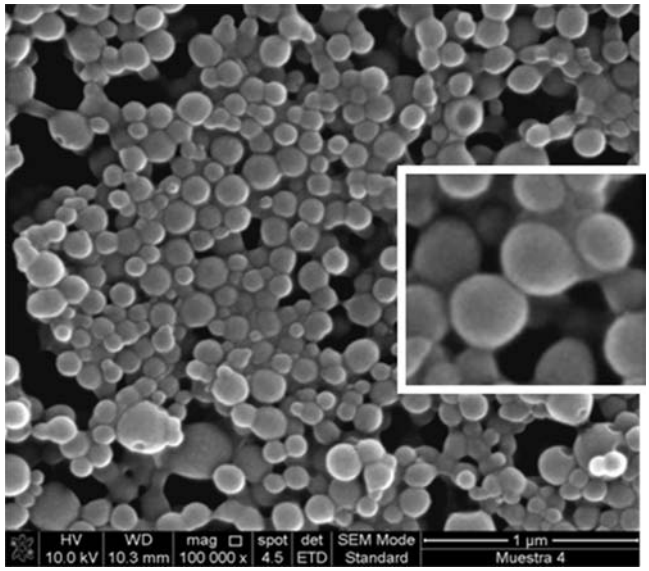

Figure 1. Scanning electron microscopy (SEM) microphotograph of resveratrol-loaded zein nanoparticles. The bar indicates the resolution (1 μm). The white box delimits a magnified area.

and the exponent n value was 0.75 ± 0.06. All of these results suggest that the release of resveratrol from the nanoparticles was due to a combination of Fickian diffusion and erosion of the nanoparticle matrix. Under these circumstances, the Peppas−Sahlin model was applied, and the erosion (K_E) and diffusion (K_D) constants were calculated (K_D = 0.08 ± 0.02 $h^{-1/2}$; K_E = 0.04 ± 0.01 h^{-1}). Figure 2B displays the contributions of both the diffusion and the erosion mechanisms to the release of resveratrol from zein nanoparticles. The time at which the two mechanisms (diffusion and erosion) similarly contributed to the release of resveratrol was calculated to be 3.5 h.

In Vivo Pharmacokinetics. Figure 3A shows the plasma concentration−time profile of a resveratrol solution in PEG400/water (1:1 by vol) after intravenous (iv) administration of a single dose of 15 mg/kg to rats. The data were adjusted to a noncompartmental model. The resveratrol plasma concentration decreased rapidly, in a biphasic way, during the first 8 h of postadministration. The peak plasma concentration (C_{max}) of resveratrol was 15.2 μg/mL, whereas the AUC and half-life ($t_{1/2}$) were calculated to be 11.4 μg h/mL and 2.04 h, respectively. The clearance and volume of distribution of resveratrol were 199 mL/h and 569 mL, respectively (Table 2).

Figure 3B shows the plasma concentration levels of resveratrol when administered orally to rats as a single dose of 15 mg/kg. Interestingly, when resveratrol was formulated as a suspension, no quantifiable levels of the polyphenol were detected in the plasma. In contrast, when resveratrol was administered as a solution (Rsv-sol), the polyphenol plasma levels displayed a maximum concentration (C_{max}), or 0.20 μg/

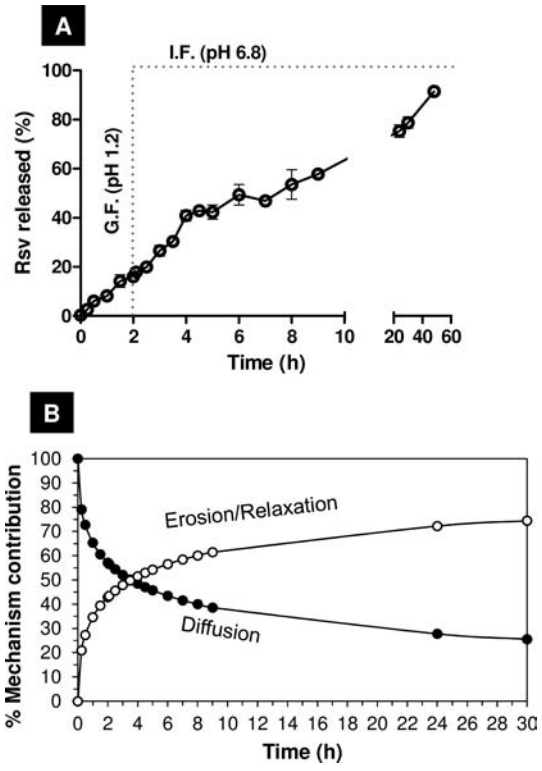

Figure 2. Resveratrol release from zein-based nanoparticles (Rsv-NP-Z). (A) Resveratrol release profile when incubated in simulated gastric fluid (SGF, pH 1.2; 0−2 h) and simulated intestinal fluid (SIF, pH 6.8; 2−48 h) under sink conditions. The data represent the mean ± standard deviation (SD) (n = 3). (B) Fractional contributions of the Fickian diffusion (●) and the erosion/relaxation (○) mechanisms to resveratrol release from zein nanoparticles (Rsv-NP-Z).

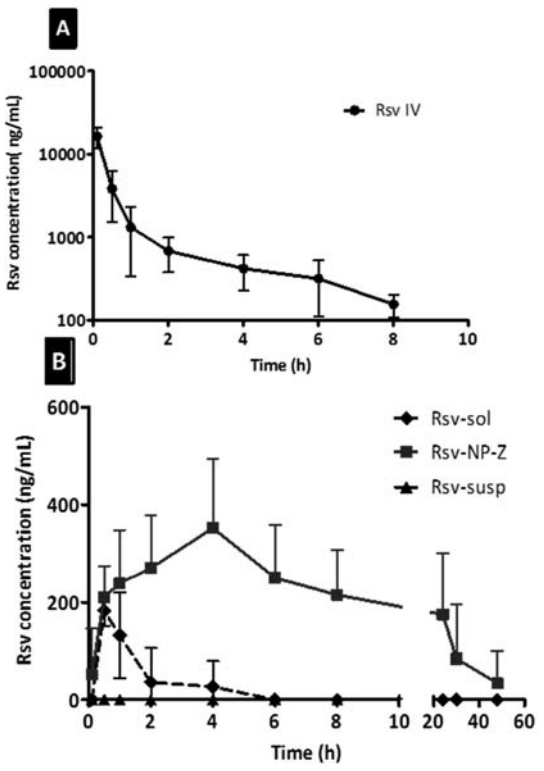

Figure 3. Resveratrol plasma concentration versus time after a single administration of the polyphenol at a dose of 15 mg/kg. (A) Intravenous (iv) administration of the resveratrol solution in the PEG400/water mixture. (B) Oral administration of the following resveratrol formulations: (i) resveratrol suspension (Rsv-susp, ▲), (ii) resveratrol solution (Rsv-sol, ◆), and (iii) resveratrol-loaded zein nanoparticles (Rsv-NP-Z, ■). Data are expressed as the mean ± SD (n = 6).

mL, 30 min after administration. The plasma levels of resveratrol then decreased rapidly, and quantifiable levels were detected only during the first 4 h postadministration.

For resveratrol loaded in zein nanoparticles (Rsv-NP-Z), the amount of the polyphenol in the plasma increased during the first 4 h after administration until reaching a maximum. The resveratrol plasma levels then decreased slowly for the following 20 h. Forty-eight hours postadministration, the amount of resveratrol in the plasma was very close to the quantitation limit of the analytical technique.

Table 2 summarizes the main pharmacokinetic parameters estimated via a noncompartmental analysis of the experimental data obtained after administration of the different formulations to rats. The resveratrol AUC values for the zein nanoparticle formulation were significantly higher ($p < 0.05$) than those observed for the polyphenol solution. Similarly, the MRT of resveratrol was 13 times higher when resveratrol was administered in the form of zein nanoparticles than when solubilized in the PEG400/water mixture and administered orally. Finally, the relative oral bioavailability of resveratrol when incorporated in zein nanoparticles was calculated to be 50%. This value was significantly higher than the bioavailability obtained with the PEG400/water solution (2.64%).

Figure 4 shows the plasma concentration versus time profile of the main resveratrol metabolite (resveratrol-*O*-3-glucuronide) after a single administration of the polyphenol in the formulations tested. Interestingly, the profiles of the plasma curves for resveratrol and its metabolite were similar; however, the metabolite levels were always higher than the levels of the polyphenol. When resveratrol was administered intravenously, the metabolite concentration reached 41.9 μg/mL (C_{max}), and then the metabolite levels decreased sharply. The AUC value was calculated to be 197 μg h/mL.

For the orally administered solution of resveratrol, the C_{max} of the metabolite in the plasma was found to be 2 times lower (22.1 μg/mL) than when resveratrol was administered by the iv route. In this case, the metabolite was only quantified in the plasma during the first 8 h postadministration. The AUC value was calculated to be 104 μg h/mL, which was approximately half of that for the iv solution.

For the nanoparticles, the metabolite was quantified during the first 24 h after administration. In addition, the metabolite AUC was approximately 342 μg h/mL for Rsv-NP-Z. This value was approximately 3 times higher than that for the resveratrol administered as an oral solution or intravenously.

In Vitro/in Vivo Correlations. Figure 5 represents the relationship between the in vitro dissolution data (expressed as the cumulative percentage of the polyphenol released) and the fraction of resveratrol absorbed during the first 8 h postadministration. An acceptable linear regression was observed between the two types of data (R^2 = 0.83 for Rsv-NP-Z).

Anti-inflammatory Efficacy Study. Figure 6A shows the rectal temperatures of the mice for 24 h after ip administration of 40 μg of LPS. Before challenge, all of the animals displayed similar rectal temperatures (data not shown). However, 6 h after challenge, important differences were observed between

the groups. Positive-control animals (without any resveratrol treatment) displayed a body temperature of approximately 4 °C below the basal normal levels. For animals treated with Rsv-sol, their body temperature was 3 °C lower than before challenge. In contrast, the rectal temperature of the animals treated with resveratrol loaded in zein nanoparticles decreased by only 0.5–1 °C. No variations were observed in the negative-control group. Twenty-four hours after challenge, the animals treated with free resveratrol or encapsulated resveratrol returned to their normal temperature.

Table 3 shows the overall endotoxic symptom score, including the number of animals displaying a temperature 2 °C lower than the basal temperature 6 h postchallenge. Positive-control animals displayed low mobility and signs of bristly hair and respiratory distress. In contrast, animals treated with Rsv-NP-Z displayed nearly normal behavior and evidently

better symptomatology than those animals receiving resveratrol as an oral solution, which appeared to be immobile or had great difficulty in coordinating any simple movement.

Figure 6B shows the serum levels of TNF-α, as measured by ELISA before and 90 min after LPS challenge. Negligible levels of TNF-α were observed before LPS administration. The oral administration of Rsv-NP-Z induced a decrease in the levels of TNF-α with respect to mice pretreated with resveratrol solution and the positive-control group; however, the differences were not statistically significant. Significant differences ($p < 0.01$) were observed between the negative control and the rest of the groups.

DISCUSSION

In the past, zein was proposed as material for the preparation of nanoparticles due to its hydrophobic character, degradability, adherence properties, and versatile processability.[19,20] However, as zein possesses abundant nonpolar amino acids, dispersibility of the resulting nanoparticles in an aqueous medium (and therefore their potential applications) is a challenge.[30] Recently, the use of citrate and phosphate salts was proposed to minimize this problem.[31] In our case, lysine was added during the process of preparing the nanoparticles. In this way, the resulting dry powder of zein nanoparticles was easily redispersed, yielding a homogeneous, fine suspension (Table 1) after the addition of water and simple manual agitation.

Resveratrol-loaded zein nanoparticles displayed a mean size close to 300 nm and a negative zeta potential. The resveratrol loading was 80 μg/mg nanoparticles, with an encapsulation efficiency of 80%. This payload is in line with values previously reported using solid lipid nanoparticles,[17] PLGA nanoparticles,[18] or nanoemulsions.[32] The release of resveratrol from zein nanoparticles was found to be pH independent. In fact, this phenomenon combined Fickian diffusion and erosion of the nanoparticle matrix (Peppas−Sahlin model). During the first hours of the release process, resveratrol molecules likely mainly diffused from the nanoparticles and into the aqueous medium by Fickian diffusion. Later (3.5 h), the release of resveratrol would be mainly due to erosion and/or relaxation of the nanoparticle matrix. Interestingly, as a consequence of both phenomena, the amount of resveratrol released (at least during the first 8 h) was constant and approached zero-order kinetics.

Pharmacokinetic studies were carried out at a single dose of 15 mg/kg, which is comparable to doses used in previous studies.[33,34] The oral administration of a single dose of resveratrol to rats as an aqueous suspension (Rsv-susp) did not produce quantifiable levels of the polyphenol in the plasma (Figure 3B). For the solution formulation in a PEG400/water mixture (Rsv-sol), the plasma levels of the polyphenol were higher than for the suspension, but the levels rapidly decreased, and 6 h postadministration, only traces of resveratrol were detected in the plasma. These findings are directly related to the extensive metabolism of resveratrol.[35] In fact, when administered orally, resveratrol (due to its lipophilic character) can rapidly enter enterocytes by passive diffusion.[36] However, resveratrol is highly metabolized to glucuronide and sulfate derivatives, which may be secreted back into the intestinal lumen through multidrug resistance proteins (MRP) and breast cancer resistance protein (BCRP).[37,38] This extensive biotransformation of resveratrol decreases the circulating levels of free resveratrol and facilitates its excretion (in the form of conjugates) by the kidneys via the urine.[14] Controversy remains about the physiological activity of the metabolites and whether they can act as resveratrol prodrugs. There is evidence that at sufficient concentrations, resveratrol metabolites have biological activity in various tissues.[36] Nevertheless, there is also evidence that these compounds have no effects in certain tissues.[39]

However, when resveratrol was administered after its encapsulation in zein nanoparticles in the current study, sustained plasma levels of the polyphenol were observed for at least 24 h (Figure 3B), and its relative oral bioavailability was approximately 50% (Table 3), which is 19-fold higher than the value observed for Rsv-sol (approximately 2.6%). This increased capability to promote the absorption and bioavailability of resveratrol by using zein nanoparticles is related to the highly hydrophobic character of zein, which offers greater stability in vivo, and to the capability of this corn protein to develop mucoadhesive interactions within the gut mucus layer.[40] Thus, this characteristic may provide a longer time in close contact with the intestinal epithelium and may facilitate the establishment of a concentration gradient from the nanoparticulate matrix until the absorptive membrane. Interestingly, the fraction of resveratrol absorbed from zein nanoparticles correlated well with the percentage of the polyphenol released in vitro (see Figure 5).

In some previous studies, it has been reported that the oral bioavailability of resveratrol and some of its derivatives is negligible.[34,41] To improve its absorption, different strategies have been proposed, such as the use of oral absorption enhancers (e.g., Tween 80, cyclodextrins) or the employment of resveratrol derivatives. In this way, Kapetanovic and coworkers reported an oral bioavailability of close to 30% for resveratrol (formulated as an aqueous solution containing methylcellulose and Tween 80) after the administration of a single dose of 50 mg/kg in rats. In the same work, administration of the same resveratrol formulation at a dose of 150 mg/kg produced an oral bioavailability of 19%.[42] In another study, resveratrol trimethyl ether administered orally in a solution formulated with randomly methylated β-cyclodextrin (15 mg/kg) yielded a bioavailability of approximately 47%. More recently, the use of nanocarriers has also been proposed. In mice, using a dose of 50 mg/kg, the oral bioavailability of resveratrol when loaded in either Eudragit or chitosan/lecithin nanoparticles was calculated to be 39 and 61%, respectively.[43] For solid lipid nanoparticles, the oral bioavailability of the polyphenol was found to be 8-fold higher than for a conventional solution of resveratrol.[44] In our case, the bioavailability of resveratrol was 19.2-fold higher when resveratrol was loaded in zein nanoparticles than when it was dissolved in the PEG400/water solution. Furthermore, zein nanoparticles offering sustained and prolonged levels of resveratrol in the plasma provide a supplementary advantage compared with other strategies.

With regard to the presence of the main metabolite (resveratrol-*O*-3-glucuronide[13]) in the plasma of animals, the levels of this compound (measured as AUC values) were higher when resveratrol was administered via encapsulation in zein nanoparticles than when administered in the conventional solution by the iv route (approximately 1.7 times) or orally (approximately 3.3 times). This result could be related to the slow release of the polyphenol from the nanoparticles (where it was protected from degradation) and the prolonged residence of nanoparticles in the gut mucosa due to their mucoadhesive properties. In other words, by using nanoparticles, more resveratrol would reach the circulation during a longer period,

DOI: 10.1021/jf505694e
J. Agric. Food Chem. 2015, 63, 5603−5611

counterbalancing the rapid natural metabolism of the polyphenol.

Finally, we studied the anti-inflammatory activity of resveratrol when loaded in zein nanoparticles. Several in vitro and in vivo studies have suggested that resveratrol inhibits the inflammatory response mediated by microbial stimuli[45] by inhibiting the transcription factor NF-κB.[10,11] Therefore, we tested the protective effect of encapsulated resveratrol against inoculation with LPS in mice. LPS is present exclusively on the outer membrane of Gram-negative bacteria, and consequently, it is one of the strongest alarm signals for the innate immune system, inducing a pathophysiological syndrome known as endotoxic shock in animals. This syndrome is similar to septic shock syndrome that progresses to multiple organ failure,[29,46] causing piloerection, hypothermia, shivering, tachycardia, and lethargy. These symptoms are related to the large amounts of inflammatory mediators released, such as TNF-α, NO, and prostaglandin E2 (PGE2), with TNF-α playing a central role as the first one to be released.[10] Under our experimental conditions, untreated mice challenged with LPS (positive control) displayed the greatest decrease in rectal temperature and the highest TNF-α serum level. In contrast, Rsv-NP-Z administered daily for 7 days diminished endotoxic symptoms, such as hypothermia or piloerection, and increased the movement of mice compared with resveratrol solution administered on a daily basis (Figure 6; Table 3). Moreover, for animals treated with Rsv-NP-Z, TNF-α levels were lower than for controls, although the high variability of the values abolished the statistical significance ($p < 0.05$). These results appear to indicate that the presence of sustained high levels of resveratrol in the plasma could be efficient in reducing the levels of inflammatory mediators in endotoxic shock induced by LPS.

In summary, zein nanoparticles appear to be interesting carriers for the oral delivery of resveratrol. The polyphenol is released from this carrier by a combination of both diffusion and erosion of the nanoparticle matrix, providing higher and more prolonged plasma levels of resveratrol up to 48 h. Consequently, these nanocarriers significantly increase the oral bioavailability of resveratrol, reaching a value close to 50%. Weeklong oral administration of these nanoparticles to mice challenged with LPS protected the mice from the inflammatory symptoms and mediators of endotoxic shock. Future studies should be performed to ascertain how this treatment modulates TNF-α production to explore the potential use of Rsv-NP-Z as an anti-inflammatory treatment.

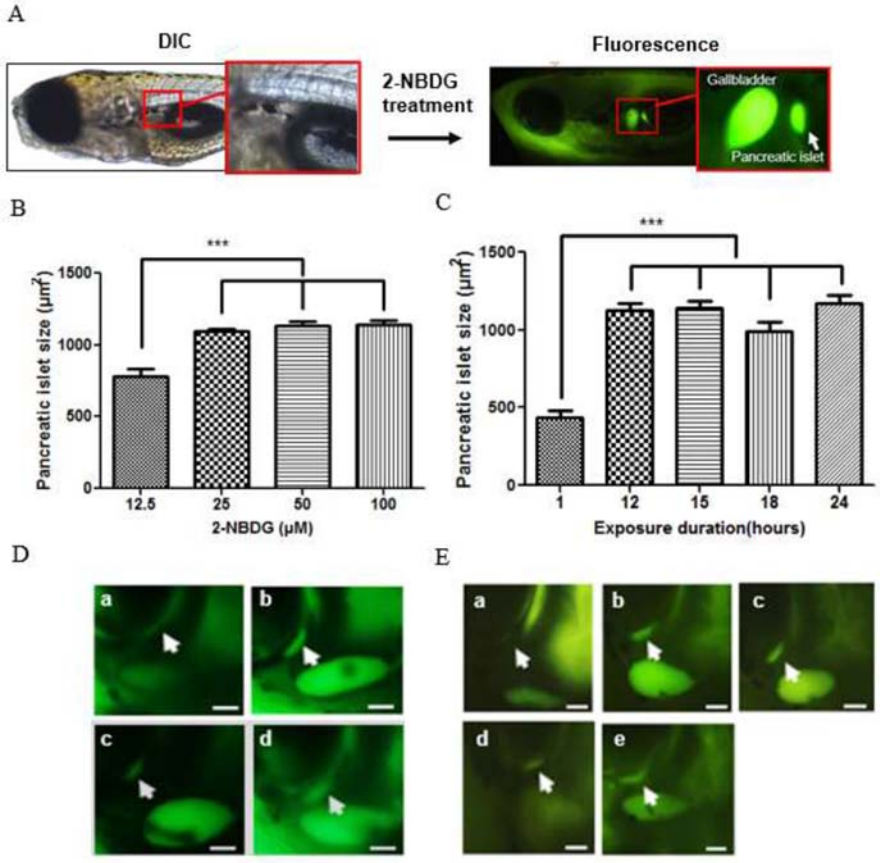

Figure 1. Changes in pancreatic islet (PI) area and fluorescence intensity caused by 2-NBDG. (A) PIs in wild-type zebrafish and zebrafish larva at 5 days postfertilization (dpf) were evaluated by differential interference contrast (DIC) and fluorescence microscopy. (B) Dose-dependent changes in PI size caused by 2-NBDG were analyzed using Focus Lite software. (***) $p < 0.001$. (C) Treatment over 24 h demonstrated a time-dependent uptake, which was visualized by fluorescent microscopy. The PI area demonstrated dose-dependent uptake. (***) $p < 0.001$. (D) Fluorescent microscopic images of PI following treatment with 2-NBDG at a concentration of (a) 12.5 μM, (b) 25 μM, (c) 50 μM, or (d) 100 μM. Scale bar = 100 μm. (E) Fluorescent microscopic images of PI at (a) 1 h, (b) 12 h, (c) 15 h, (d) 18 h, and (e) 24 h. Scale bar = 100 μm.

Sigma Chemical Co. (St. Louis, MO, USA). Trigonelline (TRG) hydrochloride was purchased from Tokyo Chemical Industry Co., Ltd. (Tokyo, Japan). 2-(*N*-(7-Nitrobenz-2-oxa-1,3-diazol-4-yl)amino)-2-deoxyglucose (2-NBDG) was purchased from Invitrogen (Life Technologies, Grand Island, NY, USA). Glimepiride (GLM) was obtained from Cayman Chemical Co. (Ann Arbor, MI, USA). Diazoxide (DZ) was purchased from Santa Cruz Biotechnology Inc. (Dallas, TX, USA). A Shimadzu LC-20A HPLC instrument was used for HPLC (Shimadzu, Japan). An Olympus 1X70 microscope was used for fluorescence microscopy (Olympus, Japan). Focus Lite (Focus Co, Daejeon, Korea) and ImageJ software (National Institutes of Health) were used for image analysis.

Zebrafish Maintenance and Egg Collection. Adult zebrafish were maintained in an S type zebrafish system (1500 mm (W) × 400 mm (D) × 2050 mm (H)) (Daejeon, Korea). To obtain ZFL, three pairs of zebrafish were placed in a spawning box overnight. The next day, zebrafish began spawning after a 30 min light period. Zebrafish eggs were collected 3 h postfertilization (hpf) for experiments and incubated in a Petri dish in a 0.03% sea salt solution. Embryos were maintained on a 14 h light/10 h dark cycle in a 28.5 °C incubator. Fish were cared for in accordance with standard zebrafish protocols approved by the Animal Care and Use Committee of Kyung Hee University (KHUASP(SE)-15-10).

Validation of 2-NBDG and AX in ZFL. Staining for PI visualization was evaluated according to a previously reported method.[17] First, 5 day postfertilization (dpf) zebrafish were placed into 96-well plates. Next, the ZFL were treated with various concentrations of 2-NBDG (12.5, 25, 50, and 100 μM, final volume = 100 μL) for various lengths of time (1, 12, 15, 18, and 24 h). Following treatment, ZFL were rinsed with a 0.03% sea salt solution and observed by fluorescence microscopy. To obtain AX-induced PI-damaged zebrafish larvae (AIPD-ZFL), ZFL were treated with 100 μL of AX solution at various concentrations (50, 100, and 300 μM) for 15 min. The AX solution was then changed to the 0.03% sea salt solution, and ZFL were observed every 2 h thereafter. To capture images, ZFL were restained for 1 h with 25 μM 2-NBDG. PI images were then captured using fluorescence microscopy and analyzed using Focus Lite and ImageJ software.

Survival Rates. Zebrafish survival rates were evaluated according to a previously reported method.[18] Briefly, at 6 hpf, zebrafish eggs were placed into 24-well plates. The zebrafish eggs were then divided into the following six groups: normal, 100 μM AX, 10 μM GLM, 300 μg/mL CE, 100 μM AX + 10 μM GLM, and 100 μM AX + 300 μg/mL CE. Next, each well in the 24-well plates was filled with 1 mL of AX, GLM, and/or CE solution or 0.03% sea salt solution. The survival rates of ZFL were calculated using the percentage of fish that remained alive after treatment for 48 h. The solutions were replaced daily with fresh solutions.

Efficacy of Coffee and Coffee Components on PIs. We measured the efficacy of CE and the coffee components CFI, TRG, and CGA in AIPD-ZFL. Wild-type ZFL at 5 dpf were treated with 25 μM 2-NBDG in 96-well plates for 12 h. After PI damage was induced using 100 μM AX, the sizes of ZFL PIs were measured using fluorescence microscopy. To determine the efficacy of CE, CFI, TRG, and CGA, ZFL were treated with 100 μL of CE (50, 100, and 300 μg/mL), coffee components (CFI, TRG, or CGA 10 μg/mL each), or GLM (10 μM) for 1 h. Next, the ZFL were treated with 25 μM 2-NBDG (100 μL) for 1 h, and images were captured using

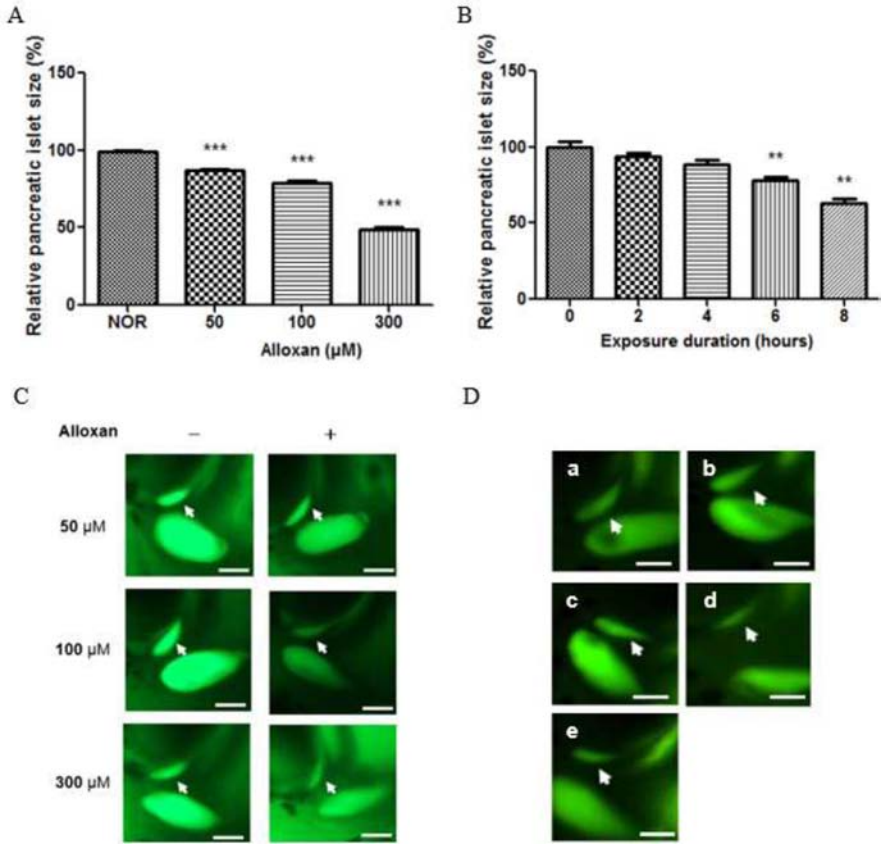

Figure 2. Dose- and time-dependent changes in pancreatic islet (PI) size following alloxan treatment (AX). (A) Dose-dependent changes in PI size after treatment with AX at 50, 100, or 300 μM after exposure to 25 μM 2-NBDG. (***) $p < 0.001$, compared to normal. (B) Time-dependent effects of 100 μM AX were quantified using image analysis of PI size. (**) $p < 0.01$ and (***) $p < 0.001$, compared to normal. (C) Fluorescent microscopic image of treatment with AX at doses of 50, 100, and 300 μM after exposure to 25 μM 2-NBDG. Scale bar = 100 μm. (D) Fluorescent microscopic image of the time dependency of 100 μM AX effects. Scale bar = 100 μm.

fluorescence microscopy. For normal group treatments, solutions including AX were replaced with the sea salt solution to compare treated groups with normal PI size and fluorescence intensity. To measure changes in PI size and intensity, images were analyzed using Focus Lite and ImageJ software, respectively. We analyzed PI size and fluorescence intensity via images before and after treatment, and all values were expressed as size change values and percent intensity change according to the following equations, respectively: size change value = PI size after treatment − PI size before treatment; percent change in fluorescence intensity value = [(PI intensity after treatment/PI intensity before treatment) × 100] − [(PI intensity before treatment/PI intensity before treatment) × 100].

Efficacy of Coffee on Islet β-Cells of ins:GFP Zebrafish. Transgenic zebrafish lines expressing GFP specifically in β-cells were obtained from the Zebrafish Organogenesis Mutant Bank (ZOMB). The GFP-tagged line was ins:GFP, which expresses GFP in the pancreas.[19] Experiments were performed using 5 dpf larvae. Transgenic ZFL were first imaged in the no-treatment state and then after exposed to 100 μM AX. Following AX treatment, transgenic ZFL were treated with 100 μg/mL of CE for 1 h and then imaged. Treatments for the normal group including AX consisted of a sea salt solution to compare treated groups with normal β-cells size and fluorescence intensity. To measure changes in β-cells, the size and intensity of all images were analyzed using Focus Lite and ImageJ software, respectively.

HPLC Analysis of Coffee Components. *CFI Analysis.* HPLC analysis of CFI was based on a modification of a previous study.[20] Briefly, chromatographic separation was performed using a Bischoff Chromatography ProntoSIL C18 column (250 × 4.6 mm, 5 μm). The mobile phase consisted of a mixture of water (80%) and acetonitrile (20%) at a flow rate of 0.7 mL/min. The column temperature was set at 40 °C, the sample injection volume was 10 μL, and the detection wavelength was set at 265 nm. The calibration curve was generated using three replicated points of CFI at 50, 100, and 200 μg/mL. CE (2 mg/mL) was injected after filtration. The analytical method was validated for the limits of detection and quantitation (LOD and LOQ, respectively).

TRG Analysis. HPLC analysis of TRG was performed using a Knauer 25XE184E2J C18 column (250 × 3 mm, 5 μm). The mobile phase consisted of a mixture of water (15%) and acetonitrile (85%) at a flow rate of 0.6 mL/min. The column temperature was set at 40 °C, the sample injection volume was 10 μL, and the detection wavelength was set to 265 nm. The calibration curve was generated using three replicated points of TRG at 10, 30, and 50 μg/mL. CE (1 mg/mL) was injected after filtration. The analytical method was validated for the LOD and LOQ.

CGA Analysis. HPLC analysis condition of CGA was performed using a Bischoff Chromatography ProntoSIL C18 column (250 × 4.6 mm, 5 μm). The mobile phase consisted of a mixture of water (70%) and 1% acetic acid in methanol (30%) at a flow rate of 0.7 mL/min. The column temperature was set at 40 °C, the sample injection volume was 10 μL, and the detection wavelength was set at 265 nm. The calibration curve was generated using three replicated points of CGA at 30, 50, and 100 μg/mL. CE (1 mg/mL) was injected after filtration. The analytical method was validated for the LOD and LOQ.

TRG and CGA Interaction in AIPD-ZFL. The interaction between TRG and CGA was analyzed using an isobologram based on 50% effect concentration (EC_{50}) data. EC_{50} data were obtained through nonlinear regression using GraphPad Prism software (version 5). To determine EC_{50} values, we measured the effects of TRG and CGA on AIPD in ZFL at concentrations ranging from 0.4 to 10 μM. TRG and

DOI: 10.1021/acs.jafc.5b00027
J. Agric. Food Chem. 2015, 63, 5612−5621

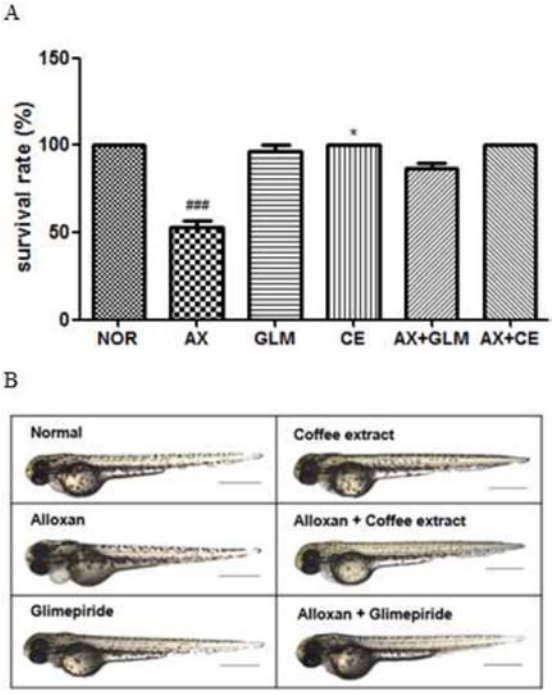

Figure 3. Survival rate of zebrafish embryos. (A) Survival rate of zebrafish embryos treated with 100 μM alloxan (AX), 10 μM glimepiride (GLM), 300 μg/mL coffee extract (CE), 100 μM AX + 10 μM GLM, or 100 μM AX + 300 μg/mL CE for different time points. Survival rates were determined at 48 h. (*) $p < 0.05$, compared to AX; (###) $p < 0.001$, compared to normal. (B) Microscopic images after 48 h of treatment. Scale bar = 1 mm.

CGA were combined at three points: $EC_{25}/EC_{12.5}$ (TRG + CGA, point 1), $EC_{25}/EC_{16.7}$ (TRG + CGA, point 2), and EC_{25}/EC_{25} (TRG + CGA, point 3). To assess synergy, experimental data were plotted on an isobologram, and a combination index (CI) was generated using CompuSyn software.[21]

Action of DZ on AIPD-ZFL. ZFL were divided into the following 12 groups: normal, normal treated with DZ or AX, AIPD-ZFL treated with DZ, and AIPD-ZFL treated with GLM, GLM+DZ, CE, CE+DZ, TRG, TRG+DZ, CGA, and CGA+DZ. The following dosages were used: GLM, TRG, and CGA at 10 μg/mL each, DZ at 25 μM, and CE at 100 μg/mL. Prior to capturing images, ZFL were treated with 25 μM 2-NBDG for 1 h. All images were analyzed using Focus Lite software.

Statistical Analyses. Statistical analyses were performed using GraphPad Prism software (version 5). Data were expressed as the mean ± standard error of the mean (SEM). Statistical significance was determined using repeated one-way ANOVA followed by Tukey's post test. The probability level for statistical significance was set at $p < 0.05$.

RESULTS

Optimization of 2-NBDG. PI sizes were significantly different ($p = 0.0005$) between groups treated with 12.5 and 25 μM 2-NBDG. Additionally, PI size remained stable at concentrations of >25 μM. Validation of 2-NBDG exposure revealed that PI sizes were stable for >12 h. Therefore, the optimal concentration and exposure time of 2-NBDG were established as 25 μM and 12 h, respectively (Figure 1).

Optimization of AX Dosage. PI sizes were significantly decreased at doses of 50, 100, and 300 μM AX in a dose-dependent manner. The 100 μM dose of AX was selected as the optimal concentration for induction of PI damage, as it resulted in a PI size decrease of approximately 20%, $p = 0.0001$.

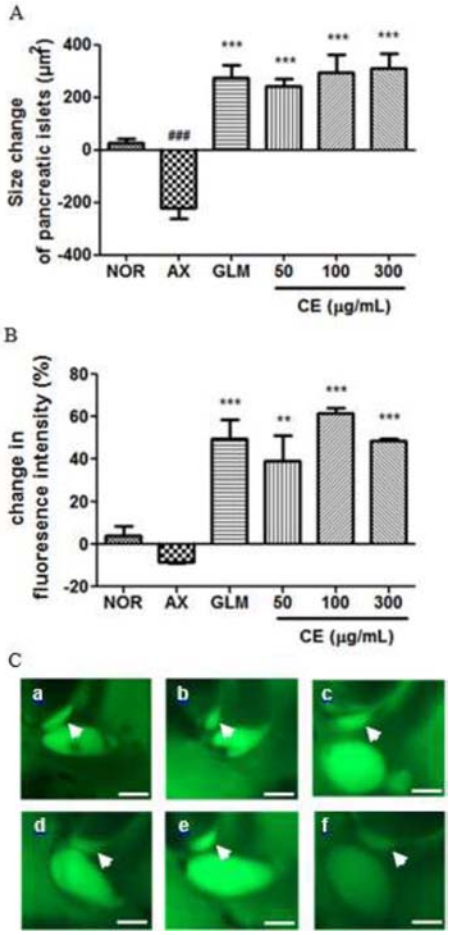

Figure 4. Dose-dependent effects of coffee extract (CE) on alloxan-induced pancreatic islet-damaged zebrafish larvae (AIPD ZFL). (A) Change in pancreatic islet (PI) size caused by CE and glimepiride (GLM). (***) $p < 0.001$, compared to alloxan (AX); (###) $p < 0.001$, compared to normal. (B) Change in PI fluorescence intensity evaluated using image analysis. (**) $p < 0.01$ and (***) $p < 0.001$, compared to alloxan (AX). (C) Fluorescent microscopic image of PI in (a) the normal group, (b) 100 μM alloxan (AX) group, (c) 10 μM GLM group, (d) 50 μg/mL CE group, (e) 100 μg/mL CE group, and (f) 300 μg/mL CE group. Scale bar = 100 μm.

PI sizes were decreased at 2, 4, 6, and 8 h of exposure in a time-dependent manner. PI size was significantly decreased at 6 h ($p = 0.0078$) and 8 h ($p = 0.0016$). An AX dose of 100 μM for 6 h was selected because an 8 h exposure caused severe damage (Figure 2).

Survival Rate. The survival rate was 100% in the normal, 10 μM GLM, 300 μg/mL CE, and 100 μM AX + 300 μg/mL CE treatment groups. However, the survival rate was 60% in the 100 μM AX group and 90% in the 100 μM AX + 10 μM GLM cotreatment group (Figure 3A). In addition, the 100 μM AX group showed toxicity-related characteristics of pericardial edema, unlike the normal group (Figure 3B).

Effect of CE on PIs. The normal group was used as the basis for comparison in the determination of the effects of AX with respect to induction of PI damage as determined by PI size and fluorescence intensity. The PI size in the AX-treated group was significantly decreased (9.8-fold, $p < 0.0001$) relative to the normal group. A 2.24-fold ($p < 0.0001$) increase in PI size was observed in the GLM-treated group. Likewise, the 50, 100, and 300 μg/mL CE-treated groups showed significantly increased

J. Agric. Food Chem. 2015, 63, 5612−5621

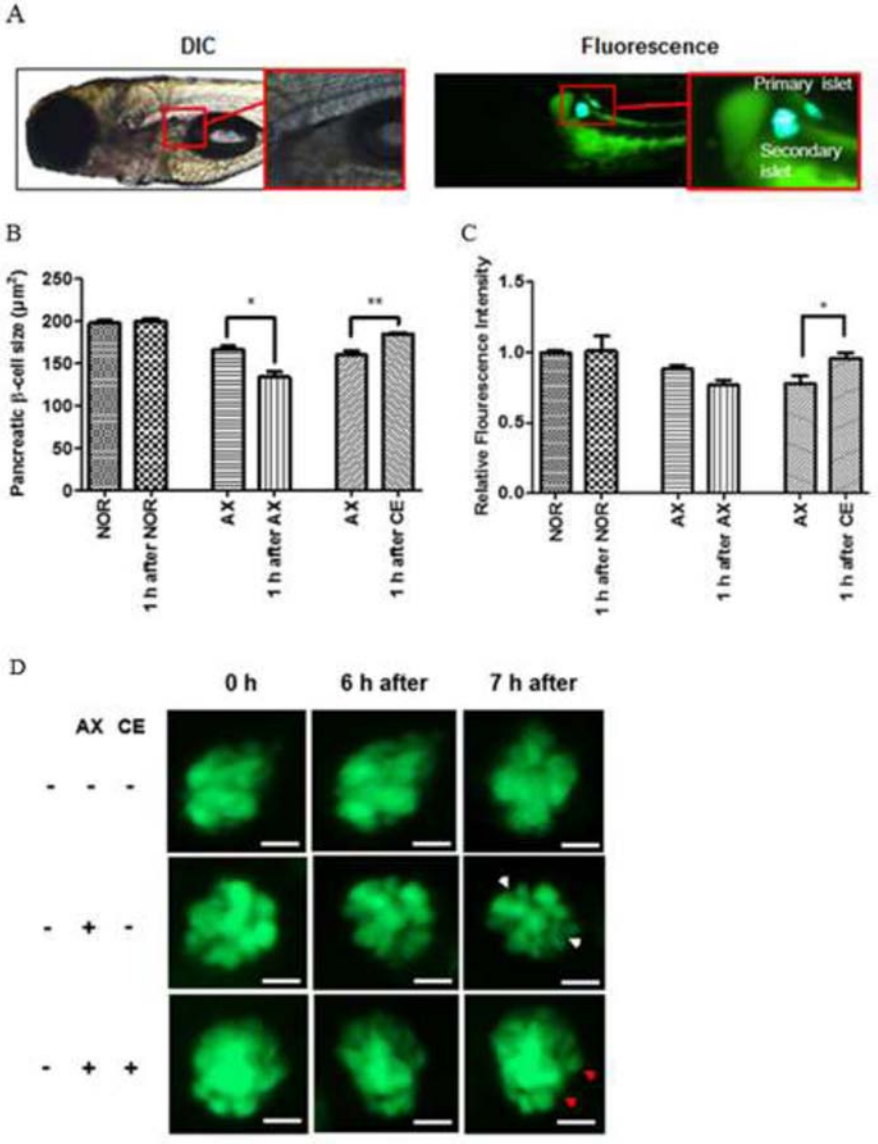

Figure 5. Effect of 100 μg/mL coffee extract (CE) on pancreatic β-cell regeneration. (A) Whole transgenic ins:GFP zebrafish and PIs were imaged by differential interference contrast (DIC), and zebrafish larva at 5 days postfertilization (dpf) were imaged by fluorescence microscopy. (B) Change in pancreatic β-cell size due to 100 μg/mL CE. (*) $p < 0.05$; (**) $p < 0.01$). (C) Relative fluorescence intensity of pancreatic β-cells due to 100 μg/mL CE. (*) $p < 0.05$. (D) Pancreatic β-cell image of each group. Damage is indicated in white and regeneration in red. Scale bar = 100 μm.

PI sizes (2.1-fold, $p < 0.0001$; 2.31-fold, $p < 0.0001$; and 2.39-fold, $p < 0.0001$, respectively; Figure 4A). We measured PI fluorescence using ImageJ software and found that the fluorescence intensity ratio in the AX group decreased (8.58 ± 0.15%) relative to the normal group (3.89 ± 7.81%) but was significantly increased in the GLM-treated (49.49 ± 16.15%, $p = 0.0034$) and 50, 100, and 300 μg/mL CE-treated groups (39.27 ± 20.18%, $p = 0.0148$; 61.75 ± 3.69%, $p < 0.0001$; and 48.58 ± 2.05%, $p < 0.0001$, respectively) relative to the AX-treated group (Figure 4B).

Efficacy of Coffee on Islet β-Cells of ins:GFP Zebrafish. Treatment of zebrafish with 2-NBDG is useful for staining PIs in tissue in their entirety. On the other hand, transgenic ins:GFP zebrafish express a fluorescent protein specifically in β-cells, allowing for specific visualization of primary and secondary islets. Using ins:GFP transgenic animals, we focused on secondary islets. The pancreatic β-cell size of the AX-treated group decreased by 33% ($p = 0.0006$) compared to the normal group. The decreased pancreatic β-cell size caused by AX treatment was increased by 16% ($p = 0.0062$) after treatment with 100 μg/mL CE (Figure 5A). The pancreatic β-cell fluorescence intensity in the AX-treated group decreased by 24% compared to the normal group. Following AX treatment, the pancreatic β-cell fluorescence intensity decreased due to damage, but was significantly increased by 18% ($p = 0.0449$) after exposure to 100 μg/mL CE (Figure 5B). We also observed pancreatic β-cell regeneration following treatment with CE in transgenic ins:GFP ZFL.

HPLC Analysis of CFI, TRG, and CGA in CE (Figure 6). A water/acetonitrile (80:20, v/v) CFI mobile phase was successfully used in the C18 column. The CFI content in 1 mg/mL CE was 60.6 μg/mL (Figure 6A, B). Likewise, a water/acetonitrile (15:85, v/v) phase was used for TRG analysis on a C18 column and showed that CE contains

J. Agric. Food Chem. 2015, 63, 5612−5621

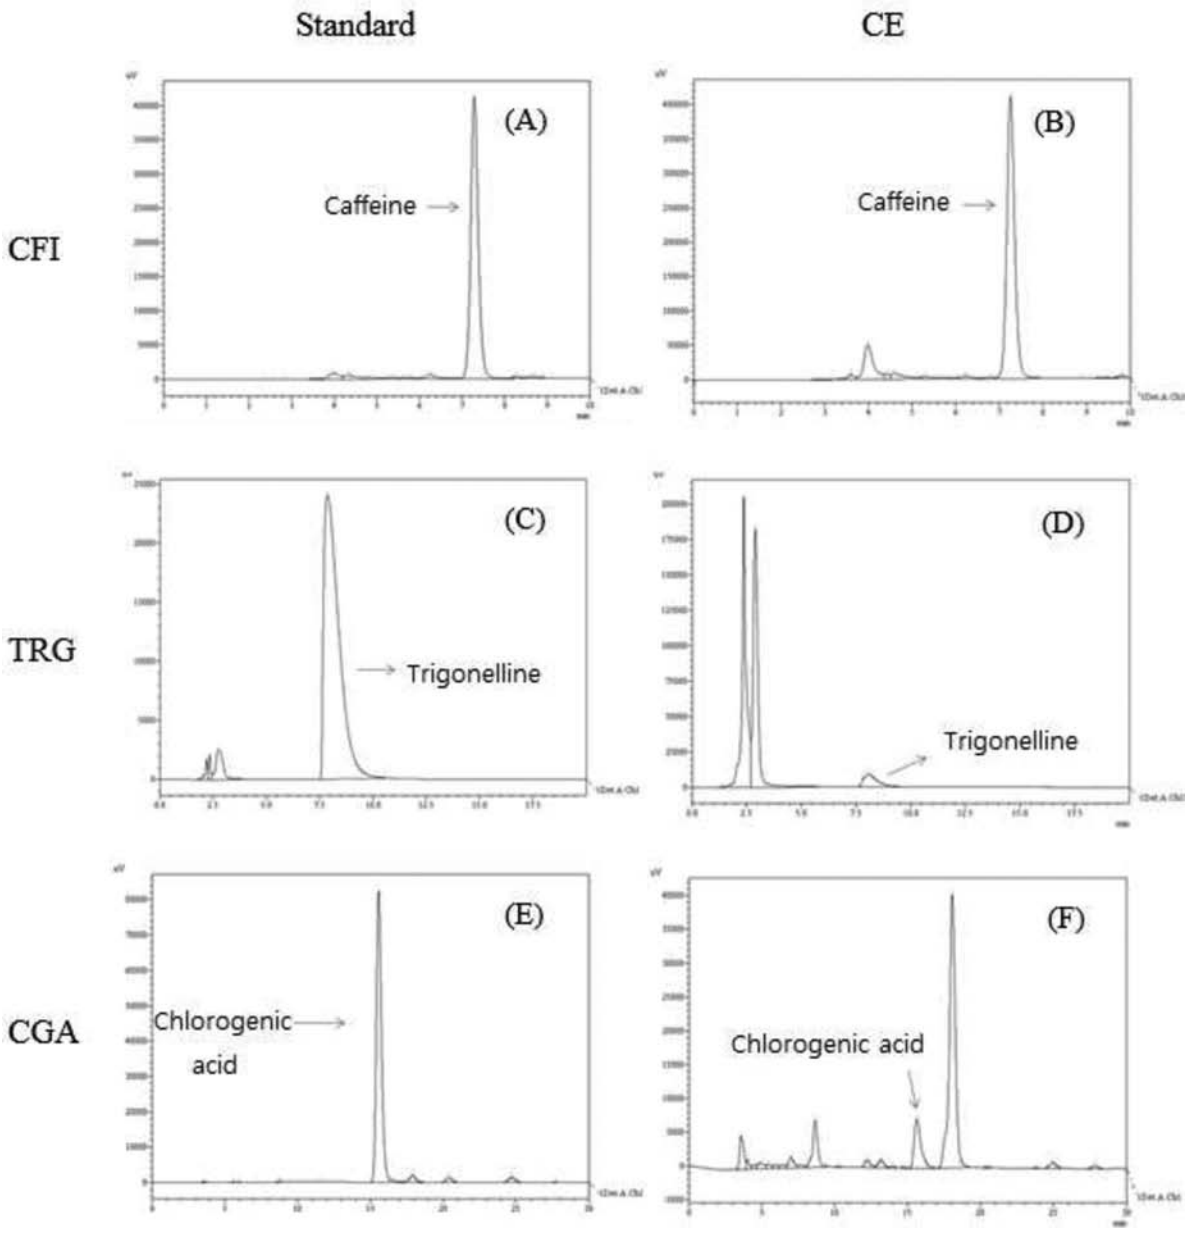

Figure 6. Chromatograms of caffeine (CFI), trigonelline (TRG), chlorogenic acid (CGA), and coffee extract (CE): (A) 100 μg/mL CFI; (B) 2 mg/mL CE; (C) 50 μg/mL TRG; (D) 1 mg/mL CE; (E) 100 μg/mL CGA; (F) 1 mg/mL CE.

11.85 μg/mL of TRG (Figure 6C, D). Lastly, CGA was analyzed using a mobile phase of water and 1% acetic acid in methanol (70:30, v/v) on a C18 column. The analysis showed that 1 mg/mL CE contains 34.1 μg/mL CGA (Figure 6E, F). Calibration curve equations, LOD, LOQ, and the CFI, TRG, and CGA concentrations are shown in Table 1.

Effects of CFI, TRG, and CGA on AIPD ZFL. The TRG- and CGA-treated groups had significantly increased PI sizes (2.16-fold, $p < 0.0001$; and 1.91-fold, $p < 0.0001$, respectively) compared to the AX-treated group. Additionally, PI size increased 0.75-fold in the CFI-treated group (Figure 7A). We next assessed PI fluorescence intensities and found that compared with the AX-treated group (8.58 $\pm$ 0.15%), the groups treated with GLM, CFI, TRG, and CGA had significantly increased fluorescence intensities (49.47 $\pm$ 16.15%, $p = 0.0034$; 44.81 $\pm$ 5.91%, $p < 0.0001$; 43.24 $\pm$ 5.44%, $p < 0.0001$; and 57.93 $\pm$ 1.88%, $p < 0.0001$, respectively; Figure 7B).

Synergy of TRG and CGA in AIPD ZFL. The 50% effect concentration (EC_{50}) was determined using nonlinear regression analysis of the logistic dose response curves with the GraphPad Prism 5 software suite. The EC_{50} values of TRG and CGA were 1.13 and 1.96 μg/mL, respectively. We determined the dose−response curves of combined TRG/CGA, TRG alone, and CGA alone in AIPD ZFL (Figure 8A). Using a CI plot of TRG/CGA combination we found that the synergistic effect had a CI value <1. Specifically, the CI values were 0.68, 0.51, and 0.47 for TRG/CGA points 1, 2, and 3, respectively (Figure 8B), indicating a synergistic effect. This synergistic effect was confirmed using an isobologram (Figure 8C).

Action of Diazoxide (DZ) on AIPD ZFL. To study the involvement of pancreatic β-cell K_{ATP} channel stimulation activity, we next evaluated PI size in response to diazoxide (DZ) treatment to open K^+ channels. We used the normal group as a baseline against which to determine significant differences in the

Table 1. Calibration Curve Equations, LOD,[a] LOQ,[b] and Concentrations of Caffeine, Trigonelline, and Chlorogenic Acid in Coffee Extract

sample	equation	R^2	LOD (μg/mL)	LOQ (μg/mL)	concentration of coffee extract (%)
caffeine	$y = 31032x + 1789355$	0.9941	0.279	0.777	6.0
trigonelline	$y = 21354x + 157253$	0.9909	0.186	0.563	1.2
chlorogenic acid	$y = 6200x + 23229$	0.9997	0.277	0.840	3.4

[a]LOD, limit of detection. [b]LOQ, limit of quantitation.

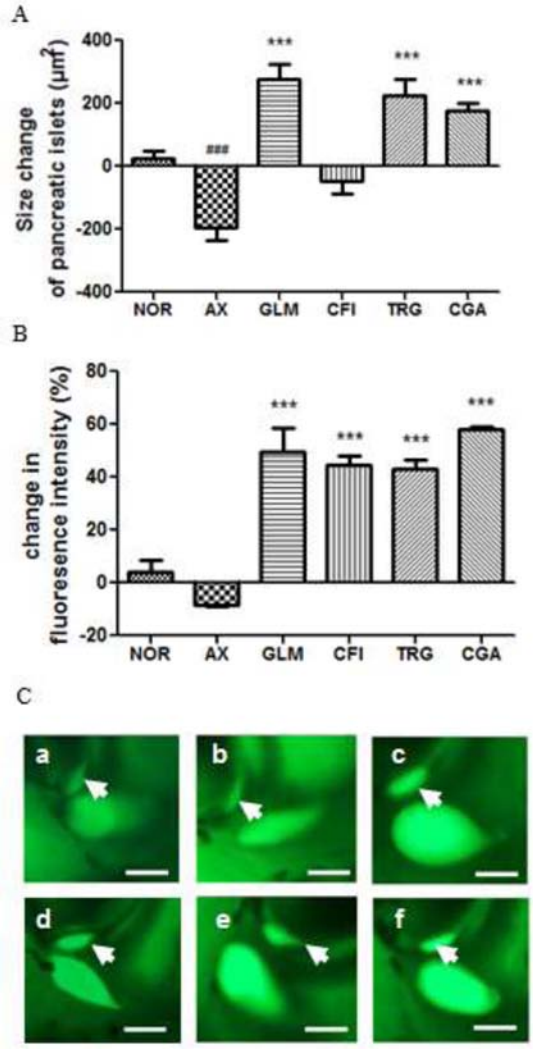

Figure 7. Effects of 10 μM caffeine (CFI), 10 μM trigonelline (TRG), and 10 μM chlorogenic acid (CGA) on alloxan-induced PI-damaged zebrafish larvae (AIPD ZFL). (A) Changes in pancreatic islet (PI) size caused by 10 μM CFI, 10 μM TRG, 10 μM CGA, and 10 μM glimepiride (GLM). (***) $p < 0.001$, compared to alloxan, AX; (###) $p < 0.001$, compared to normal. (B) Change in PI fluorescence intensity determined by image analysis. (***) $p < 0.001$, compared to alloxan, AX. (C) Fluorescent microscopic image of PIs in (a) the normal group, (b) 100 μM alloxan (AX) group, (c) 10 μM GLM group, (d) 10 μM CFI group, (e) 10 μM TRG group, and (f) 10 μM CGA group. Scale bar = 100 μm.

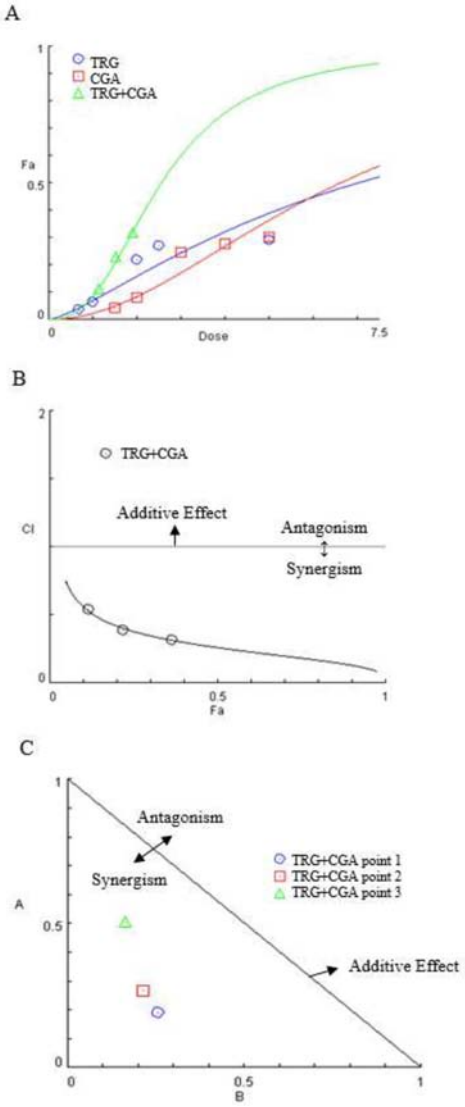

Figure 8. Combination of trigonelline (TRG) and chlorogenic acid (CGA). (A) Dose−effect curves of TRG, CGA, and combined TRG/CGA. (B) Combination index (CI)−fractional effect (Fa) plot of combined TRG/CGA. (C) Normalized isobologram constructed by connecting the EC_{50} value of TRG with the EC_{50} of CGA. The black line indicates the combined effect of TRG/CGA at points 1, 2, and 3.

AX-treated groups with or without DZ. The values of the AX-treated groups were below zero. The size of PIs in the DZ-treated normal group was significantly decreased (3.28-fold, $p = 0.0184$) relative to the no-DZ normal group. Furthermore, the AX-treated group showed no significant differences after treatment with 25 μM DZ. We next compared the GLM-, CE-, TRG-, and CCA-treated groups to the AX-treated groups, with or without DZ, as well as each DZ-treated group with the corresponding no-DZ treatment control group. The PI sizes in the 10 μM GLM with 25 μM DZ cotreatment groups were significantly decreased (0.61-fold, $p = 0.0437$) compared to the group treated with 10 μM GLM alone. Similarly, after cotreatment with 25 μM DZ, the PI sizes in the 100 μg/mL CE-treated, 10 μg/mL TRG-treated, and 10 μg/mL CGA-treated groups were significantly decreased (0.40-fold, $p = 0.0493$; 0.38-fold, $p = 0.0376$; and 0.33-fold, $p = 0.0228$, respectively; Figure 9).

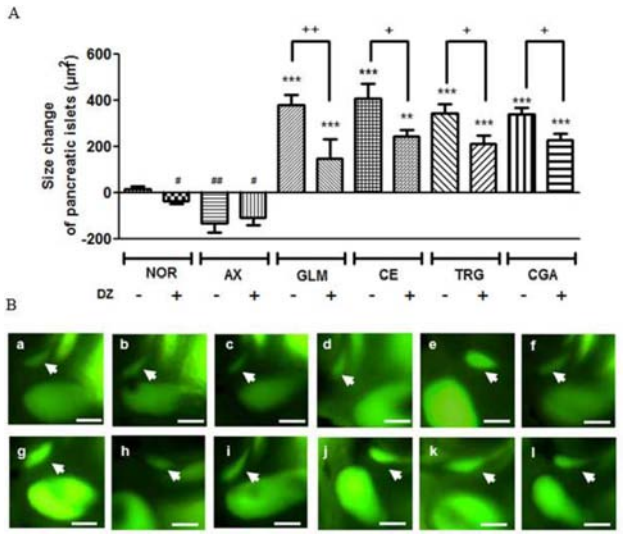

Figure 9. Effects of 10 μM glimepiride (GLM), 100 μg/mL coffee extract (CE), 10 μg/mL trigonelline (TRG), or 10 μg/mL chlorogenic acid (CGA) with 25 μM diazoxide (DZ) on alloxan-induced PI-damaged zebrafish larvae (AIPD ZFL). (A) Changes in PI size caused by 10 μM GLM, 100 μg/mL CE, 10 μg/mL TRG, and 10 μg/mL CGA with 25 μM DZ. (**) $p < 0.01$ and (***) $p < 0.001$, compared to alloxan, AX; (#) $p < 0.05$ and (##) $p < 0.01$, compared to normal; (+) $p < 0.05$ and (+2) $p < 0.01$. (a) Fluorescent macroscopic image of PI in (a) the normal group, (b) normal + 25 μM DZ group, (c) 100 μM AX group, (d) 100 μM AX + 25 μM DZ group, (e) 10 μM GLM group, (f) 10 μM GLM + 25 μM DZ group, (g) 100 μg/mL CE group, (h) 100 μg/mL CE group + 25 μM DZ group, (i) 10 μM TRG group, (j) 10 μM TRG + 25 μM DZ group, (k) 10 μM CGA group, and (l) 10 μM CGA + 25 μM DZ group. Scale bar = 100 μm.

DISCUSSION

Although immune-mediated processes are the main cause of type 1 diabetes, we used an AX-induced experimental diabetes model in this study. AX is a cytotoxic agent that acts as a diabetogenic chemical to induce experimental diabetes. Indeed, AX treatment has been widely utilized as an animal model of type 1 (insulin-dependent) diabetes mellitus.[9,13,39] AX-induced experimental diabetes decreases β-cells present in PIs, damages extra-pancreatic tissues, and consequently induces insulin deficiency.[9,40] Consistent with this model, type 1 diabetes is associated with a significant reduction of pancreas size in children.[6] In addition, type 1 diabetes mellitus adult patients have decreased pancreatic volume according to helical computed tomography (CT).[41] Consistent with these findings, we observed PI morphological changes following AX-induced diabetes mellitus in zebrafish model.

The ability to observe cells absorb glucose is a mainstay of diabetes studies. In this study, we used 2-NBDG, which is a fluorescent molecule derived from glucose that contains a 2-(*N*-(7-nitrobenz-2-oxa-1,3-diazol-4-yl)amino group at the C-2 position[22] and allows for experimental visualization of PIs. This approach was successfully employed by Lee et al.,[23] who introduced a new assay for discovering antidiabetic drugs by determining 2-NBDG uptake in the eyes of ZFL, thereby allowing for simple, economical, and rapid screening. Distinct staining of the pancreas and PI of zebrafish, unlike in humans, was reported by Wallace and Pack.[28] Mature α-, β-, and δ-cells and PP cells are located within fish PIs,[33,34] and in this study, due to the presence of insulin in PI β-cells,[32] we focused on PI observation using 2-NBDG. On the basis of preliminary experiments, we determined that the optimal treatment time and dose of 2-NBDG for PI observation were 12 h and 25 μM, respectively.

As described above, we used AX to induce PI damage in this study and first determined the optimal treatment time and dose for AX. As expected, AX significantly decreased PI size in the treated group compared to the normal group. To demonstrate the beneficial effects of diabetes therapy in AIPD ZFL, we used GLM as a positive control, as it promotes insulin secretion by closing K^+_{ATP} channels.[24,25] In the GLM-treated group, both PI size and fluorescence intensity were significantly increased compared to the AX-treated group.

We next determined the regenerative effects of CE on damaged PIs. Our results showed that CE significantly increased the size and fluorescence signal of PIs in AIPD ZFL. In addition, pancreatic β-cells damaged by AX showed improvement after treatment with CE. 2-NBDG-stained PIs and β-cells expressing GFP in zebrafish showed a similar pattern: PI staining with 2-NBDG was decreased in AX-induced damage and increased in response to CE.

To investigate the efficacy of the components of coffee together or in combination, we treated PIs with CFI, TRG, and CGA. We focused on CFI, TRG, and CGA as they are well-known major compounds in coffee and because they have been reported to have beneficial effects for diabetes.[29] First, the concentrations of CFI, TRG, and CGA in CE were determined using HPLC followed by efficacy testing in PIs. The amounts of TRG (1.2 μg/mL) and CGA (3.4 μg/mL) in CE (100 μg/mL) were lower than those used in individual TRG or CGA treatments, but the efficiency of 100 μg/mL of CE was superior to that of 10 μg/mL of TRG or CGA. Specifically, our data indicated a positive efficacy and synergistic effect of TRG and CGA in PIs, which was consistent with both previous studies and our observation that TRG and CGA have significant regenerative effects when tested individually. When we investigated the synergistic effect of TRG/CGA in CE using CI values and an isobologram, we found that the combination of TRG/CGA at three different concentrations resulted in CI values of 0.47, 0.51 and 0.68, where a CI value <1 indicates a synergistic effect. Taken together, our findings were consistent with the report by Zhou et al.,[30] who showed that organic degeneration of pancreatic β-cells in diabetes is normalized by TRG, which also preserves β-cell mass, and is associated with recovery of PI damage. CGA has also been reported to stimulate glucose transport, thereby enabling greater glucose absorption.[31]

The metabolism of glucose in pancreatic β-cells is the key step in glucose-stimulated insulin secretion.[42] Therefore, we also used 2-NBDG to observe glucose uptake in PIs and investigated the mechanism of insulin secretion by modulating K_{ATP} channels. Closure of K_{ATP} channels leads to membrane depolarization, opening of voltage-gated Ca^{2+} channels, and Ca^{2+} influx and rise and then induces insulin secretion.[43] To confirm the effects of CE and its active components on K_{ATP} channels, we performed cotreatments with DZ after inducing hyperglycemia.[26,27] DZ opens K_{ATP} channels in pancreatic β-cells, which has been shown to inhibit the secretion of insulin in AX-induced diabetic mice.[44] Furthermore, Kappel et al.[38] reported that DZ significantly decreases Ca^{2+} uptake in isolated rat pancreatic islets. Our results showed that cotreatment with DZ decreased the beneficial effects of CE and reduced the increase in PI size in response to TRG and CGA treatment. These results suggested that CE might stimulate insulin secretion by Ca^{2+} influx via closure of K_{ATP} channels in β-cells.

