To investigate their possible potential as modulators of umami taste, a subset of the known naturally occurring *N*-cinnamoyl phenethylamines similar to rubemamine (**9**) and rubescenamine (**10**) with various substitution patterns were prepared. In Figure 1, the synthesized structures are shown; their natural occurrence is listed in Table 1. Depending on the substitution pattern, there are several methods known to obtain these *N*-cinnamoyl amines. In the case of free hydroxyl groups, the cinammic acid has to be activated as the corresponding *N*-hydroxysuccinimide ester, employing *N*,*N*-dicyclohexylcarbodiimide as coupling reagent.[27] These intermediates were reacted with an appropriate amine to obtain the desired compounds. The target compounds could be purified by column chromatography or crystallization. Alternatively, if the cinnamic acid moiety contains no hydroxyl groups, then it may be more convenient to transfer the cinnamic acid into the corresponding acid chloride by using oxalyl chloride and subsequent reaction with a suitable amine under Schotten–Baumann conditions. Usually, no further purification step is necessary; in the Supporting Information, the ^{1}H NMR and GC-MS or LC-MS spectra for rubemamine (**9**) and rubescenamine (**10**) are shown to demonstrate purity. The best method to obtain (*Z*) isomers of the parent (*E*)-configured cinnamic acid amides is an isomerization reaction under UV[28] as described for *N*-(*Z*)-feruloyl-3-methoxytyramine (**8**).

All synthesized compounds were evaluated at 10, 50, and 100 ppm in pure water by a panel of eight experts (Table 1). Although many of these *N*-cinnamoyl derivatives mostly evoked bitterness or mouth drying or were associated with trigeminal sensations at 100 ppm, only rubemamine (**9**) and rubescenamine (**10**) showed an intrinsic umami taste. Zanthosinamide (**13**) was found to elicit umami taste at 100 ppm as well but it also was rated very bitter at the same concentration. Just recently, the umami taste of **9** was reported,[20] but from the remaining umami active cinnamoyl amines, only the homologue *N*-3,4-dimethoxycinnamoyl-4-methoxyphenethylamine (**16**) could be identified in natural sources. According to the study, a 3,4-dimethoxycinnamic acid moiety seems to be necessary for a strong umami activity, which is very well reflected by the results shown in Table 1 for the series of naturally occurring *N*-cinnamoyl phenethylamines.

Besides the well-known umami taste of foodstuffs or raw materials rich in amino acids, ribonucleotides, peptides, their derivatives, or their reaction products generated during food processing,[1,13,29] there are only singular reports about plant secondary metabolites exhibiting or modulating umami taste. For example, the malic acid derivative morelid was found in morel mushrooms and weakly modulates umami taste evoked by MSG,[30] and the polyphenol theogallin was identified to be one component of the umami character of green tea.[31] The reason for this paucity may be the very low concentration of such substances in the original botanical sources, e.g., rubemamine (**9**) was found in white goosefoot (*Chenopodium album*)[32] at a level of 6 mg kg^{-1}, *N*-3,4-dimethoxycinnamoyl-4-methoxyphenethylamine (**16**) as a trace compound in *Zanthoxylum piperitum*,[20] and rubescenamine (**10**) was present at a level of 10 ppm in the bark of *Zanthoxylum rubescens*.[21] The detection threshold for rubemamine (**9**) in water was determined to be a level of 2263 ppb. Therefore, even for white goosefoot, which is at least sporadically consumed in Western European countries as salad or greens, the effective amount in food prepared from goosefoot is near or even below the threshold for the pure compound. Because of the limited solubility of rubescenamine (**10**), the threshold of the neat compound was determined at elevated temperatures (30 °C) to be 903 ppb. *Z. piperitum* bark is reported to be used solely for pharmaceutical treatments; therefore, only limited sensorial data are available.

J. Agric. Food Chem. 2015, 63, 8694–8704

The ability of the investigated *N*-cinnamoyl amines **1**−**15** to activate the heterodimeric umami receptor in a heterologous cell system was investigated via calcium imaging. Of the synthesized compounds, only rubemamine (**9**) and rubescenamine (**10**) showed activation of the heterologously expressed umami receptor hTAS1R1-rTas1r3 (Figures 2 and 3). Because

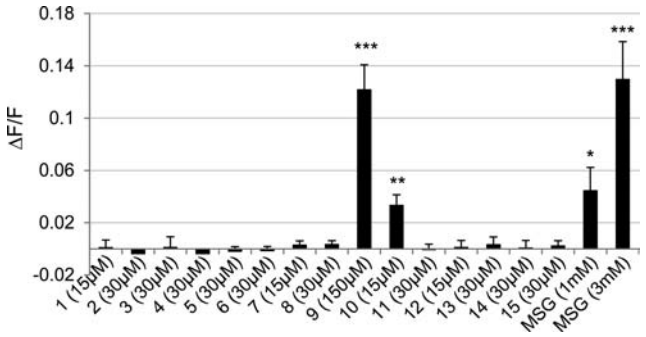

Figure 2. Test for umami receptor hTAS1R1-rTas1r3 activation in HEK293 cell model by *N*-cinnamoyl amines **1**−**15** and MSG measured in calcium imaging experiments. Data represent mean ± standard deviation of three independent experiments, each measured in triplicates. One-way variance analysis was carried out to test differences between substances, including vehicle. Contrast tests, with a multiple comparison Bonferroni adjustment, were carried out between substances and their respective vehicle. *, $p < 0.05$; **, $p < 0.01$; and ***, $p < 0.001$.

glutamate and nucleotides were shown to interact with the TAS1R1 subunit of the receptor,[6] it can be assumed that the functionally expressed umami receptor resembles the native human umami receptor in taste cells. Moreover, the EC_{50} value we found for the prototypical umami substance glutamate (MSG) is in the range of other in vitro data and also correlated well with the in vivo threshold for glutamate.[3,33−36] To compare the potency and efficacy of these newly identified umami compounds, concentration−response curves were established. Figure 3 demonstrates that rubemamine (**9**) is a powerful umami receptor agonist that is ∼40-fold more potent than MSG and equally efficient. In contrast, rubescenamine (**10**) has a much lower efficacy. However, this compound (**10**) is able to activate the receptor at even lower concentrations than rubemamine (**9**) and therefore has a 200-fold higher potency than does MSG. This is can be seen by the lower EC_{50} value of rubescenamine (**10**) (7.5 ± 0.4 μM) compared to those of rubemamine (**9**) (44 ± 8.0 μM) and MSG (1704 ± 335 μM). Although the difference in the EC_{50} value of rubemamine and rubescenamine is statistically not significant by one-way analysis of variance, the higher potency of rubescenamine (**10**) relative to that of rubemamine (**9**) to act on the umami receptor is also reflected by their detection thresholds in water (903 vs 2263 ppb).

Furthermore, the potential of the two naturally occurring compounds to modulate umami receptor activation by MSG and MSG + IMP was evaluated. Rubemamine (**9**) and rubescenamine (**10**) were both able to positively modulate the receptor response to MSG, yet the effect mediated by **9** was much larger than that mediated by (**10**). For rubescenamine (**10**), no further effect was observed in the presence of IMP (Figure 4). Most remarkably, rubemamine (**9**) further positively influenced the IMP-enhanced receptor responses to MSG, whereas IMP did not further enhance the receptor response to MSG and **9**. Thus, the data do not us allow to decide if IMP and **9** bind to the same site or different sites in

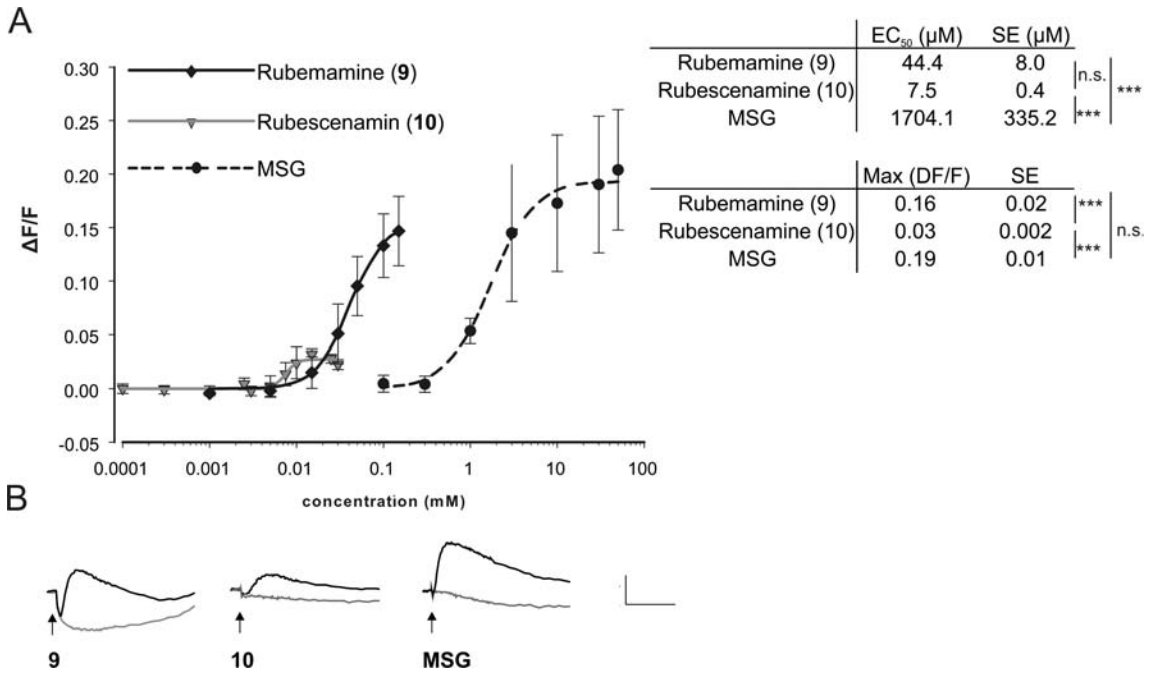

Figure 3. (A) Concentration response curve of rubemamine (**9**) and rubescenamine (**10**) in HEK293-cell model compared to that of MSG. Data represent mean ± standard deviation of three independent experiments measured in triplicate. To test for significant differences in maximal signal amplitude (Max $\Delta F/F$) and between EC_{50} values of the compounds, one-way variance analyses were carried out followed by Bonferroni posthoc test (*, $p < 0.05$; **, $p < 0.01$; and ***, $p < 0.001$). (B) Original calcium traces of hTAS1R1-rTas1r3-expressing HEK293 cells (black) and control cells (gray) in response to the application (↑) of rubemamine (**9**) (150 μM), rubescenamine (**10**) (15 μM), and MSG (3 mM); scale bar: $y = 100$ relative fluorescence units, $x = 100$ s.

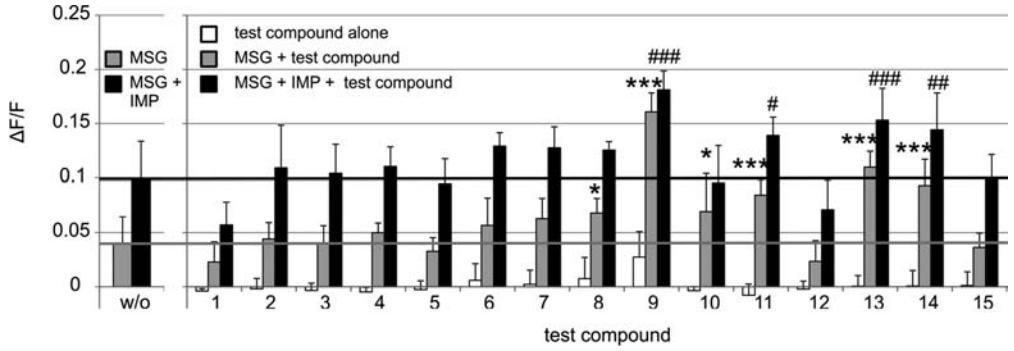

Figure 4. Umami-receptor-modulating ability of *N*-cinnamoyl amines determined by comparing the relative fluorescence elicited by the application of MSG and MSG plus IMP to the coapplication with the different test compounds. Isolated compounds were applied in nonactivating concentrations (compounds **2**−**6**, **8**, **11**, and **13**−**15**: 30 μM; compounds **1**, **9**, and **12**: 15 μM; compound **7**: 6 μM; and compound **10**: 5 μM) alone (white bars), with 1 mM MSG (gray bars), and with 1 mM MSG + 0.1 mM IMP (black bars). Gray and black horizontal lines indicate the mean fluorescence change induced the application of MSG and MSG plus IMP, respectively. Data represent mean ± standard deviation of three independent experiments, each measured in duplicate or triplicate. One-way variance analysis was carried out to test differences between substances and their respective controls (MSG or MSG plus IMP), followed by a Dunett multiple comparison posthoc test (MSG response: *, $p < 0.05$; **, $p < 0.01$; and ***, $p < 0.001$; MSG plus IMP response: $^{\#}$, $p < 0.05$; $^{\#\#}$, $p < 0.01$; and $^{\#\#\#}$, $p < 0.001$).

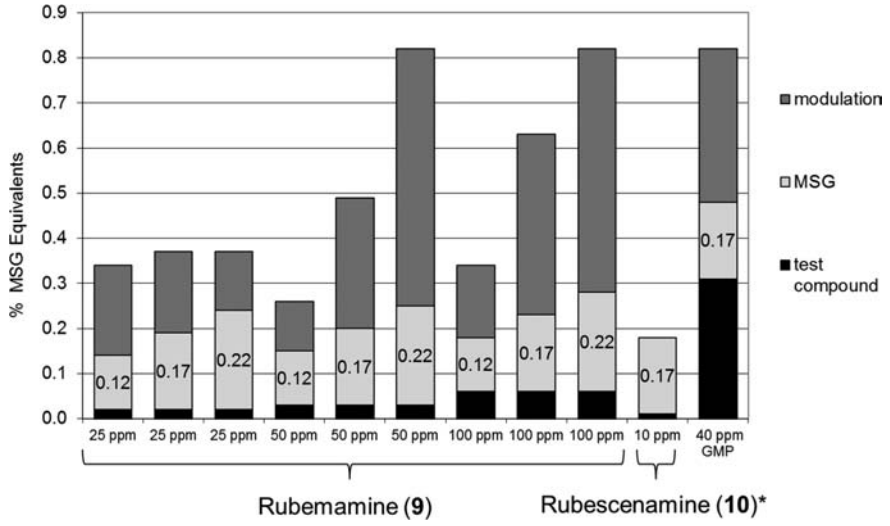

Figure 5. Quantification of positive modulating effects of rubemamine (**9**) and rubescenamine (**10**) on umami taste of MSG and comparison to that of GMP/MSG mixture according to Yamaguchi.[2] A binary solution (pH 6 0.0) containing the test compound in water was compared by forced choice methodology (2-AFC) to a series of aqueous solutions (0.17−1.82% w/w) with increasing concentrations of MSG. For the determination of the modulating activity, a binary solution (pH 6.0) containing the umami compound and MSG (0.17%) in water was compared to the same series of MSG solutions. Each test was repeated three times for each panelist.

hTAS1R1-rTas1r3, yet the data demonstrate that **9** positively modulates MSG-mediated receptor responses to an extent that cannot be further enlarged by IMP. Substances **8**, **11**, **13**, and **14**, which showed no receptor activation when applied alone onto the cells, were also capable of positively modulating receptor activation by MSG even though their effects were smaller than that of **9**. Additionally, similar to compound **9**, compounds **11**, **13**, and **14** enlarged the IMP-enhanced TAS1R1-Tas1r3 responses to MSG. However, there are differences between the effects mediated by **9** or by **11**, **13**, and **14**. First, the positive effect of rubemamine (**9**) on IMP-enhanced MSG-mediated receptor responses is smaller than that contributed by **11**, **13**, and **14**. Second, and more importantly, unlike the case of **9**, the effect of the latter compounds on MSG-mediated receptor response can be further enhanced by IMP. These findings suggest that the binding sites for **11**, **13**, and **14** differ from that of IMP. Positive modulation of a ribonucleotide-enhanced MSG-mediated umami receptor responses was also shown for another amide.[37] However, the reported effect was much smaller than effects elicited by **9**, **11**, **13**, and **14**.

Although binding and sensory studies need to confirm these results, the data show that little differences in molecular structure can have large impact on receptor responses. For the related sweet taste receptor TAS1R2-TAS1R3 that has the TAS1R3 subunit in common with the umami receptor binding of structurally related substances has been described to occur in similar regions.[7,8,38] Although umami receptor positive modulation by nucleotides is described to occur via the TAS1R1 subunit,[6] the known sweet- and umami-taste inhibitor lactisole negatively modulates the umami receptor via the transmembrane regions of the TAS1R3 subunit.[7,8] Also, the positively umami-taste-modulating compound S807 (*N*-(heptan-4-yl)benzo[*d*][1,3]dioxole-5-carboxamide) has been demonstrated to interact with the transmembrane region of the TAS1R1 subunit.[6] If the binding occurred via the rTas1r3

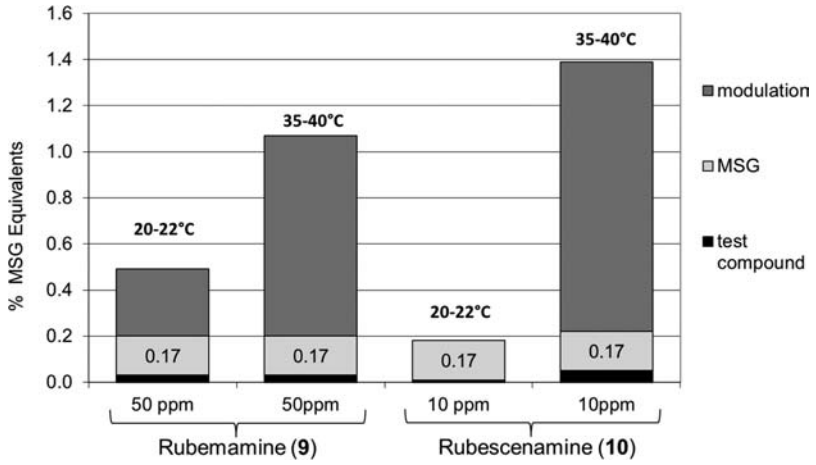

Figure 6. Positive modulation effect of rubemamine (**9**) and rubescenamine (**10**) on umami taste of MSG in ambient (20−22 °C) and warm application. Conditions were the same as those in Figure 5, but the solutions in columns 2 and 4 were warmed to 30−35 °C before tasting.

subunit, then the modulatory effect was not seen in human sensory studies, but the regions of the receptor that are targets for interaction with the *N*-cinnamoyl amides are currently unknown and need to be determined exactly in further investigations.

To quantify the modulating effects for the naturally occurring *N*-cinnamoyl amines **9**−**11**, **13**, and **14** in vivo, further sensory studies according to the method described by Yamaguchi[2] were carried out; amide **8** was not evaluated because of its disturbing dry off-taste. Generally, it is very difficult to quantify umami effects because of the strong lingering character of this taste quality. Specifically, a single experimental comparison of a test solution against a full concentration series of MSG within a single sensory session fails because of carry-over effects. Therefore, Yamaguchi proposed a series of forced-choice paired tests that compare mixtures of a standard MSG concentration (e.g., 0.17%) and the test compound with each sample of an MSG concentration series (here, from 0.17 up to 1.82% MSG). Multiple sessions for each panelist are necessary to get data on the full series of dilutions. In a single test, the panelist has only to decide which solution is stronger in umami. At the end, all experiments are ranked according to the answers of the panelists. The same experiment is done with the test compound alone, and finally, the MSG equivalent concentration is calculated as the last concentration where the mixture of MSG and test compound is nonsignificantly weaker than the MSG reference solution. The known synergistic effect for GMP[2] was used for the validation of the panel; 40 ppm GMP (corresponds to 0.37% MSG) and 0.17% MSG were described to elicit the same intensity of umami taste as an MSG solution of 0.8%. Therefore, GMP exhibited a clear and expected synergistic effect on umami taste for the panelists.

Amides **11** (10 ppm) and **13** (50 ppm) showed no significant modulating effect in the Yamaguchi sensory protocol (data not shown). Dioxamine (**14**) at 25 ppm in combination with 0.17% MSG exhibited a sensory equivalent to 0.37% MSG. Because of the limited solubility of **14**, the latter test was done at increased temperature (35−40 °C). Unfortunately, some bitterness was detected that could potentially mislead the panelists; therefore, the tests with **14** were not extended in depth. For rubemamine (**9**), positive modulating effects were found and are summarized in Figure 5. For all tested combinations of rubemamine (**9**) with MSG (columns 1−9), the compound shows a positive synergistic effect. In contrast, rubescenamine (**10**) (50 ppm column 10, 0.17% MSG) showed no effect at room temperature (20−22 °C; Figure 5, column 10), but the experiment was repeated with a warmed solution also in comparison with rubemamine (**9**) (Figure 6). At increased temperature, for **9** the effect is still more pronounced compared to ambient conditions, and rubescenamine (**10**) also shows positive modulating properties on the umami taste of MSG. The limited solubility of **10** at ambient conditions noticed in this experiment might be also the reason for the lower efficacy of **10** compared to rubemamine (**9**) seen in the dose−response studies on the hTAS1R1-rTas1r3 receptor.

Although the interaction sites of the cinnamoyl amides at the umami receptor remain to be elucidated, the quantitative sensory results support the studies using the receptor assays and the proposal of two different binding sites: Only **9** and **10** are able to induce strong intrinsic umami effects and cause a positive modulation of the MSG umami taste in vitro and in vivo. In contrast, the potential modulators **11**, **13**, and **14** putatively binding to an alternative receptor site exhibited only weak or no intrinsic umami effects. Only **14** showed some modulating effect on MSG in vivo that was slightly disturbed by limited solubility and bitterness. For the observed differences between the umami modulation in vitro and in vivo by the compounds **11** and **13**, it must be considered that we used the rat Tas1r3 in the heterologous expression system that could be responsible for this effect. To evaluate the potential of rubemamine (**9**) and rubescenamine (**10**) as flavor substances showing also general taste modifying properties, advanced profiling studies in a model broth were carried out with a larger panel (n = 16−20) on an American beef extract already containing the typical umami tastants such as glutamate and nucleotides. In this case, the attribute "umami" itself was excluded because of some uncertainty of its description in a complex flavor environment. Instead, umami-related attributes such as "mouth watering" or "meaty" were used. In Figure 7, the differences of these descriptors in relation to the ratings for the base are shown: 0.05% MSG increases most of the attributes significantly. Rubemamine (**9**) at 50 ppm significantly raises the important descriptors mouth feel, meaty, and mouth-watering; however, with the exception for the parameter mouth-watering, this amount is not able to match the intensity of the positive control (base with 0.05% MSG added, Figure 7A). Rubescenamine (**10**) at 5 ppm and especially at 10 ppm is able to boost significantly mouth feel, meaty, mouth-watering,

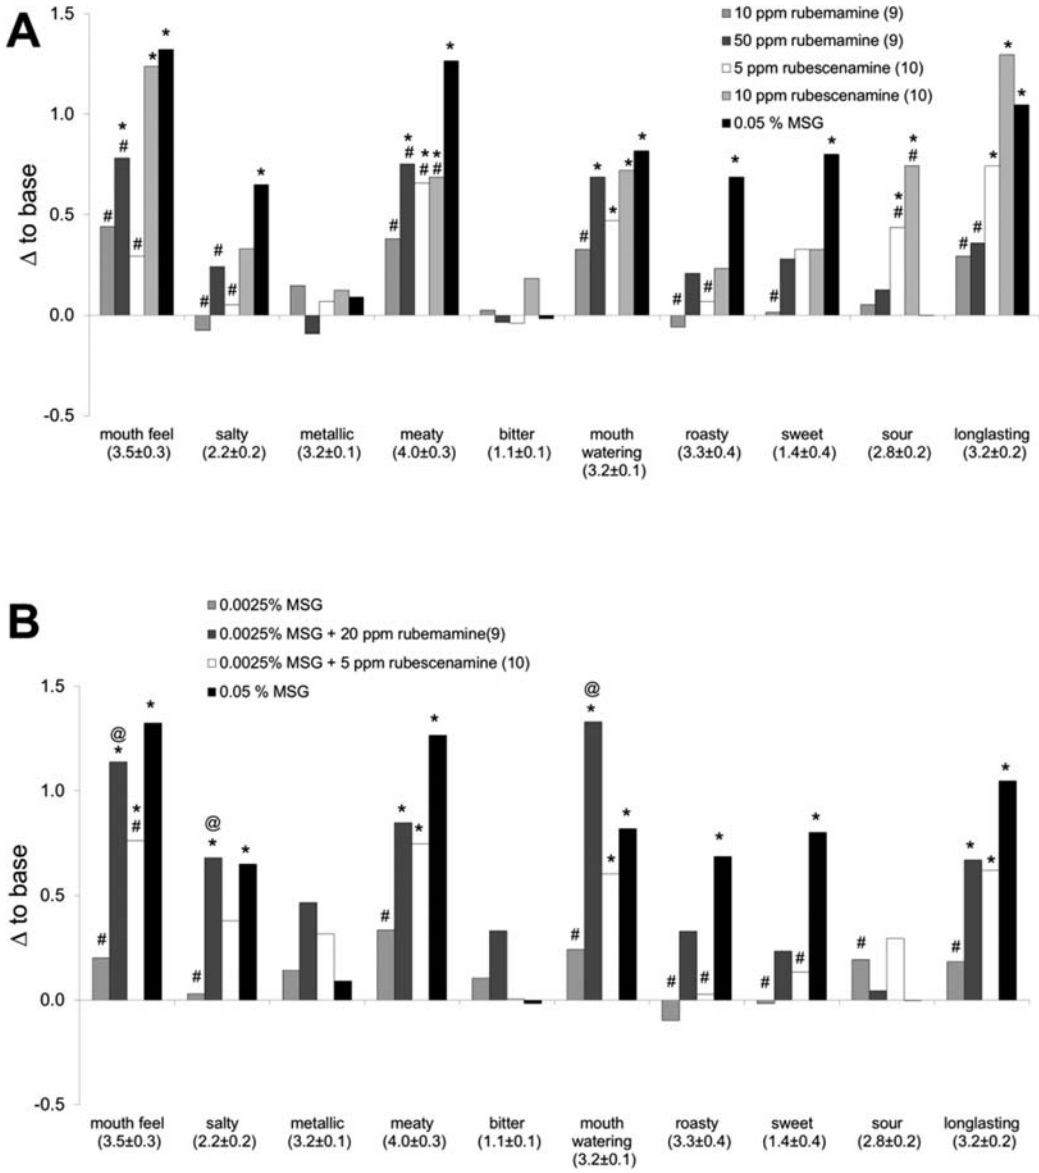

Figure 7. Taste-modulating effects of rubemamine (**9**) and rubescenamine (**10**) in an American beef extract (base) by sensory profiling at slightly elevated temperatures (30−35 °C) by a panel of trained subjects (n = 16−20). The descriptors used and their average ratings (0 through 9) and standard deviations for the base a shown on the x axis. The mean values are shown as differences of the ratings of the test samples to the respective ratings of the base. (A) Differences (Δ) between the base and base with added rubemamine (**9**) or rubescenamine (**10**) and a positive control with added MSG. Significant differences ($p < 0.05$) as determined by Student's t test (nonpaired, two-sided): *, between base and test sample, and #, between test sample and positive control. (B) Differences (Δ) between the base and base with added MSG, base with added MSG and rubemamine (**9**), base with added MSG and rubescenamine (**10**), and positive control. Significant differences ($p < 0.05$) as determined by Student's t test (nonpaired, two-sided): *, between base and test sample; @, between between test sample and base with 0.0025% added MSG; and #, between test sample and positive control.

sour, and long-lasting (Figure 7A) and shows at 10 ppm no significant difference to the positive control for mouth feel, saltiness, and mouth-watering, reflecting its higher potential as a flavor modifier. In Figure 7B, the potential of **9** and **10** to boost the flavor profile of a low concentration of added MSG in the model broth is shown. The effect of a mixture of low MSG and rubemamine (**9**) matches most ratings of the attributes of the positive control. Rubescenamine (**10**) at 5 ppm in combination with 0.0025% MSG is also able to boost the profile of the base, showing mostly significant changes compared to the base but nonsignificant differences compared to the positive control.

As result of the study, besides the known umami tastant rubemamine (**9**), also the naturally occurring rubescenamine (**10**) was found to modulate complex flavor systems. Both are able to synergistically modulate the umami sensation of MSG and act on the umami receptor as shown in heterologous cell models. New insights for the binding mode can be deduced from the combined sensory and in vitro experiments that lead to further studies to validate the binding mode and binding site within the umami receptor.

health-promoting properties, such as cardioprotective and antioxidant effects.[16−18] However, our group previously demonstrated the stability of maqui anthocyanins to be comparably poor,[10] stating that deeper insights into the degradation of the contained anthocyanin 3-*O*-glycosides as well as 3,5-*O*- and 3,7-*O*-diglycosides are urgently required.

Therefore, the present study aimed at evaluating the stability of maqui anthocyanins by thermal treatment of differently purified liquid maqui preparations, including "total matrix", "matrix-depleted", and "matrix-free" anthocyanin samples to investigate the influence of concomitant polar low-molecular-weight matrix constituents (e.g., sugars and citric acid) and non-anthocyanin phenolics. In addition, the effect of pH was studied by adjusting the preparations to pH 2.2 and 3.6 prior to thermal treatment. Moreover, the stability of maqui anthocyanins in the total matrix and matrix-depleted maqui preparations was monitored during long-term storage at 4 and 20 °C in the dark, also testing the effect of illumination during storage at 20 °C. The results were compared to those obtained after storing the respective dried preparations (powders). Besides detailed HPLC-DAD analyses on anthocyanins and initial non-anthocyanin phenolic compounds, changes in antioxidant activity (trolox equivalent antioxidant capacity, TEAC assay) and color parameters (CIE $L^*a^*b^*$) were studied in the stored samples.

MATERIALS AND METHODS

Chemicals. Cyanidin 3-*O*-glucoside, cyanidin 3,5-*O*-diglucoside, delphinidin 3-*O*-glucoside, and delphinidin 3,5-*O*-diglucoside were obtained from Extrasynthèse (Genay, France). Myricetin 3-*O*-glucoside was from Sigma-Aldrich (St. Louis, MO, USA), isoquercetin from Carl Roth (Karlsruhe, Germany,) and ellagic acid from Serva (Heidelberg, Germany). Maltodextrin (dextrose equivalent DE 19) was from Agrana (Vienna, Austria). 2,2′-Azinobis(3-ethylbenzthiazoline-6-sulfonic acid) diammonium salt (ABTS), 2,2′-azobis(2-amidinopropane) dihydrochloride (ABAP), and Folin−Ciocalteu reagent were purchased from Sigma-Aldrich. All further solvents and reagents were at least of analytical grade and obtained from Merck and VWR (Darmstadt, Germany). Ultrapure water (Milli-Q system) from EMD Millipore (Bedford, MA, USA) was used throughout.

Production of Liquid and Dried Maqui Preparations with Different Matrix Degrees. Maqui berries originating from the Aysén region near Coihaique in Patagonia (Chile) were harvested by the end of February 2013 and sent frozen to Stuttgart on dry ice by express airmail. Processing of maqui berries into a juice was conducted as described previously.[10] The term "total matrix" will be used to refer to preparations made from the juice by dilution with buffer, that is, without selective purification steps. The "matrix-depleted" preparation was prepared by removal of polar low-molecular-weight juice constituents (e.g., sugars and citric acid) according to a previously reported procedure[8] with the following modifications. The maqui juice was applied to a conditioned and equilibrated column filled with Lewatit VP OC 1064 MD PH, 1.4 L bed volume (BV) (Lanxess, Langenfeld, Germany), instead of Amberlite XAD-16 HP. For column conditioning, washing, and elution, methanol and trifluoroacetic acid were replaced by ethanol and aqueous hydrochloric acid (HCl) at pH 2. After conditioning with 1.0 BV of ethanol and washing with 1.8 BV of aqueous HCl (pH 2), 50 mL of the maqui juice (diluted 1:1 with water) was applied to the column, and nonadsorbent juice matrix components were eluted with aqueous HCl (4.0 BV). The deeply red-colored phenolic fraction was eluted from the column using 2.0 BV of ethanol with aqueous hydrochloric acid (95:5, v/v) and concentrated in vacuo to remove the solvent. To achieve an almost "matrix-free" anthocyanin extract, the non-anthocyanin phenolics present in the matrix-depleted extract were separated from anthocyanins by extracting them with ethyl acetate as previously reported.[10] Pure anthocyanin preparations were obtained by dissolving authentic standards in the respective buffers (only for cyanidin 3-*O*-glucoside, cyanidin 3,5-*O*-diglucoside, delphinidin 3-*O*-glucoside, and delphinidin 3,5-*O*-diglucoside).

In addition to the liquid samples, dried preparations (powders) were produced from the aforementioned total matrix and matrix-depleted preparations. For this purpose, aliquots of these samples were combined with 15% (w/v) of maltodextrin, homogenized for 5 min using a T25 Ultra-Turrax (IKA, Staufen, Germany), transferred to plastic pans (30 mm deep), and frozen at −20 °C prior to freeze-drying. Freeze-drying was carried out at 5 Pa for 72 h with a condenser and final plate temperatures of −60 and 30 °C, respectively. Dried preparations containing maltodextrin were manually ground and then sequentially sieved (mesh sizes of 1.0 and 0.5 mm) (Retsch, Haan, Germany). Only the powder fraction with particle sizes between 0.5 and 1.0 mm was used for the storage experiment and further analyses. Moisture contents of the powders were measured by infrared drying at 105 °C with an infrared moisture analyzer (Sartorius, Göttingen, Germany).

Storage Experiments Using Liquid and Dried Maqui Preparations. Liquid preparations for storage stability tests were obtained by adjusting the maqui juice (total matrix) and the matrix-depleted extract to a total anthocyanin concentration of 1000 μmol/L using a sodium acetate buffer solution (pH 3.6). This pH was chosen, being the genuine pH of the maqui juice used. Subsequently, the concentration-adjusted maqui preparations were filtered (0.45 μm) into transparent, previously sterilized glass bottles (50 mm × 18 mm) with plastic snap-on caps. Additionally, aliquots of 6 g powdered samples were placed in rectangular molded transparent plastic bags (PA/PE, ∼90 × 20 mm), flattened to a height of 1 mm, and sealed under vacuum. Liquid and dried samples were placed in a controlled climate chamber (Binder, Tuttlingen, Germany), where temperature (20 °C) and illumination (L36W/840 and LT36W/009) (Osram, Munich, Germany) were controlled. Sample positions were rotated periodically (twice per week) to ensure uniform light exposure. In addition to illuminated storage, liquid preparations were stored at 4 and 20 °C in the dark. All samples were stored for up to 85 days, and anthocyanin stabilities were assessed by HPLC-DAD after membrane filtration (0.45 μm) into amber HPLC vials. Moreover, the pH values, total soluble solids (refractometer, RX-5000) (Atago, Tokyo, Japan), antioxidant activities (trolox equivalent antioxidant capacity, TEAC assay), and color parameters (CIE $L^*a^*b^*$) of the samples were analyzed at selected storage days.

Heating Experiments Using Liquid Maqui Preparations and Standard Solutions. Prior to heating, the above-mentioned liquid total matrix, matrix-depleted, and matrix-free samples as well as standard solutions of cyanidin 3-*O*-glucoside, cyanidin 3,5-*O*-diglucoside, delphinidin 3-*O*-glucoside, and delphinidin 3,5-*O*-diglucoside were adjusted to pH 3.6 and 2.2 by using a sodium acetate buffer solution (pH 3.6) and aqueous hydrochloric acid (pH 2.2), respectively. Aliquots of 900 μL of the samples were heated in Eppendorf tubes in a thermoshaker at 85 °C and 1400 rpm. After 30, 60, 90, 120, 240, and 420 min, tubes were cooled in an ice bath to stop thermal anthocyanin degradation. An aliquot of each sample as well as of the unheated samples was membrane-filtered (0.45 μm) into amber HPLC vials for subsequent anthocyanin analyses by HPLC-DAD.

HPLC-DAD Analyses. Liquid heated and stored samples were prepared for HPLC analyses as described above, whereas aliquots of the dried preparations (5.0 g) were resuspended in 50 mL of deionized water prior to HPLC-DAD analysis. Identification and quantitation of anthocyanins and non-anthocyanin phenolics in liquid and dried maqui samples were carried out by HPLC-DAD-ESI/MS^n and HPLC-DAD as previously described.[10] Although quantitative analyses of anthocyanins were conducted for all maqui samples, quantitation of non-anthocyanin phenolics was executed only for the determination of their initial contents in the total matrix and matrix-depleted preparations used for the storage experiments. For this purpose, non-anthocyanin phenolics in the samples were extracted twice with ethyl acetate. The extracts were combined, evaporated to dryness by a gentle stream of nitrogen, and resuspended in methanol as previously

DOI: 10.1021/acs.jafc.5b03471
J. Agric. Food Chem. 2015, 63, 8705−8714

reported.[10] Dried preparations were dissolved in a defined volume of aqueous hydrochloric acid (pH 1.5) prior to ethyl acetate extraction.

Quantitation of maqui anthocyanins (Figure 1) was carried out using linear calibration curves of authentic standards. A delphinidin 3-*O*-glucoside calibration was used for quantitating delphinidin 3-*O*-sambubioside-5-*O*-glucoside (**1**), delphinidin 3,5-*O*-diglucoside (**2**), delphinidin 3-*O*-sambubioside (**5**), and delphinidin 3-*O*-glucoside (**6**), whereas a cyanidin 3-*O*-glucoside calibration was used for the quantitation of cyanidin 3-*O*-sambubioside-5-*O*-glucoside (**3**), cyanidin 3,5-*O*-diglucoside (**4**), cyanidin 3-*O*-sambubioside (**7**), and cyanidin 3-*O*-glucoside (**8**). In particular, compounds **3** and **4** as well as compounds **7** and **8** were quantitated together due to the lack of HPLC baseline separation. Moreover, it should be mentioned that the proposed position of sugar moieties at the delphinidin and cyanidin 3,5-*O*-diglucosides, **2** and **4**, has not yet been unambiguously confirmed by NMR spectroscopy, to the best of our knowledge. Because the differentiation between a 5-*O*- and a 7-*O*-glycosylation is most intricate if not impossible without NMR, these compounds might also represent the respective 3,7-*O*-diglucoside derivatives.[10]

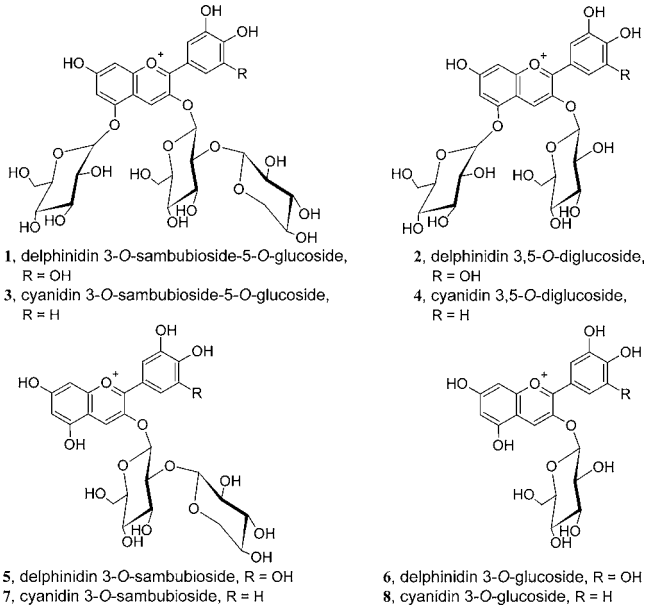

Figure 1. Chemical structures of the studied 3-*O*- and 3,5-*O*-glycosylated cyanidin and delphinidin derivatives, naturally present in maqui. Compounds are numbered according to their elution order from the HPLC column.

Initial non-anthocyanin phenolic contents were quantitated on the basis of calibration curves of authentic standards. A myricetin 3-*O*-glucoside calibration was used for myricetin 3-*O*-galloyl-glucoside (**9**), myricetin 3-*O*-galactoside (**10**), and myricetin 3-*O*-glucoside (**11**), whereas the two quercetin galloyl-hexosides, (**12**) and (**13**), dimethoxylated quercetin (**17**) and quercetin (**18**) were quantitated using an isoquercetin calibration. Due to the lack of HPLC baseline separation, ellagic acid (**14**), quercetin 3-*O*-rutinoside (**15**), and quercetin 3-*O*-galactoside (**16**) were quantitated together by using the calibration curve of the main compound (ellagic acid (**14**)). Compounds **10** and **11** as well as compounds **12** and **13** were also quantitated together.

Degradation Kinetics. The stability of individual and total anthocyanins was expressed as the ratio $A_t/A_0 \times 100\%$ (anthocyanin retention), where A_t represents the anthocyanin content after a given period t during storage or thermal treatment and A_0 the initial anthocyanin content before storage or thermal treatment. In agreement with previous papers,[19−21] first-order reaction kinetics ($A_t = A_0\, e^{-kt}$; k = reaction rate coefficient, t = storage time) were used to fit the analytical data. According to previously published papers,[19−22]

J. Agric. Food Chem. 2015, 63, 8705−8714

half-life ($t_{1/2}$) values were determined by plotting the natural logarithms of the A_t/A_0 ratios against the storage time in days or heating time in hours [$\ln(A_t/A_0) = -kt$]. The slope of the linear regression curve yielded $-k$, enabling exact calculations of $t_{1/2}$ values [$t_{1/2} = (\ln 2)/k$]. The $t_{1/2}$ values of individual anthocyanins, total delphinidins, total cyanidins, and total anthocyanins were calculated.

Antioxidant Activity and Color Measurement during Storage. The TEAC assay was used to determine the antioxidant activity as described by van den Berg et al.,[23] and values were expressed as trolox equivalents in millimoles per liter (liquid preparations) and millimoles per kilogram DM (dried preparations). If required, samples and calibration solutions were diluted in deionized water. A Power Wave XS microplate spectrophotometer (Biotek Instruments, Bad Friedrichshall, Germany) was used for the test assay. Color measurements (CIE $L^*a^*b^*$) were carried out using a Minolta Chromameter CR-300 (Illuminant D65 and 10° observer angle) (Konica Minolta, Osaka, Japan) calibrated with a standard white tile ($L^* = 97.43$, $a^* = 0.01$, $b^* = 1.64$). On the basis of a^* and b^* values, chromaticity C* [$C^* = (a^{*2} + b^{*2})^{1/2}$] and hue angle $h°$ [$h° = \arctan(b^*/a^*)$] were determined.

Statistical Analysis. HPLC-DAD and TEAC analyses were conducted in duplicate, whereas color measurements (CIE $L^*a^*b^*$) were performed in a five-fold determination. Moisture contents, moisture adsorptions, and glass transition temperatures for the characterization of maqui powders were determined in triplicate. Results were expressed as means ± standard deviation. Analysis of variance (ANOVA) including the Tukey test were conducted with JMP 6 (SAS, Cary, NC, USA) to determine significant differences of means at $p < 0.05$.

RESULTS AND DISCUSSION

Physicochemical Characterization of Liquid and Dried Preparations Used for Storage Experiments. After adjustment to a consistent initial total anthocyanin concentration (~1000 μmol/L) and pH of 3.6, the total soluble solids (TSS) in the liquid preparation derived from the total matrix juice (1.3 ± 0.0 °Brix) were expectedly higher than those of the matrix-depleted extract (0.7 ± 0.0 °Brix) (Table 1). The pH and TSS of the liquid preparations remained constant during the whole storage period under all conditions applied.

Anthocyanins present in the samples were composed of delphinidin and cyanidin derivatives substituted with different sugar moieties (glucose and sambubiose) at position 3-*O*- and/or 5-*O*- as also previously reported (Figure 1 and Table 1).[10,17,18] When water was removed from the maltodextrin-containing liquid samples, initial total anthocyanin contents in the obtained dried preparations (powders) increased from 985 μmol/L to 5416 μmol/kg (when prepared from total matrix juice) and from 1045 μmol/L to 5958 μmol/kg (when prepared from matrix-depleted extract). In both liquid and dried preparations, proportions of total delphinidins (82% of total anthocyanins) were higher than the proportions of total cyanidins (18%). Delphinidin 3-*O*-sambubioside 5-*O*-glucoside (**1**) was the predominant anthocyanin, accounting for ca. 30% of total anthocyanins in all samples, followed by delphinidin 3-*O*-sambubioside (19%; **5**), delphinidin 3-*O*-glucoside (16%; **6**), and delphinidin 3,5-*O*-diglucoside (17%; **2**). Cyanidin derivatives were less abundant [sum of cyanidin 3-*O*-sambubioside-5-*O*-glucoside (**3**) and cyanidin 3,5-*O*-diglucoside (**4**), 10% of total anthocyanins; sum of cyanidin 3-*O*-sambubioside (**7**) and cyanidin 3-*O*- glucoside (**8**) 8% of total anthocyanins].

In agreement with a previous study,[10] non-anthocyanin phenolics in the maqui samples mostly consisted of ellagic acid (**14**) as well as derivatives of myricetin and quercetin (compounds **9**–**13** and **15**–**18**) (Table 1). Initial non-anthocyanin phenolic contents in the total matrix (53 μmol/L, liquid sample; 194 μmol/kg, powder) and matrix-depleted preparations (63 μmol/L, liquid sample; 188 μmol/kg, powder) were determined to be 17–32-fold lower than the initial total anthocyanin contents. Non-anthocyanin phenolic compounds were quantitated due to their potential importance for anthocyanin stabilization. So-called intermolecular copigmentation effects between non-anthocyanin phenolics (copigment) and anthocyanins may increase pigment stability, however, being reported to occur at high copigment/pigment ratios of, for example, 31:1, in a liquid anthocyanin extract based on grapes.[24] Despite markedly lower copigment/pigment ratios of ca. 1:24 on average determined in our maqui samples, the possible stabilizing effect caused by intermolecular copigmentation was further investigated in storage and heat experiments described below.

Residual moisture contents in the dried preparations were within the range of 3–5% (Table 1), at which quality attributes such as color, odor and taste were previously reported to be retained during long-term storage,[25] resulting in free-flowing, nonsticky powders.

Impact of Different Storage Conditions on the Stability of Total Anthocyanins. In all liquid samples investigated (Figure 2 and Table 2), total anthocyanin degradation was strongly influenced by the storage temperature and light exposure. For instance, the fastest anthocyanin degradation to ca. 22% of its initial content was observed after 28 days at 20 °C under permanent illumination [half-life ($t_{1/2}$) = ca. 12 days]. When samples were stored at the same temperature (20 °C) in the dark, anthocyanin retentions below ca. 22% were obtained much later, that is, after 63 days ($t_{1/2}$ =

ca. 28 days), demonstrating the detrimental influence of light on color retention. Interestingly, total anthocyanin stability was only marginally affected by the food matrix. As shown in Figure 2, when samples were stored at 20 °C in the dark, stabilities of anthocyanins in the total matrix and the matrix-depleted preparations were almost identical ($t_{1/2} \sim 28$ days for both) (Table 2). Therefore, the presence of low-molecular-weight and non-phenolic matrix compounds appears to be irrelevant for maqui anthocyanin stability.

Expectedly, the reduction of the storage temperature from 20 to 4 °C significantly enhanced the total anthocyanin stability in liquid samples (Figure 2 and Table 2). Similar anthocyanin stabilities were found when total matrix and matrix-depleted samples were compared, exhibiting $t_{1/2}$ values ranging from ca. 141 to 153 days. For comparison, anthocyanin-rich vegetables mostly comprising high amounts of acylated anthocyanins have been shown to possess markedly higher pigment stabilities. For instance, substantially higher $t_{1/2}$ values of >365 days at 2 °C and 70 days at 25 °C have been reported in liquid anthocyanin preparations extracted from red potatoes (pH 3.5), which, however, contain high proportions of highly stable acylated anthocyanins.[26]

After drying, total anthocyanins remained stable over the whole period of storage (85 days) at 20 °C under illumination (total anthocyanin retentions ca. 100 ± 5%, Figure 2). Because the high stability of anthocyanins in dried samples hampered the deduction of reliable $t_{1/2}$ values, the retention of total anthocyanins (%) at the end of storage (85 days) is shown in Table 2 instead of $t_{1/2}$ values. The improved anthocyanin stability in the dried preparations was expected, most likely due to impaired hydration reactions by the removal of water.[27] In addition, embedding in maltodextrin has been previously reported to improve anthocyanin stability against oxidation reactions.[28] Accordingly, enhanced anthocyanin stabilities to decreasing storage temperatures and/or when liquid anthocyanin samples were processed into powders have been previously reported.[29,30] Thus, lowering the storage temperature or processing liquid maqui products into fruit powders may be a useful tool to obtain high-performance food colorants exhibiting long shelf life.

Antioxidant Activity and Color Changes (CIE *L*a*b) during Storage.** Differences in antioxidant activity were insignificant during storage of both liquid and dried maqui preparations (Table 3). Unexpectedly, antioxidant activities did not correlate with anthocyanin concentrations. Whereas the latter were reduced over time, antioxidant activities remained statistically unchanged, fluctuating between 88 and 115% in all samples. Possibly, the yet unknown anthocyanin degradation products exhibited antioxidant properties similar to those of their precursors.[31] These findings were in accordance with previous results, suggesting the formation of antioxidant polymeric compounds from anthocyanin degradation.[32]

As expected, observed color changes mostly followed those of anthocyanin concentrations. For instance, color changes were negligible during storage of the dried and liquid maqui samples at 4 °C in the dark (Table 3), in accordance with their high anthocyanin stability described above. However, color changes were notable when liquid preparations were stored at 20 °C in the dark and under illumination. Increases in lightness L^*, redness a^*, and yellowness b^* and in chromaticity C^* (only for illuminated samples) over time proved discoloration of the red color at 20 °C, resulting in a light brownish hue. Additionally, significant increases were observed in hue angles $h°$, also confirming the visually observed brownish color of the samples. In accordance with the literature, color changes were

reported to result from both anthocyanin degradation, and the formation of higher molecular-weight brown pigments.[33,34]

Storage Stability of Individual Anthocyanins. On the basis of the half-life ($t_{1/2}$) values listed in Table 2, degradation kinetics of total delphinidins and cyanidins were unexpectedly similar under a given storage condition ($p < 0.05$), in contrast to their thermal stability. Their $t_{1/2}$ values amounted to 158 days on average when stored at 4 °C in the dark, whereas $t_{1/2}$ values were 5 and 12 times smaller when samples were stored at 20 °C in the dark and under illumination, respectively (Table 2). Half-lives of total cyanidins and delphinidins of total matrix preparations were similar to those of matrix-depleted samples. Therefore, matrix constituents such as sugars and acids were suggested to have no or only a marginal impact on anthocyanin stability. These findings are in agreement with previous results,[30] in which the type of anthocyanidin core and the purity of the extract were found to have only insignificant effects when compared with anthocyanin storage stability of standard solutions to that of matrix-depleted anthocyanin extracts derived from grape pomace, purple corn, and black rice.[30] Conversely, stabilizing effects of polymeric matrix compounds, such as pectin, or even destabilizing effects (addition of citrate) on the storage stability of anthocyanins derived from black currant, strawberry, elderberry, and black carrot have been shown in other papers.[35−37]

In contrast to the marginal influence of the anthocyanidin core type and matrix constituents, the number of glycosyl moieties directly attached to the anthocyanidin apparently played a major role for stability. Irrespective of the anthocyanidin type, anthocyanins carrying two glycosylated hydroxyl functions (3,5-*O*- or 3,7-*O*-) showed $t_{1/2}$ values about 2.4 times higher (e.g., $t_{1/2}$ = ca. 15−18 days, 20 °C, illuminated) than those with only one glycosylated hydroxyl function (e.g., $t_{1/2}$ = ca. 7 days, 20 °C, illuminated) as shown in Table 2. The stability of diglycosylated maqui anthocyanins was further enhanced to $t_{1/2}$ values of ca. 38−45 and 211−301 days by light exclusion (20 °C) and cooled storage at 4 °C, respectively. A similarly improved stability was also observed for the monoglycosylated anthocyanins (Table 2), although being consistently ca. 2.5−2.6-fold less stable than their diglycosylated counterparts at a given storage condition ($t_{1/2}$ = ca. 16−18 days, 20 °C, dark; $t_{1/2}$ = ca. 88−100 days, 4 °C, dark).

In agreement with our findings, Robinson et al. reported enhanced stability of 3,5-*O*-diglucosylated anthocyanins when comparing to the corresponding 3-*O*-monoglucosides.[38] More recently, a faster degradation of 3-*O*-glucosides than of the 3,5-*O*-diglucosides has been determined during storage of a pomegranate juice (pH 3.8), which like maqui contained both 3-*O*- and 3,5-*O*-diglucosides.[39] Because sugar substitution at C5 lowers the nucleophilicity of the aromatic C6 and C8 positions of the anthocyanins, 3,5-*O*-diglycosylated anthocyanins have been suggested to be less prone to an electrophilic attack than those carrying a nonglycosylated A-ring.[40] Therefore, 3,5-*O*-diglycosylated anthocyanins were assumed to be more stable, particularly, because electrophilic attacks are followed by the fission of the C ring and subsequent chalcone

[a]Values expressed as means ± standard deviation, n = 2 (correlation coefficients, R^2, of half-life values = 0.951−0.999). Significant differences between values in the same column are indicated by different letters (P < 0.05). For assignment of compound numbers, see Figure 1.

formation, thus often representing the first step of a detrimental breakdown cascade.[8,41,42] To provide deeper insights into the differing stabilities of 3-*O*- and 3,5-*O*-glycosylated anthocyanins, a series of heating experiments was conducted.

Influence of Glycosylation on Thermal Anthocyanin Stability in Acidic Solutions. To further investigate the influence of sugar substitution at the 3-*O* and 3,5-*O* positions on anthocyanin degradation, total matrix, matrix-depleted, and matrix-free preparations as well as aqueous solutions of standards (3-*O*-glucosides and 3,5-*O*-diglucosides of cyanidin and delphinidin) were heated for 7 h at 85 °C at pH 2.2 and 3.6, respectively, the latter representing the genuine maqui pH.

During thermal treatment at pH 3.6, degradation patterns of differently glycosylated cyanidin and delphinidin derivatives were similar to those observed during the storage experiment at 20 °C. For instance, in total matrix preparations, delphinidin 3-*O*-glucoside (**6**) and 3-*O*-sambubioside (**5**) were about 1.5 times less stable ($t_{1/2}$ = 2.6 h) than their respective diglycosylated derivatives, that is, delphinidin 3,5-*O*-diglucoside (**2**) and 3-*O*-sambubioside-5-*O*-glucoside (**1**; $t_{1/2}$ = 3.8 h). By analogy, the cyanidin 3-*O*-glucoside (**8**; $t_{1/2}$ = 6.1 h) was more rapidly degraded than its diglycosylated derivatives cyanidin 3,5-*O*-diglucoside (**4**) and 3-*O*-sambubioside-5-*O*-diglucoside (**3**; $t_{1/2}$ = 10.4 h).

A similar stability behavior was observed when the matrix-depleted maqui extract, the extract being devoid of the plant matrix (matrix-free), and the individual anthocyanin standards were examined at pH 3.6. Thus, 3-*O*-glycosylated anthocyanins were considered significantly less stable at pH 3.6 than their 3,5-*O*-diglycosylated counterparts, irrespective of the food matrix.

Whereas diglycosylated anthocyanins were more heat-stable than 3-*O*-glycosylated ones at pH 3.6, a reversed behavior was encountered at pH 2.2 as expressed by the respective half-life values (Table 4) and anthocyanin degradation kinetics exemplified by the total matrix preparation and the individual standard solutions (Figure 3). These observations were consistent in all samples independent of their matrix composition including the standard solutions. Similar to pH

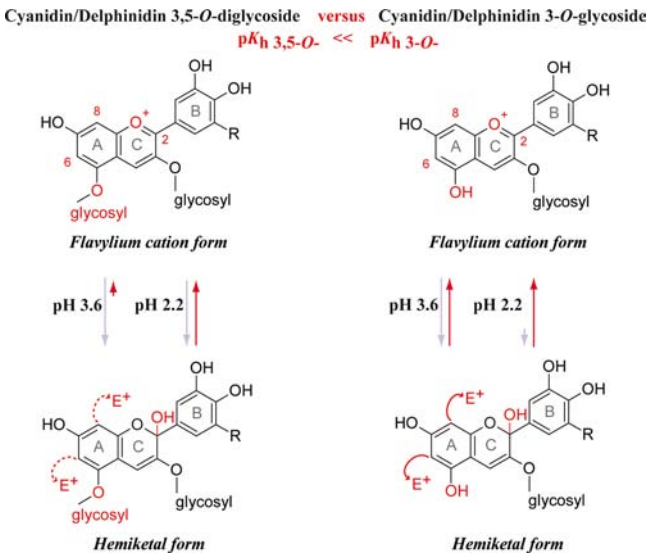

Figure 3. Anthocyanin retention (%) of delphinidin and cyanidin 3,5-*O*-diglycosides versus 3-*O*-monoglycosides of total matrix maqui preparations and standard solutions upon thermal treatment at 85 °C at pH 3.6 and 2.2. Lowered reactivity of electrophilic attacks at positions C6 and C8 of the hemiketal form is indicated by a dotted electron arrow. Enhanced reactivity is indicated by solid electron arrows. R = OH (delphinidin) / R = H (cyanidin).

3.6, stabilities of maqui anthocyanins were shown to be widely independent of matrix constituents. To provide a mechanistic hypothesis for these observations, the general pH-dependent behavior of anthocyanins in aqueous solution is briefly summarized.

Although depending slightly on the anthocyanidin type and the number of aromatic substituents, anthocyanins mainly exist in their stable flavylium cation form at low pH (pH < ∼1.0) (Figure 4). When the pH is increased (pH > ∼2), a nucleophilic attack of water at the C2 position of the pyrylium ring (C ring) leads to the formation of colorless hemiketals and, after ring fission, to chalcones. The pH-dependent behavior of

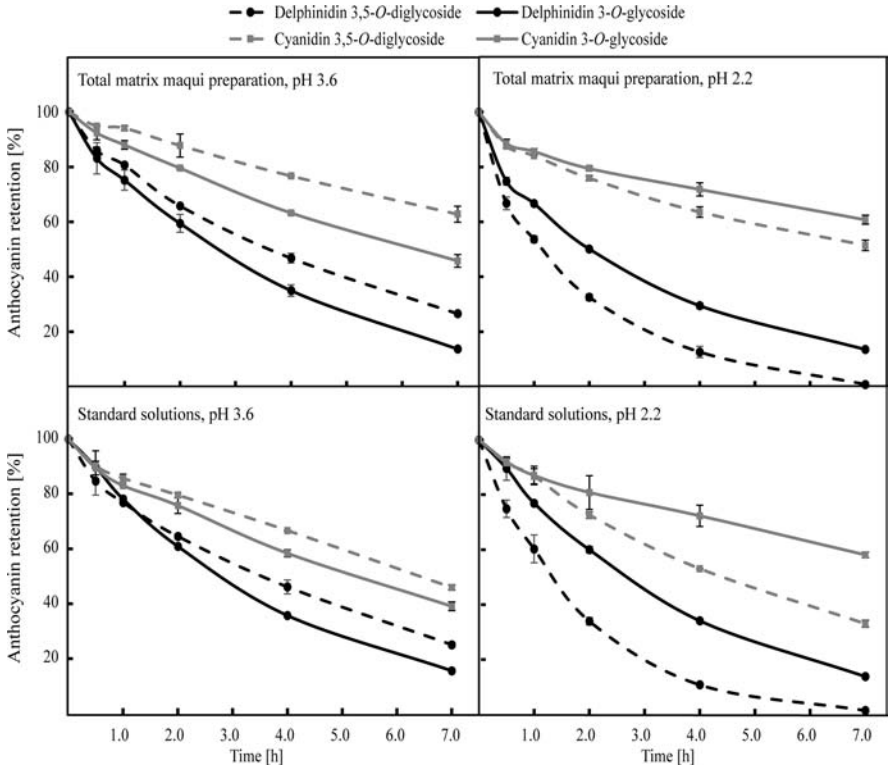

Figure 4. Impact of the hydration equilibrium constant pK_h of 3,5-*O*-diglycosylated and 3-*O*-monoglycosylated delphinidin and cyanidin on the formation of flavylium cation and colorless hemiketal species at pH 3.6 and 2.2. Lowered reactivity of electrophilic attack at positions C6 and C8 of the hemiketal form is indicated by a dotted electron arrow. Enhanced reactivity is indicated by solid electron arrows. R = OH (delphinidin)/H (cyanidin).

3-*O*-glycosylated and 3,5-*O*-diglycosylated anthocyanins was well described previously by their overall hydration equilibrium constants pK_h ranging from 1.79 to 3.02.[43−46] The pK_h constants indicate at which pH a 50:50 equilibrium of flavylium cation:hemiketal is reached. Lower hydration constants were found for 3,5-*O*-diglycosides [pK_h = 1.79 (delphinidin)[43]−2.23 (cyanidin)[44,46]] than for 3-*O*-glycosides [pK_h = 2.36 (delphinidin)[43]−3.02 (cyanidin)[45,46]], because glycosylation at position 5-*O*- decreases the electron density of the pyrylium ring, thus favoring the nucleophilic attack by water.[43,47] Therefore, in our experiments at pH 2.2, a major proportion [>50% (delphinidin); ≫50% (cyanidin)] of 3-*O*-monoglycosylated anthocyanins prevailed as flavylium cation, whereas a substantial proportion of 3,5-*O*-diglycosylated anthocyanins occurred in the hemiketal/chalcone form [≫ 50% (delphinidin); ∼50% (cyanidin)]. At pH 3.6, both 3-*O*- and particularly 3,5-*O*-glycosylated anthocyanins were present as hemiketal/chalcone to a large extent. As a result, 3,5-*O*-diglycosides should be considered more stable in their hemiketal/chalcon forms than as flavylium cation according to our findings. These hemiketals/chalcones might be particularly stable due to their glycosyl moiety at position 5-*O*- (or 7-*O*-), making the positions C6 and C8 less susceptible to electrophilic attacks as described above. Hence, the 3,5-*O*-diglycosylated anthocyanins were more stable at pH 3.6 than at pH 2.2. These findings are in agreement with previous studies,[39,40,46,48] even stating that 3,5-*O*-diglucosides of cyanidin, peonidin, delphinidin, petunidin, and malvidin show their optimum stability at pH 5.0,[48] that is, when completely occurring in their hemiketal and chalcone forms. In contrast, our results indicate that 3-*O*-glycosides were more stable as flavylium cation than as hemiketal/chalcone. The two hydroxyl groups of the anthocyanidin A-ring exert a strong positive mesomeric effect (+M), favoring electrophilic attacks at positions C6 and C8 positions (ortho/para). Thus, the stability of 3-*O*-glycosylated anthocyanins was lower at pH 3.6 than at pH 2.2 (Figure 4). Similar findings of an enhanced color stability of 3-*O*-glycosylated anthocyanins in more acidic media have been reported previously.[49,50]

In conclusion, because both 3-*O*-mono- and 3,5-*O*-diglycosylated anthocyanins occur approximately at a ratio of 50:50 in maqui samples, the resulting effect of their differing stability on total anthocyanin retention was almost outweighed when heating experiments at pH 2.2 ($t_{1/2}$ = 3.4−3.9 h) and at pH 3.6 ($t_{1/2}$ = 2.6−3.8 h) were compared (Table 4).

Influence of the Anthocyanidin Core on Thermal Anthocyanin Stability in Acidic Solutions. Besides the pH-dependent stability differences among differently glycosylated anthocyanins, the anthocyanin core type played a greater role during thermal treatment than during the above-described storage experiment, where identically glycosylated cyanidins and delphinidins were found to be similarly stable (Table 2). During thermal treatment at both pH 2.2 and 3.6, cyanidin derivatives were significantly more stable than the respective delphinidin derivatives (Table 4). This relationship was consistently found, irrespective of the level of food matrix present in the different maqui samples. The lower thermal stability of delphinidins as compared to cyanidins might be related to an increasing susceptibility to oxidation with increasing number of hydroxyl functions at the B ring.[48] Such oxidative degradation of the phenolic B ring might be the predominant degradation reaction at elevated temperatures,

DOI: 10.1021/acs.jafc.5b03471
J. Agric. Food Chem. 2015, 63, 8705−8714

being only of marginal importance at lower temperatures (4 and 20 °C).

In conclusion, two important features of maqui anthocyanins should be considered when maqui preparations are applied as coloring foodstuff or colorants. First, the major proportion of total anthocyanins is represented by delphinidin derivatives (73−82%), which per se were shown to be less stable when heated than the concomitant cyanidin derivatives (18−27% of total anthocyanins). Thus, heat exposure should be minimized during maqui processing. Second, although the pH value had an enormous effect on the differing stability of 3-*O*- and 3,5-*O*-glycosylated anthocyanins, their co-occurrence at a ratio of ∼50:50 may equally allow the application of maqui preparations between pH 2.2 and 3.6. According to our results, they might be preferably used in acidic chilled or frozen food products, such as sorbet and ice cream, because their storage stability was found to be best at low temperatures. In addition, application of maqui anthocyanins to food with low water activity, such as confectionery and cake glaze, may be a suitable option, as their stability was substantially increased after they were converted into powders. Nevertheless, maqui preparations should also be suitable for coloring beverages, fruit purees, fruit spreads, and jams when stored in the dark and, if possible, at cool temperatures.

averaged structural information on the mass distribution and shape of noncrystalline molecules in a nondestructive manner. Hence, it has been utilized widely for the nanoscale structural analysis of soft matters such as polymer gels, emulsions, and liquid crystals.[26,27] The characteristic merits of SAXS also can be used effectively for the structural analysis of proteins such as gliadins, not only of the gliadin molecule itself but also of aggregated forms at high concentrations. Some results have been reported to date concerning the structural analysis on gluten proteins by SAXS. Matsushita et al. investigated the structure of high-molecular-weight glutenin subunits by SAXS in 1-propanol/acetic acid/water mixed solutions in the concentration range of 1.0−10.0 mg/mL.[28] From Guinier and cross-section Guinier plots, they determined glutenins to have a rod-like shape. In another SAXS study, Thomson et al.[20,29] examined α-, γ-, and ω-gliadins and high-molecular-weight glutenin subunits in the alcohol/water mixed solutions in the concentration range of about 1−10 mg/mL and analyzed their SAXS profiles by means of Guinier and cross-section Guinier plots. They found that gliadins in this concentration range have a prolate ellipsoid shape with a length of 15−20 nm and a diameter of about 3.5 nm. These results shed light on the nanostructure of gluten protein molecules in dilute solution, but their structure in the alcohol-containing water is not necessarily the same as that in alcohol-free water. In addition, the structure of gluten proteins at high concentrations is still unclear. In this study, we focus on gliadins extracted with distilled water and report on the SAXS analysis of their structures over a wide range of concentrations in aqueous solutions. We also correlate the results of an electrophoresis measurement and a sedimentation velocity experiment with the nanostructure of gliadins established by SAXS.

MATERIALS AND METHODS

Materials. Gliadins used in this study were prepared by the following procedure, the details of which are described in our previous paper.[25] Dough was prepared by mixing and kneading 100 g of wheat flour (Super King, Nisshin Flour Milling, Inc.; 13.8% protein, 0.42% ash, 14% water) with 67 mL of 0.5 M NaCl in a mixer (KN-200, Taisho Denki, Tokyo, Japan) for 20 min and then repeatedly kneaded with one hand in 500 mL of distilled water for 15 min at 15 °C. The first and second wash solutions were discarded. The third to sixth wash solutions were collected and centrifuged at 18000g for 10 min at 20 °C. After NaCl was added to the supernatant to adjust its concentration to 0.5 M, the precipitated gliadins were collected by centrifugation at 18000g for 20 min at 20 °C, suspended in 300 mL of distilled water, dialyzed five times against 3 L of distilled water for 8 h at 4 °C, and finally freeze-dried. The gliadins were also extracted from wheat flour with 70% ethanol according to the method described by Tatham and Shewry.[13] Protein was assayed with an RC.DC protein assay kit from Bio-Rad Laboratories (Hercules, CA, USA).

Sedimentation Velocity Experiments. Sedimentation velocity experiments on 0.02 wt % gliadins dissolved in distilled water were performed with an Optima XL-I unit (Beckman Coulter, Inc., Brea, CA, USA) using an An50Ti rotor at 20 °C. Charcoal-filled Epon double-sector cells were used with the reference sectors filled with distilled water. All data were acquired without time intervals between successive scans. The sedimentation coefficient distribution function, $c(s)$, was obtained by use of the SEDFIT program.[30,31] The partial specific volume of gliadin was set to 0.73, which is the default value.[32] A protocol for calculating the molecular weight corresponding to each peak using the Svedberg equation was implemented in SEDFIT, where a common frictional ratio, f/f_0, was assumed for all molecular species.

Electrophoretic Analysis of Gliadin Preparations. Gliadins extracted into distilled water or 70% ethanol were subjected to 2D-PAGE isoelectric focusing and SDS-PAGE.[33,34] Gliadins were treated with a 2D cleanup kit (GE Healthcare UK Ltd.) and applied to 7 cm Ready-Strip IPG Strips (Bio-Rad Laboratories). Isoelectric focusing was performed using a Protean IEF Cell (Bio-Rad Laboratories). The strips were then subjected to SDS-PAGE and stained with Coomassie Brilliant Blue R-250.

SAXS Experiments. The SAXS experiments were carried out at the beamline BL-10C of Photon Factory, a synchrotron radiation facility of Institute of Materials Structure Science, High Energy Accelerator Research Organization (KEK). Dilute solution samples were measured in a 1 mm thick aluminum cell with 20 μm thick quartz windows. Viscous hydrated solids were measured in a 1 mm thick PTFE sandwich cell with windows of 7.5 μm thick Kapton films (TORAY-DuPont). The X-ray wavelength was 0.1488 nm, and the observed range of scattering vector (denoted q) was 0.06−2.5 nm^{-1} as calibrated with silver behenate. The scattered beam was detected with two-dimensional area detectors. The typical X-ray exposure time was 300 s. Samples were used for SAXS measurements at least 4 days after preparation. Measured two-dimensional data were converted into one-dimensional scattering profiles followed by the standard procedure of data correction for cell and background scatterings, transmission, and beam intensity.

Cross-Linking Experiments. Gliadin solutions were incubated with and without 5 mM 3,3′-dithiobis(sulfosuccinimidyl propionate) (DTSSP) from Dojindo (Tokyo Japan) at 25 °C for 60 min. After the addition of *N*-ethylmaleimide (20 mM), the solutions were incubated for 10 min at room temperature and then freeze-dried. Laemmli's SDS sample buffer[31] without reducing reagent was added to the gliadin solutions, which were then boiled for 5 min. The suspension was centrifuged at 10000g for 40 min at room temperature. The supernatant (30 μg of protein) was subjected to SDS-PAGE under nonreducing conditions. Another part of the supernatant (100 μg protein) was subjected to SDS-PAGE with a native PAGE 3−12% gel (Invitrogen, Carlsbad, CA, USA) and electrophoresed with 50 mM bis(2-hydroxyethyl)amino-tris(hydroxymethyl)methane-HCl (Bis-Tris HCl) buffer having a pH of 6.8, including 50 mM tricine and 0.1% SDS as running buffer, under nonreducing conditions. After electrophoresis, the sample lane was cut from the gel and immersed in Laemmli's SDS sample buffer with 5% 2-mercaptoethanol for 30 min and subjected to SDS-PAGE under reducing conditions. The proteins were stained with Coomassie Brilliant Blue R-250.

RESULTS AND DISCUSSION

Gliadin-Rich Proteins Extracted from NaCl-Containing Dough with Distilled Water. Previously we found that gliadins can be extracted with distilled water from dough prepared with wheat flour and a 0.51 M NaCl aqueous solution.[25] When the dough made with 100 g of wheat flour was washed with 500 mL of distilled water, starch, albumins, and globulins were eluted from the dough into the first and second wash solutions. However, gliadins were eluted into the third to sixth wash solutions when the NaCl content in the dough became <5 mg/100 g dough.[25] In the present study, we also observed abundant gliadins in the third and subsequent extracts by repeating the extraction procedure. The amount of extracted proteins (2.63 g from 100 g of flour) was almost the same as that of gliadins extracted with 70% ethanol (2.53 g from 100 g of flour). 2D-PAGE shows that the composition of proteins extracted by our procedure was almost the same as that of gliadins extracted with 70% ethanol except for a minor spot at 75 kDa in distilled water, which is probably due to contamination (Figure 1).

The gliadins obtained by our procedure can be dissolved in distilled water to yield a transparent solution at concentrations of ≤10 wt %, whereas they form gel-like hydrated solids at concentrations of ≥15 wt %. Gliadins resting in a plastic tube at ≥40 wt % do not flow even when the tube is turned upside down, which suggests the presence of a network structure.

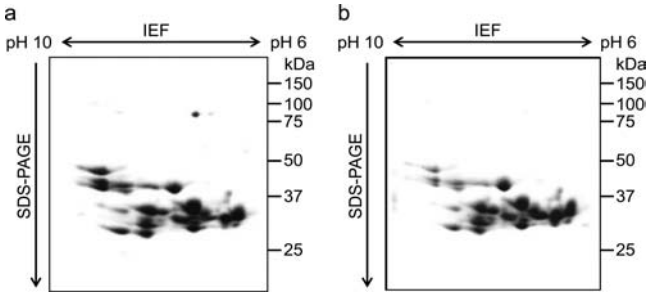

Figure 1. Two-dimensional PAGE of gliadin fractions: (a) gliadin extracted from dough made with wheat flour and a 0.5 M NaCl solution by washing with distilled water; (b) gliadin extracted from wheat flour with 70% ethanol.

Molecular Weight Distribution. A sedimentation velocity analysis revealed the molecular weight distribution of the gliadin in 0.02% distilled water solutions as shown in Figure 2. The distribution curve shows the largest peak at a sedimentation coefficient corresponding to a molecular weight of 25.7 kDa, indicating that most of the extracted gliadins are in the monomeric form. A small, broad peak found at a molecular weight of ca. 103 kDa suggests that associated gliadins exist in addition to monomeric gliadins.

Nanostructure of Gliadins in Distilled Water As Revealed by SAXS. Figure 3 shows SAXS profiles of gliadins in distilled water at various concentrations: (a) solution components of low-concentration samples (≤10 wt %) and (b) high-concentration gel-like solid samples (≥15 wt %). Because of a large difference in the physical state between the two regions, we discuss each concentration region separately.

In the low-concentration region, the scattering intensity increases gradually with increasing concentration. A small shoulder appears near $q = 0.3$ nm^{-1} at 0.5 wt % and gradually shifts to 0.13 nm^{-1} at 10 wt % with increasing intensity. The emergence of this shoulder indicates the presence of considerable interparticle interference. Therefore, it is required that the behavior of isolated gliadin molecules be observed at concentrations <0.5 wt %. We first attempted to evaluate the size of gliadin molecules at concentrations <0.5 wt % by means of a Guinier analysis of the scattering curves. However, the results could not be well fitted with a simple Guinier relationship, $I = A \exp(-R_g^2 q^2/3)$, indicating a polydispersity of scatterers. Thus, we employed the three-component Guinier equation expressed as $I(q) = A_1 \exp(-R_{g1}^2 q^2/3) + A_2 \exp(-R_{g2}^2 q^2/3) + A_3 \exp(-R_{g3}^2 q^2/3)$. As shown in Figure 4a, the scattering profiles are well fitted by this equation; the fitting parameters are summarized in Table 1. The value of the smallest radius of gyration ranges from 4.10 to 6.46 nm. Thomson et al.[20] previously reported R_g values of 3.55, 3.80, and 4.60 nm for α-, γ-, and ω-gliadins in 70% ethanol, respectively. By comparing their data with the R_{g1} values of our data, we can say that gliadin molecules are present as monomers in the 0.025 wt % solution, although some molecules with larger R_g values such as gliadin dimers and oligomers are also present. The presence of these larger molecules is consistent with the results of the sedimentation velocity experiment described above. The values of R_{g1} increase slightly with increasing concentration, indicating that some gliadin monomers associate to dimers at higher concentrations. The parameters R_{g2} and R_{g3} in Table 1 are much larger than that of gliadin monomers and likely correspond to larger aggregates or a high-molecular-weight contaminant (e.g., glutenin).

When anisotropic particles, such as those possessing a rod-like shape, are examined by SAXS, a cross-section Guinier plot may be used to obtain information about the cross-section size. Figure 4b shows the cross-section Guinier plots for the three low-concentration samples. The scattering curves in the low-q region were well fitted with straight lines obeying the relationship $qI(q) = A \exp(-R_c^2 q^2/2)$. The resulting values for the cross-sectional radius of gyration, R_c, are listed in Table 2. These values are more than twice as large as those reported by Thomson et al.[20] The reason for this is due in part to the aggregation of gliadin molecules, but also may be ascribable to structural differences between gliadins in ethanol and in water. The rod length, Λ, obtained from the equation, $R_g^2 - R_c^2 = \Lambda^2/12$, is also presented in Table 2. The radii and length become larger at 0.5 wt %. However, we think that this change is due to an increasing number of aggregated gliadins rather than to a change of molecular size itself; accordingly, the average value of each dimension becomes larger.

In the 1−10 wt % concentration range, Guinier plots do not yield reasonable physical values due to interparticle interference. Instead, the correlation length, L, was obtained from the Bragg equation, $L = 2\pi/q_s$, where q_s is the magnitude of the scattering vector of the shoulder appearing above 1 wt %. As shown in Table 3, L increases with increasing concentration,

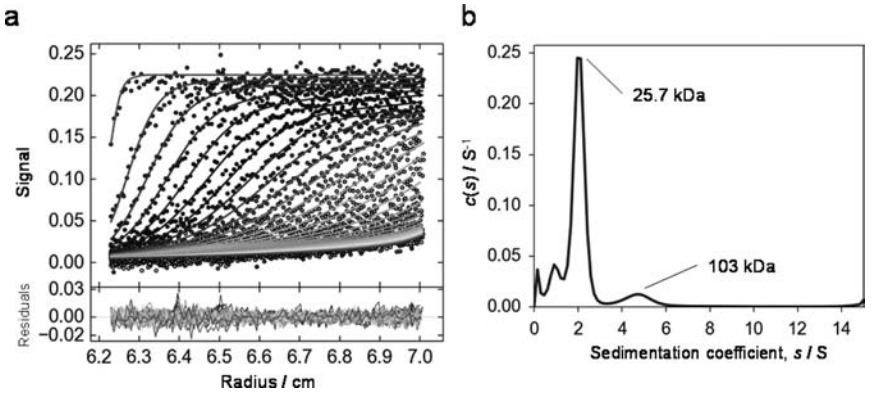

Figure 2. Sedimentation velocity analysis of 0.02 wt % gliadins in distilled water: (a) raw data of sedimentation velocity scans with best-fit curves based on the distribution shown in (b); (b) concentration distribution versus the sedimentation coefficient, s, obtained from the fitting result of (a) (the peaks appearing at 2.06 and 4.76 S correspond to molecular weights of 25.7 and 103 kDa, respectively).

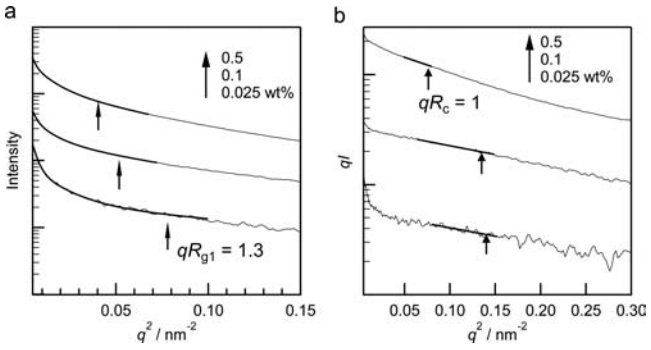

Figure 4. (a) Guinier plots for dilute aqueous solutions of gliadins. Scattering profiles are fitted by a three-component Guinier equation (thick lines). Small arrows indicate the points at which the relationship $qR_{g1} = 1.3$ holds (R_{g1}: smallest radius of gyration). (b) Cross-section Guinier plots for aqueous solutions of gliadins. Small arrows indicate the points at which the relationship $qR_c = 1$ holds (R_c: cross-sectional radius of gyration).

Table 1. Radius of Gyration Calculated by Fitting with a Three-Component Guinier Equation

concn (wt %)	R_{g1} (nm)	R_{g2} (nm)	R_{g3} (nm)
0.025	4.10 ± 0.74	13.7 ± 1.1	33.2 ± 0.9
0.1	5.68 ± 0.20	16.4 ± 0.7	34.9 ± 1.2
0.5	6.46 ± 0.05	16.7 ± 0.1	40.0 ± 0.3

Table 2. Radius of Gyration (R_{g1}), Cross-Sectional Radius of Gyration (R_c), and Rod Length (Λ) Calculated from Guinier and Cross-Section Guinier Plots

concn (wt %)	R_{g1} (nm)	R_c (nm)	Λ (nm)
0.025	4.10 ± 0.74	2.65 ± 0.05	10.8 ± 3.4
0.1	5.68 ± 0.20	2.71 ± 0.01	17.3 ± 0.8
0.5	6.46 ± 0.05	3.59 ± 0.003	18.6 ± 0.2

which suggests that the size of aggregated gliadins becomes larger and that the distance between aggregates increases under these conditions.

At concentrations above 15 wt %, gliadins are insoluble in water and form gel-like hydrated solids. The SAXS profiles in this region are displayed in Figure 3b. The scattering curve at 15 wt % is similar to that of the 10 wt % solution. This fact indicates that the nanostructures of these two samples are similar despite the difference in water solubility. It is suggested that only intermolecular association occurs in this concentration range without a significant change in the size and distribution of aggregated gliadins. As concentration increases further, the shoulder near 0.13 nm^{-1} diminishes while the upturn in the low-q region grows and a broad shoulder appears in the higher q region. When the low-q changes are examined closely, the 0.13 nm^{-1} shoulder shifts to the even lower q and finally protrudes out of the observable q range. This transition suggests the evolving formation of gliadin aggregates. As concentration increases, isolated gliadin aggregates coalesce to form larger aggregates, resulting in the growth of the low-q upturn. Concurrently, the density fluctuation inside the aggregates also increases, which is manifested as a broad peak in the high-q region. The characteristic peaks observed in this region are summarized in Table 3. When the concentration reaches 70 wt %, the broad shoulder is almost unrecognizable, and only the upturn in the low-q region remains.

Table 3. Peak positions (q_s) and Correlation Lengths (L) from Bragg's Law

Association of Gliadins Examined by Cross-Linking Experiments. The SAXS analysis described above indicates noncovalent association of gliadins in solution. Thus, cross-linking experiments were performed with DTSSP, a cross-linking molecule that is cleavable with reducing agents after cross-linking, to examine the specificity of association between gliadin molecules. By applying nonreducing SDS-PAGE to the soluble fraction after centrifugation, it is found that the gliadin bands disappear almost entirely from the DTSSP-treated samples at concentrations of ≥8 wt % (Figure 5a). This

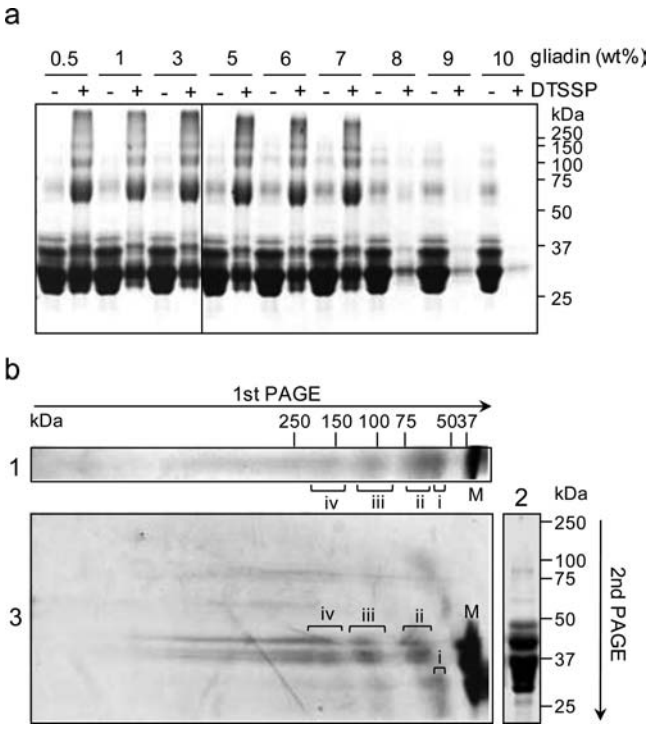

Figure 5. Detection of the self-assembled gliadins in solution. Gliadin solutions (0.5, 1, 3, 5, 6, 7, 8, 9, 10 wt % in distilled H_2O) were incubated at 25 °C for 60 min in the absence (−) or presence of 5 mM DTSSP (+). After NEM treatment for 10 min, the solutions were boiled in Laemmli's SDS sample buffer without reducing agent. The soluble fraction was separated by centrifugation and then subjected to nonreducing SDS-PAGE (a). Gliadins from the 7 wt % solution treated with DTSSP were separated by nonreducing SDS-PAGE on 3−12% gel with Bis-Tris running buffer (b, panel 1), reducing SDS-PAGE (b, panel 2), and 2D-PAGE of nonreducing SDS-PAGE on 3−12% gel with Bis-Tris running buffer and reducing SDS-PAGE (b, panel 3). Proteins were stained with Coomassie Brilliant Blue.

suggests that gliadins cross-link to form large polymers at ≥8 wt % and become insoluble in an SDS solution. Monomeric and cross-linked gliadins are detected in the supernatant for 0.5−7 wt % samples treated with DTSSP. The most prominent bands of cross-linked gliadins correspond to 50−75 kDa in size. Gliadins at 7 wt % were analyzed by 2D-PAGE (Figure 5b). By the first nonreducing SDS-PAGE with bis-Tris-HCl buffer containing tricine, cross-linked gliadins were detected as ∼55−65 kDa (i), ∼65−75 kDa (ii), ∼90−120 kDa (iii), ∼140−180 kDa (iv) in addition to the large smear bands (Figure 5b, panel 1). The cross-linked gliadins were cleaved to monomers in the gel after the first nonreducing SDS-PAGE by reduction with 2-mercaptoethanol and separated by the second reducing SDS-PAGE. The cross-linked ∼55−65 kDa bands on the first nonreducing SDS-PAGE are composed of 30−35 kDa gliadins, which have been shown to be a mixture of α- and γ-gliadins by N-terminal amino acid sequence analysis.[25] The 65−75 kDa bands on the first nonreducing SDS-PAGE are composed of ∼37 and ∼40 kDa gliadins, which have been identified as α-gliadins.[25] These results suggest that some gliadins associate specifically in distilled water. The cross-linked ∼55−65 and ∼65−75 kDa bands are predicted to be dimers on the basis of their sizes. In addition, the 90−120 and 140−180 kDa smear bands on the first nonreducing SDS-PAGE were shown to be composed of 30−35, ∼37, and ∼40 kDa gliadins, suggesting that these bands originate from the formation of oligomers.

Plausible Model for Gliadin Association in Distilled Water. From the above results, we present the model shown in Figure 6 for the nanoscale structures of gliadins in distilled water. In the 0.025−0.5 wt % concentration range, gliadins are dispersed in water as isolated particles (Figure 6a), because no shoulder peak is found due to interparticle interference. Most of the particles are monomers, but small populations of dimers and oligomers are also present on the basis of the results of the sedimentation velocity measurement and the SAXS analyses. Thomson et al. reported that α-, γ-, and ω-gliadins in 70% ethanol show R_g values of 3.55, 3.80, and 4.60 nm, respectively, at concentrations <1 wt %. However, the R_g values obtained in this study are slightly larger. This suggests that the structures of gliadin monomers in distilled water differ somewhat from those in ethanol. The cross-sectional radius of gyration and the length of gliadins at the lowest concentration are 2.50 and 11.3 nm, respectively, which is consistent with a rod-like shape. Although some gliadins form dimers and oligomers at the lowest concentration, the shape of the associated particles is rod-like. The frictional ratio of 1.52 obtained from the sedimentation velocity analysis supports the rod-like model.

In the 0.5−10 wt % concentration range, gliadin molecules self-assemble and form small soluble aggregates (Figure 6b) by noncovalent interactions. Interparticle interference is apparent, but gliadins remain soluble in distilled water up to at least 10 wt %. This interparticle interference arises from the electrostatic repulsion between small aggregates, which is confirmed by the fact that the SAXS shoulder peak vanishes when NaCl is added to the solution at a concentration of 10 mM (data not shown). The correlation length among small aggregates gradually increases with increasing concentration, indicating that the interparticle distance is becoming greater.

At 15−20 wt %, gliadins become insoluble in distilled water, but the SAXS profiles are similar to those at 10 wt % concentration (Figure 6c). We suggest that the small aggregates become more closely spaced and come in contact with one another to form a continuous network without significantly changing aggregation structure. In the SAXS profiles at concentrations >30 wt %, the shoulder near 0.13 nm^{-1} disappears and broad peaks at 0.3−1.0 nm^{-1} become noticeable. In this region, the space is almost entirely filled with gliadin molecules and a definite correlation length disappears; however, density fluctuation is present inside the aggregated gliadins (Figure 6d). Above 50 wt % (Figure 6e), the broad peaks diminish and only the upturn in the low-q region remains, suggesting that gliadins form large aggregates of >100 nm in size.

Finally the influence of NaCl on the structure of associated gliadins should be noted. In this study, NaCl acts as a water solubilizer of gliadins in dough, but it is well-known that NaCl also causes the precipitation of gliadin in aqueous solutions.[25] Because these two observations appear to be contradictory, it is of interest to clarify the effect of NaCl addition on the state of association of gluten proteins in relation to the intermolecular interactions among them. This issue will be addressed in our next paper, which will focus on the difference between the association states of highly concentrated gliadins hydrated with distilled water and the precipitates produced by NaCl addition.

In conclusion, SAXS analyses have clarified the state of association of gliadins in distilled water over a wide concentration range. At low concentrations (≤0.5 wt %), gliadin molecules are present as monomers plus a minor amount of dimers and oligomers. At greater concentrations,

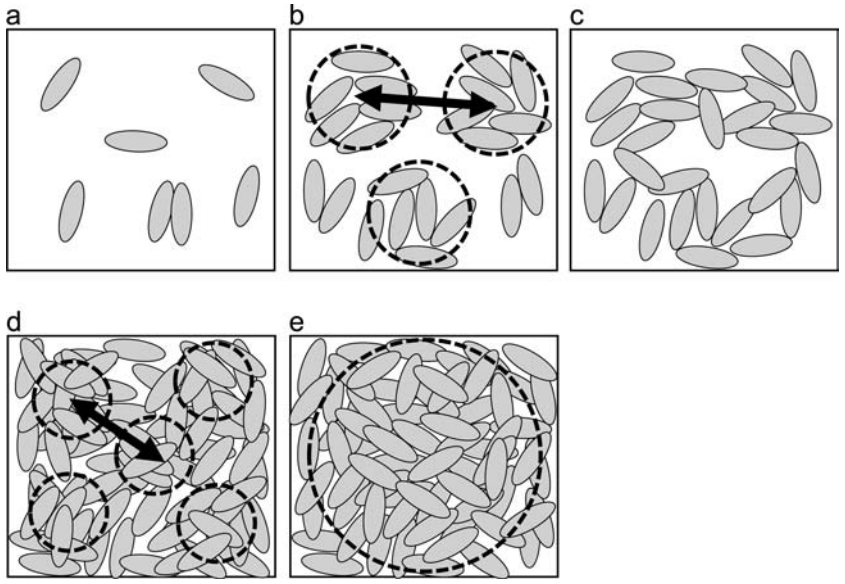

Figure 6. Schematic illustrations of the nanostructures of gliadin assemblies in distilled water over a wide range of concentrations. (a) Gliadins are present as water-soluble isolated monomers and a few dimers at 0.025−0.5 wt %. (b) Gliadin molecules self-assemble to form small aggregates (dashed line circles) at 0.5−10 wt %. The distance between the aggregates is estimated to be ∼40 nm. (c) Gliadins begin to form continuous networks at 15−20 wt %. (d) Gliadin molecules fill the space, but condensed regions due to density fluctuation (dashed line circles) appear above 30 wt %. The distance between dense domains is estimated to be 14 nm at 40 wt %. (e) Above 50 wt % the density fluctuation almost vanishes, but large aggregates over 100 nm in size are formed.

gliadin molecules begin to coalesce (0.5−1 wt %) and then show interparticle interference among aggregated molecules (1−10 wt %). In these regions, the correlation length increases as concentration increases, because the aggregates grow in size and their mutual separation distance increases. Cross-linking experiments indicate that association of gliadin molecules at 0.5−10 wt % occurs in a specific manner. Both dimers and oligomers are formed, but some are preferentially composed only of α-gliadins instead of a mixture of α- and γ-gliadins. Gliadin becomes insoluble at 15 wt %, although the SAXS profile does not show a significant difference from that at 10 wt %. This is due to the formation of a continuous network of aggregated gliadins. As concentration increases further, the space is filled with gliadin molecules while a density fluctuation remains at ∼40 wt %, and finally the large aggregates are formed.

about 50% that of apigenin in an in situ rat intestinal single-pass perfusion model. This result is consistent with the observation that oral bioavailability of luteolin (30.4%) from a *Flos chrysanthemi* extract was significantly lower than that of apigenin (51.1%).[13] Unfortunately, reports on diglucuronidation of luteolin in situ or in vivo are rare. This process might be a feasible method for eliminating luteolin and thereby controlling its bioavailability.

Given that over 35% of all drugs are metabolized via phase II enzymes, especially UGTs,[14] bioavailability of herbal medicines may be altered when their metabolism is modulated by coadministered drugs, namely, drug−drug interactions. The UGT inhibitor is also involved in many drug−drug interactions, and studies have reported that metabolic clearance of these drugs is inhibited by glucuronidation, such as zidovudine−fluconazole interactions. Fluconazole increases exposure to zidovudine, a typical probe for UGT2B7, to 74% owing to its inhibition of zidovudine glucuronidation.[15] Thus, the effect of the UGT inhibitor on luteolin remains to be elucidated.

In this study, we sought to systematically elucidate the time course of glucuronidation of luteolin by 12 human UDP-glucuronosyltransferases and to further determine the absorption characteristics and metabolic processes of luteolin using an in situ mice intestinal single-pass perfusion model. Specifically, probenecid, a nonspecific UGT inhibitor,[16] was used in this perfusion model. Our findings help us to understand first-pass metabolism and disposition of luteolin via enteric recycling.

MATERIALS AND METHODS

Chemicals and Reagents. Luteolin, propiophenone, probenecid, formic acid (HPLC grade), and testosterone were purchased from Aladdin Reagent Company (Shanghai, China). Mebubarbital was purchased from Center of Reagent, Southern Medical University (Guangzhou, China). Uridine diphosphoglucuronic acid (UDPGA), D-saccharic-1,4-lactone monohydrate, HEPES, and Hanks' balanced salt (powder form) were purchased from Sigma-Aldrich (St. Louis, MO, USA). Alamethicin was purchased from Hui Cheng Biological Technology Co. Ltd. (Shanghai, China). Human-expressed UGT isoforms (UGTs 1A1, 1A3, 1A4, 1A6, 1A7, 1A8, 1A9, 1A10, 2B4, 2B7, 2B15, and 2B17) were also obtained from BD Gentest Corp. (Woburn, MA, USA). Acetonitrile and methanol were typically analytical grade or better (≥99%, HPLC grade), and were used as received.

Animals. Use of all animals was approved by the Ethics Committee of Southern Medical University. Male KM mice weighing between 22 and 25 g were obtained from Laboratory Animal Centre of Southern Medical University. Mice were then fasted overnight with free access to water before the experiment.

Determination of the Concentration Conversion Factor (*K* Values). To quantify each metabolite, the concentration conversion factor (*K*), which represents the ratio between the molar extinction coefficient of each glucuronide and luteolin, was determined following a previously described method.[17] To calculate the *K* values, each metabolite was separated via HPLC, collected for blow drying in nitrogen, dissolved in 50 mM potassium phosphate (KPi, pH 7.4), and then divided into two parts, one of which was analyzed directly and the other was analyzed after being hydrolyzed with β-glucuronidase (100 units/mL) at 37 °C for 2 h. To determine the conjugation position of diG's, the metabolites were separated, collected, and then hydrolyzed with β-glucuronidase for 1 h to ensure that the diG's were not completely hydrolyzed and could produce two related G's. Retention time of the metabolites is a determinant for the conjugation position of luteolin (e.g., 3′,7-diG and 4′,7-diG). Relationships between the peak areas of the metabolites before hydrolysis and the peak areas of aglycones after hydrolysis were used to establish the *K* values needed to quantify the amounts of luteolin conjugates.

Luteolin Glucuronidation by 12 Expressed Human UGTs and the Time-Dependent Experiment. Magnesium chloride (0.88 mM), D-saccharic-1,4-lactone monohydrate (4.4 mM), alamethicin (0.022 mg/mL), 12 UGT isoforms (UGTs 1A1, 1A3, 1A4, 1A6, 1A7, 1A8, 1A9, 1A10, 2B4, 2B7, 2B15, and 2B17, with final concentrations between 0.0528 and 0.264 mg/mL), 1 mM luteolin (final concentration of 10 μM) in 50 mM KPi (pH 7.4), and uridine 5′-diphospho-glucuronic acid (UDPGA, 3.5 mM, added last) were mixed together. The UGT reaction was incubated for different times at 37 °C in a shaking water bath (50 rpm). About 60 μL of iced methanol containing 0.5 μg/mL propiophenone was added to stop the reaction. All experiments were performed in triplicate. The samples were centrifuged at 13 000 rpm at 4 °C for 30 min, and the supernatant was then analyzed by ultra-performance liquid chromatography (UPLC).

To elucidate the characteristics of luteolin glucuronidation by expressed human UGTs, the incubation time was set to 6 h. For the time-dependence metabolism experiment, the UGT reaction system was incubated at 37 °C for 30, 60, 90, and 120 min for each UGT isoform. The rest of the procedures were performed as described above. To identify the product of diglucuronides, the incubation time of luteolin in 12 UGTs was prolonged to 6 h, and the metabolite amount was calculated as nmol per mg.

Animal Surgery. Male KM mice weighing between 22 and 25 g were obtained from the Laboratory Animal Centre of Southern Medical University. The mice were fasted overnight with free access to water before commencing the experiment. The experiments were done with permission from the Ethics Committee of Southern Medical University. Mice were then anesthetized with an i.p. injection of 0.026 mL/g mebubarbital (0.3% m/v). The intestinal surgical procedures were essentially the same as those described in previous publications with minor modifications.[18] We perfused two segments of the intestine (small intestine and colon), with each segment 8−10 cm long. Blood circulation to the liver and intestine was not disrupted in this perfusion model. During the surgery, the body temperature was maintained at 37 °C using a heating lamp. The inlet cannulate was flushed with luteolin in HBSS, which was kept warm at 37 °C by a circulating water bath.

Perfusion Experiments. First, mice gall bladders were obtained, and two segments of mice intestine (small intestine and colon) were simultaneously perfused with a perfusate containing 10 and 20 μM luteolin using an infusion pump at a flow rate of 10 mL/h. To terminate substrate hydrolysis of the enzymes contained in the perfused sample, 0.5 mL of acetonitrile (a stop solution) was added into the receiving container prior to sample collection. Addition of acetonitrile prevented hydrolysis of luteolin and stabilized it. After 15 min of washout period, the samples were collected every 30 min. At the end of the experiment, we measured the intestinal length as described in a previous study[18] About 200 μL of acetonitrile containing 10 μg/mL propiophenone was added into 400 μL of perfusate. The samples were analyzed via UPLC after centrifugation at 13000 rpm at 4 °C for 30 min.

Effect of UGT Inhibitor on Luteolin Glucuronidation in Situ. Probenecid is a potent nonspecific inhibitor of UGTs that significantly inhibits luteolin glucuronidation in vivo. Animal surgery was done as described above. Probenecid was added at 0.5 and 1 mM to perfusate containing 10 and 20 μM luteolin, respectively. About 200 μL of 10 μg/mL propiophenone was added to 400 μL of perfusate. The samples were centrifuged at 13 000 rpm at 4 °C for 30 min, and 10 μL of the supernatant was then analyzed via UPLC. The method for analyzing luteolin was the same as previously described.[10]

UPLC Analysis of Luteolin and Its Glucuronide. The validated method for analyzing luteolin was as follows: system, Waters Acquity UPLC; column, HSS T3, 1.8 μm, 2.1 mm × 100 mm; mobile phase A, 100% acetonitrile; mobile phase B, 0.1% (v/v) formic acid; flow rate, 0.25 mL/min; gradient 0−5 min, 95−45% B, 5−5.5 min, 45−30% B, 5.5−7 min, 30−95% B; wavelength, 340 nm for luteolin and the respective glucuronides, 254 nm for propiophenone; and injection volume, 10 μL. The tested linear response range was 0.3125−40 μM (for a total of eight concentrations) for luteolin. Analytical methods for each test compound were validated for inter-day and intra-day variation using six samples at three concentrations (40, 10, and 2 μM).

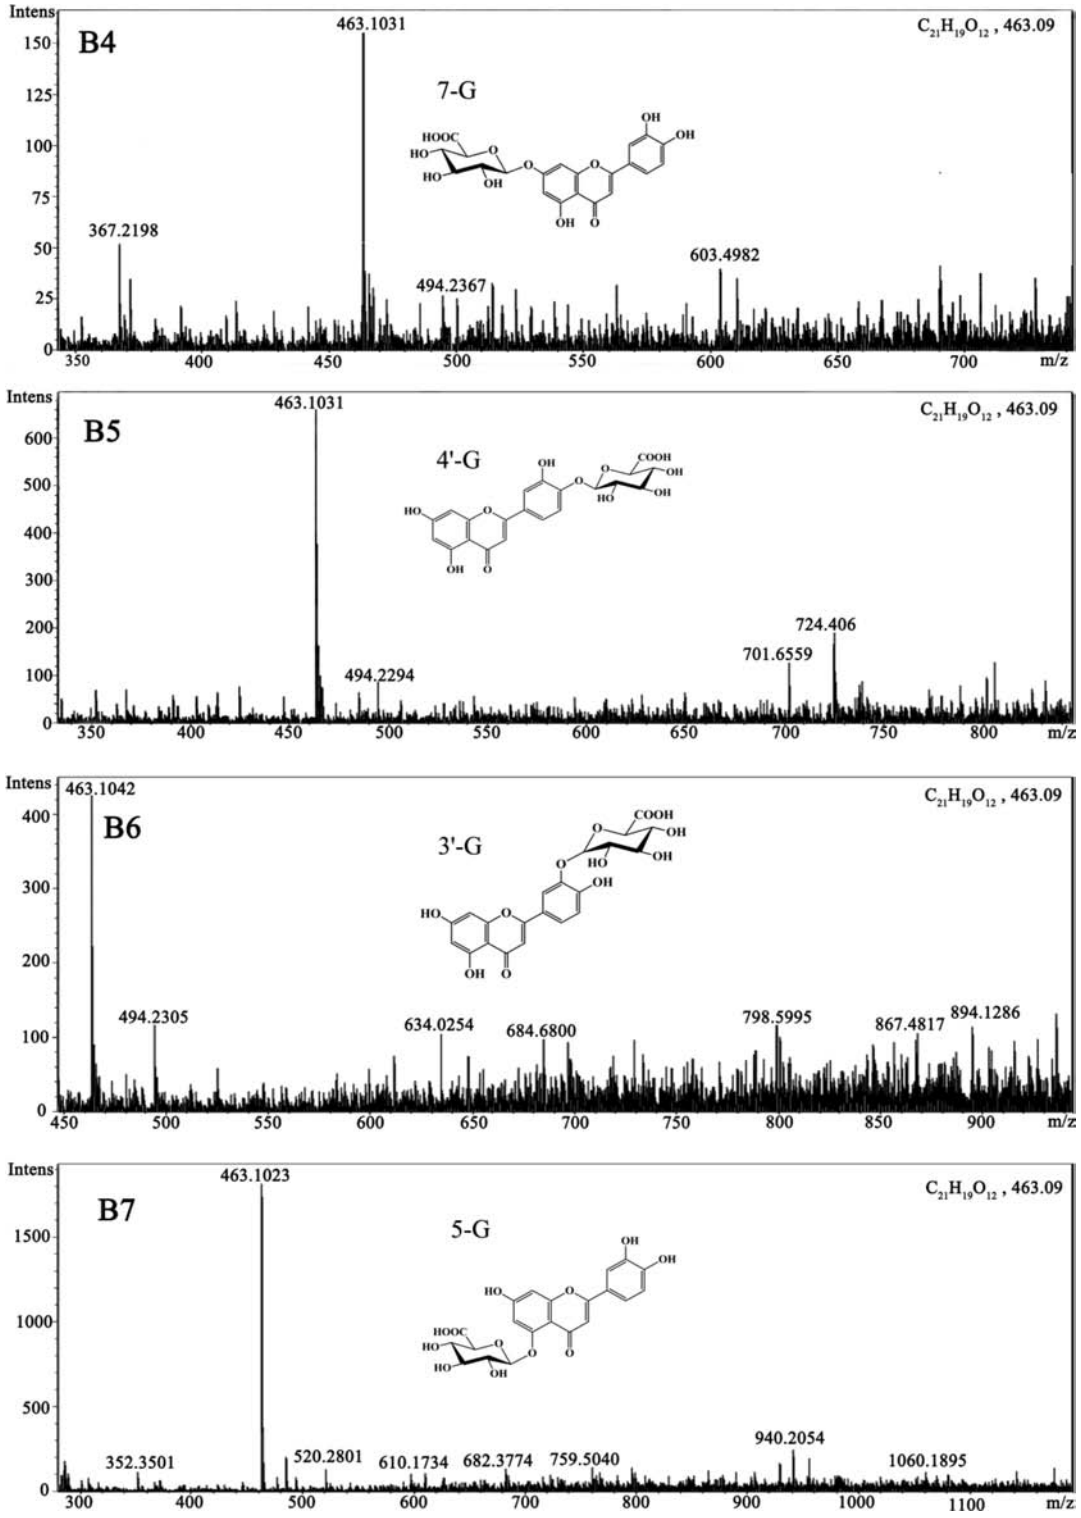

Figure 1. UPLC and HRMS profiles of luteolin and its metabolites, and the structures of the metabolites. UPLC was used to separate and quantify luteolin and its metabolites in the experimental samples generated from incubation with human UGTs and perfusate. (A1) Chromatograms of luteolin and its metabolites in sample incubated with human UGTs. (A2) Chromatograms of luteolin and its metabolites in perfusate. (B1−B3) HRMS scan of diglucuronides (diG's). (B4−B7) HRMS scans of monoglucuronides.

Precision and accuracy for luteolin were in an acceptable range (<10%). Propiophenone was used as internal standard since it is stable in the experimental system and its retention time is 6.4 min, which would not affect luteolin and its metabolites.

Determination of Luteolin Glucuronide Structure by HRMS. A quadrupole time-of-flight tandem mass spectrometer (Bruker, USA) fitted with an Agilent HPLC was used to determine the molecular weight of luteolin and its metabolites. The main working parameters for the mass spectrometers were set as follows: capillary voltage, 3.8 kV; dry heater temperature, 180 °C; nebulizer voltage, 1.0 bar; dry gas flow rate, 6.0 L/min; column, Agilent ZORBAX SB-C18, 5 μm, 4.6 mm × 150 mm; mobile phase B, 100% acetonitrile; mobile phase A, 100% aqueous buffer (0.1% formic acid); flow rate, 1 mL/min; gradient, 0 to 5 min, 92% to 80% A, 5 to 10 min, 80% to 40% A, 10 to

DOI: 10.1021/acs.jafc.5b02827
J. Agric. Food Chem. 2015, 63, 8722−8733

16.5 min, 40% to 0%, 16.5 to 17 min, 0% to 90% A, 17 to 20 min, 90% A to 90% A; wavelength, 340 nm; and injection volume, 50 μL. The MS/MS spectra were produced by collision-induced dissociation of the selected precursor ions. Data were analyzed using Bruker Daltonics software (version 4.0, Bruker, USA).

Kinetic Analysis. Permeability of luiteolin was represented by P^*_{eff}, which was obtained as described before. Likewise, the amount of luteolin absorbed (M_{ab}), amount of conjugated luteolin excreted into the intestinal lumen (M_{gut}), and the percentage absorbed and percentage metabolized values were calculated as described before.

M_{ab} and M_{gut} were expressed as eqs 1 and 2:

$$M_{ab} = Q\tau(CA_{in} - CA_{out}) \quad (1)$$

$$M_{gut} = Q\tau CA_{out} \quad (2)$$

where Q is the flow rate of perfusion (mL/min), τ is the interval time of sampling (30 min), and CA_{in} and CA_{out} are the inlet and outlet concentrations. %Absorbed and %Metabolized were calculated as

$$\%\text{Absorbed in the intestine} = \frac{M_{ab}}{M_{total}} \quad (3)$$

$$\%\text{Metabolites excreted in the intestine} = \frac{M_{gut}}{M_{total}} \quad (4)$$

where M_{total} is the total amount of compound perfused over the first 30 min period.

Rates of metabolism of human UDP-glucuronosyltransferases were expressed as the amount of metabolites formed (nmol/min/mg), as shown in eq 5:

$$V_G = \frac{P_G/P_{IS}}{C_{protein}a_G t} = \frac{P_G/P_{IS}}{C_{protein}Kat} \quad (5)$$

where V_G is the reaction rate, P_G is the peak area of the metabolites, P_{IS} is the peak area of internal standard, $C_{Protein}$ is the protein concentration of UGTs, K is the concentration conversion factor, a is the slope of the standard curve of luteolin, and t is the incubation time for the reaction system.

Statistical Analysis. One-way ANOVA with or without Tukey–Kramer multiple comparison and Student's t test were used to evaluate differences between control and treatment. Differences were considered significant if p values were less than 0.05 or 0.01.

RESULTS

Determination of Luteolin and Its Glucuronides via UPLC and HRMS. The developed UPLC method used to analyze luteolin had a run time of 7 min (Figure 1-1A). The mass spectra of the four metabolites exhibited a pseudomolecule ion $[M + H]^+$ of m/z 463.1031 in the full-scan mass spectra (Figure 1-2B), indicating that they had a molecular formula of $C_{21}H_{18}O_{12}$. On the basis of previously published data, the metabolites were identified as luteolin-7-G, luteolin-4′-G, and luteolin-3′-G. Luteolin has four hydroxyl groups, and a new G was confirmed to be luteolin-5-G (Figure 1-2B7). The mass spectra of the three metabolites showed a pseudomolecular ion $[M + H]^+$ of m/z 639.1232, whose molecular formula was $C_{27}H_{26}O_{18}$. This result suggested that the metabolites were diG's (Figure 1-1 B). Although luteolin-3′,4′-diG has previously been reported,[10] the other two metabolites have not. The two diG's were collected, and each was hydrolyzed into its respective monoglucuronides. One of the diG's was hydrolyzed to 7-G and 4′-G, and the other was hydrolyzed to 7-G and 3′-G. The retention time of the hydrolyzed G's is a determinant for the conjugation position of luteolin diG's. We confirmed the structure of the two new diG's to be luteolin-4′,7-diG and luteolin-3′,7-diG based on retention time and theory of UGT fingerprinting.[5,10,17]

Determination of the Concentration Conversion Factor of Each Luteolin Glucuronide. The extracted samples containing only luteolin glucuronides were hydrolyzed using β-glucuronidase to their corresponding G's and luteolin. The concentration conversion factors of 7-G, 4′-G, 3′-G, and 5-G were 3.63 ± 0.13, 6.36 ± 0.35, 5.74 ± 0.77, and 5.24 ± 0.31, respectively. The conversion factors of 4′,7-diG, 3′,4′-diG, and 3′,7-diG were 5.07 ± 1.14, 3.72 ± 0.12, and 2.73 ± 0.11, respectively (Table 1).

Table 1. Luteolin Metabolites in the UGT Reaction System and in Mice Perfusate

glucuronide	molecular formula	molecular mass	structural formula	K (conversion factor)
Metabolites in UGT Enymes				
7-G	$C_{21}H_{19}O_{12}$	462	luteolin-7-*O*-monoglucuronide	3.63
4′-G	$C_{21}H_{19}O_{12}$	462	luteolin-4′-*O*-monoglucuronide	6.36
3′-G	$C_{21}H_{19}O_{12}$	462	luteolin-3′-*O*-monoglucuronide	5.74
4′,7-G	$C_{27}H_{27}O_{18}$	638	luteolin-4′,7-*O*-diglucuronide	5.07
3′,4′-diG	$C_{27}H_{27}O_{18}$	638	luteolin-3′,4′-*O*-diglucuronide	3.72
3′,7-diG	$C_{27}H_{27}O_{18}$	638	luteolin-3′,7-*O*-diglucuronide	2.73
Metabolites in Mice				
7-G	$C_{21}H_{19}O_{12}$	462	luteolin-7-*O*-monoglucuronide	3.63

Metabolism of Luteolin in Human-Expressed UGTs. Twelve human-expressed UGTs were used to catalyze luteolin glucuronidation. The results showed that different glucuronides were mainly generated by different UGT isoforms. 7-G was mainly generated by UGT1A9 (the amount generated was 32.64 ± 0.99 nmol/mg), and then by UGTs 1A1, 1A3, 1A6, 1A7, 1A8, 1A10, and 2B15; UGTs 1A1, 1A3, 1A7, 1A8, 1A9, and UGT1A10 all catalyzed the formation of 4′-G, with UGT1A1 and UGT1A9 showing the highest activities (the amount was 4.11 ± 0.13 and 3.85 ± 0.11 nmol/mg); UGTs 1A1, 1A7, 1A8, 1A9, and 2B7 catalyzed the formation of 3′-G, with UGT1A9 showing the highest activity (18.71 ± 0.53 nmol/mg). All UGT isoforms catalyzed the biotransformation of luteolin to 4′,7-diG, except for UGT1A6. UGT1A1 was the most active among the 12 isoforms; 3′,4′-diG was mainly catalyzed by UGT1A7 (1.23 ± 0.10 nmol/mg), UGT1A9 (1.39 ± 0.11 nmol/mg), and UGT1A10 (1.30 ± 0.17 nmol/mg), and then by UGT1A1, UGT1A3, and UGT1A8. For conversion of luteolin to 3′,7-diG, all isoforms showed activities except UGT1A3, and UGT1A1 showed the highest activity (Figure 2A–F).

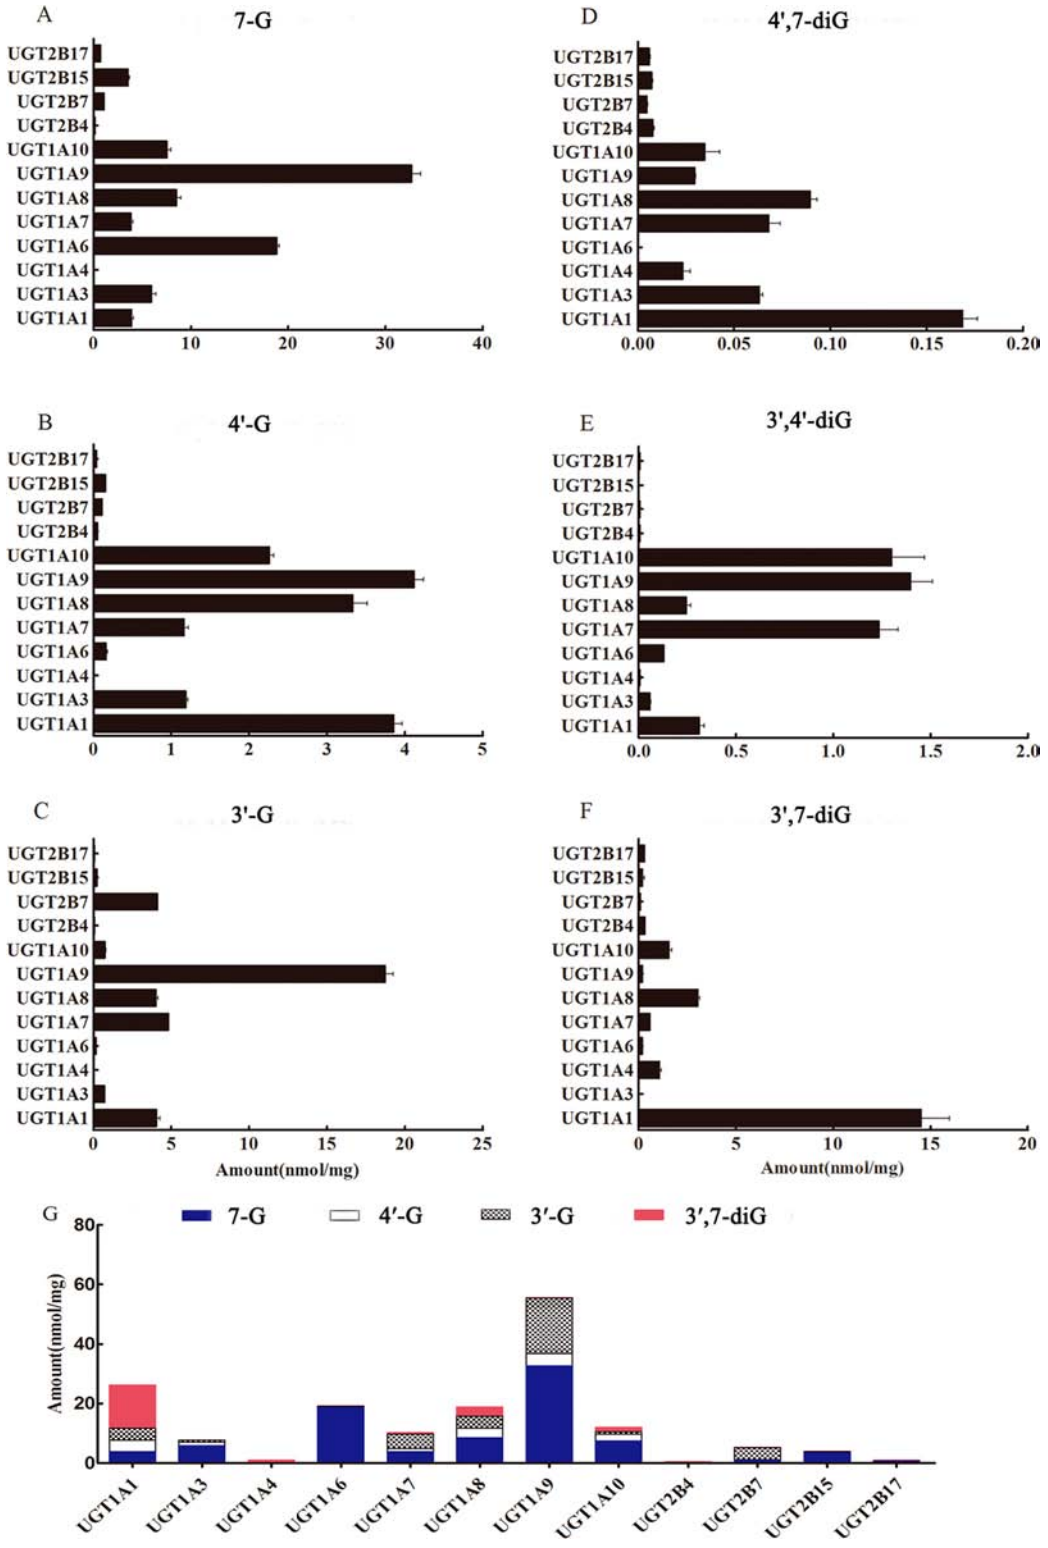

Figure 2. Luteolin glucuronidation by human-expressed UGTs. Human-expressed UGT1As and UGT2Bs were involved in glucuronation of luteolin. UGTs were incubated with luteolin for 6 h. The amount of glucuronidation was calculated as nmol/mg of protein required to obtain steady concentration. Each column represents the average of three determinations, with the error bar representing SD (n = 3).

Luteolin glucuronidation is mediated mainly by UGT1A1, UGT1A9, and UGT1A6. UGT1A1 showed the highest activity in the production of diG's, especially 3′,7-diG. UGT1A9 mainly catalyzed the production of G's, and UGT1A9 mainly catalyzed the production of 7-G (Figure 2G).

Time Dependence of Luteolin Glucuronidation via UGTs. Conducting the experiments for 30, 60, 90, and 120 min revealed that production of luteolin glucuronides was time-dependent and followed a sequential process. For UGT1A1, the amounts of luteolin-3′-G and luteolin-4′-G decreased sharply after 30 min of incubation (from 1.94 ± 0.08 to 0.84 ±

DOI: 10.1021/acs.jafc.5b02827

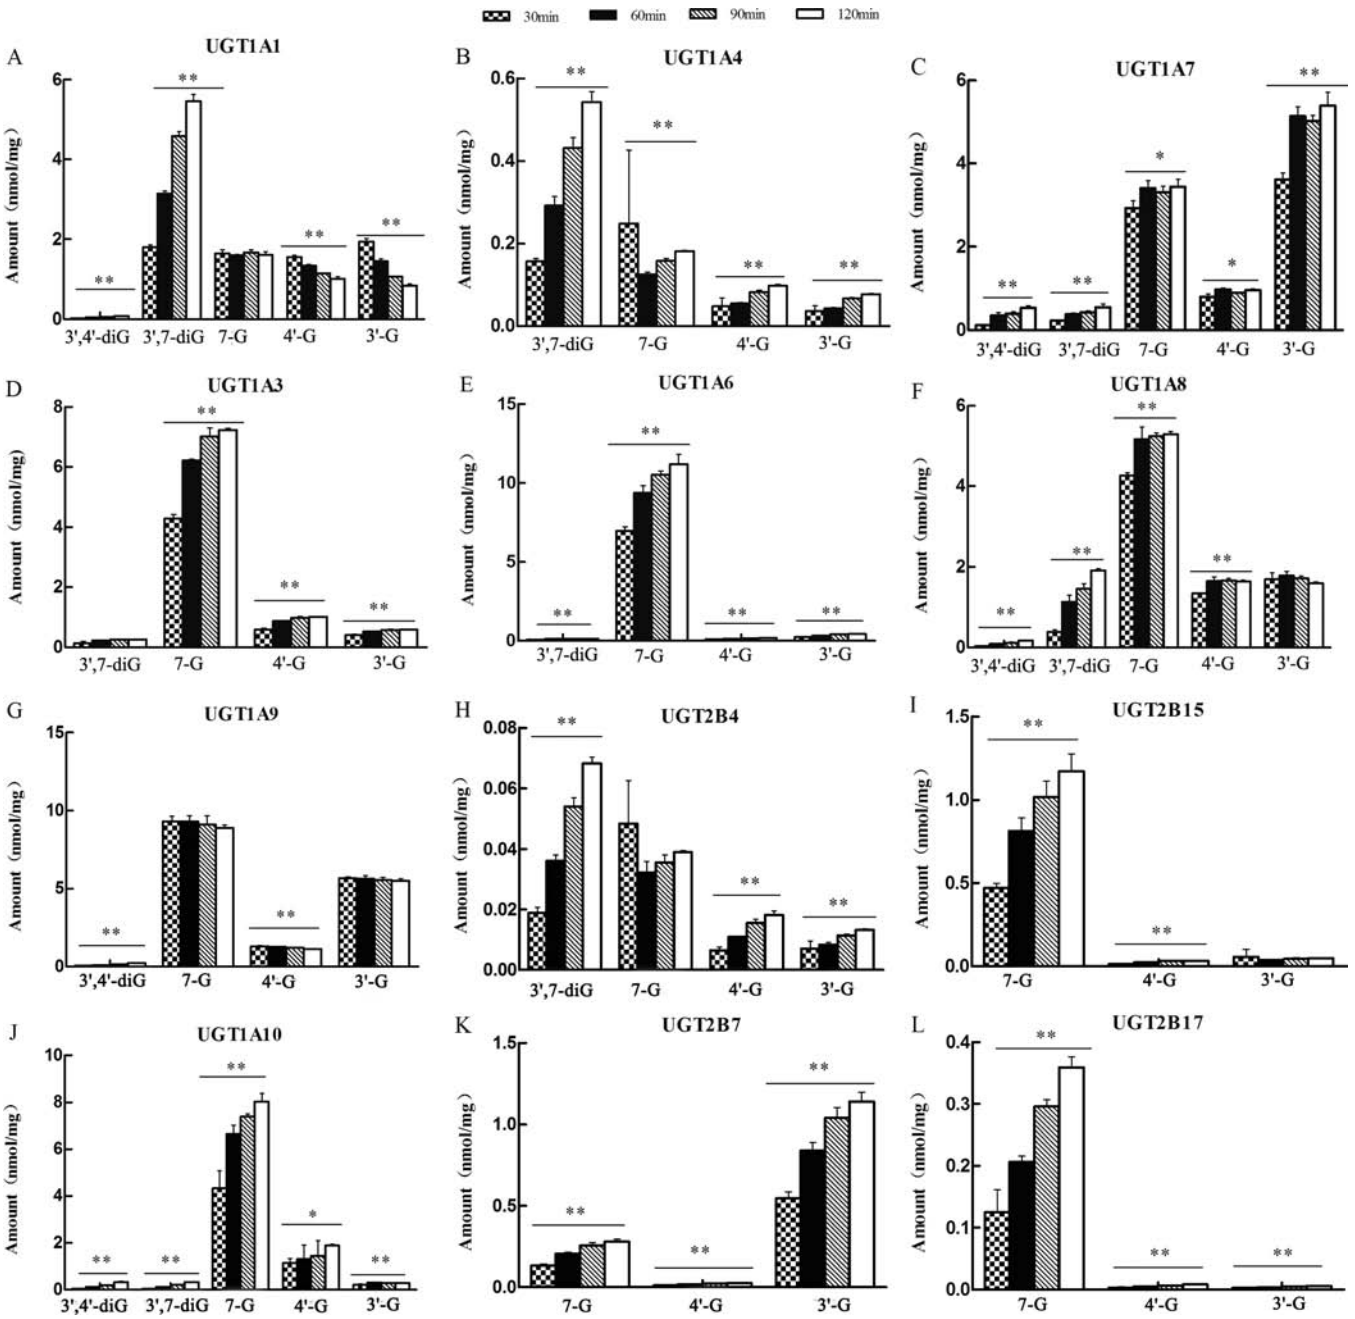

Figure 3. Time-dependent characteristics of luteolin glucuronidation. Twelve human-expressed UGT isoforms were incubated with 10 μM luteolin at 30, 60, 90, and 120 min; glucuronidation was found to be isoform-specific and time-dependent. Each column represents the average of three determinations, and the error bars indicate SD of the mean (n = 3). *p < 0.05; **p < 0.01.

0.04 nmol/mg, and from 1.55 ± 0.04 to 1.01 ± 0.05 nmol/mg, respectively). However, the amount of luteolin-7-G remained the same (1.60 ± 0.09 nmol/mg), while that of luteolin-3′,7-diG increased rapidly, and that of luteolin-3′,4′-diG increased slowly. For UGT1A9, no luteolin-3′,7-diG was produced, and the amount of 4′-G decreased very slowly. The amount of 3′,4′-diG increased slowly after 30 min of incubation, whereas those of luteolin-3′-G and luteolin-7-G had no change. In UGTs 1A3, 1A4, 1A6, 1A7, 1A8, and 1A10, the production of the three G's and diG's increased within 120 min of incubation. In UGT2B's, all the glucuronides increased slowly after 120 min of incubation time (Figure 3).

Intestinal Luteolin Absorption. The amount of luteolin absorbed was significantly different at 10 and 20 μM (p < 0.05) in the small intestine and the colon. The absorption percentage and amount were both markedly higher in the small intestine than those in the colon (amounts in small intestine and colon were 20.85 ± 3.57 and 12.29 ± 2.70 nmol at 10 μM, and 52.57 ± 5.20 and 25.26 ± 4.17 nmol at 20 μM) (Figure 4). When the nonspecific UGT inhibitor probenecid was used along with the in situ mice perfusion model at two substrate concentrations, the absorbed rate/amount of luteolin remained steady, which indicated that probenecid did not affect luteolin absorption (Figure 5).

Intestinal Metabolism of Luteolin. The excretion percentage and amount of luteolin were concentration-dependent in the small intestine and colon, but the same cannot be said for excretion rate in the colon (Figure 6). When

probenecid was added, the amount of luteolin glucuronides excreted changed that the excreted amounts of 3′,4-diG decreased from 0.37 ± 0.02 to 0.15 ± 0.06 nmol at 20 μM and from 0.07 ± 0.02 to 0.04 ± 0.02 nmol at 10 μM in the small intestine. The amount of 3′-G decreased from 1.62 ± 0.19 to 0.94 ± 0.22 nmol at 20 μM and from 0.32 ± 0.08 to 0.18 ± 0.05 nmol at 10 μM in the small intestine. Similar decreasing trends were observed for 4′-G and 3′-G. However, the amount of 5-G increased (the excreted amounts increased from 2.02 ± 0.15 to 3.94 ± 1.05 nmol at 20 μM and from 0.72 ± 0.17 to 1.66 ± 0.62 nmol at 10 μM in the small intestine), and the amount of total glucuronides did not change at all (Figure 7).

DISCUSSION

The focus of this study was on determining time-dependent production of luteolin glucuronides via UGTs and investigating the absorption and metabolism of luteolin in our in situ models of the intestines. Three new glucuronides (3′,7- and 4′,7-diG's and luteolin-5-*O*-monoglucuronide) of luteolin were identified in vitro and in vivo. The structure of the unknown diG's was speculated to be 3′,7-diG and 4′,7-diG.

This study is the first to determine the positional preference of luteolin diglucuronidation by human-expressed UGTs. The results reveal that glucuronidation of UGT1A1 is unique, compared to other UGT isoforms. UGT1A1 showed the highest activity in production of diG's, especially 3′,7-diG, among the 12 UGT isoforms (Figure 2G). Diglucuronidation at 7-OH and 3′-OH was observed to be the favored pathway, which is consistent with previous studies, including our own,

where the 7-OH group was found to be the most reactive for glucuronidation even in more complex flavones with two phenolic groups.[17−23] In addition, the 3′-OH group was found to be highly reactive.[21−23] A hypothesis that can explain the lack of a 3′ hydroxyl group in the flavonoids is that glucuronidation only occurred at position 7, and those containing this functional group also formed 3′-*O*-glucuronides and sometimes 4′-*O*-glucuronides. Thus, the presence or absence of the 3′-OH group is a major determinant of regioselectivity of glucuronidation. Moreover, the specific distribution of multiple glucuronide products (7-O, 3′-O, 4′-O) is governed by the hydroxyl group of flavonoids.[20] We also detected very small amounts of 4′,7-diG, produced mainly by UGT1A1. For 3′,4′-diG, another minor diG, UGTs 1A1, 1A7, 1A8, 1A9, and 1A10 were all identified to be the major isoforms responsible for its production. In UGT1A9, three G's and 3′,4′-diG (very small amounts) were identified. These results indicated that UGT1A9 was the most active isoform in catalyzing the formation of G's (Figure 2A). UGT1A6 was one of the top six isoforms (UGTs 1A1, 1A6, 1A7, 1A8, 1A9, and 1A10) with high activity but could only catalyze 7-G formation (Figure 2B). All UGT isoforms catalyzed the biotransformation of luteolin to 7-G and 4′-G, except UGT1A4. These findings are consistent with those of our previous study, in which luteolin metabolism was found to be mediated chiefly by UGT1A1, UGT1A9, and UGT1A6.[10]

We systematically defined the time dependence of luteolin diglucuronidation in 12 human-expressed UGT isoforms. From the beginning of the incubation up until 30 min, the amounts of 3′-G, 4′-G, 7-G, and 3′,7-diG produced in UGT1A1 were all about 2 nmol/mg. However, the outcome changed after 30 min of incubation. The amount of 7-G remained the same from 30 to 120 min. However, the amount of 3′-G decreased sharply (by 24% every 30 min), whereas that of 3′,7-diG increased rapidly (by 32% every 30 min) with time (Figure 3A). These interesting new findings suggest that UGT1A1 may conjugate to 7-OH of 3′- G to generate 3′,7-diG sequentially from 30 to 120 min (Figure 8). This process also happens during production of 3′,4′-diG (Figure 3A). The amount of 3′,7-diG produced was far greater than that of 3′,4′-diG (>80-fold higher). This surprising discovery demonstrated that UGT1A1 prefers 7-OH and 3′-OH more than 4′-OH. Furthermore, this result also revealed a sequential time-dependent process in which when the production of 7-G reaches a balance in time, UGT1A1 tends to catalyze glucuronic acid to the 3′-OH position of 7-G to produce 3′,7-diG (Figures 3A and 8). Unlike production of the three G's, which peaked within 30 min of incubation and remained stable thereafter, production of 3′,4′-diG slowly increased within 120 min of incubation. However, in UGTs 1A3, 1A4, 1A6, 1A7, 1A8, and 1A10, the amount of diG's (3′,7-diG or 3′,4′-diG) increased steadily with the three G's from the beginning to the end (0 to 120 min). In UGT2B's, the amounts of all the glucuronides slowly increased after 120 min of incubation.

Among these isoforms, UGT1A1 and UGT2B7 are well expressed in both the intestine and the liver, whereas UGT1A9 is well expressed in the liver and the kidneys[24] but either poorly expressed[14] or not expressed at all in the intestine.[25] In contrast, UGT1A8 and UGT1A10 are well expressed in the intestine but not in the liver.[24,25] Thus, we could speculate that the liver, kidney, and intestine are all major organs for luteolin glucuronidation. Moreover, since UGT1A1, UGT1A8, and

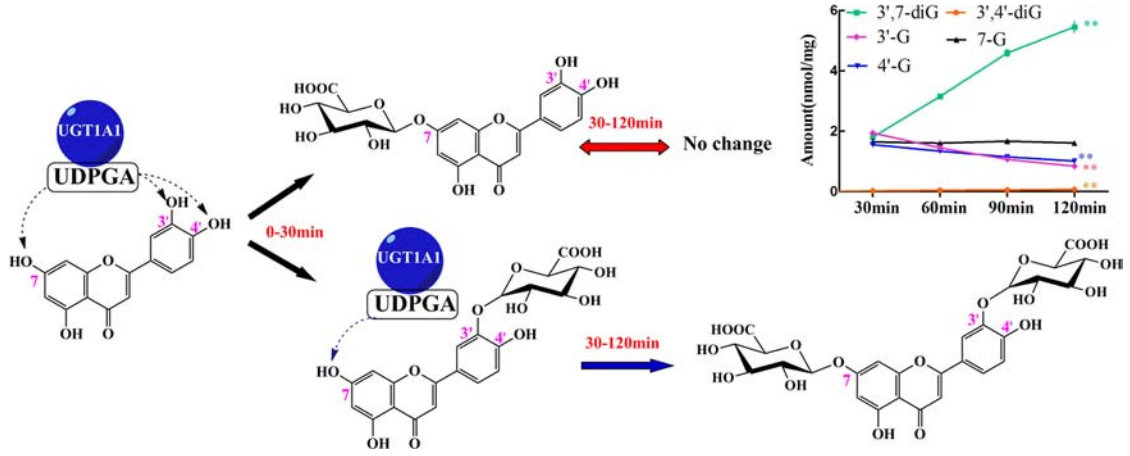

Figure 8. Glucuronic pathways for conversion of luteolin to luteolin-3′,7-*O*-diglucuronide and the sequential time-dependent process in human UGT1A1.

UGT1A10 are not expressed in the kidney, we speculate that diG's may not be produced in the kidney.

Several studies have shown that some nuclear receptors, such as constitutive androstane receptor (CAR),[26] pregnane X receptor (PXR),[27] and aryl hydrocarbon receptor (AhR), are all involved in UGT modulation. These factors play important roles in the modulation of glucuronidation of natural products through UGTs. It has been demonstrated that AhR, which can induce activities of human UGT1A1, is involved in modulation of UGT1A1 by luteolin.[28] These results suggest that more attention should be paid to drug−drug interactions by UGTs, which have brought lots of studies upon the mechanism.

In situ glucuronidation is quite different from the process that occurs in vitro because four G's and 3′,4′-diG were found

DOI: 10.1021/acs.jafc.5b02827
J. Agric. Food Chem. 2015, 63, 8722−8733

in mice perfusate in the current study. The novel 5-G was not found in UGT reaction systems. Most research on flavonoid glucuronidation in vivo and in vitro indicates that metabolism of the 5-hydroxyl group is slow or lacking, which may be due to the fact that the 5-OH group favors the formation of an intramolecular hydrogen bond with the carbonyl group at the C-4 position.[17,18,22,23] For 5-hydroxyflavone, in UGTs 1A1, 1A8, 1A9, 1A10, and 2B7, glucuronidation was apparent, but the other UGT isoforms did not metabolize it.[17,18] Thus, 5-G could be detected in mice intestine, although it was not produced in the 12 UGT isoforms.

Unexpectedly, the amount of 5-G was the highest for all glucuronides in situ. Two explanations are proposed: (1) difference in species might have caused this disparity; (2) other enzymes might be involved in the phase II reaction of luteolin. G's are the major glycoside species of mammals, and members of UGT1 and UGT2 are involved in their formation. However, the UGTs involved in the formation of most glycosides have not been identified and may belong to the UGT3A family.[29] Recently, a novel UGT2A1-mediated glucuronidation has been reported, and we speculate that 5-G may also be catalyzed by UGT2A1.[30] Further refinement of our approach is needed by incorporating additional UGT isoforms, including the newly cloned UGT3A family (UGT3A1/2) and UGT2A1.

The absorption/metabolism of luteolin was also investigated in mice. The absorption amount as well as the absorption rate of luteolin were significantly different ($p < 0.05$) at 10 and 20 μM, which were markedly higher in the small intestine than in the colon. These results are consistent with those reported previously in rat.[11] Thus, luteolin was passively absorbed in the intestine of mice, and absorption was found to be more efficient in the small intestine than in the colon (Figure 4). The amount of excreted luteolin was significant in the small intestine and colon, thereby indicating that luteolin metabolism is concentration-dependent (Figure 6). Surprisingly, probenecid (0.5 and 1 mM) had no effect on luteolin absorption (Figure 5); the excreted amounts of 7-, 4′-, 3′-G, and 3′,4′-diG decreased, but that of 5-G increased when probenecid was used. Moreover, high concentrations of probenecid resulted in production of high amounts of 5-G. The amount of total metabolites remained almost unchanged (Figure 7). We speculate that probenecid is not an inhibitor of UGT3A, since it could not inhibit 5-G production. When UGT1A and UGT2B are inhibited, a compensatory pathway may turn on for activation of other UGTs.

Many luteolin glucosides, such as luteolin 7-*O*-β-glucopyranoside and the C-glucoside homo-orientin (luteolin 6-C-glucoside),[31] are found in vivo and in vitro. Therefore, cleavage of the glucoside by gut bacteria or at the intestinal wall associated with transporters would affect the overall uptake and metabolism/metabolic fate of luteolin. We note that it is important to conduct in vivo experiments with luteolin glucosides in mice to validate these findings.

In conclusion, two novel luteolin diG's, namely 3′,7- and 4′,7-diG, were detected in UGTs for the first time, and a novel G, namely 5-G, was found in situ. UGT1A1, UGT1A6, and UGT1A9 shared the same preference for production of monoglucuronides but displayed unique preferences in diG production such that UGT1A1 preferred to generate diG. Production of 3′,7-diG exhibited time dependence based on the consumption of 3′-G and 7-G by UGT1A1. A compensatory pathway for a newly discovered UGT isoform capable of metabolizing phenols might be responsible for metabolism of luteolin in mice.

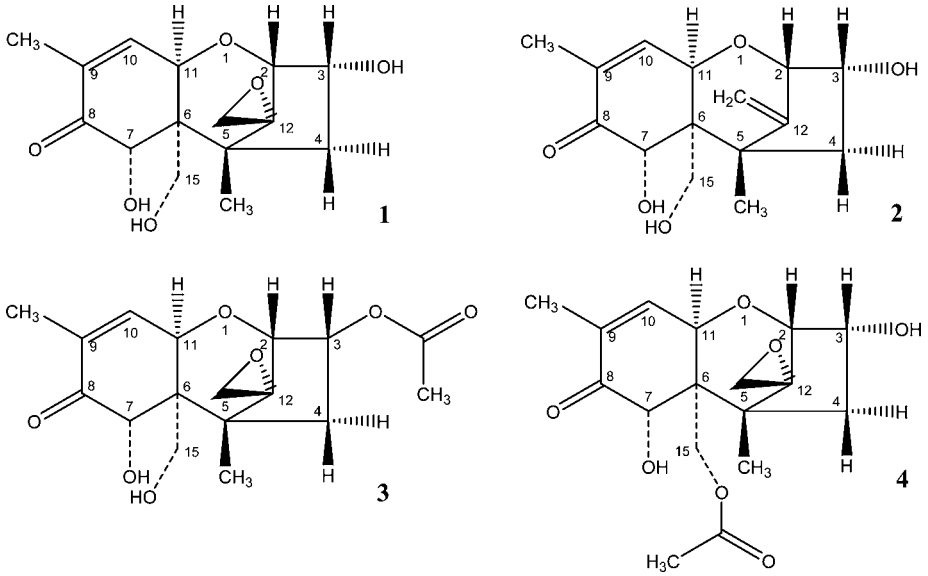

Figure 1. Structures of **1**, 3α,7α,15-trihydroxy-12,13-epoxytrichothec-9-en-8-one (deoxynivalenol or DON); **2**, a main in vivo metabolite, 3α,7α,15-trihydroxytrichothec-9,12-dien-8-one (deepoxydeoxynivalenol or DOM-1); and two acetylated forms of DON, **3**, 3α-acetoxy-7α,15-dihydroxy-12,13-epoxytrichothec-9-en-8-one (3-acetyldeoxynivalenol or 3ADON), and **4**, 15-acetoxy-3α,7α-dihydroxy-12,13-epoxytrichothec-9-en-8-one (15-acetyldeoxynivalenol or 15ADON).

expression of intestinal epithelial cell tight junction proteins.[10] It was suggested that 3ADON is less toxic than DON and, in contrast, that the toxicity of 15ADON is higher or comparable to DON. A comparison of the effect of these compounds on the interleukin-8 (IL-8) secretion in Caco-2 cells, indicating activation of the innate immune system, and intestinal transepithelial transport over Caco-2 cells has been performed.[11] The study revealed a significantly higher intestinal absorption of 15ADON compared to DON and 3ADON. Furthermore, the authors showed that the ability to induce IL-8 secretion was ranked as follows: 3ADON < DON < 15ADON. Similar effects were previously reported for the cytotoxicity on cultured human myeloid and lymphoid cell lines (K-562 and MINGL1),[12] and for DNA inhibition in Swiss mouse 3T3 fibroblasts.[13] Furthermore, one of the main in vivo metabolites, 3α,7α,15-trihydroxy-trichothec-9,12-dien-8-one (deepoxydeoxynivalenol or DOM-1), **4** (Figure 1), was included in the latter study and was found to be the least toxic compound, due to absence of the epoxide ring. In conclusion, these compounds have a distinct degree of toxicity, which can be ranked in order of increasing toxicity: DOM-1 < 3ADON < DON $\leq$ 15ADON.

A key question concerning the in vivo disposition is whether conversion of 3ADON and 15ADON to DON by in vivo hydrolysis in humans and animals would occur and posssibly imply an underestimation of the degree of contamination and the toxicity. Several in vitro studies described the hydrolysis of ADONs to DON in humans, pigs, and poultry.[14−16] In contrast, only a limited number of in vivo studies are available on the hydrolysis and metabolism of ADONs. The hydrolysis of 3ADON and 15ADON after oral administration to rats has been investigated,[17] as well as the hydrolysis and toxicokinetics of 3ADON orally administered to pigs.[18] Both studies demonstrated that an in vivo hydrolysis of ADONs to DON is possible. However, it was not reported if the hydrolysis occurs presystemically or systemically. No in vivo data are available for broiler chickens, although these animals have a high exposure to these mycotoxins because of their mainly cereal-based diet.

The goal of this study was to determine the absolute oral bioavailability, the degree of hydrolysis (differentiating between presystemic and systemic hydrolysis), and toxicokinetic characteristics of 3- and 15ADON in broiler chickens and pigs. Species selection was based, as stated above, on the high exposure of these animals to the toxins, due to their mainly cereal-based diet and the high prevalence of mycotoxins in these diets. Additionally, pigs were included because of their sensitivity to DON. Animal species susceptibility to DON can be ranked as pigs > mice > rats > poultry $\approx$ ruminants.[19] Differences in absorption, distribution, metabolism, and elimination of DON among animal species might account for this differential sensitivity.[2] Furthermore, the data from pig studies are highly relevant to humans because of the anatomical and physiological similarities of the gastrointestinal (GI) tract, liver, kidneys, and cardiovascular system in both species.[20,21]

MATERIALS AND METHODS

Chemicals, Products, and Reagents. DON, 3ADON, and 15ADON had >99% purity (Fermentek, Jerusalem, Israel). The mycotoxins were dissolved in analytical grade ethanol (EtOH) (Merck, Brussels, Belgium), yielding a stock solution of 10 mg/mL, and were used for both animal and analytical experiments. As internal standard (IS), $^{13}C_{15}$-DON (50 μg/mL) stock solution in acetonitrile was used (Romer Laboratories, Tulln, Austria). All stock solutions were stored at ≤ -15 °C. Individual working standard solutions of 10 μg/mL, used for the analytical experiments, were prepared by diluting the above stock solutions with ULC-MS grade acetonitrile (Biosolve, Valkenswaard, The Netherlands). All working standard solutions were stored at ≤ -15 °C. Standard mixture working solutions containing DON, 3ADON, and 15ADON of 1 and 0.1 μg/mL were prepared by mixing appropriate dilutions of the individual working standard solutions in ULC-MS acetonitrile and were stored at 2−8 °C. Solutions of DON in acetonitrile have been reported to be stable for 24 months at room temperature,[22] whereas the supplier reported a stability of at least 6 months at 4 °C for 100 μg/mL solutions of 3ADON and 15ADON in acetonitrile.

Water, methanol, and glacial acetic acid were of ULC-MS grade (Biosolve). Microfilters Millex GV-PVDF 0.22 μm were obtained to filter deproteinized plasma samples (Millex, Overijse, Belgium).

J. Agric. Food Chem. 2015, 63, 8734−8742

Animal Trials. Eighteen broiler chickens (Ross 308) were purchased from the Institute for Agriculture and Fisheries Research (Melle, Belgium), at the age of 3 weeks, as hatched and had an average bw ± standard deviation (SD) of 1210 ± 172 g. The broilers were randomly allocated to three groups of six animals. Water and feed were given ad libitum. The pen was climate controlled with temperatures between 21 and 25 °C, a relative humidity between 40 and 60%, and an applied light schedule similar to commercial installations (18 h light/6 h dark). After 1 week of acclimatization, the animals were treated with either DON (group 1), 3ADON (group 2), or 15ADON (group 3) by intravenous bolus injection (IV, administration in *vena basilica*) (three animals/group) or *per os* (PO, by means of gavage in the crop) (three animals/group) in a two-way crossover design. The administered doses were based on the European Union (EU) maximum guidance level of 5 mg DON/kg poultry feed.[23] Given the average feed consumption of 4-week-old broiler chickens was 100 g feed/kg bw/day, 500 μg DON/kg bw was administered. For the ADONs, an equimolar dose of 571 μg/kg bw was administered. The calculated volume of stock solution (10 mg/mL in EtOH) was diluted with saline (0.9% NaCl) (VWR, Leuven, Belgium) to a volume of 0.5 mL (IV) or 1 mL (PO). After oral administration of the toxins, 1 mL of tap water was administered to flush the gavage syringe. A washout period of 3 days was maintained between treatments. Feed was withheld for 12 h before administration and until 3 h post administration (PA). Blood (0.5−1 mL) was sampled from the leg vein by venipuncture at 0 min (before administration) and at 5, 10, 20, 30, 45, 60, 90, 120, and 240 min PA. Blood samples were centrifuged (2851*g*, 10 min, 4 °C), and plasma was stored at ≤ −15 °C until analysis.

For the pig study, nine clinically healthy male pigs (11 weeks of age, 28.6 ± 2.8 kg bw) were individually housed with feed and water ad libitum. Natural lighting was provided, the enclosure was climate controlled to keep the temperature between 20 and 24 °C and the relative humidity between 20 and 40%. After a 1 week acclimatization period, the animals were treated with either DON (n = 3), 3ADON (n = 3), or 15ADON (n = 3) by IV bolus injection using a surgically placed jugular catheter as previously described[24] or PO (by means of gavage in the stomach) in a crossover design. For this design pigs were randomly divided into groups of three pigs. Each group received four treatments (two IV and two PO treatments), resulting in a crossover for each compound in six animals. A washout period of 24 h was maintained between treatments. Twelve hours before administration of the mycotoxins, the animals were fasted until 4 h PA. The administered doses were calculated as for the broiler chicken trial. The EU maximum guidance level in pig feed is 0.9 mg/kg DON.[23] Pigs at 12 weeks of age consume on average 40 g feed/kg bw/day. This resulted in the administration of 36 μg DON/kg bw. For the ADONs, an equimolar dose of 41 μg/kg bw was administered. The calculated amount of toxin for each animal, dissolved in EtOH at 10 mg/mL, was diluted with saline to a volume of 1 mL (IV) or 10 mL (PO). After oral administration of the toxins, 50 mL of tap water was administered to flush the gavage tube. Blood (1−2 mL) was sampled from the jugular vein at 0 min (before administration) and at 5, 10, 20, 30, 45, 60, 90, 120, 240, 360, and 480 min PA. Blood samples were centrifuged (2851*g*, 10 min, 4 °C), and plasma was stored at ≤ −15 °C until analysis.

Both animal trials were approved by the Ethical Committee of the Faculty of Veterinary Medicine and Bioscience Engineering of Ghent University (EC2013/64).

LC-MS/MS Analysis. Sample pretreatment and chromatography-tandem mass spectrometry (LC-MS/MS) analysis were performed as previously described.[25] In brief, 250 μL of plasma was supplemented with IS, 5 μL of a 1 μg/mL $^{13}C_{15}$-DON working solution. After vortex mixing for 15 s, acetonitrile was added to a volume of 1 mL to precipitate plasma proteins. The samples were vortex mixed, followed by a centrifugation step (8517*g*, 10 min, 4 °C). The supernatant was transferred and evaporated to dryness under a (gentle) nitrogen stream at 45 ± 5 °C. The dry residue was redissolved in 200 μL of ULC/MS-grade water, microfiltered through a Millex GV-PVDF filter (0.22 μm), and transferred to an autosampler vial. A 10 μL aliquot was injected onto the LC-MS/MS instrument. Broiler plasma was analyzed on a Surveyor type MS pump Plus and Autosampler Plus HPLC in combination with a TSQ Quantum Ultra triple-quadrupole mass spectrometer (Thermo Fisher Scientific, Breda, The Netherlands). Pig plasma was analyzed on an Acquity UPLC system coupled to a Xevo TQ-S triple-quadrupole mass spectrometer (Waters, Zellik, Belgium).

Chromatographic separation of the analytes was achieved on a 50 mm × 2.1 mm i.d., 1.9 μm, Hypersil Gold column with a guard column of the same type (Thermo Fisher Scientific). All compounds were eluted with a gradient of ULC-MS grade water containing 0.1% glacial acetic acid (mobile phase A) and ULC-MS grade methanol containing 0.1% glacial acetic acid (mobile phase B) at a total flow rate of 300 μL/min. The following gradient elution program was run: 0−1 min, 5% B; 1.0−1.1 min, linear gradient to 20% B; 1.1−5.0 min, 20% B; 5.0−5.1 min, linear gradient to 50% B; 5.1−8.0 min, 50% B; 8.0−8.1 min, linear gradient to 95% B; 8.1−9.0 min, 95% B; 9.0−9.1 min, linear gradient to 5% B; 9.1−12.0 min, 5% B. The mass spectrometer was operated in the multiple reaction monitoring (MRM) mode with two ion transitions for each target analyte. Limits of quantitation (LOQs) varied from 0.1 ng/mL (DON in pig) to 1.0 ng/mL (ADONs in pig, DON and 3ADON in chicken) to 2.0 ng/mL (15ADON in chicken).

Toxicokinetic Modeling and Statistical Analysis. Toxicokinetic analysis was performed using WinNonlin Professional version 5.2.1. (Pharsight, St. Louis, MO, USA). Plasma concentrations below the LOQ were not taken into account. For the toxicokinetic analysis, all values were recalculated to their molar concentrations, expressed as nanomoles per milliliter. For the analysis of DON IV and PO data in chickens, a tailor-made two-compartmental model (central compartment (Vc) and peripheral compartment (Vp)) with first-order absorption and first-order elimination was applied. For the IV and PO data of ADONs in chickens, a one-compartmental model was used in combination with the two-compartmental model for DON. The fraction of the dose of DON, 3ADON, or 15ADON that was absorbed after PO administration (in any form, thus as DON and/or ADON) was indicated as FRAC (%). BioADON was the fraction of the absorbed dose that entered the systemic circulation in its unchanged form, thus as ADON (%). Consequently, the product of FRAC and BioADON indicates the absolute oral bioavailability of ADON (F, %), that is, the fraction of ADON absorbed in the systemic circulation in its unchanged form. The product of FRAC and (1-BioADON) then indicates the absorbed fraction that was presystemically hydrolyzed to DON and that entered the systemic circulation as DON (presystemic hydrolysis, %). Systemic hydrolysis was set at 100% for 3ADON and 15ADON in pigs and in broiler chickens, as the hydrolysis to DON was the only assumed clearance (CL) of ADON in the model. In Figure 2 a graphical representation of the constructed model is given for DON (IV and PO) and ADON (IV and PO) in chickens.

The constructed models for pigs were identical to those for chickens, except for the ADON PO model. Insufficient or no ADON data above the LOQ after PO administration of ADONs led to the exclusion of the ADON compartment for this administration route in pigs. This model therefore assumes a full presystemic conversion of ADON to DON.

A $1/\hat{y}$ weighing was applied for all calculations with both the chicken and pig data. For all of the described models, the Gauss−Newton (Levenberg and Hartley) algorithm was used and a maximum of 50 iterations was allowed.

The following primary and secondary toxicokinetic parameters were calculated for IV and PO administration: absorption rate constant (k_a) (identical for DON and ADONs), intercompartmental flow for DON (Q_{DON}), total body clearance of DON (CL_{DON}), total body clearance of ADON to DON (CL_{ADON}), central volume of distribution for DON (Vc_{DON}), peripheral volume of distribution for DON (Vp_{DON}), and central volume of distribution for ADONs (Vc_{ADON}). The elimination rate constant for DON (k_{eDON}) was calculated by dividing CL_{DON} by the sum of Vc_{DON} and Vp_{DON} for each animal. Additionally, for PO data the descriptive toxicokinetic parameters maximal plasma concentration (C_{max}) and time to C_{max} (t_{max}) were given for DON.

Statistical analysis of these parameters consisted of one-way ANOVA with post hoc Scheffé tests (p value < 0.05) for both animal

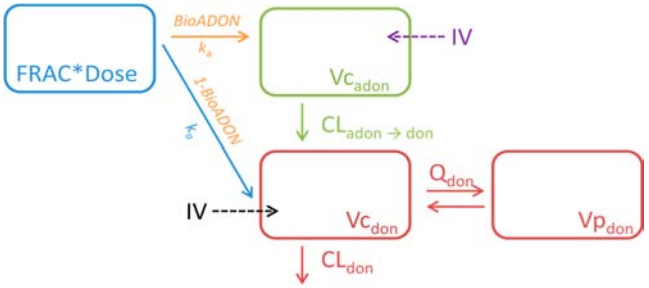

Figure 2. Graphical representation of the applied models in broiler chicken for DON IV (black and red sections), DON PO (blue and red sections), ADON iv (purple, green, and red sections), and ADON PO (blue, orange, green, and red sections). IV, intravenous administration; k_a, absorption rate constant (1/min); CL_{DON}, clearance of DON (mL/min/kg); Q_{DON}, intercompartment flow for DON (mL/min/kg); Vc_{DON} = central volume of distribution for DON (mL/kg); Vp_{DON} = peripheral volume of distribution for DON (mL/kg); CL_{ADON} = clearance of ADON to DON (mL/min/kg); Vc_{ADON} = central volume of distribution for ADON (mL/kg); FRAC = fraction of dose absorbed; BioADON = fraction of the absorbed dose that enters systemic circulation as ADON; 1-BioADON = fraction of the absorbed dose that enters systemic circulation as DON.

species (SPSS 20.0, IBM, Chicago, IL, USA). All variables were log transformed to fulfill the equality of variances criterion as determined by the Levene test for homogeneity of variances (p value > 0.01).

RESULTS AND DISCUSSION

The goal of this study was to determine the absolute oral bioavailability of 3- and 15ADON, the degree of in vivo hydrolysis (differentiating between presystemic and systemic hydrolysis), and the toxicokinetic parameters in broiler chickens and pigs. The plasma concentration−time profiles were analyzed by a tailor-made compartmental toxicokinetic model. This model has the advantage, compared to noncompartmental analysis, that for a given compound, PO and IV data can be fitted simultaneously for each animal. This is more accurate because certain toxicokinetic parameters, such as CL and Vd, are independent of the administration route, and thus more data are available to allow a reliable estimate. Furthermore, this model allows prediction of the plasma concentrations for scenarios that have not been studied yet, whereas noncompartmental analysis uses only observed values. For both ADONs, only a hydrolysis to DON is assumed in the model after IV and PO administration in broilers and pigs. It needs to be mentioned that also formation of glucuronide conjugates and possibly other metabolites can take place. Therefore, high-resolution mass spectrometry (HRMS) analysis on pig and broiler chicken plasma samples from three animals after IV and PO administration of DON was performed. The methodology applied was similar as in a previously described study.[26] After IV and PO administration of DON in pigs, mean peak area ratios of DON-glucuronide/DON of 4.98 and 4.95 were found, respectively (results not shown). Therefore, presystemic glucuronidation in pigs is considered neglibile. For chickens, only trace amounts of DON-glucuronide were detected.[26] Consequently, the impact on estimated volumes of distribution, clearances, absorption, and elimination rate constants are expected to be very small. Furthermore, this study also included IV administration and was set up as a crossover design, generating IV and PO data in the same animals, thereby minimizing variability and compensating for possible other metabolites formed systemically. The developed model allows an estimation of the degree of presystemic and systemic hydrolysis after PO administration, which is not possible using noncompartmental analysis only.

Plasma concentration−time profiles for DON, 3ADON, and 15ADON are presented in Figures 3 and 4, respectively, for broiler chickens and pigs. Each profile represents the mean of six animals ± standard deviation (SD). For broiler chickens, no adverse effects were observed during the animal trial following PO and IV bolus administration of the mycotoxins. Similarly, no adverse effects were observed during the pig trial following PO administration. Following IV dosing of DON, 3ADON, and 15ADON, respectively, three, two, and two of six pigs vomited within 0.5 h PA. However, this had no observable influence on the results as these pigs were IV dosed.

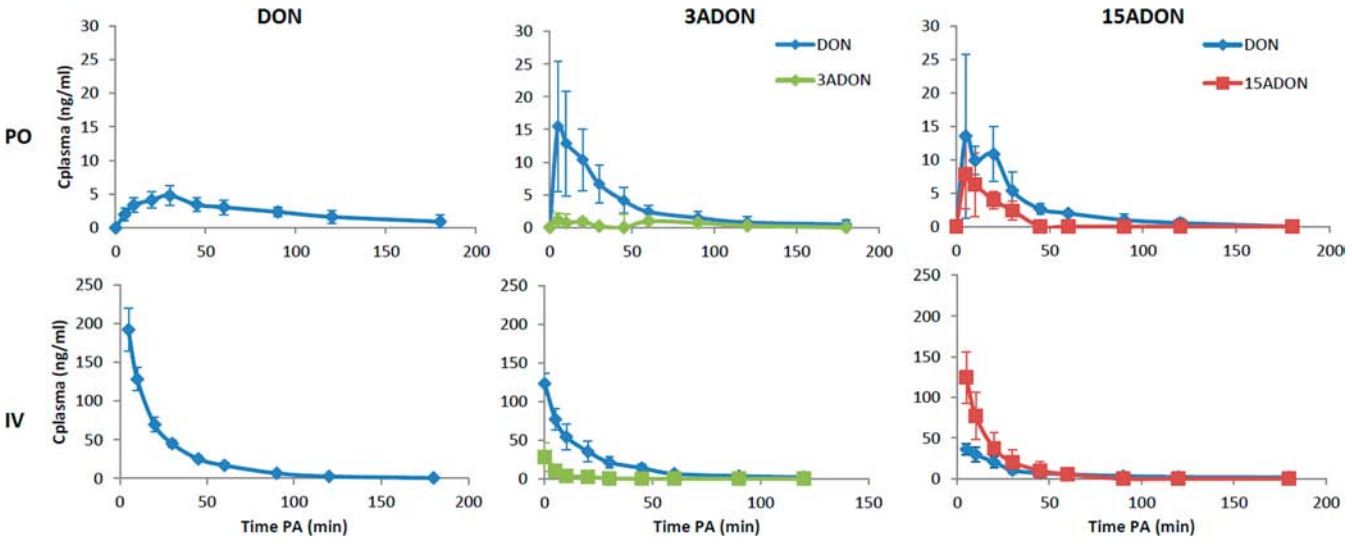

Figure 3. Plasma concentration−time profiles of deoxynivalenol (DON), 3-acetyldeoxynivalenol (3ADON), and 15-acetyldeoxynivalenol (15ADON) after oral (PO) and intravenous (IV) administration (post administration = PA) of DON (dose = 500 μg DON/kg bw), 3ADON (dose = 571 μg 3ADON/kg bw), and 15ADON (dose = 571 μg 15ADON/kg bw) to broiler chickens (n = 6 for each toxin). Values are presented as means ± SD.

DOI: 10.1021/acs.jafc.5b03270
J. Agric. Food Chem. 2015, 63, 8734−8742

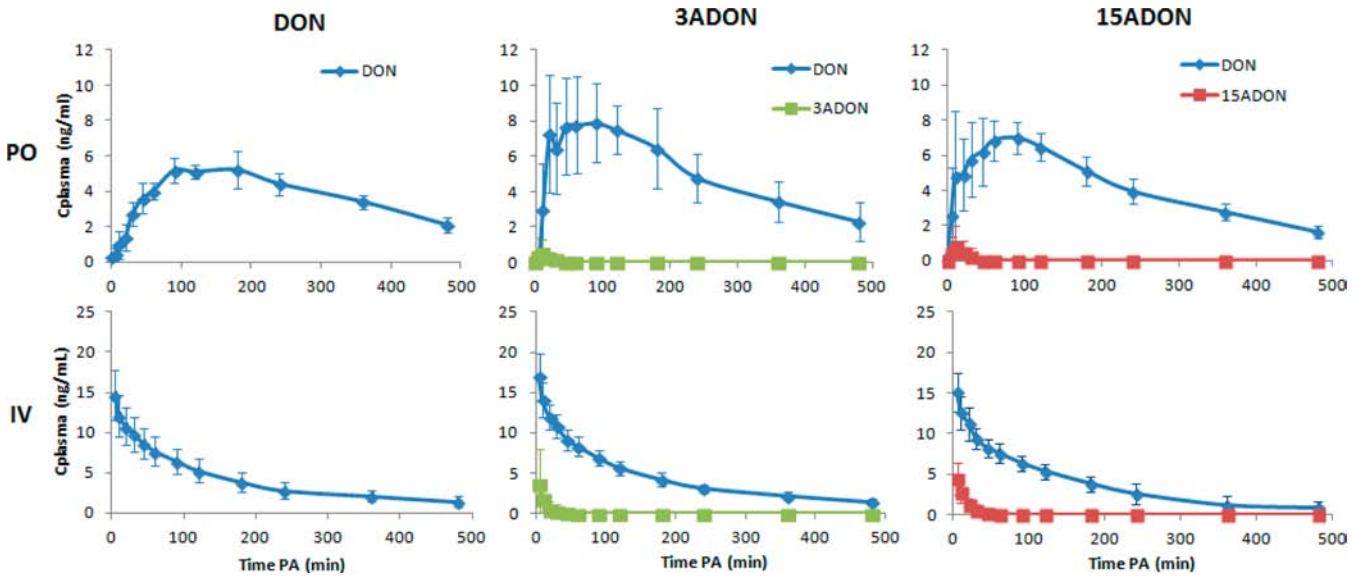

Figure 4. Plasma concentration−time profiles of deoxynivalenol (DON), 3-acetyldeoxynivalenol (3ADON), and 15-acetyldeoxynivalenol (15ADON) after oral (PO) and intravenous (IV) administration (post administration = PA) of DON (dose = 36 μg DON/kg bw), 3ADON (dose = 41 μg 3ADON/kg bw), and 15ADON (dose = 41 μg 15ADON/kg bw) to pigs (n = 6 for each toxin). Values are presented as means ± SD.

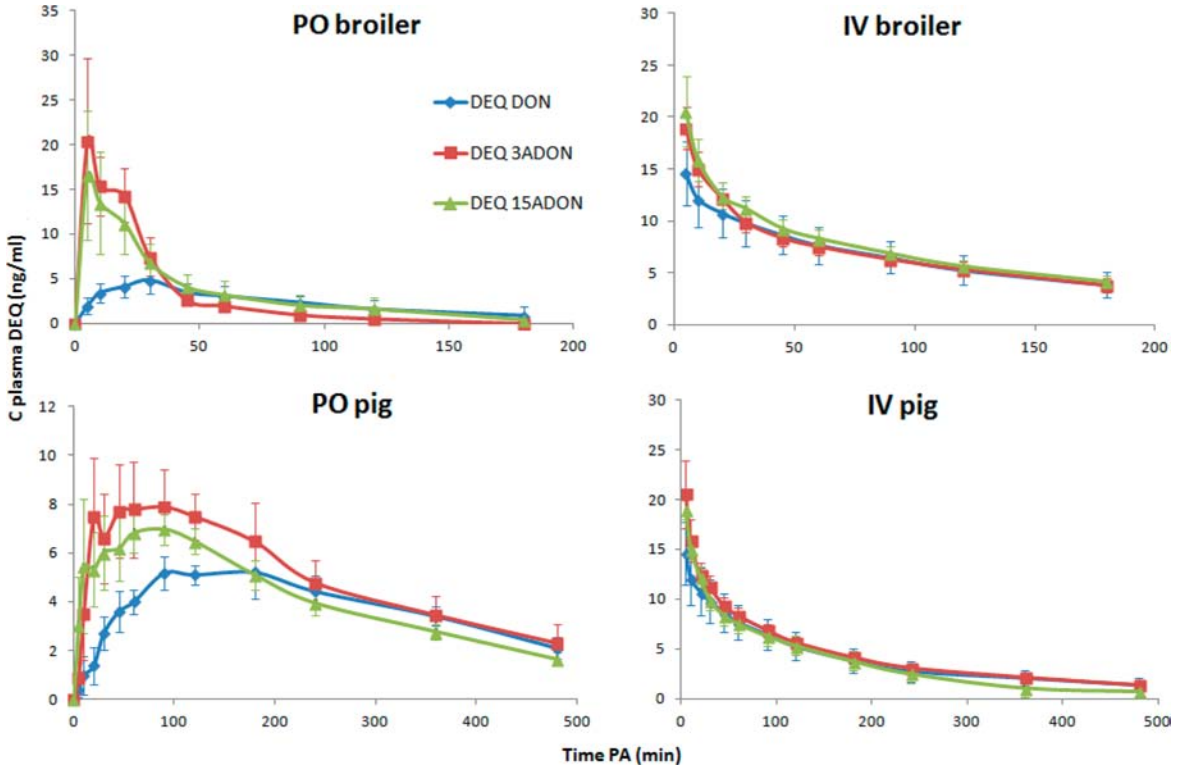

Figure 5. DON equivalent (DEQ) plasma concentration−time profiles after oral (PO) and intravenous (IV) administration of deoxynivalenol (DON), 3-acetyldeoxynivalenol (3ADON), and 15-acetyldeoxynivalenol (15 ADON) in broiler chickens and pigs (n = 6 animals for each toxin). DEQ is calculated by dividing the plasma concentration of the ADONs by their molar mass (338.3 g/mol) and by multiplying by that of DON (296.3 g/mol) and by adding this to DON plasma concentrations. Values are presented as means ± SD.

The plasma concentration−time profiles were also expressed as DON equivalents (DEQ). For this, the ADON concentrations were converted, added to the DON concentrations, and reported as DON equivalent concentrations. This was done by dividing the plasma concentration of the ADONs by their molar mass (338.3 g/mol) and by multiplying by the molar mass of DON (296.3 g/mol). The results for pigs and chickens are shown in Figure 5. Clear differences can be seen for PO administration between DON, 3ADON, and 15ADON in pigs as well as broiler chickens, whereas the IV profiles were similar, which can be regarded as a quality control of the utilized setup. Toxicokinetic parameters, absolute oral bioavailability (F, %) and degree of presystemic hydrolysis (%) were calculated using compartmental modeling, the results of which are given in Table 1.

[a]Values are presented as means ± SD. Statistical analysis was performed within each animal species; results that do not share the same letter in each column are significantly different ($p < 0.05$). Adm, administered mycotoxin; k_a, absorption rate constant (1/min); k_{ADON}, elimination rate constant for DON (1/min) (k_{eADON} could theoretically also be calculated after administration of ADONs, as data for DON were); CL_{DON}, clearance of DON (mL/min/kg); Q_{DON}, intercompartmental flow for DON (mL/min/kg); Vc_{DON}, central volume of distribution for DON (mL/kg); Vp_{DON}, peripheral volume of distribution for DON (mL/kg); CL_{ADON}, clearance of ADON to DON (mL/min/kg); Vc_{ADON}, central volume of distribution for ADON (mL/kg); FRAC, absorbed fraction; BioADON, fraction of the absorbed dose that entered the systemic circulation as ADON (%); pres hydr, percentage of the total dose that is hydrolyzed presystemically to DON and absorbed as DON (%); F, absolute oral bioavailability (%); C_{max}, maximum plasma concentration for DON (ng/mL); t_{max}, time to maximum plasma concentration for DON (min).

The absorbed fractions of 3ADON (18.2%) and 15ADON (42.2%) in broiler chickens correspond to approximately double and quadruple that of DON (10.6%), respectively. However, no statistical difference ($p = 0.061$) could be demonstrated between the absorbed fraction of DON and 3ADON in broiler chickens. The absorbed fraction of 15ADON, on the other hand, was found to be significantly higher than that of DON and 3ADON ($p < 0.05$). An increase in absorbed fractions for the ADONs might be expected as these acetylated mycotoxins are less polar and have a more favorable log D value for absorption by passive nonionic diffusion compared to DON (estimated log D_{ADON} and log D_{DON} at physiological pH are −0.5 and −1, respectively).[27] For pigs, on the other hand, the absorbed fractions of DON, 3ADON, and 15ADON were 100%. The relatively low absorbed fraction for chickens compared to pigs has been discussed[28] and may be partially due to the rapid transit time in the GI tract of chickens, leading to a reduced time for complete absorption. As another contributing factor, the high bacterial content in the GI tract of birds before the main site of absorption is proposed. These bacteria could metabolize DON and/or ADONs, thereby decreasing their bioavailability and toxicity.[27]

To correlate the absorbed fraction to the absolute oral bioavailability (F, %), the degree of in vivo hydrolysis must be considered. As the ADONs can be hydrolyzed presystemically to DON, their absorbed fraction may represent a combination of absorption as DON and as ADON and can thus differ from their oral bioavailability, which is represented by the absorption as ADON. However, this is not the case for DON. For chickens, the F value for DON is equal to its absorbed fraction, being 10.6 ± 4.6% in this study. For DON in broiler chickens, an oral F of 19.3 ± 7.42% has been observed,[29] which is in the same range. In contrast in pigs, a complete absorbed fraction and complete oral bioavailability of DON was found in fasted pigs. Prior studies in pigs observed oral F values for DON after chronic and acute exposure of 62.8 and 54.1%, respectively.[30,31] Differences in F for acute exposure can be attributed to either the prandial state (fed versus fasted) or the administration of a bolus of DON (dissolved in, e.g., ethanol) versus the administration of DON in contaminated feed. The oral absorption as well as oral bioavailability of the ADONs in pigs and chickens has thus far not been investigated.

In broiler chickens, both ADONs have a significantly different degree of presystemic hydrolysis ($p < 0.05$). Whereas for 3ADON the fraction of the dose absorbed was completely hydrolyzed presystemically, the absorbed fraction of 15ADON that entered the systemic circulation as such (BioADON) was 24.6% and was consequently 75.4% as DON. As the fraction of the dose absorbed for 3ADON was completely hydrolyzed presystemically, an F value of 0% was obtained, whereas for 15ADON an F value of 10.4% was calculated. Differences in hydrolysis/metabolism between both ADONs in broiler chickens has already been demonstrated in vitro.[14] After anaerobic incubation of 3ADON for 72 h with microbiota from the GI tract of chickens, deacetylation was the predominant reaction (94%) with only minimal subsequent de-epoxidation (6%); there was no evidence for de-epoxidation only. However, for 15ADON, a large fraction proved to have both the acetyl and epoxy moieties removed (±93%), whereas only small quantities showed either solely de-epoxidation (±1%) or deacetylation (±7%), leaving no 15ADON. The role of GI microbiota in our in vivo study has little to no influence on the

J. Agric. Food Chem. 2015, 63, 8734−8742

presented results as the high degree of hydrolysis after IV administration indicates a systemic biotransformation rather than the result of the action of GI microbiota. Additionally, the microbiota from the aforementioned in vitro study were isolated from the large intestine. At this site in the GI tract the absorption of the toxins will be negligible and transformation here will not be reflected by changes in plasma concentrations. Furthermore, the average GI transit time for chickens is 3−4 h, whereas the experimental setup of this in vitro study consisted of a 72 h anaerobic incubation.[14,32]

In pigs, 3ADON and 15ADON exhibited a presystemic hydrolysis of >99%, also leading to F values of 0%. These findings for the in vivo hydrolysis of 3ADON in pigs correspond with an earlier study.[18] Five castrated pigs were fed twice daily for 3 days 2.5 mg 3ADON/kg feed. No 3ADON, or DOM-1, could be detected in plasma. The only detected metabolite in plasma was DON as such. After incubation of the plasma samples with β-glucuronidase, an increase of 72% DON was seen, indicating the presence of DON-glucuronide. The rapid deacetylation prior to absorption, as suspected,[18] has been confirmed in our study. These data can be related to several in vitro and in vivo studies in other species. One study investigated the hydrolysis and metabolism of 3ADON and 15ADON after oral administration to rats.[17] One hour PA of 3ADON or 15ADON, 12% of the dose could be detected in the stomach as free DON, indicating a likely hydrolysis of both ADONs in the stomach. It was also observed that both ADONs were glucuronidated in the stomach (5% of the administered dose) without prior deacetylation. Another in vitro study incubated human fecal samples under anaerobic conditions for 48 h with 3ADON.[16] Of the administered dose, 78 ± 30% was recovered as DON, clearly indicating the capability of human large intestinal microbiota to hydrolyze 3ADON to DON. Remarkably, a rapid and complete hydrolysis of 3ADON and 15ADON to DON was also observed after IV administration.

The relatively higher absorbed fractions for ADONs compared to DON in broilers are also reflected by significantly higher observed maximal DON plasma concentrations after PO administration of 3ADON (C_{max} = 15.0 ± 8.8 ng/mL) and 15ADON (C_{max} = 16.2 ± 7.6 ng/mL) compared to PO administration of DON (C_{max} = 4.2 ± 0.9 ng/mL), as depicted in Table 1 and Figure 3. When transformed to DEQ plasma concentrations, this difference between DON and ADONs becomes even more explicit, as can be seen in Figure 5. Furthermore, in broiler chickens, the administration of ADONs appears to lead to a more rapid absorption of DON, reflected by a shorter t_{max} for DON after 3ADON administration (t_{max} = 5.0 ± 0 min) and after 15ADON administration (t_{max} = 9.0 ± 6.5 min) compared to after administration of DON itself (t_{max} = 32 ± 11 min). For pigs, no significant changes were seen in C_{max} or t_{max} of DON after PO administration of DON, 3ADON, or 15ADON.

In this study, an absorption rate constant k_a for DON of 0.0164 ± 0.0161/min was found in pigs, compared to 0.00995 ± 0.00292/min[18] and 0.0310 ± 0.0238/min.[30] However, these results are difficult to compare because the aforementioned study[30] utilized a contaminated feed strategy (chronic exposure), whereas this study was based on a single bolus model with fasted animals. The k_a values in broiler chickens are approximately twice the values obtained for pigs, indicating indeed a fast presystemic hydrolysis of ADONs and a fast GI transit and absorption in poultry.

The CL of DON after DON administration in broilers is approximately 10 times higher compared to that in pigs. The CL of DON in pigs, approximately 15 mL/min/kg, is comparable to a previously reported value for acute DON administration of 9.3 mL/min/kg.[30] The CL of 3ADON in broilers and pigs is remarkably higher compared to that of DON and 15ADON. In contrast, compared to DON, 15ADON showed a faster CL in pigs and a slower clearance in broiler chickens. The intercompartmental flow Q for DON is similar in both animal species. The Vc values for ADONs are in the same order of magnitude for pigs and broilers. The model had difficulties in estimating the central and peripheral volumes of distribution for DON individually. However, when making the sum of both volumes of distribution, the values are found to be in a range of 2.6−3.8 L/kg, except for 15ADON in chickens, for which the Vp was estimated to be approximately 18 L/kg, but with a higher uncertainty. It was therefore attempted to fix the value of this parameter to a lower one, but this led to a poorly fitted model. For 15ADON administration to broilers, DON and 15ADON were clearly measurable for a relatively long period of time, unlike for 15ADON in pigs and 3ADON in broilers as well as pigs. This possibly increased the difficulty for the model to correctly fit all parameters. The mean elimination rate constants for DON (k_{eDON}) in broilers and pigs were 0.0388 ± 0.0062/min and 0.00405 ± 0.00076/min, respectively. This corresponds to mean elimination half-lives for DON in broilers and pigs, calculated as $0.693/k_{eDON}$, of 17.9 and 171 min (2.85 h), respectively. For pigs elimination half-lives of 5.3 ± 2.4 h (acute PO, two-compartmental model),[30] 2.39 ± 0.71 h (acute PO, one-compartmental model),[18] and 2.73 ± 0.477 (acute PO, one-compartmental model)[33] were observed, in contrast to a value of 15.2 ± 12.9 h observed for IV (two-compartmental model).[30] For broiler chickens elimination half-lives of 27.9 ± 6.9 min (IV) and 38.2 ± 11.2 min (acute PO) were observed.[29]

When combining the above-mentioned results for the absorbed fraction, oral bioavailability, and presystemic hydrolysis of 3ADON and 15ADON in pigs, it can be concluded that the administered dose of both ADONs is completely absorbed and both show a complete presystemic hydrolysis. Therefore, both ADONs can be regarded as toxic as DON itself in pigs with regard to systemic toxicity. Moreover, the ADONs may also exert a local toxic effect in the intestine as previously proposed.[10] For broiler chickens, the absorbed fractions of 3ADON and especially 15ADON are higher than or at least equal to that of DON. Furthermore, 3ADON, which is reported to be less toxic than DON, is completely hydrolyzed presystemically to DON, whereas 15ADON is reported to be more toxic and not fully hydrolyzed. This results in a "worst case scenario" for broilers, where each mole of 15ADON could be as toxic as 4 mol of DON and where the less toxic 3ADON can be regarded as equally toxic as DON because it is completely hydrolyzed presystemically.

In conclusion, both pigs and broiler chickens are exposed to DON after oral intake of ADONs. When these findings are combined with the frequent cocontamination of ADONs and DON in food and feed, this demonstrates the possible need to consider the establishment of a TDI for 3ADON and 15ADON or the inclusion of the ADONs in a group TDI for DON-related substances.

promising alternative to GC and even NIRS analyses.[31] With the ATR technique, monolayers of analytes can be investigated through direct contact between the sample and the infrared (IR) crystal. Hence, the surface trichomes of sage are easily accessible to the ATR crystal with a low background from the plant matrix.[32]

Therefore, the aim of this study was to investigate the use of ATR−FTIR for the direct qualitative and quantitative analysis of the EO composition of dried intact leaves of sage, including the effect of different varieties, leaf age, and date of harvest. On the basis of reference analysis of solvent extracts from the plant material by gas chromatography coupled with mass spectrometry or flame ionization detection (GC−MS or GC−FID, respectively), appropriate calibration models for the EO content and composition can be developed that include the chemical diversity of different sage accessions.

MATERIALS AND METHODS

Chemicals. Pure standard substances (α- and β-thujone, α- and β-pinene, 1,8-cineole, camphor, and carvacrol) were purchased as analytical standards (at least >96%) for GC reference analysis from Roth (Karlsruhe, Germany) and Sigma-Aldrich (Taufkirchen, Germany). Isooctane [>99%, high-performance liquid chromatography (HPLC) grade] for solvent extraction of essential oil components (EOCs) was obtained from Sigma-Aldrich.

Plant Material. Seeds of 12 different sage (*S. officinalis* L.) accessions maintained in a gene bank were obtained from the Leibniz Institute of Plant Genetics and Crop Plant Research in Gatersleben (Germany) and cultivated at the experimental field of the Julius Kühn Institute in Berlin (Germany). For further botanical description, see Table 1. Five fully developed young (leaf size: maximum length, 30 mm; maximum width, 10 mm) and old (leaf size: minimum length, 50 mm; minimum width, 15 mm) leaves of 10 individual plants per accession were collected at two different harvests in 2013 (July 25, H1; September 25, H2). In the second harvest, withering meant that less than 10 plants were available for some accessions (SALV13, 7; SALV25, 9; SALV28, 9; SALV29, 6; SALV30, 8; and SALV34, 5). For external validation, 3 times 10 plants grown from seeds from a commercial sage accession (article number k58, *S. officinalis*, Bingenheimer Saatgut GmbH, Echzell, Germany) were cultivated and sampled under identical conditions as described for gene bank material. At both harvests, old and young leaves were sampled (H1, 30 plants; H2, 29 plants), and the spectra were collected by ATR−FTIR prior to extraction and GC analysis. All leaves were dried at 35 °C for 48 h prior to ATR−FTIR and GC analyses and were stored in paper bags at room temperature in desiccators.

ATR−FTIR. The mid-infrared (MIR) spectra of intact dried sage leaves and pure standards were recorded from 4000 to 375 cm^{-1} with a portable ATR diamond crystal infrared spectrometer (Alpha, Bruker Optics GmbH, Ettlingen, Germany). Approximately 5−10 mg of the standards was placed on the surface of the diamond crystal and measured directly. Intact dried sage leaves were analyzed by gently pressing the adaxial leaf side in the region of the central lamina onto the ATR crystal. Use of the standard pressing mechanism of the instrument allowed for a constant pressure for all measurements. All spectra were composed of 32 scans and acquired with a spectral resolution of 4 cm^{-1}. For each plant per accession and harvest, five old and five young leaves were measured once and the five repeated spectra per experiment were averaged and used for later chemometric analysis.

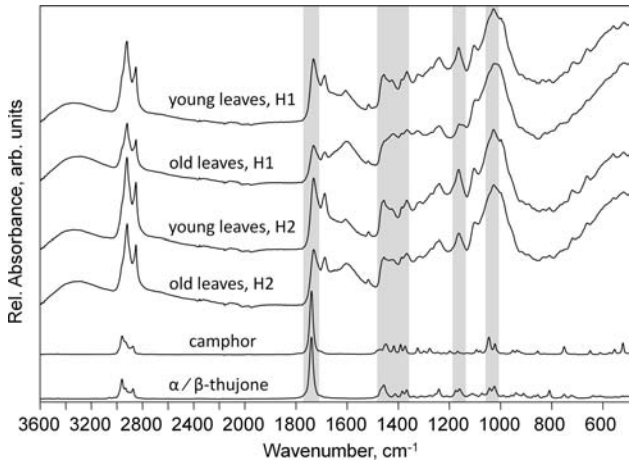

Figure 1. ATR−FTIR spectra of old and young leaves of *S. officinalis* L. for both harvest dates (July 25, 2013/H1 and September 25, 2013/H2) as averaged spectra of all considered gene bank accessions. The highlighted ranges indicate appropriate signals resulting from EO terpenoids as shown by spectra of the appropriate standards α- and β-thujone and camphor, respectively.

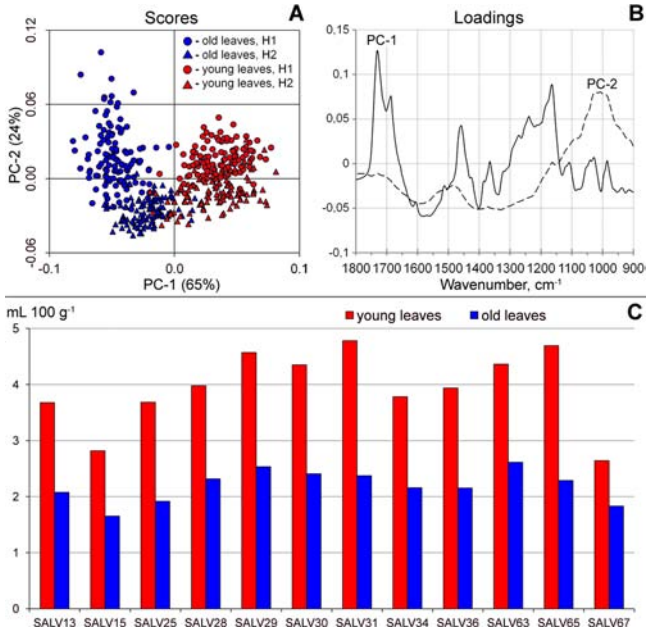

Figure 2. (A) PCA scores plot constructed from ATR−FTIR spectra of old (blue) and young (red) leaves of *S. officinalis* L., (B) corresponding loadings for PC1 and PC2, and (C) averaged EOC content for both harvests and all accessions as determined by GC−FID.

Reference GC−FID and GC−MS Analyses. For reference analysis, 200 mg of air-dried sage leaves were homogenized in 1.0 mL of isooctane [containing 1:2000 (v/v) carvacrol as the internal standard] with a Retsch ball mill MM2000 (Retsch GmbH, Germany). After centrifugation (10 min at 2415*g*), extracts were analyzed by GC−FID using an Agilent gas chromatograph 6890N, fitted with a HP-5 column (50 m × 0.32 mm i.d., with a film thickness of 0.52 μm). This GC instrument is routinely used for EO analysis and regularly validated with external standards. Hence, no repeated extraction was performed, and each sample was investigated once. Detector and injector temperatures were set at 280 and 250 °C, respectively. The following oven temperature program was used: heating from 80 to 220 °C at a rate of 8° min^{-1}. This final temperature was held for 10 min. Hydrogen was used as carrier gas with a constant

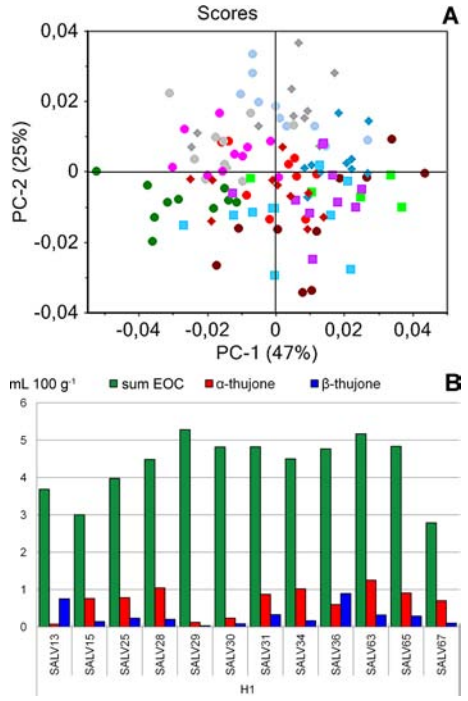

Figure 3. (A) PCA scores plot constructed from ATR−FTIR spectra of dried intact leaves of *S. officinalis* L. for harvest 1 (each color indicates one of the 12 accessions) and (B) GC reference data for the EOC content (green) and amounts of α-thujone (red) and β-thujone (blue) for the 12 different accessions.

flow rate of 1 mL min^{-1}. (split of 1:20). Analyses of the sage extracts were performed using an Agilent MSD 5972/HP 5890 Series II, equipped with a 30 m × 0.25 mm i.d., see above, 0.5 μm HP-5MS column. The column temperature was increased from 60 to 120 °C at a rate of 3° min^{-1}, finally increased to 220 °C at 8° min^{-1}, and held for 10 min. Helium was used as carrier gas with a constant flow rate of 1.1 mL min^{-1} and a split of 1:10. Injector and detector temperatures were set at 250 and 280 °C, respectively. The ionization energy was set at 70 eV. Identification of the detected compounds was based on their relative retention time and their mass spectra in comparison to those observed for the above-mentioned pure standard substances. The other compounds were tentatively identified using the NBS75K and Wiley 138 spectral library databases of the GC−MS system. The percentage composition of the volatile fraction was computed from the GC peak areas using peak area normalization.

Chemometrics. To estimate the variability of the samples, principal component analysis (PCA) was used based on the instrument software package OPUS 7.2 (Quant 2 module, Bruker Optik GmbH, Germany) and Unscrambler X (Camo, Norway).

Relevant spectral ranges were determined by comparison of sample spectra to those of appropriate reference standards and PCA. Calibration models were validated by 10-fold cross-validation ("leave 10% out") using a partial least-squares (PLS) algorithm. Appropriate models designated by cross-validation were further tested by test set validation with an external sample set. Therefore, spectra and GC data of all 30 plants of the commercial accession were averaged, resulting in 12 test samples related to the four treatments (old/young and harvest July 25, 2013/harvest September 25, 2013).

RESULTS AND DISCUSSION

Reference Analysis for *S. officinalis* L. According to the European Pharmacopoeia, EO is analyzed by hydrodistillation and GC methods.[14] Because of the comprehensive sample set and the small sample amounts (five individual leaves per sample) investigated in the present study, solvent extraction

DOI: 10.1021/acs.jafc.5b03852
J. Agric. Food Chem. 2015, 63, 8743−8750

instead of hydrodistillation was performed to describe "essential oil components (EOCs)" following previously published research on various EO plants.[17,21,30,33] Even if solvent extracts instead of hydrodistillates were investigated by GC, the term EOCs has been retained because solvent extraction and hydrodistillation of sage leaves both lead to isolates of comparable chemical composition.[34] Table 2 presents the summarized results of GC analysis of EOC composition for all accessions and all treatments.

The EOC extract was composed of about 85−90% terpenoids, which are known constituents of sage EO. As indicated by the statistical characteristics, there was a high degree of variability in the content of individual compounds in the accessions that were investigated.

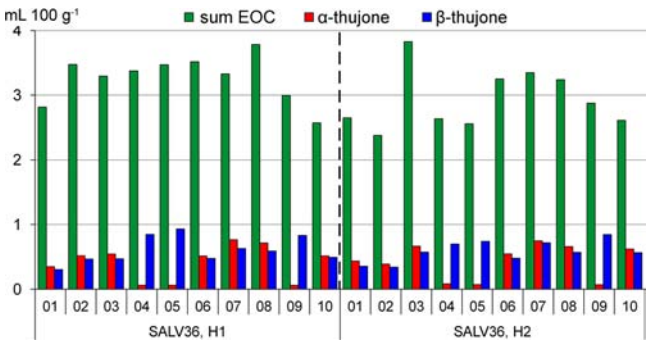

Figure 4. GC reference data for the EOC content (green) and amounts of α-thujone (red) and β-thujone (blue) for the 10 plant repetitions and both harvests of accession SALV36.

Chemotaxonomic Variability of *S. officinalis* L. Sage is known to show a large variety in the EO content and composition.[3,4,19] Therefore, the impact of genetic and geographic origin (12 gene bank accessions), age, and date of harvest on the spectroscopic and chemical variability of the EO composition was investigated, resulting in 448 individual samples (for lost plants, see the Plant Material section).

Figure 1 presents the ATR−FTIR spectra of old and young leaves at both harvests (H1 and H2) as means of all gene bank accessions and the spectra for α- and β-thujone and camphor as main constituents of sage EO.

The spectral ranges highlighted in Figure 1 indicate distinct EO terpenoid-derived signals in the spectra of the plant material compared to spectra of pure standards. Both camphor and α- and β-thujone contain keto groups substituted on a cyclopentane ring system, resulting in a characteristic stretch vibration for the C═O bond at around 1740 cm^{-1}. Furthermore, both terpenoids contain dimethyl-substituted methylene groups with a characteristic two-band deformation vibration pattern around 1390 and 1370 cm^{-1}. Besides matrix signals from cellulose around 1100 cm^{-1}, contributions of these diagnostic IR bands are also found in the spectra of sage leaves. Hence, evaluation of this fingerprint region offers a promising tool for quantification of those metabolites and differentiating sage samples based on their camphor and/or α- and β-thujone contents.

Averaging of the spectra from the adaxial leaf surface of plants followed by PCA resulted in clustering of old and young leaves separated by principal component 1 (PC1), as shown in Figure 2a. The differentiation among the clusters is caused by

the varying amounts of EOCs with different contents of thujone and camphor, as shown by the characteristic IR signals appearing in the corresponding loadings of PC1 given in Figure 2b. Young leaves generally contain up to 2-fold more EOCs compared to old leaves, as observed for all accessions and both harvests by GC reference analysis (Figure 2c). The strong differences in the amount of EOCs are already clear in the appropriate spectra of old and young leaves presented in Figure 1. Furthermore, PC2 separates samples from harvests 1 and 2 based on signals belonging mostly to the leaf matrix (Figure 2b; PC2 around 1000 cm^{-1}). A similar approach for discrimination of different citrus oils by PCA based on characteristic key Raman bands was described in a previous study.[35]

In contrast, spectroscopic differentiation according to the origin/accession of the material was not possible, as shown in Figure 3a, nor by GC reference data (see Figure S1 of the Supporting Information). Subsequent analysis of the EOCs of each accession revealed a large range in content and relative proportions of α- and β-thujone, as presented in Figure 3b.

These results show a group of accessions with either low overall thujone content (SALV29 and SALV30) or only a low ratio of α-/β-thujone (SALV13 and SALV36). In contrast, the majority of accessions is characterized by a high content of α-thujone (SALV15, SALV25, SALV28, SALV31, SALV34, SALV63, SALV65, SALV67, and BG).

However, the different accessions could not be discriminated possibly because of the large degree of scattering in the data. This might be explained by the genetic variability and heterogeneity of the plant material within the accessions. Generally, gene bank accessions are defined as sample collections taken from nature, and are characterized by the location and time of sampling. Therefore, a certain genetic diversity even within the accessions has to be considered. As indicated by the GC data for the 10 individual plants of accession SALV36 shown in Figure 4, large variations in EOCs, overall amount of thujone, and ratio of α-/β-thujone can be observed for both harvests. Such a high variability in not only the yield of EOC or sum of thujone but also the ratio of both stereoisomers results in insufficient clustering. Hence, because of the clear genetic variation discrimination into individual accessions based on ATR−FTIR spectra of intact dry leaves can only be achieved for those few accessions with an unusual chemical composition containing low amounts of α-thujone and/or high concentrations of β-thujone (Figure 3a).

Nevertheless, information about chemical heterogeneity of the accessions is highly relevant for the development of suitable calibration models with ATR−FTIR spectroscopy (where only a small amount of material is used with each measurement) because it determines an appropriate sampling (e.g., number of individual plants sampled and measurement replicates per leaf) and statistical evaluation. Therefore, a representative number of plants (repetitions per accession) has to be incorporated, and a greater degree of averaging ATR−FTIR spectra (summarizing variability by reduction of data points) has to be applied.

Quantitative Analysis of EOCs by ATR−FTIR. On the basis of the results above, quantification models for the sum of EOCs and individual compounds were validated by 10-fold cross-validation. As a first step, averaged spectra for each age and harvest (resulting in 448 samples) were correlated with GC reference data for the EOC yield as well as α-thujone, β-thujone, camphor, 1,8-cineole, α-pinene, and β-pinene. In Table 3, data preprocessing and the appropriate spectral ranges

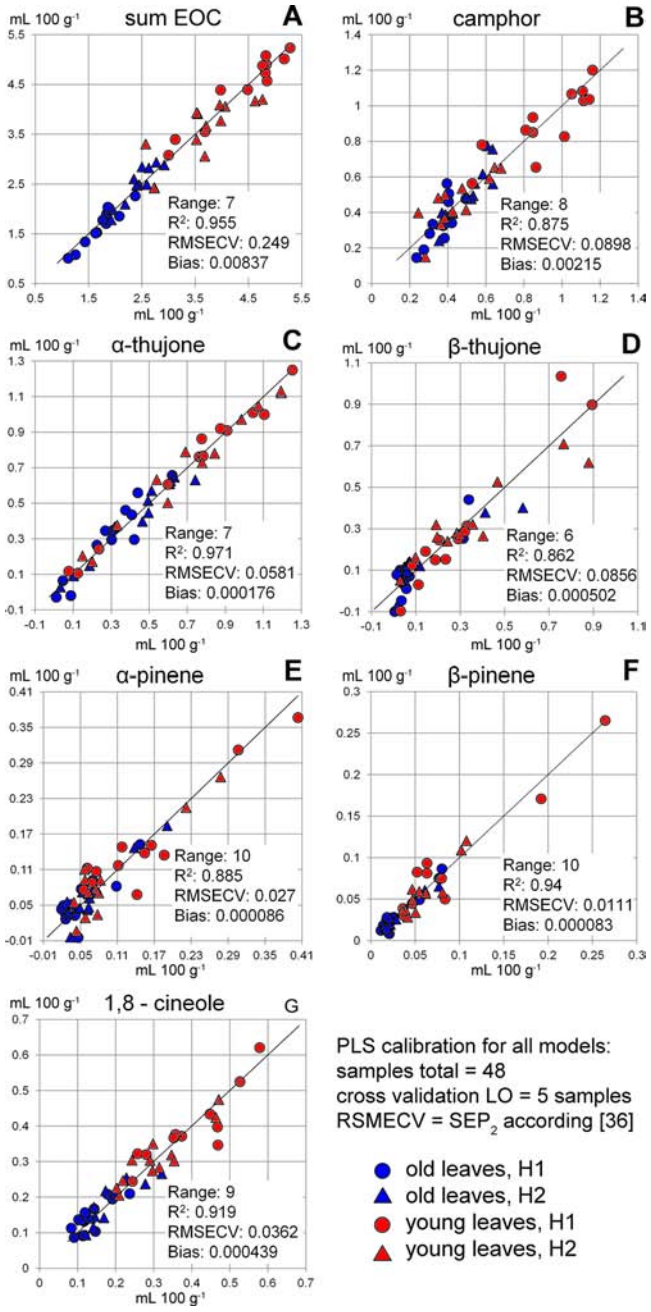

Figure 5. Results of 10-fold cross-validation of ATR−FTIR and GC data for the (A) EOC content, (B) camphor, (C) α-thujone, (D) β-thujone, (E) α-pinene, (F) β-pinene, and (G) 1,8-cineole by correlation of averaged spectra for each accession (n = 48). Blue color, old leaves; red color, young leaves; circle, harvest 1 (July 25, 2013); and triangle, harvest 2 (September 25, 2013).

are summarized, whereas Table 4 provides an overview of the statistical parameters of the corresponding models.

For all components, insufficiently good predictions were obtained, as indicated by low values for the coefficient of determination R^2 and relatively high values for the root-mean-square error of cross-validation (RMSECV) compared to the individual concentration ranges. The low correlation between ATR−FTIR and GC analyses is likely caused by the different amounts of sample used in the two methods. Spectroscopic data were composed of five measurement points of approximately 1 mm^2 in size (size of ATR diamond crystal) distributed

[a]In units of mL 100 g^{-1} of DM. [b]LV = number of latent variables.

over five individual leaves per plant. In contrast, for GC, the entire five leaves were extracted (see the Reference GC−FID and GC−MS Analyses section), and hence, variability within one plant might not be comparable.

For a better match between the amount of sample used for spectroscopy and GC, the number of ATR−FTIR measurement repetitions per plant should be increased. This will enlarge the amount of leaf area investigated by ATR−FTIR but will lead to longer measurement times. Another option could be averaging more comparable spectra, e.g., all of those belonging to the same accession and treatment (old/young and H1/H2), to make them more representative of a larger sample, e.g., a genuine batch of drug or the yield from an entire parcel of land.

Figure 5 presents the graphical results for cross-validation regarding averaged ATR−FTIR spectra from all plants belonging to the same accession, age, and time of harvest, resulting in 48 individual samples. Data preprocessing and relevant spectral ranges are summarized in Table 3.

The use of spectra averaged across accessions leads to an improved prediction for not only the EOC yield and major constituents (α-thujone, β-thujone, and camphor) but also components with lower concentrations (in per mill range), such as α- or β-pinene and 1,8-cineole.

For all EOCs, coefficients of determination higher than 0.86 were obtained with low values for bias and RMSECV of less than 10% of the corresponding mean values.

The robustness of the cross-validated models was investigated with an additional test set validation of 12 independent samples (3 sets of 10 plants, old/young and H1/H2) which came from the commercial sage accession. As shown by the values of R^2, root-mean-square error of prediction (RMSEP), and bias given in Table 5, for EOCs, a robust and reliable prediction model could be achieved with R^2 = 0.98. For the individual compounds, prediction quality was at best for 1,8-cineole (R^2 = 0.87), with R^2 = 0.74 and 0.80 for α- and β-thujone, respectively. The relatively low prediction accuracy for individual metabolites could again be explained by the genetic and chemotaxonomic diversity of sage. The accession used for test set validation was not included in the calibration model. The impacts of the plant matrix or variation in the ratio of α- and β-thujone were not considered in the calibration. Hence, application of calibration models to unknown samples of different origin might be limited, and the genetic and chemotaxonomic diversity must be taken into account. The RMSEP values were calculated according to the definition of Fearn as SEP_2.[36]

In conclusion, all cross-validated calibration models verified against an external test set resulted in reliable prediction models for the overall yield of EOCs, their major constituents (α- and β-thujone and camphor), and even minor components (α- and β-pinene and 1,8-cineole). An initial screening by ATR−FTIR enabled a rapid assessment of the chemical variability of the samples, which allowed us to adjust sampling protocols (e.g., more measurement repetitions by ATR−FTIR for better representation of sample variability). This, in turn, permitted an improvement of quantification models by different statistical pretreatments (e.g., higher degree of averaging) with only minor additional time required.

In the current ATR−FTIR quantification protocol, plant material only needs to be dried and spectral measurements take only a few minutes. This allows for rapid quality control of the material when it is first received for processing compared to the time-consuming analysis recommended in the Pharmacopoeia. Transfer of the current analytical protocol to fresh material and application in the field is currently under investigation. This will undoubtedly improve growing and quality control for both plant breeding and cultivation and assist in evaluating the chemical variation of breeding populations and identifying optimal points for harvest.

spreading to India, China, the Mediterranean basin, and eastern Europe.[7]

Saffron is widely used mainly as a spice and as a coloring and flavoring agent in both the agro-food and cosmetic industries. The saffron spice is a complex mixture of volatile and nonvolatile compounds and carotenoid derivatives, which all contribute to the overall aroma and flavor of the spice.[8,9] In addition to its color, taste, and aroma, saffron displays a variety of health benefits.[10] Saffron shows analgesic and sedative properties[11] and is a potential anticancer agent.[12,13] Furthermore, saffron is beneficial for the treatment of mental disorders such as depression[14] and dementia.[15]

AGRONOMICAL IMPROVEMENT OF SAFFRON PRODUCTION

The ideal condition for improving crop yield would be the optimization of all metabolic cues together with the environmental conditions where the crop develops.[16] For such a purpose, the rates of all important processes should be optimized and also their interactions and duration, which are generally determined by genetic mechanisms often influenced by the environment. Cultivation of saffron occurs in temperate regions. The life cycle of saffron is adapted to the climate of the Mediterranean regions and is quite similar in all producing countries, but with wide differences in the timing of events.[17] In the Mediterranean region, saffron flowers in autumn, after the formation of replacement corms at the base of the shoots is initiated. At the beginning of the dry season (April−May), the leaves senesce and wither, and the corms go into dormancy. The transition from the vegetative to the reproductive stage occurs before summer in the apex of the buds of underground corms, which do not have roots or foliage leaves.[17] Not all of the newly developed corms are able to produce flowers. Flower formation is directly related to corm size.[18] Therefore, the adequate production of corms is extremely important to guarantee flower production.

During the past decades, the area traditionally dedicated to saffron cultivation in many European countries has fallen dramatically,[19,20] mainly due to the intensive manual labor required for saffron harvest and processing (0.25−2.5 million flowers ha^{-1}). However, in recent years this tendency has reversed, and saffron production in Europe and other developed countries outside Eurasia, for example, in Tasmania (Australia), is increasing, with a specific emphasis on the production of high-quality saffron. A technological breakthrough to increase the quality of saffron cultivation would entail the cultivation under controlled conditions in containers to facilitate the mechanization of flower harvesting and stigma separation.[21] To achieve this, the flowering season must be extended as much as possible to maximize the use of harvesting installations and thus reduce overall installation and running costs. Thus, an in-depth knowledge about the regulation of the flowering process could help to increase the yield of the spice.

Another important factor that limits the areas in which saffron is cultivated is the difficulty in obtaining high-quality propagation material with guaranteed levels of purity, homogeneity, and health. It is a slow-growing species from which three to four daughter corms per mother corm are obtained each season under natural field conditions. Low multiplication and fungal diseases of corms reduce the productivity and quality, thereby restraining the availability of planting material and the widespread use of improved genotypes obtained in the future.

Every sprouting bud in the mother corm has the potential to produce a new corm, but saffron corms show only a few sprouting apical buds plus many axillary dormant buds. Furthermore, there is a heterogeneity in bud emergence and development, which results in heterogeneous flower emergence.[17] This process must therefore be controlled to establish industrial production. In this context, environmental and genetic factors affecting corm development, dormancy, and sprouting, as well as the identification of environmental signals and the genetic and regulatory mechanisms that promote or inhibit flowering in saffron, constitute the most relevant processes to be elucidated for implementing a technological breakthrough and achieving agronomical improvements in this crop.

WHAT IS KNOWN ABOUT FLOWERING AND CORM DEVELOPMENT IN SAFFRON?

Saffron Flowering. The transition from the vegetative to the reproductive stage in saffron occurs early in July when the apex becomes dome shaped and increases in size. This process is followed by the formation of the leaf primordia. By mid July the sheathing leaves begin to grow relatively quickly. Then follows the bract primordia stage, the formation of stamen primordia, the initiation of the perianth, and the formation of gynoecium. All of the flower parts are already differentiated by the end of August (Figure 2). High temperatures are required to release bud dormancy and for flower initiation, which is optimal between 23 and 27 °C[21] and occurs during early spring to mid summer, depending on location.[22−24] The release of bud dormancy could be accelerated by curing the corms at 30 °C for a short time. Storage of corms at 2 °C after flower initiation results in a time-dependent abortion of those flowers already initiated. Corms stored in the cold before flower initiation will form flowers when incubated after storage at 21−25 °C. When corms are maintained for a long time at very low temperatures (1−10 °C), the meristem does not give rise to flower primordia but to a new

corm.[19] Root development and flower emergence occur in late autumn at a markedly lower temperature, in the range of 15−17 °C.[21,25] This contrasts with spring-flowering bulbous species, which require a warm−cold−warm temperature sequence to flower.[26] The research carried out so far on saffron has produced extensive knowledge related to the influence of temperature on flower induction and flowering and the extension of the harvesting period over several months,[17,21,22] but this strategy has reached its peak.

Few works[27,28] have addressed the role of hormones on flowering. In these works flowering development is related to GA activity. The involvement of other environmental or endogenous factors has not been studied, and the molecular mechanisms controlling these processes are largely unknown. The *CEN/TFL1*-like gene (*CENTRORADIALIS/TERMINAL FLOWER1*) has been cloned and characterized in saffron.[29] *CsatCEN/TFL1* transcripts were detected in corms and flower organs but not in leaves, and their role in saffron flowering control is still unclear. Three *FLOWERING LOCUS T* (*FT*)-like genes, designated *CsatFT1*-like, *CsatFT2*-like, and *CsatFT3*-like, have been isolated.[30] The expression analysis indicated differences in the expression of the three *FT*-like genes in different organs. However, the expression has been measured in flowers already developed and in immature flowers, but not in the run-up to floral transition. Hence, the role of the *FT*-like genes awaits further progress.

In relation to the molecular mechanisms controlling flower development in cultivated *Crocus*, different full-length cDNA sequences encoding MADS-box transcription factor proteins involved in flower formation have been cloned and characterized. Homologues of the major ABC and E types from *Crocus* have been isolated and named *Csat AP1/FUL*,[31] CsatAP2,[29] *CsatAP3* and *CsatPI*,[32] and *CsatAG*[33] and *CsatSEP3*.[34] However, the expression analysis did not always show consistent results with the ABC model, and a functional understanding has to be clarified. For example, the three isolated *CsatAP1* genes were expressed in leaves, as well as in the three mature flower parts: tepals, stamen, and carpel. Furthermore, an expanded expression of class B genes in whorls 1 and 4 was also detected. The expression of class B genes into whorl 1 fits the modified ABC model for monocots; however, the additional expression is not consistent with this model.

Corm Development. There is limited knowledge about the physiology of vegetative development of saffron (Figure 3). The relative contribution of different carbon sources (leaf photosynthetic activity and mother corm reserves) to the growth of vegetative organs and the influence of internal and external factors on the photosynthetic processes sustaining corm growth have been studied.[19] After flowering, most of the remaining reserves in the mother corm are depleted during root and leaf development. Once these organs reach their maximum size, the growth of replacement corms is initiated, and this development primarily relies on photosynthesis. During this vegetative development, the reserves from the mother corm contribute to only 10% of the biomass. The photosynthetic rate is consistently high and constant (26 μmol m^{-2} s^{-1}) throughout the year, as has also been reported in *C. vernus*.[35,36] Plants with larger corms show reduced photosynthetic rate, although a significantly higher total leaf area is present.[19] A sink capacity limitation arises during growth of replacement corms because the increase of biomass is limited before total leaf senescence. A reduction in the demand of photoassimilates can lead to sugar accumulation in leaves, which in turn can promote leaf senescence.[37] The studies carried out in *C. vernus*, a spring ephemeral, support the hypothesis that corm sink strength is the most important factor determining leaf duration.[35,38] Differences in sink strength have been associated with differential carbon partitioning between sugar forms in the newly formed corms. A higher availability in hexoses at the beginning of the development of the daughter corms would affect cell division and elongation and, thus, higher corm size that allowed prolonged sink activity.[36] However, an in-depth knowledge about the environmental and genetic factors controlling the final size and the sink strength of the saffron corm still seems far from being achieved.

Sprouting Control in Saffron. Sprouting is another important aspect in saffron research. As stated previously,

DOI: 10.1021/acs.jafc.5b03194
J. Agric. Food Chem. 2015, 63, 8751−8764

every sprouted bud produces a corm and factors affecting apical dominance (para-dormancy) are highly important for corm production. However, the control of dormancy (endo-dormancy) is also crucial in solving the many problems associated with storage and distribution of corms and for extending the flowering and harvesting periods. Physiological and molecular studies support the concept that the mechanisms of flowering induction and dormancy are interrelated.[39] It has been suggested that dormancy-associated *MADS-box* (*DAM*) genes induced by cold temperatures in leafy spurge negatively regulates *FT* or similar genes, which regulate growth cessation and dormancy induction. Most of these studies were performed on species showing winter dormancy, where dormancy was regulated by low temperature and a short photoperiod. However, saffron shows summer dormancy, which is common in typical bulbous species. This plant strategy has been correlated with superior survival and high persistence under severe drought conditions. Summer dormancy is therefore of great interest because intense drought and heat are increasing due to climate change and may affect plant persistence. However, this type of dormancy is relatively uncharacterized at a molecular level. Recently, the characterization of summer dormancy in the bulbous species *Narcissus tazetta* and the role of FTs in summer dormancy has been reported.[40] In saffron, *FT* genes and *CEN/TFL1*-like genes that could be related with the dormancy pathway have been isolated.[30]

Dormancy interacts at some level with the mechanisms involved in cell cycle regulation, which also involves hormonal signals.[39,41] Studies of the hormonal regulation of dormancy in geophytes are abundant.[42] Clear roles for abscisic acid (ABA), such as inducing dormancy, have been revealed. ABA has been recognized to control dormancy in the corm tissue of *C. sativus*, where it declines at the time of dormancy release.[28] It has been proposed that ABA is synthesized from carotenoids (C40) in plants, and three genes that participate in ABA biosynthesis have been isolated and characterized in several plant species. They encode zeaxanthin epoxidase (ZEP[43]), 9-*cis*-epoxycarotenoid dioxygenase (NCED[44]), and abscisic aldehyde oxidase (AAO[45]). ZEP catalyzes the epoxidation of zeaxanthin to produce epoxycarotenoid; NCED catalyzes the cleavage reaction of epoxycarotenoids to produce xanthoxin (the first C15 intermediate) and is considered to be the regulatory enzyme of ABA biosynthesis; and AAO catalyzes the final step of ABA biosynthesis, which converts ABA aldehyde to ABA. Homologue genes for *ZEP*, *AAO*, and *NCED* have been identified in saffron. However, only one *NCED* gene, *CsNCED*, has been studied in detail.[46] *CsNCED* is expressed in floral and corm tissues. In stigmas, *CsNCED* transcript abundance closely mirrors ABA content with a maxima a day after anthesis, and it has been suggested that the ABA levels in the stigma could be related to the initiation of the senescent process in this tissue.[47] During corm development, zeaxanthin levels are correlated with the increase in *CsNCED* expression, suggesting a coordinate regulation of the carotenoid and ABA biosynthetic pathways during corm dormancy.[46]

Mature saffron corms usually show one to three apical dominant buds, which will sprout in the following season plus many axillary dormant buds.[22] Each axillary bud has the same developmental potential as the primary shoot apical meristem in its ability to produce a growing shoot axis (Figure 4). However, axillary buds enter a dormant state after forming only a few leaves. Plant hormones are major players in the control of axillary bud outgrowth. In particular, auxin, strigolactone, and cytokinin

Figure 4. Apical dominance in saffron: (A) corm with the main bud sprouting and dormant axillary buds; (B) axillary bud growth after removal of the main bud.

are involved in this control.[48] In saffron, auxin is supplied from the apical bud and, together with the strigolactones (SL), represses axillary bud outgrowth. By contrast, the cytokinins, produced in the adventitious roots, directly induce the sprout of the axillary buds.[49] Gibberellins (GAs) seem to be involved in apical sprout growth after dormancy break, but not in dormancy maintenance or release.[28]

SLs are derived from the oxidative cleavage of carotenoids and have been implicated in many processes including root growth, root hair and stem elongation, lateral root formation, adventitious rooting, secondary growth, leaf expansion, leaf senescence, and drought and salinity responses but most prominently in shoot branching.[48] SLs seem to act systemically to dampen the polar auxin transport stream, which enhances competition among buds for a common auxin sink.[50] To date, four loci involved in SL biosynthesis and three loci involved in SL signaling have been identified.[51−53] The first steps of SL biosynthesis involve isomerization by the plastidial-isomerase, followed by the sequential cleavage activity of CCD7 and CCD8 carotenoid cleavage dioxygenases. MAX1 encodes a cytP450 predicted to act downstream from CCD7 and CCD8 and is required for synthesis of active SL. Among all of the identified components of the strigolactone biosynthetic pathway, *CsCCD7* and *CsCCD8* genes have been recently isolated and studied in saffron.[54] SL production related to bud dormancy in saffron seems to be controlled at the *CsCCD8* level. In addition, CsCCD8 seems to play an important role in the development of the vasculature of the axillary buds in saffron. Recent evidence shows that SLs positively regulate cambial activity, and this function is conserved among species. Saffron is a monocot without cambial activity. However, given the relationship between cambial and procambial cells, it can be postulated that SLs could also positively regulate procambium activity and the development of vascular tissues in growing buds of monocots.

THE PHYTOCHEMISTRY OF SAFFRON: COMPOUNDS IDENTIFIED FROM SAFFRON FLOWERS AND CORMS

Apocarotenoids in Saffron Flowers, Biosynthesis, and Properties. Apocarotenoids are the products of the oxidative cleavage of carotenoids by specific carotenoid cleavage oxygenases (CCDs) that recognize and specifically cleave one or two double bonds.[55] If sufficient numbers of conjugated double bonds are maintained in the cleavage products they can show coloration, like their parent carotenoids. This is the case of the crocetin molecule (8,8′-diapo-8,8′-carotene-dioic acid) (Figure 5), widely used as a colorant in foods and cosmetics. The crocetin

DOI: 10.1021/acs.jafc.5b03194

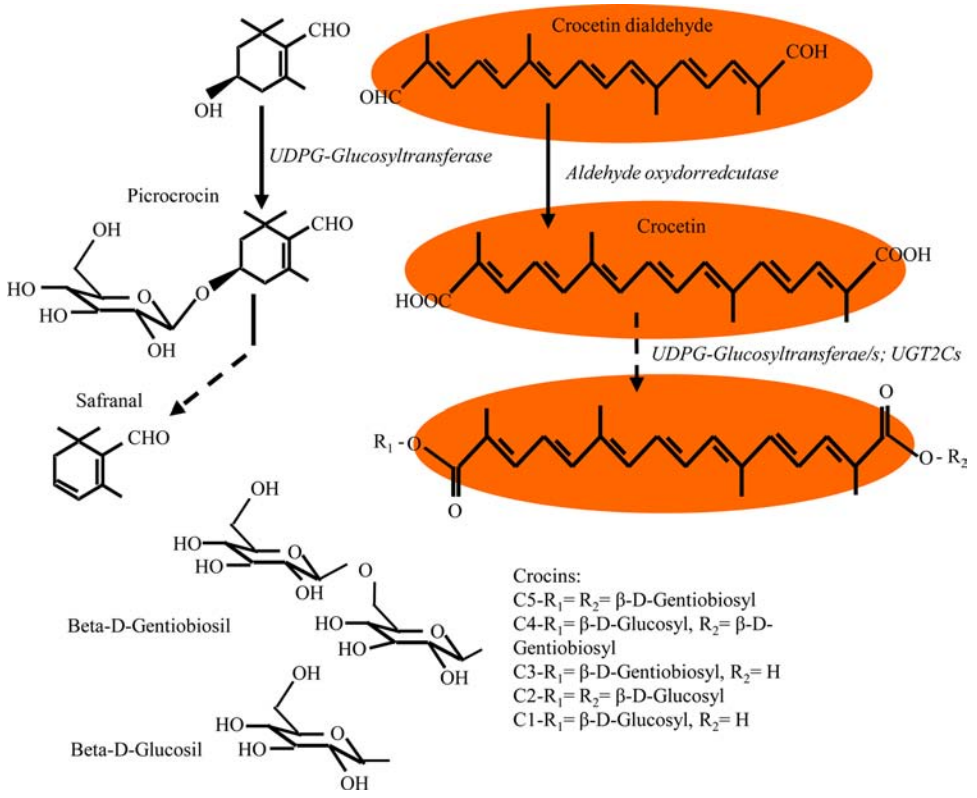

Figure 5. Pathway for crocin and picrocrocin biosynthesis in saffron stigmas.

molecule is further modified by the activity of glucosyltransferases,[56,57] which add different numbers of glucose molecules to produce characteristic crocins, these being the major components of the stigmas of saffron and which confer solubility.[58,59] Crocins are widely present in the species of the genus *Crocus*,[60] but have been also identified in *Buddleja officinalis*,[61] in *Jacquinia angustifolia*,[62] in *Coleus forskolii*,[63] in *Nyctanthes abor-tristis*,[64] in the fruits of *Artocarpus heterophyllus*,[65] *Gardenia jasminoides*,[66] and even in the cyanobacterium *Microcystis*.[67]

Crocetin is formed from the enzymatic cleavage of zeaxanthin on the 7−8/7′−8′ double bonds (Figure 6).[68,69] The resulting products are crocetindial and hydroxyl-β-cyclocitral, which is further glucosylated to form picrocrocin (β-D-glucopyranoside-hydroxyl-β-cyclocitral), the degradation product of which is the odor-active safranal.[69] Carotenoid biosynthesis, cleavage activities, and the expression of corresponding genes have been studied during the development of the stigma of *C. sativus*. A total of five CCD genes belonging to two classes of cleavage enzymes were identified from *C. sativus*.[68,70,71] Heterologous expression of CsCCD1a, CsCCD1b, CsCCD4a, CsCCD4b, and CsCCD4c sequences reduced accumulation of β-carotene in *Escherichia coli* strains engineered for the accumulation of this carotenoid.[68,72] As for volatile cleavage products produced in these strains, only C13 β-ionone could be detected, but no C10 apocarotenoids, whereas a 9−10/9′−10′ cleavage activity for both types of enzymes is predicted (Figure 6). Analysis of stigma volatiles in different stages of flower development indicated high production of β-ionone shortly before and at anthesis.[68,73] In the plant, CsCCD1a and CsCCD4a/b differ if their subcellular location is cytosolic or plastidial, respectively.[68] CsCCD4a sequences, most likely constituting an allelic variant of CsCCD4b (98% of identity) turned out to be identical to a *Crocus* ZCD sequence,[70] albeit CsZCD is a truncated sequence compared to CsCCD4a, with 200 fewer amino acids. For CsZCD a 7−8/7′−8′ cleavage activity in vitro was reported.[70] However, CsZCD lacks important residues and domains for a dioxygenase activity,[74] and no activity was found for this CsZCD in later trials.[68,75] Mining of an EST database from *C. sativus* stigmas has provided further information on potential saffron biosynthetic genes but no candidate for a novel CCD with 7−8/7′−8′ cleavage specificity.[76] Therefore, the previously isolated enzymes were analyzed against a battery of different carotenoids, including zeaxanthin and lutein,[77] and an enzyme, CsCCD2, with a confirmed specificity for the 7−8/7′−8′ double bonds was identified, showing 97% identity with the initially identified CsCCD1b[68] (Figure 6A). On the basis of the in vitro results, lutein and zeaxanthin, but not β-carotene, are good substrates for CsCCD2, and the availability or accessibility to the enzyme would determine the specificity. Accumulation of apocarotenoids in saffron is stigma specific and appears to be developmentally regulated.[73] Higher levels of saffron apocarotenoids increase as stigmas develop and reach their peak in the red stage,[73] and it is likely that the genes involved in their biosynthesis may be stimulated during the process and enhanced in the stigma tissue. *CsCCD1b* and *CsCCD2* expressions are limited to the stigma tissue and detected in the earlier developmental stages, when crocetin accumulation takes place.[68] Analysis of saffron EST collections obtained from the stigma at different developmental stages revealed that *CsCCD2* ESTs were more highly represented in libraries obtained from early stages.[77] Recently, homologues of *CsCCD2* have been identified in spring *Crocus* species, which accumulate crocins in stigmas and tepals.[78] All together, the CCD2 enzymes constitute a new CCD subfamily with no homologues identified in other plant species so far.

Apocarotenoid Properties. The stigmas of *C. sativus* have been used in folk medicine to alleviate different health

DOI: 10.1021/acs.jafc.5b03194

problems.[79] Recent pharmacological studies have demonstrated that crude extracts from saffron and purified chemicals possess antitumor effects, display anti-inflammatory properties, and counteract atherosclerosis and hepatic damage.[11,12] In studies on animal models, it has been shown that crocetin has several pharmacological properties, including antioxidant,[80,81] anti-inflammatory,[82] antiatherosclerotic,[83] insulin resistance improvement,[84] attenuation of physical fatigue,[85] and sleep.[86] Crocetin also alters the growth of cancer cells by inhibiting replication, inducing apoptosis, and enhancing the antioxidative system.[87]

Crocetin shows neuroprotective effects.[88,89] Crocetin inhibits in vitro amyloid-β aggregation,[90] and a clinical pilot study revealed significant improvements in cognition after the treatment of mild-to-moderate Alzheimer's disease patients with crocetin.[91] Crocins had protective effects on neuronal injury,[92] and attenuated the symptoms of obsessive compulsive disorder, a common psychiatric disorder defined by the presence of obsessive thoughts and repetitive compulsive actions.[93] Safranal, the main constituent of the volatile oil fraction, attenuated cerebral ischemia[94] and retinal degeneration.[95,96]

Flavonoids in Saffron Flowers. Flavonoids are among the best-characterized plant secondary metabolites in terms of chemistry, coloration mechanism, biochemistry, genetics, and molecular biology. With a basic structure of C6−C3−C6, they are widely distributed among land plants. Flavonoids are the result of the contribution of two pathways, the flavonoid branch of the phenylpropanoid and the acetate−malonate metabolic pathway. Although the central pathway for flavonoid biosynthesis is conserved in plants, depending on the species, a group of enzymes, such as isomerases, reductases, hydroxylases, and several Fe^{2+}/2-oxoglutarate-dependent dioxygenases, modify the basic flavonoid skeleton, leading to the different flavonoid subclasses.[97] Finally, transferases modify the flavonoid backbone with sugars, methyl groups, and/or acyl moieties, modulating the physiological activity of the resulting flavonoid by altering its solubility, reactivity, and interaction with cellular targets.[98] In *C. sativus*, flavonols are usually glycosylated at their 3-OH, 7-OH and 4′-OH positions,[8,99,100] producing a complex pattern of flavonols. In *C. sativus* stigmas three main glucosides of kaempferol have been identified: kaempferol 7-*O*-sophoroside, kaempferol 3-*O*-sophoroside-7-*O*-glucopyranoside, and kaempferol 3,7,4′-triglucoside. By contrast, 21 different glycosides of isorhamnetin, kaempferol, myricetin, naringenin, quercetin, tamarixetin, and taxifolin have been identified in tepals,[101] kaempferol and kaempferol glycosides being the most dominant class of flavonoids in this tissue (70 and 90% of the total content of flavonoids) followed by quercetin glycosides (5−10%).[102] In pollen kaempferide, a methylated kaempferol and the isorhamnetin glycosides isorhamnetin-3,4′-diglucoside, isorhamnetin-3-*O*-robinobioside, and isorhamnetin-3-β-D-glucoside are detected.[100] In addition, the anthocyanins delphinidin, petunidin, and malvidin have been identified in tepals, with different sugar substitutions,[102] and are responsible for their blue color.

Transcriptome analysis of saffron stigmas has allowed the identification of genes encoding for key enzymes of the flavonol pathway, and putative UDP-glycosyltransferase enzymes have been identified (data not shown). To date three genes encoding flavonol glycosyltransferases have been characterized in saffron.[99,103] The saffron CsGT45 (UGT75P1) protein showed specificity toward flavonoid aglycones and was found to be active on the C-7 position of kaempferol, kaempferol 7-*O*-sophoroside being the most abundant kaempferol glucoside present in the stigma tissue. The UGT707B1 enzyme was recently characterized as a flavonol-3-*O*-glucoside: 2″-glucosyltransferase. The expression of *UGT707B1* in the floral organs of *C. sativus* allowed the accumulation of a specific set of flavonols that influence the transport of the plant hormone auxin and could be responsible for the characteristic morphology of the stigma.[103] The last UGT characterized in saffron involved in flavonoid glucosylation is UGT703B1.[104] This enzyme recognizes isorhamnetin and kaempferol as substrates in vitro. In addition, UGT703B1 expression was found to be highly correlated with the presence of kaempferol 7-*O*-biglucoside-3-*O*-β-glucoside and isorhamnetin-3,7-*O*-diglucoside. These flavonols are present in the flowers of *Crocus* sp. from the series Crocus, but absent in *Crocus* species from other series, and could be used for quimiotaxonomic purposes.

Flavonoid Properties. In plants, flavonoids have many diverse functions including UV protection, defense, allelopathy, flower coloring to attract pollinators, auxin transport inhibition, plant−microorganism communication, and regulation of reactive oxygen species, and in many species they are required for pollen viability.[105] A number of biological processes, such as signal transduction, transcriptional regulation, and cell-to-cell communication, are also influenced by flavonoids. In addition, they play crucial roles in human nutrition, and many therapeutic benefits of flavonoids are known in animal systems. Flavonoids have antioxidant, anti-inflammatory, antitumor, antiproliferative, cardioprotective, and pro-apoptotic activities.[106−109]

The main flavonoid present in saffron tepals is kaempferol-3-*O*-β-D-glucopyranosyl-(1−2)-β-D-glucopyranoside (kaempferol 3-*O*-β-sophoroside).[103] Interestingly, this glucosylated flavonoid is not present in all *Crocus* species, and its presence is relegated to a few series, including the Crocus series. Kaempferol 3-*O*-β-sophoroside has been reported to have analgesic activity.[110] Furthermore, kaempferol 3-*O*-β-sophoroside inhibits the vascular endothelial inflammatory responses and is considered a promising target for the treatment of vascular diseases such as atherosclerosis, shock, heart attack, and sepsis.[111,112] The identification in saffron of the first UGT involved in the formation of this glucosylated flavonoid opens new possibilities for the production of this compound in other crop species or in other heterologous systems.

SAPONINS IN SAFFRON CORMS

Saponin Biosynthesis. Saponins are a widespread group of terpenoids. Saponins are important plant defense compounds, which are determinant for disease resistance due to their antimicrobial, fungicidal, allelopathic, and insecticidal activities.[113] Humans exploit saponins for their medicinal properties and antimicrobial activity. The composition of saponins depends on the genetic background of the plant material, the tissue type, and the age and physiological state of the plant as well as environmental factors.[114] The name saponin is derived from *sapo*, soap in Latin, because the surfactant properties produce soap-like foams in aqueous solution. This trait is the result of the amphiphilic nature of saponins due to linkage of the lipophilic sapogenin to hydrophilic saccharide side chains.

According to the chemical nature of the aglycone (known as sapogenin), the saponins are divided into steroidal and triterpenoid saponins. Steroidal saponins are produced especially in some families of the monocotyledons, for example, Agavaceae, Alliaceae, Asparagaceae, Convallariaceae, Dioscoreaceae, Liliaceae, Smilacaceae, and Trilliacea. In dicotyledons, steroidal saponins are detected only in a few families, for example, Fabaceae, Solanaceae, and Scrophulariaceae.[115] Cholesterol is considered the starting molecule for the biosynthesis of steroidal saponins.[116] The first committed step in the biosynthesis of triterpenoid saponins and phytosterols is the cyclization of 2,3-oxidosqualene by oxidosqualene cyclases (OSGs). The high number of possibilities for establishing different internal linkages during cyclization gives rise to a vast array of different triterpene skeletons.[117] Following formation of basal sapogenin backbone structures mediated by OSCs, various modifications take place prior to glycosylation, the most common being the addition of small functional groups such as aldehyde, hydroxyl, keto, and

DOI: 10.1021/acs.jafc.5b03194
J. Agric. Food Chem. 2015, 63, 8751−8764

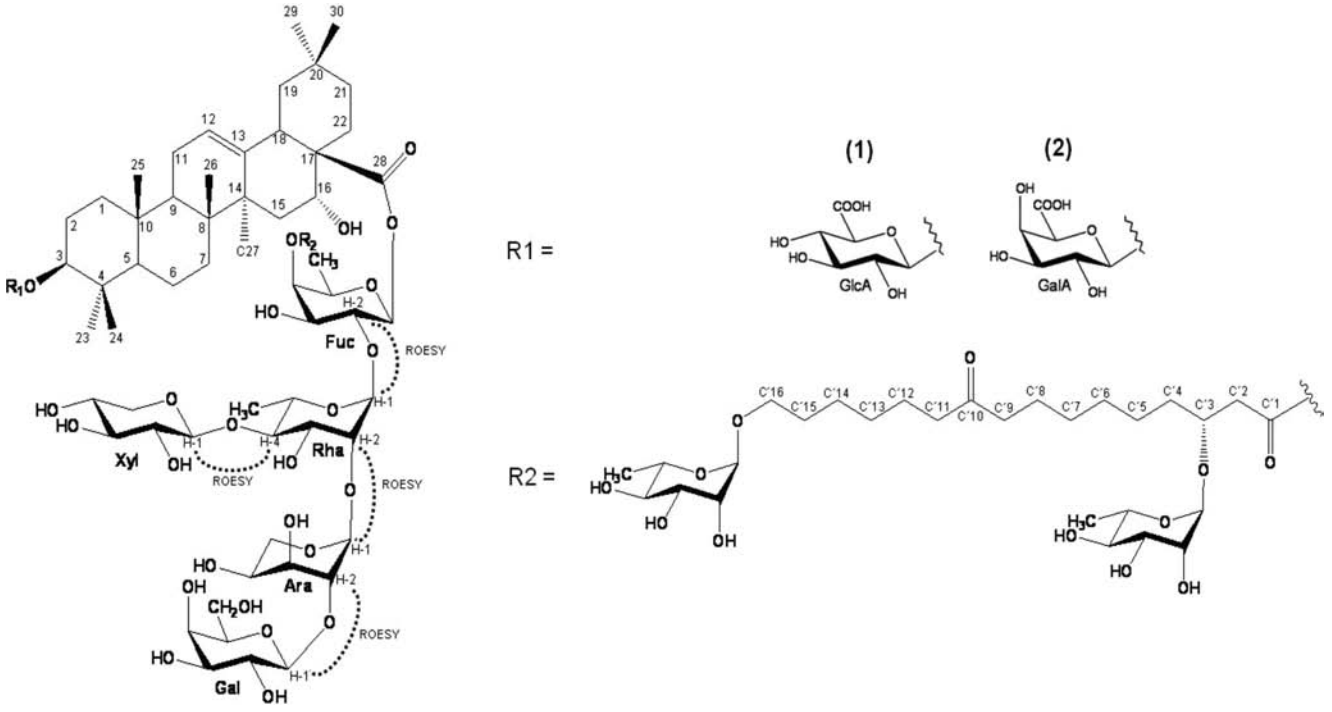

Figure 7. Structures of the triterpenic saponins, azafrines 1 and 2, identified in the corm.

carboxyl moieties at different positions of the backbone, most of them introduced by cytochromes P450 enzymes.[118] Saponin glycosylation involves sequential activity of different UGTs.[98] Typical triterpenoid saponin glycosylation patterns consist of oligomeric sugar chains, two to five monosaccharide units, which are most often linked at position C3 and/or C28.

In saffron, two triterpenic saponins have been identified in the corm, azafrines 1 and 2[119] (Figure 7). Azafrine 1 contains 3-*O*-*β*-D-glucopyranosiduronic acid echinocystic acid as prosapogenin, and azafrine 2 contains 3-*O*-*β*-D-galactopyranosiduronic acid echinocystic acid as prosapogenin. Both prosapogenins are substituted at the C28 position with a pentasaccharide consisting of *β*-D-galactopyranosyl-(1→2)-*α*-L-arabinopyranosyl-(1→2)-[*β*-D-xylopyranosyl-(1→4)]-*α*-L-rhamnopyranosyl-(1→2)-*β*-D-fucopyranose, and a 4-*O*-di-*α*-L-rhamnopyranosyl-3,16-dihydroxy-10-oxo-hexadecanoyl group is linked to C-4 of the *β*-D-fucopyranosyl residue. Azafrines 1 and 2 are localized in the external part of the corms, suggesting their involvement in plant defense.[119,120]

Saponin Properties. Saponins or saponin-containing plant extracts are exploited by the pharmaceutical industry. Several saponins, including the ones identified in saffron, exhibit pharmacological activities and thus attract attention as a target for drug discovery. Saponins are valuable adjuvants, and the first saponin-based vaccines have been introduced commercially.[121] In addition, a recent study demonstrates the potential use of azafrines 1 and 2 in human immunotherapeutic vaccines,[122] and they can also be used for further industrial applications, for instance, preservatives, flavor modifiers, and agents for removal of cholesterol from dairy products[123]

PROSPECTS FOR IMPROVING AND INNOVATING SAFFRON PRODUCTION: THE ROLE OF GENOMIC TOOLS AND BIOTECHNOLOGICAL APPLICATIONS

All over the world saffron is known as one cultivar. The continuous vegetative cultivation of saffron offers certain advantages in terms of preservation of the genetic characteristics of the plant, but makes any genetic improvement difficult. Variability studies with saffron from different countries and locations showed the absence of or very low variability among entries.[124−126] This insufficient genetic variability makes the use of this plant difficult for selection programs,[127,128] whereas the induction of genetic variability through mutagenesis has been addressed using corms at different developmental stages. Even though mutations have been identified as resulting from experimental as well as natural mutagenesis,[129,130] these are not maintained because they are not heritable.

In *C. sativus*, many experiments have been performed to obtain seeds[131] and in vitro regenerated plants[132] without success. As an alternative, researchers have been trying to elucidate how the triploid species was generated to identify the progenitors or at least the closest relatives of *C. sativus*. An autotriploid origin was initially suggested for saffron. However, an allotriploid origin from two wild species has been proposed in different papers,[102,133,134] *C. cartwrightianus* being one of the accepted progenitors.[5,34,135] Nevertheless, no such effort has been undertaken to exploit the closet relatives and hybrid generation.

A first EST collection from saffron was developed in 2007[76] comprising 6603 high-quality ESTs from a saffron mature stigma cDNA. The rapid evolution of next-generation DNA sequencing technologies has allowed the analysis of the transcriptome of six different developmental stages from saffron stigma (unpublished results). This will allow deciphering key players involved in one of the most important processes in saffron from the biotechnological point of view such as apocarotenoid metabolism.

However, it is necessary to point out that one of the most important problems in applying modern biotechnological approaches to saffron and geophytes in general is the lack of high-frequency transformation systems. Further efforts should be made to work in that direction.

Secondary Metabolism and Biotechnological Applications. The current state of the art regarding secondary metabolism in saffron has been discussed above. The identification of the key enzymes involved in apocarotenoid formation represents a very important tool for future biotechnological applications in other crop species where the substrates for crocetin formation are present. This is the case of maize and tomato, where introduction of these enzymes will provide intense red colors and higher nutritional quality, due to the higher bioavailability of the saffron apocarotenoids compared with carotenoids.[136] In addition, rice and tobacco are also good candidates to increase the production of crocins, providing added value to the crop, in the case of rice, or using the plant as a cheaper way to produce crocetin in sufficient quantities for different industrial applications. In this regard, it is also important to consider other *Crocus* species as alternative sources of saffron apocarotenoids, paying special attention to those that accumulate crocins in both stigma and tepals,[60] providing an attractive crop from an economic standpoint, due to the reduction of processing costs.

With regard to corm saponins, the genetic machinery required for the elaboration of this important family of plant secondary metabolites is as yet largely uncharacterized in saffron, despite the considerable commercial interest in this important group of natural products. The development of transcriptomes from the corm combined with metabolomic analyses will allow the identification of key enzymes involved in their biosynthesis.

Nevertheless, still little is known about the genetics that control quantitatively and qualitatively the biosynthesis of these secondary metabolites in saffron and its allies. In addition, knowledge of the regulation of these pathways is practically nonexistent, and such knowledge is of crucial importance to bypass the possibilities of low product yield of these secondary metabolites in other plants or plant cell cultures.

Control of Flower Development. Understanding flowering regulation at the molecular level in saffron, and also in other spring and autumn *Crocus*, would provide the potential for more accurately controlling both flowering time and the development of transcriptional markers for flower initiation to increase genetic variation of saffron for flowering time from spring *Crocus* using biotechnological and *omics* tools.

Although several key flowering genes (*FT*, *CEN/TFL1*, and *AP1*) have been found in saffron, understanding floral inductive pathways in *Crocus* requires not only the identification of some possible regulator genes but a precise knowledge of their expression in the different developmental stages and their control by environmental or internal factors. To date, we are far from achieving this knowledge. Limited information is available on the flower transition of bulbous species, which require high temperature for flower differentiation in species such as saffron. The results obtained by Li et al.[137] working on *Narcissus tazetta*, a bulbous species that requires high temperature for flower differentiation, showed that *Narcissus FLOWERING LOCUS T1 (NFT1)* transcripts were abundant during flower initiation in mature bulbs and were up-regulated by high temperature, suggesting that NFT1 possibly takes part in flower transition control in response to this factor. Given the similarities in the floral induction process of saffron and narcissus, the same up-regulation of *FT* by high temperature could be expected to happen in saffron, although this needs to be confirmed.

Also, the role of *CsatCEN/TFL1* needs to be clarified. Although the involvement of *TFL1* genes in floral transition and axillary meristem identity has been demonstrated in other monocot species,[138] their role in saffron is not clear.

As previously mentioned, treating dry saffron corms with GA in June−July accelerated flower formation and promoted the formation of additional flower buds from undifferentiated meristems. Furthermore, some observations point out that GAs and nutrients act through a common signaling pathway to promote flowering.[139] This pathway controlling flowering in response to gibberellin and nutrients is highly recommended to be studied in saffron. Because flower differentiation takes place in summer when the corm is located underground with no foliage or roots, the involvement of the photoperiod and vernalization pathways seems unlikely, but they should not be entirely ruled out. Another important aspect is related to the decision to bloom, which requires lower temperatures than for flower induction. The genetic control of this process has not yet been studied.

Understanding flower induction in saffron could reveal ways to extend the harvesting period, but the introduction of genetic variation from other *Crocus* species by means of biotechnological tools should also be considered. Furthermore, the development of new genotypes from *C. cartwrightianus* should not be excluded. There is a high variability for flowering time in the *Crocus* genus. This fact enables us to establish a research line aimed at acquiring in-depth knowledge about the differences in the flowering processes at the molecular level between autumn and spring *Crocus* species and making use of this knowledge to extend the saffron flowering period.

Another interesting biotechnological prospect has been pointed out by Tsaftaris and co-workers.[33] It would be desirable to have mutants without stamen formation in saffron flowers, because removal of stamens and separation of stigmas by hand is very labor intensive, leading to high costs. More interesting would be the transformation of stamens to carpel, which should increase saffron production in a single flower. However, it is not at all clear that saffron production would be doubled. The identification of saffron flower development genes that has been already carried out, as mentioned above, will facilitate the achievement of these objectives, and the usefulness of these materials can be tested.

Control of Saffron Sprouting. The understanding and control of dormancy are critical for effectively managing crop production, commercial handling, and storage. Control of endo-dormancy in saffron store corms is a requirement for staggering the production, and reliable markers for endo-dormancy in saffron and other geophytes are one of the most important issues in horticultural practice. The saffron genes *ZEP*, *AAO*, *NCED*, and dormancy-associated MADS-box (*DAM*) genes could be used as markers to determine the exact time at which environmental or internal factors trigger dormancy. It is evident that the application of molecular techniques is indispensable for clarifying the precise mechanism(s) of dormancy induction and release in bulbous species, and the establishment of such a model system is crucial for further research on dormancy of bulbous species.[42]

Another important aspect of dormancy regulation in the *Crocus* genus is the differential response of various plant organs to environmental signals as has been pointed out by Okubo.[42] The genus includes both synanthous and hysteranthous species. In both types, flower initiation occurs in summer, and the initiation orders of the leaves and flowers are similar. However, a time interval takes place between leaf elongation and anthesis in hysteranthous species, when compared to synanthous species (Figure 8). Hence, different organs might vary in their dormancy

DOI: 10.1021/acs.jafc.5b03194
J. Agric. Food Chem. 2015, 63, 8751−8764

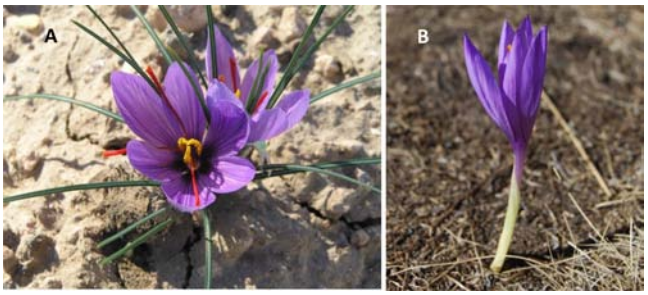

Figure 8. *Crocus* genus includes both (A) synanthous (e.g., *Crocus sativus*) and (B) hysteranthous (e.g., *Crocus nudiflorus*) species.

requirements, and the process might be controlled by both external and internal signals. The absence of leaves at flowering time is of great interest in saffron collection to make harvest work easier, and the understanding of that differential response of leaves and flowers in hysteranthous species takes on great importance.

The rate of propagation in saffron is directly related to axillary meristem formation and outgrowth, and it has been shown that there is a control exerted by the main shoot apex of the corm over the outgrowth of the lateral buds mediated by a hormonal balance. Auxin and strigolactones inhibit bud outgrowth, and cytokinins promote it. A bud-specific gene that promotes bud arrest could be the key element to integrate the bud outgrowth pathway.[140] Such a gene exists in maize (*Teosinte branched 1TB1*),[141] and there is evidence that the gene *BRANCHED1 (BRC1)* acts as an integrator of branching signals within axillary buds of *Arabidopsis*.[142] BCR1 is up-regulated by SLs and down-regulated by cytokinins. Because outgrowth of axillary buds seems to be the major limiting factor in vegetative propagation of bulbs and corms, the SL signaling pathway and *BRC1*-like genes are important targets of choice to study and optimize vegetative propagation.[140]

Improvement of Corm Growth. The manipulation of assimilate partitioning and allocation within the plant is a key factor in the improvement of corm growth. This goal could be achieved through biotechnological approaches based on the identification of the involved genes and regulatory pathways.

Photosynthesis efficiency can be improved through different targets. In relation to light reactions, it could be achieved by increasing the efficiency of light capture, energy transduction, and photoprotective processes, and for carbon fixation reactions by reducing limitations in the diffusion of CO_2 to the site of carboxylation (e.g., mesophyll conductance), in the capacity for carboxylation/oxygenation of Rubisco, and in the regeneration of RuBP.[143] In addition, other processes involving carbon metabolism, such as starch and sucrose synthesis, photorespiration, or respiration, also determine net photoassimilate production.[144]

Despite the potential of biotechnological approaches in optimizing the photosynthetic process, the study of natural genetic variation on photosynthesis within species and between related species is a valuable undertaking.[145] A survey performed on 60 different accessions of *C. sativus* in the field revealed significant differences in the photosynthetic rate and in the quantum efficiency of photosystem II (unpublished data). Research is currently being conducted to characterize the sources of variation within the photosynthetic process and to assess the relationship to biomass production in saffron and related *Crocus* species. This would provide insight into the selective forces that act on this trait and extend our understanding of the regulation of photosynthesis, ultimately increasing the productivity of crops.

Several experimental manipulations suggest that photosynthesis and sink utilization of carbohydrates are closely coordinated.[146] The regulation of carbon partitioning between sources and sinks has a great impact on plant growth and yield and is directly linked to the mechanisms of assimilate transport and allocation. Depending on the main sugar transported and the phloem loading/unloading mechanisms working, different transporters can be involved (e.g., SWEET, H^+/sucrose symporters). The biotechnological manipulation of the transport systems has been reported to positively alter carbon and also nitrogen partitioning and consequently improve crop yields, although pleiotropic effects limiting these gains can also occur.[147] However, at this time no information is available about sugar transport in *Crocus*.

The growth capacity of the sinks is a measure of its strength and depends on sink size and activity. Sink size includes cell number and cell size and is potentially regulated by hormones (gibberellins and cytokinins) along with the supply of assimilates. Bigger corms are formed when photoassimilate availability is higher.[19] Despite the genetic basis, corm size has been proposed to be influenced in *Crocus* by the content and type of soluble sugar content at earlier stages of corm development.[36] Sink activity includes multiple components and key enzymes of carbohydrate metabolism and storage, thus maintaining an assimilate gradient and transport between source and sink.[148] Sucrose is the main transported sugar in many species, and several key enzymes are involved in carbon partitioning. Cell wall and vacuole invertases (INV) in apoplastic unloaders have been related to sink strength, although other activities such as sucrose phosphate phosphatase (SPP), sucrose synthase (SS), or sucrose phosphate synthase (SPS) may also be involved. In addition, final storage products, for example, starch, are the ultimate sinks, and genes involved in their metabolism also influence sink strength.[149]

The integration of carbon assimilation and growth of organs is highly regulated, and hormonal regulation of source-sink relations has been well stated, although many aspects are not fully understood.[148,150] Another interesting approach would be the use of transcription factors to alter the activity of several genes involved in a given process. Several studies in recent years point out this possibility to enhance photosynthesis and biomass production.[150]

CONCLUSIONS

On the basis of this review, we conclude that the molecular and physiological approaches to analyzing and addressing saffron production processes and the exploitation of their secondary metabolism products remain largely unexplored. It is essential to integrate crop physiology and genomic approaches to provide a useful framework in which synergies can be explored between technology and systems-oriented approaches. This review provides a starting point for key aspects in saffron biotechnology.

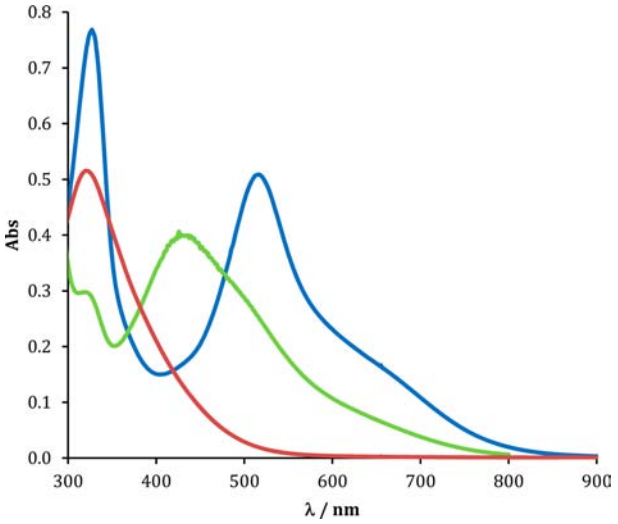

Figure 2. UV−vis spectra of DPPH• (blue, 4.7×10^{-5} M), DPPH−H (maroon, 4.2×10^{-5} M), and the anion DPPH$^-$ (green, 7×10^{-5} M) in methanol at ambient temperature.

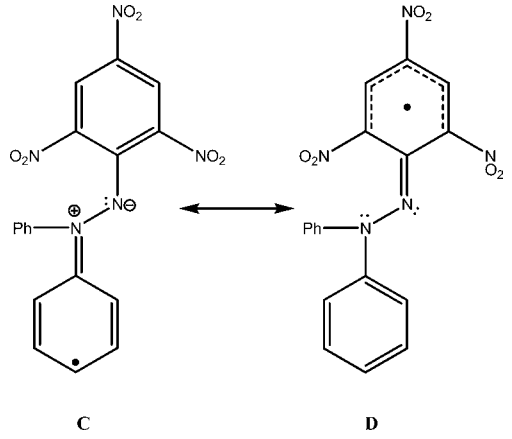
plants or single compounds (mostly phenols).[6] The potentially good intentions of the users of this test are, however, blurred by the interpretation of the data pulled from it, particularly the incorrect interpretation of the "efficient concentration"[15] (EC_{50}) as a parameter related to the antioxidant properties of chemicals.

The DPPH• radical is poorly soluble in apolar solvents, whereas in various polar organic solvents it shows a significant solubility. In water, its solubility at ambient temperature is practically nil, and this has hampered the study of the effects that this extraordinary solvent might have on the chemistry of the radical. To fill this current void of knowledge, nanoparticles of DPPH• soluble in water and *β*-cyclodextrin incorporating DPPH• were recently prepared.[13b,16] These forms could help in the understanding of the effects of water on the (electron transfer) mechanism of reactions involving biologically relevant water-soluble antioxidants (ascorbic acid, uric acid, bilirubin, glutathione, etc.). Indeed, in these past 20 years DPPH• has been very useful in the comprehension of (biologically relevant) solvent effects[17] on the rate of reactions of antioxidants + radicals and in the formulation of new[17b,18] electron transfer (ET) mechanisms involving phenols (vide infra).



CHEMISTRY OF DPPH•

The DPPH• radical reacts selectively with radicals and H-atom donors at different reaction sites. Whereas radicals usually attack the phenyl rings (or the picryl ring) (see the canonical structures **C** and **D** below), H-atom donors react with the divalent N atom. The limited space around the N atom (see Figure 1) prevents the addition of cumbersome radicals at this site. H-atom donors can approach the N atom and can release their H-atom therein with the formation of the hydrazine DPPH−H.

Molecular oxygen in its triplet-ground state, $^3O_2$, despite being a radical, does not react with DPPH• (or it does very slowly), and solutions of DPPH• kept *in the dark*[19] are stable for long times. Furthermore, the radical does not dimerize and in solution as well as in the solid[9] state is present in the free monomeric form only.

Balaban et al.[11,20] and Ionita[21] have published several papers concerning the reaction products of DPPH• with radicals and nonradical oxidant species. Some of these data are gathered in Table 1. Several oxygen radicals afford para-substitution products at the phenyl and picryl rings along with minor quantities of *p*-NO_2-DPPH−H and fragmentation products (diphenylamine, Ph_2NH, and tetraphenylhydrazine, Ph_2N-NPh_2).[11,20,21] The aryloxyl radicals of syringaldehyde and methyl syringate (two phenolic compounds) react in dichloromethane with excess DPPH• to yield para-substitution products at the picryl ring (see Figure 3).[11] Interestingly, the supramolecular complex of the anion of syringaldehyde with crown ethers yields instead a para-substitution product at the *phenyl* rings (see Figure 3).[11]

■ REACTIONS OF DPPH• WITH H-ATOM DONORS

Several chemicals react with DPPH• by H-atom donation or electron transfer. Phenols (ArOH) are probably the most reactive and the most important ones, although nontertiary aromatic amines[22] and thiols[23] are of interest, too. These reactions are often used for probing the antiradical or "antioxidant" ability of natural compounds (see below). The importance of these reactions is clearly witnessed by the number of publications. Scopus lists more than 17000 papers for the decade 2005−2015 combining the words "DPPH" and "antioxidants". Most of these papers include outcomes of the so-called "DPPH test", which consists of the addition of a certain amount of a (potential) antioxidant to a DPPH• solution and the evaluation of the pecentage of DPPH• quenched after an *arbitrary* and often *variable* time[24] (minutes to hours). This test is based on the ability of DPPH• to abstract H-atoms from A−H bonds (reaction 1). The H-atom abstraction includes those reactions that occur via electron transfer followed or preceded by proton transfer and which could be classified as *formal* H-atom transfer reactions. With natural extracts, the DPPH• test gives therefore an estimation of the total content in reducers present in solution.

Reaction 1 proceeds relatively quickly only when three constraints are met: (i) the A−H bond is relatively weak (low bond dissociation enthalpy, BDE); (ii) the radical A• is stabilized by resonance; and (iii) A is a heteroatom (O, N, S).

$$A{-}H + DPPH^{\bullet} \rightarrow A^{\bullet} + DPPH{-}H \quad (1)$$

$$A^{\bullet} + DPPH^{\bullet} \rightarrow \text{closed shell products} \quad (2)$$

$$2A^{\bullet} \rightarrow \text{closed shell products} \quad (3)$$

Hydrocarbons act very rarely as H-donors to DPPH•, and when they do, the rate constants are small (see below). 1,4-Cyclohexadiene (C−H BDE = 77.9 kcal/mol),[25a] for instance, reacts with DPPH• in CCl_4 at 298 K with a rate constant of ~0.00025 M^{-1} s^{-1} per H-atom.[12] On the other hand, α-tocopherol, the O−H BDE of which (equal to 77.2 kcal/mol) is very similar to the C−H BDE in 1,4-cyclohexadiene, reacts instead with a bimolecular rate constant of 3.6×10^3 M^{-1} s^{-1},[12,25a] that is, 14,000,000 times faster![25b]

The reasons as to why DPPH• reacts quickly with phenolic O−H bonds and slowly with C−H bonds are probably very similar to those formulated for the isoelectronic peroxyl radicals (ROO•) by Ingold and Pratt[26] in their recent review on antioxidants. Two interlinked factors have been used to explain the rate acceleration of H-atom transfers between *heteroatoms*: (1) the presence of a H-bond between the H-donor and the radical (through one of its lone-pairs) in a prereaction complex and (2) a different mechanism for H-abstraction from O−H or N−H versus C−H.

In the past, it was thought (and still is now for C−H bonds), that the H-atom (proton + valence electron) simply moved from A−H toward the SOMO of the radical along the straight line A—H—SOMO.[27] We usually refer to this mechanism with the generic expression of hydrogen atom transfer (HAT), but its domain of definition has now become less clear.[28] The accepted mechanism for the H-atom exchange between two heteroatoms (e.g., ArO-H/•OOR) is now very different. Formation of a H-bond, in the prereaction complex, involving the ArO−H and *a lone-pair* of the radical ROO• (ArO−H···:ȮOR) gives rise to a peculiar exchange of the H-atom (see Figure 4). In this complex, in fact, only the nucleus (proton) of

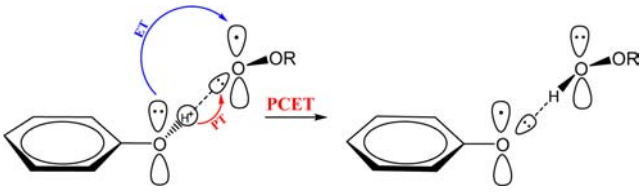

Figure 4. PCET mechanism in the reaction of phenol with an ROO• radical. The nucleus H^+ of the H-atom moves along the line O−H−O, leaving behind its valence electron. An electron is simultaneously transferred from the O lone pair to the ROO SOMO (see ref 26).

the H-atom moves toward the radical, leaving behind its bonding electron. The motion of the proton stimulates a simultaneous electron transfer from one lone pair of ArÖH toward the SOMO of ROO•, yielding the final complex (ArȮ:···H−ÖOR) in a single step. This mechanism is known as "proton-coupled electron-transfer" (PCET) because there is a concerted (single step) delivery of $1e^-$ and $1H^+$ from the donor (phenol) to the acceptor (radical) without the formation of ions.[28,29] There are cases, however (see below), in which electrons and protons are transferred to different acceptors (separated PCET),[30] and for neutral radicals (like DPPH•) this implies the formation of ion pairs. H-atom transfer via PCET is faster than HAT because the H-bond reduces the width and height of the reaction barrier.[26] As suggested by calculations, PCET is energetically favored for the exchange of H between heteroatoms. However, cases of PCET involving H exchange between C/C[31] and C/N[7] are also known. Alternative mechanisms may include electron transfer (ET) followed or preceded by proton transfer (PT) in distinct steps with the formation of high-energy intermediates (see below).

Phenols with electron-rich substituents are excellent H donors because they respond to all three requisites cited above. They are able to quickly quench ROO• radicals via PCET (see above).

DOI: 10.1021/acs.jafc.5b03839
J. Agric. Food Chem. 2015, 63, 8765−8776

$$ArOH + ROO^{\bullet} \rightarrow ArO^{\bullet} + ROOH \quad (4)$$

$$ArO^{\bullet} + ROO^{\bullet} \rightarrow \text{products} \quad (5)$$

The antioxidant abilities of ArOH are quantified by the rate constant of reaction 4, k_{ROO}. Typical values of k_{ROO} for excellent phenolic antioxidants, such as α-tocopherol, are $\sim 10^6$ M^{-1} s^{-1}.[26,33]

Up to now, reactions 4 and 5 have been considered to be of great industrial and biological importance because these reactions reduce the rate of oxidation of organic matter exposed to air (including us, of course).[26,33] In the past decade, however, the opinion that the antioxidant abilities can play a marginal role in the health benefits of dietary antioxidants such as polyphenols has taken shape.[34] This is because the in vivo concentration of these compounds is very low, and hence other mechanisms are being searched for.[34]

The study of reaction 4 can be difficult because peroxyl radicals require special precursors for their formation; moreover, they generally react rapidly with ArOH, and so sophisticated instruments are required to monitor their reaction.[35] On the contrary, the DPPH$^{\bullet}$ radical is commercially available, is colored, and is far less reactive than ROO$^{\bullet}$. In apolar solvents, the rate constant of reaction 1 for nonhindered phenols is some 3 orders of magnitude smaller than k_{ROO}; however, the two values are related because $k_{ROO} \approx 4000 \times k_1^{2/3}$.[36] Ordinary spectrophotometers can therefore be used to monitor reaction 1 (for exceptions, see below), and this has generated an explosion of works aimed at determining the *antioxidant* abilities of phenols in the general belief that the two radicals (ROO$^{\bullet}$ and DPPH$^{\bullet}$) could simply be swapped. Furthermore, kinetic solvent effects are often erroneously undervalued, and reaction 1 is made to occur in protic solvents (methanol and ethanol) because of the limited solubility of many plant-derived phenols in solvents that are not hydrogen bond acceptors, that is, alkanes. As will be shown in the pertinent section, these omissions and misconceptions make many published results and their interpretations quite improbable. This is because in polar solvents several mechanisms may coexist for ArOH + DPPH$^{\bullet}$, and the rate constants in these media do not necessarily correlate with the antioxidant ability of ArOH. Moreover, in a great many cases reaction 1 is an equilibrium reaction because the N−H BDE of DPPH−H is only 78.9 ± 0.5 kcal/mol.[10] Unreacted DPPH$^{\bullet}$ remains, for instance, in the reaction with 2,6-dimethoxyphenol (OH BDE = 82.1 kcal/mol)[7] even with a concentration ratio [ArOH]/[DPPH$^{\bullet}$] of 52:1.[10] Of course, if the initial [DPPH$^{\bullet}$] > [ArOH] (typical conditions in the DPPH$^{\bullet}$ test), then it is likely that some 2,6-dimethoxyphenol remains unreacted in solution, thereby yielding a larger EC_{50}. In both cases, slow radical/radical reactions, reactions 2 and 3, shift the equilibrium to the right.[10]

KINETIC DETERMINATION OF ArO−H BDES IN APOLAR SOLVENTS

A useful application of the kinetics of ArOH + DPPH$^{\bullet}$ was inspired by the observed relationship between the rates of ArOH + DPPH$^{\bullet}$ in apolar solvents and the phenolic O−H BDEs.[7] This correlation allowed the determination of the ArO−H BDEs of several phenols with great precision and simplicity (see Figure 5).[7]

The experimental measurement of the A−H BDE can generally be done by three broadly applicable techniques, which require considerable care: the study of radical kinetics; photoionization mass spectrometry; and the acidity/electron affinity cycle.[38] In addition, a simple and reliable EPR equilibration technique was quite recently developed by Lucarini and co-workers for the determination of ArO−H BDEs.[39a−c] This technique is based on the EPR determination of the aryloxyl radical's concentration in mixtures of 2,4,6-tri*tert*-butylphenol (*t*-BuPhOH) + ArOH submitted to continuous photolysis in the presence of di-*tert*-butylperoxide. Equilibration of the aryloxyl radicals following H-atom transfer, *t*-BuPhO$^{\bullet}$ + ArOH ⇆ *t*-BuPhOH + ArO$^{\bullet}$, is usually rapid.[40] The ΔS^0 for H-atom exchange reactions is usually very small and can be neglected. The equilibrium constant, K_{eq}, therefore, affords the value of ArO−H BDE relative to 2,4,6-tri-*tert*-butylphenol,[39c] $\Delta BDE = \Delta H^0 \cong \Delta G^0 = -RT \ln K_{eq}$.[39a] Finally, this EPR equilibration technique is valid in general and is not limited to phenols only. Recently, it was used to measure, for instance, the O−H BDE of ascorbic acid[39d] and selenenic acids[39e] (RSeOH).

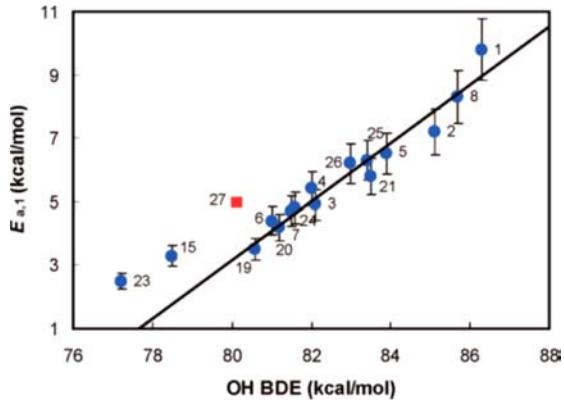

Figure 5. Plot of the activation energy for reaction 1 (A−H = ArOH) versus ArO-H BDE from ref 7. Blue circles are for 16 phenols in the group **1**−**26**. Phenols **15** and **23** were considered outliers and were excluded from the solid correlation line: $E_{a,1}$ = 0.918(O−H BDE) − 70.27 (r^2 = 0.95). The red square is for 2,4,6-tri*tert*-butylphenol, **27**.

In addition to the techniques cited above, one simple method to measure the ArO−H BDEs in apolar solvents is based on the bimolecular rate constants of ArOH + DPPH$^{\bullet}$, which correlate with the strength of the O−H bond (linear free energy relationship). Generally, this method has no critical limitations[41] except for the solubility of ArOH in apolar media. The rate constants of ArOH + DPPH$^{\bullet}$, k_{DPPH}, are easily obtainable with standard procedures, and when there are any kinetic complications, they can be obtained from the initial rates. The observed rate differences are largely due to differences in the activation energy, the Arrhenius pre-exponential factor being essentially constant, ranging from 10^5 to 10^6 M^{-1} s^{-1}.[42,43] Electronic effects of the substituents and intramolecular H-bonds influence both the ArO−H strengths and the activation energies. The equation that correlates these two parameters (in kcal/mol) is

$$E_{a,1} = 0.918 \times (\text{ArO−H BDE}) - 70.27$$

This equation can be converted in such a way that the rate constant k_{DPPH} (M^{-1} s^{-1}) appears in place of $E_{a,1}$.[43] For moderately hindered and nonhindered phenols the equations are OH BDE = 84.3 − 0.64 × ln k_{DPPH} and O−H BDE = 85.4 − 0.64 × ln k_{DPPH}, respectively, where the enthalpies are in kilocalories per mole. A single rate constant, k_{DPPH}, determined

DOI: 10.1021/acs.jafc.5b03839
J. Agric. Food Chem. 2015, 63, 8765−8776

at 298 K in apolar solvents yields by the previous equations the OH BDE of the phenol in use.[7]

SOLVENT EFFECTS: THE ROLE OF THE H-BOND

Polar solvents (PS) exert a strong influence on rates and mechanisms of H-atom abstraction by radicals. In the overwhelming majority of cases, they cause a rate *reduction*,[17a] but a few well-documented cases[44] of rate *acceleration* are also known. These kinetic solvent effects (KSEs) were fully rationalized by Ingold and co-workers in their pioneering studies done in the past 20 years.[17] The DPPH$^{\bullet}$ radical had a pivotal role in these studies[17] in combination with phenols as H-atom donors. Phenols are important antioxidants,[33] and the influence that polar environments have on their in vivo antioxidant and antiradical activities is of great importance. Phenols protect cellular membranes from peroxidation reducing the concentration of peroxyl radicals present in the membrane; they may also quench radicals in the cytoplasm, preventing cell damage. Both reactions are subjected to KSEs.

Phenols form H-bonded complexes with PS, ArOH—PS, in which the H-atom is made inaccessible by the presence of two bulky heteroatoms around. Because of this steric congestion, free radicals cannot react with these species (at least until a PCET mechanism is involved) and react only with the free fraction of ArOH (see Figure 6). Because the concentration of free ArOH decreases as the HB strength increases, the rate of reaction diminishes proportionally to the HB strength.[17a] These "standard" KSEs are observed in the vast majority of ArOH + DPPH$^{\bullet}$ reactions.

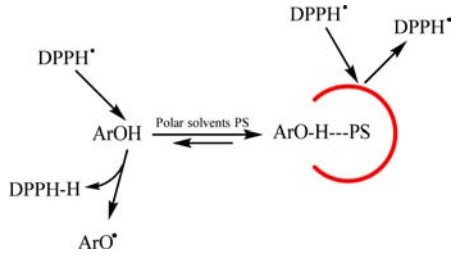

Figure 6. In polar solvents, free radicals can abstract an H-atom from the free fraction of ArOH only. H-bonded ArOHs to PSs are unable to react for steric reasons.

Nevertheless, a change in the mechanism of reaction from PCET to *separated* PCET, ET-PT, or PT-ET can have major effects on the rates because these mechanisms can bypass the steric hindrance in the H-bonded complexes.[32] Solvation of high-energy species such as ArO^{-} and ArOH$^{\bullet+}$, formed by initial PT or ET, can make the stepwise mechanisms competitive with the e^{-}/H^{+} concerted PCET (see Figure 7). These ET-PT and PT-ET mechanisms usually cause "abnormal" KSEs. In this context, Litwinienko and Ingold[45] and Foti et al.[18] discovered independently that in ionizing solvents (methanol, ethanol, water, and their mixtures) phenols react with DPPH$^{\bullet}$ essentially via ET from their anions in a PT-ET process (reactions 5 − 7), which was called sequential proton-loss electron transfer (SPLET) (see the green reaction path in Figure 7). This mechanism was proposed because (i) the KSEs in these solvents were "abnormal"[45] in that the rate constants for reaction 1 (A−H = ArOH) were found to be higher than predicted on the basis of the HB-accepting properties of alcohols;[18,17a] (ii) the rate constants decreased or increased following the addition of acids or bases, respectively;

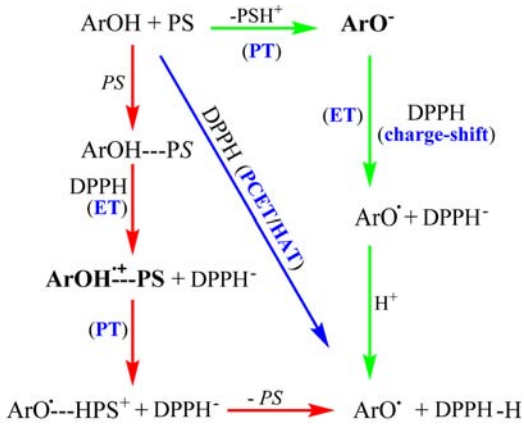

Figure 7. Reaction of phenols with DPPH$^{\bullet}$ can occur via PCET/HAT, ET-PT, or PT-ET mechanisms. The predominance of one mechanism over the others depends on various factors including the medium polarity, the ionization potentials, etc. PCET does not form any intermediate and usually prevails in both apolar and polar solvents (see text). However, for phenols with pendant bases or in a few polar solvents, for example, pyridine, separated PCET (see the corresponding paragraph) and ET-PT can be predominant despite the formation of a high-energy intermediate, ArOH$^{\bullet+}$. On the other hand, ionizing solvents support the stepwise PT-ET mechanism where the anion ArO^{-} is the high-energy intermediate. Solvation of these polar intermediates can facilitate the intervention of these stepwise mechanisms.

and (iii) the methyl esters of cinnamic acids (see Figure 8) were 3−5 times more reactive than their nonesterified counterparts.[18] The reduced reactivity of cinnamic acids relative to their esters showed that the species responsible for the DPPH$^{\bullet}$ scavenging were the phenolic anions (reaction 6). Ionization of the free COOH group reduced the amount of phenolic anions present in solution.

$$\mathrm{ArOH} \leftrightarrows \mathrm{ArO^-} + \mathrm{H^+} \quad (5)$$

$$\mathrm{ArO^-} + \mathrm{DPPH^\bullet} \rightarrow \mathrm{ArO^\bullet} + \mathrm{DPPH^-} \quad (6)$$

$$\mathrm{DPPH^-} + \mathrm{H^+} \rightarrow \mathrm{DPPH{-}H} \quad (7)$$

All of these kinetic observations led to the formulation of SPLET as a predominant mechanism for ArOH + DPPH$^{\bullet}$ reactions in protic solvents. Given the usually high oxidation potentials of phenol anions and the high reduction potentials of several biologically relevant radicals,[46] it is likely that in numerous in vivo ArOH + radical reactions the formal H-atom transfer occurs via stepwise ET mechanisms (e.g., SPLET). The E^0_{red} of DPPH$^{\bullet}$ is +0.23 V/SCE in acetonitrile[47] and perhaps larger in methanol.[48] Therefore, radicals such as $NO_2^{\bullet}$, $CO_3^{\bullet-}$, and HOO$^{\bullet}$ characterized[49] by $E^0_{red} > 0.23$ V can very likely react with phenols via ET from the anions or the neutral species. It is well-known that strongly oxidizing peroxyl radicals (e.g., halogenated peroxyls, peroxyacetyl radical $CH_3(CO)OO^{\bullet}$, etc.) react via ET with several substrates including phenolate, ascorbate, and inorganic anions, producing the corresponding radicals.[50]

REMOTE H-BOND EFFECTS AND SEPARATED PCET

Phenols with pendant piperidine **1**−**3** represent an interesting case of ArOH + DPPH$^{\bullet}$ reactions.[44a] In **1** and **2**, the presence of an intramolecular H-bond has a profound influence on the rate of H-atom abstraction from both the O−H involved in the

DOI: 10.1021/acs.jafc.5b03839
J. Agric. Food Chem. 2015, 63, 8765−8776

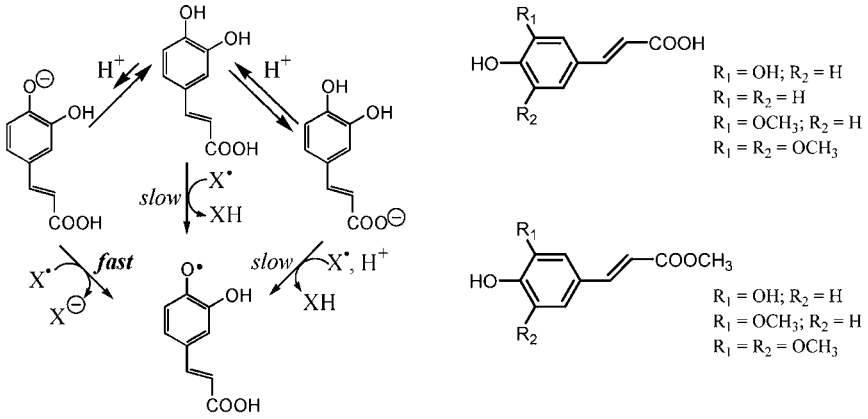

Figure 8. Cinnamic acids react with DPPH• (symbolized as X•) in methanol and ethanol via SPLET, and their rate constant k_1 decreases as the concentration of cinnamic acid increases. This happens because as the concentration of cinnamic acid rises, ionization of the COOH group limits more and more the formation of phenolic anions (the reactive species) (see ref 18). The rate constants k_1 of the methyl esters are instead large and essentially independent of their concentration.

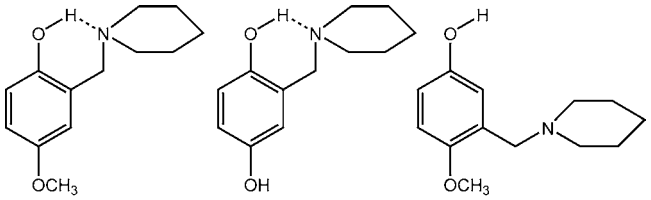
HB (compound **1**) and the HB-free *p*-OH (compound **2**). The rate constants measured in cyclohexane at 298 K for **1**, **2**, and **3** are 2.5, 7800, and 400 M^{-1} s^{-1}, respectively (Table 2). The mechanism involved in these reactions in cyclohexane is most likely PCET/HAT.

Table 2. Rate Constants for the Reactions of 1−3 with DPPH• at 25 °C from Reference 44a

	k_{DPPH} (M^{-1} s^{-1})	
phenol	cyclohexane	acetonitrile
1	2.5 ± 0.5	1200 ± 60
2	7800 ± 30	2340 ± 25
3	400 ± 30	280 ± 60



The low reactivity of **1** relative to **3** shows the "protective role" that a H-bond may have on phenolic H-atoms. Generally, free radicals react slowly with intramolecularly H-bonded phenols because the HB increases the energy required to pull the H-atom out. In a great many cases, natural polyphenols are intramolecularly H-bonded to methoxy groups, which probably serve as a sort of "padlock" to protect phenols from radicals and facilitate their arrival at the final reaction site.

On the other hand, the rate constants show that phenol **2** is much more reactive than both **1** and **3** (Table 2). The higher reactivity relative to **1** suggests immediately that the reaction site in phenol **2** is the H-bond free O−H. Interestingly, phenol **2** is also some 20 times more reactive than **3** because of the effects of the "remote H-bond".[51] H-bond effects have been observed in many other dihydroxybenzenes with catechol-, hydroquinone-, and resorcinol-like structure and also in 1,8-naphthalenediols.[37,51] The orientation of the remote H-bond determines the sign of the variation: para → meta H-bonds cause an *increase* in the rate of H-abstraction (as in the case of phenol **2**), whereas meta → para orientations determine a *decrease* in the rate relative to molecules lacking H-bonds.[51b]

The explanation given for these effects is that the −O• in the aryloxyl radical has strong electron-withdrawing character (see Figure 9). This causes an O−H group in the para position of

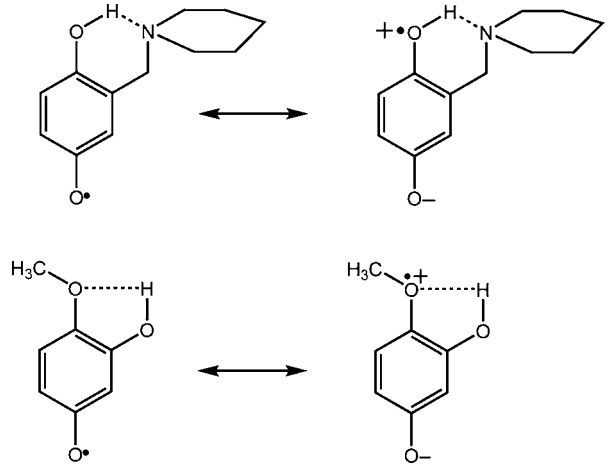


Figure 9. Canonical structures for aryloxyl radicals with remote H-bonds. In both radicals, the presence of the electron-withdrawing −O• group determines a decrease in the electron density of the O atom in the para position. This causes opposite effects in the two radicals. In the aryloxyl with para → meta oriented H-bond (upper case), the increased acidity of the H-bonded O−H determines a reinforcement of the H-bond. This stabilization is reflected in the transition state of the reaction and hence causes an increase in the reactivity of the parent phenol. Conversely, the strength of the H-bond decreases in the aryloxyl with meta → para orientation, and this causes a reduction in the reactivity of the parent phenol because the transition state is destabilized.

ArO• to become more acidic than in the parent molecules and hence capable of forming stronger H-bonds with HB-acceptors in the meta position. For the same reasons, HB-acceptors (such as OCH_3) in the para position become more electron-deficient and form therefore weaker HBs in the aryloxyl radicals than in the parent molecules (see Figure 9). These thermochemistries influence the transition states and thus the kinetics of H-abstraction from phenols by free radicals.

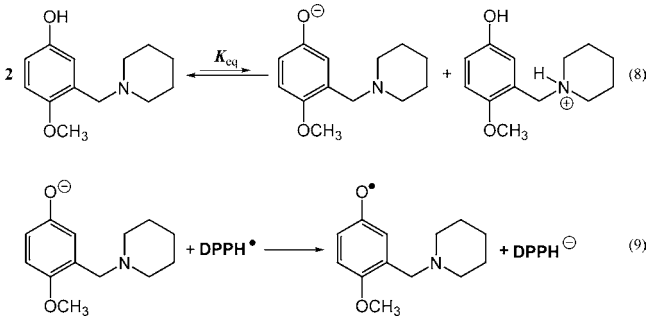
J. Agric. Food Chem. 2015, 63, 8765−8776

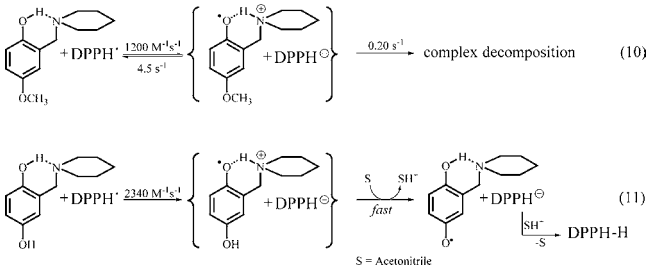
When the solvent is changed from cyclohexane to acetonitrile, the new rate constants showed clearly that the mechanism of DPPH• quenching had changed (see Table 2). The rate constant of **1** increased in acetonitrile by a factor of 480 (k_1 = 1200 M^{-1} s^{-1}), whereas those of **2** and **3** decreased a bit, but the decrease was confined within a factor of 1.4−3.3 (the expected reduction for a PCET/HAT mechanism in acetonitrile would be by a factor of about 70!).[17a]

An apparently reasonable mechanism for **3** + DPPH• in acetonitrile, consistent with the above kinetic data, was suggested by the thermodynamically plausible self-ionization of **3** (reaction 8). The equilibrium constant for this auto-



ionization was estimated[44a] to be ∼10^{-8}, a value much greater than the typical K_a ∼ 10^{-25}−10^{-20} of phenols in acetonitrile.[32] Thereby, comparatively large quantities of phenol anions[52] were formed in solution by reaction 8, and these most likely reacted via ET to DPPH• (reaction 9). The overall process represents a special case of SPLET in a nonprotic solvent (acetonitrile) stimulated by the presence of the nitrogen base.

On the other hand, it appears highly probable that phenols **1** and **2** reacted both through a separated[30] PCET pathway, with e^- and H^+ being transferred to DPPH• and piperidine nitrogen, respectively (see reactions 10 and 11) (see also Figure 10). Nevertheless, the kinetic behaviors of the two phenols were very different. Whereas **2** reacted with a pseudo-first-order process, the kinetics of **1** + DPPH• showed a biphasic behavior with an initial fast process (first 300 ms) followed by a second slower DPPH• loss for some tens of seconds. Kinetic evaluations led the first step to be attributed to the equilibrium formation of a metastable distonic radical cation in contact with $DPPH^-$, whereas the second slow step to the dissolution of the ion pair (see reaction 10).



The different kinetic behaviors of the two phenols were interpreted as due to the fact that the distonic radical cation of **2**, unlike the other case, was able to rapidly "shoot" an H^+ from the free OH into the bulk solution because radical cations of phenols are very acidic.[53] This fast process impeded the formation of the equilibrium that was instead attained with **1**, and thus the initial step became rate-determining (reaction 11).

THE REMARKABLE CASE OF QUERCETIN + DPPH• REACTION

Quercetin (QH_2) is a flavonoid widely distributed in the plant kingdom.[54] A balanced daily diet supplies us with a few tens of milligrams of flavonoids chiefly constituted by quercetin.[55] Generally, flavonoids are believed to provide certain health benefits that are usually attributed to their ability to trap free radicals. This ability is actually common to all phenols and does not necessarily reflect their "antioxidant properties" (see above). As most phenols, QH_2 is in fact able to quench both DPPH• and ROO• radicals. This might seem rather trivial in view of the nature of the molecule. The quenching process of DPPH• in methanol/water deserves, however, our attention because it shows how insidious the analysis of the DPPH• kinetics can be and how dissimilar these kinetics are from those of the ROO• radical.[56]

The reported values in the literature of the rate constant for QH_2 + DPPH• in methanol at room temperature surprisingly span a large range from a low of 264 M^{-1} s^{-1} to a high of 6433 M^{-1} s^{-1}.[57] These values were actually measured with conventional spectrophotometers at 519 nm (λ_{max} DPPH•) in a time frame long after the "true" reaction of DPPH• with QH_2 had occurred. This was deduced by using stopped-flow spectrophotometers, which allowed us to observe that the QH_2 + DPPH• reaction in methanol/water 80:20 v/v was over after only 100−300 ms![56] So what was actually being measured when the apparent loss of DPPH• was monitored with conventional spectrophotometers at $t \gg 300$ ms?

To answer this question, it is necessary to re-examine the chemistry of quercetin oxidation.[58] The two-electron oxidation of QH_2 yields quinone/quinomethide products (reaction 12), which are intensely colored.[58] Several tautomers can exist in solution, but according to quantum chemical calculations,[58] the tautomer Q shown in reaction 12 is the most stable and the most abundant in solution. The striking aspect of these compounds is that their UV−vis spectra and color are fortuitously very similar to those of DPPH•.[56] This has created

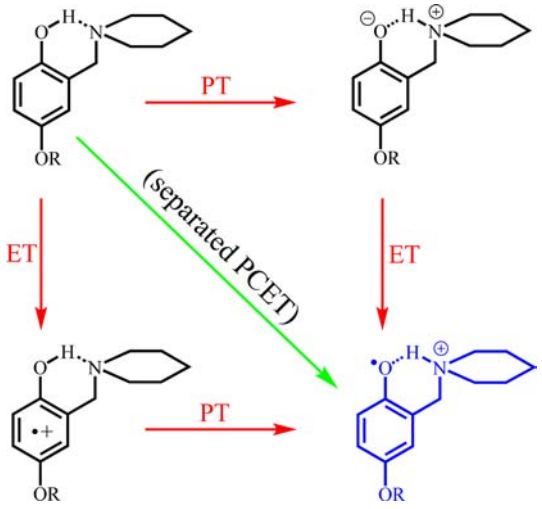


Figure 10. Peripheral pathways to the distonic radical cation shown with red arrows include high-energy species and hence may be kinetically disfavored. The diagonal path (PCET) is instead favored because e^- and H^+ are transferred simultaneously to their respective acceptors, that is, DPPH• and piperidine N, without formation of intermediates.

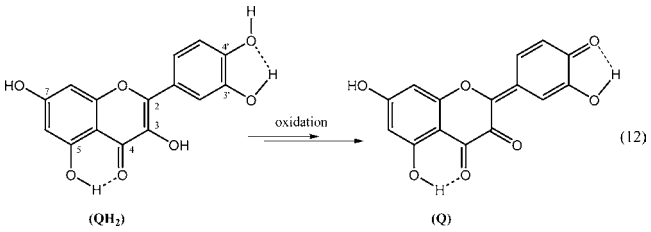
DOI: 10.1021/acs.jafc.5b03839
J. Agric. Food Chem. 2015, 63, 8765−8776



a grave problem of interpretation of the 519 nm absorbance decay at long times, because this decay has been interpreted as a relatively slow loss of DPPH• caused by QH_2. Actually, the QH_2 + DPPH• reaction is so fast that DPPH• is consumed long before any measurements in conventional spectrophotometers can be made.[56] This is because the 2e oxidation of QH_2 by DPPH• proceeds in methanol/water via SPLET in a sequence of reactions shown in Figure 11. The rate law of this process is first-order in DPPH• but only ca. 0.38 order in QH_2, which suggests that the charge-shift occurs in a complex, maybe formed by π-stacking of the reactants, $\{QH^-/DPPH^•\} \rightarrow \{QH^•/DPPH^-\}$.[56] The semiquinone radical QH• generated is likely to rapidly ionize (the Brønsted base being either the DPPH anion in the complex or the solvent) because this radical is expected to be more acidic than QH_2 for the electron-withdrawing character of the −O• group (see above).[53] The radical anion $Q^{•-}$ so derived gives rise to a second ET process to DPPH• with formation of colored quinones/quinomethides, Q (see reaction 12 and Figure 11).

The kinetics at t > 300 ms, monitored with ordinary spectrophotometers, are due to the decay of the quinomethide Q by solvent (MeOH, H_2O) and QH_2 addition. Such addition products have been identified by several workers.[56,57a,59] The quinonemethide, Q, can in fact be regarded as a highly stabilized benzylic carbocation[60] (see Figure 12), which can readily undergo a proton-assisted (Michael-type) nucleophilic addition.

The above case clearly shows how unwise is the evaluation of kinetic or chemical properties from measurements made away from the initial time (the rapid mixing of the reactants) relying particularly on the reaction color. In truth, it is very important to check the initial stage of the reaction with a stopped-flow instrument to get a clear insight into the reaction path.

The above example also shows that the kinetics of DPPH• + flavonoids in alcohols can be very complicated because they involve flavonoid ionization, complexation, and ET mechanisms.[61] These kinetics can prudently be untangled because the DPPH• radical can be directly "observed". In the case of ArOH + ROO•,[62] the most likely mechanism of reaction is PCET (although strongly oxidizing ROO• may react via ET, see above) and thus the estimate of the antioxidant properties of ArOH from the kinetics of ArOH + DPPH• in alcohols can be mistaken.

"THE DPPH• TEST"

The DPPH• test for appraising the antioxidant activity of chemicals (AH) was first suggested by Blois in 1958.[8] Then, the test was developed by Brand-Williams et al.[15] in 1995 in the form adopted by the vast majority of researchers. Briefly, different AH concentrations are used in such a way to determine the concentration of AH that quenches 50% of the initial DPPH• radical in a specific, although arbitrary, time interval. This concentration is called (efficient concentration) EC_{50} or, sometimes, (inhibitory concentration) IC_{50}. In truth, this EC_{50} designation has a proper scientific usage under a different name (LD_{50}) in drug testing. It is likely that the term was "hijacked" to put a veneer of respectability on a questionable measurement using DPPH•. At any rate, it seems obvious that the lower the EC_{50}, the higher the antiradical ability of AH. There are, however, many issues associated with the EC_{50} parameter and its interpretation.

First is the time interval. EC_{50} is time-dependent, and the effect of time can vary from compound to compound.[63] Usually, increasing the reaction time may improve the evaluation of a given compound (lower EC_{50}), and hence the test can be tailored so that a poor antiradical/antioxidant appears to be an excellent antiradical/antioxidant. It is clear therefore that the interpretation of this test is quite arbitrary, and any comparison between results from different laboratories is not possible if the adopted reaction time is different. In general, short reaction times are better than long times in the questionable evaluation of the antioxidant abilities of chemicals from the DPPH• test.[63]

Second, EC_{50} is *not* a kinetic parameter (it is just a concentration), and as such it cannot express the antioxidant or antiradical ability of a compound, because this ability must be

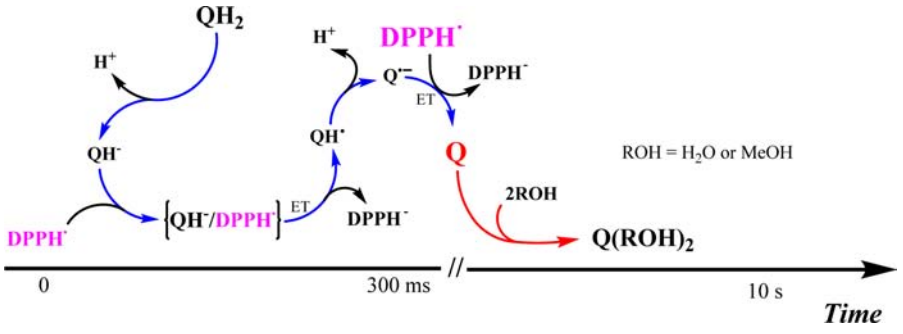


Figure 11. Time evolution of the reaction QH_2 + DPPH• in methanol/water 80:20 v/v at room temperature. The pathway in blue shows the conversion of quercetin into quinomethide Q in a time scale of about 100−300 ms. The pathway in red represents instead the slow (time scale of seconds) decay of Q by solvent and QH_2 addition (see text). The electron donor is the quercetin anion (from the 7-OH) because the addition of acetic acid blocks the reaction. On the other hand, the rate law suggests that QH^- and DPPH• are associated in a complex before reaction. π-Stacked complexes $\{QH^-/DPPH^•\}$ are likely to be present in solution and can convert into the ET products, QH• and $DPPH^-$. Ionization of the semiquinone radical QH• (see text) yields the radical anion $Q^{•-}$, which can give rise to a second ET to DPPH• with formation of quinones/quinomethides intensely colored, Q. These compounds can add solvent and QH_2 molecules forming *colorless* compounds.

J. Agric. Food Chem. 2015, 63, 8765−8776

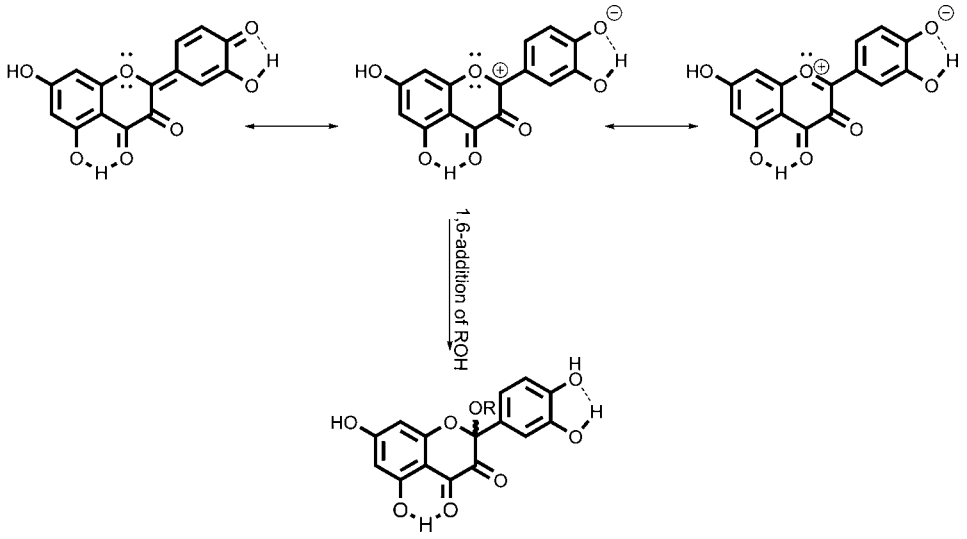

Figure 12. Carbon C2 in Q is electrophilic because of the effects of the quinone moiety. Addition of solvent can therefore easily happen with the formation of colorless compounds.

represented by a kinetic parameter. To establish whether AH is or is not a good antioxidant, it is necessary in fact to compare the *rate* at which AH quenches peroxyl radicals to the *rate* at which peroxyl radicals attack the substrate. The value of EC_{50} is instead essentially related to the stoichiometric factor, *n*, of reaction 13, which is an important complementary parameter for antioxidants (for good antioxidants, $n \geq 2$) that can be easily obtained from the DPPH$^\bullet$ test ($n = ((\Delta[DPPH])/[AH])$ at long times). If reaction 13 is complete, EC_{50} is inversely proportional to *n* because $EC_{50} = [DPPH]_0/2n$ and thus phytochemicals with large stoichiometric factors, *n*, can be classified by the test as powerful antioxidants (low values of EC_{50}) despite the fact that the quenching of DPPH$^\bullet$ may have occurred in one century! Furthermore, the stoichiometric factor *n* (and thus the EC_{50}) may depend on the concentration of AH used in the experiments[6] (see Figure 13). This dependence can be explained via the radical/radical reactions 2 and 3, which take place after the formation of the radical A$^\bullet$ (reaction 1).

$$AH + n\text{DPPH}^\bullet \rightarrow \text{products} \quad (13)$$

It is clear that if reaction 2 is faster than reaction 3, then $n \rightarrow 2$ per single H-atom donated by AH, whereas in the opposite case $n \rightarrow 1$. Anyhow, as the concentration of AH is increased, reaction 3 tends to predominate over reaction 2 and $n \rightarrow 1$ (see Figure 13). Finally, the products formed in reactions 2 and 3 may react with DPPH$^\bullet$, increasing the value of *n*. Obviously, this circumstance is extremely positive because these products contribute to the quenching of DPPH$^\bullet$ and therefore may have antioxidant properties.

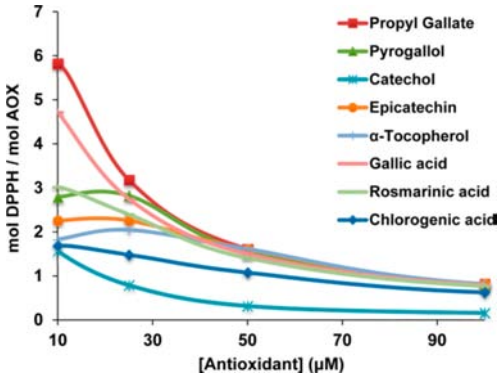

Figure 13. Stoichiometric coefficients for reaction 13 at various concentrations of the H-atom donors. Reprinted from ref 6. Copyright 2014 American Chemical Society.

Third, the quenching mechanisms of DPPH$^\bullet$ and ROO$^\bullet$ may differ. In this case, the evaluation of the antioxidant ability from the DPPH$^\bullet$ test can be deceptive. Usually, the DPPH$^\bullet$ test is done in methanol or ethanol for the ease of solubilization of many phytochemicals including phenols. In alcoholic solutions, however, phenols ionize and thus react with DPPH$^\bullet$ via SPLET (see above), that is, via ET from their anions. In many cases, acidic phenols react relatively rapidly with DPPH$^\bullet$ but slowly with ROO$^\bullet$ because this radical reacts via PCET and the O−H bonds, in this case, have large BDEs. The antioxidant ability of phenols in fact correlates in apolar media with the gas-phase ArO−H BDE (see above). One good example displaying this discrepancy is the following. The 4-cyano-2,6-di-*tert*-butylphenol shows in methanol a higher reactivity toward DPPH$^\bullet$ than the 4-methoxy- and 4-methyl-2,6-di-*tert*-butylphenol. The values of the rate constants are 16, 3.9, and 3.7 M^{-1} s^{-1}, respectively.[63−65] On the other hand, the antioxidant abilities follow the order 4-methoxy- > 4-methyl- ≫ 4-cyano-2,6-di-*tert*-butylphenol.[63]

In conclusion, the "three points" exposed above show pretty well that the much-vaunted DPPH$^\bullet$ test is in fact unsuitable to provide the information for which it was created. The antioxidant properties of phytochemicals must be expressed by a kinetic parameter that can be obtained by studying the DPPH$^\bullet$ decay versus time in appropriate solvents (alkanes, THF, CH_3CN, and other nonionizing solvents), where the complications of ionic mechanisms do not emerge, and with appropriate instruments (conventional vs stopped-flow spectrophotometers). The second-order rate constant k_{DPPH} of reaction 1 is one of the best surrogate parameters useful to prudently evaluate the antioxidant properties of chemicals. For pure compounds, the DPPH$^\bullet$ test can be used to determine the stoichiometric factor *n*, whereas for natural mixtures it serves to titrate the content in H-atom donors (or more in general "reducers") present in the sample. In these cases, the test can be

DOI: 10.1021/acs.jafc.5b03839
J. Agric. Food Chem. 2015, 63, 8765−8776

done in any solvents including alcohols because it is likely that neither *n* nor the content in H-donors is significantly influenced by the solvent.

Despite all of these complications, the DPPH• radical has contributed much to the enlargement of scientific knowledge. The long "scientific life" of this radical has allowed the study and understanding of many chemical phenomena such as kinetic solvent effects, remote H-bond effects, reaction mechanisms involving free radicals, antioxidant properties of phenols, and the strength of the ArO−H bond to name but a few. However, the extreme importance of antioxidant chemistry, as a major theme of free radical chemistry,[26] continues to be used to justify the main usage of this artificial radical: the search for the "perfect antioxidant"!

(41) The straight-line used to calculate ArO-H BDEs from $k_{DPPH}^{\bullet}$ (see Figure 5) was built using well-established values of ArO-H BDEs determined with the EPR equilibration technique. These values are based on the OH BDE of 2,4,6-tri-*tert*-butylphenol, which was recently reviewed (see ref 39c).

(42) The *A* value of strongly hindered phenols, such as 2,4,6-tri*tert*-butylphenol, is much lower, ∼10^3 M^{-1} s^{-1}. These phenols were not included in the group of phenols used to construct the E_a/ArO-H BDE relationship.

(43) The *A* values for moderately hindered phenols and nonhindered phenols are 2.2 × 10^5 and 1.2 × 10^6 M^{-1} s^{-1}, respectively (see ref 7).

(62) It is important to observe that the antioxidant properties of ArOH expressed by the value of k_{ROO} (reaction 4) are not measured by monitoring ArOH + ROO$^{\bullet}$. The rate constant k_{ROO} is obtained from the (inhibited) rate of oxygen uptake by oxidizable substrates undergoing peroxidation in the presence of ArOH (see ref 33).
(63) Amorati, R.; Valgimigli, L. Advantages and limitations of common testing methods for antioxidants. *Free Radical Res.* **2015**, *49*, 633−649.
(64) At short reaction times, it is likely (see ref 63) that the EC_{50} values of these three phenols will follow the same order of reactivity.
(65) The 4-cyano-2,6-di-*tert*-butylphenol + DPPH$^{\bullet}$ reaction is an equilibrium reaction largely shifted to the left. The degree of conversion into the reaction products (aryloxyl radical + DPPH−H) is therefore low.

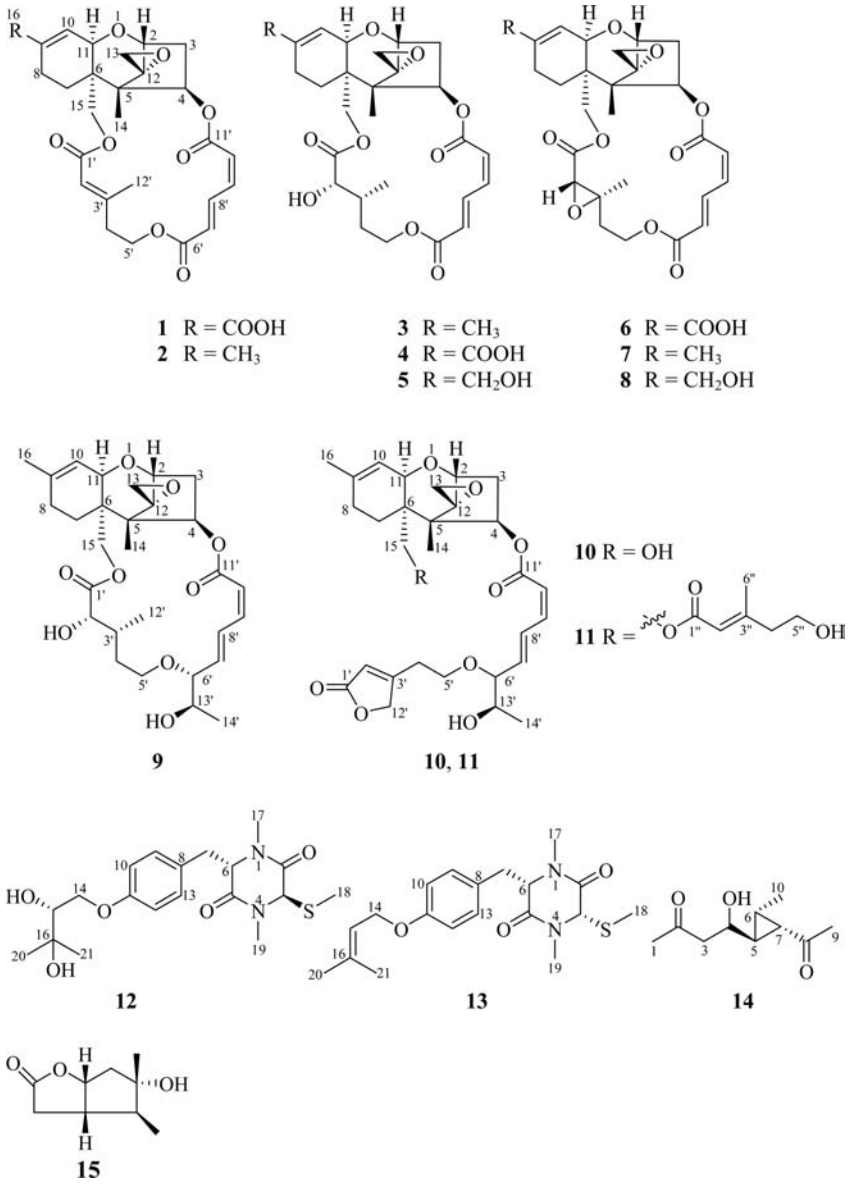

Figure 1. Structures of compounds **1**−**15**.

report the structure determination and biological activities of compounds **1**−**12**, **14**, and **15** (Figure 1) isolated from this fungus.

MATERIALS AND METHODS

Safety Information. Trichothecenes are highly toxic inhibitors of the protein biosynthesis. They may penetrate the skin and have been discussed as potential biological warfare agents ("yellow rain").

General Experimental Procedures. Optical rotation values were measured on a PerkinElmer polarimeter, model 241, at the sodium D line (λ = 589 nm). The NMR spectra were recorded on a Mercury-300 (300.141 MHz), a Varian Inova 500 (125.707 MHz for ^{13}C NMR spectra), and a Varian Inova 600 (599.740 MHz) spectrometer. IR spectra were taken on a Jasco FT/IR-4100 type A instrument. Chemical shifts (δ) were referenced to CH_3OH at 3.30 for ^{1}H and at 49.0 for ^{13}C and to $CHCl_3$ at 7.24 for ^{1}H and at 77.0 for ^{13}C. ESI-HRMS spectra were acquired on a micrOTOF 10237. Size exclusion chromatography was performed on Sephadex LH-20 purchased from Sigma-Aldrich Chemie, Steinheim, Germany. Open column chromatography was done on silica gel 60 (0.063−0.20 mm), and PTLC was performed on silica gel P/UV_{254} (both obtained from Macherey-Nagel, Düren, Germany). Mosher's reagent and nystatin were bought from Sigma-Aldrich, Steinheim, Germany. Ciprofloxacin was obtained from Square Pharmaceutical Co., Bangladesh. Solvents used for extraction and chromatography were distilled prior to use. For HPLC-MS, HPLC grade solvents (LiChrosolv, Merck AG, Darmstadt, Germany) were used.

Fungal Material and Identification. Healthy stems (∼4 cm length) of *D. metel* were collected from the garden of medicinal plants, Department of Pharmacy, Rajshahi University, Bangladesh, and kept in plastic zipper packs at 4 °C for 2 months. The surface sterilization of each stem was done according to a previously described procedure.[2] The sterilized stems were air-dried on sterile filter paper, and the bark was removed by a sterile knife. Pieces of the stem (∼1 × 1.5 cm) were then placed on a water-agar Petri dish (18 g agar per L tap water) and incubated at 25 °C. The outgrowing endophytic fungal strain M10 was isolated and maintained on M_2 agar medium (10 g of glucose, 4 g of yeast extract, 4 g of malt extract, 18 g of agar, and 1 L of tap water). The strain M10 was identified by its ITS and morphological features. The ITS sequence of M10 showed 99.8% homology to the ITS sequence of *M. roridum* strain CBS 331.51 (GenBank accession no. HQ115647). The M10 strain is kept in the Microbial Culture Collection at the Institute for Organic and Bimolecular Chemistry,

J. Agric. Food Chem. 2015, 63, 8777−8786

Georg-August-University Göttingen, Germany, under the curatorship of Prof. Laatsch.

Fermentation and Isolation. For the seed culture, the fungal strain M10 was subcultured on M_2 agar medium and incubated at 25 °C for 3 days. For the batch fermentation, 200 g of rice and 150 mL of tap water were added to each of 24 P-flasks (28 × 17 × 7 cm) and then sterilized for 15 min at 121 °C. From the seed culture, the mycelium was scraped out using a sterile loop, spread in 200 mL of sterile water, and then added into each P-flask containing the rice medium. The flasks were incubated at 30 °C for 20 days, and then the whole culture was extracted with EtOAc and filtered through Celite (diatomaceous earth). The filtrate was concentrated to dryness in vacuo using a rotary evaporator at 40 °C to obtain a reddish gum. The concentrated extract was dissolved in MeOH and treated with cyclohexane to remove fats. The methanol was then evaporated, and the extract was partitioned between EtOAc and distilled water. The water phase was evaporated to dryness (1.5 g) and separated into 30 fractions (F1−F30) using Sephadex LH-20 column chromatography, eluting with CH_2Cl_2/MeOH (1:1). Compounds **3** (6.0 mg from F7−F9) and **4** (4.5 mg from F16−F26) were isolated by PTLC using 10% MeOH in CH_2Cl_2. Compounds **5** (10.0 mg), **10** (6.0 mg), and **11** (6.5 mg) were obtained from F12 in a similar way, eluting with $CHCl_3$/*n*-hexane/MeOH (4:1:1).

The EtOAc phase was also evaporated to dryness (10.0 g) and fractionated by silica gel column chromatography using a stepwise gradient: 2% MeOH in CH_2Cl_2 (F1−F24), 7% MeOH in CH_2Cl_2 (F25−F35), and 12% MeOH in CH_2Cl_2 (F36−F43). Compounds **1** (5.4 mg from F34), **2** (5.0 mg, F25), **6** (4.5 mg, F34), **7** (5.0 mg, F24), **8** (13.0 mg, F24), **9** (15.0 mg, F36−F37), **12** (6.0 mg, F28), **14** (1.0 mg, F10), and **15** (5.0 mg, F29) were isolated by first subfractionating each fraction on Sephadex LH-20 (CH_2Cl_2/MeOH 4:6) and finally by PTLC (**2**, **8**, **9**, and **12** with $CHCl_3$/MeOH/*n*-hexane 2:0.4:0.6; **1**, **6**, and **7** with EtOAc/$CHCl_3$/*n*-hexane 1:1:1; **14** and **15** with CH_2Cl_2/MeOH 95:5).

Preparation of 11a and 11b from 11. To prepare the (*S*)- and (*R*)-MTPA esters **11a** and **11b**, two separate amounts of compound **11** (1.0 mg and 1.2 mg) were esterified with (*R*)-(−)- and (*S*)-(+)-MTPA-Cl, respectively, using the procedure described above, to obtain **11a** (1.2 mg) and **11b** (1.2 mg).

Compound **11a**: colorless oil; selected ^1H NMR data ($CDCl_3$, 600 MHz) δ_H 1.27 (H_3-14′, d, *J* = 6.5 Hz), 5.14 (H-13′, m), 3.87 (H-6′, dd, *J* = 8.0, 6.0 Hz), 5.61 (H-7′, dd, *J* = 15.4, 8.0 Hz), 7.56 (H-8′, dd, *J* = 15.4, 11.3 Hz), 6.45 (H-9′, t, *J* = 11.3 Hz), 3.41 (H-5′a, dt, *J* = 9.2, 5.6 Hz), 3.57 (H-5′b, m), 2.53 (H_2-4′, m); (+)-ESI-HRMS *m*/*z* 1097.3729 $[M + Na]^+$ (calcd for $C_{55}H_{60}F_6O_{15}Na$, 1097.3728).

Compound **11b**: colorless oil; selected ^1H NMR data ($CDCl_3$, 600 MHz) δ_H 1.19 (H_3-14′, d, *J* = 6.5 Hz), 5.15 (H-13′, m), 3.93 (H-6′, dd, *J* = 8.0, 6.8 Hz), 5.73 (H-7′, dd, *J* = 15.0, 6.8 Hz), 7.62 (H-8′, dd, *J* =

Preparation of 12a and 12b. The (*S*)-MTPA (**12a**) and (*R*)-MTPA (**12b**) esters were prepared by derivatization of **12** (1.5 mg each case) with (*R*)-(−)- and (*S*)-(+)-MTPA-Cl, following the procedure described earlier, to obtain **12a** (1.8 mg) and **12b** (1.7 mg), respectively.

Compound **12a**: colorless oil; ^{1}H NMR ($CDCl_3$, 600 MHz) δ_H 3.79 (H-3, s), 4.24 (H-6, t, J = 3.5 Hz), 3.10 (H-7a, dd, J = 14.2, 3.5 Hz), 3.22 (H-7b, dd, J = 14.2, 3.5 Hz), 6.90 (H-9, d, J = 8.5 Hz), 6.70 (H-10, d, J = 8.5 Hz), 6.70 (H-12, d, J = 8.5 Hz), 6.90 (H-13, d, J = 8.5 Hz), 4.04 (H-14a, dd, J = 10.5, 8.1 Hz), 4.23 (H-14b, dd, J = 10.5, 3.0 Hz), 5.38 (H-15, dd, J = 8.0, 3.0 Hz), 3.10 (H_3-17, s), 1.90 (H_3-18, s), 2.79 (H_3-19, s), 1.29 (H_3-20, s), 1.29 (H_3-21, s), 3.49 (OMe, s), 7.36 (H_3, m), 7.55 (H_2, dd, J = 7.1, 1.8); (+)-ESI-HRMS m/z 635.2011 $[M + Na]^+$ (calcd for $C_{29}H_{35}N_2F_3SO_7Na$, 635.2009).

Compound **12b**: colorless oil; ^{1}H NMR ($CDCl_3$, 600 MHz) δ_H 3.85 (H-3, s), 4.26 (H-6, t, J = 3.6 Hz), 3.13 (H-7a, dd, J = 14.2, 3.6 Hz), 3.24 (H-7b, dd, J = 14.2, 3.6 Hz), 6.94 (H-9, d, J = 8.6 Hz), 6.77 (H-10, d, J = 8.6 Hz), 6.77 (H-12, d, J = 8.6 Hz), 6.94 (H-13, d, J = 8.6 Hz), 4.13 (H-14a, dd, J = 10.6, 8.3 Hz), 4.32 (H-14b, dd, J = 10.6, 2.7 Hz), 5.40 (H-15, dd, J = 8.3, 2.7 Hz), 3.11 (H_3-17, s), 1.92 (H_3-18, s), 2.81 (H_3-19, s), 1.21 (H_3-20, s), 1.24 (H_3-21, s), 3.54 (OMe, s), 7.32–7.27 (H_2, m), 7.35 (H_1, d, J = 7.4 Hz), 7.58 (H_2, d, J = 7.8 Hz); (+)-ESI-HRMS m/z 635.2011 $[M + Na]^+$ (calcd for $C_{29}H_{35}N_2F_3SO_7Na$, 635.2009).

Zoospores' Motility Inhibitory and Lysis Activity Assays. The test pathogen *P. nicotianae* was isolated from leaves collected in June 2014 from the plant *Catharanthus roseus*, grown in the nursery beds of Bangabandhu Sheikh Mujibur Rahman Agricultural University, Gazipur, Bangladesh. Infected leaves of *C. roseus* were placed in water to develop sporangia. Abundant sporangia were produced overnight, and mycelia developed after 2 days. The bioassay was carried out as described previously.[11,12]

Antimicrobial Test. The antimicrobial test was performed according to a previously described procedure.[13]

RESULTS

The structure determinations of the new compounds **1**, **6**, **12**, and **14** were achieved using selected NMR experiments and by comparison of these data with published values. Using AntiBase,[10] the structures of the known compounds were identified as verrucarin A (**3**),[14] 16-hydroxyverrucarin A (**5**),[15] verrucarin B (**7**),[16] 16-hydroxyverrucarin B (**8**),[17] verrucarin J (**2**),[18] verrucarin X (**4**),[15] roridin A (**9**),[19] roridin L-2 (**10**),[20] trichoverritone (**11**),[21] and myrotheciumone A (**15**).[22]

Trichothecenes are sesquiterpene alcohols or esters that have a tricyclic skeleton in common, the trichothecane, typically with a double bond between C-9 and C-10 and a 12,13-epoxide ring.[23] There are two classes of trichothecenes: those that have only a central sesquiterpenoid structure and those that have an additional macrocyclic or opened ring (simple and macrocyclic trichothecenes, respectively).[24] Macrocyclic trichothecenes are further subdivided as either verrucarins (generally C_{27} compounds) or roridins (generally C_{29} compounds).[23] The ester groups involved in forming the macrocyclic ring or open chain are attached at positions 4β and 15 of the trichothecane core.

Compound **1** was isolated as a colorless, optically active, amorphous solid by PTLC. The ^{1}H NMR spectrum showed similarities to that of verrucarin J (**2**), and the (+)-ESI-HR mass spectrum showed a molecular ion peak at m/z 537.1731 $[M + Na]^+$ corresponding to the molecular formula $C_{27}H_{30}O_{10}$ (13 DBEs), indicating a new verrucarin-like trichothecene derivative. The ^{13}C NMR spectrum displayed 27 carbon resonances that were attributed, with the help of a phase-sensitive HSQC spectrum, to 2 methyl, 7 methylene, 9 methine (including 6 olefinic), and 9 quaternary carbons (Table 1). Because analysis of the NMR data suggested that the molecule contains four C,C double bonds and 4 carbonyl groups, 5 rings were expected.

The basic trichothecene moiety was identified by the HMBC spectrum, with signals nearly overlapping with those of verrucarin J (**2**), and confirmed by a detailed NMR analysis (Figure 2). Besides the trichothecene skeleton, two further structural subunits were observed. Using a COSY correlation between H_2-4′ and H_2-5′ and HMBC correlations of H-2′ to C-1′, -3′, -4′, and -12′ (Figure 2), the first of these was established as a 5-hydroxy-3-methylpent-2-enoic acid, a subunit also found in verrucarin J (**2**).

The second subunit was identified as hexa-2,4-dienedioic acid by COSY correlations from H-7′ to H-10′ and HMBC correlations of H-8′ to C-6′ and H-10′ to C-11′. Finally, these subunits were connected via an ester linkage to each other and to the trichothecene moiety. The resulting structure **1** was confirmed by additional HMBC correlations (H-4/C-11′, H_2-15/C-1′, and H_2-5′/C-6′, Figure 2) and was named verrucarin Y.

The configuration of **1** was elucidated by the analysis of coupling constants and ^{1}H chemical shifts and by considering its biosynthesis. The coupling constants of H-7′ (J = 15.6 Hz)

DOI: 10.1021/acs.jafc.5b02366
J. Agric. Food Chem. 2015, 63, 8777–8786

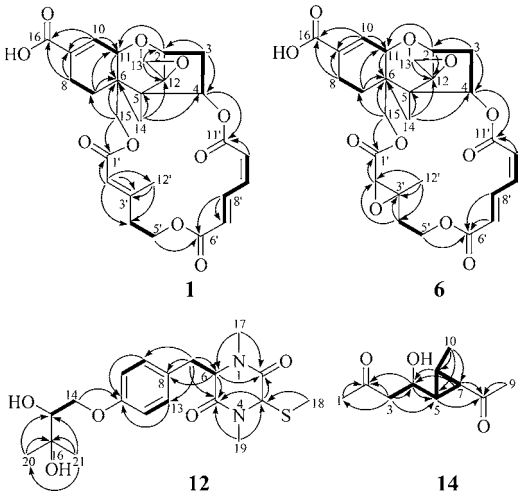

Figure 2. $^{1}H-^{1}H$ COSY (bold line) and HMBC (H→C) correlations for **1**, **6**, **12**, and **14**.

and H-10′ (J = 11.7 Hz) indicated $\Delta^{7'}$-(E) and $\Delta^{9'}$-(Z) geometries for **1**. The $\Delta^{2'}$ geometry was derived from the influence on the protons in the neighborhood. In the case of macrocyclic trichothecenes, the proton shifts, especially of H_2-15, H_2-4′, and H_2-5′, are strongly dependent on the geometry of the $\Delta^{2'}$ double bond,[18] as shown for 2′-(Z)- and 2′-(E)-verrucarin J (**2**) in Table S1 (Supporting Information).[18,25] Analysis of the current data clearly indicated a $\Delta^{2'}$-(E) configuration for **1** (Table S1).

Because the trichothecene ring in the various derivatives can be assumed to originate from common biosynthetic pathways, it is plausible that the six chiral centers in the core of **1** are (2*R*,4*R*,5*S*,6*R*,11*R*,12*S*), as is found in other trichothecenes.[24] NOE correlations between H-2β/H_2-13, H-2β/H-3β, H-13b/H_3-14β, H-4α/H_2-15, and H-4α/H-11α supported these configurations. The configurations were further confirmed by the closely related shifts for the trichothecene core in **1** compared to other verrucarins and also by the simultaneous formation of **1** and **2** by the same strain.

The molecular formula of verrucarin Z (**6**) was deduced as $C_{27}H_{30}O_{11}$ by ESI-HRMS, indicating 13 DBEs. 1D and 2D NMR data of **6** were nearly identical to those of **1**. The only differences were at C-2′ and C-3′, where an epoxide group in **6** replaced the double bond in **1**. The presence of a 2′,3′-epoxide was confirmed by the appearance of two signals of oxygenated carbons (δ_C 58.3, 61.8) in the ^{13}C NMR spectrum of **6** [replacing the two olefinic signals observed in **1** (Table 1)] and by the HMBC correlations of H_2-4′ to C-2′ and -3′ (Figure 2).

The configurations of the double bonds at $\Delta^{7'}$ and $\Delta^{9'}$ were determined as E and Z, respectively, on the basis of the observed coupling constants (Table 1). The chemical shifts of H-2′ and H_3-12′ in **6** were δ_H 3.37 and 1.53, respectively, indicating the epoxide ring was *trans* substituted[26] as in verrucarin B[16] (δ_H 3.41 and 1.56). This was also supported by an NOE correlation between H-2′β and H_2-4′. For the same reasons as in **1**, an identical core configuration can be assumed, resulting in (2*R*,4*R*,5*S*,6*R*,11*R*,12*S*,2′*S**,3′*R**)-**6**.[19,24]

In addition to the verrucarins, roridins were also isolated from strain M10. Whereas the verrucarins contain a hexadienedicarboxylic acid unit in the macrolactone ring, in all of the approximately 40 currently known roridins,[10] the dicarboxylic acid is substituted by a chiral 6,7-dihydroxyoctadienoic acid.[27]

^{1}H and ^{13}C resonances of the three roridins isolated here were identical to those published for roridin A (**9**), roridin L-2 (**10**), and trichoverritone (**11**); however, the configuration at C-6′ and C-13′ had been reported only for compound **9**.[20,21,27] Consequently, the modified Mosher's method was applied to determine the configuration of C-13′ in **10** and **11**.[28] A positive $\Delta\delta_H$ value for H_3-14′ and negative values for the rest of the selected protons (Figure 3) indicated that the 13′*R* configuration was present in both **10** and **11**, as in **9**.

Bilain D (**12**) was isolated as an optically active, colorless crystals. The molecular formula $C_{19}H_{28}N_2O_5S$ (7 DBEs) was inferred on the basis of (+)-ESI-HRMS data. The ^{1}H NMR spectrum revealed 5 methyl singlets, 2 methylene ABX signals, and 3 sp^3 methine resonances. Two aromatic 2H doublets at δ_H 6.78 and 6.90 indicated a 1,4-disubstituted benzene ring in the molecule (Table 2). With the help of an HSQC spectrum, the 19 carbon resonances were established to be 5 methyl, 2 methylene, 3 aliphatic oxymethine, 4 methine (2 signals of double intensity), and 5 quaternary carbons (Table 2).

COSY and HMBC correlations revealed three structural fragments: a phenol unit, an oxidized isopentane, and a diketopiperazine fragment (Figure 2). The typical A_2B_2 pattern and the shift values indicated a *para*-substituted phenol derivative. The phenolic carbon showed an HMBC correlation with an aliphatic methylene group, which must be connected via an ether bond. A COSY correlation indicated that C-14 was connected to an oxymethine group and then to a dimethylcarbinol (indicated by HMBC correlations; Figure 2), resulting in the presence of a dihydroxylated isoprene phenol ether.

Among the remaining signals, two *N*-methyl groups were identified as a result of their C and H shifts. Both showed HMBC correlations with CH groups and amide carbonyls (e.g., Me-17 with C-2 and C-6); further HMBC and COSY correlations resulted in an *N*,*N*-dimethyl diketopiperazine skeleton. The open bond at C-3 was determined to be

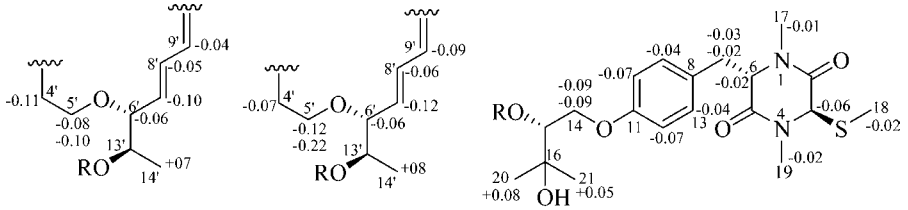

Figure 3. Selected $\Delta\delta_H$ ($\Delta\delta_H = \delta_S - \delta_R$) values for MTPA esters **10a**/**10b**, **11a**/**11b**, and for MTPA esters **12a**/**12b**.

DOI: 10.1021/acs.jafc.5b02366
J. Agric. Food Chem. 2015, 63, 8777−8786

occupied by a thiomethyl (*S*-Me) group, and the diketopiperazine ring was established to be connected to the phenol unit via a methylene group (CH_2-7), as indicated by COSY and HMBC correlations, resulting in structure **12** (Figure 2). This is a new bilain, assigned the letter D.

The configuration of C-15 in **12** was determined by using the modified Mosher's method.[28] All proton signals of the resultant two ester derivatives, **12a** and **12b**, were assigned by $^1H-^1H$ COSY experiments and through comparison of their chemical shifts with those from the original ^1H NMR data of **12**; the shift differences ($\Delta\delta_H = \delta_S - \delta_R$) are shown in Figure 3. The positive $\Delta\delta_H$ values of H_3-20 and H_3-21, but negative $\Delta\delta_H$ values of all other protons, indicated the *R* configuration at C-15.[28] The relative configurations of the further two stereocenters in **12** were established by comparing the chemical shifts with those of the synthetic thiodiketopiperazine **13** and via NOE correlations. The chemical shifts of H-3 and H-6 in the *cis*-diketopiperazine (3*S*,6*S*)-methylthiosilvatin (**13**) were δ_H 4.58 and 4.22,[29] but those in **12** were δ_H 3.82 and 4.24, respectively, indicating that the substituents at C-3 and C-6 are *trans*-oriented in **12**. This was confirmed by the observance of the expected NOE correlation between the *S*-Me group at δ_H 1.89 and H-6, and by signals between H-3 and the aromatic protons. Therefore, a (3*R**,6*S**) configuration can be assigned for **12**. Calculation of the optical rotations (see Supporting Information) indicated that this is also the absolute configurations, so that finally (3*R*,6*S*,15*R*) resulted for **12**.

Among the >200 known microbial diketopiperazines, some from fungal sources carry characteristic 3- or 6-thiomethyl or 3,6-di(thiomethyl) groups, with or without *N*-methyl and *N*,*N*′-dimethyl groups in the ring. These compounds are mostly derived from phenylalanine; however, fewer than 20 derivatives (including the bilains) contain the *O*-prenylated tyrosine unit.[30−36] In all previously described Phe-derived monothiomethyl diketopiperazines, the *S*-Me group is present at C-6; bilain D (**12**), isolated here, is the only example with an *S*-Me group at C-3.[36] It can be speculated that the bilains function as signaling compounds, as do the related benzylidene-diketopiperazines.[37]

Hamavellone C (**14**), an unusual cyclopropyl diketone,[38] was obtained as an amorphous, colorless solid, for which the molecular formula was determined as $C_{10}H_{16}O_3$ by ESI-HRMS, indicating 3 DBEs. The IR spectrum exhibited a broad absorption band centered at 3427 cm^{-1} and a sharp band at 1697 cm^{-1}, indicating hydroxy and carbonyl functionalities, respectively. Analysis of ^1H, ^{13}C, and HSQC spectra revealed two keto carbonyls (δ_C 210.0, 208.9). An oxymethine proton resonated at δ_H 3.62 (δ_C 70.4), methylene protons appeared at δ_H 2.63 (δ_C 51.1), three methine protons were observed at δ_H 1.48, 1.57, and 2.12 (δ_C 36.1, 25.4, and 32.5), and three methyl signals appeared at δ_H 1.07, 2.22, and 2.15 (δ_C 11.5, 30.8, and 32.0).

Analysis of the 1D and 2D NMR spectra of **14** revealed the spin system $C^3H_2-C^4H-C^5H(C^7H)-C^6H(C^{10}H_3)-C^7H$ and two independent methyl singlets (Figure 2). Besides the two carbonyl groups, the ^{13}C NMR spectrum showed no further double bonds; compound **14** must therefore be monocyclic. The HMBC and COSY correlations of a methyl doublet (C-10) with C-5, C-6, and C-7 established a cyclopropane moiety (Figure 2). HMBC correlations of the methyl protons H_3-1 and H_3-9 with the keto carbons C-2 and C-8, respectively, indicated their terminal positions. The methine H-5 (δ_H 1.48, td, J = 7.3, 4.9 Hz) of the cyclopropane ring was *trans*-oriented with respect to H-6 and H-7 (δ_H 2.12, dd, J = 9.2, 4.9 Hz), as indicated by the NOESY correlations between H-6 and H-7, between H-5 and Me-10, and between Me-9 and Me-10, but not between H-5 and H-6/7 (Figure 4). This was confirmed by

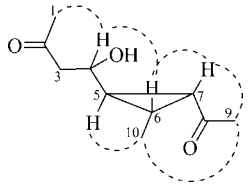

Figure 4. Key NOESY correlations for **14**.

the small coupling constant between H-5/H-6 (J = 4.9 Hz) and H-5/H-7 (J = 4.9 Hz), indicating a *trans* orientation, and by the high coupling value between H-7 and H-6 (J^{cis} = 9.2 Hz) (Table 2). Typically, *trans*-oriented protons of the cyclopropyl ring show a coupling of 4.2−5.9 Hz, whereas 8.4−9.7 Hz is indicative of a *cis* orientation.[39] It was not possible to address the absolute configuration of C-4 in **14** due to the limited amount of compound available.

Open chain alkyl-cyclopropyl ketones are very unusual in natural sources. To the best of our knowledge, hamavellones A and B, isolated from a soil fungus, are the only two microbial compounds known that are similar to **14**, which we therefore named hamavellone C.[38] Other known cyclopropyl ketones are cyclic sesquiterpenes and are mainly produced by mushrooms.[40,41]

The compounds **1**−**12**, **14**, and **15** were tested against zoospores of *P. nicotianae* and a few other microorganisms; results are presented in Tables 3 and 4, respectively. Motility inhibitory and lytic activities against zoospores clearly increased to the maximum applied dose (Table 3). None of the macrocyclic trichothecenes tested here showed motility inhibitory and lytic activities, except for those with certain distinct structural features. Compounds **6**, **7**, **9**, and **14** exhibited IC_{50} values against zoospores at a concentration of 50 μg/mL after 30, 45, 45, and 30 min, whereas double the concentration (IC_{50} = 100 μg/mL) was required for **3** and **5** to produce the same effect after 45 and 60 min of treatment, respectively (Table 3). Compound **8** showed a 50% inhibitory concentration (IC_{50}) of 250 μg/mL after 5 min of treatment. On treatment with higher concentrations (100−900 μg/mL), all of these motility inhibitors caused lysis of zoospores (zoosporicidal activity) (Table 3). Compounds **1**, **2**, **4**, **10**, **11**, **12**, and **15** did not show any motility inhibitory or lytic activities against zoospores within 60 min up to 900 μg/mL.

In the case of compounds **3**−**5**, the presence of a methyl or hydroxymethyl group at C-9 increased the motility halting activity, whereas the presence of a carboxy group (**4**) at the same position led to a complete loss of activity (Table 3). Verrucarins or roridins with double bonds at C-2′ became inactive, irrespective of their functionalities at C-9 (**1** and **2**). For the verrucarins, either a CH_3, COOH, or CH_2OH moiety at C-9 in the presence of an epoxide group at C-2′,3′ (**6**−**8**) resulted in motility inhibitory activity followed by lysis of zoospores (Figure 1 and Table 3). When the macrocyclic ring was opened (**10** and **11**), no activity was observed against the zoospores.

DISCUSSION

Motility inhibition followed by lytic activities against phytopathogenic Peronosporomycete zoospores has been reported previously for several plant and microbial metabolites, including polyflavonoid tannins from *Lannea coromandelica*,[11] polyketides from an endophytic fungus *Cryptosporiopsis* sp.,[42] lipopeptides from *Bacillus subtilis*,[12] indolocarbazole alkaloids from *Streptomyces* sp.,[43] and phloroglucinols from *Pseudomonas fluorescens*,[44] among others. However, motility inhibition and subsequent lysis of *P. nicotianae* zoospores by trichothecenes, as reported here, were previously unknown.

In our experiments with Peronosporomycetes, we observed a distinct relationship between structural features and activity in trichothecenes, as described previously by others.[45] In the agar diffusion assay for antifungal activity, among the macrocyclic trichothecenes tested here, only the 9-methyl trichothecenes (**2**, **3**, **7**, and **9**) showed noteworthy activities against *Candida albicans* and *Mucor miehei* at a concentration of 50 μg/disk when compared with nystatin (Table 4). The most notable activity against *C. albicans* and *M. miehei* was exhibited by compound **7**. It gave inhibition zones of 20 and 46 mm in diameter against *C. albicans* and *M. miehei*, whereas nystatin, a clinically used antifungal drug, gave 17 and 21 mm zones, respectively. The presence of the COOH or CH_2OH group at C-9 rendered the trichothecenes inactive against fungi, whereas among the verrucarins, the 2′,3′-epoxide ring was required for zoosporicidal activity.

The mechanisms by which trichothecenes produce cytotoxic effects in eukaryotic cells primarily involve inhibition of the macromolecule biosynthesis:[46] verrucarin A is 10 times more active than actinomycin D, one of the most active chemotherapeutic drugs. There is, however, no activity against prokaryotes (see Table 4), as also observed by others.[15]

In conclusion, trichothecenes are a large family of biologically active mycotoxins, with pronounced differential toxicity for eukaryotes[47] and strong structure-activity relationships. On the basis of these differential toxicities, trichothecenes may well be useful compounds for the development of effective agrochemicals and also as therapeutic leads.

spectra were determined with a Bruker AM-400BB (400 MHz) spectrometer (Bruker, Ltd., Karlsruhe, Germany). Values of δ in parts per million (ppm) are relative to tetramethylsilane (TMS). Values of J are given in hertz (Hz). High-resolution electrospray ionization mass spectrometry (HRESIMS) was performed with a Bruker APEX-II mass spectrometer (Bruker, Ltd., Karlsruhe, Germany), and results are presented in terms of m/z.

Fungal Material. The fungus was isolated from the healthy stems of *E. tangutorum*, collected in Qinghai Province, China. The fungus was identified on the basis of morphology and molecular phylogenetic data. The organism was determined to be a common ancestor with an *E. bromicola* strain from *Hordeum brevisubulatum*. Therefore, the isolate was defined as *E. bromicola* (NI_201216) and was deposited at the College of Pastoral Agriculture Science and Technology, Lanzhou University.[13]

Preparative Scale Culture. *E. bromicola* was grown on a sterilized moistened rice medium in 1000 mL flasks (100 g/flask × 100) at 27 °C for 30 days to produce white moldy rice.

Extraction, Isolation, and Purification Process. The rice culture was extracted with EtOAc 4 times to yield 18 g of the crude extract. The crude extract was applied to a silica gel column (90 × 15 cm) and eluted with $CHCl_3$/MeOH (4 L, 1:0−0:1 gradient system) to give four fractions labeled Fr-A−Fr-D.

Fr-A was chromatographed on a Sephadex LH-20 column (120 × 2.5 cm, $CHCl_3$/MeOH, 500 mL, 1:1) and silica gel column (30 × 4 cm, petroleum ether/acetone, 800 mL, 1:0−0:1) to yield compounds **1** (478.0 mg), **2** (13.0 mg), **6** (6.6 mg), **8** (20.9 mg), and **12** (5.8 mg).

Fr-B was subjected to a Sephadex LH-20 column (120 × 2.5 cm, pure MeOH, 200 mL) and then silica gel column (20 × 4 cm, $CHCl_3$/EtOAc, 700 mL, 1:0−0:1) to produce compounds **3** (98.0 mg), **13** (5.3 mg), **15** (7.5 mg), and **16** (6.9 mg).

Fr-C was purified by column chromatography on a RP-18 column (30 × 2 cm, 500 mL, H_2O/MeOH, 1:0−0:1) and PTLC ($CHCl_3$/acetone, 80 mL, 1:0−0:1) to afford compounds **4** (5.3 mg), **5** (12.6 mg), **7** (9.7 mg), **10** (5.1 mg), **11** (5.4 mg), and **14** (2.9 mg).

Fr-D was isolated by a RP-18 column (30 × 2 cm, H_2O/MeOH, 600 mL, 1:0−0:1) and then a silica gel column (20 × 4 cm, $CHCl_3$/MeOH, 550 mL, 1:0−0:1) to give compounds **9** (18.0 mg), and **17** (102.0 mg).

Cyclosporin T, **1**, was a white powder with $[\alpha]_D^{22}$ −197 (c 0.10 in MeOH). HRESIMS indicated m/z 1188.8337 $[M + H]^+$ (calculated for $[C_{61}H_{110}O_{12}N_{11}]$ 1188.8330). The spot color of compound **1** was red with 10% H_2SO_4 in EtOH, followed by heating and under Dragendorff's reagent. ^1H and ^{13}C NMR spectra of compound **1** in $CDCl_3$ were consistent with those reported in the literature.[14]

3-(2′-(4″-Hydroxyphenyl)acetoxy)-2*S*-methylpropanoic acid, **7**, was a yellow oil with $[\alpha]_D^{22}$ +50 (c 0.10 in MeOH). IR parameters (νKBr_{max}) were 3423, 1714, and 1632 cm^{-1}. ^1H and ^{13}C NMR data are in Table 1.

Theoretical Calculations. To identify the absolute configuration of compound **7**, quantum mechanical calculations were performed. The B3LYP functional with the 6-31G(d, p) basis set was used.[15,16] The calculations were performed using the Gaussian 09 suite of programs.[17]

General Procedure for Synthesis of Compounds 7a and 7b. Thionyl chloride (0.65 mL, 8.9 mmol) and dimethylformamide (100.0 μL, 1.3 mmol) were added to a solution of 2-phenylacetic acid (0.40 g, 3.0 mmol) in dichloromethane (10.0 mL). After the mixture was stirred at room temperature for 1 h, the solvent was removed *in vacuo* to obtain 2-phenylacetyl chloride (0.45 g, 98%) as yellow oil, which was used directly in the next step.

To a solution of 2-phenylacetyl chloride (0.45 g, 2.9 mmol) in dichloromethane (2.0 mL), a solution of methyl 3-hydroxy-2*R*/*S*-methylpropanoate (0.21 g, 1.8 mmol) in dichloromethane (5.0 mL) was added. After the reaction mixture was stirred for 4 h, the reaction was quenched by the addition of ice water and the organic phase was separated. The aqueous phase was then extracted with dichloromethane (2 × 10.0 mL). The organic phase was dried with $MgSO_4$, and the solvent was removed *in vacuo*. Purification by flash chromatography (ethyl acetate/petroleum ether, 1:10) gave methyl 2*R*-methyl-3-(2-phenylacetoxy)propanoate (**7a**) or methyl 2*S*-methyl-3-(2-phenylacetoxy)propanoate (**7b**) as an oil (0.31 g, 73%).

[a] ^1H (400 MHz) and ^{13}C (100 MHz) NMR, TMS, measured in $CDCl_3$.

*Methyl 2R-Methyl-3-(2-phenylacetoxy)propanoate (**7a**).* The colorless oil exhibited $[\alpha]_D^{22}$ −70 (c 0.10 in MeOH). ^1H NMR (400 MHz, $CDCl_3$) δ_H: 7.27−7.34 (m, 5H, ArH), 4.19, 4.25 (dd, J = 7.2 and 10.8 Hz, 2H, $-CH_2O-$), 3.64 (s, 3H, $-OCH_3$), 3.61 (s, 2H, $-CH_2-$), 2.78 (m, 1H, −CH−), 1.16 (d, J = 7.2 Hz, Me−H). ^{13}C NMR (100 MHz, $CDCl_3$) δ_C: 174.1 (−C═O), 171.2 (−C═O), 133.8, 129.2, 129.2, 128.5, 128.5, 127.1 (ArC × 6), 65.8 ($-CH_2O-$), 51.8 ($-OCH_3$), 41.2 (−CH−), 38.9 ($-CH_2-$), 13.7 (Me−C). HRESIMS: m/z 237.1118 $[M + H]^+$ (calculated for $[C_{13}H_{17}O_4]$ 237.1121).

*Methyl 2S-Methyl-3-(2-phenylacetoxy)propanoate (**7b**).* The colorless oil exhibited $[\alpha]_D^{22}$ +70 (c 0.10 in MeOH). Compounds **7b** and **7a** shared the same NMR data. HRESIMS: m/z 237.1120 $[M + H]^+$ (calculated for $[C_{13}H_{17}O_4]$ 237.1121).

Antifungal Assay. Antifungal activity against pathogenic fungi was tested using the previously reported method.[18] A sample was dissolved in dimethyl sulfoxide (DMSO) to give a test solution at a defined concentration. This solution (0.1 mL) was thoroughly mixed with 20 mL of potato dextrose agar (PDA) molten agar medium. The mixture was then equally poured onto three Petri dishes (6 cm diameter) to prepare treated culture. DMSO without a sample was processed similarly to give control culture media. Chlorothalonil served as the positive control. Discs (0.4 cm) of hyphae were cut from the edge of a colony. These hyphae were placed in the middle surface of the culture medium with the hyphae downward. The inhibition rate was obtained according to the following formula: inhibition rate (%) = $(C - T)/(C - 0.4\ cm)$, where T is the average diameter of mycelia on PDA treated with sample and C is the average number of mycelia on PDA treated with control compounds. The EC_{50} values of the tested compounds were thus determined. Each assay was performed in triplicate.

Phytotoxicity Bioassay. With glyphosate as the positive control, phytotoxic effects on *Lolium perenne* and *Poa crymophila* were examined using the method described in the literature.[19] The seedlings were soaked in cold water for 100 min, then dipped in ethanol for 5 min, and repeatedly rinsed until odorless. A 12-well microplate was placed on two sheets of aseptic filter paper. The samples to be tested were dissolved in MeOH and applied to the paper. Upon evaporation of MeOH, aseptic water was added to the wells. *L. perenne* and *P. crymophila* seedlings of uniform size and shape were put on the papers. The seedlings were kept for 5 and 9 days, respectively, at 22 °C under dark conditions. The phytotoxicities were observed after 72 and 120 h, respectively. Methanol was used as a blank control. Each experimental result was expressed as the mean ± standard deviation (SD) of three trials.

Cytotoxicity Assay. MDBK cells were purchased from the Shanghai cell bank of the Chinese Academy of Sciences and maintained at 37 °C under an atmosphere of 95% air and 5% CO_2

DOI: 10.1021/acs.jafc.5b04260
J. Agric. Food Chem. 2015, 63, 8787−8792

in Dulbecco's modified Eagle's medium (DMEM) containing 10% fetal bovine serum and 1% antibiotic/antimicrobial solution. A cytotoxicity assay was performed as previously described.[20] MDBK cells were seeded in 96-well plates at a cell concentration of 5000 cells per well in 100 μL of DMEM. After incubation of the cells for 24 h at 37 °C, various concentrations of compounds were added and the incubation was continued for 24 h. Untreated cells were used as controls. After that, 10 μL of 5 mg/mL resazurin solution was added into each well and incubation was continued for 2 h at 37 °C. The fluorescence intensity was measured using FlexStation 3 (Molecular Devices, Sunnyvale, CA) at excitation/emission wavelengths of 555/585 nm. Each assay was performed in triplicate.

RESULTS AND DISCUSSION

Cultivation, Isolation, and Structure Elucidation. The fungal strain was cultured in rice medium at 27 °C for 30 days.

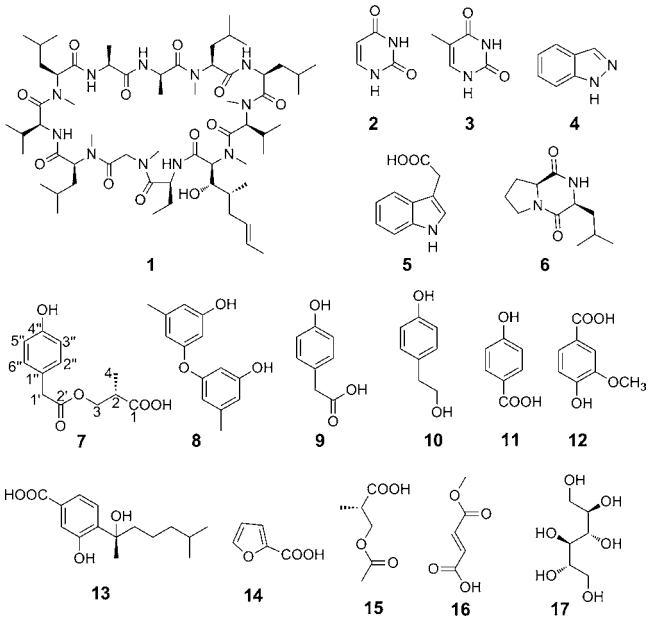

Figure 1. Structures of compounds **1**–**17**.

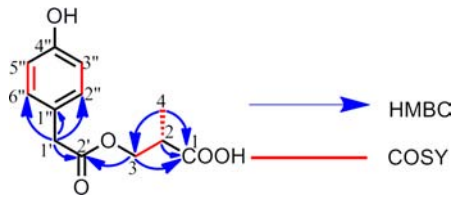

Figure 2. HMBC and COSY of compound **7**.

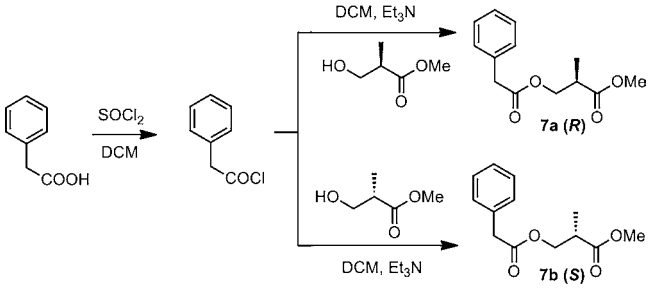

Figure 3. Synthesis of compounds **7a** and **7b**.

The cultured material was extracted 4 times with EtOAc. The EtOAc extract was then fractionated by means of chromatography on silica gel, Sephadex LH-20, PTLC, and RP-18. A new compound (**7**) and 16 known compounds (**1**–**6** and **8**–**17**), including a cyclic peptide (**1**) (Figure 1) were obtained from the EtOAc extract. It should be noted that these isolated compounds were not detected in the rice medium without the fungus (*E. bromicola*). The structures of these obtained compounds were determined by combining the extensive

spectroscopic analysis with computational optical rotation, chemical reaction, and comparison to the data in the literature.

Compound **7** was obtained as optically active yellow oil. The ^{13}C NMR and distortionless enhancement by polarization transfer (DEPT) spectra together with the molecular ion peak in the HRESIMS indicated a molecular formula of $C_{12}H_{14}O_5$. The IR spectrum of compound **7** showed absorption bands of hydroxyl (3423 cm^{-1}) and carbonyl (1632 and 1714 cm^{-1}) groups. The ^1H NMR spectrum of compound **7** showed four aromatic protons at δ_H 6.72 (2H, d, J = 8.4 Hz) and 7.09 (2H, d, J = 8.4 Hz), implying that the aromatic ring had a 1,4-disubstitution pattern. Moreover, the ^1H NMR spectrum revealed the presence of a set of oxygenated methylene protons at δ_H 4.20 and 4.28 (dd, J = 7.2, 10.8 Hz), a set of methylene proton at δ_H 3.55 (s), a methine proton at δ_H 2.82 (m), and a secondary methyl group at δ_H 1.21 (d, J = 7.2 Hz). The ^{13}C NMR and DEPT spectra of compound **7** displayed six aromatic carbons at δ_C 115.5, 115.5, 125.5, 130.4, 130.4, and 154.8, two carbonyl carbons at δ_C 172.1 and 179.4, an oxygenated methylene carbon at δ_C 65.6, a methylene carbon at δ_C 38.8, a methine carbon at δ_C 40.4, and a secondary methyl carbon at δ_C 13.5. The $^1H-^1H$ correlation spectroscopy (COSY) spectrum of compound **7** revealed a spin-coupling system of H_2-3, H-2, and H_3-4, and the heteronuclear multiple-bond correlations (HMBC) of H-4 (δ_H 1.21) with C-3 and C-1, H-3 (δ_H 4.20 and 4.28) with C-2′ and C-1, and H-1′ (δ_H 3.55) with C-2′ suggested that compound **7** has a C_6 side chain. The C_6 side chain was positioned at C-1″ according to the HMBC of the methylene group H-1′ (δ_H 3.55) with C-1″, C-2″, and C-6″ (Figure 2). With the above information taken into account, the hydroxyl was positioned at C-4″. Accordingly, the whole planar structure of compound **7** was completely elucidated.

A detailed analysis of the stereochemistry of compound **7** indicated only one chiral center at C-2, thus making it possible to identify two candidate stereostructures as either 2*S* or 2*R*. The computational optical rotation approach was used to determine the configuration of C-2. All optical rotation calculations were performed using the integral equation formalism polarizable continuum model (IEF-PCM) solvation model, and in agreement with the experimental condition, MeOH was specified as the solvent. The calculated optical rotation for 2*S* was 84.9°, while the value of 2*R* was −84.9°. The former is closer to the experimental value of 50.0°. Therefore, the absolute configuration of C-2 was 2*S*.

To further verify the absolute configuration of compound **7**, two model compounds (**7a** and **7b**) were synthesized through the esterification reactions using methyl 3-hydroxy-2*R*-methylpropanoate or methyl 3-hydroxy-2*S*-methylpropanoate as the substrates (Figure 3). The electron capture dissociation (ECD) spectra of compounds **7a** and **7b** were tested in MeOH (Figure 4), and the ECD spectrum of compound **7b** is similar to that of compound **7**. Therefore, the absolute configuration of C-2 of compound **7** is 2*S*. Accordingly, the structure of the novel compound **7** was established and named as 3-(2′-(4″-hydroxyphenyl)acetoxy)-2*S*-methylpropanoic acid.

The spectral data (MS and ^1H and ^{13}C NMR spectra) of compounds **1−6** and **8−17** were identical to those reported in the previous literature. Accordingly, their structures were identified as those of cyclosporin T (**1**),[14] uracil (**2**),[21] 5-methyluracil (**3**),[21] 1*H*-indazole (**4**),[22] 1*H*-indazole-3-acetic acid (**5**),[23] cyclo-(L-leucyl-L-prolyl) (**6**),[24] 3,3′-dihydroxy-5,5′-dimethyldiphenyl ether (**8**),[25] (4-hydroxyphenyl)-acetic acid (**9**),[26] 2-(4-hydroxyphenyl)-ethanol (**10**),[27] *p*-hydroxybenzoic acid (**11**), vanillic acid (**12**),[28] (−)-sydonic acid (**13**),[29] furan-2-

DOI: 10.1021/acs.jafc.5b04260
J. Agric. Food Chem. 2015, 63, 8787−8792

carboxylic acid (**14**),[30] 3-acetoxy-2*S*-methylpropanoic acid (**15**),[31] fumaric acid, methyl ester (**16**),[32] and dulcose (**17**).[33]

The obtained compounds were different from those alkaloids previously found in the fermentation of *Epichloë* spp., which may be due to the alteration of the cultivation parameters to one strain.[34] Analysis of the structures of the presently obtained compounds indicated that compounds **1** and **6** are peptides. In particular, compound **1** is a polypeptide. Compounds **2** and **3** are nucleobases. Compound **4** is an indazole. Compounds **7** and **9** are phenylacetic acid derivatives. Compounds **8** and **13** are a dimethyldiphenyl ether and a sesquiterpene, respectively. Compound **10** is 2-(4-hydroxyphenyl)-ethanol. Compounds **11** and **12** are substituted benzoic acids. The other compounds (**14**−**17**) were acids and sugar. These metabolites, except the alkaloid 1*H*-indole-3-acetic acid (**5**), were isolated from the genus *Epichloë* for the first time through a literature search.

Antifungal Activity of Metabolites. To determine the effects of these metabolites from *E. bromicola* on different phytopathogenic fungi, metabolites **1**, **3**, **9**, and **17** were tested for their inhibition of *Alternaria alternata*, *Bipolaris sorokiniana*, *Fusarium avenaceum*, and *Curvularia lunata in vitro* (there were insufficient quantities of compounds **2**, **4**−**8**, and **10**−**16**). The phytopathogenic fungi were chosen because they are very common in the cool-season subfamily of Pooideae grasses and caused a substantial reduction in the yield of herbage.[35] As shown in Table 2, compound **1** was the most active among the assayed compounds. The other tested compounds were weaker than chlorothalonil as the positive control, with EC_{50} values from 13.5 to 66.4 μM.[36] The EC_{50} values of compound **1** against *A. alternata*, *B. sorokiniana*, *F. avenaceum*, and *C. lunata* were 5.3, 3.9, 0.7, and 2.9 μM, respectively, suggesting that it had broad-spectrum inhibitory activity against these four plant pathogenic fungi and was stronger than chlorothalonil. Therefore, compound **1** may be considered as a lead compound for the development of new fungicides for suppression of common plant diseases, especially those caused by these tested phytopathogenic fungi. Furthermore, compound **1** was the most abundant of the 17 isolated metabolites, indicating that compound **1** plays an important role in host disease resistance against these pathogens. Thus, *E. bromicola* is a promising lead organism for the development of a natural microorganism fungicide to allow *E. tangutorum* to resist plant pathogenic fungi.

Phytotoxic Activity of Metabolites. Metabolites **1**−**17** of *E. bromicola* were tested for their phytotoxic activities against *L. perenne* seedlings. As shown in Table 3, compound **8** was the most active against the roots and shoots, with the inhibitory rates of 83.9 and 59.8%, respectively. Compound **5** (74.8%) showed similar activity with glyphosate (72.0%) in inhibiting the root growth; it displayed weaker inhibition of the shoots (48.5%) than glyphosate as the positive control (82.3%). This result was consistent with reported literature.[37] Compound **9** exhibited moderate activity against the roots and shoots, with inhibitory rates of 55.8 and 28.4%, respectively. Other metabolites showed weak activity toward the shoots and roots, with the inhibition rates ranging from 0 to 35.6%.

To determine whether compound **8** possesses inhibitory activity against *P. crymophila*, its phytotoxic effects were assayed at different concentrations. As shown in Figure 5, at high concentrations of 150−200 ppm, compound **8** exhibited inhibition rates in the range of 74.9−90.1% against roots, which was as active as glyphosate (73.1−84.7%); it displayed weaker activity (23.5−59.8%) than glyphosate (37.1−63.3%) toward the shoots. At low concentrations of 25−100 ppm, compound **8** weakly inhibited the roots (27.8−58.4%) relative to glyphosate (35.7−68.3%); however, its inhibitory rates (3.6−14.2%) were similar to that of glyphosate (2.4−12.9%) against shoots. The results showed that compound **8** displayed marked phytotoxic effects toward the roots and shoots of various seedlings at concentrations of 50−200 ppm. Therefore, compound **8** may play a crucial role for *E. tangutorum* in inhibiting the growth of other grasses, and it has potential as a new type of natural microbial herbicide. The compound may be the reason for the wide distribution of *E. tangutorum* and its high frequency of infection of *Epichloë* spp. in China. Moreover, this is the first report of phytotoxic effects of dimethyldiphenyl ethers.

Cytotoxicity of Metabolites. Metabolites **1**−**17** were tested for their cytotoxicity against MDBK cells. As shown in Table 4, none of the obtained metabolites exerted cytotoxicity toward MDBK cells. The IC_{50} values were above 100 μM. Moreover, the inhibition rates of the metabolites were between −1.6 and −17.0% at a concentration of 12.5 μM, indicating that they may promote mammalian cell growth at low concentrations. Thus, the metabolites did not exhibit cytotoxicity to MDBK cells. The results were quite different from those observed with the alkaloids isolated from *Epichloë* spp.; those alkaloids produced detrimental effects on their hosts.[6] The present results indicate that it may be safe for animals to eat *E. tangutorum* grass that is infected with *E. bromicola*. Accordingly, *E. bromicola* may be a beneficial fungus with desirable phytotoxic and antifungal properties and a lack of cytotoxicity toward mammalian cells. The results indicate the possibility of raising new varieties of herbage with resistance against infection and competition.

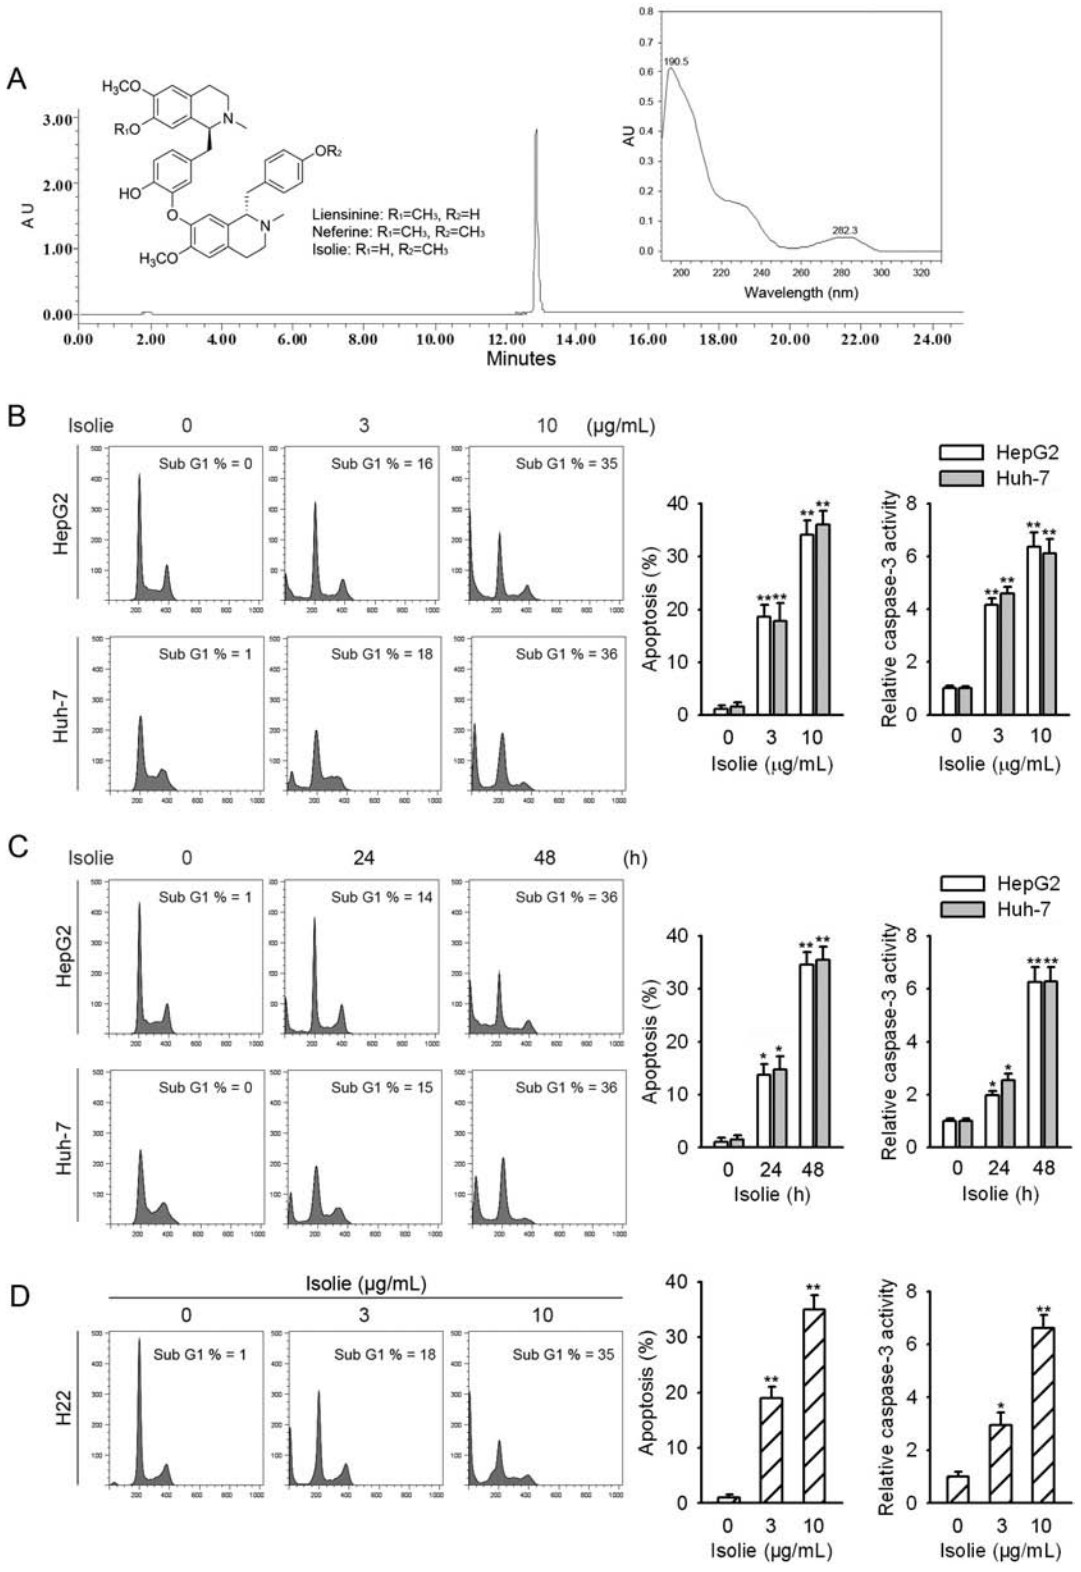

Figure 1. Isolie dose- and time-dependently provoked human and murine HCC cell apoptosis in vitro. (A) Chemical structures of liensinine, isolie, and neferine are shown. The purity of isolie was determined by both HPLC and UV spectrum analysis. (B) HCC cells were treated with indicated concentrations of isolie. After 48 h, cell apoptosis was examined by FACS (left and middle, both representative FACS diagrams and statistics are shown) and caspase-3 activity assay (right). (C) HepG2 and Huh-7 cells were treated with 10 μg/mL isolie for indicated times. Then, cell apoptosis was examined by FACS (left and middle) and caspase-3 activity assay (right). (D) H22 cells were incubated with indicated concentrations of isolie. Cell apoptosis was examined by FACS (left and middle) and caspase-3 activity assay (right) 48 h later. *$p < 0.05$ and **$p < 0.01$ versus HCC cells without isolie treatment.

J. Agric. Food Chem. 2015, 63, 8793−8803

Table 1. Cytotoxic Effects of Liensinine, Isolie, and Neferine on HCC Cells and Untransformed Hepatocytes

	IC50[a] (μg/mL)					
compound	PMH[b]	HL-7702	Huh-7	HepG2	Hep3B	Bel-7402
liensinine	53.7	49.3	9.7	11.7	14.1	15.5
isolie	72.9	70.1	4.5	4.2	6.0	5.7
neferine	23.2	20.8	6.2	8.3	10.1	9.8

[a]IC50, the concentration of a compound at which cell viability was reduced by 50%. [b]PMH, primary mouse hepatocytes.

HCC cell apoptosis. The bioavailability and toxic impact of isolie were also assessed on tumor-bearing mice.

MATERIALS AND METHODS

Isolation and Purification of Isolie. The embryos of *N. nucifera* were purchased from Jointown Pharmaceutical Group Co. Ltd. (Wuhan, Hubei Province, PR China) in September 2011 and identified by Prof. Dingrong Wan from the College of Pharmacy, South-Central University for Nationalities, Wuhan, China. Voucher specimens (2011009N) were deposited in the Herbarium of the College of Pharmacy, South-Central University for Nationalities. Air-dried embryos of *N. nucifera* (1.0 kg) were ground into powder and extracted using 90% EtOH (4 × 3.0 L). After evaporation of the collected percolate, the crude extract was acidified with diluted HCl (5%) to a pH of 1−2 and partitioned between hexane (3 × 1.5 L) and the acid water layer. The aqueous part was basified with aqueous NH_3 to a pH of 9−10 and extracted with $CHCl_3$ to yield 14.5 g of crude alkaloid. A portion of the crude alkaloid (14 g) was then subjected to column chromatography over silica gel (300−400 mesh) and eluted with the isocratic gradient solvent system of CH_2Cl_2, methanol, and diethylamide (100:5:2) to yield five major fractions (F1−F5) (F1, 1.8 L; F2, 2.4 L; F3, 1.7 L; F4, 2.6 L; F5, 3.5 L). After evaporation under vacuum, crude isolie (1.8 g) was obtained from F4 and then dissolved in anhydrous acetone (50 mL). The solution was acidified with drops of diluted $HClO_4$ (10%) to a pH of 2−3. The acidized isolie solution was kept at 4 °C to crystallize and yielded 1.9 g of pure isolie perchloride. The isolie perchloride (1.8 g) was dissolved in 50 mL of water, and this solution was basified with aqueous NH_3 to a pH of 9−10. The solution was extracted with $CHCl_3$ to give 1.3 g of the free isolie. ^1H, ^{13}C NMR and LC-ESIMS data were obtained to support the identification of isolie (Supplementary Figure 1). The isolie was analyzed by high-performance liquid chromatography (HPLC) on a Waters 1525 HPLC instrument by a single injection of 20 μL with an analytical C18 HPLC column (Betasil 150 × 4.6 mm, 5 μm) detected at 254 nm. Gradient conditions: 90% H_2O (0.1% TFA) + 10% MeCN (0.1% TFA) → 100% MeCN (0.1% TFA), 20 min, 100% MeCN (0.1% TFA), 25 min. Flow rate: 1.0 mL/min. The purity of the isolie was above 95% as detected by HPLC and UV spectrum analysis (Figure 1A).

Cells, Reagents, Kits, and Antibodies. Human HL-7702 untransformed hepatocytes and murine H22 ascitic hepatoma cells were supplied by the China Center for Type Culture Collection. HepG2 and Hep3B human HCC cells were from the American Type Culture Collection. Huh-7 HCC cells, Panc-1 pancreatic carcinoma cells, and HT-29 colon carcinoma cells were obtained from the Cell Bank of Shanghai Institute of Biological Sciences. Primary mouse hepatocytes were separated and cultured as described previously.[13] Dulbecco's modified Eagle medium (DMEM) was obtained from Hyclone (Logan, UT, USA). Fetal calf serum (FCS), penicillin, and streptomycin for cell culture and TRIzol reagents for RNA extraction were purchased from Invitrogen (Carlsbad, CA, USA). FuGENE reagents for cell transfection were purchased from Roche (Penzberg, Germany). 3-(4,5-Dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) and propidium iodide were purchased from Wolsen Biotechnology (Xi'an, Shanxi Province, PR China). Caspase-3 activity assay kits, BCA protein quantification kits, and JC-1, which is a fluorescent probe for mitochondrial membrane potential, were purchased from Beyotime Biotechnology (Nantong, Jiangsu Province, PR China). NF-κB-dependent luciferase reporters, pRL-TK plasmids, and Dual Reporter assay systems for the determination of intercellular luciferase activity were obtained from Promega (Fitchburg, WI, USA). The pRL-TK plasmid encodes the *Renilla* luciferase gene driven by the promoter of herpes simplex virus thymidine kinase gene and is used as an internal control in luciferase activity assays. Reverse transcriptase ReverTra Ace-α were obtained from Toyobo (Osaka, Japan). Primary antibodies against Bcl-2 (SC-492), Bcl-xL (SC-8392), MMP9 (SC-6841), p65 (SC-372), and IκBα (SC-371) and secondary antibodies conjugated with horseradish peroxidase were from Santa Cruz Biotechnology (Santa Cruz, CA, USA). Antibodies against Ser536-phosphorylated p65 (No. 13346), myc tag (No. 2278), and β-actin (No. 3700) were obtained from Cell Signaling Technology (Danvers, MA, USA).

Cells Culture and Transfection. Cells were maintained in DMEM containing 10% FCS, 100 U/mL penicillin, and 100 μg/mL streptomycin at 37 °C in a humidified atmosphere with 5% CO_2. To overexpress p65 phosphorylation mimics in which Ser536 is mutated into an Asp (p65-S536D), the encoding gene of human p65-S536D was cloned into the vector pcDNA3.1A. Plasmids were transfected into HCC cells using FuGENE reagents, according to the manufacturer's instructions.

Cell Viability Assay and Calculation of IC50 Value. Cells were incubated with different concentrations of the indicated compounds. After 48 h, MTT cell viability assays were performed as described previously.[14] The IC50 value of a compound is defined as the concentration at which cell viability was reduced by 50% as determined by MTT cell viability assays and calculated by using the Origin Software.

Flow Cytometry Analysis (FACS). FACS was performed as described previously.[15] Briefly, after undergoing treatment as indicated in the text, the cells were trypsinized and fixed with cold 70% ethanol (stored at −20 °C) for at least 2 h. Samples were then pelleted and washed with PBS containing 20 mM EDTA. Intracellular RNA was removed by incubating samples with 1 mg/mL RNaseA at 37 °C for more than 2 h. Finally, cells were stained with 30 μg/mL propidium iodide and subjected to FACS (Becton Dickinson FACSCalibur, Franklin Lakes, NJ, USA). Cells in Sub G1 phase were considered to be apoptotic.

Caspase-3 Activity Assay. Caspase-3 activity assay kits were used to measure caspase-3 activity in the total lysates of cultured cells or tumors tissues, according to the manufacturer's instructions.

NF-κB Luciferase Reporter Assay. Cells were cultured for 24 h in 24-well plates prior to transfection. Then, NF-κB luciferase reporters and pRL-TK plasmids were cotransfected into HCC cells using FuGENE reagents. After 24 h, the medium was replaced and cells were incubated with various stimuli as indicated in the text. The Dual Reporter assay system was used to measure luciferase activity in cell lysates, according to the manufacturer's instructions.

RNA Isolation, Reverse Transcription, and Real-Time Polymerase Chain Reaction (PCR). RNA was extracted from cultured HCC cells or in vivo tumor tissues by TRIzol reagent, according to the manufacturer's instructions. To get cDNA from each sample, 3 μg of total RNA was reverse transcribed at 42 °C for 30 min using ReverTra Ace-α. mRNA levels of indicated genes were analyzed by real-time PCR. Glyceraldehyde-3-phosphate dehydrogenase (GAPDH) was used as the loading control.

Chromatin Immunoprecipitation (ChIP). ChIP assay was performed as previously described.[16] Relative binding of p65 to promoter regions of Bcl-2 and Bcl-xL encoding genes was measured by real-time PCR.

Assessment of Mitochondria Dysfunction by JC-1 Staining. JC-1 is a fluorescent dye which forms aggregates in normal mitochondria and emits red fluorescence. However, JC-1 monomers emit green fluorescence in cells with mitochondrial dysfunction. Cells were seeded in 24-well plates and stimulated as indicated in the text. After the treatment, the medium was discarded and replaced by 500 μL of fresh medium containing 5 μg/mL JC-1. After incubating for 1

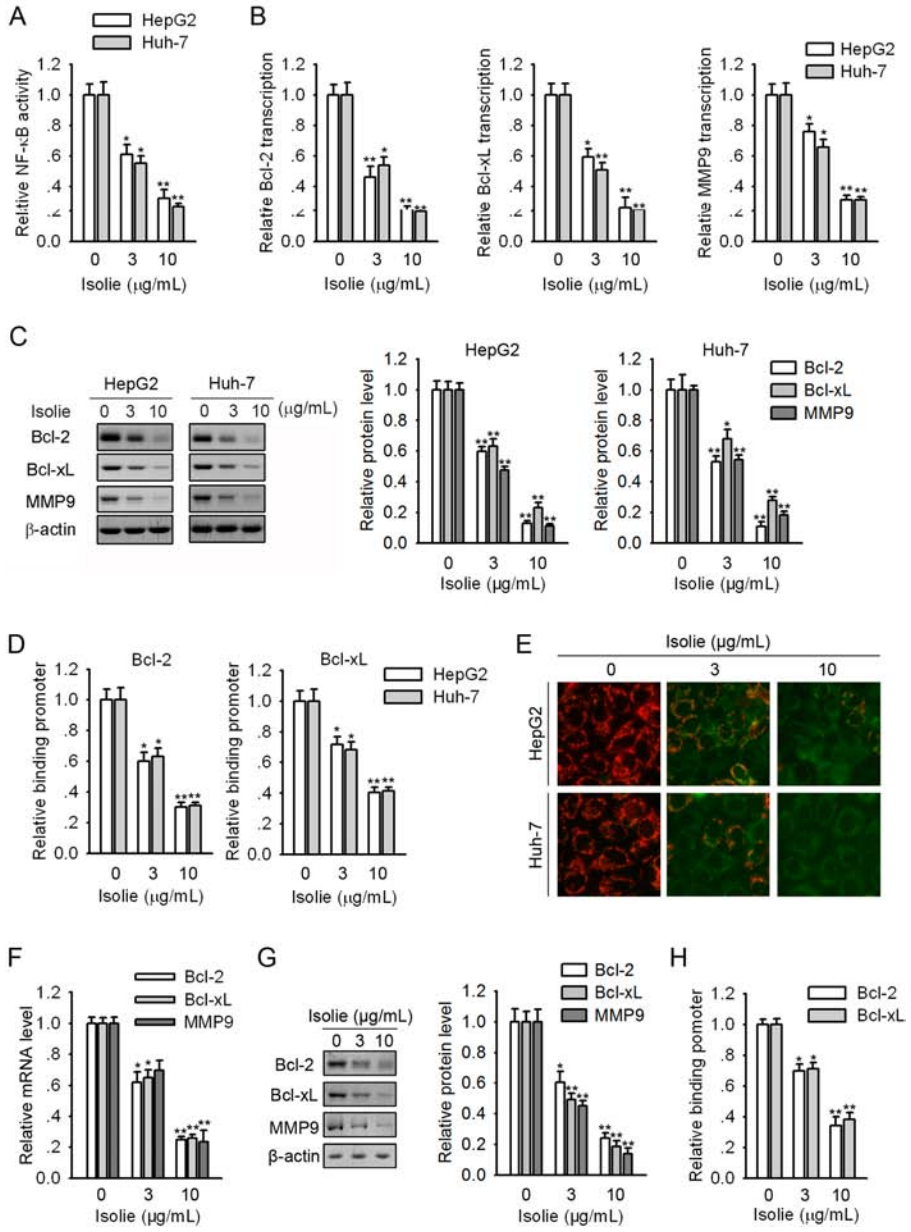

Figure 2. Isolie inhibited NF-κB activity in HCC cells. (A) Plasmids encoding *Renilla* luciferase and NF-κB-dependent luciferase reporter were cotransfected into HepG2 and Huh-7 cells. After 24 h, these cells were treated with indicated concentrations of isolie, using vehicle as the negative control. Cells were subjected to luciferase activity assay 24 h later. (B–D) HCC cells were treated with different concentrations of isolie. After 24 h, mRNA and protein levels of NF-κB target genes were determined by real-time PCR (B) and immunoblotting (C, left). Density values of immunoreactive bands of Bcl-2, Bcl-xL, and MMP9 were normalized to those of β-actin (C, middle and right). Association between p65 protein and promoter regions of indicated genes was detected by ChIP (D). (E) HepG2 and Huh-7 cells were treated with indicated concentrations of isolie for 24 h and then subjected to JC-1 staining assays. (F–H) H22 cells were treated with indicated concentrations of isolie for 24 h. Then mRNA and protein levels of Bcl-2, Bcl-xL, and MMP9 were determined by real-time PCR (F) and immunoblotting (G). Association between p65 and promoter regions of Bcl-2 and Bcl-xL were quantified by ChIP (H). *$p < 0.05$ and **$p < 0.01$ versus HCC cells without isolie treatment.

h, cells were washed twice with PBS and photographed at a magnification of 100× under a fluorescence microscope.

Animals. Male athymic nude mice (6 weeks old) and Kunming mice, weighing between 18 and 22 g, were obtained from the Center of Experimental Animals, Institute of Health and Epidemic Prevention (Wuhan, PR China), and housed under standard specific pathogen-free conditions with access to sterilized water and food ad libitum. All of the animal experimental procedures were performed in accordance with the terms approved by the Experimental Animal Care and Use Committee of South-Central University for Nationalities (Wuhan, PR China).

Huh-7 Xenograft Tumor Growth in Nude Mice. Huh-7 cells (1×10^6) were suspended in 0.2 mL of serum-free DMEM with 50% Matrigel (BD Biosciences, Bedford, MA, USA) and subcutaneously injected into the dorsal flanks of nude mice. Mice were randomly divided into groups of 6 mice each. When the xenograft tumor volume reached about 200 mm^3, isolie was administrated at the indicated dosages once daily, for 3 weeks, via intraperitoneal (ip) injection; normal saline (0.9% NaCl) was used as the negative control. Tumor volumes were monitored every 3 days by the following formula: tumor volume = length × width × width/2. Blood samples were collected from animals anesthetized with diethyl ether. All mice were then

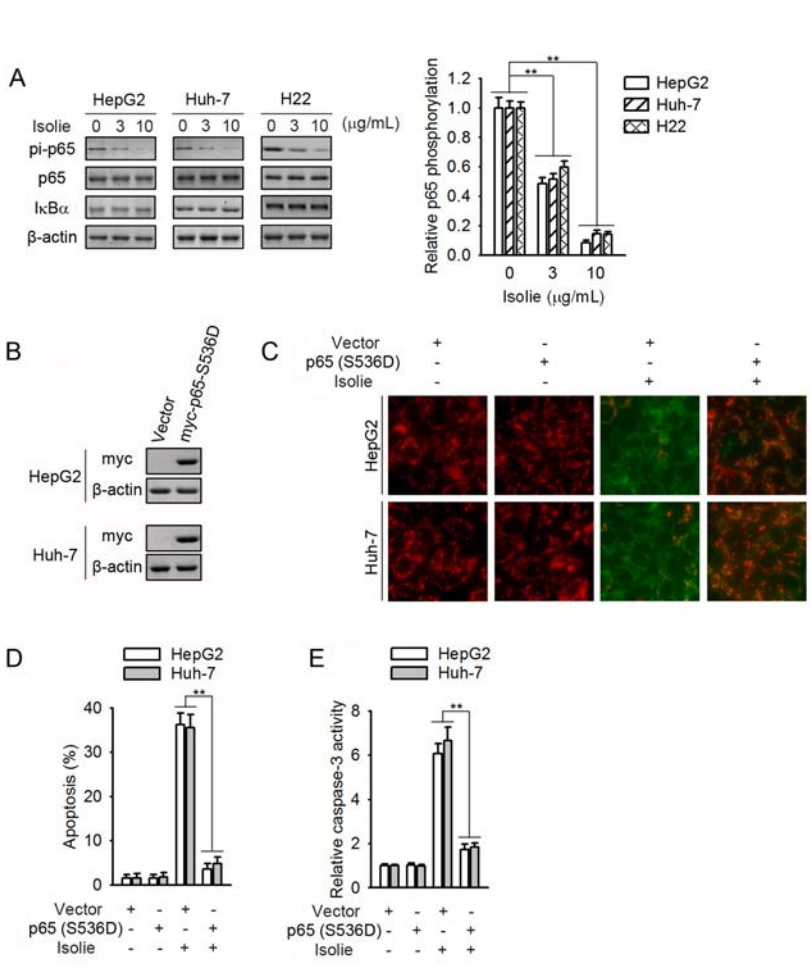

Figure 3. Isolie decreased constitutive phosphorylation of p65 protein at Ser536. (A) Effects of 24-h isolie treatment on protein levels of phosphorylated p65 (Ser536), p65 and IκB*α* in HCC cells were detected by immunoblotting (left). Density values of immunoreactive bands of Ser536-phosphorylated p65 were normalized to those of total p65 (right). (B) Myc-tagged p65-S536D was transfected into indicated HCC cells. After 24 h, exogenous p65-S536D proteins were determined by immunoblotting using the primary antibody against myc tag. (C) Cells transfected with indicated plasmids were incubated with or without 10 μg/mL isolie and subjected to JC-1 staining assays after 24 h. (D, E) Empty or p65-S536D encoding plasmids were transfected into HepG2 and Huh-7 cells. After 24 h, HCC cells were incubated with or without 10 μg/mL isolie. Cell apoptosis was examined 48 h later by FACS (D) and caspase-3 activity assay (E). *$p < 0.05$ and **$p < 0.01$ versus the indicated control.

euthanized, and the livers and xenograft tumors were immediately resected for further analysis.

H22 Transplanted Tumor Establishment and Isolie Administration. H22 cells (1×10^6) were subcutaneously transplanted into the dorsal flanks of Kunming mice. Mice were randomly divided into groups of 10 mice each. Drug treatment began 24 h later. Drugs were administrated once daily, for 10 days, via ip injection or gavage as indicated in the text. Isolie groups received different dosages (3 and 10 mg/kg). The vehicle control group received normal saline. A group of mice without tumor transplantation was also included. Tumor volumes were monitored every 2 days. At last, blood samples were collected under diethyl ether anesthesia. Immediately after all animals were euthanized, transplanted tumors and corresponding organs were resected for further analysis. The organ index was calculated using the following formula: organ index = organ weight (g)/body weight (g) × 1000.

Blood and Serum Physiochemical Indexes Determination. An automatic blood cell count apparatus (Mindray, Shenzhen, Guangdong Province, PR China) was used to record the amount of white blood cells (WBC), red blood cells (RBC), hemoglobins (HGB), and platelets (PLT). Serum was prepared by centrifuging blood samples at 4500*g* for 10 min. Serum hepatic and renal function parameters, including aspartate aminotransferace (AST), alanine aminotransferace (ALT), blood urea nitrogen (BUN), uric acid (UA), and creatinine (CRE), were measured by an automatic biochemical analyzer (Sysmex, Kobe, Japan) according to the manufacturer's instructions.

Statistical Analysis. Data shown in this study are representatives or statistics (mean value ± standard deviation) of the results from at least three independent experiments or all mice of each group. One-way analysis of variance (ANOVA) was performed to determine the statistical significance. If the treatment involved more than one concentration or dosage, Dunnett's *t* tests were further conducted to determine the statistical significance of each concentration/dosage group compared to the negative control. A *p* value of <0.05 was considered to be statistically significant and indicated by "*". A *p* value of <0.01 was considered to be statistically very significant and indicated by "**".

More detailed materials and methods are provided in the Supporting Information.

RESULTS

Isolie Induced HCC Cell Apoptosis in Vitro. To assess the ability of isolie to provoke HCC cell apoptosis, human HepG2 and Huh-7 HCC cells were treated with 3 and 10 μg/mL isolie. After 48 h, ratios of Sub-G1 DNA in the cell populations were quantified by FACS. The result showed that

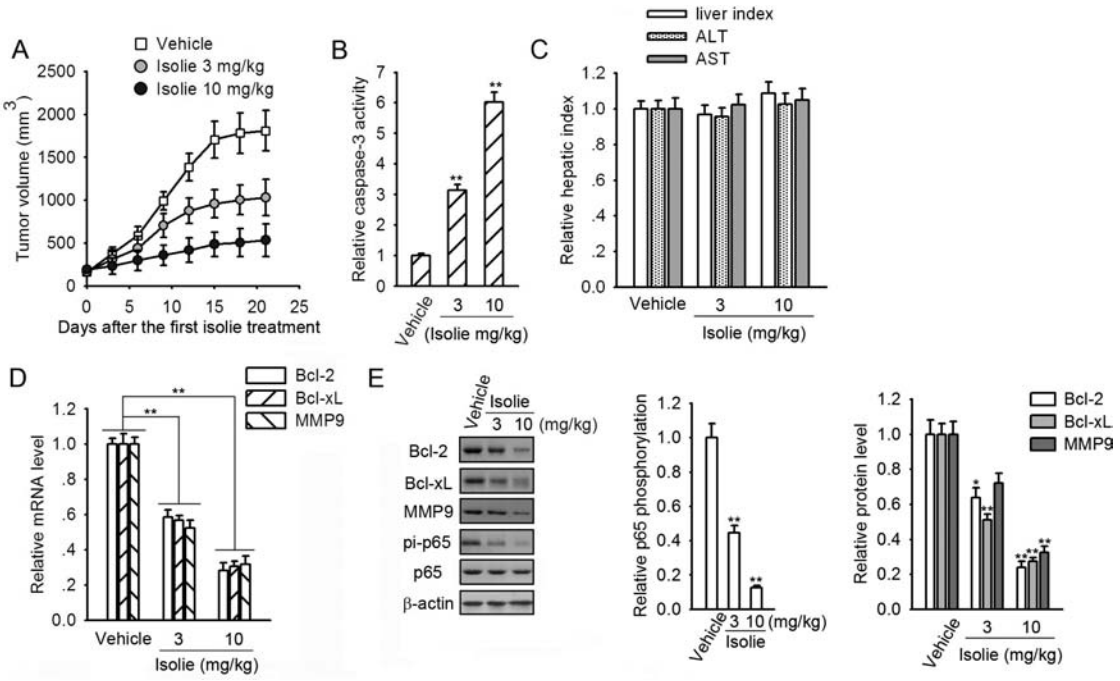

Figure 4. Isolie suppressed the growth of Huh-7 xenografts in nude mice. (A) Vehicle or indicated dosages of isolie were intraperitoneally injected into tumor-bearing nude mice for 3 weeks, and tumor growth was monitored every 3 days. (B) At the end of the study, tumor lysates were prepared and subjected to caspase-3 activity assay. (C) Serum and livers were collected from tumor-bearing mice. Serum activities of ALT and AST were detected, and liver indexes were calculated. Values were normalized to those from the vehicle control group. (D, E) At the end of isolie treatment, transcription levels of indicated genes were detected by real-time PCR (D). Levels of indicated proteins were detected by immunoblotting (E, left). Densitometric values of phosphorylated p65 at Ser536 were normalized to those of total p65 (E, middle). Densitometric values of Bcl-2, Bcl-xL, and MMP9 were normalized to those of β-actin (E, right). $^{**}p < 0.01$ versus tumors dissected from mice treated with saline.

48-h isolie treatment dose-dependently increased the ratio of Sub-G1 DNA (Figure 1B, left and middle). In addition, caspase-3 activity was dose-dependently elevated in HCC cells by isolie (Figure 1B, right). Similarly, as shown by FACS and caspase-3 activity assay, isolie time-dependently triggered HepG2 and Huh-7 cell apoptosis (Figure 1C). Moreover, isolie dose-dependently induced murine H22 ascitic hepatoma cell apoptosis (Figure 1D). These data demonstrated that isolie is capable of provoking HCC cell apoptosis in vitro.

Isolie Suppressed NF-κB Activity in HCC Cells. To understand the molecular mechanisms underlying isolie-mediated HCC cell apoptosis, we first evaluated the impacts of isolie on an array of signaling pathways that regulate cell apoptosis including p53, STAT3, Foxo3a, and NF-κB using corresponding luciferase reporter assays. Isolie showed few effects on the activity of p53, STAT3, or Foxo3a (data not shown), but substantially decreased the basal level of NF-κB activity in both HepG2 and Huh-7 HCC cells (Figure 2A). Consistently, mRNA and protein levels of typical NF-κB target genes, such as Bcl-2, Bcl-xL, and MMP9, in HCC cells were also downregulated by isolie (Figure 2B,C). ChIP assay confirmed that isolie suppressed the interaction between NF-κB p65 subunit and promoter regions of Bcl-2 and Bcl-xL encoding genes (Figure 2D). In HepG2 and Huh-7 cells without isolie treatment, mitochondria were intact and emitted red fluorescence after JC-1 staining. Isolie reduced the red fluorescence signal emitted by JC-1, but elevated the green fluorescence signal, indicating that isolie induced mitochondrial dysfunction in HCC cells (Figure 2E). In murine H22 HCC cells, isolie dose-dependently inhibited transcription and translation of NF-κB responsive genes (Figure 2F and G). Interactions between p65 proteins and promoter regions of Bcl-2 and Bcl-xL were also reduced by isolie (Figure 2H). These data suggested that isolie suppresses NF-κB activity in HCC cells.

Isolie Provoked Dephosphorylation of p65 Protein at Ser536. Degradation of IκBα protein is an important molecular event that activates NF-κB signaling. However, IκBα remained unchanged in response to isolie (Figure 3A). Phosphorylation of NF-κB p65 subunit at Ser536 plays important roles in promoting NF-κB-dependent gene transcription. Isolie dose-dependently suppressed p65 Ser536 phosphorylation in HCC cells (Figure 3A). To confirm the role of p65 dephosphorylation at Ser536 in isolie-induced HCC cell apoptosis, plasmids encoding myc-tagged p65-S536D, which is a p65 phosphorylation mimic at Ser536, were transfected into HCC cells (Figure 3B). Overexpressing p65-S536D dramatically alleviated isolie-induced mitochondrial dysfunction (Figure 3C). Accordingly, isolie-induced HCC cell apoptosis was also considerably abrogated (Figure 3D,E). These findings suggested that p65 dephosphorylation at Ser536 is a critical molecular event accounting for isolie-induced NF-κB inhibition and apoptosis in HCC cells.

Isolie Suppressed Huh-7 Xenograft Tumor Growth in Nude Mice. To explore whether the proapoptotic activity of isolie on HCC cell lines has any potential clinical implications, we evaluated the in vivo impacts of isolie on the proliferation of Huh-7 HCC xenograft tumors. Isolie substantially attenuated the proliferation of xenograft tumors as compared to vehicle (Figure 4A). Isolie-induced HCC cell apoptosis in vivo was verified by caspase-3 activity assay (Figure 4B). To assess side impacts of isolie on normal hepatocytes of tumor-bearing mice, its effects on host liver indexes and serum markers of liver function including ALT and AST were tested immediately at

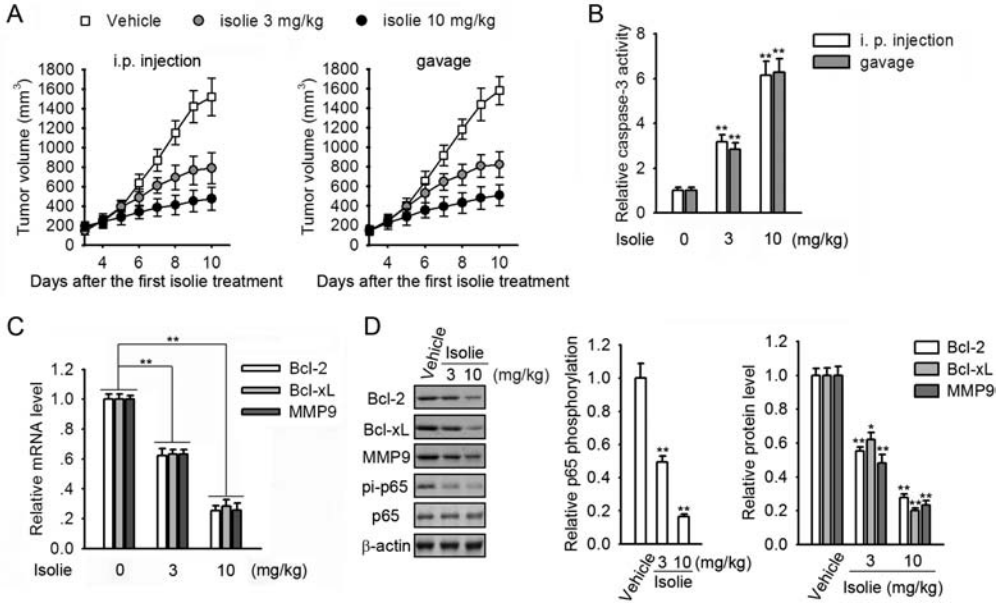

Figure 5. Effects of isolie on transplanted H22 HCC cells in Kunming mice. (A, B) Kunming mice bearing H22 tumors were treated with indicated dosages of isolie by ip injection (left) or gavage (right) for 10 d, and tumor growth was monitored every day (A). At the end of isolie treatment, tumor lysates were prepared and subjected to caspase-3 activity assay (B). (C, D) Tumor-bearing mice were treated with indicated dosages of isolie by gavage for 10 d. At the end of the study, mRNA levels of Bcl-2, Bcl-xL, and MMP9 were detected by reverse transcription real-time PCR (C). Indicated proteins were examined by immunoblotting (D). Densitometric values of phosphorylated p65 at Ser536 were normalized to those of total p65 (D, middle). Densitometric values of Bcl-2, Bcl-xL, and MMP9 were normalized to those of β-actin (D, right). $^{**}p < 0.01$ versus tumors dissected from mice treated with saline.

Table 2. Effects of Ip Injection of Isolie on WBC, RBC, HGB, and PLT in Kunming mice

		concn of blood cells (L^{-1})			
group	dosage (mg/kg)	WBC (10^9)	RBC (10^{12})	HGB (g)	PLT (10^9)
nontumor		6.62 ± 0.47	5.57 ± 0.73	109 ± 11	666 ± 63
vehicle		6.35 ± 0.55	6.48 ± 0.66	121 ± 12	680 ± 70
isolie	3	7.07 ± 0.58	5.91 ± 0.73	115 ± 12	662 ± 69
isolie	10	6.83 ± 0.62	6.61 ± 0.69	117 ± 13	692 ± 66

the end of the treatment. There was no significant change in any of these parameters in response to ip injection of isolie (Figure 4C). To correlate the tumor-suppressing activity in vivo with mechanisms of action identified in vitro, effects of isolie on p65 phosphorylation and NF-κB activity in Huh-7 xenograft tumors were detected. Isolie dose-dependently decreased p65 Ser536 phosphorylation (Figure 4E, left and middle). Moreover, mRNA and protein levels of NF-κB responsive genes were dose-dependently declined in xenograft tumors as shown by real-time PCR (Figure 4D) and immunoblotting (Figure 4E, left and right). These data suggested that, in Huh-7 xenograft HCC tumors, isolie provokes p65 dephosphorylation at Ser536 that reduces NF-κB activity and leads to cell apoptosis. Toxic impacts of isolie on normal livers were undetectable.

Effects of Isolie on Transplanted H22 HCC Cell Growth in Kunming Mice. To explore the anti-HCC activity of isolie in hosts with intact immune systems that is closer to clinical situations, effects of isolie on the proliferation of H22 HCC cells subcutaneously transplanted into the dorsal flanks of Kunming mice were evaluated. Two routes of drug administration, including ip injection and gavage, were both tested in this model. As shown in Figure 5A,B, isolie given by both routes dose-dependently reduced the growth of H22 transplanted tumors and elevated caspase-3 activity in tumor tissues. Additionally, gavage of isolie dose-dependently reduced constitutive phosphorylation of p65 at Ser536 in transplanted tumor tissues (Figure 5D, left and middle). There were also dramatic decreases in mRNA and protein levels of NF-κB target genes (Figure 5C,D, left and right). To understand isolie uptake by mice, the concentration of isolie in the blood was quantified by ultraperformance liquid chromatography tandem mass spectrometry (UPLC-MS/MS). After ip injection of isolie at the dosage of 10 mg/kg, the maximum absorption peak of isolie appeared at 15 min with the concentration of 1356.3 ng/mL in plasma. The concentration of isolie in plasma declined to 469.1 ng/mL at 30 min, and further to 95.5 ng/mL at 2 h (Supplementary Figure 2). These data provided more evidence to support the capacity of isolie to inhibit NF-κB signaling and induce apoptosis in HCC cells in vivo.

Effects of Isolie on Tumor-Bearing Mice. Finally, we evaluated toxic impacts of ip injection of isolie on Kunming mice. We found that ip injection of isolie (10 mg/kg) showed few effects on body weight of tumor-bearing mice (data not shown). Moreover, amounts of WBC, RBC, HGB, and PLT were comparable among all experimental groups (Table 2). In addition, effects of isolie on serum levels of liver function parameters including ALT and AST were unobvious. BUN, UA, and CRE are serum renal function indicators. These parameters remained almost unchanged after ip injection of isolie (Table 3). Moreover, isolie showed little influence on indexes of

DISCUSSION

In this study, we prepared isolie from embryos of *N. nucifera*. The ^{1}H NMR, ^{13}C NMR, and LC-ESIMS data of isolie we isolated are as followed. ^{1}H NMR data ($CDCl_3$, 500 MHz): δ_H 3.65 (1H, m, H-1), 3.73 (1H, m, H-1′), 2.46 (1H, s, 2-NCH_3), 2.56 (1H, s, 2′-NCH_3), 3.12 (1H, m, H_1-3), 2.76 (1H, m, H_1-3), 3.18 (1H, m, H_1-3′), 3.00 (1H, m, H_1-3′), 2.73 (2H, m, H-4), 2.74 (1H, m, H_1-4′), 2.72 (1H, m, H_1-4′), 6.65 (1H, s, H-5), 6.48 (1H, s, H-5′), 3.80 (3H, s, 6-OCH_3), 3.82 (3H, s, 6′-OCH_3), 6.25 (1H, s, H-8), 6.29 (1H, s, H-8′), 2.89 (1H, dd, J = 12.0, 8.7 Hz, H_1-9), 2.81 (1H, J = 12.0, 5.1 Hz, H_2-9), 3.12 (1H, m, H_1-9′), 2.72 (1H, J = 13.8, 6.9 Hz, H_2-9′), 6.90 (1H, d, J = 8.6 Hz, H-11, H-15), 6.43 (1H, d, J = 1.8 Hz, H-15′), 6.70 (1H, d, J = 8.6 Hz, H-12, H-14), 3.73 (3H, s, 13-OCH_3), 6.83 (1H, d, J = 8.2 Hz, H-14′), 6.76 (1H, 1H, dd, J = 8.2, 1.8 Hz, H-11′). ^{13}C NMR data ($CDCl_3$, 125 MHz): δ 64.3 (C-1), 64.5 (C-1′), 42.3 (2-NCH_3, 2′-NCH_3), 47.1 (C-3), 46.6 (C-3′), 25.7 (C-4), 24.9 (C-4′), 130.1 (C-4a), 130.5 (C-4a′), 112.4 (C-5), 110.6 (C-5′), 149.2 (C-6), 145.4 (C-6′), 55.8 (6-OCH_3), 56.0 (6′-OCH_3), 142.9 (C-7), 143.7 (C-7′), 120.0 (C-8), 113.9 (C-8′), 130.1 (C-8a), 125.4 (C-8a′), 40.4 (C-9), 39.1 (C-9′), 130.8 (C-10), 131.0 (C-10′), 130.5 (C-11, C-15), 125.4 (C-11′), 113.6 (C-12, C-14), 144.5 (C-12′), 157.9 (C-13), 145.4 (C-13′), 55.2 (13-OCH_3), 115.5 (C-14′), 119.1 (C-15′). ESI-MS: m/z 611 $[M + H]^+$. Compared with the spectroscopic data of isolie reported in the previous literature,[17] this compound we purified from embryos of *N. nucifera* could be unambiguously determined as isolie. Although isolie has been recognized for decades, it still remains poorly understood whether it possesses any proapoptotic activity against HCC cells. Here, we showed that isolie time- and dose-dependently induced apoptosis in HepG2, Huh-7, and H22 HCC cells in vitro. Additionally, isolie also displayed strong cytotoxic effects on HT-29 colon carcinoma cells and Panc-1 pancreatic carcinoma cells (Supplementary Figure 3). These data suggested that isolie is able to inhibit other cancer cells such as colon and pancreatic cancer cells.

On the basis of its favorable in vitro proapoptotic activity against HCC cells, effects of isolie on Huh-7 xenograft tumors in nude mice were assessed. It was revealed that ip injection of isolie dramatically decreased growth of xenografted Hun-7 tumors. Caspase-3 activity assay further demonstrated that isolie has the capacity of provoking apoptosis in xenografted HCC tissues in vivo. Similarly, ip injection of isolie inhibited transplanted H22 tumor growth and induced H22 HCC cell apoptosis in Kunming mice. Gavage is a safer and more convenient route than ip injection. We thus also tested the anti-HCC activity of isolie given by gavage. Excitingly, isolie gavage achieved a similar tumor-suppressing effect as compared to that of ip injection, implying a possibility that this compound is stable in the digestive tract of animals and can be efficiently absorbed into the circulatory system.

An important part of cancer chemotherapy is that the agent used should induce malignant cell death with low toxic effects on their normal counterparts. Cisplatin is a conventional chemotherapeutic anticancer drug with a high tumor-suppressing activity. However, it exhibits severe hepatotoxicity and nephrotoxicity in patients, leading to a very poor prognosis.[18] Sorafenib is one of few targeted therapeutic reagents for treating advanced HCC approved by the US Food and Drug Administration. Unfortunately, sorafenib has also been shown to exert side effects on some vital organs including the liver itself.[19,20] In this study, isolie exerted its in vivo anti-HCC effects at the dosage of 10 mg/kg. At this dosage, ip injection of isolie showed few changes in liver indexes and serum parameters of liver function in nude mice. Toxic effects of ip injection of isolie at 10 mg/kg on Kunming mice were unobvious as well. Consistently, our unpublished data showed that the median lethal dosage of isolie given by ip injection is greater than 1.2 g/kg for mice. These observations can be supported by the fact that the plant *N. nucifera* is widely consumed as food. Previous studies showed that the mass fraction of isolie in the crude extract of embryos of *N. nucifera* was 45.7 mg/g. In their report, the yield of the crude extract from embryos of *N. nucifera* was 593 g/10 kg = 5.93%.[21] The mass fraction of isolie in the raw plant material was thereby 2.71 mg/g. Hence, the dosage of isolie (10 mg/kg) in our in vivo experiment should be equivalent to an intake of about 3.69 g/kg embryos of *N. nucifera* for mice. According to the notion of animal surface area, this dosage is equivalent to 0.3 g/kg for human.[22] Thus, a person weighting 65 kg would need to consume about 20 g of embryos of *N. nucifera* every day, which is in fact a feasible dosage.

Among three alkaloids including liensinine, isolie, and neferine, isolie exhibited the most prominent cytotoxic activity on HCC cells. Cytotoxic activity of neferine on HCC cells was less potent than that of isolie, but stronger than that of liensinine. Similar to our observations, a very recent study reported that, among these three alkaloids, cytotoxic activity of isolie on MDA-MB-231 breast cancer cells was the most potent and liensinine was the least potent.[23] Based on these data,

DOI: 10.1021/acs.jafc.5b02993
J. Agric. Food Chem. 2015, 63, 8793−8803

structure−activity relationships of these three alkaloids can be summed up as follows (positions R1 and R2 are indicated in Figure 1A). Replacing the hydrogen atom at the R2 position by a methyl group is conducive to enhancing the cytotoxic potency of the compound. But the same substitution at the R1 position can potentially decline its cytotoxic potency. Mechanistically, neferine-mediated malignant cell death is associated with the inhibition of Akt signaling,[24,25] while liensinine sensitizes cancer cells to chemotherapy through DNM1L-mediated mitochondrial fission.[26] Here, we reported that suppression of NF-κB signaling is the key molecular event mediating isolie-induced HCC cell apoptosis.

Epidemiological studies revealed that viral infection and steatohepatitis are significant risk factors of HCC. Both of them have the potential to activate hepatic NF-κB, suggesting the important role of persistently activated NF-κB in hepatocarcinogenesis.[27,28] At the molecular level, activation of NF-κB has the potential to promote transcription of genes antagonizing apoptosis such as Bcl-2 and Bcl-xL as well as enzymes degrading extracellular matrix such as MMP9.[29,30] These NF-κB-responsive genes are important contributors to the survival and metastasis of HCC. Our current study clearly displayed that, in HCC cells, isolie dramatically declined their transcription and translation both in vitro and in vivo. These data suggested that isolie inhibited NF-κB in HCC cells. Similarly, previous studies reported that an array of reagent with the capacity of suppressing NF-κB signaling induced HCC cell apoptosis.[31−34] These findings not only supported the feasibility of considering NF-κB as a potential target in HCC chemotherapy but also implied a possible participation of hyperactivated NF-κB for maintaining HCC cell survival.

Declined p65 phosphorylation at Ser536 was implicated in isolie-mediated inhibition of NF-κB, which could be supported by lines of evidence in this study. First, isolie suppressed p65 phosphorylation at Ser536 both in vitro and in vivo, and p65 dephosphorylation at Ser536 was associated with HCC cell apoptosis. Second, transfection of p65 Ser536 phosphorylation mimics abrogated isolie-induced mitochondrial injury and apoptosis in HCC cells. It has been reported by previous studies that p65 phosphorylation at Ser536 plays critical roles in the proliferation and invasion of cancer cells of different origins.[35−37] In addition, aberrant p65 phosphorylation at Ser536 has been detected in some other malignant tissues dissected from human cancers and correlates with cancer progression.[38−41] A series of kinases are involved in the phosphorylation of p65 protein at Ser536. For example, activation of kinases, such as Akt and IKK, is positively associated with elevated p65 protein phosphorylation at Ser536.[42−44] Dysregulation of Akt and IKK are increasingly implicated in the pathogenesis of HCC.[45,46] In addition, Akt- and IKK-related signaling pathways have been considered as potential targets for the clinical management of HCC.[47,48] It is thus reasonable to speculate that the possible interaction between isolie and these pathways in HCC cells plays roles in isolie-mediated dephosphorylation of p65 at Ser536.

For a brief summary, in this study, proapoptotic effects of isolie on HCC cells were tested and possible molecular mechanisms underlying isolie-induced HCC cell apoptosis were explored. It was unveiled that isolie dose- and time-dependently provoked HepG2, Huh-7, and H22 HCC cell apoptosis. Mechanistically, isolie gave rise to a substantial decrease in NF-κB activity in HCC cells. Isolie dramatically declined constitutive phosphorylation of NF-κB p65 subunit at Ser536. Overexpressing p65 Ser536 phosphorylation mimics abrogated HCC cell apoptosis induced by isolie. Moreover, ip injection of isolie inhibited the growth of Huh-7 xenografts in nude mice. In Huh-7 xenografts, isolie triggered p65 Ser536 dephosphorylation and inhibited NF-κB activity. In addition, isolie given by both ip injection and gavage had the capacity of diminishing in vivo proliferation of transplanted H22 cells in Kunming mice. Toxic effects of isolie on tumor-bearing mice were undetectable. Our findings provided strong evidence for the potential anti-HCC capacity of isolie. Suppression of NF-κB via p65 dephosphorylation at Ser536 is implicated in isolie-induced HCC cell apoptosis.

Table 1. Overview on the Main Virulence Factors of Uropathogenic *E. coli*

virulence factor	gene	functions	features
		1. Adhesins	
			host receptor specificity
type 1 fimbriae	*fim*	mediates mannose-sensitive adhesion in urinary tract epithelium and tissue matrix, invasion, biofilm formation; present in >90% of patients	mannosylated glycoproteins (e.g., UPIa and CD48), Tamm–Horsfall protein, type I and type IV collagens, laminin, fibronectin
P fimbriae	*pap*	mediates mannose-resistant adhesion, cytokine induction; present in 40–60% of UPEC isolates, identified in 80% of pyelonephritis-causing UPEC	GbO3, GbO4, GbO5; P-blood group antigen specific glycosphingolipids (α-D-Gal-(1→4)-β-D-Gal)
S fimbriae	*sfa*	adhesion to bladder, kidney mucosal epithelium and to brain endothelium, involved in NMEC	neuraminic acids/sialic acid residues, plasminogen/β-GalNac-(1→4)-β-Gal
F1C fimbrae	*foc*	adhesion to mucosal and endothelial cells, cytokine induction	lactosylceramide containing glycolipids, β-GalNac-(1→4)-β-Gal
Dr fimbriae	*dra*	involved in adhesion and invasion	Dr blood group antigen present on the complement cascade regulator factor, DAF (CD55), CD66e, type IV collagen, $\alpha_5\beta_1$ integrin
afimbrial adhesin	*afa*	adhesion to mucosal epithelium	decay accelerating factor (DAF)
nonfimbrial adhesin	*nfa*	adhesion	glycophorin A
thin aggregative fimbriae (curli)	*csg*	promotes colonization of perneal area, biofilm formation, adhesion	matrix and plasma proteins (fibronectin, laminin, plasminogen, H-kininogen)
M-adhesin	*bma*	adhesion	A^M determinant of M blood group antigen
G-adhesin		adhesion	GlcNac
UPEC autotransporter adhesin	*upa*	autotransporter that promotes cell aggregation and the formation of biofilms, adhesion to bladder epithelial cells	fibronectin, laminin/localization: cell surface
		2. Host Defense Evasion	
capsular polysaccharide (K antigen)	*kps*	antiphagocytic, anticomplement, and involved in serum resistance	localization: cell surface
lipopolysaccharide (LPS; O-antigen)	*rfa*, *rfb*, *rfc*	endotoxic effects, cytokine induction, serum resistance, immunoadjuvant, leading to inflammation and exfoliation of host cells	localization: cell surface
serum resistance	*colV*, *traT*	confers resistance to killing of bacteria by serum (membrane attack system (MAC) of the complement); it can function individually or combined with effects of capsular polysaccharide, *O*-polysaccharide side chains, and surface proteins	localization: cell surface, involved proteins: Iss, TraT, Bor
TcpC	-	TcpC suppresses innate immunity by homology to TIR domain of TLR	
		3. Toxins	
α-hemolysin	*hly*	cytotoxicity, hemolysis	toxin of Rtx type/localization: exported
cytotoxic necrotizing factor	*cnf*	interference with phagocytosis and apoptosis	localization: exported
secreted autotransporter toxin	*sat*	cytotoxicity	localization: exported
vacuolating autotransporter toxin	*vat*	cytotoxicity	localization: exported
cytolethal distending toxin	*cdt*	cytotoxicity	localization: exported
		4. Iron Acquisition System	
aerobactin siderophore	*iutA*	growth under iron restriction	hydroxamate type/localization: exported
enterobactin siderophore	*ent*	growth under iron restriction	catechol type/localization: exported
hemin uptake system	*chu*	heme transporter	localization: exported
salmochelin siderophore	*iro*	growth under iron restriction	catechol type/localization: exported
yersiniabactin siderophore	*fyuA*	growth under iron restriction	localization: exported

Table 1. continued

virulence factor	gene	functions	features
5. Others			
flagellum (H-antigen)	*fliC*	motility, fitness, facilitates ascending route	localization: cell surface
outer membrane proteins	*ireA, iha, ompA/C/T*	receptor and transport function, OmpA is involved in bacterial invasion by facilitating IBC maturation and chronic bacterial persistence	;ocalization: cell surface
CPA24/CP1	*guaA/argC*	urine growth factor	localization: exported
antigen 43	*flu*	autoaggregation phenotype of UPEC during biofilm formation, autotransporter	localization: cell surface

increased biofilm formation after in vivo intake of cranberry juice for 20% of the UPEC strains.

With regard to the clinical efficacy, a recent Cochrane meta-study concluded that cranberry products are not significantly different from standard antibiotic treatment for preventing UTI, but the evidence for a potentially significant benefit seems too small for a clear recommendation for the prevention of UTI.[11] One major reason for this nonconvincing outcome of the Cochrane review is the use of nonstandardized cranberry products for clinical investigations and the high drop-out numbers of patients during the long-term studies. The need for the development of quantified and standardized cranberry preparations is therefore obvious.[11]

During examination of the very complex literature published on cranberry activity against UPEC, we found it astonishing that most of the authors claim PACs to be responsible for the antiadhesive activity.[7] On the other hand, recent studies have shown that PACs are absorbed over the intestinal barrier only to a very limited extent and, in principle, are not bioavailable in relevant concentrations.[12,13] Interestingly, polyphenols known to be microbial-derived metabolites of PACs such as phenylacetic acid, 3,4-dihydroxyphenylacetic acid, and catechol have recently been identified as antiadhesive compounds against UPEC,[14] and also myricetin has been pinpointed as an antiadhesive compound in human urine from volunteers after cranberry uptake.[15] From the current state of knowledge it might be assumed that PACs are not dominantly responsible for the antiadhesive effects of cranberry, whereas PAC metabolites, formed during the intestinal passage, or cranberry-associated flavonoids are bioavailable to a significant extent and can be found as potential antiadhesive compounds in the urine.

The purpose of this investigation was to initiate studies for systematic evaluation of (i) the influence of PAC-containing and PAC-depleted cranberry extracts on the bacterial adhesion of UPEC to bladder cells in ex vivo studies and (ii) the influence of PAC-containing and PAC-depleted cranberry extracts on UPEC virulence factors.

MATERIALS AND METHODS

Materials. If not stated otherwise, solvents, reagents, and consumables were obtained from VWR International (Darmstadt, Germany). All solvents and reagents were of analytical quality. Water was produced by a MilliporeSimplicity 185 system (Schwalbach, Germany).

The cranberry dry extract (Extract High PAC Special, batch 903514/product code HC23174; Frutarom, Londerzeel, Belgium) from the fruits of *V. macrocarpon* Ait. is certified for use as a food product. A voucher sample (IPBP-281) has been stored in the archives of the Institute of Pharmaceutical Biology and Phytochemistry, University of Münster, Germany.

Preparation of *V. macrocarpon.* (*V.m.*) Extract. Cranberry dry extract contained excipients to ensure optimal powder technology, which were insoluble in EtOH/water (1:1, v/v). These compounds were removed from 20 g of the dry extract after rotor-stator homogenization by Ultraturrax (Ika, Staufen, Germany) in 200 mL of EtOH/water (1:1, v/v) three times for 5 min. The suspension was centrifuged for 5 min at 3000*g*. The remaining residue was re-extracted again three times until the insoluble material was colorless. The combined extracts were lyophilized. The dried extract was stored under an argon atmosphere at −20 °C and is termed in the following as *V.m.* extract.

Proanthocyanidins in *V.m.* extract were quantified according to the European Pharmacopeia[16] and the content of PACs calculated as cyanidine. Quantification was performed with $n = 6$ independent determinations, using 350 mg of *V.m.* extract.

DOI: 10.1021/acs.jafc.5b03030
J. Agric. Food Chem. 2015, 63, 8804−8818

Preparation of *V.m.* Extract$^{\neq PAC}$. One hundred milligrams of *V.m.* extract was dissolved in 100 mL of water. One thousand milligrams of Polyclar AT (G.A.F. Corp., USA), a water-insoluble polyvinylpyrrolidone, was added. Polyphenols were precipitated under gentle stirring of the reaction vessel for 30 min. The suspension was centrifuged at 3000*g* for 5 min. The supernatant was filtered through a paper filter, and clear filtrates were combined, evaporated, and lyophilized to yield 66 mg of *V.m.* extract$^{\neq PAC}$. Proanthocyanidin depletion was proven by thin layer chromatography, using vanillin−hydrochloric acid reagent for specific PAC detection.

LC-MS Dereplication of *V.m.* Extracts. For the preparation of LC-MS samples, *V.m.* extract and *V.m.* extract$^{\neq PAC}$ were dissolved in methanol to a concentration of 10 mg/mL. Separation was performed on a Dionex Ultimate 3000 RS liquid chromatography system over a Dionex Acclaim RSLC 120, C18 column (2.1 × 100 mm, 2.2 μm) with a binary gradient (A, water with 0.1% formic acid; B, acetonitrile with 0.1% formic acid) at 0.4 mL/min: 0−5 min, isocratic at 5% B; 5−37 min, linear from 5 to 100% B; 37−47 min, isocratic at 100% B; 47−48 min, linear from 100 to 5% B; 48−55 min, isocratic at 5% B. The injection volume was 2 μL. Eluted compounds were detected using a Dionex Ultimate DAD-3000 RS over a wavelength range of 200−800 nm and a Bruker Daltonics micrOTOF-QII time-of-flight mass spectrometer equipped with an Apollo electrospray ionization source in positive mode at 2 Hz over a mass range of m/z 50−1500 using the following instrument settings: nebulizer gas nitrogen, 4 bar; dry gas nitrogen, 9 L/min, 200 °C; capillary voltage, −4500 V; end plate offset, −500 V; transfer time, 100 μs; prepulse storage, 6 μs; collision energy, 8 eV. MS/MS scans were triggered by AutoMS2 settings within a range of m/z 200−1500, using a collision energy of 40 eV and a collision cell RF of 130 Vpp. Internal data set calibration (HPC mode) was performed for each analysis using the mass spectrum of a 10 mM solution of sodium formate in 50% isopropanol that was infused during LC re-equilibration using a divert valve equipped with a 20 μL sample loop.

Manufacture of Cranberry Extract-Containing Capsules. Cranberry dry extract, certified as a food product for use in humans, was used for the ex vivo pilot study. Encapsulation of 150 mg of extract, without addition of further additives, was performed into hard gelatin capsules (size 0/cream colored, batch 13E27-N13; WEPA, Hilscheid, Germany). The uniformity of mass of single-dose preparations was analyzed by a weight variation test according to the requirements of the European Pharmacopoeia.[17] Capsules were stored in plastic containers protected from heat and light at room temperature.

Study Design. Four male individuals, who gave informed consent, volunteered to consume cranberry capsules over a 7 day period, with urine sampling at days 0, 3, and 7 for ex vivo studies. Exclusion criteria included antibiotic treatment 2 weeks prior to and during the study. Before starting the trial, the volunteers were instructed to abstain from consumption of any other products containing cranberry or phytochemically or botanically similar fruits (especially from the plant family Ericaceae) 2 weeks before and during the study. Each subject was asked to take two cranberry capsules of 150 mg in the morning and in the evening after a meal, equivalent to 600 mg of cranberry extract per day for 7 days. Generally, the first midstream urine of the day was collected and used for functional and analytical investigations. A control urine sample (S0) was collected prior to the consumption of the capsules. The second urine sample (S1) was collected at day 3 of medication, and the third sample (S2) was collected on the last day of cranberry capsule intake. The urine samples were centrifuged at 3000*g* for 5 min, filtered (0.22 μm pore size), and stored at −20 °C until use.

Cell Culture and Microbiology. T24 cells (ATCC HTB-4) represent a human epithelial bladder cell line, derived from the bladder carcinoma of an 82-year-old Swedish female.[18] These cells have been already demonstrated to be suitable for adhesion and invasion in vitro assays with UPEC[19] and were kindly provided by Prof. Straube (University of Jena, Germany). The influence of test compounds on the viability of T24 cells was monitored by MTT assay.[20] T24 cells were seeded in 96-well plates with 2.5 × 10^4 cells per well (100 μL) and incubated for 24 h at 37 °C with 5% CO_2. T24 cells were washed with 200 μL/well PBS. Incubation of the cells with test extracts (100 μL) was performed for 24 h at 37 °C with 5% CO_2. After the incubation with extracts, the supernatant was removed and cells were washed twice with PBS, 200 μL/well. Fifty microliters of MTT reagent was added to each well, and the 96-well plate was incubated for a further 4 h at 37 °C/5% CO_2. MTT reagent was tapped off the 96-well plate, and 50 μL of DMSO was added to dissolve the formazan crystals. After the plate had been shaken for 10 min, the absorption of the formazan was determined at λ = 492 nm and a reference wavelength of λ = 690 nm.

Bacterial strains included *E. coli* strain 2980 (DSM 10791), provided by Prof. Straube (University of Jena, Germany); UPEC NU14, a clinical cystitis isolate, provided by Prof. Dobrindt (University of Münster, Germany); and J96 provided by Inga Benz (University of Münster, Germany).

Bacteria from passages 2 to 4 were used for all tests and were cultivated from frozen stocks. For adhesion assays agar-grown bacteria were harvested and used for inoculation of Loeb agar supplemented with 0.2% $CaCl_2$, which is supposed to increase the type 1 fimbria expression.[21] For liquid culture 1 colony-forming unit (CFU) of agar-grown bacteria was transferred to 10 mL of UPEC broth in 50 mL tubes and incubated under shaking (200 rpm/37 °C) until mid-logarithmic phase.

For the agar diffusion assay, agar-grown bacteria were harvested, suspended in sterile PBS, and adjusted to an $OD_{640\ nm}$ of 0.2/mL. One hundred microliters of the bacterial suspension was transferred to a Loeb agar plate and spread homogeneously. Subsequently, five sterile BD Sensi-Disks (BD Biosciences, Franklin Lakes, NJ, USA) were distributed circularly in equal intervals on the agar plate with sterile tweezers. Twenty microliters of the respective test solutions (sterile filtered, 0.22 μm) were pipetted on the disks. Norfloxacin (50 μg/mL) (Fluka, Buchs, Switzerland) served as positive control. Plates were incubated for 48 h at 37 °C.

To monitor bacterial growth in liquid culture, 1 CFU of agar-grown bacteria was suspended in 10 mL of liquid medium and cultivated overnight in an incubator rotary shaker (200 rpm at 37 °C). Bacteria were adjusted to an $OD_{640\ nm}$ of 1.0/mL in liquid medium and pipetted in 100 μL aliquots into a 96-well plate. Additionally, 100 μL of fresh liquid medium was added to the wells plus 50 μL of sterile filtered (0.22 μm) test solution. Liquid medium served as negative control, and gentamicin (100 μg/mL) (PAA, Pasching, Austria) was used as positive control. The plate was incubated at 37 °C, and bacterial growth was monitored by measuring the optical density every 30 min over a 6 h period at λ = 640 nm.

Adhesion Assay with Urine Samples by Quantitative Flow Cytometry. In general, FITC labeling of UPEC and flow cytometric adhesion assay was performed as described in refs 22 and 23. T24 cells (2.5 × 10^5 cells/well) were seeded in 6-well plates and incubated at 37 °C and 5% CO_2 until 90% confluence was reached (corresponding to 800,000 cells, after approximately 24 h of incubation). After this incubation, T24 cell culture medium was removed, cells were washed once with PBS, and 2 mL of DMEM was added to each well. All further steps with FITC-labeled *E. coli* ($OD_{640\ nm}$ 0.4/1000 μL (corresponding to 8 × 10^7 CFU/mL) were carried out under light protection. For adhesion experiments a bacterial cell ratio (BCR) of 100:1 was used. After addition of UPEC to T24 cells, the interaction was accelerated by short centrifugation (200*g*, 1 min) of the 6-well plate, followed by 2 h of incubation at 37 °C. Subsequently, unattached UPEC were removed by gently washing the T24 cells three times with 1 mL of PBS/well. T24 cells were detached by the addition of 600 μL trypsin/EDTA for 3 min at 37 °C. Trypsination was stopped by the addition of 2 mL of DMEM. The content of each well was transferred to tubes and centrifuged for 5 min at 400*g*. The supernatant was discarded and the cell pellet suspended, dependent on the visually observable size of the pellet, in 500−1000 μL of PBS. Finally, the fluorescence of the cell suspension was measured by flow cytometer. For data evaluation 10000 counts for each sample were used. For quantitative in vitro flow cytometric adhesion assay with urine samples the adhesion assay was performed similarly to the assay described above with the following changes to the described protocol: 10 mL of sterile urine, containing 5% of UPEC liquid medium, was inoculated with 1 CFU of agar-grown bacteria and incubated in a rotary shaker (200 rpm at 37 °C) until mid-logarithmic growth phase was reached. In pre-experiments the growth rate of *E. coli* in urine, supplemented with 5% broth, had been monitored, revealing

DOI: 10.1021/acs.jafc.5b03030
J. Agric. Food Chem. 2015, 63, 8804−8818

that the mid-logarithmic growth phase was reached after 3.5 h. Additionally, a negative control sample was prepared with each urine sample from each volunteer which had not been inoculated with *E. coli* in order to prove sterility of urine samples. Bacteria were centrifuged after an incubation time of 3.5 h at 3000*g* for 5 min and washed with PBS, and the suspension was adjusted to an $OD_{640\ nm}$ of 0.5/100 μL in saline solution for FITC labeling. After fluorescence labeling, the density of bacteria was adjusted to an $OD_{640\ nm}$ of 0.4/mL in DMEM. Bacteria were added to T24 cells in 6-well plates and incubated for 2 h at 37 °C. Finally, bacterial adhesion was quantified by flow cytometry. Urine samples S0 of each volunteer served as untreated control.

In Vitro Adhesion Assay by Confocal Laser Scanning Microscopy with UPEC and T24 Cells. T24 cells (6×10^4 cells/well) were seeded on 8-well silicone FlexiPERM chambers (Greiner bio-one, Kremsmünster, Austria) and grown to 90% confluence. The supernatant was removed, the monolayer washed with PBS, and 350 μL/well DMEM was added. Agar-grown bacteria were harvested, labeled with FITC, and adjusted to an $OD_{640\ nm}$ of 2.0/mL. Fifty microliters of the bacteria suspension was mixed with 300 μL of test solution and incubated for 30 min at 37 °C. Bacteria in test solution were applied to T24 cells at a BCR of 100:1 for 2 h at 37 °C. After bacterial infection, cells were washed three times with PBS and fixed by 20 min of incubation with 3.7% paraformaldehyde in PBS. Subsequently, the fixed cells were permeabilized by incubation with 0.2% Triton X-100 in PBS for 5 min at room temperature. T24 cells were blocked with PBS containing 3% BSA for 20 min, followed by staining F-actin with Texas Red-conjugated phalloidin (Life Technologies, Carlsbad, CA, USA) for 30 min at room temperature. Nuclei were stained with 1 μg/mL DAPI for 30 min at 4 °C. Subsequently, cells were washed three times with PBS, and the FlexiPERM chamber was removed. Cells were fixed with Dako fluorescent mounting medium (Dako, Carpinteria, CA, USA), covered with a coverslip, and sealed with nail polish. Confocal laser scanning microscopy was accomplished with a Leica TCS SP2 fluorescence microscope (Leica, Wetzlar, Germany) at λ 405/420−480 nm for DAPI, 488/500−580 for FITC, and 594/620−700 for Texas Red.

In Vitro Adhesion Assay by Scanning Electron Microscopy. T24 cells (1×10^5 cells/well) were seeded on Transwell inserts (Corning, Corning, NY, USA) in 12-well plates and grown to confluence. After washing with PBS, 500 μL, respectively, of 1500 μL of DMEM was added. Agar-grown bacteria were harvested and adjusted to an $OD_{640\ nm}$ of 0.4/100 μL. Fifty microliters of the bacteria suspension was mixed with 450 μL of test solution and incubated for 30 min at 37 °C, followed by addition to the T24 cells for 2 h at 37 °C. After the incubation, cells were washed three times with PBS. The samples were prepared for electron microscopy using standard procedures[24] and a high-resolution scanning electron microscope Auriga (Zeis, Jena, Germany).

Quantitative biofilm assay was performed as described in ref 25. Quantitative Congo Red binding assay was performed as described in ref 26.

Methods of Molecular Biology. *Bacterial RNA Extraction, DNase I Treatment, and cDNA Synthesis.* For the isolation of total RNA from *E. coli* 2980 and *E. coli* NU14, bacteria were incubated in the presence of T24 cells (bacteria-host cell contact, BCR 100:1) or without T24 cells in DMEM (untreated control), respectively, containing different concentrations of the test extracts over a time period of 1.5 h at 37 °C and 5% CO_2.

After the incubation time of 1.5 h, bacteria in wells without T24 cells were transferred directly to fresh tubes. The medium in wells with T24 cells was discarded, and cells were washed three times with PBS. Subsequently, T24 cells were detached using a cell scraper and also transferred to fresh tubes. After centrifugation (6500*g*, 5 min), the cell pellets were suspended in PBS and transferred into tubes containing RNAprotect Bacteria reagent (Qiagen, Germany) and mixed by vortexing for 5 s. After 5 min of incubation at room temperature and centrifugation (5000*g*, 10 min), the cells were lysed by mixing with TE buffer containing lysozyme (1 mg/mL, Sigma-Aldrich), followed by incubation for 8 min at room temperature and 500 rpm. The stabilized RNA was purified with an RNeasy Mini Kit (Qiagen, Germany) according to the manufacturer's protocol. The quality and quantity of eluted RNA were determined by measuring the samples at λ = 260 nm and λ = 280 nm by using a BioPhotometer plus and a μCuvette G1.0 (both Eppendorf, Germany).

Potential coeluted DNA was digested by treatment of the isolated RNA with DNase I (Life Technologies, USA) for 15 min at room temperature followed by an inactivation of the enzyme by the addition of EDTA and heating to 65 °C for 10 min. After DNA digestion, samples were controlled again by measuring the $OD_{260\ nm}$ and $OD_{280\ nm}$.

For each RNA sample, 0.5 μg of RNA was transcribed into cDNA by using the Masterscript Kit (5 Prime, Germany) and a random hexamer primer (Thermo Scientific, USA) following the manufacturer's instructions. Here, minus-room temperature controls were also performed, which did not comprise the reverse transcriptase during cDNA synthesis.

Quantitative Real-Time PCR (qRT-PCR). qRT-PCR was performed with an equivalent of 25 ng of total RNA by using the iTaq Universal SYBR Green supermix (BioRad, Germany) according to the protocol recommended by the manufacturer and the CFX96 Real-Time System C1000 Touch (BioRad, Germany). The qPCR parameters were as follows: polymerase activation and initial denaturation for 15 s at 95 °C followed by 39 cycles of 5 s at 95 °C and 30 s at 60 °C. Afterward, an additional melt curve analysis was performed (65−95 °C, ramp 0.5 °C pro cycle, 1 cycle = 5 s, 60 cycles in total). Data were evaluated with the BioRad CFX Manager 3.0 software based on the comparative C_T method ($2^{-\Delta\Delta CT}$ method) and were normalized to the endogenous reference gene16S rRNA.

Primers for the qPCR were designed with the Universal ProbeLibrary Assay design Center (Roche, Switzerland), and the oligonucleotides were obtained from Eurofins MWG Operon, Luxembourg. Primer sequences used for the differential gene expression analysis are listed in Table 2.

Statistical Analysis. Statistical results were obtained by use of SPSS statistics (version 20) (IBM, Armonk, NY, USA). Results are expressed as the mean value (MV) ± standard deviation (±SD). Data ($n \geq 3$) were processed by analysis of variance (one-way ANOVA). A subsequent post hoc test was conducted using Dunnett's test (two-sided) to determine the statistical significance of differences between mean values of two with each other compared groups. *P* values <0.05 were considered as significant.

RESULTS AND DISCUSSION

Antiadhesive Activity of Urine Obtained from Volunteers after 7 Days of Intake of Cranberry Extract. EtOH-/water (1:1, v/v) soluble compounds of a commercially available food grade cranberry dry extract were characterized using LC-ESI-qTOF-DAD-MS (Figure 1). Peaks were assigned as displayed in Table 3 on the basis of a comparison of pseudomolecular ions and major fragments' exact *m*/*z* values with published data of *V. macrocarpon* constituents.

V. m. extract was used within an in vivo study with *n* = 4 male human subjects to ensure potential antiadhesive effects of the urine obtained from the volunteers. The extract was administered for 7 days at 600 mg per day. Urine samples for ex vivo analysis were collected at three time points from the first midstream urine of the day: A control urine sample (S0) was collected at day 0 prior to the application of the cranberry extract. The second urine sample (S1) was collected at day 3, and the third sample (S2) was collected after day 7. For investigation of potential antiadhesive effects of the urine samples an ex vivo antiadhesion assay was performed. A defined amount of UPEC strain NU14 from mid-logarithmic growth phase was incubated for 3.5 h in urine, supplemented with 5% of UPEC growth medium. Subsequently, bacteria were isolated, fluorescent-labeled with fluorescein isothiocyanate, followed by co-incubation with T24 bladder cells for 2 h to allow bacterial adhesion to the host cells. The amount of bacteria, attached to the eukaryotic cells was quantified by flow cytometry. As displayed in Figure 2 significant

inhibition of bacterial adhesion was obvious for S1 (−39%) and S2 (−48%) compared to the control samples S0. These data clearly indicate in vivo antiadhesive activity of the cranberry extract and confirmed a similar study on antiadhesive properties of urine obtained after the ingestion of cranberry preparations.[32]

Molecular Characterization of UPEC Strains. For detailed in vitro investigations on these antiadhesive effects three different UPEC strains were investigated and characterized. Strain J96, isolated from a human patient with pyelonephritis and frequently used in UTI research, has been described to carry the genes coding for type 1 fimbriae (*fimH*), P fimbriae (*papGI/III*), and F1C fimbriae (*focG*) and for the toxins cytotoxic necrotizing factor 1 (CNF1) (*cnf1*) and α-hemolysin (*hlyA*).[33] This strain could not be used for any adhesion experiments in the following studies due to the secretion of α-hemolysin and CNF1, which, after incubation with T24 cells, led to strong cytotoxic effects against the eukaryotic cells.

Subsequently, adhesion studies were carried out with two further UPEC strains: 2980 (isolated from human feces, characterized as an UTI-causing strain,[34] positive for the *fimH*, *papGII/III*, *focG*, *sfaS*, and *hlyA* genes; and NU14, isolated from a patient with clinical cystitis, frequently used for studies of molecular mechanisms of pathogenesis of UTI, positive for the *papGI/II*, *sfaS*, *fimH*, *hlyA*, *cnf*, and *fliC* virulence-associated genes of UPEC.[35]

For verification of these literature-based characteristics both strains were investigated for gene expression by quantitative real-time PCR (qRT-PCR) using a strain-specific sequence of the 16S rRNA from *E. coli* K-12 (clone W3110) as endogenous control. Surprisingly, no or only very limited gene expression of most of the relevant virulence factors was observed after 0.5−2 h of incubation of the bacteria in liquid medium. Thus, it was concluded that the bacteria need a stimulant which induces the expression of virulence factors. Therefore, UPEC were incubated in DMEM in the presence of T24 bladder cells (BCR 100:1, 1.5 h of incubation). This experimental setup evoked a clear up-regulation of several virulence factors, whereas others were not impaired.

For strain 2980, expression of the genes *afaE3*, *nfa*, *papGI*, *papGIII*, and *sfa* was not detectable, regardless of whether bacteria were incubated with T24 cells or not. The biofilm related protein antigen 43 (*agn43*) and the toxin α-hemolysin (*hlyA*) were expressed independent of a T24 stimulus. The presence of T24 cells significantly induced expression of the adhesins *focG*, *papGII*, and *prsGIII* (Figure 3A).

In addition, time course experiments indicated that the level of gene expression for these three adhesins was time dependent: prolonged incubation time of bacteria with T24 cells led to higher expression rates of *papGII* and *prsGIII*, whereas *hlyA* was down-regulated (Supporting Information Figure S1). Thus, *E. coli* strain 2980 is P- and F1C-fimbriae dominated, leading to mannose-resistant adhesion.

For NU14, expression of *fimH*, *papGIII*, *fliC*, *csgA*, and *agn43* was recorded for bacteria incubated in medium alone. The presence of T24 cells evoked significant up-regulation of *fimH* transcripts, whereas *papGIII* transcription was significantly down-regulated (Figure 3B). Thus, NU14 is type 1 fimbriae dominated, and mannose could be used for the inhibition of bacterial adhesion as positive control.

By comparison of both strains it became obvious that NU14 and 2980 have only one adhesin, *papGIII*, in common, which gets down-regulated in the presence of T24 cells in NU14. Therefore, *papGIII* seems not to be essential for bacterial attachment of NU14 to T24 cells.

In summary, both strains 2980 and NU14 are suitable for comparative adhesion experiments and target identification of specific adhesin inhibitors. Furthermore, NU14 and the other strains used in this study can be used for the investigation of curli (*csgA*) and biofilm (*agn43*) formation, as well as for motility studies (*fliC*).

Influence of Cranberry Extract on Bacterial in Vitro Adhesion to T24 Bladder Cells. From the cranberry dry extract used for the in vivo study, standardized on 1.24% PACs and containing >80% of non-cranberry excipients to ensure

DOI: 10.1021/acs.jafc.5b03030
J. Agric. Food Chem. 2015, 63, 8804−8818

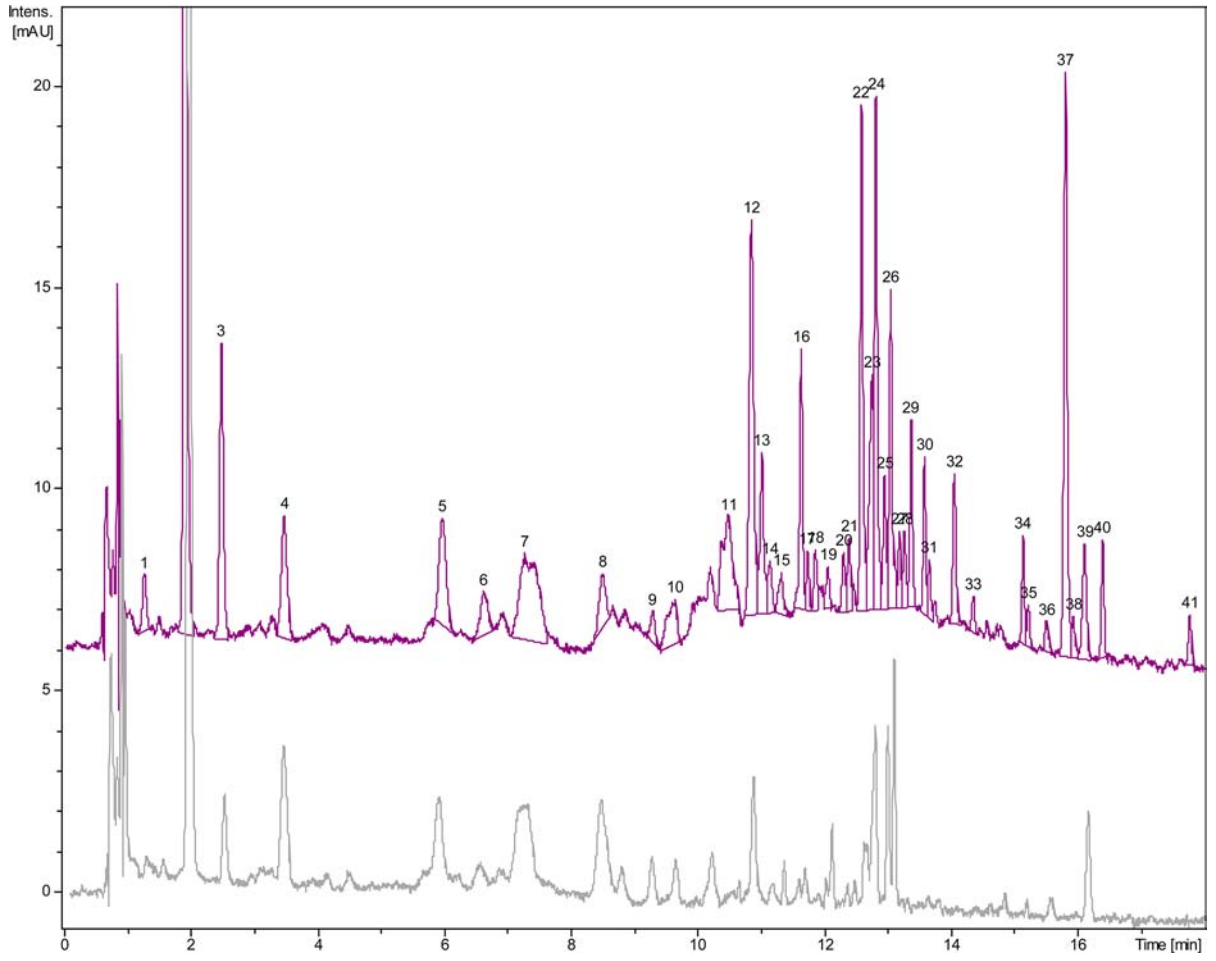

Figure 1. HPLC-UV chromatograms of *V.m.* extract (upper plot) and *V.m.* extract$^{\neq PAC}$ (lower plot) (λ = 280 nm). Peak assignment by MS. See Table 3.

optimized free floating powder technology, EtOH/water (1:1, v/v) soluble compounds were extracted. The resulting lyophilized product, *V.m.* extract, had a PAC content of 21.1 ± 1.9%, HPLC fingerprint as displayed in Figure 1, and compound dereplication as displayed in Table 3.*V.m.* extract was investigated for potential cytotoxic effects against *E. coli* 2980 by agar diffusion test over 24 h. Up to 1000 μg/mL, no inhibition of bacterial growth was observed (data not shown). *V.m.* extract up to concentrations of 250 μg/mL did not influence viability of eukaryotic T24 bladder cells over 24 h of incubation time as analyzed by MTT assay (data not shown).

Treatment of *E. coli* 2980 and NU14 with *V.m.* extract (10−100 μg/mL), addition of the suspension to T24 cells, and evaluation of bacterial adhesion to the host cells by flow cytometry resulted in a concentration-dependent increase in bacterial adhesion, due to the aggregation and clustering of the bacteria. Comparable results were also obtained in the case of a 2 h preincubation of *E. coli* 2980 with *V.m.* extract, followed by removal of extract components by successive washing steps prior to the addition of the *V.m.* extract-pretreated bacteria to the T24 cells (Figure 4). Semiquantitative evaluation of these data obtained by fluorescence microscopy confirmed these findings and clearly indicated a huge bacterial burden attached to the bladder cells (Figure 5).

Laser scanning microscopy was performed for investigating the localization of UPEC within the T24 cells. A top view of the cells indicated strongly individualized UPEC on the cell surface in the untreated control group, whereas bacterial clusters were visible for the *V.m.* extract (25 μg/mL) treated groups (Supplementary Data Figure S2).

Systematic section scanning of the monolayer preparations (30 steps, 0.2 μm) demonstrated the occurrence of mainly intracellular bacteria for the untreated control (Figure 6, series A) with most bacteria found within the cytoplasm (1−3 μm). In contrast, most of the bacteria in the *V.m.* extract-treated groups were detected as clusters on the cell surface (4−5 μm), whereas nearly no bacterial internalization was observed (Figure 6, series B).

To prove that *V.m.* extract leads to increased formation of UPEC clusters on the surface of the bladder cells, a third methodology, scanning electron microscopy (SEM), was performed. As expected, untreated control cells showed individualized bacteria on the cell surface (Figure 6A), whereas *V.m.* extract-treated UPEC formed clusters (Figure 7B). Increased magnification proved the presence of agglomerates (Figure 7C), and also the integration of the bacteria within a thin meshed film network was observed (Figure 7D). From these data it was concluded that *V.m.* extract at low concentrations under in vitro condition has the ability to agglomerate UPEC, which are strongly fixed to the T24 cell surface, and cannot be removed by repeated washing steps.

From these data a strong tendency of agglomeration of bacteria by cranberry extract was obvious. This phenomenon was also reproduced using different cranberry extracts from different suppliers and also by cranberry extract prepared directly from fresh fruits.

[a]Peaks were assigned to known constituents of *V. macrocarpon* as denominated in the refs27−31. Assignment of stereoisomers is based on published RP18 elution order and relative peak areas.[27−31] Assignments without reference are based on the interpretation of MS, MS^2, and UV spectra. Peaks 13, 26, and 30 are constituted of two compounds, respectively. Chemical structures are displayed in the cited literature. na, not accessible. [b]Preceding fragment m/z values were obtained from MS^2-CID experiments (collision energy = 40 eV) or from peak background-corrected full MS spectra (ISCID 0 eV, collision energy = 8 eV).

At this point of the investigation this phenomenon seemed confusing in relation to already published data. Most publications on antiadhesive cranberry preparations used similar in vitro protocols: Bacteria were pre-incubated with extracts or test compounds (e.g., PACs), followed by incubation with bladder cells; unattached bacteria were removed and cells fixed and stained with Giemsa. Bacterial adhesion was calculated throughout the literature by using light microscopy and determining the average number of bacteria attached to a certain number of human cells.[36−40]

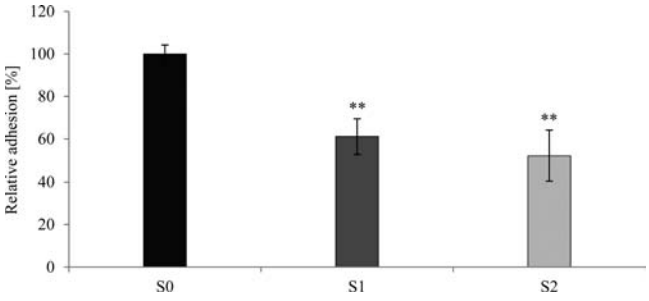

Figure 2. Relative adhesion of UPEC, strain NU14, to T24 bladder cells after 3.5 h of cultivation of bacteria in urine obtained from cranberry extract treated volunteers (n = 4, 600 mg extract for 7 days). S0, control urine, prior to cranberry consumption; S1, urine obtained at day 3 during cranberry extract application; S2, urine obtained at day 7 during cranberry extract application. Data are related to the initial adhesion values determined for S0 (=100%). (**) $p < 0.01$. Values represent the mean ± SD.

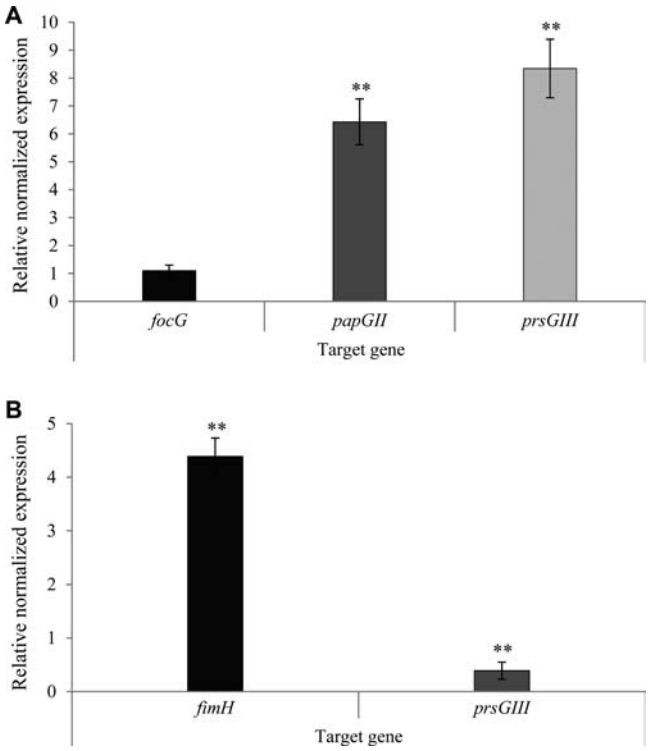

Figure 3. Relative gene expression of selected virulence factors from *E. coli* strain 2980 (A) and strain NU14 (B) as determined by qRT-PCR: comparison of relative expressions of *focG*, *papGII*, and *papGIII* (strain 2980) as well as *fimH* and *papGIII* (NU14) in UPEC incubated for 1.5 h in medium (alone) with bacteria incubated for 1.5 h in the presence of T24 cells. The relative expression of genes from bacteria in the absence of T24 cells (alone) has been set to 1. Expression levels have been normalized to the expression of the endogenous control gene 16S rRNA. (**) $p < 0.01$. Values represent the mean ± SD of six independent assays with two technical replicates for each experiment.

We speculate that during this evaluation bacterial agglomerates or clusters were not taken in account as they appear typically as dark, undefinable, spots in the microscope. Additionally, when bacteria are agglomerated and clustered, this could also imply a lower number of individual bacteria for counting. Another bias could occur during microscopy: as shown by SEM (Figure 6) the cluster-bearing host cells have typically some areas where the bacteria are strongly agglomerated in a three-dimensional mash, but many areas, if not most, of the cell surface are free of bacteria or clusters. In cases when only these cluster-free parts of a cell are evaluated, a strongly reduced number of bacteria might be counted, compared to the untreated control groups where the bacterial load is distributed very regularly over the host cell surface. For these different reasons published data on anti-adhesive cranberry activity should be reviewed very carefully concerning the respective quantitative evaluation protocols.

On the other hand, it seems not very astonishing that PAC-enriched extracts should agglomerate bacteria by an unspecific, astringent, tannin-like effect.

Another essential aspect is the limited absorption of PACs after oral intake: recent publications have shown that oligomeric PACs have a very limited bioavailability from the gut, which implies that these polyphenolic compounds will not appear in the lower urinary tract to a higher extent. To investigate the influence of PACs within the *V.m.* extract on bacterial adhesion, tannins were precipitated quantitatively from the extract by polyvinylpyrrolidone. From 100 mg of *V.m.* extract 66 mg of a PAC-free extract was obtained, designated in the following as *V.m.* extract$^{\neq PAC}$. TLC studies of this PAC-depleted extract indicated the absence of vanillin−HCl-positive spots, typically for flavan-3-ols and PACs. Also, comparative HPLC-MS (Figure 1) studies against *V.m.* extract demonstrated the disappearance of PACs in *V.m.* extract$^{\neq PAC}$: PVP treatment removed the majority of polyphenolic substances from the extract, with anthocyanidins and flavonol aglyca depleted by 100% (below the limit of detection), anthocyans and flavonoid glycosides by 97%, phenylpropane glycosides by 56%, iridoid glycosides by 42%, and benzoyl glycosides by 5% (averaged values).

Evaluation of the bacterial adhesion assay with *V.m.* extract$^{\neq PAC}$ indicated that the agglomerating effects against UPEC on the T24 cell surface did not occur (Figure 4): strain 2980, treated with the PAC-depleted extract, did not show any differences compared to the untreated control groups (Figure 4A), whereas strain NU14, treated with *V.m.* extract$^{\neq PAC}$, showed significantly decreased adhesion to the host cells, which was similar to the inhibiting effect of the positive control, 10 mmol of mannose. From these experiments it can be deduced that PAC-free cranberry extracts can interact significantly and in a dose-dependent manner with the adhesion of UPEC to T24 cells, which should be due to a more or less specific effect against *FimH* adhesin. In contrast, P-fimbriae-mediated adhesion is not influenced by cranberry extracts. The finding that PACs are not responsible for the antiadhesive effects is also in accordance with recently published data indicating that after oral cranberry intake, myricetin derivatives have been identified in the urine, which again seem to exert significant antiadhesive effects against UPEC.[41] On the other hand, *V.m.* extract$^{\neq PAC}$ used in our study was also strongly depleted from myricetin, which again might indicate that other extract compounds are responsible for the antiadhesive activity of this extract.

Influence of Cranberry Extracts of Gene Expression of Bacterial Adhesins. To investigate the influence of PAC-containing and PAC-depleted cranberry extracts on the gene expression of relevant bacterial adhesins, both *E. coli* strains 2980 and NU14 were treated with either *V.m.* or *V.m.* extract$^{\neq PAC}$ (100 μg/mL) for 1.5 h in the presence or absence of T24 cells; gene expression was monitored by qRT-PCR.

In the case of incubation of *E. coli* 2980 with *V.m.* extract in the absence of T24 cells *papGII* and *focG*, transcript levels were slightly up-regulated, whereas the transcript levels of *papGIII* remained unchanged (Figure 8A). In contrast, treatment of strain

J. Agric. Food Chem. 2015, 63, 8804−8818

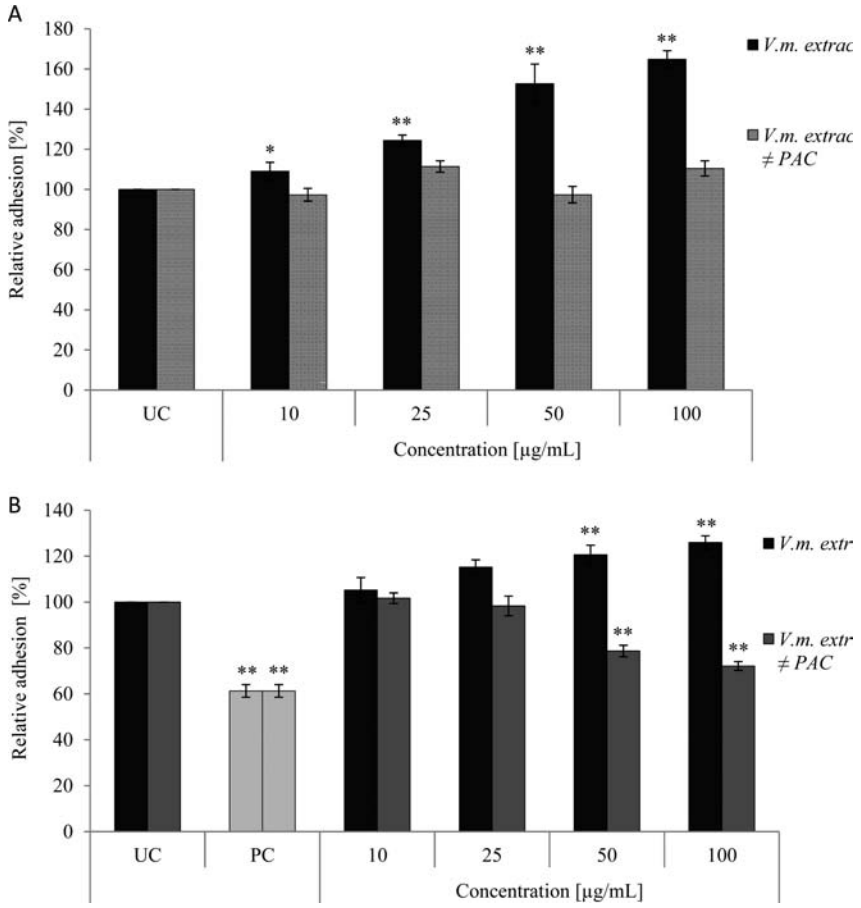

Figure 4. Influence of different concentrations of *V.m.* extract and *V.m.* extract$^{\neq PAC}$ on the adhesion of FITC-labeled *E. coli*, strain 2980 (A) and strain NU14 (B) to T24 cells after 2 h of pre-incubation of bacteria with the extracts. Data indicate the adhesion related to the untreated control (UC = 100%). For strain NU14 (B) mannose (10 mmol) served as positive control (PC). (∗) $p < 0.05$ and (∗∗) $p < 0.01$. Values represent the mean ± SD of six independent assays.

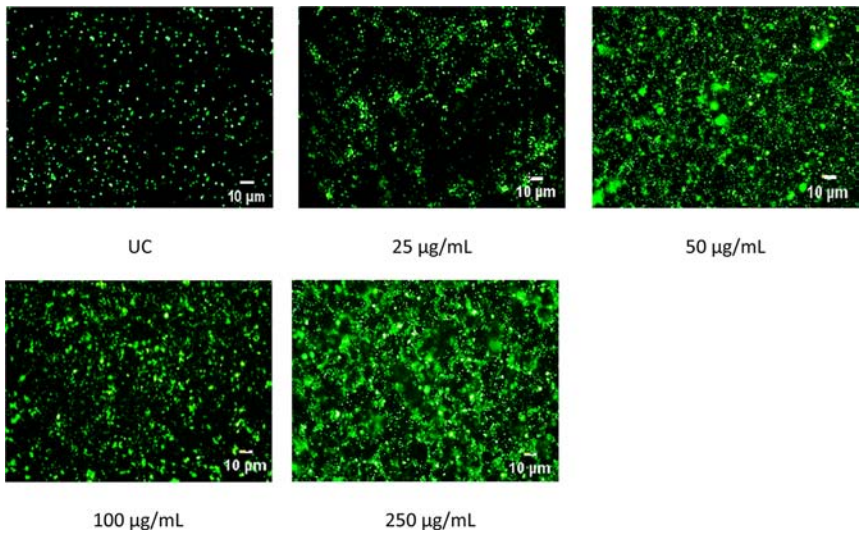

Figure 5. Influence of different concentrations of *V.m.* extract (25−250 µg/mL) on the bacterial adhesion of FITC-labeled *E. coli*, strain 2980, against T24 bladder cells (BCR 115:1) after 2 h of pretreatment of *E. coli* as determined by fluorescence microscopy. Magnification: 10×. UC, untreated control.

2980 with *V.m.* extract$^{\neq PAC}$ did not have any influence (Figure 8B). Similar experiments, but in the presence of T24 cells, indicated down-regulation of *papGII* and *focG* by *V.m.* extract (Figure 8A), whereas *V.m.* extract$^{\neq PAC}$ in the presence of T24 cells did not influence gene expression (Figure 8B).

Incubation of *E. coli* NU14 with *V.m.* extract had almost no impact on the gene expression level of adhesins (Figure 8C). Only the expression of *fimH* was slightly increased when bacteria were incubated in the absence of T24 cells. In contrast, *V.m.* extract$^{\neq PAC}$ induced transcription of *fimH*, whereas *papGIII*

J. Agric. Food Chem. 2015, 63, 8804−8818

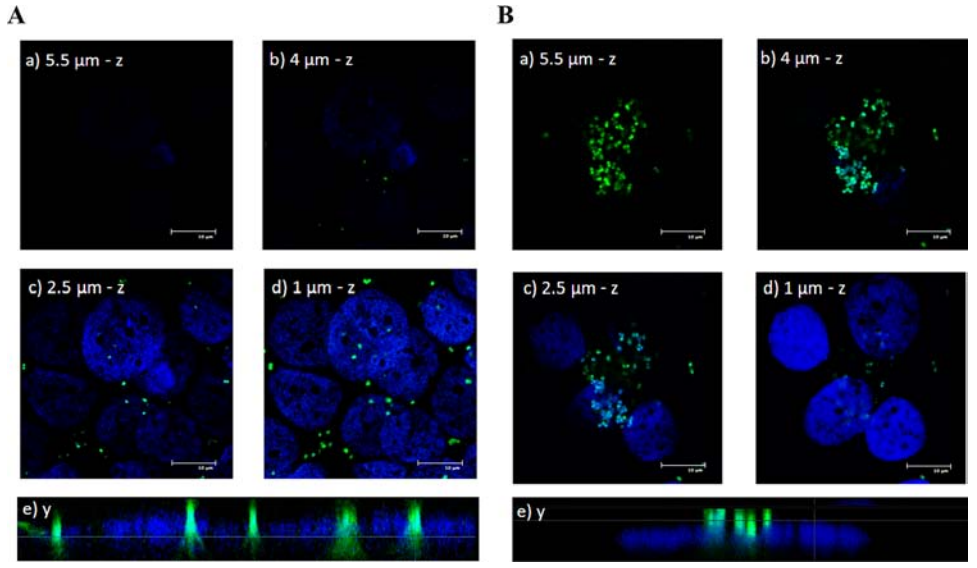

Figure 6. Sectional confocal laser scanning microscopic analysis of adhesion of UPEC to T24 bladder cells. T24 cells were incubated for 2 h with FITC-labeled *E. coli*, strain 2980. Staining of cell nuclei with DAPI is indicated by blue color, that of F-actin with Texas Red by orange color, and that of bacteria with FITC by yellow-green color. Scale bars = 47.6 μm. The images represent four 1.5 μm steps (a–d) in horizontal (z) and one image (e) side view (y) of a 30-step–0.2 μm (z-position) sectional scanning of the preparation. Scale bars = 10 μm. Series A: untreated UPEC, buffer only. Series B, UPEC pretreated with *V. m.* extract, 25 μg/mL.

transcript levels remained on a comparable level to the untreated control in the absence of T24 cells (Figure 8D). In cases when T24 cells were present, the expression of both adhesin genes, *fimH* as well as *papGIII*, was up-regulated (Figure 8D). The specific up-regulation of *fimH* transcription by both extracts, *V.m.* extract as well as *V.m.* extract$^{\neq PAC}$, is in good agreement with the inhibitory activity of the extracts against FimH: blocking of this adhesin will lead to a controlled feedback mechanism of NU14 toward a higher expression rate to ensure interaction with the host cell.

The findings concerning the reactivity of *E. coli* 2980 are more complicated and must be related to a central study in cranberry research, which is related to the finding that the *papGII* protein should be inhibited by the cranberry-specific trimeric A-type PAC.[5] In this study PAC-pretreated bacteria have been investigated concerning their interaction with an immobilized synthetic P-receptor analogue and agglutination of human red blood cells; the authors found significant lower agglutination of beads or blood cells between PAC-treated *E. coli* compared to untreated controls. Compared to our findings, we assume that the reduced agglutination of beads or blood cells might be due to inactivation of UPEC by formation of tannin-induced clustering and interaction leading to a decreased ability for bacterial adhesion. On the other hand, our finding indicates that the extract also induces up-regulation of *papGII* and *focG*, but also of *fimH* transcription. The increased expression of *focG* in *E. coli* 2980 could then be a feedback consequence of inhibition of P-fimbriae. On the basis of these results it can be assumed that bacteria which are already agglomerated by tannins exhibit additionally an enhanced density of adhesins (papGII and FocG) on their surface. Therefore, although papGII is inhibited, the bacterial clusters are still able to interact with host cells because of the availability of the second up-regulated adhesin (FocG). Thus, we conclude that the impact of cranberry extracts on UPEC adhesion is much more complicated than is described in the recent literature, where mostly UPEC strains have been used with multifunctional adhesins. Whereas non-PAC cranberry constituents block type 1 fimbriae, PAC seems additionally to inhibit P-fimbriae, which again will lead to up-regulation of F1C-fimbriae. In total, reduced bacterial inhibition is observed onlyin cases where the feedback regulation toward increased adhesins expression is not balanced by the adhesion-blocking effects of the cranberry extracts against *fimH*.

From the literature,[5] it is known that cranberry trimeric PACs interact with *papGII*. By using *V. m.* extract this leads to an up-regulation of this adhesin as shown in Figure 8. Additionally *V.m.* extract stimulates a further bacterial adhesin *fFocG* (Figure 8). This means that incubation of *E. coli* 2980 with *V. m* extract increases the density of different adhesins on the bacterial surface.

In the case when T24 bladder cells are present in combination with *V. m.* extract, we observe a different gene expression profile, where the stimulation of the adhesins is much lower (Figure 8), probably due to the fact that the bacteria attach to the cells and do not need the additional adhesins anymore. This strong adhesion is also monitored in the adhesion assay (Figure 4), where *V. m.* extract leads to a strong and dose-dependent increase in adhesion to the T24 cells.

From the gene expression data for *V.m.* extract$^{\neq PAC}$, no influence on the expression of the adhesins is observed. This indicates that PACs are responsible for induction of the bacterial adhesins. This again is in good correlation with the data from the adhesion assay (Figure 4) where no influence of *V.m.* extract$^{\neq PAC}$ on the amount of adhering *E. coli* 2980 is observed.

For UPEC NU14 it is interesting that a decreased adhesion takes place, which indicates the presence of compounds in the extract with inhibitory effects against *fimH* (Figure 4). On the other hand, NU14 up-regulates *fimH* and *papGII* expression after treatment with *V.m.* extract$^{\neq PAC}$, which means the bacteria recognize the blocking of FimH by extract compounds and counter-regulate by increasing the gene expression of this and a second adhesin.

Cranberry Extract Does Not Influence Curli and Biofilm Formation. *V.m.* extract and *V.m.* extract$^{\neq PAC}$ (50 and 100 μg/mL)

DOI: 10.1021/acs.jafc.5b03030
J. Agric. Food Chem. 2015, 63, 8804–8818

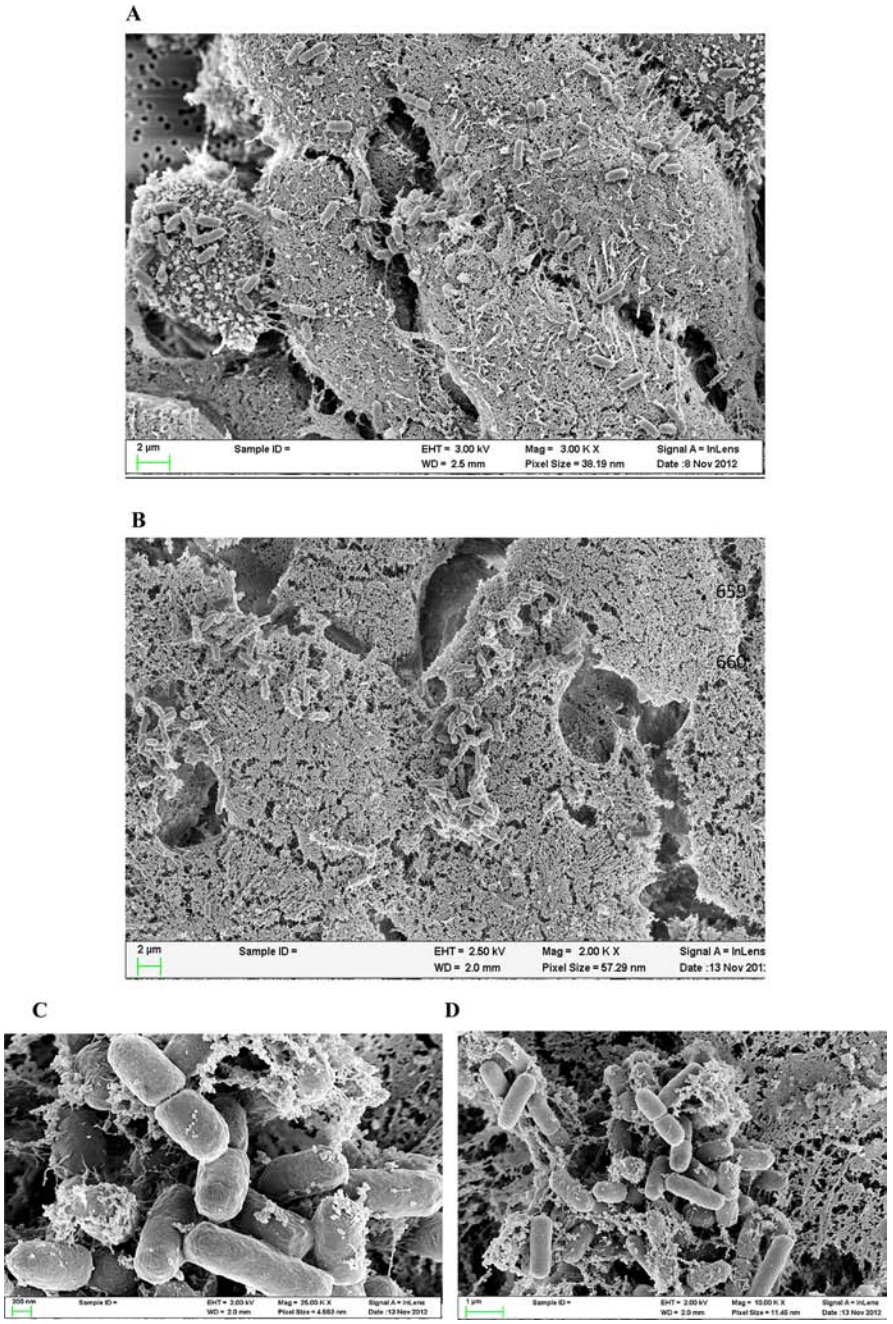

Figure 7. Scanning electron microscopy of T24 bladder cells incubated for 2 h with *E. coli* strain 2980 after pretreatment of the bacteria with *V.m.* extract (25 μg/mL) (B, C, D at different magnifications) versus untreated bacteria (A). (A) Untreated *E. coli*, buffer only; (B) *E. coli* pretreated with *V.m.* extract, 25 μg/mL; (C) *E. coli* pretreated with *V.m.* extract, 25 μg/mL; (D) *E. coli* pretreated with *V.m.* extract, 25 μg/mL.

were investigated concerning their ability to inhibit adhesion by interaction with bacterial curli formation by using the Congo Red assay.[21] On the basis of the information on gene expression analysis, *E. coli* strain NU14 should exhibit curli as it expresses *csgA*. The quantitative Congo Red binding assay confirmed this finding. The assay indicated that neither *V.m.* extract nor *V.m.* extract$^{\neq PAC}$ interacted with the formation of curli (Supplementary Data, Figure S3).

By gene expression analysis, both strains, 2980 and NU14, have been shown to express Agn43, an autotransporter protein involved in biofilm formation. Therefore, a biofilm assay[21] was performed with *V.m.* extract and *V.m.* extract$^{\neq PAC}$ in a concentration range of 25−200 μg/mL. The biofilm mass produced by *E. coli* 2980 after incubation with *V.m.* extract was slightly, but not significantly, increased. *V.m.* extract$^{\neq PAC}$ had no influence on biofilm formation of strain 2980 (Supplementary Data, Figure S4A). Incubation of *E. coli* NU14 with both extracts led to biofilm masses that were comparable to the biofilm mass determined for the untreated control (Supplementary Data, Figure S4B).

Summarizing this study, the data indicate that PAC-depleted cranberry extracts inhibit the FimH-mediated adhesion of UPEC to bladder cells, which again implies that further studies are needed to evaluate the clinical relevance of this finding, as well as the phytochemical search for the active compounds in cranberry extracts.

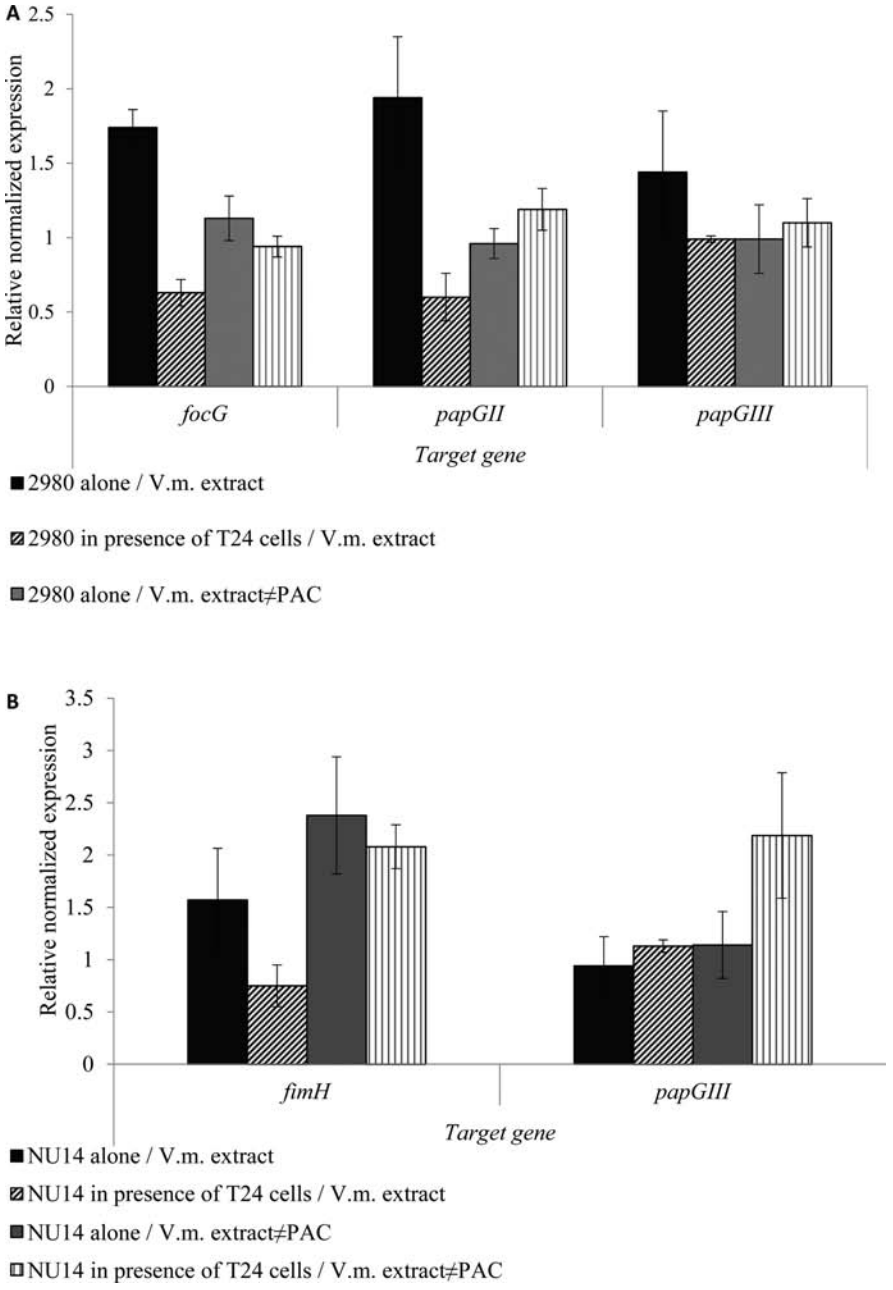

Figure 8. Influence of PAC-containing cranberry extract (*V.m.* extract, 100 μg/mL) and PAC-depleted cranberry extract (*V.m.* extract$^{\neq PAC}$, 100 μg/mL) on the relative gene expression of *E. coli* strains 2980 (A) and NU14 (B) in the presence or absence of T24 bladder cells. Relative expression levels of *focG*, *papGII*, and *papGIII* were determined for strain 2980 and *fimH* and *papGIII* for strain NU14 after incubation for 1.5 h with the respective extracts in absence or presence of T24 bladder cells. Respective expression levels are normalized to the endogenous control 16S rRNA; relative gene expression of untreated control groups = 1. Data are the mean ± SD from three independent assays with two technical replicates.

in the investigation of peptides could provide information about the presence of an analyte or evaluate the general constitutions of a peptide mixture based upon retardation factor (R_f value);[16−18] it also was used for the separation and/or identification of certain peptides with known characteristics in combination with other analytical techniques.[15,16] However, to the best of our knowledge, there have been no reports on the fractionation and isolation of the more effective components from complex protein hydrolysates, mainly by means of the common silica TLC, for the identification of potent bioactive peptides.

Therefore, the objective of this work was to develop a two-dimensional silica TLC (2D-TLC) technique using two coupled plates with different eluents to separate and divide the trypsin/chymotrypsin-treated goat casein hydrolysates into fractions with different potencies of DPP-IV inhibition, and to verify its feasibility and efficiency by RP−HPLC at different stages. The more efficient DPP-IV-inhibitory components were then isolated and their peptidic inhibitors were identified.

MATERIALS AND METHODS

Materials. Skim milk powder from Saanen goat (*Capra hircus*) was provided by Ausnutria Hyproca Dairy Group BV (Changsha, China). Trypsin (from porcine pancreas, with trypsin ≥250NF U/mg, chymotrypsin ≤75NF U/mg) was from Amresco LLC (Solon, OH). DPP-IV (from porcine kidney, ≥10 U/mg protein) and Gly-Pro-*p*-nitroanilide (H-Gly-Pro-*p*NA HCl) were purchased from Sigma-Aldrich (St. Louis, MO). Ile-Pro-Ile (diprotin A) was prepared by Qiangyao Biological Technology Co. Ltd. (Shanghai, China). Chloroform, 25% ammonia, *n*-butanol, and acetic acid were from Beijing Chemical Works (Beijing, China). Acetonitrile, methanol, trifluoroacetic acid (TFA), and formic acid (FA) were HPLC-grade and from Fisher Scientific (Fair Lawn, NJ). All other chemicals were of analytical grade.

Preparation of Hydrolysates. Goat milk casein was prepared by the acidic precipitation method, in which pH is adjusted to the isoelectric point of goat casein, 4.2. The obtained casein precipitate was lyophilized by LGJ-12 vacuum freeze-dryer (Songyuan Huaxing Technology Development Co. Ltd., Beijing, China), and the freeze-dried casein powder consisted of 95.2 ± 1.1% protein. The casein powder was dissolved in 0.05 M NaOH to 5% (w/w, protein basis) and stirred until complete dissolution; then the solution was preincubated at enzymatic temperature for 10 min, and the hydrolysis was initiated by adding commercial trypsin with a 3% (w/w) substrate-to-enzyme ratio and conducted at pH 8.0 and 37 °C for 3 h, with constant temperature and pH (holding with 1 M NaOH). After hydrolysis, the resulting hydrolysates were heated in boiling water for 10 min to inactive the enzyme, then cooled with ice water bath and centrifuged with TGL-20 M high-speed centrifuge (Pingfan Instrument Co. Ltd., Changsha, China) at 1800 × *g* (4 °C) for 20 min. The supernatant was adjusted to pH 8.0, sequentially filtered through a 0.22-μm syringe filter (Jinteng Corporation, Tianjin, China) and Amicon Ultra-15 centrifugal filter device (Millipore Corporation, Bedford, MA) with molecular-mass cutoff of 5 kDa. The <5 kDa fraction was used for further chromatographic separation and DPP-IV-inhibitory activity assay.

Analyses of <5 kDa Fraction of Hydrolysates by 2D-TLC. The <5 kDa fraction of the hydrolysates, labeled SF-0, was developed and analyzed by 2D-TLC. The TLC was carried out on a glass-backed 100 × 100 × 0.2−0.25 mm ready-use silica gel 60 TLC plate (Haiyang Corporation, Qingdao, China). The suitability of different development solvent systems for the fractionation and separation of protein hydrolysates was tested. Freeze-dried SF-0 (3 μL of 100 mg/mL dissolved in ddH_2O) was spotted (<3 mm diameter spot) onto the TLC plate origin. After air-drying under an air stream at 50 °C, the plate was developed with chloroform/methanol/25% ammonia (2:2:1, v/v/v) eluent until the solvent front reached a distance of 7.5 cm in a vertical chamber (XinYi, Shanghai, China). The control sample for this first-dimension TLC was spotted on the horizontally opposite side of the plate (1.5 μL SF-0). After the first-dimension separation, the developed plate was dried in air at room temperature to remove eluent and turned 90°; the second-dimension TLC development was carried out at a 90° angle to the first-dimension TLC development with another type of solvent (*n*-butanol/acetic acid/water, 4:1:1, v/v/v) until the solvent front reached ca. 7.5 cm. The control sample (1.5 μL of SF-0) for the second-dimension TLC was similarly located at the horizontally opposite side. After air-drying at room temperature, 0.05% (w/v) ninhydrin in ethanol was sprayed onto the plate, and peptide coloration was developed at 95 °C for 15 min.

Semipreparation of Peptide Fractions and/or Subfractions by TLC. The semipreparative 2D-TLC process was conducted by two coupled silica gel 60 plates with the same solvents and development order as above. The SF-0 sample was first fractionated by the first-dimension TLC, and the recovered fraction was transferred to a new TLC plate for the second-dimension separation. Briefly, 2.5 μL of SF-0 (100 mg/mL) was spotted onto a TLC plate with 12 repeats along the starting line (2 spots were used for peptide visualization, and the other 10 spots were used for semipreparation of the fractions after TLC development with the first- or second-dimension development solvents). Thus, 2.5 mg of SF-0 was loaded and separated on the first-dimension TLC plate. Separated peptide bands were scraped according to the R_f value of the ninhydrin-colored spots, and the silica powders were extracted twice with ddH_2O at 20 °C for 20 min (oscillation with an interval of 4 min) to recover the adsorbed peptides completely, then centrifuged at 12 000 × *g* at 4 °C for 20 min (repeated twice) to exclude the silica. The supernatant for each fraction or subfraction was adjusted to 500 μL as the initial volume of SF-0 (equivalent to 5 mg/mL concentration), and then the DPP-IV-inhibitory activity was assayed.

RP−HPLC Verification. The peptide samples from the fractions or subfractions of the first- or second-dimension semipreparative TLC were analyzed by RP−HPLC, performed on a Chuangxin Tongheng LC3050 HPLC system. A 20-μL aliquot of sample dissolved in ddH_2O was injected into an analytical C18 column with 250 × 4.6 mm i.d., 5 μm, 100 Å (Chuangxin Tongheng Science and Technology Co. Ltd., Beijing, China), and eluted with 0.1% TFA in water (solvent A) and 0.1% TFA in acetonitrile (solvent B) as follows: 10% B, followed by a linear gradient from 10 to 50% B from 5 to 45 min, at a flow rate of 1 mL/min at 30 °C. The elution was monitored at 215 nm with a UV/vis detector; the peptide peaks were collected when needed, and the separation was repeated multiple times to obtain enough samples for analysis. After removing acetonitrile by evaporation, each subfraction was also adjusted to the same initial volume as SF-0 (500 μL at 5 mg/mL concentration) for assaying their effect on DPP-IV activity as the semipreparative 2D-TLC.

Identification of Peptide Sequences by Liquid Chromatography−Tandem Mass Spectrometry. The peptide subfractions with the most efficient DPP-IV-inhibitory activities were subjected to sequence identification by LC−ESI−MS/MS (ESI = electrospray ionization) using a nanoAcquity nano HPLC system (Waters, Milford, MA) coupled to Q-Exactive high-resolution mass spectrometer (Thermo Scientific, Waltham, MA). The sample was injected into a trap column of 2 cm × 100 μm i.d. fused silica capillary (Polymicro, Phoenix, AZ) and separated on a 10 cm × 50 μm i.d. microanalytical column of the same material, which was packed with C18 stationary phase of Aqua 5 μm, 125 Å, and Aqua 3 μm, 125 Å, respectively (Phenomenex, Torrance, CA). The eluting program was conducted with 0.1% FA in water (solvent A) and 0.1% FA in acetonitrile (solvent B) following a linear gradient from 1 to 40% B from 0 to 40 min, at a flow rate of 200 nL/min. The eluate was directly injected into the MS system. A spray voltage of 2000 V was applied to the electrospray tip; the capillary temperature was 320 °C. MS analysis was operated with the following scan parameters: data-dependent MS^2 and positive ion mode, full scan mass range 100−1500 m/z, full scan resolution 70 000, MS/MS scan resolution 17 500, mass selection window 4 Da, dynamic exclusion 10 s. The 10 most intensive peptide signals from the full scan were selected for MS/MS scans. The MS/MS data were preprocessed

DOI: 10.1021/acs.jafc.5b03062
J. Agric. Food Chem. 2015, 63, 8819−8828

with Mascot Distiller 2.4 (Matrix Science, London, U.K.) for peak picking and further searched against protein data of *Capra hircus* from UniProtKB/Swiss-Prot database[19] using Mascot 2.4 search engine (Matrix Science, London, U.K.) to confirm the amino acid sequence of peptides.

Peptide Synthesis. Peptides identified by nano LC−MS/MS were synthesized by conventional 9-fluorenylmethyloxycarbonyl (Fmoc) solid-phase synthesis by China Peptides Co. Ltd. (Shanghai, China). The purity of these synthesized peptides was ≥95%, and their DPP-IV-inhibitory activity was determined.

Assay for DPP-IV-Inhibitory Activity. DPP-IV-inhibitory activity was measured according to the method described by Aart et al.[4] with minor modifications. Briefly, peptide samples were diluted in 100 mM Tris−HCl buffer pH 8.0 to the desired concentration. In a 96-well microplate, 25 μL of diluted sample was preincubated with 25 μL of Gly-Pro-*p*-nitroanilide (1.6 mM) at 37 °C for 10 min; then 50 μL of DPP-IV (8 U/L) was added, and the mixture was incubated at 37 °C for 60 min. The reaction was stopped by adding 100 μL of 1 M sodium acetate buffer, pH 4.0, and the absorbance was measured at 405 nm by Multiskan MK3 ELISA plate reader (Thermo Labsystems, Franklin, MA). Diprotin A was used as a reference inhibitor. The DPP-IV-inhibition (DI) was calculated as

$$\mathrm{DI}(\%) = \left(1 - \frac{A_{405}(\text{sample}) - A_{405}(\text{sample control})}{A_{405}(\text{negative reaction}) - A_{405}(\text{negative control})}\right) \times 100 \quad (1)$$

where A_{405}(sample) is the optical density at 405 nm (OD_{405}) in the presence of DPP-IV, its substrate Gly-Pro-*p*-nitroanilide, and inhibitor peptide sample; A_{405}(sample control) is the OD_{405} when DPP-IV is replaced with Tris-HCl buffer (100 mM, pH 8.0) as sample assay; A_{405}(negative reaction) is OD_{405} of DPP-IV and substrate with no addition of inhibitor; and A_{405}(negative control) is OD_{405} of the assay with no DPP-IV and inhibitor.

The IC_{50} value of the tested sample was determined by the plot of percent DPP-IV inhibition (%) against $\log_{10}$ (sample concentration), and Lineweaver−Burk plots were used to visualize the modes of DPP-IV inhibition.[20] After TLC separation, the total DPP-IV inhibition (totalDI) was calculated as the sum of each fraction or subfraction DPP-IV inhibition (DI_i):

$$\mathrm{totalDI}(\%) = \sum_{i=\text{SF-1 or SF-16-1}}^{n} \mathrm{DI}_i(\%) \quad (2)$$

where *i* is the fraction or subfraction serial number (SF-*i* or SF-16-*i*), *i* = 1 to *n*.

Data Analysis. All experiments were carried out at least three times, and data were expressed as means with standard deviation (SD). Significant differences ($P < 0.05$) between means were identified by Tukey's procedures using SPSS 17.0 (SPSS Inc., Chicago, IL).

RESULTS AND DISCUSSION

Fractionation of SF-0 by 2D-TLC. Our previous assays have confirmed that the DPP-IV-inhibitory activity of the trypsin/chymotrypsin-treated goat casein hydrolysates is largely distributed among peptides with molecular mass below 5 kDa (unpublished results). Therefore, the <5 kDa fraction of the hydrolysates, SF-0, was used as the starting peptide mixture for the following 2D-TLC separation in this study. Figure 1 shows the 2D-TLC profile of the SF-0 fraction after ninhydrin coloration. A weakly alkaline lower-polar solvent (chloroform/methanol/25% ammonia, 2:2:1) was adopted as the first-dimension TLC eluent, while the second-dimension TLC used to further separate the fractions was performed with a weakly acidic polar solvent (*n*-butanol/acetic acid/water, 4:1:1). Compared to one-dimensional TLC in either alkaline or acid solvent, the SF-0 was developed and separated more efficiently and divided into more constituents by the 2D-TLC. In total,

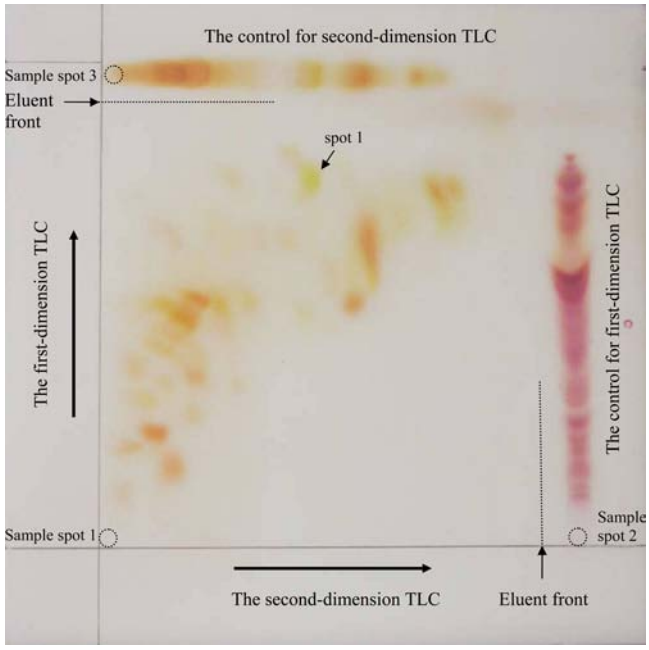

Figure 1. Two-dimensional silica thin-layer chromatography (2D-TLC) profile of the <5 kDa fraction of goat casein hydrolysates (SF-0) after ninhydrin coloration.

more than 35 visible spots were displayed on the 2D-TLC with different color tints (Figure 1), indicating the separation of potential bioactive peptide fractions from the casein hydrolysates. Therefore, semipreparation of individual fractions by 2D-TLC with two coupled plates was carried out to analyze their DPP-IV-inhibitory activities and isolate the relatively more efficient active components among the SF-0.

First-Dimension TLC Fractionation. The first-dimension of the semipreparative TLC separation of SF-0 gave 18 bands (fractions SF-1−SF-18) (Figure 2A) with different DPP-IV inhibition values (Figure 2B). We assayed their DPP-IV-inhibitory activity as was done for the initial volume of SF-0 (500 μL of 5 mg/mL) for each corresponding fraction. Of these, fraction SF-16 was found to be most effective at inhibiting the enzyme (36.1 ± 2.8% inhibition value); next were fractions SF-14, SF-15, and SF-17 with 19.1 ± 0.2, 20.9 ± 3.0, and 19.8 ± 0.9% inhibition values, respectively; fractions SF-12 and SF-13 exhibited about 10% inhibition, whereas fractions SF-1 to SF-11, as well as SF-18, showed quite low DPP-IV-inhibitory activity (inhibition value <5%) (Figure 2B).

As a type of adsorption chromatography, TLC can separate sample mixtures by elution based on a multistage distribution process. The R_f value has an important relationship with the sample's polarity: the smaller the R_f value, the stronger is the adsorption of the silica gel and the higher is the hydrophilicity of the material in question.[21] With the weakly alkaline lower-polar solvent, goat casein-derived peptides migrated rapidly on the TLC plate, as shown in Figure 2B; the dominant DPP-IV-inhibitory activities were distributed among the fractions with higher R_f values (fractions SF-12−SF-17). Peptides with larger chains and/or enriched in hydrophobic amino acids could give them relatively lower polarity, and thus the active DPP-IV-inhibitory fractions in the SF-0 might be made up of oligopeptides with the above characteristics.

At the same time, we found that the total DPP-IV-inhibition value of fractions SF-1 to SF-18 from the first-dimension TLC

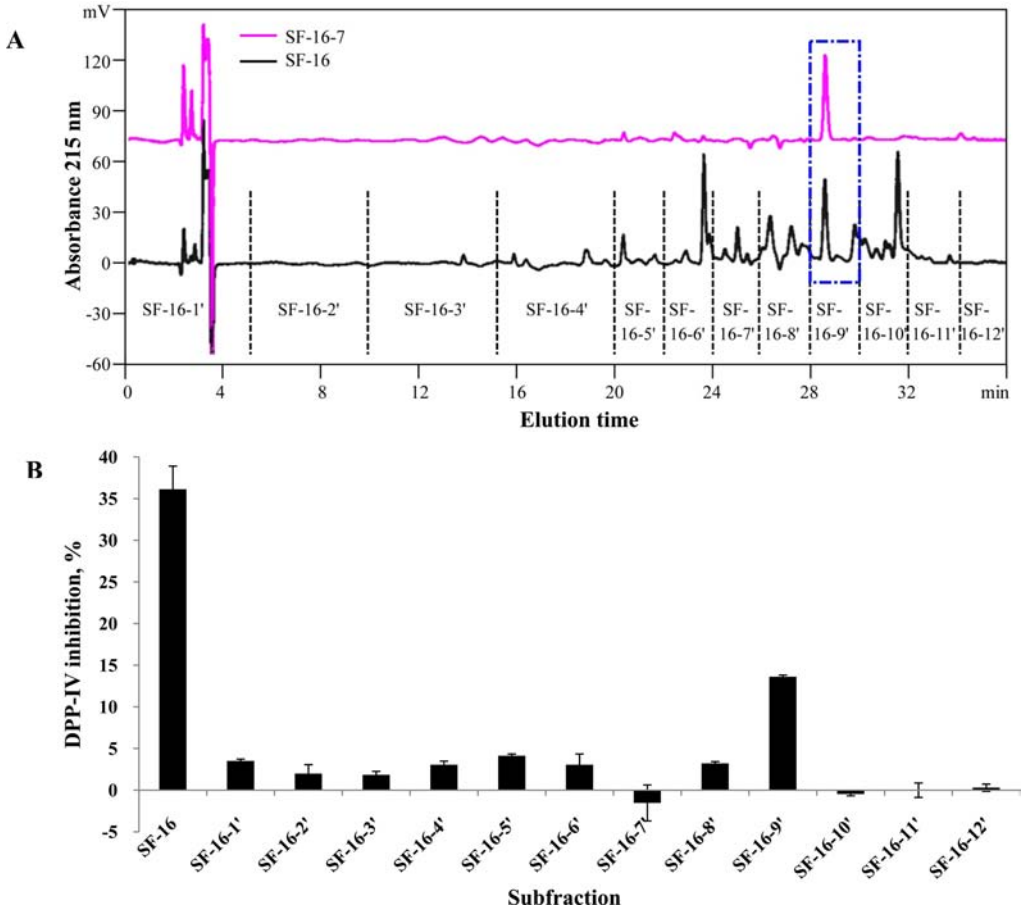

Figure 4. (A) RP−HPLC profiles of fraction SF-16 and subfraction SF-16-7 obtained from the first- and second-dimension TLC separation, respectively, and (B) DPP-IV-inhibitory activities of subfractions of SF-16 separated by RP−HPLC. The dotted line frame indicates the partial coincidence of t_R values in the RP−HPLC profiles of fraction SF-16 and subfraction SF-16-7. Bars indicate standard deviations.

separation (totalDI_{SF-0}) is ∼150%, markedly higher than the initial inhibition value of the SF-0 (DI_{SF-0}, 70.4 ± 2.0%). This suggested the interactive effects of various inhibitory peptides in mixed hydrolysates for the overall DPP-IV inhibition.[22] Among the first-dimension TLC fractions, SF-16 displayed the greatest DPP-IV-inhibitory activity (DI_{SF-16}, 36.1%) up to 50% of DI_{SF-0}, so we selected SF-16 for the second-dimension TLC separation.

Second-Dimension TLC Fractionation. Figure 3A shows separation of fraction SF-16 into 13 bands on the second-dimension TLC, designated subfractions SF-16-1 to SF-16-13. As shown in Figure 3B, except for SF-16-9 and SF-16-13, these subfractions showed widely varying DPP-IV-inhibitory activity. SF-16-7 had markedly higher DPP-IV-inhibition value ($DI_{SF-16-7}$, 15.9 ± 0.4%) than the other subfractions (Figure 3B), and it made up 44% and 23% of DI_{SF-16} and DI_{SF-0}, respectively. In addition, subfraction SF-16-7 showed yellowish-brown color (Figure 3A), contrasting with all of the other spots in the first- and second-dimension TLC (Figures 2A and 3A), indicating a certain number of secondary amine (e.g., from Trp residue) and/or acylamino structures (e.g., from Asn or Gln residue) of its contained peptide sequences.[23,24] SF-16-7 was also seen on the 2D-TLC plate as spot 1, by which it could be seen as one of the main constitutions of SF-0 (Figure 1). In addition, similar interactive effects on DPP-IV inhibition, albeit less strong, were observed after the second-dimension TLC: the total inhibition value of SF-16 subfractions (totalDI_{SF-16}, 62.0%) was significantly (1.7 times) higher than that of initial SF-16 (DI_{SF-16}, 36.1%).

During the screening of a suitable developing solvent system for TLC separation of protein hydrolysates, most of the tested solvents failed due to either incomplete development for the raw sample or ambiguous separation of the fractionated peptide components (data not shown). In contrast, two kinds of eluents described in the foregoing first-/second-dimension TLC gave satisfactory experimental results. In the first-dimension TLC, fraction SF-1, which also refers to the spotted position of raw SF-0, without ninhydrin coloration and DPP-IV inhibition (Figure 2A and B), demonstrated that the SF-0 was fully eluted by the solvent chloroform/methanol/25% ammonia (2:2:1). Moreover, apparently fractionated peptide bands distributed in the entire developing space of the first-dimension TLC plate, and fractions with obviously different DPP-IV-inhibitory activities were obtained (Figure 2A and B). This suggests that the eluent is a suitable solvent for DPP-IV-inhibitory peptides separation and concentration. The second-dimension TLC with the solvent *n*-butanol/acetic acid/water (4:1:1) further separated the narrow fraction (SF-16) into different bands with widely different R_f values (Figure 3A), confirming the satisfactory and complementary efficiency and selectivity of two coupled TLC eluents for peptide separation. Reversing the application order of the two types of TLC eluents was not recommended: when *n*-butanol/acetic acid/water (4:1:1) was used as the initial separation solvent, the SF-0 separated into

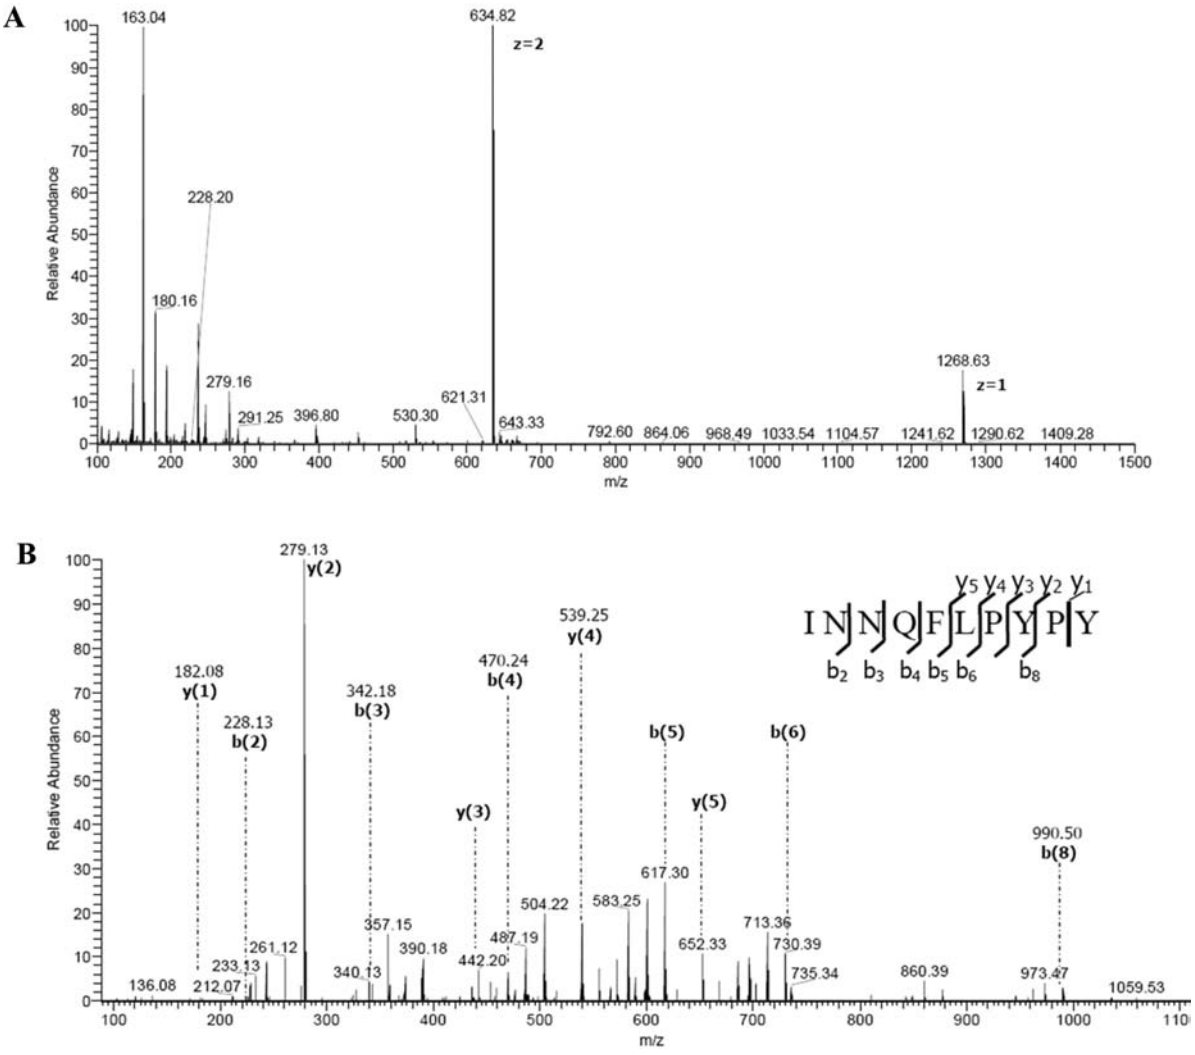

Figure 5. Identification of DPP-IV-inhibitory peptides. (A) LC−MS spectrum and (B) LC−MS/MS spectrum of single-charged ion with m/z 1268.63. Following sequence interpretation and database searching, the MS/MS spectrum of ion with m/z 1268.63 was matched to peptide INNQFLPYPY. Peptide sequence is displayed with ion fragments observed in the spectrum.

only four main fractions, whereas the chloroform/methanol/25% ammonia (2:2:1) eluent could separate the SF-0 into a dozen fractions, therefore simplifying and refining the second-dimension TLC separation of peptides (Figure 1). The contrasting results suggest the latter was more suitable as the first-dimension TLC eluent.