This study had several limitations. First, we did not measure blood glucose levels as a main marker of diabetes, nor did we investigate the relationship between increased or decreased PI and blood glucose levels. Thus, additional studies that include blood glucose level measurements will be required. In addition, although we investigated the effect of CE on K_{ATP} channels and pancreatic β-cells, specific evaluation of the effects of CE on insulin secretion will require further investigation.

In conclusion, we showed that CE significantly increases the size of PIs in AIPD ZFL. Furthermore, we determined that recovery of damaged pancreatic β-cells and restoration of insulin secretion are possible using CE, TRG, and CGA to block K_{ATP} channels in ZFL. Combined TRG/CGA treatment exhibited synergistic effects compared to treatment with TRG or CGA alone. Taken together, the results of our study demonstrate that coffee confers a regenerative effect on PIs injured by diabetes, which can increase insulin secretion by blocking K_{ATP} channels. Lastly, the synergistic effects of TRG and CGA may be primarily responsible for the beneficial effects of coffee.

to D-mannose, rather than sucrose or fructose.[10] Previously, pectic oligosaccharides were reported to inhibit the adhesion of enterohemorrhagic and enteropathogenic strains of *E. coli* to HT29 cells.[11] This establishes a precedent for plant cell wall oligosaccharides that have anti-adhesive properties for *E. coli* binding to epithelial cell receptors. The cranberry plant cell wall structure consists of parenchyma cellulose, hemicellulose, and pectin rich in arabinan.[12]

Xyloglucan is a well-known hemicellulose that cross-links type 1 plant cell walls found in dicotyledonous and non-commelinoid monocotyledonous plants.[13] Xyloglucan, which has a β-(1−4)-glucan backbone, is able to hydrogen bond to the surface of cellulose microfibrils, forming a network that connects adjacent microfibrils in cell walls. The xyloglucan network is intermeshed with the pectin network of cell wall matrix polysaccharides.[14] This makes xyloglucan an important polysaccharide in the growth and development of primary cell walls.[14] There is a block-like structure in xyloglucan in which a 6-11 sugar sequence is repeated throughout the polysaccharide. Carbohydrate characterization of xyloglucan oligosaccharide fragments has been used to describe polysaccharide structures specific for plant taxonomic groups.[15−18] Three types of xyloglucan structure have been described, with fucogalacto-xyloglucan the most commonly distributed in about half of the monocot taxonomic orders and all dicot orders except for the Solanales, Laminales, Gentianales, and Ericales.[14,18] Xyloglucan from these later orders contains arabino-xyloglucan structure. Small amounts of a third xyloglucan structure are also present in commelinoid monocots (grasses, bromeliads, palms, and cypresses) as randomly distributed single-xylose substituents on a cellulosic backbone.[14] A single-letter nomenclature was developed to describe xyloglucan substituent sequences.[19] We investigated cranberry xyloglucan structure and detected arabino-xyloglucan (SSGG) oligosaccharide fractions with anti-*E. coli* adhesion activity for epithelial cell receptors.

MATERIALS AND METHODS

Materials. The following were obtained from Sigma-Aldrich (St. Louis, MO, USA): phosphate-buffered saline tablets (PBS; pH 7.4 ± 0.2, 0.1 mol/L), nonessential amino acid solution, trypsin−EDTA solution, Dulbecco's modified Eagle medium with GlutaMAX-1 (DMEM), tryptic soy agar, and 2,5-dihydroxybenzoic acid. Fetal bovine serum was obtained from the American Type Culture Collection (ATCC, Manassas, VA, USA). PBS was filter sterilized with a 0.2 μm syringe filter prior to use.

Xyloglucan-oligosaccharides with a degree of polymerization (DP) of 7−9 were purchased from Megazyme (Bray, Ireland). Commercial juices were purchased from a local grocery store.

Oligosaccharide Isolation. A cranberry (*Vaccinium macrocarpon*, mainly Stevens variety harvested in Massachusetts during 2009) hull enzyme-treated concentrate fraction (A1) was produced using Klerzyme 150 pectinase (DSM Food Specialties, South Bend, IN, USA) during cranberry depectinization. Fractionation of A1 was accomplished by utilizing a FLASH-40 system (Biotage, Charlotte, NC, USA), converted to accept Biotage SNAP KP-C18-HS 120 g cartridges. A1 (20 g) was dissolved in 200 mL of deionized (DI) water, and 50 mL of the solution was loaded onto the preconditioned (300 mL of methanol, 300 mL of DI water) C18 column cartridge. The C18 column cartridge was eluted first with 500 mL of DI water, followed by 500 mL of a 15% methanol/water mixture (35 mL/min flow rate). The remaining phenolic content was washed from the column with 500 mL of methanol. The column was reconditioned before loading it again with the next 50 mL of A1 solution. After the C18 separation, the 15% methanol/water fractions were combined and dried to produce the A2 fraction (4.97 g of a pink colored powder). An unknown peak was observed in A2 chromatograms at approximately 6.7 min during high-pressure liquid chromatography (HPLC) analysis of fraction A2 using an 1100 series (Agilent Technologies, Santa Clara, CA, USA) system equipped with a refractive index detector and HPX-87C HPLC column (Bio-Rad Laboratories, Inc., Hercules, CA, USA). Fraction A2 was further purified by Sephadex LH20 (Sigma-Aldrich) chromatography to eliminate phenolic pigments. Fraction A2 (4.8 g) was dissolved in 60 mL of DI water, and the mixture was loaded on a 300 × 45 mm Sephadex LH20 column (preconditioned with 500 mL of DI water). The column was eluted with 500 mL of DI water using a Masterflex L/S pump (Cole-Parmer, Vernon Hill, IL, USA) at a flow rate of 2.5 mL/min, followed by lyophilization to produce 4.32 g of a slightly pink, off-white powder A6 fraction.

Carbohydrate Analysis. The neutral sugar content (NS), uronic acid content (UA), degree of methyl esterification (DE), and degree of acetylation (DA) were determined as reported previously[20] except that the NS (glucose standard) was used as the basis for DE and DA instead of the UA. Monosaccharide analysis by high-performance anion-exchange chromatography with pulsed amperometric detection (HPAEC-PAD) following methanolysis was performed according to the procedure reported previously.[21] Unhydrolyzed oligosaccharides were also separated by HPAEC-PAD according to the procedure reported previously.[11]

High-Performance Size Exclusion Chromatography. Cranberry samples (10−20 mg/mL) were dissolved in 0.05 M $NaNO_3$ and 0.01% NaN_3 mobile phase by stirring at room temperature, centrifuged at 50000*g* for 10 min, and filtered through a 0.22 or 0.45 μm Millex HV filter (Millipore Corp., Bedford, MA, USA). The model 1200 series solvent delivery system included a degasser, pump, and autosampler (Agilent Corp.) with flow rate set at 0.7 mL/min. The injection volume was 200 μL. Samples were run in triplicate. The column set consisted of three 300 mm × 7.8 mm i.d., 13 μm, TSK $GMPW_{XL}$ size exclusion columns in series and two 40 mm × 6.0 mm i.d., 12 μm, guard columns of the same material (Tosoh Bioscience, Tokyo, Japan) with one guard column placed before the separatory columns and the other prior to the detectors. The column temperature was controlled in a water bath set at 35 °C. Column effluent was detected with a HELEOS II multiangle laser light scattering photometer (Wyatt Technology, Santa Barbara, CA, USA) in series with a model Viscostar II differential pressure viscometer (Wyatt Technology) and an differential refractive index interferometer (Wyatt Technology). Electronic outputs from these three detectors were processed with ASTRA software version 6.1.1.17 (Wyatt Technology).

Mass Spectrometry. Matrix-assisted laser desorption ionization mass spectrometry with tandem time-of-flight mass spectrometry (MALDI-TOF/TOF MS/MS) utilized a 4700 Proteomics Analyzer mass spectrometer (Applied Biosystems, Framingham, MA, USA) in the positive reflectron mode. Spectra were obtained by averaging 1000 and 2500 acquired spectra in the MS and MS/MS modes, respectively. Collision-induced dissociation (CID) with air at approximately 1×10^{-6} Torr and 1 keV acceleration voltage was used for obtaining the MS/MS spectra for selected oligosaccharides. Conversion of TOF to mass (Da) for the monoisotopic ions, $[M + Na]^+$, was based on calibration of the instrument with a peptide standard calibration kit (Applied Biosystems). Oligosaccharide samples (3−5 mg) were dissolved in 1 mL of water and cleaned with CarboPrep 90 graphitized carbon cartridges, 3 mL, 250 mg (Restek, Bellefonte, PA, USA). The cartridges were first conditioned by passing 3 mL of acetonitrile/water (50:50) and then washed four times with 3 mL of water. After conditioning, the oligosaccharide solution was passed through the graphitized carbon cartridge and washed three times with 3 mL of water, and the water wash was discarded. The oligosaccharides were eluted with 1 mL of acetonitrile/water (30:70, v/v) containing 0.1% TFA. From this solution, 2 μL was mixed with 10 μL of a solution of 2,5-dihydroxybenzoic acid (10 mg/mL in acetonitrile/water (50:50), 0.1% TFA), and spotted onto a MALDI plate for analysis.

Nuclear Magnetic Resonance Spectroscopy. Cranberry fraction A6 was dissolved in ^2H_2O (99.6% ^2H, Cambridge Isotope Laboratories, Tewksbury, MA, USA), lyophilized and redissolved in 0.6 mL of 99.96% enriched ^2H_2O, and transferred to a 5 mm NMR tube. Spectra were recorded at 40 °C on either a Bruker Avance-II 700

DOI: 10.1021/acs.jafc.5b00730
J. Agric. Food Chem. 2015, 63, 5622−5633

MHz spectrometer (Billerica, MA, USA) using a 5 mm *xyz*-PFG QXI HCNP probe or a Varian INOVA 500 MHz spectrometer (Santa Clara, CA, USA) equipped with a *z*-PFG PentaProbe. Data processing was performed using NMR-Pipe[22] and analyzed using SPARKY.[23] All spectra were referenced to the internal ^{1}H and ^{13}C resonances of either 4,4-dimethyl-4-silapentane-1-sulfonic acid (DSS) or 3-(trimethylsilyl)-2,2′,3,3′-tetradeuteropropionic acid (TMSP-d_4). One-dimensional ^{1}H NMR spectra were acquired at 700 MHz using a spectral width of 5000 Hz, 32768 points, a 70° pulse width, and a recycle time of 2.5 s. One-dimensional ^{13}C NMR spectra were acquired at 176 MHz using 65536 data points, a 70° pulse width, and a recycle delay of 2.5 s. Gradient enhanced versions of the following experiments were run: three 2D TOCSY (10, 120, and 300 ms using the DIPSI-2 sequence[24] for a spin-lock), 2D ROESY (200 ms mixing time), two $^{1}H-^{13}C$-HSQC, long-range $^{1}H-^{13}C$ HSQC, J_{H-C}-coupled HSQC, $^{1}H-^{13}C$ HMBC ($J_{nC\text{-}H}$ = 6 Hz), and two HMQC TOCSY (50 and 300 ms spin-lock). The 2D homonuclear experiments were recorded with spectral widths of 5K−7K Hz in both dimensions, using 8192−16384 points in the directly detected dimension, 512 increments in the second dimension, 32 or 64 transients per acquisition depending on signal intensity, and a 2.5 s delay between scans. The heteronuclear experiments were acquired with a range of parameter values depending on the specific experiment, the instrument, and the digital resolution needed. These parameter values were 2097 or 7000 Hz spectral width in the ^{1}H dimension and 10K or 19K Hz in the ^{13}C dimension (or in the HMBC 25K Hz), using 1024−8192 points in the directly detected dimension, 512 increments in the second dimension, 32 or 64 transients per acquisition depending on signal intensity, and a 2.5 s delay between scans. These experiments were run on several batches of the sample and enabled the assignment of resonances and measurement of coupling constants to determine the sugar residue identities, their anomeric configuration, and connectivity as well as the local structure.

Anti-adhesive Activity. A bacterial adhesion assay was carried out with human bladder epithelial cells T24 (ATCC HTB-4 UEC) and *E. coli* CFT073 (ATCC 700928) and UTI89 strains.[25,26] Cranberry extracts A1 and A6 were diluted in PBS to concentrations of 0−5 mg/mL. A cranberry-enriched proanthocyanidin (PAC) fraction (55% total PAC analyzed by 4-dimethylaminocinnamaldehyde colorimetric method with purified cranberry PACs as a reference standard)[27] was used as positive control in the CFT073 assay and was diluted in PBS to concentrations of 0−0.5 mg/mL (pH 7). α-D-Mannose was used as positive control in the UTI89 assay and was diluted in PBS to concentrations of 0−2 mg/mL. PBS was used as a negative control. Briefly, fluorescent-labeled uropathogenic *E. coli* strains CFT073 and UTI89 were subcultured using colonizing factor agar (CFA) and Luria−Bertani (LB) broth, respectively. CFA was used to promote p-fimbriae growth in CFT073, whereas UTI89 only expresses type 1 fimbriae. Bacteria were pre-incubated with A1 and A6 fractions and control samples for 30 min at 35 °C before being added to T24 cells in 96-well plates at an *E. coli*/T24 ratio of 400:1. *E. coli* and T24 co-cultures were incubated in a 5% CO_2 humidified atmosphere for 1 h at 37 °C. Following the incubation, bacteria not adhering to the T24 cells were removed by washing with PBS. The fluorescence intensity (FI) was measured in a microplate reader at 480 nm excitation/516 nm emission (Synergy H1 Hybrid, Biotek Instruments, Winooski, VT, USA). All samples were tested in triplicate.

The effect of A6 on bacterial adhesion was also determined with *E. coli* O157:H7 (ATCC BAA-1883) and human colonic epithelial cells HT29 (ATCC HTB-38) using a standard assay reported earlier.[11] Working cultures of *E. coli* were prepared by inoculating slopes of agar in universal bottles and incubating the agar for 18−24 h at 37 °C. *E. coli* broth cultures for adhesion assays were grown in DMEM supplemented with 5% (v/v) fetal bovine serum and 1% (v/v) nonessential amino acid solution (SDMEM). The broth was inoculated from a slope culture and incubated anaerobically at 37 °C for 18−24 h. The overnight culture was then inoculated 1% (v/v) into fresh SDMEM and incubated for a further 18−24 h under the same conditions. This was repeated. On the day of the assay, a 10% (v/v) inoculum was again inoculated into prewarmed SDMEM and incubated for 4 h aerobically at 37 °C.

HT29 human intestinal epithelial cells were grown in 25 cm^2 tissue culture flasks in SDMEM at 37 °C in 5% CO_2 until approximately 90% confluent, split according to the method recommended by the European Collection of Cell Cultures, and stored in aliquots over liquid nitrogen. These aliquots were used to seed 25 cm^2 flasks, which after growth were split into 12-well tissue culture plates. The 12-well plates were grown to approximately 95% confluence before being used for the adhesion assays.

A culture of the *E. coli* strain was prepared as described above and then diluted 1:500 in PBS. The viable count of the diluted suspension was determined by spread plating onto plate count agar, with decimal dilution being carried out in PBS buffer as appropriate. A6 was dissolved in PBS (5 mg/mL) and sterilized by passing through a 0.2 μm syringe filter. The carbohydrate solution was further diluted in sterile PBS as required. The SDMEM was aspirated into a 12-well tissue culture plate with near-confluent monolayers of HT29 cells, prepared as described above. The monolayers were washed by pipetting in 1 mL of sterile PBS per well, swirling by hand, and then aspirating. A 0.5 mL aliquot of the A6 solution was added to the well, followed by 0.5 mL of bacterial suspension in PBS. Control wells contained unsupplemented PBS substituted for the A6 solution. All assays were performed in triplicates. The plates were swirled by hand to mix and then incubated at 37 °C aerobically for 2 h.

After incubation, the bacterial suspension was aspirated from the wells. A 1 mL aliquot of PBS was added to each well, the plate swirled briefly by hand, and the PBS removed. The washing step was repeated two more times. A 70 μL aliquot of trypsin−EDTA solution was added to each well, the plate was rocked to ensure even coverage, and then it was incubated at 37 °C for 5 min. A 1 mL aliquot of PBS was then pipetted into each well and pipet-mixed until the monolayer was completely dislodged and clumps were dissolved (as determined visually). Bacteria in cell suspension were then enumerated by plate counting on plate count agar plates with decimal dilutions performed in PBS as required. All plates were incubated at 37 °C for 18−24 h before colonies were enumerated. Viable counts were calculated for all wells and the inoculum and are expressed as colony-forming units (CFU) per milliliter. For each test the mean and the standard error of the triplicate wells were calculated. Statistical significance was determined by one-way analysis of variance, using ANOVA software.

RESULTS AND DISCUSSION

Carbohydrate Analysis. The A1 fraction produced by commercial pectinase treatment of cranberry hulls contained pectin fragments and significant amounts of neutral sugar-rich material (Table 1). The A2 fraction was neutral sugar-rich and had relatively low amounts of uronic acid, indicating little pectin was present. The most purified of the cranberry fractions (A6) consisted of a neutral sugar-rich polysaccharide with a weight-average molar mass of 2750 Da compared to 3410 Da for A2 and 5510 Da for A1. The *z*-average hydrodynamic radius and weight-average intrinsic viscosity were consistent with low-molecular-weight and low-viscosity polysaccharides. Fraction A6 had no absorption at 230 and 280 nm, indicating the lack of aromatic structures present in proanthocyanidins (PACs).

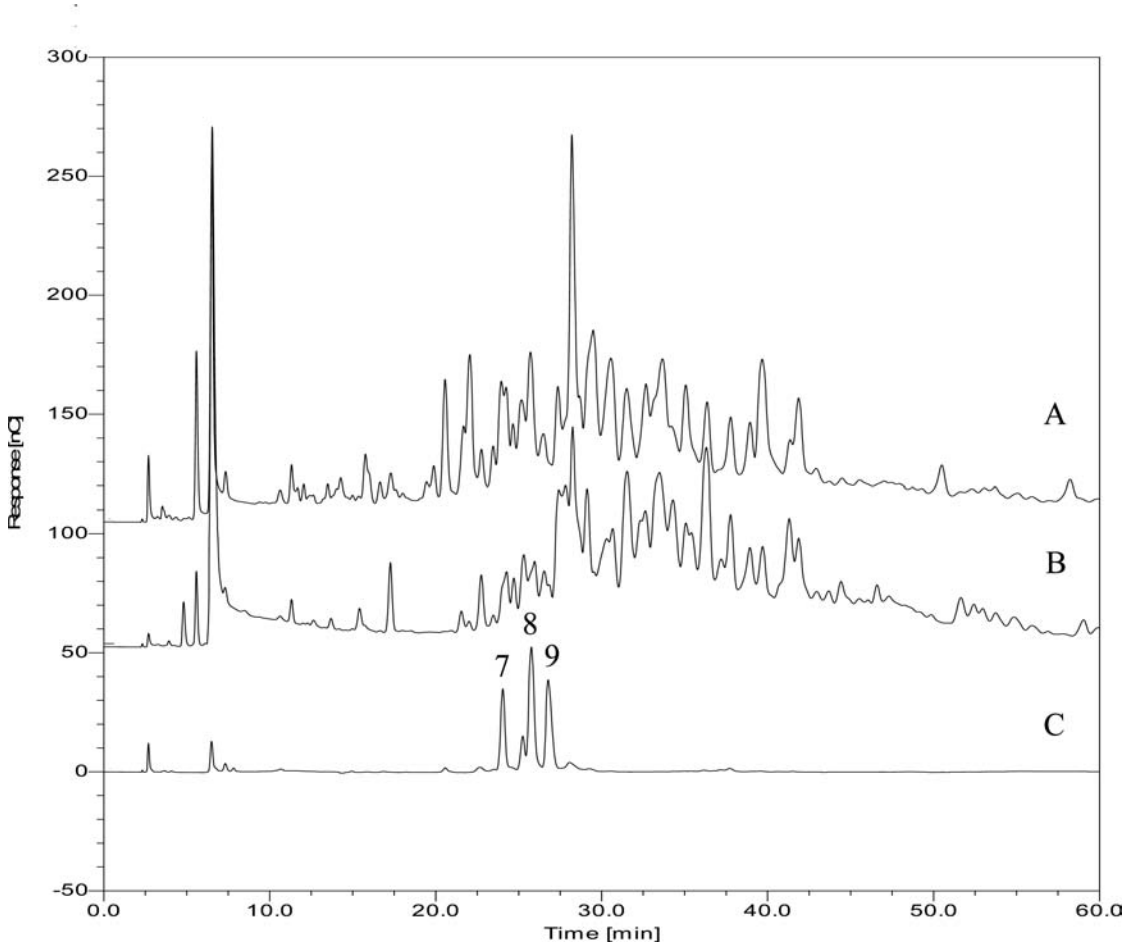

Figure 1. HPAEC-PAD oligosaccharide analysis of cranberry fractions A6 (A) and A2 (B) compared with xyloglucan oligosaccharide standards (C, degree of polymerization indicated above each peak).

The monosaccharide compositions of the A2 and A6 cranberry fractions were dominated by glucose, arabinose, and xylose with very little galacturonic acid and rhamnose present (Table 2). This indicated that the A2 and A6 polysaccharide fragments were possibly a xyloglucan. The A1 fraction contained a significant amount of galacturonic acid, but the low levels of rhamnose detected indicated that little rhamnogalacturonan was present. Therefore, A1 contained homogalacturonan-rich pectin and other polysaccharides released from the pectinase treatment of cranberry hulls.

Series of oligosaccharide peaks were present in A2 and A6 cranberry fraction HPAEC-PAD chromatograms that were consistent with the retention times of xyloglucan standard oligosaccharides (Figure 1). However, the structure of the Megazyme standard xyloglucan oligosaccharides was galacto-xyloglucan. For example, the DP 7 xyloglucan oligosaccharide consisted of a cellotetraose backbone and three single xylose substituents attached to three of the glucose residues. The DP 8 and DP 9 xyloglucan standards had one or two of the xylose residues substituted with a galactose residue, respectively. This xyloglucan structure is typical of fucogalacto-xyloglucan without fucose. However, relatively low amounts of galactose were detected in the A2 and A6 monosaccharide composition, which indicated that the cranberry xyloglucan structure might differ from fucogalacto-xyloglucan.

Mass Spectrometry. MALDI-TOF mass spectrometry of the A6 fraction produced a series of $[M + Na]^+$ ions (Figure 2) that were consistent with xyloglucan structure (Table 3). No $[M + Na]^+$ ions were observed corresponding to PACs.[9] The ions at m/z 1085, 1217, 1379, and 1525 were reported for argan tree (Sapotaceae) xyloglucan with Hex_4Pent_3, Hex_4Pent_4, Hex_5Pent_4, and Hex_5Pent_4dHex compositions, respectively, and described as fucogalacto-xyloglucan structure.[17] Ions at m/z 791 and 923 were previously reported in tobacco suspension culture xyloglucan with SGG and/or XXG and SXG and/or XSG structure, respectively.[15] The very abundant m/z 1217 ion in cranberry A6 (Figure 2) was previously reported to have XXSG structure in oleander and olive fruit xyloglucan.[16,18]

[a]Hex, hexose; Pent, pentose; dHex, deoxyhexose (rhamnose or fucose); Ac, *O*-acetyl; G, β-D-glucose; X, β-D-glucose with a terminal α-D-xylose substituent at the O-6 position; S, β-D-glucose with α-L-Ara*f*-(1−2)-α-D-Xyl*p* at the O-6 position; L, β-D-glucose with β-D-Gal*p*-(1−2)-α-D-Xyl*p* at the O-6 position; F, β-D-glucose with α-L-Fuc*p*-(1−2)-β-D-Gal*p*-(1−2)-α-D-Xyl*p* at the O-6 position; U, β-D-glucose with β-D-Xyl*p*-(1−2)-Xyl*p* with the O-6 position.

However, the diagnostic XXSG MS/MS fragments[16] were not present in the cranberry MALDI-TOF/TOF MS/MS spectrum for the *m*/*z* 1217.37 ion shown in Figure 3B. Therefore, the SSGG xyloglucan structure appeared to be the predominant cranberry xyloglucan structure as was reported for *m*/*z* 1217 in tobacco.[15] Ions at *m*/*z* 1127, 1259, 1289, 1331, and 1421 ions were previously reported as acetylated xyloglucan oligosaccharides in tobacco.[15] The *m*/*z* 1289 and 1331 ions were assigned previously as XLXG and/or XXLG and UXGGG and/or XUGGG structure, respectively.[15] However, in cranberry xyloglucan, these ions are more likely to represent an alternative structure due to the relatively low amount of galactose present in the monosaccharide composition. Therefore, XSGGG-Ac and XSGGG-Ac_2 cranberry xyloglucan structures appear to be more appropriate. The $Hex_4Pent_ndHexHexA_2Me_3$ xyloglucan composition series has never been reported before, but these structures are similar to the *m*/*z* 1525 XUFG structure reported for the argan tree (Ericales) xyloglucan and the xylan oligosaccharides containing two 4-*O*-methylglucuronic acids from the same source.[17] Another very abundant cranberry ion, *m*/*z* 1055, also has never been reported previously for a xyloglucan structure and was used for further MS/MS structural elucidation. The cranberry *m*/*z* 1055 and 1217 ions also were detected as their potassiated forms ($[M + K]^+$) at *m*/*z* 1071 and 1233, respectively. The most abundant cranberry MALDI-TOF MS ions were *m*/*z* 1055, 1085, and 1217 depending on batch-to-batch variation in A6.

The MS/MS spectra of oligosaccharides by MALDI-TOF/TOF produced a set of ions that provides the essential information for carbohydrate structural characterization.[28] The MS/MS spectrum represents two types of ions corresponding to cross-ring fragmentation between two bonds on the same

DOI: 10.1021/acs.jafc.5b00730
J. Agric. Food Chem. 2015, 63, 5622−5633

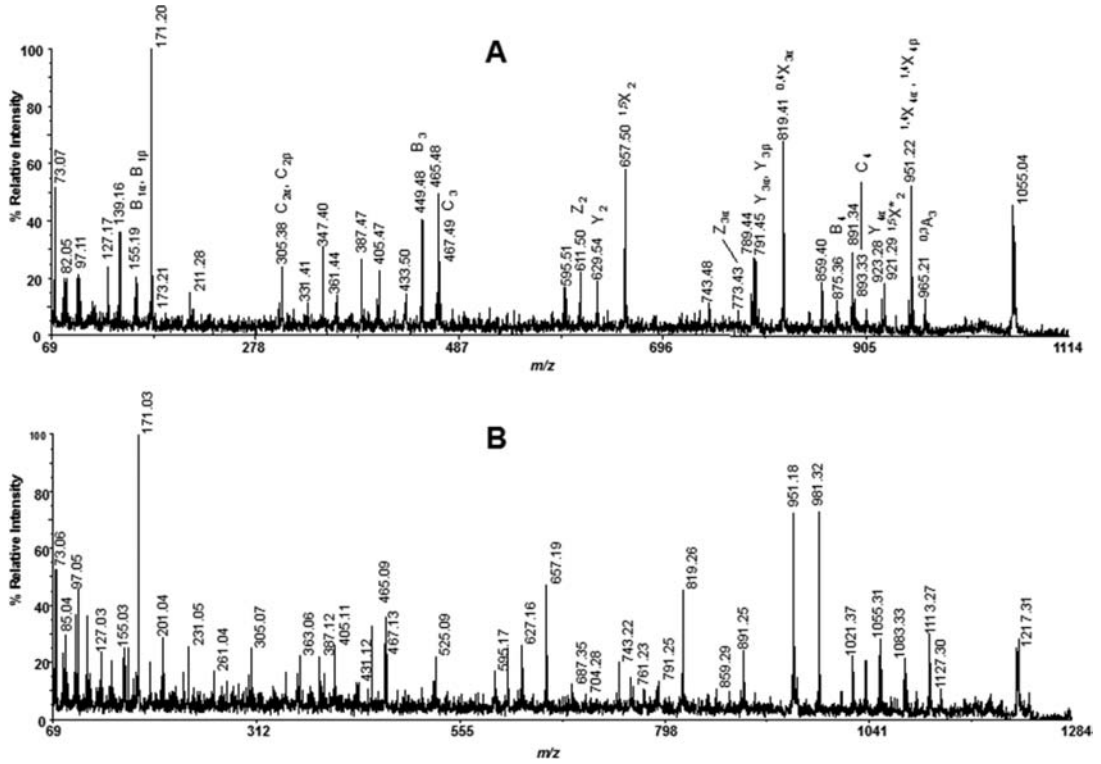

Figure 3. MALDI-TOF/TOF MS/MS of (A) m/z 1055.32 and (B) m/z 1217.37.

sugar residue and glycosidic bond cleavage between two sugar residues. When the charge of the resulting fragment is located toward the reducing end of the oligosaccharide, then the ions are designated as X ions for cross-ring fragmentation and as Y and Z ions for the glycosidic bond fragments. If the charge is located at the nonreducing end, then the ions are designated as A for cross-ring fragmentation and B and C for the glycosidic bond fragments. The fragmented bond site is indicated with the corresponding letter, a subscript number, and a Greek letter to designate the branched chain involved. Superscript numbers preceding the ions X or A indicate the cleaved bonds in the sugar ring.

The MS/MS spectrum in Figure 3A corresponds to the sodiated oligosaccharide, $[M + Na]^+$, with m/z 1055.32 (Figure 2). This precursor ion is consistent with an oligosaccharide structure formed by four pentoses and three hexoses. The ion at m/z 305.3 in the MS/MS spectrum (Figure 3A) suggests that two pentoses are present as a side chain, labeled as fragments $C_{2\alpha}$ and $C_{2\beta}$ in structure 1 (Figure 4). No ion corresponding to a side antenna with one, three, or four pentoses is observed in the spectrum. The ion at m/z 893 indicates the loss of a hexose from the precursor ion (1055−162) (cleavage C_4) (Figure 4). This suggests that one of the hexoses is not linked to a side chain. The spectrum is not dominated by Y or B ions but with ions that are consistent with cross-ring fragmentation as indicated in structure 1. As the spectrum shows, the cross-ring cleavage (loss 104 Da) at the pentose-end produces the ion at 951 ($^{1,4}X_{4\alpha}$ or $^{1,4}X_{3\beta}$ fragment) that further loses a pentose to generate the ion at 819 and a hexose to generate the ion at m/z 657. However, these two ions can also correspond to the $^{1,5}X_{3\alpha}$ and $^{1,2}X_2$ fragments, respectively. Some of the ions are generated from subsequent fragmentation of the 951 fragment, such as the ion at m/z 891 (951 − 60). The significant ion at m/z 465 could also be explained by subsequent cleavages of the ion at 951 after losing one hexose, two pentoses, and a cross-ring fragment (951 − 162 − 132 − 132 − 60 = 465). Therefore, several ions in Figure 3A could be produced by multiple fragmentation patterns. Further analysis of the fragmentation pattern suggests that the isobaric structure 2 (Figure 4) is also present. The evidence supporting structure 2 is found in the ion at m/z 921, which corresponds to the cross-ring cleavage $^{1,5}X^*_2$ of the hexose at the nonreducing terminus. Therefore, both SSG and GSS structures were present and assigned (Table 3). The spectrum in Figure 3B is consistent with the structures in Figure 4 but with an extra hexose. The cross-ring cleavage of the end terminus pentose produces the ion at m/z 1113 (1217 − 104), but also the loss of a hexose from the precursor ion, generates the ion at m/z 1055, and that fragment is consistent with the spectrum and structures in Figure 3A.

Nuclear Magnetic Resonance Spectroscopy. NMR analysis of the anomeric region in the 1D-^{1}H spectrum (Figure 5) reveals that the resonances near 4.5 ppm have H1−H2 coupling constants of $J_{H1-H2} \sim 7-9$ Hz, indicating that the H1 and H2 are in axial−axial orientation. Therefore, they were assigned as β-D-Glc and β-D-Gal. The resonances at 4.94, 5.24, 5.21, 5.15, 5.31, and 5.28 ppm have $J_{H1-H2} \sim 3.8-4.7$ Hz and denote that H1 and H2 have an axial−equatorial orientation. Likewise, the peak at 5.08 ppm has a shoulder that is also 3.5 Hz from the main peak. These chemical shifts and coupling constants are characteristic of pyranoses, such as rhamnose, fucose, and xylose. Several peaks in the region of ∼5.1−5.2 ppm have very small or indiscernible coupling in the 1D-^{1}H spectra. These attributes support an assignment of α-L-Ara$f$, and there is no evidence for β-L-Ara$f$ in the sample. Furanoses such as these undergo rapid repuckering of their rings, resulting in an averaging of the coupling constants. The absence of aromatic resonances in the 1D-^{1}H NMR spectra supported the absence

of PACs and other phenolic compounds in cranberry fraction A6.

Analysis of the 2D HSQC (Figure 6) confirms β-Glc, α-Xyl*p*, and α-Ara*f* are present, as well as other residues expected from

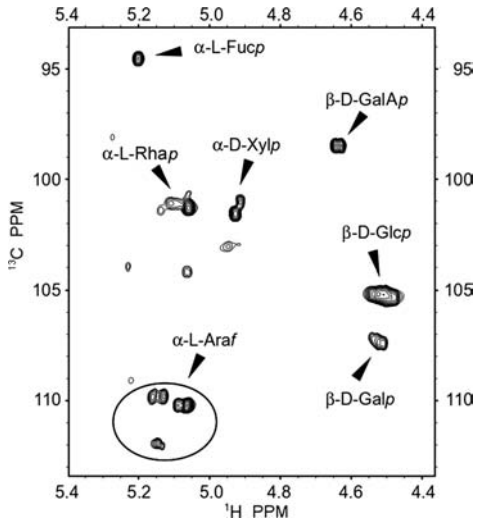

Figure 6. NMR HSQC of anomeric region showing primary assignments.

the monosaccharide composition and 1D-^{1}H spectrum. The HSQC reveals that the proton resonances at 4.48−4.57 ppm are separated into two main clusters on the basis of their ^{13}C resonances. One is centered at a ^{13}C frequency of ∼105 ppm and corresponds to β-D-Glc*p*, whereas the other cluster is at ∼107 ppm and corresponds to β-D-Gal*p*. Such β-D-Glc*p* resonances are commonly found in S and G structures in SG or GS environments.[29] Whereas the β-D-Gal*p* resonance can be found in xyloglucan F and L structures,[29] it is also present in rhamnogalacturonan pectin, and this monosaccharide is less abundant in the cranberry fractions. Therefore, it is unclear what structure includes the galactose in cranberry A6.

The HMBC and long-range HSQC experiments provide evidence for α-D-Xyl*p* -C1 → β-D-Glc*p*-H6 correlations, confirming xyloglucan structure. In addition, there are two sets of through-bond α-L-Ara*f*-C1→ α-D-Xyl*p*-H2 correlations, which are consistent with S-type structures (Figure 7). One of these xylose residues also has an HMBC correlation to a glucose H6 and thus proves an entire S-type structure of α-L-Ara*f* (1→2) α-D-Xyl*p* (1→6) β-D-Glc*p*. The fact that there are two sets of α-L-Ara*f* (1→2) α-D-Xyl*p* correlations suggests that the S structures are in slightly different environments, as would be expected from GSS and SSG sequences. Although additional arabinose and xylose residues were observed in the NMR spectra, their sequential connectivity could not be determined due to spectral congestion and overlapping resonances.

There is also evidence of acetylation of some of the sugars in the fraction. Analysis of the HSQC, HMBC, long-range HSQC, and HMQC-TOCSY experiments revealed the presence of methyl groups (∼2.2 ppm in ^{1}H and ∼20 ppm in ^{13}C) that have HMBC correlations to carbonyl carbons (∼175 ppm), and these in turn have correlations for the H2 resonances (∼4.3 ppm) of several α-L-Ara*f* residues. Whereas each sample batch demonstrated acetylation correlations, we noted that there was batch-to-batch variation in the specific arabinose residue involved in these correlations. However, acetylation was never observed for those arabinose residues identified as being in the S-type xyloglucan structure.

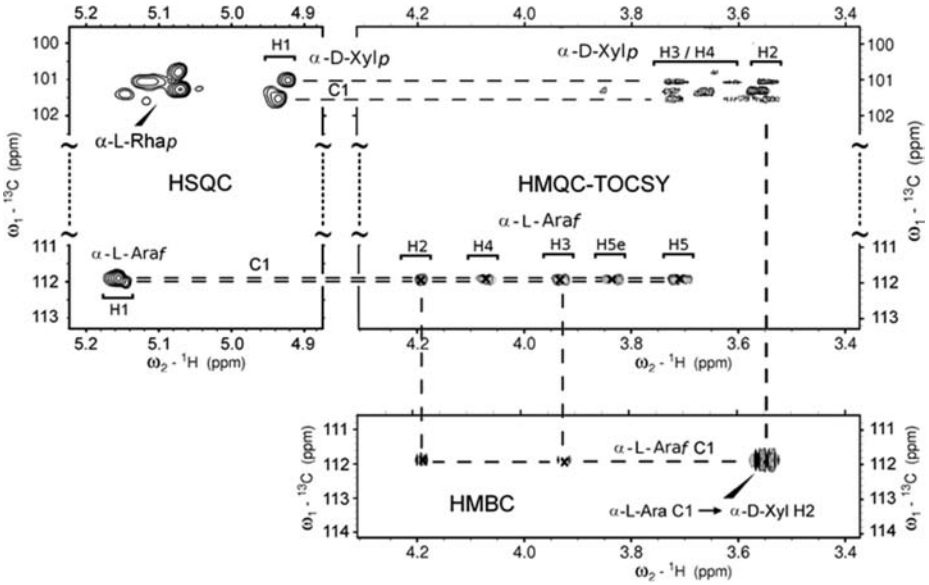

Figure 7. Correlations between α-L-Araf-C1→ α-D-Xylp-H2 were observed consistent with S structures.

The NMR data also indicate the presence of secondary components consisting of β-D-GalpA, α-L-Rhap, and α-L-Fucp in addition to the β-D-Galp discussed above. The β-D-GalpA is indicated by through-bond correlations in the HMBC spectrum between the C6 in the carboxylic acid group and the H5 in its sugar ring. The presence of α-L-Fucp is indicated by H6 methyl resonances (1.26 ppm) that have TOCSY correlations to H5 protons on the directly attached sugar rings (3.44−4.74 ppm and have J_{H5-H6} = 6−7 Hz). These α-L-Fuc correlations can be followed in the HMBC, long-range HSQC, and HMQC-TOCSY experiments from the methyl resonances to corresponding anomeric resonances (data not shown). Additional methyl resonances exist (1.10−1.20 ppm), which are consistent with α-L-Rhap. Spectral congestion does not allow through-bond correlations of these α-L-Rhap methyl protons to their anomeric resonances. Therefore, the α-L-Rhap assignment is likely but cannot be verified due to the lack of through-bond correlations.

The anomeric proton orientations (α or β) were confirmed by means of their C−H coupling constants, J_{C1-H1}, as derived from the C−H coupled HSQC and HMBC experiments. This determination helps to confirm resonance assignments and utilizes the fact that axially oriented H-1 has J_{C1-H1} ∼ 160 Hz and those with an equatorial H-1 have values ∼170 Hz.[28] A summary of the anomeric chemical shifts, their assignments, and likely substructures can be found in Table 4 and are annotated in Figure 6. These assignments are based on coupling constants and through-bond correlations and are consistent with literature values of both the ^{1}H and ^{13}C chemical shifts.[16,18,30−35] The same xyloglucan oligosaccharides with SSGG structure (*m*/*z* 1217 most abundant ion) were also detected in commercial cranberry juice with the MALDI-TOF MS ion intensity directly proportional to the amount of cranberry juice present (data not shown). No xyloglucan oligosaccharides were detected in commercial apple, grape, or pomegranate juices using the same graphitized carbon extraction method detailed above for cranberry fractions.

Anti-adhesive Activity of Cranberry Fractions. The anti-adhesive activity of cranberry xyloglucan-rich fractions was determined by bacterial adhesion to epithelial cell assays using both uropathogenic and enterohemorrhagic *E. coli* strains to identify binding to type 1 (UTI89) or p- (CFT073) fimbriae and those produced by enterohemorrhagic *E. coli* (O157:H7). Fimbriae are important bacterial virulence factors required for binding to epithelial cells in the urinary tract; type 1 fimbriae are typically associated with cystitis and p-fimbriae with pyelonephritis infections. Specific binding of p-fimbriated *E. coli* to uroepithelial cells decreased with increasing concentrations (0−5 mg/mL) of cranberry extract A6 in a dose-dependent manner (Figure 8). The half-maximal inhibitory concentration of A6 was 0.82 mg/mL. As previously reported by Kimble et al.,[25] a cranberry polyphenol extract enriched in anthocyanidins, polyphenolic acids, flavonols, and PACs was used as a positive control in the p-fimbriated *E. coli* assay and exhibited a specific binding reduction between 0 and 1.25 mg/mL with a half-maximal inhibitory concentration of 0.12 mg/mL. Therefore, the oligosaccharide enriched extract A6 showed 6.8 times lower binding affinity to the p-fimbriated *E. coli* compared to the cranberry polyphenolic enriched standard. Cranberry extract A1 showed a slightly higher inhibitory effect compared to A6 (0−30 mg/mL A1) with a half-maximal inhibitory concentration of 0.64 mg/mL (data not shown), possibly due to the presence of phenolic compounds, especially PACs in extract A1.

A concentration-dependent (0−5 mg/mL A6) reduction of binding was also observed in the type 1 *E. coli* assay (Figure 9). The half-maximal inhibitory concentration of A6 was 0.66 mg/mL. These results are comparable to the half-maximal inhibitory concentration of α-D-mannose (0.9 mg/mL) standard, a natural ligand for type 1 fimbriae. Cranberry A1 exhibited a half-maximal inhibitory concentration of 4.3 mg/mL and therefore was less effective at preventing bacterial adhesion compared to A6 for type 1 fimbriated *E. coli*. The cranberry extract A1 was enriched in pectic oligosaccharides and contained polyphenolic compounds compared to the xyloglucan oligosaccharide-enriched A6 fraction. Thus, the higher levels of xyloglucan oligosaccharides correlated with the higher anti-adhesion activity for type 1 fimbriated *E. coli*. From these results, purified cranberry A6 xyloglucan oligosaccharides have

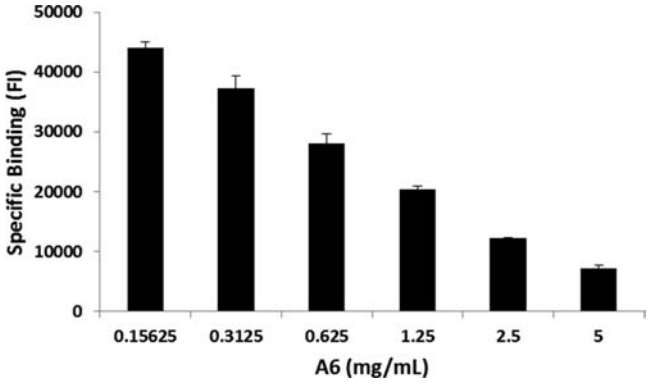

Figure 8. Adhesion of *E. coli* CFT073 to uroepithelial T24 cells in the presence of cranberry A6 fraction.

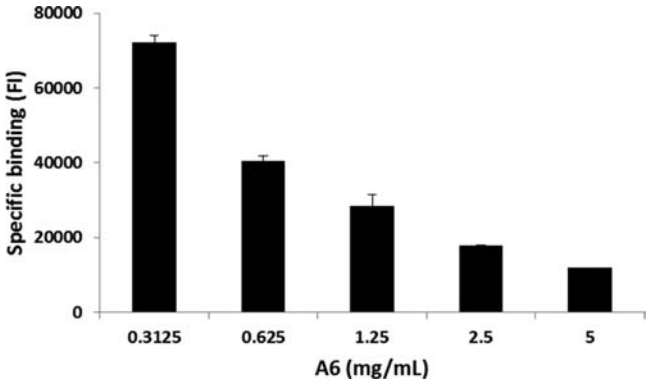

Figure 9. Adhesion of *E. coli* UTI89 to T24 cells in the presence of cranberry A6 fraction.

a higher binding affinity toward type 1 fimbriated *E. coli* compared to p-fimbriated strains.

A non-dose-dependent response was observed for the anti-adhesive activity of A6 in the bacterial adhesion assay reported earlier.[11] The adhesion of *E.coli* O157:H7 to human colonic epithelial HT29 cells was blocked by A6 at low concentrations (0.001−0.1 mg/mL) relative to the unsupplemented PBS control (Figure 10). At higher concentrations, the cranberry A6 fraction was not able to inhibit *E. coli* O157:H7 adhesion to HT29 cells. Enterohemorrhagic *E. coli* produces several adhesive structures including the *E. coli* common pilus and type IV pilli.[36,37] Prebiotic oligosaccharides (galacto-oligosaccharides and pectic-oligosaccharides) were also reported to have dose-dependent anti-adhesive properties against enterohemorrhagic and enteropathogenic *E. coli* strains.[11,38] P-fimbriated *E. coli* and verocytotoxins produced by enterohemorrhagic strains of *E. coli* utilize the same α-Gal-(1−4)-β-Gal terminal oligosaccharide receptor for adhesion to epithelial cells, whereas type 1 fimbriae utilize a α-Man-(1−2)-Man receptor.[39] It is unlikely that xyloglucan, pectic-, and galacto-oligosaccharides prevent *E. coli* adhesion through receptor mimicry because α-Man-(1−2)-Man or α-Gal-(1−4)-β-Gal have not been detected in cranberry or citrus fractions or prebiotic products. However, these data indicate that cranberry xyloglucan oligosaccharides have a higher affinity for type 1 fimbriae, whereas pectic- and galacto-oligosaccharides have higher affinity for p-fimbriae and those produced by enterohemorrhagic and enteropathogenic *E. coli* strains.

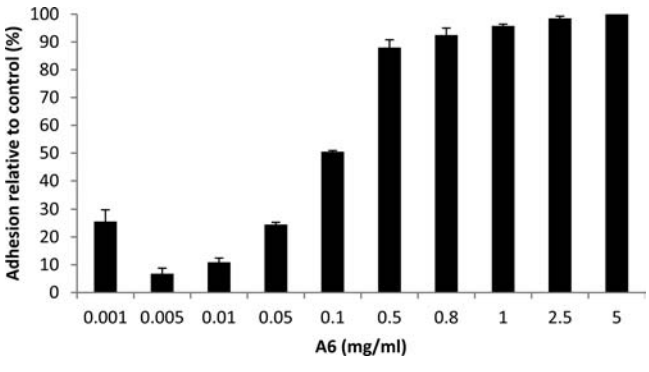

Figure 10. Adhesion of *E. coli* O157:H7 to HT29 cells in the presence of cranberry A6 fraction.

In conclusion, the cranberry xyloglucan structure was characterized for the first time as an arabino-xyloglucan with SSGG structure. This is the first member of the Ericales with this type of xyloglucan structure, but only the second plant in the order to have the xyloglucan characterized. A new xyloglucan heptasaccharide from cranberry was characterized by MALDI-TOF/TOF MS/MS and NMR with SSG and GSS oligosaccharide structure. NMR data, including through-bond correlations, coupling constants, and chemical shift values, enabled the assignment of α and β linkages and the sugar residues and confirmed the structural sequence. NMR provided direct through-bond correlation evidence for α-L-Ara*f* (1→2) α-D-Xyl*p* linkages and α-D-Xyl*p* (1→6) β-D-Glc*p* linkages, as found in xyloglucans with S-type structures. There appear to be two cranberry xyloglucan S structures with slightly different physical environments, which can be attributed to SSG and GSS sequences. The cranberry A6 fraction that included SSGG-type xyloglucan oligosaccharides prevented adhesion of both p-fimbriated and type 1 uropathogenic *E. coli* strains to human uroepithelial cells and veritoxigenic *E. coli* to colonic epithelial cells in vitro using three independent assays. In addition to proanthocyanidins, SSGG-type xyloglucan oligosaccharides are new bioactive cranberry juice ingredients with potential to control urinary tract infections. However, more research is needed to determine the exact mechanism of xyloglucan oligosaccharide anti-adhesion activity against pathogenic *E. coli*.

Neferine, **6**, a benzylisoquinoline alkaloid (Figure 1), isolated from the seed embryo of *N. nucifera* has been reported to block

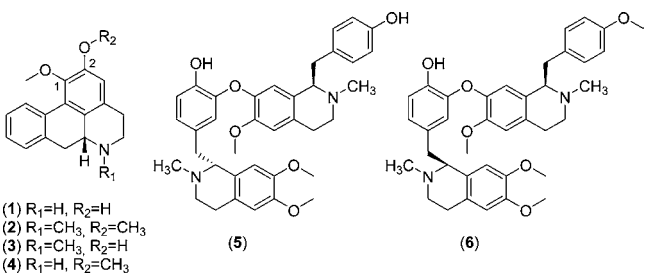

Figure 1. Chemical structures of lotus alkaloids: (−)-asimilobine, **1**, nuciferine, **2**, *O*-nornuciferine, **3**, *N*-nornuciferine, **4**, liensinine, **5**, and neferine, **6**.

hERG channels stably expressed in human embryonic kidney (HEK293) cells. In whole-cell patch clamp studies, this compound induced a concentration-dependent decrease in hERG current amplitude with an IC_{50} of 7.42 μM.[19] Moreover, Western blot analysis and immunofluorescence experiments gave insights into the effect of compound **6** on hERG protein levels in HEK293 cells. Liensinine, **5**, a structurally similar benzylisoquinoline alkaloid (Figure 1) from *N. nucifera* seed embryos, was also described to be a hERG blocker, however, at concentrations below 10 μM in much lower potency than its more hydrophobic derivative, **6**.[20]

The aim of the present study was to evaluate the hERG-blocking activity of alkaloids present in *N. nucifera* leaves and to quantitatively analyze their content in commonly consumed herbal supplements for weight loss including a critical discussion of the potential cardiotoxic risk caused by these products.

MATERIALS AND METHODS

General Experimental Procedures. Optical rotations were measured on a model 341 polarimeter (PerkinElmer, Waltham, MA, USA) at 25 °C. 1D- and 2D-NMR experiments were performed by using DRX300 and TXI600 NMR spectrometers (Bruker, Billerica, MA, USA) operating at 300 and 600 MHz, respectively. The samples were measured in $CDCl_3$ (calibrated to the residual nondeuterated solvent signals). MS analysis was performed on an Esquire 3000 plus ion-trap mass spectrometer (Bruker Daltonics, Billerica, MA, USA) equipped with electrospray ionization (ESI) in the positive and negative modes: spray voltage, 4.5 kV; sheath gas, N_2, 30 psi; dry gas, N_2, 6 L/min, 350 °C; scanning range, m/z 50−1000. Column chromatography was performed using silica gel 60 (40−63 μm) from Merck (Darmstadt, Germany) and Sephadex LH-20 (20−100 μm) from Pharmacia (Stockholm, Sweden). Fast centrifugal partition chromatography was carried out on a FCPC A200 instrument from Kromaton (Annonay, France). Fractions obtained from all chromatographic steps were analyzed by TLC (mobile phase, acetone/CH_3Cl/EtOH/NH_3 (4:3:1:0.1, v/v/v/v); stationary phase, Merck silica gel 60 PF_{254}, sprayed with Dragendorff reagent at Vis, UV_{254}, and UV_{366}). HPLC was performed on an Agilent 1200 LC system (Santa Clara, CA, USA) with a photodiode array detector (DAD). LC parameters were as follows: stationary phase, 150 × 3.0 mm i.d., 5 μm, Phenomenex Gemini NX-C18; temperature, 35 °C; mobile phase, A = 95% ammonium acetate 50 mM/5% CH_3CN (pH of mixture 6.8); B = 25% ammonium acetate 50 mM/75% CH_3CN (pH of mixture 7.6); flow rate, 0.4 mL/min; DAD detection wavelength, 270 nm; injection volume, 10 μL. Separations were performed by gradient elution (80:20 A/B in 25 min to 30/70 A/B, then within 1 min to 2/98 A/B), followed by a 4 min column wash (2A:98B) and a re-equilibration period of 10 min. All chemicals and solvents used were of analytical grade.

Plant Material. The leaves of *N. nucifera* Gaertn. (Nymphaeaceae) were obtained from Plantasia (MMag. E.A. Stöger, Oberndorf/Salzburg, Austria). A voucher specimen (JR-20100922_A1) is deposited in the Herbarium of the Department of Pharmacognosy, University of Vienna, Austria.

Extraction, Isolation, and Identification of Pure Compounds. The dried ground leaves of *N. nucifera* (712 g) were macerated with 6 L of CH_2Cl_2/MeOH (1:1) (at 22 °C, three times for 72 h each). After removal of the solvent under vacuum, 56 g of extract was obtained. This extract was then redissolved in CH_2Cl_2 and aqueous MeOH (1:1) and separated via liquid−liquid partition using petroleum ether followed by CH_2Cl_2. After removal of MeOH from the aqueous phase under vacuum, it was alkalized to a pH of 10 to extract alkaloids with CH_2Cl_2 to obtain 885 mg of an enriched alkaloid fraction (NN-A).

For the isolation of the alkaloids, NN-A was subjected in pilot scale (50 mg) to fast centrifugal partition chromatography (FCPC) using a biphasic solvent system of petroleum ether/ethyl acetate/methanol/water (1:5:1:5, v/v/v/v). The FCPC instrument was operated in descending mode (lower phase as mobile phase). The sample was dissolved in a mixture of mobile and stationary phase (1:1, v/v). After filling the stationary phase into the system, the mobile phase was pumped in while equilibrating at 800 rpm (column volume = 200 mL). Finally, the sample solution was injected, and separation was carried out at a flow rate of 1.8 mL/min and a rotation speed of 1200 rpm in a counterclockwise direction. Resulting fractions were monitored and combined according to their TLC pattern to give nine fractions (A1−A9). A7 was identified as pure compound **3** (9.96 mg).

In a large-scale approach, another 882 mg of NN-A was fractionated by FCPC applying the same parameters and conditions as described above for the small-scale separation (column volume = 200 mL). In sum, 18 fractions were obtained (B1−B18). Fractions B9 (14.35 mg) and B10 (42.24 mg) were purified via silica gel column chromatography (Merck silica gel 60 PF_{254}, 43 cm × 2 cm) by applying an isocratic system of acetone/CH_2Cl_2/EtOH/NH_3 (4:3:1:0.1, v/v/v/v) to yield compound **4** (5.41 mg) and compound **5** (8.75 mg). B7 (18.35 mg) and B17 (28.56 mg) were purified via Sephadex LH-20 column chromatography (mobile phase, MeOH), yielding compounds **1** (4.10 mg) and **2** (7.03 mg).

All isolated compounds (**1**−**5**) could be identified by using HPLC, MS analysis, optical rotation, and 1D- and 2D-NMR experiments. The physical and spectroscopic data of compounds **1**−**5** agreed with those published previously for (−)-asimilobine, **1**, nuciferine, **2**, *O*-nornuciferine, **3**, *N*-nornuciferine, **4**, and liensinine, **5**.[21−24] Their purity was checked using TLC and LC-MS and revealed to be >98% in all cases.

Expression of hERG Channels in *Xenopus* Oocytes and Voltage Clamp Studies. Preparation of stage V−VI oocytes from *X. laevis* (NASCO), synthesis of capped runoff complementary RNA (cRNA) transcripts from linearized complementary DNA (cDNA) templates, and injection of cRNA were performed as described previously.[25] cDNA of hERG (accession no. NP000229) was kindly provided by Dr. Sanguinetti (University of Utah). Currents through hERG channels were studied 1−4 days after microinjection of the cRNA by the two-microelectrode voltage clamp technique making use of a TURBO TEC-03X amplifier (npi electronic GmbH, Tamm, Germany). The bath solution contained 96 mM NaCl, 2 mM KCl, 1 mM $MgCl_2{\cdot}6H_2O$, 1.8 mM $CaCl_2{\cdot}2H_2O$, and 5 mM HEPES (all Sigma, pH 7.4). Voltage-recording and current-injecting microelectrodes (Harvard Apparatus) were filled with 3 M KCl and pulled to have resistances between 0.5 and 2 MΩ. Oocytes with maximal current amplitudes >3 μA were discarded to avoid voltage clamp errors. The pClamp software package v.10.0 (Molecular Devices, Inc.) was used for data acquisition.

Unless otherwise stated, the following voltage protocol was used: from a holding potential of −80 mV, the cell membrane was initially depolarized to +20 mV (300 ms) to achieve channel activation and subsequent rapid inactivation. During the following repolarization to −50 mV (300 ms) channels recover from inactivation and elicit the

DOI: 10.1021/acs.jafc.5b01901
J. Agric. Food Chem. 2015, 63, 5634−5639

hERG current (I_{hERG}). A final step to the holding potential ensured that channels returned to the closed state. The protocol was applied in 1 s intervals (1 Hz pulse frequency).

Drug Application and Data Analysis of Voltage Clamp Studies. Drugs were applied to *Xenopus* oocytes by means of a screening tool fast perfusion technique (npi electronic GmbH).[26] Data were analyzed using Origin software 7.0 (OriginLab Corp., Northampton, MA, USA). Each data point represents the mean ± SE from at least three oocytes and two oocyte batches.

Whole-Cell Patch Clamp Assay Using HEK293 Cells. Measurements were performed using the automated patch clamp device CytoPatch 2 Instrument.[27] Whole-cell patch clamp recordings were applied to examine the effects of the selected lotus leaf alkaloids on the hERG ion channel. To elicit hERG-mediated currents, cells were clamped for 200 ms to −80 mV and then shifted for 200 ms to −50 mV. The voltage step to −50 mV was used to determine the leak current of the cell. Thereafter, the cell was depolarized for 2 s at +40 mV. By stepping back to −50 mV for 2 s, the hERG tail current was activated. At the end of the pulse protocol, the cells were clamped again to holding potential. This voltage protocol was repeated at a frequency of 0.1 Hz. The membrane resistance, R_m, was monitored during the complete recording time. Recordings during which R_m decreased to <500 MΩ without recovery were stopped and repeated. Experiments were carried out at room temperature.

hERG tail current amplitudes were monitored before and during test compound application. The amplitude of the hERG tail current was calculated by subtraction of the leak current (determined during the −50 mV depolarization step prior to the activation of the hERG current) from the maximal current peak amplitude during the tail phase. The current inhibition for each test concentration was calculated by dividing the mean peak current of the last five current amplitudes at the end of each application phase by the respective control values. Results from the individual experiment were averaged to give the mean inhibition (±SD).

Human Embryonic Kidney (HEK293) Cells. HEK293 cells stably transfected with hERG were used in this study. These cells were frozen instant cells produced by the Cytocentrics Bioscience GmbH, Rostock, Germany.[27] They were stored in liquid nitrogen and were ready-to-use directly after thawing without any cultivation. After thawing, the cells were kept in the Cytocentrics Cells Reservoir as a cell suspension at a density of ∼2.0 million cells/mL in extracellular buffer at room temperature.

Buffers Used for Whole-Cell Patch Clamp Assay. The extracellular buffer (EC) was used for cell preparation and cell storage as well as for the dilution of compounds and patch clamp recordings.

The EC contained 140 mM NaCl, 2.5 mM KCl, 2 mM $MgCl_2$, 2 mM $CaCl_2$, 10 mM HEPES, 10 mM glucose, and 15 mM sucrose; pH adjusted to 7.4 (±0.1; NaOH), osmolality adjusted to 310−320 mOsm/L (saccharose), storage at 4 °C. Before use, the required EC was heated to room temperature and degassed. The intracellular buffer (IC) was used to fill the patch pipets. The intracellular buffer (IC) contained 100 mM K-gluconat, 20 mM KCl, 1 mM $CaCl_2$, 1 mM $MgCl_2$, 10 mM HEPES, 11 mM EGTA-KOH, 4 mM Mg ATP, 3 mM Na_2 phosphocreatine hydrate, and 9 mM sucrose; pH was adjusted to 7.2 ± 0.1; osmolality to 295 ± 5 mOsm/L, storage at −20 °C. After thawing, the IC was used for up to 4 h.

Curve Fitting. The concentration dependence of drug effects was modeled with a standard four-parameter logistic equation:

$$\text{effect} = \min + \left[\max / \left(1 + 10^{(\log IC_{50} - \log X)\cdot nH}\right)\right]$$

The parameters were minimal and maximal effects (min, max), half-maximal inhibitory drug concentration (IC_{50}), drug concentration (X), and Hill slope (nH). Minimal and maximal effects were treated as constants (max = 100 and min = 0) and IC_{50} and nH as variables (GraphPad Prism 4).

Test and Reference Compounds. To prepare working solutions, the stock solutions of the test alkaloids were diluted in DMSO and then 1:1000 in extracellular buffer, yielding the correct compound concentration in 0.1% DMSO. Work solutions were used immediately after thawing for up to 4 h and disposed of afterward. As reference compound for the hERG recordings, 100 nM cisapride was applied to three cells (positive control). To prove that the compound vehicle DMSO does not affect hERG-mediated currents, the vehicle (extracellular buffer containing 0.1% DMSO) was applied to three cells (negative control). When a stable whole-cell recording configuration was established, the cell was initially perfused with extracellular buffer to ensure stable recording conditions (control phase). Up to three increasing concentrations of the same test compound were applied to the same cell for 5 min each.

Quantitative Analysis of hERG-Blocking Alkaloids in Dietary Supplements. Five randomly selected commercially available dietary supplements (products 1−5) were analyzed according to a previously reported validated method using solid phase extraction (SPE) in combination with HPLC-DAD.[28] Briefly, the contents of three to four capsules (between 0.7 and 1.5 g) of each product were weighed and extracted with 8 mL of acidified MeOH (1% hydrochloric acid aqueous solution/MeOH; 50:50, v/v) on the ultrasonic bath for 15 min. Then the samples were centrifuged at room temperature at 5000 rpm for 5 min. This extraction was repeated twice for each sample, the resulting supernatants were combined in a volumetric flask, and the volume was filled to 25 mL with acidified MeOH.

Furthermore, an aliquot of each solution was subjected to SPE to clean up and enrich the sample. Oasis MCX (60 mg/3 mL) SPE cartridges were activated under vacuum with 4 mL of alkalized MeOH (5% ammonia in MeOH, w/w) and washed with 4 mL of H_2O. Then, 3 mL of alkaloid solution was passed through the cartridges without using vacuum. This was followed by three washing steps with 3 mL of 20% aqueous MeOH each time. Prior to HPLC analysis, the alkaloids were eluted with 4 mL of alkalized MeOH (5% ammonia in MeOH, w/w).

In Silico Screening of hERG Blocking Compounds. The pharmacophore-based hERG-blocking predictions on compounds **1**−**6** were conducted within Discovery Studio version 4.0 (Biovia, CA, USA). For each compound, up to 255 conformations were calculated in BEST quality. The compound fitting was performed using the Ligand Pharmacophore Mapping protocol and the flexible fitting option, allowing the ligand conformation to be energetically minimized within the pharmacophore model during the screening.

RESULTS AND DISCUSSION

Discovery of hERG-Blocking Natural Material. Using an automated two-microelectrode voltage clamp assay on *Xenopus* ooctyes, an in vitro screening for hERG channel blocking natural materials was performed. As a result, an enriched alkaloid fraction of *N. nucifera* leaves (NN-A; Figure 2) was found to cause strong hERG current inhibition, that is, 50.4 ± 10.3% (n = 3, data not shown), at a concentration of 100 μg/mL.

Isolation and Identification of hERG Blocking Compounds in NN-A. Separation and purification techniques including FCPC as well as silica gel and Sephadex column chromatography were applied to isolate five lotus leaf alkaloids from an enriched extract (NN-A). By using LC-MS analysis and 1D- and 2D-NMR experiments as well as by comparison with published data,[21−24] the constituents (Figure 1) were identified as (−)-asimilobine, **1**, nuciferine, **2**, *O*-nornuciferine, **3**, *N*-nornuciferine, **4**, and liensinine, **5**. Compounds **1**−**4** can be classified as aporphine-type alkaloids, whereas compound **5** belongs to the class of benzylisoquinoline alkaloids.

To evaluate the hERG channel blocking properties of the isolated compounds, we applied them to *Xenopus* oocytes making use of the automated two-microelectrode voltage clamp technique. All five isolated and identified lotus leaf constituents induced hERG current inhibition between 5.8% (compound **5**) and 81.9% (compound **2**) at 100 μM (Table 1).

Table 1. Percentage of hERG Current Inhibition in *Xenopus* Oocytes by Lotus Alkaloids at 100 μM (n = 3)

compound	% hERG channel inhibition at 100 μM
1	24.3 ± 1.7
2	81.9 ± 5.6
3	47.0 ± 0.3
4	44.2 ± 0.2
5	5.80 ± 1.5

Evaluation of hERG Blockage in HEK293 Cells. To further investigate hERG-blocking properties of the isolated *N. nucifera* leaf alkaloids, a whole-cell patch clamp assay was performed with the three most potent inhibitors, that is, compounds **2**, **3**, and **4**. All three alkaloids induced a concentration-dependent decrease in current amplitude of the hERG channel stably expressed in HEK293 cells with IC_{50} values of 2.89, 7.91, and 9.75 μM, respectively. In our system the hERG blocker cisapride (positive control) showed an IC_{50} of 56 nM.

Corresponding dose–response curves of the three lotus alkaloids and current traces are shown in Figure 3. The less pronounced channel block on *Xenopus* oocytes is likely due to the presence of a large amount of yolk particles inside the oocyte membrane, which may absorb the compounds, thereby reducing the effective intracellular free drug concentration.[29,30]

Pharmacophore Model Predicting hERG-Blocking Constituents. Recently, several ligand-based pharmacophore models were established to predict hERG-blocking properties.[7] The model showing the best performance, when validated with synthetic compounds, consists of a positively ionizable, two hydrophobic, and one hydrophobic aromatic feature. To test the reliability of the model (Catalyst hERG model) toward natural products and to get a rough insight into ligand–target interactions, the five isolated compounds and the already known hERG blocker from lotus seeds, that is, compound **6**, were virtually screened. As a result, compounds **2**, **4**, **5**, and **6** were predicted as virtual hits (VHs). Among them, **2**, **4**, and **6** were predicted correctly as hERG-blocking constituents. A feature overlay of these compounds mapping the pharmacophore is shown in Figure 4. The hERG-blocking compound **3** was not predicted because it contains a hydroxyl instead of a methoxy group in position 2. Hence, the methoxy group in position 1 is fitted to the hydrophobic feature of the model with the result that no other required hydrophobic feature can be mapped. Furthermore, compound **5** was predicted to be a hERG blocker. In our experimental evaluation this could not be confirmed. However, in an earlier study,[20] this compound was identified as a weak hERG blocker with much lower potency than its hydrophobic derivative **6**.

Quantitation of hERG-Blocking Lotus Alkaloids in Dietary Supplements. Lotus leaf products are widely advertised as weight loss dietary supplements. Moreover, nuciferine, **2**, is known to block fat absorption and fat accumulation and thus to have strong antiobesity effects.[31] In our study this compound was identified as the most potent hERG blocker in HEK293 cells, indicating potential cardiac liabilities. To investigate the relevance and significance of these findings, five randomly selected lotus leaf dietary supplements for weight loss (products 1–5) were quantitatively analyzed focusing on the identified hERG-blocking alkaloids, that is, **2**, **3**, and **4**.

A previously published method using SPE in combination with HPLC-DAD[28] was adapted for quantitation. The method was validated for linearity, limit of detection (LOD), and limit of quantitation (LOQ). The calibration curves were obtained by injecting a series of compound solutions at increasing concentrations. For all three compounds there was good linearity (correlation coefficient = 0.99998) over a wide concentration range, with the LOQ between 0.42 and 0.62 mg/mL and the LOD between 1.43 and 2.11 mg/mL.

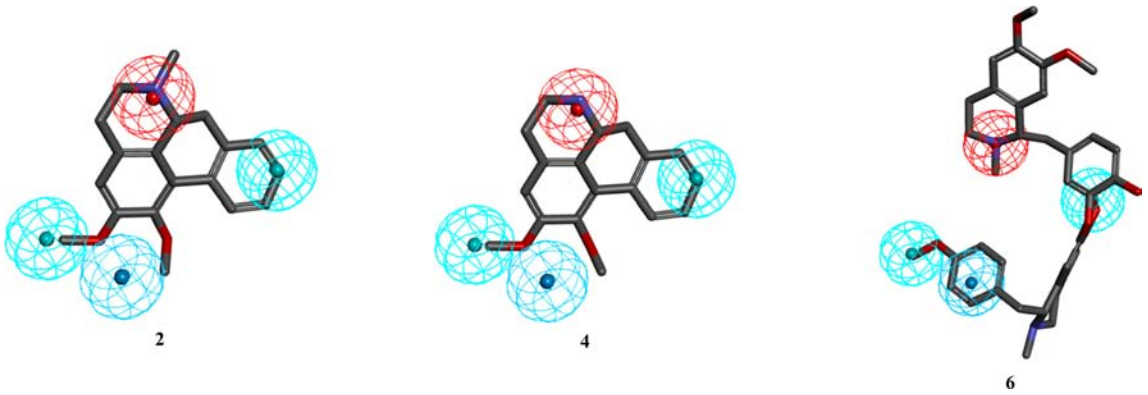

Figure 4. Feature overlay of hERG-blocking lotus alkaloids (**2**, **4**, and **6**) with Catalyst hERG pharmacophore model. The chemical features are color-coded: positively ionizable, red; hydrophobic, cyan; aromatic hydrophobic, blue.

Table 2. Percentage of Alkaloids (n = 3) in Selected Lotus Dietary Supplements[a]

compound	product 1	product 2	product 3	product 4	product 5
2	0.066 ± 0.07 (992.39)	0.011 ± 0.01 (318.54–637.08)	0.010 ± 0.01 (100.52)	n.d.[b]	0.004 ± 0.01 (57.94–77.25)
3	0.064 ± 0.12 (957.27)	0.010 ± 0.09 (283.39–566.77)	0.009 ± 0.08 (90.31)	n.d.	n.d.
4	n.d.	n.d.	n.d.	n.d.	n.d.

[a]The calculated amounts of alkaloids (μg) consumed in the recommended daily dose(s) of selected lotus dietary supplements are given in parentheses. [b]n.d. = not detectable.

The quantitative composition of the three focused alkaloids in the five commercial products varied significantly (Table 2). For instance, the highest percentages of compounds **2** and **3** were found in product 2 (0.066 and 0.064%, respectively), whereas none of the three focused alkaloids could be detected in product 4. Moreover, compound **4** was not found in any of the investigated products. With the recommended daily dose given on each package of the investigated dietary supplements taken into account, the amount of daily intake of hERG-blocking lotus leaf alkaloids was calculated (Table 2). The highest daily intake of alkaloids **2** and **3** was found for product 1, with almost up to 1 mg each. In the other three products (products 2, 3, and 5) the amount of hERG-blocking alkaloids is considerably lower (up to 637 μg per day). In sum, **2** was found as the predominant alkaloid of the selected leaf products, whereas **3** was found in lesser content and **4** was not detected in any product.

Because *N. nucifera* leaves and commercially available lotus leaf products are taken in the form of teas or capsules containing lotus extracts or powdered leaves, it is of high relevance to have knowledge on the oral bioavailability of the main hERG-blocking alkaloids. To date, first pharmacokinetic data are already available for **2**, which we identified as a hERG-blocking natural compound with an IC_{50} of 2.89 μM in HEK293 cells. Compound **2** was quantitated in rat plasma after oral and iv administration.[32,33] It was observed that there is a rapid distribution and a poor absorption into the systemic circulation, but an extensive tissue uptake. The absolute bioavailability is around 4%. Moreover, **2** is distributed into brain, liver, and adipose tissues.[32,33]

Supported by in silico ligand–target predictions, three major lotus leaf alkaloids, that is, compounds **2**, **3**, and **4**, were identified as hERG-blocking constituents. With regard to the possibility of severe cardiotoxic events combined with vague or nonexistent legislation concerning the licensing of herbal dietary supplements, it is of high relevance to screen commonly consumed botanicals for their hERG-interacting properties. The quantitative analysis of the three identified hERG-blocking alkaloids **2**, **3**, and **4** in five lotus leaf slimming products revealed that their content and thus their daily dose vary significantly. However, without complete data on the pharmacokinetics and pharmacodynamics of these compounds, a full risk estimation concerning safety is not feasible. Notably, especially in Asian countries, lotus leaves have been used in traditional medicines for thousands of years, and they have stood the test of time without a notable increase of sudden cardiac deaths. Nevertheless, if nonstandardized weight loss products are consumed in excess or taken by patients with already existing cardiac problems, the identified hERG toxic lotus alkaloids might increase health risks. Especially if taken in addition to medication with potentially cardiotoxic drug substances or in combination with lotus leaf containing food products, an accumulation of hERG-interacting compounds may increase the risk of cardiotoxic side effects.

been reported that antioxidants, such as vitamin C, hydrogen sulfide, ginsenoside, and sesamol, have great potential to enhance the proliferation capacity of a broad range of cells, likely due to their high ability to scavenge intracellular reactive oxygen species (ROS).[20−22] Sesamol (3,4-methylenedioxyphenol) is a natural phenolic compound found in sesame oil. In addition to its potent antioxidation activity, sesamol is able to inhibit malic enzyme, which is a major source of NADPH in many oleaginous microorganisms.[23,24]

C. cohnii synthesizes saturated and monounsaturated fatty acids via a NADPH-dependent fatty acid synthase complex of enzymes. The application of sesamol attenuates the intracellular production of NADPH by inhibiting malic enzyme and thus may decrease the accumulation of these de novo synthesized fatty acids leading to the buildup of fatty acid precursors in *C. cohnii*. The precursors, on the other hand, maybe redirected to the biosynthesis of DHA via the desaturase-independent PKS pathway, resulting in the possible increase in DHA content. To validate this hypothesis for improved DHA production by *C. cohnii*, a set of sesamol concentrations were tested. Our work represents, to the best of our knowledge, the first effort to utilize the natural phenolic compound sesamol for enhanced DHA production by *C. cohnii* and may provide alternative directions to lower the production cost in future industrial applications.

MATERIALS AND METHODS

Microalga and Culture Conditions. *C. cohnii* (ATCC 30556) was maintained heterotrophically in liquid By+ medium (pH 6.5) with 5 g/L glucose at 16 °C and subcultured every month. By+ medium contained (per liter) 15 g of sea salt (Sigma), 1 g of yeast extract (Oxoid), and 1 g of tryptone (Oxoid). The inocula were prepared by culturing the microalga in 500 mL Erlenmeyer flasks with 100 mL of By+ medium at 25 °C for 48 h with orbital shaking at 150 rpm in the dark. The seed of *C. cohnii* was inoculated to 100 mL of fresh modified By+ medium (containing, per liter, 15 g of sea salt, 0.5 g of yeast extract, 0.5 g of tryptone, and 20 g of glucose) for batch culture in 500 mL Erlenmeyer flasks. The media of all fermentations were supplemented with various concentrations of sesamol (0−2 mM), and each concentration was carried out in triplicate. The pH of By+ medium was adjusted to 6.5 prior to autoclaving. After inoculation, the flasks were incubated at 25 °C in an orbital shaker at 150 rpm in the dark for 96 h.

Determination of Residual Glucose Concentration, Cell Dry Weight, and Specific Growth Rate. The cells were centrifuged at 3000*g* for 5 min. The concentration of glucose in the supernatant was determined according to the method of Miller.[25] The pellet was washed with deionized water twice and filtered through a predried filter paper (Whatman GF/C). Then the cells on the disks were dried to constant weight in a vacuum oven at 80 °C. The specific growth rate (μ) in the log phase was calculated by using the equation $\mu = (\ln X_2 - \ln X_1)/(t_2 - t_1)$, where X_1 and X_2 are the cell dry weight concentrations (g/L) at time t_1 and t_2, respectively.

Fatty Acid Analysis. Twenty milligrams of lyophilized algal cells was incubated in a solvent mixture (1 mL of toluene, 2 mL of 1% sulfuric aicd in methanol (v/v), and 0.8 mg of heptadecanoic acid in 0.8 mL of hexane as the internal standard) overnight at 50 °C. The formed fatty acid methyl esters (FAMEs) were then extracted three times with hexane in a reciprocating shaker. The FAMEs were analyzed by using a GC-MS-QP 2010 SE (electron ionization type) gas chromatograph−mass spectrometer (Shimadzu, Japan) and a Stabilwax-DA capillary column (30 m × 0.25 mm × 0.25 μm) (Shimadzu, Japan). Helium was used as the carrier gas. The injection temperature, ion temperature, and interface temperature were set at 250, 200, and 260 °C, respectively. The initial column temperature was set at 150 °C. The column temperature subsequently rose to 200 °C by 10 °C/min and then to 250 °C by 15 °C/min, followed by a hold at 250 °C for 3 min. FAMEs were identified by NIST 11 mass spectral library (NIST/EPA/NIH mass spectral library, 2011 edition). FAMEs were quantified by using a standard FAMEs mix (Sigma-Aldrich) with heptadecanoic acid as the internal standard. The response factors of representative fatty acids related to the internal standard are shown in Table S1 of the Supporting Information.

Determination of Enzyme Activities. The cells were harvested by centrifugation at 3000*g* for 5 min. The pellet was resuspended in extraction buffer (containing 100 mM KH_2PO_4/KOH (pH 7.5), 20% (v/v) glycerol, 1 mM benzamidine·HCl, and 1 mM DTT) and ground with liquid nitrogen. The disrupted cell suspension was centrifuged at 12000*g* for 10 min at 4 °C, and the supernatant was used for enzyme analysis. The activities of $NADP^+$-dependent malic enzyme (ME), $NADP^+$-dependent isocitrate dehydrogenase (ICDH), and glucose-6-phosphate dehydrogenase (G-6-PDH) were determined using continuous spectrophotometric assays following the increase of NADPH at 340 nm. All assays were carried out at 25 °C. ME, ICDH, and G-6-PDH were assayed as described by Hsu and Lardy,[26] Wynn and Ratledge,[24] and Langdon,[27] respectively. The enzyme activity was defined as the reducing amount of $NADP^+$ (nmol) catalyzed by the enzyme solution with 1 mg of protein in 1 min (nmol min^{-1} (mg protein)$^{-1}$). The protein concentrations of enzyme solutions were determined according to the method of Bradford,[28] with BSA as a standard.

Determination of Intracellular Reactive Oxygen Species. The intracellular ROS levels in collected cells were determined using the ROS assay kit (Beyotime Institute of Biotechnology, China) according to the instructions. The 2′,7′-dichlorofluorescein (DCF) fluorescence intensity of 10^6 cells/mL was detected by the fluorescent microplate reader Fluoroskan Ascent (Thermo Fisher, USA) with the excitation and emission wavelengths at 485 and 535 nm, respectively.

Statistical Analysis. The data of all the measurements were obtained from three repetitions and analyzed using a one-way analysis of variance (ANOVA) with subsequent post hoc multiple-comparison LSD tests, which were calculated by using SPSS Statistics 20 software. Statistically significant values were defined as $P < 0.05$.

RESULTS AND DISCUSSION

Effect of Sesamol on Cell Growth. In the present study, several sesamol concentrations of 0, 0.5, 1, 1.5, and 2 mM were tested to examine the effect of sesamol on the cell growth of *C. cohnii*. Compared with the control group (0 mM), the addition of 0.5 mM sesamol in the medium significantly enhanced the growth of *C. cohnii*, leading to an increase in biomass concentration by 44.20% (Figure 2A). No significant difference in biomass accumulation of *C. cohnii* was observed when the concentration of sesamol was increased from 0.5 to 1 mM (Figure 2A). Further increase in sesamol concentration to 2 mM, however, severely inhibited algal growth with a biomass concentration of only 0.06 g/L, indicating that high sesamol concentration (>2 mM) is lethal to the growth of *C. cohnii* (Figure 2A). Our results were in accordance with previous studies in which phenolic compounds promoted cell growth at appropriate concentrations and caused cell apoptosis at higher concentrations (>1 mM).[29,30]

Notably, in the presence of 1 mM sesamol, there was an obvious growth lag within the first 24 h of cultivation, as evident by the much lower amount of biomass accumulated (Figure 2B). Thereafter, sesamol induced a significantly greater specific growth rate (from 0.041 to 0.067 h^{-1}), leading to a higher final cell density (Figure 2B). Microorganisms tend to accumulate ROS under certain conditions, such as nitrogen depletion.[31] The buildup of ROS may have an adverse effect on cell growth and cause oxidative damage to cellular components.[32] As indicated by Figure 3B, the intracellular ROS level in *C. cohnii* supplemented with sesamol was reduced by 63.5%

at 24 h of cultivation and remained significantly lower at 48 h, as compared to the sesamol-free cultures. This result is in line with previous works that showed sesamol or other antioxidants have the potential to attenuate intracellular ROS levels, thereby enhancing cell growth.[20,21]

To check if the increase in the final cell density is related to the consumption of glucose, the residual glucose in the culture medium supplemented or not with sesamol was monitored, and the results are shown in Figure 2B. During the whole culture period of 96 h, no significant difference in glucose concentration was observed between the sesamol-containing and sesamol-free cultures, suggesting that the presence of sesamol had little effect on the glucose consumption rate by *C. cohnii*. Likely, in the presence of sesamol, the alga may possess a higher growth coefficient based on glucose (0.35 g/g versus 0.27 g/g) and transform more carbon per glucose to algal biomass.

Effect of Sesamol on Fatty Acid Accumulation. In contrast to the enhanced biomass production, sesamol exhibited an adverse effect on the accumulation of fatty acids (Figure 3). The total fatty acids (TFA) content per cell dry weight was decreased by 25.24% in the presence of 0.5 mM sesamol. No significant difference was observed in the TFA content between the cultures with 0.5 and 1 mM sesamol; however, the further increase of sesamol concentration to 1.5 mM inhibited TFA accumulation remarkably, and the TFA content accounted for only 46.29% of the control cultures without sesamol (Figure 3A,C). After staining with the lipophilic stain Nile red, the fluorescence intensity of *C. cohnii* also showed a decrease in response to sesamol in a concentration-dependent manner (Figure 3C). This decrease in fatty acid content was accompanied by the attenuation of ROS level in *C. cohnii* (Figure 3B), indicating that sesamol may inhibit fatty acid biosynthesis by the sequestration of the intracellular ROS, which is thought to be positively linked to lipid accumulation.[33]

Effect of Sesamol on Docosahexaenoic Acid Production. Sesamol exhibited significant effects on not only TFA accumulation but also fatty acid composition (Table 1). The fatty acids in *C. cohnii* consisted mainly of C14:0, C16:0, C18:0, C18:1, and C22:6, with C22:6 being the most abundant (36.97% of TFA). The addition of sesamol showed little influence on the percentage of saturated fatty acids (C14:0, C16:0, and C18:0). In contrast, there was a significant decrease in C18:1, which was sesamol concentration dependent and

TSF	53.03	49.40	51.01	54.12
Δ/mol	2.32	2.56	2.49	2.33

[a]Cells of *C. cohnii* were collected at 96 h for FA analysis. TSF, total saturated fatty acids; Δ/mol, degree of unsaturation. Values were calculated according to ref 36. Δ/mol = [1.0 (% monoene) + 2.0 (% diene) + 3.0 (% triene)]/100. *, $P < 0.05$; **, $P < 0.01$; ***, $P < 0.001$.

dropped from 10.00 to 8.50% in the presence of 1.5 mM sesamol (Table 1). On the other hand, DHA percentage of TFA was increased significantly by sesamol and reached 41.13% in the presence of 0.5 mM sesamol, which was 11.25% higher than the control cultures without sesamol. Notably, the sesamol-mediated enhancement in DHA percentage was observed during the whole culture period (Figure 4B). Our results were in good agreement with those found in cultures of *Mucor circinelloides* and *Nannochloropsis* sp. that the C18:1 content (%TFA) decreased significantly in the presence of sesamol.[23,34] From the weight content point of view, the presence of sesamol attenuated the content of all fatty acids, but DHA was much less affected as compared to other fatty acids (Table 1). Notably, because of the considerable increase in biomass, a final DHA yield of 0.23 g/L was obtained in the presence of 1 mM sesamol, still significantly higher than the control cultures (Figure 4B). In terms of DHA productivity, it was enhanced significantly by sesamol at concentrations of 0.5−1 mM, but dropped remarkably when sesamol reached 1.5 mM (Figure 4A).

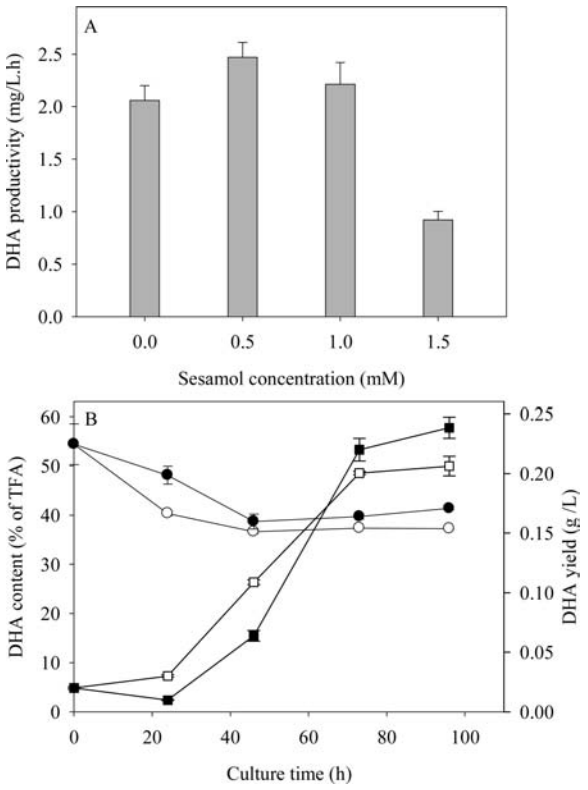

Figure 4. Effect of sesamol on DHA accumulation in *C. cohnii*: (A) DHA productivity under different concentrations of sesamol; (B) time course of DHA percentage per TFA (circles) and volumetric DHA yield (squares) in *C. cohnii* with (solid) or without (open) 1 mM sesamol supplementation.

Effects of Sesamol on the Activities of Key Enzymes Related to Fatty Acid Biosynthesis. It is well-known that the supply of reducing power in the form of NADPH plays an important role in fatty acid biosynthesis in oil-rich microorganisms.[15] NADPH is mainly used for acyl chain growth and desaturation of fatty acids, and its supply is thought to be positively linked to fatty acid biosynthesis and accumulation.[35] Efforts remain to be made to overcome the provision limitation of NADPH for enhancing lipid synthesis in oleaginous microorganisms.[13] There are several intracellular enzymes involved in the generation of NADPH, including malic enzyme (ME), isocitrate dehydrogenase ICDH, and glucose-6-phosphate dehydrogenase (G-6-PDH).

In *C. cohnii*, regardless of sesamol supplementation, the activity of ME increased as the culture time went and reached its maximum at 72 h, followed by a slight decline (Figure 5A). However, sesamol inhibited ME activity during the whole culture period, for example, 174.9 nmol min^{-1} (mg protein)$^{-1}$ at 72 h, which is 37% less as compared to the control cultures. In contrast, there was no significant difference in ICDH activity between the cultures with and without sesamol, except at 72 h, when sesamol attenuated the activity of ICDH (Figure 5B). Interestingly, unlike *Thraustochytrium* sp., in which a high level of G-6-PDH activity was observed, we detected no G-6-PDH activity in all samples of *C. cohnii*. G-6-PDH is a key enzyme involved in the pentose phosphate pathway (PPP) and serves as the prime alternative for producing NADPH.[13] Our results suggested that *C. cohnii* might utilize ME and ICDH rather than

DOI: 10.1021/acs.jafc.5b01441
J. Agric. Food Chem. 2015, 63, 5640−5645

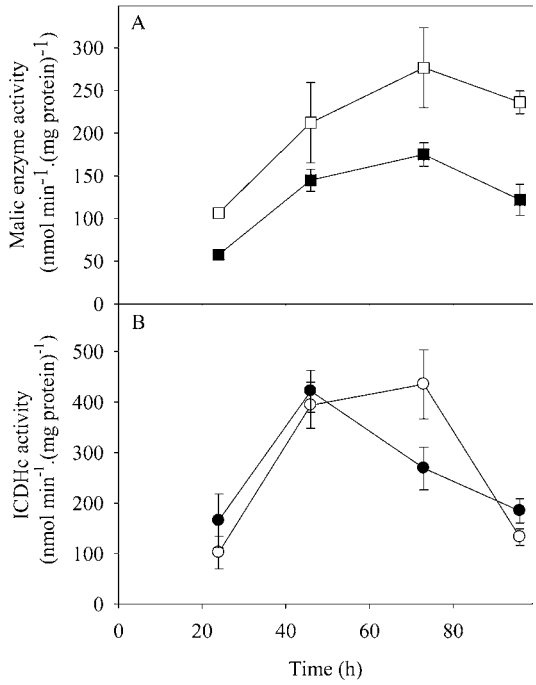

Figure 5. Effect of sesamol on the activities of ME (A) and ICDHC (B) of *C. cohnii* growing with 1 mM (solid) or without sesamol (open).

G-6-PDH to produce NADPH and that sesamol attenuated the intracellular NADPH level, to a large degree, by inhibiting ME activity instead of ICDH or G-6-PDH.

So far, the DHA biosynthetic pathway is not completely defined in *C. cohnii*.[11] DHA can be synthesized via the conventional route, which involves a series of aerobic NADPH-dependent desaturation reactions (Figure 1). Alternatively, DHA biosynthesis can utilize the PKS route, which is thought to be anaerobic and desaturase-free and present in *Schizochytrium* sp. and certain related thraustochytrid marine protists.[15] In our work, accompanied by the sesamol-mediated decrease in NADPH level, *C. cohnii* showed a drop in TFA content but an increase in DHA proportion per TFA (Figure 3A and Table 1). These results may suggest that *C. cohnii* is likely to employ, at least partially, the PKS pathway for DHA biosynthesis. In the presence of sesamol, NADPH production is attenuated due to the inhibition of malic enzyme, leading to a decrease in the accumulation of these de novo synthesized saturated and monounsaturated fatty acids and thus the buildup of fatty acid precursors in *C. cohnii*. The precursors, on the other hand, may be redirected to the biosynthesis of DHA via the desaturase-free PKS pathway, which required much less NADPH, resulting in the possible increase in the relative DHA content.

Sesamol is well-known as a potent antioxidant and inhibitor of malic enzyme. In the present study, sesamol was used to improve DHA production by the marine microalga *C. cohnii* for the first time. Sesamol attenuated the intracelluar ROS level and promoted cell density, DHA proportion per TFA, and DHA productivity of *C. cohnii*, with concomitant decreases in NADPH level and TFA content. Our results suggest that *C. cohnii*, to a large degree, utilizes ME rather than ICDH or G-6-PDH to produce NADPH for the de novo fatty acid biosynthesis. DHA, on the other hand, is likely synthesized, at least partially, via the alternative PKS pathway, which involves no oxygen or NADPH-dependent desaturases. The finding that sesamol has the potential to enhance DHA production by *C. cohnii* is scientifically interesting and provides valuable future directions for lowering production costs in industrial applications.

DOI: 10.1021/acs.jafc.5b01441
J. Agric. Food Chem. 2015, 63, 5640−5645

to carry out numerous tasks in the olive oil field.[23,24] In this case, a two-layer backpropagation neural network (BNN) was designed using the absorption information as input data to attain a fast and competent adulterant identifier as well as an EVOO of the Picual varietal quantifying system.

MATERIALS AND METHODS

Visible Spectroscopy. A Varian Cary 1E UV−vis spectrophotometer operating between 440 and 800 nm was used to obtain the absorption spectra of the binary mixtures (EVOO and adulterant). The samples were analyzed in a transparent cell of 1 cm path length.

Adulterated EVOO Samples. To accomplish this work, EVOO of the Picual varietal was mixed with different known concentrations of one of the following adulterants: corn oil (CO), sunflower oil (SO), orujo olive oil (OOO), or refined olive oil (ROO).

Twenty samples of 2 mL of EVOO with one of the adulterants were prepared within the EVOO volume percentage range of 80−100%, making a total of 81 samples (counting the pure Picual sample). No additional solvents were used apart from the oils, enabling this method to be used online. The oils used are listed in Table 1.

Table 1. Oils Used for Sample Preparation

type	supplier
Picual varietal EVOO	Borges Pont SAU Oil
corn oil (CO)	KOIPE, SOS Cuétara SA
sunflower oil (SO)	KOIPE, SOS Cuétara SA
orujo olive oil (OOO)	DIA
refined olive oil (ROO)	KOIPE, SOS Cuétara SA

The spectra obtained when the mixtures were measured were used to create two types of data sets: the maximum absorption peaks (profile descriptors) and areas under the curve (AUC). For the first type, the five maximum intensity values of the different absorption bands of the spectra were selected. For the second one, the AUC of those same five bands were calculated, avoiding overlaps as done by Díaz-Rodríguez et al. for the quantification of ionic liquids in mixtures.[25]

Mathematical Modeling. *Partial Least Squares.* PLS regression is a classic statistical modeling approach that is used to create a linear regression by the projection of both predicted and observed variables into a new space (somewhat related to principal components analysis).[21]

The resulting linear models possess the structure (eq 1)

$$y = c + \sum_n a_n x_n \tag{1}$$

where c is the constant of the model (regression coefficient for the intercept), x and y represent the independent and dependent variables, respectively, and a_n is the regression coefficient for the independent variables.

In the present context, five independent PLS equations will be obtained after the design of the PLS model using the spectroscopic information as independent variables (same variables as the BNN). A first equation will be used to estimate the EVOO content, and four others will be employed to determine the adulterating oil, which is comparable to the five outputs from the BNN. These last four equations act as discriminators, in other words, forming a PLS discriminant analysis, as the results are categorical, and, moreover, a PLS-2 model, because there are more than two groups (four adulterants) to be classified.[26]

The PLS models have been carried out through the software Statgraphics Centurion XVI.

Artificial Neural Networks. ANNs were chosen for this task due to their ability to find and adequately interpret nonlinear relationships between different variables in databases. This principal characteristic and also advantage of ANNs enables them to work with different oil mixtures at the same time, providing a versatility and flexibility that classic lineal models do not offer.[27] In addition, these algorithms have been employed by the authors in the past to achieve other olive oil adulteration-related tools and applications.[23,24]

In the present scenario, multilayer perceptron (MLP)-based ANNs have been employed. MLPs are one of the most used ANNs thanks to their notable results in many fields such as food technology,[24] chemistry,[25,27,28] and nanochemistry.[29]. The specific MLP used was a BNN.

These tools are composed by three different layers as can be seen in Figure 1: the input layer, the hidden layer, and the output layer. The

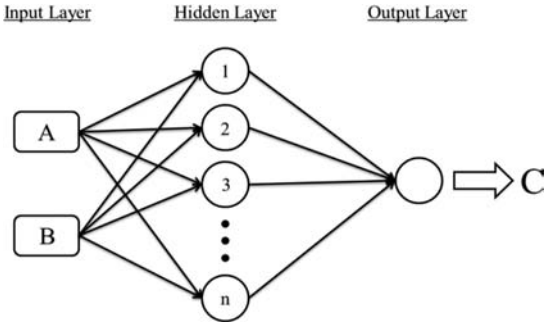

Figure 1. Multilayer perceptron scheme, where *A* and *B* are independent input variables and *C* is the dependent output variable.

first one is made of nodes in charge of introducing all of the data into the BNN, and the other two layers are formed by neurons, which are the calculation centers responsible of transforming the input signals into processed output responses, and in the present case, they all employed a sigmoid transfer function to carry out the nonlinear calculations.[30]

The signals that enter a neuron can come from another neuron or have an external origin and are modulated by weights. These weights control the connection between emitting nodes or neurons and receiving neurons. Therefore, their optimization is essential for the correct functioning of the network.[31] The way this optimization is carried out is further explained in the Supporting Information.

The learning process of a supervised neural network, such as BNNs, is carried out entering paired input−output values into the network, or, in other words, labeled data. It is based on a series of iterative calculations that minimize the difference between the real value and the one estimated by the network, therefore lowering the prediction error of the model. During this learning process, the network adjusts its parameters until obtaining weight values capable of representing the studied sample. However, the training of the network must be controlled; otherwise, "underachieving" or "over-fit" models can result. The first type takes place when the given input values are not representative or the model has not been correctly designed, and the network is incapable of defining nonlinear trends. The second undesired phenomenon is caused by excessive training, and the obtained relationships do not correspond to the wanted properties or characteristics, but to intrinsic characteristics of specific data points such as noise or experimental error.

To avoid these undesirable effects, the database used to optimize the weights is divided into two parts; training data and verification data. The training data are used to modify and optimize the weights and the verification data to analyze the applicability or generalizing capacity of the model. The goal of this second step is to stop the training cycles when the error in the estimation of these verification data points starts to increase, thus avoiding overtrained systems.[32] While the iterative process takes place, using the training data, the prediction error is reduced progressively. Meanwhile, with the verification data the weights are not modified, so the prediction error decreases until it reaches its minimum value for certain specific weights, and after that it begins to increase if the weights continue optimizing for the training data. In that precise moment the model is

DOI: 10.1021/acs.jafc.5b01700
J. Agric. Food Chem. 2015, 63, 5646−5652

considered to be optimized and the iterative calculations come to an end.[27,33]

Once the learning is completed, a representative algorithm that can interpret the relationship between the input and the output is obtained, enabling the network to generate adequate outputs for new inputs, not comprised in the learning process.[25] It is important to highlight that these mathematical tools are designed to carry out very precise interpolations, but they do not give satisfactory results when the provided data points are outside the operation range of the network.[31] In other words, ANNs are not made for extrapolating.

All of the BNN calculations have been developed through Matlab version 7.0.1.24704 (R14).[34]

Optimization of the BNN. The used BNN was designed to estimate five variables (five output neurons), four of them (CO, SO, OOO, and ROO) with a classifying purpose to identify the specific adulteration, and the fifth one (EVOO %) to quantify the volume percentage of EVOO in the mixture. The adulterants were detected with an identification vector composed by four outputs, one per adulterant, being [1, 0, 0, 0] for CO, [0, 1, 0, 0] for SO, [0, 0, 1, 0] for OOO, and [0, 0, 0, 1] for ROO.

The numbers of input nodes and output neurons are defined according to the available information and to the specific task required, respectively. In this case, visible absorption data of the adulterated EVOO samples were employed for the posterior detection of adulterants and quantification of Picual EVOO in the mixtures.

Another relevant process is the selection of an adequate training function as it controls the algorithms in the learning process of the model. Therefore, it is very important to choose a function that generates low estimative errors, thus ensuring the correct functioning of the BNN.[35] Between all of the analyzed training functions, the Levenberg−Marquardt algorithm (TrainLM) and the Bayesian regularization algorythm (TrainBR) offered a correct performance, so they were both further studied and the better one was selected for the final model. When working with medium size networks as in the present work, TrainLM is the fastest, and it also has a memory reduction feature for large training sets. On the other hand, TrainBR is a modification of the before-mentioned algorithm, and it reduces the difficulty of finding the optimum network topology as well as creating networks that generalize well.[35]

Besides the already mentioned optimization steps, to achieve a functional model, the hidden neuron number (HNN), the learning coefficient (L_c), and its own controlling parameters were also optimized.[34] The HNN must be modified until optimum performance of the model is achieved, and the chosen strategy was a heuristic approach,[32] considering that the number of neurons or weights to be optimized should not be higher than half of the amount of samples to avoid overfitting effects. On the other hand, L_c and its decreasing (L_{cd}) and increasing (L_{ci}) factors were optimized using a thorough experimental design based on the Box−Wilson Central Composite Design 2^3 + start points.[32] The experimental design has been done using Statgraphics Centurion 16.1.18.

Validation of the BNN. Once the BNN was adequately trained or optimized, an internal validation procedure was carried out to evaluate the performance of the BNN[36] in terms of adulterant identification and Picual EVOO quantification. This validation process consists of dividing randomly the database into three different groups of data: training, verification, and simulation, containing 70, 20, and 10% of the data, respectively. Three individual and randomized internal validations were carried out.

RESULTS AND DISCUSSION

Visible Spectroscopy. Different spectra of samples of the pure oils (Picual EVOO and four adulterants) were taken as a preliminary analysis of the compounds prior to their study in mixtures. According to the studies of Mínguez-Mosquera et al., chlorophyll (420 and 670 nm) and carotenoids (470 and 495 nm) present in oils are responsible for their absorption bands in the visible spectra.[37] The visible spectra of the pure Picual EVOO (Figure 2) and the four adulterants (Figure 3) are shown. Absorption between 400 and 500 nm can be observed for all five of them, whereas around 650−700 nm, only EVOO, ROO, and OOO present an absorption band.

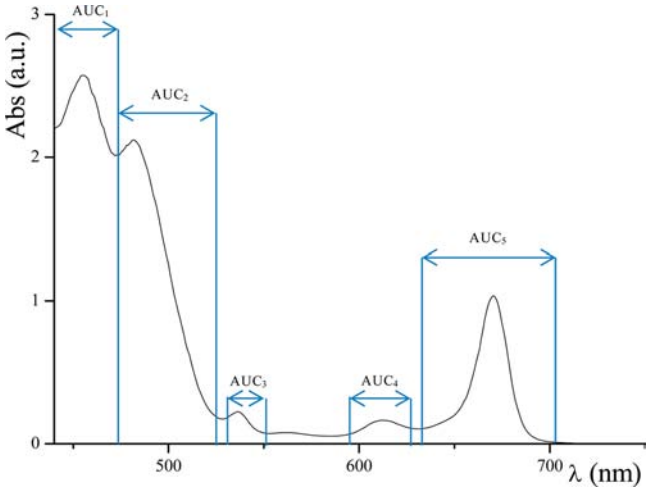

Figure 2. Visible spectrum of the pure Picual varietal EVOO used. The range of the AUC is shown.

Following this, absorption spectra of adulterated samples of Picual EVOO were analyzed. In Figure 4, examples can be found of EVOO being adulterated with ROO. The intensity of the band between 650 and 700 nm is highlighted to show how the absorption intensity decreases with greater concentrations of ROO.

The same procedure was followed for the other three adulterants (total 81 samples; data shown in the Supporting Information), and they all followed the same tendency: a lower yet specific intensity of the representative absorption bands for the samples with higher adulterant concentrations. For example, adulterants such as CO and SO originate a faster decrease in the absorption of the peak at AUC_5, compared to the effects of OOO or ROO. The reason behind this phenomenon is that neither CO nor SO presents that absorption band at that wavelength, and as absorption values are additive, this results in the mentioned quicker decline.

Even though the relationship is linear when a single binary system is analyzed, the ANN is capable of identifying four different but similar adulterants at the same time, which provides a great adaptability to the mathematical tool. This is possible due to the fact that the absorption spectra of the pure adulterants are different (Figure 3), which leads to dissimilar resulting spectra of the samples mixed with particular amounts of distinct adulterants, enabling the mathematical modeling of the system via ANNs.

Mathematical Analysis. In this subsection, two different mathematical approaches will be compared to fulfill the EVOO amount estimation and adulterant identification. First, a BNN model and all of the necessary steps to optimize it as well as to evaluate its performance will be presented, followed by a linear PLS-2 model and its validation with the same data as the BNN to achieve a controlled experiment, which enables their comparison.

Artificial Neural Networks. (a) Data Analysis for Input Selection and BNN Optimization. The information used as input in the BNN has a major influence on the correct functioning of the model. Therefore, the way in which it is presented will greatly determine the precision of the final results.

DOI: 10.1021/acs.jafc.5b01700
J. Agric. Food Chem. 2015, 63, 5646−5652

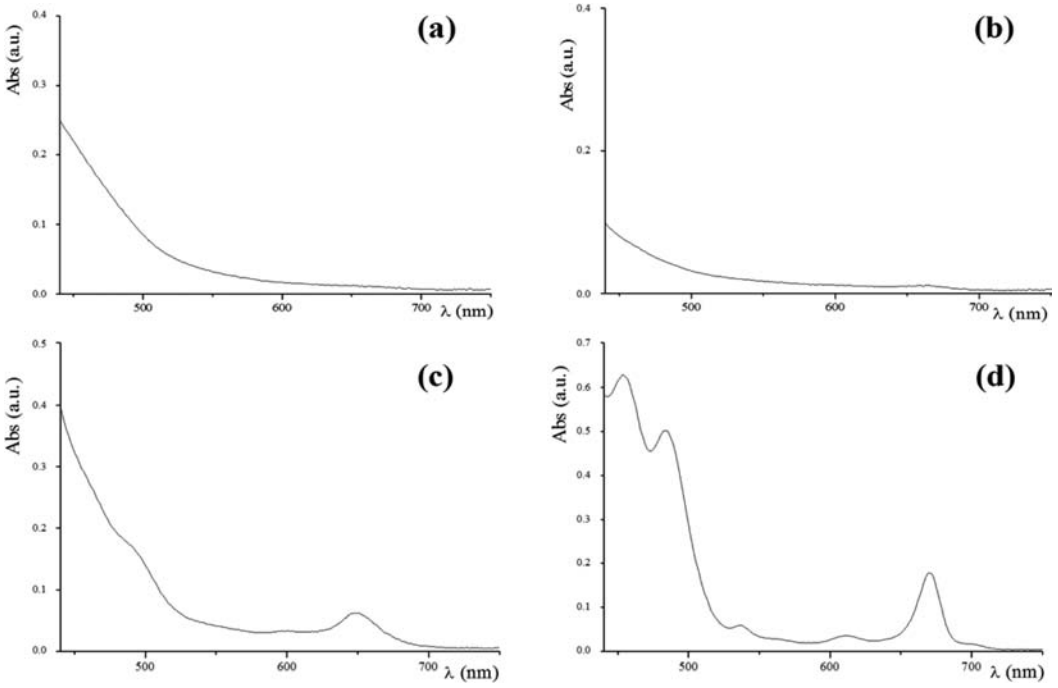

Figure 3. Absorption spectra of the four adulterants: (a) corn oil; (b) sunflower oil; (c) orujo olive oil; (d) refined olive oil.

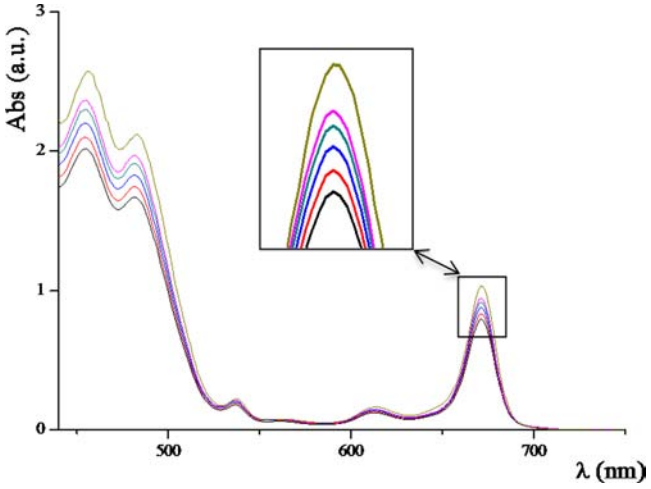

Figure 4. Absorption spectra of six samples of Picual EVOO adulterated with ROO: 100% EVOO (green), 99% EVOO (pink), 95% EVOO (greenish blue), 90% EVOO (blue), 85% EVOO (red), and 80% of EVOO (black). The absorption band centered at 670 nm is amplified to facilitate understanding the trend (same for all bands).

If all of the information contained in the absorption spectra (every wavelength−absorption pair) was used for the models, it may translate into an overfit system that would use redundant and noninformative data. Therefore, certain representative features of the obtained spectra were selected. The two types of data sets (vide supra) that were chosen as input data to simplify the calculations of the ANN were (a) five maximum absorption peaks at wavelengths 456, 483, 536, 612, and 670 nm and (b) the AUC of the previous bands, ranging from 440 to 472 nm for AUC_1, from 473 to 526 nm for AUC_2, from 529 to 551 nm for AUC_3, from 593 to 630 nm for AUC_4, and, finally, from 632 to 703 nm for AUC_5 (shown in Figure 2), which were calculated through peak integration.[32] These two sets of five inputs were used to create two BNN models.

Comparison of the results from the models that used the two different input sets is shown in Table 2. The statistical performance was much better when using the AUCs, so the maximum absorption peaks were discarded and further optimization of the model continued using only AUCs as input data. This performance was quantified through two tests, the first one being an adulterant identification rate (ideally 100%) and the second one the mean prediction error (MPE) of the estimated versus real Picual EVOO volume percentage (ideally 0%). To determine the identification rate, the four identifying outputs provided by the BNN are transformed into vectors containing a single "1" and three "0" (greatest value converted into "1"). The resulting estimated vectors are compared with the real ones to determine the final identification rate. On the other hand, to assess the Picual EVOO amount estimation, the MPE was calculated according to eq 2

Table 2. Results Obtained for the Different Input Sets, the Different Training Functions Assessed, and the HNN Study[a]

parameter optimized	option or amount	identification rate (%)	MPE of the volume percentage of EVOO (%)
input set	Abs_{max}	83	1.3
	AUC	**100**	**0.6**
training function	**TrainLM**	**100**	**0.6**
	TrainBR	100	1.0
HNN	3	100	1.3
	4	100	1.0
	5	**100**	**0.6**

[a] L_c, L_{cd}, and L_{ci} parameters kept the default values of the software (0.001, 0.1, and 10, respectively) during these three steps (best and selected choices in bold).

DOI: 10.1021/acs.jafc.5b01700
J. Agric. Food Chem. 2015, 63, 5646−5652

$$\mathrm{MPE} = \frac{1}{N}\sum_{k=1}^{N}\frac{|r_k - y_k|}{r_k} \times 100 \quad (2)$$

where N represents the number of data evaluated, r_k is the real value and y_k is the value estimated by the network (vide supra).

Once the input data that provided the best results had been selected, the selection of the training function was performed. In Table 2 the results of the two functions used, TrainBR and TrainLM, are shown. The TrainLM function gave the lowest MPE, thus eliminating TrainBR from the next step of optimization of the model.

Next, considering the amount of data points, the range of HNN was studied between three and five, so that the number of weights stayed below or near half the number of data points and, therefore, avoiding the mentioned overfitting models. The results can be seen in Table 2, and they show that the network is more accurate when it contains five hidden neurons.

As said before, the parameters L_c, L_{cd}, and L_{ci} are optimized following an experimental design based on the Box−Wilson Central Composite Design 2^3+star points". L_c and L_{cd} were analyzed between 0.001 and 1, whereas L_{ci} was studied between 2 and 100. The combination of these three parameters that provided the lowest errors was employed in the final optimized version of the nonlinear model (Table 3).

Table 3. Optimized Parameters of the Final BNN Model

parameter	results
input variables	AUC
training function	TrainLM
HNN	5
L_c	0.51
L_{cd}	0.002
L_{ci}	98

Finally, in Table 3 all of the selected and optimized parameters for the final BNN model are shown. The combination of these parameters enables the design of an ANN that is capable of accurately detecting adulterants in binary mixtures and quantifying the volume percentage of Picual EVOO within the range of the studied samples.

(b) BNN Validation. The results of the three independent internal validation tests performed for the optimized BNN are shown in Table 4.

Table 4. Results of the Internal Validation of the BNN Model (n = 8 per Validation)

internal validation	identification rate (%)	MPE of the volume percentage of EVOO (%)
1	100.0	0.9
2	87.5	1.8
3	100.0	0.9
mean value	**95.8**	**1.2**

The final results demonstrate that the designed model is able to determine the type of adulterant present in a contaminated sample of EVOO with high precision, giving an identification rate of 96% (23/24 correctly classified). It can also estimate the volume percentage of the pure EVOO in the mixture with a low mean prediction error of 1.2%.

Linear Models To Compare with BNN. A PLS-2 model was designed to compare the results with those attained through the BNN. The resulting five equations were used to estimate each of the five outputs defined for the nonlinear MLP. This was carried out three times independently, using the same data and independent variables (five AUCs) contained in the training and verification data sets of the internal validations of the BNN to make the results comparable. The final statistical performance is evaluated by testing the resulting PLS models with the 10% of the data not employed during their construction (same as simulation data sets from the BNNs; vide supra). The regression coefficients for all the PLS models are shown in the Supporting Information (Tables S1−S3). In Table 5, the results for each PLS model are shown, which are comparable to those shown in Table 4.

Table 5. Results of the Tests of the Different PLS Models Using the Same Data from the Internal Validations of the BNN (n = 8 per Validation)

PLS model (comparable to internal validations)	identification rate (%)	MPE of the volume percentage of EVOO (%)
1	100.0	1.2
2	75.0	1.8
3	87.5	1.6
mean value	**87.5**	**1.5**

The results offered by the linear PLS models are accurate in terms of both EVOO amount estimation (1.5% MPE) and adulteration identification (87.5%; 21/24 correctly classified). Nevertheless, these results are worse when compared with the BNN model optimized, showing one of the advantages of the nonlinear alternative. In contrast, the PLS models are much easier and faster to develop, as they do not present the amount of optimization steps that neural networks do.

In this work, we have successfully estimated the amount of EVOO in contaminated samples (MPE = 1.2%), as well as accurately identified the presence of four different adulterants (96% accuracy) using a nonlinear BNN and visible absorption spectroscopy. In comparison to other techniques of adulterant determination and authentication of EVOO, such as GC-MS used by Yang et al., we can observe that their identification rate is of 88.5%.[38] On the other hand, HPLC used by De la Mata-Espinosa et al. gave a root-mean-square error of prediction of 10% for the adulterant determination,[21] whereas that same error calculated with the results here obtained is of 9.5%. This is very interesting considering that our technique is much cheaper and less time-consuming than GC-MS or HPLC.

In terms of being user-friendly and requiring a low sample treatment, FT-IR spectroscopy is close to vis spectroscopy. It was employed by Oussama et al., who combined it with a lineal mathematical model (PLSs together with variable importance in projection), which resulted in a relative prediction error of 3% for the oil composition and an identification rate of 100% for two types of adulterant,[39] in contrast to the four adulterants analyzed here with a single and adaptable nonlinear MLP.

These notable results enable our flexible and updatable nonlinear model to compete with techniques such as FT-IR,[39] GC-MS,[38,40] NMR,[41] or HPLC,[21] simply by employing absorption information. Furthermore, some of the advantages of the proposed methodology are its speed and straightforwardness due to minor necessary sample treatments. The employment of the equipment is noncomplicated, and additionally it is nondestructive (samples do not suffer any alteration). The use of solvents is low, which decreases the cost of the already

DOI: 10.1021/acs.jafc.5b01700
J. Agric. Food Chem. 2015, 63, 5646−5652

inexpensive approach. Finally, it offers the possibility of applying this method for real-time applications such as EVOO online monitoring and control, which is useful for both producers and distributors.

J. Agric. Food Chem. 2015, 63, 5646−5652

Three commercially available elderberry genotypes (Adams II, Bob Gordon, and Wyldewood) were used. These three genotypes have widely disparate geographic origins, originating from wild genetic material in New York, Missouri, and Oklahoma, respectively. Phenotypically, they behave differently when cultivated side-by-side, suggesting that there are inherent genetic differences among them.[19] Experimental plots contained four plants of the same genotype, planted 1.2 m apart. Forty-eight plots were established in four rows, with plots separated 2.4 m within and 3.1 m between rows. The three genotypes were assigned to 16 of the 48 plots in a completely randomized manner. The total number of plants was 192, and the site covered 0.10 ha. The site was prepared by killing existing vegetation in the planting rows with glyphosate herbicide prior to planting, and alleyways of mixed grasses were maintained and mowed during the study. Throughout the study, plants were irrigated via drip lines to provide 2.5−4.0 cm water per week when rainfall was lacking. Weeds were managed with mulch, hand weeding, and herbicides (glyphosate, clethodim); no insecticides or fungicides were used.

For this study, fresh ripe fruit was harvested from 39 of the 48 plots on August 26−27, 2013, promptly refrigerated, transported under refrigeration to the laboratory on August 28 for analysis, and stored at −80 °C for 1 week. Elderberry samples were then thawed, destemmed, and hand pressed into juice. All other debris, pulp, and seeds were discarded. The juice obtained was filtered through a nylon filter (0.22 μm), and 1.5 mL of each replicate was individually aliquotted into 1.5 mL microcentrifuge tubes and stored at −20 °C The samples were screened for TP, TMA, and IAC initially and after 3, 6, and 9 months of frozen storage. Samples were thawed, an aliquot was removed for analysis, and then the samples were refrozen for future analysis. The number of independent juice samples ranged from 11 to 14 for each of the three genotypes for all assays conducted.

Chemicals. Cyanidin 3-*O*-glucoside chloride analytical standard (≥95%), Folin−Ciocalteu's phenol reagent, sodium acetate trihydrate (≥99.0%), and gallic acid (97.5−102.5%) were purchased from Sigma-Aldrich (St. Louis, MO, USA). Ammonium hydroxide (Optima), sodium carbonate anhydrous (certified ACS powder), potassium chloride (certified ACS crystalline), hydrochloric acid (Optima), water (HPLC grade), formic acid (HPLC grade), and acetonitrile (HPLC grade) were purchased from Fisher Scientific (Fair Lawn, NJ, USA). Trifluoroacetic acid (TFA; 99%) used for acidifying solid phase extraction (SPE) mobile phase was purchased from Acros Organics (Morris Plains, NJ, USA).

Total Phenolic. Folin−Ciocalteu's method was used with slight modifications.[20] Juice samples were initially diluted 100-fold with water, then 0.5 mL of Folin−Cicoalteu's phenol reagent (diluted 10-fold) was added, followed by 0.4 mL of sodium carbonate (75 g/L) after 30 s, but before 8 min. Samples equilibrated at room temperature, in the absence of light, for 2 h. Absorbance measurements were taken in triplicate at a wavelength of 760 nm with a PerkinElmer Enspire 2300 multimode plate reader. Five gallic acid standards of 25, 50, 100, 200, and 400 μg/mL were prepared in the same manner as the samples. The TP concentrations are expressed as gallic acid equivalents (mg GAE/mL).

Total Monomeric Anthocyanin. The TMA content of elderberry juice was measured utilizing the pH-differential method.[21] Elderberry juice samples were diluted 200-fold in potassium chloride (pH 1.0) and sodium acetate (pH 4.5) buffers and equilibrated for 60 min at room temperature. Five cyanidin 3-*O*-glucoside standards of 2, 4, 6, 8, and 10 μg/mL were prepared in the same manner as the samples. Absorbance measurements were taken in triplicate at wavelengths of 520 and 700 nm in each buffer solution. Equation 1 shows how the final absorbance values were obtained. TMA concentrations were determined using a standard curve and are expressed as cyanidin 3-*O*-glucoside equivalents (mg C3GE/mL). The standard solution concentrations were verified using the molar extinction coefficient of cyanidin 3-*O*-glucoside (MW 449.2 g/mol, ε = 26900 M^{-1} cm, λ = 520 nm).[22]

$$A = (A_{520} - A_{700})_{pH1.0} - (A_{520} - A_{700})_{pH4.5} \quad (1)$$

Solid Phase Extraction. Mixed-mode cation-exchange chromatography was employed to isolate the anthocyanins from the other potentially interfering compounds in the juice matrix.[4] Oasis MCX 3 cm^3 (60 mg) extraction cartridges were used with a Supelco Visiprep SPE vacuum manifold, operated at 10 ± 2 in.Hg. Columns were initially conditioned with 2 mL of acidified water (0.01% TFA). After conditioning, 50 μL of juice was added, followed by an additional 2 mL of water (0.01% TFA) and 2 mL of methanol (0.01% TFA). Then 1 mL of methanol (1% NH_4OH) and 1 mL of 40:60 water/methanol (1% NH_4OH) were added, and these two eluates were combined for analysis. Ten microliters of formic acid was added to reacidify the solution. The solvent was evaporated with a constant flow of nitrogen gas. Dry samples were redissolved in 1 mL of water (4.5% formic acid) and refrigerated until analysis.

Juice samples were spiked with three concentrations of cyanidin 3-*O*-glucoside standard before the extraction step to assess the overall recovery rate of the SPE procedure. The cyanidin 3-*O*-glucoside concentration of the spiked juice sample was compared to that of a control juice sample. The percent recovery was calculated using eq 2.

$$\frac{\text{spiked sample concn} - \text{control sample concn}}{\text{concn of standard added}} \times 100\% \quad (2)$$

The average SPE recovery of cyanidin 3-*O*-glucoside ranged from 94 to 107% (Table 1). Three different volumes of cyanidin 3-*O*-glucoside standard spiking solution were used to analyze recovery over a range of concentrations. Acceptable recovery was seen for all volumes of concentrations added.

Table 1. Average Recovery of Elderberry Juice Spiked with Three Different Cyanidin 3-*O*-Glucoside Concentrations before SPE[a]

	av response	C3GE (ng/mL)	C3GE added (ng/mL)	av recovery (%)
control	220,956	525.2		
2 μL spike	340,669	808.3	298.4	94.9 ± 0.8
3 μL spike	395,931	938.0	439.2	94 ± 1
5 μL spike	539,214	1,277.8	705.5	107 ± 1

[a]Three independent samples were tested for each spike concentration. Concentrations were measured using UPLC-MS/MS and are represented as C3GE (ng/mL). Concentrations of the spiked juice sample are compared to the concentration of the control juice sample. Recoveries are represented as a percentage ± the standard error of the mean (n = 3).

Ultraperformance Liquid Chromatography−Tandem Quadrupole Mass Spectrometry (UPLC-MS/MS). A previously described UPLC-MS/MS method was followed for anthocyanin quantification.[23] A Waters Acquity ultraperformance liquid chromatograph with a quaternary solvent manager was used. A C18 column (Acquity BEH, 1.7 μm, 50 mm × 2.1 mm, Waters, Milford, MA, USA) was selected to separate anthocyanins. The mobile phases used were water A (4.5% formic acid) and acetonitrile B (0.01% formic acid). The gradient used was 95% A at 0 min, 91% A at 2.5 min, 85% A at 3.5 min, 5% A at 4 min, and 95% A at 4.8 min. The flow rate was 400 μL/min, and the sample injection volume was 10 μL in full loop mode. The column and sample chamber were kept at ambient temperature.

A Waters Xevo TQ-S triple-quadrupole mass spectrometer with electrospray ionization (ESI) in the positive ion mode was used. Multiple reaction monitoring scans were conducted by selecting the parent and daughter ion masses of the anthocyanins. A desolvation temperature of 350 °C and a source temperature of 150 °C were used. A capillary voltage of 2.0 kV and cone voltage of 20 V were used, and the nebulizer gas rate was 500 L N_2/h. Individual collision energies were manually optimized. MassLynx software (version 4.1, Waters) was used for all data acquisition. Six cyanidin 3-*O*-glucoside external standards of 1, 10, 100, 200, 500, and 1000 ng/mL were prepared and used to quantitate IAC. Samples were measured in triplicate, and concentrations were determined on the basis of their ion chromato-

cyanidin 3-*O*-glucoside	449.1	287.1	3.66
cyanidin-based anthocyanin	785.3	287.1	4.45

Statistical Analysis. Data analysis was carried out in Matlab, version 8.3 (Mathworks, Natick, MA, USA). One-way ANOVA was performed to compare the effects of frozen storage on the TP and TMA contents of the elderberry juice samples. The Tukey honestly significant difference (hsd) test was conducted to compare the TP and TMA values of the same genotype at different time points during long-term frozen storage and also to compare the TP and TMA values of the three genotypes at the same time points, both done at the 95% confidence interval. Two-way t tests were performed at the 95% confidence interval to analyze the difference in IAC during frozen storage.

RESULTS AND DISCUSSION

Freeze–Thaw Analysis. The TMA content of juice samples was tested to determine if sample degradation occurs by repeated freeze–thaw cycles. Samples were initially thawed and analyzed for TMA content, frozen overnight (−20 °C), and tested each day for 4 days. Each genotype included seven independent samples (n = 7). The TMA content of the juice did not have a significant difference between any of the freeze–thaw cycles ($p > 0.05$). This was true for all three genotypes over the course of all freeze–thaw cycles.

Total Phenolic Content. The TP content was significantly different among all three genotypes initially ($p < 0.05$), suggesting genotype plays a role in TP content of elderberry fruit juice, as also shown in other papers.[14,15] Bob Gordon contained the highest TP content initially (8.1 ± 0.3 mg GAE/mL) followed by Wyldewood (6.7 ± 0.1 mg GAE/mL) and Adams II (5.6 ± 0.3 mg GAE/mL) (Figure 1). After 3 months of frozen storage, Bob Gordon had a significantly higher TP content compared with Adams II and Wyldewood; however, the latter two genotypes were not significantly different. Each genotype displayed the same trend of losing a statistically significant ($p < 0.05$) amount of polyphenols during the first 3 months of storage (Figure 1) and then remained rather stable for the course of the storage study. By the end of 9 months of frozen storage, all of the genotypes still had at least 72% of their initial polyphenol content. Some of this TP loss can be attributed to anthocyanin degradation, which is discussed further below. Therefore, the other nonanthocyanin polyphenols in elderberry fruit juice exhibited greater stability during long-term frozen storage.

Total Monomeric Anthocyanin Content. The initial TMA content of the Bob Gordon juice was also significantly different from the Adams II and Wyldewood juices ($p < 0.05$), suggesting that the genetics of the elderberry fruit is one factor that influences the anthocyanin content of the juice (Figure 2). Once again, Bob Gordon had the highest concentration initially (3.8 ± 0.2 mg C3GE/mL) followed by Wyldewood (2.4 ± 0.2 mg C3GE/mL) and Adams II (1.8 ± 0.2 mg C3GE/mL). However, after 3 and 6 months of frozen storage, the three genotypes possessed significantly different TMA contents from each other (Figure 2). Not only did the Bob Gordon genotype have the highest TMA content, but it also had the highest anthocyanin percentage of the TP content at 47% anthocyanin, followed by 36 and 32% for Wyldewood and Adams II, respectively. In another study involving American elderberry

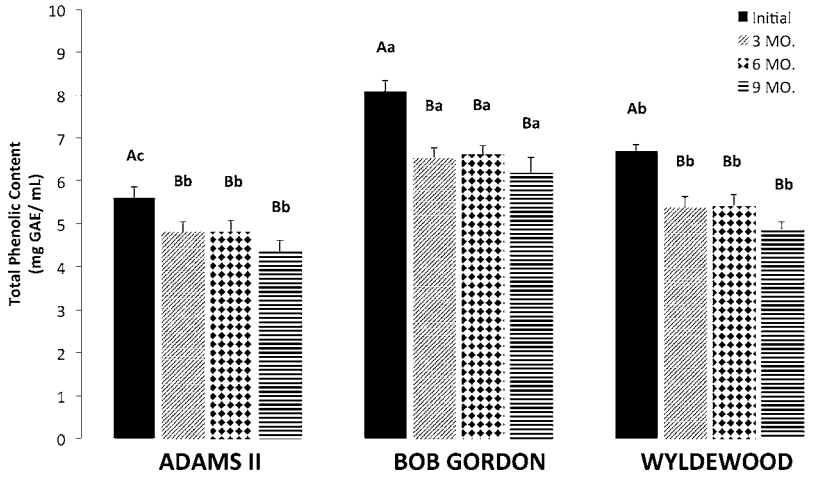

Figure 1. Total phenolic (TP) content of Adams II, Bob Gordon, and Wyldewood genotypes. The data are represented as the mean ± the standard error of the mean (n = 11–14). Each bar indicates the time period of testing, starting with the initial test, 3 months, 6 months, and 9 months (left to right). Significant differences ($p < 0.05$) between TP content of frozen storage periods are represented by different letters (A is significantly different from B, but AB is equivalent to both A and B groups, for example), according to Tukey's honest significance test. Significant differences ($p < 0.05$) between TP content between each genotype during the same time periods are indicated by different lower case letters.

J. Agric. Food Chem. 2015, 63, 5653–5659

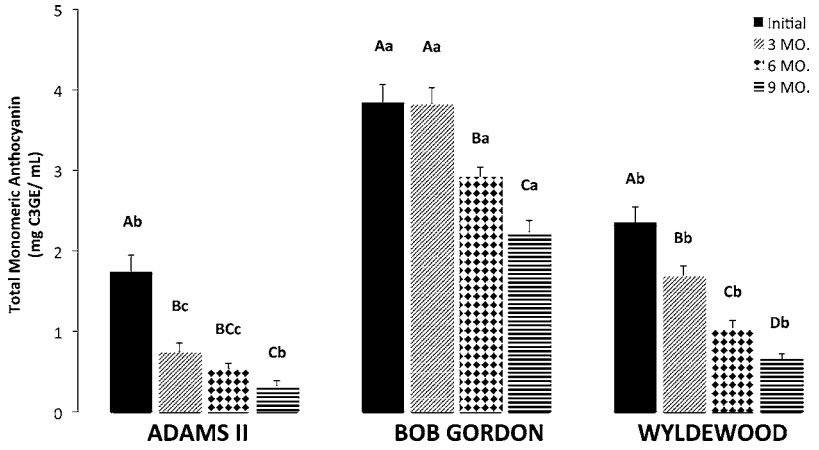

Figure 2. Total monomeric anthocyanin (TMA) content of Adams II, Bob Gordon, and Wyldewood genotypes. The data are represented as the mean ± the standard error of the mean (n = 11−14). Each column indicates the time period of testing, starting with the initial test, 3 months, 6 months, and 9 months (left to right). Significant differences ($p < 0.05$) between TMA content of frozen storage periods are represented by different letters (A is significantly different from B, but AB is equivalent to both A and B groups, for example), according to Tukey's honest significance test. Significant differences ($p < 0.05$) between TMA content between each genotype during the same time periods are indicated by different lower case letters.

fruit, the TMA content of 14 different elderberry fruit accessions varied highly (37.5%), which was much more than the 14.4% TP variance among accessions.[10] This suggests that the anthocyanin content is more susceptible to changes than other polyphenols based on the genotype, growing conditions, location, year, and other factors, which is in good agreement with our results. Future studies investigating these parameters would be helpful to understand how to optimize and preserve anthocyanins in elderberry fruit.

There were large differences in the stability of the anthocyanins during frozen storage among genotypes. Bob Gordon showed the best TMA stability during the first 3 months of frozen storage (Figure 2), whereas the other two genotypes saw a significant decline in TMA content during this time. All three genotypes saw a significant and relatively similar decline in TMA content from 3 to 6 months and also from 6 to 9 months of frozen storage. Bob Gordon retained 99, 76, and 58% of its initial anthocyanins during 3, 6, and 9 months of storage, respectively. Wyldewood retained 72, 44, and 28% and Adams II 42, 30, and 18% of their initial anthocyanins during 3, 6, and 9 months of storage, respectively. These large differences during frozen storage suggest that the genetics of the fruit also influence the stability of anthocyanins in the juice matrix, with an increase in storage time adversely affecting the TMA content of the juice.

Thomas et al. tested elderberry fruit for TMA and included the same three genotypes as in this study.[14] The TMA contents of their samples are in good agreement with the values obtained from this study, showing that Bob Gordon was more concentrated in anthocyanins than Wyldewood and Adams II, strengthening the hypothesis that the genotype of elderberry is a primary factor influencing the anthocyanin composition of the berry.

There are a variety of processes that could cause a decrease in the TMA content of the juice during frozen storage. For instance, enzymatic degradation could have contributed to anthocyanin loss, especially because the juice samples were not heated during processing. During the study, the same samples were thawed and refrozen every 3 months for analysis. Reactivation of enzymes upon repeated thawing could possibly cause anthocyanin degradation or polymerization. Nonenzymatic polymerization is also possible due to condensation reactions between anthocyanins and proanthocyanidins. To explore the role of sample degradation due to repeated freeze−thaw cycles, juice samples were tested for their integrity over multiple cycles to ensure any anthocyanin loss was due to long-term frozen storage and not another cause. During this test, there were no significant differences ($p > 0.05$) in TMA content of any of the genotypes of juice during the initial testing and after 4 days of daily freeze−thaw cycles, strengthening the theory that long-term frozen storage contributes to anthocyanin loss in elderberry juice.