Use of RP−HPLC to Verify TLC Fractionation. To monitor and estimate the compositional changes of the peptide fractions by TLC separation, RP−HPLC analysis was applied to fraction SF-16 and its subfraction SF-16-7. Figure 4A shows the changes in the RP−HPLC profile of SF-16 before and after the second-dimension TLC separation. SF-16 subjected to RP−HPLC displayed a multipeak pattern and was divided into 12 subfractions (SF-16-1′−16-12′) with different retention times (t_R). Of these, SF-16-9′, with t_R of 28−30 min, displayed the highest inhibitory activity ($DI_{SF\text{-}16\text{-}9'}$, 13.6 ± 0.2%); next was SF-16-5′ with t_R 20−22 min ($DI_{SF\text{-}16\text{-}5'}$, 4.1 ± 0.2%), while other subfractions had quite weak inhibitory activity (Figure 4B). SF-16-9′ from the RP−HPLC profile showed a relatively stronger hydrophobic property, in line with the view that most DPP-IV-inhibitory peptides contain abundant hydrophobic amino acids in their sequences.[14] As the subfractions with the highest DI, SF-16-7 and SF-16-9′, from the second-dimension TLC and RP-HPLC, respectively, showed partial coincidence of t_R values in the RP−HPLC profiles (Figure 4A) and nearly equivalent DPP-IV-inhibitory activities (Figures 3B and 4B), indicating that the two subfractions were expected to contain some bioactive sequences in common. In addition, RP−HPLC analysis of SF-16-7 and SF-16-9′ revealed a single and two main peptide peak profiles, respectively, under a rather shallow elution gradient with a 1% change in acetonitrile concentration per minute (Figure 4A), suggesting that the bioactive fractions have reached adequate purity and are suitable for LC−MS/MS to identify the peptide sequences, and both TLC/TLC or TLC/RP−HPLC are feasible methods for the separation and isolation of bioactive peptide from protein hydrolysates.

Identification of Peptide Sequences Present in Subfractions SF-16-7 and SF-16-9′ by Nano LC−MS/MS. As the most effective DPP-IV-inhibitory components, subfractions SF-16-7 from the second-dimension TLC and SF-16-9′ from RP−HPLC were analyzed by nano LC−MS/MS to identify their constituent peptides. As an example, Figure 5A showed the mass spectrum of a double-charged ion with m/z at 634.82 and/or single-charged ion of 1268.63, which matched the sequence INNQFLPYPY corresponding to goat milk κ-casein f(51−60), by MS/MS sequence interpretation and

[a]CN, casein; /, not determined; NA, not applicable; SD, standard deviation. [b]DPP-IV-inhibition values are means of triplicate determinations and measured under assay concentration of peptides. [c]IC_{50} was calculated as the peptide concentration required to inhibit 50% of DPP-IV activity under the assay conditions. [d]Inhibitory activity and mode of inhibition of diprotin A (IPI) were included as reference.

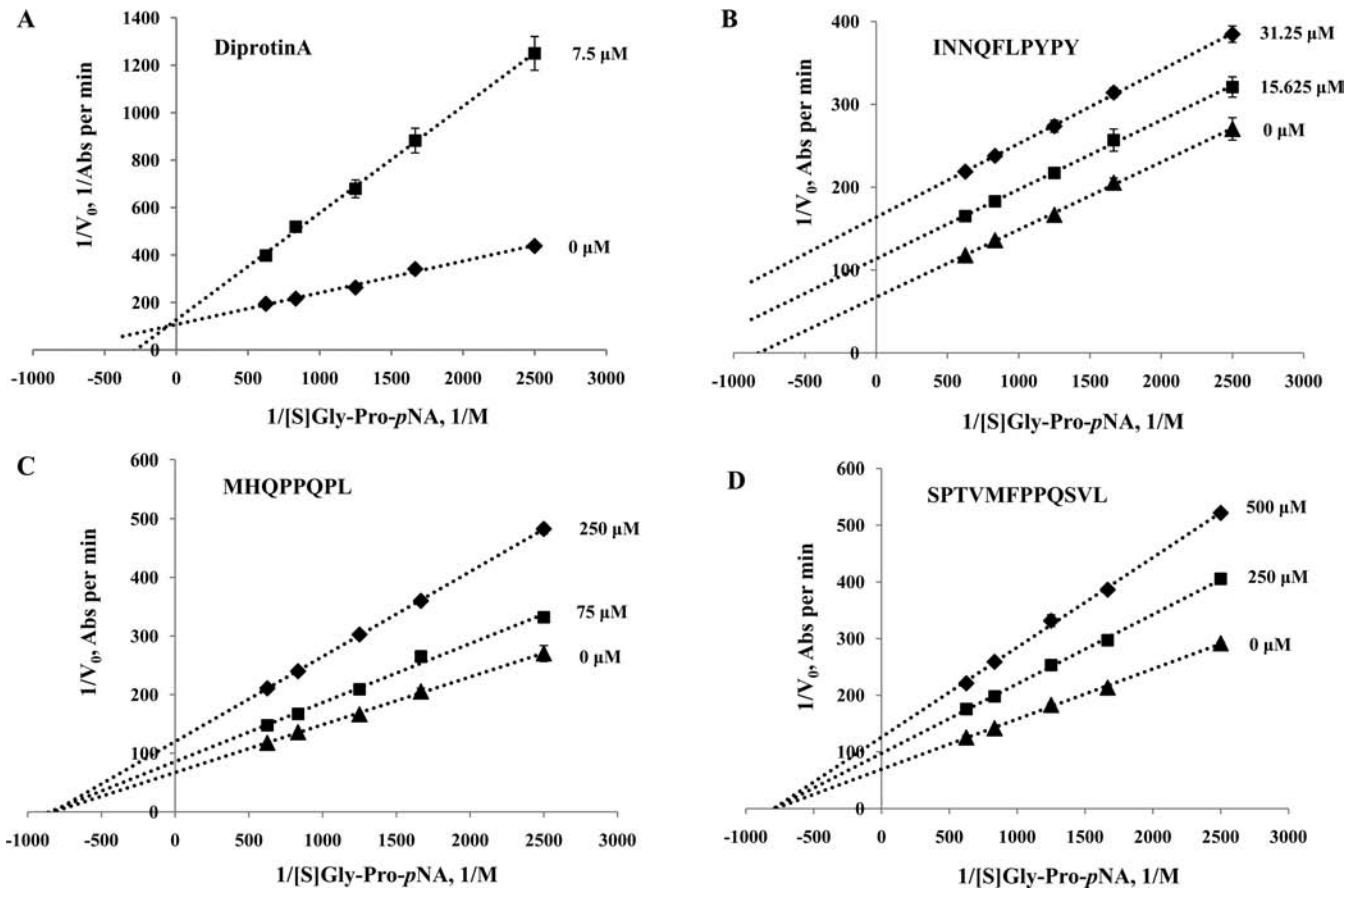

Figure 6. Lineweaver−Burk double-reciprocal plot for DPP-IV activity in the absence and presence of casein-derived peptides at different inhibitory concentrations. (A) Diprotin A (0 and 7.5 μM) as reference, (B) peptide INNQFLPYPY (0, 15.625, and 31.25 μM assay concentration), (C) peptide MHQPPQPL (0, 75, and 250 μM assay concentration), and (D) peptide SPTVMFPPQSVL (0, 250, and 500 μM assay concentration). Bars indicate standard deviations.

database searching (Figure 5B). A total of nine peptides were identified from subfractions SF-16-7/9′, mainly distributed in the β- and κ-casein chains, with lengths ranging from 6 to 12 amino acids (Table 1). The trypsin/chymotrypsin used for this study was a commercially available trypsin containing a certain amount of chymotrypsin in total activities, and therefore, the

[a]/, not determined; SD, standard deviation. [b]DPP-IV inhibition values are means of triplicate determinations and measured under different assay concentrations of peptide inhibitors: low concentration (GPFPILV 31.25 μM; INNQFLPYPY 7.815 μM; MHQPPQPL 62.5 μM), intermediate concentration (GPFPILV 62.5 μM; INNQFLPYPY 15.63 μM; MHQPPQPL 125 μM), high concentration (GPFPILV 125 μM; INNQFLPYPY 31.25 μM; MHQPPQPL 250 μM). Calculated values refer to the sum of the corresponding single peptide inhibitors. Different lowercase letters for calculated and measured values of individual samples at the same concentration and capital letters for all the measured values of inhibitor alone and in combinations indicate significant difference ($P < 0.05$).

hydrolysates were a mixture of peptides hydrolyzed by trypsin's tendency to cleave at the C-terminal Arg and Lys, whereas chymotrypsin cleaved at C-terminal hydrophobic amino acids such as Phe, Trp, Leu, and Tyr.[25] This was also reflected by the C-terminal amino acid residues of these identified sequences, for example, the C-terminal Tyr in INNQFLPYPY and Leu in MHQPPQPL, etc. (Table 1).

Among these peptides, the fragment f(194−199) of α_{s1}-casein corresponding to sequence TTMPLW has been verified to be a weak DPP-IV inhibitor by our previous in silico trypsin hydrolysis of goat casein and peptide synthesis (unpublished data), while the inhibitory activities of the other identified peptides have never been described. The most preferred inhibitory peptides reported in the literature tend to have lengths varying from dipeptides to octapeptides with molecular masses between 200 and 1000 Da,[14,26] whereas larger peptides presenting DPP-IV-inhibitory activity may act as different type of inhibitors via completely different inhibitory mechanisms.[8,20] It is interesting to note that most of our identified peptides were relatively longer peptides with 8−12 amino acid residues in length, and the structures of these identified peptides did not have the common Xaa-Pro- and Xaa-Xaa-Pro- motifs at their N termini, which are supposed to be typical of DPP-IV-inhibitory peptides;[14,26,27] on the other hand, all identified sequences contained dominant amounts of hydrophobic amino acids (such as Phe, Tyr, Leu, Ile, Trp, Val, and Met) and Pro residues in their sequences. In addition, four common peptide sequences, TQTPVVVPPF, SPTVMFPPQSVL, VMFPPQSVL, and INNQFLPYPY, were identified in both SF-16-9′ and SF-16-7 (Table 1), coinciding with the partially overlapping region in RP−HPLC elution profiles of the two subfractions (Figure 4A). Therefore, these four peptides, as well as MHQPPQPL and AWPQYL, were synthesized and evaluated for their potential inhibition of DPP-IV activity.

Table 1 shows the DPP-IV-inhibitory activity of the standard diprotin A (IPI) and the peptides identified in our hydrolysates, as well as their IC_{50} values as assayed in this study. The synthesized peptides found to cause greater inhibition of DPP-IV were further investigated to determine their modes of action on the enzyme (Figure 6). Diprotin A displayed IC_{50} of 6.36 ± 1.2 μM and behaved as a competitive inhibitor (Table 1 and Figure 6A), in accordance with reports in the literature.[12,14]

It is highlighted that, among the selected peptides, the κ-casein-derived peptide INNQFLPYPY f(51−60) displayed the highest and most notable inhibitory activity with an IC_{50} value of 40.08 ± 5.0 μM (Table 1), much lower than that of peptide LPYPY reported previously (IC_{50}, 108.3 μM).[28] Moreover, the Lineweaver−Burk plot of INNQFLPYPY showed apparently uncompetitive inhibition of DPP-IV (Figure 6B), contrasting to the competitive behavior of LPYPY that interacts with the active site of DPP-IV by involving both hydrogen bonds and hydrophobicity.[28] This suggested that addition of residues Phe, Gln, Asn, Asn, and Ile at the N terminus of the peptide LPYPY led to not only a significant increase in its DPP-IV-inhibitory activity but also the alteration of targeting domains and binding sites on DPP-IV.

The β-casein-derived octapeptide MHQPPQPL f(144−151) and dodecapeptide SPTVMFPPQSVL f(152−163) showed moderate inhibitory activities with IC_{50} values of 350.41 ± 4.1 and 676.31 ± 12.6 μM, respectively (Table 1), and they behaved as noncompetitive inhibitors (Figure 6C and 6D). SPTVMFPPQSVL contains a Pro at the second position of its N-terminal, in contrast to the general assumption of competitive DPP-IV-inhibition manner for smaller peptides with the same Pro-motif.[7,20,26] This indicates that the amino acid residues of SPTVMFPPQSVL may spatially block the interaction between the second Pro residue and the DPP-IV active site, while conversely facilitating the dodecapeptide binding to the domains outside the DPP-IV catalytic center; it also suggests that not only amino acid composition but also peptide length influences the DPP-IV-inhibition mechanism. Velarde-Salcedo et al.[8] showed that some DPP-IV-inhibitory peptides larger than 13 residues blocked the formation of the active dimeric form of DPP-IV by stagnating at the dimerization interface, using ligand−enzyme docking simulations. Moreover, the peptide VMFPPQSVL from β-casein f(155−163), lacking the N-terminal tripeptide sequence compared to SPTVMFPPQSVL, also inhibited DPP-IV but to a lesser extent (Table 1). The relationship between the structure and the bioactivity of different DPP-IV-inhibitory peptides supported the notion that the binding to DPP-IV is strongly influenced by the N-terminal amino acids, especially the tripeptide sequence of the inhibitors.[27] The N-terminal tripeptide SPT of SPTVMFPPQSVL is also indispensable for

DOI: 10.1021/acs.jafc.5b03062
J. Agric. Food Chem. 2015, 63, 8819−8828

its DPP-IV-inhibitory activity, even though other residues might determine the mode of inhibition of the dodecapeptide. In addition, another hexapeptide from goat α_{s2}-casein f(176−181), AWPQYL, was also identified to be a weak DPP-IV inhibitor, whereas the decapeptide TQTPVVVPPF had no effect on the activity of the enzyme (Table 1).

Furthermore, the alignment of goat (*Capra hircus*) α_{s2}-, β-, or κ-casein with other five main livestock including sheep (*Ovis aries*), cow (*Bos taurus*), yak (*Bos grunniens*), buffalo (*Bubalus bubalis*), and horse (*Equus caballus*) found that the goat β-casein-derived peptide VMFPPQSVL and κ-casein-derived peptide INNQFLPYPY also exist in sheep, cow, yak, and buffalo β-/κ-casein chain but not in horse; the consensus sequence MHQPPQPL was conserved in β-casein and AWPQYL in α_{s2}-casein of goat, sheep, and buffalo, while SPTVMFPPQSVL was only found in goat β-casein.

The interactive effects on DPP-IV inhibition between pure peptidic inhibitors GPFPILV (a competitive DPP-IV-inhibitory peptide obtained by our previous trypsin virtual hydrolysis of goat β-casein f(201−207), unpublished results), MHQPPQPL, and INNQFLPYPY with different types of inhibitory behaviors were tested in three levels of concentrations labeled as low, intermediate, and high concentration with a dose ratio 1:2:4 and the maximum concentration of single inhibitor no more than its IC_{50} value. As shown in Table 2, simply additive effects on inhibition were observed for the binary or ternary combination of peptide inhibitors at low concentration, which might suggest the targeting of different domains of DPP-IV without mutual interference, by GPFPILV binding to the active site while MHQPPQPL and INNQFLPYPY interfere outside the catalytic center of the enzyme or enzyme−substrate complex.[20] However, combined inhibitors at intermediate or high concentration caused greater inhibition compared to a single inhibitor rather than the sum of the individual peptides acting alone, and the higher the concentration of the peptidic inhibitor and the more the overlap among the peptides with different acting modes, the more obvious are interactive effects on DPP-IV inhibition (Table 2), which also corroborates the different extents of interactions on DPP-IV inhibition between the fractions from the first-dimension TLC (Figure 2B) or subfractions from the second-dimension TLC (Figure 3B). This might partially attribute to the apparently spatial conflicts between different targeting domains for different inhibitors caused at higher peptide concentration; varying interactive effects on DPP-IV-inhibitory properties were observed for certain binary peptide mixtures with different ratios in a previous report.[22] Besides, it also might result from that the combinations of inhibitors accelerate the tendency to plateau and/or saturation effect compared with a single inhibitor at the same concentration; a similar phenomenon has been shown in whey-derived inhibitory peptides in combination with sitagliptin.[29] In addition, Ohno et al.[30] have shown that an uncompetitive-type tripeptide inhibitor Trp-Arg-Glu could cover the binding substrate-mimicking competitive inhibitor Glu-Pro-Ala and act as a synergistic inhibitor to DPP-IV at a concentration equivalent to their respective 1/2 IC_{50} value. However, in this study, the DPP-IV-inhibition values of a combination of uncompetitive inhibitor INNQFLPYPY with competitive inhibitor GPFPILV at low (28.71 ± 1.01%) and intermediate (47.21 ± 2.10%) concentrations showed no significant ($P > 0.05$) difference compared to that of GPFPILV alone at intermediate (28.58 ± 1.38%) and high (45.50 ± 0.90%) concentrations, respectively, suggesting no positive synergistic effect between the two peptides, possibly due to the slight impact of INNQFLPYPY on substrate-binding affinity or the nonsubstrate-like competitive inhibition of GPFPILV.[30,31]

As a separation technique with characteristics of convenience, simplicity, rapidity, and lower cost, 2D-TLC method was set up to separate casein hydrolysates and was verified by RP−HPLC to be feasible and efficient. By virtue of TLC/TLC or TLC/RP−HPLC separation in combination with nano LC−MS/MS analysis, we successfully isolated components with higher efficiency and identified several new goat casein-derived DPP-IV-inhibitory peptides with different extents of bioactivities and modes of actions. Further investigation of the stability and absorbability of oligopeptides in the gastrointestinal tract, as well as the efficacy of goat milk casein-derived DPP-IV-inhibitory peptides in vivo, is warranted, so that it may serve as a natural food ingredient in the prevention of or coadjuvant therapy for the management of type 2 diabetes.

used to design the properties of the hydrogel network.[43−46] In particular, the porosity (mesh size) of biopolymer hydrogels can be tailored by factors impacting structuring elements (volume fraction, distribution and sizes of pores. etc.) of the gel such as chemical (e.g., hydrogen, covalent bonds, enzymatic cross-linking)/physical bondings (e.g., hydrophobic bonds).[44−48] For example, Klak et al. recently demonstrated that the release of different molecular weight dextrans could be retarded by transglutaminase cross-linked gelatin gels (5 wt %).[49] Klak et al. also demonstrated that the release of high molecular weight dextran was accelerated due to enzymatic degradation of the gel, highlighting that the polymer release from the hydrogels can occur via a combination of diffusion control and surface erosion.[49] Emulsions have also been incorporated into biopolymer gels to impact the textural and flavor release properties of complex food systems.[50−55] Somewhat surprisingly, there has been only limited work on the control of lipid emulsion digestion.[23,24] Li et al. encapsulated MCT emulsions stabilized by β-lactoglobulin into calcium alginate beads and demonstrated that the kinetics of fatty acid release was affected (modestly) by alginate bead size and considerably by alginate volume fraction and calcium concentration.[23] Another recent study by Guo et al. suggested that the microstructure as well as gel strength of whey protein emulsion gel had an effect on the extent of gastric proteolysis; however, the effect on intestinal digestion of lipids was not investigated.[25]

Whilst Li et al.[23] related the retardation of lipolysis to the microstructure of a polysaccharide gel, mechanistic understanding of how gel architecture (particularly gel digestibility, porosity, and network architecture) impacts the transport of enzymes/digesta through a protein hydrogel and how this relates to the rate of lipolysis is missing. Therefore, the present study sought to understand how the microstructure of protein gels affects lipolysis of gelled emulsions. The selected system consists of an oil-in-water (o/w) emulsion embedded within a gelatin gel. The microstructure of the gel was modulated with different protein concentrations. In vitro digestion of the systems was performed, and the impact of different gel microstructures on lipase diffusion was assessed. In addition, model experiments were conducted in order to understand the mechanism by which protein gels slow/retard the access of lipase to the fat droplets (diffusion control vs surface erosion).

EXPERIMENTAL PROCEDURES

Materials. For the preparation of emulsion, sunflower oil (Coop, Switzerland) and whey protein isolate (WPI) containing 95.8% protein (Bipro, Davisco Foods International, USA) were used without any further purification. Commercial gelatin type B was obtained from Gelita (240 Bloom, 30 mesh, 98% protein). Milli-Q water (water purified by treatment with a Milli-Q apparatus; Millipore Corp., Bedford, MA, USA) was used as the solvent for all of the experiments. Pepsin (porcine, 882 U/mg activity, Sigma-Aldrich, P7000), pancreatin (porcine, USP × 8, Sigma-Aldrich P7545), and bile extract porcine (total bile salt content = 49 wt %; with 10−15% glycodeoxycholic acid, 3−9% taurodeoxycholic acid, 0.5−7% deoxycholic acid; phospholipids 5 wt %) were used as obtained from Sigma-Aldrich (B8631).

Methods. *Emulsion Preparation.* The aqueous phase containing 5 wt % protein was prepared by dissolving WPI in Milli-Q water, and the pH was adjusted to pH 8. Protein dispersion was stirred at ambient conditions for 1 h. Sunflower oil was then added to the aqueous protein solution to form final emulsions containing 40 wt % oil. Pre-emulsion was prepared by homogenizing the mixture of the aqueous phase with the oil phase using a Silverson L5M-A rotor-stator mixer (Silverson Machines, UK) at 7000 rpm for 2 min. Then the pre-emulsion was further homogenized by two passes through a two-stage valve homogenizer (NIRO Soavi Panda, GEA, France) operating at 1000 bar for the first stage and at 160 bar for the second stage. Sodium azide (0.05 wt %) was added to avoid microbial growth. Emulsions were stored for not more than 1 week at 4 °C.

Gelled Emulsion Preparation for in Vitro Digestion. Gelatin was solubilized of different concentrations (2.5−15 wt %) in 0.1 M NaCl solution at 60 °C. The pH of the gelatin solution was adjusted to pH 7.0 using 1 M NaOH. Sodium azide (0.05 wt %) was added to avoid microbial growth. Stock gelatin gels were prepared by allowing gelation in 100 mL glass containers at 4 °C for 24 h.

For the preparation of gelatin-gelled emulsions, the emulsion prepared as above and the gelatin dispersion were placed in a water bath at 60 °C. Emulsion was gently added to the gelatin solutions (10−25 wt %) to reach final concentrations of 10 wt % oil, 0.7 wt % WPI, and 2.5−15 wt % gelatin in 100 mM NaCl at pH 8. The emulsion/gelatin dispersion was mixed at 60 °C in a water bath in a 100 mL glass container for 30 min and cooled by storage in a refrigerator set at 4 °C for 24 h to allow the gels to set. These gels were further used for in vitro digestion and microscopy measurements.

Confocal Microscopy. For the confocal imaging, the gels were sliced manually into 1 × 1 × 0.2−0.3 mm slices and then stained overnight in a 10^{-6} M solution of Rhodamine 6G (Sigma 83697) containing Nile red (Sigma N3013:100 μL of a 0.025% ethanol solution per 10 mL of the rhodamine solution). The confocal imaging was carried out with a Zeiss LSM 710 confocal microscope, at excitation wavelengths of 514 nm for the Rhodamine 6G (emission bandwidth, 520−560 nm) and 561 nm for the Nile red (emission bandwidth, 565−700 nm).

Lipase Diffusion Measurements. (1) Lipase Labeling. High-purity porcine pancreatic lipase EPC B.141 (1×10^6 units/22 mg protein) was purchased from Elastin Products (LC 298) and covalently labeled with fluorescein isothiocyanate according to the following procedure: 26.4 mg of FITC (Sigma F3652) was dissolved in 5 mL of DMSO (Serva 20385.01). Then, 0.5 mL of this FITC−DMSO solution was diluted in 1 mL of borate buffer (Fluka 15662), pH 8.5; 44 mg of the lipase was dissolved in 1.5 mL of Milli-Q water and mixed with 1.5 mL of the DMSO−borate FITC solution. The final mixture was incubated for 2 h at 50 °C. Finally, the free FITC was eliminated using Amicon Ultra-15 centrifugal (10 centrifugations) devices (Millipore catalog no. UFC900524).

(2) Lipase Diffusion Experiment. For the diffusion experiments, the gels were cooled in Petri dishes and punched with the capillary end of glass Pasteur pipets. This capillary end, with the sample inside, was then glued at the bottom of a 3 mm deep Plexiglas observation chamber. Finally, this experimental setup was covered with the solution containing the lipase (50 μL of labeled lipase in 1 mL of PBS). Continuous image acquisition was carried out at an excitation wavelength of 488 nm for 30 min (120 images per run). The experiments were carried out in triplicate.

Characterization of Viscoelastic Properties of Gelled Emulsion by Small Deformation Rheology. Oscillatory measurements were carried out using a Physica MCR 501 rheometer (Anton Paar, Graz, Austria). The measuring geometry was a concentric cylinder (CC-27; the inner diameter of the cup is 24.5 mm, and the diameter of bob is 23 mm) with a Peltier temperature control system. Twenty milliliters of emulsion/gelatin dispersion described under Gelled Emulsion Preparation for in Vitro Digestion and, as control, the corresponding gelatin dispersion with a similar concentration were placed in the measuring cell at 60 °C, and the surface of the sample was covered with mineral oil to avoid evaporation. The sample was then submitted to temperature ramp mimicking the temperature ramp of sample prepared for in vitro digestion protocol allowing gelation in situ of equipment. Temperature was decreased from 60 to 4 °C at −5 °C/min. Then, the temperature was maintained for 2 h at 4 °C. Finally, the temperature was raised to 25 °C at 5 °C/min. The temperature ramp was done within a linear regime with strain of 0.5% at 1 Hz frequency. A frequency sweep test was then performed from 0.1 to 100 Hz at 0.5% strain at 25 °C. Finally, a strain sweep test was performed

(E) 10 wt % gelatin, and (F) 15 wt % gelatin. Scale bar represents 50 μm (B−E) or 200 μm (F). The inset in (D) is 2.5 times magnification of the original image.

from 0.1 to 20% strain at 0.1 Hz at 25 °C. Critical gelation temperature was defined as G', G'' crossover.[56,57] Final gel strength was defined as final G' modulus obtained at 25 °C after the temperature ramp was completed. Triplicate gelatin measurements were performed for each system.

In Vitro Digestion. The digestion kinetics of gelled emulsion systems was examined using a simulated intestinal digestion model at 25 °C with conditions similar to those of Wooster et al.[24] Briefly, a single piece of gelled emulsion (20 × 20 × 5 mm, ~2 g) was mixed with 8.5 mL of simulated intestinal fluid (SIF) to achieve a final composition of 10 mM $CaCl_2$, 12 mM mixed bile salts, 0.75 mM phospholipid, 150 mM NaCl, and 4 mM tris(hydroxymethyl)-aminomethane buffer. The temperature and pH were stabilized for at least 2 min at 37 ± 0.5 °C and 6.8 ± 0.02, respectively; the titration was then initialized with the addition of pancreatin solution (200 μL, containing 150 mM NaCl, 4 mM Tris-HCl, and 125 mg/mL pancreatin). The digestion was carried out over 3 h while the pH was maintained at 6.8 by the addition of 0.05 M NaOH using a pH-STAT (TIM 854, Radiometer). During the intestinal phase of digestion, the kinetics of digestion were followed using a pH-STAT technique and expressed as titratable acid (rather than fatty acid) and were calculated by the equation

$$\mathrm{TA} = V_{\mathrm{NaOH}} \times 0.05 \times 1000 \quad (1)$$

where TA is total titratable acid released (μmol) and V_{NaOH} is the volume of NaOH used to titrate the released acid in 3 h (mL).

RESULTS AND DISCUSSION

Microstructure of Gelled Emulsions Observed by CLSM. The mixing of the WPI-stabilized emulsion with different gelatin concentrations led to the formation of gels having microstructure that changed with increasing gelatin concentration (Figure 1). The WPI-stabilized emulsion itself presents as individual droplets with a log-normal particle distribution and an average diameter, $D_{4,3}$ of 0.32 μm (Figure 1A). Mixing WPI emulsion (10 wt %) with 2.5 wt % gelatin and gelling at 4 °C result in a homogeneous structure in which emulsion droplets are evenly distributed throughout the gel (Figure 1B). Increasing the gelatin concentration to 5 wt % (Figure 1C) results in a change in gelled emulsion structure; the emulsion droplets appear as aggregates, and light green voids appear between the aggregates of droplets. The voids between the emulsion droplets consist of regions rich in gelatin as indicated by the dark green hue in the confocal images (Figure 1D, inset) and by visual observations that these gels are very firm. Increasing the gelatin concentration to 7.5, 10, and 15 wt % causes an increase in the size/number of both the emulsion aggregates and the void spaces between the aggregates (Figure 1D−F). These observations indicate that as gelatin concentration is increased, the resulting structure is a discontinuous network of aggregated emulsion droplets

DOI: 10.1021/acs.jafc.5b03700
J. Agric. Food Chem. 2015, 63, 8829−8837

(mesoscale) contained within a continuous network of gelatin (microscale). The aggregation of the emulsion droplets in the gel could be due to either the presence of salt (100 mM) or the addition of gelatin. Given the strong increase in aggregation with increasing gelatin concentration, and the fact that similar emulsions (stabilized with β-lactoglobulin, the main protein of WPI) have been shown to be (relatively) stable to the presence of 120 mM NaCl,[58] we suggest that the main driving force for aggregation is depletion interactions caused by the self-association of gelatin during the gelation process.

Viscoelastic Properties of Gelled Emulsion. The gelation behavior of gelatin is known to be mainly driven by temperature and gelatin concentration such that lower temperatures and higher concentrations resulted in faster and stronger gel formation.[52,59] Figure 2 shows the time-dependent

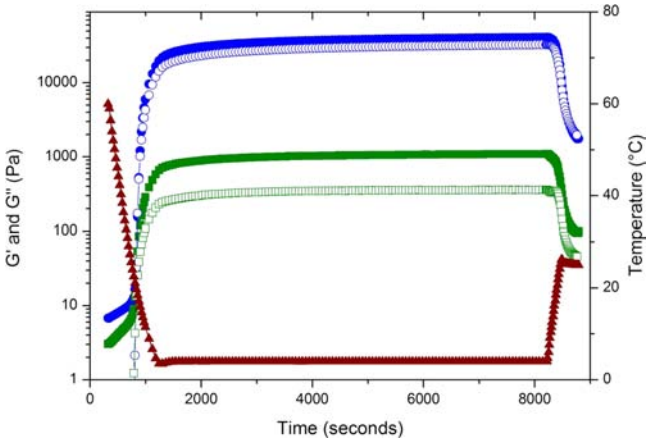

Figure 2. Kinetics of gelation of gelatin gels (empty symbols) and corresponding filled emulsion gels (10.0 wt % oil, 0.7 wt % WPI, 15.0 wt % gelatin) (filled symbols). The crossover of G' (blue circles) and G'' (green circles) indicates the gel point. Temperature curve is represented by the red triangles.

storage modulus G' and loss modulus G'' of 15.0 wt % gelatin-gelled emulsion and the corresponding 15 wt % gelatin gel as a function of temperature. Steep increases in G' and G'' were observed as the temperature was decreased to 4 °C, after which they remained fairly constant during aging at 4 °C for 2 h. Both G' and G'' decreased upon heating to 25 °C, due to weakening of the H-bonded triple helix. Similar changes in G' and G'' as a function of temperature were observed for all gelatin concentrations used to make simple gels or gelled emulsion systems (data not shown).

In order to understand the impact that incorporating an emulsion has on the properties of gelatin gels, dynamic oscillatory rheological experiments were conducted to assess gel point and viscoelastic properties of different systems as a function of gelatin concentration. Figure 3 shows the gel point (A) and storage/loss moduli (B) (at 25 °C) for simple gels and gelled emulsion systems as a function of gelatin concentration. As gelatin concentration increased from 2.5 to 10 wt %, the gel points of both systems increased linearly from 7 to 20 °C and then increased slightly to 23 °C at 15 wt % gelatin. No significant differences in gel point were found between the gelled emulsion systems and simple gelatin gels. The magnitude of the storage modulus G' at 25 °C increased from 0.95 ± 0.26 to 2325 Pa for the gelled emulsion system as the gelatin concentration increased from 2.5 to 15.0 wt %. Simple gels containing 2.5 wt % gelatin showed a higher storage modulus

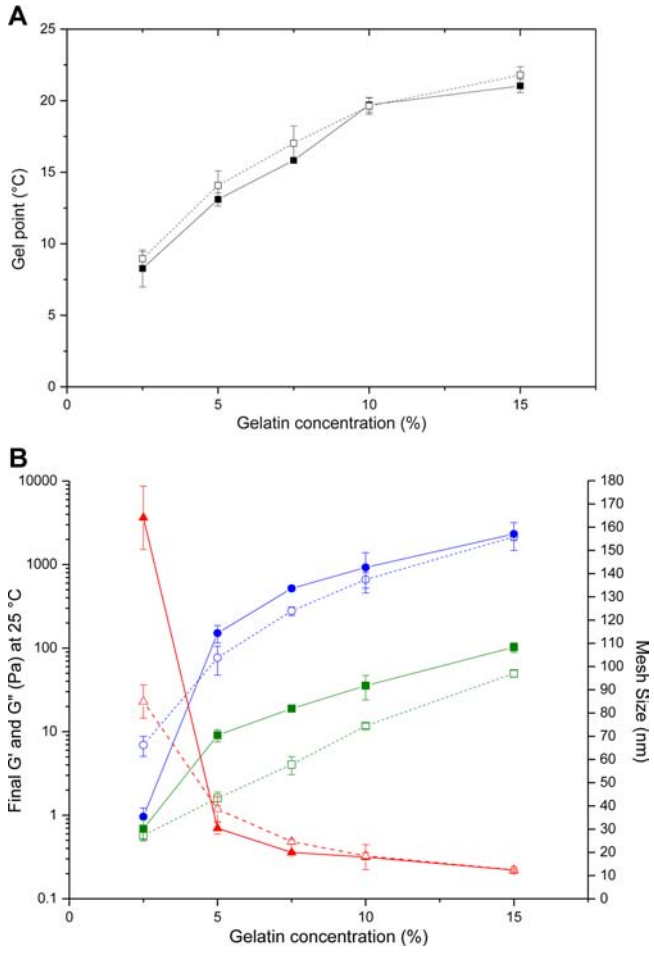

Figure 3. (A) Gel point of gelatin gels (empty squares) and corresponding gelled emulsions (10.0 wt % oil, 0.7 wt % WPI, 2.5−15.0 wt % gelatin) (filled squares) as a function of gelatin concentration. (B) Final G' (blue circles) and G'' (green squares) of gelatin gels (empty symbols) and corresponding gelled emulsions (10.0 wt % oil, 0.7 wt % WPI, 2.5−15.0 wt % gelatin) (filled symbols) as a function of gelatin concentrations; average mesh size (red triangles) of gelatin gels (empty symbols) and corresponding filled emulsion gels (10.0 wt % oil, 0.7 wt % WPI, 2.5−15.0 wt % gelatin) (filled symbols) as a function of gelatin concentrations at temperature of digestion (25 °C).

(6.9 ± 2.7 vs 0.95 ± 0.26 Pa) and a similar loss modulus (0.57 ± 0.06 vs 0.69 ± 0.19 Pa) compared to gelled emulsion systems. At and above 5 wt % gelatin, the gelled emulsion systems exhibited higher loss and storage moduli than the simple gelatin gels (Figure 3B).

A frequency sweep test of selected gelled emulsions containing different concentrations of gelatin as well as simple gelatin gels is shown in Figure 4. Similar behavior was observed for both systems at all concentrations >5.0 wt % (data not shown for 7.5 and 15%). In the presence of 5−15 wt % gelatin, a strong gel-like behavior is observed characterized by the predominance of G' over G'', the absence of crossover points between G' and G'', and also weak dependence on frequency.[60] The dependence was slightly higher at 5 wt % than at ≥10 wt % gelatin. In contrast, gelled emulsion containing 2.5 wt % gelatin presented a mechanical behavior of rather a weak gel with G' close to G'' at low frequency with little differences between the moduli and cross-over at high frequency.[57] An additional strain sweep test (not shown) formed with 2.5 wt % gelatin broke at

DOI: 10.1021/acs.jafc.5b03700
J. Agric. Food Chem. 2015, 63, 8829−8837

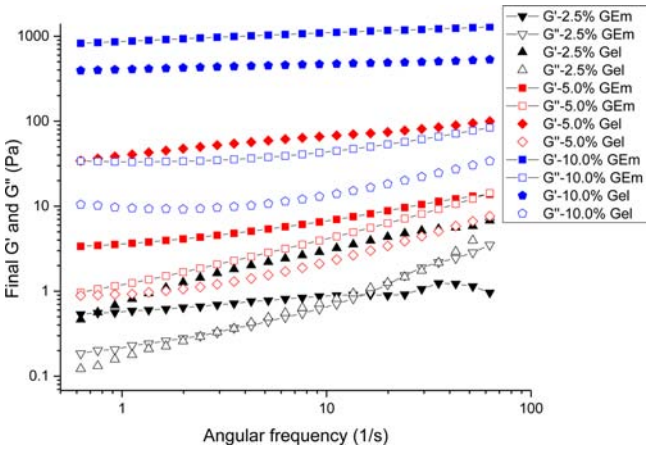

Figure 4. Frequency sweep test of gelatin gels (empty symbols) and corresponding gelled emulsions (10.0 wt % oil, 0.7 wt % WPI, 2.5, 5.0, 10.0 wt % gelatin) (filled symbols) at temperature of digestion (25 °C).

very low strain (0.2%), whereas gelled emulsion systems with higher gelatin concentration did not break in the strain range tested. Similarly, the gelatin gel showed strain breakage only for 2.5 wt % gelatin gels but at higher strain level (16.2%).

Overall results suggest that the rheology of gelled emulsion systems is mostly governed by gelatin gelation at concentrations ≥5 wt % gelatin, leading to strong gels with higher moduli than the corresponding simple gelatin gels. At 2.5 wt % gelatin, the gelled emulsion system was weaker than simple gelatin gel, suggesting a different structure. This mechanical behavior confirms the above description of the microstructure observed by CLSM, suggesting a discontinuous network of aggregated emulsion droplets (mesoscale) dispersed within a continuous network of gelatin (microscale), which governs the overall mechanical properties of the gelled emulsion. At gelatin concentration >2.5 wt %, aggregation of emulsion droplets was visible, which could be related to the higher storage modulus of the gelled emulsion compared to simple gelatin gels. Previous studies have shown that incorporation of particles or oil droplets could lead to an increase in gelatin gel rigidity depending upon the gelatin concentration.[51,61] Oil droplets seem to contribute to the stiffening of the gel as they are mechanically connected to the gel matrix and so contribute to the gel strength.[50] At 2.5 wt %, the lower storage modulus compared to the gelatin system might be related to the discontinuous dispersion of emulsion within the continuous gelatin network.[53,62]

Estimation of Gel Porosity Using Rheological Data. A key hypothesis of this work is that the digestion of gelled emulsions is related to gelatin network structure through the decrease in network porosity within increasing gelatin concentration. In order to understand this relationship, the average mesh size (i.e., pore size) of simple gelatin gels and gelled emulsions was calculated using eq 2[49]

$$\xi^3 = \kappa_B T / G' \quad (2)$$

where ξ is the mesh size, G' represents the final storage modulus (Pa), K_B is the Boltzmann constant, and T is the temperature.

Figure 3B shows the variation of mesh size as a function of gelatin concentration for gelled emulsion systems and simple gelatin gels. The mesh size of gelled emulsion systems decreases from 164 to 20 nm with increase in gelatin concentration from 2.5 to 7.5 wt % and to 12 nm with 15 wt % gelatin. The corresponding simple gelatin gels showed slightly higher mesh sizes at 5 and 7.5 wt % gelatin (38, 30 nm vs 24, 20 nm) and similar mesh sizes at 10 and 15 wt % gelatin (18.5 and 12 nm). At 2.5 wt % gelatin, the simple gelatin gels had significantly smaller average mesh size (85 nm) as compared to gelled emulsion (164 nm). These results can be understood from the structural changes observed by CLSM and viscoelastic response measured. The presence of emulsion within the gelatin network at 2.5 wt % modified its structure, suggesting a less dense network structure than that of the simple gelatin gel. Thus, the gelled emulsion has an increased mesh size as compared to the gelatin system. As gelatin concentration increased, this effect was less visible because the emulsion droplets start to aggregate locally and the gelatin network becomes the main continuous network in the gelled emulsion systems. Consequently, the average mesh size decreased in the gelled emulsion as compared to the corresponding pure gelatin gels. Overall, these results suggest that at 2.5 wt % gelatin, the emulsion droplets are evenly distributed in the gelatin network, decreasing its connectivity and overall gel strength compared to gelatin systems. At 5 and 7.5 wt % gelatin, the increase in gelatin concentration leads to a decrease in average mesh size, and the local aggregation of the emulsion droplets further contributes to the increase in gel strength compared to gelatin systems. As gelatin concentration increases further (10 and 15 wt %), fewer differences compared to gelatin systems were visible, suggesting that the local aggregation of emulsion droplet does not contribute significantly to the overall mechanical behavior of gelled emulsion. Above 10 wt % gelatin, the structure is mainly governed by the gelatin continuous network, and thus mesh sizes decreased to a minimum level as gelatin concentration increased in both the gelatin gel and gelled emulsion systems.

Impact of Gelatin Gels on Fat Emulsion Digestion. A central concept of this work is that surrounding a fat emulsion in a protein gel will slow the digestion of the fat because the protein network slows lipase diffusion to the emulsion droplet. To assess the impact of gelatin gels on the digestion of emulsions, gelled emulsions of differing gelatin concentrations were assessed by simulating only the intestine phase of digestion (at 25 °C) using a pH-STAT technique (Figure 5).[65] As a control, the digestion of emulsion alone was also measured. The emulsion underwent rapid digestion with an initial acid release rate of 100 μmol min^{-1} and released 580 μmol acid after 15 min before going through a point of inflection after which the rate of acid release slowed to 0.6 μmol min^{-1}. Surrounding the emulsion in a gelatin gel progressively decreased the rate of acid release (Table 1). The WPI emulsion in 2.5 wt % gelatin had an initial acid release rate of 35 μmol min^{-2}; this systematically slows, being 11 μmol min^{-2} at 7.5 wt % gelatin and 3.5 μmol min^{-2} at 15 wt % gelatin. Each sample released a similar maximum amount of acid of 700 μmol. Each exhibited an inflection point in the acid release curve from fast to slow acid release at increasingly longer times as gelatin concentration increased. A solution of 10 wt % gelatin had an acid release rate of 0.32 μmol min^{-2} and released 17.5 μmol acid after 60 min, showing that proteolysis of the gelatin itself contributed minimally to the observed differences in acid release and that the kinetics of acid release can essentially be regarded as the kinetics of fat digestion.

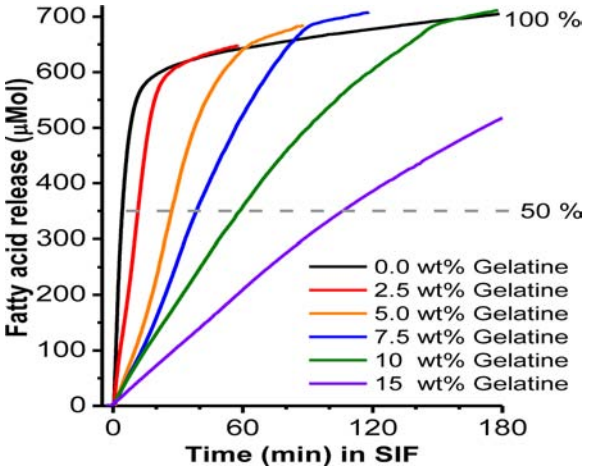

Figure 5. Acid release profiles obtained from 10 wt % O/W emulsions (stabilized by 0.7 wt % WPI) alone (i) or entrapped in various amounts of bovine gelatin (Bloom 240) as a gelled emulsion. Acid release profiles were obtained during single-step pH-STAT simulated intestinal lipolysis at pH 6.8 and 25 °C.

Table 1. Gelatin Concentration in Gelled Emulsions

	gelatin concentration in 10 wt % gelled emulsions					
	0 wt %	2.5 wt %	5 wt %	7.5 wt %	10 wt %	15 wt %
K_{lip} (μmol min^{-1})	100	35	18.5	11	6	3.5
t_{infect} (min)	13	24.5	55	90	149	260

It is apparent from Figure 5 and Table 1 that there is a systematic relationship between gelatin concentration in emulsion gelled and the kinetics of lipolysis. As described earlier, the gelatin concentration affects overall gel structure and, in particular, its porosity. It is well-known that the porosity of a gel will affect the diffusion of large molecules through the gel. Hence, an understanding of the porosity of these gelled emulsions as a function of gelatin concentration was obtained from rheology data using eq 2.[49] Figure 6 shows the relationship between the kinetics of lipolysis and mesh size of each gelled emulsion. It is apparent that there is a direct, almost linear, relationship between gel mesh size and the kinetics of lipolysis. This suggests that smaller mesh size of the gelatin gel (at higher gelatin concentration) restricts the transport of lipase to the emulsion droplet. The question is whether digestion is slowed because lipase diffusion through the gel is slowed or because lipase is not able to diffuse into the gel and proteolysis of the gel is first required for lipolysis to occur.

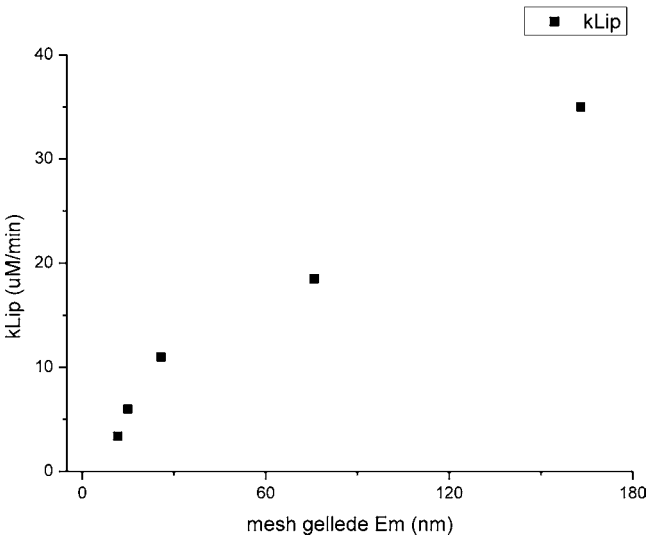

Figure 6. Relationship between the rate of acid release (lipolysis – K_{lip}) and the average mesh size calculated from G' at 25 °C using eq 2.

In order to understand the mechanisms by which protein gels slow the digestion of gelled emulsions, two experiments were conducted: (i) digestions of the gelled emulsion in the presence of pure lipase (Figure 7); (ii) measurement of lipase transport through pure gelatin control gels (Figure 8). Figure 7 compares the digestion of the 10 wt % o/w emulsion embedded within 10 wt % gelatin gel by pancreatin and pure pancreatic lipase in the presence of 12 mM mixed bile and 10 mM $CaCl_2$ at pH 6.8 and 25 °C. Digestion of the gelled emulsion by pancreatin results in a moderate rate of acid release, having a constant rate of 8.9 ± 0.3 μmol min^{-1} over the first 60 min, gradually slowing over the next 60 min to reach 90% digestion after 120 min. In contrast, digestion of the same composition by pure pancreatic lipase (with colipase) resulted in a 10-fold decrease in digestion kinetics (Figure 7ii). After an initial lag phase of ~30 min, acid release reaches a constant rate of 0.76 ± 0. 095 μmol min^{-1} between 60 and 180 min (2–15% digestion) and a constant rate of 0.45 ± 0.036 μmol min^{-1} between 420 and 840 min (30–60% digestion). The differences between digestion by pancreatin and pure pancreatic lipase correspond to an 11-fold reduction during the initial stages of digestion and a 20-fold reduction during the majority of digestion. What is interesting

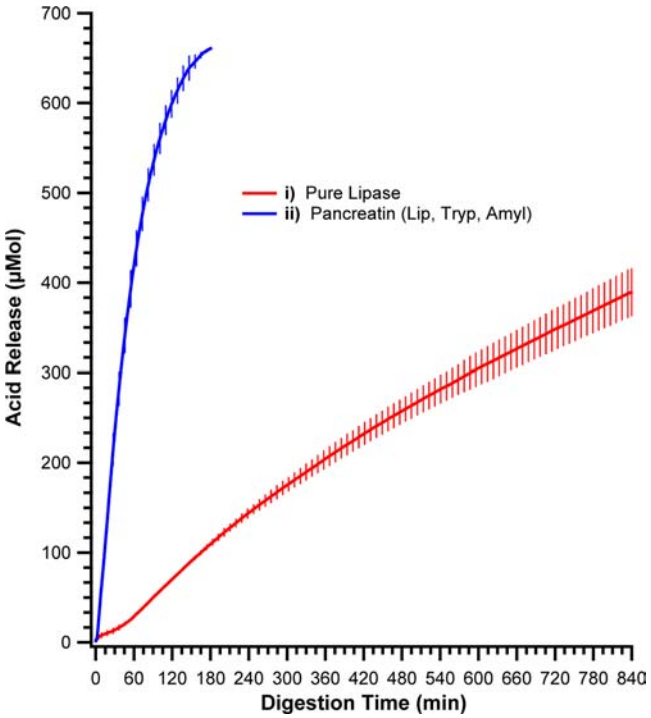

Figure 7. Kinetics of acid release (lipolysis) from 10 wt % gelatin, 10 wt % o/w gelled emulsions when they are exposed to (i) pure pancreatic lipase (11000 U, 250 U/mL), (ii) pancreatin containing pancreatic lipase (2700 U, 63 U/mL), trypsin (16575 U), and amylase (20250 U). Lines represent the average of three measurements; error bars, ±1 standard deviation.

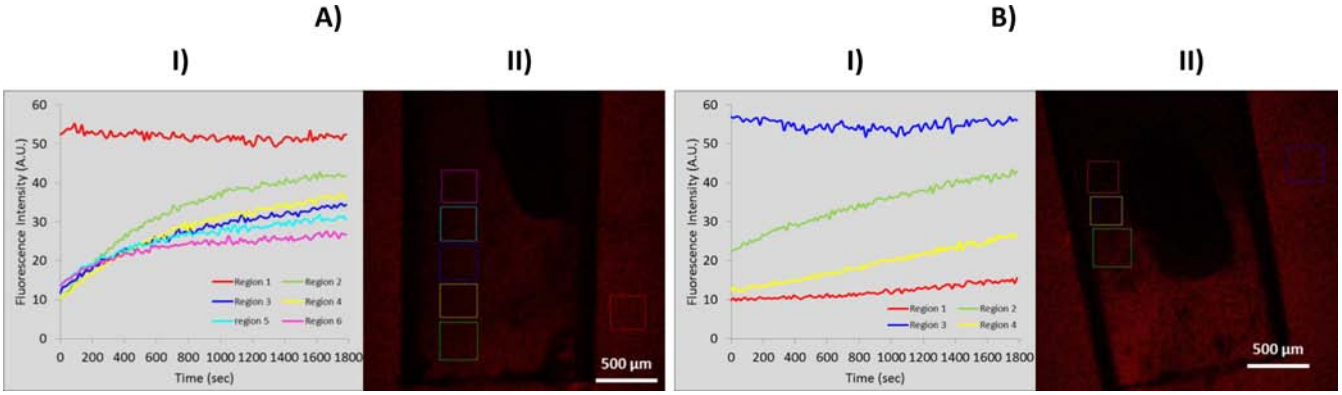

Figure 8. Diffusion of fluorescently labeled (fluorescein isothiocyanate, FITC) porcine pancreatic lipase into (A) 5 wt % gelatin gel and (B) 10 wt % gelatin gel. (I) The fluorescence intensity within different regions of the gel and (II) the external buffer (constant intensity) was monitored over time. Gel pieces were contained within glass capillaries; the faster rate of fluorescence intensity equilibration within the 5 wt % gelatin gel compared to the 10 wt % gel highlights much faster diffusion of the fluorescently labeled lipase.

is that the rate of acid release from the gelled emulsion digested with pancreatin is 10 times lower than the rate of digestion of the parent emulsion or the melted gelled emulsion (100 μmol min^{-1}). These results highlight that the gelatin gel is able to slow the diffusion of both lipase and proteases.

This dramatic reduction in lipolysis can be understood from the fact that the tight mesh of the gelatin gel restricts lipase transport to the emulsion droplets embedded within the gel. The average pore size of this system was estimated to be 18.5 nm (10 wt % gelatin), and the radius of gyration of the pancreatic lipase/co-lipase complex is 25−26 Å.[63] Given that the average pore size is approximately 3−4 times larger than the pancreatic lipase/co-lipase complex, lipase should be able to diffuse through the gel, which was confirmed by digestion experiments with pure lipase. In addition, confocal microscopy measurements show that the diffusion of lipase through 5 wt % gelatin gels is much faster than the diffusion through 10 wt % gelatin gels (Figure 8). Whilst it is apparent that lipase can diffuse through the gelatin gel, the lipolysis rate is considerably retarded compared to the free emulsion (~130 times slower), indicating that the gel provides a (restricted) diffusion barrier to the digestion of the emulsion. The fact that digestion occurs 10−20 times faster in the presence of protease indicates that the main mechanism driving gel degradation is surface erosion of the gel by proteases. A limitation of this work is that the gel systems studied are thermoreversible and melt at in-body temperatures. However, these results do demonstrate that protein gels can act to slow lipolysis. Some might consider that the gel pieces at 20 × 20 × 5 mm are too large to empty from the stomach and anyway would undergo erosion during chewing and trituration.[64] However, the effective diffusion distance is the thinnest dimension of the gel, which at 5 mm is within the range of particles that empty from the stomach.[64] Overall, this work highlights a new approach to control the digestion of lipid emulsions by controlling lipase access to the interface of emulsions via a diffusion barrier adjacent to the interface. The new insights generated in this work provide new design principles for the controlled digestion of food to impact on satiety and weight management or the controlled delivery of active ingredients at different times and/or places within the digestive tract.

Summary and Conclusions. The present study sought to understand how the structure of protein gels affects lipolysis of gelled emulsions. The selected system consisted of an o/w emulsion embedded within gelatin gels. The microstructure of the gel was modulated with different protein concentrations. In vitro digestion of the systems was performed, and the impact of different gel microstructures on lipase diffusion was assessed. The gelatin-gelled emulsions consisted of a discontinuous network of aggregated emulsion droplets (mesoscale), dispersed within a continuous network of gelatin (microscale). Rheological measurements found that the base gelatin gel exhibited thermoreversible elastic type behavior characteristic of gelatin. Incorporation the emulsion into low protein concentration gels weakened the gels due to interruption of network connectivity. Incorporation of the emulsion into gels with ≥5 wt % gelatin led to a slight strengthening of the gel. The rheology of the gelled emulsions was dominated by the rheological behavior of the gelatin network for gelatin concentrations >2.5 wt %; at no point was yielding or brittle fracture observed, suggesting a gelatin continuous microstructure rather than a bicontinuous gel. The rate of fat digestion of gelatin-gelled emulsion correlated with protein concentration within the gel. The average gel mesh size (ξ) was estimated from the storage modulus eq 2, and a direct relationship between lipolysis kinetics (K_{lip}) and average gel mesh size was found. This direct relationship between K_{lip} and ξ indicates that the digestion of fat within gelatin-gelled emulsions is controlled by the gel's ability to slow lipase diffusion to the interface of fat droplets. Additional studies using pure lipase identified that the tortuous gelatin network significantly slowed lipase diffusion into the gel, but did not stop it. The main mechanism of gel breakdown was surface erosion catalyzed by proteases. Overall, this work has demonstrated that protein gels can significantly slow the kinetics of lipolysis of gelled emulsions. This information can be of great use in the design of foods and nutraceuticals to control fat digestion.

and assembled into the active NADPH oxidase.[8,9] The active oxidase has emerged as an important source of cytosolic-derived ROS for signal transduction. During monocyte−macrophage differentiation, up-regulation of subunit NOX2 expression and p47phox membrane translocation are known to be highly induced, resulting in ROS production and contributing to pathological changes in cell function and the development of atherosclerosis.[8,10] Smooth muscle cells in mice deficient for p47phox exhibited decreased superoxide production and cell proliferation. Additionally, deletion of p47phox led to amelioration of atherosclerotic plaques in apolipoprotein E-deficient ($ApoE^{-/-}$) mice.[11,12] Therefore, reducing ROS production by limiting NADPH oxidase activity may be beneficial for the blockage of atherosclerotic progression.

Turmeric is prepared from the dried rhizomes of *Curcuma longa* and has been used as a foodstuff, in cosmetics, and as a therapeutic application in traditional Asian medicine.[13] Curcuminoids consist of a mixture of curcumin, demethoxycurcumin (DMC), and bisdemethoxycurcumin (BDMC) (Figure 1); the major active ingredients are responsible for

	R1	R2

the predominant medicinal properties of turmeric. Curcuminoids have been reported to possess several desirable characteristics, including antioxidant, anti-inflammatory, antidiabetic, neuroprotective, and anticancer activities.[14−17] Numerous reports have suggested possible beneficial effects of curcuminoids on hypocholesterolemic and antiatherosclerotic activities. Turmeric intake has been reported to reduce fibrinogen levels in patients with atherosclerosis.[18] Curcumin administration decreased serum lipid peroxides and cholesterol in healthy volunteers.[19] In animal studies, dietary supplementation with curcumin, DMC, and BDMC in rats fed a moderately high fat diet exhibited triacylglycerol- and cholesterol-lowing potency,[20] and long-term administration of curcumin lowered serum and hepatic cholesterol and suppressed atherosclerotic lesions in high-fat-fed $LDLR^{-/-}$ mice.[21] In in vitro studies, curcumin has been reported to increase LDLR expression in hepatic cell lines.[22] Recently, curcumin was demonstrated to increase LDL uptake through the down-regulation of PCSK9 gene expression in HepG2 cells.[23] Curcumin suppressed lipid accumulation in peritoneal macrophages isolated from $LDLR^{-/-}$ mice fed a high-fat diet.[24] Moreover, curcuminoids attenuated oxLDL-induced CD36 and scavenger receptor-A (SR-A) expression and reduced oxLDL uptake during monocyte to macrophage differentiation.[25]

The THP-1 cell is an acute monocytic leukemia cell line that is the most widely exploited monocyte-like cell line. THP-1 cells are used to induce monocyte to macrophage differentiation by phorbol-12-myristate-13-acetate (PMA) in studies related to atherosclerosis.[26] Curcumin, DMC, and BDMC are usually found in mixtures in natural foods. However, their individual effects on monocyte to macrophage differentiation remain unclear. In the present study, we investigated the effects and underlying mechanisms of curcumin, DMC, and BDMC on monocyte invasion during PMA-induced THP-1 to macrophage differentiation.

MATERIALS AND METHODS

Chemicals. Curcumin (purity ≥98.5%), Gö6976, DAPH-7, and rottlerin were purchased from Enzo Life Sciences (Ann Arbor, MI). Demethoxycurcumin (DMC, purity ≥98%), bisdemethoxycurcumin (BDMC, purity ≥98%), dimethyl sulfoxide (DMSO), phorbol-12-myristate-13-acetate (PMA), ECM gel, gelatin, *N*-acetyl-L-cysteine, RPMI-1640 medium, nonessential amino acids (NEAA), and other chemicals, unless otherwise indicated, were purchased from Sigma-Aldrich Co. (St. Louis, MO). Bisindolylmaleimide I (BIM) was purchased from Cayman Chemical (Ann Arbor, MI).

Cell Culture and Treatment of Cells with Curcumin, DMC, and BDMC. The THP-1 monocytelike cell line was obtained from Bioresource Collection and Research Center (Hsinchu, Taiwan) and maintained in RPMI-1640 medium supplemented with 10% fetal bovine serum (FBS) (Invitrogen, Carlsbad, CA) and 1% NEAA in a 5% CO_2 incubator at 37 °C. For monocyte to macrophage differentiation, THP-1 cells were seeded onto six-well plates (1×10^6/mL) in RPMI medium and treated with vehicle (0.1% DMSO), curcumin, DMC, or BDMC (10−20 μM) for 1 h, followed by stimulation with PMA (30 nM) for 24 h. For inhibitors treatment, THP-1 cells were treated with the inhibitors for 30 min and then curcuminoids for 1 h, followed by the addition of PMA for an additional 24 h of incubation.

Cell Invasion Assay. Polycarbonate membrane Transwell permeable supports (pore size, 8 μm) (Corning Inc.) were coated with ECM gel (5 mg/mL). THP-1 cells (3×10^5) in 300 μL of serum-free RPMI medium were inoculated into the upper chamber, and 500 μL of RPMI containing 10% FBS was added to the lower chamber. Cells were treated with vehicle or the indicated curcuminoids (20 μM) for 1 h and then incubated with PMA (30 nM). After 24 h of incubation, the Transwell inserts were fixed with 3.7% formaldehyde and stained with Wright stain buffer. The invasive cells were observed and counted under a microscope.

Gelatin Zymography Analysis. THP-1 cells (1×10^6/mL) were seeded in serum-free RPMI medium and treated with vehicle or the indicated curcuminoids (20 μM) for 1 h, followed by exposure to PMA (30 nM) for 24 h. For secreted protein preparation, the serum-free medium of the cultured cells was collected and centrifuged to remove the cells. The proteins in the media were separated with an 8% sodium dodecyl sulfate−polyacrylamide gel (SDS−PAGE) containing 0.1% gelatin. The gels were incubated in 2.5% Triton X-100 to remove the SDS. After a 30 min incubation, the gels were incubated in an enzyme buffer (40 mM Tris-HCl, 10 mM $CaCl_2$, and 0.01% NaN_3, pH 8.0) at 37 °C for 12 h. After incubation, the gels were stained in buffer containing 0.125% Coomassie Blue and destained in 20% methanol with 10% acetic acid.

Reverse-Transcription Quantitative Polymerase Chain Reaction (RT-Q-PCR) Analysis. Total cellular RNA was prepared using a Total RNA Mini Kit (Geneaid, Taipei, Taiwan). Reverse transcription was performed using a high-capacity cDNA reverse transcription kit (Applied Biosystems, Foster City, CA). Quantitative real-time PCR was performed in a reaction mixture containing cDNA, specific primers (Supporting Information, Table S1), and the Maxima SYBR Green/ROX qPCR Master Mix (Fermentas, Burlington, CA). The following PCR conditions were used: 58 °C for 2 min, 94 °C for 4 min, and 45 cycles of 94 °C for 1 min, 58 °C for 1 min, and 72 °C for 1 min. The ΔΔCt method was used for data analysis. The PCR amplification was carried out in a Roche LightCycler-480 Real-Time PCR System, and the levels of mRNA expression were determined in triplicate samples and normalized to the mRNA level of

DOI: 10.1021/acs.jafc.5b04083
J. Agric. Food Chem. 2015, 63, 8838−8848

glyceraldehyde-3-phosphate dehydrogenase (GAPDH) in the same samples.

Detection of CD11b Expression by Flow Cytometry Analysis. CD11b on the cell surface was detected by flow cytometry, as previously described.[27] Briefly, THP-1 cells were washed with PBS and incubated in PBS containing 5% bovine serum albumin (BSA) at 37 °C for 1 h. Then, the cells were incubated with a fluorescein isothiocyanate (FITC)-conjugated antihuman CD11b monoclonal antibody (eBioscience, San Diego, CA) for 30 min in the dark at 4 °C. After washing, the cells were suspended in PBS and measured on the FACSCalibur (FACScan, BD Biosciences, San Jose, CA). The data were analyzed using Cell Quest Pro software (BD Biosciences). CD11b expression on the cell surface was calculated and expressed as the relative percentage of the geometric mean fluorescence intensity.

Analysis of Reactive Oxygen Species Generation. The level of ROS was measured by flow cytometry analysis, as previously described.[28] Briefly, THP-1 cells (1×10^6/mL) were seeded onto six-well plates in RPMI medium and treated with vehicle or the indicated curcuminoids (20 μM) for 1 h, followed by exposure to PMA (30 nM) for 24 h. Then, H_2DCFDA (10 μM) was added, and the cells were incubated at 37 °C in the dark for 30 min. After incubation, the cells were harvested for ROS analysis. Three independent samples of 10 000 cells were analyzed via flow cytometry using the FL1 emission filter. The data were expressed as the relative percentage of the geometric mean fluorescence intensity.

Western Blot Analysis. THP-1 cells (1×10^6/mL) were seeded and subsequently incubated with the indicated reagents for the indicated time periods. Cells were harvested and total cellular lysates were extracted in RIPA buffer (Thermo Fisher Scientific, Inc., Rockford, IL). For membrane and cytosolic protein preparations, the cells were harvested using a Mem-PER Plus Membrane Protein Extraction Kit (Thermo Fisher Scientific) according to the manufacturer's instructions. The proteins were separated by 10% SDS–PAGE and subsequently transferred onto a polyvinylidene fluoride membrane (PerkinElmer, Boston, MA). The blots were incubated with the following specific antibodies: anti-MMP-9, anti-p47phox (anti-NCF1) (GeneTex, Irvine, CA), antiphosphor-PKCδ (Tyr311), anti-Na,K-ATPase (Cell Signaling Technology, Danvers, MA), and monoclonal anti-β-actin (Sigma-Aldrich). Then, the membranes were incubated with the appropriate horseradish peroxidase-conjugated secondary antibodies (Santa Cruz Biotechnology, Santa Cruz, CA) for 1 h. The proteins were detected using the Amersham ECL Prime Western Blotting Detection Reagent, and the signal was visualized on an Amersham Hyperfilm ECL (GE Healthcare, Buckinghamshire, UK).

Analysis of Protein Kinase C Activity. Protein kinase C (PKC) activity analysis was performed as previously described.[29] The cellular proteins were harvested using RIPA buffer, and PKC activity was measured using the Nonradioactive PKC Kinase Activity Kit (Enzo Life Sciences) according to the manufacturer's instructions. The 96-well microplate was read at 450 nm in a microplate reader.

Statistical Analysis. All experiments were repeated at least three times, and the data were expressed as the mean ± SD. Statistic calculations were carried out using IBM SPSS Statistics 22.0 software. Comparisons between results were made by analysis of variance (ANOVA). Statistic differences were assessed using one-way ANOVA with Dunnett's posthoc test. A value of $p < 0.05$ was considered statistically significant.

RESULTS

Curcumin, DMC, and BDMC Suppressed Matrix Invasion during PMA-Induced THP-1 Differentiation. The matrix invasion of macrophages into the subendothelium plays a critical role in the initial stage of atherosclerosis. To examine the effects of curcumin, DMC, and BDMC on matrix invasion during PMA-induced THP-1 differentiation, the invasion assay was performed as described in the Materials and Methods. As shown in Figure 2, PMA significantly increased the extracellular matrix (ECM) invasion ability to

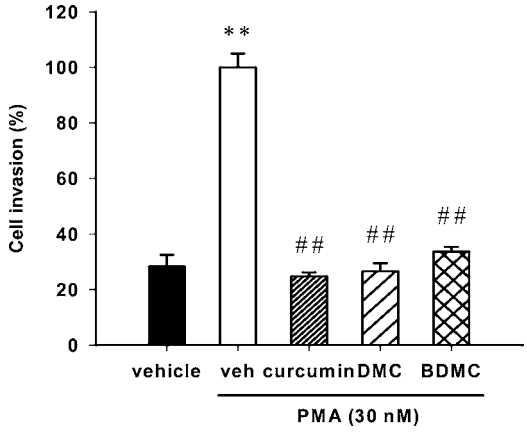

Figure 2. Curcumin, DMC, and BDMC suppressed matrix invasion during PMA-induced THP-1 differentiation. THP-1 cells were inoculated into the transwell chamber containing the ECM gel-coating filter and pretreated with vehicle (0.1% DMSO), curcumin, DMC, or BDMC (20 μM) for 1 h followed by incubation with PMA (30 nM) for 24 h. The transwell filters were fixed and stained with Wright stain buffer. The number of THP-1 cells that invaded the ECM gel was calculated, and the data are presented as the means ± SD from three independent experiments. **$p < 0.01$ represents a significant difference compared to the PMA-untreated cells (vehicle group). ##$p < 0.01$ represents a significant difference compared to the PMA-alone-treated cells (veh group).

100.0 ± 5.0% in THP-1 cells relative to cells without PMA exposure (28.3 ± 4.2%). The transwell invasion ability of cells pretreated with curcumin, DMC, and BDMC (20 μM) was markedly decreased from 100.0 ± 5.0% to 24.8 ± 1.4%, 26.6 ± 2.9%, and 33.7 ± 1.7% in PMA-treated THP-1 cells, respectively ($p < 0.01$). Curcumin, DMC, and BDMC showed similar activity on the inhibition of matrix invasion in PMA-treated THP-1 cells. These data indicate that curcuminoids suppress extracellular matrix invasion during PMA-induced THP-1 differentiation.

Effects of Curcumin, DMC, and BDMC on CD11b Expression during PMA-Induced THP-1 Differentiation. The adhesion molecule CD11b is a major marker of monocyte differentiation toward adherent macrophages.[30] To investigate the effect of curcumin, DMC, and BDMC on CD11b expression during PMA-induced THP-1 differentiation, the cells were pretreated with the three curcuminoids (10 and 20 μM) for 1 h, followed by incubation with PMA (30 nM) for 24 h. CD11b mRNA expression was measured by RT-Q-PCR. As shown in Figure 3A, CD11b mRNA expression in THP-1 cells was significantly induced by PMA. Pretreatment of THP-1 cells with the indicated curcumin, DMC, and BDMC at 20 μM concentration equally reduced CD11b mRNA expression by approximately 62%, 60%, and 65%, respectively, compared to the PMA alone-treated group ($p < 0.01$). Next, we examined the effect of curcuminoids on cell surface expression of CD11b on PMA-treated THP-1 cells by flow cytometry. The level of cell surface CD11b induced by PMA was significantly attenuated in curcumin-, DMC- and BDMC-treated cells, respectively (Figure 3B). This data showed that the inhibition ability of curcuminoids is in the order of BDMC > curcumin ≈ DMC in PMA-treated THP-1 cells. These data reveal that curcuminoids inhibit CD11b mRNA expression during PMA-induced monocyte to macrophage differentiation. The inhibitory activity against surface-CD11b expression was associated

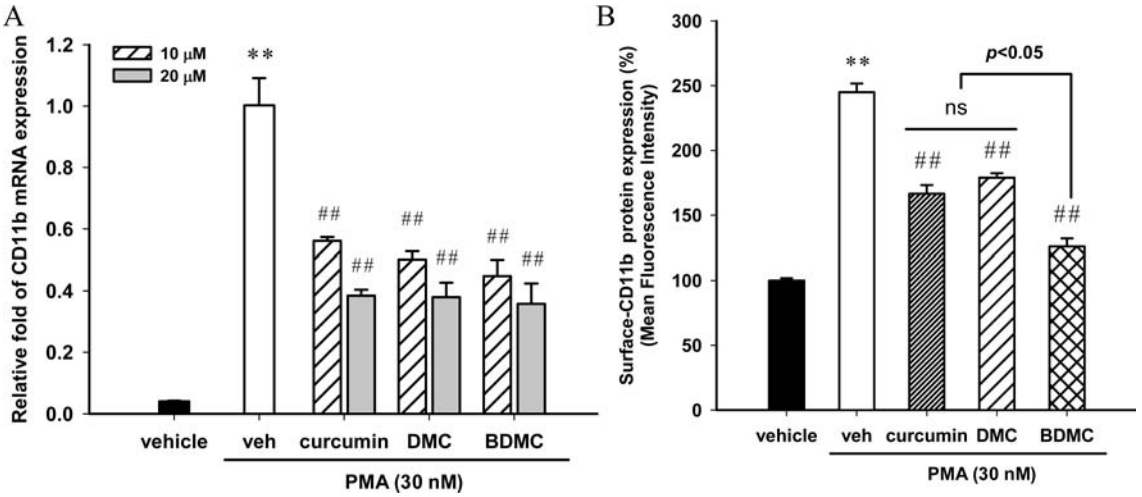

Figure 3. Curcumin, DMC, and BDMC suppressed CD11b expression during PMA-induced THP-1 differentiation. (A) THP-1 cells were pretreated with vehicle, curcumin, DMC, or BDMC (10 or 20 μM) for 1 h and then treated with PMA for 24 h. CD11b mRNA expression was measured by RT-Q-PCR. (B) Summary of cell-surface CD11b levels. The cells were pretreated with vehicle or the curcuminoids (20 μM) for 1 h and then treated with PMA for 24 h. The level of cell-surface CD11b was determined by flow cytometry analysis, as described in the Materials and Methods. The data are presented as the means ± SD from three independent experiments. $^{**}p < 0.01$ represents a significant difference compared to the PMA-untreated cells (vehicle group). $\#\#p < 0.01$ represents a significant difference compared to the PMA-alone-treated cells (veh group). ns: no significant differences.

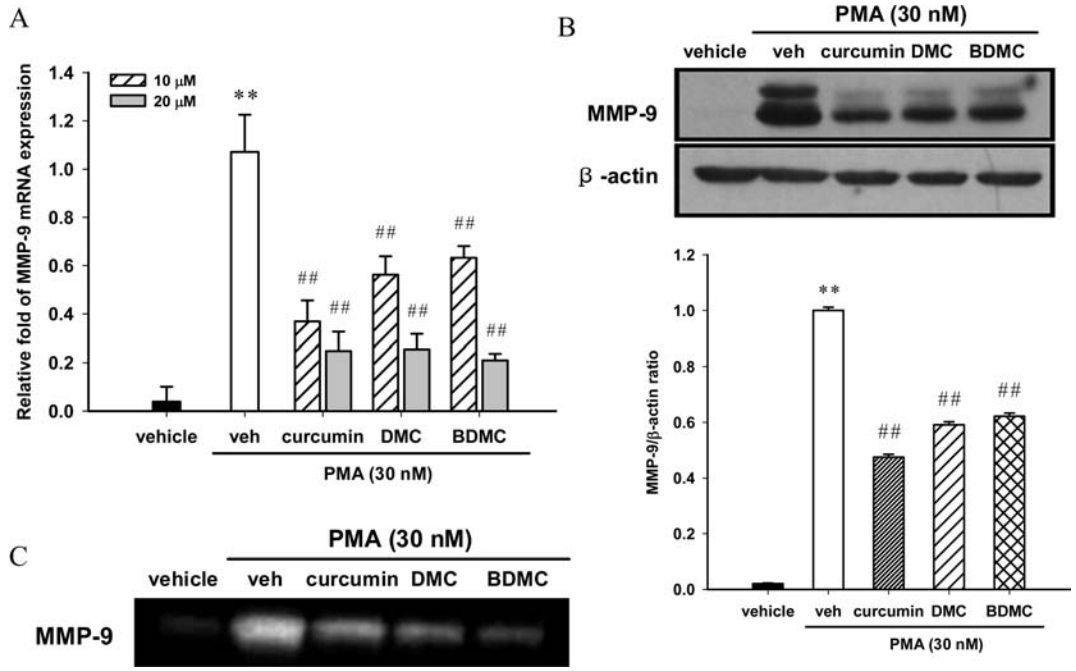

Figure 4. Curcumin, DMC, and BDMC inhibited MMP-9 expression and activity during PMA-induced THP-1 differentiation. (A) THP-1 cells were pretreated with vehicle, curcumin, DMC, or BDMC (10–20 μM) for 1 h and then treated with PMA for 24 h. MMP-9 mRNA expression was measured by RT-Q-PCR. (B) Cells were pretreated with vehicle or curcuminoids (20 μM) for 1 h and then incubated with PMA for 24 h. The MMP-9 and β-actin protein levels were analyzed via Western blot analysis. The experiments were replicated three times, and a representative blot is shown. The intensity of MMP-9 normalized to the β-actin protein is presented as the mean ± SD of three independent experiments. $^{**}p < 0.01$ represents a significant difference compared to the PMA-untreated cells (vehicle group). $\#\#p < 0.01$ represents a significant difference compared to the PMA-alone-treated cells (veh group). (C) The extracellular MMP-9 activity was measured by gelatin zymography, as described in the Materials and Methods. The experiments were replicated three times, and a representative graph is shown.

more with BDMC and less with curcumin or DMC during PMA-differenced THP-1 cells.

Effects of Curcumin, DMC, and BDMC on MMP-9 Expression and Activity during PMA-Induced THP-1 Differentiation. The invasion of monocytes into the vascular intima requires the destruction of the extracellular matrix (ECM) by matrix metalloprotease-9 (MMP-9), which is involved in early atherosclerotic processes.[5] Therefore, we investigated the effect of curcumin, DMC, and BDMC on MMP-9 gene expression and activity during PMA-induced THP-1 differentiation. As shown in Figure 4A,B, THP-1 cells treated with PMA markedly induced MMP-9 mRNA and

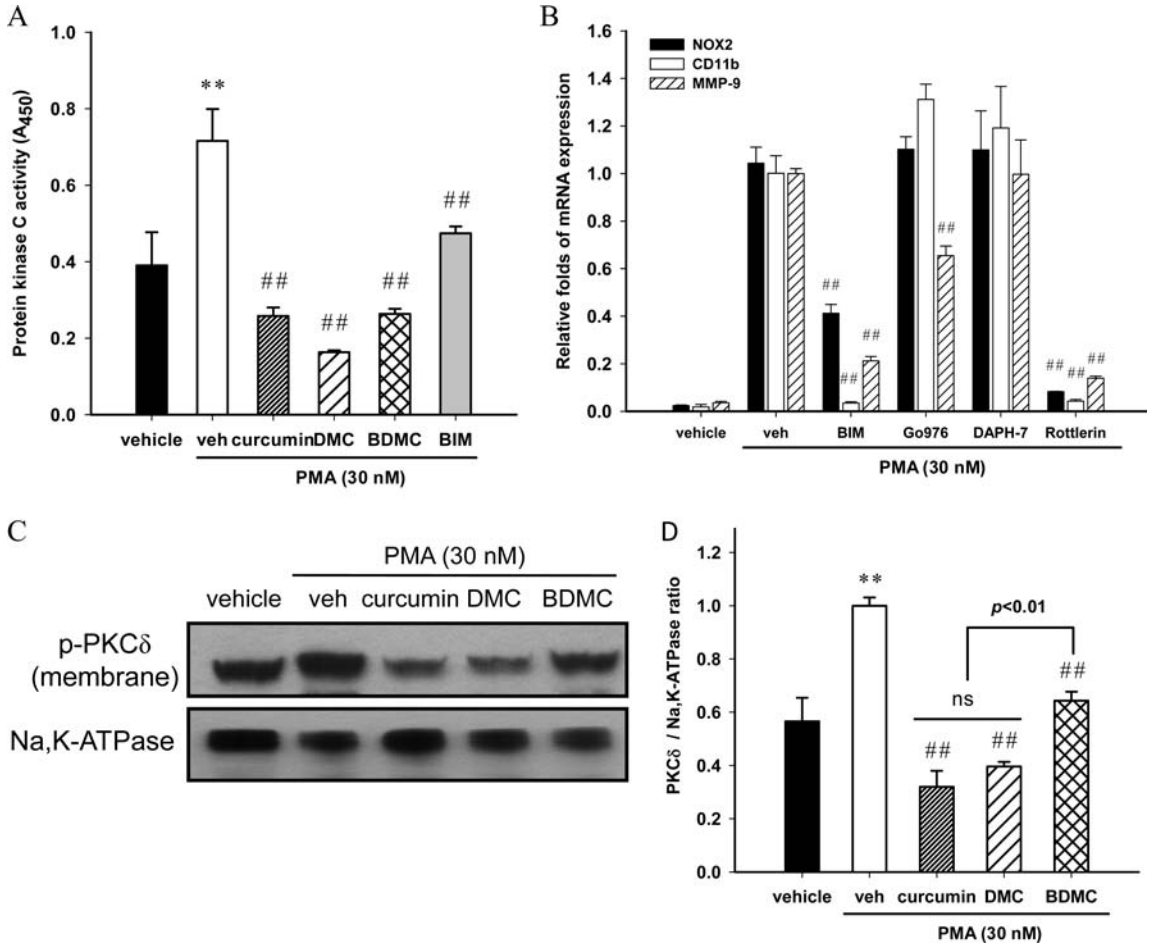

Figure 7. The effects of curcumin, DMC, and BDMC on protein kinase C (PKC) activity during PMA-induced THP-1 differentiation. (A) THP-1 cells were treated with vehicle, curcuminoids (20 μM), or PKC inhibitor (BIM) for 1 h and then treated with PMA for 24 h. PKC activity was detected using an PKC assay kit, as described in the Materials and Methods. The data represent the mean ± SD of three independent experiments. (B) THP-1 cells were pretreated for 30 min with vehicle or one of the following inhibitors: Gö6976 (1 μM), DAPH-7 (1 μM), and rottlerin (10 μM). The mRNA levels of NOX2, CD11b, and MMP-9 were determined via RT-Q-PCR. (C) The membrane form of p-PKCδ and the Na,K-ATPase internal control protein were analyzed using Western blot analysis. The experiments were replicated at least three times, and a representative blot is shown. (D) The normalized intensity of p-PKCδ versus the Na,K-ATPase internal control is presented as the mean ± SD of three independent experiments. **$p < 0.01$ represents a significant difference compared to the PMA-untreated cells (vehicle group). ##$p < 0.01$ represents a significant difference compared to the PMA-alone-treated cells (veh group). ns: no significant differences.

protein expression in THP-1 cells, which was significantly suppressed by pretreatment with curcumin, DMC, and BDMC (10 or 20 μM). We investigated the effect of curcuminoids on extracellular MMP-9 activity using gelatin zymography analysis. As shown in Figure 4C, extracellular MMP-9 activity was strongly induced after PMA stimulation for 24 h. In contrast, pretreatment of the cells with curcumin, DMC, or BDMC (20 μM) significantly reduced extracellular MMP-9 activity in PMA-treated THP-1 cells. These results indicate that curcumin, DMC, and BDMC suppress MMP-9 expression and activity during PMA-induced THP-1 differentiation.

Curcumin, DMC, and BDMC Reduced ROS Generation during PMA-Induced THP-1 Differentiation. Reactive oxygen species (ROS) generation is involved in monocyte adhesion and infiltration. To test whether ROS generation induced by PMA was involved in the CD11b and MMP-9 up-regulation in THP-1 cells, the cells were pretreated with 10 mM of the ROS scavenger *N*-acetyl-L-cysteine (NAC) for 30 min, and then PMA (30 nM) was added for an additional 24 h of incubation. CD11b and MMP-9 mRNA expression was determined by RT-Q-PCR. We found that pretreatment of THP-1 cells with NAC significantly decreased CD11b and MMP-9 mRNA expression in the PMA-treated cells (Figure 5A). These data verified the involvement of ROS in PMA-induced CD11b and MMP-9 expression. We further investigated the effect of curcumin, DMC, and BDMC on ROS production during PMA-induced differentiation. As shown in Figure 5B, treatment of THP-1 cells with PMA alone increased DCF fluorescence to 126.7 ± 2.1% compared to the PMA-untreated cells (100.0 ± 2.9%). Preincubation of the cells with curcumin, DMC, and BDMC (20 μM) markedly decreased PMA-induced intracellular ROS to 99.5 ± 7.8%, 87.8 ± 8.2%, and 89.8 ± 7.6%, respectively ($p < 0.01$). These findings suggest that ROS reduction by curcuminoids is involved in the suppression of CD11b and MMP-9 expression during PMA-induced THP-1 differentiation.

Effects of Curcumin, DMC, and BDMC on NADPH Oxidase Activation during PMA-Induced THP-1 Differentiation. During monocyte to macrophage differentiation, ROS is primarily generated by the NADPH oxidase.[31,32] Therefore, the effect of curcumin, DMC, and BDMC on NOX2/gp91phox mRNA expression in PMA-treated THP-1

DOI: 10.1021/acs.jafc.5b04083
J. Agric. Food Chem. 2015, 63, 8838−8848

cells was investigated. Figure 6A shows that curcumin, DMC, and BDMC (20 μM) significantly decreased PMA-induced NOX2 mRNA expression by approximately 80% compared to the PMA-alone-treated group ($p < 0.01$). Next, we examined the effect of curcumin, DMC, and BDMC on PMA-induced membrane translocation of p47phox in THP-1 cells. As shown in Figure 6B, treatment of THP-1 cells with PMA significantly increased both the levels of p47phox protein expression and membrane translocation of p47phox. In contrast, pretreatment of the cells with curcumin, DMC, and BDMC (20 μM) significantly inhibited the PMA-triggered membrane translocation of p47phox. The inhibition activity of curcuminoids is in the order of curcumin ≈ DMC > BDMC in PMA-treated THP-1 cells. These results indicate that curcuminoids inhibit NADPH oxidase activation via the down-regulation of NOX2/gp91phox mRNA expression and the attenuation of p47phox membrane translocation, leading to reduced ROS generation during monocyte to macrophage differentiation.

Effects of Curcumin, DMC, and BDMC on PKC Activity during PMA-Induced THP-1 Differentiation. PMA is known to activate protein kinase C (PKC); specifically, activation of the isoforms PKCα, -β, and -δ is thought to be involved in PMA-induced monocyte to macrophage differentiation.[33,34] Therefore, we analyzed the effects of curcumin, DMC, and BDMC on PKC activity during PMA-induced THP-1 differentiation. As shown in Figure 7A, treatment of THP-1 cells with PMA significantly increased PKC activity, as expected. When the cells were pretreated with curcumin, DMC, and BDMC (20 μM) or a PKC inhibitor (bisindolylmaleimide I, BIM; 2.5 μM), the PMA-induced PKC activity was significantly attenuated.

Furthermore, the possible involvement of PKC isoforms in NOX2, CD11b, and MMP-9 expression during PMA-induced cell differentiation was investigated using specific isoform inhibitors for PKCα (Gö6976), PKCβ (DAPH-7), and PKCδ (rottlerin). The THP-1 cells were pretreated with Gö6976 (1 μM), DAPH-7 (1 μM), and rottlerin (10 μM) for 30 min, and then PMA was added for an additional 24 h of incubation. The NOX2, CD11b, and MMP-9 mRNA expression levels were determined by RT-Q-PCR. As shown in Figure 7B, pretreatment of THP-1 cells with the inhibitor rottlerin significantly decreased NOX2 and CD11b mRNA expression in the PMA-treated cells. However, NOX2 and CD11b mRNA expression was not affected by treatment with the inhibitors Gö6976 or DAPH-7. PMA-induced MMP-9 expression was suppressed by the inhibitors Gö6976 and rottlerin but not by the inhibitor DAPH-7. These results reveal the involvement of PKCδ-dependent pathway activation in PMA-induced NOX2, CD11b, and MMP-9 mRNA expression.

Finally, we examined the effect of curcumin, DMC, and BDMC on PKCδ activation during PMA-induced THP-1 differentiation. The expression of membrane proteins prepared from curcuminoids-treated cells and the phosphorylated PKCδ (p-PKCδ) and Na,K-ATPase (as an internal protein control of the membrane fraction) was determined by Western blot analysis. As shown in Figure 7C,D, the level of membrane-bound p-PKCδ proteins induced by PMA was significantly decreased in THP-1 cells by the addition of curcumin, DMC, and BDMC (20 μM). This data showed that the PKCδ inhibition activity of three curcuminoids is in the order of curcumin ≈ DMC > BDMC. These data indicate that curcuminoids' inhibition of the PKCδ activity during PMA-induced THP-1 differentiation may be associated with suppression of monocyte invasion.

DISCUSSION

Monocyte recruitment, adhesion, and secretion of matrix metalloproteases (MMPs) are crucial for the initiation and progression of atherosclerotic lesions. The suppression of monocyte adhesion and infiltration and macrophage accumulation is thought to exert antiatherosclerotic effects via the attenuation of atherosclerotic plaque formation and a decrease in the plaque rupture. Therefore, investigation into the effects of curcuminoids on monocyte to macrophage differentiation could help elucidate their roles in the prevention or development of therapeutic application for atherosclerosis. In the present study, we found that curcumin, DMC, and BDMC suppressed monocytes−macrophages invasion through the inhibition of PKCδ-dependent NADPH oxidase-derived ROS generation. Attenuation of ROS production by curcumin, DMC, and BDMC led to down-regulation of the key adherent and invasive molecules (including CD11b and MMP-9) during PMA-induced THP-1 differentiation (Figure 8).

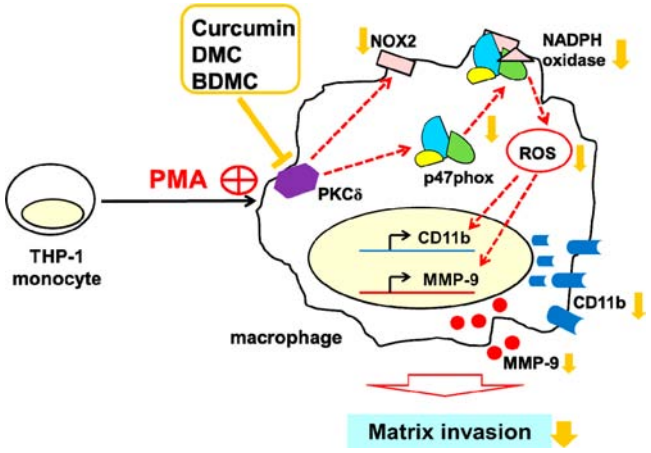

Figure 8. Hypothetical mechanism by which the curcuminoids inhibited monocyte invasion during PMA-induced THP-1 differentiation. During PMA-induced THP-1 differentiation, curcumin, DMC, and BDMC suppressed monocyte invasion through the inhibition of PKCδ-dependent NADPH oxidase-derived ROS generation, which led to the down-regulation of CD11b and MMP-9 expression.

PMA-treated THP-1 cells are generally used as a model to study the function and regulation of monocyte−macrophage differentiation. PMA differentiates THP-1 cells into macrophage-like cells with morphological changes, including a higher level of adherence and higher cell-surface CD11b and metalloprotease MMP-9 expression.[35,36] In the present study, we demonstrated that curcumin, DMC, and BDMC suppressed the matrix invasive ability associated with monocyte−macrophage differentiation. Furthermore, we found that curcumin, DMC, and BDMC decreased CD11b and MMP-9 expression in PMA-differentiated THP-1 cells. Inhibition of the adherent molecule CD11b and protease MMP-9 expression by curcuminoids may lead to a reduction in the invasive ability of monocytes−macrophages. In the present study, we found that BDMC reduced the surface-CD11b protein level more effectively than curcumin and DMC during PMA-induced THP-1 differentiation, despite its similar effect on mRNA

DOI: 10.1021/acs.jafc.5b04083
J. Agric. Food Chem. 2015, 63, 8838−8848

expression. Whether BDMC distinctly modulates the surface-CD11b level through post-transcriptional regulation remains to be investigated. Dietary curcuminoids have been reported to possess antioxidative and antiatherosclerosis activities. Treatment of THP-1 cells with PMA leads to a reduction in LDL receptor expression and an increase in scavenger receptors, such as CD36.[30] Curcuminoids exerted antioxidant activities, regulated heme oxygenase-1 (HO-1) expression and effectively attenuated ox-LDL-induced CD36 expression and activity in PMA-treated THP-1 cells.[25] Our findings supported the hypothesis that the suppression of monocyte invasion by curcuminoids might result in decreased monocyte recruitment and invasion, thereby preventing atherosclerosis initiation.

Curcumin has been reported to possess low toxicity at high doses and is considered to be safe for human subjects.[37] The oral bioavailability of curcuminoids is limited due to their water insolubility, low absorption rate, and rapid metabolism.[38,39] The phase I and II metabolites of curcuminoids, such as hydroxyl or glucuronide/sulfate conjugations, have been reported in in vivo studies. Hoehle et al. reported that the major phase I reduced metabolites of curcuminoids were tetrahydro-, hexahydro- and octahydro-products found in the precision-cut liver slices from rats.[40] During phase II metabolism, curcuminoids and their reduced metabolites are majorly conjugated with glucuronide and a mixed glucuronide/sulfate that are present in the blood circulation in rats.[41] Recently, it has been reported that most orally administrated curcumin is converted to curcumin glucuronide, but residual curcumin or its metabolites other than glucuronide conjugations may be bioactive.[42] In the present study, we demonstrated the cellular response to curcuminoids at micromolar concentrations ranging from 10 to 20 μM, which are widely used in vitro cell culture conditions,[15,23,25] although they are much higher than what can be achieved in vivo. Additionally, the curcuminoid concentrations (10−20 μM) used in this study showed no cytotoxic effects on the THP-1 cells (data not shown). To reach the concentrations employed in this study, novel formulations or delivery systems such as nanoparticle or excipient emulsions may be required to enhance their absorption and improve the bioavailability of curcuminoids.[43,44]

Elevated ROS production causing oxidative stress has been implicated in hypercholesterolemia, atherosclerosis, and heart failure.[45] ROS, especially H_2O_2, is known to be a second messenger in the activation of signaling pathways that induce monocyte adhesion, invasion, and smooth muscle cell migration in atherosclerosis.[6] The H_2O_2 molecules generated from superoxide radicals ($O_2^{\bullet-}$) by superoxide dismutase regulate the expression of several genes by modulating signaling molecules such as mitogen-activated protein kinase (MAPK) and nuclear factor κB (NF-κB).[46] PMA exposure has been reported to induce ROS generation, resulting in cell growth inhibition and monocyte−macrophage differentiation in THP-1 cells.[47] In the present study, we found that depletion of ROS by the antioxidant ROS scavenger NAC led to a reduction in CD11b and MMP-9 mRNA expression in PMA-treated cells. We further demonstrated that curcumin, DMC, and BDMC markedly suppressed ROS production during PMA-induced THP-1 differentiation. Recently, Makino et al. reported that treatment of THP-1 cells with PMA induced CD11b expression via ROS production.[48] Kim et al. reported that MMP-9 expression and cell migration were controlled by ROS production in macrophages.[49] Our current results also revealed that ROS depletion by curcuminoids resulted in a reduction in PMA-induced CD11b and MMP-9 expression in THP-1 cells. Overproduction of ROS has been reported to activate AP-1, SP1, or NF-κB, which are the most well known redox-dependent transcriptional factors and regulate genes involved in inflammation, including MMP-9 in macrophages.[50,51] Whether inhibition of ROS-dependent signaling by curcumin, DMC, and BDMC causes a reduction in the transcriptional activities of AP-1, SP1, or NF-κB remains to be investigated.

Active NADPH oxidase produces superoxide ($O_2^{\bullet-}$) by transferring one electron from cytosolic NADPH to oxygen in polymorphonuclear neutrophils (PMNs) and phagocytes in response to stimuli. Up-regulation of the NOX2 mRNA increased intracellular oxidative stress in macrophages and was associated with the severity of atherosclerosis.[6] Additionally, NOX2 upregulation was correlated with plaque macrophage content in human coronary atherosclerosis.[7] PMA is known to activate this oxidase by promoting the phosphorylation and translocation of cytosolic p47phox, which then leads to active NADPH oxidase assembly. Recently, it was reported that curcumin could act not only as a ROS-scavenging agent but also as an inhibitor of NADPH oxidase activity in a cell-free assay system.[52] In this study, we demonstrated that curcumin, DMC, and BDMC down-regulated NOX2 mRNA expression and also attenuated membrane-bound p47phox translocation during PMA-induced THP-1 to macrophage differentiation. Our current findings reveal that curcumin, DMC, and BDMC may contribute to intracellular ROS reduction through inactivation of the NADPH oxidase and modulation of cell adhesion and invasion during monocyte to macrophage differentiation. The antiatherosclerotic effect of curcuminoids is proposed to reduce ROS production by limiting NADPH oxidase activity in monocytes/macrophages.

Studies have shown that the activation of protein kinase C (PKC) modulates endothelial cells, vascular smooth muscle cells, and monocyte−macrophage functions, suggesting important roles for the PKC signaling pathway in regulating the atherosclerotic process.[53] PMA activates PKC by translocating the kinase from the cytoplasm to the membrane, causing THP-1 differentiation. Additionally, PKC signaling is important for NOX2 and CD11b expression in PMA-primed cells.[32,35] In the current study, we found that curcumin, DMC, and BDMC inhibited PMA-induced PKC activity in THP-1 cells. A change in the expression of PKC isoforms is involved in the cellular differentiation of a variety of cell types, including monocytes. Among the PKC isoforms, PKCα, -β, and -δ are thought to play major roles in many steps in the pro-atherogenic process. In PMA-treated THP-1 cells, PKCα was slightly expressed and PKCδ was highly expressed during monocyte−macrophage differentiation.[35] Activation of PKCα promoted the differentiation of THP-1 cells; however, PKCβ acted in an antagonistic role.[54] In the present study, we demonstrated that inhibition of pan-PKC activity by the inhibitor bisindolylmaleimide I resulted in the down-regulation of NOX2, CD11b, and MMP-9 mRNA expression. Our findings suggest that PKCδ is the most critical isoform of PKC involved in PMA-induced THP-1 differentiation. Furthermore, we found that PMA-induced NOX2, CD11b, and MMP-9 expression in THP-1 cells was also decreased by exposure to the PKCδ-specific inhibitor rottlerin. PKCδ is classified as a member of the new/novel PKC (nPKC) isoenzyme and is widely expressed among cells and tissues. It has been reported that PKCδ is activated by diacylglycerol or PMA. PMA enhanced PKCδ tyrosine phosphorylation and increased the enzyme

DOI: 10.1021/acs.jafc.5b04083
J. Agric. Food Chem. 2015, 63, 8838−8848

activity and translocation from the cytosol to the membrane in various cells.[55] Our current results showed that curcumin, DMC, and BDMC attenuated the membrane translocation of actively phosphorylated PKCδ in PMA-treated THP-1 cells. Recently, curcumin derivative compounds were reported to inhibit PKCδ and NADPH oxidase in equine neutrophils.[52] Taken together, these results suggested that curcuminoids suppressed the activation of the PKCδ/NADPH oxidase/ROS pathway during PMA-induced THP-1 differentiation. Several recent studies supported the hypothesis that treatment of inflammation with a low dose of a PKC isoform inhibitor (such as a PKCδ-specific inhibitor) might prevent or decrease fat accumulation and improve glucose tolerance and foam cell formation in obesity- or hyperlipidemia-associated atherosclerosis.[56,57] Our current findings suggested that curcuminoids may serve as PKCδ inhibitors and provide advantages in modulating the process of atherosclerosis.

In conclusion, this study reports the novel antiatherosclerotic mechanisms of curcuminoids. Our findings reveal for the first time that curcuminoids suppress matrix invasion via the regulation of the PKCδ/NADPH oxidase/ROS signaling pathway during monocyte to macrophage differentiation. Several comparative studies on the biological activities of curcuminoids have shown that curcumin, DMC, and BDMC possessed similar biological activities. Recently, Kou et al. reported that curcumin, DMC, and BDMC distinctly exert antioxidant activities and atheroprotective effects in PMA-differentiated THP-1 macrophage.[25] In the current study, in comparison, the rank order of PKCδ and p47phox translocation inhibition is curcumin ≈ DMC > BDMC during monocyte to macrophage differentiation. These results implied that the *o*-methoxy group of curcuminoids may be more effectively involved in the down-regulation of PKCδ-dependent NADPH oxidase activation. Our results also demonstrated that BDMC showed less activity than curcumin and DMC on PKCδ inhibition; however, equal inhibitory efficacy was demonstrated by these curcuminoids on pan-PKC activity, ROS production, CD11b/MMP-9 mRNA expression, and matrix invasion during PMA-induced THP-1 differentiation. These finding implied that a distinct PKC-isoform-dependent or different signaling pathways downstream of PKC may partly account for BDMC-mediated antiatherosclerotic effects. In addition, the relative cellular uptake of these curcuminoids may also contribute to their efficacy. Therefore, curcuminoids, despite structural similarities, may exhibit different atheroprotective effects.

function of miR528 in the adaptive response to environmental factors in rice remains unclear.

Thus, in the present study, a construct carrying the overexpressed miR528 precursor was subsequently transferred to the *japonica* rice Nipponbare cultivar, which is more tolerant to As(III) than Minghui 86. As expected, the transgenic rice plants became more sensitive to As(III) compared with WT plants. On this basis, the physiological and molecular mechanisms of miR528-mediated As(III) sensitivity were preliminarily investigated.

MATERIALS AND METHODS

Rice Cultivation and Treatments. The *japonica* rice cv. Nipponbare was used in all experiments. Rice seeds were surface sterilized with 0.5% NaOCl for 15 min, then rinsed thoroughly, and soaked in deionized water overnight. Next, the seeds were placed on filter paper and germinated for 5 days by supplying a 0.5 mM $CaCl_2$ solution. Subsequently, the rice seedlings were transferred to 10 L containers filled with half-strength Kimura solution[21] for an additional 21 days of hydroponic cultivation in a growth chamber under a 16 h light (30 °C)/8 h dark (20 °C) photoperiod. Then, the seedlings were treated with 25 μM sodium arsenite ($NaAsO_2$) for 6 days. During rice cultivation and treatment, the nutrient solution was renewed every 3 days. At different time points in the As(III) treatment (6, 24, 72, and 144 h), rice roots, shoots, and leaves were sampled separately for further analyses. At harvest, the As(III)-treated seedling roots were first immersed in an ice-cold desorption solution for 10 min to remove apoplastic As. The desorption solution was composed of 1 mM K_2HPO_4, 0.5 mM $Ca(NO_3)_2$, and 5 mM MES (pH 5.5).[21]

Cloning of miR528 and Rice Transformation. A 400 bp fragment harboring the miR528 precursor sequence was amplified from the genomic DNA of cv. Nipponbare using the primers 5′-AAA GAG CTC CCA CCC TTC ACC AAT GGA TGC ATC-3′ (forward) and 5′-AAA GGA TCC GAA ATG GAT ATG AAT TCA GAC CTG G-3′ (reverse). The amplified PCR product was cloned into the Ubiquitin promoter cassette of pCAMBIA1300 between the *Sac*I and *Bam*HI restriction sites, and this construct was subsequently transformed into *Escherichia coli* strain DH5α for proliferation. After confirmation through sequencing, the plasmid carrying pCAMBIA1300-*MIR528* was electroporated into *Agrobacterium tumefaciens* EHA105, which was then transformed into rice to generate transgenic plants. T_3 homozygous lines were used for all experiments.

Real-Time Quantitative RT-PCR (qPCR). Total RNA and small RNAs from different tissues were extracted using the RNAiso plus and RNAiso for small RNA Kits (TaKaRa, Shiga, Japan), respectively. For real-time RT-PCR analysis, a universal reverse primer and two pairs of specific primers were designed for miR528-5p and -3p, respectively (Supplementary Table 1). The real-time qPCR mix included 5 μL of cDNA, 5 μL of primers, and 10 μL of 2× SYBR Green Mix, in a final volume of 20 μL. Real-time qPCR was carried out in a Mastercycler ep realplex system (Eppendorf, Hauppauge, NY, USA) using the SYBR PrimeScript miRNA RT-PCR Kit (TaKaRa) under conditions of 95 °C for 1 min, followed by 40 cycles of 95 °C for 15 s and 60 °C for 30 s.

The expression analyses of the target genes and six functional genes were also performed using real-time qPCR. In these analyses, the RNA was first treated with DNase I and then reverse transcribed using an oligo(dT) primer. The PrimeScript RT Reagent Kit (TaKaRa) was used to generate cDNA, at 50 °C for 30−60 min. The primers employed for PCR amplification are listed in Supplementary Table 1. The Mastercycler ep realplex system (Eppendorf) was also used to carry out real-time qPCR with the SYBR Premix Ex Taq Kit (TaKaRa).

The relative expression level was calculated using the comparative CT method. The results were normalized to the expression of *U6* or β-tubulin. Each experiment was replicated at least three times.

Quantification of Total As and Copper (Cu). After 6 days of As(III) treatment, the contents of total As and Cu in the samples were quantified via inductively coupled plasma mass spectrometry (ICP-MS, Agilent 7500a; Agilent Technologies, Santa Clara, CA, USA). Briefly, the roots and shoots of the rice seedlings were separately sampled and oven-dried, after apoplastic As in the roots was removed by treatment with desorption solution for 10 min. The samples were then powdered using a ball mill (Retsch, MM301, Germany), and 0.3 g of the ground powder from each sample was digested with 0.5 mL of H_2O_2 and 2 mL of nitric acid at 120 °C for 24 h. When the digestion solution had cooled, deionized water was added to a final volume of 20 mL for the quantification of total As and Cu through ICP-MS.

Antioxidant Enzyme Assays. After 3 and 6 days of As(III) treatment, fresh root and leaf samples from each treatment were used to assess the activity of antioxidant enzymes, including superoxide dismutase (SOD), catalase (CAT), and ascorbate peroxidase (APX). The procedures and methods applied for the enzymatic activity analyses were as described previously.[22]

Amino Acid Analysis. Fresh root and leaf samples from each treatment were milled to a fine powder for amino acid analysis. Briefly, 0.3 g of the ground samples was digested with 10 mL of HCl (6 mol L^{-1}) at 110 °C for 24 h. After cooling, the digestion solution was diluted by adding 15 mL of deionized water to a final volume of 25 mL. Then, 1 mL of the diluted digestion solution was transferred to a glass tube and dried in a vacuum oven at 50 °C. After being dried completely, the sample was redried once more after the addition of 1 mL of deionized water. After redrying, 1 mL of deionized water, 0.5 mL of triethylamine hexanenitrile (14%), 0.5 mL of phenyl isothiocyanate, and 2 mL of *n*-hexane were successively added to the glass tube. The mixture was rocked intensely for 2 min and was then placed on a table for a static duration of 1 h. Finally, the obtained subnatant was filtered and injected into a Waters HPLC system to quantify the contents of different amino acids.

Statistical Analysis. All of the data are presented as the mean value ± standard error (SE) of three or four replicates. The data were analyzed via two-way analysis of variance to confirm the variability and validity of the results and using the least significant difference (LSD) test to examine the significant differences between treatments in SPSS 19.0.

RESULTS

Analysis of the Expression Pattern of miR528 at Different Developmental Stages in Transgenic Plants. To better understand the relationship between plant growth and miR528 expression, we investigated the expression patterns of miR528-5p and -3p at four different stages of development in WT and transgenic plants under normal field conditions. As clearly shown in Figure 1, both miR528-5p and -3p were highly expressed in transgenic seedlings compared with WT plants. With the time of plant growth, the expression levels of the two miR528s decreased significantly (Figure 1). Both miR528-5p and -3p reached their minimum expression level at the booting stage and then rebounded at the heading stage. Notably, the expression levels of both miR528s were >5-fold higher in the transgenic plants than in their WT counterparts at booting stage. These observations indicated that miR528 was indeed highly expressed throughout all stages of development in *Ubi::MIR528* transgenic plants.

Comparison of the Phenotypes of WT and *Ubi::MIR528* Transgenic Plants under Arsenite Stress. Under normal growth conditions, the transgenic plants showed no apparent phenotypic changes compared with WT plants, although miR528 was highly expressed throughout all developmental stages in the transgenic plants (Figure 1). However, when challenged with 25 μM As(III) for 3 days, almost the entire *Ubi::MIR528* seedling exhibited the typical As-poisoning phenotype, with chlorosis being observed in the leaves and shrinking or necrosis in aerial parts, in contrast to

J. Agric. Food Chem. 2015, 63, 8849−8861

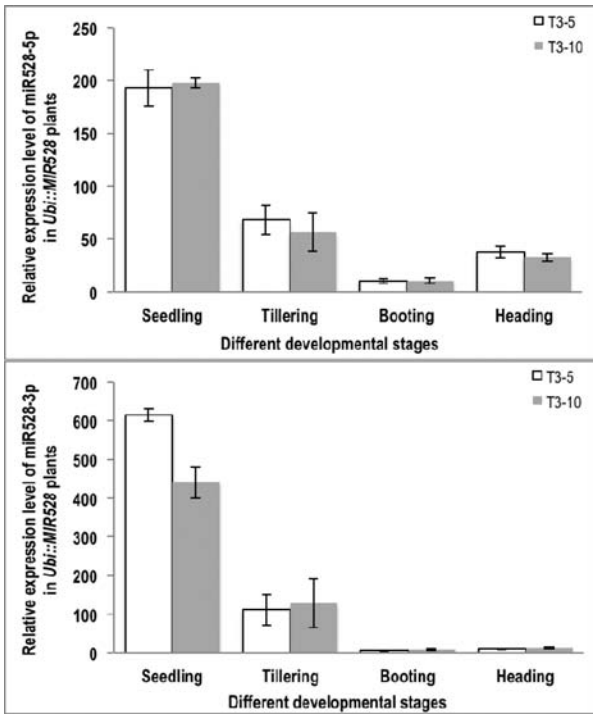

Figure 1. Expression pattern of miR528-5p and -3p in leaves during different developmental stages in rice. The leaves of WT and transgenic plants (#5 and #10) were harvested at four different developmental stages: seedling, tillering, booting, and heading stages. The rice plants were grown in the field under normal conditions. Total RNA was extracted from the harvested leaves, and real-time RT-PCR was performed to assess the relative expression levels of miR528-5p and -3p at the different stages of development. The expression levels of miR528-5p and -3p were normalized to the level of *U6* snRNA. Fold changes in expression levels were estimated using the $2^{-\Delta\Delta CT}$ method relative to levels in the leaves of WT plants at the same developmental stage. Data are reported as the mean ± SE for three independent experiments.

WT (Figure 2). The observed sensitivity of *Ubi::MIR528* plants to As(III) revealed that miR528 is directly involved in the process of As tolerance in rice.

Moreover, compared with WT plants, *Ubi::MIR528* plants accumulated a significantly lower total As level in the roots

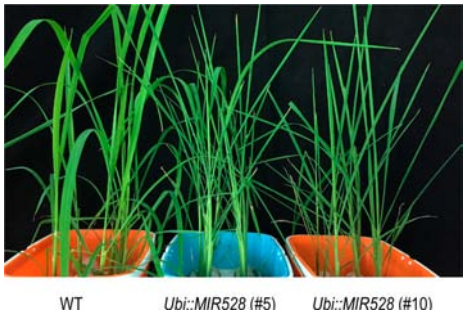

Figure 2. Phenotype of WT and *Ubi::MIR528* transgenic plants under arsenite stress. *Ubi::MIR528* plants were more sensitive to arsenite stress. Plants 5 and 10 are two different *Ubi::MIR528* transgenic lines. Plants were grown hydroponically in half-strength Kimura solution[21] for 21 days under growth conditions with a 16 h light (30 °C)/8 h dark (20 °C) photoperiod and then treated with a 25 μM concentration of arsenite in the form of $NaAsO_2$ for 3 days.

(485.2 ± 21.8 vs 1153.7 ± 69.2 mg kg^{-1}) but showed a higher concentration in the shoots (39.8 ± 1.63 vs 25.7 ± 1.15 mg kg^{-1}). Total As was decreased by 137.8% in the roots, but was increased by 54.9% in the shoots of transgenic plants. Accordingly, transgenic plants overexpressing *MIR528* exhibited significantly weaker As uptake and accumulation (588.0 ± 29.4 vs 1213.2 ± 60.7 mg kg^{-1}; $p < 0.01$) but stronger translocation from the roots to the shoots (0.082 ± 0.004 vs 0.022 ± 0.001 mg kg^{-1}; $p < 0.01$). Interestingly, significant increments of the copper content (166.8 and 440.0%) were observed in the roots (65.1 ± 5.7 vs 24.4 ± 0.7 mg kg^{-1}) and shoots (29.7 ± 1.2 vs 5.5 ± 0.3 mg kg^{-1}) of transgenic plants compared with WT plants.

Spatial−Temporal Expression Analysis of miR528 in WT and Transgenic Plants under Arsenite Stress. According to the annotation in miRBase (release 21), the rice miR528 may produce two mature miRNAs, designated miR528-5p and -3p. Therefore, the spatial−temporal expression patterns of miR528-5p and -3p were assayed in the roots and leaves of WT and *Ubi::MIR528* seedlings at different time points of As(III) treatment via real-time RT-PCR (Figure 3).

As shown in Figure 3, the two mature miRNAs exhibited similar expression patterns in the roots of WT and transgenic plants under challenge with As(III). In WT seedling roots, the expression of both miR528-5p and -3p was consistently increased from 6 to 72 h, reaching the maximum expression level at 72 h and then decreasing at 144 h after treatment with As(III). A similar phenomenon was observed in transgenic plants, where the maximum expression level was detected at 72 h of As(III) exposure (Figure 3). However, inhibition of miR528-3p expression was observed after 24 h of treatment in the roots of transgenic plants. In the leaves, both miR528-5p and -3p were highly up-regulated and reached their highest expression level at 144 h after As(III) treatment in WTs (Figure 3b,d). In contrast, the expression of miR528-3p was down-regulated throughout the treatment stages, although a slight increase was observed at 144 h in the *Ubi::MIR528* plants (Figure 3b). With the exception of the slightly induced expression of miR528-5p detected at 6 h, the expression of miR528-5p remained unchanged or was slightly inhibited during the later treatment times in the different transgenic lines (Figure 3d).

As expected, both miR528s were highly expressed in the roots and leaves of the transgenic plants compared with WT plants (Supplementary Figure 1). The highest expression was observed at 0 h of As(III) treatment, after which the difference between WT and *Ubi::MIR528* plants decreased with increasing treatment time (Supplementary Figure 1). Specifically, the expression of miR528-3p in the leaves was significantly inhibited in *Ubi::MIR528* plants under As(III) stress (from 6 to 144 h) compared with that under control conditions (0 h). Given that overexpression of miR528 confers sensitivity to As(III), it is reasonable to infer the involvement of miR528 in the As(III) response and tolerance of rice.

Time Course Analysis of miR528 and Its Target Genes in Response to Arsenite. In total, 12 and 9 genes were predicted to be potential target genes of miR528-5p and -3p, respectively (Table 1), using psRNATarget with the default parameters (http://plantgrn.noble.org/psRNATarget/). Considering that some genes showed significantly low abundance in the roots or exhibited mismatches with miR528-5p and/or -3p at 10−11 sites, 9 of the predicted target genes were used for expression analysis (Table 1). In addition, a laccase-encoding

DOI: 10.1021/acs.jafc.5b04191
J. Agric. Food Chem. 2015, 63, 8849−8861

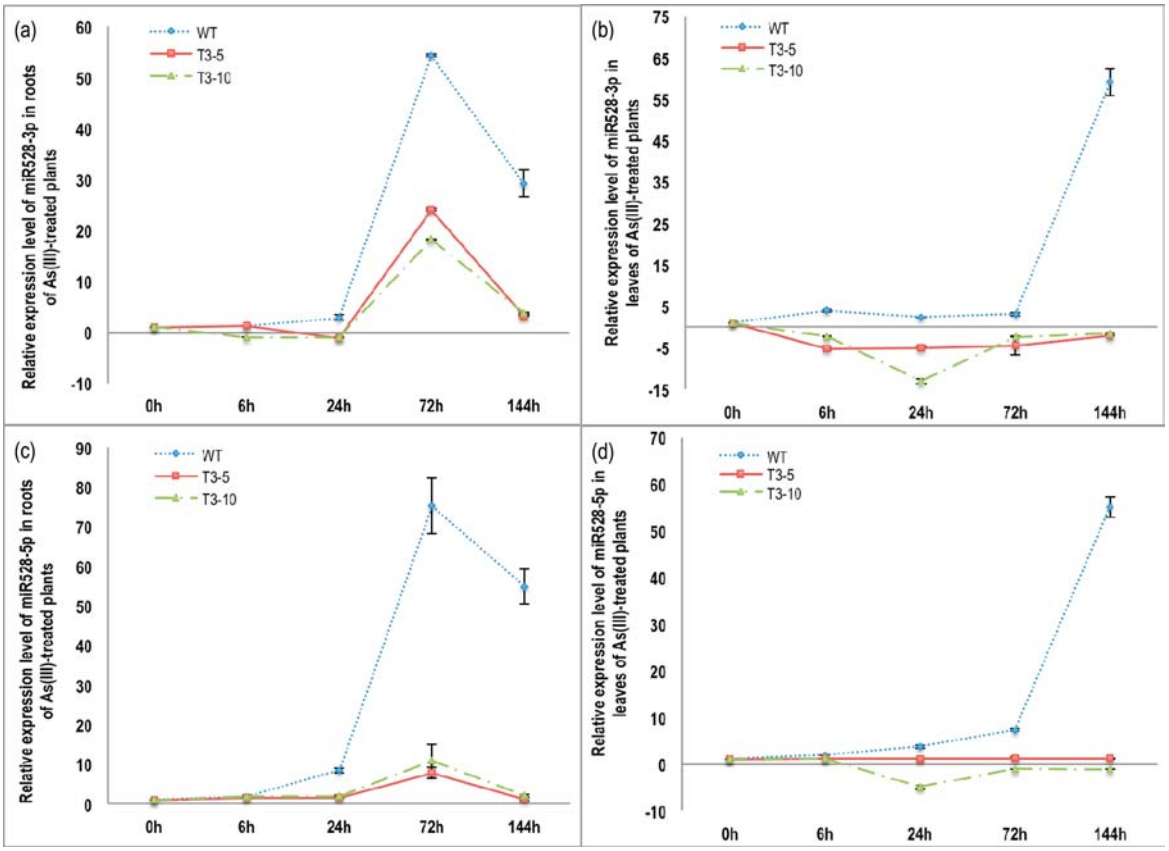

Figure 3. Expression profiles of miR528-5p and -3p in the roots (a, c) and leaves (b, d) of As(III)-treated *Ubi::MIR528* and WT plants. Both miR528-5p and -3p exhibited similar expression profiles in the roots but different profiles in the leaves in response to arsenite stress in transgenic and WT plants. Plants were grown hydroponically and treated with a 25 μM dose of arsenite for 6, 24, 72, or 144 h. Total RNA was isolated from the harvested roots and leaves. The expression levels of miR528-5p and -3p were examined using real-time RT-PCR and normalized to *U6* snRNA levels. Fold changes in expression levels were estimated using the $2^{-\Delta\Delta CT}$ method relative to the levels in *Ubi::MIR528* and WT samples without As(III) treatment (0 h). Data are reported as the mean ± SE for three independent experiments.

gene, *LOC_Os01g62600.1*, that was previously reported to be one of the targets of miR528-5p[17] was also analyzed.

The tested target genes were all expressed in the roots of the As(III)-treated WT and *Ubi::MIR528* plants (Figure 4). Both miR528-5p and -3p were significantly up-regulated at 72 h and then strongly down-regulated at 144 h in both WT and transgenic plants (Figure 4). In contrast, the 10 potential targets could be classified into two groups on the basis of their expression patterns. The first group contained seven target genes of which the expression profile was nearly exactly complementary to miR528-5p or -3p (Figure 4). These genes included one plastocyanin-like protein gene (*LOC_Os07g38290.1*), two multi-copper oxidase genes (*LOC_Os01g03640.1*, *LOC_Os01g03620.1*), two laccase-encoding genes (*LOC_Os01g62600.1*, *LOC_Os01g44330.1*), and two galactosyltransferase family protein-coding genes (*LOC_Os12g41956.1* and *LOC_Os07g09690.1*). In particular, *LOC_Os01g62600.1* and *LOC_Os07g38290.1* showed an exact negative expression pattern in comparison with miR528-5p in the roots of WT and *Ubi::MIR528* (#5) plants, respectively. The negative correlation in the expression pattern further validated the regulatory role of miR528 in relation to these target genes in the response to As(III) tolerance in rice.

The remaining three genes (*LOC_Os06g06050.1*, *LOC_Os09g33800.2*, and *LOC_Os03g40800.1*) were representatives of the second group. Their expression profiles showed no clear negative correlation with miR528s (Figure 4). The results suggested that these three potential target genes either were not true targets of miR528 or might not be involved in the process of miR528-mediated arsenite tolerance in rice.

Alteration of Antioxidant Enzyme Activity and Amino Acid Profiles under Arsenite Stress in Transgenic Plants. In plants, regulation of the expression of antioxidant enzymes, such as SOD, APX, and CAT, is an efficient detoxification mechanism for protecting plants against oxidative stress. To preliminarily elucidate the physiological mechanisms of miR528-mediated As sensitivity, the activity of the antioxidant enzymes SOD, APX, and CAT was assayed in transgenic and WT plants. Compared with the controls (CK), As(III)-treated WT plants exhibited a significant increase of SOD activity at 3 days in the roots and at 6 days in the leaves, whereas a strong decrease was observed at 6 days in the roots and at 3 days in the leaves. However, both the roots and leaves showed more SOD activity after 6 days of treatment with As(III) compared with the 3 day treatment in WT plants; in contrast, with the exception of the 6 day As(III) treatment in the leaves, SOD activity was extensively inhibited in both tested tissues in the transgenic plants upon As exposure (Figure 5a,d).

In the roots, the changes in APX activity were similar between the transgenic and WT plants (Figure 5b). However, transgenic plants exhibited APX activity in the leaves that was distinct from that observed in As(III)-treated WT plants (Figure 5e). In *Ubi::MIR528* plants, excess As strongly elevated APX activity at 3 days but decreased APX activity at 6 days of

[a]Target prediction was performed using the psRNATarget web server with the default parameters by searching against the rice cDNA sequence database (MSU v7). [b]Target accessibility allowed maximum energy to unpair the target site. [c]Predicted target genes that were used for expression analysis in this study.

As(III) exposure in the leaves. In contrast, APX activity was significantly inhibited at 3 days, but strongly induced at 6 days in the leaves of As(III)-treated WT plants (Figure 5e). Interestingly, elevation of CAT activity was observed after 3 days of As(III) exposure in both the roots and leaves of transgenic and WT plants (Figure 5c,f). However, a reverse tendency of the change in CAT activity was detected at 6 days after As(III) treatment in the roots and leaves (Figure 5c,f).

Amino acid (AA) profiles were also analyzed in the leaves and/or roots of transgenic and WT plants to examine the alterations of various AAs under As-induced oxidative stress (Figure 6). The total contents of three (Pro, Met, and Cys) and six of the examined AAs (Asp, Glu, Ser, Gly, Arg, and Tyr) were significantly greater and lower, respectively, in the leaves of *Ubi::MIR528* plants than in WT plants under normal conditions. However, a significant decrease in contents of all 16 tested AAs, with the greatest reduction occurring for Pro, was observed in both transgenic and WT plants under As(III) stress (Figure 6a). In contrast, there were 3 (Glu, Pro, and Met) and 4 AAs (His, Ala, Tyr, and Val) whose total content was significantly increased or decreased, respectively, whereas 9 of 16 AAs showed no obvious changes in the roots of transgenic plants after treatment with As(III) (Figure 6b). Furthermore, most of the AAs examined (12 of 16) significantly accumulated in the roots of WT plants compared with transgenic plants under As exposure, whereas the contents of three stress-responsive AAs (Glu, Ala, and Pro) were much more abundant in transgenic plants (Figure 6c).

Regulation of the Expression of Genes Involved in As(III) Uptake, Translocation, and Tolerance in Transgenic Plants. Previous research has identified some of the genes functioning in As(III) uptake, translocation, and tolerance in rice.[9,23,24] To preliminarily investigate the possible mechanisms underlying the sensitivity of *Ubi::MIR528* plants to As(III), the expression profiles of six functional genes were further analyzed and compared in the roots and leaves of the *Ubi::MIR528* and WT plants under As(III) stress.

The mRNA transcripts of four of the six tested genes (*NIP2;1*, *Lsi2*, *PIP2;4*, and *PIP2;6*) were strongly decreased during the entire period (from 6 to 144 h) of As(III) treatment in both WT and *Ubi::MIR528* transgenic plants (Supplementary Figure 2). In contrast, the transcripts of *NRAMP1* and *PIP2;7* were found to be highly accumulated at all treatment time points in the transgenic plants but were strongly reduced in WT plants from 72 to 144 h and from 6 to 144 h of As(III) exposure (Supplementary Figure 2).

Furthermore, we compared the expression changes in all of the tested genes in the roots between WT and transgenic plants at each time point (Figure 7). Without As(III) treatment (0 h), *NIP2;1*, *NARAMP1*, and *PIP2;7* were weakly expressed in the transgenic plants compared with WT plants, whereas the remaining genes (*Lsi2*, *NIP2;4*, and *NIP2;6*) showed a reverse expression pattern in relation to the first group of genes (Figure 7). However, under As(III) stress, the expression of *NIP2;1* and *PIP2;7* was differentially induced during the entire treatment period in transgenic plants. *NRAMP1* was also found to be up-regulated from 6 to 72 h but was then down-regulated at 144 h with the addition of As(III). In contrast, *PIP2;4* and *PIP2;6* were highly down-regulated by As(III) treatment, with the exception of *PIP2;4* at 72 h. Notably, *Lsi2* was strongly expressed at 72 h but suppressed at 24 and 144 h the exposure to As(III) in *Ubi::MIR528* plants (Figure 7).

A more complex expression pattern was observed in the leaves of WT and *Ubi::MIR528* plants (Supplementary Figure 3). Compared with the expression pattern observed in WT plants, *NIP2;1* and *Lsi2* were slightly and highly expressed at 6

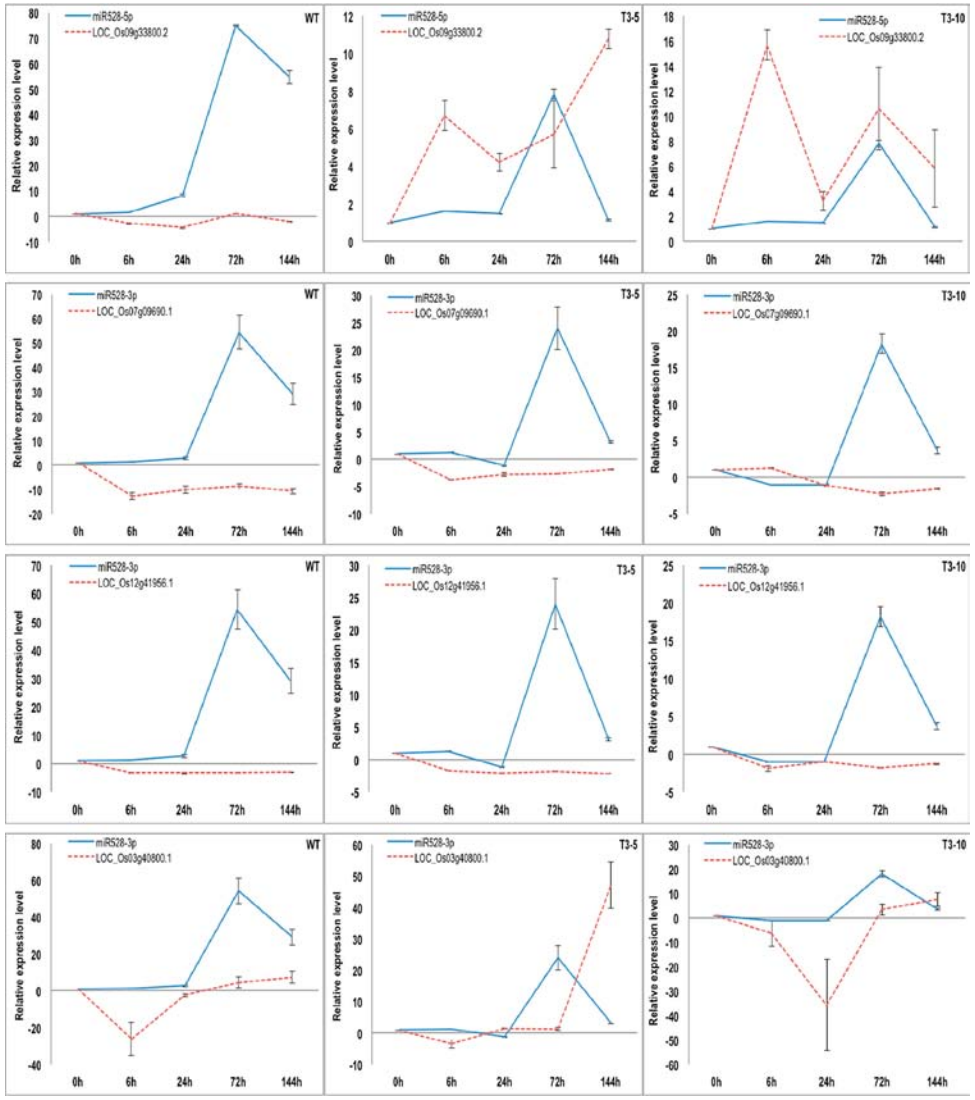

Figure 4. Spatial−temporal expression profiles of miR528 and target genes in the roots of As(III)-treated WT and *Ubi::MIR528* plants. Five genes (*LOC_Os07g38290.1*, *LOC_Os01g03640.1*, *LOC_Os01g03620.1*, *LOC_Os01g62600.1*, *LOC_Os01g44330.1*) and two target genes (*LOC_Os12g41956.1*, *LOC_Os07g09690.1*) showed a clear negative correlation with miR528-5p and -3p in terms of expression. Plants were grown hydroponically and treated with a 25 μM dose of arsenite for 6, 24, 72, or 144 h. Total RNA was isolated using the RNAiso Kit. Relative quantification of miR528 and target gene expression was carried out via real-time RT-PCR analysis. Expression levels were normalized to those of *U6* snRNA and β-tubulin. Fold changes in expression levels were estimated using the $2^{-\Delta\Delta CT}$ method relative to those in WT and *Ubi::MIR528* plants after 0 h of As(III) treatment. The results are reported as the mean ± SE for three biological replicates.

and 144 h, respectively, but were greatly inhibited at 24 and 72 h of As(III) exposure in transgenic plants (Figure 8). A similar case was also observed for *NIP2;4*, which reached its highest expression level at 144 h. With one exception (24 h), the transcripts of *NRAMP1* were highly abundant during the entire treatment period in transgenic plants. Interestingly, *NIP2;6* and *NIP2;7* showed contradictory expression patterns, with the former gene being strongly down-regulated from 0 to 72 h but then rebounding at 144 h, while the expression of the latter gene was slightly increased under As(III) challenge but decreased under normal conditions (0 h) in transgenic plants compared with WT plants (Figure 8).

DISCUSSION

Unlike animals, sessile plants are easily challenged by various environmental factors. During evolution, plants have evolved several strategies to overcome such stress challenges. One of the best-known strategies involves miRNA-mediated gene regulation. Acting as key gene expression regulators,[13] miRNAs have been found to be widely involved in the stress responses and/or tolerance of plants.[12] In the past 10 years, a monocot-specific miR528 has been identified in rice,[16] wheat,[25] maize,[26] sorghum,[26] and sugar cane,[18,27] respectively. In most monocot species, the genome encodes only one miR528, in contrast to the two members observed in maize.[26] miR528 has been demonstrated to be stress-responsive and is differentially expressed under zinc deficiency,[28] low nitrate conditions,[29] drought,[27] and arsenic stress,[16,30] respectively; nevertheless, its biological function has remained unclear thus far. Here, using an overexpression strategy, we established the defining role of miR528 in arsenite tolerance in rice, providing the first evidence contributing to a better understanding of the functions of miR528 in the stress response and/or tolerance of plants.

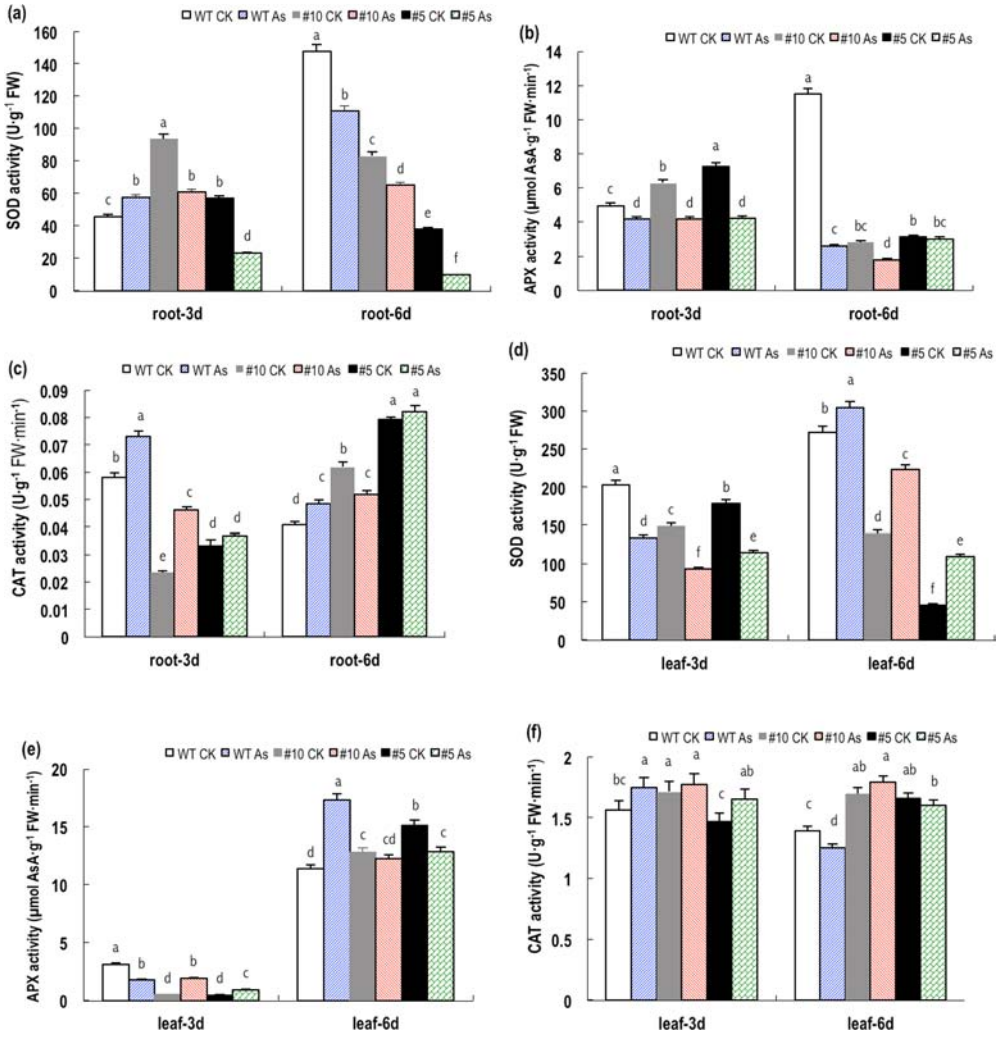

Figure 5. Effect of arsenite exposure on the activity of the antioxidant enzymes SOD, APX, and CAT in the roots (a–c) and leaves (d–f) of WT and *Ubi::MIR528* transgenic plants. Plants were grown hydroponically in a nutrient solution containing 0 or 25 μM sodium arsenite for 3 or 6 days, respectively. Data are reported as the mean ± SE of three replicates. Different letters indicate a significant difference between treatments (LSD; ANOVA analysis; $p \leq 0.05$). WT CK, WT plants without As(III) treatment; WT As, WT plants with 25 μM As(III) treatment; #10 CK, control plants of the 10th transgenic line; #10 As, 10th transgenic line plants treated with 25 μM As(III); #5 CK, control plants of the 5th transgenic line; #5 As, 5th transgenic line plants treated with 25 μM As(III).

In nature, arsenite [As(III)] and arsenate [As(V)] are the predominant forms of As under anaerobic and aerobic conditions, respectively.[1] As(III) might be rapidly oxidized to As(V) in aerobic soils under certain conditions.[1] Additionally, Guo et al.[31] revealed that approximately 10–20% of As(III) added to a nutrient solution might be oxidized to As(V) in the absence of rice seedlings. However, as discussed by Hu et al.,[22] As(III) is expected to be the dominant As species when rice seedlings are cultivated in half-strength Kimura solution with a pH of 5.5,[21] due to the relatively higher redox potential, lack of iron plaque formation,[22] and limited contribution of O_2 loss in the root rhizosphere to the oxidization of As(III) to As(V) under hydroponic culture conditions.[32]

Interestingly, in this study, a significant increment of the Cu content was observed in the roots and shoots of transgenic plants, which could be partially attributed to the following factors: (1) the remarkable deficiency of transcripts of targeted Cu protein-coding genes because of the high induction of miR528 (Table 1 and Figure 4) as well as miR408 and miR397 under arsenite stress;[16,33,34] (2) the potential acceleration of Cu uptake, translocation, and transport in As(III)-stressed transgenic plants, as in lettuce and red clover plants, Cu accumulation has been observed to increase with increasing concentrations of As;[35,36] and (3) the promoter of *MIR528*, like those of *MIR397*, *MIR398*, *MIR408*, and *MIR857*,[33,34,37] contains multiple CuRE-responsive elements (GTAC motif) that bind with AtSPL7 in *Arabidopsis* and play a crucial role in Cu homeostasis.[34] Some transcription factors, for example, OsSPL9, which is an orthologue of AtSPL7,[38] could be strongly activated and, thus, enhance the activity of Cu transporters in the roots and shoots of transgenic plants overexpressing miR528.

We found that the expression patterns of miR528-5p and -3p were similar in the roots, but dissimilar in the leaves between WT and transgenic plants (Figure 3). However, their expression levels were significantly higher in transgenic plants compared with WT plants under either normal or stress conditions (Supplementary Figure 1). Accordingly, overexpression of miR528 would result in the severe inhibition of the expression of its target genes in transgenic plants. As

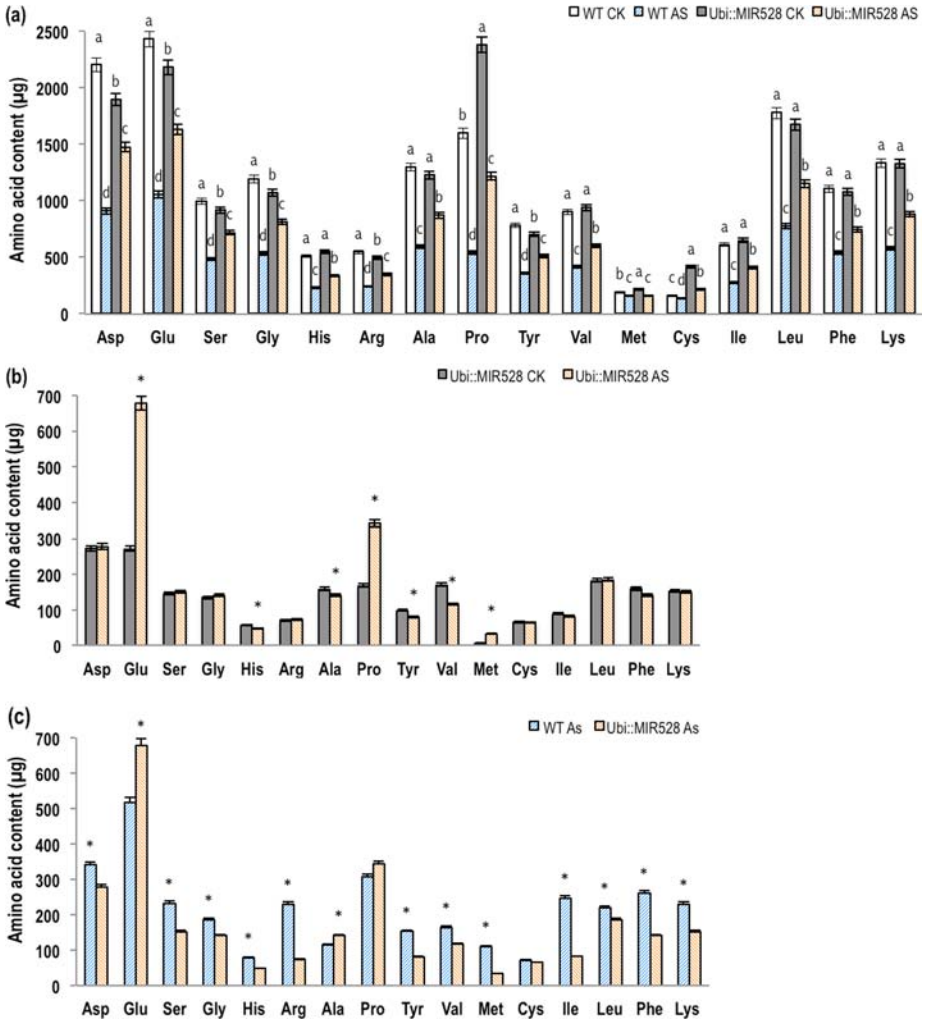

Figure 6. Differential amino acid profiles in response to arsenite stress in the leaves (a) and roots (b, c) of *Ubi::MIR528* and WT plants. The changes in amino acid contents in the roots were significantly different between WT and *Ubi::MIR528* plants. The 21-day-old seedlings were grown for 6 days in a nutrient solution containing 0 or 25 μM sodium arsenite. All values are reported as the mean of triplicates ± SE. Different letters (ANOVA) and asterisks (t test) indicate significantly different amino acid contents between treatments or genotypes ($p \leq 0.05$).

discussed above, the suppression of Cu^{2+}-binding proteins, which are potential targets of miR528-5p (Table 1), might destroy copper homeostasis in transgenic plants, as excess copper is harmful to living cells. On the other hand, two galactosyltransferase family genes were predicted to be potential targets of miR528-3p (Table 1). In plants, galactosyltransferases are reported to function in embryo[39] and anther development,[40] in cell wall synthesis, and in the determination of salt stress tolerance,[41] respectively. Thus, the observed high accumulation of miR528-5p and -3p transcripts could further lead to distortions in copper homeostasis and disorders of the development and growth of roots and leaves of transgenic plants, which might partially explain the observed sensitivity of transgenic plants to arsenite.

In two studies, Dave et al.[42] and Tripathi et al.[43] established that tolerant rice cultivars were prone to accumulate much higher levels of amino acids than sensitive cultivars. We found that the accumulation of 12 of the 16 examined amino acids was significantly lower in the roots of *Ubi::MIR528* plants under As exposure, including that of some essential AAs, such as Met, Val, Ile, Leu, Phe, and Lys (Figure 6), which are highly susceptible to free radicals.[44] However, no significant difference in the total content of Cys, which is a central metabolite that is involved in antioxidant defense and metal detoxification through GSH/PC synthesis,[45] was found between transgenic and WT plants under As stress. Several studies have demonstrated that Pro plays a protective role against active oxygen or hydroxyl radicals in plants.[44,46,47] However, increasing evidence has shown that Pro accumulation is not an indicator of stress tolerance but, merely, a consequence of stress.[48,49] The significant accumulation of free Pro detected in the roots could therefore be reasonably interpreted as a hyperirritability to arsenite in transgenic plants overexpressing miR528. In plants, Pro is known to be mainly synthesized from glutamate,[46] which is another metabolite involved in GSH and PC syntheses.[45] The strong accumulation of the two stress-responsive AAs (Glu and Pro) indicated that Glu should be the major source used for Pro biosynthesis in As-stressed transgenic plant roots. Alternatively, the observed phenomenon might have been due to increased oxidation of Pro to glutamate.[46] However, other possible explanations for the observed high abundance of Pro (for example, protein degradation) cannot be arbitrarily ruled out. Furthermore, a significant increase in glutamic acid was reported in the As-sensitive rice cv. IET-4786, which accumulates remarkably less As than the As-tolerant Triguna,[50] a phenomenon consistent

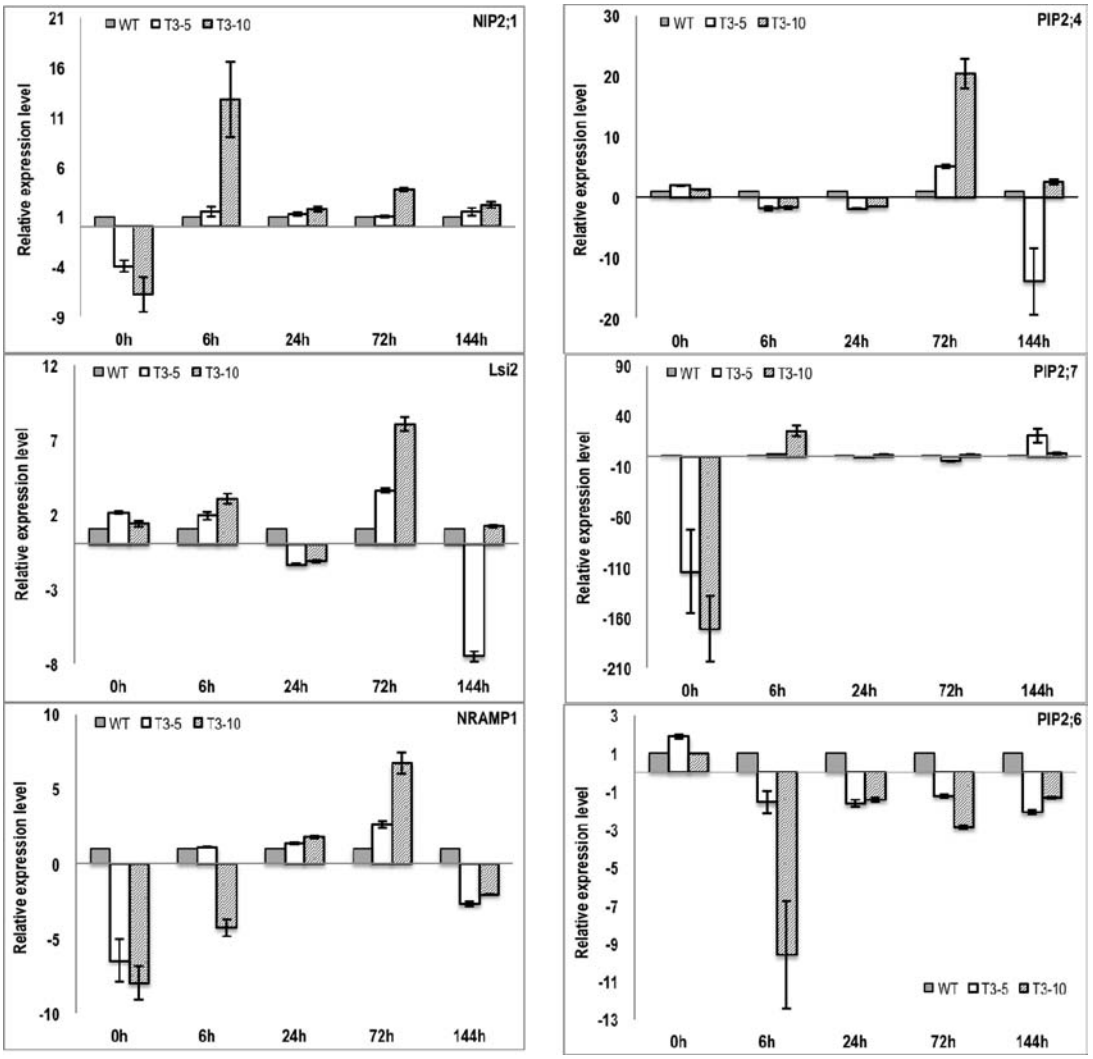

Figure 7. Temporal expression analysis of genes functioning in arsenite uptake, translocation, and tolerance in the roots of *Ubi::MIR528* plants. Plants were grown hydroponically and treated with 25 μM arsenite for 6, 24, 72, and 144 h. Total RNA was isolated using the RNAiso Kit, and expression levels were quantified through real-time RT-PCR analysis. The expression levels of the tested functional genes were normalized to that of β-tubulin. Fold changes in expression levels were estimated via the $2^{-\Delta\Delta CT}$ method relative to levels in the roots of WT plants at the same time point of As(III) treatment (6, 24, 72, or 144 h). The results are presented as the mean ± SE of three biological replicates. *NRAMP1*, *PIP2;6*, *PIP2;4*, and *PIP2;7* were identified as As tolerance related, whereas *NIP2;1* and *Lsi2* function in As(III) uptake, translocation, and accumulation in rice.

with our observations. Moreover, another stress-responsive AA, Ala, was also found to be prominent in transgenic plants under As stress. In general, it appears that the overall reduction of essential and most nonessential AAs in the roots is likely to contribute to the As(III) sensitivity of *Ubi::MIR528* plants.[43]

In rice, a number of genes have been recently identified and characterized as functioning in As(III) uptake, translocation, and tolerance.[9,23,24] To better understand the molecular mechanisms of miR528-mediated As(III) sensitivity in rice, the expression patterns of six genes were investigated in this study. We found that most of the tested genes showed similar expression patterns in the roots of WT and transgenic plants, with two exceptions: *NRAMP1* and *PIP2;7* (Supplementary Figure 2). However, we surprisingly found that *NIP2;1*, which represents the major route of As(III) influx and efflux in rice,[21,23] was slightly induced by As(III) treatment in transgenic plants compared with WT plants (Figure 7). Considering the weak accumulation of As in the transgenic plants, we speculate that the slight activation of *NIP2;1* expression might accelerate the efflux of As(III) into the external media. Another possibility is that other genes that are involved in As(III) uptake in rice,[23] including *NIP2;2*, *NIP1;1*, *NIP3;2*, and *NIP3;1*, could be extensively down-regulated by As(III) in the roots of transgenic plants. In comparison, *Lsi2* was shown to be strongly expressed at 72 h in the roots and at 144 h in the leaves upon As exposure (Figures 7 and 8). This observation better explains why *Ubi::MIR528* plants exhibited greater As translocation. In addition, the expression of two PIP subfamily members, *PIP2;4* and *PIP2;6*, which might function in As tolerance,[9] was clearly suppressed by As(III) at most treatment time points (Figures 7 and 8). Therefore, the observed sensitivity of *Ubi::MIR528* transgenic plants to As(III) might be partly attributable to the significant inhibition of the expression of the corresponding genes in the roots and leaves. *PIP2;7* and *NRAMP1* have also been reported to be related to As tolerance.[9,10] However, the expression of these two genes was increased extensively in both the roots and leaves of transgenic plants (Figures 7 and 8), suggesting that *PIP2;7* and *NRAMP1* may play minor roles in miR528-mediated As tolerance in rice. Nevertheless, the relationship between the expression of functional genes and

J. Agric. Food Chem. 2015, 63, 8849−8861

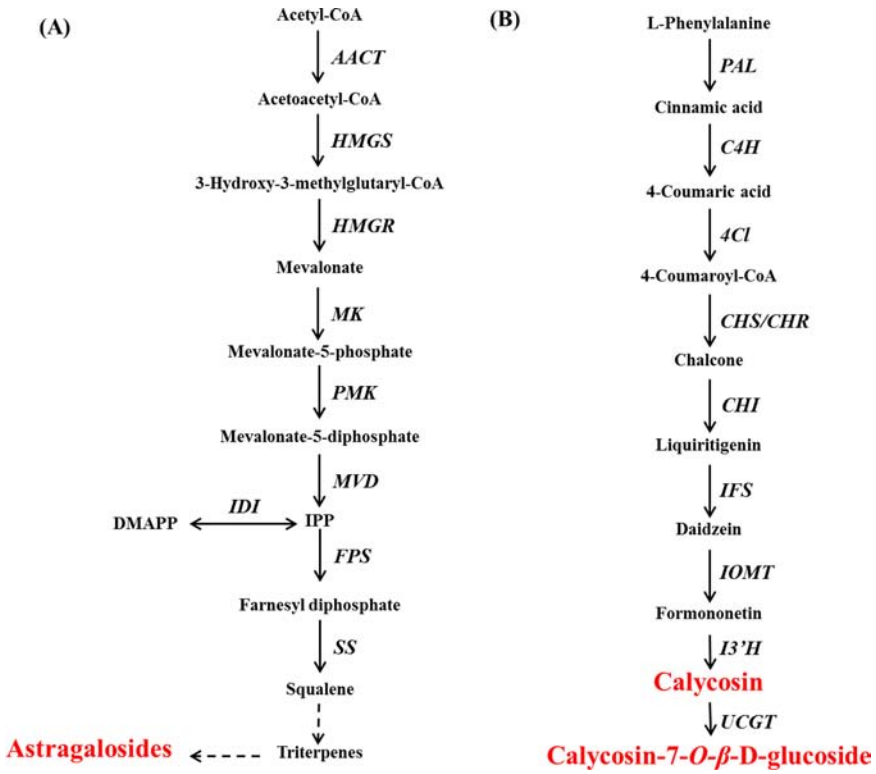

Figure 1. Putative scheme of biosynthetic pathway leading to (A) astragaloside and (B) calycosin and calycosin-7-*O*-*β*-D-glucoside. AACT, acetoacetyl-CoA thiolase; HMGS, HMG-CoA synthase; HMGR, HMG-CoA reductase; MK, mevalonate kinase; PMK, phosphomevalonate kinase; MVD, mevalonate diphosphate decarboxylase; IDI, isopentenyl diphosphate isomerase; FPS, farnesyl diphosphate synthase; DMAPP, dimethylallyl diphosphate; IPP, isoprenyl diphosphate; FPP, farnesyl diphosphate; SS, squalene synthase; PAL, phenylalanine ammonia-lyase; C4H, cinnamate-4-hydroxylase; 4CL, 4-coumarate:coenzyme A-ligase; CHS, chalcone synthase; CHR, chalcone reductase; CHI, chalcone isomerase; IFS, isoflavone synthase; IOMT, isoflavone *O*-methyltransferase; I3′H, isoflavone 3′-hydroxylase; UCGT, calycosin 7-*O*-glucosyltransferase.

by ramification into sterol and triterpene.[17] The first diversifying step in triterpenoid biosynthesis is the cyclization of 2,3-oxidosqualene, which is catalyzed by oxidosqualene cyclase (OSC); this step enables the synthesis of more than 100 variations of triterpenoids in plants.[18] Several OSCs, including cycloartenol synthase (CAS) and lanosterol synthase (LAS), are involved in both sterol biosynthesis and triterpenoid biosynthesis in higher plants.[19] Squalene synthase (SS) synthesizes 2,3-oxidosqualene from FPP and is the main backbone for the synthesis of ursane, oleanane, dammarane, and lupeol, which are the major triterpenoid skeletons.[18,20]

In the plant system isoflavones calycosin and CG are metabolically produced via the phenylpropanoid pathway (Figure 1B). Phenylalanine ammonia-lyase (PAL) is the starting enzyme, which converts L-phenylalanine into *trans*-cinnamic acid. Furthermore, cinnamate-4-hydroxylase (C4H) and 4-coumarate:coenzyme A-ligase (4CL) subsequently act on *trans*-cinnamic acid to produce *p*-coumarate CoA ester, respectively.[21] After that, *p*-coumaroyl-CoA condenses with three molecules of malonyl-CoA to synthesize chalcone by the catalytic action of chalcone synthase (CHS). In the next reaction, naringenin (5,7,4′-trihydroxyflavanone) was produced using the isomerization reaction of chalcone isomerase (CHI). In species that synthesize isoflavones, the enzyme isoflavone synthase (IFS), which catalyzes the formation of all isoflavones, has two roles: diverting naringenin into genistein production and catalyzing daidzein.[22] A methyl group is then added to daidzein by isoflavone *O*-methyltransferase (IOMT) to form formononetin.[23] Finally, calycosin is synthesized by hydroxylation of isoflavone 3′-hydroxylase (I3′H), and this compound can be modified to CG by calycosin 7-*O*-glucosyltransferase (UCGT).[24]

Through these well-characterized pathways, the common components of *A. membranaceus* are synthesized and promote the beneficial effects of the herb. In addition to these well-known synthetic pathways, *A. membranaceus* is also a good candidate for natural product isolation due to its long history in traditional medicine and abundance of beneficial compounds. Commonly called "Hwang Qi", the traditional medicine from *A. membranaceus* is prepared from the dried roots of the plant, and studies have characterized the phytochemistry, pharmacology, and clinical applications of the preparation.[25] However, to the best of our knowledge, no studies have compared the contents and expression profiles of genes involved in biosynthetic pathways between seedling roots (SRs), adventitious roots (ARs), and hairy roots (HRs) of *A. membranaceus*.

In vitro root culture is the well-known method for the bulk level production of novel plant metabolites with nutraceutical, pharmaceutical, and industrial applications.[26,27] In vitro culturing of ARs with the supply of optimized concentration of phytohormone comparatively produces valuable secondary metabolites.[27] Establishment of AR suspension culture systems has indicated that effective culture systems can promote large-scale multiplication, strain improvement, and species conservation.[28] Genetically transformed HR cultures have several beneficial properties, including rapid growth, genetic and biochemical stability, relatively low-cost culture obligation, and growth in hormone-free medium.[29] Additionally, HRs

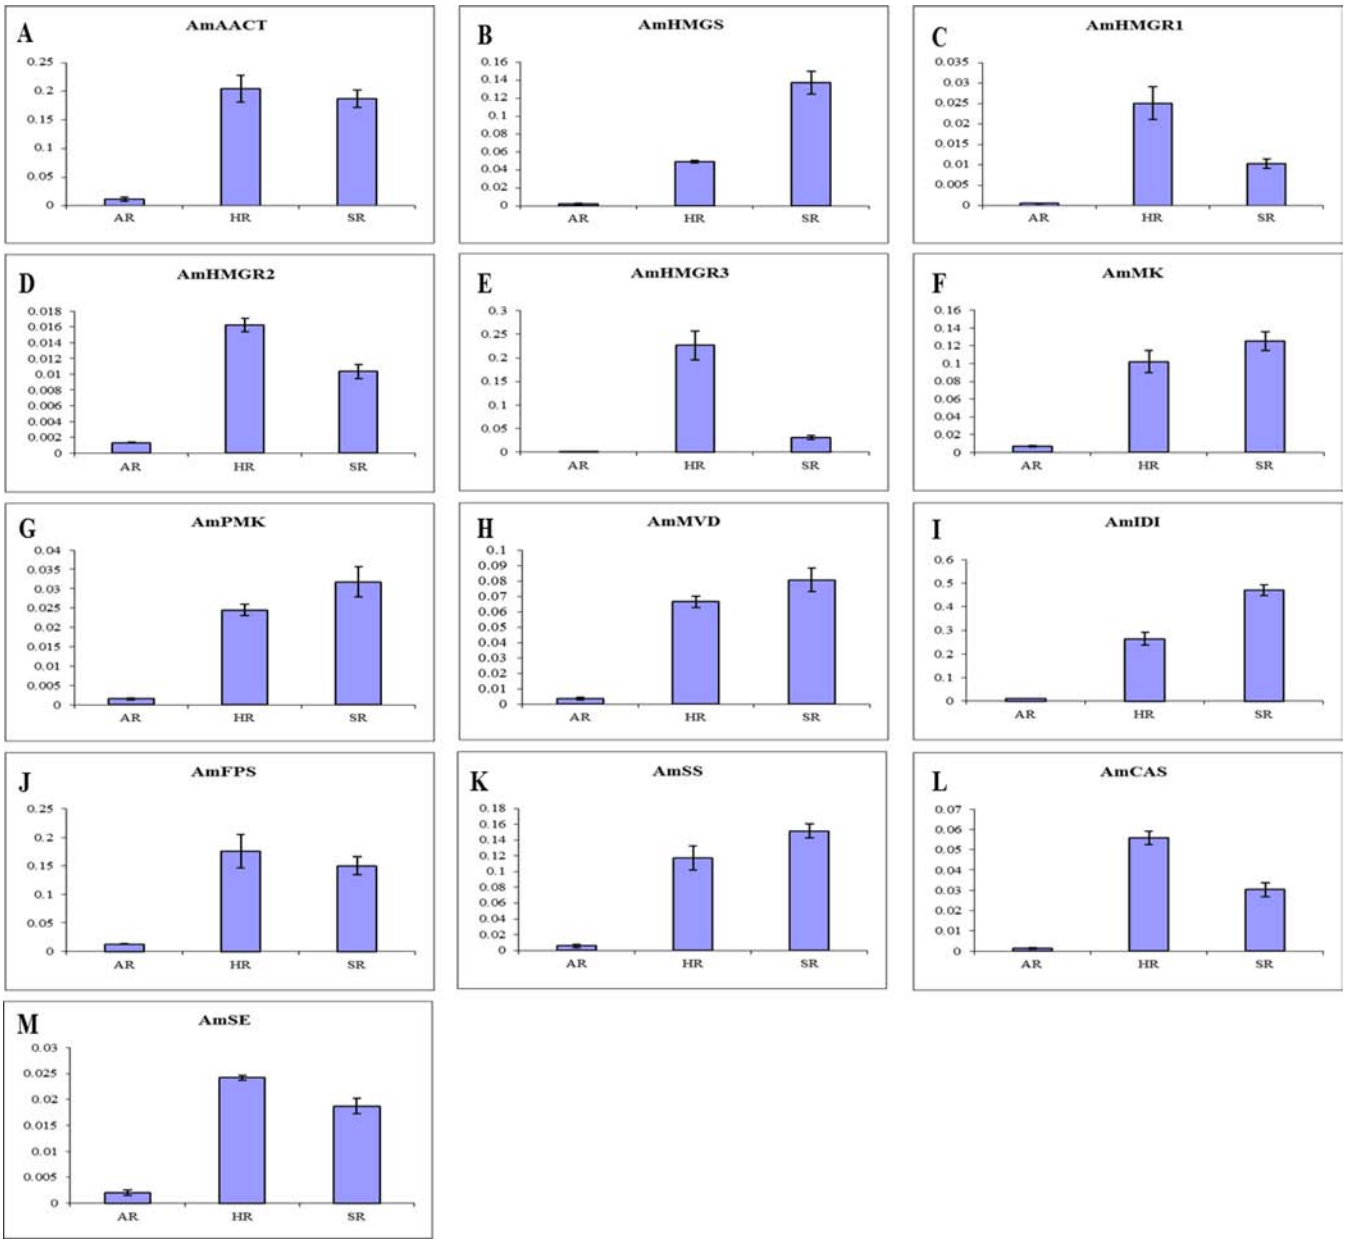

Figure 2. Accumulation of genes related to astragaloside biosynthetic in three different types of roots. AR, adventitious root; SR, seedling root; HR, hairy root. The height of each bar and the error bars indicate the means and standard errors, respectively, from three independent measurements.

derived from *Agrobacterium rhizogenes* by infection into plants exhibit multienzyme biosynthetic potential similar to or greater than those of the parent plants.[30]

Metabolomics provides a biochemical snapshot of an organism's phenotype. This technique provides the chance for in-depth identification of markers for the individual metabolite specific to species, cultivar, certain stages of development, or conditions such as disease, stress, or daily and seasonal changes, respectively.[31] A combination of gas chromatography and mass spectrometry (GC-MS) has allowed for the identification and robust quantification of several hundred metabolites within a single extract. Recently, several metabolomics studies have classified diverse biological samples varying in status, origin, and quality using GC-time-of-flight (TOF)-MS.[32−34] However, no metabolite profiles of the *A. membranaceus* have been reported to date.

In this study, we aimed to compare the expression levels of genes related to AST, calycosin, and CG biosynthetic pathways among SRs, ARs, and HRs. Moreover, ASTs, calycosin, and CG extracted from these three different types of root cultures of *A. membranaceus* were quantified using high-performance liquid chromatography (HPLC). These results demonstrated an efficient root culture system for the production of secondary metabolites in *A. membranaceus*. In addition, the levels of hydrophilic metabolites were analyzed from different root materials using GC-TOF-MS.

MATERIALS AND METHODS

Induction of HRs and ARs. Hairy roots were initiated from excised leaves of *A. membranaceus* after being infected with *Agrobacterium rhizogenes* R1000. Briefly, the excised leaves (1.0 × 1.0 cm) were washed thoroughly with distilled water and dipped into the *A. rhizogenes* for 10 min. Immediately after that, the leaves were

DOI: 10.1021/acs.jafc.5b02525
J. Agric. Food Chem. 2015, 63, 8862−8869

collected and kept in sterile filter paper for the removal of the liquid and then placed on autoclaved sterile solidified MS medium.[35] After that, the samples were kept in an incubator at 25 °C and maintained in the dark for 2 days. After that, the explants tissue was cultivated in the hormone-free MS medium for 3−4 weeks. Upon emergence of the hairy roots, they were removed from the flask and cultivated in MS medium containing 200 mg/L timentin at 25 °C under dark conditions. Furthermore, the roots were routinely cultivated by transferring them into fresh medium to collect the fresh hairy roots. Rapidly growing adventitious roots were carefully collected and initiated from leaf explants of *A. membranaceus* maintained on agar-solidified MS media containing 1.0 mg/L 1-naphthaleneacetic acid (NAA) as described by Thwe et al.[36] Seedling roots excised from *A. membranaceus* plantlets were grown in vitro.

The above obtained three types of root cultures were collected and further subcultured in hormone-free MS liquid medium, cultivated at 25 °C on a shaker (100 rpm) under dark conditions for 24 h. After 20 days of incubation, the hairy roots were harvested for the extraction of total RNA and analysis of phytochemicals. The harvested samples were immediately stored at −80 °C for further molecular and chemical analysis.

Quantitative Real-Time Reverse Transcription Polymerase Chain Reaction (qRT-PCR). On the basis of the sequences of *AmAACT*, *AmIDI*, *AmSS*, *AmPAL1*, *Am4CL*, *AmCHS1*, *AmCHI*, and *AmIOMT*, we designed real-time PCR primers using the Primer3 Web site (http://frodo.wi.mit.edu/primer3/). Total RNA was extracted from each collected sample using a modified trizol method. The first strand of cDNA was synthesized using 1 μg of total RNA according to the manufacturer's method (ReverTra ace, Toyobo, Japan). The reverse-transcribed cDNA products were used as templates for gene expression analysis with gene-specific primers. Real-time PCR products were tested for specificity of fragment sizes, melting curves, and sequences by PCR, qRT-PCR, and cloning into a T-Blunt vector for sequencing, respectively. The housekeeping phosphoribosyl transferase gene (NCBI GenBank accession no. KF355974) was used to normalize the relative expression of the targeted genes. qRT-PCR was performed on a CFX96 real time system (Bio-Rad Laboratories, Hercules, CA, USA) with the 2× real-time PCR Smart mix (BioFACT, Korea) under the following conditions: 95 °C for 15 min, followed by 40 cycles of 95 °C for 15 s, annealing for 15 s at 55 °C, and elongation for 20 s at 72 °C. Three replications for each sample were used in the real-time analyses.

HPLC Analysis. The materials were freeze-dried and ground into a fine powder. Briefly, 100 mg samples were extracted with 1.5 mL of MeOH and sonicated for 60 min. The samples were vortexed every 20 min during sonication. After centrifugation at 4000 rpm at room temperature for 10 min, the supernatant was filtered through a 0.45 μm PTFE syringe filter (Advantec DISMIC-13HP; Toyo Roshi Kaisha, Ltd., Tokyo, Japan) for HPLC analysis. HPLC grade methanol (MeOH) was purchased from J. T. Baker (Phillipsburg, NJ, USA). Formic acid was purchased from Sam Chun Pure Chemical Co., Ltd. (Gyeonggi, Korea). AST-I, AST-II, AST-III, AST-IV, calycosin, and CG were obtained from ChromaDex (Irvine, CA, USA). HPLC analysis was performed using a C_{18} column (250 × 4.6 mm, 5 μm; RStech; Daejeon, Korea). The flow rate was maintained at 1.0 mL/min, the column was maintained at 30 °C, and the injection volume was 20 μL. The mobile phases consisted of 0.3% formic acid in water (A) and acetonitrile (B), and a gradient elution protocol was used. The ultraviolet (UV) detection wavelength was 260 nm for isoflavonoids. The drift tube temperature for evaporating light scattering detection (ELSD) was 70 °C, and the nebulizing gas flow rate was 3.0 L/min. The concentration of each compound was determined using a standard curve. All samples were analyzed in triplicate.

Metabolite Analysis Using GC-TOF-MS. Analytical grade reagents and chemicals were used in this experiment. Chloroform and methanol were procured from J. T. Baker. *N*-Methyl-*N*-trimethylsilyltrifluoroacetamide (MSTFA) and ribitol and were procured from Sigma Chemical Co. (St. Louis, MO, USA). Pyridine and methoxyamine hydrochloride were procured from Thermo Fisher Scientific (Pittsburgh, PA, USA). The extraction of polar metabolite was performed as described by Kim et al.[33] The sample preparation methods, chemicals and reagents, silylation procedures, GC-TOF-MS instrument operating conditions, analytical methods for the separation of the samples and the scanning and the detection of the compounds rang were as implemented as described in our previous research paper Kim et al.[34] ChromaTOF software was used to assist with peak location. Peak identification was performed by comparison with reference compounds and the use of an in-house library.

Statistical Analysis. The data for gene expression and each constituent were analyzed using Statistical Analysis System software (SAS version 9.2). Treatment means were compared using Duncan's multiple-range test. Quantification data acquired from GC-TOF-MS were subjected to principal component analysis (PCA) (SIMCA-P version 13.0; Umetrics, Umea, Sweden) to evaluate differences among groups of multivariate data. The data file was scaled with unit variance scaling for the multivariate analysis. The PCA output consisted of score plots to visualize the contrast between different samples and loading plots to explain the cluster separation.

RESULTS AND DISCUSSION

Transcription Levels of Genes Related to AST Biosynthetic Pathways in Different Root Cultures of *A. membranaceus*. To investigate the mechanisms controlling AST biosynthesis in different root cultures of *A. membranaceus*, the expression levels of genes encoding AST-synthesizing enzymes were analyzed in SRs, ARs, and HRs. The expression levels of *AmAACT*, *AmHMGS*, *AmHMGR1*, *AmHMGR2*, *AmHMGR3*, *AmMK*, *AmPMK*, *AmMVD*, *AmIDI*, *AmFPS*, *AmSS*, *AmCAS*, and *AmSE* are shown in Figure 2. The expression patterns of *AmAACT*, *AmFPS*, *AmCAS*, and *AmSE* were similar, with observably higher expression in HRs than in SRs. Additionally, AmHMGRs (*AmHMGR1*, *AmHMGR2*, and *AmHMGR3*) exhibited lower expression in SRs than in HRs. In contrast, *AmHMGS*, *AmMK*, *AmPMK*, *AmMVD*, *AmIDI*, and *AmSS* exhibited high expression in SRs, but were moderately expressed in HRs. Although the transcripts encoding all of these enzymes were expressed in ARs, ARs exhibited the lowest expression levels for these genes.

Quantitative Analysis of ASTs. A total of four ASTs (AST-I, AST-II, AST-III, and AST-IV) were extracted and quantified in three different root cultures (Table 1). All of the identified compounds were found to be present at high levels in SRs (AST-I, 2532.87 μg/g dry wt; AST-II, 1342.25 μg/g dry wt; AST-III, 1712.40 μg/g dry wt; and AST-IV, 620.97 μg/g dry wt). ARs exhibited the least AST-I (177.34 μg/g dry wt), AST-II (189.63 μg/g dry wt), and AST-III (280.38 μg/g dry wt) and moderate levels of AST-IV (120.84 μg/g dry wt). The levels of these compounds were relatively higher in HRs than in ARs (AST-I, 785.87 μg/g dry wt; AST-II, 391.35 μg/g dry wt; AST-III, 378.92 μg/g dry wt), whereas the level of AST-IV was slightly lower in HRs (119.44 μg/g dry wt) than in ARs.

Table 1. AST Contents (μg/g Dry Weight) in Different Types of Roots of *A. membranaceus*[a]

compound	AR	HR	SR
AST-I	177.34 ± 6.72	785.87 ± 37.56	2532.87 ± 61.91
AST-II	189.63 ± 3.32	391.35 ± 12.63	1342.25 ± 2.84
AST-III	280.38 ± 8.58	378.92 ± 42.06	1712.40 ± 111.69
AST-IV	120.84 ± 5.93	119.44 ± 2.35	620.97 ± 5.46

[a]Each value is from three determinations ± SD. AR, adventitious root; SR, seedling root; HR, hairy root.

Expression Analysis of Calycosin and CG Biosynthetic Genes in Different Root Cultures of *A. membranaceus*.

DOI: 10.1021/acs.jafc.5b02525
J. Agric. Food Chem. 2015, 63, 8862−8869

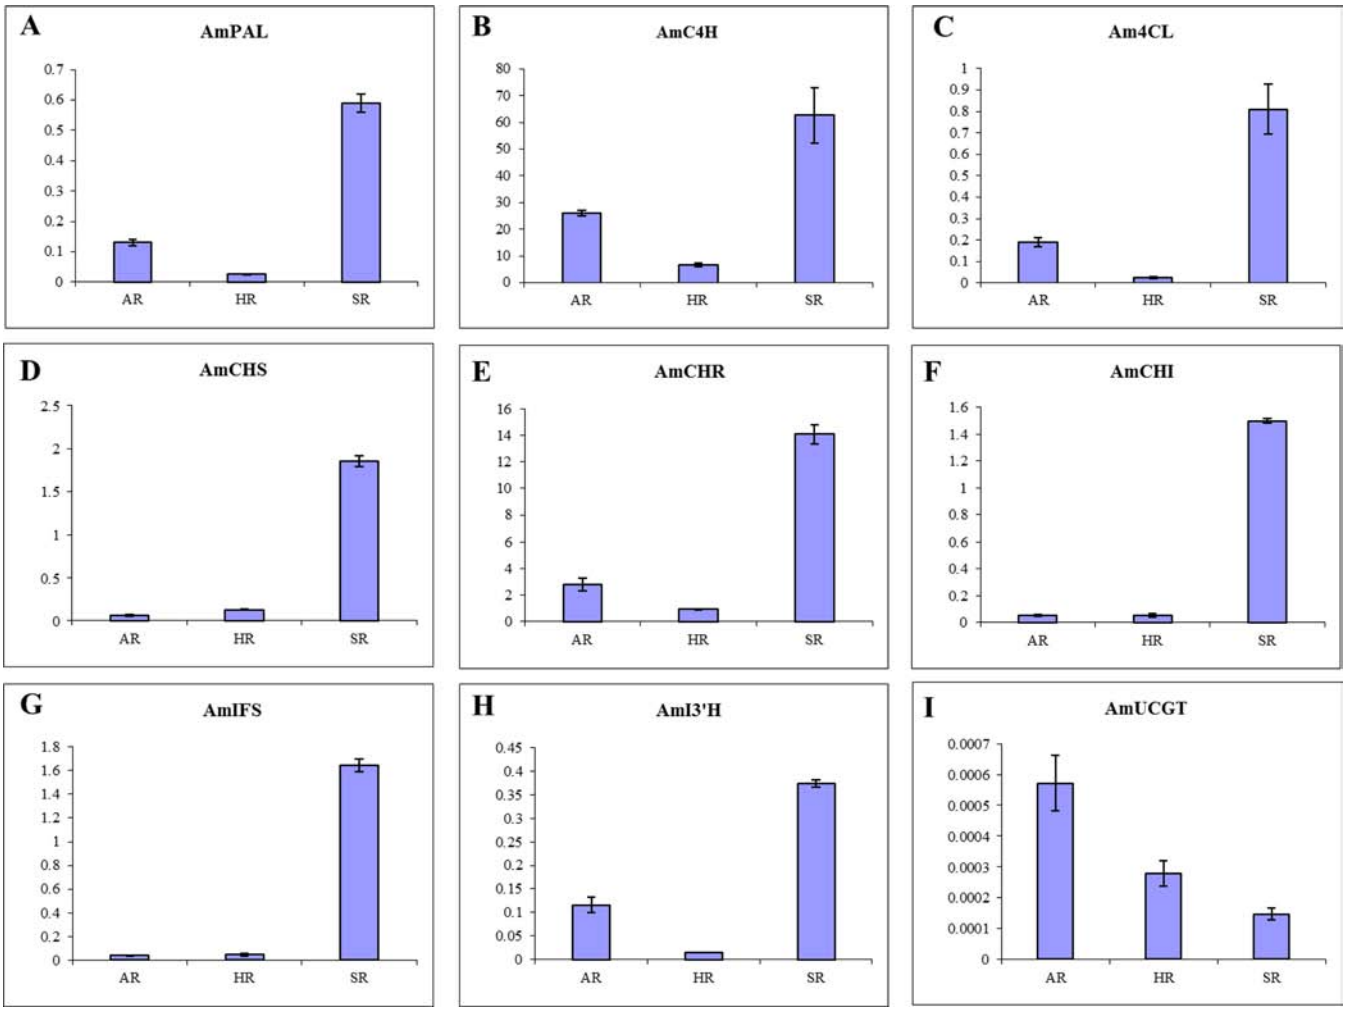

Figure 3. Expression levels in the three types of roots of genes related to the calycosin and calycosin-7-*O*-*β*-D-glucoside biosynthetic pathways: (A) *AmPAL*; (B) *AmC4H*; (C) *Am4CL*; (D) *AmCHS*; (E) *AmCHR*; (F) *AmCHI*; (G) *AmIFS*; (H) *AmI3′H*; (I) *AmUCGT*. AR, adventitious root; SR, seedling root; HR, hairy root. The height of each bar and the error bars indicate the means and standard errors, respectively, from three independent measurements.

To investigate the control of calycosin and CG biosynthesis, we examined the expression levels of genes related to calycosin biosynthesis in ARs, HRs, and SRs using qRT-PCR. The expression levels of *AmPAL*, *AmC4H*, *Am4CL*, *AmCHS*, *AmCHR*, *AmCHI*, *AmIFS*, *AmI3′H*, and *AmUCGT* are shown in Figure 3. The expression levels of these genes, with the exception of *AmUCGT*, were highest in SRs, demonstrating that *AmUCGT* exhibited a different expression profile than the other genes. The expression of *AmUCGT* was extremely low compared to that of other genes and was highest in ARs. The expression patterns of *AmPAL*, *AmC4H*, *Am4Cl*, *AmCHR*, and *AmI3′H* were similar, with observably higher expression in ARs than in HRs. However, the expression levels of *AmCHS*, *AmCHI*, and *AmIFS* were higher in ARs than in HRs.

Calycosin and CG Contents in Different Root Cultures. Next, we assessed the contents of two different flavonoids, calycosin and CG, in the three types of roots. As shown in Table 2, CG and calycosin accumulated at 5.64 and 3.56 μg/g dry wt, respectively, in ARs. The levels of CG and calycosin produced in HRs were 2.84 and 2.93 μg/g dry wt, respectively. However, calycosin (5.70 μg/g dry wt) was more abundant than CG (3.10 μg/g dry wt) in SRs; this was correlated with low expression of *AmUCGT*, which converts calycosin to CG.

Table 2. Analysis of Isoflavone Contents, Including Calycosin and CG Contents, in Different Types of Roots from *A. membranaceus*[a]

compound	AR	HR	SR
calycosin	3.56 ± 0.54	2.93 ± 1.04	5.70 ± 0.11
CG	5.64 ± 0.12	7.14 ± 3.43	3.10 ± 0.62

[a]Each value is from three determinations ± SD. AR, adventitious root; SR, seedling root; HR, hairy root.

Although *AmUCGT* transcript levels were relatively higher in ARs than in HRs, the CG content was high in HRs.

GC-TOF-MS Analysis of Polar Metabolites in Different Root Cultures. GC-TOF-MS was used to identify and quantify low-molecular-weight hydrophilic compounds in *A. membranaceus* samples. We were able to identify 40 compounds including 13 organic acids, 12 amino acids, 6 sugar alcohols, 5 sugars, 3 carbohydrates, and 1 amine in these samples (Supporting Information 1). The corresponding retention times agreed with our previous data.[34] Quantification was performed using selected ions, and the quantitative calculations of all analytes were based on the peak area ratios relative to that of the IS.

J. Agric. Food Chem. 2015, 63, 8862−8869

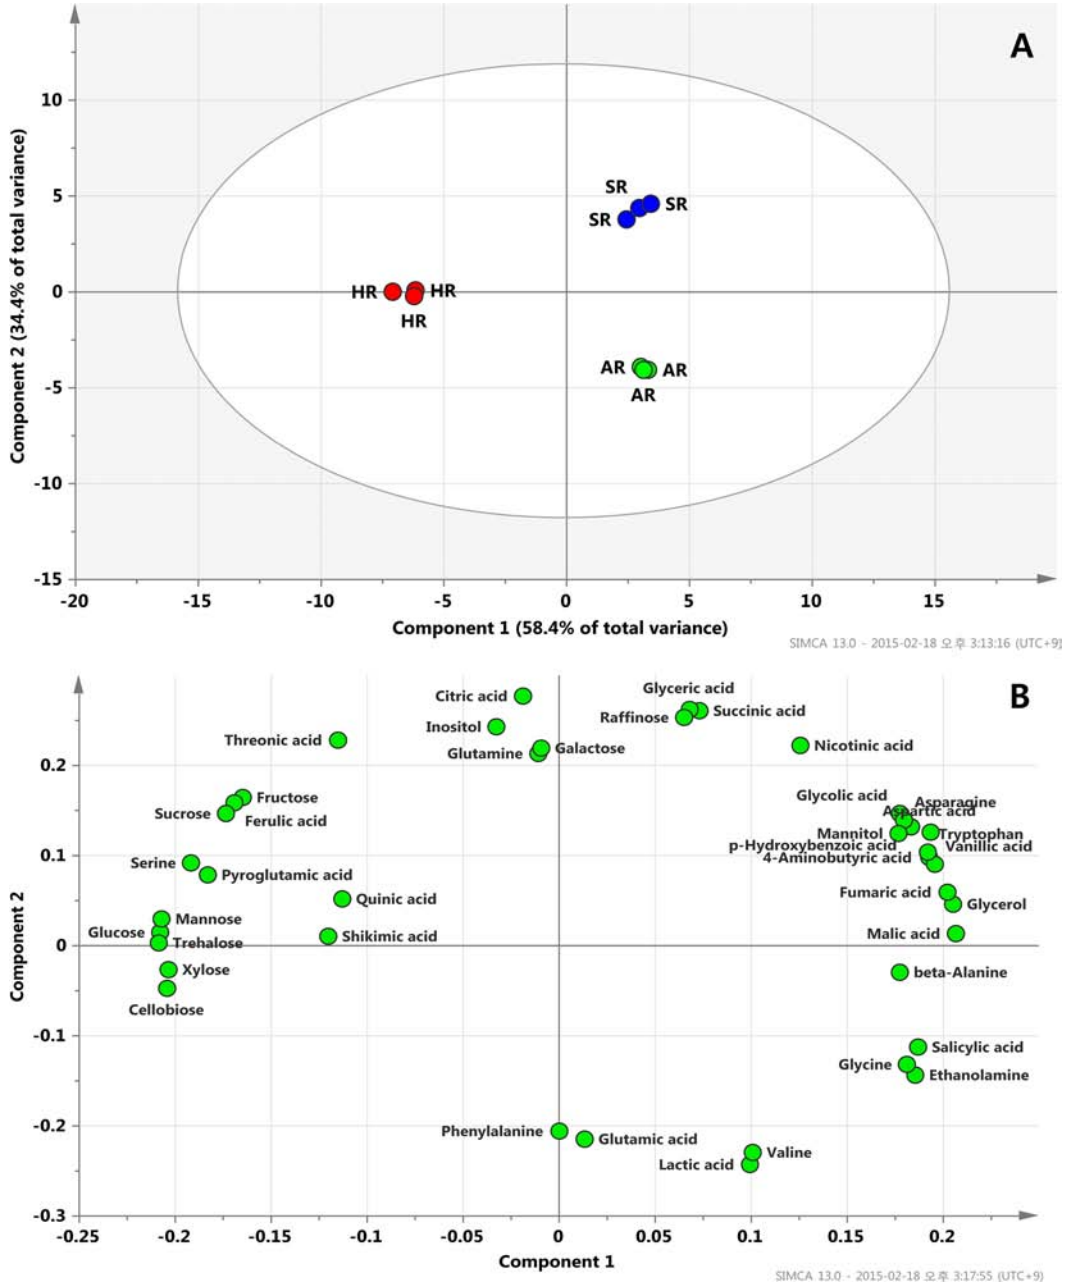

Figure 4. Scores (A) and loading plots (B) of principal components 1 and 2 from the PCA results obtained from polar metabolite data for different types of roots from *A. membranaceus*. AR, adventitious root; SR, seedling root; HR, hairy root.

PCA was used to explore the data structure obtained by GC-TOF-MS. PCA reduces the dimensionality of complex data sets and thereby facilitates the visualization of inherent patterns in the data. PCA transforms the original variables, using an orthogonal linear transformation, to a new set of uncorrelated variables known as principal components (PCs). As shown in Figure 4, the first and second PCs of the PCA score plot represented 58.4 and 34.4% of the total variance of the samples, respectively. The variance of the differences among roots was successfully captured in the two PCs. The first PC resolved the metabolite profiles of HRs and other roots. The metabolomes between SRs and ARs were separated by PC 2. The loading plot of the PCA revealed the magnitude and direction of correlation of the original variables with PCs. Correlation analysis is a common statistical method used to establish relationships between metabolite signals belonging to a biological system.[37] Sugars such as glucose, fructose, mannose, and sucrose were clustered in the left of the loading plot, indicating that the level of sugars in HRs was higher than that in other roots. In plant systems, the building blocks for secondary metabolites are derived from primary metabolism. In this study, free glucose, a building block of CG, was higher in HRs, whereas CG content was lower in HRs than in SRs and ARs (Supporting Information 2). The loading plot of PC 2 indicated that a higher amount of phenylalanine was present in ARs than in SRs and HRs and that TCA-cycle intermediates such as citric acid and succinic acid were higher in SRs than in others. Phenylalanine is a major amino acid donor for the synthesis of CG. Thus, metabolomics can assist in dissecting the

DOI: 10.1021/acs.jafc.5b02525
J. Agric. Food Chem. 2015, 63, 8862−8869

mechanisms that regulate the conversion of primary metabolites into secondary metabolites in plants.

The objective of the present study was to examine an efficient root culture system for ASTs, calycosin, and CG accumulation and the levels of hydrophilic metabolites in different root types of *A. membranaceus*. The results indicate that the highest amounts of ASTs were produced in SRs of this plant with high expression levels of genes associated with this biosynthetic pathway. Also, we observed that ARs and HRs accumulate more CG than calycosin, but SRs showed the reverse. Totally, 40 metabolites were distinguished among three samples of *A. membranaceus*. We demonstrated that HRs were clearly separate from other root cultures because of the high levels of sugars and clusters derived from closely related biochemical pathways.

In vitro root culture has been considered as an alternative method to produce secondary metabolites based on year-round cultivation and high-level quality and quantity.[38] Many researchers have demonstrated new possibilities using in vitro cultures for accumulation of useful phytochemicals in plants. Development of an AR culure system could promote large-scale multiplication, strain improvement, and species conservation,[28] but optimal conditions are necessary to boost root biomass and secondary metabolites.[39−42] AR cultures from many plant species including *Raphanus sativus*,[43] *Panax notoginseng*,[44] *Cornus capitata*,[45] and *Rhus javanica*[46] have been conducted and cultured for production of valuable phytochemicals.[27] Total saponin and flavonoid contents of 40-day-old AR derived from *A. membranaceus* were shown to be higher than those of 1-year-old roots under field cultivation.[47] HR cultures offer a remarkable experimental tool to investigate the various sides of biosynthesis related to biologically effective compounds. Numerous successful examples for HR cultures have been based on phytochemical production from medicinal plants. Du et al.[48] have reported that AST-IV and polysaccharides are produced in HR of *A. membrananceus* on a large scale. Even though we demonstrated that SRs contain the largest amounts of ASTs, ARs or HRs of *A. membranaceus* are great materials for ASTs, calycosin, and CG production possibly using optimal conditions for yield.

also studied the relationship between the calcium content and hardness of cooked soybean cotyledons. PMEs are commonly present in plants and microorganisms such as fungi and bacteria.[8,9] Evidence indicates that pectins are synthesized and methylesterified in the Golgi and thereafter secreted into the cell wall in a highly methylesterified state.[10−12] Subsequently, they are deesterified by wall-associated PMEs that convert the methoxyl groups into carboxyl groups on the polygalacturonic acid chain and release both methanol and protons. It appears that most plant PMEs deesterify pectins in a blockwise fashion, e.g., linearly along the chain, which favors pectin gelation and concomitant cell wall stiffening due to the formation of cooperative Ca^{2+} crossbridges between free carboxyl groups of adjacent pectin chains.[13]

During the cooking process, it has been postulated that middle lamella pectin of the cell walls is depolymerized by β-elimination of methyl-esterified polygalacturonic acids, promoting an increase in cell separation, and this softens the tissues.[14] In legume seeds, tissue softening seems to be achieved mainly through the middle lamella polymer solubilization, which allows cell separation, producing a mealy texture.[15] However, no report has been found on the effect of endogenous PME on the hardness of cooked beans.

In this report, we discuss the role of an endogenous PME gene on the hardness of cooked beans, which has been demonstrated here in the soybean.

MATERIALS AND METHODS

Materials. An RIL population derived from a cross between two Japanese cultivars, Natto-shoryu and Hyoukei-kuro 3, was prepared according to a previously described method.[7] To survey the candidate genetic region and validate the effect of a major QTL (*qHbs3-1*), we selected a heterozygous plant of the fifth filial generation (F_5) from the RIL population using DNA markers in the region proximal to the QTL. The residual heterozygous line (RHL)[16] in the F_5 generation was self-fertilized, and the resultant F_6 plants were harvested individually in 2011. Furthermore, F_9 seeds showing different recombinant genotypes around the QTL region were obtained by self-fertilization and DNA-marker analysis, and F_9 plants were grown in the experimental field. Seeds were harvested from 1−7 F_9 plants for each genotype and were used for texture analysis of cooked beans. Another two F_2 populations derived from a cross between two cultivars, "Enrei" and "LD00-3309" and between "Satonohohoemi" and "Sakukei 98", were used to confirm the effect of the candidate gene in this report. Soybeans were planted and grown in the experimental field at NARO Institute of Crop Science (NICS), Ibaraki, Japan, in 2013 according to the method previously described.[7] The sowing date of Natto-shoryu, Hyoukei-kuro 3, and their progenies was June 25, and that of other cultivars was June 18. Soybean cultivars grown in different locations in 2013 were collected from Kumamoto (Southern area of Japan) and Akita (Northern region of Japan) prefectures as described in Table 1. The sowing date in Akita was June 4, and those in Kumamoto were July 2, 9, or 10. Mature seeds were harvested in October or November, according to the maturing time. Moisture contents of the seeds were from 8 to 12% (Table S1). Soybean seeds were stored at 4 °C until use. The hardness of the cooked soybean cotyledons was analyzed from April 4 to June 18 in 2014.

Texture Analysis of Cooked Beans. Cooked beans were prepared and the breaking stress of the cotyledons was measured according to methods described previously.[7] Briefly, 30 seeds were soaked in 100 mL of deionized water at 20 °C for 22 ± 2 h. Imbibed seeds were boiled for 10 min in 200 mL of deionized water in a 500 mL tall glass beaker (HARIO Ltd., Tokyo, Japan) using a hot stirrer (IKA RCT basic, IKA japan K.K., Osaka, Japan). After cooking, the seeds were cooled in water at room temperature and the water was drained well. The seed coat and embryo axis were removed from the

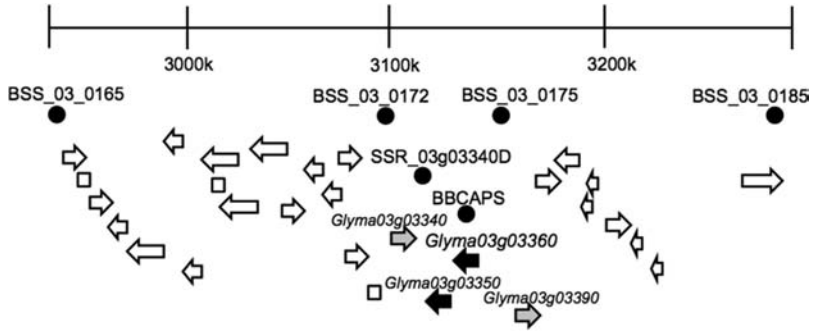

Figure 1. Locations of DNA markers (closed circles) and two genes (arrows in black; *Glyma03g03350* and *Glyma03g03360*) on chromosome 3. Physical positions on the chromosome are indicated above. SSR_03g03340D is located downstream of *Glyma03g03340* (an arrow in gray). BARCSOYSSR_03_0175 (BSS_03_0175) is located upstream of *Glyma03g03390* (an arrow in gray).

boiled seeds; then, the two cotyledons were separated from each other. The puncture strength was measured using a Rheoner RE-3305S texture analyzer (Yamaden Corp., Tokyo, Japan) fitted with a cylindrical probe (3 mm outside diameter) and a 2 kg capacity load cell. The adaxial (flat) side of a piece of cotyledon was placed facing downward on the stage of the analyzer, and the hardness was measured. The probe was operated at a distance of 2.45 mm and a speed of 1 mm/s. Puncture strength was determined as maximum force (pascals). The average score for more than 40 samples was used as an index of cooked seed hardness for each sample. The seed hardness measured by this method was positively correlated with the hardness of embryos ($r = 0.918$, $p < 0.001$) and that of whole beans ($r = 0.926$, $p < 0.001$) measured by the AACC approved method[17] after 40 min of cooking.

The 100-seed weight was calculated from the number and weight of air-dried seeds before soaking, and the water absorption ratio was calculated as the ratio of the seed weight after soaking to that before soaking.

DNA Isolation and Marker Analysis. Genomic DNA was isolated from young leaves of F_2 plants, F_9 plants, and cultivars (see Materials) using a previously described method.[7] Leaves were crushed in 400 μL of DNA extraction buffer (0.1 M Tris−HCl, pH 8.0; 0.05 M EDTA, pH 8.0; 0.5 M NaCl; 43.3 mM SDS; 10 mM dithiothreitol) with a SHAKE MASTER ball mill (Inter Bio Techno, Ltd., Tokyo, Japan), and homogenates were centrifuged at 2750*g* in a Himac CF 5RX centrifuge (Hitachi, Ltd., Tokyo, Japan) for 10 min. An aliquot of the supernatant was mixed with 100 μL of 5 M potassium acetate buffer and incubated at 5 °C for 10 min. The samples were centrifuged again at 2750*g* at 5 °C for 10 min. After centrifugation, 300 μL of the supernatant was gently mixed with 300 μL of isopropyl alcohol and incubated at 5 °C for 10 min. The total DNA was precipitated and segregated by centrifugation at 2750*g* at 5 °C for 10 min, then washed with 500 μL of 99.5% ethyl alcohol, and suspended in distilled water.

The four SSR markers used in this study were BARCSOYSSR_03_0165, BARCSOYSSR_03_0172, BARCSOYSSR_03_0175, and BARCSOYSSR_03_0185, all located on chromosome 3.[18] These markers are described in Table S2 and can be obtained from Soybase (http://soybase.org/).[19] An SSR marker located between BARCSOYSSR_03_0172 and BARCSOYSSR_03_0175 was designed and named "SSR_03g03340D". Polymerase chain reaction (PCR) was performed, and the products were analyzed by electrophoresis according to the methods described previously.[7] Amplification was performed with an initial incubation for 2 min at 95 °C, then 33 cycles of 1 min at 92 °C, 1 min at 58 or 60 °C (depending on the primers used), and 1 min at 68 °C, followed by a final incubation for 5 min at 72 °C. PCR products of SSR_03g03340D were determined using the LabChip GX electrophoresis system (PerkinElmer, MA, US).

DNA Sequencing. DNA fragments containing the open reading frame (ORF) regions of *Glyma03g03350* and *Glyma03g03360* were amplified by PCR using genomic DNA as a template. Information about predicted ORF regions was obtained from Phytozome (http://www.phytozome.net/). The primers used for amplification are described in Table S3. PCR was performed in a 20 μL reaction volume using *LA Taq* Hot Start Version according to the manufacturer's instruction (TAKARA, Shiga, Japan). Amplification was performed using the same conditions as described above. For DNA sequence analysis, DNA fragments were purified with a MonoFas DNA purification kit I (GL Sciences Inc., Tokyo, Japan) after electrophoresis using agarose gel. Sequencing reactions of purified PCR products were done with Big Dye terminators (Applied Biosystems, Foster City, CA). DNA sequences were determined with an ABI 3730xl automated sequencer (Applied Biosystems).

cDNA Synthesis and RT-PCR. Total RNA extracts were prepared using RNeasy Plant Mini Kit (Qiagen, Tokyo, Japan), followed by treatment with DNaseI using Turbo DNA-free Kit (Life Technologies Japan, Tokyo, Japan). For each sample, 1.5 μg of extracted RNA was reverse-transcribed using SuperScript Vilo cDNA Synthesis Kit (Life Technologies Japan). The RT-PCR mixture contained 1 μL of cDNA synthesis reaction mixture, 450 nM of each primer, and 10 μL of 2× KAPA2G Robust HS RM with dye (NIPPON Genetics Co, Ltd., Tokyo, Japan). Amplification was performed with an initial incubation for 3 min at 95 °C, then 33 cycles of 15 s at 95 °C; 10 s at 56, 58, or 60 °C (depending on the primers used); and 10 s at 72 °C.

Measurement of Calcium and Magnesium. Soybeans were ground into powder and 0.25 g of the sample was placed in a porcelain crucible for ashing at 500 °C for 16 h. After ashing, samples were extracted with 1 N HCl and diluted to 100 mL total. The contents of calcium and magnesium in the diluted samples were determined using ICP-AES Optima 4300 DV (PerkinElmer Japan Co., Ltd., Kanagawa, Japan).

Statistical Analysis. Statistical analysis was performed using the SPSS software package (version 22, IBM Japan, Tokyo, Japan).

RESULTS AND DISCUSSION

A *qHbs3-1* Candidate Gene and DNA Sequence Analysis. In our previous study, the analysis using progeny of the RHL derived from a cross between two Japanese cultivars, Natto-shoryu and Hyoukei-kuro 3, delimited the candidate region for *qHbs3-1* between BARCSOYSSR_03_0165 and BARCSOYSSR_03_0185, a physical distance of approximately 330 kb according to the information from Phytozome (Figure 1).[7] For further analysis to identify the gene responsible for *qHbs3-1*, F_7 and F_8 RHL progenies showing different recombinant genotypes of BARCSOYSSR_03_0165, BARCSOYSSR_03_0172, BARCSOYSSR_03_0175, and BARCSOYSSR_03_0185 were selected and the F_9 RHL progenies were obtained by self-fertilization. An SSR marker SSR_03g03340D and a cleaved amplified polymorphic sequence (CAPS) marker "BBCAPS" were further designed (Figure 1, Table S2). The breaking stress of cotyledons was compared among RHL progenies showing

Average of breaking stress of RHL progenies	A genotype	1019^{ns}	1198^{ns}	1198^{ns}	1460***	1296*	1227*	
	B genotype	1172	1031	1031	999	1006	1002	

[a]A indicates the same genotype as Natto-shoryu. B indicates the same genotype as Hyoukei-kuro 3. Breaking stress values more than 1200 kPa are shown in white type with a black background. *, ***: Values are significantly different from the B genotype at the 0.05 or 0.001 level, respectively. ^{ns}No siginificant difference was detected.

different genotypes of BARCSOYSSR_03_0165, BARCSOYSSR_03_0172, SSR_03g03340D, BARCSOYSSR_03_0175, BARCSOYSSR_03_0185, and BBCAPS. The graphical genotypes of RHL progenies and their breaking stress values indicated that *qHbs3-1* is located in the region between SSR_03g03340D and BARCSOYSSR_03_0175, where 2 genes, *Glyma03g03350* and *Glyma03g033360*, were presumed to be encoded (Soybase, Table 2 and Figure 1). BBCAPS, which is located between SSR_03g03340D and BARCSOYSSR_03_0175, detects a single base substitution of *Glyma03g03360* in Hyoukei-kuro 3 (Figures 1 and 2a, Table S2). The PCR products using BBCAPS primers were digested with a DNA restriction enzyme *Bst*1107I, which detects the GTATAC sequence of *Glyma03g03360* in Natto-shoryu (Figure 2b). All RHL progenies showing the same genotype as Hyoukei-kuro 3 at BBCAPS showed higher breaking stress values than that of Hyoukei-kuro 3, probably due to the effect of *qHbs6-1*, because all the RHL progenies examined showed the same genotypes as Natto-shoryu at SSR markers around the *qHbs6-1* region, Satt 100, Satt 277, and Satt 307.[7] Minor QTLs[7] may potentially affect the breaking stress values of RHL progenies.

The DNA sequence of the ORFs of the two genes *Glyma03g03350* and *Glyma03g03360* was analyzed. Primers used for amplification of exons of these genes are described in Table S3. Only the sequence in the third exon of *Glyma03g03360* showed a difference between Natto-shoryu and Hyoukei-kuro 3: a single DNA substitution detected by BBCAPS, resulting in a truncated protein in Hyoukei-kuro 3 (Figure 2a,b). Glyma03g03360 is predicted to be a pectin methylesterase (PME) with an inhibitor domain at the N terminus[20,21] according to Soybase. Glyma03g03360 of Hyoukei-kuro 3 is presumed to lack amino acids that are catalytically important (Figure 2a,b).[22]

PMEs deesterify pectins in the cell wall, converting methoxyl groups into carboxyl groups on the polygalacturonic acid chain and releasing both methanol and protons. The carboxyls can be cross-linked by calcium, which structurally rigidifies the cell wall.[23,24] Transcripts of *Glyma03g03360* were detected in embryo and seed coats at 45 days after anthesis (DAA) from Natto-shoryu by RT-PCR (Figure 3a). The transcripts were also detected in embryo from Hyoukei-kuro 3, although the band that was observed was fainter than that for Natto-shoryu (Figure 3b). It has been reported that mutation in the coding region affected the stability of mRNA and reduced the amount of transcripts, because premature termination of gene translation occasionally leads to transcript instability.[25] It is also possible that the amount of transcripts was affected by mutation in the promoter or flanking regions of *Glyma03g03360*. These results suggested that deesterification of pectins in the cell wall

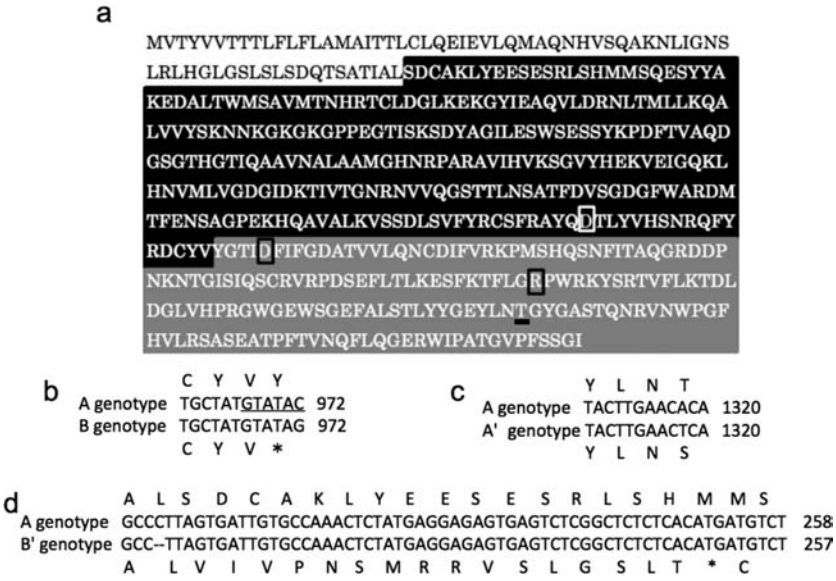

Figure 2. (a) Predicted amino acid sequence of Glyma03g03360 of Natto-shoryu (A genotype). Quadrilaterals indicate the position of catalytically important residues.[22] Glyma03g03360 of the B genotype lacks the sequence in gray. Glyma03g03360 of the B′ genotype lacks the sequence in gray and black. Underlined T indicates a single base substitution of the A′ genotype. (b) Comparison of DNA and predicted amino acid sequences of Glyma03g03360 between genotypes A and B. The nucleotides included in a *Bst*1107I restriction site are underlined. (c) Comparison of DNA and predicted amino acid sequences of Glyma03g03360 between genotypes A and A′. (d) Comparison of DNA and predicted amino acid sequences of Glyma03g03360 between genotypes A and B′.

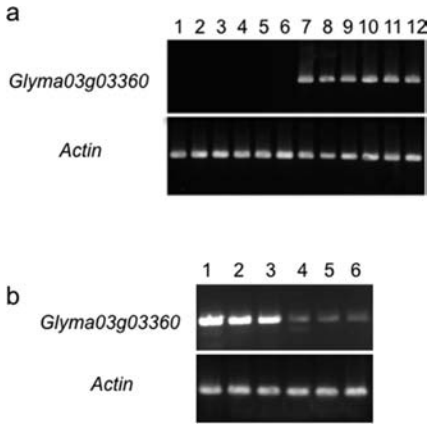

Figure 3. (a) RT-PCR analysis of RNA isolated from leaves (lanes 1−3), embryos 21 days after anthesis (DAA; lanes 4−6), embryos 45 DAA (lanes 7−9), and immature seed coats 45 DAA (lanes 10−12) from Natto-shoryu. RNAs were isolated from three independent tissues. Specific primers for *Glyma03g03360* (upper) and *actin* control (lower) were used. (b) RT-PCR analysis of RNA isolated from embryos 45 DAA from Natto-shoryu (lanes 1−3) and Hyoukei-kuro 3 (lanes 4−6). RNAs were isolated from three independent tissues. Specific primers for *Glyma03g03360* (upper) and *actin* control (lower) were used.

is preceded by the activation of Glyme03g03360 at the late stage of seed development, in both the embryo and seed coat.

Glyma03g03350 is a methionine aminopeptidase-like protein. In living organisms, proteins are synthesized with methionine as the first residue, which is specifically removed from the most mature proteins.[26−28] The free amino-terminal methionine is removed by methionine aminopeptidase. Soybase indicates that Glyma03g03350 is expressed in all tissues examined, including the leaf, flower, pod, seed, root, and nodule. Transcripts of *Glyma03g03350* were detected in embryos both from Natto-shoryu and from Hyoukei-kuro 3, even though the intensities of the bands were different among samples (Figure S1).

Cultivar Differences in the Cooked Seed Hardness and Genotype of *Glyma03g03360*. Genotypes of *Glyma03g03360* and breaking stress of cotyledons were further analyzed using 24 cultivars grown at different locations in 2013 (Table 1). CAPS analysis using the BBCAPS marker in the 24 cultivars resulted in three patterns of DNA fragments (Figure 4): one shows a single, main band designating Hyoukei-kuro 3; another shows two main bands and a minor band designating Natto-shoryu; and the last shows only two main bands. The sizes of the larger main bands were different between the latter two fragment patterns.

DNA sequence analysis indicated that four polymorphisms exist in *Glyma03g03360* among the 24 cultivars, and we named them A, A′, B, and B′. Polymorphisms A and B are the same as that of Natto-shoryu and Hyoukei-kuro 3, respectively. Polymorphism A′, which shows the third pattern by BBCAPS, contains a single base substitution in exon 3, resulting in an amino acid substitution from threonine to serine (Figure 2a,c). Because this amino acid is not predicted to be important for enzymatic activity,[22] Glyma03g03360 of this group is presumably active. Polymorphism B′, which also shows the third pattern by BBCAPS and the same pattern as polymorphism A′, contains a single base deletion in exon 1, resulting in a truncated protein. This protein is also presumed to lack amino acids that are catalytically important. (Figure 2a,d). The upper primer sequence of BBCAPS is located in the intron of *Glyma03g03360* between the second and third exons, and the lower primer sequence is located in the third exon. The expected sizes of *Bst*1107I restriction fragments from the sequence data are 434 bp and 233 bp for Natto-shoryu. The fragment pattern shown in Figure 4 agrees with the sequence data. The size difference in the larger main bands between A, and A′ and B′ genotypes is probably due to the difference in the

intron sequence. The genotypes of *Glyma03g03360* for the full 24 cultivars are described in Table 1 and Figure 4.

The breaking stress values of cotyledons were compared using the 22 cultivars (without Natto-shoryu and Hyoukei-kuro 3) grown in different locations described in Table 1. The averages of these values were 1572, 1568, and 1456 kPa for A or A′ genotypes in Ibaraki (NICS), Kumamoto (KARC), and Akita (TARC), respectively. The averages of the values were 979, 1117, and 870 kPa for B or B′ genotypes in Ibaraki, Kumamoto, and Akita, respectively (Figure 5). Statistical

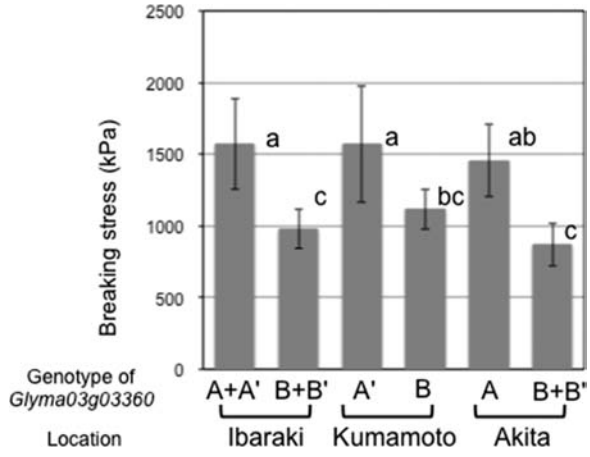

Figure 5. Averages of the breaking stress for A, A′, B, and B′ genotypes. Different letters indicate a significant difference at the 0.05 level by Tukey's test. Bars indicate SD.

analysis indicated that the breaking stress of A and A′ genotypes is significantly different from that of B and B′ genotypes in each location. However, there was no significant difference shown between the A genotype and the A′, or between the B genotype and the B′ (data not shown). These results indicated that Glyma03g03360 significantly affects the cooked seed hardness in many soybean cultivars.

Phenotypic and Genomic Variation of an F_2 Population from Enrei and LD00-3309, and Satonohohoemi and Sakukei 98. The breaking stress of cotyledons and genotypes of *Glyma03g03360* were analyzed using F_2 populations from a cross between Enrei (B genotype) and LD00-3309 (A genotype), and between Satonohohoemi (B genotype) and Sakukei 98 (A′ genotype). The averages of the breaking stress values were 1467 and 1059 kPa for progenies from Enrei and LD00-3309 with an A genotype and those with a B, respectively. The breaking stress of progenies from Enrei and LD00-3309 showing the A genotype was significantly higher than that of the progenies showing the B genotype ($p < 0.05$, Figure 6a). The breaking stress of progenies from Satonohohoemi and Sakukei 98 showing an A′ genotype was significantly higher than that of the progenies showing a B genotype ($p < 0.05$, Figure 6b). Moreover, all the progenies of the A′ genotype showed breaking stress values higher than those of the B genotype. From these results, we concluded that *Glyma03g03360*, a PME homologue, is most certainly *qHbs3-1*.

Effect of Seed Size, Water Absorption Ratio, and Calcium Content on the Cooked Seed Hardness. Negative correlations between cooked seed hardness and 100-seed weight or degree of water absorption have been reported.[29,30] However, no significant negative correlation between the breaking stress and 100-seed weight or water absorption ratio was detected using RHL populations from Natto-shoryu and Hyoukei-kuro 3 ($n = 24$), which showed no significant difference in the 100-seed weight and the water absorption ratio between progenies of the A genotype and those of the B genotype (Table 3). In contrast, statistical analysis using soybean samples described in Table 1 indicated that the 100-seed weight and water absorption ratio are significantly correlated with the breaking stress value ($r = -0.408$ and -0.391, respectively; $p < 0.01$, Table 4). Soybeans with the A and A′ genotypes showed 100-seed weight and water absorption ratio significantly lower than those with B and B′. The averages of the 100-seed weight were 24.69 and 33.24 g for A + A′ genotypes and B + B′ genotypes, respectively. The

,,***: Significant at the 0.05, 0.01, or 0.001 level, respectively.

averages of the water absorption ratio were 2.26 and 2.33 for A + A′ genotypes and B + B′ genotypes, respectively. No significant correlation between the breaking stress and 100-seed weight or water absorption ratio was detected within the A + A′ genotypes and within the B + B′ genotypes. One possible explanation for the discordance in the relationship between the 100-seed weight or the water absorption ratio and breaking stress is that Glyma03g03360 may have an effect on the 100-seed weight and the water absorption ratio, which are also affected by other factors. Another possibility is that a gene close to the *qHbs3-1* may have an effect on the 100-seed weight and the water absorption ratio, with no difference in amino-acid sequence and expression between Natto-shoryu and Hyoukei-kuro 3. In our previous study, no QTL was identified in the same chromosomal region as that of *qHbs3-1* for 100-seed weight or water absorption ratio using an RIL population derived from a cross between Natto-shoryu and Hyoukei-kuro 3, although the 100-seed weight of Hyoukei-kuro 3 was more than 4 times higher than that of Natto-shoryu.[7]

It has been reported that a PME inhibitor plays a role in the early stage of radicle emergence.[31] Glyma03g03360 likely has a role in the rigidification of the cell wall and elongation of the cell through PME activity, which may partly affect 100-seed weight and water absorption ratio. Seed weight, also characterized as seed mass or seed size generally, has been widely accepted as a complex trait controlled by polygenes.[32] Hemicellulose content of seed coat fractions, particularly xylans, has been reported to be correlated with water uptake ratio and occurrence of hard seeds (stone seeds).[33]

Calcium content was significantly correlated with breaking stress using soybean samples described in Table 1 (r = 0.424, p < 0.01, Table 4). Soybeans of A and A′ genotypes showed a correlation between calcium content and breaking stress (r = 0.702, p < 0.001, Table 4 and Figure 7) higher than those of B and B′ genotypes (r = 0.457 p < 0.01, Table 4, and Figure 7). These results imply that the Ca^{2+} crossbridges between free carboxyl groups of adjacent pectin chains play an important role in the cooked seed hardness of soybeans. B and B′ genotypes also showed a significant correlation between calcium content and breaking stress, probably due to the expression of the other PME genes. According to SoyBase, more than 100 PME-like

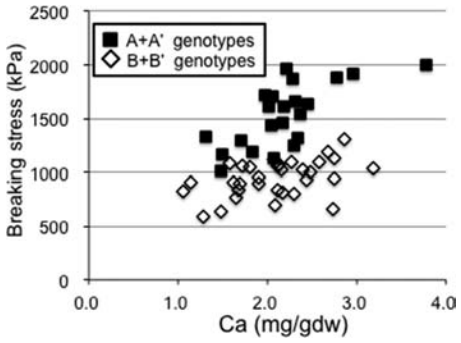

Figure 7. Correlation between calcium content and breaking stress of cotyledons of cultivars with an A or A′ genotype (black squares) and those with a B or B′ genotype (white rhombuses).

genes are found in soybean. Magnesium was also significantly correlated with breaking stress (r = 0.309, p < 0.05, Table 3). Magnesium can cross-link the carboxyl groups of pectins in a similar manner. Magnesium content showed less correlation with breaking stress than calcium, probably due to less variation of magnesium content than that of calcium content (Table 5).

Table 5. Average, Standard Deviations (SDs), and Coefficients of Variations (CVs) of Calcium and Magnesium Contents

		all samples (n = 54)	A+A′ genotypes (n = 22)	B+B′ genotypes (n = 32)

Sajjaanantakul et al. demonstrated that β-elimination of pectins was primary responsible for the heat degradation at pH 6.1 and that the rate of the β-eliminative cleavage of the prepared pectin depended on the degree of esterification.[34] It has been proposed that a decrease in degree of methylesterification necessitates both endogenous and exogenous calcium to form Ca^{2+} crossbridges between the free carboxyl groups of adjacent pectin molecules.[35] Because Ca^{2+} and Mg^{2+} are bound to protein and/or phytate,[36−38] other mechanisms in the relationship between the calcium and/or magnesium contents and the hardness of cotyledons may possibly be involved. Further studies are required to clarify the relationship between the calcium content in soybean and the degree of methylesterification.

In this study, we conclude that *Glyma03g03360*, a PME homologue, is *qHbs3-1*, a stable QTL for hardness of cooked soybean cotyledons. The contribution of the F_5 generation grown in 2010 to the total phenotypic variance of *qHbs3-1* was 47.4% and that of the F_6 generation grown in 2011 was 44.3%.[7] No QTL was identified in the same chromosomal region as that of *qHbs3-1* for 100-seed weight, also implying that *Glyma03g03360* is useful for the improvement of soybean cultivars through breeding, because larger seeds are preferable for nimame, while smaller seeds are preferable for natto. DNA markers used in this study would be useful both for DNA marker-assisted selection and for the evaluation of seed quality, because it is otherwise time-consuming and laborious to evaluate cooked seed hardness. RT-PCR indicated that Glyma03g03360 is expressed both in embryos and seed coats (Figure 3), suggesting the possible effect of Glyma03g03360 on the texture of the seed coat, although it was not analyzed in this study. The mechanisms underlying how PME activity affects cooked seed hardness still remain to be clarified, although previous studies have shown that the demethylesterification of pectins has dramatic consequences on the rheological properties of the cell wall.[14,39] Hardness after cooking is also important for other beans, such as carioca bean,[40] fava bean,[41] and chickpea.[42] Further studies may help reveal ways to improve the quality of soyfoods and of food products of other beans.

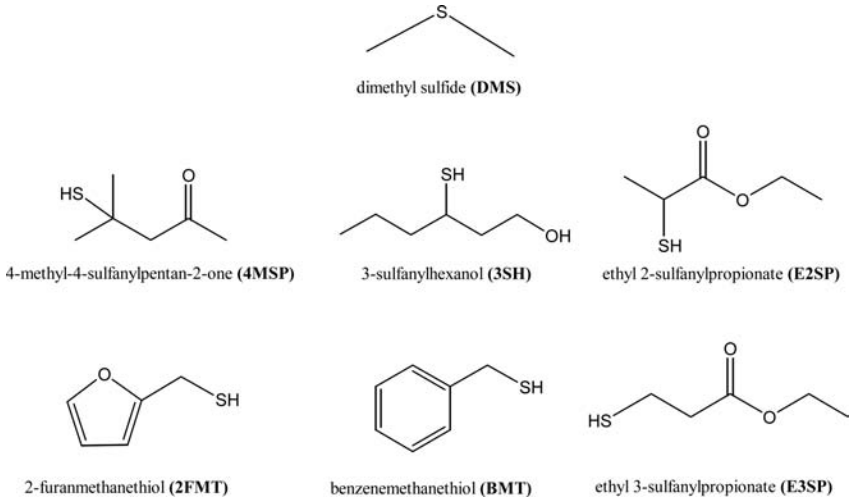

Figure 1. Chemical structures of the volatile sulfur compounds analyzed.

highly odor-active compounds with multiple influences on wine aroma. Originally associated with off flavors, they are now recognized as important contributors to wine aroma, depending on their concentrations, aromatic properties, and synergist effects.[5]

Among these compounds, DMS constitutes an interesting case since its influence on wine aroma is perceived either positively or negatively, depending on the concentration and type of wine.[9] In red wines, its positive contribution to the aroma of Cabernet Sauvignon wines has been reported,[10] and it is also known to accentuate truffle and undergrowth sensory attributes in wines.[9,11] Polyfunctional thiols are a series of volatile sulfur odorants that have received a great deal of research attention over the past decade. The group includes 4-methyl-4-sulfanyl-pentan-2-one (4MSP) and 3-sulfanylhexanol (3SH), associated with the typical fruity nuances in varietal aroma,[12−17] and 2-methyl-3-furanthiol (2M3F), benzenemethanethiol (BMT), ethyl 2-sulfanylpropionate (E2SP), and ethyl 3-sulfanylpropionate (E3SP), responsible for empyreumatic notes acquired during aging.[4,18−20] A sulfur-based furan, 2-furanmethanethiol (2FMT), belongs to another group of pleasant-smelling thiols formed in wine during oak-barrel aging and contributes to the toasty, cooked meat, and roasted coffee characteristics of oak-matured wines.[15,21,22]

Although the involvement of these volatile sulfur compounds in the pleasant truffle, toasty, and smoky aromas of aged fine wines is known and their aromatic descriptors overlap with the main characteristics of the olfactory representation of the aging bouquet concept,[7] this is the first time that a study was aimed to closely examine the combined impact of these aroma compounds on the sensory perception of the aging bouquet of red Bordeaux wines. More precisely, this study was designed to answer the following questions: (i) Do these selected volatile odorant sulfur compounds play a specific role in the typicality of the aging bouquet of red Bordeaux wines? (ii) How are their concentrations related to the occurrence, evolution, and intensity of the sensory nuances perceived in the aging bouquet of Bordeaux red wines during bottle aging?

This work was based on an approach combining sensory and quantitative chemical data, supported by several statistical methodologies, including multivariate tools, such as partial least square (PLS) analysis[23] and principal component analysis (PCA),[24] for relating sensory and compositional data.

MATERIALS AND METHODS

Chemicals. The chemical structures of the six volatile sulfur compounds are presented in Figure 1. Standard compounds were obtained from commercial sources as follows: DMS (>99%), thiophene (>99%), 2FMT (>98%), E3SP (>99%), BMT (>99%) 3SH (>98%), 6-sufanylhexanol (6SH; 97%), L-cysteine (98%), sodium acetate trihydrate (99%), and *p*-hydroxymercuribenzoic acid (*p*-HMB; > 95%) were supplied by Sigma-Aldrich (Saint-Quentin-Fallavier, France). E2SP (>98%) was obtained from Lancaster (MA, USA), 4MSP (1%; v/v ethylene glycol) solution from Interchim (Montluçon, France), and 3-methoxymethylbutanethiol (3MMB; 97%) from Oxford Chemicals (Hartlepool, United Kingdom).

Wines. During the first stage of the study, 24 commercial red wines were studied. They were selected by a panel of wine professionals with the aim of covering a wide range of red Bordeaux wines appellations, vineyards, and vintages. Nine different Bordeaux appellations were retained, from 19 vineyards and various vintages, from 1994 to 2005 inclusive were retained (Table 1). All these wines were oak-barrel matured before bottling.

In the second stage, three sets of wines were studied, each covering a 17- to 19-year period in the same vineyard. They represented three different Bordeaux appellations: Margaux (MX series: 7 wines, 19-year period, and vintages from 1995 to 2013), Pomerol (P series: 7 wines, 17-year period, and vintages from 1996 to 2012), and Saint-Emilion (SEM series: 8 wines, 18-year period, and vintages from 1995 to 2012).

The wines were tasted by two professionals of the tasting panel as soon as the bottles were opened to ascertain the absence of olfactory defects. None of the wines included in the tasting presented off-flavors, such as premature aging character or cork taint. All of the wines were tasted by the panel within 30 min after opening and subjected to both sensory and chemical analyses.

Sensory Analyses. *Professional Wine-Tasting Panel.* A panel of 13 wine professionals was recruited (4 women and 9 men; age range, 30−70; mean age, 42 years). All of the panelists were French native speakers, consumed wine regularly, worked in the Bordeaux area, and had considerable experience in tasting Bordeaux wines. They were informed about the context of the study but not given prior common training.

Experimental Design. The sensory experiments were organized in three different tasting sessions. During the first session, the aging bouquet typicality of the 24 selected wines was assessed, using the previously validated methodology.[7]

To avoid any aging bias, the 24 wines were randomized and separated into four sets of six wines. The panelists performed an ortho- and retronasal typicality evaluation task, according to their own concept of the wine aging bouquet. Wines (20 mL) were poured into clear INAO glasses with plastic covers, coded with three-digit random

[a]In bold are the 10 wines selected for sensory profiling on four aromatic descriptors of the wine aging bouquet.

numbers, and served in a different order to each taster. The presentation order was randomized among the panelists. Wine samples were tasted in a dedicated room at 18 °C (ISO 8589:2007). The instructions given were as follows: "*Imagine that you have to explain the aging bouquet of red Bordeaux wines to someone. For each wine tasted, please answer the following question: do you think this wine is a good or a poor example of reductive aging bouquet?*". Panelists answered on a 10 cm unstructured scale, ranging from "poor example" on the left to "good example" on the right (one scale per sample, one set of 6 wines per sheet). The distance between the left end and the score-mark made by each wine professional was measured and converted into a figure between 0 and 10, which corresponded to "the typicality score" (Table 1).

During the second tasting, a subset of 10 wines was chosen among the 24 wines evaluated in the first series, according to their degree of correspondence to the wine aging bouquet concept. Five wines were chosen among the group of highly typical wines and five from the less-typical group (Table 1 and Figure S1 in Supporting Information). The choice was designed to maximize the diversity of wine appellations.

In order to assess the reproducibility of the panel's perception, these 10 wines were subjected to the same typicality task as the larger group. After a 15 min break, each wine was subjected to sensory profiling to evaluate the intensity of the four aromatic descriptors previously identified as most representative of a typical aging bouquet: undergrowth, truffle, toasted, and fresh red- and black-berry fruit.[7] The panelists rated the intensity of these descriptors in each sample on a 10 cm unstructured scale, ranging from "not very intense" on the left to "very intense" on the right. The distance between the left end and the score-mark made by each wine professional was measured and converted into a figure between 0 and 10, indicating the sensory intensity of the corresponding aroma attribute. The panelists were not given prior common training.

The third tasting session involved three specific sets of wines, each from a single Bordeaux vineyard, comprising vintages from 1995 to 2013, inclusive. To avoid any vintage effect, these 22 wines were poured into black INAO glasses with plastic covers, coded with three-digit random numbers. They were presented to the panelists in a randomized order. As in the two previous sessions, wine samples were tasted in a dedicated room at 18 °C (ISO 8589:2007). The typicality task and sensory profiling were conducted in the same way as that in the previous session, with the empyreumatic note reminiscent of smoke added to the initial core group of four aromatic descriptors.

Quantitative Chemical Analysis. *DMS Analysis.* DMS was quantified by Solid Phase Micro Extraction coupled to Gas Chromatography–Mass Spectrometry (SPME-GC/MS), according to the method developed by Fedrizzi et al.,[25] but with slight modifications.

At the end of each tasting session, two 10 mL wine samples were taken from the bottles used for sensory assessment. Each 10 mL sample was added to a 20 mL headspace vial with 3 g of sodium chloride (final concentration 5 M) and 10 μL of internal standard thiophene solution (3.9 mM in ethanol solution, 50%, v/v). Extractions were performed using carboxen-polydimethylsiloxane-divinylbenzene (CAR-PDMS-DVB, 50/30 μm × 2 cm) (Supelco, Bellefonte, PA, USA) coated fiber. The basic program for the fiber selected consisted of swirling the vial at 500 rpm for 5 min at 35 °C, then inserting the fiber into the headspace for 30 min at 35 °C as the solution was swirled again, and then transferring the fiber to the injector for desorption at 250 °C for 5 min. Chromatographic analyses were carried out using an HP 5890 GC system (Agilent, Palo Alto, CA, USA) coupled to a HP 5972 quadrupole mass spectrometer (Agilent), equipped with a Gerstel MPS2 autosampler (Gerstel GmbH, Mulheim, Germany) and a BP21 capillary column (50 m × 0.32 mm, 0.25 μm; SGE). The carrier gas was Helium N55 with column head pressure at 7 psi. The oven temperature was raised from 32 °C (1 min) to 40 °C at a rate of 1 °C/min and then ramped at a rate of 10 °C/min to 220 °C (final isotherm for 15 min). The MS source temperature was set at 280 °C. DMS detection was performed in electron ionization (70 eV) and SIM mode, selecting the following ions at the corresponding m/z: 45, 47, and 62. The internal standard was identified using the following ions, m/z: 45, 58, and 84. Ions chosen for quantitation were m/z 62 and 84 for DMS and internal standard, respectively. Each wine was analyzed in duplicate.

Analysis of Polyfunctional Thiols. *Extraction.* Wine samples used for thiol analysis came from the bottles opened for the sensory evaluation. At the end of the tasting session, these bottles were refilled with N_2 and kept at 4 °C until extraction, which was carried out within a maximum of 48 h. The volatile thiols were specifically extracted by reversible combination with sodium *p*-hydroxymercuribenzoate (*p*-HMB), according to the methodology validated by Tominaga and Dubourdieu,[22] with some modifications.

p-HMB solution (7.5 mL, 2 mM in 0.1 M Tris) was added to 50 mL of wine containing 50 nmol 3MMB and 6SH as internal standards. Samples were adjusted to pH 7 and subjected to magnetic stirring for 10 min. The wine samples were then percolated on a Dowex column (Dowex 1 × 2, 50–100 mesh, 1.5 × 3 cm; Acros Organics, Noisy-le-Grand, France) previously reactivated using 0.1 M hydrochloric acid solution. The column was rinsed with 50 mL of sodium acetate buffer (0.1 M, pH 7). The volatile thiols were released from the thiol-*p*HMB conjugate fixed on the column by 50 mL of cysteine solution (0.1 M, pH 7). The eluate containing the volatile thiols was collected in a 100 mL flask, and 0.5 mL of ethyl acetate was added. The final solution was extracted twice, using 4 mL and then 3 mL of dichloromethane with magnetic stirring (5 min at 500 rpm). The organic fractions obtained were collected, dried over anhydrous sodium sulfate, and concentrated to 50 μL under a gentle nitrogen stream. Duplicate extractions were performed on each wine sample.

GC/MS Analysis. The concentrates were injected into a gas chromatograph/mass spectrometer (GC/MS) within 24 h. Analyses were performed on an Optima-Wax capillary column (60 m × 0.25 mm, 0.25 μm, Macherey-Nagel, Hoerd, France), and an Agilent 6890 GC system (Agilent, Palo Alto, CA, USA) coupled to an HP 5973b series mass-selective detector (MSD, Agilent) was used. The carrier gas was Helium N55 with column-head pressure at 19 psi and injector temperature at 230 °C. The temperature program was as follows:

[a]In hydroalcoholic solution (12% v/v). [b]In wine. Letters following mean concentrations and the asterisk indicate significant differences at $p < 0.05$ using a Kruskal−Wallis test at a significance level of 95% among HTW and LTW and IW groups.

isotherm at 45 °C for 3 min, then raised to 212 °C at 5 °C/min, and then to 255 °C at 20 °C/min (final isotherm for 10 min). The MS source temperature was set at 250 °C. Quantitation was carried out in electron ionization (70 eV) and SIM mode, based both on the retention time of each compound and the selection of specific ions as follows (the quantifier ions are underlined): m/z 53, 81 and 114 for 2FMT, m/z 61, 88 and 134 for E2SP and E3SP (retention time: 20.28 and 24.25 min, respectively), m/z 91 and 124 for BMT, m/z 75, 99 and 132 for 4MSP, and m/z 100 and 134 for 3SH. All compounds were quantified using 3MMB as internal standard (m/z: 75, 100 and 134), except 3SH, which was quantified using 6SH (m/z: 101 and 116).

Statistical Analysis. Data obtained on the 24 wines in the first wine tasting session were compiled in a wines × judges matrix. A hierarchical cluster analysis (HCA), using the Ward method (dissimilarity criteria), was also applied to the wine typicality score. This methodology was used to measure the degree of similarity among wine samples and sort them according to their typicality score. A Kruskal−Wallis nonparametric statistical test was applied to the three HCA clusters of red Bordeaux wines (less -typical, intermediate, and highly-typical wines) for all the quantitative variables (aroma compound concentrations, typicality scores, and aromatic descriptor intensities), using the Dunn test at a significance level of 95%. A PLS regression was applied to the wine age and typicality score (Y) over the concentration of sulfur odor active compounds (X). Components were added according to the Q^2 criterion, explained by Tenenhaus et al.,[23] with a confidence interval of 95%.

For the sensory profile test on the subset of 10 wines, descriptor intensities were mean-centered per wine professional and scaled to unit variance. A Mann−Whitney nonparametric statistical test at a significance level of 95% was applied to differences in the less- and highly typical wines clusters. Data on the 22 red Bordeaux wines studied in the second stage were analyzed using PCA. For each wine, the correlation matrix included mean values for the intensity of each aromatic descriptor, typicality, and DMS, 2FMT, and 3SH concentrations. Pearson product − moment correlations were also computed among typicality, aromatic intensity ratings, and aroma compounds concentrations at a significance level of $\alpha = 0.05$.

All statistical analyses were conducted using XLSTAT software (Addinsoft, Paris, France, 2015, version 17.1).

RESULTS AND DISCUSSION

Identification of Sulfur Odorants as Key Compounds in the Wine Aging Bouquet. The initial aim of the first wine tasting was to classify the 24 9- to 20-year-old red Bordeaux wines according to their typicality score (Table 1). Wines were clustered into three main groups by HCA (Figure S1, Supporting Information). Cluster 1 consisted of 10 wines with the highest average typicality scores (typicality range: 5.2−7.2), thus considered the most representative of the aging-bouquet concept. This group was called "highly-typical wines" (HTW). Cluster 3 consisted of 5 wines with the lowest average typicality scores (typicality range: 2.4−4.3), described as "less-typical wines" (LTW). Finally, cluster 2 included 9 wines that had no clearly defined correlation with the aging bouquet concept. As their typicality assessment varied drastically among the panel of wine professionals, they were considered "intermediate wines" (IW) in terms of aging bouquet (typicality range: 3.9−5.5). As previously reported[7] and in agreement with other studies on olfactory concepts in Chardonnay and Riesling wines,[26−28] no strict categorization was established of typical vs atypical examples of the wine aging bouquet, and typicality scores formed a gradient from less- to highly typical wines. This continuum was independent of vintage (in the range considered) and geographical origin, within the Bordeaux area. The results of the Kruskall-Wallis test showed that, whereas the HTW and LTW groups presented significant differences in typicality scores (test U; p-value = 0.001), no difference was detected between the LTW and IW clusters.

Following this clusterization of studied wines, sulfur volatiles were quantified in all groups to identify differences in the chemical profile of wines according to their representativeness of the wine aging bouquet. These DMS and volatile thiol quantitation data are summarized in Table 2, which is divided into three sections, corresponding to the HTW, IW, and LTW groups, according to HCA typicality rankings. DMS levels in the wines ranged from 23 to 146 μg/L, in agreement with previous published data on aged wines.[2,10,29,30] Interestingly,

[a]Aromatic descriptors which discriminated significantly between highly- and less-typical wines are in bold. ** and *** indicate significant differences at p-value < 0.01 and p-value < 0.001, respectively, using a Mann−Whitney test at a significance level of 95%.

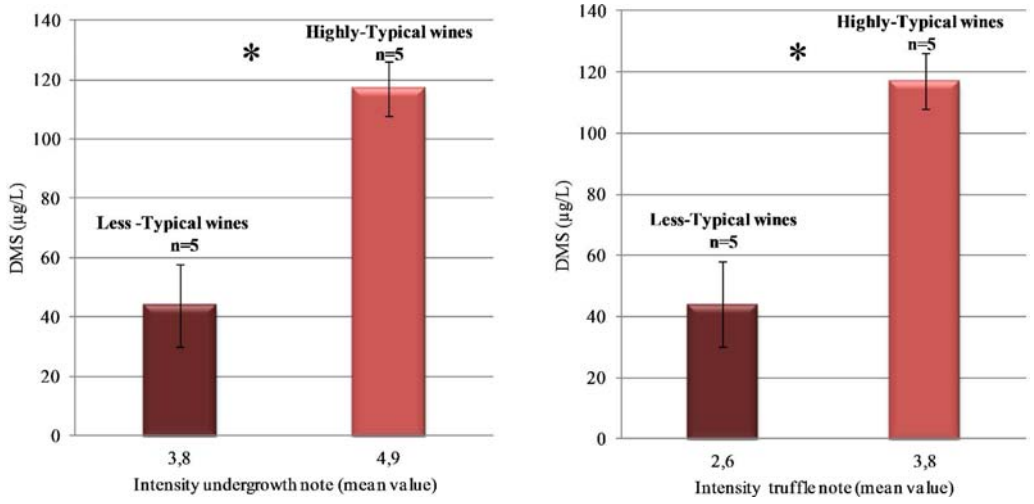

Figure 2. Mean DMS concentrations (±confidence interval) according to the typicality classification, applied to a selected set of 10 red Bordeaux wines. * indicates a significant difference using a Mann−Whitney test at a significance level of 95%.

DMS levels were significantly higher in the HTW group (test U; p-value = 0.014), with concentrations up to twice those found in the LTW group (mean values: 101 µg/L and 51 µg/L, respectively, Table 2). Except for one wine, all DMS concentrations exceeded their perception threshold in red wine (Table 2). Even if the perception threshold concept is currently subject to debate and does not necessarily account for the way complex interactions in odorant mixtures impact the perception of individual compounds,[6,31,32] the high DMS levels assayed compared to its olfactory detection threshold suggested that this compound contributed directly to the aromatic features of the wine aging bouquet. DMS was previously found to enhance truffle and undergrowth aromas when 100 µg/L was added to Syrah wines.[11] It was also shown to accentuate the fruity notes in some high-quality red wines, via complex interactions with other volatile compounds, including C13-norisoprenoids[32,33] and esters.[34] Furthermore, DMS has been reported to contribute a noticeable complexity to the aroma of aged wines.[35−37]

Aromatic profiling was carried out by the wine professional panel on a subset of 10 wines, chosen from among the 24 wines tasted during the typicality task (5 wines from the HTW group and 5 from the LTW group (Table 1). Table 3 shows their aromatic intensities for undergrowth, truffle, toasted, and fresh red- and black-berry fruit attributes. Undergrowth and truffle were the two descriptors that significantly differentiated between the highly- and less-typical groups (p-value = 0.007 and p = 0.001, respectively). Thus, the group of five HTW had significantly higher mean intensities for undergrowth and truffle (4.9 and 3.8, respectively) than the five LTW (3.8 and 2.6, respectively). As shown in Figure 2, when these sensory results were associated with quantitative DMS data, the five HTW also had significantly higher DMS concentrations than the five LTW (mean values, 117 and 44 µg/L, respectively; p-value = 0.004). Besides, a significant correlation was observed for DMS concentrations and truffle note (r = 0.664; p-value = 0.022), whereas a slight correlation with the undergrowth attribute was found (r = 0.440, p-value = 0.04). Overall, the current results demonstrated that high DMS levels, in the vicinity of 100 µg/L, contributed to the expression of the wine aging bouquet and particularly its truffle and undergrowth aromas.

Volatile thiols, with the exception of E2SP, were present in all 24 red Bordeaux wines at concentrations above their olfactory detection thresholds (Table 2). Varietal polyfunctional thiols have been reported to make a relevant contribution to wine aroma and are noted for their low perception thresholds, with 4MSP and 3SH detectable in wine at concentrations in the ng/L range.[4,14,15,38−40] Quantitative analysis of the 9- to 20-year-old red Bordeaux wines considered here revealed that concentrations ranged from 3 to 20 ng/L for 4MSP and 100 to 634 ng/L for 3SH. As shown in Table 2, no significant difference in 4MSP concentrations was found in the wines, irrespective of their aging bouquet typicality classification. Hence, 4MSP was unlikely to have any relevant impact on the fruity aroma component of the wine aging bouquet.

In contrast, 3SH was found to discriminate significantly high typical from low typical wines (test U; p-value = 0.03) between the HTW and LTW groups. Indeed, 3SH concentrations in the HTW group reached twice those found in the LTW group (mean values: 431 ng/L and 206 ng/L, respectively). The

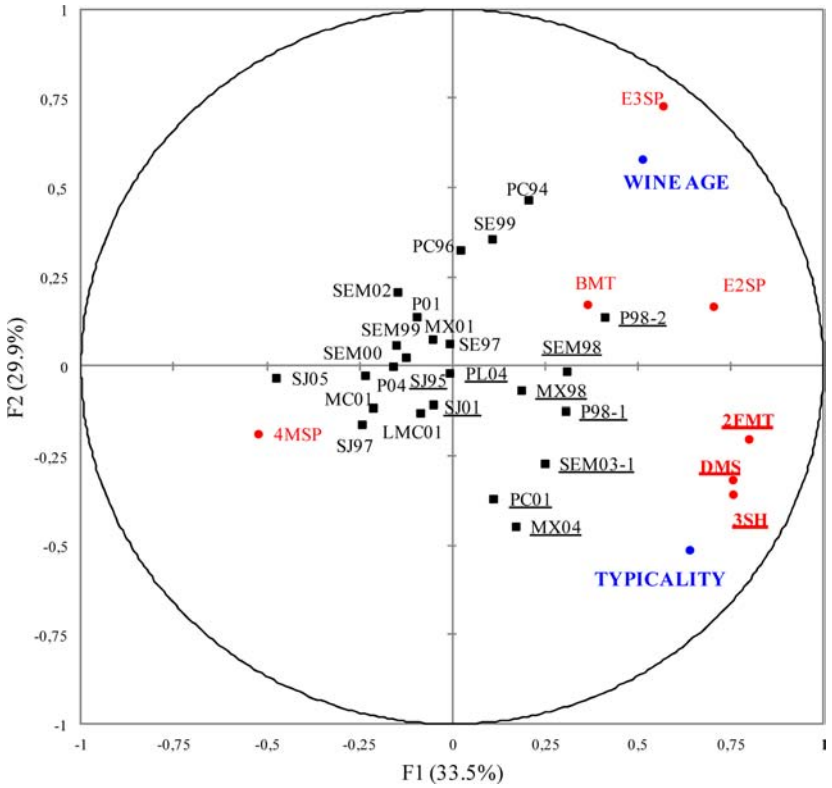

Figure 3. Partial least square (PLS) regression of the sulfur compounds studied (X matrix), typicality score, and wine age (Y matrix). Volatile compounds in bold were correlated with the typicality of the aging bouquet. Underlined labels correspond to wines identified in the HCA as highly typical wines (HTW).

presence of 3SH has been reported in red Bordeaux wines made from Cabernet Sauvignon and Merlot and, more recently, in wines made from other red grape varieties, such as Syrah and Grenache, at levels ranging from several hundred ng up to a few μg/L.[17,40] In addition, 3SH has been shown to enhance the perception of fruity aroma in rosé and red wines[17,40−43] and has also been reported to influence the overall aroma of aged red wines.[44] These results, based on quantitative data, are in agreement with a relevant involvement of 3SH in the overall aromatic balance of wines with an aging bouquet. However, its specific contribution to their fruity freshness requires further clarification, as no conclusive difference was detected between the HTW and LTW groups for fresh red- and black-berry fruit aromas (Table 3).

Three other nonvarietal volatile thiols, 2FMT, BMT, and E3SP, identified in red and white *Vitis vinifera* wines, represented a specific interest in the context of this study. It has been suggested that they contribute actively to the empyreumatic odors, evocative of smoke, toasty nuances, roasted coffee, and cooked meat, which are commonly acquired by fine wines during aging. Tominaga et al.[4,15,20] identified and quantified BMT and 2FMT for the first time in both white (Chardonnay, Semillon, Sauvignon Blanc, and Petit Manseng) and red (Merlot and Cabernet Sauvignon) wines, as well as 15-year-old Champagnes. E3SP has already been identified in both *Vitis labrusca*[45] and *Vitis vinifera* wines[19,46] and has also been shown to play a role in the empyreumatic character of old Champagne.[4] Quantitative data acquired in our study detected BMT and E3SP levels ranging from 1 to 22 ng/L and 864 to 2693 ng/L, respectively (Table 2). However, no significant difference in concentration was observed between the different clusters (Table 2). Hence, these two thiols were unlikely to have any relevant impact on the aging bouquet. In contrast, 2FMT discriminated significantly (test U; p-value = 0.019) between wines in the HTW and LTW groups. Concentrations in the 24 wines ranged from 14 to 150 ng/L (i.e., the same order of magnitude as those previously reported in red wines[15,22]), 2FMT levels were in the upper range of concentrations in the HTW group (mean value: 91 ng/L) compared to the LTW group (mean value: 35 ng/L), indicating its relevant involvement in the overall aromatic balance of wines with an aging bouquet. However, at this stage, the contribution of 2FMT to a specific sensory note requires further clarification, as no significant difference was determined between the HTW and LTW groups concerning the intensity of the toasted attribute (Table 3).

Sensory and quantitative chemical data were statistically processed using PLS regression at 5% significance. The first two components (Q^2 = 0.44) explained 33.5% of the volatile space variance and 29.9% of the typicality and wine age space variance (Figure 3). The typicality score and wine age were both projected on the positive side of the first component, in the same way as DMS, 2FMT, 3SH, BMT, E2SP, and E3SP. However, 4MSP was loaded on the negative side of the first component, indicating that this compound did not actively contribute to either the typicality score or wine aging characteristics. The second component contrasted wine bottle aging and typicality scores. This once again emphasized the good correlation between the typicality score and DMS, 2FMT, and 3SH concentrations. Wine age was correlated with E2SP and E3SP concentrations. BMT also followed the same trend but was positioned further from the correlation circle than E2SP and E3SP, indicating its minor importance as an aging marker. Besides, the regression coefficients for each volatile

J. Agric. Food Chem. 2015, 63, 8879−8889

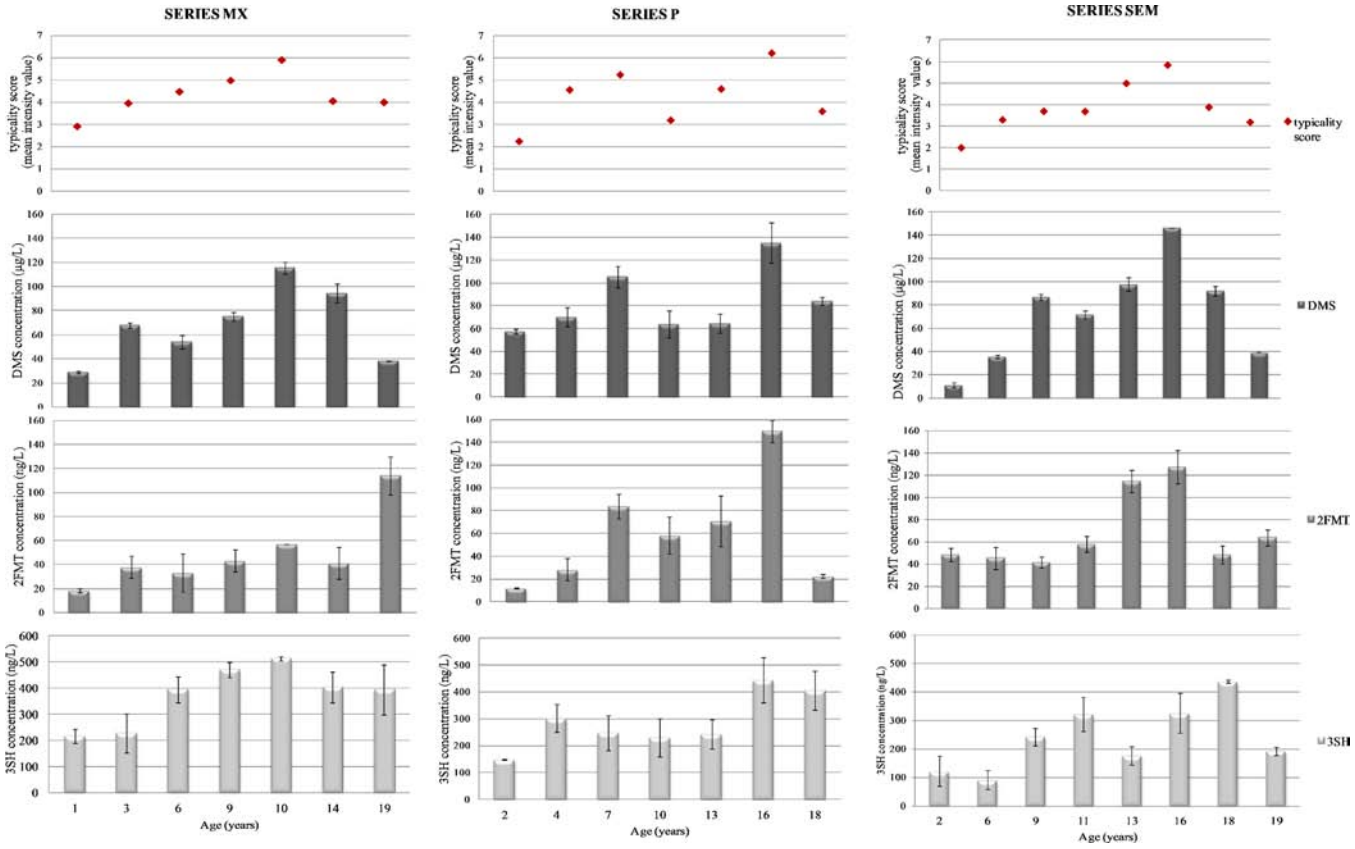

Figure 4. Variations in typicality scores and DMS, 2FMT, and 3SH concentrations during bottle aging for red Bordeaux wines from three vineyards in different appellations (series MX, P, and SEM).

sulfur compound on the first two components associated with the typicality score are presented in Figure S2 (Supporting Information). These coefficients measured the contribution of each variable in the regression model. DMS, 2FMT, and 3SH had positive regression coefficients on the first component and all loaded on the positive side on the same component (Figure 3). E3SP exhibited negative regression coefficients, indicating that this compound did not contribute to aging bouquet typicality. Finally, the regression coefficients of BMT, 4MSP, and E2SP were not significant, indicating that they probably had no influence on typicality scores. As seen in Figure 3, PLS analysis also validated the wine typicality clustering produced by HCA, indicating a good agreement between the two statistical methods in sorting the wines.

Results from this series of 24 red Bordeaux wines demonstrated that highly-typical wines contained significantly higher concentrations of DMS, 2FMT, and 3SH than the less-typical wines. PLS analysis did not reveal any strict correlation between aging bouquet typicality scores and the bottle age of the wines. To explore this point in greater detail, under conditions designed to minimize the variability factors linked to viticultural and enological practices, the next stage in this study focused on three series of wines (MX, P, and SEM), each came from a single vineyard. These three vineyards were selected from the HTW group as representative of different Bordeaux red wine appellations (MX04, P98-2, and SEM98; Table 1).

Whereas the high DMS concentrations in the HTW group were associated with intense truffle and undergrowth notes, no link was demonstrated between fresh-fruit and toasted attributes and 3SH and 2FMT concentrations. Insofar as thiol aromas were frequently associated with empyreumatic notes reminiscent of smoke (soot, smoke, and hearth),[4,20] also used to describe aging bouquet,[7] a sensory evaluation of this attribute was included in the second stage of the study.

Variations in Aging Bouquet Typicality Compared to DMS, 2FMT, and 3SH Levels during Wine Aging. Figure 4 shows the variations in aging bouquet typicality and DMS, 2FMT, and 3SH concentrations during bottle-aging.

Overall, typicality curves did not follow a linear pattern during aging but reached a maximum after 10 (MX) or 16 years (P and SEM) in bottles, with DMS, 3SH, and 2FMT levels following the same trend. The Pearson correlation test showed significant correlation between typicality ratings and DMS (r = 0.816, p-value = 0.0001), 2FMT (r = 0.630, p-value = 0.002) and 3SH levels (r = 0.609, p-value = 0.003). Indeed, in almost all cases, high levels of the three compounds were aligned with high typicality scores. In addition, with the exception of DMS in young wines, levels were above the perception thresholds in all wines analyzed. For the P series, the typicality curve, as well as the DMS and 2FMT concentration profiles, peaked in the 7-year-old wine, possibly revealing a specific vintage effect in this vineyard.

Interestingly, closer examination of the DMS profile revealed that high concentrations perfectly accounted for high typicality scores. Indeed, levels in all series increased during bottle aging, reaching a peak at 10 years for MX (115 µg/L) and 16 years for P and SEM (135 and 146 µg/L, respectively), while the secondary peak in the P series at 7 years reached 105 µg/L. These results are in agreement with those reported in the first stage of this study, highlighting a link between high DMS concentrations (around or above 100 µg/L) and high aging-bouquet typicality scores.

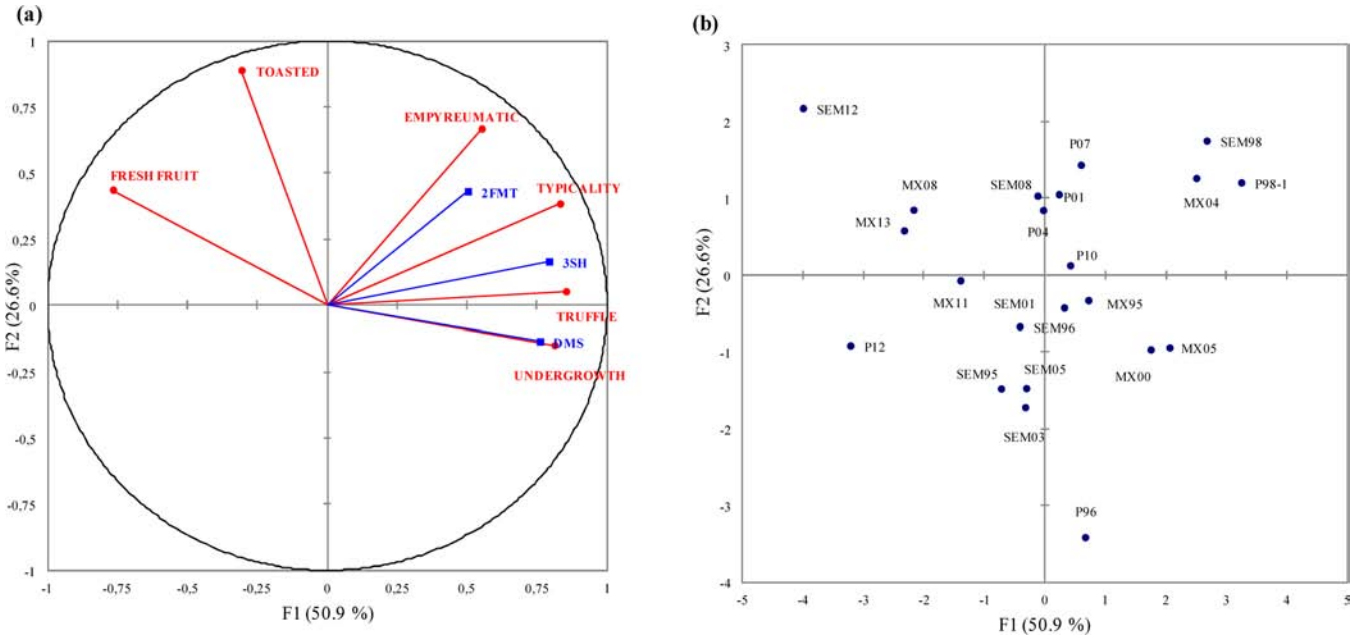

Figure 5. PCA correlation circle of (total variability: 77.5%) presenting typicality scores, aromatic descriptors, and chemical compounds (a) with the corresponding projection map of wines (b).

DMS is generated from several precursors during yeast fermentation but due to its high volatility, it is mainly stripped off during the first steps of winemaking so that its levels in young bottled wines are generally below its perception threshold.[9−11,46] This trend was also observed in this case, as the most recent vintages in all three vineyard series exhibited the lowest DMS concentrations.

An upward trend in free DMS concentrations in wine has frequently been described during aging.[9−11,36,47] The current results confirmed an increase in DMS concentrations during aging and highlighted a maximum DMS content (after 10 or 16 years in our case), which was always aligned with the maximum value for aging bouquet typicality. Different kinetics in the occurrence of this DMS peak are not surprising, bearing in mind the multiple factors reported to govern both PDMS content at bottling and DMS release and stability during bottle storage.[8,29,36,48]

Considering the evolution of 3SH and 2FMT levels in wines during aging, the results reported here revealed a less obvious correlation than for DMS between their concentrations and the corresponding typicality notes. In most cases, high thiol levels corresponded to high typicality scores, thus confirming the results obtained in the first part of the study. However, the highest thiol concentrations did not always correspond to the highest typicality scores, with the exception of the 16-year-old wine in the P series (Figure 4). Interestingly, 2FMT and DMS may have a combined effect on the typicality score: a comparison of 14- and 19-year-old wines in the MX series showed that they both maintained the same typicality note, as though the marked increase in 2FMT offset a corresponding, significant DMS loss.

While high thiol levels were generally associated with high typicality scores, the reported data tended to emphasize the influence of a subtle balance among the three sulfur volatiles. Hence, within the MX series, the 10-year-old wine exhibited the highest typicality score (5.9), as well as both the highest DMS (115 μg/L) and 3SH (494 ng/L) concentrations in the series, but only medium-range 2FMT (57 ng/L). The results obtained from the three different vineyards were not sufficiently comprehensive to draw clear-cut conclusions about the evolution of 3SH or 2FMT concentrations during bottle aging. Similarly, published data do not describe a clear trend in variations in these two thiols during wine aging. The 3SH content of red Bordeaux wines has been reported to decrease considerably during barrel aging.[41] However, under conditions that prevented a decrease in the reducing potential of the wine, 3SH was shown to be very stable,[49] but no significant correlation has been demonstrated between 3SH levels and bottle-aging time, in either wine or Champagne.[4]

2FMT is produced from furfural released from toasted oak via the yeast sulfur metabolism[49,50] and some published studies are in favor of its upward formation from furfural and hydrogen sulfide in the reductive atmosphere in bottles.[4] In our study, 2FMT levels tended to increase in the 3 series but with variable timing. The increase was observed at a later stage in the MX series, whereas it occurred earlier in the other two series and was followed by a marked decrease after 16 years. Such a decrease after a long period of bottle aging may be explained by the known reactivity of the thiol function with quinones and other reactive SH-bearing compounds in wine.

Figure 5a shows the loadings of typicality scores and sensory attribute intensities, as well as DMS, 2FMT, and 3SH levels of the first two components of the PCA. The first principal component explained 50.9% of total variance and was positively correlated with the typicality score. Furthermore, the loading plots for DMS, 2FMT, and 3SH were projected on the same positive side of the first axis and closed to the correlation circle, meaning that these three sulfur markers were well correlated with the typicality of the wine aging bouquet, thus confirming the data shown in Figure 4.

As far as aromatic intensities are concerned, the first principal component contrasted fresh-fruit and toasted notes with truffle, undergrowth, and empyreumatic notes. The latter attributes were loaded on the same positive side as the typicality score and sulfur compounds. The aromatic contribution of DMS to undergrowth and truffle notes, reported in the first part of this

study, was confirmed in the second stage since DMS well correlated with undergrowth (r = 0.743; p-value = 0.001) and truffle (r = 0.587; p-value = 0.004) notes as the PCA circle shows (Figure 5a). Furthermore, in all three vineyard series, these two aromatic descriptors were also perceived as relatively more intense in the wines with both the highest typicality scores and DMS levels (MX 04, P98, and SEM 98; Table 4 and Figure 4).

The empyreumatic attribute was correlated with 2FMT (r = 0.541; p-value = 0.009) which was confirmed by the PCA plot (Figure 5a), meaning that this compound contributed to the empyreumatic nuances perceived in all highly-typical wines. However, no correlation was found between toasted nuances and 2FMT levels. Interestingly, young wines (MX13 and SEM12) had the highest toasted score in the MX and SEM series (5.4 and 5.6, respectively; Table 4 and Figure 5b). These results were not surprising, due to the release of oak wood aromas during barrel aging, which probably confers stronger toasted aromas on young bottle-aged wines than 2FMT does. During bottle storage, fine wines acquire complexity, and the differentiated sensory impact of 2FMT and other volatile compounds released by the wood probably becomes less marked and more finely blended with the other aromas in older wines.[1]

Loading plots of the PCA and Pearson test revealed that 3SH did not contribute in the fresh fruity expression (r = 0.284, p-value = 0.156). Besides, although DMS is a known enhancer of fruity aroma,[34] no significant correlation was found between DMS levels and fresh-fruit notes (r = 0.143, p-value = 0.207). As shown in the projection of wines issued from the PCA (Figure 5b), the highest scores for this descriptor (Table 4) were mainly associated with youngest wines (MX08, MX11, MX13, and SEM12) whose scores for aging bouquet typicality were low. This logically reflects the expected fresh, fruitiness of young wines, with primary aromas that have not yet evolved toward the more complex, finer tertiary nuances that feature in an aging bouquet.

To our knowledge, the combined impact of DMS, 3SH, and 2FMT on the development of aging bouquet in red Bordeaux wines over time have not previously been described. Our results revealed that concentrations of these three sulfur compounds discriminated between wines with typical and atypical aging bouquets. The development of a bouquet during bottle aging was found to follow specific, nonlinear kinetics, associated with a subtle balance of these three sulfur compounds. The direct contribution of DMS to truffle and undergrowth attributes, as well as its key role in the overall complexity and balance of wine aroma, was highlighted. In our context, 2FMT was associated with empyreumatic nuances reminiscent of smoke, but not toasted notes, while the sensory impact of 3SH requires further investigation, as it was not directly correlated with the expected fresh-fruit attribute.

However, while these three volatile compounds have been identified as being responsible for some of the most representative aromatic notes in a typical aging bouquet, it seems unlikely that they are the only aroma compounds to account for its overall complexity. Accordingly, further work is still required to identify other marker molecules and obtain a more comprehensive understanding of the links between aroma compounds and the sensory perception of an aging bouquet in wine. In this respect, a two-tier approach is indicated, both studying the role of other targeted chemical classes and implementing wine fractionation and reconstitution experiments.

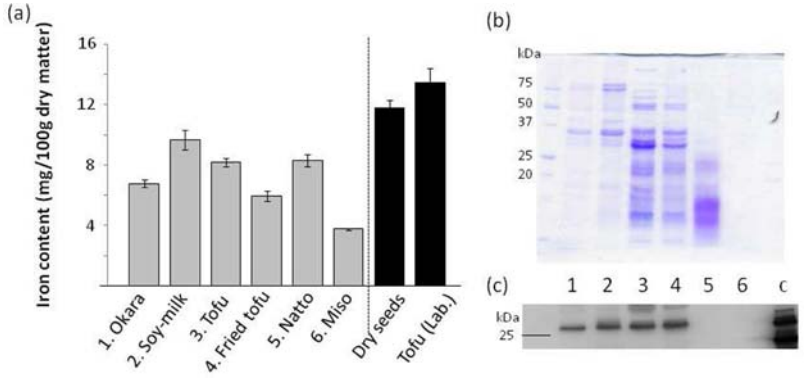

Figure 1. Iron contents and ferritin distribution in various soy-derived foods. (a) Iron contents of soy-derived foods. Blocks 1−6 indicate iron contents of soy-derived foods [soy-seed debris (okara), soymilk, tofu, fried tofu, natto, and miso] purchased at a local market. In addition, the iron contents of dry soybean seeds and tofu prepared in the laboratory are also shown. Error bars indicate SE of three independent analyses. (b) Reduced SDS−PAGE analysis of soy-derived food extracts. The gel was stained with Coomassie Brilliant Blue R-250. Lane 1, soy-seed debris (*okara*); lane 2, soymilk; lane 3, tofu; lane 4, fried tofu; lane 5, natto; and lane 6, miso. (c) Immunoblot analysis of soy-derived food extracts. Lane numbers indicate the same samples as panel b. Lane C indicates the control load of purified soybean ferritin.

storage. Here, I present the structural features of ferritin from tofu and describe the transition of iron contents during the processing of soybeans to tofu. The results presented here demonstrate the structural stability of soybean ferritin and its contribution to the iron content of soy-derived foods.

MATERIALS AND METHODS

Soybean Seeds, Soybean-Derived Foods, and Chemicals. Soybean dry seeds (*Glycine max* Merr. cv. Toyomasari) harvested in 2013 were purchased from a local market. All of the reagents used were of analytical grade or, if not available, special grade. Iron standards (Wako Pure Chemical, Tokyo, Japan) for atomic absorption spectrometry were diluted using distilled water for high-performance liquid chromatography (HPLC) grade (Nacalai, Kyoto, Japan). Commercially available soymilk, tofu, fried tofu, natto, and miso were purchased at local markets.

Preparation of Tofu. First, 250 g of dried soybean seeds was immersed in 1 L of distilled water at room temperature for 20 h. Subsequently, the water-absorbed seeds were homogenized using an electric cooking mixer. The homogenate was poured in a pan in which 1 L of distilled water was boiling. Subsequently, this soy homogenate was boiled in the pan with gently mixing for 10 min. The soymilk was squeezed from the boiled soybean seeds using cooking cloth and stored at 4 °C until the next procedure. A half volume (1 L) of the prepared soymilk was heated to 80 °C, and then 5.0 g of calcium sulfate dihydrate (Nacalai) was added to the soymilk to initiate the gelation. The resultant gel was gathered in a box and pushed gently to form tofu. The wept solution from the tofu, designated here as tofu supernatant, was also kept for further analyses. The moisture of tofu was determined by a moisture analyzer (MOC63u, Shimadzu, Kyoto, Japan).

Purification and Detection of Soybean Ferritin. Ferritin was purified from dry soybean seeds, tofu, and its supernatant by the following processes. The purification procedure of native soybean ferritin from dry soybean seeds was as described previously.[29] Ferritin was purified from tofu and its supernatant in a similar way. In brief, extraction buffer (20 mM TrisHCl at pH 7.7) was added to an equal volume of tofu (the average water content was 86.5%), followed by mixing with an electric cooking mixer and centrifugation (6000*g* for 15 min). The supernatant obtained here was designated as tofu extract. Subsequently, tofu ferritin was salted out by 30% saturated ammonium sulfate. The precipitant was dissolved in the extraction buffer followed by dialysis against the same extraction buffer. Ferritin was purified from the solution by anion-exchange chromatography (Q-toyopearl, Tosoh, Tokyo, Japan) and size-exclusion chromatography (SEC, Superdex 200 pg 16/60, GE Healthcare, Piscataway, NJ). Recombinant human H chain ferritin (rHuHF) was used as a size standard in SEC analysis. The preparation of rHuHF was described elsewhere.[30] To determine the oligomeric state of tofu ferritin, the SEC column (flow rate of 0.8 mL/min) was calibrated using the elution volumes of protein standards [rHuHF (506 000), γ-globulin (158 000), bovine serum albumin (BSA) (66 300), ovalbumin (42 700), and chymotripsinogen A (25 700)] (Figure S1). The oligomeric states of tofu ferritins were estimated using this calibration.

Ferritin was also purified from the tofu supernatant by the same procedure. Soybean ferritin was detected by sodium dodecyl sulfate−polyacrylamide gel (acrylamide concentration of 12.5%) electrophoresis (SDS−PAGE) followed by Coomassie Brilliant Blue R-250 staining and immunoblotting using anti-soybean ferritin antiserum.[29] Horseradish peroxidase (HRP)-labeled anti-rabbit immunoglobulin G (IgG, Promega, Madison, WI) was used as the secondary antibody. The signal was visualized using Chemilumi-one (Nacalai) and a laser imager (LAS-4000, GE Healthcare).

For the estimation of the recovery of ferritin in the purification steps, a dot-blot analysis was performed using the diluted recombinant soybean ferritin H-1 (rSFER1) subunit as a standard. The N-terminal amino acid sequences of purified ferritins from soybean seeds, tofu, and its supernatant were determined using the protein sequencer Procise HT (Life Technologies, Carlsbad, CA).

Iron Content Analyses. Lyophilized soy-derived food and milled soybean seeds were further dried at 120 °C for 4 h. Then, 0.5 g (dry weight) of each sample was wet-ashed with a solution of 14 mL of HNO_3 (60%, Nacalai) and 0.5 mL of H_2O_2 (Wako) for 5 h at 250 °C using a graphite block acid digestion system, Ecopre (Actac, Tokyo, Japan). The resulting digested solution of each sample was diluted with distilled water (HPLC grade, Nacalai), followed by the measurement of the iron concentration using an atomic absorption spectrophotometer (AAS, AA-6800, Shimadzu) equipped with a graphite furnace atomizer. The iron concentrations of lab-prepared soymilk, tofu supernatant, and soluble fractions after the purification steps were analyzed by the AAS after dilution. The concentration of each sample was determined from an average of three independent samples. An analysis of variance (ANOVA) with Tukey−Kramer's multiple comparison test was used to compare the iron contents among the various food products. Mean differences were considered significant at $p < 0.01$.

Circular Dichroism (CD) Measurements. Far-ultraviolet (UV) CD measurements were performed on a Jasco-720 spectropolarimeter (Jasco International, Tokyo, Japan) equipped with a temperature control unit (PTC-348, Jasco), using a spectral bandwidth of 2 nm and a cell path length of 1.0 mm. The protein concentration of recombinant soybean ferritin (rSFER1), ferritin purified from tofu, and its supernatant were adjusted to 0.2 mg/mL using a protein assay (BioRad, Hercules, CA). In temperature-controlled experiments, the molar ellipticity at a wavelength of 222 nm was taken in the range of 25−90 °C

DOI: 10.1021/acs.jafc.5b03080
J. Agric. Food Chem. 2015, 63, 8890−8895

[denaturation temperature (DT) = 0.5 °C] with an acquisition time of 0.2 s after an equilibration time of 30 s at each temperature step.

RESULTS

Iron Measurement and Ferritin Detection in Commercially Available Soy-Derived Foods. The iron contents of soy-derived foods that are available at ordinary grocery stores in Japan are shown in Figure 1a. The iron contents of these foods ranged from 3.6 to 9.6 mg/100 g of dry weight. The ferritins in the foods was detected by immunoblotting using an anti-soybean ferritin antibody. Ferritin was detected in soy-seed debris (okara), soymilk, tofu, and fried tofu, whereas it was absent in fermented foods, such as natto and miso (Figure 1c). Not only ferritin but also most of the proteins were digested in these fermented soy-derived foods (Figure 1b). Although available okara contained a detectable amount of ferritin (Figure 1c), the oligomeric form was not detected in okara (Figure S2). In contrast, oligomeric ferritin was apparently present in tofu and fried tofu purchased at a local market, suggesting that ferritin in okara or debris was aggregated or dissociated to a smaller structure (Figure S2). The iron content of tofu prepared in the laboratory was also determined as 13.5 mg/100 g of dry weight (Figure 1a). This value was higher than the value of the commercially available tofu assayed here. However, to determine the transition of iron and ferritin during the food processing of soybean seeds, the laboratory-prepared tofu was used in the subsequent experiments.

Oligomeric States and Subunit Composition of Ferritin in Tofu. For the determination of whether the oligomeric shell of ferritin is stably maintained after the heat treatment during food processing, ferritin was extracted and purified from soybean seeds and lab-prepared tofu, which included both the solid part (tofu extract) and the wept solution (tofu supernatant) (Figure 2a). All of the ferritin purified was amber-colored proteins,

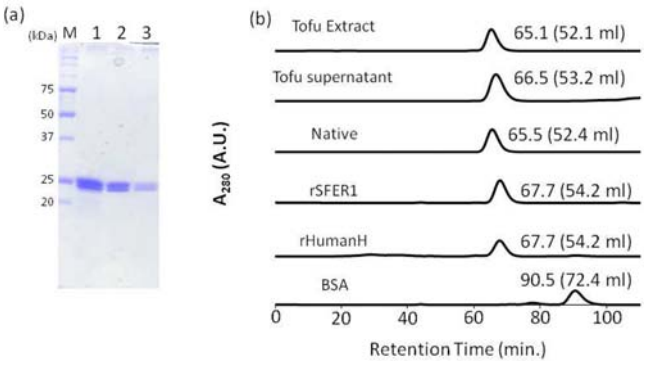

Figure 2. Purification of ferritin from tofu. (a) Purified ferritin from dry soybean seeds (lane 1), tofu extract (lane 2), and tofu supernatant (lane 3). (b) Elution chart of SEC. From the top to the bottom, the chart indicates tofu ferritin from the extract (tofu extract) and from the supernatant (tofu supernatant), native soybean ferritin (native), recombinant soybean ferritin H-1 (rSFER1), recombinant human H chain ferritin (rHumanH), and BSA (MW ≈ 66 300) as a control.

indicating that the proteins were an iron-containing form. Consistent with the observation described previously,[29] native soybean seed ferritin is composed of two types of subunits, H-1 (26.5 kDa, upper band) and H-2 (28 kDa, lower band) (Figure 2a). The ferritin purified from the tofu gel and tofu supernatant was also composed of two types of subunits, which showed similar mobility to that of native ferritin on the acrylamide gel (Figure 2a). The N-terminal amino acid sequences of these two bands (generally defined as 28 and 26.5 kDa) were ASNAPA and ASTVPL, respectively. This means that the subunit compositions of the ferritin from dry seeds and that from tofu were identical.

The oligomeric states of purified ferritins from tofu were estimated by SEC, which was adopted as the final purification step of these proteins. The elution volumes of tofu extract, tofu supernatant, native soybean ferritin, rSFER1, and rHumanH ferritins were calculated to 52.1, 53.2, 52.4, 54.2, and 54.2 mL, respectively, from the elution time of each sample (Figure 2b). Judging from the calibration plot (Figure S1), both of tofu ferritin (tofu extract and tofu supernatant) also formed a similar oligomer composed of 24 subunits.

Secondary Structure and Heat Stability of Purified Tofu Ferritin. Figure 3a shows the far-ultraviolet (UV) CD spectra of ferritin samples purified from tofu extract, tofu supernatant, and recombinant rSFER1 subunit 24-mer. These spectra commonly had the typical characteristics of α-helical proteins, i.e., local minimums of ellipticity at 207 and 222 nm and maximum ellipticity at 196 nm. In addition, the CD spectrum of tofu ferritin after heat treatment (90 °C for 10 min) showed no apparent difference from the tofu and recombinant ferritin (Figure S3); i.e., it showed a typical α-helix spectrum, and the peak intensities were not changed. These spectra indicated that the secondary structure of soybean ferritin was not denatured in the heating process of tofu preparation.

The heat denaturation processes of these proteins were followed by measuring the transition of molar ellipticity at 222 nm in the temperature range of 25−90 °C (Figure 3b). Generally, this type of plot shows the disorder in the secondary structure, especially the α-helical structure, induced by heat treatment. BSA was also treated similarly as a control. Typical proteins show a sigmoidal denaturation curve similar to that of BSA (Figure 3b). The DT can be determined by the fitting of such plots. However, tofu ferritin and recombinant soybean ferritin were not denatured completely at 90 °C, although partial denaturation in the α-helical structure was initiated in the temperature range higher than 80 °C. The secondary structure of tofu ferritin was nearly identical, even after this heating experiment (Figure S3), suggesting that soybean ferritin can recover its structure spontaneously after the partial heat denaturation state.

Iron Recovery during the Purification Steps and Iron Contents of the Purified Ferritins. The average iron content of soybean dry seed (*G. max*, Merr. cv. Toyomasari) used in this experiment was 11.8 ± 0.493 mg/100 g of dry weight (Figure 1a), while the iron concentration of soymilk prepared here was 10.1 ± 0.321 ppm [mean ± standard error (SE)] as the liquid body. In this experimental condition, 125 g of dry seeds produced approximately 1 L of soymilk. This result indicated that approximately two-thirds of iron (10.1 mg in soymilk of 14.8 mg of iron in dry seeds) were present as a soluble form in soymilk. Further, this soymilk (approximately 1 L) produced 330 g of tofu, whose moisture content was 86.5% on average. The iron content of prepared tofu was 13.5 mg/100 g of dry weight (Figure 1a). Thus, the prepared tofu was estimated to contain approximately 6 mg of iron.

On the other hand, the extractable iron amounts in the tofu and its supernatant, which were prepared from 125 g of dry soybean seed, were 807 μg (Figure 4a) and 339 μg (Figure 4c) on average, respectively. Finally, 179 and 45.5 μg of iron were recovered with purified ferritin from tofu extract and its supernatant. The recoveries of iron were 24.6 and 13.4% from

J. Agric. Food Chem. 2015, 63, 8890−8895

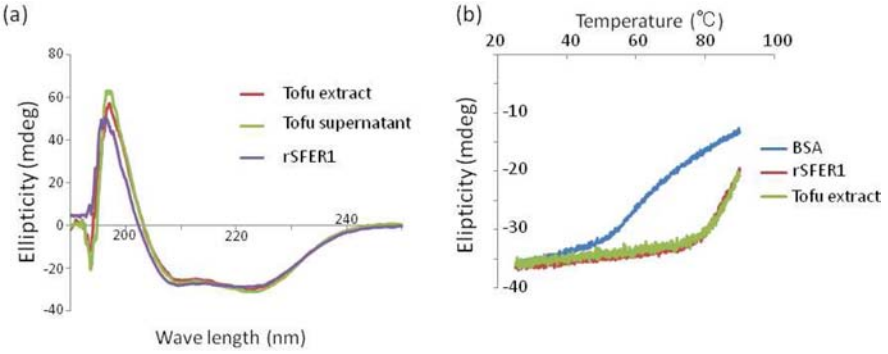

Figure 3. CD spectra of purified ferritin from tofu. (a) CD spectra of tofu ferritin purified from the extract and supernatant and rSFER1. Molar ellipticity in the far-UV region was recorded by scanning the wavelength from 250 to 190 nm. (b) Molar ellipticity at a wavelength of 222 nm was taken in the temperature range of 25−90 °C (DT = 0.5 °C) with an acquisition time of 0.2 s after an equilibration time of 30 s at each temperature step.

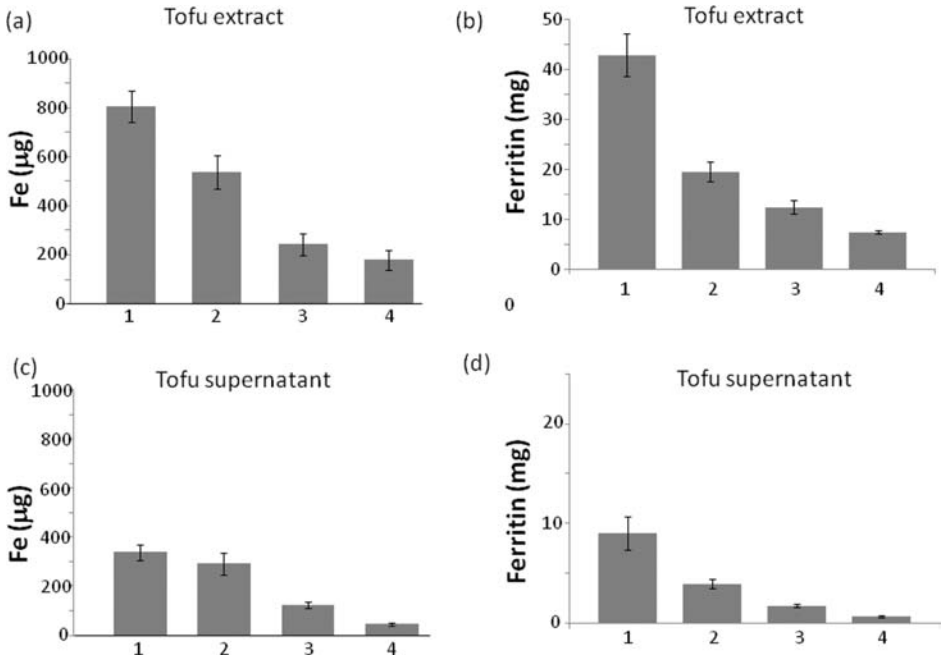

Figure 4. Iron and ferritin recovery during the purification steps. (a and c) Average iron recovery during the ferritin purification step from the tofu extract and supernatant, respectively. Error bars indicate SE of three to five independent analyses. (b and d) Ferritin recovery, which was estimated by dot-blot analyses. In these panels, numbers 1, 2, 3, and 4 mean the following purification steps: 1, crude sample; 2, after salting out and dialysis; 3, after anion-exchange chromatography; and 4, after SEC (the final purification step).

the tofu extract and supernatant, respectively. The ferritin recovery was estimated by a simple quantification of the dot-blot analysis at each purification step (Figure 4). The recoveries of ferritin from the tofu extract and supernatant were estimated to be 17.3 and 8.05%, respectively. These results indicated that large portions of soluble iron were present in ferritin, were maintained in the tofu gel, and not eluted out.

The iron contents of the purified ferritin samples are shown in Table 1. The average iron contents in the purified ferritin samples from soybean seed, tofu extract, and tofu supernatant were 2590, 1148, and 1000 atom per one oligomer, respectively (Table 1). The iron content of native soybean seed ferritin was significantly higher than those of the two types of purified tofu ferritin, whereas there was no significant difference in the iron contents of the ferritins from the tofu extract and supernatant. These results suggest that over half of the iron in soybean ferritin was lost during tofu preparation.

Table 1. Iron Contents of Purified Ferritin Oligomer[a]

ferritin source	number of iron atom per ferritin oligomer
dry seed	2590 ± 143[b]
tofu extract	1148 ± 130
tofu supernatant	1000 ± 62.6

[a]The iron contents of purified ferritin from dry seed, tofu extract, and tofu supernatant were calculated from the protein and iron concentration of each sample. Values indicate the mean ± SE. [b]Significant difference at $p < 0.01$.

DISCUSSION

One of the well-known characteristics of ferritin family proteins is the heat stability. In general, the oligomeric structure of ferritin is maintained and stabilized by large amounts of inter-subunit interactions, such as hydrophobic interactions, electrostatic interactions, hydrogen bonds, and salt bridges. In previous reports, I discussed the structural aspect that provides the heat

stability of plant-type ferritin in relation to the contribution of the plant ferritin-specific extension peptide.[31,32] The results of the present study demonstrated that the fundamental structure of soybean seed ferritin, such as the oligomeric form, secondary structure, and subunit composition, was maintained in tofu even after heat treatment.

Earlier findings obtained using differential scanning calorimetry also showed that the DT of a plant-type ferritin from green alga, *Ulva pertusa*, is higher than 90 °C.[31] Because of the high heat stability of this algal ferritin, the denaturation temperature could not be determined without some denaturant or chaotrope.[31] In the present study, the heat denaturation plots measured by a spectropolarimeter also showed that the secondary structure of soybean ferritin, regardless of the native or recombinant origin, was not completely disrupted in the temperature range of 25−90 °C. These data also support the heat stability of plant-type ferritin.

However, the number of iron atoms per ferritin oligomer was significantly decreased in the tofu ferritin, from both tofu extract and supernatant, compared to the native seed ferritin (Table 1). This indicates a loss of iron to some extent from ferritin in the process of tofu preparation. The heat denaturation plot of the native and tofu ferritin indicated that the secondary structures were affected by the heating, especially at a temperature higher than 80 °C. Such partial disorder would enhance the iron release from the ferritin oligomer. In fact, iron release from a ferritin shell, which is triggered by the partial disorder of the structure, was also reported in some vertebrate ferritins and a bacterial mini-ferritin.[33−36]

Although ferritin iron was partly released from the oligomeric protein shell during food processing, ferritin largely contributed to the soluble iron content in tofu. Ferritin is under scrutiny lately as a nutritional iron source with good bioavailability. The bioavailability of ferritin iron has been studied *in vivo* and *in vitro*, but this topic is still controversial. Initially, there was skepticism regarding the value of ferritin as a nutritional iron source,[37,38] but the appreciation of ferritin as a well-utilized iron source has become dominant.[10−12,15−17,19,26,39−41]

The two major advantages of ferritin iron as nutrition are as follows: (1) intestinal absorption via an independent pathway of heme iron or ferrous iron salts[15−17] and (2) absorption not affected by some dietary factors that have an inhibitory effect on iron absorption, such as phytic acid.[14] In addition, another advantage of the plant-type ferritin is its possibility as a nutritional phosphate source. The structural analysis of the ferritin core suggests that plant-type ferritin contains a large amount of phosphate as well as iron (Fe/P ratio of 2.8),[42] whereas the ratio is generally approximately 20 in vertebrate ferritin.[43] This fact indicates that tofu, which contains the oligomeric plant-type ferritin, may also serve as a dietary phosphate source. The endocytic pathway of ferritin absorption in intestinal epithelial cells was found in a Caco-2 cell experimental system.[16] Further characterization of the molecular mechanism in ferritin iron uptake is expected.

The question of whether ferritin originating from foods is still intact and forms the iron-containing oligomer when it reaches the duodenal epithelium where iron is mainly absorbed is another matter of controversy. Hopper et al. indicated that most plant ferritin degrades during *in vitro* gastric digestion,[44] whereas Lv et al. showed that both ferritins of plant origin and those of mammal origin are stable in simulated human digestive solution.[39] The difference in these findings could be caused by the experimental conditions used, such as pH. Hopper et al. also suggested that ferritin iron is reduced and well-utilized via DMT1 at a level similar to those of other inorganic iron forms, even though the protein shell is degraded during digestion.[44] Consistent with these *in vitro* studies, human trials in iron absorption have demonstrated the efficiency of ferritin as a nutritional iron source.[12,15,40]

The results of the present study demonstrated the fate of soybean ferritin during the processing to tofu. In tofu gel, ferritin maintained a similar oligomeric structure, which contained thousands of iron. We can presume that ferritin is present in various foods, including those of plant origin.[45,46] Despite such significant nutritional values, soybeans are not always regarded as an important staple food for humans worldwide. In addition to nutritional evaluations, further research on the utilization and development of soybean seeds as a substantial food material is needed.

MATERIALS AND METHODS

Preparation of MFP. Longissimus muscle (pH 5.6−5.9) was collected from three pork carcasses (48 h post-mortem). Individual samples (~90 g each) were vacuum-packaged and kept in a freezer (−30 °C) until use (less than 6 months). Frozen muscle samples were tempered at 4 °C for 5 h prior to MFP extraction using an isolation buffer of 0.1 M sodium chloride (NaCl), 10 mM sodium phosphate, 2 mM $MgCl_2$, and 1 mM ethylene glycol bis(2-aminoethyl ether)-*N*,*N*,*N*′,*N*′-tetraacetic acid (EGTA) (pH 7.0).[18] The pH of MFP suspension in 0.1 M NaCl at the last wash was adjusted to 6.25 before centrifugation (at 2000*g* for 15 min). The protein concentration of MFP pellet was measured by the Biuret method using bovine serum albumin (BSA) as a standard. The MFP pellet was kept on ice and used within 2 days.

Preparation of Emulsions. Commercial refined soybean oil was purchased from a local grocery; the high-performance liquid chromatography (HPLC) analysis confirmed that its tocopherol content was slightly greater than 100 mg/100 g (18.6 mg/100 g α-tocopherol, 87.6 mg/100 g γ-tocopherol, and 26.3 mg/100 g δ-tocopherol), agreeing with the reported literature.[19] Tween-20-stabilized emulsions were prepared from the mixture of 10% (v/v) soybean oil and 90% (v/v) pre-chilled buffer (25 mM phosphate at pH 6.25 containing 0.6 M NaCl at 4 °C) with 2% (w/v) Tween 20 by homogenization for 2 min with a Polytron blender (Brinkmann Instruments, Inc., Westbury, NY). A low-foaming probe (PTA-20TS) and a speed of 17 500 rpm were used. The pre-homogenized crude emulsion was then finely homogenized with a laboratory-scale jet homogenizer (NanoDeBee, B.E.E. International, Inc., Easton, MA) at an overall pressure of 35 MPa for one pass. During emulsification, the high-pressure pipeline was kept cool with ice pouches; thus, the temperature of outlet emulsion did not exceed 15 °C.

MFP-stabilized emulsions were prepared from the mixture of 10% (v/v) soybean oil and 90% (v/v) MFP in 25 mM phosphate at pH 6.25 containing 0.6 M NaCl. Three MFP concentrations (0.25, 0.5, and 1%, w/v) were used to allow for the determination of the protein concentration effect. The same two-stage homogenization process as above was used for the emulsion preparation.

Oxidation. To oxidize, Tween 20-stabilized and MFP-stabilized emulsions were incubated at 4 °C with hydroxyl radicals produced by an Fe^{2+}-recycling solution comprised of 10 μM $FeCl_3$/100 μM ascorbic acid/5 mM H_2O_2 for 0, 2, and 24 h. The oxidative reaction was terminated by propyl gallate/Trolox/EDTA (1 mM each).[18] In addition, MFP at a final concentration of 0.25, 0.5, or 1% (w/v) was added to the Tween 20 emulsion by gently mixing, followed by oxidation as described above. Because proteins would not adsorb at the interface in Tween emulsion, it was deemed appropriate to determine the antioxidative efficacy of MFP in the continuous phase, as compared to the other emulsion systems.

Measurement of the Emulsion Particle Size and Morphology. Emulsion samples for droplet size distribution were diluted with 25 mM phosphate buffer (pH 6.25, with a refractive index of 1.34) at a 1:50 emulsion/buffer ratio (v/v). The emulsion particle size was analyzed by ZetaSizer Nano-ZS (Malvern Instruments, Worcestershire, U.K.) at 22.5 °C with the following settings: measurement angle, 90°; equilibration time, 120 s; number of runs, 3; run duration, 10 s; number of measurements, 3; and delay between measurements, 10 s. The morphology of emulsified oil droplets was observed under a MICROPHOT-FXA Nikon photomicroscope equipped with a built-in digital camera (Nikon, Inc., Garden City, NY).

Fluorescence microscopy was applied to visualize the microstructure of emulsions and evidence the formation of protein coating around lipid droplets. The oil phase in the emulsions was stained with Nile Red dye (0.1%, v/v), and protein was stained with fluorescein isothiocyanate dye (0.1%, v/v). The dye-treated samples were placed in small cylindrical containers (10 μL) and incubated at room temperature in the dark for 20 min. Fluorescence was produced by excitation with a blue light (488 nm) and emission in the green region (514 nm) using a model Nikon Eclipse E800 fluorescent microscope. Furthermore, total internal reflection fluorescence (TIRF) was measured to probe dynamic morphological changes in protein-coated emulsion particles. An EMCCD (Andor) camera was mounted on the top of a Nikon Ti-U inverse microscope with a 100× oil-type objective. To detect the fluorescence of the fluorescein dye (emission wavelength of 514 nm), a 532 nm excitation filter and a 575 nm emission filter were used. An Olympus ZDC2 auto focus module was applied to limit focal drift. All of the images were obtained with a 100 ms frame rate.

Recovery of Adsorbed and Unadsorbed Proteins. Control and oxidized Tween 20-stabilized emulsions with added MFP (1%) were centrifuged (at 35000*g* for 60 min and 4 °C); the serum phase was collected, and the cream phase was discarded. Care was taken to avoid any cream or oil residue in the collected serum samples. First, the separated cream layer was removed using a spatula, and then a hole was pricked at the bottom of the plastic centrifuge tube using a needle to collect the clear part of the serum phase. The upper part of the serum phase was discarded to avoid oil residues. When MFP was added to Tween-stabilized emulsion, most proteins stayed in the continuous phase because, thermodynamically, it was difficult for them to displace the small surfactant (Tween 20).

Similarly, MFP-stabilized emulsions (1%) with or without the oxidative stress were centrifuged (at 35000*g* for 60 min and 4 °C) to separate the serum phase from the cream phase that contained oil and adsorbed protein. The serum phase was carefully collected as described above to obtain unadsorbed MFP. The cream layer was washed 2 times with deionized water and then subjected to the recovery of adsorbed protein using Tween 20 as the desorbing (displacing) agent.[20] To do so, washed cream was dispersed in 25 mM phosphate buffer (pH 6.25, with the same volume as the removed serum phase) containing 2% (v/v) Tween 20 by stirring at 4 °C for 3 h and then centrifuging at 35000*g* for 60 min and 4 °C. The cream layer was removed with a spatula, and the aqueous solution containing originally adsorbed MFP was collected. The concentration of adsorbed and unadsorbed protein was measured by the Bradford method.[21]

Determination of Lipid Oxidation. Evaluation of oxidative changes in control and oxidized emulsion samples was performed by monitoring the formation of conjugated diene hydroperoxides and 2-thiobarbituric acid reactive substances (TBARS).[22,23] For conjugated dienes, emulsion samples (0.5 mL) were mixed with 5 mL of extracting solvent (3:2, v/v, hexane/isopropanol) and vortexed for 1 min. After centrifugation at 2000*g* for 5 min, the absorbance (233 nm) of the supernatant was recorded and the value converted to conjugated dienes using the molar extinction coefficient of 25 200 M^{-1} cm^{-1}.[24]

For the measurement of TBARS, emulsion samples were mixed into the assay solution containing trichloroacetic acid (TCA) and thiobarbituric acid (TBA), followed by boiling for 30 min. The supernatant of the cooled solution was treated with chloroform and centrifuged at 2000*g* for 5 min. The absorbance of the upper phase containing the pinkish TBA−malonaldehyde adducts was measured at 532 nm, and the molar extinction coefficient of 152 000 M^{-1} cm^{-1} was used to calculate the TBARS content.[25]

Measurement of Protein Oxidation and Structural Changes. Protein modifications were examined over time through monitoring the oxidation and structural changes using the following analytical indexes.

Carbonyl. The content of protein carbonyl derivatives in control and oxidatively stressed emulsion samples was estimated using the 2,4-dinitrophenylhydrazine (DNPH) colorimetric method.[26] Briefly, the DNPH-reacted MFP samples after 20% TCA precipitation were recovered by centrifugation (at 11000*g* for 10 min) and then washed with ethanol/ethyl acetate (1:1, v/v) solvent to remove unbound pigments. The final MFP pellets were dissolved in guanidine hydrochloride (6.0 M), and the absorbances at 370 and 280 nm were recorded for the determination of carbonyl and protein concentrations, respectively. A molar extinction coefficient of 22 000 M^{-1} cm^{-1} was used for carbonyl content computation.

Sulfhydryl. Free sulfhydryl content in emulsion samples was determined by reaction with Ellman's reagent [5,5′-dithio-bis(2-nitrobenzoic acid) (DNTB)] as detailed by Beveridge et al.[27] Blanks

DOI: 10.1021/acs.jafc.5b03377
J. Agric. Food Chem. 2015, 63, 8896−8904

were run with 25 mM phosphate buffer (pH 6.25) containing 0.6 M NaCl. The sulfhydryl concentration was calculated using a molar extinction coefficient of 13 600 M^{-1} cm^{-1}.

Electrophoresis. Sodium dodecyl sulfate−polyacrylamide gel electrophoresis (SDS−PAGE) was performed with a 4% polyacrylamide stacking gel and a 10% polyacrylamide separating gel. Adsorbed and unadsorbed (continuous phase) proteins prepared as described above were dissolved in the SDS−PAGE sample buffer with and without 10% β-mercaptoethanol (βME) to obtain a final protein concentration of 2 mg/mL and then boiled for 3 min. Into each well, 60 μg of prepared sample was loaded.

Circular Dichroism (CD). Far-ultraviolet (UV) (190−260 nm) CD spectra of collected MFP samples were obtained on a Jasco J-810 spectropolarimeter (Hachioji City, Tokyo, Japan) using a 0.1 cm path length cuvette. The protein samples were concentrated on a centrifugal filter device (Amicon Ultra-15, Billerica, MA) with a molecular weight cutoff of 10 000 and then diluted to 0.2 mg/mL with a 0.45 M NaCl and 25 mM phosphate buffer (pH 7.0). After filtering through a 0.22 μm Millipore filter [polyvinylidene fluoride (PVDF)] to reduce light scattering, the spectrum was obtained immediately.[28] The results were expressed as ellipticity, θ (mdeg). The same phosphate buffer without adding MFP was used as the control. The scan rate, response, bandwidth, and step resolution were 100 nm/min, 0.25 s, 1.0 nm, and 0.5 nm, respectively. Values from three scans were averaged to obtain one spectrum.

Intrinsic Tryptophan Fluorescence. The procedure described by Estévez et al.,[29] with slight modifications, was followed to observe a fluorescence pattern and intensity of protein samples. Recovered adsorbed and unadsorbed MFPs (100 μL) were diluted in 5 mL of 25 mM phosphate buffer (pH 6.25) containing 0.6 M NaCl and then subjected to fluorescence testing in a Fluoromax-3 fluorometer (Horiba Jobin Yvon, Inc., Edison, NJ). The excitation and emission wavelengths were 283 and 300−400 nm, respectively, and the scanning speed was 1 nm/s.

Statistical Analysis. Data were collected from two independent experimental trials (replicates) with different batches of MFP isolation. All analyses were performed on triplicate samples, and the results were subjected to the analysis of variance using the procedure of the general linear model of the Statistix software 9.0 (Analytical Software, Tallahassee, FL). All pairwise multiple comparisons [least significant difference (LSD)] were used to identify significant differences ($p < 0.05$) between means.

RESULTS AND DISCUSSION

Structural Characteristics and Physical Stability of Emulsions. The light microscopy of freshly made emulsions is shown in Figure 1A. The oil droplets in Tween emulsion with added MFP exhibited a highly homogeneous distribution, while the oil droplets in MFP-stabilized emulsions (a, b, and c) were less evenly distributed, depending upon the protein concentration. The emulsion with 1% protein (c) contained the smallest oil droplets (mean diameter of 670 nm) that appeared better distributed in the continuous phase when compared to the emulsion (mean diameter of 1126 nm) prepared with 0.25% MFP (a). At lower protein concentrations, for example, 0.25% MFP, most MFP was found to accumulate at the interface as adsorbed protein, with an unmeasurable amount being present in the continuous phase. A higher protein concentration allows for greater surface loading to achieve better emulsifying capability,[12] while excess unadsorbed proteins would restrict the mobility of oil droplets as a result of enhanced viscosity of the continuous phase. Other researchers have reported a similar phenomenon that decreasing the initial concentration of emulsifier resulted in an increased average droplet size and rapid physical destabilization of emulsions.[30] In contrast, Tween 20 as a more surface-active small surfactant can effectively adsorb to

the oil droplet surface under a high pressure. This thin surfactant film surrounding nanolevel oil droplets lowered surface tension and provided long-term stability with respect to droplet flocculation, coalescence, and creaming.

To illustrate the role of the interfacial membrane in the oxidative stability of emulsions (which will be described later), morphological changes of emulsions prepared with 1% MFP or Tween 20 with added MFP (1%) during oxidation up to 24 h were compared (Figure 1B). The Tween emulsions with added MFP appeared to be relatively stable, and the concentration of the unadsorbed protein in their continuous phase did not change significantly ($p > 0.05$) over the entire oxidation period (upper panel), while droplets present in the MFP emulsions exhibited notable flocculation in 2 h and aggregates in 24 h

J. Agric. Food Chem. 2015, 63, 8896−8904

(lower panel). This morphological shift for the latter emulsion system was a dynamic process characterized by the partial release of protein from the oil−water interface, which was initially non-appreciable (2 h; $p > 0.05$) but became remarkable (24 h; $p < 0.05$); the adsorbed MFP was reduced to 2.86 mg/mL (or 72% of the total protein) from its fresh state at 4.30 mg/mL (or 89% of the total protein). Oxidant-induced structural changes and aggregation of interfacial proteins facilitated the release of protein and, consequently, destabilization (flocculation) of the emulsion. Flocculation and partial protein desorption were also observed in non-oxidized MFP control emulsions that did not exhibit any measurable oxidative change. Flocculation was not seen in the Tween emulsions even in the presence of MFP added to the continuous phase as a result of the lack of protein as an interfacial constituent. Despite its less physical stability, the MFP emulsion retained much of the membrane structure, which may serve as a barrier against radical attack.

To visualize in greater detail the effect of protein coating on the emulsion droplet morphology and distribution, fluorometry and total internal reflection fluorescence (TIRF) microscopy (Figure 2) were employed. The fluorescence image of MFP-

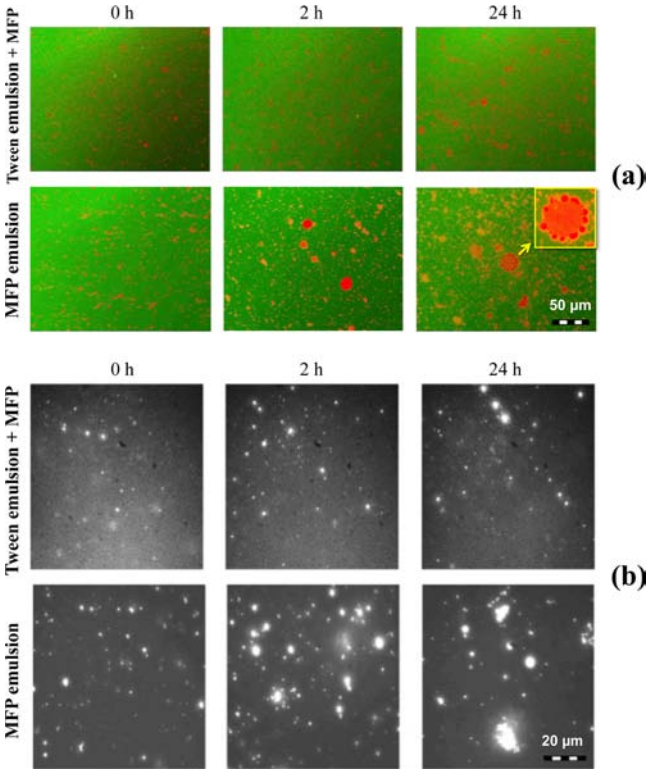

Figure 2. (a) Fluorescence microscopy and (b) TIRF images of (upper panel) Tween-stabilized emulsion with 1% added MFP and (lower panel) 1% MFP-stabilized emulsion with different oxidation times. In panel a, a large particle surrounded by small droplets in 24 h oxidized MFP emulsion is enlarged for visibility.

stabilized emulsions illuminated with two different fluorescent dyes demonstrated the coverage of oil droplets by MFP and the rearrangement of oil droplets during oxidation (Figure 2a). In 2 h, the MFP emulsion displayed a broad droplet size distribution with an obviously larger mean diameter when compared to the Tween emulsions as a result of flocculation and coalescence of small droplets. Interestingly, after 24 h of oxidation, many of the small droplets coated with protein migrated to the surface of the large, coalesced oil droplets, forming neo-interfacial clusters (pointed by arrow), resembling a milk fat emulsion stabilized by casein micelles.[31] In comparison, a different morphological image was observed for emulsions prepared with Tween 20, where oil droplets were not only much smaller but also well-separated, showing no apparent flocculation after 24 h, which was in accordance with light microscopy imaging (Figure 1b).

The above microscopic observation was corroborated by the image captured with TIRF (Figure 2b). The TIRF technique produces a live microscopic profile of dynamic aggregation of protein in MFP emulsions and reversible Brownian flocculation in Tween emulsions. Isolated fluorescent dots in the TIRF image (Figure 2b) were attributed to the emission of protein dye in the emulsion, allowing for the differentiation of morphological variations between MFP emulsions and Tween emulsions with added MFP under oxidative stress. In the MFP emulsions, flocculation occurred within 2 h, followed by partial coalescence in 24 h. The Tween emulsion samples with added MFP also showed a few fluorescent dots, and their presence exhibited no remarkable change. These were protein aggregates rather than oil droplets because of the weaker surface activity of proteins relative to Tween 20 and,[32] therefore, less likely for the continuous-phase MFP to displace the adsorbed Tween at the interface.

Lipid Oxidation. The time course of the oxidative reaction was monitored by the measurement of primary (conjugated dienes) and secondary (TBARS) products of lipid oxidation. Conjugated dienes, which mirror the production of hydroperoxides, are unstable, especially in an intense oxidative environment. Their content typically increases for a short time and then decreases as a result of spontaneous degradation into secondary products.[33] In Figure 3a, conjugated dienes decreased within 24 h oxidation in all emulsion samples, except for 1% MFP-stabilized emulsion. The relatively high protein concentration in the 1% MFP emulsion conspicuously prolonged the lag phase, thereby slowing the production of hydroperoxide-conjugated dienes, hence, the increasing pattern within 24 h. The protein concentration effect was also observed by Kiokias et al.,[34] who reported that an increasing whey protein concentration led to a decrease in the emulsion droplet size but an increase in lipid oxidative stability. At an equal protein concentration, the conjugated diene content in MFP-stabilized emulsions was approximately a half of Tween 20-stabilized emulsions with added MFP (Figure 3a). This was strong evidence that MFP, when acting as an emulsifier surrounding the oil droplets, as opposed to being in the aqueous phase, could effectively delay lipid oxidation. Moreover, the Tween emulsion mixed with MFP had a relatively high conjugated diene value at time zero when compared to MFP emulsion samples, suggesting the early protective role that MFP played in the emulsifying process.

The TBARS results are depicted in Figure 3b. The Tween emulsions with or without added MFP (0.25, 0.5, or 1%) both showed remarkably higher ($p < 0.05$) TBARS values, including time 0, when compared to MFP-generated emulsions. Therefore, interface-adsorbed protein acted as an effective mechanism for the inhibition of lipid oxidation during the homogenization process as well as during prolonged oxidative stress. The result was consistent with the conjugated diene inhibition (Figure 3a). For each emulsion sample, oxidation up to 2 h caused no significant increase in TBARS ($p > 0.05$). After 24 h of

oxidation, the TBARS content rose significantly in Tween emulsions compared to MFP emulsions that had minimal changes.

Protein Oxidation. To confirm the role of MFP as a sacrificing antioxidant to protect protein-stabilized emulsions and delineate the specific actions of interfacial and continuous-phase MFP, oxidative changes at the primary, secondary, and tertiary levels of the emulsions and separated proteins are presented below. The results obtained when compared to lipid oxidation were applied to explain in detail the sequential oxidative change of the two main emulsion constituents.

Sulfhydryl and Carbonyl Derivatives. Modification of amino acid residue side-chain groups is the primary consequence of oxidative attack of proteins. The loss of sulfhydryls and formation of carbonyls are two common measures of protein changes in oxidized muscle foods.[6,35] As presented in Table 1, the sulfhydryl content decreased, while the carbonyls increased continuously during oxidation ($p < 0.05$). For the thiol groups, almost all of the loss occurred within the first 2 h, preceding the onset of lipid oxidation,

Table 1. Sulfhydryl and Carbonyl Contents in Two Different Emulsion Systems as Affected by Oxidation (0, 2, and 24 h)[a]

J. Agric. Food Chem. 2015, 63, 8896–8904

which took place mostly between 2 and 24 h (Figure 3). However, the extent of sulfhydryl reduction was quite different between the two types of emulsions, i.e., 21.1−49.0% for Tween emulsions with added MFP compared to 60.1−71.0% for MFP-generated emulsions, irrespective of the protein concentration. Thus, interface-adsorbed MFP was more prone to hydroxyl radicals than continuous-phase MFP.

Table 1 also summarizes the protein carbonyl content in different emulsions. It is noteworthy that freshly prepared emulsions already had measurable amounts of carbonyls produced during the MFP isolation and emulsion preparation. Oxidative stress resulted in a gradual rise of the carbonyl content in MFP in both emulsion systems. For Tween emulsions, the content of carbonyls on a protein basis (μmol/g of protein) was generally not affected by the amount of MFP added ($p > 0.05$), indicating that proteins in the continuous phase were equally susceptible to radicals. However, when calculated on the basis of the volume, the net amount of carbonyl derivatives in the emulsion (μmol/100 mL) increased with the level of MFP addition. The latter value suggests that the extra oxidized proteins may serve as initiators for lipid oxidation as previously described.

In comparison, the MFP emulsions had a more rapid carbonyl formation during oxidation, with the net increase in 24 h ranging from 3.68 to 6.09 μmol/g of protein versus about 1.5 μmol/g of protein for Tween emulsions ($p < 0.05$) (Table 1). This result again substantiates the premise that interfacial protein in MFP-stabilized emulsions played a sacrificing role as an antioxidant to protect lipids. Interestingly, the pattern of sulfhydryl reduction (completed in 2 h) was not in parallel with the increase in carbonyls (progressive throughout 24 h), suggesting an independent nature of the two oxidative processes. During oxidation, free thiol groups can be readily converted to disulfide bonds, while the formation of carbonyl derivatives appeared to be progressive, which may involve lysine, arginine, proline, and threonine side-chain groups.[36] In strong agreement, results from SDS−PAGE showed disulfide-dependent polymerization of myosin because the polymers were dissociated when oxidized samples were treated with βME, a reducing agent (Figure 4). Moreover, the myosin heavy chain in adsorbed MFP completely vanished within 2 h of oxidation (see the arrows in Figure 4a), suggesting more extensive polymerization compared to the MFP in the continuous phase (Figure 4b). The observation further confirms the high reactivity of interfacial proteins relative to their counterpart in the bulk phase.

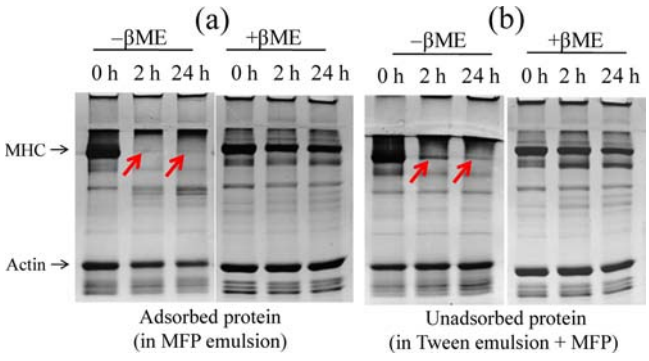

Figure 4. SDS−PAGE of (a) adsorbed protein in MFP emulsion (1%) and (b) unadsorbed protein in Tween emulsion with added MFP (1%) during oxidation. βME, β-mercaptoethanol (a disulfide-bond-breaking agent); MHC, myosin heavy chain.

Secondary and Tertiary Structures. The characteristic CD spectra of MFP in the far-UV region are depicted in panels a and b of Figure 5. The adsorbed protein recovered from MFP-stabilized emulsions exhibited a negative band near 208 and 222 nm and a strong peak at 200 nm (Figure 5a), resembling a typical α-helix curve. While the pattern of the CD spectrum changed very little, the ellipticity attenuated with the oxidation time, indicating destabilization of the secondary structures. However, the results suggest that, even after oxidation, α-helix was still a major structural component in adsorbed MFP, which can be largely ascribed to the myosin helical rod. In contrast, oxidation significantly disrupted the secondary structure of proteins present in the continuous phase of Tween emulsions with added MFP. The conformational changes were evidenced by the reduced ellipticity, the shift of the wavelength, and roughness of the CD curves (Figure 5b).

Intrinsic tryptophan fluorescence was used to assess oxidative changes in the tertiary structure of adsorbed and unadsorbed MFP, and the results are shown in panels c and d of Figure 5. Desorbed MFP from 2 h oxidized emulsion samples exhibited greater losses of fluorescence than continuous-phase MFP, confirming that interface-adsorbed proteins were more oxidizable than unadsorbed protein. This finding was in accordance with Rampon et al.[37] and Berton et al.,[38] who studied emulsions stabilized by BSA/β-lactoglobulin/β-casein and demonstrated that adsorbed proteins were more readily modified than unadsorbed proteins in the aqueous phase.

The remarkable oxidative protection by interfacial MFP can be attributed to multiple mechanisms. First, MFP surrounding the lipid droplets can prevent direct contact between radicals and the enclosed lipid, which has been demonstrated in other protein-stabilized O/W emulsions as well.[4,5] Besides radical protection, the idea of oxygen blockage by a protein interface was brought forth by Toikkanen et al.,[39] who showed that a well-formed protein viscoelastic layer was able to effectively reduce the oxygen permeability. Therefore, the inhibition of oxygen transport by the protein interface might be considered as another reason to prevent lipid from oxidation. Furthermore, induced cross-linking of the interfacial proteins from radical attack would impart a stronger coverage on lipid droplets, which, in turn, would reinforce the physical shielding effect. This premise was also discussed in caseinate-stabilized emulsion systems; the cross-linking of sodium caseinate at the emulsion interface improved the oxidative stability of emulsion.[40]

On the other hand, as a result of the adsorption to the oil droplets, MFP will unfold at the interface,[12] exposing the susceptible amino acid side-chain groups capable of scavenging radicals and donating electrons more readily than unsaturated fatty acids.[36] The reaction rate constant of many proteins, such as albumin and collagen, with a hydroxyl radical has been reported to be a magnitude higher than that of linoleic acid.[41] Therefore, protein modification occurred earlier than lipid oxidation during the oxidative chain reactions in the emulsions, in agreement with the literature report.[38]

The oxidative stability of emulsions depends upon the type of emulsifier. According to Berton et al.,[30] emulsions prepared with milk proteins (β-lactoglobulin, BSA, and β-casein) were less stable than emulsion prepared with Tween 20 or Tween 80. The authors attributed the difference to the heterogeneity and porosity of the protein membrane versus the polysorbate surfactants. While porosity, hence, oxygen diffusion, of a milk-

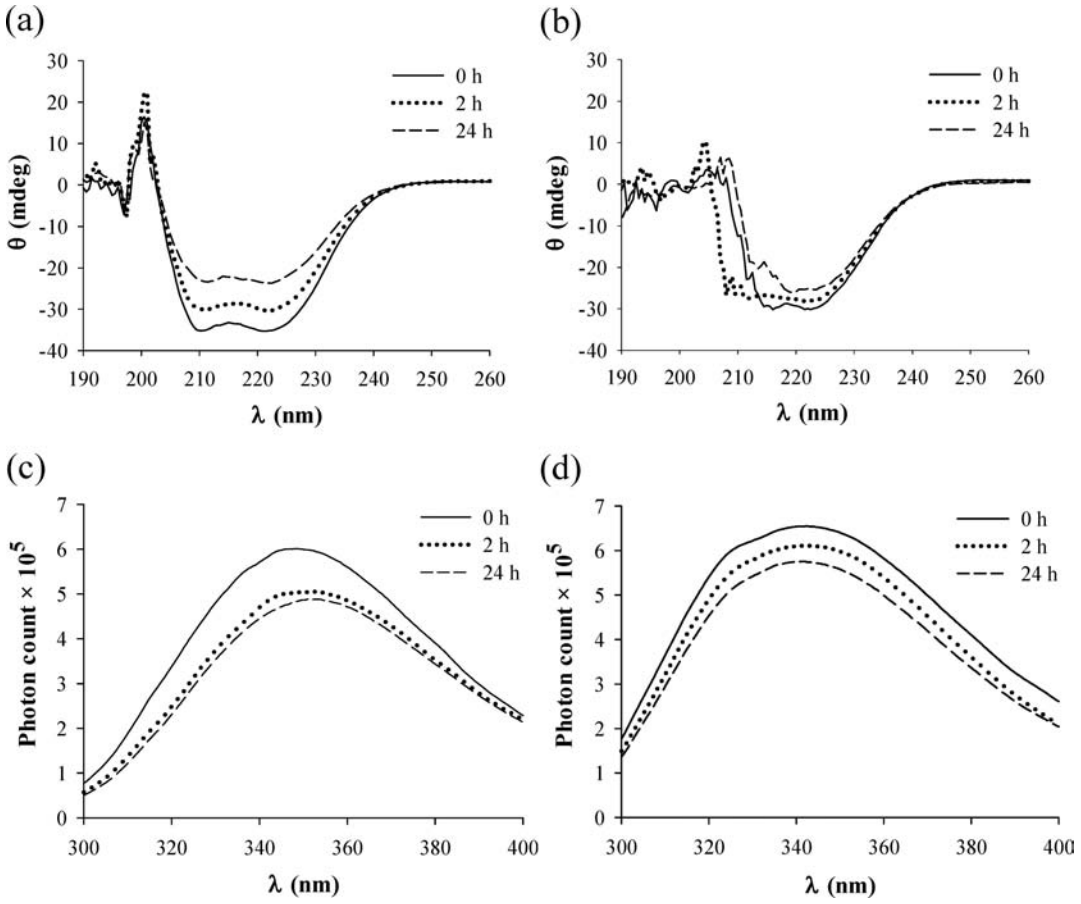

Figure 5. CD spectra of (a) adsorbed protein in MFP emulsion (1%) and (b) unadsorbed protein in Tween emulsion with added MFP (1%) during oxidation and fluorescence of (c) adsorbed protein in MFP emulsion (1%) and (d) unadsorbed protein in Tween emulsion with added MFP (1%) during oxidation.

protein-based interfacial membrane has also been reported by other researchers,[42,43] this did not seem to be applicable to MFP, which is enriched with myosin that is known for its strong surface activity and interface-stabilizing capacity in salt solutions.[44] In addition, the strong adsorption of MFP at the O/W interface (Figure 1B) would lead to a moderately thick interfacial layer when compared to Tween-only emulsions. Indeed, interfacial thickness has been shown to impact the antioxidant potential of a casein-based membrane.[45] The influence of the oil droplet size and interfacial area (larger for MFP emulsions than for Tween emulsions) on lipid oxidation would be negligible based on recent evidence.[46,47]

While interfacial proteins possess an antioxidative effect, the proteins present in the continuous phase exhibited a rather complex behavior. Comparison between Tween emulsions with and without 0.25% added MFP indicated considerable reductions of TBARS at 0 and 2 h when MFP was present in the aqueous phase (Figure 3b). This was probably due to the radical-stabilizing effect of free (unadsorbed) MFP, for example, myosin.[48] It has been reported that continuous-phase proteins, for example, whey protein isolate, soy protein isolate, and sodium caseinate, could inhibit lipid oxidation as a result of free radical scavenging and metal chelation.[49] Presumably, as a favorite target of the hydroxyl radical, MFP had a consequential "sparing" effect to protect lipids. This hypothesis is consistent with the extent of protein oxidation because, at the equal 10% oil, the net amount (μmol) of protein carbonyl derivatives produced increased ($p < 0.05$) with the concentration of MFP; i.e., the higher the MFP concentration, the more oxidation (carbonyl net amount) (Table 1), corresponding to a trend of reduction in lipid oxidation products (Figure 3). Similarly, Estévez et al.[29] reported an inverse relationship between the degree of muscle protein oxidative modification and the amount of conjugated dienes generated in an O/W emulsion incubated at 37 °C. Interestingly, the accumulation of protein oxidation products during oxidation (notably within the initial 2 h), which was moderately significant for Tween emulsion samples with 0.25% added MFP and strongly significant in samples with higher levels of MFP addition (Table 1), appeared to stimulate lipid oxidation subsequently (TBARS formation).

In conclusion, MFP present either at the interface or in the continuous aqueous solution, notably myosin, proves to be a kinetically preferred target of free radicals when compared to lipids in O/W emulsions. This is due to the high reactivity of protein thiol groups. The physical location of the proteins within the complex emulsion systems dictates their antioxidative efficacy; interfacial MFP compared to continuous-phase MFP imparts strong protection, giving rise to a remarkable oxidative stability of emulsified lipids. Hence, capable of building a cohesive interfacial membrane, MFP can be used to prepare oil-based pre-emulsions suitable for functional sausage products. Because the system complexity of meat emulsions and the diverse behaviors of emulsifiers (e.g., surface activity and partitioning efficiency) often lead to contradictory results,[50] further research is needed to explore other kinds of

and Analysis of the University of Hohenheim. Ultrapure water was used throughout the study (Milli-Q system, Millipore, France).

HPLC-PDA-ESI/MS^n Analyses. The inner bark of *Q. saponaria* Molina was crushed with a food processor until a fine powder was obtained. An aliquot of 3.8 g of the sample powder was combined with 20 mL of water, the pH was adjusted to pH 2 with diluted formic acid, and the mixture was stirred at room temperature for 12 h in the dark under nitrogen atmosphere. Samples were consecutively filtered through a folded filter (5−8 μm, cellulose) and a membrane filter (0.45 μm, regenerated cellulose) to obtain the crude bark extract. In contrast to the crude bark extract, the commercial *Quillaja* extract was dissolved in 1% (v/v) aqueous formic acid and membrane filtered (0.45 μm, regenerated cellulose). Subsequent HPLC-PDA-ESI/MS^n analyses were performed as previously described by Maier et al.[5]

Preparative Isolation of *p*-Coumaroyl Sucrose Esters. Due to the availability of larger quantities, the compounds of interest were only isolated from commercial *Quillaja* extracts. The similarity of the isolated compounds to those found in the natural bark was verified by HPLC-PDA-MS^n. Preparative isolation of phenolic constituents from *Quillaja* extracts was conducted as previously described by Maier et al.[5] Briefly, the targeted phenolic compounds present in the above-described extracts were separated with an Ultimate 3000 preparative HPLC system equipped with two solvent delivery modules, a diode array detector (DAD-3000), and an automatic fraction collector (AFC-3000). The separation column was a preparative 250 × 21.1 mm i.d., 5 μm particle size, 125 Å pore size, Phenomenex Aqua C18 reversed-phase column. The used eluents were water (eluent A) and methanol (eluent B), both being acidified to pH 2 with formic acid. Separation was started by isocratic elution at 20% B for 10 min, followed by a linear gradient from 20 to 40% B over 18 min. After isocratic elution at 40% B for 20 min, a linear gradient from 40 to 100% B within 2 min was applied. After 8 min of isocratic elution at 100% B, a linear gradient to 20% B was applied within 2 min, and the system was equilibrated at 20% B for 10 min. Total run time was 70 min at a constant flow rate of 8 mL/min. The injection volume was 1000 μL. The retention times of the compounds to be isolated, **14** and **15** (Table 1), were 40.2 and 41.0 min, respectively. Compounds were monitored at 280 and 310 nm. After solvent evaporation under reduced pressure (T_{max} = 40 °C), the collected fractions were freeze-dried and stored at −20 °C until further use. Aliquots of the isolated compounds were dissolved in aqueous 4 N HCl and heated to ∼85 °C for 120 min. After subsequent neutralization with aqueous NaOH, the hydrolysate was membrane filtered (0.45 μm) and analyzed by HPLC-PDA-MS^n as described above.

High-Resolution ESI-MS Analyses. High-resolution ESI-MS analyses of the isolated compounds **14** and **15** were performed using a Q-Exactive Plus mass spectrometer (Thermo Fisher Scientific, Bremen, Germany) equipped with an API ion source and a HESI-II probe. The instrument was operated in negative ionization mode and was externally calibrated according to the manufacturer's guidelines. Compounds isolated by preparative HPLC were redissolved in 100 μL of aqueous methanol (50%, v/v) and were analyzed by direct infusion at a flow rate of 5 μL/min. The MS conditions were as follows: capillary temperature, 250 °C; spray voltage, −3200 V; sheath gas and auxiliary gas were not applied. Mass spectra were acquired in the range of *m/z* 150−2000 at resolution of 70000 (at *m/z* 200). Mass spectrometric data were analyzed using Xcalibur 3.0.63 software (Thermo Fisher Scientific).

High-resolution mass data for minor compounds **5**, **6**, **9**, **11**−**13**, and **16**−**29** were determined by HPLC-ESI-HR-MS. An Agilent 1200 series, set up according to the above-mentioned HPLC method,[5] was coupled online to a micrOTOF-Q mass spectrometer (Bruker Daltonics, Bremen, Germany) operated in negative electrospray ionization mode. Capillary voltage was set at +4.5 kV. Nebulizing and drying gas was both nitrogen applied at 3.0 bar and 8.8 L/min. Drying gas was heated to 250 °C. Mass spectra were recorded at 20 Hz (2 GHz sampling rate) in the range of *m/z* 250−2500 at a resolution of 12900 (at *m/z* 996.8). The instrument was calibrated with sodium formate according to the manufacturer's instructions. Chemical formulas were generated by accurate mass measurements and DataAnalysis 3.4 software.

Determination of the Absolute Configuration of the Sugar Moieties. Isolated compounds (ca. 1 mg) were heated with aqueous TFA (2 M) at 85 °C for 2 h, subsequently evaporated in vacuo to 0.2 mL (45 °C). Toluene and pyridine (both 4 × 3.0 mL) were used consecutively to remove TFA and water without evaporating to dryness to avoid the degradation of apiose. Subsequently, the sample was combined with 0.1 mL of L-cysteine methyl ester hydrochloride in pyridine (120 mg/mL) and heated at 65 °C for 1 h. After the addition of 0.2 mL of the silylation reagent, heating was continued for a further 0.5 h. Analytes were partitioned between hexane and H_2O (0.3 mL each), and the hexane layer was analyzed by GC-MS equipped with a 30 m × 0.25 mm, d_f = 0.25 μm, HP-5ms column (temperature program: 100 °C for 1 min, raised at 15 °C/min to 200 °C, raised at 3 °C/min to 240 °C, raised at 15 °C/min to 300 °C, and held for 5 min; carrier gas, helium at 1.2 mL/min). Reference standards were subjected directly to the derivatization reaction (0.2 mL, 0.1 g/L in pyridine). In contrast, 10 μL of aqueous L-apiose was derivatized according to the protocol given above without TFA hydrolysis.

Retention times (retention indices relative to *n*-alkanes) of the derivatives obtained were as follows: D-apiose, 14.0 min (2240); L-rhamnose, 15.7 min (2336); D-fructose, 17.3 min (2426); and D-glucose, 18.5 min (2483). The D-rhamnose, L-fructose, and L-glucose derivatives revealed retention times (indices) of 15.9 min (2347), 17.1 min (2412), and 18.8 min (2502). An authentic standard of L-apiose was unavailable. EI-MS (70 eV) base peak fragment ions were *m/z* 217 (apiose, rhamnose, glucose) and *m/z* 248 (fructose).

NMR Spectroscopy. ^{1}H and ^{13}C NMR spectra of isolated compounds were recorded on a Varian Unity Inova 500 MHz spectrometer (Darmstadt, Germany). Compounds **14** and **15** (Figure 1) were dissolved in DMSO-d_6 (plus a drop of D_2O) and pyridine-d_5, respectively. The ^{1}H and ^{13}C chemical shifts were referenced to residual solvent signals at $\delta_{H/C}$ 2.49/39.5 (DMSO-d_6) and 8.71/149.8 (pyridine-d_5) relative to TMS. Adiabatic 2D broadband and band-selective gHSQC and gHMBC, gDQFCOSY, ROESY, and TOCSY as well as selective 1D TOCSY spectra were recorded using CHEMPACK 4.0 pulse sequences (implemented in Varian VnmrJ 2.1B software). Coupling constants *J* (in hertz) were directly taken from the spectra and are not averaged.

RESULTS AND DISCUSSION

Comparison of Freshly Prepared Bark Extracts and Commercially Available Wood Extracts of *Q. saponaria* Molina. A total of 31 phenolic compounds were previously described to be present in commercially available *Quillaja* wood extracts,[5] which are widely used as emulsifiers in foods (e.g., as E999 in the EU) and cosmetics. In the present study, we compared the composition of such commercial extracts to that of a freshly prepared aqueous extract of the inner bark. The HPLC-PDA-MS^n-based comparison revealed a highly similar phenolic pattern (Figure 2; Table 1). In agreement with our previous work,[5] (+)-piscidic acid, **1**, was found to be the major phenolic, whereas several vanillic acid derivatives (**2**, **3**), syringic acid derivatives (**4**, **8**), and catechin derivatives (**7**, **10**) were found at minor signal intensities. However, we previously described several unknown *p*-coumaric acid derivatives (**5**, **6**, **9**, **11**−**29**), two of them (**14**, **15**) at very high signal intensities. Notably, we were unable to identify some trace compounds in the inner bark extracts, which were previously detected in commercial extracts.[5] The latter compounds were mostly free phenolic acids, such as vanillic, syringic, *p*-coumaric, and ferulic acid, possibly representing artifacts generated during the manufacture of the commercial extracts.

Characterization of New *p*-Coumaroyl Sucrose Esters. After preparative isolation, compound **14** was obtained as a

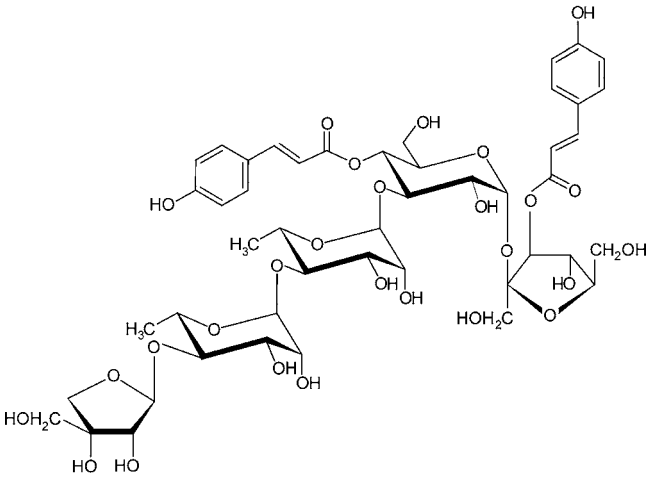
Quillajaside A (**15**)



Quillajaside B (**14**)

Figure 1. Chemical structures of the new compounds quillajaside A and quillajaside B extracted from the inner bark of *Q. saponaria* Molina.

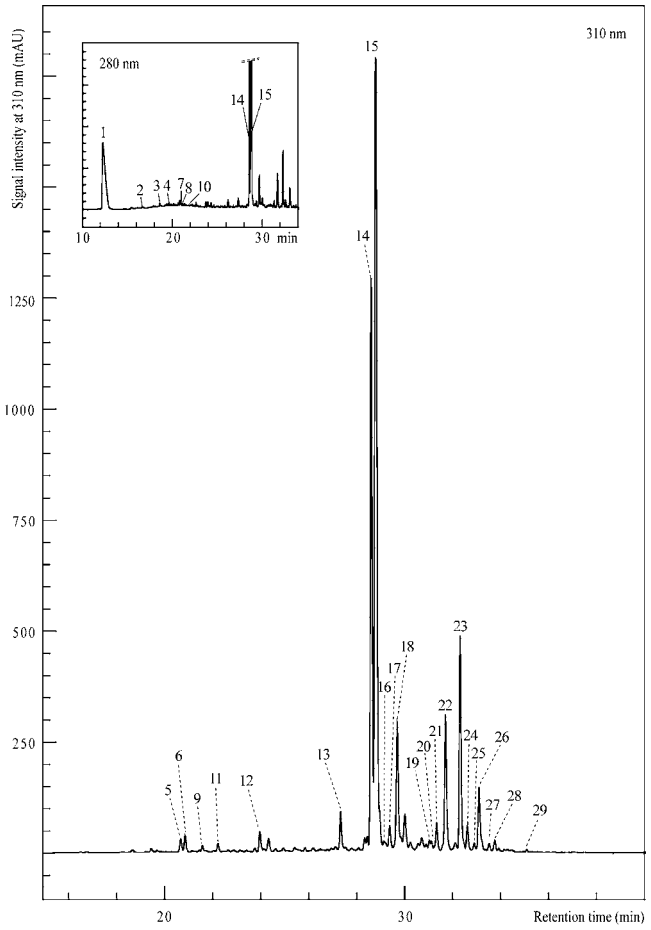


Figure 2. HPLC separation of phenolic compounds from an aqueous extract of the inner bark of *Q. saponaria* Molina at 280 and 310 nm.

white amorphous powder. HR-FT-ESI-MS measurements indicated a molecular formula of $C_{47}H_{62}O_{27}$ (see Table 1). The acidic hydrolysis yielded free *p*-coumaric acid as its only phenolic constituent as shown by HPLC-PDA-MS^n data of an authentic standard. In HPLC-ESI(−)-MS experiments, the nonhydrolyzed compound yielded a pseudomolecular ion $[M - H]^-$ at *m/z* 1057. Collision-induced dissociation (CID) experiments yielded a predominant fragment at $[M - H - 146]^-$ at *m/z* 911 (Table 1), indicating the presence of a deoxy-hexose moiety. The second most abundant, nonisotopic fragment ion $[M - H - 132]^-$ at *m/z* 925 was possibly produced after the potential loss of the pentose moiety. The fragment ion at *m/z* 779 may have resulted from the consecutive loss of the above-mentioned deoxy-hexose (146 Da) and pentose (132 Da) moieties. The fragment ion at *m/z* 633 may represent the additional loss of a deoxy-hexose moiety (146 Da loss), that is, being a fragment species $[M - H - 146 - 146 - 132]^-$ produced by the loss of two deoxy-hexose (146 Da) and one pentose moiety (132 Da). In agreement, a fragment ion $[M - H - 146 - 146]^-$ at *m/z* 765 generated by the loss of two deoxy-hexose (146 Da) units was also observed (Table 1). Further fragments at lower *m/z* values were unavailable due to insufficient signal intensity.

In agreement with the MS/MS-based proposition of one pentose and two deoxy-hexose moieties, analyses of the ^{13}C NMR spectrum showed a total of 17 characteristic signals of one apiosyl and two rhamnosyl moieties (Table 2; Figure 3). Each of the sugar moieties was assigned by evaluation of the gDQFCOSY, TOCSY, selective 1D TOCSY, and gHSQC spectra. Moreover, ROESY correlations (Figure 3A) and HMBC correlations of the H-4‴″ with C-1‴″, C-2‴″, and C-3‴″ as well as correlations of H-5‴″a/b with C-2‴″ and C-3‴″ unambiguously established apiose as one sugar moiety in **14** (Figure 3B). The downfield-shifted rhamnosyl C-4‴′ (δ 77.81) as well as long-range HMBC and ROESY correlations between the rhamnosyl H-4‴′ and the apiosyl C-1‴″ revealed a 1,4 linkage between both sugar moieties. The observation of a doublet at δ 5.17 with a coupling constant of *J* 2.5 Hz of H-1‴″, established the β-configuration of the apiose according to previous papers.[6−10] The absence of downfield-shifted C atoms other than the anomeric C-1‴″ indicated the terminal localization of the apiosyl moiety (Figure 3). The downfield-shifted C-4‴″ (δ 80.02) of the second rhamnose along with long-range HMBC interactions of H-4‴ with C-1‴′ and H-1‴′ with C4‴ as well as an ^1H NMR signal of H-1‴′ at δ 4.82 (bs) suggested the α-1,4 linkage of the two rhamnosyl moieties (Figure 3).

Besides rhamnose and apiose, the ^{13}C NMR spectrum displayed 12 carbon signals of a glucose- and fructose-based disaccharide. Analysis of the homo- and heteronuclear 1D and 2D NMR spectra ascertained the disaccharide to be a trisubstituted sucrose (Figure 3B). The glucosyl C-3″ revealed a characteristic downfield shift at δ 78.49 and displayed a long-

[a]For numbering, see Figure 3A. [b]Assignments were based on ^{1}H−^{1}H COSY, sel 1D TOCSY, gHSQC, TOCSY, gDQFCOSY, ROESY, and gHMBC experiments.

range correlation with the rhamnosyl H-1⁗ in the gHMBC spectrum, indicating the rha(1 → 3)glu linkage as shown in Figure 3B. The ^{1}H NMR signal of H-1⁗ at *δ* 4.81 (bs) indicated the *α*-configuration of the anomeric rhamnose atom.

The remaining 18 signals in the ^{13}C NMR spectrum were assigned as two *p*-coumaroyl moieties (Table 2; Figure 3). HMBC correlations of the carboxylic C-9 of a *p*-coumaroyl moiety and H-4″ of the glucose revealed the position of the *p*-coumaroyl moiety at C-4″ as shown in Figure 3B. By analogy, a long-range correlation of the fructose H-3‴ and the second *p*-coumaroyl carboxyl C-9′ unveiled the presence of a further *p*-coumaroyl ester (Figure 3B). Both *p*-coumaroyl moieties were in (*E*)-configuration as indicated by the size of the coupling constants, *J* = 15.9−16.1 Hz, of the respective ^{1}H NMR signals (H-7, H-8, H-7′, H-8′; Table 2) as previously reported for (*E*)- and (*Z*)-coumaroyl moieties.[11] According to our GC-MS analyses, the above-mentioned sugars were D-glucose, D-fructose, L-rhamnose, and D-apiose. Therefore, the structure of compound **14** was established to be *β*-D-api*f*-(1→4)-*α*-L-rha*p*-(1→4)-*α*-L-rha*p*-(1→3)-(4-*O*-(*E*)-*p*-coumaroyl)-*α*-D-glu*p*-(1→2)-(3-*O*-(*E*)-*p*-coumaroyl)-*β*-D-fru*f*.

Compound **15** was obtained as a white amorphous powder. Its molecular formula was determined to be $C_{42}H_{54}O_{23}$ according to our HR-FT-ESI-MS measurements (Table 1). Its acidic hydrolysis yielded free *p*-coumaric acid as the only phenolic constituent. Compound **15** gave a pseudomolecular ion $[M - H]^-$ at *m/z* 925, yielding predominant fragments $[M - H - 146]^-$ at *m/z* 779 and $[M - H - 146 - 146]^-$ at *m/z* 633 during CID experiments (Table 1). The consecutive losses of 146 Da indicated the presence of two deoxy-hexose moieties. A fragment ion $[M - H - 164]^-$ at *m/z* 761 was possibly caused by the loss of the above-mentioned *p*-coumaric acid moiety.

In agreement with the proposition of two deoxy-hexose moieties, analysis of the ^{13}C NMR spectrum showed 12 characteristic signals of 2 rhamnosyl moieties, respectively (Table 3). Comparison of the ^{1}H and ^{13}C NMR signals (Table 3) as well as HMBC and ROESY long-range correlations (Figure 4) revealed a highly similar structural identity of compound **14** and **15**, consisting of two *p*-coumaroyl, one glucosyl, one fructosyl, and two rhamnosyl moieties. Glycosidic linkages, anomeric configurations, and (*E*)-configuration of the *p*-coumaroyl double bonds of compound **15** were identical to those of compound **14** as shown by the NMR data in Tables 2 and 3. Likewise, the absolute sugar configurations were identical to those described for compound **14**. In summary, the structure of compound **15** was shown to be a *α*-L-rha*p*-(1→4)-*α*-L-rha*p*-(1→3)-(4-*O*-(*E*)-*p*-coumaroyl)-*α*-D-glu*p*-(1→2)-

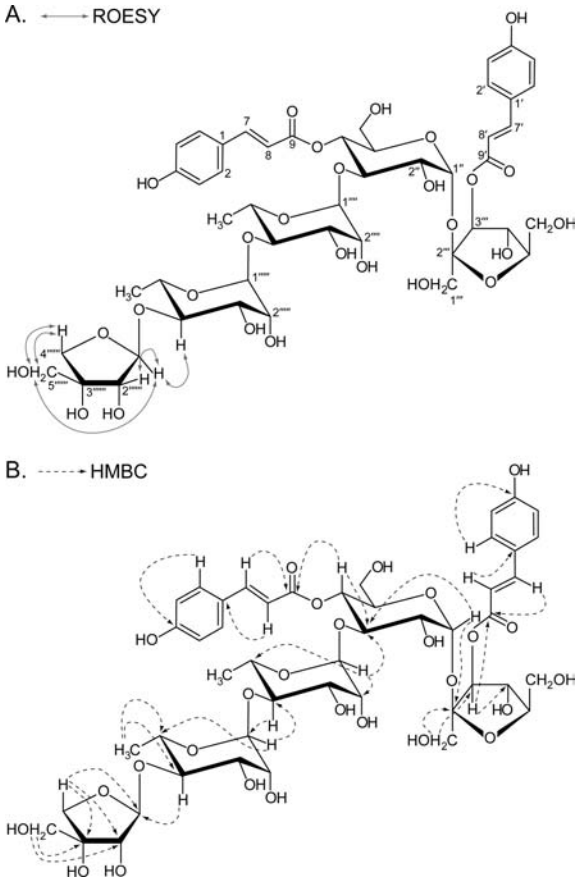

Figure 3. Important (A) ROESY and (B) HMBC long-range correlations between carbon and hydrogen atoms of quillajaside B.

(3-*O*-(*E*)-*p*-coumaroyl)-*β*-D-fruf. Due to the complexity of their systematic names, we proposed to name the smaller compound **15** quillajaside A, whereas the larger compound **14** was named quillajaside B.

Tentative Identification of Further *p*-Coumaroyl Sucrose Esters. A tentative biosynthetic series of precursors and products of quillajasides A and B may be proposed when detected compounds with highly related UV and mass spectra are considered. The most basic detectable *p*-coumaroylated substance was compound **5**, presumably representing a *p*-coumaroylated sucrose ($C_{21}H_{27}O_{13}$) according to its UV spectrum, its $[M - H]^-$ at *m*/*z* 487.1417 (calcd value in Table 1), and several characteristic CID losses and fragment ions (Table 1). A *p*-coumaroyl rhamnosyl sucrose ($C_{27}H_{37}O_{17}$, compound **11**) was tentatively identified by its UV and mass spectra, particularly, its $[M - H]^-$ at *m*/*z* 633.2022 (Table 1). Because rhamnosyl- and *p*-coumaroyl moieties are nominally isobaric, HR-MS was crucial to distinguish the identity of compound **11** clearly from a putative di-*p*-coumaroyl sucrose ($C_{30}H_{33}O_{15}$), which was not detected in the extract.

Possibly representing a direct biosynthetic derivative of the quillajaside A, a *p*-coumaroyl dirhamnosyl sucrose (compound **12**) was found according to our analytical data (Table 1). A total of three di-*p*-coumaroyl dirhamnosyl sucrose esters (compounds **15** (quillajaside A), **18**, and **21**) were identified, whereas di-*p*-coumaroyl (mono)-rhamnosyl sucroses were not detected. Furthermore, two di-*p*-coumaroyl dirhamnosyl apiosyl sucrose esters (i.e., compounds **14** (quillajaside B), **16**, and **17**) were detected. A rhamnosylated derivative of quillajaside B was observed (compound **13**), being tentatively identified as di-*p*-coumaroyl trirhamnosyl apiosyl sucrose ([M

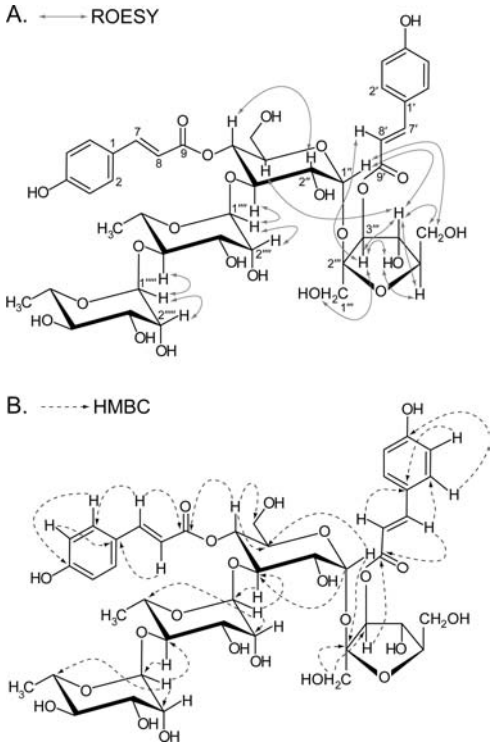

Figure 4. Important (A) ROESY and (B) HMBC long-range correlations between carbon and hydrogen atoms of quillajaside A.

$-$ H]$^-$ at m/z 1203.3957, calcd values in Table 1). Further detected compounds (**22**–**29**) represented sucrose derivatives with three *p*-coumaroyl moieties, at least two rhamnosyl moieties, and eventually an apiosyl moiety (Table 1). The highest molecular weight compounds detected in the aqueous extracts were compounds **22** and **24** with an [M $-$ H]$^-$ at m/z 1349, representing tri-*p*-coumaroyl trirhamnosyl monoapiosyl sucroses (Table 1).

In brief summary, the aqueous extracts of the inner bark of *Q. saponaria* Molina were shown to contain a total of 22 phenylpropanoid sucrose esters, being linked to up to 1 apiosyl, 3 rhamnosyl, and 3 *p*-coumaroyl moieties. Full structural elucidation was only possible for compounds **14** and **15** (quillajasides A and B). Nevertheless, because the occurrence of these unique compounds is highly characteristic of *Quillaja* extracts including the food additive E999, they may represent valuable authenticity markers for the detection of *Quillaja* extracts in food and cosmetic formulations. According to a previous paper,[12] ca. 150 phenylpropanoid sucrose esters have been identified previously, some of which exerted biological activities such as a cancer chemopreventive activity.[13] Moreover, a *p*-coumaroyl sucrose ester from wild buckwheat (*Fagopyrum esculentum* Moench) was recently shown to inhibit α-amylase activity and, thus, proposed to serve as a functional food ingredient for controlling postprandial hyperglycemia by modulating starch degradation during digestion.[14] Further studies on these *p*-coumaroyl sucrose esters, their biofunctionality in the bark of *Q. saponaria*, and their bioactivity in humans should be encouraged, particularly as these compounds are ingested daily by consumers worldwide.

ACKNOWLEDGMENTS

We are grateful to Dr. Regina Walther from Pera Ingredients (Springe-Eldagsen, Germany) for generously donating the inner bark of *Q. saponaria* Molina. We also acknowlege Dr. Jens Pfannstiel (University of Hohenheim) for conducting the high-resolution mass spectrometric analyses on the isolated compounds **14** and **15**. We thank Joachim Trinkner (University of Stuttgart, Germany) for conducting the HPLC-ESI-HR-MS analyses.

confined water (non-free diffusible) within the aggregate structure.

MATERIALS AND METHODS

Materials. Defatted soy flour was provided by Cargill BV (Amsterdam, Netherlands). Micellar casein isolate was kindly provided by Friesland Campina in a concentration of 14.6% (w/w). Anhydrous magnesium sulfate ($MgSO_4$), anhydrous magnesium chloride ($MgCl_2$), calcium sulfate dihydrate ($CaSO_4{\cdot}2H_2O$), calcium chloride dihydrate ($CaCl_2{\cdot}2H_2O$), and deuterium oxide (D_2O) with a purity of 99.9 atom % D were obtained from Sigma-Aldrich (Steinheim, Germany). Reagents were of analytical grade and used without further purification.

Preparation of (Soy) Protein Solutions. A solution of soy proteins, further denoted as SP, was prepared as described by Urbonaite et al.[1] The protein content of SP was determined by Kjeldahl (calculated using $N \times 6.25$), where the protein isolation yielded typical 11−12% (w/w) stock solutions. The ratio of the predominant proteins glycinin/β-conglycinin was estimated to be 50:50 by gel electrophoresis and reversed-phase high-performance liquid chromatography (HPLC) (results are not shown). The SP solution was stored at 4 °C in the presence of 0.02% sodium azide and used within 1 month after preparation. The enthalpy change, indicative for the protein nativity, was 15.2 J/g of protein as measured by differential scanning calorimetry (DSC, Q1000, TA Instrument, New Castle, DE).

As a reference material, a casein micelle stock solution, depleted of whey proteins, was prepared as described by Nieuwland et al.,[12] diluted to 12% (w/w) and stored at −20 °C until further use. The casein micelle stock solution further denoted as CM was defrosted overnight in the refrigerator and equilibrated at room temperature for 2 h at 20 °C before usage.

Preparation and Characterization of SP Aggregates (0.1%, v/v, Protein). *Preparation of 0.1% (v/v) SP Aggregates.* Stock solutions of SP were diluted to 2% (w/w) protein, and 20 mM salt solutions with $MgSO_4$, $MgCl_2$, $CaSO_4$, and $CaCl_2$ were prepared. A 40 mM 3-(*N*-morpholino)propanesulfonic acid (MOPS) buffer was prepared at pH 7.0. All solutions were filtered with disposable syringe filters (Machery-Nagel Chromafil RC-20/25, with a pore size of 0.45 μm). The protein stock solutions were mixed with salt solutions to a final protein concentration of 0.1% (v/v), a salt concentration of 0.35 mM, and 20 mM MOPS buffer in a total volume of 2 mL. Prepared solutions were heated at 95 °C for 30 min to allow for aggregation of the proteins, and the solution was left to cool to 25 °C. When other protein or salt concentrations were used, it is accordingly indicated in the text.

Characterization of 0.1% (v/v) SP Aggregates. Dynamic Light Scattering (DLS). The size of the protein aggregates prepared as described above was determined using DLS (Zetasizer Nano ZS, Malvern Instruments, Ltd., Worcestershire, U.K.) by 173° angle backward scattering. Measurements were performed at 20 °C and repeated 5 times per sample. The data were analyzed using a non-negative least-square analysis (general purpose model).

Static Light Scattering (SLS). To obtain a structure factor of the protein aggregates, SLS measurements were performed. Samples were prepared at a protein concentration from 0.001 to 0.3% protein (v/v) in a 20 mM MOPS buffer (pH 7.0) in the presence of salt, as described above, while keeping the protein/salt ratio constant. Measurements were performed using an ALV compact goniometer system with four detector units (ALV/CGS-4, Langen, Germany) and two ALV-5000/E multiple tau digital correlators. A Coherent Verdi V2 diode-pumped laser was used, operating with vertically linearly polarized light with a wavelength $\lambda = 532$ nm. The range of scattering wave vectors covered $4.65 \times 10^{-3} < q < 3.09 \times 10^{-2}$ nm^{-1} [$q = 4\pi n_s \sin(\theta/2)/\lambda$, with n_s the refractive index of the solution and θ the angle of observation]. The temperature of the cuvette holder was controlled by a thermostat bath at 20 ± 0.1 °C. If necessary, the solutions were diluted to exclude interparticle interactions.

Asymmetric Flow Field Flow Fractionation (AF4). AF4 was used to fractionate polydisperse SP aggregates, followed by an online multi-angle static laser light scattering (MALLS) detection and concentration measurement using ultraviolet (UV) and refractive index (RI) to determine the particle size and mass. The AF4 instrumentation comprised of a HPLC unit (Ultimate 3000, Dionex/Thermo Fisher Scientific, Sunnyvale, CA), MALLS (Dawn Heleos-II; $\lambda = 658$ nm; 130 mW laser, vertically polarized), and a RI detector (Optilab T-rEX, B, Whyatt Technology, Santa Barbara, CA). A separation channel (HF5 cartridge, Wyatt Technology, Dernbach, Germany) was comprised of a polyethersulfone hollow fiber with a nominal molecular weight cutoff of 10 kDa, corresponding to an average pore size of 5 nm (fiber type FUS 0181, Microdyn-Nadir, Wiesbaden, Germany). Data collection and analysis were performed using Astra-6 software.

Protein aggregates of 0.1% protein (v/v) in a 20 mM MOPS buffer at pH 7.0 in the presence of 0.35 mM divalent salt were measured. The sample injection volume was 20 μL using a 60 μL loop in partial inject mode. The detector flow rate was kept constant at 0.5 mL min^{-1}. The sample was injected at a flow rate of 0.2 mL min^{-1} and focused for 8 min. Elution was performed under varying cross-flow rate (V_x). At the start of elution, V_x was kept constant at 0.5 mL min^{-1} for 10 min, followed by a decay in 3 steps: from 0.5 to 0.35 mL min^{-1} in 1 min, from 0.35 to 0.2 mL min^{-1} in 2 min, and from 0.2 to 0 mL min^{-1} in 8 min. Then, V_x was kept at that zero velocity for 10 min. Light scattering signals from 53° to 100° were used for the data extrapolation using a first-order Zimm plot fit. From the fitted weight-averaged molar masses of the aggregates (M_m) and *Z*-averaged radius of gyration (R_g), the apparent density (ρ_{app}) was calculated using the following equation:

$$\rho_{app} = \frac{M_m}{N_A \frac{4}{3}\pi {R_g}^3} \quad (1)$$

where N_A is Avogadro's number.

Preparation and Characterization of SP Aggregates for Entrapped and Confined Water Measurements (1%, v/v, Protein). *Preparation of 1% (v/v) SP Aggregates.* The prerequisite for aggregates used for measurements for free diffusible water (equal to entrapped minus confined) and non-free diffusible (confined) water is that they need to be large and dense enough to be pelleted upon centrifugation [at 20 000 relative centrifugal force (RCF)]. For this reason, aggregates were prepared at 1% (v/v) protein by keeping the protein/salt ratio the same as for aggregates prepared for the structural characterization, as described above. Protein stock solutions were mixed with salt solutions to a final protein concentration of 1% (v/v) and a salt concentration of 3.5 mM, as described in the Preparation of 0.1% (v/v) SP Aggregates section earlier above. Solutions were heated at 95 °C for 30 min to allow for aggregation of the proteins to occur, and the solution was then left to cool at room temperature to 25 °C. When other protein or salt concentrations were used, it is accordingly indicated in the text.

Characterization of 1% (v/v) SP Aggregates. Scanning Electron Microscopy (SEM). Aggregates prepared at a 1% (v/v) protein concentration at pH 7.0 in the presence of 3.5 mM $MgSO_4$, $MgCl_2$, $CaSO_4$, and $CaCl_2$ salts were imaged by SEM. Circular glass coverslips of 8 mm (Menzel, Brauschweig, Germany) were cleaned by dipping twice in alcohol. The excess of remaining alcohol on the edge of the glass was carefully tipped to a filter paper. A piece of parafilm was spread on the table, using a few droplets of water for better sticking capacity, to obtain a clean hydrophobic surface. Poly-L-lysine of 0.2% (w/v) was pipetted in 100 μL quantities on the parafilm surface to obtain single droplets. Each coverslip was placed on top of the droplet, carefully turned around, and left for 5 min to ensure that both sides were completely covered with poly-L-lysine. Treated coverslips were dipped in Milli-Q water twice, and an excess of remaining water was carefully tipped to a filter paper. Rinsed coverslips were placed in the holder and left to dry overnight at room temperature. Finished coverslips were placed for 30 min in 1 mL Eppendorf tubes filled with the 0.3% (v/v) aggregate dispersions for aggregate attachment. Coverslips with attached aggregates were washed twice in Milli-Q

DOI: 10.1021/acs.jafc.5b03784
J. Agric. Food Chem. 2015, 63, 8912−8920

water, placed in a 2.5% (v/v) glutaraldehyde solution for 30 min for cross-linking of the proteins, and later washed in Milli-Q water again to rinse off the gluteraldehyde. The samples were dehydrated in a series of acetone (10, 30, 50, 70, and 100%) for 10 min per step and critical point dried (CPD) with carbon dioxide (CPD 030, BalTec, Liechtenstein, Germany). The coverslips were fitted on a sample holder by carbon adhesive tabs (Electron Microscopy Sciences, Fort Washington, PA) and subsequently sputter-coated with a 10 nm thick layer of iridium (MED 020, Leica, Vienna, Austria). Samples were analyzed in a field emission scanning electron microscope (Magellan 400, FEI, Eindhoven, Netherlands) at a working distance of approximately 4 mm, with scanning electron (SE) detection at 2 kV and 6.3 pA. The digital images were contrast-optimized with Photoshop CS5.

ImageJ 1.49d was used as a tool to evaluate bead sizes visualized in SEM images at magnifications of 100 000. On average, three images were analyzed per aggregate type. Approximately 10 spots per image were evaluated for the bead sizes. Bead sizes were obtained by direct visual inspection of the aggregate image and averaged.

Pelleting Aggregates Using Centrifugation. Prepared 1% (v/v) protein aggregate solutions at pH 7.0 in the presence of 3.5 mM $MgSO_4$, $MgCl_2$, $CaSO_4$, and $CaCl_2$ were centrifuged at 20 000 RCF for 10 min at 20 °C (centrifuge 5430R, Eppendorf AG, Hamburg, Germany). The protein content in the pellet was determined by measuring the protein content in the supernatant after the addition of 8 M urea as a powder (0.755 g of urea/g of supernatant). To optimize protein solubilization in 8 M urea, the supernatant was heated at 70 °C for 10 min. The protein content was determined by measuring the absorbance at 280 nm with a Cary 50 Bio UV−visible spectrophotometer (Agilent Technologies, Amstelveen, Netherlands). A linear calibration curve for proteins was obtained by measuring the absorbance of 0.005−1% (v/v) SP solutions in the presence of 8 M urea. Using these calibration curves, the protein content (g) in the supernatant was obtained. The difference between the total protein content of the sample and that measured in the supernatant phase was taken as the protein content of the pellet (g) ($m_{protein}$). For all four different salts, approximately 37% non-pelleted aggregates remained in the supernatant, and thus, it was assumed that 63% was present in the pellet.

Alternatively, the non-filtrated and filtrated supernatants (Machery-Nagel Chromafil RC-20/25, with a pore size of 0.45 μm) were analyzed by sodium dodecyl sulfate−polyacrylamide gel electrophoresis (SDS−PAGE) and DLS (results not shown). The results confirmed that non-pelleted proteins were actually small aggregates that did not sediment during centrifugation at 20 000 RFC for 10 min.

Pellet Density by X-ray Computer Tomography (XRT). The pellet volume was measured by XRT. Pelleted 1% (v/v) aggregates in the presence of 3.5 mM $MgSO_4$, $MgCl_2$, $CaSO_4$, and $CaCl_2$ salts were measured non-invasively as a three-dimensional (3D) structure with a spatial resolution of 10 μm by XRT, GE Phoenix v|tomelx m, 180 kV transmission tube (Windstorm, Germany). The transmission of the conical X-ray beam through the sample was recorded by a digital GE DXR detector array with 2024 × 2024 pixels (pixel size of 200 μm). Samples were imaged at the distance of 40.8 mm. Power settings of 100 kV and 135 μA were used. The 3D density map was obtained after tomographical reconstruction of images acquired under 1200 rotations over 360° with a step size of 0.3°. The acquisition time for one projection was 250 ms. Averaging three projections results in a total acquisition and read-out time of about 20 min.

Water Entrapped in the Pellet. The 1% (v/v) protein aggregate solutions prepared in the presence of 3.5 mM $MgSO_4$, $MgCl_2$, $CaSO_4$, and $CaCl_2$ salts were centrifuged at 20 000 RCF for 10 min at 20 °C (centrifuge 5430R, Eppendorf AG, Hamburg, Germany). The supernatant was carefully removed using a pipet, and the remaining serum was drained by leaving the Eppendorf tubes upside down on the filter paper for 15 min. The tubes containing the protein aggregate pellets were weighted. Water entrapped in the pellet (EW) was calculated as the water remaining in the pellet after centrifugation according to eq 2 and expressed as grams of water per gram of protein retained by the pellet.

$$EW = \frac{W_{total} - W_{removed}}{m_{protein}} \quad (2)$$

In this equation, W_{total} is the water present in the sample (g), $W_{removed}$ is the sum of the supernatant and water drained from the tube after centrifugation (g), and $m_{protein}$ is the mass of the pelleted proteins (g). When other salt concentrations were used, it is accordingly indicated in the text. Measurements were performed at least in duplicate.

Free Diffusible Water Determined by Proton Nuclear Magnetic Resonance (^{1}H NMR). Free diffusible water (EW_{FD}) is defined as the sum of water present in between pelleted aggregates and free diffusible water entrapped within aggregates. EW_{FD} was measured by ^{1}H NMR. To confirm that all free diffusible water is accounted for at the first redispersion step, the pellets were subsequently redispersed in 2 mL of D_2O using a 1 mL pipet tip by gentle manipulation with the pipet tip. Dispersions in D_2O were left for 30 min to allow for H_2O present in the aggregates to exchange with D_2O to form HDO, and subsequently, the samples were centrifuged again at 20 000 RCF for 10 min at 20 °C (centrifuge 5430R, Eppendorf AG, Hamburg, Germany). This procedure was repeated 3 times and is further denoted as consecutive washing steps. HDO present in the collected supernatant was quantified by nuclear magnetic resonance (NMR). ^{1}H NMR spectra of D_2O samples containing HDO were recorded at a probe temperature of 300 K on a Bruker AVANCE III 500 spectrometer at the Wageningen NMR Centre (WNMRC), Wageningen, Netherlands. For each spectrum, eight scans were recorded with a relaxation delay of 10 s.

Non-free Diffusible Water Confined within Aggregates. Non-free diffusible water confined within aggregates (grams of water per gram of protein) (CW) was calculated as follows:

$$CW = \frac{EW - EW_{FD}}{m_{protein}} \quad (3)$$

in which EW_{FD} was measured by ^{1}H NMR, as explained above.

To demonstrate if (partial) aggregate dissociation would release an additional amount of water, pellets were dispersed in D_2O containing 8 M deuterated urea. Deutarated urea was obtained by dissolving urea up to 10 M in D_2O and freeze-dried (repeated 3 times). Pellets in the presence of urea were heated at 70 °C for 10 min in the water bath to allow for aggregates to dissociate.

Definitions. From the experimental setup described above, the water entrapped by the aggregates once pelleted is defined as the total amount of entrapped water by the pellet (EW). The sum of water present in between pelleted aggregates and water entrapped within aggregates free to diffuse is defined as free diffusible water (EW_{FD}). Confined water within the aggregate (CW) is defined as water that is hindered in its diffusion because of the physical aggregate structure. This water is non-free diffusible on the time scale of the measurement (15 min).

RESULTS AND DISCUSSION

Aggregate Size. In this study, it was aimed to obtain protein aggregates different in size and density and to show if the acquired structures account for different amounts of entrapped and confined water present within the aggregate. The sizes of the aggregates prepared in a 0.1% (v/v) SP solution in the presence of 0.35 mM $MgSO_4$, $MgCl_2$, $CaSO_4$, and $CaCl_2$ salts were measured using DLS, and the results are shown in Figure 1. The Z-averaged diameter of these aggregates increased in size from 94 to 130 nm, going from the addition of $MgSO_4$ to $MgCl_2$, $CaSO_4$, and $CaCl_2$.

Aggregate Density. Information on the aggregate structure was further obtained using AF4 fractograms yielding a so-called conformation plot (Figure 2A), showing the scaling of the size (R_g) and the averaged molar mass (M_m). Although the conformation plot of SP aggregates shows similar curves for the different salts indicative for comparable aggregate "build-

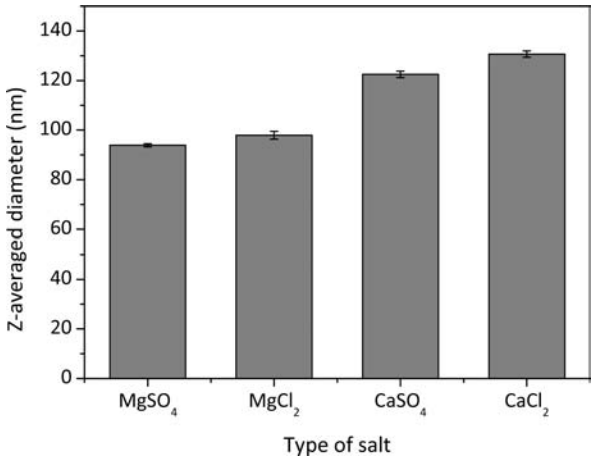

Figure 1. *Z*-averaged diameter of aggregates prepared in 0.1% (v/v) SP solution in 20 mM MOPS buffer at pH 7.0 in the presence of 0.35 mM $MgSO_4$, $MgCl_2$, $CaSO_4$, and $CaCl_2$ salts.

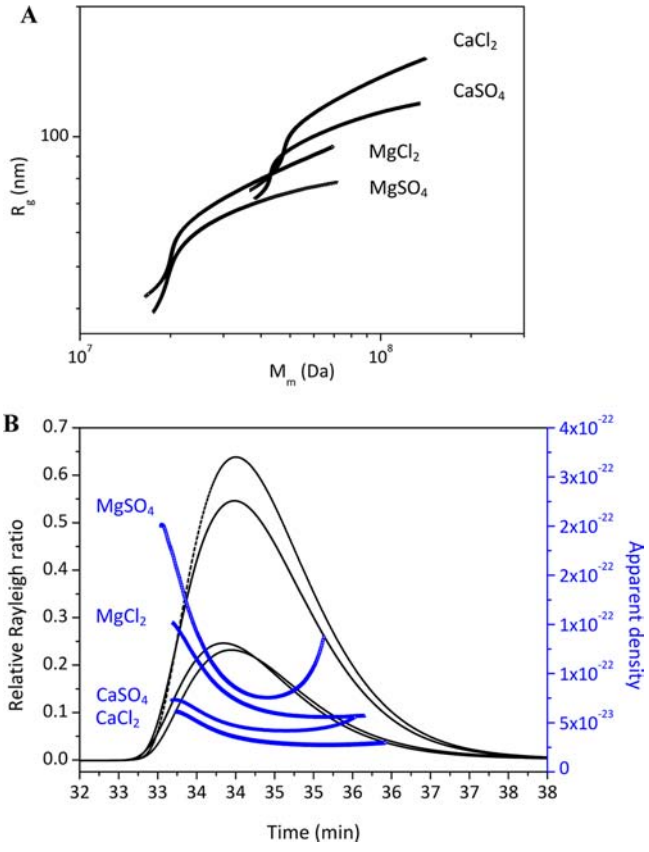

Figure 2. (A) Conformation plot indicating the scaling of size (R_g) to molar mass (M_m). (B) Rayleigh ratio (lower peaks for magnesium salts and higher peaks for calcium salts) and the calculated apparent density using eq 1 of SP aggregates in 20 mM MOPS buffer at pH 7.0 in the presence of 0.35 mM $MgSO_4$, $MgCl_2$, $CaSO_4$, and $CaCl_2$ salts.

up", it can be observed that aggregates formed in the presence of $MgSO_4$ are the smallest and aggregates formed in the presence of $CaCl_2$ are the largest in size, in agreement with DLS data. In agreement with Figure 1, aggregates prepared in the presence of magnesium salts had a lower averaged molar mass compared to aggregates prepared in the presence of calcium salts.

Assuming that R_g and M_m of aggregates have a power law relationship as $R_g \sim M_m^{1/d_f}$, the exponent of such a curve provides a fractal dimension (d_f).[13] On a log−log plot, this relation should yield a straight line, where the slope represents the fractal dimension. The fractal dimension directly relates to the openness of aggregates, where a lower d_f represents a more open aggregate structure.[14−16] From Figure 2A, it can be seen that measured SP aggregates had 1 order of magnitude variation in M_m and the curve of R_g over M_m obtained is not linear. On the basis of these results, the fractal dimension (d_f) could not be obtained for measured SP aggregates, but the results still provide an indication of the internal density of the aggregates. From the curve, two regimes can be distinguished. These curves show that the fractal dimension for smaller sized aggregates is larger (steeper slope) than for larger aggregates. The beginning of the curve indicates a range of aggregates increasing in size but having the same molar mass, and the second part of the curve shows aggregates increased in size and density. Because SPs have an affinity for divalent cations, the addition of these salts cause instantaneous protein clustering (nucleation). A fast initial clustering could yield inefficiently formed aggregates that serve as a nucleus for denatured proteins to form a dense shell during heating. As a result, a more open aggregate structure inside in the aggregate could be formed in comparison to the outer structure.

The densities of above-mentioned aggregates were derived from the aggregate size (R_g) and average mass of the aggregate (M_m) measured using AF4.[13,17] The apparent aggregate density of different SP aggregates was calculated using eq 1 and is shown in Figure 2B, depicting the Rayleigh ratio (scattering light intensity) and the calculated apparent densities. From the figure, it can be observed that aggregates decrease in apparent density following this order $MgSO_4$, $MgCl_2$, $CaSO_4$, and $CaCl_2$. To conclude, SP aggregates increased in size and decreased in density following the salt type order $MgSO_4$, $MgCl_2$, $CaSO_4$, and $CaCl_2$.

Transition from 0.1 to 1% (v/v) Aggregates. To determine the amount of water associated with the aggregate, the aggregates had to be collected as a pellet. Aggregates prepared at 0.1% (v/v) concentration were too small to be pelleted. Aggregates used for the determination of free diffusible water and water confined within the aggregate were prepared at 1% (v/v) protein concentration in the presence of 3.5 mM $MgSO_4$, $MgCl_2$, $CaSO_4$, and $CaCl_2$ salts. To translate the measured aggregate characteristics (differences in size and density) of aggregates prepared at 0.1% (v/v) protein to aggregates prepared at 1% (v/v) protein, SLS experiments were performed to obtain the size of aggregates prepared at concentrations of 0.001−0.3% (v/v) protein in the presence of salts while keeping the protein/salt ratio constant to obtain a structure factor for the different protein aggregates. For all salts, the size of the aggregates increased with increasing protein concentration (results not shown). Because these aggregates were too large at all concentrations prepared, it was not possible to obtain a reliable structure factor.

Aggregate Morphology (1%, v/v). To verify whether differences in size and density are apparent in 1% (v/v) SP aggregates in the presence of the various salts, SEM imaging of these aggregates was performed. Aggregates depicted at different length scales are shown in Figure 3. From images with the lowest magnification, it can be observed that the aggregates differ in size; aggregates prepared in the presence of $MgSO_4$ were the smallest, and aggregates prepared in the

J. Agric. Food Chem. 2015, 63, 8912−8920

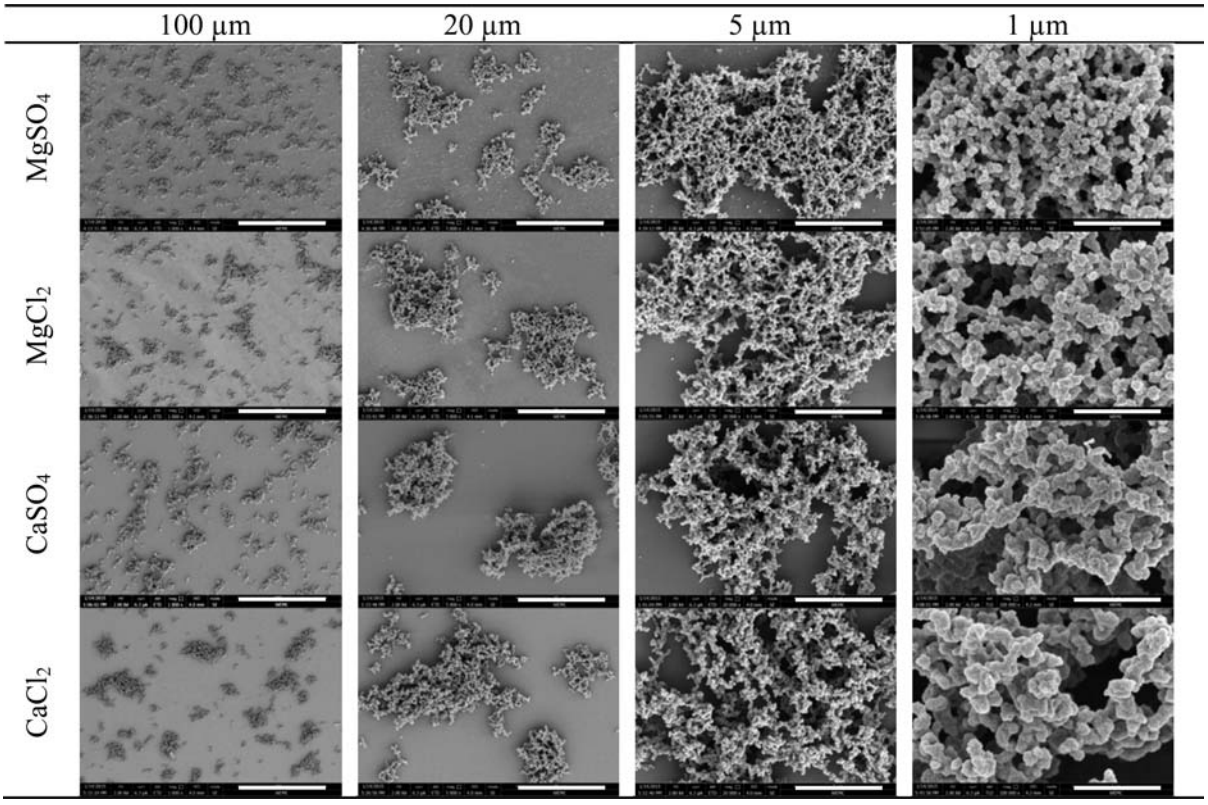

Figure 3. SEM images of 1% (v/v) SP aggregates prepared in 20 mM MOPS buffer at pH 7.0 in the presence of 3.5 mM $MgSO_4$, $MgCl_2$, $CaSO_4$, and $CaCl_2$ salts over different length scales. The indicated length scales correspond to the bar in the image.

presence of $CaCl_2$ were the largest in size, in agreement with the results above. The aggregates formed had an irregular shape and were polydisperse. In the presence of magnesium salts, aggregates varied from approximately 5 to 20 μm. In the presence of $CaSO_4$, the aggregates varied between 5 and 25 μm, and in the presence of $CaCl_2$, aggregates up to 30 μm were found. Differences in the aggregate microstructure in the presence of different salts were seen on 1 μm scale images (images on the right) in the bead size and in thickness of the strands, which were composed from these beads. The beads were fairly regular spherical particles and increased in size as measured by image analysis from 0.1 to 0.3 μm (Figure 4)

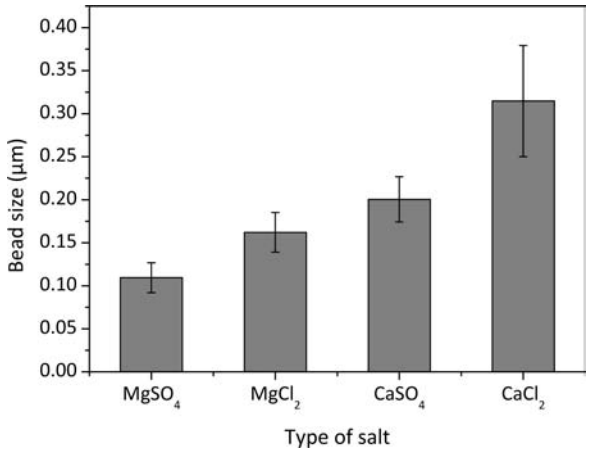

Figure 4. Bead sizes of 1% (v/v) SP aggregates prepared at pH 7.0 in the presence of 3.5 mM $MgSO_4$, $MgCl_2$, $CaSO_4$, and $CaCl_2$ salts imaged by SEM.

following the salt addition in the order of $MgSO_4$, $MgCl_2$, $CaSO_4$, and $CaCl_2$. The increment in size and more open formed structures observed in Figure 3 are in agreement with aggregate size and density results shown in Figures 2 of aggregates prepared at 0.1% (v/v) protein concentration.

Water Entrapped by the Pelleted Aggregates. Protein aggregates prepared at 1% (v/v) in the presence of 3.5 or 8.0 mM $MgSO_4$, $MgCl_2$, $CaSO_4$, and $CaCl_2$ salts were centrifuged at 20 000 RCF for 10 min at 20 °C. The quantity of water entrapped by the pelleted aggregates, *EW* (water in between and within the aggregates), is shown in Figure 5. From the figure, it can be observed that *EW* by the pelleted aggregates prepared in the presence of 3.5 mM salts increased from approximately 8 to 13 g of water/g of protein for salts in the following order of $MgSO_4$, $MgCl_2$, $CaSO_4$, and $CaCl_2$. No significant difference was found between *EW* of aggregates prepared in the presence of $MgSO_4$ and $MgCl_2$ salts (~8 g of water/g of protein). Aggregates prepared in the presence of $CaSO_4$ entrapped slightly more water (~8.5 g of water/g of protein) compared to aggregates prepared in the presence of magnesium salts, while in the presence of $CaCl_2$, this difference became much larger (~13 g of water/g of protein).

Measured pellet densities using XRT (Table 1) increased in the following order of $MgSO_4$, $MgCl_2$, $CaSO_4$, and $CaCl_2$. The protein content in the pellets was comparable for all samples measured (discussed in the Materials and Methods), but the amounts of entrapped water by the different pelleted aggregates differed (Figure 5). Because the protein content of the pellets is comparable, it can be concluded that aggregates prepared differed in size and structure as well as in the amount of entrapped water. Thus, higher pellet density (mass of sum of protein and water over volume) would indicate lower aggregate

$MgCl_2$	0.123 ± 0.002	111	1.106
$CaSO_4$	0.134 ± 0.002	121	1.105
$CaCl_2$	0.186 ± 0.002	159	1.171

[a]Single measurement.

density because the protein content in the pellets is comparable. This finding is in agreement with the results reported by Nieuwland and colleagues, where larger and denser egg ovalbumin aggregates in the gel measured on larger length scales by spin-echo small-angle neutron scattering (SESANS) resulted in lower gel WH.[10]

To illustrate whether higher salt concentrations would affect the size of the aggregate and the accompanying amount of *EW*, an additional set of aggregates was prepared from a 1% (v/v) protein solution in the presence of 8.0 mM salt. The pelleted 1% (v/v) aggregates (Figure 5) entrapped approximately double the amount of water ranging from approximately 13 to 19 g of water/g of protein compared to aggregates prepared in the presence of 3.5 mM salts. Obtained results on aggregate size confirmed that pelleted aggregates prepared at a higher salt concentration are larger and can, thereby, entrap more water.

Aggregate Compressibility. To compare the amount of *EW* in pelleted aggregates to water entrapped by the aggregates in solution, the apparent density, ρ_{app} (g/cm^3), of 0.1% (v/v) SP aggregates was calculated using the radius of gyration (R_g) and averaged molar mass (M_m) obtained from AF4 measurements (see eq 1). The quantity of water entrapped by aggregates was calculated as $1/\rho_{app}$ (grams of water per gram of protein) and is presented in Table 2. Values for entrapped water calculated for 0.1% (v/v) aggregates and measured *EW* values for 1% aggregates are shown in Table 2 and are expressed as grams of water per gram of protein. From the calculated values of entrapped water by aggregates in solution, it can be observed that aggregates larger in size and lower in density (for $CaCl_2$) can entrap more water. The difference in water entrapped by the aggregates in the solution and those compressed in a pellet (*EW*) could be explained by aggregate compressibility at the centrifugation force used. The compressibility factor, taken as the ratio between water entrapped by the aggregates in solution and *EW* (Table 2), shows that smaller and denser aggregates, such as those in the presence of magnesium salts, entrap less water and are also less compressible. Larger and more open aggregates, as in the presence of calcium salts, entrap more water and are more compressible. In agreement with our findings, Bell and colleagues suggested that aggregate strength, determined by the structure of the aggregate (on the basis of the density−size relationship), decreases with increasing aggregate size.[18]

Repetitive Forces Applied on Aggregates. To differentiate between entrapped and confined water by aggregates, pellets were redispersed in D_2O, to allow for water between the aggregates to diffuse from the aggregates and exchange with the solvent, giving HDO that is quantified by ^1H NMR (see the paragraph below on free diffusible water EW_{FD}). This step was repeated up to 3 times (further denoted as subsequent washing steps) to ensure that all free diffusible water was taken into account.

Pelleted protein aggregates were consecutively washed 3 times in D_2O. At each washing step, pelleted aggregates were redispersed in the same amount of D_2O. Changes in *EW* by the pelleted aggregates over washing steps are shown in Figure 6A. From the figure, it can be observed that, with each additional washing step, *EW* by the pelleted aggregates decreased by approximately 12−15%. The decreased amount of *EW* for the subsequent redispersion and centrifugation steps is suggested to represent compressibility of the pelleted aggregates, as described above. To verify that the decrease of *EW* is caused by pellet compressibility and not by aggregate disassembly caused by depletion of divalent ions during the washing step, a control experiment was performed where pelleted aggregates were washed in D_2O in the presence of $CaCl_2$. Obtained results did not show any significant effect on *EW* by pelleted aggregates (data not shown).

The change in the amount of *EW* retrieved from the aggregates by the subsequent washing steps was evaluated by taking the slope of entrapped water over 3 washing steps, as shown in Figure 6A and presented in Figure 6B for the different salts. From the figure, it can be seen that $MgCl_2$ and $CaCl_2$

Table 2. Water Entrapped by 0.1% (v/v) Aggregates Prepared in the Presence of 0.35 mM Salts in the Solution (Calculated) versus 1% (v/v) *EW* by the Pelleted Aggregates (Measured) Prepared in the Presence of 3.5 mM Salts

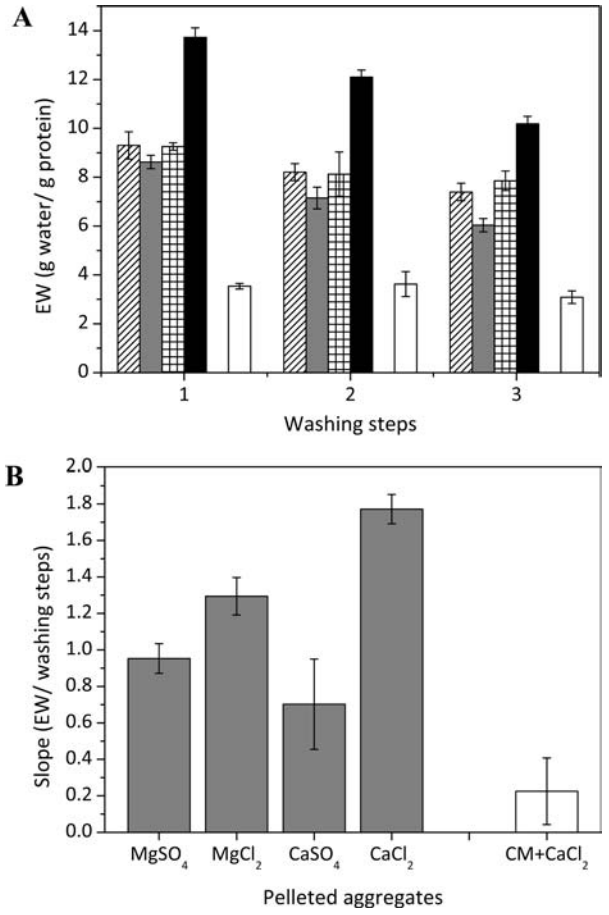

Figure 6. (A) Change in *EW* (D_2O) by 1% (v/v) SP aggregates prepared in the presence of 3.5 mM $MgSO_4$ (striped columns), $MgCl_2$ (gray columns), $CaSO_4$ (grid columns), and $CaCl_2$ (black columns) over washing steps in D_2O. (B) Rate of change in quantity of *EW* (D_2O) by pelleted aggregates prepared in the presence of 3.5 mM salt affected by 3 washing steps. In both panels, white columns stand for a control sample, 1% (v/v) CM aggregates prepared in the presence of $CaCl_2$.

aggregates were more affected by each washing step compared to $MgSO_4$ and $CaSO_4$ aggregates. To conclude, once pelleted aggregates are evaluated, larger and less dense SP aggregates are more compressible compared to smaller and denser aggregates. When reoccurring compression appears (e.g., washing steps), aggregates prepared in the presence of chloride salts (less dense) are compressed more than aggregates prepared in the presence of sulfate salts (more dense).

Free Diffusible Water in between and within Aggregates. The 1% (v/v) SP aggregate pellets were redispersed in D_2O, and free to diffuse water (EW_{FD}) from in between aggregates and from within the aggregates (HDO) was quantified by ^1H NMR. The amount of HDO from the aggregates (in between and within) prepared in the presence of 3.5 mM salt is shown in Figure 7A. More water had diffused from aggregates larger in size and lower in density ($CaSO_4$ and $CaCl_2$). This correlates positively with the results found for *EW* (Figure 5); the more water retained by pelleted aggregates, the more water free to diffuse from these aggregates. A total of 3 consecutive washing steps were performed (Figure 7A), and the results confirmed that almost all EW_{FD} already diffused in the first washing step, because almost no additional water has diffused in the second and third washing steps. This shows that, indifferent to aggregate size or density, all EW_{FD} is exchanged with D_2O on the minutes time scale.

In a parallel experiment, pelleted aggregates were redispersed in D_2O in the presence of 8 M deuterated urea to allow for aggregate dissociation. It was aimed to evaluate if, in the case destabilization of the aggregates would be induced, a larger amount of water, in addition to the regular washing, could be released (Figure 7B). From the figure, it can be seen that the addition of urea released not more than 0.5 g of water/g of protein, independent to the aggregate structure. The amount of additionally released water was marginal compared to the free diffusible water measured.

For comparison, CM aggregates prepared from a 1% (v/v) solution in the presence of 3.5 mM $CaCl_2$ were also analyzed. CMs are known for their loose packing and high porosity.[19] They have a voluminosity in milk of about 3−4 g of water/g of dry casein,[20,21] where only a relatively small proportion, around 0.5 g of H_2O/g of dry casein, is directly bound to the casein.[20] Because of the sponge-like colloidal casein micelle structure, obtained particles were expected to have a high amount of water displaced from the (pelleted) material when force is applied. CM particles visualized by SEM had very coarse open structures up to 50 μm in size (data not shown). *EW* measured of pelleted CM particles was ∼4 times lower compared to *EW* of pelleted SP ($CaCl_2$) aggregates (white columns in Figure 5). Although CM particles were larger in size compared to the soy aggregates, they entrap less water, indicating high aggregate compressibility. The small change in *EW* as affected by reoccurring compression (washing steps) indicates a small

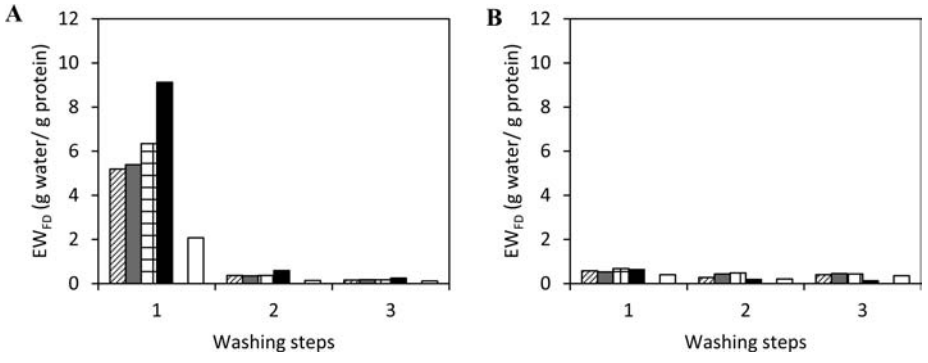

Figure 7. (A) Quantity of measured HDO diffused from aggregates (EW_{FD}) prepared in the presence of 3.5 mM $MgSO_4$ (striped columns), $MgCl_2$ (gray columns), $CaSO_4$ (grid columns), and $CaCl_2$ (black columns) salts. (B) Additionally released non-free diffusible water measured in the presence of 8 M deuterated urea. In both panels, white columns stand for the reference, 1% (v/v) CM aggregates prepared in the presence of $CaCl_2$.

DOI: 10.1021/acs.jafc.5b03784
J. Agric. Food Chem. 2015, 63, 8912−8920

degree of compression at reoccurring forces, because the maximum compression of the structures has already occurred in the first centrifugation step (Figure 6B). In comparison to SP aggregates, as expected, CM particles had the lowest amount of water entrapped. The large size, open structure, and large compressibility of CM particles lead to high water displacement from the aggregate when an external force is applied.

Confined Water within the Aggregate Structure. Confined water within the aggregate (*CW*) is defined as water that is hindered in its diffusion because of the physical aggregate structure. The results for calculated *CW* (eq 3) for different aggregates are shown in Figure 8. From the figure, it

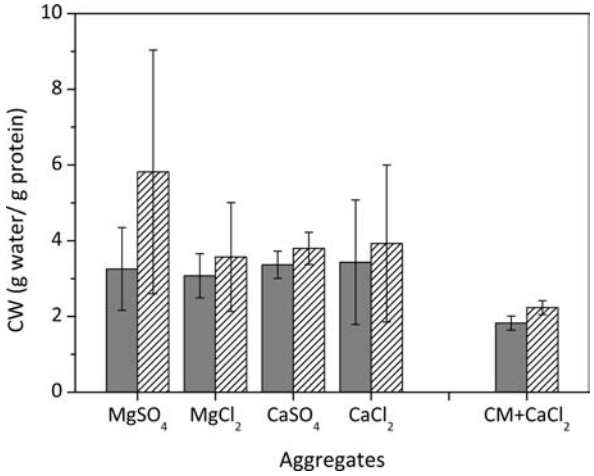

Figure 8. Confined water (*CW*) within aggregates: 3.5 mM (light gray columns) versus 8.0 mM (striped columns).

can be observed that, in case of SP aggregates, the amount of *CW* within aggregates is independent of the aggregate structure (size and density) and accounts for approximately 3.5 g of water/g of protein. The reference material accounted for approximately 2 g of water/g of protein and suggests that this quantity is protein-specific.

From the above results, it can be concluded that *EW* by pelleted aggregates depends upon the aggregate size, density, and compressibility, whereas *CW* within aggregates is aggregate-structure-independent but seems to be protein-specific.

Modulation of Entrapped Water. Above, it was shown that different types of salts can be used to obtain different aggregate structures for SPs. To evaluate to what extent these different aggregates can be tuned for the amount of *EW* and *CW*, different salt concentrations (3.5−10 mM) were tested. The obtained aggregates were measured for *EW* and EW_{FD}. The results for measured *EW* and calculated *CW* are shown in Figure 9. From Figure 9A, a transition-like behavior in *EW* of aggregates prepared at increased salt concentrations can be observed. Aggregates prepared at higher salt concentrations retained more water. The transition from lower *EW* to higher *EW* appeared earlier over the salt concentration range in the order of $CaCl_2$ > $CaSO_4$ > $MgCl_2$ > $MgSO_4$. The varied salt concentration yielded aggregates different in size and density, and as a result, the amount of *EW* in the pellet varied from approximately 10 to 25 g of water/g of protein. The same aggregates measured for *CW* within the aggregates (Figure 9B) resulted in 2−4 g of water/g of protein and confirmed that confined water is aggregate-structure-independent.

In conclusion, from this work, two types of water within SP aggregates have been distinguished: (i) entrapped water and (ii) confined water. Entrapped water is associated with (pelleted) aggregates and is not constrained in the exchangeability with a solvent. Confined water in aggregates is hindered in its diffusion because of physical restrictions. This work aimed to show whether aggregates different in structure differ in these two types of water. Prepared aggregates increased in size and decrease in apparent density following the salt type order $MgSO_4$, $MgCl_2$, $CaSO_4$, and $CaCl_2$. Calculations based on AF4 data of water entrapped by aggregates in solution resulted in 21 g of water/g of protein for $MgSO_4$ aggregates (smallest and most dense) and 58 g of water/g of protein for $CaCl_2$ aggregates (largest and least dense). The amount of water entrapped by the pelleted aggregates was from ∼2 to 4 times lower; the difference in entrapped water by the aggregates in the solution and the pelleted aggregates was accounted for by aggregate compressibility (under centrifugal force). Smaller and denser aggregates prepared in the presence of magnesium salts were about twice less compressible compared to larger and less dense aggregates prepared in the presence of calcium salts. When consecutive compression was applied (e.g., washing steps), aggregates prepared in the presence of sulfate salts (smaller and more dense structures) were less deformable, as reflected by the quantity of entrapped D_2O compared to

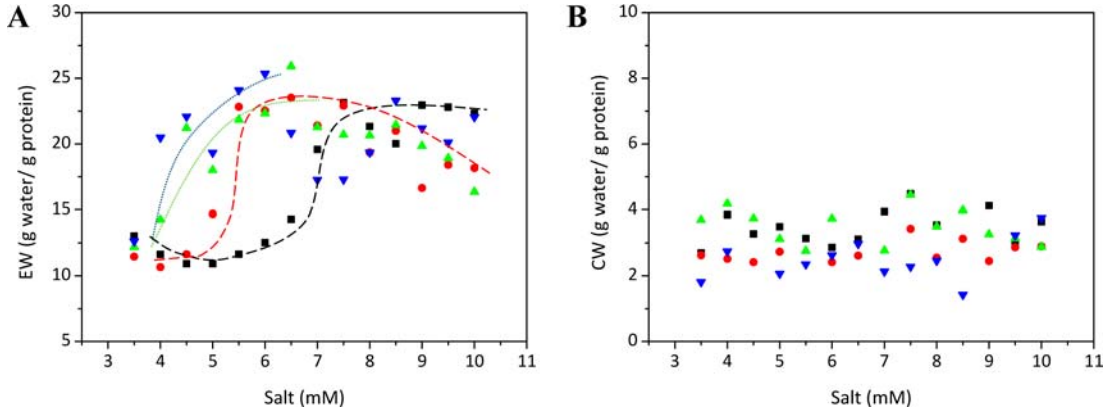

Figure 9. (A) Water entrapped (*EW*) by 1% (v/v) SP aggregates prepared in the presence of 3.5−10 mM $MgSO_4$ (black squares), $MgCl_2$ (red circles), $CaSO_4$ (green upward-facing triangles), and $CaCl_2$ (blue downward-facing triangles). To guide the eye, dashed lines are added for magnesium salts and dotted lines are added for calcium salts. (B) Water confined (*CW*) within aggregate structures.

aggregates prepared in the presence of chloride salts (larger and less dense structures). Diffusible water measurements showed that, irrespective of the aggregate size or density, all diffusible water is instantly exchanged with D_2O. The larger and less dense aggregates entrap more water, and the amount of entrapped water is proportional to the amount of diffusible water. In the case of SP aggregates, the amount of confined water within aggregates is aggregate-structure-independent and approximately 3.5 g of water is confined per gram of protein. Variation in the aggregate structure by varying the salt concentration showed that a broad range of the amount of water entrapped in the pellet can be obtained. However, confined water remained independent of the aggregate structure and varied only between 2 and 4 g of water/g of protein. To conclude, in the case where no forces are applied, larger and less dense aggregates entrap more water. When an external force is applied, more water can be displaced from these aggregates. The aggregate structural aspects do not affect the quantity of confined water within the aggregate structure. Insights in the aggregate size and deformability can be used to better tune WH on the larger length scales.

Furthermore, the presence of *a*FAs documented hitherto in food has been attributed to bacterial sources.[3,9,10] This was verified by means of stable carbon isotope analysis in that (the bacterial) *a*FAs in fish and milk fat were more depleted in ^{13}C than conventional fatty acids.[22] Hence, we also studied the bulk $\delta^{13}C$ values (‰) of Brussels sprouts (whole buds and extracted lipids) and the $\delta^{13}C$ values (‰) of *a*17:0 and other fatty acids in Brussels sprouts by compound-specific isotope analysis.

MATERIALS AND METHODS

Chemicals and Standards. Racemic standards of *a*FAs (*a*13:0, *a*14:0, *a*15:0, *a*16:0, *a*17:0, *a*18:0, *a*19:0) and *i*FAs (*i*14:0, *i*15:0, *i*16:0, *i*17:0, *i*18:0) were ordered from Larodan (Malmö, Sweden). Enantiopure (*S*)-enantiomers of *a*15:0 and *a*17:0 as well as 10,11-undecanoic acid and tetradecanoic acid ethyl ester were synthesized by Thurnhofer et al.[23,24] 8-Phenyloctanoic acid (Ph-8:0, purity = 97%) was from Alfa Aesar (Karlsruhe, Germany), whereas myristic acid (14:0) and palmitic acid (16:0) were from Fluka (St. Gallen, Switzerland). A Supelco 37-component FAME mix was ordered from Sigma-Aldrich (Taufkirchen, Germany). Methanol and *n*-hexane (both of HPLC grade, Chem Solute), as well as ethyl acetate and cyclohexane (both purest) were from Th. Geyer (Renningen, Germany). Methanol/ethyl acetate and ethyl acetate/cyclohexane were combined (1:1, v/v) and distilled to obtain the azeotrope (i.e., 44:56 and 54:46, w/w). Tetrahydrofuran (THF) (Fisher Scientific, Schwerte, Germany) was distilled and stored over a molecular filter (3 Å) in the dark until use. Bulk sorbent (isolute-HM-N) was from Biotage (Uppsala, Sweden). Urea (99.5% pure), Na_2SO_4 (99%), NaCl (99.8%), and sulfuric acid (Rotipuran, 98%) were from Carl Roth (Karlsruhe, Germany). PtO_2 was from Sigma-Aldrich (Steinheim, Germany). Hydrogen, helium (both 5.0 quality), and carbon dioxide gas (IRMS reference gas, 4.5 quality) were from Westfalen (Münster, Germany). USGS40 (certified $\delta^{13}C$ value of -26.39 ± 0.04‰ relative to Vienna PeeDee Belemnite (V_{PDB})[25]) was from the U.S. Geological Survey (Reston Stable Isotope Laboratory, Reston, VA, USA). Tin capsules for liquids (Sn purity = 99.9%, 0.04 mL volume, 3.5 × 5.5 mm size) and solids (Sn purity = 97.5%, 0.07 mL volume, 4.0 × 6.0 mm size) were from IVA Analysentechnik (Meerbusch, Germany).

Samples. Four samples of Brussels sprouts (*Brassica oleracea* L. var. *gemmifera*) were obtained from four local farmers close to Stuttgart, Germany (i.e., in Remseck, Bittenfeld, Kernen, and Remstal). The cultivars of the German Brussels sprout samples were the following: Maximus (sample 1), Genius (samples 2 and 3), and Sirius (sample 4). Five additional samples of unknown cultivars were purchased in a local supermarket (three originated from The Netherlands and two from Belgium).

Gas Chromatography with Electron Ionization Mass Spectrometry (GC-MS). FAMEs were analyzed with an HP 5890 series II gas chromatograph in combination with an HP 7673A autosampler and an HP 5971A mass selective detector (Hewlett-Packard/Agilent, Waldbronn, Germany). The temperature of the injection port, operated in splitless mode (1 μL injected), was set to 250 °C. A 60 m length, 0.25 mm internal diameter, fused silica column coated with 0.1 μm film thickness 10% cyanopropylphenyl, 90% bis-cyanopropyl polysiloxane (Rtx-2330, Restek, Bellefonte, PA, USA) was used as the stationary phase. The helium carrier gas was transported with a constant flow of 1 mL/min. The GC oven temperature started at 60 °C, was held for 1 min, and then ramped at 6 °C/min to 150 °C, at 4 °C/min to 190 °C, and finally at 7 °C/min to 250 °C (held for 7 min) (modified from Thurnhofer et al.[26]). Electron ionization was performed at 70 eV. The transfer line and the ion source temperature were set at 280 and 165 °C, respectively. In the full scan mode, *m*/*z* 50−550 was recorded after a solvent delay of 8 min. In the selected ion monitoring (SIM) mode, *m*/*z* 74, 87, 81, 79, 88, and 101 were measured from 8 min until the end of the run.[26] In addition, *m*/*z* values representing the molecular ions of different FAMEs were determined in nine time windows (Table S1, Supporting Information).[26] The time windows were set by measuring the retention times of 49 FAMEs (i.e., a 37-component FAME mix spiked with methyl esters of 7 *a*FAs and 5 *i*FAs).

By GC-MS in the SIM mode, FAMEs were identified on the basis of (i) identical retention times with FAMEs in the reference standard and (ii) the match of the molecular ion and selected fragment ions in the mass spectral data.[26] Co-elutions were observed for the methyl esters of *i*17:0 and 16:1 isomers and well as those of *i*18:0 and 17:1 isomers. Elution of *a*FA methyl esters without interference from methyl esters of unsaturated fatty acids was monitored by means of *m*/*z* 240 (M^+ of 14:1-ME), *m*/*z* 256 (M^+ of *a*15:0-ME), *m*/*z* 268 (M^+ of 16:1-ME), *m*/*z* 284 (M^+ of *a*17:0-ME), *m*/*z* 296 (M^+ of 18:1-ME), and *m*/*z* 312 (M^+ of *a*19:0-ME).

Extraction of Samples. Edible buds of Brussels sprouts (cut into pieces) were freeze-dried for 5 days in a LYOVAC GT 2 system (Leybold-Heraeus, Hürth, Germany) at 0.1 mbar (Figure 2, step 1).

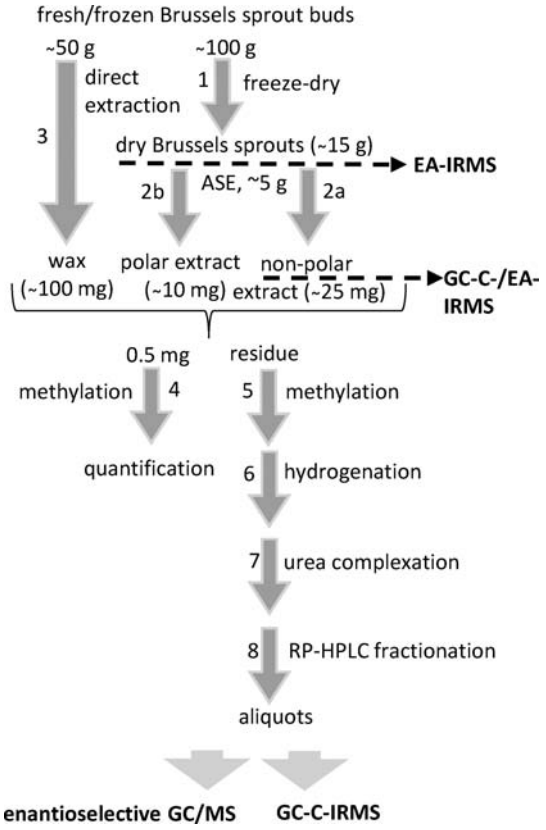

Figure 2. Work flow of the preparation of Brussels sprouts with (1) freeze-drying, (2) accelerated solvent extraction with (a) ethyl acetate/cyclohexane and (b) ethyl acetate/methanol, (3) direct extraction with *n*-hexane, (4) methylation with internal standards,[24] (5) methylation, (6) hydrogenation, (7) urea complexation, and (8) RP-HPLC fractionation.

Lipids were extracted by means of accelerated solvent extraction (ASE 200, Dionex, Idstein, Germany) according to the method of Hauff and Vetter.[27] For this purpose, ~5 g of freeze-dried sample was placed in 22 mL extraction cells and the residual space was made up with ~2 g of bulk isolute sorbent. Each cell was extracted twice with 40 mL of ethyl acetate/cyclohexane (1:1 v/v) (Figure 2, nonpolar extract, step 2a) followed by one portion of 40 mL of methanol/ethyl acetate (1:1 v/v) (Figure 2, polar extract, step 2b) (125 °C, 10 MPa, heating time of 6 min).[27] The nonpolar and polar ASE extracts were individually concentrated in a rotary evaporator (200 mbar, 35 °C bath temperature) and adjusted to exactly 5 mL in a calibrated flask. Aliquots (1 mL) were used for gravimetric determination of the lipid content.

DOI: 10.1021/acs.jafc.5b03877
J. Agric. Food Chem. 2015, 63, 8921−8929

Extraction of the wax layer was based on the method of Cannon et al., which consists of extraction with *n*-hexane followed by cooling and collection of the crystalline wax fraction from the hexane extract by filtration.[28] Initial tests showed that >97% of the extracted substances crystallized and only ~3% was separated in the form of an oily residue. Subsequent analysis of the fatty acid pattern in the hexane extract and the oily and crystalline fractions differed by <5%. Therefore, the crystallization step was omitted, and the neat hexane extract was analyzed for the wax phase. In praxis, the wax layer of edible Brussels sprout buds (50 g) was extracted with 100 mL of *n*-hexane in an ultrasonic bath (2 h, 40 °C) (Figure 2, step 3). The solution was filtered, and the organic solvent was evaporated to dryness on a rotavapor system (200 mbar, 35 °C water bath temperature). The lipid content of the wax was determined gravimetrically.

Preparation of Fatty Acid Methyl Esters. For quantitative analysis (Figure 2, step 4), aliquots (representing ~0.5 mg of fat) of the nonpolar (step 2a) and polar (step 2b) ASE extract as well as the extracted wax (step 3) were methylated with 2 mL of 1% sulfuric acid in methanol in a sand bath (80 °C, 1.5 h) after the addition of 10 μL of a solution of 10,11-dichloroundecanoic acid (internal standard I, 1 mg/mL solvent).[24] The lipid extracts of the samples were cooled on ice, 2 mL of a pure water and saturated aqueous solution of NaCl was added, and FAMEs were extracted with 2 mL of *n*-hexane according to the method of Thurnhofer et al.[24] After the addition of 10 μL of a tetradecanoic acid ethyl ester solution (internal standard II, 0.5 mg/mL),[24] the resulting sample solution was used for FAME quantification by nonchiral GC-MS. All samples were analyzed in duplicates, but only mean values will be presented, because of an excellent agreement of the replicate samples (<1% discrepancy). To calculate the fatty acid composition in the edible part of Brussels sprouts, individual amounts of FAs in the polar ASE extracts and the nonpolar ASE extracts were summed. Fatty acid standards (2.6 mg of Ph-8:0 as well as *a*FAs, *i*FAs, 14:0 and 16:0, ~5 mg per compound) were methylated without the use of internal standards.

For enantioselective and stable isotope analysis, ~20 mg of extracted nonpolar and ~5 mg of polar ASE extracts as well as ~195 mg of wax layer (after solvent removal) were methylated with 1% sulfuric acid in methanol (20 mL per 100 mg fat/extract) by refluxing for 2 h in a 250 mL round-bottom flask (Figure 2, step 5).[29] After cooling on ice, 10 mL of water and 10 mL of a saturated aqueous solution of NaCl were added, and FAMEs were extracted three times with *n*-hexane (10 mL per 100 mg fat, respectively). *n*-Hexane extracts were concentrated to 5 mL in a rotatory evaporator (40 °C bath temperature, 200 mbar) and used for *a*FAME enrichment (Figure 2, steps 6–8).

Enrichment of *anteiso*-Fatty Acid Methyl Esters for Enantioselective and Stable Carbon Isotope Analysis. FAME solutions of Brussels sprout buds (gathered from the wax as well as the nonpolar and polar ASE extracts) were separately hydrogenated to remove unsaturated fatty acids according to the method of Hauff et al. (Figure 2, step 6).[30] Briefly, FAME solutions in *n*-hexane (see above) were evaporated to dryness in a gentle stream of nitrogen (35 °C), redissolved in THF (7 mL per 100 mg FAME), and transferred into a 50 mL round-bottom, two-neck flask. PtO_2 (~3 mg) was added, and the flask was purged with nitrogen for 2 min. A hydrogen-filled balloon was set on one neck, the flask was filled with hydrogen, and the second neck was closed with a stopper. The sample solution with the FAMEs was stirred for 2 h at room temperature. After hydrogenation, the catalyst was separated by membrane filtration (0.45 μm) and the solvent was removed in a nitrogen stream (35 °C) and redissolved in 5 mL of *n*-hexane. An aliquot (about 0.1 mg/mL) was analyzed by GC-MS. The major part of the sample (~95%) was transferred into a preweighed 250 mL round-bottom flask, the solvent was removed by rotary evaporation (40 °C bath temperature and 250 mbar), and the weight of FAMEs was determined gravimetrically. Urea complexation (Figure 2, step 7) was performed by adding urea and methanol to give the ratio FAMEs/urea/methanol of 1:6:20 (w/w/v).[29] After shaking, the sample solutions were heated to 60 °C and then stored for 3 days at room temperature without any vibration.[29] Samples were transferred through a fluted filter into another flask, and the filtrate was mixed with (i) 15 mL of water (bidistilled) and (ii) 15 mL of saturated NaCl solution. Dissolved FAMEs were extracted five times with 10 mL of *n*-hexane. The combined *n*-hexane extracts were evaporated to dryness. After weighing out, the FAMEs were redissolved in 5 mL of *n*-hexane. An aliquot was analyzed by nonchiral GC-MS. The majority of the FAME fraction was fractionated by nonaqueous reversed-phase high-performance liquid chromatography (RP-HPLC) (Figure 2, step 8) using an HPLC system consisting of a 600S controller, a 717 plus autosampler, a 616 pump, and a 996 photodiode array detector operated at 210–400 nm (Waters, Milford, MA, USA). Three serially connected 250 mm length × 4 mm internal diameter C_{18} columns (ET 250/8/4 Nucleosil 7 C_{18}, 7 μm particle size, then ET 250/8/4 Nucleosil 5 C_{18}-AB, 5 μm particle size, and finally again ET 250/8/4 Nucleosil 7 C_{18}) from Macherey-Nagel (Düren, Germany) were used as stationary phase, whereas methanol served as the mobile phase (flow rate of 0.5 mL/min).[1,30] The injector was equipped with a 200 μL sample loop into which solutions of 150 μL of FAME standards or solutions of Brussels sprouts were injected.

The RP-HPLC fractionation scheme was developed by means of the injection of 10 μg of *a*15:0-ME, 10 μg of *a*17:0-ME, 50 μg of 14:0-ME, 50 μg of 16:0-ME, and 20 μg of Ph-8:0-ME (FAME standard solution in methanol). Ninety fractions of 0.5 min (250 μL) were collected between 15 and 60 min. The fractions were evaporated to dryness, redissolved in 200 μL of *n*-hexane, and analyzed by GC-MS. On the basis of these results, FAMEs from Brussels sprout samples (~0.1 mg) and ~20 μg of Ph-8:0-ME in 200 μL of methanol were injected, and the fractionation was started 2.5 min after the detection of the UV signal of the internal standard Ph-8:0-ME (retention time ~ 16.5 min) with one 3 min fraction (~19–22 min, F1), four 1 min fractions (~22–23 min, F2; ~23–24 min, F3; ~24–25 min, F4; ~25–26 min, F5), and finally one 2 min fraction (~26–28 min, F6). The solvent of the six fractions was evaporated in a gentle stream of nitrogen (40 °C) followed by the addition of 150 μL of *n*-hexane. The solutions were screened by nonchiral GC-MS analysis.

Enantioselective GC-MS Analysis. An HP GCD plus GC-MS system equipped with an HP 6890 autosampler (Hewlett-Packard, Waldbronn, Germany) was used in combination with a GC capillary column (60 m, 0.25 mm internal diameter, 0.18 μm film thickness) coated with 66% heptakis(2,3-di-*O*-methyl-6-*O*-*tert*-butyldimethylsilyl)-β-cyclodextrin (β-TBDM) in OV-1701 (custom-made by BGB Analytik, Adliswil, Switzerland). Composition and dimensions were the same as in a prototype previously used by Hauff et al.[1] Sample and standard solutions (1 μL) were injected in splitless mode at 250 °C. The transfer line and the ion source temperatures were set at 280 and 165 °C, respectively. The helium carrier gas was transported with a constant flow rate of 1.0 mL/min. Enantioselective GC-MS-SIM determinations were carried out by monitoring *m*/*z* 74, 87, and 242 (M^+ of 14:0-ME isomers), *m*/*z* 256 (M^+ of 15:0-ME isomers including *a*15:0-ME), *m*/*z* 270 (M^+ of 16:0-ME isomers), and *m*/*z* 284 (M^+ of 17:0-ME isomers including *a*17:0-ME) throughout the run.[1] Low isothermal elution temperatures of *a*FA methyl esters required longer retention times than the maximum run time of our GC-MS data processing software (650 min).[1] Therefore, two runs were programmed consecutively, injecting air in run 2 and setting the column equilibration time between runs 1 and 2 to 0 s as well as starting temperature in run 2 at the final isothermal temperature of run 1 (Figure S1, Supporting Information).[1] Different GC oven programs and carrier gas flows (0.8, 0.9, 1.0, 1.2 mL/min) were investigated, and the best enantiomer resolution was obtained with 1 mL/min under the following conditions. The GC oven temperature program started at 60 °C, which was held for 1 min. This was followed by a ramp of 20 °C/min to 112 °C (temperature held for 455 min) and a ramp of 1 °C/min to 132 °C (temperature held for 171 min) (run time = 650 min).[1] The second run started at 132 °C for 260 min (combined isothermal time at 132 °C = 431 min).[1] Then, the temperature was raised at 30 °C/min to 200 °C (temperature held for 15 min) to elute other compounds in the sample extracts. The total run time was 927 min (Figure S1, Supporting Information). Racemic *a*15:0-ME eluted after 514.3 min ((*R*)-*a*15:0) and 516.2 min ((*S*)-*a*15:0) from the β-TBDM column. The valley between the peaks was 48%. Likewise, the

DOI: 10.1021/acs.jafc.5b03877
J. Agric. Food Chem. 2015, 63, 8921–8929

enantiomers of *a*17:0-ME (868.4 min (*R*)-*a*17:0 and 872.9 min (*S*)-*a*17:0) were partly resolved (the valley between the peaks was 39%). Despite the longer GC oven program and the same carrier gas flow, the new β-TBDM column provided smaller peaks, longer retention times, and a better enantiomer resolution for *a*15:0-ME and *a*17:0-ME compared to the study of Hauff et al. (retention times *a*15:0-ME 450.2 and 456.1 min, valley of 35%, and retention times *a*17:0-ME 730.1 and 739.9 min, valley of 18%).[1] The methyl esters of 14:1n-5, 14:0, *i*15:0, 15:0, 16:1n-7, 16:0, *i*17:0, and 17:0 (t_R 360, 410, 520, 550, 650, 708, 880, and 890 min, respectively) did not interfere with the *a*FAs.

Peaks in the GC-MS-SIM chromatograms (*m*/*z* 74 and 87) of samples were smoothed using the method of Savitzky and Golay.[31] Results were expressed by the enantiomeric excess (ee in %) of the (*S*)-enantiomers according to eq 1:[32]

$$\text{ee} = \frac{[S] - [R]}{[S] + [R]} \times 100\ (\%) \quad (1)$$

with [*S*] and [*R*] being the concentrations of the (*S*)- and (*R*)-enantiomers of the methyl ester of *a*15:0 and *a*17:0, respectively.

On the basis of previous experience, we expected dominance of (*S*)-*a*FAs and possible traces of the (*R*)-enantiomers.[1,2] Evaluation was carried out relative to the following mixtures of racemic and (*S*)-enantiopure *a*15:0-ME and *a*17:0-ME: Four vials containing 100 μL of (*S*)-*a*15:0-ME and (*S*)-*a*17:0-ME (2.5 ng/μL per compound) were prepared, and 2, 5, 10, or 25 μL was removed with a microliter syringe and substituted by the same volume of racemic solution (5 ng/μL of *a*15:0-ME and *a*17:0-ME). These samples corresponded with a share of (*R*)-*a*FAMEs at 2% (ee = 96%), 5% (ee = 90%), 10% (ee = 80%), and 25% (ee = 50%). The fifth reference standard consisted of (*S*)-enantiopure *a*FAMEs. GC-MS-SIM chromatograms (after peak smoothing[31]) of the five reference standards were characterized by increasing shoulder peaks with decreasing ee (Figure 3). In the case of *a*15:0-ME, ee = 96% could be unequivocally distinguished from ee = 100%, and ">98%" was defined to be the maximum value that could be verified under these chromatographic conditions (Figure 3a). The same approach verified that "ee > 96%" was the limit for *a*17:0-ME (Figure 3b).

Samples in which the peak shape of the *a*FA methyl esters showed no noticeable deviation from the one of neat (*S*)-*a*FAME standards were classified enantiopure (ee > 98% for *a*15:0-ME and ee > 96% for *a*17:0-ME). In the case of the detection of (*R*)-enantiomers prior to the first eluting (*S*)-enantiomer in samples, ee was assigned on the basis of the closest match of the abundance of the shoulder peak with the one in the reference standards. This procedure was carried out with both *m*/*z* 74 and 87, and all samples were processed and analyzed at least in duplicate (by individual weighing in and including all enrichment steps). For verification of *a*FA methyl esters, SIM ion traces were superimposed to prove congruent run for both enantiomers (Figure S2, Supporting Information) and thereby excluding coelutions with other compounds.[2] Racemic *a*19:0-ME could not be sufficiently resolved on the β-TBDM column, and its enantioselectivity in Brussels sprout buds could not be explored.

Stable Carbon Isotope Analysis (δ^{13}C Values in ‰). Compound-specific isotope analysis was performed with a Delta plus XP mass spectrometer (Thermo Finnigan MAT, Bremen, Germany) coupled to a 6890 GC (Agilent, Waldbronn, Germany) via a GCC III combustion/reduction interface (GC-C-IRMS). The oxidation reactor (CuO, NiO, Pt) was operated at 940 °C and the reduction reactor (Cu wires) at 650 °C.[22] Removal of water was facilitated by a Nafion tube. Three ion currents (i.e., *m*/*z* 44, 45, and 46 were monitored throughout the run, and standardization of runs was achieved by injecting five times CO_2 gas with a known δ^{13}C value (−28.4‰) directly into the ion source of the mass spectrometer. A 30 m × 0.25 mm internal diameter column coated with a 0.25 μm film of 50% phenyl, 50% dimethylpolysiloxane (CP-Sil 24CB, Varian, Middelburg, The Netherlands), was used in combination with the following GC oven program: 60 °C (hold for 1 min), raised at 10 °C/min to 160 °C, raised at 2 °C/min to 200 °C, and raised at 10 °C/min to 270 °C (hold for 5 min). The injector temperature was set at 260 °C, and the

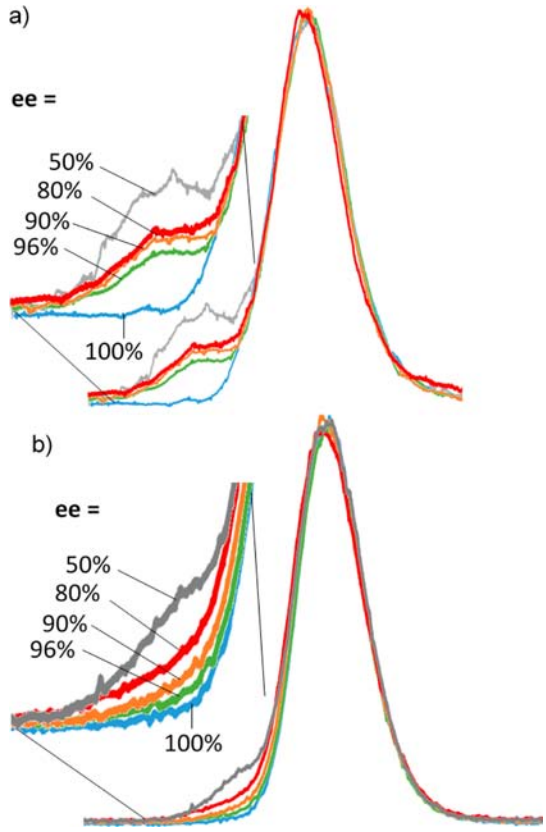

Figure 3. GC-MS-SIM chromatograms (*m*/*z* 74) of the enantioselective determination of a standard solution of (*S*)-*anteiso*-fatty acid methyl esters and admixtures with various amounts of racemic standards on β-TBDM after smoothing according to Savitzky and Golay:[31] (a) *a*15:0-ME and (b) *a*17:0-ME with partial enlargement inserted with lines in blue, ee 100%; green, ee 96%; orange, ee 90%; red, ee 80%; and gray, ee 50%.

helium carrier gas flow rate was 1.6 mL/min. HPLC fractions (step 8) of polar and nonpolar ASE extracts of four samples from Germany, two samples from Belgium, and one sample from The Netherlands (2 μL) that contained both *a*17:0-ME and 16:0-ME were used for the measurements. The HPLC fractions were adjusted to *a*17:0-ME ~ 30 ng/μL, and the solution was measured five times. The second fatty acid, 16:0-ME, was detected in two HPLC fractions. After GC-IRMS measurement of *a*17:0-ME, this and the subsequent HPLC fraction were combined and diluted to give 16:0-ME = 30 ng/μL. The resulting solution was also measured five times in the samples. Two microliters of the samples was injected in splitless mode (split opened after 2 min), and data were processed with Isodat 2.0 software (Thermo Finnigan MAT, Bremen, Germany). Due to a rapid and quantitative derivatization, no kinetic isotope effects were expected in the formation of FAMEs.[33,34] For quality control, selected samples were also analyzed without previous enrichment of *a*17:0-ME and 16:0-ME (injection of 30 ng of the analytes). Only this retention time range was transferred from the GC column to the combustion unit. The resulting δ^{13}C value (in ‰) matched the one in the enriched samples. By this measure it was verified that sample enrichment was not accompanied by isotope discrimination.

Bulk δ^{13}C values (‰) of nonpolar ASE extracts as well as freeze-dried whole edible buds of Brussels sprouts were analyzed with a Euro EA 3000 elemental analyzer (Hekatech, Wegberg, Germany) coupled to the IRMS system mentioned above. The furnace temperatures for oxidation and reduction were set to 650 and 1000 °C, respectively, and the helium carrier gas pressure was set at 70 kPa with a purge flow at 80 mL/min. Each EA-IRMS run started by measuring three times the reference CO_2 gas. For sample measurement about 2 mg of freeze-

dried Brussels sprouts was transferred by means of a spatula/syringe into tin capsules for solids, and an aliquot of the nonpolar ASE extract was placed in preweighed tin capsules for liquids. The capsules were stored overnight at room temperature for total evaporation of the solvent from the lipid samples, and the lipid amount was determined by reweighing of the fat-containing capsules.[35] Each sample was analyzed in duplicate. USGS40 was used as secondary standard to calibrate the system.[25] $\delta^{13}C$ values (‰) were calculated by means of the international internal Standard V_{PDB} (in ‰), where R is the measured isotope ratio $^{13}C/^{12}C$ eq 2:[34]

$$\delta^{13}C\ (‰) = (R_{sample} - R_{standard})/R_{standard} \times 10^3 \quad (2)$$

RESULTS AND DISCUSSION

Fatty Acid Pattern and Share of *anteiso*-Fatty Acids in Brussels Sprout Buds. Fatty acids were determined as methyl esters but will be discussed as fatty acids to keep the text simpler. Both *a*FAs and *i*FAs were detected in all Brussels sprout samples (i.e., the ASE extracts representing the edible part and *n*-hexane extracts representing the wax) (Table 1). Due to the low contribution of the wax to Brussels sprouts, the amount of *a*FAs was on average 10-fold higher in the total lipids (i.e., ~3−7 mg *a*17:0/100 g Brussels sprouts) than in the wax layer (~0.2−0.5 mg *a*17:0/100 g Brussels sprouts; Table 1). This was surprising because the presence of *a*FAs had hitherto been reported only in (surface) wax[17,18] but not in the edible part of Brussels sprouts.[36] In the present samples, the wax layer and the total lipids (sum of nonpolar and polar ASE extracts) were dominated by *a*17:0 and *a*19:0, whereas *a*15:0 and *a*21:0 occurred only as minor components (Table 1; Figure 4). Typically, *a*17:0 and *a*19:0 were on the same level in wax, whereas *a*17:0 was more abundant in the total lipids (Table 1; Figure 4). In addition, the samples also contained *i*16:0 and *i*18:0 (i.e., a total of six BCFAs). The main difference between total lipids and wax layer originated from differences in *a*17:0.

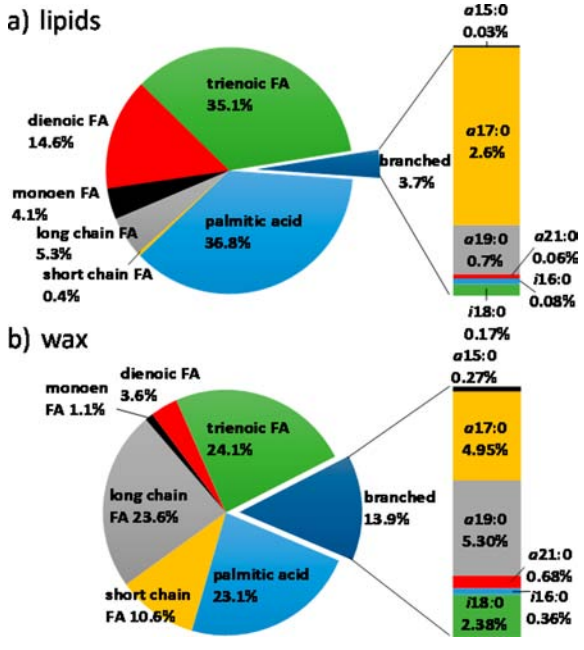

Figure 4. Share of different fatty acids in the fatty acid pattern in lipids (sum of nonpolar and polar ASE extracts) (a) and wax (b) of Brussels sprout buds with short-chain FA defined as the sum of the contribution of 8:0−15:0 and long-chain FA as the sum of the contribution of >16:0.

The BCFA pattern in our wax samples differed from two literature reports in the fact that long-chained BCFAs were more relevant in the previous studies.[17,18] Baker and Holloway additionally detected *a*23:0 (0.6%) and even-numbered, long-chained *i*FAs (up to *i*24:0) in Brussels sprout wax.[17] Even longer homologues (*a*25:0−*a*31:0, dominated by *a*29:0, 29.8%) were detected in the free fatty acid fraction of the wax of a subglaucous mutant of *B. oleracea*.[18] These examples indicate different patterns from sample to sample depending on growing conditions and genotype.[17] The presence of BCFAs has been associated with their role in membrane fluidity.[12,13,15] However, separate investigation of the nonpolar and polar ASE extracts did not reveal higher *a*FA contents in the polar fraction.

The contribution of *a*17:0 to the fatty acid pattern in the total lipids of Brussels sprouts (~2.6% of the fatty acids; Figure 4a) was higher than in the major sources of *a*FAs in food, that is, fish oil (~0.5%)[7,9] and milk fat of ruminants (~1%).[3,8,10] Apart from BCFAs, the fatty acid patterns of the wax[12] and the total lipids of Brussels sprouts[30,31] were similar to those reported in the literature. Short-chain saturated fatty acids (8:0−15:0) as well as the long-chain saturated fatty acids (>16:0) represented less than 10 and 25% of the fatty acid pattern, and 16:0 was the most abundant saturated fatty acid (>20%, Figure 4). The majority of unsaturated fatty acids originated from 18:3n-3 (trienoic acids >20%; Table 1; Figure 4,5a).

The sole presence of odd-numbered *a*FAs in Brussels sprouts agreed with reports in fish[7] and milk from ruminants.[8] By contrast, even-numbered *a*FAs were described in alpine plants (*Oxygraphos glacialis*, *Rhodiola pamiroalaica*, and *Swertia*

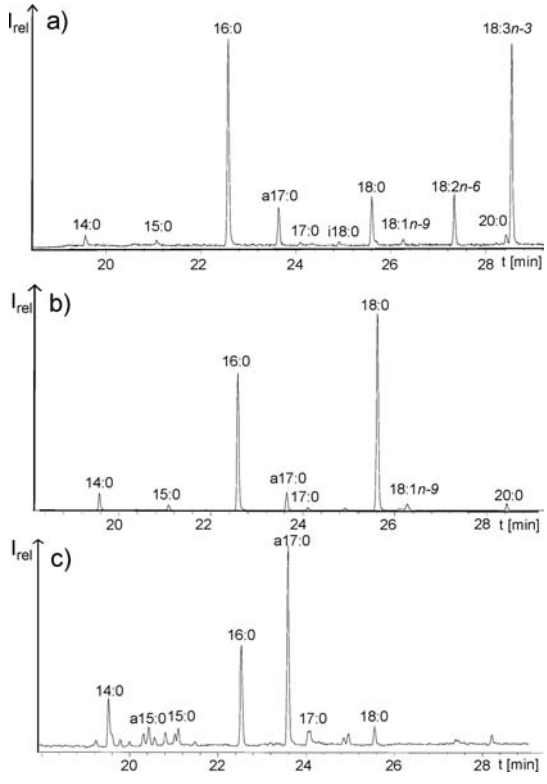

Figure 5. GC-EI-MS-SIM chromatograms (TIC) of the methyl esters from the polar lipid ASE extract of Brussels sprout buds with (a) sample before hydrogenation and urea complexation, (b) sample after hydrogenation, and (c) filtrate of the urea complexation.

marginata)[12] and in the phospholipids from petals and yellow-white leaves from *Antirrhiunum majus* (*a*22:0).[15] Only *a*17:0 was described in Pinaceae and *Ginkgo biloba* seed lipids.[14]

Enrichment of a15:0 and a17:0 from FAME Solutions of the Samples. Partly due to the low contributions of *a*FAs (Table 1) and presumably low contributions of (*R*)-*a*FAs in the samples,[1,2] it was necessary to perform a selective enrichment of the *a*FAs by (i) hydrogenation, (ii) urea complexation, and (iii) RP-HPLC (see Materials and Methods). After hydrogenation, 18:3n-3 and 18:2n-6 (~30−50% of the fatty acids in Brussels sprouts; Figure 4) were no more detected in the solutions (Figure 5a,b; Table S2, Supporting Information). Only low amounts of 18:1n-9 (<2.1% of the total FAs) were still present in the sample solutions (Table S2, Supporting Information). Consequently, the abundance of 18:0 and 16:0 increased, and these were now the most abundant FAMEs (Figure 5b). The relative contribution of *a*FAs remained unchanged (Table S2, Supporting Information). After separation of 18:0 and 16:0 by urea complexation,[29,37,38] *a*17:0 became the dominant FAME in the resulting sample solutions (Figure 5c; Table S2, Supporting Information). Despite the effective enrichment of *a*15:0-ME and *a*17:0-ME up to this point, the varied abundance of both *a*FAs (*a*17:0 ≫ *a*15:0; Table 1) and other FAMEs in the extracts still prevented the direct enantioselective determination of both compounds on the *β*-TBDM column. Hence, a final enrichment step was performed by means of nonaqueous RP-HPLC.[1] *a*15:0-ME eluted into RP-HPLC fraction F2 with a purity of ~80% (additionally <10% 14:0-ME), whereas *a*17:0-ME was collected in RP-HPLC fraction F5 (purity of ~75%, along with aliquots of 16:0-ME). Further fatty acids were not detected by means of *m*/*z* 74 and 87. Both 14:0 and *a*15:0 as well as 16:0 and *a*17:0 were well separated on the *β*-TBDM column. Hence, coelutions were not expected during enantioselective GC analysis.

Enantioselectivity of *anteiso*-Fatty Acids in the Samples. Due to low amounts in the solutions (<0.5 ng/μL sample solution) enantioselective determinations of *a*15:0 were successful in only three enriched nonpolar and polar ASE extracts from Brussels sprouts (samples 2, 3, and 6) as well as in two wax samples (samples 4 and 5). By contrast, *a*17:0 could be measured in wax, polar, and nonpolar ASE extract of all Brussels sprout samples. Without exception, the peaks of *a*15:0-ME and *a*17:0-ME were fully congruent with the peak shape of pure (*S*)-*a*15:0-ME standard (ee > 98%) and (*S*)-*a*17:0-ME standard, respectively (ee > 96%). In either case, even in the polar ASE extract, the (*R*)-enantiomer could not be detected. This contrasts with *a*FAs of dairy products and fish, where the (*R*)-enantiomers represented up to 10% of *a*15:0 and *a*17:0.[1,2] The reasons for the varied presence or absence of (*R*)-*a*FAs are currently unknown.

Stable Carbon Isotope Analysis (δ^{13}C Values in ‰). Fatty acids from bacteria living on the wax surface were a possible source of *a*FAs in this sample matrix. In this context it has been shown that bacteria utilize ^{12}C in preference to ^{13}C.[39] As a consequence, bacterial fatty acids in milk fat, including *a*FAs, were lighter in carbon than conventional fatty acids such as 16:0.[22] However, compound-specific isotope analysis of FAMEs from Brussels sprout samples showed no such difference in the δ^{13}C values between *a*17:0-ME and 16:0-ME (Table 1). Both fatty acids showed δ^{13}C values in the range from −37.7 to −32.8‰ with *a*17:0-ME being lighter in carbon in some samples and 16:0-ME being lighter in carbon in other samples (Table 1). Hammer et al. also found more negative δ^{13}C values for 17:0 isomers than in even-numbered FAs in the lipids of seagrass (*Halodule wrightii*) and redhead ducks, indicating different sources or synthesis via distinct catabolic pathways.[40] This scenario was obviously not valid for Brussels sprouts.

Because both FAMEs were comparably light in carbon, we additionally investigated bulk δ^{13}C values. Freeze-dried total Brussels sprout buds (−29.6 to −27.0‰; median, −28.4‰; Table 1; Figure 6) were in the "lighter" range of C_3-plants

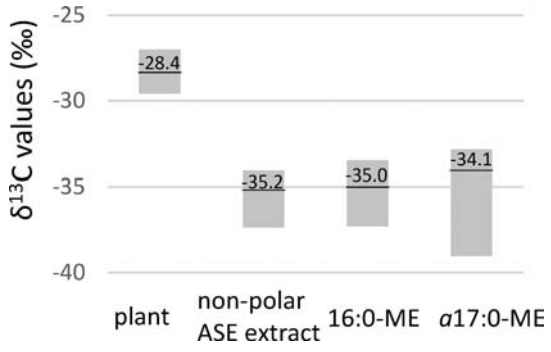

Figure 6. Range and median of the δ^{13}C values of the whole freeze-dried Brussels sprout buds and the nonpolar ASE extract (obtained with cyclohexane/ethyl acetate extraction) measured with EA-IRMS as well as the δ^{13}C values from the palmitoic acid methyl ester (16:0-ME) and the *anteiso* heptadecanoic acid methyl ester (*a*17:0-ME) measured with GC-C-IRMS.

(δ^{13}C values < −24‰).[34,41,42] The comparably wide range ($\Delta\delta^{13}$C = 2.6‰) between individual samples was most likely due to different climatic, geographic, and growing conditions (e.g., in greenhouse or field).[34] Interestingly, the range of δ^{13}C values in the samples from Germany ($\Delta\delta^{13}$C = 1.1‰) was comparably small (Table 1). In accordance with other studies,[42] the nonpolar ASE extract, representing the lipid fraction, was more depleted in ^{13}C than the whole plant (median, −35.2‰; Table 1; Figure 6). The difference (on average, 7.1‰) between the δ^{13}C values of lipids and whole plants was comparable with results from seagrass ($\Delta\delta$ ^{13}C = 6.7‰).[40] The δ^{13}C values of lipids varied by ~3‰, and samples lightest in carbon of lipids were those lightest in carbons of the FAMEs (Table 1). The difference between δ^{13}C values in lipids and the mean value of the two FAMEs was ~1‰, which is partly due to the isotope signature of the methanol used in the methylation step and also due to intrinsic differences between values obtained from EA-IRMS and GC-C-IRMS.[33,34,43] On the basis of stable carbon isotope ratios, we found no evidence that *a*FAs in Brussels sprouts originated from microorganisms but were rather from the plant itself. A possible biosynthesis pathway may include *α*-keto acid elongation without fatty acid synthase-mediated reactions, similar to the biosynthesis postulated in different plants for branched medium-chain fatty acids.[44] Further investigations are required to understand the biochemistry of *a*FAs and possibly other chiral fatty acids. It is evident from our study that such investigations should include the enantioselective determination of the final products, that is, the *a*FAs. The methods described in this work are suited for this purpose and thus justify the great efforts made during sample preparation and enantioselective evaluation.

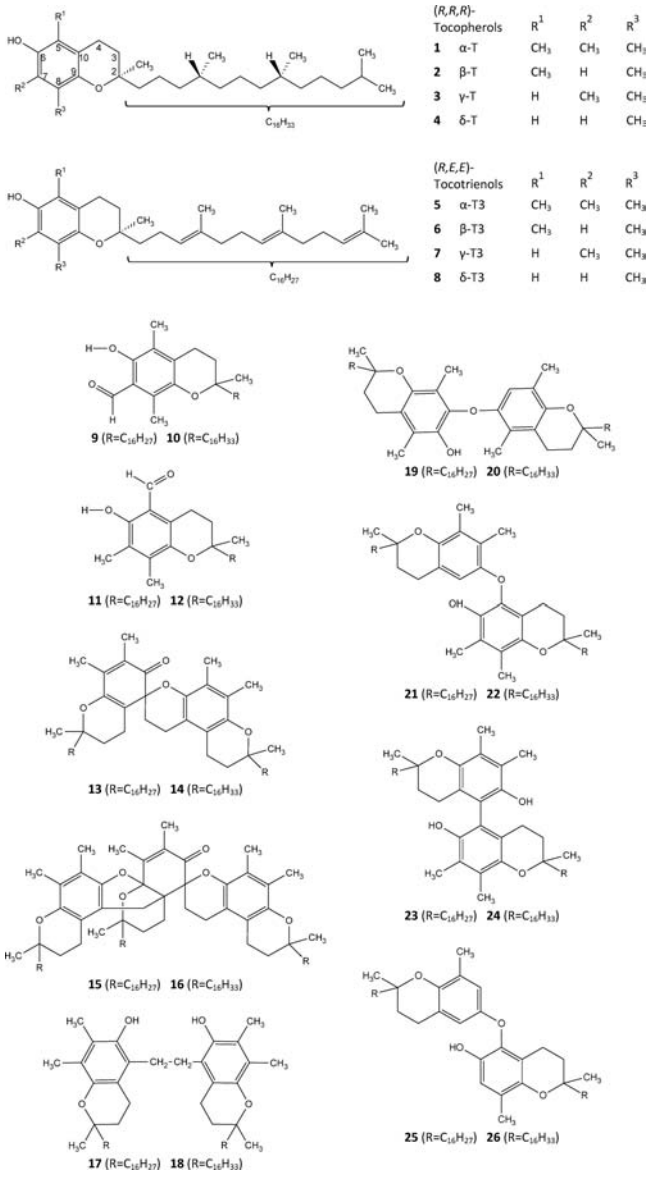

Figure 1. Structures of the vitamin E subgroups tocopherol (T) and tocotrienol (T3) and the most important oxidation products of tocotrienols and tocopherols.

h, 100 °C) of α-T3 (model matrix *n*-hexane) from the eight tocochromanols by HPLC with DAD and fluorescence detection (HPLC-DAD-F), and identified these oxidation products spectroscopically (HPLC-PBI-EIMS, i.e., HPLC-EIMS with particle beam interface (PBI)).[8,13] The predominant oxidation products from α-T3 were α-tocotrienol dihydroxydimer (**17**), 7-formyl-β-tocotrienol (**9**), and 5-formyl-γ-tocotrienol (**11**) (Figure 1). Minor proportions of α-tocotrienol quinone and its dimers were also detected with this method. Data in the literature suggest that non-α-T3 vitamers should form dimers as major oxidation products,[14−17] but there are as yet no reports of HPLC analysis of the oxidation products of β-, γ-, and δ-T3.

The potential role of tocotrienols in the treatment and prevention of breast cancer by inducing growth inhibition and apoptosis was recently reviewed.[6] Viola et al.[18] investigated human SKBR3 breast carcinoma cells and found fast and sustained mitochondrial uptake of δ-T3 followed by oxidative transformation of δ-T3 to its quinone derivative, which possibly contributes to cytotoxicity and apoptotic effects through oxidative damage of mitochondria and functional destabilization in the course of redox-recycling of the quinone. Furthermore, it has been suggested that the anticancer effect of tocotrienols is at least partially caused by targeting multiple intracellular signaling pathways associated with tumor cell viability,[19] independent of the antioxidant activity of tocotrienols.[20]

Knowledge of the in vitro bioactivity may help to design and interpret results obtained in in vivo studies. The majority of in vitro studies on the anticancer effects of γ- and δ-T3 have in common that the effective extracellular concentrations applied in vitro exceed the physiological concentrations.[21] With regard to the oral bioavailability of tocotrienol vitamers, α-T3 is preferentially transferred into the bloodstream when compared to γ- and δ-T3.[5] Strategies are being developed to overcome the limited bioavailability, to enhance the efficacy of therapeutic protocols.[21] Tocotrienols have a comparatively short elimination half-life in vivo due to their high metabolic rate and antioxidant activity. Redox inactivation should stabilize the tocotrienols in vivo. This hypothesis is supported by reports that redox-silent derivatives of tocotrienols such as esters, carbamates, or ethers, which mask the hydroxyl group at the C-6 position critical for antioxidant activity, show potent or even enhanced anticancer properties.[6,18,22]

Numerous studies have shown that tocotrienols[23−28] or palm TRF[29−31] significantly inhibit the growth of estrogen receptor-positive MCF-7 human breast cancer cells in vitro. For example, concentrations that inhibited 50% of cell growth in comparison to the control (i.e., the IC_{50} value) over 72 h were in the range from 8 to 25 μM and decreased in the order α-T3 > δ-T3 ≥ γ-T3 > palm TRF > α-T-free palm TRF, which means that the antiproliferative activities of coexisting tocotrienols from palm TRF and α-T-free palm TRF were found to be higher than those of pure tocotrienols.[32] The growth-inhibiting effect of tocotrienols on MCF-7 cells was shown to occur estrogen-independently.[21] Oxidized tocotrienol preparations have not yet been investigated in regard to their activity against breast cancer cells despite the fact that oxidation products of tocotrienols often are unavoidable during food processing or storage of tocotrienol supplements. Consequently, it was of interest to study the effect of tocotrienol-rich preparations that have undergone controlled oxidation on the viability of human breast cancer cells, in particular, the MCF-7 cell line.

The aims of this study were (i) to apply our previously described HPLC-DAD and HPLC-PBI-EIMS methods for the analysis of α-T3 oxidation products to the separation and evaluation of oxidation products generated from the other vitamers; (ii) to determine the composition of equimolar tocotrienol test compounds (α-T3, γ-T3, and palm TRF) before and after thermal oxidation in the model matrix *n*-hexane; (iii) to compare the effect of the untreated and thermally oxidized tocotrienol test compounds exemplarily on the viability of human MCF-7 breast cancer cells; and (iv) to estimate in a first approach the potential anticancer activity of the tocotrienol oxidation products. This study did not attempt to elucidate cell toxicity mechanisms but to provide first evidence of the importance of tocotrienol oxidation products by testing the effects of nonoxidized and oxidized tocotrienols under the same cell culture conditions. The results are expected to be valuable in the search for tocotrienol derivatives with

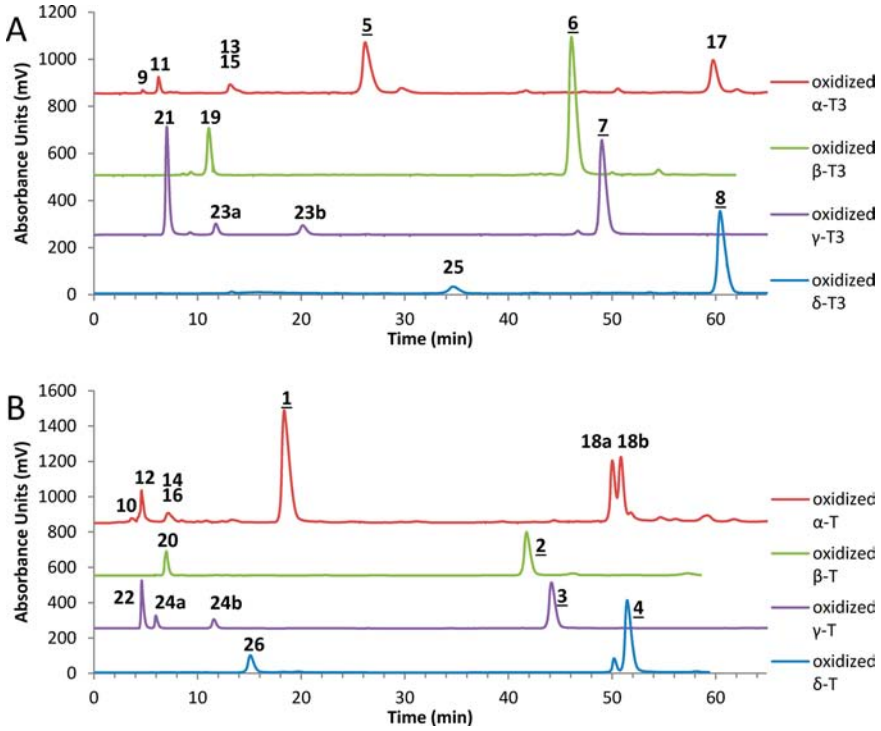

Figure 2. Normal-phase HPLC-UV chromatograms of the eight tocochromanol reference substances after thermal oxidation in *n*-hexane (3 h at 100 °C), recorded at 280 nm. The corresponding parent compounds are marked by underlined numbers. (A) Oxidized tocotrienols: **5**, α-tocotrienol; **6**, β-tocotrienol; **7**, γ-tocotrienol; **8**, δ-tocotrienol; **9**, 7-formyl-β-tocotrienol; **11**, 5-formyl-γ-tocotrienol; **13**, **15**, α-tocotrienol spirodimers/trimers; **17**, α-tocotrienol dihydroxydimer; **19**, 7-(β-tocotrienoxy)-β-tocotrienol; **21**, 5-(γ-tocotrienoxy)-γ-tocotrienol; **23a**, **23b**, 5-(γ-tocotrienyl)-γ-tocotrienol, atropisomers; **25**, 5-(δ-tocotrienoxy)-δ-tocotrienol. (B) Oxidized tocopherols: **1**, α-tocopherol; **2**, β-tocopherol; **3**, γ-tocopherol; **4**, δ-tocopherol; **10**, 7-formyl-β-tocopherol; **12**, 5-formyl-γ-tocopherol; **14**, **16**, α-tocopherol spirodimers/trimers; **18a**, **18b**, α-tocopherol dihydroxydimers; **20**, 7-(β-tocopheryl)-β-tocopherol; **22**, 5-(γ-tocopheroxy)-γ-tocopherol; **24a**, **24b**, 5-(γ-tocopheryl)-γ-tocopherol, atropisomers; **26**, 5-(δ-tocopheroxy)-δ-tocopherol.

enhanced anticancer properties and in future studies on the nature of the observed biological effects. Although it is not possible to draw direct conclusions from tocochromanol oxidation products generated in model systems on the relevance of these oxidation products in food systems, the expected results should nevertheless help in future studies dealing with unwanted oxidative degradation during storage and processing of tocotrienol-rich foods or pharmaceuticals.

MATERIALS AND METHODS

Chemicals and Test Compounds. The following tocotrienols were obtained from Davos Life Science (Singapore): α-, β-, γ-, and δ-T; α-, β-, γ-, and δ-T3 (each >97%); and palm tocotrienol-rich fraction (TRF) (>97%). The HPLC solvents used were ethanol, *n*-hexane, and acetonitrile, from Sigma-Aldrich (Steinheim, Germany); 1,4-dioxane (not stabilized), from Carl Roth (Karlsruhe, Germany); and *tert*-butyl methyl ether (TBME) and chloroform (stabilized), from Acros Organics (Geel, Belgium).

The cell culture medium used was Dulbecco's modified Eagle medium (DMEM) supplemented with 10% fetal bovine serum, 1% 10000 U/mL penicillin, 1% 10000 μg/mL streptomycin, and 1% 200 mM L-glutamine (all from Biochrom, Berlin, Germany). MCF-7 human breast cancer cells were obtained from LGC Standards (Wesel, Germany). The alamarBlue reagent was purchased from AbD Serotec (Puchheim, Germany).

Thermal Oxidation of Vitamers in Model Matrix *n*-Hexane and Preparation of Ethanolic Stock Solutions. To generate tocotrienol oxidation products for use as HPLC reference substances, our previously described method[8] for the thermal oxidation of α-T3 was applied to the test compounds studied here: 100 mg of each vitamer (α-, β-, γ-, and δ-T; α-, β-, γ-, and δ-T3) was dissolved in 100 mL of *n*-hexane; 2 mL samples of the vitamer solutions (each 1000 μg/mL) were transferred into 4 mL brown glass vials and placed in a drying oven for 3 h at 100 °C. The vials were left open during heat treatment. Thereafter, the oxidized, dry samples were brought to room temperature, and the sample volume was adjusted to 500 μL with *n*-hexane. The solutions were used for HPLC-UV and HPLC-PBI-EIMS analysis.

For use in cell viability assays, α-T3, γ-T3, and palm TRF were each dissolved in *n*-hexane at a concentration of 150 mM. Five hundred microliter samples of vitamer solutions were transferred into 1.4 mL brown glass vials and placed in a drying oven at 110 °C for 10 h (α-T3 and palm TRF) or 16 h (γ-T3). The vials were left open during heat treatment, after which the oxidized, dry samples were brought to room temperature, and the volumes were adjusted to 500 μL with ethanol. The composition of these ethanolic stock solutions was determined by HPLC-DAD after appropriate dilution.

HPLC Separation and Spectroscopic Analysis of Tocochromanol Oxidation Products. The separation and identification of the eight reference substances (individually oxidized α-, β-, γ-, and δ-T and α-, β-, γ-, and δ-T3) were performed using our previously established HPLC-PBI-MS method[8] with an additional in-line detection at 280 nm on an 8700 UV detector from Knauer (Berlin, Germany).

The HPLC-DAD analysis (200–400 nm) of the oxidized and nonoxidized test compounds α-T3, γ-T3, and palm TRF was performed using a 250 mm × 4 mm i.d., 3 μm, ProntoSil 120-3 Diol column (Knauer, Berlin, Germany) according to our previously established HPLC-DAD-F method[8] with a smaller sample loop (20 μL) and a modified gradient program for accelerated elution as follows: 0–5 min, 100% A; 20 min, 70% A; 30 min, 100% B; 30–60 min, 100% B, where eluent A was *n*-hexane and eluent B was *n*-hexane/dioxane/TBME (95:3:2, v/v/v).

Molar contents of dimeric oxidation products in oxidized test compounds were approximatively calculated from the corresponding peak area (UV detection), assuming that a dimeric tocotrienol oxidation product has the same molar extinction coefficient (ε, 1 g^{-1} cm^{-1}) as the monomeric parent compound, which results in half the molar concentration of a dimeric compound compared to its monomeric parent compound with the same peak area. This approach is supported by literature data, according to which α-T and its dihydroxydimer have very similar ε values.[33]

Cell Viability Assay. The six ethanolic stock solutions containing either 150 mM nonoxidized α-T3, γ-T3, or palm TRF or 150 mM oxidized α-T3, γ-T3, or palm TRF were diluted with ethanol to prepare 0, 20, 25, 50, and 100 mM solutions. To facilitate the comparison between oxidized and nonoxidized test compounds, the concentration values of dilutions of oxidized test compounds refer to the vitamer concentration prior to oxidation. The ethanolic dilutions were further diluted 1:1000 with complete medium to yield concentrations of 20, 25, 50, and 100 μM for use in the cell viability assays.

MCF-7 cells were grown as monolayer cultures in medium in a humidified atmosphere of 5% CO_2 at 37 °C and passaged twice a week by bringing them in suspension with 0.05% trypsin/0.02% EDTA (w/v) in PBS (Biochrom, Berlin, Germany). For the experiment, cells at passages 7−16 were seeded in 96-well plates at a density of 5×10^3 cells/well and were allowed to adhere for 24 h. Then, the medium was removed and cells were treated with 200 μL of either α-T3 (0−100 μM), γ-T3 (0−100 μM), or TRF (0−100 μM) for 72 h. Ethanol (0.1%) was used as negative control. Culture medium in all wells was then replaced by medium containing 5% (v/v) alamarBlue reagent solution. After a 3 h incubation at 25 °C, fluorescence *F* (λ_{ex} 560 nm, λ_{em} 590 nm) was measured in a plate reader. Experimental results were expressed as viability in percent relative to control (100%). The absolute half-maximal inhibitory concentration (IC_{50}) and the 95% confidence interval (CI) were determined by nonlinear regression curve fit analysis using GraphPad Prism version 6.04 (GraphPad Software, La Jolla, CA, USA).

Statistics. All cell viability experiments were performed four times with independent cell cultures. Data were tested for outliers and homoscedasticity. An analysis of variance (ANOVA) was performed to determine statistically significant differences between the different experimental groups. The selected significance level was $\alpha = 0.001$. All statistical parameters were calculated using Valoo 2.3.[34]

RESULTS AND DISCUSSION

HPLC-UV Analysis of the Eight Reference Substances (Individually Oxidized α-, β-, γ-, and δ-T3 and -T). The chromatograms resulting from HPLC-UV of each of the eight individually oxidized α-, β-, γ-, and δ-T3 and -T are shown in Figure 2. The molecular structures, main EIMS fragments, and UV spectroscopic data of the most important tocotrienol oxidation products are summarized in Figure 1 and Table 1. In all chromatograms (Figure 2), additional peaks appeared along with the recovered tocochromanols. Under the conditions applied in this experiment, both α-vitamers (**1**, **5**) showed the same types of oxidation products, the dihydroxydimer (**17**, **18**) being the most striking for each α-vitamer (Figure 2). There were no indications that quinone or epoxide derivatives were present. Chromatograms of oxidized non-α-tocotrienols (i.e., β-, γ-, and δ-T3, **6**−**8**) (Figure 2A) showed the same peak pattern as the corresponding oxidized non-α-tocopherols (**2**−**4**) (Figure 2B). By means of HPLC-PBI-MS analysis of the tocotrienol and tocopherol oxidation products, we found the same types of oxidation products for the corresponding pairs of vitamers (β-T3 and β-T, etc.) and determined that the non-α-T3 vitamers formed dimers as major oxidation products: β-T3 (**6**) formed 7-(β-tocotrienoxy)-β-tocotrienol (**19**); γ-T3 (**7**) formed 5-(γ-tocotrienoxy)-γ-tocotrienol (**21**) and two mutual atropisomers (peaks **23a** and **23b**) of 5-(γ-tocotrienyl)-γ-tocotrienol (**23**);[12] and δ-T3 (**8**) formed 5-(δ-tocotrienoxy)-δ-

tocotrienol (**25**) (Figures 1 and 2A; Table 1). As the oxidation of tocochromanols takes place at the phenolic chromanol "head" and not at the side chain, the oxidation products of tocochromanols that share the same chromanol "head" are expected to be the same, differing only in the side chain. For α-T3, this has previously been described by us in detail and confirmed by spectroscopic analysis.[8]

Tocochromanoxyl radicals primarily undergo radical−radical coupling reactions in apolar, aprotic solvents such as *n*-hexane, as used in the present study. If other potentially unstable radicals are absent, the tocochromanoxyl radicals react by self-coupling, forming dimers.[12,35] A major product of the α-tocotrienoxyl radical is the α-T3-dihydroxydimer (**17**), which is formed by dimerization through the *ortho* methyl groups at the initial position C-5. The β-, γ-, or δ-tocotrienoxyl radicals, which have free (nonmethylated) *ortho* positions, primarily form dimers through these positions, thereby leading to tocotrienol (diphenol) dimers due to *ortho*−*ortho* couplings, for example, 5-(γ-tocotrienyl)-γ-tocotrienol (**23**);, and to tocotrienol−tocotrienyl ether dimers due to coupling of the tocotrienoxyl oxygen of one tocotrienol with the *ortho* position of the other, for example, 5-(γ-tocotrienoxy)-γ-tocotrienol) (**21**) (Figure 1).

Remarkably, the HPLC-UV chromatogram of oxidized α-T showed the α-T dihydroxydimer (**18**) as a double peak (peak **18a** and **18b**) (Figure 2B). This is in agreement with prior findings.[33,36] The double peak is probably due to the presence of two α-T dihydroxydimer atropisomers (**18**), which differ in the positions of the chromanol rings caused by the rotation of the monomer-connecting ethyl bond; in the case of the α-T3-dihydroxydimer (**17**), there were no indications of the presence of atropisomers (peak **17**) (Figure 2B), thus suggesting that the specific steric structures of the tocopherol or tocotrienol side chains play a role in this phenomenon. The data on oxidized non-α-tocotrienols (Figure 2) are in agreement with previous work on tocotrienol oxidation products.[14−17] The dimeric oxidation product resulting from the β-vitamers was assigned to the ether dimer **19** and not the diphenol dimer by comparison with chromatographic and UV spectroscopic characteristics reported by Nilsson et al.[14] In accordance with data from the literature,[14,15,17] only one type of dimer was found for the δ-vitamers, that is, the ether dimer **25**. This is the first report on the HPLC-UV and -PBI-EIMS characteristics of the oxidation products of all eight tocochromanols resulting from their individual thermal oxidation (100 °C, 3 h) in *n*-hexane. However, it should be kept in mind that all of these oxidation products may decompose further to form decomposition products that cannot be detected with this method.[13]

Composition of Test Compounds before and after Thermal Oxidation. The T3 test compounds, that is, individual α-T3, individual γ-T3, and mixed tocochromanols from palm TRF, were dissolved in *n*-hexane and thermally oxidized at 110 °C for 10−16 h. Table 2 shows the composition and the total content (sum of all vitamers) of tocochromanols of the test compounds before and after thermal oxidation. Figure 3 shows the HPLC-DAD chromatograms of palm TRF before (Figure 3A) and after thermal oxidation (Figure 3B,C). The amounts of tocochromanols and oxidation products in the

test compounds were assessed using a HPLC-DAD method similar to the HPLC-UV method for the oxidized reference substances (Figure 2), but with application of a steeper elution gradient, which is the reason for their overall shorter retention times (Figure 3) in comparison to those of the reference substances.

Thermal oxidation of α-T3, γ-T3, and palm TRF, each containing 150 mM total T3, resulted in a decrease in tocochromanol compounds and the emergence of oxidation products. After a 10 h thermal oxidation of the α-T3 test compound, the percentage of α-T3 recovered was 31%. On the basis of preliminary tests and in analogy with tocopherols, where the redox potential of γ-T is higher (+0.348 V) than that of α-T (+0.273 V),[12] γ-T3 was expected to be a weaker hydrogen donor and to degrade less intensely than α-T3. Therefore, the γ-T3 test compound was treated for a longer time (for 16 h instead of 10 h). The percentage of γ-T3 recovered was 20% (Table 2); assuming linear degradation, the calculated recovery after 10 h is 75%. In the palm TRF sample, the vitamers degraded to different degrees: thermal oxidation led to an extensive loss of α-T (only 2.5% was recovered) followed by α-T3, γ-T3, δ-T3, and β-T3, with residual percentages of 9, 13, ≤25, and 32%, respectively, so that the oxidized palm TRF contained strikingly less total tocochromanols (21.0 mM) than oxidized α-T3 (45.6 mM) and γ-T3 (29.8 mM), even though the γ-T3 test compound was oxidized for a longer time (for 16 h) than the other test compounds (10 h).

The chemistry of oxidation of the tocochromanols is complex and depends largely on the oxidation conditions,[35] for example, concentration, type of solvent or lipid matrix, temperature, and presence of light or oxygen. Because of the complex test systems and the resulting difficulties in evaluating the relative antioxidant activity of tocochromanols in vitro, there is a widespread controversy regarding this topic,[9] and it is difficult to draw any general conclusions.[37] In our hexanoic palm TRF sample, tocochromanols did not compete with lipids or model substances as substrates for oxidation, but different tocochromanols competed with themselves. Clearly, the α-vitamers in the palm TRF degraded most intensely, but apparently without simultaneously protecting γ-T3 from degradation (Table 2). The results suggest that the above-mentioned pro-oxidant property of the α-vitamers may cause a higher overall degradation of the vitamers in the oxidized palm TRF sample than the samples with individual tocotrienols. There are as yet no reports in the literature on the composition of highly concentrated hexanoic solutions of T3-rich mixed tocochromanols after thermal oxidation.

The oxidation products detected in α- and γ-T3 test compounds (Table 2) were found to be the same types of oxidation products as was expected from the results from the corresponding reference substances (Table 1). The oxidation products detected in the test compounds were predominantly dimers (Table 2). All of these dimers (**17**, **21**, **23**) are phenols or diphenols and can still act as antioxidants.[12] It should be noted that HPLC-DAD analysis showed no indications of dimeric oxidation products other than those composed of two γ-T3 or two α-T3 and that at most a minor proportion of an α-T3-dimer was formed, as indicated in the footnote of Table 2. This corresponds to the findings of Ha and Igarashi,[15] who autoxidized α- and γ-T mixtures in methyl linoleate (10 h, 97.8 °C) and detected no mixed dimers, composed of different types of vitamers, among the isolated oxidation products by means of spectroscopic structure determination and found that dimers of γ-T predominated over those of α-T.

Only small amounts of the aldehydic α-T3 oxidation products 5-formyl-γ-tocotrienol (**11**) and 7-formyl-β-tocotrienol (**9**) were also present in the α-T3 and TRF sample after thermal oxidation (Table 2; Figure 3B). These compounds, analogously to the aldehydes of tocopherols,[38] should have negligible antioxidant properties because of the formation of strong intramolecular hydrogen bonds between the hydroxyl group and the corresponding carbonyl group in the *ortho* position.

The conditions of thermal oxidation applied in our study led to an intensive decrease in all tocotrienol vitamers and necessarily to the generation of oxidation products. As suggested by the material balance (Table 2), the tocotrienol oxidation products newly separated, identified, and quantitated in the present study probably coexist with small-molecule products, which have lost the characteristic molecular moieties

DOI: 10.1021/acs.jafc.5b04388
J. Agric. Food Chem. 2015, 63, 8930–8939

of tocotrienols in the course of the oxidation progress and which were not identified by any of the analytical methods applied by us. In summary, the experimental design provided distinctly composed test compounds before and after thermal oxidation and, therefore, allowed the assessment of the importance of tocotrienol oxidation products with respect to anticancer effects of test compounds in an initial in vitro approach.

Effect of Nonoxidized Tocotrienols on the Viability of Human MCF-7 Breast Cancer Cells. Treatment of human MCF-7 breast cancer cells for 72 h with α-T3, γ-T3, and palm TRF reduced the cell viability in a dose-dependent manner in comparison to the control, with no tocochromanols (Figure 4). After treatment with 100 μM α-T3, γ-T3, or palm TRF, significantly ($p < 0.001$) fewer living cells were determined by means of the alamarBlue assay: 58 ± 2, 68 ± 4, and 29 ± 5%, respectively. In accordance with Loganathan et al.,[32] we found individual α- and γ-T3 vitamers to be less potent in reducing the viability of MCF-7 cells than equimolar total concentrations of mixed tocochromanols from palm TRF (Figure 4). This also agrees with the findings of Yu et al.,[39] who found that MCF-7 cells were most sensitive to the δ-T3 vitamer, which was a component of our palm TRF.

The IC_{50} values of α-T3, γ-T3, and palm TRF were greater than 100 μM in the cases of α-T3 and γ-T3 and 59 μM (95% CI = 51−68 μM) for palm TRF (Figure 4); when the MCF-7 breast cancer cells were treated with the γ-T3 vitamer at the lowest concentration (20 μM), there was a slight increase in cell viability (115 ± 4%) (Figure 4B). The IC_{50} values determined in our study are higher than data in the literature on anticancer effects of tocotrienols in MCF-7 cells.[23−27,29−32] One explanation for this difference is that the other research groups conducted the viability tests with MCF-7 cells in media containing inactivated FBS, charcoal-stripped FBS, or a lower percentage of FBS: because FBS contains growth factors, stimulating endogenous hormones,[40] it might attenuate the effects of tocotrienols on cell viability.[24] Moreover, MCF-7 cells from different laboratories have been reported to have different biological properties, most probably due to an inherent genetic variability when cultured and passaged under different conditions.[41]

Furthermore, our observation that nonoxidized γ-T3 (IC_{50} = 134 μM, 95% CI = 92−196 μM) possesses a lower potency than nonoxidized α-T3 (IC_{50} = 125 μM, 95% CI = 107−145 μM) is in contrast to some study results reported in the literature.[21,27] Our observation was made after a treatment period of 72 h. However, after a treatment period of only 24 h, the IC_{50} values of α-T3 (93 μM, 95% CI = 72−121 μM) and γ-T3 (20 μM, 95% CI = 16−25 μM) were much lower than after 72 h, and the IC_{50} value of γ-T3 was lower than that of α-T3, which is in accordance with literature data.[27] After a treatment period of 48 h, the MCF-7 cell viability was considerably stimulated when compared to the 24 h results by nearly every one of the applied concentrations of nonoxidized and oxidized test compounds, but most intensely at the lowest concentrations of each test compound. These obvious hormetic effects were attenuated after a treatment period of 72 h and turned into a dose-dependent decrease of cell viability, except for oxidized palm TRF. Therefore, and to achieve the most conclusive comparison between the effects of nonoxidized and oxidized test compounds, we decided to evaluate the data from the 72 h experiments, as displayed in Figure 4.

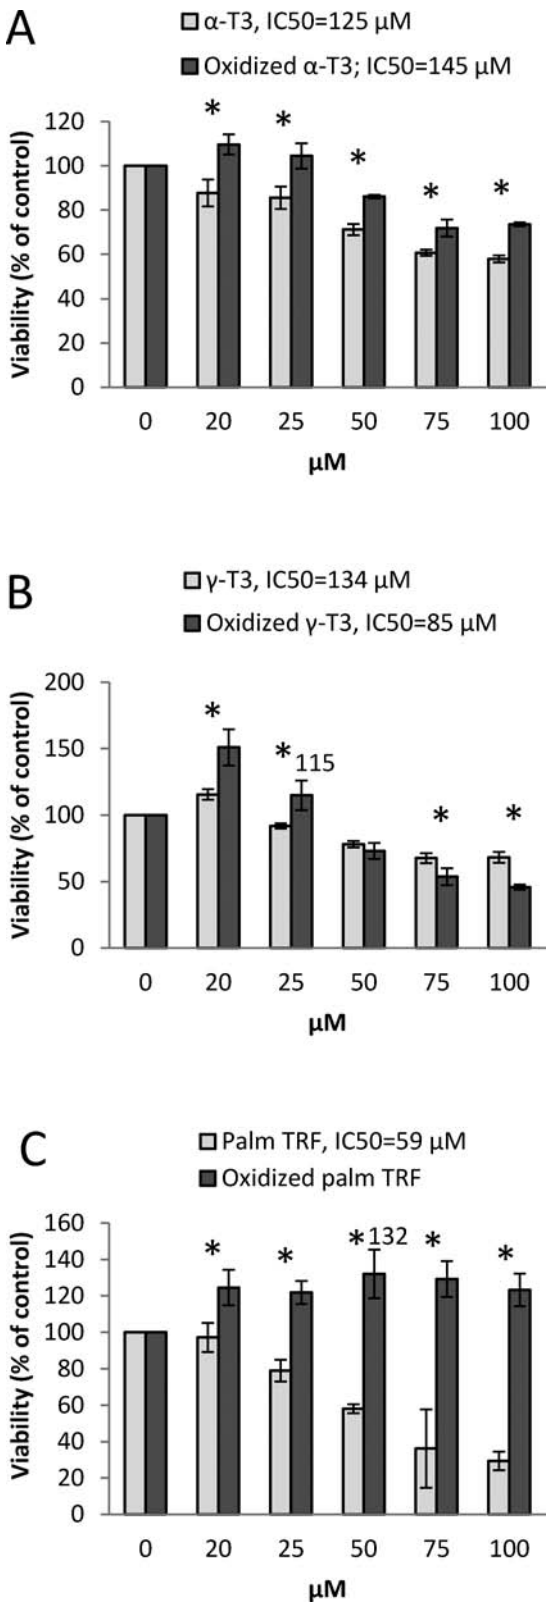

Figure 4. Effect of test compounds before and after thermal oxidation on the viability of MCF-7 human breast cancer cells in medium containing 10% fetal bovine serum after a treatment period of 72 h: (A) α-tocotrienol (α-T3); (B) γ-tocotrienol (γ-T3); (C) palm tocotrienol-rich fraction (palm TRF). Pairs of bars labeled with an asterisk (*) indicate significantly different viabilities caused by equimolar test compounds ($p < 0.001$). Data are representative of four independent experiments.

J. Agric. Food Chem. 2015, 63, 8930−8939

The increased proliferation caused by tocotrienols described in this study has also been observed by other research groups applying experimental conditions similar to ours in regard to culture medium composition and duration of incubation. For example, Nesaretnam et al.[42] observed that the lowest tested concentration of palm TRF (about 75 μM total tocochromanols) stimulated the proliferation of human MDA-MB-435 breast cancer cells when the cells were incubated in culture medium containing 10% FBS and palm TRF for 48 h, whereas higher concentrations of TRF caused an increasing inhibitory effect. Furthermore, Burdeos et al.[43] recently found an increased cell proliferation rate of about 70% compared to the control after treating mouse hepatocellular carcinoma cells (Hepa 1-6) with culture medium containing 10% FBS and 1−15 μM γ-T3 for 24 h; however, at higher concentrations, γ-T3 inhibited the proliferation of tumor cells. The reason for the increase in viability at lower tocochromanol concentration is still unknown, but it has been speculated that the antioxidative effect of γ-T3 could be responsible for this phenomenon.[43]

Explaining the differences in anticancer activity between the α- and γ-tocotrienols over time, the following literature may be relevant. The in vitro anticancer activity was shown to be a function of the cellular uptake rate and cell content of the different vitamers, as recently summarized by Viola et al.[21] Tocotrienols are more potent in suppressing mouse mammary tumor cell growth and viability than tocopherols due to their preferential uptake, which rapidly provides levels leading to cytotoxic effects, and in this context γ- and δ-tocotrienols show higher uptake rates than α-T3.[21,44] However, once the same intracellular concentration is reached, the difference in the anticancer activity between the vitamers decreases.[21] In accordance with this observation, the testing of a series of tocotrienols in human SKBR3 breast carcinoma cells revealed that δ-T3 clearly was the most potent compound capable of inhibiting cell viability after a 24 h treatment, followed by γ- and α-T3. However, after 48 h, α-T3 showed the highest inhibitory effect, and this effect was also observed in murine TUBO breast carcinoma cells.[18]

Effect of Oxidized Tocotrienols on the Viability of Human MCF-7 Breast Cancer Cells. The α- and γ-T3 test compounds that underwent thermal oxidation affected the viability of MCF-7 cells in a dose-dependent manner (Figure 4A,B), as did the nonoxidized α- and γ-T3 test compounds. The calculated IC_{50} (145 μM, 95% CI = 101−209 μM) of the oxidized α-T3 was higher than that of nonoxidized α-T3, and the viability of cancer cells was in all cases significantly higher than when treated with equimolar nonoxidized α-T3 solutions ($p < 0.001$). This is plausible in consideration of the fact that only 31% of the initial α-T3 content was recovered in the oxidized α-T3 (Table 2). However, oxidized α-T3 decreased the viability of cancer cells to a greater extent than would be expected from the recovered α-T3 content alone, indicating that the oxidation products present in the test compounds also possess some antitumor activity in vitro.

The oxidized γ-T3 compound enhanced cancer cell viability at the lowest tested concentrations (20 and 25 μM). In consideration of the fact that only 20% of the initial γ-T3 content in the oxidized γ-T3 was recovered (Table 2) and that, as mentioned above, low concentrations of tocotrienols in particular were found to stimulate cell viability, it is plausible that the cell viability increased significantly ($p < 0.001$) compared to treatment with the equimolar nonoxidized γ-T3 test compound. However, with higher concentrations of oxidized γ-T3, the viability-inhibiting effect was greater than that of equimolar nonoxidized γ-T3; consequently, the calculated IC_{50} (85 μM, 95% CI = 65−111 μM) was lower than for nonoxidized γ-T3 (Figure 4B). These data suggest that, above a minimum concentration of 25−50 μM γ-T3, the effect on cell viability of the test products containing oxidation products generated from any amount of γ-T3 given, was significantly stronger than that of the equimolar nonoxidized γ-T3 test products. However, it remains unknown whether this enhanced activity was caused by the oxidation products per se or whether the γ-T3 molecule acted more effectively through an interaction with the oxidation products. Nevertheless, our observation that the cell viability decreasing activity of the oxidized γ-T3 test compound was greater than that of equimolar, nonoxidized γ-T3 may be of value in the above-mentioned search for redox-silent tocotrienol derivatives to identify substances with higher effectivity and bioavailability and deserves further investigation. As the in vitro bioactivity greatly depends on the intracellular concentration of tocotrienol forms,[18,21] assessing the cellular uptake of the specific γ-T3 oxidation products should help in the evaluation if these can be associated with the improved activity or if other and, so far, unknown characteristics of oxidized γ-T3 or the tested MCF-7 cell line could explain these results.

Whereas the nonoxidized palm TRF test compound decreased the viability of cancer cells more extensively than the individual α- and γ-T3, the oxidized palm TRF surprisingly did not reduce cell viability; on the contrary, a stimulating effect was observed at all concentrations of oxidized palm TRF (Figure 4C), and oxidation products generated from equimolar palm TRF test compounds clearly did not affect cell viability. This surprising result was predictable neither from the results obtained with the tested oxidized α- or γ-T3 test compounds nor from the decrease of the highly anticancerous δ-T3 vitamer. However, it is likely that the oxidation of palm TRF led to the formation of much less bioactive or bioavailable products, which prevented cell viability from decreasing as was observed for oxidized α- and γ-T3. It is obvious that, particularly in systems containing mixed tocochromanols, the mechanisms leading to changes in tumor cell viability, the interactions between different compounds, and the relationship between structure and effectiveness are complex and merit further investigation. This conclusion is supported by the results of a preliminary experiment in our laboratory, in which oxidized palm TRF (0−100 μM) clearly decreased the cell number of human colon adenocarcinoma HT-29 cells after a treatment period of 96 h in a dose-dependent manner as determined by performing the sulforhodamine B (SRB) assay.

There are few studies available on the activity of oxidation products of tocochromanols in biological systems, and where such products are discussed, in most cases these are quinones, oxidation products primarily formed in polar, protic solvents. Shrader et al.[45] reported that α-tocopherol quinone, an oxidative metabolite of α-T, is a potent cellular protectant against oxidative stress, whereby its biological activity depends upon its ability to undergo reversible two-electron redox cycling. Dolfi et al.[46] observed that γ- and δ-tocopherol quinones had much higher inhibitory effects on human colon cancer HCT-116 and HT-29 cells compared to their parent compounds after a 72 h incubation; however, α-T and its quinone derivative were rather ineffective. Jones et al.[47] found that γ-tocopherol quinone, but not α-tocopherol quinone, induced apoptosis in human ZR-75-1 breast cancer cells. Goh

J. Agric. Food Chem. 2015, 63, 8930−8939

et al.[48] reported that no oxidative dimeric compounds from γ-T3 exhibited activity against tumor promotion by inhibition of the expression of Epstein−Barr virus early antigen in Raji cells, wheras monomeric γ-T3 did.

In conclusion, this study has shown that individually thermally oxidized non-α-tocotrienols formed certain dimeric oxidation products, as did the corresponding non-α-tocopherols treated in the same way. Furthermore, it was shown that our HPLC-UV method is well applicable for separating the oxidation products from the parent compound, as was the HPLC-DAD method for determining the most important components of test products, even those containing mixed tocotrienols (i.e., palm TRF) that have undergone thermal oxidation in the model matrix *n*-hexane. Moreover, it was shown that equimolar concentrations of tocotrienol test compounds subjected to thermal oxidation had significantly different effects on the viability of human MCF-7 breast cancer cells compared to nonoxidized tocotrienol test compounds after a treatment period of 72 h in culture medium containing 10% FBS. Our findings also indicate that oxidation products of γ-T3 can contribute to the decrease in viability of human MCF-7 breast cancer cells and even enhance the antitumor activity in vitro, but that oxidized tocotrienol mixtures did not behave as expected from the results obtained with the individual vitamers. This is the first approach toward estimating the biological activity of tocotrienol oxidation products against breast cancer cells. These findings should be taken into account not only in the search for tocotrienol derivatives with enhanced anticancer properties but also in dealing with unwanted oxidative degradation during storage and processing of tocotrienol-rich foods or pharmaceuticals. Over all, these results should stimulate further investigations to elucidate the mechanisms responsible for enhancing or attenuating the anticancer properties of tocotrienols through oxidation.

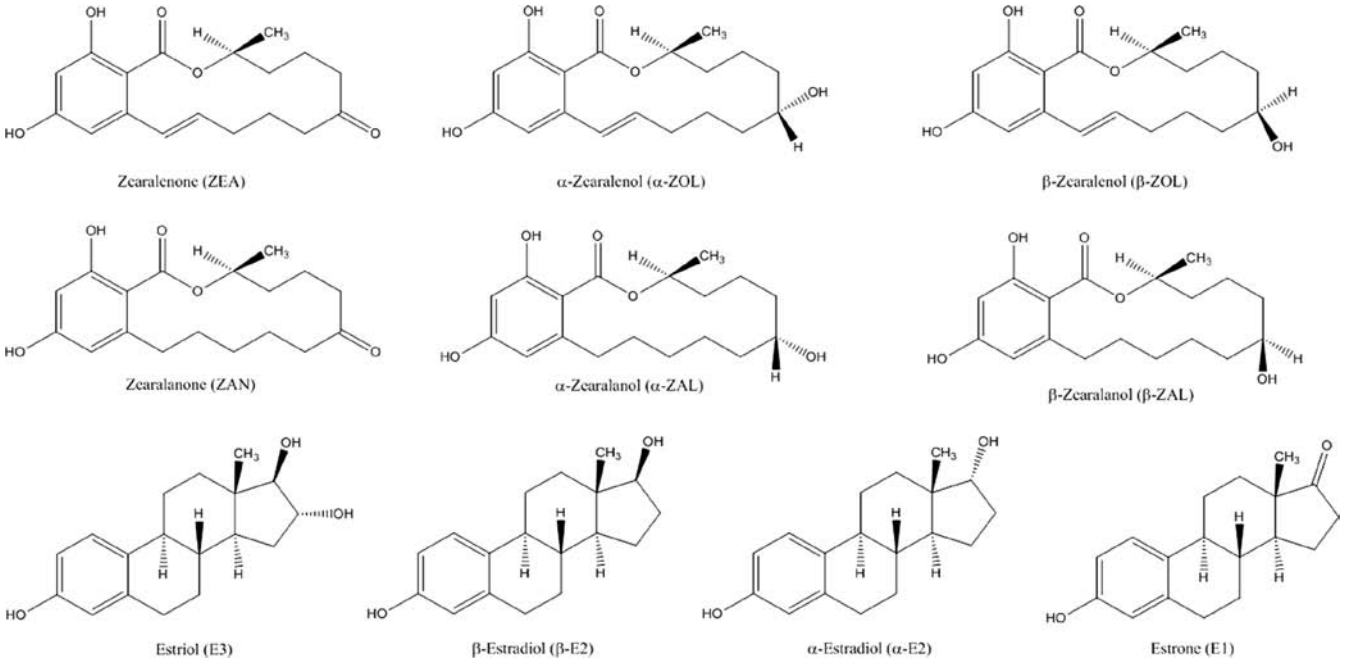

Figure 1. Chemical structure, names, and abbreviation of the free estrogens and resorcyclic acid lactones analyzed.

zearalanol (β-ZAL), which is its primary metabolite in bovine. Therefore, all of these analytes could be found in animals that had consumed feed naturally contaminated with mycoestrogens[9,10] or treated with the growth promoter α-ZAL. Moreover, α-ZAL and its metabolites are also related to the metabolism of ZEA in animals and can occur from its metabolic pathway. In all cases, all of these compounds could reach milk with the same effects of free estrogens; therefore, their presence should be monitored too. To reach this goal, an analytical methodology should be able to simultaneously detect all these compounds, natural estrogens and mycoestrogens, at trace levels despite the lack of maximum residue levels in milk and other dairy products. Because of the complexity of milk, the analysis of estrogens and related compounds is sometimes challenging, and many steps during sample preparation are required. Delipidation and deprotenization are commonly employed procedures in milk analysis, but they are time-consuming and can lead to analyte loss. At the same time, it would be difficult to employ the conventional commercial solid-phase extraction (SPE) cartridges without any sample pretreatments. In addition, the newest and fast extraction methodologies, such as QuEChERS, are rarely used for this type of analytes in milk.

To overcome these challenges, in this work we developed and validated an analytical methodology for fast, simple, and simultaneous determination of mycoestrogens and natural estrogens in different commercial milk samples, without any sample pretreatment. The developed method, based on ultrahigh-performance liquid chromatography coupled to tandem mass spectrometry via electrospray source (UHPLC/ESI-MS/MS), is able to achieve very good recoveries, negligible or very low matrix effect, and lower limits of detection and quantification than previously published methods, without any selectivity loss.

MATERIALS AND METHODS

Chemicals and Reagents. Acetonitrile (ACN), Methanol (MeOH), CH_2Cl_2, NH_3 (30%), HCOOH (>98%), and HCl were supplied by Sigma-Aldrich (Milan, Italy). All reagents were of analytical reagent grade; solvents were LC-MS grade. Ultrapure water (resistivity 18.2 MΩ cm^{-1}) was obtained using an Arium water purification system (Sartorious, Florence, Italy).

Pure standards of all selected compounds, i.e., E1, 17β-estradiol (β-E2), 17α-estradiol (α-E2), E3, ZEA, α-zearalenol (α-ZOL), β-zearalenol (β-ZOL), ZAN, α-ZAL, and β-ZAL, were purchased from Sigma-Aldrich (St. Louis, MO, US). The commercially available deuterated standards 17β-estradiol-16,16,17-d3 (β-E2-d3) and zearalenone-d6 (ZEA-d6) were purchased as pure standards from Wellington Laboratories (Toronto, Ontario, Canada) and were used as internal standards (ISs).

Full names and abbreviations of the selected compounds are reported in Figure 1. Individual stock standard solutions of the analytes were prepared in MeOH at the 1 mg mL^{-1} level. Composite working standard solutions were prepared by suitable dilution of stocks, used for recovery experiments, and renewed weekly.

Extraction and Cleanup Apparatus. A model ST ultrasonic bath at a frequency of 50 ± 3 kHz from Stimin (Milan, Italy) and an ALC (Milan, Italy) multispeed refrigerated centrifuge PK131R were used. Polypropylene tubes, polyethylene frits, and the vacuum manifold were from Supelco (Bellefonte, PA, US). All samples were extracted and cleaned by SPE cartridges packed with Carbograph-4 supplied by LARA (Rome, Italy). Carbograph-4 is a graphitized carbon black (GCB) similar to Carboprep 200 (Restek) and ENVI-carb X (Supelco).[11,12] Acrodisc 13 mm syringe filters with 0.2 μm GHP membrane (used for the filtration of samples prior to the injection into the chromatographic system) were from Pall (Pall Corp., MI, US).

Sample Collection and Preparation. Different types of cow whole milk, ultrahigh-temperature (UHT) pasteurized whole milk (3.6 g of fat, 3.30 g of protein per 100 mL), goat milk (3.9 g of fat, 3.2 g of protein per 100 mL), donkey milk (1.21 g of fat, 1.74 g of protein per 100 mL), and powder milk (0.1 g of fat and 3.3 g of protein per 100 mL of reconstituted milk) were purchased from local markets. The method was developed on whole milk, which is considered to be the worst case in terms of interferent content (such as proteins and fats).

Fortified samples were prepared by spiking 10 mL of milk with suitable amounts of composite working standard solutions and defined concentration of ISs (2 μg/L for β-E2-d3 and 1.5 μg/L for ZEA-d6), diluted to 250 mL with ultrapure water, and passed through the Carbograph-4 cartridges at about 20 mL min^{-1}. Cartridges were prepared by placing 500 mg of the adsorbent inside 6 mL polypropylene tubes between two polyethylene frits. Before the

DOI: 10.1021/acs.jafc.5b02815
J. Agric. Food Chem. 2015, 63, 8940−8946

samples were processed, these cartridges were attached to a vacuum manifold apparatus and washed sequentially with 10 mL of CH_2Cl_2/MeOH (80/20, v/v), 5 mL of MeOH, 20 mL of 10 mmol L^{-1} HCl solution, and 10 mL of ultrapure water. Then, the cartridge was washed sequentially with 50 mL of ultrapure water, 10 mL of MeOH acidified with 50 mmol L^{-1} HCOOH, and 5 mL of MeOH. Acidified MeOH was necessary to elute some compounds that could interfere with the analysis of free estrogens, especially E3.[13] Analytes were then eluted with 15 mL of CH_2Cl_2/MeOH (80/20, v/v). The eluate was evaporated to dryness in a water bath at 37 °C under a gentle stream of nitrogen. The residue was dissolved in 500 μL of water/MeOH (50/50, v/v) and then forced through a 0.2 μm GHP membrane syringe filter. A 5 μL sample of each final solution was analyzed by UHPLC/ESI-MS/MS.

UHPLC/ESI-MS/MS Analysis. Liquid chromatography was performed by using an Ultimate 3000 LC system (Thermo Fisher Scientific, Bremen, Germany) that consisted of a binary four-line pump, equipped with a degasser, a thermostated microwell-plate autosampler, and a thermostated column oven.

A 5 μL aliquot of sample was injected on a Hypersil Gold (50 × 2.1 mm i.d., 1.9 μm particle size) equipped with a Security guard Hypersil Gold (4 × 2.1 mm i.d., 5 μm particle size), both from Thermo Fisher Scientific. The column was maintained in the thermostated column compartment at 40 °C. Mobile phases were water (A) and ACN (B). For separation of the analytes, gradient elution was performed by linearly increasing the amount of B in A at flow rate of 300 μL min^{-1}. The starting mobile phase composition was 15% B. After an isocratic step at 15% B for 1 min, B was linearly increased to 50% within 7 min, brought to 99% in 2 min, and held constant for 5 min. Finally, the B content was lowered to 15% and the column was allowed to re-equilibrate for 5 min, for a total cycle time of 20 min.

A freshly prepared solution of NH_3, 80 mmol L^{-1} in water/MeOH (50/50, v/v), was added to the LC column effluent at a flow rate of 50 μL min^{-1} by means of a PerkinElmer series 200 micropump (Norwalk, CT, US). MS/MS detection was performed with a TSQ Vantage triple-stage quadrupole mass spectrometer (Thermo Fisher Scientific) connected with the LC system via a heated ESI source, operated in negative ionization mode. Spray voltages of 2.6 kV were applied, whereas declustering voltage was maintained to 0 V. The vaporizer temperature was set to 280 °C, and the capillary (ion-transfer tube) temperature to 220 °C. Sheath gas pressure, ion sweep gas pressure, and auxiliary gas pressure were set to 40, 0, and 20 (arbitrary units), respectively. Mass calibrations and resolution adjustments on the resolving lens and quadrupoles were automatically performed using the manufacturer's solution introduced via infusion pump at 5 μL min^{-1} flow rate. To optimize the tuning parameters for each compound, 1 ng μL^{-1} standard solutions in water/MeOH (50/50, v/v) were infused at 10 μL min^{-1}. The negative precursor ions were selected by the first quadrupole and fragmented in the collision cell with the appropriate collision energy. From the MS/MS full-scan spectra, suitable transitions were selected for acquisition in selected reaction monitoring (SRM) mode. The whole LC-MS system was managed by Xcalibur software (v.2.1, Thermo Fisher Scientific).

Method Performance. The method developed was evaluated according to recovery, matrix effect, linearity, precision (intra- and interday precision), and limits of detection (LODs) and limits of quantifications (LOQs) under the optimized conditions.

Recovery. The relative recoveries of the analytes were calculated by comparing the peak area ratio relative to that of the ISs obtained by spiking milk samples containing no detectable analyte quantities with the composite working standard solutions and ISs at four different concentration levels (5, 0.5, 0.2, and 0.05 μg/L) before and after the extraction procedure in triplicate.

Matrix Effect. Signal suppression (or enhancement) on ESI-MS/MS response due to matrix components, i.e., matrix effect (ME), was assessed by comparing the response of each analyte in matrix with respect to their response in solvent via the formula $[1 - (A_{matrix}/A_{standard})]\cdot 100$ where A_{matrix} and $A_{standard}$ are the relative peak area with respect to the ISs area of the analyte in matrix and in solvent, respectively. This was assessed during recovery experiments for each considered concentration.

Linearity. For linearity evaluation, two sets of calibration lines, named "standard" and "matrix-matched", were constructed. The standard calibration curve was constructed by diluting appropriate volumes of the working standard solution in water/MeOH (50/50, v/v), and adding the same amount of ISs at all times. Each point of the matrix-matched calibration curve was prepared following the procedure applied for recovery experiments as described in the previous section. Also in this case the same amount of IS was added at all times. Both standard and matrix-matched solutions were prepared at six concentration levels, ranging from 5 to 0.02 μg/L.

Precision. Precision of the method was assessed by the repeatability and reproducibility studies and expressed as recoveries and the relative standard deviation (RSD, %). The intraday precision (RSDr) was expressed as the standard deviation of the recovery values ($n = 6$) of the spiked samples at three levels measured during the same day. The interday precision (RSD_R) was determined by analyzing the spiked samples ($n = 3$) for six different days at the same levels.

LODs and LOQs. Method sensitivity was evaluated by LODs and LOQs.

The LODs and LOQs can be either instrumental (ILODs and ILOQs) or relative to the applied methodology (MLODs and MLOQs). To calculate LODs, the standard deviation of the response (σ) was divided by the slope of the calibration curve (S), according to the formula LOD = $3\sigma/S$ using the standard calibration curve for ILOD and matrix-matched calibration curve for MLOD.

In the same way, ILOQ and MLOQ were estimated according to the formula LOQs = $10\sigma/S$. These values were calculated employing data generated from regression statistics performed using standard and matrix-matched calibration points in the range of the lower concentrations (0.02−0.2 μg/L). The sum of the ion currents of the SRM transitions was considered to determine LOQs, while the less intense transition was considered to evaluate LODs.

RESULTS AND DISCUSSION

LC-MS/MS Optimization. The ESI-MS/MS fragmentation profile of all considered analytes was investigated by infusion experiments of single standards of approximately 1 ng/μL, prepared in water/MeOH (50/50, v/v).

Mycoestrogens and free estrogens were studied in negative ionization mode, giving in all cases $[M-H]^-$ as precursor ion. The list of precursor and fragment ions is shown in Table 1 together with their optimized S-lens and collision energies (CE).

UHPLC conditions were also investigated to determine the best mobile phases to separate the analytes using C18 stationary phase.

It has been reported[14] that neutral mobile phases, such as water/ACN or water/MeOH, showed great results in term of free estrogens separation; therefore, preliminary experiments were carried out testing these solvents. ACN resulted in the most appropriate organic solvents for chromatographic elution of all analytes in terms of peak separation and signal-to-noise ratio, especially because ACN allowed us to well separate ZAN, α-ZOL, and β-ZOL, which coeluted using MeOH as organic mobile phase.

In addition, to achieve more stable and reproducible signals and enhance the ionization of free estrogens, post column addition of NH_3 was introduced because of the incompatibility of high pH mobile phases with the silica-bonded C18 stationary phase. The addition of the basic modifier can significantly improve the deprotonation of the very weakly acid free estrogens; this resulted in a significant increase in the intensity and stability of the response of the ESI-MS system.

Concentration of 80 mmol/L of NH_3 in water/MeOH (50/50, v/v) mixture was chosen because of the volatility of the phase. The best conditions in terms of peak area reproducibility were achieved at a flow rate of 50 μL min^{-1}.

The mass-chromatograms of free estrogens and mycoestrogens are shown in panels a and b of Figure 2, respectively. All the examined compounds were analyzed in one chromatographic run. Each peak is relative to the sum of the selected transitions in an analyte-free milk sample spiked at the lowest level considered for recovery experiments (0.05 μg/L) using the composite standard working solution.

Sample Preparation. *Solid-Phase Extraction with GCB.* Milk analysis is very often challenging because many interfering compounds, such as proteins and fats, are present. They can suppress analyte signals, especially for compounds that can be present at a trace level. For this reason, deproteinization and/or defatting are often employed before extraction. This could lead to analyte loss, reduced reproducibility of the method, and long and time-consuming procedures. The use of Carbograph-4 can avoid these limitations because of its sorbent qualities. It is essentially a nonspecific and nonporous sorbent with a surface area of about 200 m^2 g^{-1}. The surface framework of this type of sorbent used in SPE was shown to be contaminated by oxygen complexes. These groups are able to interact so strongly with sufficiently acidic compounds that conventional solvent systems are not able to desorb them.[15,16] Because of the presence of positively charged chemical heterogeneities on their surface, GCB can be considered to be both reversed-phase sorbent and anion exchanger, showing great versatility. Therefore, it exhibits the advantage of being able to simultaneously extract neutral, basic, and acidic compounds.

In our recent work we used Carbograph-4 for the determination of free and conjugated estrogens in milk.[17] In this case, backflush elution mode was necessary because of the excessive retention of the conjugates into the sorbent.

Here we chose to directly focus on the free estrogens and mycoestrogens, present in milk and potentially dangerous for human health; therefore, the methodology was adapted and optimized for this purpose. With the optimized procedure it was possible to elute all the analytes with CH_2Cl_2/MeOH after a simple dilution of milk in water. Recovery experiments were performed at four concentration levels, and the results are shown in Table 2. The employed methodology provided very good recoveries with negligible matrix effect also at the lowest concentration level, demonstrating the effectiveness of this SPE for a very complex matrix, such as whole milk.

Comparison with Other Extraction Methods. Searching the literature for works dealing with endocrine disruptors in milk provides several publications, but only very few methods addressed the determination of resorcyclic acid lactones and endogenous estrogenic compounds in milk. In particular, most works were especially dedicated to the presence of free estrogens in milk and dairy products. On the other hand, methods for the determination of ZEA and its metabolites were developed, but they comprised other mycotoxin compounds as well. In this context only two works described methods for their analysis in milk as estrogenic compounds together with mycoestrogens by LC-MS/MS,[18,19] and in only one work were free estrogens also considered, but they were analyzed with other techniques.[20]

In their work, Xia et al.[18] analyzed the six resorcyclic acid lactones with SPE using the Oasis MAX cartridges in whole milk samples. This polymeric sorbent has properties similar to GCB sorbent because it contains quaternary amine groups on the surface; therefore, it can act as reversed-phase sorbent and anion exchanger. For this reason we decided to verify if the cited procedure could work also for simultaneous extraction of estrogens and mycoestrogens in comparison to our optimized procedure.

For this purpose recovery experiments were carried out using Oasis MAX cartridges at two concentration levels (1 μg/L and 0.05 μg/L) following the procedure reported Xia et al.[18] Results demonstrated that at high spiking levels recoveries range between 70 and 90%, except for E3 (only 13%, data not shown). This can be explained probably because E3, being the most polar analyte, could be lost during cartridge washing with ACN. At lower spiking levels, which is the scenario in milk samples, this methodology was unable to recover free estrogens, and mycoestrogens recoveries decreased significantly. This result was attributed to the low concentration levels, in which case the sample pretreatment (deproteinization step) can become a crucial and limiting step; in fact, the unavoidable analyte loss and the inefficiency of the commercial sorbent to retain and elute the analytes significantly affected sample recoveries. On the other hand, with the optimized method using GCB as sorbent, it was possible to reach lower method detection limits (MDLs) and method quantification limits (MQLs), with negligible or very low matrix effect, which

[a]Intraday precision, $n = 6$ within the same day. [b]$n = 6$ in 6 different days; $n = 3$ within each day.

did not influence analyte signals also at low concentration, demonstrating the effectiveness of the cleanup for all the considered compounds.

Method Performance. The developed method showed good linearity for all the analytes investigated also in the range of the low concentrations with correlation coefficients ranging between 0.9991 and 1, as shown in Table 3. In the majority of the works previously published, LOD and LOQ values were calculated using the signal-to-noise ratio of the transitions of the analyzed compounds. However, when operating in MS/MS mode with modern triple quadrupole mass spectrometers, the baseline noise is very often quite totally absent; therefore, the extrapolated LOD and LOQ values are notably underestimated and not realistic.

For this reason the detection and quantification limits were assessed considering the standard deviation of the response and the slope, i.e., LOD = $3\sigma/S$, where σ is the standard deviation of the response and S the slope of the calibration curve. For the estimate of σ, the standard deviation of the y-intercept of the regression line was used. In the same way, LOQ was estimated as $10\sigma/S$. For LOQ measurements, for each analyte the sum of the two transitions was considered, whereas for LOD measurements only the response of the second-most intense SRM transition was considered. To assess the reliability of the results we used the standard deviation and the slope of the linear regression generated from the lower calibration points (between 0.02 and 0.2 μg/L, nearer to LOD and LOQ values). Then, to verify the obtained values for the developed method, blank milk samples were spiked at MDL and MQL concentrations. Moreover, as reported in the Commission Decision 2002/657/EC,[21] we decided that the presence of a compound is confirmed if the relative intensities of their selected transitions correspond to those in the calibration standard, under certain set conditions, within set tolerances. For this reason, the relative intensities of the selected transition for all the analytes were checked and compared in each point of the standard and matrix matched calibration curve for their real detection. Finally, the calculated values were confirmed by spiking a blank sample with the found concentrations. As shown in Table 3, with this method it is possible to reach good detection and quantification limits, which are lower than those of other published methods. This result is crucial for this type of analysis, especially because natural contamination of estrogenic compounds is often present at trace levels.

Analysis of Milk Samples. To demonstrate its applicability, the developed method was employed to analyze different whole milk samples: 16 cow milk samples, 2 UHT cow milk samples, 3 powder cow milk samples, 4 goat milk samples, and 5 donkey milk samples. As for the method development, we chose to consider whole milk as the worst case in terms of complexity and because it is also known that free estrogens could be found in larger amounts in samples richer in fats. Results obtained in sample analysis indicated that in 4 of the 16 samples of cow milk E1 was found at concentrations between its MLOD and MLOQ value, and in one of them also ZEA was found between its MLOD and MLOQ value. The other samples did not show any contamination.

teristics such as longer emission lifetime and delayed relaxation time, making the lowest background noises from short-lived autofluorescence and scattering light of the analytical system to be achieved; therefore, RTP is favorable for analysis of complex samples as a signal transduction method.[19−31] Recently, the RTP of doped quantum dots (QDs), e.g., Mn-doped ZnS QDs, has attracted growing attention on optosensing.[20−31] Doped QDs have been considered as a novel type of luminescent material and displayed promising applications in fabricating chemosensors, biosensors, and bioimaging based on their intrinsic advantages of conventional QDs.[20] However, most research has been interested in developing QD-based fluorescent chemo/biosensors; the distinguished phosphorescent properties of QDs still have not been used sufficiently for applications in analytical chemistry.[20] As far as we know, such RTP of QDs used to detect OPPs has rarely been reported.[25] On the other hand, colorimetric assays, which can be achieved with naked eyes or UV/vis spectrometry, have shown some advantages in their simpleness such as simple instrumentation and easy operation procedures.[32−37] Typically, colorimetric detections based on gold nanoparticles (AuNPs), which generally display different colors in the visible range resulting from their localized surface plasmon resonance (LSPR) absorption and scattering,[36,37] have been applied for a variety of analytes including biomacromolecules, small molecules, and metal ions.[32−37] We believe that the sensing strategy combining phosphorimetric and colorimetric techniques will provide a novel method with simplicity and high sensitivity for analytical applications.

In this study, we demonstrate a dual-signaling sensing system by taking advantages of both phosphorimetric and colorimetric methods for the first time, which relies on the inner filter effect (IFE) of AuNPs on the phosphorescence of Mn-ZnS QDs. In this IFE system, AuNPs and Mn-ZnS QDs are designed as the absorber−phosphor pair to regulate the phosphorescence emission of Mn-ZnS QDs. The IFE of luminescent species is generally defined as the absorption of the excitation and/or emission of lumiphores by absorbers and therefore leads to the quenching of lumiphores in the IFE systems.[38] More importantly, the linking between the absorbers and the lumiphore is not required in IFE detection systems, making the IFE-based detection considerably flexible and simpler for analytical applications. On the other hand, an improved detection sensitivity may be obtained compared with the absorbance or luminescence intensity alone because the varying absorbance of absorbers results in exponential variance in the luminescence of lumiphores.[38] Recently, a few studies have demonstrated IFE-based applications in developing novel fluorescence assays, although it usually introduces undesired systematic errors to fluorescence measurements and is expected to be avoided.[39−45] However, to the best our knowledge, analytical application that relies on IFE of AuNPs on the phosphorescence of QDs has not been reported so far. In the present study, we describe a colorimetric and phosphorimetric dual-signaling strategy for sensitive assay of OPPs including paraoxon, parathion, omethoate, and dimethyl dichlorovinyl phosphate (DDVP) (Figure 1). The assay principle is attributed to the remarkable quenching of the phosphorescence of Mn-ZnS QDs by AuNPs via IFE and the inhibition of the activity of acetylcholinesterase (AChE) by OPPs. In the presence of OPPs, the production of thiocholine from the hydrolysis of acetylthiocholine catalyzed by AChE is hindered, resulting in the aggregation of AuNPs and thereby the restoration of the IFE-quenched phosphorescence of Mn-ZnS QDs. Consequently, the aggregation of AuNPs and the phosphorescence recovery of Mn-ZnS QDs are dependent on OPP concentration. On the basis of the variations of absorbance and phosphorescence of the analytical system, a dual-readout assay for OPPs has been proposed.

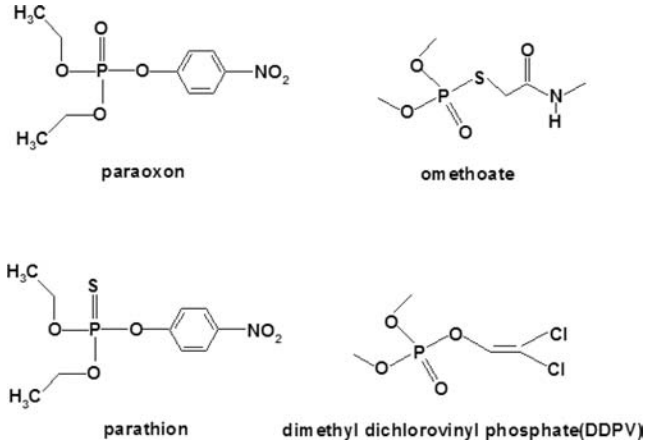

Figure 1. Chemical structures of organophosphorus pesticides tested in this study.