Individual Anthocyanin Content. Three main individual anthocyanin compounds, among all three genotypes, were identified using SPE coupled with UPLC-MS/MS: cyanidin 3-*O*-coumaroyl-sambubioside-5-glucoside, cyanidin 3-*O*-sambubioside-5-glucoside, and cyanidin 3-*O*-sophoroside (Table 3). Six other cyanidin-based anthocyanins were also present in the juice samples in smaller quantities, including cyanidin 3-*O*-coumaroyl-sambubioside, cyanidin 3-*O*-rutinoside, cyanidin 3-*O*-sambubioside, cyanidin 3-*O*-galactoside, cyanidin 3-*O*-glucoside, and a cyanidin-based anthocyanin with a tentative identification (Table 3). These nine anthocyanins were the ones present in highest concentration after SPE and represent a cross section of the anthocyanins present in elderberry juice. An example of one MRM ion channel chromatogram of cyanidin 3-*O*-coumaroyl-sambubioside-5-glucoside of a Wyldewood juice sample is presented in Figure 3. The integrated ion signal listed under the retention time indicated in the figure is used to quantitate IAC. Four chromatograms, one for each test period, are presented, and a decrease in ion signal over time was seen. A continual decrease in concentration of this particular individual anthocyanin occurs as a function of increased frozen storage time, because the area under the chromatographic peak decreases over time.

Lee and Finn showed that individual anthocyanin profiles vary dramatically between *Sambucus nigra* subsp. *canadensis* and subsp. *nigra*.[24] Cyanidin 3-coumaroyl-sambubioside-5-glucoside and cyanidin 3-sambubioside-5-glucoside were identified as the major individual anthocyanin components in subsp. *canadensis* in their study and are also two of the three main individual anthocyanins found in the three subsp. *canadensis* genotypes in

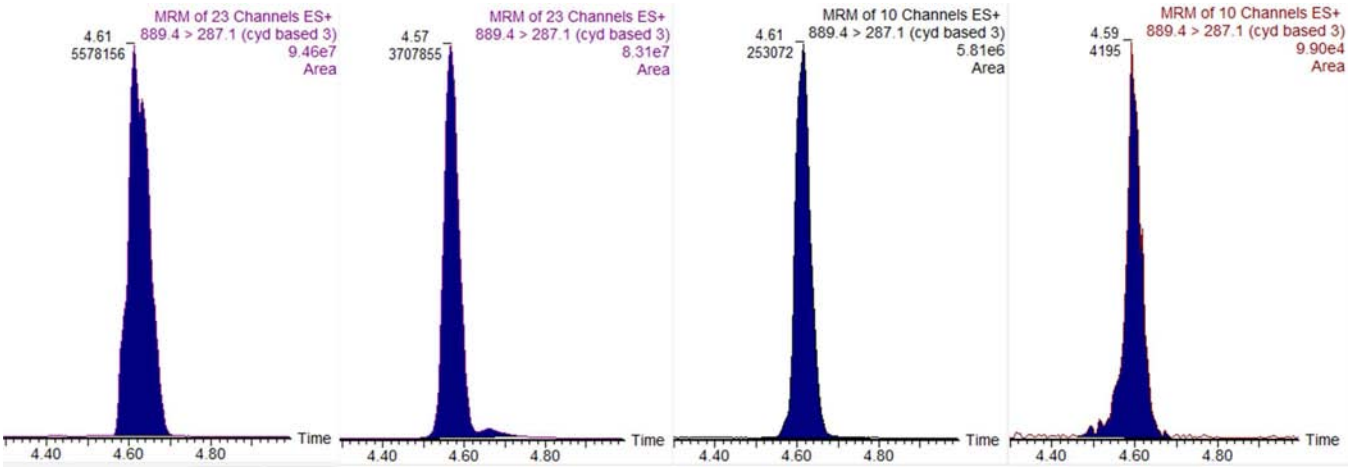

Figure 3. Ion chromatograms for cyanidin 3-*O*-coumaroyl-sambubioside-5-glucoside anthocyanin initially and after 3, 6, and 9 months of frozen storage (left to right). The retention time (min) and integrated area used for quantitation are listed at the top of each peak.

the present study. Most of the prior work analyzing the anthocyanin content of elderberry involves subsp. *nigra*[1] and identifies cyanidin 3-*O*-glucoside as a major individual anthocyanin. Cyanidin 3-*O*-glucoside is present in subsp. *canadensis*, but in much smaller quantities (Table 3), which agrees well with Lee and Finn, who tested both subspecies for IAC.[23] Although the magnitudes of IAC were different initially among the three genotypes, the relative compositions or contributions of each individual anthocyanin to the total IAC were extremely similar, especially between Adams II and Wyldewood. Bob Gordon also had a similar relative composition, except the cyanidin 3-*O*-sophoroside content was almost 2-fold higher than those of the other two genotypes. This could have relevance in future biochemical studies. Kamonpatana et al. showed that the structure of the anthocyanin affects the stability of the molecule in the human oral cavity, and some anthocyanins are more readily available for uptake by the buccal cells, whereas others degrade quickly in the mouth.[25] Between their different stabilities in vivo and during storage, anthocyanins do not interact equally. This information regarding higher levels of certain anthocyanins in different genotypes underscores the importance of developing new cultivars of fruit with different anthocyanin profiles.

Bob Gordon (198 μg C3GE/mL) had the highest IAC, followed by Wyldewood (84 μg C3GE/mL) and Adams II (78 μg C3GE/mL), respectively (Table 3). A large decline in IAC in the Adams II genotype is seen after 3 months of frozen storage, and although there is a statistical difference between Bob Gordon and Wyldewood IAC after 3 months of frozen storage, the anthocyanins are much more stable in these two genotypes during long-term frozen storage (Table 3). This trend is seen in both the cyanidin 3-*O*-coumaroyl-sambubioside-5-glucoside and cyanidin 3-*O*-sambubioside-5-glucoside anthocyanins. It is also interesting to note that cyanidin 3-*O*-sophoroside content varies highly between the genotypes initially (Table 3).

The individual anthocyanins in elderberry juice are less stable during frozen storage compared to the monomeric anthocyanins. Bob Gordon retained 65, 22, and 2% of its total IAC during 3, 6, and 9 month of frozen storage, respectively (Table 3). Wyldewood and Adams II retained 65, 10, <1% and 29, 10, and 0% of their IAC during 3, 6, and 9 months of frozen storage, respectively. These results suggest that prolonged frozen storage has a significant impact on the anthocyanin content of elderberry fruit juice. The different sugar-containing moieties may play a role in the stability of the anthocyanins during storage. It is difficult to identify a trend in the individual anthocyanins with a very small contribution because a majority fall below the detection limit after 3 months of frozen storage. Cyanidin 3-*O*-coumaroyl-sambubioside was the least stable during storage among all three genotypes, retaining <38% IAC in all three genotypes after 3 months of frozen storage. Cyanidin 3-*O*-coumaroyl-sambubioside-5-glucoside and cyanidin 3-*O*-sambubioside-5-glucoside showed much better stability in Bob Gordon with 84 and 78% anthocyanin retention, respectively, and Wyldewood with 75 and 69% anthocyanin retention, respectively.

Individual anthocyanins also displayed different stabilities between genotypes. Cyanidin 3-*O*-sophoroside had very poor stability (23% retention) in Adams II, but >53% retention in both Bob Gordon and Wyldewood after 3 months of frozen storage. Cyanidin 3-*O*-sambubioside-5-glucoside displayed a very similar trend. Adams II once again had very poor stability (30%), whereas Bob Gordon (78%) and Wyldewood (68%) showed much higher anthocyanin stability after 3 months of frozen storage. Cyanidin 3-*O*-coumaroyl-sambubioside-5-glucoside had the best stability in all three genotypes during the first 3 months of frozen storage. Bob Gordon saw 84% anthocyanin retention, and Wyldewood and Adams II had 75 and 31% retention, respectively. Cyanidin 3-*O*-coumaroyl-sambubioside had the worst stability of the individual anthocyanins tested, with all genotypes having <38% of their IAC after 3 months of frozen storage. Further exploration of the juice matrix of different genotypes of elderberry fruit juice could provide insight into which compounds may contribute to increased anthocyanin stability and degradation.

We have shown that individual anthocyanin concentrations in elderberry fruit juice can vary during frozen storage, and the UPLC-MS/MS method used here yields important information that is not obtained by commonly used TP and TMA testing methods. By conducting extensive sample cleanup, potentially interfering juice matrix compounds were removed, allowing for more accurate anthocyanin quantification. More information was gathered regarding the stability of individual anthocyanins in three genotypes of elderberry juice. The TP, TMA, and IAC contents of elderberry juice varied with genotype.

every stage of pathogenesis, and apoptosis is now recognized as an integral process during the spread of atherosclerotic plaques to neighboring healthy tissue.[19] Oxidative stress and apoptosis are even more apparent in vascular tissue following an acute ischemia-reperfusion (IR) event, such as a myocardial infarct after a lesion ruptures in a coronary artery.[20,21] The lack of waste removal and uncoupling of the electron transport chain during ischemia, combined with the oxidative burst during reperfusion, lead to large amounts of reactive oxygen species (ROS) being produced in cells. Oxidative stress can trigger apoptosis by activating the mitochondrial pathway, caspases, and mitogen-activated protein kinases (MAPK).[22] High levels of oxidative stress and apoptosis therefore characterize IR-induced myocardial damage. We hypothesized that antioxidant and anthocyanin-rich Manitoba lingonberry would have a protective effect against apoptosis induced by ischemia-reperfusion.

In this study, we aimed to extract the phenolic and anthocyanic compounds found in wild lingonberry clones collected from Newfoundland and Labrador and in a composite of two wild populations of Manitoba and to examine the anti-apoptotic effects of Manitoba lingonberry extracts by measuring caspase-3 activation, nuclear condensation, and MAPK signaling in H9c2 myoblasts undergoing simulated IR injury.

MATERIALS AND METHODS

Chemicals and Materials. Optima grade methanol, acetonitrile, HPLC grade phosphoric acid, and 2,2′-azobis(2-amidinopropane) dihydrochloride (AAPH) from Wako Chemicals (Richmond, VA, USA) and all other chemicals of at least ACS reagent grade, including the selective JNK inhibitor SP600125, were acquired from Sigma-Aldrich (St. Louis, MO, USA). Reference compounds cyanidin-3-glucoside (95%) and cyanidin-3-galactoside (95%) were purchased from Chromadex (Irvine, CA, USA) whereas cyanidin-3-arabinoside chloride (>95%) was from Cerilliant Corp. (Round Rock, TX, USA).

Plastic pots were purchased from East-Chem Inc. (Mount Pearl, NL, Canada), Acrodisc syringe filters and BioTrace Nitrocellulose Transfer Membrane were acquired from Pall Corp. (Ann Arbor, MI, USA), SepPak tC18 columns were acquired from Waters Corp. (Milford, MA, USA), SensoLyte Homogeneous AFC Caspase-3/7 Assay Kits were acquired from Anaspec (Fremont, CA, USA), and cleaved poly-ADP ribose polymerase (PARP) antibody (rat specific) was purchased from Cell Signaling (Danvers, MA, USA). HRP-conjugated goat anti-rabbit IgG and western immunoblotting equipment and reagents were purchased from Bio-Rad Laboratories (Hercules, CA, USA). Personal protective equipment and laboratory safety guidelines were implemented for all experiments.

Apparatus and Software. A Milli-Q Synthesis A10 water purification system was acquired from Millipore Corp. (Billerica, MA, USA), and the SpectraMax M5 microplate reader and SoftMax Pro (version 6.2) software were acquired from Molecular Devices (Sunnyvale, CA, USA). ACQUITY ultraperformance liquid chromatography (UPLC) equipment and Empower 3 software were acquired from Waters Corp., and the AlphaInnotech FluorChemQ system was purchased from Fisher Scientific (Fair Lawn, NJ, USA). A Billups-Rothenberg modular incubator chamber was purchased from Stem Cell Technologies (Vancouver, BC, Canada), and a Sector Imager 2400 and electrochemiluminescent assay kits were purchased from Meso Scale Discovery (Rockville, MD, USA).

Berry Collection. *Eastern Canada and European Berries.* Five wild lingonberry clones, designated L3, L10, L16, L20, and L23, collected from Newfoundland and Labrador, Canada, and the European (Polish) cultivar Mesovia (L24) have been grown and maintained at the Atlantic Cool Climate Crop Research Centre, St. John's, NL, Canada, for over 10 years. Each clone represents a single plant selected from the wild on the basis of vigor, berry color, size, and yield per plant and apparent freedom from disease and insects. GPS locations of the collection sites are shown in Table 1. All genotypes were grown in a greenhouse in plastic pots (25 cm in diameter and 18 cm deep, equivalent to 6 L) containing 2 peat:1 perlite (v/v), under natural light conditions at a maximum photosynthetic photon flux of 90 μmol m^{-2} s^{-1} at 20 ± 2 °C and 85% relative humidity. Fully ripe berries were collected and were shipped to our laboratory in Winnipeg, MB, Canada, for analysis and stored at −80 °C until use.

Table 1. GPS Locations for Collection Sites of Wild Lingonberry Clones from Newfoundland and Labrador (NL) and Harvest Sites of Wild Lingonberries (Not Clones) from Manitoba (MB) and Saskatchewan (SK)

clone	province	community	latitude (N)	longitude (W)

L10	NL	L'anse aux Meadows	51°36′	55°32′
L16	NL	Logy Bay	47°37′	52°40′
L20	NL	Gunner's Cove	51°31′	55°27′
L23	NL	Lords Cove/Pump Cove	46°52′	55°40′
not clones	MB	Sherridon Lake	55°7′	101°5′
not clones	SK	Deschambault Lake	54°55′	103°21′

Manitoba Berries. Berries from two wild populations were hand-picked by local berry pickers at Deschambault Lake, SK, Canada, and Sherridon Lake, MB, Canada, in September 2011 and immediately frozen. GPS locations of harvest sites are shown in Table 1.

Extraction. Frozen berries were ground roughly in a coffee grinder, freeze-dried, and ground to a fine powder with a mortar and pestle. Methanol, ethanol, water, acetonitrile, acetone, and ethyl acetate were tested in aqueous and acidified solutions for their ability to extract phenolic compounds from lyophilized lingonberry. Acidified methanol was selected as the extraction solvent due to its ability to extract high amounts of phenolic compounds and anthocyanins while also being a compatible solvent for other analyses, such as HPLC. Extraction conditions were optimized by testing several temperatures and sonication times to maximize total phenolic and anthocyanin extraction (data not shown). Half a gram of lyophilized berry powder was extracted twice in 6 mL of methanol (2% formic acid) with 15 min of sonication at 37 °C followed by centrifugation for 15 min at 3000*g*. The supernatants from the two extractions were combined and filtered with a 0.2 μm syringe filter and stored at −20 °C. Methanol was then removed by rotary evaporation, and the remaining extract was brought back up to the original volume with ultrapure water so it could be loaded onto the SepPak columns.

Separation of Anthocyanin-Rich and Phenolic-Rich Fractions. The filtered aqueous Manitoba lingonberry extract was named the "complete extract" (CE). Eight milliliters was removed and separated into two fractions, one named the "anthocyanin-rich fraction" (ARF) and the other named the "phenolic-rich fraction" (PRF), using a protocol modified from that of Rodriguez-Saona and Wrolstad.[23] Briefly, a SepPak tC18 column (plus long cartridge, 900 mg of silica per cartridge, 37−55 μm particle size) was conditioned using methanol (0.5% formic acid), washed with ultrapure water (0.5% formic acid), loaded with 8 mL of CE, and washed again with ultrapure water (0.5% formic acid) to remove sugars and acids. Ten milliliters of ethyl acetate was used to collect polyphenolic compounds (PRF), and 5 mL of methanol (0.5% formic acid) was used to collect anthocyanins (ARF). The ethyl acetate and acidified methanol fractions were collected in separate flasks, and solvents were removed by rotary evaporation to near dryness. Both fractions were resuspended in methanol (0.2% formic acid) to one-fifth the original loaded volume. Both fractions were filtered with a 0.2 μm syringe filter and stored at 4 °C until analysis. Fractions were standardized on the basis of ORAC and total anthocyanin content.

Determination of Total Phenolics. Total phenolic contents of the complete extract and fractions were determined colorimetrically using Folin−Ciocalteu (F-C) reagent, following a protocol modified from that of Ainsworth and Gillespie.[24] Briefly, 40 μL of 25% F-C reagent and 20 μL of sample were added to a 96-well plate. After 5 min of incubation, 140 μL of an aqueous 700 mM sodium carbonate solution was added to

DOI: 10.1021/acs.jafc.5b00797
J. Agric. Food Chem. 2015, 63, 5660−5669

each well. This was followed by 2 h of incubation at room temperature, and the developed color was measured at 765 nm using a SpectraMax M5 microplate reader; data were analyzed using SoftMax Pro (version 6.2) software. All samples and standards were tested in triplicate. Results were expressed as milligram gallic acid equiv per 100 g DW of lyophilized berries using gallic acid as a standard.

Oxygen Radical Absorbance Capacity (ORAC) Assay. The oxygen radical absorbance capacities of all samples were determined fluorescently using AAPH as a peroxyl generator to oxidize fluorescein, following a method modified from that of Gillespie, Chae, and Ainsworth.[25] Briefly, 25 μL of sample or standard was incubated with 75 μL of a 0.2 μM fluorescein solution for 10 min with agitation at 37 °C. After incubation, 100 μL of a 37 mM AAPH solution was added to each well. Loss of fluorescence intensity was measured kinetically at 1.5 min intervals over 60 min using a SpectraMax M5 microplate reader, and data were analyzed using SoftMax Pro (version 6.2) software. All samples and standards were tested in triplicate. Results were expressed as micromole Trolox equiv per 100 g DW of lyophilized berries using Trolox as a standard.

Determination of Total Anthocyanins. The total anthocyanins of the complete extract and fractions were determined using the pH differential method from Lee, Durst, and Wrolstad.[26] Briefly, samples were diluted in each of 0.025 M potassium chloride (pH 1.0) and 0.4 M sodium acetate (pH 4.5) at an appropriate dilution factor. Within 15 min, absorption was measured at both 520 and 700 nm using a SpectraMax M5 microplate reader. Data were analyzed using SoftMax Pro (version 6.2) software. Anthocyanin concentration was calculated as

$$\text{mg cyanidin-3-glucoside equiv/L sample} = \frac{A \times \text{MW} \times \text{DF} \times 10^3}{\varepsilon \times \text{PL}}$$

where $A = (A_{520} - A_{700})_{\text{pH1.0}} - (A_{520} - A_{700})_{\text{pH4.5}}$; MW = 449.2 g/mol for cyanidin-3-glucoside; DF = dilution factor; PL = path length in cm; ε = 26900 molar extinction coefficient; and 10^3 = conversion factor from g to mg. All samples were tested in quadruplicate, and results were expressed as milligram cyanidin-3-glucoside equivalents per 100 g DW of lyophilized berries.

UPLC Conditions and Analysis. Chromatography was performed using a Waters ACQUITY UPLC system. For each sample and standard, 1 μL was injected onto a 2.1 × 100 mm, 1.7 μm, ACQUITY UPLC BEH C18 column with the flow rate set at 0.6 mL min^{-1}. The column temperature was maintained at 42 °C using an ACQUITY UPLC Column Manager, and spectral data (210−600 nm) were collected with an ACQUITY UPLC photodiode array (PDA) eλ detector. The mobile phases used were (A) 0.3% phosphoric acid, 5% methanol in 18.2 MΩ·cm water and (B) acetonitrile. The gradient condition was 0 min, 1% B; 0.5 min, 1% B; 2.25 min, 8% B; 3 min, 9% B; 4.5 min, 12% B; 5 min, 15% B; 6.5 min, 16% B; 10 min, 30% B; 11 min, 95% B; 11.65 min, 95% B; 11.7 min, 1% B; and 15 min, 1% B. The system was controlled and data were collected and analyzed using Empower 3 software. Peak identification was achieved by comparing retention time and spectral data with those of standards listed under Chemicals and Materials.

Cell Culture and Cytotoxicity Assay. H9c2 rat myoblasts were purchased from ATCC (Manassas, VA, USA). H9c2 cells were cultured in high-glucose (4500 mg/L) Dulbecco's modified Eagle's medium (DMEM) supplemented with 10% fetal bovine serum. To assess the cytotoxicity of the lingonberry samples, cells were seeded into black 96-well plates (1.0 × 10^4 cells per well). After allowing cells to adhere, medium was aspirated and replaced with medium supplemented with berry samples. After 24 h, AlamarBlue cell viability reagent was added to each well, and plates were incubated for 2 h at 37 °C. Fluorescence was measured (excitation = 570 nm, emission = 585 nm) using a SpectraMax M5 microplate reader, and data were analyzed using SoftMax Pro (version 6.2) software. All samples and controls were tested in quadruplicate, and results were expressed as percentage of control (control = 100%).

Simulated Ischemia-Reperfusion (IR). After 24 h of pretreatment with berry sampless, medium was aspirated and cells were washed twice with phosphate-buffered saline (PBS), and IR was simulated using the method established in our previous studies.[27] Medium was replaced with ischemic buffer (137 mM sodium chloride 15.8 mM potassium chloride, 0.49 mM magnesium chloride, 0.9 mM calcium chloride, 4 mM HEPES, 10 mM deoxyglucose, 20 mM sodium lactate, 1 mM sodium dithionate, pH 6.4), and cells were placed in a modular incubator chamber. Oxygen was removed by flushing the chamber with a mixture of 95% N_2 and 5% CO_2 gas for 5 min at 25 L per minute. The chamber was sealed and incubated for 1 h at 37 °C to simulate ischemia. After 1 h, ischemic buffer was aspirated, cells were washed twice with PBS, and cells were incubated in medium for 30 min under normoxic conditions to simulate reperfusion. For treatment groups, both ischemic buffer and reperfusion media were supplemented with berry extract, fractions, or anthocyanins. For control cells (no ischemia reperfusion), medium was aspirated, cells were washed twice with PBS, fresh medium was added, and cells were incubated for 90 min.

Determination of Apoptosis. *Hoechst Stain.* Cells were seeded into 6-well plates (1.2 × 10^5 cells per well) and incubated in cell culture medium (control and IR groups) or cell culture medium pretreated with berry samples (IR treatment groups) for 24 h. Similarly, in place of the berry samples, the selective JNK inhibitor SP600125 was also tested at 5 and 10 μM. IR was simulated while control plates were incubated for 90 min. After 1 h of ischemia and 10 min of reperfusion, 7 μL of Hoechst 33258 was added to each well, and plates were returned to the incubator for the final 20 min of reperfusion. Cells were then fixed with 10% formalin and viewed at 200× magnification with an Olympus IX81 microscope equipped with X-CITE Fluorescence Illumination Series 120Q. Each sample was tested on 3 wells, and 34 random fields were photographed per well, for a total of 102 fields per treatment. Photos were analyzed using ImageJ software to count the numbers of apoptotic nuclei and nonapoptotic nuclei.[28] Results were expressed as percentage of nuclei that were apoptotic compared to the IR group (IR = 100%).

Caspase-3 Activity Assay. Caspase-3 assays were performed using SensoLyte Homogeneous AFC Caspase-3/7 Assay Kits. Cells were seeded into 100 mm plates (4 × 10^5 cells per well) and incubated in cell culture medium (control and IR groups) or cell culture medium pretreated with berry samples (IR treatment groups) for 24 h. IR was simulated while control plates were incubated for 90 min. Cells were washed twice with ice-cold PBS, covered with 1 mL of ice cold lysis buffer, and scraped into microfuge tubes. Tubes were shaken for 30 min at 4 °C and centrifuged for 10 min at 2500g at 4 °C, and the supernatant was collected. Protein was determined using a Bradford protein assay.[29] Supernatant and caspase-3 tetrapeptide substrate (DEVD) solution were added to each well of a black 96-well plate, using lysis buffer for blank wells. The plate was shaken at 100−200 rpm for 30−60 min at room temperature, fluorescent intensity was measured (excitation = 380 nm, emission =5 00 nm) using a SpectraMax M5 microplate reader, and data were analyzed using SoftMax Pro (version 6.2) software. All samples were tested in quadruplicate, and results were expressed as percentage of the IR group (IR = 100%).

Assays for Total and Phosphorylated JNK and c-Jun. Cells were seeded into 100 mm plates (4 × 10^5 cells per well) and incubated in cell culture medium (control and IR groups) or cell culture medium pretreated with berry samples or anthocyanins (IR treatment groups) for 24 h. IR was simulated while control plates were incubated for 90 min. Control cells, IR cells, and IR cells treated with berry samples or pure anthocyanins (cyanidin-3-galactoside, cyanidin-3-glucoside, and cyanidin-3-arabinoside at 0.1, 1, and 5 μg/mL) were collected and frozen as whole cells at −80 °C until use. On the day of the assay, cells were lysed, supernatants were collected, and assays were performed according to Meso Scale Discovery protocols. One set of electrochemiluminescent multiplex microplates was spotted with c-Jun N-terminal kinase (JNK) and phospho-JNK antibodies, and one set of microplates wsd spotted with c-Jun and phospho-c-Jun antibodies. Briefly, multiplex microplates were blocked with blocking solution, washed three times, incubated with cell lysates, washed another three times, incubated with detection antibodies, and analyzed using a Sector Imager 2400. Samples were tested in triplicate, and percent phosphoprotein was calculated as (phospho-signal/total signal) × 100. Protein was determined using a Bradford protein assay.[29] Results were expressed as percentage of IR group (IR = 100%).

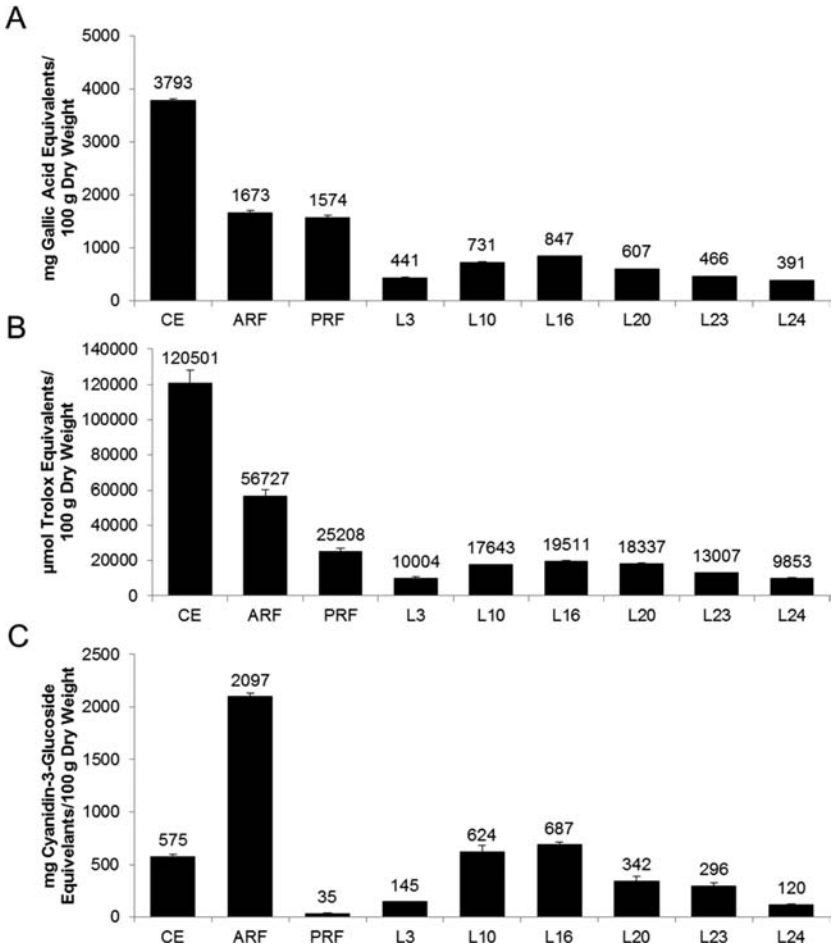

Figure 1. Phenolic content in milligram gallic acid equiv (A), antioxidant capacity in micromole Trolox equiv (B), and anthocyanin content in milligram cyanidin-3-glucoside equiv (C) per 100 g DW of lingonberry genotypes measured by total phenolics assay, oxygen radical absorbance assay, and total anthocyanins assay, respectively.

Western Immunoblotting Analysis. Cells were seeded into 100 mm plates (4×10^5 cells per well) and incubated in cell culture media (control and IR groups) or cell culture media pretreated with berry samples (IR treatment groups) for 24 h. IR was simulated while control plates were incubated for 90 min. Cleaved PARP levels were measured in control cells, IR cells, and IR cells treated with lingonberry samples using Western immunoblotting analysis. Whole cell lysate proteins (40 μg) were separated by electrophoresis on an 8% SDS-polyacrylamide gel,[30] transferred to a nitrocellulose membrane (Pall BioTrace, pore size = 0.2 μm),[31] and probed with rabbit polyclonal anticleaved PARP antibody (1:1000). Subsequent to incubation with HRP-conjugated goat anti-rabbit IgG secondary antibody (1:2000), bands were visualized using enhanced chemiluminescence reagent (Millipore Corp.) and the Alpha Innotech FluorChem Q imaging system. β-Actin was used as an internal control for equal loading of samples in the gel.

Statistical Analysis. Data are presented as means ± SE of at least three independent experiments. Results were analyzed using one-way ANOVA followed by Student−Newman−Keuls multiple-comparison test. P values <0.05 were considered statistically significant. For all data, groups specified by the same letter are not significantly different. All statistical analyses were performed using PASW Statistics 18 software (SPSS, New York, NY, USA).

RESULTS

Antioxidant Capacity and Anthocyanin Content of Lingonberry Extract and Fractions. In Figure 1, the antioxidant capacity (Figure 1A) and total phenolic content (Figure 1B) of the five eastern Canada lingonberry clones, the European cultivar, CE, ARF, and PRF, and anthocyanin content (Figure 1C) of CE, ARF, and PRF are shown; all values are shown per 100 g DW. The undiluted CE contained 240 μg cyanidin-3-glucoside equiv and 1580 μg gallic acid equiv per milliliter, the undiluted ARF contained 874 μg cyanidin-3-glucoside equiv per milliliter, and the undiluted PRF contained 656 μg gallic acid equiv per milliliter. On the basis of these results, for subsequent experiments four concentrations of each sample were used, corresponding to 1:100, 1:500, 1:1000, and 1:2000 dilutions with cell culture medium.

Overall, on the basis of the methods used in this study, the Manitoba lingonberry had high antioxidant capacity. It should be noted that the antioxidant capacities of ARF and PRF add up to only two-thirds of the antioxidant capacity of CE. This may be due to the fact that small phenolic compounds such as gallic acid are washed out of the column during the initial wash steps of the fractionation process. These compounds likely account for a significant proportion of the antioxidant capacity of CE.

UPLC Profiles of Extract and Fractions. UPLC chromatograms detected at 525 nm showed that lingonberry extract contained three main anthocyanin peaks. We identified the smallest peak as cyanidin-3-glucoside, the next smallest peak as cyanidin-3-arabinoside, and the largest peak as cyanidin-3-galactoside by comparing retention times and spectral maximums with available standards (Figure 2A). The structures of these anthocyanins are shown in Figure 3. We confirmed the

J. Agric. Food Chem. 2015, 63, 5660−5669

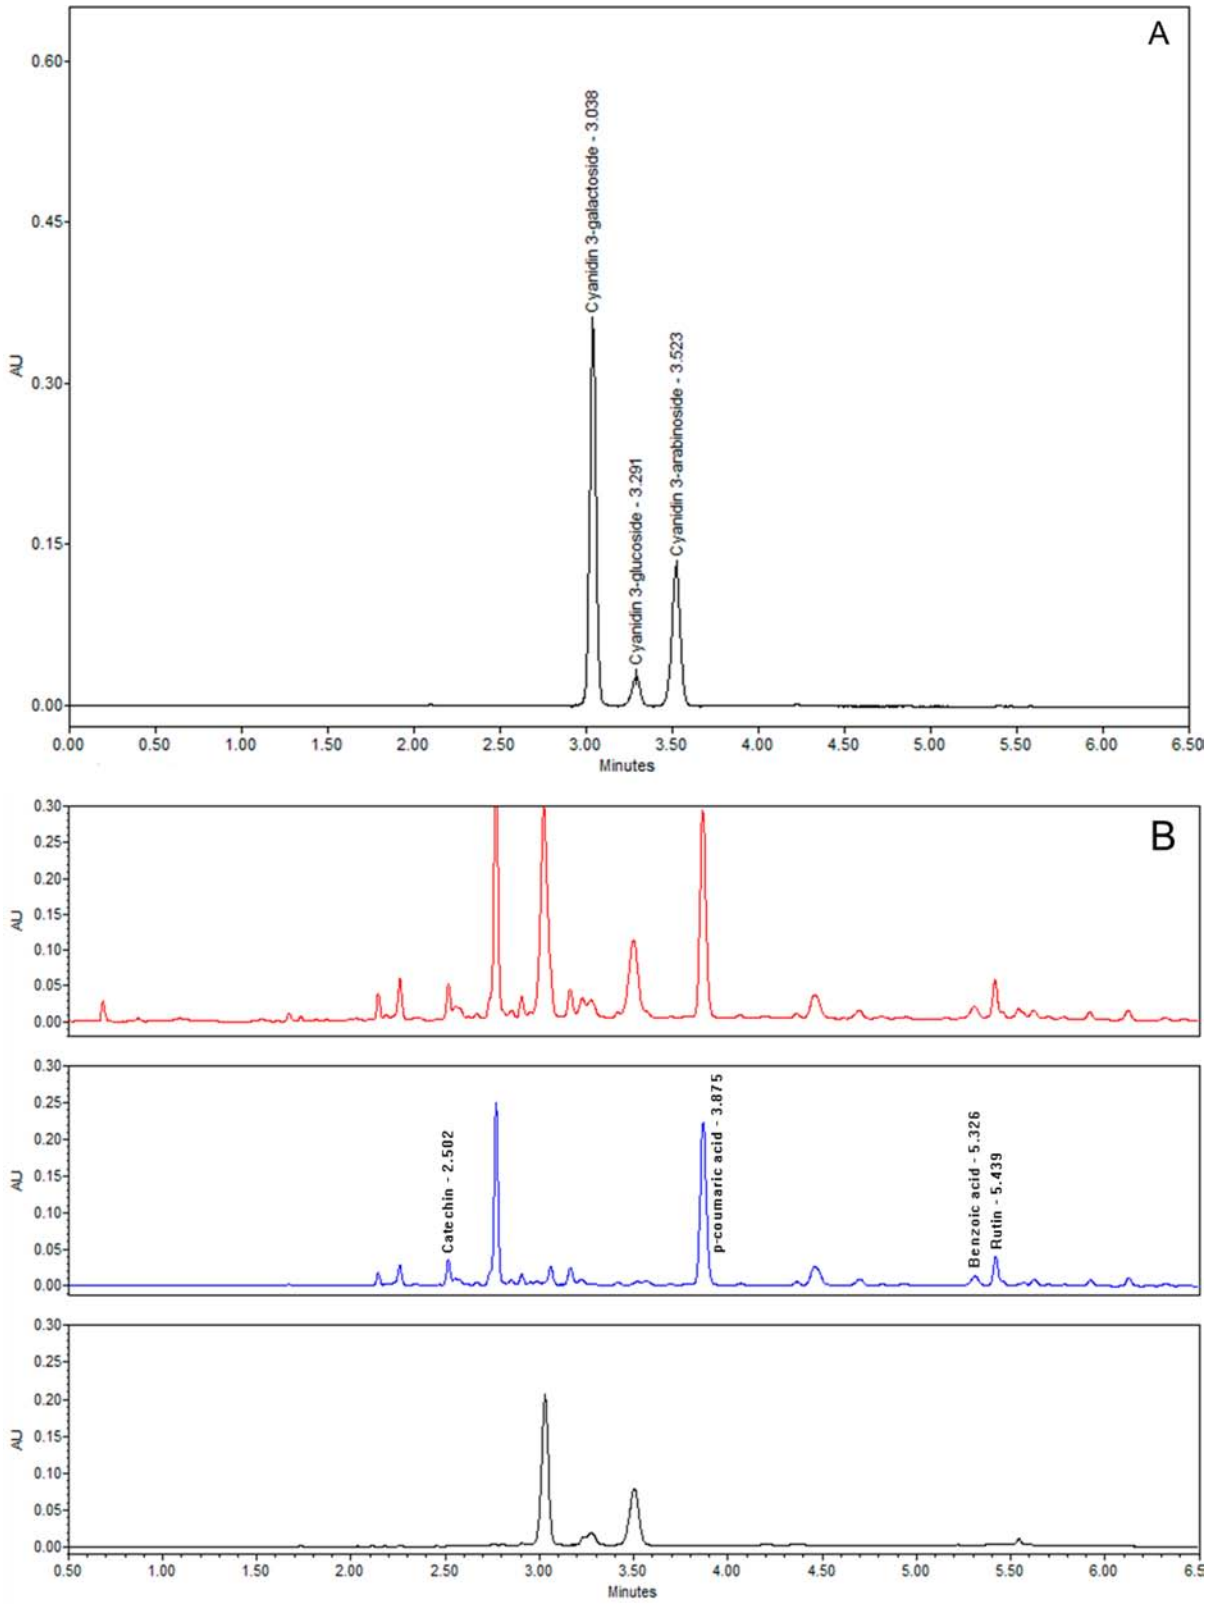

Figure 2. UPLC chromatograms of CE detected at 525 nm (A) and CE (red), PRF (blue), and ARF (black) detected at full scanning range (B). Note, in (B), ARF contains only the three anthocyanin peaks, anthocyanin peaks are absent from PRF, and CE contains all peaks present in ARF and PRF.

effectiveness of our fractionation technique by observing the chromatograms detected at 525 and maximum plots of the CE, ARF, and PRF. As expected, the chromatogram of ARF was devoid of peaks other than the three anthocyanin peaks, whereas the PRF chromatogram contained many peaks identified as phenolic compounds but did not contain any of the three anthocyanin peaks (Figure 2B).

Characterization of Apoptosis and Cytoprotection. *Inhibition of Nuclei Condensation.* All samples were tested at the high concentrations for cytotoxicity prior to subsequent

experiments. None of the concentrations tested affected cell viability, as indicated in Figure 4. Our model of IR induced a 25-

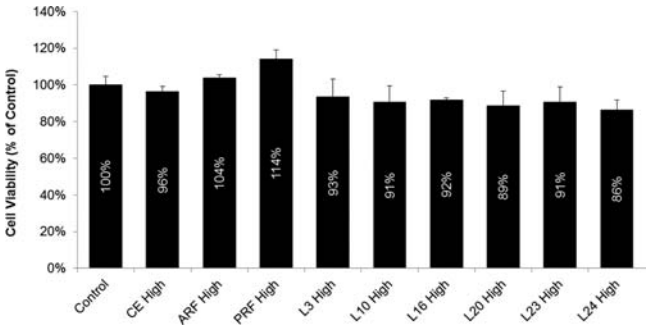

Figure 4. Cell viability of H9c2 cells treated with lingonberry extracts (1:100) as measured fluorescently using AlamarBlue cell viability reagent. None of the treatments reduced cell viability.

fold increase in nuclei condensation (an indicator of apoptosis) compared to H9c2 cells not exposed to IR (Figure 5A,B). Addition of CE (Figure 5C), ARF (Figure 5D), and PRF (Figure 5E) to the cell culture medium prevented IR-induced nuclei condensation as measured by the Hoechst stain. The ratio of condensed to normal nuclei in the IR group without treatment was set to 100%, and CE, ARF, and PRF treatment groups and controls were compared to this ratio (Figure 6). For Manitoba lingonberry, even at the lowest concentrations tested, all three samples inhibited nuclei condensation by at least 50% when compared to the IR group. Each sample exhibited a dose-dependent inhibition of nuclei condensation, which is indicative of apoptosis.

The selective JNK inhibitor SP600125 was also tested for its ability to inhibit nuclei condensation in H9c2 cells to demonstrate the role of JNK in the apoptotic mechanism induced by our model of IR (Figure 6). SP600125 was able to inhibit nuclei condensation by 75% at a concentration of 5 μM, indicating that JNK activation plays a role in apoptosis in this setting.

Inhibition of Caspase-3 Activity and Cleaved PARP Expression. In our model, IR induced a >2-fold increase in caspase-3 activity compared to control cells. The effects of all lingonberry samples on caspase-3 activity are shown in Figure 7. In the case of Manitoba lingonberry, CE exhibited stronger inhibition of caspase-3 activity than PRF and ARF, and PRF was slightly more effective than ARF at inhibiting caspase-3 activity. All three samples significantly inhibited caspase-3 activation. IR induced a 2-fold increase in levels of cleaved PARP, a target of caspase-3 in IR-injured cells, and CE prevented this increase (Figure 8).

Inhibition of JNK Activity. Using electrochemiluminescent multiplex assays, it was determined that IR induced a 20-fold increase in phosphorylated JNK and a 7-fold increase in c-Jun phosphorylation. Treatment with CE, ARF, and PRF had no effect on JNK or c-Jun phosphorylation in control cells. The effects of treatment with CE, ARF, and PRF on JNK phosphorylation are shown in Figure 9A, and the effects on c-Jun phosphorylation are shown in Figure 9B. All three samples significantly inhibited JNK activity in a concentration-dependent manner. ARF provided the strongest inhibitory effect on IR-induced JNK activation. The effects of treatment with cyanidin-3-glucoside, cyanidin-3-galactoside, and cyanidin-3-arabinoside on JNK phosphorylation are shown in Figure 10. All three anthocyanins showed an inhibitory effect on JNK phosphorylation, an indication of their protective effect against IR-induced JNK activation. Cyanidin-3-glucoside provided the highest level of protection, but all three anthocyanins effectively protected against JNK activation at physiologically relevant doses.

DISCUSSION

The novel findings of this study are that (1) Manitoba lingonberry, analyzed for the first time in the scientific literature, has high in vitro antioxidant capacity and contains large quantities of anthocyanins including three main anthocyanins in agreement with European varieties and (2) the significant protection against nuclear condensation, caspase-3 activation, and JNK phosphorylation is provided by Manitoba lingonberry samples and pure anthocyanins in a model of IR in H9c2 cells.

The antioxidant capacity of the Manitoba lingonberry CE was higher than many reported ORAC values for commonly consumed berries[7,12] and the ORAC values of eastern Canada and European lingonberry. However, from this study, it is not possible to compare the antioxidant activity among different genotypes and the Manitoba populations. The Manitoba lingonberries consist of two populations containing a number of genotypes. They were collected from the wild in 2011, but the Newfoundland clones and the cultivar Mesovia were being grown in a greenhouse under controlled conditions for more than 10 years. There is evidence that berries grown in colder temperatures and at higher latitudes produce more anthocyanins and polyphenolic compounds.[32] It is possible that the colder climate of Manitoba may be responsible for the increase in antioxidant capacity in Manitoba lingonberry. Anthocyanin and total phenolic content were strongly correlated (Pearson correlation coefficient = 0.97, data not shown) for the Newfoundland and European clones grown in-house; however, the ratio of anthocyanin content to total phenolic content in wild Manitoba lingonberry was much higher than that of the lingonberries grown in-house due to the exceptionally high levels of total phenolics. Further research will investigate whether

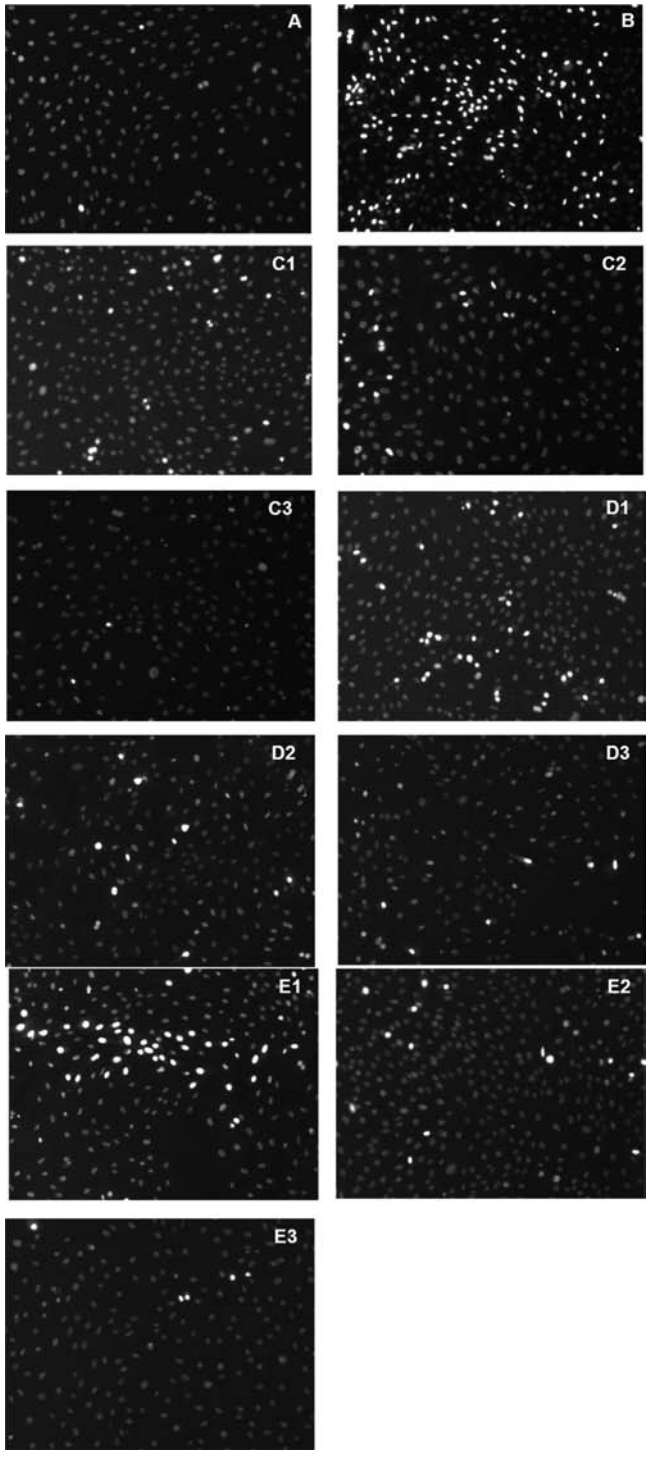

Figure 5. Hoechst staining of H9c2 cells (A) under normoxic conditions, (B) after 1 h of simulated ischemia and 30 min of simulated reperfusion (IR), (C) after 1 h of simulated ischemia and 30 min of simulated reperfusion with CE treatment at three concentrations (1, very low; 2, low; 3, medium), (D) after 1 h of simulated ischemia and 30 min of simulated reperfusion with ARF treatment at three concentrations, and (E) after 1 h of simulated ischemia and 30 min of simulated reperfusion with PRF treatment at three concentrations.

the change in ratio is due to genetic variability or growing conditions.

The identified anthocyanin peaks are in agreement with results from studies on North American and European lingonberry.[2,33]

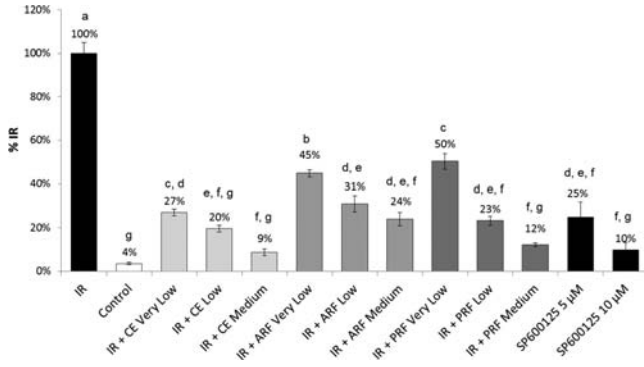

Figure 6. Effect of CE, ARF, and PRF (medium dose = 1:500 dilution in cell culture media, low dose = 1:1000 dilution, very low dose = 1:2000 dilution) on ratio of condensed to normal nuclei as measured by Hoechst stain in control cells and cells subjected to 1 h of simulated ischemia and 30 min of simulated reperfusion (IR), with IR set to 100%. Results are expressed as the mean ± SEM (n = 3). Groups specified by the same letter are not significantly different at $P < 0.05$.

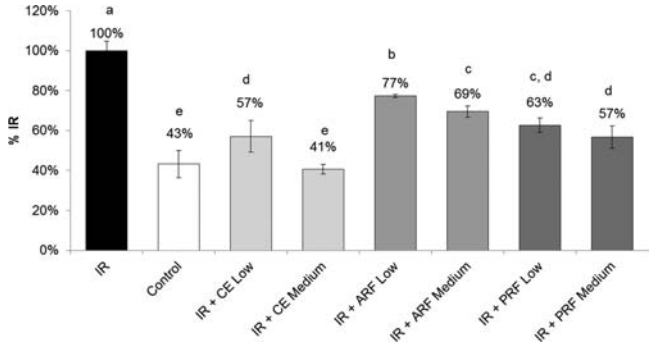

Figure 7. Effect of CE, ARF, and PRF (medium dose = 1:500 dilution in cell culture media, low dose = 1:1000 dilution) on caspase-3 activity in control cells and cells subjected to 1 h of simulated ischemia and 30 min of simulated reperfusion (IR), with IR set to 100%. Enzyme activity was measured fluorescently, and results are expressed as the mean ± SEM (n = 3). Groups specified by the same letter are not significantly different at $P < 0.05$.

Brown et al. confirmed that wild lingonberry from British Columbia, Canada, contained 300 mg of anthocyanins per 100 g DW and identified cyanidin-3-glucoside, cyanidin-3-galactoside, and cyanidin-3-arabinoside as the three major anthocyanins.[34] Using the results for the ORAC, total phenolics, and total anthocyanins assays of CE, ARF, and PRF, the doses used for the subsequent cell studies were selected on the basis of a literature review of other cellular studies on lingonberry as well as reported plasma concentrations of anthocyanins and antioxidants achieved following oral dosing.[35,36] Future studies will need to standardize berry cultivation and collection to account for these differences and also test the year-to-year variability of wild lingonberry extracts to confirm the exceptionally high anthocyanin and antioxidant content of Manitoba lingonberry.

IR injury in H9c2 cells is well-described in the literature. In these cells, IR has been shown to induce JNK and ERK activation,[37−42] nuclei condensation,[27] caspase-3 activation,[38] and pro-apoptotic protein activation.[40−42] Because reactive oxygen species accumulate rapidly during reperfusion, polyphenolic compounds with high in vitro antioxidant capacity have been hypothesized as potential therapeutic treatments for IR injury. Indeed, the polyphenols tyrosol,[27] curcumin,[38] danshensu,[40] resveratrol,[41] and others have been shown to be

protective in cardiomyocyte IR injury. Polyphenols may act as direct intracellular antioxidants, because intracellular ROS accumulation is generally inhibited with these treatments. An NADPH oxidase inhibitor has been shown to simultaneously reduce intracellular ROS and JNK phosphorylation in H9c2 cells,[37] so perhaps antioxidants may inhibit apoptosis by reducing ROS production. Recently, Bhullar and Rupasinghe demonstrated that lingonberry extracts could protect fibroblasts against peroxyl radical-induced stress by scavenging reactive oxygen species and activating the Nrf2 pathway, indicating that lingonberry polyphenols may be potent intracellular antioxidants.[43]

Several lines of evidence in this study demonstrated the anti-apoptotic effects of Manitoba lingonberry compounds. First, our results indicated that Manitoba lingonberry was efficient at preventing nuclei condensation in a model of IR. Nuclei condensation is an indicator of apoptosis because as the cell dismantles its nucleus and fragments its DNA, nuclei become small and stain brightly with Hoechst 33528. Second, Manitoba lingonberry also inhibited caspase-3 activation significantly in this model and reduced levels of cleaved PARP. Caspase-3, an executioner caspase, has numerous cellular targets, the cleavage of which is essential for apoptosis, including PARP.[44] The fact that Manitoba lingonberry treatment inhibited nuclei condensation and caspase-3 activation simultaneously suggested that apoptosis, rather than necrosis, was the primary mode of cell death in our model of IR. Third, we observed that Manitoba lingonberry inhibited JNK and c-Jun phosphorylation concurrently with inhibiting apoptosis. We used the selective JNK inhibitor, SP600125[45] to show the relevance of this MAPK signaling pathway in our model. JNK inhibition was associated with a marked decrease in apoptosis, indicating that JNK activation is relevant to apoptosis in this setting. Importantly, pure anthocyanins also inhibited JNK activation in IR-injured H9c2 cells. These results are significant because several reports have confirmed the presence of pure anthocyanins in plasma and physiologically relevant doses were used.[37] However, future

DOI: 10.1021/acs.jafc.5b00797
J. Agric. Food Chem. 2015, 63, 5660−5669

studies are needed to examine the bioactivities of lingonberry metabolites because these compounds certainly have bioactivities themselves and may be formed in cell culture studies.[46,47] MAP kinases include JNK and extracellular signal-regulated kinase (ERK) and are involved in critical signaling pathways needed for cell proliferation, differentiation, and apoptosis. In the MAPK signaling cascades, many different signals may converge on JNK at once, and the balance between the pro- and anti-apoptotic signals will decide whether JNK will be activated or not. Once activated via phosphorylation, JNK may translocate to the nucleus, where it phosphorylates specific pro-apoptotic transcription factors, or to the mitochondria, where it modulates the activity of mitochondrial proteins by phosphorylation. An important nuclear target of JNK is c-Jun, a component of the activator protein-1 pro-apoptotic transcription factor complex. JNK inhibitors have been shown to be protective against apoptosis in several cell types in vitro, and a JNK inhibitor decreased myocardial apoptosis and reduced infarct size after myocardial IR in rats.[48]

In conclusion, our study provides the first analysis of Manitoba lingonberry and demonstrates the protective effects of lingonberry in a model of IR injury, which is a clinically relevant phenomenon in many diseases. Lingonberry fruits can be safely consumed at low cost and, due to their high content of various bioactive compounds, may constitute part of a healthy diet. Future research will allow further mechanistic insight into the role of lingonberry phytochemicals in human health.

Table 1. Characteristics of the Commercial Dry Yeast Products Used in the Elaboration of White and Rosé Sparkling Wines and Doses Applied

product added	commercial supplier	dose (g/L)	expected effect (information provided by the manufacturer)	characteristics
DYA-1[a]	Agrovin	0.30	increase the volume of the lees, increase mouthfeel and foam persistence	product with autolysated yeast enriched in polysaccharides
DYA-2	Agrovin	0.30	increase the volume of the lees; increase mouthfeel and foam persistence	cell wall autolysated yeast enriched in polysaccharides and with 20−22% of soluble mannoproteins
DYA-3	Sepsa-Enartis	0.15	aromatic protection; increase freshness and prevent browning; increase colloidal stability, mouthfeel, and roundness sensations; improve foam stability	inactivate yeast with high content in parietal polysaccharides
DYA-4	Sepsa-Enartis	0.15	aromatic protection, increase freshness and prevent browning; increase colloidal stability, mouthfeel, and roundness sensations; improve foam stability; protect stability and aromatic persistence	product with polysaccharides from the yeast cell walls, highly purified and with high content in free mannoproteins

[a]DYA, commercial dry yeast autolysates.

lees for 9 months. For this purpose, four commercial dry yeast products with different compositions were used.

MATERIALS AND METHODS

Chemicals. The volatile compound standards were purchased from Fluka (Buchs, Switzerland), Sigma-Aldrich (Steinheim, Germany), and Lancaster (Strasbourg, France), as can be seen in Table 3.

L-Cysteine, L-leucine, L-phenylalanine, L-lysine, L-histidine, cadaverine, L-arginine, histamine, L-alanine, spermidine, glycine, β-alanine, L-aspartic acid, L-glutamic acid, L-tyrosine, L-serine, L-phenylethylamine, D-(+)-galacturonic acid, D-glucuronic acid, *myo*-inositol, trifluoroacetic acid, and HPLC grade orthophosphoric 85% acid were purchased from Fluka (Buchs, Switzerland). Isoamylamine, L-proline, diethyl ethoxymethylenemalonate (DEEMM), putrescine, tyramine, tryptamine, *trans*-4-hydroxy-L-proline, L-2-aminoadipic acid, L-ornithine monohydrochloride, L-tryptophan, L-asparagine, L-threonine, γ-aminobutyric acid (GABA), L-isoleucine, L-glutamine, L-methionine, sodium azide, D-(+)-fucose, L-rhamnose, 2-*O*-methyl-D-xylose, L-(+)-arabinose, D-(+)-galactose, D-(+)-glucose, D-(+)-mannose, 2-keto-3-deoxyoctonate ammonium salt (Kdo), hexane, dried methanol, pyridine, hexamethyldisilazane, trimethylchlorosilane, and D-apiose solution were purchased from Sigma-Aldrich (Steinheim, Germany).

The phenolic compounds were purchased from Extrasynthèse (Lyon, France), and Toyopearl gel HW-50F was obtained from Tosoh Corp. (Tokyo, Japan).

HPLC grade reagents, ethanol, methanol, acetonitrile, acetyl chloride, ethanol 96% (v/v), acetone, acetic acid glacial, and sodium acetate were provided by Scharlab (Barcelona, Spain). Dichloromethane (HPLC grade) was provided by Merck (Darmstadt, Germany), and the remaining reagents were supplied by Panreac (Madrid, Spain). Milli-Q water was obtained via a Millipore system (Bedford, MA, USA).

Polysaccharide Commercial Dry Yeast Products. Table 1 shows the information provided by the commercial manufacturers regarding the commercial dry yeast autolysates (DYA) used in this study as well as the doses applied. These products were selected because they were more specifically developed for sparkling wine elaboration according to the manufacturers' information. Considering this information, the maximum doses recommended by the manufacturers were assayed.

Winemaking Process. All sparkling wine production was carried out in the experimental winery of the Enological Station (ITACyL) sited in Rueda (Valladolid, Spain), following the traditional or *champenoise* method. White monovarietal base wines were elaborated with *Vitis vinifera* cv. Verdejo grapes from the Rueda Denomination of Origin (D.O.), and *V. vinifera* cv. Godello grapes from the Bierzo D.O. Rosé monovarietal base wines were obtained with *V. vinifera* cv. Tempranillo and Garnacha grapes from the Cigales D.O. Godello and Garnacha grape varieties were harvested in 2010 and Verdejo and Tempranillo in 2011.

The base wines were elaborated following the traditional white or rosé winemaking process in stainless steel tanks of 2000 and 2600 L, respectively. After cold stabilization and clarification of base wines, the tirage liquor was added and the wines were bottled. The tirage liquor was formed by yeast *S. cerevisiae* var. *bayanus* (0.30 g/L, IOC 18-2007, Oenologique Institut de Champagne, Epernay, France), sucrose (23 g/L), bentonite calcium activated (0.10 g/L) (Laffort, France), and the different commercial dry yeast products in the doses indicated in Table 1. Previously, a starter was prepared with 10% of the base wine, 180 g/L sucrose, and 0.30 g/L yeast. The experiments carried out were the control wines (C), without the addition of any product, and the sparkling wines made with the addition of the four different commercial dry yeast autolysates (DYA-1, DYA-2, DYA-3, and DYA-4). After that, the bottles were kept in a cellar at controlled a temperature (11−13 °C) and relative humidity (75−85%) for 9 months. The pressure and residual sugars were measured periodically to control the second fermentation. The pressure was measured by an aphrometer, and the sugars were measured by using an enzymatic method.

Wines were analyzed after 3, 6, and 9 months of aging on lees. Wines were riddled and disgorged, and no expedition liqueur was added. Because the second fermentation takes place in individual bottles, three bottles of each varietal sparkling wine at each sampling time were analyzed.

Analysis of Polysaccharide Composition of Commercial Dry Yeast Products and Sparkling Wine Samples. To characterize the different dry yeast preparations, the monosaccharide composition and their polysaccharide molecular weight distribution were analyzed. The monosaccharide composition of the commercial preparations was determined by GC-MS of their trimethylsilyl ester *O*-methyl glycosyl residues obtained after acidic methanolysis and derivatization.[29] GC was controlled by ChemStation software and equipped with a 7653B automatic injector consisting of an Agilent 7890A gas chromatograph (Agilent Technologies, Waldbronn, Germany) coupled to a 5975C VL quadrupole mass detector (MS). A high-resolution size exclusion chromatography (HRSEC) system (1100 Agilent Technologies) connected to a refractive index detector (RID) was used to obtain the molecular weight distributions of the polysaccharides. Two serial Shodex OHpack KB-803 and KB-805 columns (0.8 × 30 cm, Showa Denko, Japan) equilibrated at 1 mL/min in 0.1 M $LiNO_3$ were used, and calibration was performed with narrow pullulan molecular weight standards as previously described.[29] All analyses were performed in triplicate.

Wine polysaccharides were recovered by precipitation after ethanolic dehydration, and their monosaccharide composition was determined by GC-MS as commented before. The content of mannoproteins was estimated from the content of mannose as described by Guadalupe et al.[29] The content of glucans was estimated from the content of glucose.

Analysis of Phenolic Compounds. Anthocyanins, hydroxycinnamic acids, flavonols, and flavan-3-ols were analyzed by HPLC in an 1100 Agilent liquid chromatograph (Agilent Technologies) equipped with a photodiode array detector (DAD). Separation was achieved in an ACE HPLC column (Teknokroma, Barcelona, Spain) (250 mm × 4.6 mm, particle size = 5 μm), according to the methodology previously described.[30]

For analyzing proanthocyanidins, wine samples were fractionated by gel permeation chromatography (GPC) on a Toyopearl gel HP-50 F column (Tosohaas, Montgomeryville, PA, USA) as described by

DOI: 10.1021/acs.jafc.5b01336
J. Agric. Food Chem. 2015, 63, 5670−5681

Table 2. Monosaccharide Composition, Polysaccharide Purity, and Polysaccharide Composition of the Different Commercial Products[a]

	commercial product			
	DYA-1	DYA-2	DYA-3	DYA-4
mannose (%)	52.9 ± 5.1a	85.9 ± 6.1d	77.1 ± 4.5cd	62.3 ± 6.8ab
glucose (%)	47.1 ± 3.2b	14.1 ± 1.7a	22.9 ± 4.3a	37.7 ± 4.6b
polysaccharide purity[b] (%)	71.3 ± 6.2a	88.8 ± 10.2b	63.2 ± 2.8a	73.6 ± 4.3ab
∑ (P400−P50)[c] (%)	52.5 ± 4.0a	100.0 ± 0.0b	100.0 ± 7.2b	100.0 ± 7.1b
P10[c] (%)	47.5 ± 3.0			

[a]Data shown are the average and standard deviation of three analyses of each product. Values with different letters indicate statistically significant differences at $p < 0.05$. [b]Polysaccharide purity expressed as the total amount of monosaccharides in relation to the dry weight of the product analyzed. [c]∑ (P400−P50), polysaccharides with an average molecular weight between 47.3 and 404 kDa; P10, polysaccharides with an average molecular weight of 11.8 kDa. Polysaccharide fractions estimated by HRSEC as described in the text.

Guadalupe et al.[31] A first fraction was eluted with ethanol/water/trifluoroacetic acid; a second fraction containing proanthocyanidins was recovered by elution with acetone/water. Phloroglucinol adducts in the second fraction were analyzed by reversed-phase HPLC-DAD.[32] The column was an ACE HPLC (Teknokroma) (250 mm × 4.6 mm, particle size = 5 μm) protected by a guard column containing the same material. Total proanthocyanidin content was calculated as the sum of all the subunits: extension subunits (phloroglucinol adducts) and terminal subunits (catechin, epicatechin, and epicatechin gallate).

Analysis of Amino Acids and Biogenic Amines. Amino acid and biogenic amine content was determined simultaneously using the method described by Gómez-Alonso et al.[33] HPLC was performed using an 1100 Agilent liquid chromatograph (Agilent Technologies) equipped with a DAD. Chromatographic separation was performed in an ACE HPLC column (Teknokroma) (250 mm × 4.6 mm, particle size = 5 μm), thermostated at 16 °C.

Analysis of Volatile Compounds. The volatile compounds were extracted by liquid−liquid extraction following the method developed by Rodríguez-Bencomo et al.[7] Two hundred and fifty milliliters of wine, 5 mL of dichloromethane, and 75 μL of a mixture of two internal standards (550 mg/L of methyl octanoate from Sigma-Aldrich and 450 mg/L of 3,4-dimethylphenol from Lancaster) were added to a flask. The extraction was carried out for 3 h with continuous stirring (150 rpm) in an orbital shaker. The organic phase was then separated and concentrated until 400 μL. The chromatographic analyses were performed with an HP-6890N GC coupled to an HP-5973 inert MS detector equipped with a Quadrex 007CWBTR capillary column (60 m length, 0.25 mm i.d., and 0.25 μm film thickness), following the chromatographic conditions established by Rodríguez-Bencomo et al.[7]

Quantification was carried out following the internal standard quantification method. Quantitative data of the relative areas (absolute areas/internal standard area) were subsequently interpolated in the calibration graphs built from results of pure reference compounds. Quantification ions and internal standard used for each compound studied are indicated in Pérez-Magariño et al.[34]

Measurement of Foaming Properties by Instrumental Method. Foam properties of sparkling wines were evaluated using Mosalux equipment (Station Oenotechnique de Champagne, Cormontreuil, France) according to the Mosalux procedure.[35] This equipment consists of a glass cylinder with a glass frit in the bottom. This cylinder was filled with 100 mL of wine, and CO_2 was injected through the glass frit at a rate of 7 L/h under a constant pressure of 1 bar for 15 min. Then the gas injection was stopped.

Three parameters were measured: (1) maximum height reached by foam after CO_2 injection through the glass frit (HM, expressed in mm), which represents the foamability; (2) foam stability height during CO_2 injection (HS, expressed in mm), which represents the wine's ability to produce stable foam persistence of foam collar; and (3) foam stability time (TS, expressed in s), evaluated as the time until all bubbles collapsed when CO_2 injection was interrupted, which could represent the foam stability time once effervescence has decreased. Three bottles of each varietal sparkling wine at each sampling time were analyzed, and three measurements for each bottle were carried out.

Sensory Analyses. The sensory analysis was performed in a designed test room in accordance with ISO 8589 Standard (2010) and was carried out by 12 expert tasters from the Regulatory Councils of different Spanish D.O. and wineries (eight males and four females between 30 and 55 years old). These tasters defined the descriptors used in this sensory analysis, according to the methodology described in González-Sanjosé et al.,[36] and were trained to quantify them using structured numerical scales. This training was carried out in accordance with UNE-87-020-93 Standard (ISO 4121:1987).

Samples were presented in standard glasses in random order, and a structured numerical scale of seven points was used (1 representing no intensity and 7 the highest intensity). This work has focused on olfactory attributes: olfactory intensity, varietal, vegetal, yeasty, fruity, exotic fruit, citrus fruit, and floral notes were evaluated in the white sparkling wines, and olfactory intensity, varietal, vegetal, yeasty, fruity, oxidized, and reduced notes in the rose sparkling wines.