EXPERIMENTAL PROCEDURES

Materials and Apparatus. $ZnSO_4·7H_2O$, $Na_2S·9H_2O$, $MnCl_2·4H_2O$, mercaptopropionic acid (MPA), $HAuCl_4·H_2O$, sodium citrate, acetylcholinesterase (AChE, from *Electrophorus electricus*), and acetylthiocholine iodide were provided by Sigma-Aldrich (Tianjing, China). Paraoxon, dimethyl dichlorovinyl phosphate (DDVP), parathion, and omethoate were obtained from Aladdin-Reagent Co. (Beijing, China). The reagents used in this study are of analytical grade and without further purification. The ultrapure water (Mill-Q, Millipore, 18.2 MΩ resistivity) was used for all the experiments in this study. Mn-Doped ZnS QDs modified with MPA and citrate-modified AuNPs were synthesized with the procedures reported in the literature.[30,31,46]

UV/vis absorption spectra were performed on a UV-3010 spectrophotometer (Hitachi, Japan). Phosphorescence spectra were recorded on an LS-55 fluorescence spectrophotometer (PerkinElmer Company, U.S.A.) using a quartz cell (1 cm × 1 cm) in the phosphorescence mode. Decay curve measurements were carried out on a model FLS920 steady-state and lifetime spectrometer (Edinburgh Instruments Ltd., Livingston, U.K.). Apple juice was prepared with a juice extractor.

The freshly prepared aqueous solution of acetylthiocholine (1.0 mM) was used immediately (not exceeding 3 h) to reduce its hydrolysis. The stock solution of pesticides (4.0 mM) was first prepared with methanol and then was diluted to desired concentrations with ultrapure water. AChE (1.0 U/mL) was prepared with phosphate-buffered solution (pH 8.0, 10 mM) and used immediately for the following experiments.

Experimental Procedures for the Assay of OPPs. Paraoxon, one typical OPP frequently used, was selected as the representative pesticide for carrying out the experiments. AChE (20 μL, 1 U/mL) was first mixed with 0.5 mL of phosphate buffer containing different concentrations of paraoxon at 37 °C for 20 min. Acetylthiocholine (20 μL, 1 mM), AuNPs (0.67 mL, 12 nM), and Mn-ZnS QDs (0.2 mL, 40 mg/L) were introduced into each mixture, respectively, and then the resulting mixtures were scaled to 2.0 mL using phosphate buffer and mixed thoroughly. After incubating in the dark for 10 min, UV/vis absorption and phosphorescence spectra were recorded, respectively, and the phosphorescence emission spectra were measured at 580 nm under the excitation at 290 nm. All measurements were repeated at least five times.

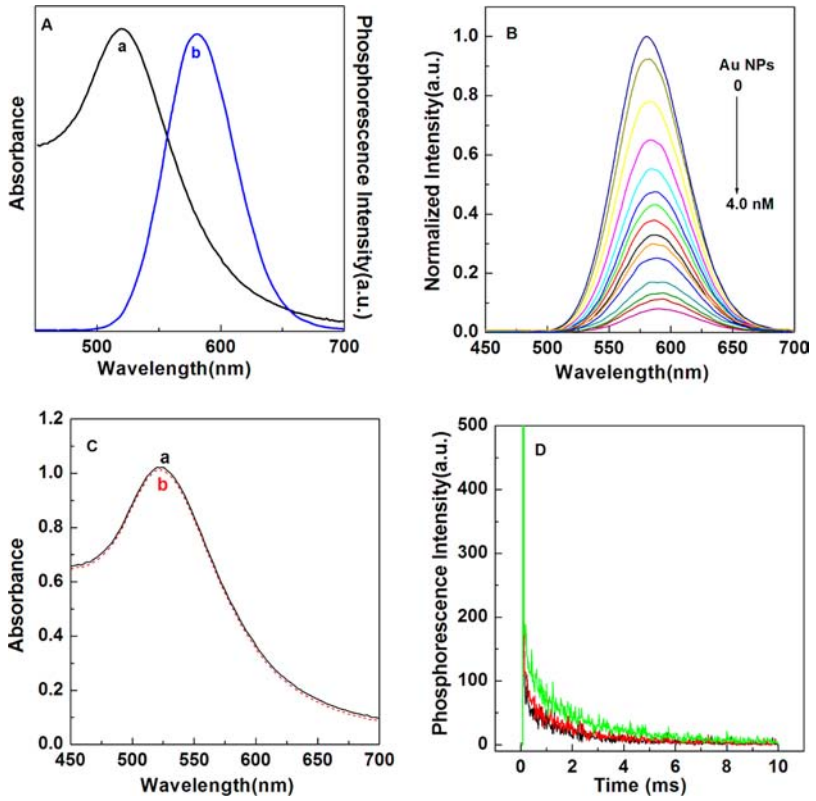

Figure 2. (A) Overlay spectra of absorption spectrum of AuNPs (a) and phosphorescence emission spectrum of Mn-ZnS QDs (b), (B) phosphorescence spectra of Mn-ZnS QDs in the presence of various concentrations of AuNPs (from top to bottom: 0, 0.2, 0.6, 0.8, 1.0, 1.3, 1.5, 1.8, 2.0, 2.5, 2.8, 3.0, 3.2, 3.5, 4.0 nM), (C) absorption spectrum of AuNPs in the absence (a) and presence (b) of Mn-ZnS QDs(C), and (D) the phosphorescence lifetime of Mn-ZnS QDs in the absence (green line) and presence of 1.0 nM (red line) and 2.0 nM (black line) AuNPs. Unless otherwise stated, the concentrations for Mn-ZnS QDs and AuNPs are 4 mg/L and 4.0 nM, respectively. The excitation wavelength for phosphorescence measurements is at 290 nm.

Analysis of Paraoxon in Spiked Samples and Contaminated Samples. In this study, lake water and apple juice made from clean apples (i.e., without sprayed OPPs) were used for spiked experiments, while the apple juice made from apples sprayed with OPPs was used for investigating OPP residues with time. The apples (with or without sprayed OPPs) were smashed into pieces and then squeezed into homogenates with juice squeezer. The obtained homogenates (20 g) were dissolved into 20 mL of methanol, and the resultant dispersion was filtered with a 0.22 μm filter (PES membrane) to get rid of the insoluble matrixes,[12] and then apple juice was collected for further experiments. For spiked experiments, different volumes of paraoxon stock solutions (4.0 mM, i.e., 1.1 g/L) were incubated in the prepared 4.0 mL of real sample (lake water or apple juice) and then scaled to 5.0 mL using buffer, resulting in final concentrations of paraoxon of 5.0 nM, 10.0 nM, and 100.0 mM, respectively. Five μL of the resulting sample was mixed with AChE (20 μL, 1U/mL) and incubated at 37 °C for 20 min, following by the introduce of acetylthiocholine (20 μL, 1 mM), AuNPs (0.67 mL, 12 nM), and Mn-ZnS QDs (0.2 mL, 40 mg/L). The mixture was then scaled to 2.0 mL by phosphate buffer, mixed thoroughly, and incubated for 10 min in the dark, and then UV/vis absorption and phosphorescence were recorded. For the contaminated apple juice, similar analytical procedures were adopted.

RESULTS AND DISCUSSION

IFE of AuNPs on Phosphorescence of Mn-ZnS QDs. Generally, the key point in designing an IFE-based analytical system is to select a suitable absorber/lumiphore pair because the effective IFE could happen under the conditions of sufficient spectral overlapping between the absorber absorption and the excitation and/or emission of the lumiphore.[38,43] However, the conventional absorber generally possesses a small absorption coefficient, which limits the IFE efficiency and therefore reduces the sensitivity of the IFE-based analytical system. Consequently, such luminescent method based on IFE has not been extensively exploited so far.[38,43] Undoubtedly, to get high sensitivity for IFE-based detection, the important thing is to improve the inner filter efficiency and, thus, to achieve a low luminescent background.[38,43] To such an attempt, a practical approach is to expand the spectral overlapping of absorber absorption with lumiphore emission, and/or to select proper absorber with larger absorption coefficient.[38,43] In this study, AuNPs have been chosen as the absorbers, which is based on the fact that AuNPs possess a much larger absorption coefficient (e.g., 2.7×10^8 /M/cm at 520 nm for the particles with a diameter of 13 nm[46]) compared to those of usual chromophores. Figure 2A shows a good overlap of the absorption band of AuNPs (curve a) with the phosphorescence emission band of Mn-ZnS QDs (curve b), which provides a precondition for possible IFE between AuNPs and Mn-ZnS QDs. To confirm the IFE occurred between AuNPs and Mn-ZnS QDs, the phosphorescence spectra of Mn-ZnS QDs were investigated when Mn-ZnS QDs were mixed with various concentrations of AuNPs. We can see from Figure 2B that the phosphorescence emission of Mn-ZnS QDs gradually decreases upon increasing concentrations of AuNPs. In the present system (pH 8.0), the AuNPs obtained with citrate reduction method were capped with citrate and negatively charged, supported by its zeta potential, −36.6 mV, because of the ionization of the −COOH group in citrate.[44] The zeta potential

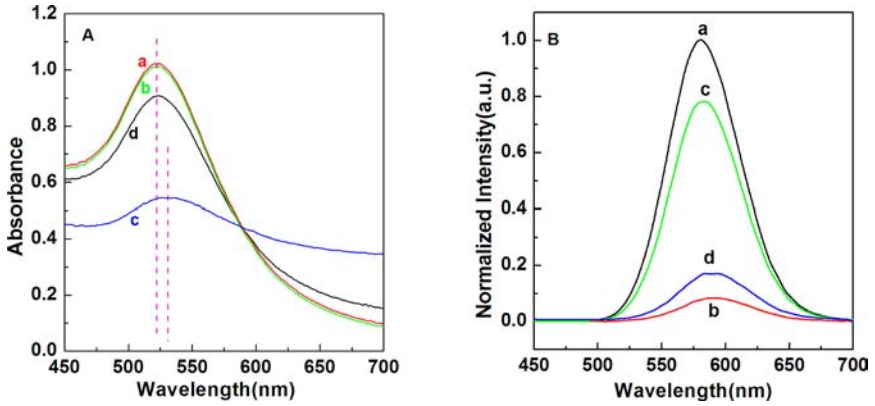

Figure 3. (A) UV/vis absorption spectra of AuNPs (a), Mn-ZnS QD−AuNP mixed solution (b), Mn-ZnS QD−AuNP solution incubated with AChE and acetylthiocholine (c), and Mn-ZnS QD−AuNP solution containing AChE was pretreated with paraoxon, and acetylthiocholine (d); (B) phosphorescence spectra of Mn-ZnS QDs (a), Mn-ZnS QD−AuNP mixed solution (b), Mn-ZnS QD−AuNP mixed solution incubated with AChE and acetylthiocholine (c), and Mn-ZnS QD−AuNP mixed solution containing AChE was pretreated with paraoxon and acetylthiocholine (d). The concentrations for AChE, acetylthiocholine, AuNPs, Mn-ZnS QDs, and paraoxon are 10 mU/mL, 10 μM, 4 nM, 4 mg/L, and 1 μM, respectively.

of the MPA-capped Mn-ZnS QDs was also measured, and the zeta potential was −46 mV in pH 8.0 phosphate buffer because of the ionization of the −COOH group in MPA (pK_{COOH} = 4.32[47]). The electrostatic repulsion interaction causes the formation of a complex, or energy transfer could not happen in the present system because the plasmon absorption band of AuNPs did not show obvious changes in the presence of Mn-ZnS QDs (Figure 2C).[43,48] Moreover, the phosphorescence lifetimes of Mn-ZnS QDs that coexisted with or without AuNPs were compared. From Figure 2D, no obvious changes in the average lifetime of the Mn-ZnS QDs were observed in the presence of AuNPs, suggesting that the complex resulting from Mn-ZnS QDs and AuNPs could not be formed through hydrogen bonding or electrostatic forces.[49] The observation from the studies on phosphorescence lifetime further confirms that there existed an efficient IFE of AuNPs on the phosphorescence of Mn-ZnS QDs, while no energy transfer between Mn-ZnS QDs and AuNPs occurs because nonradiative energy transfer basically changes the excitation lifetime of the energy donor.[49] On the basis of these experimental results, we believed that the decreased phosphorescence emission may be mainly ascribed to the IFE of AuNPs on the phosphorescence of Mn-ZnS QDs rather than other possible processes.

Notably, the quenching efficiency (E_q) of QDs by the IFE of AuNPs can be calculated via the equation:

$$E_q = 1 - P/P_0$$

Herein, P and P_0 are the phosphorescence intensity in the presence and absence of AuNPs, respectively. In this system, the maximum E_q was estimated to be as high as 80.2% in the presence of as low as 4.0 nM Au NPs, which is much greater than the IFE-based fluorescent analytical system.[43] This high quenching efficiency can be ascribed to the large absorption coefficient of AuNPs, and such a low background of the system is highly desirable for sensitive phosphorescence assay.

Dual-Signal Mechanism for OPP Assay through Inhibiting AChE Activity by OPPs. To construct a system for the OPP assay via the modulation of IFE of AuNPs on phosphorescence of Mn-ZnS QDs, a mixed solution containing optimized concentration of 4.0 nM AuNPs and 4.0 mg/L Mn-ZnS QDs was first prepared. It can be seen that the absorbance and color of the as-prepared solution (the solution color is red) (curve b in Figure 3A) remained unchanged and were the same as that of pure AuNPs solution (curve a in Figure 3A), and they displayed the typical characteristic absorption at 520 nm. Upon the addition of both acetylthiocholine and AChE into a Mn-ZnS QD−AuNP mixed solution, the quenched phosphorescence of Mn-ZnS QDs (curve b in Figure 3B) recovered significantly (curve c in Figure 3B), followed by the decreased of absorbance and the slight shift of the absorption band (solution color was changed from red to purple) (curve c in Figure 3A). To investigate the potential application in pesticides determination, AChE (10 mU/mL) was first mixed with paraoxon (1.0 μM) and incubated for 20 min at 37 °C; acetylthiocholine (10 μM), AuNPs (4.0 nM), and Mn-ZnS QDs (4.0 mg/L) were then mixed together in sequence. We found that the absorbance was recovered with a duration of 30 min (curve d in Figure 3A), and phosphorescence recovery of Mn-ZnS QDs was impeded (curve d in Figure 3B), accompanied by the change in the color of the mixed solution from purple to red. These results indicate that paraoxon can surpress the activity of AChE, thus hindering the production of thiolcholine from the hydrolysis of acetylthiocholine catalyzed by AChE. Consequently, the absence of paraoxon can not only lead to absorbance change (also color change) but also can lead to the phosphorescence recovery of Mn-ZnS QD−AuNP solutions. Additionally, we can clearly see the aggregating behavior of AuNPs that resulted from the addition of AChE and acetylthiocholine from the analysis of transmission electron microscopy (TEM). Upon the addition of AChE and acetylthiocholine, the monodispersed AuNPs show a tendency to aggregate together and form AuNPs aggregates, which is agreement with the spectral changes displayed in Figure 3A (curve c). However, AuNP aggregates are prevented while inhibiting AChE with paraoxon. TEM analysis is also in agreement with the transforms in the aggregation states of AuNPs, demonstrating that paraoxon has the ability to prevent and form AuNP aggregates.

Analytical Performances of the AuNPs−Mn-ZnS QDs Dual-Signal Readout System for OPPs Assay. To investigate the analytical performances of the present system for the assay of OPPs, we first investigated one of the most commonly used OPPs, paraoxon, as the representative model pesticide. Prior to detection, paraoxon with different concentrations was introduced to aliquots of AChE solution, respectively, and the mixtures were incubated at 37 °C to

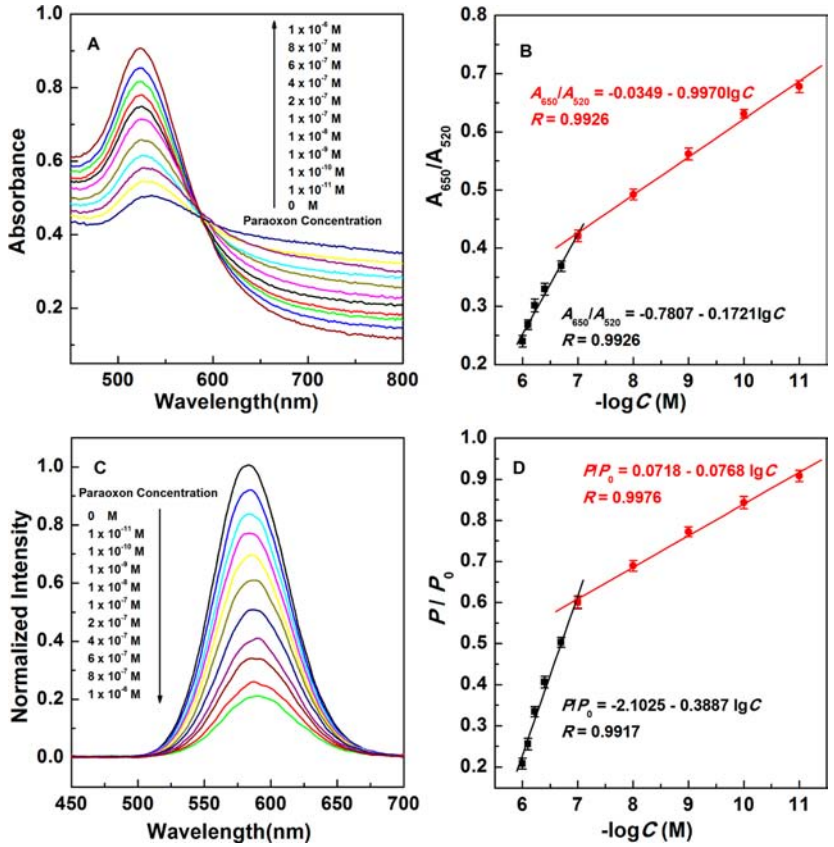

Figure 4. Absorption (A) and phosphorescence (C) spectra of the present system in the presence of increasing concentrations of paraoxon, and the linear calibration of (B) A_{650}/A_{520} and (D) P/P_0 versus the logarithm of paraoxon concentration. The concentrations for AChE, acetylthiocholine, AuNPs, and Mn-ZnS QDs are the same as those in Figure 2.

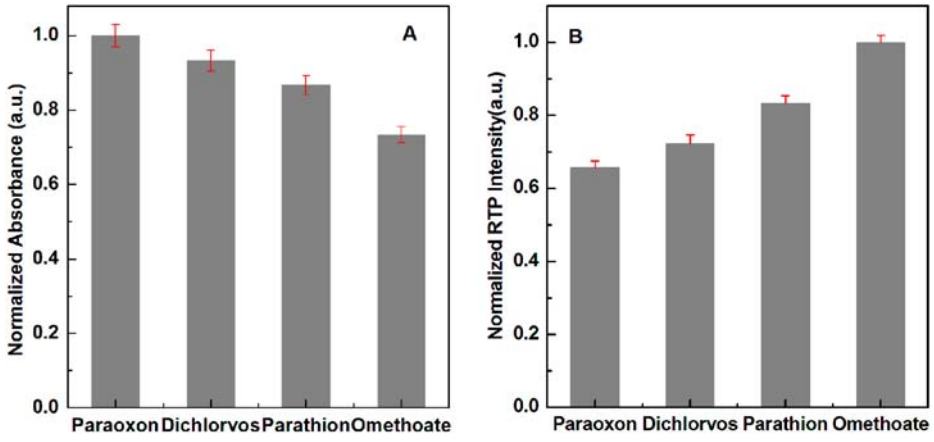

Figure 5. Normalized (A) absorbance and (B) phosphorescence response of different OPPs with the same concentration of 200 nM toward the present system. The concentrations for AChE, acetylthiocholine, AuNPs, and Mn-ZnS QDs are the same as those in Figure 2.

react for 20 min. AuNPs, Mn-ZnS QDs, and acetylthiocholine were then introduced into each mixture in sequence. After incubating for 10 min, it can be seen that the color of the solution transforms gradually from red to purple, which is dependent on paraoxon concentrations. The UV/vis absorption spectra displayed in Figure 4A demonstrated that the absorption band was slightly red-shifted, further confirming the color transforming arising from aggregation of AuNPs. The aggregation and relevant color transforming of AuNPs that resulted from AChE-catalysis hydrolysis could be exploited for fabricating colorimetric (visual) sensor of paraoxon. As shown in Figure 4A, upon increasing the paraoxon concentrations, the absorption peak located at 520 nm increased gradually, accompanied with the gradual decrease of absorption band ranging from 600 to 800 nm. The correlation analysis of A_{650}/A_{520} (the absorbance ratio at 650 and 520 nm) against the concentrations of the paraoxon displayed a linear relationship (Figure 4B), and the larger A_{650}/A_{520} values indicated lower levels in aggregation of AuNPs, consistent with lower paraoxon concentrations. In this study, good linear relationships with different slopes ranging from 10^{-11} to 10^{-7} M (i.e., 2.75 ×

[a]Average of five repeated measurements. [b]RSD represents relative standard deviation.

10^{-9}–2.75×10^{-5} g/L) and 10^{-7} to 10^{-6} M (i.e., 2.75×10^{-5}–2.75×10^{-4} g/L) were obtained, respectively.

Furthermore, on the basis of the IFE of AuNPs on Mn-ZnS QDs, a phosphorescence method for paraoxon assay was also constructed. It can be seen from Figure 4C that phosphorescence emission of Mn-ZnS QDs decreased gradually upon increasing the paraoxon concentration, corresponding to the increasing of the absorbance of AuNPs at 520 nm. As shown in Figure 4D, the intensities of phosphorescence emission of Mn-ZnS QDs were concentration-dependent, and higher concentrations of paraoxon resulted in less phosphorescence recovery. The linear plots of the relative phosphorescence intensity (P/P_0) against paraoxon concentrations ranging from 10^{-11} to 10^{-7} M (i.e., 2.75×10^{-9}–2.75×10^{-5} g/L) and 10^{-7} to 10^{-6} M (i.e., 2.75×10^{-5}–2.75×10^{-4} g/L) (Figure 4D) were obtained, respectively. The detection limit ($3\sigma/s$) for paraoxon (lower concentration range) was found to be 1.07 pM (0.29 ng/L). This lowest detectable concentration is much lower than the maximum residue limits (MRL) in European Union pesticides database (0.01 mg/L).[50] The low detection limit is also much lower than that of previous assay of paraoxon.[11,13] The repeatability of the present assay was also investigated by measuring 50 nM paraoxon, and the relative standard deviation (RSD) for seven repeated detection was calculated to be 3.73%, suggesting that the response of the present dual-signal system to paraoxon is highly reproducible.

The present dual-readout strategy for the assay of other three usual OPPs including DDVP, parathion, and omethoate was also investigated using the same detection procedures designed for paraoxon. The results show that the inhibition responses of these three OPPs are still dependent on the concentration of pesticides. The inhibition responses of the typical OPPs at the concentration of 200 nM to the system were compared. From the UV/vis absorption and corresponding phosphorescence response, the inhibition efficiency could be evaluated. As shown in Figure 5, the inhibition efficiencies of the four OPPs are different and display an order (from strong to weak) of paraoxon, DDVP, parathion, and omethoate. These results also suggested that the established biosensors could be used for determination of different kinds of OPPs. The limits of detection ($3\sigma/s$) for parathion, omethoate, and DDVP are found to be 2.03 pM (0.59 ng/L), 3.12 pM (0.67 ng/L), and 1.98 pM (0.44 ng/L), respectively. These lowest detectable concentrations are also much lower than MRLs that originated from the European Union pesticides database (MRLs are 0.05 mg/L and 0.02 mg/L for parathion andomethoate, and and not shown for DDVP).[50]

Anti-Interference Capability of the Present System for OPPs. For demonstrating the specificity of the present system for OPP assay, the influences of potential different interfering substances including glucose, sucrose and sodium acetate, histidine, tryptophan, and glycerol were investigated under the same experimental conditions. We choose paraoxon detection as a model, and the selectivity of phosphorescence for paraoxon detection was evaluated by testing a mixture of paraoxon with different interfering substances. The results demonstrate that the phosphorescence responses changed less when the interfering species with identical concentration were present in the present system, indicating that the present system displays high selectivity for assaying paraoxon and, therefore, can be applied for OPP detection in real samples.

Detection of OPP Residues in Spiked Samples and Authentic Contaminated Samples. To demonstrate the real applications of the present method for selective assaying of OPPs, we chose paraoxon as the representative model pesticide and the amounts of paraoxon in local natural lake water and apple juice samples were detected using the standard addition method. Paraoxon with different concentrations including 5.0, 10.0, and 100.0 nM was introduced into lake water and apple juice solutions, respectively, and then detected by the proposed colorimetric and phosphorimetric method. The determinated results are displayed in Table 1, and it can be seen that excellent recoveries ranging from 96.8 ± 0.4% to 104.5 ± 0.6% were obtained and the RSDs were <3.0% for all determinations, indicating that the present method is reliable and applicable for OPP assay in real samples.

The residual pesticides in contaminated apples with the present biosensor were further evaluated. A standard paraoxon solution (4.0 mM, i.e., 1.1 g/L) was sprinkled on the surface of apples with a sprayer and then stored for 24 h at ambient temperature, and the contaminated apples were then processed to get apple juice. We investigated the residual paraoxon concentration of the contaminated apples with the time, and the residual paraoxon in each aliquot sample was measured every 2 days over a duration of 1 week and compared with the results analyzed by high-performance liquid chromatography (HPLC). It can be seen from Table 2 that the obtained detection results using the proposed assay are in agreement with those analyzed with HPLC, suggesting that the present method could be used to detect residual pesticides in authentic contaminated samples accurately.

In conclusion, a colorimetric and phosphorimetric dual-signal strategy, relying on the IFE of AuNPs on phosphorescence of Mn-ZnS QDs, for the assay of OPPs has been demonstrated for the first time. The mechanism for dual-signal transduction has been investigated with different techniques including UV/vis absorption spectra, phosphorescence spectra, and TEM images. The results demonstrate that lowest detectable concentration

profile of the oils. Orthogonal projection to latent structure discriminant analysis (OPLS-DA) was used to select variables that most effectively discriminate between the authentic and adulterated sesame oils. The predictive discrimination power of the selected variables was then evaluated in a blind trial using oil samples consisting of sesame oils, sesame-flavored oils, and sesame oils to which foreign edible oils were added at different concentrations.

MATERIALS AND METHODS

Sample Preparation. Samples of authentic sesame oils (n = 35) were prepared in our laboratory by extraction from 16 samples of Korean sesame seeds and 19 samples of imported sesame seeds obtained from local grocery stores in Korea. The sesame seeds were roasted in a drum roster (model THDR-01, Taehwan Automation Industry Co., Seoul, Korea) at 200 °C for 30 min, and the oil was then extracted from the roasted seeds using an oil press (model Oil Love, National Eng. Co., Goyang, Korea). The extracted oil was centrifuged at 9600g for 10 min to remove precipitated impurities and was completely dried under nitrogen gas. Twenty-five samples of commercial sesame-flavored oils were purchased from local grocery stores in Korea. Table 1 lists the type and amount of ingredients in the commercial sesame-flavored oils, as indicated on the product labels. Four samples of commercial roasted sesame oils in which the α-linolenic acid (18:3n-3) content deviated from the standards of roasted sesame oil in the Korea Food Code[14] (i.e., 18:3n-3 content, > 0.5 w/w %) were obtained from local grocery stores. Samples of adulterated sesame oils (n = 29) consisted of commercial sesame-flavored oils and commercial roasted sesame oils. The above samples of authentic and adulterated sesame oils were used to select variables that best characterize authentic sesame oils using an OPLS-DA technique. Blind samples of sesame oils (n = 70) were provided by the National Institute of Food and Drug Safety Evaluation (NIFDS) of the Ministry of Food and Drug Safety, Korea (http://www.nifds.go.kr). The blind oil samples consisted of 14 samples of commercial sesame oils in which the 18:3n-3 content of 6 samples met the standards of roasted sesame oil in the Korea Food Code and that of the other 8 samples deviated from the standards; 6 samples of commercial sesame-flavored oils; and 50 samples of commercial sesame oils to which commercial corn oils, commercial soybean oils, or commercial sesame-flavored oils were added at concentrations of 3, 5, 10, 15, and 25 v/v%. These blind oil samples were used to examine whether their authenticity could be correctly verified by applying the range of variables found in the authentic sesame oil samples. Samples of corn (n = 5), soybean (n = 5), sunflower (n = 5), perilla (n = 5), cottonseed (n = 3), and canola oils (n = 5) were also obtained from Korea's major food companies.

Stable Isotope Analysis. The carbon stable isotope ratio ($^{13}C/^{12}C$) of the oil samples was analyzed using a Delta V Advantage (Thermo Scientific, Bremen, Germany) isotope ratio mass spectrometer (IRMS) coupled with a Flash 2000 (Thermo Scientific) elemental analyzer (EA). An aliquot of each oil sample (0.2 μL) was placed into a 3.3 × 5 mm tin capsule (IVA Analysentechnik e.K., Meerbusch, Germany) and injected into the EA. The combustion and reduction tubes were maintained at 1000 and 750 °C, respectively, to convert the carbon in the oil samples into CO_2 gas under a stream of helium and oxygen. The resultant CO_2 was diluted with helium by 60 v/v % and was separated in a gas chromatography (GC) column (PTFE, 2 m; 6 × 5 mm, Agilent Technologies, The Netherlands), and its isotopic composition was measured on the IRMS. The analysis of the hydrogen ($^2H/^1H$) and oxygen ($^{18}O/^{16}O$) stable isotope ratios of the oil samples was performed using a Flash 2000 HT (Thermo Scientific) pyrolyzer connected to the Delta V Advantage IRMS. An aliquot of each oil sample (0.2 μL for the measurement of the hydrogen stable isotope ratio and 0.5 μL for the measurement of the oxygen stable isotope ratio) was wrapped in a 3.3 × 5 mm silver capsule (IVA Analysentechnik e.K.), pyrolyzed at 1400 °C under a helium flow, and passed through a column packed with glassy carbon chips to

(‰ vs VPDB)	mean	−29.8	−27.0[c]
δ^{2}H	range	−205.6 to −137.9	−202.1 to −151.6
(‰ vs VSMOW)	mean	−181.4	−172.5[c]
δ^{18}O	range	14.5−27.6	15.1−22.5
(‰ vs VSMOW)	mean	18.8	19.2

[a]Prepared in the laboratory by extraction from sesame seeds after roasting. [b]Consists of 25 samples of commercial sesame flavored oils and 4 samples of commercial roasted sesame oils in which the 18:3n-3 content deviated from the standards of roasted sesame oil in the Korea Food Code. [c]Significantly different from authentic sesame oil, $P < 0.05$.

convert the hydrogen and oxygen in the oil samples into H_2 and CO gases, respectively. The H_2 and CO were subsequently separated in a GC column (PTFE, 2 m; 6 × 5 mm, Agilent Technologies), and their isotopic compositions were analyzed on the IRMS. The stable isotope ratio was expressed as the delta (δ) value in per mille (‰) deviation from the respective international standard, that is, Vienna Pee Dee Belemnite (VPDB, $CaCO_3$) for carbon (i.e., δ^{13}C) and Vienna Standard Mean Ocean Water (VSMOW, H_2O) for hydrogen (i.e., δ^{2}H) and oxygen (i.e., δ^{18}O), according to the equation

$$\delta\ (‰) = [(R_s - R_{std})/R_{std}] \times 1000 \quad (1,)$$

where R represents the ratio of heavy to light isotopes and R_s and R_{std} are the isotope ratios of the oil sample and the international standard, respectively. The δ^{13}C value of each oil sample was determined from the standard calibration curve of fuel oil NBS 22 (IAEA-International Atomic Energy Agency, Vienna, Austria), cellulose IAEA-CH-3 (IAEA), and sucrose IAEA-CH-6 (IAEA) with certified δ^{13}C values of −30.0, −24.7, and −10.4‰ on the PDB scale, respectively. The δ^{2}H value was calibrated with the standard curve of ice core water USGS46 (U.S. Geological Survey (USGS)), NBS 22 (IAEA), and VSMOW (IAEA) with certified δ^{2}H values of −235.8, −119.6, and 0‰ on the VSMOW scale, respectively. The δ^{18}O value of the oil samples was determined using the standard calibration curves of VSMOW (IAEA), water UC04 (USGS), and benzoic acid IAEA-602 (IAEA), which had certified δ^{18}O values of 0, 38.9, and 71.4‰ on the VSMOW scale, respectively.

^{1}H NMR Analysis. Each oil sample (100 μL) was dissolved in 600 μL of deuterated chloroform (99.8% atom D, with 0.03 v/v % tetramethylsilane (TMS)) from Sigma-Aldrich and injected into 5 mm NMR tubes (Wilmad-Lab Glass, Buena, NJ, USA). The chloroform and TMS provided a field frequency lock and a chemical shift reference, respectively. ^{1}H NMR spectra were obtained using a 600 MHz NMR spectrometer (VNS-600, Varian Inc., Palo Alto, CA, USA). Prior to analysis, a phase correction was applied to all spectra using VnmrJ software (Agilent Technologies Inc., Santa Clara, CA, USA); then, MestReNova software (Mestrelab Research, Santiago de Compostela, Spain) was used as the analytical software for the spectra. The baseline correction of all of the spectra was performed with the Whittaker smoother method, and some dislocated spectra were aligned using the align spectra method. The integration value of each peak was determined and normalized on the basis of the first peak (0.7446−1.0445 ppm), which was derived from the terminal methyl group of fatty acids to avoid dilution effects on the samples.

Fatty Acid Analysis. Each oil sample (20 mg) was saponified with 0.5 M methanolic sodium hydroxide (3 mL) at 85 °C for 10 min, cooled to room temperature, and then methylated with 14% boron trifluoride in methanol (3 mL) at 85 °C for 10 min. After the samples had cooled to room temperature, isooctane (3 mL) and saturated sodium chloride solution (5 mL) were added, and the mixture was vortexed. The upper isooctane layer containing fatty acid methyl esters (FAMEs) was collected and passed through an anhydrous sodium sulfate column. The FAMEs were analyzed using gas−liquid chromatography. An Agilent Technologies 7890 N gas chromatograph (Palo Alto, CA, USA), equipped with a flame ionization detector and a fused silica capillary column (SP-2560, 100 m × 0.25 mm i.d. × 0.2 mm film thickness, Supelco, Bellefonte, PA, USA) was used for the analysis. Each sample (1 μL) was injected in split mode (split ratio of 200:1). The carrier gas was helium at a flow rate of 1.0 mL/min. The injector and detector temperatures were maintained at 225 and 285 °C, respectively. The oven temperature was initially held at 100 °C for 4 min. It was then programmed to increase to 240 °C at a rate of 3 °C/min and held at 240 °C for 17 min. The FAMEs were identified by comparing their retention times with those of reference standards (Supelco 37 component FAME Mix), and their relative contents were calculated as w/w %.

Statistical Analysis. A two-tailed Student's t test was performed to determine the differences between the authentic and adulterated sesame oil samples ($P < 0.05$). The differences among oil samples including corn, soybean, sunflower, perilla, cottonseed, and canola oil samples as well as authentic and adulterated sesame oil samples were determined using one-way ANOVA followed by Duncan's multiple-range test ($P < 0.05$). Pearson's correlation test was performed to determine whether a significant linear relationship existed between the two variables ($P < 0.01$). The above three statistical analyses were conducted using IBM SPSS Statistics (version 20) software (SPSS Inc., Chicago, IL, USA). Using the stable isotope ratio, ^{1}H NMR spectrum, and fatty acid composition data, OPLS-DA was performed in SIMCA-P+ (version 12.0) software (Umetrics, Umeda, Sweden). Pareto scaling was applied to each of the three data sets prior to OPLS-DA. The OPLS-DA model was validated using cross-validated ANOVA. An S-plot from OPLS-DA was used to identify significant variables that effectively discriminated between the authentic and adulterated sesame oil samples.

RESULTS AND DISCUSSION

Stable Isotope Ratio. The carbon, hydrogen, and oxygen stable isotope ratios of adulterated sesame oils were compared to those of authentic sesame oils (Table 2). The δ^{13}C value of adulterated sesame oil samples was significantly ($P < 0.05$) greater than that of authentic sesame oil samples. This arose from the fact that corn oil, the δ^{13}C value of which is known to be greater than that of sesame oil,[5] is most frequently added to adulterated sesame oils. In the present study, we also analyzed the carbon stable isotope ratio of six different kinds of edible oils commonly used for the adulteration of sesame oil, that is, corn, soybean, sunflower, perilla, cottonseed, and canola oils. Our analysis showed that the δ^{13}C value was significantly greater in corn oil samples (range, −16.9 to −15.7‰; mean, −16.2‰) than in authentic sesame oil samples, whereas the δ^{13}C values of the soybean (range, −31.0 to −30.4‰; mean, −30.6‰), sunflower (range, −29.2 to −28.1‰; mean, −28.6‰), perilla (range, −30.0 to −29.1‰; mean, −29.5‰), cottonseed (range, −29.4 to −29.0‰; mean, −29.2‰), and canola oil samples (range, −31.3 to −28.2‰; mean, −29.6‰) were not significantly different from that of the authentic sesame oil samples.

The δ^{2}H value was significantly ($P < 0.05$) greater in adulterated sesame oil samples compared to authentic sesame oil samples. However, the difference in δ^{2}H values between the

authentic and adulterated sesame oil samples was not pronounced compared to that in the δ^{13}C values. This occurs because, unlike the Student's t test results, the ANOVA results showed that the δ^{2}H value of the authentic sesame oil samples was not significantly different from that of the adulterated sesame oil samples or that of the corn (range, −180.7 to −150.7‰; mean, −170.2‰) soybean (range, −174.7 to −165.3‰; mean, −170.8‰), sunflower (range, −180.6 to −150.2‰; mean, −168.4‰), perilla (range, −192.3 to −187.9‰; mean, −190.2‰), or canola oil samples (range, −230.7 to −137.1‰; mean, −197.5‰). However, the δ^{2}H value of the cottonseed oil samples (range, −143.6 to −139.9‰; mean, −142.1‰) was significantly (P < 0.05) greater than that of the authentic sesame oil samples.

The δ^{18}O value of the adulterated sesame oil samples was not significantly different from that of the authentic sesame oil samples. Our analysis found that the δ^{18}O value of the authentic sesame oil samples was also not significantly different from that of the corn (range, 19.7−23.1‰; mean, 20.6‰) soybean (range, 20.0−21.8‰; mean, 20.7‰), sunflower (range, 20.1−23.4‰; mean, 22.0‰), perilla (range, 16.4−20.3‰; mean, 17.4‰), or cottonseed oil samples (range, 19.8−22.7‰; mean, 20.8‰). However, the δ^{18}O value of the canola oil samples (range, 20.8−40.5‰; mean, 27.0‰) was significantly (P < 0.05) greater than that of the authentic sesame oil samples.

^{1}H NMR Spectrum. Figure 1 shows a typical ^{1}H NMR spectrum of the authentic sesame oils obtained in the present study. The spectrum was composed of 26 main peaks, which have been assigned previously.[15−17] The chemical shift ranges

DOI: 10.1021/acs.jafc.5b04082
J. Agric. Food Chem. 2015, 63, 8955−8965

of the 19 peaks attributed to the unsaturated acyl moieties in the triacylglycerols and lignans present in the sesame oils and their assignments are summarized in Table 3. Peak 2 signifies the terminal methyl group of n-3 fatty acids including 18:3n-3. Peaks 5 and 7 signify a methylene group next to a C=C double bond and a methylene group between two C=C double bonds, respectively. Peak 17 signifies a vinyl proton (i.e., a proton directly attached to a C=C double bond). The other 15 peaks (i.e., peaks 8−12, 15, and 18−26) are attributed to the protons of sesamin and sesamolin, which are two major sesame lignans that are unique phenolic compounds possessing a methylene dioxy fragment (−OCH_2O−), as shown in Figure 2. The carbon numbering system used in this study is also shown in the figure.

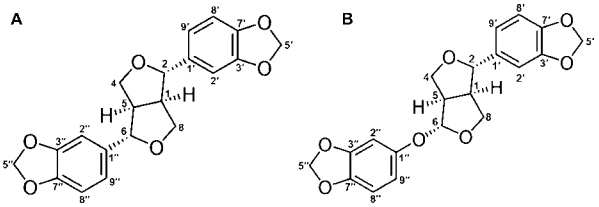

Figure 2. Carbon numbering in sesamin (A) and sesamolin (B).

Table 4 compares the integration values of the 19 peaks mentioned above for authentic and adulterated sesame oils. The integration value of peak 2 (I2 value) was significantly ($P < 0.05$) greater in the adulterated sesame oil samples than in the authentic sesame oil samples. This is attributed to the fact that the edible oils rich in 18:3n-3 such as soybean, perilla, and canola oils are commonly used for the adulteration of sesame oil. Our analysis demonstrated that the I2 value of the soybean (range, 0.0649−0.0752; mean, 0.0712), perilla (range, 0.5699−0.6049; mean, 0.5871), and canola oil samples (range, 0.0865−0.1057; mean, 0.0942) was significantly ($P < 0.05$) greater than that of the authentic sesame oil samples. However, the I2 values of corn (range, 0.0156−0.0203; mean, 0.0177), sunflower (range, 0.0051−0.0136; mean, 0.0098), and cottonseed oil samples (range, 0.0028−0.0150; mean, 0.0109) were not significantly different from that of the authentic sesame oil samples.

The integration value of peak 7 (I7 value) of the adulterated sesame oil samples was significantly ($P < 0.05$) greater than that of the authentic sesame oil samples. This result indicates that adulterated sesame oil contains greater amounts of polyunsaturated fatty acids, such as linoleic acid (18:2n-6), having methylene-interrupted double bonds in their structures. Our fatty acid analysis also demonstrated that the 18:2n-6 content was higher in the adulterated sesame oil samples than in the authentic sesame oil samples, as described below.

Adulterated sesame oil samples had significantly ($P < 0.05$) smaller integration values for all of the peaks derived from sesamin and sesamolin compared to those in the authentic sesame oil samples. For example, the adulterated and authentic sesame oil samples had mean integration values of 0.0027 and 0.0135 for peak 26 (I26 value), respectively. These results were caused by the much higher levels of lignan compounds including sesamolin and sesamin in sesame oil than in most other edible oils. In the present study, peak 26 was not detected in the ^{1}H NMR spectra of corn, soybean, sunflower, perilla, cottonseed, or canola oil.

[a]Integration values of ^{1}H NMR peaks. Numbers represent the peak numbers shown in Figure 1. [b]Prepared in the laboratory by extraction from sesame seeds after roasting. [c]Consists of 25 samples of commercial sesame flavored oils and 4 samples of commercial roasted sesame oils in which the 18:3n-3 content deviated from the standards of roasted sesame oil in the Korea Food Code. [d]Significantly different from authentic sesame oil, $P < 0.05$.

Fatty Acid Composition. The total fatty acid compositions of the authentic sesame oils were compared to those of the adulterated sesame oils (Table 5). The two major fatty acids of the authentic sesame oil samples were 18:2n-6 and oleic acid (18:1n-9). The adulterated sesame oil samples had significantly ($P < 0.05$) greater 18:2n-6 content than the authentic sesame oil samples. However, the 18:1n-9 content was significantly ($P < 0.05$) lower in the adulterated sesame oil samples than in the authentic sesame oil samples. This is attributed to the fact that most of the edible oils used for adulteration of sesame oil contain more 18:2n-6 and less 18:1n-9 than sesame oil. Our analysis found that the 18:2n-6 contents of corn (range, 48.5−53.8 w/w %; mean, 52.0 w/w %), soybean (range, 51.1−52.9

[a]Prepared in the laboratory by extraction from sesame seeds after roasting. [b]Consists of 25 samples of commercial sesame flavored oils and 4 samples of commercial roasted sesame oils in which the 18:3n-3 content deviated from the standards of roasted sesame oil in the Korea Food Code. [c]Significantly different from authentic sesame oil, $P < 0.05$. [d]na, not available.

w/w %; mean, 51.8 w/w %), sunflower (range, 52.7−61.6 w/w %; mean, 56.9 w/w %), and cottonseed oil samples (range, 55.8−57.5 w/w %; mean, 56.9 w/w %) were significantly greater ($P < 0.05$) than that of the authentic sesame oil samples, whereas the 18:1n-9 content was significantly lower ($P < 0.05$) in corn (range, 30.1−35.2 w/w %; mean, 31.6 w/w %), soybean (range, 22.0−25.0 w/w %; mean, 23.8 w/w %), sunflower (range, 26.5−35.8 w/w %; mean, 31.2 w/w %), perilla (range, 13.9−20.4 w/w %; mean, 17.5 w/w %), and cottonseed oil samples (range, 16.5−18.7 w/w %; mean, 17.3 w/w %) compared to the authentic sesame oil samples.

The adulterated sesame oil samples showed a significant ($P < 0.05$) difference from the authentic sesame oil samples in that they contained a considerable amount of 18:3n-3. This is because edible oils rich in 18:3n-3 are widely used for the adulteration of sesame oil. Our analysis showed that the 18:3n-3 content of soybean (range, 5.4−6.9 w/w %; mean, 6.0 w/w %), perilla (range, 58.9−63.1 w/w %; mean, 60.7 w/w %), and canola oil samples (range, 6.8−8.1 w/w %; mean, 7.6 w/w %) was significantly ($P < 0.05$) greater than that of the authentic sesame oil samples.

Another major difference in the fatty acid composition between the authentic and adulterated sesame oil samples was that the adulterated sesame oil samples had significantly ($P < 0.05$) higher *trans* fatty acid content, such as 18:2*t* and 18:3*t*, than the authentic sesame oil samples. The mean 18:2*t* contents of the authentic and adulterated sesame oil samples were 0.1 and 1.0 w/w %, respectively. The mean 18:3*t* content of the adulterated sesame oil samples was 0.7 w/w %, whereas authentic sesame oil samples contained little 18:3*t*. Our analysis found that the 18:2*t* and 18:3*t* contents of most edible oils (i.e., corn, soybean, sunflower, perilla, and canola oils for 18:2*t* content; corn, soybean, sunflower, perilla, and cottonseed oils for 18:3*t* content) used as the main ingredients in adulterated sesame oils were not significantly different from those of authentic sesame oil (data not shown). These results suggest the possibility that low-quality ingredients containing a considerable amount of *trans* fatty acids were added to the adulterated sesame oil samples (particularly, sesame-flavored oils) used in the present study.

Variables To Verify Sesame Oil Authenticity. OPLS-DA, a supervised multivariate statistical method, was performed to obtain information on differences in the stable isotope ratio, ^{1}H NMR spectrum, and fatty acid composition data between the authentic and adulterated sesame oils. An OPLS-DA model was generated from each of the three data sets, as well as by including all three types of analytical data. The cross-validated ANOVA P value was 4.92×10^{-2} for the model from the stable isotope ratio data; 3.24×10^{-17} for the model from the ^{1}H NMR spectral data; 1.05×10^{-19} for the model from the fatty acid composition data; and 3.79×10^{-16} for the model from all three types of data. The model fit parameters were $R^2Y = 0.316$ and $Q^2Y = 0.193$ for the model from the stable isotope ratio data; $R^2Y = 0.769$ and $Q^2Y = 0.752$ for the model from the ^{1}H NMR spectral data; $R^2Y = 0.854$ and $Q^2Y = 0.823$ for the model from the fatty acid composition data; and $R^2Y = 0.853$ and $Q^2Y = 0.792$ for the model from all three types of data. These results suggest that the model from the stable isotope ratio data had low goodness-of-fit compared to the other three models. However, these models were not employed to verify the authenticity of sesame oils in the present study because they did not clearly discriminate between the authentic and adulterated sesame oil samples when displayed as score plots (data available in Figure S1 of the Supporting Information). Instead, an S-plot constructed by the OPLS-DA model, in which the X-axis and Y-axis represent the contribution and confidence of the variables, respectively, was used to identify statistically significant variables that can be used to discriminate between the authentic and adulterated sesame oil samples (Figure 3). In the S-plot, the closer a variable is to the upper right or lower left corner of the graph, the more strongly the variable contributes to the difference between the two groups and the more significant is its contribution. Accordingly, the δ^{13}C value in the upper right corner in Figure 3A was selected as a variable to effectively discriminate between the authentic and adulterated sesame oil samples. Among the integration values of 19 different ^{1}H NMR peaks, I2 and I7 values in the upper right corner and the I26 value in the lower left corner were selected (Figure 3B). However, the I17 value, which was very close to the I7 value, was not selected as a variable to verify the authenticity of sesame oil samples because it showed strong positive correlation to the I7 value (Pearson's $R = 0.991$). In Figure 3C, among the content values of 12 different fatty acids, the 18:1n-9 content in the upper right corner and the 18:3n-3, 18:2*t*, and 18:3*t* contents in the lower left corner were regarded as the variables that contribute the most to the difference between the authentic and adulterated sesame oil samples.

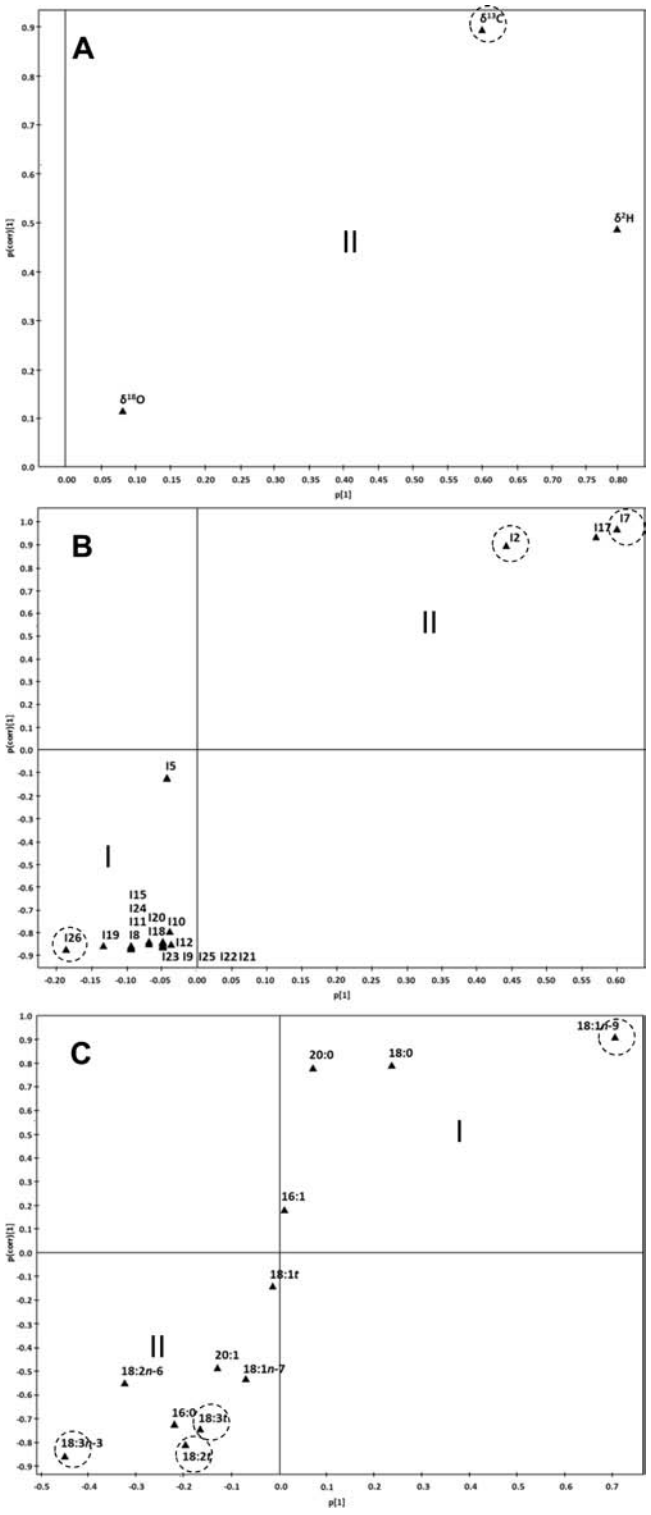

Figure 3. S-plots generated by orthogonal partial least-squares discriminant analysis (OPLS-DA) for (A) stable isotope ratio data, (B) ^{1}H NMR spectrum data, and (C) fatty acid composition data obtained from authentic and adulterated sesame oil samples: (I) authentic sesame oil; (II) adulterated sesame oil.

Table 6 lists the range of the eight selected variables in the authentic sesame oil samples used in this study.

Discrimination of Authenticity of Blind Samples. To evaluate the predictive discrimination power of the eight variables selected above, a blind trial was conducted using 70 oil samples (Table 7). The authenticity of the blind samples was determined by applying the range of variables in the authentic sesame oil samples as follows. If the measured values of the samples are all within the range of the variables, the sample is authentic sesame oil, whereas if any of the measured values is outside the range, the sample may have been adulterated. Among 70 blind samples, 18, 56, and 54 samples were classified correctly using the variables selected from the stable isotope ratio (procedure I), ^{1}H NMR spectrum (procedure II), and fatty acid composition data (procedure III), respectively. The combined use of two different types of variables increased the number of samples classified correctly. That is, procedure IV (procedures I + II), procedure V (procedures I + III), and procedure VI (procedures II + III) correctly verified the authenticity of 63, 60, and 60 samples, respectively. Finally, 65 of 70 blind samples were correctly classified using all eight variables (procedure VII), demonstrating that the combined analysis of the stable isotope ratio, ^{1}H NMR spectrum, and fatty acid profiles of the oils is a useful procedure to verify the authenticity of sesame oil.

Table 6. Range of Variables Selected To Verify Sesame Oil Authenticity in the Authentic Sesame Oil Samples Used in the Present Study

variable[a]	range
δ^{13}C (‰ vs VPDB)	−32.4 to −28.0
I2	0.0061−0.0165
I7[b]	0.2517−0.3152
I26[c]	0.0056−0.0329
18:1n-9 (w/w %)	35.3−43.0
18:3n-3 (w/w %)	0.3−0.4
18:2*t* (w/w %)	0.0−0.5
18:3*t* (w/w %)	0.0−0.1

[a]See Tables 2, 4, and 5

More specifically, all measured values of the blind samples 1−6, which were authentic commercial sesame oils, were within the range of the variables in the authentic sesame oil samples. Blind samples 7−14, which were commercial sesame oils in which the 18:3n-3 content was >0.5 w/w %, had an I2 value outside the range of the authentic sesame oil samples, indicating that the 18:3n-3 content and I2 value were closely correlated. Seven of the eight blind samples also had I7 value and 18:1n-9 content outside the range found in the authentic sesame oil samples. Blind samples 15−20, which were commercial sesame-flavored oils, had measured values of all eight variables that were outside the range found in the authentic sesame oils except for the 16, 18, and 20. These three blind samples had δ^{13}C values within the range found in the authentic sesame oil samples. These samples displayed a relatively high I2 value and 18:3n-3 content compared to blind samples 15, 17, 19, and 20. These results suggest that a possible main ingredient contained within them consists of 18:3n-3-rich edible oils (e.g., soybean, perilla, and canola oils) obtained from C_3 plants, which use the Calvin cycle for fixing atmospheric carbon dioxide. Among 70 blind samples, the 6 samples from the sesame-flavored oils were the only ones that had an I26 value outside the range found in the authentic sesame oil samples, indicating that the variable can be used as an indicator to distinguish adulterated sesame oils prepared in the same way as sesame-flavored oil. Similarly, these six blind samples had relatively high 18:2*t* and 18:3*t* contents compared to the other blind samples, suggesting that these variables can be used to

total no. of samples correctly classified										18	56	54	63	60	60	65

[a]See Tables 2, 4, and 5. [b]If measured values of the samples are all within the range of the variables listed in Table 6, the sample is an authentic sesame oil, whereas for any of the measured values outside the range, the sample may have been adulterated. Procedure I uses the δ^{13}C value; procedure II uses the I2, I7, and I26 values; procedure III uses the 18:1n-9, 18:3n-3, 18:2*t*, and 18:3*t* content values; procedure IV is a combination of procedures I and II; procedure V is a combination of procedures I and III; procedure VI is a combination of procedures II and III; and procedure VII is a combination of procedures I, II, and III. [c]CO, corn oil; SO, sesame oil; SBO, soybean oil; SFO, sesame-flavored oil. Samples 1−6 are samples of sesame oils in which the 18:3n-3 content met the standards of roasted sesame oil in the Korea Food Code; samples 7−14 are samples of sesame oils in which the 18:3n-3 content deviated from the standards. [d]Correctly classified. [e]Entries in boldface type are outside the range of values of the authentic sesame oil samples used in the present study. [f]Incorrectly classified.

J. Agric. Food Chem. 2015, 63, 8955−8965
DOI: 10.1021/acs.jafc.5b04082

effectively characterize adulterated sesame oils containing low-quality ingredients (e.g, extracts from feed sesame cake).

Finally, we evaluated the discrimination limit of using the eight variables as indictors to verify sesame oil authenticity from the results of the blind trial using commercial sesame oils to which commercial corn (samples 21−35), soybean (samples 36−50), or sesame-flavored oils (samples 51−70) were added at different concentrations. All of the samples of sesame oils with corn oils added at concentrations of 15 and 25 v/v% were correctly classified as being adulterated because they had a $\delta^{13}C$ value or 18:3n-3 content outside the range of the variables in the authentic sesame oil samples. It is noteworthy that, in the present study, the upper range limit of the 18:3n-3 content was 0.4 w/w %, although the 18:3n-3 content ≤0.5 w/w % is the standard of roasted sesame oil in the Korea Food Code.[14] However, a sample (no. 27) of sesame oil with corn oil added at a concentration 10 v/v% was incorrectly classified, indicating that it is difficult to distinguish sesame oil adulterated with corn oil at concentrations ≤10 v/v%. Conversely, all of the samples of sesame oils with soybean oils added at concentrations of 3−25 v/v% were correctly distinguished. The samples of sesame oils containing sesame-flavored oils were used to evaluate the discrimination limit of our procedure for sesame oils adulterated with more than one kind of foreign edible oil. All of the samples of sesame oils with sesame-flavored oils added at concentrations of 5−25 v/v% were correctly distinguished because their I2 value, I7 value, 18:3n-3 content, or 18:3*t* content was outside the range of the variables in the authentic sesame oil samples. However, all of the samples (nos. 67−70) of sesame oils containing sesame-flavored oils at a concentration 3 v/v% were incorrectly classified as authentic sesame oils.

In conclusion, this study is the first to report the verification of the authenticity of roasted sesame oils using combined analysis of stable isotope ratio, ^1H NMR spectroscopy, and fatty acid profiles of the oils. Commercial sesame-flavored oils were used as the principal model of adulterated sesame oils considering the fact that many adulterated sesame oils distributed in Korea are manufactured by adding more than one kind of foreign edible oil. We observed statistically significant differences in eight measured values between the authentic and adulterated sesame oils and employed them as variables to verify the authenticity of sesame oils. The variables include the $\delta^{13}C$ value from the stable isotope ratio data; I2, I7, and I26 values from ^1H NMR spectrum data, which were positively associated with the abundance of the methyl group of n-3 fatty acids; methylene between two carbon double bonds present in unsaturated acyl moieties of triacylglycerols; lignans (i.e., sesamin and sesamolin) present in the oils; and 18:1n-9, 18:3n-3, 18:2*t*, and 18:3*t* content values from the fatty acid profile data. Adulterated sesame oils had significantly ($P < 0.05$) greater $\delta^{13}C$, I2, I7, 18:3n-3 content, 18:2*t* content, and 18:3*t* content values than the authentic sesame oils, whereas the I26 and 18:1n-9 content values were significantly ($P < 0.05$) lower in the adulterated sesame oils than in the authentic sesame oils. It was demonstrated that the adulteration of sesame oils could be effectively verified by applying the range of eight variables observed in the authentic sesame oils. Thus, it would be possible to use these eight variables and their ranges as new specifications and standards of sesame oils distributed in Korea. The results of this study also showed that our discrimination procedure distinguished the sesame oils with corn oils added at concentrations ≥15 v/v %, soybean oils added at concentrations ≥3 v/v %, or sesame-flavored oils added at concentrations ≥5 v/v %.

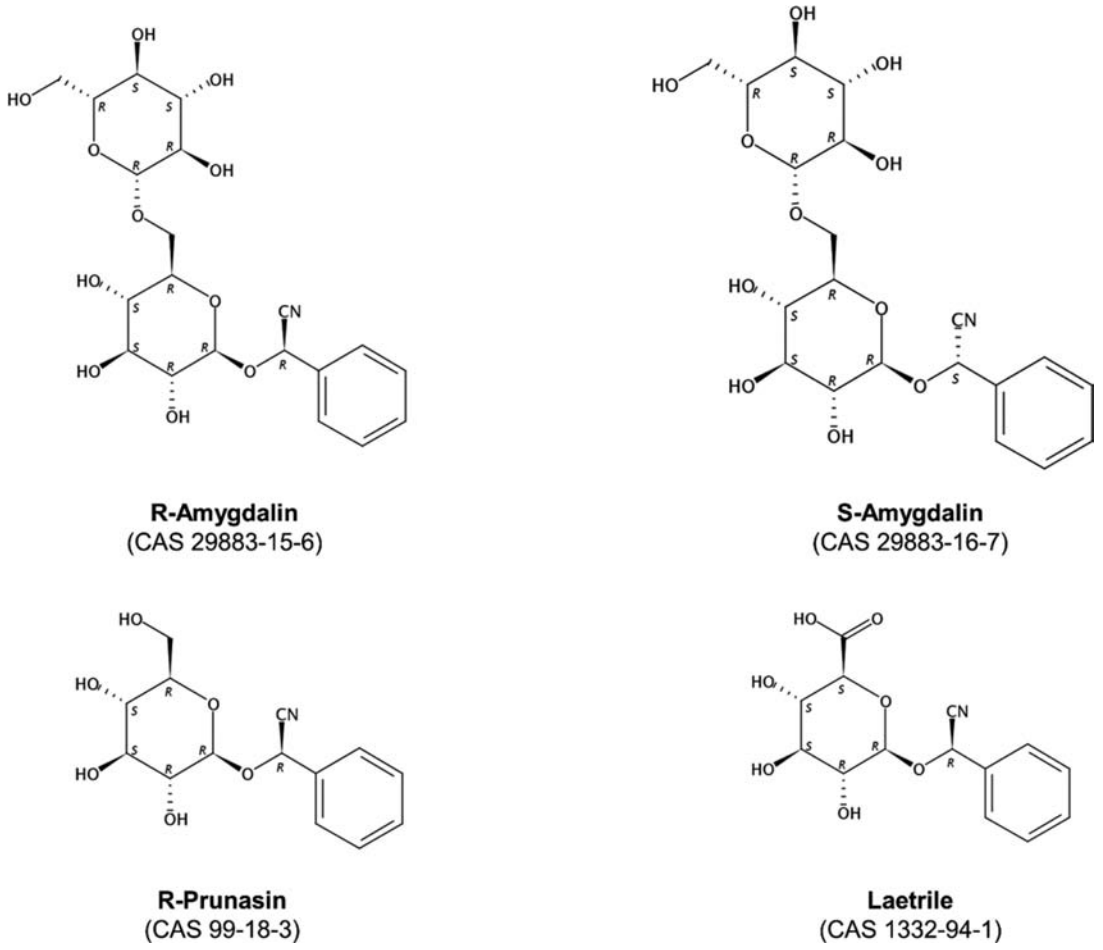

Figure 1. Chemical structures of amygdalin, D-mandelonitrile-β-D-gentiobioside with the *R*-configuration of the labeled carbon, and its *S*-amygdalin (neo-amygdalin) epimer or L-mandelonitrile- β-D-gentiobioside. Prunasin is the D-mandelonitrile-β-D-glucoside, and laetrile is the D-mandelonitrile-β-D-glucuronic acid.

chromatographic methods for the separation and quantification of amygdalin epimers, because the *R*- and *S*-configurations can have significantly different biochemical and physiological properties. Herein we outline the fastest and most reliable approaches for doing such analyses. Subsequently, the developed analytical approaches are used to evaluate the factors affecting amygdalin epimerization.

MATERIALS AND METHODS

Chemicals. Amygdalin, $C_{20}H_{27}NO_{11}$, mol wt 457.4, CAS Registry No. 29883-15-6, was obtained from Sigma-Aldrich (St. Louis, MO, USA) as ≥97% pure (BioXtra) and from Trappsol (from CTD Holdings, Shanghai DND Pharm-Technology Co. Inc., lot 20140103). Both were used as received. *S*-Amygdalin is not commercially available. It was formed by epimerization of *R*-amygdalin. We note that *Sigma-Aldrich also lists incorrectly the laetrile name as a synonym for amygdalin, whereas laetrile is a very different compound* as seen in Figure 1. Additionally, *Beilstein's Handbuch der Organischen Chemie* mentions that the dextro- and laevo- notations were interchangeably used for the naturally occurring amygdalin CAS Registry No. 29883-15-6.[2] Ten sealed ampules of commercial injectable amygdalin were purchased from www.cytopharma.com. The solutions are sold as "vitamin B17" in sealed amber glass ampules.

Methanol and acetonitrile were HPLC grade solvents obtained from Sigma-Aldrich. Ammonium hydroxide was a 29.5% w/v (about 17 M) solution from Fisher Scientific (Fair Lawn, NJ, USA). Water (18.2 MΩ) was produced by a Millipore Synergy 185 system (EMD, Billerica, MS, USA). The following glassware/vials were studied for epimerization of *R*-amygdalin: Wheaton 120 mL (catalog no. 225546, batch 1542790), Restek 20 mL vials (catalog no. 23082), VWR 8 dram glass vials (66011-165, lot 052A06), Supelco vials with a screw cap with septum (~23 mL), a 25 mL Chemglass round-bottom flask (19/22 standard taper) with a reflux condenser, and boiling glass pieces made by crushing 9″ Pasteur pipets (Fisher brand, catalog no. 13-678-6B). Two sets of glassware were studied, one as received, and the other set was soaked in KOH/2-propanol base bath, followed by detergent washing, rinsing with copious amounts of deionized water, and oven-drying before use. As an experimental control, a 250 mL high-density polyethylene bottle (HDPE) from Wheaton was used to boil amygdalin. Plastic syringes with stainless steel needles were used for transferring water and sampling.

Chromatographic Columns and Systems. The following 25 × 0.46 cm i.d. commercial columns packed with fully porous 5 μm particle size were obtained from Supelco (Bellefonte, PA, USA): Chirobiotic V, Cyclobond I 2000 RSP, and Cyclobond I 2000 HP-RSP. Porous graphitic carbon (Hypercarb, Thermo Scientific, 15 × 0.46 cm, 5 μm fully porous particle with 25 nm pore diameter and 170 m^2/g surface area) was a gift from Dionex, Thermo Scientific (Waltham, MA, USA). Additionally, hydroxypropyl-β-cyclodextrin was purchased from Sigma and bonded on 2.7 μm superficially porous silica particles with a surface area of 120 m^2/g and pore size of 120 Å according to a proprietary procedure. The particles were provided by Agilent Technologies (Wilmington, DE, USA). The core is 1.7 μm in diameter, and the surrounding shell thickness is 0.5 μm. The column was slurry packed into a 5 cm × 0.46 cm i.d. column. Two chromatographic systems from Agilent (Santa Clara, CA, USA) were used. The first one was a model Infinity 1260 Quaternary LC system

DOI: 10.1021/acs.jafc.5b03120
J. Agric. Food Chem. 2015, 63, 8966−8973

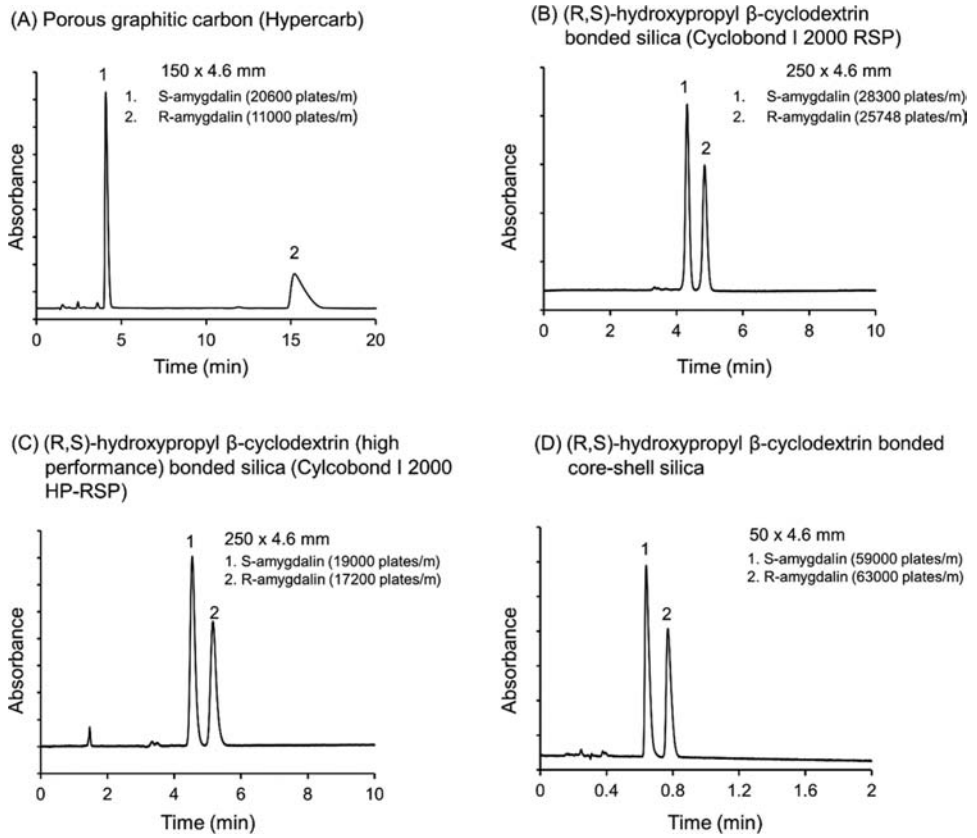

Figure 2. Amygdalin epimer LC analyses: (A) porous graphitic carbon column (15 × 0.46 cm i.d.) with 90:10 MeOH/H_2O at 1.5 mL/min; (B) Cylcobond I 2000 RSP (25 × 0.46 cm i.d.) with 20:80 MeOH/H_2O at 1.0 mL/min; (C) Cyclobond I 2000 HP-RSP (25 × 0.46 cm i.d.) with 30:70 MeOH/H_2O with 1.0 mL/min; (D) the same column chemistry as in (C) bonded on 2.7 μm core−shell particles packed in a 5 cm × 0.46 cm i.d. column 10:90 MeOH/H_2O at 1.8 mL/min. Detection wavelength = 254 nm. All analyses were done at ambient temperature.

with a gradient capable quaternary pump with a maximum pressure of 600 bar (8600 psi), an autosampler, a column oven, and a diode array detector. The second system was a model Infinity 1290 with an ultrahigh-pressure binary pump (UHPLC, maximum pressure of 1200 bar or 17000 psi) with an autosampler with an ultrafast diode array detector. The detector setting on UHPLC was 160 Hz and 0.016 s response time. Amygdalin absorbs at 220 and 254 nm. Both wavelengths can be used for detection. All separations were performed at ambient temperature.

An external calibration curve was constructed by making standards from 76 to 1525 ppm of *R*-amygdalin (Sigma, BioXtra ≥97% pure) in 0.1% aqueous acetic acid solution. The analysis was done in triplicate at 220 nm with an injection volume of 1 μL on a 5 cm × 0.46 cm core−shell hydroxypropyl-β-cylcodextrin column. The mobile phase was 90%H_2O/10% methanol at a flow rate of 1.8 mL/min. Thoroughly washed glass volumetric flasks were used. The curve was linear with a correlation coefficient R^2 value of 0.9995. We note that traces of *S*-amygdalin are present in commercial *R*-amygdalin. The commercial samples were diluted to bring their concentration within the range of the calibration curve.

Procedure for Amygdalin Epimerization. Two approaches were used in the epimerization studies. The first procedure is more efficient and faster (∼15 min), but introduces a very small amount of ammonia. This method was used for chromatographic method development for the separation of the *S*-isomer. For the "ammonia added method", 0.1 g of amygdalin was dissolved by sonication in deionized water (18.2 MΩ) in 10 mL of deionized water, and 10 μL of ACS certified concentrated ammonia (29%) was added via glass syringe. Within 15−20 min, all of the amygdalin epimerized to a ratio of 57% *S*-amygdalin and 43% *R*-amygdalin at room temperature. In the second method, where we show the glassware effect, 0.1 g/10 mL of amygdalin was heated on an oil bath in deionized water in thoroughly cleaned glassware for 60 min. An approximately 0.5 mL aliquot was drawn via stainless steel needle in a plastic syringe and transferred into a 1.8 mL amber VWR glass autosampler vial (catalog no. 82030-974).

RESULTS AND DISCUSSION

Amygdalin has 11 stereogenic centers, 10 of which are contained in the two glucopyranose moieties, and these are not easily isomerized. The remaining stereogenic center (i.e., the carbon atom with the phenyl and nitrile substituents) is susceptible to inversion, which can give rise to the formation of *S*-amygdalin. For extraction and analytical purposes, amygdalin is extracted in polar solvents including ethanol, methanol, ethyl acetate, and water, from seeds or kernels.[12] It was noted recently that polar solvents give low recoveries of amygdalin because of conversion of the natural isomer into the *S*-amygdalin, where 35% of natural amygdalin converted into the isomer upon 24 h of standing.[6] It is therefore critical to know the relative concentrations of the isomers in any study of or with these compounds. We also note that amygdalin starts to degrade even after boiling in pure water for a short period of time (∼1 h). To develop a reliable analytical method and produce *S*-amygdalin (for which there is no known commercial source), we used a small quantity of ammonia to produce the other epimer. This procedure is very efficient in promoting epimerization provided that optimal levels of ammonia are used (10 μL/10 mL). Using higher concentrations of bases can hydrolyze amygdalin into many side products including ammonia and mandelic acid, and often the cyano group is hydrated to the amide.[2,14] Existing separation methods relying

on C_{18} stationary phases or other enzymatic approaches have a very strong potential to miss the *S*-isomer, thereby producing misleading information about the actual quantification of the naturally occurring *R*-amygdalin.[4,6,9−13,15−18] As a result, it is not surprising that many recent publications on amygdalin analysis do not mention/identify the *S*-amygdalin, which is always present to some extent depending on the storage conditions, extraction solvents, and analytical procedures. Although in a few specific cases, using advanced instrumentation such as MS-MS that may allow differentiation of epimers,[19,20] ideally it is desired and usually necessary that the epimers are separated chromatographically. Thus, the separation of the natural and its unwanted isomerized amygdalin is best done chromatographically.

Analytical Scale Separation of *R*- and *S*-Amygdalin. Early on, the separation of amygdalin epimers was accomplished by gas chromatography (GC) of their trifluoroacetylated derivatives on a semipolar capillary column (versilube F-50, a trichlorophenyl polysiloxane GC stationary phase) in 25 min at 180 °C.[7] Later, capillary electrophoresis was used to separate the epimers in 15 min with good selectivity using a cyclodextrin chiral additive to the electrolyte.[21] However, in most studies, liquid chromatography (LC) seems to have been the method of choice with a C_{18} phase, which produces overlapping/shoulder peaks for *R*- and *S*-amygdalin.[6]

In Figure 2, we show the utility of the preferred stationary phases for amygdalin using simple MS friendly mobile phases in the isocratic mode ($MeOH/H_2O$ without any additives). A number of achiral and chiral phases such as porous graphitic carbon, vancomycin, teicoplanin, cyclodextrin-bonded silica, and hydroxypropyl-*β*-cyclodextrin columns were studied. Porous graphitic carbon (PGC) is a very hydrophobic phase made of sheets of graphitized carbon. The flat surface of carbon allows for excellent shape selectivity of adsorbed molecules and, therefore, the *S*- and *R*-isomers have exceptionally high selectivity, which is not seen in any silica-based column. Thus, PGC can be employed when an exceptionally wide separation window is desired between the isomers (such as in preparative work). In Figure 2A, it can be seen that the *S*-amygdalin elutes earlier than the *R*-isomer with an impressive resolution of 12. The peak shapes and efficiencies for the two isomers are very different, showing that naturally occurring *R*-amygdalin has a very strong interaction with the carbon surface (3100 vs 1650 plates for the *S*- and *R*-isomers, respectively). The previous study,[9] which utilized PGC for the separation of amygdalin for the first time and used a methanol/water mobile phase, did not observe the formation of *S*-isomer. Given the very large selectivity, it is easy to miss the formation of *S*-amygdalin during the extraction process from natural products, or any biochemical studies on porous graphitic carbon. In Figure 2B,C, the separation of amygdalin epimers is shown on (*R*,*S*)-hydroxypropyl-modified *β*-cyclodextrin chiral columns. The key difference between the two columns is the nature of bonding to the silica surface. In general, the Cyclobond-I 2000 HP-RSP separates by extended H-bonding capability, offers broad chiral selectivity for chiral screening, and is most beneficial for basic and neutral compounds. Both chiral columns are able to separate the amygdalin epimers with an isocratic methanol/water mobile phase with baseline resolution and narrow symmetrical peaks showing more than 25000 plates/m. The *S*-amygdalin eluted first on both columns. It is interesting to note that *S*-amygdalin also eluted earlier on the PGC despite being a very different material from silica. A similar chiral column Cyclobond I 2000 HP-RSP produced a complete epimer separation in 5 min with 19000 plates/m (Figure 2C) but with higher methanol concentration.

To speed the same analysis, a recently introduced core−shell (*R*,*S*)-hydroxypropyl-modified *β*-cyclodextrin[22] column of 5 cm length was tested with a modern UHPLC chromatographic system. It was able to fully separate the amygdalin epimers under 50 s (Figure 2D) needing only 1.8 mL of 10/90 v/v methanol/water mobile phase. The measured efficiency was as high as 60000 plates/m with a resolution factor >2. Again, amygdalin, with its *R*-mandelonitrile stereogenic center, eluted after the *S*-amygdalin epimer (Figure 1).

Factors Influencing Amygdalin Epimerization. The Cyclobond I 2000 RSP with a 20:80 v/v methanol/water mobile phase was used for all kinetic studies on amygdalin

Table 1. Epimerization Kinetics of Amygdalin in Different Glassware and Solvents

	expt with amygdalin	% *R*-amygdalin remaining[a] 10 min	30 min	60 min	comments and refs[b]
a	distilled water in glass at 100 °C	80.0	60.5	50.5	47% amygdalin remains intact after 2 h[24]
b	pure ethanol at 85 °C	negligible conversion			no conversion to *S*-amygdalin during 2 h of heating[24]
c	methanol/ethyl acetate azeotrope at 105 °C	100	100	100	no conversion to *S*-amygdalin during 2 h of heating[24]
d	distilled water in glass at 100 °C		66.6		45% amygdalin remains intact after 2 h minimum of boiling with a major unknown side product[29]
e	water + 0.05% citric acid at 100 °C		no conversion		negligible conversion to *S*-amygdalin in 2 h[29]
f	heating in dimethyl sulfoxide in glass		no conversion		the authors observed no conversion to the *S*-isomer (temperature and duration not mentioned)[27]
g	boiling water at in Pt vessel		no conversion		the authors observed no conversion to the *S*-isomer (boiling duration not mentioned)[27]
h	heating in deionized water in a VWR glass vial (as received)	44.5	39.7	35.0	ratio of *R*:*S* 47:53 after 1 h; oil bath temperature 109 °C
i	heating in deionized water in a washed VWR vial	93.0	68.3	55.2	ratio of *R*:*S* isomer 56:43 after 1 h; vial cleaned thoroughly before use
j	heating in deionized water in a Wheaton glass vial (as received)	43.3	41.9	35.0	ratio of *R*:*S* isomer 46:54 after 1 h; oil bath temperature 108 °C
k	heating in deionized water in a washed Wheaton glass vial	87.2	44.0	41.1	ratio of *R*:*S* isomer 46:53 after 1 h; oil bath temperature 106 °C
l	heating in deionized water Supelco glass vials (as received)	44.2	40.5	36.3	ratio of *R*:*S* isomer 47:53 after 1 h; oil bath temperature 108 °C
m	heating in deionized water in a washed Supelco glass vials	80.0	51.9	47.2	ratio of *R*:*S* isomer 49:51 after 1 h; oil bath temperature 108 °C
n	heating in deionized water in a Restek vial (as received)	51.9	41.6	40.6	ratio of *R*:*S* isomer 47:53 after 1 h; oil bath temperature 109 °C
o	heating in deionized water in a washed Restek glass vial	76.4	53.7	49.9	ratio of *R*:*S* isomer 52:48 after 1 h; oil bath temperature 109 °C
p	heating in high-density polyethylene (HDPE)	98.4	98.6	97.8	ratio *R*:*S* isomer 82:18 even after 3 h; oil bath at 110 °C

[a]The percentage of *R*-amygdalin remaining is expressed as chromatographic peak area as a function of time (note that in as-received glassware, side products form during boiling). [b]The ratio of *R*:*S* given in the column is expressed without regard for the minor side product that forms on boiling.

epimerization. Two early, very detailed, epimerization studies, which are more than four decades old, exist in the German literature.[23,24] The authors examined some of the factors influencing amygdalin epimerization such as (i) solvent, water, methanol, ethanol, ethyl acetate, and an azeotrope of methanol/ethyl acetate; (ii) temperature; and (iii) pH. The mandelonitrile stereogenic center changes configuration as indicated (Figure 1):

$$R\text{-amygdalin} \underset{k_S}{\overset{k_R}{\rightleftarrows}} S\text{-amygdalin} \tag{1}$$

$$\frac{[S]_{eq}}{[R]_{eq}} = \frac{k_R}{k_S} = K \tag{2}$$

Making measurements at different times in different conditions, Nahrstedt determined that the k_R and k_S kinetic rate constants were greatly affected by pH, solvent, and temperature but that the K thermodynamic equilibrium constant was little affected.[24] Similar observations have been made on the epimerization of lactose, where the equilibrium constant changed by only ∼10% in the temperature range of 25−49 °C.[25] This means that the epimerization equilibrium is reached more or less rapidly depending on the experimental conditions, but eventually produces a mixture of 43% *R*-amygdalin plus 57% *S*-amygdalin. This implies that, by nature, the *S*-isomer will predominate in a mixture.

Nahrstedt established that the amygdalin equilibrium constant was $K = 1.3$ with kinetic constants $k_R = 3.4 \times 10^{-4}$ s^{-1} and $k_S = 2.6 \times 10^{-4}$ s^{-1} in distilled boiling water.[24] Figure 3A shows the amygdalin epimerization data. Unfortunately, the details on water purification procedure, its storage, and glassware history were not provided in this work. In Figure 3B, we show a striking comparison when the glassware is thoroughly cleaned, deionized water (18.2 ΩM) is utilized, and there is minimum contact with other glassware. When amygdalin is heated in deionized water, the initial reaction rate is very slow (cf. Figure 3A), and after a certain period, it tends to proceed more rapidly. This reaction profile does not follow Nahrstedt's first-order kinetics in the beginning but eventually reaches the same equilibration ratio of products. We speculate that the water used by the author was perhaps distilled and stored in glass (which already contained enough "leachates" to accelerate the reaction). If the same *R*-amygdalin starting material solution is heated in the presence of glass pieces, made by crushing Pasteur pipets, the reaction proceeds more quickly with a >60 min difference in equilibration time. The glassware effect was tested using different heating methods in different flasks (direct heating on a mantle vs oil bath heating), and all produced general results; that is, initial conversion is slow and, after a certain period, the epimerization proceeds more rapidly.

We did an extensive study on the nature of the glassware (see Materials and Methods for glassware sources). Table 1 lists the epimerization amounts obtained in different conditions taken from the literature or obtained by our own experiments using the RPLC method with a cyclodextrin chiral stationary phase.[26] The first observation is that a protic solvent such as water is required for epimerization to occur; for instance, freeze-dried amygdalin samples were stable as were dimethyl sulfoxide solutions.[27] The epimerization is also negligible in ethanol at 65 °C; however, Nahrstedt noted that heating amygdalin in ethanol (95 °C oil bath temperature) also converted 14% of the *R*-amygdalin into the *S*-isomer. However, it was not clear whether the ethanol employed was anhydrous or not. In our

DOI: 10.1021/acs.jafc.5b03120
J. Agric. Food Chem. 2015, 63, 8966−8973

initial part of the experimental work, we noted that dry amygdalin remains stable with respect to epimerization.

With the availability of modern columns and instruments, it is now possible to revisit early epimerization studies. The most interesting aspect is that the nature of the container seems to have a significant effect on the epimerization of amygdalin. In Table 1, we show an extensive list of glassware (vials) that was tested for epimerization. It is likely that modern researchers will use vials/containers from one of these major manufacturers for storing/extracting amygdalin samples. *R*-Amygdalin was heated in pure deionized water to assess the glassware effect and evaluate the conversion amounts. Examination of Table 1 will show a trend in epimerization. First, if vials are used as received, the epimerization of *R*-amygdalin is very rapid (e.g., Wheaton/Restek/VWR/Supelco). All vials are considered clean for routine analytical work. However, after thorough washing of the vials in a base bath, detergent, hot water, and deionized water, the reaction rates become slower. Eventually, in most cases, the *S*-isomer dominates. One interesting observation in Table 1 is that epimerization is almost nonexistent after boiling a distilled water amygdalin solution in a platinum vessel. The authors used nuclear magnetic resonance (NMR) for their studies.[27] As seen in Table 1, boiling amygdalin in high-density polyethylene bottles does not promote epimerization like Pt vessels. Even after 3h of heating in plastic, 80% *R*-amygdalin remained intact this work. On the basis of the information included in Table 1, it is clear that glassware plays a role in the epimerization because Pt and plastic vessels significantly slow the epimerization process. It is likely that different forms of glassware leach soluble components in hot deionized water (e.g., silicates), which act as weak bases, thus promoting the epimerization of amygdalin.

Analysis of Commercial Amygdalin Samples. Commercial amygdalin is usually sold as "vitamin B17". One major vendor sells injectable solutions of amygdalin with a label D-mandelonitrile-β-D-glucosido-6-β-glucoside in amber glass vials. We directly injected the commercial amygdalin samples to see the chromatographic profile of the commercial sample on core–shell bonded (*R*,*S*)-hydroxypropyl β-cyclodextrin. Figure 4 shows the chromatograms of the ampule components. It is clear that the major components are indeed amygdalin and its isomer. In each injectable ampule, the *S*:*R* amygdalin ratio is 54:46, which is very close to the equilibrium value of 57:43 reported by Nahrsted and from our own observations.[24] It is interesting to note that the pH of the injectable solution is 6.1. At such a pH the epimerization rate is very slow.[24] We note an additional impurity, which appears to be a side product of amygdalin degradation (see Figure 4). The chromatographic fraction at 0.4 min was analyzed by ESI-mass spectrometry. The m/z ratio of the peaks is 498.25, which corresponds to the sodium adduct of the cyano group in amygdalin being replaced by the amide. Thus, the natural amygdalin being sold as injectable solution is contaminated by >50% of unnatural *S*-isomer and smaller amounts (~5%) of the amide formed by the hydration of the nitrile group in amygdalin.

The *R*-amygdalin content in "vitamin B17" was quantified using an external calibration curve. The typical concentration of *R*-amygdalin was found to be 87245 ppm with a relative standard deviation of 0.2%. The limit of detection, as calculated from 3 times the standard error in the intercept, was calculated to be 14.6 ppm. All amygdalin standards had to be prepared in ~0.1% acetic acid solution to prevent significant epimerization.

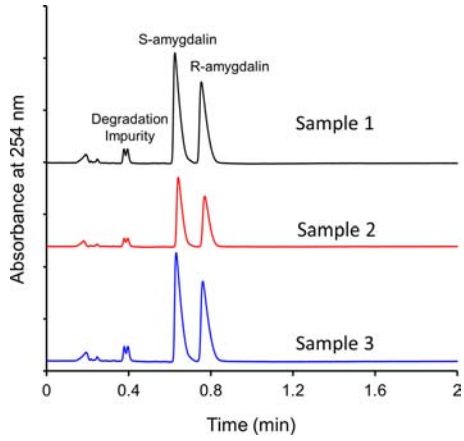

Figure 4. Ultrafast separation of commercial as-received injectable amygdalin solutions sold as vitamin B17 by a vendor. Chromatographic profiles of three separate vials are overlaid. Chromatographic conditions: 5 × 0.46 cm i.d. column containing 2.7 μm core–shell particles bonded with (*R*,*S*)-hydroxypropyl β-cyclodextrin; mobile phase, 10:90 MeOH/H_2O at 1.8 mL/min; injection volume, 0.03 μL; detection at 254 nm.

Standards prepared without acid epimerized by ~30% during the analysis.

Comments on Amygdalin Analysis and Storage. The important point when dealing with an amygdalin sample is to know the chemical nature of the compound considered. The naturally occurring amygdalin can convert into the undesired *S*-amygdalin during extraction, refluxing, and storage in various vials (all of which can be accelerated by pH, glass, and temperature). This trend is very clear in Table 1. Even worse, the amygdalin solution sold as an "alternative cure" to treat various illnesses is also sold in glass ampules. As stated earlier, most of the recent analytical methods have either neglected or missed the signal from *S*-amygdalin from the C_{18} columns. Although C_{18} or reversed phase cyano columns can practically separate the isomers as shown in the published results,[7,14] depending on the conditions, more recent studies do not seem to mention or notice the formation of the *S*-amygdalin.[4,10−12,15,16,18] Additionally, amygdalin is easily hydrolyzed by acids and bases. To reduce amygdalin hydrolysis by the digestive track, injectable solutions were sold (in alternative medicine, no FDA approval) in physiological solution and glass vials.[28] Depending on the nature of the glass making the vial, the storage time, and conservation temperature, it is most likely that epimerization changes the amygdalin content of such vials to 43% of the nominal label concentration with 57% of this concentration being *S*-amygdalin. Because both epimers can potentially release hydrogen cyanide, both are toxic.

In a recently published work, the ELISA method was proposed for amygdalin analysis. The problem is that the hapten–protein conjugate, needed to trigger the antibody formation by rabbits, was prepared in glassware at pH 9.4 using a carbonate–bicarbonate buffer for >6 h.[11] To see the effect of carbonate–bicarbonate buffer on amygdalin, we tested amygdalin epimerization in the same system at room temperature in a HPLC vial (which is certified to be clean from VWR, and at room temperature epimerization was negligible). The amygdalin–carbonate bicarbonate system was sampled after 10 min. Starting from 97% *R*-isomer, in just 30 min, 88% of the *R*-isomer remained. Within 2 h, only 68% of the *R*-amygdalin remained. After 3 h, 60% *R*-amygdalin

DOI: 10.1021/acs.jafc.5b03120
J. Agric. Food Chem. 2015, 63, 8966−8973

remained, and the rest was converted into the *S*-isomer. Note that this isomerization is slower as compared to the ammonia method (complete epimerization is within 20 min). Hence, the ELISA-reported results are likely the global epimer concentration fitting the simultaneous HPLC analyses obtained with an achiral C_{18} column that was perhaps unable to separate the epimers and therefore gave a combined peak for the two forms.[11]

Amygdalin tablets and pills are still proposed commercially today as a natural dietary supplement under the wrong name of laetrile or the questionable name of "vitamin B17". There are scientifically unsupported blog comments suggesting health benefits and possible cancer remissions.[28] Dry products may contain pure amygdalin found in apricot seeds; however, vials of liquids (for intravenous injection) upon long-standing contain only 43% amygdalin and 57% of its epimerized form. Considering that 1 g of amygdalin can release 59 mg of HCN and that the lethal dose for human cyanide poisoning is about 2.5 mg/kg body weight, six tablets containing 500 mg of amygdalin each could theoretically kill an adult if the molecule is completely hydrolyzed, releasing 180 mg of HCN. Children have been reported to have been subjected to such poisoning.[17] From an analytical point of view, it is important to know that the epimerization of amygdalin can be fast in aqueous solutions depending on the temperature and pH. Furthermore, the containers of amygdalin aqueous solutions can accelerate epimerization as seen in Figure 4.

Because the separation of the two epimers is rapid and selective when cyclodextrin chiral columns or porous graphitic carbon columns are used in liquid chromatography, these approaches are recommended for all such assays. We suggest better practices for amygdalin storage. If glassware is being used for extraction, it should be thoroughly washed (as detailed under Materials and Methods) before use. Ideally, solution or extracts of amygdalin should be stored in inert containers such as high-density polyethylene (HDPE) and the solutions should be mildly acidic (e.g., 0.1% acetic acid). Some authors recommend using citric acid/ascorbic acid to prevent epimerization for long-term storage of amygdalin solutions.[29] We also suggest that the amygdalin solutions be refrigerated to slow the kinetics of epimerization. We also note that dry amygdalin is sold and stable in glass containers with respect to epimerization.

In this work, our aim was to set good guidelines for the analysis of amygdalin and potentially other molecules, which can easily epimerize during storage. In the case of amygdalin, the importance of using chromatographic columns with different selectivity than a typical C_{18} column is essential when a given analyte can epimerize easily during storage. Using the same unique selectivity columns on superficially porous particles, the analysis time can be reduced to sub-minute separations for the first time. We showed an important result that the epimerization of amygdalin is heavily glassware dependent; its treatment history and even "clean" vials from various vendors can show drastically different reaction rates of the conversion to the optical isomer (*S*-amygdalin). We explicitly show that even clean *as-received* glassware from various vendors can also significantly alter the rate of epimerization reactions.

MATERIALS AND METHODS

General Experimental Instruments and Procedures. ^{1}H and ^{13}C NMR spectra were performed on a Bruker AM-400BB instrument (Bruker, Karlsruhe, Germany) with TMS as internal standard, operating at 400 and 100 MHz, respectively. EI-MS was measured with a VG ZAB-HS instrument (VG, East Sussex, UK), and ESI-ION trap was measured with an Esquire 6000 instrument (Bruker Daltonics, Billerica, MA, USA). Column chromatography (CC) used Sephadex LH-20 (25−100 mm) (Pharmacia Fine Chemical Co., Ltd., Berlin, Germany), silica gel 60 RP-18 (230−400 mesh) (Merck, Rahway, NJ, USA), and silica gel (200−300 mesh) (Qingdao Haiyang Chemical Co., Ltd., Qingdao, China). TLC was performed on precoated silica gel 60 F254 plates (Qingdao Haiyang Chemical Co., Ltd.), and spots were detected by ultraviolet (UV) illumination and sprayed with 5% H_2SO_4 in C_2H_5OH (v/v).

HPLC Analysis. The HPLC analysis was carried out on a HP1100 system (Agilent, Santa Clara, CA, USA) with a model G1315D diode array, and the column used was a 150 mm × 4.6 mm, 5 μm, GraceSmart Rp C18 (Grace Corp., Deerfield, IL, USA). The solvent of methanol for HPLC analysis was of HPLC gradient grade (Anhui Fulltime Co., Ltd., Hefei, China). Compounds were monitored at 211 and 254 nm, and UV spectra were recorded between 200 and 400 nm. The mobile phase, which was composed of methanol (A) and water (B), was programmed as follows: 0−30 min, A 80%. The flow rate with an injection volume of 20 μL was 0.8 mL/min at a column temperature of 35 °C.

Plant Material. The plants were collected from Mengtong of Shandong province, China, in 2014. The tobacco seeds are of Zhongyan 100 and were kindly provided by Tobacco Research Institute of Chinese Academy of Agricultural Sciences (CAAS). The seeds of *L. sativa* were purchased from a seed company in Shandong.

Soil Sample. Soil samples surrounding the root of flue-cured tobacco were collected from Mengtong (the same location where flue-cured tobacco was collected) of Shandong province, China, in 2014. Five different soil samples were collected about 15 cm deep around the root of flue-cured tobacco. The collected samples were dried in the dark at room temperature and then stored at 4 °C until they were extracted and analyzed. Soil samples were crushed and then passed through a 1 mm screen sieve to remove root contaminants, with visible root fibers picked out by hand. A sieved sample (100 g) was extracted ultrasonically with methanol three times (30 min each). The filtrate was concentrated in a vacuum to near dryness on a rotary evaporator. Then, the dry residue from the evaporation was redissolved in 100% MeOH and passed through a 0.45 μm nylon membrane filter prior to HPLC analysis.

Extraction and Isolation of Allelochemicals from Rhizosphere Soils. The tobacco plants were carefully uprooted, and clump soil was shaken off. The roots with rhizosphere soil were quickly washed in a container with distilled water, and 10 L of filtrate was collected. After clarification filtration, the resultant filtrate was adsorbed by macroporous adsorptive resin (XAD-4), eluting with ethanol. Then the desorbed solution was concentrated in a vacuum to near dryness on a rotary evaporator, yielding the exudates (1.8 g).

The exudates was submitted to silica gel CC (25 × 125 cm) with chloroform/EtOAc [1:0 (2 L), 10:1 (3 L), 5:1 (2.5 L), 2:1 (3 L), 1:1 (1 L), 0:1 (2 L)]−methanol to give fractions A−F by means of TLC analysis. Fractions A, D, and E showed significant inhibitory activities in the bioassays against lettuce seedlings. Fraction A was separated by Sephadex LH-20 column (2.5 × 160 cm, 20 mg) (1:1 $CHCl_3$/CH_3OH), then passed through silica gel CC (1.2 × 60 cm, 10 mg), and eluted with petroleum/acetone (60:1, v/v) to produce compound **3**. Fraction D was separated by Sephadex LH-20 column (2.5 × 160 cm, 20 mg) (1:1, $CHCl_3$/CH_3OH) to produce compound **4**, then passed through silica gel CC (1.2 × 60 cm,10 mg), and eluted with petroleum/EtOAc (3:1, v/v) to produce compounds **2** and **5**. Fraction E was separated by Sephadex LH-20 column (2.5 × 160 cm, 10 mg) (1:1 $CHCl_3$/CH_3OH), then passed through silica gel CC (1.2 × 60 cm, 10 mg), and eluted with petroleum/EtOAc (3:1, v/v) to produce compound **1**.

Bioassays. Inhibitory activities on the growth of tobacco and *L. sativa* seedlings were evaluated using the plate-culture method. The seeds of tobacco and *L. sativa* were soaked in 10% hypochlorite for 7 min, washed five times by distilled sterile water, and then germinated on filter paper with a photoperiod condition of 16/8 h day/night at 22 °C for 7 and 3 days, respectively. Then, the tested seedlings were transferred to 6-well plates (VWR Scientific, Inc., Shanghai, China), and the extracts of tobacco rhizospheric soil chemicals isolated were diluted with dimethyl sulfoxide (DMSO) with aliquots (10 μL) added to each of the treated wells (10 μL of DMSO was added as control). Then, the plants were incubated in a constant-temperature humidity chamber at 22 °C, under a 16 h light/8 h dark photoperiod (*L. sativa* seeds for 3 days, tobacco seeds for 7 days). The extracts of tobacco rhizospheric soil were prepared at final concentrations of 400, 200, and 100 μg/mL, and compounds **1**−**6** were prepared for 200, 100, 50, and 25 μg/mL. Three replicates were performed per treatment. The root length and stem length were measured at the end of the experiment. Inhibitory ratios (%) were determined by the formula [(control length − plant length treated)/control length] × 100.

Statistical Analysis. All data were subject to an analysis of variance using SPSS Statistics 18. Each value was expressed as the mean ± standard error (SE). The significant differences in seedling growth between the treatments and control were calculated using a one-way analysis of variance (ANOVA) followed by a Fisher's least significant difference (LSD) test.

Identification and Quantitation of Allelochemicals in the Soil. Identifications of the compounds in the soil of flue-cured tobacco were completed by comparing the retention times to the standards of compounds **1**−**3**. The quantitation of compound **1** in the soil was also done. The standard curves were performed using the linear regression method, and peak areas at 210 nm were plotted versus concentrations. The regression equation of compound **1** was $y = 14780525x + 58587$ ($r^2 = 0.9989$).

RESULTS

Isolation of Phytotoxic Chemicals from Rhizosphere Soil of Flue-Cured Tobacco. The isolation of compounds from rhizosphere soil of flue-cured tobacco was conducted by a bioassay-directed fractionation approach. The results showed that the crude root exudates from the rhizosphere soil of flue-cured tobacco had significant inhibitory effects on seedling growth of tobacco and *L. sativa* (Figure 1), indicating that there are potential inhibitors in the extracts of rhizosphere soil that affect the growth of tobacco plants themselves and other plant seedlings. The allelopathic effects of rhizosphere soil extracts

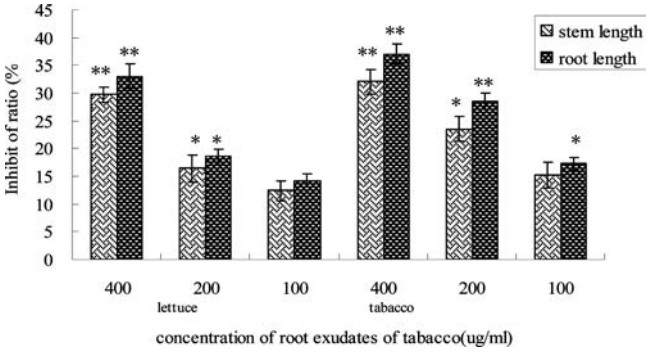

Figure 1. Phytotoxic effects of flue-cured tobacco root exudates against lettuce and tobacco seedlings at concentrations of 100, 200, and 400 μg/mL, respectively. Values are presented as a percentage of the mean compared to the control. Means significantly lower than the DMSO controls are indicated with one asterisk (*) (Dunnett's one-sided *t* test; $p < 0.05$) or two asterisks (**) ($p < 0.01$). Error bars are one standard error of the mean. $N = 3$.

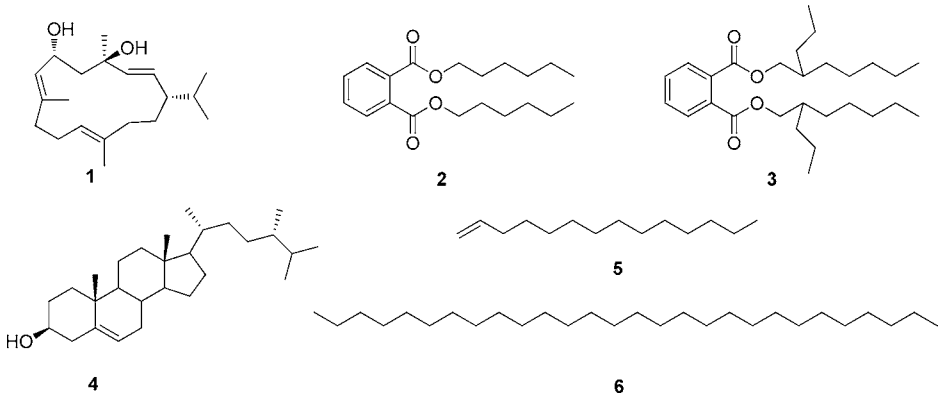

Figure 2. Structures of the compounds isolated from rhizosphere soil of flue-cured tobacco.

showed dose-dependent alterations. This was in accordance with previous studies.[18] It was also found that the extracts showed a stronger inhibitory effect on tobacco than *L. sativa* and implied remarkable autotoxicity.

Six compounds (Figure 2), including *β*-cembrenediol (**1**),[21] di-*n*-hexyl phthalate (**2**),[22] bis(2-propylheptyl) phthalate (**3**),[23] ergosta-5-en-3-ol (**4**),[24] 1-tetradecene (**5**),[25] and octacosane (**6**),[26] were isolated from rhizosphere soil and characterized by spectroscopic methods.

Phytotoxic Activities of the Purified Compounds on *L. sativa* Seedlings. The bioassay technique is commonly used to identify whether isolated compounds have allelopathic behavior. Compounds **1**–**6**, isolated and purified from the rhizosphere soil of flue-cured tobacco, were evaluated for phytotoxic activities against the seedling growth of *L. sativa*. Results indicated that compounds **1**, **2**, and **3** decreased the growth of the tested seedlings at different degrees, and the inhibitory effects of the three compounds showed dose-dependent alterations, whereas compounds **4**, **5**, and **6** had only a slight inhibitory activity (Figure 3). Compound **1** showed a significantly stronger inhibitory activity than the other two compounds at higher concentrations (≤100 μg/mL). Compounds **2** and **3** showed weaker activity than that of compound **1** at low concentrations (≤50 μg/mL), whereas all three compounds were much more effective at high concentrations (≥100 μg/mL). At higher concentrations, the inhibitory effects on the root growth of *L. sativa* are more significant than those on stem length. The root length of *L. sativa* seedlings treated with compound **1** at 200 μg/mL was reduced by 88.09% compared to the control, the seedlings showed wilting symptoms, and the roots turned yellow. Compound **1** arrested the growth of the treated plants at higher concentrations, but did not kill them.

Identification of Allelochemicals in Soil Samples. To achieve verification of the allelochemicals released from the flue-cured tobacco plant into soil during its growth, HPLC was used to confirm the existence of the allelochemicals in the zone soil by comparing their retention times with those of the standards of compounds **1**–**3** (Figure 4). With comparison to the chromatogram of the rhizosphere soil, compounds **1**, **2**, and **3** appeared in the chromatogram of soil samples. It was then verified that compounds **1**, **2**, and **3** should be released into the soil environment and act as allelochemicals by the plant in the course of its growth and development.

The standard curves were obtained by use of the linear regression method, and peak areas at 210 nm were plotted to

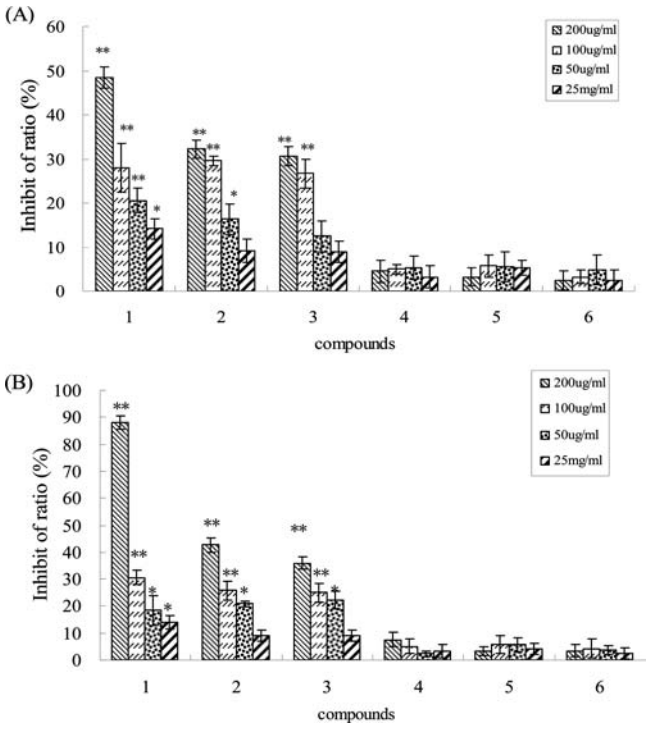

Figure 3. Phytotoxic effects of compounds **1**–**6** on lettuce seedling stem length (A) and root length (B) at concentrations of 25, 50, 100, and 200 μg/mL, respectively. Values are presented as a percentage of the mean compared to the control. Means significantly lower than the DMSO controls are indicated with one asterisk (*) (Dunnett's one-sided *t* test; $p < 0.05$) or two asterisks (**) ($p < 0.01$). Error bars are one standard error of the mean. $N = 3$.

calculate concentrations; thus, the concentration of compound **1** in the soil was determined as 2.23 μg/g.

Autotoxicity of the Allelochemicals on Flue-Cured Tobacco Seedlings. Results showed that compounds **1**, **2**, and **3** isolated as the allelochemicals of flue-cured tobacco had remarkable phytotoxicity against tobacco seedlings (Table 1). When tobacco seedlings were treated with compounds **1** and **2** at 200 μg/mL, their root and stem lengths were significantly reduced by 60.26 and 42.31% and by 45.45 and 39.80%, respectively. This indicated that tobacco can release some organic compounds into the surrounding environment with autotoxic allelopathy to the plant itself.

Allelochemicals are low-molecular-weight compounds released from living or decomposed plant tissues during growth.

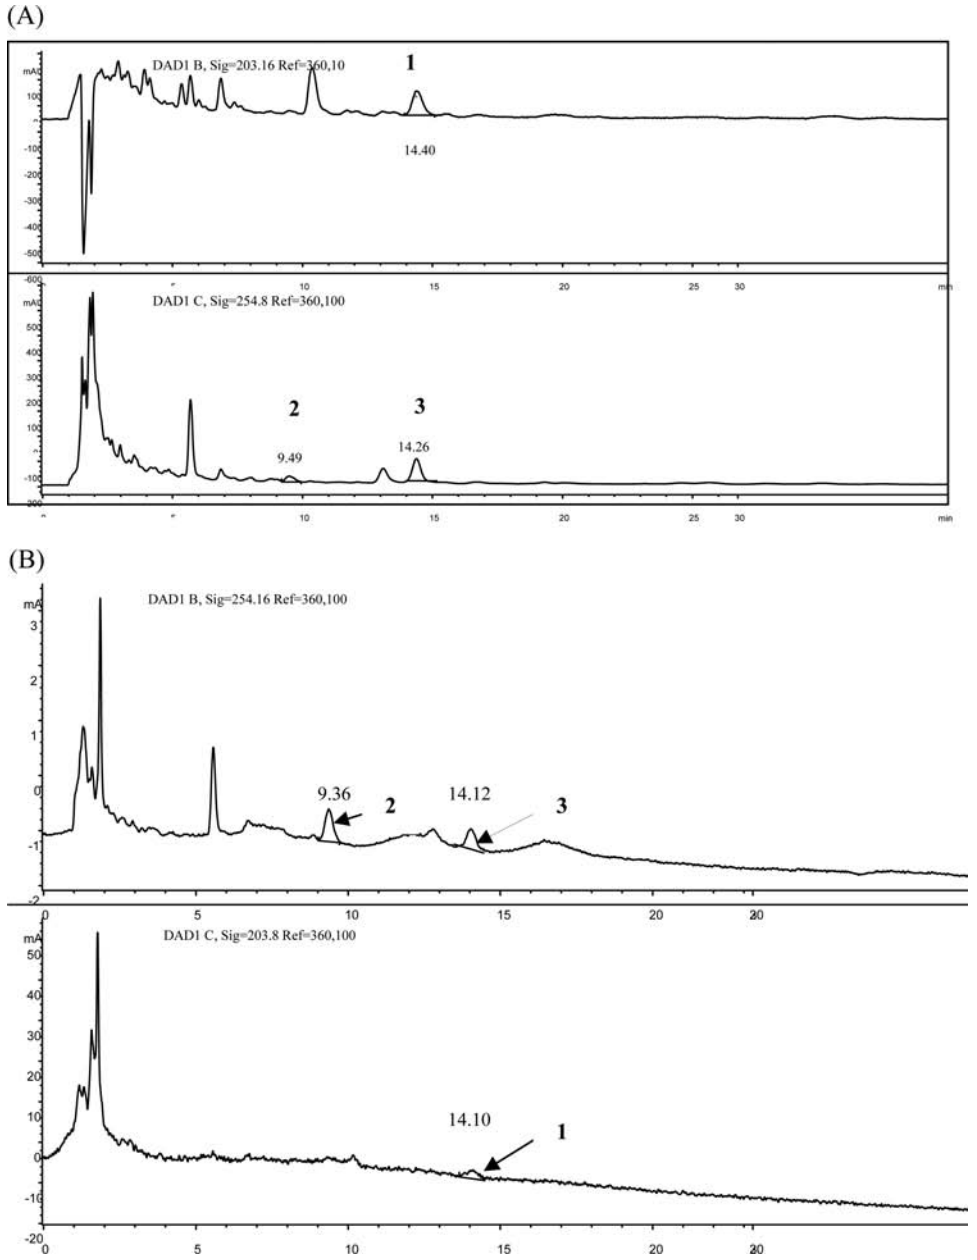

Figure 4. HPLC analysis of the rhizosphere soil and zone soil of flue-cured tobacco. (A) Compounds **1**, **2**, and **3** were confirmed in the HPLC chromatogram of the rhizosphere soil and had LC retention times of 14.40, 9.49, and 14.26 min, respectively. (B) Compounds **1**, and **2**, and **3** are shown in the HPLC chromatogram of the zone soil and had LC retention times of 14.10, 9.36, and 14.10 min, respectively.

Many plants could produce various allelochemicals such as phenols, terpenoids, and alkaloids and inhibit the growth of others. Compound **1** belongs to the terpenoids, which are the second type of allelochemicals, mostly released through volatilization and root exudation into soil to influence the growth of neighboring plant or themselves. Compound **1** is an important surface exudate of tobacco leaf, which had been reported to exhibit various activities, such as antifungal activity[27,28] and insecticide activity,[29] and might be leached into the soil, so that it is detected in soil samples. Compounds **2** and **3** are phthalate derivatives, which had been detected in root exudates of many crops and inhibit germination and seedling growth.[30,31] A prior study had found that esters and terpenoids have strong allelopathic potential in low concentration.[32] These two types of allelochemicals might be released into the soil environment through root and/or leaf exudates by flue-cured tobacco. It had been found that some of the terpenoids and esters secreted from plants exhibit strong allelopathic potential at low concentrations.[33] Our results are in good accordance with the reports in the literature, but the isolation and determination of these two types of allelochemicals of flue-cured tobacco are reported for the first time.

Autotoxicity, which is defined as a deleterious allelopathic effect among individuals of the same species, has been documented in various crops.[34,35] Autotoxicities in eggplant and peanut had been reported as one possible factor that contributes to replant failure.[36,37] Tobacco synthesizes various secondary metabolites during its growth and development; it is known that the natural products are one of the most important factors to evaluate the qualities of tobacco leaf and cigarette. The culture of flue-cured tobacco has often been hampered by replant failure exhibiting autotoxic effects on the seedlings of

this plant itself. It is considered that the homogeneity of both allelochemical and chemical compositions of tobacco accumulated in the soil environment is the major reason for allelopathic autotoxicity in the continuous cropping systems, but the specific allelochemicals released into the soil environment responsible for the autotoxic allelopathy have not been clarified until now. In this study, compounds **1**−**3** isolated from the root exudates of flue-cured tobacco showed observably phytotoxic activities against *L. sativa* and tobacco plant itself. With the results of bioassay and verification in the root zone soil by HPLC, the three compounds were determined as allelochemicals released into the soil environment by flue-cured tobacco and inhibiting its own growth. The results suggest that flue-cured tobacco exploits allelopathy as one main factor in replant failure. It is interesting to note that compound **1** has a strong inhibitory effect on *L. sativa* as well, and the treated *Lactuca* seedlings showed wilting symptoms at a concentration of 200 μg/mL. Even though the potential mechanism of action needs further study to be elucidated, our findings suggest that the high levels of compound **1** in tobacco may be utilized in many applications.

S. bicolor were obtained from LG Sementes (Goianésia, GO, Brazil), and seeds of *L. sativa* from Feltrin Sementes (Farroupilhas, RS, Brazil).

Plant Material Samples. Leaves of *P. amboinicus* were collected during the morning in Alegre (ES, Brazil). The exsiccation (n. 21590) was deposited in the herbarium (VIES) at the Federal University of Espírito Santo (UFES). Plants were classified by the botanist A.C. Tuler.

Essential Oil. Essential oil was extracted using 500 g of fresh leaves from *P. amboinicus*, cut into small pieces and placed in a round-bottom 5 L flask coupled to a Clevenger (modified). The flask was half filled with distilled water, and hydrodistillation was performed for 3 h after the water was boiled. During this time, the hydrolate (150 mL) was collected and subsequently subjected to liquid−liquid extraction using pentane (3 × 40 mL). The organic phase was dried with anhydrous sodium sulfate and filtered. The filtrate was concentrated under reduced pressure in a rotatory evaporator to obtain the essential oil.

To determine the composition of the *P. amboinicus* essential oil, gas chromatography coupled to mass spectrometry (GC-MS) was used. A capillary column of fused silica Rtx-5MS (30 m long, 0.25 mm internal diameter) was used with helium as the carrier gas. The temperatures were 220 °C for the injector and 300 °C for the detector. The initial column temperature was 60 °C, programmed for an increase of 3 °C per minute until reaching the maximum temperature of 240 °C. To determine the chemical constituents of the *P. amboinicus* essential oil, the obtained mass spectra was compared with reference data from the equipment database, using data from other sources and the Kovats index (KI).[15] To determine the KI, a mixture of linear alkanes (C_9 and C_{26}) was injected into the chromatograph, under the same conditions used in the referenced essential oil analysis. Retention indices (KI) were calculated using eq 1.

$$KI = 100Z + \frac{100[(\log t'_R X) - (\log t'_R Z)]}{(\log t'_R Z + 1) - (\log t'_R Z)} \quad (1)$$

where X is the analyzed compound, Z the number of carbon atoms of the hydrocarbon with retention time immediately preceding the retention time of X, $t'_R X$ the adjusted retention time of X, $t'_R Z$ the adjusted retention time of Z, and $t'_R Z + 1$ the adjusted retention time of the hydrocarbon with retention time immediately preceding the retention time of X.

For component quantification, *P. amboinicus* essential oil was analyzed on a gas chromatograph equipped with a flame ionization detector. The stationary phase was the capillary column Rtx-5MS (30 m long and 0.25 mm internal diameter). Nitrogen was used as carrier gas. Temperature programming was the same as previously reported for GC-MS analysis. The temperatures of the injector and the detector were 240 and 250 °C, respectively. A 10 mg sample of essential oil was diluted in 1 mL of dichloromethane, and 1 μL of the mixture was injected.[16]

Biological Assay. To perform the biological tests, solutions of essential oil from *P. amboinicus* leaves were prepared in dichloromethane at the concentrations of 0% (dichloromethane), 0.015%, 0.030%, 0.060%, and 0.120% (w v^{-1}). The compounds carvacrol and thymol were applied at the same concentrations as the essential oil. The herbicides glyphosate and boral were used as positive controls. Seeds of *Sorghum bicolor* (monocot) and of *L. sativa* (dicot) were used as plant models. For the germination tests, 2 mL of each solution were added to Petri dishes with 9 cm diameter containing filter paper. Twenty-five seeds of *S. bicolor* and of *L. sativa* were used for each treatment, with five repetitions. The dishes were sealed with plastic foil and placed in the germination chamber (BOD) at 24 ± 2 °C, where they were kept for the duration of the experiment.

Phytotoxicity. The number of germinated seeds was evaluated from 8 to 48 h, at 8 h intervals. The germination speed index (GSI) was obtained according to the formula:

$$(N_1)\cdot 1 + (N_2 - N_1)\cdot 1/2 + (N_3 - N_2)\cdot 1/3 + \ldots(N_y - (N_{y-1}))\cdot 1/y$$

where N_y represents the number of seeds germinated in a given period and y represents the total number of time intervals. The percentage of

DOI: 10.1021/acs.jafc.5b03049
J. Agric. Food Chem. 2015, 63, 8981−8990

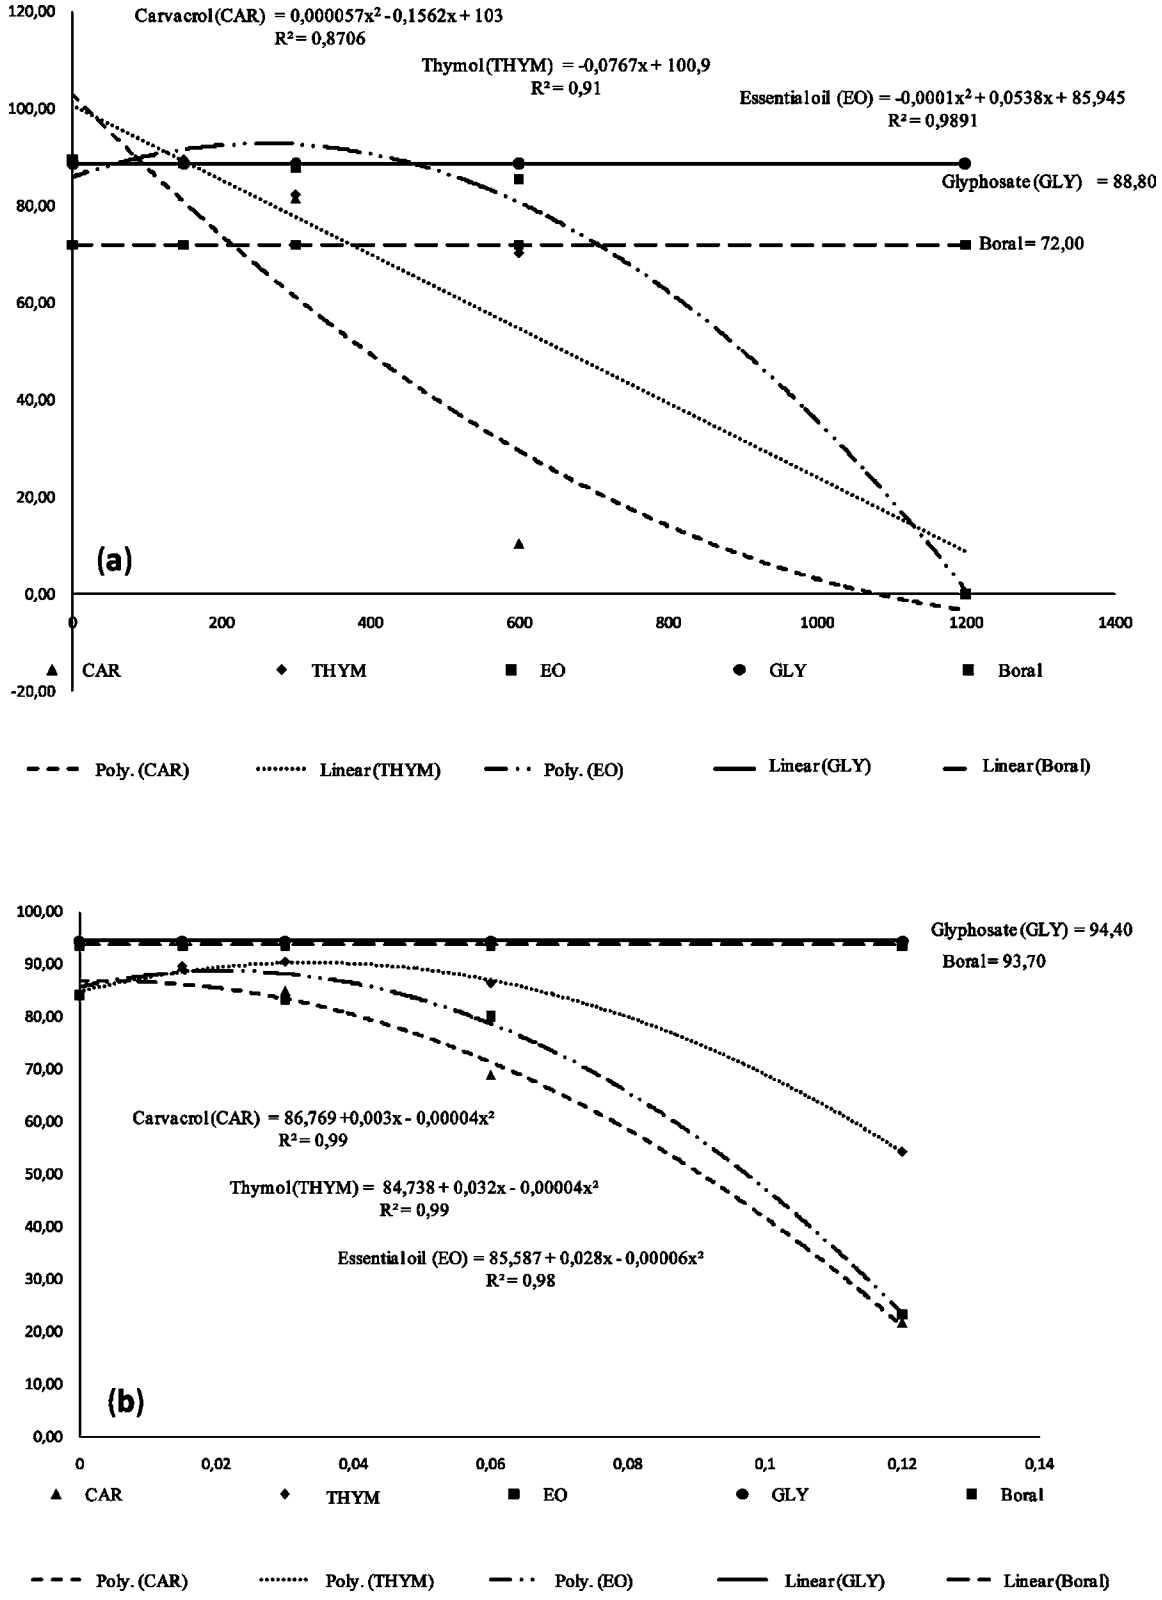

Figure 1. Graphs of GR (percentage of germination) for *L. sativa* (a) and *S. bicolor* (b) treated with solutions of *P. amboinicus* essential oil, thymol, and carvacrol.

germinated seeds (GR) and the root length (RL) were obtained after 48 h. The aerial parts of the plantlets were measured after 120 h to determine the aerial growth (AG). All measurements were taken with a digital caliper.

Cytotoxicity. After 48 h of exposure, 10 roots from each dish were collected and fixed in an ethanol: acetic acid solution (3:1/v v^{-1}), and stored at −4 °C for at least 24 h. For cytogenetic analysis, the slides were prepared using the squash technique and stained with 2% acetic orcein.[3] Approximately 5000 meristematic cells were evaluated per treatment, observing and quantifying the different stages of mitotic division. The mitotic index (MI) was obtained by dividing the number of cells in the process of division (prophase, metaphase, anaphase, and telophase) by

the total number of cells evaluated in each treatment. The frequencies of chromosome and nuclear alterations were calculated by dividing the number of alterations (chromosomal or nuclear, respectively) by the total number of cells analyzed.[17]

Statistical Analysis. The experiment was done in a completely randomized design (CRD) using a 3 × 5 + 2 factorial scheme with 3 treatments (carvacrol, thymol, and essential oil), 5 concentrations (0.120%, 0.060%, 0.030%, 0.015% w v^{-1} and 0%), and 2 additional treatments (boral and glyphosate). When significant, the obtained cytotoxicity data were subjected to analysis of variance, and the means were compared by the Dunnett's test at 5% significance. The phytotoxicity data when significant were the quantitative factors (concentrations of

DOI: 10.1021/acs.jafc.5b03049

the solutions used) applied to analysis of regression, with the models to be chosen based on the significance of the regression coefficients, using Student's t test at 5% probability and the coefficient of determination (R^2). For the significant qualitative factors related to the "solutions" variables, Dunnett's test was used at 5% significance to compare the treatments. For statistical analysis of qualitative factors (Dunnett, 5% significance) used the Genes program,[18] and quantitative factors (regression) used the Sisvar program.[19]

RESULTS AND DISCUSSION

Essential Oil. The yield of essential oil from the leaves of *P. amboinicus* was 0.12% (w w^{-1}) compared to plant dry mass. Bandeira et al. found a 0.43% essential oil content in the leaves of this species.[20] Four compounds were identified in the essential oil (Table 1). Two chemotypes have been reported for this species, one rich in thymol and the other in carvacrol. Here, carvacrol was found to be the main constituent (88.61%). These compounds are isomers and belong to the class of aromatic monoterpenes.[12]

Carvacrol was also identified as the main constituent (77.16%) in the essential oil of *P. amboinicus* leaves by Joshi et al., while Oliveira et al. found thymol to be the main component of this oil (75.54%).[21,22]

Genetic factors are responsible for determining the chemical composition of essential oils. However, other factors may also generate changes in secondary metabolite production.[23] Biotic and abiotic factors may interfere with the quality and quantity of the secondary products resulting from the plant metabolism at a given time. The main biotic factors are plant−microorganism, plant−insect, and plant−plant interactions, as well as age and development stage. Abiotic factors include luminosity, temperature, rainfall, nutrition, season and time of collection, and harvest and postharvest techniques. These factors may present correlations among themselves and do not act in isolation. In a study with *Acorus calamus* L., Kumari et al. observed that the addition of UV−B complementary indices caused a significant carvacrol increase in the plant's essential oil composition.[24]

Biological Assay. *Plectranthus amboinicus* essential oil and its chemotypes in pure form, thymol and carvacrol, in dichloromethane solution at concentrations of 0.120%, 0.060%, 0.030%, and 0.015% (w v^{-1}) and the negative control (0.000%) were tested with respect to germination and growth of *L. sativa* root (dicot) and *S. bicolor* (monocots). In all treatments, the solutions with higher concentrations had the most significant effects in the referenced tests.

The data regarding GR (percentage of germination) and GSI (germination speed index) for *L. sativa* and *S. bicolor* are described in Table 2. For all the different solutions tested in *L. sativa* at the concentration of 0.120%, the values of GR presented a significant difference compared to the positive controls (Figure 1a). The solution of carvacrol at 0.060% presented a significant difference compared to the positive controls. For GSI, only the thymol and carvacrol solutions at 0.015% did not differ from the negative control treatment (0.000%), while the essential oil presented differences at all tested concentrations. This way, germination was retarded but did not cease (Figure 2a).

The GR values for *S. bicolor* in all treatments at the concentrations of 0.120% and 0.060% were lower than the negative control, although germination occurred in all tests (Figure 1b). The GSI data for all treatments at all concentrations were different from the positive and negative controls, with only the *P. amboinicus* essential oil at 0.015% not differing from the boral herbicide (Figure 2b).

The allelopathic effects may be less intense on the final germination percentage and more intense on the germination speed, as shown by Oliveira et al. when considering the allelopathic potential of aqueous extracts from mulungu bark (*Erythrina velutina* Willd. − Leguminosae) on *L. sativa*.[25]

The results obtained referring to germination and GSI can be explained by the fact that the allelopathic effect in plants is most often expressed not by the amount of germinated seeds, but rather by the retardation of their germination.[26] Monoterpenoids may have allelopathic activity, which interferes with germination and plant development. Moreover, these substances are able to affect physiological processes, such as photosynthesis, chlorophyll synthesis, lipid accumulation in the cytoplasm, and reduction of organelles because of ruptured membranes.[27]

In a study by Romero et al. on the effect of natural monoterpenes on mycelium growth and conidium germination in *Corynespora cassiicola*, the authors found that thymol and carvacrol present the highest effects on the reduction of germination.[28]

According to Yamagushi et al., eucalyptus and guacatonga (*Casearia sylvestris*), which contain monoterpenes in their composition, may be considered potentially allelopathic by reducing and inhibiting germination and GSI in various vegetables (mustard, cabbage, broccoli, kale, turnip, rocket, lettuce, tomato, and radish).[29]

The values for root length (RL) and aerial length (AL) after germination of *L. sativa* and *S. bicolor* treated with different concentrations of *P. amboinicus* essential oil, thymol and carvacrol, are presented in Table 3. The RL of *L. sativa* decreased progressively with increased concentrations of all tested solutions (Figure 3a). RL was not reduced when using *P. amboinicus* essential oil or carvacrol at 0.015%.

(Table 3). Figures 3b and 4b represent root and aerial growth, respectively. These aspects were not significant for any essential oil concentration or for thymol at 0.030%.

Alves et al. tested *Lippia sidoides* essential oil on *L. sativa* seeds and noted there was a phytotoxic effect, with thymol being the main component present in this oil.[30] Monoterpenes may show allelopathic effects; the vapors of these substances can cause anatomical and physiological alterations in plantlets.[31] According to Formagio et al., inhibiting root growth is an important ecological aspect, as it reduces the competitive pressure of the plant, enabling the neighboring species to establish dominance features.[32] The inhibitory effect of germination and of the root and aerial growth characteristic of the allelopathic agents may be related to their interference with cell division, membrane permeability, and enzyme activation.[33,34]

The cytogenetic study was used to analyze the alterations caused by *P. amboinicus* essential oil, thymol, and carvacrol on the *L. sativa* cell cycle. The same concentrations were used as in the

and *P. amboinicus* essential oil solutions (Table 4). This result is directly related to the MI, where all treatments differed from the negative control. The carvacrol solutions caused MI to decrease, however, while the other treatments (thymol and essential oil) caused this index to increase.

In the treatment of *L. sativa* with the herbicide boral, a very high index of condensed nuclei and a very low MI were observed (Table 5). The MI is used to evaluate the cytotoxicity of allelopathic agents. MI values significantly lower than the control indicate that the alterations are caused by the action of chemical components on the growth and development of the exposed organisms. On the other hand, if the MI presents values higher than the control because of increased cell division, this may be harmful to the organism as it may lead to disordered cell proliferation and eventually chromosome abnormalities.[35]

The presence of chromosome abnormalities was greater in all treatments compared to the controls, whereas nuclear alterations only differed from the controls in the treatments with *P. amboinicus* essential oil and thymol (Table 5). The detected alterations were lost chromosome, sticky chromosome, C-metaphase, and chromosome polyploidization (Figure 5).

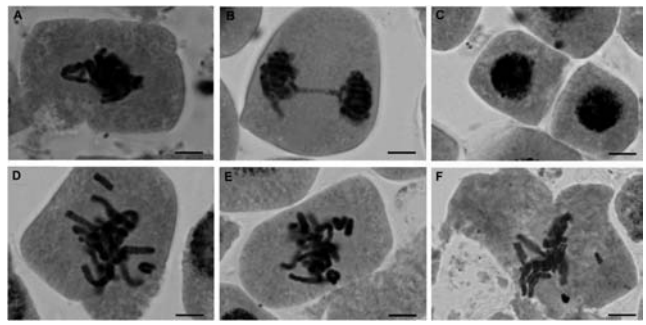

Figure 5. Abnormally dividing cells of *L. sativa* after exposure to carvacrol solution (0.060%, w v^{-1}): (A) stickiness metaphase, (B) anaphase bridge, (C) condensed nucleus, (D, E) laggard chromosomes, and (F) micro-c-metaphase. Scale bar is 5 μm.

Compared to the chromosomal alterations found, what most differentiated the controls was the percentage of sticky chromosomes (Table 5) that found significant differences between the controls and all treatments except the carvacrol.

DOI: 10.1021/acs.jafc.5b03049
J. Agric. Food Chem. 2015, 63, 8981−8990

The presence of sticky chromosomes is generally attributed to the toxic effects of chemical agents on the organization of chromatin. Because chromatin organization is affected, chromosome bridges may arise, as observed in this work (Table 5).

In view of these results, it is suggested that the essential oil of *P. amboinicus*, carvacrol, and thymol have potential for use as bioherbicides and may help to minimize the damage to biodiversity and human health caused by intensive herbicide use.

complex intestinal microflora. Moreover, current data on the change of the bioactivity of procyanidin dimers after degradation by the intestinal microflora are limited, and some results are inconsistent or contrary. For example, Li et al.[14] reported that the total antioxidant capability of litchi pericarp procyanidins was significantly enhanced after microbial incubation. However, ellagitannins from pomegranate juice that possess potent in vitro antioxidant were reported to be metabolized into poor antioxidant derivatives by the colonic microflora.[15] To the best of our knowledge, studies directly comparing the catabolites of A-type and B-type dimers, as well as the change in the antioxidant activity after bioconversions in the same system, are unavailable. Therefore, one aim of the present study was to compare the intestinal metabolism of four proanthocyanidins, namely, B-type EC dimer, A-type EC dimer, A-type ECG dimer, A-type EGCG dimer, by rat intestinal flora, and the other was to investigate how the antioxidant activities of the dimers will change after the metabolism. We believed that our results will serve as the basis for a better understanding of the chemical structure−activity relationships of A-type and B-type procyanidin dimers in vivo.

MATERIALS AND METHODS

Chemicals. High-performance liquid chromatography grade acetonitrile, methanol, and formic acid were obtained from Fisher Scientific International Inc. (Waltham, MA, USA). Commercial standards of procyanidin B1, procyanidin A2, 4′-hydroxyphenylacetic acid and 3′-hydroxyphenylacetic acid (HPLC ≥ 98%) were purchased from Shanghai yuanye Bio-Technology Co., Ltd. (Shanghai, China). Other chemicals were purchased from Sinopharm Chemical Reagent Co., Ltd. (Shanghai, China) and were of analytical grade. Ultrapure water was acquired from a Milli-Q water purification system (Millipore Corp., Bedford, MA, USA). A commercial kit for the determination of T-AOC was purchased from Nanjing Jiancheng Bioengineering Institute (Nanjing, China).

Sample Preparation. A-type ECG dimer and A-type EGCG dimer were prepared from persimmon (*Diospyros kaki*) according to the method we previously reported[16] and further purified by preparative HPLC. B-type EC dimer was isolated from Granny Smith apples (*Malus domestica*) and characterized by HPLC-MS/MS as previously reported.[17] A-type EC dimer was prepared from peanut (*Arachis hypogaea*) red skins according to the method we previously reported.[16] The purity of B-type EC dimer was analyzed by HPLC to be 87.57% with commercial procyanidin B1 as the standard, the purities of A-type EC dimer, A-type ECG dimer, and A-type EGCG dimer were confirmed by HPLC to be 88.72, 82.56, and 93.28%, respectively, using procyanidin A2 as the standard. Stock solutions (2.5 mg/mL) of the analytes were dissolved in methanol and stored at 4 °C before the incubation experiments.

Animals. Male Sprague−Dawley rats, weighing 200 ± 15 g, were purchased from the Experimental Animal Center of Wuhan University (Wuhan, China) and housed in a room at 25 °C and 50 ± 10% relative humidity. After 1 week of acclimation, the rats were anesthetized and dissected. All experimental procedures were in accordance with Chinese legislation on the use and care of laboratory animals and were authorized by the Huazhong Agricultural University of Science and Technology Committee on animal care and use.

Preparation of Inoculum. The method of Engemann et al.[13] was employed. Briefly, the feces obtained from five rats were weighed during slaughtering and then transferred to an anaerobic chamber, which was set at 37 °C. All preparations were performed in the anaerobic chamber flushed with N_2 to maintain the strict anaerobic atmosphere. In addition, all of the solutions, buffers, and glass vessels were reserved through the high-pressure steam sterilization at 121 °C for 30 min before use. The cecum was diluted with 0.15 M PBS (pH 6.2) (1:8; m/v) containing an 11.1% Na_2S solution (575.9 mg/100 mL of 0.037 M NaOH) and a 0.0125% trace element solution (13.2 g/100 mL $CaCl_2{\cdot}2H_2O$, 10.0 g/100 mL $MnCl_2{\cdot}4H_2O$, 1.0 g/100 mL $CoCl_2{\cdot}6H_2O$, and 8.0 g/100 mL $FeCl_3{\cdot}6H_2O$).[18] The inoculum suspensions were filtered through a coarsely meshed net to remove larger particles and then used for the incubation experiments. Stock solutions of four procyanidin dimers (2.5 mg/mL in methanol) were diluted 1:10 (v/v) with the active or inactivated fecal solution. The samples were fermented at 37 °C in the anaerobic chamber and were taken after incubation for 0, 6, 12, and 24 h. The metabolism of the flora was stopped after incubation by storage at −80 °C until the chromatographic analysis of the metabolites. An aliquot of the sterilized fecal suspensions with stock solutions was used as control for chemical degradation and matrix effects, and the sterilized inoculum suspensions without the stock solutions of the analytes were used as blank. All incubation experiments were performed in triplicate.

HPLC Analysis. The frozen samples were thawed quickly and extracted with an equal volume of ethyl acetate three times. Subsequently, the ethyl acetate extracts were evaporated under N_2. Each residue obtained was dissolved in 1 mL of methanol. The separation was performed on a Waters e2695 HPLC system (Milford, MA, USA) with an Agilent TC-C18 column (150 × 4.6 mm i.d., 5 μm). The solution was filtered through a 0.22 μm cellulose acetate spin filter before 10 μL was injected into the HPLC with detection at 280 nm. Separation was accomplished at 30 °C with 0.13% formic acid in water (solvent A) and acetonitrile (solvent B) using the gradient 0−10 min, 10% solvent B; 10−15 min, 20% solvent B; 15−20 min, 40% solvent B; 20−25 min, 55% solvent B; 25−35 min, 55% solvent B, and re-equilibrated at 10% solvent B for 10 min. The flow rate was 0.8 mL/min, and the eluate was monitored at 280 nm.

LC-ESI-MS Analysis. LC-MS/MS analysis was performed by an Agilent 1100 liquid chromatograph system with an Agilent TC-C18 column (150 × 4.6 mm i.d., 5 μm) and an Agilent 1100 LC-MS spectrometer equipped with a diode array UV detector and an ESI interface (Agilent Technologies Co., Ltd., Santa Clara, CA, USA). The mobile phase and gradient were the same as for the HPLC analysis mentioned above. The negative ion polarity mode was carried out, and the spray needle voltage and the heated capillary temperature were 3500 V and 325 °C, respectively. The drying gas (N_2) flow rate was set at 10 L/min. The analysis was implemented using full scan, and the mass spectra scale ranged from m/z 50 to 2000.

Assays of the Antioxidant Activity. *Total Antioxidant Capability (T-AOC).* The T-AOC of metabolites after the microbial metabolism was estimated by the total antioxidant capability assay kit (Nanjing, China) according to the method of Li et al.[14] The T-AOC value of solutions of each dimer diluted with inactivated fecal solution was set as relative level of 100%.

ABTS Radical Cation Scavenging Capability. The $ABTS^{\bullet+}$ scavenging capacity of the metabolites was examined with 7 mM ABTS stock solution containing 2.45 mM potassium persulfate, which was stored in the dark at room temperature overnight. The $ABTS^{\bullet+}$ solution was diluted with ethanol to an absorbance of 0.70 ± 0.02 at 734 nm and equilibrated at 30 °C before use.[19] The metabolites were diluted with methanol 100-fold and mixed with $ABTS^{\bullet+}$ solution (v/v, 1:20). The $ABTS^{\bullet+}$ scavenging activity was evaluated as the percentage inhibition with regard to the following equation: inhibition (%) = $[A_0 - (A_1 - A_2)]/A_0 \times 100$, where A_0, A_1, and A_2 are the absorbance of the control, sample, and blank, respectively. The inhibition of solutions of each dimer diluted with inactivated fecal solution was set as relative level of 100%.

Statistical Analysis. All of the determinations are presented as the mean ± standard deviation (SD) and performed in triplicate. Data were calculated using one-way ANOVA of SPSS 17.0 followed by Tukey's multiple-range test. Differences were considered significant at a p value <0.05.

RESULTS AND DISCUSSION

Stability of Four Dimers in Rat Intestinal Flora Model. Four PA dimers at the concentration of 2.5 mg/mL did not show inhibition on the growth of rat intestinal flora. PA dimers with different chemical structures varied significantly in the

DOI: 10.1021/acs.jafc.5b03657
J. Agric. Food Chem. 2015, 63, 8991−8998

stability after incubation with rat intestinal flora. Among the four dimers tested, A-type EC dimer was the most stable, whereas A-type ECG dimer and A-type EGCG dimer were the least stable (Figure 1). The half-lives were 24.04, 14.70, 6.23, and 7.46 h for A-type EC dimer, B-type EC dimer, A-type ECG dimer, and A-type EGCG dimer, respectively, under the current incubation condition. Our results were inconsistent with those of Engemann et al.,[13] who reported that procyanidin A2 degraded by nearly 80% after incubation with pig cecum flora. The difference was probably due to the diversity between the pig cecum microbiota and the rat intestinal microbiota. An additional C2−O−C7 ether linkage in A-type EC dimer could explain its greater stability relative to the B-type EC dimer.[3] Compared to A-type EC dimer and B-type EC dimer, A-type ECG and EGCG dimer degraded more quickly. The additional galloyl groups, which were very susceptible to be hydrolyzed, gave a possible explanation for the greater instability of A-type (E)CG dimer and A-type (E)GCG dimer against microbial degradation.[20]

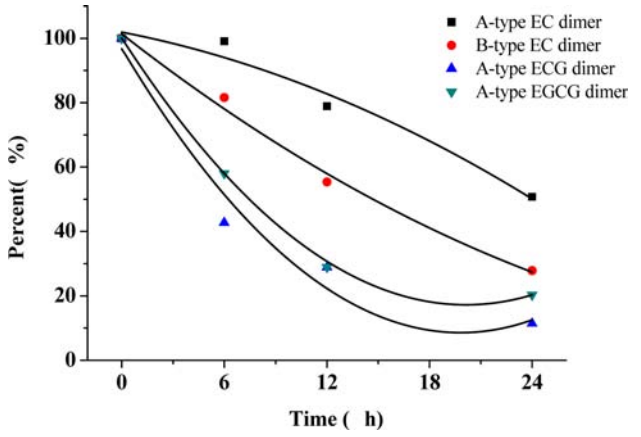

Figure 1. Stability of four dimers in rat intestinal flora model. The concentration of each dimer was 2.5 mg/mL.

Metabolites Derived from Bioconversion of Four PA Dimers. The HPLC profiles of the metabolites of four PA dimers decomposed by rat intestinal microbiota at different times are shown in Figure 2. Four new peaks (peaks 1−4 in Figure 2a) appeared after B-type EC dimer was incubated with rat intestinal microbiota. Compared to incubation for 6 h, the intensities of peaks 2 and 4 at 24 h doubled, whereas the intensities of peaks 1 and 3 did not change obviously. We excluded the possibility that these new peaks were derived from purely chemical transformation by using the control group

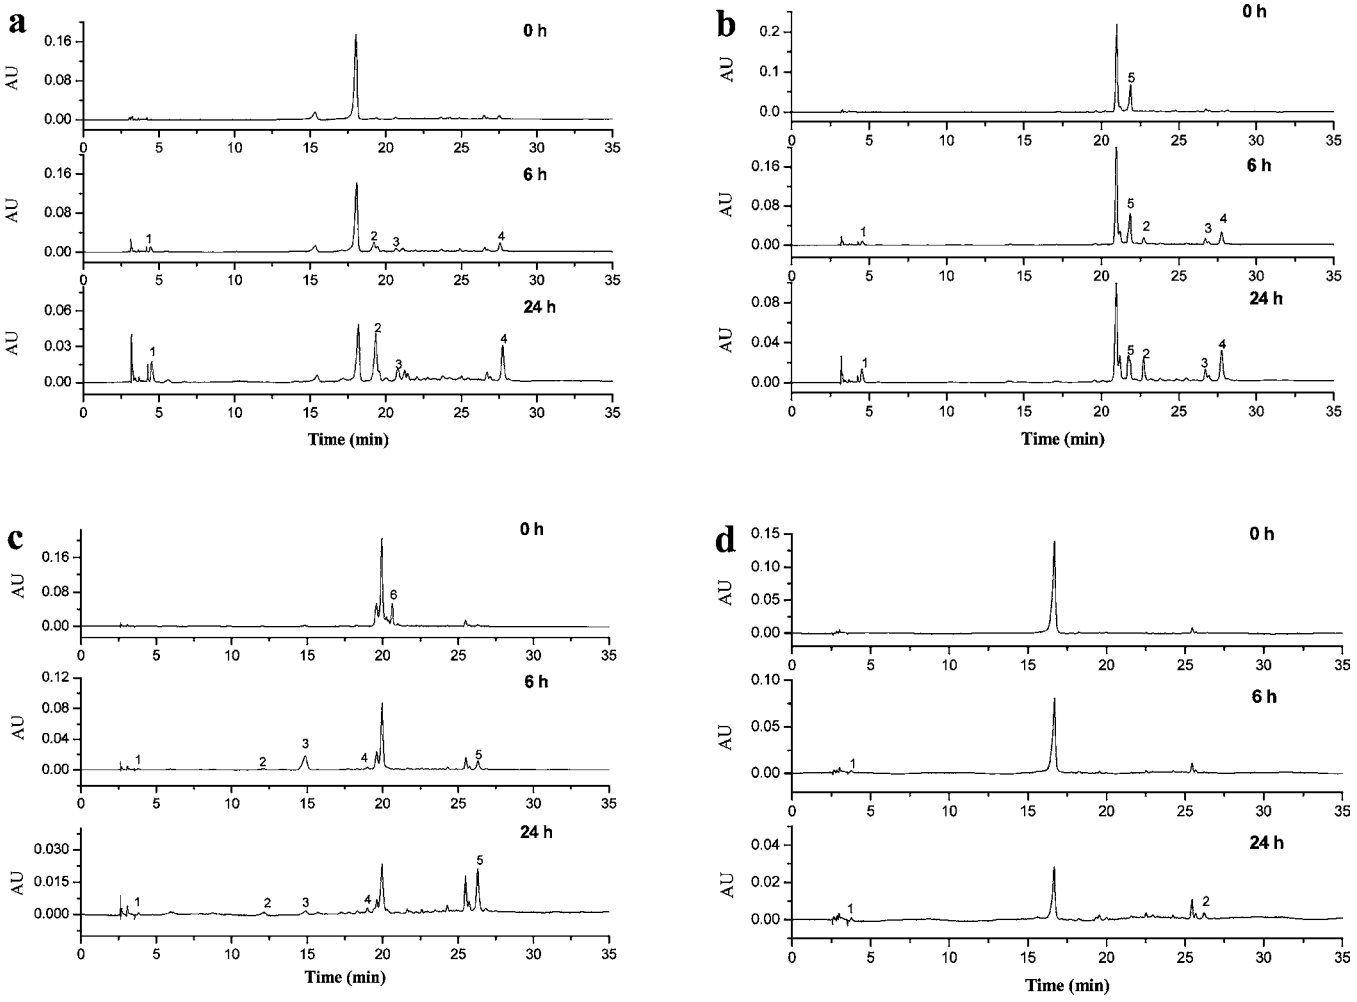

Figure 2. HPLC analysis of B-type EC dimer (a), A-type EC dimer (b), A-type ECG dimer (c), and A-type EGCG dimer (d) at different incubation times (0, 6, 24 h) with rat intestinal microbiota. Peaks 1−5 indicate newly formed metabolites.

	2	815.7	407.3	polymer

[a]Reference 13 reported by Engemann et al., 2011.

consisting of the test substance in sterilized fecal culture medium. Besides, there had little change for the peaks of these impurities. The structures of the new peaks were analyzed by LC-MS/MS (Table 1). The molecular ion of peak 1 was observed at m/z 151.2 with a characteristic fragment at m/z 107.5, which resulted from the elimination of CO_2 from the molecular ion. The MS fragmentation pattern of peak 1 was identical to that of hydroxyphenylacetic acid as previously reported.[21] Peak 1 (m/z 151.2) was identified as 4′-hydroxyphenylacetic acid by comparison of its retention time, UV−vis spectra, and mass spectra with those of the authentic standards 4′-hydroxyphenylacetic acid and 3′-hydroxyphenylacetic acid. Stoupi et al.[21] identified 3′-hydroxyphenylacetic acid from catabolites of procyanidin B2 by human fecal microbiota. Peak 2 showed an $[M - H]^-$ ion peak at m/z 291.1, suggesting the presence of a C-ring-opened diaryl-propan-2-ol unit or a flavanol unit containing a reduced A-ring,[22] which resulted from the quinine methide (QM) pathway of the dimer. The characteristic fragment ions were found at m/z 272.9 and 247.0 in the MS^2 spectrum of m/z 291.1 (Table 1), suggesting the loss of H_2O and CO_2. These fragments were in agreement with previous studies,[23,24] so the ion at m/z 291.1 was identified as 1-(3′,4′-dihydroxyphenyl)-3-(2″,4″,6″-trihydroxyphenyl)propan-2-ol. Wang et al.[25] also demonstrated that anaerobic incubation of (+)-catechin with *Eubacterium* sp. strain SDG-2 resulted in the formation of 1-(3′,4′-dihydroxyphenyl)-3-(2″,4″,6″-trihydroxyphenyl)propan-2-ol. Peak 3 was heterogeneous with a main ion at m/z 670.9 and several minor ions at m/z 689.1, 660.9, 665.3, and 693.2, respectively, indicating a mixture. Among these molecular ions, a MS^2 fragment ion of m/z 670.9 was found at m/z 589.0, which resulted from the loss of 81 amu from the molecular ion. Although methylated form of B-type EC dimer showed a molecular ion at m/z 589.0 and Shoji et al.[26] illustrated that methylated procyanidin dimers B1 and B2 (m/z 589) were detected in rat plasma 2 h after administration of these procyanidins, it was unlikely that the methylation would occur in the in vitro model. Therefore, further work is needed to verify the structure of this compound. Peak 4 showed a $[M - H]^-$ ion at m/z 815.6 with a MS^2 fragment ion at m/z 407.3. Characteristic fragment ion at m/z 425 corresponded to the loss of 152 aum upon C-ring cleavage of the terminal unit of procyanidin B2 (m/z 577), and the ion at m/z 407 was produced by a further loss of a water molecule.[21] The characteristic MS^3 fragment ions of m/z 407.3 were seen at m/z 389.3 and 371.4, separately, suggesting the loss of one and two H_2O molecules, separately. We speculated that the fragment ion at m/z 407.3 was derived from the retro-Diels−Alder (RDA) fragmentation of the B-type EC dimer, followed by a further loss of H_2O, and then peak 4 might be formed through polymerization of two molecules of m/z 407.3. The detailed structure of peak 4 needed further confirmation.

HPLC-MS analysis indicated that the A-type EC dimer we obtained contained a main component with the retention time of 20.97 min and a minor component (peak 5) with the retention time of 21.86 min. These two peaks were approved to be a pair of isomers of A-type EC dimer, as evidenced by their molecular mass and fragmentation patterns shown in Supporting Information Figure S1-a. As shown in Figure 2b, four new peaks (1, 2, 3, 4) were detected after the incubation of A-type EC dimer with rat intestinal microbiota, and the peak intensities increased as the incubation time extended, whereas the intensity of peak 5 attenuated with time. Peak 1 was heterogeneous with three main ions at m/z 151.3, 195.5, and 177.2, respectively. The molecular ion $[M - H]^-$ at m/z 151.3 was quite similar to peak 1 of B-type EC dimer, with a MS^2 fragmentation at m/z 107.2. Similar to peak 1 in Figure 2a, based on the same retention time, UV−vis spectra and mass data with the authentic 4′-hydroxyphenylacetic acid, this compound (m/z 151.3) was identified as 4′-hydroxyphenylacetic acid.[21] The MS^2 fragments of the m/z 195.5 were at m/z 176.2 and 158.3 (Table 1), which showed a similar fragmentation pathway of hydroxyphenylvaleric acid but 2 Da higher than hydroxyphenylvaleric acid as a metabolite of procyanidin dimer by human fecal microbiota reported by Stoupi et al.[21] We deduced that it might be a derivative of

DOI: 10.1021/acs.jafc.5b03657
J. Agric. Food Chem. 2015, 63, 8991−8998

hydroxyphenylvaleric acid. The MS^2 fragment ions of m/z 177.2 were found at m/z 159.1 and 77.7. The molecular ion and MS^2 fragment ions of m/z 177.2 were identical to those of 5-phenylvaleric acid standards.[21] Therefore, 5-phenylvaleric acid was identified as a metabolite of A-type EC dimer by rat intestinal microbiota. These phenolic acids were also detected in catabolites of procyanidin A2 by human gut microbiota or pig cecum microbiota.[13,27] Peak 2 showed an $[M - H]^-$ ion at m/z 577.2, and four characteristic fragment ions found at m/z 541.1, 451.3, 409.5, and 291.5 (Table 1) respectively. This peak showed a dimeric character instead of monomeric. It showed the MS fragmentation pattern identical to that of catabolite C1, which was reported by Engemann et al.[13] as a metabolite of procyanidin A2 in the pig cecum model generated by the microbiota by cleaving the ether linkage at C′-ring with the newly formed hydroxy group positioned at the A′-ring.[28] Therefore, peak 2 was identified as catabolite C1. The molecular ion of peak 3 was at m/z 407.3 with high intensity, with MS^2 fragment at m/z 387.9 and 371.3. The metabolite (m/z 407.3) may be the product from RDA fission. The fragment ion at m/z 387.9 might be derived from the elimination of water and a reductive cleavage of the C2−O−C7 ether linkage from the molecular ion (m/z 407.3), but there is no report about the metabolite of m/z 407.3, which just appeared as the MS^2 secondary ion.[21,22] Therefore, the detailed structure of peak 3 needs further confirmation. Meanwhile, peak 4 showed the same MS fragmentation patterns as peak 4 in Figure 2a, indicating the same proposed structure.

Similar to the A-type EC dimer, the A-type ECG dimer we obtained contained two isomers, with the retention times of 19.95 and 21.01 min, separately, in the HPLC-MS chromatogram of Figure 2c (0 h). The MS and MS^2 spectrum of peak 6 with the retention time at 21.01 min is provided in Figure.S1-b. After incubation with rat intestinal microbiota for 6 h, A-type ECG dimer decreased by 48%. As shown in Figure 2c, five new peaks were observed after the incubation. The intensity of peak 3 increased after 6 h of incubation, but decreased as the incubation time was extended to 24 h, whereas intensities of other peaks changed little over time. Peak 1 was heterogeneous with several ions at m/z 209.1, 335.1, 439.3, and 479.2, respectively, indicating a mixture. The MS^2 fragment ions of m/z 209.1 were m/z 163.9, 147.9, and 121.0, separately. Similar MS fragmentation patterns were reported in the metabolites of ECG by human intestinal bacteria.[29,30] Therefore, the ion at m/z 209.1 might be 5-(3′,4′-dihydroxyphenyl)valeric acid or 5-(4-hydroxy)-(3′-hydroxyphenyl)valeric acid, but the lack of the commercial standards hindered the further confirmation of the exact structure of m/z 209.1. Additionally, the cleavage of the C-ring at the lower unit or the breakage at C4−C8 and C2−O−C7 bonds can contribute to the formation of small molecular weight phenolic acids.[12,21,30] The $[M - H]^-$ ion at m/z 439.3 might be the structural unit of the A-type ECG dimer, indicating interflavan bond breakage of the dimer might have happened. Various molecular ions were detected in peaks 2 and 3 (Table 1), but we failed to get the MS^2 fragments. We also failed to obtain the MS signals of peak 4, so the identities of these three peaks are not clear. Peak 5 showed identical MS ion and MS^2 fragment ions with those of peak 4 in Figure 2a,b, indicating the same proposed compound.

Although the A-type EGCG dimer is the most unstable and degraded quickly, only two small new peaks were detected in the catabolites of A-type EGCG dimer, after incubation with rat intestinal microbiota for 24 h (Figure 2d, peaks 1 and 2). We failed to detect other new peaks in the products, which might be because the minor decomposed products could not be detected under our current analytical conditions. Little change in the intensity of peaks 1 and 2 was observed with increasing incubation time. Peak 1 showed a molecular ion $[M - H]^-$ at m/z 455.1 with the MS^2 fragment ion at m/z 329.0, which corresponded to the loss of 126 aum of phloroglucinol ($[M - H - C_6O_3H_6]^-$) from the molecular ion m/z 455.1. Therefore, peak 1 (m/z 455.1) was the structural unit of the A-type EGCG dimer. This result also gave evidence that interflavan bond breakage of the A-type EGCG dimer happened in the current conditions. It has been reported that procyanidin dimers could be degraded into monomers by the intestinal microbiota or other derivatives of benzonic acid, phenylacetic acid, and phenylpropionic acid.[31] Similarly, the molecular ion $[M - H]^-$ of peak 2 was also found at m/z 815.7, with the same MS^2 fragment ions with that of peak 4 in Figure 2a,b and peak 5 in Figure 2c, indicating the same structure.

This study is the first direct comparison of the catabolism of four structurally different PA dimers by rat intestinal microbiota. We detected some metabolites such as 4′-hydroxyphenylacetic acid, 5-phenylvaleric acid, dihydroxyphenylvaleric acid, and 1-(3′,4′-dihydroxyphenyl)-3-(2″,4″,6″-trihydroxyphenyl)-propan-2-ol, which were reported previously in other studies.[21,24] Although the exact catabolism route of the dimers was not clear, our current data suggested that the early cleavage of C4−C8 interflavan bond could happen. Because we detected the structural units of both A-type ECG and EGCG dimers in the metabolites, the presence of 4′-hydroxyphenylacetic acid in both B-type and A-type EC dimers gave indirect evidence for the cleavage of the C4−C8 interflavan bond.[13,21] It was assumed that this metabolic pathway depended on the competence of the flora, which occurred during the incubation of B-type procyanidin dimers with human fecal microbiota reported by Stoupi et al.[21] and Appeldoorn et al.[12] Our results and previous results suggested that human fecal microbiota and rat intestinal microbiota had some similar competence in studying the intestinal metabolism of PA dimers. However, the amount of the monomers was trace, which might be due to the slow and low conversion of dimers into monomers followed by a rapid conversion into phenolic acids.[12,37] Previous study revealed that EGCG could be hydrolyzed into (−)-epigallocatechin (EGC) by rat intestinal bacteria and then converted to the main metabolite, 5-(4-hydroxy)-(3′,5′-dihydroxy)-phenylvaleric acid, by decomposition of the phloroglucinol ring.[24] Nevertheless, we did not detect this compound in metabolites of A-type EGCG dimer, and it might be that the amount of EGCG monomer generated was trace and this metabolite could not be detected. In addition, 1-(3′,4′-dihydroxyphenyl)-3-(2″,4″,6″-trihydroxyphenyl)propan-2-ol and the dimeric catabolite[13] were detected in the metabolites of B-type EC dimer and A-type EC dimer, respectively, which suggested that reductive cleavage of the C-ring and cleavage of the A-ring occurred.[3] A metabolite (m/z 670.9) detected only in the metabolites of B-type EC dimer demonstrated that the degradation route of B- and A-type dimers might somewhat differ. However, Stoupi et al.[21] observed dimeric intermediates in procyanidin B2 catabolites by human fecal microflora, suggesting the catabolites may vary significantly depending on the composition of the intestinal microflora. In addition, the metabolism of the A-type ECG dimer was more complex than those of B-type and A-type EC dimer, but we failed to obtain more information on the structure of the metabolites. More

J. Agric. Food Chem. 2015, 63, 8991−8998

surprisingly, although the A-type EGCG dimer was the most unstable, few metabolites were detected. This might be explained by the very complex and small amount of decomposed products that could not be detected under our current analytical conditions. Moreover, a compound with a molecular ion at m/z 815.6 was found in all four procyanidin dimers. We checked the MS spectrum of the control and confirmed this product was a catabolite of these dimers, but its exact structure needs further confirmation. Stoupi et al.[22] also identified some "dimeric " intermediate from procyanidin B2 catabolism by human fecal microflora.

However, some small phenolic compounds, including hydroxyphenylpropionic acid, 3,4-dihydroxyphenylpropionic acid,[32] 5-(3′,4′-dihydroxylphenyl)-γ-valerolactone, 5-(3′-hydroxyphenyl)valeric acid,[21] 3-(3′,4′-dihydroxyphenyl)-propionic acid, and 3-(4′-hydroxyphenyl)propionic acid, which were often reported as key metabolites of PAs, were not detected in our experiments. In addition, we detected fewer metabolites in the current study than were found in similar studies. The different experimental conditions might explain the different results between our experiments and those from other groups. First, we used rat microbiota flora instead of human fecal microbiota or pig cecum microbiota in other studies, and the different microbiota flora compositions might lead to different metabolites. Second, we used pure PA dimers in our study, but some studies used grape seed extracts[33,34] as the parent compounds, which might bring out different results. Third, only peaks detected by HPLC were analyzed by HPLC-MS in our study. Considering MS experiments may allow the detection of compounds not detected by HPLC, we screened the whole MS spectra but detected only m/z 191 in the spectra with an extremely low intensity, and we failed to obtain the MS^2 fragment ions. Therefore, Fourier transform mass spectrometry (FTMS),[13] UPLC/DAD-ESI-Q-TOF-MS,[35,36] or some more sensitive detection experiments that were used by other authors to detect the trace metabolites are needed to further confirm the exact structures of the metabolites in future work.

Change in the Antioxidant Activity of the Four Dimers after Bioconversion by Rat Intestinal Microbiota. It is well-known that proanthocyanidins have potent antioxidant activities in vitro.[38,39] However, the bioactivity of proanthocyanidins is affected by their bioavailability and biotransformation in vivo. Because the procyanidins are poorly absorbed during passage through the gastrointestinal tract, either a decrease or an increase in the antioxidant potential caused by the bacterial metabolism is possible. However, current data concerning the change in antioxidant potential of procyanidins after metabolism is scarce. Therefore, the T-AOC and ABTS assays were used to evaluate the antioxidant activity change of the four dimers after incubation with rat intestinal microbiota.

Figure 3 shows the T-AOC of four dimers at different incubation times. It was obvious that the T-AOC values of the A-type dimers were enhanced significantly after incubation with the rat intestinal microbiota for 6 h, but attenuated as the incubation time was prolonged to 24 h. After incubation for 6 h, the T-AOC of the metabolites of A-type EC, ECG, and EGCG dimers increased by 45, 7, and 41%, compared to the original dimers without conversion, respectively. However, the T-AOC of the B-type EC dimer decreased over time after incubation. Similar results were observed in the $ABTS^{\bullet+}$ assay. The scavenging capacity of the A-type dimers on $ABTS^{\bullet+}$ was

enhanced after incubation for 6 h but attenuated after 12 h of incubation (Figure 4). However, the $ABTS^{\bullet+}$ scavenging

Results are expressed as the mean ± SD of three independent experiments. Different letters among groups indicate significant difference ($p < 0.05$) by Tukey's test.

capacity of the B-type EC dimer decreased over time. Li et al.[14] concluded that *Streptococcus thermophilus* and *Lactobacillus casei*-01 could convert litchi pericarp procyanidins to a more effective antioxidant agent. However, they compared only the T-AOC of litchi pericarp oligomeric procyanidins before and after microbial incubation for 30 h. Our present study suggested the antioxidant capability of procyanidin dimers after bioconversion by rat intestinal microbiota differed significantly with incubation time, probably due to the different metabolite compositions at different incubation times. Therefore, for the change in antioxidant potential of procyanidins after metabolism, both microbiota and incubation conditions should be taken into consideration.

In summary, the present study indicated that after incubation with rat intestinal flora, structurally different PA dimers differed

DOI: 10.1021/acs.jafc.5b03657
J. Agric. Food Chem. 2015, 63, 8991−8998

significantly not only in stability but also in catabolism routes and catabolites. The stability of four proanthocyanidins incubated with rat intestinal microbiota was in the order A-type EC dimer > B-type EC dimer > A-type ECG dimer > A-type EGCG dimer under anaerobic condition. Although the early cleavage of the C4−C8 interflavan bond as well as the reductive cleavage of the C-ring and cleavage of A-ring occurred in both B-type and A-type dimers, the degradation routes of B-type EC dimer and A-type EC dimer might somewhat differ, as evidenced by different metabolites derived from different dimers. The antioxidant capabilities of the A-type dimers were enhanced significantly after incubation with the rat intestinal microbiota for 6 h, but attenuated as the incubation time was prolonged to 24 h. In contrast, the antioxidant capacity of the B-type EC dimer decreased during the incubation. Our results suggested the change of antioxidant capability of procyanidin dimers after bioconversion by rat intestinal microbiota was not only structure dependent but also incubation conditions dependent. To better understand the health benefits of procyanidin dimers, further work on the catabolism route as well as the bioactivity activities of the microbial metabolites is needed.

urine. The chemical structures were characterized on the basis of their MS and MS^2 data. The principal metabolic pathways of salidroside were proposed as well.

MATERIALS AND METHODS

Chemicals. Salidroside was purchased from the National Institutes for Food and Drug Control (Beijing, China). *p*-Tyrosol was purchased from Sigma (St. Louis, MO, USA). HPLC grade acetonitrile and methanol were obtained from Fisher Scientific (Pittsburgh, PA, USA). HPLC grade water was purified by a Millipore Milli-Q purification system via deionized water (Billerica, MA, USA). All other reagents were of reagent grade.

Animals and Drug Administration. Male Wistar rats (200 ± 20 g of body weight) were purchased from the Laboratory Animal Center of Jilin University (Changchun, Jilin Province, China). Animals were handled according to the standard procedures approved by the institutional animal care and use committee. All rats experienced an overnight fasting with free access to water before oral administration. Rats were acclimatized for 1 week before experiments. The rats were divided into three groups: salidroside administration groups (low and high doses) and control group; each group contained three rats. Salidroside dissolved in saline was orally administered to the rats at a single dose of 100 mg/kg of body weight for the Q-TOF-MS detection or at a single dose of 500 mg/kg of body weight for the Q-trap-MS detection. The rats in the control group were administered the solvent saline orally at the same volume as the treatment group.

Sample Collection. Rats were housed in metabolic cages for 3 days. Urine samples were collected at intervals of 0−12, 12−24, 24−48, and 48−72 h after salidroside administration. All samples were stored at −40 °C until further use.

Sample Preparation. Briefly, 600 μL of methanol was added to 200 μL of urine followed by vortexing for 5 min and centrifugation at 15000*g* for 10 min. The supernatant of the sample was transferred to a clean test tube and evaporated to dryness under nitrogen. The residue was redissolved in 200 μL of water, and the supernatant was ready for the injection after centrifugation at 15000*g* for 10 min.

UPLC/Q-TOF-MS Analysis. The analysis was performed on a Waters ACQUITY ultraperformance liquid chromatographic system (Waters Corp., Milford, MA, USA) coupled with a Waters ACQUITY Synapt G2 quadrupole time-of-flight (Q-TOF) tandem mass spectrometer (Waters Corp., Manchester, UK). System control and data acquisition were performed using MassLynx V4.1 software.

Chromatographic separation was achieved on an ACQUITY UPLC HSS T3 column (1.7 μm, 50 mm × 2.1 mm; Waters Corp., Milford, MA, USA). The mobile phase system consisted of acetonitrile (A) and water (B) at a flow rate of 0.25 mL/min. The time program of the gradient was 0−2 min, 0% A; 2−5 min, 0−5% A; 5−10 min, 5−10% A; 10−15 min, 10−80% A; 15−18 min, 80−0% A; 18−20 min, 0% A for equilibration of the column. The column and autosampler temperatures were maintained at 40 and 4 °C, respectively.

Metabolites were detected in negative ionization mode. The optimized MS conditions were as follows: capillary voltage, 2.5 kV; sample cone voltage, 40 V; extraction cone voltage, 4.0 V; source temperature, 120 °C; desolvation temperature, 400 °C; desolvation gas, 800 L/h nitrogen; and cone gas, 50 L/h nitrogen. Argon was used as collision gas. For accurate mass measurement, data were collected in centroid mode, and an external reference (LockSpray) at a concentration of 200 pg/mL in 50% acetonitrile−water solution (including 0.1% formic acid) was employed to generate $[M - H]^-$ ion in negative mode at m/z 554.2615 via a lock spray interface at a flow rate of 5 μL/min to acquire accurate mass during the analysis. MS^E analysis was performed in two scan functions: 5 eV for the low collision energy scan and a collision energy ramp of 10−30 eV for the high-collision energy scan. To get more clean and accurate fragments for each metabolite, MS/MS analysis was performed with a collision energy ramp of 10−25 eV.

HPLC/Q-Trap-MS Analysis. The analysis was performed on a Shimadzu LC 20AD system (Shimadzu, Kyoto, Japan) coupled with an Applied Biosystem Sciex API 4000 Q-trap mass spectrometer (Foster City, CA, USA). The Analyst software package (version 1.6) was used for system control, data acquisition, and processing.

The separation was performed on an Aglient Proshell 120 column (2.7 μm, 100 mm × 2.1 mm; Palo Alto, CA, USA), with mobile phases of water (A) and acetonitrile (B) eluting in the following program: 0−2 min, 2% B; 2−7 min, 5% B; 7−12 min, 5−10% B; 12−13 min, 10−80% B; 13.0−13.1 min, 80−2% B; 13.1−16 min, 2% B. The flow rate was 0.3 mL/min, and the injection volume was 2 μL.

The detection was performed under negative mode with a Turbo VTM Ion Source. Polypropylene glycol dilution solvent was used to turn the ion optics. The optimized MS conditions were as follows: nitrogen as the nebulizer, heater, curtain, and collision gas with nebulizer (GS1), heater (GS2), and curtain gas flow rates of 45, 45, and 25 psi, respectively; ion-spray needle voltage, −4500 V; and heater gas temperature, 550 °C.

Multiple ion monitoring (MIM) mode was utilized to analyze the biological samples. A set of MIM ion transitions of the metabolites detected in Q-TOF-MS were introduced for the detection of potential metabolites of salidroside. The parameters were used as follows: The dwell time, declustering potential, and collision energy of each MIM ion transition were fixed at 30 ms, −40 V, and −10 eV, respectively; CE and collision energy spread (CES) of EPI were fixed at −40 and ±20 eV.

RESULTS AND DISCUSSION

Fragmentation of Salidroside Standard. Because metabolites can retain the base substructure of the parent compound, the first important step in the analysis of metabolites of salidroside in rat urine is to obtain its chromatogram and mass spectrum characterization. All of these data were the substructural "template" for interpreting the structures of the metabolites.

The chromatographic and mass spectrometric conditions were optimized using salidroside. Under negative electrospray ionization mode, the salidroside molecule ($C_{14}H_{20}O_7$, MW = 300.12 Da) could easily form a molecular ion of m/z 299.1127 ($[M - H]^-$). The product ion spectrum of the molecular ion of salidroside and its predominant fragmentation patterns are illustrated in Figure 2. Fragmentation of the molecular ion of salidroside led to four major product ions at m/z 179.0562, 137.0599, 119.0496, and 113.0230. The product ions at m/z 179.0562 ($C_6H_{11}O_6$) and m/z 137.0599 ($C_8H_9O_2$) were ions of glucose and the aglycone *p*-tyrosol produced by the salidroside molecular ion. The product ion at m/z 119.0496 (C_8H_7O) was formed by the loss of a molecule of hydrone from the ion at m/z 137.0599. The product ion at m/z 113.0230 ($C_5H_5O_3$) was inferred to be produced by the loss of one molecule of formaldehyde and two molecules of hydrone from the ion at m/z 179.05629, so it can be concluded that the ions at m/z 179.0562, 137.0599, 119.0496, and 113.0230 were the characteristic product ions of salidroside.

In Vivo Metabolites of Salidroside. Metabolites of salidroside in rat urine were achieved by comparing the data of blank and salidroside-dosed samples. Unique precursor ions found in salidroside-dosed samples were considered as potential metabolites for MS^2 analysis. Eight metabolites were thus identified (M1−M8). The retention times, measured and calculated masses, accurate masses, mass errors, and MS/MS product ions of salidroside (M0) and its speculated metabolites (M1−M8) are summarized in Table 1. The mass errors between the measured and the calculated values were < 6 ppm, which displays a high level of confidence in the compositions of the speculated metabolites. The chemical structures were proposed using MS and MS^2 data.

J. Agric. Food Chem. 2015, 63, 8999−9005

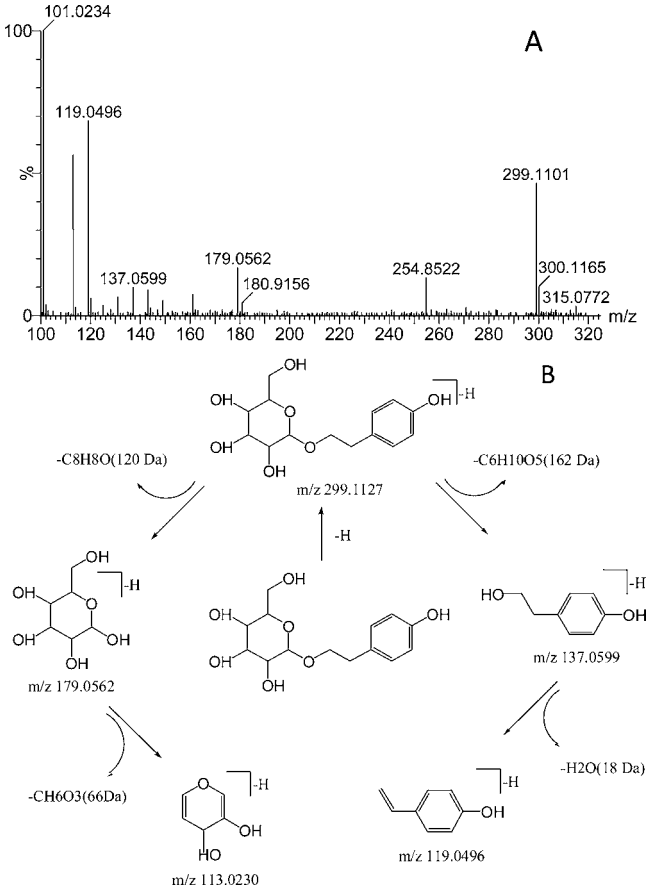

Figure 2. (A) MS^2 spectrum of salidroside; (B) its proposed fragmentation pathways in negative ion mode with m/z 299.11 as the precursor ion.

Parent Drug M0. M0 was identified with an accurate $[M - H]^-$ ion of m/z 299.1127 (−1.3 ppm, $C_{14}H_{19}O_7$). The productions of M0 were identical to those of salidroside standard. Therefore, M0 was designated salidroside.

Metabolite M1. The Q-TOF MS spectrum of M1 provided an accurate $[M - H]^-$ ion at m/z 475.1456 (0.8 ppm, $C_{20}H_{27}O_{13}$), which was 176 Da higher than that of M0. Further Q-TOF MS^2 fragmentation (Figure 3A) showed fragment ions at m/z 175.0741, 137.0607, 113.0231, and 85.0297. The diagnostic ion at m/z 175.0741 was the $[M - H]^-$ ion of glucuronic acid. The product ion at m/z 113.0231 ($C_5H_5O_3$) could be fragmentized from the salidroside fragment ion as well as glucuronic acid molecular ion, displaying a strengthened abundance. The product ion at m/z 85.0297 was the loss of 18 Da (hydrone group) from the ion at m/z 113.0231. Furthermore, another diagnostic fragment ion at m/z 137.0607 was the aglycone *p*-tyrosol, the same as the product ion of parent drug M0. M1 was assessed as the glucuronidated product of M0. The MS^2 fragmentation (Figure 4A) of M1 showed product ions at m/z 313.3 and 299.4 by Q-trap-MS, demonstrating the glucuronidation occurred at the hydroxyl group on the phenyl ring.

Metabolite M2. M2 was detected by Q-TOF-MS with an $[M - H]^-$ ion at m/z 379.0710 (2.9 ppm, $C_{14}H_{19}O_{10}S$), which was 80 Da higher than that of M0, implying sulfation of M0. Q-TOF MS^2 fragmentation (Figure 3B) showed fragment ions at m/z 137.0583, 119.0498, 113.0235, and 79.9576. The diagnostic ion at m/z 79.9576 was the sulfuric acid group; the other product ions were identical with the fragment ions of M0. Accordingly, M2 was structurally identified as the sulfated conjugate of M0. The product ion at m/z 217.0 (Figure 4B) found by Q-trap-MS detection indicated the sulfation at the hydroxyl group on the phenyl ring.

Metabolite M3. Metabolite M3 was detected with an accurate $[M - H]^-$ ion at m/z 137.0607 (2.9 ppm, elemental composition of $C_8H_9O_2$). It was similar to the product ion at m/z 137.0599 of parent drug M0. The product ion at m/z 137.0599 was assigned as the aglycone, according to the structure of salidroside. The Q-TOF MS^2 fragmentations of M3, shown in Figure 3C, were observed at m/z 119.0476, 106.0411, and 93.0329. These two characteristic fragment ions at m/z 119.0476 and 93.0329 were formed by the loss of 18 Da (hydrone group) and 44 Da (vinyl alcohol group) from the $[M - H]^-$ ion at m/z 137.0599, respectively. The MS^2 product ion at m/z 106.0411 was formed by the loss of 13 Da (methenyl group) from the fragment ion at m/z 119.0476. According to our previous study, we also found the product ion at m/z 106.0411 from the aglycone standard.[18] Hence, M3 was identified as *p*-tyrosol, the aglycone of M0.

Metabolite M4. The Q-TOF MS spectrum of M4 (Figure 3D) provided an accurate $[M - H]^-$ ion at m/z 313.0927 (1.3 ppm, $C_{14}H_{17}O_8$), which was 176 Da (glucuronic acid group) higher than that of M3. Three major fragment ions were found at m/z 175.0241 (the $[M - H]^-$ ion of glucuronic acid), 137.0607 ($[M - H]^-$ ion of the aglycone *p*-tyrosol), and 113.0231 ($C_5H_5O_3$). According to the Q-trap MS^2 spectrum of M4 (Figure 4C), the product ion at m/z 295.1 indicated the glucuronidation was at the hydroxyl group on the phenyl ring.

Table 1. Retention Times, Measured and Calculated Masses, Accurate Masses, and MS/MS Product Ions of Salidroside (M0) and Its Metabolites (M1−M8)

metabolite	retention time (min)	elemental composition	measured mass $[M - H]^-$ (m/z)	predicted mass $[M - H]^-$ (m/z)	error (ppm)	fragment ions (m/z)	metabolite description
M0	7.23	$C_{14}H_{20}O_7$	299.1127	299.1131	−1.3	179.0562, 137.0599, 119.0496, 113.0230	null
M1	1.90	$C_{20}H_{28}O_{13}$	475.1456	475.1452	+0.8	175.0741, 137.0607, 113.0231	+ GlcA

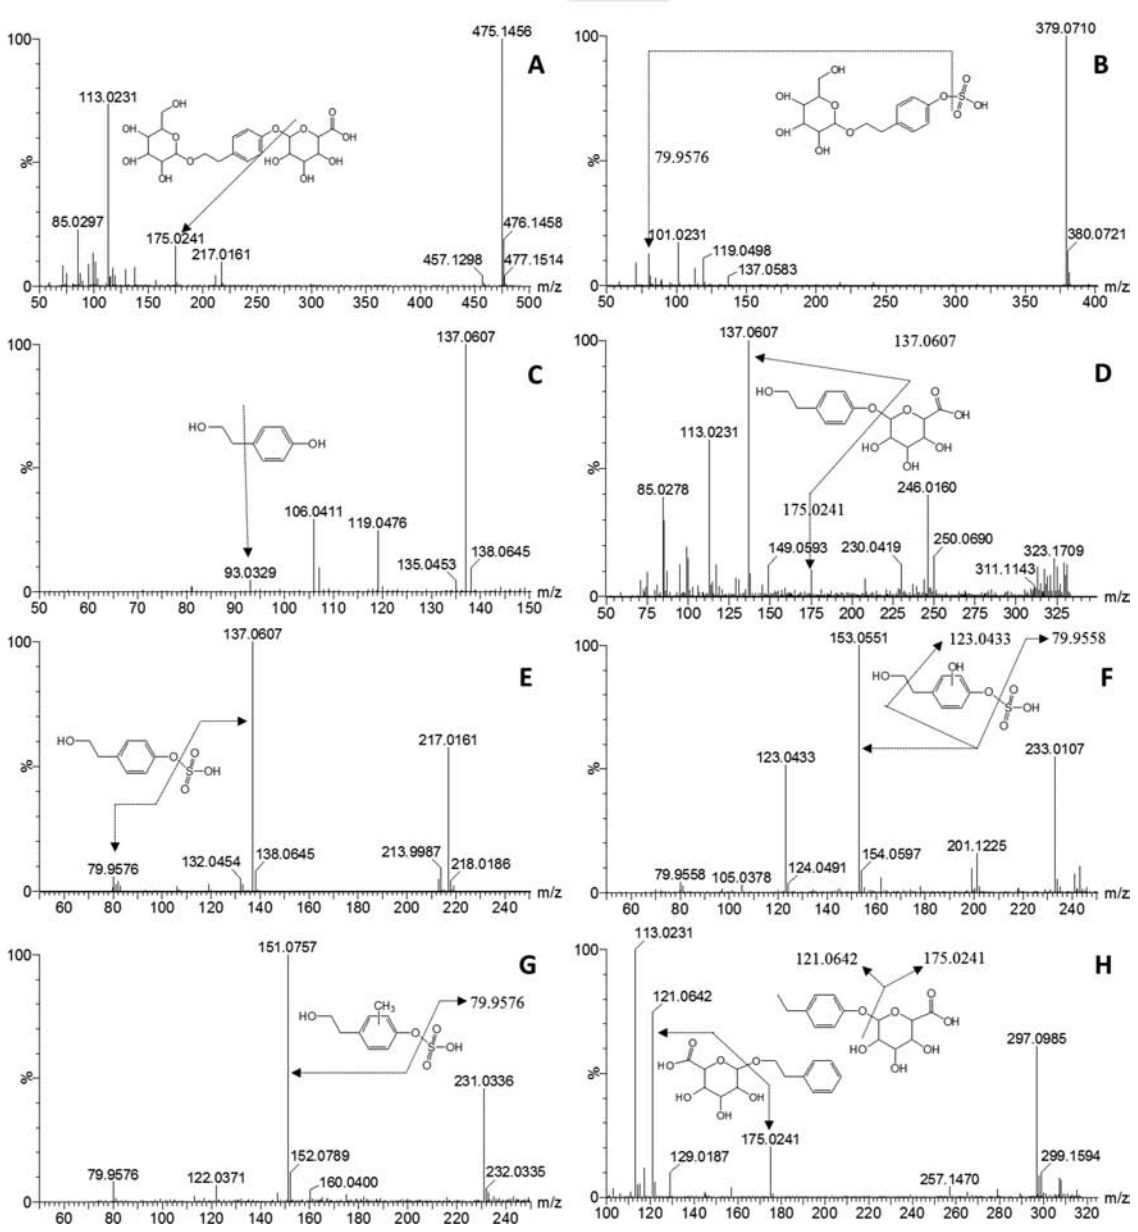

Figure 3. MS^2 spectra of metabolites M1 (A), M2 (B), M3 (C), M4 (D), M5 (E), M6 (F), M7 (G), and M8 (H) by UPLC/Q-TOF-MS. The MS^2 data were obtained with $[M - H]^-$ as the precursor ion.

M4 was identified as the glucuronidated product of M3 or the deglycosylation product of M1.

Metabolite M5. Metabolite M5 (Figure 3E) was detected with an accurate $[M - H]^-$ ion at m/z 217.0161 (−4.6 ppm, $C_8H_9O_5S$), which was 80 Da higher than that of M3, suggesting a sulfuric acid group was conjugated to M3. Fragment ions at m/z 137.0583 and 79.9576 of the Q-TOF MS^2 fragmentation also proved the existence of the aglycone and sulfate. The product ion at m/z 173.1 (Q-trap MS^2 spectrum, Figure 4D) of M5 indicated the sulfation was at the hydroxyl group on the phenyl ring. Therefore, M5 was the product from the sulfation of M3 or the deglycosylation of M2.

Metabolite M6. M6 (Figure 3F) was detected with an accurate $[M - H]^-$ ion at m/z 233.0107 (−5.6 ppm, $C_8H_9O_6S$). The molecular ion at m/z 233.0107 was 16 Da more than m/z 217.0161(M5), which suggested that M6 was a hydroxylation metabolite of M5. The fragment ion of M6 at m/z 153.0551 was also 16 Da more than the product ion at m/z 137.0583, and the ion at m/z 123.0433 was a further loss of hydroxymethyl (OCH_2) from the side chain of the ion at m/z 153.0551. The existence of 123.0433 proved that the hydroxylation occurred on the phenyl ring. The product ion at m/z 189.1 (Q-trap MS^2 spectrum, Figure 4E) of M6 further confirmed the sulfation position, the same as M5, was at the hydroxyl group on the phenyl ring. Hence, M6 was characterized as the hydroxylation product of M5.

Metabolite M7. The Q-TOF MS spectrum of M7 provided an accurate $[M - H]^-$ ion at m/z 231.0336 (3.9 ppm, $C_9H_{11}O_5S$). MS^2 fragmentation (Figure 3G) showed fragment ions at m/z 151.0757 and 79.9576. The molecular ion at m/z 231.0336 and its MS^2 fragment ion at m/z 151.0757 were 14 Da more than m/z 217.0161 (M5) and its product ion at m/z 137.0583. According to product ions at m/z 187.0 and 213.2 of M7 (Q-trap MS^2 spectrum Figure 4F), the position of

J. Agric. Food Chem. 2015, 63, 8999−9005

methylation can only be asserted on the phenyl ring, and the sulfation occurred at the hydroxyl group on the phenyl ring. Hence, M7 was characterized as the methylation product of M5.

Metabolite M8. M8 (Figure 3H) was detected at 4.54 min and with an accurate $[M - H]^-$ ion at m/z 297.0985 (3.7 ppm, $C_{14}H_{17}O_7$), Further MS^2 fragmentation (Figure 3H) showed fragment ions at m/z 175.0241, 121.0642, and 113.0231. The molecular ion at m/z 297.0985 and its MS^2 fragment ion at m/z 121.0642 were 16 Da less than m/z 313.0923 (M4) and its product ion at m/z 137.0583, suggesting M8 was the dehydroxylation product of metabolite M4. The diagnostic ions of glucuronic acid at m/z 175.0741 and 113.0231 were detected, further proving the glucuronidation. We failed to get the signals of M8 by Q-trap MS detection. We could not identify the exact position of dehydroxylation.

Metabolic Pathways of Salidroside in Rats. In the present study, metabolites in rat urine samples after oral administration of salidroside were detected and identified through UPLC/Q-TOF-MS and HPLC/Q-trap-MS. Eight metabolites have been characterized in the urine samples within 12 h after oral administration; most of these metabolites could not be detected after 12 h. *p*-Tyrosol (M3) was the only phase I metabolite detected, formed by deglycosylation of salidroside. Two phase II metabolites of salidroside were derived from glucuronidation (M1) and sulfation (M2). The other metabolites were phase II metabolites of *p*-tyrosol, including the direct glucuronidation (M4) and sulfation (M5) products. Puzzlingly, the sulfation of hydroxylated (M6) and methylated (M7) *p*-tyrosol and the glucuronidation of dehydroxylated *p*-tyrosol (M8) were identified, whereas the corresponding phase I metabolites were not detected. A possible explanation is that salidroside metabolizes to *p*-tyrosol, which probably experienced hydroxylation, methylation, and dehydroxylation in vivo and the phase I products readily converted to phase II metabolites M6, M7, and M8. We also tested the feces samples, but no metabolite was found. In our previous study, *p*-tyrosol was found in urine samples but not in plasma and feces samples after oral administration, which is consistent with our present results.[18,26] The possible structures of metabolites and predicted metabolic pathway are speculated in Figure 5.

In summary, salidroside and its deglycosylation phase I metabolite *p*-tyrosol were further metabolized to glucuronidation and sulfation products and mainly excreted through the urine excretion pathway.

[a]The assignments were based on DEPT and 2D NMR experiments.

(ODS) (MeOH in H_2O, from 81 to 92%) to yield three subfractions ($F_{2\text{-}1}$–$F_{2\text{-}3}$). $F_{2\text{-}1}$ was purified by HPLC (80% MeOH in H_2O) to obtain compound **1** (t_R = 42 min, 5.9 mg). Fraction F_3 afforded seven subfractions $F_{3\text{-}1}$–$F_{3\text{-}7}$ through the same MPLC (MeOH in H_2O, 78–94%). The further purification of $F_{3\text{-}2}$ afforded compounds **2** (t_R = 29 min, 69.4 mg) and **5** (t_R = 19 min, 7.6 mg) using the above HPLC system (84% MeOH in H_2O). Fraction F_4 (7 g) was fractioned on the same MPLC (76–92% MeOH in H_2O) to afford four subfractions $F_{4\text{-}1}$–$F_{4\text{-}4}$, and $F_{4\text{-}1}$ purified by the HPLC system (65% MeOH in H_2O) afforded compound **6** (t_R = 53 min, 14.2 mg). Fraction F_5 was chromatographed on MPLC (74–93% MeOH in H_2O) to give five subfractions $F_{5\text{-}1}$–$F_{5\text{-}5}$. The further purification of $F_{5\text{-}3}$ by HPLC (83% MeOH in H_2O) gave compound **7** (t_R = 23 min, 13.3 mg), while $F_{5\text{-}4}$ purified using HPLC (89% MeOH in H_2O) yielded compounds **3** (t_R = 22 min, 23.9 mg) and **4** (t_R = 35 min, 24.1 mg). On the basis of a similar procedure, fraction F_6 afforded seven subfractions $F_{6\text{-}1}$–$F_{6\text{-}7}$, and compound **8** (t_R = 16 min, 12.9 mg) was isolated from $F_{6\text{-}3}$ (84% MeOH in H_2O); fraction F_8 afforded eight subfractions $F_{8\text{-}1}$–$F_{8\text{-}8}$, and compounds **9** (t_R = 14 min, 17.8 mg) and **10** (t_R = 25 min, 20.8 mg) were isolated from $F_{8\text{-}4}$ (75% MeOH in H_2O).

(4*S*,6*S*,7*S*,8*R*)-1,6-*O*,*O*-Diisobutyrylbritannilactone (1). Yellow oil. $[\alpha]_D^{23}$: −18.8 (*c* 0.11, CH_2Cl_2). ECD (CH_3CN): 193 ($\Delta\varepsilon$ 1.50), 213 ($\Delta\varepsilon$ −5.64). IR (KBr) ν_{max}: 3423, 2957, 2924, 2871, 2851, 1766, 1731, 1662, 1464, 1403, 1378, 1347, 1320, 1274, 1191, 1154, 1038, 975, 946, 892, 853, 817, 760, 722, 638 cm^{-1}. ^{1}H NMR (400 MHz, $CDCl_3$) and ^{13}C NMR (100 MHz, $CDCl_3$) data: see Table 1. ESIMS *m*/*z*: 407 $[M + H]^+$. HR-ESIMS *m*/*z*: 407.2431 $[M + H]^+$, calcd for $C_{23}H_{35}O_6$ 407.2434.

(4*S*,6*S*,7*S*,8*R*)-1-*O*-Acetyl-6-*O*-(3-methylvaleryloxy)-britannilactone (2). Yellow oil. $[\alpha]_D^{23}$: −20.2 (*c* 0.16, CH_2Cl_2). ECD (CH_3CN): 193 ($\Delta\varepsilon$ 3.59), 212 ($\Delta\varepsilon$ −17.59). IR (KBr) ν_{max}: 3446, 2959, 2925, 2874, 2852, 1766, 1732, 1663, 1463, 1402, 1380, 1366, 1318, 1243, 1179, 1153, 1034, 976, 949, 893, 818, 637, 607 cm^{-1}. ^{1}H NMR (400 MHz, $CDCl_3$) and ^{13}C NMR (100 MHz, $CDCl_3$) data: see Table 1. ESIMS *m*/*z*: 429 $[M + Na]^+$. HR-ESIMS *m*/*z*: 429.2245 $[M + Na]^+$, calcd for $C_{23}H_{34}NaO_6$ 429.2253.

Japonicone U (3). Yellow oil. $[\alpha]_D^{23}$: +10.6 (*c* 0.23, CH_2Cl_2). ECD (CH_3CN): 212 ($\Delta\varepsilon$ −18.74), 238 ($\Delta\varepsilon$ 3.03). IR (KBr) ν_{max}: 3441, 2956, 2924, 2869, 2852, 1770, 1732, 1683, 1462, 1377, 1235, 1164, 1029, 984, 953, 916, 850, 816, 752, 633 cm^{-1}. ^{1}H NMR (400 MHz, $CDCl_3$) and ^{13}C NMR (100 MHz, $CDCl_3$) data: see Table 2. ESIMS *m*/*z*: 689 $[M + Na]^+$. HR-ESIMS *m*/*z*: 689.3299 $[M + Na]^+$, calcd for $C_{38}H_{50}NaO_{10}$ 689.3302.

Japonicone V (4). Yellow oil. $[\alpha]_D^{23}$: +13.0 (*c* 0.19, CH_2Cl_2). ECD (CH_3CN): 211 ($\Delta\varepsilon$ −20.36), 237 ($\Delta\varepsilon$ 3.10). IR (KBr) ν_{max}: 3443, 2956, 2924, 2869, 2852, 1770, 1732, 1670, 1463, 1377, 1236, 1166, 1126, 1085, 1030, 984, 919, 903, 815, 723, 701, 675, 633 cm^{-1}. ^{1}H NMR (400 MHz, $CDCl_3$) and ^{13}C NMR (100 MHz, $CDCl_3$) data: see Table 2. ESIMS *m*/*z*: 717 $[M + Na]^+$. HR-ESIMS *m*/*z*: 717.3613 $[M + Na]^+$, calcd for $C_{40}H_{54}NaO_{10}$ 717.3615.

Computational Methods. The calculated ECD spectra were obtained according to the published methods previously.[12,15,16]

Antiproliferative Activities. The antiproliferative activities of compounds **1**–**10** were evaluated by the 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) assay. Cells (1×10^4/well) were incubated for 48 h in the absence or presence of the tested compounds. Then, cells were incubated for another 4 h after adding MTT solution [5 mg/mL in phosphate-buffered saline (PBS)], and the formazan crystals were solubilized with dimethyl sulfoxide (DMSO). The absorbance was determined at 490 nm using a microplate reader (Thermo Fisher Scientific, Inc., Waltham, MA). Etoposide was used as a positive control. The experiments were performed in triplicate.

RESULTS AND DISCUSSION

Column chromatography (silica gel, MPLC, and HPLC) separation of the ethyl acetate layer from the methanol extract of the flowers of *I. japonica* afforded two new 1,10-*seco*-

[a]The assignments were based on DEPT and 2D NMR experiments.

eudesmanolide derivatives **1** and **2**, two new sesquiterpene lactone dimers **3** and **4**, and six known analogues **5**−**10** (Figure 1). The known compounds were identified as 1-*O*-acetyl-6-*O*-isobutyrylbritannilactone (**5**),[17] 1,6-*O*,*O*-diacetylbritannilactone (**6**),[17] 6-*O*-(3-methylvaleryloxy)britannilactone (**7**),[4] 6-*O*-isobutyryl britannilactone (**8**),[4] 1-*O*-acetyl-britannilactone (**9**),[17] and inulanolide A (**10**).[18]

Compound **1** was obtained as yellow oil, and its molecular formula was deduced to be $C_{23}H_{34}O_6$ by HR-ESIMS (HR-ESIMS m/z 407.2431 $[M + H]^+$, calcd for $C_{23}H_{35}O_6$ 407.2434), suggesting seven unsaturation degrees. The IR spectrum of compound **1** showed strong absorption bands of olefinic (1662 cm^{-1}), carbonyl (1731 cm^{-1}), γ-lactone (1766 cm^{-1}), and hydroxy (3423 cm^{-1}) groups. The ^{1}H NMR spectrum (Table 1) showed the presence of an *exo*-methylene at δ_H 5.94 (d 2.4) and 6.37 (d 2.7), two oxygenated methine protons at δ_H 5.19 (d 1.8) and 4.94 (ddd 7.8, 3.9, and 2.1), an oxygenated methylene proton at δ_H 3.93 (m), and six methyl protons at δ_H 0.86 (3H, d, 6.9), 1.14 (6H, d, 6.8), 1.16 (6H, d, 6.8), and 1.81 (3H, s). The ^{13}C NMR spectrum (Table 1) of compound **1** showed 23 carbon resonances. On the basis of the one-dimenisonal (1D) NMR spectra, two isobutyryl groups were obvious [δ_H 2.47 (m, H-2′), 1.14 (d, 6.8, H-3′), 1.16 (d, 6.8, H-4′) and 2.47 (m, H-2″), 1.14 (d, 6.8, H-3″), 1.16 (d, 6.8, H-4″); δ_C 177.0 (C-1′), 34.0 (C-2′), 18.8 (C-3′), 18.9 (C-4′) and 177.3 (C-1″), 34.2 (C-2″), 19.0 (C-3″), 19.0 (C-4″)]. The additional 15 resonances included two methyls, five methylenes (including an *exo*-methylene and one oxygenated methylene), four methines (including two oxygenated methines), and four quaternary carbons on the basis of distortionless enhancement by polarization transfer (DEPT) and heteronuclear multiple-quantum coherence (HMQC) spectra. According to the aforementioned spectroscopic evidence, the unsaturation degrees, and the *Inula* sesquiterpenes,[4,19,20] compound **1**

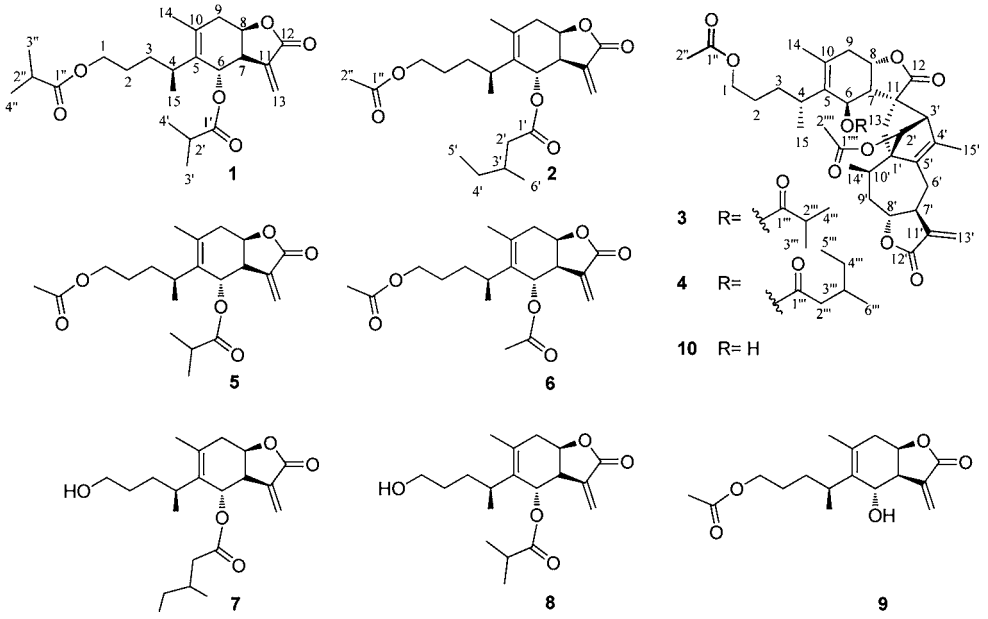

Figure 1. Structures of compounds **1**−**10** from the flowers of *I. japonica*.

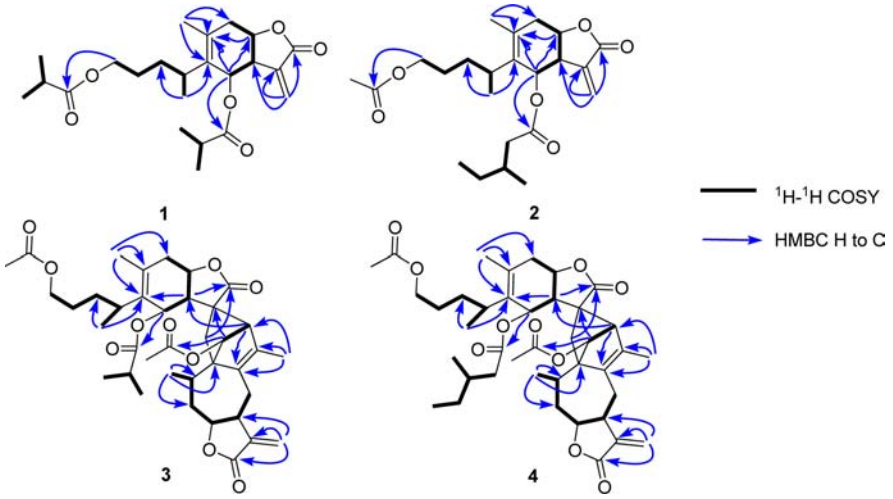

Figure 2. Selected HMBC and ^{1}H−^{1}H COSY correlations of compounds **1**−**4**.

might possess a 1,10-*seco*-eudesmanolide skeleton, which was confirmed by HMBC and ^{1}H−^{1}H correlation spectroscopy (COSY) experiments (Figure 2). HMBC correlations of H-1 (δ_H 3.93) with δ_C 177.3 and of H-6 (δ_H 5.19) with δ_C 177.0 placed two isobutyryl groups at C-1 and C-6, respectively. Further analyses of the two-dimensional (2D) NMR spectra led to the assignment of all of the proton and carbon signals, and the planar structure for compound **1** was thus established.

The relative configuration of compound **1** was determined on the basis of nuclear Overhauser effect spectroscopy (NOESY) experiment and coupling constants. The small coupling constants of H-6 with H-7 (d, 1.8 Hz) as well as NOESY correlations of H-7/H-8 and H-6/H$_3$-15 (Figure 3) suggested a *cis* configuration for the bicyclic ring and an α orientation of the 6-isobutyryl group. Through comparing the calculated and experimental ECD spectra, as shown in Figure 4, the absolute configurations of C-4, C-6, C-7, and C-8 in compound **1** were determined as 4*S*, 6*S*, 7*S*, and 8*R*, respectively. The structure of compound **1** was thus elucidated as (4*S*,6*S*,7*S*,8*R*)-1,6-*O*,*O*-diisobutyrylbritannilactone. The absolute configuration of compound **1** was consistent with the 1,10-*seco*-eudesmanolide derivative 1-*O*-acetylbritannilactone from *Inula britannica*, whose absolute configuration was

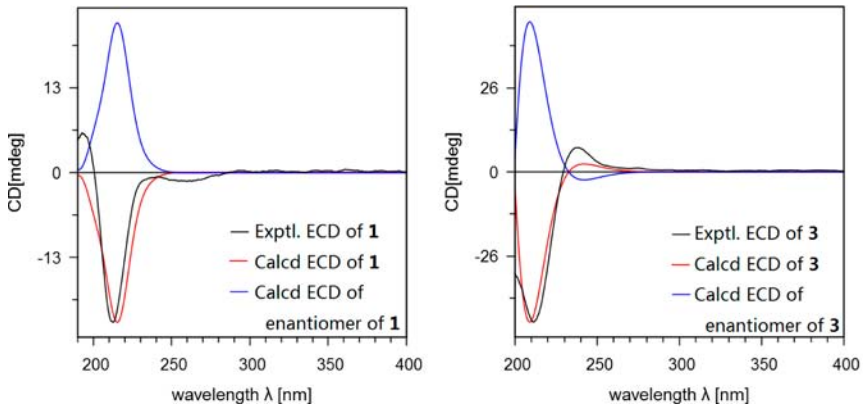

Figure 4. Calculated and experimental ECD spectra for compounds **1** (left) and **3** (right) in acetonitrile.

determined by single-crystal X-ray crystallography with Cu Kα radiation.[17]

Compound **2** possessed a molecular formula $C_{23}H_{34}O_6$ according to HR-ESIMS (HR-ESIMS *m/z* 429.2245 [M + Na]$^+$, calcd for $C_{23}H_{34}NaO_6$ 429.2253). The NMR data (Table 1) were comparable to those of compound **9**.[17] The only difference was that the hydroxy group at C-6 in compound **9** was replaced by the 3-methylvaleryloxy group in compound **2**. On the basis of confirmations with ^{1}H−^{1}H COSY, HMBC, and NOESY spectra (Figures 2 and 3), compound **2** was assigned to be 1-*O*-acetyl-6-*O*-(3-methylvaleryloxy)britannilactone. The ECD spectrum of compound **2** (Figure S24 of the Supporting Information) resembled that of compound **1** with the Cotton effects at 193 nm (positive) and 212 nm (negative), and the absolute configuration was thus defined as 4*S*, 6*S*, 7*S*, and 8*R*.

Compound **3** gave a molecular formula $C_{38}H_{50}O_{10}$ deduced from HR-ESIMS (*m/z* 689.3299 [M + Na]$^+$, calcd for $C_{38}H_{50}NaO_{10}$ 689.3302), indicating 14 unsaturation degrees. The ^{13}C and DEPT NMR spectra of compound **3** revealed 38 carbon signals, including 8 methyls, 8 methylenes, 10 methines, and 12 quarternary carbons, which was confirmed by HMQC (Table 2). It was obvious that two acetyl groups and one isobutyryl group (δ_C 171.1 and 20.9, δ_H 1.97; δ_C 170.8 and 21.1, δ_H 2.03; δ_C 175.7, 34.1, 18.7, and 18.5, δ_H 2.33 and 1.11) were present from the NMR spectra, including ^{1}H−^{1}H COSY and HMBC correlations (Table 2). On the basis of the spectroscopic data and the molecular formula, compound **3** might be a sesquiterpene dimer consisting of eudesmane and guaiane sesquiterpenoids.[6−10] A detailed comparison to known sesquiterpene dimer **10** revealed that the ^{13}C and ^{1}H NMR spectroscopic data of compound **3** resembled those of compound **10**, except for an isobutyryloxy group in compound **3** instead of the hydroxy group attached to C-6 in compound **10**. The locations of two acetoxy groups and one isobutyryloxy group were established by a HMBC experiment, revealing correlations of the proton signals at δ_H 3.95, 4.57, and 5.56 with δ_C 171.1 (C-1″), 170.8 (C-1‴″), and 175.7 (C-1‴), respectively (Figure 2). The further analysis of ^{1}H−^{1}H COSY and HMBC correlations confirmed it. The NOESY correlations of H-4/H-7, H-4/H-8, and H_3-15/H-6 were observed (Figure 3). The absolute configuration of compound **3** was also determined through the time-dependent density functional theory (TDDFT) ECD calculations. As shown in Figure 4, the calculated ECD spectrum of compound **3** matched the experimental result well (Figure 4), suggesting an absolute configuration of 4*R*, 6*R*, 7*R*, 8*S*, 11*S*, 1′*R*, 2′*R*, 3′*S*, 7′*S*, 8′*R*, and 10′*R* in compound **3**. The structure of compound **3** was therefore elucidated, and the compound was named japonicone U.

The molecular formula of compound **4** was deduced to be $C_{40}H_{54}O_{10}$ according to HR-ESIMS (*m/z* 717.3613 [M + Na]$^+$, calcd for $C_{40}H_{54}NaO_{10}$ 717.3615). The ^{13}C and ^{1}H NMR spectroscopic data of compound **4** (Table 2) resembled the sesquiterpene dimer japonicone Q,[9] except for an acetoxy group in compound **4** instead of the hydroxy group of C-1 in japonicone Q. Furthermore, the HMBC correlation from H-1 to C-1″ confirmed that the acetoxy group was located at C-1 (Figure 2). According to the above analysis, the structure of compound **4** was elucidated as shown (Figure 1). In the ECD spectrum (Figure S25 of the Supporting Information) of compound **4**, a negative Cotton effect appeared at 211 nm, while a positive Cotton effect was observed at 237 nm. The ECD features in compound **4** were identical with those of compound **3**, indicating that both compounds possessed the same configuration. The absolute configuration of compound **4** was therefore assigned to be 4*R*, 6*R*, 7*R*, 8*S*, 11*S*, 1′*R*, 2′*R*, 3′*S*, 7′*S*, 8′*R*, and 10′*R*, and the compound was named japonicone V.

The flowers of *I. japonica* have been employed for patients suffering from cancers.[3] Compounds **1**−**10** were therefore assayed *in vitro* for their antiproliferative activities against MCF-7 and MDA-MB-231 cells through the MTT method (Table 3). All of the isolated compounds displayed the antiproliferative

Table 3. Antiproliferative Activities of Compounds 1−10 against Two Human Breast Cancer Cell Lines

	IC$_{50}$ (μM)[a]	
compound	MCF-7	MDA-MB-231
1	>100	93.60 ± 6.10
2	15.56 ± 1.16	15.55 ± 1.93
3	29.64 ± 5.05	27.46 ± 3.54
4	0.20 ± 0.04	6.22 ± 1.30
5	32.30 ± 6.28	70.97 ± 3.42
6	68.00 ± 3.70	79.46 ± 8.59
7	26.34 ± 4.97	36.32 ± 3.91
8	23.64 ± 3.43	76.52 ± 4.78
9	>100	>100
10	6.69 ± 1.86	39.96 ± 2.31
etoposide[b]	21.78 ± 1.86	57.43 ± 0.56

[a]The data were expressed as means ± standard deviation. [b]Etoposide was used as a positive control.

DOI: 10.1021/acs.jafc.5b03075
J. Agric. Food Chem. 2015, 63, 9006−9011

effects. Compound **4** exhibited the most potent effect, with an IC_{50} value of 0.20 ± 0.04 μM against MCF-7 cells, followed by compounds **10** (6.69 ± 1.86 μM) and **2** (15.56 ± 1.16 μM). For the MDA-MB-231 cell line, all of the isolates, except compound **9**, showed significant cytotoxicity, with the IC_{50} values ranging from 6.22 ± 1.30 to 93.60 ± 6.10 μM. Compound **4** still displayed the highest antiproliferative activity (IC_{50} value of 6.22 ± 1.30 μM) against MDA-MB-231 cells, which was much more active than the positive control, etoposide.

In summary, ten 1,10-*seco*-eudesmanolide derivatives, including four new compounds, were isolated from the flowers of *I. japonica*. The antiproliferative potencies of these compounds were investigated through the MTT assay. The results revealed that some of them, especially the new compound **4**, showed strong antiproliferative effects on the human breast cancer cells and might be used as potential antitumor chemotherapy agent candidates.

Figure 1. Tuber appearance of the 12 iron biofortified potato clones under investigation.

or ferric iron (Fe(III)). Ferric iron, the likely predominant form of iron in potato tubers,[19] must be first reduced to Fe(II) to be taken up by the divalent metal ion transporters of the intestinal epithelial cells.[20] Intracellular iron concentration, storage, and detoxification are further under the control of the ferritin protein. Non-heme iron absorption may be enhanced by simultaneous intake of vitamin C, citric acid, and animal proteins, whereas phytates, calcium, and phenolic compounds may inhibit the absorption. Potato tubers contain significant amounts of vitamin C, which is a potent enhancer of iron uptake in humans. Phenolic compounds, also present in potato, may, on the other hand, reduce in general iron uptake, through the formation of insoluble complexes with ferric iron in the gastrointestinal tract.[21] A recent study showed however that some phenolic compounds may promote iron absorption, stressing the complexity of the interactions of this large family of compounds.[22]

Given the time and expense required for in vivo trials, in vitro models have been developed to estimate iron bioavailability from food.[23] In combination with simulated human gastrointestinal digestion, the Caco-2 cell model has been demonstrated to be effective in comparing iron bioavailability from diverse bean, rice, and maize genotypes.[24−26] The Caco-2 cell line is derived from a human colorectal adenocarcinoma. These cells may undergo differentiation and polarization to form monolayers of intestinal epithelial cells. Ferritin level in cells is a sensitive marker of iron uptake and enables measurement of iron availability in vitro.[24]

The purpose of this study was to compare the in vitro iron availability from diverse iron biofortified International Potato Center (CIP) potato clones grown in the Peruvian Andes and, thereby, to provide key information to breeders seeking to increase bioavailable iron from potato. Caco-2 cells were used as a model of human intestine, with ferritin formation as a marker of iron absorption.[27] The bioaccessibility of iron, vitamin C, phenolic compounds, and carotenoids were first measured following an in vitro gastrointestinal digestion procedure[28] in order to get a better picture of the potential interactions that could explain the observed variations in the bioavailability of iron from potato tubers.

MATERIALS AND METHODS

Chemicals. Solvents [of analytical or high-performance liquid chromatography (HPLC) grade as required] were obtained from VWR International (Leuven, Belgium). Carotenoid standards (lutein, neoxanthin, violaxanthin, zeaxanthin, antheraxanthin, β-cryptoxanthin, β-carotene, and lutein-5,6-epoxide) were purchased from Carotenature (Lupsingen, Switzerland). Phenolic compounds (chlorogenic acid, neochlorogenic acid, cryptochlorogenic acid, caffeic acid, gallic acid, and rutin) were purchased from Sigma-Aldrich (St. Louis, MO). Kaempferol-3-rutinoside and petanine were obtained from Extrasynthese (Genay, France). All digestive enzymes were purchased from Sigma-Aldrich (St. Louis, MO). Nitric acid (HNO_3) and H_2O_2 for the mineral analyses were obtained from LGC Standards (Molsheim, France) and Fisher Scientific (Tournai, Belgium), respectively. Cell culture media, unless otherwise specified, were purchased from Invitrogen (Groningen, The Netherlands).

Plant Materials. Twelve diploid ($2n = 2x = 24$) potato clones, from the biofortified potato population developed at the International Potato Center (CIP), were used for this study (Figure 1). Samples of the 12 clones were obtained from a field trial planted in April 2013 at CIP's experimental station in Huancayo (Peru, 3280 m above sea level) and harvested in September 2013. Recommended agronomical practices were applied. Five to ten representative mature tubers were collected at harvest, washed, and shipped to the Luxembourg Institute of Science and Technology (LIST), where they were stored in incubators at 10 °C prior to sampling and analysis. Tubers were washed thoroughly with acidified water (pH 3) in order to remove any soil residues and avoid mineral contamination of the samples. They were further rinsed with demineralized water. For cooking, demineralized water was added in stainless steel pots and brought to boiling on induction plates. Unpeeled tubers were cooked for 10−15 min. Once cooked, tubers were peeled using ceramic knives to avoid

DOI: 10.1021/acs.jafc.5b02904
J. Agric. Food Chem. 2015, 63, 9012−9021

metal contamination and pureed in a mortar and pestle. Homogenized samples were further submitted to the in vitro digestion protocol, while representative samples were frozen in liquid nitrogen, and kept at −80 °C until chemical analysis.

In Vitro Digestion. The in vitro digestion protocol was performed as described by Miranda et al.[28] Approximately 10 g of boiled potato flesh underwent in vitro digestion. The digestions were performed in triplicate. Salivary digestion was first simulated by adding 5 mL of α-amylase in NaCl 0.9% (450 U/g of potato flesh) at pH 6.9 and shaking for 10 min at room temperature. For the gastric step, pepsin (6500 U/g of potato flesh) and 25 mL of NaCl 0.9% were added. The pH was decreased to 2 with HCl. The mixture was then shaken for 1 h at 37 °C. For the duodenal step, the pH was increased to 5.5 using $NaHCO_3$ 1 M. Bile extract (11 mg/g of potato flesh) and pancreatin (1.8 mg/g of potato flesh) were then added and the incubation volume was set to 50 mL. The digestion mixture (pH 7) was then further shaken for 2 h at 37 °C. The final digestion extract was centrifuged (5000*g* for 20 min at 4 °C) and the supernatant was filtered (PVDF, 0.2 μm). Digests were then flash frozen in liquid nitrogen and kept at −80 °C until further analysis. A control was made using the digestive enzymes in the same conditions without plant material. For cytotoxicity and iron uptake experiments, the potato digests were quickly thawed by mixing in a water bath at 37 °C, directly appropriately diluted, and added onto the Caco-2 cells.

Vitamin C Analysis. *Extraction.* The extraction of vitamin C was conducted as described previously by Andre et al.[9] Briefly, approximately 750 mg of boiled material was weighed in a 15 mL Falcon tube and 4 mL of an aqueous solution containing 5% metaphosphoric acid and 1% dithiothreitol were added. The dithiothreitol allows the reduction of dehydroascorbic to ascorbic acid and thereby quantifying ascorbic acid as total vitamin C content. Therefore, we quantified the total vitamin C, which includes both molecules. After shaking the samples for 1 h at 4 °C, the samples were centrifuged (5000*g*, 15 min, 4 °C). The supernatant was collected and the extraction was repeated. The pooled supernatants were filtered (0.2 μm) and analyzed by high-performance liquid chromatography coupled with a diode array detector (UPLC-DAD). The extraction was done in triplicate. For the analysis of potato digests, 0.5 mL of digest was mixed with 0.5 mL of an aqueous solution containing 10% metaphosphoric acid and 2% dithiothreitol, shaken for 30 s at 4 °C, centrifuged (5000*g*, 5 min, 4 °C), and filtered (0.2 μm) prior to analysis.

UPLC-DAD Analysis. The quantification was carried out using a Waters Acquity UPLC system (Milford, MA) equipped with a photodiode array detector. An aliquot of 5 μL was injected onto an Acquity UPLC HSS T3 column (2.1 × 100 mm, 1.8 μm particle size, Waters, Milford, MA) at 40 °C and a flow rate of 0.5 mL/min. The eluents were 0.1% formic acid in water (A) and 0.1% formic acid in acetonitrile (B). The gradient was as follows: 0 min, 0% B; 1.5 min, 0% B; 2 min, 100% B; 5 min, 100% B; 5.5 min, 0% B; 7 min, 0% B. Ascorbic acid was detected at 243 nm according to its absorption maximum and quantified using a six-point calibration curve. Furthermore, a validation standard was injected after every tenth sample injection.

Phenolic Compound Analysis. *Extraction.* The extraction of phenolic compound was conducted as described previously by Andre et al.[8] Briefly, approximately 750 mg of fresh or boiled material was weighed in a 15 mL Falcon tube and 10 mL of methanol/water/acetic acid (80:19.5:0.5, v/v/v). This mixture was homogenized using a vortex for 30 s and shaken for 2 h at room temperature. After centrifugation at 5000*g* for 15 min at 4 °C, the supernatant was collected and evaporated to dryness in a SpeedVac concentrator (Heto, Thermo Electron Corp., Waltham, MA). Polyphenols were resuspended in 1 mL of an aqueous solution containing 5% methanol and filtered through a 0.2 μm PVDF syringe filter prior to UPLC-DAD injection. For the analysis of potato digests, 1 mL of filtered digest was kept in an amber HPLC vial prior to analysis.

UPLC-DAD Analysis. The quantification was carried out as reported by Deußer et al.,[29] using the same equipment and column described for the vitamin C analysis. The injection volume was 10 μL, the column temperature was 50 °C, and the flow rate was 0.75 mL/min. The eluents were 0.1% trifluoroacetic acid in water (A) and 0.1% trifluoroacetic acid in acetonitrile (B). The gradient was as follows: 0 min, 5% B; 9.27 min, 5% B; 13.53 min, 14% B; 22.60 min, 35% B; 23 min, 95% B; 25 min, 95% B; 26 min, 5% B. Phenolic compounds were detected at 280, 320, 360, or 520 nm according to their absorption maximum. For quantification, a six-point calibration curve was used. Furthermore, a validation standard was injected after every tenth injection. Anthocyanins were quantified as petanin equivalents.

Carotenoid Analysis. *Extraction.* Approximately 0.75 g of material was mixed with 5 mL of acetone. This mixture was homogenized using a vortex for 30 s and shaken on ice for 30 min to allow extraction of the lipophilic compounds. After centrifugation at 5000*g* for 15 min, the supernatant was collected. The extraction was repeated on the pellet using the same extraction solvent. Both supernatants were combined, evaporated to dryness under a gentle stream of nitrogen, and resuspended in 1 mL of MTBE:MeOH (1:1). The samples were filtered (0.2 μM) into an HPLC amber vial and stored at −80 °C prior to analysis. For the intestinal filtrates, a 4 mL aliquot was first mixed with 1 mL of 30% methanolic KOH and incubated for 30 min on ice. Carotenoids were extracted by addition of 4 mL of hexane:acetone (1:1, v/v), shaken for 1 min, and centrifuged for 2 min at 5000*g* at 4 °C to hasten phase separation. The hexane phase was collected and transferred into a second tube. The extraction process was repeated with 4 mL of hexane and the combined hexane phases were dried under a stream of nitrogen using a TurboVapLV apparatus (Biotage, Sweden). The residue was redissolved in 500 μL of MTBE/MeOH (1:1/v:v), filtered through a 0.2 μm PVDF syringe filter and stored at −80 °C until analysis.

UPLC-DAD Analysis. For the carotenoid quantification, an Acquity UPLC BEH C18 column (2.1 × 100 mm, 1.7 μm particle size, Waters) was used as described by Kaulmann et al.[30] The eluents were (A) ammonium acetate (50 mM):methanol (60:40, v/v) and (B) acetonitrile:dichloromethane (80:20, v/v), and the gradient was as follows: 0 min, 42% B, flow rate 0.35 mL/min; 4 min, 47% B; 11 min, 47% B; 13 min, 80% B, flow rate 0.40 mL/min; 18 min, 85% B; 29 min, 85% B, flow rate 0.35 mL/min; 30 min 42% B. The injection volume was 2.5 μL. Carotenoids were detected and quantified at 442 nm (violaxanthin, neoxanthin), 447 nm (lutein, antheraxanthin), and 453 nm (zeaxanthin, β-carotene) using six-point calibration curves.

Determination of Iron Content. Raw and cooked samples (about 1 g of fresh weight) were mineralized in 7 mL of nitric acid (HNO_3 for trace analysis minimum 67%) and 3 mL of H_2O_2 (30% w/w). For the mineralization of intestinal filtrates (3 mL), a mixture of 1.75 mL of HNO_3 and 0.75 mL of H_2O_2 was used. Acid mineralization was then performed in PFA tubes in a microwave oven (Anton Paar Multiwave Pro, Graz, Austria) by increasing temperature and pressure until 200 °C and 30 bar. At the end of the procedure, samples were diluted with demineralized water up to 25 mL for potatoes and up to 10 mL for filtrates, and kept at 4 °C prior to analysis. Blanks for all samples and a certified reference material for potatoes (spinach, NCS ZC 73013, LGC standards, France) were included at each mineralization cycle for quality control. The extraction was performed in triplicate for each clone on boiled and digestion materials. Samples were analyzed by inductively coupled plasma mass spectrometry (ICP-MS, PerkinElmer Elan DRC-e,Waltham, MA) as described by Lefèvre et al.[31] The concentrations in aluminum and chrome were also determined to detect any potential contamination and were below 2 and 0.04 ppm, respectively.

Cell Viability. Cytotoxicity of the potato digestion mixtures was determined using the resazurin/Alamar Blue assay. Cells were first seeded into 96-well plates at 1×10^4 cells per well and allowed to attach at 37 °C for 18 h. Cells were then exposed to digests for 24 h. Culture medium was then removed and 100 μL of cell culture medium containing 500 μM resazurin was added to each well. After 2−3 h, the formation of resorufin by cellular metabolic activity was recorded using a microplate fluorometer (excitation wavelength 530 nm, emission at 590 nm, 37 °C). A negative control with no cells was used for background subtraction. The percentage of cell viability was calculated using the nontreated cells as positive control (100% cell viability). The

DOI: 10.1021/acs.jafc.5b02904
J. Agric. Food Chem. 2015, 63, 9012−9021

toxicity of the 12 potato tubers digests has been evaluated. As a conclusion, the digests will be diluted 5 times before our iron absorption experiments. At this concentration, there was no significant difference with the negative control (100% cell viability) for any potato clones.

Cell Culture and Ferritin Measurement. The TC-7 Caco-2 subclone cells (ATCC No. HTB-37) were a generous gift from Monique Rousset (INSERM, Paris, France). Cells were seeded (50 000 cells/cm^2) into six well plates (VWR) and grown in Dulbecco's modified Eagle's medium + GlutaMAX (DMEM, Invitrogen, Halle, Belgium) with 10% fetal bovine serum (FBS, Gibco, Halle, Belgium), 1% penicillin/streptomycin (Gibco), and 1% nonessential amino acids (Sigma-Aldrich, St. Louis, MO). Cells were maintained in FBS at 37 °C in an incubator with 10% CO_2/90% O_2 under constant humidity.

Protocol 1. Cells were maintained in DMEM supplemented with 10% FBS, which was changed every couple of days. Cells were used for experiments 14 days after seeding. The integrity of the monolayer was verified by optical microscopy. At 48 h prior to the experiment, the growth medium was removed from culture wells, the cell layer was washed with phosphate buffered saline (PBS), and the growth medium was replaced with minimum essential medium (MEM) at pH 7.0. The MEM was supplemented with 10 mmol/L PIPES, 1% antibiotic/antimycotic solution, 4 mg/L hydrocortisone, 5 mg/L insulin, 5 μg/L selenium, 34 μg/L triiodothyronine, and 20 μg/L epidermal growth factor, as described by Glahn et al.[24] Caco-2 cells were treated with or without 20 μM $FeCl_3$ and 1 mM ascorbic acid to induce ferritin synthesis, as well as with or without solutions containing 20% intestinal filtrate diluted in MEM (v/v). Incubation was done for 4 h. The treatment was then removed and replaced by MEM for 20 h.

Protocol 2. After seeding, cells were maintained in DMEM supplemented with 2% FBS, which was changed every couple of days. Cells were used for experiments 14 days after seeding as described in protocol 1. At 48 h prior to the experiment, the growth medium was replaced with supplemented MEM. Caco-2 cells were treated with or without 4 μM $FeCl_3$ and 1 mM ascorbic acid to induce ferritin synthesis, with or without 100 μM $FeSO_4$, as well as with or without solutions containing 10 or 20% intestinal filtrate diluted in MEM (v/v). Incubation was done for 24 h.

Cell Harvest and Ferritin Analysis. Cells were lysed in ice-cold extraction buffer: 50 mM HEPES pH 7.6, 50 mM KCl, 50 mM NaF, 5 mM NaPPi, 5 mM EDTA, 5 mM EGTA. Inhibitor cocktail (P-8340, Sigma-Aldrich, St. Louis, MO) and Triton X-100 (1%) were added extemporaneously. The lysate was centrifuged (20 min/16000g/4 °C). Ferritin levels were determined using the human ferritin enzyme-linked immunosorbent assay (ELISA) kit provided by Biovendor (Brno, Czech Republic). The plates were read at 450 nm with a luminometer (Synergy 2, Biotek Instruments, Inc.; Drongenbos, Belgium). Results were normalized by total protein concentration measured by spectrophotometry using a Bradford kit (Biorad) and bovine serum albumin (BSA) as a standard.

Statistical Analyses. Pearson and Spearman Rank correlation coefficients were determined on (log-transformed, when necessary) data to evaluate relationships between variables. ANOVA and Tuckey tests were carried out on the bioavailable iron (ferritin) values. Principal component analysis (PCA) was performed on standardized data to evaluate the contribution of the different variables (iron, bioactives) to iron bioavailability. For these purposes, the statistical software R (www.r-project.org, version 2014) and SigmaPlot 12.5 (Systat Software Inc., San Jose, CA) were used.

RESULTS AND DISCUSSION

Concentration and Bioaccessibility of Iron, Vitamin C, Carotenoids, and Phenolics in Boiled Potatoes. The total iron concentrations in boiled peeled potato tubers ranged from 21.29 μg/g dry weight (DW) for the clone CIP_311200.003 to 39.47 μg/g DW for the clone CIP_311422.019, with an average value of 29.9 μg/g DW (Table 1). Five of the biofortified clones evaluated showed iron concentrations above 30 μg/g, a concentration that is similar to the unique highest value reported for the native Andean landrace CIP_703274.[1] The percentage of iron bioaccessibility, i.e. the amount of iron that is released during digestion, was genotype-dependent and varied from 63.7 to 79.0%, with an average value of 70.6% (Table 1). There was a strong positive relationship between the iron concentrations in the boiled tuber and the iron recovered after in vitro digestion ($r = 0.93$, $p < 0.01$), suggesting that tuber iron values are good indicators of the bioaccessible fraction. To our knowledge, this is the first report on the bioaccessibility of iron from potato. In vitro bioaccessibility of iron has been evaluated in various cereals and legumes, showing values, in general, that are lower than the ones presented here for potato. Lestienne et al.[32] reported iron bioaccessibility of about 10% from whole pearl millet flour, which increased to 24% after dephytinization. The bioaccessibility of iron from fava bean, soybean, and rice has also been shown to increase from 6.3 to 31.5%, from 6.2 to 30.7%, and from 5.6 to 19%, respectively, after phytate degradation through germination.[33] Wheat iron bioaccessibility was low (4.6%), with no improvement seen after dephytinization.[33] It is worth stressing that our study was performed on cooked and pureed material, which may not be the case for the above-mentioned studies.

Our in vitro digestion procedure allowed us to estimate that the consumption of 200 g of potato tubers triggers mean iron concentrations of 20 μM at the intestinal level (considering that potato is diluted in 1 L of gastrointestinal fluids). It is worth noting that these values represent the total bioaccessible iron content and do not reflect the bioavailable iron. Also, this measurement does not give any information about iron species. On top of this, potato is a complex matrix containing numerous components that may improve or inhibit iron absorption.[6] Absorption of non-heme iron can be improved or impeded by the binding of iron to compounds such as chelators and ligands that create complexes. Vitamin C, along with citric acid, has been described as a potent enhancer of iron uptake.[34] On the other hand, oxalic acid, phytates (as described earlier), calcium, and zinc, as well as some phenolic compounds, may reduce iron absorption.[28] Although less well-documented, carotenoids may interact with minerals including iron and form precipitates that

DOI: 10.1021/acs.jafc.5b02904
J. Agric. Food Chem. 2015, 63, 9012−9021

could potentially reduce their absorption.[35] In this study, we focused on the predominant potato phytochemicals, i.e. vitamin C, phenolic compounds, and carotenoid compounds. As was done for iron, we determined the levels of these compounds in boiled material tubers well as in intestinal digests.

The average total vitamin C concentration in boiled potato tubers was 526 μg/g DW (Table 2). About 32% of this content remained in the intestinal digest. This reduction is likely due to the instability of the compound at the pH and temperature conditions of the in vitro digestion procedure and/or the reduced extent of release from the potato matrix. To our knowledge, this is the first report on vitamin C bioaccessibility from potato tubers. Higher levels of degradation have been observed in tomatoes,[36] broccoli,[37] and blended fruit juice,[38] showing bioaccessibility values of 0, 9, and 15%, respectively, which could be due to differences in the matrix composition but also in the gastrointestinal digestion protocol.

[a]Data are expressed on a dry weight basis ± SD (n = 3).

The potato carotenoid pattern was dominated by lutein and zeaxanthin, followed by antheraxanthin, violaxanthin, neoxanthin, and β-carotene (Table 3). Their identification was confirmed by comparison of their retention times and UV spectra with those of authentic standards. The clones CIP_311575.003, CIP_311575.013, and CIP_311623.105 presented the highest total carotenoid contents and the highest zeaxanthin concentrations in particular. The bioaccessibility of lutein and zeaxanthin in the 12 biofortified clones ranged from 53 to 160% and from 24 to 388%, respectively. The bioaccessibility of lutein and zeaxanthin in the yellow clones (CIP_311575.003, CIP_311575.013, and CIP_311623.123) ranged from 76 to 82% for lutein and from 24 to 55% for zeaxanthin. In a recent study, Burgos et al.[39] estimated that the bioaccessibility of lutein and zeaxanthin in yellow fleshed potatoes ranged from 33 to 71% and from 51 to 71%, respectively. Interestingly, the gastrointestinal digestion process allowed release of zeaxanthin from the potato matrix of five clones to a greater extent than that observed in the respective boiled samples. Chemical extraction from boiled material may therefore underestimate carotenoid amounts that can be released during digestion and that are actually bioaccessible. On the other hand, the efficiency of micellarization or bioaccessibility of the other carotenoids could not be determined, as they were below the detection limit in the intestinal digest. This is likely due to the in vitro digestion method we used, which created favorable conditions for water-soluble compounds and limiting ones for the production of mixed micelles, essential for lipophilic compounds such as carotenoids. The bioaccessibility of carotenoids (micellarization) is largely enhanced when dietary fat is consumed together with carotenoids. In addition, the concentrations in β-carotene were already low in boiled potatoes. Indeed, the β-carotene level is usually negligible in the tubers of commercial potato varieties whereas it is detected in low but quantifiable amounts in some native Andean cultivars.[8]

The phenolic profile of potato extracts was dominated by chlorogenic acid, neochlorogenic acid, cryptochlorogenic acid, caffeic acid, rutin, kaempferol-3-rutinoside, and ferulic acid as a minor component (Table 4). The presence of anthocyanins was also detected in purple-fleshed clones. The mean bioaccessibility value for total chlorogenic acids (sum of the three chlorogenic acid isomers) was 24.5%, with clones CIP_311623.123 and CIP_311611.079 showing the highest bioaccessibility values (82 and 65%, respectively). Similarly, the bioaccessibility of total chlorogenic acids evaluated in another study on apple cultivars ranged from 32 to 57%.[40] Using two Luxembourg-grown potato varieties, Miranda et al.[28] showed however higher concentrations of chlorogenic acids in the intestinal filtrate than in boiled potatoes. It is worth noting that some components such as rutin and kaempferol-3-rutinoside were not detectable in boiled tubers of some genotypes under investigation but were released during digestion, suggesting that a traditional solvent extraction on boiled material may also underestimate the presence of phenolic compounds that are actually bioaccessible. The bioaccessibility of anthocyanins across the purple-fleshed clones ranged from 40 to 81%, which is similar to the recovery rate observed in chokeberries.[41] Much lower bioaccessibility values have however been reported in the literature with regard to anthocyanins, due to their high instability in the mild alkaline intestinal environment.[40] Discrepancies could be explained by the variability of the in vitro digestion protocols and also by the type of anthocyanins present in the plant matrix. Interestingly, most anthocyanins present in purple-fleshed potato tubers are acylated with hydroxycinnamic acids, which are known to increase the stability of the compounds.[8]

No significant overall correlation was evident between iron bioaccessibility and vitamin C, carotenoid, and phenolic concentrations. However, the highest iron bioaccessibility was observed in the clone CIP_311575.003 that also presented the highest vitamin C concentration, while the lowest bioaccessibility values were observed in three purple-fleshed clones with high levels of anthocyanins and chlorogenic acid (CIP_311422.016, CIP_311097.055, and CIP_311420.074).

Evaluation of the in Vitro Bioavailability of Iron from Boiled Potatoes. We used an in vitro Caco-2 cell culture model to evaluate iron bioavailability from potato tubers by measuring ferritin formation in the cells (i.e., a measure of cell iron uptake) following exposure to digests of the samples. The toxicity of the digests of the 12 genotypes was first evaluated and the cell viability was above 70% for all accessions when used at 20% on the cells. Following classical culture conditions (protocol 1), ferritin values for the control (MEM only) were about 9 ng/mg of protein. As expected, ferritin synthesis was induced up to 190 ng/mg of protein in Caco-2 cells supplemented with 20 μM $FeCl_3$ and 1 mM vitamin C. These values are in agreement with those described in the

literature.[28] There were no significant changes in ferritin concentrations when the cells were exposed to an in vitro digestion blank as compared to the control values, indicating that the variations in ferritin levels observed from potato digests are due to their constituents and not to the digestion enzyme mixture. Intrinsic iron bioavailability from the digests of the 12 genotypes was first evaluated. Ferritin concentrations were not significantly different from the baseline (control exposed to MEM only, data not shown). Similar results have previously been reported with this Caco-2 in vitro model and high phenolic-containing food such as beans.[25,42] The influence of potato components on the uptake of extrinsic iron was then investigated. The data for the Caco-2 cell ferritin formation following exposure to the digests of the 12 genotypes are summarized in Figure 2. The data are presented as the percentage of the response of the positive control (exposure to digest blank containing 20 μM $FeCl_3$ and 1 mM vitamin C). In the presence of 20% potato digest, the iron absorption ranged from 1.8% for the clone CIP_311422.016 to 8% for CIP_311624.021 as compared to the reference control. It appears therefore that potato digests host components that may interact with iron and reduce its absorption. Significant differences were found between the genotypes, with CIP_311200.003 and CIP_311624.021 exhibiting higher in vitro iron bioavailability when compared with the remaining genotypes. On the other hand, the purple-fleshed clones with the highest levels of total anthocyanins and chlorogenic acid (CIP_311422.016, CIP_311097.055, CIP_311420.074, and CIP_311422.014) showed the lowest iron bioavailability. In order to identify the major contributors or inhibitors of the in vitro iron bioavailability, a principal component analysis (PCA) was performed on the total iron content, bioactive composition, and ferritin values (Figure 3). The first two principal components (PC) accounted for 51.37% of the total variance. There was no association between variation for cell ferritin and total iron content. Interestingly, cell ferritin formation was associated with total vitamin C content and was inversely related to the phenolic compound levels, in particular total anthocyanins, caffeic acid, rutin, and kaempferol-3-rutinoside, as well as to chlorogenic acid.

Effect of Potato Digests on Iron Uptake Using Iron-Deprived Caco-2 Cells. In order to mimic anemic conditions and thereby increase the reactivity of the cells when exposed to iron, Caco-2 cells were cultured in low-iron media postseeding (see Protocol 2 under Material and Methods). The basal ferritin level was successfully reduced from 9 to 3 ng/mg of protein. Cells appeared much more reactive, showing an increase of ferritin expression up to 174 ng/mg of protein when exposed to 4 μM $FeCl_3$ (+1 mM vitamin C), an induction similar to the one we previously obtained with 20 μM $FeCl_3$ (and 1 mM vitamin C) following protocol 1. The value of 4 μM $FeCl_3$ is also the average iron concentration found in potato digests after a 5-fold dilution as used in our Caco-2 experiments. Using four contrasting genotypes in terms of iron and bioactive composition (Figure 3, genotypes in bold), the intrinsic iron bioavailability from 20% potato digest was evaluated, with no significant induction of ferritin (data not shown), as previously described with protocol 1. It appears that even with iron-deprived cells the inhibition of iron uptake is strong. The addition of 4 μM FeCl3 and 1 mM ascorbic acid induced ferritin expression, with iron uptake ranging from 4% for the clone CIP_311422.014 to 6.2% for CIP_311624.021 (Figure 4). Ferritin synthesis was further increased when the potato digests were diluted down to 10% of the media, confirming the inhibitory role of potato constituents. It is noteworthy that the yellow-fleshed clone CIP_311624.021 triggered consistently higher in vitro iron bioavailability as compared to its counterparts, suggesting a reduced level of inhibitors (including phenolic compounds) in that cultivar.

Conclusions. We showed that more than 50% of the potato iron is released from the matrix during the in vitro digestion and is therefore available at the intestinal level. Hydrophilic bioactive components such as vitamin C and phenolic compounds in potato tubers are also bioaccessible to a large extent. The intestinal absorption of intrinsic iron from potato tubers could however not be detected using our in vitro Caco-2 cell model. Inhibition of iron uptake is typically reported for foods containing high levels of phenolic compounds, which could partly explain our results. Only human studies will provide a clear and valid percentage of iron absorption from potatoes. Indeed, a recent human study showed significant iron absorption from test meals based on pearl millet (7.5%),[43]

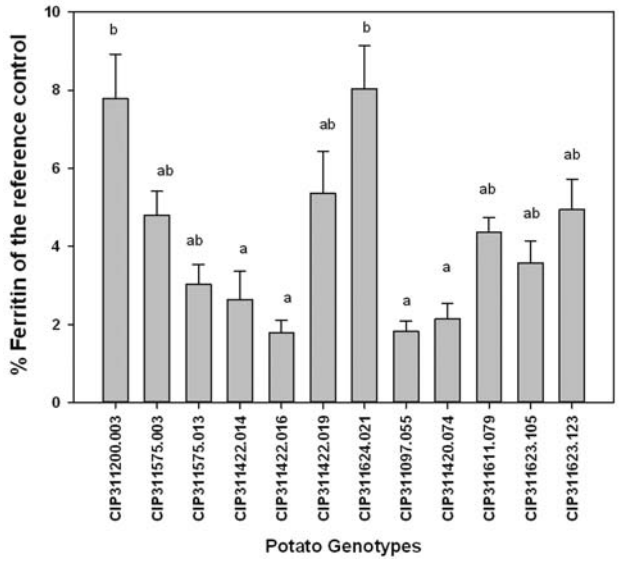

Figure 2. Iron bioavailability from 12 potato clones as measured by ferritin expression in Caco-2 cells. Ferritin expression was evaluated by an ELISA assay and normalized by total protein concentration. Caco-2 cells were exposed to potato digest supplemented with iron (20 μM $FeCl_3$) and ascorbate (1 mM). The data are presented as percentage of the positive control (exposure to digest blank containing 20 μM $FeCl_3$ and 1 mM vitamin C). Values are means ± SEM (n = 9, resulting from three independent experiments). Bar values with no letter in common are significantly different ($p < 0.05$).

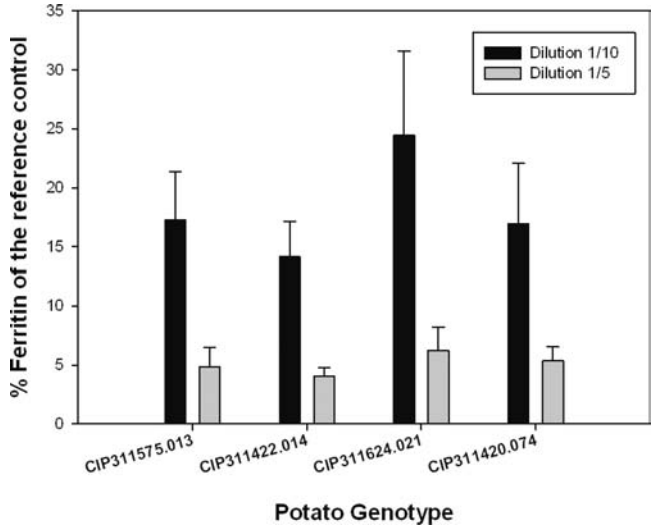

Figure 4. Iron bioavailability from four potato clones as measured by ferritin expression in Caco-2 cells grown under low iron conditions. Ferritin expression was evaluated by an ELISA assay and normalized by total protein concentrations. Caco-2 cells were exposed to 10 or 20% potato digest supplemented with iron (4 μM $FeCl_3$) and ascorbate (1 mM). The data are presented as percentages of the positive control (exposure to digest blank containing 4 μM $FeCl_3$ and 1 mM vitamin C). Values are means ± SEM (n = 9, resulting from three independent experiments). There was no significant difference between the genotypes.

whereas this food matrix is known to contain high levels of iron absorption inhibitors such as phytates and phenolic compounds. Tako et al.[42,44] also showed that the Caco-2 model predicted well animal iron absorption results for bean and pearl millet meals. The Caco-2 cell model is an advantageous preliminary in vitro screening method to efficiently identify promising clones in terms of iron bioavailability. Indeed, when an extrinsic source of iron was added ($FeCl_3$) to the digestion mixture, ferritin synthesis (marker of iron uptake) was noticed to an extent depending on the genotype. Nonsupervised multivariate analyses revealed opposing relationships between the bioavailable iron values (as determined by cell ferritin formation) and the phenolic concentrations. In our assay procedure, carotenoid concentrations did not influence iron bioavailability, whereas the potato vitamin C was positively correlated with the ferritin values. The determination of the iron content in cooked potato tubers was not a good indicator of iron bioavailability, as evaluated by our Caco-2 cell-based model. Indeed, the values of bioavailable iron are the result of various and complex interactions that could be attributed to endogenous iron, to phenolic compounds, to other non-

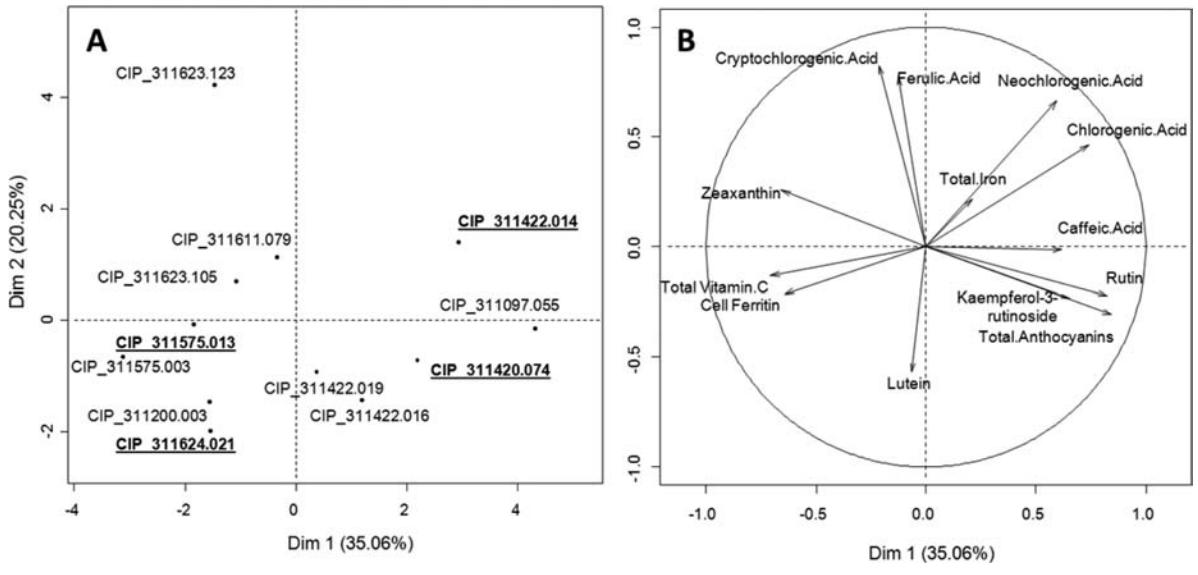

Figure 3. Principal component analysis (PCA) resulting from the in vitro iron bioavailability evaluation of 12 potato clones. (A) Score plots of the 12 potato genotypes. (B) Loading plot showing the relationships between the 13 variables.

identified molecules, and to synergistic as well as antagonistic effects among all these components. Such models may help plant breeders interested in increasing the bioavailable levels of iron and/or reducing the amount and type of iron uptake inhibitors in staple food crops such as potato. Deeper metabolite profiling studies on potato tubers, including phytate measurements, should also be performed to better identify other potential iron absorption inhibitors. Controlled human intervention or animal trials will however be needed to improve our knowledge on iron absorption from potato.

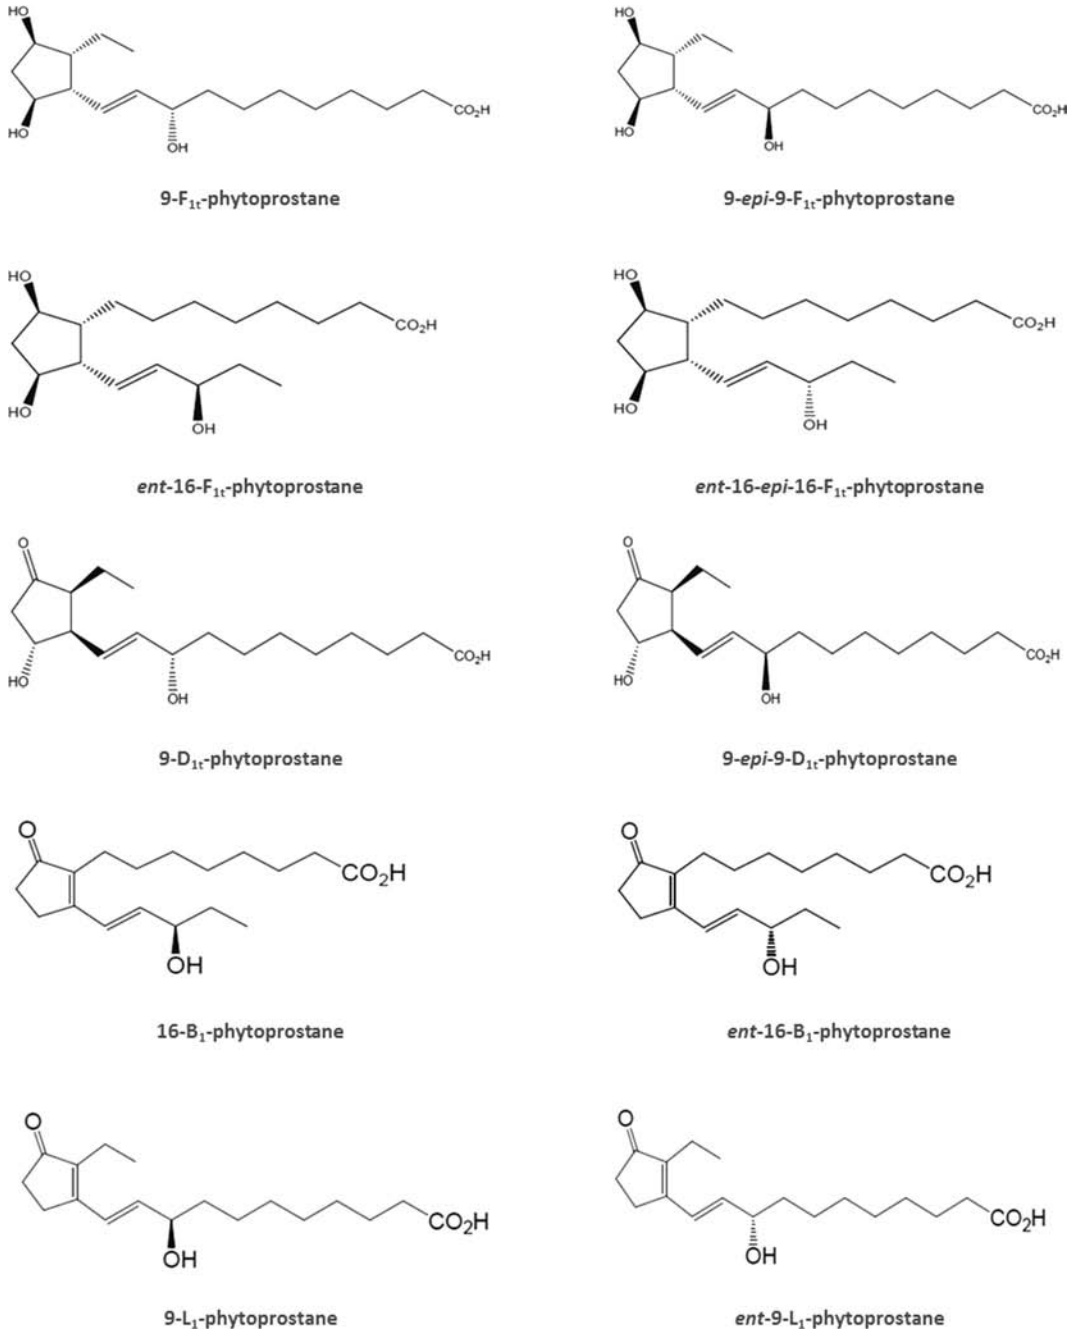

Figure 1. Metabolites of the different families of phytoprostanes.

procedure, in relation to changes in the phytoprostane content of wine or must, is a wide field to explore. It is made even more important by taking into account that the scientific literature has highlighted phytoprostanes as a representative tool for measuring in vivo stress in plants.[4,6] Phytoprostanes could also be of interest to wineries, to determine the oxidative status of their products and as a quality control in the winemaking process.

MATERIALS AND METHODS

Standards and Reagents. Phytoprostanes are very stable in their frozen form, they can remain unaltered for several years. Phytoprostane standards (9-F_{1t}-phytoprostane (Phyto1), *ent*-16-*epi*-16-F_{1t}-phytoprostane + *ent*-16-F_{1t}-phytoprostane (Phyto2+3), 9-*epi*-9-D_{1t}-phytoprostane (Phyto4), 9-D_{1t}-phytoprostane (Phyto5), 16-B_1-phytoprostane + *ent*-16-B_1-phytoprostane (Phyto6+7), 9-L_1-phytoprostane + *ent*-9-L_1-phytoprostane (Phyto8+9)) were synthesized according to previous procedures.[13−16]

Solid-phase extraction (SPE) cartridge was Strata X-AW (100 mg/3 mL) from Phenomenex (Torrance, CA, USA). Both butylated hydroxyanisole (BHA) and bis(2-hydroxyethyl)aminotris-(hydroxymethyl)methane (BIS-TRIS) were purchased from Sigma-Aldrich (St. Louis, MO, USA). Methanol (MeOH) was acquired from VWR (Fontenay-sous-Bois, France), acetonitrile was obtained from Merck (Darmstadt, Germany), and *n*-hexane was purchased from Panreac (Barcelona, Spain). All LC-MS grade solvents were obtained from J. T. Baker (Phillipsburg, NJ, USA). Water was treated in a Milli-Q water purification system (Millipore, Bedford, MA, USA).

Red Wine Samples. Red wines were provided by Baigorri winery (Bodegas Baigorri S.A.U, Samaniego, Álava, Spain). Three different wines were selected to study different vinification and aging

DOI: 10.1021/acs.jafc.5b03365
J. Agric. Food Chem. 2015, 63, 9022−9028

procedures. For correct maintenance, they were stored between 12 and 14 °C after bottling.

"Baigorri carbonic maceration 2010" wine (CMW) was made with a combination of tips of bunches from hand-harvested Tempranillo grapes. Before being fermented, the grapes were macerated for a long time. Short fermentations in stainless steel tanks were performed. No aging procedure was employed.

"Baigorri aged 2007" wine (AW) was manufactured using the tips of bunches of hand-harvested Tempranillo (90%), Garnacha (5%), and other native grape varieties (5%). Long macerations and intracellular fermentations in stainless steel tanks were employed. Large oak barrels were employed during the 14 months of aging.

"Baigorri high expression 2010" wine (HEW) was made from hand-harvested Tempranillo grapes selected from very old (>50 years) and low-yielding vineyards. For its long maceration and fermentation times, stainless steel tanks were used throughout the process. Large oak barrels were also employed during the 22 months of aging.

The alcoholic grades of CMW and AW were similar (13.5°), but that of HEW was slightly higher (14°).

Must Samples. The musts analyzed during the current study were stored at −20 °C for 7 months after the harvest of the grapes, so that the fermentation process did not begin. They were the original grape juices used for the winemaking procedure of each wine. This allows elucidation of the effect of the winemaking process, by direct comparison of each must with its respective wine.

The must samples are referred to in the text as follows: CMM for the initial must of "Baigorri carbonic maceration" wine, AM for the initial must of "Baigorri aged 2010" wine, and HEM for the initial must of "Baigorri high expression 2010" wine.

The chemical compositions of the samples were quite similar. Total acidity values of must samples were 4.44, 5.81, and 6.58 g/L for CMM, AM, and HEM, respectively. Finally, density values were 1102, 1099, and 1100, whereas pH values were 3.65, 3.42, and 3.52 for CMM, AM, and HEM, respectively.

Extraction of Phytoprostanes. For the analysis of phytoprostanes, their extraction from wines and musts was performed following the SPE method developed by Medina et al.[17] and Collado-González et al.,[12] slightly modified for the wine matrix. A mixture of three different bottles of each wine was employed for the extraction. Strata X-AW cartridges were employed for the SPE and were conditioned with 2 mL of methanol followed by 2 mL of Milli-Q water. After that, the cartridges were washed with 2 mL of water, 2 mL of methanol/water (1:3, v/v), and 2 mL of acetonitrile. Finally, the samples were eluted with 1 mL of methanol. The samples were brought to dryness under vacuum, reconstituted with 200 μL of elution phases A:B (90:10, v/v), and filtered through a Millex HV13 0.45 μm membrane filter (Millipore, Bedford, MA, USA).

UHPLC-QqQ-MS/MS Analyses. Separation of the phytoprostanes present in the samples was performed using a UHPLC coupled to a 6460 QqQ-MS/MS (Agilent Technologies, Waldbronn, Germany), as previously described.[12] Each sample was analyzed in triplicate. Chromatographic separation was carried out on a BEH 156 2.1 × 50 mm, 1.7 μm, C_{18} column (Waters, Milford, MA, USA). The column temperatures were 6 °C (left side) and 6 °C (right side). The mobile phases employed were solvent A (water/acetic acid (99.99:0.01, v/v)) and solvent B (methanol/acetic acid (99.99:0.01, v/v)). The elution was performed at a flow rate of 0.2 mL/min, using the following gradient profile: 60% B at 0 min, 62% B at 2 min, 62.5% B at 4 min, reaching 65% B at 8 min, and returning to the initial conditions at 8.01 min.

The MS analysis was applied in the multiple reaction monitoring (MRM) negative ESI mode. The ESI conditions and ion optics were as previously described.[12] Data acquisition and processing were performed using MassHunter software, version B.04.00 (Agilent Technologies). The quantitation of phytoprostanes detected in the wines and musts was performed using authentic standards of 9-F_{1t}-phytoprostane, *ent*-16-*epi*-16-F_{1t}-phytoprostane, *ent*-16-F_{1t}-phytoprostane, 9-*epi*-9-D_{1t}-phytoprostane, 9-D_{1t}-phytoprostane, 16-B_1-phytoprostane, *ent*-16-B_1-phytoprostane, 9-L_1-phytoprostane, and *ent*-9-L_1-phytoprostane. The synthetic isoprostane d_4-15-F_{2t}-IsoP (8-isoPGF$_{2\alpha}$-d_4) was used as the internal standard.

Statistical Analysis. An analysis of variance (ANOVA; Duncan) was applied to establish significant differences between the means obtained for the different samples of wine and must. A probability value of $p < 0.05$ was adopted as the criterion for significant differences. These analyses were performed with SPSS version 15 software (SPSS Inc., Chicago, IL, USA).

RESULTS AND DISCUSSION

Qualitative Analysis of Phytoprostanes. The individual phytoprostanes found in wines and musts are shown in Figure 2. Their identification was confirmed according to their molecular masses, the precursor ions (m/z 327.2 and 307.2), the characteristic MS/MS fragmentation product ions, and the corresponding retention times. In contrast to prostaglandins, phytoprostanes are formed nonenzymatically as regio- and stereoisomeric mixtures.[12] The phytoprostane profiles of the

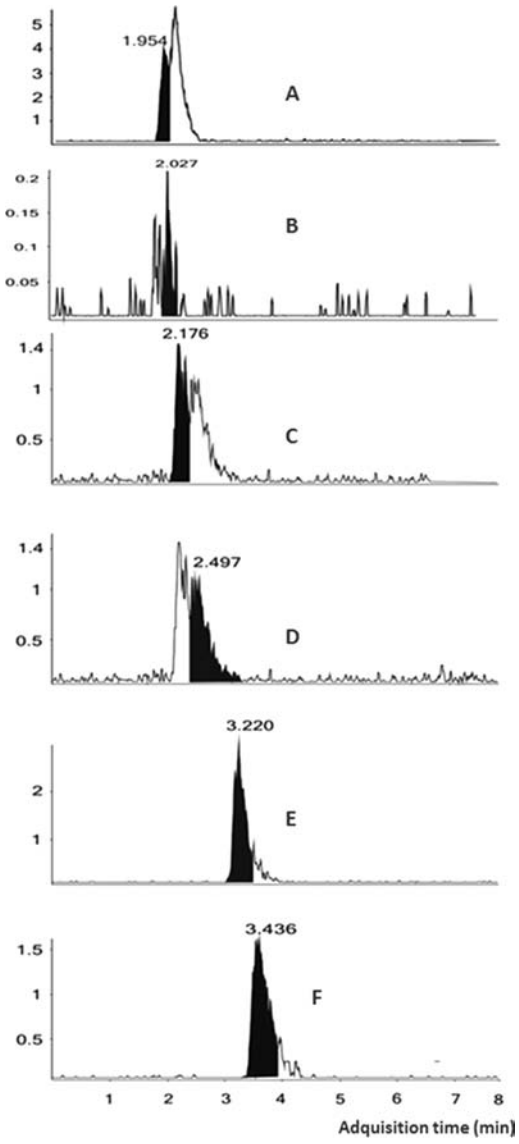

Figure 2. Phytoprostane chromatograms for CMW, measured by UPLC-MS/MS: (A) 9-F_{1t}-phytoprostane; (B) *ent*-16-*epi*-16-F_{1t}-phytoprostane + *ent*-16-F_{1t}-phytoprostane; (C) 9-*epi*-9-D_{1t}-phytoprostane; (D) 9-D_{1t}-phytoprostane; (E) 16-B_1-phytoprostane + *ent*-16-B_1-phytoprostane; (F) 9-L_1-phytoprostane + *ent*-9-L_1-phytoprostane.

DOI: 10.1021/acs.jafc.5b03365
J. Agric. Food Chem. 2015, 63, 9022−9028

analyzed beverage samples indicate the presence in all samples of the 9 and 16 series of the F_1- and D_1-classes of phytoprostanes. The B-series and L-series did not present a well standardized distribution among the different samples. In addition, only one wine (CMW) and one must (HEM) contained enantiomers of the racemic mixtures of 16-B_1- and 9-L_1-phytoprostane (Phyto6+7 and Phyto8+9). It is important to emphasize that the analytical conditions employed in this study did not allow separation of the enantiomers of the racemic mixtures of 16-B_1-phytoprostane + *ent*-16-B_1-phytoprostane and 9-L_1-phytoprostane + *ent*-9-L_1-phytoprostane. Therefore, both enantiomers of L- and B-series were quantitated together.

Four phytoprostanes were identified in all of the samples (the three wines and the three musts): Phyto1, Phyto2+3, Phyto4, and Phyto5.

Quantitative Analysis of Phytoprostanes. The concentrations of total free phytoprostanes are represented in Figure 3.

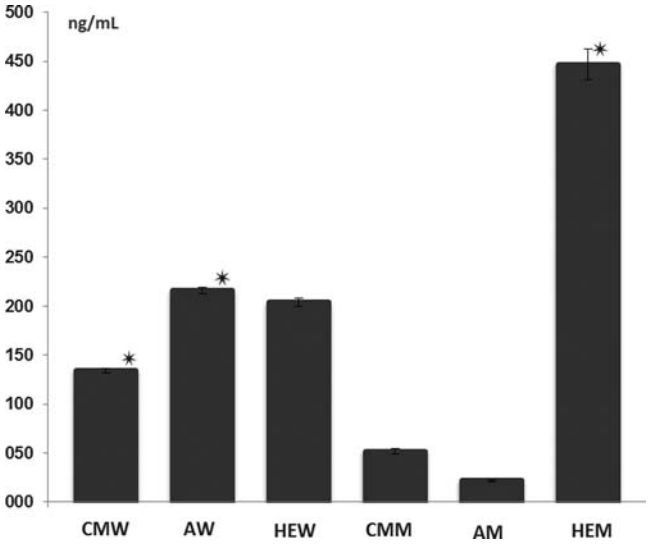

Figure 3. Concentrations of total phytoprostanes. CMW/CMM, wine/must with carbonic maceration; AW/AM, aged wine/must; HEW/HEM, high-expression wine/must.

This concentration varied widely among the three primary musts. In fact, no significant difference ($p > 0.05$) in the final concentration of total phytoprostanes was found when the primary must corresponding to carbonic maceration wine (CMM) (48.9 ± 2.6 ng/mL) and the primary must of aged wine (AM) (20.5 ± 0.8 ng/mL) were compared. However, the primary must of high-expression wine (HEM) had a significantly higher level ($p < 0.01$) of total phytoprostanes (430.9 ± 15.7 ng/mL) than CMM or AM. As commented on above, HEM came from very old and low-yielding vineyards (>50 years old), which are exposed to more stress factors than newer vineyards.[18] This would probably lead to an increase in pro-oxidant reactive species and to the subsequent formation of phytoprostanes by lipid peroxidation of ALA. Consequently, differences in agronomic factors (vineyard age) could have contributed to the different concentrations of total phytoprostanes, compared to HEM, in the must from grapes grown in the new vineyards (CMM and AM).

In the three wine samples studied, the total phytoprostane concentration did not present a standardized range. Actually, the values did not vary ($p > 0.05$) between aged wine (AW) (213.2 ± 3.1 ng/mL) and high-expression wine (HEW) (199.8 ± 4.2 ng/mL), but the total phytoprostane concentration of carbonic maceration wine (CMW) (131.7 ± 2.3 ng/mL) was significantly lower ($p > 0.05$).

The levels of individual phytoprostanes varied consistently among the different classes of phytoprostanes (Table 1). The F_1-phytoprostane series class was generally the most abundant class ($p < 0.05$) found in all of the samples, Phyto1 being the most abundant compound (436.6 ± 7.9 ng/mL). Likewise, a change in the proportion of the F_1-phytoprostane series was observed in both aged wines (AW and HEW). In CMM, AM, HEM, and CMW, Phyto1 was found at a higher concentration ($p < 0.05$) (32.7 ± 1.8, 13.5 ± 0.1, 149.8 ± 1.8, and 90 ± 0.9 ng/mL, respectively) than the sum of Phyto2+3 (6.8 ± 0.3, 4.5 ± 0.1, 50.1 ± 0.1, and 19.9 ± 0.4 ng/mL, respectively). However, in AW and HEW the opposite relationship was found: the sum of Phyto2+3 (133.8 ± 2.2 and 124.9 ± 1.7 ng/mL, respectively) exceeded the level of Phyto1 (76.9 ± 0.7 and 73.6 ± 2.4 ng/mL, respectively). Therefore, transformations of the stereoisomers during the aging of wines could change the proportion of the F_1-phytoprostane series.

The D_1-phytoprostane series class was found primarily in HEM. Two epimeric compounds (Phyto4 (25.1 ± 2.1 ng/mL) and Phyto5 (200.4 ± 11.1 ng/mL)) were abundant in HEM. However, the level of Phyto4 in the rest of the samples did not exceed 0.6 ng/mL, whereas Phyto5 was also plentiful in CMW (17.1 ± 0.7 ng/mL). Minor amounts were found in CMM and AM (8.7 ± 0.4 and 2.3 ± 0.5 ng/mL, respectively), with even lower values in the rest of the samples.

As commented above, the analytical conditions employed in the present study did not allow the separation of the different enantiomers. Therefore, enantiomers of both the 9-L- and 16-B-phytoprostanes series of B_1- and L_1- phytoprostanes were quantitated together. Consequently, these two classes were

Table 1. Content of Individual Phytoprostanes Analyzed in Three Types of Musts and Wines[a]

structure	phytoprostane	CMW	AW	HEW	CMM	AM	HEM
Phyto1	9-F_{1t}-phytoprostane	90.04 ± 0.9	76.9 ± 0.7	73.5 ± 2.4	32.7 ± 1.8	13.5 ± 0.1	149.8 ± 1.8
Phyto2+3	*ent*-16-*epi*-16-F_{1t}-phytoprostane + *ent*-16-F_{1t}-phytoprostane	19.9 ± 0.3	133.8 ± 2.2	124.9 ± 1.7	6.7 ± 0.2	4.5 ± 0.08	50.1 ± 0.08
Phyto4	9-*epi*-9-D_{1t}-phytoprostane	0.4 ± 0.02	0.1 ± 0.02	0.09 ± 0.005	0.6 ± 0.03	0.1 ± 0.06	21.5 ± 2.1
Phyto5	9-D_{1t}-phytoprostane	17.1 ± 0.7	2.2 ± 0.01	1.2 ± 0.01	8.7 ± 0.4	2.3 ± 0.5	200.4 ± 11.1
Phyto6+7	16-B_1-phytoprostane + *ent*-16-B_1-phytoprostane	0.3 ± 0.001	ND	ND	ND	ND	2.5 ± 0.1
Phyto8+9	9-L_1-phytoprostane + *ent*-9-L_1-phytoprostane	3.8 ± 0.2	ND	ND	ND	ND	6.4 ± 0.3

[a]Results are expressed in ng/mL ± SD. CMW/CMM, carbonic maceration wine/must; AW/AM, aged wine/must; HEW/HEM, high expression wine/must; ND, not detected.

DOI: 10.1021/acs.jafc.5b03365
J. Agric. Food Chem. 2015, 63, 9022−9028

identified and quantitated as the sum of 9-L_1- + 9-L_1-*ent*-16-B_1-phytoprostane and the sum of 16-B_1- + *ent*-16-$B_1$9-L_1-phytoprostane, respectively. Finally, compounds from the B_1- and L_1-phytoprostane classes (Phyto6+7 and Phyto8+9) were found in very low amounts. Only in CMW and HEM they were abundant enough to be quantitated, according to the limit of quantitation of the method developed by Collado-González et al.[12] In fact, in these two samples, the sums of the concentrations of Phyto6+7 (2.8 ± 0.1 ng/mL) and Phyto8+9 (10.3 ± 0.5 ng/mL) were not significant compared to the quantities found in the other phytoprostane classes ($p > 0.05$).

The vinification process seems to modify the initial content of phytoprostanes in the must, because wines CMW and AW showed higher total phytoprostane concentrations than CMM and AM (their corresponding primary musts). The musts CMM (48.7 ± 2.4 ng/mL) and AM (20.4 ± 0.7 ng/mL) had lower concentrations ($p < 0.05$) of total phytoprostanes than their respective finished wines (131.8 ± 2.1 and 213 ± 2.9 ng/mL for CMW and AW, respectively). The wine aging process may be an important factor in the formation of phytoprostanes. The musts CMM and AM exhibited similar ($p > 0.05$) phytoprostane levels. Nevertheless, after the vinification process, the total phytoprostane concentration in CMW was lower than in AW. In the case of CMW, this concentration could have been a consequence of the carbonic maceration process (extraction) applied to the grapes and the consequent alcoholic and malolactic fermentation in stainless steel tanks.[19] However, the vinification of AW could have been more oxidative, owing to the use of oak wood barrels for the aging procedure employed in the vinification. This could have released pro-oxidant compounds into the medium, in addition to promoting greater contact with oxygen.[20] In wine, ROS can be produced by reduced transition metals ions such as copper or iron. Superoxide radical anions, hydroperoxyl radicals, or hydrogen peroxide could be responsible of the oxidation of ALA.[21] The vinification of AW included an aging process that was not included in the production of CMW. The oxidation processes during this vinification, besides the aging of the red wine, could have led to the production of reactive pro-oxidant molecules that oxidize ALA to phytoprostanes, explaining the difference in the final level of total phytoprostanes between CMW and AW.

By contrast, in the vinification process that yielded HEW from HEM, the primary must showed a total phytoprostane concentration that was >2-fold higher (430.9 ± 15.7 ng/mL) than that of the finished wine (199.8 ± 4.2 ng/mL). This reduction could be mainly attributable to the great loss of the 9-series of the D_1-phytoprostane class. It is important to highlight that the D_1-phytoprostane class is the only one studied that is not a terminal compound (end product) in the nonenzymatic lipid peroxidation. In this sense, the decline of the total phytoprostane content may be explained by the rearrangement into J_1- and dJ_1-phytoprostanes, by a dehydration reaction, of the Phyto5, present in large amounts in HEM (200.4 ± 11.2 ng/mL). This probably occurred during the vinification process of HEW. Because pro-oxidant compounds are present during the vinification process, the stability of intermediate phytoprostanes is uncertain.[3,22] The oxidizing conditions during the vinification process probably led to the oxidation of ALA and, thus, the formation of D_1-phytoprostanes. The D_1-phytoprostanes may have been oxidized to J_1- and dJ_1-phytoprostanes, but this could not be investigated as there are no authentic markers available for these compounds.

To our knowledge, no papers that describe the phytoprostane content in wine or must have been published. Nevertheless, a few plant matrices have been investigated to report the phytoprostane occurrence.[3] Tobacco, *Arabidopsis thaliana*, *Crotalaria cobalticola*, *Eschscholzia californica*, and birch pollen have shown the presence of phytoprostanes. Birch pollen had the highest phytoprostane concentration of all these matrices (32 μg/g).[23] Consequently, the selection of the plant tissue analyzed is very important, because ROS are not produced equally throughout all of the structures of the plant. In fact, green tissues are the most likely producers of ROS, because of the singlet oxygen formed in the chloroplast during photosynthesis, leading to an increase in the number of peroxidation products.[22] Savchenko et al.[24] reported that the total amount of phytoprostanes in photosynthetic tissue is 10 times higher than in roots. In this sense, depending on the tissue studied, phytoprostane levels might vary extensively. Few researchers have reported phytoprostane contents in foods. Durand et al.[22] described high amounts of phytoprostanes in tomato leaves, F_1-, E_1-, and d-J_1-phytoprostanes being the most abundant. The level of phytoprostanes in almonds and olive/sunflower oil has been reported to range from 4.0 to 23.8 ng/100 g.[12,25,26]

Researchers have highlighted the importance of phytoprostanes as bioactive lipid derivatives, not only in plant matrices but also in mammalian systems.[27] Phytoprostanes, derived from a nonenzymatic oxidation reaction, are believed to exert beneficial effects in the organism.[3,5,27] Due to their similarities to different prostaglandins, they could mimic the effects of the latter on the organism.[4,22,28] In the present survey, F_1-phytoprostanes were the most abundant class of phytoprostanes in all of the samples studied (436.6 ± 7.9 ng/mL for 9-F_{1t}-phytoprostane and 340.1 ± 4.8 ng/mL for *ent*-16-*epi*-16-F_{1t}-phytoprostane). These phytoprostanes can regulate inflammatory responses in dendritic cells.[23] Karg et al.[5] reported that A_1- and B_1-phytoprostanes inhibited the release of nitric oxide in lipopolysaccharide-stimulated RAW264.7 macrophages. Thus, cardiovascular diseases could be ameliorated by the effects of phytoprostanes. In fact, Barden et al.[28] related the intake of F_1-phytoprostanes to protective effects on the cardiovascular system.

The importance of the intake of phytoprostanes could be related to neuroprotective effects, too. Minghetti et al.[27] showed that B_1-phytoprostanes were biologically active in experimental models of immature cells of the central nervous system, exhibiting neuroprotective effects against oxidant injury induced by hydrogen peroxide and promoting myelination through mechanisms that involve activation of the peroxisome proliferator-activated receptor (PPAR)-γ.

Bioavailability of phytoprostanes has also been demonstrated in vivo with healthy humans. Barden et al.[28] examined the effect of flaxseed oil, containing arachidonic acid; they examined the effect of a diet supplemented with flaxseed oil on F_1-phytoprostane and F_2-isoprostane concentrations in the urine and plasma of healthy men. Both the plasma and urine analyses confirmed the absorption of phytoprostanes by the intestinal tract. The esterified and nonesterified phytoprostane levels before intake of flaxseed oil were higher in plasma than in urine. Not only oil has been demonstrated to contain phytoprostanes, parenteral nutrition[5] has also shown a significant content of these metabolites (0.09−99 mg/L).

Assuming these possible beneficial effects, phytoprostanes would have an important impact on the Mediterranean diet, due to the wide consumption of wine around the world. The F_1-phytoprostane concentrations found in the red wines and musts and the suggested beneficial effects on the organism make their contribution relevant in the beneficial effects of the Mediterranean diet. However, further studies seem to be necessary to understand the physiological relevance of phytoprostanes in general and of F_1-phytoprostanes in particular, for example, their role in preventing myocardial infarction or heart disease.

To the best of our knowledge, this is the first paper describing the presence of phytoprostanes in wine or must. The results showed the F_1-phytoprostanes as the most abundant class for all samples. Likewise, D_1-phytoprostanes were present in musts in large quantities, especially in HEM. Vinification and aging procedures may influence and change the initial phytoprostane profile, favoring the formation of pro-oxidant species. Further studies are needed to elucidate the development of phytoprostanes during wine production.

With the possible beneficial effects of phytoprostanes in the cardiovascular system and the high concentrations observed in wines and musts taken into account, phytoprostanes could be an important factor in the cardioprotective or cerebrovascular effects of red wine and the Mediterranean diet, due to their possible anti-inflammatory effects. However, further clinical trials with humans and with animal models are necessary to elucidate how phytoprostanes could improve the cardiovascular system or exert neuroprotective effects.

activity of 2.4 Anson units (AU) per gram. One AU is the amount of enzyme that under standard conditions digests hemoglobin at an initial rate that produces an amount of trichloroacetic acid-soluble product which gives the same color with the Folin reagent as 1 mequiv of tyrosine released per minute. Optimal endoprotease activity was obtained by application trials to pH 8.0. Flavourzyme 1000 MG is an exopeptidase and endoprotease complex with an activity of 1.0 leucine aminopeptidase unit (LAPU) per gram. One LAPU is the amount of enzyme that hydrolyzes 1 mmol of leucine−*p*-nitroanilide per minute. Optimal exopeptidase activity was obtained by application trials at pH 7.0.

Preparation of DRB. RB mixed varieties were obtained from Padiberas National Berhad (BERNAS) rice milling factory, Tiram Jaya, Kuala Selangor, Malaysia. Freshly milled rice bran was stabilized and dried to constant weight at 100−105 °C in a custom-fabricated commercial stabilizer (Ansa Technology Sdn. Bhd, Johor, Malaysia). In brief, the rice bran powder was poured evenly into heat-resistant glass cookware and heated under high power (1000 W) in the stabilizer for approximately 180−220 s. After drying, RB was passed through a sieve (≤0.5 mm) and stored at 4 °C in a freezer prior to extractions. RB was then subjected to supercritical fluid carbon dioxide extraction (SFE; Thar 1000 F, Thar Technologies, Inc., Pitttsburgh, PA, USA) to obtain the DRB.

Preparation of DRB Protein Concentrate. DRB was mixed with deionized water in the ratio of 1:10 (w/v) and then 3 M NaOH was added until the final pH of the mixture was 10.5. The mixture was stirred for 1 h at room temperature and then centrifuged at 4000*g* for 10 min. An additional extraction was carried out with the same volume of alkaline solution. Supernatants were pooled and the pH was adjusted to the isoelectric point (pH 4.5). The precipitate was then recovered by centrifugation at 4000g for 10 min, and washed with distilled water adjusted to the isoelectric point, after which it was freeze-dried until further use.

Characterization of DRB Protein Concentrate. *Determination of Yield and Protein Content of DRB Protein Concentrate.* The Lowry assay was performed to obtain the protein content of DRB protein fractions.[19] The absorbance of the sample or standard was measured at 630 nm using a microplate reader (Opsys MR, Thermo Labsystems, Franklin, MA, USA). The results were interpreted as milligrams of bovine serum albumin equivalents per gram of dried weight of sample (mg BSA/g).

Amino Acid Analysis of DRB Protein Concentrate. The amino acid analysis of DRB protein fractions was carried out according to the method of Kwanyuen and Burton[20] with some minor modifications. Briefly, sample with at least 16% protein content was placed in a sealable test tube. The test tube was acid-washed with 6 N hydrochloric acid (HCl) and dried prior to use. Then, the lyophilized protein was hydrolyzed with 6 N HCl at 110 °C for 24 h. After hydrolysis, L-2-aminobutyric acid (AABA; 0.2578 g of AABA was made up to 1 L of 0.1 N HCl solution) was added into the hydrolysate in a ratio of 10 ml per 15 ml of the hydrolysate. The hydrolysate was then filtered using Whatman filter paper, grade 1 (Sigma-Aldrich Co.), and the supernatant was topped up to 50 mL using deionized water. The hydrolyzed sample was stored at −20 °C.

To prepare the derivatized solution, 10 μL of the hydrolyzed sample was dried under vacuum. The hydrolyzed sample was neutralized by adding 20 μL of a 2:2:1 mixture of methanol/water/TEA (v/v). The mixture was vortexed and fully dried under vacuum. Then, precolumn derivatization was performed by adding 20 μL of a mixture of 7:1:1:1 methanol/water/TEA/PITC (v/v) and mixing well with a vortex stirrer. The mixture was allowed to stand at room temperature for 20 min. Then, the sample was completely dried under vacuum. The sample was finally stored in a freezer prior to HPLC analysis.

The dried samples were redissolved in 100 μL of buffer A containing 0.1 M ammonium acetate (pH 6.5) and filtered through a Millipore membrane (0.22 μm). Then, 20 μL of the sample was injected and analyzed with an HPLC system equipped with a column heater, autosampler, variable wavelength detector, and data acquisition software controller. The reverse-phase column used was a Pico-Tag (3.9 × 150 mm), dimethyloctadecylsilyl-bonded amorphous silica, with an inline column filter. The column temperature was maintained at 43 °C. The samples were separated and eluted by a gradient resulting from mixing mobile phases A and B. Mobile phase A consisted of 0.1 M ammonium acetate, pH 6.5, whereas mobile phase B consisted of 44:46:10 0.1 M ammonium acetate/acetonitrile/methanol (v/v), pH 6.5. The flow rate was 1 mL/min throughout, and the gradient consisted of the following profiles: 100% A at start, 90% A and 10% B at 15 min, 60% A and 40% B at 30 min, 50% A and 50% B at 40 min, 100% B at 50 min, 100% A at 57−60 min. The samples eluted from the column were detected at 254 nm and recorded. The results were analyzed and compared with amino acid standards (AAS18, Sigma). The amino acid score (AAS) for the essential amino acid was calculated according to the formula

$$\text{amino acid ratio} = \frac{\text{mg of an essential amino acid in 1 g of sample}}{\text{mg of the same essential amino acid in 1 g of a reference pattern}}$$

The AAS was determined based on the lowest amino acid ratio. The scoring patterns suggested by the FAO/WHO/UHU[21] for adults were used in the present study.

Preparation of DRB Protein Hydrolysates. DRB was treated batchwise with Alcalase and Flavourzyme by individual, combination, or sequential treatment. Table 1 shows the experimental conditions of hydrolysis for different enzyme systems. Individual hydrolyses were developed over 4 h, whereas combination treatment was carried out by combining the two proteases for 4 h, and sequential treatment was carried out with an initial hydrolysis (1 h) using Alcalase and a second one (3 h) using Flavourzyme. The hydrolysis were carried out using the following parameters: (A) Alcalase hydrolysis, substrate concentration (*S*) = 10%; enzyme−substrate ratio (E/S) = 0.4 AU/g of protein; temperature *T* = 50 °C; pH 8.0; (F) Flavourzyme hydrolysis, *S* = 10%; E/S = 100 LAPU/g of protein, *T* = 50 °C, pH 7.0.

Table 1. Experimental Conditions of Hydrolysis for the Different Enzyme Systems

enzyme system[a]	detail	pH	temperature (°C)
DRB_A	partial hydrolysis using Alcalase	8.0	50
DRB_F	partial hydrolysis using Flavourzyme	7.0	50
DRB_A+F	partial hydrolysis with a combination of Alcalase and Flavourzyme	8.0	50
DRB_A●F	sequential hydrolysis using Alcalase and Flavourzyme	8.0 for Alcalase 7.0 for Flavourzyme	50

[a]DRB_A+F corresponds to simultaneous hydrolysis with Alcalase and Flavourzyme. DRB_A●F represents sequential hydrolysis using Alcalase first for 1 h followed by Flavourzyme with intermediate pH adjustment.

Briefly, the suspension was adjusted initially to the appropriate temperature and pH before the proteases, Alcalase and Flavourzyme, were added individually or in combination. Once the enzymes were added, the pH of the reaction was monitored constantly and adjusted to the optimal level by adding 0.5 N NaOH every time it decreased 0.1 unit from the optimal pH. The amount of added NaOH was recorded and later used for the calculation of degree of hydrolysis (DH). The enzymes were subsequently deactivated by heating the mixture to 95 °C for 15 min. The resulting hydrolysates were centrifuged at 3000*g* for 30 min at 4 °C to separate the soluble hydrolyzed material from the insoluble residue.

Determination of DH and Protein Content of DRB Protein Hydrolysates. The DH of DRB protein hydrolysates, defined as the percentage of peptide bonds cleaved, was calculated as

DOI: 10.1021/acs.jafc.5b03420
J. Agric. Food Chem. 2015, 63, 9029−9036

$$\mathrm{DH}\ (\%) = (BN_b)/(M_p \propto h_{total})$$

where B is the amount of alkali consumed (mL), N_b is the normality of alkali, M_p is the mass of the substrate (protein in grams, % N × 6.25), $1/\alpha$ is the calibration factor for pH-stat, and h_{total} is the content of peptide bonds.[22] The protein content was determined by using the Lowry method.[19]

Determination of Iron-Binding Capacity of DRB Protein Hydrolysates. The iron-binding capacity of DRB protein hydrolysates was determined according to the method of Decker and Welch[23] with some modifications. Briefly, 1 mL of sample solution was mixed with 3.0 mL of distilled water. The mixture was then reacted with 0.1 mL of 1 mM $FeSO_4$ and 0.2 mL of 5 mM 3-(2-pyridyl)-5,6-bis(4-phenylsulfonic acid)-1,2,4-triazine (Ferrozine) for 20 min at room temperature. The absorbance was read at 562 nm. The control was prepared in the same manner except that distilled water was used instead of the sample. EDTA was used as positive control. Iron-binding capacity was expressed as a percentage of the total iron ion content and was calculated as

$$[\text{iron solubility}]\% = [\text{iron ion}]_{\text{supernatant}}/[\text{iron ion}]_{\text{total}} \times 100$$

where $[\text{iron ion}]_{\text{supernatant}}$ is the supernatant iron ion content from the suspension and $[\text{iron ion}]_{\text{total}}$ is the total iron ion content of the suspension.

Cell Culture. Caco-2 cells originating from human colorectal carcinoma (courtesy of Chan Kim Wei from Universiti Putra Malaysia) were thawed and cultured at passage 22. The passage of the cells used in the experiments was between 25 and 33. Cells were cultivated in a 25 cm^2 tissue culture flask and grown in Dulbecco's modified Eagle medium (DMEM) supplemented with 20% (v/v) fetal bovine serum, 1% (v/v) nonessential amino acids, 1% (v/v) penicillin−streptomycin solution, and 0.1% (v/v) fungizone. The flask was incubated in a 5% CO_2 incubator at 37 °C and 95% relative humidity.

Collagen Coating and Cell Culture on the Insert of the 6-Well Transwell Plate. A 2 mg/mL stock solution of the rat tail collagen type I was prepared by adding an appropriate amount of 0.02 M acetic acid. The solution was allowed to stir at room temperature for 1 h until fully dissolved. The working collagen solution was diluted to 10 $\mu g/cm^2$ from the stock solution. Each of the inserts in the 6-well transwell plate was coated with 0.6 mL of working collagen solution. The collagen was allowed to bind for 4 h at 37 °C. The excess fluid was removed from the coated surface, and the inset was allowed to dry in a biological safety cabinet. The sterile insert was rinsed with PBS twice prior to cell seeding.

Then, 1.5 mL of the cell suspension was seeded into apical wells for each insert and incubated in the 5% CO_2 incubator at 37 °C and 95% relative humidity. The basolateral wells of the transwell were filled with 2.6 mL of fresh medium. The medium in the insert was changed every 2 days, whereas the medium in the basolateral wells was changed every 4−5 days. The sequence of medium changing was removal of medium from basolateral and then apical wells. The medium was added into apical wells and then only basolateral wells. The sequence of medium changing was chosen to avoid hydrostatic break of the cell monolayer. The cells were allowed to grow and differentiate for 18−21 days with monitoring of the TEER value, phenol red diffusion, and transmission electron microscopy (TEM) study.

Cell Viability Assay of DRB Protein Hydrolysates. Cell viability was determined by using the MTT assay. Cells were cultured in DMEM containing 10% FBS and seeded in 96-well plates (1×10^5 cells/mL) until the cells reached confluence. The cells were then treated with culture medium (control) and different concentrations of the sample (0−1000 ppm) for 24 h. The cells were subsequently incubated with MTT solution (Sigma, St. Louis, MO, USA) for another 4 h at 37 °C. The medium was then removed, and the blue formazan crystal was solubilized in 150 μL of dimethyl sulfoxide (DMSO; Sigma). Absorbance was measured at 570 nm on Opsis MR microplate reader (Dynex Technologies, Chantilly, VA, USA).

In Vitro Gastrointestinal Digestion of DRB Peptide Hydrolysates. Gastrointestinal digestion was applied to DRB using the in vitro methods described by Vattem et al.[13] and Miller et al.[24] with some modifications. Briefly, DRB peptide hydrolysates (5 g) were incubated for 1 h at 37 °C in a 0.32% (w/v) pepsin solution containing 30 mM NaCl and 0.7% (v/v) of 0.2 N HCl, pH 1.2, in a 1/20 (w/w) enzyme/protein hydrolysate relation to mimic the gastric fluid digestion condition. Then, 5 mg of $FeSO_4$ (37.5 μmol)[13] was added and followed by sufficient water to top up the solution to 50 mL.

To further simulate the intestinal fluid digestion, the pH of the pepsin digests was adjusted to 5.0 by dropwise addition of 0.05 M $NaHCO_3$. Subsequently, the mixture was incubated for 3 h at 37 °C in a pancreatin−bile solution containing 0.005 g of pancreatin and 0.03 g of bile salts/g of sample. When the intestinal digestion was completed, the samples were kept for 10 min in an ice bath. The pH of the samples was then raised to 7.2 using 0.5 M NaOH. The digests were subjected to centrifugation (4000g, 25 min, and 4 °C). The supernatants were collected and filtered through a dialysis tubing cellulose membrane (D9777 Sigma, average flat width = 25 mm, typical molecular weight cutoff = 14000) using the method of Jovani et al.[25] prior to iron uptake experiments.

Iron Uptake by Caco-2 Cells. Cells were seeded at a density of $(1-1.5) \times 10^5$ cells/cm^2 in a collagen-coated 6-well transwell plates (Costar, High Wycombe, UK). The iron uptake experiment was conducted when the percent of phenol red diffusion was <2.5% and the transmonolayer electrical resistance was >500 Ω cm^2. Briefly, growth medium was removed from the transwell by aspiration, and the upper and lower chambers were rinsed twice with phosphate-buffered saline (PBS) solution. This was followed by adding 1.5 mL of DMEM in the lower chamber and 0.5 mL of in vitro digested sample to the upper chamber. The apical samples and basal solutions were then collected after 4 h of incubation. The cells in the inset were lysed and harvested by adding 0.5 mL of 1 M NaOH. Total mineral content was measured in the apical solutions, cell monolayer, and basal solutions by using the formulas as provided in the following section.

Iron contents in DRB hydrolysates and Caco-2 cell absorption were measured by inductively coupled plasma atomic emission spectrometry (ICP-AES; ELAN DRC-e, PerkinElmer). Iron standards were prepared by diluting the $FeSO_4$ solution into series of concentrations (3.125−100.00 $\mu g/L$) with the same mixture used for the samples. The detection limit of iron analysis using ICP-MS was <0.010 $\mu g/L$. The solubility, retention, transport efficiency, and uptake efficiency percentage were determined according to the methods of Frontela et al.[26]

The experiment was conducted in a two-phases. In the first phase, rice bran protein hydrolysates with different enzymatic treatments were investigated. The best enzymatic system to obtain the optimal iron uptake in the cell model was chosen and allocated to the second phase. In the second phase, a variety of rice bran protein hydrolysates were prepared by incubation with combination of Alcalase and Flavourzyme for different periods of time, which allowed investigation of the best period of time to obtain the DRB protein hydrolysate with the highest iron-uptake capacity.

Statistical Analysis. All of the values are the mean of at least two replicates, and data are reported as the mean ± standard deviation (SD). The data were analyzed by Univariate analysis of variance (ANOVA) and Pearson's correlation coefficient. Duncan's multiple-range test (DMRT) was used to determine the differences among the samples. All of the analyses were conducted using GraphPad Prism 6 for Windows version 6.01 (GraphPad Software Inc., San Diego, CA, USA). Significant levels were defined as probabilities of ≤0.05.

RESULTS

Yield, Protein Content, and Amino Acid Content of DRB Protein Concentrate. The average yield and protein content of DRB protein concentrate were 11.85% (or 11.85 g/100 g DRB) and 82.61 mg BSA/g, respectively. The result of amino acid analysis for DRB protein concentrate and DRB protein fractions is presented in Table 2. Most of the essential amino acids in DRB protein concentrate, except phenylalanine

histidine	1.85 ± 0.09	1.60	1.16 ± 0.09
phenylalanine + tyrosine	4.23 ± 0.23	1.90	2.23 ± 0.23
methionine + cysteine	1.47 ± 0.15	1.70	0.86 ± 0.15
amino acid score for DRB protein concentrate			86

[a]Defatted rice bran protein was prepared by isoelectric point precipitation, as stated under Materials and Methods. [b]Reference protein: essential amino acid requirement for adults according to FAO/WHO/UNU (1985) (mg/g crude protein, dry basis). The protein quality of DRB was analyzed by applying the amino acid score based on the reference protein of FAO/WHO/UHU (1985). [c]Amino acid ratio referred to the ratio of a gram of the limiting amino acid (methionine + cysteine in the DRB protein concentrate) to the same amount of the corresponding amino acid in the reference protein multiplied by 100.

and methionine, exceeded the requirements of the reference protein for adults according to the FAO/WHO/UHU.[21]

Enzymatic Hydrolysis of DRB. Figure 1 shows the extracted peptide from DRB after treatment with different

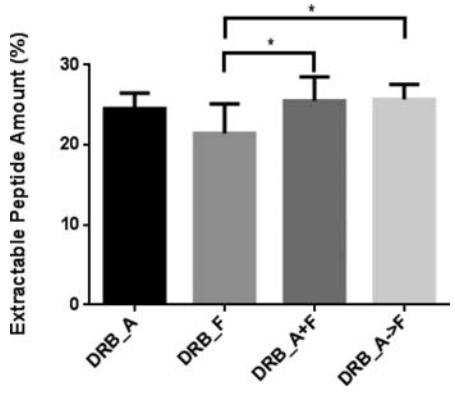

Figure 1. Extractable peptide amount (%) from DRB protein isolated by different enzyme hydrolysis treatments: treated with Alcalase (DRB_A), treated with Flavourzyme (DRB_F), treated with a combination of Alcalase and Flavourzyme (DRB_A+F), and sequentially treated with Alcalase and Flavourzyme (DRB_A•F). (*) Means were significantly different at $p \leq 0.05$ ($n = 3$).

enzymes. The peptide amounts of Alcalase-treated and Flavourzyme-treated DRB samples were 24.54 and 21.46%, respectively. DRB treated with Alcalase and Flavourzyme, either in combination (25.51%) or sequentially (25.70%), had significantly higher protein contents than the Flavourzyme-treated DRB sample, but not the Alcalase-treated DRB sample.

The added enzymes affected the DH in a time-dependent manner as shown in Figure 2. For all of the enzymatic

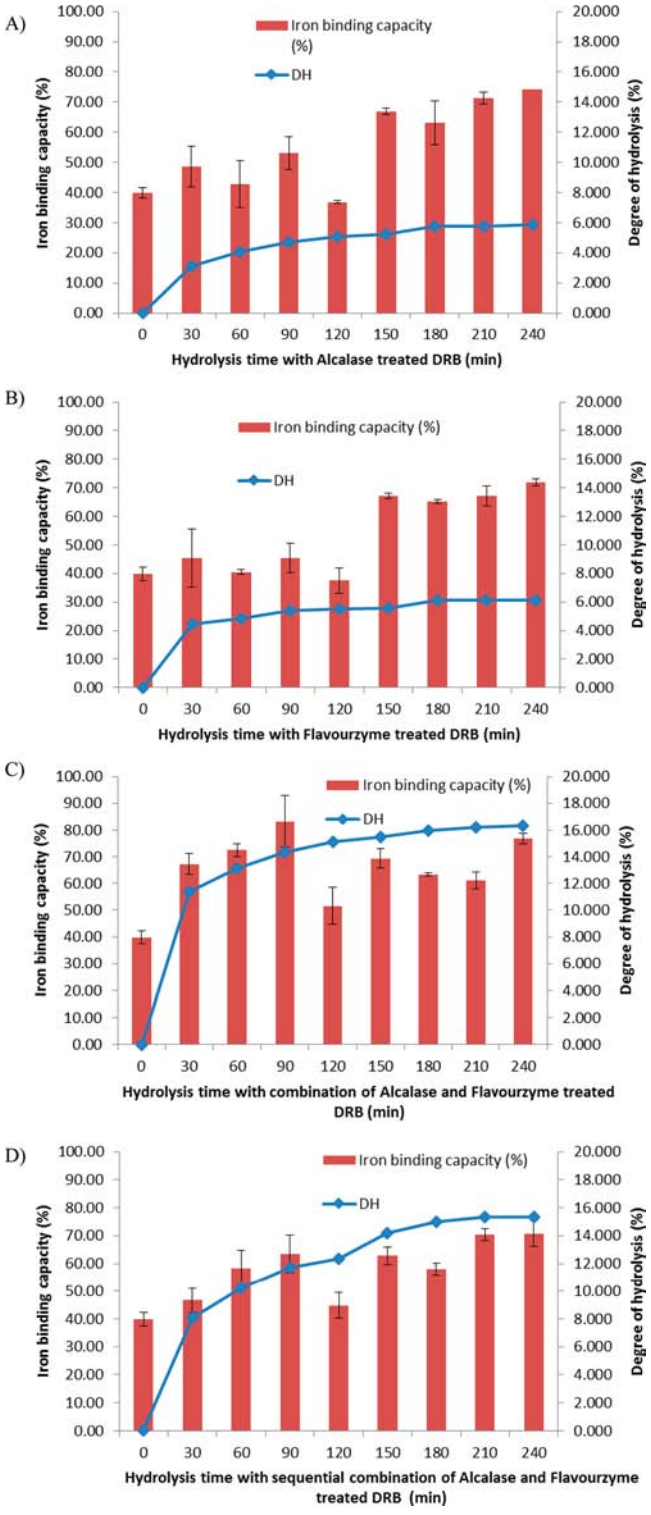

Figure 2. Effects of different hydrolysis times on the iron-binding capacities of DRB hydrolysates isolated by different enzyme hydrolysis treatments: Alcalase (A); Flavourzyme (B); combination of Alcalase and Flavourzyme (C); sequential treatment with Alcalase and Flavourzyme (D). All measurements are expressed as means ± SD of three independent experiments.

treatments, DH values increased dramatically in the primary hydrolysis stage, followed by slow increases in hydrolyses with increasing treatment times. The combination of Alcalase and Flavourzyme treatment exhibited higher DH for the DRB

DOI: 10.1021/acs.jafc.5b03420
J. Agric. Food Chem. 2015, 63, 9029−9036

hydrolysates compared with the individual enzyme treatments at all sampling times. Thus, with Alcalase, DH was 5.87%, whereas 6.12% of DH was obtained for Flavourzyme after 4 h of reaction. The DH of DRB hydrolysates with combination of Alcalase and Flavourzyme at 4 h of treatment was 16.35%. These values represent 10.48% more hydrolysis than with Alcalase and 10.23% more than with Alcalase.

Furthermore, protein hydrolysis was carried out using sequential treatment with the proteases Alcalase and Flavourzyme. After 60 min of Alcalase addition, a protein hydrolysate with a 10.22% DH was obtained (Figure 2D). Subsequent to the addition of Flavourzyme, an extensive hydrolysate with a higher DH (15.34% after 4 h of treatment) was obtained. However, it was slightly lower than that of the combination treatment set.

Iron-Binding Capacity of DRB. The iron-binding capacities of the DRB protein and its hydrolysates obtained at different hydrolysis times are shown in Figure 2. DRB protein hydrolysates taken at various hydrolysis periods (30, 60, 90, 120, 150, and 180 min) showed different iron-binding capacities. The effects of all hydrolysates obtained at different hydrolysis times were significantly higher than that of DRB itself. The peptide hydrolysate after treatment with a combination of Alcalase and Flavourzyme exhibited optimal iron-binding capacity (83%) at 90 min. Increasing the hydrolysis time after 90 min did not significantly increase the iron-binding activity of peptide hydrolysate.

Iron Uptake by Caco-2 Cells. The confluence and the confirmation of the Caco-2 differentiation were monitored by TEER and phenol red diffusion assay. These assays were also conducted during the iron uptake assay to ensure the monolayer integrity. These values were kept constant before and after the experiment (data not shown), indicating the Caco-2 cell monolayers remained intact for use in the studies. Besides that, changes of the morphology in Caco-2 cells were observed under TEM. The expression of microvilli and tight junctions were assessed by examining the cell morphology after day 20. The TEM images (data not shown) showed that the Caco-2 cells demonstrated morphologic differentiation with the presence of numerous microvilli. The integrity of the monolayer was confirmed by the presence of tight junctions in the apical zone. Therefore, the formation of these features highly indicated the validity of the Caco-2 cells as intestine-like cell model for the study of bioavailability.

To evaluate whether the DRB peptide hydrolysates were cytotoxic to cells, Caco-2 cells were treated with increasing concentrations of the DRB peptide hydrolysates from 0 to 1000 ppm. All four DRB hydrolysates showed good effects on cell viability even at a concentration of 1000 ppm (data not shown).

The results obtained in the iron retention, transport, and uptake assays by Caco-2 from DRB hydrolysates are summarized in Table 3. Hydrolysis caused an increase in retention percentage, transport, and uptake efficiencies of iron in all of the DRB hydrolysates. Significant differences ($P < 0.05$) in the iron retention percentage and transport and uptake efficiencies were observed for DRB_A+B hydrolysate compared to the DRB protein without hydrolysis treatment. In addition, the iron solubility percentages of DRB_F and DRB_A+B were increased significantly as well. Therefore, we selected the DRB hydrolysate obtained using combined treatment of Alcalase and Flavourzyme to further investigate the optimal hydrolysis time of DRB hydrolysate−iron complex.

Table 3. Iron Retention, Transport, and Uptake by DRB following Treatments with Alcalase and Flavourzyme[a]

	solubility (%)	retention (μg/L)	retention (%)	transport (μg)	transport (%)	transport efficiency (%)	uptake (μg)	uptake (%)	uptake efficiency (%)

To select the DRB hydrolysate with the highest iron-uptake capacity, a variety of hydrolysates were prepared by incubation with Alcalase and Flavourzyme for different periods of time in the present work. Depending on the hydrolysis treatment period, DRB hydrolysate exhibited improved or inhibitory effects on iron uptake by Caco-2 cells. As shown in Table 4, DRB treated with both Alcalase and Flavourzyme significantly improved ($P < 0.05$) iron solubility percentage and retention percentage as well as transport and uptake efficiencies compared with the unhydrolyzed DRB sample (DRB_A+F 0). DRB treated with Alcalase and Flavourzyme at a hydrolysis time of 180 min was found to have the highest improvement of the overall iron uptake in Caco-2 cells, with an uptake efficiency of up to 9.61% compared to that of DRB without treatment, that is, when the hydrolysis time was 0 h (1.70%). When the hydrolysis treatment was prolonged to 240 min, the iron solubility, retention percentage, and transport and uptake efficiencies decreased significantly.

DISCUSSION

The protein quality of DRB protein concentrate was analyzed by applying the amino acid score based on the reference protein for adults according to FAO/WHO/UHU.[21] The amino acid score of DRB protein concentrate was 86 (as seen in Table 3), indicating that all of the amino acids in DRB protein concentrate were in sufficient quantity required for an adult, except for methionine and cysteine. Cysteine is a semiessential amino acid that can be synthesized in the human body. Therefore, methionine, which is not synthesized in the human body, is the limiting amino acid in DRB. It is commonly depleted in plant proteins and could be supplemented easily from other diets.

Amino acids in the form of peptides are more favorably absorbed in the body compared with the whole protein or the free amino acid mixtures. The reduced hypertonicity in the presence of the peptides enhances their absorption efficiency and reduces the osmotic problems during the digestion process.[27] Besides that, chemical solvent extraction could cause undesirable denaturation and side reactions such as the Maillard reaction to the protein products, as well as reduce the purity of protein products by extracting nonprotein components that coprecipitate with protein and thus lower the protein quality.[28] As a result of these considerations, DRB in the present study was subjected to enzymatic hydrolysis to further enhance protein quality and peptide solubility as well as its functionality as an iron-binding peptide and to increase the bioavailability.

Two proteases, Alcalase and Flavourzyme, with different catalytic activities were used. Alcalase is a protease with endoprotease activity and has been widely used for the generation of protein hydrolysates.[22] Flavourzyme, on the other hand, is a mixture of endoprotease and exoprotease used for debittering and generation of extensive hydrolysate. The extractable peptide hydrolysates were significantly increased at $p \leq 0.05$ when both enzymes were used in the treatment, as compared to those of the Flavourzyme hydrolysis treatment. This might due to the synergetic effects of both enzymes to digest a broader specification of hydrolysis sites. The sequential enzymatic hydrolysis was carried out by using Alcalase as the initial digestion enzyme, followed by Flavourzyme after 60 min. With the predigestion with Alcalase, it was assumed that an increasing exposure of both terminal sites of the peptide possibly facilitates the exoprotease activity of Flavourzyme.

J. Agric. Food Chem. 2015, 63, 9029−9036

However, the results revealed that there is no significant enhancement of the extractable peptide amount in sequential enzymatic treatment when compared to those of combination enzymatic treatment, indicating the sequence of adding the enzymes in the hydrolysis process is less important.

Hydrolysates produced by combination treatment of Alcalase and Flavourzyme showed the best iron-binding capacity. The peptide hydrolysate after being treated by Alcalase and Flavourzyme exhibits optimal iron-binding capacity (83%) at the 90 min time of hydrolysis. Further increasing the hydrolysis time did not significantly increase the iron-binding activity of the peptide hydrolysate. This might be due to several factors, such as inhibitory effects of end products, enzyme inhibitors in the substrate, or the structural limitation of the enzymes to further digestion.[8]

Mineral binding and release in the human body is a dynamic process involving the absorption of the mineral in the digestive tract such as duodenum and intestine.[8] The solubility of iron, especially in the basic conditions of the duodenum and proximal jejunum, is of great importance for its in vivo absorption and bioavailability.[8,29] Iron solubility, iron retention, transport efficiency, and uptake efficiency percentages can be used as predictors for the iron intestinal bioavailability.[27,30] In this study, an in vitro digestion/human colonic adenocarcinoma (Caco-2) cell model system invented by R. P. Glahn, which mimics the gastric and intestinal digestion of humans, was used for iron bioavailability studies. The study was conducted in two parts; the iron uptake of the four DRB peptide hydrolysates was determined, and then the peptide hydrolysate with the highest iron uptake was chosen and further investigated in a time-dependent manner for its iron uptake efficiency. The iron contents were determined using ICP-MS, which is a sensitive detector for iron detection with the detection limit of 1 ppb.

When the results are expressed in percentages in relation to the soluble content, significant differences are observed among the samples. Iron solubility of the nonhydrolyzed DRB in this study was lower than those of hydrolyzed samples as well as those reported in a previous study.[25,26] This could have been due to the fiber components from the nonhydrolyzed DRB. Moreover, it is reported that some dietary fiber components decrease the mineral bioavailability by binding to the mineral ions.[31] The effect of hydrolysis caused an increase in retention percentage, transport, and uptake efficiencies of iron in all of the DRB protein hydrolysates. This indicated that the hydrolysis degree, that is, peptide length and size, is one of the important factors which influence the iron uptake efficiency of DRB protein hydrolysate in Caco-2 cells. Significant differences ($P < 0.05$) on the iron retention percentage and transport and uptake efficiencies were observed for DRB_A+B hydrolysate when compared to that of other samples. Therefore, we selected DRB_A+F, which is the DRB protein hydrolysate obtained using combined treatment of Alcalase and Flavourzyme, to further investigate the optimal hydrolysis time of the DRB protein hydrolysate−iron complex.

Furthermore, as can be recalled, although the iron-binding capacity was highest for the DRB_A+F at 90 min, the optimal cellular iron uptake was at 180 min probably indicating that at 90 min, the chemical properties of the DRB_A+F tended toward stronger bonding between the DRB constituents and the iron, which may have been weakened with the passage of time and hence the enhanced release of the iron when hydrolysis lasted for 180 min. Moreover, there was a progressive increase in cellular iron uptake with time until 180 min, when it dropped, suggesting that the bonding between the iron and DRB was weakened with increasing hydrolysis time. This hypothesis is supported by the lack of a parallel relationship between solubility and bioavailability of iron and other minerals in Caco-2 cells.[32,33]

The present study demonstrated that DRB hydrolysates produced by combination hydrolysis using Alcalase and Flavourzyme had potent iron-binding capacities. Additionally, using an in vitro digestion and absorption model (Caco-2 cell model), iron transport and uptake efficiencies of the combination Alcalase and Flavourzyme-treated DRB samples were found to be significantly higher than those of the nonhydrolyzed samples. The implications of these results are that DRB protein hydrolysates can be used as iron-fortified supplements and hence need to be studied further.

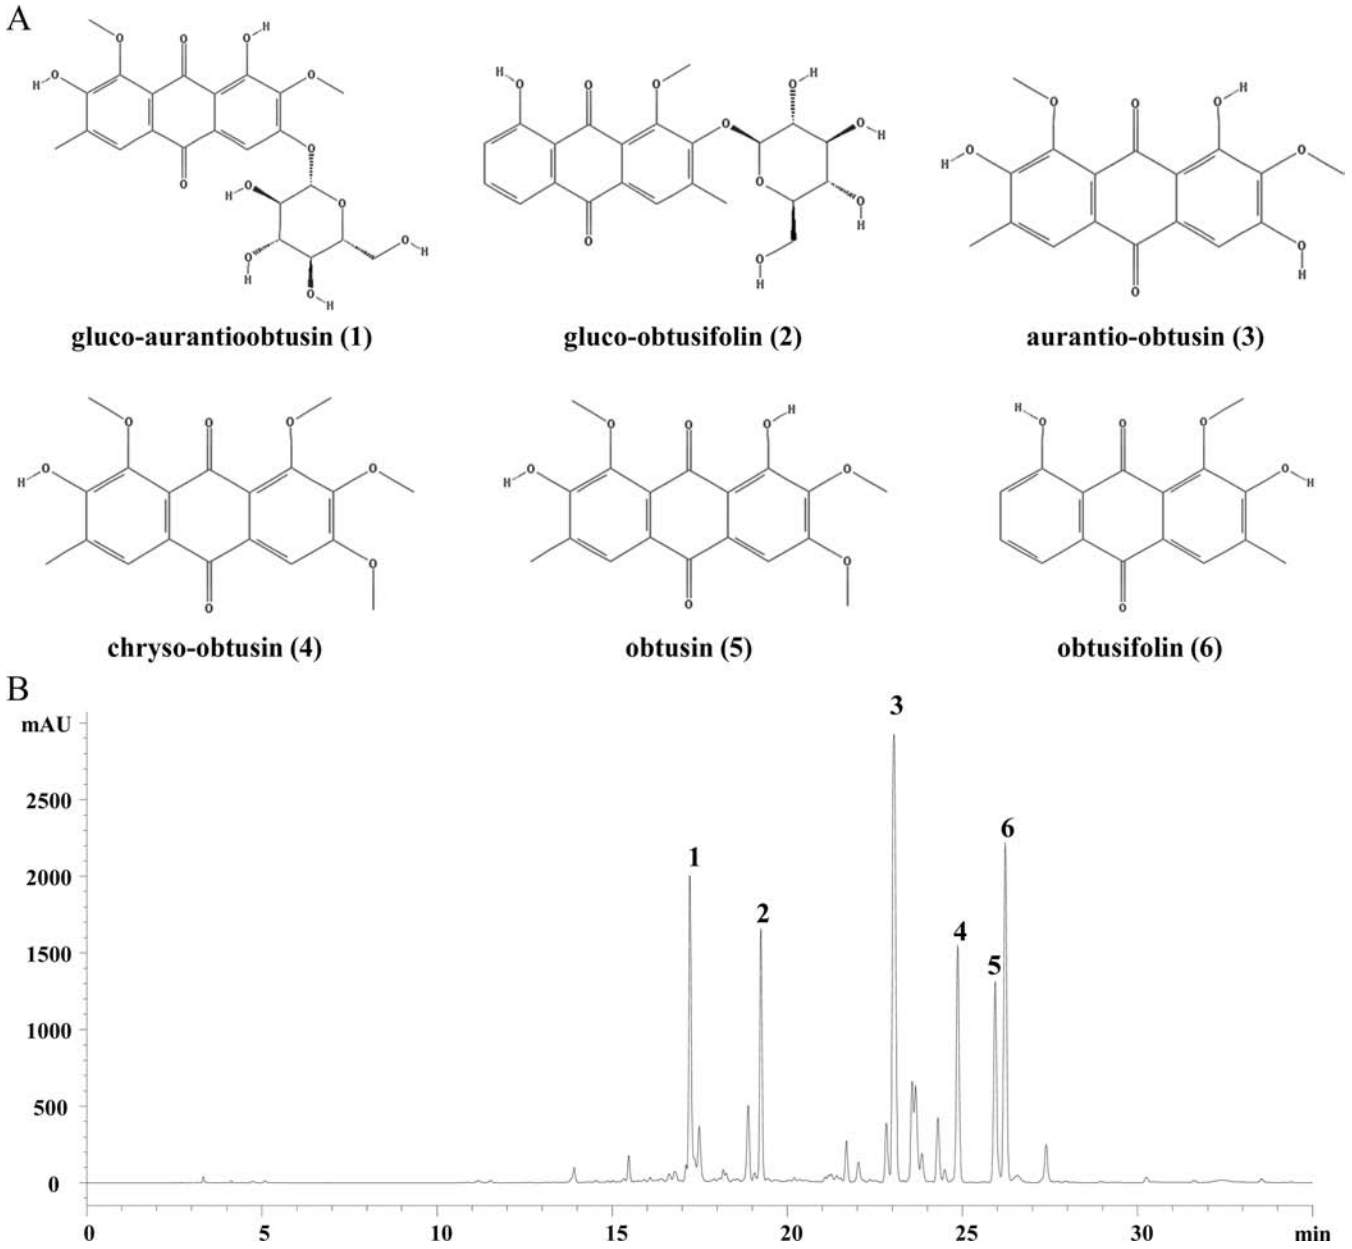

Figure 1. (A) Chemical structure of anthraquinones and (B) HPLC chromatogram from *C. tora* seed extract (CTE).

serum (FBS; Hyclone, South Logan, UT, USA), penicillin (Invitrogen, Carlsbad, CA, USA), Dulbecco's modified Eagle's medium (DMEM; Hyclone, South Logan, UT, USA), and phospho-Syk (Tyr525/526) antibody, phospho-phospholipase C (PLC)γ (Tyr783) antibody, phospho-PKD/PKCμ (Ser916) antibody, phosphor-SAPK/JNK (Thr183/Tyr185) antibody, SAPK/JNK (Thr183/Tyr185) antibody, phospho-p44/42 MAPK antibody (Erk1/2), p44/42 MAPK (Erk1/2) antibody, phospho-p38 antibody, p38 antibody, and β-actin antibody (all from Cell Signaling Technology Inc., Danvers, MA, USA).

Plant Material. Seeds of *C. tora*, collected in Yeongcheon, Gyeongsang Province, Korea, were purchased from a commercial supplier in Gyeongdong market, Seoul, Korea, in August 2013 and were identified by one of the authors (H.-J.L.). A voucher specimen was deposited at the Korea Institute of Science and Technology (KIST), Gangneung Institute. Extraction was performed by sonication using an RK158S ultrasonic bath (Bandelin, Germany).

Extraction and Isolation of Anthraquinones from *C. tora* Seeds. One kilogram of the dried seeds of *C. tora* was extracted with 1 L of 95% ethanol at room temperature and filtered through Whatman No. 1 filter paper (GE Healthcare Life Sciences, PA, USA). The filtrate was concentrated under reduced pessure by rotary evaporation at 40 °C, and 95 g of EtOH extract (CTE) was obtained. Isolation of anthraquinones (Figure 1) from *C. tora* was done as previously described.[16]

Cell Culture. RBL-2H3 cells were obtained from the American Type Culture Collection (ATCC, Manassas, VA, USA) via the Korean Cell Line Bank (KCLB No. 22256, Seoul, Korea). Cells were cultured in DMEM supplemented with 10% FBS and 100 U/mL penicillin. Cells were grown in 75 cm^2 culture flasks at 37 °C with 5% CO_2 in a humidified atmosphere.

Cell Viability Assay. Cell viability was checked using a 3-[4,5-dimethylthiazol-2-yl]-2,5-diphenyltetrazolium bromide (MTT) colorimetric assay (Sigma-Aldrich, St Louis, MO, USA). RBL-2H3 cells were grown in 24-well plates (2×10^5 cells/mL) for 24 h. After treatment of the cells with various concentrations of CTE and aurantio-obtusin for 6 h, the cells were washed and then treated with 200 μL of MTT (0.5 mg/mL) and cells were incubated for an additional 4 h. Cells were then washed, and the insoluble formazan products were dissolved in 200 μL of DMSO. Absorbance was measured by spectrophotometry at

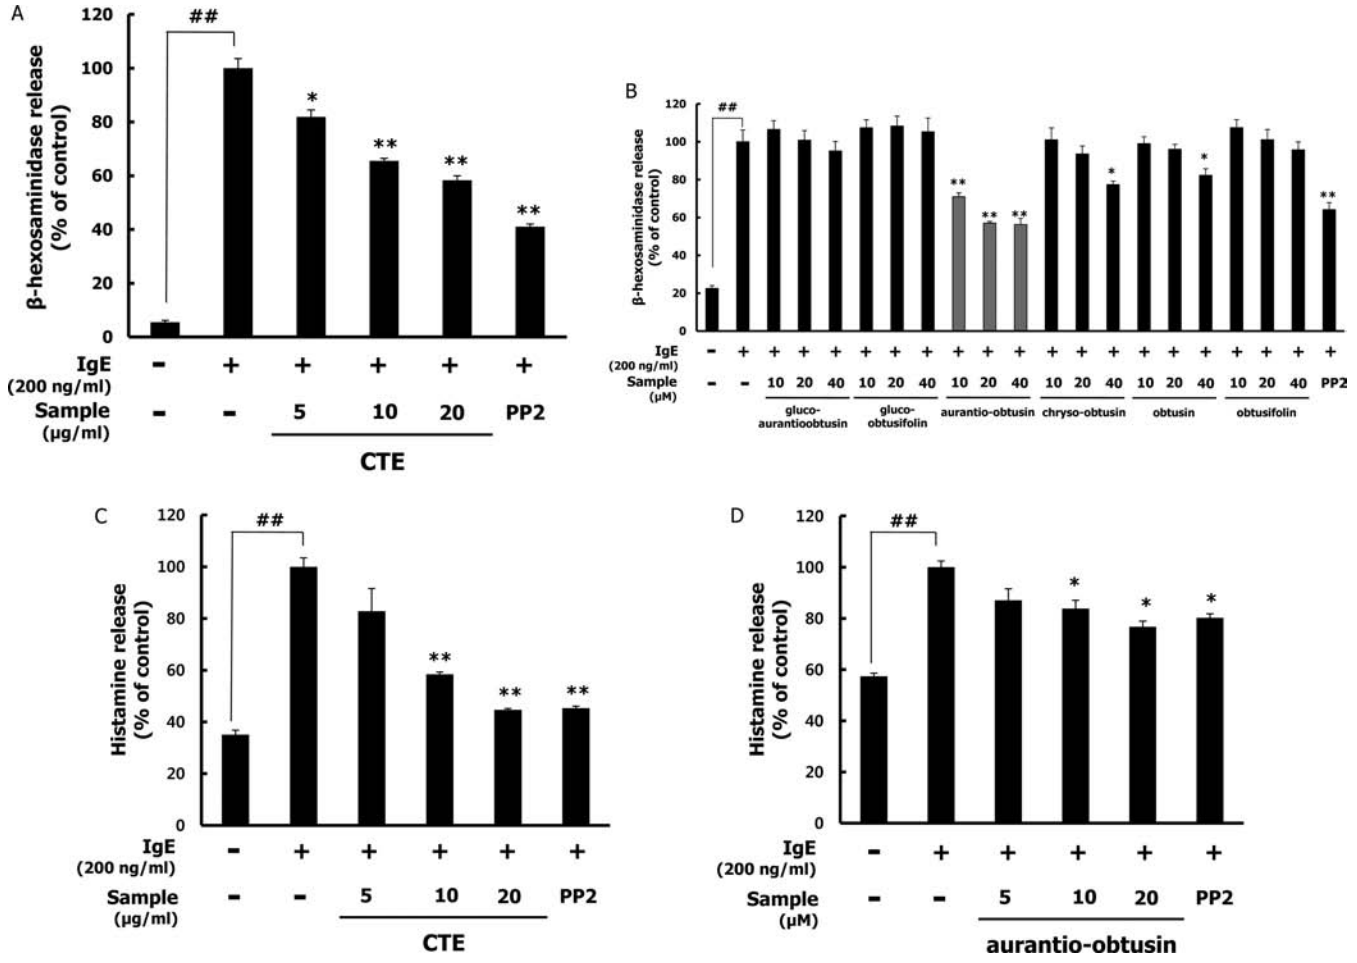

Figure 2. Effects of CTE and aurantio-obtusin on β-hexosaminidase and histamine release. (A) The degranulation was determined by measuring β-hexosaminidase release in DNP-IgE-sensitized RBL-2H3 cells. The RBL-2H3 cells were treated in the presence or absence of CTE (5, 10, or 20 μg/mL) for 1 h and then stimulated for 1 h with DNP-BSA. (B) The RBL-2H3 cells were treated in the presence or absence of gluco-aurantioobtusin (1), gluco-obtusifolin (2), aurantio-obtusin (3), chryso-obtusin (4), obtusin (5), or obtusifolin (6) (10, 20, or 40 μM) for 1 h and then stimulated for 1 h with antigen. (C, D) Histamine release was determined with enzyme-linked immunosorbent assay kit. The RBL-2H3 cells were treated in the presence or absence of CTE (5, 10, or 20 μg/mL) and aurantio-obtusin (5, 10, or 20 μM) for 1 h and then stimulated for 1 h with antigen. PP2 (10 μM) is a general Src-family kinase inhibitor. Results are expressed as the mean ± SD of three independent experiments ($^{\#\#}p < 0.01$, $^{*}p < 0.05$, and $^{**}p < 0.01$).

550 nm using a microplate reader (Bio-Tek Instruments, Winooski, VT).

Measurement of Histamine and β-Hexosaminidase Release. RBL-2H3 cells were sensitized with 0.2 μg/mL monoclonal DNP-IgE. Cells were washed with modified PIPES buffer (25 mM PIPES, pH 7.2, 119 mM NaCl, 5 mM KCl, 0.4 mM $MgCl_2 \cdot 6H_2O$, 1 mM $CaCl_2$, 5.6 mM glucose, 40 mM NaOH, and 0.1% BSA). Cells were treated with CTE or compounds **1**−**6** at the indicated concentrations for 1 h at 37 °C. After incubation, cells were challenged with 0.2 μg/mL DNP-BSA for 1 h at 37 °C. Histamine was then detected using an enzyme immunoassay kit (Oxford Biomedical Research, Rochester Hills, MI). Histamine release was expressed as a percentage of the total histamine produced by unstimulated cells. To determine β-hexosaminidase release, supernatants and lysed pellets were aliquoted into 96-well plates. Samples were mixed with substrate solution (1 mM *p*-nitrophenyl *N*-acetyl-β-D-glucosamine in 0.05 M citrate buffer, pH 4.5) and incubated for 1 h at 37 °C. Reactions were terminated by the addition of 0.05 M sodium carbonate buffer, pH 10. Absorbance was measured by spectrophotometry at 405 nm.

Measurement of Prostaglandin E_2. Cell culture medium was collected, and the secretion of prostaglandin E_2 (PGE_2) was determined using competitive radioimmunoassay kits (R&D Systems, MN, USA, and Cayman Chemical, MI, USA, respectively) according to the manufacturers' protocol.

Measurement of Cytokine Release. IgE-sensitized RBL-2H3 cells were incubated with CTE and aurantio-obtusin (various concentrations) for 1 h and stimulated with DNP-BSA for 4 h. Interleukin (IL)-4 and tumor necrosis factor (TNF)-α concentrations in cell culture supernatants were measured using enzyme-linked immunosorbent assay kits (Abcam, U.K.).

Measurement of Reactive Oxygen Species (ROS) Production. RBL-2H3 cells were pretreated with CTE and aurantio-obtusin for 1 h before being sensitized overnight with 0.2 μg/mL of DNP-specific IgE antibody. The cells were washed with PBS, and stained with 40 μM DCFH-DA for 30 min. For fluorescence staining assay, cells were then stimulated with 1 μg/mL of DNP-BSA for 30 min, and changes in fluorescence intensity were measured using a microplate reader (Bio-Tek Instruments, Winooski, VT) at excitation and emission wavelengths of 485 and 530 nm, respectively.

Reverse Transcription-Polymerase Chain Reaction. (RT-PCR). RNA was extracted with TRIzol reagent (Invitrogen) according to the manufacturer's protocol and quantified by spectrophotometry at 260 nm. The cDNA was synthesized in a 20 μL reaction containing 1 μg of total RNA, oligo (dT), and reverse transcriptase premix (Elpis-Biotech., Inc., Taejeon, Korea). Reverse transcription (RT) was initiated at 70 °C for 5 min, followed by incubation at 42 °C for 60 min, and was terminated at 94 °C for 5 min. Amplification of the cDNA products (5 μL) by PCR was performed with a PCR premix

DOI: 10.1021/acs.jafc.5b03836
J. Agric. Food Chem. 2015, 63, 9037−9046

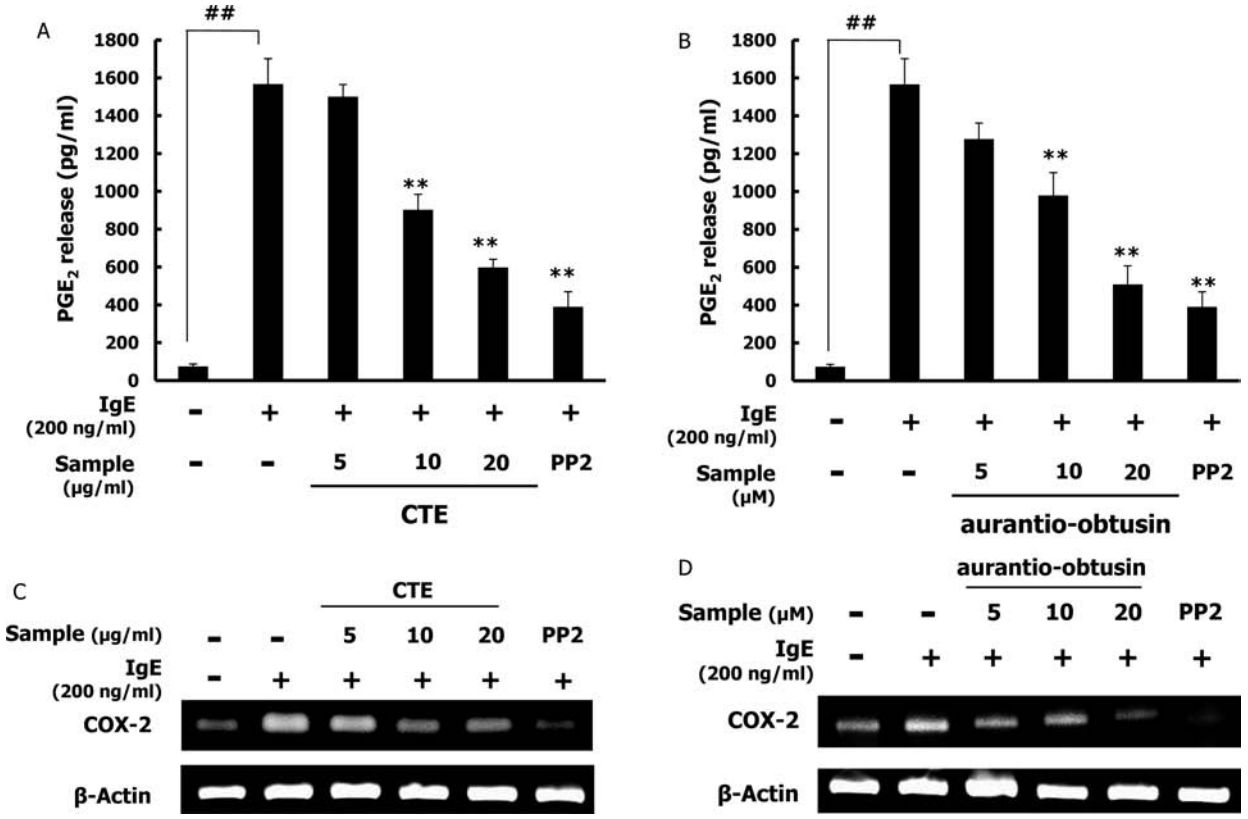

Figure 3. Effects of CTE and aurantio-obtusin on PGE_2 secretion and COX-2 mRNA expression. RBL-2H3 cells were treated with CTE (5, 10, or 20 μg/mL) and aurantio-obtusin (5, 10, or 20 μM) for 1 h and then stimulated for 4 h with antigen. (A, B) PGE_2 secretion was determined by enzyme-linked immunosorbent assay kit. (C, D) COX-2 mRNA level was determined with RT-PCR. PP2 (10 μM) is a general Src-family kinase inhibitor. Results are expressed as the mean ± SD of three independent experiments ($^{\#\#}p < 0.01$, $^{*}p < 0.05$, and $^{**}p < 0.01$).

(Elpis-Biotech) and the following primer pairs: TNF-α forward, 5′-CAA GGA GCA GAA GTT CCC AA-3′, and TNF-α reverse, 5′-CGG ACT CCG TGA TGT CTA AG-3′ (500 bp); IL-4 forward, 5′-ACC TTG CTG TCA CCC TGT TC-3′, and IL-4 reverse, 5′-TTG TGA GCG TGG ACT CAT TC-3′ (351 bp); COX-2 forward, 5′- TGA CTG TAC CCG GAC TGG AT-3′, and COX-2 reverse, 5′-CAT GGG AGT TGG GCA GTC AT-3′ (322 bp); β-actin forward, 5′-AGC CAT GTA CGT AGC CAT CC-3′, and β-actin reverse, 5′-TCT CAG CTG TGG TGG TGA AG-3′ (227 bp). Before PCR amplification, primers for cytokines and β-actin were denatured at 94 °C for 5 min. Amplification consisted of 28 cycles of denaturation at 94 °C for 30 s, annealing for 1 min, and extension at 72 °C for 1 min, followed by a final 5 min extension at 72 °C. PCR was performed using a GeneAmp PCR System 9700 (Applied Biosystems, Foster City, CA, USA). PCR products were separated by 1.5% agarose gel electrophoresis and visualized by ethidium bromide staining and UV illumination. Densitometry was performed using DIG chemiluminescent film (volume of all markers/volume of β-actin).

Passive Cutaneous Anaphylaxis (PCA) in Mice. DNP-IgE (0.5 mg) was subcutaneously injected onto the ears of BALB/c mice (4-week-old male). After 24 h, the mice were orally administered with CTE (200 mg/kg), aurantio-obtusin (50 mg/kg), or cetirizine (20 mg/kg). After 1 h, the mice were injected intravenously with DNP-BSA (250 μg) in PBS containing Evans Blue (5 mg/mL). After 60 min, the ear tissue was removed and absorbed dye was extracted overnight in formamide (700 μL) at 63 °C. The absorbance was measured at 620 nm. Animal experimental procedures were approved by the Animal Care and Use Committee of KIST.

Western Blot Analysis. RBL-2H3 cells were lysed in RIPA buffer (containing 150 mM NaCl, 1.0% IGEPAL CA-630, 0.5% sodium deoxycholate, 0.1% SDS, 50 mM Tris, pH 8.0) containing protease inhibitors and then placed on ice for 10 min. Lysate protein concentrations were determined by Bradford protein assay (Bio-Rad Laboratories, Hercules, CA, USA). Equal amounts of protein (30 μg) were loaded in each sample, separated by 10% sodium dodecyl sulfate−polyacrylamide gel electrophoresis, and transferred to nitrocellulose membranes (Whatman GmbH, Dassel, Germany). Blotted membranes were blocked with 5% skimmed milk in Tris-buffered saline containing 0.1% Tween 20 for 1 h, and then incubated with primary antibodies for 16 h at 4 °C. After three washes in Tris-buffered saline containing 0.1% Tween 20, the membranes were incubated with horseradish peroxidase-linked secondary antibodies (Santa Cruz Biotechnology, Santa Cruz, CA, USA) for 2 h. Proteins were detected with enhanced chemoluminescence (Amersham Biosciences, Little Chalfont, U.K.) and visualized using an ECL Advanced system (GE Healthcare, Hatfield, U.K.).

Statistical Analysis. Each experiment was performed at least three times. Results are expressed as the mean ± standard deviation (SD). Vehicle (DMSO) and treated groups were compared by one-way analysis of variance followed by Scheffe's test (SPSS 17.0, Chicago, IL, USA). $^{\#\#}p < 0.01$, $^{*}p < 0.05$, and $^{**}p < 0.01$ were considered statistically significant. $^{\#\#}p < 0.01$ compared with the control group (DNP-IgE treatment alone); $^{*}p < 0.05$ and $^{**}p < 0.01$ compared with the DNP-IgE and DNP-BSA stimulated group.

RESULTS

Identification of Anthraquinones in *C. tora* Seeds. Six anthraquinones were identified in *C. tora* using liquid chromatography−mass spectrometry, namely, gluco-aurantioobtusin, gluco-obtusifolin, aurantio-obtusin, chryso-obtusin, obtusin, and obtusifolin (Figure 1).

Effects of CTE and Aurantio-obtusin on Degranulation and Histamine Release in IgE-Sensitized RBL-2H3 Cells. The effects of CTE and aurantio-obtusin on cell cytotoxicity were assessed by the colorimetric MTT assay.

DOI: 10.1021/acs.jafc.5b03836
J. Agric. Food Chem. 2015, 63, 9037−9046

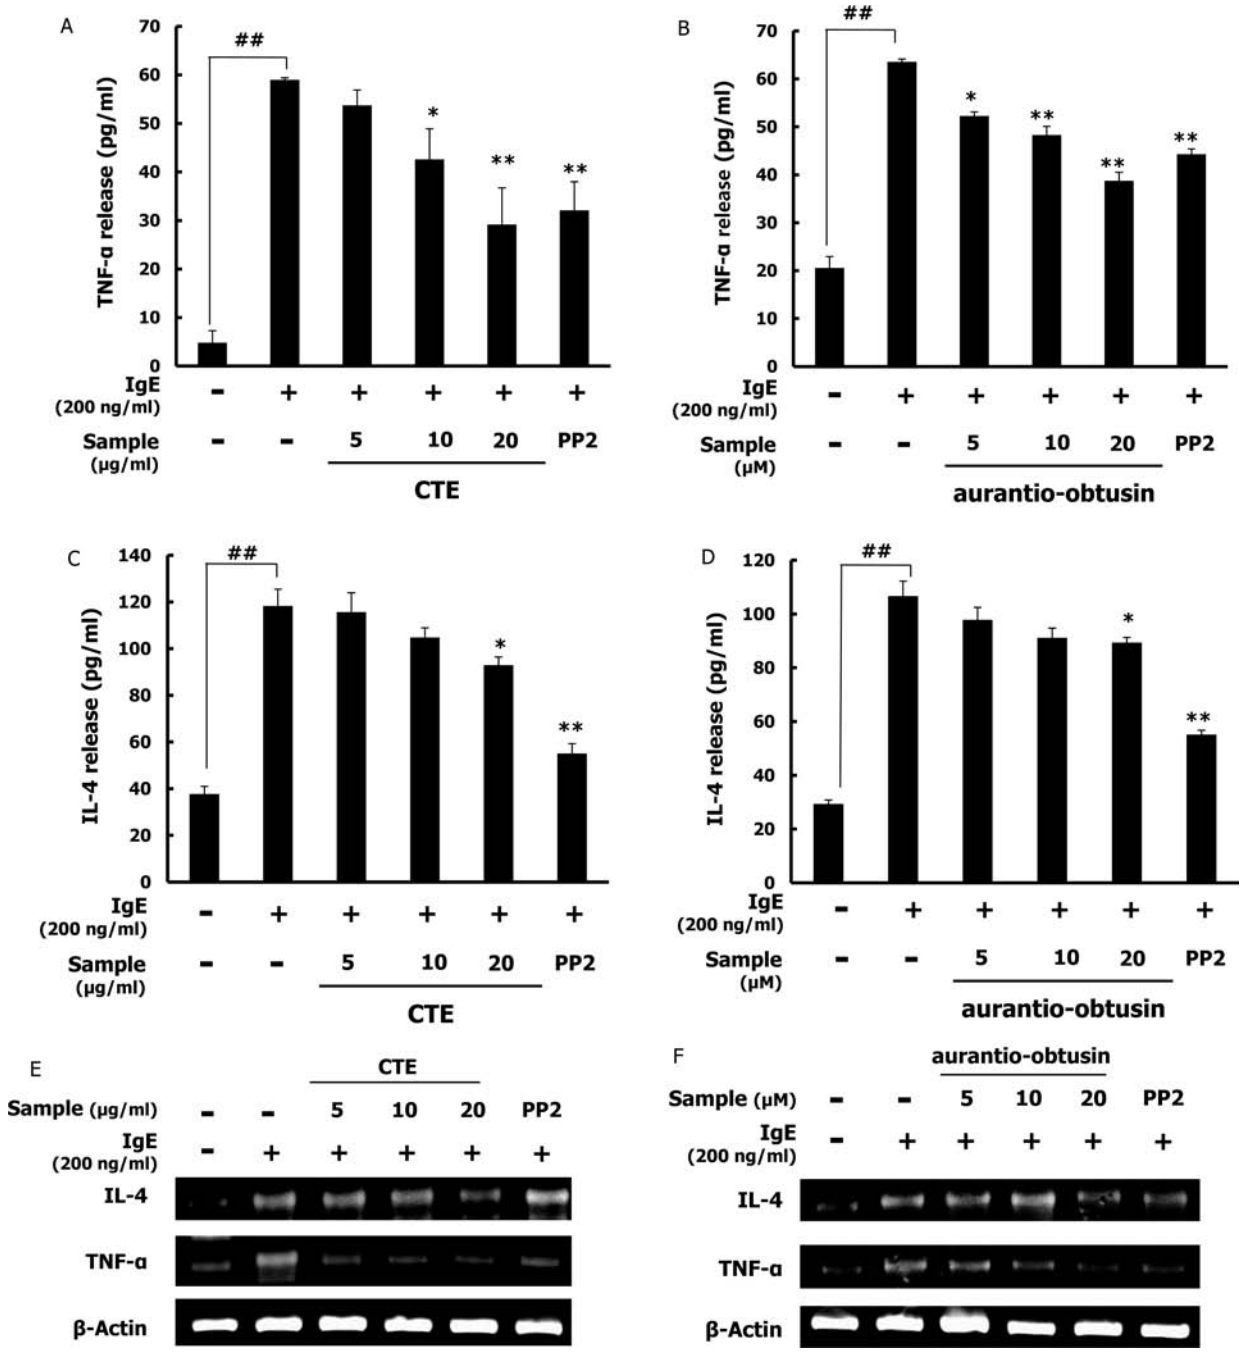

Figure 4. Effects of CTE and aurantio-obtusin on TNF-α and IL-4 production and mRNA expression. RBL-2H3 cells were treated with CTE and aurantio-obtusin for 1 h and then stimulated with DNP-BSA for 4 h. (A–D) TNF-α and IL-4 production was determined by enzyme-linked immunosorbent assay kit. (E, F) mRNA levels of TNF-α and IL-4 were determined with RT-PCR. PP2 (10 μM) is a general Src-family kinase inhibitor. Results are expressed as the mean ± SD of three independent experiments ($^{\#\#}p < 0.01$, $^{*}p < 0.05$, and $^{**}p < 0.01$).

CTE (up to 20 μg/mL) or aurantio-obtusin (up to 20 μM) had no effect on RBL-2H3 cell viability (Figures S1 and S2). To verify the effects of CTE and its isolated compounds on degranulation of mast cell, we examined their potential to suppress the β-hexosaminidase release. CTE suppressed β-hexosaminidase release in IgE-sensitized mast cells in a dose-dependent manner (Figure 2A). In addition, aurantio-obtusin inhibited β-hexosaminidase release more than gluco-aurantioobtusin, gluco-obtusifolin, chryso-obtusin, obtusin, and obtusifolin in IgE-sensitized mast cells (Figure 2B). Thus, additional experiments were carried out using aurantio-obtusin. The effects of CTE and aurantio-obtusin on histamine release were also assessed to investigate potential antiallergic activities. CTE and aurantio-obtusin repressed histamine release in IgE-sensitized mast cells (Figures 2C and 2D).

Inhibitory Effects of CTE and Aurantio-obtusin on PGE_2 Production and Cyclooxygenase 2 (COX-2) Expression in IgE-Sensitized RBL-2H3 Cells. In antigen-stimulated mast cells, the arachidonate cascade is initiated via the FcεRI receptor and recruits inflammatory cells, such as neutrophils, Th2 cells, eosinophils, and basophils.[17] Therefore, these arachidonic acid metabolites contribute to inflammation

DOI: 10.1021/acs.jafc.5b03836
J. Agric. Food Chem. 2015, 63, 9037–9046

in allergic diseases, and suppression of their production is essential to prevent or treat allergic diseases. To investigate the effects of CTE and aurantio-obtusin on the production of PGE_2, RBL-2H3 cells were sensitized with 200 ng/mL DNP-IgE overnight and treated with CTE and aurantio-obtusin for 1 h followed by the treatment with DNP-BSA for 24 h. CTE and aurantio-obtusin significantly inhibited PGE_2 production in a dose-dependent manner in IgE-stimulated RBL-2H3 cells (Figures 3A and 3B). The effects of CTE and aurantio-obtusin on COX-2 expression were confirmed by RT-PCR. DNP-BSA increased COX-2 mRNA expression in IgE-sensitized mast cells. However, treatment with CTE and aurantio-obtusin reduced IgE-mediated upregulation of COX-2 expression (Figures 3C and 3D). These results indicated that CTE and aurantio-obtusin inhibit the release of pro-inflammatory lipid mediators from activated mast cells and suggest that they may have an antiallergic effect.

Inhibitory Effects of CTE and Aurantio-obtusin on the Production and mRNA Expression of Tumor Necrosis Factor (TNF)-α and Interleukin (IL)-4 in IgE-Sensitized RBL-2H3 Cells. Allergic inflammatory responses are induced by proinflammatory cytokines from activated mast cells. TNF-α and IL-4, which are proinflammatory cytokines, are essential in allergy-related diseases.[18] We therefore determined whether CTE and aurantio-obtusin inhibited the production and mRNA expression of TNF-α and IL-4 in IgE-stimulated RBL-2H3 cells. Consistently with the previous report,[19] the increase of the production and expression of TNF-α and IL-4 was obvious by DNP-BSA stimulation in mast cells. CTE and aurantio-obtusin decreased both the production (Figures 4A–D) and mRNA expression (Figures 4E and 4F) of TNF-α and IL-4. These results showed that CTE and aurantio-obtusin have an inhibitory effect on the production and expression of proinflammatory cytokines in mast cells.

Effects of CTE and Aurantio-obtusin on Reactive Oxygen Species (ROS) Production in IgE-Sensitized RBL-2H3 Cells. Several reports suggested that activated mast cells have increased intracellular ROS levels.[20] Moreover, ROS augments histamine release in mast cells,[21] and H_2O_2 can regulate phosphorylation of PLCγ.[22] We next examined to investigate whether CTE and aurantio-obtusin attenuate ROS production following IgE-mediated mast cell activation using the DCFH-DA fluorescent indicator. Fluorometer analysis showed that the level of ROS increased from 10.60% in nonstimulated cells to 58.62% in antigen-sensitized cells. However, ROS production was significantly reduced by CTE or aurantio-obtusin treatment in a dose-dependent manner (Figures 5A and 5B).

Effects of CTE and Aurantio-obtusin on FcεRI Signaling in IgE-Sensitized RBL-2H3 Cells. Aggregation of FcεRI consecutively initiates IgE-mediated phosphorylation of tyrosine kinases such as Syk and Lyn, and subsequently tyrosine phosphorylation of cellular proteins such as PLCγ and PKC.[19] PP2, a general Scr-family kinase inhibitor, significantly suppresses Syk phosphorylation.[19] To determine the mechanisms underlying CTE- and aurantio-obtusin-mediated inhibition of allergic responses, we examined several intracellular signals. Phosphorylation of Syk, PKD/PKCμ, and PLCγ was induced in antigen-stimulated RBL-2H3 cells, and this phosphorylation was inhibited by treatment with CTE and aurantio-obtusin (Figures 6A and 6B). We also examined the effects of CTE and aurantio-obtusin on MAPKs because of their role in the production of TNF-α and IL-4.[23] Among

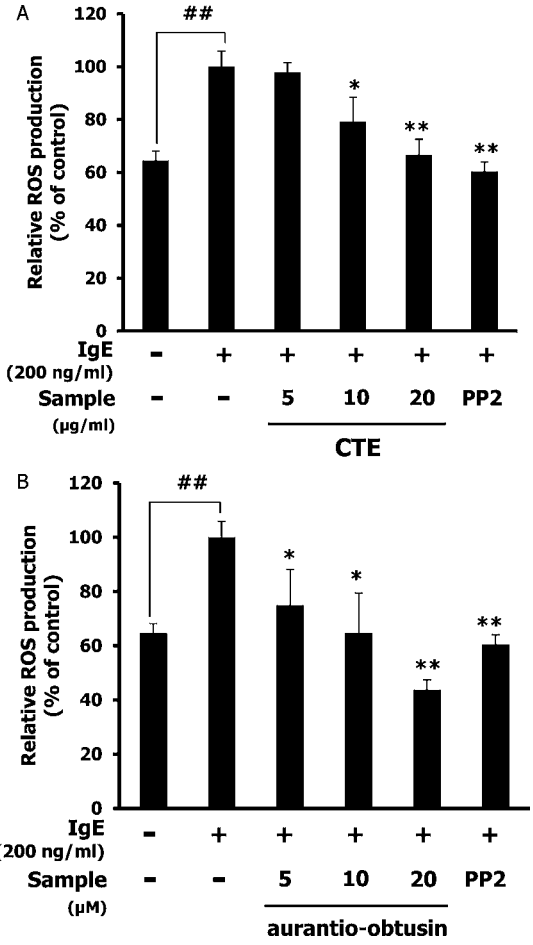

Figure 5. Effect of CTE and aurantio-obtusin on intracellular ROS production. (A, B) RBL-2H3 cells were treated with CTE and aurantio-obtusin for 1 h and then stained with 40 μM 2′7′-dichlorofluorescein diacetate (DCFH-DA; Sigma-Aldrich) for 30 min. The stained cells were then stimulated with DNP-BSA for 10 min. After 30 min, ROS levels were analyzed by flow cytometry. PP2 (10 μM) is a general Src-family kinase inhibitor. Results are expressed as the mean ± SD of three independent experiments ($^{\#\#}p < 0.01$, $^{*}p < 0.05$, and $^{**}p < 0.01$).

phosphorylation of ERK, JNK, and p38 induced by antigen stimulation, phosphorylation of ERK was only suppressed by treatment with CTE and aurantio-obtusin (Figures 6C and 6D). These results suggest that CTE and aurantio-obtusin suppresses mast cell activation by inactivation of FcεRI signaling and ERK in mast cells.

Effect of CTE and Aurantio-obtusin on IgE-Mediated PCA in Mice. PCA is generally used to measure local allergic responses in vivo.[24] To examine whether CTE and aurantio-obtusin repressed allergic reactions, we introduced a IgE-mediated PCA model. IgE was subcutaneously injected onto the left ear tissue of mouse, followed by injection of DNP-BSA containing 5% Evans Blue. CTE and aurantio-obtusin suppressed the IgE-sensitized PCA response (Figures 7A and 7B). Cetrazine, a typical antihistamine drug, was used as a positive control.[25]

DISCUSSION

Type I hypersensitivity is triggered by inflammatory chemical mediators (cytokines, ILs, LTs, and PGs) secreted from immune cells such as eosinophils, basophils, and mast cells.

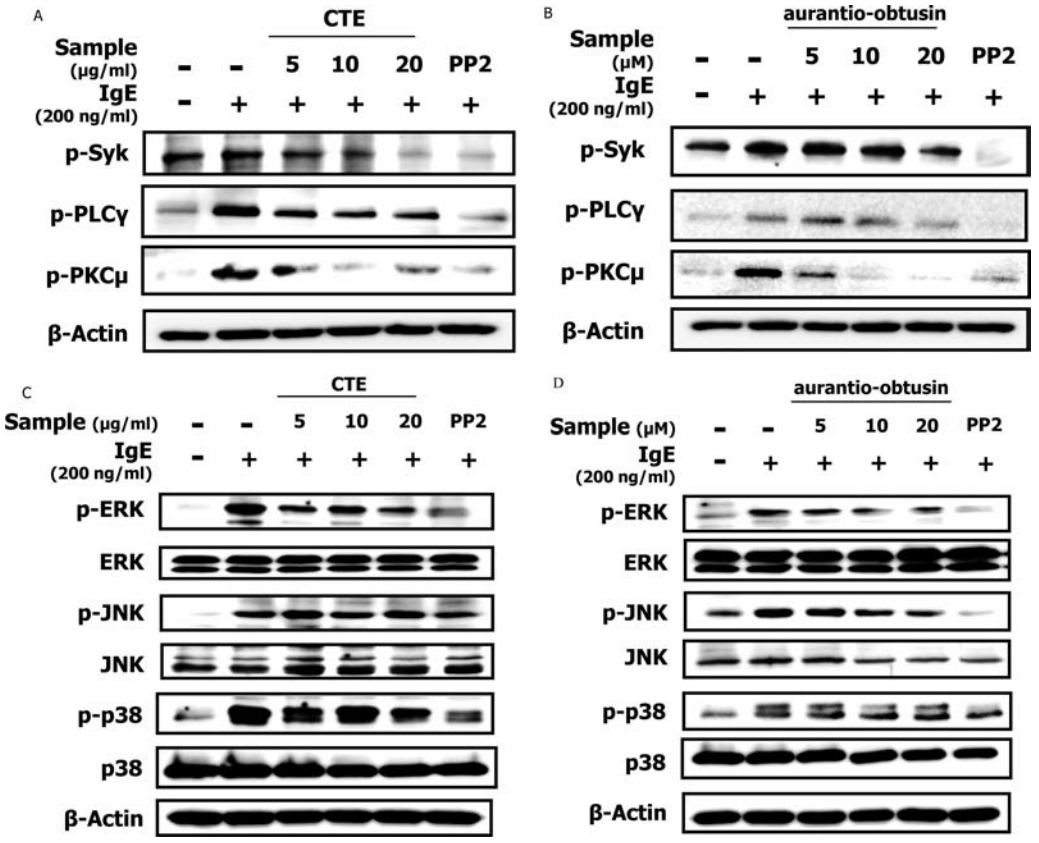

Figure 6. Effect of CTE and aurantio-obtusin on FcεRI Signaling. (A, B) RBL-2H3 cells were treated with CTE and aurantio-obtusin for 1 h and then stimulated with DNP-BSA for 10 min. Phosphorylation of Syk, PLCγ, and PKD/PKCμ was determined with Western blot analysis. (C, D) RBL-2H3 cells were treated with CTE and aurantio-obtusin for 1 h and then stimulated with DNP-BSA for 30 min. Phosphorylation of JNK, ERK, and p38 was determined with Western blot analysis. PP2 (10 μM) is a general Src-family kinase inhibitor.

Particularly, mast cells are key players in the control of allergic related reactions.[26] A recent study revealed that mast cell-released chemical mediators (histamines, cytokines, and proteases) play a crucial role during allergic mediated inflammation in mast cell-deficient mice.[27] Therefore, several studies have reported specific mediators of mast cell activation and identified novel compounds that inhibit these allergic mediators.[3,28,29]

Anthraquinones are predominantly reported in and isolated from the seeds of *Cassia tora* L. (syn. Senna tora) and *Cassia obtusifolia* L. (syn. Senna obtusifolia),[30,31] and may possess anti-inflammation, antioxidant, and anticancer properties.[32−34] Moreover, anthraquinones inhibit chemical mediators of mast cell activation. For instance, emodin, rhein, and citreorosein, three naturally occurring anthraquinone derivatives, suppress the IgE-mediated anaphylactic reaction, mast cell activation, and LT generation.[35−37] Among anthraquinone derivatives isolated from *C. tora*, aurantio-obtusin is the major compound. It is also used as a quality control marker of *C. tora* and reportedly has antihypertensive, hepatoprotective, antimutagenic, osteogenic, and estrogenic activities.[38−42] However, the effects of *C. tora* seed and aurantio-obtusin on allergic diseases have not been studied. In this study, we assessed the inhibitory effects of CTE and its active compound aurantio-obtusin on allergic inflammation in mast cells.

Activation of FcεRI receptors by the high-affinity binding and aggregation of IgE triggers a signaling cascade that led to degranulation and production of inflammatory mediators, such as inflammatory cytokines, lipid-derived mediators, and histamine.[43] CTE and aurantio-obtusin suppressed the secretion of β-hexosaminidase (Figures 2A and 2B) and histamine (Figures 2C and 2D). These results suggest that the antiallergic activities of CTE and aurantio-obtusin are caused by the inhibition of histamine release, which causes smooth muscle contraction, vascular permeability, and inflammation.

The FcεRI receptor signals through Syk, Lyn, and PLCγ to regulate mast cell activation.[17] The FcεRI receptor aggregates to IgE and starts intracellular signal cascade to derive allergic reactions. Stimulated FcεRI initiates phosphorylation of Syk, which binds to immunoreceptor tyrosine-based activation motifs present on the β and γ chains of FcεRI. Consecutively, Syk derives phosphorylation of PKC and PLCγ.[44] Remarkably, CTE and aurantio-obtusin declined the phosphorylation of Syk, PLCγ, and PKD/PKCμ (Figures 6A and 6B). These results suggest that CTE and aurantio-obtusin have antiallergic effects in IgE-sensitized mast cells by inhibiting the phosphorylation of Syk, PKC, and PLCγ, and consequently inhibiting mast cell degranulation.

CTE and aurantio-obtusin also decreased production of the inflammatory mediator PGE_2, which is an arachidonic acid metabolite, via suppression of the COX pathways (Figures 3A and 3B).[45] Furthermore, CTE and aurantio-obtusin inhibited mRNA COX-2 expression, a key enzyme in these pathways (Figures 3C and 3D). These results indicate that CTE and aurantio-obtusin inhibit generation of inflammatory lipid mediators by inhibiting the COX pathways.

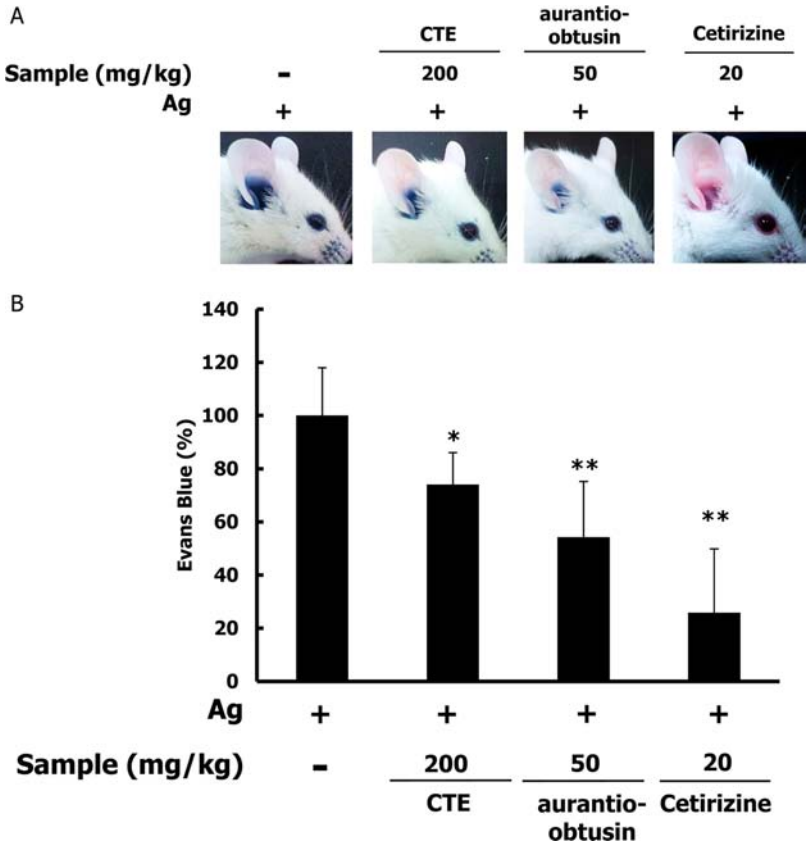

Figure 7. Effect of CTE and aurantio-obtusin on IgE-mediated passive cutaneous anaphylaxis (PCA). (A) Mice were sensitized with IgE for 1 h and then orally administered with CTE (200 mg/kg), aurantio-obtusin (50 mg/kg), or cetrizine (20 mg/kg) for 1 h. The ears of mice absorbed with Evans Blue were photographed. (B) The ear absorbed dye was extracted with formamide. The quantification data is presented as % of IgE- sensitized control. Cetrizine (20 mg/kg) is an antihistamine reference drug. Data are expressed as the mean ± SD ($n \geq 6$) (*$p < 0.05$ and **$p < 0.01$).

CTE and aurantio-obtusin inhibited both the production and mRNA expression of the proinflammatory mediators TNF-α and IL-4 (Figure 4). TNF-α and IL-4 play an essential role in activating and continuing allergic responses in mast cells. IL-4 derives T-cell development and switches B-cells to the IgE isotype. TNF-α also induces physiological immune reactions by stimulating tissue fibrosis and leukocyte infiltration, and initiates cytokine-mediated inflammatory states by promoting cytokine production.[46] Even though inflammation is a physiological defense system against pathogens, overexpression of cytokines can also cause serious inflammatory disorders such as asthma and atopic dermatitis. Our results indicate that these compounds are beneficial for the treatment of allergic disorders.

Furthermore, the function of ROS as an inducer of degranulation and Ca^{2+} increase was revealed in recent studies.[47,48] In the meantime, prevention of ROS production reportedly suppresses IgE-mediated histamine secretion.[25] Thus, blockade of ROS production is regarded to be significant for inhibition of mast cell activation. CTE and aurantio-obtusin effectively reduced ROS production in IgE-sensitized RBL-2H3 cells. Several studies reported that CTE and aurantio-obtusin have an antioxidant property,[49,50] which may result from their high ROS-elimination activity. These results suggest that the antioxidant property of CTE and aurantio-obtusin results in the inhibition of mast cell activation.

MAPK signaling is a key therapeutic target in allergic diseases.[51] Consequently, to examine the mechanism by which CTE and aurantio-obtusin suppress mast cell activation, phosphorylation of ERK, JNK, and p38 was assessed. CTE and aurantio-obtusin suppressed IgE-mediated phosphorylation of ERK, indicating that these compounds mitigate mast cell activation by inhibiting MAPK pathway (Figures 6C and 6D).

In conclusion, CTE and its active compound aurantio-obtusin suppressed degranulation, the generation of histamine, inflammatory lipid mediators, and proinflammatory cytokines, and intracellular ROS production in IgE-sensitized mast cells. CTE and aurantio-obtusin also decreased signaling cascade from the FcεRI receptor by inhibiting the activation of Syk, PLCγ, PKC, and MAPK, all of which intermediate allergic reactions in IgE-sensitized mast cells. Our results suggest that CTE and aurantio-obtusin are beneficial therapeutic agents to prevent or treat IgE-sensitized allergic disorders.

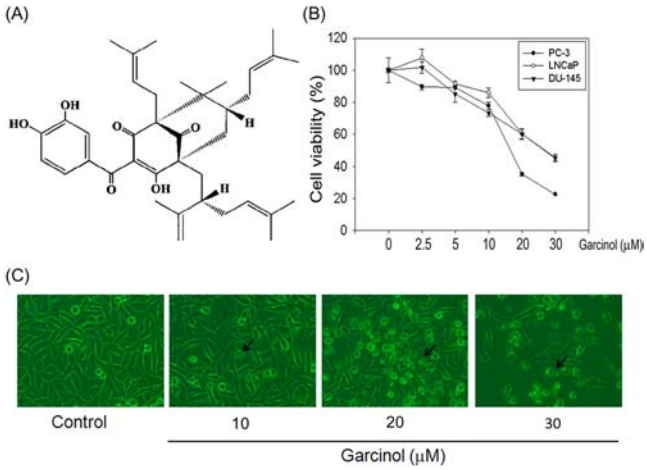

Figure 1. Effect of garcinol on the viability of human prostate cancer cells. (A) Chemical structure of garcinol. (B) The viability of DU-145, PC-3, and LNCaP cell lines was examined by MTT assay. $*p < 0.05$ compared to the control group. (C) Morphological changes of PC-3 cell after 12 h treatment with garcinol 10 μM, 20 μM, and 30 μM.

it has showed a better efficacy to induce apoptosis.[10] The mechanism of garcinol inducing apoptosis has implied that the release of cytochrome *c* into the cytosol can trigger procaspase-9 processing, activation of caspase-3 and caspase-2, and degradation of poly(ADP-ribose) polymerase (PARP). DNA fragmentation has also been observed, indicating the digestion of DNA fragmentation factor-45 (DFF-45) through the caspase-activated deoxyribonuclease.[10]

Cancer cells can be resistant through deregulation of apoptosis even though they are initially sensitive to apoptotic induction. Agents that kill cancer cells through nonapoptotic pathways or re-enhancing the apoptosis may circumvent this drug resistance. Therefore, looking for a new agent either to induce autophagy or increase the cell apoptosis has attracted attention. Systematic study of garcinol to induce cell death through both ways was applied in this study.

MATERIALS AND METHODS

Material. Garcinol was isolated from the dried rind of *G. indica* to 98% purity. The extraction procedure was adapted from the previous study.[11] Ethanol was used to extract *G. indica*, and the ethanol extract was fractionated using a silica gel column. Hexane−ethyl acetate solvent was used to elute garcinol fraction, which was redissolved in hexane after being dried. Hexane solution was kept in the freezer for 24 h, and the yellow amorphous powder precipitated. The yellow powder was dissolved in hot acetonitrile and recrystallized. The purity of garcinol was determined using 1D and 2D NMR (Varian AM-600) and APCI-MS (Fisons VG platform II) (NMR and MS data shown in the previous study[11]). The purified garcinol was dissolved in dimethyl sulfoxide (DMSO).

Cell Culture. The human prostate cancer cell lines DU-145, PC-3, and LNCaP were bought from American Type Culture Collection (ATCC, Manassas, VA). The culture media contained RPMI-1640 medium supplemented with 10% endotoxin-free, heat-inactivated fetal calf serum (GIBCO, Grand Island, NY), 100 mg/mL of streptomycin, and 100 units/mL of penicillin.

Determination of Cell Viability. Cell viability was tested using 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl tetrazolium bromide (MTT). The method was adapted from the previous paper.[10] DU-145, PC-3, and LNCaP cells were treated with a series of concentrations of garcinol, and cell viability was obtained using an enzyme-linked immunosorbent assay.

DNA Extraction and Electrophoretic Analysis. The PC-3 cells were harvested and washed with phosphate-buffered saline (PBS). The extraction method followed the previous procedure.[10] The DNA was extracted using phenol/chloroform/isoamyl alcohol (25:24:1) and was analyzed by 2% agarose gel electrophoresis. DNA was stained with ethidium bromide before being visualized under UV light and photographed.

Flow Cytometry. PC-3 cells (2×10^5) were cultured in 60 mm Petri dishes in RPMI-1640 medium and incubated for 24 h. The details of the flow cytometry methodology followed the previous experiment design.[10] The propidium iodide−DNA complex was quantitated using FACScan cytometry (Becton Dickinson, San Jose, CA). ModFit LT for Mac 3.0 software (Becton Dickinson) was used to quantify the fraction of each cell cycle stage.

Analysis of the Mitochondrial Trans-Membrane Potential. Flow cytometry was used to measure the potential change of the mitochondrial trans-membrane. PC-3 cells were treated with garcinol (30 μM) for different time periods, and the potential of mitochondrial trans-membrane was measured with the direct application of 40 nM 3,3′-dihexyloxacarbocyanine [DiOC6(3)] (Molecular Probes, Eugene, OR). The fluorescence intensity was quantified by flow cytometry after the cells were stained for 30 min at 37 °C. Histograms were analyzed using Cell Quest software. Histograms from treated cells were compared with those from untreated, control cells.

Western Blot Analysis. The basic procedure of Western blot analysis was the same as the previous study.[10] The primary antibodies used included anticaspase-3, -9 (PharMingen, San Diego, CA), anti-Bcl-2, anti-Bcl-X_L, anti-Bax, anti-Bad (Santa Cruz Biotechnology, Santa Cruz, CA), antipoly(ADP-ribose) polymerase (PARP), LC3 I/II, Beclin-1, Atg 12, Atg 5, ERK1/2, phosphoERK1/2, JNK1/2, phospho-1/2, p38, phosphor-p38, PI3K, phospho-PI3K, PDK1, phosphor-PDK1, Akt, phospho-Akt, GSK3β, phosphor-GSK3β, mTOR, phosphor-mTOR (UBI Inc., Lake Placid, NY, USA), anti-Bag-1, anti-Mcl-1 (R and D System Inc., Minneapolis, MN, USA), anti-β-actin (Transduction Laboratory, Lexington, KY, USA), and anti-DFF45/inhibitor of caspase activated DNase (ICAD) (MBL, Naka-Ku, Nagoya, Japan) antibodies.

Human Prostate Tumor Xenograft Mouse Model. Each nude mouse was injected with prostate cancer PC-3 cells (3×10^6) in 200 μL of a PBS solution between the scapulae. The tumor size was measured using a caliper, and the tumor volume was estimated via the following formula: tumor volume (mm^3) = $L \times W^2/2$, where L was the length and W was the width. When the tumor size reached the average of 50−100 mm^3, the mice were randomly divided into six groups (6−8 animals/group). In the groups with intraperitoneal treatment, the mice were injected with garcinol (50 mg/kg/d) in 200 μL of coil oil for 5 days per week, while the control group received just corn oil injections. In the groups with oral treatment, the animals were orally administered with either 200 μL of corn oil or garcinol in corn oil (50 mg/kg/d) for 5 days per week. The dietary intake and the body weight of each animal (average weight = 17 g) were monitored every day. The tumor volume was calculated twice per week. After 40−50 days, the mice were sacrificed by CO_2 asphyxiation. The livers, kidneys, spleens, and solid tumors were excised immediately and weighed. The average tumor volumes and weights of each group were represented as the means ± standard deviation (SD). The tumor tissue was cut into small portions for Western blot analysis.

Statistical Analysis. All results were obtained through three independent experiments and presented as means ± standard error of the mean (SE). The differences between the control group and the different concentrations of garcinol were analyzed by Student's *t* test. The data was considered statistically significant at a *P*-value of <0.05.

RESULTS

Cytotoxic Effects of Garcinol in DU-145, PC-3, and LNCaP Cells. To investigate the cytotoxic effect of garcinol on cells, various concentrations of garcinol were applied to three different cell lines (DU-145, PC-3, and LNCaP cells). The cell viability was verified using the MTT assay. Figure 1B showed a

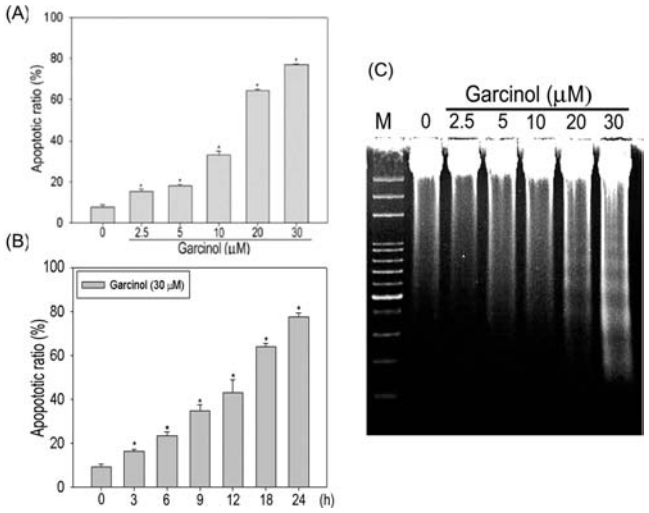

Figure 2. Effect of garcinol on induction of apoptosis and DNA fragmentation in PC-3. (A, B) PC-3 cells treated with increasing doses of garcinol for 24 h or treated with 30 μM garcinol for the indicated time and then determination of sub-G1 cells by flow cytometry. Comparisons were subjected to Student's t test. Significantly different at $^*P < 0.05$. (C) PC-3 cell were treated with 0, 2.5, 5, 10, 20, and 30 μM for 24 h. DNA fragmentation was analyzed by 2% agarose electrophoresis. Data are representative of three independent experiments.

concentration-dependent manner of cytotoxic effects, and PC-3 exhibited the highest ratio of cell death when 30 μM garcinol was applied. Therefore, PC-3 cells were used for the subsequent studies.

Sub-G1 cells and apoptotic ratio were quantified using flow cytometry. The apoptotic ratio was shown in a concentration-dependent manner with garcinol treatment at different concentrations (Figure 2A), and the highest apoptotic ratio was obtained at a concentration of 30 μM garcinol. Moreover, treated with 30 μM of garcinol in a time-course study, PC-3 cells started apoptosis after 3 h, and continued up to 24 h (Figure 2B).

Induction of DNA Fragmentation in PC-3 Cells by Garcinol. Apoptosis induces morphological changes such as cell shrinkage and DNA fragmentation. PC-3 cells were treated with garcinol at different concentrations for 24 h, and DNA fragmentation was studied. The DNA fragmentation also followed a dose-dependent pattern (Figure 2C). The emergence of DNA ladders was shown at the 5 μM of garcinol treatment. Light microscopy can be used to observe the morphological changes in PC-3 cells which were induced by garcinol treatment. As shown in Figure 1C, apoptotic bodies were obtained in PC-3 cells after treatment with garcinol in a dose-dependent manner.

Induction of Mitochondrial Dysfunction by Garcinol. Mitochondria are specialized organelles containing an outer membrane and an inner membrane separated by an intermembrane space that contains many proapoptotic proteins. Induction of apoptosis causes the changes of mitochondrial membrane potential which can be analyzed by measuring log fluorescence intensity with flow cytometry. The potential of mitochondrial membrane was reduced by the treatment of garcinol at a certain time. For example, PC-3 cells were incubated with garcinol for 60

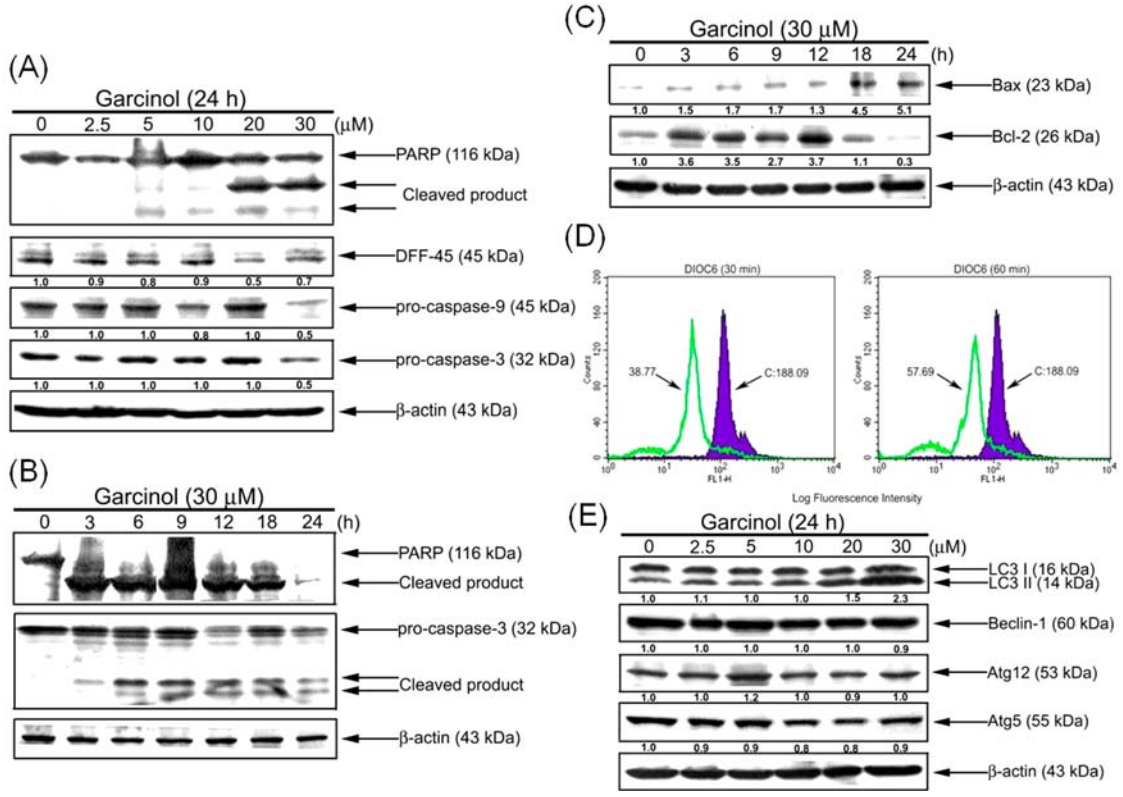

Figure 3. Intracellular response of caspase activation, mitochondrial dysfunction, and Bcl-2 protein expression in garcinol-treated PC-3 cells. (A–C, E) PC-3 cells treated with increasing doses of garcinol for 24 h or treated with 30 μM garcinol for various times. Proteins (50 μg/lane) were separated by SDS–PAGE, immunoblotted with anticaspases-9, -3, PARP, DFF-45, LC3, Beclin-1, Atg5, and Atg12 antibody. (D) PC-3 cells were treated with 30 μM garcinol for indicated times and were then incubated with 40 nM 3,3′-dihexyloxacarbocyanine iodide and analyzed by flow cytometry. Data are representative of three independent experiments.

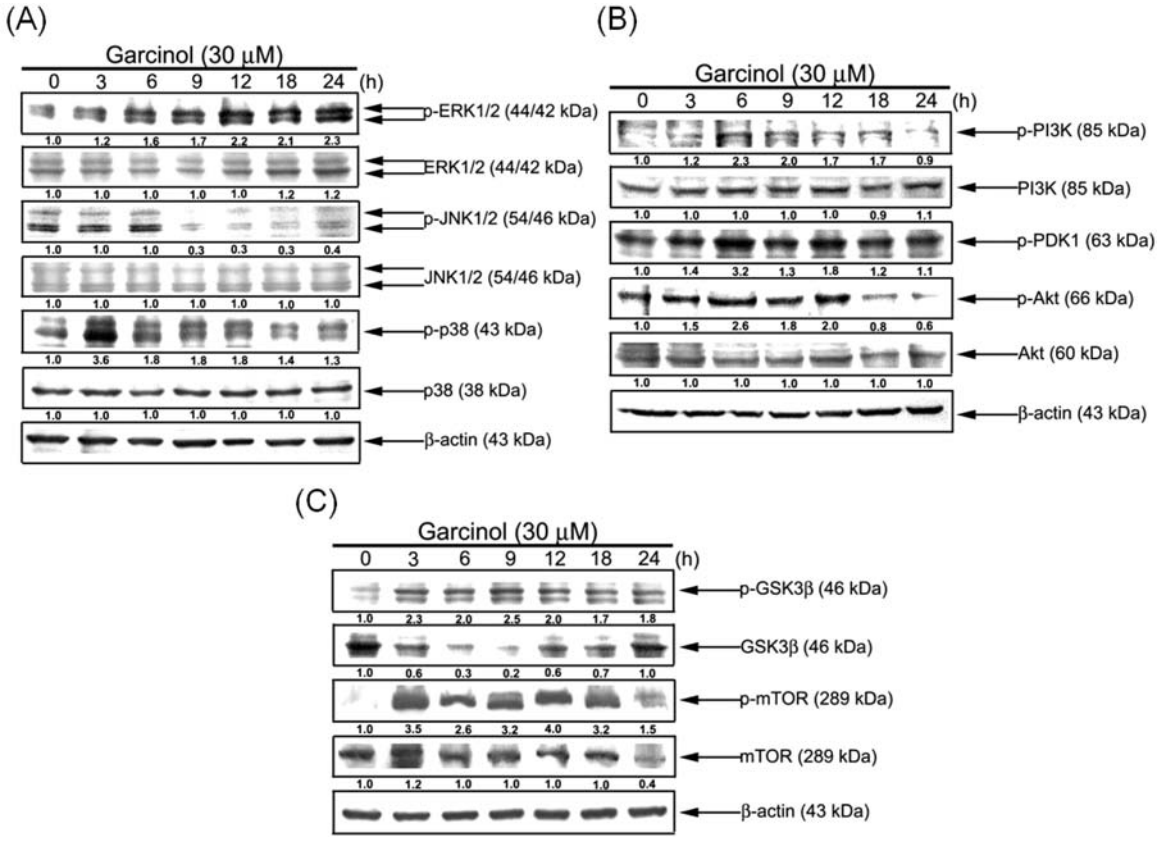

Figure 4. Effect of the expression of MAPKs, PI3k/Akt, and downstream target proteins in garcinol-treated PC-3 cells. PC-3 cells were treated with 30 μM garcinol for 0, 3, 6, 9, 12, 18, and 24 h, and the expression of MAPKs (A), PI3k/PDK1/Akt (B), GSK3β and mTOR (C) protein was analyzed by immunoblotting. The levels of β-actin, total-p38, -JNK1/2, -ERK1/2, -PI3K, -Akt, -GSK3β, and -mTOR protein were used as controls for equal loading of protein in different lanes. Data are representative of three independent experiments.

min, and the mitochondrial membrane potential reduced to 57.69, compared to the control of 168.09, indicating that garcinol induces apoptosis in PC-3 cells via the mitochondrial pathway (Figure 3D). In addition, the level of Bax and Bcl-2 was evaluated at different time points. An apparent increase of Bax was shown, while the level of Bcl-2 increased from 0 to 12 h and decreased significantly after 12 h (Figure 3C). The increase of the Bax/Bcl-2 ratio resulted in an enhancement of apoptosis.

Induction of Caspase Activity, PARP Cleavage, and DFF-45 Degradation by Garcinol. The levels of procaspases-3 and -9 in PC-3 cells were changed with the treatment of garcinol in a concentration-dependent manner indicating the effect of garcinol in the activation of caspases. Garcinol (30 μM) reduced the level of procaspases-3 and -9, indicating an increase of activity of caspase-3 and -9. Meanwhile, cleavage of PARP and DFF-45 was induced by garcinol in a dose-dependent manner (Figure 3A). As shown in Figure 3B, protein cleavage of procaspase-3 occurred after 3 h exposure to garcinol. To detect PARP cleavage as a result of caspase-3 activation, PC-3 cells were treated with 30 μM garcinol for various durations. Garcinol induced time dependent proteolytic cleavage of PARP is shown in Figure 5C.

Induction of p-mTOR and p-GSK-3β Pathways in PC-3 Cells. To clarify the occurrence of autophagy induced by garcinol, expressions of LC3B and beclin-1, which are hallmarks of autophagy, were studied in PC-3 cells treated with/without garcinol using immunoblot. As shown in Figure 3E, the amounts of LC3B I/II proteins increased after treatment with garcinol in a dose-dependent manner. However, garcinol did not cause significant changes in the expression of beclin-1, Atg 12, and Atg 5, suggesting that garcinol induced little autophagy, and apoptosis could be the major pathway inducing cell death. In addition, phosphorylation of mTOR increased from the very beginning of the garcinol treatment and so did of mTOR (Figure 4C). As shown in Figure 4C, treatment with garcinol also increased phosphorylated GSK-3β gradually, and then it decreased a little bit, but the total level still slightly increased. These results indicated that garcinol inhibited autophagy which may enhance the apoptotic cell death. Therefore, these findings suggested that garcinol may switch between autophagy and apoptosis though controlling p-mTOR/mTOR and GSK-3β signaling pathways in PC-3 cells.

PI3K/Akt and MAPK Signaling Pathways Are Involved in Garcinol Inhibiting Autophagy in PC-3 Cells. Studies showed that PI3K/Akt and ERK1/2 pathways were involved in regulating autophagy.[12,13] However, the function of p38 and JNK1/2 MAPKs is still unclear. Therefore, we investigated how these signaling pathways functioned in inhibiting autophagy by garcinol in PC-3 cells. As shown in Figure 4B, phosphorylation of PI3K, Akt, and PDK1 increased after garcinol treatment (0−12 h) and then decreased in cells. However, p-ERK1/2 was quite low, and after 6 h treatment with garcinol the level of p-ERK1/2 gradually increased, while phosphorylated JNK1/2 decreased, and p-38 increased effectively for a period of 0−3 h, respectively, and then decreased (Figure 4A). Taken together, these results indicated that garcinol activated the PI3K/Akt/mTOR and GSK-3β pathways and inhibited the ERK1/2 pathway for 0−6 h

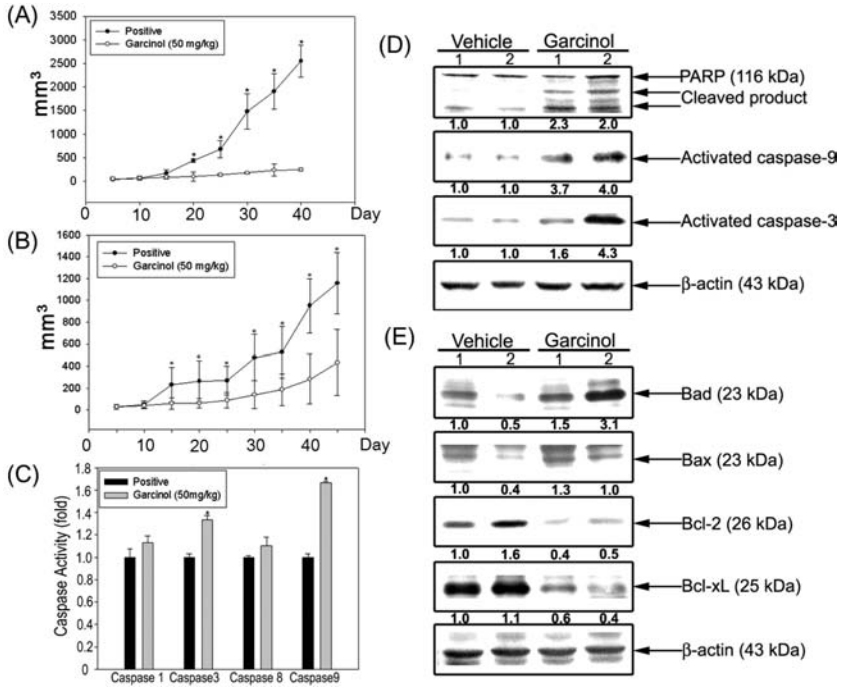

Figure 5. Apoptosis-related protein expression of PC-3 tumor xenograft in nude mice. PC-3 cells were injected subcutaneously between the scapulas of nude mice. Once tumor volume reached approximately 50 mm^3, the animal received an ip (A) or oral gavage (B) of 50 mg/kg garcinol or corn oil five times per week for 40−50 days. Average tumor volume of corn oil-treated versus garcinol-treated nude mice ($n = 5$). Five samples were analyzed in each group, and values represent the mean ± SE. Comparisons were subjected to Student's t test. Significantly different at $^*P < 0.05$. When the animal received ip dose, (C) enzymatic activity of caspase-1, caspase-3, caspase-8, caspase-9 was examined by spectrofluorimetry (excitation = 360 nm; emission = 460). With ip dose, (D, E) apoptosis-related protein expression was examined by Western blot.

treatment, suggesting that these changes mediated garcinol-inhibited autophagy in PC-3 cells.

Apoptosis-Related Protein Expression of PC-3 Tumor Xenograft in Nude Mice. Apoptosis-related protein expression was studied by using PC-3 xenograft prostate cancer mice. Those mice were accepted either an ip or oral gavage of 50 mg/kg garcinol five times per week for 40−50 days. Compared to the positive control, admission of garcinol in either way could significantly decrease the tumor volume. As shown in Figure 5C, caspase-3 and -9 were all activated by garcinol, indicating the activation of apoptosis. More expressions of caspase-3 and -9 were obtained, and the cleavage of PARP was also observed (Figure 5D). The antiapoptotic proteins such as Bcl-2 and Bcl-xL have been shown to decrease with the treatment of garcinol, while the proapoptotic proteins (Bax and Bad) have been expressed more because of the addition of garcinol. The tumor size was reduced 80 percent due to garcinol treatment. Those results suggested that garcinol could be one of the potential chemotherapy agents for human prostate cancer.

DISCUSSION

According to previous studies, the mechanisms of antitumor of garcinol mainly focus on the induction of apoptosis. Of note, the majority of cancer chemopreventive agents inhibit cancer growth by activating the mechanisms of programmed cell death such as apoptosis and autophagy. Garcinol could induce apoptosis in MCF-7 cells by downregulating NF-κB.[14] Activation of caspase-3 is a major way to induce apoptosis by treating with garcinol,[10] and downregulation of MAPK/ERK and PI3K/Akt could also induce apoptosis when HT-29 cells were incubated with garcinol.[15] However, besides apoptosis, autophagy is also an important pathway for cell death in cancer therapy. The relationship between apoptosis and autophagy is complex and depends on types of cels and stress. Tumor cells with defects in apoptosis pathways undergo autophagy.[16] It has also been suggested that autophagy may provide an alternative way to prevent cancer development, slow down tumor progression, and enhance the efficacy of cancer treatments.[8]

In this study, we systematically investigated the antitumor effect of garcinol in PC-3 cell lines and the relationship between apoptosis and autophagy. Garcinol treatment decreased cell viability and strongly induced apoptosis in PC-3 cells. Garcinol contains a phenolic, a β-diketone, and an α,β-unsaturated ketone moiety. The α,β-unsaturated carbonyls are easily bound with thiols such as glutathione, which is the most abundant non-protein thiol in vivo. Binding with glutathione, which would cause intracellular glutathione depletion, could induce mitochondrial dysfunction. As the results show, the mitochondrial membrane potential was reduced by the treatment of garcinol. Morphological changes are caused by caspase. Once the "initiator" or "effector" caspases activated (caspase-9 or -3), they would cause the release of mitochondrial proteins to trigger apoptosis pathways. Those mitochondrial proteins include pro- and antiapoptotic proteins which, for example, are Bax and Bcl-2, respectively. Meanwhile, activation of caspase-3 would also cause the cleavage of PARP and DFF-45, whose cleavage products have been observed in our results. Consider all, garcinol induced apoptosis in PC-3 by increasing the ratio of Bax/Bcl-2 ratio, reducing mitochondrial membrane potential, and suppressing procaspase-9, procaspase-3, PARP, and DFF-45.

In autophagy, caspases are not activated, and DNA fragmentation is not apparent. Most cellular systems where autophagy has been involved have defects in the apoptosis signaling pathway.[17] However, the interesting question is if any

DOI: 10.1021/acs.jafc.5b03851
J. Agric. Food Chem. 2015, 63, 9047−9052

molecular correlation between autophagy and apoptosis exists. Apoptosis can happen due to inhibition of autophagy while autophagy can be activated due to inhibition of apoptosis. In order to promote autophagy and limit tumor progression, mTOR pathway can be inhibited, because autophagy is required for the effective management of metabolic stress.[18] A large number of stimuli modulate autophagy, and numerous signaling pathways such as PI3 Kinase/AKt, MAP kinases, and AMP dependent protein Kinase regulate this process. Most of them work through the mTOR pathway.[8] Natural products have been shown to induce autophagy through inhibiting the PI3 Kinase/AKT and mTOR, and activating the MAP kinase, but garcinol inhibited autophagy through activating the PI3K/AKT and the mTOR, of which the mechanism pathways are still consistent with other studies.[19,20] Suppression of the mTOR increases the levels of activated LC-3 and beclin-1.[20,21] Garcinol inhibited autophagy, which may enhance cell apoptosis. The mechanism pathways will be discussed in a future study.

In order to verify the anticancer effect of garcinol, we also fed mice either by intraperitoneal injection or oral administration. After 40−50 days of treatment, the cancer volume was significantly reduced by treatment of garcinol, and all parameters related to apoptosis showed that apoptosis was induced by garcinol administration. Many cancer cells are resistant to some agents if the treatment proceeds for a long time. Searching for novel compounds of chemoprevention becomes a growing interest in the anticancer therapy field. The optimal antiproliferative effects of garcinol have been demonstrated in PC-3 human prostate cancer cells and nude mice. The anticancer effects of garcinol are regulated by inhibiting autophagy and re-enhancing apoptosis. The signaling pathways mediating garcinol-induced apoptosis and -inhibited autophagy have been identified. To the best of our knowledge, this study first showed that garcinol could induce apoptosis and inhibit autophagy in prostate cancer cells. In conclusion, garcinol possesses a potential property of chemoprevention.

HUVECs, the production of adhesion molecules and chemokines, and the activation of NF-κB in HUVECs.

MATERIALS AND METHODS

Materials. Endothelial cell growth medium (EGM-2) and primary cultured HUVECs were obtained from Lonza (Walkersville, MD, USA). CellTiter^{96} AQ_{ueous} One Solution Cell Proliferation assay kit and reverse transcriptase were purchased from Promega (Madison, WI, USA). Primary and secondary antibodies were obtained from Santa Cruz Biotechnology (Santa Cruz, CA, USA) and Abcam (Danvers, MA, USA). An enhanced chemiluminescence (ECL) detection system was purchased from GE Healthcare Bio-Science (Piscataway, NJ, USA). QIAzol lysis reagent was purchased from Quiagen (Valencia, CA, USA). 2′,7′-Bis(2-carboxyethyl)-5(6)-carboxyfluorescein acetoxy-methylester (BCECF-AM), Alexa Fluor 488-conjugated secondary antibody, and 4′,6-diamidino-2-phenylindole (DAPI) were purchased from Invitrogen (Carlsbad, CA, USA). 2′,7′-Dichlorofluorescin diacetate (DCFH-DA), dimethyl sulfoxide (DMSO), and phenylmethanesulfonyl fluoride (PMSF) were obtained from Sigma-Aldrich Corp. (St. Louis, MO, USA).

Isolation of SQA. *S. serratifolium* was collected along the coast of Busan, South Korea, in April 2014. Specimen identity was confirmed by an agal biologist (N. G. Kim) at the Department of Marine Biology and Aquaculture, Gyeongsang National University, South Korea. Dried seaweed (1.5 kg) was extracted twice with 95% (v/v) ethanol (6 L/each) at 70 °C for 3 h. The ethanolic extract (150.7 g) was obtained by concentration under reduced pressure. To obtain the *n*-hexane-soluble fraction, the extract was suspended in water/ethanol (9:1, v/v) and then partitioned with *n*-hexane to produce 121 g of *n*-hexane-soluble fraction. An aliquot of *n*-hexane fraction was separated by a recycled HPLC system with a Phenomenex Luna RP-18(2) column (250 × 21.2 mm, 15 μm, Phenomenex, Torrence, CA, USA). The elution profile was composed of a linear gradient from methanol (A)/water (B) (90:10) to A/B (94:6) for 35 min, A/B (94:6) to A/B (100:0) for 2 min, and re-equilibrated with A/B (90:10) for 10 min after a 10 min hold with A/B (100:0). Peaks were monitored at 270 nm, and the flow rate was 7 mL/min. The purity of a fraction exhibiting strong anti-inflammatory activity based on the inhibition of ICAM-1 production in TNF-α-stimulated HUVECs was improved by the same HPLC system with Luna RP-18 [Luna C18(2), 250 × 10 mm, 5 μm] at a flow rate of 3.0 mL/min. The fraction was eluted with a linear gradient from methanol A/B (93.4:6.6) to A/B (93.8:6.2) for 20 min, A/B (93.8:6.2) to A/B (100:0) for 2 min, and re-equilibrated with A/B (93.8:6.2) for 10 min after a 10 min hold with A/B (100:0). The purity of the separated compound was >98.0%, as evaluated by the same HPLC system with the Luna RP-18 column [Luna C18(2), 3 μm, 150 × 3.0 mm]. The content of the compound was estimated to be 0.62 ± 0.07 g per 100 g of dried *S. serratifolium*.

Spectrometry. A JNM ECP-400 spectrometer (JEOL, Japan) was used to resolve ^{1}H and ^{13}C NMR spectra. CD_3OD with tetramethylsilane was used as an internal standard. Heteronuclear multiple-bond correlation and heteronuclear multiple-quantum correlation spectra were monitored using pulsed field gradients. The structure of SQA is shown in Supporting Information Figure S1.

Structural Elucidation of SQA. $C_{27}H_{36}O_4$ (MW = 424); ^{1}H NMR (CD_3OD, 400 MHz) δ 3.12 (2H, d, *J* = 6.9 Hz, H-1), 5.17 (1H, t, *J* = 7.4 Hz, H-2), 2.08 (2H, m, H-4), 2.09 (2H, m, H-5), 5.10 (1H, m, H-6), 2.09 (2H, m, H-8), 2.59 (2H, dt, *J* = 7.2 and 7.2 Hz, H-9), 5.84 (1H, t, *J* = 7.3 Hz, H-10), 2.19 (2H, t, *J* = 7.2 Hz, H-12), 2.12 (2H, m, H-13), 5.06 (1H, tt, *J* = 7.3 and 1.4 Hz, H-14), 1.65 (3H, s, CH_3-16), 1.58 (3H, s, CH_3-17), 1.60 (3H, s, CH_3-19), 1.62 (3H, s, H-20), 6.42 (1H, m, H-3′), 6.56 (1H, quin, *J* = 1.4 Hz, H-5′), 2.12 (3H, d, *J* = 1.5 Hz, aromatic-CH_3); ^{13}C NMR (CD_3OD, 100 MHz) δ 28.5 (C-1), 120.1 (C-2), 140.4 (C-3), 40.7 (C-4), 27.3 (C-5), 125.7 (C-6), 135.8 (C-7), 40.3 (C-8), 29.0 (C-9), 142.6 (C-10), 132.9 (C-11), 36.1 (C-12), 28.9 (C-13), 124.8 (C-14), 133.4 (C-15), 25.9 (C-16), 17.8 (C-17), 171.6 (C-18), 15.97 (C-19), 16.0 (C-20), 189.4 (C-1′), 150.0 (C-2′), 133.0 (C-3′), 188.9 (C-4′), 133.96 (C-5′), 147.6 (C-6′), 16.1 (aromatic-CH_3). .

Mass Spectrometry Analysis. The molecular weight of SQA was confirmed by mass spectrometry. The mass spectrometry analysis was performed with a Shimadzu GCMS-QP2010 Ultra instrument with a direct sample inlet device (DI-2010, Kyoto, Japan). The initial probe temperature was 40 °C/min; it was ramped to 350 °C and held for 2 min. The ion source temperature was 200 °C, and the injection volume was 0.5 μL. The mass spectrum is shown in Supporting Information Figure S1.

Cell Culture and Viability Assay. 3-(4,5-Dimethylthiazol-2-yl)-5-(3-carboxymethoxyphenyl)-2-(4-sulfophenyl)-2*H*-tetrazolium (MTS) was used to assess the cytotoxicity of SQA. Briefly, cells were seeded in a 96-well plate at a density of 5 × 10^3 cells/well. The cells were treated with a serial dilution of SQA indicated in the figure legend. MTS solution was added with fresh medium for 1 h based on the manufacturer's instruction followed by measurement of the absorbance at 490 nm using a microplate reader (Glomax Multi Detection System, Promega).

Cell-Based Enzyme-Linked Immunsorbent Assay (ELISA). The expression of ICAM-1 and VCAM-1 in HUVECs was determined by cell-based ELISA as described by Manduteanu et al.[17] Briefly, HUVECs were placed in a 24-well plate at a density of 5 × 10^4 cells/well. After 24 h of incubation, cells were exposed to diverse concentrations of SQA for 1 h. After removal of culture medium, the cells were stimulated with TNF-α (10 ng/mL) for 6 h. The cells fixed by 1% paraformaldehyde were blocked with 2% BSA. After exposure to mouse anti-human ICAM-1 or VCAM-1 antibodies for 1 h followed by washing, cells were incubated with the horseradish peroxidase-conjugated secondary antibody for 1 h. Expression levels of ICAM-1 and VCAM-1 were quantified by the addition of peroxidase substrate solution, and the absorbance was measured at 490 nm with a microplate reader (Glomax Multi Detection System, Promega).

Monocyte Adhesion Assay. Confluent HUVECs pretreated with SQA for 1 h were stimulated with TNF-α (10 ng/mL) for 6 h. THP-1 monocytes (KCLB, Seoul, Korea) were tagged with the compound BCECF-AM (10 μM). The tagged THP-1 monocytes (2.5 × 10^5) were gently added to the HUVEC monolayer and incubated for 1 h. Unbound THP-1 cells were discarded by PBS washing. HUVEC-attached THP-1 cells were observed with an LSM700 laser scanning confocal microscope (Carl Zeiss, Oberkochen, Germany). In parallel, HUVEC-adherent monocytes were harvested with cell lysis solution (50 mM Tris-HCl, containing 0.1% SDS, pH 8.0), and the fluorescence intensity was determined using a fluorescence microplate reader (Dual Scanning SPECTRAmax, Molecular Devices Co., Sunnyvale, CA, USA) at 485 nm (excitation wavelength) and 535 nm (emission wavelength). The results were shown as relative monocyte adhesion levels compared with the control group.

Reverse Transcription-Polymerase Chain Reaction (RT-PCR). SQA-pretreated HUVECs were stimulated with TNF-α for 6 h. RNA was isolated using the QIAzol reagent. cDNA was synthesized with oligo-dT primer and superscript reverse transcriptase using total RNA (5 μg). PCR was conducted with corresponding primers (Supporting Information Table 1). Densitometric analysis was performed using EZ-Capture II (ATTO & Rise Co., Tokyo, Japan) and CS analyzer (ver. 3.00 software, ATTO).

Intracellular ROS Measurement. ROS scavenging activity of SQA was determined with fluorescent probe DCFH-DA. Confluent HUVECs in black 96-well plates were pretreated with 5, 10, and 15 μM SQA for 1 h. After the wells had been washed with PBS, the cells were treated with 20 μM DCFH-DA for 30 min at 37 °C and then stimulated with TNF-α (10 ng/mL) for 1 h. The fluorescence level was determined using a fluorescence microplate reader (Dual Scanning SPECTRAmax) at 485 nm (excitation wavelength) and 528 nm (emission wavelength).

Preparation of Cytosolic and Nucleus Extracts. HUVECs were seeded in a culture dishes at a density of 6 × 10^5 cells/dish and cultured for 24 h. Cultured cells were pretreated with 0, 5, 10, and 15 μM of SQA for 1 h and stimulated with TNF-α for 30 min. Separation of cytosolic and nucleus extracts was performed as previously described.[18]

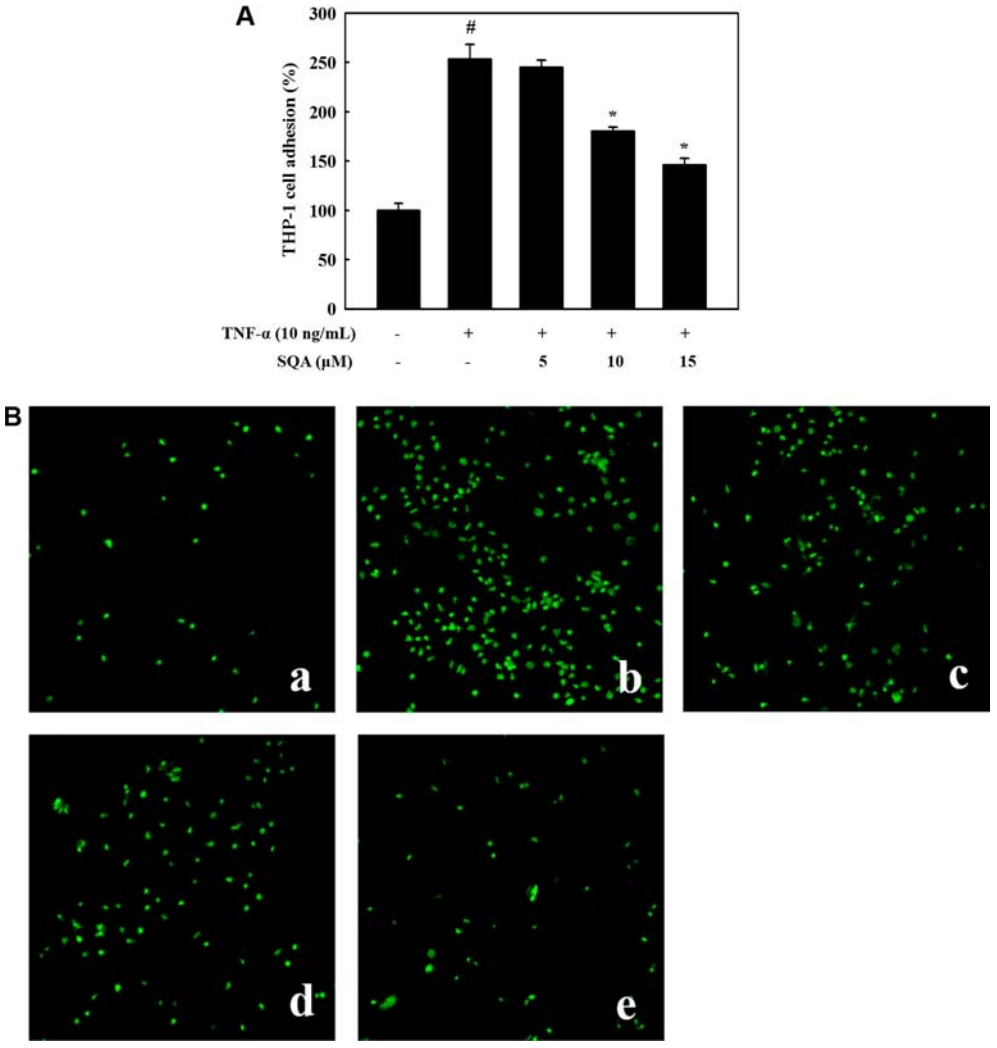

Figure 1. Effect of SQA on the adhesion of THP-1 monocytes to TNF-α-stimulated HUVECs. Cells were treated with the indicated concentrations of SQA for 1 h and then stimulated with TNF-α for 6 h. Fluorescence-labeled THP-1 was added to the HUVECs and allowed to adhere for 1 h, and adhesion was determined using a fluorescence microplate reader at excitation and emission wavelengths of 485 and 535 nm (A). Pictures are representative fields captured by fluorescence microscope (B): (a) control; (b) TNF-α; (c) cotreated with TNF-α and SQA (5 μM); (d) cotreated with TNF-α and SQA (10 μM); (e) cotreated with TNF-α and SQA (15 μM). The values are shown as the means ± SDs from three independent experiments. (#) $P < 0.05$ represents significant differences versus the control group; (*) $P < 0.05$ represents significant differences versus the TNF-α-only group.

Western Blotting Analysis. HUVECs pretreated with 0, 5, 10, and 15 μM SQA for 1 h were stimulated with TNF-α (10 ng/mL) at times indicated in the figure legends. The specific procedure for Western blotting is described in our previous paper.[18]

Immunofluorescence Analysis. HUVECs were cultured on glass coverslips (SPL Life Sciences Co., Gyeonggi-do, Korea) for 24 h. After treatment of cells with SQA for 1 h, cells were stimulated with TNF-α (10 ng/mL) for 30 min. The specific procedure for immunofluorescence analysis of NF-κB is described in our previous paper.[19]

Statistical Analysis. Data are expressed as the means ± standard deviations (SDs). Data analysis was performed using ANOVA followed by Bonferroni test. P values <0.05 were considered statistically significant. SPSS for Windows, version 10.07 (SPSS Inc., Chicago, IL, USA), was used for all analyses.

RESULTS

SQA Inhibits TNF-α-Induced Binding of Monocytes to HUVECs. To examine the cytotoxicity of SQA, the viability of HUVECs was measured by the MTS cell proliferation assay kit. HUVECs were cultured in 96-well microplates for 24 h and pretreated with various final concentrations of SQA (5, 10, and 15 μM) in TNF-α-stimulated HUVECs. The viability was not influenced up to 15 μM SQA in HUVECs (Supporting Information Figure S2). Thus, the HUVECs were treated with SQA in the concentration range of 5, 10, and 15 μM for further experiments. Because inflammation-derived monocyte adhesion to HUVECs is an essential step in atherosclerosis development, we investigated whether SQA inhibits the adhesion of THP-1 monocytes to TNF-α-treated HUVECs. Stimulation of the HUVECs with TNF-α for 6 h markedly increased cell adhesion. However, SQA dose-dependently inhibited TNF-α-induced binding of monocytes to HUVECs (Figure 1A). To verify the inhibition of SQA on the monocyte recruitment to the TNF-α-stimulated vascular endothelium, microscopic observation was performed using BCECF-AM staining assay. As shown in Figure 1B, heavy fluorescent staining was shown on the HUV treated with TNF-α alone for 6 h, indicating marked adhesion of THP-1 to the stimulated HUVECs. However, SQA

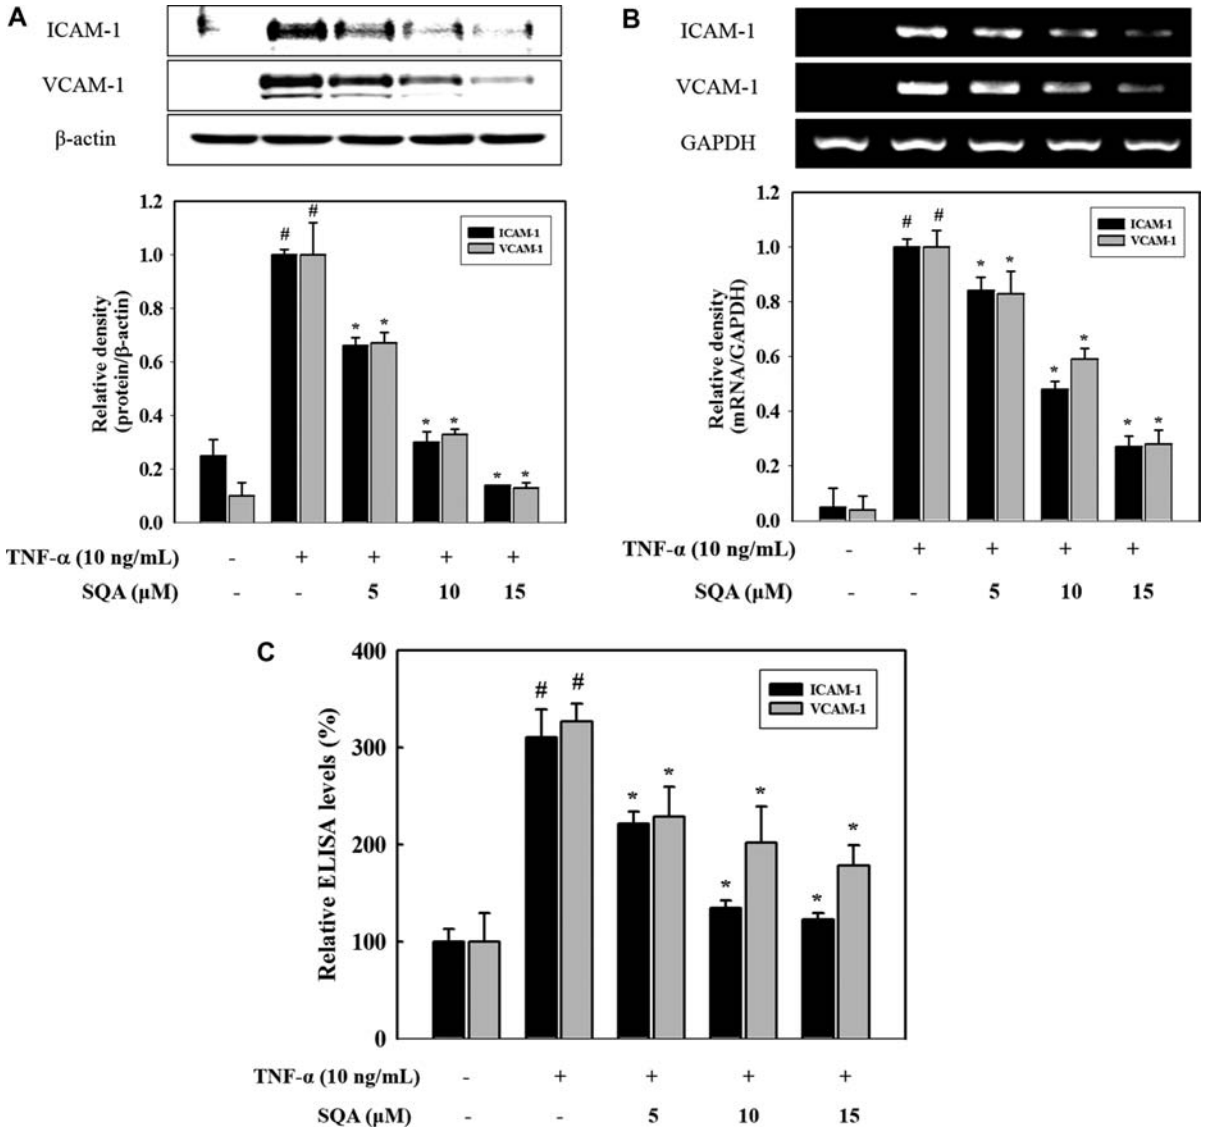

Figure 2. Effect of SQA on the production of TNF-α-induced ICAM-1 and VCAM-1 expression in HUVECs. Cells pretreated with the indicated concentration of SQA for 1 h were stimulated with TNF-α for 6 h. Equal amounts of total protein were separated by 10% SDS-PAGE. The expression of ICAM-1, VCAM-1, and β-actin protein was examined by Western blotting using corresponding antibodies (A). Cells pretreated with the indicated concentration of SQA for 1 h were stimulated with TNF-α for 6 h, and total RNA was prepared for RT-PCR (B). Fixed cells with 1% paraformaldehyde were analyzed by ELISA for the cell surface expression of ICAM-1 (black) and VCAM-1 (gray) (C). The values are shown as the means ± SDs from three independent experiments. (#) $P < 0.05$ represents significant differences versus the nontreated group; (*) $P < 0.05$ represents significant differences versus the TNF-α-only group.

decreased adhesion of THP-1 to TNF-α-treated HUVECs in a dose-dependent manner.

SQA Inhibits the Production of TNF-α-Induced Adhesion Molecules. Monocyte adhesion to HUVECs is critically regulated by ICAM-1 and VCAM-1. To further study the inhibition of adhesion molecule expression by SQA, we assessed the production of VCAM-1 and ICAM-1 proteins using Western blotting. The expression levels of both adhesion molecules were remarkably elevated in TNF-α-treated HUVECs (Figure 2A). SQA pretreatment markedly prevented the production of both VCAM-1 and ICAM-1 dose-dependently. To further investigate the effect of SQA on VCAM-1 and ICAM-1 gene expression, RT-PCR was performed. Our data showed that SQA dose-dependently suppressed the mRNA expression of both adhesion genes in TNF-α-treated HUVECs (Figure 2B). Furthermore, the result of cell-based ELISA showed that SQA dose-dependently suppressed the expression of VCAM-1 and ICAM-1 in TNF-α-treated HUVECs (Figure 2C). These data indicate that the SQA-mediated down-regulation of adhesion molecules in TNF-α-treated endothelium is primarily attributable to their transcriptional repression.

SQA Inhibits TNF-α-Induced Chemokine Production. Recruitment of monocytes to endothelium is regulated by chemokines, including IL-8 and MCP-1. As shown in Figure 3, exposure of HUVECs to TNF-α for 6 h enhanced the protein (Figure 3A) and mRNA (Figure 3B) expression of MCP-1 and IL-8. SQA concentration as low as 15 μM inhibited TNF-α-induced overexpression of both chemokines. Therefore, SQA efficiently suppressed the vascular inflammation related to the development of atherosclerosis.

SQA Inhibits TNF-α-Induced NF-κB Activation in HUVECs. To assess whether SQA inhibits the translocation

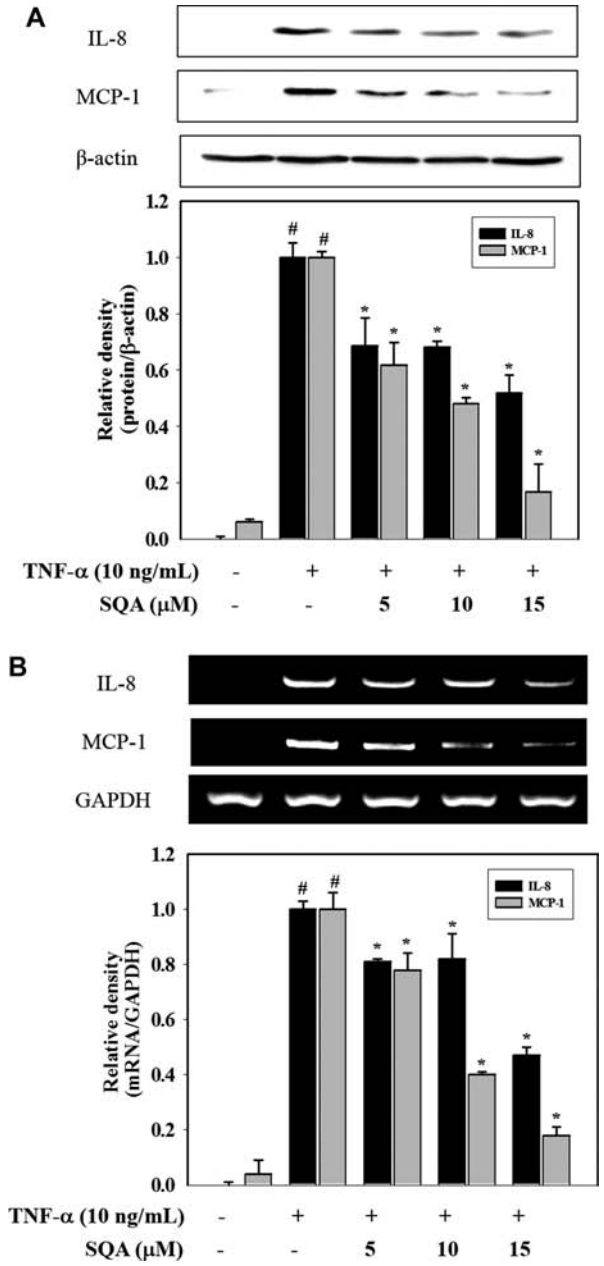

Figure 3. Effect of SQA on TNF-α-induced IL-8 and MCP-1 protein and mRNA expression. Cells pretreated with the indicated concentration of SQA for 1 h were stimulated with TNF-α for 24 h. IL-8 and MCP-1 protein expression was examined by Western blot (A). Cells pretreated with SQA for 1 h were stimulated with TNF-α for 6 h. IL-8 and MCP-1 mRNA expression was determined by RT-PCR (B). The values are shown as the means ± SDs from three independent experiments. (#) $P < 0.05$ represents significant differences versus the control group; (*) $P < 0.05$ represents significant differences versus the TNF-α-only group.

of NF-κB into the nucleus, microscopic analysis was performed. Confocal observation indicated that NF-κB/p65 was mostly located in the cytoplasmic region under unstimulated condition. With TNF-α treatment, most of the cytoplasmic NF-κB/p65 translocated to the nucleus (Figure 4A). However, SQA treatment at 15 μM markedly inhibited the NF-κB/p65 translocation. For further investigating the molecular mechanism underlying SQA-mediated inhibition of NF-κB/p65 translocation in TNF-α-stimulated cells, we examined the phosphorylation of inhibitor κB kinase (IKK)-β and inhibitor κB (IκB)-α that are associated with the NF-κB activation. TNF-α markedly caused the phosphorylation of IKK-β and led to IκB-α phosphorylation, whereas SQA inhibited the phosphorylation of both proteins dose-dependently (Figure 4B). The protein level of cytosolic IκB-α at 15 μM SQA was comparable to that of the control group possibly due to the inhibitory effect of SQA on the phosphorylation IκB-α via of IKK-β activation (Figure 4B). In addition, TNF-α-mediated increase in NF-κB protein level in the nucleus was dose-dependently decreased by SQA treatment (Figure 4C). These results suggest that the SQA-mediated inhibition of the production of adhesion molecules and pro-inflammatory chemokines was regulated through the NF-κB pathway in the TNF-α-stimulated cells.

SQA Inhibits TNF-α-Induced ROS Production. TNF-α activates the membrane-bound NADPH oxidase in endothelium and promotes ROS production, a second messenger for NF-κB activation.[20] We assessed the inhibitory effects of the SQA on intracellular ROS accumulation in HUVECs by TNF-α treatment. TNF-α-induced ROS was markedly reduced by SQA pretreatment (Figure 5, $P < 0.05$), indicating that intrinsic antioxidant activity of SQA might suppress NF-κB activation through scavenging TNF-α-induced ROS.

SQA Inhibits TNF-α-Induced MMP-9 Secretion. Matrix metalloproteinase (MMP)-9 is involved in the process of monocyte transmigration by its ability to impair the major components of basement membrane.[21] During vascular inflammation, MMP-9 is particularly essential for arterial lesion development through its regulation of migration, extravasation, and infiltration of immune cells. For this, TNF-α-treated HUVECs were cultured under serum-free conditions for 24 h, and the released MMP-9 in culture media was determined by Western blotting. TNF-α-induced MMP-9 was dose-dependently suppressed by SQA treatment (Figure 6, $P < 0.05$).

DISCUSSION

In the present study, we isolated SQA from *S. serratifolium*, and its antioxidant and anti-inflammatory activities were investigated using TNF-α-treated HUVECs. Our major findings showed that SQA blocked the adhesion of THP-1 monocytes to TNF-α-treated HUVECs by suppressing expression of adhesion molecules and pro-inflammatory chemokines; suppressed the TNF-α-induced NF-κB activation by blocking IκB-α degradation via the regulation of IKK-β phosphorylation; and suppressed TNF-α-induced MMP-9 production in HUVECs. To our knowledge, this is the first in vitro evidence that SQA is an efficient anti-inflammatory reagent to alleviate vascular inflammation and to improve endothelial dysfunction.

Attachment of monocytes to vascular endothelium is an early step in inflammatory mechanisms of atherosclerosis.[2] Pro-inflammatory stimuli, such as TNF-α exposure, initiate the endothelial expression of adhesion molecules that stimulates the attachment of circulating lymphocytes and monocytes to endothelium.[1] In this stage, the adhesion molecules such as VCAM-1 and ICAM-1 are well-known inflammatory markers, which are related to tight adhesion of monocytes in atherosclerosis-prone sites of the endothelium.[1] Both adhesion molecules are primarily produced in advanced human coronary atherosclerotic plaque and in experimental atherosclerosis animals.[9,22] Our results indicate that SQA prevented the TNF-α-induced endothelial production of VCAM-1 and ICAM-1in HUVECs as well as attachment of THP-1 cells to HUVECs. These data indicate that the anti-inflammatory effect

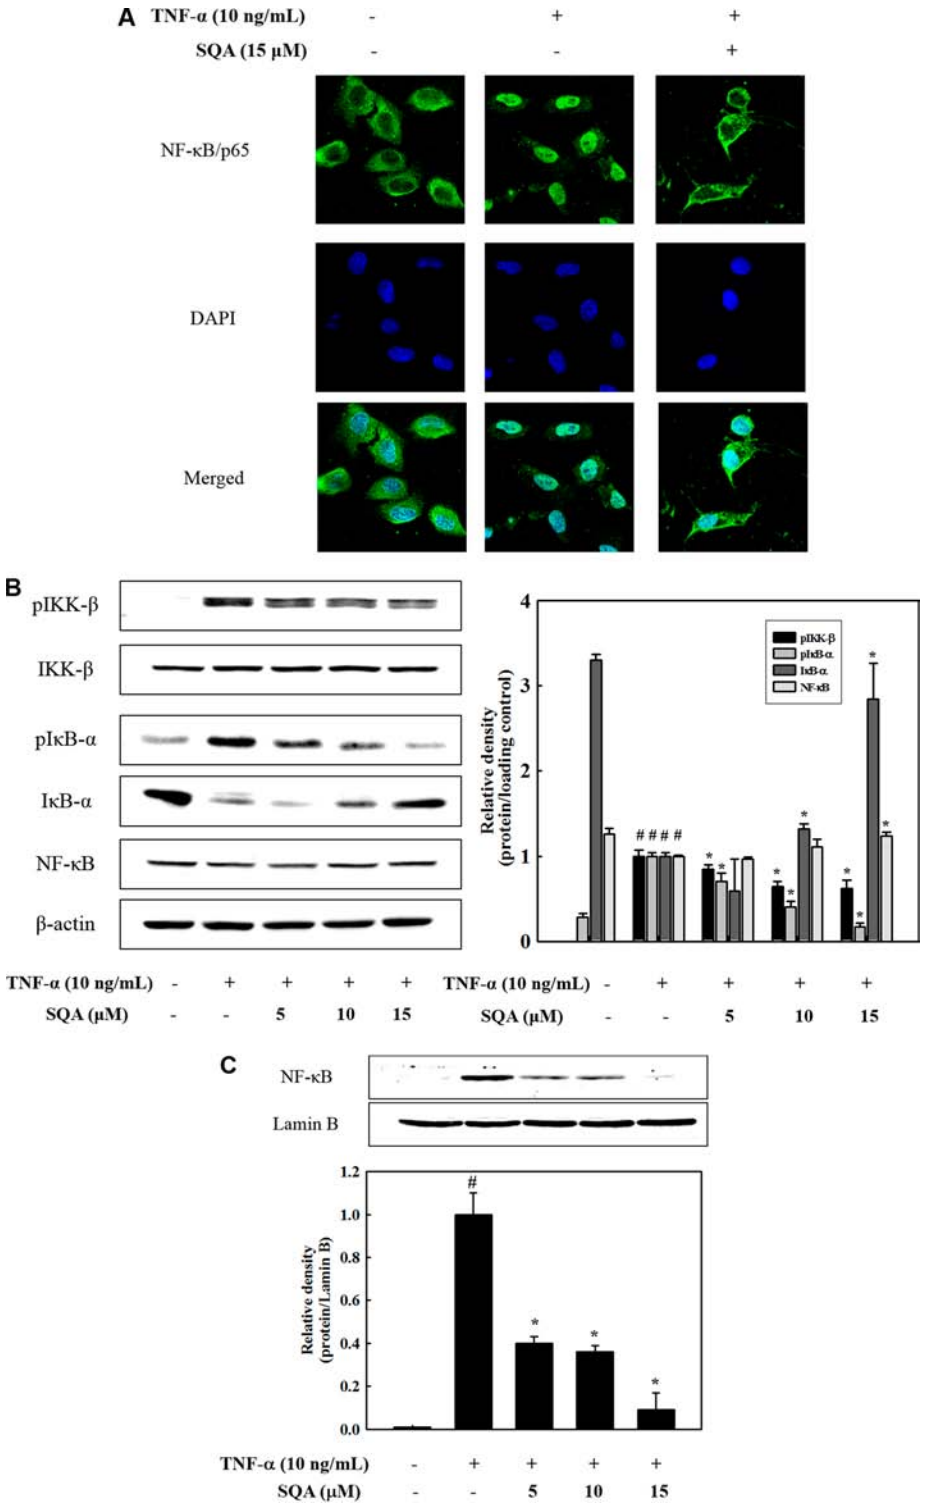

Figure 4. Effect of SQA on the NF-κB translocation in TNF-α-treated HUVECs. Cells were pretreated with or without SQA for 1 h followed by TNF-α treatment for 30 min. The subunits of NF-κB/p65 were detected by using anti-NF-κB polyclonal antibody and Alexa Fluor 488-conjugated secondary antibody. The nuclei were detected by DAPI staining, and confocal microscopy was used to capture the images (A). Cells were incubated with the indicated concentration of SQA for 1 h and then exposed to TNF-α (10 ng/mL) for 30 min. Cytosolic (B) and nucleus (C) fractions were analyzed by Western blotting. The values are shown as the means ± SDs from three independent experiments. (#) $P < 0.05$ represents significant differences versus the control group; (∗) $P < 0.05$ represents significant differences versus the TNF-α-only group.

of SQA on TNF-α-treated cells is mediated at least partially by suppressing the adhesion molecules. Importantly, the current findings suggest that the SQA-mediated reduction of adhesion molecules is closely related to transcriptional regulation of both ICAM-1 and VCAM-1 mRNA expression in TNF-α-treated HUVECs. This study appears to be the first finding to show the action of SQA on the transcriptional regulations of adhesion molecules in TNF-α-treated HUVECs.

Monocyte recruitment followed by endothelial inflammation is closely associated with inflammatory mechanisms of

atherosclerosis. Various studies demonstrated important roles of pro-inflammatory chemokines, such as IL-8 and MCP-1, in the development and progression of atherosclerosis.[3,5,9] MCP-1 is mainly involved in the recruitment of monocytes to atheroma. The recruited monocytes differentiate into macrophages in the atherosclerotic lesion.[23,24] IL-8 is an important factor for adhesion, transmigration, and retention of monocyte/macrophages in the atherosclerotic lesion. IL-8 is associated with activating intimal macrophages due to overexpression of chemokine receptors on the intimal macrophage.[23] Thus, inhibiting IL-8 and MCP-1 would block adhesion and migration of monocytes to endothelium. Therefore, blocking these chemokines may be an appropriate strategy for preventing or treating atherosclerosis. In this study, SQA inhibited the TNF-α-induced production of IL-8 and MCP-1 from endothelial cells. These data suggest that the anti-inflammatory action of SQA on TNF-α-induced endothelium is mediated at least partially by inhibition of chemokines.

The ROS-dependent NF-κB activation is an essential signaling for regulating inflammatory responses, which are closely related to vascular diseases by induction of endothelial cell adhesion molecules.[25] NF-κB is an important transcription factor that is associated with the expression of adhesion molecules and chemokines.[26] As discussed above, attachment of monocyte to endothelium is induced and stimulated through pro-inflammatory chemokines and adhesion molecules, including ICAM-1, VCAM-1, IL-8, and MCP-1 in endothelial cells.[26,27] The gene expression of these molecules is increased by NF-κB activation. In unstimulated conditions, NF-κB is primarily distributed in the cytoplasm as an inactive complex binding to IκB-α. Excess ROS production stimulated by TNF-α involves the phosphorylation of IKK complex, which phosphorylates IκB-α, thereby leading to the degradation of IκB-α and translocation of NF-κB into the nucleus.[2,28] Thus, NF-κB is an attractive target for the development of pharmaceutical agents for interfering with the development and progression of atherosclerosis. Although mechanisms underlying SQA-mediated NF-κB regulation remain unknown, the current study showed that SQA suppresses NF-κB activation by inhibiting proteolytic degradation of IκB-α induced by TNF-α in HUVECs. The confocal microscopic analysis suggests that SQA inhibited NF-κB translocation into the nucleus induced by TNF-α in HUVECs. Therefore, these results showed the ability of SQA to suppress TNF-α-mediated NF-κB activation in HUVECs. In the current study, SQA treatment significantly decreased the TNF-α-induced ROS production in HUVECs, suggesting that SQA has antioxidant activity. It was shown that ROS stimulate activation of diverse transcription factors including NF-κB in cultured HUVECs, contributing to induction of chemokines and adhesion molecules.[10,29] We found that SQA notably inhibited the TNF-α-induced NF-κB activation. On the basis of these data, the inhibitory effect of SQA on the production of adhesion molecules and chemokines is regulated by the NF-κB signaling pathway via blockade of ROS production with SQA's intrinsic antioxidant activity. Hence, it is likely that the reductions of ICAM-1, VCAM-1, IL-8, and MCP-1 expression in HUVECs are mainly related to the regulation of NF-κB pathway through the removal of ROS by SQA's antioxidant activity.

MMPs catalyze removal of the basement membrane around vascular smooth muscle cells and facilitate contacts with the interstitial matrix.[30] During the progression of atherosclerosis, endothelial cells degrade the basement membrane to recruit smooth muscle cells into intima, where type IV collagen is the major component. Among MMPs, MMP-9 has been emphasized in vascular inflammation, because the collagenolytic activity of MMP-9 makes endothelial cells intrude into the basement membrane of vascular structure.[31] Therefore, endothelial cell-secreted MMP-9 may play a mandatory role in degrading the basement membrane through its type IV collagenase activity.[32] MMP-9, expressed by TNF-α-induced NF-κB activation, is shown to enhance the infiltration of smooth muscle cells to intima by mediating the digestion of extracellular matrix.[33,34] Thus, TNF-α-induced MMP-9 expression plays an essential function during atherosclerotic

DOI: 10.1021/acs.jafc.5b04050
J. Agric. Food Chem. 2015, 63, 9053−9061

progression. In this study, we found that SQA notably suppressed the TNF-α-induced MMP-9 production. These data suggest that the progression of atherosclerosis by TNF-α may be alleviated by SQA's inhibitory action of MMP-9 production via NF-κB activation.

In summary, we have shown that SQA inhibits the mRNA and protein expression of adhesion molecules including ICAM-1 and VCAM-1 in TNF-α-stimulated HUVECs. Furthermore, the anti-inflammatory roles of SQA in TNF-α-treated cells appear to be closely related to the inactivation of the NF-κB pathway. Further confirmation of anti-inflammatory effects of SQA and underlying mechanisms in animal models will be important for therapeutic application of SQA for treating vascular inflammation-associated diseases such as atherosclerosis.

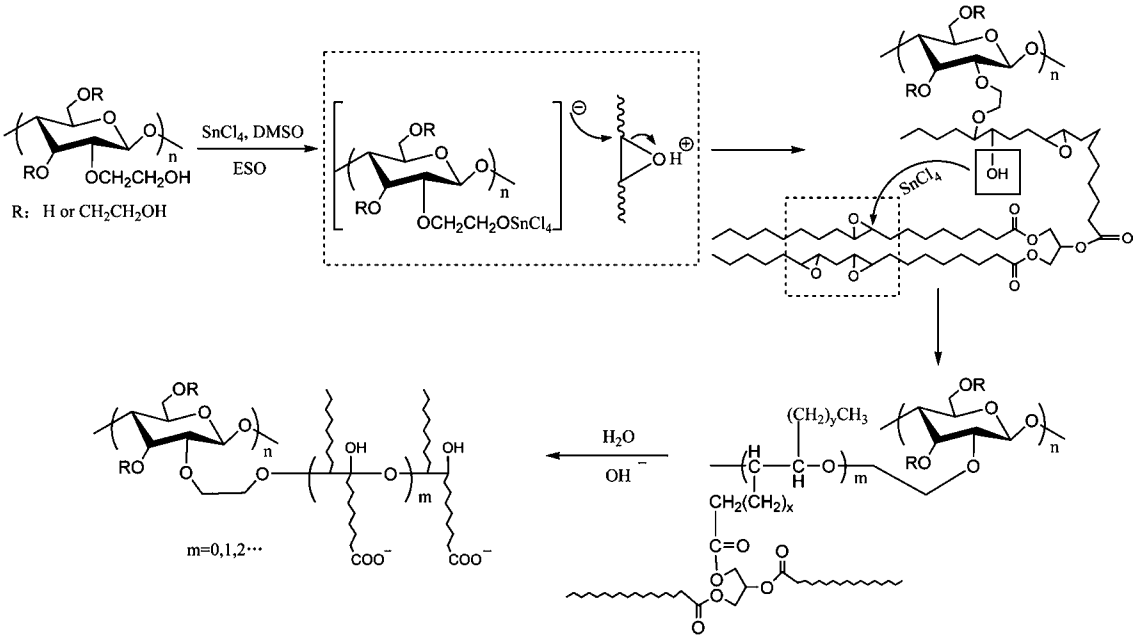

Figure 1. Synthetic route of H-ESO-HEC polymeric surfactants.

grafted cellulose surfactants formed via cellulose derivatives as backbones are polymerized saponified fatty acid surfactants. Therefore, cellulose chains grafting saponified fatty acid esters to form ionic surfactants—instead of fatty acid-esterified cellulose surfactants—may become an effective method for synthesis of cellulose-based surfactants with highly surface-active properties. Fortunately, the chemical reactivities of some fatty acids isolated from vegetable oils can achieve this vision.

Soybean oil is one of the most abundant renewable vegetable oils in the world.[23] It possesses three unsaturated fatty acids, oleic (23%), linoleic (54%), and linolenic (8%). It contains 1, 2, and 3 double bonds, respectively.[24] The double bonds can be used in many reactions including addition reaction,[25] oxidation reaction,[26] and polymerization reaction.[27] More significantly, the expoxidation reaction makes the soybean oil become epoxidized soybean oil (ESO). A ring-opening reaction of ESO with different alcohols was carried out in the presence of Amberlyst 15 (Dry) as a catalyst.[28] Furthermore, the ring-opening polymerization of ESO can be catalyzed by boron trifluoride diethyl etherate ($BF_3{\cdot}OEt_2$) in liquid carbon dioxide and methylene chloride.[26,29] The ESO-based polymeric surfactants in particular were prepared by hydrolysis of polymerized ESO with a base.[22] These interesting works suggest that hydroxyl groups of cellulose can initiate ring-opening polymerization of ESO in the presence of catalysts. Moreover, novel saponified fatty acid-modified cellulose-based polymeric surfactants are obtained by saponification of the ESO-grafted cellulose products in which fatty acid chains are combined with cellulose by an ether linkage at the middle site of a fatty acid molecular chain.

To prove this assumption, modification of HEC by grafting ESO was investigated and hydrolysis of ESO-grafted HEC (ESO-HEC) was performed with sodium hydroxide (Figure 1). The hydrolyzed ESO-HEC (H-ESO-HEC) products were characterized with Fourier transform infrared (FT-IR) and ^1H and ^{13}C nuclear magnetic resonance (NMR) spectroscopies, high-temperature gel permeation chromatography (HT-GPC), and differential scanning calorimetry (DSC). After neutralizing the carboxylic acid of H-ESO-HEC with sodium hydroxide, novel polymeric surfactants (H-ESO-HEC-Na) were obtained, and the effects of polymeric surfactants on the surface tension of water were investigated as a function of the concentration of H-ESO-HEC-Na. In addition, the rheological behaviors of the H-ESO-HEC were investigated.

MATERIALS AND METHODS

Materials. Hydroxyethyl cellulose (HEC), epoxidized soybean oil (ESO), and stannic chloride ($SnCl_4$) were purchased from Aladdin Industrial Co., Ltd. Dimethyl sulfoxide (DMSO) was purchased from Sinopharm Chemical Reagent Co., Ltd. Sodium hydroxide (NaOH), hydrochloric acid (HCl), and ethyl acetate were obtained from Nanjing Chemical Reagent Co., Ltd. Deionized water was purified to a conductivity of 18.3 MΩ·cm on a Hitech-Sciencetool Master-Q laboratory water purification system (Shanghai Hetai Reagent Co., Ltd.). All chemicals were used without further purification.

Synthesis of ESO-Grafted HEC Derivatives (ESO-HEC). HEC (1.0 g) was dissolved in 40 mL of DMSO under stirring at room temperature for 2 h and then transferred into a three-necked round-bottomed flask. ESO (1.0 g) was added to the HEC solution. The mixture was stirred by mechanical agitation at room temperature. A mixture of 10 μL of $SnCl_4$ and 10 mL of DMSO was then added dropwise into the reactor, and the reaction was maintained for 30 min. The resulting products were washed sequentially with deionized water to remove DMSO and dried under vacuum at 50 °C. Finally, the ESO-grafted HEC derivatives (ESO-HEC) were obtained.

Hydrolysis of ESO-HEC (H-ESO-HEC). The ESO-HEC (2.0 g) was added to a flask with 50 mL of 0.6 M NaOH solution. The reactor was heated to 100 °C with agitation for 12 h under a condensing condition. After reaction, the solution was separated by filtration and the aqueous solution was removed by reduced pressure distillation. The solid product was washed with ethyl acetate three times to remove the glycerin. The solid product was then redispersed in aqueous solution, and the solution was adjusted to pH 5−6 by 0.1 M HCl. The solution became turbid, and the product appeared as a floating oil. The product was extracted by ethyl acetate, and the organic phase was washed with hot distilled water three times. Finally, the H-ESO-HEC product was purified by reduced pressure distillation. The H-ESO-HEC-Na was obtained by neutralizing the carboxylic acid of H-ESO-HEC with sodium hydroxide.

FT-IR. Fourier transform infrared (FT-IR) spectra were used to confirm the structure of the H-ESO-HEC. These spectra were

[a]Expressed as grams of the H-ESO-HEC per gram of HEC (on dry mass basis). [b]Expressed as millimoles of carboxyl per gram of H-ESO-HEC (on dry mass basis). [c]Determined by M_w/M_n.

obtained on a Thermo Scientific Nicolet IS10 spectrometer with the attenuated total reflectance (ATR) method. The spectra were recorded over the range 4000−500 cm^{-1} at 4 cm^{-1} resolution and averaged over 16 scans per sample.

NMR. ^1H NMR and ^{13}C NMR spectra for H-ESO-HEC were recorded at 40 °C on a BRUKER AV400 spectrometer (Bruker, Rheinstetten, Germany) operating at frequencies of 400.13 and 100.61 MHz, respectively. Deuterated dimethyl sulfoxide (DMSO-d_6) and tetramethylsilicane (TMS) were used as the solvent and the internal standard, respectively. The chemical shift values were referenced to the signals of DMSO-d_6 and TMS.

HT-GPC. Molecular weight distribution curves and relative values of number-average (M_n) and weight-average (M_w) molecular weight of H-ESO-HEC were determined by HT-GPC (HT-GPC Module 350A, Viscotek; GPC equipped with I-MBHMW-3078 HT-GPC column) at 60 °C. The HT-GPC instrument was equipped with a refractive index detector, viscosity detector, and small-angle light scattering detector. The flow rate of the carrier solvent (HPLC-grade DMSO) was 1.0 mL/min. Samples were filtered over microfilters with a pore size of 0.2 μm (Nylon, Millex-HN 13 mm Syringes Filters, Millipore). The results were obtained from OmniSEC software.

Conductimetry. The carboxyl content of H-ESO-HEC was determined by conductometric titrations.[30] The H-ESO-HEC (30−40 mg) was suspended into 15 mL of 0.01 M hydrochloric acid solution. After 2 h of stirring, the suspensions were titrated with 0.01 M NaOH. The carboxyl content of the sample was determined from the conductivity and V_{NaOH} curve. The carboxyl content is calculated by the following equation

$$\text{carboxyl content(mmol/g)} = \frac{c(V_2 - V_1)}{m} \quad (1)$$

Here, V_1 and V_2 are the volumes of NaOH (mL) in the first and second inflection points of titration curves, respectively. c is the concentration of NaOH (mmol/L), and m is the weight of oven-dried sample (mg). To minimize errors, titrations were duplicated at least three times, and the average value was retained for the discussion.

DSC. To determine the ring-opening polymerization of ESO, the DSC measurements of the H-ESO-HEC were performed on a Diamond DSC at 40 mL/min dry nitrogen as the purge gas. Typically, ∼4 mg of the H-ESO-HEC was accurately weighed in an aluminum pan and sealed with pin-perforated lids. The sample was cooled to −50 °C at a rate of 10 °C/min, and a refrigerated cooling system was used to equilibrate the sample at −50 °C for 5 min. Data were recorded while the oven temperature was raised from −50 to 0 °C at 10 °C/min.

Surface Tension. The surface tension of H-ESO-HEC-Na was measured at 25 °C using the Wilhelmy plate T107 (width, 19.44 mm; thickness, 0.1 mm; height, 65 mm; circumference, 39.08) on a Sigma 701 Automatic Surface Tensiometer. The instrument was calibrated against pure water before measurements were made. The concentration of H-ESO-HEC-Na surfactant was gradually increased by dispersing stock solution into the measurement cell. The software automatically determined the surface tension as a function of the bulk concentration. The surface tension data were plotted against the H-ESO-HEC-Na concentration in water from 0.0003 to 2.0 g/L. Each concentration of aqueous H-ESO-HEC-Na solution was tested in triplicate—this was done automatically by the instrument. The concentration at which the equilibrium surface tension of the polymeric surfactants stopped decreasing with concentration and plateaued is the critical micelle concentration (CMC).[22] From the inflection point of the plot, the critical micelle concentration (CMC) and minimum surface tension (γ_{cmc}) were derived. All data were obtained from the OneAttention software.

Krafft Point (KP). A 20 mL amount of 0.5 wt % surfactant aqueous solution (at least quintuplicate the CMC of studied surfactant) was prepared in an alkaline solution and added to a beaker. The beaker was then heated, and the particular temperature was recorded as KP when the solution transformed from turbid to pellucid.[31]

Hydrophile Lipophile Balance (HLB) Value. The emulsions were prepared using a mixture of the nonionic surfactants Tween 60 and Span 80 to satisfy the proper HLB values for optimum emulsification conditions. The mixed HLB values were calculated with the following equation

$$HLB_{mix} = HLB_T \times T\% + HLB_S \times S\% \quad (2)$$

Here, HLB_{mix}, HLB_T, and HLB_S are the HLB values of the mixed surfactants, Tween 60 (14.9), and Span 80 (4.3), respectively. The T% and S% are the mass percentages of Tween 60 and Span 80 in the mixed surfactants, respectively.[32] All HLB values used were measured at 25 °C.

Rheology. Rheological measurements were performed at a rotational rheometer HAAKE MARS II equipped with a measuring geometry named PP60 Ti (diameter, d = 50 mm). The H-ESO-HEC-Na-III was selected to evaluate the rheological properties. H-ESO-HEC-Na-III solutions at three different concentrations (0.1, 1, and 5 g/L) were prepared to measure the shear viscosity that changed with the shear rate ranging from 0.01 to 100 s^{-1}.[15] The rheological measurements were carried out at 40 °C. All data were obtained using the HAKKE RheoWin data manager software.

Statistical Method. Origin Pro 9.0 was used to calculate the standard deviation of carboxyl content and the surface tension of H-ESO-HEC. The standard deviation was calculated with the following equation

$$S = \sqrt{\frac{\sum_{i=1}^{n}(X_i - \bar{X})^2}{n-1}} \quad (3)$$

Here, S is the standard deviation of a sample, X_i is the ith value in a sample, $\bar{X}$ is the average number of a sample, and n is the total number of a sample.

RESULTS AND DISCUSSION

Figure 1 outlines a simplified mechanism for the entire reaction. The ESO-HEC was prepared via ring-opening polymerization, in which the hydroxyl groups of HEC acted as initiators. In addition, the ring-opening polymerization generated new hydroxyl groups that can also act as initiators via the $SnCl_4$ catalyst. The polymeric ESO were covalently bound to the HEC, and hydrolysis of ESO-HEC (H-ESO-HEC) was

DOI: 10.1021/acs.jafc.5b03765
J. Agric. Food Chem. 2015, 63, 9062−9068

obtained with sodium hydroxide. As shown in Table 1, H-ESO-HEC products with different molecular weights were obtained by adjusting the mass ratio of HEC and ESO in graft reaction. The graft reaction occurred at room temperature with a short reaction time because of the high activity of the $SnCl_4$ catalyst. The yields of the H-ESO-HEC were measured and ranged from 1.2 to 2.7 g per gram of HEC as the amount of ESO increased in the graft polymerization reaction. In addition, H-ESO-HEC-Na samples with different molecular weights were obtained by neutralizing carboxylic acid of H-ESO-HEC with sodium hydroxide.

Spectroscopic Identification of the Structures of H-ESO-HEC. In Figure 2, the FT-IR spectrum of H-ESO-HEC-III

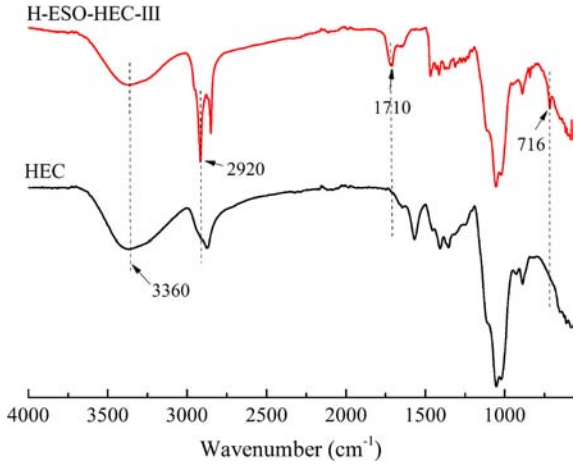

Figure 2. FT-IR spectra of HEC and H-ESO-HEC-III.

attested to the presence of ESO chains onto the HEC by appearance of the characteristic absorption bands assigned to the carbonyl functions at 1710 cm^{-1} versus the HEC. The spectral peak at 2920 cm^{-1} was attributed to the $-CH_3$ group of the alkane chains of ESO. Also, peaks at 716 cm^{-1} indicate the vibration of $-(CH_2)_n-$ ($n \geq 4$).[33] No significant change in hydroxyl group signal at 3360 cm^{-1} was noticed because the hydroxyl groups of the HEC acted as initiators and were consumed in the grafting reaction. The ring-opening polymerization generated new hydroxyl groups simultaneously—these are obvious from Figure 1. These results indicated that the H-ESO-HEC was prepared successfully.

The introduction of the ESO on HEC chains is further confirmed by the ^1H and ^{13}C NMR spectra of the H-ESO-HEC-III in Figure 3. In ^1H NMR spectrum, the clusters of signal peaks ranged from δ 0.8 to 1.6. These were related to the protons of the alkane chains of ESO on HEC. The peaks at δ 2.1 corresponded to the side groups −OH of the HEC. The alkane chains were produced by the ring-open reaction. The clusters of signal peaks in the range from δ 3.2 to 5.0 were attributed to the chemical shifts of anhydroglucose unit (AGU) protons. In the ^{13}C NMR spectrum, the possible assignments of the peaks were found according to the previous literature.[34,35] The inserted region at δ 176 correspond to carbonyl signals of the carboxylate groups.[36] The C-1 carbon resonance in AGU was poor at δ 101. The clusters of signal peaks in the range from δ 62 to 76 contributed to the chemical shifts of AGU carbons. Table 2 offers detailed information. Distinct peaks were observed at δ 62. There are attributed to the C-6 substituted by the hydroxyethylation and connected to the

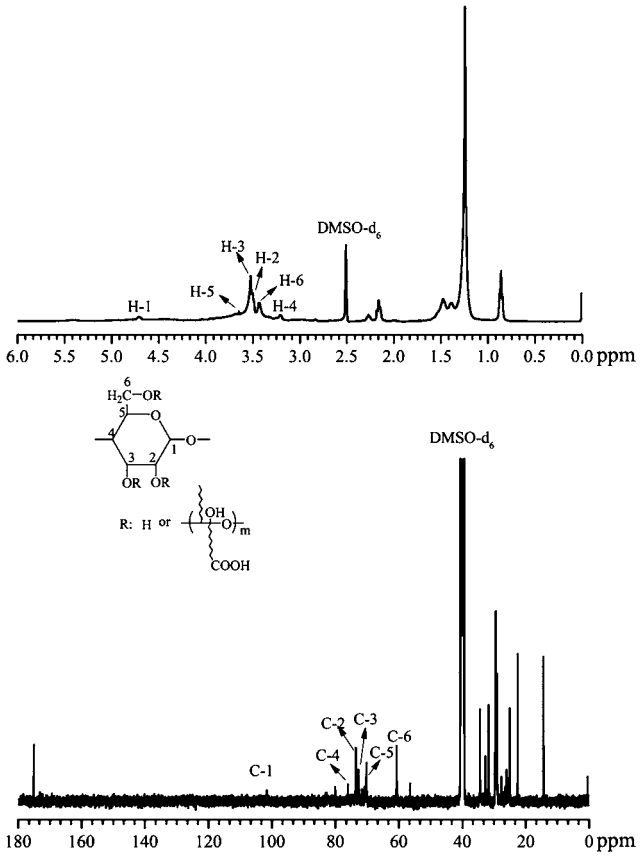

Figure 3. ^1H NMR and ^{13}C NMR spectrum of H-ESO-HEC-III sample in DMSO-d_6.

Table 2. ^1H and ^{13}C NMR Signals of H-ESO-HEC

^1H NMR		^{13}C NMR	
signal	δ (ppm)	signal	δ (ppm)
−**OH**	2.10	−**COOH**	176
$-(CH_2)_n-CH_3$	0.90	$-CH_3$	15
$-(CH_2)_n-CH_3$	1.30−1.50	$-CH_2-$	27−35

AGU−H_6	3.45	AGU−C_6	62

ether bond that is obtained by graft polymerization. The clusters of peaks in the range from δ 10 to 35 corresponding to the carbon signals of ESO chains demonstrated that the graft reaction was successful. ^1H NMR and ^{13}C NMR spectroscopy confirmed the characteristic groups of H-ESO-HEC-III.

Molecular Weight and Carboxyl Content of H-ESO-HEC. The molecular weight value of H-ESO-HEC was determined by HT-GPC. The HT-GPC profile signals of the refractive index detector are shown in Figure 4. This shows that the H-ESO-HEC with different molecular weights had a similar tendency of distribution and moved toward the higher molecular weight regions as the amount of ESO increased in the graft reaction. As listed in Table 1, the M_n of H-ESO-HEC (I−V) ranged from 1.48×10^5 to 4.58×10^5 Da and the M_w of

DOI: 10.1021/acs.jafc.5b03765
J. Agric. Food Chem. 2015, 63, 9062−9068

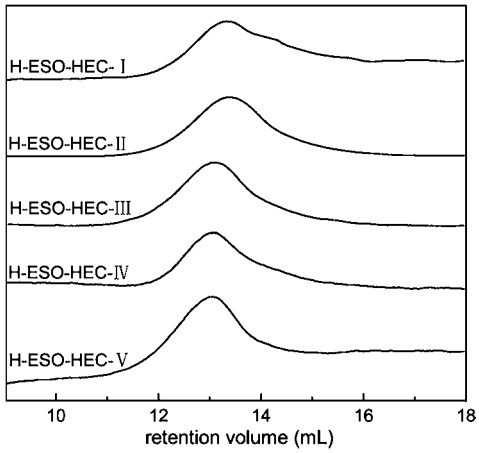

Figure 4. GPC profile signal of the refractive index of H-ESO-HEC samples.

H-ESO-HEC (I–V) ranged from 2.71×10^5 to 8.28×10^5 Da along with the mass ratio of HEC and ESO ranged from 1:1 to 1:5, respectively. The conductometric titration curve to determine the carboxyl content of H-ESO-HEC-III was divided into three parts in Figure 5. The first part showed the presence

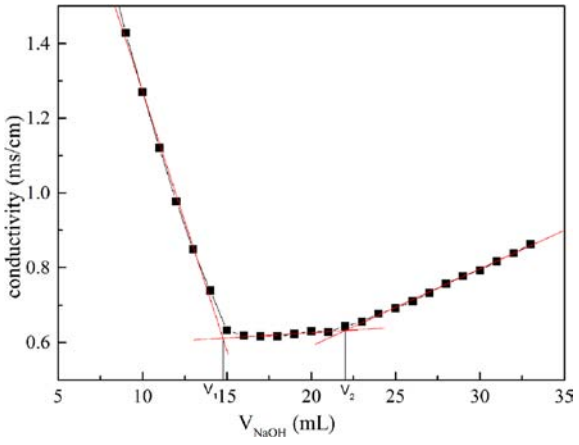

Figure 5. Conductometric titration curve of H-ESO-HEC-III.

of a strong acid corresponding to excess HCl. The second part where the conductivity remains constant showed a weak acid corresponding to the carboxyl content. The last part showed that strong base corresponded to an excess of sodium hydroxide. V_1 and V_2 are volumes of NaOH (mL) in the first and second inflection points of the titration curves, respectively. Finally, the carboxyl content can be calculated by eq 1. The carboxyl contents of H-ESO-HEC (I–V) were 1.89–2.80 mmol/g (Table 1). We concluded that the carboxyl content was closely associated with the molecular weight. As the amount of ESO increased in graft reaction, the carboxyl content increased according to the M_n of H-ESO-HEC. In addition, the polydispersity indexes (PDI) of H-ESO-HEC (I–V) ranged from 1.46 to 2.1. This indicates that the H-ESO-HEC samples had a wide distribution (Figure 4).

DSC Analysis. The ring-opening polymerization of ESO grafting on HEC was confirmed by DSC in which the glass transition temperature (T_g) was determined to be the temperature at the inflection point. Figure 6 clearly illustrates that there was no T_g in HEC and H-ESO-HEC-I because the

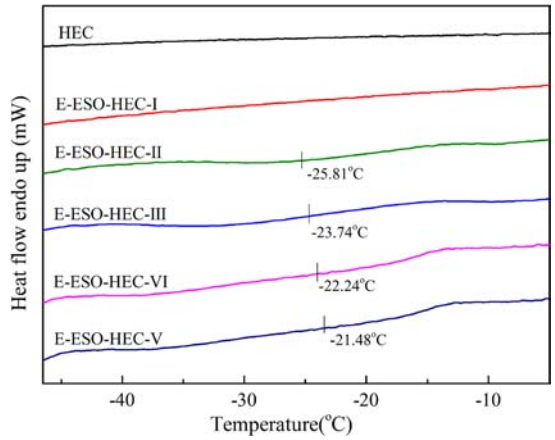

Figure 6. DSC curves of HEC and H-ESO-HEC samples.

HEC did not exhibit glass transition, and there was no polymerization of ESO on HEC in H-ESO-HEC-I. Previous literature reported that the products obtained by ring-opening polymerization of ESO had T_g.[26] The T_g values of H-ESO-HEC-II, H-ESO-HEC-III, H-ESO-HEC-IV, and H-ESO-HEC-V were −25.81, −23.74, −22.24, and −21.48 °C, respectively. As expected, increasing the amount of ESO in the graft reaction resulted in more ESO being grafted on HEC. The ring-opening polymerization reaction took place in the graft reaction—this was consistent with the GPC results. Furthermore, the T_g of H-ESO-HEC samples became higher as the molecular weights of H-ESO-HEC increased.

Surface Tension of Aqueous H-ESO-HEC Polymeric Surfactants. The H-ESO-HEC products were added to a beaker containing the required amount of NaOH to neutralize all of the acidic protons from carboxylic acid groups. This was then placed in a 60 °C water bath and stirred with a glass rod until the samples were dissolved.[28,29] A series of aqueous solutions of the H-ESO-HEC-Na were prepared, and their surface tensions were investigated at room temperature. It is well known that amphiphilic polymers with a suitable hydrophilic–hydrophobic balance can form a micelle structure when exposed to a selective solvent.[37] As shown in Figure 7, the surface tension of H-ESO-HEC-Na in water decreased markedly at low concentration at first. When the concentration was higher, the surface tension reduced slightly. Finally, the

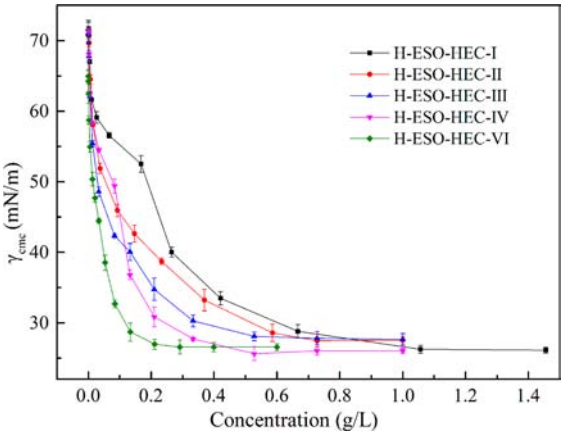

Figure 7. Effect of H-ESO-HEC-Na concentration in water on equilibrium surface tension of water.

DOI: 10.1021/acs.jafc.5b03765
J. Agric. Food Chem. 2015, 63, 9062–9068

surface tension was held nearly constant because its concentration was sufficiently high.

As shown in Table 3, the minimum surface tensions of H-ESO-HEC-Na (I–V) were almost the same and ranged from 26.33 to 28.88 mN/m. The H-ESO-HEC-Na displayed efficient surface properties versus HEC and the hydrolyzed ESO at 54.68 and 34.28 mN/m, respectively. In addition, the previous studies reported that the surface tension of fatty acid-esterified cellulose derivatives ranged between 46 and 65 mN/m.[17,18] Different efficiency of these fatty acid-modified cellulose polymeric surfactants in lowering surface tensions of water was attributed to the status of fatty acid in polymeric surfactants. In our study, hydroxyl groups of HEC acted as initiators for ring-opening polymerization of ESO. The fatty acid chains were combined with HEC by ether linkage at the middle site of the fatty acid molecular chain. In this structure, both the hydrophobic alkanes and the hydrophilic carboxyl were introduced into HEC. The simultaneous introduction of hydrophobic alkanes and hydrophilic carboxyl groups improved the hydrophilic–hydrophobic balance of HEC and provided an opportunity to form micelles in water. The CMC values of H-ESO-HEC-Na were decreased from 1.053 to 0.157 g/L along with the obviously increasing molecular weight of H-ESO-HEC-Na. As the molecular weights increased, the H-ESO-HEC-Na displayed greater propensity to form micelles because of the flexible molecular chains. This indicated that the efficiency in reducing surface tension was significantly enhanced when the molecular weight of H-ESO-HEC-Na increased. The KP of the H-ESO-HEC-Na ranged from 39 to 68 °C. It increased as a function of molecular weight accordingly. The HLB values of the samples ranged from 9.6 to 10.6.

Table 3. CMC, γ_{cmc}, KP, and HLB Values of Samples

samples	CMC (g/L)	γ_{cmc} (mN/m)	KP (°C)	HLB value
HEC		54.68 ± 1.20		
H-ESO-Na	1.105	34.28 ± 0.93	18	9.6–10.6
H-ESO-HEC-Na-I	1.053	26.33 ± 0.56	39	9.6–10.6
H-ESO-HEC-Na-II	0.702	28.88 ± 0.99	42	9.6–10.6
H-ESO-HEC-Na-III	0.514	27.83 ± 0.61	45	9.6–10.6
H-ESO-HEC-Na-IV	0.402	26.37 ± 0.50	52	9.6–10.6
H-ESO-HEC-Na-V	0.157	26.94 ± 1.26	68	9.6–10.6

Surface Rheological Properties. The apparent viscosities of the H-ESO-HEC-Na aqueous solution as a function of shear rate at different concentrations were investigated. The results of H-ESO-HEC-Na-III displayed the same properties as the other products (Figure 8). The curves were not smooth at the low-shear rate because of instrument error and the complete minor viscosity. Therefore, the curve of the 0.1 g/L H-ESO-HEC-Na-III can largely be considered a straight line. The curve of the 0.1 g/L H-ESO-HEC-Na-III below the CMC demonstrated that the solution behaved like water due to the low number of species H-ESO-HEC-Na-III in solution. The curves of the 1.0 and 5.0 g/L H-ESO-HEC-Na-III above the CMC that formed micelles in aqueous solution can be divided into two parts. First, the viscosity of the H-ESO-HEC-Na-III solution decreased as the shear rate increased, and the H-ESO-HEC-Na-III solution exhibited a pseudoplastic property at the low-shear rate.[38] This was because micelles in aqueous solution were damaged, and the macromolecules experienced conformational change.[39] Its winding structure was separated under the action of shearing force and arranged along the flow direction along with the increasing shear rate.[40] Sequentially, the viscosity remained constant when the shear rate reached a certain level. It behaved like a Newtonian property.[41] This is because the winding structure was completely destroyed, and the molecular orientation reached a limiting condition.

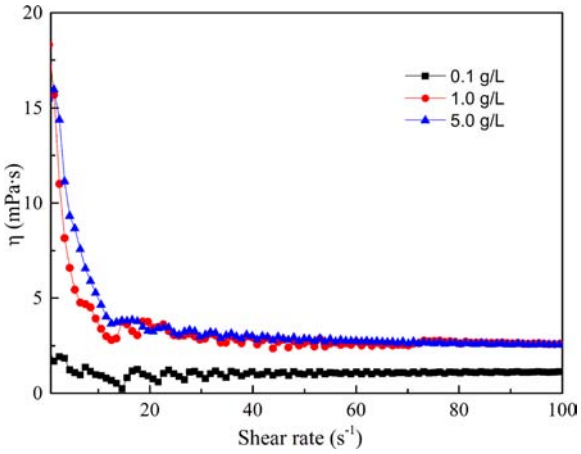

Figure 8. Apparent viscosity of the H-ESO-HEC-Na-III solution as a function of shear rate.

In summary, ESO-grafted HECs were prepared via ring-opening polymerization, and five novel polymeric surfactants H-ESO-HEC-Na (I–V) were obtained by neutralization of H-ESO-HEC with sodium hydroxide. The molecular weights of H-ESO-HEC products were varied by adjusting the mass ratio of HEC and ESO in the grafting reaction. The synthesized polymeric surfactants H-ESO-HEC-Na exhibited higher activities in reducing water surface tension. These ranged from 26.33 to 28.88 mN/m in comparison to 34.28 mN/m for hydrolyzed ESO and 54.68 mN/m for HEC. In addition, the efficiency in reducing water surface tension was definitely enhanced when the molecular weights of H-ESO-HEC increased. Rheological measurements indicated that the H-ESO-HEC-Na solutions changed from a pseudoplastic state to Newtonian with increasing shear rate. This study may facilitate an increase in the use of renewable and biodegradable materials with improved properties as polymeric surfactants.

guaiacol, and canolol (4-vinyl syringol), are natural compounds widespread in the plant kingdom.[20,21] In industry, these substances are treated as food additives and are approved as flavouring agents by regulatory agencies.[22] They are also involved in resin, elastomer, and adhesive production.[23] However, no study has examined the possibility to produce lipophilic antioxydants from vinylphenols.

In the present work, the strong nucleophilic character of vinylphenols has been exploited to propose an original way for lipophilization by means of peracids. As a vinylphenol representative, 4-vinyl guaiacol (**2**) was selected to undergo this transformation.

Thus, the perhydrolysis activity of CAL-B[24] contributed to produce a set of peracids, with different alkyl chain lengths, which were grafted by electrophilic addition to the 4-vinyl guaiacol double bond. Subsequently, the antioxidant activity of 4-vinyl guaiacol and its resulting hydroxyesters was evaluated using the conjugated autoxidizable triene (CAT) assay. The synthesized hydroxyesters can be used as effective antioxidants in multiphase food products and pharmaceuticals.

MATERIALS AND METHODS

Chemicals. Vanillin (99%), malonic acid (99%), piperidine (≥99.5%), butanoic acid (≥99%), hexanoic acid (≥98%), octanoic acid (≥98%), decanoic acid (≥98%), dodecanoic acid (≥98%), octadecanoic acid (≥95%), *tert*-butyldimethysilyl chloride (97%), imidazole (≥99%), immobilized CAL-B (Novozym 435), hydrogen peroxide (30 wt % in H_2O), tung oil from *Aleurites fordii* seeds [average molecular weight (MW) = 872 g mol^{-1}], phosphate buffered saline (PBS) at pH 7.2, polyoxyethylene(23)lauryl ether [Brij 35, estimated molar mass (MM) = 1198 g mol^{-1}], and (±)-6-hydroxy-2,5,7,8-tetramethylchromane-2-carboxylic acid (Trolox) were purchased from Sigma-Aldrich France. 2,2′-Azobis(2-methylpropionamidine) dihydrochloride (AAPH) was obtained from Wako Chemical (Neuss, Germany). Glacial acetic acid was purchased from Merck France. Hexadecanoic acid was supplied by SEPPIC France. All solvents were analytical- or high-performance liquid chromatography (HPLC)-grade (Sigma-Aldrich France) and were used as received.

All of the reactions were monitored by thin-layer chromatography (TLC) performed on silica gel 60 F254 (provided by Merck). All compounds were dissolved in $CDCl_3$ and analyzed using a Bruker 400 MHz spectrometer, operating at 400 MHz for ^1H and 100 MHz for ^{13}C. Chemical shifts were referenced using residual internal CH_3Cl signals at 7.26 and 77.0 ppm for ^1H and ^{13}C, respectively. Assignments of both proton and carbon resonances, identification, and structure characterization of products were performed using both one-dimensional (1D) and two-dimensional (2D) nuclear magnetic resonance (NMR) spectrum analysis and homonucluear ^1H and heteronuclear $^1H/^{13}C$ experiments. Elemental analyses were performed by combustion on Flash EA 1112 (ThermoFinnigan 2003). High-resolution mass spectrometry (HRMS) analyses were performed by a Xevo-G2-XS Q-Tof (from Waters). Statistical analysis [one-way analysis of variation (ANOVA)] of CAT values was performed using JMP software, version 12 (SAS Institute, Cary, NC). The means were then compared using Student's *t* test. The significance level α was set to 0.05.

Protection of the Phenolic Hydroxyl of 4-Vinyl Guaiacol (2). Under argon, a solution of *tert*-buthyldimethylsilyl chloride (1.2 mmol, 0.18 g) in *N*,*N*-dimethylformamide (DMF) (2 mL) was added dropwise to a stirred solution of 4-vinyl guaiacol (**2**) (1 mmol, 0.15 g) and imidazole (2.5 mmol, 0.17 g) in DMF (3 mL). Stirring was maintained 26 h at room temperature, and then water (25 mL) and ethyl acetate (25 mL) were added. The aqueous layer was separated and extracted with ethyl acetate (2 × 25 mL). The combined organic layers were washed with brine (30 mL), dried over anhydrous $MgSO_4$, and concentrated under reduced pressure. Flash chromatography purification (90:10 petroleum ether/ethyl acetate) afforded the following.

*tert-Butyl(2-methoxy-4-vinylphenoxy)dimethylsilane (**3**).* Colorless oil, 85% yield (0.83 mmol). ^1H NMR (400 MHz, $CDCl_3$) δ: 0.18 (s, 6H, H12), 1.02 (s, 9H, H10), 3.84 (s, 3H, H9), 5.14 (dd, *J* = 10.8 and 0.91 Hz, 1H, H8), 5.61 (dd, *J* = 17.6 and 0.91 Hz, 1H, H8), 6.65 (dd, *J* = 17.6 and 10.9 Hz, 1H, H7), 6.81 (d, *J* = 8.1 Hz, 1H, H6), 6.88 (dd, *J* = 8.2 and 1.9 Hz, 1H, H5), 6.94 (s, 1H, H2) ppm. ^{13}C NMR (100 MHz, $CDCl_3$) δ: 4.6 (C12), 18.4 (C11), 25.7 (C10), 55.4 (C9), 109.6 (C2), 111.7 (C8), 119.4 (C6), 120.4 (C5), 131.7 (C1), 136.7 (C7), 145.1 (C4), 151.0 (C3) ppm. [M + H^+] calcd, 265.1504; found, 265.1510. $C_{15}H_{24}O_2Si$ calcd C, 68.13; H, 9.15; Si, 10.62; found C, 70.02; H, 8.89; Si, 11.31.

Lipophilization of the Silylated Vinylphenol (3). In a 50 mL round-bottom flask equipped with a magnetic stirrer, 2 mmol of carboxylic acid, 3 mmol of 30% hydrogen peroxide (0.34 mL), and Novozym 435 (10 wt % relative to the weight of the silylated vinylphenol, 0.026 g) were mixed in 2 mL of toluene. After 30 min at 40 °C, a solution of compound **3** (1 mmol, 0.26 g) in toluene (1 mL) was added to the reaction medium over 2 h. The reaction was monitored by TLC. After the complete consumption of the peracid, catalyst beads were removed from the reaction mixture by filtration and 30 mL of water and 30 mL of ethyl acetate were added to the filtered reaction mixture. The aqueous layer was separated and extracted with ethyl acetate (2 × 30 mL). The combined organic layers were washed with brine (40 mL), dried over anhydrous $MgSO_4$, and concentrated under reduced pressure. The phenolic group deprotection was performed on the crude products.

Deprotection of the Phenolic Hydroxyl. The crude product formed from the reaction of compound **3** with peracids (1 mmol) was diluted in 2 mL of dry tetrahydrofuran (THF), and the solution was cooled to 0 °C. Under argon, a solution of tetra-*N*-butylammonium fluoride (TBAF) (1.2 mmol) in 2 mL of dry THF was added dropwise to the previous solution. After 3 h at 0 °C, water (25 mL) and ethyl acetate (25 mL) were added. The aqueous layer was separated and extracted with ethyl acetate (2 × 25 mL). The combined organic layers were washed with brine (30 mL), dried over anhydrous $MgSO_4$, and concentrated under reduced pressure. Flash chromatography purification (from 90:10 to 60:40 petroleum ether/ethyl acetate) afforded β-hydroxyesters **4a**−**4h** and α-hydroxyesters **5b**−**5e**. For example, the electrophilic addition of octanoic peracid to compound **3** gave rise to the following.

*2-Hydroxy-1-(4-hydroxy-3-methoxyphenyl)ethyl Octanoate (**4d**).* Yellow oil, 46% yield (0.45 mmol). ^1H NMR (400 MHz, $CDCl_3$) δ: 0.88 (t, *J* = 6.9 Hz, 3H, H17), 1.26−1.1.29 (m, 8H, H16−H13), 1.62−1.66 (m, 2H, H12), 2.38 (t, *J* = 7.40 Hz, 2H, H11), 3.78 (dd, *J* = 11.90 and 4.30 Hz, 1H, H9α), 3.86 (m, 1H, H9β), 3.90 (s, 3H, H7), 5.65 (s, 1H, OH aliphatic), 5.79 (dd, *J* = 7.60 and 4.30 Hz, 1H, H8), 6.86 (d, *J* = 8.46 Hz, 1H, H6), 6.89 (d, *J* = 7.80 Hz, 1H, H5), 6.91 (s, 1H, H2) ppm. ^{13}C NMR (100 MHz, $CDCl_3$) δ: 14.0 (C17), 22.5 (C16), 25.0 (C12), 28.8 (C15), 29.0 (C14), 31.6 (C13), 34.5 (C11), 55.9 (C7), 66.0 (C9), 76.5 (C8), 109.5 (C2), 114.5 (C5), 119.8 (C6), 129.0 (C1), 145.8 (C4), 146.5 (C3), 173.5 (C10) ppm. [M + H^+] calcd, 311.1821; found, 311.1835. $C_{17}H_{26}O_5$ calcd C, 65.78; H, 8.44; found C, 65.67; H, 8.51.

*2-Hydroxy-2-(4-hydroxy-3-methoxyphenyl)ethyl Octanoate (**5d**).* Yellow oil, 30% yield (0.29 mmol). ^1H NMR (400 MHz, $CDCl_3$) δ: 0.89 (t, *J* = 6.9 Hz, 3H, H17), 1.28−1.33 (m, 8H, H16−H13), 1.64 (m, 2H, H12), 2.36 (t, *J* = 7.50 Hz, 2H, H11), 3.90 (s, 3H, H7), 4.16 (dd, *J* = 11.50 and 3.58 Hz, 1H, H9α), 4.25 (dd, *J* = 11.50 and 3.50 Hz, 1H, H9β), 4.89 (dd, *J* = 8.40 and 3.40 Hz, 1H, H8), 5.66 (s, 1H, OH aliphatic), 6.86 (dd, *J* = 8.50 and 1.80 Hz, 1H, H6), 6.89 (d, *J* = 8.10 Hz, 1H, H5), 6.94 (s, 1H, H2) ppm. ^{13}C NMR (100 MHz, $CDCl_3$) δ: 14.0 (C17), 22.35 (C16), 24.9 (C12), 28.8 (C15), 29.0 (C14), 31.6 (C13), 34.2 (C11), 55.9 (C7), 69.2 (C9), 73.3 (C8), 108.5 (C2), 114.3 (C5), 119.2 (C6), 131.8 (C1), 145.6 (C4), 146.7 (C3), 174.0 (C10) ppm. [M + H^+] calcd, 311.1821; found, 311.1817. $C_{17}H_{26}O_5$ calcd C, 65.78; H, 8.44; found C, 65.91; H, 8.36.

The other NMR data are displayed in the Supporting Information.

Determination of the Antioxidant Capacity Using the CAT Assay. Prior to use, commercial tung oil was stripped (removal of polar compounds, including tocopherols) as follows. In a glass column packed with 25 g of alumina, 25 mL of a tung oil solution in *n*-hexane (200 mg mL^{-1}) was eluted followed by 25 mL of hexane. Then, hexane was evaporated under vacuum, and the stripped tung oil was aliquoted into brown glass tubes, inerted under nitrogen stream, and stored at −18 °C until use. All experiments were performed under shelter from light, as much as possible.

Fresh solutions of Trolox and phenolics at concentrations ranging from 0.4 to 4.0 mmol L^{-1} were prepared in chloroform/methanol (2:1), then diluted in methanol to obtain a concentration range of 0.1−1.0 μmol L^{-1}, and stored in amber vials. A total of 50 μL of these solutions was transferred to a 96-well microplate (Greiner, Frickenhausen, Germany), which was then preheated to 37 °C and shook in a thermostated shaker (PHMT Grant Instruments, Ltd., Shepreth, U.K.) for 5 min at 1200 rpm.

A total of 25 mL of PBS containing Brij 35 (34 μmol L^{-1}) was added to 5 mg of stripped tung oil into an amber glass vial. Thereafter, this premixture was vortexed for 10 s prior to homogenization in an Ultra Turrax homogenizer (Janke and Kunkel, Staufen, Germany) at 2400 rpm for 90 s. Each well of the microplate was supplemented with 100 μL of this emulsion. To enhance repeatability, the microplate was immediately preheated and maintained under stirring in a thermostated shaker (PHMT Grant Instruments, Ltd.) at 37 °C for 1 min at 1200 rpm.

A total of 50 μL of a solution of AAPH in PBS (4 mmol L^{-1}), prepared immediately before reading, was added to wells. Finally, each well contained a final volume of 200 μL, with 115 μmol L^{-1} tung oil, 17 μmol L^{-1} Brij 35, 1 mmol L^{-1} of AAPH, and antioxidants at various concentrations (0.25−1.0 μmol L^{-1}). The kinetics of the reaction were immediately assessed by monitoring absorbance decay at 273 nm. Measurements were taken every minute within 6 h at 37 ± 0.5 °C with shaking the plate 5 s before each reading, using a microplate reader model M1000 (Tecan, Groedig, Austria) equipped with software Magellan.

All measurements were performed in triplicate and reported as the average ± standard deviation (SD). To normalize data, the raw absorbance values were expressed in relative absorbance according to eq 1

$$\text{relative absorbance} = \frac{A_t}{A_0} \quad (1)$$

where A_t and A_0 are the absorbances read at times t and 0 min, respectively. The area under the curve (AUC) corresponding to the decay of relative absorbance was calculated thanks to eq 2.

$$\text{AUC} = 1 + \frac{A_1}{A_0} + \frac{A_2}{A_0} + \ldots + \frac{A_{359}}{A_0} + \frac{A_{360}}{A_0} \quad (2)$$

The chart area provided by an antioxidant sample was then calculated using the difference between AUC in the presence of a sample of antioxidant (AUC_{sample}) and the blank (AUC_{blank}) corresponding to a solution without antioxidant. Trolox was used as an internal calibration standard. Thus, the antioxidant capacity (CAT value) of a sample was given in Trolox equivalents and calculated by eq 3

$$\text{CAT value} = \frac{(\text{AUC sample} - \text{AUC blank})}{(\text{AUC Trolox} - \text{AUC blank})} \frac{(\text{moles of Trolox})}{(\text{moles of sample})} \quad (3)$$

where AUC_{sample}, AUC_{blank}, and AUC_{Trolox} are the areas in the graph where the protection of tung oil occurs in the presence of a sample, the antioxidant-free solution, and the solution containing Trolox, respectively. The CAT value is expressed in moles of Trolox per moles of the tested compound, i.e., in Trolox equivalents.

RESULTS AND DISCUSSION

To produce antioxidant 4-vinyl guaiacol derivatives with increased lipophilicity, the following four-step synthesis route was adopted: (i) 4-vinyl guaiacol (**2**) production from vanillin, (ii) protection of the compound **2** phenolic hydroxyl by silyl etherification (to avoid the undesirable oxidation or polymerization side reactions), (iii) electrophilic addition of the *in situ*-generated peracids (with different chain lengths) to protected 4-vinyl guaiacol (**3**), and (iv) phenolic hydroxyl deprotection.

Synthesis of 4-Vinyl Guaiacol (2) and Protection of Its Hydroxyl Group. Generally, the availability of vinylphenols in natural sources does not meet the industrial requirements. Hence, several chemical syntheses of these phenolic compounds, including catalytic dehydrogenation of ethylphenols, Wittig reaction, or hydroxycinnamic acid decarboxylation, have been described.[25] However, a majority of these procedures required expensive reagents and harsh conditions to eventually give rise to the products in low yields. Recently, an efficient synthesis of these compounds by the Knoevenagel−Doebner[25] reaction in mild conditions was described by Sinha et al. Hence, this synthetic pathway was adopted to produce 4-vinyl guaiacol (**2**) from vanillin (**1**).

Subsequently, the 4-vinyl guaiacol hydroxyl group was temporary masked to avoid the competitive oxidation and polymerization side reactions. Among several protecting groups, *tert*-butyldimethylsilyl (TBDMS) was selected because of its stability in a variety of organic reactions and the facility by which it can be introduced and removed under mild conditions.[26,27] The treatment of compound **2** with *tert*-butyldimethylsilyl chloride and imidazole at room temperature led to the silyl ether derivative **3** with 85% yield (Figure 1).

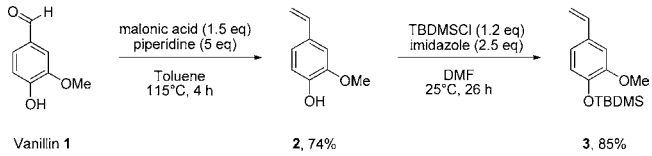

Figure 1. 4-Vinyl guaiacol synthesis and its phenolic hydroxyl etherification.

Lipophilization of Compound 3 by Electrophilic Esterification. As reported in the literature, various reaction parameters can influence the lipase activity and, thus, the peracid formation. Among several organic solvents tested, the highest yields of peracids were observed using toluene or hexane.[28] Törnvall et al.[29] and Orellana-Coca et al.[24] investigations have demonstrated that elevated temperatures (above 60 °C) together with hydrogen peroxide at high concentrations (6−12 M) resulted in a rapid loss of enzyme activity. When these different data are taken into account, the vinylic derivative **3** was reacted with caprylic peracid (octanoic peracid) in a two-phase reaction. First, the CAL-B-catalyzed perhydrolysis of caprylic acid was initiated at 40 °C during 30 min in toluene. Then, the solution of compound **3**, in the same solvent, was added to the previous mixture over 2 h. During the whole reaction, the hydrogen peroxide concentration did not exceed 1 M.

After 6 h of reaction and the usual work up (described in the Materials and Methods), the crude product was treated with TBAF in THF at 0 °C, allowing for the silyl ether cleavage and the hydroxyl group recovery within 3 h.

Instead of the expected epoxidized products, hydroxyester derivatives **4d** and **5d** were produced in 76% overall yield (Figure 2).

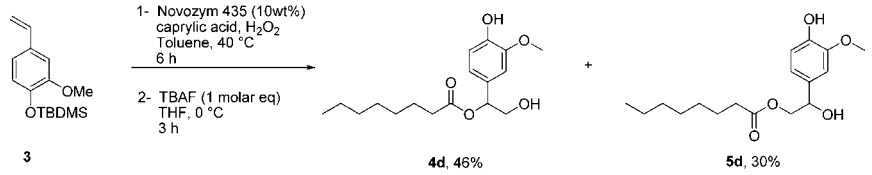

Figure 2. Electrophilic esterification of compound **3**, followed by hydroxyl group deprotection.

The addition of decanoic peracid to compound **3** was proven by NMR. Indeed, the characteristic proton signals of the vinylic double bond at 5.07, 5.64, and 6.67 ppm disappeared and were replaced by α-hydroxyl (3.78−3.86 ppm for compound **4d** and 4.89 ppm for compound **5d**) and α-ester (5.79 ppm for compound **4d** and 4.16−4.25 ppm for compound **5d**) proton signals. The appearance of shielded aliphatic proton signals on the ^{1}H NMR spectrum and the ester carboxyl signal on the ^{13}C NMR spectrum indicated the grafting of the carboxylic acid moiety on compound **3**.

On the basis of these results, other carboxylic acids (ranging from C2 to C18) were used to assess the reactivity of compound **3** with the *in situ*-generated corresponding peracids and to produce phenolic hydroxyesters with different side-chain lengths. The reaction products are depicted in both Figure 3 and Table 1.

Considering the results displayed in Table 1, two main aspects should be discussed: (i) the peracid addition to the vinylic double bond instead of its epoxidation and (ii) the arising of two addition isomers with the predominance of the derivatives bearing a primary alcohol function (**4a**−**4h** derivatives).

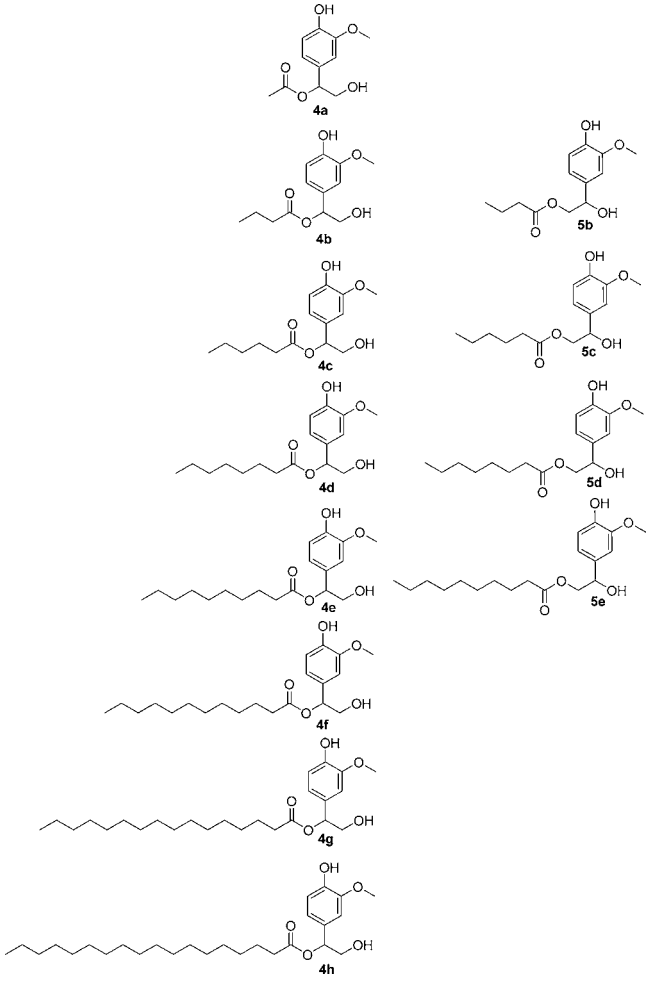

Figure 3. Chemical structures of hydroxyesters **4a**−**4h** and **5b**−**5e**.

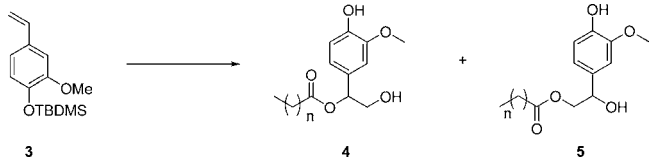
Table 1. Electrophilic Addition Products (after the Phenolic Hydroxyl Deprotection) of Peracids on Compound 3



entry	acid	reaction time (h)[a]	product	product yield (%)	CAT value[b]

			5h		

[a]Reactions were monitored by TLC and stopped after the complete conversion of compound **3**. [b]The CAT value of 4-vinyl guaiacol is 0.40 ± 0.03. [c]Reactions of compound **3** with hexanoic to octadecanoic acids were performed by loading 10 wt % of enzyme (relative to the compound **3** weight). However, the addition of both ethanoic and butanoic peracids to the compound **3** double bond required 30 and 20 wt % of enzyme, respectively.

Peracid Addition to the Double Bond of Compound 3. Generally, in the chemo-enzymatic oxidation of olefins, lipase catalyzes the formation of peracids, from the perhydrolysis reaction between carboxylic acids and an oxidizing agent, such as H_2O_2, which then donates an oxygen atom to the double bond, affording the corresponding epoxide and regenerating the carboxylic acids. The epoxidation step occurs through a concerted transition state, also known as a symmetry butterfly transition state. The bond between oxygen and alkene is being formed at the same time that the peroxy bond is breaking and the peracid proton is transferred from the hydroxyl group to carbonyl oxygen.

However, in the present instance, the generated peracids did not achieve their expected task as an oxygen carrier but an electrophilic addition rather occurred to the vinyl double bond of compound **3**. As previously mentioned, the presence of the electron-releasing groups *O*-TBDMS and *O*-methyl on the

DOI: 10.1021/acs.jafc.5b03551
J. Agric. Food Chem. 2015, 63, 9069−9075

aromatic ring of compound **3** contribute, by a mesomeric effect to enhance the electron density on the vinylic double bond. The electrophilic peroxide oxygen of peracid attacks the double bond and forms a three-membered cyclic transition state (**I**)[19] (Figure 4). Then, the electron-rich carboxylate group of peracid

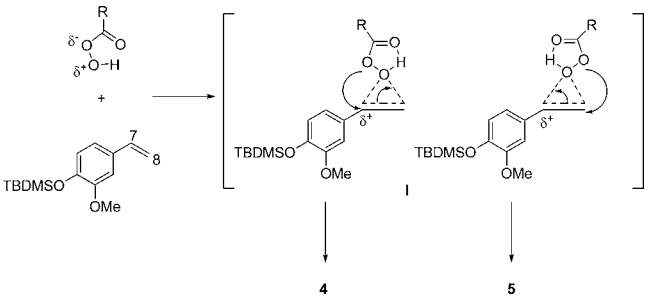

Figure 4. 1,2-Addition mechanism of compound **3** with peracids.

attacks either C7 or C8 carbons, leading to the simultaneous cleavage of the bonds between these carbons and the peroxide oxygen and the formation of compounds **4** and **5**. The intervention of the electron-releasing groups to orientate the reaction mechanism toward peracid addition is confirmed by Sarma et al.,[30] who demonstrated that styrene derivatives, with electron-withdrawing substituents, are rather epoxidized in the presence of peracids.

Peracid Addition Products. As displayed in Table 1, excluding compounds **4a**, **4b**, and **5b**, the addition products of peracids on the vinylic double bond of compound **3** after hydroxyl deprotection were obtained with fair yields ranging from 68 to 77%. The reaction of both ethanoic and butanoic peracids with compound **3** required a longer time and a higher amount of enzyme to afford addition products with relatively lower yields (entries 1 and 2). This is likely due to the peracid stability, which is highly dependent upon their molecular weight. Indeed, the smaller the peracids, the faster their decomposition; in particular, methanoic and ethanoic peracids are highly unstable.[31]

Despite the lower reaction yield of butanoic peracid, this latter led to the formation of two addition products **4b** and **5b**, with a slight predominance of the derivative bearing a primary alcohol function (**4b**). The same trend was observed for hexanoic, octanoic, and decanoic peracids, indicating that, from C4 to C8, peracids exhibit the same reactivity toward compound **3**. Although the predominance of **4**-type products is not very significant, it results from the addition of the peracid electrophilic oxygen on the most nucleophilic double bond carbon.

From dodecanoic to octadecanoic peracids (entries 6−8), only the **4**-type products were formed. The presence of a long alkyl chain in the reaction intermediate **I** seems to further polarize the C7−C8 bond, localizing the negative charge on C8. Hence, only electron-deficient C7 was attacked by the carboxylate group.

Owing to the good enzyme affinity to dodecanoic acid,[28] its corresponding peracid afforded the addition product (**4f**) with the highest yield (77%) in a relatively short time (entry 6).

This particular reactivity of peracids allowed for the production of a set of phenolic hydroxyesters with side-chain lengths ranging from C2 to C18. To obtain equivalent reaction yields, the other strategies based on the lipase-B-catalyzed esterification and transesterification generally require harsher operational conditions, such as a longer reaction time (7−30 days) and higher temperatures (50−60 °C).[32]

After synthesis, the antioxidant potency of these lipophilized phenolics was assessed by the CAT assay.

Determination of the Antioxidant Capacity of Lipophilized Derivatives of 4-Vinyl Guaiacol. In this study, the CAT assay was used to evaluate the antioxidant capacity of the synthesized phenolic hydroxyesters. The triacylglycerols of tung oil are mainly (ca. 85%) comprised of α-eleostearic acid [(9*Z*,11*E*,13*E*)-9,11,13-octadecatrienoic acid]. Owing to the presence of a conjugated triene, this fatty acid strongly absorbs at 273 nm and is highly prone to oxidation. Consequently, under oxidizing conditions, a degradation of conjugated triene may be simply observed upon the signal loss at 273 nm. These properties allow for an efficient, easy, rapid, and direct assessment of lipid oxidation in the heterophasic system. Thus, the CAT assay provides relevant screening of antioxidant abilities of molecules, because it is representative of unsaturated fatty acid oxidation pathways that occur in foods and biological systems.[33] As depicted in both Table 1 and Figure 5, the

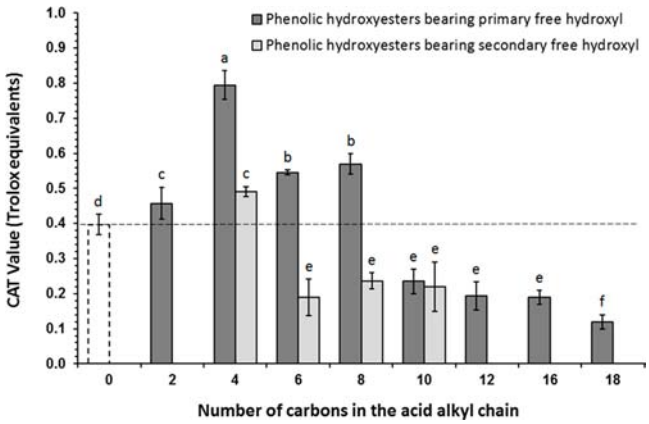

Figure 5. CAT values of 4-vinyl guaiacol (white bar) and the lypophilized molecules: phenolic hydroxyesters bearing primary free hydroxyl (dark gray bars) and phenolic hydroxyl esters bearing secondary free hydroxyl (light gray bars). Values followed by the same letter are not significantly different ($p \leq 0.05$). Values are mean ± SD ($n = 3$).

antioxidant ability of 4-vinyl guaiacol was significantly affected by the grafting of the lipophilic moiety (alkyl chain of variable length). Moreover, the isomer nature (phenolic ester bearing a primary or secondary hydroxyl) may significantly affect the antioxidant activities in such a heterogeneous medium. Indeed, isomers exhibiting the secondary alcohol function presented lower antioxidant activities, with only a slight enhancement for the butyl ester (CAT value = 0.49 ± 0.01) in comparison to 4-vinyl guaiacol (CAT value = 0.40 ± 0.03). One may argue that the difference between the two regioisomers might be explained by the negative inductive effect (−I) of the free aliphatic hydroxyl group. Thus, the one closest to the benzene ring would disrupt the resonance stabilization of the phenoxyl radicals more, resulting in a lower antioxidant ability and CAT value. As far as the phenolic esters with primary free hydroxyl (obtained with higher yields), significant improvement in the antioxidant activity was observed with the addition of 2, 4, 6, and 8 carbons in the ester alkyl chain (**4a**, **4b**, **4c**, and **4d**, respectively) when compared to 4-vinyl guaiacol. The non-lipophilized molecule **2** presented a CAT value of 0.40 ± 0.03,

DOI: 10.1021/acs.jafc.5b03551
J. Agric. Food Chem. 2015, 63, 9069−9075

while compounds **4a**−**4d** had CAT values of 0.80 ± 0.05, 0.49 ± 0.04, 0.55 ± 0.01, and 0.57 ± 0.03, respectively. Conversely, their counterparts with 10, 12, 16, and 18 carbons in the alkyl chain (**4f**, **4g**, and **4h**, respectively) showed a lower antioxidant ability in comparison to 4-vinyl guaiacol. The order of antioxidant capacity was C4 > C8 ≈ C6 > C2 ≫ C10 ≥ C12 ≈ C16 > C18, and a clear pattern with respect to the effect of the alkyl chain length on the antioxidant ability was observed. Indeed, the effectiveness of antioxidants has been shown to increase as a function of the increasing alkyl chain length to a critical point (4 carbons), followed by a steady decrease beyond that point when more hydrophobic moieties are linked. This nonlinear effect named "cut-off effect" has already been reported in the literature with similar experiments performed with a series of alkyl chlorogenates, rosmarinates, ferulates, and coumarates.[34−37] In these studies, the antioxidant activities were drastically improved with increasing alkyl chain lengths until an optimized activity ranging between 8 and 12 carbon atoms. In both series of esters synthesized from 4-vinyl guaiacol, the highest antioxidant capacity was obtained with an alkyl chain of 4 carbons.

As previously observed,[38,39] the intrinsic chemical reactivity of an antioxidant toward oxidizing species is not the only factor that governs its activity, with this feature being in fact multifactorial. A suitable location, position, mobility, and concentration of antioxidant at the interface but also its reactivity toward free radical can drastically change antioxidant efficiency. It is now accepted that lipophilization mostly affects antioxidant properties by changing the partitioning of the molecule. In such lipid-based dispersions, the antioxidant molecule may distribute in the aqueous or lipid phase as well as in the intermediate pseudo-phase (interface) as monomer, micelle, or aggregate forms, which results in a different reactivity. Thus, the antioxidant activity of the lipophilized molecules synthesized from 4-vinyl guaiacol can be explained by their polymorphism and partitioning in the present environment. The first group, composed of ethyl ester (**4a**), tends to partition within the aqueous phase with limited interaction with the interface of the lipid droplets where oxidation occurs. Consequently, it displays a CAT value equal to that of the native molecule because of their equivalent polarity (Table 1). The second group formed by butyl ester (**4b**) showed the highest CAT values. This may be explained by a better location of this molecule at the oil/water interface, promoting oil protection against the oxidizing species (R−C$^{\bullet}$, R−COO$^{\bullet}$, etc.) generated by the azo initiator. When the chain length was increased beyond this limit, the amount of esters in the intermediate phase is expected to decrease, while the amount in the lipid phase is supposed to increase, which partly explains the diminution in the CAT values in the third group composed of medium alkyl chains (C6 and C8). Also, these molecules could be found in different polymorphisms: monomers, which may protect oil droplets against oxidation when located at the interface and micelles, which will be only sparsely involved against the lipid droplet oxidation. Finally, the last group composed of esters with 10 or more carbons in the alkyl chain, exhibited very low antioxidant activities because of their high lipophilic character. These compounds are mainly located within the lipid phase, with a limited activity at the interface. Moreover, they might also be physically isolated from the emulsion interface through the formation of aggregates (micelles or precipitates) that reduce their concentration in the reactive interphase.

Generally, phenolic compound lipophilization catalyzed by CAL-B is performed through esterification or transesterification reactions. However, it has been shown in this study that the perhydrolysis activity of lipase B was an efficient way to graft alkyl chains with different lengths on 4-vinyl guaiacol. The chemical structure of this vinylphenol derivative and, particularly, its nucleophilic vinylic double bond contributed to modify the usual reactivity of peracids, leading to the one-pot production of different hydroxyesters by electrophilic addition. Within this addition, the formation of hydroxyesters bearing primary hydroxyl groups was promoted, especially when the chain length of the peracid exceeded eight carbons. The assessment of the antioxidant potency of the resulting hydroxyesters demonstrated that the 4-vinyl guaiacol antioxidant activity was enhanced by the grafting of alkyl chains with 2−8 carbons. Therefore, this new route of phenolipid synthesis through lipophilization of vinylphenols represents a good strategy to promote and optimize the effectiveness of their natural antioxidant activity in the heterophasic system encountered in food emulsions, cosmetics, and biological systems.