Sensory foam properties were valuated using the descriptors defined by Gallart et al.:[37] initial foam, foam area, foam collar, bubble size, and effervescence speed with scores from 1 to 3.

The sparkling wines were tasted after 9 months of aging on lees.

Statistical Analyses. The data were treated by applying the variance analysis (ANOVA), the least significant difference test at a significance level of $p < 0.05$, and multifactor analyses of variance. Factor analysis was applied to study the association of variables and to determine similarities or differences between wines by aging time or by treatment. Varimax rotation criterion was performed, and only factors with eigenvalues >1 were selected. Stepwise discriminant analysis is a supervised method that consists of finding a linear combination of the variables that characterizes or separates two or more classes of objects. The forward method was used to select the variables most useful for differentiating the wines according to treatment. The F statistical function was used as the criterion for variable selection. These statistical analyses were carried out using the Statgraphics Plus 5.0 statistical package.

Generalized Procrusters analysis (GPA) was applied on the mean ratings for olfactory attributes by using the Senstools 3.3.2. program (Utrecht, The Netherlands).

RESULTS AND DISCUSSION

Monosaccharide and Polysaccharide Contents in the Commercial Dry Yeast Products. Table 2 shows the monosaccharide composition, polysaccharide purity, and polysaccharide composition of the commercial dry yeast products. The monosaccharides from grape polysaccharides and from other vegetables (such as gum arabic) were not detected. Only mannose and glucose could be quantified in the commercial products. The percentage of mannose in these preparations, which is used to estimate the content of mannoproteins, was between 53 and 86%. The percentage of glucose, used to estimate the glucan content, was between 14 and 47%, which indicated

DOI: 10.1021/acs.jafc.5b01336
J. Agric. Food Chem. 2015, 63, 5670−5681

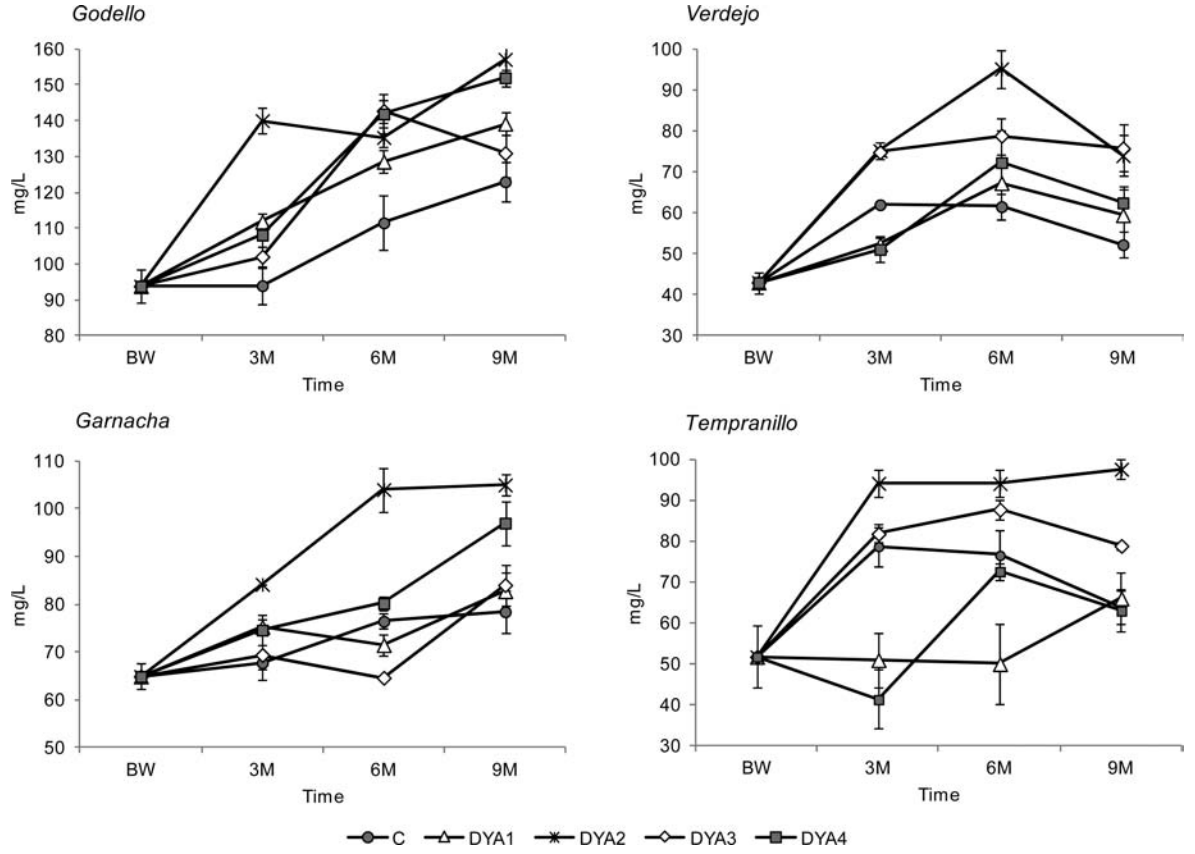

Figure 1. Concentration (mg/L) of mannoproteins during the different stages of aging on lees of the sparkling wines. C, control wines; DYA, wines treated with the commercial dry yeast autolysates; BW, base wine; 3M, 6M, 9M, 3, 6, and 9 months of aging on lees, respectively.

that during the process to obtain these products more mannoproteins were extracted than glucans. DYA-2 was the product with the highest percentage of mannoproteins, and it showed the highest mannoprotein/glucan relationship (6.1). The other mannoprotein/glucan values were 1.1 for DYA-1, 1.65 for DYA-4, and 3.3 for DYA-3.

Table 2 also shows the polysaccharide purity of the commercial products evaluated, expressed as the total amount of monosaccharides in relation to the weight of the product analyzed. Although all products showed values of purity above 60%, it is important to point out that the DYA-2 product showed significantly the highest value, showing a polysaccharide purity of 88.8%. With the exception of DYA-1, the commercial products were composed of only large polysaccharides with an average molecular weight of 47.3 kDa. In contrast, DYA-1 showed a similar content of low molecular weight polysaccharides (average molecular weight of 11.8 kDa) and high molecular weight polysaccharides.

Effect of the Addition of the Commercial Dry Yeast Products on the Phenolic Compounds, Amino Acids, and Biogenic Amines and Mannoprotein Content. In any of the varieties analyzed, no significant differences were found between control and sparkling wines treated with DYA in nonacylated, acetyl-glucoside, coumaryl-glucoside, and total monomeric anthocyanins, free, esterified, and total hydroxycinnamic acids, and total flavonols ($p < 0.05$). Other authors such as Morata et al.[38] and Guadalupe et al.[1] showed a reduction of some phenolic compounds and anthocyanins in red wines aged on lees and in red wines treated with yeast mannoproteins, respectively. The different results obtained in our work could be due to the quantitative differences in phenolic compounds shown between the red and the rosé and white wines.

No significant differences were observed either in the content of amino acids and biogenic amines ($p < 0.05$) or in the amount of total proanthocyanidins ($p < 0.05$) between control and treated sparkling wines. Therefore, it could be concluded that the added products did not have any effect on phenolic compounds, amino acids, or biogenic amines.

Contrary to that was observed with these chemical compounds, significant differences were observed in the content of mannoproteins (Figure 1). To determine the effectiveness of the addition of the commercial products, the content of mannoproteins was assessed in control and treated sparkling wines before and after the addition of the product. Except for Verdejo sparkling wines, the samples treated with the DYA-2 preparation showed significantly the highest concentrations of mannoproteins after 3 months of aging. In the same way, Garnacha, Tempranillo, and Verdejo treated with DYA-2 showed the highest content of mannoproteins after 6 months of aging. A decrease in the mannoprotein content was observed in some of the wines of Verdejo, Godello, and Tempranillo after 6 months of aging. As reported in other works, this fact could be attributed to mannoprotein precipitation phenomena as a result of their interaction with other wine components to form unstable colloids.[13]

At the end of the aging, all of the wines treated with DYA-2 showed the highest concentrations of mannoproteins, showing 21−34% more mannoproteins than their respective controls. These results were attributed to the fact that DYA-2 was the commercial product with both the highest polysaccharide purity

and mannoprotein content. Therefore, the content of mannoproteins added to the wine was higher with the addition of DYA-2 than with the rest of the products.

Effect of the Addition of Commercial Dry Yeast Products on Volatile Composition. Due to the high number of data, initially, multifactor analysis was carried out with all of the volatile compound data. Table 3 shows the effects of grape variety, treatment, and aging time for each compound. All of the wines were included in this analysis (60 wines: 4 varieties × 5 treatments × 3 aging times). It can be observed that there are strong grape variety and aging time effects on all volatile compounds evaluated. Despite these effects, treatment with DYA also showed effects on most of the compounds. Therefore, the volatile data were treated by grape variety separately due to the great influence of this factor.

Factorial analyses were performed to see whether the information given by these compounds would allow differentiating the sparkling wines by the treatment with DYA.

The four factorial analyses (one for each grape variety) selected five factors with an eigenvalue >1, which explained between 85 and 91% of the total variance.

Figure 2 shows the distribution of the different sparkling wines studied in the plane defined by the first two factors and the percentage of the total variance explained by each factor. In general, the variables associated with factor 1 mainly permit differentiation of the sparkling wines by aging time. These changes were due to the increase in ethyl esters of branched-chain fatty acids, ethyl lactate, and 2-phenylethanol and the decrease in ethyl esters of straight-chain fatty acids, alcohol acetates, and terpenes (mainly citronellol and linalool). These results are in agreement with those obtained in a previous work with several grape varieties[34] and with those obtained by other authors in white and rosé sparkling wines.[39−41] Therefore, it seems that the grape variety does not affect the changes in volatile composition that occur during the aging time on lees of the sparkling wines.

The aging time is an important factor in the volatile composition of the sparkling wines, and it does not allow observing clear differences by the addition of different DYAs. Therefore, discriminant analyses were carried out to see if volatile compounds would allow differentiating the sparkling wines treated with the different commercial products.

These discriminant analyses were carried out with all of the wines by each grape variety, and therefore four different models were obtained. Forward stepwise discriminant analysis was applied to determine the volatile compounds most useful for differentiating the sparkling wines according to treatment.

The final model for Godello sparkling wines selected 20 volatile compounds. The variables with the greatest discriminating power were decanoic acid, ethyl hexanoate, ethyl decanoate, citronellol, ethyl butyrate, and methyl vanillate. Figure 3A shows the distribution of the Godello sparkling wines in the plane

[a]Values with different letters in each attribute and grape variety indicate statistically significant differences at $p < 0.05$, and values without letters indicate no statistically significant differences. [b]C, control wine; DYA, sparkling wines treated with the different dry yeast autolysates. [c]HM, foam maximum height (mm); HS, foam stability height (mm).

the similarity between groups, the wines treated with DYA-2 were more different from control wines. The final model for Verdejo sparkling wines selected 16 volatile compounds, the first variables selected with the greatest discriminating power being ethyl butyrate, decanoic acid, methyl vanillate, terpineol, acetovanillone, and ethyl decanoate. Figure 3B shows the distribution of the Verdejo sparkling wines in the plane defined by the first two discriminant functions, which explained 93.2% of the total variance. In these wines, the treatment with DYA-2 showed also major differences compared to the control wines.

The final model for Garnacha rosé sparkling wines selected 13 volatile compounds. The variables with the greatest discriminating power were decanoic acid, acetovanillone, 2-phenylethyl acetate, ethyl butyrate, ethyl decanoate, and isoamyl acetate. Figure 3C shows the distribution of these sparkling wines in the plane defined by the first two discriminant functions, which explained 87.0% of the total variance. The final model for Tempranillo rosé sparkling wines selected 13 volatile compounds, the first variables selected with the greatest discriminating power being ethyl decanoate, ethyl lactate, octanoic acid, decanoic acid, isovaleric acid, and isobutanol. Figure 3D shows the distribution of these sparkling wines in the plane defined by the first two discriminant functions, which explained 93.6% of the total variance. In both rosé sparkling wines, treatment with DYA-2 showed also major differences compared to the control wines, as observed in white sparkling wines.

On the other hand, the differences observed between the control wines and those treated with the rest of the DYAs depended on the varietal wine.

All of the models were satisfactory with a global classification of 100% of the wines.

As indicated, the final models for each grape variety were slightly different, and the selected variables were not exactly the same for each model. However, in general, the main variables responsible for the observed distribution of wines were some ethyl esters, terpenes (mainly terpineol), decanoic acid, and some alcohols.

Considering the results obtained with the factorial and discriminant analyses, the data of the volatile compounds of sparkling wines aged on lees for 9 months were studied to see the effect of the addition of DYAs in the sparkling wines, focusing on the more discriminating compounds. Table 4 shows the mean values by treatment and the ANOVA results. Differences depending on the varietal wine and commercial product used were observed. In general, it was observed that the sparkling wines treated with DYAs had a lower content of the ethyl esters of fatty acids than the control wines, with the exception of Verdejo wines. These differences could be due to the sorption phenomenon onto the yeast lees and/or DYAs being a reversible process, and several factors can influence these interactions.[6,7,42] In addition, all of the sparkling wines treated with DYA-2 showed the lowest content mainly in ethyl decanoate. This compound has a high hydrophobicity,[43] and therefore it can be retained by the yeast cell walls and mannoproteins.[16,17]

With regard to the fatty acids, decanoic acid presented lower levels in wines treated with DYA-2 than in control wines, which indicated possible adsorption on the DYA surface. This fact could be due to the high hydrophobicity of this compound and to the high content of mannoproteins of the DYA-2.

In general, the addition of DYAs in the tirage phase of sparkling wine elaboration maintained higher concentrations of terpenes in the treated wines compared with their respective control wines and mainly of α-terpineol in white sparkling wines treated with DYA-2. Therefore, these products reduced the losses of these compounds occurring during aging in the bottle.[34]

Therefore, it can be said that the commercial product with the highest mannoprotein content (DYA-2) modified the volatile composition of the sparkling wines to a great extent. However, these changes did not affect their aging evolution or their varietal identity.

Effect of the Addition of the Commercial Dry Yeast Products on Foam Parameters. Table 5 shows the data of the different Mosalux parameters of the four grape variety sparkling wines and the ANOVA and LSD results.

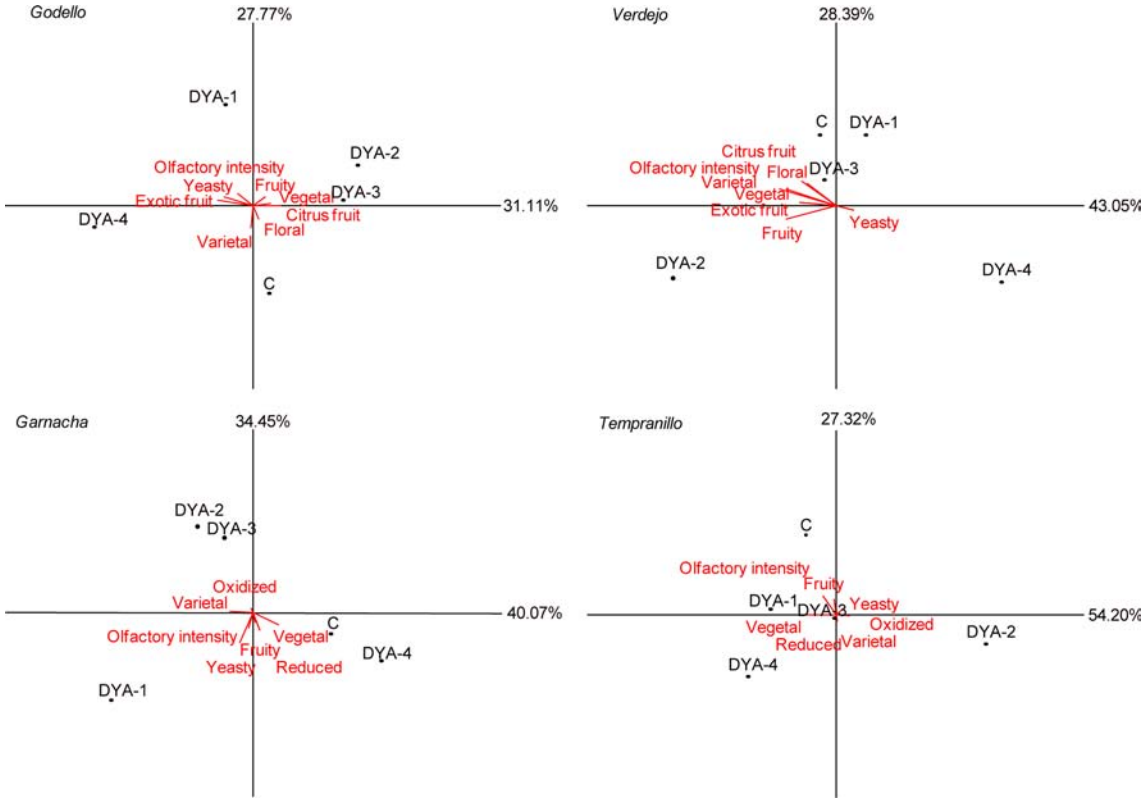

Figure 4. Generalized Procrustes analysis of the mean ratings for olfactory phase in the different sparkling wines after 9 months of aging on lees. C, control wines; DYA, wines treated with the commercial dry yeast autolysates.

The DYA addition did not modify the foam maximum height (HM) in white sparkling wines, and only slight differences were observed in rosé sparkling wines. The average values of HM were higher than those obtained in other vintages,[44] which can be due to their different composition in amino acids and in phenolic compounds in the case of rosé sparkling wines.[45]

Slight differences were found in the foam stability (HS) of the white sparkling wines, the addition of the DYA being positive in the Verdejo sparkling wines. In the rosé sparkling wines, only the Tempranillo wines treated with DYA-4 showed statistically significant higher HS values than the rest of the wines.

Nuñez et al.[19] showed a positive effect of one mannoprotein thermal extract to the foaming properties of sparkling wines. These different results could be due to the fact that they used this type of product in final sparkling wines, not during the aging time on lees.

The measurements of time stability (TS) did not show good repeatability, and therefore no conclusion of the effect of DYA addition in the sparkling wines can be drawn.

Therefore, although some differences were detected in the foam parameters of the different sparkling wines depending on the DYA treatment, it can be pointed out that, in general, these commercial products did not modify the foam properties of sparkling wines, and the few differences detected were not justified.

Effect of the Addition of the Commercial Dry Yeast Products on the Sensory Properties of the Sparkling Wines. The sensory foam properties evaluated using the descriptors defined by Gallart et al.[37] are shown in Table 5. No differences were found in the foam attributes of the different sparkling wines by treatment with DYA. Only the foam area and foam collar of Verdejo sparkling wines showed statistically significant differences.

GPA was applied to the olfactory data to provide information about the relationships between sparkling wines and olfactory attributes (Figure 4). The effects produced on the aroma by the addition of the commercial products were different in the white and rosé sparkling wines. Therefore, the addition of the DYA-2 product enhanced the fruity aromas in both the Verdejo and Godello sparkling wines. On the contrary, the increment in the fruity aromas was not observed in the sparkling rosé wines of Tempranillo or Garnacha. In summary, the addition of the DYAs used in this study in the tirage phase for sparkling wine elaboration can modify the volatile profile of these wines. However, this effect appears to be associated with the content in mannoproteins of these products, because the volatile changes were mainly observed in DYA-2, which has the highest mannoprotein content and the highest purity. In addition, the fruity aromas of white sparkling wines were enhanced by the addition of DYA-2. On the other hand, the addition of these products did not have any effect on phenolic compounds, amino acids, or biogenic amines or on foam properties.

Sigma-Aldrich (Taufkirchen, Germany). All other chemicals were of analytical grade and were obtained from Applichem (Darmstadt, Germany), Carl Roth (Karlsruhe, Germany), or Sigma-Aldrich (Taufkirchen, Germany). Protein purification columns and resins were purchased from GE (Munich, Germany) or were a friendly gift from Knauer Wissenschaftliche Geräte GmbH (Berlin, Germany).

Endopeptidase Activity Assay. The azocasein assay was performed according to the method of Iversen and Jørgensen,[24] with some modifications. The substrate azocasein (5 g/L) was dissolved in double-distilled water (H_2O_{dd}), and the assay was performed as follows: The substrate solution (125 μL) was preincubated with 125 μL of the respective buffer solution at the respective temperature for 5 min. The reaction was started with the addition of enzyme solution (50 μL), stopped by the addition of trichloroacetic acid (1.5 M, 50 μL), and subsequently centrifuged (20000*g*, 4 °C, 5 min). A volume of 195 μL of the supernatant was transferred into a microtiter plate, 65 μL of NaOH (1 M) was added, and the absorbance at 450 nm was measured using a microtiter plate reader (Multiskan FC, Thermo Scientific, Braunschweig, Germany). One azocasein unit (ACU) was defined as the increase of 1 absorbance unit per minute at 450 nm in 0.25 M NaOH.

Aminopeptidase and Dipeptidylpeptidase Activity Assay. Aminopeptidase and dipeptidylpeptidase activities were measured according to the method of Chrispeels and Boulter,[25] with some modifications.[26] The assay contained 177 μL of the respective buffer solution and 50 μL of enzyme solution. After 5 min of preincubation at the respective temperature, the reaction was started by the addition of 12.5 μL of the corresponding substrate stock solution [*p*NA derivative dissolved in dimethylformamide (DMF)]. The substrate concentration in the final reaction volume was 3.7 mM except for Lys-Ala-*p*NA (1 mM). The reaction was stopped by the addition of 50% (v/v) acetic acid (50 μL) and was centrifuged afterward (20000*g*, 4 °C, 5 min). The supernatant (240 μL) was transferred into a microtiter plate, and the absorbance at 405 nm was measured using a microtiter plate reader (Multiskan FC). One katal (kat) of aminopeptidase or dipeptidylpeptidase activity was defined as the release of 1 mol *p*NA per second.

Amylase Activity Assay. The amylase activity was measured according to the Somogyi–Nelson method,[27,28] with some modifications. The following two reagents were prepared: Reagent A consisted of $Na_2HPO_4{\cdot}2H_2O$ (35.2 g/L), $KNaC_4H_4O_6{\cdot}4H_2O$ (40 g/L), $CuSO_4{\cdot}5H_2O$ (8 g/L), and NaOH (4 g/L) dissolved in H_2O_{dd}. Reagent B consisted of $(NH_4)_6Mo_7O_{24}{\cdot}4H_2O$ (50 g/L), H_2SO_4 (42 g/L), and $Na_2HAsO_4{\cdot}7H_2O$ (6 g/L) dissolved in H_2O_{dd}.

The substrate starch (10 g/L) was dissolved at 70 °C for 60 min in H_2O_{dd}, and the assay was performed as follows. The substrate solution (125 μL) was preincubated with 75 μL of citrate phosphate buffer at the respective temperature for 5 min. The reaction was started with the addition of enzyme solution (50 μL). After the reaction, a volume of 125 μL was transferred into 125 μL of citrate phosphate buffer (100 mM, pH 7.5). Afterward, reagent A (100 μL) was added and the reaction mixture was subsequently incubated at 98 °C for 10 min (water bath). Finally, a volume of 100 μL of reagent B and 800 μL of H_2O_{dd} were added. The mixture was incubated at 20 °C for 30 min and then centrifuged (13000*g*, 20 °C, 1 min). The supernatant (200 μL) was transferred into a microtiter plate, and the absorbance at 450 nm was measured using a microtiter plate reader (Multiskan FC). The calibration was performed using glucose as a reference. One katal (kat) of amylase activity was defined as the release of 1 mol of glucose equivalents per second.

Mass Spectrometric Investigations. The respective bands from the Coomassie-stained SDS gel (see below) were eluted from the gel and hydrolyzed tryptically by the Life Science Center (University of Hohenheim) using a modified method according to Shevchenko et al.[29] The protein spots were excised from the gel and incubated in 200 μL of H_2O_{dd} for 5 min at 1000 rpm. Afterward, the supernatant was replaced by 150 μL of acetonitrile and shaken at 1000 rpm. After 10 min, the supernatant was discarded and 100 μL of 100 mM NH_4HCO_3 containing 10 mM DTT was added and incubated for 30 min at 56 °C at 1000 rpm. The supernatant was subsequently replaced by 150 μL of acetonitrile and 85 μL of 100 mM NH_4HCO_3 containing 55 mM iodoacetamide. After incubation for 20 min in the dark, the gel piece was washed in 150 μL of 100 mM NH_4HCO_3 for 10 min at 1000 rpm and dehydrated by the addition of 150 μL of acetonitrile for 10 min at 1000 rpm. Afterward, the supernatant was discarded and 25 μL of trypsin solution (10 ng/μL in 40 mM NH_4HCO_3) was added. After 30 min on ice, a further 40 mM NH_4HCO_3 was added if needed. The digestion was carried out overnight at 37 °C. The sample was centrifuged after the addition of 2 μL of 50% (v/v) formic acid, and the supernatant was used for mass spectrometric analysis (MALDI-TOF-MS). The sample was analyzed by liquid chromatography electrospray ionization–mass spectrometry (LC-ESI-MS^2) using a nano-HPLC system (Aquity Waters, Milford, MA, USA) connected to an LTQ-Orbitrap XL hybrid mass spectrometer (Thermo Fisher Scientific, Waltham, MA, USA). A gradient from 1 to 50% (v/v) acetonitrile in 0.1% (v/v) formic acid over 30 min was used for separation (Life Science Center, University of Hohenheim). The data were treated by XCalibur software version 2.0.7, and *m*/*z* spectral data were transformed to spectra representing mass values. All MS^2 samples were analyzed using Mascot (Matrix Science, London, UK; version 2.3.02). Mascot was set up to search the NCBI database no. 20131117 (selected for Other Fungi, unknown version, 2111786 entries), assuming the digestion enzyme trypsin. Mascot was searched with a fragment ion mass tolerance of 0.60 Da and a parent ion tolerance of 15 ppm. Carbamidomethyl of cysteine was specified in Mascot as a fixed modification. Oxidation of methionine was specified in Mascot as a variable modification. Scaffold (version Scaffold 4.2.1, Proteome Software Inc., Portland, OR, USA) was used to validate MS^2-based peptide and protein identifications. Peptide identifications were accepted if they could be established at >95% probability by the Peptide Prophet algorithm,[30] with Scaffold delta-mass correction. Protein identifications were accepted if they could be established at >99% probability and contained at least five identified peptides. Protein probabilities were assigned by the Protein Prophet algorithm.[31] Proteins that contained similar peptides and could not be differentiated on the basis of MS^2 analysis alone were grouped to satisfy the principles of parsimony.

Sodium Dodecyl Sulfate–Polyacrylamide Gel Electrophoresis (SDS-PAGE) and Native PAGE. Respective samples were analyzed by SDS-PAGE (12.5%) according to the method of Laemmli.[32] The molecular weight protein standard mixture was obtained from New England Biolabs (NEB, broad range, 2–212 kDa; Frankfurt, Germany) and was used as a reference. The protein bands of the SDS gel were located by staining with Coomassie Brilliant Blue R-250.[33] The protein load was 5 μg per lane for the Flavourzyme mixture and 1 μg per lane for the purified enzyme samples. The protein content was determined by using the method of Bradford[34] and bovine serum albumin as a standard.

A native molecular weight protein standard mixture (SERVA native marker, liquid mix; SERVA, Heidelberg, Germany) was used as the reference for the native PAGE (8%). The native gel was activity stained (see below) to visualize aminopeptidase and dipeptidylpeptidase activity and to determine specific marker substrates for the automated purification protocol. Samples were diluted depending on the activity toward their particular substrate for further activity staining. An enzyme activity of approximately 50 μkat was applied per lane.

Aminopeptidase and Dipeptidylpeptidase Activity Staining of Polyacrylamide Gels. After electrophoresis, the native PAGE gels were washed with Tris-HCl buffer (50 mM, pH 7.5). An amount of 5 mg of the corresponding *p*NA derivative was solved in 25 μL of DMF and filled to 5 mL with Tris-HCl buffer (50 mM, pH 7.5) for the activity staining. In total, 13 X-*p*NA derivatives were tested (X = Ala, Ala-Pro, Arg, Glu, Gly, His, Ile, Leu, Lys, Lys-Ala, Phe, Pro, and Val). The gels were incubated in the buffer containing the respective *p*NA substrate until a yellow band appeared and were then washed with H_2O_{dd}. The bands were redyed, according to the method of Božić and Vujčić,[35] for improved visibility. Therefore, the gels were incubated in 1 g/L $NaNO_2$ (dissolved in 1 M HCl) for 120 s and washed in urea buffer (10 g/L) for 30 s. The gels were incubated in 0.25 g/L *N*-(1-naphthyl)-ethylenediamine dihydrochloride dissolved in 22% (v/v) EtOH for 10 min for staining.

Zymography. Native gels were supplemented with casein to a final concentration of 0.1% (w/v). An enzyme activity of 5×10^{-4} ACU was applied per lane. The separation of the proteins was performed in an ice

DOI: 10.1021/acs.jafc.5b01665
J. Agric. Food Chem. 2015, 63, 5682–5693

bath to prevent a hydrolysis of the casein during the enzyme migration. After electrophoresis, the gel was incubated in 0.1% (w/v) Triton X-100 at 7 °C for 1 h and subsequently incubated in Tris-HCl buffer (50 mM, pH 7.5) at 20 °C for 16 h. Afterward, the gel was Coomassie-stained[33] to visualize endopeptidase activity.

Automated Nine-Step Purification of Flavourzyme Peptidases. Flavourzyme enzymes were purified using a Bioline chromatography system (Knauer, Berlin, Germany). The system was equipped with a pump (S 1000), a UV detector (S 2520), a conductivity meter (S 2900), a manual injection six-port/three-channel injection valve, two seven-port/one-channel switching valves, and two six-port/three-channel injection valves. The eluting purified enzymes were detected at 280 nm and were collected using a fraction collector (Frac 3050). The fraction collector was cooled at 10 °C. The Bioline chromatography system was controlled by ChromGate Data System V.3.3.1. The fast protein liquid chromatography system and valve position setup were the same as previously reported.[36] Modifications to the system described[36] were the columns used and that a 5 mL sample loop was used for protein parking instead of a Superloop (GE Healthcare, Munich, Germany). Valves 1 and 2 were responsible for directing the flow to the columns. Three different modes could be operated with the positions of valves 3 and 4. The first mode (V3, inject; V4, load) was used for the standard chromatography. In the second mode (V3, load; V4, load), a protein fraction was parked in the sample loop. In the third mode (V3, inject; V4, inject), the parked protein fraction was applied to the next column. The three modes and the valve configuration are shown in the Supporting Information (Figure S1). The buffers and columns used for the automated purification protocol are listed in Tables 1 and 2.

Table 1. Buffer Compositions Used during the Automated Nine-Step Purification Protocol

buffer	composition	pH
A	10 mM sodium acetate, 0.1 mM $ZnCl_2$, 0.1 mM $CaCl_2$	4.85
B	10 mM sodium acetate, 0.1 mM $ZnCl_2$, 0.1 mM $CaCl_2$, 100 mM NaCl	4.9
C	1 M NaCl	
D	20 mM Tris-HCl	7.5
E	20 mM Tris-HCl, 1.5 M $(NH_4)_2SO_4$	7.5
F	35 mM sodium acetate, 0.1 mM $ZnCl_2$, 1 mM $CaCl_2$	4.5

Table 2. Purification Stages and Columns That Were Used during the Automated Nine-Step Purification Protocol

stage	column	chromatographic principle
I	MonoS 5/50 GL (CV = 1 mL; GE Healthcare, Munich, Germany)	ion exchange
II, IV, VI	HiTrap desalting column (3 × 5 mL; GE Healthcare, Munich, Germany)	size exclusion
III, VIII	BioFox 17/1200 Q (CV = 4.3 mL; Knauer; Berlin, Germany)	ion exchange
V	RESOURCE PHE (CV = 1 mL; GE Healthcare, Munich, Germany)	hydrophobic interaction
VII	MonoQ 5/50 GL (CV = 1 mL; GE Healthcare, Munich, Germany)	ion exchange
IX	Superdex 200 10/300 GL (CV = 24 mL; GE, Munich, Germany)	size exclusion

The column temperatures were 20 °C. A schematic representation of the automated purification protocol is shown in Figure 1. Prior to the purification, Flavourzyme was diluted in H_2O_{dd} and, subsequently, buffer was exchanged for the first buffer in the purification protocol (buffer A, Table 1) using a PD10 column (GE Healthcare). A final Flavourzyme solution of 10% (v/v) was obtained, resulting in a protein content of 7.3 g/L.

A volume of 2 mL of the Flavourzyme solution was injected at a flow rate of 0.5 mL/min into a strong cation exchange chromatography (CEX) column (stage I, Table 2) with 100% buffer A. The unbound protein was washed out using 10 column volumes (CV) at a flow rate of

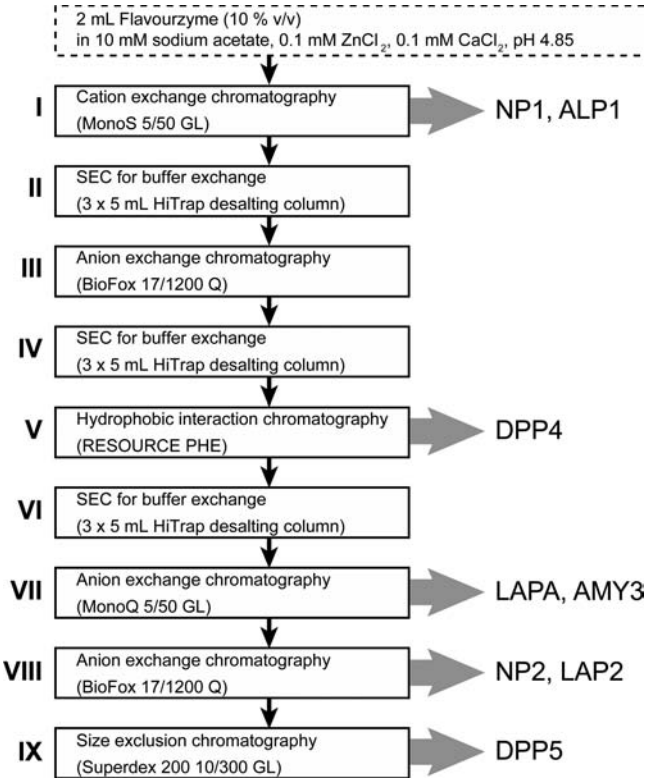

Figure 1. Schematic representation of the automated purification protocol for the Flavourzyme enzymes. Stages I–IX are in accordance with Table 2. Protein fractions, which were injected into the next purification stage, were always parked in a 5 mL sample loop. ALP1, alkaline protease 1; AMY3, α-amylase A type 3; DPP4, dipeptidyl peptidase 4; DPP5, dipeptidyl peptidase 5; LAPA, leucine aminopeptidase A; LAP2, leucine aminopeptidase 2; NP1, neutral protease 1; NP2, neutral protease 2.

0.5 mL/min. The flow-through volume (4.25 mL) was collected and automatically parked in the 5 mL sample loop. The column-bound protein was eluted using a one-step gradient and two linear gradients at a flow rate of 0.75 mL/min. The protein eluted from the step gradient (80% buffer A, 20% buffer B) was discarded. The proteins eluted from the first linear gradient (10 CV; 65% buffer A, 35% buffer B) and the second linear gradient (16 CV; 80% buffer A, 20% buffer C) were collected individually from 27.5 to 32.5 min (3.75 mL) and from 45.3 to 48.3 min (2.25 mL), respectively. Afterward, the parked protein was injected into three lined-up size exclusion chromatography (SEC) columns (stage II, Table 2) for a buffer exchange to 100% buffer D at a flow rate of 2 mL/min and, subsequently, parked (5 mL) again. Then, the desalted protein solution was injected into a strong anion exchange chromatography (AEX) column (stage III, Table 2) with 100% buffer D at 0.5 mL/min. No flow-through was collected here. One bound protein fraction was eluted using a step gradient (21% buffer C, 79% buffer D) at a flow rate of 1 mL/min. The protein eluted (3.8 mL) was automatically parked. Additional bound protein remained on the column until further notice. Again, the parked protein was injected into three lined-up SEC columns (stage IV, Table 2) for a buffer exchange to 100% buffer E at a flow rate of 2 mL/min and, subsequently, parked (5 mL) again. The parked protein was then injected into a hydrophobic interaction chromatography (HIC) column (stage V, Table 2) with 100% buffer E at 0.5 mL/min. The unbound protein was washed out using 10 CV, and no flow-through was collected at this point. The elution was performed at a flow rate of 1 mL/min. The first bound protein fraction was eluted using a linear gradient (3.75 CV; 12% buffer D, 88% buffer E) and was discarded. The second bound protein fraction (3.5 mL) was eluted with a step gradient (55% buffer D, 45% buffer E) and was automatically parked. The third bound protein fraction was eluted by linear gradient

[a]Molecular masses calculated from the respective UniProtKB entry (mature monomer).

(8 CV; 100% buffer D) and collected from 194 to 197 min (3 mL). Next, the parked protein fraction from stage V (Table 2) was injected into three lined-up SEC columns (stage VI, Table 2) for a buffer exchange to 100% buffer D at a flow rate of 2 mL/min and, subsequently, parked (5 mL) again. The parked protein fraction was injected into a strong AEX column (stage, VII Table 2) with 100% buffer D at 0.5 mL/min. The unbound protein was washed out using 20 CV, and no flow-through was collected here. The elution was performed at a flow rate of 1 mL/min. The first bound protein fraction was eluted using a linear gradient (4 CV; 35% buffer D, 65% buffer F), and the fraction was collected from 273.5 to 277.5 min (4 mL). The second bound protein fraction was eluted with a step gradient (30% buffer C, 70% buffer D), and the fraction was collected from 281.3 to 283.3 min (2 mL). Afterward, the remaining protein fractions on the column from stage III (Table 2) were eluted at a flow rate of 1 mL/min (stage VIII, Table 2). The first bound fraction was obtained after linear gradient elution (1.2 CV; 20% buffer C, 80% buffer D) from 312 to 315 min (3 mL). The gradient was kept for 2.4 CV, and then 100% buffer D was used for 0.7 CV. A second fraction was obtained by a subsequent linear gradient elution (1.9 CV; 50% buffer D, 50% buffer F) from 325.5 to 327.5 min (2 mL). A third fraction (1.15 mL) was automatically collected and parked after a step gradient (35% buffer C, 65% buffer D). The parked protein fraction was then injected directly into a SEC column (stage IX, Table 2) with 20% buffer C and 80% buffer D at a flow rate of 0.75 mL/min. A last protein fraction was obtained by isocratic elution for 1 CV from 384.8 to 387.8 min (2.25 mL). The total run time for the automated nine-step purification protocol of the Flavourzyme enzymes was 420 min (7 h). A detailed overview of the particular purification steps, including valve positions, is summarized in Table S2 (Supporting Information).

Characterization of the Purified Flavourzyme Enzymes. Protein fractions from the automated purification protocol were taken, and the buffer was exchanged using PD10 desalting columns (GE Healthcare). The exchange buffer was 10 mM Tris-HCl (pH 7.5) containing 0.1 mM $ZnCl_2$ and 0.1 mM $CaCl_2$. Formulated purified enzymes were stored at −20 °C. The enzyme samples were conveniently diluted in corresponding assay buffers for the following characterization.

Effect of pH on the Enzyme Activity. The pH profiles of the purified enzymes were determined with citrate phosphate buffer (50 mM; pH 3.0−7.5), Bis-Tris-propane buffer (50 mM; pH 7.5−10.0), CHES buffer (50 mM; pH 9.0−10.0), or glycine-NaOH buffer (50 mM; pH 10.0−12.0) at 37 °C. As an exception, the pH profile of the AMY3 was measured in the presence of 5 mM of the corresponding buffer.

Effect of Temperature on the Enzyme Activity. The temperature profiles of the purified enzymes were determined at the optimum pH in the corresponding buffer system (determined before). The assay temperatures ranged from 20 to 75 °C.

Determination of the Native Molecular Size by HPLC-SEC. The native molecular size of the purified enzymes was evaluated by SEC on an UHPLC system (PLATINblue; Knauer, Berlin, Germany). Therefore, 5 μL of the purified enzyme solution was loaded into a Yarra SEC-2000 column (Phenomenex, Aschaffenburg, Germany). The flow rate was 1 mL/min, and the mobile phase was 50 mM sodium phosphate buffer, pH 6.5, supplemented with 300 mM NaCl. Eluted proteins were detected at 280 nm. The sizes were calculated, on the basis of the retention time obtained, using a calibration curve determined with standard proteins (gel filtration LMW/HMW calibration kits; GE Healthcare). All samples were taken from the fractions of the automated purification protocol without any further preparation. Only the DPP4 fraction was concentrated 60-fold, using a vacuum centrifuge (RVC 2-33 IR, Christ, Osterode, Germany; 1 mbar, 40 °C, 4 h), due to the low protein content of the fraction.

Statistical Analysis. The standard deviation was used for data evaluation and calculated with Excel (Microsoft, Redmond, WA, USA). All trials were conducted at least in duplicate, with two independent measurements. The automated purification protocol was carried out five times to check the reproducibility of the system.

RESULTS AND DISCUSSION

Identification of Key Flavourzyme Enzymes. A comprehensive and comparative study was carried out to identify the key enzyme activities in the Flavourzyme preparation. The approach was as follows: First, relevant proteins from Flavourzyme were identified by mass spectrometric investigations (LC-ESI-MS^2). Second, a substrate screening using various aminopeptidase and dipeptidyl peptidase substrates was carried out. Third, if possible, the activities of the substrate screening were assigned to particular proteins by activity staining of native polyacrylamide gels or by zymography.

In total, eight enzymes were identified in the Flavourzyme mixture (Table 3). The table also includes the UniProtKB identifier of the particular enzyme and the molecular mass calculated from the respective UniProtKB entry (mature monomer). All enzymes identified originated from *A. oryzae* (strain ATCC 42149/RIB 40), also known as yellow koji mold. In summary, three endopeptidases (neutral protease 1, NP1; neutral protease 2, NP2; alkaline protease 1, ALP1), two aminopeptidases (leucine aminopeptidase A, LAPA; leucine aminopeptidase 2, LAP2), two dipeptidyl peptidases (dipeptidyl peptidase 4, DPP4; dipeptidyl peptidase 5, DPP5), and one amylase (α-amylase A type 3, AMY3) were identified. ALP1, NP1, and NP2 are also known as oryzin, fungalysin, and deuterolysin, respectively. LAPA is also known as leucine aminopeptidase 1. The sequence coverages (MS analysis) were 28, 30, 46, 60, 73, 7, 52, and 45% for NP1, NP2, ALP1, LAPA, LAP2, DPP4, DPP5, and AMY3, respectively.

All peptidase activities could be verified either by activity staining of native polyacrylamide gels or by zymography. Three endopeptidase activities were determined by zymography (data not shown). Four specific marker substrates were revealed for the aminopeptidases and dipeptidyl peptidases after the *p*NA substrate screening and by activity staining of native gels (Figure 2). Here, the Flavourzyme preparation was applied on a native PAGE and activity stained with different *p*NA substrates. It can be concluded that four different aminopeptidases and dipeptidyl peptidases are present in Flavourzyme due to the

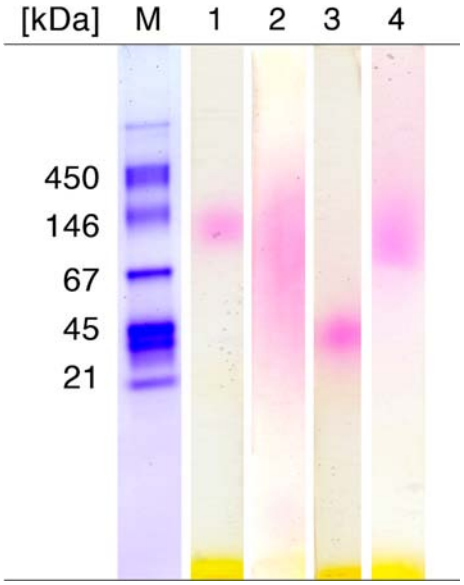

Figure 2. Native PAGE with activity staining of Flavourzyme preparation with different *p*NA substrates. Lanes: 1, Ala-Pro-*p*NA; 2, Lys-Ala-*p*NA; 3, Ile-*p*NA; 4, Pro-*p*NA. M indicates the protein marker (SERVA native marker, liquid mix; SERVA, Heidelberg, Germany). An enzyme activity of 50 μkat on the corresponding substrate was loaded per lane.

different activity staining patterns (Figure 2). Later, it was confirmed for the purified peptidases that the substrate Ile-*p*NA was hydrolyzed only by LAPA, Pro-*p*NA was hydrolyzed only by LAP2, Ala-Pro-*p*NA was hydrolyzed only by DPP4, and Lys-Ala-*p*NA was hydrolyzed only by DPP5. With these marker substrates, a distinction between these four enzymes was possible and advantageous for a later assessment of the purification of the Flavourzyme enzymes.

All marker substrates, which were used for the indication of the enzymes during the automated purification, are summarized in Table 4. Because specific marker substrates could not be determined for the endopeptidases (NP1, NP2, ALP1), the same substrate (azocasein) was used for the evaluation of the purification. Starch was used as the substrate for AMY3.

Because Flavouryzme is an industrial enzyme preparation from *A. oryzae*, the proteomic analysis of extracellular proteins from *A. oryzae* gives an indication of the enzymes present in the preparation. Oda et al.[18] evaluated the production of extracellular proteins from *A. oryzae* RIB40 under submerged and solid-state culture conditions. The cultures were cultivated on wheat bran (solid-state and submerged). The proteins were identified by MALDI-TOF-MS. A functionality (enzyme activity) of a specific protein was not determined. The authors found that mainly glucosidases were secreted during the cultivation.[18] Oryzin (ALP1) and DPP5 were expressed under solid-state conditions. Oryzin (ALP1) was also expressed under submerged conditions.[18] Because wheat bran contains around 80% carbohydrates,[37] a preferred expression of glucosidases over peptidases seems convincing. Liang et al.[19] analyzed the extracellular proteins of *A. oryzae* AS 3.951 and RIB40 grown on soy sauce koji (soybeans) by MALDI-TOF-MS. Again, functionality (enzyme activity) was not determined. Here, an ALP1, an NP1, an NP2, a DPP5, an X-prolyl aminopeptidase, a leucine aminopeptidase, and an α-amylase were found.[19] In conclusion, an impact of the cultivation medium (wheat bran or soy sauce koji) on the expression of the enzyme set can be assumed. Nakadai and Nasuno[38] also showed that the production of peptidases from *A. oryzae* ATCC 20386 varied, depending on the culture conditions. The conclusion was that submerged cultivation was preferable to solid-state cultivation for the production of peptidases.[38] In this study,[38] casein and the aminopeptidase substrate (Leu-βNA) were used to determine the particular peptidase activity. On the other hand, solid-state cultivation was preferable for the production of glucosidases.[38] The study of Sriranganadane et al.[20] showed that different sets of peptidases are expressed and secreted depending on the pH of the culture medium. The authors detected peptidases from *Aspergillus fumigatus* by MALDI-TOF-MS. The fungus was grown on a malt agar including collagen at pH 3.5 and 7.0. The authors concluded that neutral pH favors the secretion of neutral and alkaline endopeptidases and leucine aminopeptidases (LAP2, DPP4, DPP5), whereas acidic pH promotes the secretion of endopeptidases of the pepsin family and carboxypeptidases.[20] Taking these results together, *A. oryzae* ATCC 42149/RIB 40, which is used for the production of Flavourzyme, was most probably cultivated under neutral culture conditions.

Various enzyme activities in Flavourzyme were determined using an API-ZYM test system in the study of Kilcawley et al.[6] The authors used a solid preparation (Flavourzyme MG/A) and did not correlate a certain enzyme activity to a specific protein. They identified various esterase, peptidase, lipase, and glycosidase activities with the API-ZYM test.[6] In addition, various aminopeptidase activities were detected, whereas endopeptidase activity and carboxypeptidase activity could not be ascertained.[6]

Automated Nine-Step Purification of Flavourzyme Enzymes. An automated purification protocol was developed

Table 4. Purified Enzymes from Flavourzyme That Were Obtained from the Automated Nine-Step Purification Protocol[a]

no.	enzyme[b]	marker substrate	apparent purity[c] (%)	total enzyme activity	specific enzyme activity	recovery (%)	purification fold
1	LAPA	Ile-*p*NA	90	9.5 nkat	10.7 nkat/mg	42	7.5
2	LAP2	Pro-*p*NA	88	1.5 nkat	6.6 nkat/mg	42	29.5
3	DPP4	Ala-Pro-*p*NA	40	1.8 nkat	603 nkat/mg	36	1898
4	DPP5	Lys-Ala-*p*NA	94	30.1 nkat	133 nkat/mg	475	328
5	NP1	azocasein	>95	450 ACU	775 ACU/mg		na[d]

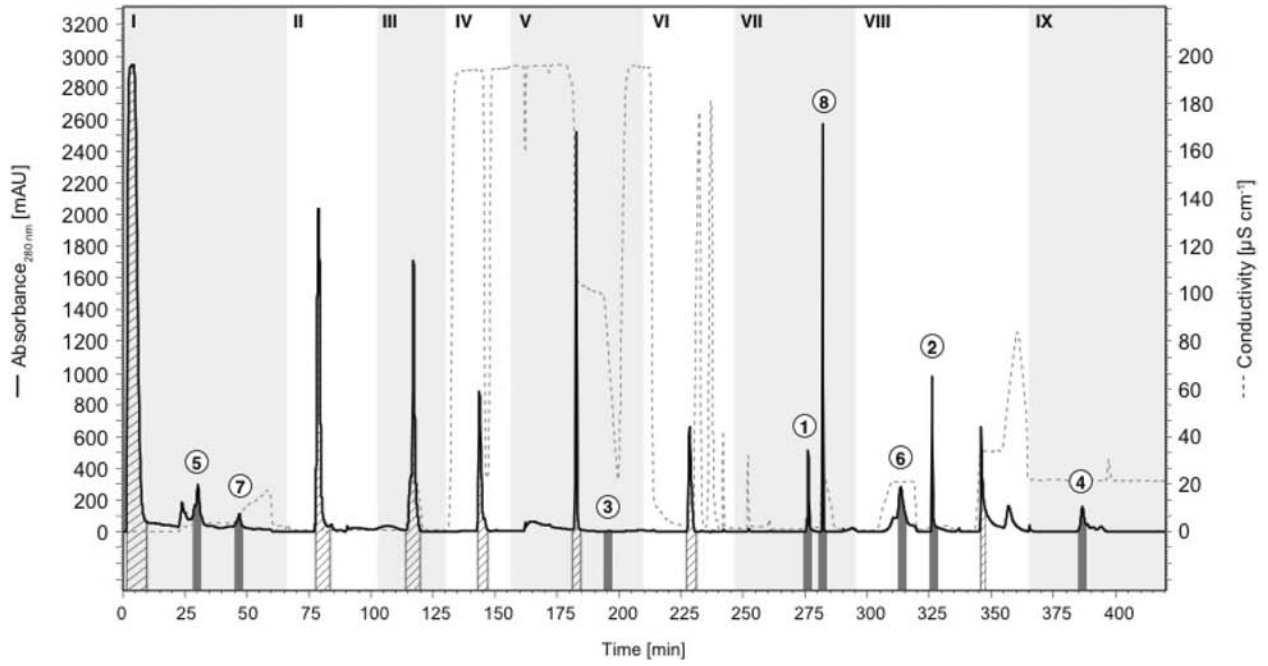

Figure 3. Automated nine-step purification of eight Flavourzyme key enzymes. The purification stages comply with Table 2 and Figure 1: I, CEX (Mono S 5/50 GL, 1 mL); II, IV, VI, buffer exchange (HiTrap desalting column, 3 × 5 mL); III, AEX (Biofox 17Q, 4.3 mL); V, HIC (ResourcePhe, 1 mL); VII, AEX (Mono Q 5/50 GL, 1 mL); VIII, AEX (Biofox 17Q, 4.3 mL); IX, SEC (Superdex 200 10/300 GL, 24 mL). Fractions of interest (isolated enzymes) are indicated with gray bars, and the encircled numbers comply with the consecutive numbering in Tables 3 and 4. Fractions that were automatically injected to the next chromatography step are indicated by hatched areas.

to purify the eight enzymes of Flavourzyme simultaneously in a semipreparative scale. All fractions collected were tested for endopeptidase, aminopeptidase, dipeptidylpeptidase, and α-amylase activity. In addition, all active fractions were investigated by MALDI-TOF-MS. The final chromatogram of the automated nine-step purification protocol is displayed in Figure 3. The different stages (I–IX) of the purification protocol correspond to Table 2. Encircled numbers in Figure 3 represent the fractions of interest (gray areas indicate the purified enzymes) and are in accordance with the consecutive numbering in Tables 3 and 4. The purified enzymes collected were immediately chilled on ice and desalted to 10 mM Tris-HCl, pH 7.5, containing 0.1 mM $ZnCl_2$ and 0.1 mM $CaCl_2$ before the enzyme activity was determined. The hatched areas in Figure 3 indicate fractions that were parked and, subsequently, injected into the next chromatography step.

We observed a loss of the LAPA activity after the CEX in preliminary experiments (data not shown). The LAPA is a zinc-dependent metallopeptidase (UniProtKB annotation) and, thus, the removal of the cation from the enzyme by the chromatography resin could be an explanation. Because most other enzymes identified are also metal-dependent (zinc, NP1, NP2, LAP2; calcium, AMY3), buffers A, B, and F (Table 1) were supplemented with zinc and calcium chloride. With these additions, the recovery of the LAPA activity was about 5-fold higher (data not shown). The other enzymes were not affected by the supplementation.

As mentioned before, a schematic representation of the automated purification protocol is shown in Figure 1. Two protein fractions were eluted from 27.5 to 32.5 min (3.75 mL) and from 45.3 to 48.3 min (2.25 mL), respectively. The proteins eluted were identified by LC-ESI-MS^2 as NP1 (⑤; Figure 3) and ALP1 (⑦; Figure 3). A total activity of 450 ACU with a specific activity of 775 ACU/mg was obtained for NP1. A total activity of 151 ACU with a specific activity of 495 ACU/mg was obtained for ALP1 (see Table 4). The next fraction of interest was eluted in stage V (Figure 3) from 194 to 197 min (3 mL) and was identified by LC-ESI-MS^2 as DPP4 (③; Figure 3). A total enzyme activity of 1.8 $nkat_{H\text{-}Ala\text{-}Pro\text{-}pNA}$ was obtained. In comparison to the Flavourzyme preparation, the specific activity increased 1898-fold to 603 $nkat_{H\text{-}Ala\text{-}Pro\text{-}pNA}$/mg for the purified peptidase. The recovery was 36% (Table 4). The next two fractions of interest were eluted in stage VII (Figure 3) from 273.5 to 277.5 min (4 mL) and from 281.3 to 283.3 min (2 mL) and were identified by LC-ESI-MS^2 as LAPA (①; Figure 3) and AMY3 (⑧; Figure 3), respectively. A total enzyme activity of 9.5 $nkat_{H\text{-}Ile\text{-}pNA}$ was obtained for LAPA. The specific activity increased 7.5-fold to 10.7 $nkat_{H\text{-}Ile\text{-}pNA}$/mg for the purified peptidase. The recovery was 42% (Table 4). A total enzyme activity of 2950 $nkat_{Starch}$ was obtained for AMY3. The specific activity increased 6.3-fold to 2190 $nkat_{Starch}$/mg for the purified amylase (recovery, 54%; Table 4). Another two protein fractions were obtained in stage VIII (Figure 3) from 312 to 315 min (3 mL) and from 325.5 to 327.5 min (2 mL) and were identified by LC-ESI-MS^2 as NP2 (⑥; Figure 3) and LAP2 (②; Figure 3), respectively. A total activity of 9 ACU with a specific activity of 6.3 ACU/mg was obtained for NP2 (Table 4). Because all endopeptidases investigated use the same substrate (azocasein), it was not possible to assign a specific recovery and a purification factor for a particular endopeptidase. In total, a recovery of 23% of the three endopeptidases was achieved. A total enzyme activity of 1.5 $nkat_{H\text{-}Pro\text{-}pNA}$ was obtained for the aminopeptidase LAP2. The specific activity of LAP2 increased 29.5-fold to 6.6 $nkat_{H\text{-}Pro\text{-}pNA}$/mg for the purified peptidase. The recovery was 42% (Table 4). The last protein fraction of interest was obtained in stage IX (Figure 3) from 384.8 to 387.8 min (2.25 mL) and was identified by LC-ESI-MS^2 as DPP5 (④; Figure 3). A total enzyme activity of 30.1 $nkat_{H\text{-}Lys\text{-}Ala\text{-}pNA}$ was obtained for DPP5.

J. Agric. Food Chem. 2015, 63, 5682–5693

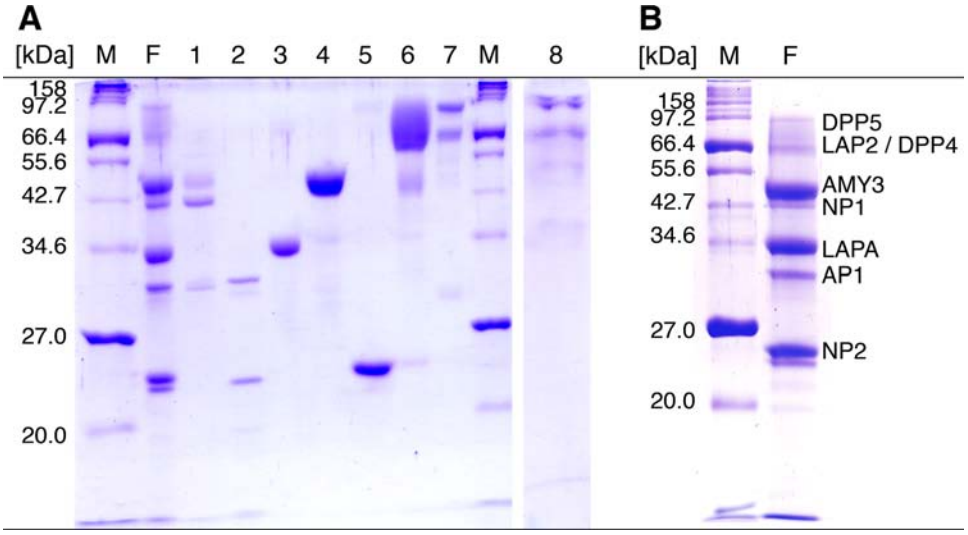

Figure 4. SDS-PAGE with Coomassie staining of protein fractions from the automated purification protocol (A) and Flavourzyme (B). M indicates the protein marker (broad range, 2−212 kDa; NEB, Frankfurt, Germany). Protein load was 1 μg per lane for the purified protein fractions (lanes 1−8) and 5 μg for the Flavourzyme samples (F). Lanes: 1, neutral protease 1; 2, alkaline protease 1; 3, leucine aminopeptidase A; 4, α-amylase A type 3; 5, neutral protease 2; 6, leucine aminopeptidase 2; 7, dipeptidyl peptidase 5; 8, dipeptidyl peptidase 4.

The specific activity increased 328-fold to 133 $nkat_{H\text{-}Lys\text{-}Ala\text{-}pNA}$/mg for the purified peptidase. The recovery was 475% (Table 4).

The reproducibility of the automated purification was tested with five independent trials. The deviation of the five purification trials was <5% concerning purification factors, yields of the enzymes, and alteration of the retention times.

The automated purification of proteins with a comparable setup was shown by Eisele et al.[36] and Stressler et al.[39] Eisele et al.[36] purified angiotensin-converting enzyme from a mammalian tissue (pig lung) with a yield of 23.6% and a 308-fold increase of the specific activity. The automated six-step purification protocol took 8 h. Stressler et al.[39] purified a prolyl-specific aminopeptidase (PepX) from *Lactobacillus helveticus* from a crude cell extract. They achieved a yield of 56% with a purification factor of 162-fold. The automated four-step purification protocol took 6 h. In contrast to the literature presented, eight proteins of interests were simultaneously purified here from a complex industrial fungal enzyme preparation.

Characterization of Purified Flavourzyme Enzymes. Purified and formulated enzymes were conveniently diluted in the appropriate buffer system. The effect of the pH and the temperature on the enzyme activity was tested using the purified enzymes and is described below. Additionally, the purified enzymes were analyzed by HPLC-SEC and SDS-PAGE to determine the native sizes and the sizes under denaturing conditions, respectively. The apparent purity (Table 4) of the particular enzyme was estimated by integration of the HPLC-SEC chromatogram (Figures S3−S10 in the Supporting Information). The extinction coefficients of the respective proteins were not considered because some areas from the HPLC-SEC chromatogram could not be assigned to a specific protein from the LC-ESI-MS^2 analysis. The major impurities in the purified fractions, found by LC-ESI-MS^2 analysis, were a β-glucosidase A, a *N*-acetylglucosaminidase, a IgE-binding protein and a glucoamylase.

All purified enzyme fractions exhibited <5% activity toward the other marker substrates (data not shown).

Leucine Aminopeptidase A (LAPA). The calculated size of LAPA is 32.5 kDa (UniProtKB). Under denaturing conditions (SDS-PAGE; Figure 4A, lane 3), a protein band at approximately 34 kDa was observed. A native size of 36.2 kDa was determined by HPLC-SEC. These results indicate a monomeric structure for the active enzyme. The apparent purity of the isolated enzyme was 90% (Table 4). The pH profile of the purified LAPA is displayed in Figure 5(1) and shows an optimum pH of 9.0 with reasonable activity between pH 6.5 and 10.0. The effect of the temperature on the activity is shown in Figure 6(1). The highest activity was measured at 65 °C. An extracellular leucine aminopeptidase from *A. oryzae* RIB40 was described previously by Matsushita et al.[40] Here, the aminopeptidase exhibited the highest activity at pH 8.5 and 60 °C and showed a molecular weight of 33 kDa by SDS-PAGE analysis.[40] A leucine aminopeptidase 1 from *A. oryzae* ATCC 20386 was purified and characterized by Nakadai et al.[41] Again, the enzyme exhibited the highest enzyme activity at pH 8.5 and 60 °C. However, in contrast to our observations, the native size determined was 26.5 kDa by SEC analysis. In the current study, the enzyme activity at optimum pH and temperature was 75.1 $nkat_{H\text{-}Ile\text{-}pNA}$/mg.

Leucine Aminopeptidase 2 (LAP2). A monomeric molecular weight of 51.9 kDa was calculated (UniProtKB) for LAP2. No discrete protein band could be detected under denaturing conditions (SDS-PAGE; Figure 4A, lane 6). A broad protein band from approximately 60 to 100 kDa was observed, and a native size of 105.7 kDa was determined by HPLC-SEC. These results indicate a seemingly dimeric structure for the active enzyme. The smeared band observed on the SDS-PAGE and the native size of 105.7 kDa can be explained by the high glycosylation of the enzyme (computed glycosylation at amino acid positions 224, 307, 341, 402, 424, and 458; UniProtKB). This observation was also described by Blinkovsky et al.[42] for aminopeptidase 2 from *A. oryzae* ATCC 20386. After deglycosylation of the N-linked sugars, the protein band was sharp at 56 kDa.[42] Thus, a heterogeneous glycosylation pattern could lead to higher and variable molecular masses for a monomer. The apparent purity of the isolated enzyme was 88% (Table 4). The pH profile of the purified LAP2 is displayed in Figure 5(2) and shows an optimum pH of 9.5 with about 50% relative activity at pH 8.5 and 10.5. An optimum pH of 8.0 was determined by Nakadai et al.,[43] and an optimum pH of 9.5 was

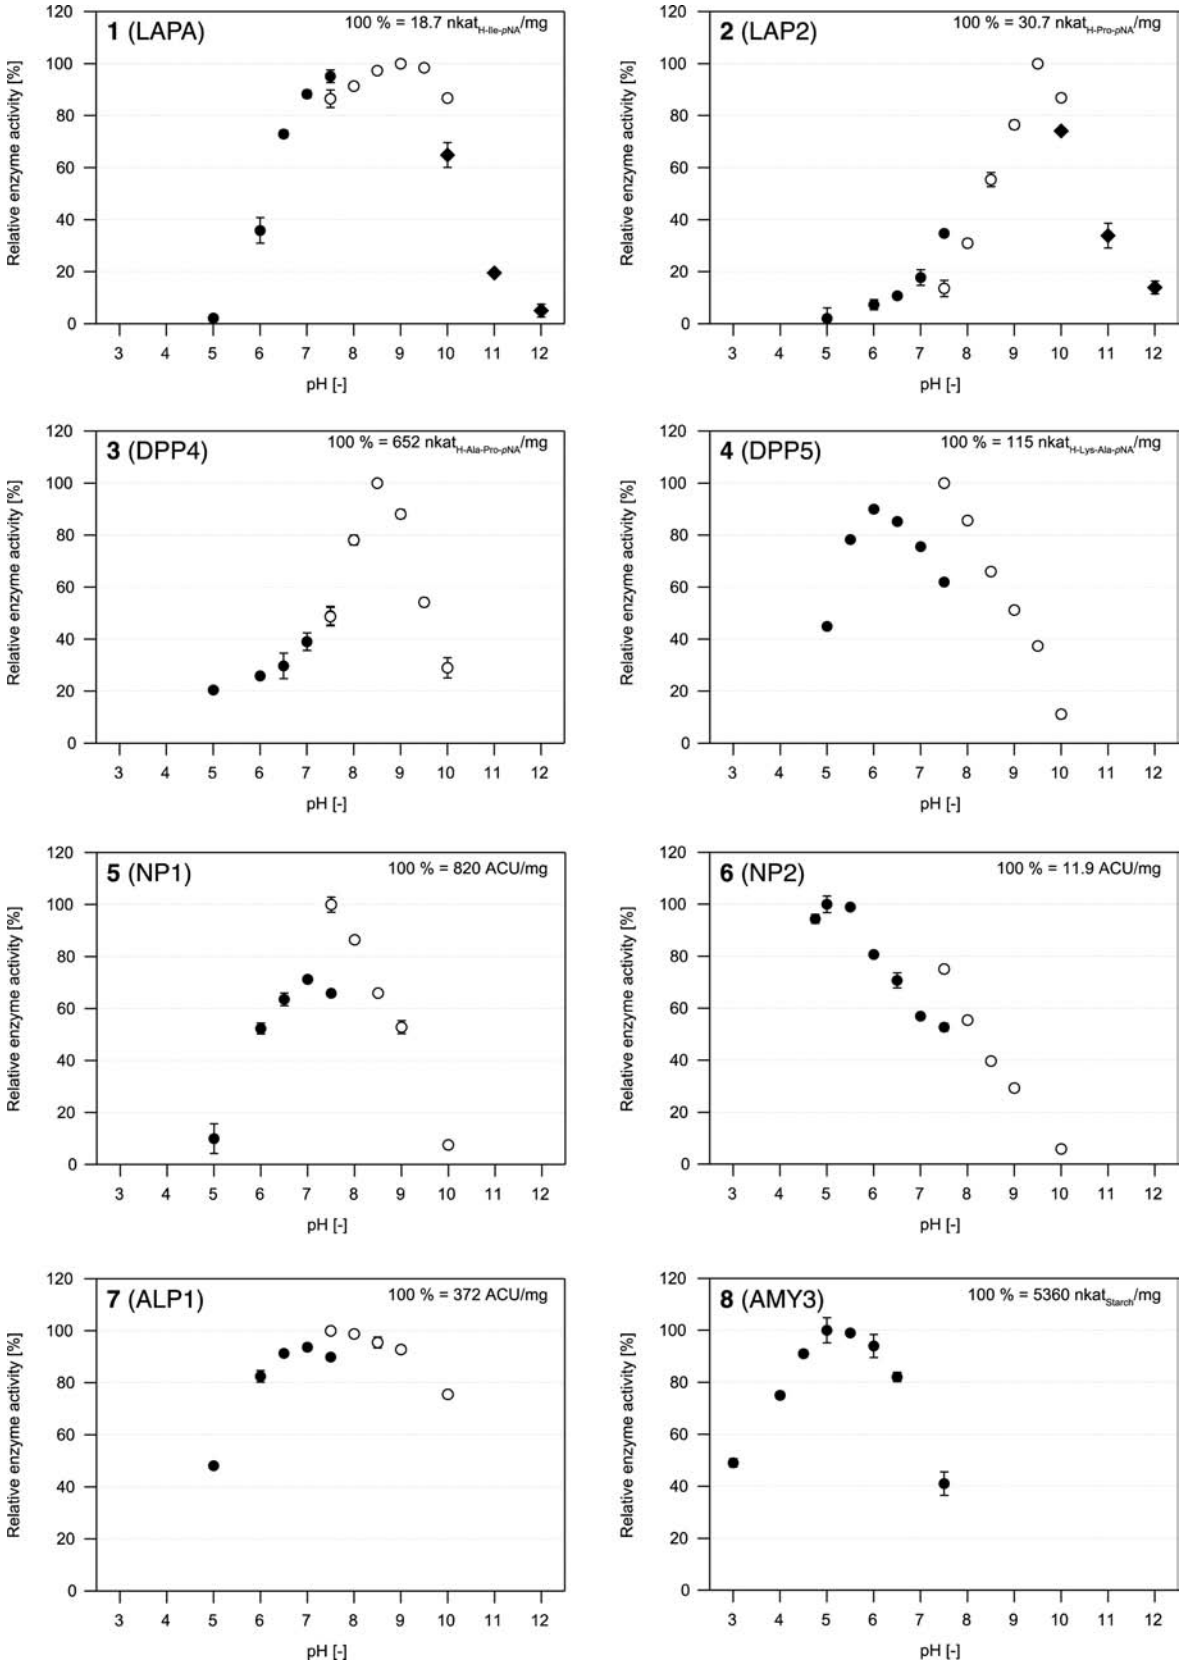

Figure 5. Influence of pH value on enzyme activity of purified Flavourzyme enzymes at 37 °C. Buffers: solid circles, 50 mM citrate phosphate; open circles, 50 mM Bis-Tris-propane; solid diamonds, 50 mM glycine-NaOH. AMY3 was incubated in 5 mM corresponding buffer.

determined by Blinkovsky et al.[42] for leucine aminopeptidase 2 from *A. oryzae* ATCC 20386, respectively. The effect of the temperature on the activity of LAP2 is shown in Figure 6(2). The highest activity was measured at 50 °C. This is in accordance with the literature.[43] The enzyme activity of LAP2 at optimum pH and temperature was 54.2 $nkat_{H\text{-}Pro\text{-}pNA}/mg$.

Dipeptidyl Peptidase 4 (DPP4). The size of DPP4 calculated was 85.1 kDa (UniProtKB). A single protein band could not be obtained on a SDS-PAGE (Figure 4A, lane 8). The presence of DPP in this fraction was ascertained by LC-ESI-MS[2]

DOI: 10.1021/acs.jafc.5b01665
J. Agric. Food Chem. 2015, 63, 5682−5693

analysis. The apparent purity of DPP4 was approximately 40% (Table 4) by HPLC-SEC. The native size (HPLC-SEC) of DPP4 was 206.6 kDa, which most probably indicates a dimeric form of the enzyme. The results are in accordance with the literature. The existence of DPP4, which was expressed as a 95 kDa glycoprotein, from *A. oryzae* has been shown.[44] Tachi et al.[45] also showed that DPP4 from *A. oryzae* existed as a homodimer. The pH profile of the purified DPP4 is shown in Figure 5(3). The optimum pH was 8.5 with about 50% relative activity at pH 7.5 and 9.5. Tachi et al.[45] determined an optimum pH of 7.0−7.5 with the substrate H-Gly-Pro-*p*NA. The effect of the temperature on the activity is shown in Figure 6(3). The highest activity was measured at 60 °C. The enzyme activity at optimum pH and temperature was 1471 $nkat_{H\text{-}Ala\text{-}Pro\text{-}pNA}$/mg.

Dipeptidyl Peptidase 5 (DPP5). To the best of our knowledge, there has been no detailed biochemical characterization of DPP5 from *A. oryzae* so far. In contrast to other dipeptidyl peptidases, DPP5 is not able to cleave X−prolyl bonds (tested with Ala-Pro-*p*NA, Gly-Pro-*p*NA, and Arg-Pro-*p*NA). This difference makes a distinction between DPP5 and DPP4 possible. Beauvais et al.[46] described a fungal DPP5 from *A. fumigatus*. They observed a monomeric size (SDS-PAGE analysis) of 79 kDa after deglycosylation (88 kDa as glycosylated protein). In our study, we determined a native size of 220.3 kDa (HPLC-SEC), which indicates a dimeric or trimeric form when considering the size of 78.6 kDa calculated (UniProtKB). In addition, the HPLC-SEC analysis showed a single and distinct peak (94% apparent purity, Table 4). In contrast to the latter, three distinct protein bands were obtained on a SDS-PAGE (Figure 4A, lane 7). All three bands were independently identified as DPP5 by LC-ESI-MS^2. The protein bands at approximately 66 and 90 kDa showed sequence coverages of 45 and 46%, respectively. The protein band at approximately 30 kDa showed a sequence coverage of 19%. The reason for the three bands on the SDS-PAGE is not clear. The presence of fractions after electrophoresis can probably explain the broad staining of the native PAGE (Figure 2, lane 2). The pH profile of the purified DPP5 is shown in Figure 5(4). The optimum pH was determined to be 6.0 with about 50% relative activity at pH 5.0 and about 80% relative activity at pH 7.0, respectively. The highest activity was measured in Bis-Tris-propane buffer at pH 7.5. A strong inactivation (buffer effect) was observed using citrate phosphate buffer. The effect of the temperature on the activity is shown in Figure 6(4). The highest activity was measured at 65 °C. The enzyme activity at optimum pH and temperature was 555 $nkat_{H\text{-}Lys\text{-}Ala\text{-}pNA}$/mg.

Neutral Protease 1 (NP1). The purified NP1 showed two distinct protein bands at approximately 29 and 42 kDa (SDS-PAGE analysis; Figure 4A, lane 1). The LC-ESI-MS^2 measurements identified both bands as NP1. Only two distinct proteins with 41.3 and 58.5 kDa were detected for the native size of the NP1 determined by HPLC-SEC. The mass calculated (UniProtKB) for the NP1 was 42.4 kDa (Table 3). The two proteins were obtained in different fractions during the automated purification. Therefore, the 41.3 and 58.5 kDa proteins were separately characterized. We observed the same properties regarding pH and temperature profiles and specific enzyme activity. Thus, the respective protein fractions of the NP1 were pooled. A proteolysis during the storage of the Flavourzyme preparation seems to be a plausible explanation for two NP1 fragments. The optimum pH was determined at pH 7.0 in citrate phosphate buffer, as shown in Figure 5(5). However, the highest activity was measured in Bis-Tris-propane buffer at pH 7.5, due to a strong inactivation (buffer effect) caused by the citrate phosphate buffer. This result complies with a characterization of a neutral protease 1 from *A. oryzae* ATCC 20386 previously described.[47] The authors determined a native size of 41 kDa and an optimum pH of 7.0 with about 50% relative enzyme activity in phosphate buffer compared to Tris-HCl buffer.[47] The effect of the temperature on the activity is shown in Figure 6(5). The highest activity was measured at 50 °C. The enzyme activity at optimum pH and temperature was 892 ACU/mg.

Neutral Protease 2 (NP2). NP2 showed a distinct band at approximately 25 kDa (SDS-PAGE analysis; Figure 4A, lane 5). A distinct peak was also obtained by HPLC-SEC analysis, which corresponds to a native size of 24.4 kDa (89% apparent purity, Table 4). The size calculated was 19.0 kDa (UniProtKB). Therefore, a monomeric state of the peptidase can be assumed. The highest activity was determined at pH 5−5.5 [Figure 5(6)] and 60 °C [Figure 6(6)]. A moderate influence of the buffer system was also observed. The NP2 activity was lower in the citrate phosphate buffer. The enzyme activity at optimum pH and temperature was 62 ACU/mg. Tatsumi et al.[48] expressed a neutral protease 2 from *A. oryzae* ATCC 20386 and determined a molecular size of 26 kDa (SDS). Nakadai et al.[49] also described a neutral protease 2 from *A. oryzae* ATCC 20386 and determined a native size of 19 kDa (SEC) with the highest activity at pH 5.5−6.

Alkaline Protease 1 (ALP1). As described for NP1, the purified ALP1 fraction also showed two distinct proteins, with approximately 25 and 30 kDa (SDS-PAGE analysis; Figure 4A, lane 2). Both proteins were identified as ALP1 by LC-ESI-MS^2. The native size (HPLC-SEC) was determined at 19.5 and 41.1 kDa, respectively. The theoretical mass for the ALP1 was 29.0 kDa (UniProtKB, Table 3). Again, the two proteins were obtained in different fractions during purification. The 19.5 and 41.1 kDa proteins were separately characterized. As described for NP1, we observed the same properties (pH profile, temperature profile, and specific enzyme activity) for both protein fractions. Therefore, we pooled the respective protein fractions of the ALP1 for further investigation. The pH profile of the ALP1 is shown in Figures 5 and 6. The optimum pH was measured at pH 7.0 with reasonable activities from pH 6.0 to 10.0. The highest activity was measured in Bis-Tris-Propane buffer at pH 7.5 due to a slight inactivation caused by the citrate phosphate buffer. The optimum temperature [Figure 6(7)] was 50 °C. The enzyme activity at optimum pH and temperature was 880 ACU/mg. In contrast to our result, Guo and Ma[50] characterized an alkaline protease from *A. oryzae* Y2942 and determined a molecular size of 34 kDa (SDS-PAGE) and the highest activity at 40 °C and pH 9.0. Nakadai and Nasuno[51] described an alkaline protease 1 from *A. oryzae* ATCC 20386 and determined a native size of 23 kDa (SEC) and the highest activity at pH 10.5.

α-Amylase A Type 3 (AMY3). The AMY3 fraction from the purification protocol showed a protein band at approximately 48 kDa (SDS-PAGE: Figure 4A, lane 4). A native size of 54.9 kDa was determined by HPLC-SEC and is in accordance with the molecular mass of 52.5 kDa calculated (UniProtKB). The pH profile of the purified AMY3 is shown in Figure 5(8). An optimum pH of 5.0−5.5 with about 50% relative activity at pH 3.0 and 7.0 was determined. The effect of the temperature on the activity is shown in Figure 6(8). The highest activity was measured at 50 °C. The enzyme activity at optimum pH and temperature was 6850 $nkat_{Starch}$/mg. The optimum conditions determined (50 °C, pH 5.0) were also described for α-amylases

DOI: 10.1021/acs.jafc.5b01665
J. Agric. Food Chem. 2015, 63, 5682−5693

from *A. oryzae* ATCC 76080[52] and *A. oryzae* IFO-30103.[53] The activity of the purified amylase of the current study was compared with a commercial amylase preparation from *A. oryzae* (Fungamyl 2500G, Novozymes, Bagsværd, Denmark). Almost the same specific enzyme activity was determined for both enzymes. The purified Flavourzyme amylase exhibited 2190 $nkat_{Starch}$/mg, whereas Fungamyl 2500G exhibited 2240 $nkat_{Starch}$/mg. The same molecular mass was also determined for both samples on SDS-PAGE (data not shown).

In summary, we could identify eight active key enzymes in Flavourzyme 1000L. Due to the results presented, the enzymes identified can be assigned to the different protein bands of a SDS-PAGE of Flavourzyme (Figure 4B). Flavourzyme 1000L is sold as an aminopeptidase preparation with at least 1000 LAPU/g (leucine aminopeptidase units/g determined with Leu-*p*NA). However, it has to be mentioned that the substrate Leu-*p*NA is only converted by the LAPA and LAP2 in the Flavourzyme complex, of which the LAPA makes around 90% of the Leu-*p*NA activity (data not shown). We showed that six proposed marker substrates [azocasein (endopeptidases NP1, NP2, ALP1), H-Ile-*p*NA (LAPA), H-Pro-*p*NA (LAP2), H-Ala-Pro-*p*NA (DPP4), H-Lys-Ala-*p*NA (DPP5), and starch (AMY3)] could be used for the characterization of the Flavourzyme enzymes. It will now be possible to distinguish between respective enzyme activities in any Flavourzyme protein hydrolysis processes. This is helpful to provide a better understanding of the enzymatic complex and to allow its improved use on different substrates. Furthermore, we realized a time-saving fully automated nine-step purification of the eight Flavourzyme enzymes.

MATERIALS AND METHODS

Materials. Fully hydrogenated coconut oil (melting point, 33.3 °C) was kindly provided by Cargill Refined Oils Europe (Izegem, Belgium) and glycerol triheptanoate oil from Eigenmann & Veronelli (Rho, Italy). Dowex 50WX8, lysozyme from chicken egg white, sodium azide, Tween 20, thiobarbituric acid (TBA), and 1,1,3,3-tetraethoxypropane (TEP) were purchased from Sigma-Aldrich (Diegem, Belgium). Whey proteins isolate (85% pure) was acquired from Acatris Food Belgium NV (Londerzeel, Belgium). KH_2PO_4, K_2HPO_4, NaOH, sodium acetate, and glacial acetic acid of analytical grade were purchased from Chem-Lab (Zedelgem, Belgium). Trichloroacetic acid (TCA) was purchased from Acros Organics (Geel, Belgium). Acetone analytical grade, methanol, and acetonitrile high-performance liquid chromatography (HPLC) grade was provided by Fisher Scientific (Aalst, Belgium).

Preparation of NaMDA. NaMDA was prepared according to a procedure previously reported with slight modifications.[15] TEP (10 mmol) was suspended in 10 mL of distilled water, mixed with 10 g of Dowex 50W-X8 resin, and shaken at room temperature for 40 min. The resin was filtered off, and the filtrate was neutralized to pH 7 with NaOH. Then the solution was rotary evaporated (Laborato 4000, VWR, Leuven) at 30 °C to approximately 3 mL and the residue was crystallized by addition of acetone. After the mixture was allowed to stand overnight at 7 °C, the crystalline NaMDA was collected by filtration, washed with a small amount of acetone, and recrystallized twice from water-acetone. ^{1}H NMR (D_2O) δ: 8.57 (2H, d), 5.23 (1H, t). ^{13}C NMR (D_2O) δ: 192.92, 109.53. The spectrum coincided with that of NaMDA reported by Cighetti et al.[16] The crystalline NaMDA was stored at −20 °C under nitrogen.

Self-Condensation and Cleavage of NaMDA in an Aqueous Buffer and Oil (Cases 1 and 2). The aldol condensation reaction and degradation of NaMDA was examined in 0.1 M potassium phosphate buffer pH 6.8 (cf. case 1) and in glycerol triheptanoate oil (cf. case 2), as shown in Figure 1. Glycerol triheptanoate oil was chosen because it is completely saturated similar to fully hydrogenated coconut oil. Therefore, it cannot oxidize and produce lipid oxidation products. This was confirmed by performing a blank analysis. In addition, because of the low melting point (−40 °C) of glycerol triheptanoate oil, the reactivity of MDA at 4 °C could be measured in a saturated oil. An aliquot of 100 μL of NaMDA in buffer solution (initial concentration, 0.7 mM) was added to 10 mL of phosphate buffer (pH 6.8) or glycerol triheptanoate oil. The samples were vortexed (VWR, Leuven, Belgium) for 2 min and incubated for 24 h at 4 and 40 °C. After mixing, the glycerol triheptanoate oil samples were turbid. No phase separation was observed during incubation. The MDA content was determined after extraction by HPLC. Each case was performed in triplicate.

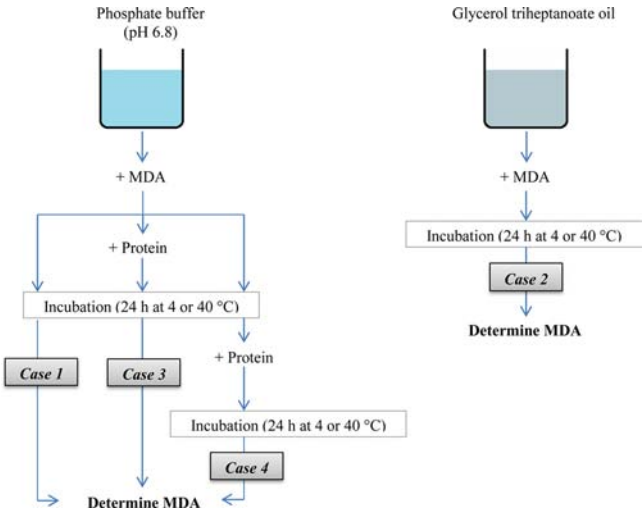

Figure 1. Model systems considered to determine the reactivity of MDA in aqueous buffer and oil. In cases 1 and 2, the condensation and cleavage of MDA was examined in phosphate buffer (pH 6.8) and glycerol triheptanoate oil, respectively. In cases 3 and 4, the interaction between MDA and food proteins (lysozyme or whey proteins) was analyzed after adding MDA and proteins together (cf. case 3) or separately (cf. case 4) to phosphate buffer. After incubation, the MDA content was determined by HPLC.

Interaction between Proteins and NaMDA in an Aqueous Buffer (Cases 3 and 4). The reactivity of NaMDA toward proteins was examined in phosphate buffer pH 6.8 (Figure 1). Two model systems were distinguished: cases 3 and 4. In case 3, 100 μL of a NaMDA solution (initial concentration, 0.7 mM) was added to 10 mL of phosphate buffer. Simultaneously, 1 mL of lysozyme (0.1 g/mL in phosphate buffer) or 2 mL of whey proteins (0.05 g/mL in phosphate buffer) solution was added to the same buffer. After 24 h at 4 or 40 °C, the MDA content was determined. In case 4, NaMDA was added to phosphate buffer and an incubation step of 24 h at 4 or 40 °C was applied. After incubation, the protein solutions were supplemented as before. Again, a 24 h incubation step was performed. Afterward the MDA content was determined by HPLC. Each case was performed in triplicate.

Preparation of Coconut O/W Emulsions. Tween 20- and whey proteins-stabilized coconut O/W emulsions were considered in this study. An aqueous solution of 1 wt % Tween 20 was prepared by dispersing the surfactant in 0.1 M potassium phosphate buffer (pH 6.8). A solution of 0.6 wt % whey proteins isolate was prepared by dissolving powdered protein in the same buffer at room temperature and subsequent stirring with a magnetic stirrer for more than 2 h to ensure complete hydration and dispersion of the whey proteins prior to homogenization. Sodium azide (0.02 wt %) was included in our solutions to prevent microbial growth. Coarse emulsions, consisting of 10 wt % fully hydrogenated coconut oil and 90 wt % emulsifier solution (Tween 20 or whey proteins), were blended using an Ultra turrax (Janke and Kunkel, IKA-Werk, Staufeb, Germany) for 10 min at 10 000 rpm. These pre-emulsions were then homogenized seven times at 250 bar/30 bar through a high-pressure valve, two-stage APV Lab 1000 homogenizer (APV Benelux NV/SA, Erpe Mere, Belgium). All procedures were carried out at 60 °C so that the crystallization of the fully hydrogenated coconut oil (melting point, 33.3 °C) was prevented during the process. After homogenization, the emulsions were cooled fast to 4 or 40 °C according to the studied model system.

Emulsified Model Systems (Cases 5−12). *Tween 20-Stabilized Coconut O/W Emulsions.* A 10 mL sample was spiked at various moments with 100 μL of NaMDA buffer solution (initial concentration, 0.7 mM) and food protein solution (1 mL of lysozyme (0.1 g/mL) or 2 mL of whey proteins (0.05 g/mL)). Figure 2 represents the different model systems studied (cases 5−10). Two scenarios were differentiated: scenario A and B. The main difference between the two scenarios is that for scenario B a preincubation step (rest period) of 24 h at 4 or 40 °C after homogenization of the emulsion was applied, while in scenario A, the reactivity of MDA was studied immediately after preparing the emulsion. In both scenarios coconut O/W emulsions were examined 24 h (at 4 or 40 °C) after supplementing MDA in the absence (cf. cases 5 and 6) or presence of proteins (cf. cases 7 and 9). Proteins were also added 24 h (at 4 or 40 °C) after the addition of MDA to the emulsions in both scenarios after which again a 24 h incubation step was applied (cf. cases 8 and 10).

Whey Proteins-Stabilized Coconut O/W Emulsions. A 10 mL sample was spiked immediately after homogenization (cf. case 11) or after a 24 h preincubation step (cf. case 12) with 100 μL of NaMDA solution (initial concentration, 0.7 mM), as shown in Figure 3.

The various model systems were incubated at 4 and 40 °C and were performed in triplicate. The MDA content was determined by HPLC.

MDA Extraction and Determination. Depending on the nature of the sample, different extraction techniques were applied, as described below.

Phosphate Buffer or Protein Solution (Cases 1, 3, and 4). Exactly 3 mL of solution was brought in a Falcon tube of 15 mL and was

DOI: 10.1021/acs.jafc.5b01780

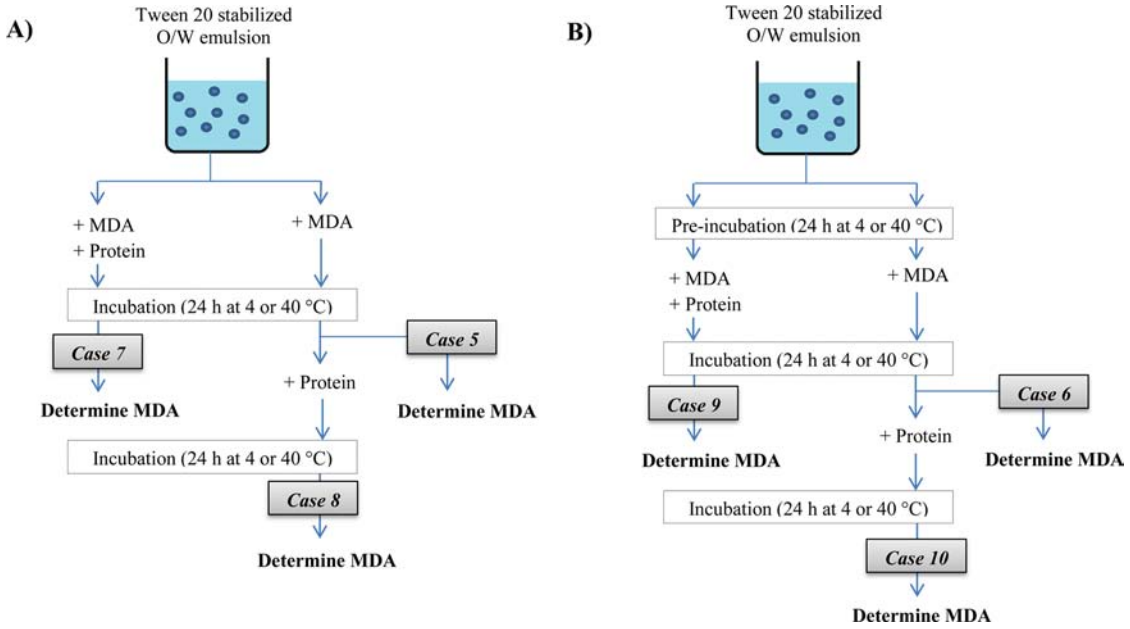

Figure 2. Summary of the various model systems studied for Tween 20-stabilized coconut O/W emulsions. In scenario B, a preincubation step (rest period) was performed before MDA (and proteins) were added. The MDA content was determined by HPLC.

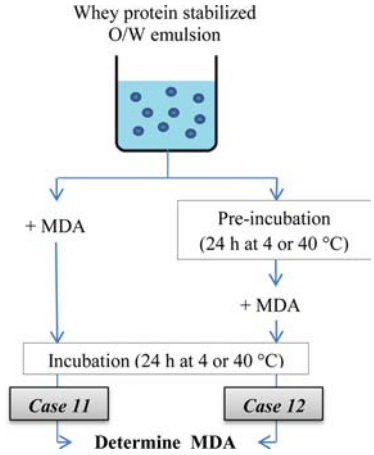

Figure 3. Overview of the different model systems studied for whey proteins-stabilized coconut O/W emulsions. In case 11, an extra incubation step was applied before adding MDA. After incubation, the MDA content was determined.

diluted with 3 mL 30% TCA. The mixture was vortexed for 1 min and was put on ice for 15 min.

Glycerol Triheptanoate Oil (Case 2). Approximately 3 g of oil was weighed in a 15 mL falcon tube. A total of 3 mL of distilled water was added. The mixture was vortexed for 2 min and centrifuged (Sigma 4K15, Sartorius, Goettingen, Germany) at 9 000*g* for 15 min.

Emulsions (Cases 5−12). A total of 3 mL of emulsion was brought in a 15 mL Falcon tube to which 3 mL of 30% TCA was added. After being vortexed for 1 min, the mixture was put on ice for 15 min.

Subsequently for all samples, the aqueous layer was collected by filtration over a paper filter (Schleicher & Schuell, Germany). The MDA content of the extract was determined after TBA derivatization by a HPLC method as described by Papastergiadis et al.[17] For quantification, standard solutions of MDA in 7.5% TCA were prepared from TEP and calibration curves were constructed at concentrations ranging from 0.6 to 10 μM.

Statistical Analyses. Initially the homogeneity of variances was determined by the Levene test. Thereafter, one-way analysis of variance (ANOVA) were applied to detect the significant differences ($p < 0.05$) between samples. When differences were detected, multiple comparisons were performed by the Tukey-b test. The analyses were carried out with the SPSS 22 statistics package (IBM, SPSS, Inc.).

RESULTS AND DISCUSSION

Reactivity of MDA in Aqueous Buffer (in Presence or Absence of Proteins) and Saturated Oil at 40 °C (Cases 1−4). As mentioned above, MDA can undergo self-condensation and cleavage in aqueous solution under physiological conditions.[6,13,14] In order to know how much MDA condensates and degrades in both phases of O/W emulsions in the absence of proteins, the reactivity of MDA in phosphate buffer (pH 6.8) and glycerol triheptanoate oil was initially examined (cf. case 1 versus 2). As shown in Table 1, a major significant difference in MDA recovery was observed between the two model systems after 24 h at 40 °C. Approximately 8% MDA reacted by means of aldol condensation and/or cleavage in the aqueous solution. When the solution was incubated for 48 h, the same recovery was found. Yet surprisingly only 15.5% recovery was found when MDA was added to oil, which indicates that the condensation and/or cleavage of MDA happens more readily in oil. These findings are quite contradictory with the multitude of reports found in the literature on the increasing MDA levels in foods upon progressive oxidation. Of course, in those cases, in contrast to in this study, MDA was continuously produced as a result of the oxidation process. However, it is shown from this experiment that a major portion of the formed MDA is further reacting in a lipid medium. Thus, the cumulative amount of MDA found is not reflecting the actual amount of MDA in a particular oil or food produced during oxidation.

In cases 3 and 4, the interaction between MDA and food proteins (lysozyme and whey proteins) in aqueous solution was examined. Because of the presence of proteins, the recoveries in both cases were significantly lower than in case 1 and moreover were protein-dependent. Although the supplemented concentration of whey proteins was lower, less MDA was measured when whey proteins were added instead of lysozyme. Hence,

Table 1. Recovery of MDA (Initial Concentration, 7 μM) in Cases 1−12 after Incubating at 40 °C (Figures 1−3)[a]

case	model description	recovery of MDA (%)		
		no protein	lysozyme	whey proteins
1	MDA in phosphate buffer (pH 6.8)	91.77 ± 0.57a	n.a.	n.a.
2	MDA in glycerol triheptanoate oil	15.46 ± 0.32b	n.a.	n.a.
3	MDA in phosphate buffer (pH 6.8) directly supplemented with protein	n.a.	58.58 ± 0.81c	30.36 ± 0.87d
4	MDA in phosphate buffer (pH 6.8), protein added after 24 h	n.a.	49.51 ± 0.10e	27.33 ± 0.98f
5	MDA in coconut O/W emulsion stabilized by Tween 20 in absence of proteins	61.06 ± 0.69g	n.a.	n.a.
6	MDA in coconut O/W emulsion stabilized by Tween 20 after preincubation in absence of proteins	66.85 ± 1.18h	n.a.	n.a.
7	coconut O/W emulsion stabilized by Tween 20: MDA added along with proteins after homogenization	n.a.	34.76 ± 1.03i	23.40 ± 0.07j
8	coconut O/W emulsion stabilized by Tween 20: MDA added after homogenization; proteins added after 24 h	n.a.	46.38 ± 1.12k	33.81 ± 0.99i
9	coconut O/W emulsion stabilized by Tween 20: MDA added along with proteins after preincubation	n.a.	28.02 ± 0.80f,n	17.43 ± 0.41l
10	coconut O/W emulsion stabilized by Tween 20: MDA added after preincubation, proteins added 24 h later	n.a.	43.63 ± 1.29m	29.61 ± 0.55d,n
11	coconut O/W emulsion stabilized by whey proteins: MDA added after homogenization	n.a.	n.a.	43.19 ± 0.46m
12	coconut O/W emulsion stabilized by whey proteins: MDA added after preincubation	n.a.	n.a.	48.28 ± 0.93k

[a]Values are the average of three replications ± the standard deviation. Different letters indicate statistically significant differences ($p < 0.05$) in the recovery of MDA. "n.a." indicates not applicable.

whey proteins were shown to be more prone to interact with MDA, probably because it contains more reactive lysine groups, as shown in Table 2.[18−20]

Table 2. Number of MDA-Reactive Groups in Lysozyme and Whey Proteins in Cases 3, 4, and 7−10[19]

reactive amino acids	lysozyme (μmol/mL)	whey proteins (μmol/mL)
lysine	3.8	6.2
arginine	7.6	1.4
histidine	0.6	1.3
cysteine	5.7	3.2

Furthermore, a significant impact of supplementing the proteins separately (after 24 h) or together with NaMDA was observed (cf. case 3 versus 4). In case 4, MDA underwent condensation and/or cleavage in aqueous solution during the first 24 h, prior to protein addition. After incubation, food proteins were added which could interact with MDA, the condensation products, and/or acetaldehyde (Figure 4).

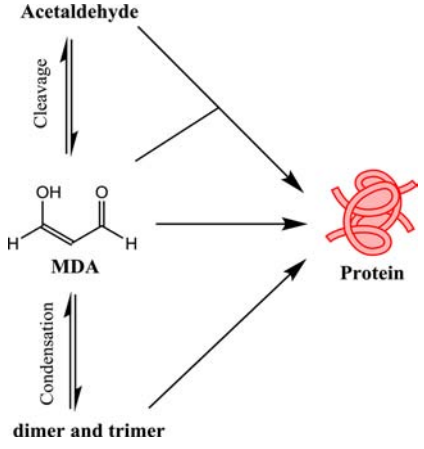

Figure 4. Possible mechanisms of interaction between MDA and proteins in aqueous buffer (pH 6.8). In aqueous solution MDA can undergo reversible condensation and cleavage reactions. The products formed from these reactions can also interact with proteins.

However, if MDA and proteins were added together (cf. case 3), there was a competition for MDA to form condensation and degradation products and protein−MDA adducts. On the basis of the results and because of the high reactivity of MDA, we assume that the interaction between MDA and proteins was favored. This is corroborated by the fact that the experimentally obtained recoveries of both proteins in case 4 corresponded quite well to the theoretically predicted recoveries considering a 91.8% recovery of MDA after 24 h of incubation in aqueous buffer, followed by an additional recovery of 58.6 and 30.4%, respectively, after incubation with lysozyme and whey proteins.

Reactivity of MDA in Coconut O/W Emulsions Stabilized by Tween 20 at 40 °C in Absence of Proteins (Cases 5 and 6). In order to investigate the condensation and/or cleavage of MDA in a coconut O/W emulsion at 40 °C, the recovery of MDA was determined upon addition of MDA directly after preparation of the emulsion (cf. case 5) or after a rest period of 24 h (cf. case 6). In both cases the recovery of MDA was significantly lower than that of case 1. Nevertheless, the recovery was still much higher than when MDA was added to a pure oil (cf. case 2). In case 2, it was shown that MDA is particularly prone to condensate and/or degrade in a lipophilic environment. As no other degradation routes are possible, these results indicate that in an emulsion a part of the supplemented MDA was translocated to the oil phase and/or interface of the oil droplets, which can be explained by its amphipathic nature.[21,22]

Furthermore, a statistically significant but limited effect of the preincubation (rest period) on the recovery of MDA was observed (cf. case 5 versus 6). Tween 20, a nonionic surfactant, stabilizes O/W emulsions against flocculation and coalescence by forming a protective membrane around the oil droplets. Nevertheless, after homogenization, there are significant quantities of nonadsorbed surfactant molecules present in the aqueous phase of emulsions.[23,24] Above the critical micelle concentration (CMC), the nonadsorbed surfactant molecules form micelles. On the other hand, adsorbed Tween 20 molecules in the O/W interface at a lower coverage can self-organize to give a denser adsorbed phase, thus opening up more surface sites for further adsorption of Tween 20[25] and making the oil droplet less permeable for MDA later. During

DOI: 10.1021/acs.jafc.5b01780
J. Agric. Food Chem. 2015, 63, 5694−5701

the rest period, the interface had probably time to undergo these rearrangements and as such to stabilize itself. In addition, Tween 20 micelles were most likely formed in the aqueous phase of O/W emulsions in view of the low CMC of the surfactant (0.007% w/v).[26] On the basis of the results in Table 1, MDA was still able to shift to the apolar phases of the emulsion, i.e., oil droplets, interfaces, and surfactant micelles, but to a lesser extent than when no stabilization period was performed. Therefore, more MDA remained in the aqueous phase, leading to a slightly higher recovery of MDA.

Reactivity of MDA in Coconut O/W Emulsions Stabilized by Tween 20 at 40 °C in the Presence of Proteins (Cases 7−10). The reactivity of MDA was further evaluated in coconut O/W emulsions in the presence of proteins (lysozyme or whey proteins) at 40 °C (cf. case 7−10). On the basis of the observations with respect to the previous set of experiments, again the impact of stabilizing the emulsion after preparation was considered (cf. case 7/8 versus 9/10). As shown in Table 1, the presence of proteins had an explicit effect on the recovery of MDA (cf. case 5 versus 7/8; case 6 versus 9/10). Less MDA was found when proteins were present, and similar to the results of cases 3 and 4, a lower recovery was observed when whey proteins were supplemented instead of lysozyme. Hence, in protein-supplemented coconut O/W emulsions, a protein-dependent interaction between MDA and proteins could be observed.

Moreover, a significant difference was observed when MDA and proteins were supplemented simultaneously (cf. cases 7 and 9) or 24 h after the MDA was added (cf. cases 8 and 10). In cases 8 and 10, MDA had 24 h to shift toward the apolar phases (i.e., oil droplets, interfaces, and micelles) of the emulsion. Based on the results obtained in view of the amphipathic character of MDA and its enolate, it is speculated that MDA present at the interfaces is less prone to react with proteins and is also more stable toward aldol condensation and degradation compared to MDA in oil. Furthermore, the impact of the stabilization period (cf. case 8 versus 10) was quite restricted for both proteins considered because the interface of the emulsion had in both cases at least 24 h to reorganize and stabilize. However, if proteins were supplemented together with MDA (cf. cases 7 and 9), there was a competition for MDA (1) to interact with proteins, (2) to shift to the apolar phases (i.e., oil droplets and interfaces), (3) to undergo condensation and/or cleavage in the aqueous phase and oil phase. Again we assume that the interaction between MDA and proteins was favored as in case 3. In addition, the stabilization period had also an effect on the recovery of MDA (cf. case 7 versus 9). As mentioned before, after homogenization, there are still free surfactant molecules present in the aqueous phase, searching for their most optimal condition. It has been reported that nonionic surfactants, such as Tween 20, are also able to interact with proteins present in the aqueous phase.[24,27,28] Thus, they could protect proteins against MDA by binding to the hydrophobic regions of the surface of proteins, decreasing the molecular interactions.[29,30] In addition, they may act as a chemical chaperone, favoring refolding by binding transiently with partially folded protein molecules and thus sterically hindering interaction with MDA.[28] Therfore, if proteins were added after stabilization of the interface, together with MDA (cf. case 9), less surfactant molecules were available to interact with the proteins and thus protected them from interacting with MDA.

Figure 5 represents an overview of the potential reaction mechanisms of MDA in coconut O/W emulsions in the presence of proteins when no stabilization period was applied, as discussed above (cf. case 7).

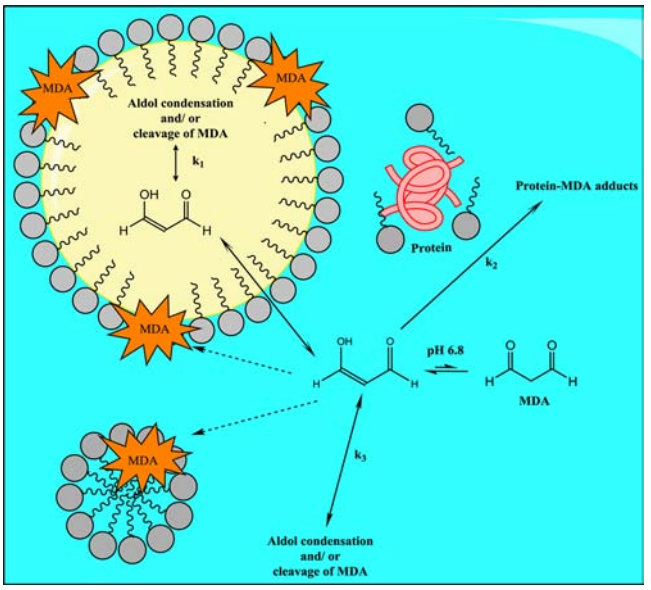

Figure 5. Potential reaction mechanisms of MDA in coconut O/W emulsions stabilized by Tween 20 in the presence of proteins when no stabilization period was applied (cf. case 7). MDA can exist in various forms depending on pH. At neutral conditions, the predominant (>99%) form is the enolate anion.[11] A competition for MDA takes place (1) to shift to the apolar phases of the emulsion (i.e., oil droplets, interfaces and micelles), (2) to interact with proteins, and (3) to condensate and/or degrade in the aqueous phase with corresponding reaction rates k_1, k_2, and k_3.

Effect of Temperature on the Reactivity of MDA in the Various Model Systems (4 versus 40 °C). In parallel to the experiments at 40 °C, a similar set of experiments was conducted at 4 °C. Obviously, temperature will affect the reactivity of MDA itself, but it will also have an impact on the physical state of the interface and the crystallization of the oil droplets (in the case of fully hydrogenated coconut oil). As shown in Table 3, no significant difference in aldol condensation and/or cleavage of MDA was observed between phosphate buffer and glycerol triheptanoate oil (cf. case 1 versus 2). Compared to 40 °C, the condensation and/or cleavage of MDA was the same for the aqueous buffer but excessively lower in the case of glycerol triheptanoate oil. This suggests that temperature has a major impact on the condensation and/or degradation of MDA in a pure oil. Consequently, when the MDA content of a particular oil is determined, the measured content will greatly depend on the storage and operating temperature of the oil.

In cases 3 and 4, proteins were supplemented in the aqueous phase together with MDA or after 24 h, respectively. Similar to the case at 40 °C, less MDA was measured in case 4, but compared to the experiments at 40 °C, the MDA content was now higher. Thus, the reactivity toward proteins was severely reduced at 4 °C. Again a lower recovery was observed when whey proteins where added instead of lysozyme, confirming the higher reactivity of whey proteins toward MDA.

In Tween 20-stabilized coconut O/W emulsions in the absence of proteins (cf. cases 5 and 6), again a considerably

[a]Values are the average of three replications ± the standard deviation. Different letters indicate statistically significant differences ($p < 0.05$) in the recovery of MDA. "n.a." indicates not applicable.

lower reactivity of MDA was observed at 4 °C compared to that at 40 °C. MDA showed moreover a higher reactivity toward proteins (cf. case 5/6 versus 3/4), similar to that observed at 40 °C. In addition, no effect of stabilizing the interface was found (cf. case 5 versus 6). In view of the high melting point of the fully hydrogenated coconut oil (33.3 °C) and the low temperature at which this set of experiments was conducted, fat crystallization in the oil droplets most likely occurred. This was also corroborated by the observed slightly higher apparent viscosity of the emulsions. It should be noted, however, that the emulsions remained stable at 4 °C. As MDA losses at 4 °C in the aqueous and oil phase (cf. case 1 and 2) were similar, in contrast to the behavior observed at 40 °C, it seems logical that no impact of the stabilization of the interface and its permeability toward MDA could be expected. However, we do assume that the oil phase became less receptive for MDA in view of its higher crystallinities; therefore, MDA remained more present in the aqueous phase or the interfaces of the emulsion.

Upon supplementing proteins to the Tween 20-stabilized emulsions at 4 °C (cf. cases 7−10), also no additional effect could be observed, except when whey proteins were added 24 h after MDA was added (cf. case 8). In view of the observed reactivity between MDA and proteins (cf. cases 3 and 4), these results seem to suggest that MDA is especially present in the interface of the emulsion where it is then protected from reaction with proteins. This would be in line with our earlier observations with respect to the experiments at 40 °C related to cases 7/9 versus 8/10. It remains unclear, however, why MDA showed the highest reactivity when whey proteins were added 24 h after MDA addition to freshly prepared emulsion (cf. case 8), especially as this was not observed at 40 °C.

Reactivity of MDA in Coconut O/W Emulsions Stabilized by Whey Proteins at 4 and 40 °C (Cases 11 and 12). In the following set of experiments, Tween 20 as the interfacial molecule was replaced by a protein itself. Whey proteins, in contrast to lysozyme, were able to stabilize the coconut O/W emulsions both at 4 and 40 °C. Tables 1 and 3 represent the recovery of MDA in whey proteins-stabilized coconut O/W emulsions incubated at 40 and 4 °C, respectively (cf. cases 11 and 12). In contrast to Tween 20-stabilized emulsions supplemented with whey proteins (cf. case 7−10), more MDA was recovered at 40 °C. It should be noted, however, that the concentration of whey proteins in these emulsions was lower than those stabilized by Tween 20: 0.5 and 0.8 wt %, respectively. However, when the same concentration of whey proteins was added to Tween 20-stabilized coconut emulsions (similar as case 7), the recovery was still significantly lower (36.97 ± 0.36%) compared to whey proteins-stabilized coconut emulsions. This indicates that whey proteins adsorbed at the interface of the oil droplets showed a lower reactivity toward MDA. When whey proteins adsorb to O/W interfaces, they may undergo substantial conformational changes and interactions due to the change in its molecular environment. The time required for these conformational changes to occur depends on the molecular flexibility and packing of the adsorbed molecules and can take even hours for whey proteins as these are rigid globular proteins. For many globular proteins including whey proteins, these conformational changes lead surprisingly to an increased exposure of nonpolar and sulfhydryl-containing amino acids to the aqueous phase.[31,32] Therefore, polar reactive amino acids such as lysine, arginine, and histidine are less accessible for MDA present in the aqueous phase, explaining the higher recovery of MDA in these type of emulsions compared to Tween 20-stabilized coconut emulsions. Additionally, a significant effect was found when a 24 h stabilization step (cf. case 12) was applied before MDA was added at both storage temperatures. During this step, whey proteins, adsorbed at the interface, had 24 h to undergo conformational rearrangement, reducing further the accessibility of the polar amino acids for MDA and resulting in a higher recovery in case 12.

However, at 4 °C, MDA was shown to be more reactive in the whey proteins-stabilized coconut emulsions compared to the Tween 20-stabilized coconut emulsions to which whey proteins were added (cf. cases 7 and 9). However, we assume this is not likely because of the higher interaction between MDA and whey proteins at the interface, but because of a lower extent of fat crystallization in the whey proteins-stabilized coconut emulsions. It has been reported that the onset temperature for fat crystallization within the oil droplets

DOI: 10.1021/acs.jafc.5b01780
J. Agric. Food Chem. 2015, 63, 5694−5701

depends on emulsifier type and is substantially lower for whey proteins than for Tween 20.[33] Therefore, at 4 °C, the solid fat content of the oil droplets was likely to be considerably lower in whey proteins-stabilized emulsions. Hence, the translocation of MDA toward the apolar phases (i.e., oil droplets and interfaces) happened more readily. Thus, an additional degradation route of MDA was favored (degradation in oil phase), apart from the other routes already available (degradation in aqueous phase and reaction with proteins), explaining the lower recovery of MDA in whey proteins-stabilized coconut emulsions at 4 °C.

In Figure 6, an overview of the potential reaction mechanisms of MDA in whey proteins-stabilized coconut O/W emulsions (cf. cases 11 and 12) at 40 °C is given.

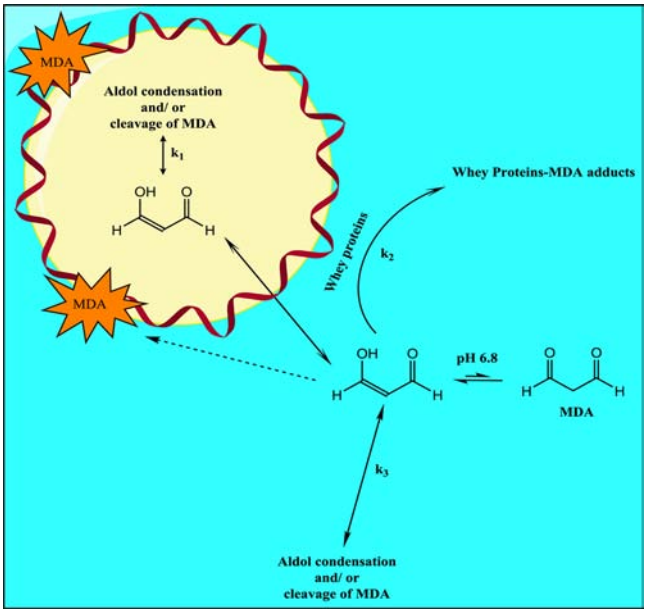

Figure 6. Potential reaction mechanisms of MDA in whey proteins-stabilized coconut O/W emulsions at 40 °C (cf. cases 11 and 12). MDA can (1) shift to the apolar phases (i.e., oil droplets and interfaces) of the emulsion to undergo condensation and/or cleavage, (2) interact with whey proteins at the interface, and (3) condensate and/or degrade in the aqueous phase with corresponding reaction rates k_1, k_2 and k_3.

From this study it can be concluded that the behavior of MDA in O/W emulsions is influenced by many factors and thus depends greatly on the model system parameters. At the one hand, degradation of MDA itself was shown to be considerable in both the aqueous and oil phases. With respect to the oil phase, especially at higher temperatures, the MDA degradation proved to be quite significant. Second, the reactivity of MDA toward proteins should be considered. Finally, it seems that MDA is present in the interface of the emulsion as well in which it is likely to be protected from the various degradation routes considered. Therefore, when a model system is selected to study the interaction between proteins and MDA in foods, it is advisible to choose the model system parameters wisely because the applied parameters can favor or even inhibit the interaction. Further research is necessary to elucidate the interactions between MDA and food proteins in O/W emulsions, keeping in mind the influences of the model parameters.

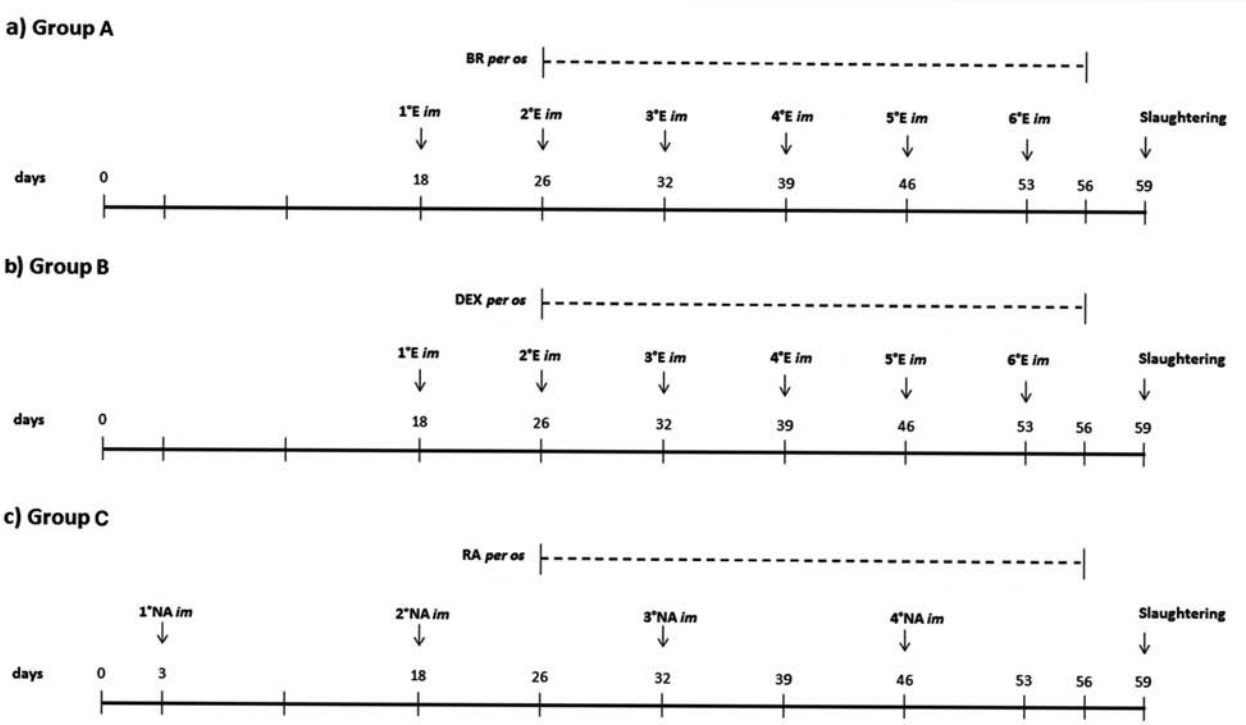

Figure 1. Treatment schedule of veal calves. Group A was weekly administered 5 mg/animal of estradiol benzoate (E) intramuscularly for 6 weeks in combination with 0.25 mg/animal/day of brotizolam (BR) per os for the last 31 days of treatment (a); group B was weekly administered 5 mg/animal of estradiol benzoate intramuscularly for 6 weeks in combination with 0.40 mg/animal/day of dexamethasone (DEX) per os for the last 31 days of treatment (b); group C was administered 150 mg/animal of Nandrosol (NA) every 2 weeks four times in combination with 80 mg/animal/day of ractopamine (RA) per os for the last 31 days of treatment (c). The calves were slaughtered 3 days after the last treatment.

intramuscularly for 6 weeks in combination with 0.25 mg/animal/day of brotizolam per os for the last 31 days of treatment; group B (n = 6) was weekly administered 5 mg/animal of estradiol benzoate intramuscularly for 6 weeks in combination with 0.40 mg/animal/day of dexamethasone (DEX) per os for the last 31 days of treatment; group C (n = 8) was administered 150 mg/animal of Nandrosol (17β-19-nortestosterone phenylpropionate) every 2 weeks for four times in combination with 80 mg/animal/day of ractopamine per os for the last 31 days of treatment; group K (n = 8) served as control (Figure 1). The calves were slaughtered 3 days after the last treatment. The hormone dosages were selected according to previous studies.[2,21,22]

The animals were healthy upon intravitam and post-mortem examinations. The experiments were authorized through the Italian Ministry of Health and the Ethical Committee of the University of Turin. The carcasses of the treated animals were appropriately destroyed (2003/74/CE-DL 16 March 2006, No. 158).

Tissue Sampling and Processing. Samples of bulbo-urethral glands, prostate and testis tissues were obtained from each animal at slaughter. The samples were immediately frozen in liquid nitrogen and then stored at −80 °C for molecular and Western blot (WB) analyses.

RNA Extraction, Reverse Transcription, and qPCR. Several milligrams of each tissue sample were disrupted using a TissueLyser II (Qiagen, Hilden, Germany) using stainless steel beads in 1 mL of TRIzol reagent (Ambion, Life Technologies, Carlsbad, CA, USA) according to the manufacturer's protocol. The RNA concentration was spectrophotometrically determined, and the RNA integrity was evaluated using an automated electrophoresis station (Experion Instrument, Bio-Rad, Hercules, CA, USA). cDNA was synthesized from 1 μg of total RNA using the QuantiTect Reverse Transcription Kit (Qiagen).

The effect of sex steroid hormones on RGN mRNA expression in the bulbo-urethral glands, prostate, and testis of veal calves was evaluated through quantitative polymerase chain reaction (qPCR). To determine the relative amounts of specific RGN transcripts, the cDNA obtained from retrotranscription was subjected to qPCR[23] using the IQ5 detection system (Bio-Rad) and respective gene primers in an IQ SYBR Green Supermix (Bio-Rad). Primer sequences of RGN were designed using Primer3 (vers. 0.4.0), as previously described.[20] The cyclophilin A (PPIA) gene was used as a housekeeping gene, as previously described.[20] The levels of gene expression were calculated using a relative quantification assay based on the comparative Cq method (ΔΔCq method),[24] previously verifying that efficiencies of target and housekeeping gene amplification were similar. Subsequently, the relative abundances of each transcript, normalized to the endogenous housekeeping gene (PPIA) and relative to the control sample, were calculated as $2^{-\Delta\Delta Cq}$ (fold increase).[25]

Western Blot Analysis. The effect of sex steroid hormones on RGN protein expression in the bulbo-urethral glands, prostate, and testis of veal calves was evaluated through WB analysis. Total protein was isolated from veal calves' bulbo-urethral glands, prostate, and testis using RIPA buffer (50 mM Tris, pH 8.0, 150 mM NaCl, 1.0% IGEPAL CA-630, 0.5% sodium deoxycholate, 0.1% SDS, 2 mM EDTA) supplemented with protease inhibitor cocktail (Sigma). Protein concentration was determined using the Bio-Rad DC Protein Assay. Twenty micrograms of total protein were resolved through 12.5% SDS-PAGE. The proteins were blotted onto Trans-Blot Turbo Mini Nitrocellulose Transfer membrane (Bio-Rad) using a Trans-Blot Turbo Blotting System (Bio-Rad). The blotted membranes were blocked with 5% BSA in TBS-0.1% Tween for 1 h at room temperature, followed by overnight incubation with an anti-RGN rabbit polyclonal antibody (1:200; Sigma, St. Louis, MO, USA). The membranes were subsequently incubated with secondary anti-rabbit horseradish peroxidase (HRP)-conjugated antibody (1:1000), developed using the SuperSignal West Pico IgG Detection Kit (Thermo Fisher Scientific, Waltham, MA, USA), and recorded on CL-XPosure X-ray film (Thermo Fisher Scientific).

α-tubulin (1:10000; clone B-5-1-2; Sigma) was used as a total protein loading control.

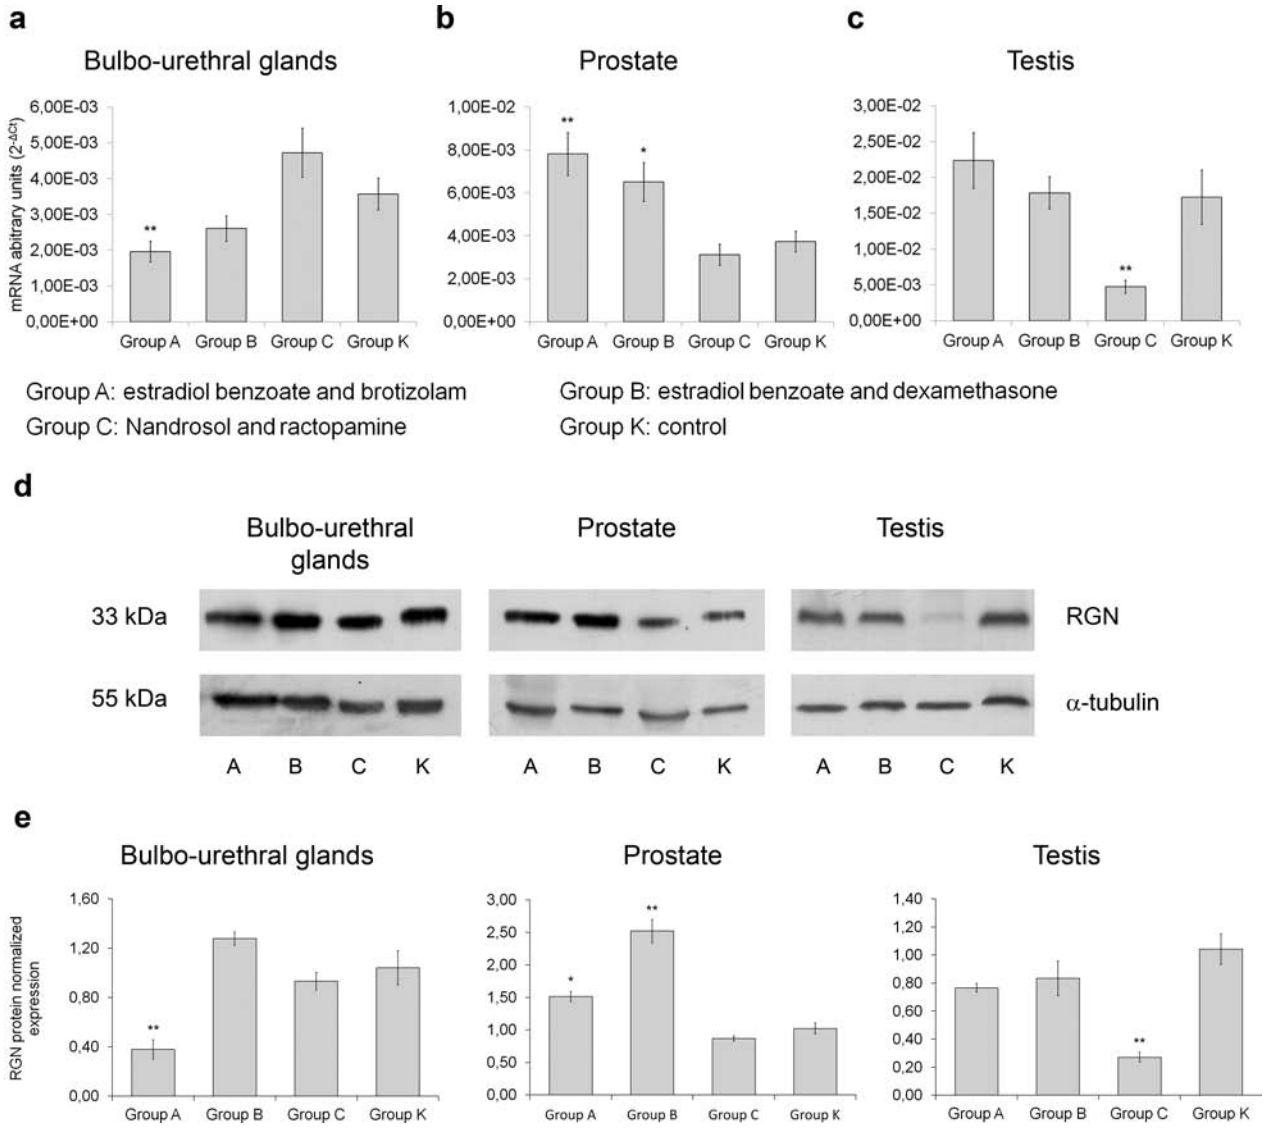

Figure 2. Effects of estradiol benzoate combined with brotizolam (group A), estradiol benzoate combined with dexamethasone (group B), and Nandrosol combined with ractopamine (group C) on *RGN* gene expression compared with the control group K in the bulbo-urethral glands (a), prostate (b), and testis (c) of veal calves. The results are presented as the means ± SEM. The *y*-axes show arbitrary units representing mRNA relative expression levels. A representative Western blot showing RGN protein expression in the bulbo-urethral glands, prostate, and testis (d) of veal calves using an anti-RGN polyclonal antibody (1:200). α-Tubulin (1:10000) was used as loading control. The relative expression levels of RGN protein in the bulbo-urethral glands, prostate, and testis (e) of veal calves were determined and normalized using α-tubulin. The results are presented as the means ± SEM. (∗) $P < 0.05$ and (∗∗) $P < 0.01$ versus the control group K.

Band densities were obtained according to standard methods using ImageJ software (U.S. National Institutes of Health) and normalized by division with the respective α-tubulin band density.

Statistical Analysis. Statistical analyses were performed using Graph-Pad InStat (vers. 3.05) statistical software (GraphPad Inc., San Diego, CA, USA). The analysis of RGN expression was performed using one-way analysis of variance (ANOVA), followed by Dunnett's post-test versus the control group K. The Grubbs test was used to reveal potential outliers. A P value of <0.05 was considered statistically significant. The data obtained by qPCR are shown as the mean arbitrary units ($2^{-\Delta Cq}$) ± standard error of the mean (SEM).

RESULTS

Effect of Sex Steroid Hormones on RGN Gene Expression in the Accessory Sex Glands of Veal Calves. *RGN* gene expression decreased in the bulbo-urethral glands of group A (mean of mRNA arbitrary units ± SEM, $1.96 \times 10^{-3} \pm 2.94 \times 10^{-4}$) compared with the control group K ($3.57 \times 10^{-3} \pm 4.45 \times 10^{-4}$) ($P < 0.01$) (Figure 2a). The RGN expression increased in the prostate of group A ($7.82 \times 10^{-3} \pm 9.88 \times 10^{-4}$) ($P < 0.01$) and group B ($6.51 \times 10^{-3} \pm 9.05 \times 10^{-4}$) ($P < 0.05$) compared with the control group K ($3.73 \times 10^{-3} \pm 4.84 \times 10^{-4}$) (Figure 2b). The RGN expression decreased in the testis of group C ($4.73 \times 10^{-3} \pm 8.88 \times 10^{-4}$) ($P < 0.01$) compared with the control group K ($1.72 \times 10^{-2} \pm 3.80 \times 10^{-3}$) (Figure 2c).

Western Blot Analysis. RGN protein expression was down-regulated in the bulbo-urethral glands of group A compared with control group K ($P < 0.01$) (Figure 2d,e) and up-regulated in the prostate of groups A and B compared with control group K ($P < 0.05$ and $P < 0.01$, respectively) (Figure 2d,e). RGN protein expression decreased only in the testis of

DOI: 10.1021/acs.jafc.5b01337
J. Agric. Food Chem. 2015, 63, 5702−5706

group C compared with the control group K ($P < 0.01$) (Figure 2d,e).

DISCUSSION

The European Union bans the use of sex steroid hormones in bovine husbandry to preserve consumers' health. Indeed, measurable levels of these molecules have been found in muscle, fat, liver, kidney, and other organs in meat products.[26] The potential effects of estrogen residues include, among others, impaired fertility,[27] increased incidence of hormone-related cancers,[28] and congenital malformations[29] in humans.

In bovine livestock, in addition to the desired effects, such as the increase of live weight and reduced fat deposits, the anabolic agents cause severe changes and alterations in target organs.[24,30,31] Estrogenic hormones induce characteristic lesions such as hyperplasia and squamous metaplasia in the prostate and bulbo-urethral glands of male animals and in the Bartholin's glands of females.[24,32,33] This histological method can identify the illicit E_2 treatment up to 15 days after the last drug administration in veal calves[2,34] and in adult male animals.[3] This screening method is officially adopted by the Italian National Program for Residue Surveillance (PNR) for the detection of illicit hormone treatment (PNR 2014). However, low-dosage cocktails often elude the preliminary screening and official tests. Therefore, in this context novel methods of detection, as transcriptomic techniques, have been employed. *RGN* gene expression is clearly estrogen-regulated in several reproductive and nonreproductive organs.[6,16−20] Recently, down-regulation of *RGN* gene expression in the accessory sex glands of veal calves following E_2 administration was demonstrated.[20] In the present study low doses of estradiol benzoate combined with the benzodiazepine brotizolam down-regulated RGN expression in the bulbo-urethral glands. Moreover, *RGN* gene expression was up-regulated by the combination of estradiol benzoate with brotizolam or DEX in the prostate.

The expression of RGN mRNA is regulated by several factors, including Ca^{2+}.[35,36] Several studies have demonstrated that E_2 can induce an increase of intracellular Ca^{2+} in the prostate cells,[37−39] and these effects have been suggested to be associated with rapid nongenomic mechanisms, through a membrane-bound estrogen receptor (mER).[6,40] RGN up-regulation in the prostate following estrogen administration could be sustained through this mechanism. In this context further studies are needed to better understand this relationship.