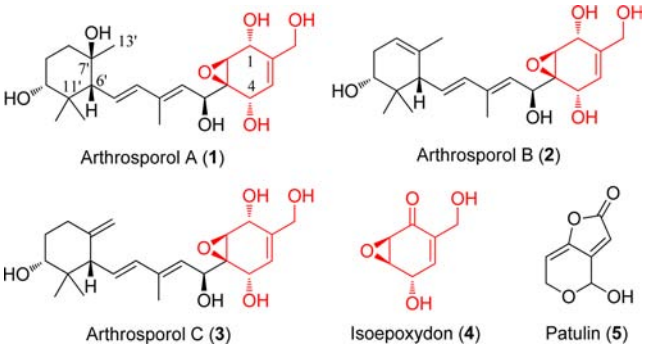

Figure 1. Arthrosporols A–C (**1**–**3**) from nematode-trapping fungus *A. oligospora*, isoepoxydon (**4**), and patulin (**5**).

been evoking our great interest in the biosynthesis of this class of naturally occurring metabolites from *A. oligospora*.

We now report the identification of the polyketide synthase (PKS) gene encoding 6-methylsalicylic acid synthase involved in the biosynthesis of the arthrosporol metabolites in *A. oligospora*. The effect of disruption of the PKS gene on the production of arthrosporol metabolites was investigated. The formation of adhesive trapping networks and capture of nematodes by the mutant strain were also studied. Our results suggested that the PKS gene might play an important role in regulating the trap formation and the lifestyle switching of this fungus.

MATERIALS AND METHODS

Sequence and Phylogenetic Analysis of *AOL_s00215g283* in *A. oligospora*. Predicted *AOL_s00215g283* in *A. oligospora* was annotated by BLAST searches against protein databases and InterProScan searches against protein domain databases. The amino acid sequence of AOL_s00215g283 in *A. oligospora* was downloaded from GenBank, and the sequences from different fungi were downloaded from GenBank. The amino acid sequences from different fungi were analyzed using the DNAman software package, version 5.2.2 (Lynnon Biosoft, Vaudreuil, Quebec, Canada). A neighbor-joining tree was constructed using the Mega 5.1 software package. A web-based analysis platform antiSMASH 2.0[15] was applied to perform genome mining of the biosynthetic gene clusters. The conserved functional domains were analyzed using InterProScan 4.8 with default parameter settings.

Fungal Material. The strain *A. oligospora* YMF 1.3170 was isolated from Jiuquan, Gansu, People's Republic of China,[14] and identified as *A. oligospora* by morphological features. The isolate was deposited in the strain collection of the Laboratory for Conservation and Utilization of Bio-Resources and Key Laboratory for Microbial Resources of the Ministry of Education, Yunnan University. After the conidia of *A. oligospora* YMF 1.3170 had developed on potato dextrose agar (PDA) slants in test tubes at 25 °C, the strain was kept at −30 °C as stock cultures. DNA extraction of *A. oligospora* YMF 1.3170 and polymerase chain reaction (PCR) amplification of the internal transcribed spacer (ITS) rRNA gene were carried out according to the literature. A characteristic fragment (GenBank accession number JX244893) was amplified by PCR using the species-specific primers ITS4 and ITS5 and the genome DNA of *A. oligospora* YMF 1.3170 as the template. The BLAST searches in the GenBank showed that the DNA fragment was most similar to the published ITS sequences of *A. oligospora*, consistent with morphological identifications.

Disruption Vector Construction. The plasmid pAg1-H3,[16] which was used for gene disruption vector construction and transformation, was maintained in *Escherichia coli* strain DH5a (Takara, Shiga, Japan). The strain *A. oligospora* YMF 1.3170 used in this study was maintained on PDA at 28 °C. Genomic DNA of *A. oligospora* YMF 1.3170 was extracted as previously described.[17] Restriction endonucleases and DNA-modifying enzymes were from New England Biolabs (Beverly, MA). In-Fusion HD Cloning Kits were from Clontech Laboratories (Mountain View, CA). The left and right DNA fragments flanking the hygromycin-resistant gene (hygR) in pAg1-H3 vector were PCR-amplified from the genomic DNA of *A. oligospora* YMF 1.3170 by GXL high-fidelity DNA polymerase (Takara, Shiga, Japan), using primer sets 283-5f, GAGCTCGGTACCAAGGCCCGGGGGAGCCGCAGAGGACAACA; 283-5r, AGGCCTGATCATCGATGGGCCCCGACATGCCATGCCGATT; 283-3f, TCTAGAGGATCCCCCGACTAGTATTATCGGTAGCCTTTGTC; and 283-3r, CACGAAGCTTGCATGCCTGCAGGAGGATTCGGTATTGTTGTT. The DNA fragments (5′ flank and 3′ flank) were purified using NucleoSpin Gel and PCR Clean-up Kit (Macherey-Nagel, Düren, Germany). The purified 5′ flank DNA fragment was inserted into the *Sma*I- and *Apa*I-digested pAg1-H3 vector by the in-fusion method to produce pAg1-H3-283-5′. Similarly, the 3′ flank DNA fragment was inserted into the *Spe*I and *Sbf*I sites of pAg1-H3-283-5′ to generate the completed disruption vector pAg1-H3-283-5′-3′.

The homologous fragment amplifications were carried out as follows. A total of 1 μL of the prepared genomic DNA template from *A. oligospora* YMF 1.3170 was added to a 50 μL PCR amplification system using GXL high-fidelity DNA polymerase following the instructions of the manufacturer (Takara). All PCRs were carried out in a Veriti 96-well thermal cycler (PE Applied Biosystems). The amplification program consisted of predenaturation at 95 °C for 3 min, followed by 30 cycles of denaturation at 98 °C for 10 s, annealing at 57 °C for 15 s, and elongation at 68 °C for 2 min, with a final extension step at 68 °C for 10 min.

Preparation of Fungal Protoplasts. Regeneration medium PDASS (PDA supplied with 0.6 M sucrose, 0.3 g/L yeast extract, 0.3 g/L tryptone, and 0.3 g/L peptone) was used for protoplast regeneration,[18] and PDASS supplemented with 200 μg/mL hygromycin B (Amresco, Solon, OH) was used for selecting transformants. In the initial transformation for the disruption of the PKS gene, four 1 cm diameter mycelia plugs from YMA medium (2 g/L yeast extract, 10 g/L malt extract, and 18 g/L agar) for 7 days at 28 °C were inoculated into 100 mL of TG medium consisting of 1% tryptone (Oxoid, Basingstoke, U.K.) and 1% glucose and cultures at 30 °C and 180 rpm for 36 h. The mycelia were harvested and resuspended in 20 mL of a filter-sterilized enzyme solution that contained 120 mg of lysing enzymes (Sigma, St. Louis, MO), 0.4 mL of cellulase (Sigma, St. Louis, MO), and 100 mg of snailase (Solarbio, Beijing, China) in 0.6 M $MgSO_4$ at pH 6.0. Snailase, extracted from the crop and digestive tract of snails, consists of more than 30 enzymes, including cellulase, hemicellulase, β-glucuronidase, etc. The suspension was incubated for 4 h at 28 °C on a rotary shaker at 180 rpm. Protoplasts were collected by filtering through six layers of sterile lens-cleaning tissue and centrifuged at 1000*g*. The protoplasts were washed twice with KTC (1.2 M KCl, 10 mM Tris-HCl, and 50 mM $CaCl_2$) solution and finally resuspended in the same solution.

Transformation of Fungus *A. oligospora*. The protoplast-based protocol for the gene disruption in *A. oligospora* YMF 1.3170 was performed as described in a previous report,[18] with modifications. A total of 100 μL of protoplasts (ca. 8.0×10^7 mL^{-1}) were mixed with 10 μg of linear DNA in a 1.5 mL centrifuge tube. After 30 min of incubation on ice, 600 μL of PTC (50% polyethylene glycol 6000, 20 mM Tris–HCl at pH 7.5, and 50 mM $CaCl_2$) was added to the mixture and mixed gently. After incubation at 28 °C for 1 h and regeneration for 12 h, the putatively transformed protoplasts were plated onto PDAS medium (PDA supplemented with 5 g/L molasses, 0.6 M saccharose, 0.3 g/L yeast extract, 0.3 g/L tryptone, and 0.3 g/L casein peptone) containing 200 μg/mL hygromycin B (Roche Corporation, Germany). The transformation colonies were selected after incubation at 28 °C for 6–7 days. After single-spore isolation, the putative transformants were transferred onto TYGA medium alone (10 g/L tryptone, 10 g/L glucose, 5 g/L yeast extract, 5 g/L molasses, and 18 g/L agar) containing 200 μg/mL hygromycin B and incubated for 5 days at 28 °C. Genomic DNA of putative transformants were extracted and verified by PCR to check for the integration of genes in

DOI: 10.1021/acs.jafc.5b04244
J. Agric. Food Chem. 2015, 63, 9076–9082

the genome. The positive transformants were further confirmed by Southern blot analyses. Southern analysis was carried out according to the instructions provided by the North2South chemiluminescent hybridization and detection kit (Pierce, Rockford, IL). The primer pair 283-S1 (TTGGAGAAACCGAACAACCT) and 283-S2 (TTGGTGAGGAGTGAATAGCG) were used as Southern hybridization probes, and restriction enzyme *Ssp*I was used to digest the genomic DNA of the wild-type *A. oligospora* and the mutant strains for Southern analysis.

Vegetative Growth and Conidia Yield Comparisons. The 9 mm diameter mycelia plugs from 7-day-old fungal colonies of the wild-type and mutant strains were inoculated onto 9 cm plates with different media (6 replicates/strain). The mycelia plugs of the same size and age were incubated at 28 °C at both light and dark conditions for 6−10 days, respectively. Radial colony growth rates and colony morphology were recorded at a 24 h interval for 1 week, and the growth rate was calculated as millimeters per hour each day. The growth rates and colony morphology of the wild-type and mutant strains were compared in PDA, YMA (2 g/L yeast extract, 10 g/L malt extract, and 18 g/L agar), and TYGA (10 g/L tryptone, 10 g/L glucose, 5 g/L yeast extract, 5 g/L molasses, and 18 g/L agar) media. Similarly, to test the adaptive abilities, the growth rates were compared in TGA medium supplemented with stress-related compounds, including 0.1−0.3 mol/L NaCl, 5−15 mmol/L H_2O_2, and 0.01−0.03% sodium dodecyl sulfate (SDS).

To assess sporulation capacities of the wild-type and mutant strains, 100 μL aliquots of conidial suspension were spread on 9 cm plates with YMA medium and incubated for 10 days at 28 °C and the conidia were washed in 10 mL of sterile water, followed by filtration through four layers of lens tissues to remove mycelial debris. The concentrations of the conidial suspension were determined with microscopic counts on a hemocytometer.[18]

Induction of Trap Formation and Virulence Assays. *Caenorhabditis elegans* (strain N2) was cultured in oatmeal medium at 22 °C for 6−7 days. The wild-type and mutant strains were cultivated on agar plates by spreading approximately 10^6 conidia per plate. After 3 days of incubation at 28 °C, 300 adult nematodes were added to the middle of the plate. Fungal mycelia and traps were observed, and the numbers of captured nematodes were recorded after 12 and 24 h, respectively, under light microscopy (Olympus, Tokyo, Japan). The experiments were performed in triplicate.

Fermentation and Extraction Procedures. The wild-type *A. oligospora* and the Δ*AOL_s00215g283* mutant strains cultured on PDA medium at 28 °C for 7 days were inoculated into 500 mL flasks containing 250 mL of production PD medium (200 g/L potato and 20 g/L dextrose). The culture broths of the 14-day-old liquid fermentations (1.5 L each strain) were filtered to separate the mycelia from the cultures. The culture filtrates were concentrated *in vacuo* to 50 mL and were exhaustively extracted overnight with ethyl acetate (1:1, v/v). The organic fractions were evaporated to dryness to give residues. The dried organic residues were then dissolved in 500 μL of methanol, filtered through 0.22 μm membranes, and further analyzed using high-performance liquid chromatography with photodiode array detection (HPLC−DAD) and gas chromatography−mass spectrometry (GC−MS).

HPLC Analysis. HPLC analysis was carried out using a HPLC-1200 series (Agilent, Waldbronn, Germany) system equipped with a G1311A binary pump and G1315A photodiode array ultraviolet/visible (UV/vis) detector, employing the following instrumental conditions: column, CAPCELL PAK C18, 5 μm, 4.6 × 250 mm (Shiseido). The total flow rate was 1 mL/min; mobile phase A was 0.1% formic acid in water; and mobile phase B was 0.1% formic acid in acetonitrile. The column temperature was maintained at 40 °C. The injection volume for the extracts was 25 μL. The liquid chromatography (LC) conditions were manually optimized on the basis of separation patterns with the following gradient: 0−2 min, 10% B; 10 min, 25% B; 30 min, 35% B; 35 min, 50% B; 45 min, 90% B; 47 min, 10% B; and 49 min, 10% B. UV spectra were recorded at 220−400 nm. The standard sample arthrosporol A was isolated from wild-type *A. oligospora* according to the modified method described in the literature.[14] A 14-day-old fermentation broth of strain *A. oligospora* YMF 1.3170 cultured on PDA medium was filtered to separate the mycelia from the culture. The culture filtrate was concentrated *in vacuo* and partitioned with acetyl acetate, and the organic part was evaporated to dryness to give an oily residue. The residue was loaded onto a macroporous resin column (7 × 80 cm) and eluted with H_2O−MeOH (0, 25, 50, and 90%, each in 3 L) to yield four fractions (A−D) based on thin-layer chromatography (TLC) behavior. Fraction C obtained on elution with 50−90% MeOH−H_2O was further subjected to a Sephadex LH-20 gel column (4 × 150 cm) eluting with MeOH (2.5 L) to yield six subfractions. Subfraction 3 was repeatedly subjected to a Sephadex LH-20 gel column (3 × 100 cm) eluting with acetone (2.3 L), a C18 column (3 × 50 cm) eluting with H_2O−MeOH (35, 37, and 39%, each in 1.8 L), and a silica gel column (2 × 40 cm) eluting with $CHCl_3$−MeOH (35:1 and 20:1, each in 1.5 L) to obtain arthrosporol A. The purified sample arthrosporol A was elucidated and confirmed with nuclear magnetic resonance (NMR) data.[14]

GC−MS Analysis, Metabolite Identification, and Semi-quantitation. The GC−MS analysis was performed with a 5890 series II Plus gas chromatograph interfaced with a model 5972 mass spectrometric detector (Hewlett-Packard, Avondale, PA) equipped with a 30 m long, 0.25 mm inner diameter, and 0.5 μm film thickness HP5-MS capillary column. The temperature was programmed from 100 to 300 °C at a rate of 5 °C/min. Helium was used as a carrier gas at a flow rate of 0.7 mL/min. The split ratio was 1:20; the injector temperature was 280 °C; the interface temperature was 300 °C; and the ionization voltage was 70 eV.

Identification of these peaks was performed through retention time index and mass spectrum.[19] Compounds were designated as metabolites if they were identified with a match 900 on a scale of 0−1000 and retention index (RI) deviation of 3.0. The semi-quantitative analysis of the main compounds was carried out by internal normalization with the area of each compound. The addition of each area of the compounds corresponds to 100% area.[20]

Statistical Analysis. Statistical analysis were performed using the SPSS package, version 17.0 for Windows (Chicago, IL). Differences with $p < 0.05$ were regarded as statistically significant, and differences with $p < 0.01$ were regarded as highly statistically significant.

RESULTS AND DISCUSSION

The arthrosporol metabolites possess a novel hybrid carbon skeleton consisting of a polyketide-derived epoxycyclohexenol combined with a terpenoid-derived monocyclic sesquiterpenol substructure. Arthrosporols B (**2**) and C (**3**) were assumed to be two dehydration derivatives of arthrosporol A (**1**).[14] All of the arthrosporols shared the same epoxycyclohexenol moiety, and the difference among them only occurred in the monocyclic sesquiterpenol substructure. From the biosynthetic point of view, a PKS gene should be involved in the production of arthrosporols in nematode-trapping fungus *A. oligospora*.

A search for the epoxycyclohexenol moiety in the SciFinder database found that the epoxycyclohexenol moiety of arthrosporols was quite similar to a known compound isoepoxydon (**4**) (Figure 1).[21] They even shared the same stereochemistry for the epoxy ring and the hydroxyl group at C-4. The only difference between them was that the hydroxyl group at C-1 in the epoxycyclohexenol moiety of arthrosporols was replaced by a ketone at C-1 in isoepoxydon.

Isoepoxydon is an important intermediate metabolite for the biosynthesis of a well-studied antibiotic and mycotoxin, patulin (**5**). Patulin a toxic chemical contaminant produced by *Aspergillus*, *Penicillium*, and *Byssochlamys* spp.[22] It is the most common mycotoxin found in apples and apple-derived products, such as juice, cider, compotes, and other food, intended for young children. The fact that exposure to this mycotoxin is associated with immunological, neurological, and gastrointestinal outcomes has led to patulin being included

among mycotoxins whose level in food is regulated in many countries around the world.[23] Similar to several other major mycotoxins, including aflatoxins, fumonisins, zearalenone, and ochratoxins, patulin is a polyketide metabolite.[24] The first step in the biosynthesis of patulin needs the involvement of a PKS, identified as 6-methylsalicylic acid synthase.[25] The most recent study revealed that 6-methylsalicylic acid synthase is also involved in the production of a meroterpenoid antibiotic yanuthone D in *Aspergillus niger*.[26]

Bioinformatic analysis of the *A. oligospora* genome identified five putative PKS genes. Among these genes, the gene *AOL_s00215g283* was annotated for type I PKS synthase.[17] Sequence analysis and a database search using the BLASTP program revealed that the amino acid sequence of AOL_s00215g283 shared 53% similarity to 6-methylsalicyclic acid synthases from *Endocarpon pusillum* (XP_007785679.1), *Byssochlamys nivea* (AAK48943.1), and *Aspergillus terreus* (BAA20102.2 and XP_001215453.1). A total of 42 homologues of AOL_s00215g283 were retrieved, and a neighbor-joining phylogenetic tree was built using these amino acid sequences of these proteins. From this tree, we found that AOL_s00215g283 was clustered within the fungal polyketide synthases and formed a distinct monophyletic branch with no other closely related PKS as of yet. Strangely, no homologues identified from other nematode-trapping fungi, such as *Dactylellina haptotyla* and *Drechslerella stenobrocha*,[17] clustered with the amino acid sequence of AOL_s00215g283.

A previous study revealed that the genes involved in the patulin biosynthesis pathway have been found to be located in a cluster on one chromosome as is the case for a large number of

DOI: 10.1021/acs.jafc.5b04244
J. Agric. Food Chem. 2015, 63, 9076−9082

mycotoxin pathways.[24] Five genes in the early portion of the patulin biosynthesis pathway up to the production of isoepoxydon have been identified as *PatK*, *PatG*, *PatH*, *PatI*, and *PatN*, encoding 6-methylsalicylic acid synthase, 6-methylsalicylic acid decarboxylase, and three cytochrome P450s, including *m*-cresol hydroxylase (P450), *m*-hydroxybenzyl alcohol hydroxylase (P450), and isoepoxydon dehydrogenase (P450), respectively.[22]

The analysis of the similar cluster involved in the biosynthesis of isoepoxydon in the *A. oligospora* genome was carried out. Through antiSMASH 2.0, a cluster containing the predicted PKS gene *AOL_s00215g283* was identified (Figure 2A). Most notably, the upstream flanking region of the gene *AOL_s00215g283* encodes an amidohydrolase (AOL_s00215g281), a dehydrogenase (AOL_s00215g279), a mannose-6-phosphate isomerase (AOL_s00215g277), a polyprenyltransferase (AOL_s00215g276), and three cytochrome P450s (AOL_s00215g278, AOL_s00215g280, and AOL_s00215g282). Interestingly, the downstream flank of the cluster encodes a DNA translocase (AOL_s00215g284), a member of the Gcd10p family (AOL_s00215g285), and a single-stranded nucleic-acid-binding domain (AOL_s00215g286). The amino acid sequence of AOL_s00215g281 shares 55% similarity to the 6-methylsalicylic acid decarboxylase (PatG). The amino acid sequence of AOL_s00215g282 shares 48 and 44% similarity to cytochrome P450s, PatH and PatI, respectively.

All of the above indicated that the gene cluster with the gene *AOL_s00215g283* was likely involved in the production of 6-methylsalicylic acid, which was predicted to be the first precursor for the biosynthesis of the polyketide-derived epoxycyclohexenol in arthrosporols.

To investigate the biological function of the gene *AOL_s00215g283*, the target fragment of this gene was knocked out by homologous recombination. Conserved domain analysis demonstrated that the gene *AOL_s00215g283* encoded five typical catalytic domains, including ketide synthase (KS), acyltransferase (AT), dehydratase (DH), *β*-ketoacylreductase domain (KR), and acyl carrier protein (ACP) for the PKS (Figure 2A). The fragment in the sequence encoding the KS domain was chosen to be the target. A modified method for genetic disruption of the gene *AOL_s00215g283* was developed using double-crossover recombination with the hygromycin-resistance gene (hyg) as a selection marker. The two homologous regions were amplified from *A. oligospora* genomic DNA using primers containing overlapping regions with the vector and the hyg-resistance cassette (Figure 2B). The disruption vector was transformed into the protoplasts of *A. oligospora* and yielded 20 transformants. Genomic DNAs of these transformants were isolated, and the site-specific insertion were confirmed using diagnostic PCR. In comparison to a 2035 bp fragment from the wild-type strain of *A. oligospora*, a 3637 bp fragment was amplified from the transformants using the primers 283yz-5f/283yz-3r (Figure 2C). In addition, these transformants were further confirmed using Southern blot analysis; the single band hybridizing the Δ*AOL_s00215g283* gene probe was observed in the wild-type strains and transformants (Figure 2D); and the sizes of the hybridized bands were consistent with expectation, indicating that the sequence encoding for the KS domain in the gene *AOL_s00215g283* in the mutant Δ*AOL_s00215g283* strain was disrupted. In comparison to the wild-type strain, the mutant Δ*AOL_s00215g283* strain showed similar growth rates and conditions on YMA, PDA, and TYGA media (Figure 3) and displayed a slight reduction in conidiation on the YMA

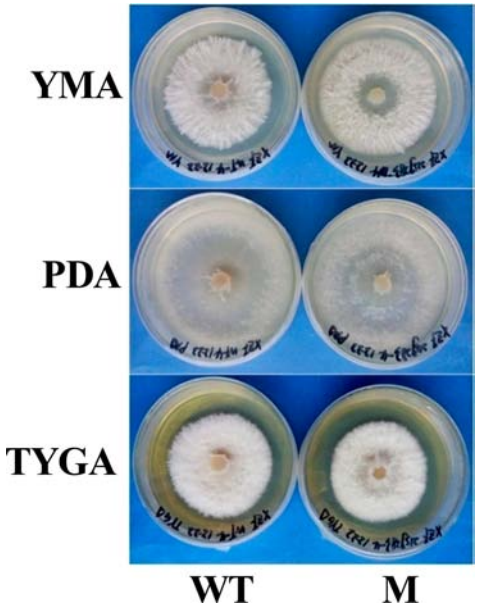

Figure 3. Comparison of the mycelia growths of the wild-type and mutant Δ*AOL_s00215g283* strains on YMA, PDA, or TYGA for 6 days at 28 °C.

medium. Similarly, both the mutant Δ*AOL_s00215g283* and wild-type strains exhibited the same growths in the presence of stress-related compounds. However, the mutant Δ*AOL_s00215g283* strain formed more adhesive networks than the wild-type strain after the nematodes were added on the 4 day cultures (Figure 4). After 12 h, the number of adhesive networks formed by the mutant Δ*AOL_s00215g283* was 318 cm^{-2} (Figure 4B), 10 times more than that of the wild-type strain (27 cm^{-2}). At the same time, the number of captured nematodes by the mutant Δ*AOL_s00215g283* was more than twice that of the wild-type strain (Figure 4C).

It was obvious that the mutant Δ*AOL_s00215g283* strain cultivated in liquid PDB for 14 days yielded light-colored culture compared to the wild-type strain. Both cultures were extracted, and the extracting organic portions were dried under *vacuo* to give a 276 mg extract for the wild-type strain and 54 mg for the mutant Δ*AOL_s00215g283*. The weight of the extract from the mutant Δ*AOL_s00215g283* strain was less than one-fifth of that from the wild-type strain. To investigate the involvement of the gene *AOL_s00215g283* in the biosynthesis of arthrosporols, both the extracts were then analyzed with the HPLC−DAD method (Figure 5). It is noteworthy that the HPLC metabolite profile of the mutant Δ*AOL_s00215g283* strain showed a significant difference from that of the wild-type strain. In comparison to the wild-type strain, the mutant Δ*AOL_s00215g283* strain lacked almost most of the peaks during the retention times ranging between 21 and 40 min in the HPLC chromatogram (Figure 5A). This was consistent with the above result that much less extract was obtained from the mutant Δ*AOL_s00215g283* strain. Further detailed analysis showed that no arthrosporol A was detected in the cultural broth of the mutant Δ*AOL_s00215g283* strain (Figure 5B), indicating that the disruption of the *AOL_s00215g283* gene led to a total loss of arthrosporol A

(A) Formation of traps of the wild-type and mutant Δ*AOL_s00215g283* strains at 12 and 24 h: WT, wild-type strain; M, mutant Δ*AOL_s00215g283*. Scale bar = 50 μm. (B) Comparison of the trap formations. (**) $p < 0.01$ versus the wild-type strain. (C) Comparison of the fungal nematicidal activity against *C. elegans*.

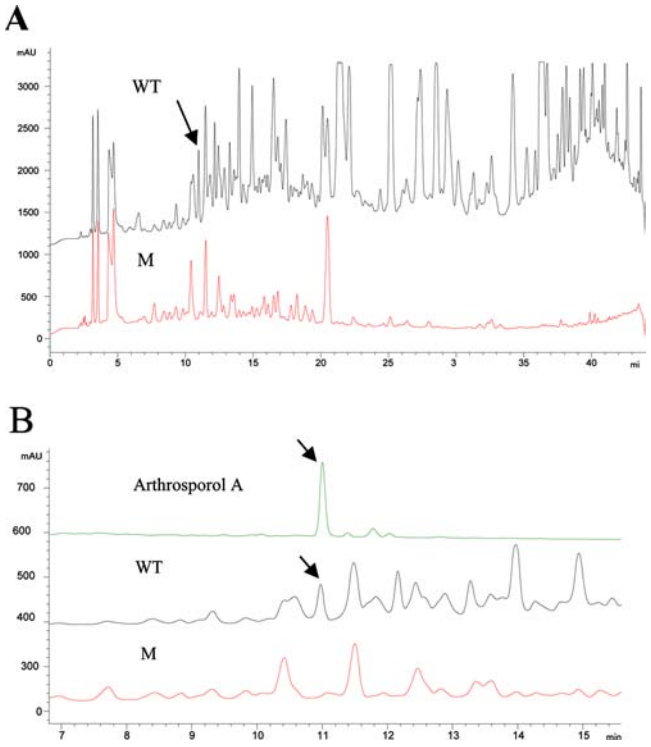

Figure 5. (A) HPLC analysis of the methanol extracts of the cultural broths from the wild-type strain (black line) and Δ*AOL_s00215g283* mutant (red line). (B) Amplified portion of the HPLC spectrum of the methanol extracts of the cultural broths from the wild-type strain (black line), mutant Δ*AOL_s00215g283* (red line), and arthrosporol A (green line). Black arrows indicate the peak of arthrosporol A at around 11 min.

and the gene *AOL_s00215g283* played a key role in the biosynthetic pathway for arthrosporol A.

Considering the possibility that the lack of the epoxycyclohexenol moiety caused by the disruption of the *AOL_s00215g283* gene might lead to the accumulation of the terpenoid-derived sesquiterpenol substructure, together with the fact that most sesquiterpenoids are volatile compounds, the culture broth of the wild-type and mutant Δ*AOL_s00215g283* strains were further analyzed by the GC−MS method. Surprisingly, two linear sesquiterpenoids, sesquirosefuran and 3,7,11-trimethyl-2,6,10-dodecatrienal, were found only in the wild-type strain. It is likely that the disruption of the *AOL_s00215g283* gene might also affect the production of the farnesol derivatives in *A. oligospora*.

A previous study displayed that farnesol secreted by *Candida albicans* could block the transition from yeast to hypha.[27] Reports of farnesol production by ascomycetes other than yeasts are rare, although some studies reported that farnesol blocked conidiation of *A. niger*,[28] inhibited cell wall integrity signaling and caused mislocalization of regulatory Rho proteins in *Aspergillus fumigatus*,[29] and also inhibited growth of other ascomycetes, for example, that of *Fusarium graminearum*.[30] In addition, farnesol displayed an intriguing effect on the *Neurospora crassa* circadian clock, which coordinated rhythmic asexual reproduction during vegetative growth.[31] Whether the lack of farnesol derivatives or terpenoid-derived arthrosporols in nematode-trapping fungus *A. oligospora* induced higher trap formation and less metabolite production need further detailed study.

In conclusion, by gene engineering and chemical metabolite profiling, we have identified the PKS gene *AOL_s00215g283* in nematode-trapping fungus *A. oligospora*. Our result revealed that the PKS gene played significant roles in not only the biosynthesis for the arthrosporols but also the fungal ability for predatory trap formation.

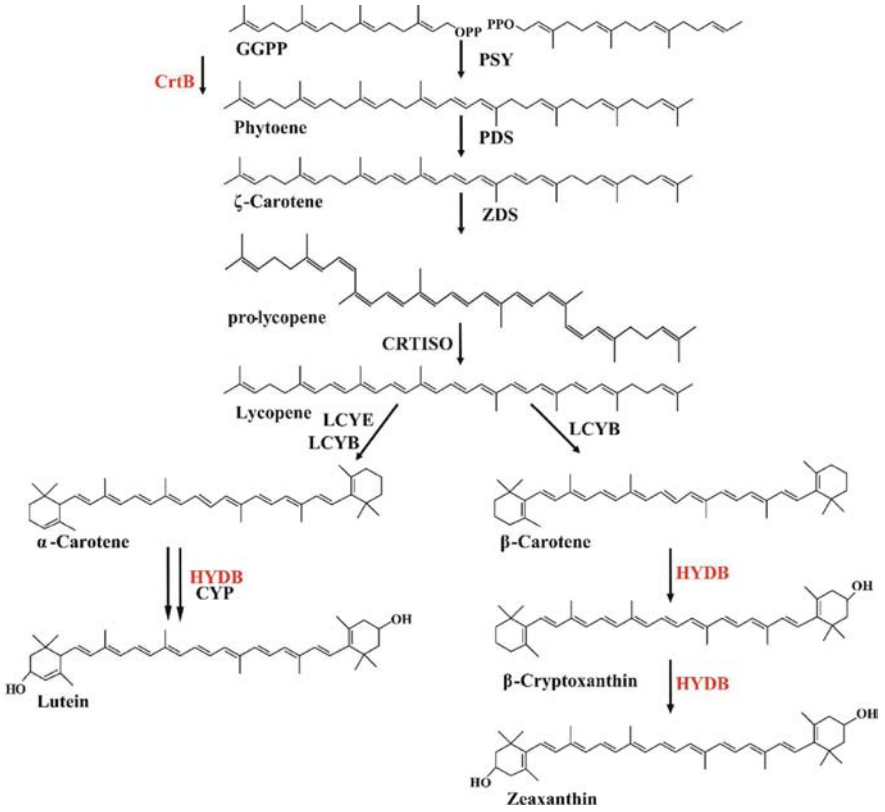

Figure 1. Carotenoid biosynthetic pathway. Enzymatic conversions are indicated with arrows, with the enzymes in bold. PSY/CrtB, phytoene synthase; PDS, phytoene desaturase; ZDS, ζ-carotene desaturase; CRTISO, carotenoid isomerases; LCYB, lycopene β-cyclase; LCYE, lycopene ε-cyclase; HYDB, β-carotene hydroxylase; CYP, carotenoid ε-hydroxylase (cytochrome P450 type).

hydroxylase expression was implemented and accumulated a high ratio of β-carotene in total carotenoid content, indicating that it is a practicable and effective approach to improve provitamin A.[25,26]

Up to now, there are two strategies to accumulate carotenoids in plant metabolic engineering. The first strategies are "push strategies", which are dependent on the overexpression of a rate-limiting enzyme in the pathway, such as successful reports in rice and maize with overexpression of *PSY* or bacterial phytoene synthase gene (*CrtB*).[27−31] The second strategies are "block strategies", which rely on the silencing of a downstream biosynthetic step. Besides the examples of potato and orange, other researches of "block strategies" include the silencing of lycopene β-cyclases to increase lycopene in tomato fruits or the silencing of zeaxanthin epoxidase to accumulate zeaxanthin in potato tubers.[32,33] Although carotenoid is one of the major pigments and determines the nutritional value of wheat,[34] wheat grains have very low carotenoid content and mainly accumulate lutein, which lacks provitamin A activity. In our previous study, the β-carotene content was increased by introducing *CrtB* and *CrtI* genes, whereas the high ratio of β-carotene accumulation could not be previously estimated, which also unveiled three important regulation nodes to be regulated in the carotenoid biosynthetic pathway of hexaploid wheat: (i) phytoene biosynthesis; (ii) lycopene cyclization; and (iii) carotene hydroxylation.[9] There are two types of *HYD* genes (*TaHYD1* and *TaHYD2*) in common wheat, which encode proteins that are 72% identical to each other over 90% of the protein length.[35] In this work, the expression of an endogenous *TaHYD* was blocked by RNA interference (RNAi) in transgenic wheat. To specifically and quantitatively increase the provitamin A content in the wheat endosperm, "push strategies" and "block strategies" were combined in wheat metabolic engineering. The expected result of this engineering was that the content of β-carotene would increase in the endosperm of transgenic wheat compared with that in the wild type.

MATERIALS AND METHODS

Plant Materials and Treatments. Wheat plants (*Triticum aestivum* L. cv. Bobwhite) were grown in the experimental field of Huazhong University of Science and Technology in Wuhan, China. To more favorably accumulate carotenoid, a yellow-kernel cultivar was chosen.

RNA and Genomic DNA Isolation. Total RNA was extracted from different wheat tissues using TRIzol reagent (Invitrogen, Carlsbad, CA, USA) according to the manufacturer's instructions. The RNA concentration and purity were analyzed using a NanoDrop ND-2000 spectrophotometer (Thermo Scientific, Wilmington, DE, USA). The integrity of the RNA sample was assessed by nondenaturing agarose gel analysis. Genomic DNA was isolated from the wheat leaves using the cetyltrimethylammonium bromide (CTAB) extraction method.[36]

Plasmid Constructs. The pLRPT vector containing the endosperm-specific promoter *1Dx5* and *35S* terminator was used to construct the overexpression (OE) and RNAi vector. Fragments of 225 bp corresponding to *TaHYD1* and *TaHYD2* were isolated by RT-PCR using specific primers with incorporated restriction sites (Supporting Information Table S1). The selected fragments followed the selection strategies for RNAi in wheat, and the highly conserved fragment was chosen as the silencing target.[37] The RNAi construct contained a cDNA fragment derived from *TaHYD* and was oriented in the sense and antisense directions at the ends of the construct, respectively, separated by an intron sequence, and the resulting

DOI: 10.1021/acs.jafc.5b04279
J. Agric. Food Chem. 2015, 63, 9083−9092

plasmid was named pLRPT-HYD-RNAi (Figure 2). The intron was derived from the wheat *TAK14* gene (AF325198). pLRPT-CrtB

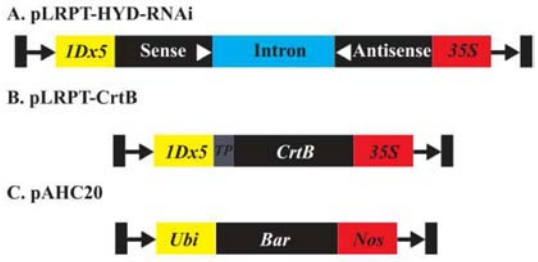

Figure 2. Structures of the three transformation plasmids (pLRPT-HYD-RNAi, pLRPT-CrtB, and pAHC20) used in this study. *1Dx5*, endosperm-specific promoter of the high-molecular-mass glutenin subunit gene *1Dx5* from wheat; *CaMV35S*, cauliflower mosaic virus (*CaMV*) *35S* terminator; *Ubi*, constitutive maize ubiquitin-1 promoter; *TP*, transit peptide from pea Rubisco small subunit (rbcS); CrtB, phytoene synthase gene from *E. uredovora*; *Bar*, bialaphos resistance gene; *NOS*, *Agrobacterium tumefaciens* nopaline synthase (*NOS*) terminator.

carries the bacterial phytoene synthase gene under the control of *1Dx5* promoter, which had been used in previous research and was stored in our laboratory.[9] A sequence encoding a transit peptide from the pea Rubisco small subunit (*rbcS*) was fused to the *1Dx5* promoter in the plasmid pLRPT-CrtB. Plasmid pAHC20 carrying a selectable *bar* gene, which confers resistance to the herbicide phosphinothricin, was also used.

Wheat Transformation and Regeneration. Transgenic wheat lines were generated according to the bombardment method as reported by Sparks et al.[38] Wheat immature scutella (14 days after pollination, DAP) from the Bobwhite cultivar were transformed with the plasmids of pLRPT-HYD-RNAi/pLRPT-CrtB/pAHC20 at a 2:2:1 molar ratio, pLRPT-HYD-RNAi/pAHC20 at a 3:1 molar ratio, and pLRPT-CrtB/pAHC20 at a 3:1 molar ratio. The regenerated plants were screened using the herbicide phosphinotricin (3 mg L^{-1}). The surviving plants were transferred to soil and grown to maturity under growth chamber conditions (22/16 °C day/night, 16/8 h light/dark cycle, and 300 μmol m^{-2} s^{-1} photosynthetic photon flux density). The regenerated plants were confirmed by PCR amplification using gene-specific primers, and then the products were sequenced (Supporting Information Tables S1 and S2). The immature seed from PCR-positive transgenic plants was also confirmed by Western blotting. Then, the transgenic plants were self-pollinated, and the nonsegregant lines were selected for analyses of the carotenoid composition and carotenoid biosynthetic gene expression levels.

Western Blotting. The bacterial expression vectors pET-32a and pET-28 were used to express CrtB and HYD proteins in *Escherichia coli*, respectively. The primers were designed to amplify only the coding regions (*CrtB* and *HYD*) (Supporting Information Table S1). The construction of the expression vector pET-32a-CrtB and pET-28-HYD and the expression and purification of the recombinant proteins were performed as described by Miao et al.[39] The CrtB and HYD proteins were purified from a heterologous system. Polyclonal antibodies against the CrtB and HYD proteins were generated by immunizing Japanese white rabbits with CrtB and HYD proteins.

Total wheat seed proteins were extracted from the transgenic and control lines according to the method of He et al.[40] Western blotting was performed following the method of Ma et al.[41] An antibody against the plant housekeeping protein actin was used to normalize for equal amounts of proteins and to calculate the relative loading volume for each sample. The amounts of CrtB and HYD proteins were determined by a densitometry analysis of the Western blotting results in three biological replicates using Bio-Rad Quantity One 1-D software version 4.6.2 (Bio-Rad, Hercules, CA, USA).

Analysis of Carotenoid Composition by HPLC. Carotenoid extracts from mature grain were prepared according to the method of Rodríguez-Suárez et al. with modifications.[42] Seed samples were ground into fine powder and placed in a 50 mL volumetric centrifuge tube. Pigments were extracted with 4 mL of acetone (containing 0.1% BHT) during 2 min by vortexing, following sonication for 1 min. The mixture was centrifuged at 5000 rpm for 5 min at 4 °C, and the extracted carotenoids in the acetone phase were collected. The extraction operation was repeated three times, and the acetone fractions were pooled. The solvent was evaporated under a nitrogen stream, and the pigments were dissolved in 0.3 mL of methyl *tert*-butyl ether containing 0.01% (w/v) BHT. After centrifuging at 12000 rpm at 4 °C for 30 min, the sample was filtered through a 0.22 μm filter before high-performance liquid chromatography (HPLC) analysis. For quantitative purposes, β-apo-8′-carotenal was added to each sample as an internal standard prior to extraction (10 μg g^{-1} of freeze-dried sample). Analyses were performed in quadruplicate. All of the operations were performed under dimmed light to prevent the isomerization and photodegradation of carotenoids.

The sample was injected into the HPLC system. The HPLC system included a model 2996 photodiode array detection (DAD) system, a 1525 solvent delivery system, and a Breeze2 Chromatography Manager (Waters Corp., Milford, MA, USA). The carotenoids were separated on a YMC C30 carotenoid column (150 × 4.6 mm, packing 3 μm) (Wilmington, NC, USA) at 25 °C. All of the eluate was under 200−700 nm monitoring. Solvent A was acetonitrile/methanol (3:1, v/v), containing 0.01% BHT and 0.05% triethylamine (TEA, Sigma, Shanghai, China), and solvent B was 100% MTBE, containing 0.01% BHT. The parameters of mobile phase gradient were programmed as follows: 0−10 min, A/B (95:5); 10−19 min, A/B (86:14); 19−29 min, A/B (75:25); 29−54 min, A/B (50:50); 54−66 min, A/B (26:74), and back to the initial condition for re-equilibration. All of the solvents were of HPLC grade (J. T. Baker, Phillipsburg, NJ, USA). Carotenoid standards for lutein, zeaxanthin, β-cryptoxanthin, α-carotene, *trans*-β-carotene, β-apo-8′-carotenal, and *trans*-lycopene calibration were purchased from Sigma-Aldrich (Shanghai, China); 9-*cis*-β-carotene was purchased from Carotenature (Lupsingen, Switzerland) (Supporting Information Figure S1). These standards and the β-apo-8′-carotenal internal standard were used to generate standard calibration curves.[43−46]

Quantitative PCR (qPCR) Analysis. The qPCR analysis was performed with a Real-Time PCR Detection System (CFX Connect Optics Module, Bio-Rad, Hercules, CA, USA) using SuperReal PreMix Plus (SYBR Green) (FP205, Tiangen, Beijing, China). The amplification was performed with the following program: 40 cycles of 95 °C for 15 s and 60 °C for 60 s. Fluorescence was acquired at 60 °C. The specificity of the unique amplification product was determined by a melt curve analysis from 55 to 99 °C. The data were analyzed using Lightcycler software version 4 and were normalized to the expression of the wheat *β-actin* gene due to its relatively constitutive expression level throughout the wheat developmental process. The quality of the cDNA templates and PCR amplifications was verified by an analysis of negative controls without template and no-reverse transcription for each primer pair. A dissociation curve analysis was performed following qPCR, and a single peak was observed for each primer pair. Some of the qPCR products were separated on agarose gels, and single bands at expected sizes were detected.

RESULTS

Different Metabolic Strategies Generate Different Effects with Distinct Carotenoid Profiles. The immature scutella from the Bobwhite cultivar were transformed with three constructs containing unlinked transgenes. The pLRPT-HYD-RNAi and pLRPT-CrtB were controlled by the endosperm-specific *1Dx5* promoter. The selectable marker bialaphos resistance gene (*bar*) gene was expressed constitutively (Figure 2). The hypothesis is that the successful transformations would

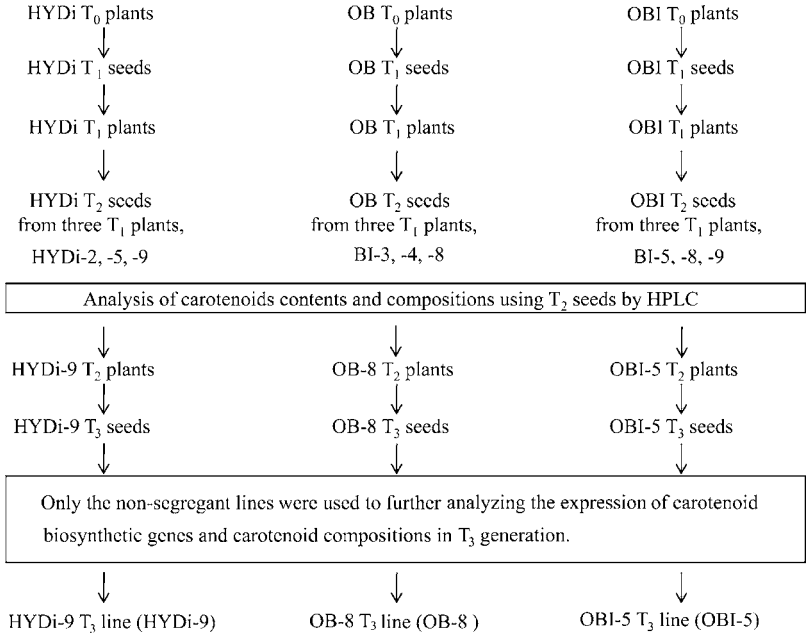

Figure 3. Propagation of transgenic wheat and selection of nonsegregant lines. OB is the line with expression of *CrtB*; HYDi is the line with silencing of *HYD*; OBI is the line with expression of *CrtB* and silencing of *HYD*.

result in a yellower kernel appearance in transgenic lines. The differences in the external coloration of the grains were confirmed by measuring the color index by Chroma Meter.[47] Colorimetric results of grains demonstrated that transgenic lines had higher values of b^* (yellowness), which showed significant correlation with lutein and β-carotene content, in contrast to two controls (Supporting Information Figure S2). The differences of the color index indicate that different transgenic lines accumulated different levels of carotenoid in grains. The most intense red/yellow grains from the positive lines were chosen to generate the transgenic progeny by self-pollination for further analyses (Figure 3).

To examine carotenoid accumulation in the seeds of different transgenic lines, a HPLC analysis was conducted to compare the profiles of carotenoid content and composition in wheat seeds. There were no significant differences in carotenoid composition between the wild type and vector control (VC). The carotenoid profiles of the mature seeds from three T_2 transgenic lines were different from those of the wild-type controls. Several novel carotenes were detected in the transgenic wheat lines including lycopene, β-cryptoxanthin, α-carotene, and phytoene (Supporting Information Table S3). Meanwhile, the HPLC results revealed that, consistent with the silencing of the *HYD* gene, the levels of β-carotene were significantly increased in seeds from the *HYD* RNAi (HYDi) lines compared with that of the VC lines.

Detailed HPLC analyses were conducted to determine the carotenoid content and composition of seeds from different transgenic lines of the T_3 generation (Figure 4). Total carotenoid and provitamin A contents in three T_3 transgenic lines were significantly improved, and the content also showed the difference between the same generation from the same T_2 transgenic lines (Figure 5A). The total carotenoid content increased to 3.7 μg g^{-1} dry weight (DW) in the HYDi-9 plants, to 7.35 μg g^{-1} DW in the OB-8 plants, and to 9.3 μg g^{-1} DW in the OBI-5 plants compared with the wild type (1.22 μg g^{-1} DW). Furthermore, the provitamin A content significantly increased in all three of the transgenic wheat lines, ranging from 2.24 μg g^{-1} DW (HYDi) to 5.55 μg g^{-1} DW (OBI). The β-carotene contents of the HYDi-9, OB-8, and OBI-5 lines significantly increased by 10.5-, 14.6-, and 31-fold, respectively (Figure 5B). Thus, the significantly increased carotenoid and provitamin A contents in the transgenic lines were due primarily to the increased β-carotene levels.

The different transgenic lines showed diverse changes under the effects of different transgenes. The content of β-carotene in the transgenic line HYDi-9 increased 10.5-fold (1.76 μg g^{-1} DW) by silencing *HYD* compared with the wild-type (0.167 μg g^{-1} DW), accompanied by decreased lutein and zeaxanthin contents. The overexpression of *CrtB* in the wheat endosperm, introducing more flux into the carotenoid biosynthetic pathway, increased the total carotenoid content, particularly the content of lutein and β-carotene. The combination of overexpressing *CrtB* and silencing *HYD* resulted in the highest accumulation of β-carotene, with levels up to 31-fold (5.06 μg g^{-1} DW) higher than that of the wild type. The contents of lutein and zeaxanthin in the OBI lines were lower than those in the OB lines but higher than those in the HYDi lines. Notably, lycopene appeared and accumulated in all three of the transgenic lines. By contrast, the first committed carotenoid product, phytoene, appeared only in the transgenic lines that expressed *CrtB*. Different geometric isomers of carotenoid were also detected in the three classes of transgenic lines (Figure 4). 9-*cis*-β-carotene was the major component of β-carotene isomers. In addition, *trans*-lycopene and *cis*-lycopene were also detected in the three transgenic lines. An undefined carotenoid appeared in the carotenoid profiles of three transgenic lines, the absorbance spectrum of which was similar to that of a lycopene isomer (Figure 4). The phenotype of the transgenic lines was stably inherited (Supporting Information Table S4).

Profiles of Endogenous Carotenoid Biosynthetic Genes in Different Transgenic Wheat Lines. Expression of both transgenes, *CrtB* and *HYD*, was determined by qRT-PCR in the endosperms of transgenic and control wheat lines (Table 1). As anticipated, transcript levels of *CrtB* and *HYD*

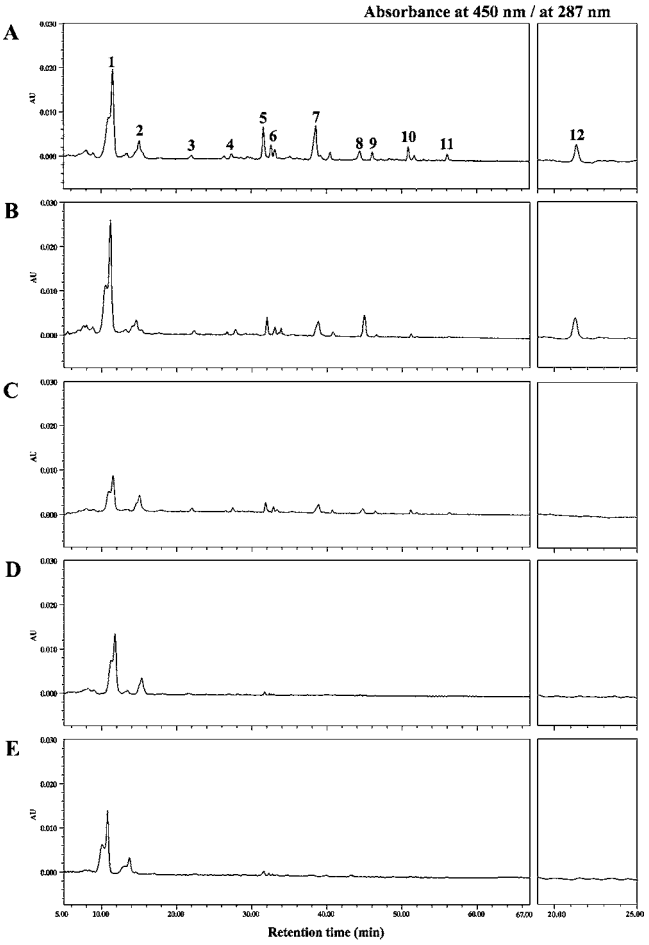

Figure 4. HPLC characterization of carotenoids that were extracted from the grains of T_3 transgenic and control wheat: (A) OBI-5; (B) OB-8; (C) HYDi-9; (D) VC-10 (transgenic vector control); (E) Bobwhite (wild-type). Peaks: 1, lutein; 2, zeaxanthin; 3, β-cryptoxanthin; 4, α-carotene; 5, *trans*-β-carotene; 6, 9-*cis*-β-carotene; 7, undefined carotene; 8,9, *cis*-lycopene; 10, *trans*-lycopene; 11, isomer of lycopene; 12, phytoene.

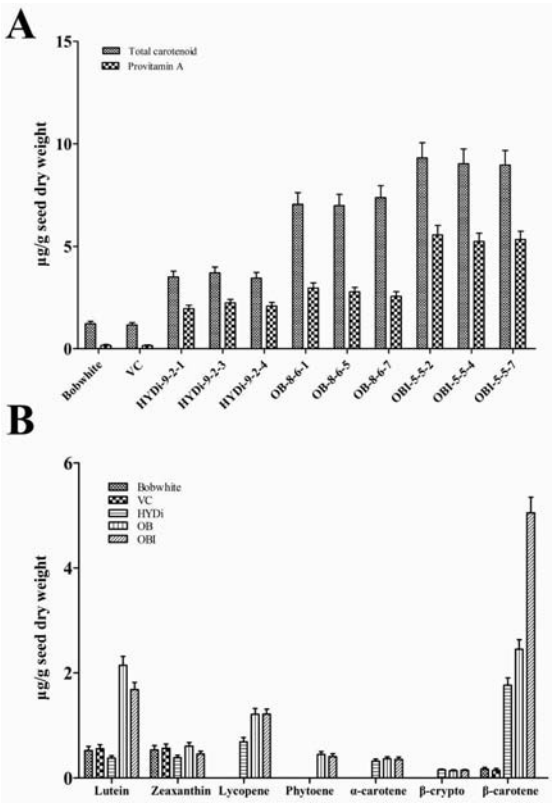

Figure 5. Carotenoid and provitamin A contents in the grains from transgenic wheat. (A) Total carotenoid and provitamin A contents in the wheat whole grains of T_3 transgenic lines (OBI-5, HYDi-9, and OB-8) and their untransformed control, Bobwhite. The amount of total carotenoid is equal to the sum of all of the carotenoids, and the provitamin A carotenoids were calculated as the sum of α-carotene, β-cryptoxanthin, and β-carotene contents in the extracted samples. (B) Carotenoid compositions in the wheat grains from transgenic and control lines in the T_3 generation. The average of each carotenoid species was determined from five individual plant heads per line. The data are presented as the means ± SD.

were detected only in the corresponding transgenic lines. Then, the expression of CrtB and HYD proteins in the transgenic and control lines was also analyzed by Western blot. The levels of CrtB and HYD proteins in the transgenic and control lines are shown in Figure 6, in which a clear band of CrtB with expected molecular weight was detected only in the transgenic OB and OBI lines. HYD expression was detected in the transgenic, wild-type, and VC lines. However, significant differences were observed between the transgenic and control lines, and all of the transgenic lines exhibited decreased levels of HYD in comparison with wild type, which meant that the translational level of HYD was down-regulated by RNAi.

To further understand changes of carotenoid content in the transgenic wheat lines, the expression of endogenous carotenoid biosynthetic genes was analyzed to determine whether they were regulated in response to transgene expressing. In the present study, the *1Dx5* endosperm-specific promoter was employed to avoid influencing the expression levels in other tissues. As shown in Figure 6, the expression of *CrtB* was only detected in the OB and OBI lines and most of the lines showed similar expression, indicating the stability driven by the *1Dx5* promoter. To further examine the effect of the transgenes on the expression of carotenogenic genes in the transgenic plants, expression of the endogenous carotenogenic gene was measured by qRT-PCR. As shown in Figure 7, the expression of the endogenous carotenogenic genes was different in the transgenic, VC, and wild-type lines, whereas that in the VC and wild-type lines showed no difference in the wheat endosperm. In the transgenic line OB with the exogenous gene *CrtB*, the expression levels of Phytoene desaturase (*PDS*), ζ-carotene desaturase (*ZDS*), *LCYE*, and *LCYB* were up-regulated, whereas in the HYDi and OBI lines, *PSY* was up-regulated. Because of the down-regulation of *HYD* in the transgenic line HYDi, the transcript levels of *PDS*, *LCYE*, and *LCYB* showed the same tendencies and presented greater changes, except for *ZDS* expression. The combination of overexpressing *CrtB* and silencing *HYD* efficiently improved provitamin A levels by increasing the β-carotene content in the transgenic line OBI. Thus, *PDS*, *ZDS*, *LCYE*, and *LCYB* expression levels had superimposed effects accompanied by the highest expression levels in the three classes of transgenic lines.

DISCUSSION

Vitamin A deficiency is a global health problem and accounts for increased childhood mortality and disease.[7,48−50] Due to the widespread effects of vitamin A deficiency and effective benefits of carotenoid, there are attempts to improve carotenoid content

Table 1. Transgene Expression Level and Carotenoid Content in Transgenic Lines[a]

transgenic line (T_3 generation)	relative transcript levels[b] *crtB*	relative transcript levels[b] *HYDi*	total carotenoids[c] ($\mu g\ g^{-1}$ dry seed wt)	provitamin A[c] ($\mu g\ g^{-1}$ dry seed wt)
Bobwhite	0	0	1.22 ± 0.12	0.16 ± 0.04
OB-8	0.124 ± 0.005	0	7.37 ± 0.59	2.56 ± 0.23
HYDi-9	0	0.046 ± 0.003	3.70 ± 0.29	2.25 ± 0.17
OBI-5	0.098 ± 0.004	0.062 ± 0.004	9.31 ± 0.74	5.55 ± 0.46

[a]The data represent mean values ± SD and are derived from at least three independent plants per line. [b]Relative transpcript levels (normalized with respect to the *β-actin* transcript) were determined by qRT-PCR. [c]Total carotenoids (sum of all carotenoid content measured) and provitamin A content (sum of *α*-carotene, *β*-cryptoxanthin, *β*-carotene) were determined by HPLC analysis.

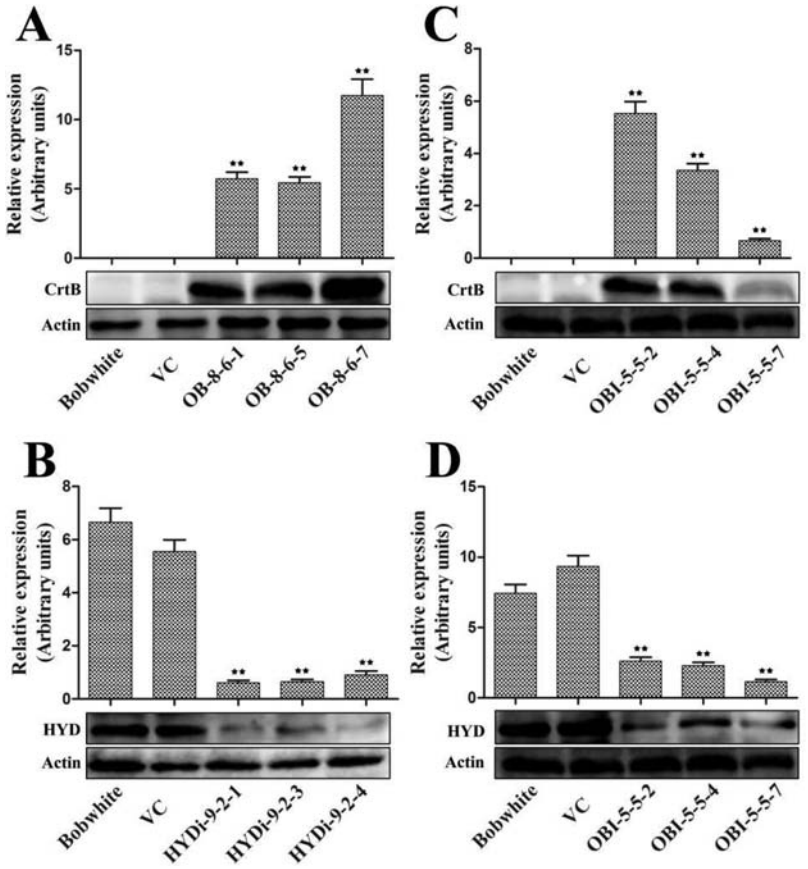

Figure 6. Levels of CrtB and HYD proteins in the endosperms from transgenic and control wheat lines as indicated by Western blotting: (A) CrtB proteins in the OB-8 and control lines; (B) HYD proteins in the HYDi-9 and control lines; (C) CrtB proteins in the OBI-5 and control lines; (D) HYD proteins in the OBI-5 and control lines. The double asterisk indicates significant differences between the control Bobwhite and transgenic lines at a $P = 0.01$ probability level. The relative amounts of the CrtB and HYD proteins in the transgenic lines were densitometrically quantified with respect to the nontransformed control line (cv. Bobwhite).

in staple crops by metabolic engineering, especially improving *β*-carotene content.[27,28] In our study, improving the content of *β*-carotene was the first goal. A combination of "push strategy" and "block strategy" holds good prospect to further increase of the provitamin A content in wheat.

Endosperm-Specific Expression of CrtB Introduces More Substrate Flux into Carotenoid Biosynthetic Pathway. In this study, our results demonstrate that *CrtB* expression in the wheat endosperm significantly increased the carotenoid content, suggesting that the expression of *CrtB* can provide an additional carotenoid flux into carotenoid biosynthesis. The results of Western blotting detected only the expression of *CrtB* in transgenic lines (Figure 6), which was also consolidated this conclusion. The total carotenoid and provitamin A contents were significant improved, up to 6.5-fold (7.37 $\mu g\ g^{-1}$ DW) and 14.6-fold (2.45 $\mu g\ g^{-1}$ DW) in transgenic lines OB as compared with wild type (Figure 5). Although CrtB expression varied, the carotenoid contents in the different transgenic lines were not significantly different, suggesting that the enzyme activity of CrtB was sufficient for product synthesis. This may be due to the limitation of isoprenoid precursors in the carotenoid pathway.[28,30] Meanwhile, it is interesting to note that when the *CrtB* gene was overexpressed in a low-carotenoid wheat phenotype, of which the kernel was light yellow, the accumulations of total carotenoid and *β*-carotene were less than those in the present study with a yellow kernel.[9] This phenomenon might be explained by the observation that storage capacity also appears to be responsible for the enhanced accumulation of carotenoids, such as *high-pigment* (*hp*) mutants of tomato

J. Agric. Food Chem. 2015, 63, 9083−9092

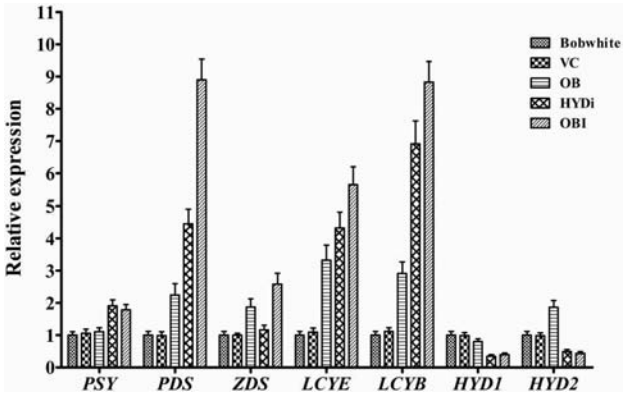

Figure 7. Expression levels of the endogenous carotenoid biosynthetic genes in the endosperm from transgenic and control wheat lines. The gene expression levels were measured by quantitative reverse transcription PCR and are determined relative to the transcript levels of the constitutively expressed *β-actin* gene in the same samples. The expression levels of these genes for the transformed lines are given as the expression levels relative to the values for the nontransformed control line Bobwhite. The qRT-PCR results for each gene were generated from three biological replicates with three technical replicates each, and the data are shown as the means ± SD.

accumulated more carotenoid due to the increased plastid volume per cell.[51,52] This result indicates that storage capacity for carotenoid accumulation is a potential target to improve carotenoid content in metabolic engineering.[53] In wheat grain, lutein existed in whole grains, not just in the seed endosperm. Experimental evidence from Qin showed that the content of zeaxanthin and lutein in mature wheat embryos was very low, and other compounds were hardly detected.[35] This implies that most of the carotenoid content is stored in wheat endosperm, including β-carotene. In addition, the up-regulation of carotenogenic gene expression levels explains the lutein and β-carotene increase, and the phytoene accumulation suggests that desaturation enzymes are insufficient in carotenoid biosynthesis, indicating that the carotenoid pathway can be further manipulated at the levels of PDS and ZDS in these transgenic lines.

HYD enzymes play a significant role in the downstream carotenoid pathway, which influences the accumulation of provitamin A in plants. In *Arabidopsis chy1chy2lut2* mutants, β-carotene is the main carotenoid in leaves due to the loss of hydroxylase function.[54] In potato carotenoid metabolic engineering, the accumulation of β-carotene was enhanced by silencing of β-carotene hydroxylases (*CHY1* and *CHY2*) in potato tuber.[26] The transcriptional and translational levels of carotene hydroxylase were simultaneously down-regulated by *HYD* silencing, accompanied by the β-carotene content increasing 10-fold and the lutein and zeaxanthin decreasing in the HYDi-9 transgenic line compared with that of the wild type, suggesting that silencing of *HYD* prevented a part of β-carotene from hydroxylating into lutein or zeaxanthin. Furthermore, although *LCYE* and *LCYB* expression levels were up-regulated in HYDi-9, lycopene accumulation revealed insufficient cyclases in carotene biosynthesis. However, lycopene was not detected in wild-type, suggesting that the activity of cyclases is enough for carotene biosynthesis. One of the possible reasons for this observed phenotype could be that the down-regulation of HYD might lead to a feedback regulation to up-regulate *PSY* expression and add more flux into the pathway. This phenomenon was also reported in other studies, which showed that tuber-specific silencing of *LCYE* and *HYD* in potato resulted in the up-regulation of *PSY*.[26,55] It also suggested that the feedback induction of endogeneous genes was correlated with increased levels of carotenoids or intermediates.[56] In the transgenic line OB-8, the additional carotenoid flux that was added into metabolic flux in the pathway coincided with the up-regulation of genes encoding downstream enzymes, whereas HYD down-regulation led to β-carotene accumulation accompanied by the up-regulation of upstream genes. These results suggest that carotenoid biosynthesis is a complicated system and that metabolic feedback regulation generally exists in the carotenoid biosynthetic pathway.

Combination of "Push Strategy" and "Block Strategy" Significantly Enhances Provitamin A Content in Wheat Endosperm. From the results of transgenic line HYDi-9, β-carotene content was significantly improved compared with wild type. However, wheat grains have a very low carotenoid content, which does not have sufficient flux to accumulate abundant specific products by blocking downstream genes; therefore, the possibility thus exists to further improve β-carotene content by adding upstream flux. In our transgenic line OB-8, the carotenoid content significantly increased, indicating that the additional flux could be introduced by *CrtB* expression. The highest levels of β-carotene accumulation to date were obtained using a combination of "push" and "block" strategies in wheat. Several carotenoid isomers were not calculated into the total carotenoid content; thus, the actual total carotenoid content was even higher than the calculated content. The most famous and successful exploitation case of carotenoid metabolic engineering is "Golden Rice", which can supply sufficient provitamin A through the daily diet. The U.S. recommended dietary allowance (RDA) for 1−3-year-old children is 300 μg of vitamin A.[57] Transgenic staple crops such as maize and potato also reached this RDA standard.[28,58] Although the best wheat transgenic lines were not yet up to the standard, phytoene and lycopene accumulation also showed that there still existed huge potentials for more β-carotene accumulation. Although desaturation and cyclase gene expression levels were highest in the OBI transgenic lines, phytoene and lycopene accumulation showed that changing the expression levels of other carotenogenic genes would shift the rate-limiting action to another step in the wheat carotenoid pathway. These results also showed that integration of another gene, the carotene desaturase gene (*CrtI*), could further improve the content of β-carotene and other carotenoids by increasing the desaturation activity in wheat carotenoid biosynthetic pathway. For instance, in the transgenic wheat with introduced *CrtB* and *CrtI*, the accumulation of β-carotene and total carotenoid was more abundant than sole expression of *CrtB* in transgenic wheat.[9]

In the transgenic line OBI-5, the contents of lutein and zeaxanthin showed a decrease compared with the OB-8 lines, which suggests that the HYDi could exert the effect simultaneously on both β,ε-carotenoid and β,β-carotenoid to accumulate β-carotene. Meanwhile, the higher accumulation of lutein than zeaxanthin in the OB and OBI transgenic lines suggests that the transgenic lines also exhibited a preference for carotenoid metabolic flux toward the β,ε-carotene branch when additional flux was added into the pathway, similar to the wild-type accumulation of lutein.

CrtB and HYDi Regulate β-Carotene Accumulation in Wheat Endosperm through Different Mechanisms. In the present study, overexpression of *CrtB* and silencing of *HYD*

DOI: 10.1021/acs.jafc.5b04279
J. Agric. Food Chem. 2015, 63, 9083−9092

regulate different endogenous carotenoid biosynthesis genes with different variation, suggesting the accumulation of β-carotene through different mechanisms. In OB lines, the expressions of *PDS*, *ZDS*, *LCYE*, *LCYB*, and *HYD2* were up-regulated, and only *PSY* and *HYD1* were unaffected (Figure 7). In contrast, in HYDi lines, the expression of *PSY* was up-regulated, but *ZDS* was unaffected. In both transgenic lines, β-carotene and total carotenoid were enriched by the transgenes. In transgenic line OB expressing *CrtB*, the greater upstream flux introduced into the pathway forward the corresponding downstream gene up-regulation. In contrast, in the HYDi line silencing *HYD*, the accumulation of β-carotene resulted in feedback regulation accompanied by the up-regulation of upstream genes. In addition, the up-regulation levels in HYDi lines were higher than in OB lines. These results suggest that the flux added into OB and HYDi lines may be through different mechanisms, in one case due to the additional flux introduced and in another through the feedback regulation to up-regulate *PSY*.

The presented results indicate that the block strategy to silence *HYD* in the wheat carotenoid pathway seems to be feasible to accumulate β-carotene content specifically. Indeed, the combination of these two strategies is effective in accumulating β-carotene in the wheat endosperm. Our results show that this strategy leads to the highest accumulation of β-carotene in the wheat endosperm; the results also demonstrate the feasibility of utilizing this strategy in carotenoid metabolic engineering and reveal the different mechanisms of β-carotene accumulation.

Table 1. Summary of Reported Findings from Previous in Vivo Investigations into the Effect of Gel Strength on Volatile Release

study system	ref	volatile release with chewing	perception	conclusion
whey protein gels 4−11% APCI-MS	16	no difference in nose-space concentrations as gel strength increased for diacetyl or ethyl butanoate	decrease in time intensity flavor perception as gel strength increased	differences in perceived flavor were psychophysical rather than based on differences in in vivo release
HPMC gels 0−2% APCI-MS	17	no differences in in-nose release of ethyl butanoate	decrease in perceived strawberry flavor with greater viscosity	cross-modal perceptual or receptor level influence of viscosity on perceived flavor, i.e., not physicochemical
gelatin gels 2−10% APCI-MS	14	ethyl hexanoate, AUC ↓ with ↑ firmness, increase T_{max}	no sensory data reported	decrease in release with increased gel thickness
pectin 1.5−2.0% PTR-MS	36	some differences in release depending on the mastication rates	no sensory data reported	
pectin 0.75−1% PTR-MS	15	increase in AUC, I_{max}, or T_{max} for range of volatiles with increased rigidity	decrease in perceived strawberry odor and flavor	in contrast to static headspace data, where release ↓ with increased pectin
gelatin 1.3−1.8% PTR-MS	15	no increase in AUC, I_{max} or T_{max} for range of volatiles	decrease in perceived strawberry odor and flavor	in contrast to static headspace data, where release ↓ with increased gelatin
whey protein gels 4−10%	12, 13	no differences in total AUC or I_{max} for ethyl butanoate, but increased preswallow T_{max}; significantly greater release from 4% gel in the first 10 s of chewing	lower sensory ratings for harder gels	faster volatile release from softer gels, however total release similar in hard and soft gels
casein gels of different hardness	37	release of a range of volatiles was greater and faster from harder gels in vivo; no differences in the in vitro model systems.	no sensory information measured	key parameter for release differences was the interaction of the gels of different hardness with the human masticatory apparatus
gelatin 5−15% PTR-MS	18	few differences in release patterns between 5 and 15% gelatin with chewing; large differences with melting (nonchewing) protocol	mean temporal dominance of sensation data increased with gel strength	decrease in release of ethyl hexanoate with increased gel strength; timing of release different with the in mouth melting
cheese model system APCI-MS	38	ethyl propanoate release, ↑ firmness, ↑ fat 2-nonanone release ≠ firmness 2-nonanone ↓ fat		despite large differences in individual release, overall observations valid

grade aroma compounds were donated by Givaudan (Baulkam Hills, Australia), namely, a homologous series of methyl ketones (2-butanone, 2-pentanone, 2-heptanone, 2-octanone, and 2-nonanone), ethyl butanoate, and ethyl hexanoate (Table 2). A stock solution of the volatile mix was prepared at 5% (v/v) of each compound in ethanol. Sodium chloride was purchased from Sigma-Aldrich (USP grade; Castle Hill, Australia). A soy-based stable lipid emulsion, IVELIP (20% fat), was supplied by Baxter Health (Toongabbie, Australia).

Gel Preparation. The stock solution of volatiles was used for aromatization of the gels. Most of the volatiles are present in blue cheese flavor and have been used previously by our group.[4,11,24] Characteristic odor qualities and fat solubility ($K_{o/w}$) are listed in Table 2. Sodium chloride was added to all gels at a concentration of 0.8% w/w sodium. This concentration was chosen to represent the average salt present in cheese (NUTTAB 2010 food nutrient database, Food Standards Australia New Zealand). It should be noted that the IVELIP was very low in sodium (0.03% w/v). Deionized (reverse osmosis) water was used to prepare the gels. Gels of increasing rigidity were made by adding agar according to a logarithmic concentration series: 1.0, 1.7, 2.9, and 5.0% (w/v). The total amount of fat in gels (2, 5, and 10% w/v) was adjusted by addition of appropriate amounts IVELIP. Two drops of red food coloring were added to allow easy visual inspection of the homogeneity of mixing.

Dry ingredients and fat emulsion (if used) were weighed into Schott bottles (500 mL) placed in a boiling water bath for 30 min with vigorous shaking at 5 min intervals. Hot samples were poured into graduated cylindrical screw-top plastic containers (~120 mL volume) to the 100 mL mark. After cooling to ~50 °C, a volume of the volatile mix stock solution (50 μL; 5% each compound) was quickly added under the surface of the liquid to obtain a final concentration of ~25 ppm (Table 2). Containers were immediately sealed and agitated to ensure homogeneous mixing and then placed in an ice bath to set. Samples were stored at 4 °C overnight to fully set. Prior to evaluation, samples were unmolded, sliced into cylinders (19 mm radius × 15 mm thickness), and then cut into quarters of ~5 g (total sample weight ~ 20 g).

Gel Rheology. Agar gel cylinders (14 mm × 14 mm height) were prepared for large deformation analysis. Dodecane (99%, Sigma-Aldrich) was used as lubricant on the interactive surfaces between the cylinder and the instrument. Compression tests were performed in duplicate using an Instron 5564 instrument (Instron Pty. Ltd., Melbourne, Australia) loaded with a 500N cell and a 35 mm aluminum cylinder probe at a crosshead speed of 60 mm/min. The sample was compressed to 50% of its original height (7 mm). Once the set height was reached, the probe was automatically lifted back to the starting position. The true stress (σ_e) and true strain (ε_e) of the first compression were calculated using the following equations: $\sigma_e = FH/(A_0H_0)$ and $\varepsilon_e = \ln(H/H_0)$, where F is the force measured during compression, A_0 is the initial cross-sectional area of the sample, H_0 is the initial sample height, and H is the deformed sample height. Young's modulus was calculated as $E = \sigma_e/\varepsilon_e$, where E is a measure of the rigidity or brittleness of a gel. E was determined in duplicate for the pure agar gels series and also for the 5% agar gels with the addition of different fat levels (0, 2, 5, and 10% fat).

Time−Intensity Sensory Evaluation and Oral Breakdown Studies. Approval to conduct the sensory studies with human subjects was obtained from the CSIRO low risk ethics committee (LR06-2011). A discrete interval time−intensity method was used to measure dynamic sensory perception anchored by chew number, similar to a progressive profiling method.[25] This method was developed to enable comparisons between measurements of sensory perception with aroma release data at the same point during mastication.

An experienced trained sensory panel (n = 10) participated in two training sessions prior to evaluation. Assessors were familiarized with the samples, and the assessment technique was standardized. The sensory characteristics of the gels and changes over the course of the eating event were defined by a consensus descriptive vocabulary that included five attributes: *resistance to chewing* (force required to bite down on the sample), *particle size* (perceived particle size assessed by moving the sample between the tongue and the palate), *blue cheese flavor* (the dominant integrated flavor percept in the volatile mix), *overall flavor*

Table 2. Volatile Compounds Spiked into the Agar Gels, Corresponding Ions (m/z) Measured by the PTR-MS, Lipophilicity ($K_{o/w}$), Concentration in Gel, and Aroma Character

aroma compound	ion m/z ($M + H^+$)	$K_{o/w}$[a]	concn in gel (mg/kg)	concn in gel (mM)	aroma perception[b]
2-butanone	73	1.9	20.02	0.28	chemical, slight fruity green
2-pentanone	87	8.1	20.02	0.23	sweet, fruity, banana-like
2-heptanone	115	95.5	20.32	0.18	fruity, spicy, banana
2-octanone	129	234.4	20.32	0.19	dairy, waxy, cheese, woody, mushroom
2-nonanone	143	1380	20.42	0.17	cheesy, green, fruity, dairy, dirty, buttery
ethyl butanoate	117	70.8	21.75	0.18	fruity, sweet, tutti-frutti
ethyl hexanoate	145	676	21.67	0.15	fruity, pineapple, banana, winey

[a] $K_{o/w}$ values were obtained from the ChemSpider database (http://www.chemspider.com/), Royal Society of Chemistry. [b] From ref 39.

intensity (the sum of all flavor sensations in the mouth, including taste and aroma), and *salty taste* (the saltiness intensity defined by reference sodium chloride solutions). The panel proceeded to the evaluation of the attributes at four time points, 2, 5, and 10 chews, and finally when subjects naturally wanted to swallow. Subjects were instructed to spit out the masticated samples into a provided spittoon.

Samples were presented in triplicate in randomized order in 2 h sessions over two consecutive days. The perceived intensity of attributes was measured using 100 mm unstructured line scales scale anchored at 5 and 95%. For a given day, assessors evaluated only three attributes to minimize sensory fatigue (resistance to chewing/particle size/overall flavor intensity or resistance to chewing/blue cheese flavor/salty taste). Data were collected using Compusense *five* (release 4.6, Guelph, ON, Canada). Hence, a total of 30 replicate assessments were available for each sensory attribute (10 assessors × 3) per sample at each time point.

On separate days, panelists evaluated the oral processing parameters. Evaluation was conducted in triplicate, and samples were presented in a randomized order. The number of chews to swallow (NCS) as well as the time to reach the need to swallow (TTS) measured with a stopwatch was recorded. Subjects were instructed to continue chewing each sample until there was no further reduction in the perceived size of particles (size of the pieces sensed with the tongue and palate). This was measured as the number of chews to fine particles (NCF) and time to form fine particles (TTF). A total of 32 replicate assessments (16 subjects × 2) were used in statistical analyses.

In Vivo Aroma Release Using Proton Transfer Reaction Mass Spectrometry (PTR-MS). Aroma release during mastication of agar gels was measured using human subjects ($n = 6$) interfaced with a high-sensitivity quadrupole PTR-MS (Ionicon Analytik GmbH, Innsbruck, Austria) using a controlled breathing and chewing protocol.[5] The selected subjects had participated in the descriptive profiling of the gels and had previous experience performing in vivo PTR-MS experiments. During initial piloting experiments, the absence of interfering ions from the pure lipid emulsion was confirmed (Table 2).

Subjects introduced one 5 g cube of gel sample into their mouth after five background breaths. After sample introduction (on breath 6), subjects were required to chew once only during each inhalation for the first five breath cycles for maximum resolution in the early stages of mastication. For the subsequent breath cycles (11−25) subjects were trained to chew twice during the in-breath and twice during the out-breath (4 chews per breath cycle); full breath cycle duration was 3 s. Previous testing determined that this was a sufficient number of chews to process the hardest gel (5% agar) to the point of swallow for all subjects. Regardless of the gel hardness and swallow time, subjects were required to continue chewing each sample for the full 25 breath cycles (65 chews) to obtain a complete data set for each sample. Each subject assessed samples in quadruplicate (i.e., 6 samples × 6 subjects × 4 replicates × 7 ions = 1008 release data). Hence, for each sample there were a total of 24 replicates (6 panelists × 4 replicates).

Volatiles were measured by the PTR-MS using multiple ion detection mode. Subjects breathed through a soft plastic disposable cannula, and the exhaled breath was drawn into the reaction chamber of the PTR-MS.[4] The parameters of the drift tube were as follows: drift voltage, 550 V; pressure, 2.2 mbar; temperature, 70 °C. Exhaled nostril breath was drawn through the inlet tubing at a rate of 400 mL min^{-1} and at a rate of 15 mL min^{-1} into the reaction chamber. Data were acquired at a rate of 2 Hz.

In Vitro Volatile Release. To help clarify the in vivo data, a simple in vitro system was developed using a commercial coffee grinder (Breville, Australia; model-BCG 300/A). Gas-tight inlet and outlet Luer-lock fittings were engineered into the grinder lid and connected directly to the inlet tube of PTR-MS via an automated solenoid switching relay. Agar gel samples, prepared identically as for in vivo studies, were sliced (∼20 g) into four equal portions of ∼5g and placed inside the grinder, between the four cutting blades. The headspace was allowed to equilibrate for 5 min before the solenoid valve was opened to sample the headspace concentrations. After 100 s of volatile measurement, the blender was turned on for 20 s to break the gel into fine particles and then turned off, and the PTR-MS analysis was continued for ∼100 s. Data from the first 30 s of turning on the blender were used in the statistical analyses. The same PTR-MS conditions, protocols, and gels were used as in vivo experiments. Four replicates were obtained for each sample.

Data Processing and Data Analysis. The quantitative ratings for each sensory attribute were collated and analyzed at each time point (after 2, 5, and 10 chews and final) using analysis of variance (ANOVA) with agar, fat (when relevant), and assessor as main fixed treatment factors and attributes as dependent variables.

PTR-MS concentration data files were imported into Excel (Microsoft) and processed in a manner similar to that described in previous work.[5] Data from the initial five breath cycles were removed from files before calculation of the area under the volatile release curve (AUC) and maximum intensity (I_{max}) using the replicate raw release curves for statistical analysis by multivariate analysis of variance (MANOVA) using the GenStat statistical software package (16th edition, VSN International, Hemel Hempstead, UK). Initial rate of flavor release was expressed as average AUC per chew for the first nine chews only. Fixed effects of agar strength, fat level, volatile ion, and subject on the release curve parameters were determined. Panel-averaged AUC per chew data were used to model volatile release curves for each volatile ion using the data modeling software IGOR-Pro (Wavemetrics Inc., Lake Oswego, OR, USA). Panel-averaged raw volatile release curves were imported into IGOR-PRO, and the curves were smoothed twice using a moving box average function (20 data points). A similar approach was used to analyze the in vitro release data. To assess agar effects, the raw data from the pure agar series were analyzed. For the effect of fat, data from 1 and 5% gar gels, with either no added fat (0%) or 10% fat, were analyzed.

RESULTS AND DISCUSSION

Gel Rheological Parameters. As expected, E increased with increasing gel strength, which was more or less linear at lower gels strengths (Table 3). A strong increase in the value of E in the transition from 2.9 to 5% agar was measured; the 5% gel was >3 times more rigid than the 2.9% agar gel. Similar nonlinear or exponential relationships between agar concentration and gel hardness were reported previously and possibly reflected a corresponding abrupt increase in the agarose network density.[22,26] The introduction of fat (2%) into the 5% agar gel

J. Agric. Food Chem. 2015, 63, 9093−9102

Table 3. Mean Values (n = 2) of Young's Modulus (E) ± Standard Deviation for Pure Agar Gels and 5% Agar Gels with Added Fat

pure agar series		5% agar with fat	
agar (%)	E (N m^{-2})	fat (%)	E (N m^{-2})
1.0	46 ± 6	0	635 ± 6
1.7	83 ± 2	2	175 ± 12
2.9	186 ± 5	5	156 ± 3
5.0	635 ± 6	10	145 ± 9

profoundly decreased the gel rigidity; a >3-fold reduction in E was measured. Fat droplets disrupt the agarose gel network and introduce stress points, which fail more easily. Further addition of fat resulted in smaller incremental decreases in E, indicating softer gels.

Effect of Agar and Fat on Oral Processing Parameters. Both the gel strength and fat content had highly significant effects on the oral processing parameters measured (Table 4). As expected, both the NCS and the TTS increased as the agar strength increased, signifying that a greater amount of oral processing was required to reduce the gel into particles and form a bolus ready for swallowing. The largest incremental increase in NCS and TTS was measured when the gel strength increased from 1.7 to 2.9% agar content, suggesting a significant change in the gel structure affecting oral processing. A smaller increase in the parameters was measured in the transition from 2.9 to 5% agar, somewhat different from the rheological data (E). It should be noted that we did not measure the peak force of each chew; this parameter may have corresponded more closely to the rheological data. Fat (10%) decreased both NCS and TTS for each agar gel strength; this is thought to be due to the softening effect of the oil as it disrupts the agar network and provides areas of structural weakness. The greatest impact of fat was in the 2.9% agar gel, indicated by the largest drop in E, resulting in less oral breakdown work (Table 3). The added fat would have also resulted in greater lubrication, a more cohesive bolus formation, and subsequent shorter swallowing times.[8] These data clearly show that the preswallow residence time in the oral cavity increased with increased agar gel strength because more chews were required before a bolus for swallowing could be produced.

Effect of Agar on Gel Sensory Properties. The perceived resistance to chewing of the gel was directly proportional to the agar gel strength (Figure 1, top row). Significant differences (P < 0.001) in gel resistance were measured at each time point during chewing for the pure agar gels, except at the point of swallow (final chew), where only small differences were measured. Perceived particle size was also proportional to the gel strength, with only small differences at final chew. The overall effect of agar on perceived saltiness was significant (P < 0.001). Perceived saltiness increased with chew number (up to 10 chews) for all samples. Agar concentration also affected saltiness perception with no difference measured between the 1 and 1.7% agar gels but large decreases in the transition to the 2.9 and 5% agar gels. Even after reduction of gels to fine particles, differences in perceived saltiness persisted, suggesting residual physical entrapment of sodium ions. Decreasing perceived saltiness with increasing gel strength has been described previously.[27] Although blue cheese flavor perception decreased with increased gel strength, the difference reached significance only at the final chew in the 5% agar gel. Overall flavor intensity decreased proportionally to gel strength. In summary, the sensory data clearly indicated that the flavor perception decreased as the agar gel strength increased, in agreement with most other studies (Table 1).

Effect of Fat on Gel Sensory Properties. Addition of 10% fat to 1 and 5% agar gels decreased the perceived resistance to chewing and perceived particle size compared to the pure agar gels (Figure 1, bottom row). This effect was mainly apparent for the harder 5% agar gels, probably because at 1% agar, the gel is already soft and the oil droplets easily fit within the agar structure, affecting only slightly the agar biopolymer network. Blue cheese flavor decreased with the addition of fat, especially in the softer 1% agar gel systems. Lipophilic volatiles would have partitioned into the fat droplets within the gels. In the softer gel, the relative effect of fat on blue cheese flavor suppression was greater than at 5%. At the higher agar concentration, structural impedance of diffusion within the agarose biopolymer was also expected to be a significant mechanism in release suppression.

Unexpectedly, the effect of fat on saltiness perception was not significant at any time point, in contrast to other studies.[28] Interestingly, the perceived overall flavor intensity decreased with fat addition at 1% agar gel strength, but increased significantly with fat addition at 5% gel strength. Although blue cheese flavor decreased with added fat, the effect was significant only after 10 chews and at the final chew for the 5% agar gel. Perceived overall flavor intensity was suppressed by fat in the softer 1% gel, but increased in the 5% gel. These differences in overall flavor perception appeared to be independent of the differences in perceived saltiness. A possible explanation was that the 1% agar gel (with and without added fat) had the same perceived resistance to chew, suggesting a similar rate of gel breakdown. Once the gel structure was fully broken down, partitioning of volatiles into the fat phase was expected to significantly affect release. In the 5% agar gels the addition of fat decreased resistance to chewing, facilitating more rapid gel breakdown, an increase in surface area, and faster release.

Agar Effect on in Vivo Volatile Release. Smoothed average agar curves for 2-butanone (low fat solubility), 2-heptanone (intermediate fat solubility), 2-nonanone (high fat solubility), ethyl butanoate (intermediate fat solubility), and ethyl hexanoate (high fat solubility) are shown in Figure 2 (top

row). The initial (zero-time) concentration (before chewing) generally mirrored gel strength, regardless of the lipophilicity of volatiles, suggesting slower diffusion from the gels. During mastication, release increased for the entire chewing period (50 s). This release pattern was consistent with continuous breakdown of the agar structure and concomitant increase in surface area being the main rate-limiting factor. It can be seen from the release curves that overall the greatest release (AUC) per unit time was measured for the weakest gel (1% agar). As the gel strength increased, total AUC decreased; this was most apparent between the 2.9 and 5% gel transition. The release curve patterns were similar regardless of volatile lipophilicity, suggesting that release impedance was predominantly related to diffusion phenomena and the available surface area. The effect of agar strength on AUC, I_{max}, and initial release rate is summarized in Table 5. Both agar and volatile type had highly significant effects on release, as did the agar−volatile ion interaction. Incremental decreases were larger for the more hydrophilic compounds, for example, 2-butanone and 2-pentanone, compared to the more lipophilic compounds, fore example, 2-nonanone and ethyl hexanoate, as the agar strength increased. This suggests that some positive electrostatic forces resulting in agar−volatile interactions were likely to be in operation as well as pure structural impedance effects.[29,30] The in

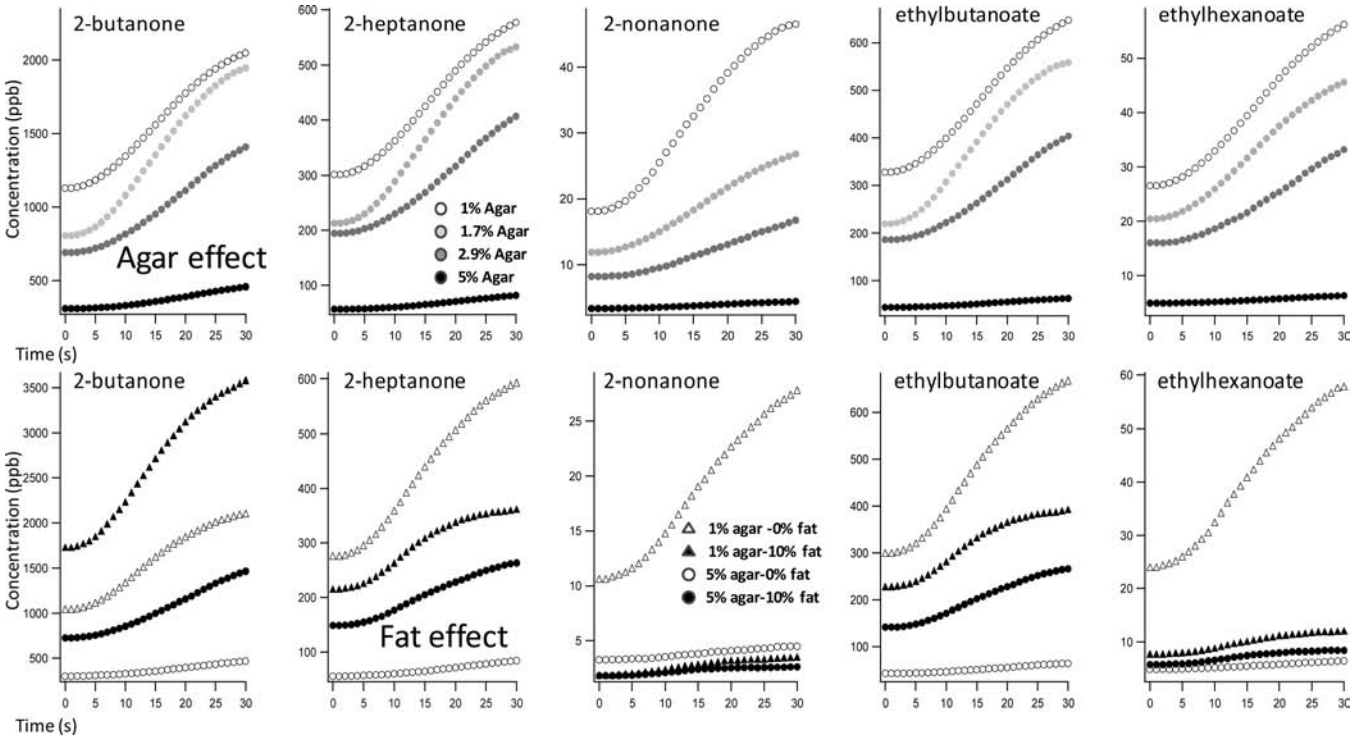

Figure 3. Smoothed average ($n = 4$) in vitro volatile release curves for selected volatiles in pure agar gels (top row) and in agar gels with fat (bottom row).

vivo data for the pure agar gels clearly showed that the release of all volatiles, irrespective of $K_{o/w}$, was impeded with increased gel rigidity, therefore supporting the sensory data. It is important to note that softer gels will be swallowed earlier compared to more rigid gels, having a shorter average residence time in the oral cavity.

Fat Effect on in Vivo Volatile Release. The combined effect of fat and agar together on in vivo release was more complex than pure agar effects. In the combined experiment, the effect of agar on volatile release (AUC) was overall significant, and the effect of fat approached significance (Table 6). The interactions of agar−volatile ion and fat−volatile ion were, however, both highly significant ($P < 0.001$), indicating that the effects differed depending on the lipophilicity of the volatile compounds. Similar effects were measured for I_{max} and the initial release rate (Table 6). The effect of fat addition to release curves is shown for 1 and 5% agar gels with either 0 or 10% added lipid (Figure 2, bottom row). Curves for 2-butanone (low fat solubility, $K_{o/w} = 1.9$), 2-heptanone (intermediate fat solubility, $K_{o/w} = 95.5$), and 2-nonanone (high fat solubility, $K_{o/w} = 1380$), ethyl butanoate (intermediate fat solubility, $K_{o/w} = 70.8$), and ethyl hexanoate (high fat solubility $K_{o/w} = 676$) are shown. Theory predicts that 2-butanone, the least fat-soluble volatile, would be minimally affected by the presence of lipid.[11] Although fat had a negligible effect on the release of 2-butanone from the 1% gel, in the 5% gel, a significant increase was measured. Given that the release of more lipophilic compounds (2-octanone, 2-nonanone) decreased, this observation suggested that a repulsive or lipophobic interaction between the fat and 2-butanone pushed the water-soluble volatile more rapidly out of the matrix. In a previous study, 2-butanone was released more rapidly when lipid emulsion was present in a dynamic in vitro system.[4] For 2-heptanone, the presence of fat profoundly decreased release in 1% agar; however, a slight increase in release was measured at 5% gel strength with the addition of fat. For 2-nonanone, the most fat soluble volatile, the suppressive effect of fat was apparent at both gel strengths. For ethyl butanoate, fat decreased release at 1% agar strength, but the opposite was observed at the higher gel strength, similar to 2-heptanone (Figure 2, bottom row).

The oral breakdown data indicated that the resistance to chewing was similar for the 1% agar gel with and without fat, implying that the structure broke down at a similar rate and the differences in release were likely due to fat effects rather than differences in surface area and diffusion. In contrast, at 5% gel strength, the softening effect of fat was apparent by the reduced modulus (Table 3) and lower resistance to chewing, implying a faster breakdown of the gel and greater surface area exposure, increasing the rate of release of the flavor compound. The harder particles formed from the 5% gel (with 10% fat) were more rubbery and rigid. It is hypothesized that particles coalesced in the mouth more slowly than the softer 1% agar (with 10% fat) particles, contributing to the observed greater release of some compounds, such as 2-butanone and ethyl butanoate in the harder gels. Another hypothesis was that lipophobic forces were acting on these two volatiles of low or intermediate fat solubility.

In Vitro System Data: Agar Effects. Although the in vivo data demonstrated a strong agar gel effect, it was not clear whether this was mainly due to differences in the rate of structure breakdown and corresponding increased surface area or other electrostatic (positive or negative) interactions between the agarose material and volatile compounds or both. In the in vitro system, the agar gels were broken into small particles only to form a large increase in surface area. No process to mimic bolus formation was present. It should also be noted that no saliva was present in the in vitro cell. The mean ($n = 4$) smoothed in vitro release curves for the pure agar gels are shown in Figure 3. As expected, the in vitro release showed lower variability compared to the data obtained from human subjects. The initial equilibrium concentration of volatiles above the gels (before the structure was broken) mirrored the gel strength (Figure 3). The release

[a]Data are the mean of four replicates. [b]LSD_{agar}, least significant difference for comparing the effect of agar on individual volatiles within column ($P < 0.05$). [c] $LSD_{agar\times fat}$, least significant difference for comparing the effect of agar×fat interaction on individual volatiles within column ($P < 0.05$).

from the gels increased rapidly during the initial shear period (10 s) to a maximum value within ∼50 s. As the agar concentration increased, the rate of release decreased, regardless of the volatile $K_{o/w}$. Even after reduction to fine particles, the release remained proportional to the agar gel strength (even after a further 15 min of monitoring, data not shown). In agreement with the in vivo data, the in vitro release rate decreased with increased gel strength regardless of the volatile lipophilicity. The main effects of agar strength and volatile type were significant ($P < 0.001$) (Table 7). The in vitro data clearly showed that the greatest impedance of release occurred in the transition from 2.9 to 5% agar gel strength, which was also supported by the rheological data. The agar−ion interaction term was significant ($P < 0.001$), where the relative decreases in the release of 2-nonanone were greater with increased agar strength compared to less lipophilic compounds, for example, 2-butanone.

In Vitro System Data: Fat Effects. As samples were rapidly sheared under in vitro conditions, differences in the rate of structural breakdown were not expected to be important, but rather true physicochemical effects. Once small particles were formed in the in vitro cell, they were not forced to recoalesce into a bolus, as would be the case in the mouth during mastication. Although the in vitro system was only a crude approximation of the masticatory apparatus, the main effects of agar and fat on release could be separated from other physiological effects. In vitro release curves for 2-butanone, 2-heptanone, 2-nonanone, ethyl butanoate, and ethyl hexanoate in agar gels with and without fat (10%) are shown (Figure 3, bottom row). For 2-butanone, the rate of release was greater with 10% fat at both gel strengths, supporting the hypothesis that a hydrophobic interaction may have occurred. The release of 2-butanone from the 1% gel release was different from the in vivo data, where no increase in release was measured with the addition of fat. It is hypothesized that the soft gel particles more easily recombined or recoalesced under in vivo conditions than in the in vitro system.

For 2-heptanone, the suppressive effect of fat was clear at 1%, but reversed at 5% strength. This result was similar to the in vivo data, where a similar trend was measured. For the more fat soluble volatiles 2-octanone and 2-nonanone, the inhibitory effect of fat on release was profound, regardless of gel strength. The release pattern of ethyl butanoate was similar to that of 2-heptanone (similar $K_{o/w}$) and also similar to the in vivo data. There are few published studies in which both gel strength and fat effects are simultaneously measured.[14,23] Whereas the strong suppressive effect of fat on the release of lipophilic volatiles is well-known,[4,11,31,32] the potential for lipophobic interactions, increasing the rate of release of molecules with low fat solubility, is barely described in the literature. For example, the release of volatiles with low fat solubility (e.g., 2-butanone[4,11] and 2,3-butanedione[33]) was slightly higher in emulsions under dynamic conditions in the presence of fat. It was of interest that the sensory panel rated the 5% agar with 10% fat sample higher in overall flavor intensity than the pure agar 5% gel. The in vivo and in vitro data clearly showed higher release for a number of volatiles, for example, 2-butanone and 2-pentanone, thus supporting the sensory data.

Both the in vivo and in vitro data showed unambiguously that volatile release decreased as the agar strength or gel rigidity increased, although the magnitude of the measured agar effect was relatively larger in the in vitro system. Previous studies have demonstrated a significant decrease in release with increased gel

J. Agric. Food Chem. 2015, 63, 9093−9102

strength,[14,23] but not others,[16,34] whereas various effects were reported in one study.[15] The in vitro cell only decreased the particle size and increased the surface area; it did not replicate the complex process of saliva mixing and bolus formation that occurs during mastication. The in vitro data were more reproducible and easier to interpret than the in vivo data, with high inter- and intraindividual variation in oral behavior being well-known. Regardless, both data sets showed similar directional trends. The effect of agar concentration on volatile release was relatively stronger for the more hydrophilic compounds, for example, 2-butanone and 2-pentanone, suggesting an electrostatic attractive force was in operation as well as other effects, for example, diffusion through structural hindrance. Overall, the findings strongly indicated that physicochemical mechanisms were mainly responsible for perceived flavor differences in agar gels rather than cross-modal interactions between texture and flavor perception.[16,17] It should be emphasized that gels made from gelatin and other hydrocolloids may have different release properties due to melting behavior or other physicochemical properties.

The release curve information generated here may be used as data input into future computational models of human oral processing and flavor release with some adaptation, for example, release per chew data, to better understand flavor release and sensory perception.[7,35] Using similar approaches, it may be possible to better understand the effects of the food matrix and fat in real food systems and also contribute to the development of reformulated manufactured food products.

[a]RI for Kovats retention index on polar (DB-Wax) and apolar (HP-5) columns. [b]Quant. ion = ions used for quantitation. [c]r^2 = coefficient of determination. [d]The limits of detection (LODs) (concentration for signal/noise = 3) and the limits of quantitation (LOQs) (concentration for signal/noise = 10) were manually calculated from the ratio of the peak heights to the average noise before and after each peak. [e]Repeatability was assessed for low concentrations at 0.05 and 0.4 μg/L for 1,4-cineole and 1,8-cineole, respectively, and for medium concentrations at 0.5 and 2 μg/L, respectively.

as "minty", "cooling piney", "camphoraceous", and "eucalyptol-like",[18] but no detection threshold of this compound has been reported in the literature.

Because of the comparable natural occurrence of 1,4-cineole and 1,8-cineole, their olfactory similarity, and the importance of 1,8-cineole in Australian red wines, this study aimed to investigate the occurrence and potential contribution of 1,4-cineole to red wine aroma. A headspace−solid-phase microextraction−gas chromatography−mass spectrometry (HS−SPME−GC−MS) method was developed and validated to quantitate 1,4-cineole and 1,8-cineole in Australian red wines. Discriminative and descriptive sensory methods were used to characterize the contribution of 1,4-cineole, both independently and in combination with 1,8-cineole, upon Cabernet Sauvignon wine aroma.

MATERIALS AND METHODS

Material. Standards including 1,4-cineole (98.5%), 1,8-cineole (99%), octan-2-ol (97%), 3-isobutyl-2-methoxypyrazine (IBMP, 99%), and menthol (99%) were purchased from Sigma-Aldrich (Castle Hill, New South Wales, Australia). Stock and working solutions of standards were prepared volumetrically in ethanol (AnalaR NORMAPUR, VWR, Fontenay-sous-Bois, France) and stored at −20 °C. Water was obtained from a Milli-Q purification system (Millipore, North Ryde, New South Wales, Australia). Sodium chloride (NaCl) was purchased from Merck (Darmstadt, Germany). Deionized water was obtained from a Milli-Q mixed bed resin system (18 MΩ/cm and 25 °C).

Wines. A range of commercial Australian red wines (104 in total) comprising of 51 Cabernet Sauvignon, 4 Cabernet Sauvignon/Merlot blends (60−80% Cabernet Sauvignon), 27 Shiraz, and 22 Pinot Noir wines were purchased. The wines originated from important regions for Cabernet Sauvignon, Shiraz, and Pinot Noir wine production. Cabernet Sauvignon wines (varietal and blends) were from Coonawarra (31%), Margaret River (27%), Barossa and McLaren Vale (25%), and other regions located in South Australia, Victoria, and New South Wales (17%). Shiraz wines were from Barossa and McLaren Vale (37%), Coonawarra (19%), Margaret River (11%), and other regions located in South Australia, Victoria, and New South Wales (33%). Pinot Noir wines were from Victoria (50%), Orange (36%), other regions located in South Australia and Tasmania (14%). Cabernet Sauvignon and Shiraz wines were mainly from 2012, 2011, 2010, and 2009 (mean age of 3.5 years). Pinot Noir wines were from 2013, 2012, and 2011 (mean age of 2 years).

Cineole Isomer Analysis. The method for quantitating 1,4-cineole and 1,8-cineole by HS−SPME−GC−MS was developed in combination of previously published methods for wine volatiles.[8,19]

Spiking and Sample Preparation. The development and the validation of the method were carried out using Australian red wines from the 2013 vintage. The method consisted of adding 20 μL of a stock solution of octan-2-ol (internal standard) at 5 mg/L in absolute ethanol to 10 mL of wine. To a 20 mL headspace vial 3 g of NaCl, 5 mL of wine spiked with internal standard, and 5 mL of deionized water were added. The vial was then tightly sealed with a polytetrafluoroethylene (PTFE)-lined cap, and contents were homogenized.

Instrumentation. An Agilent 7890A gas chromatograph, equipped with a Gerstel multipurpose sampler with automated SPME capability, interfaced to an Agilent 5975C triple-axis mass detector was used. A MSD Chemstation E.02.00.493 (Agilent Technologies, Ltd.) and National Institute of Standards and Technology (NIST) MS Search 2.0 version 2008 were used to control the instrument and for mass spectra assessment. Prepared samples were placed in the tray until analysis, whereupon vials were transferred to a heater block. The extraction consisted of preincubating the vial for 10 min at 40 °C with swirling at 500 rpm, inserting a 1 cm divinylbenzene/carboxen/polydimethylsiloxane (DVB/CAR/PDMS) 50/30 μm fiber (Supelco, Bellefonte, PA) into the headspace for 30 min at 40 °C while the solution was swirled again. The fiber was then transferred to the injector for desorption at 250 °C for 1 min, withdrawn, and injected into a second injector set at 270 °C with a 50:1 split for 10 min with a 10 mL/min purge flow to clean the fiber, prior to the next sample analysis. A fused silica capillary column (DB-Waxetr, 60 m × 0.25 mm inner diameter, 0.25 μm film thickness, Agilent Technologies, Santa Clara, CA) was used for compound separation by gas chromatography. The injector block was fitted with a 1 mm internal diameter borosilicate liner (SGE), and the injector temperature set to 260 °C in splitless mode. The oven temperature program commenced at 40 °C for 5 min, increased to 120 °C at a rate of 3 °C/min, with a final increase to 220 °C at a rate of 15 °C/min, and held for 15 min. The total run time was 53.3 min. The flow rate of ultrahigh-purity helium gas was constant at 3 mL/min. The MS source, quadrupole, and transfer line temperatures were set to 230, 150, and 275 °C, respectively.

Compound Identification and Quantitative Analysis. The identification of 1,4-cineole and 1,8-cineole (Figure 1) in wines was performed by comparing retention times and mass spectra (scan mode) to those of pure standards at 20 μg/L in water and red wine. Kovats retention indices (RIs) were checked for each compound using a commercial mixture of n-alkanes (Sigma, Steinheim, Germany), with an identical oven ramp profile and gas flow rates as used for the final analyzes on DB-Waxetr (60 m × 0.25 mm inner diameter, 0.25 μm film thickness) and HP-5MS (30 m × 0.25 mm inner diameter, 0.25 μm film thickness) columns. Mass spectral data were collected in both selective ion monitoring (SIM) and scan mode (m/z 35−350) at an ionization voltage of 70 eV. The mass spectra of both cineole isomers are available in the NIST 08 MS database. Quantifier and qualifier ions were selected as described in the literature for 1,8-cineole[8] and based on the best signal/noise ratio measured in red wines for 1,4-cineole. The ions monitored in SIM runs were m/z 71, 81, 93, 108, 111, 125, 139, and 154 for the cineole isomers and m/z 45 and 55 for octan-2-ol. The quantitation ions used for the cineole isomers are listed in Table 1, while m/z 45 was used for octan-2-ol. The other ions were used as qualifiers.

Table 2. Code of Samples Used for Sensory Analysis

code	description	concentration
wat	water	
CS	Cabernet Sauvignon wine	3.4 ng/L IBMP
		0.09 μg/L 1,4-cineole
CSi	CS wine spiked with IBMP	10 ng/L IBMP
wat + 1,4c-0.13	1,4-cineole in water	0.13 μg/L 1,4-cineole
wat + 1,4c-0.27	1,4-cineole in water	0.27 μg/L 1,4-cineole
CS + 1,4c-0.13	1,4-cineole in CS wine	0.22 μg/L 1,4-cineole
CS + 1,4c-0.27	1,4-cineole in CS wine	0.36 μg/L 1,4-cineole
CS + 1,4c-0.54	1,4-cineole in CS wine	0.63 μg/L 1,4-cineole
CS + 1,8c	1,8-cineole in CS wine	2.5 μg/L 1,8-cineole
CSi + 1,4c	1,4-cineole in CSi wine	1.6 μg/L 1,4-cineole
CSi + 1,8c	1,8-cineole in CSi wine	2.5 μg/L 1,8-cineole
CSi + 1,8c-10	1,8-cineole in CSi wine	10 μg/L 1,8-cineole
CSi + 1,4c + 1,8c	1,4-cineole + 1,8-cineole in CSi wine	1.6 μg/L 1,4-cineole
		2.5 μg/L 1,8-cineole
CSi + 1,4c + 1,8c-10	1,4-cineole + 1,8-cineole in CSi wine	1.6 μg/L 1,4-cineole
		10 μg/L 1,8-cineole

Method Validation. Linearity was validated by a series of seven standard additions of 1,4-cineole and 1,8-cineole in three different commercial red wines (Shiraz, Cabernet Sauvignon, and Merlot). The initial concentrations of 1,4-cineole and 1,8-cineole in the wines used for validation were below 0.1 and 0.5 μg/L, respectively. The calibration ranges are displayed in Table 1. The precision of the method was assessed by analyzing 10 replicates of a commercial Shiraz with 1,4-cineole and 1,8-cineole at 0.05 and 0.4 μg/L, respectively, which covered the low range of concentrations. A second trial for the assessment of precision was made at a medium range of the concentration for both 1,4-cineole and 1,8-cineole, with the same wine spiked at 0.5 and 2 μg/L, respectively. The robustness of the method was determined by analyzing five replicates of the same spiked wine over a period of 2 weeks. For the accuracy study (recovery), three different varietal red wines (Cabernet Sauvignon, Shiraz, and Pinot Noir) were spiked with 1,4-cineole and 1,8-cineole at the same concentrations as used for repeatability. To ensure that the accuracy of the method was maintained, a control red wine sample spiked with cineole isomers as previously indicated was regularly included in the set of samples to be quantitated.

Sensory Analyses. *General Conditions.* Sensory analyses were performed with samples prepared in water and wine as previously described.[20] Sample assessments were undertaken in a temperature-controlled room, in individual booths (ISO 8589:2007), using covered, white ISO glasses (ISO 3591:1977) containing about 30 mL of liquid, coded with random three-digit numbers. Sessions lasted approximately 10 min. All sensory samples underwent orthonasal evaluation. The wine used for the discriminative and descriptive analyses was a 2012 Cabernet Sauvignon wine from the south of France (CS) with the following parameters measured by Fourier transform mid-infrared spectroscopy (WineScan Instrument, Foss Analytical, Hillerød, Denmark): alcohol, 12.9% (v/v); pH, 3.6; titratable acidity, 4.6 g/L as tartaric acid; and volatile acidity, 0.43 g/L. The initial concentrations of IBMP measured as described[21] and 1,4-cineole were 3.8 ng/L and 0.09 μg/L, respectively. The concentration of 1,8-cineole was below the limit of quantitation. Coded samples (Table 2) were prepared approximately 15 h prior to the session and kept at 18 °C in sealed vials to ensure chemical and sensory equilibrium. Analyses were also performed to check the solution stability between the sensory sessions. No significant loss of cineoles or IBMP was observed in either the water or wine solutions.

Sensory Panel. Judges were selected on the basis of availability and interest. A total of 16−33 volunteers participated in the various sensory panels. All panelists were research laboratory staff at the Institute of the Sciences of Vines and Wines (ISVV), Bordeaux University, and showed different levels of expertise in sensory analysis. The ages of the panelists ranged from 21 to 53 years, and the panel was comprised of between 55 and 65% females depending upon the panel.

Discriminative Analysis. Triangle tests were performed for 1,4-cineole solution samples in deionized water and CS wine. Each solution of 1,4-cineole, present at the concentrations listed in Table 2, was compared to either deionized water or the base CS wine. For each triangle test, three numbered samples (two identical and one different) were presented in a random order. Each judge used direct olfaction to identify the sample perceived as different in each test and was instructed to provide a response, even if they were uncertain of the correctness of their answer. Each triangle test was performed in duplicate.

Descriptive Analysis. The descriptive analysis focused on the impact of 1,4-cineole, in both isolation and combination with 1,8-cineole on the aromatic profile of Cabernet Sauvignon wines using an adapted version of the Deviation from Reference Method.[22] CS wine was spiked with IBMP to reach a final concentration of 10 ng/L (CSi in Table 2). This reflected the IBMP levels measured[21] in 14 wines from Margaret River and Coonawarra regions in a preliminary survey (data not shown). Additions of 1,4-cineole and 1,8-cineole were performed in the CSi wine at concentrations comparable to that found in Australian Cabernet Sauvignon wines (Table 2) and perceptible by the panel (Table 3). The tests were performed by comparing the aromatic perception of the hay, bay leaf, and blackcurrant reference

Table 3. Proportion of Positive Answers for Triangle Tests Performed in Water (Wat) and Cabernet Sauvignon Wine (CS) for 1,4-Cineole[a]

test	proportion of positive answer (%) (number of responses)	level of significance
wat + 1,4c-0.13 versus wat	38 (16)	NS[b]
wat + 1,4c-0.27 versus wat	56 (32)	$p = 0.01$
CS + 1,4c-0.13 versus CS	31 (36)	NS
CS + 1,4c-0.27 versus CS	28 (36)	NS
CS + 1,4c-0.54 versus CS	53 (34)	$p = 0.05$
CS + 1,8c versus CS	53 (36)	$p = 0.05$

[a]Sample codes are shown in Table 2. For each comparison, results were calculated by adding one and two positive sample tests. [b]NS = non-significant.

DOI: 10.1021/acs.jafc.5b03847
J. Agric. Food Chem. 2015, 63, 9103−9111

standards (Table 4) to CSi wine that has been spiked with 1,4-cineole and 1,8-cineole (Table 2). For each test, the panel assessed the olfactory similarity of spiked CSi wine samples compared to the standard presented. A previous series of triangle tests had shown that a similar range of 1,4-cineole and 1,8-cineole concentrations was able to be detected by the panel (Table 3). Panelists scored the similarity between spiked wine and standard using a 10 cm scale, with the highest scores plotted on the right side of the scale (0, low; 10, high). The samples with the highest scores were perceived as most similar to the corresponding reference standard.

Table 4. Descriptors and Corresponding Reference Standards Used for Descriptive Analysis

attribute	composition of the reference
bay leaf	maceration of 50 mg of commercial crumbled bay leaves for 2 min in water/wine
capsicum	solution of IBMP at 100 μg/L in water
eucalyptus	solution of 1,8-cineole at 100 μg/L in water
forest floor	maceration of 3 g of a mix of forest humus and oak leaves for 10 min in water
fresh	solution of menthol at 100 μg/L in water
hay	diluted macerate (1:3) of 500 mg of commercial hay in 100 mL in water/wine for 2 min
licorice	one licorice candy (Ricola) dissolved in 100 mL of water
spicy	500 mg of a commercial mix of ground black, red, and green pepper corns in 100 mL of water
blackcurrant	maceration of 40 g of commercial blackcurrant jam in 100 mL of water/wine for 1 min
black cherry	maceration of 40 g of commercial black cherry jam in 100 mL of water/wine for 1 min
dark fruit	maceration of 20 g of commercial blackberry jam and 20 g of blueberry jam in 100 mL of water for 10 min
red fruit	maceration of 40 g of commercial red berry fruit jam (strawberry, red cherry, and raspberry) in 100 mL of water

Multidimensional Scaling. A descriptive sorting task was used to characterize the aromatic differences between 10 Cabernet Sauvignon wines originating from the Coonawarra (n = 5) and Margaret River (n = 5) regions. Coonawarra wines were from 2010 (n = 3), 2011, and 2012 vintages, and Margaret River wines were from 2011 (n = 3), 2010, and 2012 vintages. The protocol of the sorting focused on orthonasal evaluation was as recently described.[23] The sensory description of the wine groups during the sorting task was based on 12 descriptors with appropriate reference standards that are commonly used by wine experts to describe the aroma of Australian Cabernet Sauvignon wines (Table 4). The panelists were asked to choose the most relevant terms from this list to define each group and were instructed to form between two and nine groups, with a maximum of five descriptors per group. During the session, participants had the opportunity to refresh their aroma memory by reassessing the reference standards.

Statistical Analysis. *Chemical Analysis.* The significance was examined using one-way analysis of variance (ANOVA), and the means were separated using Fisher's least significant difference (LSD) test (different letters account for significant differences at $p \leq 0.05$). ANOVA was performed using Excel software (Microsoft Corporation, Redmond, WA).

Sensory Analysis. The results of all of the triangle tests were statistically analyzed on the basis of the binomial law corresponding to the distribution of answers in this type of test (NF EN ISO 4120, 2007).

Descriptive data were analyzed using a one-way ANOVA (XLSTAT software). When more than two samples were compared, all descriptors were mean-centered per panelist and scaled to unit variance. Samples were considered as significant at $p < 0.05$. The data from multiple comparison tests were processed with a Duncan post-hoc test.

For the sorting task, dissimilarities between samples were analyzed using non-metric multidimensional scaling (MDS) as described elsewhere.[23] The analysis of 1,4-cineole, 1,8-cineole, and IBMP of the wines aimed to identify potential relationships between wine composition and the effect of regionality on aroma. The correlations between wines, attributes, and chemical compounds were plotted on a MDS map.

RESULTS AND DISCUSSION

Development and Validation of a Quantitation Method of 1,4-Cineole and 1,8-Cineole in Red Wines. Cineole isomers are symmetrical monoterpenic cyclic ethers exhibiting an epoxy-*p*-menthane structure, differing only by the position of the epoxy group (Figure 1). While 1,8-cineole has been previously quantitated in Australian red wines,[8] quantitative data for 1,4-cineole in wine have not been previously reported. However, 1,4-cineole has already been identified in red wines.[15,16] The identification of 1,4-cineole in red wines has been confirmed in the present study by the presence of peaks that displayed the identical mass spectrum of 1,4-cineole at the retention time that matched the 1,4-cineole retention index on two types of columns. The GC−MS parameters were adapted to cineole isomer analysis from a published method developed for wine volatile analysis.[19] Quantitation method validation was carried out assessing linearity, repeatability, reproducibility, limits of detection and quantitation, and recoveries in different red wines (Table 1). The standard curves obtained were linear and repeatable throughout the concentration range. The calculated limits of quantitation (LOQs) were 4 and 10 ng/L for 1,4-cineole and 1,8-cineole, respectively, and the calculated limits of detection (LODs) were 1 and 3 ng/L for 1,4-cineole and 1,8-cineole, respectively. The precision, robustness, and accuracy of the method were satisfactory for both compounds. The relative standard deviations for repeatability and reproducibility were below 7%, and recovery rates were measured at between 90 and 106% (Table 1). Interestingly, the method validation data revealed that the use of deuterated analogues was not necessary and octan-2-ol was well-adapted to HS−SPME−GC−MS analysis of 1,4-cineole and 1,8-cineole in red wines.

Survey of Cineole Isomers in Red Wines. The method was applied to analyze 1,4-cineole and 1,8-cineole in 104 commercial Australian Cabernet Sauvignon, Shiraz, and Pinot Noir wines from different regions and vintages. The results of this quantitative investigation are summarized in Table 5.

Table 5. Mean Concentrations ± Standard Deviation (SD) of 1,4-Cineole and 1,8-Cineole in Australian Cabernet Sauvignon, Shiraz, Pinot Noir Wines[a]

	Cabernet Sauvignon (n = 51)	Shiraz (n = 27)	Pinot Noir (n = 22)
1,4-cineole	0.59 ± 0.33 a	0.07 ± 0.04 c	0.22 ± 0.2 b
1,8-cineole	2.82 ± 3.26 a	1.75 ± 1.42 a	0.99 ± 0.33 b

[a]One-way ANOVA was used to compare data. Means followed by different letters in a row are significant at $p \leq 0.05$ (Fischer's LSD). All quoted uncertainty is the standard deviation of each group of wines.

Varietal Differences. 1,4-Cineole was detected in all of the wines analyzed with concentrations ranging from 0.023 to 1.6 μg/L. An important varietal effect was observed with an average concentration of 8.4- and 2.7-fold higher in Cabernet Sauvignon than in Shiraz and Pinot Noir wines, respectively (Table 5). All of the Shiraz wines exhibited concentrations below 0.2 μg/L, and 87% of Pinot Noir wines showed

DOI: 10.1021/acs.jafc.5b03847
J. Agric. Food Chem. 2015, 63, 9103−9111

concentrations below 0.4 μg/L. Conversely, 1,4-cineole concentrations were above 0.4 μg/L in 68% of the Cabernet Sauvignon wines analyzed, including seven wines with concentrations above 1 μg/L (Figure 2). The varietal differences measured in this study between Pinot Noir and Cabernet Sauvignon will require further investigations because Pinot Noir wines originated from different regions compared to Cabernet Sauvignon wines. The 1,4-cineole/1,8-cineole concentration ratios in Cabernet Sauvignon wines ranged from 0.015 to 1.24 (Supplementary Figure 1 of the Supporting Information). The distribution of 1,4-cineole in Australian red wines was therefore very different in comparison to 1,8-cineole. These results indicate that 1,4-cineole and 1,8-cineole in wines might have different origins and suggest that the occurrence of 1,4-cineole in wine is probably not due to the presence of eucalyptus trees in the vicinity of the vineyard, as has been reported for 1,8-cineole.[9] Further studies investigating the origin of 1,4-cineole in wine are warranted.

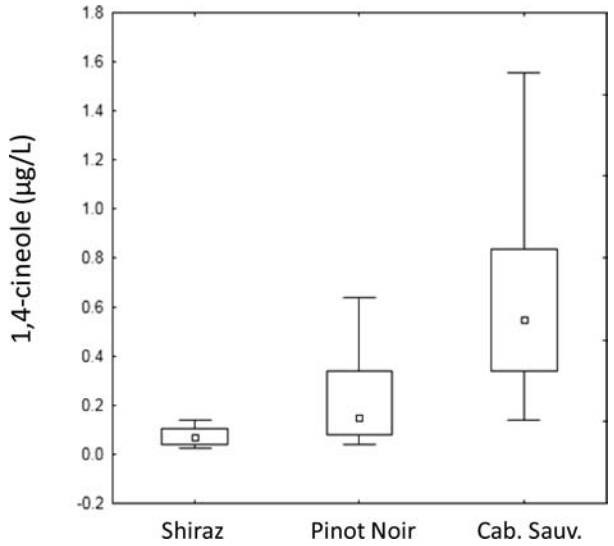

Figure 2. Distribution of 1,4-cineole concentrations in Australian red wines represented as box plots with the minimum, maximum, median, and quartiles. Cab. Sauv. = Cabernet Sauvignon.

The concentrations of 1,8-cineole were also cultivar-dependent, with higher concentrations in Australian Cabernet Sauvignon and Shiraz than Pinot Noir wines (Table 4). However, one Pinot Noir wine contained 23 μg/L 1,8-cineole. Both this wine and two Cabernet Sauvignon wines containing 19 and 66 μg/L, respectively, were considered as outliers and were not taken into account for the varietal comparison. These findings add to the uncertainty regarding the origin of 1,8-cineole in red wines and suggest that, as previously hypothesized,[5,11] factors other than proximity to eucalyptus trees may be important in determining the final concentration of this compound in wines.

Influence of the Wine Geographic Origin. Significant variations in 1,4-cineole and 1,8-cineole concentrations were measured between wines originating from different regions of Australia (Figure 3A). The Cabernet Sauvignon wines originating from Margaret River exhibited higher concentrations of 1,4-cineole than wines from Barossa and McLaren Vale ($p < 0.05$) and to a lesser extent Coonawarra ($p = 0.08$). Conversely, higher concentrations of 1,8-cineole were found in Cabernet Sauvignon and Shiraz wines produced from Coonawarra compared to Barossa and McLaren Vale ($p < 0.05$) and Margaret River to a lesser extent ($p = 0.13$) (Figure 3B). Regional variations of 1,8-cineole in Australian Cabernet Sauvignon have been previously reported.[5] The higher levels of 1,8-cineole found in the Coonawarra Cabernet Sauvignon wines are in agreement with anecdotal sensory descriptions, which include "eucalyptus" and "minty"[6] aromas, which are reminiscent of 1,8-cineole.

These results suggest that 1,4-cineole and 1,8-cineole concentrations in wine could be related to abiotic factors that characterize a terroir unit[24] (climate × soil moisture) and influence grape composition. Appropriate studies to investigate the effect of the temperature and water availability on the grape

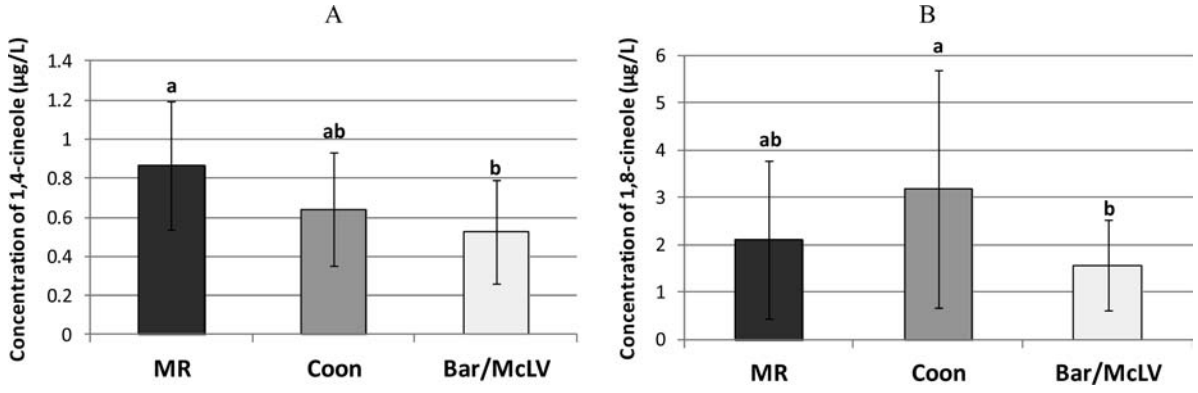

Figure 3. Effect of the geographic origin on the (A) 1,4-cineole concentration in Australian Cabernet Sauvignon wines and (B) 1,8-cineole concentration in Australian Cabernet Sauvignon and Shiraz wines. One-way ANOVA was used to compare data. Different letters on a column represent significantly ($p \leq 0.05$) different concentrations expressed in micrograms per liter. Standard errors were used for the error bars. MR, Margaret River; Bar/McLV, Barossa and McLaren Vale; and Coon, Coonawarra. The wine distribution for Figure 5A is as follows: for Margaret River, $n = 13$ with vintages as follows: 2011, $n = 9$; 2010, $n = 3$; and 2009, $n = 1$; for Coonawarra, $n = 12$ with vintages as follows: 2011, $n = 3$; 2010, $n = 7$; and 2009, $n = 2$; and for Barossa and McLaren Vale, $n = 13$ with vintages as follows: 2011, $n = 8$; 2010, $n = 4$; and 2009, $n = 1$. The wine distribution for Figure 5B is as follows: for Margaret River, $n = 17$ as follows: Cabernet Sauvignon/Shiraz, $n = 14/n = 3$ with vintages as follows: 2012, $n = 1$; 2011, $n = 11$; 2010, $n = 4$; and 2009, $n = 1$; for Coonawarra, $n = 21$ as follows: Cabernet Sauvignon/Shiraz, $n = 16/n = 5$ with vintages as follows: 2012, $n = 3$; 2011, $n = 5$; 2010, $n = 10$; 2009, $n = 2$; and 2005, $n = 1$; and for Barossa and McLaren Vale, $n = 22$ as follows: Cabernet Sauvignon/Shiraz, $n = 13/n = 9$ with vintages as follows: 2012, $n = 1$; 2011, $n = 14$; 2010, $n = 6$; and 2009, $n = 1$.

metabolites that influence 1,4-cineole and 1,8-cineole concentrations in wines should be considered.

Sensory Characterization of Cineoles in Red Wine. *Impact Level of 1,4-Cineole in Red Wine.* The measurement of the perception threshold, performed with the ascending three-alternative forced choice (3AFC) task method, is one of the most common techniques used to evaluate quantitatively the aromatic potency of wine odorants.[25] However, recent works on perceptive interactions demonstrated, using single triangle tests, that aromatic compounds could potentially contribute to wine aromas through synergistic effects when their levels were below reported perception thresholds.[26−28] The method of single triangle tests was therefore used in the present study to check if levels of 1,4-cineole measured in Australian red wines were perceivable in water and red wines. Comparisons presented in Table 3 show that 1,4-cineole was perceived in water at 0.27 μg/L and that an addition of 0.54 μg/L in Cabernet Sauvignon wine, to produce a final concentration of 0.63 μg/L, was required before panelist perception. In comparison to the concentrations of 1,4-cineole found in the Cabernet Sauvignon wines, this suggests that 60% of the Australian Cabernet Sauvignon wines in this study had concentrations of 1,4-cineole potentially perceivable. In contrast, the average concentration of 1,4-cineole in Shiraz and Pinot Noir wines was 7- and 2.5-fold lower, respectively, than the range of concentrations potentially detectable in Cabernet Sauvignon wines. These findings suggest that 1,4-cineole has an influence on the aromatic profile of Australian Cabernet Sauvignon wines.

Sensory Characterization of 1,4-Cineole and 1,8-Cineole in Cabernet Sauvignon Wines. Descriptive analysis was undertaken to characterize the impact of 1,4-cineole in the presence and absence of 1,8-cineole on the aroma of Australian Cabernet Sauvignon wines. The presence of IBMP was also considered because this compound contributes highly to the herbaceous aroma of Cabernet Sauvignon wines investigated in this study.[2] Preliminary sensory evaluation of Cabernet Sauvignon wines with concentrations of IBMP, 1,4-cineole, and 1,8-cineole at 10 ng/L, 1.6 μg/L, and 2.5 μg/L respectively (Table 2), was performed by a small panel of five experts with extensive experience in wine aroma evaluation to generate relevant descriptors. The main sensory attributes used to describe the wines spiked with 1,4-cineole and 1,8-cineole were "hay", "dried herbs", "fresh", "mint", and "blackcurrant". The "fresh" and "minty" aromas are common characteristics of numerous Australian Cabernet Sauvignon wines to which 1,8-cineole has been previously associated.[4] Therefore, the descriptive analysis focused on the investigation of the "hay", "bay leaf", and "blackcurrant" attributes using an adapted version of the Deviation from Reference Method.[22] The ANOVA and Duncan post-hoc test showed that the addition of 1,4-cineole, both independently and in combination with 1,8-cineole, enhanced hay aromas compared to the control wine ($p < 0.05$) (Figure 4A). The intensity of bay leaf notes was significantly enhanced by the association of 1,4-cineole and 1,8-cineole ($p < 0.05$) (Figure 4B). An additional comparison showed that raising the concentrations of 1,8-cineole (10 μg/L) in this combination led to an increase in the intensity of bay leaf aromas ($p < 0.05$) (Figure 4C). In contrast, the panel was not able to significantly separate the different wines according to blackcurrant aromas, even though the addition of only 1,8-cineole tended to be perceived with more pronounced notes of blackcurrant (Supplementary Figure 2 of the Supporting Information). To check the veracity of these observations, a final comparison between the control wine and the same wine spiked with high concentrations of 1,8-cineole (10 μg/L) was

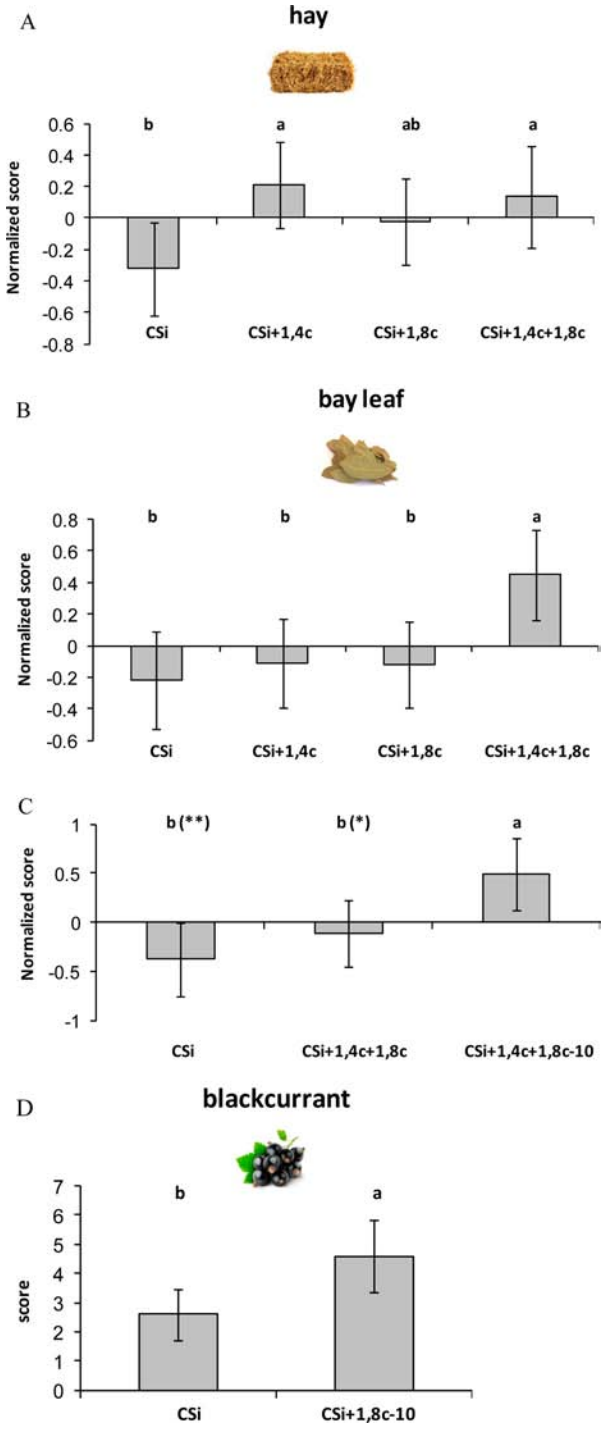

Figure 4. Descriptive analysis: evaluation of the contribution of 1,4-cineole and 1,8-cineole to (A) hay, (B and C) bay leaf, and (D) blackcurrant aromas in Cabernet Sauvignon wines using the Deviation from Reference Method (test of similarity). Sample codes are shown in Table 2. Wines and reference standards were prepared as indicated in Tables 2 and 4, respectively. The number of panelists was 33 for trials A and B and 17 for trials C and D. Results were expressed in normalized score for trials A−C and in absolute score for trial D. Standard errors measured on normalized score (A−C) and absolute score (D) were used for the error bars.

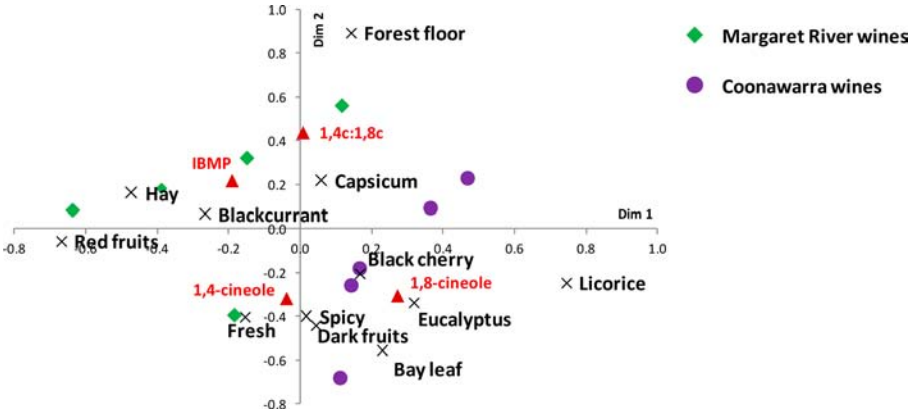

Figure 5. Two-dimensional MDS configuration of the 10 sorted Australian Cabernet Sauvignon wines from Margaret River (diamonds) and Coonawarra (circles) and correlations of the sensory terms (crosses) and chemical compounds (triangles) with the dimensions.

undertaken. The wine spiked with 1,8-cineole was perceived significantly higher for blackcurrant aromas than the control wine, confirming the previous trend ($p < 0.05$) (Figure 4D).

These findings indicate that 1,4-cineole, in both isolation and combination with 1,8-cineole, may contribute to the hay and dried herbs aromas that have been reported in Australian Cabernet Sauvignon wines. These compounds have both been reported in different aromatic herbs, such as thyme,[29] sage,[30] and bay leaf,[31] and the contribution of 1,8-cineole to the sensory perception of aromatic herbs has been reported in bay leaf and rosemary essential oils.[32,33]

While several studies have identified 1,8-cineole as a potent aroma of blackcurrant,[34,35] the current study suggests a relationship between 1,8-cineole and blackcurrant aroma in red wines. In particular, a contribution to the pronounced blackcurrant aroma in some Australian Cabernet Sauvignon wines, possibly in combination with other compounds, such as dimethyl sulfide,[36] is plausible.

Contribution of Cineole Isomers to Regional Aromas of Australian Cabernet Sauvignon Wines. The potential contribution of 1,4-cineole and 1,8-cineole to the regional typicity of Australian Cabernet Sauvignon wine aroma was investigated by comparison of Coonawarra and Margaret River wines using a sorting method. Wines were grouped according to their geographic origin (Figure 5), with Coonawarra wines associated with 1,8-cineole and attributes such as "eucalyptus", "bay leaf", "licorice", and "black cherry". These results indicate that 1,8-cineole might be an important marker of Coonawarra Cabernet Sauvignon and contribute to the eucalyptus, bay leaf, and fresh licorice aromas that are often empirically reported in these wines.[6,37] Margaret River wines were more associated with the 1,4-cineole/1,8-cineole ratio, IBMP, and descriptors such as "hay", "forest floor", "capsicum", "red fruit", and "blackcurrant". This region is generally known to produce wines with some elegant herbaceous aromas.[6,37] IBMP has been reported to contribute to green aromas perceived in Cabernet Sauvignon wines from Margaret River.[38] Even though IBMP was more correlated to Margaret River than Coonawarra wines, the concentrations measured in the present study were considerably lower (<13 ng/L) than reported in a previous work.[38] This suggests that compounds other than IBMP might contribute to Margaret River Cabernet Sauvignon typicality. The average concentrations of 1,4-cineole in Margaret River and Coonawarra wines selected for the sorting task were in the same range (0.74 and 0.69 μg/L, respectively). However, the 1,4-cineole/1,8-cineole ratios were higher in Margaret River wines and more correlated with the herbaceous attributes perceived in these wines (Figure 5).

Contrary to the descriptive analysis results, no relationship between 1,8-cineole and blackcurrant aromas was identified when the Coonawarra and Margaret River wines were compared. This lack of consistency confirms that the perception of blackcurrant aromas in red wines is complex and probably not due to only one or two compounds.[36]

The descriptors used for the sorting task were selected because they closely aligned to cineole isomers and IBMP aromas reported in the literature.[2,8] Some relationships between the sorting task and cineole isomer composition were also supported by the previously described descriptive analysis. These findings suggest that 1,4-cineole might contribute to the aromatic typicality of Margaret River Cabernet Sauvignon, when it is associated with moderate levels of IBMP and 1,8-cineole. In contrast, high concentrations of 1,8-cineole in combination with 1,4-cineole and IBMP seem to favor the expression of bay leaf aromas. A bay leaf aroma was found to be a more important descriptor for Coonawarra wines with an average concentration of 1,8-cineole of 7.7 μg/L, which was 2.9-fold higher than in the Margaret River wines. It appears that the relative concentrations of 1,4-cineole and 1,8-cineole contribute, probably with other compounds, to the regional differentiation found between Margaret River and Coonawarra Cabernet Sauvignon wines.

These results demonstrate that cineole isomers may be valuable aromatic markers for Australian Cabernet Sauvignon wines and to a lesser regional typicality. Further studies to investigate the occurrence of cineole isomers in other cultivars and wines from other important regions in the world are warranted.

chosen as the treatment method because it represents the maximum temperature for cooking in water under atmospheric pressure. The meat and cooking water were separated and analyzed using sodium dodecyl sulfate−polyacrylamide gel electrophoresis (SDS−PAGE) in conjunction with LC−MS/MS (GeLC) and 1D LC−MS/MS, respectively.

MATERIALS AND METHODS

Porcine trypsin used for proteomic sample preparation was of sequencing grade and was purchased from Promega (Madison, WI).

Experimental Design. Lamb longissimus thoracis et lumborum, pooled from five animals and carefully blended to minimize tissue inhomogeneity and animal-to-animal variation between replicates, was used for the study. Each cooking control/treatment was performed in triplicate. The experimental workflows, GeLC of meat, cooking water (including water from control, which is described later in the Materials and Methods section) peptidomics, and cooking water and meat homogenate residue proteomics, are briefly summarized in Figure 1. Each experimental workflow was subjected to one LC−MS/MS analysis.

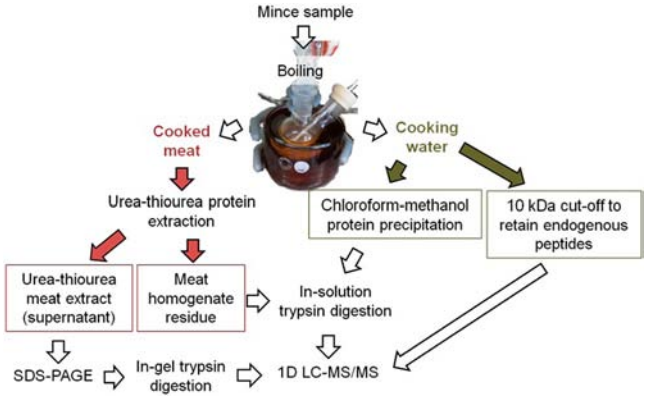

Figure 1. A schematic representation of the experimental workflows.

Lamb Meat. Five 11-month-old Coopworth ram lambs were slaughtered on August 29, 2013, at a local processing plant. The average carcass weight was 22.3 ± 4 kg. After hanging in the chiller of the processing plant for 24 ± 2 h, the backstrap [longissimus thoracis et lumborum (LTL)] was removed from each animal and the bulk of connective tissue was removed. The meat was vacuum-packed and transported to AgResearch (Lincoln campus) on crushed ice in an ice box. After additional aging at −1 °C to 48 ± 1 h post-mortem, meat was subsampled and stored at −80 °C until use. Meat subsamples from each animal (average 17.7 ± 0.5 g) were thawed in a fridge for about 4 h, diced into ∼1 cm^3 cubes, pooled with gentle stirring and minced using the chopper accessory of a Braun MR 4050 CA blender (Kronberg, Germany) according to the manufacturer's instruction for 12 × 2 s (<1 s pause in between). Ground meat was aliquoted, snap-frozen in liquid nitrogen to minimize freezing damage, and stored at −80 °C until use. The pH of the aged mince was 6.05, as measured directly by a HI 99163 meat pH meter (Hannah Instruments, Woonsocket, RI).

Meat Boiling. The design of the cooking method was based on the work of Deb-Choudhury et al.[6] with modifications. An aliquot of lamb meat mince was thawed at room temperature for 30 min, and then 0.6 ± 0.09 g (wet weight) of meat was transferred into a round-bottom flask and boiled at a meat to water ratio of 1:8 (w/v) for 10 or 240 min under reflux. The detailed method and the images of the cooking setup are shown in Supporting Information 1. For the control (raw meat without boiling), the setup was the same as described above except a room temperature oil bath was used and the "total heating" time (i.e., the period of time when the flask was in the oil bath) was 15 min. This 15 min period is roughly equal to the time meat and water spent in the heating source during the 10 min boiling, as it took around 1.9−2.9 min to raise water from room temperature to 100 °C in this study. Once the boiling time was reached, the flask was immediately placed in an ice−water bath for 10 min. After cooling, the bulk of meat surrounded by water during cooking and cooking water were carefully transferred to a glass centrifuge tube and centrifuged for 40 min at 10 840*g* at 4 °C. The supernatant (i.e., cooking water) was aliquoted and stored at −80 °C while the meat was subjected to protein extraction as described below. The control was treated with the same procedure as cooked samples.

Protein Extraction. Cooked meat was weighed, followed by soaking in urea−thiourea solution [7 M urea, 2 M thiourea, and 2% freshly added dithiothreitol (DTT)] at 1:16 ratio (w/v based on wet weight after cooking) for 5 min followed by homogenization in a hand-held, serrated pestle homogenizer over ice for four cycles of 1 min grinding and 10 s pause. The homogenates were shaken vigorously using a reciprocal shaker at room temperature for 1 h and then aliquoted and stored at −80 °C. For SDS−PAGE, the homogenate was centrifuged at 17 810*g* for 20 min at 15 °C and the supernatant (hereinafter termed "urea−thiourea extract") was used. Residues from meat homogenate (hereinafter termed "meat homogenate residue") were also obtained for proteomic analysis: 100 μL of the meat homogenate sample was centrifuged at 17 810*g* for 20 min at 15 °C. Supernatants were removed by aspiration. The remaining pellets were washed by vortexing in double deionized water twice, followed by one wash with methanol, and defatted with one wash of chloroform−methanol (2:1, v/v), based on the method of Kannamkumarath et al.,[12] and one wash with methanol. Pellets were dried in a vacuum centrifuge at 30 °C and then subjected to in-solution digestion with trypsin.

Protein was extracted from cooking water using a chloroform−methanol precipitation method based on the work of Wessel and Flügge.[13] The pellet was dried in a vacuum centrifuge at 30 °C and stored at −80 °C. Protein concentrations of cooking water samples and urea−thiourea extracts were estimated using a 2D-Quant kit (GE Healthcare Bio-Sciences AB, Uppsala, Sweden) according to the manufacturer's instruction. Protein from the cooking water of samples boiled 10 min was preconcentrated by the protein precipitation method before doing the assay to ensure a protein concentration above the detection limit of the kit.

SDS−PAGE. Urea−thiourea extract was mixed with SDS−sample buffer (93.8 mM Tris-HCl, 25% glycerol, 5% SDS, 0.01% bromophenol blue, pH 6.8, and freshly added 350 mM DTT) in 1:1.5 ratio (v/v) and shaken gently at 30 °C for 1 h. Samples were run on a 4−20% T precast gel (Bio-Rad, 133 × 87 × 1 mm) at a constant voltage of 200 V with current and power limits set to 80 mA (160 mA for two gels) and 15 W, respectively for 42 min. Each set of replicates was run on a separate gel. For preparative gel lanes used for GeLC, 100 μg of protein per meat sample was loaded in a well. For analytical gel lanes, 25 μg of protein per meat sample was loaded in a well. Protein fixation and gel staining and destaining procedures are described in Supporting Information 1. Gel images were taken using a Nikon D100 digital camera over a light box. Relative stain intensity across each analytical lane was estimated using ImageJ v1.45s (Rasband, National Institutes of Health).

Protein Digestion for LC−MS/MS Analysis. Each preparative lane was divided into nine sections of approximately equal length (Figures 2 and S1-5). Each gel section was split perpendicularly into two slices; one slice was used for a LC−MS/MS analysis, while the other was stored at −80 °C as a back-up. In-gel digestion was based on the method of Deb-Choudhury et al.[8] with modifications. The procedure is provided in Supporting Information 1.

For cooking water samples, protein (11 μg) extracted from a sample was sonicated in 10 mM of tris(2-carboxyethyl)phosphine hydrochloride (TCEP), 60 mM ammonium bicarbonate at a temperature below 25 °C (achieved by adding ice slurry in the sonication bath) for 10 min and then vortexed for 45 min at 37 °C to reduce the disulfide bonds. After returning to room temperature, the samples were alkylated in 25 mM (final concentration) iodoacetamide for 30 min at 25 °C under shaking. Alkylation was followed by incubation in 10 mM TCEP (final concentration) for 1 h at 25 °C under gentle shaking.

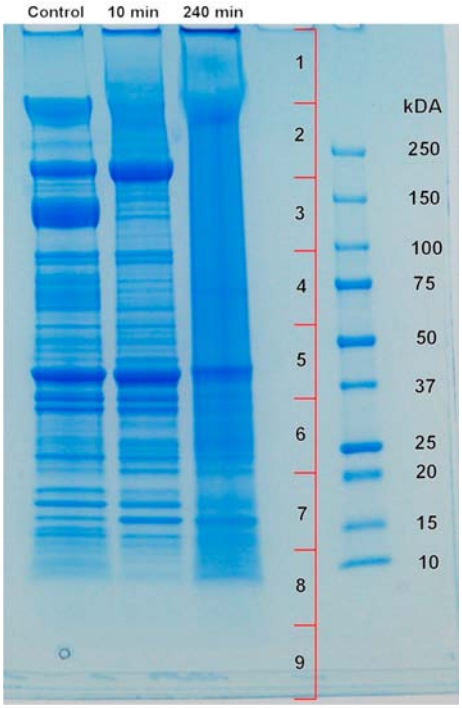

Figure 2. Representative analytical SDS−PAGE gel lanes of lamb meat protein extracts (from cooking replicate 1; refer to Supporting Information 2). Red marks on the right-hand side of the image indicate the approximate position of the gel sections from the preparative lanes sliced for proteomic analysis.

Samples were diluted by adding one volume of 50 mM ammonium bicarbonate, following by addition of 0.22 μg of trypsin. Acetonitrile was added to each sample to a final concentration of 10% (v/v). Digestion was performed at 37 °C with shaking overnight. Digests were centrifuged at 17 810*g* for 10 min at 15 °C. Around 200 μL of supernatant from each sample was dried in a vacuum centrifuge at 30 °C and stored at −80 °C until analysis. For meat homogenate residue samples, the dried pellet was sonicated in 10 mM of TCEP in 60 mM ammonium bicarbonate at a temperature below 25 °C for 10 min and then vortexed for 45 min at 37 °C. The rest of the in-solution digestion steps were as described above for the cooking water samples, except 1.25 μg of trypsin was used for digesting each pellet sample. The supernatant from each sample was dried in a vacuum centrifuge at 30 °C and stored at −80 °C until analysis.

Cooking Water Peptidomic (Undigested) Samples. To determine endogenous peptides from cooking water by LC−MS/MS analysis, 396 μL of each sample was acidified with 4 μL of formic acid (1% final concentration) and centrifuged in a 10 kDa MW cutoff spin column (Merck Millipore) at 13 800*g* at 4 °C. For the control and 10 and 240 min cooking samples, centrifugation was performed for 61−72, 38−44, and 56−68 min, respectively, to collect the bulk of the liquid phase. These different times were used because the filtering speed varied between the samples. The filtrate was dried down in the vacuum centrifuge at 30 °C and stored at −80 °C until analysis.

LC−MS/MS Sample Preparation and Conditions. For gel samples, the tryptic digest of each slice was resuspended in 50 μL of 2% acetonitrile/0.5% formic acid. The reconstituted samples were spun at 17 810*g* for 10 min at 4 °C. The supernatant was used for LC−MS/MS. Dilution was performed on the basis of stain intensity with 2% acetonitrile/0.5% formic acid as specified in Tables S1−2 and S1−3. For nongel samples, dried tryptic digests or cooking water peptidomic (undigested) samples were reconstituted in 2% acetonitrile/5% formic acid in a sonication bath kept below 25 °C for 5 min prior to vortexing. Reconstituted samples were centrifuged for 10 min at 4 °C at 17 810*g*. The supernatant was cleaned using a C18 material StageTip (Thermo Scientific) according to the established protocol,[14] except that more washing with 0.5% formic acid was applied. After drying in a vacuum centrifuge, the samples were reconstituted in 50 μL of 2% acetonitrile/0.5% formic acid using sonication and vortexing as described above. After 5 min of centrifugation at 4 °C and 17 810*g*, the supernatant was diluted with 2% acetonitrile/0.5% formic acid (1 in 4 for cooking water digested and undigested samples; 1 in 2 for meat homogenate residue sample) for LC−MS/MS.

LC−MS/MS was carried out as described by Yu et al.[15] with modifications. For a single LC−MS/MS run of each sample, 5 μL (out of 50 μL) was loaded on a C18 trap column (UHPLC Nanopeptide Trap Magic C18AQ, particle size 5 μm, pore size 200 Å, Bruker Michrom) at a flow rate of 5 μL/min. The trap column was switched in line with a reversed-phase analytical column (Intensity C18P UHPLC Nano Column, particle size 1.8 μm, pore size 100 Å, i.d. 0.1 mm, length 300 mm, Bruker Michrom). The loading and desalting solvent used was the same as mobile phase A (0.1% formic acid). The reverse-phase elution gradient was 2−45% mobile phase B (98% acetonitrile/0.1% formic acid) in 60 min at a flow rate of 400 nL/min at a column oven temperature of 60 °C. Between runs, the column was reconditioned by increasing mobile phase B to 95% in 2 min, holding for 3 min, and then bringing it down to 0% solvent B in 1 min. The column was equilibrated in 100% mobile phase A for 4 min.

Data Analysis. MS/MS spectra of each LC−MS/MS run were converted into a peak list in mgf format using DataAnalysis v4.1 software (Bruker).

Creation of a Small Sequence Database. Peak lists were searched against the combined *Ovis aries* sequence database[15] using a local Mascot server (Matrix Science) version 2.4. The search parameters, the peptide and protein score thresholds, are described in Supporting Information 1. All Mascot search results were compiled into a minimal protein list using the ProteinExtractor algorithm (Bruker Daltonics). All protein sequences (396 sequences, including keratins) from this list were retrieved to create a separate, shortlist database adapted for subsequent Mascot searches involving a higher number of variable modifications or no enzyme specificity.

Protein Identification. Briefly, two types of Mascot searches against the shortlist database were performed. One is the Percolator[16] (v1.14) postprocessed search, and the other is the standard Mascot search. Only a protein that was identified in a Percolator postprocessed search, as well as in the standard Mascot search of a single LC−MS/MS run, was accepted as identified. All entries with a name containing keratin were rejected. The two Mascot search approaches are described in Supporting Information 1. The accepted protein identifications and the number of their corresponding peptide identifications (peptide IDs), according to the standard Mascot search results, in each LC−MS/MS run are summarized in Tables S2-10−S2-13. The raw protein identification reports from which Tables S2-10−S2-13 were compiled are provided in Tables S2-14−S2-25.

Protein Modifications. Original, unmerged peak lists were searched against the shortlist database using the Mascot search approach for creating the shortlist database as mentioned above, but with the following changes: searches were performed against the shortlist database, and the MS/MS error tolerance was set to 0.4 Da. Furthermore, additional variable modifications (Table S1-4) divided into 16 groups (each group for one Mascot search) were included. These additional modifications are known potential heating and/or reactive oxygen species induced modifications. Not all of them may be well-suited for the MS/MS data acquisition setup used in the present study according to the literature, for example, Hex (K)[17] and the −1 Da allysine (K).[18] Peptide IDs carrying a modification of interest were manually evaluated as specified in Supporting Information 1. ProteinScape (Bruker Daltonics) annotated MS/MS spectra of the qualified peptides and their unmodified counterparts (defined in Supporting Information 1) are given in Supporting Information 3.

Estimation of Percent Non/Semitryptic Peptides. Peak lists corresponding to all the sections of a single gel lane were merged into one file. Peak lists were searched against the shortlist database using the standard Mascot search approach employed for protein identification. Estimation was based on a minimal list of accepted

peptide IDs compiled by ProteinScape, and the results are given in Tables S1-6 and S1-7.

Statistical Analysis. Paired *t* test (Analysis ToolPak on Microsoft Excel 2007) was used to support discussion of differences in numbers of protein identifications between control and a treatment. The statistical significance was set at $p < 0.05$.

RESULTS AND DISCUSSION

This study aims to improve the understanding of the effect of boiling, a commonly practiced cooking method, on the primary structure of lamb meat proteins using a shotgun proteomic approach. Meat and cooking water were separated after cooking. The meat was extracted in a urea−thiourea solution for the GeLC analysis, while the residue was washed with water and organic solvents for the direct LC−MS/MS analysis. The denaturing character of the urea−thiourea solution should solubilize most myofibrillar and sarcoplasmic proteins from raw meat. This was validated by the presence of the major sarcoplasmic and myofibrillar proteins, e.g., pyruvate kinase isozymes M1/M2 and myosin heavy chains, in the control urea−thiourea extract (Table S2−10). A GeLC approach has previously been utilized to characterize the lamb meat proteome from longissimus lumborum muscle.[15] The proteins and endogenous peptides from the cooking water were separately analyzed by direct LC−MS/MS. Peptide and protein identification was initially carried out by Mascot, a very widely used MS/MS data searching software, followed by stringent evaluation as described in the Materials and Methods and in the Data Analysis section of Supporting Information 1. The results are presented and discussed in terms of (1) change in proteomic profile and (2) protein primary level modifications characterized.

Proteomic Profile Change in Response to Boiling. *GeLC of the Meat Protein Extract.* The results showed that meat samples boiled for 10 min had the highest number of protein identifications, while boiling for 240 min resulted in the least, with an average difference of 65 proteins between the two treatments (Table 1). In total, 232 proteins were identified from the control and cooked samples under this experimental workflow (Table S2-10). The average number of protein identifications at 10 min boiling was significantly higher than that of 240 min ($p = 0.037$), but there was no difference with the control ($p = 0.225$). It is not surprising that the samples that underwent the harshest treatment had the lowest number of protein identifications, as also observed by Arena et al.[19] and Deb-Choudhury et al.[6] This is consistent with proteins becoming more resistant to trypsin digestion, due to arginine/lysine modifications or cross-linking/aggregation, and/or too modified or fragmented to be detected by an automatic MS/MS database search approach.

The SDS−PAGE profiles showed alteration in banding pattern between the short (10 min) and long (240 min) boiling times and the control (Figure 2; gel images for the other two cooking replicates are given in Figure S1-5). The overall banding patterns between replicates looked similar, although the protein mobility varied between the 42 min electrophoresis runs. The control and 10 min samples showed defined but somewhat different banding patterns, while the 240 min sample exhibited almost a smear above the 50 kDa marker. Five regions across the gel lanes (specified in Table S1-8) showed distinct changes in banding patterns in response to boiling. These changes, along with the potentially related GeLC results, are summarized in Table S1-8. Several water-soluble proteins, e.g., adenylate kinase 1 and β-enolase, were released into water during the control soaking, because many fewer peptide IDs from these proteins were found in the control as opposed to the 10 min boiling (Table S2-10). The reason is likely to be protein denaturation upon boiling resulting in reduced water solubility.

The overall results showed that the 240 min boiling potentially aggregates, polymerizes, and/or fragments several proteins, including the sarcoplasmic proteins L-lactate dehydrogenase A chain isoform 1 and glycogen myophosphorylase and the myofibrillar proteins TPM1, tropomyosin β-chain isoform 1, and α-actinin-2 and -3, as a greater number of peptides derived from these proteins were identified in the higher and/or lower molecular weight gel sections relative to their theoretical M_r (M_{rt}) than the control and 10 min samples (Table S2-10).

The giant myofibrillar protein titin was highly abundant in the control and 10 min samples according to the number of peptide IDs. The number greatly declined at 240 min boiling. The myosin light chain 1/3 (one of the myosin light chain isoforms) showed signs of truncation, whereas fast skeletal myosin light chain 2 exhibited signs of aggregation at 10 min of boiling, but at 240 min, both protein aggregation and fragmentation were observed (Table S2-10). Meat protein aggregation induced by cooking can involve both noncovalent and covalent binding. An increase in protein surface hydrophobicity due to thermal denaturation has been shown to play an important role in cooking-induced protein aggregation in meat.[3,20] Several types of cross-links have been shown to be implicated in aggregation of meat protein upon heating, including dityrosine, Schiff bases,[20] disulfide bridges,[3] and protein carbonylation.[21]

At 240 min of boiling, several bands remained relatively more defined. They were all found below the 50 kDa marker (Figures 2 and S1-5). Two of them are particularly distinguished: one had an M_r around 40 kDa and the other had an M_r of approximately 16 kDa. The results here as well as previous findings[15] suggest that one band is mainly creatine kinase M-type, skeletal muscle α-actin, and fructose-bisphosphate aldolase A isoform 1, whereas the other is myoglobin. Creatine kinase M-type and fructose-bisphosphate aldolase A isoform 1

DOI: 10.1021/acs.jafc.5b03324
J. Agric. Food Chem. 2015, 63, 9112−9123

seemed to be involved in the cooking-induced protein aggregation on account of their appearance in the higher molecular weight gel sections of the boiled samples. Actin and myoglobin appeared to be involved in both protein aggregation/polymerization and fragmentation at 240 min of boiling according to the GeLC results (Tables S2-10). There were also actin peptides identified in multiple gel sections in the control both above and below its M_{rt}, although to a noticeably lesser extent compared to the 240 min samples. This was probably associated with post-mortem actomyosin complex formation and proteolysis.[22] Wen et al.[23] found myosin light chain 3 and triosephosphate isomerase were more tolerant to cooking (up to 100 °C) than several other major meat proteins. While the former was not detected in the present study, the latter also seemed to exhibit relatively higher heat stability, because at 240 min the gel section(s) from the M_{rt} range of the intact protein contained similar numbers of the peptide IDs to those of the 10 min samples.

With regard to myosin heavy chains (M_{rt} ranging from 221 to 223 kDa), one of the most abundant meat proteins, the extent of involvement from boiling on their aggregation remains to be uncovered, because quite a few of their peptides were identified in the top gel sections, regardless of treatment (Table S2-10). It was recently shown that even in raw, fresh bovine LTL, four myosin heavy chain isoforms have been identified in a band above 600 kDa.[24] It is worth noting that the number of peptide IDs among control/cooked samples for some myosin heavy chain isoforms, e.g., myosin-8, varied greatly between replicates (Table S2-10). This may be caused by the protein inference issue in shotgun proteomics[25] due to the high amino acid sequence similarity among these proteins.

Protein aggregation has important implications for the food industry and the consumer. It has been shown to interfere with protein and peptide extraction processes and to reduce the sensitivity of meat protein to enzymatic proteolysis in some model studies.[26] The former can increase the production cost, whereas the latter might be related to retardation of protein absorption. On the other hand, aggregation can be manipulated to modulate gel formation and textural properties, which is essential in the making of comminuted meat products.[2] Identification of the protein species and modifications involved in aggregation via proteomic techniques can help better inform the control of such process-induced protein aggregation.

Cooking Water. Meat soup and stock are widely consumed globally. Hence, proteomic and peptidomic evaluation of the meat cooking water are of particular interest. The numbers of protein and peptide identifications in the proteomic (digested) samples were clearly higher than those in their corresponding peptidomic (undigested) samples (Tables 1 and S2-11 and S2-12). Boiling for 10 min gave the highest number of protein identifications in the digested samples but the least in the undigested samples, while the converse was true for the 240 min samples.

The proteomic (digested) results showed distinctly different protein profiles between the control and boiled samples (Tables 1 and S2-11). In the 10 min digested samples, the numbers of the identified sarcoplasmic proteins were clearly reduced compared to the control value. Type I collagen was the most abundant protein in terms of the number of peptide IDs, while type III collagen was not detected. The findings here agree with those of Burson and Hunt.[27] Although protocollagen strands are long, they are not known to aggregate.[28] This special characteristic is very likely attributed to the prevalence of proline and glysine residues in protocollagen, the two residues with the lowest propensity to form a β-sheet.[28] A number of cytoskeletal proteins, e.g., nebulin, titin, and myosin light chain isoforms but not myosin heavy chains and actin, also emerged at 10 min boiling. In the 240 min digested samples, myosin heavy chains appeared and became the most abundant protein. Actin also appeared at this time point. TPM1 and tropomyosin β-chain isoform 1 seemed to become more abundant in this fraction. The number of peptide IDs for myosin light chain isoforms did not vary much between 10 and 240 min of boiling. The undigested results strongly suggest that the backbones of six proteins consisting of sarcoplasmic, myofibrillar, and mitochondrial proteins have been cleaved upon prolonged boiling, because they were found in at least two replicates of the 240 min samples but not in those from control or 10 min samples (Table S2-12).

The protein concentrations in the control cooking water were much higher than those of the boiled samples (Table 2).

Table 2. Estimated Protein Concentrations of Cooking Water and Urea−Thiourea Extracts

		mean protein concentration (μg/μL, ±SD)	
treatment	n	cooking water	urea−thiourea extract
control	3	3.42 ± 0.39	8.67 ± 0.50
10 min boiling	3	0.07 ± 0.01	12.95 ± 0.49
240 min boiling	3	0.64 ± 0.11	10.97 ± 0.61

At 240 min the protein concentrations increased by about 7-fold of those in the 10 min samples. A similar trend was also found by Deb-Choudhury et al.[6] The higher protein concentrations observed in the control cooking water should arise from the water-soluble proteins (Table S2-11) extracted during the control cooking (see the Materials and Methods), where the raw mince was stirred in water at room temperature. The initial drop in protein content at short boiling time may be explained by the aggregation of water-soluble proteins according to the digested results. Curiously, the marked increase of peptide IDs derived from the myofibrillar proteins observed in the cooking water digested results of the boiling samples (especially at 240 min), but not the corresponding cooking water undigested results, might be explained by the peptide aggregation hypothesis proposed by Deb-Choudhury et al.[6] Taking myosin heavy chains as an example (Tables S2-11 and S2-12), myosin heavy chains are normally not water-soluble unless cleaved into peptides. If their heat-hydrolysis products were part of large soluble peptide aggregates, then they might suit the proteomic, rather than the peptidomic (undigested), approach better.

These cooking water results suggest that meat soups, broths, and sauces prepared by sustained periods of boiling will likely contain several major myofibrillar and connective tissue proteins as the main proteinaceous component and have a higher protein content than those prepared by short periods of boiling.

Meat Homogenate Residue. In this fraction, the total number of peptide IDs for the major meat connective tissue collagens, collagen α-1(I) chain, collagen α-2(I) chain, and collagen α-1(III) chain (Table S2-13), were noticeably higher than those found in the urea−thiourea extract (Table S2-10). These collagens were found in all replicates of control and 10 min samples but not in any of the 240 min samples. It is speculated that after 240 min of boiling, both type I and III

[d]Rounded to the first decimal place. [e]Charge. [f]Retention time. [g]Amino acid residue preceding the peptide sequence. [h]Amino acid residue following the peptide sequence. [i]"Counterpart" refers to an "unmodified" version of the modified peptide. Refer to the Data Analysis section of Supporting Information 1 for details.

collagens may have been severely hydrolyzed and/or modified. Curiously, more nebulin-derived peptides were found in the meat homogenate residue of the control and 10 min samples than in the corresponding urea−thiourea extracts. This did not happen to the highly abundant myofibrillar proteins, including myosin heavy chains, actin, and titin. The observation implies that the urea−thiourea solution is perhaps less effective in solubilizing nebulin.

All the proteins identified here can also be found in the urea−thiourea extract except three histones, 60S ribosomal protein, fibrillin-1, and pyruvate dehydrogenase E1 component subunit α (somatic form, mitochondrial). The peptide IDs of

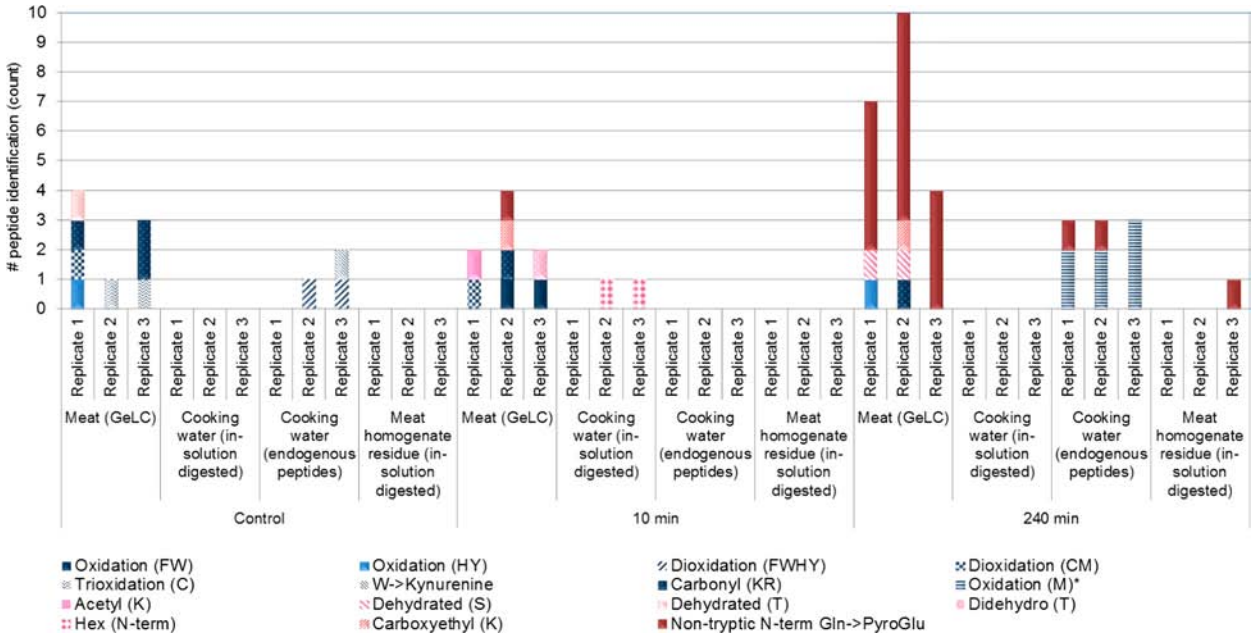

Figure 3. Relative numbers of observed modified peptides. *This modification was only investigated in the cooking water peptidomic (undigested) samples; the rationale is given in the Results and Discussion of the text.

many sarcoplasmic and myofibrillar proteins found in this fraction may originate from the proteins precipitated from the residue urea−thiourea extract during the pellet washing with water. This protein precipitation process might somewhat resemble the effect of thermal denaturation on the protein aggregation in cooked meat. Urea, as a chemical denaturant, disrupts hydrogen bonds, unfolds a protein's hydrophobic cores, and reduces ionic bonds between proteins,[29] but it generally binds weakly to proteins.[30] Therefore, the pellet washing step probably caused the partially folded intermediates to interact, similar to the process that results in formation of inclusion bodies during expression of recombinant proteins.[31] Thermal denaturation in proteins is generally linked to rupture of hydrogen bonds or electrostatic bonds, as well as an increase in protein surface hydrophobicity.[20] Exposure to the protein surface of hydrophobic amino acids may promote formation of noncovalently linked aggregates, as proteins can now stick together more easily.[26]

Heat-Induced Modifications. A summary of peptides observed with hydrothermally induced side-chain modifications (and detected only in the cooked samples) are presented in Table 3. The rest of the observed non-native peptides, including those observed in the control uncooked samples, are presented in Tables S2-26−S2-27. The relative numbers of observed modified peptides found are summarized in Figure 3.

GeLC of the Meat Protein Extract. Three peptides were identified with oxidative modification to aromatic residues resulting from heat treatment (Table 3). Two of these, with either a phenylalanine oxidation or a tryptophan oxidation (hydroxytryptophan), appeared to come from truncated proteins based on their observed positions of the gel sections.

The oxidation of aromatic residues has been shown to be associated with reactive oxygen species (ROS) attack.[10] Oxidation of phenylalanine has previously been reported in beef mince boiled in water,[6] while hydroxytryptophan and dihydroxyphenylalanine (DOPA) have both been identified in hydrothermally treated wool proteins.[10] Indeed, hydrothermal treatment has been found to be capable of inducing formation of certain ROS, such as the hydroxyl radical.[10] In addition, heating of ground meat in boiling water can cause the nonheme iron level to rise[32] and the nonheme iron can catalyze oxidative reactions.[33] Site-specific hydroxytryptophan formation has also been found previously to increase with heating in milk, another important dietary protein source.[34] Further, this study on milk suggested that this modification product can be unstable upon prolonged heating. The extent of tryptophan modification has been observed in some cases to depend on the amino acid microenvironment.[35] Oxidation of methionine (methionine sulfoxide) can sometimes occur during sample handling such as during in-gel trypsin digestion.[36] Therefore, in this study methionine sulfoxide was only considered as a modification of interest in the cooking water peptidomic analysis, in which the samples were handled at much lower temperature overall without the 37 °C incubation in ammonium bicarbonate, as performed in the proteomic analysis.

There were also oxidative modifications observed on other nonaromatic amino acid residues. Notably, cysteine trioxidation (sulfonic acid) was identified in two of the control replicates, whereas methionine double oxidation (methionine sulfone) was identified in one of the control replicates (Table S2-26). The latter was also found in one of the 10 min cooking replicates. Meltretter et al.[34] have detected the site-specific cysteine-derived sulfonic acid formation in raw, defatted milk, but its level was found to increase significantly when the samples were heated at 99 °C. The authors also detected methionine sulfone at a specific methionine residue in the raw milk, and its level was found to remain stable during the heating (at 99 °C up to 23 min).[34] Indeed, meat mincing,[37] freeze−thaw,[38] and the subsequent sample handling may all expose the meat protein to oxidation.

Carbonylation of lysine[39] was observed in both the control and boiled samples. Curiously, it did not seem to prevent trypsin cleavage (Table S2-26). A background level of oxidized protein has been previously observed in raw meat.[3,21] Formation of 2-amino-3-ketobutyric acid from a threonine residue[40] (didehydro of threonine) was also here identified in

DOI: 10.1021/acs.jafc.5b03324
J. Agric. Food Chem. 2015, 63, 9112−9123

one of the 10 min samples. Notably, N^{ϵ}-carboxyethyllysine (CEL) was detected at 10 min heating and also at 240 min heating. CEL and N^{ϵ}-carboxymethyllysine (CML) are common AGEs that have been found to increase steadily with heating time and heating temperature in ground beef under pasteurization conditions.[7] However, CML was not identified in the present study.

One semitryptic peptide (a "semi-tryptic" peptide is a peptide that was cleaved at the C-terminal side of arginine or lysine at one end but not the other), L.SDGEWQLVLNAWGK.V, with a nontryptic cleavage at the N-terminus and a dehydrated serine (serine-derived dehydroalanine) at the N-terminal residue was identified exclusively at 240 min cooking time. Protein and peptide backbone hydrolysis have been observed in hydrothermally aged wool fabric[41] and dry-heat-stressed buserelin peptide,[42] respectively, whereas the formation of serine-derived dehydroalanine has been detected in heated β-casein solutions.[43]

Cyclization of N-terminal glutamine to pyroglutamic acid (N-terminal Gln → pyro-Glu) tryptic peptides was observed (Tables S2-14−S2-16 and S2-23−S2-25). This is not unexpected, since the conditions of trypsin digestion have been shown to promote this cyclization process.[44] However, semitryptic peptides and cooking water endogenous peptides containing this modification were also found in the cooked samples, primarily at 240 min boiling (Figure 3). In addition, the majority of these peptides were cleaved at the C-terminal side of aspartic acid residue (Table 3). Heating alone has been found to cause N-terminal pyroglutamic acid formation in the tripeptide Gln-Leu-ProNH_2 in 50 mM Tris-HCl buffer (pH 7).[45] Site-specific cleavage at the C-terminal side of aspartic residue has been shown to occur when heating the solid sample of the peptides/lysozyme for 10 s to a final temperature of 220−250 °C under atmospheric condition, and a hydrolysis mechanism via a cyclic intermediate was proposed.[46] Taken together, the results suggested that prolonged boiling is capable of introducing protein cleavage and probably also causing N-terminal Gln → pyro-Glu.

Cyclization of N-terminal glutamic acid to pyroglutamic acid (N-terminal Glu → pyro-Glu) has been detected in one of the control replicates (Table S2-28). Chelius et al.[47] have reported that N-terminal Glu → pyro-Glu can take place in vitro at fairly mild temperatures and is pH-dependent. By contrasting with the study of Dick et al.[44] on N-terminal Gln → pyro-Glu formation, it appears that N-terminal Glu → pyro-Glu occurs much more slowly at similar temperature and pH. This likely explains why much fewer tryptic peptides with an N-terminal Glu → pyro-Glu were detected in the present study.

With regard to the levels of semitryptic peptides, which can be used to reflect the extent of hydrothermal protein backbone hydrolysis,[41] the 240 min samples had a higher average figure compared to the control and the 10 min samples (Figure 4). Fully nontryptic peptides, in comparison, were scarce in number (three or less per cooking replicate) regardless of treatment (Table S1-6), with no clear trend observed among the samples.

Cooking Water. In the cooking water digested samples, one peptide with both a deamidated asparagine residue and a +162 Da modification at the nontryptic N-terminal residue was exclusively identified in the 10 min boiling samples (Table 3). The annotated MS/MS spectrum for this peptide is shown in Figure 5. This mass increase is consistent with the heat-induced

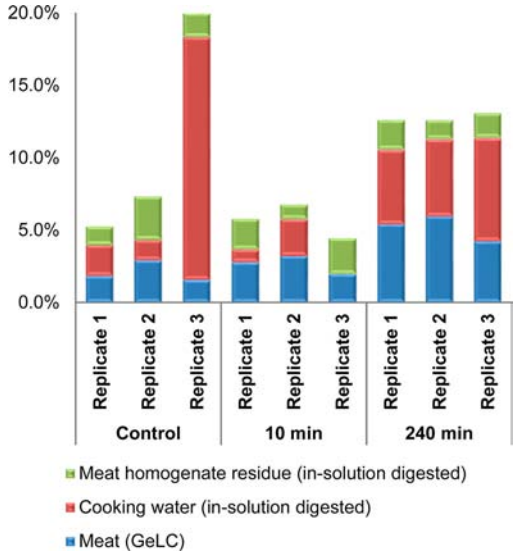

Figure 4. Percentage of semitryptic peptide identification in the proteomic (digested) samples. Please note that the values obtained from different experimental workflows for each cooking replicate are independent of each other and do not necessarily add up to 100%.

formation of glucose-derived Amadori compound, an early-stage Maillard glycation adduct.

The level of semitryptic peptides is shown in Figure 4. No marked difference in proteomic profiles was found between the control replicates (Table S2-11). The proportion of semitryptic peptides in the control and 10 min boiling samples were similar (except one outlier in the controls; its higher level of nontryptic cleavages might be associated with certain endogenous proteolytic system(s) in meat[48,49] that could be at work during the "control cooking" process and the subsequent centrifugation) while the 240 min boiling appeared to generate a distinctly higher proportion of semitryptic peptides.

One particular peptide from myoglobin was observed to undergo progressive truncation in the course of boiling (Table 3):

R.NDMAAQYKVLGFQG.- (exclusively in controls) →
N.DMAAQYKVLGFQG.- (10 and 240 min samples) →
D.MAAQYKVLGFQG.- (10 and 240 min samples).

Protein cleavage occurred at the C-terminal side of aspartic acid and asparagine. C-terminal side cleavage at aspartic acid was also found in the urea−thiourea extracts of the cooked meat, as already discussed. Methionine sulfoxide and modification of the N-terminal Gln → pyro-Glu were observed after 240 min boiling (Table 3).

Physical properties (e.g., texture, color, and flavor) as well as the nutritional value of meat can be affected when the primary structure of meat proteins is altered.[50] For example, an increase in meat protein oxidation has been associated with lower water-holding capacity and a decrease in protein solubility, whereas some studies showed that protein oxidation contributes to the increased gel-forming ability.[4] Modification of the essential amino acid residues (tryptophan, phenylalanine, threonine, lysine, and methoinine) observed in this study after cooking will affect the nutritional value of the meat. This issue is particularly important for amino acids that are already present in relative lower abundance in meat, e.g., tryptophan. In addition, certain modifications of the residues used by a pancreatic protease as cleavage sites, e.g., the lysine → CEL characterized here, result in miscleavage of the proteins and

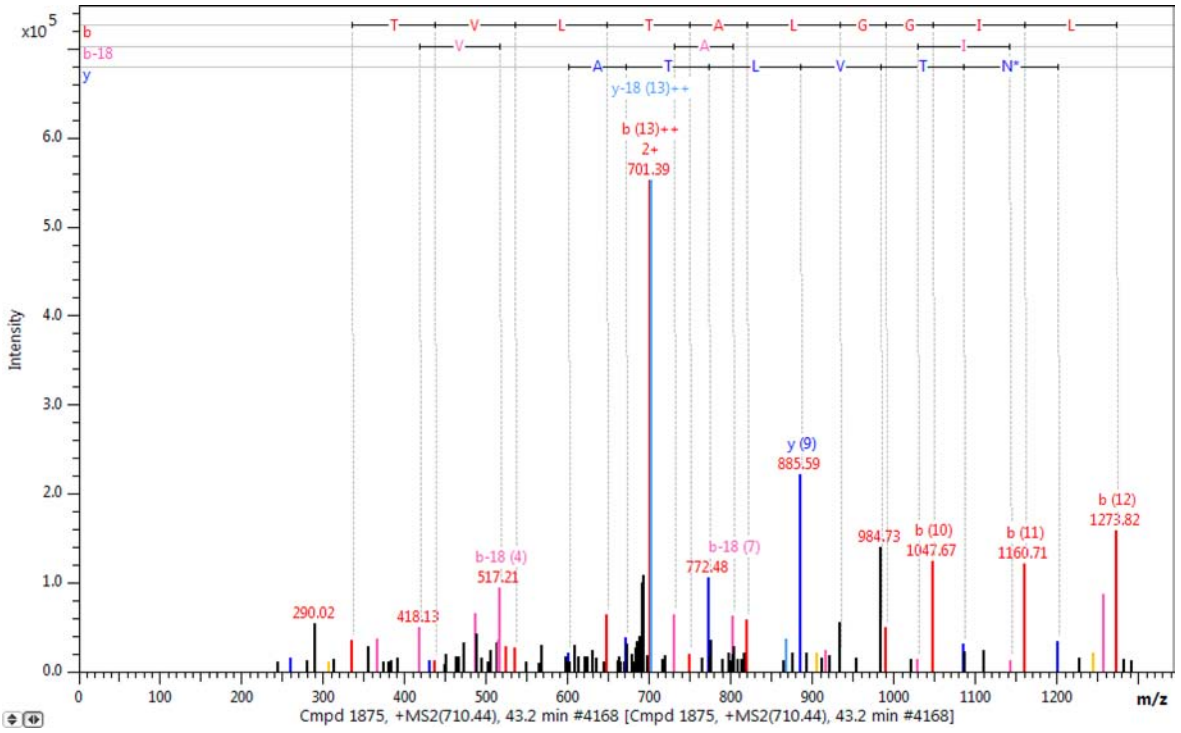

Figure 5. ProteinScape annotated MS/MS spectrum showing a hexose glycated N-terminus from one of the two 10 min boiling samples where the peptide was detected.

may compromise their bioavailability. On the other hand, in a competing process, production of smaller peptides through heat-induced backbone cleavage may facilitate the absorption of proteins.

Meat Homogenate Residue. Fewer potential heat-modified peptides were detected in this fraction compared to the urea–thiourea extract and the cooking water (Table 3). This may imply the presence of higher levels of protein cross-links and/or arginine and lysine modifications. In one of the control replicates, a tryptic peptide with N-terminal Glu → pyro-Glu was identified (Table S2-28). In the boiled samples, the modification Gln → pyro-Glu at a nontryptic N-terminus was observed after 240 min boiling.

Future work utilizing alternative sample preparation (e.g., employing Glu-C for protein digestion) and MS/MS approaches (e.g., electron transfer dissociation or using a high-resolution instrument) could help identify more modified peptides. In addition, technical replicates can be implemented to further increase the certainty on the identification of the amino acid residue level modifications that have not been observed in all the control or boiling replicates (Figure 3).

In summary, this study has generated new knowledge and insights into the molecular-level modifications occurring in lamb meat proteins during boiling, through a detailed proteomic and peptidomic evaluation. The modifications characterized provide a good basis for better understanding the effect of this common food processing and preparation method on the nutritional and functional properties of red-meat-based foods.

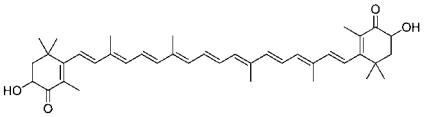
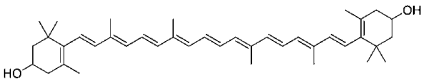
(d) *β*-Carotene (*β*-Car)



(e) Astaxanthin (Ast)



(f) Zeaxanthin (Zea)

(Beijing, China). Purified water was prepared using a Milli-Q Academic Water Purification System (Millipore Corp., Billerica, MA).

Electroformation of GUVs. GUVs were prepared using an electroformation method with certain modifications.[17] Briefly, the cell used for GUV preparation consisted of two indium tin oxide (ITO) glass substrates separated by a Teflon spacer with a thickness of ~3 mm. The PC reagent was dissolved in chloroform at a concentration of 4 mg/mL. Chl *a* was predissolved in methanol and used as the photosensitizer. *β*-Car and Lyc predissolved in chloroform and Zea and Ast predissolved in methanol were used as antioxidants. The final molar ratio of PC reagent and Chl *a* was 100:1, and the final molar ratio of PC reagent and each individual carotenoid was 200:1. The solutions were deposited on one of the conductive surfaces of ITO glass substrates and then dried in vacuum for 2 h. About 2.5 mL of 100 mM sucrose solution was injected into the cell, which was afterward sealed using silicone grease. Alternative electrical fields from a Rigol DG1022U function generator (Rigol Technologies, Beijing, China) were applied to the cell to generate a turbid GUV suspension with a volume of approximately 2.5 mL.

Optical Microscopy and Digital Image Processing. The experimental setup for fluorescence microscopy was described elsewhere.[13] Briefly, 200 *μ*L of liposome suspension was added to a Costar 24-well cell culturing cluster (Corning Incorporated, Corning, NY), which was fixed on the translational stage. Light radiation in 400−440 nm from an ultrahigh-pressure mercury lamp was used for excitation with a power of 0.81 mW and was focused on an area with a diameter of 80 *μ*m. A band-pass filter (500−570 nm) was used to minimize the fluorescence emission from Chl *a*. Liposome images were collected every 1 s, and each GUV preparation was measured independently for at least 30 times. GUVs unsensitized with Chl *a* were used as a blank, whereas sensitized GUVs without antioxidant added were used as a control. Evaluation of the liposome physical integrity was performed using digital image processing on the basis of heterogeneity.[18,19] Briefly, raw images were digitized into 16-bit grayscale format with an area of 100 × 100 pixels selected as region of interest (ROI). The 16-bit grayscale intensity interval was divided into 256 subintervals by default. Histogram counts (p) over these subintervals were used to calculate the entropy, defined as $E = -\sum p \log_2 p$, which was used as a statistical scalar for measuring the heterogeneity.[19] The budding process of GUVs was characterized by entropy change (ΔE) with reference to the average entropy at minus delay time, i.e., before light irradiation.[13]

RESULTS AND DISCUSSION

The blank soybean PC GUVs used as a membrane model were found resistant to light exposure (400−440 nm) because no change in GUV morphology was observed. Incorporating Chl *a* (Scheme 1) as a photosensitizer made them sensitive to light exposure as evidenced by the fast increase in entropy and budding (Figures 1−3), which could be quantified using the entropy change ΔE defined in the Materials and Methods.[13] It is seen in Figures 1 and 2 that ΔE increased immediately upon light exposure for control and Chl *a*-sensitized GUVs with *β*-Car. In contrast, Lyc, Zea, and Ast, each added separately, induced a significant lag phase for the increase of ΔE. The spatial arrangement of the GUVs as a model for membranes is depicted in Scheme 2. In this scheme, Chl *a* as a hydrophobic molecule lies in the interior of the lipid bilayer together with hydrophobic Lyc (or *β*-Car), while Ast (or Zea) with polar substituents to ending rings anchors in the water/lipid interfaces.

Three effects on the budding process resulting from photosensitization may be identified from the temporal evolution of ΔE during light exposure, as results from the addition of each individual carotenoid investigated (Figures 2 and 3): (i) Lyc, Zea, and Ast each, in contrast to *β*-Car, resulted in a significant lag phase, during which ΔE was essentially unchanged. (ii) The ΔE increasing rate after the lag phase decreased upon incorporation of each individual carotenoid, especially for the case of Ast. (iii) The final level of heterogeneity was found similar for Ast and Zea, both similar to the control, but for *β*-Car and Lyc, the levels were found to be comparable and significantly lower.

The length of the lag phase increased in the order of control < *β*-Car < Lyc < Zea < Ast as most clearly seen from Figure 3. Notably, Zea and Ast are both xanthophylls with hydrophilic groups (Scheme 1). Xanthophylls are known to be anchored in the water/lipid interfaces of membranes resulting in the decrease of the membrane fluidity,[12,20] and such effects may be important in the initial protection against photosensitized oxidation and result in a lag phase (*vide infra*).

The rate of ΔE increase following the initial lag phase obeys another ordering than the length of the lag phase: Ast < Lyc < *β*-Car < Zea < control (Table 1). Ast accordingly

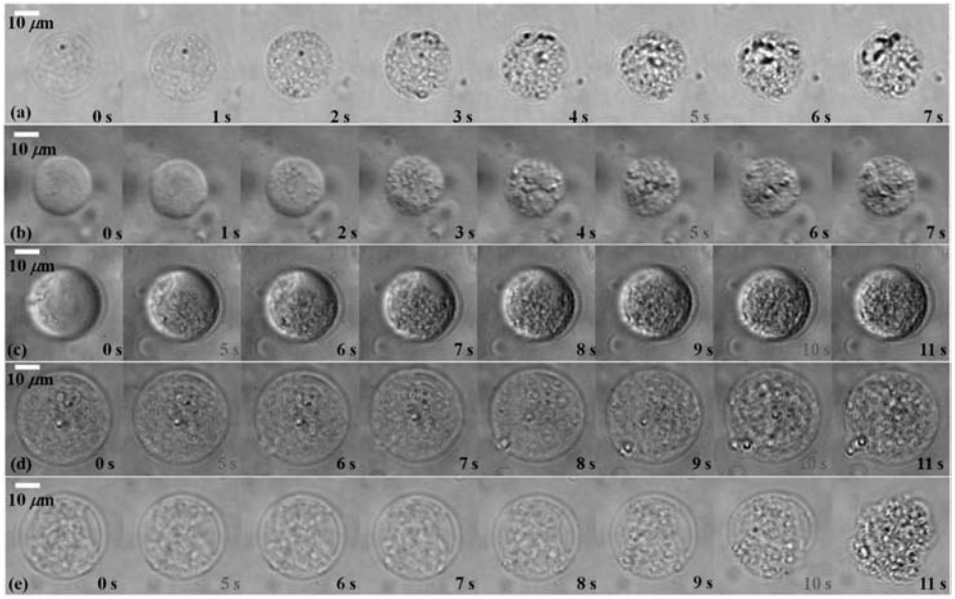

Figure 1. Images of Chl *a*-sensitized GUV samples exposed to light (400−440 nm, 160 mW/mm^2) for an indicated time at room temperature: (a) control, (b) *β*-Car, (c) Lyc, (d) Zea, and (e) Ast added.

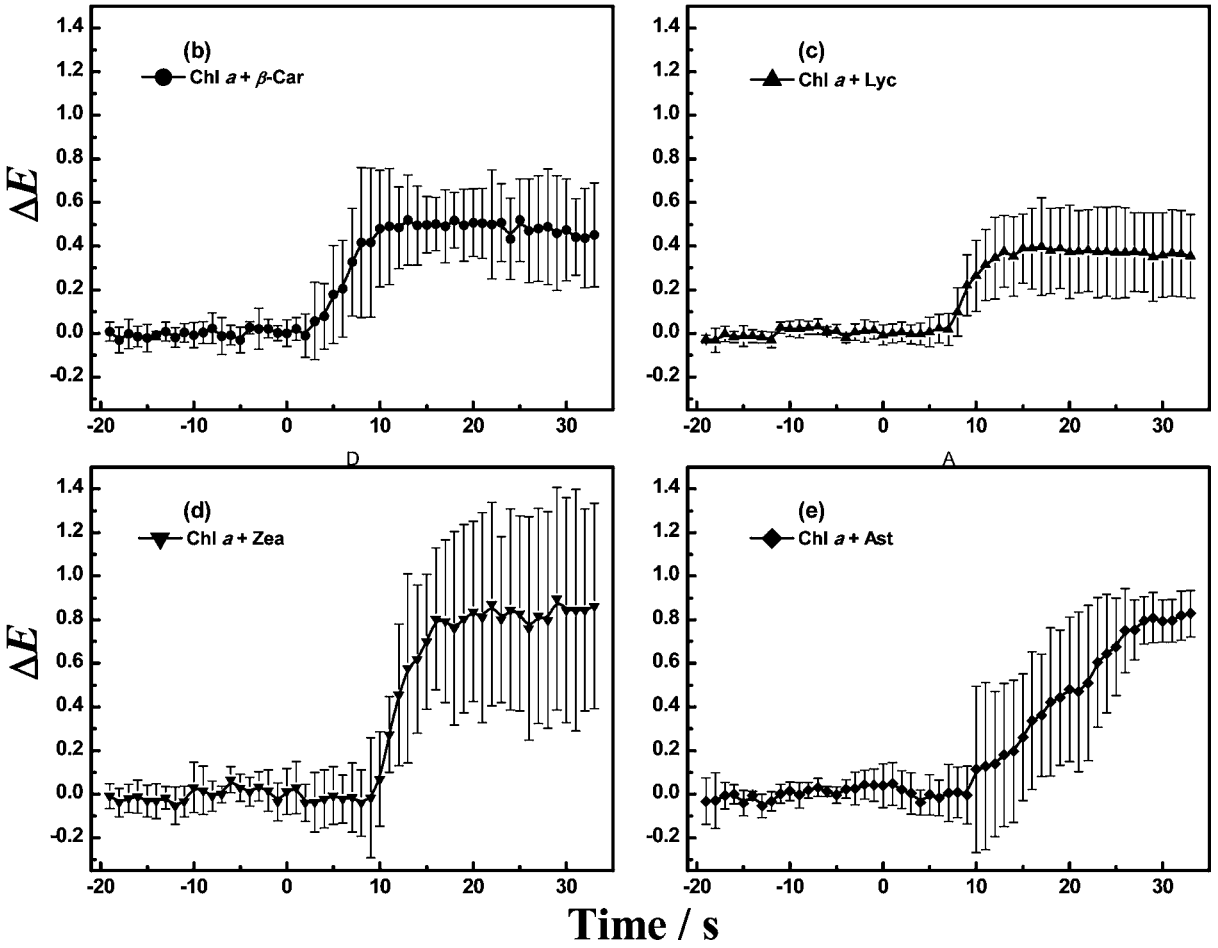

Figure 2. Δ*E* as a metric of image heterogeneity versus time for budding of Chl *a*-sensitized GUVs with the addition of individual carotenoid exposed to light (400−440 nm, 160 mW/mm^2). For control, see Figure 3. Statistics: mean ± standard deviation (SD) (n = 6).

both induces the longest lag phase and results in the slowest Δ*E* increasing rate, while Zea, which also induces a long lag phase as a xanthophyll, yields little protection during the subsequent development of Δ*E* (Table 1). Notably, the two carotenes, Lyc and *β*-Car, have comparable Δ*E* increasing rates.

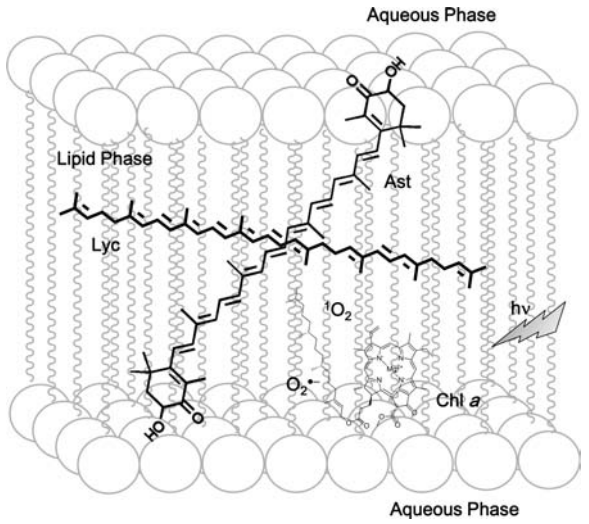
Scheme 2. Ast and Lyc in a Liposomal Membrane[a]



[a]Membrane thickness is approximately 4 nm.

Table 1. Lag Phases, Initial Rates, Final Levels (ΔE_∞), and Area under Curve (AUC) of $\Delta E/t$ Evolutions for Each GUV Preparation[a]

sample (n = 6)	lag phase (s)	initial rate (s^{-1})	ΔE_∞	AUC (au)
control	0.15	$(165 \pm 13) \times 10^{-3}$	0.90	29
β-Car	1.8	$(75 \pm 5) \times 10^{-3}$	0.46	14
Lyc	7.3	$(65 \pm 6) \times 10^{-3}$	0.37	8.9
Zea	7.8	$(121 \pm 9) \times 10^{-3}$	0.82	17
Ast	8.9	$(40.4 \pm 1.3) \times 10^{-3}$	0.80	12
Ast + β-Car	14	$(18.3 \pm 0.9) \times 10^{-3}$	0.32	6.7
Ast + Zea	17	$(10.3 \pm 1.7) \times 10^{-3}$	0.24	3.2
Ast + Lyc	26	$(52 \pm 4) \times 10^{-3}$	0.30	2.2

[a]AUCs were calculated from the end of lag phases until 31 s for GUV preparations with incorporating single carotenoids or until 40 s for those with combined carotenoids added.

The final level of heterogeneity was quantified as both the final value for ΔE and the area under the $\Delta E-t$ curve in arbitrary units after the lag phase, which are compared in Figure 3 and Table 1. The GUVs with Lyc and β-Car are seen to yield the best protection as evaluated by the final level of heterogeneity. GUVs with Ast and Zea both reach approximately the same final levels of heterogeneity as the control.

Two factors seem to control the pattern of protection of GUVs against budding. One could be related to the decreased fluidity of membranes of GUVs as resulting from incorporation of Ast or Zea. Chl *a*, as a photosensitizer, may operate through two mechanisms as outlined in Figure 4.[21] Type II

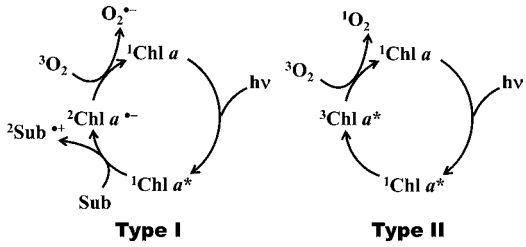


Figure 4. Type I and type II photosensitization by Chl *a*.[16]

photosensitization will yield singlet oxygen $^1O_2$, which will diffuse from Chl *a* with a rate depending upon the fluidity of the membrane in competition with quenching. The $^1O_2$ quenching rates are comparable for the four carotenoids in homogeneous solutions (Table 2), and hence, the other factor

Table 2. Second-Order Rate Constant, k_2, for Quenching of Singlet Oxygen by Carotenoids in Benzene and in Unilamellar Liposomes, Standard Reduction Potential for Carotenoid Radical Cation versus NHE, $E°$, in Dichloromethane, Electron Acceptor Capacities, R_a, and Electron Donor Capabilities, R_d, All at Room Temperature

	k_2 (L mol^{-1} s^{-1})				
carotenoid	benzene[a]	liposomes[a]	$E°$ (V)[b]	R_a[c]	R_d[c]
β-Car	1.3×10^{10}	2.3×10^{10}	0.84	0.46	1.40
Lyc	1.7×10^{10}	2.4×10^{10}	0.81		
Zea	1.6×10^{10}	2.3×10^{10}	0.85	0.49	1.44
Ast	1.1×10^{10}	5.9×10^{9}	0.97	0.94	2.10

[a]From ref 22. [b]From refs 25 and 26. [c]From ref 24.

may be important in controlling the oxidation of the phospholipids by $^1O_2$.[22] Tentatively, the longer lag phases seen for Ast and Zea relative to Lyc and β-Car may be assigned to a decrease in the rate of diffusion as a result of the decreased fluidity of the membrane by anchoring of Ast and Zea in the membrane surface. A lower diffusion rate will delay the oxidation of the phospholipids at the lipid/water interface but will not prevent the formation of the hydroperoxides that result in a final increase in ΔE and budding. The second factor could be related to the electron-accepting capability of Ast. Ast is the least reducing among the four carotenoids (Table 2). It has a high electron-accepting capability, as provided by quantum chemical calculations, and has been suggested to oxidize the superoxide radical anion

$$\text{Ast} + O_2^{\bullet-} \rightarrow \text{Ast}^{\bullet-} + O_2$$

in contrary to most other carotenoids.[6,23] Chl *a* may operate partly through a type I mechanism for photosensitization, resulting in the formation of radicals (Figure 4). $O_2^{\bullet-}$, when produced in the membrane, many react with Ast but not Zea or the carotenes like β-Car and Lyc. This could explain

DOI: 10.1021/acs.jafc.5b03658
J. Agric. Food Chem. 2015, 63, 9124−9130

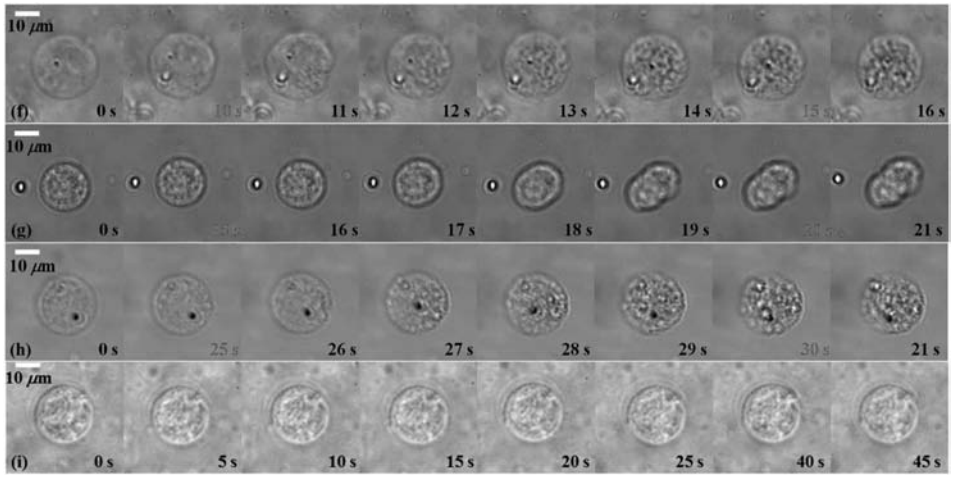

Figure 5. Images of Chl *a*-sensitized GUV samples exposed to light (400−440 nm, 160 mW/mm^2) at the indicated time at room temperature: (f) *β*-Car and Ast, (g) Zea and Ast, (h) Lyc and Ast, and (i) unsensitized blank GUVs.

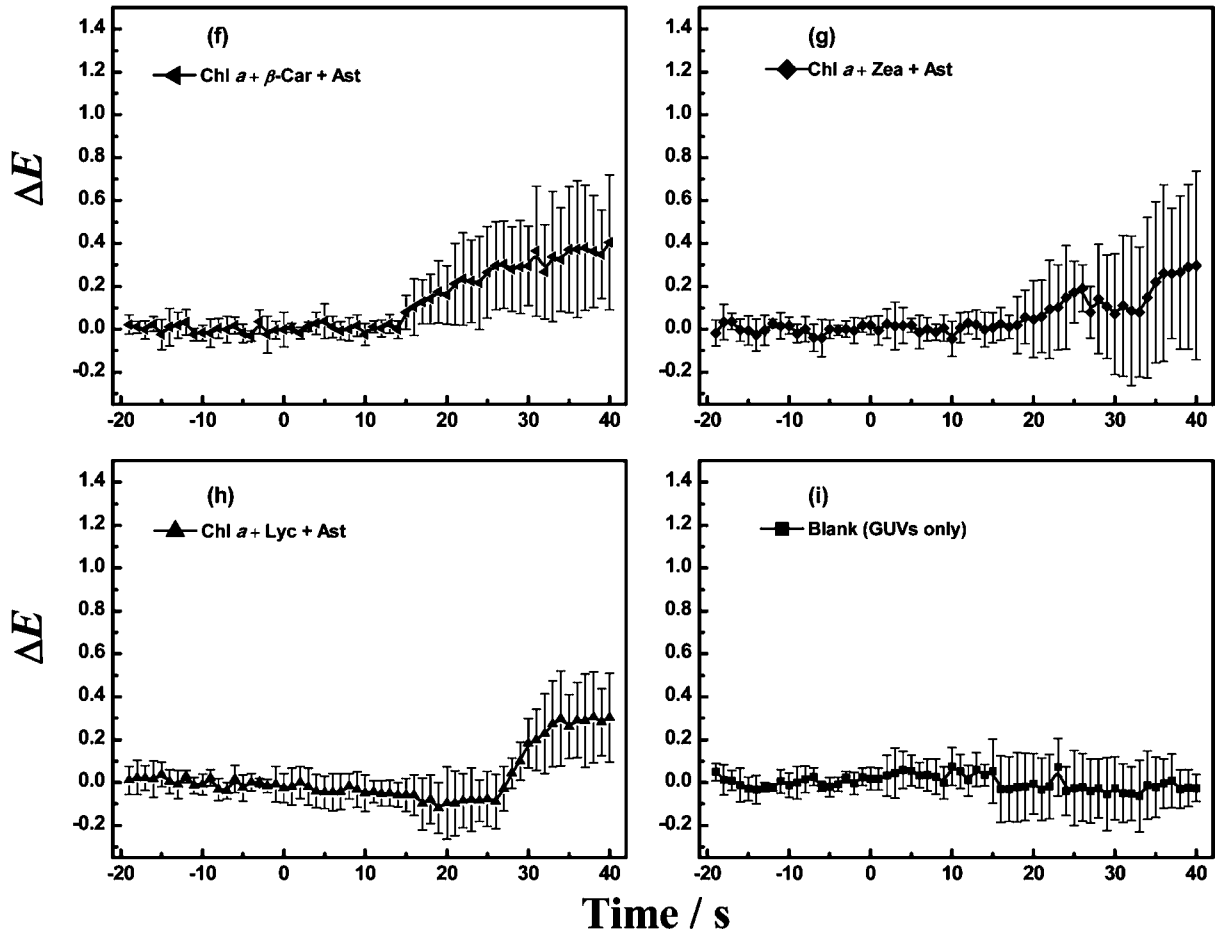

Figure 6. Δ*E* as a metric of image heterogeneity versus time for budding of Chl *a*-sensitized GUVs with the addition of combined carotenoids and blank GUVs exposed to light (400−440 nm, 160 mW/mm^2). Statistics: mean ± SD (n = 6).

the decreased rate in the development of Δ*E* following the lag phase as seen for Ast but not for the other three carotenoids. What still remains to be explained is, however, the higher final level of Δ*E* for Zea and Ast compared to *β*-Car and Lyc. It may be the result of another type of process not directly related to the type I and type II photosensitized oxidation but involving reduction of an initially formed radical precursor to peroxides by the more reducing Lyc and *β*-Car but not by Ast and Zea to give the lowest values for final Δ*E*

$$\text{Lyc} + \text{R}^{\bullet} + \text{H}^{+} \rightarrow \text{Lyc}^{\bullet +} + \text{RH}$$

The combination of Ast with each of the three other carotenoids clearly showed synergetic effects, which may help to explain in more details the complex pattern of reactions Figures 5 and 6. Ast combined with Lyc resulted in the longest

DOI: 10.1021/acs.jafc.5b03658
J. Agric. Food Chem. 2015, 63, 9124−9130

lag phase and also the lowest level for the final heterogeneity. The combination of the most reducing and the most oxidizing carotenoid seems optimal for protection of the membrane against photosensitized budding and disintegration. Apparently, the longer lag phase is the result of a decrease in the rate of $^1O_2$ diffusion from type II photosensitization by Chl *a* via anchoring of Ast, while the lower level for final heterogeneity is the result of reduction of hydroperoxides by the strongly reducing Lyc. The combination of Ast and *β*-Car shows a similar protective effect, confirming that a carotenoid with a high electron-accepting capability together with another carotenoid with a strong electron-donating capability results in prominent synergistic effects (Figure 7). Carotenoids have

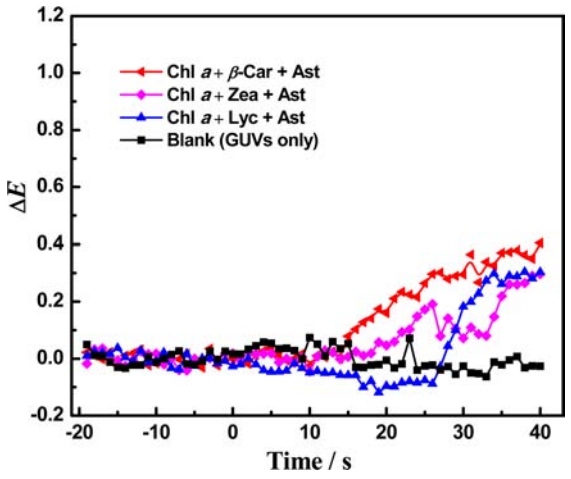

Figure 7. Comparison of time evolution of Δ*E* as a metric of heterogeneity for budding of Chl *a*-sensitized GUVs with combined carotenoids and blank GUVs. The time evolutions are from Figure 6. For clarity, error bars are not shown.

both the capability for electron donation and for electron acceptance depending upon their structures.[24−26] Most carotenoids are good electron donors, but the conclusion from the present study seems to be that combination of carotenoids being good electron donors with those being good electron acceptors like Ast may yield the optimal protection against photosensitized degradation of membranes. The use of GUVs for the study of oxidative processes in membranes is promising because spatial aspects of oxidation may be understood on the basis of the distribution of Chl *a* as a photosensitizer located in the lipophilic interior and potential antioxidants with distribution depending upon their hydrophilic/lipophilic balance (Scheme 2).

has been reported in tobacco products such as cigarettes[10] and chewable tobacco mixtures including other plant material such as betel leaf.[11] Exposure to aflatoxins in cigarettes may be mitigated by their potential destruction in the combustion process;[12] however, aflatoxins present in a smokeless product are likely to be introduced into the body via ingestion.[13]

AFB_1 has traditionally been detected in commodities by use of HPLC with fluorescence detection,[14] with HPLC-MS/MS and UHPLC-MS/MS methods becoming more common.[15−17] The use of mass spectrometry for AFB_1 detection is not new,[18] but advances in these technologies have resulted in methods for AFB_1 with limits of detection (LOD) in the low parts per trillion (ppt) range.[15] In this study, we have developed and validated a method for the determination of AFB_1 in smokeless tobacco products and applied it to the analysis of a selection of smokeless tobacco products commercially available in the United States. Although our method was optimized for AFB_1 detection and quantitation, we have also validated it for detecting and quantifying aflatoxins B_2 (AFB_2), G_1 (AFG_1), and G_2 (AFG_2). To ensure the highest possible degree of specificity and sensitivity toward AFB_1 measurement, we employed immunoaffinity chromatography (IAC) to selectively bind AFB_1 from product sample extracts and UHPLC-MS/MS with $^{13}C_{17}$-labeled internal standards for detection.

MATERIALS AND METHODS

Samples, Standards, and Reagents. Reverse osmosis deionized water, HPLC grade solvents, and high-purity reagents were used throughout. Stock solutions of AFB_1 (2.0 ng/μL) as well as the internal standard $^{13}C_{17}$-AFB_1 (0.5 ng/μL) in acetonitrile were purchased (Romer Laboratories, Union, MO, USA) and stored at −20 °C, from which calibrators were made as needed. Internal standard (100 μL) was diluted into 1900 μL of acetonitrile to generate a solution of 12.5 pg/μL. 2S3 Kentucky Reference Moist Snuff (University of Kentucky, College of Agriculture, Lexington, KY, USA) was used as a matrix for blanks, calibrators, and quality control (QC) samples. A convenience sample of 32 commercially available smokeless tobacco products was acquired by purchasing products at the retail point-of-sale in the Washington, DC, USA, and Atlanta, GA, USA, metropolitan areas in 2013. The convenience sample consisted of 12 loose moist snuffs, 4 pouched moist snuffs, 6 dry snuffs, 7 chewing tobaccos, and 3 snus. A total of 17 product brands produced by 8 manufacturers were sampled. Tobacco products purchased in the Washington, DC, area were shipped to CDC at room temperature, arriving within 48 h following shipment. Products were inventoried and then stored at −70 °C until further use.

Sample Preparation. Tobacco products stored at −70 °C were first transferred to a −20 °C freezer for 1 h and then allowed to acclimate to room temperature. Once at room temperature, an entire retail package (i.e., tin, pouch, etc.) of each product was weighed to determine its fresh weight. Products were then dried for at least 10 h at 55 °C. After drying, the products were reweighed to obtain a dry weight. The difference between the two values was then used to determine the relative moisture (i.e., oven volatiles) content (%) of the products. The dried products were next milled to a fine powder under liquid nitrogen by use of a model 6770 cryomill (SPEX Sample Prep, Metuchen, NJ, USA). The resulting powder was then thoroughly mixed to ensure uniform distribution, and 2 g aliquots (± ≤0.0015 g) were weighed out in 15 mL polypropylene centrifuge tubes (Becton Dickinson, Franklin Lakes, NJ, USA). This process was also performed on the reference smokeless tobacco product used as the matrix for blanks, calibrators, and QC samples. Aliquots of the reference smokeless tobacco product were then amended with 40 μL of the $^{13}C_{17}$-AFB_1 and AFB_1 to generate 10 calibrators (0.005, 0.010, 0.020, 0.050, 0.100, 0.200, 0.500, 1.000, 2.000, and 5.000 ppb), and 3 QC samples (0.07 ppb (low), 0.21 ppb (medium), and 0.7 ppb (high)). Test samples were also amended with 40 μL of the $^{13}C_{17}$-AFB_1 internal standards. Ten milliliters of 80:20 methanol/water solution and 0.2% Tween 20 (Fisher, Fair Lawn, NJ, USA) was then added to the blank, calibrator standards, and samples, and they were capped and sealed with parafilm and extracted for 4 h on a rotary mixer set at a 45° angle at 30 rpm. After extraction, the tubes were transferred to a centrifuge equipped with a swing-bucket rotor and centrifuged at 3700 rpm for 10 min to separate the tobacco samples from their respective extraction solutions. The clarified sample extracts were then transferred to new 15 mL polypropylene centrifuge tubes and stored overnight at 4 °C.

IAC Column Cleanup. Samples were first allowed to come to room temperature if previously refrigerated. The samples were diluted (1 mL of sample in 4 mL of water, 0.2% Tween 20), loaded onto an Aflatest WB immunoaffinity column (Vicam, Milford, MA, USA) and allowed to elute via gravity. The IAC column was then washed once with 10 mL of methanol/water (20:80, v/v) and 0.2% Tween 20, followed by 10 mL of methanol/water (20:80, v/v). Analytes were finally eluted with 1.0 mL of acetonitrile into 13 × 100 mm level 2 borosilicate silanized glass collection tubes (Kimble Chase, Vineland, NJ, USA). The collection tubes were then transferred to a Savant SpeedVac Plus SC210A rotary vacuum concentrator (Thermo Fisher, Asheville, NC, USA) and evaporated to dryness under gentle conditions (drying rate set to low). The samples were next reconstituted with 400 μL of methanol/water (60:40, v/v) and transferred to 2 mL autosampler vials with a PTFE/silicone septa for UHPLC-MS/MS analysis.

UHPLC-MS/MS Analysis. Our UHPLC-MS/MS system consisted of an Acquity I-Class Binary Solvent Manager, an Acquity I-Class Sample Manager, and an Acquity I-Class Column Compartment coupled to a Waters Xevo TQ-S tandem quadrupole mass spectrometer (Waters, Milford MA, USA). The UHPLC-MS/MS was controlled by Acquity UPLC Console Software 1.51.3347 and MassLynx Software 4.1 (Waters). Analytes of interest were separated using a 100 × 3 mm, 2.7 μm particle Supelco Ascentis Express C_{18} column (Supelco Analytical, Bellefonte, PA, USA) with a 0.5 μm × 0.004 in. i.d. KrudKatcher Ultra HPLC in-line filter (Phenomenex, Torrance, CA, USA). A gradient consisting of water with 0.1 mM ammonium formate (solvent A) and 99:1 methanol/water with 0.1 mM ammonium formate (solvent B) at a constant flow rate of 1.0 mL/min was used. The solvent gradient program was as follows: 0 min, 40% B; 1.0 min, 55% B; 1.25 min, 100% B; 1.75 min, 100% B; 2.0 min, 40% B; 2.5 min, 40% B. The injection volume used was 10 μL. The column temperature was maintained at 70 °C. MS/MS transitions (m/z) for AFB_1 were as follows: 313.32 → 241.22 (quantitation); 313.32 → 285.08 (confirmation); 330.37 → 301.09 ($^{13}C_{17}$-labeled internal standard). Global mass spectrometer settings were as follows: capillary voltage, 3.5 kV; cone voltage, 75 V; source offset voltage, 50 V; source temperature, 150 °C; desolvation temperature, 650 °C; cone gas, nitrogen (600 L/h); desolvation gas, nitrogen (600 L/h); collision gas, argon (0.20 mL/min); nebulizer gas, nitrogen (6.00 bar). Analytes were quantified by interpolation of peak area ratios of the analyte over its $^{13}C_{17}$-labeled internal standard for MS/MS transitions against a 10-point calibration curve ($1/x$ weighting).

Validation. QC samples were prepared at three distinct concentrations levels across the calibration range. QC samples were generated for each run via direct spiking of blank reference tobacco. All QC samples were run at the beginning and end of each analysis batch. Data from the first 20 independent runs (days) were used to establish the QC limits as part of a multirule procedure for determining whether instrument runs were in or out of control.[19] QC samples were also used for determining the recovery of the method, extraction efficiency, and other validation tests as indicated. The within-run and between-run coefficients of variation from the 20 day duplicate analysis of the three QC samples were also used to assess within-run and between-run imprecision, respectively.

Method robustness was tested by varying the solvent extraction conditions from the proposed method to different percentages of water and methanol (30:70 and 10:90, v/v) as well as by varying the mass of tobacco extracted from the method from 2 to 1 or 3 g. The robustness of the IAC step was also tested by varying the volume of

sample extract loaded on the IAC column and the volume of solvent used to elute the analytes as well as substitution of the IAC column specified in the method with similar IAC column products. In all cases seven replicates of the test condition were performed on a single day.

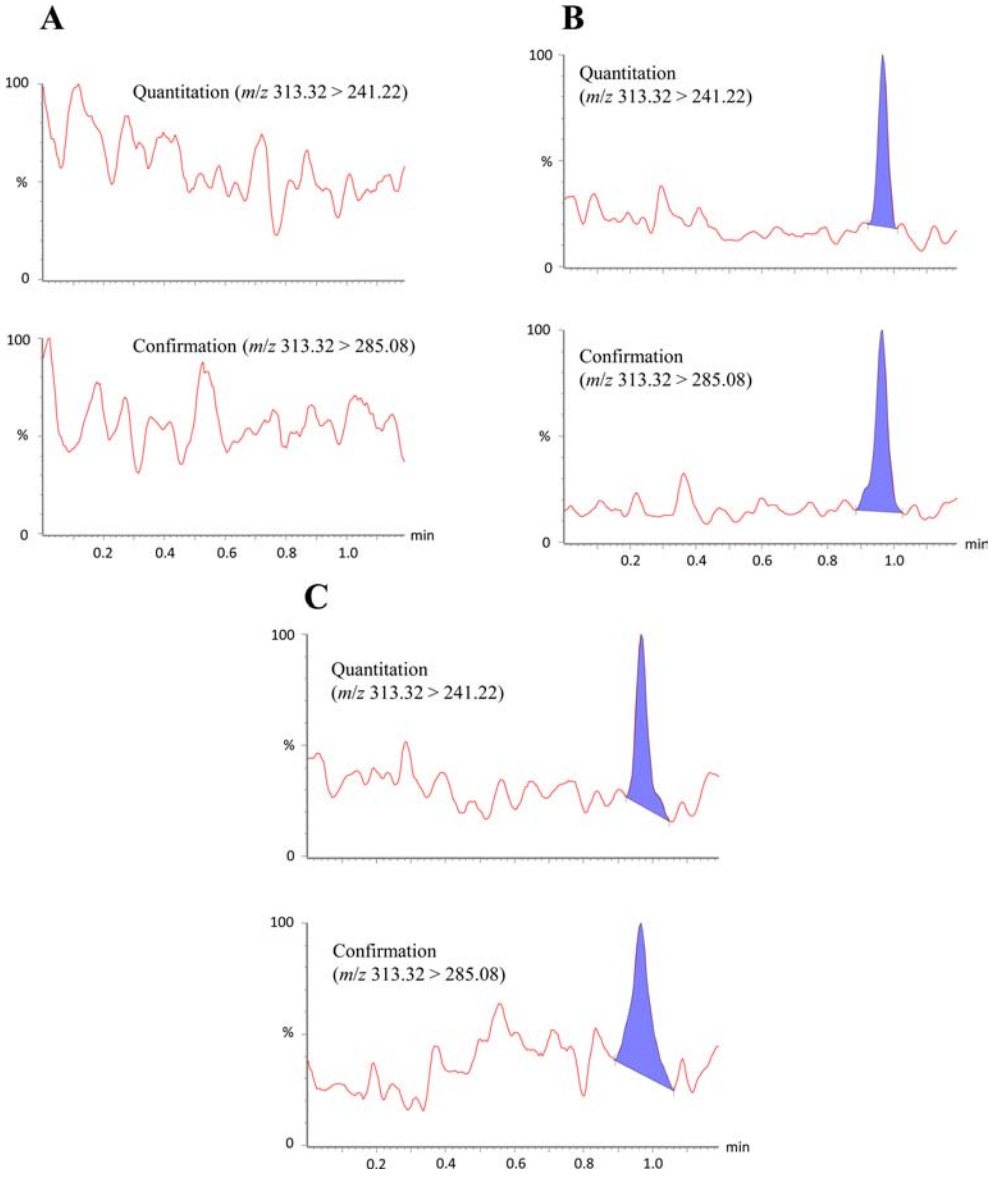

Figure 4. Sample MS/MS AFB_1 (**1**) chromatograms: (A) reference tobacco blank (2S3 Kentucky Reference Moist Snuff); (B) low QC sample (2S3 Kentucky Reference Moist Snuff spiked with 0.07 ppb of AFB_1); (C) commercial smokeless tobacco product (endogenous concentration of 0.007 ppb AFB_1).

LODs were determined by performing repeat measurements in samples spiked with concentrations near the LOD. By plotting the standard deviation of these samples as a function of concentration, an estimate of the standard deviation at a concentration of zero (σ_0) was obtained by extrapolation, and the LOD was calculated as $3\sigma_0$.[20]

Product Analysis. A minimum of seven replicate measurements were made on each commercial product tested. Each replicate consisted of an independent sample that was prepared and run on a different day. QC samples and calibrators were prepared and analyzed in duplicate, bracketing the product samples in the analysis sequence. Calibrations were determined as the average from these duplicate injections. Run performance was determined by comparing QC values from each run versus acceptance rules determined from QC limits.[19]

RESULTS AND DISCUSSION

Method Development and Optimization. We infused a standard of AFB_1 and were able to generate a mass spectrum dominated by a $[M + H]^+$ molecular ion of m/z 313.2, with evidence of a $[M + Na]^+$ adduct at m/z 335.16. Similarly, we found a $[M + H]^+$ molecular ion of m/z 330.21 and a $[M + Na]^+$ adduct at m/z 352.19 when infusing the $^{13}C_{17}$-AFB_1 internal standard (Figure 2). Using the $[M + H]^+$ molecular ion as our precursor ion for both the standard and internal standard, we observed predominant MS/MS fragment product ions at m/z 241.29, 269.12, and 285.10 for AFB_1 and at m/z 255.32, 284.50, and 301.15 for $^{13}C_{17}$-AFB_1. After optimizing the MS/MS parameters for each of the fragments, we selected m/z 313.32 → 241.22 for AFB_1 quantitation, m/z 313.32 → 285.08 for AFB_1 confirmation, and m/z 330.37 → 301.09 for internal standardization with $^{13}C_{17}$-AFB_1. These transitions were selected because they represented the best available choices in terms of signal intensity, signal-to-noise ratio, and blank baseline in the chromatographic method, and the product ions did not appear to be the product of nonspecific losses (e.g., H_2O, NH_3). Our selection of the m/z 313.32 → 241.22 transition for AFB_1 quantitation is consistent with its use in other LC-MS/MS methods.[16,21,22] Using an analogous approach we also identified quantitation and confirmation

Chromatographic separations based on C_{18} stationary phases have frequently been used in LC-MS/MS methods for aflatoxins.[16,23] After testing a sampling of C_{18} columns as well as other stationary phases, we decided upon a fused-core C_{18} column for our method. Using this column and a methanol/water gradient with 0.1 M ammonium formate, we were able to develop a separation that resolved AFB_1, AFB_2, AFG_1, and AFG_2 in <1 min (Figure 3) with performance optimized for AFB_1 quantitation and confirmation (Figure 4). Using our QC sample data, we found that the average retention time for AFB_1 was 0.94 min and varied by <2% CV over 15 days. Our selection of a fused-core particle stationary phase over traditional porous particles proved to be advantageous in that it allowed us to perform the chromatographic separation at a relatively high flow rate (1 mL/min) with very high peak resolution while still operating at the lower end of LC pressures (~450 bar). This relatively low operating pressure permits the possible adaptation of our method beyond UHPLC systems to midpressure HPLC systems capable of operating pressures of up to 600 bar.

Because smokeless tobacco products can occur in a variety of heterogeneous forms, we dried and cryogenically milled all products prior to analysis to generate homogeneous, powdered samples that were of similar consistency across all product types. The drying step also enabled us to determine the moisture content (i.e., oven volatiles) of the products as part of the sample preparation process as opposed to performing a separate moisture determination. Our drying conditions for the smokeless tobacco products (55 °C, >10 h) differed from those typically used for determining moisture content (100 °C, 3 h).[24,25] We evaluated our drying step for possible aflatoxin losses by calculating analyte recoveries based on the addition of the internal standard both before and after the drying step. We observed quantitative recovery in replicate analyses (n = 5) of a dry snuff product with ~0.3 ppb of endogenous AFB_1 present, as well as samples of 2S3 Kentucky Reference Moist Snuff to which a net concentration of 0.7 ppb of AFB_1 was added. Although our testing of a selection of smokeless tobacco products dried at 100 °C did not show any noticeable aflatoxin losses, we decided to dry products at 55 °C as a more conservative approach. We also observed no differences in the moisture content determinations of several smokeless tobacco products performed under both drying conditions.

We used a methanol/water extraction followed by IAC column cleanup to isolate aflatoxins from smokeless tobacco samples. Our extraction methodology is similar to that developed for analyses of aflatoxins from corn, peanuts, and peanut butter (AOAC Method 991.31).[26] In optimizing the extraction step we found that acetonitrile/water mixtures[14] were as effective as methanol/water mixtures in terms of analyte recovery; however, we decided to use a methanol/water extraction as it was consistent with the IAC column manufacturer recommendations as well as other published methods.[26] The use of IAC, or a comparable postextraction cleanup technique such as SPE, was necessary to analyze the tobacco extracts for AFB_1. Attempts that we made to perform direct analyses on the tobacco extracts without a postextraction cleanup step resulted in complete suppression of all analyte and internal standard signals. We also found that the use of a surfactant was essential to the IAC process to mitigate nonspecific binding. When we omitted the surfactant from the IAC process, we frequently encountered discoloration and clogging of the IAC column bed. In addition to IAC, SPE has been used for postcolumn cleanup of aflatoxin extracts.[15,27] We tested an SPE substrate used for determining aflatoxins, but in our application we were unable to attain SPE recoveries as high as those we observed with IAC (~70% recovery for SPE vs ~100% for the IAC). In light of the apparently better analyte recovery and the specificity and selectivity inherent to the immunoaffinity process, we decided to use IAC over SPE in our method.

Through the course of method development, we noted steps in the sample preparation process that were particularly susceptible to analyte losses with the potential to greatly affect analyte recovery and overall method performance. First, we observed that aflatoxins were susceptible to apparent binding during the dry-down and reconstitution step if untreated borosilicate glass was used versus silanized glass. When using untreated borosilicate glass tubes, we found that analyte recoveries were ~5% lower in acetonitrile samples and ~70% lower in methanol samples than when silanized glass was used with either solvent type. Consequently, we used acetonitrile and silanized glass for all dry-down steps. Second, we observed that prolonged exposure to air during the dry-down step resulted in analyte losses, presumably to oxidation. In dried samples that were exposed to air, we found that ~95% of aflatoxins were lost after 8 h, with complete loss occurring after 72 h. By comparison, we observed no analyte losses in dried samples that were purged with nitrogen and capped for the same time frame. For this reason, care had to be taken to perform the dry-down step under gentle conditions and promptly reconstitute the dried samples to minimize analyte losses due to oxidation.

Method Validation. We prepared QC samples for each run at three levels (low, medium, and high) to track instrument run

control as well as to perform certain aspects of method validation. The QC pools were assigned target values and uncertainty limits by duplicate analysis over 20 days. These data were also used to determine method imprecision for AFB_1 (Table 1). Between-run imprecision for AFB_1 was 4.5–8.4% and within run imprecision was 4.4–6.0%, depending on the QC level. Overall imprecision of the method was 5.5–9.4%. Recovery of the target amount in our QC samples was generally within 10% of being quantitative (100%), ranging from 105 to 111%.

The LOD of our method is estimated to be 0.007 ppb for AFB_1. Although direct comparison of LODs among different methods is not straightforward because of differences and/or missing details in how LODs were calculated, we believe that our detection limit of 0.007 ppb for AFB_1 is among the lowest of comparable LC-MS/MS methods. For instance, Huang et al.[15] demonstrated a LOD of 0.009 ppb for AFB_1 in peanuts by LC-MS/MS. An LOD in the low parts per trillion range is beneficial, as our method can be used not only for potential regulatory level investigation work, which is typically in the parts per billion range, but also for characterization of products at much lower AFB_1 concentrations.

We examined the confirmation ratio, that is, the peak area of the confirmation MS/MS transition divided by the area of the quantitation MS/MS transition, for AFB_1 across all calibrators and QC samples during the 20 day characterization period. The confirmation ratio was 1.03–1.04 with a CV of <10% at concentrations ≥0.07 ppb (the target concentration of the low QC). At concentrations of <0.07 ppb the CV of the ratio gradually increased to ∼20% at 0.02 ppb and to ∼30% at 0.01 ppb.

We investigated method robustness by identifying five critical method parameters and evaluating the effect of intentionally varying these parameters on QC sample results. The variables we investigated were the volume of sample extract loaded onto the IAC, elution volume from the IAC, extraction solvent composition, mass of tobacco extracted, and IAC type. We performed seven replicates of each test condition on a single day and compared these results with those obtained from the 20 day characterization. When we increased the volume of sample extract loaded on the IAC column from 1 to 2 mL, the accuracy and precision of the AFB_1 and AFB_2 results appeared to be unaffected; however, AFG_1 and AFG_2 recoveries in the low pool appeared to be slightly lower. We found that decreasing the volume of extract loaded on the IAC column to 0.5 mL resulted in apparent higher imprecision for all aflatoxins, and in some cases a spurious effect on recovery of the pool target value was observed. Changing the extraction composition or the IAC products did not appear to have an appreciable effect on the accuracy or precision of the QC analyses. We observed that reducing the amount of tobacco in the extraction from 2 to 1 g did not seem to affect AFB_1 but resulted in lower recoveries for AFG_2. Increasing the amount of tobacco to 3 g frequently resulted in the extraction tubes cracking during the centrifugation step. Altering the volume of elution solvent used, as well as substituting different IAC products, did not appear to have much effect on the QC values.

Product Analyses. We first determined the moisture content of the loose moist snuff, pouched moist snuff, dry snuff, snus, and chewing tobacco products selected for our analyses. We observed that dry snuffs were generally <5% moisture by weight, chews were ∼20% moisture, snus were ∼30% moisture, and moist snuffs were ∼50% moisture (Table 2). Our moisture determinations were generally consistent with the expected values for these product classes reported in the literature.[5,28]

Using our LC-MS/MS method, we then analyzed samples of the selected smokeless tobacco products for AFB_1 and reported these data as the mean concentration found in the dry product (n = 7–9, depending on the product) (Table 2). We observed that AFB_1 concentrations were less than our method LOD of 0.007 ppb in all of the loose moist snuff, pouched moist snuff, and snus products we tested. All of the dry snuff products and a majority of the chew products (5 of 7) we tested had detectable concentrations of AFB_1. The dry snuffs had the highest AFB_1 concentrations among all product types we tested, with the

DOI: 10.1021/acs.jafc.5b02622
J. Agric. Food Chem. 2015, 63, 9131–9138

highest mean AFB_1 concentration among the dry snuffs tested being 0.271 ± 0.051 ppb. By comparison, the highest concentration of AFB_1 we observed among the chew products tested was approximately an order of magnitude lower (0.029 ± 0.002 ppb). For two chew products we tested different lot numbers of the same product to gain insight into within-product variability (Table 2). We observed a high degree of variability among the two lots tested for one of the chew products (chew 1, 0.029 ± 0.002 vs 0.013 ± 0.002 ppb), whereas the other product (chew 2) showed much closer agreement among tested lots (0.015 ± 0.003 vs 0.016 ± 0.002 ppb).

Overall, the concentrations of AFB_1 we found in the smokeless tobacco products we surveyed were much lower than the 20 ppb regulatory limit typical for foods and feeds.[1] We did not detect AFB_2, AFG_1, or AFG_2 in any of the smokeless tobacco products we tested. AFB_1 concentrations tend to be higher than other aflatoxins when contamination is present, and given the AFB_1 concentrations we detected were already in the parts per trillion range, it is not surprising that we did not detect any other aflatoxins. Furthermore, the LODs for AFB_2 (0.01 ppb), AFG_1 (0.02 ppb), and AFG_2 (0.1 ppb) with our method were higher than that of AFB_1 (0.007 ppb).

Interpretation of our findings is not straightforward. First, although we were able to confirm the presence of AFB_1 in several smokeless tobacco products, we have no way to identify the source of the AFB_1 contamination. Although AFB_1 contamination can occur directly in tobacco leaves,[8,9] it is also possible that AFB_1 contamination found in a smokeless tobacco product may result from an additive. For example, heavy casings, such as molasses, licorice, and fruit extracts, that are added during processing are potential sources of AFB_1 contamination. The amounts of these additives can be significant, such as in chewing tobacco, where added sugar content is typically 35%.[5] Conversely, the absence of AFB_1 in many of the smokeless tobacco products we tested may also be due to additives introduced during processing, such as the addition of sodium propionate as a fungicide. Additives raising the pH of smokeless tobacco products as a means of increasing nicotine potency may also affect AFB_1 concentrations.[5] Second, we noted with interest that the smokeless tobacco products with the lowest moisture content (dry snuffs) had the highest AFB_1 concentrations, whereas we were unable to detect AFB_1 in any of the products with the highest moisture content (moist snuff). This seems counterintuitive, as from a simplistic standpoint we would expect moisture encountered in storage to contribute to higher aflatoxin concentrations, and suggests to us that the mechanism by which AFB_1 contamination is introduced into smokeless tobacco products is much more complex. Finally, the potential health effects of AFB_1 in a smokeless tobacco depend not only upon the amount of AFB_1 present but also on the different ways in which a smokeless tobacco product can be used. This may be particularly important in the case of dry snuffs, as not only did we observe the highest AFB_1 concentrations in these products, but it is also the only class of smokeless tobacco product we tested that is used both orally and nasally. Even among smokeless tobacco products that are strictly used orally, product class and cultural practices can determine whether a product is used for minutes versus hours and consequently influence potential AFB_1 exposure.[5]

We believe that our work has two key strengths: we believe it to be the first published report of an LC-MS/MS method specifically designed for determining aflatoxin concentrations in tobacco products and that the data we present are also the first published survey of AFB_1 concentrations in a subset of smokeless tobacco products commercially available in the United States. We do acknowledge, however, that there are limitations to our work that warrant further investigation. Although we were able to apply our method to a variety of smokeless tobacco products (moist and dry snuffs, snus, chews), there exist other product classes that we did not test (e.g., dissolvables, "sticks"), and these products may not be amenable to our procedure without modification and additional validation. We were able to identify a reference smokeless tobacco product (2S3 Kentucky Reference Moist Snuff) that was free of detectable aflatoxin and successfully used it as a matrix for blanks, calibrators, and QC samples. The availability, however, of a reference material with a detectable endogenous concentration of AFB_1 would be beneficial as it could potentially be used as a QC material without the need for analyte spiking and could possibly be developed as a positive AFB_1 reference material. We were successful in using the IAC process to isolate AFB_1 from the complex sample extracts with a great degree of specificity; however, this process was performed manually in our study and was time-consuming. Automating the IAC process as well as other steps in the sample extraction process should be investigated in the future as a means of improving sample throughput.

introduced into the market by BioFront Technologies (Tallahassee, FL, USA). The kit claims include targeting a thermally stable antigen, assay specificity, 0.3 ppm sensitivity, and good recovery (>85%) from spiked samples. We were interested in assessing the kit specificity, sensitivity, and robustness. Included in these investigations were (a) laboratory-prepared ingredients and foods, (b) commercially processed and sold foods with declared and undeclared pistachio presence, (c) pistachio seed/flour and pistachio-containing foods/matrices exposed to select food-processing methods in the laboratory, and (d) commercial and laboratory-prepared foods spiked with known amounts of pistachio proteins.

MATERIALS AND METHODS

Materials. Dehulled raw pistachio seeds, food ingredients, and commercially processed foods were purchased from local grocery stores and restaurants and were processed as needed as earlier described in detail by Tiwari et al.[18] The MonoTrace pistachio ELISA kits were purchased from BioFront Technologies (Tallahassee, FL, USA). Sources of chemicals, reagents, supplies, and instruments have been reported earlier.[20]

Methods. *Pistachio Seed Processing.* Dehulled whole pistachio raw seeds were processed as follows.[21]

1. Pressure cooking in a SterileMax benchtop autoclave (Barnstead International, Inc., Dubuque, IA, USA) at 121 °C, 15 psi, for 15 and 30 min. Autoclaved samples were air-dried at room temperature (~25 °C) in a fume hood until constant weight.

2. Blanching in boiling water (94 °C) for 5 and 10 min. The ratio of nut seeds to water was 1:10 w/v. Samples were patted dry on paper towels and further air-dried at room temperature in a fume hood until constant weight.

3. Frying in Crisco vegetable oil at 191 °C for 1 min. Excess oil was allowed to drain completely on paper towels prior to further handling.

4. Microwave heating in a Panasonic microwave oven (Sears, Roebuck and Co., Hoffman Estates, IL, USA) at 50% (500 W) and 100% power (1000 W) for 3 min.

5. Dry roasting at 140 °C for 30 min and at 168 °C for 12 min. Samples were placed in aluminum pans and subjected to roasting in a TempCon oven (American Scientific Products, McGaw Park, IL, USA) previously heated to the desired temperatures and monitored using a thermometer.

Kaju Roll. Kaju roll is a sweet, popular in India, made by rolling a cashew dough sheet around a pistachio dough log. Cashew and pistachio doughs were each prepared separately using two different recipes: (1) Nestlé recipe[22] and (2) laboratory recipe. Doughs were prepared as described below.

1. Nestlé Recipe. For the cashew dough, 60 g of full-fat cashew nut seed flour, 40 g of Nestlé sweetened condensed milk, 1 g of Ziyad ghee (Indian clarified butter), and 1 g of Dabur rose water were manually mixed in a pan with a spatula and heated at medium-low heat [stove temperature = 130 °C, dough temperature = 77 °C, monitored by a Traceable infrared thermometer (VWR International, LLC, Radnor, PA, USA)] for 10 min to form the dough. Subsequently, 3 g of Nestlé nonfat dry milk powder was added to the dough and the dough was allowed to cool to room temperature.

For the pistachio dough, 60 g of full-fat pistachio seed flour, 40 g of Nestlé sweetened condensed milk, 1 g of Ziyad ghee, 1 g of McCormick cardamom, and 0.5 g of McCormick green food coloring (FD&C Yellow 5 and Blue 1) were manually mixed in a pan with a spatula and heated at medium-low heat for 10 min to form the dough. Subsequently, 3 g of Nestlé nonfat dry milk was added to the dough and the dough was allowed to cool to room temperature.

2. Laboratory Recipe. For the cashew dough, 50 g of cashew full-fat flour and 60 g of Publix confectionery sugar were ground in an Osterizer blender (speed setting "grind"; Galaxy model 869-18R, Jaden Consumer Solutions, Boca Raton, FL, USA) for 1 min followed by the addition of 1 g of Dabur rose water and 8 g of water. The mixture was manually kneaded into dough.

For the pistachio dough, 50 g of pistachio full-fat flour, 60 g of Publix confectionery sugar, and 1 g of McCormick cardamom were ground in an Osterizer blender (speed setting "grind") for 1 min followed by the addition of 0.5 g of McCormick green food coloring and 8 g of water. The mixture was manually kneaded into dough.

To prepare the rolls, 10 g of cashew dough was rolled into a flat sheet (~3 mm thick) and cut into a rectangular shape, whereas pistachio dough (0.1, 0.6, and 1.2 g) was formed into log shapes (2−10 mm diameter) and placed in the center of the cashew sheets. The cashew sheets were tightly rolled around the pistachio logs to form the kaju rolls. Pistachio contents in rolls prepared according to recipe 1 (Nestlé recipe) were 0, 0.6, 3.4, and 6.3% (w/w) and in rolls prepared according to recipe 2 (laboratory recipe) were 0, 0.4, 2.4, and 4.5% (w/w).

Corn Flakes. Forty-five grams of Publix sweet corn kernels were ground in an Osterizer blender (speed setting "grind") for 1 min with 50 mL of distilled water and baked at 120 °C in a KitchenAid Architect II oven (KitchenAid, Benton Harbor, MI, USA) until dry. The moisture content of the sweet corn was 78% as determined according to AOAC Official Method 925.40.[23] The final yield of the corn flakes was approximately 10 g. Pistachio full-fat flour was incurred at 10, 50, 100, 5000, 10000, 20000, and 50000 ppm levels prior to baking.

Sponge Cakes. Seventeen grams of egg was beaten by a KitchenAid hand mixer (speed setting "1") for 4 min. Thirty-four grams of Publix sugar was added, and the mixture was beaten for another 4−5 min until light and fluffy. Twenty-three grams of Publix all-purpose flour, 0.7 g of Argo baking powder, and 0.2 g of Publix salt were sifted into the mixture, and 0.4 g of McCormick vanilla extract was added. In a sauce pan, 20 g of Publix whole milk and 4.7 g of Publix butter were heated on low heat until the butter was melted. The milk and butter were combined with the batter and baked in greased cake pans at 163 °C in a KitchenAid Architect II oven for 30 min. Pistachio full-fat flour was incurred at 10, 50, 100, 5000, 10000, 20000, and 50000 ppm levels prior to baking.

Sugar Cookies. Twenty-three grams of Publix butter was creamed with 30 g of Publix sugar using a KitchenAid hand mixer (speed setting "1") and were then mixed with 6 g of egg and 0.3 g of McCormick vanilla extract. Subsequently, 40 g of Publix all-purpose flour, 0.5 g of Arm & Hammer baking soda, and 0.2 g of Argo baking powder were sifted into the batter and blended to form the dough. The dough was rolled to 0.69 cm thickness and baked at 190 °C in a KitchenAid Architect II oven for 12 min. Pistachio full-fat flour was incurred at 10, 50, 100, 5000, 10000, 20000, and 50000 ppm levels prior to baking.

Flour Preparation. All high moisture content ingredients and foods were dried as described earlier.[17,18] Specifically, heat-sensitive foods (e.g., ice cream, cheese) were freeze-dried (VirTis BenchTop K freeze-dryer, SP Scientific, Warminster, PA, USA), whereas fresh produce (e.g., fruits and vegetables) and high-sugar dried fruit (e.g., raisins, dates) were oven-dried for 24 h at 50−60 °C. All seeds, food ingredients, and processed foods, in their dried from, were ground in an Osterizer blender (speed setting "grind"; Galaxy model 869-18R, Jaden Consumer Solutions, Boca Raton, FL, USA) to obtain uniform flours. As needed, the flours were defatted for 8 h using a Soxhlet apparatus (Thermo Fisher Scientific Inc., Waltham, MA, USA) with petroleum ether (boiling point range of 38.2−54.3 °C) as the solvent (flour-to-solvent ratio of 1:10 w/v). After overnight drying in a fume hood at room temperature, the powders were passed through a 40 mesh sieve and then stored in screw-capped plastic bottles at −20 °C until further use.

Protein Extract Preparation. Protein extracts were prepared as per the ELISA kit instructions. Briefly, sample flours (100 mg each for pistachio and other food ingredients, 1 g each for commercially prepared foods, pistachio-spiked samples, and samples incurred with ≥5000 ppm of pistachio) were extracted in extraction buffer (provided with the ELISA kit; flour-to-solvent ratio of 1:10 w/v) at 60 °C for 10 min with vigorous manual vortex mixing every 2 min. For corn flakes, sponge cakes, and sugar cookies incurred with ≤100 ppm of pistachio, the entire batch of each sample was blended in an Osterizer blender (speed setting "grind") with borate saline buffer (BSB, 0.1 M boric acid, 0.025 M sodium borate, 0.075 M sodium chloride, pH 8.45; sample-to-solvent ratio of 1:10 w/v) at room temperature for 1 min and then magnetically stirred at room temperature for 1 h. The extracts were subsequently centrifuged at 2000*g* (Centrific 225 centrifuge, Thermo Fisher Scientific

[a]Food matrix from a single batch was weighed in triplicate, and each sample was extracted using buffer provided in the kit. No cross-reactivity was detected (i.e., signal equivalent to <0.09 ppm pistachio).

Inc., Waltham, MA, USA) for 10 min at room temperature. Aliquots of the supernatant were analyzed (supernatants were stored at 4 °C prior to analysis) within 48 h of preparation, and the remainder was stored in plastic microcentrifuge tubes (1.5 mL capacity) at −20 °C until further use.

To compare the antigen extraction efficiency of different buffers under different conditions, full-fat pistachio flours were extracted (flour-to-solvent ratio of 1:10 w/v) in BioFront extraction buffer (EXB; containing 4.51 ± 0.37 mg protein/mL, pH 8.52 ± 0.01), borate saline buffer (BSB; 0.1 M boric acid, 0.025 M sodium borate, 0.075 M sodium chloride, pH 8.45), phosphate-buffered saline (PBS; 0.1 M sodium phosphate, 0.9% w/v sodium chloride, pH 7.20), and sodium bicarbonate buffer (SBC; 0.1 M sodium bicarbonate, 0.9% w/v sodium chloride, pH 9.60) at two different conditions: (1) at room temperature for 1 h with constant vortex mixing or (2) at 60 °C for 10 min with vigorous manual vortex mixing every 2 min. The extracts were centrifuged at 2000*g* for 10 min at room temperature, and the supernatants were collected for soluble protein determination and ELISA.

Osborne Fractionation. Pistachio protein fractions were prepared according to the Osborne method[24] as described in detail by Sze-Tao and Sathe.[25] Briefly, 5 g of defatted pistachio flour was extracted sequentially with 100 mL of 1.0 M NaCl (albumin and globulin), 70% aqueous ethanol (prolamin), and 0.1 M NaOH (alkaline glutelin) for 1 h at room temperature with constant magnetic stirring. The slurry was centrifuged at 12600*g* (J2-21 centrifuge, Beckman Coulter, Inc., Brea, CA, USA) and 4 °C for 15 min following each extraction, and the supernatant was vacuum filtered using Whatman no. 4 filter paper. Residues from centrifugation and filtration were used for the next extraction, whereas filtrates were dialyzed against distilled water for 24 h with six water changes (4 L each). After dialysis, the albumin and globulin fraction (1 M NaCl extract) was centrifuged (12600*g*, 4 °C, 15 min), and the precipitate (globulin) and supernatant (albumin) were separately freeze-dried. Prolamin and glutelin fractions were lyophilized directly after dialysis. All freeze-dried protein fractions were stored in airtight plastic bottles at −20 °C until further analysis.

Protein Determination. The Bradford method[26] using bovine serum albumin (BSA) fraction V (Sigma Chemical Co., St. Louis, MO, USA) as the standard protein (0−600 μg/mL) was used for soluble protein determination.

ELISA Procedure. Ninety-six-well microtiter plates (coated with murine antipistachio mAb and blocked), sample diluent, ready-to-use pistachio standards (0, 0.5, 2, 6, 18, and 36 ppm pistachio), washing buffer, murine anti-pistachio mAb conjugated with horseradish peroxidase (HRP), 3,3′,5,5′-tetramethylbenzidine (TMB) substrate solution, and HRP quench solution were provided in the ELISA kits. Sample extracts were suitably diluted in sample diluent. Two hundred microliters of diluted samples and ready-to-use standards were added to each well and incubated at room temperature for 30 min. The plates were washed three times with washing buffer and blot dried. After washing, 100 μL of HRP-conjugated detection mAb was added to each well, incubated in the dark at room temperature for 30 min, and again washed three times with washing buffer. Subsequently, 100 μL of TMB substrate solution was added and incubated in the dark at room temperature for 10 min. The reaction was stopped by adding 100 μL of quench solution to each well and mixed by gentle pipetting. The absorbance was read at 450 nm by a BioTek PowerWave 200 microplate scanning spectrophotometer (Winooski, VT, USA).