In addition, *RGN* gene expression is also under androgen control. The presence of numerous androgen response elements consensus sequences in the promoter region of the *RGN* gene has been demonstrated.[6] Testosterone administration greatly decreased RGN mRNA expression only in the testis of veal calves.[20] In the present study, even low doses of Nandrosol induced a significant decrease of RGN mRNA levels in the testis of group C animals compared with the control group. Moreover, RGN protein expression was dramatically decreased by Nandrosol administration in the testis. Conversely, this treatment induced no change of RGN expression in the bulbo-urethral glands and prostate. Therefore, the down-regulation of RGN expression following androgen treatment seems to be a specific response of testis.

A tightly regulated equilibrium between germ cell apoptosis and proliferation is required for a successful spermatogenesis,[41] as approximately 75% of testicular germ cells undergo apoptosis.[42] RGN inhibits apoptosis through the up-regulation of Akt-1 and Bcl-2 expression and the down-regulation of caspase-3.[43] The reduction of RGN expression via androgen administration could inhibit normal spermatogenesis through the stimulation of abnormal apoptosis and the termination of germ cell line maturation, as previously described.[20]

In conclusion, these results confirm that sex steroid hormones, even at low doses and in combination with other GPs, specifically affect RGN expression in the accessory sex glands and testis of veal calves. Interestingly, *RGN* gene expression in the testis changes only following androgen administration. This finding could allow the application of RGN expression as a first indirect biomarker in a low-cost screening test to detect the illicit treatment of veal calves with androgens in the official residue-monitoring programs. Therefore, the detection of androgen abuse by RGN down-regulation is a promising tool to further ensure food safety and quality, considering that changes of the expression of this gene may persist for up to some days after the suspension of androgen treatment.

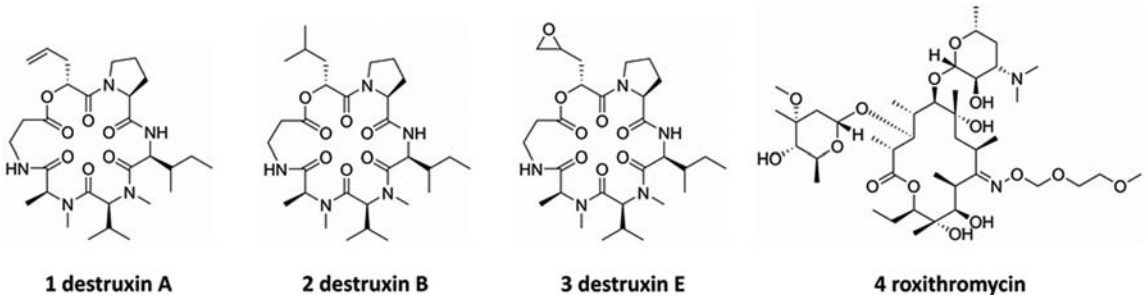

Figure 1. Structural formulas of the main destruxin congeners **1**, **2**, and **3** and the internal standard roxithromycin **4**.

decided to use this reference extraction procedure for our approach because no appropriate method for the analysis of destruxins in crop matrices is currently available. A novel QuEChERS-based sample preparation protocol for the extraction of destruxins from different crop matrices was developed and combined with a quantitative UHPLC-QTOF-MS method with an anticipated sensitivity in the lower parts per billion range. The destruxin isolation and purification protocol from strawberry and maize as well as the chromatographic separation and mass spectrometric detection method for the quantitative determination of three major congeners, namely, destruxin A, **1**, destruxin B, **2**, and destruxin E, **3**, are now reported. These plants have been chosen as model crops due to the application of *M. brunneum* as BCA in such cultivation settings.

MATERIALS AND METHODS

Materials and Chemicals. Destruxin reference materials with a NMR purity ≥98% (**1**−**3**) were isolated from *M. brunneum* strain BIPESCO 5 as previously described.[34] Matrix samples were harvested products from untreated field plots; strawberry samples (without calyx) were obtained from Martell (South Tyrol, Italy) and maize samples from Dietzen (Styria, Austria). Any harvested material was frozen as soon as possible to avoid rotting or molding during transport and storage. Gradient grade acetonitrile, Sabouraud−2% dextrose (SD) broth, and anhydrous sodium sulfate for analysis were purchased from Merck (Darmstadt, Germany); technical grade dichloromethane was from VWR International (Rue Carnot, France); water free glucose was from Roth (Karlsruhe, Germany); agar was from Kottas Pharma (Vienna, Austria); ammonium formate for mass spectrometry ≥99.0% and HPLC grade roxithromycin ≥90% (**4**) were from Sigma-Aldrich (Vienna, Austria); and Clerol FBA antifoam agent was from Cognis (Monheim, Germany). Nitrogen for mass spectrometry was produced on site by a nitrogen generator (PeakScientific Instruments, Fountain Crescent, UK). HPLC grade water was prepared on site.

Cultivation of *Metarhizium brunneum*, Preparation of Crude Extract, and Isolation of Reference Materials. *M. brunneum* strain BIPESCO 5 from the Innsbruck culture collection was cultivated in a D304 stirred tank bioreactor (NLF Bioengineering, Wald, Switzerland) containing SD medium supplemented with 2% glucose as previously described.[25] Destruxin enrichment was achieved by extraction of the culture filtrate with dichloromethane.[34] Aliquots of the culture filtrate were extracted five times with dichloromethane at a ratio of 3 volumes per volume culture filtrate. Combined organic layers were washed twice with 50 mL of water, dried with sodium sulfate, and evaporated to dryness. The obtained crude extract was stored at −20 °C until needed. Reference materials were isolated from this crude extract as described previously.[34]

Preparation of Stock Solutions and Standards. Calibration curves were obtained for a dilution series of **1**−**3** in acetonitrile as well as in strawberry and maize serving as matrix models. Starting from two stock solutions in acetonitrile containing a combination of **1**−**3**, a series of nine spike solutions for strawberries was prepared at the following concentrations: 0.1, 0.25, 0.5, 0.75, 1.0, 2.5, 5.0 7.5, and 10.0 μg/mL, each fortified with 1 μg/mL internal standard (IS) roxithromycin, **4**. On the basis of these spike solutions a second series for the maize samples was prepared by a 1:1 dilution in acetonitrile. Final calibration levels were obtained by adding 100 μL of the appropriate standard solution to 10 g of strawberry or 5 g of maize sample. Calibration levels in acetonitrile were obtained by a 1:100 dilution in acetonitrile of the spike solutions for strawberry samples.

For the production of quality control (QC) materials (assessment of precision and accuracy) a third stock solution in acetonitrile containing **1**−**3** was prepared. Four spike solutions for strawberry samples with concentration levels of **1**−**3** of 0.5, 1.0, 5.0, and 7.5 μg/mL were generated. A second series for maize samples was obtained by a 1:1 dilution of those spike solutions. Final QC materials were obtained by adding 100 μL of the appropriate spike solution to either strawberry or maize. For additional spike experiments a *M. brunneum* (BIPESCO 5) crude extract stock solution (100 μg extract/mL acetonitrile fortified with 1 μg/mL internal standard) was prepared. This stock was used without further dilution to spike the strawberry matrix; for maize samples it was further diluted 1:1 with acetonitrile.

QuEChERS-Based Sample Preparation Protocol. Sample preparation was based on a commercially available QuEChERS protocol (EN method 15662, buffered extraction tubes) (Agilent, Waldbronn, Germany). All crop materials were stored at −20 °C until used. Frozen strawberries were defrosted, mixed with a hand blender, and weighed (10 g ± 0.1 g) into a 50 mL extraction tube. Dry and frozen maize samples were ground in an MF10 basic mill (IKA Labortechnik, Staufen, Germany) and weighed (5 ± 0.1 g) into an extraction tube, and 10 mL of water was added. Samples for calibration curves and quality control material were prepared by spiking the appropriate amounts of spike solutions as described above. Real samples were imitated by spiking crude extract and internal standard solution (IS) into strawberry and maize samples. Ten milliliters of acetonitrile was added to the samples and vigorously shaken for 1 min, and the partitioning buffer salts (6 g of magnesium sulfate, 1 g of sodium chloride, 1 g of sodium citrate, 0.5 g of disodium citrate sesquihydrate) were added. The mixture was vigorously shaken for 1 min and subsequently centrifuged for 5 min at 1547*g*. An aliquot of 6 mL of the organic supernatant was transferred into a 15 mL centrifuge tube containing 150 mg of PSA, 45 mg of GCB, and 855 mg of $MgSO_4$ ("QuEChERS Dispersive Kit for HIGHLY Pigmented Fruits and Vegetables") (Agilent), vigorously shaken for 1 min, and centrifuged for 5 min at 1547*g*. An aliquot of 1 mL of the purified sample was transferred to an HPLC vial and either directly analyzed by UHPLC-QTOF-MS (strawberry samples) or evaporated to dryness, reconstituted in 500 μL of acetonitrile, and filtered through a 0.45 μm membrane filter prior to analysis (maize samples).

UHPLC-DAD Conditions. Chromatographic analyses were performed on the basis of a previously published method, which was slightly modified for the needs of this project.[25] A model 1200 UHPLC liquid chromatograph (Agilent) equipped with a diode array detector (DAD), an autosampler set at 10 °C, an automatic injector, and a column oven was used for all measurements. As stationary phase a 50 mm × 2.1 mm i.d., 1.8 μm particle size column, Zorbax Eclipse XDB-C18, guarded with an 0.2 μm pore size frit, 2.1 mm diameter in-line filter (Agilent), kept in a column oven at 40 °C, was applied.

DOI: 10.1021/acs.jafc.5b01562
J. Agric. Food Chem. 2015, 63, 5707−5713

Analyses were performed at a flow rate of 0.3 mL/min using a mobile phase consisting of water (A) and 95% acetonitrile (v/v) (B), each containing 10 mM ammonium formate, with the following gradient: 0 min, 75% A; 0.5 min, 75% A; 3.5 min, 60% A; 4.5 min, 50% A; 5.5 min, 35% A; 6.5 min, 5% A; 7.0 min, 2% A; 12 min, 2% A. Between runs the column was equilibrated with 75% A for 12 min. The injection volume was 2.5 μL, and chromatograms were recorded at 210 nm.

UHPLC-QTOF-MS Conditions. For the quantitative analysis of **1**−**3** UHPLC-QTOF-MS experiments were carried out using a micrOTOF-QII mass spectrometer (Bruker Daltonics, Bremen, Germany) hyphenated to the UHPLC-DAD instrument described above. Experiments were performed in positive ESI mode with the following ionizer and transfer parameters: capillary energy, 4500 V; nebulizer gas, 23.2 psi; dry gas, 6.0 L/min at a temperature of 200 °C; scan range, m/z 400−1000 with a scan rate of 2 Hz; quadrupole, ion energy 5 eV; low mass m/z 300.00; collision cell, collision energy 10 eV; transfer time, 40 μs; collision RF, 916.7 Vpp; prepulse storage, 16 μs; transfer, funnel 1 RF 200.0 Vpp, funnel 2 RF 395.2 Vpp, hexapole RF 500.0 Vpp. High-resolution mass calibration was facilitated by injecting 10 mM NaOH in isopropanol/water (1:1, v/v) fortified with 0.1% formic acid at the beginning of each analysis. The exact mass of the sodium formate clusters was used as calibrant. Destruxins were monitored by using the $[M + H]^+$ as quantifier ion and $[M + Na]^+$ as qualifier; for both ions the mass error had to better than 5 ppm.

Assay Validation for the Quantitative Analysis of Destruxins from Strawberry and Maize Samples. Calibration functions were obtained for a dilution series containing **1**−**3** and the internal standard roxithromycin, **4**, in acetonitrile as well as for a dilution series spiked in strawberry and maize matrix. Sample preparation of the matrix calibration levels was carried out using the QuEChERS protocol described above, and acetonitrile reference standards were used without further preparation steps. All calibration levels were analyzed in triplicates. Validation results were evaluated using the Bruker analysis software (QuantAnalysis version 2.0 SP4), and calibration functions were obtained for all three models. The limit of detection (LOD) and the limit of quantitation (LOQ) were calculated from the regression models including only the lowest four dilution levels. From the obtained regression equation data the LOD was calculated as 3 times the standard deviation (STD) of the y-intercept divided by the slope, whereas the LOQ was calculated as 10 times the STD of the y-intercept divided by the slope.[14,25,35]

The precision and accuracy of the method were assessed at four different concentration levels (covering the range of the calibration curve) by using spiked strawberry and maize matrix samples. All samples were prepared in triplicates; sample preparation was carried out using the QuEChERS protocol described above. For intra- and interday repeatability, samples were measured on three different days in triplicate. Precision was determined as the relative standard deviation (RSD) of the respective replicate measurements of the different levels; accuracy was expressed as percentage of recovery of the measured analyte concentration in relation to the spiked concentration.

RESULTS AND DISCUSSION

Internal Standard. As internal standards everolimus, cyclosporin A (both immunosuppressant), rifampicin (antibiotic drug of the rifamycin group), azithromycin (an azalide, a subclass of macrolide antibiotics), roxithromycin, and clarithromycin (both semisynthetic macrolide antibiotics) have been tested. All of them with the exception of roxithromycin showed either a loss of analyte during the sample preparation procedure, instability in the extraction solvent, elution in the wash phase of the method, or broad distorted peaks during chromatography. Finally, roxithromycin was chosen as internal standard, which showed a good recovery and was eluting in the retention time window between **1** and **2**.

Optimization of the Sample Preparation Protocol. Different sample preparation procedures to extract destruxin congeners from the crop matrices such as liquid−liquid extraction or solid phase extraction (SPE) protocols with various organic solvents were tested. For example, SPE over C18 materials, Supel Tox AflaZea, or Tricho SPE cartridges (Sigma-Aldrich, Vienna, Austria) has been evaluated. However, none of those procedures was suitable for destruxin analysis due to a loss of either analytes or the internal standard. Therefore, a QuEChERS-based protocol was chosen for sample preparation. Using this procedure achieved good recovery for the targeted analytes **1**−**3**, as well as for the chosen internal standard **4**.

Mixed strawberry (10 g) or ground maize (5 g) samples were weighed into the QuEChERS extraction tube and spiked with the internal standard. Depending on the matrix and its own water content, a specific volume of water had to be added to the sample to guarantee entire extraction of the analytes. In contrast to strawberry, which has a typical water content of approximately 90%, maize has a water content of only 10%. Therefore, homogenized maize samples were diluted with 2 mL water/g sample and mixed by vigorous shaking before the subsequent sample preparation. Extraction was carried out using 10 mL of acetonitrile followed by a partitioning step after the addition of a salt mixture. An aliquot of the organic layer was then purified by dispersive solid phase extraction (d-SPE) using the QuEChERS Dispersive Kit for HIGHLY Pigmented Fruits and Vegetables, which removes polar organic acids, some sugars and lipids, carotenoids, and chlorophyll.

UHPLC-QTOF-MS Assay Optimization. Analyses were performed using an Agilent 1200 UHPLC liquid chromatograph coupled to a micrOTOF-QII mass spectrometer with an electrospray ionization (ESI) interface operating in positive mode. For the initial method setup the MS was equipped with a syringe pump to enable experiments for the optimization of ionization parameters of the main metabolites **1**−**3**. Therefore, a destruxin standard solution of **1**−**3**, each at a concentration of 0.1 μg/mL, was directly infused into the mass spectrometer using a 500 μL syringe operating the syringe pump at a flow rate of 300 μL/h. UHPLC was operated at a flow rate of 0.1 mL/min with a solvent mixture of 20% water (A). To improve the ionization of analytes, the binary solvent system consisting of water (A) and acetonitrile (B) was modified while mass spectrometric parameters kept constant. Different concentrations of acetic acid, formic acid, ammonium formate, ammonium acetate, and mixtures were added to the mobile phase. Depending on the concentration of ammonium acetate and ammonium formate, it was necessary to add 2−5% water to completely dissolve the salt. Optimal conditions for ionization of analytes were obtained using water (A) and 95% acetonitrile (v/v) (B), each containing 10 mM ammonium formate, as mobile phase. This chromatographic setup was used for optimization of ion source parameters such as capillary voltage (3−5 kV), nebulizer gas (10−30 psi), dry gas flow (4−10 mL/min), and temperature (180−250 °C) as well as for optimization of further mass spectrometric parameters such as voltages of funnels (50−400 Vpp), of hexapole (50−800 Vpp), or collision cell (5−16 eV), as well as transfer (20−120 μs) and prepulse storage time (6−18 μs). Figure 2 shows the extracted ion chromatograms of destruxins, **1**−**3**, and the internal standard roxithromycin, **4**, under optimized chromatographic and mass spectrometric conditions.

Assay Validation for the Quantitative Analysis of Destruxins from Strawberry and Maize Samples. Assay

DOI: 10.1021/acs.jafc.5b01562
J. Agric. Food Chem. 2015, 63, 5707−5713

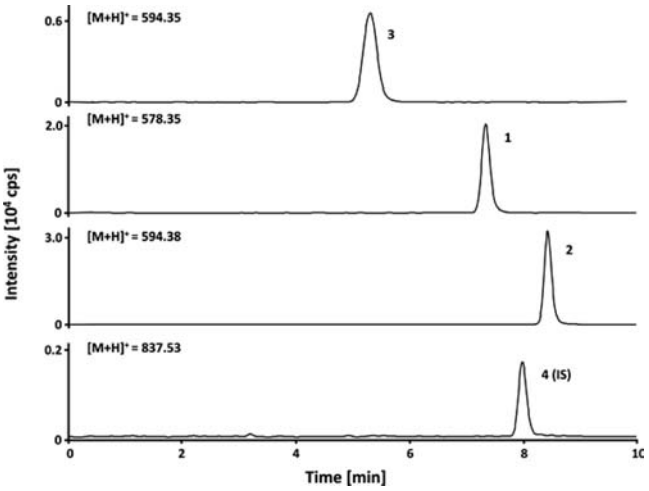

Figure 2. UHPLC-QTOF-MS extracted ion chromatograms of the main metabolites **1**−**3** (each 50 ng/mL) and the internal standard roxithromycin (10 ng/mL) in acetonitrile under optimized chromatographic and mass spectrometric conditions.

validation was performed with a dilution series containing destruxins, **1**−**3**, and the internal standard roxithromycin, **4**, in acetonitrile as well as with a dilution series spiked in strawberry and maize matrix. Calibration levels in acetonitrile were analyzed without further treatment, whereas matrix samples were prepared using the described QuEChERS-based extraction protocol. All solutions were measured in triplicates. During sample workup sample dilution was chosen such that nanogram per milliliter concentrations in solution correspond to parts per billion (ppb; μg analyte/kg matrix) concentrations in the matrix. Calibration curve equations were generated resulting in quadratic functions with correlation coefficient values (R^2) exceeding 0.999. Calibration ranges were found to be valid from 1.0 to 100.0 ng/mL (corresponding to ppb in spiked matrix) for destruxins, **1**−**3**, for all three matrices with the exception of destruxin E in maize ranging from 2.5 to 100.0 ng/mL (ppb). LOD and LOQ ranged from <1.0 to 1.4 ng/mL and from 1.7 to 4.3 ng/mL, respectively, for the analytical assay, with nanograms per milliliter corresponding to parts per billion. Precision and accuracy of the method were assessed using spiked matrix samples of four different concentration levels, each in triplicates. Intraday and interday assay precisions of all levels of destruxins, **1**−**3**, in strawberry samples were found to be <11.2% RSD and <10.7% RSD, respectively. Accuracy of strawberry samples was found to be between 82.3 and 105.0% for destruxins A and B and between 83.2 and 97.7% for destruxin E, independent of the calibrator matrix used for quantitative analysis (Table 1).

For all but the lowest fortification level, intraday RSDs for destruxins A and B in maize ranged between 4.0 and 15.3% and interday RSDs between 8.6 and 12.8%, whereas precision of the measurement was lowered for the fortification level close to the LOQ with intraday and interday RSDs better than 24%. In the case of destruxin E, assay precision for all fortification levels was found to be between 7.3 and 26.7% for intraday RSD and <23.9% for interday RSD, which indicated a loss of the

[a]Three samples were prepared for each fortification level (n = 12), and each sample was measured 3-fold on three different days (n = 9). Precision and accuracy were calculated using the calibration curve in either acetonitrile or crop matrix. [b]Analyte concentration in the final sample solution. It corresponds to ppb analyte in matrix.

respective metabolite. Accuracy of destruxins A and B in maize samples ranged from 78.7 to 115.4%, but was strongly reduced for destruxin E (Table 2). Depending on the calibration curve used for calculation, destruxin E accuracy ranged from 25.2 to 48.0% (calibration in acetonitrile) and from 55.3 to 81.7% (calibration in spiked matrix samples); destruxin E is underestimated up to approximately 45% even if the quantitative analysis is based on matrix-matched calibrators. In summary, it can be stated that accuracy and precision data proved the internal standard fortified assay design to be matrix independent with the exception of destruxin E in maize matrix, for which severe analyte loss was observed. For all analytes except destruxin E in maize, the analytical sensitivity (slope of the calibration function) in standard solution (acetonitrile) was identical to the matrix materials. This as well as validation results proves that the QuEChERS-based extraction protocol is suitable for the application in strawberry and (with some limitations) maize. This was additionally proved by spike experiments using a stock solution of a dichloromethane crude extract (BIPESCO 5) and the internal standard. Samples were prepared in both matrices and as reference in acetonitrile. Even if the complete removal of more polar maize constituents was not achieved (Figure 3), destruxin congeners were completely extracted from all matrices.

Because recoveries of the structurally similar destruxins A and B from maize were satisfying, the loss of destruxin E (Figure 44) in this matrix may be explained with either the obvious structural differences of this congener featuring a chemically highly reactive epoxide moiety in the variable side chain or the presence of additional polar constituents in this crop leading to a matrix-related detection problem (e.g., an ion yield attenuation effect). Consequently, in maize the quantitative analysis of destruxin congeners has to be limited to destruxins A and B, which are, however, major metabolites of

Figure 3. the investigated *M. brunneum* strains and therefore can be used as surrogate markers for the presence of this fungus or its secondary metabolites in the investigated matrices.[14,19,22,25,34]

Consequently, we consider this platform as a new sensitive, precise, accurate, and stable method for routine risk assessment of the use of *M. brunneum* as BCA in food production. It allows monitoring the presence of destruxins in crop products in the lower parts per billion range.

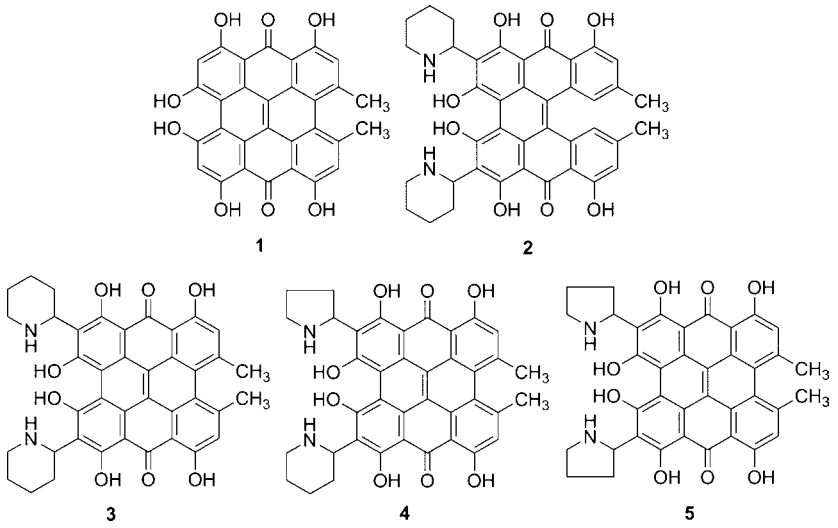

Figure 1. Structures of hypericin (**1**), protofagopyrin (**2**), fagopyrin A (**3**), fagopyrin E (**4**), and fagopyrin F (**5**).

Figure 1 are currently known, five yet remaining to be elucidated.

Melting Point. The melting points of two isolated, incompletely purified, and unidentified fagopyrins were tested. One of them did not melt at 375 °C, whereas the other melted at 375 °C, but did not melt sharply, suggesting that the product was impure.[19]

Chemical Reactivity. Many contradictions on the chemical reactivity of fagopyrins exist among different studies. Chick[21] reported that the extracts became inactive in the terms of phototoxicity, tested on rats, after treatment of the extracts with heat and alkaline solvents such as sodium bicarbonate, diethylene glycol, enzymatic digestion with trypsin, boiling ethyl alcohol, and, to our surprise, even ethanol, which is not entirely in accordance with other data, where fagopyrins were not soluble in or sensitive to ethanol. The findings by Chick were later confirmed only in part, when the alkaline hydrolysis of fagopyrins to hypericin-like compounds was observed in ammonia and pyridine solutions. In contrast, acidic conditions slowed the conversion of protofagopyrins to fagopyrins but did not affect the short-term stability of fagopyrins.[20] On the basis of thin-layer chromatography (TLC), fagopyrins hydrolyze to a compound that is similar to hypericin when heated with pyridinium chloride at 220 °C.[22,23] Bromination of fagopyrin and hypericin resulted in the same product, from which it can be suggested that during bromination, fagopyrins are hydrolyzed.[24]

IR Spectrum. The IR spectrum of fagopyrins exhibited a broad band at 3350−3450 cm^{-1} (OH groups) and strong bands at 2850 and 2925 cm^{-1} (CH_2 groups from the piperidine side chain) and at 1600 cm^{-1} (carbonyl groups associated through hydrogen bonding).[23]

UV−Visible Spectrum. In the UV−visible spectrum, the absorption maxima of all eight fagopyrins occur at 284, 329, 545, and 590 nm.[20,25]

Fluorescence. Fagopyrins fluoresce orange to red under UV light at 366 nm. Fluorescence detection using an excitation wavelength of 330 nm and an emission wavelength of 590 nm is more sensitive than UV−vis detection.[20]

Protofagopyrin Transformation. Many authors observed the transformation of "invisible" molecular forms, termed protofagopyrins (Figure 1), to "visible" fagopyrins upon excitation with light.[20,22,26] They declared that protofagopyrins do not fluoresce and exhibit low absorption. Although the structural elucidation of protofagopyrins has not yet been performed, substantial evidence supports their existence. There are two theories about the presence of fagopyrins and their protoforms in buckwheat plant. The first is that fagopyrins and their protoforms are both present in the plant, analogously to hypericin and protohypericin. The second is that the compounds convert only after solubilization in the extraction solvent and that protofagopyrins are the only genuine plant products. We believe there is more evidence for the second theory, which we prove in the following section.

The second theory is supported by the experiment where protofagopyrins were observed in a light-protected extract sample using an HPLC-DAD instrument as a weak signal at 590 nm; they showed retention times similar, but not equal, to those of fagopyrins from an identical but light-exposed sample. Before light exposure, there were no fagopyrin peaks in the sample. In the UV−vis spectra, a strong absorbance maximum at 590 nm was observed upon exposure to light, indicating the formation of fagopyrins. Simultaneously, the compounds began to fluoresce (excitation at 330 nm and emission at 590 nm). The reaction was not reversible under normal light−darkness conditions. In another study it was deduced that the reactivity of protofagopyrins could be decreased because of piperidine rings and the esterification or etherification of para-hydroxyl groups with phenols, naphthols, anthranols, or other molecules.[22] Due to the ease of acid hydrolysis, 7,7′-hydroxy glycoside esters were postulated to be present in the plant. These moieties could in fact affect the solubility of the substances, which was observed in one of the experiments: The extraction of fagopyrins with acetone resulted in fagopyrin-rich extracts, but, when dry, the fagopyrins became insoluble in the same solvent.[22] The fact that other buckwheat moieties may help to solubilize fagopyrins was further supported by animal studies, in which buckwheat extract exhibited more activity than the purified pigment, which appeared to be insoluble.[21]

In contrast to the second theory, Samel[23] did not observe the transformation of protofagopyrins to fagopyrins in the UV−vis absorption spectra of an irradiated purified extract. Their experiment seemed to disprove the occurrence of chemical conversions from protofagopyrins to fagopyrins. However, from

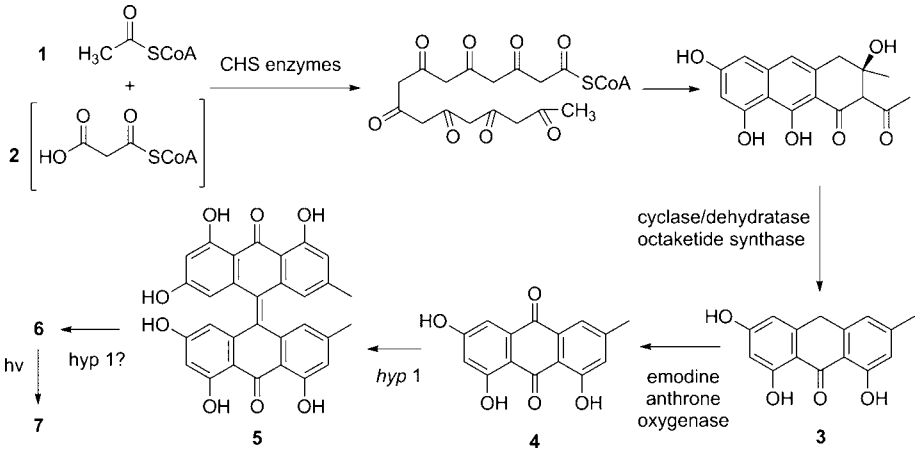

Figure 2. Possible route of fagopyrin biosynthesis:[28] acetyl coenzyme A (1), malonyl coenzyme A (2), emodianthrone (3), emodine (4), emodine dianthrone (5), protofagopyrin (6), and fagopyrin (7).

his description, we can deduce that the initial unpurified extract changed from yellow to red over a period of 2 days. We believe that the majority of the substance had already been converted at that point, which resulted in the false conclusions of a later experiment.[23]

To conclude, many comparisons between protohypericins and protofagopyrins have been made, but we believe that the conversions of these two compound classes do not occur in the same manner. We conclude that the OH groups of hypericin are not shielded with piperidine rings, whereas those of fagopyrins are, so the more reactive protohypericin readily transforms to hypericin in plants, whereas fagopyrins develop only after solubilization, upon light exposure.[27]

Biosynthesis. By analogy with the biosynthesis of other phenolic compounds, the chalcone synthase- and benzophenone synthase-related polyketide pathway (type III PKS) was predicted to be the most probable fagopyrin synthesis pathway (Figure 2). The polyketide chain that generates aromatic ring compounds is formed from acetate and malonate units by an enzyme complex, known as polyketide synthase. The precursor to protofagopyrin is emodin anthrone, which is generated by the condensation of one acetyl coenzyme A molecule and seven malonyl coenzyme A molecules. Emodin anthrone is further oxidized to emodin by emodin anthrone oxygenase and is condensed to dianthrone. The last conversion from protofagopyrin to fagopyrin occurs during extraction from the herb upon exposure to light.[28] Similar findings were confirmed for hypericin.[29] Unfortunately, the authors did not discuss the biosynthetic processes from which the structural differences between fagopyrin and hypericin (e.g., attachment of piperidine rings) arise. This information might be useful for the design of fagopyrin synthesis on the basis of hypericin synthesis.[30,31]

Solubility and Extraction Solvents. A variety of different extraction solvents was tested with fagopyrins, as summarized in Table 5. Previous authors agree that fagopyrins are insoluble in polar solvents and in organic solvents that possess no hydroxyl groups. Most authors reported efficient solubility in protic organic solvents, mixtures of aprotic solvents with water, pyridine, and dimethylformamide. As shown in Table 1, the results of different investigators are not always in agreement. For example, Tavčar Benković et al.[20] could not confirm the solubility of fagopyrins in ether or chloroform as indicated by Wender et al.[19] These contradictions confirm that the effective solubility of fagopyrins in a certain solvent is highly influenced by other parameters, such as light exposure, temperature, and the presence of chlorophylls, polyphenols, or presumed esters and ethers of fagopyrins. The analytical methods used to determine the fagopyrin content were also different and not always appropriate, a consideration that is discussed in detail in other sections of this paper

Structural Elucidation. Many authors observed three different fagopyrin pigments and speculated that (as for hypericin, isohypericin, and pseudohypericin) these pigments could represent fagopyrin, isofagopyrin, and pseudofagopyrin. A molecular structure of fagopyrin with two piperidine groups was first elucidated through chromatographic separation and by the NMR spectral analysis of fagopyrins that were acetylated with acetic anhydride and pyridine.[24] The structure was later confirmed by analyzing the pure compound, which was termed fagopyrin F. Two additional novel structures were elucidated (fagopyrins A and E) by using UV−vis absorption, NMR spectroscopy, and mass spectrometry. The aforementioned isofagopyrin and pseudofagopyrin forms were not confirmed, but at least five additional structures are reported to be in need of elucidation.[20]

Mass Spectrometric Analyses. The following fragments were observed in positive spectra of LC-MS TOF ESI analysis:[20,25] fagopyrin A, *m/z* 643, 626, 625, 609, 574, 70; fagopyrin E, *m/z* 657, 640, 639, 622, 588, 84, 70; fagopyrin F, *m/z* 671, 654, 653, 636, 588, 84.

NMR Analyses. The signals that were observed in the NMR spectrum of fagopyrins F, E, and A are presented in Table 2.

■ ISOLATION ATTEMPTS

The first isolation of fagopyrins was performed using an alcohol extraction; subsequent precipitation of chlorophyll with lead acetate and boiling with lead oxide yielded a fluorescent substance that was not further evaluated.[32] Many further attempts to isolate the red pigment have been undertaken, as described in Table 3.

Although the isolation of pure fagopyrins had already been reported in 1943, the product did not melt sharply, which indicated the presence of impurities.[19] The most promising isolation approach appears to be reported by Samel,[23] but our unpublished reproduction of their procedure was unsuccessful, as we were unable to elute a fluorescent fraction from silica gel 60 with any solvent.[23] In all reported isolation attempts, effective extraction solvents for fagopyrins are evidently highly

unspecific and are difficult to evaporate due to their high boiling points. Given the need to evaporate the solvent, we conclude that the best extraction solvent is acetone/water (9:1). A higher temperature (60 °C) and the use of ultrasound can significantly accelerate the extraction procedure. Protofagopyrins are probably extractable with many organic solvents (methanol, acetone) before transformation, but no analytical method is available to examine this process due to the "invisibility" of the compounds. Besides fagopyrins, buckwheat contains high amounts of chlorophyll (especially in the leaves and flowers), anthocyanins, and other polyphenols. Hence, yellow, red, and green fractions were difficult to remove in most studies. The best solvent for chlorophyll removal is dichloromethane, and some flavonoids can be removed with 30% ethanol. Flowers are a superior extraction material compared to other plant parts due to their higher fagopyrin content and lower chlorophyll levels. Currently, the most efficient isolation method is an HPLC method, which enables the full separation

of fagopyrins from other compounds. However, an analytical system was used, which did not allow a sufficient quantity of fagopyrins to be obtained for weight determination.[20] We therefore recommend that the method be scaled up to allow preparative quantities of product to be isolated and to improve the resolution of the method. Many authors have reported difficulties in the solubilization of their dried, purified extracts. We conclude that solvents allowing efficient extraction are not necessarily also able to solubilize isolated fagopyrins, as the presence of other compounds may influence their solubility.

The task of eliminating fagopyrins from extracts is much easier. To obtain polyphenol-rich buckwheat extract with no risk of phototoxicity, a 30% ethanol in water solution is adequate for extracting phenols while simultaneously avoiding fagopyrins.[33]

■ ANALYTICAL METHODS

Fagopyrins and their acetylated derivatives were first analyzed by chromatography on silica gel with chloroform/methanol (97:3). The compounds with the highest retention times were hexa-acetylated fagopyrins. Fagopyrin and the hydrolyzed products of acetates did not migrate with the mobile phase. Fagopyrins were separated into several red spots using a $CaSO_4$ stationary phase.[24]

A successful method to separate three fagopyrin spots used silica gel 60 F_{254} with a mobile phase of toluene/ethyl formate/formic acid/pyridine (5:4:1:2).[23,34] This method was successfully used for preparative purposes, starting with 50 μL of extract.[35] Eguchi[25] used the same method but analyzed the plate at 302 nm and observed two spots.[25]

For spectrophotometric determination of fagopyrin content, several modifications of the pharmacopoeial method for the determination of hypericin have been used. Samples of dry buckwheat extracts were suspended in tetrahydrofuran; the supernatant was evaporated, and the residue was extracted again with methanol. Some authors used methanol directly as an extraction solvent and then centrifuged the sample. The absorbance of the supernatant was measured at 590 nm. The authors calculated the fagopyrin concentration compared with a standard solution of hypericin.[25,33,36,37]

The first HPLC method for fagopyrin isolation was developed with water/methanol/trifluoroacetic acid/tetrahydrofuran (3:40:1:1) as a mobile phase. The authors monitored the absorbance at 590 nm and observed three barely resolved peaks.[25] This method was improved with the use of an acetonitrile/water gradient with 0.1% trifluoroacetic acid, employing fluorescent detection (excitation at 330 nm, emission at 590 nm). Eight peaks of fagopyrins were partially separated.[20]

We must emphasize the fact that, to date, no quantitative isolation and characterization of entirely pure fagopyrins to use as a reference standard has been reported.

■ CONTENT

The fagopyrin contents in different materials and determined in different studies are summarized in Table 4.

All parts of tartary buckwheat contain at least 2 times more fagopyrin than the corresponding part of common buckwheat.[25,37,38] The fagopyrin content was influenced by the cultivation method.[37] Illumination and cultivation in sprouters increased the fagopyrin content by 2-fold. The fagopyrin

DOI: 10.1021/acs.jafc.5b01163
J. Agric. Food Chem. 2015, 63, 5715−5724

content was independent of whether the seeds were soaked in different solutions of selenium or the level of UV-B radiation.[36] Similarly to hypericin, a nitrogen-limited environment was postulated to favor fagopyrin production in a highly sensitive manner.[28]

In quantitative evaluations of fagopyrin content, none of the authors reported using a fagopyrin reference standard, which would be necessary to obtain genuine results. Therefore, all values from Table 4 can be considered only as estimates. The authors mainly expressed the fagopyrin content by using hypericin equivalents. Parameters such as absorbance or fluorescence depend on complex molecular characteristics and thus cannot be directly compared between two different compounds such as hypericin and fagopyrin, despite their similarity. A justification of these statements can be found in the next section.

Photodynamic Properties of Fagopyrins. Fagopyrin is a photodynamic agent, which is a molecule that absorbs light and transforms itself into an excited state. Two paths are possible for emitting the absorbed energy: the first is through a photochemical reaction, which releases orange to red fluorescence in the case of fagopyrins, and the second is a transfer of the absorbed energy to an acceptor molecule. In the latter case, the photodynamic molecule transforms from a singlet to a triplet state. When returning to the singlet state in the presence of triplet oxygen as an acceptor molecule, singlet oxygen forms. Singlet oxygen further oxidizes cell lipids, proteins, and nucleic acids, which leads to inflammation.[39] The formation of superoxide radical instead of singlet oxygen is also possible but was not observed in a study of the photoexcited forms of hypericin.[17] Hypericin underwent a one-electron transfer to singlet oxygen in egg yolk lecithin liposomes at pH 7.0. However, at a higher pH of 9.7, superoxide radical production proceeded mainly via electron transfer between excited hypericin and its ground state with little participation of singlet oxygen.[40] Energy transfer paths are therefore highly dependent on the environment. Efficient cell death has been demonstrated to occur when light, oxygen, and the evaluated photosensitizer are not limited,[41] and reports of the phototoxicity and fluorescence of fagopyrins are consistent with this idea. In our unpublished work, we found that the fluorescence of solubilized fagopyrins depends greatly on the solvent conditions, especially pH. This phenomenon should be considered in all experiments that evaluate fagopyrin content. Solution pH apparently influences the energy emission pathways of fagopyrin molecules. Excitation also undoubtedly depends on the light source. Amber glass did not stop the photosensitization process, but blue glass did.[42] In vivo, fagopyrins have demonstrated excitation at wavelengths of visible light between 530 and 690 nm, which is important information for the occurrence of fagopyrism and for the potential therapeutic use of fagopyrins.[21]

Fagopyrism. The first reports about fagopyrism are epidemiological observations of its manifestation in stock animals, feeding on pastures rich in buckwheat. As early as 1843, Fuchs correlated the symptoms of buckwheat sensitivity with the level of exposed light necessary for their expression. Chick[21] was the first to conduct controlled experiments. He observed the lesions on animals after feeding with buckwheat and compared them with animals kept in the dark. He also compared covered and uncovered areas of the skin. In the beginning of the 20th century, many reports were published on fagopyrism that confirmed the effect and its symptoms. The whole plant was observed to be more effective than the seeds alone for inducing the condition. The symptoms in guinea pigs persisted for 36 months after feeding with a buckwheat diet. Several attempts at isolation and pharmacological testing on animals were also made. Öhmke successfully sensitized mice, guinea pigs, and rabbits by feeding them buckwheat seeds and hulls, which should not contain very high amounts of fagopyrins.[21,32,43−45] The characteristic absorption bands of fagopyrins were observed in swine serum, which demonstrated that these compounds can be absorbed through the walls of the digestive system.[42] The safety of commercially available Fagorutin tablets with powdered buckwheat herb was also investigated in a randomized, double-blind placebo-controlled study. The influence of UV-A and UV-B on skin after a single dose and after 14 days of application (3 × 2 tablets daily, 500 mg of buckwheat herb each) was tested. No differences relative to the placebo were observed. We can thus conclude that the evaluated doses were below the phototoxicity-causing threshold.[46]

The typical symptoms of fagopyrism are similar in all observed in vivo systems, as indicated in Table 5. They occur in sunlight-exposed areas of the skin after the ingestion of fagopyrin-rich buckwheat products. These reactions do not primarily involve immune system responses, and so fagopyrism cannot be correctly described as a buckwheat allergy. Other possible symptoms that are not directly connected to photosensitivity include hyperemia, swelling of the intestinal canal, and gastrointestinal hemorrhage.[45,47]

Table 5. Symptoms of Fagopyrism[21,42,49,61]

livestock (sheep, horses, cattle, swine, goats, chickens)	rats, mice, guinea pigs	humans
erythema	erythema of the naked parts of the skin	burns
swelling	uncovered portions of the skin becoming swollen and inflamed	tingling and numbness in the hands
skin lesions	dilation of the veins but not capillaries	cold sensitivity
skin irritation	hair loss	
inflammation	scratching	
blindness	irritable, uncomfortable behavior	
sensory disturbances	temporary loss of appetite and weight	
intestinal disturbances	conjunctivitis	
	diarrhea	
	convulsions	

Information about the minimum toxic doses of fagopyrin is scarce. The safe consumption limits of buckwheat were estimated by comparison to hypericin toxic doses. For sprouts, the safe limit was 0.14 g of dry sprout mass (corresponding to 40 sprouts) per kg body mass per day; a severe phototoxic dose would correspond to the consumption of 10 g of dry mass per person.[37] However, the findings of Theurer[34] are not in accordance with these results. The authors examined the effect of an ethanol buckwheat extract, irradiated with artificial sunlight, on 3T3 fibroblasts and found that fagopyrin is 10 times less phototoxic than hypericin (6 μg/mL). An aqueous extract demonstrated no activity.[34] Epidermal growth factor receptor- and insulin receptor-associated protein kinases were inhibited with purified buckwheat extract to a similar extent as

DOI: 10.1021/acs.jafc.5b01163
J. Agric. Food Chem. 2015, 63, 5715−5724

hypericin. They both inhibited serine/threonine kinases and cytosolic protein kinases (Lyn, Fgr, CSK) to a lesser extent. In the case of casein kinase 2, hypericin was found to be a much more potent inhibitor.[23] From both studies, we can conclude that comparison with hypericin is not an appropriate benchmark from which to obtain quantitative results. Similarly, pseudohypericin was a much less efficient photosensitizer in biological systems than hypericin due to its high adsorption to serum components. This discrepancy can serve as further proof of the high dependence of photodynamic effects on the structural features of individual molecules.[48] Unfortunately, no fagopyrin reference standard is currently available, so only buckwheat extracts with unknown fagopyrin contents were tested. In experiments on rats, the minimal activating dose of dried flowers was 0.25 g/100 g animal.[21] Maximal reactions were observed between the fourth and eighth day and could take up to 4 weeks. After several days, local irradiation produced a general effect, with inflammation occurring on exposed but non-irradiated parts of the body. The duration of the symptoms was proportional to the size of the dose and worsened after light exposure. Fagopyrins were not detected in urine or feces. A second relevant study is a retrospective report about one author's personal encounter with fagopyrism as a consequence of the daily consumption of "healthful" juice that contained buckwheat herb. Unfortunately, accurate records of the amount of buckwheat consumed are not provided. From the author's description, we can infer that he drank one glass of buckwheat juice per day, but it is uncertain as to whether the juice was diluted with water. His personal experience was followed by an inquiry, which revealed that many other people reported similar experiences. Their symptoms always appeared after an extended-duration diet, which suggests that fagopyrins require accumulation over time.[49] Like hypericins, fagopyrins are presumably largely unable to cross the blood−brain barrier in animals, so the neurological symptoms described in several cases are probably consequences of oxidative stress from inflammation.[50] Notably, porphyrin derivatives that are present in buckwheat herbs, such as phylloerythrin, an anaerobic fermentation product of chlorophyll molecules, can also induce phototoxicity, but at different wavelengths.[42,47,51] Other components of buckwheat extract, such as quercetin, may also contribute to the formation of reactive oxygen species, which are involved in photosensitizing activity; however, their contribution is likely negligible.[35] No reports can be found about fagopyrins in milk during lactation. Considering hypericin, the compound is poorly excreted into human milk. The only report is about a mother that was on a postnatal depression therapy, taking 900 mg of St. John's wort extract (3−6:1) per day; the plasma of the breast-fed infant was analyzed. Hypericin was found to be in concentrations below the quantification limit (0.20 ng/mL).[52,53]

We can summarize from all available pharmacological data that acute poisoning of humans with any parts of the whole buckwheat plant is not probable, as the amounts required would be too large given the ratios with other buckwheat compounds. From solubility studies, we can conclude that aqueous extracts such as tea should not threaten human health. The most problematic consumption method is an extended-term diet, lasting more than a few days, of buckwheat herbs, especially flowers, or of protic lipophilic buckwheat extracts.

Pharmacotherapeutic Potential. The phenomenon of photosensitization described above can be exploited in photodynamic therapy, in which initiation of the photochemical formation of singlet oxygen in a restricted area is deliberate and limited in extent. Photosensitizers can be applied locally or systemically, and a selected area is irradiated with laser light of chosen wavelengths to induce oxidation of the biological tissue.[39] Hypericin has been widely tested as a therapeutic agent in recent years, mainly for tumor treatment.[54] Hypericin exhibits several advantages over common photosensitizers, including substantial quantum yield, intense absorption in the visible region, low photobleaching, and a large excitation range. The delivery of hypericin by most pharmaceutically suitable vehicles is limited due to its hydrophobicity.[55] Nevertheless, its hydrophobicity could favor local application and higher selectivity for certain tissues. In the present paper, we show that fagopyrin is even more specific in its solvation environment, so it may serve as a potential photodynamic agent with even greater selectivity.

Hypericin also exhibits antiviral activity. Interestingly, its potential for photo-oxidation plays only a minor role in this observed activity. Instead, the antiviral activity is primarily mediated by other mechanisms, which are potential avenues for the investigation of fagopyrins.[56] Molecules with anthrone skeletons are also often used as topical antipsoriatic treatments.[57]

To summarize, the long-term consumption and study of buckwheat have provided only rough information about the safety of phototoxic fagopyrins. Unfortunately, reliable quantitative data on their toxicity are not yet available. Buckwheat seeds, flour, or teas are safe in normal amounts. However, an extensive diet that includes buckwheat sprouts or herbs and particularly flowers or fagopyrin-rich buckwheat extracts may cause fagopyrism on parts of the skin upon simultaneous exposure to visible light. Fagopyrins were discovered more than 100 years ago but remain poorly characterized substances. The main difficulty lies in their unique molecular characteristics, which hinder their isolation. Consequently, no reference standard is currently available; a reference standard would enable proper fagopyrin content evaluation in buckwheat products and proper testing of their undiscovered characteristics, biosynthetic pathways, and biological activities. Many methods remain to be established. Nevertheless, fagopyrins are not only health-threatening compounds but also potent photodynamic agents that warrant further research.

(Fortaleza, Ceará, Brazil). Tween 80, sodium acetate, acetic acid, and sodium hydroxide were purchased from Synth (Diadema, São Paulo, Brazil). DEAE chloride, deuterium chloride (35%) in deuterium oxide, and deuterium oxide were purchased from Sigma-Aldrich Chemical Co. (São Paulo, Brazil). Potato dextrose agar (PDA) was purchased from Acumedia Manufacturers, Inc. (Lansing, MI, USA). Water was deionized using a Gehaka water purification system. Spectra/Pore membranes (Spectrum) were employed for dialysis. All solvents were of reagent grade and were used as received.

Instrumentation. ^1H NMR spectra were recorded using a Bruker ARX-500 500 MHz spectrometer (Bruker, Germany). UV−vis spectra were measured using a Cary 100 spectrophotometer equipped with a Peltier system. pH was measured using a DM-23 Digimed pH meter (Digimed, Campo Grande, Brazil).

Synthesis of Amphiphilic Derivatives of DEAE-CH. CH derivatives were synthesized using deacetylated CH samples, prepared as previously described by Tiera et al.[20] CH derivatives were obtained by reacting DEAE chloride with CH of different M_w values (517.7, 176, and 16.7 kDa) in aqueous media at pH 8.0 under an N_2 atmosphere.[21] The resulting derivatives (DEAE-CH) were purified by dialysis against water for 4 days and were then lyophilized. Subsequently, the derivatives were subjected to hydrophobic modifications through reductive amination with dodecylaldehyde, as shown in Figure 1. The procedure for generating $DEAE_{30}$-CH-Dod_{10} with a sample containing 30% DEAE groups and 10% Dod groups is

DOI: 10.1021/acs.jafc.5b00278
J. Agric. Food Chem. 2015, 63, 5725−5731

described below. Deacetylated CH (0.8 g, 176 kDa) was solubilized in a mixture of 90 mL of 2% acetic acid and 50 mL of ethanol. The pH was adjusted to 5.0, and while the reaction mixture was stirred, 0.12 mL of dodecylaldehyde dissolved in 10 mL of ethanol was added to it in a dropwise manner. The reaction mixture was continuously stirred for 25 h at room temperature, and sodium cyanoborohydride (3:1, $NaCNBH_3/NH_2$, mol/mol) was added after the first hour. Thereafter, the reaction mixture was dialyzed (using a membrane with a MWCO of 6000−8000 g/mol), first against water for 2 days, then against aqueous NaOH (0.05 M) for 1 day, and finally against water for 3 days. The derivative $DEAE_{30}$-CH-Dod_{10} was lyophilized. Other DEAE-CH-Dod derivatives were prepared under identical conditions using different initial NH_2/dodecylaldehyde molar ratios (Table 1). The derivatives were subsequently purified with a Soxhlet system using chloroform to remove nonreacted dodecylaldehyde. The derivatives were characterized by ^{1}H NMR, FTIR and gel permeation chromatography (GPC) measurements.

GPC Analysis. GPC measurements were performed using an LC-20 Shimadzu liquid chromatograph (Shimadzu, Japan) equipped with a refractive index detector (model RID-10) using OHpak SB-803 HQ and OHpak SB-805 HQ columns (Shodex) and pullulan standards from 805 to 6.2 kDa (Supporting Information, Supplementary Figure S1). A mixture of acetic acid (0.3 M)/sodium acetate (0.2 M) (pH 4.5) was used as the mobile phase at a flow rate of 0.8 mL/min at 35 °C. Solutions were prepared for GPC analysis by dissolving the polymer in an acetic acid (0.3 M)/sodium acetate (0.2 M) buffer to achieve concentrations of between 0.5 and 1.0 mg/mL. The polymer solutions were stirred for 3 days and then filtered through 0.45 μm membranes before analysis.

Self-Association Study: Determination of Critical Aggregation Concentrations (CACs). The self-association of the amphiphilic derivatives was evaluated at 25.0 ± 0.1 °C using a Hitachi 4500 fluorescence spectrometer (Hitachi, Japan). The temperature of the water-jacketed cell holder was controlled using a circulating bath. Pyrene fluorescence was assessed to monitor the solution properties of the modified CHs. One microliter of a stock solution of pyrene (1 mM) in methanol was added to quartz cuvettes, and the solvent was removed by blowing N_2. To each of these pyrene-containing cuvettes was added 2 mL of an acetic acid/sodium acetate buffer, pH 5.0, followed by sonication for 4−5 min. Measured amounts (5 μL) of concentrated stock solutions of the derivatives (2.0 g/L) were added to buffered aqueous solutions of pyrene (5.0×10^{-7} M) under magnetic stirring, and fluorescence spectra were recorded after each addition. The ratio between the fluorescence intensities of peaks I (372.4 nm) and III (384 nm) of the emission spectrum of pyrene (I_1/I_3 ratio) was used to evaluate the polarity of the local environment[22] and to determine the CAC. Pyrene was excited at 310 nm, and its emission was recorded from 350 to 650 nm.

Fungal Strains and Culture Conditions. The antifungal activities of CH and its derivatives were tested against *A. flavus* and *Aspergillus parasiticus*. The strains used were kindly provided by the Brazilian Collection of Microorganisms from the Environment and Industry (CBMAI; Campinas, São Paulo, Brazil) and were maintained on PDA (200 g/L potato infusion, 20 g/L dextrose, and 15 g/L agar) in the dark at 25 ± 2 °C.

Effects of CH Derivatives on Mycelial Growth of *Aspergillus flavus*. To compare the antifungal potentials of deacetylated and commercial CH to those of the synthesized amphiphilic DEAE-CH-Dod derivatives, an in vitro mycelial growth inhibition assay was conducted. The different CH solutions were previously prepared in an aqueous solution of acetic acid (1% m/m) and adjusted to pH 5.5. Next, 10 mL of the derivatives was added aseptically to 10 mL of sterile melted culture medium (PDA, 10%) to obtain 20 mL of culture medium at the desired polymer concentration (0−1.0 g L^{-1}), which was then transferred to Petri dishes. After solidification, the mixtures were inoculated with fragments of *A. flavus* mycelium (1 mm in diameter), which were placed at the center of the Petri dishes. The plates were then incubated in an oven for 7 days at 25 ± 2 °C. The inhibition index, which is a measure of the inhibition of the fungus by the derivatives, was determined on the basis of the radial growth of the colony, as measured using a caliper on the third, fifth, and seventh days of cultivation. The results obtained on the seventh day were used for comparative purposes.

The antifungal index was calculated as

$$\text{antifungal index (\%)} = [1 - (D_a/D_b)] \times 100$$

where D_a is the diameter of the growth zone on the test plates and D_b is the growth zone on the control plate.[23]

All experiments were performed in quadruplicate, and the data were averaged. Student's t test and the Kruskal−Wallis test with Dunn's multiple-comparison test were used to evaluate differences in the antifungal index obtained using the antifungal tests. Results with $P < 0.05$ were considered statistically significant.

RESULTS AND DISCUSSION

Synthesis and Characterization of Amphiphilic Derivatives. Deacetylation was carried out under continuous nitrogen bubbling to prevent degradation of the polymer. The degrees of deacetylation, expressed as $-NH_2$ mol %, and determined on the basis of the ^{1}H NMR spectra of commercial chitosan (CCH) and the deacetylated samples (CH), were 86.0 and 98.0 mol %, respectively. These values were calculated on the basis of the area of the singlet at 3.7 ppm, which was assigned to the proton linked to carbon 2 of the glucosamine ring (H2), and on the singlet at 2.5 ppm, which was assigned to the acetamido methyl protons (Support Information, Supplementary Figure S2a). The degrees of substitution by DEAE groups (DS) were calculated on the basis of the areas (I_{CH_3}) of the signal at 1.72 ppm, which were assigned to the methyl protons NH−$(CH_2-\boldsymbol{CH_3})_2$, and on the signals at 5.1−5.35 ppm, which were assigned to the anomeric protons of substituted and unsubstituted glucosamine residues, H_{1s} and H_1, respectively (Figure S2b). The degrees of substitution were calculated using eq 1:

$$DS_{DEAE} = \frac{I_{CH_3}/6}{(I_{H_1} + I_{H_{1s}})} \quad (1)$$

Derivatives substituted with DEAE ($DEAE_{30}$-CH and $DEAE_{43}$-CH) were subsequently grafted with increasing proportions of Dod groups. The ^{1}H NMR spectra of the derivatives $DEAE_{43}$-CH and $DEAE_{43}$-CH-Dod_{30} are shown in the Support Information (Supplementary Figures S2b and S2c, respectively). The ^{1}H NMR spectra of the amphiphilic derivatives exhibited three new signals after substitution with Dod, including a singlet at 1.47 ppm, corresponding to the protons of the methyl group on the Dod chain, and signals at 1.94 and 2.35 ppm (Supplementary Figures S3−S5). The latter signals corresponded to protons in the hydrocarbon chain and the methylene protons of the carbon atom linked to the amino group of CH, respectively. The attachment of Dod groups to the DEAE-CH framework further altered the ^{1}H NMR spectrum of $DEAE_{43}$-CH, most notably with respect to the resonances of the methyl protons of the DEAE groups and the anomeric protons of substituted and unsubstituted glucosamine units. The former underwent a downfield shift from 1.72 to 1.88 ppm, and the latter underwent a shift from 5.15 to 5.3 to 5.5−5.7 ppm, which might have resulted from aggregation of the amphiphilic chains (Supplementary Figures S2b and S2c). The integrated areas of the signal at 1.47 ppm and those assigned to the anomeric protons of CH chains at 5.5−5.7 ppm were used to calculate the degree of substitution by Dod (DS_{Dod}) using eq 2:[24]

DOI: 10.1021/acs.jafc.5b00278
J. Agric. Food Chem. 2015, 63, 5725−5731

$$DS_{Dod} = \frac{I_{CH_3}}{I_{H_1} + I_{H_{1s}}} \quad (2)$$

The DEAE-CH derivatives were synthesized at pH 8.0 under an N_2 atmosphere. As shown in Table 1, GPC analysis confirmed that the molecular masses of the DEAE derivatives ($DEAE_{14}$-CH, $DEAE_{30}$-CH, and $DEAE_{43}$-CH) did not significantly differ from those of the starting CHs (CH_H, CH_M, and CH_L). Although degradation can occur during the first step of the reaction, the M_w values of the $DEAE_x$-CH derivatives remained similar to those of the starting CHs (Table 1). However, the obtained M_w values of the DEAE-CH derivatives may be rationalized by considering that the attachment of DEAE can induce conformational changes, thus affecting retention time. Moreover, the M_w distribution is also affected by extensive dialysis. Thus, the polydispersities (M_w/M_n) of the DEAE derivatives were smaller than those of the starting CHs. The reductive amination reaction carried out during the second synthesis step was performed at a low temperature and pH 5.0; thus, significant degradation was not expected to have occurred during the reaction.

Amphiphilic Properties. The self-association of the amphiphilic derivatives was studied in aqueous buffered solutions at pH 5.0. At this pH, CH is positively charged, and medium-M_w samples might aggregate at concentrations >3.0 g/L.[25] Hence, it is expected that at low concentrations, hydrophobically modified CHs will self-associate in aqueous solutions to form intra- and intermolecular aggregates. This intrinsic property might affect not only the conformation of the polymer chains but also their interactions with the cell wall. Hydrophobic modifications might strengthen the interaction with the cell membrane but could also introduce intra- and intermolecular interactions that affect antimicrobial activity. Therefore, amphiphilic polycations, such as small amphiphilic molecules, may be active as aggregate assemblies rather than as discrete polymer chains.[26]

The CAC values were determined on the basis of fluorescence experiments using pyrene as a probe. Figure 2 shows typical graphs of I_1/I_3 based on the emission spectra of pyrene in the presence of increasing concentrations of CH and its derivatives. The obtained I_1/I_3 ratios reflect the microenvironments probed by pyrene and indicate the concentration range at which self-association begins. The less substituted derivatives, $DEAE_{30}$-CH-Dod_3 and $DEAE_{43}$-CH-Dod_5, exhibited no clear breaks in the curves (I_1/I_3 vs concentration) at concentrations of >0.2 g/L, and the I_1/I_3 ratio values remained at approximately 1.7−2.0, indicating that the derivatives were of hydrophilic character. Electrostatic repulsion between positively charged chains overcame the hydrophobic effects of Dod groups, hindering intermolecular aggregation at this concentration range (Figure 2).

The more substituted derivatives exhibited clear decreases in the I_1/I_3 ratios in the range from 5.0×10^{-3} to 1.2×10^{-2} g/L, indicating that aggregates were formed due to intermolecular interactions. The CACs decreased modestly with the degree of substitution with Dod groups (Table 1); however, the CAC values indicate the onset of aggregation in the polydisperse samples. The amphiphilic derivatives prepared from $DEAE_{14}$-CH (M_w = 548.6 kDa), the highest M_w derivative, exhibited a more gradual decrease in the I_1/I_3 ratio (Support Information, Supplementary Figure S6), which might have resulted from the concurrent formation of inter- and intramolecular aggregates. Overall, amphiphilic derivatives of increasing hydrophobicity

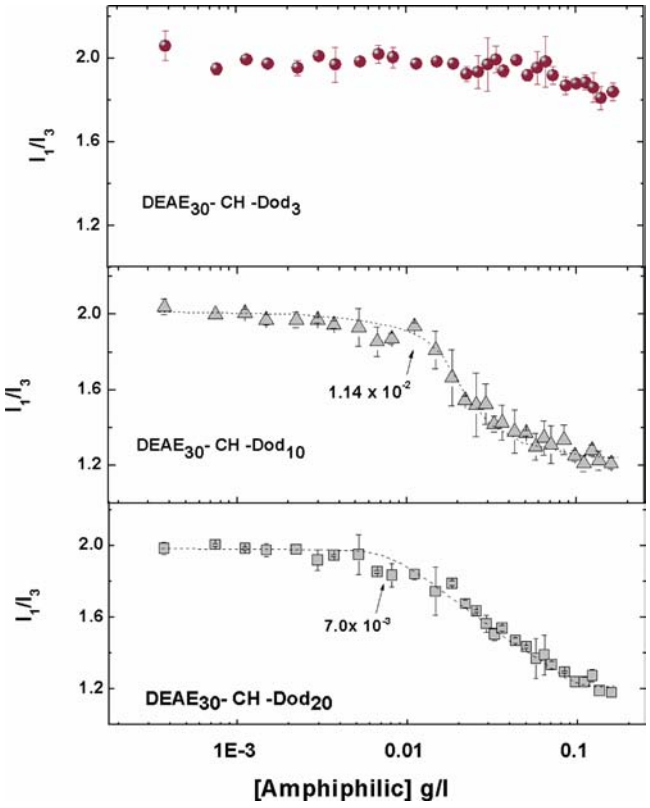

Figure 2. I_1/I_3 ratio versus $DEAE_{30}$-CH-Dod_x concentration at pH 5.0.

may be obtained by increasing the proportion of dodecylaldehyde in the feed.

In Vitro Antifungal Activity against *A. flavus*. The antimicrobial activity of CH has been mainly attributed to its cationic nature in acidic media, which enables its interaction with fungal cell walls and triggers its mechanisms of action. To evaluate the effect of M_w on antifungal activity, we tested three highly deacetylated CHs (16.9, 176, and 517.7 kDa). Figure 3a shows the effects of deacetylated and commercial CHs at various polymer concentrations (0.1 to 1.0 g/L) on the mycelial growth of *A. flavus* after an incubation period of 7 days at 25 ± 2 °C. As can be inferred from Figure 3a, the inhibitory effects of both the deacetylated and commercial samples increased with increasing polymer concentrations and M_w values (16.9 kDa < 176 kDa < 517.7 kDa). The effect of M_w on the antifungal activity of CH has been reported to depend on the type of fungus; for example, fungal growth has been reported to decrease with increasing M_w for *Fusarium oxysporum* and with decreasing DA for *Alternaria solani*, but no dependence on MW or DA has been observed for A*spergillus niger*.[27] Seyfarth et al. reported that antifungal activity against *Candida* species decreases with declining molecular mass;[28] however, oligochitosans with M_w values ranging from 2 to 20 kDa have been recently reported to efficiently inhibit the growth of *Candida* species and clinical isolates of *Candida albicans*.[13] Although the mechanism of antifungal activity remains controversial, reports of cell wall alterations and membrane damage have been shown for oligochitosans against *Candida* species.[13] In the case of *A. parasiticus*, the mechanism has been reported to be mainly fungistatic and has been attributed to the high M_w values (170−300 kDa) of the CH samples employed.[29] Therefore, the increase in activity with increasing M_w may be due to improved fungistatic activity because higher M_w CHs do not permeate the

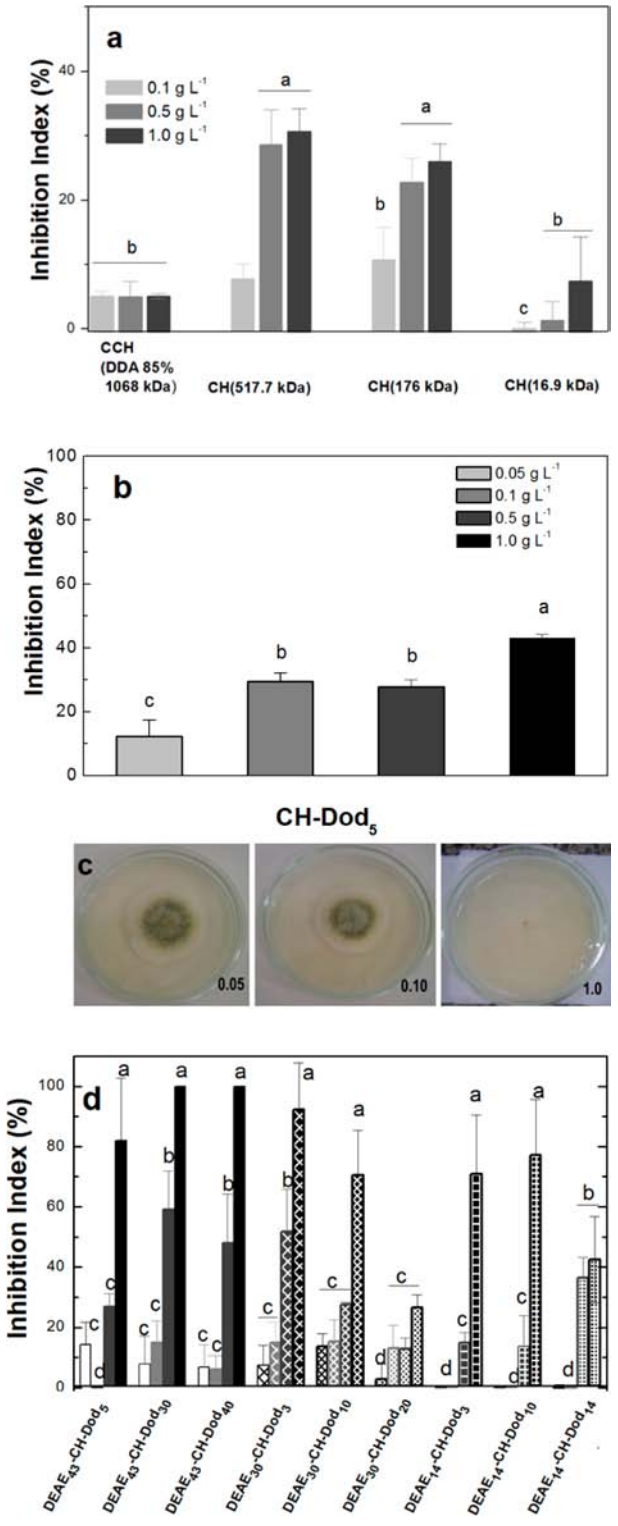

Figure 3. (a) Effect of chitosan molecular weight (CH_H, CH_M, and CH_L) on the mycelial growth of *A. flavus*. (b) Effect of CH-Dod_5 concentration on the inhibition index of *A. flavus*. (c) Effect of $DEAE_{43}$-CH-Dod_{30} concentration on the radial growth of *A. flavus* on the seventh day after inoculation. From left to right: 0.05, 0.1, and 1.0 g/L. (d) Effect of $DEAE_x$-CH-Dod_y derivative concentration on the inhibition index of *A. flavus*. From left to right: 0.05, 0.1, 0.5, and 1.0 g/L. Vertical bars with different letters indicate significant differences according to the Kruskal–Wallis test ($P < 0.05$).

hypha but may affect nutrition through the cell wall.[11] CCH exhibited a lower level of activity (5% at 1.0 g/L), possibly due to the lower availability of amino groups (DDA 85%). The greater antifungal activities exhibited by the CH_H and CH_M samples compared with CCH is attributed to stronger interactions with the cell membrane.