ELISA Validation. 1. Limit of Detection (LOD). The LOD is defined as the minimum concentration of analyte that can be reliably distinguished from background. The LOD of the ELISA was calculated using the following two commonly applied methods. $LOD_1 = 3\sigma/S$, where σ is the standard deviation of the blank (mean) and S is the slope of the standard curve.[27] $LOD_2 = M + 3\sigma$, where M is the mean absorbance of the blank and σ is the standard deviation of the blank.[28] The resulting absorbance of LOD_2 was converted to concentration using the standard curve.

2. Limit of Quantification (LOQ). The LOQ is defined as the minimum concentration of analyte that can be quantitatively

DOI: 10.1021/acs.jafc.5b03066
J. Agric. Food Chem. 2015, 63, 9139−9149

determined with suitable precision and accuracy. The LOQ of the ELISA was calculated using the following formulas. $LOQ_1 = 10\sigma/S$, where σ is the standard deviation of the blank (mean) and S is the slope of the regression line for the linear range.[27] $LOQ_2 = M + 10\sigma$, where M is the mean absorbance of the blank and σ is the standard deviation of the blank.[29] The resulting absorbance of LOQ_2 was converted to concentration using the standard curve.

3. Linear Detection Range. Two hundred microliters of pistachio full-fat flour protein extract (8000 ng pistachio protein/mL diluent) was added to the top row of the horizontally oriented (i.e., 8 rows ×12 columns/row) 96-well microtiter plate, and three times serially diluted samples were processed down the plate. The ELISA was performed as described earlier. A four-parameter curve was generated by KC4 software (version 2.0, Bio-Tek Instruments, Inc., Winooski, VT, USA) to determine the linear detection range and the concentration for 50% maximum signal in the assay.

4. Specificity and Cross-Reactivity. Assay specificity is defined as the ability of an antibody to produce a measurable response only for the analyte of interest (i.e., pistachio protein). Cross-reactivity is a measurement of antibody response to substances other than the analyte.[30] A total of 156 commonly used foods and food ingredients at 100,000 ppm each were tested for cross-reactivity (Table 1). Samples with signal equivalent to <0.09 ppm of pistachio were not considered cross-reactive.

5. Reproducibility. Reproducibility, also called precision, describes the ability of the assay to duplicate results in repeat determinations. Reproducibility was determined by the percent coefficient of variation (%CV) between replicates determined in the same assay (intra-assay variability) and in different assays (inter-assay variability). Variation of six pistachio standards was measured, each with 3 replicates within the plate for intra-assay variability and 12 replicates in different plates for inter-assay variability. The %CV was calculated by using the formula

$$\mathrm{CV}\ (\%) = (\sigma/X) \times 100\%$$

where σ is the standard deviation and X is the mean of the replicate determinations.[20]

6. Uncertainty Estimation. Measurement uncertainty of the validated BioFront MonoTrace pistachio ELISA was estimated at each concentration level of the pistachio standards. The bias uncertainty (u_δ), the combined uncertainty (u_c) of bias and intralaboratory reproducibility, the expanded uncertainty (U), and the relative uncertainty (u_r) were calculated using the following formulas.[31,32]

$$S_R^2 = S_W^2 + S_B^2$$

where S_R^2, S_W^2, and S_B^2 are the intralaboratory reproducibility variance, intra-assay variance, and inter-assay variance, respectively.

$$S_W^2 = \frac{\sum_{i=1}^{p}\sum_{j=1}^{n}(x_{ij} - \overline{x}_i)^2}{p(n-1)} \text{ with } \overline{x}_i = \frac{\sum_{j=1}^{n} x_{ij}}{n}$$

$$S_B^2 = \frac{\sum_{i=1}^{p}(\overline{x}_i - \overline{x})^2}{p-1} - \frac{S_W^2}{n} \text{ with } \overline{x} = \frac{\sum_{i=1}^{p}\sum_{j=1}^{n} x_{ij}}{pn}$$

where x is the analytical result (ppm pistachio), p is the number of kits analyzed, and n is the number of replications within a kit.

$$u_\delta = \sqrt{\frac{S_R^2\left(1 - \gamma + \frac{\gamma}{n}\right)}{p}} \text{ with } \gamma = \frac{S_W^2}{S_R^2} \qquad u_c = \sqrt{S_R^2 + u_\delta^2}$$

$$U = k \times u_c \qquad u_r = \frac{U}{\text{tested concentration}} \times 100\%$$

A coverage factor of $k = 2$ was used to define a 95% confidence interval (assuming the values are normally distributed) where the unknown true value is believed to lie.[31]

7. Recovery. Diluted pistachio soluble protein extracts were spiked to finely ground cereal, corn flake, cookie, dark chocolate, milk chocolate, white chocolate, ice cream, and sponge cake matrices to reach a spiking level equivalent to 10 ppm of pistachio flour.

Pistachio-incurred corn flakes, sponge cakes, and sugar cookies were prepared as described earlier. Pistachio full-fat flours were incurred at 10, 50, 100, 5000, 10000, 20000, and 50000 ppm levels prior to food processing and were processed along with the other ingredients.

The spiked and incurred matrices were then subjected to protein extraction as described under Protein Extract Preparation. The pistachio content was measured and the percent recovery was determined using the following formula:

$$\text{recovery}\ (\%) = (\text{measured pistachio concentration} / \text{predicted pistachio concentration}) \times 100\%$$

8. Assay Applicability and Robustness. Thermally processed pistachio samples (described earlier), commercially sold, matched samples (with and without pistachio), and laboratory-prepared samples were analyzed to determine if the assay can detect processed pistachios and if food matrices interfere with the assay. Each commercial food analyzed was obtained in a single batch to ensure sample homogeneity. Protein extracts of processed pistachios were normalized to 125 ng pistachio protein/mL extraction buffer. The absorbance of the processed samples was compared with the absorbance of the reference. The relative immunoreactivity was calculated as follows:

$$\text{relative immunoreactivity}\ (\%) = [(\mathrm{OD}_{\mathrm{sample}} - \mathrm{OD}_{\mathrm{blank}})/(\mathrm{OD}_{\mathrm{reference}} - \mathrm{OD}_{\mathrm{blank}})] \times 100\%$$

where $\mathrm{OD}_{\mathrm{reference}}$ = OD generated by 25 ng of unprocessed pistachio protein used as the reference and $\mathrm{OD}_{\mathrm{sample}}$ = OD generated by 25 ng of protein from the sample assayed.

Sodium Dodecyl Sulfate–Polyacrylamide Gel Electrophoresis (SDS-PAGE). SDS-PAGE was performed as described by Fling and Gregerson.[33] BSB-solubilized tree nut and legume seed proteins as well as pistachio protein fractions were heat denatured in SDS-PAGE sample buffer (50 mM Tris-HCl, 1% w/v SDS, 0.01% w/v bromophenol blue, and 30% v/v glycerol, pH 6.8) with and without 2% v/v β-mercaptoethanol for 10 min by placing the microcentrifuge tubes containing these samples in a boiling water bath (100 °C). A 4% stacking gel with either a 12% separating gel (6 μg protein/lane) or an 8–25% gradient gel (20 μg protein/lane) was used. Protein samples and molecular mass markers were loaded on the stacking gel and electrophoresed at a constant current of 8 mA/gel (12 h) followed by 30 mA/gel (4–5 h) until the tracking dye reached the separating gel edge.

Western Blot. Following SDS-PAGE, the proteins were transferred onto a 0.22 μm nitrocellulose membrane as described by Towbin et al.[34] The transferred polypeptides were visualized by staining with (0.1% w/v) Ponceau S solution prepared using distilled deionized water. The unbound sites on the nitrocellulose membrane were blocked with 5% (w/v) nonfat dry milk in Tris-buffered saline–Tween 20 (TBS-T, 10 mM Tris, 0.9% w/v sodium chloride, 0.05% v/v Tween 20, pH 7.6) at room temperature for 1 h. The membranes were subsequently washed with three changes of TBS-T, 5 min each. The membranes were then incubated with the HRP-conjugated detection antibody provided in the MonoTrace pistachio ELISA kit (1:10 or 1:50 v/v dilution in TBS-T) overnight at 4 °C on a Lab-line thermal rocker (speed 2; Thermo Fisher Scientific Inc., Waltham, MA, USA). After three washings with TBS-T for 15 min each, the membranes were incubated with HRP-labeled goat anti-mouse IgG polyclonal antibody (pAb, 1:10000 v/v dilution in TBS-T) for 1 h at room temperature on a rocker. The membranes were washed again as described above and incubated with 1.3 mM luminol, 0.2 mM *p*-coumaric acid, and 0.01% (v/v) hydrogen peroxide in 0.1 M Tris-HCl buffer (pH 8.5) for 5 min. The membranes were then exposed (60 s) to an X-ray film for autoradiographic visualization. The molecular mass of recognized polypeptide was determined by the ChemiDoc XRS + Image System (Bio-Rad Laboratories, Inc., Hercules, CA, USA).

Statistics. All ELISA experiments were performed at least in triplicate on a single sample, and data are reported as the mean ± standard deviation of the mean. One-way ANOVA was performed with SPSS software (19.0, SPSS Inc., Chicago, IL, USA) to compare means for

DOI: 10.1021/acs.jafc.5b03066
J. Agric. Food Chem. 2015, 63, 9139–9149

difference. Post hoc analysis was performed using Fisher's least significant difference (LSD) at $P \leq 0.05$.

RESULTS AND DISCUSSION

Assay Sensitivity. The MonoTrace pistachio ELISA kit registered a low background absorbance (0.073 ± 0.009). The LOD_1 (0.09 ppm) and LOD_2 (0.19 ppm) for soluble pistachio proteins suggested the assay is sensitive (Table 2). The assay sensitivity is comparable to the reported sensitivity by Romer (0.13 ppm) and Bio-Check (0.2 ppm) ELISA kits and the recently reported real-time PCR assay sensitivity (0.1 ppm).[13] Compared to the Genon ELISA kit (10 ppm) and the PCR methods reported by Brežná et al.[35] (4 ppm) and Barbieri and Frigeri[36] (100 ppm), the MonoTrace pistachio ELISA kit assay exhibited better sensitivity. The LOQ_1 (0.30 ppm) and LOQ_2 (0.38 ppm) of the MonoTrace pistachio kit are comparable with the LOQ of a previously reported pistachio ELISA (<1 ppm).[37] The kit linear detection range of 0.5−36 ppm (linear regression $R > 0.99$) is similar to the linear range (1−40 ppm) for the Romer kit. The concentration of pistachio soluble protein that registered 50% of the maximum signal is 152 ng/mL (7.9 ppm) (Figure 1), comparable to the value (~137 ng/mL) reported by Lim.[37]

The sensitivity of an assay is considered sufficient when it can reliably detect the minimum dose of an allergen capable of eliciting a clinically measurable response. Many attempts have been made to determine the allergen threshold that causes an adverse reaction. The U.S. Food and Drug Administration established a Threshold Working Group in 2005 but failed to establish the threshold for the major food allergens due to insufficient data at the time.[38] In 2010, the Australian Allergen Bureau first introduced defined allergen threshold levels for precautionary labeling. In their most recent update, the eliciting doses (EDp, dose of allergen at which p% of the allergic population would react) for an allergic reaction in 1% of the population estimated for hazelnut and peanut were 0.2 and 0.1 mg of protein, respectively, and the reference dose for cashew (lower 95% confidence interval of ED_{05}) was 2.0 mg of protein.[39,40] The reference dose for most allergenic foods ranged from 0.03 mg of protein (ED_{01} for egg) to 10 mg of protein (lower 95% confidence interval of ED_{05} for shrimp). Currently, no threshold data are available for pistachio and other tree nuts, and thus the tested kit detection range 0.5−36 ppm must be interpreted with caution.

Table 2. Summary of the MonoTrace Pistachio ELISA Kit for 50% Maximum Signal Concentration, Linear Detection Range, Limit of Detection (LOD), and Limit of Quantification (LOQ)[a]

	ppm pistacho full fat flour	ng pistachio protein/mL
50% max signal concentration (n = 3)	7.9 ± 0.7	151.9 ± 14.7
linear detection range (n = 3)	0.5−36 (R > 0.99)	9.5−684 (R > 0.99)
LOD_1[b] (n = 3)	0.09 ± 0.02	1.73 ± 0.32
LOD_2[c] (n = 3)	0.19 ± 0.07	5.76 ± 1.07
LOQ_1[d] (n = 3)	0.30 ± 0.06	3.64 ± 1.36
LOQ_2[e] (n = 3)	0.38 ± 0.13	7.20 ± 2.40

[a]Data are expressed as mean ± SD. The 50% maximum signal concentration and linear detection range were determined using protein extracts from three different batches of pistachios and repeated in two different kits. The limits of detection and quantification were determined in three different kits using pistachio standards provided in those kits. [b]Limit of detection 1 (LOD_1) was determined on the basis of the standard deviation of the blank (σ) and the slope of the standard curve (S) according to the formula $LOD_1 = 3\sigma/S$. [c]Limit of detection 2 (LOD_2) was determined on the basis of the mean absorbance (M) and standard deviation of the blank (σ) according to the formula $LOD_2 = M + 3\sigma$. [d]Limit of quantification 1 (LOQ_1) was determined on the basis of the standard deviation of the blank (σ) and the slope of the standard curve (S) according to the formula $LOQ_1 = 10\sigma/S$. [e]Limit of quantification 2 (LOQ_2) was determined based on the mean absorbance (M) and standard deviation of the blank (σ) according to the formula $LOQ_2 = M + 10\sigma$.

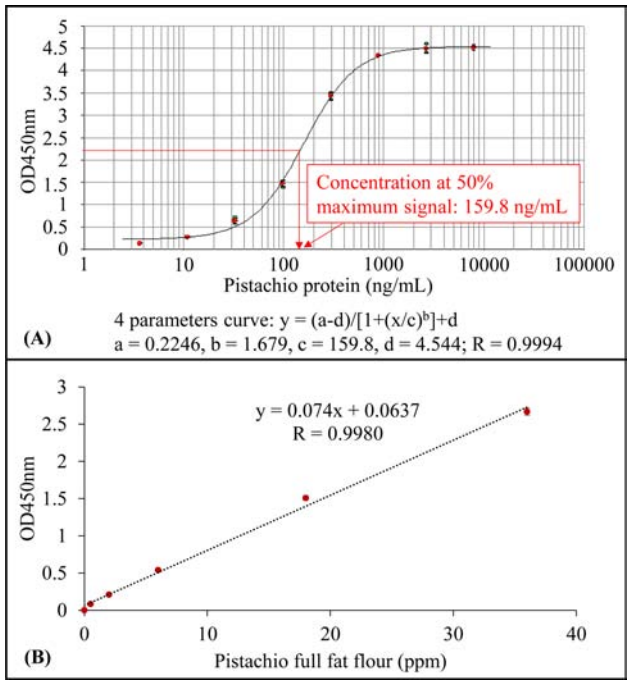

Figure 1. Typical MonoTrace pistachio ELISA kit four-parameter curve (A) and linear standard curve using pistachio protein standards (0, 0.5, 2, 6, 18, and 36 ppm pistachio) provided within the kit (B). The standard curves were repeated three times within a kit.

Assay Efficiency. The MonoTrace pistachio ELISA was rapid with an assay time of approximately 1.5 h (extraction, 10 min; incubation with antigen, 30 min; incubation with detection antibody, 30 min; and color development, 10 min). The updated version of the MonoTrace Pistachio ELISA claims improvement in the assay efficiency and short incubations with antigen/food sample extract, detection antibody, and substrate (10 min each). To determine if the antigen extraction was sufficient, pistachio full-fat flours were extracted in four different buffers (EXB, BSB, PBS, and SBC) under two separate conditions (60 °C, 10 min and room temperature, 1 h). Under both conditions, the kit-provided buffer, EXB, yielded the highest soluble protein extractability and antigen recovery (Table 3). Protein extractions by EXB at 60 °C for 10 min and at room temperature for 1 h were equivalent (P > 0.05).

Assay Specificity. Individuals allergic to one tree nut often exhibit IgE reactivity to other edible nut seed proteins.[41] Cross-reactive tree nuts are usually found in the same botanical family. Strong cross-reactivities have been documented in nut seed proteins of (a) pecan and walnut species of the Juglandaceae family[42−46] and (b) cashew and pistachio of the Anacardiaceae family.[5,43,44,47−53] Cross-reactivity is likely due to the homologous linear amino acid sequence, three-dimensional structural similarity, or both, of different nut seed proteins. Several murine

mAbs raised against cashew Ana o 1 have been reported to recognize the recombinant Pis v 3 in a dot blot assay, indicating that the antibodies are likely targeting the conserved regions of the Anacardiaceae seed proteins.[52] Pistachio seed proteins are also found to be cross-reactive with protein(s) from mango seeds[48] and with proteins from seeds of taxonomically unrelated botanical families such as sunflower, peanut, and walnut.[47] A previously observed cross-reactivity of pistachio ELISA (at 4 ppm level) using sheep antisera as the capture reagent and rabbit antisera as detection reagent with cashew nut seed proteins was therefore not unexpected.[37] Recently, in a multiplex ELISA simultaneously detecting 14 different food allergens and gluten, cross-reactivity of pistachio detection assay with Brazil nut, cashew, and hazelnut seed proteins has also been reported.[54] The MonoTrace pistachio ELISA kit, under the test conditions, is specific and did not display cross-reactivity (signal equivalent to <0.09 ppm of pistachio) with 156 tested commonly used food ingredients at 100,000 ppm including certain Anacardiaceae seeds such as cashew (*Anacardium occidentale*), charoli (*Buchanania lanzan*), and mango (*Mangifera indica*) peel, pulp, and seed (Table 1). The specificity of the kit is likely due to the use of mAbs.

To partially test the aforementioned assumption, the cross-reactivity of the kit detection murine mAb with select tree nut and legume seed proteins was assessed using Western blot. The detection mAb (1:10 v/v dilution in TBS-T) was found to be reactive with the 51 kDa polypeptide of cashew and the 55 kDa polypeptide of charoli in the absence of β-mercaptoethanol (Figure 2). In the presence of β-mercaptoethanol, the detection mAb recognized the 19 and 21 kDa polypeptides in cashew and the 23 kDa polypeptide in charoli. The discrepancy between the ELISA kit results (no cross-reactivity with cashew and charoli)

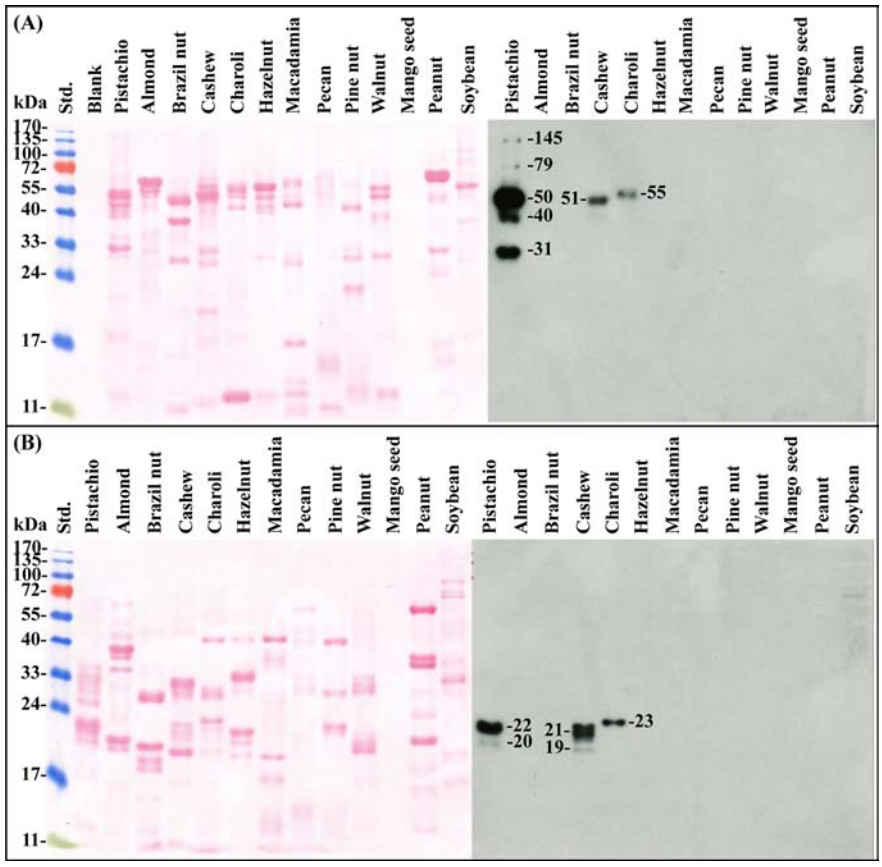

Figure 2. SDS-PAGE pattern (Ponceau S staining) and Western blot of the soluble protein extracts (6 μg/lane) from select tree nut and legume seeds in the absence (A) and presence (B) of 2% (v/v) β-mercaptoethanol. MonoTrace murine anti-pistachio mAb (1:10 v/v dilution in TBS-T) was used as the detection antibody, and goat anti-mouse IgG pAb−HRP (1:10000 v/v dilution in TBS-T) was used as the secondary antibody in the Western blot.

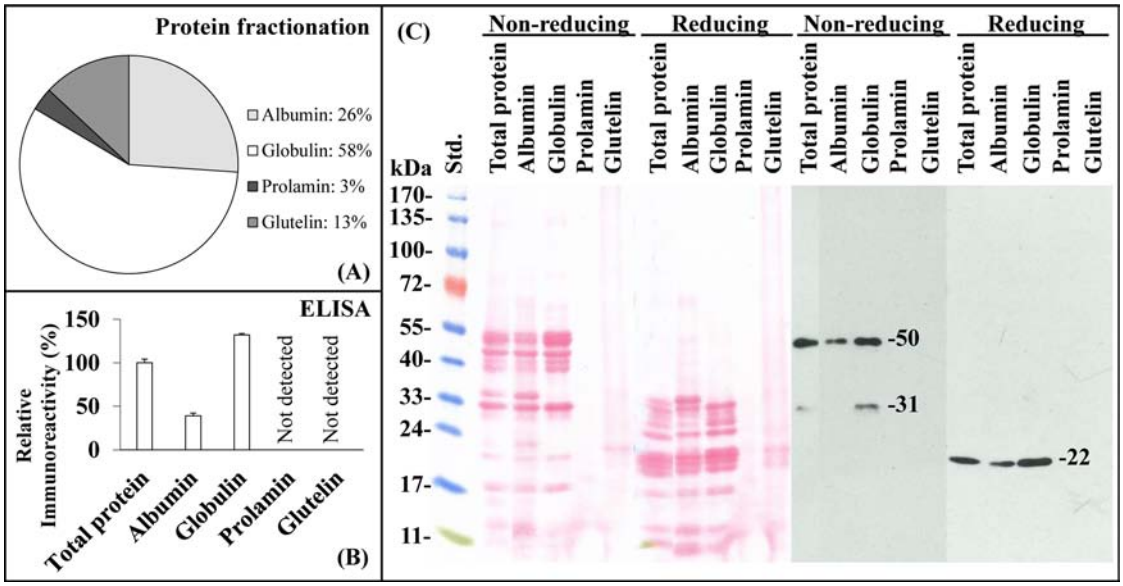

Figure 3. Pistachio protein fractionations (A) and their immunoreactivity assessed by MonoTrace pistachio ELISA kit (B) and Western blot (C). Protein content in ELISA and Western blot was 30 ng/well and 20 μg/lane, respectively. MonoTrace murine anti-pistachio mAb (1:50 v/v dilution in TBS-T) was used as the detection antibody, and goat anti-mouse IgG pAb-HRP (1:10000 v/v dilution in TBS-T) was used as the secondary antibody in the Western blot. Pistachio protein fractions were prepared using three different batches of pistachios. Fractions from all three batches were tested by ELISA, and one batch was tested by Western blot.

Table 4. Intra- and Inter-assay Variability and Uncertainty Estimation for the MonoTrace Pistachio ELISA Kit Using the 0.5−36 ppm Pistachio Standards[a]

					uncertainty[b]			
ppm	intra-assay %CV	inter-assay %CV	back-calculated concentration (ppm)	recovery (%)	u_δ (ppm)	u_c (ppm)	U (ppm)	u_r (%)
0.5	1.3−3.7	24.0	0.4	79.9	0.09	0.22	0.43	87
2	1.4−8.4	15.9	2.1	102.6	0.13	0.32	0.64	32
6	1.2−3.9	19.5	6.6	110.4	0.20	0.48	0.95	16
18	1.2−3.5	14.9	18.7	103.9	0.57	1.35	2.70	15
36	0.5−1.7	12.3	34.8	96.7	0.18	0.50	1.00	3

[a]Pistachio standards from four different kits were tested three times in each kit. [b]u_δ = bias uncertainty, u_c = combined uncertainty, U = expanded uncertainty, and u_r = relative uncertainty.

and Western blot results was likely due to (1) the *capture* antibody not being reactive to cashew and charoli and/or (2) SDS-induced protein unfolding in the Western blot exposing buried epitopes that were inaccessible to the ELISA detection antibody in cashew and charoli native proteins.

Identification of the Target Antigen. As observed in Western blot (Figure 2), the detection mAb (1:10 v/v dilution in TBS-T) of the MonoTrace pistachio ELISA kit recognized three pistachio polypeptides (50, 40, and 31 kDa) in the absence of β-mercaptoethanol. Two polypeptides, molecular masses of 79 and 145 kDa, were weakly recognized. Under reducing condition, the detection mAb exhibited a strong reactivity to a 22 kDa polypeptide and a weaker reaction to a 20 kDa polypeptide.

At 1:50 v/v dilution, the detection mAb recognized the 50 and 31 kDa polypeptides under nonreducing conditions and the 22 kDa polypeptide under reducing conditions (Figure 3). The globulin protein fraction had more intense bands than the total protein extract, indicating the globulins were mainly responsible for the reaction. The detection mAb recognized the albumin protein fraction, suggesting the target antigen was partially soluble in water. Shokraii and Esen have noted the presence of common pistachio globulin polypeptide(s) in the albumin fraction.[55] No polypeptide was recognized by the detection mAb in the prolamin and glutelin fractions under both reducing and nonreducing conditions. The ELISA and Western blot results were consistent. Compared to the total protein extract immunoreactivity designated 100%, the albumins, globulins, prolamins, and glutelins, respectively, registered 39.0, 132, 0, and 0% immunoreactivity.

On the basis of the solubility profile and Western blot, the target antigen of the detection antibody is likely to be the small/basic subunit of the pistachio 11S globulin. The electrophoretic pattern of the recognized pistachio polypeptides under non-reducing conditions was similar to those of purified soybean 11S glycinin, namely, two major bands at 57 and 28 kDa and two light bands at 85 and >100 kDa.[56] So far, four distinct pistachio 11S globulin protein sequences have been reported with predicted molecular masses ranging from 53.2 to 56.5 kDa.[57−59] Among pistachio 11S acidic (35−40 kDa) and basic (22−27 kDa) subunits, the latter have been reported to exhibit a stronger reactivity, compared to the 11S acidic subunit and 2S albumin polypeptides, tested with pooled tree nut-allergic human sera.[51] Therefore, pistachio 11S globulin basic subunit may serve as a good antigen for producing antibodies targeting human allergy relevant epitopes.

Assay Reproducibility, Uncertainty, and Recovery. The intra- and inter-assay variability of the MonoTrace pistachio ELISA kit was <24% CV, demonstrating that the assay is

DOI: 10.1021/acs.jafc.5b03066
J. Agric. Food Chem. 2015, 63, 9139−9149

reproducible (Table 4). Measurement uncertainties of the assay were estimated using the pistachio standards (Table 4). Among the uncertainties, u_δ estimates the uncertainty of the bias (the difference between the ELISA result and the true pistachio concentration), u_c combines the uncertainties of the bias and the reproducibility, U defines an interval about the ELISA result where the true value is confidently believed to lie, and u_r describes the expanded uncertainty in proportion to the corresponding concentration. The relative uncertainty (u_r) had a range of 3−87%, which decreased with increasing concentration. For the 36 ppm of pistachio standard, the unknown true value is located between 35 and 37 ppm with a confidence level of 95%.

Food matrices that may come in contact with pistachio during food manufacturing and processing were tested for their possible assay interference. Previous studies have indicated that certain food matrices may result in over- or under-estimation of the target antigen.[17,18,20] In the current investigation, a spiking level of 10 ppm of pistachio was used. The pistachio recovery range for spiked cereal, corn flake, cookie, dark chocolate, milk chocolate, white chocolate, ice cream, and sponge cake was 81−125% (Table 5). The highest pistachio recovery was observed in spiked

Table 5. Pistachio Recovery from Foods Spiked with Pistachio Soluble Protein Extract As Determined by the MonoTrace Pistachio ELISA Kit

food	manufacturer[a]	spike level (ppm)	recovery[b] (%)
ice cream	Häagen-Dazs	0	ND[c]
		10	92.6 ± 2.3

[a]Commercial sample brands were used for comparison, not for endorsement. [b]Laboratory samples were prepared in triplicate. Commercial foods were obtained in a single batch. All samples were analyzed in triplicate using a kit. Data are expressed as mean ± SD. [c]ND, not detected (signal equivalent to <0.09 ppm pistachio).

corn flakes, whereas the lowest was in dark chocolate. ELISA recovery of 183% for 11S globulin (amandin) for almond-spiked corn flakes has also been reported.[18] The reduced recovery in dark chocolate was consistent with previous observations and was likely induced by the formation of pistachio protein−chocolate polyphenol insoluble complexes.[17,18,20] For foods containing dark chocolate, the addition of 5% w/v nonfat dry milk (NFDM) to the extraction buffer was suggested in the latest version of the kit user's manual. To test this, we added 5% NFDM to the extraction buffer and repeated the assay. This modification in the extraction step significantly improved pistachio recovery from dark chocolate to 93% (from 82%). NFDM proteins may possibly interact with the chocolate polyphenols and acids, thereby improving target antigen solubilization.

To demonstrate how food processing along with the food matrix affects the allergen detection and quantification, laboratory-prepared corn flakes, sponge cakes, and sugar cookies were incurred with full-fat pistachio flour and subjected to thermal processing. Samples were incurred with 10, 50, and 100 ppm of pistachio to mimic the case of inadvertent contamination with pistachio during food processing and with 5000 ppm (0.5% w/w), 10000 ppm (1% w/w), 20000 ppm (2% w/w), and 50000 ppm (5% w/w) pistachio to simulate the case of intentional use of pistachio as an ingredient in food processing. The pistachio recovery ranges for corn flakes, sponge cakes, and sugar cookies were, respectively, 37.3−44.8, 50.3−67.1, and 68.9−82.6% at 10−100 ppm incurring level, and 35.7−49.1, 71.2−99.2, and 78.6−112.2% at 5000−50000 ppm incurring level (Table 6). The

[a]Samples were prepared and analyzed in triplicate. Data are expressed as mean ± SD.

decreased pistachio recovery from certain incurred samples was in agreement with decreased antigen recovery from gluten-incurred corn bread and milk-incurred cookies and was likely due to (1) interference from other food ingredients, (2) thermally induced antigen denaturation, (3) chemical modification (e.g., Maillard reaction) of the antigen, and/or (4) hindered antigen solubility/extractability.[60,61]

Assay Robustness and Applicability. The assay kit detected pistachio traces when protein extracts prepared from thermally processed pistachio seeds were tested (Table 7). Relative immunoreactivity of the processed pistachio samples ranged from 86% (dry roasting, 168 °C, 12 min) to 182% (blanching, 94 °C, 10 min). The elevated immunoreactivity under certain processing conditions may be due to improved accessibility of a possibly buried epitope.[15] The target antigen, possibly pistachio 11S globulin, is thermally stable, a finding consistent with our previous observations for tree nut 11S globulins including almond amandin[21,62,63] and cashew anacardein.[15,21,64] To test whether the MonoTrace kit targeted antigen is a reliable marker or not, selected 20 paired commercial samples, with and without declared pistachio, were examined. No false-positive or false-negative results were observed for the tested samples except for kaju roll (Table 8). No pistachio was detected in commercially sold kaju roll that was declared to contain pistachio. Kaju roll is a dessert made by rolling rectangular-shaped cashew dough around a log-shaped pistachio

[a]Commercial sample brands were used for comparison, not for endorsement. [b]Commercial samples from a single batch were weighed into three subsamples, each extracted in extraction buffer and analyzed in a kit. Data are expressed as mean ± SD. ND = not detected (signal equivalent to <0.09 ppm pistachio). [c](−) = without declared pistachio; (+) = with declared pistachio.

dough, into a cylinder. We were unable to detect pistachio presence in tested commercial kaju roll batches (purchased in 2011, 2013, and 2014) using the MonoTrace kits. This "false negative" result was not caused by the interference from the kaju roll matrix as when pistachio full-fat flour was spiked (10 ppm) into the same commercial kaju roll samples, 102.5% of the pistachio protein could be recovered using the kit. It was unclear whether commercial kaju rolls contained pistachio or perhaps just green food colorant. Therefore, we prepared kaju rolls with different pistachio contents (0.6−6.3% w/w for recipe 1, 0.4−4.5% w/w for recipe 2) in our laboratory using two separate recipes. The MonoTrace pistachio kit was able to detect pistachio in all laboratory-prepared kaju rolls. The pistachio recovery ranged from 83 to 89% for recipe 1 kaju rolls and 93−127% for recipe 2 kaju rolls (Table 9). These results suggest that the

Table 9. Pistachio Detection in Laboratory Prepared Kaju Rolls Using the MonoTrace Pistachio ELISA Kit

recipe 1 (Nestlé)		recipe 2 (laboratory developed)	
pistachio % (w/w)	recovery (%)	pistachio % (w/w)	recovery (%)
0	ND[a]	0	ND
0.001 (spiking)	97.7 ± 17.3	0.001 (spiking)	109.4 ± 15.0
0.6	82.5 ± 2.0	0.4	93.0 ± 27.0
3.4	87.1 ± 2.6	2.4	98.3 ± 10.6
6.3	88.6 ± 0.9	4.5	127.1 ± 10.9
LSD ($P \leq 0.05$, $n = 3$)	16.54	LSD ($P \leq 0.05$, $n = 3$)	32.40
LSD ($P \leq 0.05$, $n = 3$)		23.65	

[a]Kaju rolls were prepared using two different recipes, each in triplicate. ND = not detected (signal equivalent to <0.09 ppm pistachio).

negative results obtained on the tested commercial kaju rolls may represent (a) the presence of pistachio below the detection limit of the test kit, (b) the use of a pistachio variety in the tested kaju roll not amenable for detection by the test kit, or (c) a possible example of intentional misbranding.

In conclusion, the results of investigations in this paper indicate that under the test conditions the BioFront MonoTrace pistachio ELISA kit was sensitive, robust, and specific for pistachio detection and quantification.

first hazelnut allergen with a resolved three-dimensional structure.

MATERIALS AND METHODS

Protein Purification. Shelled, raw hazelnuts were frozen, ground in a blender, and defatted by extraction with hexane. Proteins from dried hazelnut flour were extracted with 10 volumes of extraction buffer (20 mM sodium acetate, pH 4.5, containing 0.5 M NaCl and 3% polyvinyl polypyrrolidone). Globulins were removed by precipitation with cold methanol (60%, v/v), and prolamins were precipitated with acetone. After removal of the 2S albumin fraction by anion exchange chromatography (10 mL of Q sepharose; GE Healthcare, Little Chalfont, UK), Cor a 8 was purified from the flow-through by cation exchange chromatography. The flow-through was dialyzed against 20 mM sodium acetate, pH 7.6, and loaded onto a prepacked 1 mL Mono S column (GE Healthcare). Proteins bound to the column were eluted by a linear gradient of increasing concentrations (0−20%) of 1 M NaCl with a flow rate of 1 mL/min. Both columns were attached to a GE ÄKTA FPLC system (GE Healthcare). Fractions were analyzed by Coomassie-stained 15% SDS-PAGE.

Circular Dichroism (CD) Spectroscopy. CD spectra of native Cor a 8 (0.2 μg/μL in 10 mM sodium phosphate buffer, pH 2.5 or 7.5) were measured from 190 to 260 nm on a Jasco J-810 spectropolarimeter (Jasco International Co., Tokyo, Japan) at 20 °C using a 1 mm path length quartz cell. The effect of heating (2 °C/min) was measured at 222 nm. Spectra represent the average of four accumulations collected at 100 nm/min with a 2 s time constant, 0.5 nm resolution, and sensitivity of ±100 mdeg.

N-Terminal Sequencing by Edman Degradation. The N-terminal sequence was determined using an Applied Biosystems Procise 491 sequencer (Applied Biosystems, Foster City, CA, USA). Cor a 8 (100 pmol) was adsorbed onto a Prosorb cartridge and subjected to sequence analysis.

MALDI-TOF-MS. For mass determination nonreduced Cor a 8 was spotted with α-cyano-4-hydroxycinnamic acid onto a ground steel MALDI target plate and measured in linear mode on a MALDI-TOF mass spectrometer (Microflex, Bruker Daltonics, Bremen, Germany).

Crystallization, Data Collection, and Processing. Crystallization experiments were performed at room temperature using the hanging-drop vapor diffusion method and screw-top hanging drop plates (Molecular Dimensions, Altamonte Springs, FL, USA). Purified, natural Cor a 8 in 20 mM Tris, pH 7.5, was mixed with well solution (0.49 M sodium phosphate monobasic monohydrate, 0.91 M potassium phosphate dibasic, pH 6.9) in a 1:1 ratio. Crystals were cryo-protected with well solution and cooled in liquid N_2. Data were collected from single crystals at 100 K at SER-CAT 22BM beamline at the Advanced Photon Source (APS), Argonne National Laboratory (ANL). Crystals belonged to the $P2_1$ spacegroup, and the protein crystallized with two molecules per asymmetric unit (AU). Data were processed with the HKL-2000 software package.[25] Data collection statistics are reported in Table 1.

Structure Determination and Refinement. The structure of Cor a 8 was solved by molecular replacement using nsLTPs Pru p 3 from peach (PDB ID 2ALG) as the start model. Molecular replacement was performed with HKL-3000[26] integrated with MOLREP[27] and selected programs from the CCP4 package.[28] Models were rebuilt using COOT,[29] Buccaneer,[30] and ARP/wARP[31] and refined with REFMAC.[32] MOLPROBITY[33] and ADIT[34] were used for structure validation. Refinement statistics are summarized in Table 1.

Molecular Dynamics Simulations. Molecular force fields of lauric acid anion and *n*-heptane were described with the general amber force field (GAFF), whereas for the proteins, the amber force field ff03.r1 was employed. *n*-Heptane molecule and laureate anion were first optimized in extended conformations in vacuum at the B3LYP/6-31G(d,p) level, and then the electrostatic potential around them was computed at the level that is consistent with the GAFF, that is, HF/6-31G(d). Quantum chemical computations were performed with the Gaussian 09 suite of programs.[35] From the electrostatic potential RESP atomic charges were fitted with the use of antechamber and resp programs from the AmberTools package.[36]

The ionization state of individual protein residues was tested with PROPKA 3.1 software.[37] For pH 7 all residues were predicted to be in their standard ionization state (N- and C-termini all LYS, ARG, and ASP charged).

Initial coordinates of the proteins were taken from PDB 2B5S for Pru p 3 and from PDB 4XUW for Cor a 8, respectively (chains A). The N-terminal Met residue of the Pru p 3 structure was removed, as it was added to the protein due to its heterologous expression in a bacterial host. Protein molecules were subsequently placed in a periodic box filled with explicit water molecules described with the TIP3P model[38] and the appropriate number of chloride anions to compensate the charge of the protein or protein/laureate complex. The box was chosen such that its edge was 10 Å away from the protein surface in either direction. The system was first minimized in three steps: 5000 steps with protein atoms restrained with 500 kcal/mol Å^2 harmonic constant, 5000 steps with 10 kcal/mol Å^2 harmonic restraint on protein, and then 10000 steps of an unrestrained minimization. The minimized system was heated from 0 to 300 K during a 50 ps NV dynamics, and then its density was equilibrated in a 0.5 ns NPT dynamics; in both steps protein backbone atoms were restrained with 1 kcal/mol Å^2. Subsequent unrestrained NPT (T = 300 K, p = 1 atm) dynamics simulation spanned 150 ns for each system, with a snapshot saved every 10 ps. Integration time step was 2 fs, SHAKE algorithm was used to constrain bonds of hydrogen atoms, and temperature and pressure were controlled with the Langevin dynamics and isotropic position scaling algorithm, respectively. MD simulations were conducted with the Amber12 suite with a GPU version of the PMEMD program.[39,40] Snapshots of the last 10 ns of simulations were clustered with the average linkage algorithm applied to Ca carbons of the protein backbone. Representative structures of dominating clusters were used for structure comparisons.

Other Computational Calculations. Protein anisotropic refinement validation and analysis tool (PARVATI) was used to validate anisotropic displacement parameters.[41,42] The SSM algorithm[43] in COOT was used to superpose protein models. All figures containing

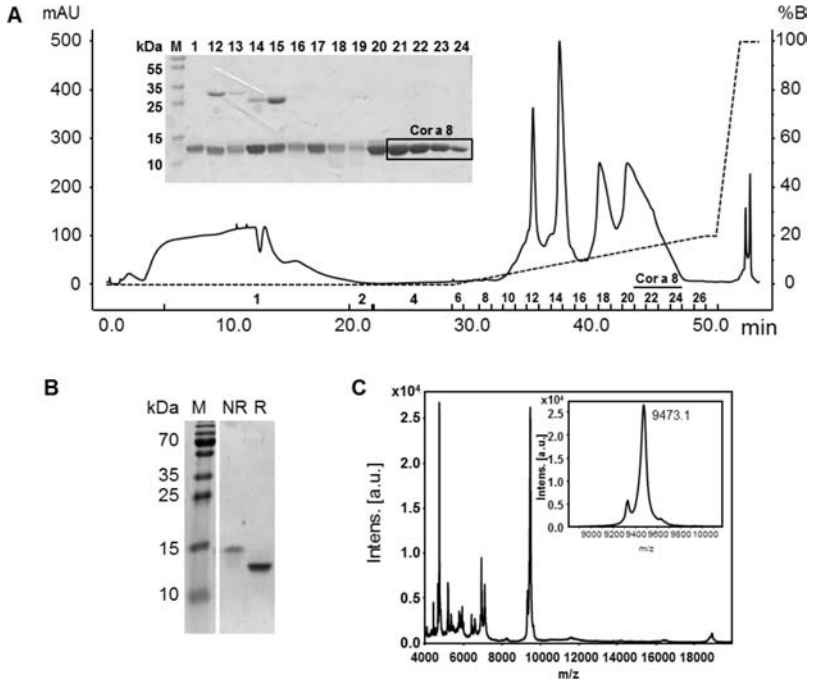

Figure 1. Purification of Cor a 8: (A) cation exchange chromatography of the hazelnut prolamin extract and Coomassie-stained 15% SDS-PAGE of Cor a 8-containing fractions; (B) 15% SDS-PAGE of purified Cor a 8 under nonreducing (NR) and reducing (R) conditions; (C) mass spectrum of Cor a 8.

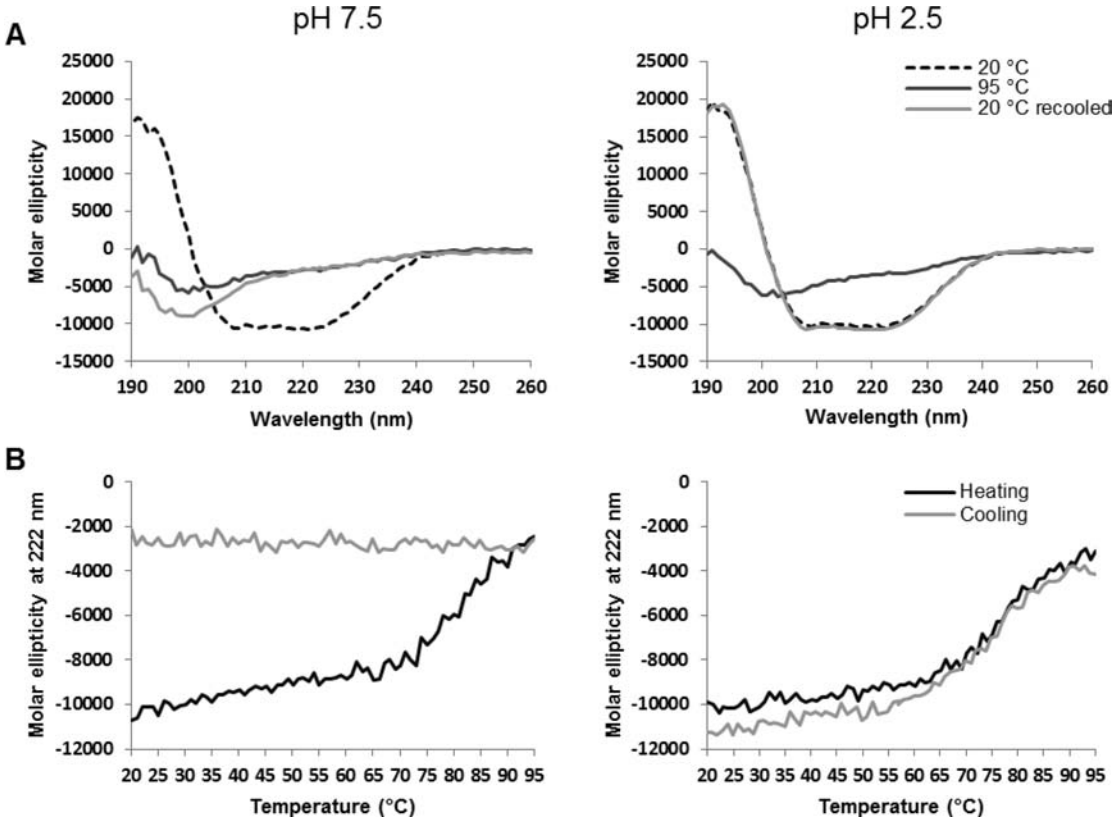

Figure 2. Far-UV CD spectra of Cor a 8: (A) spectra of Cor a 8 at room temperature (dotted line), after heating to 95 °C (dark gray line), and after recooling to room temperature (light gray line) at pH 2.5 and 7.5, respectively; (B) change in molar ellipticity at 222 nm during heating and cooling.

protein structures were prepared with PyMOL[44] or Chimera.[45] PDBePISA was used to calculate the probability of quaternary structure.[46] The Dali server[47] was used to identify structurally similar proteins. The ConSurf server was used to map sequence conservation on the structure of Cor a 8.[48]

RESULTS

Purification and Characterization of Natural Cor a 8.

Cor a 8 was separated from the prolamin fraction of hazelnut extract by using ion exchange chromatography techniques. SDS-

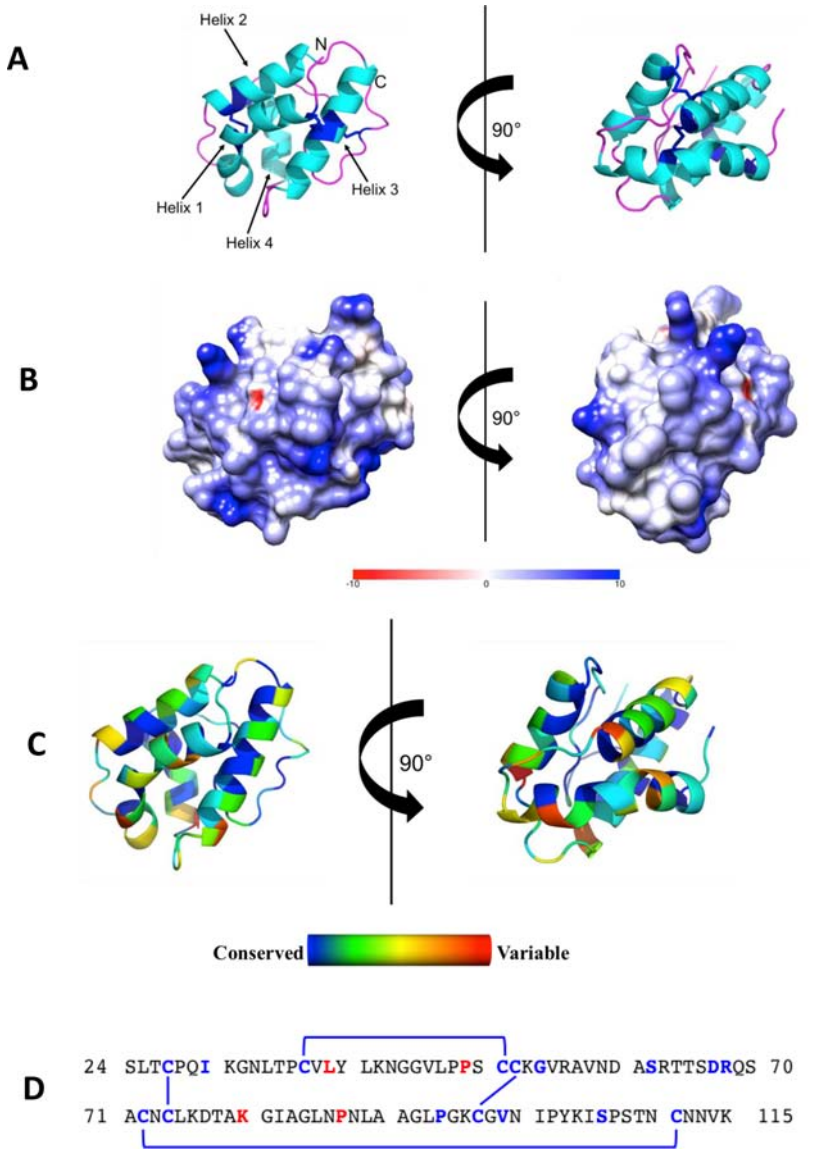

Figure 3. (A) Overall structure of Cor a 8. Secondary structural elements are colored separately where α-helices are cyan, β-sheets are red, loops are magenta, and disulfide bonds are blue. (B) Surface representation of Cor a 8 with electrostatic potentials where blue indicates positive charge and red indicates negative charge in units of kcal/(mol·e). (C) Ribbon representation of Cor a 8 showing conserved residues derived from an alignment of 150 Cor a 8-related protein sequences selected by ConSurf. The most conserved residues are shown in blue, whereas the most variable residues are shown in red. (D) Sequence of Cor a 8, in which the most conserved residues are blue and the most variable residues are red. The cysteine residues participating in disulfide linkages are bracketed.

PAGE analysis revealed that fractions F21−F24 were highly enriched in a protein with a molecular mass of ∼14000 Da (Figure 1A). Upon reduction, a band of about 12000 Da became visible (Figure 1B). This higher apparent molecular weight in SDS-PAGE seems to be characteristic for nsLTPs, as it was also shown for other members of this protein family.[22,49] MALDI-TOF-MS analysis yielded a mass of 9473.1 Da ($[M + H]^+$ = 9475.8; $[M + 2H]^{2+}$ = 4736.7) (Figure 1C), which is in good correlation with the theoretical mass of 9468.0 Da (Uniprot Q9ATH2, aa 24−115). Further evidence came from the N-terminal sequencing, which confirmed the first six N-terminal amino acid residues (SLTCPQ).

Secondary Structure and Thermostability. The overall secondary structural composition and heat stability were investigated using CD spectroscopy (Figure 2). CD spectra of the native protein at room temperature showed the typical characteristics of nsLTPs with high α-helical content. At room temperature, differences in pH did not change the secondary structure. However, the spectra of Cor a 8 prior to and after heating at pH 7.5 were different, showing that thermal unfolding was irreversible, whereas at pH 2.5 the overall protein fold was partially recovered. This demonstrates that Cor a 8 is more stable at acidic than at neutral conditions.

Structural Analysis of Cor a 8. The full-length, immature, Cor a 8 molecule is composed of 115 residues; residues 1−23 correspond to the signal peptide, which is cleaved upon maturation. All residues that comprise the mature protein, 24−115, are visible in the electron density map in both chains A and B. Overall, the mature Cor a 8 molecule is composed of four α-helices connected by loop regions. Eight cysteine residues are present in the mature protein, all of which participate in disulfide bonds: residues 27 and 74, 37 and 51, 52 and 97, and 72 and 111

J. Agric. Food Chem. 2015, 63, 9150−9158

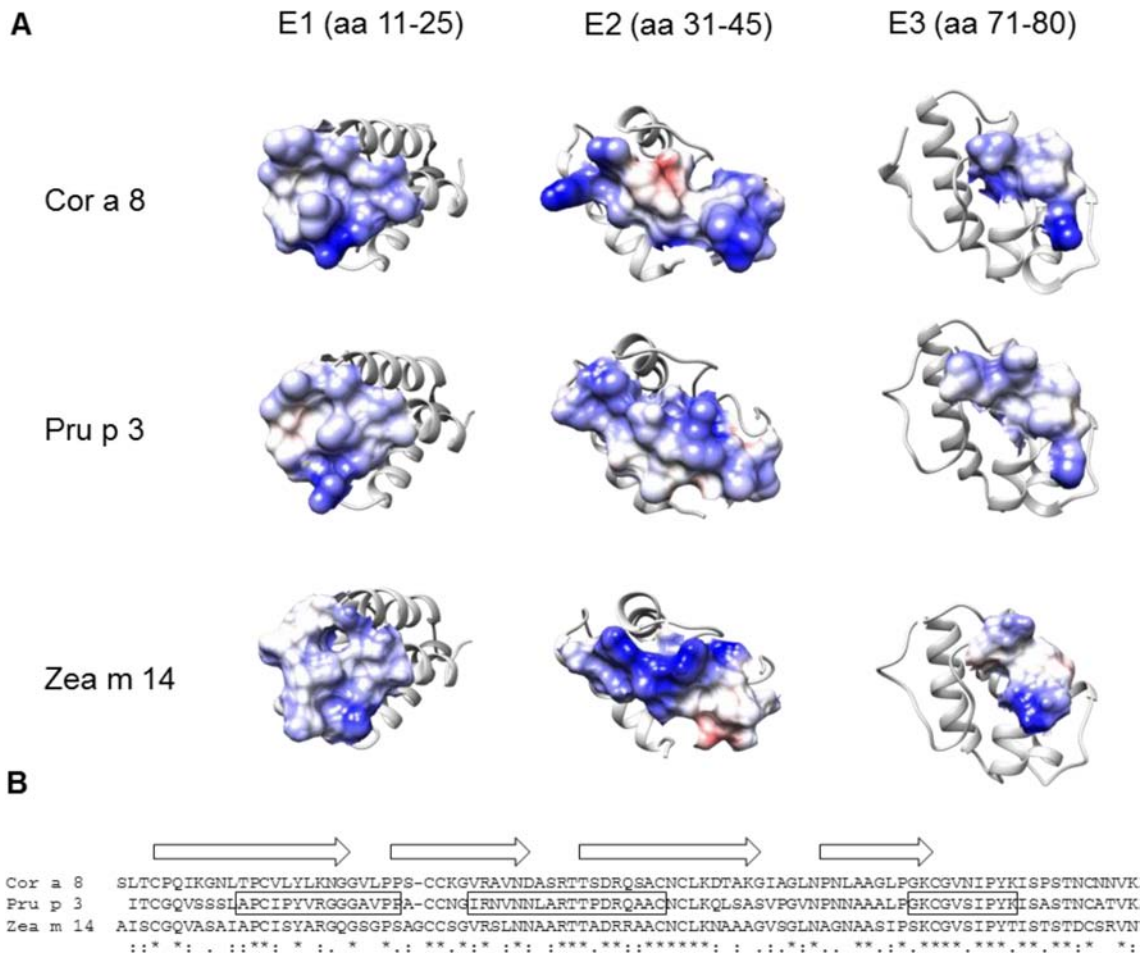

Figure 4. (A) Comparison of known epitope surface regions between Cor a 8, Pru p 3, and Zea m 14 (maize nsLTP); surface representation with electrostatic potentials where blue indicates positive charge and red indicates negative charge in units of kcal/(mol·e). (B) Primary sequence alignment of the mature protein sequences of Cor a 8, Pru p 3, and Zea m 14. Arrows indicate α-helices, and previously identified IgE-binding epitopes of Pru p 3 are marked with boxes.

(Figure 3). A comparison of chains A and B reveals very slight differences between the two, namely, at residues 64−68, 86−89, and 112−115. Chains A and B superpose with a root-mean-square deviation (RMSD) of 0.4 Å over 92 aligned Cα atoms. Although Cor a 8 crystallized with two subunits per asymmetric unit, PDBePISA suggests that this protein is monomeric. Electrostatic potentials were calculated using Chimera and are mapped out on the surface of Cor a 8, shown in Figure 3B.

Structural Comparison of Cor a 8 with Other Members of the nsLTP-family. Upon performing a search to find structurally similar proteins to Cor a 8, the Dali server identified the nsLTP Pru p 3 from peach (PDB ID 2B5S) as the most closely related structure. A superposition of 2B5S on our structure results in a RMSD of 1.4 Å over 91 aligned Cα atoms and a sequence identity of 57%. The peach allergen Pru p 3 (PDB ID 2B5S) has lauric acid bound in both subunits. A comparison of subunit A from Cor a 8 with subunit A of 2B5S reveals large structural differences at the C-terminus, residues 99−115 according to Cor a 8's numbering. Pru p 3's C-terminal loop is moved out toward the surface of the molecule, whereas the same region on Cor a 8 is closer to the core of the molecule. These changes are due to the binding of lauric acid between the third α-helix and the C-terminal loop of Pru p 3. Interestingly, a superposition of the two reveals that the pocket, where lauric acid is bound in the Pru p 3 structure, is occupied by Tyr103 of Cor a 8 (corresponding to Tyr79 of Pru p 3). The corresponding Tyr from Pru p 3 (Tyr79) is flipped outward, allowing for lauric acid to bind.

Dali also identified several nsLTPs from a variety of sources as structurally similar to Cor a 8. Aside from peach, an nsLTP from *Oryza sativa*, rice (for example, PDB ID 1UVC, RMSD value 1.2 Å over 90 aligned Cα atoms, sequence identity of 48%), was identified as the second most structurally similar nsLTP to Cor a 8. 1UVC crystallized with two subunits per asymmetric unit. Each subunit has stearic acid bound, and it is bound to the core of the protein between all four α-helices. A comparison of subunit A from Cor a 8 with subunit A of 1UVC reveals no drastic structural changes between the two structures. There are slight conformational shifts in the α-helices, and the largest structural change is seen at the C-terminal loop, namely, residues 100−115 of Cor a 8 (which correspond to residues 76−91 of 1UVC).

Additionally, Dali identified nsLTPs from barley (for example, PDB ID 3GSH, RMSD value 1.2 Å over 90 aligned Cα atoms, sequence identity of 43%) and maize nsLTP (Zea m 14; PDB ID 1MZL, RMSD value 1.4 Å over 92 aligned Cα atoms, sequence identity of 48%) as structurally similar to Cor a 8. Barley nsLTP (3GSH) has an oxylipin adduct (PDB Ligand ID ASY) bound in both subunits. The adduct splits into two branches, where one branch is buried in the core of the protein between the first and third α-helix and the second branch interacts with the surface of

DOI: 10.1021/acs.jafc.5b03534
J. Agric. Food Chem. 2015, 63, 9150−9158

the protein at the third α-helix. This ligand's mode of binding is very different from that seen in both 2B5S and 1UVC. A superposition of Cor a 8 and 3GSH reveals slight structural differences with the largest conformational change located at the loop that connects helix 1 and helix 2. These differences, however, do not appear to be attributed to bound ligand. Zea m 14 (1MZL) is an apo nsLTP, like that of Cor a 8. A superposition of the two reveals differences in the loop region that connects helix 1 and helix 2, as well as differences in the loop that connects helix 3 and helix 4, and the differences continue on through the C-terminal loop. Furthermore, Dali identified nsLTPs from tobacco (PDB ID 1T12), mung bean (PDB ID 1SIY), and lentil (PDB ID 2MAL) as Cor a 8 related structures that have lower structural similarity than those listed above, but higher sequence identity, at >50% for all three. Figure 3C shows a ribbon representation of the Cor a 8 molecule, indicating conservation among 150 Cor a 8-related protein sequences selected by ConSurf. Furthermore, Figure 3D includes Cor a 8's sequence, where the most and least conserved residues are shown and disulfide linkages are indicated.

Figure 4 shows a comparison of the surface topology of relevant epitope regions of Pru p 3 (E1, aa 11−25; E2, aa 31−45; and E3, aa 71−80)[23] with that of Cor a 8 and Zea m 14. Despite a common backbone structure, differences in the surface topology, defined by the different side chains, are obvious. When E1 from Pru p 3 is compared to the respective areas of Cor a 8 and Zea m 14, the electrostatic potentials seem to be similar. In contrast, E2 from Pru p 3 lacks the negative charges present in Cor a 8 and Zea m 14. Epitope 3 seems to be predominantly neutral in Pru p 3 and Zea m 14, whereas Cor a 8 presents more positive charges in this area.

MD Simulations for Cor a 8. Overall, the structure of the MD relaxed model of the apo form of Cor a 8 is very similar to that seen in the crystal structure. RMSD calculated for all backbone atoms between the crystal structure and a representative snapshot amounts to 2.2 Å, with somewhat larger displacements for fragments 59−63 (2.6 Å), 77−87 (3.0 Å), and the C-terminal fragment 89−92 (3.2 Å). Conformations of the disulfide bridges are preserved throughout the simulated trajectory. For Tyr79, the same rotamer (CG−CB−CA−C ca. −80°) that is observed in the crystal structure prevails (88% of snapshots) during the 150 ns long trajectory. The side chain of Tyr79 remains mostly in hydrophobic regions of the interior of the protein with nearest neighbors Val35, Ser39, Ala48, Cys49, Leu52, and Ile78. Another rotamer of Tyr79 observed in the MD trajectory (12%; CG−CB−CA−C ca. 45°) also features the side chain buried in the hydrophobic interior of the protein.

To model the structure of a Cor a 8 with laureate bound, coordinates of laureate from the stable structure of the Pru p 3/laureate complex (vide infra) were merged with those for the protein from the crystal structure 4XUW. Throughout the whole trajectory laureate remained in this binding site, that is, in the middle of the protein between the four helices, whereas Tyr79 changed its conformation at the eighth ns of the simulation. More specifically, the dihedral angle CG−CB−CA−C changed its value from ca. −63° to ca. +45° (this is a minor (12%) rotamer of Tyr79 observed for the apo form of Cor a 8), which results in placing the phenolic ring of Tyr79 in contact with the aliphatic tail of laureate. Once this configuration was attained, it remained stable until the end of the simulated trajectory. RMSD calculated for all backbone atoms amounts to 1.7 Å, and a larger displacement with respect to the crystal structure was observed for the 76−87 fragment (3.2 Å). As in other simulations, conformation of the disulfide bonds remains the same as in the crystal structure.

MD Simulations for Pru p 3. *Pru p 3/Laureate/n-Heptane Complex.* Simulation for Pru p 3 with laureate and *n*-heptane bound revealed the structure of the complex remains almost unchanged throughout the initial fragment (0−40 ns) of the simulated trajectory. Both ligands occupy the same sites as in the crystal structure, and Tyr79 is exposed at the protein surface. RMSD for the protein backbone calculated with respect to the crystal structure amounts to only 1.2 Å.

A clearly visible conformational change takes place between te 40th and 50th ns of the simulated trajectory, and it consists of movement of the 60−69 fragment (loop and helix) toward the 40−58 helix and simultaneous displacement of the *n*-heptane ligand from its original binding site toward the site originally occupied by laureate. Concertedly, Tyr79 moves into the protein's interior via changing its CG−CB−CA−C dihedral angle from around 180° to around −80°. RMSD for the backbone atoms is 1.85 Å with respect to the crystal structure, and larger differences are observed for fragment 60−69 (3.5 Å), which has moved during the conformational transition, and the C-terminal region 74−91 (2.4 Å). Laureate forms a salt bridge with Arg32, whereas its aliphatic tail takes the place occupied by *n*-heptane in the crystal structure.

Pru p 3/Laureate Complex. The initial geometry of the Pru p 3/laureate complex was obtained by removal of *n*-heptane from the crystal structure (2B5S). After simulations, the overall structure of the protein is very similar to that observed in the crystal; RMSD for all backbone atoms amounts to 1.3 Å, and it is slightly larger for the loop 19−23 (1.7 Å) and fragments 75−86 (2.0 Å) and 86−92 (2.0 Å). Notably, at a fairly early stage of the MD simulation (around 37 ns), the laureate moved from its initial binding site to the site in the middle of the protein, that is, between the four helices, which was previously occupied by *n*-heptane, and it remained in this pocket until the end of the trajectory (150 ns). Once the laureate moved deeper into the protein's interior, Tyr79 followed, finally attaining the same rotamer state as observed for a corresponding residue of Cor a 8.

Apo Pru p 3. Simulations for the apo form of Pru p 3 revealed the side chain of Tyr79 enters the hydrophobic interior of the protein within the first 2 ns of the simulation and later on this residue remains in the same rotamer state as observed for the Pru p 3/laureate complex. RMSD calculated for all backbone atoms with respect to the crystal structure is 2.7 Å; larger displacements are observed for fragments 60−69 (4.3 Å) and 74−91 (4.5 Å).

DISCUSSION

Nonspecific lipid transfer proteins are ubiquitously expressed throughout the plant kingdom, and a number of those have been identified to be important food allergens, such as Pru p 3 from peach, Mal d 3 from apple, and Act d 10 from kiwifruit. Immunological cross-reactivity is primarily due to shared 3D structures, accessible for IgE antibody recognition. However, despite their common structure, nsLTPs display low sequence identities and thus surface-exposed areas. Consequently, it was shown that members from distantly related species do not cross-react to the same extent as members within the same plant family.[50,51] Therefore, structural analysis of individual nsLTPs provides detailed information for allergenic risk assessment.

Purified natural Cor a 8 crystallized in a monoclinic crystal form with an extremely low solvent content of 28% and a Matthews coefficient of 1.71 $Å^3\ Da^{-1}$. These circumstances may contribute to how well the crystal diffracted, because crystals with

DOI: 10.1021/acs.jafc.5b03534
J. Agric. Food Chem. 2015, 63, 9150−9158

lower solvent content tend to diffract better.[52] Notably, the structure of Cor a 8 reported here (PDB ID 4XUW) is one of the most tightly packed structures reported to the PDB.[53] Cor a 8 is the first hazelnut allergen with its structure determined, and the high-resolution model that was obtained provides a very accurate template for in silico analysis of IgE cross-reactivity among Cor a 8 and other nsLTPs.

Moreover, it was shown that the allergen is more stable in an acidic environment, enabling proper refolding post thermal denaturation. These results are in good correlation with a study from Gaier et al., who showed that natural Pru p 3 is more stable under acidic conditions as compared to neutral ones.[54] The authors discuss that cleavage of disulfide bonds at neutral pH and high temperature is due to β-elimination, a reaction in which a base-catalyzed subtraction of a β-proton from a cysteine results in cleavage of disulfide bonds, which was shown for thaumatin.

Molecular dynamics simulations performed for apo- and laureate-bound forms of Cor a 8 and Pru p 3 and the laureate/*n*-heptane double complex of Pru p 3 revealed several structural features of these proteins. First, the preferred site for binding a hydrophobic ligand is located in the center of the protein's core. Second, only when two ligands are bound simultaneously, as in the 2B5S crystal structure of Pru p 3, can the Tyr79 side chain be exposed at the surface of the protein as it can be expelled from the hydrophobic interior by the second ligand. Extended MD simulation for Pru p 3/laureate/*n*-heptane complex indicates, however, that binding of two ligands is not enough to force Tyr79 out, as with binding the two ligands differently (laureate and *n*-heptane swapped and laureate bound more shallowly) Tyr79 attains a rotameric state with its side chain pointing toward the protein's core. In apo forms of the proteins and in complexes with one (laureate) ligand, the Tyr79 side chain is buried in the interior of the protein, where it lines up a substrate pocket.

Two distinctive conformational states have been observed for Pru p 3, an open conformation, which is stable when a hydrophobic ligand occupies a bottom of the substrate pocket in the center of the protein (lined up by Leu10, Cys13-Cys27, Ile14, Val17, Ala66, and Leu69 side chains). This conformation is observed in the crystal structure 2B5S, as well as in the MD simulation for the Pru p 3/laureate complex. When a ligand binds more shallowly, or it is missing completely, the 62−74 helix moves toward the 40−58 helix and a closed conformation forms. No such easily noticeable conformational changes take place upon laureate binding to Cor a 8.

Although the overall structure of nsLTPs is highly conserved, sequence identities among nsLTPs are rather low, showing different degrees of identity among different sources. Members from the Rosaceae family (peach, apple, and almond), for example, show closely related primary structures (88−97% identity), whereas nsLTPs from more distantly related plant species such as seeds, cereals, or pollens are clearly less similar to the Rosaceae allergens, as well as to each other. Borges et al. showed that, on the basis of their relatively high sequence identities, nsLTPs from Rosaceae share consensus epitopes responsible for their IgE-binding cross-reactivity.[55] However, despite their high structural conservation, it seems that nsLTPs from distantly related species do not cross-react to the same extent as members belonging to the Rosaceae family.[22,24] Cross-inhibition experiments indicate that Pru p 3 was able to at least diminish binding to other members of the nsLTP family.[24]

To get a better understanding of the structural determinants relevant for IgE cross-reactivity, we compared the obtained three-dimensional structure of Cor a 8 with known structures of other nsLTPs. Figure 4 shows a comparison of already defined Pru p 3 epitope regions[23] with the corresponding regions from Cor a 8 and Zea m 14. Differences observed in the surface topology, defined by the different side chains, became obvious (Figure 4). Focusing on the electrostatic potentials, these areas demonstrated that differences between Cor a 8 and Pru p 3 were lower as compared to differences between Pru p 3 and maize LTP. Thus, it seems that the occurrence of IgE cross-reactive epitopes is based on the degree of surface topology, dependent on side chains, which are determinants of the allergen−antibody interaction. Since the exposed residues are based on the primary sequence, one could conclude that the degree of IgE cross-reactivity between different members of the nsLTP family depends on similarities of the respective epitope region, defining the molecular surface. This finding correlates with data from a recent study by Morales et al.,[24] who demonstrated that Pru p 3 shares some common epitopes with other nsLTPs, such as Cor a 8, Mal d 3, and Zea m 14. However, no complete inhibition was observed in cross-reactivity studies. This is in accordance with data from Hartz et al., who identified patients with allergic reactions to hazelnut but tolerant for peach.[23]

Currently, only a small fraction of food allergens have their structures determined experimentally. However, it is evident that only "real" structures help us to identify relevant surface-exposed areas, which are important for antibody binding and recognition. Furthermore, obtaining structural data from distantly related members of a protein family allow for more refined/reliable predictions for the range of cross-reactivities, with and without clinical implications. In addition, this information will contribute to the development of molecules with a reduced allergenic activity that would allow for a safer immunotherapeutic approach. As a first step we think that this newly identified Cor a 8 structure will help to elucidate the range of cross-reactivity and major IgE epitopes within the nsLTP family.

to its immiscibility in water, its low concentration, and the complexity of milk matrices. The determination of milk 17β-estradiol has been carried out by immunological[18] techniques, which offer several advantages compared to conventional analysis (i.e., low cost per sample, high selectivity, and high sensitivity) but are time-consuming. A really valid alternative to detect hormonal contaminants in foods, even 17β-estradiol levels in milk, is biosensors. It has recently been acknowledged that biosensor technologies represent a greatly versatile approach for their capability to solve a large number of analytical problems related to agriculture and food safety as well as environmental security, pharmacology, and medicine.[19] Recently, our laboratory has increased the knowledge about this topic and developed fluorescence polarization assays for the detection of penicillin G directly in milk[20] and of patulin in fruit juices.[21] In the present work, we describe a similar fluorescence polarization approach to measure traces of 17β-estradiol in milk. This assay is based on the use of an ad hoc synthesized 17β-estradiol hemisuccinate−glutamine-binding protein (GlnBP) conjugate labeled with fluorescent probe (Biotium CF647) and of polyclonal monospecific anti-17β-estradiol antibodies. Then, a competitive immunoassay has been performed with the aim to detect 17β-estradiol in milk sample without pretreatment steps. This method is rapid and innovative, and the analysis can be conducted directly in the real matrix with no interference due to different milk compounds, using an infrared emitting probe.

In conclusion, this technique represents a novel approach that allows the detection of any contaminant in a food matrix only by changing fluorescent conjugate molecules and specific antibodies; thus, it is a promising analytical tool in food quality and safety control.

MATERIALS AND METHODS

Reagents. All commercially available reagents were chosen for the highest quality. 1-[3-(Dimethylamino)propyl]-3-ethylcarbodiimide (EDC), bovine serum albumin (BSA; fraction V), 17β-estradiol, ovalbumin (OVA), and 3,5-tetramethylbenzidine (TMB) were purchased from Sigma-Aldrich (St. Louis, MO, USA). A PURE1A Protein A Antibody Purification Kit was purchased from Sigma. Goat polyclonal to rabbit IgG−HRP conjugate (secondary antibody) was from Abcam (Cambridge, UK). Affinity resin EAH Sepharose 4B and ECL detection reagents used in Western blot experiments were purchased from Amersham Biosciences (GE Healthcare Switzerland). Protran nitrocellulose transfer membranes were purchased from Schleicher & Schuell (Dassel, Germany). Microplates (96-well), Nunc LockWell MaxiSorp form, and a microplate reader, Multiskan EX from Thermo Scientific, were used for ELISA experiments. UV measurements were carried out on a Varian Cary 50 Bio spectrophotometer (Agilent Technologies, Santa Clara CA, USA). The fluorescent probe CF647 was purchased from Biotium (Hayward, CA, USA). Fluorescence experiments were performed with an FP-8600 fluorescence spectrometer (Jasco, Japan).

Synthesis of 17β-Estradiol-hemisuccinate. The 17β-estradiol-hemisuccinate (Figure 1B) was synthesized from 17β-estradiol (Figure 1A) following the previously reported procedure[22] but with minor modifications. Briefly, the 17β-estradiol (270 mg, 1.0 mmol) was dissolved in 12 mL of a mixture of benzene/pyridine (8:2, v/v) and refluxed with a succinic anhydride solution (600 mg, 6 mmol) for 24 h. TLC analysis showed the disappearance of the 17β-estradiol and the formation of two bands with a R_f lower than that of 17β-estradiol. The reaction mixture was dried under reduced pressure, and the residue was dissolved in acetone/ethanol (3 mL, 1:1, v/v) and purified by silica gel chromatography. For this purpose, the solution was absorbed on a small amount of silica gel (5.0 g) and, after evaporation of the solvent, the silica was applied on the top of a silica gel column, which

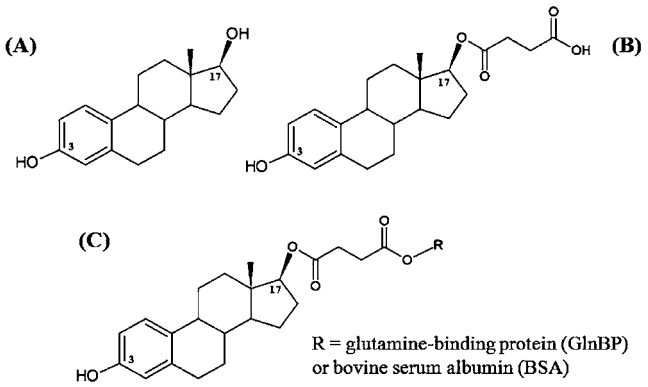

Figure 1. Chemical structure of the 17β-estradiol (A), 17β-estradiol-hemisuccinate derivative (B), and the GlnBP conjugate used for the production of the rabbit anti-17β-estradiol antibodies (C).

was eluted with an increasing amount of methanol in dichloromethane (DCM) (from 0 to 5% of MeOH). The purification furnished the estradiol-3,17β-bis-succinate (70% yield, lower R_f) and a product (at higher R_f), which was identified as a mixture of β-estradiol-3-hemisuccinate (15% yield) and β-estradiol-17-hemisuccinate (15% yield). The estradiol-3,17β-bis-succinate (300 mg), suspended in 10 mL of MeOH, was then treated with 10 mL of a 1.2 M solution of $NaHCO_3$, and the mixture was kept at room temperature under stirring for 15 h. The selective hydrolysis of phenolic ester furnished, as expected, a mixture of estradiol-3β and estradiol-17β-hemisuccinate. The latter (95% yield from bis-succinate) was further purified on a silica gel column (as previously described) eluted with an increasing amount of MeOH in DCM (from 0 to 20%, v/v). ^{1}H NMR and MS results were in agreement with those reported previously.[22]

Preparation of the 17β-Estradiol-hemisuccinate−BSA Conjugate for the Immunization Procedure. The 17β-estradiol-hemisuccinate−BSA conjugate (Figure 1C) was prepared by adding a solution of 17β-estradiol-hemisuccinate (2 mg) in 1 mL of 0.1 M MES buffer, pH 6.0, to a BSA solution (2 mg/mL) in 0.5 mL of the same buffer and 0.1 mL of an EDC solution in H_2O (10 mg/mL). The reaction mixture was incubated for 16 h at 4 °C and then extensively dialyzed for 3 days, against potassium phosphate buffer (20 mM), pH 7.4. The obtained conjugate was spectrophotometrically analyzed at λ = 278 nm (2 mg/mL), but the efficiency of conjugation could not be determined because the maximum absorptions at 278 nm of estradiol (275 nm) and BSA are overlapped.

Antibody Production and Purification. Two rabbits were immunized following a standard protocol by intradermal inoculation of an antigen (0.5 mg per rabbit). After the immunization period, the rabbits were sacrificed, and their blood was recovered and centrifuged to separate blood cells from serum. A 1.5 mL sample of rabbit serum diluted with 1.5 mL of binding buffer Tris (50 mM), pH 7.0, was applied to a protein A column of the PURE 1A Protein A Antibody Purification Kit, Sigma, and the IgG fraction was purified in agreement with the manufacturer's instructions. The IgG fraction was eluted with glycine (0.1 M) at pH 3.0, and immediately buffered in Tris-HCl (1.0 M), at pH 9.0, and its concentration and purity were checked by absorbance measurement at λ = 278 nm and sodium dodecyl sulfate−polyacrylamide gel electrophoresis (SDS-PAGE) analysis, respectively.

Affinity Column Preparation of 17β-Estradiol-hemisuccinate−EAH Sepharose 4B. The affinity column was obtained by conjugating 17β-estradiol-hemisuccinate to EAH Sepharose 4B. Briefly, Sepharose resin (0.6 mL) was washed with distilled water adjusted to pH 4.5 (20 mL) and with HCl, followed by 0.5 M NaCl (80 mL), and then added to a solution of 17β-estradiol-hemisuccinate (2 mg in 0.5 mL of H_2O), and the resulting suspension was gently shaken. The slurry was cooled to 0 °C, and EDC was added to a final concentration of 0.1 M. The reaction mixture was incubated overnight at 4 °C and then it was taken to room temperature. The suspension was washed with H_2O at pH 4.5, 0.1 M acetate buffer containing 0.5 M

DOI: 10.1021/acs.jafc.5b03689
J. Agric. Food Chem. 2015, 63, 9159−9164

NaCl (20 mL), pH 4.0, and 0.1 M PBS containing 0.3 M NaCl, pH 7.4, and finally packed into a polystyrene column (2 mL, Bio-Rad). For the affinity chromatography purification, a solution of IgG (8.0 mg/mL), obtained from protein A purification, was applied dropwise to the previously prepared affinity column. Before elution of the monospecific IgG, three high-salt buffers at pH 7, all containing 10 mM PBS but increasing concentrations of NaCl (0.1, 0.5, amd 1.0 M, respectively), were used to wash away antibodies weakly and unspecifically bound to the column. Instead, monospecific IgG was eluted with 0.1 M glycine, at pH 3.0, and appropriately monitored by absorbance measurements at 278 nm and SDS-PAGE. The fractions containing the antibodies were collected and dialyzed against a buffer containing 0.01 M PBS and 0.1 M NaCl, pH 7.4. The concentration of the monospecific antibodies, spectrophotometrically determined at λ = 278 nm, was 1.3 mg/mL

Preparation of 17β-Estradiol-hemisuccinate−GlnBP Conjugate. The 17β-estradiol-hemisuccinate was conjugated to *Escherichia coli* GlnBP, a protein different from that used for the immunization process, with the aim of avoiding interferences due to BSA during the polyclonal antibody detection. The synthesis of 17β-estradiol-hemisuccinate−GlnBP conjugate (Figure 1C) was carried out following the same procedure previously described for the 17β-estradiol-hemisuccinate−BSA conjugate.

Antibody Titration Experiments. The antibody titer was determined by an indirect ELISA. The antigen (17β-estradiol-hemisuccinate−GlnBP), dissolved in 0.1 M PBS, pH 7.4, was used to coat 96-well microplates, at increasing concentrations from 125 to 5000 ng/mL, and incubated overnight at 4 °C. Control wells were incubated for the same period with GlnBP dissolved in the same buffer. The wells were flushed three times with TBS 1× containing 0.05% Tween (TBST), pH 7.4, and blocked by incubation for 1 h at room temperature with TBST containing OVA (1%). After two washings with TBST, polyclonal and polyclonal monospecific anti-estradiol antibodies were serially diluted in blocking buffer, added to the wells, incubated at room temperature for 1 h, and then washed twice with TBST. Horseradish peroxidase-conjugated anti-rabbit IgG antibodies, diluted 1:12000 in blocking buffer, were added to the wells and incubated at room temperature for 1 h. After two washings with TBST, the enzyme substrate TMB was added, and the color reaction was quenched by adding 2 M HCl, for 5 min. The absorbance measurements were recorded at 450 nm.

Western Blot Experiments. Proteins (BSA, GlnBP, and 17β-estradiol-hemisuccinate−GlnBP, 20 μg for each lane) were separated by 12% SDS-PAGE and then transferred overnight at 4 °C onto a nitrocellulose membrane. Membranes were blocked for 30 min at room temperature in 50 mL of the blocking buffer (TBS containing 5% of milk), washed with TBST (10 min for each washing), and incubated with purified monospecific IgG (1:100000 in the blocking buffer containing Tween 0.05%) for 1 h at room temperature. After three washings with TBST, the filters were incubated with secondary antibody (goat anti-rabbit HRP conjugate, 1:6000 in the blocking buffer containing Tween 0.05%) for 1 h at room temperature and washed three times as described above. Finally, proteins were visualized by chemoluminescence using the Amersham ECL plus and X-ray films developed on the Compact X4, Xograph Imaging systems.

Fluorescence Labeling of 17β-Estradiol-hemisuccinate−GlnBP and Steady-State Fluorescence Measurements. A solution of 17β-estradiol-hemisuccinate−GlnBP (2.0 mg/mL) was concentrated by nitrogen flow and diluted with 0.1 M sodium bicarbonate buffer, pH 7.0, at a final concentration of 4.0 mg/mL. This solution was mixed with the CF647 dye (Biotium) at a protein/dye molar ratio of 1:10 and incubated for 1 h at 37 °C. The labeled molecules were separated from unreacted probe by gel filtration and extensive dialysis in PBS buffer at pH 7.0. Steady-state fluorescence experiments were performed by using an FP-8600 fluorescence spectrometer, equipped with a thermostatic cell holder. The excitation wavelength was fixed at 630 nm, and emission spectra were recorded between 650 and 800 nm with excitation and emission slit widths of 5 and 2.5 nm, respectively. The fluorescence measurements were performed at 25 °C on five times diluted solutions of milk with PBS at pH 7.4. 17β-Estradiol-hemisuccinate−GlnBP-CF647 was incubated with a range of concentrations of antibodies against 17β-estradiol from 0.0 to 2.2 pmol for 10 min, and polarization fluorescence measurements were acquired by inserting a Glan polarizer between the excitation source and the sample, with a vertical (0°) excitation and emission polarized filter.

17β-Estradiol Competitive Assay. A competitive polarization assay was performed at a fixed concentration of antibody against 17β-estradiol (2.2 pmol) in the presence of increasing concentrations of unlabeled 17β-estradiol contaminating the milk (five times diluted with PBS at pH 7.4) at a range of concentration from 0.0 to 47 pmol. The incubation was performed at 25 °C for 10 min. After this pre-incubation in the presence of unlabeled 17β-estradiol, polarization fluorescence measurements were carried out with an FP-8600 fluorescence spectrometer with an excitation and an emission polarized filter set at 0°. The temperature of samples was measured directly in the cuvette with an accuracy of ±0.2 °C.

RESULTS AND DISCUSSION

Steroids have been widely used as growth-promoting agents in livestock with the principal aim to reduce the FCE and increase the animal weight gain and the milk yield in breeding of meat and milk animals. The administration of naturally and synthetic anabolic growth promoters in food-producing animals is now prohibited by the EU because of their potential risk to consumer's health. Nevertheless, illegal use or abuse of 17β-estradiol as an additive in animal feed or as subcutaneous injections, in hormonal treatments, implies a contamination of produced milk with several consequences for human health.[23] In the absence of a precise regulation that sets the maximum limit of such substances in milk and official methods of analysis, the development of procedures addressed at this aim is of great importance. A rapid and simple method to detect the concentration of 17β-estradiol in milk is urgently needed to control all phases of milk production, from the cattle shed to the consumers' table.

Antibody Fluorescence Polarization-Based Sensor for 17β-Estradiol Sensing. In the context of high competence in the biosensor field, we propose a new method of 17β-estradiol detection that combines fluorescence polarization assays and a strategy well-established by our research group (Figure 2), starting from the functionalization of the 17β-estradiol to a more reactive carboxylic derivative with a significantly higher antibody response. Actually, in this context, the 17β-estradiol derivatization process is markedly necessary to obtain a derivate exhibiting a higher stability and a short arm to be conjugated to the protein carrier while maintaining the original skeleton of estradiol. 17β-Estradiol binding to a carrier protein through a spacer such as a hemisuccinic arm is necessary to distance the antigen from the same protein. On the other hand, the presence of a carrier protein conjugated to the hormone was then strongly required for amplifying the immunological response of antibodies against 17β-estradiol that would otherwise be too small because of its very low molecular weight. Then, the synthesis of 17β-estradiol-hemisuccinate was preliminarily carried out with the aim of preparing the antigen 17β-estradiol-hemisuccinate−BSA conjugate (BSA was chosen as carrier protein) to be used in the standard protocols of immunization on two different rabbits (Figure 2). At the end of the immunization period, a protein A antibody chromatograph was used to separate the IgG fraction from the complex pool of serum protein, whereas a further affinity chromatography by EAH Sepharose 4B resin was carried out to isolate specifically

the monospecific antibodies against 17β-estradiol from total IgG fraction. To verify the specificity and titer of produced antibodies, the 17β-estradiol-hemisuccinate−GlnBP conjugate instead of the 17β-estradiol-hemisuccinate−BSA conjugate was used for the further analysis because of interference problems due to the presence of BSA during the polyclonal antibody detection.

Specificity and Titer of Produced Monospecific Antibodies. The preliminary SDS-PAGE analysis (Figure 3A) of BSA, GlnBP, and 17β-estradiol-hemisuccinate−GlnBP

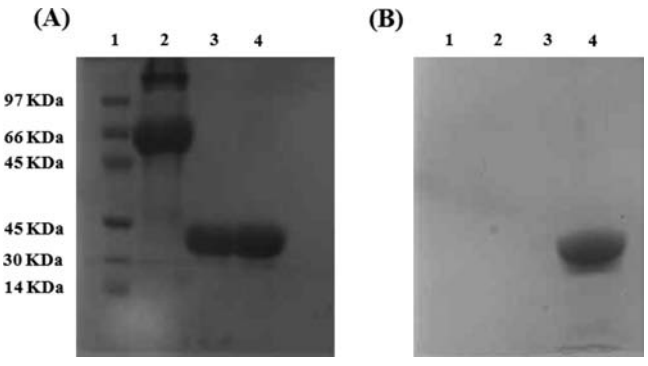

Figure 3. SDS-PAGE (A) and nitrocellulose filter (B) after incubation with 17β-estradiol antibodies. Lanes: 1, molecular weight standards; 2, BSA; 3, GlnBP; 4, 17β-estradiol-hemisuccinate−GlnBP.

demonstrated the purity of the preparations, used in the Western blotting experiments (Figure 3B) to verify the specificity of the produced antibodies. The response to antibody binding was observed only for the conjugate 17β-estradiol-hemisuccinate−GlnBP, and a negative response was registered for BSA and GlnBP (Figure 3B). This confirms the specificity of antibodies versus the only estradiol. In addition, an indirect ELISA test was performed to evaluate the titer of polyclonal monospecific purified antibodies. The results have shown that no signal was registered as a consequence of incubation with different diluted samples of IgG for noncoated wells, whereas an increase of the absorbance was registered as a function of decreasing the dilution factor of polyclonal monospecific antibodies against 17β-estradiol (data not shown). The titer was considered as the maximum antibody dilution able to give a reading of 0.1 absorbance unit. The experiment, performed in triplicate, showed that the titer of anti-17β-estradiol antibodies was excellent. In fact, it was possible to perform the ELISA test with mono-specific IgG dilutions up to 1 to 100000.

Fluorescence Steady-State Measurements of 17β-Estradiol-hemisuccinate−GlnBP-CF 647 Conjugate and Competitive Immunoassay. 17β-Estradiol-hemisuccinate−GlnBP was labeled with a fluorescence probe (CF647 dye), possessing near-infrared emission, to record changes in the emission processes on the basis of specific binding to anti-estradiol antibodies. The polarized emission spectra of 17β-estradiol-hemisuccinate−GlnBP-CF647 fluorescent conjugate were acquired in the absence and in the presence of increasing concentrations of antibodies against estradiol ranging from 0.0 to 2.2 pmol (Figure 4). The fluorescence polarization spectrum

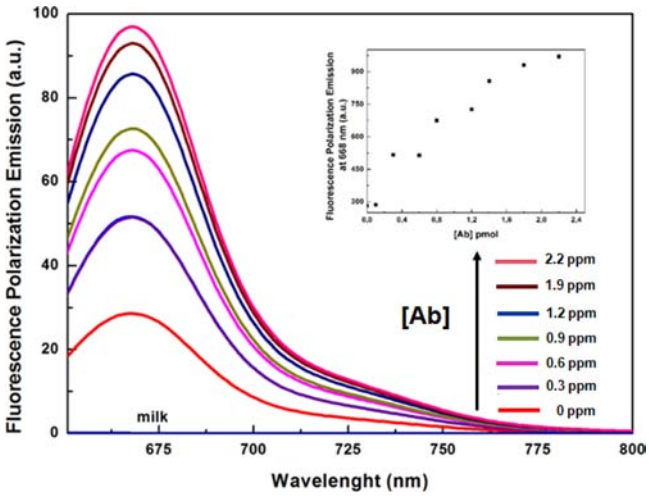

Figure 4. Polarization emission spectra of 17β-estradiol-hemisuccinate−GlnBP-CF647 in the absence and in the presence of increasing concentration of antibodies against 17β-estradiol.

of milk samples showed a maximum of fluorescence emission, centered at 668 nm, and revealed an increase of 17β-estradiol-hemisuccinate−GlnBP-CF647 fluorescence polarization emission as a consequence of binding with anti-17β-estradiol antibody, present in solution. Subsequently, a fluorescence polarization competitive immunoassay was used to measure unlabeled 17β-estradiol in solution. To evaluate the competition between 17β-estradiol-hemisuccinate−GlnBP-CF647 and unlabeled 17β-estradiol for binding with monospecific antibodies against 17β-estradiol, different samples at a fixed concentration of antibody (2.2 pmol) were incubated in the presence of increasing concentrations of unlabeled 17β-estradiol in a range between 0.0 and 47 pmol, before the fluorescence polarization measurements were performed. The polarized fluorescence spectrum in the presence of increasing concentrations of unlabeled 17β-estradiol showed a reduction of fluorescence emission following increasing concentrations of unlabeled 17β-estradiol (Figure 5). The presence of increasing concentrations of the analyte in the milk samples allowed return to the minimum measurable value of the analyte. The

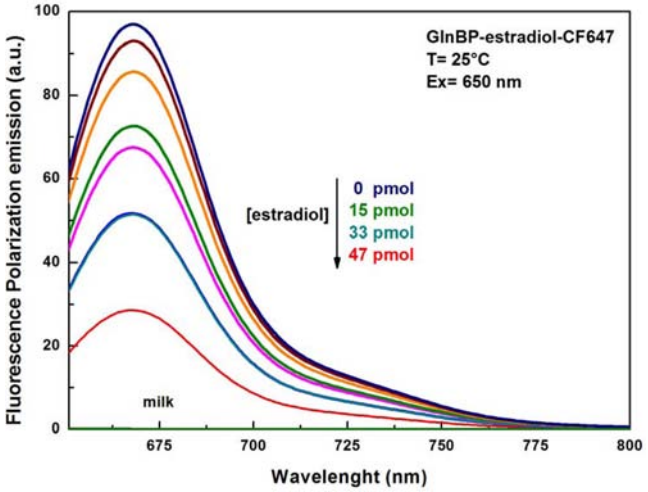

Figure 5. Polarization fluorescence emission spectra of 17β-estradiol-hemisuccinate−GlnBP-CF647.

dose response curve for 17β-estradiol detection in diluted milk reported the polarization fluorescence variations (at 668 nm) as a function of 17β-estradiol concentration (Figure 6). The results demonstrated that 17β-estradiol concentration was easily calculable in milk with a limit of detection (LOD)[24] of <10 pmol, lower than the EU limit.

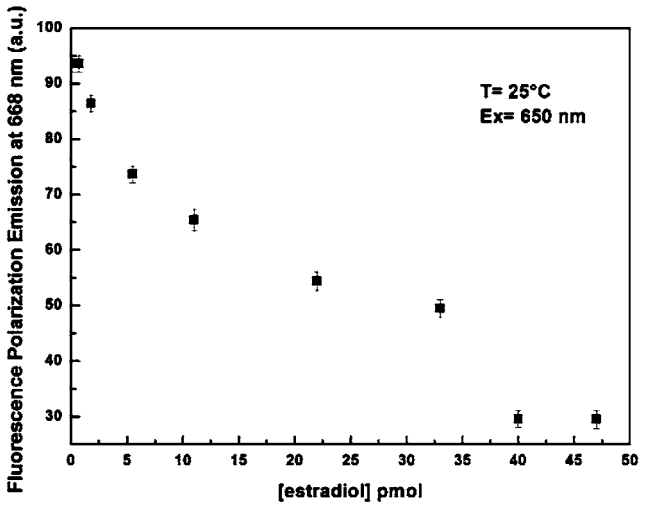

Figure 6. Titration of fluorescence polarization immunoassay with increasing concentration of unlabeled 17β-estradiol.

During the past decade, different efforts have been made by other groups to identify and quantify the presence of 17β-estradiol in food. In the field of biosensor, several assays based on the use of human estrogen receptor have been developed for the determination of 17β-estradiol. These biosensors are highly sensitive but unfortunately not suitably specific due to the wide range of affinity of estrogen receptor to other xenoendocrines.[25,26] Recently, immunosensors and nanobiosensors have also been developed for sensitive and rapid detection of 17β-estradiol by utilizing antibodies or functional polymers,[27,28] ane a DNA-Aptamer optical biosensor has been realized for the detection of 17β-estradiol in water.[29] The present paper shows a fluorescence polarization competitive immunoassay for detecting 17β-estradiol up to a concentration of <10 pmol. This assay can be carried out directly in a real matrix, without any sample pretreatment, providing great advantages in time and cost terms. In addition, the simplicity and quickness of 17β-estradiol quantification, performable during every step of milk production from milking to the commercial product, offer further reasons why our procedure could be preferred to others. Actually, it is not the first time that we have developed a fluorescence polarization-based method to measure a contaminant analyte in a food matrix. During past years, several papers from our laboratory have demonstrated the possibility of detecting other contaminants such as penicillin G[20] and patulin,[21] in milk and in juice, respectively, by using a very similar strategy (Figure 2), even at concentrations much lower than the established EU limit. Our expertise in this field gives us great confidence that this approach can be extended to any contaminant and to any food by carrying out minor modifications, thanks to the high flexibility of the developed method. Therefore, it is our opinion that the fluorescence immunoassay is a valid alternative to the analytical techniques, currently in use, and it can become a promising tool in the control of food quality and safety.

J. Agric. Food Chem. 2015, 63, 9159−9164

regulated at the transcriptional level by regulatory genes, and thus plant pigmentation patterns are mainly controlled by the expression profiles of regulatory genes.[15−17] The anthocyanin biosynthetic pathway includes genes encoding the enzymes chalcone synthase (*CHS*), chalcone isomerase (*CHI*), flavanone 3′-hydroxylase (*F3H*), dihydroflavonol reductase (*DFR*), leucoanthocyanidin dioxygenase (*LDOX*), and UDP-glucose:-flavonoid 3-*O*-glucosyltransferase (*UFGT*), which were partially cloned in grapevine by Sparvoli et al.[18] The *CHI* (X75963) and *UFGT* (AF000372) genes have been identified in *V. vinifera* and are located in chromosomes 13 and 16, respectively. Despite their localization in the anthocyanin pathway, UFGT and CHI are considered key enzymes.[19] CHI leads to the formation of flavanones in a central branching point of the flavonoid pathway;[16] on the other hand, UFGT is located in a final position of the anthocyanin pathway and is associated with the accumulation of anthocyanins in the berries' skin.[20−22] The *CHI* gene and the remaining genes (*PAL*, *CHS*, *F3H*, *DFR*, *LDOX*) are expressed in both white and red grapevine varieties. *UFGT* is expressed only in red grapevine varieties, and its expression is crucial for anthocyanin biosynthesis.[14,20]

The aim of this study was to develop a new HRM assay for grapevine varietal identification based on the detection of SNPs, insertions, and/or deletions (IN/DELs) in two genes involved in the anthocyanin pathway.

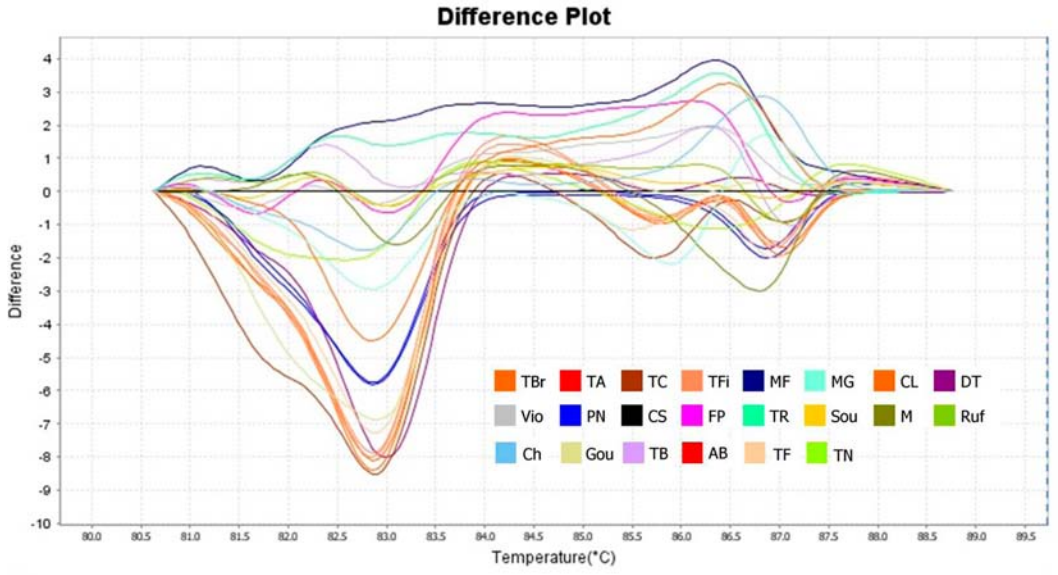

Figure 2. HRM difference plot of 22 grapevine varieties for UFGT fragment showing 18 different genotypes.

MATERIALS AND METHODS

***Vitis vinifera* L. Samples.** Twenty-two *V. vinifera* grapevine varieties (red and white) considered as the most representative genotypes used in wine production in Portugal, including both national and international accessions, were used. Young leaves of each grapevine variety (Table 1) were collected from the Sogrape Vinhos S.A. and Real Companhia Velha vineyards located in the Douro region and immediately frozen in liquid nitrogen.

Young leaves belonging to the clones of each grapevine variety were collected and immediately frozen in liquid nitrogen, from clonal fields belonging to the Sogrape enterprise, to the Sociedade Borges S.A., the Direção Regional de Agricultura e Pescas do Norte, and to the National Ampelographic Collection (CAN), located at Dois Portos in the National Vitivinicultural Research Station (EVN-INIAV).

Genomic DNA Extraction. Total genomic DNA was extracted from frozen young leaves using the CTAB method.[23] Each DNA sample was eluted in 100 μL of 0.1× TE buffer (100 mM Tris-HCl, 0.1 mM EDTA, pH 8), and the purity, integrity, and quantity of all DNA samples were estimated on Nanodrop 1000 spectrophotometer (Thermo Fisher Scientific, Wilmington, DE, USA) measurements and by electrophoresis on 0.8% agarose in 1×Tris−acetate−EDTA (TAE).

SNP Detection: Primer Design, PCR Assays, and PCR Product Sequencing. For SNP detection, single-copy genes are preferred over multicopy to avoid problems associated with paralog genes. In *Vitis*, both *UFGT* and *CHI* genes are single-copy genes; however, the number of *CHI* genes is dependent on the species.[17,24,25] The National Center for Biotechnology Information database (NCBI) was used to find sequences related to these genes using *V. vinifera* genome database (VvGDB). The *UFGT* and *CHI* genes were amplified using primers UFGTfwd (5′-ATGTCTCAAACCACCACCAAC-3′) and UFGTrev (5′-CCGGGAAACCTTTATTTTCA-3′) (Figure 1) and CHIfwd (5′-TATCCCCGAAGATGTCTCCA-3′) and CHIrev (5′-AAAGTG-TCCCGGATGTTAC-3′). generating 1500 and 1725 bp amplicons, respectively. Primers were designed in Primer3 software, considering the following parameters: size (between 18 and 22 bases in length), melting temperature (T_m) in the range of 50−60 °C; a %GC between 40 and 60, and absence of dimerization capability and of significant hairpin formation (>3 bp). The PCR reactions were performed in a 20 μL volume, containing 20 ng of genomic DNA, 1× PCR buffer, 25 mM $MgCl_2$, 0.2 mM dNTPs, 0.2 μM of each primer, and 0.3 U of *Taq* DNA polymerase (Roche). The reactions were incubated at 94 °C for 3 min, followed by 30 cycles of 94 °C/1 min, 58 °C/1 min, 72 °C/2 min, and a final step of 72 °C for 10 min.

PCR amplicons resulting from the amplification of *UFGT* and *CHI* genes were directly sequenced (STAB VIDA; http://www.stabvida.com), and the genotypes of the 22 grapevine varieties were obtained. Sequence alignment was performed using the BioEdit program (http://www.mbio.ncsu.edu/BioEdit/BioEdit.html). The alignments of reverse and forward sequences were applied to produce consensus sequences. The sequences of each individual DNA fragments were aligned with the original sequence to identify the SNP presence.

High-Resolution Melting Assay Design. HRM analysis was performed in a specific 704 bp fragment of the *UFGT* gene using primers U_HRMfwd (5′-GCAATGTAATATCAAGTCC-3′) (starting at 180 bp) and U_HRMrev (5′-TTTCTTTCTTTGAGCCATT-3′) (ending at 884 bp) (Figure 1).

PCR and HRM analyses were performed in a StepOne Real-Time PCR System (Applied Biosystems, Foster City, CA, USA) in a final volume of 20 μL containing the respective primer pair (5 pmol of each primer), 20 ng of gDNA, and the MeltDoctor HRM Master Mix (Applied Biosystems). PCR/HRM included an initial step of 10 min at 95 °C and 40 cycles of 30 s at 95 °C, 30 s at 58 °C, and 30 s at 72 °C. The melting curve was obtained continuously, performed as follows: 30 s at 95 °C, 1 min at 65 °C, 15 s at 95 °C, rising 0.3 °C/s, and 15 s at 65 °C. All reactions were performed in triplicate. High Resolution Melt Software v3.0.1 (Applied Biosystems) was used to analyze the data. After normalization and determination of the temperature shift, the different melting curves of the several plots were generated.

To validate the reference HRM profile for each grapevine variety, DNA from the clones was analyzed using the developed HRM assay, using the previously described conditions.

Phylogenetic Analysis. Predicted amino acid sequences were used for phylogenetic analysis using the COBALT multiple-sequence alignment tool, which takes into consideration the conserved domain database, protein motif database, and sequence similarity (http://www.st-va.ncbi.nlm.nih.gov/tools/cobalt/re_cobalt.cgi).[26]

RESULTS AND DISCUSSION

SNP Identification. The *CHI* gene is located in a central position in the anthocyanin pathway. This gene was sequenced in 22 grapevine varieties (14 Portuguese and 8 international), revealing the existence of only 5 SNPs among all of these varieties (data not shown). The low number of SNPs detected within this gene is in accordance with previous studies, making it a noninteresting marker for varietal identification purposes.[11,27]

J. Agric. Food Chem. 2015, 63, 9165−9174

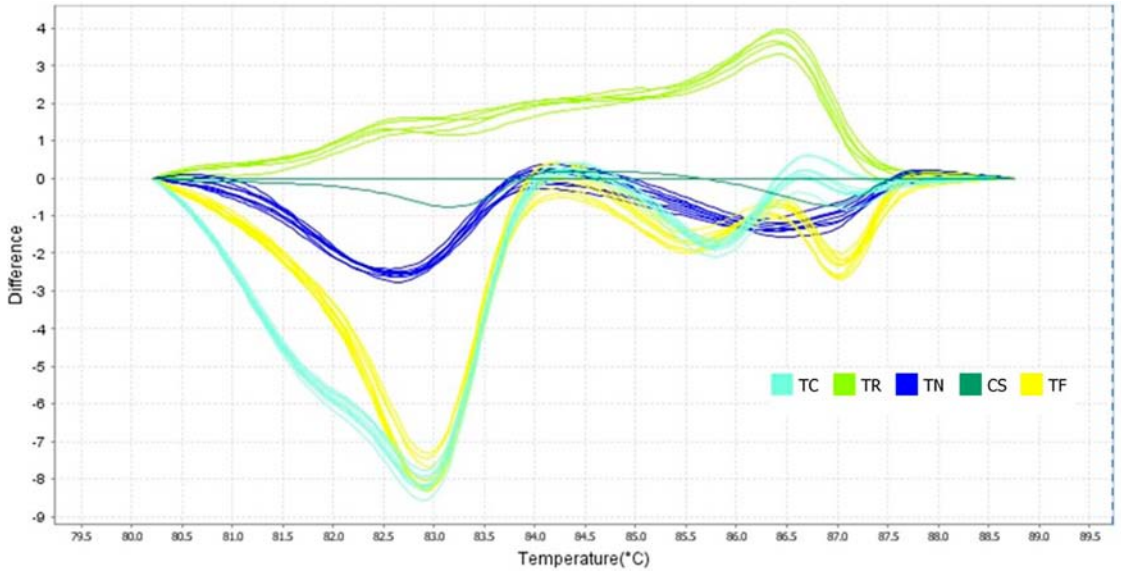

Figure 3. HRM different curves of the most representative grapevine varieties used in wine production in Portugal and corresponding clones for UFGT fragment.

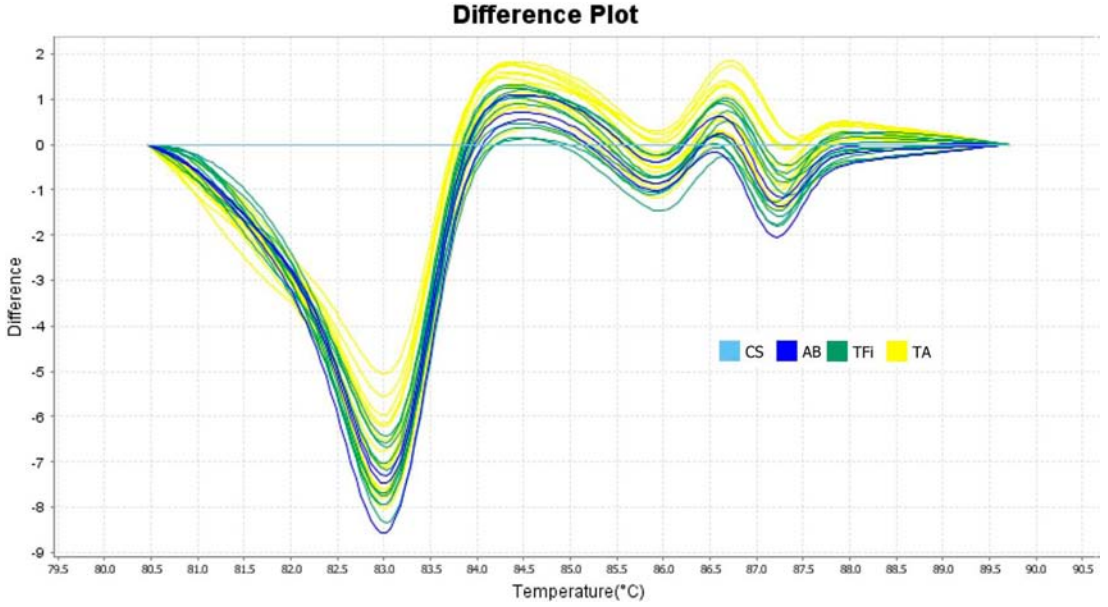

Figure 4. Difference plot of the grapevine varieties and corresponding clones presenting the same genotype for UFGT fragment.

On the contrary, the *UFGT* gene was revealed to be highly polymorphic, presenting a high number of SNPs among the grapevine varieties studied. The *UFGT* gene length covered 1500 bp, and within this region a total of 58 SNPs and an insertion were detected (Table 2). Eighteen SNPs and the insertion were found within the exon 1 region (493 bp) with an average frequency of 1 SNP/25.9 nucleotides. Four SNPs were found in the intron (74 bp) with an average frequency of 1 SNP/18.5 nucleotides. The remaining 36 SNPs were positioned within the exon 2 region (881 bp) with an average frequency of 1 SNP/24.5 nucleotides. These results are interesting because the number of SNPs detected within the coding region is high, contrary to previous studies (sunflower,[28] cotton,[29] and grapevine[30]) where the majority of the SNPs were located in the noncoding region of the genes. The high SNP frequency found within this gene is particularly interesting because *UFGT* has been previously associated with several different types of anthocyanins,[11] which are directly involved in berry skin color and grape organoleptic characteristics.

High-Resolution Melting Curve PCR Analysis. The *CHI* gene was not considered for the HRM approach because the number of SNPs found did not allow the discrimination of the varieties under study.

The HRM assay was designed for *UFGT* gene considering a fragment size of 704 bp. The UFGT HRM fragment included 32 of the 58 SNPs present and the detected insertion, considering the 22 grapevine varieties under study, with an average frequency of 1 SNP/22 nucleotides. Considering the same fragment length, Nicolè et al.[31] reported a frequency of 1 SNP/31.69 nucleotides, revealing that this gene is highly polymorphic and, therefore, interesting for varietal identification.

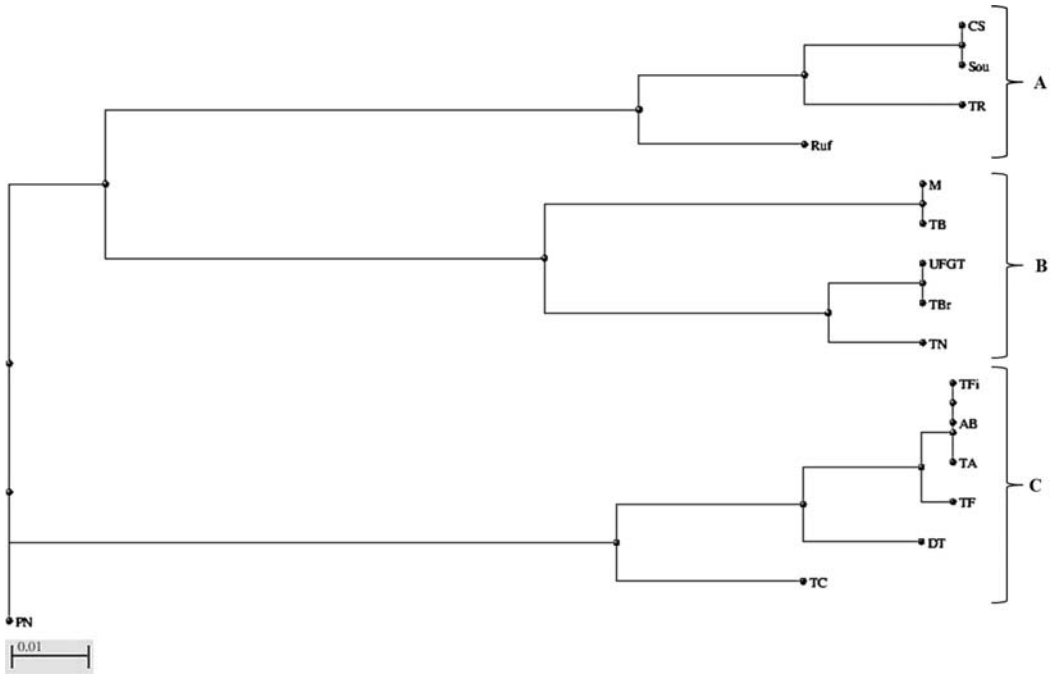

Figure 5. Phylogenetic tree based on deduced amino acid sequence variations of UFGT from the red grapevine varieties using the Cobalt multiple-sequence alignment tool.

Fragment size influences the sensitivity of subsequent HRM analysis, and it is usually advisible that the size does not exceed 300 bp length.[32] In addition, long amplicons may contain several melting domains, resulting in complex melting profiles, meaning that longer amplicons represent small differences in the melting curve caused by small sequence variation. In plants, the studies using HRM report a PCR amplicon range of 50−260 bp.[8,33−35] To our knowledge this is the first paper considering such a large fragment size (704 bp). Therefore, this method is quite promising as it broadens the genotyping potential using HRM analysis. The UFGT targeted sequence generated 18 different melting curve profiles (Figure 2). The T_m values found within all of the samples were similar (T_{m1} = 82.7−83.0 °C; T_{m2} = 86.6−86.9 °C), which did not distinguish the different haplotypes. However, the shapes of the melting curves were very informative, and even when the grapevine variety sequence differed by only a single SNP, this variation was detectable for (a) CS, Sou, and Vio and (b) FP, TR, and MF grapevine varieties (Table 2). Additionally, all of these SNPs belong to class 4, A/T, which is the most challenging genotype variation mainly due to the difficulty associated with the difference in T_m.[7]

These results demonstrate the power, sensitivity, and specificity of this particular HRM assay that allows the identification of several complex genotypes and subsequently the detection of different melting curves (Figure 2). The assay was successful in the definition of the several haplotypes once it was based on the combination of a high number of SNPs within the amplified fragment.

Even though the assay is based on a long fragment, this HRM assay proved to be highly sensitive and was able to distinguish 18 haplotypes based on a combination of 33 nucleotide differences in a unique assay. Previous studies reported the detection of several SNPs and INDELs but always considering simple events,[33,36−39] and not a combination of nucleotide differences. Never, until now, has it been reported that by using a unique assay was it possible to detect such a high number of events in one reaction. The designed HRM assay proved to be powerful and specific.

The shape of the HRM curve for each grapevine variety needed to be further validated in relation to their varietal specification, once there are a high number of clones available within each grapevine variety.[40] Therefore, DNA samples from different clones of each grapevine variety were used and tested for reproducibility. The plants were sampled in established clonal field collections, maintained jointly in private and public institutions, including samples of different regions of the country. The melting curve profiles obtained for each variety were coincident among clones of the same haplotype, indicating that such an assay can be used in the genotype identification of these particular grapevine varieties (Figure 3). The shapes of the melting curve profiles of five red grapevine varieties used in the Douro region are presented as an example in Figure 3. Among them, Cabernet Sauvignon (CS) is used as an international grapevine reference variety. The clones of each grapevine variety present the same genetic profile, reinforcing the assay's robustness.

Four of the 22 grapevine varieties studied (Tinta Francisca, Alicante Bouschet, Côdega de Larinho, and Tinta Amarela) could not be distinguished using this particular HRM assay (Figure 4), once they presented the same sequence for this particular region (Table 2). The sequences of these grapevine varieties differ only from Touriga Franca (TF) in a unique SNP at the 425 bp position (Table 2), which is discriminated using this particular assay.

The robustness of the HRM assay could also be confirmed by the profiles obtained in the clones of the undistinguishable grapevine varieties herein tested (Figure 4), once all of the samples tested presented the same shape HRM melting curve, as expected.

With all of the nucleotide sequences taken into consideration, in particular, the SNPs found in the 22 grapevine

DOI: 10.1021/acs.jafc.5b03463
J. Agric. Food Chem. 2015, 63, 9165−9174

varieties, the amino acid sequences were deduced and aligned. A total of 31 amino acid residue variations were found within the grapevine varieties studied (Table 3).

UFGT gene expression is correlated with the grapevine phenotype, and its transcription is needed for berry pigmentation (no color/red color).[41,42] The anthocyanin profile and content can deeply influence the final wine quality.[43] With the variation of the red grapevine variety amino acid sequences studied taken into consideration, a Cobalt tree was constructed, giving rise to three major groups (Figure 5). Group A included CS, Sou, TR, and Ruf; group B incorporated M, TB, TBr, and TN; and group C comprised TFi, AB, TA, TF, DT, and TC. The Pinot Noir clones analyzed were completely distinguished from all of the grapevine varieties, and therefore they generated an independent branch. The differences found between the amino acid sequence of Pinot Noir and the sequence of the NCBI database were expected, becaue the NCBI reference genome is a hybrid of Pinot Noir.[4] Touriga Brasileira presented the same amino acid sequence as reported in the NCBI database relative to the *UFGT* locus.

Although the *UFGT* gene expression is related to the anthocyanin profile of the grapes,[41] there is a lack of information on the specific profile of each grapevine variety. Some of the most widely used grapevine varieties have been characterized, among them Pinot Noir, Merlot, and Cabernet Sauvignon.

Pinot Noir grapes have a differentiated anthocyanin profile, with only monoglucoside anthocyanins, in contrast with other grapevine varieties (Merlot, Cabernet Sauvignon, Touriga Franca, Tinta Roriz, Touriga Nacional, Sousão, Rufete, Tinta Amarela, Tinta Barroca, Tinto Cão) that present all three types of anthocyanin (monoglucosides, acetates, and coumarates).[44−47] This may justify the outstanding position of Pinot Noir in relation to the other grapevine varieties studied. However, the amino acid variation present within the UFGT sequence has a direct implication on the protein composition, which may or not influence the protein function.

The results obtained through this work represent a good landmark in this particular area and should be considered as a suitable platform for further studies. The deduced amino acid sequences set the bases for a better understanding of the correlation between anthocyanin content and the amino acid profiles.

The present work confirmed the low level of polymorphism of the *CHI* gene and revealed a high level of polymorphism present within the *UFGT* gene of grapevine. The *UFGT* gene allowed the discrimination of 18 different grapevine genotypes among 22 grapevine varieties. From the 58 SNPs and 1 INDEL were predicted a total of 31 amino acid residual changes, enhancing the potential effect on the anthocyanin profile of each variety, which opens doors for further omic studies considering this particular gene.

This study provides the first report on the use of a large fragment in HRM assays, thereby allowing the detection of multiple events (SNP and INDEL) in a unique assay, which can be adapted for large-scale genotyping and mapping in *Vitis*. This assay can be extended for grapevine varietal certification procedures, which are imperative throughout the entire wine chain (plant nursery to wine), because it allows varietal identification.

Cephalosporin C	β-Lactams		C16H21N3O8S	1.10	**416.11221**	433.13876	438.09416	208.55974	low sensitivity or not recovered				

[a]Number in bold font style and underlined indicates ionization form or charge state for data processing or quantification. [b]Bold and underlined are antibiotics with recoveries not in the range of 71 to 120%. [c]Bold and underlined are antibiotics with intermediate precision >20%. [d]Bold and underlined are antibiotics with MU > 50%. [e]For data in red color font, the method performance was based on three spike levels, i.e. 25.0, 50.0, and 80.0 μg/kg, due to its poor sensitivity. For data in sky blue color font, the method performance was based on two spike levels, i.e. 50.0 and 80.0 μg/kg, due to its poor sensitivity. [f]LCL: lowest concentration level of the matrix-matched calibration curve. [g]Column number. [h]The method performance of unstable antibiotics was estimated from one experiment when working solution was prepared fresh. [i]Dimetridazole-d_3 was used as an internal standard for compounds that have no isotopically labeled standards for quantification. [k]Canadian Maximum Residue Limits (MRLs) for Veterinary Drugs in Foods (http://www.hc-sc.gc.ca/dhp-mps/vet/mrl-lmr/mrl-lmr_versus_new-nouveau-eng.php). [l]IU = international unit. 0.006 μg of penicillin G is equivalent to 0.01 IU.

to extract both polar and relatively nonpolar veterinary drugs in a single sample preparation procedure.[4]

In our current study, we further explored the applications of QuEChERS and SOSLE for a single analysis of 125 veterinary drugs from 12 different classes in milk, which were monitored under the Canadian National Chemical Residue Monitoring Program. This paper discusses the respective advantages of either QuEChERS or SOSLE in terms of method simplicity or inclusive coverage of veterinary drugs for quantification or screening in a single analysis. SOSLE was further modified and was adopted as the final extraction method for validation. Furthermore, we employed the same UHPLC/ESI Q-Orbitrap instrument parameters that we used for the determination of 451 pesticides in fruits and vegetables[12] for the analysis of the veterinary drugs in milk. The whole idea was to simplify the routine practice of instrument operations. The same Q-Orbitrap parameters, LC column, LC mobile phases, and LC gradient profile could be used to analyze either pesticides or veterinary drugs in various matrices for different monitoring programs.

Finally, this paper presents a multiclass method using UHPLC/ESI Q-Orbitrap MS along with SOSLE to quantify or screen up to 105 veterinary drug residues from 11 different classes (except aminoglycosides) in milk at low parts-per-billion (ppb) concentration levels. Based on the method performance, the UHPLC/ESI Q-Orbitrap MS method proved to be robust

DOI: 10.1021/acs.jafc.5b04096
J. Agric. Food Chem. 2015, 63, 9175−9187

and sensitive enough to determine over 100 veterinary drug residues of interest from 1.0 to 100.0 μg/kg in milk. The method allows for high throughput testing of routine samples, which greatly benefits monitoring programs, while satisfying regulatory purposes for analysis of a number large of veterinary drugs in a single analysis.

MATERIALS AND METHODS

Materials and Reagents. Five batches of whole milk were collected from five different local farms. All milk samples, which were tested free of the veterinary drug residues using the developed UHPLC/ESI Q-Orbitrap method in the current study, were kept at −20 °C. The Pierce LTQ ESI positive ion calibration solution (10 mL) was purchased from ThermoFisher Scientific (Rockford, IL, USA). The calibration solution, which includes *n*-butylamine (*m*/*z* 74), caffeine (*m*/*z* 195 and its fragment *m*/*z* 138), Ultramark 1621 (*m*/*z* 1022, 1122, 1222, 1322, 1422, 1522, 1622, 1722, 1822), and MRFA (*m*/*z* 524), was used to tune and calibrate the Q-Orbitrap. Ammonium acetate (reagent grade), ammonium sulfate (reagent plus, >99.0%), formic acid (LC-MS grade, ~98%), ammonium formate (for mass spectrometry, >99.0%), oxalic acid (reagent plus, >99.0%), ammonium hydroxide (28−30%), and LC-MS acetonitrile (Chromasolv, 2.5 L) were purchased from Sigma-Aldrich Corp (MO, USA). Acetic acid (glacial acetic acid, reagent grade, 99.7%), acetonitrile (distilled in glass), methanol (distilled in glass), and EDTA disodium salt were obtained from Caledon Laboratories Ltd. (Ont, Canada). Water (18.2 MΩ·cm) used for reagent and sample preparation was obtained from a Barnstead Nanopure system (Thermo Scientific, OH, USA). Veterinary drug standards (Table 1, column 1) were obtained from Sigma-Aldrich Corp or Toronto Research Chemicals (Ont, Canada). Internal standards dimetridazole-d_3, HMMNI-d_3, ipronidazole-d_3, ipronidazole-OH-d_3, and ronidazole-d_3 were purchased from Sigma-Aldrich Corp. A LC vial was a 0.45 μm PVDF Syringeless Filter Device Mini-UniPrep with polypropylene housing (GE Healthcare UK Limited, UK). ENVIRO-CLEAN QuEChERS Mylar pouches that contain 6 g of $MgSO_4$ and 1.5 g of sodium acetate were purchased from UCT Inc. (PA, USA). OASIS HLB Plus 225 mg cartridges were purchased from Waters Corp (MA, USA).

Preparation of Standard Solutions. Individual veterinary drug standard stock solutions were generally prepared at a concentration of 1000 or 2000 μg/mL in methanol, acetonitrile, or water. Intermediate veterinary drug working solutions were prepared at 5.0 μg/mL in methanol from stock solutions. Stock and intermediate solutions were stored at −20 °C. A six-level veterinary drug standard mix working solution was prepared by transferring 0.1, 0.5, 2.0, 4.0, 6.0, and 10.0 mL of 5.0 μg/mL into six separate 50 mL volumetric flasks for their respective concentration levels, and then making up to volume with acetonitrile. The resulting concentrations were 0.010, 0.050, 0.200, 0.400, 0.600, and 1.000 μg/mL, which were used to construct the matrix-matched standard calibration curves. Four-level sample spike veterinary drug standard working solutions were prepared by transferring 4.0, 10.0, 20.0, and 32.0 mL of 5.0 μg/mL into four separate 100 mL volumetric flasks and making up to volume with acetonitrile for their respective concentration levels. The resulting concentrations were 0.200, 0.500, 1.000, and 1.600 μg/mL, which were used for sample fortification. Internal standard working solutions (5.0 μg/mL and 0.5 μg/mL) including dimetridazole-d_3, HMMNI-d_3, ipronidazole-d_3, ipronidazole-OH-d_3, and ronidazole-d_3 were prepared in acetonitrile. All working solutions were stored at 4 °C.

UHPLC/ESI Q-Orbitrap Parameters. The UHPLC/ESI Q-Orbitrap system consisted of an Accela 1250 LC pump and an Accela open autosampler coupled with a Q-Exactive mass spectrometer (ThermoFisher Scientific, Germany). The system was controlled by Xcalibur 2.2 software. The UHPLC/ESI Q-Orbitrap instrument parameters were the same as those we used for the determination of 451 pesticides in fruits and vegetables.[12]

(a). Ultrahigh Pressure Liquid Chromatography. UHPLC mobile phases A and B consisted of 4 mM ammonium formate and 0.10% formic acid in water and methanol, respectively. The UHPLC column utilized was a Hypersil Gold, 100 mm × 2.1 mm, 1.9 μm column (Thermo Scientific, USA). The UHPLC guard column was an Accucore aQ 10 × 2.1 mm, 2.6 μm Defender cartridge (Thermo Scientific, USA). The UHPLC gradient profile and flow rate are shown in Figure 1. The column oven temperature was set at 45 °C, and the autosampler temperature was set at 5 °C. The injection volume was 5 μL, and the total run-time was 14 min.

B

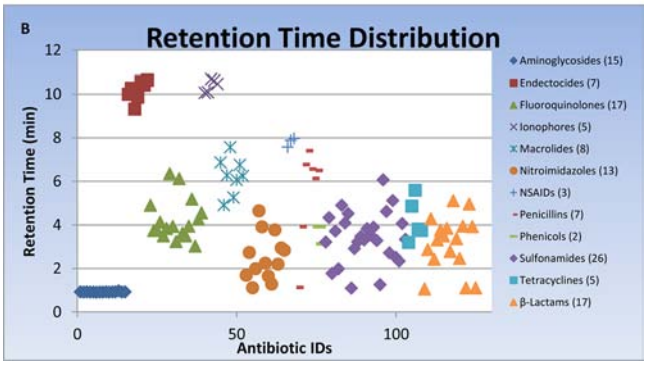

Figure 1. UHPLC gradient profile and liquid chromatographic elution distribution profile for 125 veterinary drugs. Q-Orbitrap was operated in Full MS-SIM mode.

(b). Q-Orbitrap Parameters. The Q-Exactive ion source was equipped with a heated electrospray ionization (HESI) probe, and the Q-Orbitrap was tuned and calibrated using a positive LTQ calibration solution once a week. The Q-Exactive was operated in either Full MS-SIM or Full MS/dd-MS^2 in positive mode. In Full MS-SIM, the Q-Orbitrap performed a full MS scan without HCD (high energy collision dissociation) fragmentation for quantification. The full MS scan range was set from *m*/*z* 80 to 1100 (0 to 12.0 min). The mass resolution was set to 70,000 FWHM at *m*/*z* 200, and the instrument was tuned for maximum ion throughput. The AGC (automatic gain control) target or the number of ions to fill the C-Trap was set at 1.0E6 with a maximum injection time (IT) of 250 ms. All quantitative data in this study were acquired using Full MS-SIM mode. Q-Orbitrap MS means the Q-Exactive that was operated in Full MS-SIM mode for quantification throughout the text.

Targeted identification was achieved by full scan MS, and if a targeted veterinary drug was present, its precursor ion scan, provided by an inclusion list, triggered a data-dependent MS^2 (dd-MS^2) scan. During full MS scan, the mass resolution was set at 70,000 FWHM, AGC target at 1.0E6, maximum IT 250 ms, and scan range from *m*/*z* 80 to 1100. If the targeted compound was detected within the 10 ppm mass error window and achieved by a designated intensity threshold (i.e., setting of 1.7E5), the precursor ions in the inclusion list were then isolated by the quadrupole, and sent to the HCD collision cell for fragmentation via the C-trap. The inclusion list consists of precursor ions that are of interest for targeted identification, and is provided in Table 1 (columns 6−9). The precursor ions were fragmented with stepped normalized collision energy (NCE) to generate the resulting dd-MS^2 product-ion spectra. At this stage, the mass resolution of the Orbitrap analyzer was set at 35,000 FWHM, AGC target at 2E5, maximum IT 120 ms, isolation window 1.0 *m*/*z*, NCE 40 ± 50%, underfill ratio 10%, intensity threshold 1.7E5, apex trigger 2 to 4 s, and dynamic exclusion 10.0 s.

J. Agric. Food Chem. 2015, 63, 9175−9187

Other Q-Exactive generic parameters were sheath gas flow rate set at 60, Aux gas flow rate 30, sweep gas flow rate 2, spray voltage 3.50 kV, capillary temp 350 °C, S-lens level 55.0, and heater temp 350 °C.

During the initial method development stage, 125 veterinary drugs and 5 isotopically labeled standards (Table 1, column 1) were injected individually onto the UHPLC column (Hypersil Gold, 100 mm × 2.1 mm, 1.9 μm) and the Q-Orbitrap was operated in Full MS/dd-MS^2 positive mode to determine the retention time and identity of each veterinary drug.

Method Development on Sample Extraction. *Method A.* This is the conventional QuEChERS method after slight modification of a published method for the determination of 59 veterinary drug residues in milk[11] with references to other methods.[13,14] QuEChERS performed in this study means a procedure that consists of two steps throughout the text: i.e. Step 1 salting-out acetonitrile/water extraction, and Step 2 dispersive solid-phase extraction (*d-SPE*) cleanup.

Step 1 Extraction. Triplicate milk samples (10 g/sample) were weighed into 50 mL centrifuge tubes (VWR International, Canada). Five hundred μL of 1 ppm working solution was spiked to each sample, which was 50.0 μg/kg of veterinary drugs equivalent in sample. After 15 min, 10 mL of a mixture of acetonitrile and acetic acid (99 + 1, v/v) was added to the sample. The centrifuge tube was capped and vortexed to mix for 45 s, and then 6 g of $MgSO_4$ and 1.5 g of sodium acetate (ENVIRO-CLEAN QuEChERS Mylar pouch) were added to the sample. The sample mixture was capped and shaken at 1500 rpm for 1 min using a 2010 Geno/Grinder (SPEX SamplePrep, Metuchen, NJ, USA) and then centrifuged at 3000 rpm (~2100*g*) for 3 min using a centrifuge (Allegra X-15R Centrifuge, Beckman Coulter Inc., CA, USA).

Step 2 d-SPE Clean-up. Seven mL of supernatant from Step 1 was transferred to a 15 mL centrifuge tube that contained 500 mg of end-capped C_{18} (obtained from the Sep-Pak tC18, Waters Corp.). Five mL of hexane (presaturated with acetonitrile) was added to the supernatant, which was shaken for 30 s by hand. The mixture was centrifuged at 3000 rpm (~2100*g*) for 3 min. The top hexane layer was aspirated to waste. Three mL of sample extracts were transferred into individual 5 mL PYREX brand centrifuge tubes, which were precalibrated with 1 mL volume accuracy (VWR International, Edmonton, AB, Canada). The sample extracts were evaporated to 0.1−0.2 mL, which took approximately 20 min, using an N-EVAP nitrogen evaporator (Organomation Associates Inc., Berlin, MA, USA) at 50 °C under a stream of nitrogen. The extracts were reconstituted up to 0.5 mL with acetonitrile and then to 1.0 mL with 0.1 M ammonium acetate. The extracts were vortexed for 30 s. Five hundred μL of sample extracts was transferred into a 0.45 μm PVDF Syringeless Filter Device Mini-UniPrep vial (Whatman, GE Healthcare Life Science, UK) and pressed to filter. Sample extracts were ready to be injected into an UHPLC/ESI Q-Orbitrap MS for analysis.

Method B. This is a procedure that combines salting-out acetonitrile/water extraction and SPE cleanup, which is known as salting-out supported liquid extraction (SOSLE).[4] SOSLE performed in this study means a procedure that consists of two steps: i.e. Step 1 salting-out acetonitrile/water extraction, and Step 2 solid-phase extraction (SPE) cleanup throughout the text.

Step 1 Extraction. The extraction step of this method was based on SOSLE[4] with a slight modification. Triplicate milk samples (5 g/sample) were weighed into 50 mL centrifuge tubes (VWR International, Canada). Two hundred fifty μL of 1 ppm working solution was spiked to each sample, equivalent to 50.0 μg/kg of veterinary drugs in sample. After 15 min, 5 mL of extraction buffer and 10 mL of acetonitrile were added to the sample. The extraction buffer contained 0.86% oxalic acid and 0.74% EDTA disodium salt, and its pH was adjusted to 3.0 using ammonium hydroxide. The sample mixture was capped and shaken for 30 s by hand and then centrifuged at 3000 rpm (~2100*g*) for 5 min using a centrifuge. The supernatant was transferred into another 50 mL centrifuge tube, to which 1 g of ammonium sulfate was added. The sample mixture was mixed for 2 min by hand, and then was left to stand for 2 min. A phase separation was observed from the mixture, and two layers were obtained.

Step 2 SPE Clean-up. Instead of diatomaceous earth cartridges as in the original SOSLE,[4] polymeric reversed-phase sorbent such as OASIS HLB Plus cartridges was used for SPE cleanup. OASIS HLB Plus 225 mg cartridges, which were paired with 25 mL of syringe barrels, were set up for solid-phase extraction using a Visiprep 24-port SPE Vacuum Manifold (Sigma-Aldrich Corp). The cartridges were preconditioned sequentially with 10 mL of methanol, 10 mL of water, and 2 mL of extraction buffer. The sample extracts from Step 1 were separated into three layers after centrifugation (3000 rpm or ~2100*g*, 3 min). The top acetonitrile layer (~10 mL) was transferred to a 16 × 125 mm disposable test tube and set aside for later to be loaded onto OASIS HLB cartridges. The lower aqueous layer was transferred onto the preconditioned Oasis HLB cartridges under vacuum at −2 to −3 inHg with a flow rate of ~1 mL/min. The very thin middle white layer (~1 or 2 mm), which was supposed to be fat from the sample, was discarded and should be avoided from being transferred onto the cartridges. Oasis HLB cartridges were rinsed further with 2 mL of extraction buffer and allowed to run dry. Finally, the top acetonitrile layer, which served as eluting solvent as well, was dispensed onto the OASIS HLB cartridges. The flow (~1 mL/min) of the eluting solvent was maintained under vacuum at −2 to −3 in Hg, and the eluent was collected into a 16 × 125 mm disposable glass test tube. The OASIS HLB cartridges were run dry under vacuum. The eluent was capped and inverted to mix a few times by hand. Two hundred fifty μL of sample extracts was transferred to a 0.45 μm PVDF Syringeless Filter Device Mini-UniPrep vial, and then 250 μL of 0.1 M ammonium acetate was added. The Mini-UniPrep unit was capped, mixed, and pressed to filter. Sample extracts were ready to be injected to UHPLC/ESI Q-Orbitrap MS for analysis.

Method C. This is a SOSLE method, which is modified from Method B. It consisted of two steps: i.e. Step 1 salting-out acetonitrile/water extraction, and Step 2 SPE cleanup.

Step 1 Extraction. This step is the same as that of Method B.

Step 2 SPE Clean-up. All procedures were the same as Step 2 of Method B until the last step. After the top acetonitrile layer was loaded onto the OASIS HLB cartridges and the eluent was collected into a 16 × 125 mm disposable glass test tube, an additional 5 mL of methanol was dispensed onto the cartridges to elute further. The eluent was collected into the same test tube. The OASIS HLB cartridges were run dry under vacuum. The eluent (~15 mL) was capped and inverted to mix a few times. Two hundred fifty μL of sample extracts was transferred to a 0.45 μm PVDF Syringeless Filter Device Mini-UniPrep vial, and then 250 μL of 0.1 M ammonium acetate was added. The Mini-UniPrep unit was capped, mixed, and pressed to filter. Sample extracts were ready to be injected to UHPLC/ESI Q-Orbitrap MS for analysis.

Method D. This is a SOSLE method, which is modified from Method C. It consisted of two steps: i.e. Step 1 salting-out acetonitrile/water extraction, and Step 2 SPE cleanup.

Step 1 Extraction. This step is the same as that of Method B or C.

Step 2 SPE Clean-up. The procedure was the same as Step 2 of Method C, except the final extracts were concentrated three times. Right after the SPE step, 3 mL of eluent was transferred into individual 5 mL PYREX brand centrifuge tubes, which were precalibrated with 1 mL volume accuracy (VWR International, Canada). The sample extracts was evaporated to 0.1−0.2 mL, which took approximately 20 min, using an N-EVAP nitrogen evaporator (Organomation Associates Inc., USA) at 50 °C under a stream of nitrogen. Then the extracts were reconstituted up to 0.5 mL with acetonitrile and then to 1.0 mL with 0.1 M ammonium acetate. The extracts were vortexed for 30 s. Five hundred μL of sample extracts was transferred into a 0.45 μm PVDF Syringeless Filter Device Mini-UniPrep vial and pressed to filter. Sample extracts were ready to be injected to an UHPLC/ESI Q-Orbitrap MS for analysis.

To calculate an absolute recovery (%) or extraction efficiency of veterinary drugs from each individual method A to D, the UHPLC/ESI Q-Orbitrap MS response (peak area spiked before sample extraction) of a veterinary drug extracted from a sample was compared to that (peak area spiked after sample extraction and cleanup) of a

veterinary drug prepared in a blank sample extract at 50 μg/kg equivalent in sample. That is

$$\text{Absolute Recovery (\%)} = \frac{\textit{Peak area spiked before}}{\textit{Peak area spiked after}} \times 100$$

Nested Experimental Design and Method Validation. Method D was adopted as the final method for validation in this study.

Fortification Experiment. Milk samples (5.0 g/sample) were weighed into individual 50 mL polypropylene centrifuge tubes (VWR International, Canada). Two hundred fifty μL per four-level sample spike veterinary drug standard working solution(s) were added into four centrifuge tubes to provide 10.0, 25.0, 50.0, and 80.0 μg/kg of veterinary drugs equivalent in sample, followed by the addition of 25 μL of 5.0 μg/mL internal calibration standard working solution (25.0 μg/kg equivalent in sample). Then the samples proceeded to extraction and cleanup.

Preparation of Matrix-Matched Calibration Standards and Calculation. Matrix-matched calibration standards were prepared by adding standards and internal standards to blank sample extracts that were processed through extraction and cleanup. A blank milk sample (5.0 g) was weighed into a 50 mL centrifuge tube, and the sample was processed through the extraction and cleanup as described in Method D. Before reconstitution, 100 μL of each six-level veterinary drug standard mix working solution and 50 μL of 0.50 μg/mL internal calibration working solution were added to the individual sample extracts to provide 1.0, 5.0, 20.0, 40.0, 60.0, and 100.0 μg/kg per standard and 25.0 μg/kg per internal standard equivalent in sample. The rest of the preparation was the same as in Method D.

Matrix-matched standard calibration curves for each individual veterinary drug were constructed using TraceFinder 3.2 (optimized for Environmental and Food Safety) software. Concentration, μg/kg (ppb), versus the ratio (analyte area/IS area) of each individual veterinary drug was plotted. Five commercially available deuterium labeled standards, i.e. dimetridazole-d_3, HMMNI-d_3, ipronidazole-d_3,

DOI: 10.1021/acs.jafc.5b04096
J. Agric. Food Chem. 2015, 63, 9175−9187

ipronidazole-OH-d_3, and ronidazole-d_3, were used as internal standards for quantifying their respective native compounds, and dimetridazole-d_3 was utilized for all other veterinary drugs that had no isotopically labeled standards available. In general, a quadratic function was applied to the calibration curves based on the line of best fit. Occasionally, linear regression may be used for quantification. The $1/x$ weighting was used to improve the accuracy for the quantification of veterinary drugs at low concentrations. Responses for the unknown concentration or fortified samples were compared to the standard curves to calculate the amount of veterinary drug residues, μg/kg (ppb), in samples. Matrix-matched calibration standards were prepared fresh for each batch of samples.

The method was validated according to the nested experimental design, which was described elsewhere.[15] The main factors of variances associated with the method performance or measurement uncertainty of an in-house validated method were concentrations or spiked levels of analytes, matrix effects, day-to-day variation, and within day variation of the method. The last two factors were designated as the intermediate precision. In this study, there were a total of 5 batches of milk samples from 5 different local farms. For each matrix, samples were spiked at 10.0, 25.0, 50.0, and 80.0 μg/kg, in triplicate. Spike experiments were repeated on two different days or by two analysts. Overall recovery, intermediate precision, and measurement uncertainty were calculated using a combined computer program that consisted of SAS codes (SAS Software Release 9.3, SAS Institute Inc., USA) along with a Microsoft Excel (Microsoft Office 2010) workbook.

RESULTS AND DISCUSSION

Ultrahigh Performance Liquid Chromatography. For practical reasons, the same UHPLC/ESI Q-Orbitrap instrument parameters used for the determination of 451 pesticides in fruits and vegetables[12] were utilized for the analysis of veterinary drugs in milk. This includes the same Q-Orbitrap parameters, LC column, LC mobile phases, and LC gradient profile. During the method development stage, 125 veterinary drugs and 5 isotopically labeled standards (Table 1, column 1) were injected individually onto the UHPLC column (Hypersil Gold, 100 mm × 2.1 mm, 1.9 μm), and the Q-Orbitrap was operated in Full MS/dd-MS^2 positive mode. These data ensured that the correct retention times were assigned to the respective compounds, and to determine the identities of veterinary drugs in a mixture of standards. Full MS/dd-MS^2 data were critical to differentiate isobaric compounds. The mobile phases were methanol and water, each containing 4 mM ammonium formate and 0.10% formic acid, and the gradient profile is shown in Figure 1A. Veterinary drugs from a particular class or group demonstrated a similar chemical property in terms of liquid chromatographic retention (Figure 1B). For example, the very polar aminoglycosides were hardly retained on the column, and all were eluted as a group around 0.91 min. Endectocides and ionophores, which are relatively nonpolar, were well retained on the column, and all were eluded between 9.31 and 10.68 min. The elution pattern of the 125 veterinary drugs showed up as clusters of individual classes as depicted in Figure 1B. Aminoglycosides were excluded from the method due to their poor chromatographic retention.

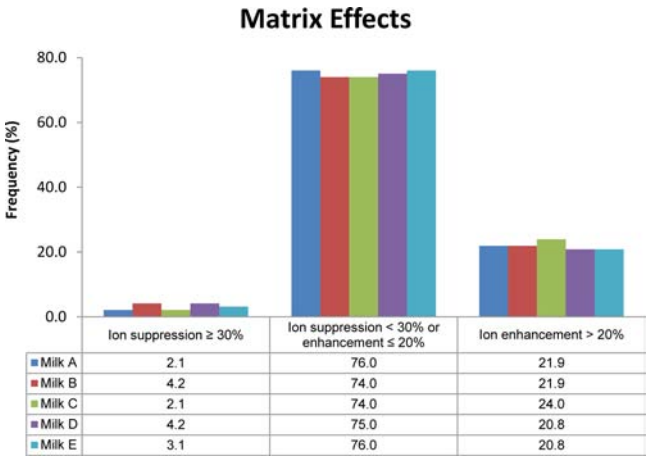

Figure 3. UHPLC/ESI Q-Orbitrap MS matrix effects. The veterinary drugs (Table 1, Section A and B) were prepared in milk sample extracts (a total of 5 matrices) and solvent buffer at a concentration of 50 μg/kg equivalent in sample.

The elution pattern on the reversed-phase column may possibly be perceived as an indication of the extraction efficiency of the method for a class of veterinary drugs. In other words, the retention time (RT) of a veterinary drug may be correlated to the method extraction efficiency. For example when using Method D described in the Materials and Methods, the polar compounds with poor chromatographic retention (<1.28 min), remained as challenges to be extracted from milk samples. Amoxicillin, cefadroxil, and cephalosporin C (Table 1, Section D), which were eluded between 1.03 and 1.10 min, were likely not recovered by the method. Desacetyl cephapirin, etanidazole, nimorazole, and sulfaguanidine (Table 1, Section A), which were eluded between 1.05 and 1.28 min, had recoveries from 15.0 to 72.4%. Sulfanilamide (RT: 1.25 min and recovery: 97.1%) was the only one exception from this observation. In general, the well-retained compounds (RT > 1.5 min) showed good recoveries (Table 1, Section A and B). This is to assume that the chromatographic retention of a veterinary drug as a result of its polarity may serve as an indicator of the extraction efficiency of a method. However, this assumption may not be necessarily true in reverse, since there are many other factors, such as matrix effects, solvent, and solid-phase extract sorbent used that contribute to the extraction efficiency.

Under most circumstances, an extracted ion of a veterinary drug was presented as a single LC peak. Most veterinary drugs had baseline separation from others, resulting from the superior resolving power of both UHPLC and Q-Orbitrap MS. Some were coeluted because they were isobaric compounds such as ampicillin and cephradine (Table 1, Section C). Veterinary drugs were eluted between 1.0 and 11.0 min, and their peak shapes were of Gaussian distribution with a baseline peak-width of 5 to 10 s. The retention times were reproducible under ±0.2 min within- and between-batches for most of the veterinary drugs. With the scan rate of 3 Hz for the resolution of 70,000 FWHM at m/z 200, the Q-Orbitrap provided sufficient data points for quantification. For example, at least 18 data points across the chromatographic peak were generated with a 6 s (0.1 min) baseline peak-width.

Q-Orbitrap Mass Spectrometry. When operated in Full MS-SIM mode with a range from m/z 80.0 to 1100.0 and 70,000 FWHM resolution at m/z 200, the Q-Orbitrap acquired full MS scan data for the quantitation of veterinary drugs. The quantitative results are provided in Table 1 (columns 10−12). When operated in Full MS/dd-MS^2 mode, the Q-Orbitrap acquired product-ion spectra with accurate mass measurements for identification according to a list of targeted exact masses (Table 1, columns 6−9). A three-step normalized collision energy (NCE) of 40 ± 50% (i.e., the center energy 40 NCE; plus one above, 60 NCE; and one below, 20 NCE) was used for the fragmentation of precursor ions in the high-energy collision

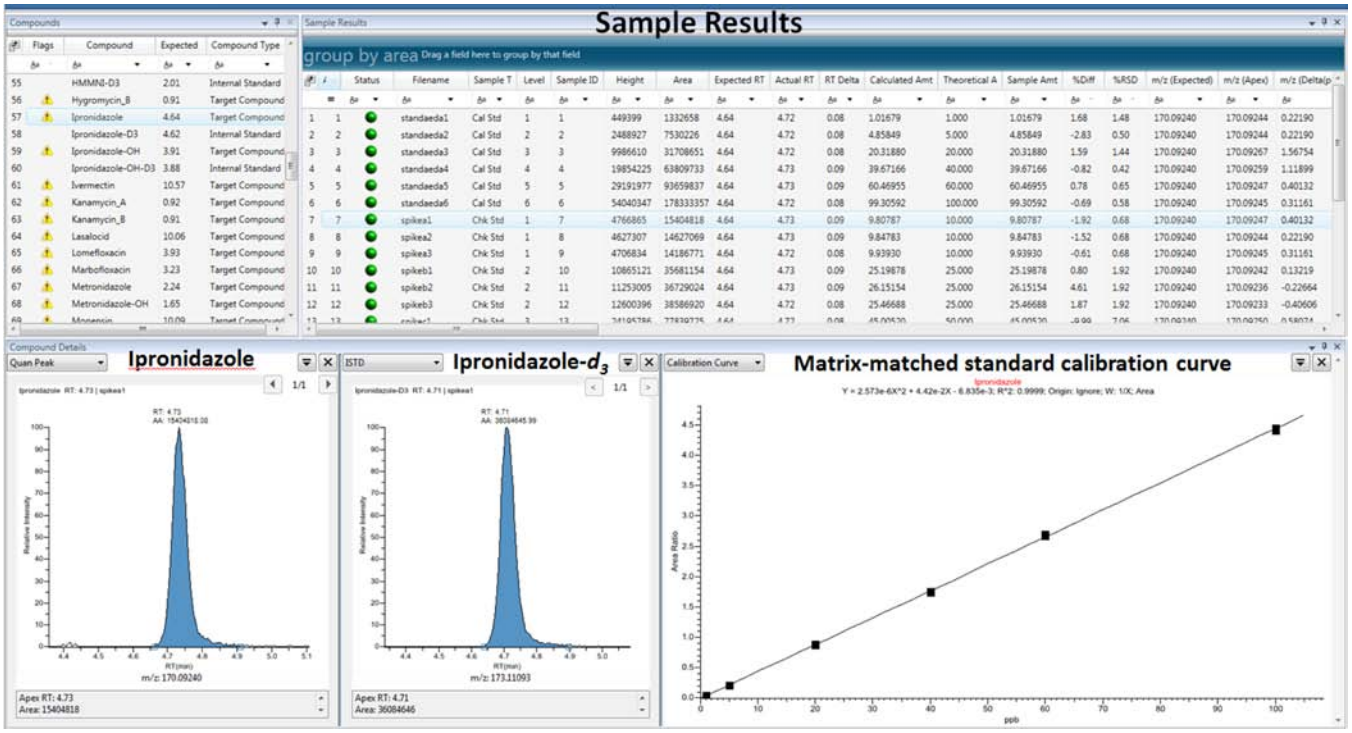

Figure 4. Example of a matrix-matched standard calibration curve along with its isotopically labeled standard (ipronidazole and ipronidazole-d_3).

dissociation (HCD) cell to produce product ions for identification. The product ions created in the three-step NCE were collected sequentially in the HCD and transferred together to the Orbitrap mass analyzer for a single scan detection. Stepped NCE did not work for all of the veterinary drugs because not all were optimally fragmented in the 40 ± 50% NCE range. As a routine practice from our previous experience,[12] the Full MS/dd-MS^2 data of individual veterinary drugs were acquired to determine their identities in a mixture. The data set was also intentionally collected to build a "Compound Database" or automated searchable exact mass spectral library for identification or screening purposes. However, in the current study, we focused on the quantitative aspect of UHPLC/ESI Q-Orbitrap applications for veterinary drugs.

Method Development on Sample Extraction. We began with a list of 125 veterinary drugs, which were included under the CFIA routine monitoring program for determination of veterinary drug residues in milk. The plan was to develop a generic extraction method to include 125 compounds in a single analysis, which previously was achieved using multiple separate single-class methods, and to improve the monitoring program efficiency. Method development was initiated with a conventional QuEChERS but was gradually evolved into SOSLE, to include as many analytes as possible. Because β-lactams, penicillins, and tetracyclines are not stable molecules, their data for absolute recovery comparisons during the method development are not included.

Method A was based on the conventional QuEChERS, which was slightly modified from a published method for the determination of 59 veterinary drug residues in milk[11] with references[13,14] therein. Step 1 utilized the typical salting-out acetonitrile/water extraction, while Step 2 invoked the use of dispersive solid-phase extraction (*d-SPE*) for cleanup to remove nonpolar compounds such as fat in milk. The method was very simple and fast. It worked well for endectocides, ionophores, macrolides, nitroimidazole, NSAIDS, and sulfonamides with absolute recoveries over 70% (Figure 2, left), but the method showed poor repeatability for quantification with relative standard deviations as high as 40−50% (Figure 2, right). Fluoroquinolones (Figure 2-B1) had recoveries ranging from 0.5 to 43.5%, while β-lactams, penicillins, and tetracyclines were not recovered at all (data not shown), as similar observations have been reported elsewhere.[11]

In order to recover β-lactams, penicillins, and tetracyclines, and to improve the recoveries of fluoroquinolones, we looked into other methodologies. Kaufmann et al. developed a procedure known as salting-out supported liquid extraction (SOSLE), which combines the salting-out acetonitrile/water extraction (Step 1) and solid-phase extraction (SPE) cleanup (Step 2) to extract the veterinary drugs in milk.[4] In SOSLE, both acetonitrile and water, from which a phase separation was induced afterward by salting-out using ammonium sulfate, were used to ensure the quantitative extraction of analytes that were distributed in either the aqueous or acetonitrile layer. The mixture of acetonitrile and water was capable of extracting a wide range of analytes from the matrix because it provided significantly higher extraction efficiency for both polar analytes as well as nonpolar compounds.[4] The recoveries of tetracyclines and fluoroquinolones were significantly increased as a result of the addition of complexing agents like EDTA and the use of ammonium sulfate rather than magnesium sulfate to prevent chelation to inorganic salts and to induce a phase separation of the acetonitrile and water mixture. The resulting heavier aqueous phase was loaded onto SPE cartridges which contained coarse-grained kieselguhr (also known as diatomaceous earth). The compounds retained on the cartridges were eluted with the supernatant organic phase (acetonitrile). Final extraction and elution of the analytes was achieved through additional volumes

J. Agric. Food Chem. 2015, 63, 9175−9187

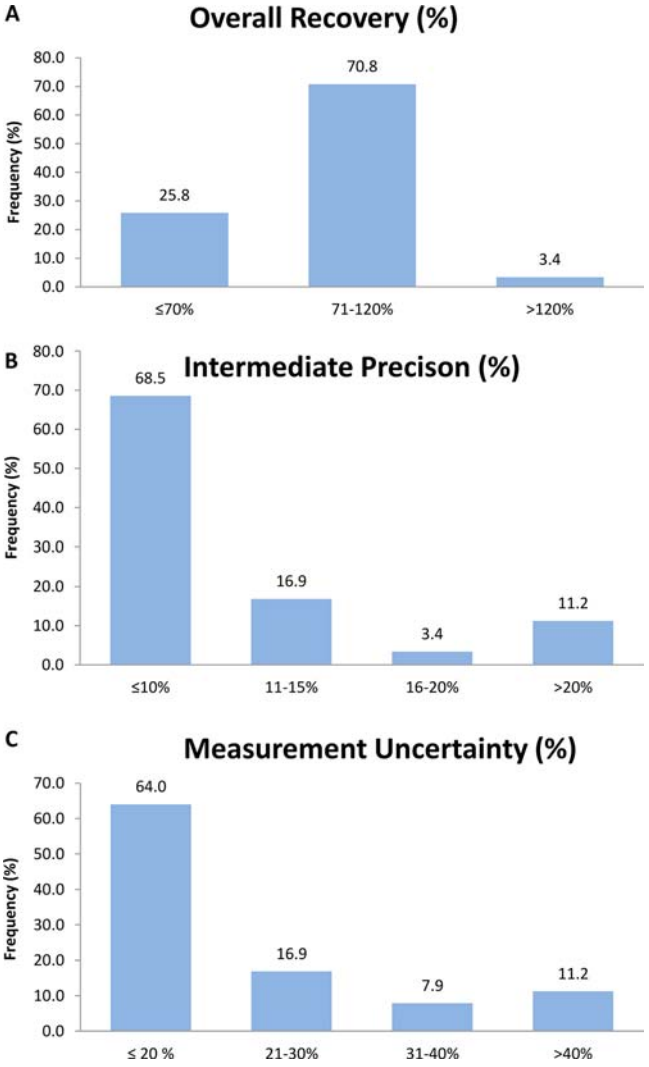

Figure 5. UHPLC/ESI Q-Orbitrap MS method performance for analysis of veterinary drug residues (Table 1, Section A) in milk. A: Overall recovery. B: Intermediate precision. C: Measurement uncertainty.

of acetonitrile. The combined eluents were evaporated to produce the injection-ready extracts.[4]

Due to the relatively large volume of the final extracts (25 mL) resulting from the 45 mL/8.3 g bed size of CHROMABOND XTR columns (diatomaceous earth cartridges, MACHEREY-NAGEL GmbH & Co. KG, Düren,Germany) in the original method[4] and poor repeatability of recoveries from these cartridges in our experiments (data not shown), we modified the method for a more practical application. By switching to polymeric reversed-phase sorbent SPE cartridges (i.e., OASIS HLB Plus 225 mg cartridges), the cleanup process required a significantly smaller volume of organic solvent to elute and the results showed improved repeatability. The polymeric reversed-phase sorbent cartridges have been found to be efficient in extracting both polar and relatively nonpolar veterinary drugs in milk, eggs, and honey.[16,17] As described in the Materials and Methods, in Step 1, Method B used an extraction buffer (0.86% oxalic acid and 0.74% EDTA, pH 3) and acetonitrile to precipitate proteins in milk. After removal of protein by centrifugation, ammonium sulfate was added to the supernatant to induce a phase separation of the sample mixture. In Step 2, the resulting heavier aqueous phase was loaded onto the SPE cartridges to retain polar compounds (such as β-lactams, penicillins, tetracyclines, etc.), followed by the top acetonitrile layer, which contained relatively nonpolar compounds (such as endectocides, ionophores, etc.), to serve as the eluting solvent to elute veterinary drugs on the cartridges. Figure 2 (A2-H2) illustrates that Method B significantly improved the repeatability of recoveries for all veterinary drugs. Figure 2 (A1-H1) also demonstrates that Method B increases the recoveries of fluoroquinolones but decreases recoveries for the ionophores, macrolides, and NSAIDS, while the recoveries of endectocides, nitroimidozles, phenicols, and sulfonamides remained unchanged. It was observed that the recoveries of some macrolides, such as neospiramycin I and spiramycin I, decreased significantly, which might be as a result of their degradation under acid conditions (pH 3).[18]

To improve the recoveries, Method C was modified from Method B by increasing the amount of the eluting solvent in Step 2. Besides the ~10 mL of acetonitrile (top layer after the phase separation) as the eluting solvent, an additional 5 mL of methanol was added to elute any strongly retained veterinary drug residues on the cartridges. Figure 2 (A1-H1) reveals that the recoveries of all veterinary drugs from Method C were increased as compared to Method B. Most of the recoveries increased from 60 or 80% to ~100%, and RSDs were less than 10%, with the exception of a few fluoroquinolones and macrolides. The results indicated that the additional 5 mL of methanol was critical to improve the recoveries in SOSLE when polymeric reversed-phase sorbent cartridges were used for cleanup.

In both Methods B and C, the final extracts were diluted 1:1 rather than being concentrated. These methods may not be applicable to detect low concentration levels of veterinary drugs in milk samples. To lower the detection limits into low parts-per-billion levels (such as 1 ppb), in Step 2, additional concentration and reconstitution steps were implemented in the development of Method D from Method C. As observed from Figure 2, the recoveries of some veterinary drugs from Method D were slightly lower and RSDs higher than the results provided by Method C. Method D proved to be well suited for analyzing milk samples fortified at the 1 ppb concentration level (Table 1, column 13). The final concentrations of veterinary drugs in vials (prior to UHPLC/ESI Q-Orbitrap MS injection) from Method A to D were 150, 12.5, 8.33, and 50 ppb (or ng/mL), respectively. Method D resulted in 6 times concentrated sample extracts compared to Method C. Apparently, the concentration and reconstitution steps caused losses of some compounds and led to slightly increased variation. Overall, in terms of recoveries and RSDs, Method C provided the best performance among the four methods. However, in order to detect veterinary drugs at low concentration levels, especially at the 1 ppb level, Method D was chosen to be validated for the determination of veterinary drugs in milk. It is worth noting that Method D is also able to recover β-lactams, penicillins, and tetracyclines as shown in Table 1.

In summary, as shown in Figure 2, Method A (except for β-lactams, penicillins, and tetracyclines), C, or D can serve as independent methods to be validated for various applications depending on testing scopes and instrument sensitivity. For example, Method A (i.e., QuEChERS) can potentially be validated and used for analysis of endectocides, ionophores, macroldies, nitromidazole, NSAIDS, phenicols, and sulfona-

DOI: 10.1021/acs.jafc.5b04096
J. Agric. Food Chem. 2015, 63, 9175−9187

mides in milk or other matrices because it is simple and fast. For highly sensitive LC-MS systems, Method C (i.e., SOSLE) is the best choice for all veterinary drugs due to its method performance in terms of recovery and repeatability. Method D (i.e., SOSLE) proves to be the most sensitive among all, and it was found it fit for the needs of using UHPLC/ESI Q-Orbitrap MS to quantify veterinary drug residues in milk at low ppb concentration levels.

Matrix Effects. The sample matrix can either enhance or suppress the ionization of veterinary drugs, and its effects can vary from sample-to-sample, which ultimately affects the UHPLC/ESI Q-Orbitrap MS quantitative results. To evaluate matrix effects, the responses (peak areas) of veterinary drugs in sample extracts were compared to those of veterinary drug standards prepared in solvent buffer at 50 μg/kg equivalent in sample. In general, about 74.0−76.0% veterinary drugs had ion suppression <30% or ion enhancement ≤20%, 2.1−4.2% were subjected to ion suppression ≥30%, and 20.8−24.0% were subjected to ion enhancement >20% in milk (Figure 3). Veterinary drugs that were suppressed ≥30% included flunixin, roxithromycin, and thiamphenicol. Veterinary drugs that were enhanced >20% included doramectin, eprinomectin B_{1a}, ivermectin, HMMNI, metronidazole, metronidazole-OH, nimorazole, ternidazole, sulfacetamide, sulfadiazine, sulfaguanidine, sulfamerazine, sulfamethoxypyridazine, sulfathiazole, sulfisomidine, sulfanilamide, 4-epitetracycline, chlortetracycline, oxytetracycline, cefapirin, and desacetyl cephapirin. Therefore, matrix-matched standard calibration curves along with isotopically labeled standards (Figure 4) were used to minimize or compensate for matrix effects to improve the accuracy of the UPLC/ESI Q-Orbitrap MS quantification. Five commercially available deuterium labeled standards, i.e. dimetridazole-d_3, HMMNI-d_3, ipronidazole-d_3, ipronidazole-OH-d_3, and ronidazole-d_3, were used as internal standards for quantifying their respective native compounds, and dimetridazole-d_3 was utilized for all other veterinary drugs. The calibration curves were observed to be linear or quadratic, with coefficient of determinations (R^2) ≥ 0.97. Because of matrix effects, ion source contamination, or other unidentified factors, the responses of some veterinary drugs either decreased or increased slightly over time. To average out the response changes during the course, matrix-matched standard calibration curves were constructed based on the two injections, i.e. before and after spike samples, so as to improve the method performance (Figure 4).

Quantification and Method Performance. The UHPLC/ESI Q-Orbitrap MS method was validated according to a nested design, reported elsewhere. To evaluate the method performance characteristics, including accuracy, expressed as overall recovery, intermediate precision, and measurement uncertainty (MU),[15] four factors, such as concentrations or spiked levels of veterinary drugs, matrix effects, day-to-day variation, and within-day variation (described in the Materials and Methods), were considered. For the 89 veterinary drugs that were chemically stable and were evaluated through the fully nested experimental design, their method performance results are summarized in Tables 1 Section A, and are illustrated in Figure 5. About 70.8% of the veterinary drugs in milk had recoveries between 71% and 120%; 88.8% had intermediate precision ≤20%; and 93.3% showed measurement uncertainty ≤50%. The Codex CAC/GL 71-2009[19] recommended method performance criteria such as recovery of 70−120% and repeatability ≤20% for quantitative analytical methods to support the maximum residue limit for veterinary drug residues in foods. Therefore, Method D demonstrated the optimized performance to quantify a majority of veterinary drugs listed in Table 1 Section A.

For the 13 veterinary drugs, primarily penicillins and β-lactams that were not chemically stable and not able to go through the fully nested experimental design but were still quantifiable, their method performance was summarized according to a one-day experiment and the results are listed in Table 1 Section B. In general, the method for those veterinary drugs demonstrated a good repeatability with the exception of cefapirin and some additional compounds that had a recovery <70% or >120% (Table 1, Section B).

Table 1 Section C lists three veterinary drugs, ampicillin, cephradine, and tylosin B, that can be screened but not quantified. This is becasue ampicillin and cephradine are isobaric compounds and cannot be chromatographically separated, and tylosin B has no standard commercially available to prepare calibration curves for quantification.

Aminoglycosides (a total of 15, Table 1 Section D) were poorly retained due to their polarity on the reversed-phase C_{18} column with retention times ∼0.91 min. Amoxicillin, cefadroxil, cefalonium, cephalexin, and cephalosporin C (a total of 5, Table 1 Section D) showed low sensitivity or were not recovered during the extraction procedure. Therefore, those veterinary drugs (a total of 20) were not included in the final method.

Overall, the UHPLC/ESI Q-Orbitrap MS along with SOSLE can serve as a reliable and practical method for quantifying or screening a total of 105 veterinary drugs in a single extraction process and within a 14 min analytical runtime.

Veterinary Drug Identification. According to Codex CAC/GL 71−2009[19] for veterinary drug analysis and identification, when high resolution mass spectrometers are used in a confirmatory method, the high resolution provides more reliable identification of the mass and may be used to predict the elemental composition of each fragment. For a single stage high resolution mass spectrometer, each structurally significant fragment detected is assigned a value of two identification points, while each product ion generated in a tandem high resolution mass spectrometer is assigned an identification point value of 2.5. In addition, at least one ion ratio must also be measured to eliminate the potential for product ions of the same mass arising from isobaric compounds of similar structure. SANCO/12495/2013[20] required ≥2 diagnostic ions (preferably the precursor ion and its product ion) with mass accuracy <5 ppm along with retention time tolerance of ±0.2 min for identification of pesticides. The UHPLC/ESI Q-Orbitrap provided a measured mass accuracy <5 ppm and a retention time tolerance within ±0.2 min. Full MS/dd-MS^2 was able to obtain product-ion spectra that included both precursor and product ions with accurate masses. Currently, identification was achieved using the Thermo Xcalibur Qual Browser by comparing to the Full MS/dd-MS^2 data of individual veterinary drugs. Studies are in progress to develop "Compound Database" or a searchable exact mass spectral library that can be used for efficient screening and identification including calculating ion ratios using the system software.

Method Sensitivity. The lowest concentration levels (LCL) of individual veterinary drugs, which indicated the method sensitivity, were determined according to the recommended default LC peak height value, i.e. 1.0×10^4, reported elsewhere for the Orbitrap.[21,22] Among 102

DOI: 10.1021/acs.jafc.5b04096
J. Agric. Food Chem. 2015, 63, 9175−9187

quantifiable veterinary drugs (Table 1, Section A and B), 71.6% could be detected and quantified at a concentration level ≤1.0 μg/kg, and 83.3% ≤ 5.0 μg/kg. The method appeared to be less sensitive to tetracyclines, penicillins, and β-lactams, which had LCLs ranging from 20.0 to 60.0 μg/kg. Table 1 lists the Canadian Maximum Residue Limits (MRLs) for veterinary drugs in milk.[23] Except for penicillin G, LCLs were all below their respective MRLs of individual veterinary drugs, demonstrating that the method could be fit for the regulatory purposes of monitoring veterinary drug residues in milk in Canada.

In conclusion, UHPLC/ESI Q-Orbitrap along with SOSLE proved to be a reliable and practical multiclass method for the determination of up to 105 veterinary drug residues from 11 different classes (except aminoglycosides) in milk. The UHPLC/ESI Q-Orbitrap MS, i.e. full MS scan, provided good method accuracy, repeatability, and sensitivity for quantification. Generally, about 70.8% of the 89 veterinary drug residues in milk, which went through the full method validation, had recoveries between 71% and 120%; 88.8% had intermediate precision ≤20%; and 93.3% showed measurement uncertainty ≤50%. UHPLC/ESI Q-Orbitrap dd-MS^2 provided product-ion spectra with accurate mass measurements that allowed for the identification of veterinary drugs. Overall, UHPLC/ESI Q-Orbitrap offers a practical tool for the analysis of a large number of veterinary drug residues in milk for monitoring programs, all with a single extraction in a 14 min analytical runtime.

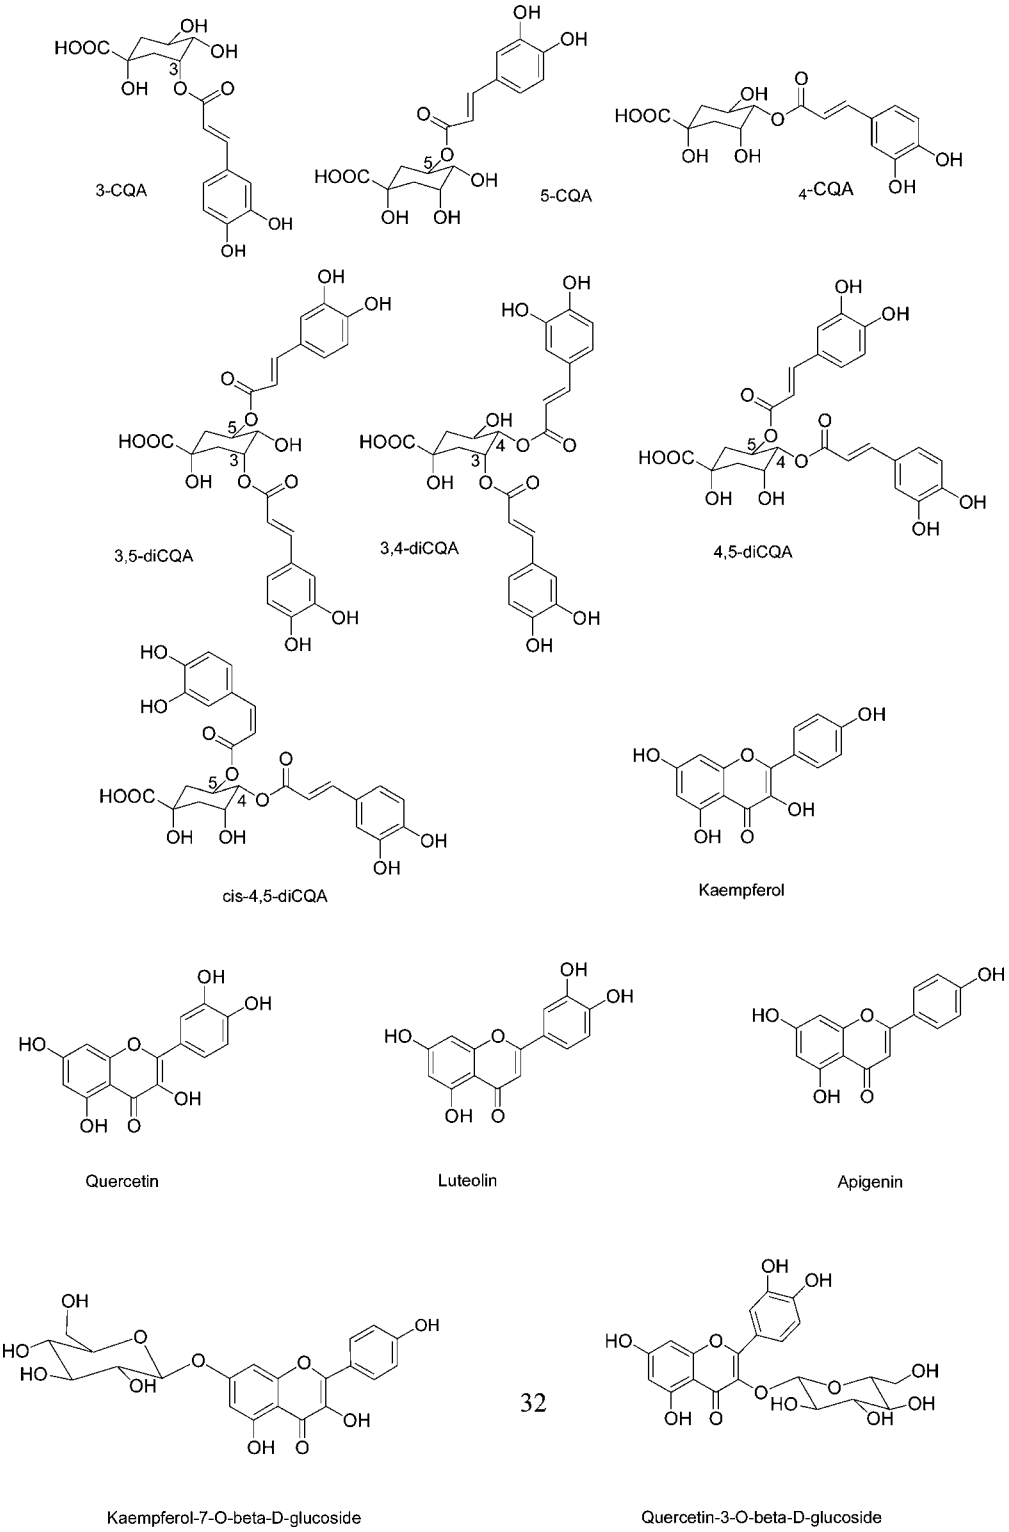

Figure 1. Structures of caffeoylquinic acids and flavonoid glycosides.

and sugar components at different positions attaching on the aglycone ring.[7]

S. rebaudiana belongs to the Asteraceae family of plants, and it is native to Paraguay. The high content of natural sweeteners, the steviol glycosides of the ent-kaurene class of compounds, contained in its leaves makes *S. rebaudiana* of a significant economic value in food industry in many applications as a zero-calorie sweetener. Purified steviol glycosides have only recently been approved as food additives by European and United States legislative authorities, leading to a dramatic increase in its global use and scientific interest in the crop.

MATERIALS AND METHODS

Chemicals. IUPAC numbering has been used for chlorogenic acids and the chlorogenic acids of 3-caffeoylquinic acid (3-CQA), 4-caffeoylquinic acid (4-CQA), 5-caffeoylquinic acid (chlorogenic acid),

[a]Compounds named for flavonoid glycosides are only possible structures, which were not identified or confirmed.

3,4-dicaffeoylquinic acid (3,4-diCQA), 3,5-dicaffeoylquinic acid (3,5-diCQA), and 4,5-dicaffeoylquinic acid (4,5-diCQA); the compounds were purchased from PhytoLab (Vestenbergsgreuth, Germany). Flavonoid glycoside standards were obtained from Sigma-Aldrich; HPLC-grade acetonitrile, methanol, and chloroform were obtained from Carl-Roth GmbH, Karlsruhe.

S. rebaudiana leaves were obtained from Universität Hohenheim who led the trial cultivation in eight different E.U. regions.

Sample Preparation. A 2 g sample of *S. rebaudiana* leaves was immersed in liquid nitrogen, ground in a hammer mill, and extracted first with 150 mL of chloroform in a Soxhlet apparatus (Buchi B-811 extraction system) for 2 h and then with 150 mL of methanol for another 2 h. Solvents were removed from the methanolic extract in vacuo, and extracts were stored at −20 °C until required.

LC-TOF MS. The LC equipment (Agilent 1100 series, Bremen, Germany) comprised a binary pump, an autosampler with a 100 μL loop, and a diode array detector with a light-pipe flow cell (recording at 254 nm and scanning from 200 to 600 nm). This was interfaced with a MicroTOF Focus mass spectrometer (Bruker Daltonics) fitted with an ESI source. The MS parameters were as follows: nebulizer 1.6 bar, dry gas 12.0 L/min, dry temperature 220 °C. The MicroTOF was operated in negative ion mode, and the mass range was 150−1200 m/z. Internal calibration was achieved with 10 mL of 0.1 mol/L sodium formate solution injected through a six-port valve prior to each chromatographic run. Calibration was carried out using the enhanced quadratic calibration mode.

LC-MS^n. The LC equipment (Agilent 1100 series, Bremen, Germany) comprised a binary pump, an autosampler with a 100 μL loop, and a diode array detector with a light-pipe flow cell (recording at 254 nm and scanning from 200 to 600 nm). This was interfaced with an ion-trap mass spectrometer fitted with an ESI source (Bruker Daltonics HCT Ultra, Bremen, Germany) operating in Auto-MS^n mode to obtain

fragment ions *m/z*. Tandem mass spectra were acquired in Auto-MS^n mode (smart fragmentation) using a ramping of the collision energy. Maximum fragmentation amplitude was set to 1 V, starting at 30% and ending at 200%. MS operating conditions (negative mode) were as follows: capillary temperature 365 °C, dry gas flow rate 10 L/min, and nebulizer pressure 50 psi.

HPLC. Separation was achieved on a 250 × 3 mm^2 C18 column (Varian Pursuit XRS) with 5 μm particle size. Solvent A was water/formic acid (1000 + 0.005% v/v), and solvent B was acetonitrile (ACN). Solvents were delivered at a total flow rate of 0.5 mL/min, and the column temperature was set to 25 °C. A 5 μL aliquot of each sample was injected into the LC-MS system unless stated otherwise. The gradient profile was 10−80% B in 60 min and a return to 10% B at 65 and 5 min isocratic to re-equilibrate.

Calibration Curve of Standard Compounds. The most abundant chlorogenic acid derivatives (3-CQA, 4-CQA, 5-CQA, 3,5-diCQA, and 4,5 diCQA) and two flavonoid glycosides (quercetin-3-glycoside and kaempferol-7-glycoside) were chosen for calibration curves.

Stock solutions of the standard compounds were prepared in 80% ACN/water. A series of standard solutions were injected (5 μL) into the LC-MS system. The areas of the peaks of each standard from extracted ion chromatograms (EIC) were used to make the respective standard curves.

Statistical Analyses. Statistical analyses of the data were performed using IBM SPSS 20. The distributions of the variables were tested for normality using the Kolmogorov−Smirnov test. Associations between the variables were investigated using both parametric (Pearson's correlation) and nonparametric (Spearman's correlation) techniques. Results were interpreted using the widely accepted 5% level of significance.

To test whether there were differences on each chlorogenic acid with respect to its origin or variety, separate one-way ANOVA analyses were employed, followed by two posthoc tests: Fisher's least significant difference (LSD) as the least conservative test where equal variances are assumed and Games-Howell test where nonequal variances are assumed for the multiple pair wise comparison tests. All empirical results were interpreted using the widely accepted 5% level of significance ($p < 0.05$).

Principle component analyses (PCA) were carried out on the basis of the LC-MS data set of stevia phenols using Profile Analysis 1.1 (Bruker Daltonics), with kernelizing prior to bucketing and normalization to sum of peaks to allow differentiation between different stevia varieties and geographic origins.

RESULTS AND DISCUSSION

Within a large agricultural trial, *S. rebaudiana* was cultivated in nine southern European locations from 2010 to 2011. Up to three times a year, leaves were harvested from July to September. In total, seven different botanical varieties of *S. rebaudiana* were cultivated. Following harvesting, leaves were dried and analyzed at least three months after harvesting. The European *S. rebaudiana* samples were complemented by commercial *S. rebaudiana* samples cultivated in South America and Asia, resulting in a total of 166 samples.

Table 2. Linearity and Equations of Calibration Curves Obtained by the Least Square Methods

reference compound	linearity (μg/mL)	equation	R^2
3-CQA	1−100	82912*x* + 346549	0.99
5-CQA	5−500	49062*x* + 907693	0.99
4-CQA	1−150	129889*x* + 395550	0.99
3,5-diCQA	10−200	138064*x* + 7000000	0.98
4,5-diCQA	10−400	138243*x* + 4000000	0.98
kaempferol-7-glucoside	50−1000	26105*x* + 6000000	0.98
quercetin-3-glucoside	2−150	97003*x* + 2000000	0.98

Compound Identification. Methanolic *S. rebaudiana* extracts were analyzed by LC-MS^n in the negative ion mode using an ESI ion-trap mass spectrometer, allowing assignments of compounds to regio-isomeric level, and additionally by high-resolution mass spectrometry using LC-ESI-TOF MS in negative ion mode, allowing determination of molecular formulae on the basis of the accurate mass measurements (Supporting Information). Molecular formulas were, in general, accepted if an error below 5 ppm was experimentally observed. The *S. rebaudiana* samples under investigation contained up to 29

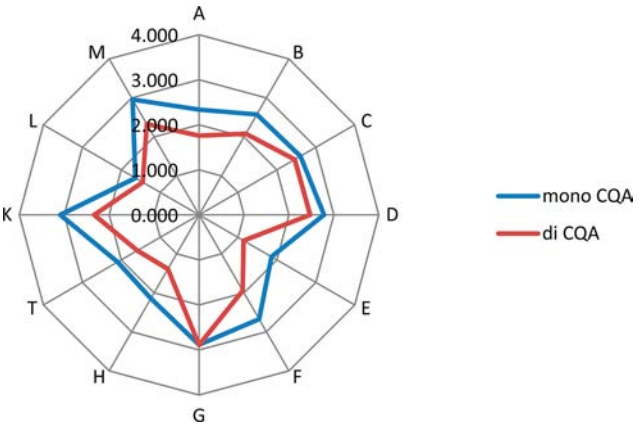

Figure 6. Radar plot of total mono- and diacyl quinic acids (chlorogenic acids) concentrations varying between all origins (average values taken within ±3 σ) and in comparison to non-European Union samples. Concentrations are given on radial axis in grams per 100 g of dry leaf material.

chlorogenic acid derivatives, as published by our group previously.[8] Furthermore, the samples contained a series of flavonoid glycosides. No new additional compounds were identified in any of the samples. Structures are presented in Figure 1.

All analytes showed baseline separation with the exception of the pair of 3,4- and 4,5 dicaffeoylquinic acid. Peak assignments of CGAs have been made on the basis of structure diagnostic hierarchical keys previously developed,[12−15] supported by means of their parent-ion high-resolution mass, UV spectra, and retention times relative to 5-CQA using validated methods in our laboratory.[5] The base-peak chromatogram of *S. rebaudiana* extract is shown in Figure 2. Within the chromatogram, CGAs and flavonoid glycosides elute between 8 and 25 min, whereas steviol glycosides elute at later retention times, between 28 and 40 min.

Four peaks were detected at m/z 353.1 and assigned using the hierarchial keys previously developed as well-known 3-CQA, 5-CQA, 4-CQA, and *cis*-5CQA.[12] Three dicaffeoylquinic acid isomers were identified by their parent ion m/z 515.2 and were assigned as 3,5-diCQA, 3,4-diCQA, and 4,5-diCQA using the hierarchial key.[13] Two further peaks present as minor components showed fragmentation patterns, similar to that of 4,5-diCQA, which are identified as *cis*-isomers of 4,5-diCQA.[16] Tricaffeoylquinic acids and caffeoylshikimates were present as minor compounds, and their regiochemistry assigned using published tandem MS methods.[14,15]

A total of 15 peaks in the chromatogram correspond to flavonoid glycosides with their characteristic fragmentation patterns in tandem MS showing neutral losses of sugar moieties of 162 Da ($C_6H_{10}O_5$) followed by characteristic fragment spectra of the aglycones quercetin (m/z 300), kaempferol (m/z 285), luteolin (m/z 285), and apigenin (m/z 269) in MS^3 (Table 1 and Figure 3). For example, three peaks were located with an m/z value of 447.1 (Figure 4), showing after a neutral loss of 162 Da, a base peak at m/z 285 in MS^2. Further fragmentation in MS^3 with the ion at 285.1 as a precursor ion revealed two fragment ions characteristic for kaempferol and one fragment ion characteristic for luteolin. Additional hydrolysis experiments followed by LC-MS analyses confirmed the presence of aglycones of kaempferol, quercetin, luteolin, and apigenin by comparison of retention times, high-resolution MS data, and tandem MS data compared to those of reference substances in *S. rebaudiana* leaves. Therefore, we tentatively assigned the flavonoid glycosides as hexose conjugates of kaempferol, quercetin, luteolin, and apigenin.

Comparison of the 15 flavonoid glycosides present in *S. rebaudiana* leaves with reference standards, either commercial or obtained through preparative HPLC purification in previous work, showed that all compounds, with the exception of rutin and naringenin, were not identical to the reference compounds available (all 8 glucosides reported in dietary plants and 2 galactosides), as judged by their retention times and fragment spectra. We suggest that the flavonoids present in *S. rebaudiana* are presumably based on fructose, galactose, or mannose. For other plants of the Asteraceae family, it was shown by Harrison et al.[17] that polyfructans are present and by the group of Goffner[18] that additionally galactomannans form the most abundant polymeric carbohydrate structures in this plant family.[18] Hence, it can be speculated that these C6 sugars are present in *S. rebaudiana* leaf flavonoids for which no reference materials are available.

Quantification of Chlorogenic Acids and Flavonoids. Quantitation was carried out using eight-point calibration curves. Chlorogenic acids were quantified by LC-UV at 320 nm and by LC-MS using EICs of the pseudomolecular ions at *m*/*z* 353.1 and 515.2 in negative ion mode using an ESI-TOF MS spectrometer. Additionally, flavonoids were quantified by LC-UV using kaempferol-7-glucoside and quercetin-3-glucoside as reference standards, resulting in relative rather than absolute values for flavonoids. All values obtained are quoted in grams per 100 g of dried leaf material (g/100 g).

Chlorogenic acid standard solutions were analyzed by LC-MS using the same chromatographic method as those used for *S. rebaudiana* leaf extracts. Calibration curves for monocaffeoyl derivatives 3-CQA, 4-CQA, and 5-CQA and for dicaffeoyl derivatives 3,4-diCQA, 3,5-diCQA, and 4,5 diCQA were obtained using EICs (Table 2). Pearson correlation coefficients of the calibration curves using LC-MS quantifications are given in Table 2. All calibration curves were linear within the quantification range. Values obtained from LC-UV and LC-MS quantification gave the same absolute concentration values with an error of less than ±5%, showing validity of the method. All quantitative CGA values for all 166 samples are given in the Supporting Information. The quantitative values obtained for all chlorogenic acid derivatives were found to be a factor of 3−5 higher than values previously reported by our group.[8] On occasions, the data showed a 10-fold increase of CGA concentrations. It must be concluded that the material previously investigated which was obtained from commercial sources was of unknown age and origin. Fresh leaves of *S. rebaudiana* contain

significant quantities of CGAs, much higher than previously determined. In terms of absolute quantities, *S. rebaudiana* shows, following green coffee beans and mate leaves, the third highest concentration of CGAs among all dietary materials.

The four flavonoid aglycones quercetin, kaempferol, luteolin, and apigenin were quantified using a LC-UV method monitoring absorption at 280 nm for selected *S. rebaudiana* samples following hydrolysis of the sugar moiety in dilute acid. It is well-established that the molar extinction coefficient of flavonoid glycosides varies only to a small degree if structural variation of the sugar moiety occurs.[19,20] Quantitative values for the four glycones are given in the Supporting Information. All flavonoid glycosides were quantified using a LC-MS method with quercetin-3-glucoside and kaempferol-7-glucoside as reference compounds, complementing the aglycone structure of the flavonoid glycosides.

Analyses of Data. With the quantitation carried out we have obtained a unique data set of the phenolic metabolome of *S. rebaudiana*. This data set requires statistical evaluation, allowing interesting observations and conclusions. We decided to address the following questions in this contribution.

- What is the statistical distribution of quantitative data? Little data is available in the literature that allows for a definite answer to this question.
- How do phenolic quantities vary with variation of origin, harvest, and plant variety?
- Does the data set allow distinction between varieties or origin in a predictive manner by using quantitative phenol concentrations?
- Do quantities of a set of distinct secondary metabolites correlate with one another?

Further questions addressing the influence of the phenolic metabolome on sensory properties or the influence of agricultural parameters on the phenolic metabolome are outside the scope of this contribution and will be commented on at a later stage.

Statistical Spread of Data. The distribution of the data set is an essential step for examination of data in statistical analyses.

The most frequent distribution of data is the Gaussian or normal distribution. A normal distribution can be easily characterized by observing its symmetrical bell shaped curve on a histogram (Figure S1). Skewness and Kurtosis values below 1 also show that the data is normally distributed. The Kolmogorov−Smirnov (KS) test was used for the analyses of data distribution. The significance value above 0.05 means that the data is normally distributed.

The quantity of each mono- and di-CQA as well as the total mono- and di-CQAs quantities obtained from 166 *S. rebaudiana* samples showed normal distribution. The KS test result, mean values, standard deviations, skewness, and kurtosis of the curve for each CGA is represented in Table 3. A histogram of 5-CQA is presented as an example in the Supporting Information. The observation of an almost perfect Gaussian distribution in all quantitative data came as a surprise. Normally, phenolic metabolites are assumed to act as defense compounds produced by the plant in various stress situations, in particular, stress induced by pathogens. Hence, a bimodial-shaped distribution of CGA concentrations could be expected with two maxima, whereby the higher concentration maximum corresponds to compound production under stress. The experimental data clearly show that this is not the case. It can be speculated that none of the 166 *S. rebaudiana* samples were under stress. A more reasonable scenario would suggest that CGA quantities right of the maximum of the Gaussian curve, shifted to higher concentrations, constitute a situation of a plant under stress; hence, CGA concentrations are only gradually increased by the plant.

Sample Variation. *Variation between Varieties.* Seven defined botanical varieties of *S. rebaudiana* were cultivated, and their phenolic profile was determined. Average values determined for the seven botanical varieties are presented in a radar plot in Figure 5. From the data, it can be seen that the average concentration of all monocaffeoylquinic acids remains rather constant over all seven varieties (2.123−2.686 g/100 g), whereas a larger spread of data is observed for dicaffeoylquinic acids (1.484−2.432 g/100 g). Varieties 3, 5, 6 ,and 7 show on average increased levels of chlorogenic acids compared to those of variety 2 (Figure 5).

Variation between Origins. *S. rebaudiana* cultivated in nine different locations within the European Union and additional samples from outside the European Union (Supporting Information) were available for comparison. According to the literature, polyphenol concentrations are due to their physiological function as UV protection agents, which are a direct function of growth altitude and climatic conditions, particularly sunshine hours. Accordingly, variations of chlorogenic acid concentrations between different origins should be expected. Indeed, the data reveal significant variations in average CGA concentrations varying from 3.090−1.637 g/100 g for total monocaffeoylquinic acids and 2.890−1.144 g/100 g for dicaffeoylquinic acids. (See the Supporting Information for average values of all origins.) E.U.-cultivated *S. rebaudiana* shows

DOI: 10.1021/acs.jafc.5b01944
J. Agric. Food Chem. 2015, 63, 9188−9198

concentrations of CGAs sandwiched between extreme values at both ends observed in samples from outside the European Union (e.g., highest for origin G samples with an average value of 2.890 g/100 g dicaffeoylquinic acids and trial location L and E samples with a lowest average value of 1.448 and 1.144 g/100 g, respectively). A radar plot shown in Figure 6 was used to display variations between different origins.

The data allow insight into variations between minimum and maximum values of phenolics. Our data show that depending on the compound in question an average factor of 5−8 is observed between minimum and maximum values encountered in plants from an individual harvest, indicating a large statistical spread of phenol concentrations.

Principal Component Analyses. To allow differentiation between different *S. rebaudiana* varieties and geographic origins, a principal component analysis (PCA) was carried out on the basis of the LC-MS data set of *S. rebaudiana* phenols. PCA analysis was carried out with an aim to distinguish E.U.-cultivated samples from non-E.U.-cultivated samples. For this purpose, 20 E.U. and 20 non-E.U. samples were subjected to a PCA analysis. Score and loading plots are shown in Figure 7. From the score plot, it can be seen that the samples fall in three groupings. Group A, from South American samples, can clearly be distinguished from all other samples on the basis of their high diCQA content (from loading plot).

Group B contains exclusively European samples from the a single Southern European cooperative. Finally, group C contains both E.U. and non-E.U. samples, e.g., from Turkey, Ukraine and India, that group together. The sample distinction information from the loading plot suggests that a combination of rebaudioside A concentrations and diCQA concentrations allows distinction here.

A second PCA analysis was carried out to compare variations between different botanical varieties. For this purpose, data from four different botanical varieties were chosen, and a PCA analysis of the full LC-MS data set was carried out. Score plot of PC1 versus PC2 shows little differentiation between sample varieties (Figure S2). However, when looking at higher-order principle components, e.g., PC2 versus PC4, three of the varieties group in the score plot, with two varieties grouping together in the same area of the plot. The loading plot reveals that the compounds responsible for the variations include dicaffeoylquinic acids along with rutin.

Statistical Evaluation of Data. From the obtained data, a series of statistical analyses was carried out. For each variety, origin, or harvest, average values and standard deviations were determined. Additionally, the statistical pattern and type of statistical distribution of the data was analyzed for each subgroup. The correlation studies were performed by Pearson's correlation, with the significance value of $p < 0.05$. Significant differences among *S. rebaudiana* leaves for each variable were assessed with analyses of variance (ANOVA). In contrast to PCA, which provides a more global picture on variances in the sample set, ANOVA allows for identification of more subtle differences, e.g., between two or more sample sets that differs only in a single or a few parameters.

Analyses of Variance. One-way ANOVA was performed to study the influence of origin and, in another test, variety on the mono- and di-CQA content of *S. rebaudiana* leaves cultivated in various regions of European Union with different soil and climatic conditions. A posthoc test was applied to find out which origin destinations or varieties differ, if any.

Influence of Origin. Levene's test was performed to assess whether the assumption of homogeneity of variance between groups is met within the data.

Test of homogeneity results revealed that for dependent variable 3-CQA and 4,5-diCQA Levene's test is not significant ($F_{8/116} = 1.783$, $p = 0.087$ and $F_{8/116} = 1.430$, $p = 0.191$, respectively). However, for 5-CQA, 4CQA, and 3,5-diCQA, Levene's test was significant at the level of 0.05 (Table S4), which indicates that the variances in the different groups of origins are different. (The groups do not have equal variance on the dependent variable, in this case, origin.) Therefore, a modified procedure that does not assume equality of variance (Welch statistic) was also applied to these data along with ANOVA.

ANOVA results (Table S5) did not reveal significant differences between the average CGA content of *S. rebaudiana* leaves of different origins. The data only hints at some differences in the average content of *S. rebaudiana* leaves from different origin destinations. These, however, can be considered only marginally significant at the 5% level ($p = 0.054$ for 4-CQA). Moreover, from the ANOVA output, a robust test of equality of means (Welch test) is considered for the CQAs that do not meet the assumption of homogeneity of variance. Similar to the ANOVA test, if the significance value is less than 0.05 in Welch test, then it means there are statistically significant differences between the groups.

From the results of Welch test and one-way ANOVA, the conclusion is that at least two of the group means are significantly different from the other. Beyond this, it is necessary to conduct a posthoc comparison test to determine exactly which pairs of groups are significantly different. There are varieties of posthoc tests available. A commonly used LSD test is applied for CQAs (3CQA and 4,5-diCQA), which met the assumption of homogeneity of variance. The Games-Howell posthoc test is applied for the CQAs 5CQA, 4CQA, and 3,5diCQA), violating the assumption of homogeneity of variance (equal variances not assumed).

Multiple comparison (post hoc) results obtained from LSD test (Fisher's least significant difference) revealed that the 3-CQA amounts are significantly different at the 0.05 level between the trial locations of C/H, H/A, H/B, and H/N origins. 4,5-diCQAs were significantly different at the 0.05 level for origin H and all the other origins except E.

Multiple comparison (post hoc) results obtained from Games-Howell test revealed that there is no significant difference at the 0.05 level between origins for 5-CQA and 4-CQA. However, a significant difference was observed for 3,5-diCQA between origins F and D with a significance value of 0.008.

Influence of Variety. Test of homogeneity results revealed that for dependent variable 3-CQA ($F_{7/117} = 1.207$, $p = 0.304$), 3,5-diCQA ($F_{7/117} = 0.545$, $p = 0.799$), and 4,5-diCQA ($F_{7/117} = 1.193$, $p = 0.312$) Levene's test was not significant. However, for 5-CQA and 4-CQA, Levene's test was significant at the level of 0.05 ($p = 0.018$; Table S6). As in the analyses of origins, the Welch test was also applied to data for the cases of violation of homogeneity of variances.

ANOVA results did not reveal significant differences between the average CGA content of *S. rebaudiana* leaves of different varieties. Moreover, the Welch test did not reveal any significant difference at the level of 0.05. The results of ANOVA test and Welch test are presented in Table 4.

Posthoc tests with Games-Howell method resulted in no pairwise differences for 5-CQA and 4-CQA for each variety. However, for 3-CQA with the LSD test, the mean difference

DOI: 10.1021/acs.jafc.5b01944
J. Agric. Food Chem. 2015, 63, 9188−9198

between varieties 1 and 5 and between varieties 3 and 5 was significant at the 0.05 level ($p = 0.04$). The varietiey pairs 4−6, 5−7, and 6−7 had a significant difference ($p = 0.04$) when 4,5-diCQA quantity in *S. rebaudiana* leaves was taken as a dependent variable. Variety 6 showed significant difference with varieties 2, 3, 4, and 7 for 3,5-diCQA quantity in *S. rebaudiana* leaves.

With the obtained data set, differences between *S. rebaudiana* leaves and influence of the origin of cultivation and the botanical varieties on the CQAs profile were studied with the most common used statistical method, ANOVA. Pair-wise comparisons of varieties and origins for each CQA were achieved by less conservative statistical post hoc test (LSD) and Games-Howell post hoc test to determine the exact pair of variety/origin that are different from each other.

Correlations: Pearson Parametric Test. The correlation analyses were performed to measure the degree of relation between two chosen CGAs. Correlations of CGAs grouped as mono-CQA to mono-CQA, di-CQA to di-CQA, and mono-CQA to di-CQAs were tested according to Pearson's correlation. Overall, correlation was observed for all CGAs with each other (Table 5). However, a strong correlation was observed between the mono-CQAs and 3,5-diCQA with 4,5-diCQA (Pearson correlation of 0.762 and 0.791, respectively) and 5-CQA with 4,5-diCQA as well as 4-CQA with 4,5-diCQA (Pearson correlation of 0.573 for both cases). The remaining correlations were slightly weaker. All correlation coefficients closer to +1, indicating, for example, that increasing quantity of 5-CQA leads to a quantitative increase of 4,5-diCQA. The square of the correlation coefficient (R^2) is the percent of the variation in one variable that is related to the variation in the other. In the case of correlation of 3,5-diCQA with 4,5-diCQA, 62% of the variance is related (or is correlated) (Figure 8). We have recently shown that concentrations of various *cis*-CGA derivatives produced photochemically by UV irradiation in *S. rebaudiana* leaves show a linear concentration correlation.[21]

Table 6 provides an overview of correlations between 10 selected phenolic metabolites with Pearson R^2 values given. The data can be divided into three subgroups. We assume that an R^2 value between 1 and 0.7 corresponds to a positive correlation, that R^2 values between 0.7 and 0.4 correspond to unclear cases, and that R^2 values lower than 0.4 are evidence of no correlation at all. The presence or absence of positive correlations between the concentrations for several phenolic metabolites deserves some attention and comments. First, the data clearly show that all six CGAs analyzed show a correlation between individual compound concentrations. Therefore, no single compound is biosynthesized at an elevated level. In all 166 samples, an increase of the concentration of a single CGA is accompanied by a concentration increase of all other CGAs. Following an environmental or biochemical stimulus, the biosynthesis of the complete set of CGAs is turned on. We name this phenomenon the "better safe than sorry principle". This observation has been made for the first time for a class of natural products and is not expected. On the basis of the observation that most plants produce a rather large set of CGA isomers, we have argued previously that isomerism in CGA chemistry might be a cunning strategy of gaining evolutionary advantage by covering a large pharmacophoric space through multiple compounds.[13]

In contrast to the class of the CGAs, individual flavonoid glycoside concentrations show no correlation. This indicates that individual flavonoid glycosides are biosynthesized selectively with a specific function for each individual compound.

Interestingly, neither the concentrations of individual flavonoid glycosides and individual chlorogenic acids nor the total CGA and total flavonoid concentrations correlate. This observation is surprising because both classes of compounds are believed to serve plants primarily as UV protecting agents; hence, their concentrations are expected to increase simultaneously. Accordingly, these findings do not confer with the hypothesis that both classes of compounds serve as UV protection agents. However, drawing such a conclusion from statistical data should be done with caution because regulatory feedback mechanisms might be operational that modulate the biosynthesis of compounds which could be cytotoxic to the biosynthesizing organism.

In plants, under stressful conditions, accumulation and depletion of several primary metabolites are commonly observed.[14,15] Therefore, monitoring the changes in metabolic levels can provide clues to their roles in stress responses and regulation. A key metabolic pathway in plants is the shikimate pathway that links carbon and nitrogen metabolism.[16] Apart from its role in aromatic amino acid synthesis, the shikimate pathway also serves as a major sink for intermediate metabolites from the central carbon metabolism pathways (glycolytic and pentose phosphate pathways). Any perturbations in the shikimate pathway will lead to a disruption in aromatic amino acid synthesis, as well as alter the metabolic stoichiometry of other carbon intermediates, resulting in system-wide perturbations. Metabolomics would therefore be an ideal approach not only to map the glyphosate-induced disruption of plant metabolism, but also to illuminate the physiology that confers resistance to some biotypes.

The glyphosate-mediated disruption of the shikimate pathway could have potential adverse effects on other cellular processes, resulting in secondary effects such as creation of reactive radicals. Earlier studies reported that, in addition to site-specific action, glyphosate also disrupts the photosynthetic machinery by reducing ribulose-1,5-bisphosphate carboxylase/oxygenase (RuBisCO) activity and 3-phosphoglyceric acid (3-PGA) levels,[17] which can result in the generation of reactive oxygen species (ROS), causing a several-fold increase in lipid peroxidation.[18,19] This ROS-mediated glyphosate damage is further supported by the proteomic analysis, which shows glyphosate-treated rice plants have a compositionally similar, but quantitatively lower, proteomic profile compared to that of rice plants treated with paraquat,[20] a free-radical-producing herbicide. Thus, inhibition of EPSPS could result in secondary toxic effects mediated through the production of ROS. Such an effect might be enhanced in glyphosate-resistant *A. palmeri* if some tissues have inadequate protection by *EPSPS* gene amplification as there is evidence that *EPSPS* gene expression is not equal in all tissue types in these plants.[21]

Previous application of metabolomics in understanding the effect of glyphosate on the physiology of plants was limited to the model plant species *Arabidopsis thaliana* and transgenic crop plants.[22−24] Also the metabolomics approach has been recently adopted to understand the effect of chemical stresses on *Lolium perenne* upon exposure to a nonlethal dose of glyphosate.[25] However, to date no studies have employed metabolomics to characterize the physiology of herbicide resistance in weeds. The objective of the present study is to use nontargeted metabolite profiling to elucidate the differential metabolite-level responses to glyphosate in resistant and susceptible biotypes of *A. palmeri*, and to assess the potential role of antioxidant machinery in complementing glyphosate resistance.

MATERIALS AND METHODS

Plant Biotypes. Glyphosate-susceptible (S-biotype) and glyphosate-resistant (T4B1, R-biotype) *A. palmeri* seeds were obtained from Stoneville, MS (Crop Production Systems Research Unit, U.S. Department of Agriculture, Agricultural Research Service (USDA-ARS)). These biotypes have been well characterized, and GR_{50} values for the R-biotype and S-biotype were previously calculated as 1.3 and 0.09 kg ha^{-1}, respectively (∼15-fold resistance).[11] The S-biotype had a single *EPSPS* gene copy, whereas T4B1 had 33 *EPSPS* gene copies.[11] T4B1 was grown from field collected seeds and the resistance was verified by spraying with glyphosate at 0.42 kg ae ha^{-1}. Only those plants that survived this treatment were classified to be glyphosate resistant (first-generation resistant, F-1) and represented that population. Second-generation (F-2) resistant biotypes were obtained by physically spreading the pollen (generated from the greenhouse-grown glyphosate-resistant F-1 generations) from male plants on the female plants (greenhouse-grown glyphosate-resistant F-1 generations) every morning over a period of 2 weeks. Each female plant that produced viable seeds was considered a unique F-2 biotype within a population, with all biotypes within the population having the same male parent. Biotypes raised from the F-2 seeds were confirmed to be resistant to glyphosate following screening with glyphosate at a rate of 0.42 kg ae ha^{-1}. F-2 generated seeds were planted in germination trays containing a commercial germination mixture and then were transplanted to individual pots (10 cm diameter × 9 cm deep) containing the germination mixture upon germination. The plants were grown in a greenhouse at 30 °C/20 °C day/night temperatures with a 14 h photoperiod. The rationale for conducting the experiment in a greenhouse rather than a growth chamber was that the fluorescent lighting routinely used in growth chamber is relatively high in longer wavelength (red region), than shorter wavelengths (blue region). As antioxidant capacity is greatly related to the intensity and the wavelength spectrum of the solar radiation, the spectral energy distribution differences between greenhouse and growth chamber was taken into account in deciding to conduct the study under ambient natural light. The pots were fertilized 5 days after transplantation with 50 mL of 4 g L^{-1} fertilizer (MiracleGrow, 24%−8%−16% [N−P−K], Scotts Miracle-Gro Products, Inc., Marysville, OH) and subirrigated every alternate day until harvest.

Experimental Design and Glyphosate Application. Two weeks after transplanting, the S- and R-biotypes were randomly assigned to two treatment groups, control and glyphosate (Roundup ProMax, Monsanto Co, St. Louis, MO), and sprayed at a rate of 0.4 kg ae ha^{-1}, which corresponds to approximately half the recommended field application rate of glyphosate. Roundup ProMax has about 49% glyphosate potassium salt. We were not able to obtain the other proprietary ingredients that make up 51.2% of this formulation that could be used to treat the control plants; hence, the control plants were treated with water. The respective treatments (water or glyphosate) were applied to 12 plants per biotype using an enclosed spray chamber (DeVries Manufacturing, Hollandale, MN) calibrated to deliver 374 L ha^{-1} through an 8001E flat fan nozzle (Tee Jet Spraying Systems Co., Wheaton, IL). Both R- and S-biotypes were morphologically similar (plant height ∼20 cm) at the time of treatment application. Three youngest apical leaves along with the meristem were harvested from each treatment replicate (six plants per glyphosate and control treatment) at 8 h after treatment (HAT) and 80 HAT, immediately frozen in dry ice, and stored at −80 °C. Six independent treatment replicates were maintained for all subsequent analyses. At 8 HAT, no visible injuries were observed on the glyphosate-treated S- and R-biotypes. At 80 HAT, the glyphosate-treated S-biotype displayed visible leaf necrosis, while the glyphosate-treated R-biotype and the water-treated S- and R-biotypes showed no visible injuries. To minimize the variations due to circadian rhythm, the plants were harvested at the same time of the day (∼10 h after sunrise) for both the sampling times. The harvested leaves were finely ground with dry ice using a mortar and pestle and stored at −80 °C, and the finely powdered leaves were used for all subsequent analyses.

Metabolite Profiling by GC−MS. Low-molecular-weight polar metabolites in the tissues were identified and quantified using gas chromatography−mass-spectrometry (GC−MS). Polar metabolites were extracted from the ground tissues as described by Lisec et al.[26] and Suseela et al.,[15] with slight modifications. Briefly, about 100 mg of finely powdered leaf tissues was weighed into 1 mL of methanol and homogenized by sonication in an ice bath for 20 s at 50% amplitude, centrifuged at 12000*g*, and rapidly cooled on ice. The supernatant was transferred to precooled glass tubes, an equal volume of cold chloroform was added, and the solution was cooled at 4 °C. The metabolites were fractioned into polar and nonpolar phases with addition of 1 mL of cold water and then centrifuged at 671*g* for 1 min. About 1.5 mL of the aqueous−methanol phase was transferred to microfuge tubes. A subsample (150 μL) of this extract was transferred

DOI: 10.1021/acs.jafc.5b04223
J. Agric. Food Chem. 2015, 63, 9199−9209

into vials with glass inserts, 5 μL of 500 μg ml^{-1} ribitol (internal standard) in hexane and 5 μL of 2 mg ml^{-1} of d_{27}-myristic acid (retention time lock) in hexane were added to the vials, and then the samples were completely dried under a nitrogen stream. The dried samples were methoxylaminated at 60 °C with 20 μL of methoxylamine hydrochloride (20 mg mL^{-1}) in pyridine for 90 min followed by silylation of the metabolites with 90 μL of *N*-methyl-*N*-(trimethylsilyl)trifluoroacetamide (MSTFA) with 1% trimethylchlorosilane (TMCS) for 30 min at 40 °C. The derivatized metabolites were separated by gas chromatography (Agilent 7980, Agilent Technologies, Santa Clara, CA) on a J&W DB-5 ms column (30 m × 0.25 mm × 0.25 μm, Agilent Technologies) and analyzed using a transmission quadrupole mass detector (Agilent 5975 C series) with an electron ionization interface.[13] The initial oven temperature was maintained at 60 °C for 1 min, followed by temperature ramp at 10 °C/min to 300 °C, with a 7 min hold at 300 °C. Carrier gas (He) flow was maintained at a constant pressure of 76.53 kPa, and the injection port and the MS interphase were maintained at a constant temperature of 270 °C. The MS quadrupole temperature was maintained at 150 °C, and the MS source temperature was set at 260 °C. The electron multiplier was operated at a constant gain of 10 (EMV = 1478 V), and the scanning range was set at 50−600 amu, achieving 2.66 scans s^{-1}. Metabolite peaks were identified by comparing the absolute retention time and retention-time index of the sample with those of the in-house metabolomics library supplemented with the Fiehn Library (Agilent Technologies, Wilmington, DE, G1676AA).[27] Data deconvolution was performed using the Automatic Mass Spectral Deconvolution and Identification System (AMDIS v2.71, NIST) using the following parameters: Peak identification was limited to a minimum match factor of 70 relative to the retention index (RI) library and having an RI threshold window of 10 × 0.01(RI). A maximum match factor penalty of 30 was deducted from the final calculated net value in the case of RI mismatch. The peak abundance (integrated signal) was normalized with that of the ribitol (internal standard) abundance and expressed as a percentage of ribitol.

Phenylalanine Ammonia-Lyase (PAL) Assay. The PAL assay was carried out according to Shang et al.[28] with slight modifications. Briefly, 0.15 g of the ground leaves was homogenized in 1 mL of ice-cold sodium borate buffer (pH 8.3) by sonication, and the homogenates were immediately centrifuged (12000*g*, 5 min). The reaction mixtures consisting of the buffer and homogenates were preincubated at 40 °C for 5 min. The reaction was started by the addition of 50 mM L-phenylalanine. Controls (without L-phenylalanine) were prepared to determine the plant endogenous *trans*-cinnamic acid (*t*-CA) content. The reaction was terminated after 1 h with 5 N HCl and analyzed on HPLC−UV (LC 20-AT UFLC and Prominence SPD M20-A photodiode array, Shimadzu Scientific, Columbia, MD) by monitoring the abundance of *t*-CA at 290 nm. HPLC separation of *t*-CA was performed on a Kinetex XB-C18 column (100 mm × 4.60 mm × 2.6 μm, 100 Å, Phenomenex, Torrance, CA) at an isocratic flow rate of 0.7 mL min^{-1} using a solvent composition of 50:50 0.05% formic acid in water and methanol. The *t*-CA levels in the samples were calculated with respect to the calibration curve of the *t*-CA standard solution prepared in the same sodium borate buffer as that of the samples.

Glutathione Reductase and Thiobarbituric Acid Reactive Substance (TBARS) Assays. Glutathione reductase (GR) activity was determined on the basis of the oxidation of NADPH at 340 nm in the presence of oxidized glutathione disulfide (GSSG).[29] GR enzyme was extracted from the leaves by sonication with extraction buffer [0.1 M potassium phosphate (pH 7.6) and 2 mM EDTA] and then transferred into the assay mixture composed of 100 mM potassium phosphate buffer (pH 7.8), 0.5 M GSSG, and 0.2 M DTT. The assay was initiated with the addition of 0.2 M NADPH and incubated at 25 °C for 30 min. Endogenous levels of NADPH were determined with a blank (no NADPH addition). The GR activity was determined spectrophotometrically on the basis of the extinction coefficient of NADPH measured at 340 nm using a JASCO V-550 UV−vis spectrophotometer (eq S1).

Malondialdehyde (MDA) was quantified by a modified TBARS assay as reported by Hodges et al.[30] Briefly, about 0.1 g of ground tissue was weighed into 1 mL of extraction buffer (80:20 methanol/water solution) and sonicated three times for 20 s. A 250 μL volume of the extract was added to a final volume of 1 mL of assay mixture (50 mM NaOH, 25% (v/v) HCl, and 7.5 mM thiobarbituric acid (TBA)), and the reaction was started by incubating the assay mixture at 95 °C. After 30 min, the reaction was stopped by rapid cooling in ice for about 10 min. To account for interfering compounds, the absorbance was read at wavelengths of 440, 532, and 600 nm. False-positive absorbance (absorbance by non-MDA compounds) was corrected by incubating the extracts in a TBA-free assay solution. MDA equivalents were calculated as described by Hodges et al.[30] (eq S2).

Total Soluble Protein Quantification. Proteins were quantified with the bicinchoninic acid (BCA) protein assay kit according to the manufacture's recommended protocol (Pierce Chemical Co., Rockford, IL). Proteins were extracted from ground tissue into extraction buffer (20 mM phosphate buffer, pH 7.6) by sonication. The extract was diluted 10× with water, added to 400 μL of BCA working reagent (BCA-WR, 50:1 BCA reagent A/BCA reagent B), and made up to 1 mL using deionized (DI) water. The assay mix was incubated for 30 min at 37 °C and then rapidly cooled in ice for 5 min. The absorbance of all the samples was measured at 562 nm using a UV−vis spectrophotometer within 10 min of cooling. The concentrations of total soluble proteins (TSPs) were quantified using a protein concentration curve with bovine serum albumin as the standard protein.

Statistical Analysis. The relative concentrations of metabolites across the biotypes and treatments were analyzed by multivariate and univariate statistical analyses. To evaluate the main and interactive effects of the biotypes and herbicide treatments, we first analyzed the metabolomics data with permutational multivariate analysis of variance (PERMANOVA; Primer 7 PERMANOVA+, version 7.0.5, Primer-E Ltd., Plymouth, U.K.). Due to the non-normal distribution nature of metabolic data, PERMANOVA analysis is a more robust test than ANOVA/MANNOVA to identify statistical significance of the treatments.[31,32] Errors due to multiple comparisons were controlled using false discovery rates (FDR). The metabolomics data were autoscaled to satisfy the assumptions of normality and equal variance before multivariate analyses. Supervised partial least squares-discriminant analysis (PLS-DA) models were constructed using Metaboanalyst[33] and the Microsoft Excel add-in Multibase package (Numerical Dynamics, Japan) to test the significance of the effects of the biotype and herbicide treatments on the metabolite profiles, and the PLS-DA model was validated using permutation testing.[34] Hierarchical cluster analysis, using the Euclidean distance as a similarity measure, of the metabolite responses with respect to the treatments were visualized using heat maps. Univariate statistical analysis (ANOVA) was also performed to determine the statistical significance of the metabolite among the different treatment groups (biotypes and herbicide) followed by Tukey's HSD posthoc test. The statistical significances of the biochemical assay responses (concentrations of *t*-CA, NADPH, and MDA) were tested by two-way analysis of variance. Differences among individual means were tested using Tukey's HSD multiple comparison tests with $P_{value} < 0.05$ considered statistically significant. Statistical analyses were done using SAS (v9.2, SAS Institute, Cary, NC).

RESULTS AND DISCUSSION

GC−MS Metabolite Profiling. On the basis of the predefined deconvolution parameters (see the Materials and Methods), GC−MS analysis positively identified more than 60 metabolites across all samples on the basis of their mass-spectral fingerprints and retention-index matches (Table S1). PERMANOVA analysis confirmed that there was a significant interaction effect between biotype and herbicide treatment for both the time points of harvest (Table S2). From the total identified metabolite pool at 8 and 80 HAT, 49 and 52

J. Agric. Food Chem. 2015, 63, 9199−9209

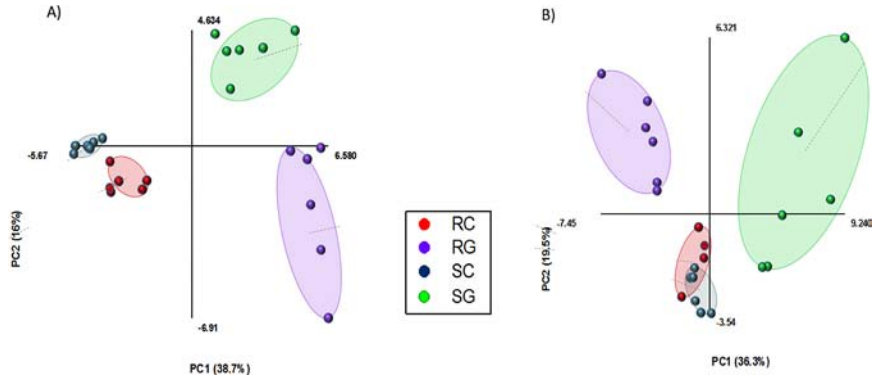

Figure 1. Partial least squares Discriminant Analysis (PLS-DA) score plot of first two principal components of the analysis of polar metabolites obtained from water- and glyphosate-treated S- and R-biotypes of *A. palmeri* at (A) 8 HAT and (B) 80 HAT. The permutation cross-validation of the PLS-DA model for 8 and 80 HAT had $P = 0.0005$ over 2000 iterations. The ellipses represent the 95% confidence regions.

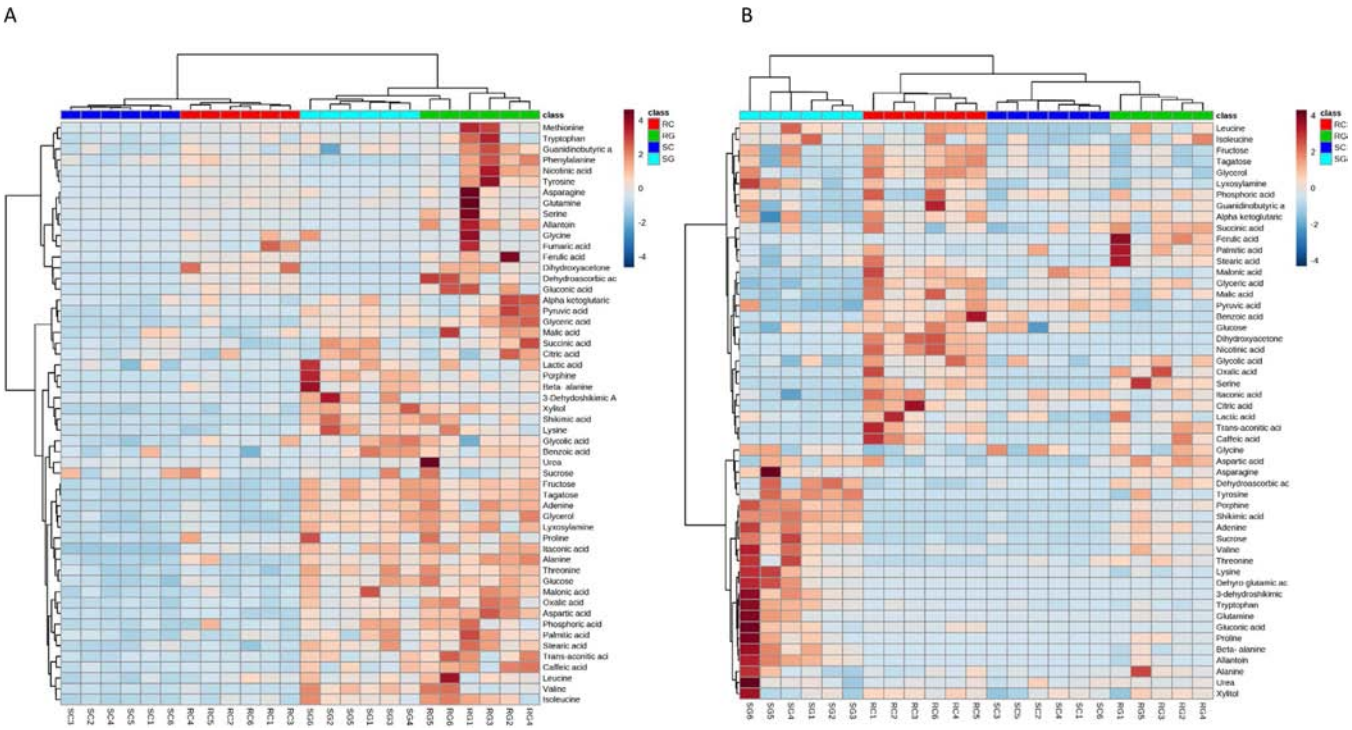

Figure 2. Heat map and two-way hierarchical clustering of polar metabolites in S- and R- biotypes of *A. palmeri* treated with water and glyphosate at (A) 8 HAT and (B) 80 HAT. The algorithm for heat map clustering was based on the Euclidean distance measure for similarity and the Ward linkage method for biotype clustering. ANOVA results comparing the means of each metabolite across treatment groups and the false discovery rate (FDR) for multiple testing corrections are given in Table S3. An enlarged dendrogram is given in Figure S1.

compounds were selected for further analysis that had a false discovery rate (FDR; percentage of false positives that are predicted to be significant) corrected *p*-values below 0.05 (Table S3). The robustness of the PLS-DA class discrimination was verified through permutation testing of separation distance on the basis of the ratio of the between-group sum of the squares and the within-group sum of the squares. The permutation cross-validation of the PLS-DA model for 8 and 80 HAT had $P = 0.0005$ over 2000 iterations, and the model goodness of fit was >0.85. PLS-DA revealed a clustering of the treatments for both the harvest times (Figure 1). At 8 HAT, the component 1 axis differentiated between the two treatments (water and glyphosate), while the PC-2 axis delineated the two biotypes (S and R) (Figure 1A). Interestingly, at 80 HAT, along the PC-1 axis, the glyphosate-treated R-biotype had a metabolic pool similar to that of the control R- and S-biotypes, indicating a potential recovery of the R-biotype from glyphosate toxicity (Figure 1B).

At 8 HAT, hierarchical clustering grouped the water control and glyphosate treatment into major clusters, indicating that, irrespective of their resistance level, the metabolisms of both biotypes were similarly influenced by glyphosate (Figure 2A, Figure S1A). Within the herbicide treatment clusters, the metabolic profile of the S-biotype was different from that of the R-biotype. At 8 HAT, the glyphosate treated R-biotypes had a higher abundance of phenylalanine, tyrosine, serine and nicotinic acid compared to the glyphosate treated S-biotype (Figure 2A, Table S3A). Also, the metabolite pools of nontreated S- and R-biotypes were more similar to each other compared to the metabolic responses between glyph-

DOI: 10.1021/acs.jafc.5b04223
J. Agric. Food Chem. 2015, 63, 9199−9209

osate-treated S- and R-biotypes (Figure 2A). At 24 HAT, the T4B1 absorbed 27% of the applied glyphosate and translocated 37% of the absorbed glyphosate out of the treated site, while the S-biotype absorbed 38% and translocated 40%.[11] Though less than 50% of the glyphosate was translocated out of the treated site, it was potent enough to induce metabolic perturbations in both biotypes within 8 HAT (Figure 2A). At 80 HAT, hierarchical clustering analysis grouped the glyphosate-treated S-biotype into a distinct cluster, while the glyphosate-treated R-biotype was more closely associated with the water-treated (control) S- and R-biotypes (Figure S1B). The metabolite pool of the glyphosate-treated R-biotype resembled that of the water-treated S-biotype rather than the water-treated R-biotype at 80 HAT (Figure 2B). The distinction of the glyphosate-treated S-biotype at 80 HAT from the rest of the treatments could be due to the continued glyphosate-induced disruption of the shikimate pathway, resulting in the differential abundance of several key metabolites such as shikimate, 3-dehydroshikimate, tyrosine, tryptophan, and asparagine (Figure 2B).

Shikimic acid accumulated in both the glyphosate-treated S- and R-biotypes in 8 HAT, indicating an initial, rapid, inhibition of EPSPS enzyme in both biotypes. A similar accumulation of shikimate following glyphosate treatment has been previously reported in T4B1.[11] Compared to that at 8 HAT, at 80 HAT the shikimate accumulation did not differ significantly in the R-biotype, while the shikimate concentration increased by 3-fold in the S-biotype (Figure 3). This continued accumulation of

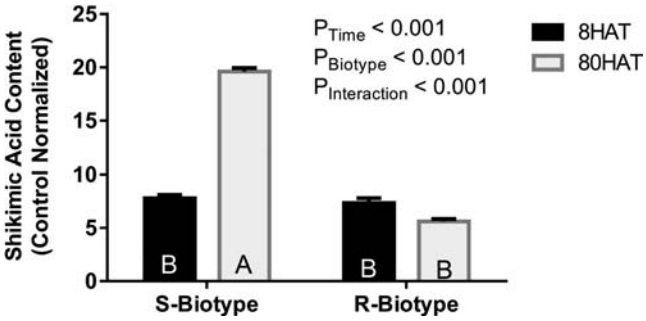

Figure 3. Shikimic acid abundance in glyphosate-treated *A. palmeri* during two harvest times. The data represent the mean ± SD of shikimic acid abundance in glyphosate-treated plants normalized with the abundance of shikimic acid in the water-treated control at respective harvest times. Bars with the same letters are not significantly different at 0.05% confidence (Tukey's HSD).

shikimic acid in the S-biotype could be due to the continued inhibition of EPSPS by glyphosate, and/or a loss of feedback control of the shikimate pathway. In plants, about 20% of the fixed carbon that flows through the shikimate pathway is regulated by the enzyme 3-deoxy-D-arabinoheptulosonate 7-phosphate (DAHP) synthase. Though no known inhibitor of plant DAHP synthase has been identified, arogenate is considered as a potential candidate for the allosteric inhibition of DAHP synthase.[35] As arogenate is synthesized downstream of shikimic acid, inhibition of EPSPS by glyphosate could result in decreased levels of arogenate, therefore impairing the allosteric regulation of DAHP synthase in the S-biotype, leading to continued accumulation of shikimic acid. Studies have reported an initial increase, followed by a subsequent decrease, in shikimate levels following exposure to sublethal doses of glyphosate in both glyphosate-susceptible and glyphosate-resistant plants.[36−38] The stable levels of shikimic acid at 80 HAT in the R-biotype could possibly be due to its conversion into downstream metabolites such as simple phenolic acid derivatives and/or loss of shikimic acid pathway inhibition due to the induction of expression of the multiple *EPSPS* gene copies, thereby diluting glyphosate effects on EPSPS.[39,40] The difference in translocation of glyphosate between T4B1 and the S-biotypes could also partly facilitate the observed reinstatement of cellular homeostasis. After 48 HAT, the glyphosate absorption in the T4B1 was 29%, while in the S-biotype, it was 50% of the applied glyphosate. Interestingly, though about 67% of the absorbed glyphosate in the T4B1 translocated out of the target site by 48 HAT,[11] it did not have an damaging effect on the plant metabolism at 80 HAT. Conversely, in the S-biotype, despite less than half of the absorbed glyphosate (46% of absorbed) being translocated out of the treated site,[11] plants continued to exhibit glyphosate toxicity. This shows that, though glyphosate was persistent in the R-biotype, glyphosate toxicity was mitigated, possibly through the increased *EPSPS* gene copies, complemented by a potential increased anti-oxidant machinery.

The inhibition of the shikimate pathway by glyphosate results in the disruption of aromatic amino acid biosynthesis. The aromatic amino acid concentrations in the control S- and R-biotypes were similar at both 8 and 80 HAT, indicating a lower inherent differences between the biotypes in the absence of herbicide-induced stress. However, after 80 HAT there were significant changes in the concentrations of the aromatic amino acids in both of the biotypes, where the glyphosate treated S-biotype had three times higher abundance of tryptophan and tyrosine (Figure 4). A similar observation of tyrosine accumulation after glyphosate application was reported in glyphosate-susceptible purple nutsedge.[41] In glyphosate-treated R-biotype, the concentration of phenylalanine increased by more than 7-fold, while the levels of tyrosine and tryptophan decreased at 80 HAT (Figure 4). However, phenylalanine increased similarly in the untreated S-biotype between 8 and 80 HAT. A few studies have reported the effect of these aromatic amino acids in reversing glyphosate toxicity,[42−44] although other studies have reported little or no effects of exogenous application of phenylalanine and tryptophan in reducing the toxicity of glyphosate.[45] The several-fold larger phenylalanine pool in the glyphosate-treated R-biotype than in the S-biotype at 80 HAT could serve as a significant pool for antioxidant phenylpropanoid metabolite synthesis in the R-biotype, which could partially mitigate the toxicity of glyphosate. Although the non-aromatic amino acids did not differ in the control S- and R-biotypes, the glyphosate-treated S-biotype had a higher pool of non-aromatic amino acids, possibly due to reduced protein synthesis or other amino acid utilization because of metabolic disruption caused by inhibition of the shikimate pathway. However, it should be noted that the interpretation of the physiology of plants based on pool sizes of pathway intermediates is difficult because pool size does not reflect pool flux.

Glyphosate has only one enzyme binding target in the plant, EPSPS. Blockage of the shikimate pathway at this site leads to many adverse secondary and tertiary effects on other pathways and processes. Most of the measured metabolite changes occur in the linked glycolysis pathway, oxidative pentose pathway, and tricarboxylic acid (TCA) cycle (Figure 5). In plants, the energy-producing stage of glycolysis is regulated by at least six known mechanisms.[46] The rate-limiting step of glycolysis, conversion

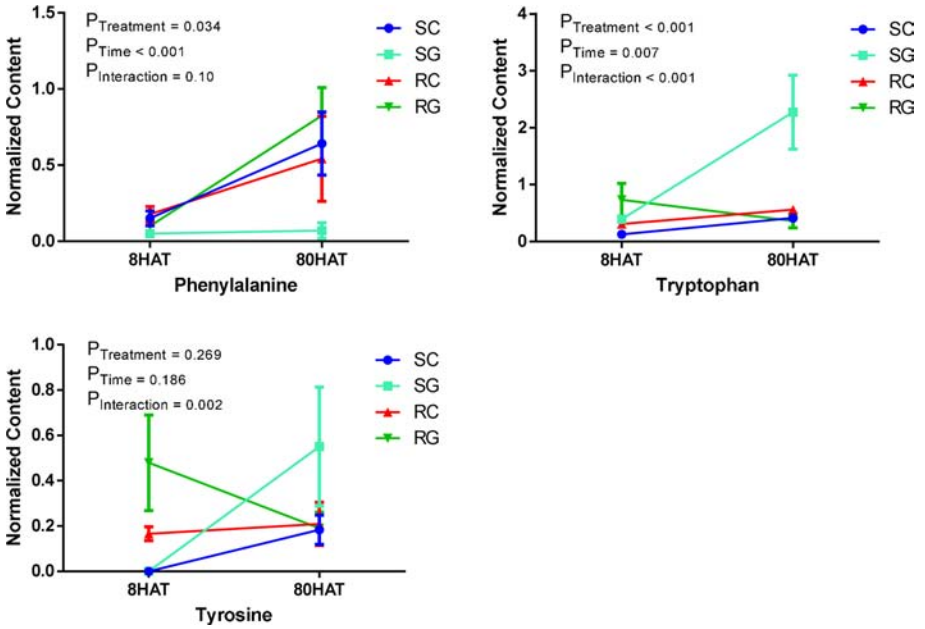

Figure 4. Comparisons of aromatic amino acids across water- and glyphosate-treated S- and R-biotypes of A. palmeri harvested at 8 and 80 HAT. The data represent the mean ± SD of the metabolites normalized to the total ion intensity of the internal standard (ribitol, 500 μg ml^{-1}). The mean ± SD was tested by two-way ANOVA with Tukey's HSD comparing across all treatments and biotypes at a confidence level of 0.05%. Tukey's comparison between the treatment means is given in Table S2.

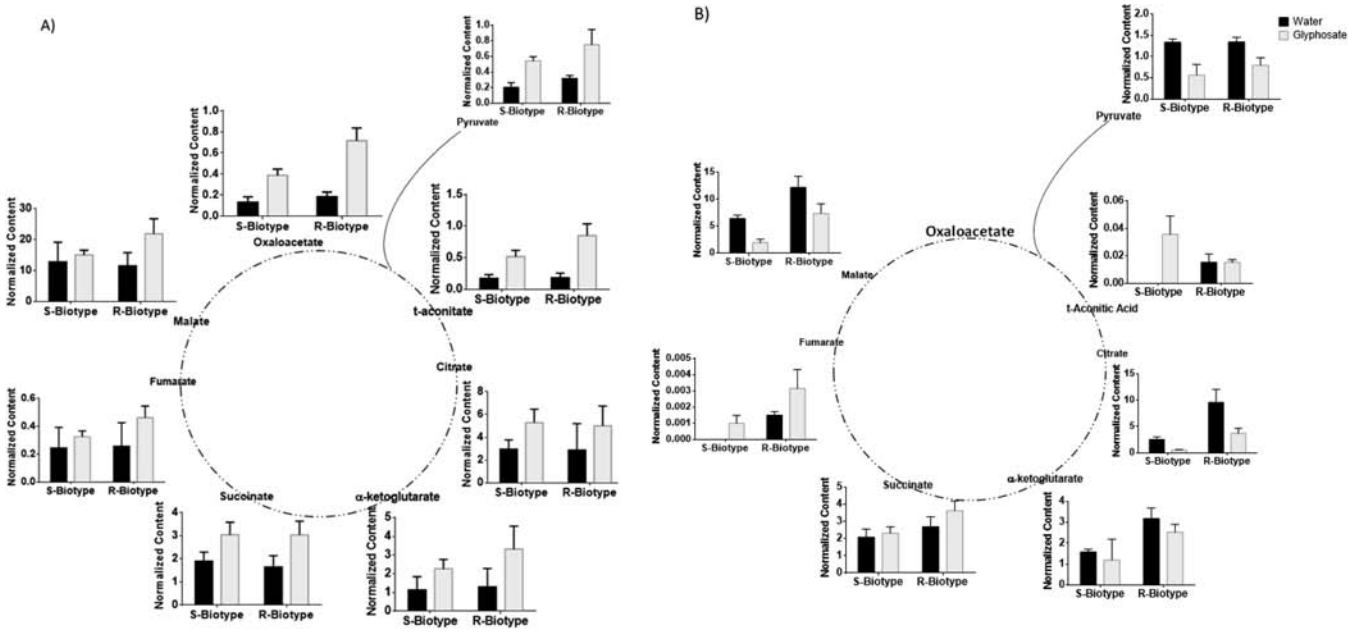

Figure 5. Tricarboxylic acid cycle metabolite pools in water- and glyphosate-treated S- and R-biotypes at (A) 8 HAT and (B) 80 HAT. The data represent the mean ± SD of the abundance of metabolites normalized to the total ion intensity of the internal standard (ribitol, 500 μg ml^{-1}). Tukey's comparison between the treatment means is given in Table S4.

of fructose-6-phosphate to fructose-1,6-bisphosphate by pyrophosphate-dependent phosphofructokinase (PPi-PFK), is activated by inorganic phosphates (Pi) and inhibited by phosphoenol pyruvate (PEP).[47] The ratio of Pi to PEP regulates the activity of PPPi-PFK. As glyphosate competes with PEP for binding to EPSPS, the glyphosate-sensitive biotype will have higher levels of underutilized PEP which could then inhibit the conversion of fructose-6-phosphate to fructose-1,6-bisphosphate. This block in the rate-limiting step of glycolysis could then lead to an overall accumulation of sugars due to impaired carbon metabolism.[48,49] This influence of glyphosate on carbohydrate metabolism is reflected in the accumulation of sugars in both the S- and R-biotypes within 8 HAT (Figure 6A). Sugar moves from sources (photosynthetically active tissues) to metabolically active sinks (e.g., meristems and young leaves), so inhibition of growth of the sinks results in sugar accumulation. Interestingly, at 80 HAT, the sugar levels in the glyphosate-treated S-biotype continued to accumulate, while that of the glyphosate-treated R-biotype was similar to

that of the control biotypes (Figure 6B), indicating a recovery of the R-biotype.

The blockage of the shikimate pathway by glyphosate reverberated across other biochemical pathways and processes as evident by the fluxes of intermediates of the TCA cycle wherein all the major metabolites of the TCA cycle (pyruvic, *trans*-aconitic, citric, α-ketoglutaric, succinic, and malic acids) responded to glyphosate application (Table S4). At 8 HAT, a differential abundance in the concentrations of organic acids was observed in the glyphosate-treated S- and R-biotypes compared to the respective water control, with the glyphosate-treated biotypes exhibiting a substantial increase in concentrations of multiple organic acids (Figure 5A). However, at 80 HAT, in the glyphosate-treated S-biotype, except for succinate and α-ketoglutarate, all other metabolites of the TCA cycle responded to glyphosate application with a drastic reduction in citrate. In contrast, no significant perturbations of the TCA cycle were observed in the glyphosate-treated R-biotype except for the reduction in the levels of citric acid, similar to that of the glyphosate-treated S-biotype (Figure 5B). Overall, our results not only highlight the robustness of the metabolomics approach in identifying differential physiological responses of the S- and R-biotypes to glyphosate, but also identify metabolic-level differences between the R- and S-biotypes in the absence of herbicidal stress.

Biochemical Assays. The observed disruption of the oxidative pentose pathway and the energy-producing tricarboxylic acid cycle, following glyphosate application, could result in generation of reactive free radicals, which could then further initiate lipid peroxidation, resulting in the formation of the reactive compound malondialdehyde (MDA). Compared to the glyphosate-treated R-biotype, the glyphosate-treated S-biotype accumulated 49% higher MDA after 80 HAT (Figure 7A), indicating that higher levels of free radicals mediated lipid peroxidation occurs in the glyphosate-treated S-biotype. A similar observation of the deleterious effect of glyphosate on maize plants due to increased lipid peroxidation via MDA production was reported by Sergiev et al.[19] Thus, the death of the glyphosate-treated S-biotype could be partially accelerated by the complementary action of free radicals that result in observed lipid peroxidation.

Reduced levels of MDA accumulation in the R-biotype following glyphosate application (Figure 7A) could indicate an apparent increase in the activities of enzymes and secondary metabolites which can effectively quench the free radicals. Plants have a well-defined and extensive enzymatic and nonenzymatic antioxidant machinery to protect them from the free radicals generated during normal physiological metabolism.[50] In plants, the GR enzyme system serves as a major antioxidant defense. GR catalyzes the reduction of GSSG to glutathione (GSH), its antioxidant compound which neutralizes highly reactive ROS molecules. Increased GR activity results in increased production of GSH, enhancing the antioxidant potential. The reduction of GSSG to GSH is energy-dependent and utilizes NADPH as the energy supplier. Therefore, the GR activity is captured by monitoring the levels of NADPH[29] wherein a decrease/increase in NADPH levels indicates a proportional increase/decrease in GR activity. At 8 HAT, compared to the water-treated S-biotype, the glyphosate-treated S-biotype had a 26% decrease in NADPH levels (Figure 7B), thereby indicating higher GR activity than in the nontreated control. At 8 HAT, in the glyphosate-treated R-biotype, there was an 85% increase in NADPH levels, indicating lower GR activity in the glyphosate-treated R-biotype

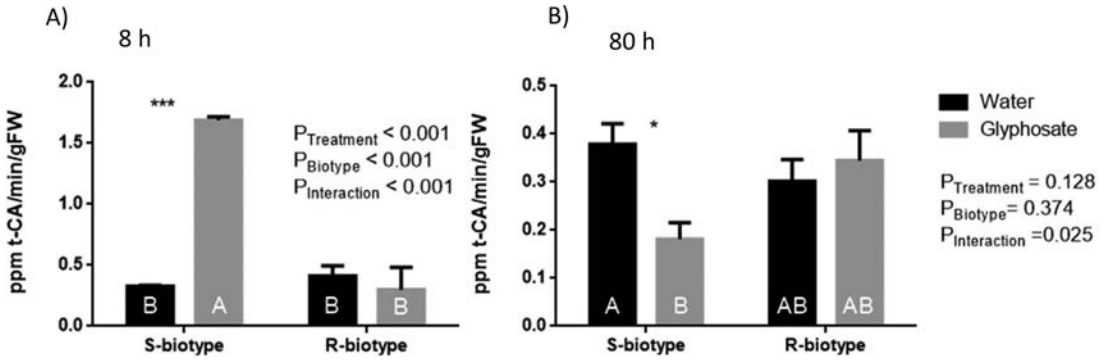

Figure 8. Phenylalanine ammonia-lyase (PAL) assay comparing the difference in activities of the PAL enzyme in the S- and R-biotypes of *A. plameri* across the treatments at (A) 8 HAT and (B) 80 HAT. The data represent the mean ± SD of the assays. Bars with the same letters are not significantly different at 0.05% confidence.

compared to its nontreated control (Figure 7B). However, at 80 HAT, compared to the water control R-biotype, there was a 51% reduction in the NADPH levels in the GR activity of the glyphosate-treated R-biotype, which potentially indicates higher GR activity in the glyphosate-treated R-biotype. Contrastingly, at 80 HAT, compared to those in the water-treated S-biotype, the NADPH levels increased 37% in the glyphosate-treated S-biotype, indicating a decrease in NADPH consumption. Lower GR activity (as indicated by higher NADPH levels) in the glyphosate-treated S-biotype at 80 HAT could indicate a decrease in synthesis of glutathione by GR, resulting in lower antioxidant potential despite higher levels of oxidative damage. Although it is possible that the lower utilization of NADPH in the S-biotype could also be due to the cessation of carbon fixation induced by the glyphosate toxicity, the concomitant higher accumulation of MDA in the glyphosate-treated S-biotype at 80 HAT (Figure 7A) indicates a lower GR activity (Figure 7B). The increased GR activity in the glyphosate-treated R-biotype at 80 HAT indicates a responsive but delayed GR-dependent antioxidant activity. Similar observations of the induction of plant stress response genes following glyphosate application was shown in *Festuca arundinacea* by Unver et al.[51] following miRNA and transcriptome analysis. Furthermore, transcriptome analysis of glyphosate-treated susceptible and resistant soybean plants (*Glycine max* (L.) Merr.) by Zhu et al.[52] had similar conclusions. Thus, the observed higher GR activity combined with the lower accumulation of MDA in glyphosate-treated R-biotypes indicates the existence of a robust free radical scavenging system in this biotype that could potentially complement the glyphosate resistance conferred by *EPSPS* gene copy amplification. Though less evident at 8HAT, at 80 HAT, compared to the S-biotyes, the R-biotypes exhibited 84% higher capacity to scavenge the 2,2-Diphenyl-2-picryl-hydrazyl (DPPH) free-radical (Method S2, Figure S5). This higher radical scavenging capacity of R-biotype is in agreement with the observed lower accumulation of MDA in the R-biotype (Figure 7A).

The phenylpropanoid pathway is a major secondary metabolic pathway that synthesizes a wide array of phenolic compounds (such as flavonoids and betalains) with radical scavenging capacity to reduce oxidative stress. As the rate-limiting step of this pathway is the conversion of phenylalanine to *t*-CA catalyzed by the PAL enzyme, the rate of formation of *t*-CA could partially reflect the antioxidant capacity of the plant. At 8 HAT, the extracted PAL activity was the same in the control groups for both biotypes and in the treated R-biotype (Figure 8A). The activity from the treated S-biotype was much higher at this time. However, at 80 HAT, the PAL activity was the same in all treatments except for reduced activity in the treated S-biotype (Figure 8B). This is in accordance with previous studies which observed rapid increases in PAL activity in glyphosate-treated plants that were transient, often peaking at about 24 HAT.[53,54] In this previous work, extracted PAL activity was temporarily enhanced by glyphosate treatment, while phenylpropanoid levels were decreased, suggesting that the PAL gene(s) is up-regulated by blockage of the shikimate pathway.

On the basis of the metabolite profiles of the S- and R-biotypes under both water and glyphosate treatment, two phenylpropanoid secondary metabolites, ferulic and caffeic acids, were identified. While ferulic acid was detected in the R-biotype in both the water control and glyphosate treatments at 8 HAT and only in the glyphosate treatment at 80 HAT, no ferulic acid was detected in the S-biotype in either water- or glyphosate-treated plants at both 8 and 80 HAT (Figure S2A). Similarly, at 8 HAT, caffeic acid was detected in both the control and glyphosate-treated S- and R-biotypes, but at 80 HAT, it was not detected in either the control or glyphosate-treated S-biotype, but was still present in the R-biotype in all treatments at all times. Interestingly, while the caffeic acid levels were elevated in the glyphosate treatment over the control at 8 HAT and not at 80 HAT, the level of caffeic acid in the control was much higher at 80 HAT than at 8 HAT (Figure S2B). This suggests that, due to the extra copies of the *EPSPS* gene in the R-biotype, there could be an increase in the levels of metabolites downstream of the shikimate pathway, including metabolites of the phenylpropanoid pathway. Further profiling of plant extracts using liquid chromatography tandem-mass spectrometry (LC-MS/MS) (Method S1) identified significantly higher abundance of certain phenylpropanoids, in R-biotype, particularly quinic acid conjugates of cinnamates (4-*O*-feruloylquinic acid (4-FQA) and 4-*O*-caffeoylquinic acid (4-CQA, crypto-chlorogenic acid)) (Figure S3, Figure S4). Compared to the water-treated S-biotype, the water-treated R-biotype had 2.5 and 4 fold higher abundance of 4-FQA and 4-CQA, respectively (Figure S4). This further supports our hypothesis that the R-biotype could possess an enhanced antioxidant capability which may play a complementary role in conferring resistance to glyphosate. The enhanced levels of certain phenylpropanoid compounds in the R-biotype may play a role in the different spectral reflectivities of the two *A. palmeri* biotypes.[56]

J. Agric. Food Chem. 2015, 63, 9199−9209

At 80 HAT, the control R-biotype contained 0.6 fold higher TSPs compared to the S-biotype, and the TSPs in both biotypes decreased at 80 HAT following glyphosate application. The R-biotype had about 35% reduction in protein levels as compared to the S-biotype (Figure 9). This decrease in protein

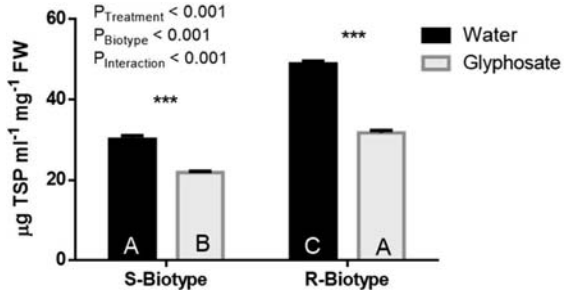

Figure 9. Bicinchoninic acid (BCA) assay for total soluble protein (TSP) quantification in water- and glyphosate-treated S- and R-biotypes of *A. palmeri* harvested at 80 HAT. levels in the R-biotype could be attributed to the initial inhibition of the shikimate pathway as evident in the accumulation of shikimic acid at 8 HAT. The potential transient inhibition of the shikimate pathway could lead to protein catabolism to sustain growth, which might partly explain this observation. The reduced protein levels in the S-biotype could be attributed to the combined effect of catabolism and termination of protein synthesis.

Our results demonstrate the application of metabolomics as a complementary tool for further elucidating glyphosate resistance at the phenotypic level in *A. palmeri*. Metabolite profiling differentiated physiological differences between the S- and R-biotypes, both in the presence and in the absence of glyphosate treatment. Though both the S- and R-biotypes were exposed to identical environments under the two treatment conditions (water or glyphosate), the metabolite profile patterns of water-treated (control) plants within each biotype were not similar between the two harvest times. This could be attributed to the rapid fluxes of the measured metabolites that were altered in the intervening period between the two sampling time points. Importantly, the metabolic changes observed after glyphosate application capture the differences in response to glyphosate application by the two biotypes. The resistance to glyphosate, though primarily conferred by the multiple copies of the *EPSPS* gene in this resistant *A. palmeri* biotype, may be complemented by the antioxidative protective mechanisms. Considering the recent findings that *EPSPS* gene expression is not equal in all tissue types within a single individual of glyphosate-resistant *A. palmeri* biotypes,[21] the enhanced antioxidant potential might help to mitigate the secondary toxicity of glyphosate due to the production of free radicals in tissues with lower *EPSPS* copies. Also, the observed higher abundance of the anti-oxidant compounds derived from the phenylpropanoid pathway could potentially enhance the performance of this R-biotype under environmental stress.