The hydrophobic modification of CH has been reported to effectively enhance antibacterial[15] and antifungal activities by strengthening its interaction with the cell wall.[16,29,30] To investigate the effect of the hydrophobic modification itself, 517.7 kDa deacetylated chitosan (CH_H) was grafted with only Dod (5.0%) (Figure 3b). At a concentration of 1.0 g/L, the inhibition produced was 43%, which was higher than that provided by CH_H (30%). A similar result has also been obtained against *A. parasiticus* in a previous study showing 32% inhibition of radial growth, indicating the importance of hydrophobic interactions in causing further activity.[17]

Conversely, the attachments of both groups (DEAE and Dod) appeared to be synergistic, and a marked increase in antifungal activity was noted. A representative experiment comparing the effect of $DEAE_{43}$-CH-Dod_5 concentration on the radial growth of *A. flavus* after the seventh day of inoculation is shown in Figure 3c, revealing that at a concentration of 1.0 g/L, fungal growth was completely inhibited. At 0.5 g/L, the inhibition indices obtained for the less substituted derivatives of the three series ($DEAE_{14}$-CH-$Dod_{2.5}$, $DEAE_{30}$-CH-Dod_3, and $DEAE_{43}$-CH-Dod_5) were 15, 51, and 27%, respectively. Overall, amphiphilic compounds synthesized from $DEAE_{43}$-CH (M_w = 15.7 kDa) exhibited the highest activities; however, complete inhibition of *A. flavus* was achieved with the most hydrophobic derivatives ($DEAE_{43}$-CH-Dod_{28} and $DEAE_{43}$-CH-Dod_{39}; Figure 3d). Despite their different degrees of substitution, all amphiphilic derivatives exhibited higher activities than those of the starting CHs and their hydrophilic DEAE-CH derivatives. At 1.0 g/L, the most substituted derivatives of the three series ($DEAE_{43}$-CH-Dod_{39}, $DEAE_{30}$-CH-Dod_{19}, and $DEAE_{14}$-CH-Dod_{14}) were able to reduce the mycelial growth of *A. flavus* by 100, 29, and 34%, respectively, indicating that the antifungal activities decreased with the increasing M_w values of the starting DEAE-CH derivatives (15.7, 176.0, and 548.6 kDa, respectively).

The importance of hydrophobic effects on the antimicrobial activities of CH derivatives has been recently reported by our group[16,17] and by others.[15,31] The improved activities of hydrophobized CH derivatives have been attributed to the reinforcement of hydrophobic interactions with the cell membrane.[16,32] Therefore, the attachment of Dod groups is considered important for the antifungal activities of these derivatives. However, the lower inhibition indices observed for the most substituted derivatives of this series indicate that the hydrophilic/hydrophobic balance must be adjusted to obtain higher antifungal activities. As shown in Figure 4a, the attachment of increasing numbers of Dod groups initially increased antifungal activity, but it was decreased for the more substituted derivatives ($DEAE_{14}$-CH-Dod_{14} and $DEAE_{30}$-CH-Dod_{20}).

To confirm this trend, we tested the $DEAE_{14}$-CH-Dod derivatives against *A. parasiticus* and found that inhibition increased with increasing derivative concentration; however, less substituted derivatives were again more effective in inhibiting fungal growth (Figure 4b). It is postulated that the discrete amphiphilic chains of less substituted derivatives might interact with cell membranes more effectively than aggregates

J. Agric. Food Chem. 2015, 63, 5725–5731

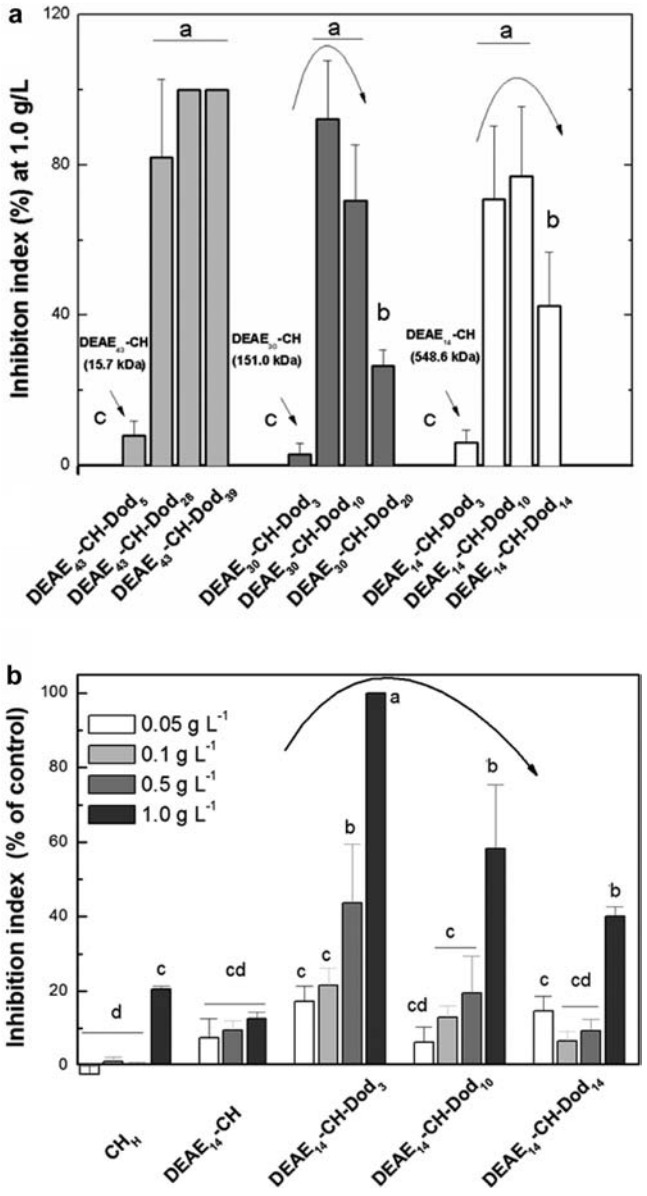

Figure 4. (a) Effects of changes in hydrophobicity: inhibitory effects of $DEAE_x$-CH-Dod_y derivatives (1.0 g/L) on the mycelial fungal growth of *A. flavus*. (b) Inhibition of in vitro growth of *A. parasiticus* in the presence of various concentrations of $DEAE_{14}$-CH-Dod_x derivatives. Vertical bars with different letters indicate significant differences according to the Kruskal–Wallis test ($P < 0.05$). The arrows on the top indicate the trend for inhibition indices with increasing hydrophobe content.

that are formed due to the self-association of more hydrophobic derivatives, thus decreasing the antifungal activities of these two types of derivatives. Overall, the results confirm the importance of hydrophobic groups for the antifungal activities of CH derivatives and may enable the development of more effective biofungicides based on natural polysaccharides.

Conclusions. Novel amphiphilic derivatives of CH were synthesized and characterized, and their antifungal activities against *A. flavus* were tested. Our results showed that deacetylated, medium-M_w (200–500 kDa) CHs were the most effective in inhibiting the mycelial growth of *A. flavus*, achieving an inhibition index of >25%. Attaching DEAE groups increased the solubilities of these derivatives at a neutral pH; however, no significant reduction in the mycelial growth of *A. flavus* was observed as a result of these modifications, indicating that small changes in the polymer structure may significantly affect activity. Hydrophobic modifications with Dod groups strengthened the interaction with the fungal cell wall and markedly increased the antifungal activity of CH against *A. flavus*. These results clearly show that M_w and hydrophobicity must both be controlled to increase antifungal activity. Overall, higher inhibition can be achieved using amphiphilic compounds with high M_w values and low hydrophobicities or using compounds with low M_w values and high hydrophobicities. The synthesis and characterization of new derivatives containing an appropriate hydrophilic/hydrophobic balance are ongoing in our laboratory to optimize their antifungal activities.

[a]Reaction conditions: 2,3,4,6-tetra-*O*-benzyl-*α*-D-glucopyranosyl chloride (300 mg, 0.54 mmol), benzoic acid (1.05 equiv), base, water, PTC, granular PTFE (5 g), mechanical stirring (400 rpm). [b]Determined by ^{1}H NMR. [c]Reaction conditions: 2,3,4,6-tetra-*O*-benzyl-*α*-D-glucopyranosyl chloride (300 mg, 0.54 mmol), TBAB (182 mg, 0.56 mmol), water (97 mg, 5.38 mmol), granular PTFE (5 g), mechanical stirring (400 rpm). [d]No reaction.

mechanically stirred (400 rpm) at 80 °C for 2 min followed by the addition of water (10 equiv, 97 mg, 5.38 mmol). Initially, the reaction media appeared as thick milk, and it gradually turned to a semisolid, which adhered to the glass. After thin-layer chromatography (TLC) indicated completion of the reaction, ethyl acetate (2 × 10 mL) was added to extract the crude product, which was washed with 5% aqueous Na_2CO_3 (1 × 10 mL) and water (1 × 10 mL) and dried over Na_2SO_4. Concentration under reduced pressure gave benzoic acid 1-*O*-[2,3,4,6-tetra-*O*-benzyl-*β*-D-glucopyranosyl] ester: (351 mg, >99%).

Typical 5−12 g Scale Glycosylation Procedure Using Glucosylation of Benzoic Acid at an 11.7 g Scale as an Example. A mixture of 2,3,4,6-tetra-*O*-benzyl-*α*-D-glucopyranosyl chloride (10 g, 17.89 mmol), benzoic acid (1.05 equiv, 2.29 g, 18.75 mmol), Cs_2CO_3 (0.51 equiv, 2.97 g, 9.12 mmol), TBAB (0.05 equiv, 288 mg, 0.89 mmol), and granular PTFE (5 g) was mechanically stirred (400 rpm) at 80 °C for 2 min, followed by the addition of water (10 equiv, 3.22 g, 178.69 mmol). Initially, the reaction mixture appeared as thick milk and had good fluidity. After completion of the reactions as detected by TLC and removing the oil bath, the products started to solidify and eventually became fine granules. The product was filtered after the addition of water (3 × 15 mL) to wash the reaction flask, and the filtrates were washed with 5% aqueous Na_2CO_3 (3 × 10 mL) and water (3 × 10 mL) and air-dried to give benzoic acid 1-*O*-[2,3,4,6-tetra-*O*-benzyl-*β*-D-glucopyranosyl] ester (11.7 g, > 99%).

Benzoic acid 1-*O*-[2,3,4,6-tetra-*O*-benzyl-*β*-D-glucopyranosyl] ester,[9] *p*-nitrobenzoic acid 1-*O*-[2,3,4,6-tetra-*O*-benzyl-*β*-D-glucopyranosyl] ester,[9] 2-acetyloxybenzoic acid 1-*O*-[2,3,4,6-tetra-*O*-benzyl-*β*-D-glucopyranosyl] ester,[26] palmitic acid 1-*O*-[2,3,4,6-tetra-*O*-benzyl-*β*-D-glucopyranosyl] ester,[27] bile acid 24-*O*-[2,3,4,6-tetra-*O*-benzyl-*β*-D-glucopyranosyl] ester,[28] benzoic acid 1-*O*-[2,3,4,6-tetra-*O*-benzyl-*β*-D-galactopyranosyl] ester,[29] *p*-nitrobenzoic acid 1-*O*-[2,3,4,6-tetra-*O*-benzyl-*β*-D-galactopyranosyl] ester,[30] and *p*-nitrobenzoic acid 1-*O*-[2,3,4-tri-*O*-benzyl-*β*-D-xylopyranosyl] ester[31] are known compounds.

RESULTS AND DISCUSSION

Initially, a mixture of benzoic acid with acetobromoglucose or acetochloroglucose in the presence of a carbonate, a PTC, water, and granular PTFE was stirred mechanically at various temperatures using the modified stirring rod.[22,23] Various carbonates including lithium, sodium, potassium, and cesium were used; the PTC was Aliquat 336 or TBAB, the amount of water was varied from 10 to 310 equiv, and the reaction temperature ranged from 25 to 80 °C. For all reaction combinations, the desired product, *β*-glucosyl ester, was contaminated with a substantial amount of the partially hydrolyzed products. Therefore, 2,3,4,6-tetra-*O*-benzyl-*α*-D-glucopyranosyl chloride (**1**, Table 1) was used as the starting material. When Li_2CO_3, Na_2CO_3, K_2CO_3, or tetrabutylammonium hydroxide ($TBAOH{\cdot}30H_2O$) was used as the base and Aliquat 336 (0.15 equiv) as the catalyst, the amount of undesired hydrolysis product, 2,3,4,6-tetra-*O*-benzyl-D-glucose (**3**) varied from 29 to 19% (Table 1, entries 4−7). However, the amount of **3** was affected by the amount of water, and 10 equiv of water was found to be optimal in reducing the amount of side product **3** (Table 1, entries 1−6 and 8).

When Li_2CO_3 was replaced with Cs_2CO_3 and the reactions were performed at 40 and 25 °C, the yields of the desired product ***β*-2** were 67 and 36% (Table 1, entries 8 and 9), respectively. Thus, raising the reaction temperature could improve the reaction yield. When the temperature was increased to 60 °C, the yield of ***β*-2** increased to 84% and only 16% of **3** was formed (Table 1, entry 10). Further raising the temperature to 80 °C completely avoided the side reaction (the hydrolysis of **1** to **3**) and gave ***β*-2** in quantitative yield (Table 1, entry 11). When the amount of Aliquat 336 was reduced to 0.05 equiv, the yields were similar, but the reaction time increased from 0.33 to 0.67 h (Table 1, entries 11 and 12).

The only problem associated with this new synthesis is that Aliquat 336 is water-insoluble and contaminates the product. Replacing 0.05 equiv of Aliquat 336 with 0.05 equiv of TBAB led to the quantitative and stereospecific synthesis of ***β*-2** (Table 1, entry 16). Increasing the amount of water to 20 or 310 equiv yielded a mixture of ***β*-2**:**3** in ratios of 74:26 and 29:71 (Table 1, entries 18 and 17), respectively. Decreasing the amount of water to 5 equiv increased the reaction time (1.5 h) (Table 1, entry 20). The reaction rates were altered by variation of the amounts of TBAB (0.01 equiv, 2 h; 0.05 equiv, 0.67 h; and 0.1 equiv, 0.58 h) (Table 1, entries 21, 16, and 22). The reaction rates and yields became worse after using Li_2CO_3, Na_2CO_3, and K_2CO_3 to replace Cs_2CO_3 (Table 1, entries 13−15). The fact that Cs_2CO_3 is much better than the other bases for this glucosylation (Table 1, entries 1−6 vs 8 and 13−15 vs 16) is probably due to the cesium effect.[26,32] It has been reported by Lemieux et al.[33−35] that the anomerizations of tetra-*O*-acetyl-*β*-D-glucopyranosyl chloride took place in the presence of tetraethylammonium chloride, TBAB, or tetrabutylammonium iodide in organic solvents. However, no anomerization was observed when **1** was treated with 1.05 equiv of TBAB (Table 1, entry 23) in this aqueous reaction. The only detected products were **3** and **1** (68:32). This indicated that the reaction rates of **1** with carboxylates were fast enough to avoid the possible hydrolysis of **1** in these aqueous conditions. Using sodium dodecyl sulfate (SDS) (0.05 equiv) instead of TBAB did not produce ***β*-2** (Table 1, entry 24). On the basis of all these results, the optimized conditions are 2,3,4,6-tetra-*O*-benzyl-*α*-D-glucopyranosyl chloride (1.0 equiv), benzoic acid (1.05 equiv), TBAB (0.05 equiv), Cs_2CO_3 (0.51 equiv), water (10 equiv), and granular PTFE (5 g) at 80 °C with mechanical agitation at 400 rpm (Table 1, entry 16).

We believe that this reaction system is probably micelle-catalyzed,[36,37] which is based on the following observations. First, the reaction mixture was milky at the beginning of the reaction and then turned to a semisolid, which adhered to the

[a]Reaction conditions: glycosyl chloride (300 mg, 0.54 mmol), acid (1.05 equiv), water (10 equiv), Cs_2CO_3 (0.51 equiv), TBAB (0.05 equiv), granular PTFE (5 g), mechanical stirring (400 rpm) at 80 °C. [b]All conversions were 100%, and all yields are isolated yields.

flask walls and the stirrer after the completion of the reaction. Second, in our previous research in which Aliquat 336 was used as both a solvent and a catalyst,[21−25] the amount of water used was not important. In contrast, the amount of water was critical for this reaction (Table 1, entries 20, 18, and 17 vs entry 16). Third, the reaction temperature had to be raised to 80 °C to reduce the amount of side product **3**. This can be attributed to the efficient formation of micelles at this temperature. All of these facts support the reaction being micelle-catalyzed.

One of the reasons for the stereospecificity of the β-glycosylation is the closer contact between the carboxylates and the glucosyl chlorides in the micelles than in conventional organic solvents. Although it is commonly believed that the negatively charged head of the carboxylates is oriented toward the aqueous phase, it is possible that certain amounts of the carboxylates are oriented toward the glycosyl chlorides because of the geometry or charge demands in the micelles.

Water-soluble TBAB can form ionic pairs with carboxylic acids under basic conditions, which are lipophilic enough to replace Aliquat 336 to form micelles with glycosyl chloride. In the literature, surfactants containing 8−18 carbon atoms in straight alkyl chains are often used in micelle-catalyzed reactions, but there have been no reports of using TBAB in these types of reactions.[38]

Next a series of β-glycosyl esters were synthesized under the optimized conditions. Most of the reaction yields were >90%,

DOI: 10.1021/acs.jafc.5b02534
J. Agric. Food Chem. 2015, 63, 5732−5739

with some being quantitative, and all of the reaction times were short (0.67−2.5 h) (Table 2). In all cases, only the β-glycosyl esters were obtained. The reactions were compatible with a series of functional groups including alkenes (Table 2, entries 1, 12, 14, and 18), nitro groups (Table 2, entries 2, 20, and 24), ethers (Table 2, entries 3 and 25), halide (Table 2, entry 5), aliphatic esters (Table 2, entry 10), phenolic esters (Table 2, entries 6, 9, and 23), benzyloxycarbonylamino group (Table 2, entry 7), ketone (Table 2, entry 8), silyl ethers (Table 2, entries 11 and 25), and hydroxyl groups (Table 2, entries 17 and 18). The ^{1}H NMR and ^{13}C NMR data for the β-glycosyl esters are 5.49−5.92 ppm (1H, J = 7.1−8.2 Hz, H-1) and 94.01−95.48 ppm (C-1), respectively, which are in agreement with the data from the literature.[9,26−31]

It has been reported that glycosylation can improve the properties of peptide biopharmaceuticals.[2,39,40] Therefore, three amino acid derivatives were subjected to the glucosylation conditions, and the yields were excellent (Table 2, entries 7, 10, and 11). However, the yields for carbohydrate−peptide conjugations are around 30% in the literature.[39] Bile acid glycoside, which has been identified in biological materials, has been synthesized as a mixture of α- and β-anomers (ratio of α:β = 1:3) in <30% yields, and it had to be purified via HPLC.[28] However, under our reaction conditions, the β-glycoside was obtained stereospecifically in 83% yield with no chromatography (Table 2, entry 17). Similar results were obtained starting from carboxylic acids and 2,3,4,6-tetra-*O*-benzyl-α-D-galactopyranosyl chloride (Table 2, entries 19−23) or 2,3,4-tri-*O*-benzyl-α-D-xylopyranosyl chloride (Table 2, entries 24−27) in terms of reaction yields, rates, and stereoselectivities.

An additional advantage of the reaction is the simplicity of the workup. In the synthesis of glycosyl esters starting from 300 mg of glycosyl chloride, some of the products adhered to the wall of the flask. These were recovered after in-flask extraction with ethyl acetate and were concentrated to yield pure products without chromatography. In the enlarged scale synthesis of benzoic acid 1-*O*-[2,3,4,6-tetra-*O*-benzyl-β-D-glucopyranosyl] ester using 5 or 10 g of glucosyl chloride, the reaction phenomena were different. The reaction mixture resembled thick milk and had good fluidity at 80 °C. When the oil bath was removed after completion of the reaction, the product gradually became fine granules, which could be filtered with the aid of additional water. The product was quantitative and pure.

In this way, five β-glucosyl esters (Figure 1, ***β*-2**, **4**, **5**, **6**, and **7**) were synthesized quantitatively and stereospecifically in quantities from 5.8 to 12.3 g without using any organic solvents in the entire process. In the 300 mg scale synthesis of **5** and **6**, the yields were not quantitative and organic solvents were used for in-flask extractions. After the scale had been enlarged, the adhesion of the products on the glass was avoided and organic solvent extraction was not needed.

Among the five products, β-glucosyl ester **4** is a useful glucosyl donor.[26,41,42] The advantages of β-glucosyl esters as glucosyl donors over their α-isomers in glucosylations have been reported.[26] Previously it has been prepared as an unspecified stereoisomer mixture in 90−95% yields using 4-pentenoic acid and 1-hydroxyl sugar in organic solvents.[41,42] Glucosyl ester **5** is a precursor of an aspirin prodrug.[43,44] Glucosyl ester **5** has previously been obtained in 67% yield from the reaction of 2,3,4,6-tetra-*O*-benzyl-α-D-glucopyranosyl chloride, aspirin, and Cs_2CO_3.[26] Ursolic acid occurs in various fruits such as apples, basil, bilberries, and cranberries and plants.[45] Glucosyl ester **6** is a key intermediate for ursolic acid

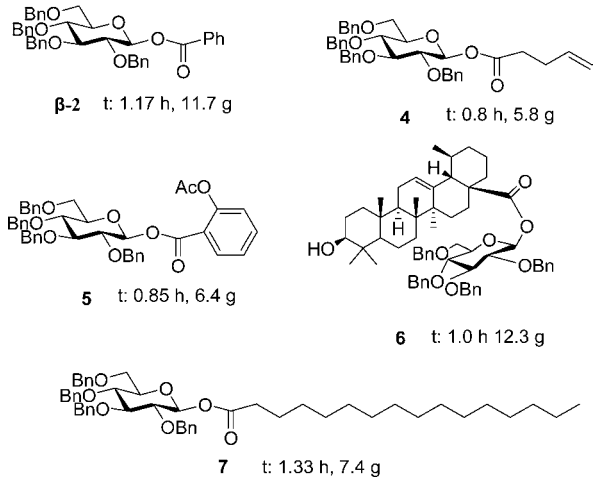

Figure 1. Quantitative synthesis of β-glucosyl esters in 5−12 g scales.

28-*O*-(β-D-glucopyranosyl) ester, an antitumor reagent.[3,46] In previous synthetic routes, the hydroxyl group of the ursolic acid had to be protected in some cases, but this was not necessary for our method.[46,47] It is well-documented in the literature that deprotection of the benzyl group can be achieved using H_2 and Pd/C, in which the olefin double bond can even survive.[48−51] Glycosyl ester ***β*-2** was debenzylated to produce benzoic acid 1-*O*-β-D-glucopyranosyl ester in 97% yield through H_2 and Pd/C hydrogenolysis.

Six experiments were carried out to demonstrate the acceleration effects of the granular PTFE. A mixture of **1** (300 or 1000 mg), benzoic acid (1.05 equiv), Cs_2CO_3 (0.51 equiv), H_2O (10 equiv), and TBAB (0.05 equiv) was mechanically stirred (400 rpm) with granular PTFE (5000 or 0 mg) at 80 °C. For both reaction scales (300 and 1000 mg of **1**), quantitative and stereospecific β-glycoside ***β*-2** was formed (Table 3, entries 1 and 3) when granular PTFE (5000 mg) was used. Without granular PTFE, both reactions ended in a mixture of glucosyl ester and aldosyl hemiacetal **3**, with the latter being the major product of the reaction (81 and 55%) (Table 3, entries 2 and 4). In the 1000 mg scale, both anomers ***α*-2** and ***β*-2** were produced without granular PTFE (Table 3, entry 4). Varying the reactions scaled from 300 to 5000 mg of **1** while keeping the two ratios of granular PTFE to **1** equal to 1:1, we noted that the reaction rate at 300 mg scale was worse than the one at 5000 mg scale (Table 3, entries 5 and 6). This clearly indicated that this type of glycosylation would be more efficient for large-scale preparations and that granular PTFE is critical for this method.

In our previous studies of the synthesis of high-melting-point water-insoluble organic compounds, the granular PTFE functioned as hundreds of individual stirrers, which dispersed the solid materials.[21−25] In this case, the starting glycosyl chlorides are syrups, and the carboxylates are partially or completely water-soluble, giving thick-milk-like reaction mixtures. Most likely the role of the granular PTFE is to promote ion exchange between TBAB and the carboxylates, which facilitates the formation of the micelles.

To demonstrate the advantages of water as a solvent, reactions in water and in organic solvents were compared. A mixture of 2,3,4,6-tetra-*O*-benzyl-α-D-glucopyranosyl chloride (1.0 equiv), benzoic acid (1.05 equiv), TBAB (0.05 equiv), and Cs_2CO_3 (0.51 equiv) was heated in DMF, AcOEt, THF, toluene, or $CHCl_3$, respectively, and the results are shown in

6	300:300	43	34 (only ***β*-2**)	23	64 (only ***β*-2**)	36

[a]Reaction conditions: 2,3,4,6-tetra-*O*-benzyl-*α*-D-glucopyranosyl chloride (300 mg, 0.54 mmol), benzoic acid (1.05 equiv), Cs_2CO_3 (0.51 equiv), water (10 equiv), TBAB (0.05 equiv), granular PTFE, mechanical stirring (400 rpm) at 80 °C. [b]Determined by ^{1}H NMR.

Table 4. Control Experiments in Water and in Organic Solvents

		t = 40 min			t = 6 h		
entry	solvent	recovered **1** (%)	yield[a] (***β*-2**:***α*-2**) (%)	**3** (%)	recovered **1** (%)	yield[a] (***β*-2**:***α*-2**) (%)	**3** (%)
1[b]	H_2O		>99 (only ***β*-2**)				
2[c]	DMF	12	69 (54:15)	19		59 (only ***β*-2**)	41
3[c]	AcOEt	15	21(12:9)	64	3	27 (19:8)	70
4[c]	THF		NR[d]		66	21 (only ***β*-2**)	13
5[c]	toluene		NR[d]		28	55 (42:13)	17
6[c]	$CHCl_3$		NR[d]			NR[d]	

[a]Determined by ^{1}H NMR, [b]Reaction conditions: 2,3,4,6-tetra-*O*-benzyl-*α*-D-glucopyranosyl chloride (300 mg, 0.54 mmol), benzoic acid (1.05 equiv), Cs_2CO_3 (0.51 equiv), water (10 equiv), TBAB (0.05 equiv), granular PTFE (5 g), mechanical stirring (400 rpm) at 80 °C. [c]Reaction conditions: 2,3,4,6-tetra-*O*-benzyl-*α*-D-glucopyranosyl chloride (100 mg, 0.18 mmol), benzoic acid (1.05 equiv), Cs_2CO_3 (0.51 equiv) in DMF or toluene (1 mL) at 80 °C or AcOEt, THF or $CHCl_3$ (1 mL) at refluxing temperatures. [d]No reaction.

Table 4. In DMF and AcOEt, a mixture of ***α*-2** and ***β*-2** (***β*-2**:***α*-**2** = 54:15 and 12:9, respectively) and byproduct **3** (19 and 64%, respectively) was obtained in 40 min (Table 4, entries 2 and 3). When the reaction time was prolonged to 6 h, the product distributions were 59% (***β*-2** only) and 41% (**3**) in DMF and 27% (***β*-2**:***α*-2** = 19:8) and 70% (**3**) in AcOEt (Table 4, entries 2 and 3). No reactions occurred in THF and toluene after 40 min, and after 6 h, yields of only 21% of ***β*-2** and 55% of ***β*-2**/***α*-2** (42:13) were obtained, respectively (Table 4, entries 4 and 5). The reaction did not take place in $CHCl_3$ after 6 h (Table 4, entry 6). Only in water could the *β*-glycosyl esters be synthesized with excellent yields and high stereoselectivities.

In conclusion, a simple, efficient, and green method for synthesizing *β*-glycosyl esters has been developed. The glycosylation is stereospecific and produces excellent yields. The micelle-catalyzed reactions used water-soluble TBAB as the surfactant and water as the medium. Therefore, the workup was simple with no need for chromatography. Five *β*-glucosyl esters were scaled up to 5−12 g, and all of the yields were quantitative. No organic solvents were used in the entire processes. The indispensable roles of granular PTFE and the correct amount of water in these reactions have also been demonstrated. This procedure should be assumed to be particularly useful in synthesizing food additives and modifying the properties of bioactive molecules through glycosylation.

Treatment of Biochars with Soil Minerals. The biochars obtained after thermal treatment (at 400 and 600 °C) were treated in an aqueous suspension of alumina or Ca-mont at a ratio of 10 g of mineral per gram of biochar sample. First, 1 g of biochar sample was mixed with mineral powder and then soaked in 100 mL of deionized pure water. The suspension was mixed with gentle stirring at room temperature for 24 h and placed in a thermostatic bath at 25 ± 0.1 °C with shaking for an additional 6 days at a rotation speed of 125 rpm. The pH during the treatment was monitored, and final pH values in the suspension close to neutral (7.0–7.8) were observed. The biochar pieces were separated by filtration through a sieve with a pore diameter of 0.15 mm, and the pieces caught on the sieve were washed with deionized pure water to remove the surface-adhered minerals. Finally, the treated biochar products were oven-dried at 70 °C and are referred to hereafter as Al-BC400, Al-BC600, Mo-BC400, and Mo-BC600, according to the fresh biochars (BC400 or BC600) that were treated with either alumina (Al-) or Ca-mont (Mo-). All of the biochar samples were ground to <0.15 mm in size for use in the following characterization and sorption experiments.

Biochar Sample Characterization. The elemental (C, H, O, N) compositions of the biochars were determined in an EA3000 elemental analyzer (Euro Vector) with an average of triplicate experiments. Specifically, the oxygen content was directly measured with the oxygen analysis model in the same analyzer at the set furnace temperature of 1080 °C. The ash content of biochars was determined by heating the samples at 800 °C for 4 h. The surface characteristics of the biochars and two minerals (alumina and Ca-mont) were obtained from nitrogen adsorption isotherms at 77 K (Figure S1 in the Supporting Information) in a Tristar II 3020 surface area and porosity analyzer (Micromeritics) after degassing at 473 K. The specific surface area (SA_{BET}) was determined using the Brunauer–Emmett–Teller (BET) method, and the micropore area (SA_{micro}) was obtained with the *t*-plot method. The pore size distribution, average pore diameter (PD), cumulative surface area, and cumulative volume of the pores between diameters of 17 and 500 Å ($SA_{17-500\ Å}$ and $PV_{17-500\ Å}$) were established by analyzing the N_2 adsorption data using the Barrett–Joyner–Halenda (BJH) method. Infrared spectra (IR) were recorded in the 4000–400 cm^{-1} region on a Nexus FT-IR spectrophotometer (Nicolet) using a KBr pellet. A JSM-6360LV scanning electron microscope (SEM) (JEOL) equipped with an X-act energy-dispersive X-ray spectrometer (EDX) (Oxford) was used for the morphological survey and elemental identification of the surface of the biochars.

Sorption Experiments. The sorption isotherms of two herbicides on the biochar samples were determined by batch equilibration of the solid biochars (0.10 g for sorption of acetochlor and 0.20 g for sorption of metribuzin) in 25 mL of aqueous solutions of various initial herbicide concentrations (C_0, μmol L^{-1}), which ranged from 100 to 700 μmol L^{-1} for acetochlor (the saturated concentration C_s = 827 μmol L^{-1} (25 °C)) and from 700 to 4200 μmol L^{-1} for metribuzin (C_s = 5600 μmol L^{-1} (20 °C)), respectively. For comparison, the sorption of herbicides to the two minerals was carried at the same range of initial herbicide concentrations, but with different doses of solid minerals (0.10 and 0.20 g for sorption of acetochlor to alumina and Ca-mont and 2.0 g for sorption of metribuzin to alumina, respectively). The sorption experiment was carried out in a thermostatic shaker bath at 25 ± 0.1 °C for 24 h according to a previous method,[24] and the preliminary kinetic studies (Figure S2 in the Supporting Information) indicated that the sorption equilibrium had been reached before 24 h. The analysis of the supernatant solution was conducted in an LC-20A HPLC system (Shimadzu) equipped with an ultraviolet detector. The herbicides, acetochlor and metribuzin, were analyzed at 225 and 228 nm, respectively, with a detection limit of 0.2 μmol L^{-1} for both herbicides. The amount adsorbed (Q_e, μmol g^{-1}) was calculated from the difference in concentration between the initial (C_0, μmol L^{-1}) and the equilibrium (C_e, μmol L^{-1}) solutions. Blanks without herbicide and duplicates of each sorption point were used in every experiment series.

RESULTS AND DISCUSSION

Influence of Soil Minerals on Biochars' Properties. Elemental compositions of biochars before and after treatment with soil minerals are listed in Table 2. The total amount of measured elements (C, H, and O) accounted for 99.0% (weight) and 94.5% for the untreated BC400 and BC600 biochars, respectively. The very low ash contents indicated few intrinsic minerals in these two biochars. However, much lower percentages of C, H, and O elements were measured for the mineral-treated biochars (Al-BC400, Al-BC600, Mo-BC400, and Mo-BC600). This difference is attributed to the residual minerals (accounting for 10.4–18.1% in weight) in these treated biochars, which was confirmed by SEM/EDX analysis as shown in Figure 1. In this figure, Si and Al elements of Ca-mont were observed on the surface of the Mo-BC600 biochar, and Al element of alumina on the surface of the Al-BC600 biochar (more details can be found in Figures S4 and S5 in the Supporting Information). The increased H/C and O/C ratios

Table 2. Elemental Composition of Biochar Samples

biochar	C[a] (%)	H[a] (%)	O[a] (%)	C + H + O (%)	H/C[b]	O/C[b]	mineral[c] (%)	ash (%)
BC400	73.8	2.89	22.3	99.0	0.471	0.226		0.9
Al-BC400	59.2	2.52	19.2	80.9	0.511	0.244	18.1	16.1

[a]SA_{BET}, BET specific surface area; PD, BJH adsorption average pore diameter; SA_{micro}, *t*-plot micropore area; $SA_{17-500\ Å}$, BJH adsorption cumulative surface area of pores between 17 and 500 Å diameter; $PV_{17-500\ Å}$, BJH adsorption cumulative volume of pores between 17 and 500 Å diameter. [b]Data in parentheses are corrected values obtained by deducting the contribution of residual minerals in the treated biochar samples.

for the mineral-treated biochars are likely related to the water bonded in the residual minerals. The mineral-bonded water was evaporated in measurement of ash content, which resulted in the lower value of ash content than the estimated mineral content in the same mineral-treated biochar.

Significant changes of surface characteristics were obtained for both biochars after treatment with soil minerals, as shown in Table 3. Both the surface area (SA_{BET}) and the average pore diameter (PD) of the BC400 biochar were increased after treatment with minerals ($p < 0.05$). Additionally, the average PD of the BC600 biochar was increased ($p < 0.10$), although no obvious enhancement of its surface area was observed. The residual minerals in the treated biochar samples should be considered before we discuss these enhancements, because both alumina and clay are materials containing porous structures (Table 3 and Figure S6 in the Supporting Information). If their porous structure was assumed to not be changed during the mixing with the biochars, the surface

DOI: 10.1021/acs.jafc.5b01654
J. Agric. Food Chem. 2015, 63, 5740−5746

characteristics of the treated biochars may be corrected by deducting the fractions that should be attributed to the residual minerals. We observe from the corrected data (as shown in parentheses) that the micropore area (SA_{micro}) of the BC400 biochar was enhanced by 2.4 times after treatment with alumina, and its mesopore area ($SA_{17-500\ Å}$) was doubled ($p < 0.05$). In our treatment of the biochars with alumina, neither thermal nor chemical processes were involved, so the porous structure would have been produced during the pyrolysis of the wood biomass. During the cooling process after thermal treatment, some micropores should be blocked by condensed noncarbonized organic matter, the byproducts of wood pyrolysis at relatively low temperature.[26−28] Most likely, the alumina removed some of these organic blocks from the biochar pores during the mineral treatment.

However, only a slight increase in the micropore area (SA_{micro}) was observed after alumina treatment for the higher temperature biochar (BC600 vs Al-BC600) ($p < 0.10$), and the increased surface area was mainly attributed to the mesopores, as suggested in the corrected data in parentheses in Table 3 and pore size distribution shown in Figure 2. In contrast to the

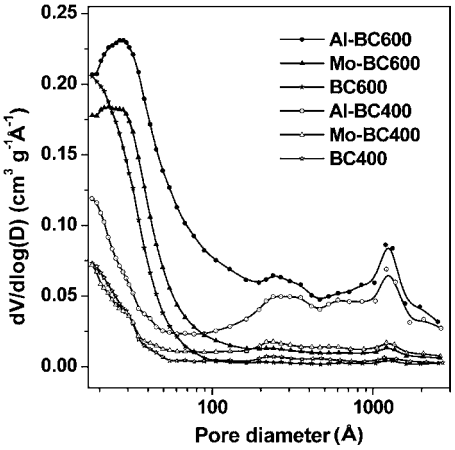

Figure 2. BJH pore size distribution (17−3000 Å diameter) of various biochars.

biochar obtained at lower temperature (400 °C), the microporous structures were well developed during pyrolysis at the higher temperature (600 °C), and the alumina further expanded some micropores into mesopores by digging the condensed organic matter out from the micropores. The decrease of micropore area after pore expansion should be compensated by the new opening of some blocked micropores by alumna treatment, resulting in the lesser increase of SA_{micro} for the higher temperature biochar. According to the pore size distribution shown in Figure 2 and Figure S6 in the Supporting Information, the fraction of macropores (>500 Å) for the alumina-treated biochars (Al-BC400 and Al-BC600) should be attributed to the residual alumina. In conclusion, the alumina expanded the pores, and the contribution of mesopores (17−500 Å) to the total pore volume and pore area was increased for the higher temperature biochar (BC600), whereas both micropores and mesopores contributed to the enlarged pore volume and pore area for the lower temperature biochar (BC400).

The pore-expanding effect was also observed in the clay-treated biochars (Mo-BC400 and Mo-BC600). For the lower temperature (BC400) biochar, expansion of the surface area by the Ca-mont was due to the increased micropore area ($p < 0.10$), whereas the pore expansion of the BC600 biochar was mainly due to the increased mesopore area ($p < 0.10$). Specifically, the clay expanded the pores in the biochars in a similar manner as alumina expanded them, despite the smaller pore area in comparison to the alumina-treated biochars.

Potential Role of Soil Minerals on Expanding the Pore of Biochars. The pore expansion of the biochars after mineral treatment may be explained by the adsorption of biochars' authigentic organic matter by soil minerals. Previous studies showed that alumina and its hydrated form (Al-OOH) are both good adsorbents for natural organic matter,[22,25] and such adsorption is believed to be an important method of retention of organic matter in soils and sediments.[29] Montmorillonite clay is also a well-known adsorbent for organic matter. Lin et al.[30] investigated recently the water-extractable organic carbon (WEOC) in biochars and found that the dominant fractions of WEOC in the low-temperature biochar are humic acids and low-molecular-weight neutrals (alcohols, aldehydes, ketones, sugars, etc.). Despite their trace amount (e.g., 93.4 $\mu g\ g^{-1}$ in a wood biochar by slow pyrolysis at 450 °C),[30] these dissolved organic matters may affect the sorption of herbicides and influence the herbicides' mobility in biochar-amended soil.[31,32] In addition, solvent-extractable hydrocarbons (e.g., polycyclic aromatic hydrocarbons, PAHs) have been detected in biochars, with maximum PAH content of 26.6 $\mu g\ g^{-1}$ in a wood biochar produced at 400 °C.[26,33] If these solvent-extractable matters were removed from the wood biochar, the obviously enhanced surface area and pore volume were observed by Nguyen et al.[34] Therefore, it is reasonable to propose that the biochars prepared at moderate temperatures (400−600 °C) have a porous structure, and the pore surface is coated by some organic matter removable by soil minerals. The FT-IR spectra (Figure S7 in the Supporting Information) show apparent attenuation of absorption at 1640 cm^{-1} (C═O) and 1040 cm^{-1} (C—O—C) for both the Al-BC400 and Mo-BC400 biochars in comparison with the BC400 biochar, which suggests the removal of some oxygen-containing organic matter from the biochar surface. Thus, the removal may involve the interaction with surface functional groups of minerals. Specifically, at a pH close to neutral (7.0−8.5, as shown in Figure S8 in the Supporting Information) but below the point of zero charge for alumina,[22] there exists on the mineral surface some crystallographically bound $>Al-OH_2^+$ groups,[25] which probably interact with those oxygen-containing organic matter by the reaction

$$>Al-OH_2^+ + HO-R \rightarrow >Al-OH_2-O-R + H^+ \quad (1)$$

The release of hydrogen protons is confirmed by the falling pH during the treatment of biochars with alumina and Ca-mont, specifically in the first 3 days (Figure S8 in the Supporting Information). The latter mineral may possibly interact with biochars in a similar way as alumina, as surface bound $>Al-OH_2^+$ groups might also exist on the clay if its high content of aluminum oxide were considered.

The pore-expanding effect of soil minerals on the biochars may explain the change in surface properties of biochars with soil applications, particularly the increased surface area during aging in soil.[35,36] Trigo et al.[35] suggested that the increase resulted from the elimination of the organic film from the biochar surface, which is in good agreement with our research results.

[a]Atl and Mtb refer to acetochlor and metribuzin, respectively. [b]Data in parentheses are corrected values by deducting the contribution of residual minerals in the treated biochars.

Changed Sorption of Herbicides to Mineral-Treated Biochars. Alumina-treated biochars (Al-BC600 and Al-BC400) exhibit an increase in sorption for the herbicide acetochlor as shown in Figure 3. For the same equilibrium concentration of the acetochlor solution, the amount of herbicide that adsorbed on both alumina-treated biochars was 2 times higher than on the untreated biochars (BC600 and BC400). In contrast, sorption of the acetochlor in the clay-treated biochar (Mo-BC600) was slightly increased, and the sorption even decreased for the clay-treated lower temperature biochar (Mo-BC400). To understand why there was a difference, the sorption data for various biochars were analyzed with the combined adsorption and partition model (eq 2)[2,37] in which Q_A represents the amount of surface adsorption and K_P is the partition coefficient. On the basis of the isotherm shape shown in Figure 3, a linear regression was conducted at a concentration of $C_e/C_s > 0.1$, and the fitting results with correlation coefficients $R > 0.97$ are shown in Table 4. Thus, the relative contribution of surface adsorption (Q_A/Q_e, %) to the total sorption at each equilibrium concentration was calculated, and Q_A/Q_e (%) values at $C_e/C_s = 0.3$ (a middle concentration) for various biochars are shown in Table 4.

$$Q_{total} = Q_e = Q_A + K_P C_e \quad (2)$$

According to the data in Table 4, both surface adsorption (Q_A) and its contribution to the total sorption (Q_A/Q_e) of acetochlor to the alumina-treated biochars (Al-BC400 and Al-BC600) were increased in comparison to the untreated biochars, which resulted from the expanded pore areas of the alumina-treated biochars (Table 3). As acetochlor is a pesticide composed of aromatic structure, the $\pi-\pi$ interactions between herbicide molecules and turbostratic graphene crystallites in biochars may play an important role for the surface adsorption.[38,39] The removal of oxygen-containing organic matter away from the biochar makes it easier for acetochlor molecules to access these adsorption sites in the expanded pores. Therefore, it is understandable that the surface adsorption (Q_A) to the Ca-mont-treated BC600 biochar (Mo-BC600) was also improved, corresponding to its expanded mesopore area. However, the Ca-mont treatment did not increase the surface adsorption of acetochlor to the BC400 biochar, although the BC400 biochar's micropore area was enlarged. This may be related to the inaccessibility of micropores to the herbicide molecules to allow surface adsorption. According to previous studies,[40,41] the pore size of the carbons should be large enough (with diameter >1.7 times the molecule's second widest dimension) for adsorption to occur, and most herbicides have a molecular weight >200 g mol^{-1} and an estimated length >10 Å.[42] Therefore, a significant fraction of micropores (<17 Å in diameter) in biochars may be inaccessible for the acetochlor molecules (with a molecular weight of 269.77 g mol^{-1}). The residual minerals in the treated biochars may play a potential role in herbicide adsorption, because aluminol (═AlOH) and silanol (═SiOH) groups on

DOI: 10.1021/acs.jafc.5b01654
J. Agric. Food Chem. 2015, 63, 5740−5746

the mineral surface can form H-bonding with −O− groups in acetochlor molecules.[43] However, the low surface area of these minerals (Table 3) restricts their adsorption sites available for herbicide molecules, so the limited adsorption capability of a small amount of residual minerals in treated biochars should not contribute much to the dramatic increment of herbicide adsorption particularly observed on the alumina-treated biochars. In other words, the enhanced acetochlor sorption to the mineral-treated biochars is predominantly related to their enlarged mesopore (17−500 Å in diameter) areas. This is particularly true for the higher temperature biochar (BC600), the micropore area of which did not change significantly after treatment with the soil minerals. The significant increase in surface adsorption of the herbicide can be attributed only to the magnified mesopore areas.

A similar enhancement in sorption of metribuzin by alumina-treated biochars was observed as shown in Figure 4. In contrast

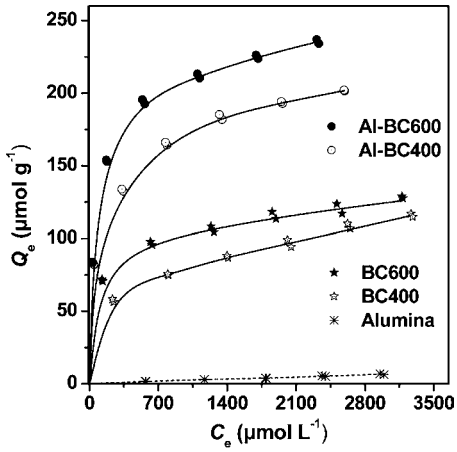

Figure 4. Sorption isotherms of metribuzin to biochars and alumina at 25 °C.

to acetochlor, the sorption of metribuzin by alumina is almost negligible, which should be related to the higher hydrophilicity of metribuzin (as indicated by its lower logK_{ow} and higher water solubility) and its weak affinity to the aluminol surface sites.[43] Thus, the enhanced sorption can be attributed only to the change in porous structure of the biochars after alumina treatment, because the residual alumina in the treated biochar will not do any favor for the sorption of metribuzin. The fitting results of the sorption data of metribuzin with the above-mentioned combined adsorption and partition model are listed in Table 4, and an increase in surface adsorption (Q_A) and contribution of Q_A to the total sorption (Q_A/Q_e) for this herbicide were also observed.

Relationship of Enhanced Sorption and Expanded Pore of Biochars. Further comparisons were made with the corrected values of adsorption capacity (Q_A) (data in parentheses in Table 4) by deducting the contribution of the residual minerals, and surface-normalized adsorptions (Q_A/SA_{BET} and $Q_A/SA_{17-500\ Å}$) were calculated by dividing Q_A with the corrected SA_{BET} and $SA_{17-500\ Å}$ values. When the reported size of the metribuzin molecule (10.43 Å in length and 4.43 Å in width)[42] was used, the theoretical value of maximal monolayer adsorption was calculated to be 3.60 μmol m^{-2}, which is much closer to the $Q_A/SA_{17-500\ Å}$ values for the lower temperature biochar (BC400 and Al-BC400) than to the Q_A/SA_{BET} values. The results showed again the dominant contribution of the mesopores (17−500 Å) on the surface adsorption of the herbicides.

When all of the $Q_A/SA_{17-500\ Å}$ values for both acetochlor and metribuzin were considered, the lower $Q_A/SA_{17-500\ Å}$ values were obtained for the higher temperature biochars (BC600, Al-BC600, and Mo-BC600), suggesting that part of the mesopores in these biochars act only as a passageway for the herbicides' entry into the adsorption sites. In addition, on the same biochar sorbent, the surface-normalized adsorption ($Q_A/SA_{17-500\ Å}$) is obviously larger for metribuzin than for acetochlor, which may be partially due to the smaller molecular size of metribuzin.

Our results are useful for understanding the change in the sorption properties of the biochars with soil applications. Thus, soil minerals may transport some authigenic organic matters from biochars and expand their porous structure, leading to enlarged surface area and enhanced sorption for herbicides. This can explain the enhancement of sorption to biochars after aging in soil[35] and also suggests that the sorption property of biochars may change quickly in soil without experiencing long biological processes, especially in infertile croplands poor in natural organic matter. Furthermore, the increased surface adsorption with mesopore area of mineral-treated biochars implied that more herbicide molecules were entrapped in these mesopores, which will affect the availability of herbicides for both plant uptake and utilization by soil microorganisms. Therefore, the efficacy and environmental fate of soil-applied pesticides will be influenced by the interaction of biochars with soil minerals, which needs further investigation by considering more environmental factors such as pH and coexisting matter.

enzyme instead of amyloglucosidase (improved method).[27] The contents of FOS, GOS, and raffinose were accurately determined as nondigestible oligosaccharides by the improved method, whereas sucrose, isomaltulose, panose, and maltotriose were completely hydrolyzed and did not affect the determination of nondigestible oligosaccharides.[27] Although the improved method was superior to the existing AOAC method in terms of determining oligosaccharides, its application in nondigestible oligosaccharide in marketed processed foods remains untested.

In the present study, we applied the improved method to measure nondigestible oligosaccharides in processed foods and made comparisons with the existing AOAC method. Here, we show that the improved method using porcine small intestinal enzyme, instead of amyloglucosidase, accurately determined nondigestible oligosaccharide contents in currently marketed food products.

MATERIALS AND METHODS

Test Samples and Preparation. We analyzed two types of test samples by the improved method and the existing AOAC method.

In the first, we prepared five different cookies with added oligosaccharides. Cookies (Morinaga & Co. Ltd., Tokyo, Japan) were chosen as test sample without nondigestible oligosaccharide by evidence based on our previous experiments.[29,30] Cookies were crushed using a mortar and pestle and were passed through a mesh sieve of 500 μm. Each oligosaccharide (1.000 g) and cookie (9.000 g) were accurately weighed and mixed using a mortar. Added oligosaccharides were FOS, GOS, or raffinose as nondigestible oligosaccharides as well as isomaltooligosaccharide (IMO) or sucrose as digestible oligosaccharides. FOS (purity > 98%) was donated by Meiji Co., Ltd. (Tokyo, Japan). GOS (purity > 90%) was donated by Nissin Sugar Manufacturing Co., Ltd. (Tokyo, Japan). IMO (purity > 90.8%) was donated by Showa Sangyo Co. (Tokyo, Japan). Raffinose (purity > 98.0%) and sucrose (purity > 99.5%) were purchased from Wako Pure Chemical Industries Ltd. (Osaka, Japan).

In the second analytical experiment, we employed three commercially available syrups containing nondigestible oligosaccharide. In Japan, two syrups approved as "food for specified health uses" and one so-called healthy food was used. Nutrient compositions of three syrups containing nondigestible oligosaccharide are shown in Table 1. Syrup samples were purchased over the internet.

Analytical Method. *AOAC Method 2009.01 (Existing AOAC Method). (a) Chemicals.* All chemicals were of analytical grade or of the highest grade available. The Integrated Total Dietary Fiber kit specified in the existing AOAC method was purchased from Megazyme International Ireland, Ltd. (Wicklow, Ireland). The kit contains pancreatic α-amylase from swine, amyloglucosidase from *Aspergillus niger*, and protease from *Bacillus licheniformis*. Ion-exchange resin (Amberlite MB-4), diatomaceous earth, and Trizma base were purchased from Japan Organo Co., Ltd. (Tokyo, Japan), Kishida Chemical Co., Ltd. (Osaka, Japan), and Sigma-Aldrich Japan Co. LLC (Tokyo, Japan), respectively.

(b) Procedure. Nondigestible oligosaccharide contents in test samples were determined using the existing AOAC method.[26] The apparatus for the existing AOAC method was used. HPLC analyses were performed using a liquid chromatography system (LC-20AD, Shimadzu Corp., Kyoto, Japan) with a refractive index detector (RID-10A, Shimadzu Corp.) and a Shodex SUGAR KS-802 column (8.0 φ × 300 mm, Showa Denko Co., Tokyo, Japan), and analyses were conducted at a column temperature of 40 °C. Samples were eluted with deionized distilled water at a flow rate of 0.5 mL/min. The limit of detection for glucose was 10 μg/mL in HPLC analysis.

Improved AOAC Method 2009.01 (Improved Method). (a) Chemicals. Chemicals used were the same as for the existing AOAC method.

(b) Preparation of Porcine Small Intestinal Brush Border Membrane Vesicles (PSIBBMVs). PSIBBMVs were prepared using the method described by Kessler et al.[31] with modifications. Small intestine from the pylorus to the ileocecal junction with the mesentery of an adult swine was obtained from the Isahaya Prefectural Office of Meat Inspection (Isahaya, Japan). PSIBBMVs were suspended in sufficient volumes of 50 mM sodium maleate buffer containing 2 mM $CaCl_2$ and 0.02% sodium azide (pH 6.0) and were stored at −80 °C until assay.

(c) Determination of α-Glucosidase and Disaccharidase Activities. The α-glucosidase activity (units/mg protein) was determined using the method described by Robertson and Halvorson with *p*-nitrophenyl-α-D-methyl-glucopyranoside as a substrate.[32] One unit of α-glucosidase activity per milligram of protein was defined as the amount of enzyme that produced 1 μmol of glucose from *p*-nitrophenyl-α-D-methyl glucopyranoside per minute.

Assays of disaccharidase activity in PSIBBMVs were performed according to the methods described by Oku et al.,[33] which were modified from the method described by Dahlqvist et al.[34] Sucrose, maltose, trehalose, lactose, and isomaltulose used substrates included. Specific activity (SA) per milligram of protein was defined as the activity of enzyme that hydrolyzed 1 μmol of glucose from substrate per hour (μmol substrate hydrolyzed/mg protein/h). Concentrations of protein were determined using the Bradford assay with bovine serum albumin as a standard.[35]

(d) Procedure. Nondigestible oligosaccharide contents of test samples were determined according to the method of Tanabe et al.[27] Digestible saccharides were hydrolyzed using an enzyme mixture containing pancreatic α-amylase (50 units/mL) and PSIBBMVs (2720 units/mL as α-glucosidase; SA, sucrase, 125.8; maltase, 453.2; trehalase, 35.3; lactase, 8.7; isomaltulase, 14.4) for 16 h at 37 °C. Test samples were added to enzyme mixtures, and nondigestible oligosaccharide contents were determined using the method described by Tanabe et al.[27]

Calculation of the Recovery of Nondigestible Oligosaccharides in Processed Food. Each nondigestible oligosaccharide in added oligosaccharides in processed food was assayed once in duplicate. On the other hand, each nondigestible oligosaccharide in commercially available processed food was assessed five times, and it was expressed the mean ± standard deviation (SD). Nondigestible oligosaccharide contents were measured according to the calculation for nonprecipitable soluble dietary fiber using the existing AOAC method.[26] Nondigestible oligosaccharides were defined as saccharides with degrees of polymerization (DP) of ≥2, according to the definition of "luminacoid", which is a comprehensive concept of nondigestible component from the Japanese Association for Dietary Fiber Research, suggesting[36] nondigestible oligosaccharide was defined as saccharide with DP 2 or more than DP 2. The margin of error was accepted as ±20% on the contents of nondigestible oligosaccharides in processed foods for Japanese nutrition labeling;[37] accurate determination thus

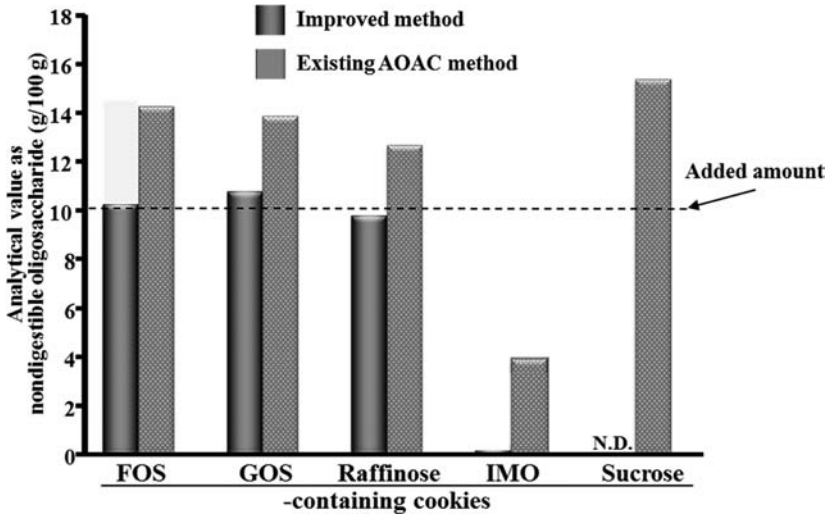

Figure 1. Comparison of nondigestible oligosaccharides in cookies using the improved method and the existing AOAC method. Data was expressed average of duplicate analysis. The nondigestible oligosaccharide fractions were DP ≥ 2. N.D., not detected.

was accepted as ±20% on the contents of nondigestible oligosaccharides in processed foods on the label.

Ethics. Porcine experiments were performed according to the guidelines for the care and use of laboratory animals of the University of Nagasaki, Siebold. All experiments were performed at the Laboratory of Public Health Nutrition, University of Nagasaki, Siebold.

RESULTS

Quantification of Oligosaccharides Added to Processed Foods by the Improved Method and the Existing AOAC Method. Nondigestible oligosaccharide fractions were recovered from cookies using the improved method and the existing AOAC method (Figure 1). After the treatment of cookies containing 10% of FOS, GOS, and raffinose by hydrolyzing enzymes in the improved method, recoveries of these nondigestible oligosaccharides were 10.1, 10.7, and 9.7%, respectively. When IMO and sucrose were hydrolyzed by enzymes in the improved method, the content of IMO that was recovered as nondigestible oligosaccharide fraction was only 0.1%, and sucrose was not detected. It was reported that IMO with α-1,4- and α-1,6-glucosidic linkages was digested readily by human intestinal disaccharidases.[38] This suggests that the improved method is able to measure accurately the quantity of nondigestible oligosaccharide in foods.

In contrast, when oligosaccharides in the same samples were determined by the existing AOAC method, the recoveries as nondigestible oligosaccharide were 14.2% for FOS, 13.8% for GOS, 12.6% for raffinose, and 15.3% for sucrose. Especially, the recovery of IMO was only 4.0%. Thus, the results demonstrate that the existing AOAC method overestimates more than the quantity of nondigestible oligosaccharide in foods.

Quantification of Nondigestible Oligosaccharide in the Syrups by the Improved Method and the Existing AOAC Method. Nondigestible oligosaccharides were determined in the syrups using the improved method and the existing AOAC method (Table 2). The improved method provided the concentrations of FOS and raffinose in the syrups similar to those stated on the label, but the level of GOS was lower than that stated on the food label. In contrast, treatment with hydrolyzing enzymes in the existing AOAC method gave approximately 30% greater than values of FOS, GOS, and raffinose on the label.

Table 2. Analyses of Nondigestible Oligosaccharides in the Syrups Using the Improved Method and the Existing AOAC Method and Comparison with Nutritional Label Values[a]

	nondigestible oligosaccharide value/100 g (%)		
	improved method	existing AO AC method	labeled value
syrup containing FOS (/100 g)	41.2 ± 1.8 (103.0%)	54.8 ± 1.3 (137.0%)	40.0
syrup containing GOS (/100 g)	37.2 ± 2.5 (83.8%)	58.9 ± 1.6 (132.7%)	44.4
syrup containing raffinose (/100 g)	9.6 ± 0.5 (102.1%)	50.1 ± 0.2 (533.0%)	9.4

[a]The values in parentheses show relative ratio of nondigestible oligosaccharide determined by each method and that on the label. Analytical values are expressed as the mean ± SD in duplicate experiments. Nondigestible fractions, ≥DP 2; FOS, fructooligosaccharide; GOS, galactooligosaccharide.

DISCUSSION

In the previous study on the improved method, PSIBBMVs completely hydrolyzed digestible oligosaccharide and distinguished nondigestible oligosaccharide from digestible oligosaccharide.[27] Although the improved method was superior to the existing AOAC method in terms of determining oligosaccharides, its application to nondigestible oligosaccharides in marketed processed foods remains untested. We previously have confirmed that cookies used in the present study do not contain nondigestible oligosaccharides.[29,30] Here, cookies were added digestible (sucrose or IMO) or nondigestible oligosaccharides (FOS, GOS or raffinose) at the level of 10%. As shown Figure 1, the improved method hydrolyzed digestible oligosaccharides such as sucrose and IMO in cookies and gave almost complete recovery of added nondigestible oligosaccharides such as FOS, GOS, and raffinose.

Next, the improved method was applied to marketed syrups, and contents of FOS and raffinose were shown to be similar to those indicated on the food label (Table 2). According to the improved method, the concentration of GOS in the syrups was lower than that stated on the food label (Table 2). This discrepancy may reflect the accepted ±20% margin of error for Japanese nutrition labeling;[37] the content of GOS in the syrup would be between 35.5 and 53.2 g in case of 44.4 g of GOS in

DOI: 10.1021/jf505844y
J. Agric. Food Chem. 2015, 63, 5747−5752

the product. The value (37.2 ± 2.5) by the improved method was within the value accepted by Japanese nutrition labeling. Although porcine small intestinal disaccharidases may hydrolyze GOS with low efficiency, GOS added to cookies was not hydrolyzed (Figure 1), indicating that the improved method accurately measured GOS. Therefore, it is concluded that the improved method is proper to determine GOS in processed foods.

When commercially available processed foods and cookies with added oligosaccharides were treated with the hydrolyzing enzyme amyloglucosidase, of the existing AOAC method, nondigestible oligosaccharide contents were overestimated (Figure 1 and Table 2). These results indicate that the existing AOAC method cannot hydrolyze digestible saccharides such as sucrose and starch-decomposed products and maltodextrin in processed foods, consequently quantifying digestible saccharides as nondigestible oligosaccharides. In agreement, Brunt and Sanders showed that the existing AOAC method does not fully convert digestible starch and maltooligosaccharide fractions into glucose, leading to an erroneous quantification of partially hydrolyzed digestible starch as dietary fiber.[39] Our previous study showed that digestible oligosaccharides are barely hydrolyzed by either AOAC method 2001.03 or 2009.01 using amyloglucosidase,[27,40] which also failed to hydrolyze digestible saccharides.[41] Taken together, these studies show that the hydrolyzing activity of enzymes from bacteria does not reflect the hydrolyzing activities of enzymes of the human gastrointestinal tract.

Pigs are omnivorous with physiological characteristics that allow their use as a model of human digestive functions.[42] Many studies have characterized hydrolyzing specificity of small intestinal disaccharidases in pigs.[43−45] In particular, pigs have been used as models in studies of dietary fiber and nondigestible oligosaccharide digestion.[46−48] Porcine small intestinal disaccharidases could substitute for those in humans. Moreover, pigs are common low-cost domestic animals. Therefore, porcine small intestinal disaccharidases may be suitable for determining nondigestible oligosaccharides in foods for human consumption.

Prebiotic agents are not digested in the human gastrointestinal tract, and their effectiveness is dependent on the quantity of fermentable nondigestible saccharides in the large intestine.[49] Therefore, a precise quantification of nondigestible oligosaccharides in food is necessary to find good sources of prebiotic agents and to accurately label the content of nondigestible oligosaccharides in food.

In conclusion, we developed the improved method for the accurate quantification of nondigestible oligosaccharides in processed foods using porcine small intestinal disaccharidases. The present improved method may be used to comprehensively determine nondigestible oligosaccharides in commercially available processed foods. An appropriate quantification of nondigestible oligosaccharides in foods is essential to estimate health benefits. Moreover, an accurate determination method for newly developed nondigestible oligosaccharides is imperative for nutrition labeling, which indicates prebiotic contents to help consumers chose healthy foods. Improved AOAC method 2009.01 could be the determination method for nondigestible oligosaccharide dietary fiber. Furthermore, the partially purified enzymes isolated from PSIBBMVs and a stable supply of these enzymes should be required to make the improved method as a commercial dietary fiber assay kit.
